Assuming a cofacial geometry of two phthalocyanine rings, the spectral blue shift upon dimerization can be explained using exciton theory.[12] The transition $^1A_{1g} \rightarrow {}^1E_u$ gives rise to a Q band absorption in metallophthalocyanines. The coupling of the doubly-degenerate excited states of the two monomers gives rise to two excited states, ^1E_g and ^1E_u. The nature of the coupling depends on the dimer geometry.[13] In the case of the cofacial dimer the higher energy transition ($^1A_{1g} \rightarrow {}^1E_u$) is allowed, whereas the lower energy transition ($^1A_{1g} \rightarrow {}^1E_g$) is forbidden. Thus, the blue shift obtained upon dimerization is in accordance with this prediction. The exciton splitting parameter (V), estimated as twice the energy difference between the monomeric Q band and the dimeric Q band energy, is 1556 cm^{-1} for AgtCRPc and 2009 cm^{-1} for VOtCRPc. This compares well with those observed for Nit CRPc (1760 cm^{-1}), CotCRPc (1960 cm^{-1}), Cut CRPc (1910 cm^{-1}) and ZntCRPc (1960 cm^{-1}).[6]

ESR spectral studies

The frozen solution ESR spectra of VOtCRPc before and after the addition of K^+ ions is displayed in Fig. 5. The spectrum observed in the presence of K^+ ions is typical of a triplet state with axial symmetry, the hyperfine splitting indicating the presence of two equivalent interacting VO^{2+} nuclei. The eight-line pattern arising from both the parallel and perpendicular regions is now decomposed due to zero-field splitting into two sets, each containing 15 lines corresponding to a total spin of 7 ($I = 7/2$ for the VO^{2+} ion). Due to the similarity of $g_\parallel$ and $g_\perp$ values, the lines from both parts are superimposed.[14] Furthermore, the appearance of a weak transition ($\Delta M_s = \pm 2$) arising from the triplet state ($S = 1$) in the half field ($g = 4$) region provides strong support for the existence of a dimer in solution.[15] The spin-Hamiltonian parameters evaluated from the spectra by the standard literature method[16] are listed in Table 2.

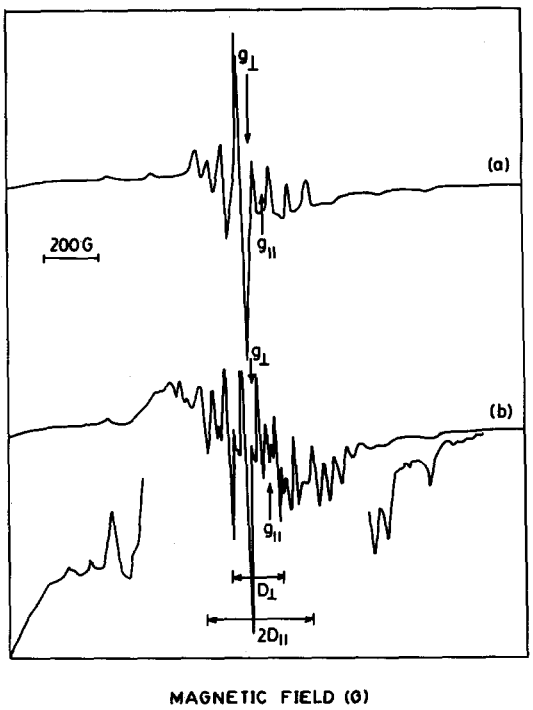

Fig. 5. ESR spectra of (a) VOtCRPc and (b) VOt CRPc + K^+ ions in $CHCl_3$: CH_3OH (98 : 2 V/V) at 100 K. Approximately 1×10^{-4} M of phthalocyanine solution was used for recording the spectra.

AgtCRPc also shows a well-resolved spectrum for the monomeric species. The g and hyperfine values evaluated (Table 2) compare well with those reported for Ag^{2+} ($I = 3/2$) porphyrins. The addition of K^+ ions results in the appearance of additional lines due to dimer formation. However, the dimer spectrum was contaminated with monomer lines in the $g = 2$ region. Nevertheless, the spectrum was resolved enough to evaluate the zero-field splitting parameter.

The zero-field splitting parameter, D, evaluated both in parallel and perpendicular regions, was used to compute the (V—V) and (Ag—Ag) distance in the dimer, making use of the expression developed by Chasteen and Belford[17] (Table 2). The V—V distances calculated in the present study compare well with those observed for the vanadyl tetracrownporphyrin dimer (4.7 Å) and the dimer of vanadyl tetrasulphonato-phthalocyanine[18] (4.5 Å), probably indicating similar solution structures (Fig.

Table 2. ESR parameters of VO^{2+} and Ag^{2+} tetra-crowned phthalocyanines

6). The Ag—Ag distance estimated in the present study also compares well with the only reported Ag—Ag distance of 5 Å for the silver meso-porphyrin dimethylester dimer.[19]

EXPERIMENTAL

The electronic spectra were recorded on a Shimadzu UV-160 spectrophotometer. ESR measurements were made using a Varian E-109 *X*-band spectrometer at liquid nitrogen temperature. Benzo-15-crown-5, SDS, CTAB and TX-100 were procured from Aldrich Chemical Company, U.S.A. 4,5-Dibromobenzo-15-crown-5, 4,5-dicyanobenzo-15-crown-5, H_2tCRPc and CutCRPc were prepared using literature procedure.[3,5]

Preparation of vanadyl tetra-crowned phthalocyanine (VOtCRPc)

H_2tCRPc (40 mg) and vanadyl sulphate (100 mg) were dissolved in dry DMF (100 cm^3) and the mixture was refluxed for 7 days. The solvent was then removed under reduced pressure. The dark green powder obtained was washed with excess water to remove unreacted $VOSO_4$. The crude product was purified by column chromatography over basic alumina. The unreacted H_2tCRPc moved as a light green band in $CHCl_3$:CH_3OH (98:2 V/V). VOt CRPc was eluted as a bluish-green band in $CHCl_3$:CH_3OH (95:5 V/V). Yield: 13 mg (30%).

Preparation of silver tetra-crowned phthalocyanine (AgtCRPc)

H_2tCRPc (20 mg), $AgNO_3$ (20 mg) and sodium acetate (20 mg) were taken in a mixture of 1,2-dichloroethane (15 cm^3) and acetic acid (20 cm^3) and the mixture was refluxed for 2.5 h. The reaction mixture was filtered and the resulting solid was washed with excess water. The crude product was dissolved in chloroform and subjected to column chromatography over basic alumina. An initial light green band eluted in $CHCl_3$:CH_3OH (98:2 V/V)

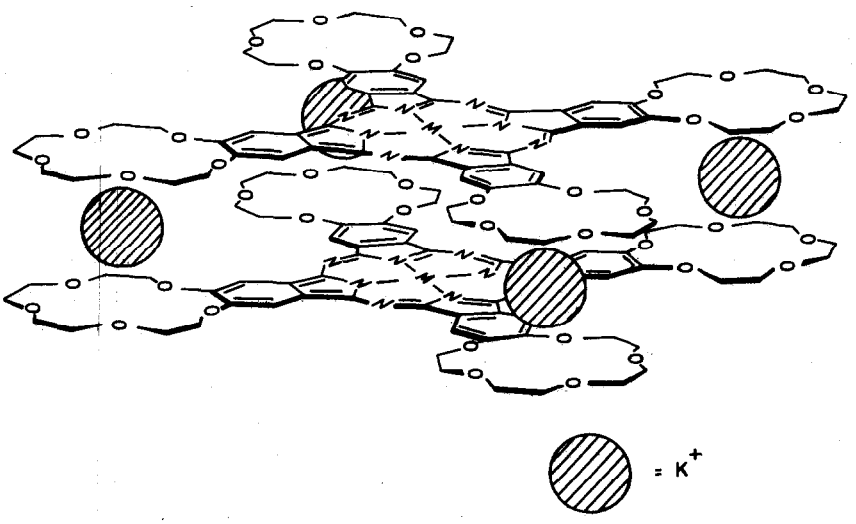

Fig. 6. Proposed cofacial dimer structure.

to give unreacted H_2tCRPc. The bluish-green band eluted in $CHCl_3$: CH_3OH (95 : 5 V/V) gave the pure AgtCRPc. Yield : 8 mg (40%).

ENDOR STUDY OF $VO(acac)_2$ AND ITS INTERACTION WITH CHLOROFORM IN FROZEN SOLUTION

N. D. YORDANOV* and M. ZDRAVKOVA

Institute of Kinetics and Catalysis, Bulgarian Academy of Sciences, 1113 Sofia, Bulgaria

(*Received* 15 *October* 1992; *accepted* 6 *November* 1992)

Abstract—Proton ENDOR studies in the region between the turning points of the EPR spectrum of $VO(acac)_2$ dissolved in toluene-d_8/$CDCl_3$, as well as in toluene-d_8/$CHCl_3$, are reported. Structural information about the position of the methyl and 3-C protons of the acetylacetonate ligand are extracted from the spectra and compared with data available from X-ray structural analysis and previous ENDOR studies. The formation of outer-sphere complexes between molecules of chloroform and $VO(acac)_2$ has been recorded. This complex is suggested to be formed via hydrogen bonding between the hydrogen atom of $CHCl_3$ and an oxygen atom of the chelate ligand. Another molecule of chloroform is coordinated along the *z*-axis of $VO(acac)_2$ via a hydrogen bond with the oxygen atom from the V=O moiety.

It is well known that the ligand superhyperfine structure in the EPR spectra of oxovanadium complexes is unresolved because of the non-bonding character of the orbital d_{xy}, in which the unpaired electron is situated,[1,2] and of the limited resolution of the EPR method itself.[3] Thus, the information which can be obtained about the electronic and geometric structure of these complexes from their EPR spectra is limited to only the chromophore (VOX_4), where X are donor atoms of the ligand.[2] The spectra obtained by ENDOR spectroscopy are much more informative due to its nearly 10^3 times higher resolution.[3] In view of this advantage the structure of some adducts of VO^{2+} complexes in solution were determined within the last decade by means of ENDOR spectroscopy.[4,5] In these communications the ENDOR spectra were taken at the "turning points" of the EPR spectra of the related compound.[6] Recently, it has been suggested[7–10] that the studies of the region between the turning points give more detailed and exact information about the true values of the hyperfine coupling, as well as about the position of the atoms with respect to the *g*-tensor axes (or *z*-axis of the molecule). Such a study has been reported[11] on the 3-C protons from a molecule of $VO(acac)_2$ in frozen solution.

In the present paper we report more precise results obtained for the structure of $VO(acac)_2$ in frozen solution, as well as for its interaction with chloroform molecules. The results are interpreted using the method previously described.[10] The results obtained were checked with a computer-aided ENDOR spectroscopy, the programme of which was developed in this laboratory.

EXPERIMENTAL

$VO(acac)_2$ (Merk) was used after recrystallization from toluene.

Toluene (p.a.) was used; ethanol, typically available in commercial chloroform as a stabilizer, has been removed by washing several times with water, drying for a few days over $CaCl_2$ and distilling as described.[12] Deuterated solvents, toluene-d_8 and chloroform-d_1 were used as obtained from Merck.

Samples suitable for ENDOR measurements were prepared by filling quartz EPR sample tubes (o.d. 4.5 mm, i.d. 3.5 mm) with a solution of $VO(acac)_2$ (approx. 2×10^{-2} M) dissolved in a solvent mixture of toluene/chloroform in the ratio 1 : 1 v/v. The oxygen was removed from the solutions on a vacuum line by several freeze–pump–thaw cycles until the pressure reached the value of *ca* 1×10^{-3} mm Hg. After that the sample tubes were sealed.

ENDOR spectra were recorded on a Bruker ER

* Author to whom correspondence should be addressed.

200 D-SRC spectrometer equipped with a computer controlled ENDOR accessory. The EPR and ENDOR spectra acquisition as well as post-acquisition processings were performed on a Bruker Aspect 2000 computer. All the EPR and ENDOR measurements were performed at 100 K. Typical experimental conditions for the ENDOR measurements were: microwave power 50 mW, radio-frequency power 200–300 W, modulation frequency 12.5 kHz, modulation depth 60–80 kHz. Magnetic field modulation was not used while recording the ENDOR spectra. The spectra for the computer-aided ENDOR studies were generated using a special program written in this laboratory for IBM PC.[13]

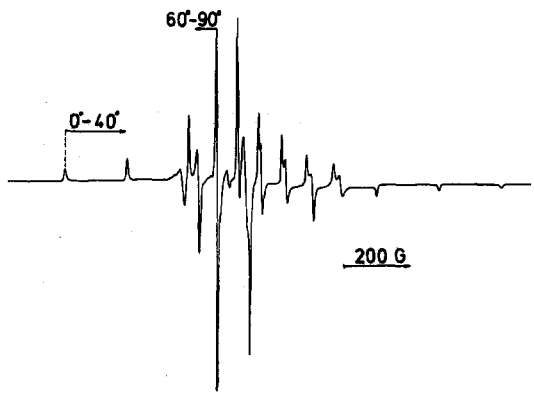

Fig. 1. EPR spectrum of a frozen solution of $VO(acac)_2$ (2×10^2 M) in toluene-d_8/$CDCl_3$; $T = 77$ K.

RESULTS AND DISCUSSION

EPR spectra of VO^{2+} *complexes*

The electronic configuration of the moiety VO^{2+} is $3d^1$ and a hyperfine structure with eight lines ($I = 7/2$) is observed in the EPR spectra of VO^{2+} complexes at room temperature. Since to a first approximation VO^{2+} complexes possess an axial symmetry, their frozen solution EPR spectra typically show an EPR spectrum consisting of eight parallel and eight perpendicular lines.

The EPR spectrum of $VO(acac)_2$ in a frozen solution of toluene-d_8/chloroform-d_1 recorded by us (Fig. 1) shows a slight rhombic distortion. EPR parameters derived from that spectrum as well as those reported by other authors are collected in Table 1. Since the rhombic distortion $g_{xx} - g_{yy} \leqslant 0.006$ is relatively low it may be assumed that the $VO(acac)_2$ complex is axially symmetric with a g-value in the perpendicular region of 1.979.

^1H *ENDOR spectroscopy of* $VO(acac)_2$

The ENDOR study of a paramagnetic system, where the nuclear spin of the central metal atom is larger than 1/2, usually avoids positions in the EPR spectrum where contributions from more than one m_I value would be observed, as they make the resulting ENDOR spectrum more complex.[14] For that reason, in the case of VO^{2+} complexes, typically the regions with $M_I = -7/2$ in the parallel orientation and $M_I = -3/2$ in the perpendicular are chosen in order to take ENDOR spectra from only one EPR transition.[14] These regions, in which the magnetic field was consecutively set in order to cover the whole range, $0° \leqslant \theta \leqslant 90°$, of polar angles θ, are shown in Fig. 1.

