Abstract—The complexes of $K_{17}Ln(CuW_{11}O_{39})_2 \cdot nH_2O$ (Ln = La, Ce, Pr, Nd, Sm, Eu, Gd, Dy, Ho, Yb) have been prepared by the stepwise acidification and the stepwise addition of materials. The products were characterized by elemental analysis, ion-exchange, conductometric titration, IR, UV, X-ray powder diffraction and thermal analysis. The results show that the structure of the products is similar to that of $Cs_{12}U(GeW_{11}O_{39})_2$. The thermal analysis indicated that the complexes with undecatungstocuprate heteropolyanion as a ligand had higher thermal stability than that of saturated Keggin structure dodecatungstocuprate.

The studies on the mixed heteropoly complexes are a frontal work in the basic studies on heteropoly compounds. Lanthanides can react with lacunar heteropolyanions $XW_{11}O_{39}$ (X = Si, P, As, Ga, Ge) to give bisundecatungstolanthanates. The structure of this kind of heteropolyanions is a square antiprism consisted of eight oxygen atoms of two $XW_{11}O_{39}$ heteropolyanions and a lanthanide ion.[1] These triheteropoly complexes containing lanthanide elements are efficient catalysts in some organic synthesis reactions.[2] However, there have been few reports on the heteropoly complexes with subgroup element-centred undecatungstate ligands. We describe here the synthesis and characterization of $K_{17}Ln(CuW_{11}O_{39})_2 \cdot nH_2O$ (Ln = La, Ce, Pr, Nd, Sm, Eu, Gd, Dy, Ho, Yb).

EXPERIMENTAL

Preparation

36.3 g (0.11 mol) of $Na_2WO_4 \cdot 2H_2O$ was dissolved in 200 cm^3 of water and the pH of the solution was adjusted to 6.3 with acetic acid. The solution was then heated to 90°C and a solution of 2.4 g (0.01 mol) $Cu(NO_3)_2 \cdot 3H_2O$ in 30 cm^3 of hot water was added dropwise with stirring. After the reaction proceeded for 35 min, a solution of 2.2 g (0.005 mol) $Ln(NO_3)_3$ in 25 cm^3 of water was added. The pH was readjusted to 5.6 and stirring was continued for 30 min. After cooling, the light yellow oil, which precipitated by adding absolute alcohol, was dissolved in a little water, then 25 g of KCl was added to it and the mixture was stirred for several minutes at room temperature. The oily product was cooled out and was left for a period of time until it solidified. There was no precipitation during the synthesis. The product was recrystallized from warm water three times and kept in a desiccator over P_2O_5. The yields were in the region of 20%.

Chemical analyses

Potassium was determined gravimetrically as the tetraphenylborate. The lanthanides were determined by EDTA volumetry with cresol orange as the indicator.[3] Copper was determined by atomic absorption spectrophotometry.[4] Tungsten was

determined by 8-hydroxy-quinoline-tannin acid-methylviolet gravimetry.[5] The water content was determined by thermogravimetry. The analytical results are presented in Table 1.

Physical measurements

IR spectra were obtained on an Alpha Centauri FT infrared spectrometer in the range 400–4000 cm^{-1} using KBr pellets. UV spectra were recorded on a DU–8B UV spectrophotometer. X-ray powder diffraction patterns were made with a D/max-IIIC diffractometer. Thermogravimetric experiments were conducted on a Q-Derivatograph thermal analyzer with a rate of temperature increase of 10°C min^{-1}. A P–E 3030 atomic absorption spectrophotometer, a pH S-2 acidimeter and a DDS-11A conductometer were also used.

RESULTS AND DISCUSSION

Stability and basicity

The stability of the solution of heteropoly complex $K_{17}Ce(CuW_{11}O_{39})_2 \cdot 36H_2O$ towards acid and base was investigated by spectrophotometry. The variation of absorbance of $K_{17}Ce(CuW_{11}O_{39})_2 \cdot 36H_2O$ at 253.3 nm under different pH values was measured. If the heteropolyanion was hydrolyzed at a pH value, its concentration and absorbance A would be changed accordingly. It can be seen from A-pH curve that the absorbance A is almost unchanged at pH = 3.6–6.2, indicating that the heteropoly complex is stable under such conditions.

The basicity of the heteropolyanions can be determined by conductometric titration. The conductometric titration curve of $K_{17}La(CuW_{11}O_{39})_2 \cdot 33H_2O$ is shown in Fig. 1. The result shows that at end point of conductometric titration, $Ag^+/La(CuW_{11}O_{39})_2^{17-} = 16.8$. This value is close to the real value of 17. The basicity of $K_{17}La(CuW_{11}O_{39})_2 \cdot 33H_2O$ is 16.8.

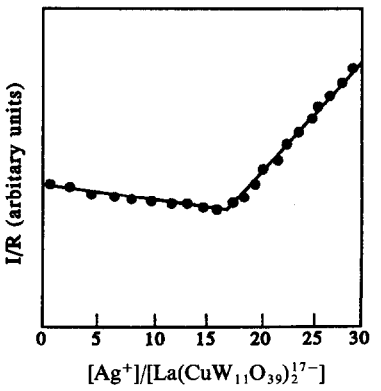

Fig. 1.

Ion-exchange experiment

In order to prove lanthanides to be inside the coordination sphere, we performed ion-exchange experiments. Before and after the experiment of ion-exchange on a column fitted with the resin of K^+ type, the colour of the solution, the characteristic peak of UV and chemical composition were almost unchanged. This indicates that after ion-exchange Ln^{3+} and Cu^{2+} ions are not replaced, showed Ln^{3+} and Cu^{2+} ions to be inside the heteropolyanion, unlike balance ions or free ions. After ion-exchange on a bed fitted with the resin of H^+ type, it was found that the IR spectrum of $K_{17}Pr(CuW_{11}O_{39})_2 \cdot 30H_2O$ before elution is obviously different from that of $K_{17}Pr(CuW_{11}O_{39})_2 \cdot 30H_2O$ after elution (Fig. 2), indicating the heteropolyanions are being decomposed.

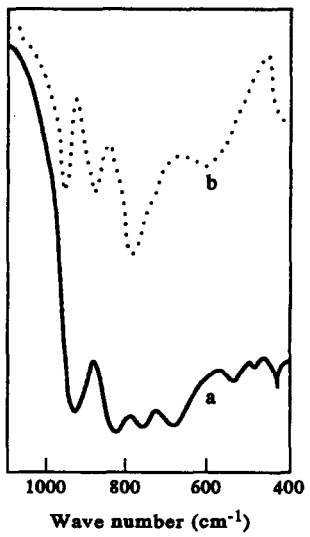

Fig. 2.

IR spectra

The observed frequencies of the complexes and the tentative assignments of the main absorption bands are listed in Table 2.

The following conclusions can be drawn from Table 2.

(i) After the formation of $Ln(CuW_{11})_2$, the structural symmetry is reduced, i.e. from Td of CuW_{12} to D_{4d} due to the coordination effect. In $Ln(CuW_{11})_2$, Ln^{3+} does not occupy the original position, but is bonded to the four oxygen atoms surrounding the hole. The formation of Ln—O bond destroys the symmetry of Keggin structure and a big distortion takes place.

(ii) Comparing $Ln(CuW_{11})_2$ with CuW_{12}, both $\nu_{as}(W—O_d)$ and $\nu_{as}(W—O_b—W)$ are lower, because the coordination of Ln^{3+} by O_b and O_c causes electronic cloud transfer of O_d in the direction of $O_d—W—C_c(O_b)$ and the density reduction of electronic cloud of $O_d—W$ bond, changing the force constant of the bond and making the frequency reduced.[6] Compared with CuW_{12}, $\nu_{as}(W—O_b—W)$ is not split, while $\nu_{as}(W—O_c—W)$ is split, because the unsaturated heteropolyanion is a four-dentate ligand and Ln^{3+} bonds to both O_b and O_c. In addition to the coordination bond, there is also an electrostatic force between Ln^{3+} and O_c (or O_b) due to the higher charges of Ln^{3+}, which attracts the oxygen atoms nearby. In Keggin structure, $W—O_c—W$ does not combine as firmly as $W—O_b—W$ does and under the influence of Ln^{3+}, $W—O_c—W$ distorts easily, so that the symmetry turns lower, causing the split of the band.[7]

(iii) The $\nu_{as}(W—O_d)$ vibrational frequencies of samples are similar to each other but change in

$Dy(CuW_{11})_2$	196.1	253.4
$Ho(CuW_{11})_2$	197.1	254.1
$Yb(CuW_{11})_2$	197.6	253.8

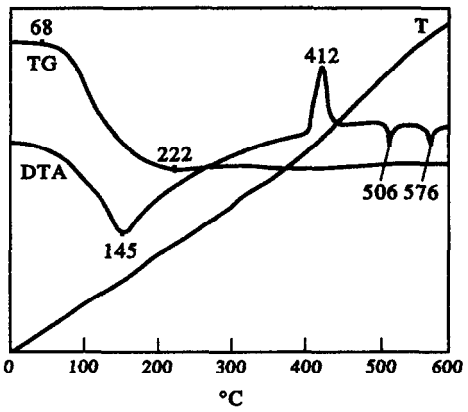

Fig. 3.

fluctuation. The general tendency is that the change of $\nu_{as}(W—O_d)$ increases with the increased atomic number of Ln^{3+}, so does $\nu_{as}(W—O_b—W)$. This is due to the effect of the periodical arrangement of electrons and the lanthanide contract.

UV spectra

There is a strong absorption band in UV region resulting from the $p\pi$–$d\pi$ transition of W—O bonds in polyacid complexes. Two absorption peaks appear in the UV region for $Ln(CuW_{11})_2$, of which one with a higher energy is assigned to $O_d \rightarrow W$ charge transition, and the other wth a lower energy to O_b(or O_c)$\rightarrow$W charge transition.[8] The UV spectra are listed in Table 3.

Compared with those of CuW_{12}, the bands of charge transition are shifted to short wave and high energy field.[9] This is due to the increase of negative charge density.

X-ray powder diffraction

X-ray diffraction analysis is used extensively to study the structure of heteropoly complexes. The data of X-ray powder diffraction of some products synthesized are listed in Table 4.

It can be seen that the data of X-ray diffraction of the products synthesized are similar. The intensities and positions of the diffraction peaks are similar to those of $Cs_{12}U(GeW_{11}O_{39})_2$. This is consistent with the conclusion of reference.[10]

Thermal stability

In general, we take the temperature of the exothermic peak of DTA curves as the sign of thermal

stability of heteropoly complexes. The thermogram of $Sm(CuW_{11})_2$ is shown in Fig. 3 and DTA data of $K_{17}Ln(CuW_{11}O_{39})_2 \cdot nH_2O$ are listed in Table 5.

It can be shown from the thermogram that all $Ln(CuW_{11})_2$ show weight loss by one step. Before 250°C there is a continuous weight loss process corresponding to a big endothermal peak. The IR spectra at different temperatures and solubility tests show that under such conditions the heteropoly complexes did not decompose, so the weight loss because of absorbing heat could be assigned to the loss of zeolite water or the water weakly bonded to balancing-ions and the water between $Ln(CuW_{11})_2$. At a higher temperature (above 500°C) the two endothermal peaks on the DTA curve can be assigned to the crystallization or melting of decomposed products.

Both the formation of bridge bond W—O—W and the existence of $W{=}O_d$ with partial double bond are the sign of the formation of heteropoly complexes. The change of these bonds can be tested by IR spectra at different temperatures and by solubility experiments. The IR spectra of $Sm(CuW_{11})_2$ at different temperatures are shown in Fig. 4 and the results of solubility experiments of $K_{17}Sm(CuW_{11}O_{39})_2 \cdot 34H_2O$ at different temperatures are listed in Table 6. The decomposing temperature is 350–400°C. As can be seen from Table 5 the thermal stability of the complexes with undecatungstocuprate heteropolyanion as ligand is higher than that of saturated Keggin structure dodecatungstocuprate.

PREPARATION OF SOME MIXED CHLORO-CATECHOLATE AND CHLORO-OXO-CATECHOLATE COMPLEXES OF HIGH OXIDATION STATE TUNGSTEN AND MOLYBDENUM

CHRISTINA PERSSON and CARLAXEL ANDERSSON*

Department of Inorganic Chemistry 1, Chemical Centre, University of Lund, P.O. Box 124, S 221 00 Lund, Sweden

(*Received* 27 *April* 1993; *accepted* 12 *July* 1993)

Abstract—9,10-Phenanthrenequinone (phq) reacts with WCl_4(DME) and $MoCl_4(OEt_2)_2$ to give the complexes tetrachloro[9,10-phenanthrenediolato(2−)-O,O′]tungsten(VI) and tetrachloro[9,10-phenanthrenesemiquinonato(1−)-O,O′]molybdenum(V), respectively; and with the oxohalide complexes $MOCl_3$(DME) (M = Mo, W) to give the complexes trichlorooxo[9,10-phenanthrenequinone-O,O′]molybdenum(V) and trichlorooxo[9,10-phenanthrenesemiquinonato(1−)-O,O′]tungsten(VI).

Tetrachloro[3,4,5,6-tetrachloro-1,2-benzenediolato(2−)-O,O′]molybdenum(VI) is obtained in less than 50% yield by reaction of tetrachloro-1,2-benzoquinone (tcq) with $MoCl_5$, and tetrachloro[3,4,5,6-tetrachloro-1,2-benzenediolato(2−)-O,O′]tungsten(VI) is obtained in quantitative yield by reaction of WCl_6 with tcq, concomitant with oxidation of the toluene solvent.

Tetrachloro[9,10-phenanthrenesemiquinonato(1−)-O,O′]molybdenum(V) reacts with *t*-$BuOSiMe_3$ to give dichlorooxo[1,1-oxybis(ethane)][9,10-phenanthrenediolato(2−)-O,O′] molybdenum(VI).

Based on analytical, IR and magnetic data suggested assignments of formal oxidation states of the metal and the quinone ligands in the complexes are presented.

Research in the field of high-valent organometallic chemistry has resulted in the development of highly effective olefin metathesis catalysts of molybdenum,[1,2] tungsten,[3] and rhenium.[4] Hard donors, e.g. oxo, imido, alkoxy, and aryloxy groups, which stabilize the high oxidation state of the metal, are recurrent auxiliary ligands in high valent organometallic complexes. The steric and electronic properties of the auxiliary ligands can to some extent be used to tune the catalytic properties of a particular complex. This is nicely demonstrated by the $(RO)_2M(NR')(=CH-R'')$ [M = Mo, W; R″ = *t*-Bu, NR′ = 2,6-di-*iso*-propylaniline, R = *t*-Bu or $CMe(CF_3)_2$] class of metathesis catalysts.[2,5]

Catechols/quinones are ligands of significance in biological redox systems.[6,7] By their ability to coordinate metal ions in the quinone, semiquinone, or catecholate form[8,9] this class of ligands spans a wide range of electronic properties. Redox properties of the quinones/catechols are also influenced by the ligand substituents. Moreover, the steric requirements of catecholate/quinone ligands can be varied extensively.

Phenoxide complexes of tungsten have been used as catalyst precursors in the metathesis of olefins[10,11] and an alkylation of mixed chloro-phenoxide complexes of tungsten have lead to the isolation of catalytically active tungsten alkylidene complexes.[12–14] Following this line of research we have been interested in the preparation of mixed chloro-catecholate complexes of the type (cat)MCl_4 (M = Mo, W; cat = catecholate, semiquinone, or quinone) and to use these as starting materials for further syntheses. In particular the known method to convert halide complexes to imido complexes[15] or the alkylation of such precursors have been considered of interest. In this paper we present the preparations of some mixed chloro-catecholate and some mixed oxo-chloro catecholate complexes.

RESULTS AND DISCUSSION

Known methods to prepare catecholate complexes include alcoholysis of metal-halides with catechol,[16,17] condensation of catechols with metal-oxo groups,[18] and the oxidative addition of quinones to low valent metal complexes.[19,20] The reactions of quinones with homoleptic metal carbonyl complexes have been used frequently to prepare catecholate complexes of tungsten and molybdenum.[21-24] The term oxidative addition is often used for this reaction although the reaction is better characterized as an oxidative substitution since the coordination number remains intact.

We have recently described the syntheses of WCl_4L_2 and $MoCl_4L_2$ (L = monodentate ether; L_2 = bidentate ether).[25] These complexes are labile and the ether ligands are easily displaced by other ligands. Since an oxidation from the +IV oxidation state to the +VI oxidation state seemed within reach using quinones as entering ligands these complexes were considered as suitable starting materials for the syntheses of complexes of the general formulation MCl_4(cat). The present study has been limited to tetrachloro-1,2-benzoquinone and 9,10-phenanthrenequinone as entering ligands. In the following the abbreviations tcq = tetrachloro-1,2-benzoquinone, tcsq = tetrachloro-1,2-benzosemiquinone, tcc = tetrachlorocatecholate and phq = 9,10-phenanthrenequinone, phsq = 9,10-phenanthrenesemiquinone, phc = 9,10-phenanthrenecatecholate are used to denote the oxidation states of these ligands.

$MCl_4(L_2)$ [M = Mo, W, L = THF, Et_2O, L_2 = DME (*dimethoxyethane*)] *as starting material*

WCl_4(DME) and $MoCl_4(OEt_2)_2$ react smoothly in CH_2Cl_2 solution at room temperature with an equimolar amount of phq to furnish the complexes WCl_4(phc) (**1**) and $MoCl_4$(phsq) (**2**) as dark microcrystalline powders. The yields [(**1**) = 79%; (**2**) = 87%] are high and the complexes are obtained in analytically pure state by filtration and washing with diethyl ether. These are the only cases where the oxidative substitution reaction have led to well-defined products.

All attempts to react $WCl_4(THF)_2$ with 9,10-phenanthrenequinone gave crude products showing a strong IR band at 962 cm^{-1}, which is not present in (**1**). Tungsten(V) is very prone to abstract oxygen from THF[25-27] and the IR band at 962 cm^{-1} is most likely a terminal tungsten-oxo stretching vibration resulting from an oxygen abstraction from THF. A reaction path involving an initial substitution and a one-electron oxidation of the tungsten atom with subsequent abstraction of an oxygen atom from THF is a possible reason for the formation of a tungsten–oxygen bond.

Likewise, none of the precursor complexes, i.e. WCl_4(DME), $WCl_4(THF)_2$, $MoCl_4$(DME) or $MoCl_4(OEt_2)_2$ is suitable for reactions with tetrachloro-1,2-benzoquinone. Nothing but an ill-defined mixture of products has been obtained independent of solvent and reaction conditions applied. A more complex reaction pattern than a single oxidative addition is likely and has been observed in a similar context,[28] i.e. in the reaction of the acetylene complex $WCl_4(C_2I_2)$ with tcq.

Syntheses of tetrachloroquinone complexes from $WCl_5(OEt_2)$, $MoCl_5$ *and* WCl_6

The failure of the attempted oxidative substitution reaction to give the target substances in the case of tcq indicate that the redox chemistry involved is complicated. To elaborate somewhat on the redox chemistry some further experiments, with limited prospects of being synthetically useful, were carried out using precursors in oxidation states +V and +VI.

Dark, olive-green crystals of a compound analysing as $MoCl_4$(tcc) (**3**) were obtained in slightly less than 50% yield by reaction of $MoCl_5$ suspended in CH_2Cl_2 with tcq. Similarly, the reaction of $WCl_5(OEt_2)$ with tcq in CH_2Cl_2 gave, after work up, a low yield (< 20%) of a compound which by IR spectroscopy was shown to be identical to WCl_4(tcc) (**4**). The formation of (**4**) in the reaction between $WCl_5(OEt_2)$ and tcq is accompanied by the formation of small amounts of WCl_6. Based on the low yields (less than 50%) of complexes (**3**) and (**4**) together with the identification of WCl_6 in the reaction with $WCl_5(OEt_2)$ it can be suggested that the chemistry involved may be described by the net disproportionation reactions:

$$2WCl_5 + tcq \longrightarrow WCl_4(tcc) + WCl_6 \quad (1)$$

$$2MoCl_5 + tcq \longrightarrow MoCl_4(tcc) + \text{“Mo(VI)”}. \quad (2)$$

Most likely, eqs (1) and (2) do not completely describe the situation. IR spectra run on the solid residues obtained after isolation of the metal complexes show strong absorption peaks in the range 1775–1716 cm^{-1}. C—O stretching frequencies in that range are usually found in organic carbonyl compounds having two chlorine substituents at the α-carbon atom. The observed high frequency peaks may therefore indicate that a reaction involving oxidation of tcq also occurs.

A possible way to make the reactions more synthetically useful i.e. to avoid the disproportionation of the metal and/or the oxidation of tcq would be the use of a solvent with reducing properties which could act as chlorine acceptor. In the case of the M(V) precursors efforts in that direction have been discouraging. A complex, formulated as $MoCl(tcc)_2$ on the basis of elemental analysis, is formed in the reaction of $MoCl_5$ with tcq using toluene as solvent. Based on the diamagnetism of this complex it is most likely a dimer $[MoCl(tcc)_2]_2$ (**5**). The formation of chlorotoluene, as observed by GC–MS analyses on the volatile reaction products, shows that toluene acts as reducing agent. Aromatic compounds, e.g. benzene[29,30] or toluene,[31] have been used previously as reducing agents in the preparation of $MoCl_4$ and complexes thereof.

The synthetic feasibility of the concept of reducing solvents is, however, nicely demonstrated by the preparation of WCl_4(tcc) (**4**) from WCl_6. WCl_6 reacts in toluene suspension at room temperature with an equimolar amount of tcq to give (**4**) in a quantitative yield. This reaction can also be carried out in benzene, although benzene is not as easily oxidized as toluene and the reaction is considerably slower in this solvent. The oxidized products found by GC–MS analyses of the volatile reaction products using toluene or benzene as solvent are chlorotoluene (two isomers) and chlorobenzene, respectively. It is noteworthy that the chlorination of toluene does not give benzylchloride. This indicates that the reducing solvents are not acting as chlorine radical acceptors but that their participation in the reaction sequence follow another reaction pathway.

Reactions of phenanthrenequinone with $MOCl_3$(DME) (M = Mo, W) *and synthesis of* $MoOCl_2$(phc)(OEt_2)

The formal oxidation state (see below) of the metals and thereby of the phenanthrenequinone ligands differs in complexes WCl_4(phc) (**1**) and $MoCl_4$(phsq) (**2**); **1** is a catecholate complex of tungsten(VI) while **2** is a semiquinonate complex of molybdenum(V). This difference prompted attempts to prepare phenanthrenequinone complexes of M(+V) oxohalides from the easily accessible starting materials $WOCl_3$(DME) and $MoOCl_3$(DME). Both starting materials react straightforwardly with phq in CH_2Cl_2 at room temperature affording the complexes $WOCl_3$(phsq) (**6**) and $MoOCl_3$(phq) (**7**) in high to fair yield. The formal oxidation state of the metal and the quinone ligands of these complexes will be discussed below.

Chloro complexes of tungsten and molybdenum in the +V oxidation state are easily converted to the corresponding oxochloride complexes using oxygen transfer reagents as $Me_3SiOSiMe_3$[32,33] or *t*-BuO-$SiMe_3$.[33] It was considered of interest to apply this kind of oxygen-transfer reaction on the catecholate complexes in the present study, especially in relation to the different oxidation states assigned to the metal in complexes (**1**) and (**2**). The molybdenum complex (**2**) reacts smoothly with *t*-$BuOSiMe_3$ in the presence of diethyl ether to give $MoOCl_2$(phc)(OEt_2) (**8**) in high isolated yield. The corresponding reaction using the tungsten complex (**1**) is considerably more sluggish and no well-defined products were isolated despite several attempts. IR spectroscopic investigations of the solids isolated in the reactions of the tungsten complex showed the presence of $OSiMe_3$- groups in the product, indicating that the reaction does not go to completion. This difference in reactivity may be a reflection of the different oxidation states of the starting materials, Mo(V) and W(VI), respectively; the formation of the molybdenum-oxo group in complex (**8**) is accompanied by an oxidation of the molybdenum atom and a reduction of phsq to phc.

Formal oxidation states of the quinone ligands and the metals in the complexes

Elemental analysis data for the complexes (**1–8**) are given in Table 1. The complexes have also been subjected to analysis by mass-spectroscopy. Spectra run in the FAB^+ mode in ethylene glycol matrix are non-informative while fragments of the molecules can be observed in the EI spectra (70 eV) (Table 2). The molecular ion peaks of the complexes, which appear as the $[M+1]^+$ ion, are usually very weak or not at all observable. A ready elimination of chloro ligands and ligand redistribution reactions in the spectrometer are common features observed in the mass spectra of these types of complexes.

The oxidation state of the metal and the quinone, semiquinone, or catecholate character of the ligand is one important question relating to the complexes prepared in the present study. As observed in a large number of structurally characterized catecholate complexes,[8] the oxidation state of the ligand is reflected in the C—O bonding distance of the ligand. X-ray quality single crystals for either of complexes (**1–8**) have, however, not been obtained, so the discussion on oxidation states must be based on other observations.

The stretching frequency of the C—O bond in quinones has been used to distinguish between different modes of quinone coordination.[9] The IR bands observed for complexes (**1–2**) and (**4–8**) are

Table 1. Analytical data

		Analysed % (Calculated %)			
		C	H	Cl	M
1	WCl_4(phc)	31.9 (31.5)	1.6 (1.5)	25.4 (26.6)	34.3 (34.4)
2	$MoCl_4$(phsq)	36.9 (37.7)	1.9 (1.8)	31.3 (31.8)	21.2 (21.5)
3	$MoCl_4$(tcc)	15.2 (14.9)	—	58.2 (58.6)	19.6 (19.8)
4	WCl_4(tcc)	12.6 (12.6)	—	49.1 (49.6)	32.1 (32.2)
5	$[MoCl(tcc)_2]_2$	23.2 (23.1)	—	50.6 (51.2)	15.8 (15.4)
6	$WOCl_3$(phsq)	33.4 (32.7)	1.8 (1.6)	20.8 (20.7)	34.7 (35.6)
7	$MoOCl_3$(phq)	39.5 (39.4)	1.9 (1.9)	24.8 (24.9)	22.9 (22.5)
8	$MoOCl_3$(phc)(OEt_2)	45.8 (46.5)	4.0 (3.9)	15.5 (15.2)	20.3 (20.6)

given in the Experimental section and the values of ν_{M-Cl} and $\nu_{M=O}$ in Table 2. For the complex $MoOCl_3$(phq) (**7**) a band at 1627 cm^{-1} of medium intensity is observed; it is shifted 47 cm^{-1} relative to the C—O stretching frequency of free phq. This band can rather safely be assigned to a C—O stretching band[9] and the phq ligand in complex (**7**) is therefore coordinated in its quinone form giving the metal a formal oxidation state of +V. Complex (**7**) is the only one which by IR criteria can be stated to contain the ligand in its quinone form; the absence of bands at wavenumbers above 1600 cm^{-1} in the IR spectra of all the other complexes indicate that these contain the ligands in their reduced semiquinone or catecholate state.

Magnetic susceptibility and magnetic moments for the complexes are collected in Table 3. The compounds WCl_4(phc) (**1**), $MoCl_4$(tcc) (**3**), WCl_4(tcc) (**4**) and $MoOCl_2$(phc)(OEt_2) (**8**) are diamagnetic and can therefore be formulated as catecholate complexes of molybdenum and tungsten in the +VI oxidation state (d^0). The dimeric complex $[MoCl(tcc)_2]_2$ (**5**) is also diamagnetic, indicating that this is a catecholate complex of

molybdenum +V with spin pairing of the two paramagnetic metal ions. $MoCl_4$(phsq) (**2**), $WOCl_3$(phsq) (**6**) and $MoOCl_3$(phq) (**7**) are paramagnetic. The IR spectra discussed above is consistent with a fully oxidized phenanthrenequinone ligand in complex (**7**) thus leaving the unpaired electron localized in a metal orbital. The analogous tungsten complex (**6**) is also paramagnetic with a magnetic moment close to that observed for the molybdenum complex (**7**). For complex (**6**), however, no IR evidence substantiating the formulation of the ligand as a quinone was observed and the unpaired electron is most likely localized in a quinone orbital.

The molybdenum complex (**2**) is paramagnetic with a magnetic moment close to the value expected for two unpaired electrons. Given the composition of complex (**2**) two different possible formulations are in accordance with the observed magnetic moment; a molybdenum(+IV) complex with phenanthrenequinone ligand or a molybdenum(+V) complex with a phenanthrenesemiquinone ligand. The IR spectra of complex (**2**) is, however, inconsistent with a fully oxidized phq ligand. This leaves a formulation involving molybdenum(+V) and a phsq ligand as the most likely one. The difference with regard to electronic structure between complexes (**6**) and (**7**) and between complexes (**1**) and (**2**) is noteworthy and reflects a general trend for molybdenum and tungsten.[9,34]

Complexes (**3**) and (**4**) have also been characterized by ^{13}C-NMR (cf. Experimental section). The low field signals are tentatively assigned to the carbonyl carbon atom. The coordination shift of that atom, δ(free ligand)–δ(complex), is positive for both complexes although the values are substantially lower than for other metal-catecholate complexes.[35,36] The value of the coordination shift for the tungsten complex is greater than for the molybdenum complex. This can be due to a greater catecholate character in the tcc ligand of the tungsten complex. Unfortunately, low solubility precluded NMR measurements on the other complexes.

EXPERIMENTAL

General procedures and chemicals

All preparations were carried out under dried argon using conventional Schlenk technique. Solvents were dried by and stored over activated molecular sieves. Tungsten hexachloride (Aldrich, 99.9%) and molybdenum pentachloride (Aldrich 99.9%) were used as received. Tetrachloro-1,2-benzoquinone and 9,10-phenanthrenequinone (Janssen Chimica) were used as received. WCl_4(DME), $MoCl_4(OEt_2)_2$,[25] $WOCl_3$(DME) and $MoOCl_3$(DME)[33] were prepared as described earlier.

Tungsten and molybdenum were determined gravimetrically as WO_3 and MoO_3, respectively. Elemental analyses were done by Mikro Kemi AB (Uppsala, Sweden) and Analyslaboratoriet (Lund, Sweden).

Infrared spectra were recorded on a Nicolet 20 SXC FT-IR or a PE 580B spectrometer as Nujol mulls between CsI windows. ^{13}C-NMR spectra were recorded on a Varian Unity 300 spectrometer. Magnetic susceptibilities were measured at ambient temperature by Evans's method using a Sherwood Scientific Magnetic Susceptibility Balance.

Preparations

Tetrachloro[9,10-*phenanthrenediolato*(2−)-O,O′] *tungsten*(VI) (**1**). Dichloromethane (20 cm^3) was added to a mixture of WCl_4(DME) (1.3 g, 3.1 mmol) and phenanthrenequinone (0.65 g, 3.1 mmol). Stirring at room temperature gave a green solution which rapidly turned blue as a dark precipitate formed. The solid was isolated by Schlenk-filtration after 20 min, washed once with diethyl ether and dried *in vacuo* giving WCl_4(phc) (**I**) as a dark bluish–black shining solid. Yield: 1.3 g, 79%. IR: 1600s, 1588w, 1557m, 1547w, 1508s, 1494m, 1415s, 1347m, 1329m, 1311s, 1298m, 1257m, 1124m, 1040w, 992m, 960m, 935m, 871w, 760vs, 735sh, 716s, 672w, 651w, 612w, 531ms, 460m, 433m, 394s, 376s, 327vs, 289m.

Tetrachloro[9,10 - *phenanthrenesemiquinonato* (1−)-O,O′]*molybdenum*(V) (**2**). Phenanthrenequinone (1.35 g, 6.48 mmol) in dichloromethane (45 cm^3) was added at room temperature to a stirred suspension of $MoCl_4(OEt_2)_2$ (2.5 g, 6.48 mmol) in dichloromethane (20 cm^3). The solution immedi-

ately turned dark bluish–green and a dark precipitate started to form. The reaction was continued overnight. $MoCl_4$(phsq) (**2**) was isolated as a black solid by Schlenk-filtration, washed with three aliquots of diethyl ether (10 cm^3) and dried *in vacuo*. Yield: 2.5 g, 87%. IR: 1592s, 1571sh, 1548s, 1491ms, 1364s, 1324m, 1304s, 1292sh, 1237w, 1171m, 1159ms, 1124ms, 1098w, 1080w, 1037w, 993m, 974w, 967w, 937m, 885w, 811w, 787m, 773m, 766vs, 735sh, 705s, 684m, 674m, 633w, 527ms, 428ms, 412m, 385s, 374s, 351sh, 328vs.

Tetrachloro[3,4,5,6 - *tetrachloro* - 1,2 - *benzenediolato*(2−)-O,O′]*molybdenum*(VI) (**3**). Tetrachloroquinone (3.28 g, 13.33 mmol) in dichloromethane (30 cm^3) was slowly added to a cooled (−25°C), stirred suspension of $MoCl_5$ (3.65 g, 13.35 mmol) in dichloromethane (60 cm^3). The reddish–brown suspension rapidly turned intensely green and a dark precipitate formed. The reaction was continued at −25°C for 30 min and then at room temperature for 45 min. Cooling and Schlenk-filtration gave dark olive–green crystals of $MoCl_4$(tcc) (**3**) which were washed with diethyl ether and dried *in vacuo*. Yield: 2.7 g, 42%. The substance does not mull in Nujol and, consequently, no IR spectrum was obtained. ^{13}C-NMR (CH_2Cl_2/CD_2Cl_2 3:1): 163.77, 155.97, 111.19 ppm.

Tetrachloro[3,4,5,6 - *tetrachloro* - 1,2 - *benzenediolato*(2−)-O,O′]*tungsten*(VI) (**4**). Solid tetrachloroquinone (1.55 g, 6.30 mmol) was added to a dark blue suspension of WCl_6 (2.5 g, 6.30 mmol) in toluene (40 cm^3) giving a dark green solution and a black precipitate. The reaction mixture was stirred for 24 h at room temperature, causing the precipitate to slowly dissolve. The deep purple solution obtained was cooled at −25°C overnight. Schlenk-filtration and evaporation of the filtrate gave dark green crystals of WCl_4(tcc) (**4**). Yield: 3.52 g, 98%. Minor impurities of $WOCl_4$ were removed by washing with diethyl ether or by sublimation. IR: 1529w, 1400m, 1269w, 1240m, 1017m, 1006w, 819m, 786s, 616m, 582m, 513w, 419ms, 401s, 388s, 349vs, 291ms. ^{13}C-NMR (CH_2Cl_2/CD_2Cl_2 3:1): 153.87, 145.24, 116.06 ppm.

Tetrakis[3,4,5,6 - *tetrachloro* - 1,2 - *benzenediolato*(2−)-O,O′]*dichlorodimolybdenum*(V) (**5**). $MoCl_5$ (1.0 g, 3.66 mmol) and tetrachloroquinone (0.9 g, 3.66 mmol) were treated with toluene (15 cm^3) under stirring at room temperature. An immediate reaction ensued, giving a clear, green solution which turned blue within 20 min. The reaction was allowed to continue for 24 h, resulting in a dark blue solution and a dark precipitate. Schlenk-filtration, washing with diethyl ether and drying *in vacuo* gave a dark reddish–brown compound which according to its IR-spectrum and elemental analysis contained toluene. Toluene was removed by stirring the solid in dichloromethane overnight followed by filtration and drying *in vacuo* giving (**5**) as a red–black powder. Yield: 1.11 g, 49%. IR: 1577w, 1558w, 1511s, 1409s, 1330m, 1299ms, 1269m, 1224vs, 1006s, 1000sh, 898w, 810w, 794s, 730m, 572m, 560m, 495m, 435s, 393w, 370s, 277m.

Trichlorooxo[9,10 - *phenanthrenesemiquinonato*(1−)-O,O′]*tungsten*(VI) (**6**). Phenanthrenequinone (0.92 g, 4.42 mmol) in dichloromethane (25 cm^3) was added to a stirred solution of $WOCl_3$(DME) (1.75 g, 4.42 mmol) in dichloromethane (40 cm^3) at room temperature. The blue solution immediately turned red–violet and a dark precipitate started to form. The reaction was continued for 2 h. $WOCl_3$(phsq) (**6**) was isolated by Schlenk-filtration, washed with two aliquots of diethyl ether (5 cm^3) and dried *in vacuo*. Concentration of the filtrate followed by addition of diethyl ether gave a second crop of (**6**). Total yield: 1.75 g, 77%. IR: 1597ms, 1585s, 1519w, 1494m, 1394ms, 1341m, 1311s, 1290s, 1279s, 1240w, 1230m, 1210s, 1160m, 1125m, 1105m, 1081w, 1037m, 1004w, 995vs (W=O), 986m, 969m, 960w, 938m, 877m, 784m, 766vs, 735m, 710s, 677m, 636m, 531ms, 495m, 417w, 393m, 384m, 366vs, 350s, 339s, 320m, 248m.

Trichlorooxo[9,10 - *phenanthrenequinone* - O,O′]*molybdenum*(V) (**7**). The preparation was carried out as described for (**6**) giving $MoOCl_3$(phq) (**7**) in 48% yield. IR: 1627m (C=O), 1585s, 1573s, 1557s, 1545sh, 1361m, 1325w, 1299s, 1290sh, 1260w, 1246w, 1171m, 1159ms, 1124ms, 993vs (Mo=O), 965w, 938m, 925w, 883w, 822w, 787m, 780m, 766vs, 733sh, 707s, 683mw, 676m, 633w, 531ms, 510m, 476mw, 430m, 399mw, 383s, 376s, 351vs, 341vs, 313m.

Dichlorooxo[1,1 - *oxybis*(*ethane*)][9,10 - *phenanthrenediolato*(2−)-O,O′]*molybdenum*(VI) (**8**). *t*-$BuOSiMe_3$ (1.18 g, 8.07 mmol) was added to a stirred suspension of $MoCl_4$(phsq) (3.6 g, 8.07 mmol) in dichloromethane (100 cm^3) at room temperature. The blue solution rapidly turned purple. Addition of diethyl ether (15 cm^3) after 5 min caused the solid to partly dissolve. The reaction was continued for 24 h and $MoOCl_2$(phc)(OEt_2) (**8**) was collected by Schlenk-filtration and dried *in vacuo*. Concentration and cooling of the filtrate gave a second crop of (**8**). A third crop was obtained by the addition of diethyl ether to the filtrate. Total yield: 3.4 g, 91%. IR: 1598ms, 1573m, 1549w, 1498s, 1408m, 1394s, 1324m, 1317m, 1301ms, 1236m, 1228sh, 1187m, 1165w, 1153w, 1147m, 1124m, 1082m, 1040w, 1012m (C—O—C ether), 985m, 962vs (Mo=O), 941m, 891m, 867w, 862w, 826m, 789m, 771s, 757vs, 713s, 689m, 673m, 640w,

551m, 540ms, 502m, 466m, 444w, 433m, 401m, 393m, 382m, 358vs, 336vs, 291m.

Abstract—Reaction of RSeCl (R = 4-Cl-C_6H_4) with titanocene pentasulphide Cp_2TiS_5 affords the novel $RSeS_5SeR$ as a yellow oil which is quite stable at 20°C. Using $Cp_4'Ti_2S_4$ (Cp′ = $CH_3C_5H_4$) as a sulphur transfer reagent the reaction with RSeCl results in a mixture of $(RSe)_2S_n$ molecules with n = 0–10, which on heating produces even longer chains as demonstrated by HPLC analysis. Titanocene pentaselenide Cp_2TiSe_5 reacts with RSeCl at 4°C to give a mixture of R_2Se_x molecules (x = 1–7) and Se_8, the relative concentrations sharply decrease with increasing x. ^{77}Se NMR and UV spectra as well as retention index data of the new molecules are reported.

While organic polysulphanes **1** are known in large numbers,[2] little information on the analogous organic polyselanes **2** is available and the same holds for organic selenasulphanes **3**.

R—S_n—R R—Se_n—R R—Se_nS_m—R
1 **2** **3**

This is due to the fact that the bond energy of SeSe bonds is much lower than that of SS bonds and therefore polyselenium compounds usually decompose rapidly even at 20°C, especially in solution, and often with precipitation of elemental selenium. In the case of R = aryl and $n > 2$ only some triselanes have been prepared (R = substituted phenyl groups).[3] In addition, a cyclic ferrocenyltriselane $Fe(C_5H_4)_2Se_3$ is known.[4]

In recent years a number of polysulphur and polyselenium compounds has been prepared using the titanocene chelate complexes Cp_2TiS_5 and Cp_2TiSe_5 (Cp = C_5H_5) as sulphur and selenium transfer reagents.[5–7] By reaction with SCl or SeCl compounds these reagents transfer the —S_5—, respectively —Se_5— groups in exchange for chlorine atoms. The dinuclear complex $Cp_2'Ti(\mu\text{-}S_2)_2TiCp_2'$ (Cp′ = $C_5H_4CH_3$) reacts in a similar manner as a transfer reagent for —S_2— units.[8]

In this work we report on the attempts to synthesize acyclic diarylpolychalcogen compounds of types **2** and **3** from the above mentioned titanocene complexes by reactions shown in eqs (1)–(4) with R = 4-Cl-C_6H_4:

$$R_2Se_2 + Cl_2 \longrightarrow 2RSeCl, \quad (1)$$

$$2RSeCl + Cp_2TiS_5 \longrightarrow (RSe)_2S_5 + Cp_2TiCl_2, \quad (2)$$

$$4RSeCl + Cp_2'Ti(\mu\text{-}S_2)_2TiCp_2' \longrightarrow 2(RSe)_2S_2 + 2Cp_2'TiCl_2, \quad (3)$$

$$2RSeCl + Cp_2TiSe_5 \longrightarrow R_2Se_7 + Cp_2TiCl_2. \quad (4)$$

* Part 169 of the Series Sulphur Compounds; for Part 168 see ref. 1.

† Author to whom correspondence should be addressed.

The reactions were followed by reversed-phase high-pressure liquid chromatography (HPLC) and ^{77}Se NMR spectroscopy using the natural abundance of ^{77}Se (7.6%, I = 1/2). Both HPLC[9] and ^{77}Se NMR spectroscopy[10,11] have previously been applied successfully to analyse mixtures of organic polyselenium compounds.

EXPERIMENTAL

Materials

Carbon disulphide (techn. grade) was purified and dried by distillation from P_4O_{10}. Cp_2TiS_5 (Cp = C_5H_5) and $Cp'_4Ti_2S_4$ (Cp' = $CH_3C_5H_4$) were prepared according to literature methods.[12] Bis(4-chlorophenyl)diselane (98%, Aldrich) was used as delivered. For chlorination reactions a solution of Cl_2 in CCl_4 was prepared by bubbling dry Cl_2 into 1.5 l of CCl_4 (p.a. Merck). The concentration was determined as 15.2 mg Cl_2/(ml CCl_4) by differential weighing. Technical methanol used as an eluent was distilled from anhydrous magnesium sulphate and degassed under reduced pressure and with application of ultrasound prior to use. Silica gel (Kieselgel 40, Merck Rt. 10181) was used for filtration.

Procedures and instrumentation

HPLC analysis was performed with the following equipment: Millipore Waters Radial-Pak cartridges filled with C18 phase (particle size 5 μm, length 10 cm, inner diameter 8 mm) contained in a compression module (Waters RCM 100); Perkin–Elmer LC 75 (variable wavelength detector with deuterium lamp) for UV detection at 254 nm; Perkin–Elmer Series 2 pump; Rheodyne syringe loading injector 7125 (sixport) with a 10 μl sample loop; electronic integrator HP 3390A for retention time measurements. UV spectra were recorded using a diode array detector (Waters 990) with a resolution of 2 nm controlled by a NEC APC III computer. ^{77}Se NMR spectra were recorded at 68.679 MHz with a Bruker WM 360 spectrometer controlled by an Aspect 3000 computer. Sample tubes of 10 mm outer diameter were used.

The samples were dissolved in CS_2/C_6D_6 (3/1). Neat Me_2Se sealed in an NMR glass tube surrounded by neat C_6D_6 in an outer coaxial NMR tube was used as a standard and chemical shifts refer to this compound. Raman spectra were obtained with a Kr ion laser (Spectra Physics) operating at 647.1 nm, a double monochromator Ramanor U1000 (Jobin Yvon), equipped with a GaAs photomultiplier R943-02 (Hamamatsu) and a data processing and controlling unit MAC 80 A with the software Spectra Control (Spectra Data) under the following conditions: slit width 650 μm, sample temperature, −50°C, laser power 80 mW, wavelength accuracy ± 1 cm^{-1}.

Synthesis of $RSeS_5SeR$ (R = 4-ClC_6H_4)

A solution (16.1 cm^3) of Cl_2 (3.45 mmol) in CCl_4 was added to a stirred solution of 0.982 g R_2Se_2 (2.56 mmol) in 15 cm^3 carbon disulphide to prepare RSeCl. After 25 min the excess of Cl_2 was removed *in vacuo*. Within 2 min the reaction mixture was added dropwise to a stirred solution of 0.868 g Cp_2TiS_5 (2.56 mmol) in 80 cm^3 CS_2. After 5 min the reaction mixture was sucked through a column filled with 10 cm silica gel. The eluate was filtered again. After removing the solvent *in vacuo* 1.39 g (83%) $RSeS_5SeR$ was obtained as a yellow oil. Found: C, 26.9; H, 1.6; S, 29.8. Calc.: C, 26.6; H, 1.5; S, 29.6%.

Vibrational spectra (values in cm^{-1}, relative intensities in brackets): (a) Raman spectrum: 166(m), 233(vw), 250(m),. 334(vw), 372(vs), 403(vw), 430(w), 452(s), 469(s). 626(w), 729(m), 1066(s), 1088(m), 1176(w), 1570(m), 3046(vw), 3062(vw). (b) IR spectrum: 303(w), 330(w), 332(w), 370(w), 400(w), 480(vs), 622(vw), 692(w), 727(s), 807(vs), 947(w), 953(w), 1008(vs), 1058(m), 1062(m), 1087(vs), 1105(s), 1172(s), 1220(w), 1263(m), 1291(m), 1340(vw), 1383(vs), 1424(m), 1470(vs), 1568(s), 1635(m), 1773(w), 1818(vw), 1890(m).

Synthesis of $RSeS_2SeR$ *and* $RSeS_ySeR$ (y = 1–15)

A solution (18.7 cm^3) of Cl_2 (5.19 mmol) in CCl_4 was added to a stirred solution of 1.524 g R_2Se_2 (4.0 mmol) in 16 cm^3 carbon disulphide. After 15 min the excess of Cl_2 was removed *in vacuo*. Within 5 min the cold reaction mixture was added dropwise to a stirred solution of 1.081 g $Cp'_4Ti_2S_4$ (2.00 mmol) in 80 cm^3 CS_2 at 4°C. After 3 min the reaction mixture was sucked through a column filled with 10 cm silica gel. The eluate was filtered again. After removing the solvent *in vacuo* a yellow oil was obtained containing several $RSeS_ySeR$ molecules (y = 1–7) and R_2Se_2 with $RSeS_2SeR$ as the main sulphur containing product. Heating of this mixture resulted in the formation of additional $RSeS_ySeR$ molecules (y = 1–10), strong heating yielded $RSeS_ySeR$ (y = 1–15) and traces of S_8.

Synthesis of R_2Se_x (x = 1–7)

A solution (8.3 cm^3) of Cl_2 (1.8 mmol) in CCl_4 was added to the stirred solution of 0.520 g (1.365

mmol) R_2Se_2 in 10 cm^3 carbon disulphide. After 25 min any excess of Cl_2 was removed *in vacuo*. The reaction mixture was added to a stirred solution of 0.781 g Cp_2TiSe_5 (1.365 mmol) in 80 ml CS_2 at 20°C. After 9 min the mixture was sucked through a column filled with 10 cm of silica gel to remove Cp_2TiCl_2. The eluate was filtered again. After evaporation *in vacuo* a red solid consisting of a mixture of R_2Se_x molecules (x = 1–7) and Se_8 was obtained.

RESULTS

$RSeS_5SeR$

4-Chlorobenzeneselenylchloride reacts with Cp_2TiS_5 at 20°C quantitatively according to eq. (2) to give the mixed polychalcogenide $(RSe)_2S_5$ which was isolated as a yellow oil. The HPLC analysis of the yellow oil showed that the freshly prepared product contained small amounts (*ca* 2 mol%) of the starting material R_2Se_2 but no other $(RSe)_2S_y$ molecules could be detected (Fig. 1a). On standing at 20°C the yellow oil as well as its solution in CS_2/C_6D_6 (for NMR measurements) slowly decomposed yielding new molecules which originate from a sulphur atom exchange reaction; eq. (5).

$$2(RSe)_2S_y \rightleftharpoons (RSe)_2S_{y+n} + (RSe)_2S_{y-n}. \quad (5)$$

The HPLC analysis of such a mixture showed small peaks of almost equal size (by area) for all species with 1–10 sulphur atoms. The natural abundance ^{77}Se NMR spectrum (recording time 12 h) exhibited a major signal for $(RSe)_2S_5$ at 650.9 ppm and in addition signals for other $(RSe)_2S_y$ molecules which are assigned to the species with y = 1, 2, 3 and 4 (Fig. 2). The NMR signals of the species with y = 6–10 are probably hidden in the wing on the left side of the tallest signal. Enhancement of the resolution by data processing showed a triplet with a coupling constant of 2.7 ± 0.1 Hz for the Se—H coupling in $(RSe)_2S_5$ ($^3J_{Se-H}$).

The Raman spectrum of neat $(RSe)_2S_5$ (Fig. 3) exhibits the expected lines for 4 SS stretching vibrations at 430, 452, 469 and 490 cm^{-1} as well as two lines at 372 and 389 cm^{-1} which can be assigned to the SeS stretching modes by comparison with the spectra of other SeS compounds.[13]

R_2Se_2 has its strongest Raman line at 269 cm^{-1} (SeSe stretching mode); this line is not observed in the $(RSe)_2S_5$ spectrum indicating that the concentration of R_2Se_2 is very low. The other Raman lines as well as most of the IR frequencies may be assigned to vibrations of the *para*-substituted benzene ring.

The EI mass spectrum of $(RSe)_2S_5$, as expected, did not show a peak of the molecular ion. The

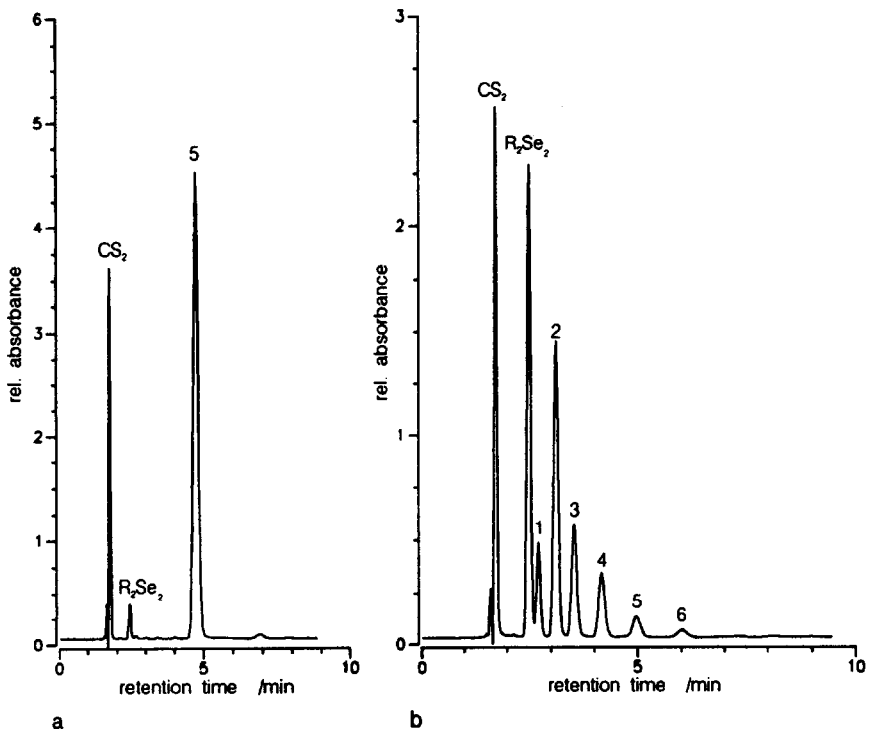

Fig. 1. HPLC analysis of (a) the yellow oil obtained by reaction shown in eq. (2) and (b) of the mixture obtained by reaction in eq. (3). The numbers at the peaks give the number of sulphur atoms in the formula $(RSe)_2S_y$.

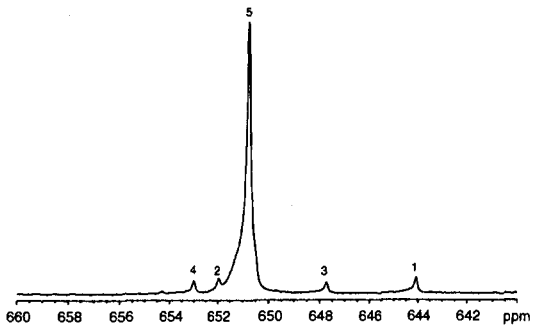

Fig. 2. ^{77}Se NMR spectrum of the yellow oil obtained in reaction shown in eq. (2). Solvent: CS_2/C_6D_6. The numbers at the peaks give the number of sulphur atoms in the formula $(RSe)_2S_y$. The shoulder at the left wing of the tallest peak probably represents molecules with six and more sulphur atoms.

heaviest fragment was observed at $m/z = 414$ and corresponds to $(RSe)_2S^+$. In addition, peaks for $R_2Se_2^+$, R_2Se^+, Se_2^+, and S_y^+ ($y = 2$–8) were observed (sample temperature 100°C; electron energy 60 eV).

$RSeS_2SeR$

When freshly prepared RSeCl was treated with $Cp'_4Ti_2S_4$ in CS_2 at 20°C the primary reaction was the formation of $(RSe)_2S_2$ according to eq. (3). The HPLC analysis after removal of Cp'_2TiCl_2 (Fig. 1b) showed, however, the presence of considerable concentrations of R_2Se_2 as well as of other members of the homologous series $(RSe)_2S_y$. This may be explained by a series of sulphur transfer reactions [eq. (5)] which are probably catalysed by either titanocene complexes or by the silica gel used to remove Cp'_2TiCl_2. Part of the R_2Se_2 observed may stem from the preparation of RSeCl, however (imperfect chlorination).

The ^{77}Se NMR spectrum of the mixture obtained by reaction (3) exhibits large peaks for R_2Se_2 and $(RSe)_2S_2$ as well as smaller ones for the other members of the homologous series with 1–6 sulphur atoms connecting the two RSe units (Fig. 4). From the peak heights in the NMR spectrum the following molecular composition (mol-%) was derived: R_2Se_2 28.5, $(RSe)_2$ 7.8, $(RSe)_2S_2$ (30.6), $(RSe)_2S_3$ 13.5, $(RSe)_2S_4$ 10.4, $(RSe)_2S_5$ 5.7, $(RSe)_2S_6$ 3.6%.

When this mixture was heated to above 100°C for a short time the decomposition according to equation (5) was accelerated and in addition S_8 was formed:

$$(RSe)_2S_{8+n} \longrightarrow (RSe)_2S_n + S_8. \qquad (6)$$

The chromatogram of this decomposed sample shows $(RSe)_2S_{15}$ as the largest molecule present (Fig. 5). The assignment of these peaks is straightforward since members of homologous series show the following dependence of the retention time t_r on the chain-length y (k' = capacity factor, t_0 = dead time):

$$\ln k' = a \cdot y + b,$$

$$k' = (t_r - t_0)/t_0.$$

In Fig. 6 it is shown that for $(RSe)_2S_y$ molecules this relationship holds for $y = 1$–12 with small deviations for $y = 1$ and 2. It is often observed that the first members of a series do not fit the linear equation too well. Since $(RSe)_2S_2$ is the main product

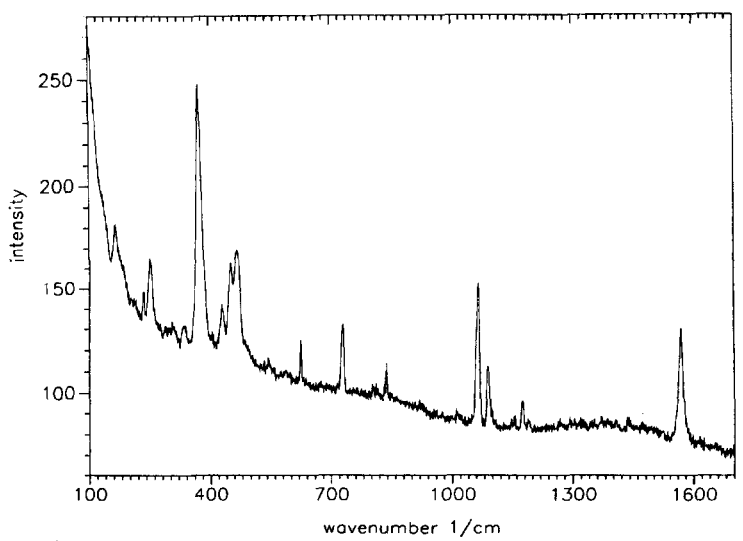

Fig. 3. Raman spectrum of neat $(RSe)_2S_5$ at −50°C.

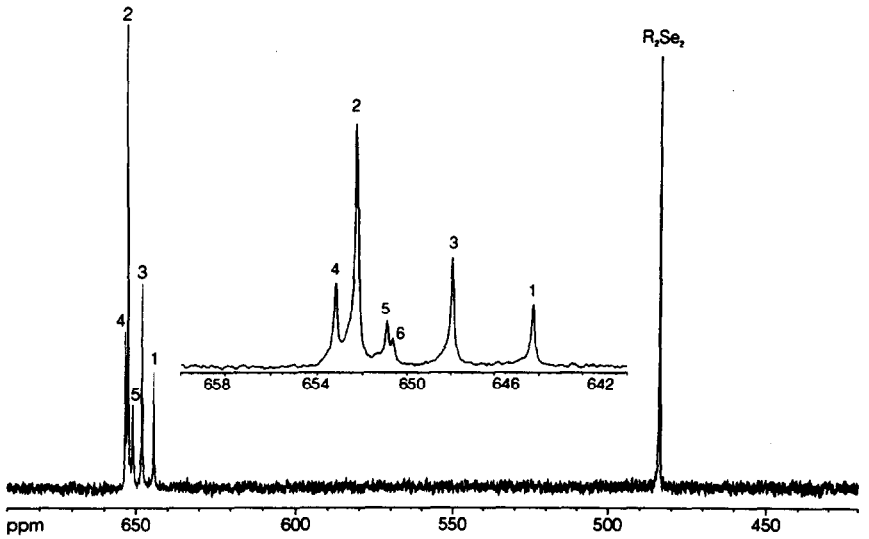

Fig. 4. ^{77}Se NMR spectrum of the mixture obtained by reaction shown in eq. (3). The numbers at the peaks give the number of sulphur atoms in the formula $(RSe)_2S_y$.

in the reactions in eq. (3) and $(RSe)_2S_5$ in eq. (2) the assignment of the peaks in Fig. 5 is straightforward. The correlation coefficient of the linear relationship applying to $(RSe)_2S_y$ with $y > 2$ is better than 0.9999. The retention times are given in Table 1.

This Table also gives the retention index values RS which, like Kovats retention indices in gas chromatography, give the retention relative to the sulphur homocycles S_6, S_8, S_9 and S_{10}. Such RS values are characteristic properties of compounds and independent on the HPLC apparatus used.[2,14]

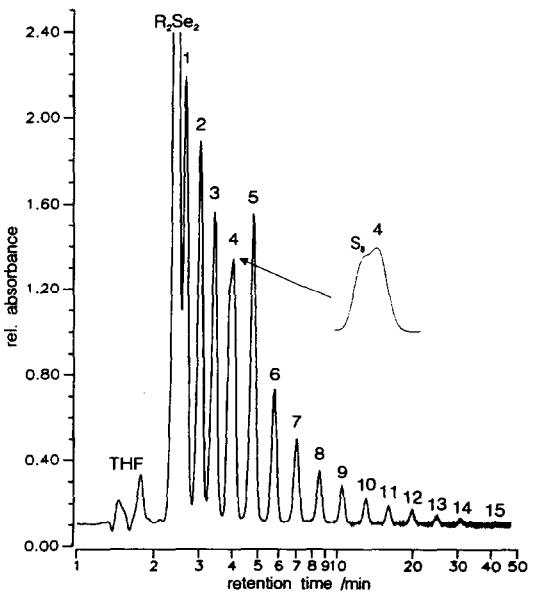

Fig. 5. HPLC analysis of a mixture of $(RSe)_2S_y$ molecules ($y = 0$–15) obtained by heating the products of reaction shown in eq. (3). Note the logarithmic plot of the retention time. The numbering of peaks gives the number of sulphur atoms in the formula. THF was used as a solvent.

The assignment of the NMR signals in Figs 2 and 4 is more complicated but by correlating the NMR peak heights with the HPLC peak areas of various mixtures of $(RSe)_2S_y$ molecules it was possible to assign the signals caused by the first six members of this series ($y = 1$–6). The corresponding chemical shifts are given in Table 2. Using a diode array detector connected to the HPLC apparatus the absorption spectra of freshly separated $(RSe)_2S_y$ molecules ($y = 1$–5) could be recorded on-line in the eluent methanol and in the range 200–600 nm. Two absorption maxima were observed for each compound. No absorbance coefficients can be

determined in this way but the relative intensities of the two maxima at 248 and 353 ± 2 nm are given in Table 3.

RSe_xR

When RSeCl was reacted with Cp_2TiSe_5 in CS_2 at 20°C the HPLC analysis of the mixture showed that the reaction in eq. (4) had taken place but the expected main product RSe_7R was present in traces only, even when the reaction was carried out at −50°C and with exclusion of light. The precipitation of Se_8 from the reaction mixture shows that decomposition according to eqs (7) and (8) rapidly occurred.

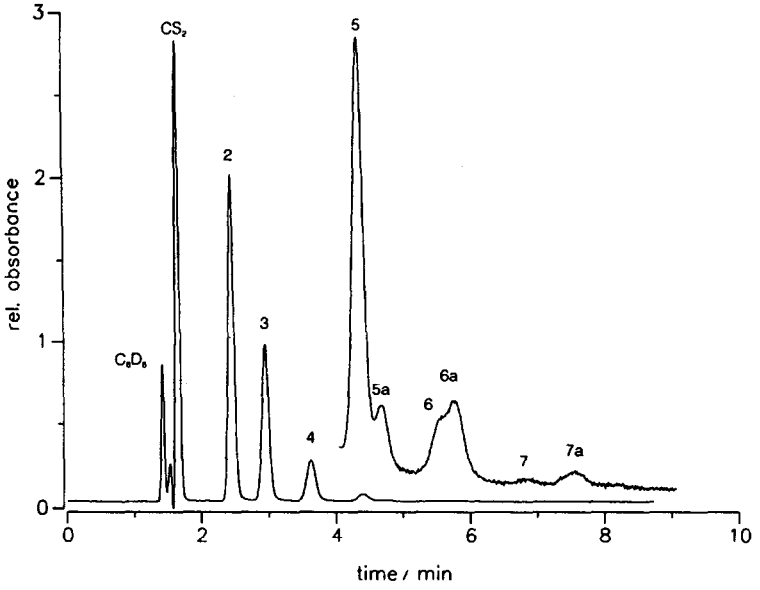

Fig. 7. HPLC analysis of the products of reaction shown in eq. (4) after storage at 20°C for 12 h. The peak numbers give the number of Se atoms in the formula R_2Se_x; peaks 5a, 6a, and 7a have not been identified.

HPLC analysis of this sample are shown in Figs 7 and 8. The chromatogram shows in decreasing concentrations R_2Se_2, R_2Se_3 and R_2Se_4 as the main constituents. Since the molar extinction coefficients must increase with the length of the selenium chain the decrease in concentration is even more dramatic than suggested by the peak areas in Fig. 7. R_2Se_5 is present in trace amounts only. In addition, there are a few very weak peaks (5a, 6, 6a, 7, 7a) of which 6 and 7 can be assigned to R_2Se_6 and R_2Se_7 on the

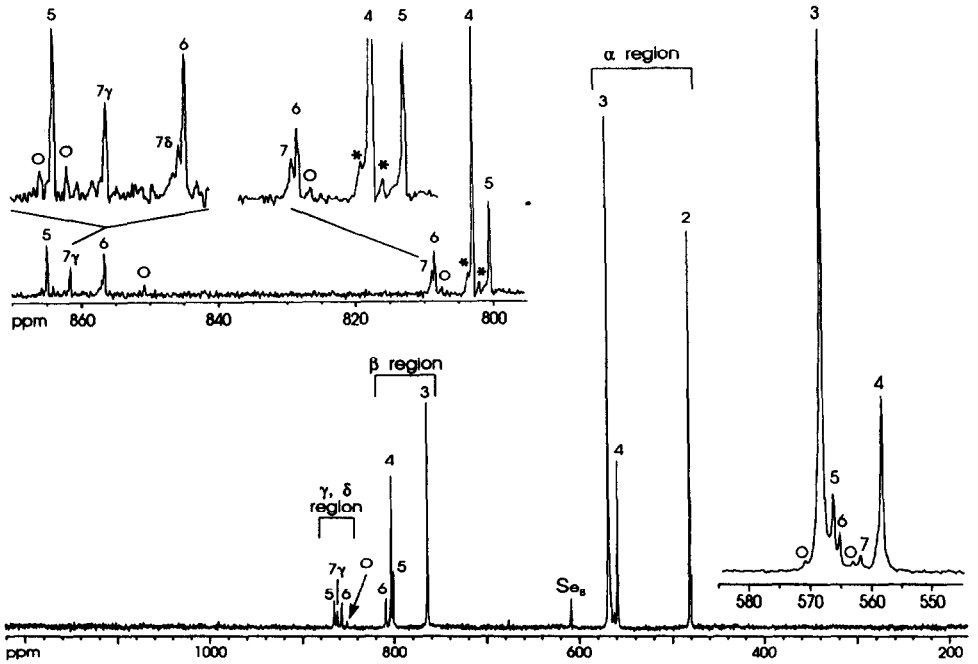

Fig. 8. ^{77}Se NMR spectrum of the mixture of R_2Se_x molecules obtained by reaction shown in eq. (4). The atom numbering α through δ is explained in Fig. 9. The numbers at the peaks give the chain-length x. Open circles indicate signals possibly arising from the minor components R_2Se_8 and R_2Se_9. The two satellites of peak 4 in the β region marked by asterisks arise from Se—Se coupling. For chemical shift data see Table 2.

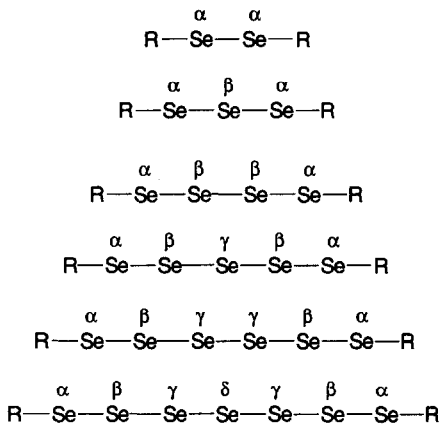

Fig. 9. Labelling of Se atoms in organic polyselanes.

basis of the linear relationship depicted in Fig. 6. The correlation coefficient of this relationship for x = 1–7 amounts to 0.9998. However, peaks 5a, 6a and 7a cannot be explained at present. No HPLC signals for Se_6, Se_7 or Se_8 could be detected. The absorption spectra of R_2Se_x molecules in methanol are characterized by two maxima in the range 200–600 nm occurring near 255 and 390 nm for x = 3–6 while for R_2Se_2 the second maximum is observed at 338 nm (see Table 3).

The complex ^{77}Se NMR spectrum of the mixture obtained by eqs (4), (7) and (8) (Fig. 8) was assigned mainly on the basis of the HPLC peak areas and taking the sparse literature data[10,11] into account. It is common practise to term the terminal Se atoms in R_2Se_x molecules as α, the neighboring atoms as β, and so forth (Fig. 9). The available data indicate that the chemical shift increases in going from α over β to γ Se atoms.[10,11] Data for δ Se atoms are known from Et_2Se_7 only.[11] Consequently, we assign the signals in the range 475–600 ppm to α Se atoms, those in the range 760–820 ppm to β atoms and signals above 820 ppm to γ and δ atoms (see Table 2). The width of the NMR lines at half height will depend on the coupling between ^{77}Se and ^{1}H, ^{13}C and other ^{77}Se atoms.

The latter should result in satellites of 3.8% the intensity of the centre line. Only in one case we observed a Se—Se coupling: the lines arising from the β Se atoms of R_2Se_4 show two satellites with a coupling constant $^2J_{Se-Se}$ of 113 Hz (see Fig. 8). All other couplings were not resolved and will contribute to the line half-width which for α Se atoms increases with the chain-length from 38 Hz for R_2Se_2 to *ca* 55 Hz for R_2Se_7. The typical half-width of the lines of β, γ and δ Se atoms is 30–40 Hz.

DISCUSSION

Our results demonstrate that titanocene polychalcogenide complexes may be used to synthesize organic selenium containing compounds of type **2** and **3**. However, only such species not containing Se—Se bonds seem to be stable enough to be isolated as pure materials. The $RSeS_5SeR$ prepared in this work as a pure material represents the longest mixed chain of chalcogen atoms ever prepared in an acyclic organic compound. And the $(RSe)_2S_y$ molecules with $y = 1$–15 as detected by HPLC form the longest series of Se containing chain-like compounds observed so far. HPLC and ^{77}Se NMR spectroscopy are ideal complementary techniques to elucidate the composition of such mixtures. The longest homoatomic Se chain detected in this work with certainty is R_2Se_7. This species is similar to the $(C_2H_5)_2Se_7$ detected in trace amounts by ^{77}Se NMR spectroscopy in an Et_2Se_x mixture prepared from EtSH and $SeOCl_2$ followed by distillation in a high vacuum; the residue thus obtained contains higher members of the series Et_2Se_x (x = 1–7).[11]

The interconversion reactions [eqs (5)–(8)] are known to be catalysed by traces of nucleophiles[2] and also by titanocene complexes.[15] Therefore, reactions shown in eqs (3) and (4) did not yield the pure compounds $(RSe)_2S_2$ and R_2Se_7 which we had expected. But nevertheless the chromatographic and spectroscopic analysis of the reaction mixtures provided valuable data about the members of the homologous series $(RSe)_2S_y$ and R_2Se_x.

(*Received* 16 *June* 1993; *accepted* 28 *June* 1993)

Abstract—A novel method for the synthesis of pillared smectites (cross linked intercalated smectites) by refluxing a mixture of bentonite (2 wt%) and nano hydroxy aluminium oxide (boehmite, Al—O—OH) sol in aqueous medium is reported. Mixed sol containing boehmite and hydrous cerium oxide has resulted in mixed oxide pillared smectites. The various conditions of the intercalation are reported and the characteristics of the intercalated smectites have been evaluated using XRD, surface area analysis and thermogravimetric techniques. The present method is shown to be effective in reducing the time of pillaring. High order of intercalation 20 Å and specific surface area of 260 $m^2 g^{-1}$ are achieved by this method. Further, the possibility of handling a higher concentration of the smectite, which has been a limiting factor in the usual methods, is highlighted. The dielectric constants of the dried smectites after intercalation by reflux are compared with those prepared by usual methods. The present technique of refluxing a mixture of mono ion exchanged smectite and hydrous metal oxide sols is novel due to its capability to intercalate smectites having high surface area, increased interlayer spacing and also enhanced thermal stability.

Alumino silicate minerals of the montmorillonite type, generally known as smectites, can be intercalated with suitable large size organic molecules or hydrated metal oxide clusters. Such intercalated alumino silicates have been found to possess large specific surface area and hence have gained commercial importance as catalysts. Specifically when the intercalation is done using hydroxy metal oxide oligomers, they can be dehydroxylated to metal oxide intercalated smectites or also known as pillared intercalated clays (PILC) or cross linked smectites (CLS).[1–4] Usually montmorillonite clays are used as the alumino silicate source. A dilute suspension (about 1 wt%) of the montmorillonite after mono ion exchange is mixed with intercalating species of hydrated metal oxide (aluminium, zirconium, iron etc.) and allowed to stand under constant shaking for 15–40 h. The solid is separated and washed several times and dehydroxylated.[4–6]

Some of the major difficulties involved in the synthesis of such smectites are the low solid content used in the suspension, long reaction times, control of pH and the drying and dehydroxylation.[2] The possibility of using high solid content has been reported through the hydrothermal reaction.[7] Similarly hydrated metal oxide nanosize dispersion such as sols[8,9] have been successfully used as intercalating agents associated with enhanced thermal stability. Further, microwave drying of the intercalated smectites as well as drying under supercritical condition[10] has been successful in reducing the drying time considerably. Recent studies have shown that intercalation at elevated temperature can increase the extent of pillaring.[8]

The present work is on the possibility of conducting intercalation reactions involving hydroxy metal oxide and mixed oxide sols under reflux conditions. Such intercalated smectites have been compared with those derived from sol cross linked smectites (SCLS) at a lower temperature. The rate of intercalation reaction is fast under reflux and such smectites have improved properties. Further, intercalation from a mixed sol system is also possible under reflux conditions.

EXPERIMENTAL

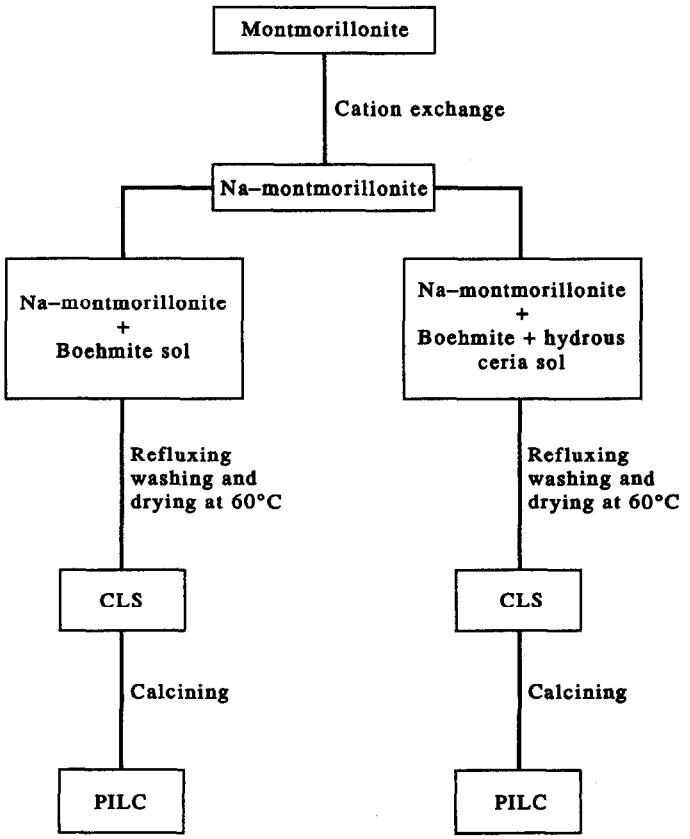
The montmorillonite sample was of high purity having a cation exchange capacity of 34.4 meq g^{-1} and was characterized by the usual methods. The montmorillonite was converted to a sodium exchanged one by treating with 0.1 M NaCl under shaking for 12 h followed by centrifugal separation and repeated washing.

A suspension containing 2 wt% sodium exchanged montmorillonite and a boehmite sol[11] containing 0.25 g Al g^{-1} of montmorillonite was refluxed for a period of 2 h and kept for another 12 h. The initial pH was 4.05 which was lowered to 4.0 after the intercalation. The time of reaction was fixed after trials. Similarly, mixtures of sols in a 50 : 50 ratio were made from aluminium and cerium hydroxides and the intercalating mixture contained 2 wt% montmorillonite and 0.25 g metal g^{-1} of montmorillonite. The details of the preparation are presented in the flow chart.

The reaction mixture was centrifuged to remove the solid part and washed repeatedly with distilled water. Intercalated montmorillonite was dried at 60°C in an air oven. Part of this was heated for 2 h at 500 and 700°C. One experiment was conducted with the same mixture at 32°C for comparison. The basal spacings were detected by the XRD technique using a diffractometer (Rigaku, Japan) with Ni filtered Cu-K_α radiation. The specific surface area was measured using the BET technique (Surface Area Analyser, Micromeritics Model 2000). Thermogravimetry of the samples was done at a heating rate of 5°C min^{-1} (TGA Dupont, U.S.A.). Dielectric constants on 10 mm pellets pressed out of air dried samples were measured on an Impedence Analyser (Hewlett Packard, Switzerland).

RESULTS AND DISCUSSION

The montmorillonite sample after sodium exchange had a specific surface area of 77 m^2 g^{-1} which on intercalation with boehmite sol at 32°C gave a value of 160 m^2 g^{-1}. On the other hand, the mixed sol intercalation gave only about 105 m^2 g^{-1}. The reflux method resulted in values as high as 213 m^2 g^{-1} in the case of boehmite sol and a still higher value of 265 m^2 g^{-1} for the boehmite-hydrous ceria sol in a 1 : 1 ratio. The possibility of delamination under the reflux conditions and also control of the optimum pH would have assisted the cationic species to attach themselves in the interlayer space as pillars. The



polymerized molecular aggregates of the sol could hold on to the reactive sites in the delaminated montmorillonite layers and thus resulted in high surface areas. From the specific surface area values of intercalated smectites between the reflux and low temperature conditions, it is reasonable to assume a sort of staggered pillaring pattern to prop up the layers of the smectites. The high values also indicate the efficiency of reflux method within short reaction time. Even after heating above 700°C over a fairly long period, these values have remained above 175 $m^2 g^{-1}$ which is quite reasonable for such intercalated smectites.[8,9]

The XRD patterns of the mono ion exchanged montmorillonite, boehmite and boehmite–hydrous ceria sols at 32°C and at reflux conditions are presented in Fig. 1. The relevant XRD peaks characteristic of the basal plane are presented in Table 1. The montmorillonite as received had a basal spacing of 12 Å which increased on sodium exchange to 13.19 Å. Intercalation experiments conducted in the usual manner[8,9] at 32°C resulted in the increase of basal value to 18.03 and 13.99 Å in the case of boehmite and boehmite–ceria mixed sol, respectively. There was only marginal improvement in the mixed sol probably because of the lack of sufficient delamination of the smectite layers to allow the fairly large size mixed cationic species in the aqueous suspension. The possible staggered intercalation is also reflected in the broad XRD peaks in this sample. However, under reflux conditions the intercalation has taken place to considerable extent resulting in an increase of basal spacing to 20.08 and 20.55 Å, respectively for boehmite and boehmite–ceria mixed sol. Further, there was only marginal reduction in the basal spacing of these samples after heat treatment above 500°C to 18.88 and 18.81 Å, respectively, being still fairly stable up to 700°C.

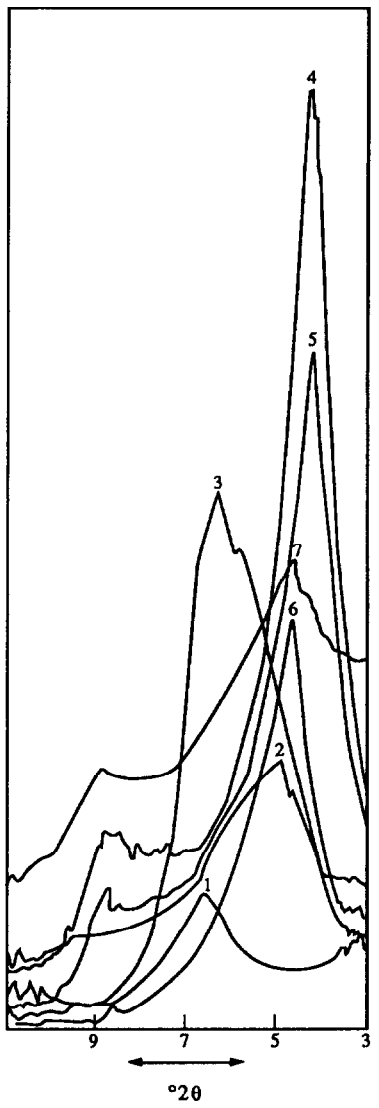


Fig. 1. XRD patterns of: (a) Na-montmorillonite; (2) Boehmite intercalated at 32°C; (3) Boehmite–ceria sol mixed intercalated at 32°C; (4) Boehmite intercalated at reflux condition; (5) Boehmite–ceria intercalated at reflux condition; (6) Boehmite intercalated at reflux condition (500°C) and (7) Boehmite–ceria intercalated at reflux condition (500°C).

Table 1. Basal spacings of intercalated montmorillonite

No.	Sample	Basal spacing (001) Å: As intercalated	Basal spacing (001) Å: After calcination at 500°C
1.	Boehmite intercalated at 32°C	18.03	16.36
2.	Boehmite intercalated at reflux condition	20.08	18.88
3.	Boehmite–ceria sol mixed intercalated at 32°C	13.99	—
4.	Boehmite–ceria sol mixed intercalated at reflux condition	20.55	18.81

The thermal stability and dehydroxylation characteristics have been followed from the data on thermogravimetric analysis presented in Fig. 2. The boehmite and mixed sol intercalated smectite under reflux conditions had total volatiles of about 25 and 22%, respectively, while the one prepared from mixed sol at 32°C had only about 18%. There appears a clear difference in the decomposition between these samples. While the boehmite interca-

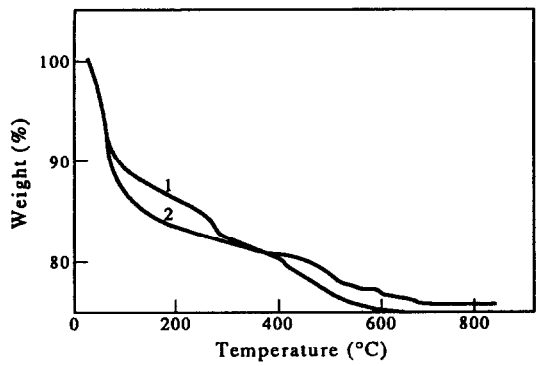

Fig. 2. Thermogravimetric analysis of: (1) Boehmite intercalated at reflux condition and (2) Boehmite–ceria sol mixed at reflux condition.

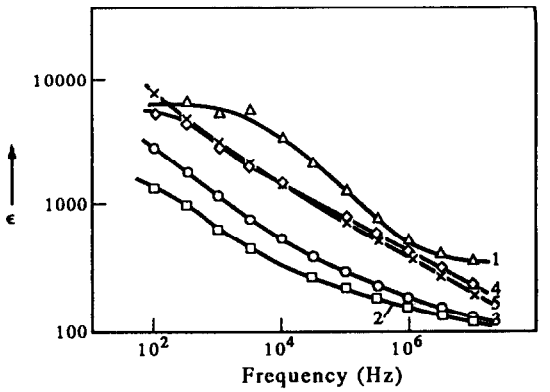

Fig. 3. Dielectric constant (ε) *vs* frequency curve of: (1) Na-montmorillonite; (2) Boehmite intercalated at reflux condition; (3) Boehmite intercalated at 32°C; (4) Boehmite–ceria sol mixed intercalated at reflux condition and (5) Boehmite–ceria sol mixed intercalated at 32°C.

lated one has a two step decomposition pattern, the mixed sol one has those above 600°C. This probably indicates the staggered intercalated pattern. The two major decompositions of the boehmite intercalated smectite are at 280 and 500°C. On the other hand, the mixed sol intercalated montmorillonite eliminates the major portion of the hydroxyls above 600°C indicating the increased stability of the latter. The mixed sol intercalated smectite sample at 32°C has very small loss by weight above 600°C, indicating a relatively low level of intercalation, with reasonable stability. Therefore, intercalation from mixed sols could provide enhanced stability to CLS in any case; which is further supported by the observation that there is only a 20% loss of specific surface area in the case of the mixed sol intercalated samples, in the present experiment.

The dielectric constant is a direct measure of the charge carriers in a material and in the present set of materials the major charge carriers are the hydroxyls and impurity ions. In layered aluminosilicates dipolarity as well as space charge polarization are the major mechanisms of electrical condition and hence the dielectric constant values could be indicative of the intercalated species. It is seen from Fig. 3 that the sodium exchanged montmorillonite has the higher dielectric constant which decreases over a range of temperatures. As usual, the dielectric constant decreases with frequency. This is naturally so, the high order of sodium ions which are also charge carriers, present in the mono ion exchanged smectite result in higher order of dielectric constant. This is true as shown in Fig. 3 on intercalation, the sodium ions are substituted by a hydrogen bonded large hydroxy metal oxide network and hence the number of charge carriers decreases as is evident from Fig. 3. There is only a slight difference in the dielectric constant values corresponding to samples derived from the mixed boehmite and ceria sols, irrespective of the temperature of intercalation. Between the two there is marginal enhancement in loss in the case of refluxed sample compared to that prepared at 32°C. Furthermore, there is a reduction in surface area and line broadening due to the disordered pillaring. On the other hand, the intercalation from a boehmite sol, is distinctly clear because of the maximum substitution of sodium ions by aluminium ions. In this case, there is considerable difference in the extent of intercalation between the samples prepared at 32°C and at reflux condition. All the differences are more pronounced at the low frequency range of 1–10 MHz and the difference slowly narrows down as the frequency increases. This clearly shows that the dipolar and space charge polization effects cause the change in dielectric constant values. The extent of intercalation can thus indirectly be derived based on the electrical measurements.

CONCLUSION

Intercalation reactions under reflux conditions of a mixture of mono ion exchanged smectite and nano dispersed hydroxy metal oxide sol, have shown an enhanced value of specific surface area, thermal stability and interlayer spacing. These values have been compared with those obtained through methods already reported for such intercalation reactions. The possibility of starting with high concentrations of smectite suspension and short reaction time are also highlighted. The method is also convenient to intercalate smectite from mixed sols.

Intercalated smectites using boehmite sol under reflux condition resulted in a specific surface area of 213 $m^2 g^{-1}$ as compared to 159 $m^2 g^{-1}$ obtained through the usual method at 32°C. Similarly, the intercalation done by reflux from a mixed sol system containing 1 : 1 boehmite and hydrous cerium oxide reached a specific surface area of 255 $m^2 g^{-1}$ against 105 $m^2 g^{-1}$ obtained in the usual way. The initial basal spacing of 13.19 Å was elevated to 20.08 and 20.55 Å in the case of boehmite and mixed sols under reflux conditions. Thermal treatment at 700°C brought down the specific surface area to about 22% in the case of boehmite and 25% in the case of mixed sol intercalation. The dielectric constant of the dried intercalated smectite as a function of frequency has been presented and indicated towards the extent of intercalation.

AMINE COMPLEXES OF TUNGSTEN(II) AND MOLYBDENUM(II): $M(NH_2R)Cl_2(PMePh_2)_3$ AND $M(NH_2CH_2CH_2NH_2)Cl_2(PMePh_2)_2$

DIANA E. OVER* and JAMES M. MAYER†

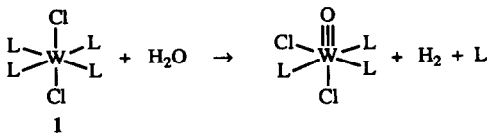
Department of Chemistry BG-10, University of Washington, Seattle, WA 98195, U.S.A.

(*Received* 24 *March* 1993; *accepted* 10 *June* 1993)

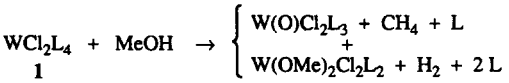
Abstract—Addition of primary amines or ammonia to solutions of $WCl_2(PMePh_2)_4$ (**1**) or $MoCl_2(PMePh_2)_4$ (**6**) results in the formation of $[M(NH_2R)Cl_2(PMePh_2)_3]$ (M=W (**2**), Mo (**7**); R=H, Me, ^{n}Pr, ^{i}Pr, C_6H_{11}, CH_2CF_3, or $CH_2CH{=}CH_2$). With larger secondary amines, no reaction is observed, except for a transient adduct of aziridine. Ethylenediamine substitutes for two phosphines, forming $M(en)Cl_2(PMePh_2)_2$, but further substitution has not been observed even in neat ligand. Reactions of $[WCl_2(CH_2{=}CH_2)_2(PMePh_2)_2]$ (**4**) with NH_2Me and $NH_2{}^nPr$ yield equilibrium amounts of amine–ethylene complexes $[W(NH_2R)Cl_2(CH_2{=}CH_2)(PMePh_2)_2]$ (**5**) plus ethylene. The characterization of these compounds by paramagnetic NMR, IR, and mass spectra is described. The amine complexes do not lose hydrogen to form imido complexes, in contrast to the analogous reactions of alcohols and thiols with **1** which yield oxo and sulphido complexes. This appears to be related to the lower acidity of amines versus alcohols and thiols.

Amine complexes are the wellspring of coordination chemistry, and have been widely studied for first-row transition metals and for the later second and third row metals (groups 8–11). There has been much less work on amine complexes of the earlier transition metals, particularly for the +2 and +3 oxidation states which dominate the chemistry of first-row transition metal amine compounds.[1–3] The early transition metals in their lower oxidation states have a tendency to form metal–metal bonds and are often quite reducing (in the absence of carbonyl ligands), both of which hinder the formation of monomeric amine complexes.

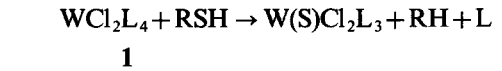
Our interest in tungsten(II) and molybdenum(II) complexes derives from their reducing nature and their desire to form metal–ligand multiple bonds.[4–13] WCl_2L_4 (**1**, L = $PMePh_2$ throughout this report) removes oxygen atoms from a wide range of substrates, for instance reacting with water to form hydrogen and the tungsten(IV) oxo complex $W(O)Cl_2L_3$ (eq.1).[6] Similarly, reaction of **1** with alcohols forms both oxo and alkoxide compounds and thiols are reduced by **1** to alkanes and a terminal sulfido complex (eqs 2, 3).[6]



(1)



(2)



(3)

We report here[14] that the analogous reaction with amines do not yield the imido compounds $W(NR)Cl_2L_3$, even though stable tungsten(IV)–imido complexes are well established for a range of R groups.[15] Instead, novel amine adducts are formed through substitution of a phosphine ligand with an amine. The characterization of these tungsten and molybdenum amine complexes, expecially their paramagnetic ^{1}H NMR spectra, is also described.

EXPERIMENTAL

General considerations

All experiments were performed in a nitrogen atmosphere using standard high vacuum line or Schlenk techniques and a glove box. Solvents were

* Current address: Université René Descarte, Paris, France.

† Author to whom correspondence should be addressed. US NSF Presidential Young Investigator, 1988–1993.

degassed and dried by standard methods,[16] as were the amine reagents (Aldrich) except NH_3, NH_2Me, and $NHMe_2$ (Matheson) which were used without purification directly from their cylinders. NMR spectra were obtained using a Varian VXR-300 Fourier Transform spectrometer. The chemical shifts in ^1H NMR spectra are given in ppm relative to the solvent peak (C_6D_6). Two-dimensional NMR spectra for $Mo(NH_2Me)Cl_2L_3$ (**7b**) and $Mo(en)Cl_2L_2$ (**8**) were obtained from a two-dimensional homonuclear Hartmann–Hahn (HOHAHA) experiment as previously described.[17] IR spectra were obtained as nujol mulls on NaCl plates with a Perkin–Elmer FT1604 spectrometer and are reported in cm^{-1}. FAB-mass spectra were acquired using a VG 70 SEQ tandem hybrid instrument (VG Analytical, Altrincham, U.K.). The instrument was equipped with a standard unheated VG FAB ion source and a standard saddlefield gun (Ion Tech Ltd, Middlesex, U.K.) producing a beam of xenon atoms at 8 keV and 1mA. The mass spectrometer was adjusted to a resolving power of 1000 and spectra were obtained at 8 kV and at a scan speed of 10 s per decade. Either 3-nitrobenzylalcohol or thioglycerol was used as the matrix in the positive ion FAB/MS mode. All apectral data are given in Table 1. Elemental analyses were performed by Canadian Microanalytical Service Ltd. (Delta, British Columbia).

Some reactions were performed in an NMR tube. In a typical procedure, a benzene-d_6 solution of 15 mg (0.014 mmol) WCl_2L_4 was loaded in the glovebox into an NMR tube sealed to a ground glass joint. Ethylenediamine [1×10^{-3} cm^3 (= 1 μl), 0.014 mmol] was added (gases were vacuum transferred on the vacuum line), the NMR tube was capped with a teflon valve, and removed to a vacuum line where the reaction solution was cooled to $-196°C$, evacuated and flame sealed. All spectra were taken at 25°C.

$WCl_2(PMePh_2)_4$ (**1**), $WCl_2(CH_2{=}CH_2)_2(PMePh_2)_2$ (**4**),[18] and $MoCl_2(PMePh_2)_4$ (**6**)[12] we prepared following published procedures.

Syntheses

The following procedure is representative for the preparation of all tungsten- or molybdenum-amine adducts.

$W(NH_2Me)Cl_2(PMePh_2)_3$ (**2b**). To a suspension of 0.25 g (0.24 mmol) WCl_2L_4 (**1**) in 30 cm^3 pentane, a 10-fold excess of NH_2Me (1 cm^3, 2.4 mmol) was added via vacuum transfer. The mixture was stirred at room temperature under an atmosphere of argon overnight. Within the first hour red solids have already formed. The next day the red solids are filtered and washed with fresh pentane and dried *in vacuo*; yielding 0.17 g, 83%. The solids can be recrystallized from toluene and pentane. Isolated yields for the tungsten amine adducts $W(NH_2R)Cl_2L_3$ were as follows: **2a** (NH_3) 79%; **2b** (NH_2Me) 83%; **2c** ($NH_2{}^nPr$) 81%; **2d** ($NH_2{}^iPr$) 84%; **2e** ($NH_2C_6H_{11}$) 81%; **3** (en) 74% Yields for the molybdenum derivatives were: **7a** (NH_3) 76%; **7b** (NH_2Me) 86%; **7c** ($NH_2{}^nPr$) 60%; **7d** ($NH_2{}^iPr$) 65%; **7e** ($NH_2C_6H_{11}$) 95%; **8** (en) 70%. Analytical data: Found for $W(NH_2Me)Cl_2L_3$ (**2b**) $WCl_2NP_3C_{40}H_{44}$: C, 54.5; H, 6.1; N, 1.6. Calc. C, 54.2; H, 5.0; N, 1.6%. RESULTS

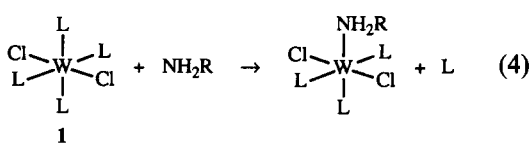
Syntheses

The tungsten(II) complex $WCl_2(PMePh_2)_4$ (**1**) reacts at ambient temperatures with primary amines and ammonia to form the tungsten(II)–amine adducts $W(NH_2R)Cl_2L_3$ (**2**) (eq. 4).



(4)

1

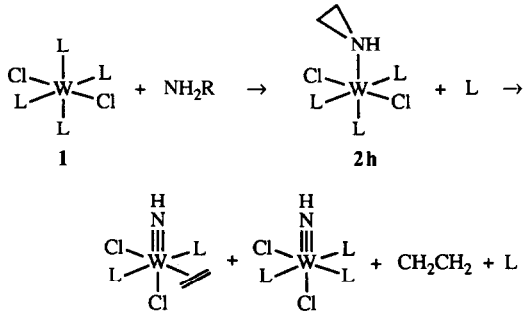
NH_2R = NH_3 (**2a**), NH_2Me (**2b**), $NH_2{}^nPr$ (**2c**) $NH_2{}^iPr$ (**2d**), NH_2–⬡ (**2e**), $NH_2CH_2CF_3$ (**2f**)

The reaction goes to completion in 5–10 min, and the resulting compounds vary in colour from deep orange to bright red depending on the amine. Even in the presence of a large excess of the amine, no further substitution is observed. Monitoring the reactions by NMR show the concurrent formation of one equivalent of free $PMePh_2$. Isolation of **2a–2e** is best accomplished in pentane, a solvent in which the starting material and product are only slightly soluble. The reaction proceeds readily in other solvents, such as toluene or benzene, but the products are usually isolated as oils, typically contaminated with free phosphine. In pentane, the liberated phosphine is in solution and the products precipitate as they are formed—the suspension of **1** slowly becomes a suspension of **2**. Compounds **2a–2e** have been isolated as air sensitive solids in *ca* 80% yield, while the trifluoroethyl amine adduct **2f** has only been observed by NMR. The complexes were identified by ^1H NMR, IR

and FAB/MS spectroscopies and magnetic susceptibility measurements, as described below.

The tungsten(II) amine complexes **2** are stable for a couple of months in the solid state when stored under nitrogen, but decompose in THF in about 2 h, and in benzene solutions over a period of 2 weeks. The decomposition products have not been identified. Generally, decomposition in solution gives dark, paramagnetic solids, which do not give NMR spectra even when dissolved in other solvents. In some cases, small amounts of WCl_3L_3[11] are observed.

One equivalent of *t*-butyl amine does not react with **1** over a week at ambient temperatures. But with 10 equivalents of $NH_2{}^tBu$, the solution turns from the yellow colour of **1** to orange within minutes, and ^1H NMR spectra show peaks characteristic of the tungsten–amine adducts. Allyl amine, $NH_2CH_2CH{=}CH_2$, reacts rapidly with **1** to form a red amine adduct, $W(NH_2CH_2CH{=}CH_2)Cl_2L_3$ (**2g**) from **1** (by NMR), but this is completely decomposed within 15 min in benzene solution. The NMR spectrum indicates that only the nitrogen of the allyl group is coordinated (see below). No reaction has been observed with secondary amines or with aniline (NH_2Ph) at 25°C (heating the solution causes decomposition of **1**, as in the absence of amine). Aziridine, $HNCH_2CH_2$, a very small secondary amine, does rapidly form a red adduct (**2h**), whose NMR is indicative of an amine adduct (Table 1).[19] This species reacts further within minutes at ambient temperatures to form the tungsten(IV) imido products $W(NH)Cl_2L_3$ and $W(NH)Cl_2(CH_2{=}CH_2)L_2$ (eq. 5).[7] Tertiary aziridines $RNCH_2CH_2$ also yield imido products, although more slowly and simple adducts are not observable.[7]

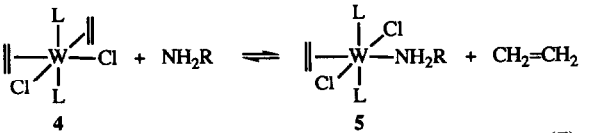


(5)

Complex **1** reacts upon mixing with ethylenediamine ($NH_2CH_2CH_2NH_2$=en) to form $W(NH_2CH_2CH_2NH_2)Cl_2L_2$, **3** (eq. 6), with substitution of two phosphine ligands. This red, paramagnetic complex has been isolated in 74% yield. It displays a greater stability than the other monodentate amine complexes, as benzene and THF solutions are stable for weeks.

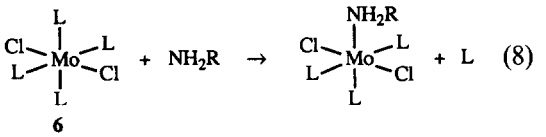
$$\underset{\mathbf{1}}{WCl_2L_4} + NH_2CH_2CH_2NH_2 \rightarrow \underset{\mathbf{3}}{W(NH_2CH_2CH_2NH_2)Cl_2L_2} + 2L \quad (6)$$

The tungsten(II) bis-ethylene complex, $WCl_2(CH_2{=}CH_2)_2L_2$ (**4**)[18a] reacts at ambient temperatures with the primary amines NH_2Me and $NH_2{}^nPr$ with loss of one equivalent of ethylene, to form $W(NH_2R)Cl_2(CH_2{=}CH_2)L_2$ (R=Me, **5b**, ^nPr, **5c**; eq. 7). These products are formed in equilibrium with **4** and have not been isolated; they have been characterized by ^1H NMR. The equilibrium in eq. 6 can also be established by addition of excess ethylene to the methylamine adduct **2b**; addition of one equivalent of ethylene to **2c** gives **5c**.



(7)

The molybdenum complex analogous to **1**, $MoCl_2L_4$ (**6**), reacts similarly with primary amines to form bright red molybdenum(II) amine adducts, $Mo(NH_2R)Cl_2L_3$ (**7**), within minutes (eq. 8). These complexes are isolated from pentane in 60–95% yield. Ethylenediamine also displaces two phosphines from molybdenum, producing the complex $Mo(en)Cl_2L_2$ (**8**).



(8)

NH_2R = NH_3 (**7a**), NH_2Me (**7b**), $NH_2{}^nPr$ (**7c**) $NH_2{}^iPr$ (**7d**), NH_2–⬡ (**7e**)

Spectroscopic characterization

The identification of the amine adducts is based primarily on ^1H NMR, IR and mass spectral data, which are given in Table 1. The FAB mass spectra of compounds **2** and **7** typically show a parent ion for $M(NH_2R)Cl_2L_3$ and peaks corresponding to loss of the amine, loss of a phosphine, and loss of both the amine and a phosphine. The $[MCl_2L_2]$ fragment is thus observed in all the spectra (568 for M=Mo; 654, 656 for M=W). The ethylenediamine complexes **3** and **8** show peaks corresponding to M^+ and M^+-$PMePh_2$. In all cases the complex envelope of peaks for each ion matches the calculated isotopic abundances quite well.

The IR spectra of the isolated amine complexes all show two N–H stretches, in the range of 3240–

[a] Spectra taken in C_6D_6 solution and reported as chemical shift (multiplicity, coupling constant, # hydrogens), with chemical shifts given in ppm relative to the solvent peak. br = broad, s = singlet, d = doublet, t = triplet, m = mutiplet.

[b] Phenyl resonances reported as chemical shift (multiplicity, # hydrogens); the coupling constants, when observed, are all 6 or 7 Hz and are not listed here.

[c] IR spectra obtained as Nujol mulls.

[d] The largest peak(s) in the highest mass envelope reported, either the parent ion or, when noted, M^+-$PMePh_2$. In all cases, the observed envelope closely matches the calculated isotope abundances.

[e] Not all amine resonances were observed, especially for the molybdenum complexes due to the breadth of some of the peaks.

[f] Observed masses 913.7 and 915.7. The envelope is only very slightly shifted from that of the ^{i}Pr derivative **2d**, and closely matches the calculated isotopic abundances.

[g] Spectrum taken at 5°C.

[h] Observed mass 827.6. The observed envelope closely matches the calculated isotopic abundances.

3350 cm^{-1}. This implies the presence of an NH_2 group in each compound and indicates that the amine ligand is intact, rather than, for instance, having oxidatively added to the metal centre to form an amide–hydride complex.

The amine complexes are paramagnetic, as indicated by the wide range of chemical shifts observed in their ^1H NMR spectra, from $\delta + 12$ to -17. The magnetic susceptibilities of $W(NH_2{}^iPr)Cl_2L_3$ (**2d**), $Mo(NH_2Me)Cl_2L_3$ (**7b**), and $Mo(NH_2{}^iPr)Cl_2L_3$ (**7d**), determined on a Faraday balance, are 1.7, 2.45 and 2.49 BM, respectively. The values are consistent with a description of these molecules as low-spin d^4 octahedral species (four electrons in the "t_{2g} set"), as has been concluded for a number of related d^4 phosphine complexes of the second- and third-row transition metals.[20] The magnetic moments are less than the spin-only value for complexes with two unpaired electrons, 2.83 BM, especially for the tungsten complex, probably due to large spin-orbit coupling.

The ^1H NMR spectra of the amine complexes (Table 1) contain a great deal of information about the composition and structure of these molecules, although the interpretation is complicated by the absence of standard chemical shift information because of the paramagnetic shifting. The tungsten compounds **2**, **3**, and **5** give spectra that are in places sharp enough to see spin–spin coupling, but spectra of the molybdenum analogues are invariably broader (see Fig. 1). This is a typical feature of these paramagnetic, low-spin d^4 octahedral complexes.[11,20] For the tungsten compounds which exhibit sharp peaks, the paramagnetic shifting is an advantage because the resonances are well separated and there is little likelihood of two peaks being accidentally degenerate. Assignments have been made based on integrals and coupling, the latter either observed directly or using two-dimensional NMR spectra with a HOHAHA (homonuclear Hartmann–Hahn) pulse sequence (Fig. 2).[17] The two-dimensional experiments can be of great assistance in assigning these paramagnetic spectra.

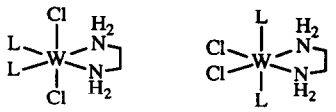
The ^1H NMR spectra of the $W(NH_2R)Cl_2L_3$ compounds (**2**) (Table 1) have a distinctive pattern of peaks that are independent of the amine used in the reaction, due to the three $PMePh_2$ ligands (Fig. 1, top), In the range of 8 to 11 ppm, the spectra exhibit two doublets, two broad signlets, and two triplets with intensities 8:4:8:4:4:2. These are due to six phenyl groups in a 4:2 ratio, with less intense triplets for the para hydrogens. Irradiation of the triplets in the spectrum of **2d** causes collapse of the doublets, indicating that the doublets should be assigned as the meta protons. The broadened peaks are therefore the ortho protons, consistent with their closer proximity to the metal centre. There are also two broad singlets due to the phosphine methyl groups (ratio 6:3), the larger having a chemical shift between -2 and -4 ppm and the smaller appearing between 2 and 5 ppm.

The spectra show that two of the three coordinated phosphine ligands are equivalent, and that none of the pairs of phenyl groups are diastereotopic. This is consistent only with the C_{2v} *meridional-trans* structure shown in eqs 4 and 8. The other possible isomers, *meridional-cis* and *facial*, have only C_s symmetry and would show a 2:2:2 ratio of phenyl groups. The similarity of the spectrum of the allyl amine complex **2g** with the spectra of saturated amines complexes (Table 1) indicates a similar structure, with the allyl amine coordinated to tungsten via only the nitrogen.

The analogous molybdenum complexes **7** have broader ^1H NMR spectra, in which no coupling can be resolved (Fig. 1, bottom). But, as in the tungsten case, a characteristic pattern is observed independent of the amine ligand (Table 1). For instance, resonances are found at -8 top -11 and at -15 to -16 in the ratio of 3:6 for each compound, due to the methyl groups on the three phosphines. The phenyl regions are not very well separated and show four distinctive peaks (integral 2:4:4:8) and one broad lump. Despite the broadness in this region, clear cross peaks are observed in the HOHAHA spectrum of **7b** (Fig. 2). The cross peaks between the resonances at 10.81 (2H) and at 7.61 ppm (4H), and between the resonances at 10.53 (4H) and at 6.55 ppm (8H) allow the assignment of these as *para* and *meta* phenyl proton resonances. The former are due to the unique phosphine ligand, the latter due to the *trans* pair of phosphines. The broad lump from 9.1 ppm to 10.4 ppm, too broad to be observed in the two-dimensional NMR spectrum, is thus due to the twelve *ortho* protons. Just as found for the tungsten compounds, these are the closest to the metal centre and their peaks are most broadened. The greater broadening for compounds 7 has often prevented assignment of the resonances for the amine alkyl group.

The spectrum of $W(en)Cl_2L_2$ (**3**) is similar to those of **2**, but shows a single set of phenyl resonances, a single peak at $\delta 3.56$ for the two phosphine methyl groups, and one resonance ($\delta 12.99$) for the methylene groups of the ethylenediamine ligand. A similar (though broader) spectrum is observed for the molybdenum analogue, which was again assigned with the help of a two-dimensional spectrum. Two C_{2v} structures—both *cis–cis–trans*—are consistent with these data (**A** and **B** below), although only one of the isomers is formed. Considering the steric bulk of the $PMePh_2$ ligands, the

isomer with trans phosphines (**B**) might be more likely.



A similar analysis of the spectra of the amine–ethylene complexes **5** also indicates C_{2v} symmetry, which is consistent only with the all-*trans* geometry shown in eq. 7. No resonances are observed for the ethylene protons or the NH_2 protons in any of these compounds. They may be broadened too severely by the paramagnetic metal centre or possibly shifted out of the chemical shift range we examined: a recent report of isoelectronic rhenium(III) amine complexes such as $ReCl_2(en)_2^+$ gives chemical shifts for the amine protons in the range δ134–207.[21]

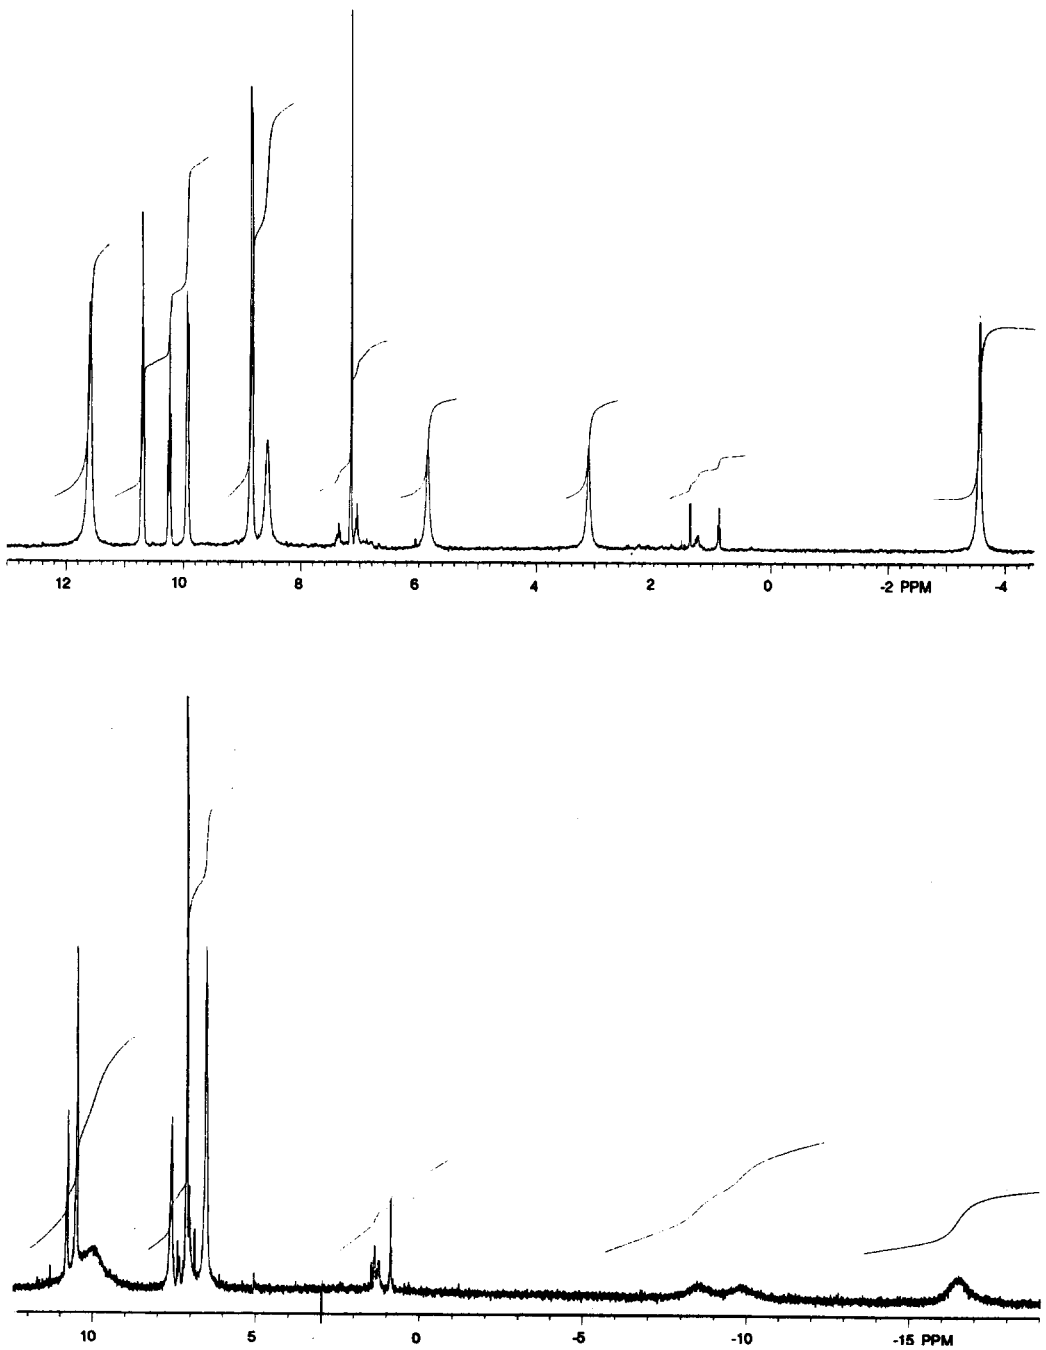


Fig. 1. ^1H NMR spectra for $W(NH_2Me)Cl_2L_3$ **2b** and $Mo(NH_2Me)Cl_2L_3$ **7b**. Solvent or impurity peaks are visible at δ7.15 (C_6D_6), 0.8 and 1.3 (pentane), and 1.4, 7.1, and 7.4 (free $PMePh_2$).

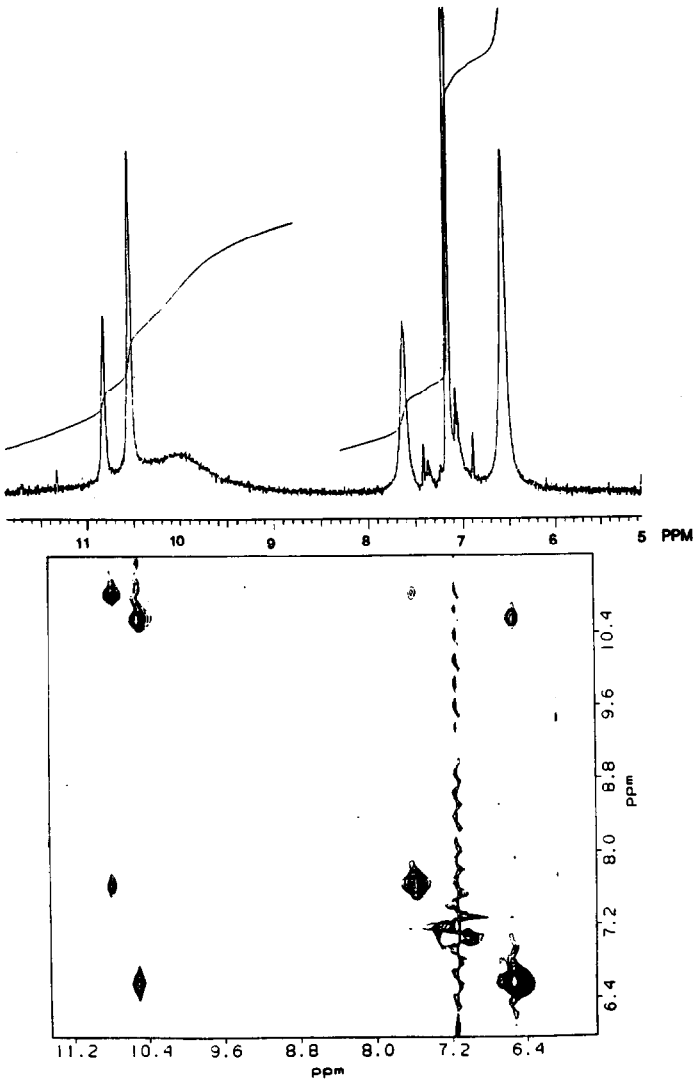

Fig. 2. Two-Dimensional ^{1}H NMR HOHAHA spectrum (δ6–11) of $Mo(NH_2Me)Cl_2L_3$ (**7b**). The normal NMR spectrum in this region is shown above; solvent (δ7.15, C_6D_6) and $PMePh_2$ (δ7.1, 7.4) resonances are also visible.

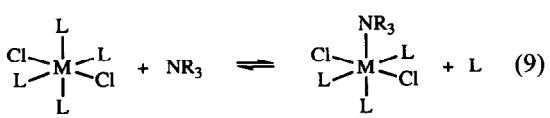
DISCUSSION

Formation of amine complexes

Addition of amines to the tungsten(II) and molybdenum(II) complexes **1** and **6** forms an apparently equilibrium amount of amine adducts **1** and **6** (eq. 9).



(9)

A similar equilibrium is established between the tungsten ethylene complex **4** and the ethylene–amine adducts **5** (eq. 6 previously). The equilibrium mixtures are rapidly established, consistent with the high lability of the phosphine ligands in **1** and **2**.[12]

The position of the equilibria depend to a large extent on the steric bulk of the amine: with small primary amines the equilibria lie toward the amine adducts, while with *t*-butyl amine adducts can be observed but not formed quantitatively. No reaction is observed with secondary amines (except aziridine). Reaction of one equivalent of *t*-butyl amine with **6** gives an observable molybdenum amine adduct but excess amine is required to form a significant amount of a tungsten adduct from **1**, suggesting that molybdenum has a higher affinity for an amine ligand than tungsten does. The lack of reaction of **1** with aniline is due to its lower basicity rather than steric effects, as aniline is smaller than cyclohexylamine which binds well. In contrast, aziridines bind more strongly than simple secondary amines even though they are somewhat less basic

(the lone pair on aziridines has more s-character and is therefore less basic). In this case, steric effects override the difference in basicity. Similarly, the small $CF_3CH_2NH_2$ ligand binds well, even though it is substantially less basic than simple alkyl amines.[22]

Substitution of more than one phosphine ligand has been achieved only with the chelating ethylenediamine. But even in neat ethylenediamine, no more than two phosphine ligands are replaced. Phosphine loss from the sterically crowded tetrakisphosphine complexes **1** and **6** is quite facile[12] but appears to be less favourable once an amine ligand is present in the coordination sphere. The electron-rich metal centres also seem to prefer a mix of π-acid and σ-donor ligands. The amine complexes **2** substitute a phosphine ligand for ethylene but not for a second amine. One of the two ethylene ligands in **4** is readily substituted by an amine while the phosphines are unaffected. Allyl amine binds to the $WCl_2(PMePh_2)_3$ fragment through the nitrogen rather than the more π-acidic but more sterically hindered alkene. Alkene coordination has been implicated as the initial step in the deoxygenation of allylic alcohols and ethers by **1**,[6,10] but the alcohol and ether groups are not as good ligands as an amine (see below).

Contrast with reactions of alcohols and thiols

The formation of stable amine complexes from **1** contrasts with the deoxygenation of alcohols and desulphurization of thiols by **1** (eqs 1–3, previously). Alcohol and thiol adducts analogous to the amine complexes **2** have not been observed.[23] Phosphine substitution reactions of **1** and **6** are quite rapid: addition of amines, ethylene, ketones, or other phosphines form products or equilibrium mixtures within minutes.[5,8,12,13,18a] The reactions of alcohols and thiols with **1** occur over a much slower timescale (weeks and hours, respectively[6]), so equilibria analogous to the amine reactions (eq. 9) are undoubtedly established but the concentrations of alcohol and thiol adducts are evidently too low to detect. This is consistent with the poorer ligating ability of alcohols and thiols versus amines. Alcohol and thiol adducts, however, are likely to be intermediates in the deoxygenation and desulphurization reactions, although it is also possible that oxidative addition of an O—H or S—H bond occurs without prior coordination of the heteroatom.[24]

The amine complexes are fairly stable in solution and do not decompose to tungsten(IV) imido complexes $W(NR)Cl_2(PMePh_2)_3$, as might have been expected by analogy with the reactions of alcohols and thiols. This is not due to any instability of the imido compounds, as these are readily formed,[15] for instance in the reactions of **1** with aziridines[7] (see previously). The observation that reactions with **1** cleave O—H and S—H bonds but not N—H bonds suggests that the substrate acidity is the key parameter, as the acidities vary in the order RSH > ROH > RNH_2.[25] This trend does not correlate with bond strengths, which vary in the order O—H > N—H > S—H.[25] The importance of acidity is illustrated by the relative rates of reactions with **1**: phenol reacts over a week to make a phenoxide complex, while the more acidic *para*-bromophenol requires only a day to go to completion (aqueous pK_a values: phenol, 10.0; BrC_6H_4OH, 9.4). The less acidic aliphatic alcohols (aqueous $pK_a \cong 16$) require 3 weeks for reaction. pK_a values are much lower for aniline (30.6 in DMSO) and primary amines (aqueous $pK_a > 30$). Even the more acidic $CF_3CH_2NH_2$[22] simply coordinates to tungsten, without formation of an imido complex.

MOLYBDENUM(VI) DIOXO COMPLEXES WITH MACROCYCLIC AMINE LIGANDS

ABDESSADEK LACHGAR,* PAUL FARRALL and JAMES M. MAYER†

Department of Chemistry BG-10, University of Washington, Seattle, WA 98195, U.S.A.

(*Received* 1 *March* 1993; *accepted* 19 *May* 1993)

Abstract—Reaction of MoO_2Cl_2 with the tetradentate amine ligand 1,4,8,12-tetraazacyclopentadecane ([15]aneN$_4$) yields the molybdenum(VI) dioxo complex [MoO_2([15]aneN$_4$-H)]Cl (**I**), a rare example of a cationic complex containing the MoO_2^{2+} unit. The oxo ligands are *cis* and the macrocyclic amine coordinates in a non-planar fashion, as revealed by X-ray crystal structure and NMR data. One of the nitrogen donors *cis* to the oxo groups has been deprotonated to give an amide ligand (NR_2^-). In contrast, reaction of MoO_2Cl_2 with tetramethylcyclam (1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecane, TMC) yields the neutral adduct $MoO_2Cl_2(\eta^2$-TMC) (**III**), in which only two of the amine nitrogens are coordinated. An X-ray structure of **III** shows it to have an all-*cis* octahedral geometry, very unusual for $MoO_2X_2L_2$ complexes, with one oxo ligand *trans* to an amine and the other *trans* to a chloride. Compounds [MoO_2([15]aneN$_4$-H)]BPh_4 **II** and **III** are not very stable in solution; **II** is not reduced electrochemically or by PPh_3.

The chemistry of molybdenum oxo complexes has been intensively studied, particularly as models for active sites in metalloenzymes and on heterogeneous catalysts.[1] Yet, despite the large number of molybdenum(VI) oxo complexes,[2] to our knowledge there is only one well-characterized cationic derivative, $[MoO_2Br(tacn)]^+$ (tacn = triazacyclononane),[3] and there are no complexes with tetradentate amine ligands.[2] We report here two complexes formed from reaction of MoO_2Cl_2 with the macrocyclic amine ligands 1,4,8,12-tetraazacyclopentadecane ([15]aneN$_4$) and 1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecane (tetramethylcyclam, TMC).

EXPERIMENTAL

General considerations

All experiments were performed under a nitrogen atmosphere or under vacuum employing high vacuum-line, Schlenk and standard glove-box techniques, unless otherwise noted. Solvents were dried according to standard procedures.[4] Acetonitrile was first dried over 3 Å molecular sieves and then vacuum transferred into a flask containing CaH_2, from which it was vacuum transferred immediately before use. MoO_2Cl_2 (Aldrich) was sublimed at 50°C under a static vacuum. 1,4,8,12-Tetraazacyclopentadecane (**A**) and 1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecane (**B**) were sublimed *in vacuo* at 73 and 40°C, respectively, and stored under nitrogen. ^{1}H NMR spectra were acquired at ambient temperatures using a Varian VXR-300 Fourier-transform spectrometer (300 MHz). The ^{1}H NMR spectra are reported in ppm downfield of TMS or DSS and were referenced relative to the residual protons in the solvent or to DSS for spectra in D_2O. The $^{13}C\{^1H\}$ NMR spectra were recorded at 75.43 MHz. Spectra are reported as: δ (ppm) [multiplicity, coupling constants (in Hz), number of hydrogens]. IR spectra were recorded on a Perkin–Elmer 1600 FT-IR spectrometer

as Nujol mulls using NaCl plates and are reported in cm^{-1}. Intensities of IR bands are reported as (s) = strong, (w) = weak or (sh) = shoulder. Elemental analyses were performed by Canadian Microanalytical Services Ltd (Delta, B.C., Canada). Electrochemical measurements were obtained using a Bioanalytical Systems CV-27 with a platinum disk electrode, platinum wire auxiliary electrode and an Ag/AgCl reference electrode. The concentration of **I** in CH_3CN was *ca* 10^{-3} M, with 0.1 M $^nBu_4NPF_6$ as a supporting electrolyte.

$[MoO_2([15]aneN_4\text{-}H)]Cl$ (I)

A solution of [15]aneN$_4$ (67 mg, 0.31 mmol) in CH_2Cl_2 (10 cm^3) was added to a solution of MoO_2Cl_2 (62 mg, 0.31 mmol) in CH_2Cl_2 (10 cm^3). An immediate colour change to yellow was followed quickly by the appearance of solids and a change to a forest green colour. The reaction was stirred for 10 min and then exposed to air and filtered to give a green filtrate, which changed to a bright yellow colour after sitting for 24 h. Filtration, concentration to *ca* 2 cm^3 and addition of diethyl ether (9 cm^3) yielded a bright yellow precipitate, which was collected by filtration and washed with 2×3 cm^3 of Et_2O. Yield: 59.1 mg (0.16 mmol); 51%. X-ray quality crystals were grown by slow evaporation of a CH_2Cl_2 solution at 10°C. Found: C, 35.8; H, 6.9; N, 15.1. Calc. for $MoO_2C_{11}N_4H_{25}Cl$: C, 35.1; H, 6.7; N, 14.9%. ^1H NMR (D_2O): 4.34 (d of t, 13 and 5 Hz, 1 H); 3.98 (t, 13 Hz, 1H); 3.75 (d, 13 Hz, 1H); 3.38 (m, 3H); 3.18 (d, 7 Hz, 1H); 2.85 (m, 11H); 2.35 (br s, 1H); 2.02 (m, 2H); 1.70 (m, 3H); 1.45 (q, 14 Hz, 1H). $^{13}C\{^1H\}$ NMR (D_2O, referenced to DSS at 0 ppm): 72.1, 67.1, 58.4, 55.8, 55.3, 54.3, 52.3, 47.4, 30.9, 30.7, 25.3. IR: 3053 [ν(NH)], 1304, 1112, 1038, 1024, 976, 900 [$\nu(MoO_2)$], 882 [$\nu(MoO_2)$], 815.

$[MoO_2([15]aneN_4\text{-}H)]BPh_4$ (II)

$[MoO_2([15]aneN_4\text{-}H)]Cl$ (28 mg) was dissolved in distilled H_2O (10 cm^3) and filtered on a glass frit in the air. Addition of a saturated aqueous solution of $NaBPh_4$ (15 cm^3) (Aldrich) forms a pale yellow precipitate, which was collected by filtration and washed with H_2O and Et_2O. Recrystallization by vapour diffusion of hexane into a CH_2Cl_2 solution gives the desired yellow crystals and an impurity as white needle-like crystals. The formation of a white solid always accompanies recrystallization of **I** and **II**. ^1H NMR (CD_3CN): 7.30 (s, 8H); 7.00 (t, 8 Hz, 8H); 6.84 (t, 8 Hz, 4H) [BPh_4]; 4.28 (m, 1H); 3.98 (m, 1H); 3.72 (m, 2H); 3.48 (m, 1H); 2.95 (m, 16H); 2.49 (m, 1H); 1.78 (m, 2H); 1.52 (m, 1H). IR: 3053, 1612, 1578, 1303, 1268, 1148, 1033, 910–754, 736, 710, 613.

$MoO_2Cl_2(\eta^2\text{-TMC})$ (III)

Following a procedure similar to that for $[MoO_2([15]aneN_4\text{-}H)]Cl$, a solution of tetramethylcyclam (TMC) (39 mg) in MeCN (2.5 cm^3) was slowly added to a solution of MoO_2Cl_2 (30 mg) in MeCN [$MoO_2Cl_2(MeCN)_2$[5]] in a flow of nitrogen. Removal of solvent from the yellow solution typically yielded a yellow–brown oil; yellow solids were most reproducibly obtained on cooling to −20°C and filtering. The yellow solution and yellow solids are not very stable, turning brown and forming white solids. ^1H NMR spectra of isolated **III** and of a reaction solution containing MoO_2Cl_2 and TMC (1 : 1) in CD_3CN were both broad: 2.65 (br s, 8H, NCH_2), 2.59 (br s, 8H, NCH_2), 2.37 (br s, 12H, NCH_3), 1.78 (br s, 4H, $NCH_2CH_2CH_2N$); a small peak at δ 9.40 was also typically observed.

X-ray crystal structure of $[MoO_2([15]aneN_4\text{-}H)]Cl$ (I)

A rhombus-like single crystal ($0.57 \times 0.45 \times 0.4$ mm^3) was sealed in a glass capillary. Oscillation and zero level Weissenberg photographs gave preliminary unit cell parameters and showed $2/m$ Laue symmetry. This was confirmed by diffraction data collected on a four-circle diffractometer (CAD4) using graphite-monochromated Mo-K_α radiation. Compound **I** was found to crystallize in the monoclinic space group $P2_1/n$ ($Z = 4$) with cell parameters: $a = 7.2147(9)$, $b = 12.3041(11)$, $c = 17.4031(18)$ Å, $\beta = 99.601(16)°$, $V = 1523.1(9)$ Å^3, $Z = 4$, $D_{calc} = 1.63$ g cm^{-3}. Data in two octants ($hk \pm l$) were collected ($2° < 2\theta < 55°$) and three Ψ-scans were used for an empirical absorption correction[6] ($\mu = 10.2$ cm^{-1}, transmission factors = 0.997–0.714, av. = 0.820). 2794 symmetry independent observed reflections [$I/\sigma(I) > 3$] out of 3942 measured were considered in subsequent calculations. Direct methods (SHLEXS-86[7]) provided an initial model, which was successfully completed with the aid of standard least-squares full-matrix refinement and Fourier synthesis. The carbon backbone between N(1) and N(4) shows a flip-flop-like disorder, which was modelled by splitting C(7) into two positions, C(7a) and C(7b), with equal occupancies. Three hydrogen atoms, H(1N) H(2N) and H(4N) were located on a difference-Fourier map and refined; no hydrogen atom could be found on N(3). The hydrogen atoms attached to carbon atoms were calculated and not refined. Anisotropic refinement (scattering factors from ref. 8) of all non-hydrogen atoms (192 par-

ameters) converged with $R = 0.040$ and $R_w = 0.051$ (G.O.F. = 1.73). The final difference-Fourier map was flat with the largest background electron residual being 0.60 e $Å^{-3}$ near the molybdenum atom and 0.30 e $Å^{-3}$ elsewhere.

X-ray crystal structure of $MoO_2Cl_2(\eta^2$-TMC) (**III**)

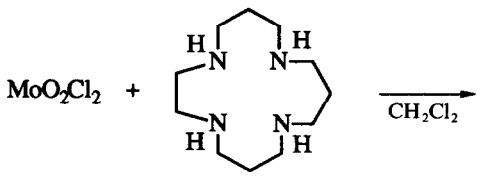
Tetrahedral shaped yellow crystals of **III** were grown in an NMR tube from a reaction of $MoO_2Cl_2(MeCN)_2$ and TMC in a 1/1 molar ratio. A suitable single crystal ($0.35 \times 0.25 \times 0.25$ mm^3) was mounted and sealed in a thin-walled glass capillary. Preliminary studies using a single-crystal X-ray diffractometer (CAD4) confirmed the orthorhombic *mmm* symmetry obtained from film studies. Unit cell parameters obtained from the least square refinement of 25 reflections are $a = 13.752(1)$, $b = 12.157(2)$, $c = 24.061(4)$ Å, $Z = 8$, $D_{calc} = 1.503$ g cm^{-3}. Analysis of reflection data collected ($h \pm kl$) showed the extinction conditions $0kl$, $k = 2n+1$; $h0l$, $l = 2n+1$; $hk0$, $h = 2n+1$, consistent with space group *Pbca*. A large decay of 58% (probably due to the chemical instability of **III**) was observed as shown by the observation of 1415 unique reflections with $I/\sigma(I) > 3$ out of 7944 measured. A decay correction based on the program CHORT[6a] was applied rather than a linear decay correction. An empirical absorption correction[6] was applied ($\mu = 9.17$ cm^{-1}, transmission factors 0.9988–0.8771, av. = 0.9582). Direct methods (SHLEXS-86[7]) gave the initial atomic positions of Mo, Cl(1), Cl(2), O(1) and O(2) atoms. Subsequent least squares refinement and difference-Fourier map revealed the positions of the carbon and nitrogen atoms. Hydrogen atom positions were calculated and included in the model, but not refined. Anisotropic refinement of all non-hydrogen atoms (208 parameters) converged to $R = 0.057$ and $R_w = 0.068$ (G.O.F. = 1.22). The final difference-Fourier map was featureless with the largest residual electron density of 1.1 e $Å^{-3}$ at 1.1 Å from the molybdenum atom.

Atomic coordinates for compounds **I** and **III** have been deposited with the Cambridge Crystallographic Centre.

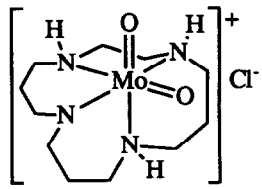
RESULTS AND DISCUSSION

Syntheses

Addition of a methylene chloride solution of [15]aneN$_4$ to MoO_2Cl_2 in CH_2Cl_2 results in a yellow solution, from which yellow solid (**I**) can be isolated [eq. (1)]. An X-ray crystal structure (described below) shows **I** to contain MoO_2^{2+} coordinated to a singly deprotonated macrocyclic amine ligand, with a chloride counter-ion: [MoO_2([15]aneN$_4$-H)]Cl. The chloride can be exchanged to give [MoO_2([15]aneN$_4$-H)]BPh_4 (**II**) by addition of a saturated aqueous solution of $NaBPh_4$ to an aqueous solution of **I**.



[15]aneN$_4$



[+ HCl] (1)

I

The NMR spectra for **I** and **II** are consistent with the X-ray structure of **I**. The carbons of the amine ligand give rise to 11 resonances in the $^{13}C\{^1H\}$ NMR, consistent with the lack of molecular symmetry in the solid state. The ^1H NMR spectra of **I** and **II** show a number of complex multiplets for the coordinated amine, including separate resonances for six individual protons, again supporting C_1 symmetry. The IR spectrum of **I** is consistent with a *cis*-MoO_2^{2+} unit, with bands at 900 and 882 cm^{-1}.

Monitoring reaction (1) by ^1H NMR in CD_3CN shows rapid formation of **I** as well as other species. A broad peak at δ 9.4 is observed, suggesting that an aldimine function (—N=CH—) is formed by oxidation of the macrocyclic ligand. Conversion of macrocyclic amine ligands to imines is a common reaction for oxidizing metal centres.[9] Both compounds **I** and **II** are unstable in solution, slowly depositing a white insoluble material; this has hampered efforts to obtain analytically pure material and to investigate their chemistry.

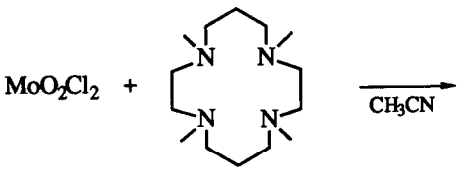
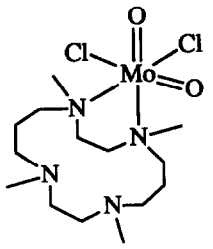
Addition of tetramethylcyclam (TMC) to MoO_2Cl_2 in acetonitrile has also resulted in the formation of X-ray quality crystals, although the yellow product **III** is quite different from **I** [eq. (2)]. Complex **III** is a neutral adduct of MoO_2Cl_2 and TMC with only two of the macrocyclic nitrogen atoms coordinated, $MoO_2Cl_2(\eta^2$-TMC).



TMC



III (2)

The synthesis of **III** is temperamental and solids can be difficult to obtain. The yellow reaction solution begins to deposit white solid within minutes at ambient temperatures and turns brown in a few hours; removal of the acetonitrile typically results in the formation of a yellow–brown oil. ^{1}H NMR spectra of the yellow oil and of reaction solutions in CD_3CN show broad resonances, with a pattern similar to that of free tetramethylcyclam but with different chemical shifts. Spectra of **III** in the presence of excess amine show shifted broad peaks without the sharp resonances for the free ligand, implying facile ligand exchange. Cooling the NMR sample to -30°C does not sharpen the spectra. ^{1}H NMR spectra of **III** always display a small peak at *ca* δ 9.4, similar to that seen in reactions with [15]aneN$_4$, which suggests decomposition via ligand oxidation to an imine (as discussed above).

X-ray structures of $[MoO_2([15]aneN_4\text{-}H)]Cl$ **(I)** *and* MoO_2Cl_2(TMC) **(III)**

The structure of **I** consists of molybdenum-oxo-amine cations and chloride anions, with the chloride forming hydrogen bonds to the hydrogen on N(4) in two different molecules. Bond lengths and angles are listed in Tables 1 and 2. The cation has a distorted octahedral geometry typical of MoO_2^{2+} complexes (Fig. 1), with *trans* angles of 160.4(1)° [O(1)—Mo—N(2)], 162.6(1)° [O(2)—Mo—N(4)] and 156.9(1)° [N(1)—Mo—N(3)]. The large O(1)—Mo—O(2) angle of 109.1(1)° and short Mo=O distances [1.716 and 1.714(2) Å] are also typical of octahedral MoO_2^{2+} complexes.[10]

All four nitrogens of the macrocyclic amine are coordinated to the molybdenum, in a non-planar fashion to allow the preferred *cis*-coordination of the MoO_2^{2+} unit. One of the nitrogens [N(3)] has been deprotonated, forming an amide (NR_2^-) ligand. This is clearly shown by a number of structural features, in addition to the presence of only one chloride counter-ion.[11] The amide distance, Mo—N(3) = 1.932(3) Å, is substantially shorter than the Mo-amine distances (2.287(2) [N(1)], 2.320(2) [N(2)] and 2.415(2) Å [N(4)]). The angles about the amine nitrogens N(1), N(2) and N(4) are all in the range 108.0(3)–118.2(2)°, while those about the amide nitrogen are: 120.4(2)° [Mo—N(3)—C(5)], 125.8(2)° [Mo—N(3)—C(5)] and 113.0(3)° [Mo—N(3)—C(5)]. The sum of the

N(3)—Mo—N(4)	88.5(1)		

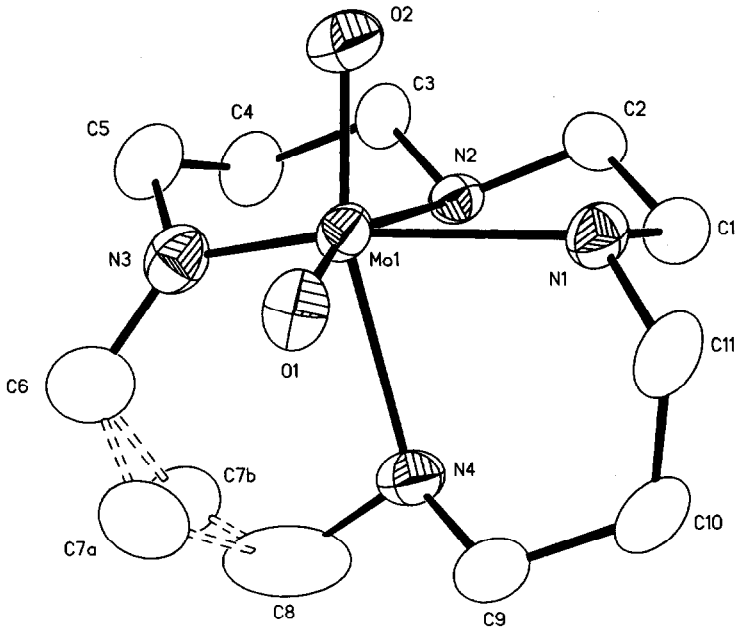

Fig. 1. ORTEP drawing of the cation in $[MoO_2([15]aneN_4\text{-}H)]Cl$ (I). The two equally populated positions of C(7) are shown.

angles about N(3) is thus 359.2°, indicating a trigonal planar(sp^2) nitrogen, while the sums of the angles about N(1), N(2) and N(4) to the non-hydrogen atoms are 343.1°, 333.4° and 334.1°. The difference between the sp^2 and sp^3 nitrogens is even reflected in the N—C distances: the bonds to N(3) are 1.466(4) and 1.462(4) Å, while the bond distances in the amine portions range from 1.478(4) to 1.498(4) Å. Deprotonation of N(3) is favoured by N(3)→Mo π-donation; the facial orientation of O(1), O(2) and N(3) is typical of three π-donors on a d^0 metal centre.[10]

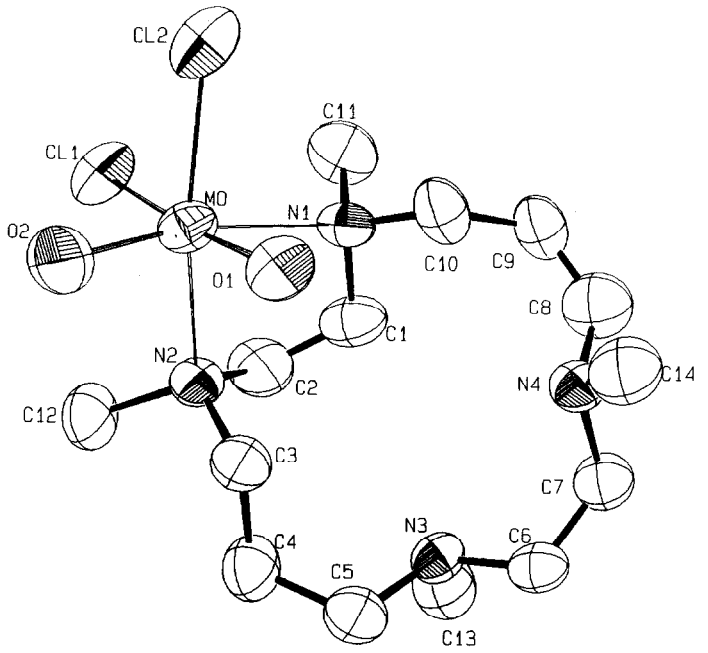

Fig. 2. ORTEP drawing of $MoO_2Cl_2(TMC)$ (III)

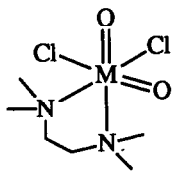
Table 3. Bond distances in MoO_2Cl_2(TMC) (**III**) (Å)

Mo—O(1)	1.701(7)	Mo—Cl(1)	2.486(3)
Mo—O(2)	1.673(7)	Mo—Cl(2)	2.331(3)
Mo—N(1)	2.478(8)	Mo—N(2)	2.289(8)

Complex **III** consists of isolated molecules in the solid state, in which only two of the four nitrogen atoms of the macrocycle are coordinated to the molybdenum (Fig. 2, Tables 3 and 4). Complex **III** is, therefore, a member of a rather large class of octahedral $MoO_2X_2L_2$ compounds, including a number of adducts of MoO_2Cl_2.[2] Complex **III** adopts an all-*cis* structure, with a chloride ligand *trans* to one oxo group and an amine nitrogen *trans* to the other, which is very unusual for $MoO_2X_2L_2$ species. In all previous examples, save one, the neutral ligands (L) are found *trans* to the oxo groups and the anionic ligands (X) avoid the strong oxo *trans* influence.[2] While this manuscript was in preparation, a report in this journal[12] described tetramethylethylenediamine adducts of MoO_2Cl_2 and WO_2Cl_2 (**A**). The stereochemistry was indicated by an X-ray crystal structure of the tungsten derivative (as well as NMR data); the molybdenum complex was determined to be isostructural from powder X-ray diffraction data.



A

The lack of symmetry in the structure of **III** and the large differences in *trans* influence of the ligands lead to substantial disparities in bond lengths. The chloride *trans* to oxo forms a bond 0.15 Å longer than that *trans* to nitrogen [Mo—Cl(1) 2.486(3), Mo—Cl(2) 2.331(3) Å] and the difference in molybdenum–nitrogen distances is almost 0.2 Å (Mo—N1, 2.478(8) Å; Mo—N2, 2.289(8) Å). Even the Mo=O distances of 1.701(7) and 1.673(7) Å are significantly different, although still in the normal range for MoO_2^{2+} complexes, as is the O—Mo—O angle of 101.5(3)°.[10] The tungsten-ethylenediamine complex (**A**, M = W) has very similar bond lengths and angles, except that the two W=O distances are more comparable [1.705(7) and 1.711(7) Å]. The similarity of the two structures is not surprising, as the portion of the macrocycle that coordinates to molybdenum in **III** is essentially tetramethylethylenediamine. However, the fact that these two structures are the only known all-*cis* $MoO_2X_2L_2$ compounds indicates that it is the tertiary amine ligand that is controlling the coordination geometry, perhaps for the reason suggested for **A**:[12] to avoid unfavourable steric interactions between the chelating ligand and the chloride ligands in the more typical, *trans*-halide form.

Reactivity of $[MoO_2([15]aneN_4\text{-}H)]BPh_4$ (**II**)

The instability of **I**, **II** and **III** have hampered our efforts to monitor their reaction chemistry in depth, but preliminary studies indicate that **II** is not a good oxidant. Cyclic voltammograms of **II** in acetonitrile show no evidence of a reduction to −2.0 V (vs Ag/AgCl). Irregular oxidation waves were observed, perhaps due to ligand oxidation. Complex **II** is also inert to PPh_3 in methylene chloride solution for 2 days at ambient temperatures and does not oxidize benzaldehyde under these conditions. These results argue against our initial hypothesis that a cationic derivative might be more easily reduced and show more electrophilic character at oxygen. However, the presence of an amide ligand in **II** provides an additional stabilization for molybdenum(VI) and likely destabilizes molybdenum(V) and molybdenum(IV), because of a π-antibonding interaction with any molybdenum *d*-electrons. The reactivity of $[MoO_2Br(tacn)]^+$[3a] might provide more insight into these issues.

(*Received* 27 *April* 1993; *accepted* 8 *June* 1993)

Abstract—The title compound, $(p\text{-}CH_3C_6H_4)_2SbS_2P(C_2H_5)_2$, was obtained in high yield by reacting $(p\text{-}CH_3C_6H_4)_2SbCl$ with $(C_2H_5)_2PS_2Na\cdot 2H_2O$ and was characterized by means of IR, ^1H and ^{31}P NMR and mass spectra. The solid-state structure was determined using the X-ray diffraction method. The compound is a cyclic dimer in which the fragments are held together by weak (semibonding) antimony–sulphur interactions, i.e. Sb(1)—S(1) 2.485, Sb(1)...S(4) 3.556, Sb(2)—S(3) 2.509 and Sb(2)...S(2) 3.318 Å, respectively, to form an eight-membered $P_2S_4Sb_2$ inorganic ring system. The anisobidentate behaviour of the bridging, bimetallic biconnective dithioligand is reflected in the different lengths of the phosphorus–sulphur bonds, which can be considered as single (P—S 2.077 Å) and double (P=S 1.965 Å). The antimony lone pair of electrons seems to be stereochemically active; the coordination geometry around the metal can be described as pseudo-trigonal bipyramidal, with two carbon atoms of the aromatic groups and the lone pair in equatorial positions and sulphur atoms in axial positions (S—Sb...S angle of *ca* 174°).