Some experimentally obtained ENDOR spectra taken at different settings of the magnetic field in the region $0° \leqslant \theta \leqslant 90°$ are shown in Fig. 2(a). Inspecting Fig. 2(a) it is clear that one intensive pair of lines with a splitting of *ca* 0.72 MHz exists in all the spectra. After selective deuteration of the 3-C protons[4] these lines have been assigned to the methyl protons of $VO(acac)_2$. They were the only lines observed before at $\theta = 0°$; the lack of lines from 3-C protons being explained by the fact that they are very weak and probably obscured by the strong methyl proton peaks.[2] As can be seen in Fig. 2 we have first recorded a pair of lines due to 3-C protons at 0°. These resonance peaks with a splitting of 1.2 MHz are really very weak.

The spectrum taken at 90° is exactly the same as in the literature. Lines with splitting of 3.40 MHz (see Fig. 3) are from 3-C protons, and lines with

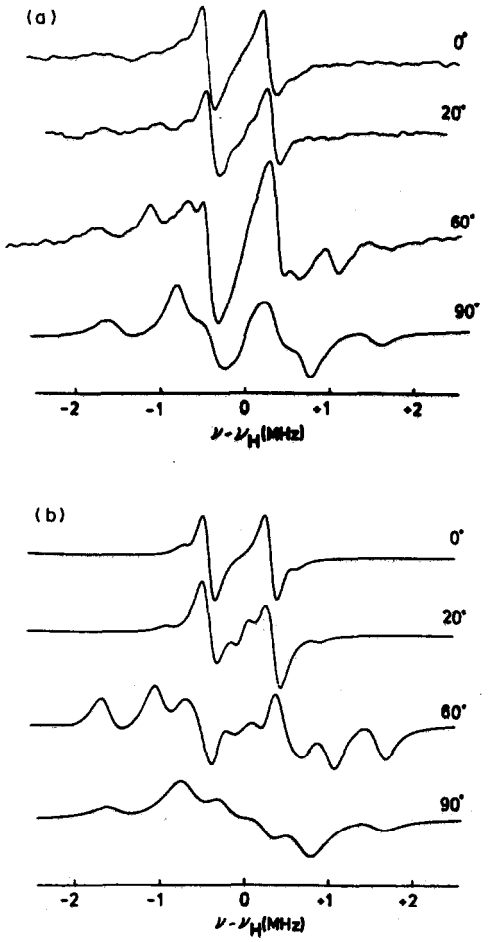

Fig. 2. Proton ENDOR spectra of $VO(acac)_2$ in toluene-d_8/$CDCl_3$ (1 : 1) at differents angles θ: (a) experimental spectra, $T = 100$ K; and (b) simulated spectra.

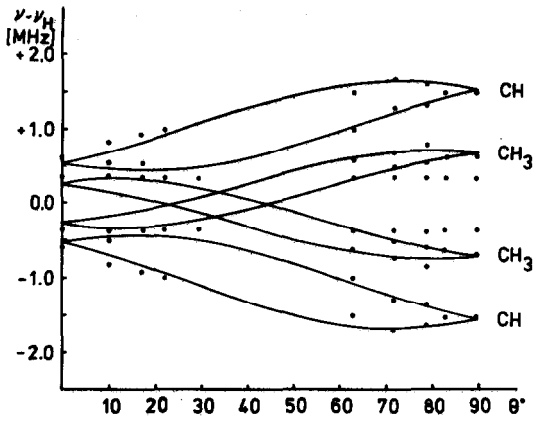

Fig. 3. Angular dependence of proton ENDOR transitions of $VO(acac)_2$ in toluene-d_8/$CDCl_3$. The experimental values are shown with points.

splitting of 1.40 MHz are assigned to the methyl protons.

The experimental proton hyperfine splittings found at settings of the magnetic field at different values of θ in the region $0° < \theta < 90°$ are presented in Fig. 3 (points). The magnitudes of A_{aniso}, A_{iso} and α for 3-C and methyl protons were calculated on the basis of the experimental data and they are all collected in Table 2. In Table 2 are also shown the distances between the vanadium ion and the corresponding proton, which are calculated from the values of A_{aniso} using the point-dipole approximation.

The X-ray structural analysis of the $VO(acac)_2$ complex[15] and a recent publication on a gas-phase electron diffraction study[16] show that methyl and 3-C protons are situated below the equatorial plane. The angle between the two pseudo-aromatic rings and V=O axis is found to be 106°. Approximately the same angle, 109°, was reported on the basis of the ENDOR study.[11] These data are also in good agreement with our results, showing that 3-C protons are situated at an angle of 17° from the xy-plane.

The principal values of the hyperfine splitting for CH_3 and 3-C protons were also calculated and the results are shown in Table 3. The parameters thus obtained were used for simulation of the ENDOR spectra at different angles of the EPR observer (Fig. 2b). Hyperfine splittings determined from the simulated spectra are plotted with solid lines on Fig. 3. It should be noted that in Fig. 3 are presented only their angle-depending parts, which are the most important. As can be seen the coincidence between experiment and theoretical calculations is quite good.

ENDOR study of the interaction between $VO(acac)_2$ *and* $CHCl_3$

The addition of chloroform (alcohol free) to a toluene solution of $VO(acac)_2$ does not change the shape and parameters of its EPR spectrum. However, the ENDOR spectra shown in Fig. 4(a) reveal new large splitting due to the interaction of the unpaired electron with a proton from the chloroform, indicating a well-defined $VO(acac)_2$–

Table 2. Parameters of proton hyperfine splitting (MHz), angles H—V=O (°) and distances V—H (Å)

Proton	A_{iso}	A_{aniso}	α	r
3-C	1.70	0.83	73	4.57
Methyl	0.12	0.67	81	4.90

Proton	A_{xx}	A_{yy}	A_{zz}	Ref.
Methyl	1.34	−0.71	−0.63	4
	1.45	−0.72	−0.60	This work
3-C	3.37	0.2(?)	0.90(?)	4
	3.69	−1.09	1.41	11
	3.35	−1.10	0.87	This work

$CHCl_3$ interaction. The splittings at 0° and 90° are 2.17 and 2.12 MHz, respectively. In a previous study of this adduct by the method of the "turning points"[4] it was suggested that the most likely binding site is the vanadyl oxygen via a hydrogen bond.

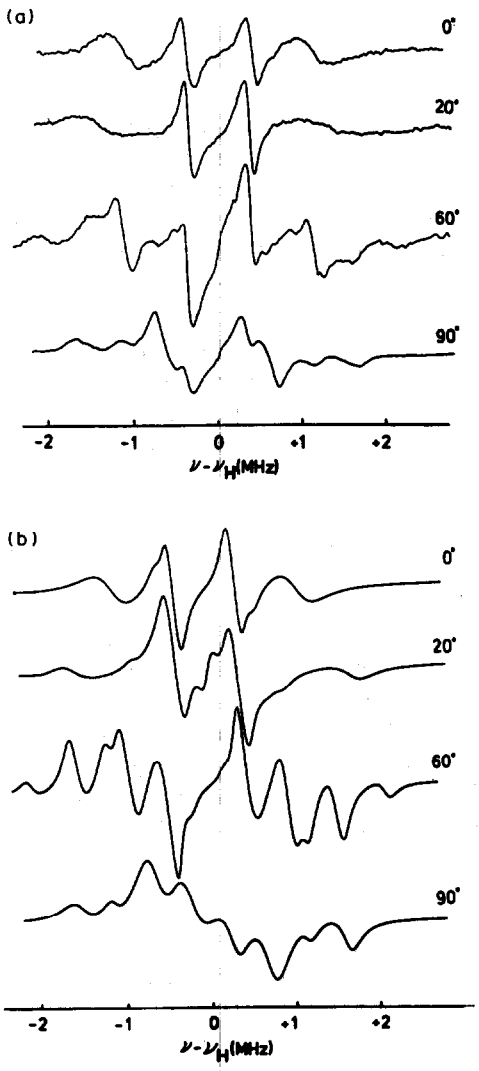

Fig. 4. Proton ENDOR spectra of $VO(acac)_2$ in toluene-$d_8/CHCl_3$ (1:1) at different angles θ: (a) experimental spectra, $T = 100$ K; and (b) simulated spectra.

The authors have calculated the tensor of *hf* coupling, assuming an O···H distance of 1.75 Å and a V=O···H angle of 120°. Nevertheless, they emphasize that the exact geometry of the adduct is not known. Our study of the region between turning points of the $VO(acac)_2$ complex shows that in fact two ENDOR transitions from two differently situated molecules of chloroform are observed. In Fig. 5 they are marked as A and B. The following values were found: for transition B: $A_{aniso} = 1.15$ MHz, $A_{iso} = 0$ MHz, $\alpha = 8.5°$; for transition A: $A_{aniso} = 2.33$ MHz, $A_{iso} = 0$ MHz and $\alpha = 46°$. Some ENDOR spectra simulated with the values thus obtained are shown in Fig. 4(b).

Transition B is due to a proton coordinated by a hydrogen atom, bound to the oxygen atom from the V=O moiety and situated practically along the z-axis of the complex. The distance of 4.10 Å between the proton and the vanadium was calculated. Bearing in mind that the bond length V=O is 1.56 Å,[15] it was found that the O···H distance was 2.57 Å, which is very close to that typical of hydrogen bonds.[17]

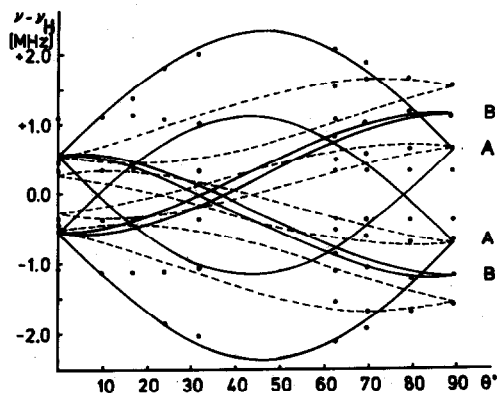

Fig. 5. Angular dependence of proton ENDOR transitions of $VO(acac)_2$ in toluene-$d_8/CHCl_3$: transitions due to the interaction with chloroform are marked with full lines; transitions due to protons of $VO(acac)_2$ are indicated with dashed lines.

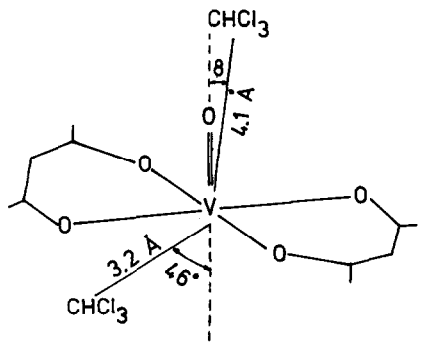

Fig. 6. The proposed model of the outersphere complex between $VO(acac)_2$ and $CHCl_3$.

Transition A is due to the interaction of the unpaired electron with a proton situated at a distance of 3.24 Å from vanadium and at an angle of 46° from the z-axis of the complex. This proton seems to be coordinated to the donor oxygen atoms from the acetylacetonate ligand. Such outersphere complexes, in which chloroform and oxygen atoms from chelate ligands of the metal complexes, including β-diketonate complexes of transition metal ions, from hydrogen bonds, have been studied before by NMR.[18] For example, the distance between the proton of the solvent ($CHCl_3$ or CH_2Cl_2) molecule and cobalt(II) from $CO(acac)_2py_2$ was estimated to be 4.0 ± 0.2 Å, and the angle between the direction Co···H and the z-axis of the complex to be 32°.[19]

The results obtained above on the basis of ENDOR studies suggest that the coordination structure of the outersphere complex between $VO(acac)_2$ and chloroform is as shown in Fig. 6.

Abstract—The electrochemical reduction of $Fe^{III}(L)Cl$, where L is a Schiff base, has been investigated in aprotic solvents by cyclic voltammetry and coulometry with UV–vis spectroscopy. Six complexes derived from Schiff base ligands with N_2O_2 environments are described. The reduction of $Fe^{III}(L)Cl$ into $Fe^{II}(L)Cl$ occurs at a potential around -0.5 V vs S.C.E. through an EC mechanism where the following reaction concerns the decomposition of iron(II), a highly reactive complex. A high electronic delocalization of the Schiff base, such as in SALOPH, stabilizes the oxidation state II of iron and shifts the redox potential anodically. The study reveals the extreme reactivity of iron(II) towards dioxygen. Traces of dioxygen with $Fe^{II}(L)Cl$ yield the μ-oxo bridged Fe^{III} dimers (L)Fe—O—Fe(L), whose reduction potentials lie around -1 V vs S.C.E. The redox couple $Fe^{II}(L)/Fe^{III}(L)$ is potentially a good electrochemical mediator for redox catalysis.

In the chemistry of dioxygen activation, iron is one of the most involved metals.[1,2] In this context, the μ-oxo-bridged dinuclear complexes Fe—O—Fe have received extensive studies on the structural, magnetic and spectroscopic properties and are potentially models of biological systems.[2,3]

In this way the chemistry of iron Schiff base complexes has been investigated.[4] The monomeric complexes which are obtained under aerobic conditions exhibit the Fe^{III} oxidation state and present a distorted square-pyramidal structure with $Fe^{III}(L)X$ (L = Schiff base and X = anionic axial ligand, such as halide, pseudohalide, carboxylate, phenolate, thiolate, etc.) or six-coordinate species with a bidentate extra ligand.[4,5]

The iron(II) oxidation state may be reached under drastic anaerobic conditions and isolated as $Fe^{II}(L)$ species.[4] These complexes are extremely sensitive to dioxygen and lead to the formation upon oxygenation of the μ-oxo-bridged dinuclear complexes $(L)Fe^{III}—O—Fe^{III}(L)$, whose synthetic route is, by contrast, an acid–base reaction.[6–8]

$$2Fe(SALEN)^+ + H_2O \Leftrightarrow \mu\text{-O-}[Fe(SALEN)]_2 + 2H^+$$

Unfortunately, little work has been undertaken on the electrochemistry of such complexes. The interaction with dioxygen involves redox processes and the determination of the electrochemical behaviour of these complexes must provide a clearer understanding of the oxygenation reaction.

In the course of investigating redox catalysis by coordination compounds, we engaged in the study of metal (Schiff base) redox properties.[10] The iron complexes have been found to be electrochemical mediators for the reduction of dioxygen. In this paper (Part I) we describe the electrochemical behaviour of several complexes, $Fe^{III}(L)Cl$, where L is an N_2O_2 Schiff base (SALEN type, Fig. 1): H_2BAE = N,N′-ethylene-bis(acetylacetoneimine);[11] H_2AESAL = N,N′-ethylene(acetylacetoneimine)(salicylideneimine);[12] H_2AEAP = N,N′-ethylene(acetylacetoneimine)(hydroxyacetophenoneimine);[12] H_2BBE = N,N′-ethylene-bis(benzoylacetoneimine);[11] H_2SALEN = N,N′-ethylene-bis(salicylideneimine);[13] and $H_2SALOPH$ = N,N′-orthophenylene-bis(salicylideneimine).[13] The complexes are referred to as Fe(BAE)Cl,[14] Fe(AESAL)Cl,[15] Fe(AEAP)Cl,[16] Fe(BBE)Cl,[14] Fe(SALEN)Cl[13] and Fe(SALOPH)Cl.[13]

RESULTS AND DISCUSSION

Within the electroactivity domain of the solvent, the voltammograms show distinct electrode processes (Fig. 2):

(1) An oxidation process around 1 V, which has been described to be the Schiff base oxidation. It leads to deposition of the complex at the electrode.[17]

(2) A reduction process around −0.5 V, which corresponds to the electrochemical system.[4,8,20]

$$Fe(L)Cl + e \Leftrightarrow Fe(L)Cl^- \qquad (2)$$

This system appears reversible if the potential sweep is restricted to the observation of this electrochemical process [Fig. 2(a), curve (+ + +)].

(3) A second reduction process around −1 V, which is observed when dioxygen is still present. It corresponds to the reduction of the μ-oxo bridged dinuclear complex (L)Fe—O—Fe(L).[10,18,21] With no dioxygen [Fig. 2(b), curve (—)], the voltamperogram presents only the Fe^{II}/Fe^{III} redox couple. With an incomplete deoxygenation [Fig. 2(b), curve(···)], the voltamperogram shows two successive reduction processes. The first one is slightly displaced anodically and corresponds to the original signal. The following system at −1.2 V comes from the oxygenation of Fe^{II}. If we compare with the voltamperogram of μ-oxo (L)Fe—O—Fe(L) [Fig. 2(b), curve (+ + +)], we observe that the reduction potentials are of the same order of magnitude. Then, the final product of the oxygenation of $Fe^{II}(L)$ is the dimer $(L)Fe^{III}—O—Fe^{III}(L)$. This reaction is very fast and no intermediates could be detected using cyclic voltammetry at a scan speed up to 2000 V s^{-1}.[22]

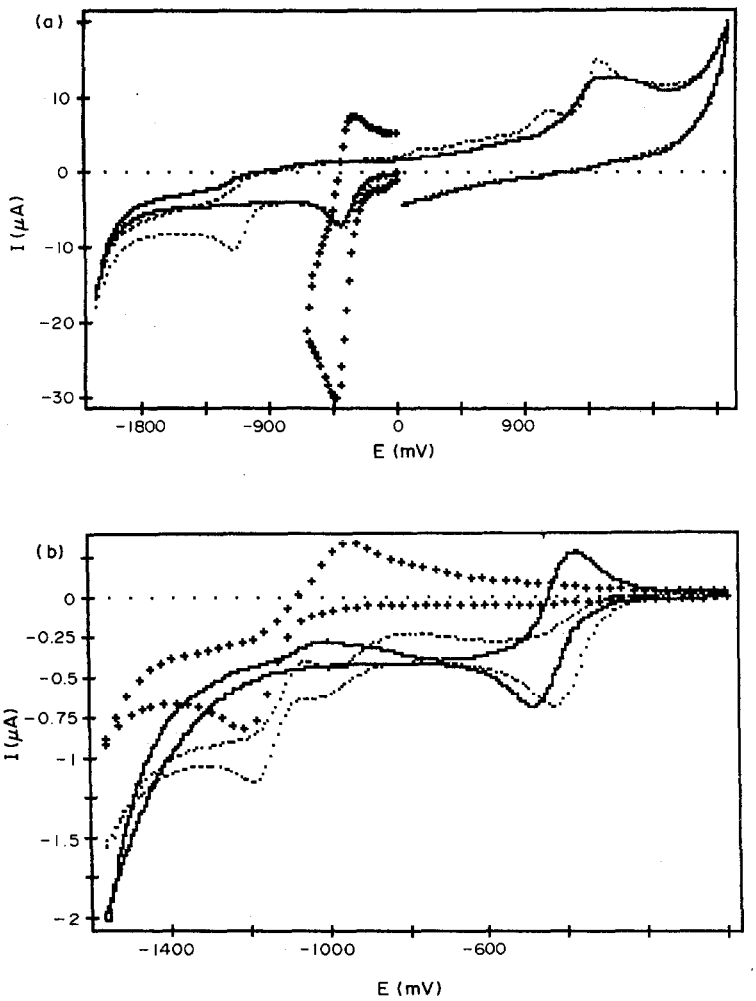

Fig. 2. General voltamperogram of $Fe^{III}(L)Cl$ complexes at a platinum electrode: (a) in CH_3CN–TBAHFP (0.1 mol dm^{-3}) and Fe(SALEN) (1 mmol dm^{-3}), Pt diameter 2 mm, potential sweep rate 0.1 (——) and (...) 2 V s^{-1} (+ + +); (b) in CH_2Cl_2–TBAHFP (0.1 mol dm^{-3}), potential sweep rate 0.1 V s^{-1}, Pt diameter 0.5 mm. (SALEN)Fe—O—Fe(SALEN) (1 mmol dm^{-3}) (+ + +); Fe(SALEN) (1 mmol dm^{-3}), under Ar (——) and with O_2 traces (· · ·).

(4) In CH_3CN or DMF on a gold electrode, voltammograms may show a reduction process around −1.8 V, which has been attributed to a second reduction of iron:[19,23]

$$Fe^{II}(L)+e \Leftrightarrow Fe^{I}(L) \qquad (3)$$

In the sequel the study is restricted to the electrochemical reduction of Fe^{III} into Fe^{II}. Exhaustive electrolysis of $Fe^{III}(L)Cl$ at the potential −0.6 to −0.8 V confirms that there is a monoelectronic exchange. With L = SALEN, the orange–brown solution (λ = 480 nm) turns light yellow (λ = 280 nm); reoxidation of the solution gives back the initial solution. It must be pointed out that electrolysis must be conducted under rigorously anaerobic conditions. $Fe^{II}(L)Cl$ solutions are extremely sensitive to dioxygen and yield the μ-oxo-bridged dinuclear complex. Even with bubbling Argon U as a blanket, we noticed the oxygenation of $Fe^{II}(L)Cl$.

As expected, the potential of this couple depends on the nature of the Schiff base (Fig. 3). Quantitative evaluations of the effect on the redox potential of changing the ligand structure have been made for Schiff base complexes of cobalt(II), nickel(II) and copper(II).[24] The increase in the electronic delocalization of the Schiff base ring (from BAE to SALOPH) shifts the redox potential towards the anodic side. It makes the electrochemical reduction of Fe^{III} into Fe^{II} easier. According to the general equation of the potential shifts with the complexation constants:[25]

$$E'^{0} = E^{0} + 0.058 \log \frac{\alpha Fe^{II}}{\alpha Fe^{III}},$$

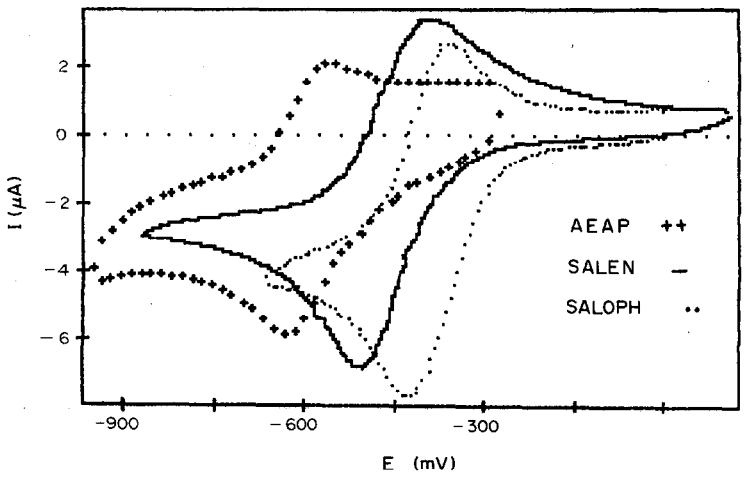

Fig. 3. Cyclic voltamperograms in CH_2Cl_2–TBAHFP (0.1 mol dm^{-3}) of $Fe^{III}(L)Cl$ (1 mmol dm^{-3}), potential sweep rate 0.1 V s^{-1}. L = AEAP (+ + +), SALEN (——), SALOPH (···).

where E'^0 is the observed redox potential, E^0 is the redox potential of Fe^{2+}/Fe^{3+} [26] and α represents the complexation coefficient and is a linear function of the complexation constants $(1+\beta_X[L])$, it appears that vs the free Fe^{2+}/Fe^{3+} redox couple the potential of these complexes is more cathodic: Fe^{3+} is more complexed than Fe^{2+}, $\beta_{III} > \beta_{II}$. $Fe^{II}(L)Cl$ complexes are powerful reducers. When delocalization is introduced on the ligand, the anodic shift of the potential traduces an increase in the complexation of Fe^{2+} vs Fe^{3+}. The potential shift is almost proportional to the ratio of the complexation constants of $Fe^{III}(L)Cl$ and $Fe^{II}(L)Cl$. The ratio β_{III}/β_{II} decreases when the delocalization increases which means that delocalized bases are better stabilizers for Fe^{2+}.

Besides the thermodynamic influence of the Schiff base, the delocalization on the base increases the kinetics of the electron transfer. By cyclic voltammetry (Table 2) the peak separation ΔE_p is decreased and the peak ratio RI_p tends to 1 from BAE to SALOPH (see below).

Stationary conditions, Table 1

At a rotating platinum disc electrode, the voltammograms show the diffusion controlled wave of the reduction of Fe^{III} into Fe^{II}. The waves can be badly defined and show the presence of a slow electron-transfer, according to the nature of the Schiff base and also to the electrode surface. We observed some passivation phenomena, especially

Fe(SALOPH)Cl	−314	−21.8	92

[a] p = slope of the linear regression of $E = f(\log|I_D - I/I|)$.

when the potential sweeps the whole electroactivity domain. The reduction passivation may be attributed to the imine bond reduction of the base (L),[27] yielding C—C bonds and then polymeric deposits. This implies direct reduction of the base or electron-transfer from the metal to the base.[28] In each case when the voltamperogram was badly defined the electrode was cleaned until the spectra were reproducible.

In CH_3CN or CH_2Cl_2 the limiting currents obey the Levich law; they are proportional to the square root of the electrode rotation speed (from 500 t min^{-1} to 4000 t min^{-1}) as for a diffusion controlled process. However, from Table 1 we can see a large discrepancy for the diffusion currents in dichloromethane, especially for Fe^{III}(BBE)Cl. We cannot explain this behaviour: it could be a surface phenomenon because in acetonitrile the diffusion current of Fe^{III}(BBE) is of the same order of magnitude. If we assume that Fe^{III}(SALEN)Cl and Fe^{III}(SALOPH)Cl present the behaviour of a simple reversible system, we obtain in dichloromethane a diffusion coefficient of 6×10^{-6} cm^2 s^{-1}. Versus this reference, when the currents are lower than the reference, passivation phenomena can be invoked and the wave is broadened. When the currents are higher than the reference a redox reaction (catalytic dioxygen reduction, for example) may explain this observation as for Fe^{III}(BBE)Cl.

The study of the variation of the limiting currents as a function of the complex concentration shows two types of behaviour. In CH_3CN, a dissociative solvent,[27,29] limiting currents are proportional to the concentration in the usual domain (up to 5 mmol dm^{-3}). In CH_2Cl_2, a non-dissociative and non-donor solvent[25,29] (Fig. 4), the linearity between the diffusion current and concentration is only observed at low concentrations, the upper limit depends on the nature of the base: 0.6 for AESAL, 1 for BBE, 2 for SALOPH, 3 mmol dm^{-3} for AEAP, etc. We tried to explain the different behaviours according to the solvent by solvation of the species. In the solid phase RX diffraction reveals dimeric structures,[13] which is hexa-coordination of iron with a distorted Schiff base. The sixth coordination comes from an oxygen of a proximal Schiff base.[13,30] Then, in low dissociative solvents such as dichloromethane, the deviation from linearity of $I_D = f(C)$ may come from the formation of dimers at high concentrations, traducing a limited solvation:

$$[Fe(L)Cl]_2 \longrightarrow 2Fe(L)Cl \quad (4)$$

$$Fe(L)Cl + e \Leftrightarrow Fe(L)Cl^- \quad (5)$$

Least-squares fittings of the curves $I_D = f(C)$ do not give satisfactory results and UV–vis spectroscopy does not prove this formation. However, it would explain the different behaviour between acetonitrile and dichloromethane. In dissociative and donor solvent such as CH_3CN the hexa-coordination of iron may be reached with the help of the solvent:

$$Fe(L)Cl + CH_3CN \longrightarrow Fe(L)Cl(CH_3CN) \quad (6)$$

Such solvation can go further, as in DMSO where the axial Cl^- ligand is replaced by the solvent.[18,31] However, we did not observe free Cl^- in CH_3CN, which is detected by an oxidation potential around 0.9 V. CH_3CN is too weak a donor solvent to replace the axial Cl^- ligand.

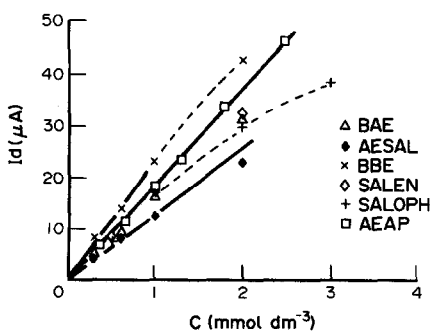

Fig. 4. Limiting current $|I_D|$ vs concentration for Fe(L)Cl complexes in CH_2Cl_2–TBAHFP (0.1 mol dm^{-3}); electrode rotation speed $\omega = 1000$ t min^{-1}.

Cyclic voltammetry, Table 2 (Figs 3 and 5)

At a platinum electrode, the voltammograms of the redox couple Fe^{II}/Fe^{III} present the shape of reversible systems (Fig. 5). As under stationary conditions passivation phenomena disturb the recordings: the peaks are broadened and the peak separation ΔE_p is increased. However, as mentioned above, the reported values are taken with the best drawn voltamperograms.