The interest in the chemistry of organoantimony derivatives of dithiophosphorus ligands arises from their potential biological activity, i.e. antitumor properties,[1–5] and from their frequently displayed unusual coordination geometries and other structural features. Thus, previous studies based on X-ray diffraction have shown that (diphenyldithiophosphinato)diphenylantimony (III), $Ph_2SbS_2PPh_2$,[6] and (di-isopropyldithiophosphato) diphenylantimony (III), $Ph_2SbS_2P(OPr^i)_2$,[7] exhibit basically different structures. Thus, the diphenyldithiophosphinate is a dimer,[6] whereas the di-isopropyldithiophosphate is a polymer.[7] Both are formed by weak Sb...S interactions, leading to interatomic distances longer than expected for a covalent bond (sum of covalent radii Sb—S 2.45 Å),[8] but significantly shorter than the sum of van der Waals radii (Sb 2.20 Å, S 1.80 Å, sum *ca* 4.0 Å).[9] Such interactions are called *semibonding*[10] and this term will be used here to describe them in various structures.

Dithiophosphorus ligands exhibit a broad variety of coordination patterns: monodentate, isobidentate, anisobidentate and bridging.[11] The latter can lead to dimer or polymer formation and different structures are formed, depending on whether the bridge is bimetallic biconnective or bimetallic triconnective. Some examples are illustrated in Fig. 1.

Monodentate coordination **a** is rare; it occurs,

* Author to whom correspondence should be addressed.

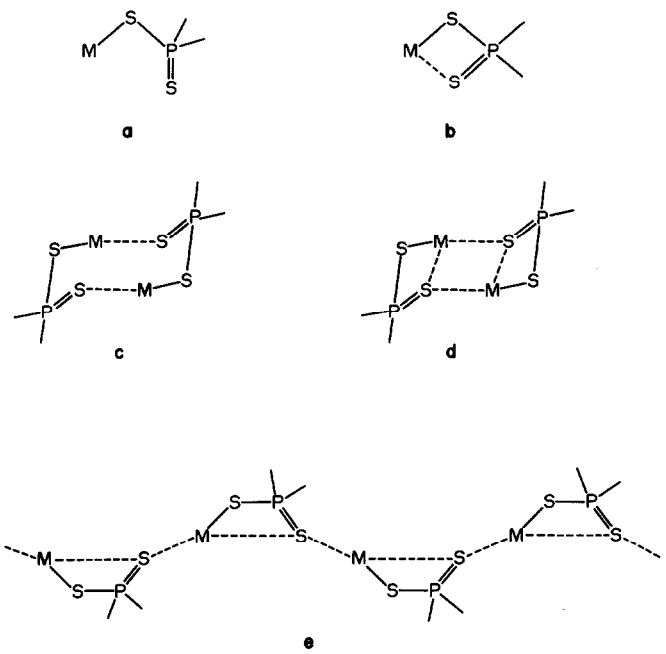

Fig. 1. Some coordination patterns of dithiophosphorus ligands.

for example, in $Ph_3SnS_2P(OEt)_2$[12] and in the germanium compounds $Ph_3GeS_2P(OMe)_2$ and $Ph_2Ge[S_2P(OMe)_2]_2$,[13] but has not been reported for any antimony compound. Anisobidentate coordination **b** is very frequent (for a review see ref. 14); in antimony chemistry it has been well documented.[6,15] The formation of monocyclic dimers based upon an eight-membered ring system **c** is known for zinc,[16] cadmium[17] and mercury[18] compounds, but, so far, has not been found in antimony chemistry. The tricyclic dimer **d**, first reported for $\{Sn^{II}[S_2P(OPh)_2]_2\}_2$,[19] is known in antimony chemistry, e.g. for $[Ph_2SbS_2PPh_2]_2$.[6] The polymeric structure **e** is unique for $\{Ph_2Sb[S_2P(OPr^i)_2]\}_\infty$.[7]

We now report the first example of an antimony compound containing a monocyclic, eight-membered ring system **c**, found by determining the crystal and molecular structure of (diethyldithiophosphinato)di(*p*-tolyl)-antimony(III), $(p\text{-}CH_3C_6H_4)_2SbS_2P(C_2H_5)_2$.

EXPERIMENTAL

Di(*p*-tolyl)antimony(III) chloride was prepared by scrambling at room temperature $(p\text{-tolyl})_3Sb$ and $SbCl_3$ in a 2:1 molar ratio[20] and used without further purification. $Et_2PS_2Na \cdot 2H_2O$ was obtained using a published procedure.[21] The IR spectrum was recorded in the 4000–400 cm^{-1} range on BIORAD spectrometer, using Nujol mulls. ^1H and ^{31}P NMR spectra were recorded in C_6D_6 solutions with a Bruker WH 360 instrument operating at 360 and 146 MHz, respectively, and the mass spectrum was recorded on a FINNIGAN MAT 8222 apparatus. Elemental analyses (carbon and hydrogen) were performed by BELLER Mikroanalytisches Laboratorium (Göttingen).

Preparation of $(p\text{-}CH_3C_6H_4)_2SbS_2P(C_2H_5)_2$

Stoichiometric amounts of $(p\text{-}CH_3C_6H_4)_2SbCl$ (0.68 g, 2 mmol) and $Et_2PS_2Na \cdot 2H_2O$ (0.43 g, 2 mmol) in anhydrous benzene (25 cm^3) were stirred under reflux for 2 h. The resulting sodium chloride was filtered off and the yellow filtrate was evaporated *in vacuo*, leading to a yellow oily product, partially crystallized. This was dissolved in acetonitrile and a small volume of n-hexane was added. Slow evaporation of the solvent mixture allowed the isolation of the title compound as slightly yellowish, prismatic crystals. $C_{18}H_{24}PS_2Sb$ (457.2): Yield: 0.8 g (88%); m.p. 120–122°C. Found: C, 47.3; H, 5.2. Calc.: C, 47.3; H, 5.3%. ^1H-NMR (C_6D_6): 1.05 ppm, dt (6H, CH_3—CH_2—P), $^3J(^{31}PCC^1H) = 22.7$ Hz, $^3J(^1HCC^1H) = 7.6$ Hz; 1.73 ppm, dq (4H, CH_3—CH_2—P), $^2J(^{31}PC^1H) = 13.7$ Hz, $^3J(^1HCC^1H) = 7.6$ Hz; 2.03 ppm, s (6H, *p*-CH_3—C_6H_4); 6.98 ppm, ds (4H, *p*-CH_3—C_6H_4, *meta*), $^3J(^1HCC^1H) = 7.6$ Hz; 7.67 ppm, ds (4H, *p*-CH_3—C_6H_4, *ortho*), $^3J(^1HCC^1H) = 7.6$ Hz. ^{31}P NMR (C_6D_6, H_3PO_4 85%): 76.2 Hz.

Crystal structure determination

Crystal data. $C_{18}H_{24}PS_2Sb$, $M = 457.2$, orthorhombic, $a = 19.907$ (4), $b = 12.293(2)$, $c = 16.285(2)$ Å, $U = 3985.2(10)$ Å^3, $Z = 8$, $D_{calc} = 1.524$ g cm^{-3}, $F(000) = 1840$, space group $Pna2_1$, Mo-K_α radiation, $\lambda = 0.71073$ Å, μ (Mo-K_α) = 1.669 mm^{-1}, crystal size $0.9 \times 0.6 \times 0.4$ mm^3 as a colourless fragment.

Structure determination. Data were collected on a Siemens P4 four-circle diffractometer for 5211 reflections in the 2θ–ω mode, of which 4768 were independent reflections ($R_{int} = 1.16\%$) and 3960 [$F > 4.0\sigma(F)$] were used in the full-matrix least-squares refinement with the SHELXTL PLUS (VMS)[22] program system. The structure was solved by direct methods for the antimony and the difference-Fourier synthesis revealed the positions for the other non-hydrogen atoms. All non-hydrogen atoms were refined anisotropically and hydrogen atoms were calculated as a riding model with isotropic U. The final R values are $R = 4.5\%$ and $wR = 5.59\%$ ($R = 5.58\%$ and $wR = 6.02\%$ for all data) with weights $w^{-1} = \sigma^2(F) + 0.0012F^2$. Our goodness-of-fit (Goof) finished at 1.24. The residual electron density from a final difference-Fourier synthesis was in the range -1.02–1.30 e A^{-3}. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft fur wissenschaftlich-technische Informations mbH, D-W-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the deposit number CSD−57231, the names of the authors and the journal citation.

RESULTS AND DISCUSSION

Di(*p*-tolyl)antimony(III) chloride reacts with sodium diethyldithiophosphinate, in benzene, according to eq. (1):

$$(p\text{-}CH_3C_6H_4)_2SbCl + Et_2PS_2Na \cdot 2H_2O \longrightarrow (p\text{-}CH_3C_6H_4)_2SbS_2PEt_2 + NaCl + 2H_2O \quad (1)$$

(Diethyldithiophosphinato)di(*p* - tolyl)antimony(III) was isolated from the reaction mixture (see Experimental) as slightly yellowish prismatic crystals. The compound is quite soluble in organic solvents, e.g. benzene, acetonitrile and chloroform.

The IR spectrum of the title compound exhibits strong absorptions in the 600–400 cm^{-1} range, i.e. 591 and 479 cm^{-1}, which can be assigned to asymmetric and symmetric PS_2 stretching vibrations, by comparison with those observed for $Et_2P(S)SMe$ (585 cm^{-1} for the P=S bond and 477 cm^{-1} for the P—S bond).[23] The difference $\Delta = \nu_{as}(PS_2) - \nu_s(PS_2) = 112$ cm^{-1} suggests a monodentate coordination of the dithiophosphinato ligand.[24] However, taking into account (a) the affinity of antimony for sulphur, (b) the tendency of antimony to increase its coordination number to five or six and (c) the dimeric structure already established for the related $Ph_2SbS_2PPh_2$,[6] a bridging pattern of the dithiophosphinato ligand, involving weak Sb...S(=P) interactions, cannot be ruled out.

The ^{1}H NMR spectrum confirms the identity of the compound. It contains a doublet of doublets of the same intensity, centred at 7.67 and 6.88 ppm [$^3J(^1HCC^1H) = 7.6$ Hz], as expected for the *ortho* and *meta* protons of the aromatic groups, and a singlet resonance for the methyl protons of the *p*-tolyl groups, at 2.03 ppm. The proton resonances of the ethyl groups attached to phosphorus exhibit the expected pattern, i.e. a doublet of quartets ($\delta = 1.73$ ppm) for methylene protons and a doublet of triplets ($\delta = 1.05$ ppm) for the methyl protons, due to phosphorus–proton and proton–proton couplings. The number and pattern of the proton resonances indicate the equivalence of both aromatic and ethyl groups bound to antimony and phosphorus, respectively. As a consequence, the structure of the compound in solution might be regarded as either monomeric (thus allowing the free rotation of the organic groups and of the whole dithiophosphinato ligand) or dimeric, as found in the solid state (see later). The latter would suggest rapid exchanges in the conformation of the eight-membered $P_2S_4Sb_2$ ring to occur in solution at room temperature.

The ^{31}P NMR spectrum in deuterated benzene shows a singlet resonance at 76.2 ppm, consistent with a unique kind of phosphorus atom.

The DCI(−) mass spectrum of the title compound exhibits some particular features. A dimeric fragment (see the molecular structure description below) was not observed and the monomeric molecular ion $[M—H]^{+\cdot}$ has very low intensity. One of the expected ions of the first fragmentation, i.e. $(p\text{-}CH_3C_6H_4)SbS_2PEt_2^+$, was not observed either (or has a very low intensity). The base peak is $Et_2PS_2^+$. Other ions of the first fragmentation are $(p\text{-}CH_3C_6H_4)_2Sb^+$ and $(p\text{-}CH_3C_6H_4)_2SbS^+$ and could be accounted for by the loss of $Et_2PS_2^{\cdot}$ or $Et_2P(S)^{\cdot}$ radicals, as a result of the cleavage of antimony–sulphur or phosphorus–sulphur bonds, respectively. A tentative fragmentation scheme, with monoisotopic m/z values and relative abundances, is given in Fig. 2.

The crystal and molecular structure of $(p\text{-}CH_3C_6H_4)_2SbS_2P(C_2H_5)_2$ was determined by X-

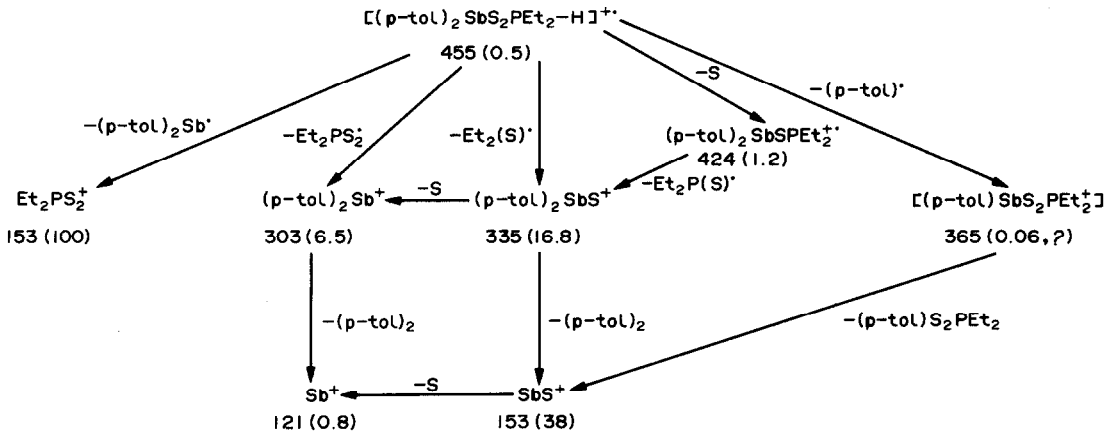

Fig. 2. Fragmentation pattern of $(p\text{-}CH_3C_6H_4)_2SbS_2PEt_2$ ($p\text{-}CH_3C_6H_4$ is abbreviated as *p*-tol).

ray diffraction. Important bond distances and angles are listed in Table 1, and the structure with the numbering atom scheme is shown in Fig. 3.

The two phosphorus–sulphur distances in the ligand unit (averages of two molecules) 2.077 and 1.965 (Å) are close to those reported for $Ph_2P(S)SH$ (2.077 and 1.954 Å)[25] and may be regarded as basically single (long) and double (short) phosphorus–sulphur bonds, in good agreement with the IR data. Comparison of these bond lengths with those observed in the sodium salt, $Et_2PS_2Na \cdot 2H_2O$,[26] i.e. 2.034 and 1.993 Å, provides further evidence concerning the absence of a strong delocalization of the π-electron pair over the PS_2 system in the organometallic compound. The distortion of the tetrahedral environment around the phosphorus atom is reflected in the S—P—S and C—P—C bond angles (av. 115.6 and 105.0°, respectively), which are very close to those found in $Et_2PS_2Na \cdot 2H_2O$ (115.8 and 106.5°, respectively).[26]

If only primary bonded atoms to antimony, i.e. a monodentate behaviour of the dithioligand, are

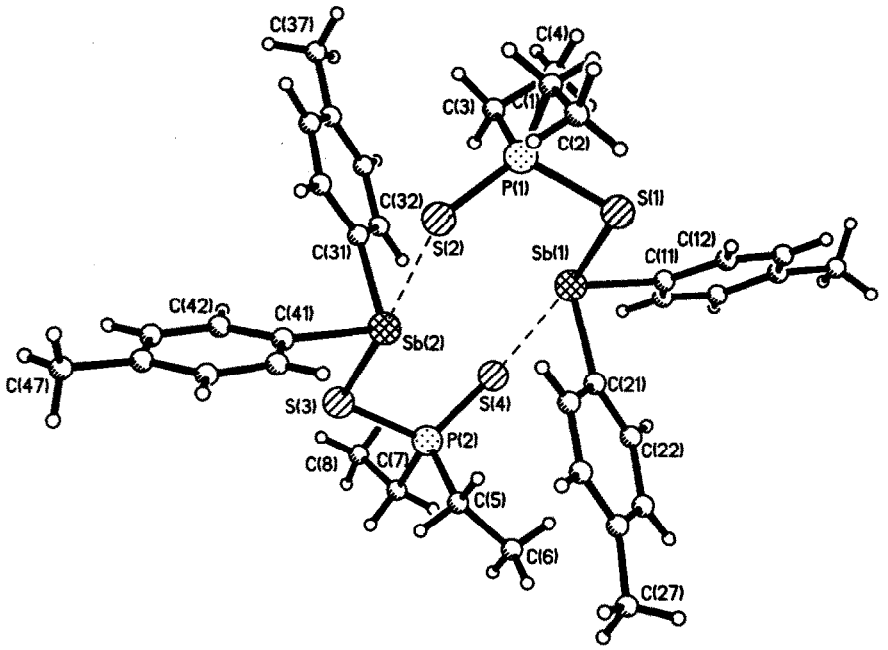

Fig. 3. View of the dimeric molecule of (diethyldithiophosphinato)di(*p*-tolyl)antimony(III), illustrating the atomic numbering.

considered the coordination geometry of the metal atom can be described as pyramidal, with angles at the metal atom ranging between 88.8 and 95.6°. However, each antimony atom forms a longer intermolecular contact, with the sulphur atom doubly bonded to phosphorus of a neighbouring molecule, i.e. Sb(1)...S(4) 3.556 Å, Sb(2)...S(2) 3.318° Å, which are well below the sum of van der Waals radii (*ca* 4.0 Å). This leads to dimeric associations, containing eight-membered inorganic $P_2S_4Sb_2$ rings, as shown in Fig. 3.

As mentioned above, a dimeric structure was reported for $Ph_2SbS_2PPh_2$.[6] However, here further intramolecular interactions between antimony and sulphur (S=P) have been noted (Table 2). Therefore, taking into account the secondary antimony–sulphur bondings, the coordination pattern of the dithiophosphinato ligand is essentially different in these two related compounds, i.e. *bimetallic triconnective* (bridging)[6] in $[Ph_2SbS_2PPh_2]_2$ and *bimetallic biconnective* (bridging) in $[(p\text{-}CH_3C_6H_4)_2SbS_2PEt_2]_2$, respectively.

The eight-membered $P_2S_4Sb_2$ ring has a twist-chair conformation, with the sulphur and antimony atoms almost in the same plane [deviations from the best S_4Sb_2 plane are Sb(1) +0.052, S(1) +0.102, S(2) −0.152, Sb(2) +0.034, S(3) +0.119, S(4) −0.155 Å] and phosphorus atoms lying up and down, respectively, relative to this plane [deviations: P(1) −0.993, and P(2) +0.850 Å] (Fig. 4.).

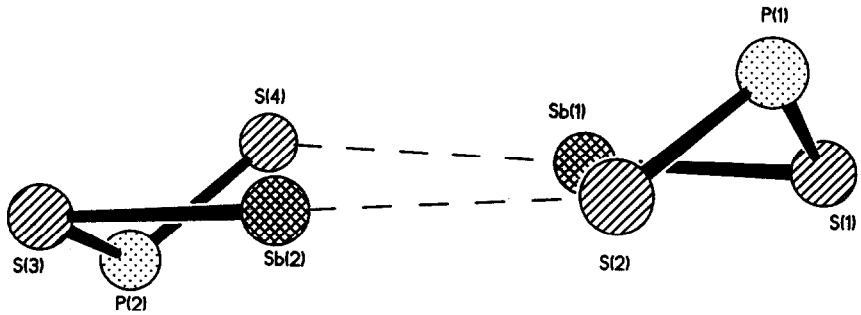

Fig. 4. Schematic illustration of the eight-membered $P_2S_4Sb_2$ inorganic ring system.

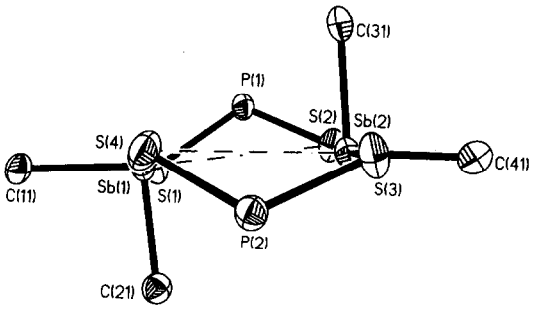

Fig. 5. View of the dimer skeleton along the imaginary phosphorus–phosphorus axis.

If these weaker antimony–sulphur interactions are considered the coordination geometry around the metal atom becomes a distorted square pyramid (with possibly the antimony lone pair of electrons being stereochemically inactive) in $[Ph_2SbS_2PPh_2]_2$ and distorted pseudo-trigonal bipyramidal in the title compound, with the two sulphur atoms in axial positions and carbon atoms of the aromatic groups bound to antimony in equatorial positions. The third equatorial position would be occupied by the stereochemically active lone pair of electrons. A view of the molecule along the imaginary P(1)...P(2) axis (Fig. 5) reveals much apparently free space above Sb(1) and below Sb(2), which could be occupied by the lone pair, if stereochemically active. It would be in an equatorial plane also comprising C(11) and C(21) at Sb(1) and C(31) and C(41) at Sb(2). Both electron pairs should be along a direction bent towards the centre of the ring. This is supported by the bond angles at antimony: S(1)Sb(1)...S(4) 173.7°, C(11)—Sb(1)—C(21) 95.6°, C—Sb(1)—S (range) 89.2–93.4°.

THERMAL DECOMPOSITION STUDIES OF TRIS(N,N′-DIALKYLDITHIOCARBAMATO)IRON(III) COMPLEXES BY MÖSSBAUER SPECTROSCOPY

R. B. LANJEWAR and A. N. GARG*

Department of Chemistry, Nagpur University, Nagpur 440 010, India

(*Received* 23 *March* 1993; *accepted* 8 *June* 1993)

Abstract—A series of complexes of the type $[Fe(R'R''NCS_2)_3]$ with $R' = R'' = CH_3$ and C_2H_5; $R' = CH_3$, $R'' = C_2H_5$; $R' = CH_3$, $R'' = i\text{-}C_3H_7$; $R' = CH_3$, $R'' = C_6H_5$ and $R'NR''$ = pyrrolidyl and piperidyl, has been synthesized and their thermal decomposition studied. The complexes have been characterized by elemental analysis, electronic, IR and Mössbauer spectral and magnetic measurements. Mössbauer spectra of all the complexes at room temperature exhibit a quadrupole doublet with $\delta = 0.58$–0.68 mm s^{-1} (w.r. to SNP) and $\Delta E_Q = 0.25$–0.70 mm s^{-1}, except for pyrrolidyl and piperidyl complexes which exhibit $\delta = 0.93$ and 0.42 mm s^{-1}, respectively. Thermal decomposition behaviour can be divided into three groups of volatile, non-volatile and those yielding metal sulphides/oxides. An attempt has been made to identify intermediate and final products. Mössbauer spectra of the complexes at $>650°C$ exhibit six line patterns with $H_{eff} = 515 \pm 5$ kOe, suggesting the formation of $\alpha\text{-}Fe_2O_3$ in all cases.

Sulphur donor ligands are well known for their anticancer, antiviral and antifungal activities as well as widespread industrial applications in the vulcanization of rubber.[1] The dithiocarbamate ligand has coordinating ability to act as a unidentate, bidentate chelating or bridging ligand.[2,3] Cambi *et al.*[4] performed pioneering work on N,N′-dialkyldithiocarbamato iron(III) complexes, which provided a basis for the understanding of the spin state equilibrium in iron(III) complexes. Since then a large number of studies have been reported on the structure and magnetic behaviour of $[Fe(R,R''NCS_2)_3]$ by electronic,[5] IR[6], ESR and Mössbauer spectroscopic[7,8] studies down to liquid nitrogen temperature. The thermal decomposition of metal dithiocarbamates has also been of interest to many workers.[9–11] D'Ascenzo and Wendlendt[10] and Cardwell *et al.*[11] studied the thermal behaviour of $[Fe(S_2CNEt_2)_3]$ by TGA, DTA and found it to be completely volatile. It has been stated that most volatile compounds contain branched groups like i-butyl and i-propyl, while replacement by the benzyl group may lead to a sharp decline in volatility. Earlier we have reported thermal decomposition studies of some mixed-ligand dithiocarbamato iron(III) complexes, where loss of the ligand and/or the formation of Fe_2O_3/Fe_2S_3 was suggested.[12] Willemse *et al.*[13] have reviewed transition metal group complexes and the role of the dithiocarbamate ligand in stabilizing unusual oxidation states.

In this paper we report the synthesis of tris-(dialkyldithiocarbamato)iron(III) complexes with dimethyl, diethyl, methylethyl, i-propylmethyl, phenylmethyl, pyrrolidyl and piperidyl heterocyclic bases and their electronic, IR and Mössbauer spectroscopic studies. Thermal decomposition behaviour of the complexes was studied and its intermediate and final products were identified employing Mössbauer spectral measurements.

EXPERIMENTAL

All the chemicals used were of AR, GR or high purity grade. All solvents were purified before use.

Preparation of the complexes

First sodium salts of the ligands were prepared by the reaction of the respective amine (N-methylaniline, N,N′-dimethylamine, N,N′-methyl-

ethylamine, piperidine and pyrrolidine) in dried diethyl ether with carbon disulphide and adding NaOH solution in an equal mole ratio with vigorous stirring. The crude products were recrystallized from chloroform. Sodium diethyldithiocarbamate was of AnalaR (BDH, England) grade. Complexes were prepared by mixing an ethanolic solution of 0.1 M ferric nitrate (GR, S. Merck) with a 0.3 M solution of the respective sodium dialkyldithiocarbamate.[8] Ferric nitrate (4 g) and a calculated amount of sodium dialkyldithiocarbamate were dissolved separately in minimum amounts of absolute ethanol and mixed with thorough stirring at room temperature for 1–2 h. In most cases a black coloured precipitate separated out, which was filtered, washed with water and then with acetone and diethylether and dried in a desiccator over fused $CaCl_2$. The complexes were characterized by the elemental analysis of C, H, N, S and Fe. Analytical data of the complexes are given in Table 1.

Physical measurements

Mössbauer spectra were recorded using a constant acceleration transducer driven Mössbauer spectrometer in conjunction with a PC based 1k multichannel analyser (Nucleonix, Hyderabad). A 5mCi ^{57}Co(Rh) source (procured from the Isotope group, BARC, Bombay) was used. All the spectra were recorded at room temperature and few simple ones were computer fitted with Lorentzian line shape. The spectrometer was calibrated using natural iron foil.[14] Sodium nitroprusside dihydrate (SNP) was used as a standard for isomer shift measurements.

Reflectance spectra were recorded using a Shimadzu Model UV-240 spectrophotometer employing MgO as a reference. IR spectra (4000–200 cm^{-1}) were recorded in KBr medium on a Perkin–Elmer 157 IR spectrophotometer. Thermograms were recorded on a Perkin–Elmer Thermogravimetric analyser System Model TGS-2 and Thermal Analysis Data Station TADS-3600 at a heating rate of 10 and 20°C per min. Magnetic moments were determined from magnetic susceptibility measurements using a Gouy balance and $Hg[Co(SCN)_4]$ as the standard.

The complexes were heated at different temperatures (as ascertained from TGA plot) in an electronically controlled muffle furnace for 3 h and then Mössbauer spectra of quenched samples were recorded.

RESULTS AND DISCUSSION

All the complexes were black coloured solids and stable under normal atmospheric conditions. Characteristic IR frequencies due to C···N, C···S and M—S stretching vibrations are listed in Table 1. Typical Mössbauer spectra of dimethyl, phenylmethyl and piperidyl dithiocarbamato iron(III) complexes at room temperature and after heating at different temperatures are shown in Figs 1, 2 and 3, respectively. Mössbauer parameters at various temperatures and magnetic moments are listed in Table 2. In Figs 4, 5 and 6 are shown the TGA and DTG plots of all the complexes and their respective thermogravimetric data are given in Table 3.

$Fe(dtc)_3$ is likely to have trigonally distorted octahedral geometry with six sulphur donor atoms surrounding it.[13] As a first approximation in O_h symmetry, the electronic configuration in the high

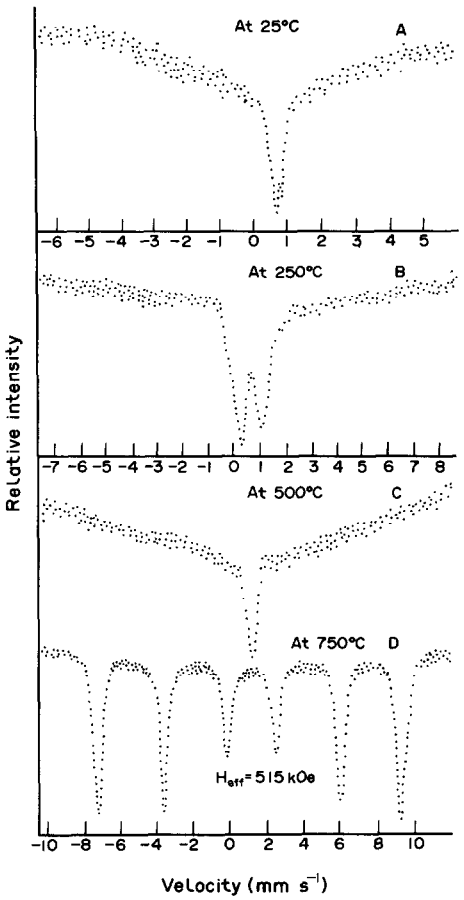

Fig. 1. Mössbauer spectra of tris(dimethyldithiocarbamato)iron(III) at (A) room temperature and after heating at (B) 250°C, (C) 500°C and (D) 750°C for 3 h in air.

spin state will be $t_{2g}^3 e_g^2$ or $^6A_{1g}$. However, in the case of the low spin state the electronic configuration would be t_{2g}^5 or $^2T_{2g}$. Magnetic moments of the complexes at room temperature are in the range 3.81–5.76 B.M. (Table 2) for spin free and spin paired configurations. The magnetic moment of the pyrrolidyldithiocarbamate complex (5.76 B.M.) is comparable to that for one spin free state (5.9 B.M.), while the phenyl methyl, dimethyl and i-propylmethyl substituted dithiocarbamate complexes appear to be in equilibrium between low and high spin states. Mitchell and Parker[15] have suggested that the most probable explanation for such low magnetic moments may be attributed to the presence of iron(III) in the intermediate spin state, $S = 3/2$.

Reflectance spectra of the complexes exhibit three bands of varying intensities at 15,000, 19,500 and 25,000 cm^{-1} corresponding to $^6A_{1g} \rightarrow {}^4T_{1g}$, $^6A_{1g} \rightarrow {}^4T_{2g}$ and $^6A_{1g} \rightarrow {}^4T_{1g}$, ^4E_g transitions,[16] respectively. It is observed that for ethylmethyl, phenylmethyl and i-propylmethyl substituted dithiocarbamate complexes the band at 25,000 cm^{-1} is more intense compared with a symmetric band of low intensity at *ca* 20,000 cm^{-1}. Contrary to this for other complexes the band at 25,000 cm^{-1} is less intense and only a broad intense shoulder is observed at 20,000 cm^{-1}.

IR spectra

Kellner *et al.*[17] attempted to detect the type of metal–ligand bonding from the solid-state vibrational spectra. We have observed a single band at 315 cm^{-1} for the supposedly high spin pyrrolidyl complex, which is in accordance with the earlier observation of 320 cm^{-1} by Ewald *et al*[18]. For the piperidyl complex also a single band observed at 340 cm^{-1} is suggestive of its high spin nature. However, for other complexes two bands at 260 and 350 cm^{-1} are observed. On the basis of these observations an equilibrium between the two spin states or a mixed spin state is expected.

The stretching vibration due to C···N has been observed at 1500 ± 100 cm^{-1}. Interestingly for high spin pyrrolidyl and piperidyl complexes it is

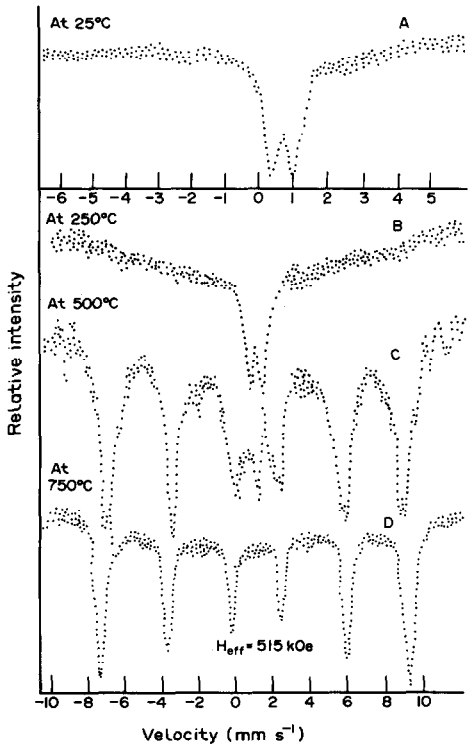

Fig. 2. Mössbauer spectra of tris(phenylmethyldithiocarbamato)iron(III) at (A) room temperature and after heating at (B) 250°C, (C) 500°C and (D) 750°C for 3 h in air.

observed at the lower frequency of 1450 cm^{-1} while for other complexes it is observed at 1500 and 1630 cm^{-1}. Bradley and Gitlitz[19] have found these bands to be insensitive of the nature of the metal or alkyl group. A strong band in the region 1000–970 cm^{-1} due to C=S stretching vibrations is suggestive of the chelating character of the dithiocarbamate ligands in all these cases.

Mössbauer parameters

Room-temperature Mössbauer spectra of dimethyl and diethyl substituted dithiocarbamate complexes show a doublet with $\Delta E_Q = 0.36$ and 0.25 mm s^{-1}, respectively. The corresponding δ values (Table 2) are 0.63 and 0.60 mm s^{-1}, which are in reasonably good agreement with those of $\delta = 0.65$ mm s^{-1} (for both) reported by Fiddy *et al.*[7] In all other cases well-resolved doublets were observed. Our ΔE_Q values for various dithiocarbamate complexes compare well with those reported in the literature.[20]

Since the *zz*-component of the electric field gradient tensor at the iron nucleus is zero for the configuration $t_{2g}^3 e_g^2$ ($^6A_{1g}$), the high spin state is not expected to show any quadrupole splitting and a

single absorption peak is expected. On the other hand a well-defined quadrupole doublet is expected for the low spin state ($^2T_{2g}$). The well-resolved doublet in the unsymmetrically substituted dialkyldithiocarbamate complexes with phenylmethyl, ethylmethyl and i-propylmethyl groups is noteworthy. It suggests that the substitution of the

stitution of different alkyl groups. In the present study δ values vary in the range 0.56–0.68 mm s^{-1}, except for N-heterocyclic base substituted pyrrolidyl and piperidyl complexes which show $\delta = 0.93$ and 0.42 mm s^{-1}, respectively. The large difference in δ values for the two complexes may possibly be due to the ring structure and size. If the average $\delta = 0.62$ mm s^{-1} is assumed for the dialkyldithiocarbamates, then for pyrrolidyldithiocarbamato iron(III) it is enhanced by 0.20 mm s^{-1}, whereas for piperidyldithiocarbamato iron(III) it is reduced by the same extent. Possibly the ring structure may be playing a role in enhancing or decreasing *s*-electron density at the iron nucleus. Interestingly, both the complexes show similar ΔE_Q values of 0.70 mm s^{-1}, suggesting distortion to the same extent.

Thermal decomposition studies

Thermal decomposition of metal dithiocarbamates has been a subject matter of detailed investigations.[9,10,12] It has been suggested that metal dialkyldithiocarbamates may be divided into two groups; volatile and non-volatile. Decomposition seems to proceed via the formation of metal thiocyanate as an intermediate, which may ultimately yield metal sulphide and/or oxide. However, a perusal of thermogravimetric data in Table 3

inequivalent alkyl groups causes a greater distortion in the axial symmetry of the complex. Interestingly, ΔE_Q values decrease in the order phenylmethyl > ethylmethyl > i-propylmethyl. Recently Terzis *et al.*[21] observed $\Delta E_Q = 0.10$ mm s^{-1} in tris(N-methyl-N′-n-butyldithiocarbamato) iron (III), which is smaller than for all the unsymmetrically substituted dithiocarbamate complexes of this study.

The Mössbauer spectra of pyrrolidyl and piperidyl dithiocarbamate complexes are somewhat complex, but the quadrupole splitting is well defined. High magnetic moments of these complexes suggest the predominance of the high spin state ($^6A_{1g}$) with little contribution from the low spin state ($^2T_{2g}$). Our value of $\mu_{eff} = 4.5$ B.M. for piperidyl substituted complex compares well with 4.04 B.M. reported by Wazda *et al.*[20] In spite of this, large ΔE_Q values may be attributed to the distortion in the octahedral geometry, as already confirmed by X-ray crystal structure.[22] It has been suggested that δ values in these complexes remain fairly constant as *s*-electron density is unduly sensitive to the sub-

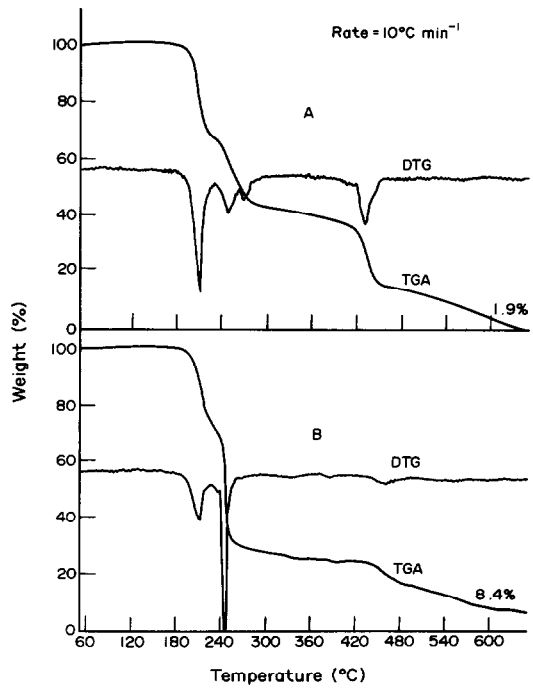

Fig. 6. Thermogravimetric plots of tris (A) (pyrrolidyl-) and (B) (piperidyldithiocarbamato)iron(III) complexes.

shows that the tris(dialkyldithiocarbamato) iron(III) complexes investigated in this study may be divided into three distinct groups:

(A) *Non-volatile complexes of symmetrically substituted dithiocarbamates.* Thermograms of dimethyl and diethyl substituted dithiocarbamate complexes (Fig. 4) show a sharp and single stage decomposition at ~250°C yielding 24.1 and 20.0% residual weights, respectively. These correspond to the formation of Fe_2S_3 (cf. calculated weights 25.0 and 20.8%, respectively, for the two complexes). D'Ascenzo and Wendlendt[10] have reported iron(III) diethyldithiocarbamate as a volatile metal chelate, which is contrary to our observation. In our earlier study of mixed-ligand diethyldithiocarbamates with different chelating ligands, the residual weights of 17.4–55.0% were observed and none of the complexes were found to be volatile.[12]

Mössbauer spectra of dimethyl and diethyl substituted dithiocarbamate complexes heated at 250°C for 3 h exhibit an asymmetric doublet (Fig. 1) with increased ΔE_Q of 0.78 and 0.87 mm s^{-1}, respectively. On further heating at 500°C, Mössbauer spectra of the dimethyl substituted complex show a singlet with $\delta = 0.63$ mm s^{-1}, whereas for the diethyl substituted complex a magnetic hyperfine splitting with $\delta = 0.72$ mm s^{-1} and $H_{eff} = 520$ kOe is observed. It seems on heating up to 250°C either a ligand is lost or iron(III) thiocyanate is formed, giving a doublet in both cases. At 500°C, however, in the case of the dimethyl dithiocarbamate complex, a single line spectrum is suggestive of a highly symmetric environment around the iron atom. When this complex is further heated to 750°C a well defined six-line spectrum is observed with $\delta = 0.75$ mm s^{-1} and $H_{eff} = 515$ kOe (Fig. 1). This difference in behaviour is more intriguing. Fiddy *et al.*[7] have also noted some difference in the low-temperature Mössbauer spectral behaviour of dimethyl and diethyl substituted dithiocarbamates and attributed it to crystallographic phase change. Even though thermogravimetric studies suggest the formation of Fe_2S_3 in both cases, six-line Mössbauer spectra with $H_{eff} = 515$–520 kOe suggest the formation of α-Fe_2O_3. The line separations also match with those reported in the literature.[23,24] In order to further resolve the ambiguity about Fe_2O_3 or Fe_2S_3 we attempted to determine sulphur content in the end product, but could not find any sulphur in it. Therefore, as Mössbauer spectral and elemental analysis evidences, formation of α-Fe_2O_3 is a certainty. Presumably, in TGA studies where a sample is heated at 10°C min^{-1}, Fe_2S_3 is being formed which on prolonged heating in air for 3 h maybe converted to α-Fe_2O_3 to exhibit a six-line spectrum.

(B) *Non-volatile complexes of unsymmetrically substituted dithiocarbamates.* Thermograms of phenylmethyl, ethylmethyl and i-propylmethyl substituted complexes (Fig. 5) yield 71.5, 77.5 and 75.8% residual weights, respectively, at 900°C. The weight losses correspond to approximately one ligand in all three cases. The phenylmethyl dithiocarbamate complex gives a DTG peak at 230°C [Fig. 5(A)], exhibiting fast decomposition up to 300°C and later it decomposes slowly up to 900°C. In the case of the ethylmethyl substituted complex decomposition starts at 50°C, giving a DTG peak at 80°C and another at 240°C. Beyond 300°C it decomposes very slowly. For tris(i-propylmethyldithiocarbamato)iron(III), decomposition is uniformly slow in the entire temperature range up to 900°C. Again two broad DTG peaks are observed at 100 and 250°C. Therefore, not only are these complexes non-volatile but their decomposition behaviour is also complex.

Mössbauer spectra of all the three complexes heated at 250°C exhibit doublets with $\Delta E_Q = 0.60$–0.64 mm s^{-1} and $\delta = 0.63$–0.72 mm s^{-1}. It may be noted that as compared with room temperature ΔE_Q increases insignificantly. It seems that the dithiocarbamate ligand is decomposed partially, whereby the substitutent alkyl group may be eliminated. On further heating at 500°C six-line hyperfine splitting ($H_{eff} = 495$–510 kOe) along with a singlet may correspond to a somewhat symmetric environment around the iron nucleus while the decomposition is still in progress. At the same time a partially magnetic phase as evidenced by hyperfine splitting with $H_{eff} = 510$–515 kOe is observed for all the three complexes. Identical δ values of 0.70 mm s^{-1} and the strength of the magnetic field in all three cases suggest the formation of α-Fe_2O_3.[21]

(C) *Volatile complexes of N-heterocyclic substituted dithiocarbamates.* As evident from thermograms in Fig. 6 pyrrolidyl and piperidyl dithiocarbamate complexes show a three-stage decomposition. In both the complexes two sharp DTG peaks appear at 200 and 250°C and a third broad peak at *ca* 440°C. Ultimately 1.9 and 8.4% residual weights are obtained at 650°C for both the complexes. It clearly suggests the volatile nature of both the complexes because even their metal contents are 11.3 and 10.4%, respectively. Presumably, it represents the removal of the three ligands, one at a time, when part of the iron metal seems to be converted to oxide at 650°C, as evidenced by six-line hyperfine splitting with $H_{eff} = 520$ kOe.

Mössbauer spectra of both the complexes heated at 250°C show a doublet with little increase in quadrupole splitting. It may be due to detachment of

one of the ligands. At 350°C the spectrum consists of three lines of unequal intensities [Fig. 3(C)]. It may be resolved into two sets of doublets. The first set shows a large $\Delta E_Q = 3.0$ mm s^{-1} and $\delta = 1.65$ mm s^{-1}, which may correspond to iron(II) in the high spin state.[25] Another doublet, however, has a smaller $\Delta E_Q = 0.82$ and 0.86 mm s^{-1} with $\delta = 0.58 \pm 0.02$ mm s^{-1}. These are the same as at 250°C and correspond to iron(III) in the low spin state. It seems that after the detachment of the first ligand at 250°C iron(III) is partially reduced to iron(II), giving the complex in the high spin state. On further heating up to 600°C in air the whole complex volatilizes. In this process part of the metal may be oxidized to form a ferromagnetic phase of α-Fe_2O_3. δ values of 0.75 and 0.72 mm s^{-1} and $H_{eff} = 520$ kOe for both complexes clearly suggest the formation of α-Fe_2O_3.[24]

Possibly, these compounds may be of special technical importance in the rubber industry, whereby metal oxides are added during vulcanization thus altering its properties for useful purposes. In view of some of these investigations, the thermal decomposition of dithiocarbamates needs to be reinvestigated (in the absence of air) and more precise identification of thermal decomposition products is essential.

(*Received* 21 *April* 1993; *accepted* 4 *June* 1993)

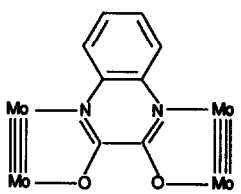
Abstract—$[Mo_2(O_2CBu^t)_3(CH_3CN)_2]^+[BF_4]^-$ and the disodium salt of the dioxypyridazine dianion (DOP) react in CH_2Cl_2/CH_3CN/MeOH solution to give the red microcrystalline tetranuclear compound $[Mo_2(O_2CBu^t)_3]_2(\mu$-DOP) (**1**), which is soluble in coordinating solvents such as THF and pyridine (py). Compound **1** shows two oxidation potentials by cyclic voltammetry, $\mathbf{1} \rightarrow \mathbf{1}^+$, $E_{1/2} = -0.15$ V, and $\mathbf{1}^+ \rightarrow \mathbf{1}^{2+}$, $E_{1/2} = +0.28$ V, vs the Cp_2Fe/Cp_2Fe^+ couple. The first oxidation is chemically reversible and the cationic complex $[\mathbf{1}]^+[BF_4]^-$ was isolated. The reaction between $[Mo_2(O_2CBu^t)_3(CH_3CN)_2]^+[BF_4]^-$ and the sodium salt of the dianion derived from deprotonation of 2-imidazolinethione in a CH_2Cl_2/CH_3CN/MeOH solvent mixture gave $Mo_2(O_2CBu^t)_3$(IMT) (**2**), where IMT represents the anion from a single deprotonation of 2-imidazolinethione. Compound **2** was structurally characterized as its pyridine adduct $\mathbf{2}\cdot(py)_2$ and contained a central Mo$\overset{4}{-}$Mo bond, 2.116(1) Å, bridged by three O_2CBu^t ligands and an IMT ligand which forms Mo—N and Mo—S bonds of lengths 2.12(1) and 2.49(1) Å, respectively. The two molecules of pyridine are coordinated along the Mo—Mo axis, one in a rather normal manner, Mo—N = 2.63(1) Å, but the other in a more distant arrangement with Mo---N = 2.97(1) Å. The latter py is coordinated to the molybdenum atom that is bonded to the nitrogen atom of the IMT ligand. These results are compared with those of earlier studies aimed at covalently linking M$\overset{4}{-}$M bonds.

The wide range of optical, magnetic and electrochemical properties associated with complexes containing metal–metal multiple bonds[1] promoted our investigation of macromolecular ordered assemblies (oligomers, polymers and metallomesogens) containing such subunits.[2,3] One of the goals of this research is the preparation of covalently-linked, stiff-chain polymers wherein facile electron transfer is possible between quadruple bonds incorporated along the polymeric backbone.[4] We have concentrated on the use of dimetal tetracarboxylates as the quadruply-bonded subunit and bridging ligands containing conjugated π-systems as the linking moieties. In principle the 1-D polymer can be ordered such that the M—M axis is either perpendicular or parallel to the polymer axis.[2]

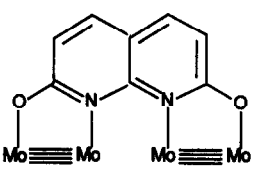
The potential conductivity of these targeted polymeric systems can be estimated from the redox chemistry of smaller molecular fragments, such as two dinuclear subunits linked by a single polydentate ligand. This strategy was utilized previously to prepare tetranuclear complexes coupled through dicarboxylate and di-α-oxypyridinato links.[2] The electronic coupling of the quadruple bonds in these complexes was shown to be a function of both the metal (Mo vs W) and the nature of the bridging group. For example, the complexes $[Mo_2(O_2CR)_3]_2$(DOQ) (**A**) and $[Mo_2(O_2CR)_3]_2$(DON) (**B**) (where R = Bu^t, DOQ = dioxyquinoxaline, DON = dioxynaph-

† Author to whom correspondence should be addressed.

thyridine) exhibit different oxidation behaviour. In the drawing three carboxylato ligands were omitted from each Mo–Mo for clarity. Compound **A** displays a 366 mV separation between its first and second oxidation potentials, whereas compound **B** shows more communication with a separation of 373 mV between the same redox couples. Despite the different alignment of the Mo—Mo axes in **A** and **B**, the coupling occurs through the mixing of metal–metal δ-orbitals with those of the π^*-orbitals of the ligands. This was evident from the use of $[p\text{-}O_2C\text{—}C_6F_4\text{—}CO_2]^{2-}$ and the 1,8-anthracene dicarboxylate dianion which yielded tetranuclear compounds stereochemically related to **A** and **B**, but with very small electronic couplings between the Mo_2 centres, i.e. the separation between the first and second oxidation potentials was *ca* 50 mV or less.[2]



A

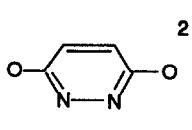


B

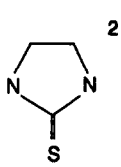
In this work we report further studies aimed at the preparation of tetranuclear complexes containing quadruply-bonded dimolybdenum centres linked with bridges that we expected would show even greater electronic communication.

RESULTS AND DISCUSSION

Anticipating that bridging groups that are capable of providing even shorter conjugation paths between the quadruple bonds would lead to greater charge delocalization, we examined the potentially bridging ligands derived from deprotonation of dihydroxypyridazine and 2-imidazolinethione shown in **C** and **D** below.



C



D

The synthetic strategy employed the substitution chemistry of the labile complex $Mo_2(O_2CBu^t)_3(CH_3CN)_2{}^+BF_4{}^-$, which can be prepared via alkylation of $Mo_2(O_2CBu^t)_4$ in CH_3CN.[5] The acetonitrile ligands, as well as the pivalate groups are kinetically labile, such that the equilibrium shown in eq. (1) is established in acetonitrile.

$$Mo_2(O_2CBu^t)_4 + Mo_2(O_2CBu^t)_2{}^{2+} \overset{K}{\rightleftharpoons} 2Mo_2(O_2CBu^t)_3{}^+BF_4{}^- \quad (1)$$

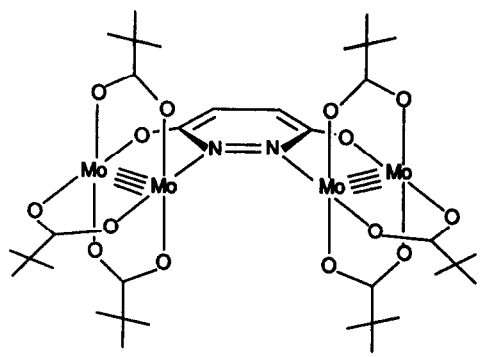
At room temperature K is on the order 60 and most of the material exists as the tris-pivalato cation.

The compound $[Mo_2(O_2CBu^t)_3]_2$(DOP) (**1**) was prepared from the dimolybdenum trispivalato cation as shown in eq. (2).

$$2Mo_2(O_2CBu^t)_3{}^+BF_4{}^- + Na_2DOP \longrightarrow [Mo_2(O_2CBu^t)_3]_2(\mu\text{-DOP}) + 2NaBF_4 \quad (2)$$

1

The ^1H NMR spectrum displays the expected 2 : 1 ratio of the Bu^t resonances along with a doublet in the aromatic region indicative of a symmetrically disubstituted DOP ligand. Assuming the usual coordination mode of α-oxypyridinato ligands,[2] the structure of **1** would be that shown below in **E**.



E

In **1** the shortest pathway between the linked quadruple bonds is via the two π-conjugated nitrogen atoms of the DOP ligand. This represents a shorter path than in either of compounds **A** (four atoms) or **B** (three atoms). Although the π-system in this series of compounds is different in each case, we felt that the electronic coupling in **1** may be stronger than for the other tetranuclear complexes because of the shorter pathway available. We carried out the cyclic voltammetry of **1** in THF and the response is depicted in Fig. 1. Two chemically reversible one-electron oxidation waves were observed and the resulting potentials are listed in Table 1, along with those for **A** and **B** and related compounds for comparison. The $E_{1/2}$ values for the redox couples of **1** were determined to be $E_{1/2}{}^1 = -0.15$ V and $E_{1/2}{}^2 = +0.28$ V vs the $Cp_2Fe^{0/1+}$ couple used as an internal standard.

The oxidation processes shown in Table 1 represent successive removal of one-electron from each of the complexes. The magnitude of the separation of the two oxidation processes is indicative of the

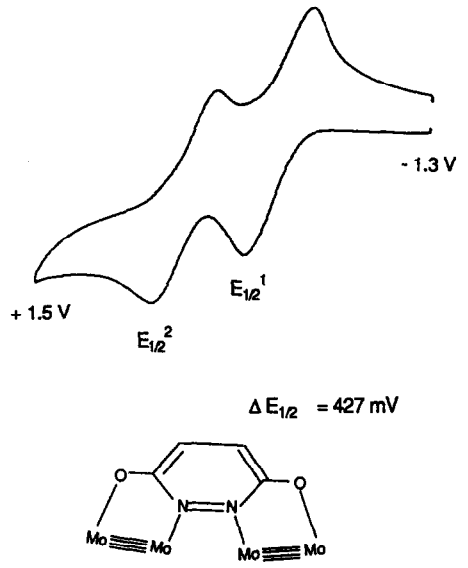


Fig. 1. Cyclic voltammogram of **1** in THF with 2.0 $M[N(Bu^n)_4][PF_6]$ as the supporting electrolyte at 200 mV s^{-1}.

extent of electron delocalization in the singly oxidized radical cation $\mathbf{1}^+$. The greater the separation between the oxidation processes, the more highly delocalized the charge in the radical cation.[8] Compared with the electrochemical behaviour of the compounds **A** and **B**, the DOP ligand does indeed provide for greater electronic communication between the Mo—Mo multiple bonds (see Table 1).

This also results in a more stable radical cation with respect to disproportionation to the neutral and dicationic species. The equilibrium reaction is depicted in eq. (3) as a comproportionation.

$$\mathbf{1} + \mathbf{1}^{2+} \overset{K_c}{\rightleftharpoons} 2[\mathbf{1}]^+ \qquad (3)$$

The comproportionation equilibrium constant can be calculated from the electrochemical data according to the formula $K_c = \exp(\Delta E_{1/2}/25.69)$ and results in a value of 1.7×10^7 for $\mathbf{1}^{1+}$.[8]

With the hope of preparing a linked tetranuclear complex displaying even stronger electronic communication between quadruple bonds, we focused on the potentially single-atom-bridged ligand derived from double deprotonation of 2-imidazolidinethione. However, treatment of the disodium salt of this dianion with 2 equivalents of the tris-pivalato Mo_2 cation resulted in the isolation of the dimolybdenum dinuclear complex **2**, which contains a single deprotonated 2-imidazolinethione ligand. Either we were unsuccessful in deprotonating the ligand twice or the dianion has scavenged a proton in the formation of **2**. The failure of the ligand to link two Mo_2 units was evident in

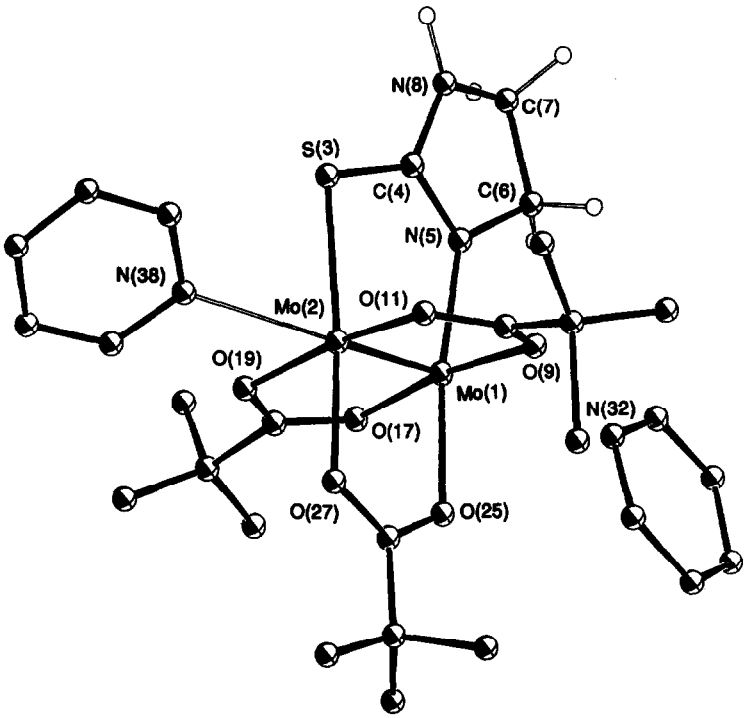

Fig. 2. Ball-and-stick representation of $Mo_2(O_2CBu^t)_3(IMT) \cdot 2py$. The hydrogen atoms of the Bu^t groups have been omitted for clarity.

the ^{1}H NMR spectrum. Two pivalate resonances at 1.50 and 1.62 ppm in a 1 : 2 ratio, a multiplet at 3.55 integrating to one IMT ligand per $[Mo_2piv_3]$ unit and a singlet at 8.18 ppm due to the N—H proton were observed in pyridine-d_5.

Crystals of **2** suitable for a single-crystal X-ray diffraction study were obtained from pyridine and a ball-and-stick diagram of the molecule is shown in Fig. 2. Pertinent bond distances and angles for **2** are provided in Table 2. The compound crystallized with two weakly bound pyridine ligands in the axial sites [Mo—N distances are 2.97(1) and 2.63(1) Å]. The longer Mo—N distance is accompanied by a tilting of the pyridine such that the nitrogen lone pair is not optimized for Mo—py bonding. It appears almost as if a Mo—py bond is being formed or broken. Why pyridine coordination to Mo(2) is preferred relative to Mo(1) could be due to either steric or electronic factors, or both. Inspection of the Mo—O distances reveals that Mo(1) and Mo(2) are equivalently bonded to the pivalate ligands. The Mo—Mo distance of 2.116(2) Å is typical of a quadruple bond. The IMT ligand spans the Mo—Mo bond with the expected N—C—S coordination mode, however, the second nitrogen atom of the IMT ligand is protonated rather than being coordinated to another Mo_2 unit. The bidentate nature of the IMT ligand may be compared with that seen by Constable and Raithby[9] in ruthenium mononuclear complexes involving the anion derived from 2-pyridinethione.

EXPERIMENTAL

^{1}H NMR spectra were recorded on a Varian XL-300 spectrometer in dry and oxygen-free solvents. Electrochemical measurements were obtained with a PAR 173 potentiostat and 175 programmer along with a Houston Instruments 2000 *XY* recorder. The cyclic voltammogram was recorded in an air-free cell under a nitrogen atmosphere in THF with 2.0 M tetra-n-butylammonium hexafluorophosphate as the supporting electrolyte. The working electrode was a glassy carbon electrode and the counter electrode was a platinum-gauze electrode. All potentials reported are relative to the $(C_5H_5)_2Fe/(C_5H_5)_2Fe^+$ couple which occurs at +0.89 V (ΔE = 70 mV) under the conditions specified above when compared with Ag/Ag^+.

Elemental analyses were performed by Oneida Research Services, Whitesboro, New York. All reactions were performed under an atmosphere of dry and oxygen-free nitrogen using standard Schlenk and glove-box techniques. All solvents were dried and degassed by standard methods and distilled prior to use.

Dihydroxypyridazine and 2-imidazolinethione were purchased from Aldrich. $[Mo_2(O_2CBu^t)_3(CH_3$

$CN)_2]^+BF_4^-$ was prepared according to published procedures.[5]

Synthesis

$[Mo_2(O_2CBu^t)_3]_2(DOP)$ (**1**). A 1:1 mixture of $Mo_2(O_2CBu^t)_4$ and $Mo_2(O_2CBu^t)_2^{2+}$ (total weight of 1.00 g, 1.56 mmol) was dissolved in a mixture of CH_2Cl_2 (30 cm^3) and CH_3CN (5 cm^3) and stirred for 1 h at 60°C. After the initially red solution became orange, it was cooled to room temperature. Dihydroxypyridazine (0.088 g) was dissolved in MeOH (10 cm^3) and deprotonated with 2 equivalents of NaOMe (0.36 cm^3, 1.56 mmol) in MeOH at room temperature to give a colourless solution. This solution was added dropwise to the "$Mo_2(O_2CBu^t)_3^{1+}$" solution. The colour changed upon mixing to deep wine–red. The mixture of solvents was removed and the remaining $Mo_2(O_2CBu^t)_4$ was extracted with CH_2Cl_2. The final product was recrystallized from a small amount of THF at −40°C.

^1H NMR (CD_3OD), δ: 1.32 (s, 18H); 1.37 (s, 36H); 7.21 (d, 2H). Found: C, 37.1; N, 2.5; H, 5.1. Calc. for $Mo_4C_{34}O_{14}N_2H_{56}$: C, 36.9; N, 2.3; H, 4.7%.

$[Mo_2(O_2CBu^t)_3]IMT$ (**2**). $Mo_2(O_2CBu^t)_3^{1+}$ (1.10 mmol) was prepared according to the procedure described above from $Mo_2(O_2CBu^t)_2(CH_3CN)_6(BF_4)_2$ (0.806 g, 1.10 mmol) and $Mo_2(O_2CBu^t)_4$ (0.675 g, 1.10 mmol). 2-Imidazolinethione (0.112 g, 1.10 mmol) was dissolved in MeOH (10 cm^3), deprotonated with NaOMe (0.51 cm^3, 2.20 mmol) in MeOH and added to the "$Mo_2(O_2CBu^t)_3^{1+}$" solution at room temperature. The colour turned brown upon mixing. The mixture of solvents was removed and the product was recrystallized at −40°C from a small amount of pyridine.

^1H NMR (pyridine-d_5) δ: 1.50 (s, 9H); 1.62 (s, 18H); 3.55 (m, 4H); 8.18 (s, 1H).

Crystallographic studies. General operating procedures and listings of programs have been given.[10] A summary of crystal data is given in Table 3.

Maximum δ/σ for last cycle	0.05

$Mo_2(O_2CBu^t)_3(IMT)$ (**2**). A suitable small crystal was selected from the bulk sample using inert atmosphere handling techniques. The crystal was transferred to the goniostat where it was cooled to −170°C for characterization and data collection. A systematic search of a limited hemisphere of reciprocal space yielded a set of reflections which exhibited monoclinic (2/*m*) symmetry. The systematic extinction of 0*k*0 for $k = 2n+1$ and of *h*01 for $h+1 = 2n+1$ uniquely determined the space group as $P2_1/c$ (No. 14). This choice was confirmed by the successful solution and refinement of the structure. Unit cell dimensions were determined from a least squares fit of the setting angles for 52 carefully centred reflections. The reflections used had two theta values between 19 and 30°.

Data collection was undertaken as detailed in Table 3. It should be noted that the diffraction was not too strong beyond 35° (two theta). The *R* for the averaging was 0.085 for 755 unique reflections observed more than once. A plot of the four standard reflections (4 0 0, 0 2 0, −4 0 8 and 0 0 4) measured every 400 reflections did not show any significant trends. A correction for absorption was carried out.

The structure was solved using the usual combination of direct methods and difference Fourier techniques. The two molybdenum atoms were located in the best *E*-map from MULTAN78. The remaining non-hydrogen atoms were located in successive difference maps. Two of the tertiary butyl groups were found to be disordered. Following the initial refinement a few of the hydrogen atoms were evident in a difference map. Hydrogen atoms were introduced in fixed idealized positions, except on the disordered t-butyl groups. The full-matrix least-squares refinement was completed using anisotropic thermal parameters on all non-hydrogen atoms (except for the two disordered t-butyl groups). The *R*(*F*) for the full data set was 0.082. The limited data set was used for the least-squares refinement, for all other calculations the full data set was used.

The final difference map was essentially featureless, the maximum and minimum electron densities were 1.8 and −1.4 e $Å^{-3}$, respectively. The largest density was observed in the region of the disordered t-butyl groups. Atomic coordinates have been deposited with the Cambridge Crystallographic Data Center.

SYNTHESIS AND CHARACTERIZATION OF IRON(III) COMPLEXES WITH TRIDENTATE LIGANDS CONTAINING N_2O/N_2S DONOR SITES

GITA BATRA and PAVAN MATHUR*

Department of Chemistry, University of Delhi, Delhi 110 007, India

(*Received* 5 *April* 1993; *accepted* 3 *June* 1993)

Abstract—Iron(III) complexes of tridentate ligands bis(2-benzimidazolylmethyl) ether, sulphide and their N-butyl derivatives have been synthesized and characterized. *X*-band EPR spectra in frozen DMF reveal the presence of a number of signals in the region $g_{eff} = ca\ 4$ to $g_{eff} = ca\ 9$. The departure of signals away from $g_{eff} = ca\ 4.3$ is indicative of distortion from purely rhombic to axial geometry. The ^1H NMR spectra of iron(III) depict dipolar, broadened, isotropically contact shifted resonances in the range -10 to $+40$ ppm, with respect to TMS, typical of high spin iron(III). Cyclic voltammograms of these complexes have been recorded which show complexes containing chloride as an inner sphere ligand have a consistently lower redox potential, which suggests that the Cl^- anion is more effective in reducing the Lewis acidity of the iron(III) centre compared with the nitrate anion. These complexes may have relevance to iron coordination sites in phenylalanine hydroxylase and soyabean lipoxygenase.

There has been a growing interest in probing the active site structure of non-haeme oxygenases in order to reveal how the coordination of the iron centre relates to the function of the enzyme.[1,2] Non-haeme iron oxygenases such as phenylalanine hydroxylase and soyabean lipoxygenase catalyse the hydroxylation of phenylalanine to tyrosine and the oxidation of linoleic acid by oxygen to the 9,11-*cis*,*trans*-diene-1,3,5-hydroperoxide, respectively. Both these enzymes have ferric forms that exhibit no visible chromophore.[3,4] EXAFS estimates three to four histidines coordinated to the iron in soyabean lipoxygenase,[5] a ligand also implicated in binding the iron site in phenylalanine hydroxylase.

The present study is directed at the synthesis and characterization of high-spin ferric complexes with tridentate bis(2-benzimidazolylmethyl)ether (DGB), bis(2-benzimidazolylmethyl)sulphide (TGB) and their N-butyl derivatives (BDGB and BTGB). These ligands provide an N_2O/N_2S type of donor environments and incorporate benzimidazole groups, mimetic of histidine imidazoles.

EXPERIMENTAL

Chemicals and starting materials

Solvents and reagents were of AR grade and used without further purification. Acetonitrile and THF were dried as described earlier.[6–8] Chloroform was dried over fused calcium chloride before a final reflux and distillation. Diethyl ether was dried first with fused calcium chloride and then refluxed with and stored over sodium.

Synthesis of ligands

Bis(2-benzimidazolylmethyl)ether (DGB), bis(2-benzimidazolylmethyl)sulphide (TGB) and their N-butyl derivatives (BDGB and BTGB) were synthesized as follows.

Diglycolic acid (12.1 g, 90 mmol) for DGB and thiodiglycolic acid (13.5 g, 90 mmol) for TGB were combined with *o*-phenylenediamine (19.5 g, 180 mmol) and powdered. The mixture was heated for *ca* 3 h at a temperature of *ca* 150°C on an oil bath until all efferverscence ceases. The resulting red–blue glass-like solid after cooling was powdered

and was added to 4 M HCl (250 cm^3). Upon scratching the sides of the flask a grey–white precipitate was obtained. This was filtered out and washed by slurrying in acetone several times. The above hydrochloride was dissolved in distilled water (200 cm^3) and the resulting filtrate was then neutralized with 1 : 1 ammonia until a white precipitate was formed. This white precipitate was collected, washed with ether and recrystallized from acetone; yield 14 g, m.p. 280–295°C.

A sample (5 g) of dried ligand (DGB or TGB) was suspended in dry tetrahydrofuran and was stirred overnight with NaOH (1.4 g). Butyl bromide (4 cm^3) was then added and the solution was left stirring for *ca* 72 h. The solvents were stripped off and the resulting residue was dissolved in chloroform and the solution filtered. To the filtrate was added n-hexane and a yellow powder deposited. This yellow powder was washed with hexane. The procedure is similar to that of Reed *et al.*[9]

The ligands were characterized by elemental analysis, NMR spectroscopy and UV spectroscopy. Found: C, 68.2; H, 4.7; N, 20.7. Calc. for $C_{16}H_{14}N_4O$(DGB): C, 69.0; H, 5.0; N, 20.1%. Found: C, 69.8; H, 7.4; N, 15.2. Calc. for $C_{24}H_{30}N_4S$(BTGB): C, 70.9; H, 7.4; N, 14.3%. ^1H NMR (DMSO-d_6) of $C_{16}H_{14}N_4O$(DGB): δ 7.7 (4H, m), 7.3 (4H, m), 4.95 (4H, s). UV (ethanol), λ_{max} (log ε): 282 (4.18), 272 (4.23), 252 (4.14). ^1H NMR (DMSO-d_6) of $C_{16}H_{14}N_4S$(TGB): δ 7.6 (4H, m), 7.2 (4H, m), 4.05 (4H, s). UV (butanol), λ_{max} (log ε): 286 (4.12), 277 (4.17), 256 (4.12). ^1H NMR (CCl_4) of $C_{24}H_{30}N_4O$(BDGB): δ 7.5 (4H, m), 7.05 (4H, m), 4.6 (4H, s), 3.95 (4H, t), 1.65 (4H, m), 1.55 (4H, m), 0.7 (6H, d). UV (methanol), λ_{max} (log ε): 286 (4.13), 277 (4.18), 258 (4.19). ^1H NMR (CCl_4) of $C_{24}H_{30}N_4S$(BTGB): δ 7.7 (4H, m), 7.2 (4H, m), 4.2 (8H, t), 1.75 (4H, m), 1.45 (4H, m), 1.0 (6H, d). UV (methanol), λ_{max} (log ε): 285 (4.17), 276 (4.16), 246 (4.02).

Synthesis of complexes

The ligand [91 mg (DGB), 129 mg (BDGB), 97 mg (TGB), 133 mg (BTGB); 0.33 mM] was suspended in methanol (5 cm^3) and $FeCl_3$ (53 mg, 0.33 mM) solution (5 cm^3) in methanol and was added to the suspension. The ligand went into solution and turned dark brown. After 15 min of stirring a dark yellow coloured compound precipitated in the cases of DGB, TGB and BTGB iron(III) complexes, while in the case of the reaction between $FeCl_3$ and BDGB a dark reddish-orange coloured precipitate resulted. The solution was left stirring for an additional 3 h. The precipitate was filtered and washed with methanol. The crude product obtained was then recrystallized from a DMF : methanol (1 : 2) mixture.

$[Fe(L)(NO_3)_3]\cdot nH_2O$ (*where* L = BDGB, TGB *and* BTGB). The ligand [129 mg (BDGB), 97 mg (TGB), 133 mg (BTGB); 0.33 mM] was suspended in methanol (5 cm^3) and $Fe(NO_3)_3\cdot 9H_2O$ (133 mg, 0.33 mM) solution (5 cm^3) in methanol was added to the suspension. The ligand went into solution and a clear dark brown coloured solution resulted. A clear solution was obtained after 15 min of stirring at room temperature in all cases, except for the iron(III)TGB reaction, for which a dark yellow coloured precipitate resulted. The solutions were left with stirring for *ca* 2 h. The clear solution was then concentrated to a small volume on a rotary evaporator. The addition of ether to the clear solution precipitated a dark brown coloured powder. This was collected and recrystallized from methanol : ether (1 : 2) mixture. The precipitate formed in the case of TGB was filtered and washed with methanol. The crude product was then recrystallized from a DMF : methanol (1 : 2) mixture. Elemental analyses of all the iron(III) complexes are reported in Table 1.

Table 2. EPR data of iron(III) complexes

Compound	Observed EPR[a] g-values
$[Fe(DGB)Cl_3]$	8.8, 5.3, 4.1
$[Fe(BDGB)Cl_3]$	9.0, 5.0, 4.0
$[Fe(TGB)Cl_3]$	9.0, 5.2, 4.2
$[Fe(BTGB)Cl_3]\cdot H_2O$	8.7, 5.1, 4.2
$[Fe(TGB)(NO_3)_3]$	8.7, 5.1, 4.3
$[Fe(BDGB)(NO_3)_3]$	7.7, 4.4
$[Fe(BTGB)(NO_3)_3]$	7.5, 4.4

[a] These are effective g values, the real g-value being very close to 2.00.

along with a $g = ca$ 4.4 are observed. The $[Fe(DGB)Cl_3]$, $[Fe(BDGB)Cl_3]$, $[Fe(TGB)Cl_3]$, $[Fe(BTGB)Cl_3]$ and $[Fe(TGB)(NO_3)_3]$ complexes show a $g = ca\,4$ signal accompanied by EPR signals at lower fields (1250 G, 750 G). Dowsing and Gibson[10a] have shown that the absorptions at 1500 G and 700 G are expected if λ is almost equal to 1/3 and D is greater than 0.23 cm^{-1}. The line at 1500 G is known to broaden or split as λ departs from 1/3. Thus, the departure of the absorption away from $g_{eff} = ca$ 4.3 is a signal for distortion from purely rhombic to axial geometry. Recently Collison and Powell[10b] have given computer simulated EPR plots using different λ and D values for FeO_6 tris chelate complexes; these show that a very high value of D (1.8 cm^{-1}) is needed to fit two resonances at *ca* 1500 G and 1100 G; a case found for our $[Fe(L)Cl_3]$ and $[Fe(TGB)(NO_3)_3]$ complexes (Table 2).

^1H *NMR spectroscopy*

Figures 2(a)–(c) depict the dipolar broadened isotropic contact shifted resonances typically in the range -10 to $+40$ ppm with respect to TMS. Figure 2(a) depicts the ^1H NMR spectrum of the $[Fe(TGB)Cl_3]$ complex. The peaks observed are listed in Table 3. In the PMR spectra the broadest peaks (line width 2000 Hz) are observed at $+40$ ppm and $+20$ ppm. Since the paramagnetic relaxation time is proportional to the sixth power of dipolar separation, a pronounced broadening is expected for protons that are in close proximity to the iron centre. We thus tentatively assign these peaks to the 4-H of the benzimidazole nucleus and α-CH_2 of the aliphatic chain, respectively. The spectra also reveal broad upfield shifted peaks at around -4, -10 and -20 ppm. This reflects that besides the dominant σ-spin delocalization, the complex also has a mechanism of π-spin delocalization. We, therefore, tend to assign these peaks to the *meta*-

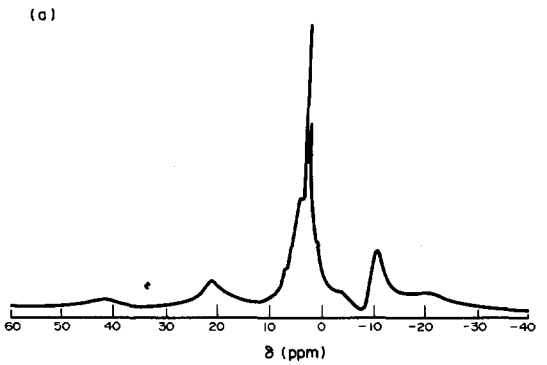

Fig. 2(a). ^1H NMR spectra of $[Fe(TGB)Cl_3]$ complex in d_6-DMSO at room temperature at 400 MHz.

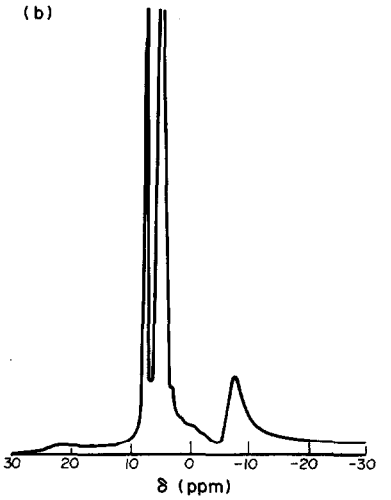

Fig. 2(b). ^1H NMR spectra of $[Fe(DGB)Cl_3]$ complex in d_6-DMSO at room temperature at 400 MHz.

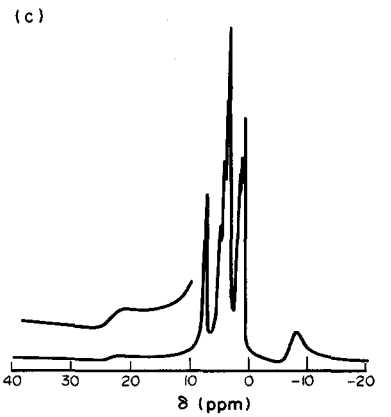

Fig. 2(c). ^1H NMR spectra of $[Fe(BDGB)Cl_3]$ complex in d_6-DMSO at room temperature at 400 MHz.

Table 3. Proton contact shifts of iron(III) complexes in ppm

[Fe(TGB)Cl_3]	[Fe(DGB)Cl_3]	[Fe(BDGB)Cl_3]	Tentative assignments
42.0	—	—	C-4H
21.0	25.0	20.0	α-CH_2
		3.51 1.65 1.20 0.80	N-butyl chain
−10.66	−7.7	−8.2	*Meta*-protons

protons of the benzimidazole nucleus. Such a σ- and π-delocalization mechanism has been invoked to explain the PMR of other paramagnetic metal ion complexes.[11-14]

Upon comparing the ^1H NMR spectrum of the [Fe(TGB)Cl_3] complex with that of the [Fe(DGB)Cl_3] complex [Fig. 2(b)] we find a comparatively simpler spectrum; a weak broad peak can be picked up at around +20 ppm which using the analogy of the above assignment are due to protons of the aliphatic carbon chain (α-CH_2). An upfield shifted peak at −7.7 ppm is observed, which again reinforces the idea of both σ- and π-spin delocalization.

Since it is found that weakly electronegative and strongly π-bonding groups tend to occupy equatorial positions, the [Fe(TGB)Cl_3] complex may adopt a meridonial configuration with the sulphur atom occupying an equatorial site, in contrast to the [Fe(DGB)Cl_3] complex which is likely to be facial. This seems to be borne out from the NMR data. The larger number of peaks observed for the [Fe(TGB)Cl_3] complex in comparison with [Fe(DGB)Cl_3] could be interpreted as arising from inequivalent benzimidazole rings. This is expected in a meridonial isomer as a facial isomer would possess a vertical plane of symmetry.

Figure 2(c) represents the ^1H NMR spectra of [Fe(BDGB)Cl_3] and is similar to that of [Fe(DGB)Cl_3], except that the N-butyl chain protons could be identified as peaks at 0.80, 1.23, 1.65 and 3.5 ppm (Table 3).

Electronic spectroscopy

The present series of iron(III) complexes show UV spectra characteristic of the benzimidazolyl group. The absorption bands and respective extinction coefficients for the above iron(III) complexes are reported in Table 4. The UV bands are in general shifted upon coordination suggesting the binding of iron(III) to the ligand donor atom. In the case of [Fe(DGB)Cl_3], [Fe(BDGB)Cl_3], [Fe(TGB)Cl_3] and [Fe(BTGB)Cl_3] complexes bands appear at 309, 319, 305 and 308 nm. These are assigned as benzimidazole(N) → iron(III) charge-transfer bands.[15] The bands at 356, 354, 362 and 360 nm in the above complexes are predominantly

Table 4. Electronic spectral and cyclic voltammetric data of iron(III) complexes at 298 K

Compound	Solvent	λ_{max} (nm) (log ε)	λ_{max} (nm) in the presence of catechol	λ_{max} (nm) in the presence of *p*-cresol	$E_{1/2}$ (V) vs Ag/AgCl	$E_{1/2}$ (V) vs NHE
[Fe(DGB)Cl_3]	DMF	356(3.52), 309(3.60)	—	—	0.16	(0.38)
[Fe(BDGB)Cl_3]	Acetonitrile	360(2.86), 319(2.96)	756	540	0.15	(0.37)
[Fe(TGB)Cl_3]	DMF	362(3.20), 305(3.20)	—	—	—	—
[Fe(BTGB)Cl_3]·H_2O	DMF	360(3.47), 308(3.79)	685, 450	492	—	—
[Fe(BDGB)$(NO_3)_3$]	DMF	480(2.95)	—	500	0.30	(0.52)
[Fe(TGB)$(NO_3)_3$]	DMF	479(2.10)	—	—	—	—
[Fe(BTGB)$(NO_3)_3$]	DMF	469(2.44)	—	500	0.41	(0.63)

assigned as $Cl^- \rightarrow Fe^{III}$ charge-transfer bands.[16,17]

The corresponding $[Fe(BDGB)(NO_3)_3]$, $[Fe(TGB)(NO_3)_3]$ and $[Fe(BTGB)(NO_3)_3]$ complexes show bands at 479, 469 and 380 nm, respectively. These are assigned to $NO_3^- \rightarrow Fe^{3+}$ charge-transfer bands.

Complexation with catechol and p-*cresol*

The present series of iron complexes were reacted with catechol and *p*-cresol (in equimolar quantities) in DMF solution. The change observed in their absorption spectra is shown in Figs 3(a)–(c) and λ_{max} of the new bands is reported in Table 4. The visible spectra of iron complexes with the above tridentate ligands are characterized by two new absorption features in the ranges 450–460 and 650–750 nm. Since the present iron complexes do not show bands in these regions, these features in the visible region are assigned to catecholate–Fe^{3+} LMCT bands.[18] This implies that catechol binds as a bidentate ligand to yield a distorted octahedral complex[19] for the chloride complexes. The nitrate complexes show no reactivity. A colour change does appear after 48 h.

In contrast to catechol, *p*-cresol is a monodentate ligand and hence its binding need only displace one of the axial ligands already on the iron(III) complex (Fig. 5). The trend for the iron(III)–*p*-cresolate LMCT band is the same as for the catecholate complexes, i.e. the BTGB complex has a higher energy band compared with the BDGB complex (Table 4).

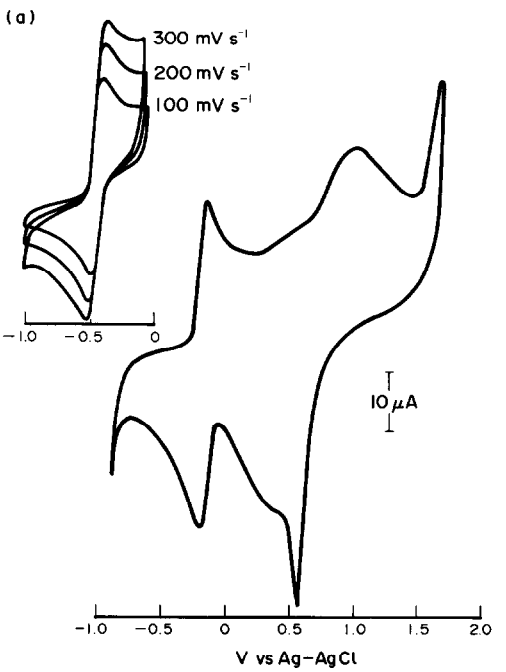

Fig. 4(a). Cyclic voltammogram of $[Fe(DGB)Cl_3]$ complex in DMSO: scan rate 180 mV s^{-1}.

Electrochemistry

Cyclic voltammograms for $[Fe(DGB)Cl_3]$, $[Fe(BDGB)Cl_3]$, $[Fe(BDGB)(NO_3)_3]$ and $[Fe(BTGB)(NO_3)_3]$ are shown in Figs 4(a)–(d). The voltammograms were recorded in DMSO as a solvent, using tetraethyl ammonium perchlorate (0.1 M) as the supporting electrolyte, on a BAS CV-27 voltammograph. All potentials are with respect

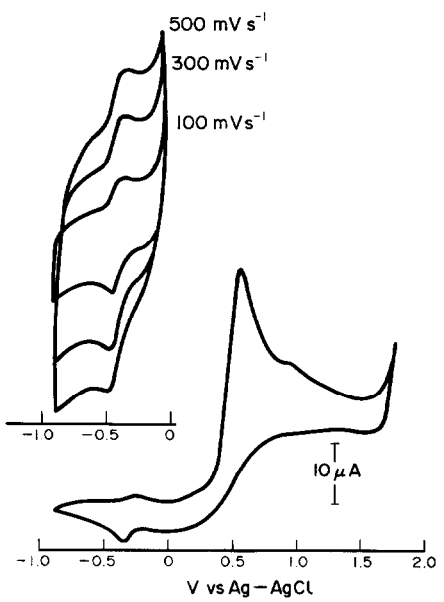

Fig. 4(b). Cyclic voltammogram of $[Fe(BDGB)Cl_3]$ complex in DMSO: scan rate 100 mV s^{-1}.

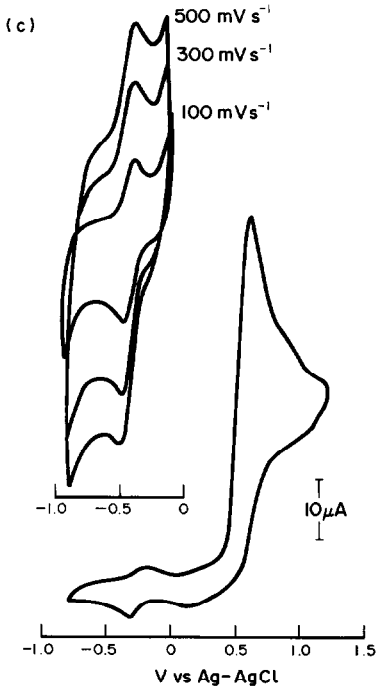

Fig. 4(c). Cyclic voltammogram of $[Fe(BDGB)(NO_3)_3]$ complex in DMSO: scan rate 150 mV s^{-1}.

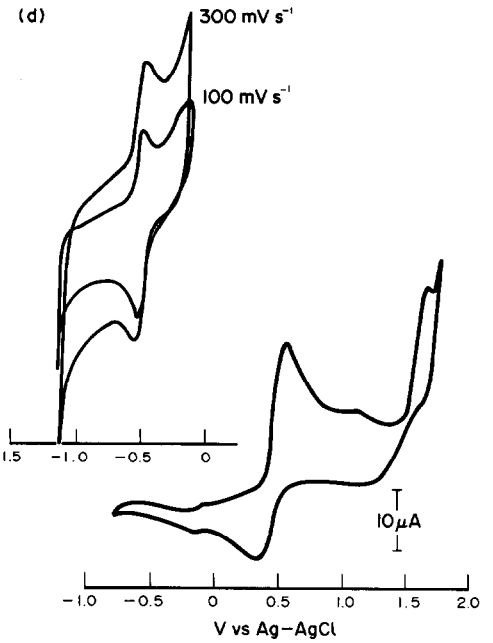

Fig. 4(d). Cyclic voltammogram of $[Fe(BTGB)(NO_3)_3]$ complex in DMSO: scan rate 150 mV s^{-1}.

to an Ag/AgCl electrode. The cyclic voltammograms show a one-electron redox wave, assigned to the Fe^{III}/Fe^{II} redox couple. A scan rate dependence confirms the reversibility of the above redox couple.

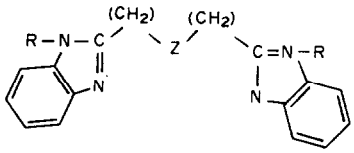
The averages of the peak potentials for the oxidation and reduction waves are tabulated in Table 4. The chloride complexes have a consistently lower redox potential; this suggests that the Cl^- anion is more effective in reducing the Lewis acidity of the iron(III) centre compared with the NO_3^- anion.

Magnetic susceptibility

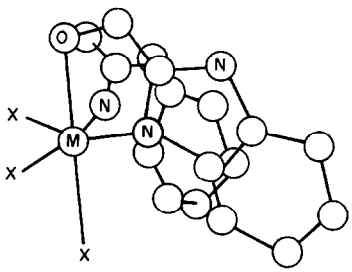
The magnetic susceptibility of all the iron(III) complexes was obtained using a CAHN-2000 magnetic balance and are reported in Table 1. The data incorporates the diamagnetic correction for the ligand in each complex and has been obtained using Pascal's constant. It is found that these magnetic moments are close to the spin-only value of 5.9 B.M./Fe^{3+} atom. This is expected since Fe^{3+} has a $^6A_{1g}$ ground term with negligible temperature-independent paramagnetism. It also does not show any reduction in magnetic moment below the spin-only value due to spin-orbit coupling with higher ligand field terms.

IR spectroscopy

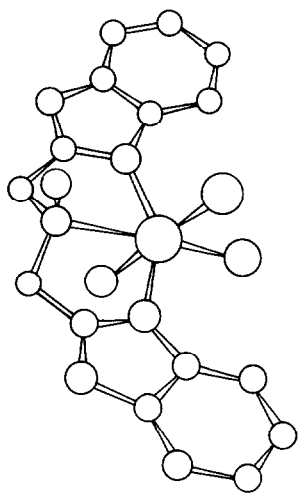
IR spectra of iron(III) complexes have been obtained in Nujol mulls. The band appearing at *ca* 1460 cm^{-1} is assigned to the (C=N—C=C)



when Z=O, R=H, L=DGB
when Z=S, R=H, L=TGB
when Z=O, R=H, L=BDGB
when Z=S, R=H, L=BTGB



Facial Coordination



Meridonial Coordination

Fig. 5.

stretching. In our iron(III) complexes the shift is around 10 cm^{-1}. This implies direct coordination of all three imine nitrogen atoms of the ligand to iron(III). This is the preferred nitrogen atom for coordination, as found for other metal complexes with benzimidazoles.[20]

Gatehouse *et al.*[21] have reported earlier that when the nitrate group is bound as a terminal ligand in the unidentate mode IR bands appear at 1420, 1305 and 1008 cm^{-1}, respectively. The separation of the two highest frequency bands is less than 100 cm^{-1} for a chelating bidentate nitrate. In our nitrato complexes bands are found in the same region. Hence, it is likely that we have a monodentate nitrate bound to iron in the ferric complexes. Other examples of monodentate nitrate coordination to iron(III) as studied by X-ray crystallography[22,23] and EXAFS[24] have been reported in the literature. Solution EPR, NMR and CV studies are indicative of the monomeric nature of the complexes. However, in the absence of a crystal structure and in view of their low solubility in weakly polar solvents, the solution structure may be different from the solid-state structure.

The Lewis acidity of the ferric centre in these complexes compares favourably with that displayed by the ferric centre in phenylalanine hydroxylase and soyabean lipoxygenase, as indicated by the catecholate → iron(III) CT bands; thus, the ferric complexes with Cl^- as an inner sphere ligand may have relevance to iron coordination sites in the above enzymes.

^{1}H AND ^{19}F EMR STUDY OF POWDERED SAMPLES OF COPPER(II) ETHYLXANTHATE AND TRIFLUOROETHYLXANTHATE COMPLEXES MAGNETICALLY DILUTED IN THE CORRESPONDING NICKEL(II) HOST LATTICES

(*Received* 26 *February* 1993; *accepted* 2 *June* 1993)

Abstract—Powdered samples of bis(ethyldithiocarbonato)copper(II) and bis(trifluor-ethyldithiocarbonato)copper(II) complexes magnetically diluted in the corresponding nickel(II) host lattices have been studied by ^{1}H and ^{19}F Electron Magnetic Resonance (ENDOR) spectroscopy. The values of isotropic and anisotropic components of electron-nuclear interactions with the CH_2 and CF_3 groups were extracted from the spectra. Interactions with protons from neighbouring molecules of the lattice were also recorded. With the use of computer-aided EMR spectroscopy some aspects of the geometric structure of the copper(II)–xanthate complex studied were found. The structure of the guest molecules of copper complexes appears to accept the nickel(II) host lattice structure.

The metal complexes of xanthates (dithiocarbonates), $[M(ROCS_2)_2]$, are of great interest because of their biological activity, analytical application, as vulcanization accelerators, utilization in flotation, etc. This is the reason why many investigators have concentrated their attention on the structure, properties and reactivity of these complexes using different chemical and physical methods.[1] The bis(*R*-xanthate)copper(II) complexes are known to be unstable in solution and in general do not exist in the solid state due to a "self-redox" reaction[2,3] which makes it impossible to perform X-ray structure analysis on them. In view of this any structural information available about this class of complexes is very important.

In the present paper we make use of the fact that when trapped[2,3] the upper bis-chelates are stable for an unlimited period of time.[2] We report here the results obtained with ^{1}H and ^{19}F Electron Magnetic Resonance—EMR (ENDOR) spectroscopy concerning the structure of bis(ethylxanthate) copper(II), $[Cu(Et\text{-}xant)_2]$, and bis(trifluoroethylxanthate)copper(II), $[Cu(F\text{-}Et\text{-}xant)_2]$, magnetically diluted in the corresponding nickel(II) host lattices. Generally the information obtained by EPR spectroscopy of copper(II) xanthate complexes concerns only the chromophore CuS_4[2,3] because of the limited resolution of the method. Structural information about the remote ligand substituents may be reached only with the use of ENDOR spectroscopy. The studies reported here were performed on powdered samples by the previously described method.[4,5] Many groups working in this field[5–8] have shown that its approach is very useful particularly for the understanding of electronic and geometric structure of samples with a large anisotropy of the EPR parameters such as metal complexes.

EXPERIMENTAL

Sodium ethylxanthate was synthesized by the method previously described.[1,9] The nickel(II) complex was obtained by mixing of aqueous solutions of $NiCl_2$ and Na(Et-xant) followed by extraction with chloroform. After evaporation of the chloroform the complex obtained was recrystallized twice from chloroform.

The fluorinated sample of bis(ethyl-xanthato) nickel(II) complex was obtained by the previously described method.[10]

Magnetically diluted samples were prepared by exchange of approximately 2% of nickel(II) by ^{63}copper(II) in chloroform–water, followed by separation of the $CHCl_3$ layer and evaporation of the solvent.

^{1}H and ^{19}F ENDOR spectra were recorded with a Bruker ER 200 D-SRC spectrometer equipped with an Aspect 2000 computer. All measurements were performed at 100 K. Typical experimental conditions were: microwave power 20 mW, radio-frequency power 200–300 W, modulation frequency 12.5 kHz, modulation depth 80–100 kHz. No field modulation was used while the ENDOR spectra were recorded.

Analysis of the experimental data and EMR simulation were performed with a computer programme based on the algorithm described previously.[4]

RESULTS AND DISCUSSION

The EMR (EPR) spectrum of ^{63}Cu(Et-xant)$_2$, magnetically diluted in the corresponding nickel(II) host lattice at 100 K is shown in Fig. 1. Under the same conditions the spectrum of ^{63}Cu(F-Et-xant)$_2$ is not affected by the fluorination. The shape of the EPR spectra as well as the EPR data collected in Table 1 suggest axial symmetry of the complexes. Since the corresponding nickel(II) complexes are known from X-ray structural analysis to have a planar chromophore (NiS_4)[11–14] the conclusion is made that copper(II) chelates are accepting the host lattice structure. This behaviour is very suitable for applying the method of ENDOR study of powdered samples.[4,5] The EMR spectral "windows", as shown in Fig. 1, in which only one EMR transition takes place, were used for recording the ENDOR spectra. The windows were chosen so as to cover the whole range between $0° \leqslant \theta° \leqslant 90°$ (θ is the angle between the direction of the magnetic field and the symmetry axis of the complex).

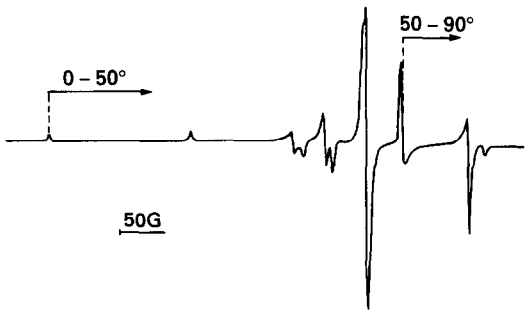

Fig. 1. EMR (EPR) spectrum typical for powdered samples of ^{63}Cu(Et-xant)$_2$ and ^{63}Cu(F-Et-xant)$_2$ magnetically diluted in the corresponding nickel(II) host lattices.

Table 1. EMR parameters of Cu/Ni(Et-xant)$_2$ and Cu/Ni(F-Et-xant)$_2$ samples

Complex	$g_\parallel$[a]	$g_\perp$[a]	$A_\parallel$[b]	$A_\perp$[b]
^{63}Cu(Et-xant)$_2$	2.086	2.027	153	42
^{63}Cu(F-Et-xant)$_2$	2.088	2.025	154	43

[a] ± 0.002.
[b] $\pm 2G$.

The electron–nuclear couplings A_i measured at different settings of the magnetic field and thus choosing different polar angles θ_i[4,5] are related to the anisotropic and isotropic shf couplings by eq. (1):

$$A(\theta_i) = \{\beta_e\beta_n g_n g(\theta_i)[3\cos^2(\theta_i - a) - 1]/r^3\} + A_{iso}, \quad (1)$$

where a is the angle between g_z direction (or the z-axis of the complex) and the line connecting the unpaired electron and the corresponding nucleus.

In the ^{1}H region of the ENDOR spectra of Cu(Et-xant)$_2$ complex we can expect that several ENDOR transitions, due to the electron–nuclear interactions with protons from its own molecule as well as an unknown number of "matrix" ENDOR transitions due to pure dipole–dipole interactions of the copper(II) unpaired electron with protons from neighbouring molecules of the host lattice, will appear. Since all this will complicate the interpretation of the spectra we decided to synthesize and investigate also the partially fluorinated samples and thus to increase the resolution of the method. On the other hand the ratio between the theoretical ^{19}F and ^{1}H isotropic shf couplings ($^{19}Fa_{iso}/{}^1Ha_{iso} = 33.8$) makes the studies more sensitive.[16]

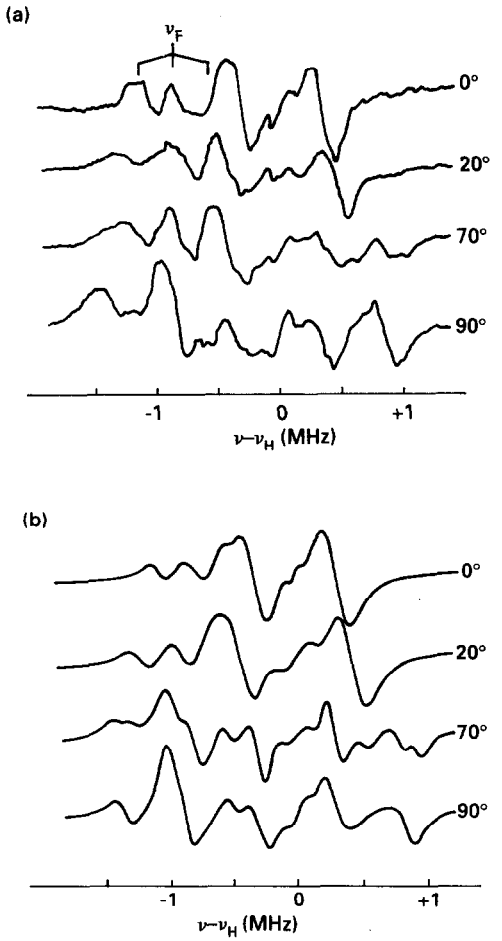

Fig. 2. ^{1}H and ^{19}F EMR (ENDOR) spectra of ^{63}Cu/Ni(F-Et-xant)$_2$ taken and computed at different polar angles θ: (a) experimental spectra, $T = 100$ K; (b) simulated spectra.

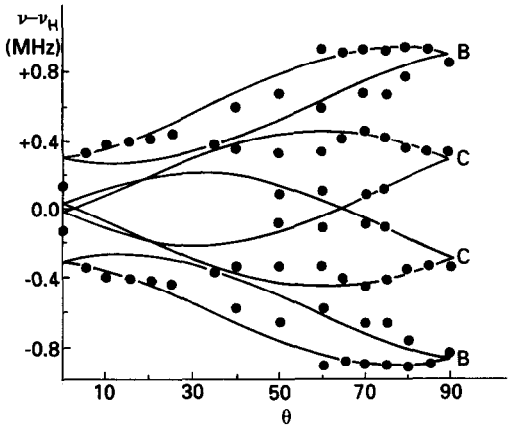

Fig. 3. Angular dependence of ^{1}H EMR (ENDOR) transitions of ^{63}Cu/Ni(F-Et-xant)$_2$. The experimental values are represented by dots. Full lines show the theoretical calculation.

^{1}H *EMR spectroscopy*

^{1}H EMR spectra of ^{63}Cu/Ni(F-Et-xant)$_2$. Some ^{1}H EMR (ENDOR) spectra, recorded at different polar angles θ, are shown in Fig. 2(a). The experimental results obtained for the angular dependence of ^{1}H shf coupling are marked in Fig. 3 with dots, and full lines represent the best fit between experimental data and theoretical calculations using eq. (1).

The central ENDOR lines, which can be seen in all spectra in Fig. 2(a), are due to far "matrix" ENDOR since their splitting of *ca* 0.20 MHz practically does not change with the angle.

The principal value of transition B is situated at an angle of about 80° towards the axis of symmetry of the complex (or g_z). The best fit between experimental and theoretical results is obtained with the following parameters: $A_{aniso} = 0.44$ MHz; $A_{iso} = 0.98$ MHz and $a = 78°$. The isotropic component shows unambiguously that this transition is due to interaction of the unpaired electron of copper(II) with protons of its own molecule. The only possible interaction of this type is with the protons from the CH_2 group.

The distance between the copper atom and these protons can be calculated by using the point-dipole approximation. It is found that $r = 4.76$ Å which is in good agreement with X-ray data for the fluorinated bis(ethyl-xanthate)nickel(II) complex[14]; the protons from the CH_2 group are situated at 4.40 Å away from the copper ion and have a polar angle $a = 78°$ with the symmetry axis.

Transition C can be described by the following parameters: $a = 60°$, $A_{aniso} = 0.46$ and $A_{iso} = 0.00$ MHz. Consequently it is a pure dipole–dipole interaction between the unpaired electron and protons from neighbouring molecules. Using the point dipole approximation the distance Cu—H of 4.67 Å was calculated which can be compared with X-ray data.[14] The molecules in the lattice are arranged in linear layers. Two neighbouring molecules from one layer are oriented with their equal ends and hence interaction with proton of another molecule is possible only between molecules from different layers. From the X-ray data[14] an angle $a = 62°$ is calculated which is in good agreement with the experimental ^{1}H EMR (ENDOR) data.

In order to check our results some ^{1}H EMR spectra were simulated by a computer programme based on the algorithm described in ref. 4 and with the use of the parameters reported here. The simulated spectra [Fig. 2(b)] are compared with the experimental ENDOR spectra taken at the same

angle θ [Fig. 2(a)]. The good agreement between them confirms the correctness of the structural parameters reported above.

^{1}H *EMR spectra of* ^{63}Cu/Ni(Et-xant)$_2$. Some ^{1}H EMR spectra recorded at different angles θ are shown in Fig. 4. The angular dependence of ^{1}H shf coupling is shown in Fig. 5. The two transitions—C and D which can be seen, differ from the analogous dependence for the fluorinated complex.

Transitions C and D are traceless ($A_\parallel = 2A_\perp$) and their principal values are found at an angle of 90°. Therefore these two transitions are due to interaction of the unpaired electron with protons from neighbouring molecules of the matrix, situated in the plane of the copper(II) complex. The best fit between the experimental results and theoretical calculations was obtained using the following parameters: $a^c = 90°$, $A^c_{aniso} = 0.93$ Mhz, $A^c_{iso} = 0.00$ MHz and $a^D = 90°$, $A^D_{aniso} = 0.44$ Mhz, $A^D_{iso} = 0.00$ MHz. Distances between the copper and the protons were also calculated: $r_{Cu—H} = 3.71$ Å for transition C and $r_{Cu—H} = 4.75$ Å for transition D. The data are collected in Table 2.

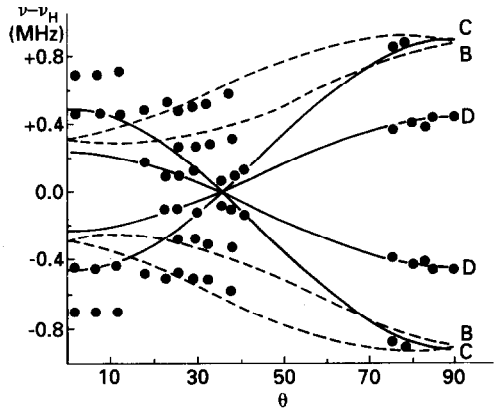

Fig. 5. Angular dependence of ^{1}H EMR (ENDOR) transitions of ^{63}Cu/Ni(Et-xant)$_2$. The experimental values are represented by dots. Full lines show the theoretical calculation.

The existence of equatorially situated protons from neighbouring molecules detected with ^{1}H EMR can be explained with the space structure of the complex. The X-ray studies of the nickel(II) complex[11–14] show that the complex exists in two different modifications—triclinic and rhombic. The only difference between them is the manner of the spacial arrangement of the molecules. Both modifications crystallize simultaneously from chloroform[13] and therefore are present in the powder sample. Thus transition C can be due to the interaction of the unpaired electron with a methyl proton from a neighbouring molecule in the triclinic modification, transition D—being due to the methyl group in rhombic modification.

Transition B, found in the fluorinated ethylxanthate complex, is marked with a dashed line in Fig. 5. As can be seen from the figure, transition B is undetectable without partial fluorination of the ethylxanthate (*vide supra*).

At the moment we are not in a position to explain the origin of some weak ^{1}H EMR lines appearing in the region 0°–10° for the ethylxanthate and in the region 20°–50° for the fluorinated complex.

^{19}F *EMR spectroscopy*

In the ^{19}F EMR spectra of the fluorinated complex a pair of lines are centred at the ^{19}F frequency.

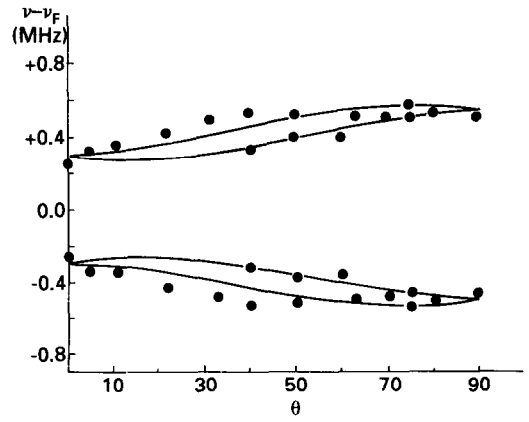

Fig. 6. Angular dependence of ^{19}F EMR (ENDOR) transitions of ^{63}Cu/Ni(F-Et-xant)$_2$.

One of them exists in all spectra and is due to fluorine atoms situated a long distance away from copper. In Fig. 6 the angular dependence of the rest of the lines is shown. Its characteristic parameters are: $a = 77°$, $A_{iso} = 0.74$ MHz and $A_{aniso} = 0.18$ MHz. The values of A_{iso} and A_{aniso} indicate that the interaction of the unpaired electron is with the fluorine atom from the methyl group of its own molecule. This type of interaction is very weak and can be recorded only in the fluorinated complex (*vide supra*). In the ^{1}H-ethylxanthate such an interaction (with the methyl group) will not be observable because the corresponding isotropic shf splitting from the methyl group CH_3 must be 33.7 times weaker—$^{1}Ha_{iso} = 0.02$ MHz. It is obvious that this value is too small for the resolution of the ENDOR spectroscopy of disordered systems.

The angle of 77° is also unexpected. The most likely angle seems to be 90° or near it by analogy with the CH_3 group which is freely rotating and the three protons are equivalent. A similar case is reported for a CF_3 group in ref. 15. In the ^{19}F-ethylxanthate it is very possible that the CF_3 group is not freely rotating and therefore interaction with only one fluorine atom at 77° is registered.

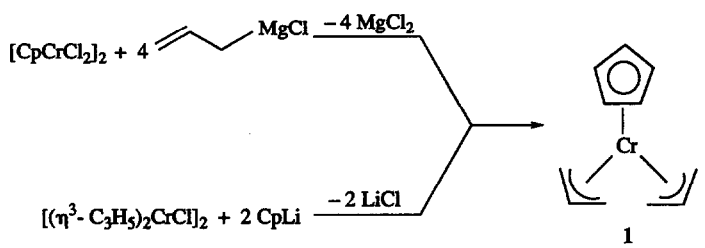
(*Received* 3 *June* 1993; *accepted* 15 *July* 1993)

Abstract—The title compounds have been prepared by reacting a Cp′CrCl$_2$ or a (η^3-allyl)$_2$CrCl species with either an allylmagnesium halide or a substituted cyclopentadienyllithium derivative. The compounds react further at room temperature to give the dinuclear species [Cp′(μ-η^3-allyl)Cr]$_2$, and with P-donor ligands with reductive coupling of the allyl groups to give Cp′(η^2,η^2-1,5-hexadiene)CrPR$_3$ species. Diene exchange is observed upon reacting the hexadiene compounds with butadiene or cyclohexadiene. The crystal structures of [Cp(μ-η^3-C$_3$H$_5$)Cr]$_2$, [(η^5-indenyl)(μ-η^3-C$_3$H$_5$)Cr]$_2$, (η^5-indenyl)(η^2,η^2-1,5-hexadiene)CrP(OMe)$_3$ and three compounds containing a 1,3-diene, *viz.* Cp(η^4-1,3-C$_4$H$_6$)CrPMe$_3$, (η^5-Me$_5$C$_5$)(η^4-1,3-C$_4$H$_6$)CrCO and Cp(η^4-1,3-cyclohexadiene)CrP(OMe)$_3$ have been established by X-ray diffraction.

In this and the following two publications we describe the preparation of a series of paramagnetic Cp′(η^3-allyl)$_2$Cr complexes and discuss their reactions with donor ligands and unsaturated organic compounds. Some of the results have been mentioned in a short communication.[2]

RESULTS AND DISCUSSION

The simplest member of the series, Cp(η^3-C$_3$H$_5$)$_2$Cr (**1**), may be prepared in high yield by reacting [CpCrCl$_2$]$_2$ with *ca* 10% excess of allylmagnesium chloride in ether at −60°C. The yields are lower if the reaction is carried out at higher temperatures, if allylmagnesium bromide is used or if the Grignard reagent is added too quickly. The compound can also be prepared in *ca* 70% yield by reacting [(η^3-C$_3$H$_5$)$_2$CrCl]$_2$ (prepared from (η^3-C$_3$H$_5$)$_3$Cr and HCl; see experimental section) with cyclopentadienyllithium (eq. 1).



(1)

1

Compound **1** is an orange–red solid which is soluble in all common solvents. Solutions react further above *ca* −15°C (see below) whereas the solid can be handled briefly at room temperature in an inert atmosphere without noticeable decomposition. Samples should, however, be stored at −20°C. The allyl groups are readily displaced as 1,5-hexadiene upon reaction with HCl, CH_2Cl_2 or I_2 and [CpCrX$_2$]$_2$ (X = Cl, I) is formed. Protonation with acetylacetone results in the formation of Cr(acac)$_3$ and the liberation of propene and cyclopentadiene. Treatment with excess triphenylphosphine at 100°C

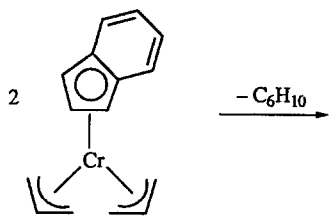
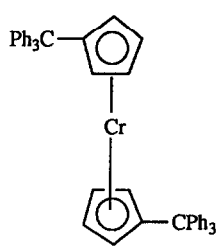
is accompanied by the release of a mixture of C_6-hydrocarbons. The magnetic moment (μ_B 1.9 B.M.) is consistent with the presence of one unpaired electron and the crystal structure has been confirmed by X-ray diffraction and reported in a preliminary communication.[2]

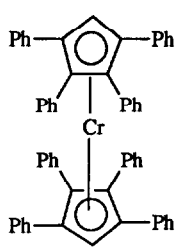


6

The related compounds $(\eta^5\text{-}RC_5H_4)(\eta^3\text{-}C_3H_5)_2Cr$ (R = Me, **2**; R = t-C_4H_9, **3**; R = Me_2PhC, **4**), $(\eta^5\text{-}Me_5C_5)(\eta^3\text{-}C_3H_5)_2Cr$ (**5**) and (η^5-indenyl)$(\eta^3\text{-}C_3H_5)_2Cr$ (**6**) have been prepared by reacting $[(\eta^3\text{-}C_3H_5)_2CrCl]_2$ with the appropriate organolithium derivative. In addition, $Cp(\eta^3\text{-}2\text{-}MeC_3H_4)_2Cr$ (**7**) and (η^5-indenyl)$(\eta^3\text{-}2\text{-}MeC_3H_4)_2Cr$ (**8**) have been prepared from $[(\eta^3\text{-}2\text{-}MeC_3H_4)_2CrCl]_2$. Reaction between $[(\eta^3\text{-}C_3H_5)_2CrCl]_2$ and tritylcyclopentadienyllithium or tetraphenylcyclopentadienyllithium takes a different course: the allyl groups are displaced and the chromocene derivatives **9** (MS: *m/z* 666, M^+) and **10** (MS: *m/z* 792, M^+) are formed



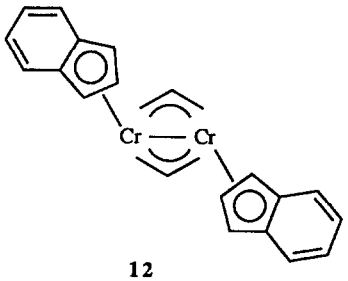
9



10

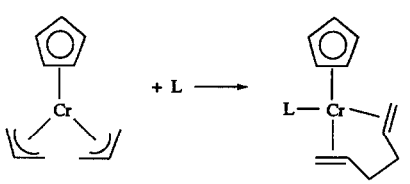
in *ca* 20% yield. Both of these compounds are more conveniently prepared directly from $CrCl_2$.[3]

$Cp(\eta^3\text{-}C_3H_5)_2Cr$ (**1**) reacts further in solution above *ca* −15°C to give a brown, paramagnetic (μ_B 4.1) species which had previously been isolated from the reaction between $[CpCrCl_2]_2$ and allylmagnesium chloride in THF at room temperature and identified as the dinuclear species $[Cp(\mu\text{-}\eta^3\text{-}C_3H_5)Cr]_2$ (**11**).[4] The corresponding indenyl derivative **6** reacts similarly to give the dark brown dinuclear compound **12**. The presence of bridging allyl groups in both **11** and **12** has been confirmed by X-ray diffraction (see below).



12 (2)

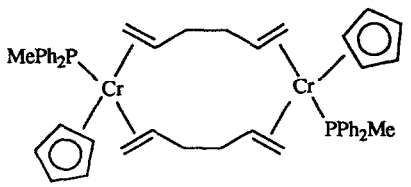
$Cp(\eta^3\text{-}C_3H_5)_2Cr$ (**1**) reacts with a variety of donor ligands with reductive coupling of the allyl groups to give compounds containing metal-bonded 1,5-hexadiene (eq. 3). The products of the reaction with the monodentate ligands CO, PMe_3, $P(OMe)_3$ and $P(OPh)_3$ are the dark green compounds **13–16** in which the hexadiene is bonded as an η^2,η^2-organic ligand. These compounds, which can also be prepared in a one-pot procedure by reacting $[CpCrCl_2]_2$ consecutively with allylmagnesium chloride and the donor ligand, are stable at room temperature and are relatively insensitive towards oxygen. The crystal structures of **14** and **15** have been determined by X-ray diffraction and have been reported earlier.[2] The reaction of **1** with CO or PMe_3 is accompanied by the formation in low yield of species having the composition $Cp_2Cr_2L_5$ (L = CO, PMe_3).



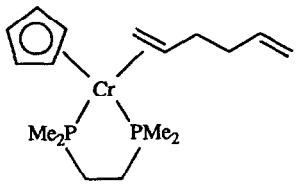
1 (3)

13 L = CO; **14** L = PMe_3;
15 L = $P(OMe)_3$; **16** L = $P(OPh)_3$

In contrast to the examples described above, the adducts formed by reacting **1** with PPh_2Me or PPh_3 are bright yellow and a cryoscopic molecular weight determination of the species containing diphenylmethylphosphine shows it to be dimeric. This, combined with the magnetic moment (two unpaired electrons), suggests a structure (**17**) in which two hexadiene molecules bridge two $CpCr(PPh_2Me)$-fragments. The presence of an uncomplexed double bond (ν 1635 cm^{-1}) in the IR-spectrum of the adduct formed by reacting **1** with the bidentate ligand bis(dimethylphosphino)ethane, suggests that this has a structure (**18**) in which the hexadiene molecule is acting as an η^2-organic ligand. Steri-



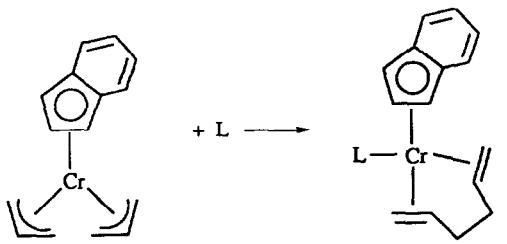
17



18

cally demanding phosphines such as $P(C_3H_7\text{-}i)_3$, $P(C_4H_9\text{-}t)_3$ and PCy_3 react with **1** much less readily and well defined products could not be isolated.

(η^5-Indenyl)(η^3-C_3H_5)$_2$Cr (**6**) reacts with donor ligands in an analogous manner and the adducts **19** and **20** have been isolated from the reaction with trimethylphosphite or trimethylphosphine (eq. 4). The structure of **19** has been confirmed by X-ray diffraction (see below).

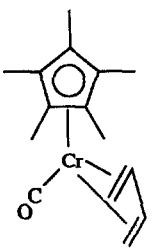


(4)

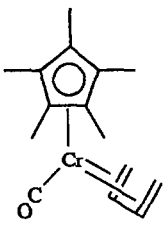
6

19 L = $P(OMe)_3$;
20 L = PMe_3

The hexadiene molecule in compounds **14**, **15** and **20** can be readily displaced by 1,3-butadiene and Cp(η^4-1,3-C_4H_6)$CrPR_3$ (**21**, R = Me; **22**, R = OMe) and (η^5-indenyl)(η^4-1,3-C_4H_6)$CrPMe_3$ (**23**) have been isolated. Compounds **21** and **22** can also be prepared by reacting $[CpCrCl_2]_2$ with magnesium-butadiene in the presence of the donor ligand and the same procedure has been used to prepare (η^5-Me_5C_5)(η^4-1,3-C_4H_6)$CrPR_3$ (**24**, R = Me; **25**, R = OMe). The reaction of **24** (R = Me) with CO is accompanied by donor-ligand exchange and (η^5-Me_5C_5)(η^4-1,3-C_4H_6)CrCO (**26**) is formed. The *prone* arrangement of the butadiene molecule in **21** and **26** has been established by the crystal structure determinations discussed below and extended-Hückel MO calculations for **26** indicate that this arrangement (**a**)



26a



26b

is *ca* 9 kcal mol^{-1} more stable than the *supine* arrangement (**b**).[12] This result is in contrast to that obtained for related compounds containing early transition metals such as Cp(η^4-1,3-C_4H_6)$TaCl_2$ for which it has been calculated that the *supine* arrangement is *ca* 16 kcal mol^{-1} more stable than the *prone* arrangement.[13]

The reaction of **15** with 1,3-cyclohexadiene also results in diene exchange and the η^4-1,3-cyclohexadiene compound **27** is formed as a red, crystalline solid (eq. 5). This reaction is accompanied by the formation of lesser amounts of Cp(η^6-C_6H_6)Cr (**28**) which is the product of the further reaction of **27** in solution at room temperature. This last reaction presumably proceeds by phosphite dissociation followed by Cr-induced dehydrogenation of the cyclohexadiene molecule. A related reaction leading to the formation of **28** has been observed upon reacting Cp(η^3-C_3H_5)$_2$Cr (**1**) with 1,3-cyclohexadiene and has been suggested to involve H-transfer from the diene to the metal followed by homolytic cleavage of the resulting Cr—H bond and the indiscriminant reaction of the H-radical with the reaction media.[5]

CRYSTAL STRUCTURE DETERMINATIONS

We have already discussed in an earlier publication the crystal structure of Cp(η^2,η^2-1,5-hexadiene)CrPMe$_3$ (**14**)[2] and here we report that of the related complex (η^5-indenyl)(η^2,η^2-1,5-hexadiene)CrP(OMe)$_3$ (**19**) the analysis of which was undertaken mainly to determine the hapticity of the indenyl fragment. The molecular structure is shown in Fig. 1 and selected structural parameters are listed in Table 1. The structure is similar to that of **14** with the indenyl group acting as an η^5-organic ligand, i.e. the indenyl group is essentially planar: the fold angle between the five- and six-membered rings is only 1.8°.

The crystal structure of both [Cp(μ-η^3-C_3H_5)Cr]$_2$ (**11**) and [(η^5-indenyl)(μ-η^3-C_3H_5)Cr]$_2$ (**12**) have been determined by X-ray diffraction. **12** contains two independent molecules in the unit cell which differ slightly in the coordination of the indenyl-group to the metal atom. The molecular structure of **11** and **12a** (molecule 1) is shown in Fig. 2 while selected bond distances and angles for **11** and both molecules of **12** are listed in Table 2.

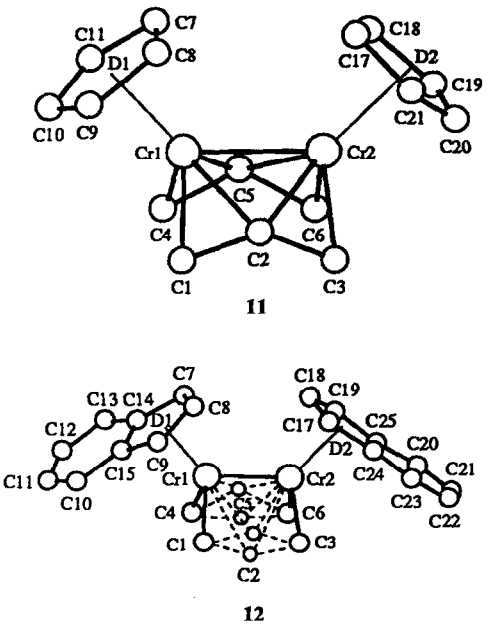

Fig. 2. The molecular structure of [Cp(μ-η^3-C_3H_5)Cr]$_2$ (**11**) and [(η^5-indenyl)(μ-η^3-C_3H_5)Cr]$_2$ (**12**, molecule 1).

In both compounds, two Cr-atoms are bridged by two μ-η^3-allyl groups. In **11**, the two allyl groups adopt a *cis*-configuration with the two meso-C atoms pointing towards the Cr—Cr bond and with a dihedral angle of 54.9° between the two allyl planes (C1/C2/C3 and C4/C5/C6). Three of the four allyl groups in the two independent molecules of **12** are disordered and have been treated accordingly.

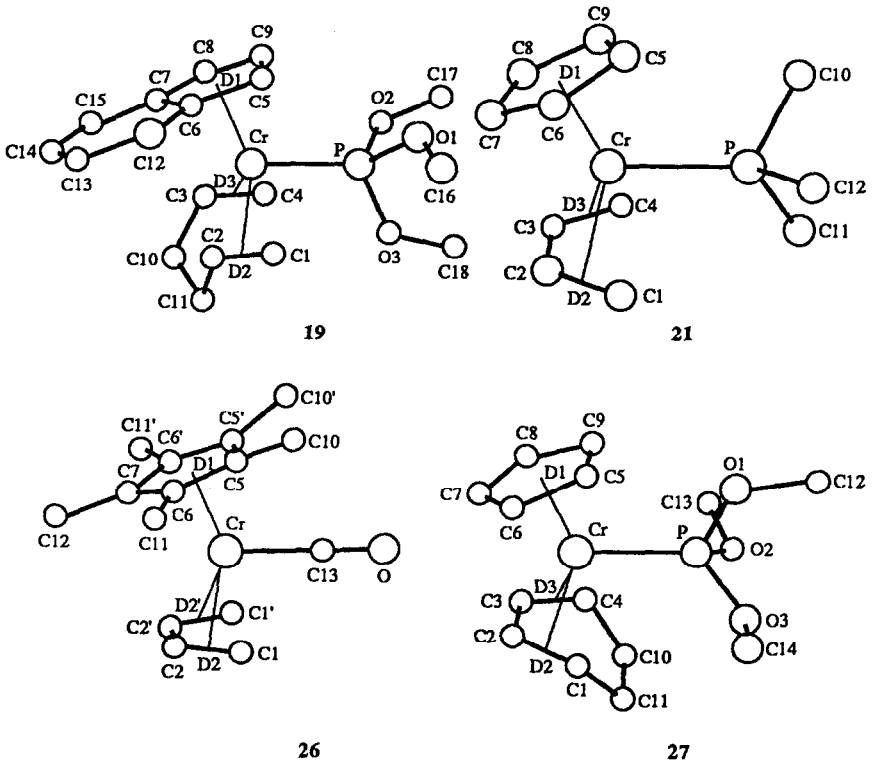

Fig. 1. The molecular structures of (η^5-indenyl)(η^2,η^2-1,5-hexadiene)CrP(OMe)$_3$ (**19**), Cp(η^4-1,3-C_4H_6)CrPMe$_3$ (**21**), (η^5-Me_5C_5)(η^4-1,3-C_4H_6)CrCO (**26**) and Cp(η^4-1,3-cyclohexadiene)Cr P(OMe)$_3$ (**27**).

Table 1. Selected structural parameters for (η^5-indenyl)(η^2,η^2-1,5-hexadiene)CrP(OMe)$_3$ (**19**), Cp(η^4-1,3-C_4H_6)CrPMe$_3$ (**21**), (η^5-Me_5C_5)(η^4-1,3-C_4H_6)CrCO (**26**) and Cp(η^4-1,3-cyclohexadiene)CrP(OMe)$_3$ (**27**)

No significance should therefore be attached to the associated bonding parameters. The main interest in **12** centres on the hapticity of the indenyl—Cr bond: the indenyl group in both molecules is essentially planar (the fold angle between the five- and six-membered rings are 2.2°/4.7° for molecule 1 and 2.4°/2.4° for molecule 2) while all of the C-atoms of the five-membered ring are within a bonding distance to the metal so that the indenyl group is best regarded as being bonded in an η^5-manner to the metal atom and not in an η^3-manner. In contrast, in (η^3-indenyl)Ir(PMe_2Ph)$_3$ for example, the two C-atoms shared by both the five- and six-membered rings are much further away [3.036/3.014(8) Å] from the metal atom than the other three [2.047(8)–2.236(13) Å] and there is a 20° angle between the planes of the allyl group and the six-membered ring.[6] The slight differences in the indenyl—Cr bond lengths for the two independent molecules of **12** suggest that **12b** has more η^5-character than **12a** and this may well be the result of packing effects within the crystal. **12** is diamagnetic (NMR; see experimental) and this combined with the much shorter Cr—Cr distance observed in the structurally related [(η^3-C_3H_5)(μ-η^3-C_3H_5)Cr]$_2$ [1.97(6) Å] for which a quadruple metal–metal bond has been suggested,[7,8] could be taken as an indication that **12** contains a metal–metal double bond. One ambiguity, however, remains unresolved: [Cp(μ-η^3-C_3H_5)Cr]$_2$ (**11**) is paramagnetic and it remains unclear whether this is an artefact (due to impurities in the bulk sample) or is the result of a difference in the multiplicity of the metal–metal bond.

The crystal structures of two donor-ligand stabilized Cp′(η^4-1,3-C_4H_6)-species (**21** and **26**) have been determined by X-ray diffraction. The molecular structures are shown in Fig. 1 and selected structural parameters are compared in Table 1. In both cases the butadiene molecule has a single-*cis* geometry and is bonded in an η^4-manner to the metal atom. The pentamethylcyclopentadienyl group in **26** is essentially planar with the methyl groups bent by an average of only 1.8° out of the ring-plane away from the metal atom. The Cr—C—O fragment is practically linear [Cr—C13—O 178.8(4)°] with the oxygen atom bent slightly towards the ring.

The crystal structure of Cp(η^4-1,3-cyclohexadiene)CrP(OMe)$_3$ (**27**) has also been determined (Fig. 1) and selected structural parameters are listed in Table 1. The 1,3-cyclohexadiene molecule is bonded as an η^4-organic ligand, the methylenic C-atoms are directed away from the metal atom. Complexation to the metal leads to a delocalization of the electrons within the 1,3-diene fragment (for free 1,3-cyclohexadiene C1—C2 = 1.348 and C2—C3 = 1.465 Å).[14] The cyclopentadienyl ring is planar.

EXPERIMENTAL

All experiments were carried out under an atmosphere of argon. Solvents (diethylether, pentane) were dried and freed from dissolved oxygen by distillation from diethylmagnesium. Chromocene,[9] (η^3-C_3H_5)$_3$Cr and (η^3-2-MeC_3H_4)$_3$Cr[10] were prepared by published procedures. The alkali metal salts of cyclopentadiene, substituted cyclopentadiene and indene were prepared by standard methods either by reaction with n-butyllithium or the alkali metal.

Infrared spectra were recorded with a Nicolet-FT-IR-spectrometer and the magnetic susceptibility was measured using a magnetic balance constructed in the Institute mainly from Varian parts (field strength 9000 G).

[$CpCrCl_2$]$_2$

The following synthesis is a modification of the published procedure.[11] Cp_2Cr (20 g, 110 mmol) was dissolved in pentane (1 l) at 0°C. The resulting red solution was stirred vigorously and treated with dry, gaseous HCl. The product was formed immediately as a green precipitate and the reaction was continued until the pentane became colourless. The compound, a green powder (dec. > 250°C) which is relatively insensitive to air but extremely moisture sensitive, was isolated and washed with pentane (3×100 cm^3) at room temperature. Yield 18.6 g (90% theory).

[(η^3-C_3H_5)$_2$CrCl]$_2$

The following synthesis is a modification of the published procedure.[11] (η^3-C_3H_5)$_3$Cr[10] (6.1 g, 34.9 mmol) was dissolved in diethylether (200 cm^3) and an ethereal solution of HCl (66 cm^3 of a 0.5 N solution, 33 mmol) was added dropwise at −78°C with vigorous stirring to give the product as a red–brown precipitate. Solvent was removed at −25°C under high vacuum and the residue washed with 50 cm^3 aliquots of pentane [to remove unreacted (η^3-C_3H_5)$_3$Cr] until the washings were colourless. The compound, which decomposes above −20°C, was dried at −40°C. Yield 5.33 g (90% theory). Found: C, 42.4; H, 5.9; Cl, 21.0; Cr, 30.7. Calc. for $C_{12}H_{20}Cl_2Cr_2$: C, 42.5; H, 5.9; Cl, 20.9; Cr, 30.7%. MS: *m/z* 296 (M^+-C_3H_6), 221, 210, 185, 175, 134, 93.

$[(\eta^3\text{-}2\text{-}MeC_3H_4)_2CrCl]_2$

$(\eta^3\text{-}2\text{-}MeC_3H_4)_3Cr$ [prepared in an analogous manner to $(\eta^3\text{-}C_3H_5)_3Cr$[10]] (7.6 g, 34.9 mmol) was dissolved in diethylether (200 cm^3) at −78°C and treated with ethereal-HCl (66 cm^3 of a 0.5 N solution, 33 mmol) as described above. The compound was isolated as a red–brown powder which decomposed above −20°C and which inflamed spontaneously in air. Yield 6.23 g (90% theory). Found: C, 48.2; H, 7.6; Cl, 18.0; Cr, 25.8. Calc. for $C_{16}H_{28}Cl_2Cr_2$: C, 48.6; H, 7.1; Cl, 17.9; Cr, 26.3%. MS: *m/z* 394 (M^+), 339 (M^+-C_4H_7), 284, 229, 217, 162, 107.

$Cp(\eta^3\text{-}C_3H_5)_2Cr$ (**1**)

Allylmagnesium chloride (1.06 l of a 0.308 mol l^{-1} ethereal solution, 325.6 mmol) was added dropwise to a suspension of $[CpCrCl_2]_2$ (27.86 g, 74.1 mmol) in diethylether (300 cm^3) at −60°C over 12 h. The reaction mixture was stirred at −60°C for a further 14 h and the solvent removed under high vacuum at −50°C. The residue was dried under high vacuum and then extracted with aliquots of carefully dried pentane at −30°C until the extract was colourless. The combined extract (*ca* 5 l) was cooled to −78°C to give the compound as orange–red crystals. Yield 24.78 g (83.9% theory). The compound can also be prepared (yield *ca* 70%) by reacting $[(\eta^3\text{-}C_3H_5)_2CrCl]_2$ with cyclopentadienyllithium in ether at −35°C. The compound reacts further above −20°C. Found: C, 66.2; H, 7.6; Cr, 26.0. Calc. for $C_{11}H_{15}Cr$: C, 66.3; H, 7.6; Cr, 26.1%. MS (70 eV, 40°): *m/z* 199 (M^+), 171, 158 (M^+-C_3H_5), 117. Magn. moment: μ_{eff} 1.8 BM. IR (KBr, −45°C): *v* 3100, 3000, 1495, 1435, 1370, 1210, 1125, 1060, 1005, 910, 825, 750, 580. Crystal structure: see ref. 2.

Reaction of **1** *with* HCl

$Cp(\eta^3\text{-}C_3H_5)_2Cr$ (1.31 g, 6.57 mmol) was suspended in pentane (40 cm^3) at −50°C and treated with gaseous HCl (306.7 cm^3, 13.69 mmol) from a gas burette. Propene was liberated and determined by GC (98.6% theory) and a turquoise-coloured suspension of $(CpCrCl_2)_2$ was formed. Yield 1.08 g (87.9% theory). The same compound is also formed upon treatment of **1** with CH_2Cl_2 and is accompanied by the liberation of 1,5-hexadiene.

Reaction of **1** *with* I_2

$Cp(\eta^3\text{-}C_3H_5)_2Cr$ (0.95 g, 4.77 mmol) was suspended in pentane (60 cm^3) at −78°C and iodine (1.82 g, 7.17 mmol) in diethylether (5 cm^3) was added. The reaction mixture was allowed to warm to 0°C and stirred overnight. 1,5-Hexadiene (33% theory, GC) was liberated with formation of green $(CpCrI_2)_2$. Yield 1.26 g (71.3% theory). Found: Cr, 13.9; I, 68.6. Calc. for $C_{10}H_{10}Cr_2I_4$: Cr, 14.0; I, 68.4%. MS (CI, 230°): *m/z* 742 (M^+), 615 (M^+—I).

Reaction of **1** *with acetylacetone*

$Cp(\eta^3\text{-}C_3H_5)_2Cr$ (1.69 g, 8.9 mmol) was dissolved in diethylether (100 cm^3) at −78°C and treated with excess acetylacetone (3 cm^3) at −20°C. The reaction mixture became dark red. The solvent was distilled off and shown by GC to contain propane (61.6% theory) and cyclopentadiene (100.4% theory) and the solid identified as $Cr(acac)_3$. Yield 1.98 g (66.8% theory).

Reaction of **1** *with excess* PPh_3

Excess PPh_3 (5.2 g) was added to solid $Cp(\eta^3\text{-}C_3H_5)_2Cr$ (1.23 g, 6.17 mmol) at −78°C and the reaction vessel connected by a glass bridge to a trap. The apparatus was evacuated and closed and the reaction vessel lowered into a bath at 100°C while the trap was cooled in liquid N_2. 0.53 g (103.9% theory) of condensate was liberated and shown to consist of 1,5-hexadiene (60.9% theory) and other C_6-hydrocarbons (33.4% theory).

$(\eta^5\text{-}MeC_5H_4)(\eta^3\text{-}C_3H_5)_2Cr$ (**2**)

Methylcyclopentadienyllithium (1.17 g, 13.6 mmol) was added to a stirred suspension of $[(\eta^3\text{-}C_3H_5)_2CrCl]_2$ (2.1 g, 6.2 mmol) in diethylether (200 cm^3) at −78°C. The reaction mixture was stirred at −35°C for 16 h, evaporated to dryness and the residue extracted with pentane (3 × 100 cm^3). The extract was filtered and cooled to −78°C to give the compound as red, cubic crystals which decomposed at −20°C. Yield 1.85 g (70% theory). Found: C, 67.4; H, 8.1; Cr, 24.4. Calc. for $C_{12}H_{17}Cr$: C, 67.6; H, 8.0; Cr, 24.4%. MS: *m/z* (M^+), 172 (M^+-C_3H_5), 131. Magn. moment: μ_B 1.6 BM. IR (KBr, −45°C): *v* 3080, 2990, 2920, 1495, 1455, 1375, 1210, 1050, 1000, 830, 745, 580.

$(\eta^5\text{-}t\text{-}C_4H_9C_5H_4)(\eta^3\text{-}C_3H_5)_2Cr$ (**3**)

Prepared as above from t-butylcyclopentadienyllithium as yellow crystals which decompose above −20°C. Yield 65% theory. Found: C, 70.1; H, 9.2; Cr, 20.9. Calc. for $C_{15}H_{23}Cr$: C, 70.6; H, 9.1; Cr, 20.4%. MS: the compound decomposed. IR (KBr,

−45°C): *v* 3100, 3000, 2930, 1490, 1380, 1360, 1215, 1045, 1005, 920, 830, 745, 580.

(η^5-$Me_2PhCC_5H_4$)(η^3-C_3H_5)$_2$Cr (**4**)

Prepared as above from 2-phenylisopropylcyclopentadienyllithium as red needles which decompose above −20°C. Yield 65% theory. Found: C, 75.6; H, 7.8; Cr, 16.5. Calc. for $C_{20}H_{25}Cr$: C, 75.7; H, 7.9; Cr, 16.4%. MS: the compound decomposed. IR (KBr, −45°C): *v* 3100, 3060–3040, 2980, 1620, 1590, 1490, 1380, 1205, 1040, 1000, 775, 705, 580.

(η^5-Me_5C_5)(η^3-C_3H_5)$_2$Cr (**5**)

Prepared as above from pentamethylcyclopentadienyllithium as red needles which decompose above −20°C. Yield 65% theory. Found: C, 71.0; H, 9.4; Cr, 19.7. Calc. for $C_{16}H_{25}Cr$: C, 71.3; H, 9.4; Cr, 19.3%. MS. *m/z* 269 (M^+), 187 (M^+-C_6H_{10}), 131. Magn. moment: μ_B 2.0 BM. IR (KBr, −45°C): *v* 3060, 2990, 2920, 1490, 1435, 1375, 1210, 995, 590.

(η^5-*Indenyl*)(η^3-C_3H_5)$_2$Cr (**6**)

[(η^3-C_3H_5)$_2$CrCl]$_2$ (5.1 g, 15 mmol) was suspended in diethylether (400 cm^3) at −78°C and treated with indenyllithium (3.78 g, 31 mmol). The reaction mixture was warmed to −40°C and stirred for 14 h to give an intensive red–brown solution. The solvent was removed at −35°C and the residue extracted with pentane (3 × 100 cm^3). The resulting solution was cooled to −78°C to give the compound as dark brown needles which decompose above −20°C. Yield 5.16 g (69% theory). Found: C, 72.1; H, 7.1; Cr, 20.7. Calc. for $C_{15}H_{17}Cr$: C, 72.3; H, 6.9; Cr, 20.9%. MS (70 eV, 30°C): *m/z* 249 (M^+), 208 (M^+-C_3H_5), 167. Magn. moment: μ_B 1.6/1.8. IR (KBr, −45°): *v* 3090–3040, 1630, 1610, 1490, 1450, 1380, 1350, 1210, 995, 745, 580.

Cp(η^3-2-MeC_3H_4)$_2$Cr (**7**)

[(η^3-2-MeC_3H_4)$_2$CrCl]$_2$ (2.1 g, 5.3 mmol) was suspended in diethylether (200 cm^3) at −78°C and treated with cyclopentadienyllithium (0.79 g, 11 mmol). The reaction mixture was stirred for 16 h at −35°C to give a red–violet solution. The solvent was evaporated at −35°C and the residue extracted with pentane (3 × 100 cm^3). Cooling to −78°C failed to cause precipitation of the compound which was isolated as a red–violet oil (which decomposed at −20°C) by evaporation to dryness. Yield 0.72 g (30% theory). Satisfactory elemental analysis of this thermolabile oil could not be obtained. MS: *m/z* 227 (M^+), 117 (M^+-C_8H_{14}). IR (film): *v* 3080, 2940, 2860, 2810, 1480, 1375, 1095, 1010, 790, 580.

(η^5-*Indenyl*)(η^3-2-MeC_3H_4)$_2$Cr (**8**)

[(η^3-2-MeC_3H_4)$_2$CrCl]$_2$ (2.1 g, 5.3 mmol) was suspended in diethylether (200 cm^3) at −78°C and treated with indenyllithium (1.34 g, 11 mmol). The reaction mixture was stirred for 16 h at −35°C. The solvent was removed and the residue extracted with pentane (3 × 100 cm^3). Removal of the solvent at −40°C gave the product as a violet oil which decomposed above −20°C. Yield 0.88 g (30% theory). Satisfactory analytical data could not be obtained for this thermolabile oil. MS: the compound decomposed. IR (film): *v* 3060, 2960–2860, 1480, 1440, 1375, 1210, 740.

[Cp(μ-η^3-C_3H_5)Cr]$_2$ (**11**)[4]

Cp(η^3-C_3H_5)$_2$Cr (**1**) (1.83 g, 9.19 mmol) was suspended in pentane (50 cm^3) at −78°C and toluene (30 cm^3) was added. The reaction mixture was allowed to slowly warm to −15°C and stirred for 24 h. A brown solid precipitated. Yield 1.01 g (69.8% theory; the yield in the absence of toluene was only *ca* 25%). Found: C, 60.9; H, 6.3; Cr, 32.8. Calc. for $C_{16}H_{20}Cr_2$: C, 60.8; H, 6.4; Cr, 32.9%. Magn. moment: μ_{eff} 4.1 BM. Crystal structure: see Fig. 2.

[(η^5-*Indenyl*)(μ-η^3-C_3H_5)Cr]$_2$ (**12**)

(η^5-Indenyl)(η^3-C_3H_5)$_2$Cr (**6**) (0.60 g, 2.4 mmol) was dissolved in diethylether (50 cm^3) at −30°C in an atmosphere of ethylene and the solution allowed to reach room temperature over 24 h. The solvent was removed and the residue separated from polyethylene (0.6 g) by extraction. The resulting brown solid was treated with Avicel and cooled to −78°C to give the compound as dark brown crystals. Yield 0.21 g (40% theory). The same compound is formed in the absence of ethylene. Found: C, 69.1; H, 5.9; Cr, 25.1. Calc. for $C_{24}H_{24}Cr_2$: C, 69.2; H, 5.8; Cr, 25.0%. MS: *m/z* 374 (M^+-C_3H_6), 334 (M^+-C_6H_{12}), 282, 208, 167. IR (KBr, room temperature): *v* 2040, 1605, 1480, 1335, 1215, 995, 820, 745. ^{1}H NMR (d_8-THF, 30°C): δ 7.01, 6.75 (indenyl); 6.26, 5.91 (indenyl); 4.79, 3.27, 2.28, 1.50 (allyl). Crystal structure: see Fig. 2.

Cp(η^2,η^2-1,5-*hexadiene*)CrCO (**13**)[2]

Cp(η^3-C_3H_5)$_2$Cr (**1**) (2.18 g, 10.94 mmol) was suspended in pentane (40 cm^3) at −78°C and the

reaction vessel connected to a glass burette filled with CO. The reaction mixture was stirred vigorously and warmed to 0°C. CO (12.83 mmol) was absorbed and the solution became dark green. A small amount of a green–grey solid (yield *ca* 4%; presumably $Cp_2Cr_2(CO)_5$, ν(CO) 1945, 1845, 1780, 1730) was filtered off and the solution evaporated to dryness to give the compound as green needles. Yield 2.12 g (85.3% theory). Found: C, 65.1; H, 7.1; Cr, 22.8. Calc. for $C_{12}H_{15}CrO$: C, 63.4; H, 6.7; Cr, 22.8%. MS (70 eV, 30°C): *m/z* 227 (M^+), 144 (M^+-CO), 171, 117. Magn. moment: μ_{eff} 1.61/1.58 BM. IR (KBr, −40°C): ν(CO) 1870vs, 1830sh, 1012, 1002, 820, 803, 590, 556, 546, 487.

Cp(η^2,η^2-1,5-*hexadiene*)CrPMe$_3$ (**14**)[2]

Cp(η^3-C_3H_5)$_2$Cr (**1**) (6.33 g, 31.8 mmol) was suspended in pentane (100 cm^3) at −78°C and PMe_3 (2.42 g, 3.3 cm^3, 31.8 mmol) added slowly with a pipette. The reaction mixture was allowed to warm to 0°C during which the colour changed to dark green. The solution was stirred overnight, filtered to remove a small amount of a grey–green solid [approx. composition $Cp_2Cr_2(PMe_3)_5$] and cooled to −78°C to give the compound as a dark green, crystalline solid which decomposed at 80°C. Yield 7.18 g (82% theory). Found: C; 61.1; H, 8.7; Cr, 18.8; P, 11.3. Calc. for $C_{14}H_{24}CrP$: C, 61.1; H, 8.8; Cr, 18.9; P, 11.3%. MS (70 eV, 50°C): *m/z* 275 (M^+), 193 (M^+-C_6H_{10}), 117. Magn. moment: μ_B 1.9 BM. IR (KBr, room temperature): ν 3100, 3020, 2920, 1470, 1465, 1420, 1120, 950, 800. Crystal structure: see ref. 2.

Cp(η^2,η^2-1,5-*hexadiene*)CrP(OMe)$_3$ (**15**)[2]

Prepared as above as dark green needles in 89% yield. Found: C, 52.1; H, 7.6; Cr, 16.1; P, 9.5. Calc. for $C_{14}H_{24}CrO_3P$: C, 52.0; H, 7.5; Cr, 16.1; P, 9.6%. MS (70 eV, 50°C): *m/z* 323 (M^+), 241 (M^+-C_6H_{10}), 182, 117. Magn. moment: μ_{eff} 1.9/2.0 BM. IR (KBr, room temperature): ν 3100, 3040, 2940, 2840, 1480, 1450, 1440, 1120, 1040, 805, 760, 700. Crystal structure: the structure has been confirmed by an X-ray diffraction study but disorder prevented refinement of the data.

Cp(η^2,η^2-1,5-*hexadiene*)CrP(OPh)$_3$ (**16**)

Prepared as above as a dark green, relatively insoluble compound in 85% yield. Found: Cr, 10.1; P, 6.0. Calc. for $C_{29}H_{30}CrO_3P$: Cr, 10.2; P, 6.1%. MS (70 eV, 110°C): *m/z* 509 (M^+), 428, 427 (M^+-C_6H_{10}), 326, 311, 182, 117. Magn. moment: μ_{eff} 2.2 BM.

[Cp(η^2,η^2-1,5-*hexadiene*)CrPPh$_2$Me]$_2$ (**17**)

Cp(η^3-C_3H_5)$_2$Cr (**1**) (1.50 g, 7.5 mmol) and PPh_2Me (1.60 g, 8 mmol) were dissolved in diethylether (80 cm^3) at −30°C and the mixture warmed to 0°C and stirred overnight. The resulting yellow solution was evaporated, the residue extracted with pentane and the extract cooled to −78°C to give the compound as lemon-yellow crystals which decompose at 80°C. Yield 2.41 g (80% theory). Found: C, 72.1; H, 7.0; Cr, 13.0; P, 7.9. Calc. for $C_{48}H_{56}Cr_2P_2$: C, 72.2; H, 7.1; Cr, 13.0; P, 7.8%. Mol. wt (cryoscopic, C_6H_6): 782 (calc. 799). MS (70 eV, 90°C): *m/z* 317 ([CpCrPPh$_2$Me]$^+$). Magn. moment: μ_{eff} 2.7/2.6 BM. IR (KBr, room temperature): ν 3080, 3000, 2920, 2820, 1540, 1480, 1435, 1270, 815.

Cp(η^2-1,5-*hexadiene*)Cr($Me_2PC_2H_4PMe_2$) (**18**)

Cp(η^3-C_3H_5)$_2$Cr (**1**) (1.50 g, 7.5 mmol) and 1,2-bis(dimethylphosphino)ethane (1.20 g, 8 mmol) were dissolved in diethylether (100 cm^3) at −30°C and the solution allowed to reach 0°C over 16 h. The reaction mixture was evaporated to dryness and the residue extracted with pentane. Filtration and cooling to −78°C gave the compound as a brown, crystalline solid which decomposed at 80°C. Yield 2.36 g (90% theory). Found: C, 58.6; H, 8.6; Cr, 14.7; P, 17.9. Calc. for $C_{17}H_{31}CrP_2$: C, 58.4, H, 8.9; Cr, 14.9; P, 17.7%. MS: *m/z* 349 (M^+), 267 (M^+-C_6H_{10}). Magn. moment: μ_{eff} 1.8 BM. IR (KBr, room temperature): ν 3100, 3060, 2960, 2840, 1635, 1535, 1005, 990, 905.

(η^5-*Indenyl*)(η^2,η^2-1,5-*hexadiene*)CrP(OMe)$_3$ (**19**)

Trimethylphosphite (0.57 g, 4.6 mmol) was added to an ethereal solution of (η^5-indenyl)(η^3-C_3H_5)$_2$Cr (**6**) at −30°C and the solution stirred at −10°C for 12 h. The solution was evaporated to dryness at room temperature in a high vacuum and the residue dissolved in hexane, filtered and the solution cooled to −78°C to give the compound as red, needle-shaped crystals which were dried under high vacuum and which decompose above 70°. Yield 1.16 g (80% theory). Found: C, 57.9; H, 7.0; Cr, 13.9; P, 8.3. Calc. for $C_{18}H_{26}CrO_3P$: C, 58.2; H, 6.9; Cr, 14.2; P, 8.3%. IR (KBr, room temperature): ν 3080, 2940, 2820, 1600, 1480, 1460, 1040. MS: *m/z* 373 (M^+), 291 (M^+-C_6H_{10}), 249 [M^+-P(OMe)$_3$]. Crystal structure: see Fig. 1.

(η^5-*Indenyl*)(η^2,η^2-1,5-*hexadiene*)$CrPMe_3$ (**20**)

Prepared as above by reacting trimethylphosphine with (η^5-indenyl)(η^3-C_3H_5)$_2$Cr (**6**) in diethylether at -10°C. The compound decomposes above 70°C. Yield 80%. Found: C, 66.5; H, 8.1; Cr, 16.0; P, 9.5. Calc. for $C_{18}H_{26}CrP$: C, 66.3; H, 7.9; Cr, 16.2; P, 9.3%. IR (KBr, room temperature): ν 3070, 3030, 2950, 2800, 1600, 1470, 1420, 1340, 1270, 940. MS. m/z 325 (M^+), 249 (M^+-PMe_3), 243 (M^+-C_6H_{10}).

Cp(η^4-1,3-C_4H_6)$CrPMe_3$ (**21**)

Cp(η^2,η^2-1,5-hexadiene)$CrPMe_3$ (**14**) (1.79 g, 6.5 mmol) was dissolved in diethylether (100 cm^3) and treated with a 10-fold excess of 1,3-butadiene at 0°C and stirred for 48 h. The colour of the reaction mixture changed from dark green to orange–red. The solvent was removed under high vacuum and the residue extracted with pentane. The extract was cooled to -78°C to give the compound as ruby red needles which melt at 94°C and decompose above 130°C. Yield 1.45 g (90% theory). The compound can also be prepared in a manner analogous to that described below (yield 61% theory) by reacting [CpCrCl$_2$]$_2$ consecutively with PMe_3 and magnesium-butadiene in THF. Found: C, 57.9; H, 8.0; Cr, 21.2; P, 12.4. Calc. for $C_{12}H_{20}CrP$: C, 58.3; H, 8.2; Cr, 21.0; P, 12.5%. MS: m/z 247 (M^+), 193, 171, 117, 76, 52. IR (KBr): ν 3110, 3040, 2960, 2910, 1445, 1420, 1280, 1210, 1105, 1000, 950, 800. Crystal structure: see Fig. 1.

Cp(η^4-1,3-C_4H_6)$CrP(OMe)_3$ (**22**)

[CpCrCl]$_2$ (1.88 g, 5 mmol) was suspended in THF (300 cm^3) and $P(OMe)_3$ (1.36 g, 11 mmol) was added. The resulting deep blue solution was cooled to -78°C and $C_4H_6Mg(THF)_2$ (2.33 g, 10.5 mmol) was added. The reaction mixture was stirred and allowed to warm to room temperature over 16 h during which time it became red. Solvent was removed under high vacuum and the residue extracted with pentane (3 × 100 cm^3) at room temperature. The resulting red extract was concentrated and cooled to -78°C to give the compound as orange red crystals (m.p. 120°C) which were recrystallized from hexane. Yield 1.77 g (60% theory). The compound can also be prepared as described above (yield 90% theory) by reacting Cp(η^2,η^2-1,5-hexadiene)$CrP(OMe)_3$ (**15**) with excess butadiene in ether. Found: C, 48.7; H, 7.0; Cr, 17.9; P, 10.3. Calc. for $C_{12}H_{20}CrO_3P$: C, 48.8; H, 6.8; Cr, 17.6; P, 10.5%. MS: m/z 295 (M^+), 241, 171, 117, 52. IR (KBr): ν 3105, 3040, 2940, 2830, 1455, 1430, 1110, 1020, 805, 770, 725.

(η^5-*Indenyl*)(η^4-1,3-C_4H_6)$CrPMe_3$ (**23**)

Prepared as described for **21** by reacting (η^5-indenyl)(η^2,η^2-1,5-hexadiene)$CrPMe_3$ with excess butadiene at 0°C. The compound was isolated as dark green needles (m.p. 50°C dec.) in 79% yield. Found: C, 64.7; H, 7.4; Cr, 17.6; P, 10.2. Calc. for $C_{16}H_{22}CrP$: C, 64.6; H, 7.5; Cr, 17.5; P, 10.4%. MS: m/z 243 (M^+-C_4H_6), 221, 167. IR (KBr): ν 3080, 3030, 2960, 2910, 1605, 1470, 1420, 1330, 945.

(η^5-Me_5C_5)(η^4-1,3-C_4H_6)$CrPMe_3$ (**24**)

Cp*Cr(THF)Cl$_2$ (100 cm^3 of a 0.081 molar solution, 8.1 mmol) was treated with PMe_3 (1 cm^3, 9.6 mmol) in THF at room temperature. The solution was cooled to -78°C and a suspension of (C_4H_6)Mg(THF)$_2$ (2 g, 9 mmol) in THF (100 cm^3) was added. The reaction mixture was stirred at -20°C for 7 h, evaporated to dryness and the residue extracted with pentane (210 cm^3) at -10°C. The extract was filtered, concentrated and cooled to -78°C to give the compound as dark red platelets. Yield: 1.85 g (72% theory). Found: C, 63.9; H, 10.2; Cr, 16.2; P, 9.7. Calc. for $C_{17}H_{30}CrP$: C, 64.3; H; 9.5; Cr, 16.4; P, 9.8%. MS (70 eV): m/z 241 (M^+-PMe_3, 60%), 187 (M^+-PMe_3/C_4H_6, 100%). IR (KBr): ν(Cp*) 1460m, 1370s, 1070m, 1020s; (C_4H_6) 1490m, 1230m, 880m, 830m; (PMe_3) 1300m, 1280s, 950s, 720m.

(η^5-Me_5C_5)(η^4-1,3-C_4H_6)$CrP(OMe)_3$ (**25**)

Prepared as above in the presence of $P(OMe)_3$ as a red crystalline compound in 75% yield. Found: C, 55.8; H, 8.7; Cr, 14.2; P, 8.4. Calc. for $C_{17}H_{30}CrO_3P$: C, 55.9; H, 8.3; Cr, 14.2; P, 8.5%. MS (70 eV): m/z 365 (M^+, 10%), 334 (3%), 311 (M^+-C_4H_6, 8%), 241 (M^+-$P(OMe)_3$, 89%), 218 (64%), 187 (M^+-C_4H_6/$P(OMe)_3$, 100%). IR (KBr): ν(Cp*) 1440m, 1370m, 1080m; (C_4H_6) 1490msh, 1230m, 880m; (PR_3) 1470m, 1180m, 1020s, 760m, 720s, 545m.

(η^5-Me_5C_5)(η^4-1,3-C_4H_6)CrCO (**26**)

(η^5-Me_5C_5)(η^4-1,3-C_4H_6)$CrPMe_3$ (**24**) (0.5 g, 1.58 mmol) was dissolved in pentane (50 cm^3), cooled to -70°C and the apparatus connected to a gas-burette filled with CO. The reaction mixture was stirred and allowed to warm to room temperature. The resulting green solution was cooled to -78°C to give the compound as red crystals.

Yield 0.35 g (81% theory). Found: C, 66.7; H, 8.0; Cr, 19.2. Calc. for $C_{15}H_{21}CrO$: C, 66.9; H, 7.8; Cr, 19.3%. MS: m/z 269 (M^+), 241, 187, 52. IR (KBr): ν 3060, 3040, 2980–2920, 2880, 1900 (CrCO), 1480, 1380, 1220, 1180, 880, 860. Crystal structure: see Fig. 1.

Cp(η^4-1,3-*cyclohexadiene*)CrP(OMe)$_3$ (**27**)

Cp(η^2,η^2-1,5-hexadiene)CrP(OMe)$_3$ (**15**) (1.62 g, 5 mmol) in diethylether was treated with a 10-fold excess of 1,3-cyclohexadiene and stirred at room temperature for 4 days. The resulting orange–brown solution was evaporated to dryness and the residue extracted with pentane. Diethylether was added to the extract (ether: pentane 1 : 5) and the compound isolated by fractional crystallization. Yellow crystals of Cp(η^6-C_6H_6)Cr (**28**) (0.25 g, 28% yield[5]) were deposited initially followed by **27** as dark red crystals which decomposed in solution above 25°C. Yield 0.92 g (57% theory). Found: C, 52.4; H, 7.0; Cr, 16.3; P, 9.5. Calc. for $C_{14}H_{22}CrO_3P$: C, 52.3; H, 6.9; Cr, 16.2; P, 9.6%. MS: m/z 321 (M^+), 197, 195, 124, 117, 52. IR (KBr): ν 3080, 2940, 2820, 1460, 1430, 1110, 1020, 800, 755, 710. Crystal structure: see Fig. 1.

Crystal structure determination

Crystal data for **19**, **21**, **26**, and **27** are summarized in Table 3 and those for **11** and **12** in Table 4.

ORGANOCHROMIUM π-COMPLEXES—VII.* THE REACTIONS OF Cp(η^3-ALLYL)$_2$Cr COMPOUNDS WITH ALKYNES AND ALKENES

K. ANGERMUND, P. BETZ, A. DÖHRING, P. W. JOLLY,† C. KRÜGER and K. U. SCHÖNFELDER

Max-Planck-Institut für Kohlenforschung, D-45466 Mülheim an der Ruhr, Germany

(*Received* 3 *June* 1993; *accepted* 15 *July* 1993)

Abstract—The compounds (η^5-RC_5H_4)(η^3-C_3H_5)$_2$Cr (R = H, Me, t-C_4H_9) and (η^5-indenyl)(η^3-C_3H_5)$_2$Cr react with alkynes (RC_2R) with displacement of 1,5-hexadiene to give Cp′(η^6-R_6C_6)Cr species. Treatment with cyclooctatetraene gives compounds containing an η^6-C_8H_8 group while the final product of the reaction with cycloheptatriene contains an η^7-cycloheptatrienyl fragment. 1,3-Butadiene reacts with dimerization to give the diamagnetic, dinuclear species (Cp′Cr)$_2$(μ-η^3,η^3-C_8H_{12}). The molecular structures of Cp(η^6-Me_6C_6)Cr, (η^5-indenyl)(η^6-Me_6C_6)Cr and Cp(η^6-C_8H_8)Cr have been confirmed by X-ray diffraction.

In the preceding publication we reported the synthesis of a series of Cp′(η^3-allyl)$_2$Cr compounds by reacting [CpCrCl$_2$]$_2$ or [(η^3-allyl)$_2$CrCl]$_2$ with allylmagnesium chloride or a substituted cyclopentadienyllithium derivative.[1] These compounds react with nucleophiles with reductive coupling of the two allyl groups to give a 1,5-diene which can in turn be readily displaced from the metal atom and they can hence be regarded as a ready source of the [Cp′Cr]-fragment for synthetic purposes. Here we discuss the reaction with alkynes and polyenes.

RESULTS AND DISCUSSION

Perhaps the most interesting reaction reported here is that with alkynes: cyclotrimerization occurs at the metal centre with displacement of 1,5-hexadiene to give species containing an η^6-arene molecule as paramagnetic, orange to red, sublimable solids in 80–90% yield (eq. 1).

$$Cp'(\eta^3\text{-}C_3H_5)_2Cr + 3RC{\equiv}CR \longrightarrow Cp'(\eta^6\text{-}R_6C_6)Cr + C_6H_{10} \quad (1)$$

The reaction appears to be general and provides a convenient access to these systems. Most attention has been given to the reaction involving Cp(η^3-C_3H_5)$_2$Cr but individual compounds have been prepared from systems containing η^5-MeC_5H_4, η^5-t-$C_4H_9C_5H_4$ and η^5-indenyl. Reactions with acetylene, 2-butyne, 3-hexyne and diphenylacetylene are described in the experimental section and in addition the mass spectroscopic data indicate that (η^6-arene)Cr-species are also formed in the reaction between Cp(η^3-C_3H_5)$_2$Cr and 2-pentyne or 1-butyne.

Cp(η^6-C_6H_6)Cr was first isolated over 30 years ago and has been prepared in low yield by reacting $CrCl_3$ with the cyclopentadienyl anion and phenylmagnesium bromide,[2,3] and sporadic attention has been given to its spectroscopic properties and to a description of the bonding.[4–7] In addition it has been reported that (η^5-Me_5C_5)(η^6-Me_6C_6)Cr is the product of a curious reaction involving the reduction of the product of the treatment of $CrCl_3$ with an aluminium alkyl and 2-butyne.[8,9]

Repeated attempts in this institute over the last two decades to confirm the molecular structure of a member of this class of compound by X-ray diffraction have been thwarted by disorder in both rings and although in the case of Cp(η^6-Me_6C_6)Cr disorder in the six-membered ring prevented us from refining the diffraction data (see experimental section), the sandwich structure could be confirmed. Fortunately, (η^5-indenyl)(η^6-Me_6C_6)Cr does not exhibit disorder and the molecular structure and

selected structural parameters are shown in Fig. 1 and Table 1, respectively. There is no evidence for alternation of the bonds within the six-membered ring and both C—C and Cr—C bond distances are similar to those observed for (η^6-C_6H_6)$_2$Cr (1.41 and 2.13 Å, respectively[10]). The six-membered ring is planar (maximum deviation $\pm$0.01 Å). The methyl groups at C7/C8/C11/C12 lie in the ring plane while those at C9 and C10 are bent by 3.4° and 4.8°, respectively towards the Cr-atom. The indenyl group is also planar (maximum deviation $\pm$0.002 Å) supporting its formulation as an η^5-ligand. Although the two chromium-bonded rings are almost parallel to each other, an interplanar angle of 6.3° indicates some steric interference between the methyl groups (C7/C8/C9) and the six-membered ring of the indenyl group.

We have also investigated the reaction of the

$Cp'(\eta^3\text{-}C_3H_5)_2Cr$ species with selected polyenes, and in all cases reductive coupling of the two allyl groups and displacement of 1,5-hexadiene is observed. The product of the reaction of the cyclopentadienyl- and indenyl-stabilized species with cyclooctatetraene is $Cp(\eta^6\text{-}C_8H_8)Cr$ and $(\eta^5\text{-indenyl})(\eta^6\text{-}C_8H_8)Cr$, respectively. The first of these is a known compound having been prepared by reacting $[CpCrCl_2]_2$ with isopropylmagnesium and cyclooctatetraene.[11-13] The presence of an absorption at *ca* 1650 cm^{-1} in both compounds supports the suggestion that one double bond of the tetraene is not complexed to the metal atom and this has been confirmed by a crystal structure determination for $Cp(\eta^6\text{-}C_8H_8)Cr$. The molecular structure is shown in Fig. 1(b). There are two independent molecules in the unit cell which have very similar structural parameters and averaged values are listed in Table 2. The planes formed by the Cp-ring and Cl—C6 of the cyclooctatetraene molecule are almost parallel forming an angle of only 4.4° to each other. The planes C1—C6 and C1/C8/C7/C6 lie at 63.7° to each other.

Related reactions have been observed with cyclopentadiene, 1,3-cyclohexadiene and 1,3,5-cycloheptatriene but in these cases the reaction is accompanied by deprotonation of the polyene. The product of the reaction between $Cp(\eta^3\text{-}C_3H_5)_2Cr$ and cyclopentadiene is chromocene (90% yield) while both $Cp(\eta^3\text{-}C_3H_5)_2Cr$ and $(\eta^5\text{-indenyl})(\eta^3\text{-}C_3H_5)_2Cr$ react with 1,3-cyclohexadiene to give $Cp(\eta^6\text{-}C_6H_6)Cr$ and $(\eta^5\text{-indenyl})(\eta^6\text{-}C_6H_6)Cr$, respectively. The initial product of the reaction between $Cp(\eta^3\text{-}C_3H_5)_2Cr$ and cycloheptatriene is the paramagnetic compound $Cp(\eta^6\text{-}C_7H_8)Cr$[14] which reacts further upon heating in solution to the diamagnetic, cycloheptatrienyl-chromium species $Cp(\eta^7\text{-}C_7H_7)Cr$.[14-20] Related species have been isolated from the reaction between cycloheptatriene and $(\eta^5\text{-indenyl})(\eta^3\text{-}C_3H_5)_2Cr$ or $(\eta^5\text{-}Me_5C_5)(\eta^3\text{-}C_3H_5)_2Cr$. In all of these cases, we have confirmed the displacement of the two allyl groups in the starting material as 1,5-hexadiene but in none of them were we able to determine the fate of the H-atoms abstracted from the polyene: since neither propene, hydrogen nor the products of disproportionation of the polyene (e.g. cyclohexene and benzene from 1,3-cyclohexadiene) could be detected, we assume that the reaction proceeds by complexation of the polyene to the Cp'Cr-fragment, followed by H-transfer to the metal, homolytic cleavage of the resulting Cr—H bond and indiscriminant reaction of the H-radical with the reaction media.

1,5-Hexadiene is also eliminated upon reacting

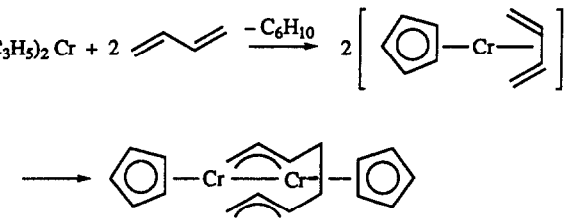
[a] D1 is the mid-point of the plane defined by C1—C6.
[b] D2 is the mid-point of the plane defined by C9—C13.

$Cp'(\eta^3\text{-}C_3H_5)_2Cr$ (Cp' = Cp, MeC_5H_4, indenyl) with 1,3-butadiene.[21] The product is not, however, the expected $Cp'(\eta^4\text{-}1,3\text{-}C_4H_6)Cr$ species, instead diamagnetic, dinuclear complexes are formed whose NMR spectroscopic data indicate that two diene molecules have coupled to form an η^3,η^3-octadienediyl fragment which bridges both metal atoms (eq. 2).



(2)

The intermediate formation of an $(\eta^4\text{-}1,3\text{-}C_4H_6)Cr$-species is suggested by the isolation of $Cp'(\eta^4\text{-}1,3\text{-}C_4H_6)CrPR_3$ complexes when the reaction is carried out in the presence of tertiary phosphines[1] as well as by the formation of $(\eta^5\text{-}Me_5C_5)(\eta^4\text{-}1,4\text{-}Me_2C_4H_4)Cr$ upon reaction of $(\eta^5\text{-}Me_5C_5)(\eta^3\text{-}C_3H_5)_2Cr$ with 2,4-hexadiene.[22] Related dinuclear species containing bridging allyl groups, e.g. $(CpCr)_2(\mu\text{-}C_3H_5)_2$, are the products of the further reaction of the $Cp'(\eta^3\text{-}C_3H_5)_2Cr$ (Cp' = Cp, indenyl) in the absence of nucleophiles and their structures have been confirmed by crystal structure determinations.[1]

EXPERIMENTAL

The preparation of the $Cp'(\eta^3\text{-}C_3H_5)_2Cr$ compounds and the general experimental conditions have been described in ref. 1.

$Cp(\eta^6\text{-}C_6H_6)Cr$[2,3]

$Cp(\eta^3\text{-}C_3H_5)_2Cr$ (0.90 g, 4.52 mmol) was suspended in pentane (70 cm^3) at −78°C and the reaction vessel connected to a gas burette filled with dry acetylene. The reaction mixture was allowed to warm slowly to 0°C and stirred at this temperature for a further 48 h during which time 310.9 cm^3 (13.88 mmol) of acetylene were absorbed. The resulting brown suspension was filtered and the filtrate cooled to −78°C to give the product as an orange–red crystalline solid. Yield: 0.76 g (86.2% theory). The presence of 1,5-hexadiene (85% theory) in the solvent was confirmed by GC. Found: C, 67.6; H, 5.2; Cr, 26.8. Calc. for $C_{11}H_{11}Cr$: 67.7; H, 5.2; Cr, 26.6%. MS (70 eV, 30°C): *m/z* 195 (M^+), 117, 52. The compound may also be prepared (yield: 54%) by reacting $Cp(\eta^3\text{-}C_3H_5)_2Cr$ with 1,3-cyclohexadiene in pentane at 0°C.

$Cp(\eta^6\text{-}Me_6C_6)Cr$

$Cp(\eta^3\text{-}C_3H_5)_2Cr$ (0.74 g, 3.71 mmol) was suspended in pentane at −78°C and 2-butyne (0.69 g, 12.80 mmol) was added. The reaction mixture was stirred and allowed to reach 0°C over 7 h (slow warming is necessary to suppress the catalytic formation of hexamethylbenzene) and held at this temperature for a further 48 h. The reaction mixture was filtered and the filtrate cooled to −78°C to give the product as red needles. Yield: 0.98 g (94.6% theory). The presence of 1,5-hexadiene (86% theory) in the solvent was confirmed by GC. Found: C, 73.3; H, 8.2; Cr, 18.5. Calc. for $C_{17}H_{23}Cr$: C, 73.1; H, 8.3; Cr, 18.0%. MS (70 eV, 60°C): *m/z* 279 (M^+), 147, 117, 52. Magn. moment: μ_{eff} 1.72 BM. IR (KBr, −40°C): *v* 1440, 1380, 1096, 992, 770, 456. Crystal structure: rotational disorder in the Me_6C_6 ring prevented refinement of the data below an R-factor of 0.071 (space group $P2_1/n$, $a = 8.368(1)$, $b = 14.744(1)$, $c = 11.835(1)$, $\beta = 94.281$, $Z = 4$).

$Cp(\eta^6\text{-}Et_6C_6)Cr$

Prepared as described above by reacting 3-hexyne. Orange–brown crystals. Yield: 77.9% theory. The presence of 1,5-hexadiene (40% theory) in the solvent was confirmed by GC. Found: C, 75.9; H, 9.8; Cr, 14.2. Calc. for $C_{23}H_{35}Cr$: C, 76.0; H, 9.8; Cr, 14.3%. MS (70 eV, 50°C): *m/z* 363 (M^+), 231, 117, 52. Binuclear species, $(CpCr)_2(Et_6C_6)$, are detected if the MS is measured at higher temperatures. Magn. moment: μ_{eff} 1.73 BM.

$Cp(\eta^6\text{-}Ph_6C_6)Cr$

Prepared as described above by reacting diphenylacetylene. Yellow solid. Yield: 88.3%. The presence of 1,5-hexadiene (65.2% theory) in the solvent was confirmed by GC. Found: C, 79.6; H, 4.7; Cr, 7.4. Calc. for $C_{47}H_{35}Cr$: C, 86.6; H, 5.4; Cr, 8.0%. The unsatisfactory analytical data are presumably a result of the high stability of hexaphenylbenzene.

MS (70 eV, 100°C): *m/z* 651 (M^+), 586, 534 (Ph_6C_6), 117, 52. Magn. moment: μ_{eff} 2.3 BM. IR (KBr): *ν* 1600, 1497, 1440, 780, 732, 695, 572.

$(\eta^5\text{-}MeC_5H_4)(\eta^6\text{-}Me_6C_6)Cr$

Prepared as described above by reacting $(\eta^5\text{-}MeC_5H_4)(\eta^3\text{-}C_3H_5)_2Cr$ with 2-butyne in diethyl ether. Red crystals. Yield: 61%. The presence of 1,5-hexadiene (67% theory) in the solvent was confirmed by GC. Found: C, 73.6; H, 8.5; Cr, 17.7. Calc. for $C_{18}H_{25}Cr$: C, 73.7; H, 8.6; Cr, 17.7%. MS: *m/z* 293 (M^+), 214, 162, 131, 52. IR (KBr): *ν* 3080, 2860, 1380, 1015.

$(\eta^5\text{-}t\text{-}C_4H_9C_5H_4)(\eta^6\text{-}C_6H_6)Cr$

Prepared as described above by reacting $(\eta^5\text{-}t\text{-}C_4H_9C_5H_4)(\eta^3\text{-}C_3H_5)_2Cr$ with acetylene-saturated diethyl ether. Yellow crystals. Yield: 60% theory. The presence of 1,5-hexadiene (75% theory) in the solvent was confirmed by GC. Found: C 71.5; H, 7.7; Cr, 20.8. Calc. for $C_{15}H_{19}Cr$: C, 71.7; H, 7.6; Cr, 20.7%.

MS: *m/z* 251 (M^+), 173, 157, 78, 52. IR (KBr): *ν* 3100, 3070, 2960, 1390, 1360, 980, 955, 790.

$(\eta^5\text{-Indenyl})(\eta^6\text{-}C_6H_6)Cr$

Prepared as described above by reacting $(\eta^5\text{-indenyl})(\eta^3\text{-}C_3H_5)_2Cr$ with acetylene-saturated diethyl ether. The compound was isolated as a red–brown solid by high-vacuum sublimation at 90°C. Yield: 56% theory. Found: C, 73.3; H, 5.6; Cr, 21.2. Calc. for $C_{15}H_{13}Cr$: C, 73.5; H, 5.3; Cr, 21.2%. MS: *m/z* 245 (M^+), 167. IR (KBr): *ν* 3080, 3050, 1600, 1450, 1330, 1030, 980, 955, 770, 740.

The compounds may also be prepared (yield 51%) by reacting $(\eta^5\text{-indenyl})(\eta^3\text{-}C_3H_5)_2Cr$ with 1,3-cyclohexadiene.

$(\eta^5\text{-Indenyl})(\eta^6\text{-}Me_6C_6)Cr$

Prepared as described above by reacting $(\eta^5\text{-indenyl})(\eta^3\text{-}C_3H_5)_2Cr$ with 2-butyne in diethyl ether. Red needles (dec. > 120°): Yield: 76% theory. Found: C, 76.8; H, 7.6; Cr, 15.7. Calc. for $C_{21}H_{25}Cr$: C, 76.6; H, 7.7; Cr, 15.8%. MS: *m/z* 329 (M^+), 214, 167. IR (KBr): *ν* 3040, 2900, 1600, 1445, 1375, 1325, 1015, 735. Crystal structure: see Fig. 1(a) and Table 1.

$Cp(\eta^6\text{-}C_8H_8)Cr$[11–13]

$Cp(\eta^3\text{-}C_3H_5)_2Cr$ (3.24 g, 16.3 mmol) was suspended in pentane at −78°C and cyclooctatetraene (1.84 g, 17.7 mmol) was added. The reaction mixture was stirred for 3 days at −20°C to give a beige suspension which was evaporated to dryness and the residue sublimed at 60°C under high vacuum to give the compound as a beige–yellow solid. Yield: 3.09 g (85.7% theory). The presence of 1,5-hexadiene (94% theory) in the solvent was confirmed by GC. Found: C, 70.7; H, 5.5; Cr, 23.7. Calc. for $C_{13}H_{13}Cr$: C, 70.6; H, 5.9; Cr, 23.5%. MS (70 eV, 50°C): *m/z* 221 (M^+), 195, 117, 52. Magn. moment: μ_{eff} 1.7 BM. IR (KBr): *ν* (C:C) 1647. Crystal structure: see Fig. 1(b) and Table 2.

$(\eta^5\text{-Indenyl})(\eta^6\text{-}C_8H_8)Cr$

Prepared as described above by reacting $(\eta^5\text{-indenyl})(\eta^3\text{-}C_3H_5)_2Cr$ in diethyl ether. The compound was isolated as a dark-red solid by high vacuum sublimation at 110°C. Yield: 60% theory. Found: Cr, 19.3. Calc. for $C_{17}H_{15}Cr$: Cr, 19.2%. MS: *m/z* 271 (M^+), 258, 245, 167, 115. IR (KBr): *ν* (C:C) 1645; 1515, 1335, 1015, 845, 795, 740.

$Cp(\eta^7\text{-}C_7H_7)Cr$[14–20]

$Cp(\eta^3\text{-}C_3H_5)_2Cr$ (2.96 g, 14.86 mmol) was suspended in pentane (150 cm^3) and treated with cycloheptatriene (1.37 g, 1.53 cm^3, 14.86 mmol). The reaction mixture was allowed to warm to +5°C and stirred for 72 h. The solvent was evaporated and the residue sublimed at 60°C under high vacuum to give the compound as a dark-brown (dark-green![16]) solid. Yield: 1.22 g (39.4% theory). Found: C, 68.9; H, 6.3; Cr, 24.7. Calc. for $C_{12}H_{12}Cr$: C, 68.9; H, 6.3; Cr, 24.9%. MS (70 eV, 50°C): *m/z* 208 (M^+), 182, 131, 117, 91, 52. ^1H NMR (D_8-THF): *δ* 5.61 (s, C_7H_7), 3.84 (s, Cp).[19] ^{13}C NMR (D_8-THF): *δ* 87.5 (C_7H_7, *J*(C,H) 163), 75.2 (Cp, *J*(C,H) 172).[19] The compound can also be prepared (yield 31%) by reacting 1,3-cycloheptadiene.

$(\eta^5\text{-}Me_5C_5)(\eta^7\text{-}C_7H_7)Cr$

Prepared as described above by reacting $(\eta^5\text{-}Me_5C_5)(\eta^3\text{-}C_3H_5)_2Cr$ in diethyl ether and isolated as a dark-red solid by sublimation at 90°C in high vacuum. Yield: 60%. Found: C, 73.5; H, 7.9; Cr, 18.8. Calc. for $C_{17}H_{22}Cr$: C, 73.4; H; 8.0; Cr, 18.7%. MS. *m/z* 278 (M^+, 100%), 187, 91, 52. IR (KBr). *ν* 3020, 2960, 2920, 1375, 960, 850, 820.

$(\eta^5\text{-Indenyl})(\eta^7\text{-}C_7H_7)Cr$

Prepared as described above by reacting $(\eta^5\text{-indenyl})(\eta^3\text{-}C_3H_5)_2Cr$ and isolated as a dark-green solid by high vacuum sublimation at 100°C. Yield:

64%. Found: C, 74.3; H, 5.6; Cr, 20.2. Calc. for $C_{16}H_{14}Cr$: C, 74.4; H, 5.5; Cr, 20.1%. MS. *m/z* 258 (M^+), 167, 143. IR (KBr): *v* 3020, 2980, 2920, 1600, 1335, 1240, 1030, 960, 855, 815, 800, 741. ^1H NMR (D_8-THF): δ 7.65 (m, 2H), 6.90 (m, 2H), 5.05 (m, 2H), 3.90 (s, 1H)-indenyl; 5.50 (s, 7H)-C_7H_7.

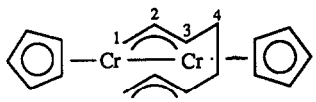
$[(\eta^5\text{-Indenyl})Cr]_2(\mu\text{-}\eta^3,\eta^3\text{-}C_8H_{12})$

Prepared as described below by reacting $(\eta^5$-indenyl$)(\eta^3\text{-}C_3H_5)_2Cr$. Green–brown solid (dec. > 140°C). Found: C, 70.3; H, 6.2; Cr, 23.4. Calc. for $C_{26}H_{26}Cr_2$: C, 70.6; H, 5.9; Cr, 23.5%. MS: *m/z* 442 (M^+), 388, 334, 282, 167, 115, 52. IR (KBr): *v* 3090, 3050, 2990–2820, 1605, 1470, 1445, 1330, 1005, 810, 780. ^1H NMR (D_8-toluene): 7.50–6.70 (4H), 6.20/6.10/5.45 (3H)-indenyl; *ca* 3.7 (br. 2-H), 3.05 (m, 1-H, anti), 2.40–2.10/1.95–1.50-C_8H_{12}, assignment provisional.

$(CpCr)_2(\mu\text{-}\eta^3,\eta^3\text{-}C_8H_{12})$[21]

$Cp(\eta^3\text{-}C_3H_5)_2Cr$ (1.0 g, 5 mmol) was dissolved in diethyl ether at −30°C, treated with a 10-fold excess of 1,3-butadiene and the reaction mixture warmed to −5°C over 12 h. Solvent was evaporated and the residue extracted with pentane. Cooling the extract to −78°C gave the compound as dark-brown crystals (dec. > 130°). Yield: 0.62 g (72% theory). The presence of 1,5-hexadiene in the solvent (83% theory) was confirmed by GC. Found: C, 62.7; H, 7.0; Cr, 30.2. Calc. for $C_{18}H_{22}Cr_2$: C, 63.2; H, 6.5; Cr, 30.4%.

MS: *m/z* 342 (M^+), 286, 182, 117, 52. IR (KBr): *v* 3090, 3030, 2960–2820, 1440, 1430, 1105, 1000, 810, 785. ^1H NMR (D_8-toluene, −30°C): δ 4.89/4.75 (s, Cp), 3.76 (brs, 2-H), 2.83/2.54 (br, 4-H), 2.71 (d, 1-H, syn), 2.17 (m, 1-H, anti). Numbering scheme shown below, assignment provisional.



The compound can also be prepared (55% yield) by reacting $(CpCrCl_2)_2$ with (1,3-butadiene)Mg$(THF)_2$ in THF.

$[(\eta^5\text{-}MeC_5H_4)Cr]_2(\mu\text{-}\eta^3,\eta^3\text{-}C_8H_{12})$

Prepared as described above by reacting $(\eta^5$-$MeC_5H_4)(\eta^3\text{-}C_3H_5)_2Cr$. Dark-brown crystals (m.p. 100° dec.). Yield: 60% theory. Found: C, 64.6;

ORGANOCHROMIUM π-COMPLEXES—VIII.† REACTIONS OF THE (η^5-Me_5C_5)Cr-SYSTEM WITH 1,3-DIENES AND ALKYNES

A. DÖHRING, R. EMRICH, R. GODDARD, P. W. JOLLY‡ and C. KRÜGER

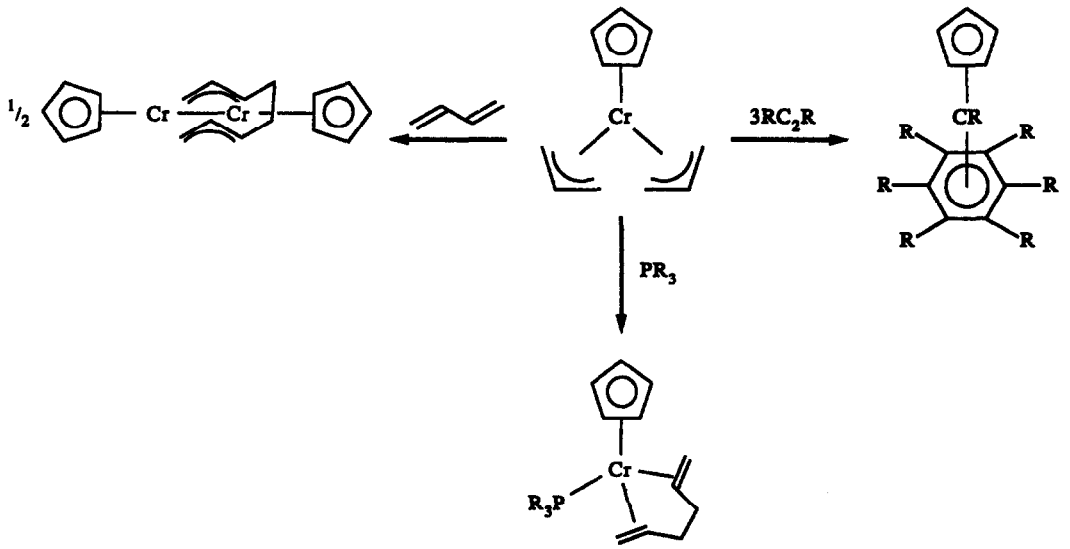
Max-Planck-Institut für Kohlenforschung, D-45466 Mülheim an der Ruhr, Germany

(*Received* 3 *June* 1993; *accepted* 15 *July* 1993)

Abstract—Cp*(η^4-1,3-diene)Cr compounds have been prepared either by reacting Cp*(η^3-$C_3H_5)_2$Cr with a diene or by reducing Cp*Cr(THF)Cl_2 with activated-Mg in the presence of the diene. These coordinatively and electronically unsaturated species readily form adducts with CO or P-donor ligands. The reaction of Cp*(η^4-1,3-C_4H_6)Cr with further butadiene leads to the formation of Cp*(η^3,η^3-octadienediyl)Cr which in turn reacts with a disubstitued alkyne (RC_2R) with addition to the 2,7-positions of the octadienediyl chain to give Cp*(η^1,η^2,η^1-$R_2C_{10}H_{12}$)Cr species. The crystal structures of representative compounds have been established by X-ray diffraction.

The isolation of Cp(η^3-$C_3H_5)_2$Cr in 1986 opened a new entry into the chemistry of the CpCr-system and a few typical reactions are shown in the scheme below.[1–3] As part of our attempts to prepare model compounds relevant to the chromium-catalysed oligomerization of alkenes, we have turned our attention to the chemistry of the Cp*-stabilized analogue (Cp* = η^5-Me_5C_5) since it has been well established[4–9] that the introduction of five methyl groups into the five-membered ring has a considerable effect upon the reactivity of the cyclopentadienyl-stabilized species, the increase in the electronic density at the metal centre decreasing the reactivity towards nucleophiles.

Here, we describe the preparation and reaction of Cp*Cr-stabilized 1,3-diene compounds.



Scheme 1.

† For parts VI and VII see refs. 1 and 2.

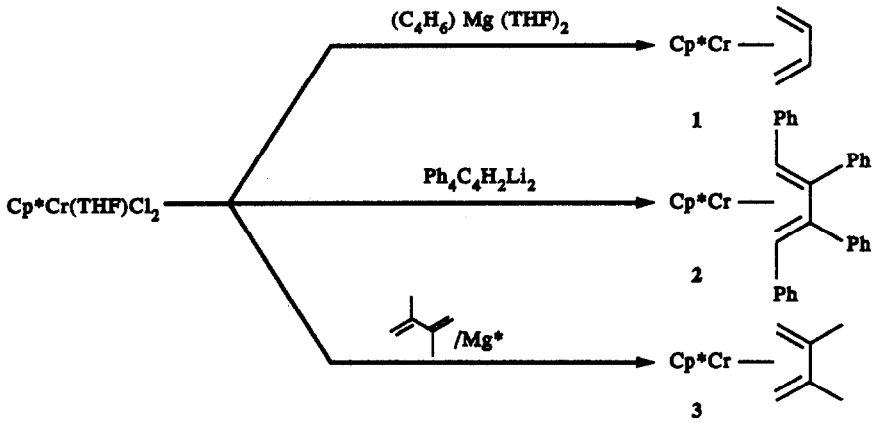
RESULTS AND DISCUSSION

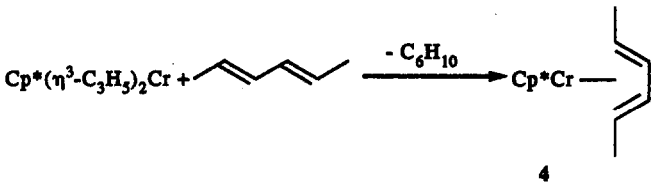
The Cp*(η^4-1,3-diene)Cr complexes **1** and **2** containing butadiene or 1,2,3,4-tetraphenylbutadiene have been prepared by reacting Cp*Cr(THF)Cl_2 with the metallated dienes $(C_4H_6)Mg(THF)_2$ or $Ph_4C_4H_2Li_2$ while the 2,3-dimethylbutadiene analogue **3** is the product of the reaction with active-Mg[10] in the presence of the diene (eq. 1).



(1)

Compounds of this type, e.g. Cp*(η^4-1,3-C_4H_6)$CrPR_3$ (**8**, R = Me; **9**, R = OMe), can also be prepared by reacting Cp*Cr(THF)Cl_2 with $(C_4H_6)Mg(THF)_2$ in the presence of the donor ligand while **5** is also the product of a ligand exchange reaction between **8** or **9** and CO[1]. The structure of Cp*(η^4-1,3-C_4H_6)CrCO (**5**) has been confirmed by X-ray diffraction and has been discussed with those of related compounds in an earlier publication.[1] The adducts are stable at room temperature.

The 2,4-hexadiene-containing compound **4** (but not the butadiene compound **1**; see Scheme 2 below) is the product of the reaction between the diene and Cp*(η^3-C_3H_5)$_2$Cr (eq. 2).



(2)

Compounds **1–4** are isolated as dark red–brown crystals which are stable below −20°C.

The 1,3-diene compounds **1–4** are electronically and coordinatively unsaturated and react readily with CO or P-donor ligands and the adducts **5–7** have been isolated (eq. 3).

Cp*(η^4-1,3-C_4H_6)Cr (**1**) reacts readily with further butadiene with oxidative coupling of the two diene molecules to give Cp*(η^3,η^3-octadienediyl)Cr (**10**). The same compound can also be prepared by reducing Cp*Cr(THF)Cl_2 in the presence of

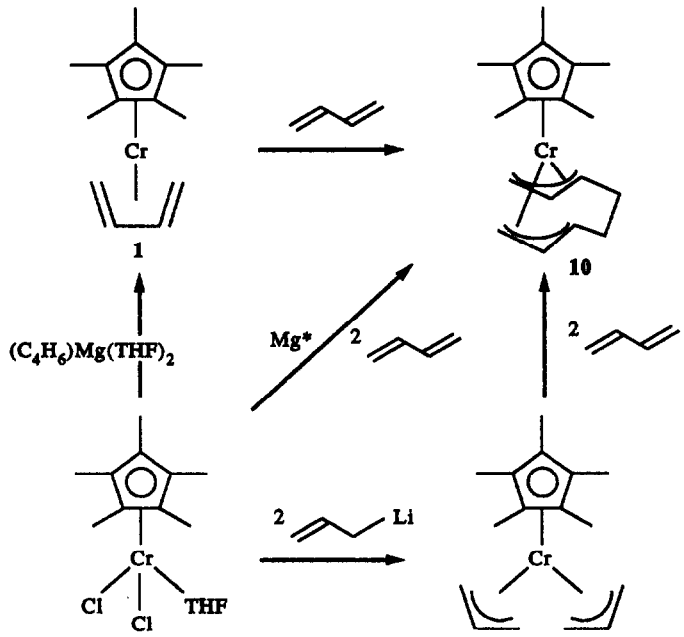
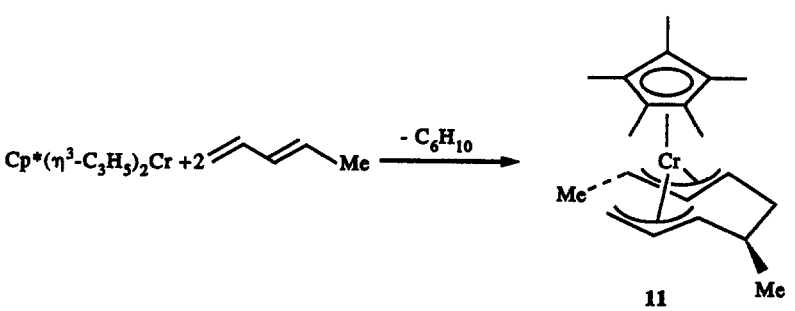
7 R = Me, R' = H, L = PMe_3



Scheme 2.

butadiene or by reacting $Cp^*(\eta^3\text{-}C_3H_5)_2Cr$ with butadiene (Scheme 2).

Although an analogous reaction between $Cp^*(\eta^3\text{-}C_3H_5)_2Cr$ and *cis*- or *trans*-piperylene leads to the formation of $Cp^*(\eta^3,\eta^3\text{-}1,5\text{-}Me_2C_8H_{10})Cr$ (**11**, eq. 4), 2,4-hexadiene reacts to give the mono-diene compound **4** (eq. 2). This difference in behaviour between the dienes presumably has a steric origin.



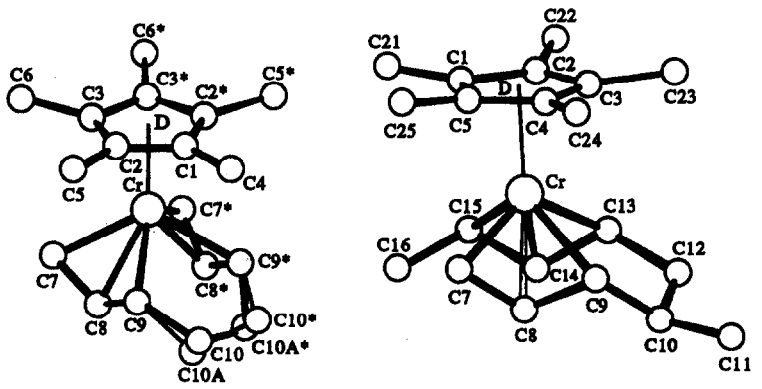
(4)

The crystal structures of **10** and **11** have been determined by X-ray diffraction and are shown in Fig. 1; selected structural parameters are listed in Table 1. Both compounds contain an octadienediyl chain bonded in an η^3,η^3-manner to the chromium atom with the meso-C-atoms of the C_8-chain pointing away from the metal.

The bis-methylene bridge in **10** is disordered. This disorder was resolved during the refinement procedure assuming a 50% occupancy for each C-atom. The Cp*-group is oriented with one C-atom (C1) directed towards the methylene bridge. The η^3-allyl fragments have typical bonding parameters with the planes defined by the allylic C-atoms arranged at an angle of 40° to each other.

The octadienediyl chain in **11** is substituted in the 1,5-position by methyl groups and the compound is thus the product of the head-to-tail coupling of two *trans*-piperylene molecules. The different substitution pattern for the two allyl fragments is reflected in differences in the observed structural parameters. Exactly as observed for **10**, one C-atom of the Cp*-ring (C3) is directed towards the bridging C-atom while the two allyl groups are also arranged at *ca* 40° to each other.

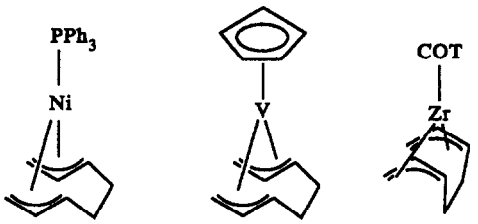
Organotransition metal compounds containing the octadienediyl-group have attracted attention as model compounds for intermediates in the catalytic cyclodimerization of butadiene to 1,5-cyclo-



10 **11**

Fig. 1 The molecular structures of Cp*(η^3,η^3-C_8H_{10})Cr (**10**) and Cp*(η^3,η^3-1,5-$Me_2C_8H_8$)Cr (**11**).

octadiene, 4-vinylcyclohexene or 1,2-divinylcyclobutane. A similar arrangement to that observed for **10** has been established by NMR spectroscopy for the nickel compound **12**[11] and has also been proposed for the related vanadium species **13** as well as its Cp*-stabilized analogue.[12]



12 **13** **14**

In contrast, the zirconium compound **14** has been shown by NMR spectroscopy to contain an anti-substituted octadienediyl-chain.[13] As far as we are aware, compound **11** is the only known example in which the dimethyl-C_8-fragment is formed by the head-to-tail coupling of two piperylene molecules: nickel-containing species related to **12** have the methyl groups in the 4,5-positions as the result of a tail-to-tail coupling[11] while the crystal structure determination of (cot)(η^3,η^3-1,8-$Me_2C_8H_{10}$)Zr has confirmed the head-to-head coupling of the two diene molecules.[14]

The chromium-atom in the octadienediyl compounds **10** and **11** (as well as in Cp*(η^3-C_3H_5)$_2$Cr) has 17-electrons in its valence shell and as expected

these species are paramagnetic. A one-electron reduction should lead to the formation of a diamagnetic, 18-electron system and indeed a cyclic voltammogram of **10** in THF indicates reversible redox behaviour (E_{ox} −0.13 V, E_{red} −0.99 V; Pt-electrode vs SCE). However, the profile of the curve indicates that structural changes occur during both the reduction and oxidation and therefore an attempt was made to reduce **10** chemically. Treatment with Li(naphthalene) in THF followed by the addition of tetramethylethylenediamine led to the formation in high yield of a red crystalline compound having the composition $[Cp^*(C_8H_{12})Cr][Li(Me_2NC_2H_4NMe_2)_2]$. However, a magnetic susceptibility measurement indicates that the species is not diamagnetic as expected but has a value corresponding to two unpaired electrons (2.9 μ_B). Furthermore, the IR spectrum suggests that the species no longer contains η^3-allyl groups and it seems probable that here also rearrangement of the organic group has occurred. Unfortunately, we were unable to obtain crystals of suitable quality for an X-ray diffraction study so that the suggestion that coupling of the allyl groups has occurred to give a $[Cp^*(\eta^2,\eta^2\text{-cod})Cr]^+$-species remains speculation.

Since it is known that η^3-allyl-transition metal compounds react readily with alkynes (examples from our research group are discussed in ref. 15), we have investigated the behaviour of **10**. An unusual reaction occurs in which the alkyne adds to the 2,7-position of the C_8-chain to give the species **15–17** as room temperature stable, red crystalline compounds.

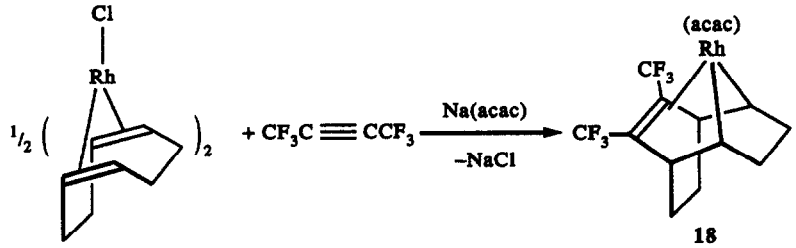
(5)

The mass spectrum of the product of the stoichiometric reaction between **10** and acetylene [*m/z*: 321 (M^+, 30%), 319 (40%), 295 (M^+-HC_2H, 15%), 293 (16%), 187 (100%)] indicates that an analogous reaction has occurred although the compound could not be obtained analytically pure, while in the presence of excess acetylene, *cis/trans*-polyacetylene (IR (KBr): ν 1015, 735 cm^{-1}) is formed. The reaction of **10** with *t*-butylacetylene takes a different course: the C_8H_{12}-fragment is displaced and a brown–green oil is formed which has the composition $Cp^*(t\text{-}C_4H_9C_2H)_4Cr$ and which was not investigated in detail although the liberation of $(t\text{-}C_4H_9)_4C_8H_4$ upon thermolysis (MS) suggests that it may contain a tetra-substituted cyclooctatetraene molecule. The crystal structure of **16** was established by X-ray diffraction and is shown in Fig. 2 along with selected structural parameters. The

bicyclic hydrocarbon fragment is bonded to the chromium atom through σ-bonds to C9/C9* and a π-bond to C7/C7*.

The only reaction which we are aware of which might be related is that shown in eq. (6) in which **18** is formed as the result of a 1,4-addition of the alkyne to a cyclooctadiene molecule.[16]

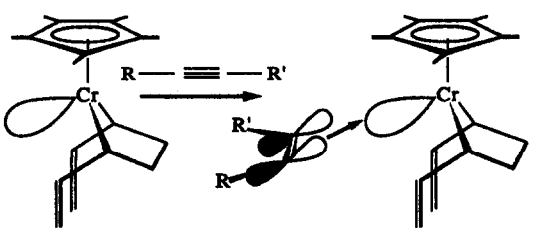


(6)

18

Having determined the crystal structure of both the starting material, Cp*(η^3,η^3-C_8H_{12})Cr, and of the product of the reaction with 1-hexyne, Cp*(η^1,η^2,η^1-1,2-$Et_2C_{10}H_{12}$)Cr, we are in a position to speculate on the mechanism. A possible course is shown below (Scheme 3): the η^3,η^3-C_8H_{12}-fragment rearranges either thermally or under the influence of the alkyne to the related η^1,η^1-form (compounds containing this fragment have been reported for Pd[17] and Pt[18]) which isomerizes by disrotatory rotation about the vinyl axis (a computer simulation indicates that a conrotatory rotation is unlikely since this would bring the meso-H atom and one of the terminal H-atoms to within 0.4 Å of each other) and is followed by a $2_\pi+2_\pi+2_\pi$-cycloaddition involving the second π-bond of the complexed alkyne molecule.

The results of an extended-Hückel MO treatment of the three species involved is shown in simplified form as Fig. 3(i–iii). On the left hand side are shown the relative levels of the Cr-*d*-orbitals for the coordination of the bis(η^3-allyl)fragment to Cr(III). η^3-to-η^1 rearrangement of the allyl groups by disrotatory rotation of the vinyl groups (as discussed above) with maintenance of the symmetry to give (ii) is accompanid by a significant decrease in the energies of the d_{xy} and d_{xz} orbitals as a result of the loss of the antibonding contribution to the atomic orbitals of the terminal allylic-C-atoms. This results in an increase in the acceptor ability of the metal and the HOMO of the alkyne molecule which has the correct symmetry to overlap with the d_{xz}-orbital of the chromium atom (eq. 7).

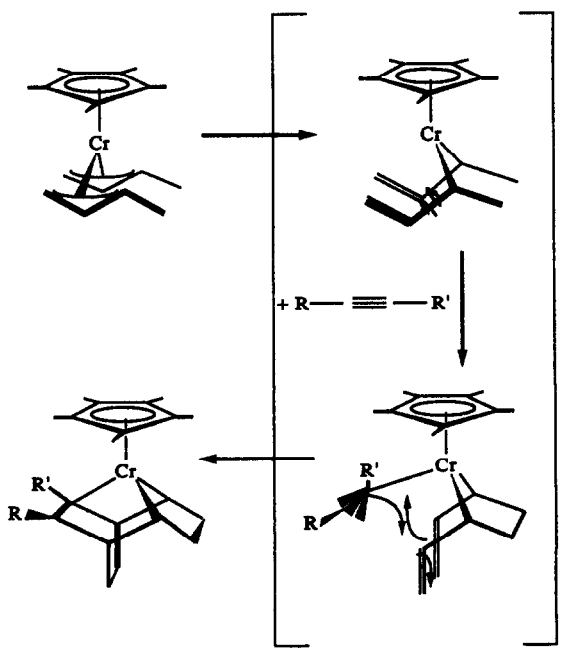


(7)

Additional changes in the *d*-orbital energies upon formation of the product are shown in Fig. 3(iii). Of particular significance is the further stabilization of the d_{xy}-orbital (the degeneracy with the $d_{x^2-y^2}$-orbital is coincidental) as a result of a bonding interaction between the metal orbitals and the π*-orbital (LUMO) of the alkyne. A consequence of Hund's rule is that the metal atom in the product should have a high-spin configuration with three unpaired electrons: the observation of a value of 3.1 μ_B for the magnetic susceptibility of **16** confirms the relevance of this simple MO-description.

EXPERIMENTAL

The general experimental conditions have been described in ref. 1. Cp*Cr(THF)Cl_2 was prepared by reacting $Cr(THF)_3Cl_3$ with Cp*Li[19] in THF or diethyl ether at −30°C to 0°C and reacted further using solutions whose concentrations were



Scheme 3.

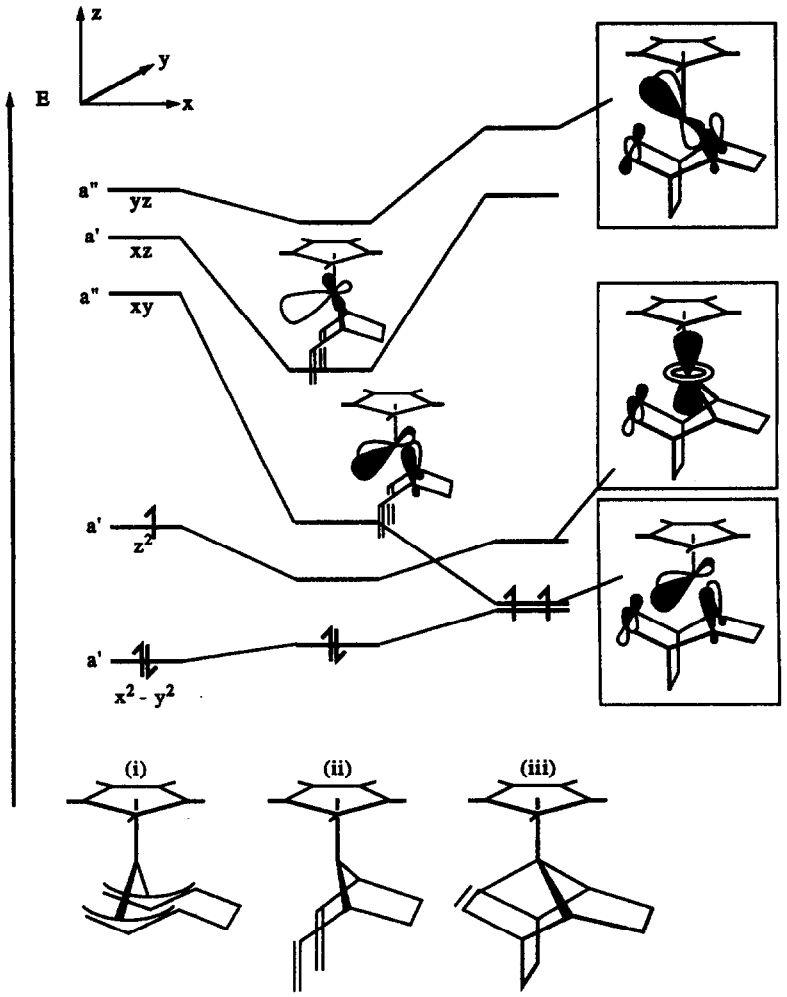


Fig. 3. MO-scheme illustrating the change in the energy of the Cr-*d*-orbitals during the transition from Cp*(η^3,η^3-C_8H_{12})Cr to Cp*(η^1,η^2,η^1-1,2-$C_{10}H_{14}$)Cr.

determined by measuring the intensity of the 670 nm absorption in the UV-spectrum. (C_4H_6)$Mg(THF)_2$ was prepared by reacting Mg-turnings with butadiene in THF.[20] Dilithium-1,2,3,4-tetraphenylbutadiene was prepared by reacting 1,2,3,4-tetraphenylbutadiene with excess lithium in THF at 0°C to 5°C.[21] Cp*(η^3-C_3H_5)$_2$Cr was prepared either by reacting [(η^3-C_3H_5)$_2$CrCl]$_2$ and Cp*Li[1] or by reacting Cp*Cr(THF)Cl_2 with allyllithium in ether at −60°C to −30°C (yield *ca* 85%). Active Mg was kindly supplied by Prof. B. Bogdanović and his co-workers and was prepared by the dehydrogenation of MgH_2 in the presence of $FeCl_2$.

Cp*(η^4-1,3-C_4H_6)Cr (**1**)

An ethereal solution of Cp*Cr(THF)Cl_2 (100 cm^3 of a 0.063 molar solution, 6.3 mmol) was added to a suspension of (C_4H_6)$Mg(THF)_2$ (1.5 g, 6.67 mmol) in ether at −78°C. The reaction mixture was allowed to warm to 5°C and stirred for a further 5 h. The resulting yellow–brown solution was evaporated to dryness and the compound extracted and cooled to −78°C to give the product as red–brown crystals. A further fraction was obtained by concentrating the mother liquor. Yield: 0.86 g (70% theory). Found: C, 69.7; H, 8.8; Cr, 21.5. Calc. for $C_{14}H_{21}Cr$: C, 69.7; H; 8.8; Cr, 21.6%. MS (70 eV): *m/z* 241 (M^+, 47%), 187 (M^+-C_4H_6, 100%). IR (KBr): ν(Cp*) 1460s, 1375s, 1030m; (C_4H_6) 1210s, 1155s, 1040m, 930m.

Cp*(η^4-1,2,3,4-$Ph_4C_4H_2$)Cr (**2**)

Cp*Cr(THF)Cl_2 (65 cm^3 of a 0.081 molar solution, 5.3 mmol) in ether was treated with dilithium-1,2,3,4-tetraphenylbutadiene (150 cm^3 of a 0.037 molar solution, 5.55 mmol) in THF at −55°C. The reaction mixture was allowed to warm to 0°C and stirred for a further 4 h. The resulting brown solu-

tion was evaporated to dryness and the compound extracted with pentane (2×70 cm^3). The filtrate was concentrated and cooled to -78°C to give the product as a dark brown powder. Yield: 1.93 g (67% theory). The compound was contaminated by tetraphenylbutadiene and this could not be completely removed by repeated recrystallization. Found: C, 83.9; H, 7.5; Cr, 8.7. Calc. for $C_{38}H_{37}Cr$: C, 83.6; H, 6.8; Cr, 9.5%. MS (70 eV): *m/z* 545 (M^+, 40%), 187 (M^+-$Ph_4C_4H_2$, 6%). IR (KBr): ν(Cp*) 1440m, 1380m, 1030m.

Cp*(η^4-2,3-$Me_2C_4H_4$)Cr (**3**)

A suspension of activated-Mg (0.12 g, 5 mmol) in THF (20 cm^3) at -78°C was treated with a solution of Cp*Cr(THF)Cl_2 (50 cm^3 of a 0.09 molar solution, 4.5 mmol) in THF and excess 2,3-dimethylbutadiene (15 cm^3). The reaction mixture was stirred at -50°C overnight to give a red–brown solution which was stirred for a further 3 h at room temperature. The solution was filtered and cooled to -78°C to give the compound as red–brown crystals. Yield: 0.73 g (60% theory). Found: C, 70.6; H, 9.5; Cr, 19.8. Calc. for $C_{16}H_{25}Cr$: C, 71.3; H, 9.4; Cr, 19.3%. MS (70 eV): *m/z* 269 (M^+, 50%), 187 (M^+-C_6H_{10}, 100%). IR (KBr): ν(Cp*) 1470m, 1370s, 1065m, 1020s; (diene) 1330m, 1225m, 1180m, 980m.

Cp*(η^4-1,4-$Me_2C_4H_4$)Cr (**4**)

Cp*(η^3-C_3H_5)$_2$Cr (0.9 g, 3.34 mmol) was stirred in pentane (100 cm^3) at -70°C and treated with excess *trans,trans*-2,4-hexadiene (3 cm^3). The reaction mixture was allowed to warm to 0°C and the resulting dark red solution filtered and evaporated to dryness. The residue was extracted with pentane (40 cm^3) at 5°C and the extract concentrated and cooled to -78°C to give the compound as red crystals. Yield: 0.57 g (63% theory). Unsatisfactory analytical data were obtained since the compound was contaminated by an oil which could not be completely removed by repeated recrystallization. Found: C, 70.2; H, 9.2; Cr, 18.6. Calc. for $C_{16}H_{25}Cr$: C, 71.3; H, 9.4; Cr, 19.3%. MS (70 eV): *m/z* 269 (M^+, 3%), 241 (M^+-C_2H_4, 70%), 187 (M^+-C_6H_{10}, 100%). IR (KBr): ν(Cp*) 1440m, 1430s, 1370s, 1020m; (diene) 1495s, 1200s, 795s, 785s.

Cp*(η^4-1,3-C_4H_6)CrCO (**5**)

The compound, which has been reported as the product of the reaction between Cp*(η^4-1,3-C_4H_6)CrPMe$_3$ (**8**) and CO[1], can also be prepared by reacting Cp*(η^4-1,3-C_4H_6)Cr (**1**) with CO in pentane -60°C to 0°C or by reacting [Cp*(η^4-1,3-C_4H_6)Cr]$_2$($Ph_2PC_2H_4PPh_2$) (prepared as a red–brown insoluble compound by reacting Cp*Cr(THF)Cl_2 with (C_4H_6)Mg(THF)$_2$ and bis(diphenylphosphino)ethane in THF) with CO in pentane at room temperature (yield 82%).

Cp*(η^4-2,3-$Me_2C_4H_4$)CrCO (**6**)

Prepared as described above from Cp*(η^4-2,3-$Me_2C_4H_4$)Cr and CO as green crystals in 86% yield. Found: C, 68.1; H, 8.7; Cr, 17.8. Calc. for $C_{17}H_{25}CrO$: C, 68.7; H, 8.5; Cr, 17.5%. MS (70 eV): *m/z* 297 (M^+, 4%), 269 (M^+-CO, 94%), 187 (M^+-CO/C_6H_{10}, 100%). IR (KBr): ν(CO) 1880s; (Cp*) 1960m, 1900m, 1430m, 1380m, 1030m; (C_6H_{10}) 1480m, 1450m, 1380s, 1265m, 880m.

Cp*(η^4-1,4-$Me_2C_4H_4$)CrPMe$_3$ (**7**)

Prepared as described above by reacting Cp*(η^4-1,4-$Me_2C_4H_4$)Cr with PMe$_3$ in pentane at 5°C.

Cp*(η^4-1,3-C_4H_6)CrPMe$_3$ (**8**) *and* Cp*(η^4-1,3-C_4H_6)CrP(OMe)$_3$ (**9**)

These compounds have been reported previously as the product of the reaction between Cp*Cr(THF)Cl_2, PR_3 (R = Me, OMe) and (C_4H_6)Mg(THF)$_2$ in THF at -78°C to -20°C.[1]

Cp*(η^3,η^3-C_8H_{12})Cr (**10**)

Cp*(η^3-C_3H_5)$_2$Cr (1.1 g, 4.1 mmol) was dissolved in pentane (150 cm^3) at -30°C and the solution cooled to -78°C. 1,3-butadiene (35 cm^3) was added and the reaction mixture warmed to 0°C and stirred for 10 h. The solution was filtered and the filtrate cooled to -78°C to give the compound as a dark red crystalline solid which was dried under high vacuum at 0°C. Yield: 1.02 g (84% theory). Found: C, 72.8; H, 9.3; Cr, 17.9. Calc. for $C_{18}H_{27}Cr$: C, 73.2; H, 9.2; Cr, 17.6%. MS (70 eV): *m/z* 295 (M^+, 30%), 263 (32%), 241 (M^+-C_4H_6, 20%), 187 (M^+-C_8H_{12}, 100%). IR (KBr): ν(Cp*) 1430m, 1370s, 1020m; (allyl) 1235m, 1215m, 1195m, 1065m, 945m. Magn. suscept.: 1.9–2.3 μ_B. Crystal structure: see Fig. 1 and Table 1. Treatment with ethereal–HCl leads to the liberation of a mixture of *t,t*-, *t,c*- and *c,c*-2,6-octadiene (1 : 2 : 1) in 75% yield. A pentane solution of the compound reacts with CO at 5°C with displacement of 1,5-cyclooctadiene and 4-vinylcyclohexene (1 : 2) and formation of [Cp*Cr(CO)$_2$]$_2$; ν(CO) 1865vs, 1840vs.

The compound can also be prepared by reacting

$Cp^*Cr(THF)Cl_2$ with active-Mg and 1,3-butadiene in ether at −78°C to −10°C (yield 61%), by reacting $Cp^*Cr(THF)Cl_2$ with $(C_4H_6)Mg(THF)_2$ and 1,3-butadiene in THF at 0°C (yield 57%) or by reacting $Cp^*(\eta^4\text{-}1,3\text{-}C_4H_6)Cr$ with butadiene in pentane at 5°C (yield 88%).

$Cp^*(1,5\text{-}Me_2C_8H_{10})Cr$ (11)

Prepared as described above by reacting *trans,trans*-1,3-pentadiene in the form of red plates in 72% yield. Found: C, 73.8; H, 9.8; Cr, 16.1. Calc. for $C_{20}H_{31}Cr$: C, 74.2; H, 9.7; Cr, 16.1%. MS (70 eV): *m/z* 323 (M^+, 26%), 321 (25%), 255 ($M^+\text{-}C_5H_8$, 36%), 187 ($M^+\text{-}C_{10}H_{16}$, 100%). IR (KBr): ν(Cp*) 1445s, 1370s, 1020s; (allyl) 1485s, 1220m, 860m. Crystal structure: see Fig. 1 and Table 1.

The compound was formed in lower (58%) yield upon reacting a mixture of *cis*- and *trans*-piperylene (7:13). An analogous reaction with *cis*-piperylene led to the formation of a red–brown oil which is presumably a mixture of isomers [MS: *m/z* 323 (M^+)] differing in the arrangement of the methyl groups.

$[Cp^*(C_8H_{12})Cr][Li(Me_2NC_2H_4NMe_2)_2]$

$Cp^*(\eta^3,\eta^3\text{-}C_8H_{12})Cr$ (**10**, 0.9 g, 3.05 mmol) was dissolved in THF (50 cm^3) and the solution cooled to −78°C and treated with Li(naphthalene) (25 cm^3 of a 0.13 mol solution, 3.25 mmol). The reaction mixture was allowed to warm to room temperature and stirred for a further 5 h. The solvent was removed *in vacuo* and the oily residue dissolved in ether (40 cm^3), filtered and the red–brown filtrate treated with tetramethylethylenediamine (2 cm^3, 13.36 mmol). The resulting solution was cooled to −30°C to give the compound as red crystals. Yield: 1.35 g (83% theory). Found: C, 66.6; H, 11.3; Cr, 10.0; Li, 1.1; N, 10.1%. Calc. for $C_{30}H_{59}CrLiN_4$: C, 67.4; H, 11.1; Cr, 9.7; Li, 1.3; N, 10.5%. MS:

$Cp^*(1,2\text{-}Me_2C_{10}H_{12})Cr$ (**15**)

$Cp^*(\eta^3,\eta^3\text{-}C_8H_{12})Cr$ (**10**, 0.8 g, 2.7 mmol) was dissolved in pentane at −45°C and treated with 2-butyne (0.4 cm^3, 5.12 mmol). The reaction mixture was warmed to 5°C and stirred for 15 h, evaporated to dryness and the residue extracted with pentane (10 cm^3). The extract was cooled to −78°C to give the compound as red crystals. Yield: 0.43 g (46% theory). Found: C, 75.6; H, 9.5; Cr, 14.9. Calc. for $C_{22}H_{33}Cr$: C, 75.3; H, 9.3; Cr, 15.4%. MS (70 eV): *m/z* 349 (M^+, 26%), 347 (56%), 293 (M^+-Me_2C_2, 9%), 187 (100%). IR (KBr): $\nu(Cp^*)$ 1430s, 1370s; (C:C) 1580m, 1485m; 1280m, 1020s.

$Cp^*(1,2\text{-}Et_2C_{10}H_{12})Cr$ (**16**)

Prepared as described above by reacting $Cp^*(\eta^3,\eta^3\text{-}C_8H_{12})Cr$ (**10**) with 1-hexyne in pentane at −78°C to room temperature. The red crystals were recrystallized from pentane. Yield 48% theory. Found: C, 76.4; H, 9.9; Cr, 13.7. Calc. for $C_{24}H_{37}Cr$: C, 76.4; H, 9.9; Cr, 13.8%. MS (70 eV): *m/z* 377 (M^+, 27%), 375 (44%), 321 (14%), 187 (63%). IR (KBr): $\nu(Cp^*)$ 1440m, 1365m, 1020m; 1580m, 1460m, 1050. Magn. suscept.: 3.1 μ_B. Crystal structure: see Fig. 2.

$Cp^*(1,2\text{-}EtMeC_{10}H_{12})Cr$ (**17**)

Prepared as above by reacting $Cp^*(\eta^3,\eta^3\text{-}C_8H_{12})Cr$ (**10**) with 2-pentyne. Yield: 41% theory. Found: Cr, 14.2. Calc. for $C_{23}H_{35}Cr$: Cr, 14.3%. MS (70 eV): *m/z* 363 (M^+, 47%), 361 (90%), 187 (100%). IR (KBr): $\nu(Cp^*)$ 1375m, 1030m; 1550m, 1485m, 1450m, 1375m, 1045m.

X-ray diffraction studies and MO calculations

Single crystal structure analyses were carried out using an Enraf–Nonius CAD-4 diffractometer. Crystallographic data for **10**, **11** and **16** and details of the refinement are summarized in Table 2 and in the supplementary material.

Extended Hückel MO calculations based on the structures of **10** and **16** were carried out using the programme ICON (v. 8, 1974).

(*Received* 2 *June* 1993; *accepted* 15 *July* 1993)

Abstract—The new fluorine containing ligand, tris(2,6-difluorophenyl)phosphite, prepared from the reaction between 2,6-difluorophenol and phosphorus trichloride, reacts with η^5-pentamethylcyclopentadienyldichloroiridium dimer to give the title compound in high yield. The molecular structure of this compound has been determined by single crystal X-ray crystallography.

We are interested in the properties the presence of fluorine in ligands, particularly phenylphosphines and phenylphosphites, can bestow upon transition-metal complexes of those ligands. Although tris (pentafluorophenyl)phosphite has been reported,[1] there are no reports of metal complexes of phenyl-phosphites containing *ortho* fluorines. Here we report the synthesis and characterization of the new fluorine containing ligand tris(2,6-difluorophenyl) phosphite, **1**, and the complex η^5-pentamethyl-cyclopentadienyliridiumdichlorotris(2,6 - difluoro-phenyl)phosphite, **2**, which has been structurally characterized by X-ray crystallography.

EXPERIMENTAL

$[Cp^*IrCl_2]_2$ (Aldrich), PCl_3 (BDH) and 2,6-difluorophenol (Fluorochem) were used as supplied. Triethylamine was dried by storage over CaH_2 prior to use. THF was dried over sodium wire and then distilled from sodium/benzophenone under dinitrogen. NMR spectra were recorded on a Bruker AM300 spectrometer. ^1H NMR spectra were recorded at 300 MHz and referenced internally using the residual protio solvent resonance relative to tetramethylsilane ($\delta = 0$ ppm). ^{13}C NMR spectra were recorded at 75.47 MHz and referenced internally using the solvent resonance relative to tetramethylsilane ($\delta = 0$ ppm). ^{19}F NMR spectra were recorded at 282.41 MHz and referenced externally to $CFCl_3$ ($\delta = 0$ ppm). ^{31}P NMR spectra were recorded at 121.50 MHz and referenced externally to 85% H_3PO_4 ($\delta = 0$ ppm). All chemical shifts are quoted in δ (ppm) and coupling constants in Hz. Abbreviations used in multiplicities are s = singlet, d = doublet, t = triplet and m = multiplet. IR spectra were recorded as Nujol mulls on a Digilab FTS40 Fourier transform spectrometer. The mass

spectrum was recorded on a V.G. Micromass 16B mass spectrometer.

Preparation of tris(2,6-difluorophenyl)phosphite (**1**)

2,6-Difluorophenol (25 g, 0.19 mol) and triethylamine (21.8 g, 0.22 mol) in THF (100 cm^3) were added during 2 h to PCl_3 (7.9 g, 0.06 mol) in THF (200 cm^3) at 0°C. The white solid was separated by filtration and washed with THF (150 cm^3). The filtrate and washings were combined and the solvent removed by rotary evaporation to give a pale yellow oil, which was dried *in vacuo* affording impure product as an off-white solid. No attempts were made to purify **1** as it was found to be amenable for further reactions. Yield 12.85 g (51%). ^1H NMR ($CDCl_3$): δ 6.96 (m, 3H, *para*); 6.91 (m, 6H, *meta*). ^{31}P-{^1H} ($CDCl_3$): δ 131.79 [septet, $^4J(PF) = 34.2$ Hz]. ^{19}F-{^1H} ($CDCl_3$): δ −126.50 [d, $^4J(PF) = 34.2$ Hz]. ^{13}C ($CDCl_3$): δ 154.79 [dd, $^1J(CF) = 249.7$ Hz, $^2J(CH) = 11.6$ Hz, *ortho*]; 127.82 [t, $^2J(CF) = 15.8$ Hz, *ipso*]; 124.00 [dt, $^1J(CH) = 166.0$ Hz, $^3J(CF) = 8.4$ Hz, *para*]; 111.82 [ddd, $^1J(CH) = 166.0$ Hz, $^2J(CF) = 22.0$ Hz, $^2J(CH) = 7.5$ Hz, *meta*]. Mass spectrum *m/z* (%): 420 (0.5), 419 (4.4), 418 (22.0) [{$P(OC_6H_3F_2)_3$}$^+$]; 291 (0.6), 290 (7.7), 289 (56.0) [{$P(OC_6H_3F_2)_2$}$^+$]; 132 (0.5), 131 (6.5), 130 (100) [$(OC_6H_3F_2)^+$]. IR (cm^{-1}, Nujol mull): 2983 (w), 2864 (w), 1604 (m), 1560 (w), 1502 (s,br), 1296 (s), 1244 (m), 1201 (s), 1148 (w), 1064 (m), 1013 (s), 916 (m), 870 (s), 775 (s), 748 (s), 721 (m), 653 (w), 574 (w), 501 (w).

Preparation of η^5*-pentamethylcyclopentadienyldichloroiridiumtris(2,6-difluorophenyl)phosphite* (**2**)

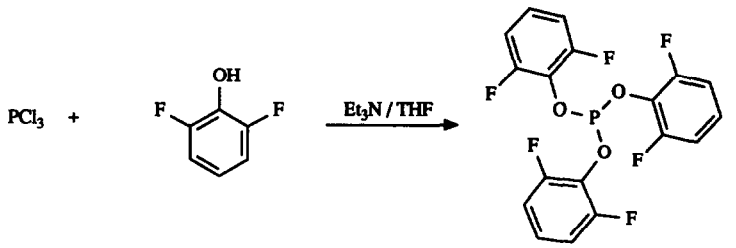
A slurry of $[Cp^*IrCl_2]_2$ (0.10 g, 0.13 mmol) and **1** (0.20 g, 0.48 mmol) in benzene (50 cm^3) was heated under reflux under nitrogen for 2 h. The orange solution was allowed to cool and concentrated by rotary evaporation. Hexane (30 cm^3) was added to afford, on further concentration, a yellow solid. The solid was filtered, washed with hexane (4 × 10 cm^3) and dried *in vacuo*. Yield 0.19 g (90%). Found: C, 41.8; H, 2.8; Cl, 7.8. Calc. for $\{\eta^5\text{-}C_5(CH_3)_5\}IrCl_2\{P(OC_6H_3F_2)_3\} \cdot 1/6\ C_6H_6$: C, 42.0; H, 3.0; Cl, 8.55%. ^1H NMR ($CDCl_3$): 7.37 (s, C_6H_6); 7.03 (m, 3H, *para*); 6.85 (m, 6H, *meta*); 1.81 [d, $J(PH) = 4.0$ Hz, 15H, CH_3]. ^{31}P-{^1H} ($CDCl_3$): 62.80 (m). ^{19}F-{^1H} ($CDCl_3$): −123.07 [d, $^4J(PF) = 3.1$ Hz]. IR (cm^{-1}, Nujol mull): 1606 (m), 1568 (w), 1501 (s), 1480 (m), 1452 (sh), 1378 (m), 1300 (s), 1247 (w), 1229 (w), 1205 (m), 1198 (m), 1150 (w), 1009 (s), 932 (s), 912 (s), 790 (m), 765 (m), 759 (s), 727 (w), 662 (w), 645 (w), 575 (w), 514 (w).

Crystal structure determination

Crystals suitable for a single crystal X-ray crystallographic study were obtained by slow evaporation of solvent from a solution of complex **1** in $CDCl_3$. A crystal with dimensions 0.7 × 0.12 × 0.28 mm was glued to the end of a thin glass fibre using epoxy resin. Unit cell parameters were determined by least squares refinement of omega angles from 24 centred reflections with $15 < 2\theta < 25°$. Intensities of 6083 reflections in the range $4 < 2\theta < 51.7°$ and $-1 \leqslant h \leqslant 11$, $-1 \leqslant k \leqslant 12$, $-27 \leqslant l \leqslant 27$ were measured on a Siemens P4 Diffractometer using a $\theta/2\theta$ technique and graphite monochromated Mo-K_α radiation. No crystal decay was detected from periodically measured check reflections. The data were corrected for Lorentz and polarization effects. The reflections merged to a unique data set of 4380 reflections ($R_{int} = 2.38\%$) with 3205 having $I > 2\sigma(I)$ regarded as observed. An absorption correction was applied to the data set, maximum and minimum transmission factors 0.422 and 0.305, respectively. Crystal data for **2**: $[C_{28}H_{24}Cl_2F_6IrO_3P]$, $M_r = 816.2$, monoclinic, $P2_1/c$, $a = 10.311(2)$, $b = 11.203(2)$, $c = 24.328(5)$ Å, $\beta = 92.13(3)°$, $V = 2808.3(14)$ Å^3, $Z = 4$, $D_{calc} = 1.931$ g cm^{-3}, λ(Mo-K_α) = 0.71073 Å, $\mu = 48.55$ cm^{-1}, $F(000) = 1584$, $T = 293$ K. Structure solution by Patterson methods and refinement were carried out using the SHELXTL-PC programme package.[2] All hydrogen atoms were included in calculated positions (C—H = 0.95 Å) with a common fixed isotropic thermal parameter (0.08 Å^2). All non-hydrogen atoms were refined as anisotropic. Final $R = 0.0336$ and $R_w = 0.0333$, $w = [\sigma^2(F) + 0.0010F^2]^{-1}$, for the 368 parameters refined with largest Δ/σ 0.018. Maximum and minimum peak heights in the difference Fourier map were +0.91 and −0.45 e Å^{-3}. An analysis of the weighting scheme over $|F_o|$ and $\sin\theta/\lambda$ was satisfactory.

RESULTS AND DISCUSSION

Treatment of PCl_3 with 2,6-difluorophenol in the presence of triethylamine yielded impure tris(2,6-difluorophenyl)phosphite, **1**, in *ca* 50% yield as an off-white solid which decomposes slowly in the presence of moisture (Scheme 1). Phosphite **1** was characterized by mass spectrometry, and NMR and IR spectroscopies. In particular the ^{31}P-{^1H} NMR spectrum exhibits a septet at δ 131.79 with a coupling constant, $^4J(PF)$, of 34.2 Hz, and the ^{19}F-{^1H} NMR spectrum exhibits a doublet at δ −126.50 with the same coupling constant. The value of



Scheme 1.

^4J(PF) is similar to those of ^3J(PF) for *ortho*-fluorine containing phenylphosphines.[3]

η^5-Pentamethylcyclopentadienyldichloroiridium dimer was treated with an excess of tris(2,6-difluorophenyl)phosphite in refluxing benzene. Concentration of the orange solution and addition of hexane yielded complex **2** as a yellow, air-stable, microcrystalline solid, containing 1/6 mole of solvent of crystallization, in 90% yield. The product was characterized by elemental analysis, and NMR and IR spectroscopies. The ^{31}P-{^{1}H} NMR spectrum, recorded in $CDCl_3$, exhibits a multiplet at δ 62.80, and the ^{19}F-{^{1}H} NMR spectrum exhibits a doublet at δ −123.07 with a coupling constant, ^4J(PF), of 3.1 Hz. This value is significantly lower than ^4J(PF) for the uncomplexed phosphite. This is consistent with the fact that values of ^3J(PF) coupling constants for uncomplexed *ortho*-fluorine containing phenylphosphines are significantly larger than those of the complexed phosphines.[3]

The molecular structure of complex **2** is shown in Fig. 1. The geometry of $Cp^*IrCl_2\{P(OC_6H_3F_2)_3\}$ about the iridium atom is that of a three-legged piano stool with the Ir—P and Ir—Cl bonds being almost orthogonal, as found for $Cp^*IrCl_2(PMe_3)$[4] and the isocyanide complex $Cp^*IrCl_2(CNR)$ (R = $C_5H_5(OCOCH_3)_4O$).[5] Selected bond distances and angles are given in Table 1. The Ir—C distances range from 2.166(8) to 2.247(9) Å with an average of 2.195 Å, which is close to that of 2.194 Å in $Cp^*IrCl_2(CNR)$ and intermediate between those of 2.13 and 2.23 Å for $[Cp^*IrCl(\mu\text{-}Cl)]_2$[6] and $Cp^*IrCl_2(PMe_3)$, respectively. The Ir—Cl distances of 2.363(3) and 2.376(3) Å are slightly shorter than those of $Cp^*IrCl_2(CNR)$ [2.389(6) and 2.391(5) Å] and $Cp^*IrCl_2(PMe_3)$ [2.37(1) and 2.39(1) Å]. The $C(sp^2)$—$C(sp^2)$ distances [1.416(13) to 1.441(12) Å], $C(sp^2)$—$C(sp^3)$ distances [1.471(13) to 1.505(12) Å], internal C—C—C angles [105.6(8) to 110.1(7)°] and C—C—CH_3 angles [123.1(8) to 128.0(8)°] of the Cp* ring are consistent with those of $Cp^*IrCl_2(CNR)$; $Cp^*IrCl_2(PMe_3)$ and $[Cp^*IrCl]_2(\mu\text{-}H)(\mu\text{-}Cl)$.[6] The Ir—P bond distance of 2.211(2) Å is shorter than that of $Cp^*IrCl_2(PMe_3)$ by 0.07 Å. This is consistent with the π-bonding capability of phosphites being greater than that of phosphines.[7]

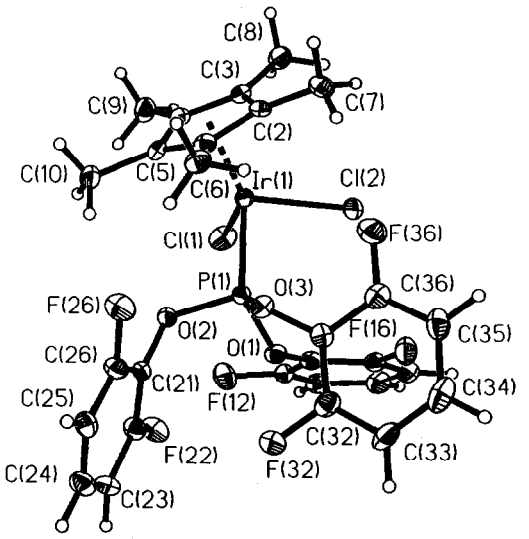


Fig. 1. Molecular structure of $Cp^*IrCl_2\{P(OC_6H_3F_2)_3\}$, **2**.

The coordination about the phosphorus atom may be described as distorted tetrahedral with significant distortions from C_3 symmetry about the axis along the Ir—P bond. The three Ir—P—O angles differ greatly, ranging from 109.2(2) to 126.2(2)°. The three O—P—O angles are similar, but the P—O—C angles range from 125.4(5) to 133.7(5)°, such that the greater than Ir—P—O angle the greater the respective P—O—C angle. All three P—O distances are close to 1.60 Å, and the O—C distances are *ca* 1.38 Å. The C—C bond distances of the phenyl rings range from 1.343(15) to 1.381(12) Å. The O—C—C angles are all slightly greater than 120° with concomittant smaller C—C(O)—C angles. The C—F bond distances range from 1.323(12) to 1.355(11) Å. These values can be compared to those of the iridium(III) triphenylphosphite complex, $IrCl\{P(OPh)_2OC_6H_4\}_2\{P(OPh)_3\}$[8] in which the non-*ortho*-metallated phosphite shows only small deviations from local C_{3v} symmetry about the phosphorus atom. The Ir—P—O angles of the triphenylphosphite ligand are all *ca* 114°, the O—P—O angles of

[a] ESDs are given in parentheses.
[b] Centroid.

105.5, 102.9 and 105.4° are significantly greater than those of complex **2**, and the P—O—C angles are 128.5, 129.2 and 126.4°. All the O—C—C bond angles are significantly less than 120°, ranging from 114.4 to 119.1°. Thus there are significant differences in the geometries about the phosphorus and oxygen atoms between triphenylphosphite and tris(2,6-difluorophenyl)phosphite coordinated to iridium(III) centres, in particular the Ir—P—O and P—O—C angles. These differences cannot be ascribed solely to the differences between the iridium(III) centres, and are, at least in part, due to the steric and electronic properties bestowed upon the phenyl rings by the *ortho*-fluorine atoms. This is corroborated by the structure of $Cp^*IrCl_2(PMe_3)$, where the Cp^*IrCl_2 moiety does not cause deviations from local C_{3v} symmetry about the phosphorus atom [P—C bond distances are 1.84(3), 1.86(3) and 1.83(4) Å, and the corresponding Ir—P—C bond angles are 113(1), 114(1) and 115(1)°, respectively].[4]

In summary the iridium(III) complex, **2**, has been prepared from the new fluorine containing ligand, tris(2,6-difluorophenyl)phosphite, **1**, and its structure has been determined by single crystal X-ray crystallography. There are significant differences between tris(2,6-difluorophenyl)phosphite and triphenylphosphite coordinated to iridium(III) centres, which are due to the presence of the *ortho*-fluorine atoms.

(*Received* 21 *April* 1993; *accepted* 15 *July* 1993)

Abstract—Mixed ligand ethylenediaminecopper(II) perchlorate complexes, [Cu(en)LL$(H_2O)](ClO_4)_2$, en = ethylenediamine and LL stands for 2,2′-bipyridine (bipy), 1,10-phenanthroline (phen), and *N,N,N′,N′*-tetramethylethylenediamine (tmen), have been prepared and characterized by elementary analyses, and electronic, vibrational, and EPR spectroscopic measurements. The crystal and molecular structures of [Cu(en)(bipy)$(H_2O)](ClO_4)_2$ (**1**) and [Cu(en)(phen)$(H_2O)](ClO_4)_2$ (**2**) have been determined from single-crystal, three-dimensional X-ray diffraction data. Both complexes, crystallized in triclinic $P\bar{1}$ group, contain discrete copper(II) cations having a CuN_4 basal plane and a H_2O on the apex. A similar structure was suggested for [Cu(en)(tmen)$(H_2O)](ClO_4)_2$ (**3**). The single-crystal polarized electronic spectra of **1** and **2** were measured and resolved into a set of three Gaussian component peaks for each spectrum. Gaussian analyses performed on the crystal and the powder LF bands for these complexes yielded a one-electron orbital sequence $d_{xy} > d_{z^2} > d_{x^2-y^2} > d_{yz} > d_{xz}$. Bonding properties of the bidentate ligands are elucidated suggesting virtually no π-interactions between the heterocyclic diimine ligands and the central copper(II) ion in these ethylene–diamine complexes.

The complexity of copper(II) stereochemistry has been well documented,[1] and many factors,[2–4] such as ligand field stabilization energies, the Pauling electroneutrality principle, the Jahn–Teller effect, semicoordination, counter ion effects, steric effects, etc., have been invoked to account for the complicated structures of copper(II) complexes. Basically, the energies of the frontier orbitals, which result from coordination of ligands, can reflect the bond strengths and the geometries of the complexes. It is, therefore, valuable to examine the bonding properties of ligands in order to correlate with the stereo-chemistry of the complexes.

Usually, the donor abilities of ligands may be

* Author to whom correspondence should be addressed.

estimated from their pK_a values. However, this often suffers from considerable interference, for instance, the potential π-interactions between the central metal ion and ligands, and the steric congestion between ligands. In addition, it is even more difficult to evaluate the extent of π-interactions. Because the layout of *d* orbitals is a direct response of the strengths of the metal–ligand bonds, it is anticipated that the bonding abilities of ligands, namely, the σ- and π-bonding capabilities, may be elucidated from the energies of the corresponding d_σ and d_π orbitals of the complexes, provided that the structures of the complexes are analogous. Herein, we report the molecular and electronic structures of two mixed ligand ethylenediamine and heterocyclic diimine copper(II) complexes, **1** and **2**, and discuss their bonding properties.

EXPERIMENTAL

Materials and preparations

Ethylenediamine (Fluka), 2,2′-bipyridine (Sigma), 1,10-phenanthroline (Sigma), *N,N,N′,N′*-tetramethylethylenediamine (Aldrich), $Cu(ClO_4)_2 \cdot 6H_2O$ (Aldrich), and organic solvents were used as received. Bis(ethylenediamine)copper(II) diperchlorate[5] was prepared according to the cited literature. The diimine complexes were prepared by the following procedure: to a MeOH solution of $Cu(ClO_4)_2 \cdot 6H_2O$, a stoichiometric amount of the heterocyclic diimine ligand in MeCN was added. After stirring for 30 min, a stoichiometric amount of ethylenediamine in MeCN was added dropwise. The reaction mixture was stirred at room temperature for 3 h. Ether was added to give the blue 2,2′-bipyridine complex, which was further recrystallized from MeCN and ether. For the 1,10-phenanthroline complex, the blue product was obtained from the concentrated reaction mixture, and recrystallized from MeCN. $[Cu(en)(tmen)(H_2O)](ClO_4)_2$[6] (**3**) was prepared by adding a stoichiometric amount of MeOH solution containing equal molar tmen and en to a MeOH solution of $Cu(ClO_4)_2 \cdot 6H_2O$. The blue solids were filtered and washed with ether and dried *in vacuo* over P_4O_{10}.

$[Cu(en)(bipy)(H_2O)](ClO_4)_2$ (**1**), Yield 55%, m.p. 268°C. Found: C, 29.8; H, 3.2; N, 11.4. Calc. for $C_{12}H_{18}N_4O_9Cl_2Cu$: C, 29.0; H, 3.6; N, 11.3%.

$[Cu(en)(phen)(H_2O)](ClO_4)_2$ (**2**), Yield 48%, m.p. 278°C (dec.). Found: C, 32.4; H, 3.2; N, 10.8. Calc. for $C_{14}H_{18}N_4O_9Cl_2Cu$: C, 32.3; H, 3.5; N, 10.8%.

$[Cu(en)(tmen)(H_2O)](ClO_4)_2$ (**3**), Yield 42%, m.p. 180°C (dec.). Found: C; 20.1; H, 5.3; N, 12.4. Calc. for $C_8H_{26}N_4O_9Cl_2Cu$: C; 20.2; H, 5.9; N, 11.8%.

Single crystals suitable for X-ray structure determination were obtained by diffusion of ether into an MeCN solution of complex **1**, and by slow evaporation of an MeCN solution of complex **2**. Crystals suitable for polarized LF spectroscopic measurements were grown by slow crystallization from MeCN between quartz plates.

Physical measurements

Perkin–Elmer lambda 9 and Jasco model 7850 spectrophotometers were used for electronic spectra measurements. Spectra of solid samples were recorded as Nujol mulls on Whatman No. 1 filter paper. The deconvolution of visible spectra into Gaussian component bands was performed on a VAX 6510 computer using the profile-fitting program CUVFIT.[7] The single crystal polarized spectra were recorded at ambient temperature using a Hitachi model 3501 spectrophotometer. The light was polarized with a Glan–Thompson polarizer. Both complexes **1** and **2** had the (001) plane well developed. This was checked by X-ray precession measurements on the crystals, and by trying several possible faces and performing the calculation for each possibility. The extinction directions for the faces were found to lie at angles of $+26.4°$ and $-63.6°$ to the *a* axis for **1** and $+21.3°$ and $-68.7°$ to the *a* axis for **2**. The positive sign corresponds to a rotation of the electric vector into the quadrant containing an obtuse angle. Epr spectra were obtained by using a Bruker ER 200D model spectrometer and calibrated with DPPH (g = 2.0037). IR spectra were recorded as Nujol mulls or KBr pellets on a BIO–RAD FTS-40 FTIR. A Micro VAX II computer-controlled Siemens R3m/V diffractometer was used for crystal and molecular structure determination. Elemental analyses were carried out by the microanalysis laboratories of Taiwan University, Taipei.

Structure determination and refinement

Details of crystal data and intensity collection are summarized in Table 1. Nineteen independent reflections with $11.23° \leqslant 2\theta \leqslant 30.98°$ for complex **1** and thirteen with $13.56° \leqslant 2\theta \leqslant 26.39°$ for complex **2** were used for least-squares determination of the cell constants. Diffractometer examination of the reciprocal lattice revealed no systematic absences. Intensity data [$\theta/2\theta$ scan, $2.5° \leqslant 2\theta \leqslant 50.0°$, $(\sin\theta/\lambda)_{max} \simeq 0.6$] were corrected for Lorentz and polarization effects but not for absorption. Three standard reflections were

monitored every 50 reflections and showed no signs of crystal deterioration. The structures were solved by direct methods using SHELXTL PLUS program[8] and refined by full-matrix least-squares on F values. Scattering factors and anomalous dispersion correction terms were taken from the *International Tables for X-ray Crystallography*.[9] The quantity minimized was $\Sigma w(K|F_o| - |F_c|)^2$, with $w = [\sigma^2(F_o) + gF_o^2]^{-1}$, where $g = 0.0017$ for complex **1**, and 0.0024 for complex **2**. All hydrogen atoms included in the refinement were placed in idealized positions (C—H = 0.96 Å, H—C—H = 109.4°) with a fixed U (0.08 Å^2) after the non-hydrogen atoms were refined anisotropically. All calculations were done on a Micro Vax II-based Nicolet SHELXTL PLUS system. Additional material deposited comprises structure factors, atomic coordinates, anisotropic thermal parameters, H atom coordinates, and a full list of bond lengths and angles.

RESULTS AND DISCUSSION

Description of the structures

The molecular and crystal structures of complexes **1** and **2** are shown in Figs 1–4. Selected bond lengths and angles are listed in Table 2. The structures of **1** and **2** consist of ClO_4^- anions and discrete square-pyramidal $CuN_4(H_2O)^{2+}$ cations

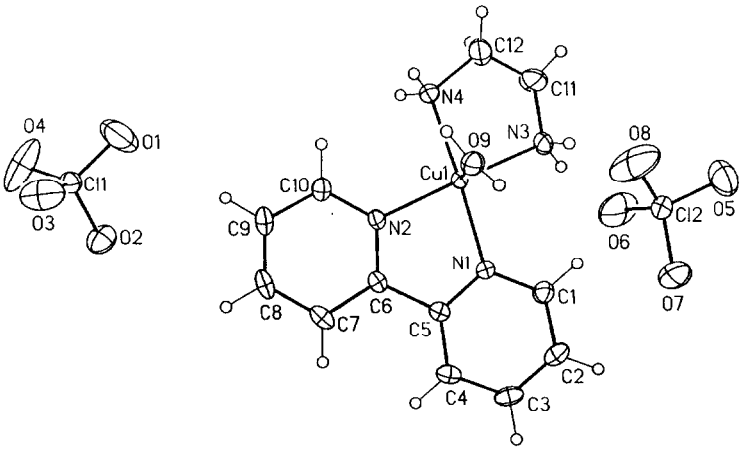

Fig. 1. Molecular structure of $[Cu(en)(bipy)(H_2O)](ClO_4)_2$ with numbering scheme.

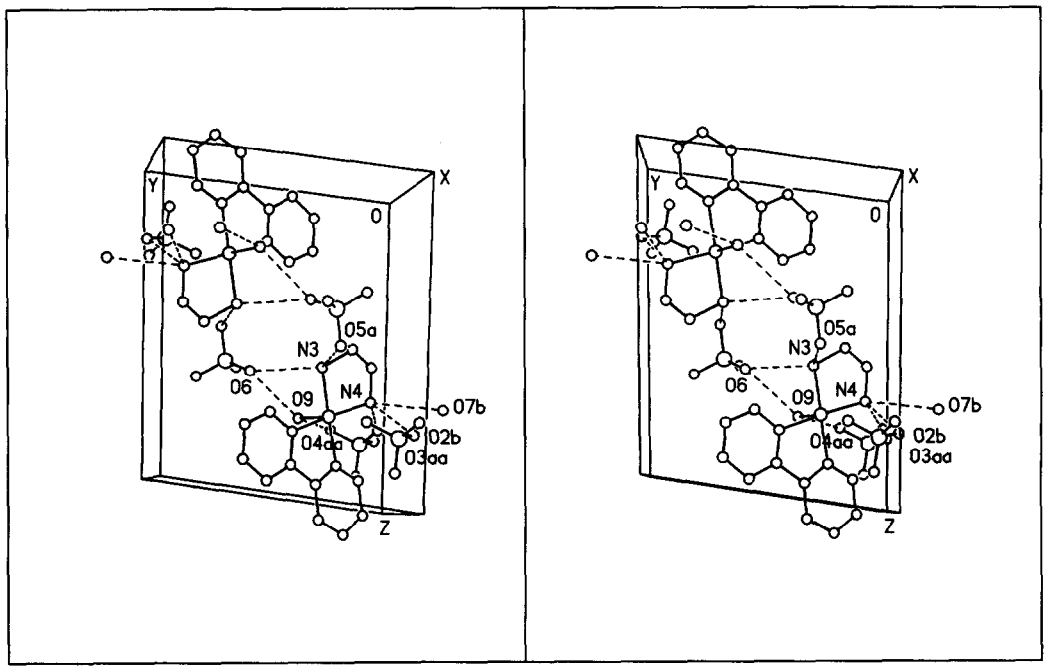

Fig. 2. Stereoscopic drawing of the molecular packing of $[Cu(en)(bipy)(H_2O)](ClO_4)_2$ in the unit cell. Hydrogen bonds: N(3)···O(5a), 3.207 Å, N(3)···O(6), 3.103 Å, N(4)···O(2b), 3.031 Å, N(4)···O(3aa), 3.006 Å, N(4)···O(7b), 3.015 Å, O(9)···O(6), 3.090 Å and O(9)···O(4aa), 3.037 Å.

with one ethylenediamine and one heterocyclic diimine ligand forming the basal plane and a water molecule on the apex [**1**, 2.435(4) Å; **2**, 2.393(3) Å]. Although one of the perchlorate anions is geometrically oriented for potential axial Cu—$OClO_3$ bonding, the shortest Cu—O distance is greater than 2.7 Å, and the axial bonding is considered to be absent. The CuN_4 units are nearly coplanar; the copper atom lies above (**1**, 0.1312 Å, **2**, 0.0772 Å) toward the H_2O. The ethylenediamine ligands bind to the central copper atom with Cu—N distances of ~ 2.0 Å and the N—Cu—N bite angle of ~ 85°, which are typical for ethylenediamine copper(II) complexes.[5,10–12] Disorder on the ethylene carbons of the en chelate is apparent and has been successfully modelled with the presence of both δ and λ conformations to give normal bond lengths and angles. The Cu—N distances of ~ 2.02 Å and the bite angles of ~ 81° of the bipy and phen ligands are close to the average values for bipy[13–15] and

phen[16,17] copper(II) complexes. The dimensions of the heterocyclic ligands are normal. The perchlorate ions appear to be loosely held in lattice holes by Coulombic forces and by weak hydrogen bonds to the water hydroxyl and ethylenediamine N—H groups as shown in Figs 2 and 4. The perchlorate bond distances and angles are in the normal ranges. Note that the molecules of both complexes are packed in nearly the same orientations in the unit cells with $P\bar{1}$ space group.

IR, EPR, and LF spectra of en—Cu(II) *complexes*

The IR spectral data are listed in Table 3. The appearance of two relatively sharp O—H stretchings in the region of ~ 3550 cm^{-1} is consistent with the structures of complexes **1** and **2** having a H_2O on the apex. This also suggests a H_2O bonded to the central copper(II) ion in the tmen complex. The very strong ClO_4^- stretching in the region of ~ 1085 cm^{-1} is broad, but not very broad, for each of the three complexes, indicating that the perchlorate anions are not coordinated to the central copper(II) ion in these complexes. Since both en and tmen are much stronger ligands than H_2O, it is conceivable that the structure of the tmen complex is a five coordinate square-pyramid with an apical H_2O. The slight variation of the O—H(H_2O) and N—H(en) vibrations for these complexes is probably mainly due to the hydrogen bonds. The Cu—N(en) stretchings[18,19] are tentatively assigned in the region of 420–320 cm^{-1}, while Cu—N(LL) stretchings are at lower energy.[20–22]

The LF spectral data and the EPR parameters for the mixed ligand ethylenediamine copper(II) complexes are listed in Table 4. The mull LF spectra with λ_{max} appeared in the region of ~ 550 nm and tailing toward the long wavelength region are consistent with the square-pyramidal structure.[23] In aqueous methanol (1 : 1) solution, these complexes likely consist of tetragonal CuN_4 units with one or two H_2O molecules loosely bound on the axial positions. This is consistent with the observations that the *d–d* spectra are red-shifted by ~ 20 nm and the band envelopes are not much changed as compared with their mull spectra. The structures of the solution species are also supported by the glass EPR spectral data, measured in aqueous methanol (1 : 1) matrix at 77 K. These axial EPR spectra are characteristic of tetragonal copper(II) chromophores with CuN_4 coordination plane. The approximately 9-line nitrogen hyperfine splitting on the $g_\perp$ peaks arises from the four N donors, which appear essentially equivalent. The nearly invariant $g_\perp$ parameters for complexes **1**, **2** and **3** either in solid state or in aqueous methanol solution infer that their coordination bond properties are similar. In other words, it is likely that no out-of-plane π-interactions involve in the bipy–copper(II) and phen–copper(II) bonds.

In order to compare the energy levels of the *d* orbitals for these structurally similar mixed ligand en–copper(II) complexes, resolution of the solid state *d–d* spectra is necessary. Starting from a set of three or four trial peaks, the computer iteration processes for curve fitting were carried out until a minimum value of the reliability factor,[24] *R*, was reached. Unfortunately, two final sets with either three or four Gaussian component peaks, both with excellent fit, were obtained for these nearly featureless LF spectra. It is, therefore, necessary to investigate the single crystal polarized spectra. The sets with four Gaussian component bands for the solid state LF spectra of these complexes were

Single-crystal polarized spectra

The single-crystal polarized LF spectra for complexes **1** and **2** are very similar both in peak positions and spectral contours, and accordingly their Gaussian component bands are expected to be very much alike as shown in Figs 6 and 7. It is noteworthy that the optical densities of the parallel spectra are about five times larger than those of the perpendicular spectra in the high energy region and about twice in the low energy region. The observed extinction axes also appear in approximately the same direction for both complexes. This is in agreement with the analogy of their molecular and crystal structures, suggesting that the bonding properties of bipy and phen ligands are highly analogous. For both complexes, each of the spectra was resolved into three Gaussian component peaks with excellent fit. The reliability factors were minimized down to ~ 0.5%. However, the perpendicular spectrum for complex **1** is less reliable owing to its low intensity. Attempts to fit with two peaks were unsuccessful. Attempts to resolve the highest energy peak into two components did not improve the R values. The peak positions for the two low energy peaks are in good agreement for the parallel and the perpendicular spectra for both complexes. The highest energy peaks agree resonably well for complex **2**, but they are significantly off for complex **1**. The one at 18.9 kK in the perpendicular spectrum for complex **1** is less reliable.

The coordinate system used to discuss the spectra was defined with y lying parallel to the least-squares plane of $N_1N_2N_3N_4$ and along the vector from the central copper atom to the midpoint of the two nitrogen atoms of the heterocyclic chelate ring, with x orthogonal to y and lying in the least-squares plane through the copper atom, and with z orthogonal to x and y toward the water oxygen atom.

The molecular projections made by a unit electric vector along the extinction directions in the (001) face for each spectrum were calculated. The optical densities of the parallel and perpendicular crystal spectra can be equated to the sum of the molecular projections squared time the extinction coefficients in the molecular coordinate system (eqs 1–4), where the transformation matrices for a vector in crystal

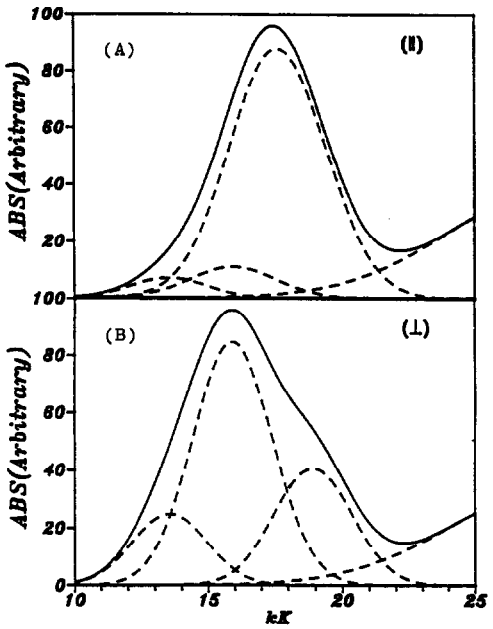

Fig. 6. The polarized spectrum of the (001) face of $[Cu(en)(bipy)(H_2O)](ClO_4)_2$ with the electric vector (A) 26.4° from the a axis and (B) −63.6° from the a axis.

coordinates into molecular coordinates are:

$$\begin{bmatrix} x \\ y \\ z \end{bmatrix} = \begin{bmatrix} 0.6600 & 0.7361 & -0.5490 \\ -0.2028 & -0.2419 & -0.7096 \\ -0.7230 & 0.6320 & 0.4415 \end{bmatrix} \begin{bmatrix} a \\ b \\ c \end{bmatrix}$$

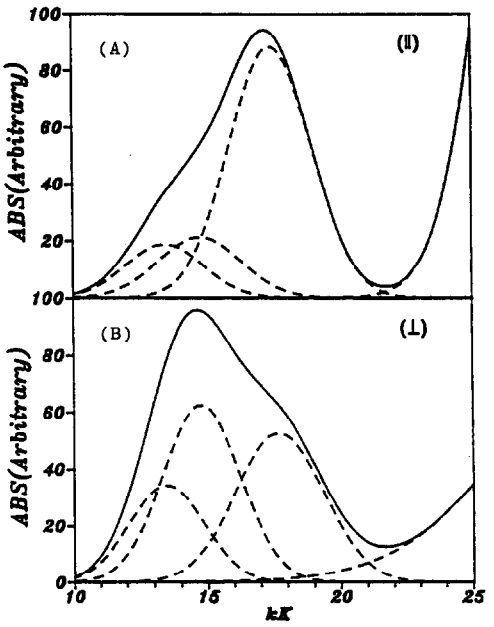

Fig. 7. The polarized spectrum of the (001) face of $[Cu(en)(phen)(H_2O)](ClO_4)_2$ with the electric vector (A) 21.3° from the a axis and (B) −68.7° from the a axis.

and

$$\begin{bmatrix} x \\ y \\ z \end{bmatrix} = \begin{bmatrix} -0.4955 & -0.7120 & 0.4415 \\ 0.0584 & 0.3040 & 0.7278 \\ 0.8043 & -0.6334 & -0.5255 \end{bmatrix} \begin{bmatrix} a \\ b \\ c \end{bmatrix}$$

for **1** and **2**, respectively.

$$0.5928\varepsilon_x + 0.0401\varepsilon_y + 0.4142\varepsilon_z = \mathrm{OD}(//)(\mathbf{1}), \quad (1)$$

$$0.3730\varepsilon_x + 0.0777\varepsilon_y + 0.5329\varepsilon_z = \mathrm{OD}(\perp)(\mathbf{1}), \quad (2)$$

$$0.9375\varepsilon_x + 0.0928\varepsilon_y + 0.1790\varepsilon_z = \mathrm{OD}(//)(\mathbf{2}), \quad (3)$$

$$0.2178\varepsilon_x + 0.0248\varepsilon_y + 0.6287\varepsilon_z = \mathrm{OD}(\perp)(\mathbf{2}). \quad (4)$$

Because the crystal spectra were measured in only one face, transformation of the crystal spectra into molecular spectra[25] was not performed. Inspection of the values of the molecular projections reveals that the parallel spectra are mainly x polarized for both complexes, while the perpendicular spectra are mainly z polarized with some extent of x polarization. This is in agreement with the observed polarized spectra assuming an effective symmetry of C_{2v} for both complexes.

The molecules have C_s symmetry, but the contours of the powder spectra having high intensity in the high energy region suggest the symmetry must be higher to C_{2v} group. The ground state in this point group is $A_2(d_{xy})$. The only allowed d–d transitions by a static electric dipole mechanism are $A_2(d_{xy}) \leftarrow B_2(d_{xz})$ in y polarization and $A_2(d_{xy}) \leftarrow B_2(d_{yz})$ in x polarization. The intense component appeared in the parallel spectra at 17.6 kK for both **1** and **2** can be assigned as $A_2(d_{xy}) \leftarrow B_2(d_{yz})$ and the highest energy peak in the perpendicular spectra at 17.7 kK for **2** also as $A_2(d_{xy}) \leftarrow B_2(d_{yz})$. The peak at 18.9 kK, which is not reliable, must be assigned as $A_2(d_{xy}) \leftarrow B_2(d_{yz})$ in accordance with the above analysis. The two low energy peaks with low intensities are assigned as the statically forbidden $A_2(d_{xy}) \leftarrow A_1(d_{z^2})$ and $A_2(d_{xy}) \leftarrow A_2(d_{x^2-y^2})$ transitions. The sequence of the d orbitals is therefore suggested as $d_{xy} > d_{z^2} > d_{x^2-y^2} > d_{yz}$, where d_{xz} is not observed.

Inspecting the Gaussian components of the crystal and the powder spectra for complexes **1** and **2**, the agreement in peak positions and contours is striking. For the powder spectra, two intense peaks were resolved in the high energy region for the bipy and the phen complexes, corresponding to the d_{yz} and d_{xz} orbitals, and two small peaks as d_{z^2} and $d_{x^2-y^2}$ in the low energy region. The spectra agree with C_{2v} local symmetry and the coordinate system mentioned above for complexes **1** and **2**. The sequence of the d orbitals is $d_{xy} > d_{z^2} > d_{x^2-y^2} > d_{yz} > d_{xz}$.

Since the symmetry group for the tmen complex is similar to that of complexes **1** and **2** and there are also two intense high energy component peaks and two weak low energy peaks for the tmen complex, an effective symmetry of C_{2v} is again appropriate for this square-pyramidal complex and the sequence of the d orbitals is suggested to be $d_{xy} > d_{z^2} > d_{x^2-y^2} > d_{yz} > d_{xz}$.

Finally, it is interesting to consider the energy levels for these complexes. Note that the energy differences between the d_{xz} and the d_{yz} orbitals are nearly the same for the tmen complex and the bipy and the phen complexes, indicating that they are of non-bonding orbitals and are resulted from the geometries of the complexes. Should there by π-interactions between the d_{yz} orbitals and the π-orbitals of the bipy and phen ligands, the d_{yz} orbitals should be ascended or descended with respect to that of the tmen complex, where no π-interaction is possible. We therefore conclude no π-interactions in the bipy–copper(II) and phen–copper(II) bonds in these square-pyramidal complexes. This could be ascribed to the large energy separation between the ligand π orbitals and the copper d_{yz} orbital.

(*Received* 16 *June* 1993; *accepted* 12 *July* 1993)

Abstract—Three new trinuclear copper(II) complexes were synthesized: {[(ettmd)Cu]$_2$[μ-Cu(pba)]}(ClO$_4$)$_2$ (**1**), {[(pmd)Cu]$_2$[μ-Cu(Me$_2$pba)]}(ClO$_4$)$_2$·3H$_2$O (**2**) and {[(bapa)Cu]$_2$[μ-Cu(Me$_2$pba)]}(ClO$_4$)$_2$ (**3**) where Cu(pba) = 1,3-propanediyl-bis(oxamato)cuprate(II), Cu(Me$_2$pba) = 2,2-dimethyl-1,3-propanediyl-bis(oxamato)cuprate(II), ettmd = 4-ethyl-1,1,7,7-tetramethyldiethylenetriamine; pmd = N,N,N′,N″, N″-pentamethyldiethylenetriamine, bapa = bis(3-aminopropyl)amine. The structures of compounds **1**, **2** and **3** were determined by X-ray analysis. The crystals of **1** are monoclinic, space group $P2_1/c$, with a = 18.463(4), b = 14.402(3), c = 16.537(4) Å, β = 109.00(3)°, Z = 4 and R = 0.072 for 2447 reflections observed. The crystals of **2** are triclinic, space group $P\bar{1}$, with a = 19.610(4), b = 16.626(4), c = 16.007(3) Å, α = 115.75(3)°, β = 89.97(3)°, γ = 100.86(4)°, Z = 4 and R = 0.068 for 7342 reflections observed. The crystals of **3** are orthorhombic, space group *Pcba*, a = 40.492(4), b = 16.363(3), c = 10.944(3) Å, Z = 8 and R = 0.034 for 1634 reflections observed. The central copper(II) ions of compounds **1** and **2** are square-pyramidal, the apical positions being occupied by a perchlorate anion. In **3** the central copper ion is square-planar. The terminal copper ions of compounds **1**, **2** and **3** are all pentacoordinated with geometries that are intermediate between square-pyramidal and trigonal-bipyramidal. If the coordination is described in terms of square-pyramidal geometry, the basal plane of each terminal copper atom is approximately perpendicular to the basal plane of the central copper ion. The distortion towards trigonal-bipyramidal geometry is largest for compound **1** and smallest for **3**. Magnetic susceptibility measurements were carried out for this series of complexes. The magnetic data were interpreted using the Heisenberg Hamiltonian and led to J values of −137.1, −128.1 and −92.1 cm^{-1} for **1**, **2** and **3**, respectively. The intensity of the magnetic coupling is discussed in terms of the relative orientation of magnetic orbitals.

Magneto-structural correlations in binuclear copper(II) complexes have been exhaustively investigated[1–5] in the last two decades. It is now well established that $C_2X_2Y_2$ (X, Y = O, N, S) ligands are efficient in propagating the magnetic interaction when they bridge two copper(II) centres, giving antiferromagnetic coupling. It has been shown in binuclear systems that it is possible to tune the magnitude of the interaction by retaining the same bridging ligand and changing only the terminal ones.[2c,3d] In comparison, the literature on magnetic properties of trinuclear systems is rather limited.[6] We have recently studied the influence of terminal ligands on the magnitude of the magnetic exchange

* Author to whom correspondence should be addressed.

interaction through the oxamato bridge in trinuclear copper(II) complexes.[7] With tridentate amine as terminal blocking ligand, the tendency to have bpt or sqp geometry according to the bulkiness of the N-substituents allows us to correlate geometry and magnetic coupling. In order to improve the magneto-structural correlations already found, we have undertaken the synthesis and characterization of new complexes with different terminal tridentate amine ligands, and also with a slightly different central copper(II) ligand. We now present the study of three new trinuclear compounds structurally characterized: $\{[(ettmd)Cu]_2[\mu\text{-}Cu(pba)]\}(ClO_4)_2$ (**1**), $\{[(pmd)Cu]_2[\mu\text{-}Cu(Me_2pba)]\}(ClO_4)_2\cdot 3H_2O$ (**2**) and $\{[(bapa)Cu]_2[\mu\text{-}Cu(Me_2pba)]\}(ClO_4)_2$ (**3**) where Cu(pba) = 1,3-propanediyl-bis(oxamato)cuprate(II), $Cu(Me_2pba)$ = 2,2-dimethyl-1,3-propanediyl-bis(oxamato) cuprate(II), ettmd = 4-ethyl-1,1,7,7-tetramethyldiethylenetriamine; pmd = N,N,N′,N″,N″-pentamethyldiethylenetriamine, bapa = bis(3-aminopropyl)amine.

EXPERIMENTAL

Preparation of the copper(II) complexes

The syntheses of sodium propanediylbis (oxamato)cuprate(II) hexahydrate ($Na_2[Cu(pba)]\cdot 6H_2O$) was carried out according to the literature method.[8] The 2,2-dimethyl-derivative was synthesized in a similar manner, using 2,2-dimethyl-1,3-propanediamine (Aldrich) instead of 1,3-propanediamine.

The compounds $\{[(ettmd)Cu]_2[\mu\text{-}Cu(pba)]\}(ClO_4)_2$ (**1**), $\{[(pmd)Cu]_2[\mu\text{-}Cu(Me_2pba)]\}(ClO_4)_2\cdot 3H_2O$ (**2**) and $\{[(bapa)Cu]_2[\mu\text{-}Cu(Me_2pba)]\}(ClO_4)_2$ (**3**) were synthesized as follows: 1 mmol of the tridentate amine (ettmd, pmd, bapa; Aldrich, without further purification) was added dropwise with stirring to 0.37 g (1 mmol) of copper(II) perchlorate hexahydrate dissolved in 10 cm^3 of water. The solutions turned dark blue. After some minutes, a hot solution of 0.5 mmol of $Na_2[Cu(pba)]\cdot 6H_2O$ or $Na_2[Cu(Me_2pba)]\cdot 3H_2O$ in 10 cm^3 of water was added slowly to the stirred solutions. The resulting blue mixtures were left to stand until dark blue crystals of the complexes were formed. The products were recrystallized in acetonitrile. In all cases the analytical results agree with the formulae proposed.

X-ray data collection and structure determination

Data for compounds **1**, **2** and **3** were collected on a Philips PW-1100 diffractometer, using monochromatic Mo-K_α radiation. Unit cell parameters were determined from 25 automatically centered reflections in the θ-ranges 8–12°. Intensity data were collected in the θ-ranges 2–25°, with the ω-scan technique. The total number of unique reflections recorded was 2447, 7342, and 1634 for compounds **1**, **2** and **3**, respectively. In each case the three reference reflections monitored throughout the data collection showed no significant intensity decay with time. The data were corrected for Lorentz and polarization effects.

Structure **1** was solved by direct methods, using the Multan system[9]; structures **2** and **3** by Patterson synthesis, using SHELXS program.[10] Refinements were performed by least-squares methods minimizing the function $\Sigma w||F_o|-|F_c||^2$, with $w = [\sigma^2(F_o)+k|F_o|^2]^{-1}$, where k = 0.002 for **1**, 0 for **2** and 0.0028 for **3**. The calculations were carried out with the SHELX76 computer program.[11] f,f′,f″ were taken from International Tables of Crystallography.[12] Special aspects of solution and refinement of each structure are described separately as follows.

Compound **1**. Oxygen atoms of perchlorate ions and some carbon atoms of ethyl groups are disordered, the occupancy factor was assumed to be 0.5 according to the height of the peaks of Fourier synthesis. The position of hydrogen atoms linked to carbon atoms was computed and refined with an overall isotropic temperature factor using a riding model. All non-hydrogen and non-disordered atoms were refined anisotropically. The final R factor was 0.072 ($R_w = 0.078$) for all reflections observed. Max. shift/ESD = 0.06 in z of O(102); max and min peaks in the final difference synthesis were 0.4 and −0.2 e $Å^{-3}$, respectively.

Compound **2**. The final R factor was 0.068 ($R_w = 0.074$) for all reflections observed. Number of parameters refined was 1062. Max. shift/ESD = 0.1; max and min peaks in final difference synthesis were 0.4 and −0.4 e $Å^{-3}$, respectively.

Compound **3**. 44 H atoms were computed in its position and refined with an overall isotropic temperature factor using a riding model. The final R factor was 0.034 ($R_w = 0.036$) for all reflections observed. Number of parameters refined was 438. Max. shift/ESD = 0.1; max and min peaks in final difference synthesis were 0.4 and −0.4 e $Å^{-3}$, respectively.

Crystal data for **1**. $C_{27}H_{56}Cu_3N_8O_2(ClO_4)_2$, formula weight = 978.29, monoclinic, a = 18.463(4), b = 14.402(3) c = 16.537(4) Å, β = 109.00(3)°, V = 4158(3) $Å^3$, $P2_1/c$, $D_{calc.}$ 1.562 g cm^{-3}, Z = 4, $F(000)$ = 2028.0, λ(Mo-K_α) = 0.71069, μ(Mo-K_α) = 17.78 cm^{-1}, 298 K.

Crystal data for **2**. $C_{27}H_{56}Cu_3N_8O_6(ClO_4)_2 \cdot 3H_2O$, formula weight = 1032.32, triclinic, a = 19.610(4), b = 16.626(4), c = 16.007(3) Å, α = 115.75(3)°, β = 89.97(3)°, γ = 100.86(4)°, V = 4597(3) Å^3, P-1, D_{calc} = 1.491 g cm^{-3}, Z = 4, $F(000)$ = 2148.0, λ(Mo-K_α) = 0.71069 Å, μ(Mo-K_α) = 16.17 cm^{-1}, 298 K.

Crystal data for **3**. $C_{21}H_{44}Cu_3N_8O_6(ClO_4)_2$, formula weight = 894.2, orthorhombic, a = 40.492(4), b = 16.363(3), c = 10.944(3) Å, V = 7251(4) Å^3, $Pcab$, D_{calc} = 1.638 g cm^{-3}, Z = 8, $F(000)$ = 3672.0, λ(Mo-K_α) = 0.71069 Å, μ(Mo-K_α) = 20.30 cm^{-1}, 298 K.

Physical measurements. Magnetic susceptibility of powdered samples of products **1**, **2** and **3** was measured in a 15 kG field on a MANICS-DSM8 susceptometer equipped with an Oxford Instruments liquid helium cryostat, working down to 4.2 K. The independence of the susceptibility vs the applied field was checked at room temperature for all compounds. Mercury tetrakis(thiocyanato) cobaltate(II) was used as a susceptibility standard.

RESULTS

Description of structures

The structures of compounds **1** and **3** are made up of a cationic trinuclear copper(II) unit and two perchlorate anions. The cation structures are depicted with their labelling schemes in Figs 1 and 2, respectively. For complex **2**, two very similar trinuclear units are present in the crystal net, together with three water molecules. The structure of one of the trinuclear cations with its labeling scheme is shown in Fig. 3. Main bond lengths and angles for compounds **1**, **2** and **3** are listed in Tables 1, 2 and 3, respectively.

The central copper atom of the trinuclear cations of compounds **1** and **2** have approximately square-pyramidal coordinations. In the basal plane they are surrounded by two nitrogen atoms and two oxygen atoms of the oxamato bridges. The apical positions are occupied by oxygen atoms of a perchlorate ion at 2.52 Å (compound **1**) and 2.45 Å (compound **2**, unit **A**) and 2.67 Å (compound **2**,

unit **B**). In compound **3** the central copper atom has an approximately square planar coordination, surrounded by two nitrogen atoms and two oxygen atoms of the oxamato bridge.

In all cases the terminal copper atoms are in similar environments, intermediate between trigonal-bipyramidal and square-pyramidal coordinations. In the two cases, the equatorial or basal planes, respectively, are orthogonal to the oxamato bridging groups. Deviation from these ideal geometries will be analysed immediately.

RELATIONSHIPS BETWEEN bpt AND sqp GEOMETRIES FOR TERMINAL COPPER(II) IONS

The evolution between the two geometries can be quantified using the τ parameter[13] defined as:

$$\tau = (\beta - \alpha)/60,$$

the angles α and β are defined in the above scheme. The main factor in the distortion is the variation of the α angle going from square-pyramid (sqp, $\alpha = 180°$, $\tau = 0$) to trigonal-bipyramid (bpt, $\alpha = 120°$, $\tau = 1$). The average τ for **1**, **2** and **3** are 0.45, 0.44 and 0.29, respectively. This means that complexes **1** and **2** are really intermediate between sqp and bpt and complex **3** is more pronouncedly sqp. These results agree with literature data on these tridentate amines when they coordinate copper(II) ions: the more N-substituted or the more bulky substituents, the more pronounced is the tendency to bpt geometry.

Magnetic properties

The susceptibility measurements were carried out in the 300–4.2 K temperature range. The $\chi_M \cdot T$ plots vs T are shown in Fig. 4 for all compounds. At room temperature $\chi_M \cdot T$ values are lower than expected for three uncoupled copper(II) ions (1.3 $cm^3\ mol^{-1}\ K$) and are equal to 1.03, 1.07 and 1.10 $cm^3\ mol^{-1} \cdot K$ for **1**, **2** and **3**, respectively. The $\chi_M \cdot T$ product decreases upon cooling and presents a plateau at low temperature with $\chi_M \cdot T$ values equal to 0.44, 0.47 and 0.43 $cm^3\ mol^{-1} \cdot K$ for **1**, **2** and **3**. These values are in the expected range for spin doublet states. At very low temperature, the $\chi_M \cdot T$ product of **1**, **2** and **3** decreases, indicating that an intermolecular antiferromagnetic interaction occurs in these compounds. The experimental data were fitted using the theoretical expression deduced from the following spin Hamiltonian:

$$\hat{H} = -J[\hat{S}_{T1}\hat{S}_C + \hat{S}_C\hat{S}_{T2}] + \beta\vec{H}(g_T[\hat{S}_{T1} + \hat{S}_{T2}] + g_C\hat{S}_C), \quad (1)$$

where T1 and T2 are the two terminal copper(II) ions and C the central one. In this Hamiltonian, the interaction between the terminal ions is assumed to be nil. Using the Van-Vleck formula, the sus-

ceptibility expression is given as:

$$\chi_M = \frac{N\beta^2}{kT} \cdot \frac{\frac{1}{2}\left(\frac{4g_T - g_C}{3}\right)^2 e^{-J/kT} + \frac{1}{2}g_C^2 + 5\left(\frac{2g_T + g_C}{3}\right)^2 e^{J/kT}}{2e^{-J/kT} + 2 + 4e^{J/kT}} \quad (2)$$

The different g factors of the doublet ground state and the excited doublet and quartet states are taken from Bencini and Gatteschi.[14,15] Minimizing $R = \Sigma[(\chi_M T)^{obs} - (\chi_M T)^{calc}]^2/[(\chi_M T)^{obs}]^2$ by a simplex method leads to the values listed in Table 4. For compound **2**, due to the presence of two different trinuclear entities in the unit cell, the J value corresponds to their average.

DISCUSSION

According to the literature data,[7c,16] the variation in the coupling constant J varies approximately as S^2, S being the overlap integral between the magnetic orbitals.

In the series presented here, the coordination around the central copper atoms is either 4 or 4+1. Thus, the magnetic orbitals are well described by the antibonding combination of the $d_{x^2-y^2}$ metallic orbitals with the symmetry adapted molecular orbitals of the oxamato bridge. Concerning the terminal copper atoms, the tridentate amine ligands impose five-coordination which varies between two ideal geometries, trigonal-bipyramidal and square-pyramidal, depending on the bulkiness of the substituents on the nitrogen atoms. Indeed, the bulkier the substituents, the closer the geometry is to the trigonal-bipyramid. The two extreme situations are shown in Fig. 5. In the square-pyramidal case the magnetic orbitals are located in planes orthogonal to the oxamato bridge. When the terminal ligands

Complex	J	g_C	g_T	R
1	−137.1	2.25	2.26	1.2×10^{-4}
2	−128.1	2.25	2.19	2.8×10^{-4}
3	−92.1	2.22	2.15	6.7×10^{-5}

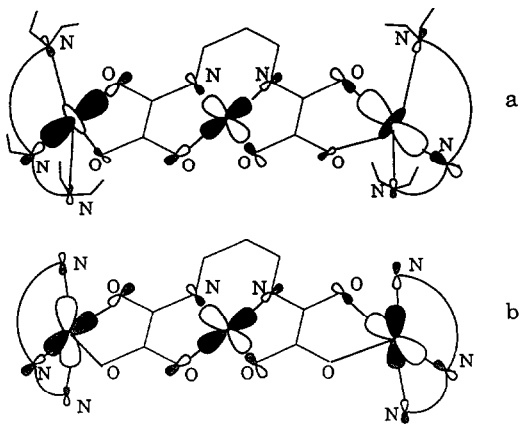

Fig. 5. Relative orientations of the magnetic orbitals when they lie in different planes with trigonal-bipyramidal coordination for both copper(II) terminal ions (a) and square-pyramidal coordination for both copper(II) terminal ions (b).

restrict the geometry in such a way that the magnetic orbitals of the three copper atoms are not in the same place or of the same type, the overlap is reduced and the extent of the interaction is small. J value should be greater when the geometry is bpt than when it is sqp. Structural data for compounds **1**, **2** and **3** present intermediate situations between the two latter cases. Despite the drastic approximation of the model, the J parameter values lie in the expected ranged. Figure 6 shows a simple linear relationship between the values of the experimental J parameter and the average values of the experimentally determined distortion parameter τ. In this figure we also show the average τ for four similar complexes previously reported[7c] together with their J values. This relation confirms that the closer the geometry of the terminal copper(II) ions is to a trigonal-bipyramid the higher is the coupling constant.

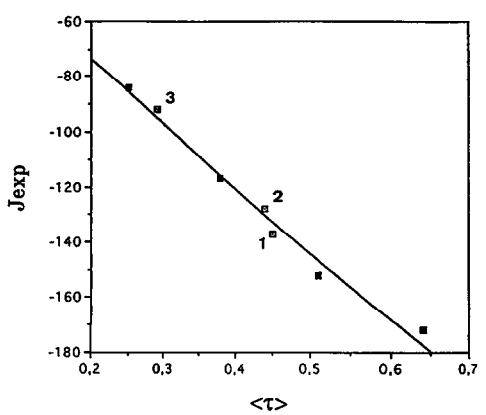

Fig. 6. Representation of the experimental J values for compounds **1**, **2** and **3** vs the average $\langle\tau\rangle$ parameters of their terminal copper(II) ions. $\langle\tau\rangle$ values of the similar complexes reported in reference 7c are also shown.

FORMATION OF AN UNUSUAL POLYMERIC 24-MEMBERED MACROCYCLIC COMPLEX OF PRASEODYMIUM(III): X-RAY CRYSTAL STRUCTURE OF $[Pr(Ph_3PAuL)_2(NO_3)_3]_n$ (L = SUCCINIMIDE ANION) AND OF ITS $(Ph_3P)AuL$ PRECURSOR

(*Received* 2 *June* 1993; *accepted* 12 *July* 1993)

Abstract—The syntheses and X-ray structures are reported of $(Ph_3P)AuL$, where L = the anion of succinimide, and of the polymeric, macrocyclic array $[Pr(Ph_3PAuL)_2(NO_3)_3]_n$. In the latter compound the Pr atoms are linked by succinimide anions, *via* Pr—O bonding, to produce sheets of fused 24-membered Pr_4L_4 rings.

A variety of gold(I) phosphine complexes exhibit oral anti-inflammatory activity; for example, (1-thio-β-D-glucopyranose-2,3,4,6-tetra-acetato-S)(triethylphosphine)gold(I), "auranofin", is effective in the treatment of rheumatoid arthritis.[1,2] It has also been demonstrated that some gold(I) compounds display anticancer activity.[3]

We have recently reported a range of novel heterometallic, Hg/M, polymeric complexes displaying a diversity of structural types, involving the formation of large metallamacrocycles. These have all included relatively simple ambidentate (N,O donor) ligands, such as β-propiolactam[4,5] (I), 2-pyrrolidone[6] (II), and 2-oxazolidone[5,7] (III). An important, but not necessarily exclusive,[8] component in such systems has been the use of mercury(II) to bind to a deprotonated ring nitrogen atom of the organic ligand, with consequent formation of an essentially linear N—Hg—N arrangement, leaving the exocyclic oxygen atoms free to bind to other metal ions.

In expanding this work, we have sought to replace mercury(II) with gold(I), keeping the other facets of the system essentially unchanged. Attempts to synthesize AuL_2^- species directly analogous to the HgL_2 units used to form the mercury(II)/M polymeric complexes, have so far proved to be unsuccessful. Gold(I) shows a much greater tendency to form complexes with sulphur and phosphorus donor ligands than with those in which O or N are the donor atoms. A correspondingly small number of N-donor complexes, especially with a linear N—Au—N arrangement, have been structurally characterized.[9] The structure of sodium bis(N-methylhydantoinato)gold(I)[10] contains AuL_2^- units (where LH = N-methylhydantoin, IV) analogous to the HgL_2 units of bis(N-methylhydantoinato)mercury(II),[11] but the overall structure is very different. This is due to the presence of the sodium counter ions in the gold compound.

The situation prompted us to investigate complexes of the type $(R_3P)AuL$, where L is an imido-ligand related to those used previously (I–V). Sadler and co-workers[12] have synthesized a range of gold(I) tertiary phosphine complexes with imido-ligands and investigated their anti-inflammatory activity. The synthesis of tertiary phosphine gold(I) derivatives of 2-pyridones has also been reported.[13]

Using succinimide (V) as the imido ligand, the complex $(Ph_3P)AuL$ (where LH = V) (**1**) was readily obtained. This, in turn, has been reacted with praseodymium(III) nitrate to explore its potential as a bridging unit in the formation of macrocyclic compounds. This reaction gave crystals of the polymer $[Pr(Ph_3PAuL)_2(NO_3)_3]_n$ (**2**). We report here the preparation and X-ray structural characterization of both **1** and **2**.

EXPERIMENTAL

Preparation

Ph_3PAuCl. This was prepared by a method analogous to those previously described.[14,15] A solution of Ph_3P (0.77 g) in ether (10 cm^3) was added dropwise, with stirring, to a solution of $HAuCl_4$ (0.5 g) in ether (30 cm^3) at 0°C. After 1 h the initial yellow precipitate turned white. The solution was stirred for a further 2 h and then allowed to warm to room temperature. The white solid was filtered off and dried. Yield 85%. Found: C, 43.8; H, 2.9. Calc. for $C_{18}H_{15}AuClP$: C; 43.6; H, 3.1%.

Ph_3PAuL (LH = *succinimide*) (**1**). To a cooled, stirred solution of Ph_3PAuCl (0.6 g) in methanol (20 cm^3) was added dropwise a solution of succinimide (0.24 g) in methanol (5 cm^3) containing an equimolar amount of NaOH. The solution was stirred for 2 h and the product precipitated by addition of water (*ca* 30 cm^3). The solid was filtered off and recrystallized from methanol (5 cm^3) by the addition of water. The yield of white crystals was 0.535 g (79%). Found: C, 47.1; H, 3.3; N, 2.5. Calc. for $C_{22}H_{19}AuNO_2P$: C, 47.4; H, 3.4; N, 2.5%. The infrared spectrum of **1** shows a single ν(C=O) band at 1650 cm^{-1}. Crystals suitable for X-ray analysis were obtained by slow evaporation of a solution of **1** in methanol.

$[Pr(Ph_3PAuL)_2(NO_3)_3]_n$ (LH = *succinimide*) (**2**). Small pale green crystals of **2** separated over 5 days from a methanolic solution of **1** (0.05 g) and hydrated praseodymium(III) nitrate (0.02 g). These were filtered off, washed with ethanol and ether and recrystallized from methanol six times before a crystal of suitable quality could be obtained for X-ray analysis.

X-ray study

Compound **1**. Crystal data for **1**: $C_{22}H_{19}AuNO_2P$, $M = 557.3$, monoclinic, $a = 10.844(3)$, $b = 7.947(1)$, $c = 22.948(4)$ Å, $\beta = 92.38(2)°$, $V = 1976$ $Å^3$, space group $P2_1/n$, $Z = 4$, $D_{calc} = 1.87$ g cm^{-3}, Cu radiation, $\lambda = 1.54178$ Å, μ(Cu-K_α) = 149 cm^{-1}, $F(000) = 1072$. Data were measured on a Nicolet R3m diffractometer with Cu-K_α radiation (graphite monochromator) using ω-scans. A crystal of dimensions $0.06 \times 0.13 \times 0.30$ mm was used. 2668 independent reflections ($2\theta \leqslant 116°$) were measured, of which 2424 had $|F_o| > 3\sigma(|F_o|)$ and were considered observed. The data were corrected for Lorentz and polarization factors; a numerical absorption correction (face-indexed crystal) was applied; maximum and minimum transmission factors were 0.463 and 0.186.

The structure was solved by the heavy atom method. The non-hydrogen atoms were refined anisotropically. The positions of the hydrogen atoms were idealized, C—H = 0.96 Å, assigned isotropic thermal parameters, $U(H) = 1.2U_{eq}(C)$, and allowed to ride on their parent carbon atoms. Refinement was by block-cascade full-matrix least-squares to $R = 0.028$, $R_w = 0.029$ [$w^{-1} = \sigma^2(F) + 0.00031F^2$]. The maximum and minimum residual electron densities in the final ΔF map were 1.00 and −0.79 e $Å^{-3}$, respectively. The mean and maximum shift/error in the final refinement were 0.001 and 0.003, respectively. Computations for both **1** and **2** were carried out on a 486 PC using the SHELXTL-PC program system.

Selected bond lengths and angles for **1** are listed in Table 1.

Compound **2**. Crystal data for **2**: $C_{44}H_{38}Au_2N_5O_{13}P_2Pr$, $M = 1441.6$, monoclinic, $a = 13.856(3)$, $b = 11.691(2)$, $c = 29.208(6)$ Å, $\beta = 90.99(3)°$, $V = 4731$ $Å^3$, space group $C2/c$, $Z = 4$, $D_{calc} = 2.024$ g cm^{-3}, Cu radiation, $\lambda = 1.54178$ Å, μ(Cu-K_α) = 204 cm^{-1}, $F(000) = 2752$. Data were collected on a Nicolet R3m diffractometer with Cu-K_α radiation (graphite monochromator) using ω-scans. A crystal of dimensions $0.09 \times 0.09 \times 0.17$ mm was used. 2404 independent reflections ($2\theta \leqslant 116°$) were measured, of which 2043 had $|F_o| > 6\sigma(|F_o|)$ and were considered observed. The data were corrected for Lorentz and polarization factors; an empirical absorption correction (ellipsoidal) was applied; maximum and minimum transmission factors were 0.092 and 0.025.

The structure was solved by the heavy atom method. The Pr and Au atoms were refined anisotropically; the remaining non-hydrogen atoms were refined isotropically. The phenyl rings of the triphenylphosphine unit were geometrically optimized and refined as rigid bodies. The nitrate groups were constrained to a trigonal geometry and refined subject to N—O and O···O distance constraints. All hydrogen atoms were placed in calculated positions and assigned fixed isotropic thermal parameters ($U = 0.08$). Refinement was by full-matrix least squares to $R = 0.131$, $R_w = 0.155$ [$w^{-1} = \sigma^2(F) + 0.0007F^2$]. The maximum and minimum residual electron densities in the final ΔF map

were 5.50 and −4.43 e $Å^{-3}$, respectively in the regions of the Pr and Au atoms. The mean and maximum shift/error in the final refinement were 0.050 and 0.177, respectively.

Because of the severe twinning in the crystalline sample, the resulting data were of poor quality and the final *R* factors are appreciably higher than we would normally accept, indeed data collections were carried out for three different crystals and the results reported correspond to those from the best of those crystals. Attempts at refining the light atoms anisotropically resulted in several of the atoms becoming non-positive definite, probably due to the inability to correct adequately for absorption. However, the gross structural features, in particular the nature of the polymeric array, are undoubtedly correct.

RESULTS AND DISCUSSION

The X-ray structure of **1** (Fig. 1) confirms the main features expected for this type of compound. The gold is bound to the nitrogen atom of the succinimide and to the phosphine in a linear (176.9°) geometry. The Au—N and Au—P distances [2.045(5) and 2.235(2) Å, respectively] do not differ significantly from those in similar compounds.[9,12,13] The succinimide nitrogen atom retains a trigonal planar geometry. Within the crystal, there are no significant short intermolecular contacts. Despite the fairly close approach of the succinimide oxygen atoms to the gold atom (3.26 and 3.29 Å) the environment of the metal is not as crowded as the bulk of the two ligands might indicate. Approach of another metal to the oxygen atoms would not, therefore, be significantly hindered.

Slow evaporation of a methanolic solution of **1** and praseodymium nitrate resulted in the simultaneous formation of large crystals of **1** and crystals of praseodymium nitrate aggregated with those of a new complex $[Pr(Ph_3PAuL)_2(NO_3)_3]_n$ (**2**). Extensive crystal surgery was only able to provide a partially twinned fragment of **2**. This was adequate to provide a definitive structural characterization of the complex, though severely limited in accuracy.