In fact, the electrochemical process is not restricted to a mono-electronic transfer; the reduction of Fe^{III} yields a more or less stable Fe^{II}, whose accepted electron may be transferred to the Schiff base[27] or to a substrate in solution. Thus, the apparent reversibility depends on the stability of Fe^{II}; if the potential sweep rate is increased the decomposition of Fe^{II} is limited and the peak ratio RI_p increases according to an EC scheme. The electronic delocalization of the Schiff base increases the stability of Fe^{II}: the peak ratio RI_p (Fig. 6) increases with the number of aromatic rings in the base and approaches 1 for Fe^{III}(SALOPH)Cl. Furthermore, the delocalization of the base im-

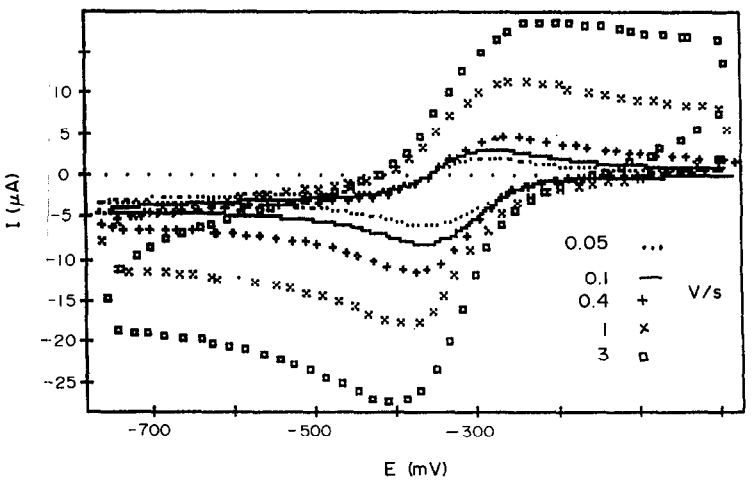

Fig. 5. Cyclic voltamperograms in CH_3CN–TBAHFP (0.1 mol dm^{-3}) of Fe^{III}(SALOPH)Cl (1 mmol dm^{-3}) for various potential sweep rates.

proves the electron transfer: the peak separation ΔE_p (Table 2) decreases with the number of aromatic rings in the base. Taking into account the above results and the chemical reactivity of these complexes, the electrochemical process is expressed by the following scheme:

$$Fe^{III}(L)Cl + e \Leftrightarrow Fe^{II}(L)Cl^- \qquad E$$

$$Fe^{II}(L)Cl^- \xrightarrow{k_1} Fe^{III}(L^\circ)Cl^- \longrightarrow$$

$$\text{dimers} \longrightarrow \text{polymers} \qquad C1$$

$$Fe^{II}(L)Cl^- + S \xrightarrow{k'_1} Fe^{III}(L)Cl + S^\circ \longrightarrow \text{pdts} \qquad C'1$$

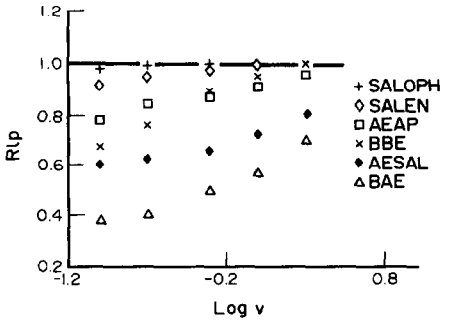

Fig. 6. Plots of RI_p ($= |Ip_{ox}/Ip_{red}|$) vs log V (potential scan rate) for Fe(L)Cl (1 mmol dm^{-3}) in CH_2Cl_2 and TBAHFP (0.1 mol dm^{-3}).

Reactions C1 and C'1 represent the following reaction of an EC scheme: C1 is the intramolecular electron transfer which should yield dimeric species bridged by a C—C bond of the imine of the base and C'1 is a bimolecular redox reaction in solution.

Exhaustive electrolysis of Fe^{III}(SALEN)Cl does not yield dimeric species as in the chemical reduction with sodium[27,28] or in the electrochemical reduction of Ni^{II}(SALOPH).[32] When electrolysis was performed with high concentrations of the complex (10^{-2} mol dm^{-3}), passivation phenomena occurred and the electrolysis was blocked at ~0.8–0.9 Faraday per mole with a red-brownish deposit on the working electrode. If the electrolysis was conducted in CH_3CN–Et_4NBF_4 and the reddish solution after electrolysis evaporated, then, by the addition of CH_2Cl_2 the complex was dissolved and separated from the supporting electrolyte. After evaporation of the solvent a reddish powder was recovered. The mass spectrum of this powder gave by impact electronic ionization (70 eV) the pattern of the initial compound Fe^{III}(SALEN)Cl: m/z at 357 then m/z at 322 (loss of Cl); no higher mass was detected. Moreover, the mass spectrum of the deposit on the electrode gave, by NH_3 chemical ionization, quite a simple spectrum: MH^+/z at 661 corresponding to the μ-oxo-bridged dinuclear complex (L)Fe—O—Fe(L) then MH^+/z at 340 for (L)Fe—O and MH^+/z at 323 for Fe(L). The appearance of this compound derives from dioxygen traces of Argon U, which is used as a blanket in the electrochemical cell. According to these results, we do not give the evidence of the reaction C1 but of the reaction C'1. Due to the high reactivity of iron(II), dioxygen traces (or residual water) are reduced. The process is not catalytic because the final product is the μ-oxo (L)Fe—O—Fe(L) complex:

$$2Fe^{II}(SALEN)CL + \tfrac{1}{2}O_2 \longrightarrow \mu\text{-O-[Fe(SALEN)]}_2. \quad (7)$$

It appears that the electrochemical behaviour of iron complexes is different from that of the nickel analogues.[32] The reduction of Ni^{II}(SALOPH) yields a dimer according to:

$$Ni^{II}(L) + e \Leftrightarrow [Ni^{II}(L^{\circ})]^- \quad (8)$$

$$2[Ni^{II}(L^{\circ})]^- \longrightarrow [Ni^{II}(L)]_2^{2-}; \quad (9)$$

this dimer, being electroactive, is easily electrochemically detected. This electrochemical difference may be attributed to the energy level of the reduction, that is the potential. The Ni^{II}(L) reduction is around 1 V more negative than the Fe^{III}(L)Cl reduction: the intramolecular electron-transfer towards the ligand may proceed in the reduced form of Ni^{II}(L).

Coming back to the kinetics view of the electrochemical system, the analysis of the I_p peak current vs the square root of the potential sweep rate shows different behaviour between CH_3CN and CH_2Cl_2. In CH_3CN peak currents are proportional to the square root of the potential sweep rate, whatever the nature of the base. The plots I_p vs $\sqrt{v}$ present almost the same slope. The electrochemical system follows the EC1' pathway. The peak ratio RI_p is generally lower than in CH_2Cl_2, indicating a higher constant, k'_1 (or higher amounts of O_2 traces), in CH_3CN than in CH_2Cl_2. In CH_2Cl_2 (Fig. 7) different types of behaviour are observed, according to the Schiff base vs the theoretical law[33] of a reversible system [with $D = 6 \times 10^{-6}$ cm^2 s^{-1}, average value gathered from the Levich law under stationary conditions for Fe^{III}(SALEN)Cl and Fe^{III}(SALOPH)Cl]. Among the complexes only those derived from SALEN and SALOPH present $I_p/\sqrt{v}$ plots which follow this law. The complexes of BAE, AESAL and AEAP show $I_p/\sqrt{v}$ plots with values of peak currents lower than expected, indicating that the process is controlled by a preceding step. This limiting step may be the dimerization reaction[4] already invoked under stationary conditions. This reaction is complete in dissociative and donor solvents, where the Fe(L)Cl complex can reach hexa-coordination by ligating a solvent molecule.

CONCLUSION

Up until now, not much data have been given on the electrochemical properties of Fe^{III} Schiff base complexes. This is surprising because iron is one of the most engaged metals in the bio-activation of dioxygen. Only iron porphyrin-type complexes have been fully described. We have presented the electrochemical behaviour of six iron N_2O_2 donor-Schiff base complexes (SALEN type) in an aprotic solvent. It appears that Fe^{II} is much more stabilized

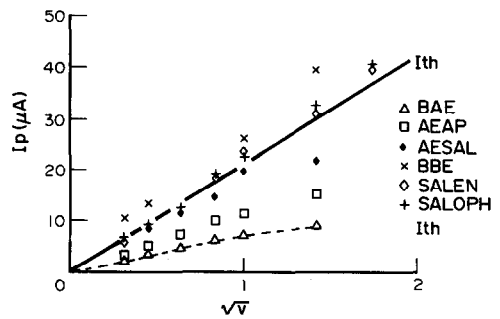

Fig. 7. Plots of $|I_{p\,red}|$ vs $\sqrt{v}$ (potential scan rate) for Fe(L)Cl (1 mmol dm^{-3}) in CH_2Cl_2–TBAHFP.

by a high electronic delocalization of the ligand than Fe^{III}. Moreover, these complexes tend to reach hexa-coordination either by dimerization in non-dissociative solvents, as in the solid phase, or by solvent coordination. This free position, as well as the replaceable Cl axial ligand, is promising for activation of molecules by redox catalysis. Furthermore, $Fe^{II}(L)Cl$ is extremely reactive and presents good opportunities for mediated electrochemical reduction. We must keep in mind that the working potential can be adjusted by the nature of the Schiff base. The reactivity of Fe^{II} with the dioxygen traces of Argon U has been noted. Reaction with O_2 yields the μ-oxo-bridged dinuclear complex (L)Fe—O—Fe(L), which appears as a thermodynamic well.[23] However, the $Fe^{III}(L)Cl$ complexes can manage the dioxygen activation through $Fe^{II}(L)Cl$. This will be the subject of a forthcoming paper.

EXPERIMENTAL

Products

The Schiff bases are prepared according to literature methods through the well-known amine–aldehyde (or –ketone) condensation: H_2BAE,[11] H_2AESAL,[12] H_2AEAP,[12] H_2BBE,[11] H_2SALEN[13] and $H_2SALOPH$.[13]

The monomeric complexes Fe(L)Cl are synthesized by the complexation of $FeCl_3$ with the protonated ligand H_2L in basic methanol.

Fe(AESAL)Cl. To a methanolic solution (20 cm^3) of H_2AESAL (0.5 g, 2.03 mmol) were added triethylamine, NEt_3 (0.6 cm^3), and $FeCl_3$ (0.33 g, 2.03 mmol) dissolved in methanol (20 cm^3). The solution was refluxed for 40 min and then concentrated *in vacuo* to *ca* 20 cm^3. On cooling, the black microcrystalline solid which precipitated was filtered and dried (0.41 g, 60%). Found: C, 50.8; H, 4.6; N, 8.6. Calc. for $C_{14}H_{16}FeN_2O_2$: C, 50.1; H, 4.8; N, 8.3%. The synthesis of this compound was first described[15] according to a complex process through a copper complex which was demetallated before the iron complexation.

The other complexes were prepared according to literature methods: Fe(BAE)Cl,[14] Fe(AEAP)Cl,[16] Fe(BBE)Cl,[15] Fe(SALEN)Cl[13] and Fe(SALOPH)Cl.[13]

Physical measurements

Electrochemical measurements were carried out with a home-made potentiostat controlled by an Apple IIe micro-computer.[34] The electrochemical cell was a conventional one with three electrodes [working electrode: Pt (diameter 2 mm, EDI, Tacusse, or diameter 0.5 mm) for analytical purposes and Pt foil for electrolysis; counter electrode: Pt wire; reference electrode: Ag/AgCl, KCl (0.1 mol dm^{-3}) or S.C.E.]; the potentials are measured vs S.C.E. The supporting electrolyte Bu_4NPF_6 (TBAHPF, Aldrich analytical grade) was used as received. Acetonitrile, CH_3CN (Aldrich, Gold Label), was used without any further purification, whilst dichloromethane, CH_2Cl_2 (SDS, purex), was passed over alumina prior to use. UV–vis spectroscopic measurements were conducted with an UVIKON 930 spectrophotometer (Kontron Instruments).

Acknowledgements—We thank Suzy Richelme [Service de Spectrométrie de Masse (Nermag R10-10), Université Paul Sabatier, Toulouse] for her technical assistance with the mass spectra.

(*Received* 13 *October* 1992; *accepted* 2 *November* 1992)

Abstract—ESR spectra of [Co(Me,H,H)·H_2O] [Me,H,H = N^1,N^4-bis(salicylidene)-S-methyl-isothiosemicarbazone^{2-}] and its adducts with ligands containing nitrogen (pyridine, 4-CN pyridine, α- and γ-picoline, N-methyl- and N-ethylimidazole), phosphorus (tributyl-, triphenyl-, diphenylmethyl-, diphenylethylphosphine, triphenyl- and triethylphosphite), arsenic (triphenyl arsine), oxygen (DMF, THF) and sulphur (dimethyl-, diethyl-, diphenyl- and methylphenylsulphide) donor bases were studied in frozen solutions. All spectra were indicative of low-spin cobalt(II) centres with predominantly d_{z^2} character of the ground state. The determined values of A^{Co} and g tensor components and superhyperfine coupling constants observed for base donor atoms indicated the formation of five-coordinate mono-adducts. For some nitrogen bases (pyridine, 4-CN pyridine and γ-picoline) the formation of 1 : 2 six-coordinate bis-adducts was also observed. The bonding parameters were calculated. The activity of the N-donor adducts towards dioxygen is also reported.

Cobalt(II) Schiff-base complexes have attracted much attention because of their extensive coordination chemistry. In particular, the formation of adducts with Lewis bases and reversible dioxygen binding are well recognized features of these chelates.[1] The parent four-coordinate chelates and their adducts may be low-spin,[2] high-spin or exhibit spin cross-over properties.[3] Hitchman[4] has shown that for square pyramidal [Co(N_2O_2)·B] complexes a decrease in the in-plane ligand field strength and a shift of the cobalt(II) atom above the macrocycle plane are decisive for achieving the high-spin configuration. The addition of a second axial ligand may result in six-coordinate cross-over systems with an abrupt spin-state transition, as demonstrated by Charpin *et al.*[5] for bis(pyridine)[N,N′-ethylene-bis(3-carboxy-salicylaldimino)] cobalt(II). Although extensive efforts have been focused on tetradentate cobalt(II) Schiff-base complexes, some essential problems remain open: i.e. (1) the factors determining the formation and spin state of the six-coordinate species of the Co(Schiff base)(Lewis base)$_2$ type; and (2) the relation between structural features of the molecule and the affinity/reversibility of dioxygen binding.