The praseodymium atom is nine coordinate (Fig. 2) and is bonded to four succinimide oxygen atoms, each from a different succinimide unit, two bidentate nitrates and one monodentate nitrate. The structure has crystallographic C_2 symmetry (the monodentate nitrate is disordered about this axis). The coordination geometry about the Pr atom can best be described as pentagonal bipyramidal with four succinimide oxygen atoms and the oxygen of the monodentate nitrate forming the equatorial plane and the two bidentate groups occupying the axial positions (Fig. 3). (These bidentate nitrates are also disordered about the NO_3—Pr—NO_3 axis, the

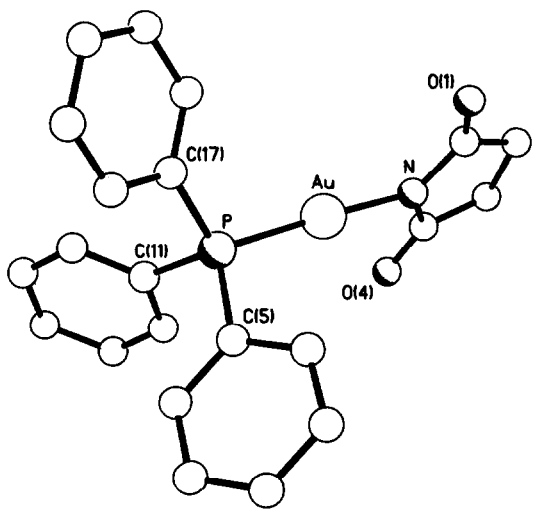

Fig. 1. Perspective view of the structure of **1**.

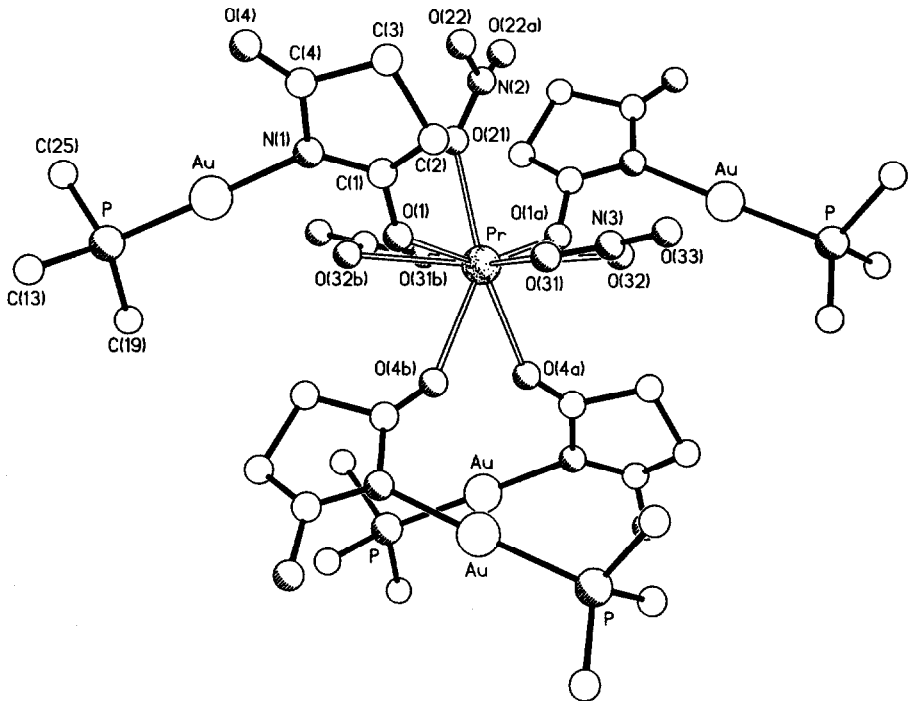

Fig. 2. Molecular environment of each Pr atom in **2**. The phenyl rings on C(13), C(19) and C(25) have been omitted for clarity.

alternate orientation of the nitrates being essentially orthogonal to those depicted.) The in-plane O—Pr—O angles are in the range 63–80° and the axial N—Pr—N angle is 165°. The Pr—O distances lie in the range 2.41(5) to 2.64(3) Å. The Au—P and Au—N distances [2.25(1) and 2.06(3) Å, respectively] do not differ significantly from those observed in **1**.*

The succinimides bridge adjacent Pr centres, thus creating an extended polymeric array comprising fused 24-membered macrocycles, each containing four Pr atoms (Fig. 4a). The periphery of each macrocycle is approximately planar (as is the contiguous array), and the $(Ph_3P)Au$ units and the bidentate nitrates are directed above and below the ring plane (Fig. 4b). The phosphine ligands and the monodentate nitrate groups are all directed in towards the ring centre.

An interesting feature of each 24-membered ring, and of the resulting contiguous array, is their polar nature. However the crystal structure is centrosymmetric and adjacent sheets have opposite polarities.

The result further demonstrates that lanthanide ions can form large macrocyclic arrays without the need for mercury atoms as links between the organic units which bridge the adjacent lanthanide centres. Although the gold atom does not play a direct part in the ring framework, the $(Ph_3P)Au$ unit does appear to play an important role in the macrocycle

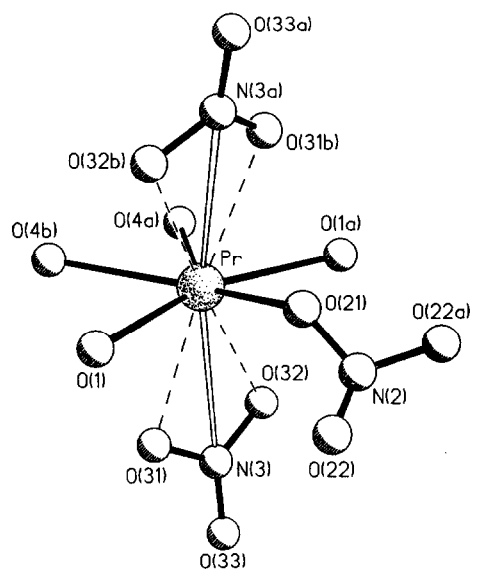

Fig. 3. Pentagonal bipyramidal coordination geometry about Pr in **2**.

* In view of the very limited accuracy of this structure determination, it is not realistic to analyse further in detail aspects of the molecular geometry.

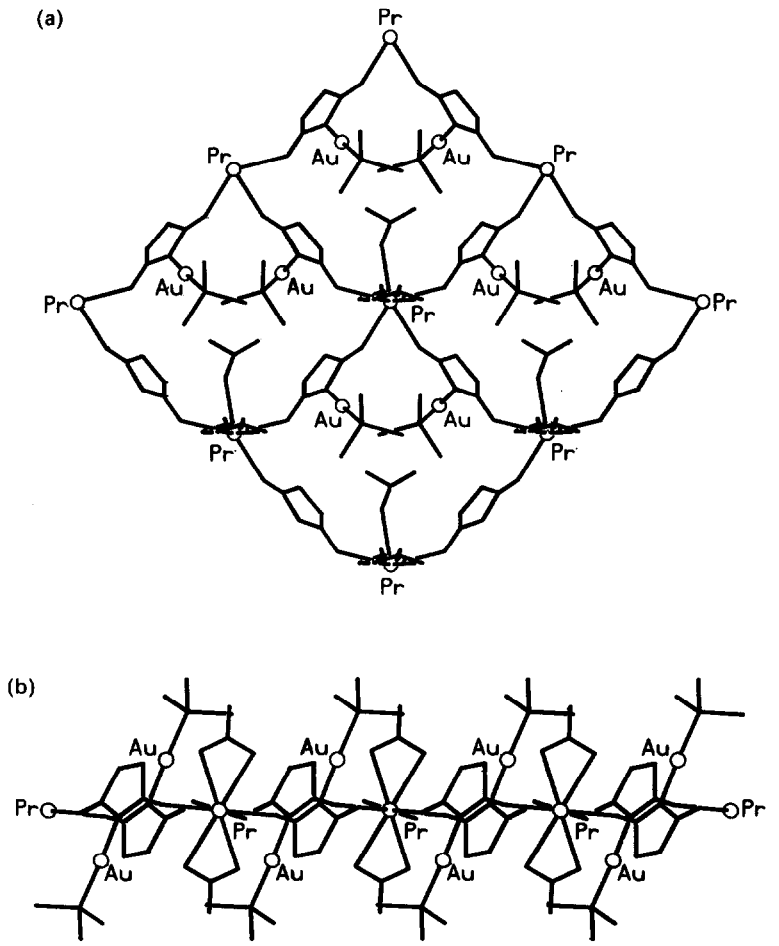

Fig. 4. Part of the contiguous macrocyclic array in the crystals of **2**: (a) plan view; (b) elevation. (In each case, the phenyl rings have been omitted for clarity, and only one set of orientations for the disordered nitrate groups is shown).

formation, as attempts to form such rings using uncomplexed succinimide, its anion, or N-methylsuccinimide have so far been unsuccessful.

(*Received* 11 *May* 1993; *accepted* 12 *July* 1993)

Abstract—The crystal and molecular structure of 1-phenylethynyl-2-phenyl-1,2-dicarbadodecaborane(12) (**1**), prepared by the reaction between 1,4-diphenylbutadi-yne and the decaborane adduct $B_{10}H_{12}(NCMe)_2$ in boiling toluene, have been established by an X-ray crystallographic study. Evidence of some delocalization of pi-electronic charge in the phenylethynyl ligand towards the carborane cage is provided by the carbon—carbon bond distances [1.431(2), 1.194(2) and 1.433(2) Å, respectively from benzene ring to carborane isocahedron] and Molecular Orbital Bond Index (MOBI) calculations, which also reveal subtle differences in the bonding of the two skeletal carbon atoms to their boron neighbours in the icosahedron. Consideration of (**1**) as an adduct in which one alkyne function of PhC≡CC≡CPh coordinates to an *arachno*-shaped $B_{10}H_{10}$ residue reveals the strong electron-withdrawing capacity of the latter, which is compared with other borane and metal cluster residues.

A recent report[1] of some aryl carboranes, prepared for a study of their second-harmonic generation (SHG) properties, included reference to the new compound 1-phenylethynyl-2-phenyl-1,2-dicarbadodecaborane(12), 1-(PhC≡C)-1-Ph-1,2-$C_2B_{10}H_{10}$ (**1**). We prepared this same compound during our own continuing studies of carborane derivatives for polymer synthesis.[2–6] Our work included a single crystal X-ray study of (**1**) which revealed several features of structural and bonding interest, which we discuss below. They include the rich variety of carbon–carbon bond types; evidence of conjugation between the alkynyl function and the carborane cage; and the presence of an uncoordinated alkynyl unit PhC_2 adjacent to the phenyl-*ortho*-carborane unit $PhC_2B_{10}H_{10}$, which itself can be regarded as an alkyne complex in which a PhC_2 unit coordinates to an *arachno*-shaped $B_{10}H_{10}$ cluster.

RESULTS AND DISCUSSION

Our synthesis of **1**, like that of Mingos and co-workers[1] involved the reaction in boiling toluene between 1,4-diphenylbutadi-yne, PhC≡CC≡CPh, and decaborane. However, instead of carrying out the reaction in the presence of the Lewis base, we used a previously prepared sample of the *arachno* bis(nitrile) adduct $B_{10}H_{12}(NCMe)_2$:

nido → *arachno* → *closo*

Single crystals of compound **1** suitable for X-ray diffraction were grown from hexane. The molecular structure is shown in Fig. 1. Selected bond lengths and angles are given in Table 1.

One feature of the molecular structure worthy of comment is the orientation of the phenyl groups. If they were oriented so as to minimize intramolecular nonbonded repulsions between them, both would lie in planes perpendicular to the plane of the atoms (C2, 1, 13 and 14) that connect them. In fact, although the phenyl group directly attached to the carborane cage does have roughly the expected orientation [shown in projection in Fig. 2(b)—the

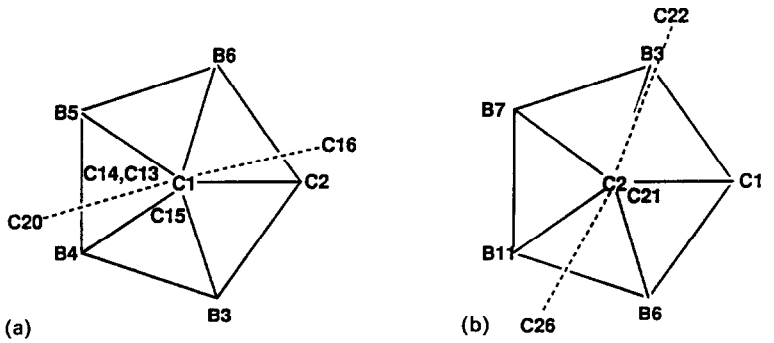

Fig. 2. The pentagonal pyramidal environments of the carboranyl carbon atoms (a) C1 and (b) C2, viewed down their *exo* bonds (C13 to C1, C21 to C2) and showing in projection the orientations of the phenyl groups.

ring plane almost exactly eclipses the link C2—B3, rather than lying parallel to the B3—B6 axis; torsion angle C22—C21—C2—B3 = −0.6°] the other phenyl group [Fig. 2(a)] lies close to the plane of C2, 1, 13, 14 (torsion angle C16—C15···C1—C2 = 13.8°) and the alkyne function bends slightly [by 5.4(2)° at C13 and by 1.9(2)° at C14] *towards* the first phenyl group, as if attracted to it, placing one *ortho* hydrogen atom of the second benzene ring near to the pseudo-6-fold axis of the first ring (H16 lies 3.21 Å from the plane of this ring). These orientations of the phenyl groups have implications for their respective capacities to participate in conjugative interactions with the tangentially-orientated p AO's on the cluster carbon atoms 1 and 2, which in turn are the orbitals through which C1 and C2 bond to their neighbours within the caborane icosahedron (Fig. 3), a point to which we return below.

In principle, significant conjugative interactions involving the phenyl or phenylethynyl ligands should be apparent from their carbon–carbon bond distances. Compound **1** contains an unusually rich variety of carbon–carbon bond types. Their bond distances are given in Table 2, classified according to the connectivities (coordination numbers), k, of the atoms they link. The bonds in the benzene rings, linking atoms for which k = 3, are treated as all of one type, and averaged in this Table, which also lists typical interatomic distances in related compounds for purposes of comparison. From these, it is apparent that the formally single bonds to the ligands (and the bond C14—C15) are a little shorter than might have been expected for single bonds of the connectivities concerned, and both phenyl groups show slight lengthening (by *ca* 0.01 Å) of the bonds to the substituted carbon atoms, i.e. C15—C16/20 and C21—C22/26.

In order to probe the bonding in **1**, we have carried out a Molecular Orbital Bond Index calculation to determine the bond indices (B.I.) which correspond to (though they are typically slightly lower than) formal bond orders.[13] From the bond indices of the carbon–carbon bonds (Table 2) it is

Table 2. Carbon–carbon bond distances (d) and indices (B.I.) in **1**

d/Å	k	B.I.	Carbon atoms involved	Literature values of d/Å
1.710(2)	6–6	0.60	1–2	1.62–1.75[1,9,10a]

1.194(2)	2–2	2.69	13–14	1.17–1.20[12c]

[a] Higher values have been found in systems in which the *exo* atoms form strong dative π-bonds to the skeletal atoms (see refs 11, 25, 26).

[b] For single bonds between sp^2 and sp^1 carbon atoms.

[c] For triple bonds in alkynes RC≡CR′.

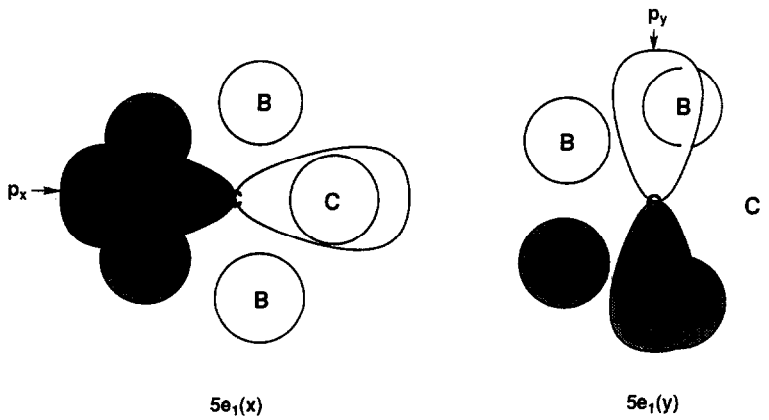

Fig. 3. Frontier orbitals[7,8] through which atoms C1 and C2 bond to their neighbours in the pentagonal faces of the *nido*-shaped CB_{10} residues.

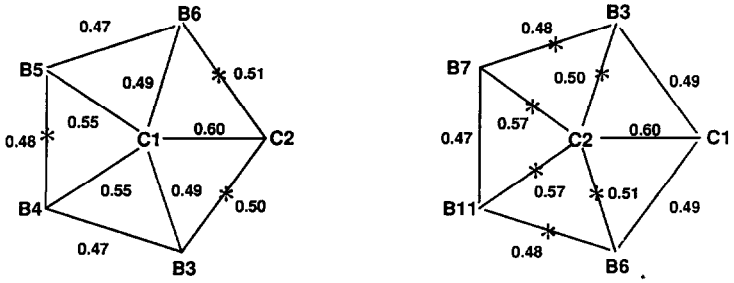
clear that, within the phenylethynyl ligand, the bonds either side of the alkyne unit (particularly that adjacent to the icosahedron) have acquired some multiple bond character at the expense of the triple bond.

Bond indices for all of the links involving the carbon atoms within the carborane icosahedron are shown in Fig. 4. From these it is apparent that atoms C1 and C2 differ subtly but nevertheless significantly in the way they bond to their neighbouring atoms in the icosahedron (C2 and B3, 4, 5 and 6) than does C(2) (whose skeletal neighbours are C1 and B6, 11, 7 and 3), a difference intelligible in that the *exo* π-bonding to C1 referred to above slightly reduces its capacity for cluster bonding compared with C2. A particularly revealing feature of the difference between C1 and C2 in the manner in which they bond to their neighbours within the carborane icosahedron is the pattern of stronger bonds in Fig. 4 (indicated by asterisks), when the environments of C1 [Fig. 4(a)] and C2 [Fig. 4(b)] are compared. Atom C2 is seen to bond some 3–4% more strongly to its four boron neighbours than does C1, and moreover there is stronger bonding between B6 and B11, and between B7 and B3, than is the case between the corresponding atoms adjacent to C1 (B3–B4 and B5–B6).

Comparison of Fig. 4 with Figs 2 and 3 shows that these features are fully in line with the conclusion that conjugative interactions *exo* to the carborane icosahedron involve primarily the p_y orbital on C1 and the p_x orbital on C2, so reducing their contributions to the bonding within the icosahedron, which accordingly is dominated by the p_x orbital on C1 and the p_y orbital on C2.

A further feature of the structure of **1** worthy of comment is prompted by its synthesis from the di-yne PhC≡C—C≡CPh and the *arachno*-borane adduct $B_{10}H_{12}(NCMe)_2$. Compound **1** can be regarded as an adduct in which one of the alkyne functions coordinates to an *arachno*-shaped $B_{10}H_{10}$ residue. The other remains intact as the substituent phenylethynyl unit PhC≡C (Fig. 5); this aspect is also emphasised in Fig. 1 by the representation of open bonds within the $B_{10}H_{10}$ residue and filled bonds in the di-yne residue. Coordination to the



Asterisks mark the stronger bonds when the environments of **C1** and **C2** are compared.

Fig. 4. Bond indices of the cluster bonds near C1 and C2, (a) C1 neighbours, (b) C2 neighbours.

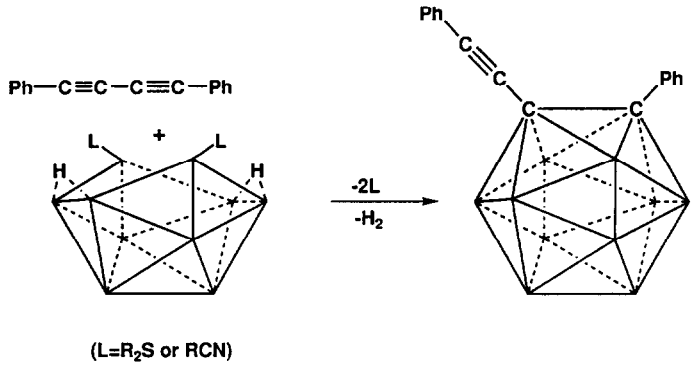


Fig. 5. Formation of **1** represented as the coordination of one alkyne unit of PhC≡CC≡CPh to an *arachno*-shaped $B_{10}H_{10}$ residue.

boat-shaped $B_{10}H_{10}$ residue causes the carbon atoms originally linked by a triple bond of length 1.20 Å in PhC≡CC≡CPh to separate to a distance of 1.71 Å (corresponding to a bond of bond index 0.60) while the C—C—C bond angles at the two carbon atoms [C1 and C2 in **1**] decrease from 180° to 115–118°.

These dramatic changes resemble in kind (though surpassing in extent) those that occur when alkynes coordinate to transition metal clusters. It is usual, for electron book-keeping purposes, to regard the alkynes as 4-electron ligands, donating both pairs of electrons from their pi-systems, when they coordinate to two or more metal atoms, the sigma C—C bond pair being retained by the coordinating alkyne. However, compound **1** provides a reminder that alkynes RC≡CR′ may alternatively be regarded as sources of two carbyne units, RC and R′C, each a source of three electrons. Indeed, in the formation of **1** from $B_{10}H_{12}(NCMe)_2$ and PhC≡CC≡CPh, the loss of two 2-electron ligands (2MeCN) and two 1-electron ligands (2H) from the former is compensated by the provision of two 3-electron units (PhC≡CC and PhC) from the latter, allowing the *arachno* shape of the $B_{10}H_{10}$ residue to be retained. The dramatic reduction in the carbon–carbon bond order of the alkyne effectively results from conversion to a boron–carbon bonding role of the electrons originally forming the alkyne triple bond, sigma as well as pi, even though a weak carbon–carbon link persists.

The effect on the carbon–carbon bond distance of coordination of an alkyne to assorted metal or boron residues is illustrated by the data in Table 3, from which it is apparent that compound **1**, viewed as an η^2-alkyne complex, like other icosahedral carboranes, falls near the upper end of the range of carbon–carbon distances found in such systems.[1,14–24] It is also apparent that the effect on the coordinated alkyne increases with the nuclearity of the system to which it is coordinating, whether metallic (when the carbon–carbon distances can range from *ca* 1.30–1.45 Å, depending on the number of metal atoms and the identity of the other ligands) or boron (when the carbon–carbon distances span the higher range of *ca* 1.43–1.73 Å). Even greater C—C distances have been found in certain other icosahedral carborane systems, such as the anions $[1,2\text{-}X(Ph)C_2B_{10}H_{10}]^-$ (1.86 Å when X = S, 2.00 Å when X = O) in which special circumstances—strong *exo* π-bonding to the substituent sulphur or oxygen atom—apply.[25,26]

EXPERIMENTAL

Synthesis of 1

A solution of 1,4-diphenylbutadi-yne (1.01 g, 5 mmol) in dry toluene (25 cm^3) was added to a suspension of decaborane bis(acetonitrile) adduct (1.01 g, 5 mmol) in toluene (20 cm^3) under nitrogen. After 24 h reflux the red solution was cooled, treated with

methanol (20 cm^3) then evaporated. The residue was extracted with hexane from which **1** (0.52 g, 33%) crystallized on partial evaporation, m.p. 119–120°C [Found: C, 60.7; H, 6.3%; M_r (mass spectrum) 316–322. Calc. for $C_{16}H_{20}B_{10}$: C, 60.0; H, 6.3%; M_r, 312–322] ν_{max} (KBr disc/cm^{-1}) 3108w, 3086w, 3077w, 3060w, 3044w, (ArH) 2661w, 2649m, 2605s, 2581s, 2577s, (BH) 2239m (C≡C) 756s, 687s (C_6H_5).

NMR spectra of **1** (*solvent* $CDCl_3$)

^1H (300 MHz), $^{11}B\{^1H\}$ (96.25 MHz) and $^{13}C\{^1H\}$ (75.5 MHz) spectra were recorded at the frequencies indicated using $CDCl_3$ as solvent; δ values were identical to, or not significantly different from, those given in ref. 1.

Crystal data for **1**

$C_{16}H_{20}B_{10}$, $M_r = 320.42$, triclinic, space group $P\bar{1}$, $a = 7.2825(10)$, $b = 10.4122(14)$, $c = 12.763(2)$ Å, $\alpha = 74.336(11)$, $\beta = 81.418(10)$, $\gamma = 86.172(10)°$, $V = 921.0(2)$ $Å^3$ at 240 K (Cu–K_α radiation, $\lambda = 1.54184$ Å), $Z = 2$, $D_c = 1.155$ g cm^{-3}, $\mu = 0.405$ mm^{-1}, $F(000) = 332$.

Data collection and processing: crystal size $0.68 \times 0.44 \times 0.24$ mm, Stoe–Siemens diffractometer with Cryostream cooler,[27] cell parameters from 2θ values (44–57°) of 32 reflections measured at $\pm\omega$, intensities from ω/θ scans with on-line profile fitting,[28] 2θ range 7 to 130°, index ranges h 0 to 8, k −12 to 12, l −14 to 14 (Friedel opposites were measured instead for some inaccessible reflections); corrections for 5% intensity decay of 3 standard reflections, no absorption corrections.

Structure solution and refinement:[29] non-hydrogen atoms by direct methods, H atoms constrained [riding model, with C—H 0.94 Å, B—H 1.11 Å, $U(H) = 1.2\ U_{eq}$ (C or B)]; full-matrix least-squares refinement on F^2 for all 3082 measured data, with weighting $W^{-1} = \sigma^2(F_o^2) + (0.0892P)^2 + 0.3378P$, where $P = (F_o^2 + 2F_c^2)/3$; isotropic extinction parameter $\chi = 0.007(1)$, where F_c^2 is multiplied by $(1 + 0.001\chi F_c^2 \lambda^3/\sin 2\theta)^{-1/4}$; all shifts < 0.001 times corresponding parameter ESD; final difference map between +0.211 and −0.252 e $Å^{-3}$. For 236 parameters, $wR2 = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2]^{1/2} = 0.1517$ for all data, conventional $R = 0.0531$ for unweighted F values of 2804 reflections having $F_o^2 > 2\sigma(F_o^2)$, goodness of fit on $F^2 = 1.037$.

Atomic coordinates, complete bond lengths and angles, and displacement parameters have been deposited as supplementary material at the Cambridge Crystallographic Data Centre.

Abstract—An X-ray study showed that 1-phenyl-3-methyl-4-butanoylpyrazol-5-one, $RCOC_{10}H_9N_2O$ (abH, R = Pr) (**1**), crystallized in the enol form. It reacted with iron(III) salts to give a dark red complex, $[Fe(ab)_3]$, which crystallized from butanol as the *mer*-isomer. The complex $[Fe(ab)_3]$ (R = Me) was prepared similarly, but the *fac*-isomer was obtained.

Selective extraction is a key step in many hydrometallurgical processes. Among the many reagents which have been examined as extractants the 1-phenyl-3-methyl-4-acylpyrazolones, $RCOC_{10}H_8N_2OH$ (**1–4**) have several possible advantages.[1–4] They are more efficient extractants for metals in strongly acidic solution and cheaper than the widely used 4,4,4-trifluoro-1-(2-thienyl)-1,3-butanedione, $C_4H_3SCOCH_2COCF_3$,[5,6] and the R substituents can be easily varied to optimize particular separations. One of the most powerful extractants is the butanoyl derivative (R = Pr)[7] and a method for separation of iron and uranium based on this reagent has been proposed.[2]

In order to understand the factors which determine selectivity it is necessary to examine the structures of both ligands and metal complexes. It has been suggested that the free pyrazolone ligands may be obtained in several tautomeric forms (e.g. **a–c**) by crystallization from various solvents under a variety of experimental conditions. As far as we are aware, however, only two compounds have been examined by X-ray crystallography, viz. the benzoyl derivative, which crystallizes as the NH tautomer **1b**, R = Ph, and the 1,3-butanedionyl (acetoacetyl) compound, which crystallizes as the OH tautomer **3c**, R = CH=C(OH)CH_3.[8] We describe herein the structure of the enol form **2c** of the butanoylpyrazolone and the synthesis, properties and structures of the iron(III) complexes $Fe(ab)_3$ (**5**) (abH = **2**) and **6** (abH = **4**). The crystal structures of two uranium complexes, viz. $[UO_2(ab)_2H_2O]$ (**7**) obtained from the acetylpyrazolone **4** and $[UO_2(ab)_2(PrOH)]$ from the benzoyl compound **1**, have been described elsewhere.[9]

EXPERIMENTAL

The ^1H and ^{13}C NMR data for samples in acetone-d_6 at 25°C were recorded on a Bruker WM360 instrument at 360 or 90.6 MHz, respectively; chemical shifts were relative to $SiMe_4$. The carbon atoms were numbered as in Figs 1–3.

1-*Phenyl*-3-*methyl*-4-*butanoylpyrazol*-5-*one* (2)

The synthesis of this compound has been described previously.[10] Yield: 85%. UV: λ_{max} 251 (ε 161), 287 nm (ε 6940 $dm^3\ mol^{-1}\ cm^{-1}$). IR (Nujol mull): 3100w (νOH), 2650wb (νOH···O), 1618s (νCO), 1590m, 1550b, 608w, 503w, 370w, 330 cm^{-1}

Iron complexes

A solution of $Fe(NO_3)_3 \cdot 9H_2O$ (1.25 g, 3.1 mmol) in water (50 cm^3) at 45°C was added to a stirred warm (45°C) solution of **4** (2.0 g, 9.3 mmol) in ethanol (50 cm^3). The mixture was kept at 45°C until a precipitate was obtained. This was filtered off, washed with water, recrystallized from butanol and dried in air. The dark red crystals were tris(1-*onato*)*iron*(III) (**5**). This compound was made similarly from **2** and isolated as dark red needles, which were shown to comprise the *mer*-isomer. Yield: 2.4 g, 99%; m.p. 162°C. Found: C, 63.8; H, 5.53; N, 10.6%. Calc. for $C_{42}H_{45}O_6N_6Fe$: C, 64.2; H, 5.77; N, 10.7%. UV ($CHCl_3$): λ_{max} 253 (ε 5760), 291 (ε 23,200), 463 nm (ε 4800 $dm^3\ mol^{-1}\ cm^{-1}$). IR: 1624m (νCO), 283 cm^{-1} (mb) (ν FeO). μ_{eff}: 5.81 B.M.

Solvent extraction

Aqueous solutions of $Fe(NO_3)_3$ (5 cm^3), containing 10 ppm of iron and buffered to various pH, were shaken with a 0.02 M solution of **2** (5 cm^3) in xylene. Approximately 80% of the iron(III) was extracted at pH 0.5 and the extraction was almost quantitative between pH 1.4 and 4.3. When the complex was used for the spectrophotometric determination of iron(III) there was no detectable interference from Mg^{2+}, Al^{3+}, Zn^{2+}, Co^{2+}, Cu^{2+}, Ni^{2+}, Zr^{4+}, Cd^{2+}, Ba^{2+} and Pb^{2+}, present in each case in 500-fold excess. The formula of the complex in the organic layer was established as FeL_3 (LH = **2**) by Job's method[11] and the extraction constant $K = [FeL_3]_{org}[H^+]^3_{aq}/[Fe^{3+}]_{aq}[HL]^3_{org}$ at an ionic strength of 0.2 M was found to be $10^{0.5\pm0.1}$.

Crystal structures

Data were collected at 295 K on an Enraf–Nonius CAD4 diffractometer: those from **5** were of poor quality, perhaps because of disorder in the structure. Intensities, measured by a θ–2θ scan with $\Delta\theta = (0.8 \pm 0.35 \tan\theta)°$ and $2 < \theta < 25°$, were corrected for Lorentz and polarization effects but not for absorption. A MicroVax II computer and the Enraf–Nonius Structure Determination Package were used for structure solutions and refinement. The positions of the carbon, nitrogen and oxygen atoms of **2c** were found by MULTAN[12] and the structures of **5** and **6** were solved by heavy-atom methods. All the non-hydrogen atoms were refined by full-matrix least-squares techniques with anisotropic temperature factors, except for C(39) and C(40) of **5** for which the temperature factors were isotropic: C(40) was disordered between two sites. The hydrogen atoms of **2c** were located on a difference map and refined isotropically; those of the phenyl groups in **5** and **6** were placed at calculated positions (C—H = 0.95 Å) with $B_{iso} = 1.3\ B_{eq}$ for the attached carbon atom, where B_{eq} is defined as one third of the trace of the orthogonalized B_{ij} tensor. The other hydrogen atoms were omitted. More details are given in Table 1 and selected bond lengths and angles in Tables 2 and 3.

RESULTS AND DISCUSSION

The butanoyl compound was isolated from water–ethanol as colourless crystals. It was thought

earlier[10] that the lack of colour indicated that the crystals comprised the keto form **2a**, but the structure determination described here shows that the enol form **2c** was obtained. The acylpyrazolone skeleton is planar (Fig. 1) with the phenyl ring twisted from the pyrazolone plane. The C—O and adjacent C—C and C—N bond lengths within the pyrazolone ring (Table 2) differ significantly from those in the benzoyl compound **1**, but are the same within the limits of error as those in the 1,3-butanedionyl compound **3**. The labile proton is attached to the pyrazolone rather than to the adjacent acyl carbonyl group and is linked to the acyl carbonyl by an intramolecular hydrogen bond. There are no intermolecular hydrogen bonds as found in **1**. It is difficult to deduce the structure of acylpyrazolones by IR measurements without confirmatory diffraction data,[4] but it is noteworthy that the absorptions at 3100 and 2650 cm^{-1} and the carbonyl peak at 1618 cm^{-1} found in the IR spectrum of solid **2c** are observed in other β-diketones which crystallize in the enol form.[13]

The butanoyl compound **2** is an extremely efficient selective extractant for iron(III), even in

strongly acidic solution. In order to examine more carefully why this is so, we have isolated the wine–red complex $Fe(ab)_3$ (**5**), with abH = **2** (R = Pr). Complex **6** derived from **4** was also isolated: this is only 20% extracted with xylene at pH 0.5, but almost quantitatively in the pH range 2–4. UV spectra show that the ligand absorptions at 251 and 287 nm in the free ligands are also found in the complexes, suggesting that intraligand $\pi \rightarrow \pi^*$ transitions are almost unchanged. New peaks at longer wavelengths ascribed to ligand → metal charge-transfer transitions account for the colour of the complexes.

The structures of the iron compounds found by X-ray diffraction make possible a more precise comparison of bond lengths in coordinated complexes and complexes **7** and **8** where the presence of a heavy atom led to large uncertainties in estimated standard deviations. After coordination of the three bidentate enolato ligands there is no room for further coordination of solvent. The O—Fe—O angles in the metallocyclic rings are *ca* 88°, so there is only slight distortion from octahedral coordination at the metal. In contrast, the metal is seven-coordinate in the uranium derivatives **7** and **8**: U—O bonds are *ca* 0.3 Å longer than Fe—O bonds, so the O—U—O angles can be compressed to 72° to make room for coordination of H_2O or ROH. The mean bond lengths in the enol forms of the free pyrazolone ligands **2** and **3**[8] are insignificantly different from those in the iron complexes, except for the C—C bonds which are shared between the pyrazolone and metallocyclic rings. A comparison between the bond lengths in the ligand **2c** and the iron complexes **5** and **6** shows the effects of increased delocalization in the chelate ring with C—C and C—O bonds becoming more similar in length as the metal complexes are formed. The intramolecular hydrogen bond in **2c** is associated with a lengthening of the C—O bond of the acyl group [cf. 1.233(8) Å in **1**], so that it is almost the same as that in the iron complexes. In **3**, where there are two intramolecular hydrogen bonds to the central carbonyl, the lengthening is even more marked.[8]

It is not possible to be sure that the pattern of hydrogen bonds involving a particular pyrazolone ligand is the same in aqueous solution as it is in the crystalline state. However, the results here do suggest that if the enol form is present in solution, little overall reorganization is required to form the neutral iron complexes $[Fe(ab)_3]$.

It is interesting that changing the R group from butyl to methyl results in the isolation of the *fac*- rather than the *mer*-iron(III) complex. The crystallographic data give no explanation for this observation. Magnetic measurements indicate that the complexes are d^5 high-spin and therefore labile: *fac*-⇌*mer*-isomerization is thus expected to be facile. Which isomer is obtained on crystallization is probably determined by subtle differences in solubility. There are no significant differences between the bond lengths and angles in the coordination sphere and pyrazolone rings of **5** and the corresponding parameters in **6** (Table 3). The greater efficiency of **2** than that of **4** as an extractant is probably therefore a reflection of the higher solubility of the butanoyl complex in the organic layer.

Supplementary material. Tables of fractional atomic coordinates, bond lengths and angles, observed and calculated structure factors, hydrogen atom positions and temperature factors have been deposited with the Editor and are available on request.

(*Received* 5 *May* 1993; *accepted* 28 *June* 1993)

Abstract—The reaction of $Na[Fe(RL)_3]\cdot H_2O$ with imidazole (im) in acidified methanol affords the green-coloured low-spin (t_2^6) complexes $Him[Fe(RL)_3]$, where $[RL^-]$ is $[RC(NO)NNPh^-]$ and R is Me, Ph, p-MeC_6H_4. The X-ray structure of the solvate $Him[Fe(p\text{-}MeC_6H_4L)_3]\cdot 2MeOH$ has revealed that the iron(II) atom is tris-chelated in facial geometry, the FeN_6 coordination sphere being distorted octahedral. Hydrogen bonding among the oximato oxygen, imidazole nitrogen and methanol oxygen atoms affords a centrosymmetric dimeric arrangement. The imidazole ring lies near the oximato periphery of the tris chelate. The different oximato functions are differently hydrogen bonded and the stronger the hydrogen bonding the longer the Fe—N(oxime) length. The shortest non-bonded Fe···N(im) length is 4.260(6) Å [motif Fe—NO···N(im)], which can be compared with the Fe···N(distal) length in oxyhaemoglobin, 4.34 Å, and oxymyoglobin, 4.53 Å [motif Fe—OO···N(im)]. The $Him[Fe(RL)_3]$ salts have low electrical conductivity in solution, showing that strong association persists in the dissolved state. An allowed band near 600 nm is assigned to the MLCT excitation $d\pi(Fe) \rightarrow \pi^*(azo)$ on the basis of an extended Hückel examination of a model system. A quasi-reversible stereoretentive one-electron couple, $[Fe^{III}(RL)_3]/[Fe^{II}(RL)_3^-]$, is electrochemically observable, the EPR spectrum of electrogenerated $[Fe(RL)_3]$ being axial ($g_{\parallel}$, ~2.0; $g_{\perp}$, ~2.1).

The common mode of imidazole (im) binding in metal complexes is direct coordination through a nitrogen atom. A relatively rare binding mode is shown in motif **1**, where the diatomic fragment XY coordinates to the metal through X and associates with the imidazole nitrogen through Y. An example is oxyhaemoglobin (or oxymyoglobin), in which the imidazole nitrogen of the distal histidine residue is hydrogen bonded to the iron-bound oxygen molecule, motif **2**.[1,2] While studying the interaction of imidazole with oximato complexes of iron we have come across the motif **3**, in which the NO fragment belongs to an oximato function. The synthesis and characterization of a family of such species are reported in this work. The X-ray structure of a representative member is described.

tion of acetonitrile for electrochemical and spectroscopic work were performed as previously described.[5] All the other chemicals and solvents were of reagent grade and used as obtained.

Physical measurements and computations

UV–vis–NIR spectra were recorded on a Hitachi 330 spectrophotometer. Solution (10^{-3} mol cm^{-3}) electrical conductivities were measured on a Philips PR 9500 bridge. Electrochemical measurements were performed on a PAR model 370-4 electrochemistry system, as reported earlier.[6] All potentials reported in this work are uncorrected for junction contribution and referenced to a saturated calomol electrode (S.C.E.). The EPR spectra were recorded in the *X*-band with a Varian E-109C spectrometer fitted with a quartz Dewar flask for measurements at 77 K (liquid nitrogen) and dpph ($g = 2.0037$) was used for their calibration. Microanalytical data (carbon, hydrogen and nitrogen) were obtained with a Perkin–Elmer model 240C elemental analyser. Extended Hückel computations were performed using a variation of the ICON-8 software package originally developed by Hoffmann.[7]

Synthesis of the complexes

The same general procedure was followed for all the three complexes. Details are given for Him[Fe(PhL)$_3$]. To a methanolic solution of Na[Fe(PhL)$_3$]·H_2O (0.500 g, 0.65 mmol) was added $HClO_4$ (0.66 mmol) in methanol (10 cm^3). To the resulting brown solution was added imidazole (0.045 g, 0.66 mmol) and the solution was stirred for 15 min. The green solution was evaporated to dryness *in vacuo* and the solid obtained was washed with water and then with a 1 : 2 ethanol–water mixture. Finally, the green solid was dried *in vacuo* over boiling toluene; yield: 97%. Found: C, 62.9; H, 4.3; N, 19.1. Calc. for $C_{42}H_{35}N_{11}O_3Fe$: C, 63.2; H, 4.4; N, 19.3%.

The complexes Him[Fe(MeL)$_3$] and Him[Fe(*p*-$MeC_6H_4L)_3$] were synthesized similarly in 92% and 96% yields, respectively. Found: C, 53.2; H, 4.7; N, 23.1. Calc. for $C_{27}H_{29}N_{11}O_3Fe$: C, 53,0; H, 4.7; N, 25.2%. Found: C, 64.2; H, 4.9; N, 18.2. Calc. for $C_{45}H_{41}N_{11}O_3Fe$: C, 64.4; H, 4.9; N, 18.4%.

X-ray structure determination

Single crystals of Him[Fe(*p*-$MeC_6H_4L)_3$]·2MeOH were grown by slow evaporation of a methanol solution. Cell dimensions were obtained by the least-squares refinement of diffractometer angles of 30 automatically centred reflections. Data were collected at 296 K on a Nicolet R3m/V diffractometer with graphite monochromated Mo-K_α ($\lambda = 0.71073$ Å) radiation in the ω–2θ scan mode. Two check reflections measured after every 98 reflections showed no significant variations. Lorentz and polarization corrections as well as a semi-empirical absorption correction[8] were made. The structure was solved by direct methods and was refined by block-matrix least-squares procedures. All the non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included at the calculated positions in the final refinement cycle with isotropic thermal parameters (0.08 $Å^2$). Crystal data and other details are collected in Table 1. Computations were performed on a MicroVAX II computer using the SHELXTL-PLUS program system.[9]

Tables of atomic coordinates, anisotropic thermal parameters, full listing of bond lengths and angles and observed and calculated structure factors are available as supplementary material from the Editor.

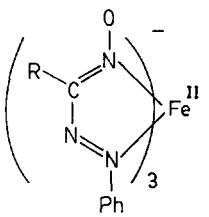
RESULTS AND DISCUSSION

Synthesis and structure

The oximato complex concerned is the tris-(arylazo oximato)iron(II) anion, $[Fe(RL)_3^-]$ (**4**) (R = Me, Ph or *p*-MeC_6H_4). The proven ability of **4** in sequestering metal cations via the pendent oximato oxygen atoms[10–13] prompted us to explore its interaction with protonated organic bases, imidazole (im) in the present case. The reaction of $Na[Fe(RL)_3]\cdot H_2O$ with imidazole in acidified methanol afforded green species of the composition (when dried *in vacuo*) $Him[Fe(RL)_3]$ in excellent yields. The complexes are diamagnetic, corresponding to a low-spin (t_2^6) configuration for the iron(II) atom.



$Fe(RL)_3^-$

4

The complex with R = *p*-MeC_6H_4 afforded good single crystals in the form of a bis-methanol adduct. The X-ray structure (Figs 1 and 2) of the solvate has been determined. Selected bond parameters are listed in Table 2. The iron(II) atom is tris-chelated into facial geometry (Fig. 1). In the distorted octahedral FeN_6 coordination sphere, the Fe—N lengths lie in the range 1.905(4)–1.945(4) Å, showing no systematic difference between Fe—N(oxime) and Fe—N(azo). The bond parameters within the excellently planar chelate rings are comparable to those observed in the metal complexes of $[Fe(RL)_3^-]$.[10,12,13]

The centrosymmetric dimeric units (Fig. 2) are afforded through hydrogen bonding among the oximato oxygen, imidazole nitrogen and methanol oxygen atoms. The relevant distances are shown in Table 2. The imidazole ring is associated at the oximato periphery of the tris chelate via the imidazole N(11) atom, which is strongly hydrogen bonded to the oximato O(2) atom, the N(11)···O(2) length being 2.719(11) Å. The N(11) atom has a weaker contact with O(1), N(11)···O(1), 2.903(12) Å.

The net strength of hydrogen bonding (Fig. 1, Table 2) at the oxygen atoms of the oximato functions can be ordered as O(1) < O(3) < O(2). Interestingly, the stronger the hydrogen bond the longer the corresponding Fe—N(oxime) distance [Fe—N(3) < Fe—N(9) < Fe—N(6)]. The bond parameters within the imidazolium ion are normal.[14]

The non-bonded Fe···N(11) length in $Him[Fe(p\text{-}MeC_6H_4L)_3]\cdot 2MeOH$ is 4.260(6) Å. This can be compared with the Fe···N(distal) distances in oxyhaemoglobin and oxymyoglobin. From available coordinates,[2] these are calculated to be 4.34 and 4.53 Å, respectively.

Solution properties: conductivity, spectra and metal redox

Relevant data taken in acetonitrile solution are collected in Table 3. The low electrical conductivity of the salts show that strong [Him$^+$]$\cdots$[Fe(RL)$_3^-$] association persists in solution also. The green solutions display an allowed band at *ca* 600 nm with a shoulder at *ca* 900 nm.

Extended Hückel molecular orbital calculations on the hypothetical anion [FeL$_3^-$] (**4** with R and Ph replaced by hydrogen; C_3 symmetry imposed) has revealed that the HOMO is largely (66%) metal $3d\pi$ in character and the LUMO is a ligand orbital with 70% azo π^* character. The transition near 600 nm is assigned to an MLCT excitation, primarily $d\pi$(Fe) $\rightarrow$ π^*(azo) in character.

The salts display a quasi-reversible one-electron cyclic voltammetric metal redox response (Fig. 3) due to the [Fe^{III}(RL)$_3$]/[Fe^{II}(RL)$_3^-$] couple. The [Fe(RL)$_3$] complex ($S = 1/2$) can be generated in solution by constant potential (0.7 V) coulometry and in the frozen state (77 K) it has axial EPR spectra (Fig. 3) corresponding to facial geometry (effective C_3 symmetry). The [Fe^{III}(RL)$_3$]/[Fe^{II}(RL)$_3^-$] redox is thus stereoretentive.

CONCLUSIONS

In Him[Fe(RL)$_3$] the imidazole ring is associated at the oximato periphery of the facial iron(II) trisarylazo oximate. The shortest non-bonded Fe$\cdots$N(imidazole) length is comparable with distal Fe$\cdots$N distances in oxyhaemoglobin and oxymyoglobin. Strong [Him$^+$]$\cdots$[Fe(RL)$_3^-$] association persists in solution. The complexes display an MLCT (Fe $\rightarrow$ azo) transition in the visible region and undergo stereoretentive oxidation affording the axially symmetric [Fe(RL)$_3$].

DIOXOMOLYBDENUM(VI) COMPLEXES OF NEW BINUCLEATING SCHIFF BASES DERIVED FROM METHYLENE- OR DITHIO-BIS(SALICYLALDEHYDE) AND VARIOUS AMINES†

MANNAR R. MAURYA,‡ DEENA C. ANTONY, S. GOPINATHAN‡ and C. GOPINATHAN

Inorganic Chemistry Division, National Chemical Laboratory, Pune 411 008, India

(*Received* 5 *May* 1993; *accepted* 25 *June* 1993)

Abstract—The syntheses of binuclear dioxomolybdenum(VI) complexes of the type $[(MoO_2)_2L]$, where L is a flexibly-bridged hexadentate tetraanionic Schiff base derived from the condensation of methylene- or dithio-bis(salicylaldehyde) with *o*-aminophenol, 2-aminoethanol, 2-amino-2-methyl propanol or 1-amino-2-propanol, are reported. The IR and NMR spectral data suggest an oligomeric structure in which each molybdenum ion achieves a pseudo-octahedral structure via Mo=O---Mo bridging. Treatment of $[(MoO_2)_2L]$ with pyridine leads to the formation of $[MoO_2)_2L(py)_2]$ in which pyridine binds at the sixth labile binding sites in both $[MoO_2]^{2+}$ units. $[(MoO_2)_2L(py)_2]$ is readily convertable into $[(MoO_2)_2L]$ at *ca* 180°C in a single endothermic step, as seen from their DTA analysis. The pyridine adducts show two IR absorptions at *ca* 900 cm^{-1}, attributable to a *cis*-MoO_2 structure, whereas the oligomeric complexes usually show one intense ν(Mo=O) band at 910–938 cm^{-1} and a broad but strong band at *ca* 820 cm^{-1} due to a weakened ν(Mo=O) band as a result of Mo=O → Mo interactions.

The discovery of molybdenum in a number of enzymes has led to the continued growth of the coordination chemistry of molybdenum.[1] The potential for biological and physiological activity and the industrial use of these complexes have also stimulated the discovery of a variety of molybdenum complexes in various oxidation states.[2] Amongst the −II to +VI oxidation states, the most stable is +VI, associated with the dioxo group. Although a number of reports are available in the literature dealing with mononuclear dioxomolybdenum(VI) complexes of tridentate Schiff base ligands, where one labile binding site allows the binding and displacement of various substrate molecules, such systems with binuclear dioxomolybdenum(VI) complexes are rare.[2c] The present report is mainly concerned with binuclear dioxomolybdenum(VI) complexes whose two labile sites are easily accessible within the molecule. The following tetraanionic Schiff base ligands (**A**) have been selected for the present study.

EXPERIMENTAL

Reagents

All the reagents and solvents used were of analytical grade. *o*-Aminophenol, salicylaldehyde and acetylacetone were used after purification. Methylene-bis(salicylaldehyde)[3] and dithio-bis(salicylaldehyde)[4] were prepared following the literature procedures. $[MoO_2(acac)_2]$ was synthesized by the method described previously.[5]

Preparation of the Schiff bases

A solution of the appropriate amine (0.002 mol) in methanol (*ca* 10 cm^3) was added to a hot solution of the respective aldehyde (0.001 mol) in methanol (10 cm^3) and the reaction mixture was refluxed for 2 h on a water bath. After reducing the solvent to *ca* 5 cm^3 the solution was cooled to 10°C overnight. The separated solid product was filtered, washed with cold methanol and dried under reduced pressure at ambient temperature. Finally, the Schiff bases were recrystallized from methanol; yield: 50–80%.

Preparation of the complexes

$[(MoO_2)_2(CH_2\{sal\text{-}OAP\}_2)]$. The Schiff base $CH_2(H_2sal\text{-}OPA)_2$ (0.44 g, 0.001 mol) was dissolved in methanol (50 cm^3) by heating on a water bath and added $MoO_2(acac)_2$ (0.66 g, 0.002 mol) as a solid with vigorous shaking. The resulting turbid solution was filtered and then refluxed on a water bath for 6 h. After concentrating the solution to *ca* 10 cm^3 and cooling to 10°C overnight the separated solid was filtered, washed with methanol and dried at 100°C in air; yield 70%.

The other molybdenum complexes (listed in Table 1) were prepared following the above method, with slight modifications, in 50–70% yield.

$[(MoO_2)_2L(py)_2]$. These complexes were prepared in quantitative yield by dissolving $[(MoO_2)_2L]$ in a minimum amount of pyridine with heating on a water bath and then evaporating the excess pyridine *in vacuo*.

The analytical and physicochemical data of all the new Schiff bases and their $[(MoO_2)_2L]$ and $[(MoO_2)_2L(py)_2]$ complexes are presented in Table 1.

Measurements

Molybdenum was determined gravimetrically as dioxo-bis(8-quinolinolato)molybdenum(VI), as described previously.[6] Other elemental analyses were performed by the microanalytical section of this laboratory. The IR spectra were recorded as Nujol mulls and as KBr discs on a Perkin–Elmer model 1620 FT-IR spectrophotometer. The electronic spectra were recorded in DMF on a Shimadzu model UV-2101PC UV–vis scanning spectrophotometer. The ^1H NMR spectra were obtained on a Bruker WH-200 spectrometer in DMSO-d_6 and $CDCl_3$. Chemical shifts (δ in ppm) are reported relative to DMSO-d_6 (2.40 ppm) or $CDCl_3$ (7.24 ppm). The electrical conductance measurements were performed in 1×10^{-3} M DMF solutions using a Biochem model DC 808 digital conductivity bridge calibrated with potassium chloride solution. The mass spectra of the ligands were recorded on a Finnigan Mat model 1020 automated GC/MS spectrometer.

RESULTS AND DISCUSSION

Methylene- and dithio-bis(salicylaldehyde) behave like salicylaldehyde and react with amines in a 1:2 molar ratio to form the binucleating tetraanionic Schiff base ligands **1**–**8**. The mass spectral data of the representative ligands [e.g. molecular ion peak *m/z* of **1** at 438 (calc. 438), **3** at 398 (calc. 398), **5** at 488 (calc. 488) and 7 at 448 (calc. 448)] indicate the high degree of stability of the molecular ion to electron impact. These data also indicate that *para*-substituted methylene or disulphide groups are still attached to the two salicylaldehyde moieties. These ligands were further characterized by elemental analysis and other spectral techniques.

The tetraanionic binucleating Schiff base ligands **1**–**8** react with $[MoO_2(acac)_2]$ in a 1:2 molar ratio in refluxing methanol and complexes of the type $[(MoO_2)_2L]$ are formed as follows:

$$2[MoO_2(acac)_2] + LH_4 \xrightarrow[MeOH]{} [(MoO_2)_2L] + 4acacH.$$

Under these reaction conditions complete replacement of the bidentate acetylacetone groups occurs. The analytical data support the formulation of the complexes as $[(MoO_2)_2L]$ and not as $[(MoO_2)_2L \cdot 2MeOH]$, the expected octahedral complex. However, the coordination of methanol was observed in some complexes when dried only at ambient temperature. However, on drying at 100°C the complexes are invariably converted into a stable species, $[(MoO_2)_2L]$. Treatment of $[(MoO_2)_2L]$ with pyridine results in the formation of $[(MoO_2)_2L(py)_2]$, in which pyridine occupies the sixth coordination position in both $[MoO_2]^{2+}$ units. The $[(MoO_2)_2L]$ complexes do not lose weight on heating up to 200°C. However, the thermal analysis data for pyri-

[a] Abbreviations as listed earlier.
[b] Satisfactory molybdenum analysis of the complexes have also been obtained.
[c] Conductance values are in $\Omega\ mol^{-1}\ cm^2$.
[d] Elemental analysis could not be recorded.

dine adducts reveal a well-defined endothermic step at around 180°C, corresponding to the loss of two molecules of pyridine, which confirms the coordination of pyridine in $[(MoO_2)_2L(py)_2]$. The coordinated monodentate ligands in complexes of the type $[MoO_2L\cdot X]$ (X = monodentate ligand) are known to undergo dissociation on heating due to weak coordination and their labile nature.[7]

All the complexes reported here are diamagnetic, as expected for the $4d^\circ$ molybdenum ion. The low molar conductance values (3.0–9.0 $\Omega\ mol^{-1}\ cm^2$) of the complexes in DMF indicate their non-electrolytic behaviour. They are soluble in coordinating solvents such as pyridine, DMSO and DMF. The high decomposition temperature (>250°C) indicates the increased stability of the complexes.

IR studies

The IR spectra of the pyridine adducts exhibit two bands in the regions 920–936 and 905–915 cm^{-1}, due to the ν_{sym} and ν_{asym}(O=Mo=O) stretches, respectively. These data indicate the presence of a *cis*-MoO_2 structure as a *trans*-MoO_2 structure would only show one ν(O=Mo=O) band due to the asymmetric stretch.[1b] On the other hand, $[(MoO_2)_2L]$ complexes exhibit a sharp single band (but not in all the complexes) at 910–938 cm^{-1}, due to the ν(O=Mo=O) stretch, and a broad but strong band at *ca* 820 cm^{-1}, due to a Mo=O → Mo interaction.[1b] These observations suggest the presence of an oligomeric (pseudo-octahedral) structure for $[(MoO_2)_2L]$, in which each molybdenum ion achieves a pseudo-octahedral structure via oxo bridging.[7] Adduct formation with pyridine essentially shows the breaking of this bridge as the band at *ca* 820 cm^{-1} disappears and a new band appears at *ca* 910 cm^{-1} due to the ν_{asym}(O=Mo=O) stretch. This observation suggests bridging through the Mo=O → Mo moiety. The occurrence of the ν(C—O) (phenolic) band at almost identical positions in $[(MoO_2)_2L]$ and $[(MoO_2)_2L(py)_2]$ also suggests the presence of oligomeric bridges only through Mo=O → Mo, as oligomerization via the phenolic oxygen bridges would be expected to produce a substantial increase in the ν(C—O)(phenolic) stretch.[8]

The IR spectra of the Schiff bases show two medium intensity bands at *ca* 3200 and 2700 cm^{-1} (only one band at *ca* 2700 cm^{-1} in the Schiff bases derived from *o*-aminophenol), attributable to the ν(OH) band of alcoholic and intramolecularly hydrogen-bonded phenolic hydroxyl groups, respectively. These bands are absent in the spectra of the complexes, which indicates the deprotonation of the alcoholic and phenolic groups and coordination of the oxygen atoms to molybdenum. A strong band in the region 1630–1645 cm^{-1} is assigned to the azomethine ν(C=N) stretch and this band shifts to a lower frequency by 2–36 cm^{-1}, indicating the participation of the azomethine nitrogen atom in coordination.[9] Thus, the IR data suggest the dibasic tridentate and ONO donor behaviour of each Schiff base unit.

The coordination of pyridine is characterized by the shift of the ring breathing mode of pyridine, which occurs at 990 cm^{-1} in free pyridine,[10] to a

[d] Alcoholic OH resonance.

higher energy by 15–20 cm^{-1}. In addition, the shift of the totally symmetric ring stretching mode at 1587 cm^{-1}, the in-plane antisymmetric ring stretching mode at 1438 cm^{-1} and the in-plane totally symmetric ring breathing mode at 1030 cm^{-1} to higher energy are indicative of the pyridine coordination to the molybdenum ion.

Electronic spectral studies

The electronic spectra of the complexes are recorded in DMF and the data are listed in Table 2. The Schiff bases exhibit two or three electronic spectral bands in the regions 34,960–37,740, 27,860–31,060 and 23,980–24,690 cm^{-1}. These bands are assigned to $\pi \rightarrow \pi_1^*$, $\pi \rightarrow \pi_2^*$ and $n \rightarrow \pi^*$ transitions, respectively[13]. There is no indication of bands due to hydrogen bonding and association in any ligand, which indicates the breaking of the hydrogen bonding in DMF. Usually this band appears in non-coordinating solvents. These ligand bands are also observed in the complexes, but there is no systematic trend in the change of energy. In addition, some complexes show a new band at 20,220–23,580 cm^{-1}, which is assigned to the ligand-to-metal charge transfer transition between the highest occupied ligand molecular orbital and the lowest empty *d*-orbital of molybdenum.

^{1}H *NMR studies*

Further evidence for the coordinating mode of the ligands is obtained from the study of their ^{1}H NMR spectra. The NMR spectra of the ligands and complexes are presented in Table 3. The ligands exhibit resonances due to the phenolic protons of the salicylaldehyde residue between 13.50 and 14.85 ppm as a singlet and an additional signal at 9.56–9.71 ppm in ligands **1** and **5** due to the phenolic proton of the *o*-aminophenol residue. In the ligands **2** and **6** the phenolic proton signal was not observed in the 0–15 ppm region. The absence of hydroxyl resonances in the spectra of the complexes indicates the coordination of the phenolic oxygen atoms to molybdenum after proton replacement.[11] The sharp singlet due to the azomethine proton shifts downfield, suggesting the coordination of the lone pair of the nitrogen of the azomethine group to the molybdenum atom. The Schiff bases do not show resonances due to alcoholic protons in $CDCl_3$ solution, which may possibly be due to intramolecular hydrogen bonding between the alcoholic proton and the azomethine group.[12] However, the spectra of Schiff bases (**2**, **3**, **6** and **7**) in DMSO show the alcoholic proton signal at *ca* 4.26–5.10 ppm, which is confirmed by D_2O exchange studies. The absence of this signal in the complexes suggests deprotonation as a result of complex formation. The complexes $[(MoO_2)_2L]$ when dried at 100°C did not show signals due to coordinated methanol, supporting the oligomeric structure.

The coordination of pyridine to the molybdenum ion in $[(MoO_2)_2L(py)_2]$ is evidenced by the appearance of two to three new signals in the aromatic region. Other signals in the complexes due to aromatic protons, —CH_3 protons, —CH— protons, —CH_2— protons and —CH_2CH_2— protons are observed in almost the same positions as in the respective Schiff bases. The occurrence of a singlet due to the —CH_2— protons attached to two aromatic rings at 3.80–3.97 ppm in the Schiff bases derived from methylene-bis(salicylaldehyde) and in their complexes indicates that the two Schiff base groups are still attached to the methylene group. Thus, the NMR data agree well with the conclusion drawn from the IR data.

Abstract—The cluster cation of $[(PtMe_3)_3\{\mu\text{-I}, \mu\text{-S(CH}_2)_2NHEt_2\}_2]I$. CH_3CN has a cubane type structure, $[(PtMe_3)_4(\mu\text{-I}, \mu\text{-SR})_2]$, but lacking one $PtMe_3$ vertex. Each platinum atom exhibits octahedral coordination, one sulphur is triply bridging, the other sulphur and the two iodine atoms are doubly bridging.

Despite the wide diversity of structure types already established for metal thiolates,[1] only two have so far been observed for platinum(IV): cubanes $[(Me_3Pt)_4(\mu_3\text{-SR})_4]$, where R = Me[2] or Ph,[3] and thiolate-bridged mixed Pt(II)–Pt(IV) complexes of general formula $[(dppe)M(\mu_2\text{-SMe})_2PtXMe_3]$, with M = Pd or Pt, and X = Cl, Br or I.[4] Our interest in metal aminoalkanethiolate complexes, together with the scarcity of data on Pt(IV) thiolate complexes, encouraged us to study the reaction of tetrameric trimethylplatinum iodide with 2- and 3-aminoalkanethiols. These ligands can behave as simple thiols with a solubilizing and potentially ligating amine group, which becomes non-coordinating if it is protonated. Hence they give complexes different solubility properties from those of complexes of monofunctional thiols, thus facilitating the discovery of new structural types. Accordingly, previously unknown confacial bioctahedral diplatinum(IV) complexes with 3-aminoalkanethiolate bridges, $Na[(Me_3Pt)_2\{\mu_2\text{-SCH(CH}_2CH_2)_2NMe\}_3]$ and $[(Me_3Pt)_2\{\mu_2\text{-S(CH}_2)_3NHMe_2\}_3](BPh_4)_2$, have just been characterized structurally.[5] We now report the synthesis and crystal structure of an unprecedented complex, $[(Me_3Pt)_3\{\mu\text{-S(CH}_2)_2NHEt_2, \mu\text{-I}\}_2]I\cdot CH_3CN$, consisting of a Pt_3 cluster with an incomplete cubane structure.

The complex was prepared from the tetranuclear cubane-like $[(Me_3PtI)_4]$ by treatment with the aminothiol $HS(CH_2)_2NEt_2$ in methanol, and was recrystallized from isopropanol–acetonitrile solution. The crystal structure determination indicates that the complex consists of a trinuclear cluster cation $[(Me_3Pt)_3\{\mu\text{-I}, \mu\text{-S(CH}_2)_2NHEt_2\}_2]^+$ (Fig. 1), an I^- counterion, and a molecule of acetonitrile solvent. The cation can be described as a cubane-type $[(Me_3Pt)_4(\mu\text{-SR})_2(\mu\text{-I})_2]$ cluster, but lacking one Me_3Pt vertex group. Substitution of two of the iodide bridges of the starting material by thiolates has caused also loss of one of the trimethylplatinum units. The $Pt_3S_2I_2$ core is composed of a Pt_3 triangle and a distorted S_2I_2 tetrahedron. The cluster has an approximate mirror plane passing through Pt(3) and the two sulphur atoms. Each platinum atom has a distorted octahedral coordination, with a *fac* arrangement of the three methyl groups; each

* Authors to whom correspondence should be addressed.

octahedron shares two adjacent edges with the other two. Atoms S(1), I(1) and I(2) are doubly bridging, while S(2) is triply bridging; in the presence of a fourth Me_3Pt vertex, all these ligands would, of course, be triply bridging.

Values of individual bond lengths and angles for the cation are given in Fig. 1. Bond lengths and angles are essentially the same for the doubly-bridging and triply-bridging S atoms. Pt—C, Pt—S and Pt—I bond lengths, and angles within the $Pt_3I_2S_2$ core, are remarkably close to corresponding values in the complete cubane structures of $[(Me_3PtX)_4]$ (X = SMe,[2] SPh,[3] or I[6]), despite the lack of one Pt vertex and the mixture of bridging ligands in the current structure.

This structure is totally unprecedented among octahedrally coordinated metals and any type of thiolate ligands. A novel cadmium thiolate, $[Cd_3(SC_6H_2Pr^i_3)_7]^-$,[7] and the Fe_3S_4 cluster in *Desulfovibrio gigas* Ferredoxin II[8] are the closest examples of incomplete cubane clusters (similar Fe_3S_4 clusters are now known in about 20 proteins), even though in both cases coordination around the metal centres is essentially tetrahedral. For metals with octahedral coordination the present structure type is confined to early transition metal trinuclear cluster species. There are many molybdenum and tungsten trinuclear complexes with metal–metal bonding interactions and with oxo, sulphido, selenido, or halo ligands,[9] and a few structures of Cr, Mo and W are also known with carbonyl, alkoxo and alkylimido bridging ligands.[10] Several trinuclear complexes of niobium and tantalum, largely with halo and sulphido bridges, have also been structurally characterized.[11]

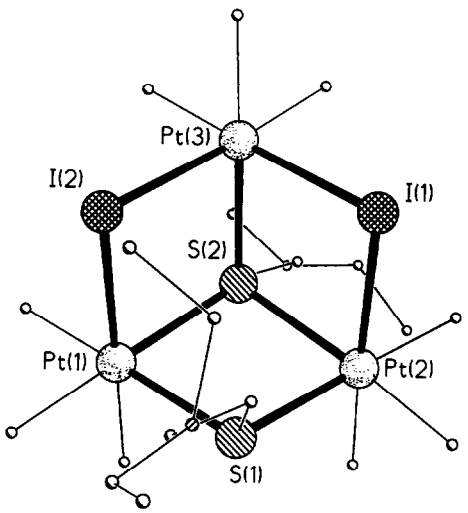

Fig. 1. Structure of the cation without hydrogen atoms, and with selected atoms labelled. Key dimensions: Pt(1)—S(1) 2.491(5), Pt(1)—S(2) 2.473(4), Pt(2)—S(1) 2.488(4), Pt(2)—S(2) 2.516(4), Pt(3)—S(2) 2.474(5), Pt(1)—I(2) 2.808(2), Pt(2)—I(1) 2.834(2), Pt(3)—I(1) 2.820(2), Pt(3)—I(2) 2.802(1) Å; S(1)—Pt(1)—S(2) 82.31(14), S(1)—Pt(1)—I(2) 94.61(11), S(2)—Pt(1)—I(2) 83.67(11), S(1)—Pt(2)—S(2) 81.49(14), S(1)—Pt(2)—I(1) 95.34(11), S(2)—Pt(2)—I(1) 81.76(11), S(2)—Pt(3)—I(1) 82.78(10), S(2)—Pt(3)—I(2) 83.77(10), I(1)—Pt(3)—I(2) 92.44(4), Pt(1)—S(1)—Pt(2) 97.8(2), Pt(1)—S(2)—Pt(2) 97.5(2), Pt(1)—S(2)—Pt(3) 104.0(2), Pt(2)—S(2)—Pt(3) 105.8(2), Pt(2)—I(1)—Pt(3) 89.51(4), Pt(1)—I(2)—Pt(3) 88.04(4)°.

EXPERIMENTAL

The complex was prepared by adding $[(Me_3PtI)_4]$ (0.205 mmol) to a filtered solution containing initially $HS(CH_2)_2NEt_2{\cdot}HCl$ (0.87 mmol) in dry and degassed acetonitrile (10 cm^3) and KMeO (0.85 mmol) in absolute methanol (0.25 cm^3). The reaction mixture was stirred under a nitrogen atmosphere for 5 days and then the solvent of the filtrate was evaporated. Subsequent additions of diethyl ether to the remaining oil yielded a yellow powder, which was treated with chloroform several times. After centrifugation, the solvent was decanted and the solid was dried *in vacuo* (yield 0.04 g, 11%). Alternatively, the same complex was obtained as a by-product in the synthesis of $[(Me_3Pt)_4\{\mu\text{-}S(CH_2)_2NEt_2\}_3(\mu\text{-}I)]$.[12] Yellow air-stable single crystals were produced by slow evaporation of an isopropanol solution containing a few drops of acetonitrile. Satisfactory analyses (C, H, N, S) were obtained.

Crystallography

The complex crystallizes as yellow blocks from isopropanol–acetonitrile solution. $[C_{21}H_{57}I_2N_2Pt_3S_2]I{\cdot}CH_3CN$, $M = 1408.8$, monoclinic, space group $P2_1/n$, $a = 11.301(2)$, $b = 20.455(4)$, $c = 16.884(3)$ Å, $\beta = 95.65(2)°$, $V = 3884.0(12)$ Å^3, $Z = 4$, $D_c = 2.409$ g cm^{-3}, $F(000) = 2576$. Reflections (9752) were measured on a Stoe-Siemens diffractometer with graphite-monochromated Mo-K_α radiation ($\lambda = 0.71073$ Å, $\mu = 13.29$ mm^{-1}) and on-line profile fitting.[13] Semi-empirical absorption corrections were applied and equivalent reflections merged to give 6814 unique data ($R_{int} = 0.080$, $2\theta_{max} = 50°$). Structure solution was by direct methods, refinement by full-matrix least-squares on F^2 for all measured data,[14] to give final $R' = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2]^{1/2} = 0.1891$ for all data, conventional R [on F values for 4592 reflections with $I > 2\sigma(I)$] = 0.0568. Atomic coordinates, bond lengths and angles, and atomic displacement parameters have been deposited as

supplementary material at the Cambridge Crystallographic Data Centre.

A STERIC PREFERENCE FOR LINEAR VERSUS BENT IMIDO LIGATION? SYNTHESIS AND X-RAY CRYSTAL STRUCTURE OF $[Mo(NAr)_2(edtc)_2]$ (Ar = 2,6-^{i}Pr$_2$C$_6$H$_3$; edtc = S_2CNEt_2) CONTAINING TWO LINEAR IMIDO MOIETIES

THÉRÈSE A. COFFEY, GLYN D. FORSTER, GRAEME HOGARTH* and ANDREA SELLA

Chemistry Department, University College London, 20 Gordon Street, London WC1H 0AJ, U.K.

(*Received* 26 *July* 1993; *accepted* 31 *August* 1993)

Abstract—Reaction of two equivalents of ArNCO (Ar = 2,6-^{i}Pr$_2$C$_6$H$_3$) with $[MoO_2(edtc)_2]$ affords the bisimido complex $[Mo(NAr)_2(edtc)_2]$ shown by crystallography to contain two linear imido ligands; this is in contrast to the parent complex $[Mo(NPh)_2(edtc)_2]$ previously shown to contain both linear and bent imido groups.

Complexes containing the imido ligand continue to attract considerable attention, primarily since they are envisaged as potential amination and aziridination reagents for organic synthesis. It is well documented that, depending upon the metal–nitrogen–carbon angle, the ligand may act as either a 2- or 4-electron donor to a metal centre, and this is easily understood in terms of the simple valence bond models.[1] More recently, a number of studies have considered the bonding in such complexes in more detail and concluded that when more than one imido ligand is present, the donor ability may be intermediate between these two valence bond extremes.[2,3] An interesting dilemma arises for a molecule that contains two imido ligands, from which the metal requires only six electrons. This is the case for complexes of the stoicheiometry $[Mo(NR)_2L_2]$ (where L is a three electron donor ligand), since the MoL_2 moiety is a 12 electron fragment. To date only one complex of this type has been structurally characterized, namely $[Mo(NPh)_2(edtc)_2]$, shown to contain one bent and one linear imido ligand.[4] We now report the synthesis and structure of another compound of this stoicheiometry which differs only in the steric bulk associated with the aryl group, but adopts a structure in which both imido ligands are linear.

Addition of two equivalents of 2,6-diisopropylphenylisocyanate to a toluene solution of $[MoO_2(edtc)_2]$ affords after chromatography the bisimido complex $[Mo(NAr)_2(edtc)_2]$ **1** in 50% yield.† Addition of only one equivalent of arylisocyanate also yielded **1** as the major product and the mixed oxo-imido complex was not isolated, indicating that the second substitution process occurs considerably faster than the first.

$$MoO_2(edtc)_2 + 2\,ArNCO \rightarrow Mo(NAr)_2(edtc)_2 + 2CO_2$$

†Complex **1** was characterized by elemental analyses and IR and NMR (^{1}H and ^{13}C) spectra.

Selected data: ^{1}H NMR. (C_7D_8, 373 K) δ 6.95 (*d*, 4H, *J* 7.6, m-C_6H_3), 6.80 (t, 2H, *J* 7.6, p-C_6H_3), 4.08 (septet, 4H, *J* 6.8, C*H*Me$_2$), 3.46 (q, 8H, *J* 7.0, C*H*$_2$Me), 1.19 (*d*, 24H, *J* 6.8, CH*Me*$_2$), 0.96 (t, 12H, *J* 7.0, CH$_2$*Me*); (C_7D_8, 253 K) δ 6.96 (*d*, 4H, *J* 7.6, m-C_6H_3), 6.84 (t, 2H, *J* 7.6, p-C_6H_3), 4.17 (septet, 4H, *J* 6.8, C*H*Me$_2$), 3.47 (sextet, 2H, *J* 6.8, C*H*$_2$Me), 3.14 (m, 4H, *CH*$_2$Me), 2.93 (sextet, 2H, C*H*$_2$Me), 1.28 (*d*, 12H, *J* 6.8, CH*Me*$_2$), 1.16 (*d*, 12H, *J* 6.8, CH*Me*$_2$), 0.81 (t, 6H, *J* 6.8, CH$_2$*Me*), 0.74 (t, 6H, *J* 7.0, CH$_2$*Me*); IR (KBr) 1267s, 1210m, 1149m, 1095w, 1075m, 962m, 847w, 755s cm^{-1}. Satisfactory elemental analyses were obtained.

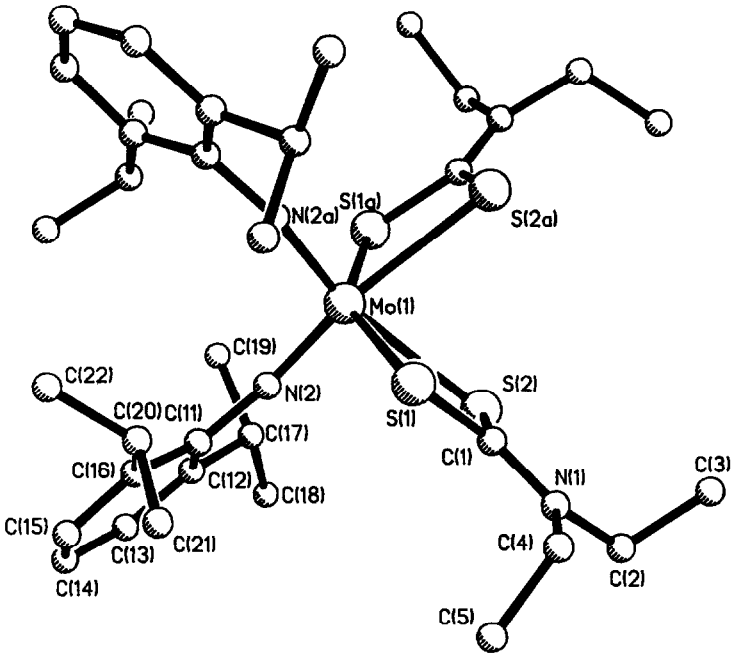

Fig. 1. Molecular geometry of **1**.

The structure of **1** has been determined crystallographically and is shown in Fig. 1.* As expected, the complex exhibits approximate octahedral coordination at molybdenum and contains a *cis* configuration of arylimido ligands [N(2)—Mo(1)—N(2A) 104.7(1)°]. The most surprising feature is that both are linear [Mo(1)—N(2)—C(11) 169.9(2)°], in marked contrast to the situation found in the parent complex $[Mo(NPh)_2(edtc)_2]$ which shows both linear [169.4(4) Å] and bent [139.4(4) Å] imido ligation (Fig. 2). Thus in **1** it appears that each imido ligand is acting as three electron donor to the molybdenum centre. For all known molybdenum imido complexes, the molybdenum–nitrogen bond length varies only within 0.1 Å, and thus this criterion alone is not necessarily a good measure of the donor properties of the imido ligand.[1] It is noteworthy however that in **1** the Mo(1)—N(2) distance of 1.766(2) Å is intermediate between those found in $[Mo(NPh)_2(edtc)_2]$, thus suggesting an intermediate bond order in **1**. A better insight into the molybdenum–nitrogen bond order can be gained in this instance by considering the *trans* influence of the imido ligand. Thus in $[Mo(NPh)_2(edtc)_2]$, while both the molybdenum–sulphur bonds *trans* to the imido ligands are elongated, that *trans* to the bent [2.755(2) Å] imido ligand, is considerably longer than that *trans* to the linear one [2.602(2) Å]. In **1** the *trans* molybdenum–sulphur bond is intermediate between these two extremes [Mo(1)—S(2) 2.672(1) Å], lending further weight to the postulation of two three electron donor imido ligands in **1**.

The concept of two imido ligands each acting as three electron donors is not new, indeed we ourselves have observed this behaviour in the somewhat related organometallic dimers $[CpMo(NAr)(\mu\text{-}NAr)]_2$.[2] The example reported here however

Crystal data: $Mo_1S_4N_4C_{34}H_{54}$, $M = 742.99$, monoclinic, space group C_2/c, $a = 16.336(2)$, $b = 12.977(2)$, $c = 19.230(2)$ Å, $\beta = 111.70(1)$, $U = 3788.7(9)$ Å^3, $Z = 4$, $T = 292$ K, $D_c = 1.30$ g cm^{-3}, $F(000) = 1568$, $\lambda = 0.71073$ Å, $\mu(\text{Mo-}K_\alpha) = 5.76$ cm^{-1}. Intensity data were collected on a crystal of dimensions 0.90 × 0.70 × 0.48 mm mounted on a Nicolet R3mV diffractometer, by the ω-2θ scan technique ($5 \leqslant 2\theta \leqslant 50°$). From 4593 measured data, 3059 with $I \geqslant 3\sigma(I)$ were considered observed. The structure was solved by direct methods and refined by full-matrix least-squares to R and R_w values of 0.031 and 0.034.

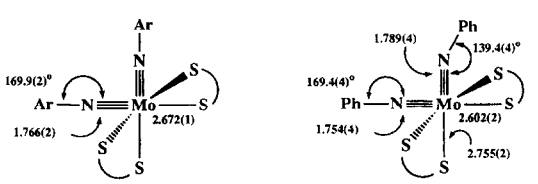

Fig. 2. A comparison of bond lengths and angles between **1** and $[Mo(NPh)_2(edtc)_2]$.

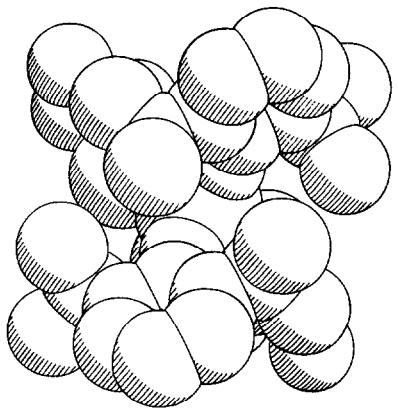

Fig. 3. Space filling diagram of **1**.

appears to be the first instance in which both possible configurations have been found within the same system. We believe that **1** adopts a configuration with two linear imido moieties due to steric effects. Figure 3 shows a space filling diagram for **1**. As can be clearly seen, a methyl from one isopropyl group lies above the arene ring of the second imido ligand, and sits in a pocket formed by its isopropyl groups. Adoption of a linear/bent structure would lead to steric clashes between two aryl groups, or between an aryl moiety and a dithiocarbamate ligand. We believe this conformation is maintained in solution since in the ^{1}H NMR spectrum at low temperatures two methyl environments are seen for both the isopropyl groups (in and out) and the dithiocarbamate ligands (up and down). Warming results in coalescence, until at 100°C a single resonance is observed for both of the different methyl environments. We attribute these spectral changes to two processes; geared rotation of the aryl groups about the N—C carbon bond, and rotation of the dithiocarbamates again about the C—N bond.

Complexes of the type $[Mo(NAr)_2L_2]$ are of particular interest as possible imido transfer agents due to the widespread use of the bisoxo complexes $[MoO_2L_2]$ in related oxidation processes.[5] We are currently investigating the reactivity of **1** in this respect, and it will be especially interesting to compare this with that of $[Mo(NPh)_2(edtc)_2]$, some reactivity studies of which have been reported.[6]

(*Received* 7 *July* 1993; *accepted* 28 *August* 1993)

Abstract—The title compound $Cs_4H_2V_{10}O_{28}\cdot 3H_2O$ was obtained from a polyvanadate system containing H_2O_2. No peroxo group or hydrogen peroxide molecule was found in the structure. The polyanions are ordered parallel to the *bc*-plane forming a layered structure. The water molecules and the caesium ions make a hydrogen bonding network with decavanadate ions and each other to support the whole crystal structure.

We have studied polyacids of the early transition metal with peroxide ligands obtained from metal, metal oxide or metal carbide—H_2O_2 systems.[1] Structures of tungsten-, molybdenum- or niobium-based oxides from the calcination of alkaline metal salts of those acids have been determined by the powder X-ray diffraction method.[2] In this series of studies the title compound was obtained from vanadium metal—H_2O_2—Cs^+ system as single crystals and its structure was determined by single crystal X-ray diffraction.

EXPERIMENTAL

Preparation

The compound $Cs_4H_2V_{10}O_{28}\cdot 3H_2O$ was obtained by the following method: vanadium metal powder (325 mesh) 0.3 g was completely dissolved in 10 cm^3 of 30% hydrogen peroxide aqueous solution in an ice-cooled water bath. Then 1.5 g CsBr in 10 cm^3 water was added in small portions into the vanadium solution. Orange flakey crystals appeared after storage for a day at room temperature. Found: Cs, 34.9; V, 32.4; H_2O, 4.01. Calc. for $Cs_4H_2V_{10}O_{28}\cdot 3H_2O$; Cs, 34.4; V, 33.0; H_2O, 3.50%.

X-ray measurement and structure determination

A single crystal with dimensions $0.25\times 0.20\times 0.01$ mm was subjected to single crystal X-ray diffraction method. Intensity data were collected on RIGAKU AFC-5R automated four-circle diffractometer with graphite monochromated Mo-K_α radiation ($\lambda = 0.71069$ Å) at 296 K. Crystallographic data are: FW = 1545.1, monoclinic, $P2_1/c$, $a =$ 10.079 (3), $b = 14.116(2)$, $c = 11.544(1)$ Å, $\beta =$ 108.20(1)°, $V = 1560(1)$ Å^3, and $Z = 2$. Of total 3958 reflections, 1348 unique observed ones with $Io \geqslant 3.0\sigma(Io)$ and $4° \leqslant 2\theta \leqslant 55°$ were used for calculation by using TEXSAN.[3] Lorenz polarization correction was applied, anomalous dis-

*Authors to whom correspondence should be addressed.

persion factors including imaginary part were taken from International Tables for X-Ray Crystallography,[4] Cs and V atoms were refined anisotropically and oxygen atoms isotropically. The occupation factors of the oxygen atoms of water molecules were estimated from the water content by thermogravimetry and their thermal parameters. Full matrix least-squares refinement based on F gave $R = 0.068$ and $R_w = 0.079$ (sigma weight) for 128 parameters.

STRUCTURE DESCRIPTION AND DISCUSSION

An ORTEP[5] view of the decavanadate anion with atomic notation is shown in Fig. 1. Although H_2O_2 was used in the preparation no peroxo groups were found in the electron density map by the difference Fourier syntheses. The polyanion structure is similar to the normal decavanadate[6] and is different from the peroxodecamolybate structure.[7] The bond distances and angles of the V—O bonds are similar to those in another decavanadate.[6] Figure 2 shows the packing diagram of the crystal. The polyanions are arranged to form a layered structure through the centre of the crystal parallel to the *bc*-plane. Thus the interlayer distance is 9.57 Å, and, considering the van der Waals radius of the oxygen atom (*ca* 1.40 Å), the width of the interlayer space is about 1.8 Å. Molecules of the water of crystallization are almost on a plane sandwiched between the vanadate layers; two of four caesium cations are also located between the layers, *ca* 0.7 Å apart from the water plane, and another two are included in the vanadate layers. Interatomic distances (see Table 1) between the caesium cations and neighbouring waters of crystallization are 3.12(4) to 3.31(4) Å, and those between caesium and oxygen atoms of the polyanion shows 3.07(2) Å as the minimum. Those between each water of crystallization and the nearest oxygen in the polyanion are 2.70(4) and 3.08(4) Å, and the shortest distance between water of crystallization is 2.62(5) Å. These interatomic distances indicate that the

Symmetry operations: [a]1−x, 1/2+y, 3/2−z; [b]x, 3/2−y, 1/2+z; [c]1−x, 1−y, 2−z; [d]x, 1/2−y, z−1/2; [e]x−1, 1/2−y, z−1/2; [f]−x, 1−y, 1−z; [g]1−x, y−1/2, 3/2−z; [h]−x, y−1/2, 3/2−z; [i]x, 1/2−y, 1/2+z; [j]1+x, y, z; [k]−x, 1−y, 2−z.

water molecules and caesium cations form the hydrogen bonding network among themselves or with decavanadate anion supporting the whole crystal structure. Some short interatomic distances were observed between neighbouring vanadate oxygens [O1—O3 3.14(3), O1—O5 3.26(3), O6—O12 2.57(2) Å]. The vanadium–oxygen bond length around bridging O6 are not elongated compared with another V—O(bridging) one, but those around O12 are relatively long. Terminal oxygen–vanadium distances of V1—O1, V5—O5 [1.61(2), 1.60(2) Å] are longer than two other V2—O2 and V4—O4 [1.58(2) Å each]. Considering these bond lengths and the influence of the hydrogen bonding with water molecule, but not with caesium cation which strongly correlated with O1, O2, O5, O7, and O9, bond orders[8] of O3 (1.39) and O12 (1.27) are remarkably smaller than those of other oxygen atoms, and this probably indicates that one of these oxygen atoms is protonated.

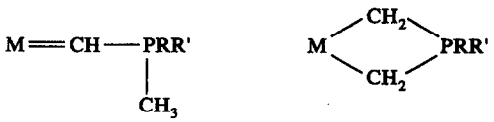
Abstract—The interaction of $(C_5H_5)_2SmCl \cdot LiCl$ with one equivalent of $Li[(CH_2)(CH_2)PPh_2]$ in refluxing tetrahydrofuran gives the yellow complex $[(C_5H_5)_3SmCH_2P(Me)Ph_2]$ in 30% yield. The compound has been fully characterized by analytical, spectroscopic and X-ray diffraction methods.

Phosphorus ylides have been shown to possess an extensive coordination chemistry with main group and transition metal atoms and to form metal–carbon σ-bonds of unusual stability.[1] Schumann[2] and Gilje[3] have extended the ylidic chemistry to lanthanide and actinide metals, respectively. Gilje and co-workers have further demonstrated that the phosphorus ylidic ligand, depending on the reaction conditions, can act either as a monodentate or a bidentate ligand as shown below.[3a]

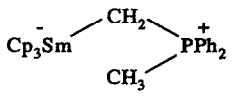


Recently we have described the preparation, solution dynamics and reactivities of a series of phosphorus ylidic organolanthanide complexes of the general formula $Cp'_2M[(CH_2)(CH_2)PRR'] \cdot (LiCl)_2$, ($Cp' = C_5Me_5$; M = Sm, Nd).[4] We are interested in examining the factors that affect the mode of coordination of the phosphorus ylidic ligand, particularly the steric and electronic effects of substituents of the cyclopentadienyl rings on the mode of coordination. In this communication, we report the result of the reaction of $(C_5H_5)_2SmCl \cdot LiCl$ with $Li[(CH_2)(CH_2)PPh_2]$.

The interaction of $(C_5H_5)_2SmCl \cdot LiCl$ with one equivalent of $Li[(CH_2)(CH_2)PPh_2]$ in refluxing tetrahydrofuran for 16 h, work up gave yellow crystals of stoichiometry $(C_5H_5)_3Sm[(CH_2)(CH_3)$

* Authors to whom correspondence should be addressed.

$PPh_2]\cdot C_4H_8O$, (**1**),* in 30% yield after recrystallization from a tetrahydrofuran–toluene mixture. Other than the resonances due to the tetrahydrofuran protons, the ^1H NMR of **1** exhibits a broad singlet, a multiplet, a doublet (J_{P-H} = 13.5 Hz), and a doublet (J_{P-H} = 8.0 Hz) of relative intensity 15, 10, 3 and 2 for the protons of the three Cp rings, the two phenyl rings, the methyl group, and the methylene group at δ 10.36, 7.17–7.60, 2.08, and 0.80 ppm, respectively. The $^{31}P\{^1H\}$ NMR spectrum of **1** exhibits a singlet at δ 21.2 ppm. The ^{31}P chemical shift is consistent with a ylide complex.[5] Based on the above spectroscopic data, **1** can be formulated as $[(C_5H_5)_3SmCH_2P(Me)Ph_2]$, a ylide complex having structure **A** as shown below.



A

A similar structure has been proposed for $[(C_5H_5)_3LuCH_2PPh_3]$.[5] The structure of **1** was established by an X-ray diffraction study.† Crystals of stoichiometry $[(C_5H_5)_3SmCH_2P(Me)Ph_2]\cdot C_4H_8O$ suitable for X-ray diffraction study were grown from a solution of tetrahydrofuran. A perspective drawing and selected bond lengths and bond angles of **1** are shown in Fig. 1 and its caption.

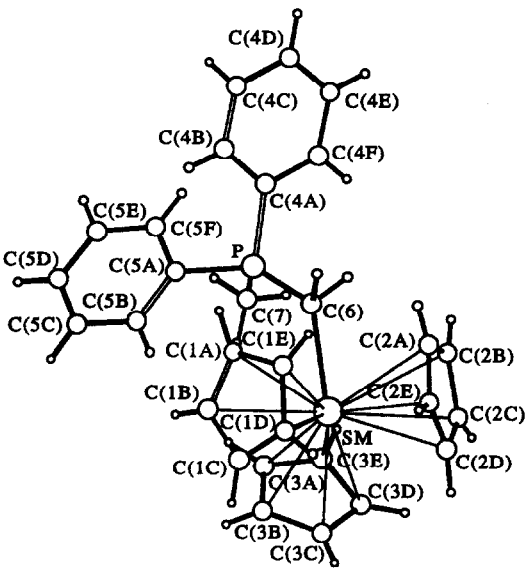


Fig. 1. A perspective view of the structure of $[Cp_3SmCH_2P(Me)Ph_2]$. Selected bond lengths (Å) and bond angles (°): Sm—C(6), 2.622(6); P—C(6), 1.734(6); P—C(7), 1.811(6); P—C(4A), 1.817(6); P—C(5A), 1.811(5); Sm—C(6)—P 138.2(2); C(6)—P—C(7), 112.2(3); C(6)—P—C(4A), 114.3(2); C(6)—P—C(5A), 113.3(1); C(7)—P—C(4A), 104.9(3); C(7)—P—C(5A), 106.5(2); C(4A)—P—C(5A), 105.0(3).

The solid state structure of **1** is consistent with the spectroscopic data and can be described as a distorted tetrahedron if one considers that the metal coordinated to the centroid of the cyclopentadienyl rings. The cyclopentadienyl rings are bonded in a η^5-fashion with Sm—C bond lengths ranging from 2.725(9) to 2.827(7) Å. The mean Sm—C distances for the three Cp rings are 2.75, 2.78, and 2.79 Å. These values are slightly longer than that of $[(MeC_5H_4)_2SmC{\equiv}CCMe_3]_2$ (2.71 and 2.72 Å)[6] and $(C_9H_7)_3Sm$ (2.75 Å),[7] and similar to that of $(C_5H_5)_3Sm(C_5H_5N)$ (2.75, 2.77, and 2.78 Å)[8] and $[(C_5H_5)_3Sm(\mu\text{-}Cl)Sm(C_5H_5)_3]^-$ (2.77 Å).[9] This is an agreement with structure **A** where a negative charge is delocalized on to the Sm metal. The Sm—C(6) distance is 2.622(6) Å and is longer than the Sm—C terminal distance in $(C_5Me_5)_2Sm(R)(THF)$ [R = Me, 2.484(14) Å;[10] R = Ph, 2.511(8) Å;[11] R = CH_2Ph, 2.528(8)[10] Å and shorter than the Sm—C bridging distance in $(C_5Me_5)_2Sm(\mu\text{-}Et)_2AlEt_2$ [2.662(4) Å].[12] This is consistent with the fact that the Sm—C(6) bond is a dative bond which should be weaker than a Sm—C σ-bond as in $(C_5Me_5)_2Sm(R)(THF)$ and stronger than an electron-deficient three centre-two electron Sm—C bridging bond as in $(C_5Me_5)_2Sm(\mu\text{-}Et)_2AlEt_2$. The P—C distances for the P—CH_2 and P—CH_3 groups are 1.734(6) and 1.811(6) Å, respectively. These

*$[(C_5H_5)_3SmCH_2P(Me)Ph_2]\cdot C_4H_8O$: Yellow crystals, m.p. 180–183°C. Found: C, 63.0; H, 6.1; Cl, 0.0; Sm, 23.6. Calc. for $C_{33}H_{38}OPSm$: C, 62.8; H, 6.0; Cl, 0.0; Sm, 23.8%. IR (cm^{-1}, in Nujol): 3087m, 3049m, 2883vs, 2844vs, 2721w, 1589w, 1576w, 1437s, 1416w, 1338w, 1317m, 1298w, 1157m, 1121m, 1109m, 1070w, 1010s, 994m, 931w, 898s, 886s, 846w, 773vs, 752vs, 738vs, 706m, 692s, 677w, 665w. $^{31}P\{^1H\}$ NMR (d_8-THF): 21.2(s) ppm. ^1H NMR (d_8-THF): Cp protons, δ 10.36 (15H, br s) ppm; phenyl protons, δ 7.17–7.60 (10H, m) ppm; methyl protons, δ 2.08 (3H, *d*; J_{P-H} = 13.5 Hz) ppm; methylene protons, δ 0.80 (2H, *d*; J_{P-H} = 8.0 Hz) ppm; THF protons, δ 3.54(m) and 1.70(m) ppm.

†Crystal data: $C_{29}H_{30}PSm\cdot C_4H_8O$, F_w = 632.01, triclinic, $P\bar{1}$ (No. 2), a = 10.760(6), b = 11.999(4), c = 12.441(6) Å, α = 74.84(3), β = 68.21(4), γ = 85.43(3), V = 1439.3 $Å^3$, Z = 2, $F(000)$ = 642, D_c = 1.458 $g\,cm^{-3}$, μ = 21.23 cm^{-1}. Crystal dimensions: 0.32 × 0.42 × 0.44 mm. Intensity data were collected on an Enraf-Nonius CAD4 diffractometer with grapahite monochromated Mo-K_α radiation (λ = 0.71073 Å) using ω–2θ scans ($2\theta_{max}$ = 50°). The structure was solved by a combination of Patterson and direct methods (DIRDIF) after an absorption correction (ψ-scan method) was applied and refined by full-matrix least-squares to give R = 0.035, R_w = 0.044 for 4085 independent observed reflections [$I > 3\sigma(I)$].

bond lengths are in very good agreement with comparable bond lengths in $(C_5Me_5)_2Lu[(CH_2)(CH_2)PMe_2]$[2a] [P—$CH_2$, 1.769(16) and 1.782(15) Å; P—CH_3, 1.816(22) and 1.823(23) Å] and $(C_5Me_5)_2U(Cl)[(CH_2)(CH_2)P(Me)Ph]$ [P—CH_2, 1.74(1) and 1.74(1) Å; P—CH_3, 1.77(1) Å].[3b]

In contrast to $(C_5Me_5)_2SmCl \cdot LiCl$ which reacted with $Li[(CH_2)(CH_2)PPh_2]$ to give the expected cyclic ylidic complex $(C_5Me_5)_2Sm(CH_2)(CH_2)PPh_2$,[4] interaction of $(C_5H_5)_2SmCl \cdot LiCl$ with $Li[(CH_2)(CH_2)PPh_2]$ gives the unexpected ylide complex $[(C_5H_5)_3SmCH_2P(Me)Ph_2]$. The result suggests that the nature of the products of the above reaction may be influenced by the substituents of the Cp rings. We are in the process of examining this effect.

FUSED-RING METALLAMACROCYCLIC MERCURY/LANTHANIDE COMPLEXES FORMED BY FUSED-RING LACTAMS

DAVID M. L. GOODGAME,* STUART P. W. HILL, ROGER LINCOLN, MIGUEL QUIROS and DAVID J. WILLIAMS

Chemistry Department, Imperial College of Science, Technology, and Medicine, London SW7 2AY, U.K.

(*Received* 4 *May* 1993; *accepted* 28 *June* 1993)

Abstract—Mercury(II) acetate reacts with the fused-ring lactams (**I**) and lanthanide(III) nitrates, Ln = La–Gd (Pm not studied), to give $[LnHg_2L_4(NO_3)_3]_n$ and with Y and Ln = Tb–Yb to yield $[Y_2Hg_3L_6(NO_3)_6]_n$ and $[Ln_2Hg_3L_6(NO_3)_6]_n$, respectively. Each set of compounds forms an isostructural series. For the ligand **Ic** representative members of each series (Ln = Nd and Er, respectively) have been characterized by single-crystal X-ray diffraction methods. Both compounds form two-dimensional polymeric metallamacrocyclic arrays. They differ in the sense that the erbium complex comprises sheets of contiguous 48-membered rings, whereas in the neodymium compound two sizes of metallamacrocyclic coexist—one 48-membered and one 16-membered, which are fused together. The erbium ion is nine-coordinate and the neodymium atom 10-coordinate. The nitrate anions are involved in weak intra- and intermolecular interactions within the macrocycles.

Recently we reported the results of investigations into the ability of the anions of 2-oxazolidone[1,2] (**II**) and 2-azetidinone[1,3] (**III**) to link dissimilar metal ions to produce unusual new polynuclear compounds. The differences between the metal binding preferences of the deprotonated ring nitrogen and the exocyclic oxygen permit a heavy post-transition metal, such as mercury, to bind strongly to the nitrogen atom, leaving the oxygen atom free to coordinate to a wider range of other metal ions (e.g. transition metals[1] and lanthanides[2,3]).

The compounds formed thus far are very insoluble in common organic solvents due to their polymeric nature. To extend these studies we have examined the use of fused-ring lactams (**I**). These contain the same ambidentate N, O donor unit as the single-ring lactams for binding the respective metals and they also provide a bulky cycloalkyl group to favour enhanced solubility in common organic solvents. The ligand 2-azetidinone (**III**) possesses the largest HN—CO "bite" and thus favours the binding of two metals; also, it is the most acidic of the lactams [pK_a = 22.7]. Hence, the fused-ring ligands we have employed are based on this four-membered ring lactam. We report here the preparation and properties of complexes of **Ia–c** with combinations of mercury(II) and a range of lanthanide metal ions.

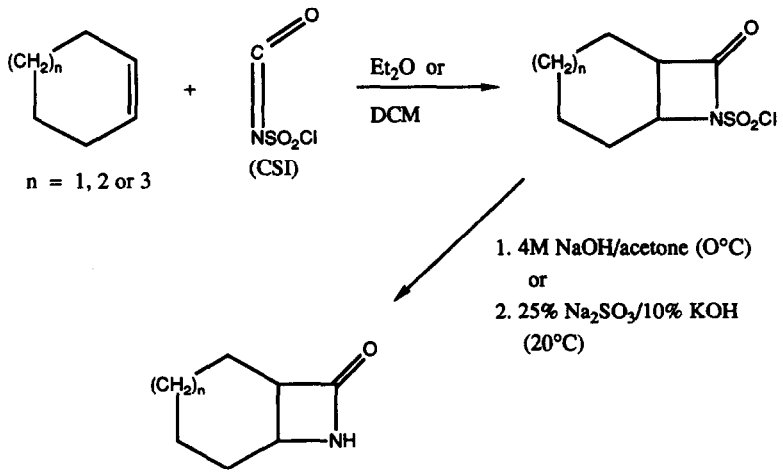
EXPERIMENTAL

Preparation of the ligands

The fused-ring lactams were prepared by modification of the methods of Jendralla[4] and Malpass[5] (Scheme 1).

Ia. Chlorosulphonyl isocyanate (7.1 g, 4.4 cm^3, 50 mmol) was added to dichloromethane (40 cm^3) cooled to −5°C under nitrogen. Cyclohexene (4.26 g, 5.25 cm^3, 52 mmol) was added dropwise through a syringe. The stirred mixture was allowed to warm to room temperature and then refluxed gently for 24 h. The progress of the reaction was followed by IR, by the disappearance of the isocyanate ν(C=N) band at 2200 cm^{-1} and the appearance of the lactam ν(C=O) band at *ca* 1810 cm^{-1}. When the reaction was complete, ice-cold water (40 cm^3) was added down the condenser dropwise with care,

*Author to whom correspondence should be addressed.



Scheme 1.

whilst keeping the flask in an ice/salt bath. The organic phase was separated, washed with ice-cold water (5×40 cm^3) and then dried over anhydrous sodium sulphate. After filtration, the solvent was removed under reduced pressure. The residue was dissolved in *n*-pentane (35 cm^3) to remove any unreacted cyclohexene and then cooled to between -40 and -70°C to crystallize the cycloadduct. The mother liquor was decanted off and any remaining solvent removed *in vacuo*.

The *n*-chlorosulphonyl-β-lactam was dissolved in diethyl ether (50 cm^3) and a solution of sodium sulphite heptahydrate (30 g in 100 cm^3 water) was added. The mixture was stirred for 2 h and 10% aqueous potassium hydroxide added dropwise to a constant pH of 7–8. The ether phase was separated, dried over anhydrous sodium sulphate and the solvent removed under reduced pressure. The resulting waxy, colourless solid was recrystallized from boiling hexane to produce colourless crystals (2.4 g, 37% yield). IR (cm^{-1}): 3420, 3265 (N—H); 1738 (C=O). NMR: δ_H (270 MHz, $CDCl_3$): 1.2–2.0 (8H, m), 3.22 [1H, ddt, H(1)], 3.84 [1H, m, H(6)], 6.19 [1H, s, H(7)]; δ_C (270 MHz, $CDCl_3$): 173.01 [C(8)], 48.23 [C(1)], 47.40 [C(2)], 26.24 [C(6)], 20.47 [C(3)], 19.55 [C(5)], 17.43 [C(4)].

For ligand **Ib** the same procedure was followed but using cycloheptene (5 g) (yield 3.7 g, 54%). IR (cm^{-1}): 3415, 3250 (N—H); 1746 (C=O). NMR: δ_H (270 MHz, $CDCl_3$): 1.2–2.0 (10H, m), 3.31 [1H, ddt, H(1), 3.82 [1H, m, H(7)], 5.90 [1H, s, H(8)]; δ_C (270 MHz, $CDCl_3$): 171.69 [C(9), 55.63 [C(1)], 53.84 [C(2)], 32.47 [C(7)], 32.18 [C(3)], 28.66 [C(6)], 25.75 [C(4)], 25.30 [C(5)].

For ligand **Ic** the same procedure was followed but using cyclooctene (5.72 g) and dry diethyl ether instead of dichloromethane (yield 5.9 g, 73%). IR (cm^{-1}): 3412, 3240 (N—H); 1750 (C=O); NMR: δ_H (270 MHz, $CDCl_3$): 1.2–2.0 (12H, m), 3.01 [1H, ddt, H(1)], 3.64 [1H, dq, H(8)], 5.91 [1H, s, H(9)]; δ_C (270 MHz, $CDCl_3$): 172.04 [C(10)], 54.63 [C(1), C(2)], 29.76 [C(8)], 29.66 [C(3)], 28.30 [C(7)], 26.74 [C(6)], 22.45 [C(5)].

Preparation of the complexes

The compounds HgL_2 (L = **Ia–c**) were prepared by mixing mercury(II) acetate (0.1 mmol) and the appropriate ligand (0.2 mmol) in methanol or acetonitrile (10 cm^3). The solid complexes separated when the solutions were left in a desiccator over concentrated sulphuric acid. The heterometallic complexes (Table 1) were prepared similarly but with the addition of the appropriate hydrated metal nitrate (0.05 mmol). The transition metal complexes were best prepared in acetonitrile. With the lanthanides from La to Gd the use of acetonitrile resulted in the immediate formation of powders, but crystals were obtained from a 50 : 50 mixture of acetonitrile/methanol; in methanol oils were produced. For yttrium and the lanthanides from Tb to Yb the best crystalline products formed from methanol, but the complexes may also be obtained from acetonitrile or acetonitrile/methanol mixtures. The products which formed were removed by filtration and allowed to dry.

Analytical data (Microanalytical Laboratory, Imperial College and Medac Ltd, Brunel University) are given in Table 1.

Data collection and processing

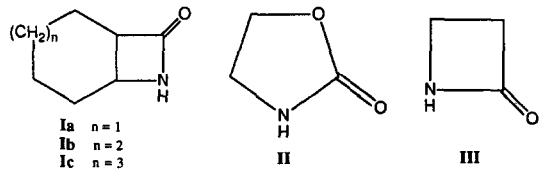
Siemens P4/PC diffractometer, ω-scan method ($2\theta < 45°$), graphite-monochromated Mo-K_α radiation. For compounds **1** and **2** 9248 and 4854 independent reflections, respectively, were measured; 4526 [$|F_o| > 5\sigma(|F_o|)$] and 2778 [$|F_o| > 4\sigma(|F_o|)$] were considered observed and corrected for Lorentz and polarization factors. For **1** a Gaussian absorption correction (face-indexed numerical) was applied; minimum and maximum transmission factors 0.40 and 0.66; crystal **2** decomposed and absorption correction was not possible.

Structure analysis and refinement

Both structures were solved by the heavy-atom method, revealing the position of the mercury atoms. For **1** and **2** all non-hydrogen atoms were located from subsequent ΔF maps. In **1** there is disorder in all four of the eight-membered rings. In two of these the disorder was resolved into partial occupancy, alternate atom positions. In all four rings the atoms were refined isotropically, subject to a C—C distance constraint. A ΔF map also revealed the presence of two partial weight water molecules, which were refined isotropically. In **2** a ΔF map revealed the presence of a partial occupancy methanol molecule. This and all the other non-hydrogen atoms were refined anisotropically. The hydrogen atoms in both structures, with the exception of those of the partial weight water and methanol molecules, which could not be located, were idealized (C—H 0.96 Å), assigned isotropic thermal parameters, $U(H) = 1.2_{eq}(C)$, and allowed to ride on their parent carbons. Refinements were by full-matrix least-squares to give: for **1**, $R = 0.060$, $R_w = 0.058$ [$w^{-1} = \sigma^2(F) + 0.0007F^2$]; for **2**, $R = 0.064$, $R_w = 0.054$ [$w^{-1} = \sigma^2(F) + 0.0004F^2$]. The maximum residual electron densities in the final ΔF maps were 1.51 and 1.77 for **1** and **2**, respectively. The mean and maximum shift/error ratios in the final refinement cycle were: for **1**, 0.04 and 0.56; for **2**, 0.05 and 0.58. Computations were carried out on an IBM 386 PS2 computer using the SHELXTL-PC program system[6] and published scattering factors[7]. Important bond lengths and angles are listed in Tables 2 and 3.

RESULTS AND DISCUSSION

Two methods were used for the preparation of the ligands (**I**) (Scheme 1). The first step, which is common to both and has been employed in similar preparations,[8–12] is the direct reaction of the cycloalkene with chlorosulphonyl isocyanate (CSI) in diethyl ether (for **Ic**) or dichloromethane (for **Ia**, **b**). The second step, the reduction of the intermediate, can be performed in a number of ways.[10] The two usual methods include the use of cold 4 M NaOH/acetone[9] or aqueous sodium sulphite/KOH.[10] The former method suffers in that the final product is contaminated with by-products, causing difficulty in separation. We found the latter method to have the advantages of simplicity of the reaction and isolation procedures, mild reaction conditions and a good yield of pure product.



Reaction of the ligands **Ia–c** with mercury(II) acetate in methanol or acetonitrile gave the expected HgL_2 complexes as monohydrates with **Ia** and **Ib** and as a hemi-hydrate with **Ic**. Similar hydration was found for the analogous complex with 2-azetidinone and the role of the solvent water in that compound was elucidated by an X-ray structural study.[3]

The stoichiometries of the solid products obtained from the reaction of mercury(II) acetate, the fused-ring lactams **Ia** and **Ic** and yttrium(III) or lanthanide(III) nitrates depend on the lanthanide ion employed. Use of the trivalent lanthanide ions in the series lanthanum to gadolinium (promethium not studied) afforded the compounds $[LnHg_2L_4(NO_3)_3]_n$, whereas yttrium and the lanthanides in the series terbium to ytterbium inclusive gave compounds of the stoichiometry $[Ln_2Hg_3L_6(NO_3)_6]_n$. The size of the metal ion appears to influence which complex type is formed, with the change occurring on passing from Gd^{3+} to Tb^{3+}, and with Y^{3+} adopting the same type as the smaller lanthanide ions. In view of the similarity of

the stoichiometries of the Hg/lanthanide complexes formed by **Ia** and **Ic**, we performed only a partial survey of the compounds formed by **Ib** (Table 1) and this ligand appears to follow the same pattern.

Reaction of mercury(II) acetate, ligand **Ic**, and the hydrated nitrates of manganese(II), cobalt(II), copper(II) and cadmium(II) gives the complexes $[M_2Hg_3L_6(NO_3)_4]\cdot 2H_2O$ (M = Mn, Co, Cu) and $[Cd_2Hg_3L_6(NO_3)_4]$. The electronic spectrum of the cobalt complex and the EPR spectra of the manganese and copper complexes pointed to the presence of distorted six-coordinate geometry about the transition metal ions, but crystals suitable for X-ray studies could not be obtained so their precise nature could not be determined.

Structural studies on the lanthanide complexes

X-ray powder diffraction measurements on the lanthanide complexes of **Ic** showed that all the compounds within each respective series, $[LnHg_2L_4(NO_3)_3]$ and $[Ln_2Hg_3L_6(NO_3)_6]$ are isostructural. The data, which were obtained photographically, were adequate to establish the isomorphous character of the related compounds, but not sufficiently resolved to permit accurate indexing and accurate lattice parameter determination. A representative member of each series, $[NdHg_2(C_9H_{14}NO)_4(NO_3)_3]_n$ (**1**) and $[Er_2Hg_3(C_9H_{14}NO)_6(NO_3)_6]_n$ (**2**), was obtained in a form suitable for single-crystal X-ray analysis.

Structure of $[NdHg_2(C_9H_{14}NO)_4(NO_3)_3]_n$ (**1**)

In the Nd complex (**1**) the lanthanide ion is bound to 10 oxygen atoms, four of which are from the lactam ligands [Nd—O 2.34–2.47 Å] and six from bidentate nitrate groups [Nd—O 2.54–2.84 Å]. The resultant coordination geometry is a distorted bicapped square anti-prism (Fig. 1). The principle cause of the distortion is the small "bite" of the

bidentate NO_3 anions, which reduces the site symmetry to C_1. A similar coordination arrangement is observed in the thorium/mercury complex formed by 2-pyrrolidone,[13] but not, hitherto, in a lanthanide/mercury heterometallic complex.

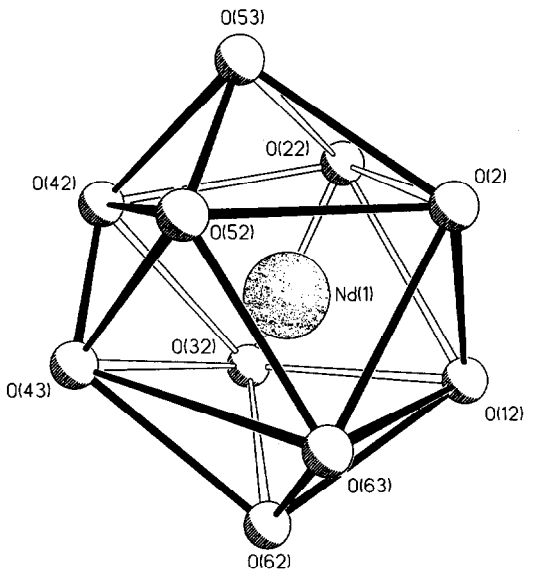

Fig. 1. The distorted bicapped square anti-prismatic coordination geometry about the Nd atom in **1**.

In the asymmetric unit (Fig. 2) the N—Hg—N units are essentially linear [180.0° at Hg(1) and Hg(2) and 179.2° at Hg(3)], with Hg—N distances in the range 1.98–2.04 Å. It is interesting to note that, although the crystal contains *cis*-fused lactam ligands of both chiralities, those bonded to any one Nd centre all have the same chirality.

Adjacent neodymium centres are linked via L—Hg—L bridges to form a polymeric array which is very different from those formed previously by lanthanide/mercury/lactam complexes (Fig. 3). Two of the HgL_2 units bridge centrosymmetrically-related neodymium centres, forming a 16-membered ring (A) containing two neodymium, two mercury, four carbon, four nitrogen and four oxygen atoms. The other two units, however, bridge via a glide-related neodymium centre to another lattice-translated neodymium atom, creating a 48-membered centrosymmetric macrocycle (B) which consists of six neodymium, six mercury, 12 carbon, 12 nitrogen and 12 oxygen atoms.

This coexistence of both 16- and 48-membered macrocycles, each with a common edge, is reminiscent of the structure found[2] for the gadolinium/mercury complex formed by **II**. In the latter case the 16-membered rings were offset with respect to each other. The array found for **1** also has some

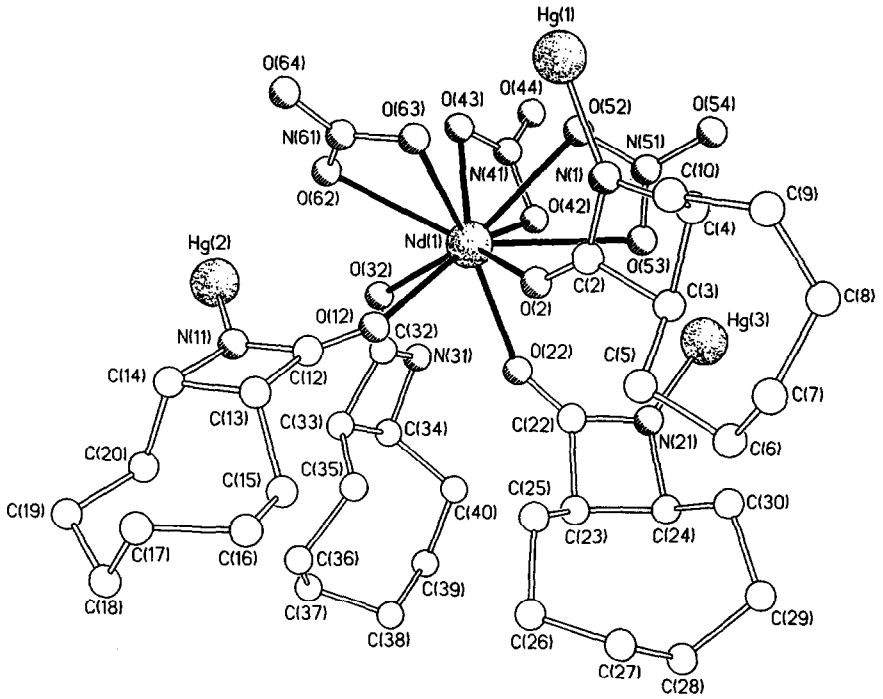

Fig. 2. The neodymium environment in **1**, showing the crystallographic numbering scheme.

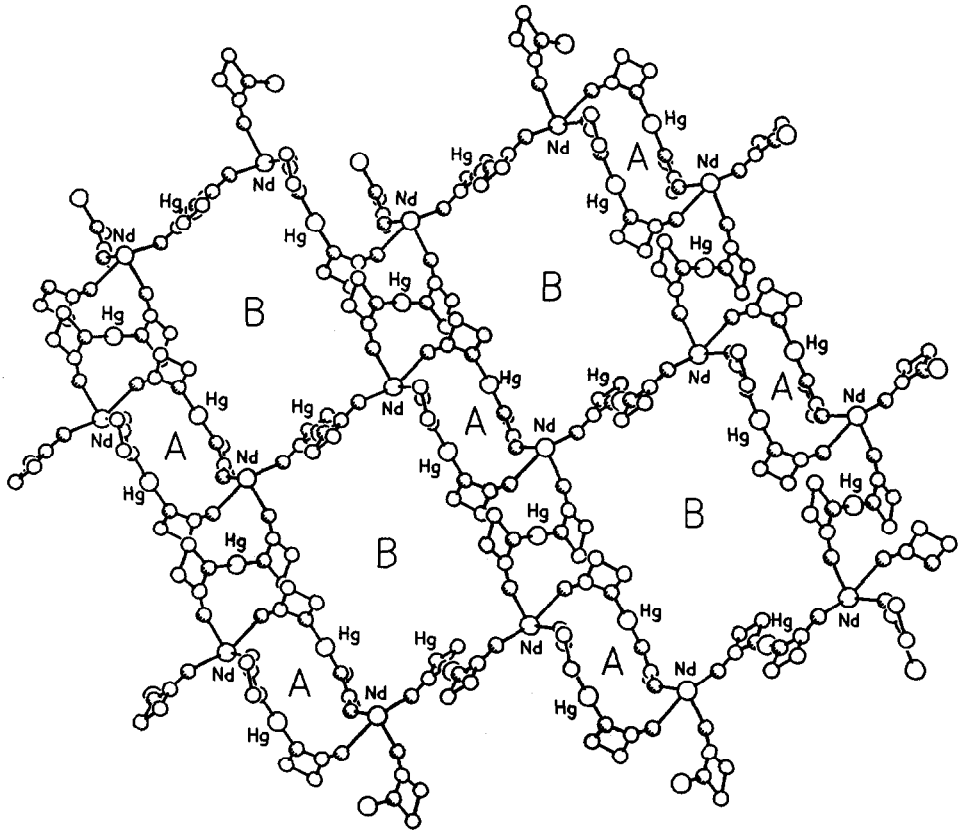

Fig. 3. Part of the contiguous array of fused 16- and 48-membered rings in the structure of **1**.

similarities to the structure of the terbium/mercury complex formed by 2-pyrrolidone[14] where an HgL_2 strut links separate 16-membered macrocycles to make a one-dimensional chain polymer. There, three carbonyl oxygens are bound to the lanthanide ion, whereas in **1** there are four. This additional carbonyl oxygen forms part of another HgL_2 strut, which joins the separate chains and, in so doing, generates the 48-membered macrocycle (Fig. 3).

There are two different dispositions of the lactam moieties about the mercury–nitrogen bonds in the HgL_2 units. The mercury atoms involved in the 48-membered macrocycle alone have organic ligands which are coplanar, whereas the lactams bound to the mercury atoms in the 16-membered rings have a large distortion from ligand coplanarity (114.7°). This latter arrangement is similar to those found in the 16-membered rings of the gadolinium/mercury complex with 2-oxazolidone, where angles of 119.8 and 122.3° are observed.[2] The shortest transannular Nd···Nd and Hg···Hg distances in **1** are 8.13 and 5.07 Å, respectively.

Structure of $[Er_2Hg_3(C_9H_{14}NO)_6(NO_3)_6]_n$ (**2**)

In **2** each erbium ion is bonded to nine oxygen atoms in a distorted tricapped trigonal prismatic geometry (Fig. 4). Three of the oxygen atoms are organic ligand carbonyl oxygens (Er—O 2.26–2.27 Å) and six are from the bidentate nitrate groups (2.40–2.52 Å).

In the asymmetric unit (Fig. 5) one of the HgL_2 units has linear N—Hg—N geometry, but the other is slightly bent [N(1A)—Hg(1)—N(11) = 172.9(8)°]. The Hg—N distances are in the range 2.00–2.06 Å. The HgL_2 units bridge adjacent erbium centres forming 48-membered metallamacrocycles which interlock at the erbium atoms, generating a sheet polymer (Fig. 6). This offset parquet-like pattern of fused metallamacrocyclic rings is very similar to that observed for the analogous complex formed by erbium with 2-azetidinone.[3]

In both **1** and **2** there are inter- and intramolecular stabilizing links between the nitrate anions and the mercury atoms in adjacent asymmetric units [in **1** Hg(1)—O(52) 2.82, Hg(1)—O(63) 2.88, Hg(2)—O(32) 2.90, Hg(2)—O(62) 2.85, Hg(3)—O(42) 3.02, Hg(3)—O(53) 2.76, Å; in **2** Hg(1)—O(22) 3.10, Hg(1)—O(41) 2.78, Hg(1)—O(51) 2.89, Hg(1)—O(63) 3.03, Hg(2)—O(42) 2.83, Hg(2)—O(53) 3.08 Å].

Both structures reported here consist of sheets of 48-membered rings, the only principal difference being in **1** the presence of an extra HgL_2 unit which links adjacent neodymium centres, forming an additional 16-membered macrocycle fused to the larger macrocycle. The X-ray powder studies show that this significant change in structural type occurs on passing from Gd to Tb within the lanthanide series, as the Gd complex is isostructural with **1** and the Tb complex is isostructural with **2**. In general terms, one can understand that the decrease in ionic size across the lanthanide series may result in fewer lactam ligands (three rather than four) being able

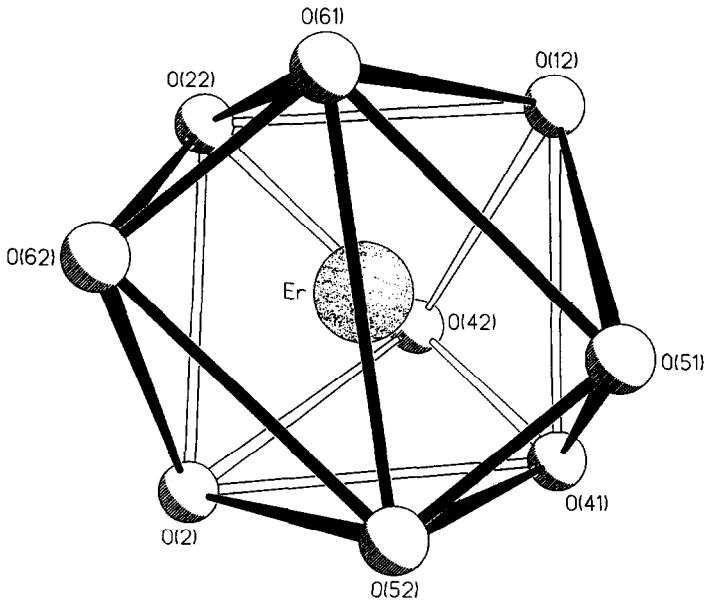

Fig. 4. The distorted tricapped trigonal prismatic coordination geometry about the erbium atom in **2**.

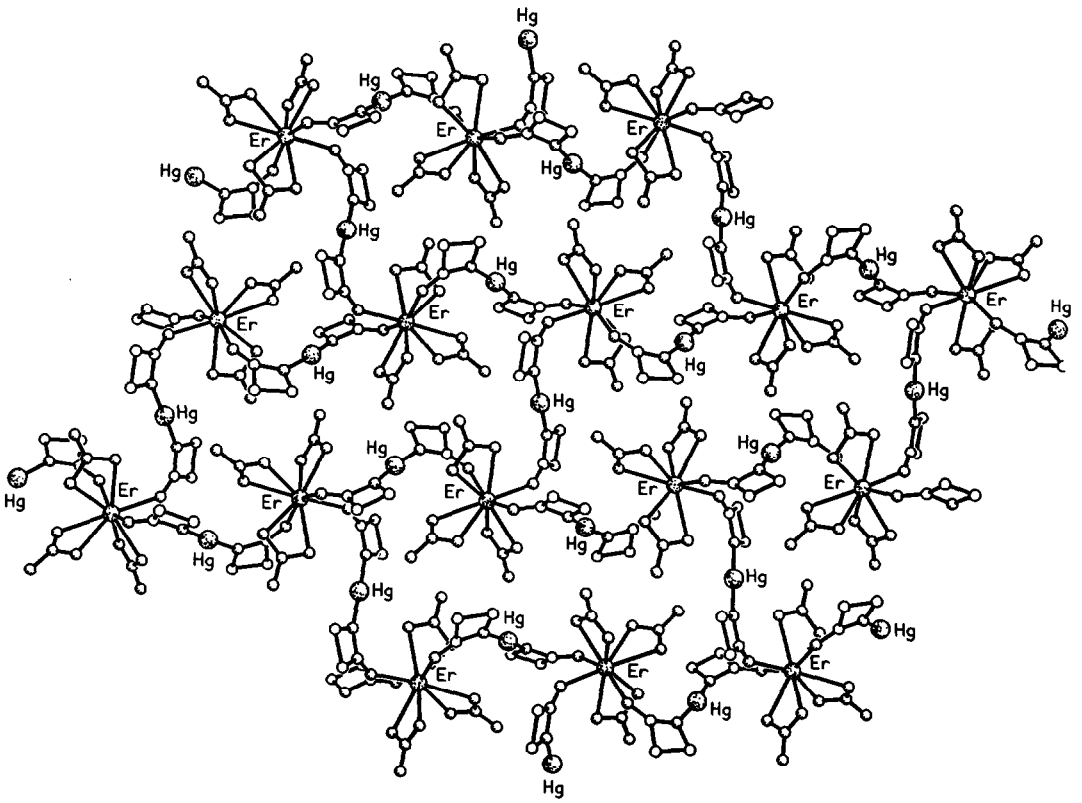

Fig. 6. Part of the contiguous, 48-membered, polymeric, macrocyclic array of **2**.

to be coordinated to the rare-earth metal centre. However, it is intriguing to find that the change in stoichiometry and the concomitant large change in polymeric structure occur at exactly the same point (Gd/Tb) with these more spatially-demanding fused-ring lactams as with 2-azetidinone itself[15] and with 2-pyrrolidone.[14]

(*Received* 20 *April* 1993; *accepted* 28 *June* 1993)

Abstract—A series of europium(III) complexes with 5,5-dimethyl-2,4-hexanedione and various organic bases, $Eu(But\text{-}ac)_2OH$ and $Eu(But\text{-}ac)_3 \cdot B$, where But-ac = 5,5-dimethyl-2,4-hexanedionate, and B = 1,10-phenanthroline, 2,2′-bipyridine or 5-nitro-1,10-phenanthroline, were synthesized and characterized by elemental analysis, UV and IR spectroscopy and melting point data. IR data confirmed that the europium is coordinated via oxygen donor atoms to 5,5-dimethyl-2,4-hexanedione and via nitrogen donor atoms to the diimine bases. The $Eu(But\text{-}ac)_2OH$ complex appears to be polymeric. Luminescence spectra, lifetime and quenching studies are reported.

The narrow line emission of rare earth chelates, including β-diketonates, following irradiation with UV light has been studied intensely following the first report by Weissman[1] over 50 years ago. Interest in this phenomenon was stimulated by the potential use of these compounds as laser materials,[2,3] which prompted extensive investigations of fluorescence among these compounds, including studies of the mode of intramolecular energy transfer and metal ion excitation,[4–8] measurement of quantum efficiencies and lifetimes.[9] The efficiency of energy transfer depends on the nature of the metal–ligand bond and variations in luminescence intensity as a result of substitution in β-diketone ligands[10] have been attributed to changes in the donor ability of the diketonate oxygen atoms towards the europium.[11] A review of europium complexes with diketones and polyketones has been provided by Forsburg.[12]

Our studies have sought to broaden the knowledge of some areas of europium coordination chemistry. In this work we present the synthesis and luminescence of complexes with an unsymmetrical β-diketone, But-ac (5,5-dimethyl-2,4-hexanedione), and different organic Lewis base ligands which affect the luminescence of the complexes. The quenching of $Eu(But\text{-}ac)_2(phen)$ by naphthalene in methanol is also reported.

EXPERIMENTAL

Materials

Europium chloride was prepared from Eu_2O_3 (99.99%) supplied by Yue Long Chemical Plant, Shanghai, P.R.C. Other chemicals were analytical or reagent grade.

Methods

Elemental analyses (carbon, hydrogen and nitrogen) were performed using a Perkin–Elmer model

* Authors to whom correspondence should be addressed.
† Present address: Department of Chemistry, Teacher's College, Yangzhou University, Yangzhou 225002, P.R.C.

240-C elemental analyser. IR spectra were run on a Nicolet model 5-DX spectrophotometer. UV spectra and europium analysis[13] were performed on Hewlett–Packard models 8451A and 8452 UV–vis diode array spectrophotometers. Melting points were measured with an X-4 macro melting point appliance. Conductivities were measured using DDS-11A conductivity equipment. Luminescence spectra were measured with an SLM model 8000C spectrofluorometer and corrected for instrument response as a function of wavelength. Luminescence lifetimes were measured using a pulsed-nitrogen laser for excitation (337 nm) and monitoring the emission utilizing the SLM emission optics with the photomultiplier output fed into a Stanford Research Systems boxcar integrator for data reduction.

Synthesis of the ligand, 5,5-dimethyl-2,4-hexanedione, But-ac[14]

The syntheses of pinacol hydrate[15] and pinacolone[16] are essentially literature procedures. To synthesize 5,5-dimethyl-2,4-hexanedione, pinacolone (100 g) was added to water (1 dm^3) and distilled. Concentrated sulphuric acid (80 cm^3) was then added to the distilled liquid. Pinacolone was deposited, dried with potassium carbonate and redistilled at 104–108°C.

A piece of sodium ribbon (7.8 g, 0.34 mol) was placed in anhydrous ethyl acetate and the mixture was cooled. Pinacolone (34 g, 0.34 mol) was then added and after 2 h the sodium ribbon had disappeared. The mixture was placed in a boiling water bath to evaporate the solvent. After the solid had cooled for 45 min, ice-water was added. The organic layer was separated and washed with water. The water washings were combined with the aqueous layer and this was neutralized with acetic acid and treated with copper acetate solution. A blue copper salt was deposited. The copper compound was heated to 188°C, where it fused to a solid and then turned to a liquid at 190°C. Upon cooling, it reverted to a crystalline form. The crystals were mixed with ether and dilute sulphuric acid and the resulting liquid was purified by several distillations. A fragrant oil was obtained which boiled at 170–171°C (745 mm Hg).

Synthesis of bis(5,5-dimethyl-2,4-hexanedionato) hydroxoeuropium(III), $Eu(But\text{-}ac)_2(OH)$[10]

A sample (5 cm^3) of aqueous $EuCl_3$ (0.20 M, 1 mmol) was evaporated to dryness with gentle heating. The resulting solid $EuCl_3$ was dissolved in a minimum amount of water and 95% ethanol (5 cm^3) was added. A sample of 5,5-dimethyl-2,4-hexanedione (0.426 g, 3 mmol) was dissolved in more 95% ethanol (5 cm^3) and KOH (0.206 g, 3 mmol) was added to form the potassium salt of the β-diketone ligand. The ligand potassium salt solution was added dropwise to the $EuCl_3$ solution with stirring. Stirring was continued for 1 h after a white precipitate formed. The product was filtered, washed with methanol and ether and air-dried, yield 0.32 g.

Synthesis of tris(5,5-dimethyl-2,4-hexanedionato)1,10-phenanthrolineeuropium(III), $Eu(But\text{-}ac)_3(phen)$

A sample (5 cm^3) of aqueous $EuCl_3$ (0.20 M, 1 mmol) was mixed with 95% ethanol (10 cm^3) and 5,5-dimethyl-2,4-hexanedione (0.426 g, 3 mmol) was added. This solution was then mixed with methanol (10 cm^3) containing phenanthroline (0.198 g, 1 mmol). The pH of the solution was adjusted with KOH until a white precipitate formed. The mixture was stirred for 1 h, filtered and the solid was washed with ethanol and ether and air-dried, yield 0.64 g. The product was recrystallized from 95% ethanol.

Synthesis of tris(5,5-dimethyl-2,4-hexanedionato)5-nitro-1,10-phenanthrolineeuropium(III), $Eu(But\text{-}ac)_3(5\text{-}NO_2\text{-}phen)$

A sample (5 cm^3) of aqueous $EuCl_3$ (0.20 M, 1 mmol) was added to 95% ethanol (10 cm^3). A sample of 5-nitro-1,10-phenanthroline (0.241 g, 1 mmol) was then added to more 95% ethanol (10 cm^3), the mixture was heated to dissolve the ligand and then 5,5-dimethyl-2,4-hexanedione (0.426 g, 3 mmol) was added. The two solutions were mixed and the mixture was treated with NaOH (0.1 N) to form a pale yellow precipitate. The resulting suspension was stirred for 1 h, filtered, washed with ethanol and ether and air-dried, yield 0.52 g. The product was recrystallized from 95% ethanol.

Synthesis of tris(5,5-dimethyl-2,4-hexanedione)2,2′-bipyridyleuropium(III), $Eu(But\text{-}ac)_3(bpy)$

To a solution of 2,2′-bipyridine (1.56 g, 1 mmol) dissolved in 95% ethanol (20 cm^3) were added 5,5-dimethyl-2,4-hexanedione (0.426 g, 3 mmol) and europium nitrate (5 cm^3; 0.20 M, 1 mmol). The mixture was treated with NaOH (0.1 N) to form a white precipitate. The resulting suspension was stirred for 1 h, filtered, washed with ethanol and ether and air-dried, yield 0.54 g. The product was recrystallized from 95% ethanol.

RESULTS AND DISCUSSION

Properties of the complexes

The new complexes are all white solids, with the exception of the 5-nitro-phenanthroline complex which is pale yellow. Their elemental analysis, melting point, synthetic yield, conductimetric, and IR data are summarized in Table 1. The conductivity data indicate that the complexes are all non-electrolytes. They are insoluble in water, but they are dissolved by organic solvents such as methanol, ethanol, carbon tetrachloride, N,N-dimethylformamide and dimethylsulphoxide. They have constant composition and are stable to air, light and heat.

IR spectra of the complexes

The characteristic peaks and assignments of the IR absorption spectra of the complexes are given in Table 2.

The IR spectrum of Eu(But-ac)$_3$(phen) exhibits a methyl stretching band at 2965 cm^{-1}. The carbonyl peak of 5,5-dimethyl-2,4-hexanedione is shifted to 1597–1631 cm^{-1}, indicating chelation via the oxygens.[17] The characteristic C—N stretching of the 1,10-phenanthroline is absent, indicating chelation via the nitrogens. Other assignments are given in Table 2. On the basis of the IR data, the europium is assigned a coordination number of eight.

The crystal structure of the analogous complex Eu(acac)$_3$(phen) has been previously published.[18] That compound has a distorted square-antiprismatic geometry. The same geometry is assumed for the complexes reported in this study on the basis of the similarity of their vibrational and luminescence spectra.

Excited states

The UV absorption peaks of the complexes in ethanol are summarized in Table 3. The strong absorption at *ca* 270 nm is characteristic of the complexes since the europium(III) ion has no absorption in the 270–320 nm range.[19] That peak also appears in the excitation spectra and it is assigned as a ligand absorption. Absorption to the initially formed ligand singlet, S_1, excited state is followed by either non-radiative intersystem crossing to the ligand triplet manifold or by non-radiative or radiative decay (ligand fluorescence) back to the ground state. The latter processes quench any subsequent metal luminescence. If the ligand triplet is formed, it may undergo non-radiative energy transfer to the metal ion or undergo non-radiative or radiative decay (ligand phosphorescence) to the original ground state. Energy transfer to the metal ion produces an excited state, $^5D_0$, which may decay to the ground state $^7F_{0-4}$ with luminescence.

Luminescence studies

Emission spectra were recorded at room temperature and at 77 K using 345 or 350 nm excitation. Although all the spectra were recorded in the range 400–800 nm (25.0–12.5 kK), no emission peaks were observed outside the 14–18 kK range shown in Fig. 1. As expected, the emission intensity increases at 77 K and the bands are sharper and exhibit more detail than the room-temperature spectra. The details of the 77 K luminescence spectra of all the complexes are summarized in Tables 4–7. The room-temperature spectra of solid and DMSO solution samples exhibited the same features as those reported for 77 K. Band assignments were made by consideration of the calculated free ion energy levels

given by Dieke[20] and calculations on similar compounds by Filipescue *et al.*[21]

The excited-state spectra of the complexes show only small differences, with emission peaks belonging to the $^5D_0 \rightarrow {}^7F_{0-4}$ transitions, indicating that energy transfer in the molecule is fast[22] and that the effect of the ligands on the 4*f* electron levels is small. The peak patterns are consistent with square antiprismatic site symmetry.[23–25]

Although luminescence quantum yields have not been measured, when solid emission intensities were measured using sample plates under controlled excitation conditions, the luminescence intensities showed the following trend: Eu(acac)$_3$(phen) > Eu(But-ac)$_3$(phen) > Eu(But-ac)$_3$(bpy) > Eu(But-ac)$_2$(OH) > Eu(But-ac)$_3$(5-NO_2phen). Eu(acac)$_3$(phen), where acac is 2,4-pentanedione, was prepared by a published method.[10] The fact that the luminescence spectrum and intensity are similar for Eu(acac)$_3$(phen) and Eu(But-ac)$_3$(phen) indicates that asymmetry in the β-diketone has little effect on the excited state. However, introduction of the nitro group on the phenanthroline ligand results in an eight-fold decrease in luminescence intensity in the major band at 16.35 kK. The electron donor ability of 1,10-phenanthroline increases intramolecular energy transfer efficiency, resulting in a strong luminescence,[26] whereas introduction of the electron-withdrawing nitro group decreases luminescence, consistent with the accepted mechanism of rare earth ion luminescence. These data indicate that only organic bases whose triplet energy is close to the resonance energy of the europium ion will enhance the luminescence efficiency.[27]

Table 3. UV absorption features of the complexes (in ethanol at room temperature)

Complex	Wavelength (nm)	Extinction coefficient ($M^{-1}\,cm^{-1}$)
Eu(But-ac)$_2$(OH)	204	1900
	278	18,000
Eu(But-ac)$_3$(phen)	204	2400
	232	56,000

	272	57,000
Eu(But-ac)$_3$(bpy)	204	22,000
	238	34,000
	280	57,000

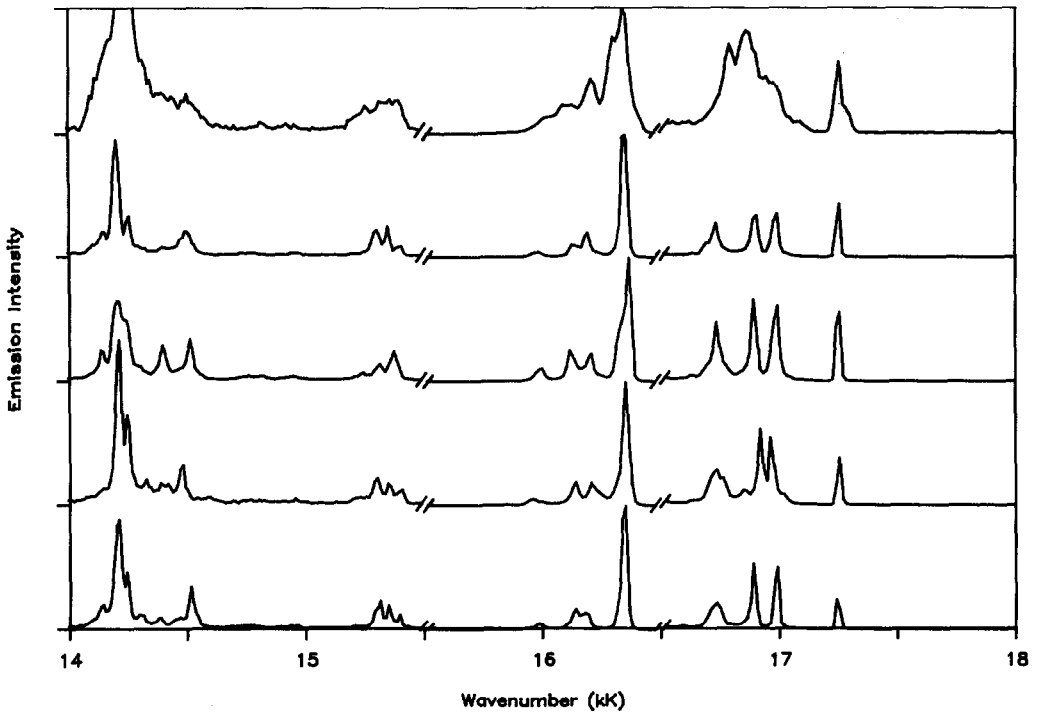

Fig. 1. Normalized, corrected emission spectra of the solid samples at 77 K, 0.5 nm resolution, 350 nm excitation. Top to bottom: Eu(But-ac)$_2$(OH), Eu(But-ac)$_3$(phen), Eu(But-ac)$_3$(5-NO$_2$-phen), Eu(But-ac)$_3$(bpy) and Eu(acac)$_3$(phen). The $^5D_0 \rightarrow {}^7F_2$ region (15.5–16.5 kK) of each spectrum has been attenuated by a factor of 10 in order to show the weaker peaks in the rest of the spectra.

Ethanol solutions of the complexes showed the same trend in luminescence intensity as was observed for the solids. Benzene and carbon tetrachloride solutions decreased luminescence intensities and lifetimes.

A Stern–Volmer plot of the quenching of Eu(But-ac)$_3$(phen) (1.40×10^{-4} M in methanol) by naphthalene is shown in Fig. 2. On the basis of the data in Fig. 2, the quenching is assumed to be both collisional and triplet quenching.[28]

Table 8. Luminescence lifetime data for the solid samples

Complex	Lifetimes (ms) 77 K	Lifetimes (ms) Room temperature
Eu(But-ac)$_2$(OH)	0.45	0.38
Eu(But-ac)$_3$(phen)	0.80	0.79
Eu(But-ac)$_3$(5-NO$_2$-phen)	0.78	0.74
Eu(But-ac)$_3$(bpy)	0.85	0.79

Luminescence lifetime data for the $^5D_0$ level measured for solid samples at room temperature and at 77 K are summarized in Table 8. The lifetime of the Eu(But-ac)$_2$(OH) complex is approximately half that of the other complexes and very little temperature effect on the lifetime is observed. The structure of that complex is different from the others and it is probably polymeric.[10] The absence of any significant temperature effect on the lifetime is taken as an indication that a large number of vibrational quanta participate in the non-radiative decay process.[10]

Abstract—A tetrahydrofurfurylcyclopentadienyl sodium tetrahydrofuranate complex was prepared by the reaction of tetrahydrofurfurylcyclopentadiene with metallic sodium in THF. Its crystal structure was determined by X-ray analysis. In the crystal, the tetrahydrofuranate complex $C_4H_7OCH_2C_5H_4Na \cdot THF$ adopts a puckered chain structure with an η^5-$(C_4H_7OCH_2)C_5H_4$ ring connected by a bridging Na(THF) unit. The oxygen in the η^5-$(C_4H_7OCH_2)C_5H_4$ ring is coordinated to the sodium atom.

There is a rapidly growing interest in early-transition metal and lanthanide compounds with bidentate ligands, such as cyclopentadienyl ligands with built-in alkoxide or similar groups. Several papers have appeared describing the preparation of functionally-substituted cyclopentadienyl metal complexes,[1–3] the synthesis of tetrahydrofurfurylcyclopentadiene and its thallium complexes.[4] In this paper, we report the synthesis and crystal structure of its sodium complex.

EXPERIMENTAL

Synthesis of tetrahydrofurfurylcyclopentadiene

Tetrahydrofurfuryl chloride, was prepared according to the literature.[5] Sodium cyclopentadienide (0.2 mol) was prepared from sodium dispersion and cyclopentadiene in THF. Tetrahydrofurfuryl chloride (25.0 g, 0.207 mol) was added in a single portion and the solution was maintained at 60°C with stirring for 8 h. After cooling to room temperature, the solution was poured into water, the clear THF solution was separated, anhydrous $MgSO_4$ was added to dryness and then THF was distilled off from it. The residual solution was distilled under reduced pressure and a colourless distillate boiling at 48–56°C (0.1 mm Hg) was collected in a 40% yield.

Synthesis of tetrahydrofurfurylcyclopentadienyl sodium

Tetrahydrofurfurylcyclopentadiene (7.5 g, 0.05 mol) was dissolved in THF (50 cm^3). To the solution was added metallic sodium under an atmosphere of nitrogen and the reaction mixture heated to reflux for 8 h. The warm solution was filtered through Celite. When the resulting solution was cooled, colourless crystals were formed at 0 to −20°C, yield 50%.

Determination of the crystal structure

A single crystal with the dimensions 0.36 × 0.42 × 0.60 mm, suitable for X-ray analysis, was sealed under nitrogen in thin-walled glass capillaries. X-ray diffraction data were collected on a Nicolet XRD R_{3m}/E four-circle diffractometer at room

*Author to whom correspondence should be addressed.

temperature by the use of graphite monochromated Mo-K_α radiation, with a scan speed of 6° min^{-1} and scan range of 1.2°. One check reflection was measured after 70 reflections. A total of 2727 reflections were collected using the ω scan mode ($3° < 2\theta < 60°$), of which 1111 with $I > 3\sigma(I)$ were considered to be observed. The crystal data are listed in Table 1.

The crystal structure was solved by heavy atom methods using the SHELXTL program. The coordinates of the sodium atom, derived from a Patterson analysis, were used to calculate the Fourier map. Successive Fourier syntheses gave the positions of all the non-hydrogen atoms. The coordinates of the hydrogen atoms were added according to theoretical models. The atomic coordinates and anisotropic temperature factors for all the non-hydrogen atoms were refined by used block-diagonal least-squares. Further refinements led to final values of $R = 0.05$, and $R_w = 0.065$ ($w = 1/[\sigma^2(F_o)+0.00168F_o^2]$).

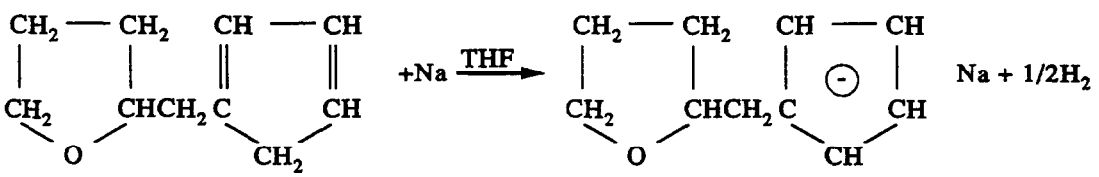
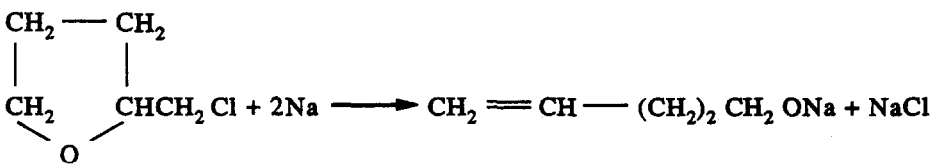
RESULTS AND DISCUSSION

The reaction of tetrahydrofurfuryl chloride with sodium cyclopentadienide in THF yielded, after work up and distillation, tetrahydrofurfurylcyclopentadiene with a small unreacted tetrahydrofurfuryl chloride contamination. The reaction of the mixture with metallic sodium gave $C_4H_7OCH_2C_5H_4Na \cdot THF$ [eq. (1)] and a small amount of $CH_2{=}CH(CH_2)_2CH_2ONa$ [eq. (2)].[5] The warm solution was filtered through Celite in order to remove the white precipitate of $CH_2{=}CH(CH_2)_2CH_2ONa$.



(1)



(2)

When the resulting solution was cooled, colourless rod-like crystals were formed. The stereoscopic drawing with the atom numbering scheme of the molecule is shown in Fig. 1. Selected bond lengths and angles are given in Tables 2 and 3.

In the molecule $C_4H_7OCH_2C_5H_4Na \cdot THF$, the central sodium atom is bonded to five carbon atoms and the oxygen atom of tetrahydrofurfurylcyclopentadienyl and one THF ligand is coordinated to each sodium atom. The skeletal structure consists of a puckered chain of sodium atoms, linked by bridging pentahapto-cyclopentadienyl groups inclined at 87.3° to the Na–Na axes (in $C_5H_5Na \cdot TMEDA$,[6] the angle is 88°), and there is a displacement from the ring centre. This slippage from the ideal η^5-geometry is attributed to non-bonded repulsions between adjacent $C_4H_7OCH_2C_5H_4$ rings. The puckering angle of Na—Na—Na is 139° (in $C_6H_5CH_2C_5H_4Na4 \cdot THF$,[7] the Na—Na—Na angle is 130°). The degree of puckering of the chain is indicative of

the distorted tetrahedral coordination of the metal atoms.

The distance from sodium to each of the carbons C(11)–C(15) is in the range 2.734(4)–2.899(5) Å. It is apparent that the influence of the Na—O_1 coordination produces significantly longer Na—C(12) and Na—C(13) bonds.

The Na—O(1) bond distance is 2.375(4) Å. The Na—O(2) bond length is 2.42 Å, which is considerably longer than those found in $(C_5H_4CO$ Me)Na · THF[1] (2.35 Å) and $(C_6H_5CH_2C_5H_4)$Na · THF[7] (2.337 Å). This is presumably due to the additional Na—O(1) coordination.

The best planes and torsion angles of some of the atomic groups are given in Table 4. As a rule, the smaller the deviations of the atoms from the best planes, the closer they are to a planar configuration. In view of this, the cyclopentadienyl ring, labelled

DIVALENT COBALT, NICKEL, COPPER AND ZINC COMPLEXES OF TETRAAZA MACROCYCLES BEARING POLYAMIDE GROUPS: SYNTHESIS AND CHARACTERIZATION

MOHAMMAD SHAKIR,*† SAJI P. VARKEY and P. SHAHUL HAMEED

Division of Inorganic Chemistry, Department of Chemistry, Aligarh Muslim University, Aligarh-202 002, India

(*Received* 6 *April* 1993; *accepted* 25 *June* 1993)

Abstract—A new series of 14–20-membered tetraamide macrocyclic complexes, $[ML_1]Cl_2$–$[ML_8]Cl_2$, of cobalt(II), nickel(II), copper(II) and zinc(II) have been prepared via the template condensation of dicarboxylic acid with primary diamines. All the complexes are soluble in most polar solvents. The complexes have been characterized by IR, ^1H NMR, mass, ESR and electronic spectral studies and magnetic measurements. A square planar geometry for the complexes, $[ML_n]^{2+}$, where M = Ni^{II} and Cu^{II}, or a tetrahedral geometry for M = Co^{II} and Zn^{II} have been assigned. The electrical conductivity data in DMSO are as expected for 1:2 electrolytes.

Metal template syntheses of multidentate and macromonocyclic ligands have been established over the last two decades as offering high-yielding and selective routes to new ligands and their complexes. There have been recent interest in the study of macrocyclic complexes containing transition metals since they have been found to act as possible models for biochemically important proteins and enzymes.[1–4] Copper(II) peptide complexes have been studied extensively as models for copper(II)–protein interactions.[5,6] Macrocyclic polyamides of different ring sizes are now readily available by convenient methods as already reported.[7–13] In most cases the high dilution technique is employed for the cyclization process.[10] A series of polyamide macrocycles incorporating two α-phenylglycine units and a variable number of ethyleneoxy units have been reported[13] as new ionophore models and their transport studies showed that certain polyamide macrocycles mimic naturally-occurring cyclic ionophores (valinomycin, nonactin) in their ability to transport K^+ and Na^+ ions across the lipophilic membrane. A number of macrocyclic amides, containing oxygen or sulphur atoms as ring components through cyclization via aminolysis of the dimethyl esters of α,ω-dicarboxylic acid with polyethylenepolyamines, have been reported.[14] Generally, the macrocyclic polyamide ligand is prepared[14–16] by the reaction of polyamines with either the diester salt of a dicarboxylic acid or the dicarboxylic acid dichloride. In most cases the polyamide macrocycles thus formed on reduction with B_2H_6 or $LiAlH_4$ lead to the formation of their corresponding polyazamacrocycles,[14,17,18] which may be used to construct various macropolycyclic systems. Although a variety of macrocyclic moieties bearing the amide group have been reported, the tetraamides formed from the template condensation of dicarboxylic acid with primary diamines have not been reported so far. We report herein the metal ion-controlled syntheses and characterization of macrocyclic tetraamides from diacids and diamines.

EXPERIMENTAL

The metal salts $CoCl_2 \cdot 6H_2O$, $NiCl_2 \cdot 6H_2O$, $CuCl_2 \cdot 2H_2O$ and $ZnCl_2$ (all BDH) are commercially-available pure samples. The dicarboxylic acids malonic acid, succinic acid and glutaric acid

* Author to whom correspondence should be addressed.

(all Fluka) were used as purchased. The primary diamines 1,2-diaminoethane and 1,3-diaminopropane were purchased from E. Merck and used without further purification.

Synthesis of (2,4,9,11-*tetraoxo*-1,5,8,12-*tetraazacyclotetradecane*)*metal*(II) *chloride and* (2,4,10,12-*tetraoxo*-1,5,9,13-*tetraazacyclohexadecane*)*metal*(II) *chloride*, $[ML_1]Cl_2$ *and* $[ML_2]Cl_2$ (M = Co^{II}, Ni^{II}, Cu^{II} *and* Zn^{II}

To an ice-cold solution of metal salt (0.005 mol) in methanol (50 cm^3) was added either 1,2-diaminoethane or 1,3-diaminopropane (0.01 mol) dissolved in methanol (50 cm^3), followed by the addition of malonic acid solution (0.01 mol, 50 cm^3) in methanol. The resulting mixture was stirred continuously for *ca* 7 h. The resultant polycrystalline solid product was filtered, washed several times with methanol and dried *in vacuo*. All the experiments were performed under dry nitrogen.

Synthesis of (2,5,10,13-*tetraoxo*-1,6,9,14-*tetraazacyclohexadecane*)*metal*(II) *chloride and* (2,5,11,14-*tetraoxo*-1,6,10,15-*tetraazacyclooctadecane*)*metal*(II) *chloride*, $[ML_3]Cl_2$ *and* $(ML_4]Cl_2$ (M = Co^{II}, Ni^{II}, Cu^{II} and Zn^{II})

The procedure used for these complexes was the same as detailed above, using succinic acid rather than malonic acid as the diacid.

Synthesis of (2,6,11,15-*tetraoxo*-1,7,10,16-*tetraazacyclooctadecane*)*metal*(II) *chloride and* (2,6,12,16-*tetraoxo* - 1,7,11,17 - *tetraazacycloeicosane*)*metal*(II) *chloride*, $(ML_5]Cl_2$ *and* $[ML_6]Cl_2$ (M = Co^{II}, Ni^{II}, Cu^{II} and Zn^{II})

This preparation was analogous to the above, except glutaric acid (0.01 mol) was introduced.

Synthesis of (3,4,11,12-*dibenzo*-2,5,10,13-*tetraoxo*-1,6,9,14-*tetraazacyclohexadecane*)*metal*(II) *chloride and* (3,4,12,13-*dibenzo*-2,5,11,14-*tetraoxo*-1,6,10,15-*tetraazacyclooctadecane*)*metal*(II) *chloride*, $[ML_7]Cl_2$ *and* $[ML_8]Cl_2$ (M = Co^{II}, Ni^{II}, Cu^{II} and Zn^{II})

These complexes were also prepared using the above method with phthalic acid (0.01 mol).

The mass spectra (JMSD-300) and elemental analyses were obtained from the microanalytical laboratory of CDRI, Lucknow, India. ^1H NMR spectra in DMSO-d_6, using a Bruker AC 200E nuclear magnetic resonance spectrometer with Me_4Si as an internal standard, were obtained from GNDU, Amritsar, India. The metals and chloride were determined volumetrically[19] and gravimetrically,[20] respectively. The IR spectra (4000–200 cm^{-1}) were recorded as CsCl discs on a Perkin–Elmer 621 spectrophotometer. The electronic spectra of the compounds in DMSO were recorded on a Pye–Unicam 8800 spectrophotometer at room temperature. The ESR spectra were recorded on a Jeol JES RE2X ESR spectrophotometer. Magnetic susceptibility measurements were performed using a Faraday balance at 25°C. The electrical conductivities of 10^{-3} M solutions in DMSO were obtained on a Systronics type 302 conductivity bridge equilibrated at 25 ± 0.01°C.

RESULTS AND DISCUSSION

A new series of tetraamide macrocyclic complexes have been prepared by the template action of metal ions, as shown in Scheme 1.

The cyclic amide complexes corresponding to either a high-membered diacid or phenylene diamine under the same reaction conditions could not be formed, which may be due to the increased size of the macrocyclic cavity selectively needed for these metal ions. Most of the compounds were obtained in moderate yields (Table 1) and all were soluble in most polar solvents.

The results of the elemental analyses and the position of the molecular ion peaks in the mass spectra are consistent with their proposed 1:1 metal-to-ligand stoichiometry (Table 1). The observed molar conductance values of all the compounds indicate[21] that they are 1:2 electrolytes in DMSO (Table 1).

The IR spectra of all the macrocyclic complexes $[ML_1[Cl_2–[ML_8]Cl_2$, derived by the condensation of primary amines with dicarboxylic acids, show bands mainly in the regions 1680–1730, 1500–1520, 1240–1270 and 650–675 cm^{-1}, which may be assigned to amide I [ν(C═O)], amide II [ν(C—N) + δ(N—H)], amide III [δ(N—H)] and amide IV [ϕ(C═O)] vibrations, respectively.[9] All the complexes gave a single, sharp secondary amine peak, ν(NH), at *ca* 3220–3260 cm^{-1}, which is found to be lower by 40–60 cm^{-1} than the analogous metal-free tetraaza ligands.[22] This indicates that the amide nitrogens take part in coordination to the metal ions. This has been further corroborated by the appearance of bands at 340–380 cm^{-1} in the spectra of all the complexes, which may be assigned to ν(M—N) vibrations. However, the IR spectra of the complexes do not show bands which could be assigned either for primary amine or alcoholic groups, suggesting that the condensation has occurred.

Scheme 1.

The ESR spectra of the polycrystalline copper complexes were recorded at room temperature and their $g_\parallel$, $g_\perp$, $A_\parallel$ and $A_\perp$ values have been calculated. All the complexes gave the same type of spectrum, although the spectrum of $[CuL_5]Cl_2$ and $[CuL_6]Cl_2$ showed no hyperfine splitting. The values of $g_\parallel$ and $g_\perp$ have been found to fall in the regions 2.01–2.05 and 2.17–2.24, respectively. However, hyperfine splittings have been observed for the complexes $[CuL_1]Cl_2$, $[CuL_2]Cl_2$, $[CuL_3]Cl_2$, $[CuL_4]Cl_2$, $[CuL_7]Cl_2$ and $[CuL_8]Cl_2$, where the $A_\parallel$ and $A_\perp$ values lie in the ranges 95–120 and 20–35 G, respectively. The large value of $A_\parallel$ along with the small value of $g_\parallel$ are quite consistent[23] with the square planar environment around the copper ion. The existence of $g_\parallel$ at lower values than $g_\perp$ for all the tetraazamacrocyclic complexes may be due to the presence of an unpaired electron in the d_{z^2} orbital, which is expected[24] for a ground state Cu^{2+} ion.

The ^1H NMR spectra of all the nickel(II) and zinc(II) complexes show a multiplet in the region 3.37–3.56 ppm, corresponding to CO—N—CH_2 (8H) protons.[8] However, a singlet in the regions 3.30–3.41 and 3.29–3.33 ppm and a multiplet in the region 3.20–3.24 ppm was observed for the respective complexes $[ML_1]Cl_2$, $[ML_2]Cl_2$, $[ML_3]Cl_2$, $[ML_4]Cl_2$ and $[ML_5]Cl_2$, $[ML_6]Cl_2$ and can be assigned to CO—CH_2—CO (4H), CO—$(CH_2)_2$—CO (8H) and CO—$(CH_2)_3$—CO (12H) protons, respectively.[8,25] The ^1H NMR spectra of $[ML_2]Cl_2$, $[ML_4]Cl_2$, $[ML_6]Cl_2$ and $[ML_8]Cl_2$ show multiplets in the region 1.98–2.12 ppm, corresponding to C—CH_2—C (4H) protons. A broad signal observed in all the complexes at 8.11–8.34 ppm may, unambiguously, be assigned to the amide CO—NH (4H) protons.[26] A multiplet was observed in the region 6.95–7.21 ppm for the complexes $[ML_7]Cl_2$ and $[ML_8]Cl_2$, corresponding to phenyl ring protons. However, no signals could be observed for primary amine or alcoholic protons.

The electronic spectra of the cobalt complexes show a band at 14,500–16,400 cm^{-1}, assignable to $^4A_{2g}(F) \rightarrow {}^4T_{1g}(P)$ transitions which is consistent with the tetrahedral environment around the cobalt ion.[27] The band below 11,100 cm^{-1} could not be recorded since it lies beyond the range of the instrument used. The observed values of the magnetic moments (4.2–4.6 B.M.) further confirm the tetrahedral geometry around the CO^{2+} ion.

The magnetic measurement studies on nickel(II) complexes suggest their diamagnetic nature which corresponds to the square planar geometry around the nickel(II) ion. The positions of the bands observed in the electronic spectra are in agreement with the transitions which support the magnetic measurement studies.[27]

The electronic spectra of the copper complexes exhibit a broad band centred at *ca* 16,000 cm^{-1}, assignable to $^2B_{1g} \rightarrow {}^2A_{1g}$ transitions. However, two weak shoulders appearing in the regions 21,000–22,400 and 11,500–12,600 cm^{-1} may be ascribed to $^2B_{1g} \rightarrow {}^2E_g$ and $^2B_{1g} \rightarrow {}^2B_{2g}$ transitions, respectively, suggesting a square planar geometry[27] around the copper(II) ion. The observed magnetic moment values (1.83–1.87 B.M.) further confirm the electronic spectral data.[27]

Table 1. μ_{eff} (B.M.), yield, m.p., colour, elemental analyses, molecular ion peaks and molar conductivity values of the compounds

(*Received* 5 *April* 1993; *accepted* 25 *June* 1993)

Abstract—Seven novel μ-oxamido heterotetranuclear complexes, namely $Cu_3(oxae)_3Ln(ClO_4)_3$ [Ln = La, Nd, Gd, Tb, Dy, Ho, Er; where oxae = N,N′-bis(2-aminoethyl) oxamido dianion] have been synthesized and characterized by elemental analyses, IR, conductivity measurements and electronic spectra. The magnetic susceptibility of $Cu_3(oxae)_3Gd(ClO_4)_3 \cdot H_2O$ was measured over the range 4–300 K and the observed data were successfully simulated by the equation based on the spin-Hamiltonian operator $[\hat{H} = -2J(\hat{S}_1\hat{S}_0+\hat{S}_2\hat{S}_0+\hat{S}_3\hat{S}_0)]$, giving the exchange integral J(Cu–Gd) = 2.72 cm^{-1}. This indicates a weak ferromagnetic spin exchange interaction between the Cu^{II} and Gd^{III} ions.

The study of polynuclear complexes with extended ligand bridges is an active area of coordination chemistry.[1] The main reason is probably that many metalloproteins and enzymes have multi-metal sites, which are essential for their biological and catalytic function.

In view of the effective bridging ability of the oxamido group, many efforts have currently been devoted to the synthesis of μ-oxamido complexes containing *d*-transition metal ions.[2–8] However, relatively few studies containing *d*-transition metal ions and lanthanide ions have been reported,[9,10] especially for tetranuclear complexes.

We first reported the synthesis and magnetism of the heterotetranuclear complexes[11] $Cu_3(oxpn)_3Ln(ClO_4)_3$ [Ln = Nd, Gd; oxpn = N,N′-bis(3-aminopropyl) oxamide] and as an extension of that investigation, we now report on seven novel heterotetranuclear complexes, $Cu_3(oxae)_3Ln(ClO_4)_3$ (Ln = La, Nd, Gd, Tb, Dy, Ho, Er) using N,N′-bis(2-aminoethyl) oxamido copper(II) [abbreviated as Cu(oxae)] as a starting material. The magnetic properties of the complex $Cu_3(oxae)_3Gd(ClO_4)_3 \cdot H_2O$ have also been studied.

EXPERIMENTAL

Materials

All of the reagents used were of analytical grade. The hydrated lanthanide perchlorates were prepared by general methods.[12] The starting material Cu(oxae) was synthesized by the literature method[13] from ethylenediamine, diethyl oxalate and copper hydroxide.

Synthesis of $Cu_3(oxae)_3Ln(ClO_4)_3$ (Ln = La, Nd, Gd, Tb, Dy, Ho, Er)

All seven complexes were prepared in a similar fashion and it will suffice to detail the typical preparation of $Cu_3(oxae)_3Gd(ClO_4)_3 \cdot H_2O$.

To a solution of Cu(oxae) (0.6 mmol, 141.5 mg) in absolute ethanol (20 cm^3) was added an absolute ethanol solution (10 cm^3) of $Gd(ClO_4)_3 \cdot 6H_2O$ (0.2 mmol, 112.8 mg) with stirring. After *ca* 1 h a small amount of violet–red precipitate formed and stirring was continued for 8 h. The violet–red microcrystals thus obtained were filtered, washed with

absolute ethanol and ether several times and dried *in vacuo*.

All the analytical data of the complexes are collected in Table 1.

Measurements

Elemental analyses for carbon, hydrogen and nitrogen were performed with a Perkin–Elmer elemental analyser Model 240. The metal contents were determined by EDTA titration.[14] The IR spectra were recorded with an IR-408 IR spectrophotometer on KBr discs. The electronic spectra (DMF solution) were measured on a Perkin–Elmer Hitachi-240 spectrophotometer. Molar conductances were measured with a DDS-11A conductometer. Variable-temperature magnetic susceptibilities (4–300 K) were performed at the Institute of Physics, Chinese Academy of Sciences, using the vibrating sample magnetometer CF-1 (sensitivity $m = 10^{-4}$ emu). Diamagnetic corrections were made with Pascal's constants[15] for all the constituent atoms and the magnetic moments were calculated by the equation $\mu_{eff} = 2.828(XT)^{1/2}$. The ESR spectra were measured with JES-FEIXG ESR-apparatus using *X*-band.

RESULTS AND DISCUSSION

General characterization

Elemental analyses have indicated that the reaction of Cu(oxae) with $Ln(ClO_4)_3 \cdot 6H_2O$ (Ln = La, Nd, Gd, Tb, Dy, Ho, Er) yielded the heterotetranuclear complexes $Cu_3Ln(oxae)_3(ClO_4)_3$. The presumed coordination environment of the complexes is shown in Fig. 1. For all the $Cu_3Ln(oxae)_3(ClO_4)_3$ complexes, the molar conductance values (see Table 2) fall in the expected range for 1:2 electrolytes,[16] which indicates that the two perchlorate anions are outside and only one perchlorate anion is inside the coordination sphere. The significant bands from the IR spectra for the complexes are collected in Table 2. It is noted that the carbonyl stretching vibration of the mononuclear fragment Cu(oxae) at 1615 cm^{-1} was con-

$Cu_3Ho(oxae)_3(ClO_4)_3$	158	3250	1650	1100	18.4

siderably shifted towards higher frequencies in their tetranuclear complexes. It is likely that the bond order of C=O in the tetranuclear complexes is higher than that in the corresponding mononuclear complex Cu(oxae). This shift has often been used as definite proof of an oxamido-bridge.[17,18] On the other hand, the C=O deformation at 720 cm^{-1} of the Cu(oxae) complex disappeared in the spectra of the tetranuclear complexes. This fact may be attributed to the coordination of the carbonyl oxygen to the lanthanide(III) ions.[19] In addition, the —NH_2 vibration at 3250 cm^{-1} for Cu(oxae) was present for all the complexes and the splitting bands were observed at 1100 cm^{-1}, which are typical for the coordinated perchlorate ions.[17] This is consistent with the measured conductance data. The absorption maxima of the ligand field band due to copper(II) ions are summarized in Table 2. The electronic spectra show a band at (18.3–18.5) $\times 10^3$ cm^{-1} for all the tetranuclear complexes. The frequency is lower than that for the mononuclear copper complex (18.7 $\times 10^3$ cm^{-1}). Such a red shift of the *d–d* band may be attributed to the decreased planarity of the [CuN_4] chromophore on forming a tetranuclear complex with a lanthanide ion.[20] In addition, the band at 13,600 cm^{-1} for $Cu_3Nd(oxae)_3(ClO_4)_3 \cdot 2H_2O$ is assigned to the $^4I_{9/2} \rightarrow {}^4F_{7/2}$ hypersensitive transition of Nd^{III}, the band at 22,300 cm^{-1} for $Cu_3Tb(oxae)_3 \cdot (ClO_4)_3 \cdot 3H_2O$ to the $^7F_6 \rightarrow {}^5D_4$ hypersensitive transition of Tb^{III} and the band at 23,500 cm^{-1} for $Cu_3Dy(oxae)_3(ClO_4)_3$ to the $^6H_{15/2} \rightarrow {}^6F_{5/2}$ hypersensitive transition of Dy^{III}.[21]

Spin-exchange interaction of $Cu_3Gd(oxae)_3(ClO_4)_3 \cdot H_2O$

The temperature dependence of the magnetic susceptibility and magnetic moment for $Cu_3Gd(oxae)_3(ClO_4)_3 \cdot H_2O$ are shown in Fig. 2. The reason for the choice of gadolinium is the relative simplicity of its magnetic properties, which do not show large anisotropy effects as other lanthanides do. Gadolinium(III) is an f^7 ion; its ground state is $^8S_{7/2}$. Since the excited states are relatively high in energy, the zero-field splitting in the ground state

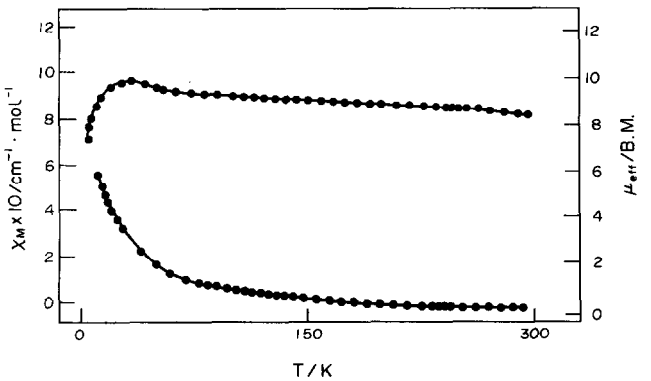

Fig. 2. Variable-temperature magnetic susceptibility and magnetic moment data for $Cu_3(oxae)_3Gd(ClO_4)_3 \cdot H_2O$; ··· experiment data and — — — calculated curves as described in the text.

is fairly small, so that $s = 7/2$ is a good quantum number.[22] From Fig. 2 it is noted that the effective magnetic moments increased with a decrease in temperature. This suggests a weakly ferromagnetic spin-exchange interaction between Cu^{II} and Gd^{III} ions.

In order to understand quantitatively the properties of spin-exchange interactions, the magnetic susceptibility expression for the Cu_3Gd system was derived by an extension of Kambe's approach.[23] The Hamiltonian expression for this system is given by:

$$\hat{H} = -2J(\hat{S}_1\hat{S}_0 + \hat{S}_2\hat{S}_0 + \hat{S}_3\hat{S}_0), \qquad (1)$$

where J is the exchange integral between Gd^{III} and Cu^{II}. The magnetic susceptibility and effective moment data were very successfully simulated by eq. (2), based on the Heisenberg model:

$$X_M = \frac{Ng^2\beta^2}{kT}\{[110\exp(24y) + 60\exp(14y) + 28\exp(6y) + 120\exp(17y) + 56\exp(9y) + 10]/[11\exp(24y) + 9\exp(14y) + 7\exp(6y) + 18\exp(17y) + 14\exp(9y) + 5]\} \qquad (2)$$

where, $y = J/kT$, X_M is the molecular susceptibility and the other symbols have their usual meanings. As shown in Fig. 2, good fits to the experimental data were obtained for $J = 2.72$ cm^{-1} and $g = 1.996$. The agreement factor F, defined here as $F = \Sigma[(X_M)_{obs} - (X_M)_{calc}]^2/\Sigma(X_M)_{obs}$, is then equal to 3×10^{-5}. The positive sign of J corresponds to a ferromagnetic Gd^{III}–Cu^{II} interaction. The small J value indicates a weak ferromagnetic spin-exchange interaction between Gd^{III} and Cu^{II} ions. This may account for the fact that the 4*f*-electrons are shielded by the outer shell electrons.[20]

We also previously investigated the magnetic behaviour of $Cu_3Gd(oxpn)_3(NO_3)_3$[11] [oxpn = N,N′-bis(3-aminopropyl)oxamido] and observed antiferromagnetic coupling between the Gd^{III} and Cu^{II} ions in this complex.

The two complexes $Cu_3Gd(oxpn)_3(NO_3)_3$ and $Cu_3Gd(oxae)_3(ClO_4)_3$ have essentially the same skeletal structure and their IR and electronic spectra are also similar. The main difference between $Cu_3Gd(oxpn)_3(NO_3)_3$ and $Cu_3Gd(oxae)_3(ClO_4)_3$ is that the chelate ring around the copper(II) consists 6–5–6 members in the former case and 5–5–5 members in the latter. The essential difference between the sign of the exchange parameter J in the two complexes indicates that the chelate ring arrangement may affect the nature of the exchange interaction. We have no reasonable explanation for this behaviour. Indeed, further investigations on these and similar systems are still required in order to obtain a reasonable explanation and are in progress.

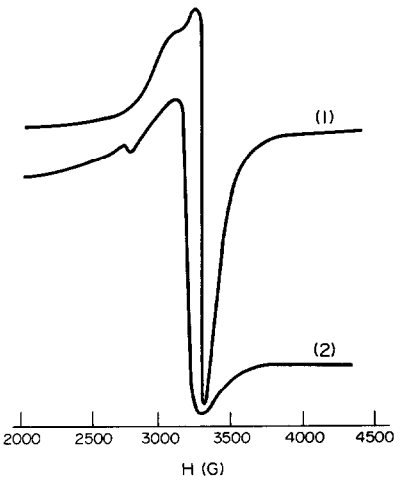

Fig. 3. *X*-band powder ESR spectra of (1) $Cu_3(oxae)_3$ and (2) $Cu_3Gd(oxae)_3(ClO_4)_3 \cdot H_2O$ at room temperature.

ESR spectra

The *X*-band powder ESR spectra at room temperature for $Cu_3Gd(oxae)_3(ClO_4)_3$ and Cu(oxae) are shown in Fig. 3. The spectra of the former are obviously different from that of the latter and exhibit a broad band, which also indicates a magnetic spin-exchange interaction between Gd^{III} and three Cu^{II} ions. According to Kambe's approach,[23] the four spins $S_{Gd} = 7/2$, $S_{Cu(1)} = S_{Cu(2)} = S_{Cu(3)} = 1/2$ coupled to yield the total spin state of one $S = 5$, three $S = 4$, three $S = 3$, one $S = 2$ and one $S = 1$. On the basis of Boltzmann's distribution all these states are in a thermal population at room temperature owing to very weak interactions ($J = 2.72$ cm^{-1}). Thus, the asymmetric broad signals may be ascribed to complexes in these spin states.

Abstract—In the title compound the coordination environment around nickel(II) is an octahedron composed of atoms N(1) and N(2) of 2,2′-bipyridine, O(5), O(6) and O(7) of three aquamolecules and O(3) of one carboxyl of the phthalate. The oxygen, O(1), of the other carboxyl of the phthalate does not coordinate to nickel(II). There is an electrostatic interaction between the negative ion of this carboxyl and the nickel(II) positive ion.

The phthalato ion is a bridging ligand and several binuclear and multinuclear complexes with phthalato bridges have been prepared in our laboratory.[1,2] In these complexes the phthalato bridges are in a bidentate coordination. However, to our knowledge no mononuclear nickel(II) complex with the phthalato ligand in a unidentate coordination has been reported. In this paper we report on the novel structure of a mononuclear nickel(II) complex, Ni(phth)(bpy)$(H_2O)_3$ ($phth^{2-}$ is the dianion of phthalic acid and bpy is 2,2′-bipyridine).

EXPERIMENTAL

Synthesis of Ni(phth)(bpy)$(H_2O)_3$

To $Ni(ClO_4)_2 \cdot 6H_2O$ (146 mg) stirred in ethanol (4 cm^3) was successively added a solution of the piperidinium phthalate (202 mg) in ethanol (6 cm^3) and bpy (62 mg) in ethanol (4 cm^3). After stirring for 10 h at room temperature, the solution was filtered and washed with water. The purple–blue filtrate was left for 3 days at room temperature. The blue crystals of the title complex, Ni(phth)(bpy)$(H_2O)_3$, were grown from an aqueous ethanol solution under vaporization.

X-ray diffraction of the title complex

Crystal data: $C_{20}H_{26}N_2NiO_9$, $Mr = 497.15$, triclinic, space group $P\bar{1}$, $a = 7.732(1)$, $b = 11.645(3)$, $c = 13.600(3)$ Å, $\alpha = 74.66(2)$, $\beta = 71.98(2)$, $\gamma = 73.11(2)°$, $V = 1093.5$ Å^3, $Z = 2$, $D_x = 1.51$ g cm^{-3}, $\mu = 9.41$ cm^{-1}, $F(000) = 520$. A total of 3192 reflections were collected with a single crystal of the dimensions $0.25 \times 0.3 \times 0.3$ mm on a CAD4 diffractometer with graphite monochromatized Mo-K_α ($\lambda = 0.71073$ Å) radiation using the ω–2θ scan mode in the range $2° \leqslant \theta \leqslant 25°$ at room temperature. Data were corrected for Lp factors and 2420 observed reflections [$I \geqslant 3\sigma(I)$] were used for the structure solution and refinement.

The structure of the complex was obtained by direct methods (MULTAN 82). The nickel atom was located from an E-map. The other non-hydrogen atoms were determined from successive difference-Fourier syntheses. The positions of the hydro-

gen atoms of the phenyl and 2,2′-bipyridyl groups were calculated theoretically. The final refinement for the coordinates and anisotropic thermal parameters of all the non-hydrogen atoms and the isotropic thermal parameters of the hydrogen atoms by full-matrix least-squares methods converged to an unweighted R of 0.057 and a weighted R_w of 0.055 with $w = \exp[20*(\sin\theta/\lambda)^2]$.[3] The highest peak in the final difference-Fourier map had a height of 0.7 e Å^{-3}. All of the calculations were performed on a PDP 11/44 computer with the SDP software package.

Selected bond lengths and angles are given in Table 1 and the perspective view of the molecule is shown in Fig. 1.

RESULTS AND DISCUSSION

The coordination environment around nickel(II) is a distorted octahedron. The nickel atom lies generally in the least-squares plane composed of the atoms N(1), O(5), O(6) and O(7) (see Table 2). The other nitrogen atom of bpy, N(2) and O(3) of one carboxyl of the phthalate are in the axial positions. The axis does not show much distortion from linearity, N(2)—Ni—O(3)

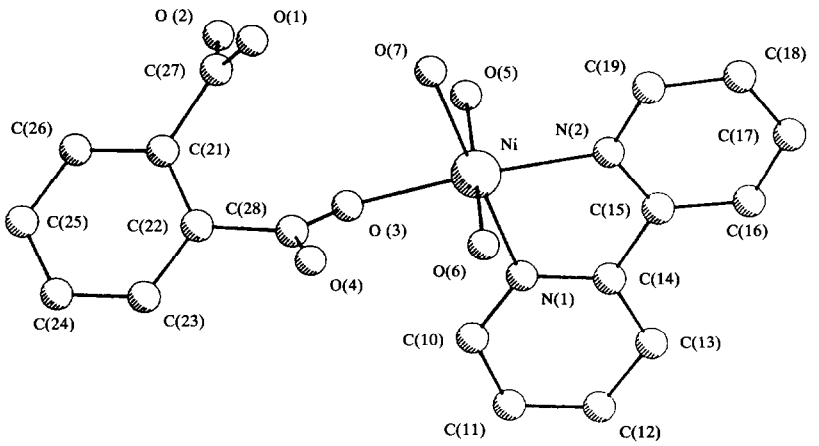

Fig. 1. A perspective view of the complex Ni(phth)(bpy)$(H_2O)_3$.

being 172.37(5)°. The nickel–nitrogen and nickel–oxygen [except O(5)] distances are almost equivalent [Ni—N(1) = 2.053(2), Ni—N(2) = 2.059(1), Ni—O(3) = 2.045(1), Ni—O(6) = 2.087(1), Ni—O(7) = 2.068(1) Å] and are shorter than the Ni—O(5) distance [Ni—O(5) = 2.128(1)]. Phthalic acid has two univalent negative "arms". It is a good bridging ligand which links with two metal ions via its two "arms".[2] In the present mononuclear complex an unstable seven-membered ring would be formed if phthalate chelated one nickel ion. Therefore, the novel structure of the present complex was obtained (Fig. 1). Only O(3) of one carboxyl group of the phalate coordinates to the nickel ion; O(1) of the other carboxyl group of the phthalate does not coordinate and we presume there is an electrostatic interaction between the negative ion of this carboxyl and the nickel ion. Three water molecules coordinate to nickel(II) to form an octahedral six-coordination environment.

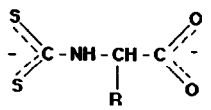
Abstract—The reaction between dithiocarbamate derivatives of α-amino acids (glycine, alanine, α-amino-butyric acid, norvaline, valine, norleucine, leucine and isoleucine) and sodium molybdate in acid medium leads to the formation of molybdenum(V) complexes with the general formula $[Mo_2O_3(dtc\ a.a.)_4]\cdot 2H_2O$ (a.a. = amino acid). The complexes were characterized by elemental analysis, FT-IR and uv–vis spectroscopies and XPS. They are binuclear complexes with a linear oxygen bridge, the dithiocarbamate moiety acting as a bidentate ligand and thus yielding a distorted octahedral coordination for the metal cation. In organic solvents, these compounds undergo a chemical transformation, yielding complexes with the general formula $[MoO(dtc\ a.a.)_2]$, whose synthesis is also described. These complexes were characterized using the same experimental techniques as above. The kinetics of transformation in organic media were studied, proposing a multi-step reaction mechanism, and the rate constants have also been determined.

Molybdenum is an essential trace element in living organisms, existing in active sites of molybdoenzymes, proteins which act on redox reactions. The study of the actual state (coordination geometry, oxidation state, etc.) of molybdenum in enzymes, as well as the mechanism followed by the reactions where these enzymes act, has attracted the attention of many researchers, mainly with a view to understanding the role played by molybdenum in these processes. Generally speaking, this type of work has been aimed in two directions: the study of the chemical environment of the molybdenum cations, through a direct study of molybdoenzymes using different analytical techniques (mainly EXAFS and EPR), and the synthesis and characterization of model compounds. For oxoenzymes it has been found that molybdenum cations are directly bonded to oxygen and sulphur atoms,[1,2] thus, most model compounds synthesized correspond to coordination compounds where the donor atoms are sulphur or oxygen.[2,3] On the other hand, an EPR signal characteristic of molybdenum(V) species has been recorded along the catalytic process, suggesting that a mononuclear complex of molybdenum(V) might be the active site in molybdo-

† Author to whom correspondence should be addressed.

enzymes since this signal is not recorded for binuclear complexes. In addition, binuclear molybdenum(V) complexes are rather stable and, therefore, only evolve to the +4 oxidation state with difficulty. This is the state shown by molybdenum in the reduced state of molybdoenzymes. For these reasons, a great deal of effort has been directed towards the synthesis of model compounds of molybdenum(V) with bulky ligands in order to avoid dimerization.[4-6] However, many binuclear complexes have been synthesized which are also able to participate in two-electron redox processes, similar to those found for molybdoenzymes and those with dithiocarbamate ligands.[3,4,7,8] Nevertheless, the organic chain linked to the dithiocarbamate moiety is also a hydrocarbon chain, despite the fact that in molybdoenzymes these are amino acid chains. In the light of this, in the present work a series of complexes was synthesized and characterized, using as ligands dithiocarbamate derivatives of α-amino acids, with the general formula:



where R = H, glycine (gly); —CH_3, alanine (ala); —CH_2—CH_3, α-aminobutyric acid (α-ambut); —CH_2—CH_2—CH_3, norvaline (norval); —CH—$(CH_3)_2$, valine (val); —CH_2—CH_2—CH_2—CH_3, norleucine (norleu); —CH_2—CH—$(CH_3)_2$, leucine (leu); —CH—(CH_2—CH_3)(CH_3), isoleucine (isoleu). Our aim was to study the role played by the lateral chain in the amino acid on the donor properties of the dithiocarbamate ligand. Moreover, the presence of the carboxylate group may elicit important changes in the properties of the molecule, mainly with respect to the solubility of the compounds in polar solvents.

As described below, these ligands are readily prepared by reaction between the amino acid and carbon sulphide in basic medium, as described elsewhere.[9,10]

EXPERIMENTAL

Materials

All starting amino acids were in the DL form (except glycine) from Fluka; carbon sulphide and $Na_2MoO_4 \cdot 2H_2O$ were also from Fluka (p.a.). $MoO_2(acac)_2$ was from Aldrich and the organic solvents—acetone, absolute ethanol, diethyl ether, methanol and dimethyl formamide (DMF)—were from Carlo Erba (R.P.E.).

Physical measurements

Chemical analyses for carbon, hydrogen and nitrogen were performed on a 2400 elemental analyser from Perkin–Elmer, while sulphur was analysed in the CSIC laboratories (Barcelona, Spain). Molybdenum was determined on an I.C.P. spectrometer, Perkin–Elmer, model 2380 Plasma 2. The magnetic susceptibilities of the solids were determined following the Gouy method on a Stanton MC-5 microbalance, using $Hg[Co(SCN)_4]$ as a reference. FT-IR spectra were recorded in the 4000–275 cm^{-1} range on a Perkin–Elmer FT-IR 1730 instrument, coupled to a Perkin–Elmer 3600 Data Station by the KBr pellet technique. Electronic spectra were recorded on a Shidmazu UV-240 double beam spectrophotometer with an integrating sphere for solid samples, using MgO as a reference. The kinetics of transformation of the complexes in different organic solvents were studied using a Hitachi 150–20 spectrophotometer at 25°C. X-ray photoelectron spectra were recorded using Leybold–Heraeus LHS-10 apparatus, with Al-K_α radiation, at an intensity of 20 mA, under a pressure of 10^{-9} torr and using the C1*s* peak at 284.6 eV as a reference.

Preparation of the complexes

$[Mo_2O_3(dtc\ a.a.)_4] \cdot 2H_2O$ *complexes.* This series of compounds was prepared by direct reaction between sodium molybdate and the dithiocarbamate derivative of the corresponding α-amino acid. A fresh aqueous solution obtained by dissolving the sodium salt of the dithiocarbamate derivative of α-amino acid (8.8×10^{-3} mol, 10 cm^3) was slowly dropped into a vigorously stirred solution containing $Na_2MoO_4 \cdot 2H_2O$ (4.4×10^{-3} mol) in HCl (6 M, 10 cm^3). With long-chain amino acids a dark brown precipitate was formed. This was filtered, washed with doubly-distilled water and dried over P_2O_5. With the derivatives of glycine and alanine, however, cooling of the solution in an ice–salt freezing mixture was needed to attain precipitation of the complexes. The dark brown solids thus obtained were almost insoluble in water, but dissolved in organic solvents such as methanol, acetone and DMF. The data from the chemical analyses agree with the general formula $[Mo_2O_3(dtc\ a.a.)_4] \cdot 2H_2O$. The yield was *ca* 40% for compounds prepared with long-chain amino acids, but lower for those with shorter lateral chains.

The same compounds were also prepared starting from molybdenum(VI) acetylacetonate: $MoO_2(acac)_2$ (0.002 mol) was dissolved in methanol (10 cm^3) and doubly-distilled water (10 cm^3). The

solution was filtered and cooled at 0°C and then HNO_3 (1 M) was added until pH = 4.5–5 was reached. Another solution (also maintained at 0°C with a freezing mixture) containing the dithiocarbamate derivative (0.0015 mol in 10 cm^3 doubly-distilled water) was added to the former solution. A purple solution was formed immediately, giving rise to dark brown precipitates. When washed with water and dried over P_2O_5 these compounds were identical to those prepared following the above-described method. However, the yield was only 25–30%, depending on the length of the lateral chain.

[MoO(dtc a.a.)$_2$] *complexes.* Sodium molybdate (0.004 mol in 10 cm^3 doubly-distilled water) was added to the sodium salt of the dithiocarbamate derivative of the α-amino acid (0.008 mol, 25 cm^3) in a 500 cm^3 separation funnel. Diethyl-ether (50 cm^3) was then added to the separation funnel and portions of HCl (0.1 M, 5 cm^3) were then added. A violet precipitate was formed, which dissolved in the organic layer, giving rise to a green solution as more HCl (0.1 M) was added and the funnel vigorously shaken. After the addition of *ca* 40 cm^3 of the acid solution, the two phases separated and the evaporation of ether from the organic layer yielded a microcrystalline dark green powder. In this process, it is important that the ether should be added before the addition of the hydrochloric acid in order to avoid decomposition of the products formed. The chemical analyses for these solids are in agreement with the general formula [MoO(dtc a.a.)$_2$], although a slight excess of carbon and hydrogen suggests the presence of small amounts of ether, which is difficult to completely eliminate; yield 15–20%.

RESULTS AND DISCUSSION

Synthetic aspects and general characterization

Reaction of molybdenum(VI) with dithiocarbamates derived from α-amino acids in a medium of HCl (6 M) leads to a reduction of the metallic cation to molybdenum(V), probably according to the following reaction:

$$2Na_2MoO_4 + 6Na_2[SSC{-}NH{-}CH(R){-}COO] + 16HCl \rightarrow [Mo_2O_3(dtc\ a.a.)_4] + [HOOC{-}CH(R){-}NH{-}CS_2]_2 + 16NaCl + 5H_2O.$$

According to this reaction, one third of the dithiocarbamate is used to reduce molybdenum(VI) to molybdenum(V), probably accounting for the low yield achieved in this reaction. The formation of the disulphide has been confirmed experimentally, especially with the short-length derivatives, where a white crystalline powder is formed whose chemical analyses coincide with the percentages for this compound. The disulphide is also characterized by a strong IR band at 1250 cm^{-1} due to the C=S stretching mode, in addition to other bands characteristic of this substance.

Such a reduction of molybdenum(VI) species has been previously reported in the literature with some dialkyldithiocarbamates and also with alkylxanthates.[11] However, as our original aim was to synthesize molybdenum complexes in the three highest oxidation states of the element, we attempted to prepare molybdenum(VI) complexes by ligand substitution in $MoO_2(acac)_2$. The results were negative: in a neutral medium the ligands are not substituted and in an acidic medium molybdenum(VI) species are reduced, giving rise to the same compounds obtained using the former method.

In any case, the complexes are rather unstable in acidic solution, transforming to green compounds; this transformation was also observed in organic solvents. The above-described method, consisting of extracting the compound in diethyl-ether and a rapid removal of this solvent, allows the preparation of the compounds without decomposition. Unfortunately, due to this lack of stability, neither of the groups of complexes could be obtained in the crystalline state and hence the molecular structure could not be determined by X-ray diffraction. Electroanalytical methods such as cyclic voltammetry were also assayed, but non-reproducible curves were obtained, due to decomposition in solution during measurement.

It should be mentioned that all the compounds prepared are diamagnetic, a behaviour characteristic of binuclear molybdenum(V) compounds with a linear oxo bridge (Mo—O—Mo) and of oxomolybdenum(IV) complexes (d^2 configuration).

IR spectra

The positions of the most relevant bands recorded in the spectra of these compounds are given in Table 1. The band due to the C—N stretching is recorded between 1542 and 1500 cm^{-1}, indicating the double bond character already reported for dithiocarbamate complexes.[12] For the compounds prepared by extraction in ether, the bands are slightly shifted towards lower wave numbers, in agreement with the lower oxidation state of molybdenum in these compounds.[13,14] Contrary to the behaviour found with dialkyldithiocarbamate derivatives,[15] no steady change in the position of

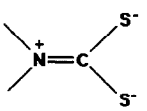
vs = very strong; s = strong; m = medium; w = weak.

the bands with the length of the side-chain is observed. This might be due to the presence of a relatively heavy carboxylic group in all ligands, which masks to some extent the changes in the point masses of these chains, thus decreasing the effect of the kinematic factor. In addition, the effect of the electronic factor cannot be exactly evaluated because of the presence of both linear and branched lateral chains in the series of complexes prepared.

Bands due to C=O stretching, at 1723 cm^{-1}, and to the coupled C—O stretching and O—H in-plane deformation, at 1400 and 1250 cm^{-1}, undoubtedly indicate the presence of the uncoordinated carboxylic group in all the compounds. According to Newton *et al.*,[16,17] bands due to the Mo=O stretching mode are recorded at 965 ± 8 cm^{-1} for molybdenum(IV) complexes with the general formula $MoO(LL)_2$ and 945 ± 16 cm^{-1} for oxygen-bridged molybdenum(V) complexes with the general formula $Mo_2O_3(LL)_4$. In all complexes prepared here, the bands are recorded within these wave number margins. The band corresponding to the single Mo—O bond in the bridging region is recorded at 730–700 cm^{-1}. Also, the band corresponding to the Mo—S stretching is recorded in the expected wave number range for molybdenum complexes containing sulphur donor atoms.[18–20]

X-ray photoelectron spectroscopy

Data for the complexes studied are included in Table 2. Energies for the N_{1s} level are slightly higher than those reported for other dithiocarbamates,[21] thus suggesting, in agreement with the FT-IR data, that the canonic form:



mainly contributes to the structure. Values for the S_{2p} level are high, but within the value range reported by Walton,[22] indicating the strong donor character of the sulphur atoms when bonded to the molybdenum atoms, although these values are similar to those reported for dithiocarbamate complexes of different metal cations.[23,24] As expected, Mo_{3d} values are lower for molybdenum(IV) complexes than for molybdenum(V), although the differences are not too great, as previously reported for complexes containing the S—Mo bond.[25,26]

Table 2. Binding energies (eV) of the relevant energy levels of molybdenum complexes

	$[Mo_2O_3(dtc\ a.a.)_4]$	$[MoO(dtc\ a.a.)_2]$

$Mo_{3d_{5/2}}$	231.1	230.6

Electronic absorption spectra and transformation kinetics

The electronic spectra recorded for the complexes in solution were identical for a given solvent, with only very small differences due to the length of the side-chain, which slightly modifies the molar extinction coefficients (Table 3). For $[Mo_2O_3(dtc\ a.a.)_4]$ complexes, the strongest band is centred at 500 nm and can be associated with the presence of the linear Mo—O—Mo bridge, absent in binuclear complexes with two bridging oxygen atoms. Large molar extinction coefficients are also typical of this type of bridge.[11,27–29] The band at 365 nm in DMF and the shoulder close to 380 nm recorded when using acetone as a solvent must be originated by the same electronic transition, probably an S → Mo charge transfer process.[27,30] The remaining bands are deeply solvent-dependent and are probably due to electronic transitions between energy levels of the ligands. Using the diffuse reflectance technique the spectrum recorded in the solid state is very similar, indicating that the chemical environment of the molybdenum atoms would be rather similar in the solid state and in solution.

The spectra are more complicated for the $[MoO(dtc\ a.a.)_2]$ complexes. From the stoichiometry of these complexes and from data in the literature for similar compounds with the $[MoOS_4]$ moiety, it can be concluded that the geometry should be square-planar pyramidal, C_{4v}. Since the complexes are diamagnetic, from a simplistic point of view electron transitions from energy level b_2 to levels e, b_1 and a_1 would give rise to three bands in the spectrum, but the existence of electron repulsions, two-electron excitations, etc., complicates the spectrum. Thus, only the band at 585–600 nm can be ascribed to molybdenum *d–d* transitions, despite the extinction coefficient being rather high. The spectrum of the complex formed between molybdenum(IV) and diethyldithiocarbamate shows a band almost in the same position,[31] although other bands in the visible range are also expected. The shoulder at 370 nm can be ascribed to an S → Mo charge-transfer process and the remaining bands to intraligand transitions.

As mentioned above, we have observed that $[Mo_2O_3(dtc\ a.a.)_4]$ complexes are transformed to

$[MoO(dtc\ a.a.)_2]$, as shown by the shift of the main visible band of the former at *ca* 500 to 585 nm, characteristic of the latter complexes. This fact has been used to follow the kinetics of such a transformation. The changes are shown in Fig. 1 and these data can be used to follow the kinetics evolution, which was performed at both 500 and 585 nm. The intensity of the band at 500 nm decreases steadily (Fig. 2), while that of the band at 585 nm shows some oscillations, which complicates the analysis of such a transformation somewhat.

The change in absorbance with time [Fig. 3(a)] can be interpreted assuming that only the initial and the final species absorb at this wavelength, following first-order kinetics. In such a case

$$A - A_\infty = (A_0 - A_\infty)e^{-kt} \quad (1)$$

and then

$$\ln(A - A_\infty) = \ln(A_0 - A_\infty) - kt, \quad (2)$$

whose plot should be a straight line [Fig. 3(b)] and whose slope coincides with the rate constant. This is *ca* $1.2 \times 10^{-2}\ s^{-1}$ and does not depend on the concentration; the small differences found probably being due to the lack of stability of the dithiocarbamate derivatives in solution.

The behaviour shown by the band at 585 nm is rather more complicated. One can assume that a series of reactions occurs once the complex is dissolved, with the formation and disappearance of different intermediates whose specific absorptivities are sufficiently different for the total absorbance of

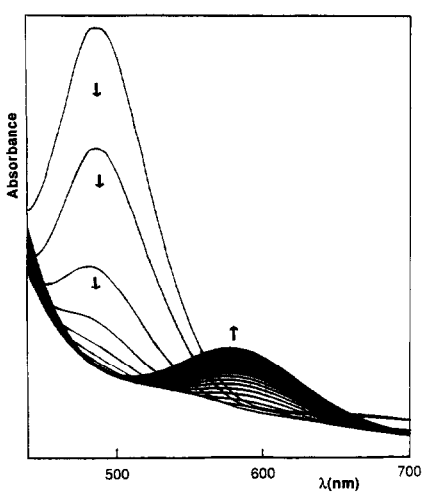

Fig. 1. UV–vis spectra showing the $[Mo_2O_3(dtc\ a.a.)_4] \rightarrow [MoO(dtc\ a.a.)_2]$ transformation. The interscan time was 1 min.

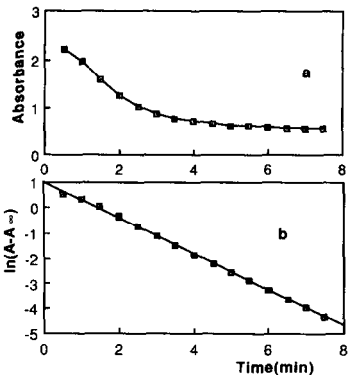

Fig. 3. (a) Time dependence of the absorbance at 500 nm of a DMF solution of the DL-norvaline complex (concentration = 1.4 g dm^{-3}). (b) Least-squares fit. The calculated equation for the straight line adjusted to the experimental data is $\ln(A-A_\infty) = 1.012-0.711t$.

the system to be subject to alternating variation. Disproportion of molybdenum(V) according to the reaction:

$$2Mo^{V} \rightarrow Mo^{VI} + Mo^{IV}$$

has been proposed for similar processes.[8,29,32] However, this does not seem to hold in this case as dithiocarbamate derivatives of α-amino acids already reduce molybdenum(VI) to molybdenum(V), which then undergoes a further reduction to molybdenum(IV) according to the reaction:

$$2Mo_2O_3(\text{dtc a.a.})_4 \rightarrow MoO(\text{dtc a.a.})_2 + MoO_2 + HOOC\text{—}CH(R)\text{—}NH\text{—}C(=S)\text{—}S\text{—}S\text{—}C(=S)\text{—}NH\text{—}CH(R)\text{—}COOH;$$

i.e. molybdenum(V) is reduced to molybdenum(IV) and the dithiocarbamate is oxidized to the disulphide. A tentative reaction scheme could be as follows:

$$Mo^{V}{}_2O_3(\text{dtc a.a.})_4 \xrightarrow{k_1} Mo^{V}{}_2O_3(\text{dtc a.a.})_2^* + 2(\text{dtc a.a.})^*$$

$$Mo^{V}{}_2O_3(\text{dtc a.a.})_2^* \xrightarrow{k_2} Mo^{VI}O_2(\text{dtc a.a.})^* + Mo^{IV}O(\text{dtc a.a.})^*$$

$$Mo^{VI}O_2(\text{dtc a.a.})^* + Mo^{IV}O(\text{dtc a.a.})^* \xrightarrow{k_3} MoO_2 + Mo^{IV}O(\text{dtc a.a.})_2$$

$$(2\text{dtc a.a.})^* \xrightarrow{k_4} (\text{dtc a.a.–dtc a.a.}),$$

which can be rewritten as:

$$C_1 \xrightarrow{k_1} C_2 + 2C_7$$

$$C_2 \xrightarrow{k_2} C_3 + C_4$$

$$C_3 + C_4 \xrightarrow{k_3} C_5 + C_6$$

$$2C_7 \xrightarrow{k_4} C_8,$$

where k_1, k_2 and k_3 are rate constants for reactions where species C_1, C_2, C_3, C_4 and C_5 (responsible for the absorption at 585 nm) participate. Thus, the total absorption would be:

$$A = \varepsilon_1(C_1) + \varepsilon_2(C_2) + \varepsilon_3(C_3) + \varepsilon_4(C_4) + \varepsilon_5(C_5), \quad (3)$$

where ε_i is the molar extinction coefficient of each species.

The rate equations for these processes would be:

$$d(C_1)/dt = -k_1(C_1) \quad (4)$$

$$d(C_2/)dt = k_1(C_1) - k_2(C_2) \quad (5)$$

$$d(C_3)/dt = d(C_4)/dt = k_2(C_2) - k_3(C_3)(C_4) \quad (6)$$

$$d(C_5)/dt = k_3(C_3)(C_4). \quad (7)$$

Unfortunately, integration of these equations to obtain a close mathematical equation involving the total absorbance, A, and time is impossible. We have, therefore, applied a numerical integration process based on Euler's method. According to this, if A_0 is the initial absorption at $t = 0$ and given values are assumed for the fit parameters (the rate constant k_1, k_2 and k_3 in our case), the specific absorptivities of the absorbing species can be written as a function of the specific absorptivity of the initial species ε_i; that is: $(\varepsilon_2/\varepsilon_1)$, $(\varepsilon_3/\varepsilon_1)$, $(\varepsilon_4/\varepsilon_1)$ and $(\varepsilon_5/\varepsilon_1)$. A sequential integration gives rise to the following equations:

$$C_1(i) = C_1(i-1) + k_1C_1(i-1)\Delta t, \quad (8)$$

$$C_2(i) = C_2(i-1) + [k_1C_1(i-1) - k_2C_2(i-1)]\Delta t \quad (9)$$

$$C_3(i) = C_3(i-1) + [k_2C_2(i-1) - k_3C_3(i-1)C_4(i-1)]\Delta t \quad (10)$$

$$C_4(i) = C_3(i) \quad (11)$$

$$C_5(i) = C_5(i-1) + k_3C_3(i-1)C_4(i-1)\Delta t, \quad (12)$$

where i is the corresponding iteration step, Δt is the step iteration time (we have taken 0.01 min) and hence, at iteration i time can be calculated as:

$$t(i) = t(i-1) + \Delta t \quad (13)$$

and

$$t(0) = 0 \quad (14)$$

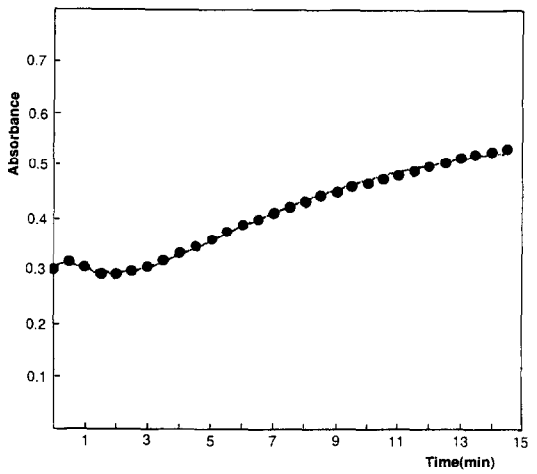

Fig. 4. Time dependence of the absorbance at 585 nm of a DMF solution of the DL-norvaline complex (concentration = 1.4 g dm^{-3}). The calculated parameters following the reaction scheme were: $k_1 = 0.476$, $k_2 = 2.20$, $k_3 = 0.686$; $\varepsilon_2/\varepsilon_1 = 1.03$, $\varepsilon_3/\varepsilon_1 = 0.108$, $\varepsilon_4/\varepsilon_1 = 0.665$ and $\varepsilon_5/\varepsilon_1 = 2.26$.

$$C_1(0) = C_1{}^0 \quad (15)$$

$$C_2(0) = C_3(0) = C_4(0) = C_5(0) = 0. \quad (16)$$

At a given time, the total absorbance is calculated as the sum of the absorbances of the different absorbing species.

The fitting process is controlled by comparing the absorbance values calculated with the experimental ones by the χ^2 parameter:

$$\chi^2 = \Sigma(A^2_{calc} - A^2_{exp}) \quad (17)$$

and the process is repeated until a minimum value for χ^2 is calculated. A computing program was used for this calculation. The application of this calculation to the molybdenum complexes studied in this work acceptably reproduces the kinetic evolution of the absorption of the band at 585 nm, as shown in Fig. 4 for the norvaline derivative. Rate constants and absorptivities are almost independent of the complex concentration, thus supporting the approximation used. On the other hand, the rate constant for the first step, k_1, almost coincides with that determined for the decomposition process studied from changes in the intensity of the band at 500 nm. The formation of the green complexes, $[MoO(dtc\ a.a.)_2]$, takes more time (*ca* 15 min) than the decomposition of the $[Mo_2O_3(dtc\ a.a.)_4]$ complexes.

(*Received* 2 *February* 1993; *accepted* 25 *June* 1993)

Abstract—The 1:1 adducts of $UCl_3[HB(3,5\text{-}Me_2Pz)_3]$ with thf, pyridine (NC_5H_5), acetonitrile (MeCN), benzonitrile (PhCN), cyclohexylisocyanide ($C_6H_{12}NC$), triethylphosphate (tep), tributylphosphate (tbp) and triphenylphosphine oxide (tppo) have been prepared and characterized. The structure of the tep compound was determined by single-crystal X-ray analysis. The charge distribution within the molecules was determined and its correlation with spectroscopic data is discussed. The relative affinity of the Lewis base to the uranium central ion was determined by base exchange reactions and found to be tppo > RNC > RCN > tep > tbp > NC_5H_5 > thf.

During our investigations on polypyrazolylborates of the tetravalent actinides uranium[1–5] and neptunium,[6] we had found that the compound $UCl_3[HB(3,5Me_2Pz)_3]\cdot thf$,[7] which is an excellent precursor for the synthesis of a wide variety of uranium organocompounds easily loses the thf molecule by prolonged treatment *in vacuo* or by recrystallization from pentane solution. The same behaviour occurs with the analogous neptunium compound. In order to check if the lability of the thf molecule was due to steric crowding around the uranium(IV) ion or to the weakness of the thf—U bonding, we estimated the partial charge distribution in the molecule of the complexes with different Lewis bases; we realized that thf can be easily substituted by another Lewis base when the partial dipole moment between the central ion and the coordinating atom of the base is greater than that between the central ion and the oxygen of the thf molecule.

EXPERIMENTAL

Materials

All operations were performed under argon with the exclusion of oxygen and moisture using

† Author to whom correspondence should be addressed.

Schlenk-tube techniques. Thf, pentane and benzene were dried by refluxing under argon with potassium metal and were distilled before use. NCMe, NCPh, py and RNC were dried with $CaCl_2$ and distillated. $UCl_3[HB(3,5Me_2Pz)_3]$ (I) and $UCl_3[HB(3,5Me_2Pz)_3]\cdot$thf were prepared according to procedures described previously.[7]

Physical and analytical methods

IR spectra of the compounds embedded in KBr pellets were recorded with a Perkin–Elmer M283 spectrometer (4000–200 cm^{-1}). Electronic absorption spectra were recorded with a Lambda 9 Perkin–Elmer spectrophotometer on samples in solution and/or in KBr pellets. ^1H NMR spectroscopic investigations were performed in CD_3Cl with a Bruker AC-250 NMR spectrometer. The dipole moments of the adducts dissolved in benzene were measured with a DM 01 (2 MHz) WTW apparatus.

Synthesis of $UCl_3[HB(3,5Me_2Pz)_3]\cdot B$ **(II)** (B = MeCN, PhCN, Py, $C_6H_{11}NC$, tep, tbp *or* tppo)

One equivalent of the appropriate base B was added to a solution of I in benzene. After stirring overnight the solution was evaporated to dryness. The dried crude product was extracted with pentane and recrystallized several times before further investigaton or use.

Crystal and molecular structure of $UCl_3[HB(3,5Me_2Pz)_3]\cdot OP(OC_2H_5)_3$

Crystals of the compound, suitable for X-ray diffraction, were obtained by slow diffusion of n-pentane into a saturated solution of the compound in thf. A crystal was sealed in a thin-walled glass capillary in an argon-filled glove-box.

Data were collected at room temperature on an Enraf–Nonius CAD4 diffractometer with graphite monochromatized Mo-K_α radiation. Accurate cell dimensions were obtained from a least-squares refinement of the setting angles of 25 reflections with $14 < 2\theta < 28°$. Intensities were measured with an ω–2θ scan mode. A summary of the crystal data, data collection and refinement are given in Table 1. Data were corrected for Lorentz-polarization, linear decay and for absorption by empirical correction based on ψ-scans using the Enraf–Nonius program. The structure was solved by Patterson and Fourier methods and refined by full-matrix least-squares.[8] All but the methyl carbon atoms of the phosphate ligand were refined anisotropically and the hydrogen atoms were introduced in calculated positions, constrained to ride on their carbon and boron atoms with group U_{iso} values assigned. In the final difference Fourier map the highest peak was 1.6 e $Å^{-3}$ and was near the uranium atom. Atomic scattering factors and anomalous dispersion terms were taken from the International Tables of X-ray Crystallography. Tables of final atomic positional and thermal parameters, full lists of bond lengths and angles, equations of mean least-square planes and tables of F_o/F_c values have been deposited as supplementary material with the editor.

RESULTS AND DISCUSSION

The relative affinity of the Lewis bases towards the tetravalent uranium in the $UCl_3[HB(3,5Me_2Pz)_3]\cdot B$ compounds was determined by base exchange reactions.

$$UCl_3[HB(3,5Me_2Pz)_3]\cdot B + B' \longrightarrow UCl_3[HB(3,5Me_2Pz)_3]\cdot B' + B$$

was found to be:

$$tppo > C_6H_{11}NC > C_6H_5CN > CH_3CN > tep > tbp > py > thf.$$

Phosphine oxides were found to give the most stable coordination compounds, followed in base

strength by nitriles, phosphates, pyridine and thf. When stored under an argon atmosphere, the solid compounds remain stable. The green solids are very soluble in polar solvents.

The molecular structure and electric dipole moment of $UCl_3[HB(3,5Me_2Pz)_3]$ **(I)** *and* $UCl_3[HB(3,5Me_2Pz)_3]\cdot B$ **(II)**

The crystal and molecular structure of $UCl_3[HB(3,5Me_2Pz)_3]\cdot OP(OC_2H_3)_3$. As in the case of the thf compound,[7] the crystal structure of $UCl_3[HB(3,5Me_2Pz)_3]\cdot OP(OC_2H_3)_3$ consists of discrete molecules in which the uranium atom is seven-coordinate and displays capped octahedral (CO) geometry. The tridentate pyrazolylborate ligand and the three chlorine atoms define the two staggered triangular faces of the octahedron, the latter is capped by the phosphate oxygen. Figure 1 shows a PLUTO drawing of the molecule with the atomic labelling scheme. A view of the CO coordination polyhedron with edge lengths is given in Fig. 2. Selected bond distances and angles are given in Table 2.

The angles at the metal atom from the capping phosphate oxygen to the Cl(1), Cl(2) and Cl(3) atoms of the capped face are 76.0(2), 75.6(3) and 75.9(3)°, respectively, and to the three nitrogen atoms of the uncapped face are 137.5(3), 134.4(3) and 134.3(3)°. The average angles of 75.8° and 135.3° compare with the predicted values of 74.6° and 130.3° for the capped octahedral in ML7,[9] and with 74.6° and 134.4° reported for the related seven-coordinate $UCl_3[HB(3,5Me_2Pz)_3]\cdot$thf. A comparison of U—Cl and U—N bond lengths with those of the structure of $UCl_3[HB(3,5Me_2Pz)_3]\cdot$thf[7] also shows similar distances, so it may be assumed that all complexes of the $UCl_3{*}L\cdot B$-type **(II)** have the same molecular structure. The only difference between the two structures is in the

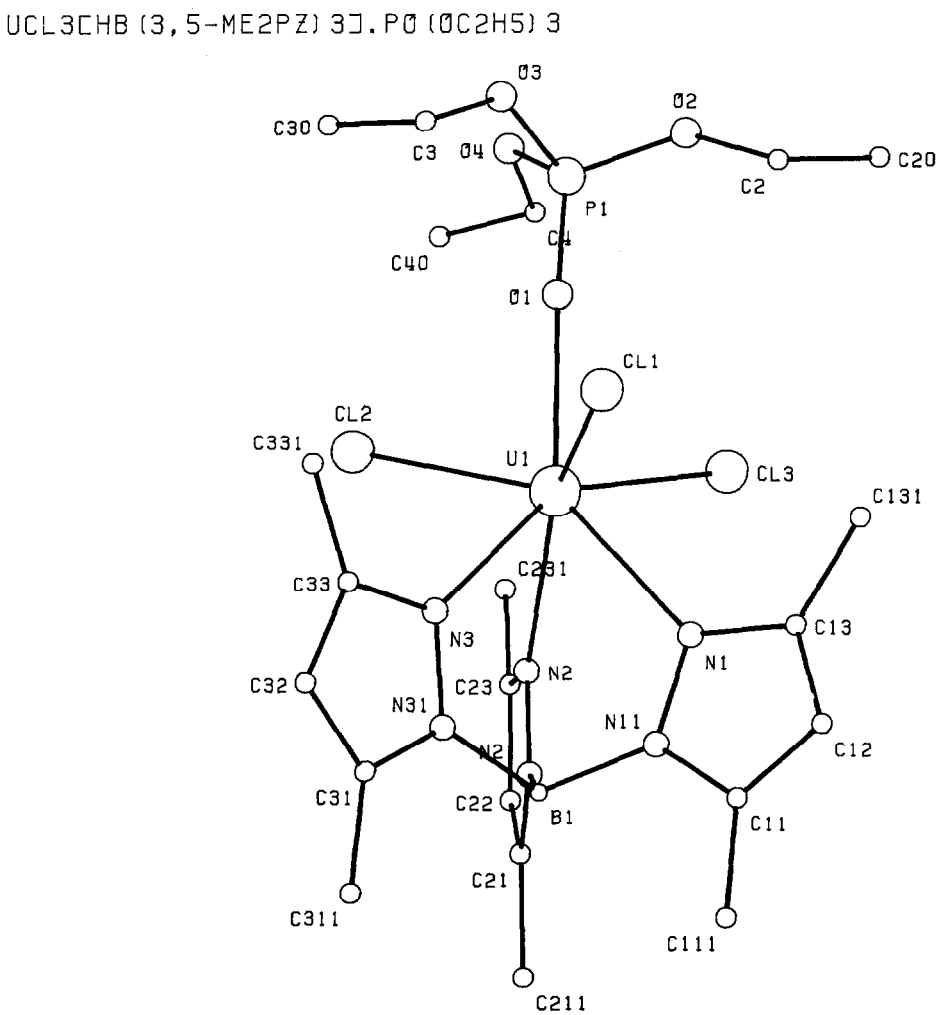

Fig. 1. The molecular structure of $UCl_3[HB(3,5Me_2Pz)_3]\cdot OP(OC_2H_5)_3$.

U—O bond distance [2.373(7) Å in $UCl_3[HB(3,5Me_2Pz)_3]\cdot$tep, 2.546(4) Å in $UCl_3[HB(3,5Me_2Pz)_3]\cdot$thf.[7]

The crystal and molecular structure of the base-free compound $UCl_3[HB(3,5Me_2Pz)_3]$ is known.[5] The compound is six-coordinate and displays octahedral geometry, close to C_{3v} symmetry. The average U—Cl and U—N bond distances are comparable with those found for the complexes discussed above; the main differences between the two classes of compounds **I** and **II** being the Cl—U—Cl angles. For compound **I** the average angle is 97.0°, while for compounds **II** the corresponding angles are larger (114.7° for the tep,

113.2° for the thf compound) in order to accommodate the base B.

The dipole moment of $UCl_3[HB(3,5Me_2Pz)_3]$ (= UCl_3*L). From the crystallographic data the partial charge distribution in the molecule can be estimated empirically. The permanent electric moment μ of a compound dissolved in a non-polar organic solvent can also be estimated from the permanent polarization $P_{2\infty}$ and the electronic polarization ${}_DP_E$ using the Debye equation.[10]

$$\mu^2 = (9kT/4\pi N_L)(P_{2\infty} - {}_DP_E)$$

The total dipole moment of compound **I** is given by the vectorial sum of the partial moments between the central uranium(IV) ion and:

(a) the chlorine atoms;
(b) the nitrogen atoms of the ligand *L (*L = $[HB(3,5Me_2Pz)_3]$; and
(c) the total negative ligand *L,

parallel and perpendicular to the C_3-axis of the molecule containing the uranium and the boron atoms and of the partial moment of the ligand *L:

$$\mu_{exp} = \Sigma\mu_{U-N(j)} \sin(\alpha_j - 90)^\circ + \cos(\alpha_j - 90)^\circ - \Sigma q_{eff(Cl^-)} r_{U-Cl} \sin(\Phi_i - 90)^\circ + \cos(\phi_i - 90)^\circ + q_{eff(*L^-)} r_{U-B}, \quad (1)$$

where, $q_{eff(Cl^-)} = 0.751\ e^-$, as has been calculated for uranium(IV)-chlorocomplexes,[6] $q_{eff(*L^-)} = 1.0\ e^-$, U—N(*j*), U—Cl(*i*), U—B distances in pm, α the C_3-axis–U—N angle and ϕ the C_3-axis–U—Cl angle in degrees, which are known from the crystallographic analysis. Due to the quasi-C_{3v} molecular symmetry of the compound, the sum of the vectorial parts of the partial moments $\Sigma r_{U-N(j)} \cos(\alpha_j - 90)^\circ$ and $\Sigma q_{eff(Cl^-)} r_{U-Cl(i)} \cos(\phi_i - 90)^\circ$ perpendicular to the C_3-axis are zero. The partial moment μ_{*L} of the ligand *L can be calculated; its value is almost zero also. Thus, eq. (1) gives:

$$\mu_{exp} = \Sigma\mu_{U-N(j)} \sin(\alpha_j - 90)^\circ - \Sigma q_{eff(Cl^-)} r_{U-Cl} \sin(\phi_i - 90)^\circ + q_{eff(*L)} r_{U-B} \quad (2)$$

The only unknown parameter in eq. (2) is now the partial moment $\mu_{U-N(j)}$ between uranium and nitrogen and can be calculated from (2):

$$\mu_{U-N(j)} = \{\mu_{exp} + \Sigma q_{eff(Cl^-)} r_{U-Cl} \sin(\phi_i - 90)^\circ - q_{eff(*L)} r_{U-B}\} / \Sigma \sin(\alpha_i - 90^\circ) = 1.40\,D \quad (3)$$

The dipole moment of UCl_3*L·B *compounds* (**II**)

The total dipole moment of compounds **II** can be calculated as discussed previously for the base-free compound by taking into account the moment contribution of the base molecule:

$$\mu_{exp} = \Sigma\mu_{U-N(j)}\{\sin(\alpha_j - 90)^\circ + \cos(\alpha_j - 90)^\circ - \Sigma q_{eff(Cl^-)} r_{UCl,i}\{\sin(\phi_i - 90)^\circ + \cos(\phi_i - 90^\circ)\} + q_{eff(*L^-)} r_{U-B} - \mu_{*L^-} - \mu_{U-B(base)} + \mu_{base}. \quad (3a)$$

Under the assumptions made for the base-free compounds eq. (3) can be written as:

$$\mu_{exp} = \Sigma\mu_{U-N(j)} \sin(\alpha_j - 90)^\circ - \Sigma q_{eff(Cl^-)} r_{UCl,i}\{\sin(\phi_i - 90)^\circ + q_{eff(*L^-)} r_{U-B} - \mu_{*L} - \mu_{U-B(base)} + \mu_{base}. \quad (3b)$$

Distances and angles are well known from the crystallographic analysis of the thf compound[7] and of the analogous tep-complex (this paper). The first four terms of eq. (3b) represent the partial moment of the "UCl_3*L" unity of the complex:

$$\mu_{"UCl_3*L"} = \Sigma\mu_{U-N(j)} \sin(\alpha_j - 90)^\circ - \Sigma q_{eff(Cl^-)} r_{UCl,i}\{\sin(\phi_i - 90)^\circ + q_{eff(*L^-)} r_{U-B} - \mu_{*L} \quad (4)$$

and is calculated to be 13.07 D for the thf compound and 13.11 D for the tep compound; $\mu_{"UCl_3*L"}$ can be treated as a constant because its value does not change with variation of the base B. Furthermore, the dipole moment of the free base, μ_B, is known from the literature or it can be easily measured experimentally; thus, the only unknown term in eq. (3b) is the partial moment μ_{U-base} between the uranium ion and the coordinated atom of the base B. The measured dipole moments of the free Lewis bases, μ_B, of the 1:1 adducts and the calculated partial moments, μ_{U-base}, are summarized in Table 3.

Table 3. Dipole moment of the UCl_3*L·B complexes and the free base B and partial electric moment for the coordinative uranium–Lewis base bonding

Charge distribution and IR-spectroscopic investigations

The partial bonding moment $\mu_{U-B(base)}$ between the uranium ion and the coordinated atom of the base B increases with an increase in the electron-donor strength of the Lewis base B (Fig. 3).

Extrapolation of the linear μ_{exp} *vs* μ_{base} plot in Fig. 3 yields a dipole moment of 6.17 D. This electric moment corresponds to the moment of a molecule in which the uranium ion is coordinated to a hypothetical, non-polar Lewis base B (with $\mu = 0$). For this molecule a partial electric moment between the central ion and the hypothetical non-polar base of 6.90 D is obtained by extrapolation of the μ_{U-B} vs μ_B plot in Fig. 3. The same value is obtained by using eq. (3b):

$$\mu_{U-B(base)} = \mu_{\text{"}UCl_3{}^*L\text{"}} - \mu_{exp} + \mu_B = 6.90\,D$$

with $\mu_{\text{"}UCl_2{}^*L\text{"}} = 13.07$, $\mu_{exp} = 6.17$ and $\mu_B = 0.0$ D.

The interaction between the coordinated atom of a hypothetical, non-polar Lewis base and the uranium central ion (6.90 D) is strong enough to change the geometry of the UCl_3*L molecule into the coordination geometry of the UCl_3*L · B adduct, which means increasing the Cl—U—Cl angle from 97.0° to *ca* 114°. When a Lewis base B is coordinated to the UCl_3*L molecule, the electronic density of the uranium ion along the main symmetry C_3-axis in the UCl_3*L · B compound increases. An increase in the electron-donor strength of the coordinated base causes a decrease in the electronic inter action between the central ion and the pyrazolyl rings of the ligand *L and consequently, the interaction between the proton and the boron ion becomes weaker. This is reflected in the characteristic B—H vibration in the IR spectra. Compared with the B—H vibrational frequency of the base-free molecule **I**, the B—H frequencies of the adducts are shifted to lower energies (Table 4). The plot $\mu_{U-B(base)}$ vs $\Delta\nu_{B-H}$ $[\nu_{B-H(I)} - \nu_{B-H(II)}]$ demonstrates well the electronic interaction between the coordinated ligand and the uranium ion along the C_3-axis. If the interaction between the base B and the uranium ion is not too strong, a linear correlation between the bonding moment $\mu_{U-B(base)}$ and the frequency of the B—H stretch vibration ν_{B-H} was observed (Fig. 4).

The value of $\Delta\nu_{B-H}$ for the hypothetical compound in which the uranium ion is coordinated to a non-polar Lewis base ($\mu_B = 0$, $\mu_{U-B} = 6.90$ D) is 3.5 cm^{-1}. This difference in the B—H vibrational frequency corresponds to the change of the molecular geometry when UCl_3*L becomes UCl_3*L · B. An increase in the interaction strength between the Lewis base and the central ion causes a saturation effect in the μ_{U-B} vs $\Delta\nu_{B-H}$ plot (Fig. 4). The partial moment cannot increase beyond a maximum, because the uranium–base distance (r_{U-B}) is limited by the ionic radii of tetravalent uranium and the coordination atom of the base B.

The apparent discrepancy in the relationship between $\mu_{U-B(base)}$ and the ν_{B-H} vibrational frequency for the cyclohexylisonitrile and triphenylphosphine oxide complex [$\Delta\nu_{B-H(tppo)}$ >

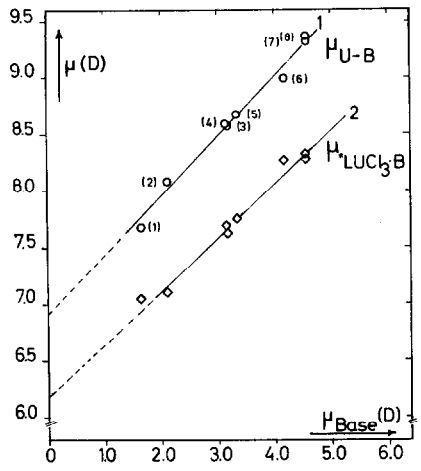

Fig. 3. Experimentally measured dipole moments (μ) of the $UCl_3[HB(3,5Me_2Pz)_3]$ · B complexes and calculated partial electrical moments (μ_{U-B}) between uranium and base as a function of the dipole moment of the free base [(1) thf; (2) py; (3) MeCN; (4) tep; (5) tbp; (6) PhCN; (7) $C_6H_{11}NC$; (8) tppo].

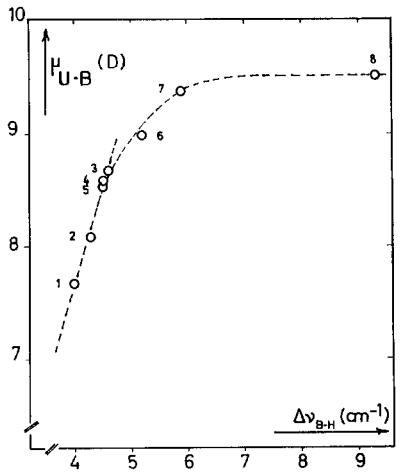

Fig. 4. The correlation between partial electrical moment μ_{U-B} and $\Delta\nu_{B-H}$ in the $UCl_3[HB(3,5Me_2Pz)_3]$ · B compounds [(1) thf; (2) py; (3) MeCN; (4) tep; (5) tbp; (6) PhCN; (7) $C_6H_{11}NC$; (8) tppo].

$\Delta\nu_{B-H(CNR)}$, while $\mu_{U-O(tppo)} < \mu_{U-C(C_6H_{11}NC)}$] is due to the back-bonding character of the isonitrile group through the electron density transfer into the anti-bonding orbitals of the isocyanide group. Therefore, the electron-acceptor character of the central ion and the partial bonding moment $\mu_{U-B(base)}$ are stronger in the isonitrile complex. The tppo molecule represents a very strong Lewis base without any π-acceptor back-bonding character and consequently, the $\Delta\nu_{B-H}$ value increases, whereas the partial electric moment $\mu_{U-B(base)}$ remains almost constant (saturation).

Electronic absorption spectra

The absorption spectra of all the UCl_3*L · B complexes in the region 1600–400 nm in the solid state (KBr matrix) and in benzene solution show the characteristic absorption band groups for uranium(IV) and are quite similar (Fig. 5); an indication of the similar coordination geometry around the uranium ion in all the compounds investigated. It can be assumed that all the analogous compounds

Table 4. Partial bonding moment μ_{U-B}, vibrational frequency of the B—H vibration and absorption band wavelength for the ^3F-term of the uranium ion of the UCl_3* L · B compounds

Base	μ_{U-B} (D)	ν_{B-H} (cm^{-1})	ν_{B-H} (cm^{-1})	λ (nm)
—	—	2565.0	—	1101.2
thf	7.67	2561.0	4.0	1168.0
py	8.08	2560.8	4.3	1169.9
tep	8.59	2560.5	4.5	1173.2
tbp	8.56	2560.5	4.5	1173.1
MeCN	8.67	2560.4	4.6	1174.4
PhCN	8.99	2559.8	5.2	1175.1
tppo	9.30	2556.5	9.5	1178.2
$C_6H_{11}NC$	9.37	2559.1	5.9	1176.5

are isomorphic (see crystal structure of UCl_3*L · thf and UCl_3*L · tep).

As can be seen in Fig. 5, the shape of the absorption band at 1170 cm^{-1} is sensitive towards the base B; the absorption energy changes with a change in the Lewis basity of the coordinated molecule (Table 4). The absorption band belongs to the ^3F-term of the $5f^2$ electronic configuration of the tetravalent uranium. Its energy must correlate with the electron-density along the C_3-axis of the molecule and with the partial electric moment $\mu_{U-B(base)}$. The bigger electronic density in the 1 : 1 adduct causes a lower absorption energy for the ^3F-term than in the base-free molecule, as is shown in the $\mu_{U-B(base)}$ vs $E_{^3F}$ plot of Fig. 6.

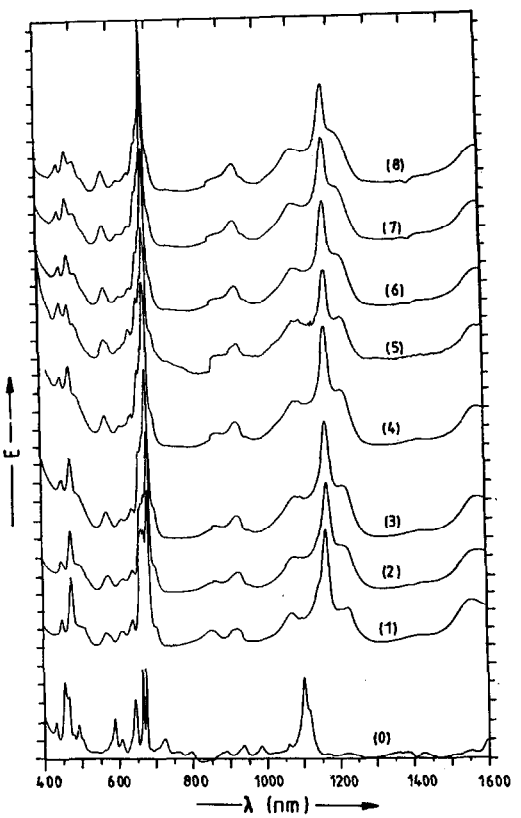

Fig. 5. Electron absorption spectra of the $UCl_3[HB(3,5Me_2Pz)_3]$ · B compounds [(0) base-free compound; (1) thf; (2) py; (3) MeCN; (4) tep; (5) tbp; (6) PhCN; (7) $C_6H_{11}NC$; (8) tppo].

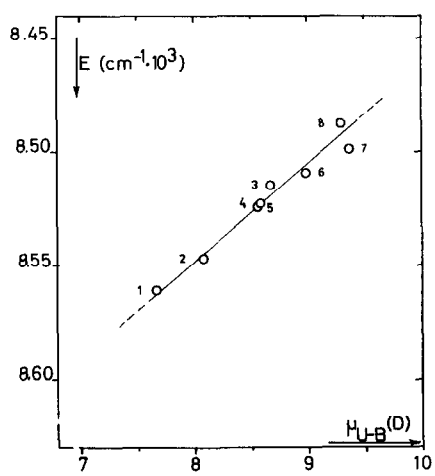

Fig. 6. The energy of the 1170 nm absorption band as a function of the dipole moment of the free base B [(1) thf; (2) py; (3) MeCN; (4) tep; (5) tbp; (6) PhCN; (7) $C_6H_{11}NC$; (8) tppo].

Extrapolation of the plot of Fig. 6 vs $\mu_{U-B(base)} = 0$ yields an energy of 8960 cm^{-1}, which is smaller than the absorption energy of 9081 cm^{-1} experimentally measured in L^*UCl_3. The energy difference, ΔE, between the extrapolated and measured value for the L^*UCl_3 compound is 121 cm^{-1} (= 1.447 kJ mol^{-1}) and corresponds to the energy which is needed to change the molecular symmetry by forming the 1:1 adduct $L^*UCl_3 \cdot B$, starting from L^*UCl_3.

^1H *NMR spectra*

As expected for C_{3v}-symmetry, in all the $UCl_3[HB(3,5MePz)_3] \cdot B$ compounds only one set of ^1H resonances was observed for the protons of $CH_3(3)$, $CH_3(5)$ and H(4) of the three pyrazolyl rings. Although the NMR spectra of all the compounds are similar, the chemical shifts of the protons of the pyrazolyl rings, especially those observed for the protons of the $CH_3(3)$ groups, vary over a wide range from −20 to −4 ppm. The chemical shifts of the resonances of the pyrazolyl protons of the different complexes at 300 K are summarized in Table 5. Measurements in $CDCl_3$ solutions at different temperatures show an almost linear correlation between the chemical shift and the temperature for all the adducts (Table 5).

Abstract—New complexes of lanthanide nitrates with 3,4-methylenedioxybenzaldehyde thiosemicarbazone having the general formula $[Ln(LH)_2(NO_3)_2]NO_3$ (where Ln = La, Ce, Pr, Nd, Sm, Eu, Gd, Dy, Ho, Er, Yb and Y) have been prepared and characterized by elemental analysis, molar conductance, magnetic measurements, electronic, infrared, ^1H NMR, fluorescence spectra and thermal studies. Molar conductance studies indicate 1 : 1 electrolytic behaviour for these complexes. The spectral studies show that two thiosemicarbazone ligands and two nitrate groups are bound to the lanthanide ion in a bidentate fashion. TG and DTA studies indicate that these complexes are stable up to 255°C and do not contain water or alcohol molecules.

Thiosemicarbazones are amongst the most widely studied nitrogen and sulphur donor ligands. They are capable of acting as neutral or charged ligands. The importance of these compounds is mainly due to their anticarcinogenic,[1] antibacterial[2] and antifungal activities,[3] as well as their ability to form chelate complexes with transition metals.[4,5]

In cancer treatment it has been shown that the metal chelates are more potent than chelating agents.[6] The donor properties and biological activities of thiosemicarbazones of benzaldehyde and substituted benzaldehyde have been investigated in detail.[7,8] A thorough survey of the literature reveals that there is no report on the lanthanide complexes of 3,4-methylenedioxybenzaldehyde thiosemicarbazone (LH). This paper, therefore, describes the synthesis and characterization of lanthanide complexes with the above ligand.

EXPERIMENTAL

All the reagents used were of analytical grade. The ligand, LH, was synthesized by refluxing 3,4-methylenedioxybenzaldehyde and thiosemicarbazide (1 : 1 ratio) in absolute alcohol for 2 h and recrystallizing the product from ethanol,[9] m.p. 190–191°C.

Synthesis of the complexes

The following general procedure was used to isolate all the lanthanide(III) complexes. Lanthanide(III) nitrate (0.002 M) was dissolved in absolute alcohol (10 cm^3). The ligand, LH (0.004 M), dissolved in the same solvent (*ca* 20 cm^3) was added to the above solution with constant stirring. The mixture was refluxed on a water bath for *ca* 4 h and the pH of the mixture was then raised to *ca* 6.5 by the dropwise addition of alcoholic ammonia and again refluxed for 2 h. The solid complexes thus formed were filtered, washed with absolute alcohol and dried *in vacuo* at room temperature.

Physical measurements

Elemental analyses (C, H and N) were performed on an auto-elemental analyser, model 1106. The metal contents were estimated by complexometric EDTA titration using xylenol orange as an indicator[10] at pH 6. Sulphur was determined by the standard method.[11] Conductance measurements were performed on 10^{-3} M solutions of the complexes in methanol using an Elico conductivity

* Author to whom correspondence should be addressed.

bridge, type CM-82, attached to a dip type conductivity cell fitted with platinum electrodes (cell constant 0.51). The magnetic moments of the complexes were determined by the Gouy method at room temperature. The electronic spectra of the ligand and complexes were recorded on a Hitachi 150-20 spectrophotometer. IR and ^{1}H NMR spectra were recorded on a Perkin–Elmer model 337 spectrophotometer in Nujol mulls and a VXR 300S Varian supercon NMR spectrometer using DMSO-d_6 as a solvent, respectively. The fluorescence spectrum of the Eu^{III} complex was determined using a Perkin–Elmer MPF 3L fluorescence spectrophotometer from the solid compound by excitation with 400 nm radiation at room temperature. The thermal analyses, such as the TG and DTA measurements, were performed in static air, using a limiting temperature of 1000°C and a heating rate of 10°C min^{-1}.

RESULTS AND DISCUSSION

The stoichiometries of the complexes were confirmed by the elemental analyses reported in Table 1. All the complexes are air stable, non-hygroscopic and soluble in polar solvents. They are pale white to cream in colour, except praseodymium and neodymium which are green and violet, respectively. The complexes have the general formula $[Ln(LH)_2(NO_3)_2]NO_3$.

Molar conductance

The molar conductance data of the complexes are presented in Table 1. From these data it is clear that all the complexes show 1 : 1 electrolytic behaviour in methanol.[12]

The magnetic moments of these lanthanide complexes, recorded in Table 1, show little deviation from the Van Vleck values,[13] thereby indicating that the 4*f*-electrons do not participate in bond formation in these complexes. Thus, the magnetic moments of these complexes are within the range predicted and observed in compounds of the lanthanide ions.[14] The data also suggest that there are no metal–metal interactions or spin–spin coupling.

Electronic spectra

The ligand shows two absorption maxima, a sharp peak (of weak intensity) at 38,314 cm^{-1} due to the $\pi \rightarrow \pi^*$ transition and a broad peak (strong

intensity) at 29,940 cm^{-1} due to the $n \rightarrow \pi^*$ transition. It was found that the electronic spectra of the lanthanide complexes are dominated by ligand absorption bands with a hyperchromic effect. The domination of the ligand absorption bands could be related to the high absorption coefficient of the ligand as compared with the Ln^{III} ions, which masks any splitting of the bands.[15]

IR spectra

The IR spectra of the ligand and complexes were recorded in the 4000–200 cm^{-1} range. The highest frequency of the ligand at 3450 cm^{-1} can be assigned to the asymmetric (N—H) vibration of the terminal $—NH_2$ group. The other bands at 3110 and 3280 cm^{-1} may be due to the vibration of the imino group and the symmetric (N—H) vibration of the terminal amino group. The absence of bands at 2650–2500 cm^{-1} in the ligand spectrum indicates that there is no S—H group in the free ligand in the solid state.[8] The band of strong intensity at 1580 cm^{-1} with a shoulder at 1650 cm^{-1} in the ligand spectrum may be assigned to the azomethine stretch. In all the complexes it undergoes a red shift by 20–30 cm^{-1}, indicating the participation of the azomethine nitrogen in coordination.[16] The band of medium intensity at 800 cm^{-1} with distinct shoulders at 815 and 845 cm^{-1} in the ligand spectrum may be assigned to pure ν(C=S). In all the complexes we found a band of strong intensity around 790 cm^{-1}, a band of medium intensity around 855 cm^{-1} and a new band of weak intensity around 760 cm^{-1}. In addition, the band position assigned to secondary (N—H) remained unaltered. These observations strongly suggest the coordination of thiocarbonyl sulphur to the lanthanide ion[17] (Table 2).

The complexes show six absorption bands near 1500, 1290, 1030, 820, 750 and 705 cm^{-1}, which are assigned to ν_4, ν_1. ν_2, ν_6, ν_3 and ν_5 vibrations, respectively, of the coordinated (C_{2v}) nitrate group.[18,19] The magnitudes of ν_4–ν_1 and ν_3–ν_5 are in the range 201–210 and 43–47 cm^{-1}, respectively, indicating that the nitrate groups are coordinated in a bidentate fashion. The band at 1350 cm^{-1} expected for ionic nitrate is not observed in the spectra as it might be obscured by the broad Nujol band in the range 1390–1340 cm^{-1}.

^1H NMR spectra

The methylene protons in the free ligand are represented by a sharp singlet at δ 6.08. The two doublets at *ca* δ 6.87 and 7.06 in the spectra of the ligand and the complexes are due to the two phenyl protons H(5) and H(6). This can easily be understood from the vicinal coupling constant ($J \approx 8.5$ Hz). The singlet at δ 7.55 is due to the third proton, H(2) of the phenyl ring. The signal for the azomethine proton is expected to appear at a lower field compared with the phenyl protons. Thus, the singlet at δ 8.02 due to the azomethine proton in the ligand spectrum is shifted downfield to δ 8.20–8.30 in the spectra of the diamagnetic complexes, showing its deshielding as a result of coordination through the nitrogen of the azomethine group to

the metal ion. The spectra of thiosemicarbazones are expected to exhibit two resonances for the NH_2 protons, indicating hindered rotation about the C(S)—NH_2 bond due to its partial double bond character.[20] However, in the spectrum of the present ligand, there is only a singlet at δ 7.88 for the —NH_2 protons. This is not unexpected as one of these signals may be obscured by that of the aromatic protons, as in the case of benzaldehyde thiosemicarbazone. The secondary NH proton signal is found at δ 10.88 in the spectrum of the ligand. The shifting of secondary NH proton signal from δ 10.88 to 11.02 in the complexes indicates the coordination of the metal ion to the thiocarbonyl sulphur without deprotonation. Thus, IR and ^1H NMR spectral observations supplement each other.

Fluorescence spectrum of the europium(III) *complex*

The fluorescence spectrum of the europium(III) complex (Fig. 1) exhibits sharp emissions in the regions 475–515 and 560–570 nm. The more intense band observed in the 560–570 nm region is assigned to the transition $^7F_1 \leftarrow {}^5D_0$.[21] Comparatively weak bands between 475 and 515 nm may be assigned to phosphorescence emission.[22]

Thermal studies

The thermal analytical results of some complexes (Table 3 and Fig. 2) show that the complexes are stable up to 235°C. This observation shows that there are no water or solvent molecules in the lattice.

Table 3. Thermal analysis data for some of the complexes

S. No.	Complexes	Decomposition range in TG (°C)	Peaks in DTA (°C)
1.	$[La(LH)_2(NO_3)_2]NO_3$	240–650	295, 330, 570, 620
2.	$[Pr(LH)_2(NO_3)_2]NO_3$	245–640	285, 320, 580, 610
3.	$[Nd(LH)_2(NO_3)_2]NO_3$	245–645	295, 335, 575, 615
4.	$[Gd(LH)_2(NO_3)_2]NO_3$	250–630	285, 325, 580, 610
5.	$[Dy(LH)_2(NO_3)_2]NO_3$	250–640	290, 320, 560, 610

The complexes undergo complete decomposition in the region 620–650°C.

On the basis of elemental analysis, molar conductance, magnetic moments, IR, ^{1}H NMR and fluorescence spectra and thermal analysis, it is concluded that two LH ligands and two nitrate groups are bound to the lanthanide ion and another nitrate group is in the outer coordination sphere. Hence, the present complexes may be formulated as $[Ln(LH)_2(NO_3)_2]NO_3$. The lanthanide ions in the complexes exhibit coordination number eight.

Abstract—Complexes of copper(II) bromide and copper(II) azide with 2-benzoylpyridine (2-Bzpy), namely *trans*-dibromobis(2-benzoylpyridine)copper(II) (**1**) and *trans*-diazidobis(2-benzoylpyridine)copper(II) (**2**), have been prepared and characterized by spectroscopic methods and X-ray crystallography. The copper atom in centrosymmetric [$CuBr_2$(2-Bzpy)$_2$] (**1**) is six-coordinated by two nitrogen atoms [Cu—N = 1.970(4) Å] and two oxygen atoms [Cu—O = 2.407(4) Å] belonging to the two 2-Bzpy molecules and two *trans*-bromide atoms at Cu—Br distances of 2.468(1) Å. In the structure of complex **2**, [$Cu(N_3)_2$(2-Bzpy)$_2$], the copper atom which is also located at an inversion centre is six-coordinated by pairs of *trans*-N,O-bidentate chelating 2-Bzpy molecules [Cu—N = 2.005(3) Å, Cu—O = 2.467(3) Å] and the terminal azido ligands at Cu—N distances of 1.989(4) Å. The azido ligands are almost linear [N—N—N = 176.6(4)°] and asymmetric [N_α—N_β = 1.201(5) and N_β—N_γ = 1.158(5) Å]. The IR and electronic spectral data for both complexes are presented and discussed.

Monopyridyl ketones are potentially bidentate, or ambidentate, ligands which may show interesting coordination properties towards metal ions in the border region between class (a) and class (b) acceptors,[1] such as cobalt(II) and nickel(II). Plytzanopoulos *et al.*[2] and others[3–5] have reported complexes formed by first row transition metal ions with 2-benzoylpyridine (hereafter abbreviated as 2-Bzpy) and assigned the coordination geometry mainly on the basis of spectroscopic data. They found that 2-Bzpy acts as either a mono- or bidentate ligand in these complexes, depending on the central metal ions, the anions and the solvent used. Recent X-ray studies have shown that 2-Bzpy functions as an N,O-coordinating ligand in the polymeric complex Cu_3(2-Bzpy)$_2(N_3)_6$,[6] as well as in the dimeric complexes [Cu(2-Bzpy)$(N_3)_2]_2$[7] and [CuI(2-Bzpy)]$_2$.[8]

When a mixture of 2-Bzpy and copper(II) nitrate trihydrate and KI in aqueous/ethanolic medium was reduced by L(+)-ascorbic acid and the final mixture boiled and then allowed to stand over several weeks, an intramolecular oxidative cyclization of 2-Bzpy occurs and the complex [9H-indeno[2,1-b]pyridin-9-one)H]·CuI_2 is separated.[9] Trials to prepare the corresponding copper(I) azide complex led to the oxidation of copper(I) rather than 2-Bzpy, with the formation of a new 1 : 2 complex of copper(II) azide with 2-Bzpy. In the present paper we report our investigation of this complex along

with the corresponding 1 : 2 bromide complex elucidated by spectroscopic methods and X-ray crystallography. The latter complex has been described previously and suggested to possess a *cis*-octahedral structure.[2] As the IR and electronic spectra and other physical data of a sample prepared by us are very similar to those for the 1:2 azido complex having a *trans*-configuration, we have undertaken a reinvestigation of the bromide complex.

EXPERIMENTAL

Preparation of $[CuBr_2(2\text{-benzoylpyridine})_2]$ *complex* (**1**)

This complex was prepared by adding excess L(+)-ascorbic acid to a mixture of $Cu(NO_3)_2 \cdot 3H_2O$ (0.48 g, 2 mmol) and KBr (0.59 g, 5 mmol) in ethanol/aqueous medium (15/5 cm^3) followed by addition of 2-Bzpy (0.55 g, 3 mmol) dissolved in 10 cm^3 water. The final mixture was boiled for several minutes and then allowed to stand over several weeks. The complex was separated as dark green crystals. Found: C, 50.2; H, 2.9; N, 4.5; Br, 26.1; Cu, 11.1. Calc.: C, 48.9; H, 3.1; N, 4.7; Br, 27.1; Cu, 10.8%.

Preparation of $[Cu(N_3)_2(2\text{-benzoylpyridine})_2]$ *complex* (**2**)

Ethanolic solutions of copper(II) nitrate trihydrate (10 cm^3, 0.48 g, 2 mmol) and 2-Bzpy (10 cm^3, 1.10 g, 6 mmol) were mixed together, followed by addition of excess L(+)-ascorbic acid. To the resulting red solution, an aqueous solution of NaN_3 (5 cm^3, 0.26 g, 4 mmol) was added dropwise, and the final mixture boiled for several minutes and then allowed to stand over about 1 month in an open beaker. The complex was separated as dark green (almost black) crystals. Found: C, 55.7; H, 3.7; N, 22.1; Cu, 12.7. Calc.: C, 56.1; H, 3.5; N, 21.8; Cu, 12.4%.

X-ray crystallography

A modified STOE four-circle diffractometer was used for single crystal X-ray measurements. Lattice parameters were obtained by least-squares refinement of the diffraction data from 20 (compound **1**) and 18 (compound **2**) reflections in the 2θ range 8–18°. Data were collected at 300(1) K using graphite crystal-monochromatized Mo-K_α radiation ($\lambda = 0.71069$ Å) and the ω-scan technique. The intensities were corrected for Lorentz and polar-

ization effects, and for absorption by an empirical method. Crystallographic data are given in Table 1.

The structures were solved by direct methods. Anisotropic displacement parameters were only applied to the non-hydrogen atoms in full-matrix least-squares refinements. The hydrogen atoms were included in the final refinement cycles on calculated positions. The programs DIFABS,[10] SHELX-76,[11] SHELXS-86,[12] PLATON[13] and THE XRAY SYSTEM[14] were used for computations. Analytical expressions of neutral-atom scattering factors were employed, and anomalous dispersion corrections were incorporated.[15] Selected bond distances and bond angles are given in Table 2. Positional parameters, anisotropic displacement parameters, hydrogen atom coordinates, a full list of bond lengths and angles and observed and calculated structure factors have been deposited with the Editor as supplementary material.

Spectral data

The IR absorption spectral bands are listed in Table 3, and electronic spectra of the solid complexes are shown in Fig. 5. The experimental procedures and instruments used for spectral and other measurements have been given previously.[16]

DISCUSSION

The interactions between copper(I) bromide or copper(I) azide and 2-Bzpy in the presence of the respective anions for a long time led to the oxidation

of copper(I) rather than the organic ligand, as found in the case of copper(I) iodide,[9] and afforded the eponymous copper(II) complexes. These complexes can also be prepared by direct interaction between the components or by mixing of copper(II) nitrate trihydrate and 2-Bzpy followed by addition of KX (X = Br or N_3) in ethanol. A sample of the 1:2 bromide complex was also prepared according to the method given previously.[2,3] X-ray powder diffraction patterns, IR and electronic spectral data of samples prepared by different procedures are so similar that we could not distinguish one from the other. One or the other of the title complexes are soluble in ethanol, acetonitrile, chloroform and DMF, and both gave non-conducting solutions in nitromethane as reported previously.[2,3]

Complex molecules of the bromide compound **1** have crystallographically imposed $\bar{1}$ symmetry. Figure 1 is a perspective drawing showing its *trans*-configuration along with the atom labelling. Taking the different size of ligating atoms into account, the coordination about the copper atom can be described as a tetragonal bipyramid with the oxygen atoms of the two 2-Bzpy ligands occupying the axial positions. This arrangement is different from that of *cis*-$Cu(2\text{-Bzpy})_2X_2$ (X = Cl or Br), the structure of which was inferred from IR and UV–vis spectra.[2,3] In accordance with the division of Cu—L distances into three ranges,[17] the measured axial Cu—Br bond of 2.468(1) Å is long and the equatorial Cu—N(2-Bzpy) bond of 1.970(4) Å is short, whereas the other Cu—O(2-Bzpy) bond of 2.407(4) Å is long. This long Cu—O distance, which reflects a weak interaction between the oxygen atom of 2-Bzpy and copper atoms, confirms the previous conclusion based on spectroscopic data.[2,3] A *trans* arrangement in other complexes of 2-Bzpy has been revealed in the structures of the $[Cu(2\text{-Bzpy})_2(H_2O)_2]^{2+}$ cation with intermediate Cu—O(aqua) bonds of 2.256(3) Å,[18] and $[Cu(2\text{-Bzpy})_2(ClO_4)_2]$ with long axial Cu—O(ClO_4) bonds of 2.485(17) and 2.492(7) Å.[19] The five-membered ring formed by copper atoms and the bidentate 2-Bzpy deviates from planarity [torsion angle N(1)—C(5)—C(6′)—O(1′) = 20.2(8)°].

Figure 3 illustrates the principal structural features of the $[Cu(N_3)_2(2\text{-Bzpy})_2]$ complex **2**, in which the copper atom is also located at an inversion centre. Each copper centre is coordinated by pairs of *trans*-N,O-bidentate chelating 2-Bzpy ligands [Cu—N = 2.005(3), Cu—O = 2.467(3) Å] and terminal azido ligands at Cu—N distances of 1.989(4) Å. The coordination about the copper atom can be described as a tetragonal bipyramid with the oxygen atoms of the 2-Bzpy ligands occupying the axial positions, very similar to the geometry around the copper atom in complex **1**. The five-membered chelate ring formed by copper atom and the bidentate 2-Bzpy also deviates from planarity [torsion angle N(1)—C(5)—C(6)—O(1) = −24.7(5)°]. The interaction between the copper atoms and carbonyl oxygen of the 2-Bzpy ligand is weaker than that in the case of the bromide complex, as indicated by the difference in Cu—O bonds in both compounds.

The terminal azido ligands are almost linear within experimental error [∠N—N—N = 176.6(4)°] and asymmetric [N_α—N_β = 1.201(5), N_β—N_γ = 1.158(5) Å]. The Cu—N(N_3) bond lengths match very well those reported in the structures of [CuBr(N_3)(tedt)] (tedt = 1,1,7,7-tetraethyldiethylenetriamine) [1.927(6) Å],[20] [Cu

$(pymep)(N_3)_2]$ (pymep = *N*-(2′-(6-methyl)pyridyl) (methylene-2-(2′-pyridyl)ethylamine) [1.986(7) and 2.039(8) Å][21] and $[Cu(N_3)_2$'diEten)] (diEten = *N*,*N*-diethylenediamine) [2.004(3) Å],[22] but are a little shorter than the corresponding values [2.015(3) and 2.176(3) Å] found in the structure of [Cu(2-pyridinecarbaldehyde)-histamine$(N_3)_2$],[23] all of which contain terminal azido ligands.

Stereoviews of the packing of both crystal structures are shown in Figs 2 and 4, respectively.

It is of interest to compare the 1 : 2 mixed ligand copper(II) azido complexes of pyridine,[24] 3-picoline,[25] 4-picoline[26] and 2-Bzpy. A common structural feature in this series of complexes is a six-coordination about the copper atom. The monomeric nature of the 2-Bzpy complex arises from the fact that the organic ligand acts as a bidentate, thus enforcing the two azides to function as terminal monodentate ligands. The organic ligand is monodentate in the first three complexes and the unsaturation in the copper sphere is satisfied by converting one or both azido groups from terminal to bridge mode. In the pyridine complex, as one of the two azides remains terminal, the other azide serves as a $\mu(1,1,3)$ bridging ligand, whereas the two azides function as $\mu(1,1)$ bridges in the 4-picoline complex and as $\mu(1,1)$ and $\mu(1,3)$ bridges in the 3-picoline complex, giving rise to polymeric structures for these three complexes.

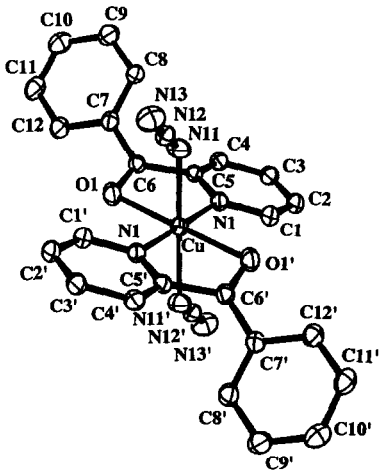

Fig. 3. Coordination figure and atom numbering scheme of $[Cu(N_3)_2(2\text{-Bzpy})_2]$ (**2**).

The IR spectral data given in Table 3 show a small decrease of ν(C=O) from 1663 cm^{-1} in free 2-Bzpy to 1640 and 1648 cm^{-1} in complexes **1** and **2**, respectively. Indeed, a substantial reduction of ν(C=O) with $\Delta\nu \cong 30$–70 cm^{-1} was observed for other metal complexes of 2-Bzpy and taken as good evidence for the coordination of the carbonyl oxygen.[2,3] The observed small decrease of ν(C=O) in the case of complexes **1** and **2** does not mean the exclusion of ν(C=O) from coordination. In fact, although a strong copper–carbonyl oxygen interaction occurs in the complex cation $[Cu(2\text{-bzpy})_2(H_2O)_2]^{2+}$, as indicated by the Cu—O distance of 2.068(2) Å, its spectrum shows only a very slight shift of ν(C=O) to 1555 cm^{-1}.[18] Thus the reduction of ν(C=O), together with the shift of pyridine ring vibrations to higher frequencies, suggests a simultaneous N,O-coordination of 2-Bzpy.

The crystal structure determinations show that complex **2** contains two crystallographically identical asymmetric terminal azido ligands with $\Delta d = 0.043$ Å (Δd is the difference between the N—N distances). Thus, only a single band associated with each of $\nu_{as}(N_3)$ and $\nu_s(N_3)$ is expected.

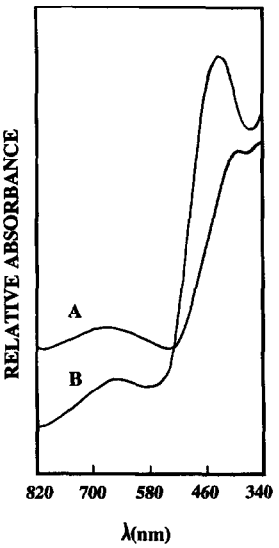

Fig. 5. Reflectance spectra of solid complexes: (A) $[CuBr_2(2\text{-Bzpy})_2]$ and (B) $[Cu(N_3)_2(2\text{-Bzpy})_2]$.

Moreover, from the relationship between Δd and $\nu_{as}(N_3)$ given earlier,[27,28] the single absorption band due to $\nu_{as}(N_3)$ is expected to be around 2043 cm^{-1}, a value which is very close to that of 2038 cm^{-1} given in Table 3. The strong absorptions of the ligand in the region 1350–1270 cm^{-1} masks the $\nu_s(N_3)$ absorption band.

The electronic spectra of complexes **1** and **2** are given in Fig. 5. The strong absorption bands at 25,640 and 23,255 cm^{-1} in the spectra of complexes **1** and **2**, respectively, are due to LMCT transitions from the bromide or azide to copper. The position of these bands indicates the influence of the azide group on the charge transfer as compared to the halide ions. Both complexes, however, exhibit an asymmetric *d–d* absorption band at 14,930 and 15,500 cm^{-1} for complexes **1** and **2**, respectively. For the bromide complex the previous value was 14,500 cm^{-1}.[2,3] These spectra are consistent with distorted octahedral copper(II) environments.[29,30] Previous studies[7,25,31–34] have shown that the electronic spectra of solid copper(II) azido complexes containing cyclic $Cu_2N_2(N_3)$ units usually exhibit a distinct absorption band in the vicinity of 17,000–20,000 cm^{-1}. The intensity of this band is so strong that it could not be attributed to *d–d* transitions. This band was considered as due to LMCT transition from bridging azides of the type $\mu(1,1)$ to copper(II).[35] The disappearance of any absorption in the range 17,000–20,000 cm^{-1} from the spectrum of complex **2** having only terminal azides, confirms our previous conclusion that the existence of such a band should be taken as strong evidence of the existence of binuclear cyclic Cu_2N_2 units, and hence at least two $\mu(1,1)$ bridging azido ligands.[35] The results given here may be of value in distinguishing between copper(II) azido complexes containing only terminal azide groups and those containing $\mu(1,1)$ bridging azido ligands.

(*Received* 30 *April* 1993; *accepted* 15 *June* 1993)

Abstract—Two mixed ligand complexes of copper(II) azide with 3-picoline and 4-picoline, namely di-μ(1,1)-azido-μ(*O*,*O*)-nitrato)(*O*-nitrato)tetrakis(3-picoline)dicopper(II) (**1**) and catena-di-μ(1,3)-azido-[di-μ(1,1)-azido-bis(4-picoline)dicopper(II)] (**2**), have been synthesized and characterized by X-ray crystallography. The structure of complex **1** consists of asymmetric dimeric units in which Cu(1) is six-coordinated to two nitrogen atoms from the picoline molecules, two nitrogen atoms of the two μ(1,1) bridging azido ligands and two oxygen atoms of the two nitrate anions. Cu(2) is also six-coordinated to two nitrogen atoms of the other two picolines, two nitrogen atoms of the two μ(1,1) bridging azido ligands, an oxygen atom of the aqua molecule and an oxygen atom of the μ(*O*,*O*) bridging nitrato group. The structure of complex **2** features distorted square pyramidal Cu^{II} coordination geometry, centrosymmetric di-μ(1,1) azido bridged Cu_2N_2 rings and di-μ(1,3) azido bridges which link the binuclear Cu_2(4-picoline)$_2(N_3)_2$ moieties into chains along the short *a*-axis. The IR and electronic spectra of the solid complexes are presented and discussed.

Copper(II) ion forms coordination compounds of a rich variety of stereochemistries.[1,2] The array of structural types are further enriched in copper(II) azide–nitrogen base adducts, owing to the variable manner of azide ligand binding[3] giving rise to the terminal end-to-end bridging and end-on bridging modes illustrated elsewhere.[4] Thus, the copper(II) ion is in a tetragonally distorted octahedral environment in the polymeric complexes Cu(py)$_2(N_3)_2$[5] and Cu$(NH_3)_2(N_3)_2$,[6] but adopts a distorted trigonal bipyramidal coordination geometry in the dimeric complex [Cu(pymep)$(N_3)_2]_2 \cdot 2H_2O$ (pymep = (*N*-(2′-6-methyl)pyridyl)methylene-(2,2′-pyridyl)ethylamine), in which the water molecules form hydrogen bonds with the azide groups.[7] Recently, we isolated and characterized the structures of polymeric Cu(3-picoline)$(N_3)_2$,[8] Cu(3-picoline)$_2(N_3)_2$[9] and Cu(4-picoline)$_2(N_3)_2$[10] complexes. The 1:1 copper(II) azide complex of 3-picoline possesses distorted trigonal pyramidal coordination polyhedra about the copper(II) ion and contains only

* Author to whom correspondence should be addressed.

μ(1,1) bridging azido ligands, whereas the 1:2 complex displays two crystallographically independent six-coordinate copper octahedra and contains μ(1,1) and μ(1,3) bridging azido groups. The 4-picoline complex, on the other hand, features oligomeric edge-sharing chains of polyhedra. Further work led to the synthesis of a new 1:1 complex of copper(II) azide with 4-picoline (hereafter abbreviated as 4-pic) and another new complex with 3-picoline (3-pic) of the composition $[Cu_2(N_3)_2(NO_3)_2(3\text{-pic})_4(H_2O)]$. The structure elucidation of these two complexes by X-ray and spectroscopic methods is presented in this report.

EXPERIMENTAL

Preparation of $[Cu_2(N_3)_2(NO_3)_2(3\text{-pic})_4(H_2O)]$ (**1**)

Copper(II) nitrate trihydrate (0.46 g, 2 mmol) dissolved in 30 cm^3 ethanol and 3-pic (0.93 g, 10 mmol) were mixed together followed by the addition of NaN_3 (0.13 g, 2 mmol) in 3 cm^3 water. The green coloured mixture was allowed to stand in an open beaker over two or three days until near dryness, upon which large black crystals separated. Crystals are sensitive to daylight and X-ray exposure. Found: C, 39.6; H, 4.3; N, 23.1; Cu, 17.5. Calc.: C, 39.7; H, 4.2; N, 23.2; Cu, 17.5%.

Preparation of polymeric $Cu(4\text{-pic})(N_3)_2$ (**2**)

Copper(II) nitrate trihydrate (0.96 g, 4 mmol) dissolved in 40 cm^3 ethanol and 4-pic (0.56 g, 6 mmol) were mixed together, followed by addition of NaN_3 (0.65 g, 10 mmol) in 5 cm^3 water. The brown mixture was allowed to stand over several weeks until black needles separated. Found: C, 30.0; H, 2.8; N, 40.5; Cu, 26.5. Calc.: C, 29.9; H, 2.9; N, 40.7; Cu, 26.4%.

Procedures and instruments used for other measurements are as described previously.[11]

X-ray crystallography

A modified STOE four-circle diffractometer was used for single crystal X-ray measurements. Orientation matrix and lattice parameters were obtained by least-squares refinement of the diffraction data from 24 (compound **1**) and 35 (compound **2**) reflections in the 2θ range 8–21°. Data were collected at 300(1) K using graphite crystal-monochromatized Mo-K_α radiation (λ = 0.71069 Å) and the ω-scan technique. The intensities were corrected for Lorentz and polarization effects, and for absorption.[12] For compound **1** an intensity decay correction was also included in the data reduction procedure (the intensity of three standard reflections dropped to 64% during X-ray exposure). Crystallographic data are given in Table 1.

The structures were solved by Patterson superposition methods and subsequent Fourier analyses. Anisotropic displacement parameters were applied to the non-hydrogen atoms in full-matrix least-squares refinements. The hydrogen atoms were included in the final refinement cycles on calculated positions. In order to improve the data/parameter ratio for the data set of compound **1**, atoms of nitrato groups were assigned with isotropic U values, and blocked-matrix least-squares techniques applied for refinements. The programs DIFABS,[12] SHELX-76,[13] SHELXS-86,[14] PLATON[15] and THE XRAY SYSTEM[16] were used for computations. Analytical expressions of neutral-atom scattering factors were employed, and anomalous dispersion corrections were incorporated.[17] Selected bond distances and bond angles are given in Table 2. Positional parameters, anisotropic displacement parameters, hydrogen atom coordinates, a full list of bond lengths and angles and observed and calculated structure factors have been deposited with the Editor as supplementary material.

DISCUSSION

Figures 1 and 2 illustrate the principal structural features of $[Cu_2(N_3)_2(NO_3)_2(3\text{-pic})_4(H_2O)]$ (**1**). The structure consists of asymmetric dimers. Both copper(II) atoms in each dimer, however, have distorted elongated octahedral environments. Cu(1) is coordinated to N(1) and N(2) of two picoline

molecules at Cu—N bond lengths of 1.986(10) and 1.980(10) Å, and two nitrogen atoms N(11) and N(21) of two μ(1,1) bridging azido ligands [Cu—N distances are 1.986(9) and 1.998(9) Å]. This copper atom further links two oxygen atoms of the two nitrato groups. The Cu(2) atom, on the other hand, is bonded to N(3) and N(4) of further 3-pic molecules with Cu—N bond lengths of 1.988(9) and 2.007(9) Å, and N(11) and N(21) of the two μ(1,1) bridging azido groups at Cu—N distances of 1.994(9) and 2.012(10) Å. The coordination number six of Cu(2) is completed through its binding to the aqua molecule [Cu(2)—O(7) = 2.338(8) Å] and the O(1) of a nitrato group with a long Cu(2)—O(1) bond length of 2.670(8) Å. The two nitrato groups, therefore, behave differently in this complex; one of them acts as a monodentate ligand bonded to Cu(1) and the other functions as a bridging bidentate group. The Cu—O distances with the $\mu(O,O)$ bridging nitrato ligand are much longer than the Cu—O distance with the monodentate nitrato group (Table 2).

Symmetry code: (a) $x-1, y, z$; (b) $x+1, y, z$; (c) $-x, -y, -z$.

The Cu—N(3-pic) distances are very close to, whereas the Cu—N(N_3) distances in the Cu_2N_2 cyclic unit are shorter than, the corresponding values found in the structure of Cu(3-pic)$_2$(N_3)$_2$.[9] The latter Cu—N distances, however, fall in the range reported for similar bond distances in structures containing cyclic Cu_2N_2 units, e.g. Cu(4-methylquinoline)(N_3)$_2$ [1.972(6) and 1.974(5) Å],[18] Cu(2-picoline)(N_3)$_2$ [2.020(2) and 2.002(2) Å][18] and Cu(diethylnicotinamide)(N_3)$_2$ [2.006(2) Å].[19] The two azide ligands are almost linear [angle N(11)—N(12)—N(13) = 178.4(13)° and N(21)—N(22)—N(23) = 175.9(13)°] and asymmetric [N(11)—N(12) = 1.21(1) Å, N(12)—N(13) = 1.17(2) Å, and N(21)—N(22) = 1.22(1) Å, N(22)—N(23) = 1.17(2) Å]. These N—N distances correspond very well with the values reported for μ(1,1) bridging azido ligands in similar copper(II) azido complexes.[8,10,19]

A linear polymeric copper(II) complex, [Cu_2(N_3)$_2$(NO_3)$_2$(BET)$_2$]$_n$ (BET = $(CH_3)_3NCH_2CO_2$) was recently reported by Mak and co-workers.[20] Two different copper atoms, both featuring elongated octahedral environments, are simultaneously bridged by a μ(1,1) azido group, a μ(*O*,*O*) nitrato group, and a μ(*O*,*O*) carboxylato group of the betaine molecule. The apical sites of polyhedra are occupied by nitrato oxygen atoms [Cu—O from 2.419(4) to 2.446(3) Å]; the other Cu—N(O) bond lengths are in the range from 1.960(4) to 1.997(3) Å. The Cu···Cu separation of 3.436(1) Å is responsible for the unusually large Cu—N—Cu angle of 119.5(2)° of the symmetric bridging μ(1,1) azide group.

The principal structural features of the title complex (**2**) are illustrated in Fig. 3. The stereochemistry about each copper(II) atom is best described as distorted square pyramidal with basal bonds to N(11), N(21), N(1) and N(11c) in the range from 1.980(3) to 2.005(3) Å, and a longer apical bond of 2.457(3) Å to N(23). The 4-pic molecule coordinates the copper through N(1) with a Cu—N distance of 1.983(3) Å, which is very close to the corresponding Cu—N distances found in the structure of Cu(4-pic)$_2$(N_3)$_2$ [from 1.95(2) to 2.06(2) Å]. Centrosymmetric dimers are formed via μ(1,1) bridging azido groups N(11)—N(12)—N(13). The other azido group N(21)—N(22)—N(23b) functions as a μ(1,3) bridging ligand. As seen in Fig. 4, the structure contains chains of Cu_2N_2 units connected via two μ(1,3) azido groups along the short *a*-axis. The two independent azido groups are almost linear, and the N_α—N_β and N_β—N_γ bond lengths show a much smaller difference in the case of μ(1,3) bridging (Table 2).

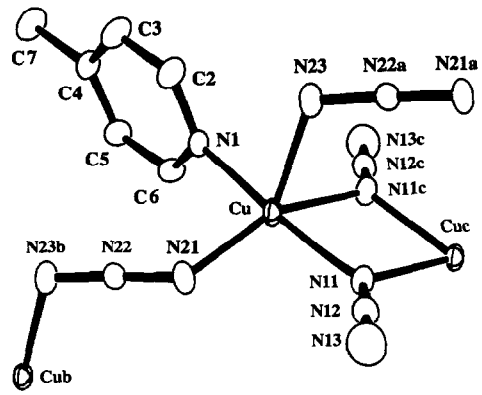

Fig. 3. Tetragonal pyramidal environment of the copper(II) centre and the atom numbering scheme of Cu(4-pic)(N_3)$_2$ (**2**) (symmetry code according to Table 2, b).

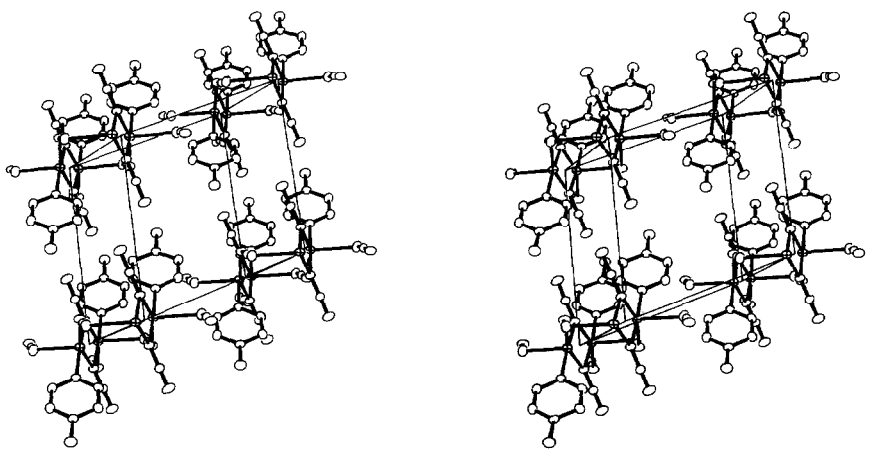

Fig. 4. Stereoplot of the structure of Cu(4-pic)(N_3)$_2$ viewed down approximately the *a*-axis of the unit cell.

The structure of the title complex **2** resembles that of di-μ(1,3)-azido-[di-μ(1,1)-azido-bis(2-picoline)dicopper(II)][18] (**3**), but also differs from it in several subtle aspects. Although complex **3** also exhibits distorted tetragonal pyramidal coordination about each copper atom, the Cu_2N_2 units are connected by μ(1,3) azido ligands to form layers of polyhedra, and the apical Cu—N distance is much shorter [2.273(2) Å] than the corresponding distance of 2.457(3) Å in **2**. The Cu(4-pic)$(N_3)_2$ complex also differs from the corresponding Zn(4-pic)$(N_3)_2$, although the zinc atom has a five-coordinate environment. In the latter complex, both azido groups function in the μ(1,1) fashion.[21]

Compared with other 1:1 complexes of copper(II) azide with substituted pyridine ligands, the structure of **2** differs from that of Cu(3-pic)$(N_3)_2$ (**4**), in which the coordination polyhedron of the copper atom is distorted trigonal bipyramid.[8] The structure of **4** contains three distinct μ(1,1) bridging azido groups; two azides bridge a pair of copper atoms forming a planar Cu_2N_2 ring and the third group asymmetrically links alternate copper atoms to yield an infinite zig-zag chain. The title complex **2** also differs from that of the polymeric 1:1 copper(II) azide complex of *N,N*-diethylnicotinamide.[19] In the latter complex, the coordination about each copper atom is an elongated octahedron with four short Cu—N bonds [from 1.979(5) to 2.006(5) Å] and two much longer axial Cu—N bonds [2.755(5) and 2.841(5) Å]. One of the two crystallographically independent azide groups acts as a μ(1,1) bridge, whereas the other is a μ(1,1,3) bridging group which interlinks the Cu_2N_2 units into a corrugated chain.

The interest in the IR spectra of these complexes lies mainly in the bands due to the nitrate groups and aqua molecule in complex **1**, in addition to those due to azido groups in both complexes. As seen from Table 3, the IR spectrum of complex **1** shows several bands due to the nitrato groups. The positions of these bands suggest that unidentate and bidentate types of coordinated nitrato groups are mixed in this complex, as has been found for other similar complexes.[22] The medium broad band with two peaks around 3400 and 3300 cm^{-1} indicates a hydrogen-bonded aqua molecule.[23,24] The IR spectrum of complex **1** also shows a very strong band at 2045 cm^{-1}, with a shoulder around 2060 cm^{-1} associated with the relation between the frequency of the asymmetric stretching vibration of azide groups and the difference between the two N—N distances (Δd).[25,26] The $\nu_s(N_3)$ is masked by the nitrate absorption. The IR spectrum of the solid complex **2** exhibits two well defined, very strong bands at 2070 and 2020 cm^{-1} due to the $\nu_{as}(N_3)$ modes of the N(11)—N(12)—N(13) and N(21)—N(22)—N(23b) groups, respectively. The appearance of the $\nu_s(N_3)$ mode as strong absorption bands in the region 1340–1280 cm^{-1} is strong evidence of the asymmetric nature of the azido ligands.

Table 3. IR spectral data

Frequency (cm^{-1})		
1	**2**	Assignments
2060 sh[a]	2070 vs	$\nu_{as}(N_3)$

The electronic spectrum (Fig. 5) of the solid complex **1** exhibits its *d–d* absorption band at 15,260 cm^{-1}, together with a distinct absorption band at 20,200 cm^{-1}. This result is consistent with distorted octahedral environments about the copper atoms.[27] For complex **2** the *d–d* band appears at 13,888 cm^{-1}, together with a distinct absorption band at 18,518 cm^{-1}. This *d–d* absorption band falls in the region frequently reported for five-coordinate

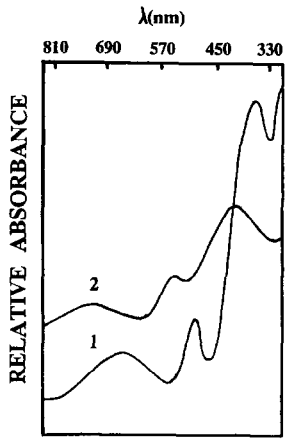

Fig. 5. Reflectance spectra of solid complexes. 1: [$Cu_2(N_3)_2(NO_3)_2$(3-pic)$_4(H_2O)$]; 2: Cu(4-pic)$(N_3)_2$.

copper(II) complexes.[1,2,28] The whole spectrum is very close to that reported for $Cu(3\text{-pic})(N_3)_2$, which features a distorted trigonal bipyramid.[8] The position of the *d–d* band, however, differs from those found for $[Cu(2\text{-ampy})(N_3)_2(H_2O)]_2$ (14,490 cm^{-1}),[29] Cu(Et-nicotinate)$(N_3)_2$ (12,048 cm^{-1}),[11] $[Cu(2\text{-Bzpy}(N_3)_2]_2$, (15,625 cm^{-1})[30] and $Cu(2\text{-pic})(N_3)_2$ (13,333 cm^{-1}),[18] all of which possess distorted pyramidal copper(II) atoms.

(*Received* 20 *April* 1993; *accepted* 15 *June* 1993)

Abstract—Three quinolinium (HC_9H_7N = Hquin) salts of planar inorganic dithiooxalato complexes: $(Hquin)_2[Ni(S_2C_2O_2)_2]$ (**1**), $(Hquin)_2[Pd(S_2C_2O_2)_2]$ (**2**) and $(Hquin)_2[Pt(S_2C_2O_2)_2]$ (**3**) were synthesized and characterized by elemental analysis, IR and UV–vis spectroscopies, thermal analysis (TG, DTG and DTA) and X-ray diffraction techniques. Spectroscopic data support the presence of the aromatic cation and the complex anion. The complexes show a high thermal stability and the thermal studies give evidence that the onset temperatures of their thermal decompositions, the corresponding reaction mechanism and the final solid products are strongly influencd by the atmospheric conditions, as well as the chemical and structural features of the starting compounds. X-ray diffraction analyses show that **2** and **3** are isomorphous with **1**, which crystallizes in the monoclinic space group $P2_1/n$ with $Z = 2$ so that the anion straddles a crystallographic centre of symmetry. The crystal structure of **1** is built up by layers of quasi-planar $[Ni(S_2C_2O_2)_2]^{2-}$ complexes (A) and quinolinium cations (C) stacked along the *c*-axis, following an $\cdots$ACCACC$\cdots$ sequence, with alternative interplanar spacings of 3.3–3.8 Å (A$\cdots$C) and 3.44 Å (C$\cdots$C), which suggest the existence of significant π–π and d_{z^2}–π interactions between the cations and the complexes' anions. These interactions, together with the electrostatic forces and an extensive network of hydrogen contacts, ensure the lattice cohesion and give the compound a three-dimensional character.

Recently, much attention has been devoted to the coordination chemistry of metal complexes involving sulphur donor ligands, due to the applications of these compounds in analytical chemistry, catalysis and their relevance to bioinorganic systems.[1] One of these sulphur donor ligands is the dithiooxalate dianion, in which the presence of four donor atoms and the possibilities of charge delocalization on its atoms results in a multifunctional ligand with unique coordination properties.[2–4]

On the other hand, oxidative thermal decompositions of various nickel, palladium and platinum complexes are used for the production of metal and metal oxides which are extensively applied as catalysts in a variety of important chemical processes.[5]

In this context we have studied the reaction between aromatic cations and several square-planar inorganic metal(II) 1,2-dithiooxalato-*S,S′* anions in order to obtain a deeper insight into the cation and metal effects on the crystal packing and the strength of the intramolecular interactions in this type of compound.[6–9] The present paper reports the syntheses, the chemical characterization and the thermal behaviour of quinolinium salts of 1,2-dithiooxalate-*S,S′* metalate anions, $[M(S_2C_2O_2)_2]^{2-}$, where M is Ni^{II}, Pd^{II} or Pt^{II}, as well as the crystal and

molecular structure of the compound quinolinium bis(1,2-dithiooxalato-*S*,*S*′)nickelate(II).

EXPERIMENTAL

General and instrumental

The dithiooxalate ligand was used as purchased from Eastman Kodak. The potassium salts of the complex anions, $[M(S_2C_2O_2)_2]^{2-}$, were prepared according to the literature method.[10] Elemental analyses of carbon, hydrogen and nitrogen were performed on a Perkin–Elmer 240 analyser. Metal analyses were made on a Perkin–Elmer 360 Atomic Absorption/Flame Emission spectrometer. IR and UV–vis spectra were run on IR Beckman 4240 and Bausch-Lomb Spectronic 2000 spectrophotometers, respectively. Density values were measured by flotation in a mixture of CCl_4–$CHBr_3$. The thermoanalytical data (TG, DTG and DTA) were obtained, simultaneously, in argon and argon–oxygen atmospheres on a Setaram Tag 24 S16 thermobalance, with a heating rate of 5°C min^{-1}. X-ray powder diffraction patterns of **2**, **3** and the final products from thermal decompositions of compounds **1–3** were obtained on a Philips PW 1710 instrument with nickel-filtered Cu-K_α radiation. Diffraction patterns of thermal decomposition residues were compared with those obtained from the ASTM powder diffraction files of the Joint Committee on Powder Diffraction Standards (JCPDS).[11]

Synthesis of complexes

Quinolinium bis(1,2-dithiooxalato-S,S′)nickelate(II) $(HC_9H_7N)_2[Ni(S_2C_2O_2)_2]$ (**1**). An aqueous solution (25 cm^3) of quinolinium hydrochloride (0.60 g, 3.62 mmol) was added to 25 cm^3 of an aqueous solution of $K_2[Ni(S_2C_2O_2)_2]$ (0.55 g, 1.46 mmol) with stirring at room temperature. Immediately, an insoluble microcrystalline powder of **1** was obtained. Dark purple single crystals suitable for X-ray investigations were obtained by recrystallization from an H_2O–DMF (1 : 1, v/v) mixture, after 3 weeks. Yield: 0.62 g, 1.11 mmol, 76% based on nickel. Found: C, 47.3; H, 2.8; N, 5.0; Ni, 10.4. Calc. for $C_{22}H_{16}N_2NiO_4S_4$: C, 47.2; H, 2.9; N, 5.0; Ni. 10.5%. Selected IR data (KBr, cm^{-1}): 1600vs, 1545vs, 1425s [ν(C═O)]; 1075vs, [ν(C—C)+ν(C—S)]; 965s, 925s [δ(C—O)+ν_{as}(C—S)]; 575w, 443w [ν_s(C—S)]; 400m [ν_{as}(Ni—S)]; 352w [ν_s(Ni—S)].

Quinolinium bis(1,2-dithiooxalato-S,S′)palladate(II) $(HC_9H_7N)_2[Pd(S_2C_2O_2)_2]$ (**2**). This compound was synthesized from $K_2[Pd(S_2C_2O_2)_2]$ (0.50 g, 1.18 mmol) and quinolinium hydrochloride (0.45 g, 2.72 mmol) in water (50 cm^3) following the general method described for **1**. The resultant yellow precipitate was isolated by vacuum filtration, washed with EtOH and Me_2O and recrystallized from DMF. Unfortunately, yellow dark crystals were twinned and were not suitable for X-ray single crystal diffraction. Yield: 0.57 g, 0.93 mmol, 79.1% based on palladium. Found: C, 43.4; H, 2.6; N, 4.5; Pd, 17.6. Calc. for $C_{22}H_{16}N_2O_4PdS_4$: C, 43.5; H, 2.7; N, 4.6; Pd, 17.5%. Selected IR data (KBr, cm^{-1}): 1595vs, 1575vs, 1440w [ν(C═O)]; 1080vs [ν(C—C)+ν(C—S)]; 935m [δ(C—O)+ν_{as}(C—S)]; 570m [ν_s(C—S)]; 415w [ν_s(Pd—S)]; 340m [ν_{as}(Pd—S)].

Quinolinium bis(1,2-dithiooxalato-S,S′)platinate(II) $(HC_9H_7N)_2[Pt(S_2C_2O_2)_2]$ (**3**). Red crystals of this compound were prepared from $K_2[Pt(S_2C_2O_2)_2]$ (0.13 g, 0.25 mmol) and quinolinium hydrochloride (0.10 g, 0.60 mmol) in water (15 cm^3) by a similar procedure to above. Yield: 0.23 g, 0.37 mmol, 63% based on platinum. Found: C, 38.1; H, 2.4; N, 3.9; Pt, 27.9. Calc. for $C_{22}H_{16}N_2O_4PtS_4$: C, 38.0; H, 2.3; N, 4.0; Pt, 28.0%. Selected IR data (KBr, cm^{-1}): 1585vs [ν(C═O)]; 1085vs [ν(C—C)+ν(C—S)]; 950s [δ(C—O)+ν_{as}(C—S)]; 630w [ν_s(C—S)]; 465w [ν_{as}(Pt—S)]; 405w [ν_s(Pt—S)].

Crystallographic data collection and structural refinement of **1**

A dark purple prismatic single crystal of **1** (0.25 × 0.30 × 0.15 mm) was mounted on an Enraf–Nonius CAD4 four-circle diffractometer. Cell parameters and an orientation matrix for data collection, obtained from a least-squares analysis of the setting angles of 25 carefully centred reflections in the range 8–15°, correspond to the monoclinic space group $P2_1/n$. X-ray data were collected at 295 K using graphite-monochromated Cu-K_α radiation (λ = 1.54178 Å) and the ω–2θ scan technique. A total of 2160 independent reflections were measured in the range $2 \leqslant \theta \leqslant 72°$ ($0 \leqslant h \leqslant 14$; $0 \leqslant k \leqslant 10$; $-14 \leqslant l \leqslant 14$), 1865 of which, with $I > 3\sigma(I)$, were used in the development and refinement of the structure. The intensity data were corrected for Lorentz and polarization effects. An empirical absorption correction (μ = 49.885 cm^{-1}) following the procedure DIFABS[12] with minimum and maximum correction coefficients 0.765–1.231 was applied. The atomic scattering factors for neutral atoms and anomalous dispersion corrections for non-hydrogen atoms were taken from the *International Tables for X-ray Crystallography*.[13] The structure was solved by combination of Patterson and difference

Fourier methods and refined by full-matrix least-squares. Anisotropic thermal parameters were used for non-hydrogen atoms. A convenient weighting scheme[14] was used to obtain flat dependence in $\langle w\Delta^2F\rangle$ vs $\langle F_0\rangle$ and $\langle \sin\theta/\lambda\rangle$. All aromatic hydrogen atoms were clearly visible in a difference-Fourier synthesis and were refined isotropically. Last cycles of refinement lead to the discrepancy indices $R = 0.040$ and $R_w = 0.040$ for 183 parameters; goodness of fit = 0.99; maximum shift/error in the final cycle = 0.15 and the highest peak in the final Fourier difference map was 0.85 e Å^{-3}. Most calculations were carried out using the X-RAY76 System[15] running on a Micro VAX II computer. Final atomic positional and thermal parameters, together with observed and calculated structure factors, have been deposited as supplementary material with the Editor, from whom copies are available on request. Atomic coordinates have also been submitted to the Cambridge Crystallographic Data Centre.

Compounds **2** and **3** crystallized in insufficient quality to be studied by X-ray single crystal diffraction, but their cell parameters have been obtained by X-ray powder diffraction data. Table 1 summarizes the crystal data for the three compounds and shows that all of them are isostructural.

RESULTS AND DISCUSSION

Spectroscopic characterization

IR spectra of the three complexes certify the presence of the quinolinium cations, as shown by the corresponding bands at about 3000 cm^{-1} for the C—H groups, and the characteristic and very strong bands of quinolinium cations between 1650 and 600 cm^{-1}. IR assignments of the bis(dithiooxalato)metalate(II) anions have been made in the 1600–350 cm^{-1} region and a comparison of the results with the observed spectra of the reported compounds[6,7,16] leads to the assignments described in the Experimental section.

Table 2 lists the maximum peaks of the UV–vis spectra, as well as their assignments according to the literature.[2,17,18] The spectra of the three complexes show absorptions at *ca* 312, 299 and 223 nm, attributable to the $\pi \rightarrow \pi^*$ and $n \rightarrow \pi^*$ transitions of the quinolinium cations,[17] which are not affected by the complex anion. The rest of the spectral bands correspond to electronic transitions into the complex anions, with discrepancies due to the existence of different M—S bonds. For the $[Pd(S_2C_2O_2)]^{2-}$, the $M \rightarrow L(\pi^*)$ and $d_{xy} \rightarrow d_{x^2-y^2}$ bands are probably covered by the very intense $L \rightarrow M$ band at 276.7 nm.

Thermal analysis

Very little has been published to date about the thermal decomposition of thioxalate complexes in general and 1,2-dithiooxalate complexes in particular.[8,9] The purpose of this study is to reveal the influence of the surrounding atmosphere and metal nature on the thermal decomposition, as well as to obtain different final products that may develop novel catalytic properties. Table 3 lists the steps, initial and final temperatures (°C), partial and total weight losses, enthalpy (endothermic or exothermic) and maximum peak for each step in the thermal decompositions of the three compounds in argon–oxygen and argon atmospheres.

The TG–DTA curves for the compounds in the oxidative and inert atmospheres are shown in Figs 1 and 2. Thermogravimetric curves indicate that the decompositions are not simple, and stable intermediate products are not found during the thermal processes since most of the stages were not resolved. Attempts to correlate the results with theoretical mass losses were not successful, except for the final solid products, which were identified by X-ray powder diffraction methods.

The thermal decompositions of the compounds are quite different in oxidative and inert atmospheres and the final residues depend on the starting compound. In an argon–oxygen atmosphere, the nickel complex is stable up to approximately 200°C, beyond which two abrupt weight losses take place corresponding to two exothermic peaks in the DTA curve, attributable to the pyrolysis of organic cations and the breakdown of the dithiooxalate ligands. The chemical analysis of the solid stable final residue, obtained above 270°C, gives no indication of carbon, nitrogen or hydrogen present in its composition and it was mainly identified as NiS by comparing its X-ray powder diffraction pattern with the Powder Diffraction File No 2-1280; however, its X-ray powder diffractogram also shows the presence of some diffraction maxima which could be identified according to different nickel oxides and sulphides (NiO, Ni_2O_3 and Ni_2S_3) presented in the JCPDS. In the inert atmosphere, **1** undergoes decomposition in a single step between 205 and 260°C, and the final black residue, whose elemental analyses did not reveal the presence of carbon, was identified as nickel(II) sulphide. In the oxidative atmosphere, **2** undergoes decomposition in one endothermic process followed by two exothermic ones. The final product obtained above 330°C was mainly identified as a mixture of palladium(0), palladium(II) oxide and palladium(II) sulphide. The elemental analysis of the final residue from the thermal decomposition of **2** in an inert atmosphere above 550°C gave no indication of carbon, nitrogen or hydrogen present in its composition, and it was

identified by its X-ray power diffraction pattern as palladium(II) sulphide. The thermal decomposition of the platinum complex in both atmospheres yielded platinum(0) as the final product.