Recently, a new type of four-coordinate Schiff base ligand has been reported. In the course of template condensation of salicylaldehyde S-alkyl-isothiosemicarbazone with a salicylaldehyde molecule in the presence of VO^{II}, Cu^{II}, Ni^{II}, Fe^{III} and Zn^{II} ions the corresponding chelates $M(R^1R^2R^3)$ of N^1,N^4-bis(salicylidene)-S-alkylisothiosemicarbazone as the ligand are formed (see Scheme 1).[6,7]

Demetallation of the nickel(II) complex with gaseous HCl yields the free ligand hydrochloride.[8] Gerbeleu *et al.*[9,10] synthesized the cobalt(II) complexes [Co($R^1R^2R^3$)·H_2O] (R^1 = Me, Et, Pr^n; $R^2 = R^3$ = H) from cobalt(II) diacetate tetrahydrate and the appropriate ligand hydrochloride. The complexes were characterized by their IR and electronic spectra. Magnetic susceptibility measurements proved the complexes to be low-spin.

In our recent paper a more convenient synthetic route to the above complexes involving the direct template synthesis has been reported, together with ESR studies of CoL·H_2O complexes doped into

the corresponding $ZnL \cdot H_2O$ host lattices.[11] In the present paper ESR studies of five- and six-coordinate adducts of the title complexes are presented. The redox properties and reactivity of base adducts towards dioxygen are also reported.

EXPERIMENTAL

Preparation of the ligands and complexes

The S-alkyl isothiosemicarbazone ligands were prepared according to the method described by Gerbeleu *et al.*[6] The complexes were synthesized as previously reported[11] by the direct template reaction of salicylaldehyde S-alkyl isothiosemicarbazones and salicylaldehyde in the presence of cobalt(II) diacetate tetrahydrate under a purified dinitrogen atmosphere in standard Schlenk-type glassware. The dehydration of the $[Co(R^1R^2R^3) \cdot H_2O]$ complexes was performed *in vacuo* at 100°C for a period of 1 h, yielding the unsolvated chelates.

ESR sample preparation

Samples for ESR studies were prepared under anaerobic conditions. The appropriate complex (1 mg) was placed in a quartz tube sealed with a serum-type stopper and toluene/CH_2Cl_2 (1:3, *ca* 0.25 cm^3), deoxygenated using the double syringe technique, was added. Toluene solutions of Lewis bases were added to the sample solutions with the use of a gas tight microsyringe.

Nematic phase solutions of $[Co(Me,H,H) \cdot H_2O]$ and $[Co(Me,H,H) \cdot py]$ in MBBA were oriented according to ref. 12 at 300 K with a magnetic field of 800 mT for 15 min and then rapidly frozen at 77 K.

Physicochemical methods

Magnetic susceptibilities were measured for the solid samples by the Gouy method at 80–295 K. Diamagnetic corrections were calculated from Pascal constants. Electronic spectra were measured at room temperature on a Beckman UV 5240 spectrometer. ESR spectra were recorded using an *X*-band SE/X spectrometer (Radiopan, Poland) equipped with a NMR magnetometer and MnO/MgO as the *g* calibrant. If not otherwise indicated the spectra were measured at 77 K. The details of the electrochemical experiments and processing data are given in ref. 13.

Calculations

ESR spectra were simulated using the computer program previously described.[11] The principal axes of the *g*, hyperfine and line-width tensors were assumed to be coincident in all but one case (*vide infra*). Quadrupole effects were neglected. An orientation dependent line-width was allowed for by means of a line-width tensor. Spectra were fitted by means of the Marquardt method.[14]

RESULTS AND DISCUSSION

Formation of five- and six-coordinate adducts of Lewis bases

The ESR spectra of five- and six-coordinate complexes were measured upon the addition of the appropriate nitrogen, phosphorus, arsenic, oxygen and sulphur donor bases to the toluene/dichloromethane solutions of $[Co(Me,H,H) \cdot H_2O]$. The amounts of bases needed to observe the spectra of adducts as well as the corresponding spectral patterns do not depend on whether samples of hydrated or dehydrated $Co(R^1R^2R^3)$ chelates have been used. However, it is noteworthy that the initial spectrum, i.e. that before the addition of the base, is strongly solvent dependent. If the solid complex (monohydrate or dehydrated) was dissolved in dry, freshly distilled CH_2Cl_2 and/or toluene only a broad, unresolved signal with $g \cong 2.3$ was observed at 77 K. On the other hand, if wet CH_2Cl_2 (saturated in H_2O) was used a neatly resolved spectrum was observed (Fig. 1). Similar effects were observed for complexes with R^1 = Et, Pr^n and Bu^n. The reason for the above behaviour is not obvious, but most likely results from association of the four-coordinate species, particularly at lower temperatures. Addition of the Lewis base resulted in the development of the spectrum of the adduct.

Nitrogen donor Lewis bases. For pyridine, γ-picoline, 4-cyanopyridine, N-methyl- and N-ethylimidazole (py, γ-pic, 4-CNpy, MeIm and EtIm,

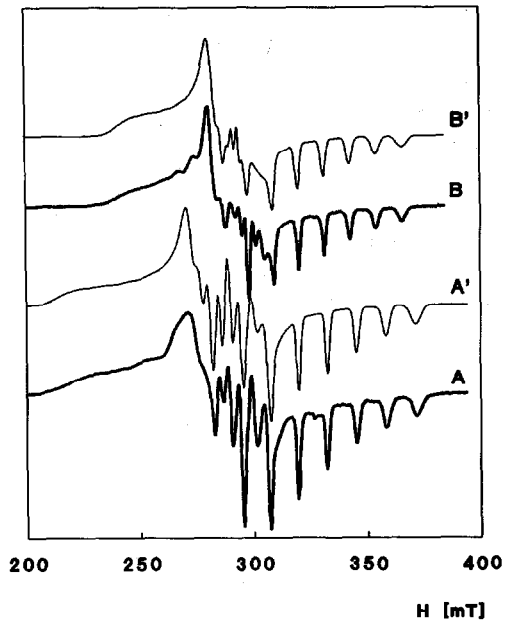

Fig. 1. ESR spectra of (A) [Co(Me,H,H)·H_2O], (B) [Co(Me,H,H)·Et_2S] in CH_2Cl_2/toluene at 77 K. (A′) and (B′) are best fits of (A) and (B), respectively.

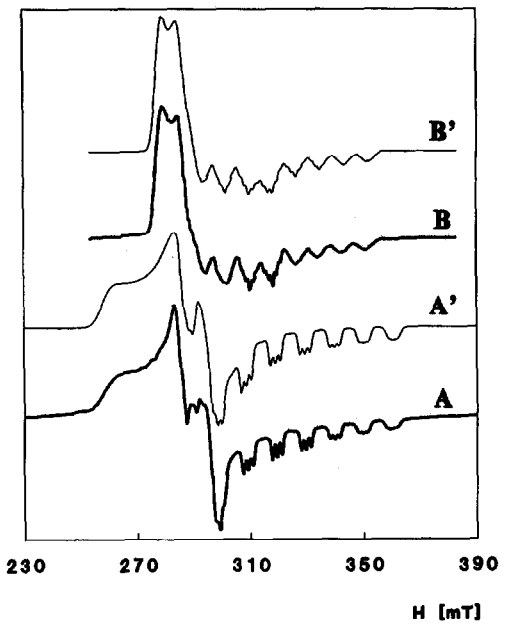

Fig. 2. ESR spectra of (A) [Co(Me,H,H,)·4-CNpy], (B) [Co(Me,H,H)·(4-CNpy)$_2$] in CH_2Cl_2/toluene at 77 K. (A′) and (B′) are best fits of (A) and (B), respectively.

respectively) the spectra of CoL·B complexes were observed at chelate-to-base ratios as low as 1 : 1.5 (at this ratio the last traces of the initial spectrum vanish). The spectra are orthorhombic, showing superhyperfine structure in the high-field region due to one ^{14}N nucleus. For py, γ-pic and 4-CNpy a further spectral evolution was observed, eventually yielding the spectra of the low-spin six-coordinate bis-adducts at a chelate-to-base ratio as low as 1 : 2.5. In these spectra superhyperfine splitting due to two equivalent ^{14}N nuclei is observed. The anisotropy of the spectrum is reduced in comparison with that of the monoadduct, as might be expected.[2] Similar behaviour was observed for all R^1-substituted complexes. This implies that introducing a substituent having a longer chain on the equatorial ligand does not produce any considerable steric hindrance and the formation of bis-adducts is still possible. On the other hand, the steric overcrowding plays an important role if present on the axial ligand. For α-picoline (α-pic) the formation of bis-adducts was not observed, even at a chelate-to-base ratio as large as 1 : 200. This might be interpreted in terms of steric effects of the α-methyl group, resulting in an appreciable shift of the central ion out of the N_2O_2 plane of the Schiff base upon coordination, which is more pronounced than in the case of less sterically demanding bases, and therefore preventing the coordination of a second base molecule.

For N-methyl- and N-ethylimidazole an increase of the base concentration resulted in a gradual disappearance of the initially observed mono-adduct spectrum. Hence, the formation of a high-spin, ESR silent six-coordinate species is inferred.

Typical spectra of five- and six-coordinate nitrogen donor adducts are presented in Fig. 2.

As mentioned above, the formation of mono- and bis-pyridine adducts of [Co(R^1HH)·H_2O], where R^1 = Et, Pr^n and Bu^n, has been studied. In all cases both types of adducts were formed. However, the ESR parameters were virtually identical to those observed for R^1 = Me adducts and, therefore, no detailed studies were performed for these systems.

The adduct formation at room temperature was also investigated by means of electronic spectroscopy. The titration of a CH_2Cl_2 solution of [Co(Me,H,H)·H_2O] with pyridine and 4-cyanopyridine revealed an alteration of the spectral pattern. In both cases the intensities of bands at *ca* 8000, 17,500, 23,200 and 25,000 cm^{-1} decrease. A new band at *ca* 20,000 cm^{-1} and an ill-defined shoulder at *ca* 11,000 cm^{-1} were observed with increasing amine concentration. The lack of isosbestic points implies the simultaneous presence of mono- and dipyridine adducts, beside the starting chelate.

Phosphorus donor Lewis bases. The five-coordinated adducts of the general formula [Co(Me,H,H)·B] [B = PPh_3, PPh_2Me, PPh_2Et, $P(OPh)_3$ and

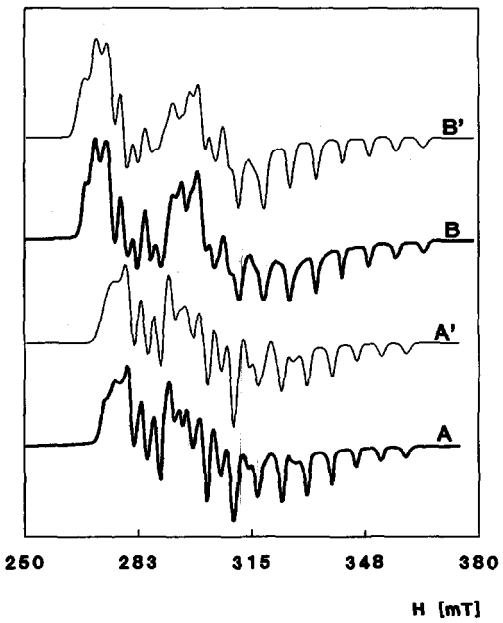

Fig. 3. ESR spectra of (A) [Co(Me,H,H)·PBu_3] and (B) [Co(Me,H,H)·$P(OEt)_3$] in CH_2Cl_2/toluene at 77 K. (A′) and (B′) are best fits of (A) and (B), respectively.

$P(OEt)_3$] are formed upon the addition of phosphorus Lewis bases (see Fig. 3). No traces of the starting complex (aquo-adduct) were detected at a chelate-to-base ratio of *ca* 1 : 5. A further increase of the base concentration does not produce any change in the spectrum up to a complex-to-base ratio of 1 : 100. The spectra are typical for phosphorus donor adducts observed previously for low-spin cobalt(II) complexes of Schiff bases,[15–17] porphyrins,[18] dimethylglyoximates[19] and tetraazamacrocycles.[20,21]

Oxygen, sulphur and arsenic donor ligands. The spectra of [Co(Me,H,H)·H_2O] in dimethylformamide and tetrahydrofurane resemble those of Co[saloph] in the corresponding solvents, reported by Haas and von Zelewsky.[15] One cannot definitely say whether these spectra are due to five- and six-coordinate complexes. However, the titration of a toluene/CH_2Cl_2 solution of [Co(R,H,H)·H_2O] with DMF results in the spectrum observed for a frozen solution of [Co(Me,H,H)·H_2O] in neat DMF, suggesting that the spectrum corresponds to the complex with one coordinated solvent molecule. Unfortunately, the spectrum of [Co(Me,H,H)·H_2O] in a DMSO/toluene frozen solution indicates the presence of *ca* 50% of the starting monoaquo adduct, the spectrum thereof being superimposed on a signal which is most likely due to the DMSO adduct. Therefore, the ESR parameters of the latter were not determined.

The addition of dialkyl and arylalkyl sulphides to solutions of [Co(Me,H,H)·H_2O] resulted in spectral changes and at a *ca* 50-fold excess of sulphide the initial spectrum disappeared [see Fig. 1(B)]. During the addition of sulphide we observed only two types of spectra: the initial one due to [Co(Me,H,H)·H_2O] and that formed after the addition of sulphide. On this basis we believe that the latter might be attributed to coordination of one sulphide molecule.

It seems that the thioether sulphur donor atom has a much higher affinity to the cobalt(II) centre than the oxygen atom in ethers. In contrast to diethyl sulphide comparable or even higher concentrations of added diethyl ether do not affect the ESR spectrum of [Co(Me,H,H)·H_2O].

The triphenylarsine monoadduct formation was established on the basis of the superhyperfine splitting, due to the ^{75}As ($I = 3/2$) nucleus, observed in the central and low-field part of the spectrum (Fig. 4).

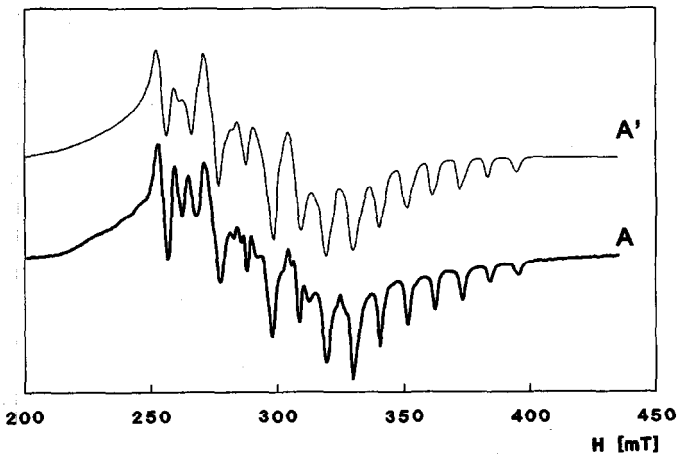

Fig. 4. ESR spectrum of (A) [Co(Me,H,H)·$AsPh_3$] in CH_2Cl_2/toluene at 77 K. (A′) is the best fit of (A).

It has to be pointed out that in no case, either for solid doped samples[11] or solutions, have traces of signals which might correspond to a four-coordinate species been observed.

Interpretation of the ESR spectra

In order to assign the principal magnetic axes of the systems under study the ESR spectra in an oriented nematic liquid crystal were studied. A rapidly frozen MBBA solution of [Co(Me,H,H)·H_2O] exhibits an ESR spectrum with a different pattern than that observed for frozen CH_2Cl_2/toluene solutions. The superhyperfine splitting observed on the high-field lines of the spectra in MBBA ($g = 2.010$, $A^{Co} = 107 \times 10^{-4}$ and $A^{N} = 13 \times 10^{-4}$ cm^{-1}) indicate coordination of one nitrogen atom to the cobalt(II) ion. This could be attributed to the coordination of the azomethine nitrogen atom of the MBBA molecule. On the other hand, a frozen MBBA solution of the [Co(Me,H,H)·py] adduct shows a spectrum with parameters identical to those observed for [Co(Me,H,H)·py] in non-coordinating solvents (see Table 1), but differing from those observed for the postulated [Co(Me,H,H)·MBBA] adduct. Consequently, we believe that neither the pyridine molecule can be replaced by MBBA in [Co(Me,H,H)·py] nor the sixth coordination site of the cobalt(II) centre occupied by an MBBA liquid crystal molecule.

The spectra showed an orientation dependence typical for planar complexes aligned in the direction of the long axis of the liquid crystal.[12] At an orientation of 0° (no rotation) the high-field component of the spectrum was quenched, giving rise to sharp features after sample rotation of 90° (Fig. 5). Accordingly, this component could be assigned as parallel to the z-axis of the complex, being normal to the plane established by the equatorial ligand.[12] The smallest value of the out-of-plane component of the g tensor is indicative of a d_{z^2} ground state.[22] Therefore, the largest component of g was assigned to the x component.

The spin-Hamiltonian parameters for cobalt(II) complexes under study are collected in Table 1. All these parameters were obtained from computer simulations of the experimental spectra. For the analysis of the g and cobalt hyperfine tensors

McGarvey's theory of low-spin d^7 ions has been applied.[23]

As there are more unknowns than equations we have assumed, following Raynor *et al.*,[16,17] $c_3 = c_4 = c_5$, $c_6 = 0$ and $a^2 + b^2 = 1$ (where a and b are the contributions of the d_{z^2} and $d_{x^2-y^2}$ orbitals in the ground state function, respectively).

The values of the energy separations $\Delta B_1(d_{z^2}-d_{xz})$, $\Delta B_2(d_{z^2}-d_{yz})$ and ΔQ (average energy of quartet states) have been calculated from McGarvey's coefficients c_i $(i = 1/3)$, considering $c_i = (\rho_{3d}\lambda)/\Delta E_i$. The spin density in the d_{z^2} orbital ρ_{3d} was calculated as P/P^{2+}, with $P^{2+} = 0.0254$ cm^{-1},[23] and the free ion spin-orbit coupling parameter λ for the Co^{2+} ion has been chosen to be 533 cm^{-1}.[24] The cobalt 4s spin densities ρ_{4s} have been estimated according to eq. (1):[25]

$$-kP = \rho_{4s}a^*_{4s}(^{59}Co) + \rho_{3d}a^*_{3d}(^{59}Co) \qquad (1)$$

with $a^*_{4s}(^{59}Co) = 0.1232$, $a^*_{3d}(^{59}Co) = -0.0084$ cm^{-1}.[15]

The calculated values of c_i $(i = 1/3)$, a^2, b^2, P, k, ρ_{3d}, ρ_{4s}, ΔB_1, ΔB_2 and ΔQ are given in Table 2.

The signs for the cobalt coupling constants were established from the best fit of the experimental data, taking into account that P must be positive.

Table 2. The calculated values of c_i $(i = 1/3)$, a^2, b^2, P, k, ρ_{3d}, ρ_{4s}, ΔB_1, ΔB_2 and ΔQ and [Co(Me,H,H)·B] and [Co(Me,H,H)·2B] adducts

[b] In 10^{-4} cm^{-1}.
[c] In cm^{-1}.

The values of g_i and A_i^{Co} for five- and six-coordinate adducts with oxygen, nitrogen and phosphorus donors lie in the ranges typical for cobalt(II) complexes of tetradentate Schiff bases.[2,15–17] Among the five-coordinate systems the higher anisotropy of g tensors is found for oxygen and sulphur donors, whereas the lowest was established for phosphorus bases reflecting the alteration of axial perturbation.[22] The link between the axial perturbation and anisotropy of g is also illustrated in the case of the α-picoline adduct. Due to the steric effect of the methyl group α-picoline should reveal weaker donor properties than other pyridine derivatives. In fact, adduct formation is observed at higher base concentrations and the spectrum displays appreciably higher g anisotropy than that of pyridine, γ-picoline and 4-cyanopyridine adducts (Table 1).

It is also to be noted that g anisotropy is considerably smaller for six-coordinate than for five-coordinate complexes in all cases where both adducts are formed. One can observe changes in the values of $\Delta_{xy}(g_x - g_y)$, usually taken as a measure of the rhombic distortion,[19,26] on going from five- to six-coordinate adducts. The value of Δ_{xy} observed for the six-coordinate bis-adducts is about half that calculated for the five-coordinate species. Such behaviour was found for the nitrogen base adducts of Co(saloph)[15] and phosphorus donor adducts of $Co(Hdmg)_2$ ($Hdmg^-$ = dimethylglyoximate),[19] and interpreted in terms of changes of the metal ion position with respect to equatorial ligands.[4,19,22]

The values of calculated energy gaps (ΔB_1 and ΔB_2, Table 2) between the ground state ($^2A_1$) and two doublet excited states ($^2B_1$ and $^2B_2$, respectively) fit well the range of those reported previously for the low-spin cobalt(II) chelates. Also, the values of average energy difference between the ground state and lowest lying quartets are close to those calculated for other systems.[15–17,19] A comparison of the calculated energy separations with those deduced from the electronic spectra agrees only roughly. The intense CT bands in the visible region reaching 14,000 cm^{-1} obviously obscure the much weaker *d–d* bands in this region. Nevertheless, at least part of the bands observed in the electronic spectra can be assigned to certain *d–d* transitions, mainly on the basis of spectral changes observed upon ligation of the nitrogen base (*vide supra*). Thus, the band at *ca* 8000 cm^{-1} can be assigned as the $^2A_1 \rightarrow {}^2B_1$ transition for [Co(Me,H,H)·H_2O] (calculated $\Delta B_1 = 7100\ cm^{-1}$). The intensity of this band decreases with increasing base concentration, which is consistent with the predicted absence of any transition in this range for mono- and bis-adducts (Table 2). The shoulder observed near 11,000 cm^{-1} in the presence of the base can be attributed to the $^2A_1 \rightarrow {}^2B_1$ transition in the monoadduct or to the $^2A_1 \rightarrow {}^2B_2$ transition in the bis-adduct.

It has to be noted that for all but two adducts $\Delta B_1 > \Delta B_2$ holds and the difference between these values ranges from 4000 to 7000 cm^{-1}. The exceptions are the diethyl- and diphenylphosphite adducts, where the relation between these energies is reversed. Such an exception has not been observed for other cobalt(II) Schiff base and dimethylglyoxamate complexes.[15,19]

For mono-adducts of oxygen, sulphur and nitrogen bases the signs of all A tensor components are positive, whereas for bis-adducts of nitrogen and phosphorus donor ligands the A_x^{Co} and A_y^{Co} components are negative.

For the adducts with nitrogen bases, for which the steric factors in the vicinity of the nitrogen donor seem to be similar (i.e. for all but α-pic), a dependence of the cobalt hyperfine tensor components on the basicity of the ligand is observed. For the 1 : 1 adducts A_x values decrease in the order 4-CNpy > py > γ-pic > MeIm = EtIm. A similar ordering is observed for $\langle A \rangle$. In the case of six-coordinated complexes values of both A_x and A_z follow the same trend. These tendencies are obviously due to the variations of the donor ability of the nitrogen base ligand being in line with predictions drawn for the dependence of hyperfine constants on axial perturbation.[22]

The fact that both 1 : 1 and 1 : 2 adducts for various pyridines are observed gives us the opportunity to discuss the influence of the coordination number on the spin density parameters. The ρ_{3d} values are considerably higher in the case of six-coordinate complexes, while the opposite trend is observed for ρ_{4s}. A similar observation for the ρ_{4s} parameter was reported by Symons and Wilkinson for the C-bonded ligands.[25] On the other hand, we did not observe any pronounced dependence of both spin densities on the basicity of the N-bonded donors. For adducts with phosphorus donors the ρ_{3d} and ρ_{4s} spin densities on the cobalt atom lie in the range observed previously for adducts of other four-coordinate cobalt(II) Schiff base complexes.[15–17]

The values of all phosphorus superhyperfine tensor components are assumed to be positive. The values of A_i^P obtained from fitting the spectra are similar to those reported for other cobalt(II) Schiff base phosphorus adducts,[15–17] but for the compounds under investigation the values of A_x^P are appreciably higher in the case of the triphenylphosphine adduct.

The isotropic hyperfine coupling constants ($\langle A^P \rangle$) for ^{31}P yield the 3*s* spin density, $\rho_{3s} = \langle A^P \rangle /$

Table 3. The ρ_{3s} and ρ_{3p} spin densities on the phosphorus atoms

[a] Ligand (Me,H,H).

0.3396. The anisotropic coupling gives $3p$ spin density, $\rho_{3p} = (A_z^P - \langle A^P \rangle)/0.01922$.[21] The calculated values of ρ_{3s} and ρ_{3p} are collected in Table 3. Comparison of data presented in this table with those concerning the spin densities on the cobalt $3d$ orbital (see Table 2) led us to the conclusion that, as reported previously,[16,17-19] the more spin density that is localized on the cobalt atom the larger the spin densities on the phosphorus atom.

Redox properties and dioxygen binding

Cyclic voltammetry studies were carried out for [Co(Me,H,H)·H_2O] in dichloromethane and dichloromethane/pyridine solutions with the use of tetrabutylammonium perchlorate as a supporting electrolyte. The voltammogram of [Co(Me,H,H)·H_2O] in CH_2Cl_2 is shown in Fig. 6(a). The complex exhibits one quasi-reversible ($\Delta E_p = 120$ mV) peak at 0.594 V (vs S.C.E.), assigned to the Co^{III}/Co^{II} couple. No additional peaks reported for the corresponding VO^{II} and Ni^{II} complexes in DMF[26] were observed. An ill-defined irreversible cathodic response was additionally found at *ca* −0.95 V. The picture becomes more complicated if the parent chelate is dissolved in dichloromethane containing 1% v/v of pyridine [Fig. 6(b)]. Here, a quasi-reversible peak ($\Delta E_p = 100$ mV) is observed at −0.15 V. This peak was assigned to the Co^{III}/Co^{II} couple of the pyridine adduct. Such a decrease of the oxidation potential upon coordination of an axial N-base is typical for Co-Schiff base systems and is crucial for reversible dioxygen binding.[1a] The anodic peak of the above couple, particularly at low scan rates, is not clearly resolved, being followed by a plateau. This indicates a subsequent homogeneous reaction. By applying the method described by Savéant *et al.*[27] the homogeneous rate constant, $k = 5\ s^{-1}$, was determined. Passing dioxygen through the above solution for *ca* 5 min causes a change in colour from dark green to reddish-brown.

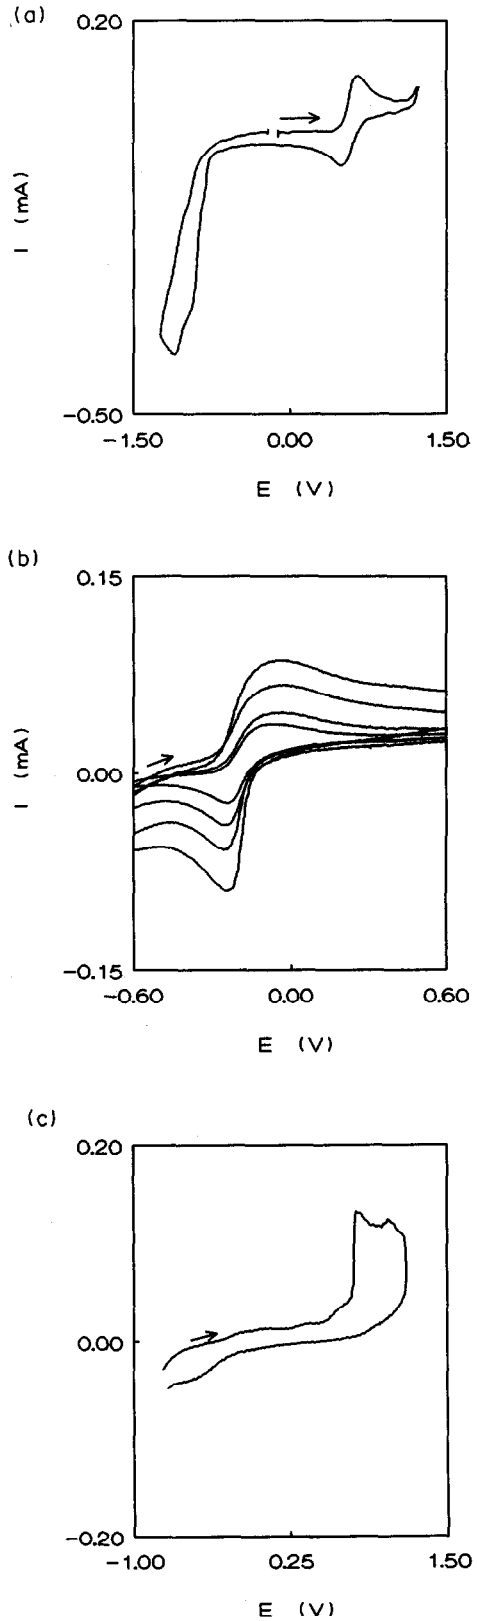

Fig. 6. Cyclic voltammograms of (a) $Co(Me,H,H)^-$ in CH_2Cl_2, (b) Co(Me,H,H) in CH_2Cl_2 containing 1% v/v of pyridine, and (c) as for (b) after passing dioxygen through. Scan rates 100 mV s^{-1}; supporting electrolyte = tetrabutylammonium perchlorate (0.1 M).