X-ray structure determination

The asymmetric unit of **1** consists of one quinolinium cation and one-half of a complex anion, $[Ni(S_2C_2O_2)_2]^{2-}$, with the nickel atom lying on a centre of symmetry. Figure 3 shows the structures of the complex dianion and the cation with the atomic numbering scheme. Selected bond lengths, bond angles and the hydrogen contacts are listed in Table 4. The complex dianion is almost planar and the dihedral angle between the strictly planar NiS_4 group and the $S_2C_2O_2$ ligand mean plane [1.66(4)°] is in the lower end of the range previously observed for similar bis(dithiooxalato)metalate(II) anions in compounds also containing aromatic cations (1–9°)[6–9] and is considerably lower than those observed in analogous complexes containing large and bulky cations (7–20°).[19] The value of this angle is affected by a combination of factors, including the hydrogen contacts between the oxygen atoms and the hydrogen atoms of cations, as well as the π–π interactions between the aromatic cations and the dithiooxalate groups. Both of them may produce a displacement of the ligand atoms and a higher value of the dihedral angle between the MS_4 and the dithioxalate groups. Bond distances and angles within the dithioxalate group are comparable with those reported in the literature[2] and are consistent with the existence of a significant degree of delocalization throughout the S—C—O units in the dianion, with a single C—C bond of 1.549(5) Å. As far as the

quinolinium cation is concerned, the two almost planar rings are tilted relative to one another by 1.5(1)° and show no abnormal geometry.[20]

The laminar structure of compound **1** is built up by mixed stacks of complex anions (A) and organic cations (C) developing along the *c*-axis, according to the scheme ··· ACCACC ··· (Fig. 4). The best A and C planes form a dihedral angle of 14.59(6)° and the mean plane of the anion is tilted by *ca* 24° with respect to the *ab* plane.

Of particular interest is the positioning of the anion which lies sandwiched between two quinolinium cations which are related by the centrosymmetric centre (Fig. 5a). The N-containing ring of the quinolinium lies up and down the NiS_4 plane (Ni ··· ring, 3.62 Å) and makes an angle of 76.4° with the nickel d_{z^2} orbital. A similar disposition is observed in metalloporphyrins, in which the metal atom lies above the centre of the porphyrin ring.[21] The second ring of the quinolinium cation is disposed above and below the dithiooxalate ligands, where a significant degree of electronic delocalization is present, with an interplanar space of 3.3–3.8 Å and a dihedral angle of 15.4°.

[b] Interplanar distances (Å) between strictly parallel ions. A = anion, C = cation.

[c] Distance (Å) of metallic cation (M) to aromatic ring and angle (°) between the d_{z^2} orbital and the planar aromatic ring (C).

[d] Interplanar distances (Å) between organic cation (C) and dithiooxalate ligand (L).

The shortest contact, between C(1) and C(19), is 3.26 Å. The above described arrangement suggests the existence of significant interactions between the π systems of the aromatic cations, the metal d_{z^2} orbital and the partially delocalized structure of the dithiooxalate ligand. On the other hand, the two neighbouring cations in the same column, related by an inversion centre, show the usual *trans* conformation, with a lateral offset of 1 Å and an interstack distance of 3.44 Å (Fig. 5b). These values are comparable to those found in aromatic π systems (3.2–3.6 Å) with strong π–π interactions.[22]

Similar interactions have also been found in analogous dithiooxalate complexes containing aromatic cations, but they are affected by the nature and size of the cation. Table 5 shows different types of interaction in organoammonium dithiooxalate complexes. The π–π interactions between the π systems of the aromatic cations and the dithiooxalate ligands are the most usual ones and they are found in all the complexes except the 4-aminopyridinium salts. Only for the polycyclic cations and the 4-aminopyridinium cation does the arrangement suggest the existence of a significant interaction between their π systems and the metal d_{z^2} orbital.

In the crystal structure of **1**, there is an extended hydrogen bond network of the types N—H···O[26] and C—H···O[27] (Table 4). The ions situated in the same x level are linked by means of two hydrogen contacts between the hydrogen atoms of C(12) and C(13) of the quinolinium cation and two oxygen atoms of the same dithiooxalate ligand. The sheets placed in different x levels are connected by two hydrogen contacts involving the N(11) and C(19) atoms of the cation and the O(1) atom of the complex anion.

Abstract—In the *closo*-boranes, the B—B bond distances vary widely, from 1.580 to 1.990 Å. These large variations are consistent with the notion of highly delocalized skeletal bonding in electron-deficient polyhedral clusters. In this paper, we show correlations between B—B bond distances and four different calculated bond order indices: (1) Wade's fractional bond orders; (2) Coulson's bond orders from three-dimensional Hückel MO theory; (3) Mulliken bond populations from extended Hückel MO theory; and (4) Mulliken bond populations from *ab initio* SCF MO calculations.

The *closo*-boranes, $B_nH_n^{2-}$, n = 5–12, have structures in which the boron atoms occupy the vertices of closed polyhedra with triangular faces and the hydrogens are attached, one per boron polyhedral vertex, in *exo*-positions projecting outward from each vertex.[1–8] Figure 1 displays these deltahedra and defines the numbering system for the polyhedron vertices. The $n = 5$ member of the series has not yet been prepared. It is included here because the isoelectronic and presumably isostructural carborane $C_2B_3H_5$ is known. Its structure is the trigonal bipyramid assumed for $B_5H_5^{2-}$ in Fig. 1.

The 25 different B—B bond distances in the *closo*-borane series exhibit a remarkable range, from 1.580 Å, one of four different distances in $B_8H_8^{2-}$, to 1.990 Å, one of nine distinct distances in $B_{11}H_{11}^{2-}$. Such variability is consistent with the notion of delocalized bonding in the *closo*-boranes. The numbers of edges connecting borons in the polyhedra far exceed the numbers of electron pairs available to form the bonds that must hold together the polyhedral structures. Consider the following arguments. In $B_nH_n^{2-}$ there are $3n+n+2 = 4n+2$ valence electrons. Of these, $2n$ electrons must be involved in the n normal, two-electron two-centre B—H bonds. Thus, $2n+2$ electrons or $n+1$ pairs remain for forming polyhedral skeletal bonds. However, each polyhedron contains $3n-6$ edges or bonds and for $n \geqslant 4$, for which these fomulae apply, the ratio

$$\frac{\text{number of skeleton electrons}}{\text{number of skeletal bonds}} = \frac{2n+2}{3n-6}$$

is always less than 2.0 and it declines with increasing n. Therefore, the *closo*-boranes are said to be electron deficient. Bonding has been discussed as combinations of two-centre and three-centre electron pair bonds, but a much more satisfactory description is based on molecular orbital (MO) theory, which assumes completely delocalized bonding across the surface of the polyhedron.[9,10]

In this paper, we attempt to correlate polyhedral B—B distances with several different calculated bond indices: (1) Wade's fractional bond orders; (2) Coulson bond orders calculated from three-dimensional Hückel theory; (3) Mulliken bond populations from extended Hückel theory; and (4)

Mulliken bond populations obtained from *ab initio* wavefunctions.

In connection with other work, we performed geometry optimized *ab initio* SCF MO calculations at the STO-3G level for the eight *closo*-boranes.[11] Table 1 compares B—B bond distances as obtained from our *ab initio* calculations[11] and from experiments.[2-8] Although the STO-3G basis set is minimal, the agreement between calculated and experimental distances is excellent, generally closer than 0.03 Å and in only two instances as large as 0.06 Å. Indeed, these differences appear to be no worse than those among different experimental determinations of the same distances where such comparisons are available. Furthermore, for each n, the order of bond distances, from shortest to longest, is the same for *ab initio* calculated distances as for experimentally determined distances. Because the *ab initio* distances form a complete set, including values for $n = 5$ and $n = 7$ for which no experimental results are available, we use the *ab initio* distances for comparison with various bond order indices described in this paper.

WADE'S FRACTIONAL BOND ORDER

Wade proposed a fractional bond order to account for variations in bond distances in the *closo*-boranes.[10] Suppose the $n+1$ skeletal electron pairs are evenly distributed over the n vertices of the polyhedron to give each atom $(n+1)/n$ electron pairs with which to form bonds. Further, suppose atom r shares its $(n+1)/n$ electron pairs with x_r neighbour atoms, where x_r is the degree of vertex r or the polyhedral coordination number of atom r. Atom r shares $(n+1)/nx_r$ electron pairs with each neighbour. Two adjacent vertices r and s share f_{rs} pairs of electrons, where

$$f_{rs} = \frac{(n+1)}{nx_r} + \frac{(n+1)}{nx_s} = \frac{(n+1)}{n}\left(\frac{x_r+x_s}{x_rx_s}\right).$$

A value of $f_{rs} = 1.0$ would mean one electron pair per bond or a normal single covalent bond linking atoms r and s. For the electron-deficient *closo*-boranes, f_{rs} turns out to be much less than 1.0. Thus, f_{rs} is the fractional bond order between atoms r and s. For example, in the trigonal bipyramid, $n = 5$,

[h] Bond distance deviations from standard 1.70 Å for $B_nH_n^{2-}$: $n = 8$, 1,3 = 1.7008, 3,5 = 1.7037; $n = 11$, 1,4 = 1.99, 2,4 = 1.7002, 4,8 = 1.6998, 8,10 = 1.703.

[i] Bond distance deviations from standard 1.54 Å for C_n^{2-}: $n = 8$, 1,3 = 1.5410, 3,5 = 1.5410; $n = 11$, 1,4 = 1.80, 2,4 = 1.5401, 4,8 = 1.5395, 8,10 = 1.5414.

and for atoms in the axial positions $x_a = 3$ and for the equatorial atoms $x_e = 4$. For axial–equatorial bonds,

$$f_{ae} = \left(\frac{5+1}{5}\right)\left(\frac{3+4}{3\times 4}\right) = 0.700,$$

and for equatorial–equatorial bonds,

$$f_{ee} = \left(\frac{5+1}{5}\right)\left(\frac{4+4}{4\times 4}\right) = 0.600.$$

These results look promising because axial–equatorial bonds in $B_5H_5^{2-}$ are shorter (1.607 Å) than the equatorial–equatorial bonds (1.820 Å). Fractional bond orders appropriately account for the trend.

Wade's fractional bond orders have their limitations. The assumption that the $n+1$ skeletal electron pairs are spread evenly over n vertices is generally not true. For example, in trigonal bipyramidal $B_5H_5^{2-}$ topology directs more electron density to the axial positions than to the equatorial sites. Only in the highly symmetric octahedral ($n = 6$) and icosahedral ($n = 12$) cases can the distribution of charge be uniform. Furthermore, working up fractional bond orders for the less symmetric polyhedra, one encounters instances in which distinctly non-equivalent bonds have the same x_r, x_s combinations and therefore the same fractional bond order. For $n = 11$, there are five different kinds of bonds between pairs of five-coordinate atoms, giving them all the same fractional bond

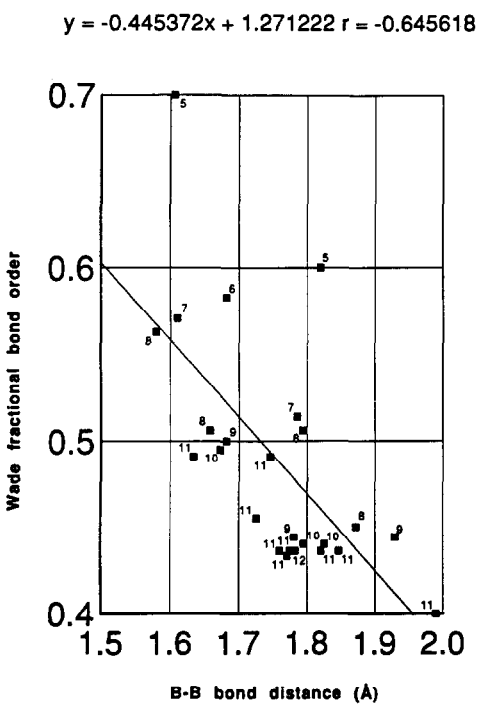

Fig. 2. Wade's functional bond order for $B_nH_n^{2-}$ polyhedra correlated with B—B bond distances. The number that accompanies each point indicates the size n of the polyhedron involved. One of the limitations of the Wade index is that in several instances it cannot distinguish among different bonds in the same polyhedron. For example, in the $n = 11$ polyhedron, there are five different bonds with the same fractional bond order.

order, $f_{rs} = 0.436$. These bonds range in length from 1.760 to 1.847 Å (experimental distances range from 1.77 to 1.85 Å). Wade's fractional bond orders for the *closo*-boranes are reproduced in Table 1. Figure 2 is an attempt to correlate fractional bond orders with corresponding bond distances. This figure includes a more extensive set of data than an earlier diagram prepared by Burdett.[12]

The f_{rs} function gives a qualitative rationale to bond distance trends. In f_{rs}, the factor $(n+1)/n$ decreases only slightly from $n = 5$ (1.200) to $n = 12$ (1.083). Larger changes occur in the factor $(x_r+x_s)/x_rx_s$, which is smaller for bonds that end at atoms with larger coordination numbers. Thus, in $B_5H_5^{2-}$ the axial–equatorial bonds (3,4-coordination) are shorter than the equatorial–equatorial bonds (4,4-coordination), while the reverse is true for the pentagonal bipyramidal $B_7H_7^{2-}$ (4,5 vs 4,4). For $B_{11}H_{11}^{2-}$, the model predicts the bonds with 5,6-coordination to have the smallest bond orders and therefore the longest bond distance in the whole series and this is born out in the bond distances. However, on the whole, fractional bond order–bond length correlations are not acceptable, as one can see from Fig. 2.

SIMPLE HÜCKEL THEORY

A model of the electronic structures for the *closo*-boranes was proposed by Wade,[10] with significant modifications by King and Rouvray.[13] According to this model, each of the boron atoms in the polyhedron contributes four valence atomic orbitals (AOs), one s and three p AOs, to the basis set for a total of $4n$ AOs. Imagine one of the p AOs at each vertex oriented along an axis such that it points toward the centre of the polyhedron. This is the radial AO. The other two p AOs are perpendicular to the radial axis and tangential to the surface of the polyhedron. These are the tangential AOs. The s AO and the radial p AO can be combined to form two sp hybrids, an internal hybrid pointing to the centre of the polyhedron and an external hybrid that points away from the polyhedral surface and towards the *exo*-hydrogen. The external hybrid is involved in normal localized two-centre, two-electron bonding between boron and hydrogen and its effect on polyhedral skeletal bonding can be neglected. The internal hybrid and the tangential AOs form a set of $3n$ AOs from which MOs can be constructed. These MOs then receive the $n+1$ delocalized skeletal electron pairs.

We have recently developed an MO method that combines the $3n$ tangential and internal orbitals according to the usual simple Hückel assumptions plus a few additional approximations that are completely within the spirit of simple Hückel theory.[14] This three-dimensional Hückel theory was developed specifically for applications to polyhedral cluster molecules. The additional assumptions involve the establishment of an internal coordinate system and the calculation of interactions between non-parallel internal and tangential AOs of adjacent vertices. Details and vital comparisons appear elsewhere.[14] The input for simple Hückel calculations consists of the number of delocalized electrons, the number of polyhedral vertices and an adjacency matrix that specifies neighbour–neighbour interactions between pairs of AOs.

In simple Hückel theory, the Coulson bond order p_{rs} between atoms r and s is defined as[15,16]

$$p_{rs} = \sum_i 2c_{ir}c_{is},$$

where c_{ir} and c_{is} are coefficients of AOs X_r and X_s in the MO $\phi_i = \Sigma_r c_{ir}X_r$ obtained from simple Hückel calculations and the summation is over all of the occupied MOs ϕ_i. Applications to many examples of planar conjugated hydrocarbons show that correlations of bond orders with bond lengths,

although far from perfect, are often useful and suggestive. Further correlations of this type have been made with comparable success for planar inorganic molecules that contain B—O and S—N bonds.[17,18]

Two-dimensional Hückel theory assumes only one AO per vertex and one pair of interacting AOs on bonded atoms. Three-dimensional Hückel theory involves three AOs per vertex and each of these can interact with AOs on neighbouring vertices in several different ways. Sums of contributions from each interacting AO pair produce total bond orders that are rather large. Typical values run from 1.5 to 2.0. Coulson bond orders for skeletal bonds for the polyhedral *closo*-boranes as obtained from three-dimensional Hückel theory appear in Table 1. Figure 3 shows how these values correlate with B—B bond distances.

EXTENDED HÜCKEL THEORY

The extended Hückel method is well known.[19] The *closo* boranes were among the first classes of molecules to be treated by this method.[20] In practice each boron or other main-group atom in the molecule contributes one s and three p AOs to the basis set. Hydrogen atoms are explicitly included and each hydrogen contributes its 1s AO. The coulomb integral for each AO is approximated by an empirical value of the valence state ionization energy for the orbital. Resonance integrals are taken as averages of the coloumb integrals of the two interacting AOs multiplied by computed AO overlap and perhaps another calibration parameter. Overlaps are distance-dependent quantities and bond distances enter the calculation as Cartesian spatial coordinates for each atom.

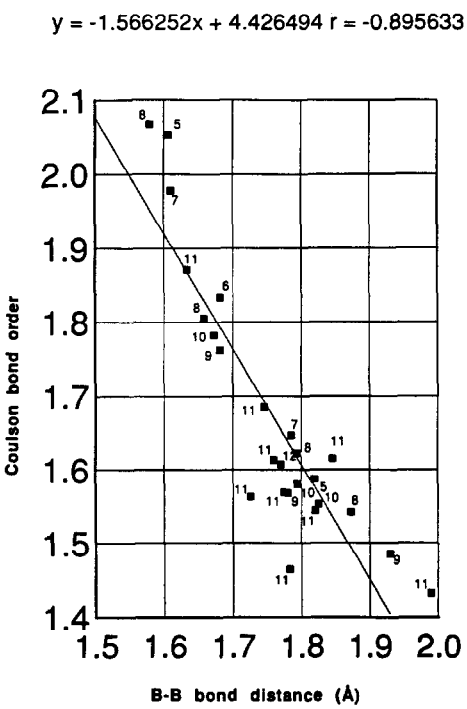

Fig. 3. Coulson's bond orders, obtained from three-dimensional Hückel MO calculations for the *closo*-boranes, correlated with B—B bond distances. The three-dimensional Hückel model includes no information other than atom connectivity or topology and electron count.

Mulliken described the overlap population[21,22] between a pair of AOs X_{rk} and X_{sl} on atoms r and s due to an electron in the MO ϕ_i as

$$p^i_{rksl} = 2c_{rki}c_{sli}S_{rksl},$$

where $S_{rksl} = \langle X_{rk}|X_{sl}\rangle$ is the overlap integral between the two AOs and c_{rki} and c_{sli} are the coefficients of the two AOs in ϕ_i. Summing over pairs of AOs on atoms r and s gives

$$p^i_{rs} = \sum_{k,l} p^i_{rksl}.$$

Summing over all MOs, each occupied by n_i electrons, gives the Mulliken overlap population between atoms r and s:

$$p_{rs} = \sum_i n_i p^i_{rs}.$$

Mulliken overlap populations are easily obtained from extended Hückel calculations.

Table 1 contains two sets of extended Hückel overlap populations, one for $B_nH_n^{2-}$ and another for the hypothetical isoelectronic and presumably isostructural C_n^{2-} polyhedra. We include the C_n^{2-} results to get a measure of the effect of neglecting the *exo*-hydrogens.

Since Mulliken overlap populations are proportional to AO overlaps, which in turn depend on interatomic distances, closer atoms might be expected to have larger bond orders than would atoms further removed from each other. Therefore, assigning different bond distances between atoms prejudices the outcomes of bond population calculations. To establish a uniform basis for calculations, we have assumed equal bond distances between all bonded atoms, even though the symmetry of most structures does not require all bond distances to be equal and experimental measurements and *ab initio* calculations demonstrate that those bonds are not of equal lengths. Indeed, for the eight- and 11-atom polyhedra, it is impossible to devise structures in which all bond distances are identical. For our extended Hückel calculations, we chose arbitrary but standard distances of 1.54 Å for C—C bonds and 1.70 Å for B—B bonds in all polyhedra. In the eight-atom cage, variations from

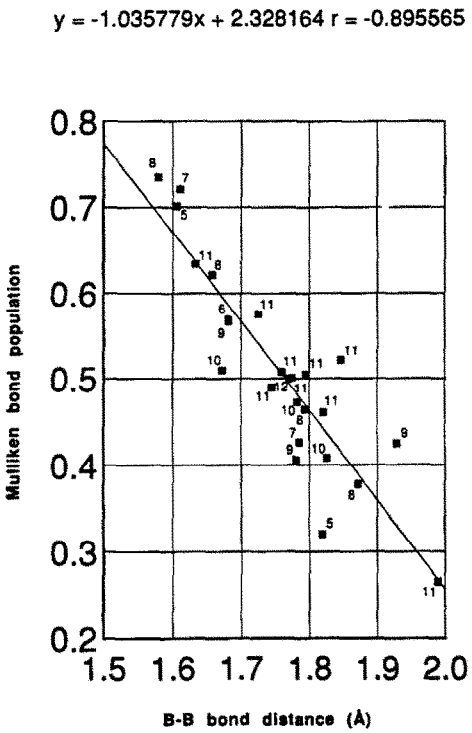

Fig. 4. Mulliken's bond populations from extended Hückel calculations for $B_nH_n^{2-}$ as functions of B—B bond distances.

the standard distances occur in the third or fourth decimal places. In the 11-atom polyhedron, deviations from standard distances are more serious. Since the 1,4-bond in the real $B_{11}H_{11}^{2-}$ turns out to be unusually long, indeed the longest of all B—B bonds in the *closo* borane series, we took long 1,4-distances in our calculations, allowing other distances to be within three or four decimal places of the standard values. Details are given in the footnotes to Table 1. Bond population–bond distance correlations appear in Figs 4 and 5.

AB INITIO BOND POPULATIONS

The STO-3G basis set *ab initio* SCF MO calculations that produced the table of geometry optimized B—B bond distances also gave comparable Mulliken bond populations.[11] These results appear in Table 1. Figure 6 plots *ab initio* bond populations against the optimized B—B distances.

DISCUSSION

How well do the various bond order indices agree with the reverse order of bond distances within each polyhedron of n vertices? Table 2 shows the irregu-

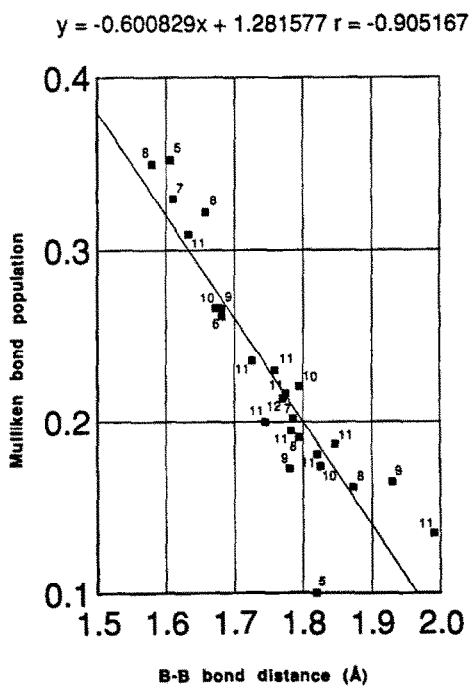

Fig. 6. Mulliken's bond populations from geometry optimized *ab initio* SCF MO calculations at the STO-3G level correlated with B—B bond distances determined by the same calculations.

Table 2. Irregularities in trends of decreasing bond orders with longer bond distances for polyhedra of given size, n

Wade's fractional bond orders		
$n = 8$	Distances:	1,2 < 1,5 < 1,3 < 3,5
	Bond orders:	1,2 > 1,5 = 1,3 > 3,5
$n = 9$	Distances:	1,4 < 1,7 < 1,2
	Bond orders:	1,4 > 1,7 = 1,2
$n = 10$	Distances:	1,2 < 2,9 < 2,3
	Bond orders:	1,2 > 2,9 = 2,3
$n = 11$	Distances:	2,4 < 1,2 < 2,8 < 8,10 < 4,10 < 4,8 < 10,11 < 4,7 < 1,4
	Bond orders:	2,4 = 2,8 > 1,2 > 8,10 = 4,10 = 4,8 = 10,11 = 4,7 > 1,4
Three-dimensional simple Hückel bond orders		
$n = 11$	Distances:	2,4 < 1,2 < 2,8 < 8,10 < 4,10 < 4,8 < 10,11 < 4,7 < 1,4
	Bond orders:	2,4 > 2,8 > 4,10 > 8,10 > 4,8 > 1,2 > 10,11 > 4,7 > 1,4
Extended Hückel bond orders, $B_nH_n^{2-}$		
$n = 9$	Distances:	1,4 < 1,7 < 1,2
	Bond orders:	1,4 > 1,2 > 1,7
$n = 11$	Distances:	2,4 < 1,2 < 2,8 < 8,10 < 4,10 < 4,8 < 10,11 < 4,7 < 1,4
	Bond orders:	2,4 > 1,2 > 4,7 > 8,10 > 4,10 > 2,8 > 4,8 > 10,11 > 1,4
Extended Hückel bond orders, C_n^{2-}		
$n = 11$	Distances:	2,4 < 1,2 < 2,8 < 8,10 < 4,10 < 4,8 < 10,11 < 4,7 < 1,4
	Bond orders:	1,2 > 4,7 > 2,4 > 4,10 > 8,10 > 10,11 > 2,8 > 4,8 > 1,4
Ab initio bond orders		
$n = 11$	Distances:	2,4 < 1,2 < 2,8 < 8,10 < 4,10 < 4,8 < 10,11 < 4,7 < 1,4
	Bond orders:	2,4 > 2,8 > 4,10 > 8,10 > 4,8 > 1,2 > 10,11 > 4,7 > 1,4

larities in trends. Not shown are the situations in which bond order–bond distance trends are in complete agreement. For example, for $n = 5$, all four methods give bond order indices such that 1,2 > 2,3, which is exactly the reverse of the bond distance trend: 1,2 < 2,3. Therefore, these agreements do not appear in Table 2. Only one distance is possible for the regular polyhedra $n = 6$ and $n = 12$. Since no internal trends exist for these cases, they are not listed in Table 2.

As shown in Table 2, the main difficulty with the Wade fractional bond order is its inability to distinguish between different bonds that link atoms of the same degrees. The worst case is $n = 11$. However, all models, including the *ab initio* bond orders vs *ab initio* distances, show reversals for the $n = 11$ polyhedron. One measure of order irregularities is the number of permutations required to put bond orders into the order dictated by bond distances. In this regard it takes three permutations to put the $n = 11$ bond orders into coincidence with bond distances for the three-dimensional Hückel, extended Hückel ($B_nH_n^{2-}$) and *ab initio* results. The extended Hückel bond orders for C_{11}^{2-} require six permutations.

Figures 2–6 show correlations of bond orders calculated by the various models applied here as functions of the 25 different polyhedral B—B bond distances that were previously determined by *ab initio* SCF MO calculations at the STO-3G level. We have attempted a linear fit among each set of points. Quality of fit is indicated by the correlation coefficient r reported with the equation of the line for each figure. It is likely that a linear relationship is not the most appropriate. For example, the points in Figs 3 and 6 might be better approximated by a quadratic curve, but in fact they are the two sets that best fit a linear plot. Other graphs show considerably more scatter. It is clear from the figures that bond order–bond distance correlations are only qualitative and, therefore, heroic attempts to fit points with many parameters is without justification. Perhaps not surprisingly, we obtain the best fit with Mulliken populations from the *ab initio* calculations that determined the distances (Fig. 6). Only slightly less satisfactory are the Coulson bond orders from three-dimensional Hückel theory (Fig. 3). It is gratifying that while they give almost as close a fit as the *ab initio* bond populations, the three-dimensional Hückel results contain no more

information, only molecular topology and electron count, than Wade's fractional bond orders (Fig. 2), which exhibit the greatest scatter. Not quite as good as the three-dimensional Hückel results are the extended Hückel–Mulliken bond populations for $B_nH_n^{2-}$ (Fig. 4). Still slightly less satisfactory are the extended Hückel results for C_n^{2-} plotted against B—B bond distances (Fig. 5). Part of the scatter among extended Hückel bond populations must be a result of the standard bond distances assumed to set up the structures for the calculations. Both sets of extended Hückel results would probably be improved by repeating the calculations using structures based on experiment or geometry optimized *ab initio* calculations. However, such a procedure would obviate the attractiveness of a computationally simple model. Points that lie farthest from the lines in all plots often come from the trigonal bipyramid ($n = 5$) and the octadecahedron ($n = 11$).

There has long been interest in correlating experimental bond distances with some sort of calculated bond index. Rarely have there been attempts to survey bond distance–bond index correlations among such a large number of bonds through a series of related molecules. The four indices we have considered here hardly exhaust the possible methods. All four indices are applicable to other classes of boranes, as well as to other cluster compounds. As chemists accustomed to counting bonds and electrons, it is satisfying to see that the Coulson bond orders, based on three-dimensional Hückel MO calculations and requiring as input information only atomic connectivity and electron count, perform almost as effectively in correlating bond lengths as do *ab initio* calculated Mulliken bond populations.

SYNTHESIS AND CHARACTERIZATION OF $[M(dmit)_2]^{2-}$ AND $[M(dmt)_2]^{2-}$ COMPLEXES (M = Se^{II} OR Te^{II}; dmit = 4,5-DIMERCAPTO-1,3-DITHIOLE-2-THIONE AND dmt = 4,5-DIMERCAPTO-1,2-DITHIOLE-3-THIONE)

(*Received* 5 *May* 1993; *accepted* 14 *June* 1993)

Abstract—Reactions of disodium salt of the ligands 4,5-dimercapto-1,3-dithiole-2-thione [H_2(dmit)] and 4,5-dimercapto-1,2-dithiole-3-thione [H_2(dmt)] with "sodium selenopentathionate"-3-hydrate [$Na_2Se(S_2O_3)_2]\cdot 3H_2O$ and "sodium telluropentathionate"-2-hydrate [$Na_2Te(S_2O_3)_2\cdot 2H_2O$, in the presence of cations Me_3Te^+, Ph_4As^+, $(C_5H_5)_2Co^+$ and PPN^+, yielded the corresponding complexes of stoichiometry [cation]$_2$[M(dmit)$_2$] and [cation]$_2$[M(dmt)$_2$]$_2$ (M = Se or Te). These complexes are thermally unstable and undergo redox decomposition in solution. Oxidation reactions of these complexes with iodine or tetracyanoquinodimethane afforded sulphocarbon C_6S_{10}. In order to study the oxidation–reduction process of these complexes, detailed electrochemical investigations have been carried out.

Square planar complexes, $[M(dmit)_2]^{n-}$, (M = d^8 metal; dmit = 4,5-dimercapto-1,3-dithiole-2-thione; n = 0–2), have attracted considerable attention recently.[1–3] This system has yielded several low temperature molecular metals and superconductors, namely [TTF][Ni(dmit)$_2$]$_2$,[4] [α-TTF][Pd(dmit)$_2$], [α′-TTF][Pd(dmit)$_2$]$_2$,[5] [Me_4N][Ni(dmit)$_2$]$_2$[6] and [Me_4N][Pd(dmit)$_2$]$_2$.[7] Molecular interactions through S···S contacts form effective conduction pathways in the crystals. The incorporation of tellurium in these systems may give rise to new unknown interactions, since tellurium is well known to participate in intermolecular interactions with sulphur. Recently, we prepared [Me_3Te][Au(dmit)$_2$] complex. The structure, as expected, exhibited several Te···S inter- and intramolecular interactions.[8] Hence it was decided to investigate further other systems containing tellurium as part of the cation and/or anion. Attention focussed upon **2** since the anion not only contained the more polarizable and large tellurium, but it was expected to be planar as well. Both Se^{II} and Te^{II} complexes with bidentate sulphur donor ligands have been shown to have trapezoid planar geometry around the central atom.[9–11] Furthermore, the presence of the dithiolene ligands may stabilize tellurium in unusual oxidation states (other than +II, +IV) similar to those observed for [Et_4N][Te(mnt)$_2$Cl] (mnt = 1,2-dicyanoethylene-1,2-dithiolate) where the effective magnetic moment of 1.5±0.1 BM has been interpreted in terms of the presence of an unpaired electron and a formal oxidation state of Te^{III}.[12] Recently, we[13] and others[14] have reported examples of Te^{III} derivatives. The majority of dmit complexes studied have involved transition metals. The dmit complexes of main group elements have attracted only limited attention; not a single dmit complex of selenium/tellurium has been reported. We reasoned that planar dmit complexes with Se^{II} and Te^{II} would have several features in common with transition metal dmit complexes and might lead to highly conducting complexes. We note that some examples of $[Se(dmt)_2]^{2-}$[15] and $[Te(dmt)_2]^{2-}$[16] have been reported; however, no attempt has been made to evaluate the efficacy of the systems as conducting solids. This paper reports the synthesis, chemical oxidation and detailed electrochemical study of the Se^{II} and Te^{II} complexes with dmit and dmt.

RESULTS AND DISCUSSION

The dithiolene complexes **1–11** were most conveniently prepared by the substitution reactions of labile Se^{II} and Te^{II} pentathionate complexes with

Scheme 1.

disodium salts of the ligands 4,5-dimercapto-1,3-dithiole-2-thione [Na_2(dmit)] and its isomer, 4,5-dimercapto-1,2-dithiole-3-thione [Na_2(dmt)] (Scheme 1). The anionic complexes were isolated as salts with cations like Me_3Te^+, $(C_5H_5)_2Co^+$, Ph_4As^+ and PPN^+.

The complexes are orange–red to dark reddish brown in colour and are sharp melting solids (Table 1). The complexes with bulky cations like PPN^+, Ph_4As^+ and $(C_5H_5)_2Co^+$ are quite stable and remain unaffected by atmospheric oxygen and moisture for a long time. However, the complexes with the Me_3Te^+ cation are unstable and start to decompose after some time at room temperature; therefore, they were prepared and stored at 0°C under dinitrogen. The selenium complexes of both ligands, Na_2(dmit) and Na_2(dmt), were found to be relatively more stable as compared to their tellurium counterparts. The complexes have poor to moderate solubility in common organic solvents such as acetone, chloroform, dichloromethane, carbon disulphide, pyridine and dimethylformamide. The stability of the complexes in solution is rather poor. Solutions of the complexes decompose after a few hours at room temperature to give reduced metals. Attempts to isolate solid complexes with the smaller cations Me_4N^+ and Bu_4N^+ were unsuccessful. This is probably due to both low stability and high solubility of these complexes. Also, attempts to prepare the tellurium-containing thione **12** by 1:1 reaction of Na_2(dmit) and $Na_2[Te(S_2O_3)] \cdot 2H_2O$ afforded a yellowish-orange product of indefinite composition.

The complexes are well characterized by elemental analyses (C, H, N), IR, UV–vis spectroscopy and cyclic voltammetry studies. Attempts were made to record ^{77}Se and ^{125}Te NMR spectra in DMSO-d_6. The complexes, unfortunately, proved too insoluble to allow for meaningful measurements. Also in DMSO-d_6, considerable decomposition of the complexes was observed and a black–brown solid (probably metal) settled after some time.

The IR spectra of complexes (Table 2) exhibit the characteristic ν(C=C) stretching frequency at 1440 ± 10 cm^{-1} (for dmit complexes)[17] and 1320 ± 10 cm^{-1} with a shoulder at 1290 ± 10 cm^{-1} (for dmt complexes)[18] and are quite similar to those reported for tin[19] and indium.[20] These frequencies support the dianionic nature of the ligands. Upon oxidation, a negative shift in ν(C=C) is generally observed. The other bands associated with the ligands, ν(C=S) and ν(C—S) were observed in

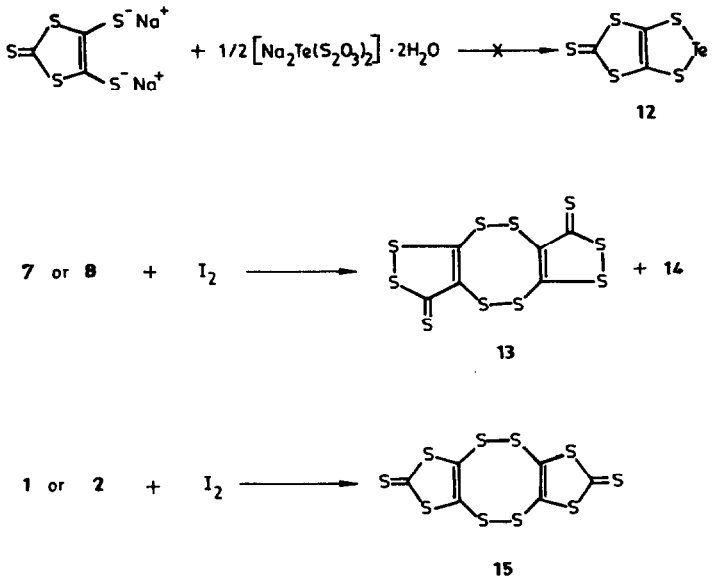
the regions 1080–1020 cm^{-1} and 930–890 cm^{-1}, respectively.

The electronic absorption spectra show an intense band in the region 473–402 nm (Table 2) for both the dmit and dmt complexes. This is assigned to π–π^* transition of the ligand and is observed at 475 nm for $Na_2(dmit)$ in acetonitrile. A second π–π^* transition of the ligand is observed at 273–246 nm (for the dmit complex) and at ~ 292–244 nm (for the dmt complex). An intense band in the region 390–300 nm is assigned to the $M^{II} \leftarrow S$ charge transfer transition.[21]

The complexes, as expected, did not show an ESR signal and were insulated in the solid state, further supporting a dianionic nature of the ligand.

Chemical oxidation

Attempts were made to obtain odd-electron potentially conducting species, $[M(dmit)_2]^-$ and $[M(dmt)_2]^-$, where the formal oxidation state of selenium or tellurium would be III. Treatment of the $[M(dmt)_2]^{2-}$ complexes with iodine or TCNQ gave novel sulphocarbon C_6S_{10} (**13**), along with CS_2 insoluble polymeric sulphocarbon of the formula C_3S_x ($x = 5.5$; **14**). To the best of our knowledge,



Scheme 2.

this is the first report on **13**, although its isomer (**15**) has recently been reported. Similarly chemical oxidation of the $[M(dmit)_2]^{2-}$ complexes with catalytic or excess of iodine led to the isolation of orange–red sulphocarbon C_6S_{10} (**15**) (Scheme 2), which was characterized by elemental analysis and comparing m.p. and IR with an authentic sample. It is worth noting that the results of chemical oxidation of the dmit complexes are in line with the conclusions from the electrochemical study (*vide infra*). These oxidation products do not exhibit an ESR signal.

Electrochemistry

Cyclic voltammetric studies of selenium and tellurium complexes are very few and are limited to only Te^{II} and Te^{IV} dithiocarbamates. Cyclic voltammograms of the complexes (**1–3**, **7–9** and **11**) have been obtained in dichloromethane and acetonitrile. Chemically and electrochemically irreversible reduction and oxidation processes can be inferred for all the complexes. In Table 3, electrochemical data are given for both reduction and oxidation steps.

$M(dmit)^{2-}$ *complexes.* The $M(dmit)^{2-}$ complexes (**1–3**; Fig. 1) in the direction of increasingly positive potentials reveal one electrochemically irreversible oxidation process in the range of +0.15 to +0.28 V. The sodium salt of the ligand $[Na_2(dmit)]$ also shows a single peak with peak potential at 0.07 V presumably corresponding to the formation of the oxidized derivative (**15**) (*vide supra*). In comparison to the sodium salt, the complexes are oxidized at more positive potentials. This oxidation behaviour of complexes is very similar to that of the ligand and the oxidation of the complexes is ligand-based only. We never observed any peak corresponding to Te^{II} or Te^{IV} species, although the +IV and +VI oxidation states are also well known for selenium and tellurium.

Unlike oxidation, the reduction process shows two peaks for the complexes at peak potentials in the range of −0.39 to −0.76 V. The reduction processes are also irreversible. The tellurium complexes show an interesting behaviour. An initial increase followed by a decrease in subsequent cycles of the reduction peaks was observed when the same solution was scanned several times (Fig. 2). A dark coating formed on the working electrode after the reduction process had been scanned and no follow-up peak, like $Te(dtc)_2$, was observed during oxidation.[22,23] The sodium salt of the ligand shows two irreversible reduction peaks at peak potentials of −0.46 and −0.78 V. Thus, in $M(dmit)^{2-}$ complexes the reduction processes are probably both ligand and metal based. The central metal is finally converted into the elemental form and the complexes do not show any indication of short-lived species formed by metal, similar to that reported for tellurium(II) dithiocarbamates,[22] during the electrochemical process. The data clearly indicate a metal dependence of the reduction potential. The ease of reduction decreases in the order Te > Se. It also appears that the solvent effect on the reduction of dithiolates has a profound effect.

$M(dmt)^{2-}$ *complexes.* The cyclic voltammetry experiments for the $M(dmt)^{2-}$ complexes (**7–9** and

11) show two oxidation–reduction processes. The $Na_2(dmt)$ ligand in acetonitriles shows two oxidation peaks at peak potentials of +0.3 and +0.8 V. The complexes show similar behaviour, but the peaks are more prominent. The cyclic voltammogram of complex $(PPN)_2[Te(dmt)_2]^{2-}$ (**8**) showed one prominent irreversible reduction peak at −0.46 V with a very weak peak at −0.85 V. The

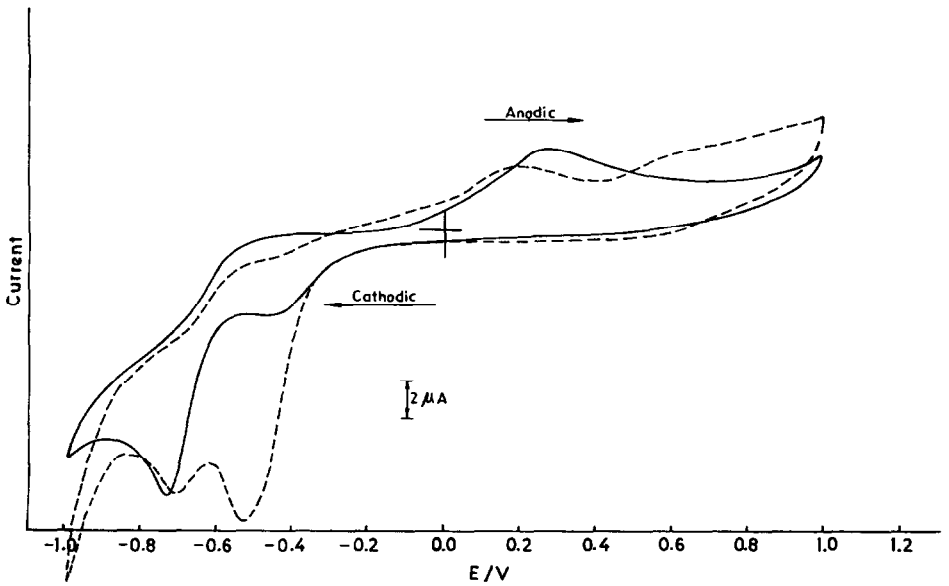

Fig. 1. Cyclic voltammograms for the reduction and oxidation of dmit complexes at platinum (– – –, **2**; ——, **1**) in CH_2Cl_2 solution containing 0.1 mol dm^{-3} $(C_4H_9)_4NPF_6$; SCE reference electrode, scan rate 50 $mV\ s^{-1}$.

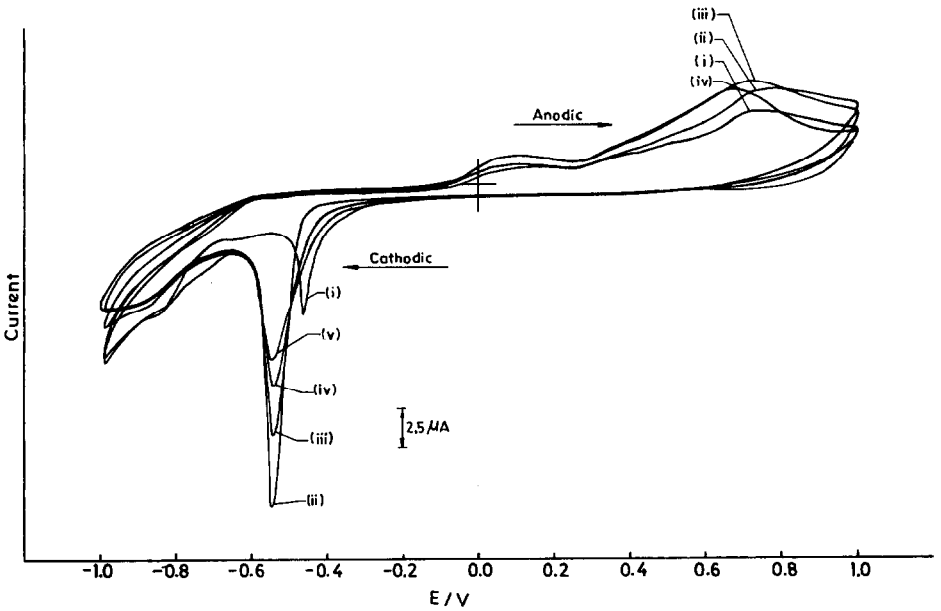

Fig. 2. Cyclic voltammograms for the reduction and oxidation of **8** when recycled in MeCN solution containing 0.1 mol dm^{-3} $(C_4H_9)_4NPF_6$; SCE reference electrode, scan rate 25 mV s^{-1}.

latter disappeared on recycling. However, the first peak at peak potential −0.46 V, similar to the Te $(dmit)_2$ complexes, first increases with shift (−0.54 V) and subsequently decreases by repeated recycling. The sharpness of the peak indicates metal deposition. In positive scan, two oxidation peaks at +0.1 V and +0.7 V were observed. Similarly for the complex $(PPN)_2[Se(dmt)_2]^{2-}$ (**7**), two prominent oxidation peaks at peak potentials +0.24 and +0.65 V were observed. The reduction peaks develop slowly on recycling of the solution during electrochemical study and becomes prominent after two or three recycles at −0.5 and −0.87 V (Fig. 3). Complex **11** showed a flat spectrum at positive potential, which may be due to rapid oxidation of the complex during electrochemical investigation, while the reduction process is prominent for the complexes **7** and **8**.

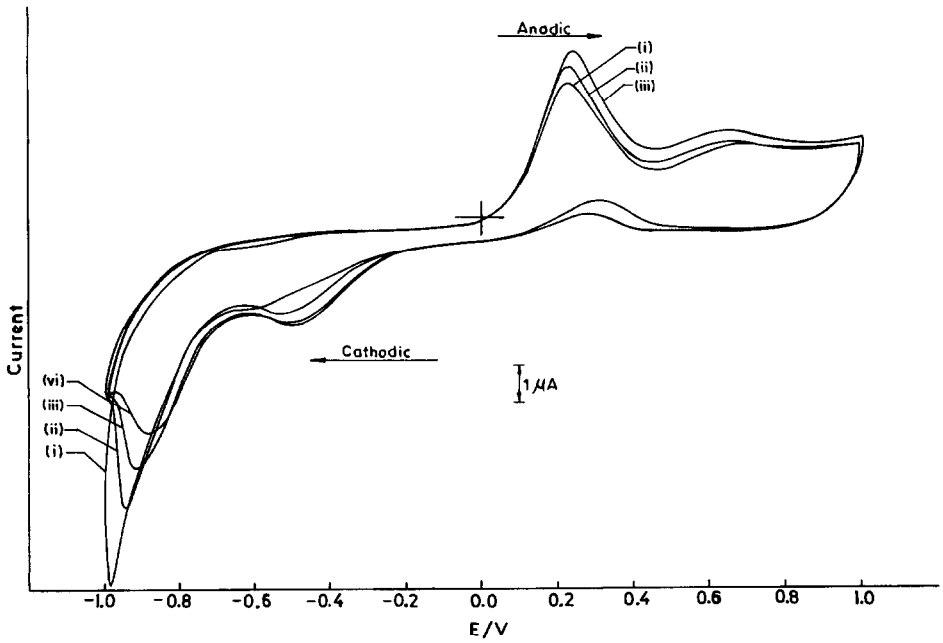

Fig. 3. Cyclic voltammograms for the reduction and oxidation of **7** when recycled in MeCN solution containing 0.1 mol dm^{-3} $(C_4H_9)_4NPF_6$; SCE reference electrode, scan rate 25 mV s^{-1}.

In summary, although planar dithiolene complexes which contain several chalcogen atoms (ligand, central metalloid ion and cation) have been prepared, no partially oxidized species could be isolated. Chemical and electrochemical methods to obtain partially oxidized species have led to the reduction of the central metalloid ion and oxidation of the ligands. Also, attempts to incorporate Te^{II} to isolate thione **12** have led to the reduction of the central metalloid ion. These results further emphasize the role of the transition metal ions (d^8) in obtaining highly conductive complexes. The problem with main group metal ions is probably the high reactivity associated with the unpaired electron on the main group metal ion which is present in a frontier orbital, whereas in a transition metal derivative, the unpaired electrons are in low-lying non-bonding *d*-orbitals.[24] The instability of odd-electron states in Main Group Chemistry is attributable not so much to thermodynamic facts, but rather to the kinetic reaction.

EXPERIMENTAL

General

Melting points were determined using a Ketan melting point apparatus and are uncorrected. Elemental analysis was performed on a Carlo Erba elemental analyser model 1106. IR spectra were recorded as KBr pellets on a Perkin–Elmer 681 IR spectrophotometer. UV–vis spectra were recorded on a Shimadzu UV-260 spectrophotometer (CH_2Cl_2 as solvent) and are reported as λ_{max}. ^{77}Se and ^{125}Te NMR spectral measurements were attempted on a Varian 90 MHz instrument in DMSO-d_6. Mass spectra were determined with a Shimadzu QP-1000 mass spectrometer operating at 70 eV and are reported as *m/z* (P, %). Solid state ESR spectra were investigated using a Varian E-112 ESR spectrometer. The solid state conductivities were measured on powdered samples at room temperature by the two-probe method. All electrochemical experiments were performed in a one-compartmental cell with platinum working electrode and platinum wire counter electrode. The reference electrodes were $Ag^+/AgCl$ or saturated calomel electrode (SCE). Measurements were done on an EG and G Princeton Applied Research, Potentiostat/Galvanostat Model 273. The solutions of complexes (5×10^{-4} mol dm^{-3}) with tetrabutylammonium hexafluorophosphate (0.1 mol dm^{-3}) as supporting electrolyte in dry dichloromethane (15 cm^3) were purged with dry nitrogen and a nitrogen blanket was kept over the solutions at all times. The sweep rate was varied from 25 to 100 mV s^{-1} over ranges of 0.0 to +1.0 V and 0.0 to −1.0 V.

All the reactions were carried out under a dry nitrogen–argon atmosphere. Solvents used were deoxygenated prior to use. Disodium salts of the ligands 4,5-dimercapto-1,3-dithiole-2-thione [H_2(dmit)][25] and 4,5-dimercapto-1,2-dithiole-3-thione [H_2(dmit)][18] were prepared by reported procedures. The complexes $Na_2[Se(S_2O_3)_2]\cdot 3H_2O$ and $Na_2[Te(S_2O_3)_2]\cdot 2H_2O$[26] were prepared as described. $Me_3Te^+I^-$ was prepared by the literature procedure[27] and converted to $Me_3Te^+Cl^-$ by reacting it with AgCl in methanol. Salts such as bis(triphenylphosphine)iminium chloride (PPN^+Cl^-) (Strem. Chem.), tetraphenylarsonium chloride ($Ph_4As^+Cl^-$) and cobaltecenium tetrafluoroborate $(C_5H_5)_2Co^+BF_4^-$ (Fluka) were used as received.

Synthesis

All the complexes were prepared in a similar fashion. Two examples are outlined below.

Preparation of $[(Ph_4As)_2][Te(dmit)_2]$. To a dark red solution of Na_2(dmit) (0.48 g; 2 mmol) in methanol (30 cm^3), was added a methanol (40 cm^3) solution of $Ph_4As^+Cl^-$ (0.98 g; 2 mmol), followed by the addition of $Na_2[Se(S_2O_3)_2]\cdot 3H_2O$ (0.40 g, 1 mmol) in methanol (20 cm^3). The reaction mixture was stirred for 1 h. Dilution of the reaction mixture with water gave the dark brown crude product, which was filtered off and dried. Recrystallization from acetone (without heating at any stage) afforded a crystalline solid.

Preparation of $[PPN]_2[Te(dmt)_2]$. $Na_2(Te(S_2O_3)_2]\cdot 2H_2O$ (0.43 g; 1 mmol) dissolved in methanol (40 cm^3) was added slowly to a mixture of Na_2(dmit) (0.48 g, 2 mmol) and PPN^+Cl^- (1.14 g, 2 mmol) in methanol (40 cm^3). The black finely crystalline compound which precipitated was filtered off, washed with water followed by isopropanol–ether and dried *in vacuo*. The complex was recrystallized by dissolving in pyridine followed by cautious addition of isopropanol till the solution became turbid. A dark red crystalline complex separated after ~ 2 h at 0°C.

Attempted synthesis of oxidized $[Te(dmt)_2]^{n-}$ $(n < 2)$

To an acetonitrile (25 cm^3) solution of $[PPN]_2[Te(dmt)_2]$ (0.319 g, 0.2 mmol) was added a solution of iodine (0.025 g, 0.025 mmol) in acetonitrile (15 cm^3). A yellow–orange product which was precipitated immediately was filtered off, washed with acetonitrile and dried *in vacuo*. Extraction of the crude product with CS_2 afforded an orange

coloured crystalline material (**13**) and a CS_2-insoluble red–brown product (**14**).

Compound **13**. Yield 12%, 0.07 g; m.p. 152–153°C. Found: C, 18.6. Calc. for C_6S_{10}: 18.4%. IR: 1310s, 1250m, 1210m, 1110s, 1040s, 940s, 820m. MS (*m/z*): 328 ($M^+ - 2S$, 53.3%).

Compound **14**. Yield, 0.01 g; m.p. 221°C (d). Found: C, 17.0. Calc. for $(C_3S_x)_n$ ($x = 5.5$): 17.0%. IR: 1470s, 1325m, 1255m, 1210m, 1115s, 1040s, 940s, 820m.

Similar oxidation reactions of $[PPN]_2[Te(dmit)_2]$ and $[PPN]_2[Se(dmit)_2]$ with iodine in a molar ratio of 1 : 2 in acetonitrile afforded **15**. Red solid, (0.06 g), m.p. 148–149°C (d) [lit.[28] 149°C (d)]. Found: C, 17.5. Calc. for C_6S_{10}: 18.4%. IR: 1470m, 1430s, 1250s, 1170m, 1105s, 1000m, 730m, 710s, 680s.

Attempted oxidation of $[PPN]_2[Se(dmt)_2]$ *with* 7,7,8,8-*tetracyano*-p-*quinodimethane* (*TCNQ*)

To an acetonitrile (30 cm^3) solution of $[PPN]_2[Se(dmt)_2]$ (0.15 g; 0.1 mmol) was added a solution of TCNQ (0.040 g; 0.2 mmol) in acetonitrile (15 cm^3). A yellow–orange compound which precipitated immediately was filtered off, washed with acetonitrile and dried *in vacuo* to give **13**.

Attempted aerial oxidation of $[PPN]_2[Se(dmt)_2]$

Air was bubbled into a solution of $[PPN]_2[Se(dmit)_2]$ (0.15 g, 0.1 mmol) in acetonitrile (30 cm^3) for 2 h. The resulting solution was concentrated *in vacuo* to give the starting material.

Abstract—The equilibria in the systems glycylglycine and glycylglycylglycine+VO^{2+} in aqueous solution have been studied in the pH range 1.5–4.5 by a combination of pH potentiometry and spectroscopy (EPR and visible absorption). The results of the various methods are made self-consistent, then rationalized assuming an equilibrium model including species MLH, ML_2H_2, MLH_{-1} and several hydrolysis products (where HL denotes glycylglycine or glycylglycylglycine); individual formation constants and absorption spectra are given. Plausible isomeric structures for each stoichiometry are discussed.

Knowledge of the complex equilibria of VO^{2+} in the presence of amino acids is relevant in understanding its possible interaction with likely biological ligands.

The first part of this study[1] introduced our work and gave detailed results for the system L-alanine+VO^{2+} in the pH range 2–12. Part II[2] involved the study of the L-serine and L-threonine+VO^{2+} systems, part III[3] L-aspartic acid+VO^{2+}, part IV[4,5] L-cysteine and D-penicillamine+VO^{2+}, and part V[6] the L-glutamic acid+VO^{2+} system. This paper reports our work on the glycylglycine and glycylglycylglycine+VO^{2+} systems by combining the results of potentiometric and spectroscopic techniques. Part of this work has been presented in preliminary form.[7] In common with biochemical studies, we abbreviate the HL forms of glycylglycine (I) and glycylglycylglycine (II) as glygly and glyglygly, respectively. When a shorter abbreviation is convenient, we use GG and GGG.

(I) (glygly or GG)

(II) (glyglygly or GGG)

* Authors to whom correspondence should be addressed.

To our knowledge the only report mentioning these systems is from Crans *et al.*[8] These authors used a phosphatase catalysed enzyme assay to determine the extent of interaction between 10^{-7}–10^{-5} M vanadium(IV) and selected organic molecules, namely glycine (gly), glycylglycine (glygly) and glycylglycylglycine (glyglygly). From the V_0/V_i ratios (V_0, rate of hydrolysis; V_i, inhibited rates) determined in the presence of these biomolecules, and assuming the formation of a single complex species in each case, Crans and co-workers[8] estimated formation constants of 5000, 20,000 and 40,000 for gly, glygly and glyglygly, respectively.

There are several experimental difficulties in studying the systems produced by oxovanadium(IV) and amino acids. These are discussed in Part I.[1] Our results with the glygly (and glyglygly) $+VO^{2+}$ systems differ greatly from those for the gly$+VO^{2+}$ or L-ala$+VO^{2+}$ [1] systems. For the vanadium(IV) concentrations used in our potentiometric and spectroscopic studies, it is possible with gly or L-ala to avoid vanadyl hydroxide precipitation by using relatively high ligand-to-metal ratios (L/M ratios). In contrast, with glygly or glyglygly, very extensive hydrolysis and precipitation of $VO(OH)_2$ occurs for pH > 4–5, even when using L/M ratios of 180.

As only pK_{a1} (terminal —COOH) and pK_{a2} (terminal —NH_2) can be determined, our calculations of formation constants correspond to the general reaction:

$$pM^{2+} + qL^- + rH^+ \overset{\beta_{pqr}}{\rightleftharpoons} M_pL_qH_r. \qquad (1)$$

For the formulations $(VO)_p$(GG or GGG)$_q H_r$ we normally use the abbreviation $M_pL_qH_r$. For each $M_pL_qH_r$ proposed in our final equilibrium models, possible stuctures are discussed.

EXPERIMENTAL

Materials and methods

All solutions were prepared in an inert atmosphere (high purity dinitrogen passed through soda lime and glass wool). All measurements were performed at 25°C with solutions containing 2.25 M $NaNO_3$.

Stock VO^{2+} and NaOH were prepared and standardized as described in part I.[1] Glygly and glyglygly (Sigma) for stock solutions were dried for several days (in a desiccator with silica gel *in vacuo*). Their purity was checked by HPLC (C_{18} column with several different eluents, one of them giving adequate selectivity to separate the *o*-phthalaldehyde derivatives of gly, GG and GGG), thin layer chromatography on silica plates and elemental analysis.

For potentiometric titrations we used a special glass vessel with a double wall, with entries for the glass electrode (Orion Ross/81-01) and reference electrode (Orion Ross/80-05), thermometer, nitrogen and base from the burette (Metrohm). A computerized system developed locally was used to control the titration conditions (e.g. the interval between the additions of base, criteria of stability of the point).[9] The e.m.f. measurements were made with a Crison 517 pH meter and the titrations were controlled by an IBM-PC XT computer. Visible spectra were recorded with a Perkin–Elmer lambda 9 spectrophotometer. Cell compartments were kept at 25°C with circulating water from a thermostatted bath. Unless otherwise stated, by visible spectra we always mean a representation of ε_m values vs λ [ε_m = absorption/($b \times C_{VO}$); b = optical path and C_{VO} = total oxovanadium(IV) concentration]. The X-band EPR spectra were recorded at 77 K (on glasses made by freezing solutions in liquid nitrogen) with a Bruker ESR-ER 200tt connected to a Bruker B-MN C5 EPR spectrometer and to a Bruker EPR data system (linked to an IBM AT computer).

The calibration procedure for pH measurements was described in Part I.[1] We continue to assume that the e.m.f. values (E) depend on [H^+] according to:

$$E = E^{0\prime} + Q \log [H^+] + J_H[H^+] + J_{OH}[OH^-]. \qquad (2)$$

As $J_H \sim 20$, the corrections in the acid range are significant only for pH < 2.0.

Eight titration curves ($0.02 < C_L < 0.07$ M; C_L = total peptide concentration) were obtained to determine the protonation constants in 2.25 M $NaNO_3$. NaOH (1.016 M) with a total ionic strength of 2.25 M was used as titrant.

As vanadyl hydroxide precipitates for pH > 4–5, even when using high L/M ratios, titrations of solutions containing glygly (and glyglygly) and VO^{2+} were only performed for $1.7 \leqslant$ pH $\leqslant 4.2$ (with $0.010 \leqslant C_{VO} \leqslant 0.022$ and $0.5 \leqslant$ L/M $\leqslant 6.0$).

Depending on C_{VO} and L/M ratio, for pH > 3.8–4.3 the e.m.f. readings become unstable. As in previous work,[1-6] such instability is probably due to oxidation and/or extensive hydrolysis of oxovanadium(IV).

Two types of sets of visible absorption spectra were recorded:

(a) varying the pH with approximately fixed total vanadium and peptide concentrations, at several ligand-to-metal ratios;

(b) at approximately fixed pH and total peptide

concentration and varying the total vanadium concentration (C_{VO}).

For the glygly + VO^{2+} system, a total of 63 visible absorption spectra were used for the calculation of spectra of individual species, with total concentrations in the range 3.3×10^{-3} M $\leqslant C_{VO} \leqslant$ 3.1×10^{-2} M and 1.8×10^{-2} M $\leqslant C_{GG} \leqslant 3.0 \times 10^{-1}$ M, respectively. Ligand-to-metal ratios were in the range $1 \leqslant L/M \leqslant 50$. For the glyglygly + VO^{2+} system, a total of 65 visible absorption spectra were used for the calculation of spectra of individual species, with total concentrations in the range 7.0×10^{-3} M $\leqslant C_{VO} \leqslant 3.0 \times 10^{-2}$ M and 1.4×10^{-2} M $\leqslant C_{GGG} \leqslant 1.8 \times 10^{-1}$ M, respectively. Ligand-to-metal ratios were also in the range $1 \leqslant L/M \leqslant 50$. The calculations were performed on results for 450–860 nm.

For the refinement of formation constants and calculation of spectra of individual species, the SUPERQUAD[10] and the SQUAD[11] programs were used. These were run in a Vax 780 DIGITAL computer.

For pH > 4–4.3, the bands in the experimental visible spectra are ill-defined, except when using quite high L/M ratios, e.g. L/M > 20–30, where accurate and reproducible spectra may be obtained till pH ~ 4.5. Further, inaccuracies in the calculation of the contributions of the hydrolysis of vanadium and/or oxidation of a small fraction of the total vanadium(IV) may have a substantial effect on the spectra and preclude a critical analysis of the results. We therefore present no results of calculation with SQUAD using visible spectra of solutions with pH > 4.5.

Using high L/M ratios, $VO(OH)_2$ dissolves for pH $\geqslant$ 7.5–8.0. However, as $pK_{a2} \simeq$ 8.3–8.4, the buffer effect of the R—NH_3^+ groups precludes the use of potentiometry. On the other hand, oxovanadium(IV) is quite extensively hydrolysed and visible absorption spectra are not very useful (see, for example, ref. 1). It is possible to use circular dichroism spectra to study such solutions for peptides such as gly–L-ala, L-alagly and L-ala–L-ala, but these will be discussed in a separate paper.[12]

RESULTS

EPR spectra

The X-band EPR spectra with frozen "solutions" containing GG or GGG and VO^{2+} at 77 K are typical VO^{2+} axial spectra. The field region that corresponds to $A_{\parallel}$ and $M_I = 5/2$ and 7/2 (3800/4300 G) gives more information about the type and number of species present.

For the glygly + VO^{2+} system, spectra were recorded with (1) L/M = 5, $C_{VO} \simeq 0.024$ M, $2.0 \leqslant$ pH $\leqslant 4.0$; (2) L/M = 20, $C_{VO} \simeq 0.017$ M, $1.5 \leqslant$ pH $\leqslant 4.4$; (3) L/M = 25, $C_{VO} \simeq 0.005$ M and $3.9 \leqslant$ pH $\leqslant 4.5$. For the glyglygly + VO^{2+} system, spectra were recorded with (1) L/M = 5, $C_{VO} \simeq 0.024$ M, $2.0 \leqslant$ pH $\leqslant 4.0$; (2) L/M = 15, $C_{VO} \simeq 0.026$ M, $1.5 \leqslant$ pH $\leqslant 4.4$; (3) L/M = 25, $C_{VO} \simeq 0.005$ M and $4.1 \leqslant$ pH $\leqslant 4.6$. For comparison, spectra were also recorded for the gly + VO^{2+} system with L/M = 5, $C_{VO} \simeq 0.038$ M and $1.5 \leqslant$ pH $\leqslant 4.2$.

Some spectra for the glyglygly + VO^{2+} system are included in Fig. 1. Results are similar for the glygly + VO^{2+} system and for the gly + VO^{2+} system

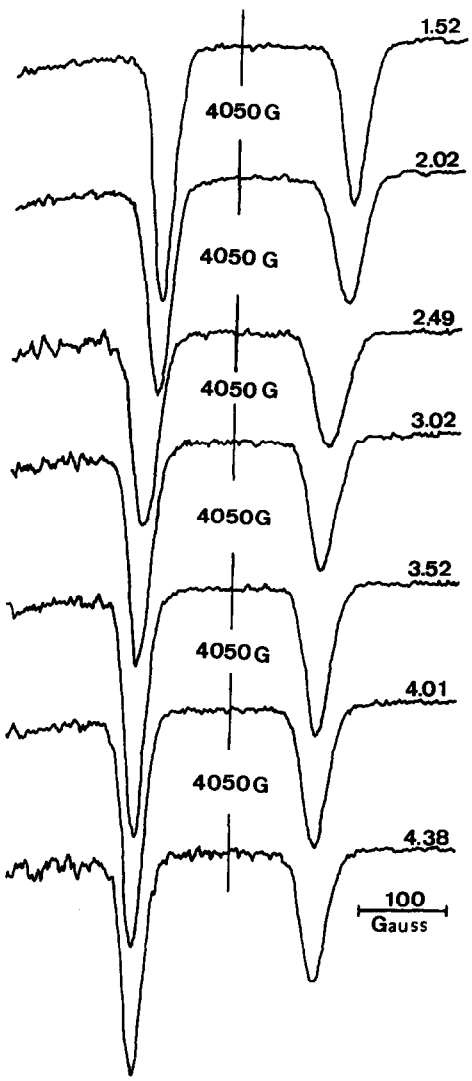

Fig. 1. First derivative EPR spectra (high field range, 3800–4300 G) of solutions containing glyglygly + VO^{2+} for 1.5 < pH < 4.4, L/M = 15 and $C_{VO} \simeq 0.026$ M. The pH corresponding to each spectrum is indicated.

Table 1. Vanadium hyperfine coupling constants and g values calculated[a] from the first derivative EPR spectra at 77 K of frozen "solutions" containing glygly (and glyglygly) + VO^{2+} with $C_{VO} \simeq 0.017$ M, L/M = 20 (GG) and $C_{VO} \simeq 0.026$ M, L/M = 15 (GGG)

	pH	$g_\perp$	$g_\parallel$	$A_\perp \times 10^4$ (cm^{-1})	$A_\parallel \times 10^4$ (cm^{-1})

[a] Absolute values of g and A ($\parallel$ and $\perp$) are probably within ± 0.007 and ± 1, respectively, of the tabulated values.

for pH <4.2. In all cases, as the pH is increased from 1.5 to 4, each spectrum appears like that of only one component but the peaks actually shift to lower field (in an approximately continuous manner). That is, in this pH range, more than one species exists with rather similar $A_\parallel$ values. For pH $\geqslant$ 4, the spectra practically coincide and apparently only one EPR component is detected, except for the gly + VO^{2+} system, where a distinct species may be clearly seen. Table 1 summarizes the relevant g and A ($\perp$ and $\parallel$) parameters calculated using an iterative procedure using the correct equations[13] based on Chasteen's method.[14]

Visible absorption spectra

The visible spectra recorded for solutions containing glygly + VO^{2+} are similar to those obtained for solutions of glyglygly + VO^{2+} in similar experimental conditions.

Figure 2 includes visible spectra of solutions of GG + VO^{2+} with an L/M ratio of 5 and Fig. 3 of GGG + VO^{2+} solutions with an L/M ratio of 20. For pH < 3, the spectra are similar (except for ε_m values) to those of aqueous oxovanadium(IV) solutions. For pH > 3, the spectra apparently reveal an increase of the ligand field around VO^{2+} as λ_{max} of band II[15] shifts to shorter wavelengths. The general

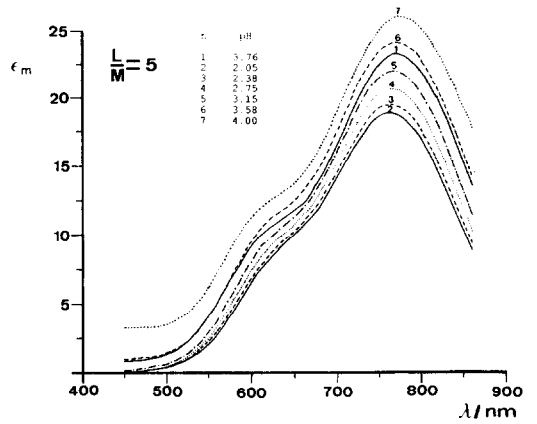

Fig. 2. Visible spectra of solutions containing glygly and VO^{2+} with L/M = 5 and $C_{VO} \simeq 0.016$–0.019 M. The pH corresponding to each spectrum is indicated. Spectrum 7 indicates hydrolysis of the complexes.

increase in ε_m (especially for $450 < \lambda < 650$ nm) in both systems for pH ~ 3.6–3.8 (for L/M = 2), 3.7–3.9 (for L/M = 5), 3.8–4.0 (for L/M = 10), 4.0–4.2 (for L/M = 20) and 4.4–4.8 (for L/M = 50) suggests hydrolysis of VO^{2+}. Addition of base to these solutions to increase the pH by 0.2 or more produces instability of the pH readings and after a while precipitation of vanadyl hydroxide. Even when using L/M ratios of 180, $VO(OH)_2$ precipitates for pH $\gtrsim$ 4.8.

Figure 4 gives examples of spectra at fixed pH varying the ligand-to-vanadium ratio at approximately fixed ligand concentration. For pH $\simeq$ 2.8, ε_m values hardly change as the metal concentration varies from 3.0×10^{-3} to 3.0×10^{-2} M (Fig. 4A) or from 3.4×10^{-3} to 2.4×10^{-2} M for the GGG + VO^{2+} or GG + VO^{2+} systems, respectively. For pH $\simeq$ 3.6, the ε_m values in the range 600–850 nm

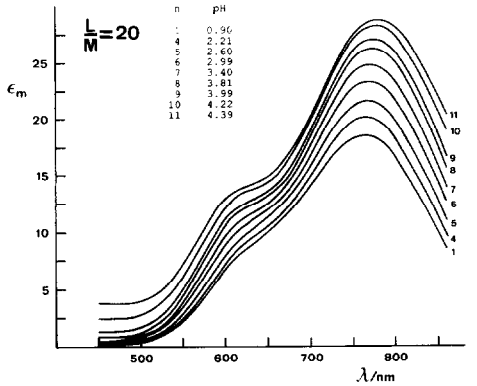

Fig. 3. Visible spectra of solutions containing glyglygly and VO^{2+} with L/M = 20 and $C_{VO} = 0.007$–0.009 M. Spectra 1–4 are similar to those of aqueous oxovanadium(IV) solutions.

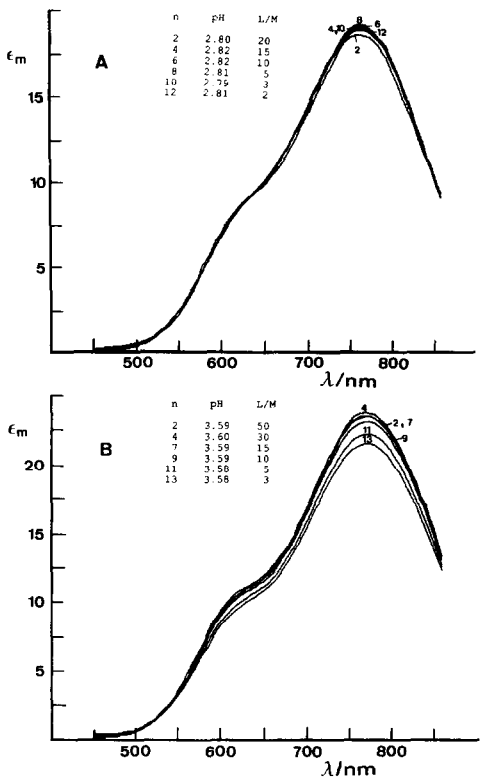

Fig. 4. Visible absorption spectra of solutions containing glygly and VO^{2+} at approximately fixed pH and ligand concentration, at several ligand-to-metal ratios. In A, the initial total vanadium concentration was 3.41×10^{-3} M and the L/M ratio was varied by successive addition of relatively concentrated oxovanadium(IV) solution. In B, the procedure was identical but the initial vanadium concentration was 3.28×10^{-3} M.

decrease about 3% as the L/M ratio varies between 50 and 10 and about 9% between 50 and 3; for solutions containing GGG and VO^{2+}, the corresponding ε_m decrease is about 1% and 6%, respectively. These results indicate that up to pH $\simeq$ 3.6, polymeric species do not form in significant concentration in the experimental conditions used.[1] The slight variations recorded are probably due to equilibria between complexes of different ligand-to-vanadium stoichiometry.

Potentiometry

From SUPERQUAD[10] in solutions containing 2.25 M $NaNO_3$ (at 25°C): $pK_{a1} = 3.31$, $pK_{a2} = 8.42$ and $pK_{a1} = 3.39$, $pK_{a2} = 8.30$ for glygly and glyglygly, respectively, values used in all calculations. These values compare well with literature[16] values; for glygly $pK_{a1} = 3.16$ and $pK_{a2} = 8.10$, and for glyglygly $pK_{a1} = 3.26$ and $pK_{a2} = 8.01$ ($I = 1$ M).

Vanadyl hydroxide precipitated for pH > 4–5, even for very high ligand-to-metal ratios, unlike several systems previously studied.[1-6] It was impossible to titrate in the pH range 4.5–7.5, where the ligands have no buffer effect. Therefore, a titration curve with L/M = 6 was the maximum ligand-to-vanadium ratio included in the calculations with SUPERQUAD for each of the systems.

In these experimental conditions, most of the vanadium(IV) is in the uncomplexed form, $VO(H_2O)_5^{2+}$. Further, the peptides are mainly or significantly in the protonated form, HL, in the pH range 2–4, so that no H^+ is involved in the formation of MLH or ML_2H_2. Consequently, the situation for calculating formation constants is unfavourable.

In the calculations with SUPERQUAD, only for MLH could $\log\beta$ be refined in a reasonably consistent manner: even this was not entirely satisfactory. In combinations of this species MLH with other reasonable guesses, e.g. ML, ML_2H_2, ML_2H, ML_2, MLH_{-1}, values of $\log\beta$ for groups of two or three (total) species could be refined, but not in a consistent way and with relatively high standard deviations (SDs). SUPERQUAD, therefore, afforded only preliminary results: model selection and calculation of formation constants were mainly based on the spectrophotometric results.

Spectrometry

In solutions of VO^{2+} and GG or GGG only vanadium complexes contribute to ε_m in the visible region. This fact removes the limitation (major, but not always appreciated) of potentiometry to those experimental conditions (L/M ratios and pH) where the ligand has no significant buffer effect. Therefore, when calculating formation constants based on visible spectra, we are better off for species that predominate in the pH range 2–4, because increasing the L/M ratio also increases the degree of complex formation.

As for the systems previously studied, the SQUAD program was run assuming many different models, taking combinations of plausible species (see above). For pH $\gtrsim$ 3.5–4.2 (depending on L/M ratio), hydrolysis products such as MH_{-1} and especially M_2H_{-2} may have significant concentrations. Therefore in many of these preliminary calculations $\varepsilon_{20\text{-}2}$ (and $\varepsilon_{10\text{-}1}$) and in some cases the corresponding values of $\log\beta$ were also included as parameters to be refined. These calculations suggested that standard deviations for $\log\beta$ and calculated ε, sum of squares and type of spectra calculated were more reasonable if the model includes

Table 2. Composition and formation constants of species in the glygly and glyglygly + VO^{2+} systems in the region $1.5 \leqslant pH \leqslant 5$[a]

Stoichiometry	glygly	glyglygly
MLH	10.3 (0.2)	10.1 (0.2)
ML_2H_2	19.5 (0.3)	19.4 (0.3)
MLH_{-1}	1.9 (0.3)	1.6 (0.3)
HL	8.42 (0.02)	8.30 (0.03)
H_2L	11.73 (0.03)	11.69 (0.03)

[a] Values for $\log\beta$ of eq. (1) are given (at 25°C and 2.25 M $NaNO_3$). Log β for vanadium hydrolysis products were:[1] −5.98, −6.95 and −22.22 for MH_{-1}, M_2H_{-2} and M_2H_{-5}, respectively.

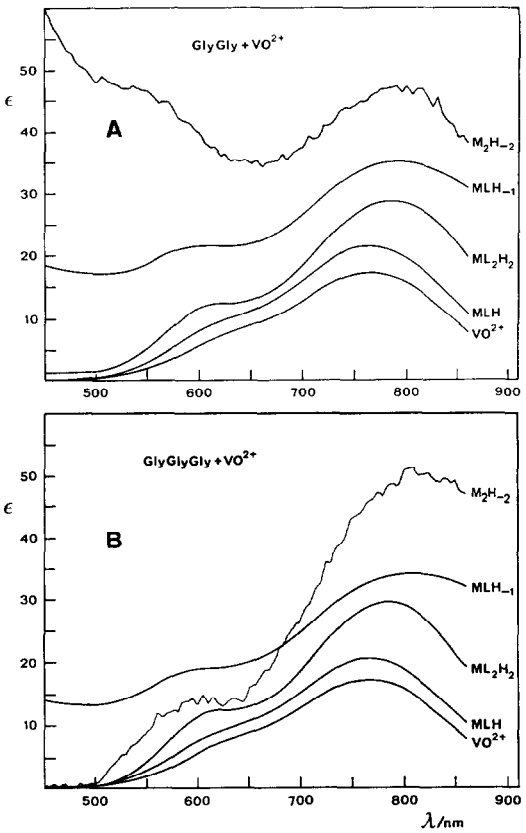

Fig. 5. Visible absorption spectra (calculated using the SQUAD program[11]—see text for details) for species that may form in solutions containing oxovanadium(IV) and glygly (A) or glyglygly (B) (high L/M ratios), using formation constants in Table 2 and experimental visible spectra in the pH range 2–4.5. Spectra for M_2H_{-2} were calculated with high SDs.

species MLH, ML_2H_2 and MLH_{-1}. For both GG and GGG + VO^{2+} systems, calculations involving models including ML, ML_2H, ML_2 or dimeric complexes generally gave unsatisfactory results.

Having obtained an order of magnitude of the appropriate values of $\log\beta$, we used a step-by-step procedure starting in the low pH region. Sets of experimental spectra were chosen where only $VO(H_2O)_5^{2+}$ and the MLH form are expected: $\log\beta_{111}$ and ε_{111} were refined. These agreed well with values obtained in the preliminary calculations described above and were included in the input file of SQUAD as fixed parameters for the next step. The SQUAD program was then run assuming many different models, taking combinations of ML_2H_2, ML, MLH_{-1}, ML_2H, ML_2 and dimeric species, and again the results suggest that besides MLH, only ML_2H_2 and MLH_{-1} should be included in the final equilibrium model.

Sets of experimental spectra were then chosen where M, MLH, ML_2H_2 and MLH_{-1} are expected to have significant concentrations and M_2H_{-2} is below 1%. SQUAD was run with $\log\beta_{122}$, $\log\beta_{11\text{-}1}$, ε_{122} and $\varepsilon_{11\text{-}1}$ as parameters to be refined and the β_{122} and ε_{122} obtained were taken as fixed for the next step. Taking the whole set of experimental spectra, $\log\beta_{11\text{-}1}$, $\varepsilon_{11\text{-}1}$ and $\varepsilon_{20\text{-}2}$ were refined; several calculations also included $\log\beta_{20\text{-}2}$ as a parameter to be refined. Table 2 includes the selected final equilibrium models incorporating both the potentiometric and spectroscopic results. For each of the $\log\beta_{xyz}$ values, plausible ranges are also given, established by a critical examination of all the calculations. The calculated spectra are given in Fig. 5.

The visible absorption spectra for M_2H_{-2} were calculated with high SD, both for GG and GGG + VO^{2+} systems. The spectra obtained for M_2H_{-2} in both calculations should coincide; therefore they could be considered as a good internal calibration pair of independent results. However, M_2H_{-2} is a minor species in the experimental conditions used for all spectra included in the input file of SQUAD: it is not possible to get reliable spectra for solutions where it has a significant concentration, as the pH readings are unstable and vanadyl hydroxide precipitates after a while. Recycling both sets of SQUAD calculations giving the values for M_2H_{-2} as fixed input can be done, but as calculated spectra reflect both the real spectrum for M_2H_{-2} and the "noise" in the SQUAD analysis, this precludes the quantitative use of these calculations to test the self-consistency of the results. Therefore, the fact that reasonable values are obtained for $\varepsilon_{20\text{-}2}$ indicates only that the models presented in Table 2 are correct. Calculations involving the refinement of $\log\beta_{20\text{-}2}$ also yielded satisfactory results.

Assuming SQUAD taking $\log\beta_{111}$, $\log\beta_{11\text{-}1}$, ε_{111}

and $\varepsilon_{11\text{-}1}$ as fixed and $\log\beta_{122}$ and ε_{122} (and also $\varepsilon_{20\text{-}2}$) as parameters to be refined gave results that agree quite well with those presented in Table 2 and Fig. 5, indicating that the various methods of calculation are self-consistent.

DISCUSSION

The proposed equilibrium models—the set of species (with plausible values for their formation constants)—to account for all the experimental potentiometric and spectroscopic results are given in Table 2. In the present systems potentiometry can only afford preliminary results: most of the calculations were based on spectrophotometric results.

Figure 6 gives the concentration distribution calculated for L/M = 20 for both systems and Fig. 7 a representation of (A) $\log\beta_{pqr}^{(GGG)}$ vs $\log\beta_{pqr}^{(GG)}$ and (B) $\log\beta^{VO}$ (GG and GGG) vs $\log\beta^{Cu}$ (GG and GGG). Such representations may help to indicate structures for each $M_pL_qH_r$ species in the models.

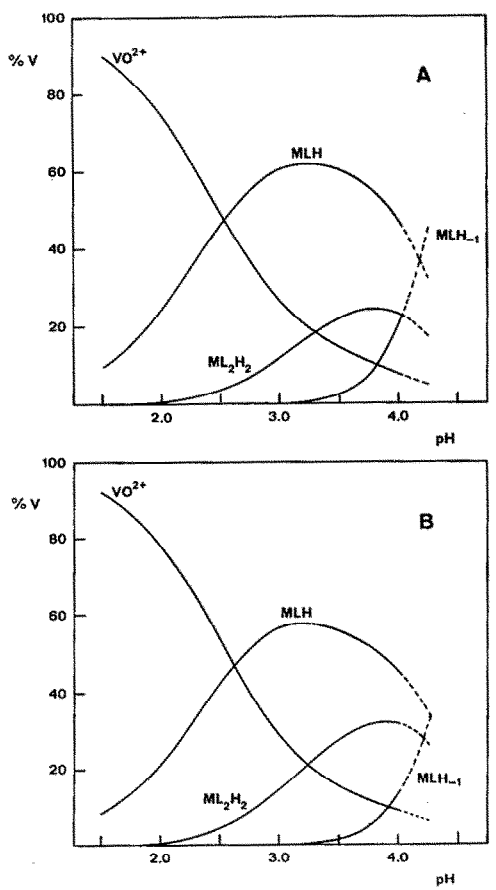

Fig. 6. Concentration distribution of the complexes formed in the glygly (A) and glyglygly (B)+VO^{2+} systems in solutions with $C_{VO} = 5\times10^{-3}$ M and L/M = 20, calculated[17] using β_{pqr} of the equilibrium models of Table 2.

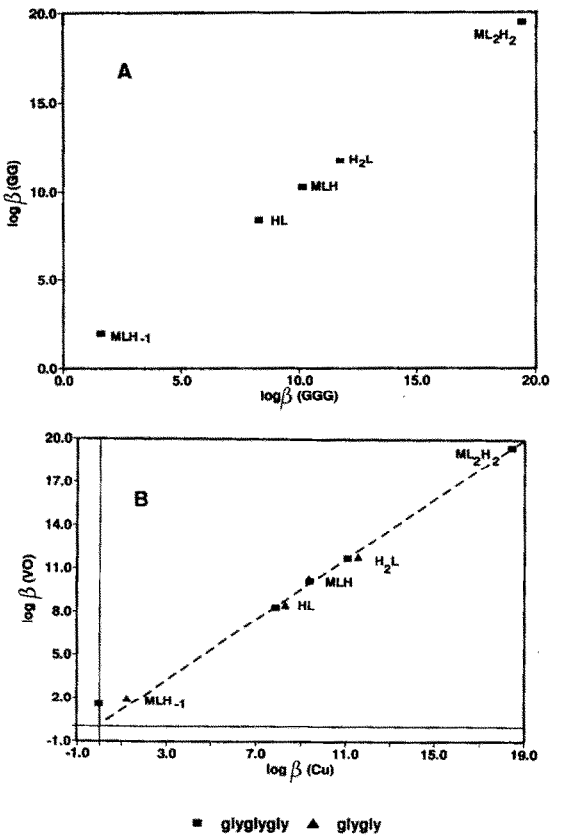

Fig. 7. Representation of: (A) $\log\beta_{pqr}^{GG}$ vs $\log\beta_{pqr}^{GGG}$ for vanadium complexes; (B) $\log\beta_{GG}^{VO}$ vs $\log\beta_{GG}^{Cu}$[18] and $\log\beta_{GGG}^{VO}$ vs $\log\beta_{GGG}^{Cu}$.[16] (▲) glygly; (■) glyglygly. In B, the straight lines are based solely on $\log\beta_{011}$, $\log\beta_{012}$ and $\log\beta_{111}$ (and also β_{122} in the case of glyglygly) and practically coincide for both systems.

The linear plots can also be used to estimate $\log\beta$ for vanadium or copper complexes as long as the coordination geometries are similar and one of the constants is known.

Structures

In relating the molecular structure of an aqueous species to its stability, it is generally useful to compare a spectroscopic property with that of the crystalline solid of known structure. Unfortunately, in our present studies of peptide complexes with oxovanadium(IV), there are as yet no well-characterized solid complex compounds, so there are no crystal structures to serve as points of reference. Our discussion of the structures of these species is based entirely on their properties in solution.

Four types of donor atoms, amino-N, carbonyl-O, amide-N and carboxylate-O, are present in simple peptides, such as glygly (**I**) or glyglygly (**II**): all are capable of metal ion coordination. The

basicity of various groups influences the coordination chemistry of these peptides: the amide group has an extremely weak basic character,[19–21] the pK_a values being of the order of 15. However, the pK_a values for amide deprotonation followed by coordination in copper(II) complexes is relatively low, 4.0 for GG and 5.2 for GGG; in Ni^{II} complexes it is ~ 9.3 for the first amide deprotonation and 10 for the second glygly bound.[19]

In discussing amino acid–vanadium(IV) coordination chemistry, comparisons are often made[1–6] with Cu^{II} and Ni^{II}. However, in the present systems vanadyl hydroxide precipitates for pH > 4–5, even when using high L/M ratios, and no such comparisons can be made.

For pH < 4–5, neither the EPR nor visible absorption spectra give any indication of deprotonation of the peptide group. Besides, if coordination in this pH range involves the amino group at some stage, this acts as an ineffective anchoring group for competition with vanadium hydrolysis, even when using high L/M ratios. Therefore the situation is quite different from that found for Cu^{II}, where a species ML forms with a coordination geometry of the type shown in **III**,[19–21] followed by the deprotonation and coordination of the peptide nitrogen at slightly acidic pH.

The situation is further complicated by the vanadyl ion being lop-sided: many of its chelates may give rise to more isomers than do apparently analogous mono-atomic metal centres such as the copper(II) ion; refs 1 and 15 briefly discuss this. Even in the absence of this extra isomerism, i.e. for monodentate ligands such as an amino acid or peptide via attached carboxylate, the common geometric isomers may both be present (if there are two such ligands).

We now discuss on the basis of Figs 5 and 7 and Table 2 the dominant structure for each stoichiometry. Potentiometry alone cannot of course distinguish structures of the same stoichiometry, except in favourable cases.

MLH. This stoichiometry probably has the α-COO^- group in an equatorial position. The visible spectrum of MLH is like those for the corresponding stoichiometries: MAH, MSH, MDH_2, MPH_2 and MEH_2 (L-alanine, L-serine, L-aspartic acid, D-penicillamine and L-glutamic acid, respectivcly), with amino acids monodentate via carboxylate.

Chasteen's method[14] gives estimated $g_\parallel \sim 1.935$ and $A_\parallel \sim 180 \times 10^{-4}$ cm^{-1} for this geometry. Consequently, values presented in Table 1 in the pH range 1.5–2.5 agree with those expected for solutions containing $VO(H_2O)_5^{2+}$ and MLH ($g_\parallel$ values somewhat lower than predicted).

Writing the formation as

$$VO^{2+} + nHL \overset{K_n}{\rightleftharpoons} VO(HL)_n^{2+},$$

$K_1 \sim 71$ and $K_1 \sim 69$ for glygly and glyglygly, respectively. These are higher than the corresponding K_1 values for several other amino acids, for gly (14.8),[22] L-ala (15.6),[1] L-ser (12.5),[2] L-thr (12.9),[2] D-pen (20.0),[5] L-cys (15.0)[5] and L-glu (9.3)[6] (the gly values relate to a different medium, 1 M $NaClO_4$), and of the same magnitude as K_1 for aspartic acid (78).[3]

K_1 values were reported as 186 and 245 for nickel complexes of GG and GGG, respectively, and $K_{ML} = 3.8$ for Ni^{II} binding at *N*-acetylglycine.[23] For Cu^{II}, several values have been reported for MLH complexes (L = GG or GGG) in the range $\log K_1 = 1.04–1.89$[16,18,24–28] and $\log K_{ML} = 1.3$ for monodentate coordination of *N*-acetylglycinate.[19] Apparently, the most reliable data come from the work of Shtyrlin *et al.*[18] for the Cu^{II}–glygly system, $\log \beta_{111} = 9.36$ and $\log K_1 = 1.04$ at 25°C and $I = 1.0$ M KNO_3. In that work the β_{111} value was determined from spectrophotometric data in calculations including spectra at high L/M ratios, where this complex has a significant concentration (for L/M = 1, MLH never exceeds 5% of the total copper).

In Fig. 8 we include a representation of $\log K_1$ vs pK_{a1} for vanadyl complexes involving the "monodentate" coordination of the carboxylate group. In this figure, "normal" values are expected to lie inside the region marked with dashed lines and it

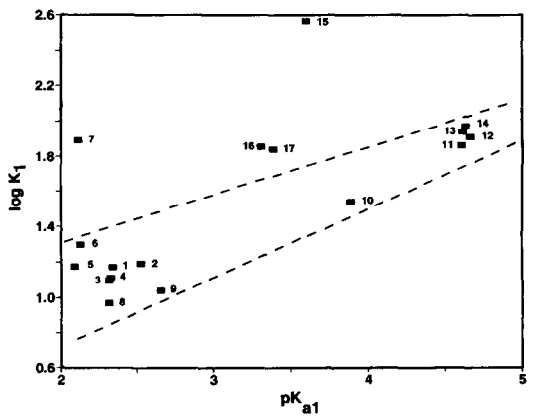

Fig. 8. Representation of $\log K_1$ (see text) vs pK_{a1} for vanadyl complexes involving the "monodentate" coordination of the carboxylate group. (1) Gly;[22] (2) L-ala;[1] (3) L-ser;[2] (4) L-thr;[2] (5) L-cys;[5] (6) D-pen;[5] (7) asp;[3] (8) L-glu;[6] (9) chloroacetate;[31] (10) chloropropionate;[29] (11) acetate;[29] (12) propionate;[30] (13) butyrate;[30] (14) isobutyrate;[30] (15) hydroxyacetate;[31] (16) glygly (this work); (17) glyglygly (this work).

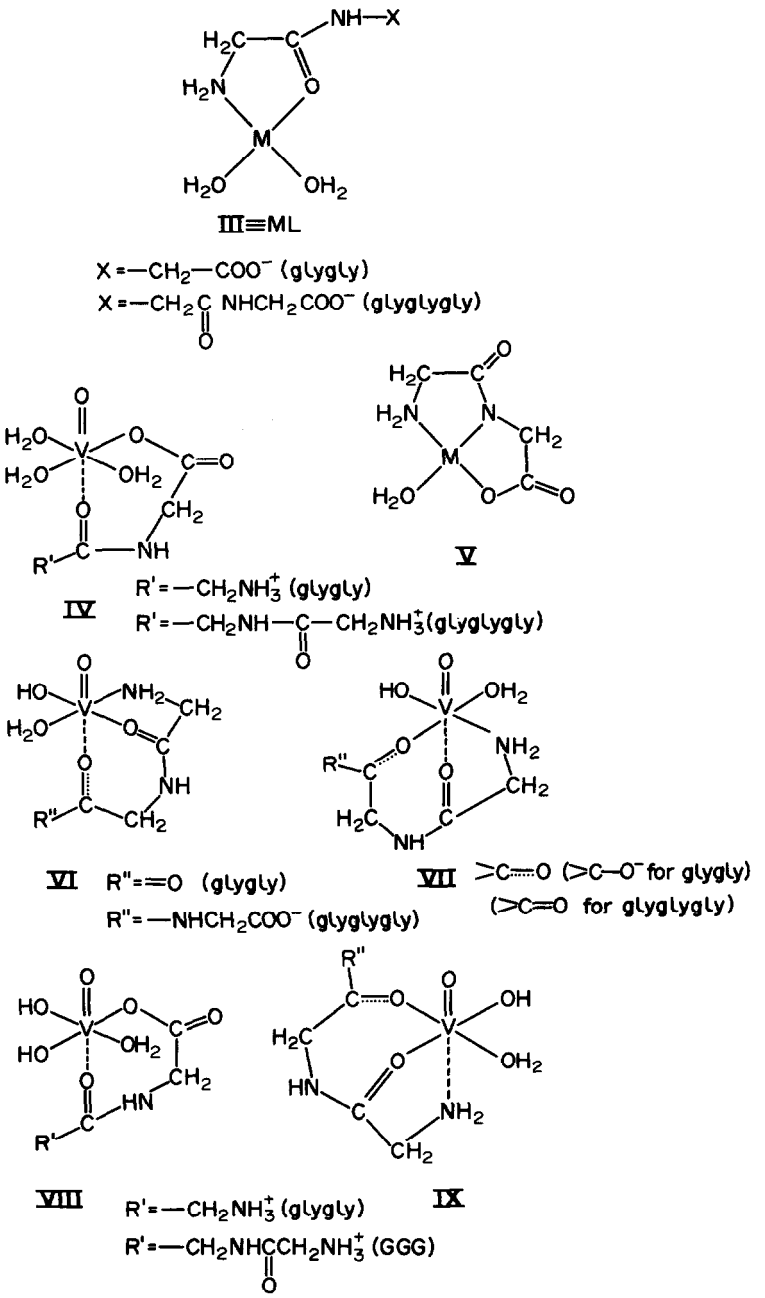

may be seen that values for glygly and glyglygly fall outside (above) this region. The fact that K_1 values for GG and GGG are considerably higher than those obtained for several other amino acids and carboxylates[29–31] cannot be easily understood. Shtyrlin *et al.*[18] argue that for Cu^{II}, coordination in the zwitterionic form (HL) is more favoured for dipeptides as compared to amino acids, because intramolecular hydrogen bonding between the $—NH_3^+$ group and the $—COO^-$ group of the non-coordinated zwitterion (cyclization) is more advantageous for amino acids owing to the steric requirements. The high K_1 values obtained may also arise from amide oxygen coordination. This requires the formation of a seven-membered chelate ring, which is unlikely for bidentate coordination in equatorial positions. However, if coordination is equatorial/axial as in **IV**, steric constraints appear to be much less, due to the much longer bonds typically formed in vanadyl axial positions, 2.3–2.4 as against 1.9–2.0 Å[15] in equatorial/equatorial. For glyglygly the coordination of the second amide oxygen in an equatorial position can also be envisaged.

ML_2H_2. This stoichiometry probably corresponds to complexes with two monodentate α-carboxylate groups coordinated equatorially. For

this coordination geometry, one can estimate[14] $g_{\parallel} \sim 1.937$ and $A_{\parallel} \sim 177 \times 10^{-4}$ cm^{-1}. The values presented in Table 1 in the pH range 2.5–3.5 consequently agree with those expected for solutions containing $VO(H_2O)_5^{2+}$, MLH and ML_2H_2 ($g_{\parallel}$ somewhat lower than predicted).

From Table 2, $K_1K_2 \sim 454$ and ~ 637 for glygly and glyglygly, respectively, again higher than the corresponding values for L-ala (30)[1], L-ser (24),[2] L-cys (45),[5] D-pen (70)[5] and L-glu (15).[6] Apart from differences in ε values, both visible spectra for ML_2H_2 are similar to those for the corresponding MA_2H_2, MS_2H_2, MP_2H_4 and ME_2H_4. K_2 values are ~ 6 and ~ 9 for GG and GGG, respectively. These are "normal" values, suggesting that coordination of a second ligand molecule involves monodentate coordination of the carboxylate group. At this point, we re-emphasize that the stoichiometry for each "species", $M_pL_qH_r$, corresponds to more than one isomer. Relative isomeric concentrations are independent of concentrations of metal, ligand and H^+, so our experimental techniques do not discriminate between them (in some cases, detailed study of the EPR spectra may ultimately help do this). Therefore, not only each formation constant, but also the visible (and CD) spectra reflect the features of each isomer in proportion to the relative importance. For example, in the case of ML_2H_2 stoichiometry, the value for β_{122}(*trans*) and the electronic spectra may involve contributions from both.

In the present cases, and for steric reasons, it is possible that the *trans* isomer predominates over the *cis*. However, three observations suggest that if different ratios of *cis* and *trans* isomers do indeed form in these various systems, these are not clearly reflected in the calculated visible absorption spectra and in the experimental EPR spectra:

(i) the similar types of visible absorption spectra for VO^{2+}, MLH and ML_2H_2 for both GG and GGG + VO^{2+} systems;

(ii) the similarity between the spectra calculated for MLH and ML_2H_2 and the corresponding species in most of the systems previously studied;[1–6] and

(iii) the type of EPR spectra obtained in the low pH region, where—as pH is increased—the spectrum appears like that of only one component but the peaks actually shift to lower field in an approximately continuous manner.

It is possible that CD spectra for peptides such as gly–L-ala, L-alagly and L-ala–L-ala[12] reflect these differences much more strongly than do visible spectra. However, because the systems are quite complicated, the differences found in CD spectra for the corresponding stoichiometries in the several systems studied[1–6] may also partly arise from mathematical artifacts, so that no safe conclusions can be made.

MLH_{-1}. Except for the absence of ML, species distributions as a function of pH for pH $\lesssim 4.5$ are quite similar in the VO^{2+} + GG and Cu^{2+} + GG[18] systems. Namely, for pH $\gtrsim 4$, the concentration of the MLH_{-1} stoichiometry increases steeply in both systems. However, while in the Cu^{2+} + GG (and GGG) system this stoichiometry corresponds to the formation of a complex such as **V**, in the VO^{2+} + GG (and GGG) systems, the spectroscopic results indicate that rather than deprotonation of the amide hydrogen in the pH range 4–5, hydrolysis occurs. Besides, the fact that the representations of $\log \beta_{11-1}$(VO) vs $\log \beta_{11-1}$(Cu), either for GG or GGG, lie above the straight line indicates different structures for Cu^{II} and VO^{II} complexes.

Several plausible structures, e.g. **VI–IX** may then be envisaged for this stoichiometry. In **VI** and **VIII**, coordination in an axial position may occur, although for **VI** this involves some steric constraints. For GGG there is still the possibility of coordination of the carboxylate group (in **VI**, **VII** and **IX**) in an equatorial position. The OH^- groups may be coordinated in different sites and the vanadyl group is lop-sided; therefore each structure **VI–IX** only indicates a type of coordination geometry corresponding to several isomers.

CD spectra of gly–L-ala, L-ala–L-ala and L-alaninamide + VO^{2+} solutions in the pH range 3.5–4.5 suggest[12] the formation of **VI** and, in the case of glygly, the coordination of the carboxylate group. Species **VI** may result from hydrolysis of complexes such as **III**. As mentioned above, our results suggest that complexes corresponding to ML stoichiometry do not form in significant concentrations in solutions containing GG or GGG + VO^{2+}. At pH values where ML could eventually form, hydrolysis occurs in competition with $-NH_3^+$ dissociation and in calculations with SQUAD only $\log \beta_{11-1}$ is refined in a consistent manner. Therefore, on increasing pH, MLH and ML_2H_2 form MLH_{-1} "directly".

(*Received* 5 *February* 1993; *accepted* 14 *June* 1993)

Abstract—The syntheses and characterizations of two new amine oxime ligands are described. In addition, the crystal structure of the dihydrochloride salt of the previously reported 2-[*N*-(4-aminobenzyl)]amino-3-methyl-2-butanone oxime (aminobenzAO) is reported. This structure features a three-dimensional network of hydrogen bonds involving the amine and oxime groups, the chloride ions and the water molecule of crystallization. The crystal structure of the nickel(II) complex of this ligand, $[Ni(aminobenzAO)_2]ClO_4$, is reported. This structure features near square planar bonding of the two oxime nitrogen atoms and the two aliphatic amine nitrogen atoms to the nickel(II) atom with dangling aromatic amine groups. A strong intramolecular O---O hydrogen bond links the two *cis* oxime groups. Because of crystallization difficulty only a qualitative crystal structure of the rhodium(III) complex of the corresponding 4-nitrobenzyl ligand $[Rh(nitrobenzAO)_2Cl_2]$ is included. The octahedral structure is analogous to previously reported complexes with *cis* oxime nitrogen atoms, *cis* amine nitrogen atoms and *trans* chloride ligands.

Labelling of monoclonal antibodies with radioisotopes for imaging or therapeutic purposes continues to be under investigation in our laboratory for possible application in the field of nuclear medicine. One approach for labelling antibodies is the use of bifunctional chelating agents. These compounds can bind tightly to a metal ion and also covalently link with amino acid residues of the antibody. A review of the field has recently been given by Goldenberg.[1] We have been investigating the preparation of bifunctional chelating agents to complex the ^{105}Rh radioisotope[2–4] and have shown that rhodium readily forms a very stable bis complex with 3-amino-3-methyl-2-butanone oxime (α-amine oxime).[5] We recently reported the synthesis of a bifunctional ligand formed by adding a *p*-aminobenzyl substituent on the amine nitrogen of an α-amine oxime.[6] Radiochemical studies with the ^{105}Rh complex of this ligand were also reported. Here we report the crystal structures of the chloride salt as well as the nickel complex of that ligand. The syntheses of two more amine-nitrogen substituted ligands with *p*-nitrobenzyl and *p*-(amino)phenyl substituents are described. Low quality crystals of the rhodium complex of the *p*-nitrobenzyl substituted α-amine oxime could be isolated, and a crude structure was determined by X-ray diffraction.

EXPERIMENTAL

Preparation of the compounds

3-[N-(4-*Nitrobenzyl*) *amino*]-3-*methyl*-2-*butanone oxime* (p-*nitrobenzyl amine oxime*). 4-Nitrobenzylamine hydrochloride (2.20 g, 11.66 mmol) was dissolved in 70 cm^3 of water. NaOH (11.66 mmol) was added slowly and the solution was extracted with $CHCl_3$. $CHCl_3$ portions were col-

* Present address: Department of Chemistry, University of Southwestern Louisiana, Lafayette, LA 70504, U.S.A.

† Author to whom correspondence should be addressed.

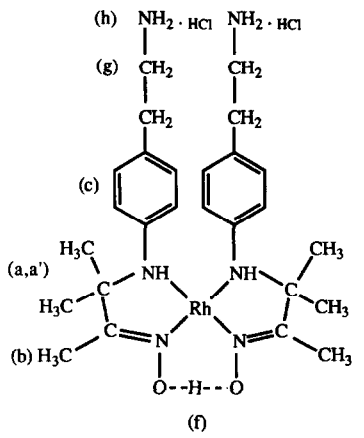
lected, the solvent was evaporated and the resulting 4-nitrobenzylamine was dried (1.379 g, 9.072 mmol). The amine was dissolved in 50.0 cm^3 of absolute methanol, brought to 0°C in an ice bath and combined with 1.414 g (10.43 mmol) of α-chloro oxime. The mixture was brought to room temperature very slowly and then refluxed for 24 h. After the solvent was evaporated, the residue was dissolved in water and the free α-amine oxime was precipitated by the addition of KOH solution. The precipitate was recrystallized from ethanol. Yield was 58% after recrystallization, m.p. 135–136°C. ^{1}H NMR (DMSO-d^6): (a) 1.19s, 6H, (b) 1.71s, 3H, (c) doublet centred at 3.54 ppm, 2H, (d) triplet centred at 2.61 ppm, < 1H, (e) two doublets centred at 7.61 and 8.16 ppm, 4H, (f) 10.48s, 1H.

3-[N-(4-(2-*Aminoethyl*) *phenyl*) *amino*]-3-*methyl*-2-*butanone oxime*·HCl [*(aminoethyl)phenylamine oxime hydrochloride*]. 2-(4-Aminophenyl)ethylamine (1.32 ml, 1.36 g, 10 mmol) was put into 15 cm^3 of absolute methanol. α-Chloro oxime (1.35 g, 10 mmol) was added and stirred at room temperature for 18 h. The solvent was evaporated to dryness. The residue was an orange oily solid. It was dried under vacuum. The ^{1}H NMR spectrum indicated that the reaction mainly occurred through the aromatic amine, with a very small amount through the aliphatic amine. Comparison of the peak intensities showed that the product was mainly (> 80%) composed of that form. In melting point determination, a small part of the solid melted at 139–140°C, but the main portion melted at 149–150°C. ^{1}H NMR (DMSO-d_6): (a) 1.36s, 6H, (b) 1.69s, 3H, (g) broad multiplet around 2.78 ppm, (e) multiplet centred at 6.73 ppm, (h) broad, 8.12 ppm, 3H, (f) 10.60s, 1H.

[Ni(aminobenzAO)$_2$]ClO_4. Aminobenzyl amine oxime (0.0286 g, 0.129 mmol)[6] was dissolved in 2.5 cm^3 of ethanol, and $NiCl_2 \cdot 6H_2O$ (0.0285 g, 0.12 mmol) in 2 cm^3 of water was added. The pH was 6. The addition of $NiCl_2 \cdot 6H_2O$ changed the colour from light yellow to very dark yellow–orange. The solution was saturated with $NaClO_4$. Slow evaporation of the solvent first produced yellow crystals which were the protonated form of the ligand as indicated by ^{1}H NMR spectrum. A few days later, dark orange coloured crystals of the product formed. ^{1}H NMR (DMSO-d^6): (a,a') 0.93s and 1.43s, 12H, (b), 1.80s, 6H, (d) 5.31, 2H, (g) 4.73m, (e) two doublets centred at 6.67 and 7.41 ppm, (f) 18.31s, 1H. The (c) protons are covered by the H_2O signal at 3.30 ppm. IR (fluorolube mulls in NaCl cells): weak band at 1790 cm^{-1} due to short hydrogen bond between the oxime oxygens.

[Rh(nitrobenzAO)$_2$Cl$_2$]. NitrobenzAO ligand (0.374 g, 1.3 mmol)[6] in 10 cm^3 ethanol was combined with $RhCl_3 \cdot 3H_2O$ (0.153 g, 0.58 mmol) in 3 cm^3 water. The solution was refluxed for several hours, and the colour remained dark brown. Upon cooling, a brownish yellow precipitate formed and was collected by filtration. Yield was 51.5%. This precipitate was soluble in DMSO, $CHCl_3$, acetic acid, acetone, ethanol and methanol, but none of these solvents produced suitable X-ray crystals. Finally, poor quality crystals were obtained from ethyl acetate after the solution was left in the refrigerator for several days. The crystal used for the X-ray study contained approximately two molecules of ethyl acetate per rhodium complex, some of which was clearly lost in the analysed material. Found: C, 43.5; H, 5.1; N, 11.9. Calc. for $RhCl_2O_6N_6C_{24}H_{33} \cdot 0.5CH_3COOC_2H_5$: C, 43.4; H, 5.2; N, 11.7%. ^{1}H NMR (DMSO-d^6): (a,a') 1.21s and 1.39s, 12H, (b) 2.10s, 6H, (c) and (d) complex pattern at 4.18–5.31 ppm, 6H, (e) 7.38–8.18m, (f) 19.36–19.49 ppm. IR (fluorolube mulls in NaCl cells): weak band at 1792 cm^{-1} due to short hydrogen bond between the oxime oxygens.

[Rh(aminoethylphenAO)$_2$Cl$_2$]



[Rh(aminoethylphenAO)$_2$Cl$_2$]. Aminoethylphen AO (0.104 g, 0.441 mmol) was dissolved in 6.5 cm^3 ethanol, and to this was added $RhCl_3 \cdot 3H_2O$ (0.058 g, 0.22 mmol) in 3 cm^3 of H_2O. The mixture was refluxed for 2 h and the pH dropped from 2 to 0.5. The pH was adjusted to 7 with NaOH, and refluxing was continued for 15 min. Evaporation of some of the solution yielded a dark yellow, finely divided solid which had very limited solubility in common solvents. Numerous attempts to grow crystals were unsuccessful. However, solubility in DMSO was sufficient to obtain the ^{1}H NMR spectrum of the HCl salt. The IR spectrum as a fluorolube mull showed the expected C—H and N—H stretching vibrations, as well as a weak bond at 1758 cm^{-1}, attributed to a strong

hydrogen bond between oxime oxygen atoms as normally observed for the *cis* bonded oxime groups in related complexes.[4] The NMR spectrum was assigned by comparison with the ligand spectrum and the spectrum of $[Rh(phenAO)_2Cl_2]$[4] as follows: (a,a') 1.09, 1.31s, 12H, (b) 2.21s, 6H, (c) broad multiplet 6.55–7.86, 8H, (f) 19.5s, 1H, (g) multiplet 2.99, 8H, (h) broad 8.37s, 6H (see structure above).

X-ray diffraction

Collection and reduction of X-ray data. X-ray data were collected on an Enraf–Nonius CAD4 automated diffractometer controlled by a Digital PDP 11/34 computer using Mo-K_α radiation ($\lambda = 0.7107$ Å) obtained from a graphite monochromator. Lattice constants were obtained by least-squares fit of 25 carefully centred reflections on each compound. The intensities of three standard reflections measured after every 7200 s of X-ray exposure showed no signficiant variation. Orientation was checked after every 200 reflections with the use of the same standards and all 25 original reflections were recentered when the measured deviation of any of the three standards exceeded 0.07°. The cell data, data collection parameters and refinement results for each structure are summarized in Table 1.

Solution and refinement of the structures. The structures were solved by conventional Patterson and Fourier methods. The full-matrix least-squares refinements minimized the function $\Sigma w(|F_o| - |F_c|)^2$, where $w = 1/\sigma^2(F_o)$, $\sigma(F_o) = \sigma(F_o^2)/2F_o$ and $\sigma(F_o^2) = [\sigma^2_{counting} + (0.04F_o^2)^2]^{1/2}$. Atomic scattering factors were taken from the *International Tables for X-ray Crystallography*[7] and included anomalous scattering contributions. Hydrogen atoms were located by difference Fourier methods or were placed in chemically reasonable positions with $B \sim 1.3 \times B$ of atom attached. For compounds **I** and **II**, positional and anisotropic thermal parameters of non-hydrogen atoms were refined in the least-squares cycles. The ethyl acetate molecules

were badly disordered in compound **III** and were placed with fractional occupancy (isotropic fixed *B*) to accommodate the electron density. This disorder and the related low quality of the data resulted in poor resolution of the entire structure. Thus, details of this structure are not well determined. Coordinates and thermal parameters for the three compounds are available.* The high thermal parameters for some of the atoms of compound **III** are a result of the low quality of the data set.

RESULTS AND DISCUSSION

Figure 1 shows a perspective view of the [Ni(aminobenzAO)$_2$]ClO$_4$. The structure of the compound consists of discrete, mononuclear, cationic nickel(II) complexes with the nickel atoms in a distorted square-planar configuration. The nickel atom coordinates to two amine nitrogens and two oxime nitrogens from the amine oxime ligands, forming two five-membered chelate rings. Also, the loss of an oxime hydrogen results in the other oxime hydrogen forming a hydrogen bond between the two oxime oxygens, closing a six-membered ring. The *p*-amino substituted benzyl groups on the amine nitrogens are in the *trans* position. The positive two charge of the nickel atom is balanced by the loss of one oxime hydrogen and a perchlorate ion. Three of the oxygens in the perchlorate ion [OS(2), OS(3), OS(4)] have second positions [OS(5), OS(6), OS(7)] occupied to the extent of 0.20. The crystal structure also contains a water molecule. The torsional angles indicate that the twist angles of the two methylene bridges from the molecular plane are the same, but the two ring planes make angles that are about 27° different with respect to the metal coordination plane. The dihedral angles between the least-squares plane of coordination and the phenyl rings confirm the results derived from the torsional angles. One of the phenyl rings is only 6.9(1)° away from being perfectly perpendicular to the coordination plane, while the other phenyl ring makes an angle of 51.3(1)° with this plane. The square plane around nickel is significantly distorted towards tetrahedral geometry. The *trans* N(1) and N(2′) atoms are 0.183(3) and 0.170(3) Å, respectively, above the plane and the *trans* N(1′) and N(2) atoms are 0.159(4) and 0.148(3) Å, respectively, below the plane. Pertinent intramolecular bond distances and bond angles involving non-hydrogen atoms are given in Table 2. The short intramolecular O---O hydrogen bond length in this compound is 2.404(4) Å. The only intermolecular contact less than 3.5 Å involving non-hydrogen atoms and non hydrogen bonding is the O(1)—C(3′) distance of 3.303(9) Å. The distances less than 3.3 Å and involving ClO$_4$ and water contacts with the molecule are: O(1′)—OW: 2.964(8) Å, N(1′)—OS(2): 3.30(1) Å, N(2′)—OS(2): 3.085(9) Å, N(3)—OS(1): 2.958(8) and N(3)—OW: 2.967(7) Å. There is a weak hydrogen bond between N(3) and OW as can be seen from the following distances: H(1)N(3)—OW: 1.84 Å, H(1)N(3)—N(3): 1.17 Å and the angle N(3)—H(1)N(3)—OW: 162°. Other weak hydrogen bonding interactions are as follows: HN(2′) interacts with OS(2) [HN(2′)—OS(2): 1.96 Å, HN(2′)—N(2′): 1.24 Å, N(2′)—HN(2′)—OS(2): 148°]; H(2)N(3) interacts with OS(1) [H(2)N(3)—OS(1): 1.81 Å, H(2)—N(3)—N(3): 0.89 Å, N(3)—H(2)N(3)—OS(1): 150°]; H(2)—N(3′) interacts with O(1′) [H(2)N(3′)—O(1′): 2.34 Å, H(2)N(3′)—N(3′): 1.06 Å, N(3′)—H(2)N(3′)—O(1′): 146°] and OW [H(2)N(3′)—OW: 2.96 Å, N(3′)—H(2)N(3′)—OW: 126°]. The hydrogen bonds involving OW as the donor are less well defined since hydrogen atoms on OW could not be satisfactorily located.

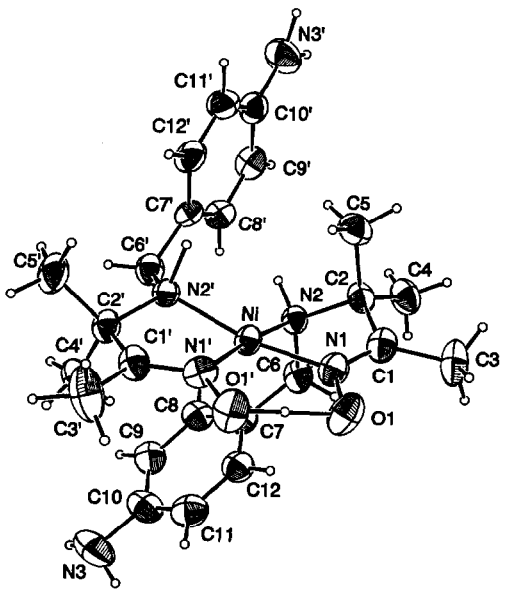

Fig. 1. Perspective view of [Ni(aminobenzAO)$_2$]ClO$_4$.

Figure 2 shows a perspective view of the aminobenzAO·2HCl molecule. Both of the amine nitrogens are protonated in the dipositive organic cation. The molecule forms a three-dimensional network of hydrogen bonds involving amine and oxime groups, chloride ions and water molecules. The crystal contains one water molecule per organic molecule. Pertinent intramolecular bond distances and bond angles involving non-hydrogen atoms are given in

*Atomic parameters, least-squares planes and complete tables of bond distances and angles are available through the Cambridge Crystallographic Data Centre.

N(3)—H(2)N(3)---OW	0.96	1.79	172
N(3)—H(3)N(3)—Cl(2)	0.97	2.25	168

Table 2. Bond distances and angles are rather normal. An interesting comparison is that of the oxime N—O [1.416(3) Å] and C=N [1.267(4) Å] with those in the nickel complex of 1.36(1) and 1.283(2) Å, respectively. Thus, the fully protonated oxime has a considerably longer N—O distance but only a slightly shorter C=N distance. The protonated aromatic amine nitrogen has a considerably longer C—N bond [1.448(4) Å] than the unprotonated counterpart in the nickel complex [1.390(2) Å]. Apparently there is significant π interaction of the amine lone pair of the latter with the aromatic system. Other distances in the uncomplexed ligand are very similar to those in the nickel complex. There are major differences in bond angles, particularly for those atoms involved in the chelate ring with the nickel(II) atom. The bond distances and the bond angles involved in the hydrogen bonding interactions (shown in Fig. 2) are summarized in Table 3. All of the amine and oxime hydrogen atoms and one of the water hydrogen atoms are involved in the hydrogen bonding network. Each chloride accepts three hydrogen bonds while the water is the acceptor for one hydrogen bond.

The ^{1}H NMR spectral results were given earlier in the preparation section. The most characteristic peaks of the ^{1}H NMR spectra of the ligands are the low field oxime proton signal around 10.5 ppm for the uncomplexed ligand and the high field signals due to the methyl protons. The formation of the complexes is generally revealed by the movement of the 10.5 ppm oxime peak to 18–19 ppm and by the splitting of the geminal methyl signal (singlet in the ligand) due to the different environments these methyl groups experience in the complex. That is observed here in going from the hydrochloride salt to the nickel complex. The IR spectrum of [Ni(aminobenzAO)$_2$]ClO_4 shows a broad, very weak band at 1790 cm^{-1}, due to the intramolecular O---O hydrogen bond, as normally found for this type of hydrogen bond.

The structural results for [Rh(nitrobenzAO)$_2$$Cl_2$] suffer from the disordered ethyl acetates of

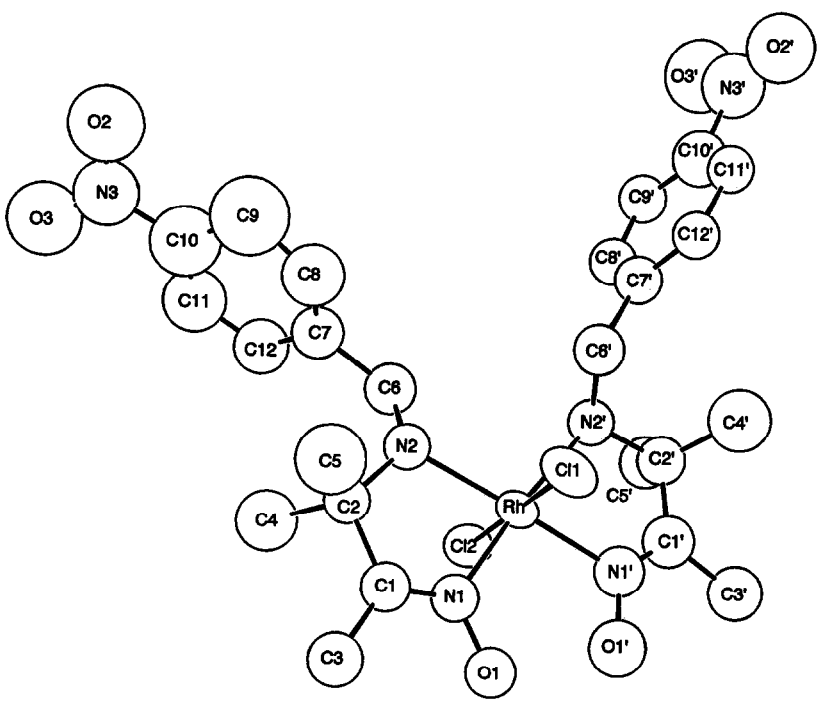

Fig. 3. Perspective view of [Rh(nitrobenzAO)$_2$$Cl_2$].

solvation. However, the immediate coordination of the rhodium(III) is clearly resolved (Fig. 3), as is all of the ligand geometry except for the nitro moiety on one of the benzyl groups. Despite the poor resolutions, the orientations of both benzyl groups are clearly defined. Pertinent bond distances and angles (Table 2) are generally reasonable (albeit of very low precision) except for those involving the poorly resolved nitro group [N(3), O(2), O(3)]. The phenyl rings make similar dihedral angles of 76.8(7)° and 75.4(5)° with the Rh, N(1), N(1′), N(2), N(2′) coordination plane. The latter is truly planar within experimental error.

The structures of the two metal complexes clearly demonstrate the steric freedom of the *para* substituents on the phenyl rings for possible use in additional reactions such as attachment to protein molecules.[4]

METAL HYDROXYCARBENE-LIKE INTERMEDIATES IN THE HYDROCARBONYLATION OF ALKENES TO ALCOHOLS CATALYSED BY RHODIUM COMPLEXES

JOANNA K. MACDOUGALL, MICHAEL C. SIMPSON and DAVID J. COLE-HAMILTON*

Chemistry Department, University of St Andrews, St Andrews, Fife KY16 9ST, U.K.

(*Received* 10 *September* 1993; *accepted* 28 *September* 1993)

Abstract—Labelling studies show that aldehydes are not intermediates in the formation of heptanol from 1-hexene, CO and H_2 catalysed by $[RhH(PEt_3)_3]$ in ethanol, whilst studies of model intermediates suggest that ethanol hydrogen bonds to or even protonates an acyl oxygen atom to give a hydroxycarbene-like intermediate in the direct formation of heptanol.

Metal carbenes have been shown to be important intermediates in e.g. alkene metathesis, where the catalyst is a high oxidation state early transition metal complex.[1] However, they have not been identified as catalytic intermediates in reactions catalysed by platinum group metal complexes although we have suggested,[2] on the basis of model studies,[3] that carbon monoxide hydrogenation catalysed by ruthenium complexes may involve protonation of a formyl complex to give a hydroxycarbene intermediate and Consiglio and co-workers have suggested that related cyclic oxacarbenes may be intermediates in the stereoregular copolymerisation of CO and propene in the presence of palladium catalysts.[4] We now report studies which suggest that hydroxycarbene-like complexes are important intermediates in the hydrocarbonylation of alkenes to alcohols catalysed by e.g. $[RhH(PEt_3)_3]$ in alcoholic solvents.

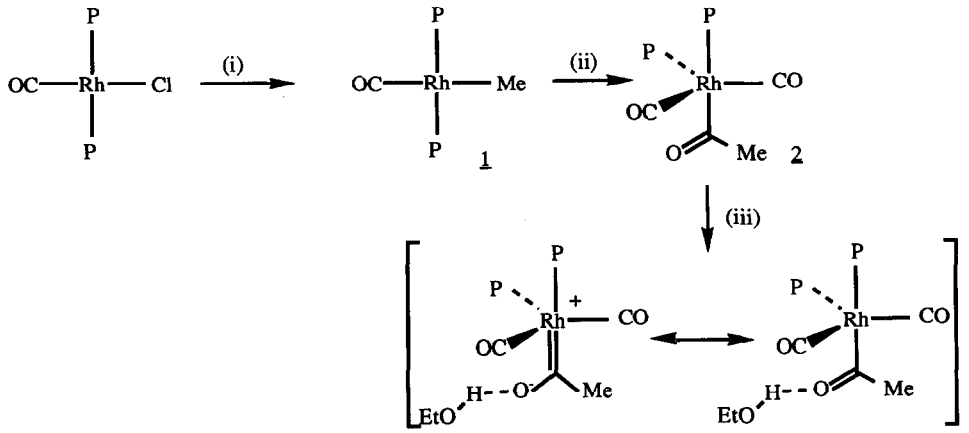
We have recently reported[5] that, under hydroformylation conditions using $[RhH(PEt_3)_3]$ as catalyst precursor, alkenes give high selectivities to alcohols rather than aldehydes if the reaction is carried out in e.g. ethanol as solvent. In order to try to understand the reason for this unusual selectivity, we have carried out labelling studies and some stoichiometric reactions.

Hydrocarbonylation of 1-hexene using this system and D_2 in place of H_2 selectively produces $CH_3CH_2CH_2CH_2CHDCH_2CD_2OH/D$.† However, when the same catalyst system is used for the hydrogenation of heptanal using D_2 and CO in ethanol the product is a mixture of $CH_3CH_2CH_2CH_2CH_2CHXOH/D$ [X = H (60%) or D (40%)]. Experiments using H_2 in EtOD or D_2 in EtOD have confirmed that the source of added H on C_1 in the product of heptanal hydrogenation with CO/D_2 in ethanol is the alcoholic hydrogen atom of the solvent. If heptanal were an intermediate in the formation of heptanol from hexene then, when D_2 in EtOH is employed, some $CH_3CH_2CH_2CH_2CHDCH_2CHDOD$ would be expected in the product heptanol. Since this is not observed, we must conclude that the formation of heptanol from 1-hexene, CO and H_2 in this system does not pass through heptanal as an intermediate.

In order to seek for an alternative mechanism for the formation of heptanol from hexene in this system, we have carried out stoichiometric studies aimed at identifying the active species in the catalytic cycle. Thus, most hydroformylation mechanisms using complexes of the form $[RhH(CO)P_3]$ (P = tertiary phosphine) go through steps (loss of P, coordination of alkene and insertion of alkene into the M—H bond) which lead to intermediates

*Author to whom correspondence should be addressed.

†The branched product, $C_4H_9CH(CH_2D)CD_2OH$, is also formed.



Scheme 1. Stoichiometric reactions of rhodium complexes. (i) MeLi, Et_2O; (ii) CO, toluene; (iii) EtOH; P = PEt_3.

of the form $[RhR(CO)P_2]$ (R = alkyl)[6]; CO coordination and insertion then give an acyl intermediate. In order to investigate these intermediates, we have synthesised $[RhMe(CO)(PEt_3)_2]$ (**1**)* by reaction of $[RhCl(CO)(PEt_3)_2]$ with MeLi and studied its chemistry. $[RhMe(CO)(PEt_3)_2]$ reacts with CO at 1 atm in toluene, thf or CH_2Cl_2 to give high yields of $[Rh(COMe)(CO)_2(PEt_3)_2]$ (**2**)* with the structure shown in Scheme 1. This compound is analogous to an intermediate identified by Brown and co-workers in hydroformylation of oct-1-ene catalysed by $[RhH(CO)(PPh_3)_3]$.[7]

On addition of ethanol (0.2 cm^3) to a solution of $[Rh(COMe)(CO)_2(PEt_3)_2]$ ($\sim$0.2 mol dm^{-3}) in toluene, thf, or CH_2Cl_2 (0.9 cm^3), important changes occur in the ^{31}P and ^{13}C NMR spectra. Although the general form of the spectra is the same, the resonance from one of the phosphorus atoms shifts to higher field, whilst the resonance from the acyl carbon atom shifts from 238.0 to 246.8 ppm (values given are for toluene but very similar values are obtained in thf or CH_2Cl_2). This large downfield shift (10.2 ppm if $[Rh(COMe)(CO)_2(PEt_3)_2]$ is dissolved in neat ethanol) is in the direction of the region where the carbenic carbon atom of alkyl hydroxycarbene[8] or alkoxycarbene[9] ligands are known to resonate (290–330 ppm). Figure 1 illustrates the effect on the chemical shift of the acyl carbon atom of $[Rh(COMe)(CO)_2(PEt_3)_2]$ of adding increasing amounts of ethanol. Analysis of these results indicates that the reaction involves 1 mol of ethanol per mol of complex and that the apparent equilibrium constant for the interaction is $\sim$0.3 dm^3 mol^{-1}. These measurements were made at -60°C and in all cases only one resonance was observed for the acyl C atom indicating that whatever the equilibrium process it is occurring rapidly on the NMR time-scale. Furthermore, the acyl species gives a non-conducting solution in ethanol. All of these results suggest that ethanol becomes hydrogen bonded to the acyl oxygen atom of the model complex, $[Rh(COMe)(CO)_2(PEt_3)_2]$ and this conclusion is supported by ^{13}C NMR studies on addition of CF_3CH_2OH to $[Rh(COMe)(CO)_2(PEt_3)_2]$ (Fig. 1). The overall shift of the resonance from the acyl C atom (19.7 ppm) is greater than for ethanol, as expected for the more acidic alcohol, but the apparent equilibrium constant is not greatly different.

In the catalytic cycle, the related intermediate to which oxidative addition of hydrogen will occur is the four coordinate $[Rh(COR)(CO)(PEt_3)_2]$. Having one less CO ligand, the electron density on the metal will be even higher than for $[Rh(COMe)(CO)_2(PEt_3)_2]$ and hence the oxygen atom of the acyl ligand will hold a higher negative charge. Hydrogen bonding by an ethanol molecule will be even stronger for this complex and may even lead

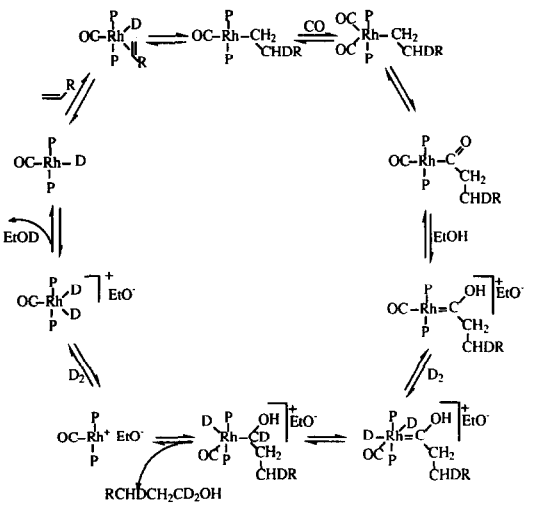
Fig. 1. Effect of adding ethanol (⊡) or trifluoroethanol (●) on the chemical shift of the acyl C atom of $[Rh(COMe)(CO)_2(PEt_3)_2]$. The shifts are to lower field. The initial solutions contained $[RhMe(CO)(PEt_3)_2]$ (0.15 g for EtOH, 0.10 g for CF_3CH_2OH) in thf (0.5 cm^3). They were treated with CO to give quantitative conversion to $[Rh(COMe)(CO)_2(PEt_3)_2]$ prior to addition of the alcohol.

to protonation to give a hydroxycarbene. Indeed, the difference between protonation and H-bonding is only a small shift in position for the potential well in which the H atom sits. Protonations of formyl or acyl oxygen atoms to give hydroxycarbene complexes are known in other systems, although strong acids are usually required.[3,10–12] Whether full protonation or strong hydrogen bonding occurs, the M—C bond will have significant double bond character making the acyl ligand more carbene-like. Many metal formyl complexes have short M—C bonds and long C—O bonds indicative of a similar contribution of an oxycarbene resonance form.[13]

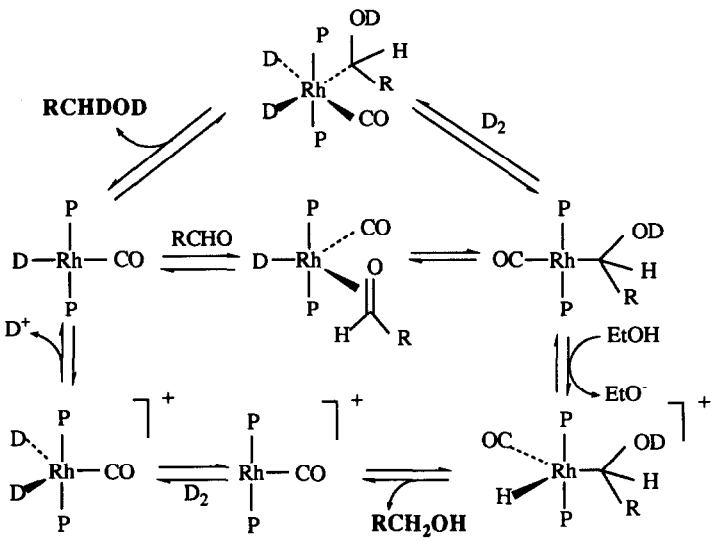
After oxidative addition of H_2 to the four coordinate complex containing the carbene-like ligand, transfer of H to the carbene-like C atom would not lead to reductive elimination of aldehyde, but rather to the formation of a hydroxyalkyl complex which would reductively eliminate with the other H atom on the metal to give C_7 alcohols as the primary products (see Scheme 2).

Evidence that similar intermediates to those we have modelled are important under catalytic conditions is provided by ^{31}P studies of a reaction solution containing $[RhH(PEt_3)_3]$ in ethanol under 20 atm. of CO, H_2 and C_2H_4. After heating to 100°C and cooling to −60°C, resonances with similar chemical shifts and couplings to those from $[Rh(COMe)(CO)_2(PEt_3)_2]$ in ethanol are observed as significant features of the spectrum.* These presumably arise from $[Rh(COEt)(CO)_2(PEt_3)_2]$ with ethanol hydrogen bonded to the acyl oxygen atom.



Scheme 2. Proposed mechanism for production of deuterated heptanol from 1-hexene, CO and D_2 catalysed by $[RhH(PEt_3)_3]$. $[RhHCO(PEt_3)_2]$ is formed from $[RhH(PEt_3)_3]$; deuterated 2-methylhexanol is produced *via* a similar mechanism involving Markownikoff insertion of the alkene into the M—H bond. Full protonation of the acyl is shown, although hydrogen bonding of ethanol to the acyl oxygen is also possible. P = PEt_3.

*^{31}P NMR (EtOH, 213 K) 17.2 *dd*, J_{RhP} = 68.5; 10.2 *dd*, J_{RhP} = 135, J_{PP} = 36.



Scheme 3. Possible mechanism for production of $C_6H_{13}CHXOH/D$, X = H or D on hydrogenation of heptanal in EtOH catalysed by $[RhH(PEt_3)_3]$ with D_2/CO in the gas phase. P = PEt_3, R = C_6H_{13}.

Further support for the importance of hydrogen bonding or protonation in this system comes from observations of the products of hydrocarbonylation of 1-hexene in thf catalysed by $[RhH(PEt_3)_3]$. After 2 h, the products are aldehydes (100%) whilst if the same reaction is carried out in the presence of water (50%), alcohols are formed in substantial quantities (50%). The deuteration pattern for $(CH_3)_2CH$-CH_2OH produced on hydrocarbonylation of 2-propen-1-ol by rhodium–triethylphosphine complexes can also best be explained if ethanol protonates or hydrogen bonds to a related hydroxycarbene intermediate.[14]

Unfortunately, $[RhMe(CO)(PPh_3)_2]$ cannot be synthesized from $[RhCl(CO)(PPh_3)_3]$ and MeLi, so a direct comparison between the PPh_3 and PEt_3 systems cannot be made. However, solutions obtained from $[RhH(CO)(PPh_3)_3]$ and hex-1-ene under CO in toluene exhibit resonances* very similar to those of $[Rh(COMe)(CO)_2(PEt_3)_2]$. We tentatively assign them to $[Rh(C(O)hexyl)(CO)_2(PPh_3)_2]$. These resonances remain completely unchanged on addition of ethanol (20%) indicating that the electron withdrawing nature of PPh_3 means that there is insufficient negative change density on the acyl oxygen atom for significant hydrogen bonding to occur to ethanol. These results together with the mechanism of Scheme 2 explain why alcohol production occurs for trialkylphosphines but not for PPh_3. Since PPh_3 is a better π-acceptor than PEt_3, there is then less electron density on the acyl oxygen atom so that protonation is not favoured. C_7 aldehydes, together with acetals are the major products in this case.[5]

Finally, a possible mechanism, which explains the unusual labelling pattern obtained on hydrogenation of heptanal with CO/D_2 in EtOH is shown in Scheme 3. It assumes that insertion of the aldehyde into the Rh—D bond occurs to give a hydroxyalkyl intermediate and that protonation of this intermediate competes with oxidative addition of D_2. Reductive elimination from the cation will give $C_6H_{13}CH_2OH$, whilst reductive elimination from the dideuteride will give $C_6H_{13}CHDOH$.

HYDROCARBONYLATION OF 2-PROPEN-1-OL CATALYSED BY TRIETHYLPHOSPHINE RHODIUM COMPLEXES—FORMATION OF 1,4-BUTANEDIOL AND MECHANISTIC STUDIES

MICHAEL C. SIMPSON, KAREN PORTEOUS, JOANNA K. MACDOUGALL and DAVID J. COLE-HAMILTON*

Department of Chemistry, University of St Andrews, St Andrews, Fife KY16 9ST, U.K.

(*Received* 10 *September* 1993; *accepted* 28 *September* 1993)

Abstract—In ethanol in the presence of $[Rh_2(OAc)_4]$ and PEt_3, 2-propen-1-ol (allyl alcohol) is hydrocarbonylated to a mixture of 1,4-butanediol and 2-methylpropanol; labelling and other studies indicate a mechanism for the formation of 2-methylpropanol in which key steps include protonation of an acyl intermediate by the solvent, dehydration of a bound hydroxycarbene intermediate, formation of a vinyl alcohol *via* an $\eta(1-3)$ allyl intermediate, tautomerization of the vinyl alcohol and hydrogenation of the 2-methylpropanal so formed.

We have reported that reaction of hexene with CO/H_2 in e.g. ethanol in the presence of rhodium catalysts containing PEt_3 gives C_7 alcohols as the products.[1] Labelling and model studies indicate that aldehydes are not intermediates in these reactions and that ethanol hydrogen bonds to or protonates an acyl intermediate to give a hydroxycarbene like species.[2]

We now report that the same catalytic system can be employed for the direct formation of 1,4-butanediol from 2-propen-1-ol (allyl alcohol) and that labelling studies, particularly on the formation of the other product, 2-methylpropanol, are also consistent with the proposed protonation of the acyl intermediate.

Reaction of CO, H_2 and 2-propen-1-ol in ethanol at 120°C in the presence of $[Rh_2(OAc)_4]$ and PEt_3 produces 1,4-butanediol and 2-methylpropanol as the major products (Table 1). 1,4-Butanediol is an important medium volume chemical, which is largely used for tetrahydrofuran synthesis.[3] A plant has recently been installed for its production from 2-propen-1-ol by hydroformylation followed by hydrogenation of the product, 4-hydroxybutanal. The direct synthesis of 1,4-butanediol from 2-propen-1-ol, avoiding the hydrogenation step, is therefore, potentially of considerable interest. 2-Methylpropanol has been observed as a hydroformylation product of 2-propen-1-ol and it has generally been assumed that it arises from dehydration of the branched aldehyde, 2-methyl-3-hydroxypropanal followed by hydrogenation.[4]

We have attempted to determine the mechanisms of formation of 2-methylpropanol and find that neither 2-methyl-2-propenal (methacrolein) nor 2-methyl-2-propen-1-ol (methallylalcohol) are intermediates in its production since neither of these gives more than traces of 2-methylpropanol under the reaction conditions.†

Clearly the product arises from dehydration at some stage in the cycle followed by hydrogenation. A plausible mechanism is shown in the scheme, particularly in view of our studies on other alkenes which suggest that alcoholic solvents protonate, or hydrogen bond to, the acyl oxygen atom of intermediates such as A.[2] Dehydration of the resulting

*Author to whom correspondence should be addressed.

†Methacrolein gives a series of products that have not been identified, whilst methallyl alcohol gives low conversions to 2-methylbutane-1,4-diol and 3-methyl-4-hydroxybutanal, with traces of 2,2-dimethylpropane-1,3-diol.

Table. 1 Products obtained from 2-propen-1-ol under hydrocarbonylation conditions[a]

Pressure (atm.)	[PEt_3] (mol dm^{-3})	Conversion (%)	2-methylpropan-1-ol (%)	1,4-butanediol (%)
10[b]	0.8	100	22	28
20	0.8	100	50	50
30	0.8	100	61	39
40	0.8	100	78	22
50	0.8	100	70	30
60	0.8	100	59	41
40	0.27	100	51	49
40	2.0	100	68	32

[a]$[Rh_2(OAc)_4]$ = 0.04 mol dm^{-3}; H_2 : CO (1 : 1); 120°C, 4 h, 2-propen-1-ol, 1 cm^3 (2.9 mol dm^{-3}) in ethanol, 4 cm^3.

[b]Other products account for *ca* 50% of the total. These include propan-1-ol, γ-butyrolactone and 2-methyl-2-pentenal.

hydroxycarbene would then give the unsaturated carbene species, **B**, with the formation of conjugated double bonds being a strong driving force. Hydrogen transfer would then give the hydroxyallyl intermediate, **C**. Further hydrogen transfer would then give 2-methyl-2-propen-1-ol but since this is not observed as a product and is not an intermediate on the pathway to 2-methylpropanol, we propose that this does not occur but rather that the hydroxyallyl group adopts an $\eta(1\text{–}3)$ bonding mode, **D**. Hydrogen transfer to the unsubstituted end of the allyl group would then give the vinyl alcohol, **E**, which would tautomerize to 2-methylpropanal. Finally, the 2-methylpropanal would be hydrogenated to the observed final product.

Evidence in favour of this mechanism includes the following:

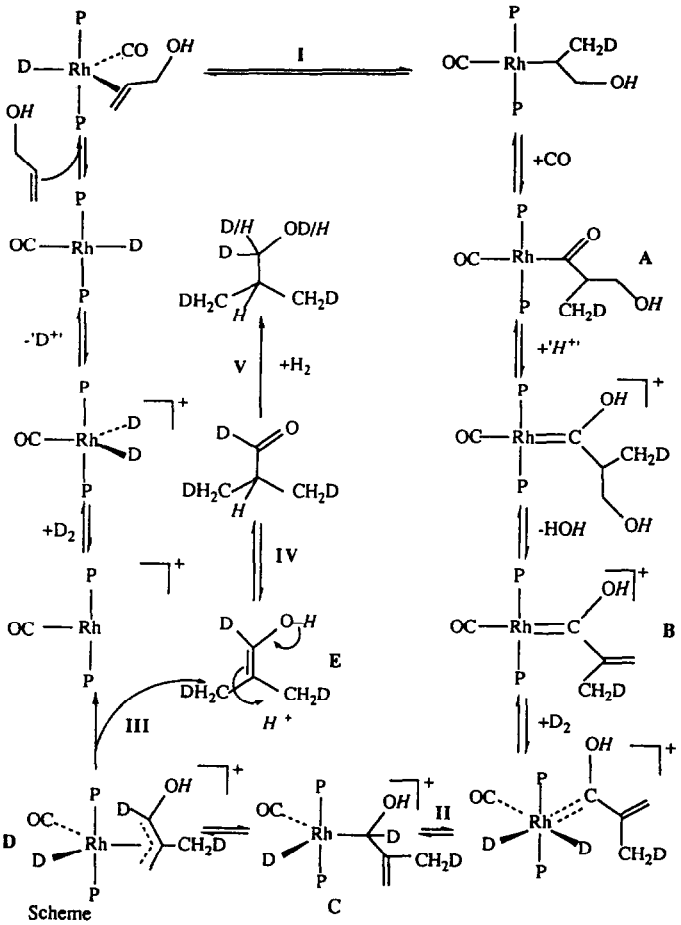
(i) the same catalyst system does hydrogenate 2-methylpropanal to 2-methylpropan-1-ol, exclusively, under the hydrocarbonylation conditions.

(ii) In separate experiments, 2-methylpropanal was hydrogenated under the same conditions but using D_2 in place of H_2. The product is a mixture of $Me_2CHCHDOH/D$ (40%) and Me_2CHCH_2OH/D (60%), showing that some of the H incorporated onto the C atom attached to OHD derives from the gas-phase and some from the solvent (a similar labelling pattern is observed with heptanal and this has been attributed to competitive attack of H^+ and D_2 on a hydroxyalkyl intermediate).[2] Clearly, hydrogenation of the proposed Me_2CHCDO intermediate (as required in step V of the scheme) should lead to Me_2CHCD_2OH/D (40%) and Me_2CH-CHDOH/D (60%). The observed labelling pattern at this C atom is slightly higher in H than expected on this basis because of the larger concentration of OH in the solution (see below) but they are sufficiently close to give us confidence that one H/D atom on this C atom of the final product comes exclusively from the gas-phase (in step II) whilst the other arises from hydrogenation of the aldehyde (step V).

(iii) Under D_2, both of the methyl groups in the product 2-methylpropanol are $-CH_2D$ indicating that both added H atoms originate from the gas-phase. This is as expected, the transfers occurring directly from the metal in steps I and II of the scheme.

(iv) Under D_2 in C_2H_5OH there is no D incorporation onto the secondary C atom of the 2-methylpropanol. This could be explained either if the H atom remained on this C atom throughout the cycle (i.e. dehydration did not involve this H atom) or by the mechanism of the scheme; since the H atom on this C is derived from the solvent in the tautomerism of the vinyl alcohol (step IV). It is well known that this reaction occurs as shown in step IV of the scheme.

(v) Using D_2 in place of H_2 and EtOD in place of EtOH, substantial D incorporation (~50%) does occur onto the secondary C atom of the 2-methylpropanol. Incorporation of D is not 100% because (a) the alcoholic hydrogen in the solution is partly OD (from ethanol) and partly OH (from the substrate propenol) and partly because water (as H_2O or HDO) is released during the cycle and the H atoms in the water will exchange with the alcoholic OH. The exact



Scheme 1. Proposed mechanism for the formation of 2-methylpropan-1-ol from hydrocarbonylation of 2-propen-1-ol. Atoms labelled D arise exclusively from the gas-phase H_2 or D_2; atoms labelled *H* arise exclusively from the solvent OH or OD. Intermediates B to D are shown as cationic—they may have H bonding from the OH group to OEt^-.

percentage of D incorporation onto the secondary C atom can be modelled if a kinetic isotope effect (k_H/k_D) of 3–4 operates on the tautomerization reaction. Isotope effects in this range have been observed for ketonisation of allyl alcohols.[5,6]

These studies allow us to conclude (a) that the final step in the mechanism of formation of 2-methylpropanol is hydrogenation of 2-methylpropanal; (b) that the 2-methylpropanal is almost certainly formed by tautomerism of 2-methyl-2-propen-1-ol; (c) that dehydration of an intermediate must occur and that this intermediate is neither 2-methylpropane-1,3-diol (giving 2-methyl-2-propen-1-ol) nor 2-methyl-3-hydroxypropanol (giving 2-methyl-2-propenal). The dehydration must, therefore, occur from a metal bound intermediate and this cannot be the acyl species, (even though this too would give a conjugated double bond) since H transfer from the metal to this dehydrated species would give 2-methyl-2-propenal, which we have shown is neither a product nor an intermediate.

Overall, the evidence appears to support a mechanism involving steps similar to those shown in the scheme and hence to provide further evidence that this type of rhodium catalyst, containing trialkylphosphines, places sufficient electron density on the acyl oxygen atom to allow protonation of, or hydrogen bonding to, it by solvent alcohols.

(*Received* 6 *September* 1993; *accepted* 28 *September* 1993)

Abstract—A new range of dialkyl α-hydroxyiminophosphonates has been prepared and the first examples of metal complexes of this class of compound have been obtained; X-ray crystal structure analysis of the dichlorobis(diethyl *E*-(α)-hydroxyiminopropanephosphonate)nickel(II) complex shows a distorted octahedral coordination at the nickel atom giving two symmetry related diethyl-(*E*)-α-hydroxyiminopropanephosphonate ligands and two chlorine donors.

Bioactive phosphorus containing molecules have long been used in the fields of agriculture[1] and drug design, however their role as active ligands with biologically important metals[2] has yet to be fully exploited. α-Hydroxyiminophosphonic acid derivatives are widely known not only as intermediates in the synthesis of the important aminophosphonic acids,[3,4] but also as phosphorylating agents,[5] potential metalloenzyme inhibitors,[6] and as having fungicidal activity.[7] In this work the scope of these compounds has been extended considerably by the synthesis of a number of novel dialkyl derivatives. For the first time the potential of these dialkyl α-hydroxyiminophosphonates as ligands has been demonstrated by the successful synthesis of a range of transition metal complexes. X-ray structure analysis confirms the formation of a five membered chelate ring on coordination of diethyl *E*-(α)-hydroxyiminopropanephosphonate to nickel(II).

The new dialkyl esters were prepared by adaptation of a literature method.[8] Reaction of acylphosphonates with hydroxylamine, using 3 M HCl in the work up procedure, gives dialkyl α-hydroxyiminophosphonates with predominating *E* isomers and in good yield (>90%). $^{31}P(CDCl_3)$ NMR data of a number of these compounds are presented in Table 1. The ^{31}P assignment of the structural isomers was initially based on literature data[9] for related compounds and has been confirmed by a single crystal structure analysis† of diisopropyl *E*-(α)-hydroxyiminobenzylphosphonate L^2 (Fig. 1).

The solid state structure of L^2 consists spiral chains formed by hydrogen bonding between the phosphoryl and oxime group of adjacent molecules {H(O4)···O(1″)1.60Å}. The structure of the individual molecules of L^2, shown in Fig. 1, establishes a conformation ideally adapted to complex formation; the potential donor atoms, the oxygen atom of the phosphoryl and the nitrogen atom of the oxime, being *cis* to each other resulting in a preformed "chelate-bite" of 2.886 Å in the solid state. Very few compounds of this type are crystalline, but there have been two recent characterizations of the *E* and *Z* form of dimethyl α-hydroxyiminobenzylphosphonate[9] and diisopropyl *E*-(α)-hydroxyiminophthalimidopropylphosphon-

ate.[10] The equivalent bond lengths in these compounds do not differ significantly from those in L^2, but in both the *E* isomers *trans*-conformations of the potential donor atoms are observed. Interestingly for a monoalkyl α-hydroxyiminophosphonates where metal complex formation has been reported, X-ray structure analysis of the uncoordinated molecule also show a preformed chelate conformation similar to that in L^2.[11]

To date no examples of metal complexes of the bifunctional dialkyl α-hydroxyiminophosphonates have been reported, which is surprising considering that in addition to complexes of the monoalkyl esters,[11] both phosphoryl[12] and oxime[13] functional

Selected bond lengths (Å) and angles (°): Ni—Cl, 2.346(4); Ni—O(1), 2.118(8); Ni—N(1), 2.036(9); P(1)—O(1), 1.478(8); P(1)—O(2), 1.550(9) and P(1)—O(3) 1.550(8); O(1)—Ni—Cl 168.3(2), N(1)—Ni—Cl 89.6(3), N(1)—Ni—O(1) 80.9(3), Cl—Ni—Cl′ 96.0(2), O(1)—Ni—O(1′) 83.1(4), N(1)—Ni—N(1′) 176.6(3), P(1)—O(1)—Ni 115.1(4), C(21)—O(2)—P(1) 120.5(7), C(31)—O(3)—P(1) 120.4(9), O(4)—N(1)—Ni 120.2(7), C(1)—N(1)—Ni 125.3(8).

groups can coordinate to metal ions. In this study it has been found that reaction of methanolic solutions of the diesters and the transition metal salt MX_2 gives ML_2X_2 (M = Co and Ni; L = L^1-L^6; X = Cl or NO_3).

All the cobalt(II) and nickel(II) complexes were characterized by satisfactory elemental analyses, and by liquid secondary ion mass spectrometry (LSIMS) which gave base peaks corresponding to $[M+H-Cl_2]^+$ in all cases. The infra-red spectra of the ligands and their metal complexes indicated that the oxime stretch at ν(C=N), 1614 cm^{-1} shifts to 1645 cm^{-1} on complexation and the two phosphoryl stretches at ν(P=O), 1173 and 1234 cm^{-1} condense and shift to 1164 and 1213 cm^{-1}. Magnetic moment measurements of CoL_2X_2 are 4.6 to 4.7 BM and NiL_2X_2 are 3.1 to 3.2 BM, which are in the normal range for six coordinate complexes of cobalt(II) and nickel(II). The formulation of the complexes has been confirmed by a single crystal structure analysis* of $NiL^1{}_2Cl_2$. This shows the *cis*-dichloro molecule of exact C_2 symmetry illustrated in Fig. 2, and confirms the *E* isomeric form of the phosphonate diester L^1. The atom pairs O(1), O(1′) and N(1), N(1′) from the two symmetry related chelating ligands coordinate in *cis* and *trans* configurations, respectively. The five membered chelate rings adopt an envelope conformation with maximum deviation from planarity of 0.125 Å for P(1). The oxime hydrogen atom is 2.26 Å from the coordinated chlorine atom, indicating strong intramolecular hydrogen bonding.

The selective complexation of the *E* isomers provides a useful method to separate the two isomeric forms and their biological activity can therefore be studied individually. Work is in progress in pre-

(*Received* 26 *June* 1993; *accepted* 7 *September* 1993)

Abstract—4′-Ferrocenyl-2,2′:6′,2″-terpyridine(Fctrpy) has been prepared from ferrocene carboxaldehyde and 2-acetylpyridine. A single crystal X-ray structure analysis indicates typical bond distances and angles with nearly coplanar aromatic rings. The angle between the cyclopentadienyl ring of the ferrocene moiety and the central pyridyl ring of the terpyridine is 19.2° Ruthenium complexes, $Ru(Fctrpy)_2^{2+}$ and $Ru(trpy)(Fctrpy)^{2+}$ (trpy = 2,2′:6′,2″-terpyridine) have been prepared and characterized electrochemically and spectrophotometrically.

The synthesis of substituted 2,2′:6′,2″-terpyridines is an area of great current interest.[1–4] The properties of transition metal complexes can be fine tuned by the use of substituents on the terpyridine ligands. We have synthesized a terpyridine ligand that contains a ferrocenyl moiety at the 4′ position. The ligand is unique in that the substituent itself can be modified *in situ* by oxidation of the ferrocenyl moiety to ferrocenium. We report here the synthesis and X-ray structural characterization of 4′-ferrocenyl-2,2′:6′,2″-terpyridine, Fctrpy, (**1**), its coordination to a ruthenium centre, and the properties of ruthenium complexes containing the Fctrpy ligand.

The ligand **1** was synthesized in two steps from ferrocenecarboxaldehyde using the elegant method reported by Constable, *et al.* who synthesized 4′-phenyl-2,2′:6′2″-terpyridine, 4′-Phtrpy, (**2**), from benzaldehyde.[3] Ferrocenecarboxaldehyde was reacted with two equivalents of 2-acetylpyridine, in the presence of base, to yield orange crystals of 2-ferrocenyl-1,5-bis(2-pyridyl)-1,5-pentanedione (**3**), in reasonable yield, eq. 1.

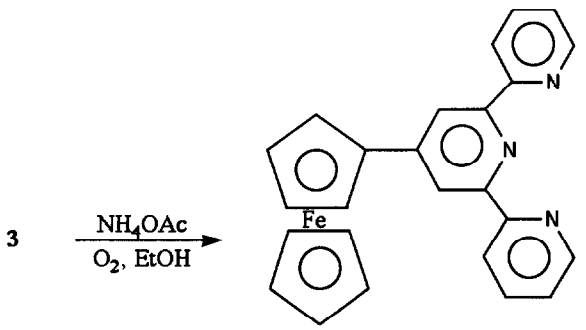
The pentanedione was converted to **1** in good yield by reaction with ammonium acetate in refluxing ethanol in the air, eq. 2.



1 (2)

Both new compounds were characterized by ^1H NMR and microanalysis.*

The structure of **1** was confirmed by a single crystal X-ray structural determination.† An ORTEP view of **1** is shown in Fig. 1. As in the structure of **2**[3] the three pyridyl rings are in a *trans-oid* arrangement and are approximately co-planar: the angles between the central and the outer pyridyl rings average 7.3°, which is comparable to a value of 8.2° in **2**. The average C—C and C—N bond distances are 1.384±0.010 Å and 1.342±0.003 Å, respectively. These compare with values of 1.370±0.013 Å and 1.342±0.002 Å for **2**.[3] The terpyridine moiety is not co-planar with the ferrocenyl cyclopentadienyl ring, the dihedral angle between the two rings being 19.2°. For a series of closely related species **1**, **2** and 4-biphenylferrocene[5] (**4**), there is a correlation between the interannular bond distance and the twist angle. For **4**, **2** and **1**, the bond distances are 1.55 Å, 1.492 Å, and 1.471 Å, respectively, and the twist angles are 5.9°, 10.9°, and 19.2°. The larger twist angle occurs because of greater steric interactions between nonbonded hydrogen atoms as the interannular distance decreases. The ferrocene moiety has C—C bond distances of 1.416±0.008 Å, compared to 1.42±0.07 Å for **4**.

The properties of **1** are a combination of those of the constituent parts. The UV-visible spectrum of **1** essentially consists of π to π^* (trpy) bands[6] at 248 and 280 nm and ferrocene charge transfer bands at 351 and 452 nm[7] (Table 1). The red shift of the ferrocenyl bands of **1** relative to the 322 and 439 nm of ferrocene, and the reduction potential of the ferrocenyl moiety (0.57 V vs 0.41 V for ferrocene), reflect the electron withdrawing character of the trpy substituent.

Ruthenium complexes $[Ru(trpy)(Fctrpy)]^{2+}$ (**5**), and $[Ru(Fctrpy)_2]^{2+}$ (**6**), were prepared from Fctrpy and $RuCl_3 \cdot xH_2O$ or $Ru(DMSO)_4Cl_2$,[8] respectively. In the first case, a two step synthetic route through the intermediate $Ru(Fctrpy)Cl_3$ was used.[9] In each case, alcoholic solvents were used because use of DMSO or dimethylformamide lead to decomposition of Fctrpy to generate $Fe(trpy)_2$-type bypro-

ducts. Both **5** and **6** were characterized by ^{1}H NMR and microanalysis.*

The intensely red ruthenium complexes exhibit typical d(Ru)$\cdots\pi^*$(trpy) transitions around 480 nm and π(trpy)$\cdots\pi^*$(trpy) transitions in the UV region[4] (Table 1). Surprisingly, an additional absorption band is observed around 530 nm with an intensity proportional to the number of Fctrpy ligands. Other than $Ru(tro)_2^{2+}$ (tro = 4′-phenyl-2,2′:6′,2″-terpyridyl), for which absorption maxima at 490 nm (ε = 24,200) and 560 nm (ε = 8,000) are reported, substituted terpyridyl complexes of ruthenium(II) tend to exhibit a single maximum in the visible region.[4,6] The absence of a 530 nm band in free Fctrpy and its disappearance upon oxidation of the ferrocene site suggests that the 530 nm band may be a ruthenium-to-ferrocene charge transfer band and is presently under further investigation.

Results of cyclic voltammetric studies on Fctrpy, $[Ru(trpy)(Fctrpy)]^{2+}$, and $[Ru(Fctrpy)_2]^{2+}$ are listed in Table 2. The ferrocene moieties of each exhibit a reversible oxidation to ferrocenium at about 0.6 V and ruthenium(III/II) waves are observed at about 1.4 V (vs Ag/AgCl reference). The ruthenium(III/II) waves are irreversible due to deposition on the electrode and/or decomposition of the complex. Coulometric studies show that oxidation of $[Ru(trpy)(Fctrpy)]^{2+}$ at 0.8 V results in the loss of one electron whereas oxidation of $[Ru(Fctrpy)_2]^{2+}$ at the same voltage results in the loss of two electrons. This oxidation of the ferrocenyl moiety of $[Ru(trpy)(Fctrpy)]^{2+}$ or $[Ru(Fctrpy)_2]^{2+}$ leads to the loss of the 530 nm shoulder or maximum, respectively, in the visible spectrum and the d(Ru)$\cdots\pi^*$(trpy) band shifts

[b] CH_2Cl_2/TBAH.

to 501 nm. Oxidation of the ferrocenyl moiety apparently stabilizes the trpy π^* orbital, leading to a lower energy $d(Ru)\cdots\pi^*(trpy)$ transition. Comparison to ruthenium complexes of other substituted trpy ligands[4,6] suggests that the effect of the ferrocene or the ferricinium substituent is similar to that observed for other substituents. A weak absorption band is observed above 900 nm in $[Ru(Fctrpy)_2]^{4+}$, presumably a ruthenium(II)-ferrocenium intervalence transfer transition.

Attachment of a terpyridyl moiety to the ferrocene increases the ferrocenium/ferrocene reduction potential by about 0.17 V, independent of whether or not the terpyridyl is bound to a ruthenium(II) centre. This increase is similar to that observed for 3- or 4-ferrocenylpyridine[10] and considerably larger than the increase observed for phenylferrocene.[11]

(*Received* 2 *July* 1993; *accepted* 3 *September* 1993)

Abstract—The neutral tetradecanuclear copper(I) thiolate cluster complex has been formed from the reaction of $(Ph_3P)_2Cu(S_2CSPh)$ with CH_2Cl_2 and MeOH and structurally characterized by X-ray diffraction analysis. The core of the $[Cu_{14}(\mu_2\text{-}S)(SPh)_{12}(PPh_3)_6]$ cluster consists of a sulphur ion at the centre of a cube of eight copper(I) atoms, which is inscribed into an icosahedron of twelve sulphur atoms. The other six copper(I) atoms form an octahedron and the icosahedron of S_{12} fits inside the octahedron of Cu_6.

The insertion reactions of CS_2 into Ag—S and Cu—S bonds have been studied by us in recent years.[1–6] We have found that silver or copper thiolate complexes react readily with CS_2 in the presence of PPh_3 to give almost the same structure of mononuclear product[1,6–8]

$$(MSR)_n + PPh_3 + CS_2 \leftrightarrows (Ph_3P)_2M(S_2CSR).$$
$$(M = Cu, Ag;\ R = aryl, alkyl)$$

This is a reversible reaction.[1,7] Recently, we also found some insertion products of this kind of reaction can easily react with various solvents to form unexpected cluster complexes. A novel tetradecanuclear silver cluster complex $[Ag_{14}(SPh)_{12}(PPh_3)_8Cl]^+Cl^-$ has been synthesized and structurally characterized.[9] In this communication we report the formation and crystal structure of a novel neutral tetradecanuclear copper(I) cluster complex $[Cu_{14}(\mu_2\text{-}S)(SPh)_{12}(PPh_3)_6]$.

The title complex was prepared as follows: the orange crystals of insertion product of CS_2 into Cu—S bond, $(Ph_3P)_2Cu(S_2CSPh)$, was readily obtained by stirring a solution of $(CuSPh)_n$ (0.173 g, 1 mmol) and PPh_3 (0.525 g, 2 mmol) in CS_2 (30 cm^3) for 4 h at room temperature and then cooling it to $-30 \sim -20$°C overnight. The crystal melts with effervescence at 101–104°C to a cream-coloured solid that subsequently melts at 165–167°C. This indicates that its structure is in agreement with that previously reported by Eller.[7] When the orange crystals of $[(PH_3P)_2Cu(S_2CSPh)]$ (30 mg) were dissolved in CH_2Cl_2 (4 cm^3), the initial orange colour of solution faded quickly. Then a layer of MeOH (12 cm^3) was placed above this solution and after two months colourless polyhedron-shaped crystals formed on the wall of the test tube. The crystals are air stable and decompose gradually above 140°C.

The crystal structure determination indicates that the complex is a neutral tetradecanuclear copper(I) cluster.† The core and the molecular structure are illustrated in Figs 1 and 2, respectively. Selected bond lengths and angles are given in Table 1. The molecule has a peculiar $Cu_{14}S_{12}$ cage which is composed of $Cu_8^{(I)}$, $Cu_6^{(I)}$ and S_{12} polyhedra centred around a sulphur ion. They are arranged in such a

which is longer than the normal Cu—S bond length. Therefore it is a distorted cube with slight compression along this diagonal. Twelve S atoms of thiolate ligands form an icosahedron, and these S atoms sit on the 12 edges of the Cu_8 octahedron. The bond angles of Cu—S—Cu average 172.1° (170.7–173.4°). Every thiolate S atom forms a bridge between two Cu atoms of the cube and one Cu atom of the octahedron. The Cu—S bond lengths vary from 2.257 to 2.312 Å. The six Cu atoms in the structure form the octahedron in such an orientation that each Cu atom of the octahedron centres above one of six faces of the Cu_8 cube, the distances average 3.09 Å. The Cu-centred trigonal icosahedronal face is approximately coplanar with a face of the Cu_6 octahedron. There is a terminal PPh_3 ligand on each of the vertices of the Cu_6 octahedron. The mean value of Cu—P bond length is 2.217 Å (2.205–2.225 Å). All copper atoms are trigonally coordinated except that the two coordinated by the central S atom are tetrahedronally coordinated. Furthermore, there are 12 $Cu_3(\mu_3\text{-}S)_3$ six-membered rings in the cluster, all of which are boat-like conformation. Viewing the whole molecule, we can find that all copper atoms are surrounded by the exterior phenyl groups, that is, the array of ligand substituents is on the surface of the molecule. So they protect the univalent metals sterically against oxidation or chemical attack.

The geometry of the core of $[Cu_{14}(\mu_2\text{-}S)(SPh)_{12}(PPh_3)_6]$ cluster resembles the geometries of the mixed-valent copper thiolate cluster compounds $[Cu_8^{(I)}Cu_6^{(II)}L_{12}Cl]$ (L = penicillamine (Pen)[10], α-mercaptoisobutyric acid (MIBA)[11], β,β-dimethyl cysteamine (DMC)[12]), and they have similar metal–metal and metal–ligand distances which are compared in Table 2. However, there are several main differences between our compound and mixed-valent copper thiolate cluster compounds. (i) Our compound is a neutral tetradeca-nuclear

Table 2. Comparison of metal–metal and metal–ligand distances in $Cu_{14}(\mu_2\text{-}S)(SPh)_{12}(PPh_3)_6$ within $[Cu_8^{(I)}Cu_6^{(II)}L_{12}Cl]$ compounds

copper cluster, but all the mixed-valent copper thiolate clusters are anionic cluster complexes. (ii) All 14 copper atoms in our compound are of unitary valence, that is, univalent, but in the mixed-valent copper cluster compounds only eight of the 14 Cu atoms are univalent and the other six Cu atoms are bivalent. Therefore our compound is the first example of unitary valent neutral tetradecanuclear copper cluster to our knowledge. (iii) Instead of a chloride ion which is at the centre of mixed-valent copper thiolate clusters, a sulphur ion is at the centre of our cluster. And it is considered that the central S ion is essential for the formation of the whole structure. The initial presence of the central S ion was only fortuitous. It is estimated that the central S atom might be the result of nucleophilic reaction of PhS^- and CS_2, which are formed from dissociation of $(Ph_3P)_2Cu(S_2CSPh)$ in CH_2Cl_2 and MeOH solution. However, further investigation of the formation mechanism of the cluster is needed.

SYNTHESES AND X-RAY CRYSTAL STRUCTURES OF TETRAKIS(DIPHENYLAMIDO)NIOBIUM(IV) AND NIOBIUM(IV) AMIDO-HALIDE COMPLEXES

DAVID M. HOFFMAN* and SRI PRAKASH RANGARAJAN

Department of Chemistry, University of Houston, Houston, TX 77204, U.S.A.

(*Received* 17 *June* 1993; *accepted* 2 *September* 1993)

Abstract—The syntheses of three niobium(IV) amido complexes, tetrakis(diphenylamido)-niobium(IV), bis(bistrimethylsilylamido)dichloroniobium(IV) and bis(bistrimethylsilyl-amido)-dibromoniobium(IV), are reported as well as the X-ray crystal structure of the homoleptic amide.

The syntheses of homoleptic dialkylamido niobium(IV) complexes were first reported in 1962 by Bradley and Thomas.[1] Later, Bradley and Chisholm assigned a D_{2d} pseudo-tetrahedral structure for the compounds on the basis of electronic spectra, magnetic susceptibilities and ESR studies,[2] but a definitive structural characterization could not be carried out because the compounds are liquids. We report here the synthesis and X-ray structure of a new homoleptic niobium(IV) amide, tetrakis(diphenylamido)niobium(IV), and describe the syntheses of two niobium(IV) amido-halide complexes that may be of use in the synthesis of other four coordinate niobium(IV) compounds. Our interest in this chemistry was motivated by our use of $Nb(NEt_2)_4$ as a precursor to niobium nitrides.[3]

Thin purple–black plates of tetrakis (diphenylamido)niobium(IV), $Nb(NPh_2)_4$, were isolated in moderate yield (63%) by reacting $NbCl_4(thf)_2$ with four equivalents of $LiNPh_2$ in ether, stripping and extracting with benzene, and crystallizing from thf/acetonitrile (4:1). In the ^1H NMR (C_6D_6) only a single broad resonance at δ 9.5 is observed. The Evans' NMR method gives a room temperature magnetic moment of 0.98 BM.[4]

A plot of $Nb(NPh_2)_4$ from an X-ray crystallographic study is shown in Fig. 1.† The structure is best analysed in the context of the idealized D_{2d} structure **I**, which is close to the actual structure

†Crystal data for $Nb(NPh_2)_4$ at −50°C, $C_{48}H_{40}N_4Nb$, thin purple–black plate, 0.44 × 0.24 × 0.04 mm, M = 765.83, triclinic, a = 10.596 (3), b = 11.622 (4), c = 16.177 (5) Å, α = 86.75 (2)°, β = 80.63 (2)°, γ = 80.33 (3)°, U = 1937 Å^3, space group $P\bar{1}$, Z = 2, D_c = 1.31 g cm^{-3}, μ(Mo-K_α) = 3.33 cm^{-1}. Data were collected on a Nicolet R3m/V diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) in the θ:2θ scan mode. Lorentz and polarization corrections were applied to the data. A total of 4157 reflections were collected in the range 4° < 2θ < 42°; 3195 unique reflections with $I > 3\sigma(I)$ were used in the structure solution. One of the phenyl groups (C7—C12) was found to be disordered over two slightly different positions, and this was treated by refining separate rigid bodies having 50% occupancies. Only one orientation is shown in Fig. 1. $R(F)$ = 0.031; $R_w(F)$ = 0.027. Atomic coordinates, bond lengths and angles, and thermal parameters for $Nb(NPh_2)_4$ have been deposited as supplementary material with the editor from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre. Crystal data for $Nb[N(SiMe_3)_2]_2Cl_2$ at −50°C, $C_{12}H_{36}N_2Si_4Cl_2Nb$, dark blue block, 0.50 × 0.45 × 0.35 mm, M = 484.67, orthorhombic, a = 15.174 (5), b = 12.628 (5), c = 12.919 (4) Å, U = 2476 Å^3, space group Pbcn, Z = 4, D_c = 1.30 g cm^{-3}, μ(Mo-K_α) = 8.71 cm^{-1}.

Bond angles (°): N(1)—Nb—N(2) 102.5 (1), N(1)—Nb—N(3) 108.2 (1), N(2)—Nb—N(3) 120.8 (1), N(1)—Nb—N(4) 116.7 (1), N(2)—Nb—N(4) 107.5 (1), N(3)—Nb—N(4) 101.9 (1), Nb—N(1)—C(1) 127.9 (2), Nb—N(1)—C(7) 112.8 (2), Nb—N(1)—C(7′) 117.7 (2), Nb—N(2)—C(19) 134.8 (2), Nb—N(2)—C(13) 106.3 (2), Nb—N(3)—C(25) 126.6 (2), Nb—N(3)—C(31) 119.2 (2), Nb—N(4)—C(37) 115.3 (2), Nb—N(4)—C(43) 131.2 (2), C(1)—N(1)—C(7) 117.1 (3), C(1)—N(1)—C(7′) 114.4 (3), C(13)—N(2)—C(19) 115.4 (3), C(25)—N(3)—C(31) 114.0 (3), C(37)—N(4)—C(43) 113.1 (3).

of d^2 $Mo(NMe_2)_4$.[5] In $Nb(NPh_2)_4$ the two N—Nb—N angles bisected by the $C_2(z)$ axis [N(1)NbN(2) and N(3)NbN(4)] are closed from 109.5° to an average of 102.2°. The closing of these two angles and a twist of the N(1)NbN(2) and N(3)NbN(4) blades by 8.2° from mutually perpendicular results in the two other pairs of N—Nb—N angles averaging 118.8° and 107.9°. The amido ligands are all close to planar, but the Nb—N—C angles vary widely (106–135°). Bond distances are unexceptional, although Nb—N(4) is nearly 10σ shorter than the average of the other three statistically equal Nb—N distances.

The orientations of the amido phenyl substituents are curious. The N(3) and N(4) amido ligand phenyl rings are rotated such that there is virtual C_2 symmetry in the $Nb(N(3)Ph_2)(N(4)Ph_2)$ moiety, an arrangement that minimizes interligand steric interactions between rings. On the other hand, the N(1) and N(2) phenyl substituents are oriented such that two of the rings [C(1) and C(13)] are in extremely close contact (≈3.2 Å), which would seem to maximize steric interactions.

It appears that steric interactions are the primary reason why the structure of $Nb(NPh_2)_4$ is substantially different from **I**, as evidenced by the wide variation in Nb—N—C angles. In this regard it should also be noted that a $(d_{x^2-y^2})^1$ configuration is expected for $Nb(NPh_2)_4$ (i.e. a $^2B_1$ or ^2A ground state in D_{2d} or D_2 symmetry, respectively),[5] and this does not provide a Jahn–Teller driving force for a distortion.

We have also prepared niobium(IV) amido halides. For example, dark blue crystals of $Nb[N(SiMe_3)_2]_2Cl_2$ were isolated in ≈60% yield by reacting $NbCl_4(thf)_2$ with two equivalents of $LiN(SiMe_3)_2$ in hexane/ether (2:1), stripping and extracting with hexane, and crystallizing from cold hexane. A similar procedure produced blue $Nb[N(SiMe_3)_2]_2Br_2$ in a comparable yield. In both preparations there is typically ≈10% contamination of the final product by $LiN(SiMe_3)_2$ which has proved difficult to remedy because of the similar solubilities of the lithium salt and niobium products. The ^1H NMR spectrum of $Nb[N(SiMe_3)_2]_2Cl_2$ in C_6D_6 has only a broad resonance centered at δ 1.9. An X-ray crystallographic study of $Nb[N(SiMe_3)_2]_2Cl_2$ indicates that the space group is the same as for $Ta[N(SiMe_3)_2]_2Cl_2$ and the cell constants are virtually identical,[6] suggesting that the two compounds are isostructural.

SYNTHESIS AND X-RAY STRUCTURE OF THE POLYNUCLEAR COMPLEX BIS(μ-TRIFLUOROACETATO-O,O′)(1,10-PHENANTHROLINE)MANGANESE(II)

MARIUS ANDRUH, HERBERT W. ROESKY,* MATHIAS NOLTEMEYER and HANS-GEORG SCHMIDT

Institut für Anorganische Chemie der Universität Göttingen, Tammannstraße 4, D-37077 Göttingen, Germany

(*Received* 11 *August* 1993; *accepted* 31 *August* 1993)

Abstract—The reaction of $Mn(CF_3COO)_2$ (**1**) and 1,10-phenanthroline in 1 : 1 molar ratio yields the polynuclear compound $[Mn(CF_3COO)_2(phen)]_n$ **2**. The crystal structure of **2** reveals zig-zag infinite chains with *syn–syn* bridging trifluoroacetate ions.

The versatility of the carboxylate ligands, $RCOO^-$, has contributed over the past few years to the development of a rich co-ordination chemistry. Numerous complexes of a variety of metal ions have been prepared and structurally characterized. It is worth mentioning that some of these polynuclear compounds illustrate general structural types in modern inorganic chemistry.[1,2] The increasing interest in this chemistry is due to several reasons: (i) the carboxylate ions play a key role as ligands in many biochemical systems involving mono- or poly-metallic active sites; (ii) polynuclear carboxylates are good candidates for the investigation of exchange-coupling interactions between adjacent metal ions.

A successful strategy leading to polynuclear metal(II)carboxylates is the reaction of the corresponding salt with a bidentate organic ligand, LL, in a molar ratio preventing the formation of mononuclear species. It is difficult, however, to predict the nuclearity of the crystalline compounds. Taking into account the case of manganese(II) coordination chemistry, a survey of the recent literature reveals several interesting features. Lippard, Bino *et al.* have reported[3] the structures of two binuclear complexes with biological relevance: $[Mn_2(H_2O)(piv)_4(Me_2bipy)_2]$ and $[Mn_2(H_2O)(OAc)_4(tmeda)_2]$, both being rare examples of water-bridged dinuclear complexes. Two trinuclear species of the type $[Mn_3(RCOO)_6(bipy)_2]$ have been structurally characterized by Christou ($R = C_6H_5$)[4] and Kahn, Girerd *et al.* (the acetato analogue).[5] All these compounds have been obtained by keeping a manganese(II) to ligand LL molar ratio equal to 1 : 1. Another trinuclear compound, $[Mn_3(CF_3COO)_6(C_6H_5CN)_6]$, has been synthesized and characterized in our laboratory.[6]

Following our systematic structural investigation of trifluoroacetate manganese(II) complexes,[6,7] we now report here on the synthesis and X-ray structure of a new polynuclear complex of manganese(II): bis(μ-trifluoracetato-O,O′)(1,10-phenanthroline)manganese(II), $[Mn(CF_3COO)_2(phen)]_n$ (**2**).† The molecular structure of this compound has

been determined by X-ray diffraction.‡ A view of the layered polymer is depicted in Fig. 1. A dimer of the asymmetric unit along with the atom numbering scheme is represented in Fig. 2. Selected bond distances and angles are given in Table 1.

The structure consists of *cis*-[MnN_2O_4] chromophores held by trifluoroacetate bridges, resulting in zig-zag infinite chains, which propagate in *c* direction and whose aromatic parts are parallel to [001] plane. The manganese(II) ion displays a (pseudo)-octahedral co-ordination, being linked to four O atoms of four CF_3COO^- ligands and to two N atoms of the phenanthroline ligand. The Mn—O distances are shorter than the Mn—N ones. The bridging mode of the trifluoroacetate ions is *syn-syn* bidentate asymmetric, with two short and two long Mn—O bonds (213.4 and 221.7 pm, respectively). The Mn···Mn distance (479.1 pm) is longer with respect to other bis- or tris(μ-carboxilato-O,O′) complexes of manganese(II).[3,5,6,10]

Although predictible, such a polymeric structure of metal(II) carboxylate complexes with bidentate ligands (phenanthroline and related compounds) has not been reported so far.

SOLUBILITIES OF CALCIUM SALTS OF DICARBOXYLIC ACIDS IN METHANOL–WATER MIXTURES; TRANSFER CHEMICAL POTENTIALS OF DICARBOXYLATE ANIONS

JOHN BURGESS* and DUNCAN N. DRASDO

Chemistry Department, University of Leicester, Leicester LE1 7RH, U.K.

(*Received* 26 *February* 1993; *accepted* 11 *August* 1993)

Abstract—Solubilities are reported of the calcium salts of a series of dicarboxylic acids, $HO_2C(CH_2)_nCO_2H$, with $n = 0$, 1, 2, 4, 8 and 12, and of cyclobutane-1,1-dicarboxylic acid in methanol–water mixtures containing 0–80% methanol. From these results, and known values for transfer chemical potentials for Ca^{2+}, transfer chemical potentials for the dicarboxylate anions have been calculated. The derived trends are discussed in terms of the hydrophilic/lipophilic properties of the anions and consequent preferential solvation.

The α,ω-dicarboxylic acids (**1**) furnish a homologous series whose character changes from strongly hydrophilic at the start (oxalate) to predominantly lipophilic for the higher members. All the acids with $0 \leqslant n \leqslant 8$ are commonly enough encountered to have trivial names; some higher members (n up to 14 and $n = 20, 22$) are also readily available. A number of these dicarboxylates and their calcium salts[1] are of pharmacological and biological relevance. Succinate, obtainable by distilling amber or by bacterial fermentation of tartaric or malic acids, assists the sometimes difficult[2] absorption of Fe^{2+} from the gastrointestinal tract,[3] azelate occurs in rancid fats, adipate (like oxalate) exhibits high oral toxicity. Thapsic acid occurs in *Thapsia garganica* ("Spanish Turpethroot", source of a resin used in plasters and a purgative) and in *Juniperus sabina* (whence "Oil of Savin", a multipurpose medicine for combatting intestinal worms, for controlling menstruation, for inducing sweating and a constituent in perfumery). Malonic, suberic, sebacic and pimelic acids are produced from malic acid (apples), cork, castor oil and atropine, respectively. Endothall, the rather more complicated dicarboxylic acid (**2**), is closely related to the beetle vesicant cantharidin and, in the form of its calcium salt, is an effective herbicide.[4] A number of cyclobutanedicarboxylate (CBDCA) (**3**), complexes of platinum, for example carboplatin (**4**),[5] zeniplatin (**5**), enloplatin (**6**) and the recently reported **7**,[6] are of proven or potential value in cancer chemotherapy.

The oxalate anion ($n = 0$) and its calcium salt are particularly important. Oxalate, as in for example rhubarb, inhibits the absorption of Ca^{2+} from the gastro-intestinal tract.[7] Calcium oxalate (as the monohydrate Whewellite or the dihydrate Weddellite) occurs in many plants[8] (cf. thapsic acid above), in the sap and as a calcium store. Calcium oxalate can appear as microscopic star-shaped crystals in the urine and is the main constituent of urinary calculi in man.[9,10]

Solvation is important in respect to these biologically and pharmacologically relevant areas, both in the obvious sense of being a key factor in determining (in-) solubility of the acids and their salts and in relation to absorption. This involves transport across membranes, whose ease is determined by the hydrophilic/lipophilic properties of the substrate,[11] as intimated for calcium oxalate and iron(II) succinate above. These properties are particularly relevant to the initial step in trans-membrane transport, viz. stabilization at the membrane–aqueous interface. Hydrophilic/lipophilic properties are generally assessed through determination of the water–1-octanol partition coefficient.[12] An alternative approach is to determine solubility or transfer chemical potential trends in alcohol–water mixtures.[13] The solubilities in the two pure components give an indication of the hydrophilic/lipophilic balance, HLB.[14] Any increase in

solubility in mixed solvents indicates favourable synergic solvation, i.e. hydration of hydrophilic regions by the water complementing solvation of lipophilic regions by the alcohol. Such synergic solvation has been demonstrated for, for instance, the ternary iron(II) complex $[Fe(CN)_2(bipy)_2]$, which has hydrophilic cyanide ligands balancing the very lipophilic surface of the coordinated 2,2′-bipyridyl ligands.[15]

Previous work in the area of the present paper has established solubilities of calcium oxalate in a series of primary alcohols and in ethanol–water mixtures[16] and the salting-in of calcium oxalate into aqueous solution by added sodium citrate.[17] We now report and discuss solubilities of the calcium salts of the dicarboxylic acids **1** with $n = 0$, 1, 2, 4, 8 and 12 and of CBDCA (**3**) in methanol–water. We thus derive, using established and estimated transfer chemical potentials for Ca^{2+},[18] transfer chemical potentials for the respective dicarboxylate anions and discuss the information these parameters provide on solvation of these anions.

EXPERIMENTAL

Preparation of salts

The dicarboxylic acids, and a sample of calcium oxalate, were obtained from Aldrich. Calcium salts were prepared by adding aqueous ammonia and a solution of the dicarboxylic acid (in water for the lower homologues, methanol for the higher) to a strong aqueous solution of calcium chloride. The products were washed with water and dried *in vacuo*. The calcium dicarboxylates studied here are almost all established compounds (although their numbers of waters of crystallization are not all firmly established, *vide infra*). We were unable to find a reference to the preparation of the calcium

salt of CBDCA in the literature and so characterized our product by microanalysis, as a dihydrate. Found: C, 33.0; H, 4.7. Calc. for $Ca(CBDC)2H_2O$: C, 33.0; H, 4.6%.

Determination of solubilities

A generous excess of calcium salt was agitated with the respective solvent medium in a thermostatted container for several days. Aliquots of the supernatant saturated solution were removed, diluted appropriately with water and analysed for calcium content by atomic absorption spectroscopy (Perkin–Elmer 1100B).

RESULTS AND DISCUSSION

Solubilities

The results of our solubility determinations are collected in Table 1. The values for calcium (ppm) are believed to be accurate to within *ca* 5%; a generous number of significant figures has been retained in the ppm and Δ values in this table; rounding off of Δ values to an appropriate number of figures has been carried out in Table 2. A selection of solubilities are plotted in Fig. 1 for ease of comparison. The solubility trends are all remarkably similar, except for the salts of the two most hydrophobic acids. In these cases the eight (sebacic) or 12 methylene groups significantly affect solubilities compared with the salts of the other acids.

[a] Values derived as explained in text.

Favourable interactions between the methyl of the methanol and methylenes of the anion result in the solubilities of the calcium salts decreasing less markedly as the proportion of methanol in the mixed solvents increases. The effects of methanol and ethanol[16] as co-solvents are also compared, for calcium oxalate as solute, in Fig. 1. The addition of ethanol has, on a volume basis, slightly less effect than methanol, but it should be borne in mind that the water–ethanol solubilities were obtained at 20°C. An attempt was made to correlate solubilities with solvent dielectric properties for the ethanol–water solubilities, but there appeared to be no simple correlation.[16] However, a good correlation of solubility with reciprocal dielectric constant has been claimed for zinc and cadmium oxalates dissolved in a series of primary alcohols.[19] The rapidly decreasing solubilities of the calcium salts of the lower dicarboxylates as the proportion of methanol (or ethanol) increases reflects the strongly hydrophilic natures of Ca^{2+} and $^{-}O_2C(CH_2)_nCO_2^{-}$ (when $n = 0$ or is small). Decreasing solubilities of oxalic acid in the order[20]

water > methanol > ethanol > propanol

and solubilities of adipic acid in alcohol–water mixtures[21] similarly reflect the strongly hydrophilic properties of carboxylate moieties.

It is more difficult to comment satisfactorily on relative solubilities of a series of salts in a given solvent than on solubility trends for a given salt in a series of solvent media, since the solubility of a salt represents a balance between lattice energy and solvation of constituent ions. It is interesting to note (Table 1) that the solubilities of $Ca[O_2C(CH_2)_nCO_2]$ in water increase from $n = 0$ to $n = 4$, then decrease as n increases further. The low solubility of calcium oxalate ($n = 0$) presumably reflects its high lattice energy; the almost equally low solubility of the dodecanedioate must reflect poor hydration of this anion with its lipophilic $-(CH_2)_{12}-$chain.

Transfer chemical potentials: assumptions

Solubility trends are of interest and importance in their own right, but in order to obtain more detailed information on solvation it is useful to derive transfer chemical potentials (Δ) for the constituent ions. Transfer chemical potentials for electrolytes can be calculated from solubility products from the formula:

$$\Delta = -RT \ln\{(K_{sp} \text{ in medium 2})/(K_{sp} \text{ in medium 1})\}.$$

In the present case all transfer chemical potentials have been calculated from water as a reference solvent (medium 1). It is necessary to make some assumptions, detailed briefly here, in order to derive transfer chemical potentials for the constituent ions. Firstly, an extrathermodynamic assumption is essential to split whole salt values into individual ion contributions.[22] Here we shall use the well-established TPTB convention that transfer chemical potentials for $[Ph_4P][BPh_4]$ can be divided into equal contributions for the two large and lightly-solvated ions. As transfer chemical potentials are available on this assumption for Ca^{2+} from water into methanol–water mixtures, we can derive values for our dicarboxylate anions. We use published values in water-rich mixtures[18] and values estimated from published data on other M^{2+} ions at higher methanol contents;[23] Tissier's estimates in higher proportions of methanol[24] diverge increasingly towards intuitively implausible stabilization. Unfortunately, analogous calculations for oxalate to ethanol–water mixtures from published calcium oxalate solubilities[16] are not possible since transfer chemical potentials for Ca^{2+} are not available for this co-solvent, although they could in principle be estimated[25] using published solubilities of potassium sulphate[26] and calcium sulphate.[27]

The second assumption that has been made is that the ratios of the activity coefficients in mixed solvents to those in water are unity. This assumption is generally acceptable for sparingly soluble salts, as here, especially when solubilities decrease as the dielectric constant of the solvent medium decreases. Earlier workers have suggested[16] that ion association in calcium oxalate solutions in ethanol–water mixtures only becomes significant at dielectric constants below *ca* 60 (corresponding to approximately 50% methanol), although Nancollas predicted significant ion pairing even in water.[10] As the size of the dicarboxylate anion increases, the tendency to ion pairing will decrease, although this will be offset for the lower dicarboxylates by

increasing solubility. Overall, bearing in mind that our assumption involves *ratios* of activity coefficients rather than their absolute values, we do not expect ion association to have a major effect on our estimated transfer chemical potentials—perhaps introducing errors of 1 or 2 kJ mol^{-1}. The chemical potential of an uncharged ion pair would be expected to change less with change in solvent composition than the sum of the transfer chemical potentials of the two constituent ions.

The third assumption is that the solid phase in equilibrium with saturated solution is the same over the whole solvent composition range studied. The existence of various hydrates of calcium oxalate at first sight might appear to complicate matters, but published information on stability ranges[8,10,28] indicates that the monohydrate will be solid phase in contact with 0–40% methanol. Several other calcium dicarboxylates exist in hydrated forms,[29,30] so transfer chemical potentials to 100% methanol will not be directly obtainable. To test the validity of the assumption of constancy of solid phase in equilibrium with saturated solutions in media ranging from water to 80% methanol, thermogravimetric analyses were carried out on samples of the solid phases of three of the salts after completion of solubility determinations. As is shown by the results outlined in Table 3, the solid phase in equilibrium with saturated solution was the same for water and for 80% methanol for each of the three salts. As a by-product of the thermogravimetric experiments some light has been shed on the stoichiometry of some of the calcium dicarboxylates, over which there is some disagreement in the literature. Thus, Beilstein mentions a monohydrate of calcium sebacate, whereas earlier thermogravimetric analysis indicated a trihydrate.[31] Our results (Table 3) confirm the existence of both. In the case of calcium succinate, 1.5, 2 and 3 waters of crystallization have all been claimed. Our thermogravimetric results suggest that the trihydrate (of known structure[32]) loses two molecules of water between 100 and 150°C, with a resultant monohydrate losing its water of crystallization between 160 and 220°C. This indication of the existence of a monohydrate is supported by microanalysis of a sample of hydrated calcium succinate, which had been dried on a vacuum line. Found: C, 28.1; H, 3.2. Calc. for $CaC_4H_4O_4 \cdot H_2O$; C, 27.6; H, 3.4%.

Transfer chemical potentials: results

Transfer chemical potentials calculated from our measured solubilities with the use of the equation and assumptions given in the preceding section are given in Tables 1 and 2. The level of accuracy in the Δ values in Table 2 is believed to be between ± 0.5 and ± 1 kJ mol^{-1}. If, however, our choice of values for Ca^{2+} (cf. discussion above) is incorrect, individual values for Δ(dicarboxylate) will be in error by more than $\pm$ 1 kJ mol^{-1}. However, it should be stressed that differences between Δ values for dicarboxylates will still be accurate to ± 1 kJ mol^{-1} and that the pattern of trends discussed below will not be significantly affected. The transfer chemical potential trends for the dicarboxylates (Table 2) are shown in the context of a selection of other ions in Fig. 2. This shows the stabilization of the two most lipophilic dicarboxylates by methanol, but marked preferential hydration of the dicarboxylates up to adipate. The trend for cyclobutanedicarboxylate is very similar to that for its straight-chain analogue, adipate. The plot for oxalate appears to be out of the expected order. This may be due to errors introduced from non-conformance with one or more of the assumptions described above or, more likely, to strong preferential hydration. This would result in a very marked curvature of the complete (i.e. 0–100%) transfer chemical potential vs methanol content plot, so that the transfer chemical potential to pure methanol may well be large and positive. In water-rich mixtures the oxalate may

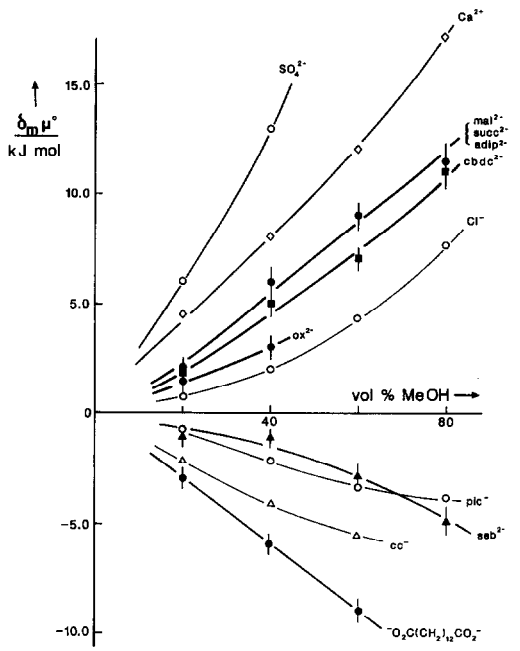

Fig. 2. Transfer chemical potentials for dicarboxylate anions (thick lines), for Ca^{2+}, and for a selection of other ions for comparison, for transfer to methanol–water mixtures; TPTB single ion assumption, molar scale, at 298.2 K. Abbreviations: pic = picrate, cc = chromone carboxylate.

retain its hydration shell essentially unchanged and thus be only slightly destabilized on the addition of methanol. Such behaviour has previously been described for the very hydrophilic cyanide and hexacyanoferrate(III) anions.[23] The more hydrophilic dicarboxylates have transfer chemical potential plots lying between those for chloride and for sulphate (Fig. 2); their smaller response than sulphate to increasing methanol content can readily be attributed to their larger size.

Transfer chemical potentials can be valuable in understanding solvent effects on reactivities, as they provide key information on initial state solvation.[33] Kinetics of hexachloroiridate(IV) oxidation of oxalate have been studied in dioxan–water mixtures[34]—it would be interesting to extend this kinetic study to methanol–water media so that an initial state–transition state analysis of reactivity could be carried out, to add to the body of information on hexachloroiridate(IV) oxidation of iodide and of catechol in several series of mixed aqueous solvents.[35]

Acknowledgements—We are most grateful to Dr S. H. Laurie and Mrs N. Garrington of the De Montfort University for arranging and carrying out the thermogravimetric analyses.

Abstract—We report the crystal and molecular structures of the complex of 18-C-6 with $H_3O^+BF_4^-$ (I) and the complex of 18-C-6 with $BF_3OH_2 \cdot H_2O$ (II). The different modes of appearance of the "BF_3" species as BF_3, BF_3OH_2, $BF_3OH_2 \cdot H_2O$ and BF_4^-, as well as their structurally significant intermolecular and intramolecular interactions, are discussed. In complex **I** the oxonium ion is bound at the centre of the 18-C-6 macrocycle. The oxonium oxygen is located practically equidistant (2.68–2.73 Å) from the six macrocyclic ethereal oxygens. The BF_4^- counter-ion is positioned 7.3 Å away from the oxonium ion in the same general plane of the crown ether. This anion is not involved in any direct intermolecular contacts, a fact that may explain why it is spherically disordered. In complex **II** there is no guest molecule (or ion) present in the "cavity" of the macrocycle, but there are two hydrogen-bonded systems of $BF_3OH_2 \cdot H_2O$ that are interacting with the crown ether on either side of the general macrocyclic plane. Complex **II** features three types of hydrogen bonds—the O(water)-H···O(crown) bonds (2.83 and 2.85 Å), the O(water)···H-O(BF_3) bond (2.49 Å) and the O(BF_3)-H···O(crown) bond (2.65 Å). The strong intermolecular O(crown)···O(water)···O(BF_3) and O(crown)···O(BF_3) interactions stabilize the normally unstable $BF_3OH_2 \cdot H_2O$ species.

The H_2O/BF_3 has been the subject of numerous investigations.[1] Two complexes have been isolated from this system, $BF_3 \cdot H_2O$ and $BF_3 \cdot 2H_2O$. The latter complex is more stable, apparently due to the formation of the oxonium ion (H_3O^+), according to the following equilibrium:

$$BF_3 \cdot 2H_2O \leftrightarrow H_3O^+ + BF_3OH^-.$$

Above 20°C both hydrates decompose while releasing BF_3.[2] In the presence of HF, low melting phases of $H_3OBF_4 \cdot nH_2O$ ($n = 0$–3) have been shown to exist.[3] The complex $H_3O^+BF_4^-$ has also been reported by Christe *et al.*[4] but was not further characterized. This complex appears as a liquid at room temperature with a significant dissociation pressure. Its structure has been determined by Mootz and Steffen[5] by growing single crystals at low temperatures.

Some of the "BF_3" species have been shown to be significantly stabilized by macrocyclic ligands such as 18-crown-6. For example, the complex of H_3O^+/BF_4^- with 18-C-6 has been isolated, but its crystal structure has not yet been determined.[6] IR and Raman spectra indicate that a conformational change of the crown ether in this complex occurs over the temperature range -50 to -100°C. The symmetry of the crown ether appears to be relatively high at room temperature. It should be noted, however, that vibrational spectra do not yield precise enough information as to the relative geometry of the crown *vis-a-vis* the oxonium ion.[6]

In general, the possible structure of the oxonium cation (co-planar geometry vs pyramidal geometry) has been extensively discussed in the literature, as well as the influence of the coordination to a macrocyclic ring on its geometry. The distance between

*Author to whom correspondence should be addressed.

the oxygen of the oxonium and the plane defined by the hydrogen-bonded oxygens of the crown is 0.61 in $[H_3O^+/18\text{-crown-6(COOH)}_4]Cl$,[7] 0.439 in $(H_3O^+/\text{dicyclohexyl-18-crown-6})ClO_4^-$,[8] 0.09 in the complex $(H_3O^+/18\text{-crown-6})(Cl\text{-}H\text{-}Cl)$[9] and 0.1 Å in the complex $(H_3O^+/18\text{-crown-6})_2(Mo_6O_{19})$.[10] Thus, no clear-cut criteria can be formulated regarding which factors determine the exact geometry of H_3O^+ and whether the anion exerts any influence on the exact geometry of the H_3O^+ ion. Moreover, a number of crown ether complexes are known of the type 18-C-6/(H_2O·acid) (where the acid is HNO_3, H_2TiF_6 or H_3PO_4),[11] in which the oxonium plays no structural role at all. It should be noted, however, that on the basis of vibrational spectra it is believed that these acids are coordinated to the crown ether via water molecules.

In the present paper we report the crystal and molecular structures of the complex of 18-C-6 with an $H_3O^+BF_4^-$ species (**I**) and of the complex of 18-C-6 with a $BF_3{\cdot}OH_2{\cdot}H_2O$ species (**II**). These structures are then compared with the reported structure of the complex of 18-C-6/BF_3OH_2, in which BF_3 is covalently bonded to the oxygen atom of the water molecule, which is itself hydrogen bonded to the 18-C-6 molecule.[12] It is shown that the $BF_3{\cdot}OH_2$, $BF_3{\cdot}OH_2{\cdot}H_2O$ and BF_4^-/H_3O^+ species in these structures are rather different in appearance and geometry.

The coordination of these species relative to the macrocyclic ring are discussed in terms of the known conformations which this system can assume.[13] With relatively few exceptions, the coordination of an oxonium by the crown ether causes the latter to assume a relatively high symmetrical configuration approximating D_{3d} symmetry. The new structures reported here are the complex of 18-C-6 with an oxonium ion encaptured in the crown (complex **I**) and the complex of 18-C-6 with two water molecules hydrogen bonded on both sides of the crown ether (complex **II**). Both complexes show a similar configuration of the crown ether macrocycle.

EXPERIMENTAL

Preparation and crystallization of the complexes

18-Crown-6 was obtained from Aldrich Co. and used as supplied without further purification. Fluoroboric acid (*ca* 40% HBF_4), technical grade, was obtained from BDH Ltd. The complex of 18-crown-6 with BF_4^- (**I**) was prepared according to a previously described procedure.[6] Single crystals of **I** (thin plates of approximate dimensions $0.4\times0.4\times0.1$ mm) were obtained by slow evaporation from a methylene chloride solution. Single crystals of **II** (well formed with sharp edges, elongated trigonal prisms of approximate dimensions $0.5\times0.2\times0.2$ mm), were obtained from the same general procedure, with the fluoroboric acid mixture being slowly evaporated from a 1 : 1 (v/v) methylene chloride/carbon tetrachloride mixture. One of each of these single crystals was used for the complete crystallographic analysis. The crystals of **I** have a m.p. of 140–143°C,[6] while the crystals of the newly obtained complex **II** have a melting point of 85°C.

Crystal structure analyses

Crystal data. 18-crown-6/$BF_4^-{\cdot}H_3O^+$, $C_{12}H_{27}O_7BF_4$ (**I**), $M = 370.14$, tetragonal space group $P4_12_12$, $a = b = 10.575(3)$, $c = 16.471(3)$ Å, $V = 1842(1)$ Å^3, $D_c = 1.33$ g cm^{-3}, $Z = 4$, $\lambda(CuK\alpha) = 1.54178$ Å, $\mu(CuK\alpha) = 11.14$ cm^{-1}, $F_{000} = 784$, T = room temperature.

18-crown-6/2($BF_3{\cdot}OH_2{\cdot}H_2O$), $C_{12}O_{10}H_{32}B_2F_6$ (**II**), $M = 471.99$, triclinic space group $P\bar{1}$, $a = 8.366(2)$, $b = 10.405(2)$, $c = 7.344(3)$ Å, $\alpha = 108.79(2)°$, $\beta = 112.11(2)°$, $\gamma = 93.38(2)°$, $V = 549(1)$ Å^3, $D_c = 1.43$ g cm^{-3}, $Z = 1$, $\lambda(CuK\alpha) = 1.54178$ Å, $\mu(CuK\alpha) = 12.86$ cm^{-1}, $F_{000} = 248$, T = room temperature.

Data collection and processing. The molecular scheme and the numbering system for complexes **I** and **II** are shown in Figs 1 and 2, respectively. Diffraction data for both structures were measured on an Enraf–Nonius CAD-4 automatic four-circle

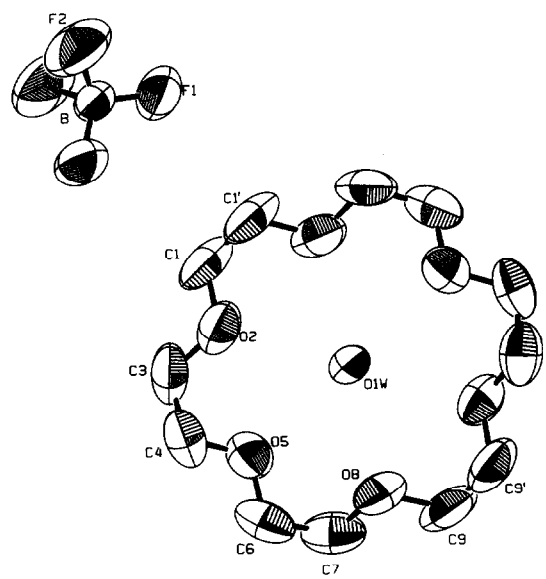

Fig. 1. The final crystal structure of the complex 18-c-6/$H_3O^+ \cdot BF_4^-$ (compound **I**).

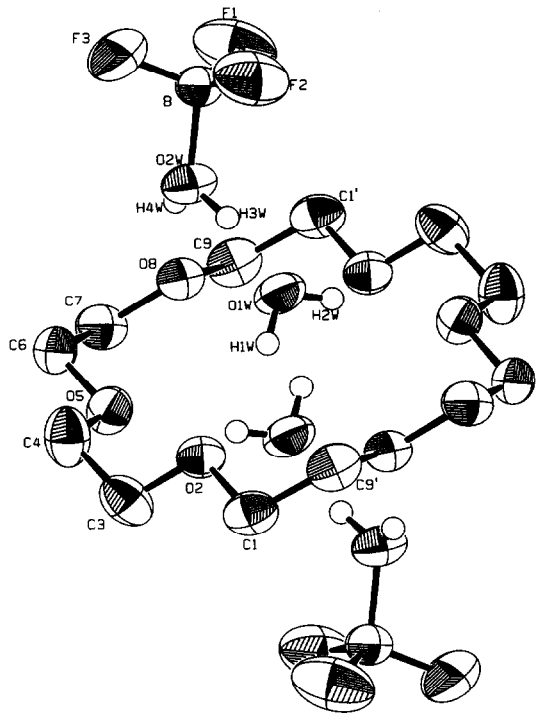

Fig. 2. The final crystal structure of the complex 18-c-6/2($BF_3OH_2 \cdot OH_2$) (compound **II**).

diffractometer. The lattice parameters and orientation matrix for the crystals were obtained using a least-squares procedure involving 25 carefully centred reflections in the range $25 < 2\theta < 40°$. Intensity data were collected in the $\omega/2\theta$ scan mode in the range $4 < 2\theta < 140°$, using a variable scan speed. The data were reduced and corrected for Lorentz and polarization effects.[14] An empirical extinction correction was applied, but due to the small absorption coefficient and insignificant radiation damage it was unnecessary to make corrections for radiation decay or absorption.

Crystal structure determination of **I**. Of the 2020 reflections which were collected, 1089 were unique ($R_{int} = 0.015$). Of these unique data only those 720 reflections with $I_o > 3\sigma(I_o)$ were included in further calculations. The structure was solved by direct methods (MULTAN-78).[15] The best phase set yielded a preliminary model with most of the non-hydrogen atoms of the molecule. The remainder of the non-hydrogen atoms were then located by successive cycles of least-squares refinement and difference electron density maps using standard Fourier syntheses and full-matrix least-squares techniques.[16] Most of the hydrogen atoms could be located in the difference electron density maps. Nevertheless, for convenience all of the hydrogen atoms in the initial model were calculated at idealized positions relative to their corresponding carbon atoms. All non-hydrogen atoms were refined using anisotropic thermal parameters. It should be noted that the crystallographic asymmetric unit of this structure is only one half of the complex (Fig. 1) and that both O_w (the water oxygen) and B are located at crystallographic special positions. During the course of refinement it was apparent that the BF_4^- group is disordered between several spherically related orientations around the boron atom. Three such orientations were assigned in the final model with the corresponding statistical occupancies of 0.45, 0.30 and 0.25 for the atom sets of F(1)—F(2), F(3)—F(4) and F(5)—F(6), respectively. The refinement of the structure converged smoothly to final crystallographic factors of $R = 0.072$ and $Rw = 0.10$. The final values of the thermal parameters of some of the atoms remained relatively high even at the final cycles of refinement, reflecting partial local disorder in several sites of the molecular system in the crystal. Nevertheless, in the final model there are no ambiguities as to the molecular structure of the entire complex or the conformation of the crown macrocycle.

Crystal structure determination of **II**. The integrated intensities of 2069 independent reflections were measured, of which only those 1924 reflections with $I_o > 3\sigma(I_o)$ were included in further calculations. The structure was solved by direct methods (MITHRIL).[17] The best phase set yielded very clearly all the non-hydrogen atoms of the molecule. For convenience, all hydrogen atoms of the crown ether were initially calculated at idealized positions relative to their corresponding carbon atoms. The hydrogen atoms of the BF_3OH_2 and the water molecules were located in the following difference electron density maps. The complete model was then refined by successive cycles of full-matrix least-squares techniques.[16] The positions of all non-hydrogen atoms were refined using anisotropic thermal parameters (nine parameters per atom), while the positions of all hydrogen atoms were refined with isotropic thermal parameters (four parameters per atom). The refinement converged rapidly to final crystallographic factors of $R = 0.061$ and $Rw = 0.123$. The relatively small thermal parameters of the atoms (Table S4) and the small ratios of shift/ESD in the last cycle of refinement (average of 0.0002) are evidence for the high quality of the diffraction data and the high accuracy in the final structure of **II**.

RESULTS AND DISCUSSION

Relevant bond lengths and angles for the structure of complex **I** are listed in Tables 1 and 2, respectively. Relevant bond lengths and angles for

the structure of complex **II** are listed in Tables 3 and 4, respectively. A stereoview of the crystallographic packing of the unit cell of **II** is shown in Fig. 3 and a side-view of the structure of **II** (including intermolecular hydrogen bond scheme) is depicted in Fig. 4.

In the complex of **I**, the crown adopts the most commonly encountered "round" conformation (D_{3d}-like symmetry[13]), where the oxonium ion is bound at the centre of the macrocycle (Fig. 1). The oxonium oxygen (Ow) is located practically equidistant (2.68–2.73 Å) from the six macrocyclic ethereal oxygens. Of the six macrocyclic oxygens, three alternating oxygens are pointing "down", while the

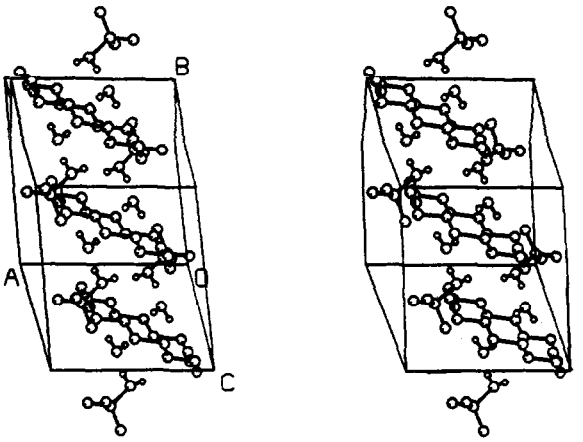

Fig. 3. Crystallographic unit cell packing of 18-C-6/2(BF_3OH_2·OH_2) (compound **I**). For clarity, only non-hydrogen atoms of the crown ring and all atoms of the BF_3OH_2·OH_2 species are shown.

other three oxygens are pointing "up". The planes formed by these two sets of oxygens are nearly parallel to each other (interplanar angle of 173°) and the oxonium oxygen is positioned between these two planes (0.175 Å below and above the two planes, respectively). Since we cannot locate the oxonium hydrogens in the electron density maps, we assume that the oxonium ion adopts two alternative orientations (each at 50% statistical occupancy) around its oxygen, such that two alternative sets of hydrogen bonds are formed. One such set of hydrogen bonds involves the three crown oxygens which point "down", while the other set involves the three oxygens which point "up". The BF_4^- counter-ion is positioned 7.3 Å away from the oxonium ion in the same general plane of the crown ether.

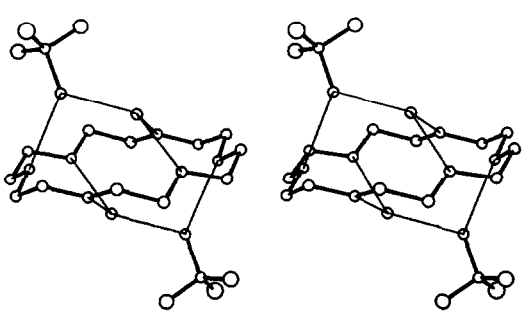

Fig. 4. Side-view of the structure of 18-C-6/2(BF_3OH_2·OH_2) (compound **II**), including the intermolecular hydrogen bonds (thin lines) O(1w)—O(2w), O(1w′)—O(2w′) = 2.49; O(1w)—O(2), O(1w′)—O(2′) = 2.85; O(1w)—O(5′), O(1w′)—O5 = 2.83; O(2w)—O(8), O(2w′)—O(8′) = 2.65 Å.

This anion is not involved in any direct intermolecular contacts, a fact that may explain why it is spherically disordered, as discussed above.

In complex **II** the macrocyclic ring of the crown ether appears also as the "round" conformation (conformer "A" D_{3d})[13] in a similar, yet not identical, conformation to the 18-C-6 ring of **I**. Here again, the crystallographic asymmetric unit is only one half of the complex (Fig. 2). There is a crystallographic centre of inversion at the centre of the macrocycle, although there is no ion or molecule in the "cavity" of the macrocycle. Two hydrogen-bonded systems of BF_3OH_2·H_2O interact with the crown ether on either side of the general macrocyclic plane (as demonstrated in Fig. 4). The six macrocyclic oxygens form a "chair shape" structure, where four of them [O(2), O(5) and their symmetry related atoms O(2′), O(5′)] form a perfect plane (plane *a*) and the other two oxygens are located 0.70 Å above [O(8)] and below [O(8′)] this plane. The two BF_3OH_2·H_2O systems which lie above and below plane *a* are diagonally oriented along the O(8)O(8)—O(8′) axis and located directly above O(8′) or O(8). The oxygen atom of the BF_3OH_2 species is hydrogen bonded to O(8′) (2.65 Å) of the crown ether and to the "free" water molecule via considerably shortened hydrogen bonds connecting it to the crown ring (2.49 Å). The water molecule is positioned 1.48 Å above plane *a* and interacts with O(2) and O(5′) via two specific hydrogen bonds. The O(1w)—O(2) and O(1w)—O(5′) distances are almost identical (2.85 and 2.83 Å, respectively) and the water hydrogens (which were clearly observed in the electron density maps) are located approximately along the O···O direction (± 20°), indicating a strong and symmetrical hydrogen bonding system. Such an arrangement is repeated, of course, on the other side of the macrocycle, such that the other BF_3OH_2·H_2O system is located below O(8) and hydrogen bonded through the water molecule to O(5) and O(2′). It is also hydrogen bonded to the crown's O(8) through the other hydrogen water in BF_3OH_2.

In these BF_3OH_2·H_2O systems the water oxygen is hydrogen bonded to the oxygen atom of BF_3OH_2. This hydrogen bond presents a short O_w···O distance (2.49 Å). The boron atom in the BF_3OH_2 moiety is almost tetrahedral (all angles are within the range 109 ± 4°), where the B—F(1), B—F(2), B—F(3) bonds (1.34–1.36 Å) are significantly shorter than the B—O bond (1.51 Å). This geometry of the BF_3OH_2 moiety is similar to that observed for BF_3OH_2 and $BF_3O(CH_3)H$ in the solid state determined at low temperature.[18] The recently determined structure of 18-C-6/BF_3OH_2 shows similar geometry of the BF_3OH_2 moiety,[12] yet the specific interactions to the

crown ether are significantly different. The main difference between complex **II** and the reported structure of 18-C-6/BF_3OH_2 is the insertion of an H_2O between the BF_3OH_2 and the crown ring. In complex **II** the water molecule features two hydrogen bonds to the macrocyclic ring—the O(1w)—H···O_c bonds (2.83–2.85 Å) and an additional bond to the oxygen atom of the BF_3OH_2 moiety, O(1w)···O(2w)—B (2.49 Å). Another difference between these two complexes is the BF_3OH_2/crown ratio. In complex **II** there are two BF_3OH_2·H_2O species bonded by one crown, while there is a 1:1 ratio in the 18-C-6/BF_3OH_2 complex. The solid-state structure of BF_3OH_2 with H_2O was determined at low temperature.[19] A comparison with the BF_3OH_2·H_2O moiety of complex **II** shows a significant difference in the distance between the two oxygens. In the solid-state structure of BF_3OH_2·H_2O the O···O distance is 2.63 Å, compared with a O···O distance of 2.49 Å in the complex structure of BF_3OH_2·H_2O with 18-C-6 crown ether. The strong intermolecular interaction in the latter stabilizes the normally unstable BF_3OH_2·H_2O system, as discussed above. The precise geometry required for such intermolecular hydrogen bonding may account for the fact that such a stabilized BF_3OH_2·H_2O complex has not been observed before. It is interesting to note that although the two BF_3OH_2·H_2O units associated with each crown ether are extended outwards (the relevant boron atoms are located *ca* 4.1 Å away from plane *a*), they are not involved in any additional intermolecular specific interactions in the crystal, as demonstrated in the unit-cell crystal packing (Fig. 3).

The present work shows that the normally unstable BF_3OH_2·H_2O system can be stabilized by its coordination to a crown ether. Hydrogen bonding obviously plays a major role, but no clear-cut pattern emerges as to what factors determine the stabilization of BF_3/BF_4^- species. Electrostatic effects appear to be of minor significance, since the covalently bonded species are at least as stable. Complex **I** has normal O···H bond distances similar to those found in other oxonium/crown-ether complexes. The oxonium ion is well shielded by the crown so that the BF_4^- ion is not involved in intermolecular contacts, perhaps accounting for the fact that it is spherically disordered.

It is of interest that in both cases the conformation adopted by the crown ether is independent of whether the oxonium ion is encapsulated in the cavity of the crown ether or whether the complex is formed outside of the cavity. The conformation adopted in all cases is the "round" D_{3d} or "D_{3d} like" conformation, which is the most commonly encountered and which has been calculated to be the conformer of lowest energy.[13] Such an observation is important not only for the evaluation of the specific case of the 18-C-6/oxonium (water) system, but also for other host–guest systems where multiple conformations of the host molecule are possible.

Supplementary material. A list of the coordinates of all atoms of **I** and **II** (Tables S1, S2), anisotropic temperature factors for non-hydrogen atoms of **I** and **II** (Tables S3, S4), all intramolecular distances in **I** and **II** (Tables S5, S6), all intramolecular bond angles in **I** and **II** (Tables S7, S8), all torsion angles for non-hydrogen atoms in **I** and **II** (Tables S9, S10), ESDs and interplanar angles for least squares planes in **I** and **II** (Tables S11, S12) and lists of observed and calculated structure factors for **I** and **II** (Tables S13, S14) are provided in the supplementary material (34 pages).

Acknowledgements—We gratefully acknowledge the comments of Professor D. Mootz on an earlier version of this manuscript which drew our attention to the relevant studies concerning the BF_3OH_2·H_2O species. We thank the Israeli Academy of Sciences (Grant No. 253/88 to GS), the Friends of the Hebrew University in England and Ms Myrtle Franklin, and the Bat Sheva de Rothchild Foundation for financial support. One of us (HF) thanks the Wolf Foundation for a predoctoral fellowship.

Abstract—Both title complexes have been synthesized and subsequently characterized by X-ray diffraction. Results available on the Cambridge Crystallographic Database (V.3) suggest that this is the first tris complex of a fully substituted 0,0′-bonded acetylacetone to be characterized as a crystal structure from X-ray methods.

One step catalytic procedures which lead to the regiospecific introduction of the isotopes (^{2}H, ^{3}H) of hydrogen are becoming increasingly attractive methods for incorporating the label in a wide range of organic compounds, particularly those of interest to the pharmaceutical industry and until recently, the preferred catalyst for this has been hydrated rhodium(III) chloride.[1] The discovery that ruthenium acetylacetonate complexes catalyse the regiospecific tritiation of aromatic carboxylates offers the dual advantages of improved specific activity and ease of chemical investigation owing to improved homogeneous retention. Only the ruthenium(III) complex of this ligand is known to catalyse the reaction; current work reflects modifications made to the catalyst structure and subsequent investigations in the potential for tritiation catalysis shown by homologous complexes. The apparently unique exhibition of catalytic behaviour by the ruthenium(III) complex suggested that structural considerations may be responsible, but this structure determination refutes such suggestions.

EXPERIMENTAL

Syntheses

There are two routes to complex **I**, both involving refluxing hydrated ruthenium(III) chloride in aqueous solution. Route A proceeds via an ethanolic reduction to $[Ru_3Cl_{12}]^{2-}$ with the subsequent addition and reaction of the ligand with the cluster anion,[2] whereas in route B[3] the ligand is added directly to the solution of hot ruthenium(III) chloride.

$$RuCl_3 \cdot 3H_2O \xrightarrow[\text{(B) non-reductive addition}]{\text{(A) reductive addition}}$$

$$\underset{\text{(I)}}{Ru(acac)_3} \xrightarrow{\text{NBS, room temperature}} \underset{\text{(II)}}{Ru(3Br\text{-}acac)_3}$$

The microcrystalline product from route A was crystallized over the course of several days from ethanol, giving ruby–red prisms which were suitable for crystallographic analysis. It was subsequently found that route B gave a cleaner reaction and product and a better yield; thus, for the preparation of complex **II** the reaction of N-bromosuccinimide (NBS) with complex **I** prepared via route B was

employed.[4] Complex **II** gave maroon polyhedral plates when recrystallized from hot acetone.

Both cell determinations and data collections were performed on an Enraf–Nonius CAD4 four-circle diffractometer using graphite monochromated Mo-K_α radiation ($\lambda = 0.71069$ Å). In both cases, 25 reflections taken from the angular range $13 > \theta > 15°$ were used to determine the unit cell and no mechanical or chemical deterioration was observed in either case. Details of data collection and results for both complexes are summarized in Table 1.

For complex **I**, bond lengths and angles are summarized in Table 2 and those of complex **II** in Table 3.

Solution to crystal structures

Both structures were solved using the Enraf–Nonius Structure Determination package.[5]

Complex **I.** Solution of a three-dimensional Patterson synthesis gave a ruthenium position in the Harker plane (u, $\frac{1}{2}$, w) which refined to 34%. Iterative Fourier synthesis with isotropic refinement yielded a complete molecule with $R = 8.8\%$. Subsequent anisotropic refinement, of the ruthenium only, with the Killean–Lawrence weighting scheme[6] reduced R to 5.3%. Anisotropic refinement of the whole molecule converged to give a final R value of 3.7%. Figure 1 shows an ORTEP drawing of complex **I**.

Complex **II.** The direct methods program MULTAN[7] was used to provide four heavy atom positions which refined to $R = 32\%$. Further isotropic refinement with a single Fourier map yielded one ligand with R at 23% and then a single difference map provided the atomic complement necessary to complete the molecular skeleton, causing R to fall to 16%. Hydrogen atoms were added at calculated positions (bond length of 1 Å) and anisotropic refinement of the whole molecule using the Killean–Lawrence weighting scheme reduced R to

RESULTS AND DISCUSSION

Following the discovery of tritiation catalysis shown by the ruthenium(III) complex, analogous

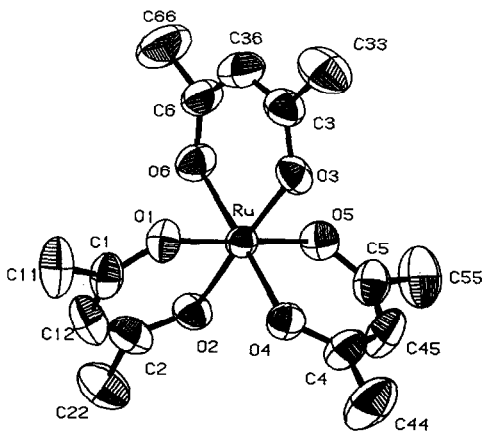

Fig. 1. ORTEP drawing of tris(2,4-pentanedionato) ruthenium(III) with 50% probability thermal ellipsoids.

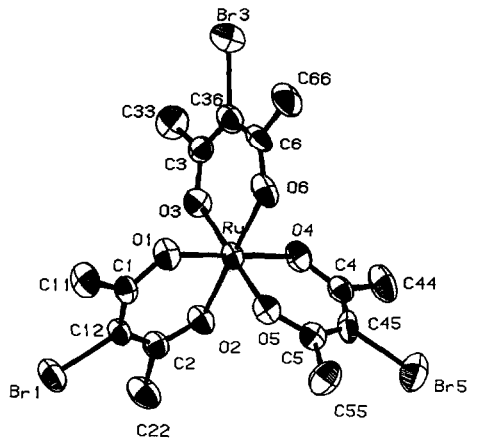

Fig. 2. ORTEP drawing of tris(3-bromo-2,4-pentanedionato) ruthenium(III) with 50% probability thermal ellipsoids.

chelates of a variety of closely related metals were investigated; none of these exhibited catalytic activity. A structural examination of those complexes tested, aided by the Cambridge Crystallographic Database (V.3),[8] revealed distortion in the structure of the racemic ruthenium complex which has already been reported to crystallize in the monoclinic space group $P2_1/c$.[9]

The redetermination of the structure of complex **I** resulted in the discovery of a dimorphic relationship which does not confirm the variation in ruthenium–oxygen bond lengths previously recorded. As the previous determination and labelling work both employed the commercially available compound, powder photographs were taken to investigate the relationship between these forms. The resulting photographs were identical, suggesting that structural irregularities do not account for the observed catalytic effect.

A dimorphic relationship in *Pbca* and $P2_1/c$ is observed in the acetylacetone complexes of vanadium(III)[10] and manganese(III);[11] by analogy, this is the α-form, the β-form being that previously reported. Furthermore, this ruthenium complex is isomorphic with the acetylacetone complexes of iron(III)[12] and scandium(III).[13]

In both structures the mean ruthenium–oxygen bond distance is 2.00 Å, which is within the range observed in other β-diketonato complexes of ruthenium(III)[14,15] and in agreement with the racemic and enantiomeric forms.[16] Evidence for pseudoaromatic character in both cases comes from the typical 0.01 Å shortening observed in ring carbon–carbon bonds in comparison to the terminal carbon–carbon bonds. In complex **II**, the mean carbon–bromine distance is 1.914(9) Å, which is

comparable to those observed in other substituted bromoaromatic systems.[17,18]

The structure of **II** represents a new development in the chemistry of acetylacetonate complexes; the only previous structural determinations are on the 3-methyl and 3-phenyl derivatives of copper(II).[19,20] There appears to be a slight reduction in the external angles at the 3-position in comparison to the aforementioned methyl derivative, but substitution of hydrogen by bromine at the 3-position does not affect the geometry.

Acknowledgements—We would like to thank Mr G. W. Smith for his kind guidance in overseeing the structural solutions, Dr J. H. Aupers for valuable discussion and helpful comments and Mr N. D. Wright for his instruction on the Cambridge Crystallographic Database.

EQUILIBRIA IN COMPLEXES OF N-HETEROCYCLIC COMPOUNDS—LI.* SYNERGIC SOLUBILITY AND X-RAY CRYSTAL STRUCTURE ANALYSIS OF *MER*-CHLORO-OXALATO-TRIS-PYRIDINE-IRIDIUM(III), $[IrCl(py)_3(C_2O_4)]$

NICOLA S. A. EDWARDS, R. D. GILLARD,† MICHAEL B. HURSTHOUSE,† HARVEY F. LIEBERMAN and K. M. ABDUL MALIK

School of Chemistry and Applied Chemistry, University of Wales, P.O. Box 912, Cardiff CF1 3TB, U.K.

(*Received* 8 *June* 1993; *accepted* 6 *August* 1993)

Abstract—The title compound, *mer*-$[IrCl(py)_3(C_2O_4)]$, has been made by the reaction of the known *trans*-dichloro-tetrapyridine-iridium(III) chloride with ethanedioate ion(oxalate) in aqueous ethanol. A non-electrolyte, it resembles its rhodium eutrope in showing extraordinary synergic solubility in water: pyridine. An X-ray structure determination has confirmed the *mer* geometry.

Complex ions of rhodium (and to an extent iridium) with pyridine and with chelating dicarboxylates such as ethane-1,2-dioate (oxalate) have been well studied. A few mixed species, such as $[RhCl(py)_3(C_2O_4)]$ (**A**) are known. The unusual synergic solubility of this compound had been known for many years and we are trying to understand its molecular origin. We therefore synthesized the new iridium(III) mixed compound *mer*-$[IrCl(py)_3(C_2O_4)]$ (**B**) and report here some of its properties, including its structure. The known bromo-rhodium compound $[RhBr(py)_3(C_2O_4)]$ (**C**) is also further described with a convenient synthesis.

EXPERIMENTAL

Preparation of complexes

Mer-*Chlorotrispyridineoxalatoiridium(III)* (B). *Trans*-$[IrCl_2(py)_4]Cl \cdot 6H_2O$[2] (0.444 g, 0.614 mmol) and potassium oxalate (0.113 g, 0.614 mmol) were refluxed for 7 days in 50% ethanol solution (100 cm^3). Yellow needles (0.08 g) formed on cooling: these were collected by filtration. The filtrate was treated with an excess of ethanol to precipitate unreacted potassium oxalate. After filtration, the volume was reduced on a rotary evaporator when a further crop of crystals of the desired product was obtained (0.116 g). Yield: 58%. Found: C, 36.8; H, 2.8; N, 7.5. Calc. for $C_{17}ClH_{15}N_3O_4Ir$: C, 36.9; H, 2.7; N, 7.6%. IR: 1700m, 1670m, 1610m, 1245w, 1160w, 1072m-w, 1020w, 880w, 805w, 762m-w, 700s, 655w, 560w, 485w, 465w, 365w, 345s, 310w, 290w, 265m, 235w cm^{-1}.

A measurement of conductance (*ca* 10^{-3} M in aqueous pyridine) gave $\Lambda_m = 6.82$ S $mol^{-1}dm^3$. Complex **B** dissolves in boiling concentrated hydrochloric acid and on cooling, the solution yields the known complex $[IrCl_3(py)_3]$ as its *mer* isomer,[3] identified by its electronic spectrum in chloroform. Three bands were observed in the UV region at 320–317 shoulder, 266 and 238 nm. A visible absorption was also observed at 421–436 nm. These are in accordance with the electronic spectrum of the *mer*-$[IrCl_3(py)_3]$[4] isomer.

Mer-*bromotrispyridineoxalatorhodium(III)* (**C**). *Trans*-$[RhBr_2(py)_4]Br$ was prepared by boiling *trans*-$[RhCl_2(py)_4] \cdot 6H_2O$ with an excess of aqueous potassium bromide. After approximately 2 h the desired orange solid formed. This was collected by filtration, washed with ice-cold water and recrystallized from hot water; **C** was synthesized from it, *mutatis mutandis*, as with **A**.[2] Found: C, 40.3; H, 3.0; N, 8.3. Calc. for $C_{17}BrH_{15}N_3O_4Rh$: C, 40.18; H, 2.98: N, 8.27%. IR: 1703m, 1668m,

*See ref. 1.

1605m, 1242w, 1212m, 1153w, 1068m, 1015w, 881w, 796w, 775m, 761m, 708s, 697s, 686m, 651s, 553s, 480m, 470s, 412m, 360s, 350s, 275m, 251w cm^{-1}.

Electronic spectra were measured using a Kontron–Uvikon 930 UV–vis spectrophotometer. IR spectra were measured using a Perkin–Elmer 577 IR grating spectrophotometer, as Nujol mulls on caesium iodide plates; wave numbers are quoted to $\pm 2\ cm^{-1}$.

Crystallography

Data for compound **B** were collected on a FAST TV Area Detector diffractometer following previously described procedures.[5] The structure was solved and developed via the heavy-atom method and refined by full-matrix least-squares techniques. A correction for absorption was made using DIFABS.[6] All hydrogens were placed in idealized positions. Crystal data and details of the structure refinement are given in Table 1. Atomic coordinates, bond lengths and angles and thermal parameters have been deposited as supplementary material with the Editor. Atomic coordinates have also been deposited at the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

The three compounds, [MX(py)$_3$(C$_2$O$_4$)] (**A**: M = Rh, X = Cl; **B**: M = Ir, X = Cl; **C**: M = Rh, X = Br) show synergic solubility in aqueous pyridine, as depicted in Fig. 1. The property was discovered[7] for the chloro-rhodium species and Reichardt[8] singled out this case in his discussion of solvent effects in organic systems. Chloro-oxalato-tris-pyridine-iridium(III) forms only slowly, even with ethanol present. Such a substitution at rhodium(III) centres is often strongly catalysed by the 2e-reductant ethanol, but that is not obvious here. Powder patterns show that compounds **A** and **B** are clearly isostructural (powder data have been deposited). The crystalline form which we have is isostructural with the well-known rhodium(III) eutrope. Our structure, therefore, confirms both that the rhodium compound is indeed the *mer* isomer and that its reaction [eq. (1)] with hydrochloric acid is, like many such acid displacements of oxalate in acid, stereoretentive: the product with an absorption at 428 nm was already known from spectroscopy to be the *mer* isomer.

$$mer\text{-}[RhCl(py)_3(C_2O_4)] + 2HCl \rightarrow mer\text{-}[RhCl_3(py)_3] + H_2C_2O_4 \quad (1)$$

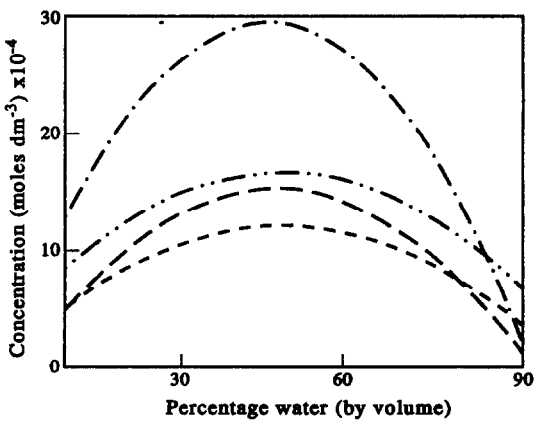

Fig. 1. Solubilities (given as concentrations of saturated solutions at 30° C) in water/pyridine of *mer*-[MX(py)$_3$(C$_2$O$_4$)]: ----, **A**(M = Rh, X = Cl$^-$); -------, **B**(M = Ir, X = Cl$^-$); -----, **C**(M = Rh, X = Br$^-$). The curve ---- is that reported[7] for **A**, *mer*-[RhCl(py)$_3$(C$_2$O$_4$)], measured at 15° C.

Table 2. Selected bond lengths (Å) and angles (°) for **B**

Ir—Cl	2.341(6)	Ir—O(1)	2.040(11)
Ir—O(2)	2.033(11)	Ir—N(11)	2.045(14)
Ir—N(21)	2.045(13)	Ir—N(31)	2.061(11)
O(1)—Ir—Cl	174.0(3)	O(1)—Ir—O(2)	83.0(5)
O(2)—Ir—Cl	91.1(4)	N(11)—Ir—Cl	89.9(5)
N(11)—Ir—O(2)	87.6(5)	N(11)—Ir—O(1)	90.0(5)
N(21)—Ir—Cl	91.3(4)	N(21)—Ir—O(1)	88.5(5)
N(21)—Ir—O(2)	88.5(5)	N(21)—Ir—N(11)	176.0(5)
N(31)—Ir—Cl	92.8(4)	N(31)—Ir—O(1)	93.2(5)
N(31)—Ir—O(2)	176.0(5)	N(31)—Ir—N(11)	93.4(6)
N(31)—Ir—N(21)	90.4(5)		

We have also shown this stereoretention for eq. (2):

$$mer\text{-}[IrCl(py)_3(C_2O_4)] + 2HCl \rightarrow mer\text{-}[IrCl_3(py)_3] + H_2C_2O_4 \quad (2)$$

Our crystals of the product from eq. (1) indeed have the well-known spectroscopic properties of *mer*-$[RhCl_3(py)_3]$ (e.g. *d–d* absorption at 428 nm). They have the same space group and unit cell as those studied in crystallographic detail elsewhere.[9] The available[9] crystal and molecular structure of *mer*-$[RhCl_3(py)_3]$, determined for a compound of unknown spectroscopic properties and provenance, is that of the isomer absorbing at 428 nm.

The vibrational spectra of **A** and **B** (as solids) are also very similar. The IR spectrum of **C**, the bromorhodium member, is closely similar, but its crystal lattice is entirely different (data deposited). Despite this (and it may be that a second dimorph crystallizes in this case alone), the solubility properties of all three are alike. The vibrational spectra of these $[MX(py)_3(C_2O_4)]$ complexes are superimposable to 360 cm^{-1}: the vibrations involving metal ions may be compared in **A**(Rh—Cl) and **B**(Ir—Cl), suggesting υ(Rh—Cl) at 318 ± 3 and υ(Ir—Cl) at 290 cm^{-1}. These frequencies are in line with others from the literature.

We interpret the synergism in solubility as representing the specific solvation of the polar meridian (P) by water and the non-polar (NP) meridian by pyridine. Describing the solvation enthalpies $\Sigma\Delta H$ as ΔH_P or ΔH_{NP}, in any solvent mixture we have:

$$\Sigma\Delta H = \Delta H_P + \Delta H_{NP}.$$

Using suffixes W for water and H for heterocycle, we see that:

$$\Delta H_{P(W)} \gg \Delta H_{P(H)}; \quad \Delta H_{NP(H)} \gg \Delta H_{NP(W)}.$$

Denoting the lattice enthalpy by U, dissolution occurs when

$$\Sigma\Delta H > U.$$

We believe that:

$$U > \Sigma\Delta H_W[= \Delta H_{P(W)} + \Delta H_{NP(W)}]$$
$$> \Sigma\Delta H_H[= \Delta H_{P(H)} + \Delta H_{NP(H)}]$$
$$\text{but} < \Sigma\Delta H_M[= \Delta H_{P(W)} + \Delta H_{NP(H)}],$$

where M refers to the mixture.

Our detailed thermodynamic and spectroscopic work on the molecular bases for these variations of ΔH will be published elsewhere.

Figure 2 shows the molecular structure of **B**. Table 2 contains selected bond lengths and angles. The measured iridium–chloride bond length of 2.341(6) Å compares well with those measured for $K_3[IrCl_6]$[10] (2.36 Å) and *trans*-$[IrCl_2(py)_4]Cl \cdot 6H_2O$(2.35 Å). The measured iridium–oxygen bond lengths are slightly longer in *mer*-$[IrCl(py)_3(C_2O_4)]$, at 2.033 and 2.040 Å, than in $K_3[Ir(ox)_3] \cdot 3H_2O$[11] (1.96 Å). In contrast, one of the Ir—N bond lengths in **B** (2.06 Å) is identical to one of the lengths in *trans*-$[IrCl_2(py)_4]Cl \cdot 6H_2O$. The

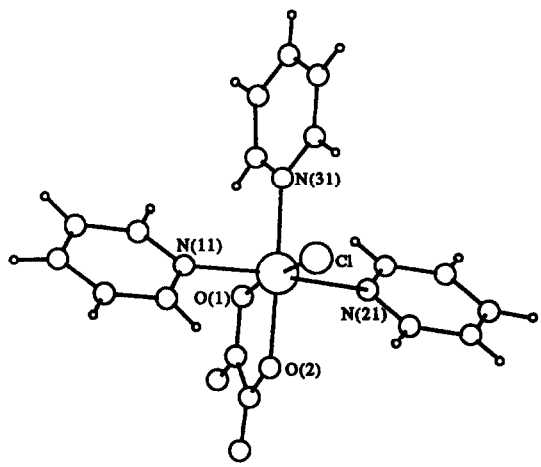

Fig. 2. The molecular structure of **B**.

Table 3. Pyridine ring orientations

	B	E	F	G	H
a*	138.36	130.08	42.48	49.00	65.09
b	79.68	136.20	110.10	43.47	48.58
c*	46.66	125.30	43.31	52.26	119.38

Values given are the dihedral angles between the pyridine ring planes and the meridional py_3MX plane. a* and c* are the outer rings and are interchangeable due to the "chemical" symmetry of the molecule. Similar values correspond to a propeller arrangement, approximate supplementary values correspond to different orientations relative to the meridianal plane.

B = This work; E = *mer*-$[CrCl_3(py)_3]$;[12] F = *mer*-$[InBr_3(py)_3]$;[13] G = *mer*-$[RhCl_3(py)_3]$;[9] H = *mer*-$[TlBr_3(py)_3]$.[14]

other Ir—N bond lengths [2.045(14) Å] are both shorter than those in *trans*-$[IrCl_2(py)_4]Cl \cdot 6H_2O$. A particular feature of this and related structures is the orientation of the pyridine rings with respect to the plane through the iridium and the three nitrogens. A comparison of data for these dihedral angles is given in Table 3.

SYNTHESIS OF ISOCYANIDE COMPLEXES OF ZINC. THE MOLECULAR AND CRYSTAL STRUCTURE OF $Zn(SeC_6H_2Bu^t_3)_2(CNBu^t)_2$

MANFRED BOCHMANN,* GABRIEL C. BWEMBYA and ANNE K. POWELL

School of Chemical Sciences, University of East Anglia, Norwich NR4 7TJ, U.K.

(*Received* 8 *June* 1993; *accepted* 4 *August* 1993)

Abstract—The sterically hindered zinc chalcogenolato complexes $[Zn(EAr'')_2]_2$ (E = S, Se; Ar'' = 2,4,6-$Bu^t_3C_6H_2$) react with 1 equivalent of tert-butylisocyanide in non-coordinating solvents to give $Zn(EC_6H_2Bu^t_3)_2(CNBu^t)$ (**1**, E = S; **2**, E = Se) as thermally stable crystalline adducts; the compounds are thought to be chalcogenolato-bridged dimers. In the presence of excess isocyanide ligand the 1:2 adducts $Zn(EAr'')_2(CNBu^t)_2$ (**3**, E = S; **4**, E = Se) are isolated. The compounds represent the first examples of well-characterized isocyanide complexes of zinc. The X-ray structure of **4** showed that it is monomeric with a distorted tetrahedral coordination geometry of the metal centre, which reflects the steric requirements of the chalcogenolato and isocyanide ligands, respectively.

Isocyanides are among the most widely used ligands in transition metal chemistry. By contrast, isocyanide complexes of metals of the zinc triad are, to our knowledge, almost unknown. An incompletely characterized adduct with a zinc halide, $ZnBr_2(CNBu^t)_2$, has been reported[1] and a similar complex with ZnI_2 has been claimed in a patent.[2] As part of our search for potential single-source precursors for the deposition of II–VI semiconductor films from the gas phase[3] we have shown earlier that the coordinatively unsaturated zinc thiolato and selenolato complexes $[Zn(EAr'')_2]_2$ (E = S, Se; Ar'' = 2,4,6-$Bu^t_3C_6H_2$) readily react with O, N and P donor ligands to give three- and four-coordinate compounds[4–6] and react even with weak ligands such as ketones and aldehydes to give stable crystalline complexes.[7] We report here the synthesis and characterization of isocyanide complexes of bulky zinc chalcogenolato complexes.

EXPERIMENTAL

All operations were performed under dry argon using standard vacuum-line techniques. The complexes $[Zn(EAr'')_2]_2$ (E = S, Se; Ar'' = 2,4,6-$Bu^t_3C_6H_2$) were prepared as described previously.[4] Petroleum ether was distilled from sodium benzophenone under nitrogen. Bu^tNC (Aldrich) was dried over molecular sieves and distilled under nitrogen prior to use. Perkin–Elmer 684 (IR) and JEOL EX90Q and EX270 (^1H, ^{13}C NMR) spectrometers were used.

Preparation of $[Zn(SAr'')_2(Bu^tNC)]_2$ (1)

To a stirred suspension of $[Zn(SAr'')_2]_2$ (200 mg, 0.16 mmol) in petroleum ether (15 cm^3) at room temperature was added tert-butylisocyanide (27 mg, 0.32 mmol). The solid dissolved to give a clear colourless solution from which a white solid precipitated within a few minutes. After stirring the mixture for 2 h the precipitate was filtered off and recrystallized from hot toluene (5 cm^3) to give **1** as colourless crystals (83 mg, 0.06 mmol, 37%), dec. 200°C. The air-sensitive compound is soluble in chloroform and toluene. Found: C, 70.1; H, 9.7; N, 1.9; S, 9.7. Calc. for $C_{41}H_{67}NS_2Zn$: C, 70.0; H, 9.6; N, 2.0; S, 9.1%. IR (cm^{-1}): 2244 (s) [ν(CN)]. ^1H NMR (90 MHz, $CDCl_3$): δ 0.85 (s, 9 H, Me of Bu^tNC), 1.07 (s, 18 H, *p*-Bu^t), 1.45 (s, 36 H, *o*-Bu^t), 7.14 (s, 4 H, aryl). ^{13}C NMR (25 MHz, $CDCl_3$): δ 29.3 (Me of Bu^tNC), 31.6 (*p*-CMe_3), 32.0 (*o*-CMe_3),

*Author to whom correspondence should be addressed.

34.8 (*p*-CMe_3), 38.3 (*o*-CMe_3), 121.9 (*m*-C), 145.4 (*p*-C), 152.9 (*o*-C).

$Zn(SeAr'')_2(Bu^tNC)]_2$ (2)

In an analogous procedure, $[Zn(SeAr'')_2]_2$ (150 mg, 0.095 mmol) in petroleum ether (10 cm^3) was reacted with Bu^tNC (15 mg, 0.18 mmol) to give **2** as colourless crystals (56 mg, 0.035 mmol, 39%), dec 196–198°C. Found: C, 61.2; H, 8.5; N, 1.7. Calc. for $C_{41}H_{67}NSe_2Zn$: C, 61.8; H, 8.5; N, 1.8%. IR (cm^{-1}): 2218 (s) [ν(CN)]. ^1H NMR (270 MHz, $CDCl_3$): δ 1.04 (s, 9 H, Me of Bu^tNC), 1.28 (s, 18 H, *p*-Bu^t), 1.69 (s, 36 H, *o*-Bu^t), 7.37 (s, 4 H, aryl). ^{13}C NMR (25 MHz, $CDCl_3$): δ 29.4 (Me of Bu^tNC), 31.5 (*p*-C*Me*$_3$), 32.3 (*o*-C*Me*$_3$), 34.8 (*p*-*C*Me_3), 39.1 (*o*-*C*Me_3), 122.0 (*m*-C), 146.3 (*p*-C), 153.6 (*o*-C).

$Zn(SAr'')_2(Bu^tNC)_2$ (3)

To a stirred suspension of $[Zn(SAr'')_2]_2$ (198 mg, 0.16 mmol) in petroleum ether (15 cm^3) at room temperature was added tert-butylisocyanide (265 mg, 3.19 mmol). The solid dissolved to give a clear colourless solution, from which a white solid precipitated within a few minutes. Stirring was continued for 1 h. The precipitate was filtered off and recrystallized from warm toluene (5 cm^3) to give **3** as colourless crystals (93 mg, 0.12 mmol, 37%), dec. 192°C. The air-sensitive compound was soluble in dichloromethane, chloroform and toluene. Found: C, 70.5; H, 9.8; N, 3.4; S, 8.3. Calc. for $C_{46}H_{76}N_2S_2Zn$: C, 70.2; H, 9.7; N, 3.6; S, 8.2%. IR (cm^{-1}): 2223 (s) [ν(CN)]. ^1H NMR (270 MHz, CD_2Cl_2): δ 1.14 (s, 18 H, Me of Bu^tNC), 1.26 (s, 18 H, *p*-Bu^t), 1.62 (s, 36 H, *o*-Bu^t), 7.33 (s, 4 H, aryl). ^{13}C NMR (25 MHz, $CDCl_3$): δ 29.8 (Me of Bu^tNC), 31.6 (*p*-C*Me*$_3$), 32.1 (*o*-C*Me*$_3$), 35.0 (*p*-*C*Me_3), 38.6 (*o*-*C*Me_3), 122.3 (*m*-C), 145.4 (*p*-C), 153.2 (*o*-C).

$Zn(SeAr'')_2(Bu^tNC)_2$ (4)

The procedure given for **3** was followed to prepare **4** from $[Zn(SeAr'')_2]_2$ (394 mg, 0.28 mmol) and tert-butylisocyanide (458 mg, 5.51 mmol) as colourless crystals (218 mg, 0.248 mmol, 45%), dec. 190°C. The crystalline compound contains small amounts of hexane as one solvent of crystallization, most of which was released in prolonged evacuation at room temperature. Found: C, 63.4; H, 8.6; N, 3.3. Calc. for $C_{46}H_{76}N_2Se_2Zn$: C, 62.8; H, 8.7; N, 3.2%. IR (cm^{-1}): 2218 (s) [ν(CN)]. ^1H NMR (270 MHz, CD_2Cl_2): δ 1.18 (s, 18 H, Me of Bu^tNC), 1.27 (s, 18 H, *p*-Bu^t), 1.68 (s, 36 H, *o*-Bu^t), 7.35 (s, 4 H, aryl). ^{13}C NMR (25 MHz, $CDCl_3$): δ 29.8 (Me of Bu^tNC), 31.6 (*p*-C*Me*$_3$), 32.5 (*o*-C*Me*$_3$), 35.0 (*p*-*C*Me_3), 39.6 (*o*-*C*Me_3), 122.3 (*m*-C), 146.0 (*p*-C), 153.2 (*o*-C).

X-ray crystallography

Crystal data. $C_{46}H_{76}N_2Se_2Zn \cdot 1.6\ C_5H_{12}$, $M_r = 995.8$, monoclinic, space group $C2/c$ (no. 15), $a = 9.570(3)$, $b = 18.628(9)$, $c = 31.442(11)$ Å, $\beta = 94.63(3)°$, $V = 5587$ Å^3, $Z = 4$, $D_{calc} = 1.184$ g cm^{-3}, $F(000) = 2125$, μ(Mo-K_α) = 1.655 mm^{-1}.

Data collection and processing. Measurements were made on a crystal of the approximate dimensions 0.24 × 0.32 × 0.45 mm with a Siemens R3m/V diffractometer and graphite monochromated Mo-K_α radiation ($\lambda = 0.71073$ Å) using the ω-scan mode, scan range 0.60° in ω, scan speeds 3.00–19.53° min^{-1} in ω, $2 < 2\theta < 46°$, $-10 \leqslant h \leqslant 10$, $0 \leqslant k \leqslant 22$, $-37 \leqslant l \leqslant 37$. 4142 unique reflections, 1194 with $F_o > 6.0\sigma(F_o)$. The crystals deteriorated noticeably during data collection and a correction for this was applied, as well as Lorentz and polarization corrections.

Structure analysis and refinement. The structure was solved using the heavy-atom procedure and refined *via* full-matrix least-squares methods using SHELXTL programs. The zinc and selenium atoms were located from the Patterson map. Successive difference Fourier syntheses and full-matrix refinements revealed all other non-hydrogen atoms. There was evidence of the presence of disordered solvent molecules which were modelled with two fully occupied and four partially (1/2) occupied carbon sites per asymmetric unit. The marked deterioration of the crystal during data collection is probably partly the result of loss of this solvent. Hydrogen atoms were constrained to their calculated positions on carbons in the complex using a riding model and refined with fixed isotropic temperature factors. Only the zinc and selenium atoms were refined anisotropically, since more satisfactory refinement resulted from omitting the weak reflections and refining all but zinc and selenium isotropically in order to maintain a reasonable data/parameter ratio, rather than including these and refining all atoms anisotropically. A weighting scheme of the form $w^{-1} = \sigma^2(F) + 0.0070\ F^2$ was applied. The final difference-Fourier synthesis was essentially featureless, largest difference peak 0.69 e Å^{-3}, largest hole 1.14 e Å^{-3}. Final data: parameter ratio was 8.8:1, $R = 0.0876$, $R_w = 0.0922$.

Displacement factor coefficients, full lists of bond lengths and angles and F_o/F_c lists have been deposited with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

The addition of 1 equivalent of tert-butylisocyanide to a suspension of $[Zn(EAr'')_2]_2$ (E = S, Se) in petroleum ether at room temperature leads to the rapid formation of a clear solution, from which colourless crystals of $[Zn(EAr'')_2(CNBu^t)]_2$ (**1**, E = S; **2**, E = Se) are obtained (Scheme 1). The IR spectra of **1** and **2** exhibit the ν(CN) stretching modes at 2244 and 2218 cm^{-1}, respectively, and display the usual shift to higher frequency on coordination compared with the free ligand (2125 cm^{-1}). Although only one type of chalcogenolato ligands could be discerned by ^1H and ^{13}C NMR spectroscopy and molecular weight measurements do not give meaningful results because of the facile dissociation of donor ligands in solvents such as benzene, complexes **1** and **2** are thought to be dimeric on the basis of the small cone angle of the isocyanide ligands and the precedence for a similar dimeric structure in the case of the aldehyde complex $[Zn(SeAr'')_2(OCHC_6H_4OMe)]_2$.[7] Unfortunately crystals of **1** or **2** proved to be twinned and attempts at determining the crystal structures were unsuccessful.

Treatment of suspensions of $[Zn(EAr'')_2]_2$ in petroleum ether with an excess of Bu^tNC gives the 1:2 complexes $Zn(EAr'')_2(CNBu^t)_2$ (**3**, E = S; **4**, E = Se) as colourless crystals. The ν(CN) bands in the IR spectra are found at similar frequencies, 2223 and 2218 cm^{-1} for **3** and **4**, respectively. The crystal structure of **4** was determined (Fig. 1). Selected bond lengths and angles are given in Table 1.

The complex has a distorted tetrahedral geometry which reflects the steric requirements of the bulky selenolato and small isocyanide ligands. Hence, the Se(1)—Zn—Se(1A) angle is widened to 119.8(2)°, while the angle C(19)—Zn—C(19A) is only 89.9(13)°. The Zn—Se distance of 2.380(3) Å is slightly longer than the bond length between zinc and a terminal selenolato ligand in the related complex $[Zn(SeAr'')_2(OCHC_6H_4OMe)]_2$ (**5**) [2.345(3) Å], but significantly shorter than bridging Zn—Se distances (2.45–2.55 Å).[7] There is to our knowledge no precedence for a zinc complex π-bonded to carbon. However, the Zn—C(19) bond length to the isocyanide ligand appears to be rather long, 2.131(23) Å, when compared for example with the Zn—O distances to the aldehyde ligand in **5** [2.059(7) Å][7] and to the tetrahydrothiophene oxide ligand in $Zn(SeAr'')_2(OSC_4H_8)$ [1.925(14) Å].[6] The C(19)—N(1) bond length of 1.093(28) Å is short compared with transition metal isocyanide ligands, even those which lack *d*-electrons for back-bonding. Some structural parameters of isocyanide complexes are collected in Table 2 for comparison. The shortness of the C—N bonds, together with the long C—Zn distances, indicates that isocyanide ligands

FORMATION OF A NOVEL "BEDSPRING"-LIKE FRAMEWORK STRUCTURE BY A NEODYMIUM NITRATE COMPLEX WITH N,N′-BUTYLENEBIS(2-PYRIDONE)

DAVID M. L. GOODGAME,* STUART P. W. HILL and DAVID J. WILLIAMS

Chemistry Department, Imperial College of Science, Technology and Medicine, London SW7 2AY, U.K.

(*Received* 3 *June* 1993; *accepted* 4 *August* 1993)

Abstract—Reaction of N,N′-butylenebis(2-pyridone) (BBP) with hydrated $M(NO_3)_3$ salts (M = Y or a lanthanide ion) affords the complexes $M_2(BBP)_3(NO_3)_6$. Thorium(IV) nitrate and dioxouranium(VI) nitrate give $Th_2(BBP)_3(NO_3)_8 \cdot 0.5Me_2CO$ and $UO_2(BBP)(NO_3)_2$, respectively. X-ray diffraction studies on the Nd complex show it to contain arrays of contiguous 66-membered macrocyclic rings arranged so as to form an unusual "bedspring"-like network structure.

We recently reported a general strategy for the synthesis of polymeric complexes containing arrays of large metallomacrocyclic rings, by the use of bis(pyridone) (**I**) or bis(lactam) ligands (**II**).[1] In order fully to exploit this approach, which is proving to be very fruitful in generating a diversity of new compounds,[2] we are currently assessing how the choice of metal ion, anion and the nature of the bridge between the pyridone (or lactam) units influences the final, polymeric structure adopted. Variations in the ligand bridging unit can be in terms of the bridge length, flexibility or conformational preference(s). As part of this programme, we report here a new and unusual network structure adopted by some lanthanide complexes formed with N,N′-butylenebis(2-pyridone) (**I**, $n = 4$, BBP).

EXPERIMENTAL

Preparation of compounds

N,N′-butylenebis(2-pyridone). This was prepared by a literature procedure.[3] Pyridine (9.8 g, 0.125 mol) and 1,4-dibromobutane (15.1 g, 0.062 mol) were refluxed in ethanol (80 cm^3) for several hours. Concentration of the solution gave a white precipitate of the bis-pyridinium salt, which was oxidized to the bis-pyridone by reaction with potassium ferricyanide and sodium hydroxide. The product was extracted with chloroform; yield 55%. Found: C, 67.6; H, 6.7; N, 11.2. Calc. for $C_{14}H_{16}N_2O_2 \cdot 0.25H_2O$: C, 67.6; H, 6.6; N, 11.3%.

Metal complexes. The complexes obtained are listed in Table 1, together with their analytical data (Microanalytical Laboratory, Imperial College). They were prepared by reacting the appropriate

Crystallography

Crystal data for $Nd_2(BBP)_3(NO_3)_6$, $C_{42}H_{48}N_{12}Nd_2O_{24}$, $M = 1393.4$, monoclinic, $a = 16.252(7)$, $b = 9.599(6)$, $c = 17.466(9)$ Å, $\beta = 91.46(2)°$, $U = 2724$ Å^3, space group $P2_1/c$, $Z = 2$, $D_c = 1.699$ g cm^{-3}, μ(Mo-K_α) = 20 cm^{-1}, $\lambda = 0.71073$ Å, $F(000) = 1392$. Lilac–purple rhombic prisms, crystal dimensions 0.13 × 0.30 × 0.30 mm.

Data collection and processing

Siemens P4/PC diffractometer, ω-scan method ($4 < 2\theta < 50°$), graphite monochromated Mo-K_α radiation. 4802 independent reflections were measured, of which 3880 were considered observed [$|F_o| > 4\sigma(|F_o|)$] and corrected for Lorentz and polarization factors; no absorption correction was applied.

Structure analysis and refinement

The structure was solved by the heavy atom method. The non-hydrogen atoms were refined

anisotropically. The positions of the hydrogen atoms were idealized, C—H = 0.96 Å, assigned isotropic thermal parameters, $U(H) = 1.2U_{eq}(C)$, and allowed to ride on their parent carbon atoms. Refinement was by full-matrix least-squares to give $R = 0.033$, $R_w = 0.033$ [$w^{-1} = \sigma^2(F) + 0.0005F^2$]. The mean and maximum shift/error in the final refinement were 0.000 and 0.002, respectively, and the maximum and minimum residual electron densities in the final ΔF map were 0.89 and -1.42 eÅ^{-3}, respectively.

Computations were performed on an IBM PS2 model 70 386 computer using the SHELXTL PC system[4] and published scattering factors.[5] Selected bond lengths and angles are listed in Table 2.

RESULTS AND DISCUSSION

Reaction of BBP with the hydrated nitrates of yttrium(III), the M^{3+} lanthanide ions and thorium(IV) in methanol/2,2-dimethoxypropane in each case afforded complexes with a 3:2 BBP:M ratio. In some cases, particularly with the larger metal ions, the solids initially isolated tended to retain some acetone of solvation, presumably formed from the reaction between the 2,2-dimethoxypropane and the water of hydration of the metal salts employed.

X-ray powder diffraction studies showed that the lanthanide compounds from Nd to Tb are isostructural. (The powder patterns of the Ho and Yb complexes are virtually identical to those of the earlier members of the series, but with a small displacement of some of the diffraction arcs. It is probable that they have essentially the same gross structure as the earlier lanthanide complexes but with a small difference in lattice size.)

A representative member of the series, the neodymium complex (**I**), was obtained in a form suitable for a single-crystal X-ray study. This analysis shows that the stoichiometry is $Nd(BBP)_{1.5}(NO_3)_3$. Each Nd atom is nine-coordinate, being bonded to one oxygen atom from each of three different BBP ligands and six oxygen atoms from three bidentate nitrate groups (Fig. 1). The geometry about the Nd centre is best described as very distorted tricapped trigonal prismatic, with O(2)O(12)O(52) and O(22)O(32)O(41) defining the trigonal faces and O(31), O(42) and O(51) as the face-capping atoms. The Nd—O distances are in the range 2.361(4)–2.385(4) Å to the carbonyl oxygens and 2.511(4)–2.560(4) Å to the nitrate oxygens. It is noticeable that the nitrate groups are concentrated in one coordination hemisphere, whilst the pyridones of the BBP ligands dominate the other.

The BBP ligands bridge adjacent Nd atoms to

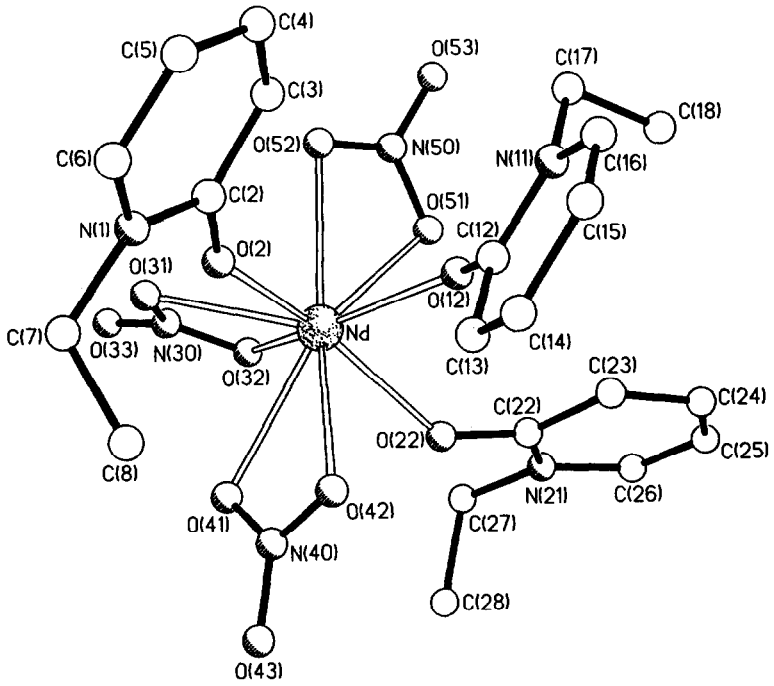

Fig. 1. The nine-coordinate neodymium environment in I showing the crystallographic numbering scheme.

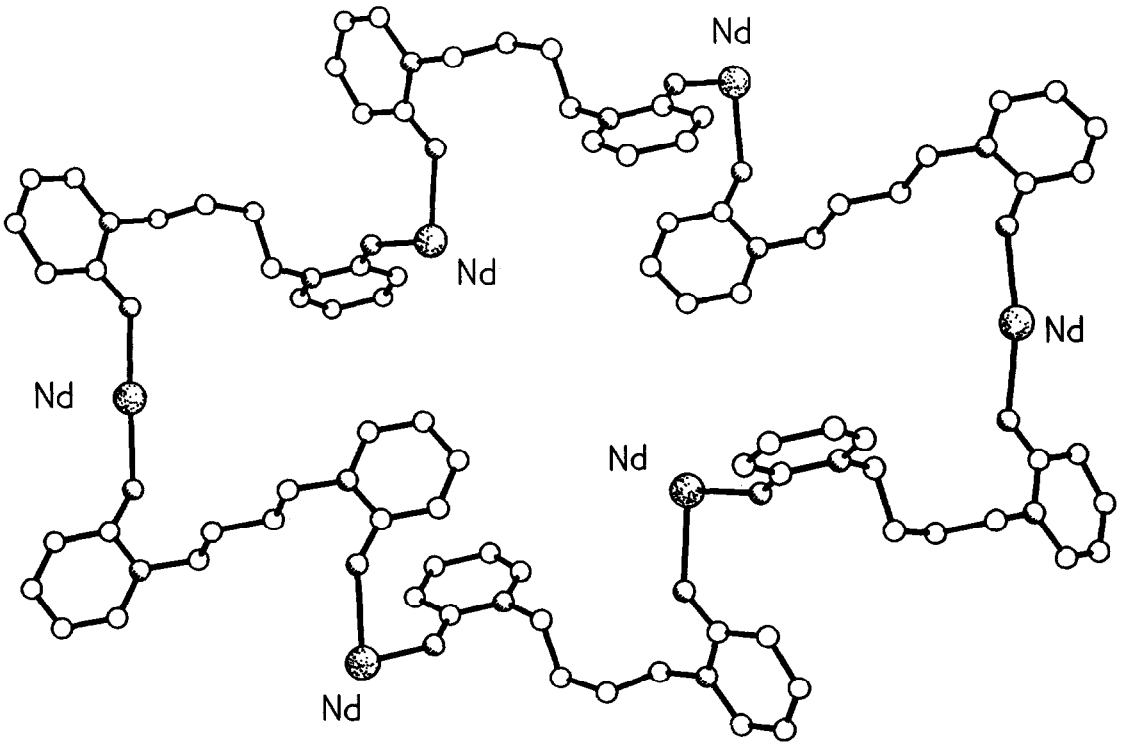

Fig. 2. The 66-membered metallomacrocyclic ring, which comprises the basic repeat unit in the structure of I. (The nitrate groups and one of the pyridone units bonded to each Nd atom have been omitted for clarity.)

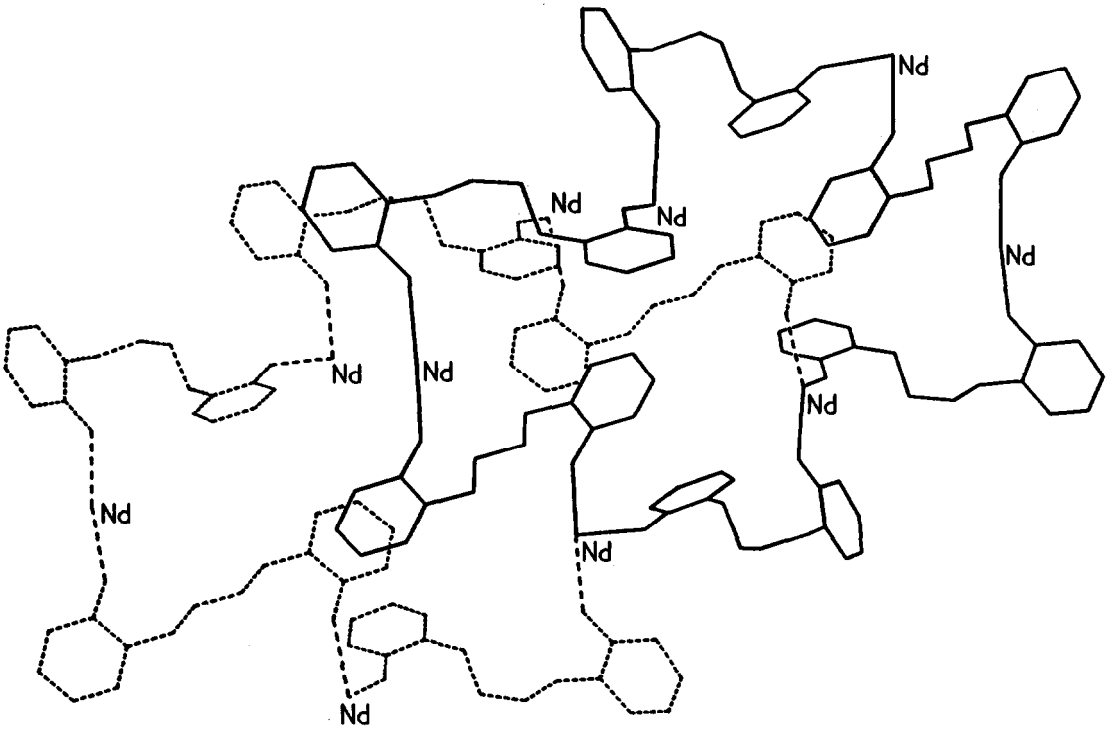

Fig. 3. Illustration of the way adjacent pairs of 66-membered rings are joined in the structure of **I**.

form a complex network of fused 66-membered metallomacrocyclic rings, each containing six neodymium, 12 nitrogen, 12 oxygen and 36 carbon atoms. The basic ring framework is shown in Fig. 2 in a simplified form, i.e. without the nitrate groups and without the BBP ligands which connect each Nd atom to two other, equivalent 66-membered rings. Within each 66-membered ring the $-(CH_2)_4-$ units of the 6 BBP ligands adopt two different conformations. In two of them the pyridone rings are essentially co-planar, but in the other four the rings are virtually orthogonal. Associated with these two geometries are two different butylene chain conformations. When the rings are parallel

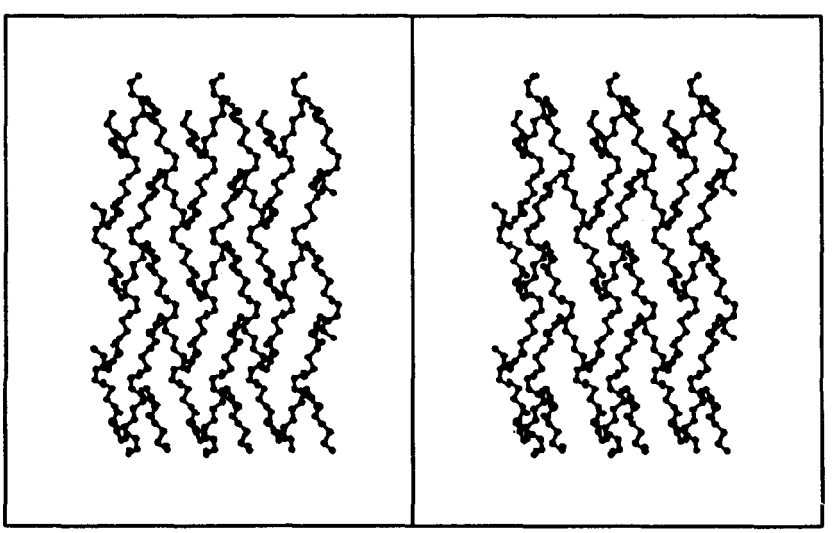

Fig. 4. Stereoscopic view down the crystallographic *a* axis of the polymeric units formed by **I** in the crystal.

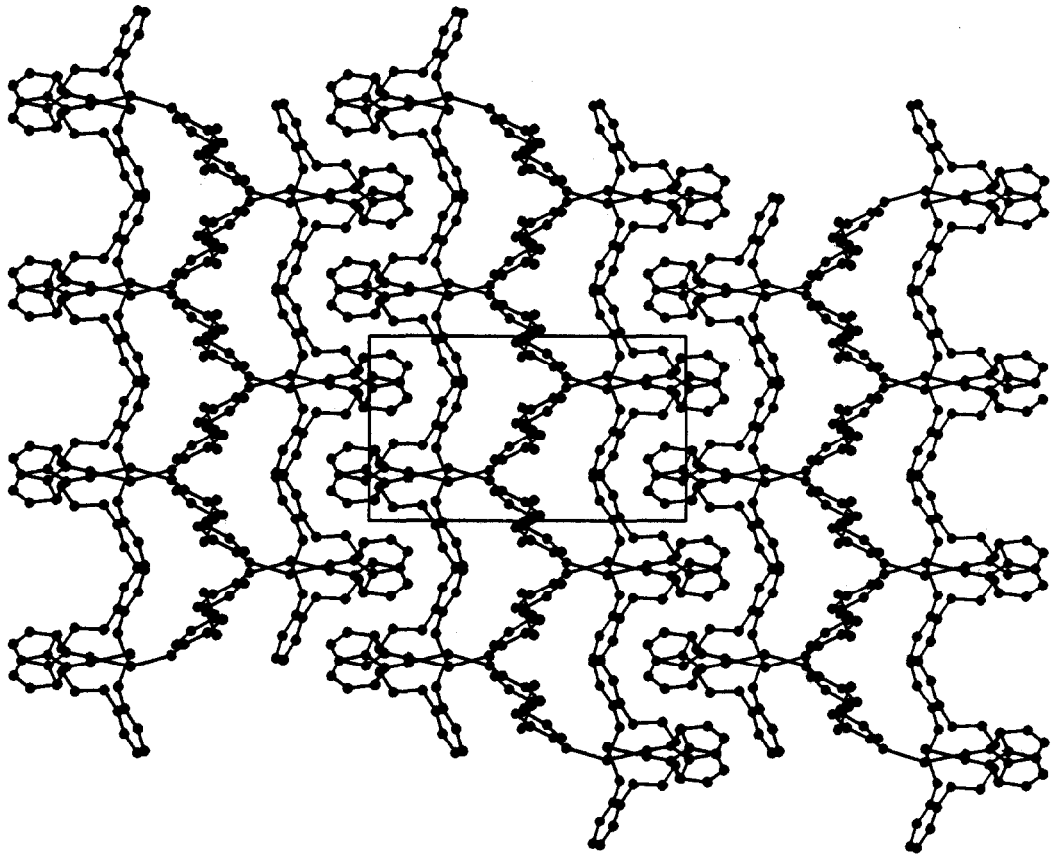

Fig. 5. Parallel projection down the crystallographic *c* axis of the interleaving sheets in **I** (nitrates omitted for clarity).

the chain adopts conventional all-*anti*-geometry, whereas when the rings are orthogonal the central CH_2—CH_2 bond is essentially *gauche*.

The nature of the linking of the 66-membered rings to form the contiguous network is somewhat complex. Figure 3 illustrates two such linked rings, both of which have identical conformations, and Fig. 4 shows a stereoscopic view (down the crystallographic *a* direction) of the extended network that results (the nitrates and parts of the phenyl rings have been omitted for clarity).

The network is not contiguous throughout the crystal. It comprises interleaving corrugated sheets that extend in the crystallographic *b* and *c* directions. Figure 5 is a projection of the structure down the crystallographic *c* direction and shows the interleaving of adjacent sheets that occurs within the (100) plane. Associated with this interleaving are parallel π–π stacking interactions between the pyridone rings of adjacent sheets. The interplanar separations are 3.37 Å, with a ring centroid–ring centroid distance of 3.9 Å.

It is interesting to compare the core geometry of **I** with that of the closely-related complex (**II**) formed by manganese(II) nitrate with N,N′-ethylenebis(2-pyridone) (**I**, $n = 2$).[1] In both instances, the oxygen donor atoms from the pyridone ligands adopt a meridional arrangement about the metal ion. Also, in the linking between adjacent metal centres in **I** and **II**, both orthogonal and essentially co-planar arrangements of pyridone rings are present. However, the final overall structures adopted are dramatically different, with chains of 36-membered macrocycles being formed in **II** in contrast to the 66-membered rings observed for **I**. It is not immediately obvious whether the difference in the arrays formed is due to the increase in the length of the spacer alkane groups or to the larger number of coordinated nitrates in **I**.

(*Received* 3 *June* 1993; *accepted* 4 *August* 1993)

Abstract—The monosilylated acyclic phosphazene ligand $Me_3SiNP(NMe_2)_2NP(NMe_2)_2NH_2$ (**3**) has been synthesized and characterized. The reaction of **3** with antimony triacetate, $Sb(OOCMe)_3$, in refluxing toluene forms a cyclic phosphazene derivative, $[N\{P(NMe_2)_2NH\}_2Sb(OOCMe)_2]$ (**4**), which is characterized by elemental analyses, mass, IR and NMR spectroscopy and single-crystal X-ray structural analysis. Complex **4** crystallizes in the form of a *cis* and *trans* isomeric chain in the solid state.

In the past few decades a large amount of work has been carried out on various reactions of cyclophosphazenes.[1] Recently, the development of cyclometallaphosphazene chemistry has created a versatile field of research, particularly when transition metals are used as the building blocks for the cyclophosphazene skeleton.[2] These complexes have interesting structural aspects as well as physical properties.[3,4] A careful literature search shows the paucity of information on such derivatives where main group metals are part of the cyclophosphazene ring system. However, no such antimony(III) derivative has been reported.[1,5,6] In contrast, various derivatives having Sb—O and Sb—S units have been synthesized in recent years.[5,6] In this paper, we report on the synthesis and characterization of a monosilylated phosphazene ligand, along with the X-ray structure of a cycloantimony(III)phosphazene complex. We used antimony(III)acetate as a starting material knowing that the carboxylate moiety has shown various structural arrangements.[7]

RESULTS AND DISCUSSION

The monosilylated acyclic phosphazene ligand **3** was obtained as a viscous liquid in a two step synthesis (Ia and Ib). In the first step (Ia), the Bezman salt[8] (**1**) reacted with NaH with the evolution of hydrogen forming compound **2**, which on silylation with Me_3SiNMe_2 resulted in the formation of **3**.

Ia- $[N\{P(NMe_2)_2NH_2\}_2]^+Cl^- + NaH$

1

$$\xrightarrow[-NaCl\ -H_2]{toluene} HN[P(NMe_2)_2NH]_2$$

2

Ib- **2** $+ Me_3SiNMe_2 \xrightarrow[-HNMe_2]{}$

$$Me_3SiNP(NMe_2)_2NP(NMe_2)_2NH_2$$

3

Compound **3** was characterized by elemental analyses, mass, NMR and IR spectral data. It reacts with antimony(III)acetate, $Sb(OOCMe)_3$, in refluxing toluene in a 1 : 1 molar ratio resulting in the formation of the cycloantimony(III)phosphazene complex (**4**). The reaction can be depicted as below.

3 $+ Sb(OOCMe)_3 \xrightarrow[-MeCOOSiMe_3]{toluene}$

$$[N\{P(NMe_2)_2NH\}_2Sb(OOCMe)_2]$$

4

The reaction occurs with the elimination of 1 mol of $MeCOOSiMe_3$, which can be easily removed *in vacuo*. The product obtained is sufficiently pure for spectroscopic studies. However, it can be further purified by crystallization from n-hexane solution.

*Author to whom correspondence should be addressed.

Complex **4** is a white solid, moisture-sensitive and fairly soluble in organic solvents. The IR spectra of **4** shows the P—N bands in the 1170–1287 cm^{-1} region, which are in accordance with a P—N—P ring system. The C—O frequency appears at 1670 cm^{-1}, which is indicative of the monodentate nature of the acetate moiety. In the ^1H NMR spectra of **4** the presence of the —NH proton at 3.60 ppm and the disappearence of —$SiMe_3$ protons is observed. The —NMe_2 protons in **3** were found as double doublets in the 2.4–2.5 ppm region, while only one doublet is observed for **4**. The ^{31}P NMR chemical shift of **3** consists of two doublets (δ 11.6 and 23.3 ppm), due to the non-equivalent nature of phosphorus nuclei, while in complex **4** only one singlet is found (δ 25.6 ppm), which is indicative of one type of phosphorus nucleus.

X-ray structure of **4**

Suitable crystals were obtained by cooling the n-hexane solution of compound **4** to 0°C. This compound crystallizes as *cis* and *trans* isomeric chains in the solid state. The X-ray analysis of **4** shows two independent monomers in the asymmetric unit (Fig. 1). The backbone of these monomers consists of slightly twisted six-membered antimony diphosphatriazene ring systems. The average deviation from the best plane of the six-ring atoms is 15.8 (a) and 9.7 pm (b), respectively. The antimony atoms can be described as trigonal bipyramidal coordinate, with the lone pair stereochemically active in the equatorial position. The oxygen atoms of the axial coordinated acetate groups are bound in an average distance of 226 pm to the antimony atom. The average O—Sb—O angle is 162°. The Sb—N distances are 201 and 205 pm, respectively. The average N—Sb—N angle is 94°. This arrangement is in accordance with valence bond theory. The two independent monomers occur in two different conformations: in (a) the acetyl groups are oriented *trans* and in (b) they are oriented *cis* with respect to each other. The molecules are linked via NH···O··· hydrogen bridges to form infinite chains (Fig. 2). In the *trans* isomer one NH— and two acetyl groups and in the *cis* isomer two NH— and one acetyl group are involved in hydrogen bonding. The polymeric chain adopts the [$(cis)_2(trans)_2$] pattern. The centre of inversion is located between two *trans* and two *cis* isomers.

EXPERIMENTAL

General methods

All manipulations were performed under dry nitrogen using Schlenk, vacuum-line and glovebox techniques. Solvents were dried and degassed prior to use. IR and mass spectra were recorded on a Bio-Rad FTS 7 spectrophotometer and a Finnigan MAT system 8230, respectively. ^1H and ^{31}P NMR spectra were recorded on a Bruker AM 250 spectrometer using TMS and 85% H_3PO_4 as an external reference. Elemental analyses were obtained from the analytical laboratory, Institute of Inorganic Chemistry, Göttingen. Antimony(III) acetate was prepared using a literature method.[9]

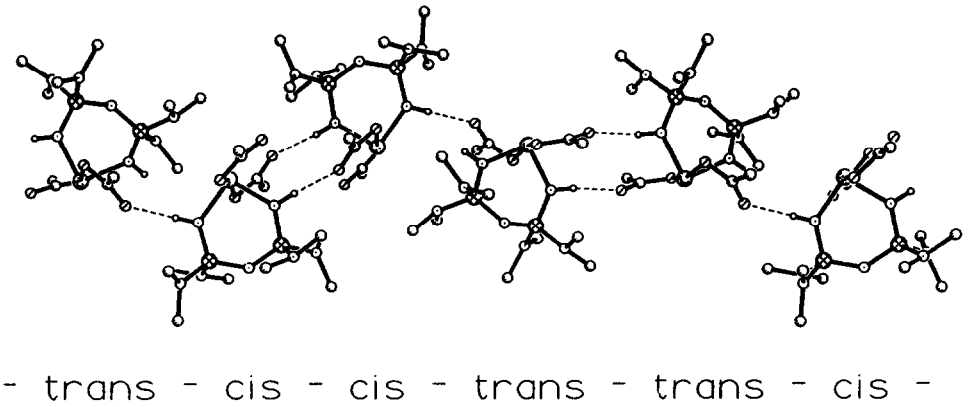

Fig. 2. Polymeric chain of **4** with a $[(cis)_2(trans)_2]$ pattern.

Crystallography

Intensity data for the crystal were measured at 153 K on a Stoe-Siemens AED diffractometer equipped with Mo-K_α radiation (graphite monochromator, $\lambda = 0.71073$ Å), employing the ω–2θ scan technique. The data sets were corrected for Lorentz and polarization effects. Crystal data are listed in Table 1. The structure was solved by direct methods[10] and each refined by full-matrix least-squares procedures on F^2.[11] All non-hydrogen atoms were refined with anisotropic displacement parameters and hydrogen atoms were set geometrically. A weighting scheme of the form $w^{-1} = \sigma(F_0^2)+(g1\ P)^2+g^2\ P$, with $P = (F_0^2+2F_c^2)/3$, was introduced for the structure. Selected bond lengths and angles are given in Table 2. Additional material available from the Cambridge

Synthesis of $Me_3SiNP(NMe_2)_2NP(NMe_2)_2NH_2$ **(3)**

Compound **1** (0.9 g, 60 mmol) was refluxed with NaH (0.25 g, 6.3 mmol) in toluene (25 cm^3) for 6 h until the elimination of hydrogen gas ceased. The mixture was then cooled to room temperature and Me_3SiNMe_2 (0.7 g, 6 mmol) was added dropwise. The contents were further refluxed for 4 h, cooled to room temperature and filtered using a sintered glass funnel. All volatiles were removed *in vacuo* and then distilled. Compound **3** was obtained as a light yellow viscous liquid at 104°C and 0.1 mm.

Elemental analysis: Found: C, 36.3; H, 9.8; N, 29.6. Calc. for $C_{11}H_{35}N_7P_2Si$(355 g mol^{-1}): C, 37.2; H, 9.9; N, 27.6%. EI-MS, m/z(%): 355 (54) (M), 268 (100) ($M-2NMe_2+H$). ^1H NMR ($CDCl_3$): δ 0.09 (d, 9H, —$SiMe_3$), δ 2.48 (d, 12H, —NMe_2), δ 2.53 (d, 12H, —NMe_2) ppm. ^{31}P NMR ($CDCl_3$): δ 11.6 (d, P=$NSiMe_3$), δ 23.3 (d, P=NH) ppm. IR (Nujol): 3453m, 3200b, 2944vs, 2878vs, 2794s, 1630s, 1534m, 1282vs, 1239vs, 1189vs, 1148s, 979vs, 856s, 825s and 747s cm^{-1}.

Synthesis of $[N\{P(NMe_2)_2NH\}_2Sb(OOCMe)_2]$ **(4)**

A toluene solution (25 cm^3) of $Sb(OOCMe)_3$ (0.84 g, 2.8 mmol) was added to a toluene (25 cm^3) solution of **3** (1.0 g, 2.8 mmol). The contents were heated for 3 h and a clear colourless solution was thus obtained. All volatiles were removed under reduced pressure and a white solid remained, which was crystallized from n-hexane at 0°C; m.p. 72.5 °C. Elemental analysis: Found: C, 27.5; H, 6.2; N, 17.9; Sb, 24.2. Calc. for $C_{12}H_{32}N_7O_4P_2Sb$ (521.81 g mol^{-1}): C, 27.6; H, 6.1; N, 18.8; Sb, 23.3%. EI-MS, *m/z* (%): 461 (2) (M − MeCOO), 169 (100) [Sb(O) ($OOCCH_3$)]. ^1H NMR ($CDCl_3$): δ 1.90 (s, 6H, —MeCOO), δ 2.58 (d, 24H, —NMe_2, J=11.4 Hz), δ 3.60 (s, 2H, —NH) ppm. ^{31}P NMR ($CDCl_3$): δ 25.63 (s) ppm. IR (Nujol): 1670m, 1622s, 1556m, 1465vs, 1287mb, 1261m, 1183m, 1170m, 1062m, 980vs, 804m, 741vs, 671s, 620m, 486s and 462m cm^{-1}.

(*Received* 3 *June* 1993; *accepted* 4 *August* 1993)

Abstract—The reaction between $Ru_2Cl(\mu\text{-}O_2CCH_3)_4$ and molten *p*-tert-butylbenzamide led to the formation of $Ru_2Cl(\mu\text{-}HNOCC_6H_4\text{-}p\text{-}CMe_3)_4$. The polymeric structure of this insoluble compound was broken with $AgBF_4$, in anhydrous thf, giving $[Ru_2(\mu\text{-}HNOCC_6H_4\text{-}p\text{-}CMe_3)_4(thf)_2]BF_4$. The reaction of this cationic complex with $OPPh_3$ gave $[Ru_2(\mu\text{-}HNOCC_6H_4\text{-}p\text{-}CMe_3)_4(OPPh_3)_2]BF_4$. The compounds have been characterized by elemental analysis, spectroscopic data and magnetic measurements and the crystal structure of $[Ru_2(\mu\text{-}HNOCC_6H_4\text{-}p\text{-}CMe_3)_4(OPPh_3)_2]BF_4$ was determined by X-ray crystallography. The asymmetric unit is composed of halves of two different crystallographically independent centrosymmetric cations. Each ruthenium(II,III) dimer is bonded to four bridging *p*-tert-butylbenzamidate ligands and to two axial triphenylphosphine oxide molecules. The Ru—Ru distances in the two dimeric cations of the unit cell are 2.281(2) and 2.280(2) Å. The compound has a non-polar 2 : 2 arrangement of the tert-butylbenzamidate ligands.

Since the reaction of $Ru_2Cl(\mu\text{-}O_2CCH_3)_4$ with molten trifluoroacetamide to give $Ru_2Cl(\mu\text{-}HNOCCF_3)_4$ was described,[1] several diruthenium(II,III) compounds with three atom-bridging ligands, with N,O- and N,N-atom donors, have been obtained.[2–15] Thus, with 2-hydroxypyridine and its derivatives, diruthenium(II,III) compounds containing four N,O-bridging units have been obtained.[2–5] In a similar way, with different aminopyridine ligands, several tetra-N,N-aminopyridinate compounds have been prepared,[5–7] although these ligands sometimes lead to partial substitution products.[8–11] By the same procedure, some tetraamidate complexes have also been obtained.[1,12–15]

Several X-ray crystal structure determinations of diruthenium(II,III) compounds with substituted 2-hydroxy-pyridinate[2,3,5] and 2-amino-pyridinate[5,7] ligands have shown that, in all cases, a completely polar 4 : 0 arrangement of the ligands was produced. However, in the case of tetraamidate complexes only the crystal structure of the polymer $Ru_2Cl(\mu\text{-}HNOCC_6H_4\text{-}p\text{-}Cl)_4$ is known and shows a non-polar 2 : 2 arrangement of the ligands. The low solubility of the tetraamidate complexes is probably the reason why only one crystal structure for these compounds has been described. In this paper, we

*Author to whom correspondence should be addressed.

report the synthesis, characterization and reaction with $AgBF_4$ of a new tetraamidate compound, $Ru_2Cl(\mu\text{-}HNOCC_6H_4\text{-}p\text{-}CMe_3)_4$. The synthesis, properties and crystal structure of the soluble (in polar organic solvents) $Ru_2(\mu\text{-}HNOCC_6H_4\text{-}p\text{-}CMe_3)_4(OPPh_3)_2]BF_4$ is also described.

RESULTS AND DISCUSSION

The reaction between $Ru_2Cl(\mu\text{-}O_2CCH_3)_4$ and $Me_3CC_6H_4CONH_2$ at 180°C for 72 h leads to the complete substitution of the acetate ligands, with the formation of $Ru_2Cl(\mu\text{-}HNOCC_6H_4\text{-}p\text{-}CMe_3)_4$ in a near quantitative yield. The compound is a brown solid, almost insoluble in all solvents tested, but slightly soluble in dmso. Due to this insolubility it has not been possible to obtain single crystals. However, elemental analysis, spectroscopic data and magnetic measurements indicate that the structure of this compound must be similar to the starting material $Ru_2Cl(\mu\text{-}O_2CCH_3)_4$, with two ruthenium atoms bonded to four bridging *p*-tert-butylbenzamidate ligands and to an axial chlorine atom, which links the dimetal units. This axial chlorine atom is abstracted by $AgBF_4$ in anhydrous thf, thus breaking the polymer structure to give $[Ru_2(\mu\text{-}HNOCC_6H_4\text{-}p\text{-}CMe_3)_4(thf)_2]BF_4$. This compound is soluble in most of the usual organic solvents, such as thf, dichloromethane, acetone, etc., and insoluble in petroleum ether and diethylether. The compound crystallizes from thf/petroleum ether (40–60°C), but easily loses thf. This facile loss of the coordinated thf has been previously observed in other thf adducts of diruthenium(II,III) carboxylate compounds.[16–20] The thf ligands can be substituted by $OPPh_3$, giving $[Ru_2(\mu\text{-}HNOCC_6H_4\text{-}p\text{-}CMe_3)_4(OPPh_3)_2]BF_4$. The solubility of this compound is similar to that of thf adduct and can be recrystallized from CH_2Cl_2/petroleum ether (40–60°C).

The IR spectra show, in all cases, corresponding absorption bands due to the *p*-tert-butylbenzamidate ligands. The absorption bands due to the thf molecules in $[Ru_2(\mu\text{-}HNOCC_6H_4\text{-}p\text{-}CMe_3)_4(thf)_2]BF_4$, similar to other thf adducts,[18–20] are absent when the IR spectrum is registered in KBr discs due to the lability of this ligand. In $[Ru_2(\mu\text{-}HNOCC_6H_4\text{-}p\text{-}CMe_3)_4(OPPh_3)_2]BF_4$ bands due to $OPPh_3$ are also observed. A strong band at 1100 cm^{-1} due to the BF_4^- group is also observed in the cationic compounds.

The magnetic measurements in the 70–290 K range (Table 1) show that the compounds obey the Curie–Weiss law over a range of temperatures. The

magnetic moment corresponds to three unpaired electrons, which are in accord with the ground state configuration $\sigma^2\pi^4\delta^2(\pi^*\delta^*)^3$, similar to those described for the carboxylate compounds.[21]

The electronic spectra of the compounds show two bands. The band at 422–450 nm is assigned to a $\pi(Ru—O,Ru_2)\rightarrow\pi^*(Ru_2)$ transition, in agreement with Norman *et al.*[21] In $Ru_2Cl(\mu\text{-}HNOCC_6H_4\text{-}p\text{-}CMe_3)_4$ a strong absorption is observed at 320 nm (ε = 25,000 $dm^3\ mol^{-1}\ cm^{-1}$), which is consistent with those observed[15] in $Ru_2Cl(\mu\text{-}HNOCC_6H_4\text{-}p\text{-}Cl)_4$ and is assigned to a $Cl\rightarrow\pi^*$ or $Cl\rightarrow\delta^*$ transition. In $[Ru_2(\mu\text{-}HNOCC_6H_4\text{-}p\text{-}CMe_3)_4(thf)_2]BF_4$ and $[Ru_2(\mu\text{-}HNOCC_6H_4\text{-}p\text{-}CMe_3)_4(OPPh_3)_2]BF_4$ similar bands at 304 (18,240 $dm^3\ mol^{-1}\ cm^{-1}$) and 303 nm (21,400 $dm^3\ mol^{-1}\ cm^{-1}$), respectively, are observed, which could be due to an $O(OPPh_3)\rightarrow\pi^*$ or $O(OPPh_3)\rightarrow\delta^*$ transition.