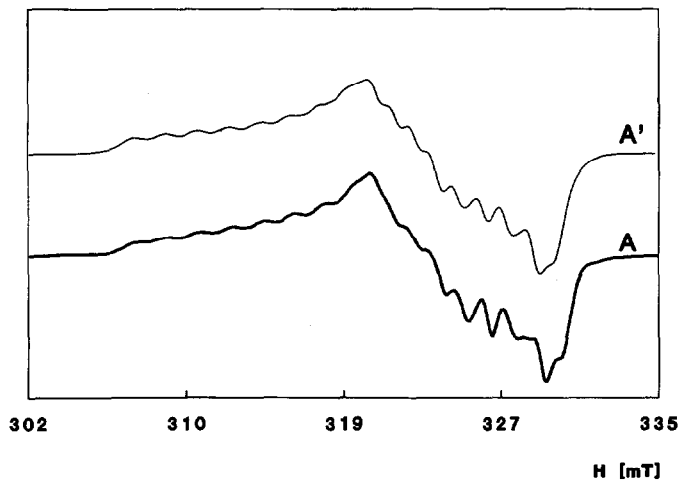

Fig. 7. ESR spectrum of (A) [Co(Me,H,H)·py·O_2] in CH_2Cl_2/toluene at 77 K. (A') is the best fit of (A).

The cyclic voltammetric curve [Fig. 6(c)] reveals only two irreversible peaks at 0.79 and 1.03 V. Bubbling with dinitrogen did not result in any change of the voltammetric pattern. The ESR spectrum of this solution does not display any distinct signals. It is therefore clear that, at least at room temperature, the oxygenation of [Co(Me,H,H)·py] is highly irreversible. This conclusion was further supported by ESR studies. The formation of the oxygenated species was observed only at low temperatures, and the ESR spectrum due to the dioxygen adduct was detected solely in frozen solutions. A complete conversion of the [Co(Me,H,H)·py] and [Co(Me,H,H)·2py] adducts to the [Co(Me,H,H)·O_2·py] dioxygen adduct was possible only by passing pure oxygen through the solution kept over the liquid nitrogen (see Fig. 7). Simulation of the ESR spectrum of [Co(Me,H,H)·py·O_2], using the monoclinic spin-Hamiltonian,[28] yielded the following parameters: $g_x = 2.011$, $g_y = 2.080$, $g_z = 1.994$, $A_x = 7.0 \times 10^{-4}$ cm^{-1}, $A_y = 18.0 \times 10^{-4}$ cm^{-1}, $A_z = 8.1 \times 10^{-4}$ cm^{-1} and $\alpha = 31°$. These values are in the typical range for cobalt superoxo complexes with O_2N_3 donor sets.[29]

Passing argon through the oxygenated sample resulted in recovery of the initial spectrum of five- or six-coordinate adducts of appreciably reduced intensity. In the next repeated oxygenation–deoxygenation cycles the spectral intensities of both oxygenated and deoxygenated forms decreased, resulting in a lack of any ESR signals (after five cycles). The observed disappearance of the ESR active species may be due to either formation of the diamagnetic μ-peroxo dimers or other irreversible processes involving, e.g. oxidation of the ligand or direct oxidation of the cobalt atom.

PREPARATION AND SPECTROSCOPIC STUDY OF *TRANS*-[$PtCl_2(C_2H_4)L$] (L = QNO, IQNO, 4-ClQNO, 2-MeQNO, 4-MeQNO). LIGAND EXCHANGE OF *TRANS*-[$PtCl_2(C_2H_4)$(4-MeQNO)]

MARIA-AGLAIA D. STIAKAKI and ARISTIDES CHRISTOFIDES†

Department of General and Inorganic Chemistry, Aristotelian University of Thessaloniki, P.O.B. 135, Thessaloniki 540 06, Greece

(*Received* 9 *August* 1990; *accepted* 2 *November* 1992)

Abstract—A series of *trans*-[$PtCl_2(C_2H_4)L$] [L = QNO (quinoline N-oxide), IQNO (isoquinoline N-oxide), 4-ClQNO, 2-MeQNO and 4-MeQNO] complexes have been prepared by the addition of L to aqueous solutions of Zeise's salt. ^1H NMR and IR studies have been employed to compare the coordination ability of L and ethylene towards platinum metal. The reactions of [$PtCl_2(C_2H_4)$(4-MeQNO)] with L′ [L′ = CO, PPh_3, py(pyridine) and 4-NMe_2py] afforded the *trans* complexes [$PtCl_2$L′(4-MeQNO)], [$PtCl_2$L′$_2$] and [$PtCl_2(C_2H_4)$(4-NMe_2py)]. Furthermore, the ability of [$PtCl_2(C_2H_4)$L] to react towards styrene resulted in the formation of five novel complexes of the type *trans*-[$PtCl_2$(styrene)L], which have been characterized by spectroscopic means (^1H, ^{13}C NMR and IR).

The formation of the first platinum(II) complex, containing N-oxide, was achieved several years ago by stirring [$PtCl_3(C_2H_4)$]K, Zeise's salt, with pyridine N-oxide.[1] Similarly, a small number of other platinum(II) complexes have been prepared using pyridine N-oxides bearing different substituents in the 4-position.[2,3] All these compounds have been characterized by spectroscopic means and in some cases, specifically dichloro(pyridine-1-oxide)-ethyleneplatinum(II) complexes, ^1H NMR studies have been performed.[4] However, reports of platinum(II) complexes incorporating either quinoline N-oxide or its substituted derivatives are scarce, and only the preparation of [$PtCl_2(C_2H_4)$(QNO)] has been reported so far.[5]

We have recently described the synthesis and study of some rhodium(I) quinoline N-oxide complexes[6] and now we report the preparation and spectroscopic study of five platinum(II) complexes.

EXPERIMENTAL

IR spectra were recorded on a Perkin–Elmer Model 1430 ratio recording spectrophotometer (over the range 4000–200 cm^{-1}) with calibration against the absorption band of polystyrene at 1601 cm^{-1}, and samples prepared as KBr discs. The ^1H NMR spectra were measured on Jeol FX-90 QFT and Jeol G×400 spectrometers by the staff of the NMR Service of the School of Chemistry, University of Bristol, U.K., and those of the styrene compounds were recorded on a Bruker AW-80 instrument in our department. The ^{13}C spectra were measured on a Bruker AC-200 spectrometer. The mass spectra were obtained on an RMU-6L Hitachi–Perkin–Elmer mass spectrometer. The thermoanalytical curves of **4** were obtained with a Dupont 951 thermogravimetric analyser. Quinoline N-oxide and its derivatives were prepared by published procedures,[6] whereas [$PtCl_3(C_2H_4)$]K was purchased from Aldrich Chem. Co. All reactions, unless otherwise stated, were conducted in air at room temperature.

Electrochemical studies were carried out using an AMEL Electrochemolab instrument in conjunction with a three-electrode cell. Nitrogen presaturated with solvent (CH_2Cl_2) was used to deoxygenate the solution. The working electrode was a platinum bead, the auxiliary electrode a platinum wire and the reference an aqueous saturated calomel electrode (S.C.E.), separated from the test solution by a fine-porosity frit and an agar bridge saturated

with KCl. Solutions were 0.5×10^{-3} mol dm^{-3} in complexes and 0.1 mol dm^{-3} in $[NBu^n_4][PF_6]$ as the supporting electrolyte. Under these conditions, E° for the couple $Fe(\eta^5\text{-}C_5H_5)_2^+/Fe(\eta^5\text{-}C_5H_5)_2$ is -0.47 V.

Preparation of complexes of the type $[PtCl_2(C_2H_4)L]$ **(1–4)**

To a solution of Zeise's salt (0.184 g, 0.5 mmol) in water (25 cm^3), the quinoline N-oxide L was added under constant stirring, the molar ratio being 1 : 2 or 1 : 1, respectively. The yellow solution was stirred for a few minutes affording a precipitate of $[PtCl_2(C_2H_4)L]$, which was selected by suctional filtration, washed with water (2×5 cm^3) and dried *in vacuo*.

Reactions of $[PtCl_2(C_2H_4)(4\text{-MeQNO})]$

(1) Addition of PPh_3 (0.2 mmol) and excess py (0.6 cm^3) to chloroform solutions of **4** (0.1 mmol) caused the complete displacement of organic ligands; concentration under vacuum and addition of diethylether afforded microcrystals of *trans*-$[PtCl_2(PPh_3)_2]$[7] and *trans*-$[PtCl_2py_2]$.[8]

(2) A solution of **4** (0.3 mmol) in chloroform was treated with an equimolar amount of 4-NMe_2py affording *trans*-$[PtCl_2(C_2H_4)(4\text{-}NMe_2py)]$[9] [work-up was as in (1)].

Preparation of complexes of the type $[PtCl_2(styrene)L]$ **(5–9)**

(1) $[PtCl_2(C_2H_4)L]$ (0.2 mmol) was dissolved in hot benzene (20 cm^3). To this solution degassed $C_6H_5CH{=}CH_2$ (0.1 cm^3) was added via a syringe with constant stirring. Minute bubbles of gas were evolved immediately, meanwhile the colour changed from pale yellow to orange. The solution was filtered and the clear orange filtrate was concentrated to one third of its original volume. The mixture was diluted with an equal volume of petroleum ether and after stirring and subsequent cooling on an ice bath afforded yellow microcrystals, which were washed with petroleum ether (b.p. 70–80°C) (4×5 cm^3) and dried in air.

(2) $[PtCl_3(styrene)]K$, which was used as a starting material in this preparation, was prepared by a published method.[2,10]

$[PtCl_3(styrene)]K$ (0.044 g, 0.1 mmol) was dissolved in acetone (15 cm^3). To this yellow solution the ligand L (0.2 mmol) was added and the mixture was stirred for 15 min. The solution was concentrated to a small volume (1 cm^3) and addition of diethylether (10 cm^3) caused the precipitation of yellow microcrystals. The supernatant liquid was discarded, the crystals were washed with diethylether (4×3 cm^3) and dried in air.

Preparation of $[PtCl_2(CO)(4\text{-MeQNO})]$

The complex $[PtCl_2(C_2H_4)(4\text{-MeQNO})]$ (0.045 g, 0.1 mmol) was dissolved in dry and freshly distilled chloroform (5 cm^3), contained in a Schlenk tube. Carbon monoxide was bubbled through the solution until the first sign of a colour change. The treatment was then interrupted and the solution concentrated to a small volume (*ca* 1 cm^3). The addition of petroleum ether (10 cm^3) (b.p. 70–80°C) precipitated a residue which was further washed with petroleum ether (4×3 cm^3) to give khaki microcrystals of $[PtCl_2(CO)(4\text{-MeQNO})]$ (**10**), and dried in air. Yield: 0.03 g, 66%. Found: C, 29.0; H, 2.7; N, 3.2. Calc. for $C_{11}H_9N_1Cl_2Pt_1O_2$: C, 29.2; H, 2.0; N, 3.1%.

RESULTS AND DISCUSSION

Treatment of aqueous solutions of $[PtCl_3(C_2H_4)]K$ with either an excess or a stoichiometric amount of L (L = IQNO, 4-ClQNO, 2-MeQNO, 4-MeQNO) results in the displacement of the chloride opposite to ethylene and the formation of complexes **1–4**.

[a] Melting points were determined in open tubes.
[b] Found values are given in parentheses.
[c] Decomposition temperatures.

In a preliminary report we announced some data concerning the title complexes.[11] Due to the strong *trans*-directing effect of the ethylene, the entering quinoline N-oxide displaces the chloride *trans* to ethylene.[12] However, neither $4\text{-}NO_2QNO$ nor 2-PhQNO react with Zeise's salt.

The elemental analyses (carbon, hydrogen and nitrogen) of all the compounds compare well to those expected, indicating that the new complexes precipitate in pure form and they do not need recrystallization. Their yields are quite high and they melt with decomposition. Table 1 displays the analytical and other data for the new complexes **1–4**.

In the mass spectrum of **3** there is a small peak at *m/z* 453, indicating the presence of molecular ions, and more intense peaks at *m/z* 143, 159 and 223, which can be assigned to $[2\text{-MeQN}]^{+\cdot}$, $[2\text{-MeQNO}]^{+\cdot}$ and $[Pt(C_2H_4)]^+$, respectively.

The ^1H NMR spectra of all the complexes show peaks at *ca* 4.36 ppm with $^{195}Pt\text{–}C\text{–}^1H$ coupling constants at *ca* 69 Hz (Table 2), indicating η^2-ethylene–platinum bonding arrangements.[13] In this series of compounds the $J(Pt\text{—}H)$ values of coordinated C_2H_4 are slightly higher than those of their pyridine N-oxide counterparts, which reflect better bonding of this ligand and a correspondingly lower *trans*-influence of quinoline N-oxides than the analogous pyridine ones. No safe conclusion can be drawn from the chemical shifts of ethylene protons (Table 2), since they do not show appreciable differences, mainly due to the fact that the nature of the *cis*-ligand in all complexes remains unchanged. Interestingly, all the spectra exhibit sharp peaks and well-defined platinum satellites and only in the spectrum of **2** has a slight broadening of all peaks been observed, in contrast with previous data.[4] The ^1H NMR spectra of $[PtCl_2(C_2H_4)(QNO)]$ and **4**, taken in deuterated methylene chloride at $-60°C$, displayed a single resonance for the ethylene protons, indicating that the ethylene moiety still rotates about the ligand–metal bond (Fig. 1). The low-temperature spectra measured with a high-resolution instrument (400 MHz) do not exhibit platinum satellites although the ethylene continues to be bonded to the metal. The disappearance of satellites is an implication of a dominant ^{195}Pt chemical shift anisotropy relaxation mechanism, since the spectra were taken at high field and low temperature.[14]

Table 2. ^1H NMR data[a] of $[PtCl_2(C_2H_4)L]$ compounds

Complex	δ ^1H (Ethylene)	$J(^{195}Pt\text{—}^1H)$ (Hz)	Substituted quinoline N-oxide —CH_3
$[PtCl_2(C_2H_4)(QNO)]$	4.37	69.1

$[PtCl_2(C_2H_4)(4\text{-}ClQNO)]$	4.38	70.0	
$[PtCl_2(C_2H_4)(2\text{-}MeQNO)]$	4.34	69.0	3.16
$[PtCl_2(C_2H_4)(4\text{-}MeQNO)]$	4.34	68.3	2.89

[a] Measured in $\{^2H_1\}$ chloroform, δ values (ppm).