The crystal structure of $[Ru_2(\mu\text{-}HNOCC_6H_4\text{-}p\text{-}CMe_3)_4(OPPh_3)_2]BF_4$ has been determined by X-ray diffraction. Some important bond distances and angles are listed in Table 2. In this structure the asymmetric unit is composed of halves of two different crystallographically independent centrosymmetric cations (**1** and **2**), with the inversion centre in the middle of the Ru—Ru bond. An

ORTEP view of the cation **2** is shown in Fig. 1. The differences between the two cations of $[Ru_2(\mu\text{-}HNOCC_6H_4\text{-}p\text{-}CMe_3)_4(OPPh_3)_2]^+$ are insignificant, except for the Ru—O_{axial} bond, which is slightly longer in cation **2**. Each ruthenium dimer is bonded to four bridging *p*-tert-butylbenzamidate ligands and two axial triphenylphosphine oxide molecules. The compound has a non-polar 2:2 arrangement of the ligands. This type of arrangement of ligands is the most common in other metals,[22–24] but in the case of ruthenium only has been found previously in the similar[15] $Ru_2Cl(\mu\text{-}HNOCC_6H_4\text{-}p\text{-}Cl)_4$.

The Ru—Ru distances in the two dimeric units are 2.281(2) and 2.280(2) Å. These Ru—Ru distances are similar to those observed[15] in $Ru_2Cl(\mu\text{-}HNOCC_6H_4\text{-}p\text{-}Cl)_4$ and are slightly longer than the same distances reported in the compounds with a totally polar arrangement of ligands.[2,3,5,7] On the other hand, these distances are longer than those found in the analogous carboxylate cation[20] $[Ru_2(\mu\text{-}O_2CC_6H_4\text{-}p\text{-}CMe_3)_4(thf)_2]^+$.

The Ru—O_{axial} distances, 2.262(9) (cation **1**) and 2.28(1) Å (cation **2**), are longer than those observed in $[Ru_2(\mu\text{-}O_2CCH_3)_4(OPPh_3)_2]^+$, which would indicate a lower acceptor character of $[Ru_2(\mu\text{-}HNOCC_6H_4\text{-}p\text{-}CMe_3)_4]^+$ than the $[Ru_2(\mu\text{-}O_2CCH_3)_4]^+$ unit.

EXPERIMENTAL

All reactions were performed under an inert atmosphere, using standard Schlenk techniques. Ruthenium trichloride, tertbutylbenzoic acid, silver tetrafluoroborate, thionyl chloride and triphenylphosphine oxide were purchased from commercial sources. The solvents were purified and distilled by standard methods. Methanol was used

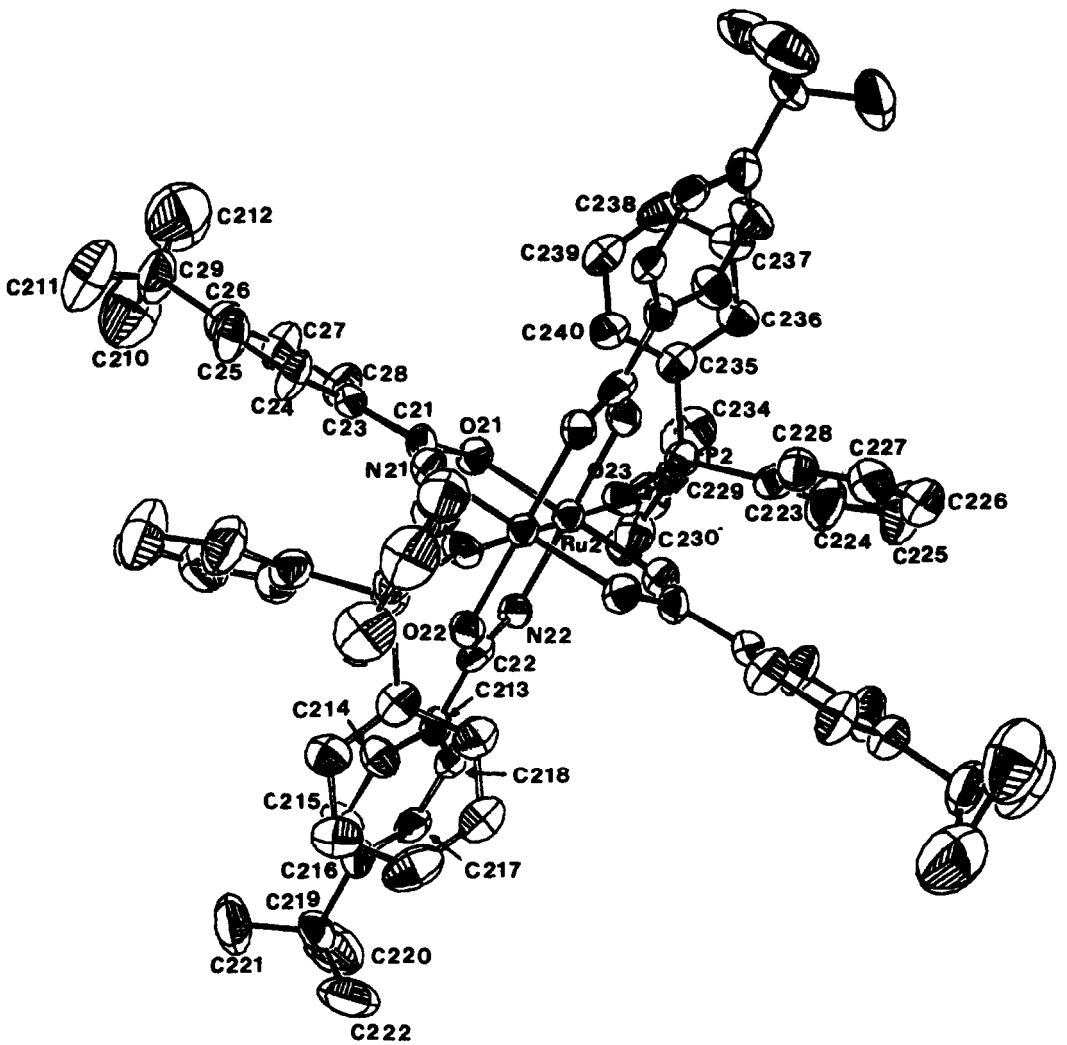

Fig. 1. ORTEP view of cation **2**, $[Ru_2(\mu\text{-}HNOCC_6H_4\text{-}p\text{-}CMe_3)_4(OPPh_3)_2]^+$. The hydrogen atoms are omitted for clarity.

without previous purification. $Ru_2Cl(\mu\text{-}O_2CCH_3)_4$ was prepared by the literature procedure.[25] Tert-butylbenzamide was prepared by the reaction of tert-butylbenzoic acid and thionyl chloride with the addition of NH_3 (ac.); the white solid obtained was recrystallized from hot methanol/water.

The IR spectra were recorded, as KBr discs, on Philips PU 9712 or Perkin–Elmer 1330 IR spectrophotometers. Magnetic susceptibility measurements were obtained using a fully automatic DSM 8 magneto-susceptometer, based on the Faraday methods. Electronic spectra in the 280–800 nm region were recorded on a gbc UV–vis 911 spectrophotometer. Elemental analysis for carbon, hydrogen and nitrogen were performed in the Microanalytical Service of the Complutense University of Madrid.

Synthesis of $Ru_2Cl(\mu\text{-}HNOCC_6H_4\text{-}p\text{-}CMe_3)_4$

$Ru_2Cl(\mu\text{-}O_2CCH_3)_4$ (0.1 g) and *p*-tert-butylbenzamide (5 g) were heated with stirring at 180°C (m.p. of *p*-tertbutylbenzamide-172°C) for 72 h. Excess ligand was removed by sublimation under reduced pressure, leaving a brown solid which was washed twice with acetone (10 cm^3) and dried *in vacuo*. Found: C, 55.3; H, 5.9; N, 5.4. Calc. for $Ru_2Cl(\mu\text{-}HNOCC_6H_4CMe_3)_4$: C, 56.1; H, 6.0; N, 5.9%. IR (KBr discs): 3390m, 3350m, 2960s, 2900m, 2860m, 1640m, 1610m, 1520m, 1480s, 1440vs, 1400s, 1360m, 1265m, 1210m, 1120s, 1100w, 1010m, 845m, 770w, 760m, 720s, 620m, 600m, 505m cm^{-1}. λ_{max} (nm) (ε, $dm^3\ mol^{-1}\ cm^{-1}$): 450 (658), 320 (25,000) (in dmso); due to the insolubility of the compound, the ε values are approximate.

Synthesis of $[Ru_2(\mu\text{-}HNOCC_6H_4\text{-}p\text{-}CMe_3)_4(thf)_2]BF_4$

A suspension of $Ru_2Cl(\mu\text{-}HNOCC_6H_4\text{-}p\text{-}CMe_3)_4$ (0.2 g, 0.21 mmol) in anhydrous thf (40 cm^3) was treated with $AgBF_4$ (0.041 g, 0.21 mmol). The mixture was stirred at room temperature for 24 h, leaving a red solution and a white precipitate of AgCl. The precipitate was removed by filtration over celite. The solution was concentrated under reduced pressure to half its initial volume and layered with petroleum ether (40–60°C). Red crystals of $[Ru_2(\mu\text{-}HNOCC_6H_4\text{-}p\text{-}CMe_3)_4(thf)_2]BF_4$ were formed, filtered and dried in a stream of nitrogen. Found: C, 53.2; H, 6.0; N, 5.0. Calc. for $[Ru_2(\mu\text{-}HNOC$

X-ray structure determination

A summary of the fundamental crystal data is given in Table 3. A dark brown prismatic crystal was coated with epoxy resin and mounted on a kappa diffractometer. The cell dimensions were refined by least-squares, fitting the θ values of 25 reflections. The intensities were corrected for Lorentz and polarization effects. Scattering factors for neutral atoms and anomalous dispersion corrections for ruthenium and phosphorus were taken from the International Tables of X-Ray Crystallography.[26] The structure was solved by Patterson and Fourier methods. An empirical absorption correction[27] was applied at the end of the isotropic refinement.

A final refinement was undertaken with fixed isotropic factors and coordinates for all H atoms and unit weights.

A final difference synthesis showed no significant electron density. Most of the calculations were performed using the X-ray 80 system.[28]

Complete tables of distances and angles as well as atomic positional and thermal parameters and structure factors have been deposited as supplementary material.

FLUORINATED TERTIARY ALKOXIDES OF SOME LANTHANIDES : TRIS-TRIFLUOROTERTIARYBUTOXIDES OF LANTHANUM, PRASEODYMIUM AND EUROPIUM

DONALD C. BRADLEY,* HALINA CHUDZYNSKA, MICHAEL B. HURSTHOUSE,† MAJID MOTEVALLI and RUOWEN WU

Department of Chemistry, Queen Mary & Westfield College, Mile End Road, London E1 4NS, U.K.

(*Received* 16 *July* 1993 ; *accepted* 28 *July* 1993)

Abstract—From reactions involving $M\{N(SiMe_3)_2\}_3$ (M = La, Pr and Eu) and trifluorotertiary butanol[$(CF_3)Me_2COH$; tftb.H], the compounds $[La(tftb)_3(thf)_{1.5}]$ (**1**), $[Pr(tftb)_3]$ (**2**) and $[Eu(tftb)_3]$ (**3**) have been isolated. From variable temperature ^1H and ^{19}F NMR studies it is suggested that **1** is a mixture of $[La_3(tftb)_9(thf)_2]$ (**1a**) and $[La_2(tftb)_6(thf)_4]$ (**1b**). X-ray crystallography has shown that **2** is the trimer $[Pr_3(tftb)_9]$ and variable temperature ^1H and ^{19}F NMR suggests that **3** is also a trimer, $[Eu_3(tftb)_9]$.

In a previous paper we reported on the synthesis of a number of fluorinated alkoxides of yttrium from reactions involving $Y\{N(SiMe_3)_2\}_3$ and fluoroalcohol.[1] With trifluorotertiarybutanol (tftb.H), the unsolvated compound $Y(tftb)_3$ was obtained from a reaction in benzene solution and from its ^1H NMR spectrum a trinuclear structure $[Y_3(\mu_3-tftb)_2(\mu\text{-}tftb)_3(tftb)_4]$ was proposed. When the reaction was conducted in thf, the product had the composition $[Y(tftb)_3(thf)_{2.5}]$, which was believed to be a mixture of the mononuclear $[Y(tftb)_3(thf)_3]$ and the dimer $[Y_2(tftb)_6(thf)_4]$. We now report the results obtained from the reactions of $M\{N(SiMe_3)_2\}_3$ (M = La, Pr and Eu) with tftb.H.

RESULTS AND DISCUSSION

The analysis of the product **1** of the reaction of $La\{N(SiMe_3)_2\}_3$ and tftb.H in thf corresponded to the formula $[La(tftb)_3(thf)_{1.5}]$. The complex ^1H NMR spectra in C_6D_6 or C_7D_8 were not completely resolved due to overlap of some of the tftb peaks with one of the thf peaks, but in $CDCl_3$ all peaks were separated and integration confirmed the presence of two tftb groups per thf ligand, in agreement with the elemental analysis. The low temperature (233 K) spectrum in $CDCl_3$ gave a set of five singlets (δ 1.76, 1.65, 1.61, 1.45 and 1.24) in the ratio 2 : 1 : 2 : 2 : 2, corresponding to a trinuclear species $[La_3(\mu_3\text{-}tftb)_2(\mu\text{-}tftb)_3(tftb)_4(thf)_2]$ (**1a**) related to the known structure of $[La_3(\mu_3\text{-}OBu^t)_2(\mu\text{-}OBu^t)_3(OBu^t)_4(Bu^tOH)_2]$.[2] In addition to the two peaks for thf (δ 3.80 and 1.90), the spectrum also showed a singlet at δ 1.30 due to tftb in another species, probably a dimer, $[La_2(tftb)_6(thf)_4]$ (**1b**). The ^{19}F NMR spectrum in C_7D_8 at 300 K also gave a set of five peaks in the ratio 1 : 2 : 2 : 2 : 2 which shifted slightly at low temperature (240 K), giving a ratio 2 : 2 : 1 : 2 : 2. Other peaks suggested the presence of another species besides the trinuclear compound. Interestingly, the ^1H spectrum in thf-d_8 at 305 K was dominated by a tftb peak at δ 1.21 in addition to the five smaller peaks for the trinuclear species at 1.61, 1.58, 1.52, 1.47 and 1.45. With thf as solvent it would be expected that an equilibrium between trinuclear (**1a**) and dimer (**1b**) species would be driven in favour of the dimer or even a mononuclear $[La(tftb)_3(thf)_3]$ species, thus explaining the strong peak at δ 1.21.

From the reaction of $Pr\{N(SiMe_3)_2\}_3$ and tftb.H in benzene, the pale green crystalline compound $[Pr_3(tftb)_9]$ (**2**) was isolated. The trimeric structure

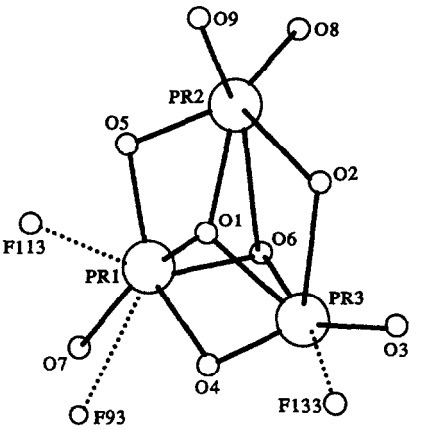

Fig. 2. The suggested coordination sphere of $[Pr_3(TFTB)_9]$.

(Fig. 1) was determined by single crystal X-ray diffraction. A preliminary account of the structure has been reported previously[3] and we now give full details (Tables 1–3). As can be more clearly seen in Fig. 2, showing the metal–oxygen framework, the trimeric structure is based on an isosceles triangle of metals capped by two μ_3-tftb ligands above and below the metal plane and by three μ_2-tftb ligands in the plane. One metal [Pr(2)] has two terminal ligands, giving it a distorted octahedral configuration, whilst the other two metals each have a single terminal ligand, giving five-coordinate structures. However, closer inspection shows that Pr(1) and Pr(3) are each interacting agostically with fluorine atoms. Thus, Pr(1) interacts with F(93) and F(113), whilst Pr(3) interacts with F(133), giving rise to distorted seven-coordination and six-coor-

dination, respectively. The C—F bond lengths of these agostic fluorine atoms are significantly longer than the average C—F bond length of the CF_3 groups (Table 2). The agostic Pr(1)···F (2.774 and 2.759 Å) and Pr(3)···F (2.756 Å) distances are comparable with some of the longer Pr—O(μ_3) distances (2.834 and 2.718 Å). The Pr—O bond lengths involving the μ_3-tftb ligands show some interesting features. Thus the shortest bonds are to the "five-coordinated" metals [Pr(3)—O(1), 2.438 ; Pr(1)—O(6), 2.407 Å] and the longest are to the six-coordinated metal [Pr(2)—O(6), 2.834 ; Pr(2)—O(1), 2.718 Å]. Whilst the μ_2—O(4) bridging the "five-coordinated" metals is almost symmetrical [Pr(3)—O(4), 2.430 ± 0.013 ; Pr(1)—O(4), 2.408 ± 0.012 Å], the other μ_2 bridges are unsymmetrical [Pr(1)—O(5), 2.371 ; Pr(2)—O(5), 2.434 and Pr(2)—O(2), 2.459 ; Pr(3)—O(2), 2.400 Å]. As would be expected, the terminal Pr—O bond lengths are longer to the six-coordinated metal [Pr(2)—O(8) ; 2.156 ; Pr(2)—O(9), 2.168 Å] than to the "five-coordinated" metals [Pr(1)—O(7), 2.141 ; Pr(3)—O(3), 2.112 Å].

The ^1H and ^{19}F NMR spectra of $Pr_3(tftb)_9$ suggest that the trinuclear structure retains its integrity in solution. The paramagnetism of the Pr^{3+} ion causes large pseudo-contact shifts and at room temperature the ^1H spectrum (C_7D_8) shows five peaks at δ 52 (broad), 21, −18.5, −20 and −34.5 ppm in the ratio of 2 : 2 : 2 : 1. From the crystal structure, the terminal ligands are distinguishable into two sets, i.e. two bonded to Pr(2) and the two equivalent groups bonded to Pr(1) and Pr(3). The three μ_2 ligands are distinguishable in a 2 : 1 ratio and the two μ_3 ligands are equivalent, giving an overall 2 : 2 : 2 : 1 : 2 arrangement. The ^{19}F NMR spectra could also be interpreted on the basis of the crystal structure. The variable temperature spectra (C_7D_8) showed an interesting fluxional behaviour (Table 4 and Fig. 3). Thus, at 363 K there are four broad peaks in a 4 : 1 : 3 : 1 ratio which become narrower at 343 K, giving five peaks in a 2 : 2 : 1 : 3 : 1 ratio. At 313 K, there are again four peaks but in the ratio 2 : 2 : 3 : 2, whilst at 283 K the five line spectrum is in accordance with the crystal structure, giving the 2 : 2 : 2 : 1 : 2 ratio. Attempts to sublime compound **2** *in vacuo* were unsuccessful due to decomposition.

The europium compound $[Eu_3(tftb)_9]$ (**3**) was

[a]Overlapping peaks.

obtained as pale yellow crystals from the reaction of $Eu\{N(SiMe_3)_2\}_3$ and tftb.H in benzene solution. The trinuclear structure proposed is based on the ^1H and ^{19}F NMR spectra. Thus, at room temperature, the ^1H spectrum gave five peaks at δ 46, 5, −17, −26 (v.broad) and −60 ppm in the ratio 2 : 2 : 2 : 2 : 1. The variable temperature ^{19}F spectra (Table 5 and Fig. 4) show interesting fluxional behaviour. Thus, at 373 K there are only three broad peaks in a 4 : 1 : 4 ratio, which become sharper on lowering the temperature to 343 K (four peaks in a 2 : 2 : 1 : 4 ratio). At 313 K, further splitting occurs and at 283 K the five line spectrum is fully resolved into a 2 : 2 : 1 : 2 : 2 pattern. The IR spectra of **2** and **3** are also very similar and there seems little doubt that these compounds have the same structure. Although $[Eu_3(tftb)_9]$ could not be sublimed *in vacuo* due to decomposition, a mass spectrum gave peaks at *m/z* 400.8, 398.8 and 396.8, corresponding to the isotopic species $^{153}Eu_2F_5^+$, $^{153}Eu^{151}EuF_5^+$ and $^{151}Eu_2F_5^+$. This suggests that fluorine abstraction from the ligand takes place in the mass spectrometer.

EXPERIMENTAL

All manipulations were conducted under dry nitrogen using vacuum-line, glove-box and Schlenk-style apparatus. Solvents were dried using the sodium ketyl of benzophenone and then distilled.

The trifluoro-tert.butanol (Fluorochem Ltd) was dried over molecular sieves. The metal tris-(bis-trimethylsilylamides) were prepared by reaction of the metal trichloride with $LiN(SiMe_3)_2$ as reported previously.[4]

NMR spectra were obtained using Bruker WM250FT and WH400FT spectrometers, using solvent signals from incomplete deuteration for ^1H chemical shifts (relative to TMS), with ^{19}F chemical shifts relative to $CFCl_3$. IR spectra were obtained as Nujoll mulls in the range 4000–200 cm^{-1} using a Perkin–Elmer FT1720 spectrometer. Attempts to obtain mass spectra were made using a Kratos MS50TC spectrometer operating at 70 eV. The carbon and hydrogen analyses were obtained commercially from either Microanalytical Services, University College, London or Butterworth Microanalytical Laboratories. Metals were determined gravimetrically as oxides.

Preparation of $[La(tftb)_3(thf)_{1.5}]$ (1)

$(CF_3)Me_2COH$ (2.1 g) in thf (10 cm^3) was added to a solution of $La\{N(SiMe_3)_2\}_3$ (3.0 g) in thf (100 cm^3) and left overnight. Solvent and $(Me_3Si)_2NH$ were then evaporated off *in vacuo* and the residue crystallized from a mixture of thf and pentane, giving **1** as white crystals (1.6 g, m.p. 78–86°C dec.). Found : La, 22.0 ; C, 33.4 ; H, 4.7. Calc. for $La\{OC(CH_3)_2(CF_3)\}_3(thf)_{1.5}$: La, 22.1 ; C, 34.4 ; H, 4.8%. ^1H NMR ($CDCl_3$) at 283 K : δ 3.85 (m, thf), 1.89 (m, thf), 1.77, 1.68, 1.63, 1.50, 1.44 (tftb-trinuclear), 1.31 (tftb-dinuclear) ; at 233 K : 3.80 (m, thf), 1.90 (m, thf), 1.76, 1.65, 1.61, 1.45, 1.24 (tftb-trinuclear), 1.30 (tftb-dinuclear). ^1H NMR (thf-d_8) at 305 K : δ 1.61, 1.58, 1.52, 1.47, 1.45 (tftb-trinuclear), 1.21 (tftb-dinuclear). ^{19}F NMR ($C_6D_5CD_3$) at 300 K : δ −76.91, −78.04, −78.16, −81.59, −82.64 (ratio 1 : 2 : 2 : 2 : 2) and small peaks at −79.50, −83.09 and −83.27 ; at 240 K : −78.42, −78.95, −79.43, −81.06, −81.76 (ratio, 2 : 2 : 1 : 2 : 2) and small peaks at −79.73, −82.48, −82.66, −82.91 and −83.16. IR : 1318m, 1207s, 1137vs, 1015s, 992s, 918w, 877s, 755m, 669w, 618s, 594m, 484m, 413w, 372wm 275w, 233w, 221m cm^{-1}.

Preparation of $[Pr_3(tftb)_9]$ (2)

$(CF_3)Me_2COH$ (5 cm^3) was added to a solution of $Pr\{N(SiMe_3)_2\}_3$ (1.8 g) in benzene (80 cm^3). After standing for 24 h the solution was concentrated at 70°C and allowed to cool. Pale green crystals of **2** were deposited (1.35 g, m.p. 180°C dec.). Found : Pr, 28.4 ; C, 27.2 ; H, 3.5. $Pr(tftb)_3$ requires : Pr, 27.0 ; C, 27.1 ; H, 3.5%. ^1H NMR ($C_6D_5CD_3$) at 300 K : δ 52 (12H), 21 (12H), −18.5 (6H), −20 (12H), −34.5 (12H). ^{19}F NMR data : see Table 4. IR : 1320s, 1261s, 1205s, 1147s, 1127s, 1015s, 990s, 886m, 872m, 801m, 753m, 723m, 677w, 612s, 586m, 506m, 490m, 373w cm^{-1}.

Preparation of $[Eu_3(tftb)_9]$ (3)

When $(CF_3)Me_2COH$ (5 cm^3) was added to a solution of $Eu[N(SiMe_3)_2]_3$ (2.2 g) in benzene (80 cm^3) there was an immediate colour change from orange to pale yellow. After standing for 24 h, the solution was concentrated and cooled to *ca* 5°C. Pale yellow crystals of **3** were deposited (1.2 g, m.p. 210°C dec.). Found : Eu, 29.2 ; C, 25.7 ; H, 3.9. $Eu(tftb)_3$ requires : Eu, 28.5 ; C, 27.6 ; H, 3.4%. ^1H NMR ($C_6D_5D_3$) at 300 K : δ 45.8 (12H), 5.0 (12H), −16.8 (12H), −26.0 (v.br, 12H), 39.8 (6H). ^{19}F NMR data : see Table 5. IR : 1320s, 1142s, 1017s, 988s, 885s, 754s, 723m, 677w, 613s, 586s, 511s, 492s, 481s, 424s, 375m cm^{-1}.

Crystal structure of $[Pr_3(tftb)_9]$ (2)

A preliminary account of the single crystal X-ray structure determination of **2** has already been reported.[3] The crystal structure parameters are given in Table 1 and the more important bond distances and bond angles are listed in Tables 2 and 3, respectively.

METATHESIS ROUTES TO TIN AND LEAD CHALCOGENIDES

I. P. PARKIN* and A. T. ROWLEY

Department of Chemistry, The Open University, Milton Keynes, MK7 6AA, U.K.

(*Received* 16 *June* 1993; *accepted* 15 *July* 1993)

Abstract—Thermal initiation (550°C) of a mixture of SnI_4 and Li_2E produces SnE_2 (E = O, S, Se). Similarly, $PbCl_2$ and Li_2E' produces PbE' (E' = O, S, Se, Te) via an exothermic solid state metathesis reaction. The PbE' and SnE_2 compounds were characterized by microanalysis, SEM/EDAX, FT-IR spectroscopy, magnetic moment measurements, X-ray powder diffraction and, in the case of tin, by solid state NMR.

Tin and lead chalcogenides are found as minerals and manufactured for semi-conductors, mosaic golds, pigments, photo-conductors and radio receivers.[1] Traditionally they are made by high temperature combination of the elements, by solution precipitation methods or by reaction of H_2E (E = S, Se, Te) on the metal.[2]

Self-propagating high temperature synthesis (SHS) methods to materials have been developed by Russian chemists[3] in the 1960s. These process involve initiating a solid-state reaction between pressed discs of the elements by means of an electric filament or an oven. Kaner *et al.*[4] and others[5] have utilized a similar idea by synthesizing transition metal chalcogenides via a solid state metathesis reaction involving sodium chalcogenides and metal halides. These syntheses have a number of advantages, firstly the reaction can be extremely rapid (2–3 s), secondly the by-product NaCl is easily removed by trituration, thirdly high purity crystalline products are produced and fourthly the reaction requires low energy initiation. Modifications to this technique have allowed control of crystallite size and morphology.[6]

Here we outline an extension of solid state metathesis reactions to main group metals in the synthesis of tin and lead chalcogenides.

EXPERIMENTAL

All reactions and preparations were carried out *in vacuo* or in a dinitrogen-filled dry box. Glass ampoules were made out of pyrex glass and were either flame dried *in vacuo* or heated to 400°C for 6 h prior to reaction. All solvents were degassed with dinitrogen. Methanol was distilled from MgI_2 and stored over 3 Å molecular sieves prior to use. Metal halides and Li_2O were purchased from Aldrich Chemical Co. and used as supplied. Lithium chalcogenides, Li_2S, Li_2Se and Li_2Te, were made by combining lithium and the chalcogenide in liquid ammonia followed by evaporation of the ammonia and thermolysis of the residue to 550°C for 10 h. X-ray powder diffraction patterns were obtained using a Seimens D5000 diffractometer using nickel filtered copper K_α (λ = 1.5406 Å) radiation; SEM and electron microprobe analysis on a Jeol JSM 820 equipped with Kevex program,[7] FT-IR as pressed KBr discs on a Nicolet 205 (CsI); magnetic susceptibility measurements were determined on a Johnson Matthey balance. Solid state ^{119}Sn MAS NMR spectra were obtained at 111.862 MHz at a spin rate of 12.25 kHz on the SERC machine at Durham University with chemical shift measurements given relative to $Sn(CH_3)_4$. Ultrasound sonication was achieved at 20 kHz using a Soniprep ultrasonic gun. Thermal initiation of the reactions was performed in a Lenton Thermal Design tube furnace.

Preparation of tin and lead chalcogenides

Lithium chalcogenide and anhydrous metal halide (SnI_4 or $PbCl_2$) were ground together using an agate pestle and mortar in a dinitrogen-filled dry box (such that the ratio of lithium to halide was 1 : 1). The powder was added to a thick-walled glass

*Author to whom correspondence should be addressed.

ampoule, sealed under vacuum and sonicated with an ultrasonic gun for 10 min. The ampoule was then wrapped in glass wool and placed in a conventional oven at 550°C for 5 h. The ampoule was removed from the oven, allowed to cool to room temperature and opened in a glove box. Trituration of the grey, orange or yellow solid with methanol, aqua regia, water or dilute HCl for 1 h produced a fine precipitate and a cloudy layer (Table 1). Evaporation of the methanol filtrate produces crystals of a white solid identified as LiCl or LiI by X-ray powder diffraction, lithium flame test and chlorine/iodine EDAX analysis. The coloured powders were identified as tin or lead chalcogenides by X-ray powder diffraction (Table 1), EDAX analysis, magnetic moment measurements, FT-IR and ^{119}Sn NMR. Ceramic yields, based on the metal after THF trituration, varied from 20% (Pb_2O_2Cl) to 80% (PbSe, SnS_2) depending on the sample.

RESULTS AND DISCUSSION

Reaction of SnI_4 or $PbCl_2$ with Li_2E (E = O, S, Se, Te) produces tin or lead chalcogenides and lithium halide via an exothermic solid-state metathesis reaction:

$$SnI_4 + 2Li_2E \xrightarrow{500°C} SnE_2 + 4LiI \quad (E = O, S, Se) \quad (1)$$

$$PbCl_2 + Li_2E \xrightarrow{500°C} PbE + 2LiCl \quad (E = S, Se, Te) \quad (2)$$

$$PbCl_2 + Li_2O \xrightarrow{500°C} Pb_2O_2Cl + LiCl + [Pb]. \quad (3)$$

After thermolysis the product was contained in fused grey, gold or orange lumps which showed a smooth morphology by SEM indicative of a coating of sublimed LiCl. Metal, chalcogenide and chloride were detected by EDAX analysis, which is consistent with the formation of a metal chalcogenide that contains amorphous lithium chloride on the surface. The metal chalcogenides were purified by trituration with methanol, aqua regia or dilute HCl (Table 1) to remove the LiCl, tin metal and unreacted metal halide, respectively. Characterization was by X-ray powder diffraction, magnetic moment measurement and solid state ^{119}Sn NMR spectroscopy.

The SEM profile of the triturated metal chalcogenides showed a rough porous surface, whilst the EDAX step analysis revealed only metal and chalcogen with no halide present (2–3% detection limit, except for Pb_2O_2Cl, where Cl was observed). The FT-IR spectra of the metal chalcogenides were featureless in the range 4000–400 cm^{-1}. No lithium (<0.1%) was detected by microanalysis for the triturated powders. The solid state ^{119}Sn NMR spectrum of SnS_2 showed a single resonance at −764 ppm, indicating that only one environment for tin is present in the lattice and that no detectable free tin is produced from the reaction of SnI_4 and Li_2S.

The X-ray powder diffraction data for the metal chalcogenides formed from reaction of Li_2E and $SnI_4/PbCl_2$ are summarized in Table 1. In general, after a reaction time of 4 h at 550°C, a crystalline metal chalcogenide was formed.[8] The crystalline size as determined by the Scherrer equation[9] based on the powder XRD line widths varied from 300 to 600 Å. The metal chalcogenides after trituration had no crystalline lithium halide present and showed the material as a single phase, SnE_2 or PbE.

Table 1. Crystallographic and experimental data from the reaction of SnI_4 and $PbCl_2$ with Li_2E (E = O, S, Se, Te)

Reagents	Work-up	Colour	Crystalline phase detected	Literature **a** spacing[8] (Å)	Observed **a** spacing (Å)	Crystalline size (Å)

[a]Before trituration tin metal was also detected by XRD.

In general, the reaction of SnI_4 or $PbCl_2$ with Li_2E involves no redox chemistry, with the metal in the same oxidation state as the starting material. The reaction times and crystallinity of the products were comparable for all the chalcogens studied; however, the yield of Pb_2O_2Cl was considerably lower than the rest at 20%. Formation of Pb_2O_2Cl involves oxidation at the metal and may form from a dispropotronation reaction with formation of some lead metal, although this was not detected by XRPD.

Analogous studies of reaction of sodium chalcogenides with transition metal halides showed that initiation can be achieved at room temperature by light grinding of the reagents.[4] No initiation of the reaction of $PbCl_2$ or SnI_4 and Li_2E could be achieved either by grinding or mixing the reagents or by means of a heated filament. The reactions required heating at 450–500°C to initiate; however, the presence of sublimed LiCl (b.p. = 1300°C) and occasional warping/pitting of the ampoules indicates that these reactions are exothermic and it is this that provides for a relatively rapid reaction generating crystalline products.

Hess' law calculations[10] of the reaction of metal halide and lithium chalcogenide indicate that the reaction is exothermic with $\Delta H \approx -200$ kJ mol^{-1}. The primary driving force for the reaction is due to the large lattice energy of the co-product LiX, which accounts for up to 80% of the reaction enthalphy.

Reaction of SnI_4 with mixed lithium chalcogenides $Li_2Se_{0.5}S_{0.5}$ proceeds analogously to the reactions to produce binary SnE_2 materials. The X-ray diffraction patterns of the mixed $Sn(S_xSe_y)$ materials are intermediate between and slightly broader than the patterns observed for the corresponding binary SnS_2, $SnSe_2$ materials. The EDAX step analysis of the mixed tin chalcogenide showed constant ratios of sulphur and selenium, indicating that an intermixed species was formed. Similar behaviour is observed for the reactions with $PbCl_2$ and $Li_2Se_{0.5}S_{0.5}$, $Li_2Se_{0.5}Te_{0.5}$ which formed the mixed species $PbSe_xS_y$ and $PbSe_xTe_y$, respectively. The composition of the mixed lead chalcogenide species as assessed from the lattice spacing, **a** (assuming Vegards' law[11]) and the EDAX analysis indicates that species of composition close to $PbSe_{0.5}S_{0.5}$ and $PbSe_{0.5}Te_{0.5}$ were formed. A representative powder pattern for $PbSe_{0.5}S_{0.5}$ is shown in Fig. 1.

Kaner[4] has suggested that reaction of MCl_5 and $Li_2S_xSe_y$ may proceed by formation of the salt LiCl, co-reduction to the metal and chalcogen followed by recombination of the metal and chalcogen promoted by the heat of reaction. This accounts for the slight differences in chalcogen ratio in a range of reactions.[12] The mixed chalcogenide reactions to form PbS_xSe_y showed that $x = y$. However, the amount of selenium incorporation (as assessed by EDAX and **a** value) was found to be slightly lower than that of sulphur, in agreement with Kaner's findings. Interestingly, reaction of SnI_4 with Li_2O formed some tin metal in the reaction, unlike the reactions for Li_2S and Li_2Se. If the partial reduction to the elements followed by recombination mechanism was correct, then combination of tin metal with O_2 (g) would be expected to be less likely than with sulphur or selenium.

CONCLUSION

Solid state metathesis reactions offer a route to crystalline tin and lead chalcogenides via an exothermic reaction. The reactions are at lower temperature and reasonably rapid, requiring shorter annealing times than conventional preparations. The purity of the metal chalcogenide is high, with the by-product lithium halides either subliming out during the course of the reaction or being removed by trituration.

RAMAN SPECTROSCOPIC CHARACTERIZATION OF HIGH TEMPERATURE $MGaCl_8$ (M = Nb, Ta) DINUCLEAR MOLECULAR COMPLEXES IN THE LIQUID AND GASEOUS STATE

S. BOGHOSIAN* and G. A. VOYIATZIS

Institute of Chemical Engineering and High Temperature Chemical Processes and Department of Chemical Engineering, University of Patras, P.O. Box 1414, GR-26500 Patras, Greece

(*Received* 2 *June* 1993; *accepted* 15 *July* 1993)

Abstract—Raman spectra were obtained at temperatures 375–650 K and pressures up to 4 atm from $GaCl_3$–$NbCl_5$ and $GaCl_3$–$TaCl_5$ binary mixtures in the liquid and vapour state. The data indicate formation of $NbGaCl_8$ and $TaGaCl_8$ liquid and vapour dinuclear addition complexes. The spectra were interpreted in terms of a C_{2v} configuration for the $MGaCl_8$ (M = Nb, Ta) molecules consisting of a MCl_6 octahedron sharing an edge with a $GaCl_4$ tetrahedron. A comparison of the spectral features of 1 : 1 $GaCl_3$–$NbCl_5$ and $GaCl_3$–$TaCl_5$ molten mixtures with the spectra of the corresponding polycrystalline samples indicates that the proposed identity for the complexes is maintained in all three phases. The $NbGaCl_8$ and $TaGaCl_8$ complexes exist in the liquid state in a wide temperature range beyond their melting points (125 and 150°C, respectively) and are shown to undergo dissociation to their components [Nb_2Cl_{10}(l)/$NbCl_5$(l), Ga_2Cl_6(l) and Ta_2Cl_{10}(l)/$TaCl_5$(l)] with increasing temperature. Both complex molecules are identified in the gaseous state in low percentages among the vapours of their components and are almost totally decomposed at temperatures higher than *ca* 325°C. The enthalpy of the reaction $TaCl_5(g)+1/2Ga_2Cl_6(g) \rightleftharpoons TaGaCl_8(g)$ was determined from accurate relative Raman intensity measurements as $\Delta H^0 = -38 \pm 2$ kJ mol^{-1}.

In the field of high temperature chemistry, the formation of metal halide complexes in the liquid and/or the vapour state has attracted a special interest due to potential applications in several technological problems. Comprehensive reviews on this apparently general phenomenon are available.[1–4] Raman spectroscopy has been used in the past as a powerful tool for establishing the vibrational and structural properties of a large number of liquid and/or vapour complexes as well as "adduct" compounds of inorganic salts at elevated temperatures.[1,2,5,6] It has also been demonstrated that in certain cases Raman spectroscopy can be used for establishing the stoichiometry and thermodynamics of formation of vapour complexes.[7,8]

The trihalides of aluminum, gallium, indium and iron are among the most commonly studied complex forming agents, since they form complex molecules with a variety of metal halides in the gas phase or in the condensed state.[1] Previous investigations concerning complex formation between trihalides and pentahalides involved vibrational, electronic and mass spectrometric studies as well as X-ray work in a limited number of systems. Particularly the $UAlCl_8$[9,10] and $TaAlCl_8$[11] vapour complexes have been identified, the $PCl_4^+MCl_4^-$ (M = B, Al, Ga) ionic structures are derived[12] and the $NbAlCl_8$ molecular complex in the solid, melt and vapour phases has been thoroughly characterized.[13]

The present work concerns the mixed halide complex compounds formed by $GaCl_3$ with $TaCl_5$ and $NbCl_5$ in the liquid, solid and gaseous state. Raman spectra of the formed complexes in the liquid and gaseous phases are obtained. The vibrational band frequencies of the complexes formed in the liquid or gaseous state are determined and possible complex structures are considered and discussed. Finally, for

the $TaCl_5$–$GaCl_3$ vapour system the data obtained are shown to be suitable for a determination of the enthalpy of the reaction:

$$TaCl_5(g) + 1/2Ga_2Cl_6(g) \rightleftharpoons TaGaCl_8(g) \quad (1)$$

$$500\ K < T < 575\ K \quad 0.5\ atm < P < 1.5\ atm.$$

EXPERIMENTAL

High purity anhydrous $NbCl_5$, $TaCl_5$ and $GaCl_3$ were prepared from the corresponding Cerac/Pure Inc. reagents by repeated slow sublimations in fused silica tubes *in vacuo*. All handling of these chemicals took place in a nitrogen-filled glove-box with a water vapour content of less than 1 ppm.

The Raman (optical) cells containing the melt mixtures consisted of fused silica tubing (4 ± 0.1 mm o.d. and 2 ± 0.1 mm i.d., ~ 3 cm long). In the case of cells containing vapour mixtures, silica tubing with 20 ± 2 mm o.d., 18 ± 0.2 mm i.d. was used. Preweighed amounts of salts were transferred into clean, dry, flamed and degassed optical cells of known volume and sealed afterwards *in vacuo*. The salt mixtures were reacted inside a side tube (6 ± 0.1 mm o.d., 4 ± 0.1 mm i.d.), vapour transported into the main cell compartment and finally the side tube was sealed off. In this way a high degree of sample purity could be achieved. The ideal gas pressure, P_0, of each undissociated and non-reacted compound at a temperature T was calculated from the number of moles added to the cell.

Raman spectra were excited with the 514.5 and 488.0 nm lines of a 4 W Spectra Physics Ar^+ laser and the 647.1 and 676.4 nm lines of a Spectra Physics Kr^+ laser. The scattered light was collected at an angle of 90° (vertical scattering plane) and analyzed with a Spex 1403, 0.85-m double monochromator equipped with a −20°C cooled RCA photomultiplier and EG&G/ORTEC rate meter and photon counting electronics. The optical furnace for obtaining the high-temperature Raman spectra and the procedures for obtaining accurate relative Raman intensity data at high temperatures have been described in detail elsewhere.[14,7]

RESULTS AND DISCUSSION

The $GaCl_3$–MCl_5 (M = Nb, Ta) *molten systems*

Melts consisted of mixtures of pure gallium chloride, niobium pentachloride and tantalum pentachloride are considered as molecular liquids (Ga_2Cl_6, Nb_2Cl_{10} in equilibrium with $NbCl_5$ and Ta_2Cl_{10} in equilibrium with $TaCl_5$, respectively) and their Raman spectra are well characterized.[15–18]

Raman spectra of molten $NbCl_5$–$GaCl_3$ and $TaCl_5$–$GaCl_3$ mixtures have been recorded in the temperature range 390–580 K. Figure 1 shows representative Raman spectra obtained for $NbCl_5$–Nb_2Cl_{10}(l), Ga_2Cl_6(l) and for three different $NbCl_5$–$GaCl_3$ molten mixtures at 490 K. The spectra consist of superposition of bands due to the pure components plus several new bands, which are attributed to complex formation. The spectral data in Fig. 1 indicate that the predominant complex species is most probably a dinuclear addition compound of $NbCl_5 \cdot GaCl_3$ (m.p. $\sim$ 125°C) type, characterized principally by two strong polarized bands at 366 and 422 cm^{-1}. This is further justified by a study of temperature dependence measurements of Raman spectra obtained from a 1 : 1 molten mixture in the range 410–570 K (shown in Fig. 2). The spectral features in Fig. 2 reveal that: (i) in total eight bands can be assigned as due to the $NbGaCl_8$ liquid compound (see Table 1 for wave-numbers and polarization characteristics) and (ii) the intensities of the bands assigned to the complex are decreasing with increasing temperature, most probably due to thermal decomposition of the complex. At 410 K the strongest Ga_2Cl_6(l) and $NbCl_5$(l) bands at 96 and 395 cm^{-1} are observed as weak

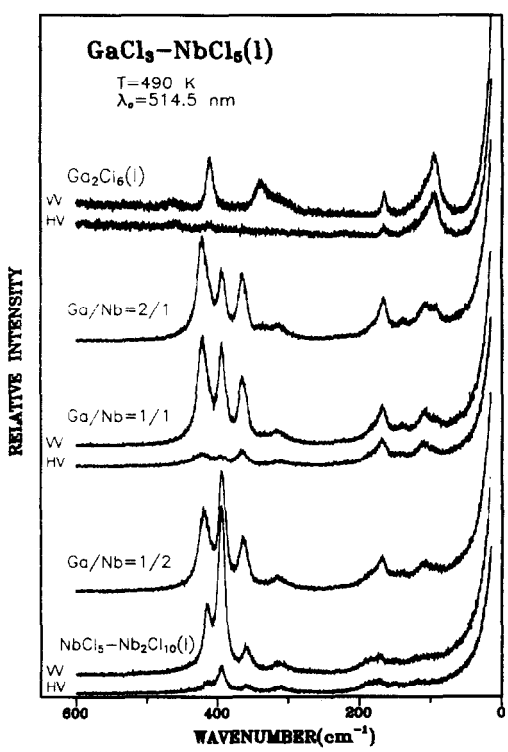

Fig. 1. Raman spectra of $GaCl_3$–$NbCl_5$ molten mixtures. Laser power, w = 15 mW; spectral slit width, ssw = 3.5 cm^{-1}; time constant, τ = 0.1 s; scan speed, ss = 1 cm^{-1} s^{-1}.

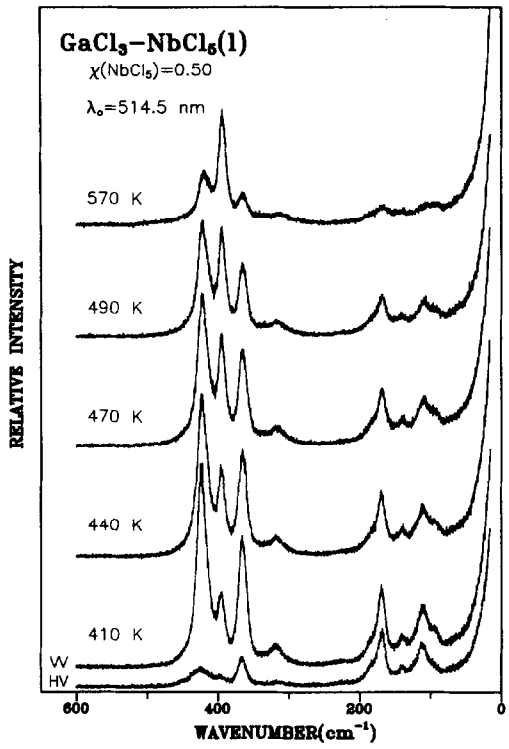

Fig. 2. Temperature dependence of Raman spectrum of liquid. $GaCl_3$–$NbCl_5$ mixture with $\chi(NbCl_5) = 0.50$. w = 15 mW; ssw = 3.5 cm^{-1}; $\tau = 0.1$ s; ss = 1 $cm^{-1}\,s^{-1}$.

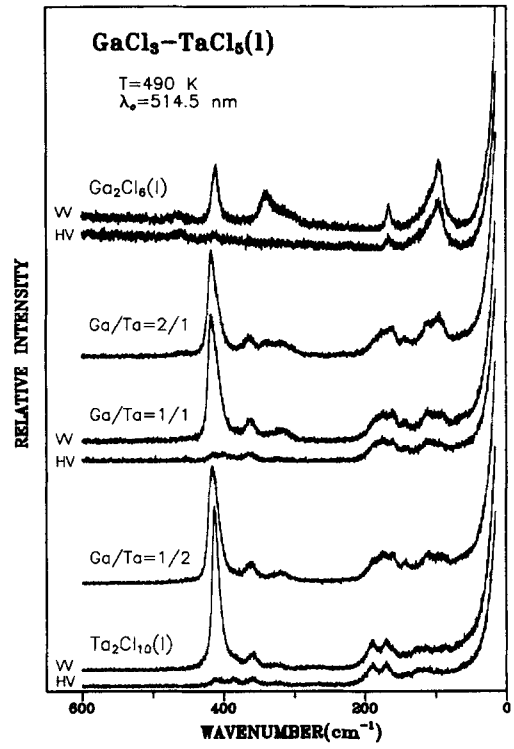

Fig. 3. Raman spectra of $GaCl_3$–$TaCl_5$ molten mixtures. w = 15 mW; ssw = 3.5 cm^{-1}; $\tau = 0.1$ s; ss = 1 $cm^{-1}\,s^{-1}$.

bands among the bands due to $NbGaCl_8$(l), which is the predominant species present. It is noteworthy that a temperature rise shifts also the dissociation equilibrium:

$$Nb_2Cl_{10}(l) \rightleftharpoons 2NbCl_5(l),$$

to the right. Thus, while at 500 K niobium pentachloride melts are considered as monomer-dimer mixtures, at 600 K the dimer is almost completely dissociated.[16]

Figure 3 shows representative Raman spectra obtained for Ta_2Cl_{10}(l), Ga_2Cl_6(l) and $TaCl_5$–$GaCl_3$ mixtures at 490 K. It should be pointed out here, that higher temperatures are needed to dissociate Ta_2Cl_{10} than to dissociate Nb_2Cl_{10}.[17] A careful comparison of the spectral features in Fig. 3 indicates that at least eight bands (attaining their maximum intensities in the spectrum with the composition: Ga/Ta = 1/1) can be assigned as due to a new complex species, presumably $TaGaCl_8$. Although there is an accidental frequency overlap of characteristic bands due to Ta_2Cl_{10} and Ga_2Cl_6 at ~ 412 cm^{-1}, one can easily observe by comparing the relative intensities of other bands of the different species that the spectral feature centred at ~ 417 cm^{-1} is mainly due to the $TaGaCl_8$ complex. Wavenumbers, polarization characteristics and species assignments of the observed bands in the $TaCl_5$–$GaCl_3$ molten system are summarized in Table 1. The temperature dependent features of the 1:1 $TaCl_5$–$GaCl_3$ liquid Raman spectra are similar to those of the $NbCl_5$–$GaCl_3$ system (Fig. 2) and are interpreted as indicating a thermal decomposition of the $TaGaCl_8$(l) to $TaCl_5$(l) and Ga_2Cl_6(l). The melting point of $TaGaCl_8$ was found to be ~ 150°C.

In summary, the molten MCl_5–$GaCl_3$ (M = Nb, Ta) mixtures in the composition and temperature range studied can be considered as molecular liquids consisting of Ga_2Cl_6, M_2Cl_{10}, MCl_5 and $MGaCl_8$ molecules linked by the equilibria:

$$2MGaCl_8(l) \rightleftharpoons M_2Cl_{10}(l) + Ga_2Cl_6(l)$$

$$M_2Cl_{10}(l) \rightleftharpoons 2MCl_5(l),$$

(M = Nb, Ta).

Raman spectra of polycrystalline 1:1 $NbCl_5 \cdot GaCl_3$ and $TaCl_5 \cdot GaCl_3$ were also recorded at room temperature. The observed wavenumbers are listed in Table 1.

Vapour Raman spectra

Raman spectra of vapours over liquid mixtures Ga_2Cl_6–MCl_5 at temperatures between 453 and 573 K are mainly due to Ga_2Cl_6–$GaCl_3$(g) and MCl_5(g). The temperature dependent features of the Raman spectra of Ga_2Cl_6–$GaCl_3$ vapours are well established,[8] while niobium and tantalum pentachloride vapours are known to consist of monomeric MCl_5 molecules and their Raman spectra are described elsewhere.[18] Several gas-cells were prepared containing varying amounts of $GaCl_3$ and MCl_5. The chemicals were sublimed into the cells and the Raman measurements were made by using the techniques described in detail elsewhere.[7] The vapour Raman spectra obtained gave evidence of formation of vapour complexes. Figure 4 shows representative Raman spectra of $NbCl_5$–$GaCl_3$ vapours. Raman spectra of gaseous niobium pentachloride[18] and gallium chloride[8] are included for comparison. Two new polarized weak bands observed in spectra of $NbCl_5$–$GaCl_3$ vapours (marked by "C" in Fig. 4) at 369 and 425 cm^{-1} are attributed to vapour complexation. Figure 5 illustrates a similar behaviour exhibited in the $TaCl_5$–$GaCl_3$ vapour system. The spectra of $TaCl_5$–$GaCl_3$ vapour mixtures consist of superposition of bands due to $TaCl_5$(g) and Ga_2Cl_6(g)/$GaCl_3$(g) plus a new polarized band at 370 cm^{-1}. Another complex band is possibly obscured from the strong asymmetric doublet feature (centred at *ca* 407 cm^{-1}) due to the $\nu_1(A'_1)TaCl_5$ and $\nu_1(A_g)Ga_2Cl_6$ bands at 406 and 412 cm^{-1}, respectively.

A comparison of the spectral features in the MCl_5–$GaCl_3$ gaseous systems with the spectra of the corresponding liquids, indicates that most probably the vapour complexes also have a 1 : 1 stoichiometry. A temperature rise leads to thermal

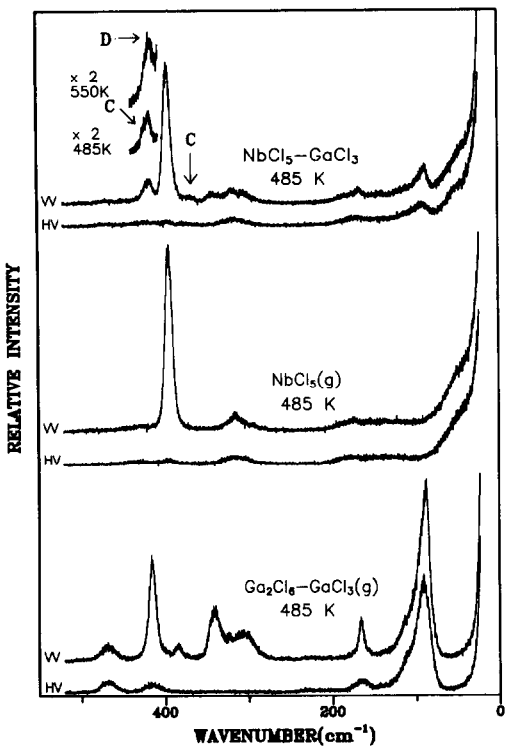

Fig. 4. Vapour Raman spectra of $Ga_2Cl_6/GaCl_3$, $NbCl_5$ and a $GaCl_3$–$NbCl_5$ mixture with $P_{0,NbCl_5} = 0.7$ atm. and $P_{0,Ga_2Cl_6} = 0.35$ atm. $\lambda_0 = 514.5$ nm; w = 420 mW; ssw = 5 cm^{-1}; $\tau = 0.15$ s; ss = 0.5 cm^{-1} s^{-1}.

decomposition of the $MGaCl_8$ vapour compounds (see Figs 4, 5).

Enthalpy of $TaGaCl_8(g)$ *formation.* Measurements of the vapour Raman spectra using different laser powers showed no changes in the relative intensities of the observed bands. On the other hand, changing the laser light frequency from red to blue altered the intensities of the $NbCl_5(g)$ and $NbGaCl_8(g)$ bands relative to those of the $Ga_2Cl_6(g)$ bands. As the frequency was changed from $\lambda_0 =$ 647.1 nm to $\lambda_0 = 488.0$ nm, the intensities of the ~ 425 cm^{-1} $NbGaCl_8$ and ~ 393 cm^{-1} $NbCl_5$ bands were almost tripled relative to those of $Ga_2Cl_6(g)$. This indicates preresonance enhancement of the $NbCl_5(g)$ and $NbGaCl_8$ fundamentals due to overlap of the excitation lines with the tail of the UV-absorption bands of the niobium vapour species.

On the other hand, no such overlap of the laser lines with the electronic bands of the tantalum vapour species could be observed. Therefore, contrary to the $NbCl_5$–$GaCl_3$ system, the procedure and method described in ref. 7 could be applied for determining the enthalpy of the gaseous reaction:

$$TaCl_5(g) + 1/2Ga_2Cl_6(g) \leftrightharpoons TaGaCl_8(g), \quad (1)$$

from a study of temperature dependence of the Raman intensities, I_i, of representative bands due to the participating species. Three different cells were made for studying the temperature dependence of the Raman spectra in the $TaCl_5$–Ga_2Cl_6 system. The first column in Table A (supplementary material, deposited with the editor) gives the characteristics of each cell. The intensity data obtained and the procedures used to derive band intensities that were not directly measured from the specta due to band overlaps are also described in Table A.

It is noteworthy that the Raman intensities listed in Table 1 were obtained under exactly the same experimental conditions (laser power, geometry of optics, position of cells), and thus they could be reproduced to within 2% and the relative Raman intensities of gases at different temperatures and pressures could be obtained within the same error.[7]

The calculation of the "second law" enthalpy is based on the following equation:[7]

$$R \ln K = R \ln [T^{\Delta n} K_f K_I] = -\Delta H^0 (1/T) + (\Delta S^0 - R \ln K_L), \quad (2)$$

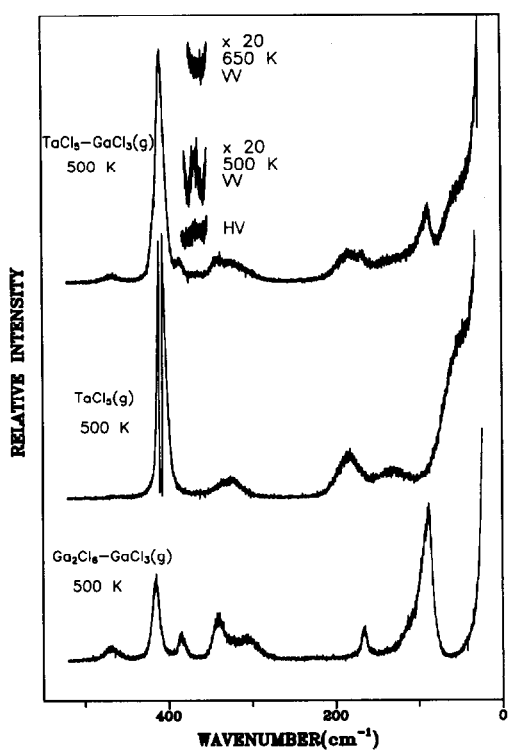

Fig. 5. Vapour Raman spectra of $Ga_2Cl_6/GaCl_3$, $TaCl_5$ and a $GaCl_3$–$TaCl_5$ mixture with $P_{o,TaCl_5} = 0.7$ atm. and $P_{0,Ga_2Cl_6} = 0.35$. $\lambda_0 = 514.5$ nm; w = 420 mW; ssw = 5 cm^{-1}; $\tau = 0.15$ s; ss = 0.5 cm^{-1} s^{-1}. Inserts show the Raman bands of $NbGaCl_8(g)$ at 425 cm^{-1} and $Ga_2Cl_6(g)$ at 412 cm^{-1} marked as "C" and "D", respectively.

where K_I is the quotient of the terms $I_i(v_i)$ (with v_i being the vibrational wave number) due to the gaseous species participating in reaction (1), K_f is the quotient of the terms $1-\exp(-hcv/kT)$ and K_L is a temperature-independent parameter involving the intensity of the excitation laser line, the molecular scattering properties and the sensitivity of the spectrometric system used.[7]

For the enthalpy of reaction (1) a plot (Fig. 6) of $R \ln K$, where $K = 1/T^{0.5}K_fK_I$, *vs* $1/T$ (i.e. eq. (2), $\Delta n = -0.5$), for all three cells used gives:

$$\Delta H_1^0 = -37.6 \pm 20 \text{ kJ mol}^{-1}.$$

Possible structures for $MGaCl_8$ (M = Nb, Ta) *complexes*

Formation of ionic $GaCl_2^+MCl_6^-$ or $GaCl_4^-MCl_4^+$ liquid compounds by chlorine ion transfer can be safely excluded because of the absence of the characteristic $NbCl_6^-$, $TaCl_6^-$ and $GaCl_4^-$ bands[2] from the spectra in Figs 1–4. Most probably, within the $MGaCl_8$ molecular unit, a $GaCl_4$ tetrahedron shares an edge with a MCl_6 octahedron (C_{2v} symmetry). The 24 vibrational modes of the $MGaCl_8$ complexes for such a molecular configuration can be classified according to:

$$\Gamma_{C_{2v},\text{vib}} = 9A_1 + 3A_2 + 6B_1 + 6B_2,$$

and are all Raman active. Identical structures have been established earlier for $NbAlCl_8$[13] and postulated for $NbGaCl_8$.[19]

Therefore, the bands at 422 cm^{-1} due to $NbGaCl_8$(l) and 417 cm^{-1} due to $TaGaCl_8$ (Table 1) can be assigned as due to the $\nu(M—Cl_{terminal})$ vibrations, of hexacoordinate Nb or Ta atoms while the bands at 366 cm^{-1} ($NbGaCl_8$) and 364 cm^{-1} ($TaGaCl_8$) can be due to $\nu(M—Cl_{bridging})$ modes. The positions of these bands are compatible with the proposed structures and lie—as it should be expected—very close to the respective bands due to the M_2Cl_{10}(l) dimers,[2] where an internal arrangement of two MCl_6 octahedra sharing an edge creates a similar environment around the metal atom as in the case of the $MGaCl_8$ complexes. Figure 7 shows molecular models for the $MGaCl_8$ complexes (C_{2v} symmetry) and the M_2Cl_{10} dimers (D_{2h} symmetry). Furthermore by considering the gaseous dissociation reaction:[11]

$$1/2Ta_2Cl_{10}(g) \rightleftharpoons TaCl_5(g), \quad \Delta H^0 = 25 \text{ kJ mol}^{-1},$$

the enthalpy of the following reaction can be derived in combination with the enthalpy of reaction (1):

$$1/2Ta_2Cl_{10}(g) + 1/2Ga_2Cl_6(g) \rightleftharpoons TaGaCl_8(g)$$
$$\Delta H^0 = -12.6 \pm 2.0 \text{ kJ mol}^{-1}.$$

The resulting value is rather small, indicating that the coordination number[3] and geometry[1] of Ta(V) and Ga(III) are not altered during the reaction. Thus, the tetrahedral coordination of Ga(III) in $Ga_2Cl_6(g)$[1] and the octahedral coordination of Ta(V) in $Ta_2Cl_{10}(g)$[1] are preserved in the $TaGaCl_8$ vapour complex (see Fig. 7).

It is noteworthy how little the $MGaCl_8$ strong bands shift from the liquid phase (422 and 366 cm^{-1}

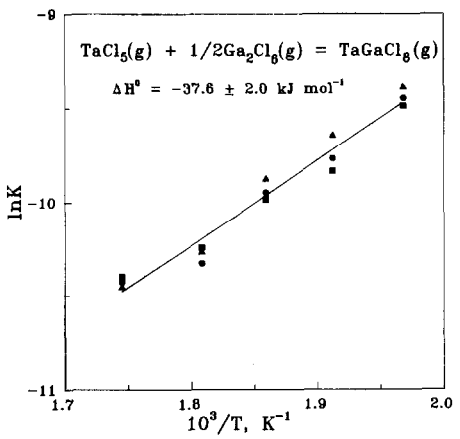

Fig. 6. Plot of ln K ($K = (1/T^{0.5})K_fK_I$ vs $1/T$ for reaction: $TaCl_5(g) + 1/2Ga_2Cl_6(g) \rightleftharpoons TaGaCl_8(g)$. Points indicate measurements from the different cells as follows: (a) cell I, ●; cell II, ■; cell III, ▲.

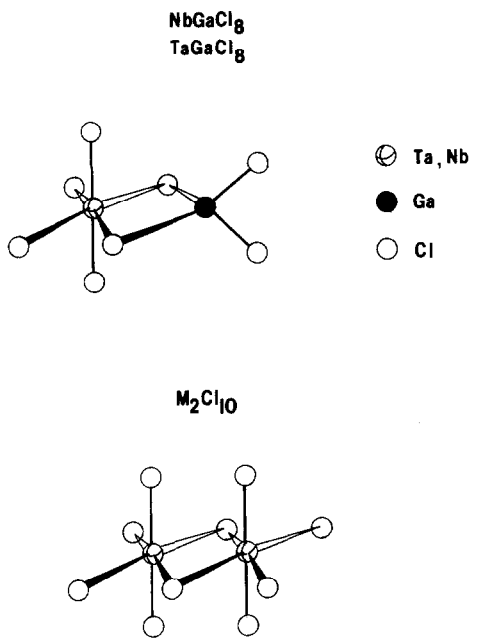

Fig. 7. Molecular models for $MGaCl_8$ (M = Nb or Ta) liquid and vapour complexes with C_{2v} symmetry and M_2Cl_{10} dimer vapour and liquid molecules with D_{2h} symmetry.

for $NbGaCl_8$, 417 and 364 cm^{-1} for $TaGaCl_8$) to the gas phase (425 and 369 cm^{-1} for $NbGaCl_8$, 370 cm^{-1} for $TaGaCl_8$) and to the crystalline phase (433 and 362 cm^{-1} for $NbGaCl_8$, 412 and 358 cm^{-1} for $TaGaCl_8$). This is interpreted as indicating that the proposed identity of the complexes is retained in all three phases.

Acknowledgement—The authors wish to thank Professor G. N. Papatheodorou for many helpful comments during the course of the present investigation.

SYNTHESIS AND X-RAY CRYSTAL STRUCTURES OF TETRAKIS-(2,2,6,6-TETRAMETHYLHEPTANE-3,5-DIONATO)BIS(2,2′-BIPYRIDYL)DIBARIUM $Ba_2(thd)_4(bipy)_2$ AND *catena*-[DODECAKIS(2,2-DIMETHYLPROPANOATO)BIS(2,2,6,6-TETRAMETHYLHEPTANE-3,5-DIONATO)TETRA(PYRIDINE)TETRA(AQUA)HEPTABARIUM] PYRIDINE SOLVATE $\{[Ba_7(piv)_{12}(thd)_2(py)_4(H_2O)_4]\cdot 2py\}$

(*Received* 21 *April* 1993; *accepted* 15 *July* 1993)

Abstract—Two new volatile mixed ligand barium complexes have been synthesized and their X-ray crystal structures determined. $Ba_2(thd)_4(bipy)_2$ (**1**) consists of dimeric molecules; with two barium atoms linked by four bridging Ba—O—Ba bonds. The structure of $\{[Ba_7(piv)_{12}(thd)_2(py)_4(H_2O)_4]\cdot 2py\}$ (**2**) contains Ba_3 units and separate Ba atoms which are connected into infinite chains through Ba—O—Ba bridges.

The search for new $Ba(thd)_2$ derivatives (Hthd = 2,2,6,6-tetramethylheptane-3,5-dione) more volatile than $Ba_4(thd)_8$ is rather important for the application of the MOCVD technique for $YBa_2Cu_3O_{7-\delta}$ thin films deposition. In the last two years a number of barium compounds containing both thd and O- and N- Lewis bases (e.g. H_2O, NH_3, CH_3OH etc) have been synthesized in laboratories in France,[1,2] the Netherlands[3] and the U.S.A.[4,5] In a previous paper[6] we discussed the crystal structures and thermal behaviour of $Ba_4(thd)_8$ and its derivatives containing the pivalate anion. Here we present two new compounds: an adduct of barium bis(2,2,6,6-tetramethylheptane-3,5-dionate) with 2,2′-bipyridyl (bipy) and a mixed ligand complex containing both thd-ligands and a number of pivalate anions (piv) as well as H_2O and pyridine (py) molecules. While the former compound consists of dimeric molecules, the latter contains infinite chains. For Ba-thd derivatives it is the first example of a polymeric structure.

EXPERIMENTAL

Synthesis

$Ba_2(thd)_4(bipy)_2$ (**1**) has been synthesized by the reaction of barium metal with the solution of Hthd and bipy (taken according to stoichiometry) in dry pentane–ether mixture (1 : 1) under dry nitrogen. Colourless crystalline plates formed by slow evaporation of the solvent. To isolate them from the air they were placed into glass capillaries.

$\{[Ba_7(thd)_2(piv)_{12}(py)_4(H_2O)_4]\cdot 2py\}$ (**2**). The colourless prismatic crystals of **2** were obtained from the pyridine solution of the product synthesized by the reaction between barium chloride and Hthd containing 3% admixture of pivalic acid in aqua-ethanol medium. As has been found previously, the dissolving of barium metal in this mixture of Hthd and Hpiv resulted in a mixed ligand compound $Ba_5(thd)_9(piv)$.[6]

Crystal structure determination

The experimental data for both structures were recorded using a CAD-4 diffractometer and Mo-K_α radiation. Cell data and details of the structure analysis are given in Table 1.

Compound **1**. The coordinates of the barium atoms were derived from an initial Patterson synthesis, and the positions of other atoms were found from subsequent difference Fourier synthesis. The structure was refined in anisotropic approximation for all barium, oxygen, nitrogen and non-terminal carbon atoms and isotropically for the other carbon atoms. The positions of H-atoms were not determined.

* Author to whom correspondence should be addressed.

Compound **2**. The structure was solved and refined via the direct methods followed by subsequent difference Fourier syntheses. We found that some ^{t}Bu groups are disordered about the threefold axes. The structure was refined by least-squares full matrix method with anisotropic thermal parameters for barium, oxygen, nitrogen and not disordered carbon atoms. Disordered carbon atoms were refined isotropically and their multiplicities were found for both positions.

Selected bond distances for **1** and **2** are listed in Tables 2 and 3, respectively. Positional and thermal parameters for both structures have been deposited at the Cambridge Structure Centre.

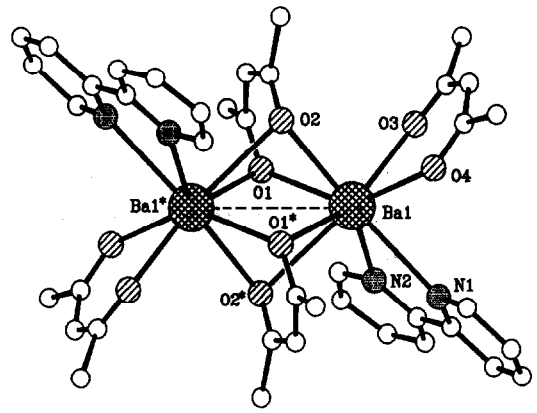

Fig. 1. A binuclear molecule in the crystal structure **1**. Terminal carbon atoms of ^{t}Bu groups are omitted.

RESULTS AND DISCUSSION

The structure of **1** is a packing of two crystallographically independent molecules $Ba_2(thd)_4(bipy)_2$. Two Ba atoms forming each dimer (Ba(1)···Ba(1′) 3.905 Å, Ba(2)···Ba(2′) 3.855 Å) are bound by two bridging thd ligands O(1), O(2); O(1′), O(2′) in the first dimer and O(5), O(6); O(5′), O(6′) in the second, with —OC—CH—CO— groups occupying positions in a plane nearly perpendicular to the line Ba···Ba (Fig. 1). The same type of tetradentate (O,O) bridging coordination of the thd anion has been recently found in a mixed ligand chelate $Ba_5(thd)_9(piv)$[6] (**3**) and adduct $Ba_2(thd)_4(NH_3)_4$[5] (**4**). While in the former chelate the ligands of this type link barium atoms in the square like framework, the latter binuclear complex **4** is much more similar to **1**; the place of the bidentate bipy ligand being occupied by two adjacent NH_3 molecules.

Two other thd anions in **1** (as well as in **4**) form usual bidentate O,O chelate rings; in **1** distances Ba—O being a little longer than in ammonia adduct

(average distances are 2.64 and 2.65 Å for two types of dimers in **1** and 2.60 Å for **4**). The slight elongation of Ba—O bonds in **1** compared to the ammonia adduct could be connected with the more rigid coordination of the chelating bipy ligand than NH_3. The lengths of Ba—O bonds forming bridges Ba—O—Ba lie between the limits of 2.76 and 3.01 Å in **1** being close to the range 2.77–2.87 Å in the ammonia complex. The elongation of the Ba—O—Ba bridges in the dimers results in a slight increase of distances Ba···Ba in chelate **1** (3.86 and 3.91 Å compared with Ba···Ba in **4** 3.83 Å). The last two positions in the coordination sphere of barium in **1** are occupied by two bipy molecules forming six-membered chelate ring, with average distances Ba—N in two dimers being 2.90 and 2.92 Å, respectively. The values of Ba—N distances are nearly the same in **4** (average 2.91 Å) but are longer in comparison with Ba—N(bipy) in $[Ba(bipy)_2(SCN)_2]$ (2.865 Å) consisting of infinite chains formed by the means of bridging SCN^- anions[7] (Ba—S is a very weak bridge: Ba—S distance is 3.36 Å).

The structure of **2** (Fig. 2) consists of triangular fragments Ba(2)Ba(3)Ba(4) with approximately equal sides (Ba(2)···Ba(3) 4.21, Ba(3)···Ba(4) 4.26, Ba(2)···Ba(4) 4.38 Å) linked into infinite chains on the one hand by the pairs of Ba(4)—O(5)—Ba(4′) bridges and on the other hand bound with Ba(1) atom lying in the centre of inversion and therefore being connected with the next triangular fragment. It is interesting to note that the ratio thd : piv in **3** (discussed in previous paper) is 9 : 1, while in **2** is almost the reverse—1 : 6, although the admixture of pivalic acid in Hthd was one and the same (3%). This may be connected with the influence of pyri-

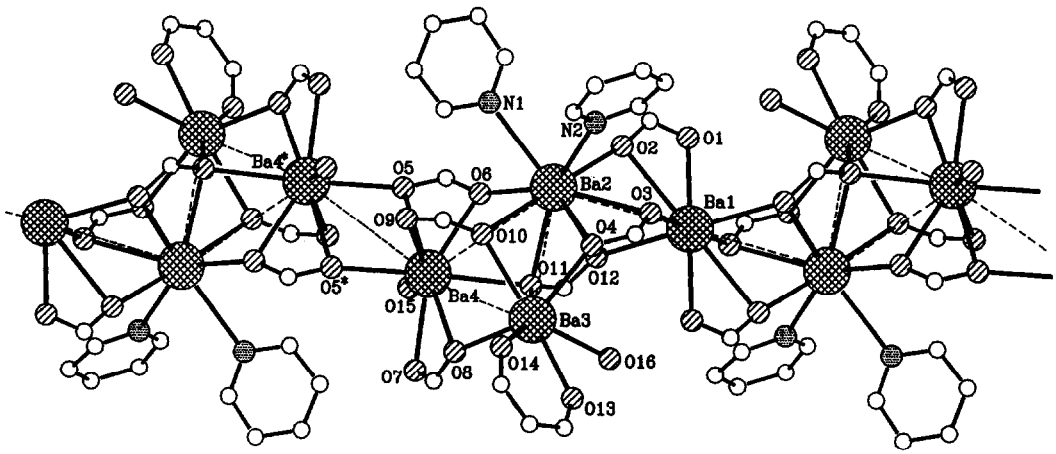

Fig. 2. A complex chain directed along the y-axis in the crystal structure **2**. Terminal carbon atoms of ^{t}Bu groups are omitted.

dine present in the system. Four barium atoms in the structure under discussion have different coordination spheres and CN's. The Ba(1) atom has a centrosymmetric coordination consisting of eight oxygen atoms from six piv-groups. The atoms O(1), O(1′), O(2), O(2′), O(3), O(3′), O(12), O(12′) connect Ba(1) with Ba(2) and Ba(2′) bridging two triangular units. The Ba(2) atom has a mixed coordination (CN = 9) formed by seven O-atoms from five piv anions and two N atoms of two py molecules, situated in *cis*-positions. The lowest CN of Ba(3) atom (CN = 7: four O atoms from four piv groups, two O atoms from thd and one $O(H_2O)$ atom) appears to be caused by the steric effect of thd ligand. It is common knowledge that barium requires high CNs; relatively low CN = 7 has been also found in sterically unsaturated $Ba_4(thd)_8$ obtained either by vacuum sublimation[1] or by crystallization from the pentane solution.[6] The Ba(4) atom possesses CN = 9, with the coordination sphere consisting of eight O atoms from five piv groups* and one $O(H_2O)$ atom. Two O(5)—Ba(4)—O(5′) bridges form a second linkage, connecting triangles Ba(2)Ba(3)Ba(4) into a chain.

Though the thd ligand forms a usual O,O bidentate six-membered chelate ring (Ba(3)—O(13) 2.68 Å, Ba(3)—O(14) 2.64 Å) one may distinguish four types of pivalate groups having different functions in the structure (Table 3). The groups of the first type form, besides a five-membered chelate ring, an additional bond with the other barium atom. Pivalate anions of both types 2 and 3 are tetradentate; two O atoms in every piv group of the second type possessing the same function in the structure (bidentate), while in the third type their functions are quite different (mono- and tridentate). The last type (4) of pivalate's coordination includes pentadentate ligand which links all four barium atoms. The piv group with similar function (which binds five barium atoms) has been found in the structure of the mixed ligand thd-piv complex **3**[6] (Table 3).

The longer Ba—N(py) distances in **2** (3.01–3.05 Å) in comparison with **1** and **4** are connected with the increase in coordination number in **2** CN(Ba(2)) = 9, in **1** and **4** and with the fact that the N atoms are not included in the chelate ring.

Thermal behaviour of chelates **1** and **2** is quite different. Thus, heating of the former compound in vacuum 0.01 torr results in the loss of bipy (80–90°C) followed by $Ba_4(thd)_8$ sublimation (200–220°C). The latter compound decomposes to $Ba_4(thd)_8$ (which sublimes in the same temperature range, vs) and barium pivalate, which can be partly sublimed at higher temperatures.

The results of crystal structure determinations for both homoligand and mixed ligand Ba-thd compounds allows us to make some previous conclusions concerning the influence of the type of additional ligand on the oligomerization degree and thermal stability of barium complexes. Thus, addition of N- and O-donor neutral chelating or macrocyclic ligands leads to decrease of oligomerization degree gradually from 4 in the case of $Ba_4(thd)_8$[1,6] to 2 in **1**, **2** and $Ba_2(thd)_4(diglyme)_2(H_2O)$[8] complex and even to mononuclear [$Ba(thd)_2(tetraglyme)$[8]]; the CN of barium increasing from 6, 7 in tetrameric barium dipivaloylmethanates to 8 in **1**, **4** and even to 9 in adduct with tetraglyme. In the case of negatively charged nonchelating additional ligands piv and OH^- the situation is more complicated. Being multidonor these anions link barium-thd fragments into pentameric units $Ba_5(thd)_9(piv)$[6] and $Ba_5(thd)_9(OH)(H_2O)_3$.[4] The piv ligands are multidonor and at the same time create less steric hindrances than the thd-ligand. The large number of piv-groups present in the structure leads to the higher oligomerization degree. According to this tendency even the presence of a great excess of py, which is a rather strong donor does not result in the formation of complexes with low nuclearity (structure of **2**). To make further investigations of these phenomena the structural studies of a greater number of mixed ligand barium compounds are required.

* If Ba(4)—O(10) distance (3.07 Å) is considered to be an interaction.

UV–VISIBLE SPECTROSCOPIC STUDIES ON THE PLATINUM-METAL PENTAFLUORIDES

ERIC G. HOPE

Department of Chemistry, University of Leicester, Leicester LE1 7RH, U.K.

(*Received* 1 *July* 1993; *accepted* 14 *July* 1993)

Abstract—The diffuse reflectance UV–vis spectra of RuF_5, RhF_5, OsF_5, IrF_5 and PtF_5 have been recorded for the first time and assigned on the basis of the strong-field model and optical electronegativity approach. The electronic transitions are interpreted in terms of a pseudo-tetragonally distorted octahedral field at the metal centres, which affords insights into the intense colours of these complexes.

The pentafluorides of the platinum metals, as rare examples of these metals in their +5 oxidation states, have been extensively studied. A range of physical properties has been described[1,2] while single crystal X-ray structure determinations on three of the compounds, ruthenium,[3,4] rhodium[5] and platinum,[6] illustrate their *cis*-octahedral bent fluorine-bridged tetrameric geometries. Most workers in this area have commented upon the intense colours of these species, in comparison to their related hexafluorometallate(V) derivatives, which are pale yellow or buff solids, and it is therefore surprising that the electronic spectra of the platinum-metal pentafluorides have received scant attention. Only two papers describe previous research in this area, a brief note on the electronic spectrum of liquid RuF_5[7] and a footnote to a preparative paper[8] describing limited electronic data for OsF_5 and IrF_5 in HF solution. Here we report and assign the electronic spectra for all the platinum-metal pentafluorides, which afford insights into their intense colours.

EXPERIMENTAL

The platinum-metal pentafluorides were prepared by literature routes; ruthenium and rhodium,[9] osmium,[10] iridium,[11] platinum[12] and stored in pre-passivated FEP (perfluoroethylene–propylene copolymer) containers in a dry-box. Commerical CaF_2 (BDH Ltd.) was dried in a furnace at 725 K and stored in the dry-box.

Electronic spectra were obtained from finely powdered neat $[MF_5]_4$ on dry CaF_2 in sealed silica cells. Spectra were recorded over the range 2000–200 nm (5000–50,000 cm^{-1}) on a Perkin–Elmer Lambda-19 instrument fitted with a diffuse-reflectance attachment, using the Kubelka–Munk function $F(R)$ available in the PECS software. Spectra were also recorded from samples exposed to moist air, to ensure that features in the reported spectra were not due to hydrolysis of these extremely moisture-sensitive materials.

RESULTS

The electronic spectra data are shown in Fig. 1 and recorded, with assignments, in Table 1. There is general agreement between these data and those reported previously over the limited range for RuF_5,[7] OsF_5 and IrF_5,[8] in view of the different physical states used whilst recording the earlier spectra.

The room-temperature magnetic moments of the platinum-metal pentafluorides, 3.06 BM (Ru),[3] 2.39 BM (Rh),[13] 2.06 BM (Os),[3] 1.32 BM (Ir)[11] and 2.05 BM (Pt),[14] are comparable to those reported[15–19] for the corresponding MF_6^- species, indicating that both types of metal(V) complexes have the same number of unpaired electrons. Hence, as might be expected, there is considerable correlation between the spectra for each platinum-metal pentafluoride and its hexafluorometallate. The intense low-energy bands which, as expected, move significantly to lower energy across each period (Ru → Rh, Os → Pt) are readily assigned as $\pi(F) \rightarrow$ metal charge-transfer for all these systems. The lowest energy charge-transfer transition may be treated by the optical electronegativity formula $E_{max} = 30{,}000\ \{\chi(F) - \chi(M)\}$[20] after corrections for spin-pairing and, for the 5*d* metals, spin-orbit effects have been

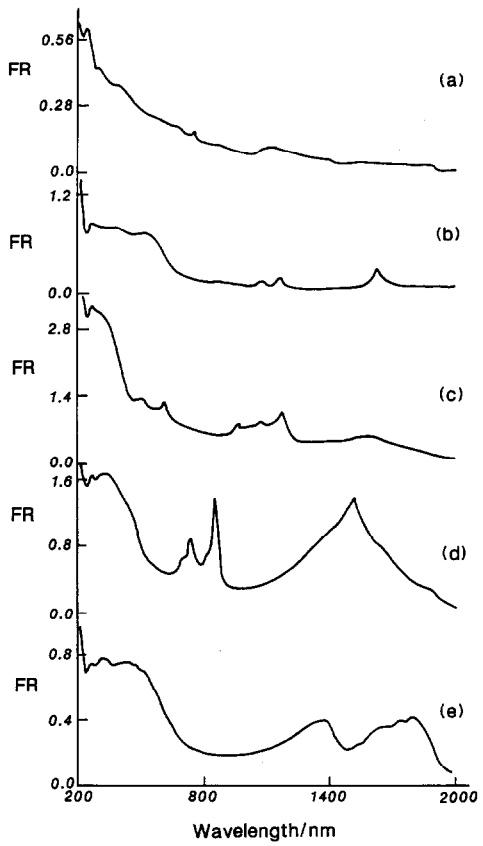

Fig. 1. Diffuse reflectance UV–vis spectra of: (a) RuF_5, (b) RhF_5, (c) OsF_5, (d) IrF_5 and (e) PtF_5 diluted in CaF_2.

considered. We follow convention[21] in not attempting to correct for the small spin-orbit effects in the 4*d* series. The relevant equations are therefore:

$$E_{obs} = 30{,}000\{\chi(F) - \chi(Ru)\} + 2D$$

$$E_{obs} = 30{,}000\{\chi(F) - \chi(Rh)\} + 4/3D$$

$$E_{obs} = 30{,}000\{\chi(F) - \chi(Os)\} + 2D - 2\xi$$

$$E_{obs} = 30{,}000\{\chi(F) - \chi(Ir)\} + 4/3D + \xi$$

$$E_{obs} = 30{,}000\{\chi(F) - \chi(Pt)\} + 2/3D + \xi.$$

D and ξ are not known accurately for these systems, but taking average values of $D = 3500\ cm^{-1}$ and $\xi = 3400\ cm^{-1}$, and $\chi_{opt}(F) = 3.9$, these equations afford $\chi_{opt}(Ru^V) = 2.7$, $\chi_{opt}(Rh^V) = 3.2$, $\chi_{opt}(Os^V) = 2.6$, $\chi_{opt}(Ir^V) = 2.9$ and $\chi_{opt}(Pt^V) = 3.3$. In view of the approximations inherent in these calculations, these values may be in error by ± 0.2, but they are nonetheless reasonable in comparison with the corresponding values for the M^{IV} and M^{VI} species.[9,22,23]

The remaining, weaker, higher energy features are either spin-forbidden intra-configurational bands arising from a redistribution of electrons within the spin-orbit split t_{2g}^n levels or spin-allowed *d–d* transitions between the t_{2g} and e_g levels. The intensity enhancement of the spin-forbidden transitions is, as expected, greater for the 5*d* than the 4*d* complexes as a result of larger spin-orbit coupling and, as observed previously for the platinum-metal hexafluorides,[9,22] the spin-allowed *d–d* transitions are either obscured by, or appear as shoulders on, the more intense charge-transfer transitions for the later metals in each period. The positions of each type of band are in similar spectral regions to those arising from the MF_6^- species, but each band appears more intense and shows considerable splittings. The more intense, split, spin-forbidden intra-configurational bands typically occur in the near IR/visible region of the spectrum and undoubtedly account for the intense colours of the platinum-metal pentafluorides.

These splittings and variations in band intensities may be accounted for by differences in the local site symmetry at the metal centres. All the MF_6^- complexes have a rhombohedral, $KOsF_6$-type lattice, in which the MF_6 unit is slightly distorted from a regular octahedron by compression along the trigonal axis, but with all the M—F bond distances approximately equal.[15,18,24,25] It was therefore assumed[23] that the analyses of the electronic spectral data of these complexes on the basis of O_h symmetry about the metal would be, and are, a satisfactory approximation. As mentioned above, the platinum-metal pentafluorides have *cis*-octahedral bent fluorine-bridged tetrameric structures in which the $M—F_{bridge}$ bonds are *ca* 10% longer that the $M—F_{terminal}$ bonds.[3–6] Since only the sum of the point charges on each axis determines the electronic structure of a given complex,[26] the symmetry groups of these *cis*-complexes are, in electronic spectroscopy terms, in practice tetragonally (D_{4h}) distorted. The increased intensities of the spin-forbidden transitions for the platinum-metal pentafluorides, as compared to the corresponding hexafluorometallates, may be ascribed to the greater influence of spin-orbit effects under the lower symmetry. Furthermore, descent in the double groups, $O^* \rightarrow D_4^*$, does indicate significant splittings as a result of the change in symmetry, e.g. for the d^3 systems, $(RuF_5)_4$ and $(OsF_5)_4$, the intra-configurational transitions are $^4A_{2g} \rightarrow {}^2E_g$, $^2T_{1g}$ and $^2T_{2g}$, which in the D_4^* double group give rise to eight possible states, $\Gamma_6+\Gamma_7$, $\Gamma_6+\Gamma_7+\Gamma_6$ and $\Gamma_7+\Gamma_6+\Gamma_7$, respectively. The complex theory behind spin-orbit split pseudo-tetragonally distorted octahedral complexes is unavailable, particularly when there is no information on the size of the pseudo-tetragonal splitting, so, the assign-

Abstract—Dark-brown copper(I) complexes of the type CuXL, for X = Cl, Br, I, SCN and N_3, and orange–yellow complexes of the type $(CuX)_2L$, for X = Cl or Br, where L = 2-benzoylpyridine, have been prepared and characterized. All complexes exhibit strong CT bands in the visible region and gave non-conducting solutions in acetone and nitrobenzene. The IR spectral data suggest that 2-benzoylpyridine acts as a monodentate ligand in the orange–yellow complexes and as a bidentate chelating ligand in the brown complexes, whereas bridging halides and pseudohalides exist in both types. The structure of the 1 : 1 black iodide complex, as determined by X-ray crystallography, features a discrete, centrosymmetric $[CuI(2\text{-benzoylpyridine})]_2$ molecule with a short Cu · · · Cu distance of 2.587(1) Å. Each copper atom in the dimeric molecule is tetrahedrally coordinated by two μ-iodine atoms and the carbonyl oxygen and nitrogen atoms of the chelating 2-benzoylpyridine ligand. The orange–yellow complexes display visible emission when excited in the UV region, whereas the brown complexes do not.

Complexes of copper(I) halides with unidentate nitrogen donor ligands have been observed to display a wide variety of stoichiometries, structures[1,2] and emission characteristics[3] in the solid state. Among other stoichiometries, the 1 : 1 : 1 copper–halide–base complexes most often occur with a cubane-like stereochemistry, as exemplified by $[CuIL]_4$ (L = pyridine,[4] morpholine[5]), or adopt a polymeric structure known as the ribbon or stair polymer as exemplified by $[CuX]_\infty$ adducts with pyridine,[6] isonicotinic acid,[7] methylcyanide[8,9] and benzonitrile.[10] Structures of the type CuXL–L, in which L–L is a bidentate ligand with hetero donor atoms, have been reported in the literature,[11–13] but definitive crystallographic data are lacking for these materials. X-ray structure determinations have been performed only for CuIL–L complexes, where L–L = methyl, isopropyl and n-butyl quinaldate.[14] These copper(I) iodide quinaldate complexes were found to display no visible emission when excited in the UV region.

Recently we reported the crystal structures of copper(I) chloride adducts of isonicotinic acid, $[CuClL]_\infty$,[7] nicotinic acid, $[CuClL_2]_\infty$[15] and 4-methylquinoline, $[Cu_2Cl_2L_3]$.[16] In the nicotinic acid complex the $(CuCl)_\infty$ chain takes the place of the Cu_2Cl_2 stair or ribbon in the isonicotinic acid adduct. The 4-methylquinoline complex comprises discrete centrosymmetric molecules with a Cu_4Cl_4 core of the step geometry.

†Authors to whom correspondence should be addressed.

Further work led to the isolation of copper(I) halide complexes of 2-benzoylpyridine (hereafter abbreviated as 2-Bzpy), a ligand which contains potential oxygen and nitrogen ligand sites. Some of these complexes exhibit solid-state emission at room temperature, whereas the others do not. We have now performed an X-ray structure determination of the title complex for which suitable crystals were available.

EXPERIMENTAL

2-Benzoylpyridine was obtained from Aldrich company and the other chemicals were of analytical grade quality.

Preparation of the complexes

(i) $(CuX)_2$(2-Bzpy) *complexes*, X = Cl *or* Br. A boiled ethanolic solution of 2-benzoylpyridine (10 mmol) was mixed with $Cu(NO_3)_2 \cdot 3H_2O$ (4 mmol) in ethanol and the subsequent addition of excess L(+)-ascorbic acid resulted in a clear dark brown solution. To this solution an aqueous solution of KX (X = Cl or Br) was added dropwise and the mixture was boiled for several minutes and allowed to stand over several hours to produce fine orange–yellow needles of the complex.

When NaN_3 solution was used in a similar way, the brown precipitate which was formed after a few minutes changed with time to a yellow precipitate. This yellow copper(I) azide compound was so easily oxidized that we could not isolate it by filtration.

(ii) Cu(2-Bzpy)X *complexes*, X = Cl, Br, I, SCN *and* N_3. An aqueous solution of $Cu(NO_3)_2 \cdot 3H_2O$ (5 mmol) was mixed with KX or NaX (X = Br, SCN or N_3), followed by the addition of L(+)-ascorbic acid. An ethanolic solution of 2-benzoylpyridine (8 mmol) was then added and the mixture stirred for *ca* 10 min. The final mixture was allowed to stand over several hours or days until a deep-brown crystalline product separated.

The chloro complex was prepared by the above procedure, except that $CuCl_2 \cdot 2H_2O$ was used instead of the nitrate salt.

Crystals of the dark-brown copper(I) iodide complex suitable for X-ray structure analysis were prepared by the procedure given for the orange–yellow complexes, except that a large excess of the ligand was added. Anisotropic thermal parameters and structure factors are available from the authors and also have been deposited with the Editor.

Elemental analysis results of the isolated complexes are given in Table 1.

Spectral data

The electronic spectral data of the complexes measured as solid Nujol mulls and some IR absorption bands are collected in Table 2. The experimental procedures and instruments used are as described previously.[17]

X-ray structure analysis of [CuI(2-benzoylpyridine)]$_2$

Intensities were recorded on a Nicolet R3m/V four-circle diffractometer[18] at 18°C and data collection and processing parameters are summarized in Table 3. The raw intensities were processed with

the learnt-profile procedure[19] and an absorption correction was based on a pseudo-ellipsoidal fit to azimuthal scans of selected strong reflections over a range of 2θ values.[20,21]

The structure was solved by Patterson superposition and Fourier methods. All non-hydrogen atoms were subjected to anisotropic refinement. The aromatic hydrogen atoms were generated geometrically (C—H fixed at 0.96 Å), allowed to ride on their respective carbon atoms and included in structure–factor calculations with assigned isotropic thermal parameters.

All computations were performed on a DEC MicroVAX-II computer with the SHELXTL-PLUS system.[22,23] Analytical expressions of neutral-atom scattering factors incorporating the real and imaginary components of anomalous dispersion were employed.[24] Least-squares refinement converged to the R indices and other parameters, as listed in Table 3. Selected bond distances and angles are listed in Table 4, the atom labelling being shown in Fig. 1.

DISCUSSION

The reactions between the copper(I) halide and pseudohalide salts and 2-benzoylpyridine afforded the complexes given in Table 1. The orange–yellow copper(I) azide complex of 2-Bzpy formed in solution was too unstable to be filtered off. All other copper(I) complexes are coloured and stable against air oxidation when well dried. Solutions of these complexes are non-conducting in acetone and nitrobenzene.

The electronic spectra (Table 2) of these copper(I) complexes exhibit strong bands in the visible region, which are undoubtedly due to charge transfer transitions[2] from $Cu^{I}d^{10}$ to an empty π^*-orbital on 2-Bzpy. As found for other copper(I) complexes of similar ligands,[25,26] the λ_{max} value of the MLCT bands depends on the halide/pseudohalide ion as well as the ligand-to-metal molar ratio in the complex.

The IR spectra (Table 2) may distinguish between the bonding mode of 2-Bzpy in the yellow and brown copper(I) complexes. The spectra of the $(CuX)_2$(2-Bzpy) complexes show the ν(C=O) vibration at slightly higher frequencies than that of free 2-Bzpy, suggesting a unidentate ligand coordinating via its heterocyclic nitrogen atom only. On the other hand, the spectra of the brown complexes show a substantial downward shift of the carbonyl stretch by $\Delta\tilde{\nu} \simeq 25$–$40$ cm^{-1}, when compared with that of the uncoordinated ligand. This result indi-

Symmetry transformation: a$(1-x, -y, -z)$.

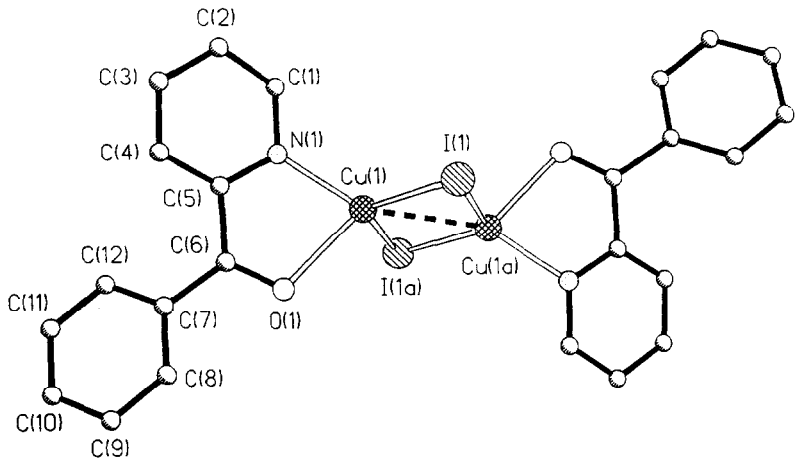

Fig. 1. Perspective view of the structure of the $[CuI(2\text{-benzoylpyridine})]_2$ dimer with atom labelling. The non-bonded interactions between the copper(I) atoms are indicated by a broken line.

cates the presence of N,O-bidentate 2-benzoylpyridine in such complexes, as found in the structure of $[Cu(2\text{-Bzpy})(N_3)_2]_2$,[27] with a similar downward shift of $\nu(C{=}O)$. The 1 : 1 thiocyanate complex shows two CN and two CS stretching bands, which are indicative of a μ(N,S)-thiocyanate ligand.[28] The dark-brown 1 : 1 azide complex on the other hand shows a very strong and sharp band at 2060 cm^{-1}, associated with the asymmetric stretch of the azide group, which is very similar to that reported for $[CuN_3(PPh_3)_2]_2$ having a $\mu(1,3)$-azido bridge.[29] The existence of this type of bridging azide in the 1 : 1 complex of 2-Bzpy is supported by the disappearance of symmetric stretching azide frequencies in the region 1275–1350 cm^{-1}. Accordingly, both complexes have the same bridging pseudohalide groups, assuming dimeric or polymeric structures with tetrahedral copper atoms in these 1 : 1 complexes.

In the far-IR spectra (400–200 cm^{-1}) of the brown and orange–yellow copper(I) chloride adducts of 2-Bzpy no bands could be attributed to terminal ν(Cu–Cl), which is suggestive of bridging chlorides in such complexes. For the brown copper(I) halide complexes with N,O-bidentate 2-Bzpy, we may assume dimeric or polymeric structures corresponding to those of 1 : 1 copper(I) iodide adducts of quinaldic acid esters having a chain of alternating copper and iodine atoms or planar Cu_2I_2 rhombohedra.[14] For the orange–yellow $(CuX)_2$(2-Bzpy) complexes with the N-monodentate 2-benzoylpyridine ligand, we may assume a polymer of chains linked side by side, as found in the structure of $[(CuI)_2(2\text{-Mepy})]$ (2-Mepy = 2-methylpyridine).[30] The bridging nature of the halide atoms in the brown 1 : 1 adducts is supported by crystal structure analysis of the iodide complex.

The present study has shown the title complex as $[CuI(2\text{-benzoylpyridine})]_2$ (Fig. 1), another example of a metal–halide–bidentate ligand with hetero atoms of the stoichiometry CuIL–L to be structurally characterized. This dinuclear complex is disposed about a crystallographic inversion centre with a planar Cu_2I_2 rhombohedral core of alternating copper and iodine atoms. The Cu—I distances of 2.555(1) and 2.599(1) Å are shorter than those usually observed for $[CuIL]_4$ cubes or polymeric pleated sheets where each copper atom has three iodine neighbours [av. 2.698(3)[31] and 2.706(3) Å,[32] respectively], but longer than those observed [2.388(2) Å][33] in CuI_2^- where copper has two neighbours (both iodine) and presumably exhibits multiple bonding character. The Cu—I bond lengths and I—Cu—I angles (Table 4), however, match the corresponding values reported for [CuI(isopropyl quinaldate)]$_2$ (2) and [CuI(n-butylquinaldate)]$_2$ (3) [Cu—I = 2.585(3) and 2.56(8) Å, I—Cu—I = 120.9(2) and 121.0(1)° for **2** and **3**, respectively] very well.[14] Each copper centre in the Cu_2I_2 unit is further coordinated by the carbonyl oxygen at Cu—O = 2.304(1) Å and the heterocyclic nitrogen at Cu—N = 2.035(4) Å, thus forming a five-membered chelate ring. The Cu—O distance is a little shorter than that found in complex **2** [2.33(1) Å], but a little longer than Cu—O [2.26(6) Å] in complex **3**, whereas the Cu—N distance agrees very well with corresponding values in both complexes [2.04(1) for **2** and 2.04(2) Å for **3**]. Similar Cu–carbonyl oxygen bond lengths in the complex of bis(10-methylisoalloxazine)[34] with copper(I) are

2.27(2) and 2.21(2) Å. In this complex a similar (—Cu···N=C—C=O—) five-membered chelate ring exists with both nitrogen and carbonyl oxygen coordinated to copper(I) [Cu—N = 1.94(2) and 1.92(2) Å].

Structures such as the title complex with a Cu_2I_2 rhombohedral unit are common in the literature of CuIL and $CuIL_2$ (L = nitrogen donor ligand), with Cu—Cu distances ranging from 2.535(9) Å in CuI(2,2,6,6-tetramethylpiperidine)[2] to 3.706(5) Å in CuI(2-Mepy).[35] It is noted that the smaller the bulk of the organic ligand, the closer the Cu···Cu distance. For example, the Cu···Cu separation in $[CuI(py)_2]$ is 2.699(5) Å,[35] whereas in [CuI(phenanthroline)$_2$] it reaches 3.083(3) Å.[36] The Cu···Cu distance of 2.587(1) Å found for the present complex is, however, comparable with values observed in other Cu_2I_2 rhombohedra, e.g. 2.544(2) Å in complex **2** and 2.53(1) Å in complex **3**.[14]

It is generally known that three structural features are identified with the emission spectra of solid-state CuX–ligand systems: (a) copper–copper distances of less than 2.8 Å lead to emission at 550–628 nm, attributed to metal–metal interactions;[31] (b) when copper links a ligand that permits charge-transfer transitions (MLCT); and/or (c) when aromatic ligands are packed in parallel planes separated by 3.225–3.279 Å, resulting in emission spectra of the ligand alone. Accordingly, the complex $[CuI(2\text{-Bzpy})]_2$ with a Cu···Cu separation of 2.587(1) Å is expected to demonstrate visible evidence of excitation of types (a) and (b), since both $[CuI(quin)]_4$ (Cu···Cu = 2.558(10) Å) and $[Cu_2I_2(quin)_4]$ (Cu···Cu = 3.364(5) Å) display room-temperature emission due to MLCT excitation.[37] However, neither the copper(I) iodide complex nor any of the brown 1 : 1 complexes of 2-Bzpy display emission at room temperature. This result resembles that reported for CuI (quinaldate) complexes,[14] where their non-emitting character was considered to be effected by the electron-withdrawing ester groups which alter the energy levels of the aromatic ring to make the excitation of greater energy or to make other radiationless decay mechanisms more efficient. Similar reasons may be suggested in the case of the brown complexes of 2-Bzpy. The lack of evidence of metal–metal interactions is apparently due to the alteration of the metal energy levels by the coordination to oxygen in such complexes. This view is supported by the observation of room-temperature emission of the orange–yellow $(CuX)_2$(2-Bzpy) complexes, where the metal centre is not coordinated to oxygen as inferred from the IR spectra. The chloride adduct displays poor emission, whereas the orange–yellow copper(I) bromide of 2-benzoylpyridine shows a broad-band emission with λ_{max} at 655 nm (excitation at 365 nm). The position of this emission band is somewhat higher than those reported for the tetrameric clusters of polymeric complexes of CuI with pyridines (emission from 550 to 628 nm)[38,39] or quinoline (emission around 620–632 nm).[31] Despite the lack of structural details of the bromide adduct, the 655 nm room-temperature emission may be suspected to arise from metal-centred excitation, since those assigned to metal–ligand charge-transfer excitations usually appear in the region 420–550 nm.[31,40]

(*Received* 5 *May* 1993; *accepted* 18 *June* 1993)

Abstract—The nickel(II) Schiff base complexes with 2-methylbutyl or 2-methylpentyl groups and their benzoyl derivatives have been prepared and characterized by ^1H and ^{13}C NMR spectroscopy. The structure of the benzoyl derivatives in chloroform solution can be estimated as follows: the donor set of N_2O_2 has a square planar coordination, the benzoyl substituents are perpendicular to the chelate plane and the long alkyl chains (2-methylbutyl or 2-methylpentyl groups) move segmentally to aproach the benzoyl substituents.

It is well known that weak interactions such as hydrogen bonds and hydrophobic interactions play an important role in most biological processes.[1] Recently, the hydrophobic interactions have been extensively studied and found to be applicable for selective syntheses of geometrical and optical isomers.[2]

In a previous paper[3] we prepared the nickel(II) Schiff base complexes with 2-methylpropyl(isobutyl) groups and benzoyl substituents and discussed their structures in solution from the results of their ^1H and ^{13}C NMR spectra and relaxation time (T_1) measurements. The results indicated that in the complex the donor set of N_2O_2 has a square planar coordination, the benzoyl substituents are perpendicular to the chelate plane and the isobutyl groups move segmentally so that they may approach the benzoyl substituents. The characteristic behaviour of the isobutyl groups in the complex could be affected by the so-called CH$\cdots\pi$ interaction[4] between alkyl and phenyl groups. However, as the isobutyl group is a rather short alkyl chain and its freedom of movement is not naturally high, the CH$\cdots\pi$ interaction is weak. Therefore, we decided that novel nickel(II) complexes with longer alkyl chains should be prepared and characterized. In this paper we report the preparation and characterization of the nickel(II) Schiff base complexes with both benzoyl substituents and 2-methylbutyl (isopentyl) or 2-methylpentyl (isohexyl) chains. Their structures and dynamics in chloroform solution will be discussed from the results of their ^1H and ^{13}C NMR spectra and ^{13}C relaxation time measurements. It will be made clear that the interaction between isopentyl or isohexyl groups and benzoyl substituents in nickel(II) Schiff base complexes affects the characteristic structure and dynamics of the long alkyl chains in chloroform solution.

EXPERIMENTAL

Preparation of nickel(II) *Schiff base complexes with isopentyl or isohexyl groups*

7-Methyl-2,4-octanedione and 8-methyl-2,4-nonanedione were prepared using the literature method.[5] The Schiff base ligands and their nickel(II) complexes [(2,7,12,17-tetramethyl-8,11-diazaocta-

* Author to whom correspondence should be addressed.

deca-5,14-dione-6,12-dienato)nickel(II), Ni(iso-Pe,Meen), and (2,8,13,19-tetramethyl-9,12-diaza-octadeca-6,15-dione-7,13-dienato)nickel(II), Ni (iso-Hx,Meen)] were prepared by refluxing an ethanol solution (200 cm^3) of 7-methyl-2,4-octanedione or 8-methyl-2,4-nonanedione (0.10 mol), ethylenediamine (0.05 mol) and nickel(II) acetate tetrahydrate (0.05 mol) for 1 h. The resulting solution was evaporated at reduced pressure and the residue was recrystallized from a mixed solution of ethanol and ether (1 : 1). The red–brown crystals were collected on a glass filter and dried *in vacuo*. The yields were *ca* 60%.

Preparation of benzoyl derivatives of nickel(II) *Schiff base complexes*

To a dry chloroform solution (500 cm^3) of the nickel(II) Schiff base complex (0.05 mol) mentioned above and excess trimethylamine (0.12 mol) was added excess benzoyl chloride [*m*-nitrobenzoyl chloride (*m*NB-Cl) or 3,5-dinitrobenzoyl chloride (DNB-Cl)]. The mixture was refluxed for 60 h and evaporated under reduced pressure. The residue was recrystallized from ethanol giving orange crystals in *ca* 50% yields. The results of the elemental analyses, IR and electronic spectral data of all the complexes indicate that they are pure and are consistent with their chemical structures (see Fig. 1). However, in the reaction of Ni(isoPe,Meen) with *m*NB-Cl, the reaction mixture of the parent complex, the mono-substituted complex and the di-substituted complex was obtained and attempts to separate pure Ni(isoPe,Meen)-*m*NB have been unsuccessful.

Measurements

The ^1H and ^{13}C NMR spectra and ^{13}C relaxation time (T_1) measurements were recorded using a JEOL FX-90 spectrometer at 90 MHz for ^1H and at 22.5 MHz for ^{13}C nuclei. Chloroform-d_3 ($CDCl_3$) and TMS were used as the solvent and internal standard, respectively. Each sample solution was almost saturated with the respective complexes.

RESULTS AND DISCUSSION

^1H *NMR spectra*

Figure 2 shows the ^1H and ^{13}C NMR spectra for Ni(isoPe,Meen)-DNB in $CDCl_3$. The chemical shift values for the ^1H NMR spectra of the nickel(II) Schiff base complexes in $CDCl_3$ are summarized in Table 1, except the signals due to the phenyl protons. For Ni(isoPe,Meen) the ^1H NMR spectrum has a doublet resonance due to the methyl protons of the isopentyl groups [CH_3(O)] at 0.88 ppm, a triplet due to the methylene protons on the 4-positions of the isopentyl groups, attached to the keto moiety [$^4CH_2$(O)] at 1.41 ppm, a singlet due to the methyl protons attached to the azomethine moieties [CH_3(N)] at 1.85 ppm, an overlapping multiplet resonance due to the methine and is neighbouring methylene protons of the isopentyl groups [$^3CH_2$+CH(O)] at 2.05 ppm, a singlet due to the methylene protons of the ethylenediamine moiety [CH_2(en)] at 2.99 ppm and a singlet due to the methine protons on the γ-positions of the chelate ring at 4.88 ppm. For its 3,5-dinitrobenzoyl derivative, Ni(isoPe,Meen)-DNB, a similar spectrum in a higher region was obtained (< 4.0 ppm), although the signals due to CH_3(N), CH_3(O), CH_2(O) and CH_2+CH(O) shifted to a higher field and the signal due to CH_2(en) to a lower field. The lower-field shift was caused by the electron-withdrawing effect of the DNB substituents and the higher-field shifts were as a consequence of a combination of the electron-withdrawing effect and the magnetic anisotropy effect of the DNB substituents; the latter is associated with the higher-field shift and the former with the lower-field shift. It is evident that the latter effect is stronger than the former in the case of Ni(isoPe,Meen)-DNB.

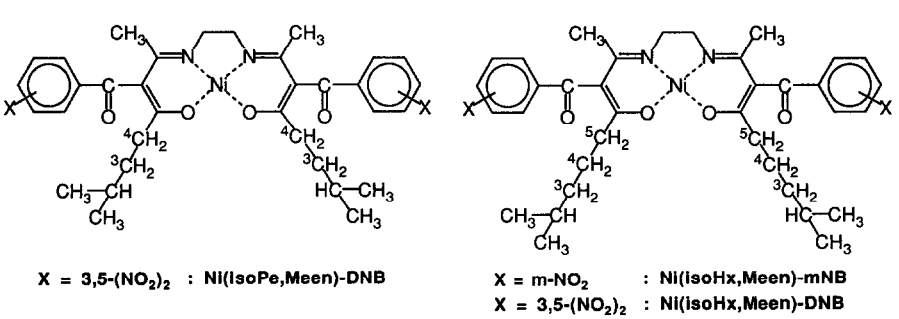

Fig. 1. Chemical structures of the nickel(II) Schiff base complexes with benzoyl substituents.

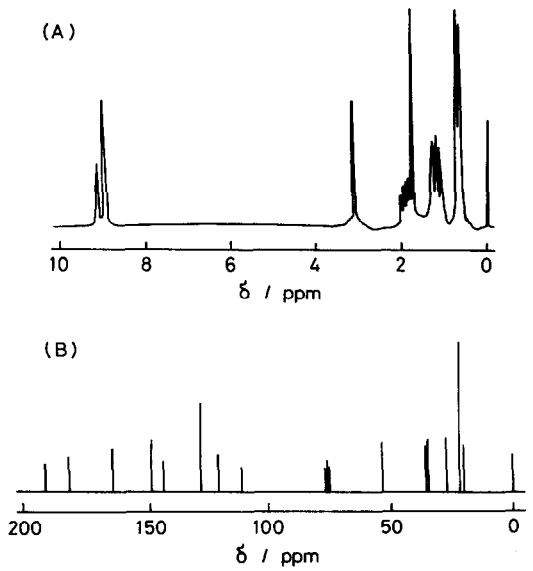

Fig. 2. (A) ^{1}H and (B) ^{13}C NMR spectra for Ni(isoPe, Meen)-DNB in $CDCl_3$.

On the other hand, for Ni(isoHx,Meen) the spectrum has a doublet resonance due to CH_3(O) at 0.86 ppm, a multiplet due to the methylene protons on the 4-positions of the isohexyl groups [$^4CH_2$(O)] at 1.24 ppm, a triplet due to the methylene protons on the 5-positions of the isohexyl groups [$^5CH_2$(O)] at 1.50 ppm, a singlet due to CH_3(N) at 1.86 ppm, an overlapping multiplet resonance due to $^3CH_2$+CH(O) at 1.97 pm, a singlet due to CH_2(en) at 3.01 ppm and a singlet due to the methine protons on the γ-positions of the chelate ring at 4.88 ppm. For its mNB and DNB derivatives, Ni(isoHx,Meen)-*m*NB and Ni(isoHx,Meen)-DNB, similar spectra in the higher region were obtained (< 4.0 ppm), although the signals due to CH_3(N), CH_3(O), $^4CH_2$(O), $^5CH_2$(O) and $^3CH_2$+CH(O) shifted to a higher field, except for CH_3(N) and $^3CH_2$+CH(O) in Ni(isoHx,Meen)-DNB, and the signals due to CH_2(en) to a lower field. The lower-field shifts were caused by the electron-withdrawing effect of the *m*NB and DNB substituents, respectively, and the higher-field shifts were as a consequence of a combination of the electron-withdrawing effects and the magnetic anisotropy effects by the *m*NB and DNB substituents; the latter effects are associated with the higher-field shift and the former effects with the lower-field shift. It is evident that the latter effect is stronger than the former in the case of Ni(isoHx,Meen)-*m*NB, but both are the same for the CH_3(N) and $^3CH_2$+CH(O) moieties in Ni(isoHx,Meen)-DNB.

^{13}C *NMR spectra*

The ^{13}C NMR spectrum of Ni(isoPe,Meen) in $CDCl_3$ has nine sharp signals at 20.9, 22.4, 27.8, 36.0, 36.4, 53.0, 98.4, 164.3 and 180.0 ppm, assignable to the methyl carbons attached to the azomethine moities [CH_3(N)], the methyl carbons of the isopentyl groups [CH_3(O)], the methine carbons of the isopentyl groups [CH(O)], the methylene carbons at the 4-positions of the isopentyl groups [$^4CH_2$(O)], the methylene carbons at the 3-positions of the isopentyl groups [$^3CH_2$(O)], the methylene carbons of the ethylenediamine moiety [CH_2(en)], the methine carbons at the γ-positions of the chelate ring, the azomethine carbons and the keto carbons, respectively. Similarly, the spectrum of Ni(isoPe, Meen)-DNB has 14 sharp signals. The higher-field peaks can be assigned to CH_3(N), CH_3(O), CH(O), $^4CH_2$(O), $^3CH_2$(O), CH_2(en), the quarternary carbons at the γ-positions of the chelate ring, the phenyl carbons of the DNB substituents (four signals), the azomethine carbons, the keto carbons and the carbonyl carbons of the DNB substituents, respectively. These results are consistent with the structure of the nickel(II) Schiff base complex shown in Fig. 1.

On the other hand, the ^{13}C NMR spectrum of Ni(isoHx,Meen) in $CDCl_3$ has 10 sharp signals at 20.7, 22.6, 28.0, 38.5, 39.0, 39.1, 53.2, 98.8, 164.4 and 181.1 ppm assignable to CH_3(N), the methyl carbons of the isohexyl groups [CH_3(O)], the methine carbons of the isohexyl groups [CH(O)], the

Ni(isoHx,Meen)-*m*NB	1.83	0.76	1.40	1.98	1.18	3.22	4.89
Ni(isoHx,Meen)-DNB	1.87	0.77	1.42	1.99	1.20	3.27	

methylene carbons at the 3-positions of the isohexyl groups [$^3CH_2(O)$], the methylene carbons at the 5-positions of the isohexyl groups [$^5CH_2(O)$], the methylene carbons at the 4-positions of the isohexyl groups [$^4CH_2(O)$], CH_2(en), the methine carbons at the γ-positions of the chelate ring, the azomethine carbons and the keto carbons, respectively. Similarly, the spectra of Ni(isoHx,Meen)-*m*NB and Ni(isoHx,Meen)-DNB have 17 and 15 sharp signals, respectively. The higher-field peaks can be assigned to CH_3(N), CH_3(O), CH(O), $^3CH_2(O)$, $^5CH_2(O)$, $^4CH_2(O)$, CH_2(en), the quarternary carbons at the γ-positions of the chelate ring, the phenyl carbons of the *m*NB or DNB substituents (six or four signals), the azomethine carbons, the keto carbons and the carbonyl carbons of *m*NB or DNB substituents, respectively. These results are also consistent with the structures of the nickel(II) Schiff base complexes shown in Fig. 1.

T_1 *measurements*

The T_1 measurements were obtained using the inversion recovery method[6] for the nickel(II) Schiff base complexes Ni(isoPe,Meen), Ni(isoPe,Meen)-DNB, Bi(isoHx,Meen) and Ni(isoHx,Meen)-*m*NB in $CDCl_3$ at 25.0°C. The T_1 data for the four nickel(II) complexes are listed in Table 2. It is considered that in large molecules, such as the nickel(II) complex investigated here, dipole–dipole relaxation is dominant.[7] It is difficult to extract intramolecular movements such as the distortion and the rotation of the benzoyl group, the segmental movements of the isopentyl or isohexyl groups from the whole movements of the complex molecule. However, the relative difference in intramolecular movements between Ni(isoPe,Meen) and Ni(isoHx,Meen) and/or the nickel(II) Schiff base complexes with shorter alkyl chains, Ni(Me,Meen) and Ni(isoBu, Meen), can be discussed qualitatively based on the T_1 data.[3] In addition, the difference between the parent complex and its benzoyl derivative can also be investigated. It is said that the larger the T_1 value of the ^{13}C atom, the faster its motion.

All the T_1 values of ^{13}C atoms were reduced greatly owing to the insertion of *m*NB or DNB groups in the nickel(II) Schiff base complex. This is caused by the reduction of movements such as translation and rotation for the whole complex molecule due to the increase in molecular weight. This effect can be extracted directly from the T_1 value of CH_2(en) because its molecular structure and intramolecular movement may be steady before and after the insertion of benzoyl groups. The T_1 values of CH_2(en) in Ni(isoPe,Meen)-DNB and Ni(isoHx,Meen)-*m*NB decrease to *ca* 30 and 40% of those in their parent complexes by the insertion of DNB and mNB substituents, respectively. However, the magnitude of the decrease in T_1 values for other carbons is not similar to that for CH_2(en).

The parent complexes, Ni(isoPe,Meen) and Ni(isoHx,Meen), exhibit similar T_1 values for the corresponding carbons and these results indicate that the isopentyl and isohexyl groups in Ni(isoPe, Meen) and Ni(isoHx,Meen) move segmentally.

Table 2. ^{13}C NMR spectral data and T_1 values for nickel(II) Schiff base complexes

Carbon	Ni(isoPe,Meen) δ (ppm)	T_1 (s)	Ni(isoPe,Meen)-DNB δ (ppm)	T_1 (s)
CH_3(N)	20.9	2.5	20.9	1.0
CH_3(O)	22.4	2.1	22.3	1.3
CH(O)	27.8	3.8	27.7	1.7
$^3CH_2(O)$	36.4	1.8	36.2	0.4
$^4CH_2(O)$	36.0	1.4	35.5	0.6
CH_2(en)	53.0	0.9	53.8	0.3
Carbon	**Ni(isoHx,Meen) δ (ppm)**	**T_1 (s)**	**Ni(isoHx,Men)-*m*NB δ (ppm)**	**T_1 (s)**
CH_3(N)	20.7	2.2	20.5	0.9
CH_3(O)	22.6	2.5	22.4	1.9
CH(O)	28.0	3.8	27.7	2.9
$^3CH_2(O)$	39.1	1.8	38.6	0.9
$^4CH_2(O)$	39.0	1.5	38.0	0.8
$^5CH_2(O)$	38.5	1.1	37.7	0.5
CH_2(en)	53.2	1.0	53.6	0.4

However, the activity of their segmental motion is slightly higher for Ni(isoHx,Meen) than for Ni (isoPe,Meen).

The T_1 values for CH_2(en), CH_3(N), $^4CH_2$(O) and $^3CH_2$(O) in Ni(isoPe,Meen)-DNB decrease remarkably to *ca* 30% in comparison with those for Ni(isoPe,Meen). However, the degree to which T_1 value decreases also decreases for CH(O) and CH_3(O), the end group of the isopentyl group, and in Ni(isoPe,Meen)-DNB is very low. The T_1 values for CH(O) and CH_3(O) reduce to *ca* 50 and 60% in comparison with those for CH(O) and CH_3(O) in Ni(isoPe,Meen), respectively. These results indicate that the intramolecular movements such as the segmental movements in the terminal moieties of the isopentyl groups in Ni(isoPe,Meen)-DNB are rather activated by the insertion of DNB substituents. This can be interpreted as follows: the CH(O) and CH_3(O) groups in isopentyl are attracted to the benzoyl substituents by the CH $\cdots \pi$ interaction.

On the other hand, for Ni(isoHx,Meen)-*m*NB the trend in T_1 values is almost equal to that for Ni(isoPe,Meen)-DNB, but the segmental movements for CH(O) and CH_3(O) of the isohexyl groups are rather more activated than those for Ni(isoHx,Meen). The T_1 values for CH(O) and CH_3(O) in Ni(isoHx,Meen)-*m*NB are slightly reduced (*ca* 80%) in comparison with those in Ni(isoHx,Meen). These results may be due to the same reason mentioned above for Ni(isoPe,Meen)-DNB and further indicate that the CH $\cdots \pi$ interaction is stronger between isohexyl and *m*NB groups than between isopentyl and DNB groups.

Structures and dynamics of nickel(II) *complexes in solution*

The structures and dynamics of nickel(II) Schiff base complexes in chloroform solution can be proposed from the results of the ^1H and ^{13}C NMR spectra and ^{13}C relaxation time measurements. In all the nickel(II) complexes studied, the donor sets of N_2O_2, which belong to three chelate rings, have a square-planar coordination. Their intramolecular movements are rather slow. For *m*NB or DNB derivatives, the inserted benzoyl groups are perpendicular to the chelate planes containing the nickel(II) ions. There is steric hindrance between the benzoyl groups and the adjacent methylene moieties [$^4CH_2$(O) or $^5CH_2$(O)] of isopentyl or isohexyl groups, respectively. Therefore, the benzoyl groups are inclined to approach the methyl groups attached to the azomethine moieties to avoid the isopentyl or isohexyl chains. This is the reason why the ^1H NMR signals due to CH_3(N) in the benzoyl derivatives were shifted to a higher field in comparison with those in the parent complexes. The isopentyl or isohexyl groups move segmentally so that they may chase the fleeing benzoyl groups. The movements of the terminal methyl moities and their neighbouring methine moieties are especially high so that they can experience the magnetic anisotropy effect of the benzoyl groups most strongly. Apparently, they are attracted by the benzoyl groups. Their results are different from those obtained for Ni(isoBu,Meen),[3] where the isobutyl groups move segmentally, but the movements of the methine moieties alone in the isobutyl groups are not activated but restricted by the benzoyl substituents. The large differences between the isobutyl group and the larger alkyl groups, isopentyl and isohexyl groups, in the molecular behaviour in chloroform would be mainly due to the differences in their freedom of movement; that for the isobutyl group is naturally low and those for the isopentyl and isohexyl groups are high. The isopentyl and isohexyl groups in the benzoyl derivatives of the nickel(II) Schiff base complexes are attracted to the benzoyl substituents by the CH $\cdots \pi$ interaction, especially on their terminal moieties, so that they segmentally move much more vigorously to experience the magnetic anisotropy effect of the benzoyl groups for a longer period. The CH $\cdots \pi$ interaction between the isoalkyl chains and benzoyl groups and the intramolecular movements of the isoalkyl chains in the nickel(II) Schiff base complexes in a non-polar solvent such as chloroform can be clarified by the results obtained in this study. In a polar solvent such as water, the CH $\cdots \pi$ interaction may be found to be much different in its nature and strength. Therefore, the preparation of water-soluble metal complexes with both alkyl and phenyl groups and their NMR investigation will be very interesting in the future.

(*Received* 22 *February* 1993; *accepted* 15 *June* 1993)

Abstract—The first representatives of a new class of TcN complexes with thiacrown ethers have been prepared by ligand exchange reaction of $NBu_4[TcNCl_4]$ with 1,4,8,11-tetrathiacyclotetradecane (14S4), 1,5,9,13-tetrathiacyclohexadecane (16S4), 1,5,9,13-tetrathiacyclohexadecane-3,11-diole (16S4-$(OH)_2$) and 1,4,7,10,13,16-hexathiacyclooctadecane (18S6). The crystal structure of $[TcNCl(14S4)]TcNCl_4$ (**1**) consists of couples of independent cations with the metal in the oxidation state +5 and hexavalent $TcNCl_4^-$ anions. In the complex cation the metal is six-coordinated in a rather distorted octahedral geometry, being directly bound to four sulphur atoms from the macrocyclic ligand in the equatorial plane and to the nitrido atom and to one chlorine atom in the axial positions. The strong *trans* influence of the nitrido ligand causes an extreme lengthening of the Tc—Cl bond distance to 2.718 Å. The octahedral molecular structure of $[TcNCl(18S6)]TcNCl_4$ (**3**) is comparable with that of **1**, but only four sulphur atoms of the thiacrown ether form the equatorial plane, two sulphur atoms remain non-coordinated, and the nitrido and Cl^- ligands are in axial positions. The most interesting feature in the structure of $[TcNCl(16S4\text{-}(OH)_2)]Cl$ (**5**) is the observation of an exceptionally long Tc—N distance of 1.95 Å.

The chemistry of technetium is currently receiving considerable attention, mainly because of the pre-eminence of ^{99m}Tc in diagnostic medicine. This includes the search for new classes of technetium complexes and the evaluation of their ability to be used as diagnostic tracers.[1]

Although the high affinity of the soft sulphur donor atom to technetium is proved by a large variety of complexes with thiolate donor ligands, technetium complexes with neutral thioether ligands have scarcely been investigated until now. The number of fully characterized Tc/thioether compounds is rather limited. Recently reported complexes with the $Tc_2O_3^{4+}$ and the $O{=}Tc{-}O^{-2+}$ core,[2] compounds in which tetrathia ligands are coordinated to Tc^{3+} [3] and a Tc^{2+} complex with 1,4,7-trithiacyclononane,[4] demonstrate the pronounced capability of thioether ligands of binding technetium at different oxidation states.

An interesting extension involves the use of the nitrido technetium group in Tc/thioether chemistry. This core shows a high capacity to stabilize the metal in high oxidation states[5–7] and is known to form stable complexes with the tetraaza macrocycles 1,4,8,11-tetraazacyclotetradecane (cyclam),[8]

1,4,8,11-tetraazacyclotetradecane-5,7-dione[9] and the analogous aza/thia ligand 1,4-diaza-8,11-dithiacyclotetradecane.[10].

In order to gain an insight into the effects on coordination geometry and complex stabilities of factors such as ring size and functional group substituent in macrocyclic polythioether ligands, we synthesized a number of technetium chelates with the thiacrown ethers 1,4,8,11-tetrathiacyclotetradecane (14S4), 1,5,9,13-tetrathiacyclohexadecane (16S4), 1,5,9,13-tetrathiacyclohexadecane-3,11-diole (16S4-$(OH)_2$) and 1,4,7,10,13,16-hexathiacyclooctadecane (18S6). Some representatives were characterized by X-ray crystal structure determination.

EXPERIMENTAL

The thiacrown ethers were obtained from Aldrich and used without further purification. UV–vis spectra were recorded on a Specord M 40 from Carl Zeiss Jena (solvent acetone). IR spectra were measured on KBr discs on a UR 20 spectrometer from Carl Zeiss Jena. The content of technetium was determined by liquid-scintillation counting.

Health precautions

In view of the radioactivity of ^{99}Tc, some health precautions were taken. All operations were carried out in a fume cupboard with gloves. ^{99}Tc is only a weak β^--emitter so that apart from some elementary precautions no further safety measures are required. Normal glassware gives adequate protection against the weak β^--emission. Bremsstrahlung becomes important if ^{99}Tc is handled on a larger scale.

Structure determination and crystal data

The X-ray data were collected at room temperature (296 K) on an automatic Enraf–Nonius CAD 4 diffractometer, using graphite monochromatized Mo-K_α radiation ($\lambda = 0.71073$ Å). A summary of the crystallographic data of the complexes is given in Table 1. The structure determination using a straightforward application of the direct method MULTAN 82 failed, therefore the structures were solved by the heavy atom technique. The positions of technetium were derived from three-dimensional Patterson functions. Subsequent difference Fourier syntheses containing additionally strong wrong maxima were interpreted by the program CELLGRAF.[11] In this way all non-hydrogen atoms were found.

After anisotropic refinement of the positions of the inner atoms, the hydrogen positions were calculated according to ideal geometries. Empirical absorption corrections with the program DIFABS[12] were made at two stages during the structure refinement. Most of the calculations were carried out in the Enraf–Nonius SDP system with some local modifications. Relevant bond lengths and angles are contained in Tables 2—4.

Atomic positional and thermal parameters, full lists of bond lengths and angles, and F_o/F_c values have been deposited as supplementary material.

Synthesis of [TcNCl(14S4)]$TcNCl_4$ (1), [TcNCl(16S4)]$TcNCl_4$ (2) *and* [TcNCl(18S6)]$TcNCl_4$ (3)

The appropriate thiacrown ether (130 μmol), dissolved in 1 cm^3 acetone, was added to 50 mg (100 μmol) $NBu_4[TcNCl_4]$, dissolved in 1 cm^3 acetone. After addition of 2 cm^3 methanol the colour changed to dark red–brown. Standing of the reaction mixture overnight yielded red crystals suitable for X-ray analysis.

Synthesis of [TcNCl(14S4)]BPh_4 (4)

1,4,8,11-Tetrathiacyclotetradecane (35 mg, 130 μmol), dissolved in 1 cm^3 acetone, was added to 50 mg (100 μmol) $NBu_4[TcNCl_4]$, dissolved in 1 cm^3 acetone. After addition of 51 mg (150 μmol) sodium tetraphenyl boranate in 2 cm^3 methanol the colour changed to light orange. Standing of the reaction mixture overnight yielded a beige microcrystalline powder, which was washed with diethylether.

Synthesis of [TcNCl(16S4-$(OH)_2$)]Cl (5)

1,5,9,13 - Tetrathiacyclohexadecane - 3,11 - diole (43 mg, 130 μmol), dissolved in 1 cm^3 acetone, was added to 50 mg (100 μmol) $NBu_4[TcNCl_4]$, dissolved in 1 cm^3 acetone. After addition of 2 cm^3 methanol the colour changed to dark red–brown and then to yellow. After standing overnight the mixture yielded small amounts of an orange–red powder and yellow crystals suitable for X-ray analysis.

RESULTS AND DISCUSSION

The ligand exchange reactions on $NBu_4[TcNCl_4]$ proceeding in acetone–methanol solutions at ambient temperature result in the formation of cationic complexes $[TcNCl(S_4)]^+$.

The crystalline compounds precipitate from the reaction mixtures in analytically pure form. The elemental analyses correspond to the formulations $[TcNCl(S_4)]TcNCl_4$ for 14S4 (1), 16S4 (2) and 18S6

$3\,S_4$: 18S6

$$TcNCl_4^- \xrightarrow[\text{acetone–methanol}]{16S4\text{-}(OH)_2} [TcNCl(16S4\text{-}(OH)_2)]Cl. \quad (5)$$

From a mechanistic point of view it is interesting to note that the complexation reaction proceeds only after addition of methanol to the acetonic solution of the reaction participants. This may be explained by the fact that the exchange reaction is coupled with a reduction of Tc^{VI} and Tc^{V}, and methanol is assumed to be the reducing agent.

The exchange rates for the ligands 14S4, 16S4 and 18S6 are about 50%. The complex cations formed obviously combine with the precursor to produce an only slightly soluble salt, thus preventing further exchange. The reaction is practically quantitative in the presence of alternative counterions (e.g. BPh_4^-, PF_6^-).

The assumption that the solubility of the complexes formed in the reaction media governs the reaction route is supported by the reaction of 16S4-$(OH)_2$. The exchange reaction with this ligand, which bears two hydroxyl groups, is practically

quantitative in the absence of additional counterions.

The UV–vis spectra of all complexes without alternative counterions (**1–3**) are characterized by the absorption band of the $TcNCl_4^-$ moiety (λ_{max}: 404, 460 nm (sh) in acetone–methanol).

The IR spectra show less characteristic bands in the range between 1000 and 1100 cm^{-1}, which we assign to the TcN core of the complex cations, and additional peaks at 1080 cm^{-1} for compounds **1–3**, which contain he $TcNCl_4^-$ anion.

Structure of [TcNCl(14S4)]$TcNCl_4$ (**1**) *and* [TcNCl(18S6)]$TcNCl_4$ (**3**)

The molecular structures of compounds **1** and **3**, together with the atomic numbering schemes, are given in Figs 1 and 2. Selected interatomic distances and angles are summarized in Tables 2 and 3.

Compounds **1** and **3** consist of couples of independent cations with the metal in the oxidation state +5 and hexavalent $TcNCl_4^-$ anions. In both complex cations the technetium atom is six-coordinated in a rather distorted octahedral geometry, being directly bound in the equatorial plane to four sulphur atoms of the macrocyclic ligand. The nitrido and the chlorine atoms occupy the axial positions.

While the molecular cation **1** has a non-crystallographic mirror plane through Tc(1), N(1), Cl(1), C(4) and C(9), a mirror plane through Tc(1), N(1), Cl(1), S(5) and S(6) does not exist in **3**. The non-crystallographic symmetry was disturbed by a dislocation of the atoms C(5) and C(6) caused by packing of the molecules in the unit cell.

The technetium atom is displaced from the plane formed by the four sulphur atoms by 0.236 Å toward the N(1) atom in compound **1** and by 0.209 Å in compound **3**. The Tc(1)—N bond distances of 1.615 Å for **1** and 1.707 Å for **3** are consistent with the triple-bond distances found in all Tc^V–nitrido complexes structurally characterized.[13]

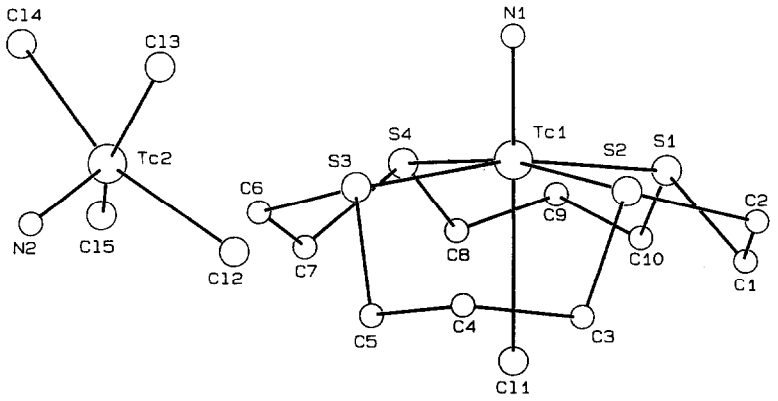

Fig. 1. CELLGRAF drawing of [TcNCl(14S4)]$TcNCl_4$ (**1**).

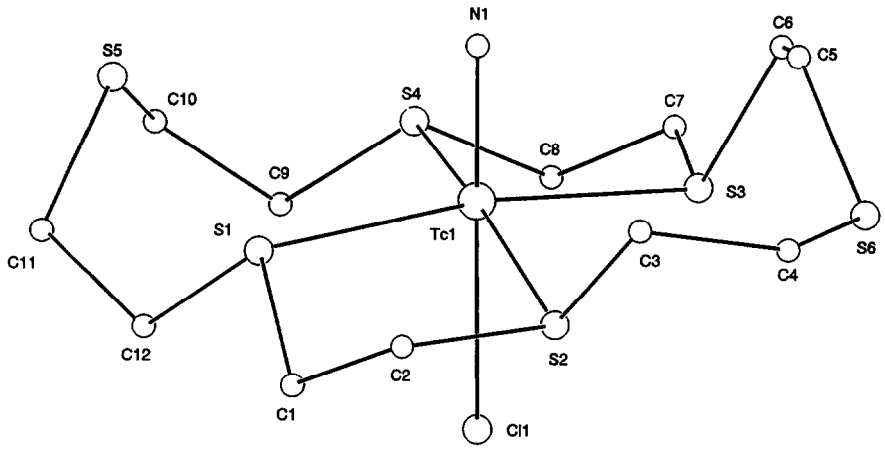

Fig. 2. CELLGRAF drawing of the molecular cation of $[TcNCl(18S6)]TcNCl_4$ (**3**).

The structure of **1** resembles closely that of the $[TcNCl(N_4)]^+$ cations (N_4 = 2 en, 1,5,8,12-tetraazadodecane).[14]

Structure of $[TcNCl(16S4\text{-}(OH)_2]Cl$ (**5**)

The octahedral molecular structure of **5** is comparable to that of $[TcNCl(14S4)]^+$: four sulphur atoms of the thiacrown ether form the equatorial plane, the nitrido and Cl^- ligands are in the axial positions (Fig. 3, Table 4). The metal is displaced from the equatorial plane by 0.114 Å toward the nitrogen atom. As found for **1**, the complex cation has a non-crystallographic mirror plane through technetium, nitrogen, Cl(1), C(2), O(2), C(8) and O(1).

In the crystal, the cations and the Cl^- counterions are connected by two symmetry-independent hydrogen bonds O(1)—H---Cl(2) (3.045 Å) and Cl(2)---H—O(2)′ (2.973 Å) forming chains in the [1 1 0] direction.

$[TcNCl(16S4\text{-}(OH)_2]Cl$ (**5**) differs from **1** and **3** concerning the extremely long Tc—N bond distance of 1.95 Å.

For all three compounds studied by X-ray analysis, coordination of technetium by four sulphur atoms in the equatorial plane was found to be the common feature, regardless of differences in ring size or the presence of two additional sulphur atoms in the ring of 18S6 or two hydroxyl groups in 16S4-$(OH)_2$.

The geometry of the distorted octahedral TcN complexes having a sixth, negatively charged ligand in the *trans* position to the TcN bond may be explained in terms of balancing the strong influence of the nitrido group, which destabilizes the octahedral coordination, and by the demand for an effective neutralization of the residual charge on the

$[ReNCl_2(PEt_2Ph)_3]$	1.788	2.563	20
$[ReNCl(dpae)_2]^+$	1.839	2.451	21

Abbreviations: en, ethylenediamine; tad, 1,5,8,12-tetraazadodecane; dpae, 1,2-bis(diphenylarsino)ethane; dmpe, 1,2-bis(dimethylphosphino)ethane.

TcN^{2+} group.[15] The *trans* influence of the nitrido ligand is, for example, apparent in $[TcNCl_2(PMe_2Ph)_3]$ in the *cis* and *trans* Tc—Cl bond lengths of 2.441 and 2.665 Å, respectively.

As shown in Table 6 for previously described complexes, as well as for compounds reported here, both the Tc—N and Tc—Cl bond lengths vary over a wide range. The same is true for the congener rhenium. Considerable Tc—N bond lengthening was found for $[TcN(dmpe)_2Cl]^+$ (dmpe = dimethylphosphinoethane; Tc—N bond distance: 1.85 Å)[16,17] and attributed to steric interactions between the nitrido group and the co-planar phosphorus atoms.[18]

Marchi *et al.*[14] have already pointed out that the lengths of the Tc—N and Tc—Cl bonds are inversely related. On the one hand, the strong *trans* influence of the nitrido ligand in $[TcNCl(en)_2]^+$ causes a considerable lengthening of the Tc—Cl bond distance at 2.732 Å, the longest Tc—Cl bond distance ever observed in technetium complexes.[14] On the other, the extremely long Tc—N bond distance in $[TcNCl(16S4\text{-}(OH)_2]^+$ (**5**) is accompanied by a decrease of the Tc—Cl bond to a distance normally found for equatorial bound chlorine (2.469 Å). This is also true of the TcN complexes contained in Table 6. The sums of the appropriate Tc—N and Tc—Cl bond lengths are relatively constant for compounds with "normal" Tc—N bond distances.

While the Tc—N bond lengths of **1** and **3** fall in the range between about 1.60 and 1.854 Å, the distance of 1.950 Å observed in the preliminary X-ray structural analysis of $[TcNCl(16S4\text{-}(OH)_2]Cl$ (**5**) is exceptionally long. This fact indicates a tendency to adopt a less distorted octahedral geometry. Accordingly, technetium is closer to the S_4 plane (0.114 Å) than found for **1** (0.236 Å) and **3** (0.209 Å). Whereas bond lengthening is accepted as a well known effect in these systems (see above), it is difficult to find a reasonable explanation for the extremely long Tc—N bond. Because the equatorial S_4 donor set is the same in the three complexes it is unlikely to attribute Tc—N bond lengthening to electronic donor atom influence. On the other hand, there is no evidence for hydrogen bonds between the hydroxyl groups of the ligand and the terminal nitrogen. The most likely explanation is to assume some disorder between the nitrido and the *trans*-chloro ligand, which causes an artifact in the X-ray structure determination. Such artifacts and disorders have been generally discussed in refs 22 and 23, for the Tc≡O bond distance in $[TcO(dmpe)_2(OH)]^+$[24] and by Baldas *et al.*[25] with regard to refs 16 and 17.

Additional X-ray crystal data can be obtained from Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-76344 Eggenstein-Leopoldshafen, Germany, quoting CSD-No. 56459, and authors' names as well as the title of the paper.

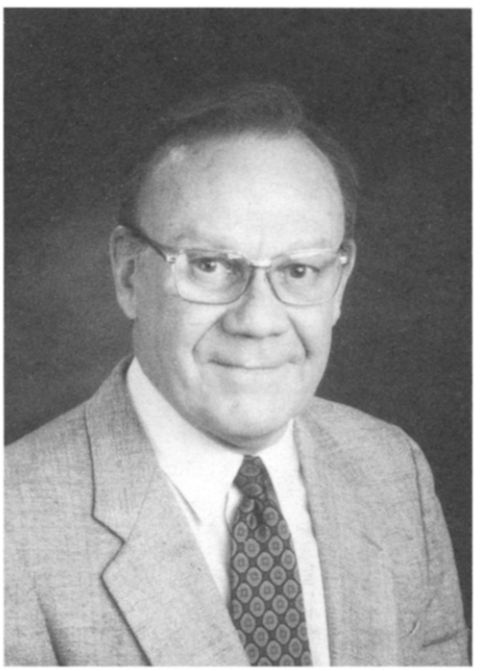
ANNOUNCEMENT

POLYHEDRON PRIZE FOR CREATIVITY IN INORGANIC CHEMISTRY 1993

It is with great pleasure that the selection committee for the *Polyhedron Prize* announce that the Prize for 1993 has been awarded to M. Frederick Hawthorne of the University of California, Los Angeles, "for his pioneering studies on boron hydrides, carborane complexes, and their uses in catalysis and biology radioimaging."



Dr M. Frederick Hawthorne, Professor of Chemistry at the University of California, Los Angeles, was born on August 24, 1928 in Ft. Scott, Kansas. He received his B.A. degree from Pomona College, Claremont, California in 1949 and his Ph.D. from UCLA in 1953 under the guidance of D. J. Cram. After postdoctoral work at Iowa State University with G. S. Hammond, he joined the Rohm and Haas Co. as a research chemist, working initially at the Redstone Arsenal Research Division in Huntsville, Alabama. Subsequently, he became a Laboratory Head in Philadelphia. It was in this period, as part of a high energy fuel program, that his research in the area of boron chemistry began. In 1962, Hawthorne left Rohm and Haas to join the Chemistry Department of the University of California at Riverside as a full Professor. He moved to his present position at UCLA in 1969.

Dr Hawthorne, more than any single individual, founded the field of modern borane and metallacarborane cluster chemistry. His research has provided the majority of seminal discoveries in this area, made at the interface of experimental chemistry and molecular structural theory. The wide range of cluster compounds and cluster fragment species that have

originated within Professor Hawthorne's laboratory has led to the development of principles governing the geometric and electronic relationships between a wide range of organic and inorganic molecules, and have served to link diverse regions of the periodic table of elements. His current research interests include "Anti-Crown" host–guest chemistry based upon electron-deficient macrocyclic mercuracarboranes, the development of radiometallacarborane reagents for the monoclonal antibody-mediated imaging and therapy of cancer, the discovery of new chemical methodologies for the selective delivery of boron-10 to tumours for the purpose of boron neutron capture therapy; and the use of ordered carborane arrays for the construction of supramolecular species.

Dr Hawthorne has received numerous awards and honours. He is a fellow of the American Academy of Arts and Sciences, and a member of the U.S. National Academy of Sciences. He has received the American Chemical Society awards for Research in Inorganic Chemistry (1973), and for Distinguished Service in the Advancement of Inorganic Chemistry (1988). He has also been an Alfred P. Sloan Fellow, received the Tolman Medal of the Southern California Section of the ACS, the Herbert Newby McCoy Award and the Bailar Medal. He was awarded a D.Sc. *honoris causa* from Pomona College in 1974 and a Ph.D. *honoris causa* from Uppsala University in 1992. He currently holds an Alexander von Humboldt U.S. Senior Scientist Award. In 1986 he received the Meritorious Civilian Service Medal from the U.S. Air Force. Dr Hawthorne has been the Editor-in-Chief of the American Chemical Society journal, *Inorganic Chemistry*, since 1969, and he is a member of the editorial boards of several other journals. He has published over 400 primary journal articles and holds numerous patents.

The *Polyhedron Prize* is awarded biennially and consists of a gold medal, a citation and U.S. $10,000.

Previous prize winners are:

1989 Professor Sir Geoffrey Wilkinson "for the outstanding contributions made to organometallic chemistry and the new horizons opened in this field".

1991 Professor Richard H. Holm "for his pioneering contributions to transition metal compounds with sulphur, thiolato and related ligands, in particular those cluster compounds of iron and molybdenum that have relevance to, and provide models for, species in biological systems such as ferredoxins, and for his continuing work in these areas and others such as oxygen and imido group transfer reactions".