Fig. 1. ^{1}H NMR spectrum of $[PtCl_2(C_2H_4)(4\text{-MeQNO})]$ at room temperature and at $-60°C$, recorded at 90 MHz in $CDCl_3$ and 400 MHz in CD_2Cl_2, respectively.

Attempts to measure the ^{13}C NMR spectra of **1–4** were unsuccessful due to their low solubility.

IR spectra

The IR spectra of all these complexes show bands characteristic of the coordinated quinoline N-oxides, along with absorptions due to the Pt—Cl bonds. Table 3 lists the main stretching frequencies of the investigated complexes. Generally, their spectra show strong bands in the 1146–1300 cm^{-1} region, assignable to ν(N—O) of the coordinated quinoline N-oxides. As far as the complexes of QNO, IQNO and 2-MeQNO are concerned their ν(N—O) bands are shifted to lower frequencies, compared to those of the free ligands. However, in the spectra of 4-ClQNO and 4-MeQNO compounds the corresponding bands are shifted to higher frequencies for the former, whereas the latter does not show any appreciable shift. It is known that the (C=C) stretching frequency is a low intensity band for olefins such as ethylene; on the other hand, the band in question may be confused with the aromatic (C=C) stretching modes, since the studied complexes incorporate aromatic systems. Therefore, it is apparent that unambiguous assignments concerning this band cannot be made.[2,3] Complexes of QNO and 4-MeQNO show weak peaks at 323 and 318 cm^{-1}, respectively, which could be attributed to Pt—O bonds; such peaks probably are obscured in the spectra of the other complexes.[10,12] Bands due to platinum–olefin stretching frequencies were observed at 412 and 410 cm^{-1} for 4-ClQNO and 4-MeQNO compounds, respectively. The rest of the complexes either do not show such a band (IQNO complex) or the corresponding bands occur around

Table 3. IR data (cm^{-1}) of [$PtCl_2(C_2H_4)L$] and [$PtCl_2$(styrene)L] complexes

Complex–ligand	Ligand ν(N—O)	Complex ν(N—O)	$\Delta\nu$(N—O)	ν(Pt—Cl)

400 cm^{-1} (QNO and 2-MeQNO complexes).[12] In all the complexes there is only one Pt—Cl stretching band around 345 cm^{-1}, indicating the *trans* arrangement of the two chlorines. This observation, combined with the NMR data showing the usual η^2-ethylene–platinum bonding, justified by the ^{195}Pt—C–^1H coupling constant of 69 Hz, shows that there is a square planar arrangement around the platinum atom.[13]

Ligand exchange reactions

Siedle *et al.*[13] pointed out that the non-bonded interaction between the *peri* hydrogens of the nitrogen containing ligand and the chlorine atoms in [$PtCl_2(C_2H_4)$(phz)] (phz = phenazine) leads to a twisting of the heterocyclic ligand, being almost perpendicular to the plane defined by the $PtCl_2$ moiety. This configuration leads to the limited reactivity of the complex towards attacking reagents, since its free coordination sites are blocked by the *peri* hydrogens of the ligand. Furthermore, the ethylene of [$PtCl_2(C_2H_4)$(phz)] cannot be displaced easily because the π^*-orbitals of the two unsaturated ligands, being orthogonal, do not compete for the same 5*d* electrons to achieve back-bonding, thereby strengthening their linkages to the metal. In our complexes, however, the incorporated quinoline N-oxides provide only one *peri* hydrogen, which is more distant from the metal atom than those of the phenazine in [$PtCl_2(C_2H_4)$(phz)]. Therefore, their reactivity is as expected and found to be more pronounced.

Displacement of ethylene by styrene in **1**–**4** proceeds rapidly in hot benzene, affording the new complexes *trans*-[$PtCl_2$(styrene)L] [L = QNO, IQNO, 4-ClQNO, 2-MeQNO, 4-MeQNO) (**5**–**9**) in satisfactory yields] (Table 4). Bubbling carbon monoxide through a chloroform solution of **4** also results in the displacement of ethylene and the formation of *trans*-[$PtCl_2$(CO)(4-MeQNO)] (**10**).

5	QNO
6	IQNO
7	4-ClQNO
8	2-MeQNO
9	4-MeQNO

The spectroscopic data (IR, ^1H NMR) of **5**–**9** support the above structure. The ^1H NMR spectra of all styrene complexes show the expected peaks; their chemical shifts as well as their coupling constants (Table 5) are rather close to those reported for similar complexes.[15] The pattern is complicated, because the olefinic protons are coupled to each other and with the platinum-195 nucleus (Fig. 2). In particular, the H_A protons give rise to a doublet of doublets centred at *ca* 6.28 ppm with $^3J(H_A, H_B)$ at *ca* 8.2, $^3J(H_A, H_C)$ at *ca* 13.5 and $J(^{195}Pt—H_A)$ at *ca* 79.3 Hz. The H_B protons exhibit a doublet centred at *ca* 4.30 ppm with $^3J(H_B, H_A)$ at *ca* 8.1 and

$J(^{195}Pt—H_B)$ at *ca* 74.6 Hz. The H_C protons also exhibit a doublet at *ca* 4.95 ppm with $^3J(H_C, H_A)$ at *ca* 13.5 and $J(^{195}Pt—H_C)$ at 65.5 Hz; coupling between H_B and H_C was not observed. The mean value of $J(^{195}Pt—H) = 73.1$ Hz is indicative of π-coordinated styrene; moreover, the resonances of the H_A, H_B and H_C hydrogens are shifted upfield compared to those of the free ligand (H_A 6.71, H_B 5.27, H_C 5.82 ppm).[15] The value of $J(^{195}Pt—H_A) = 79.3$ Hz may suggest that H_A is closer to the platinum atom than the other hydrogens, although other factors can contribute as well to the magnitude of this constant.[16] The same arguments could also be applied for the interpretation of the differences of the corresponding coupling constants of H_B and H_C. The ^{13}C NMR spectra of **5**, **7** and **9** (Table 6) are not very informative due to their low solubility in deuterated chloroform; however, resonances assignable to olefinic carbons of styrene can be seen at *ca* 49.97 and *ca* 82.34 ppm, the former corresponding to the carbon atom attached to the phenyl group. Both resonances are significantly shifted upfield compared to those of the free ligand (112.3 and 135.8 ppm) upon coordination. No ^{195}Pt–carbon coupling, which would be a valuable source of information, could be seen under the conditions of the experiment. Unfortunately, the very low solubility of **6** and **8** excludes the possibility of measuring their ^{13}C NMR spectra on the available instrument.

The IR spectra of **5**–**9** show strong absorption bands in the range 1152–1300 cm^{-1}, assignable to ν(N—O) of quinoline N-oxide ligands (Table 3). They appear to be negatively shifted in complexes of IQNO, 2-MeQNO and 4-MeQNO, compared to those of the free ligands, but there is a slight positive shift in the 4-ClQNO complex; as for [$PtCl_2$(styrene)(QNO)] (**5**), no appreciable shifting was observed. The negative shift could well be an indication that the involved ligands coordinate to the metal via the oxygen atom, but there are two complexes which do not follow the trend. This behaviour is akin to other pyridine and quinoline N-complexes and no safe conclusion can be drawn, from the IR data only, on the effect of coordination on the N—O bond, since ν(N—O) bands are coupled with the vibrations of the aromatic ring.[17] The IR spectrum of **10** exhibits two very strong ν(CO) bands at 2102 and 2115 cm^{-1}, the latter being a little less intense than the former, as well as a medium absorption ν(NO) at 1217 cm^{-1}, indicating coordination of 4-MeQNO. All styrene compounds and the carbonyl complex exhibit single ν(Pt—Cl) bands around 341 cm^{-1}, justifying their *trans*-configuration.

Reactions of **4** in chloroform with two equi-

valents of PPh_3 and excess pyridine result in the formation of the known complexes *trans*-$[PtCl_2(PPh_3)_2]$[18] and *trans*-$[PtCl_2py_2]$,[8] presumably by first displacing the 4-MeQNO. The products were identified by their colours, IR spectra and elemental analyses. The reaction between **4** and PPh_3 in a 1:2 molar ratio proceeds rapidly, giving the product in high yield (83%) with satisfactory elemental analysis (carbon and hydrogen). This ready preparation of *trans*-$[PtCl_2(PPh_3)_2]$ may imply replacement of its synthesis reported by Mastin *et al.*,[7] which involves irradiation of the *cis* isomer with UV light at 366 nm, lower yield (42%) and is more laborious than the proposed one. Reaction of **4** with 4-(NMe_2)py in a 1:1 molar ratio affords the known complex *trans*-$[PtCl_2(C_2H_4)(4\text{-}NMe_2py)]$.[9] The characterization of this product was achieved as above, as well as by its ^1H NMR spectrum, which has not been reported so far (Fig. 3). The above-mentioned spectrum shows two double resonances centred at δ 8.42 and 6.50 ppm, assignable to H_α and H_β hydrogens, respectively, coupled to each other by $^3J(H_\alpha, H_\beta) = ca\ 7.4$ Hz. The ethylenic protons give rise to a single sharp peak at δ 4.75 ppm, accompanied by platinum-195 satellites, $J(^{195}Pt{-}H) = 58.6$ Hz, indicative of a π-complexed spinning ethylene. The sharp single peak at 3.10 ppm is attributed to the six protons of the methyls. Obviously, the ^1H NMR data favour the proposed *trans* structure. Moreover, they give decisive evidence that coordination of 4-NMe_2py occurs via the heterocyclic nitrogen, since only the H_α hydrogens are shifted downfield compared to those of the free ligand [δ 8.25d (H_α), 6.50d (H_β), 3.00 ppm (—NMe_2)]. Perhaps the most important fact supporting the above mode of coordination is the existence of two sets of platinum satellites attached to the doublet at 8.42 ppm. An expansion of this part of the spectrum enabled us to measure with certainty the $J(^{195}Pt{-}H_\alpha)$ coupling constant, the value

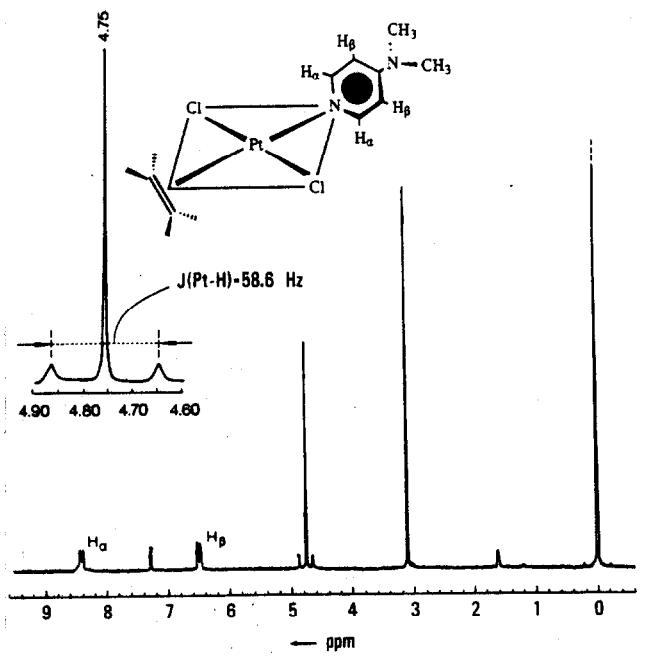

Fig. 3. ^1H NMR spectrum of $[PtCl_2(C_2H_4)(4\text{-}NMe_2py)]$ recorded at 270 MHz in $CDCl_3$.

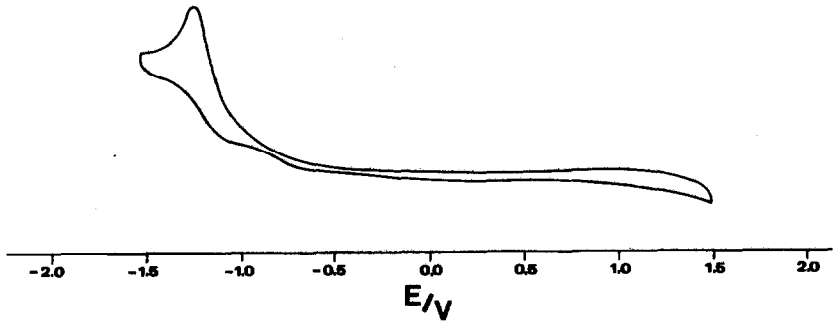

Fig. 4. The single scan cyclic voltammogram of $[PtCl_2(C_2H_4)(4\text{-MeQNO})]$ (**4**) in CH_2Cl_2, at a platinum bead electrode. Scan rate = 200 mV s^{-1}.

of which was 32.5 Hz. The phosphine, pyridine and 4-NMe_2py complexes exhibit a single ν(Pt—Cl) band around 341 cm^{-1} in their IR spectra, indicative of their *trans* configuration.

As can be seen from a survey of the ligand exchange reactions, either the new or known products adopt the *trans* configuration, the main reason for this preference being the strong *trans*-directing effect of ethylene. In addition, it is well known that the *trans* isomers are the most stable thermodynamically due to entropy reasons.[19] On the other hand, π-acceptor ligands displace preferably π-coordinated ethylene. These facts can be explained assuming that quinoline N-oxides lessen the extent of back-donation from platinum to ethylene, thereby facilitating its displacement by ligands with a similar nature.[20] There are also equilibrium reasons favouring the displacement of ethylene. In the case of the reaction with styrene the entering ligand is less volatile,[21] whereas the reaction with CO takes place in a solution saturated with the reacting ligand.

Other studies

The thermogravimetric curve (TG) of **4** shows that it loses 39.0% of its weight in two consecutive steps up to 410°C. The corresponding mass losses indicate clearly that ethylene (6.8%, Calc. 6.2%) is evolved during the first step, whereas removal of 4-MeQNO (32.2%, Calc. 31.6%) is accomplished during the second step. The percentage of the residue left (61.2%) is very close to the calculated one (62.2%), if it is considered to be $\{PtOCl_2\}$.

Platinum complexes may undergo one-electron reversible reduction if they contain ligands capable of supporting a delocalized negative charge.[22] In most cases, however, the reduction is an irreversible two-electron process producing metallic platinum.[23] In order to find out whether the quinoline N-oxide ligands are capable of supporting a delocalized negative charge, we studied **4** by cyclic voltammetry. However, our expectations proved wrong since reduction of **4** dichloromethane/$(C_4H_9)_4NPF_6$ at a scan rate of 200 mV s^{-1} discloses one irreversible reduction wave at $E^\circ = -1.20$ V, leading to decomposition products (Fig. 4).

Abstract—The thiocyanate complexes $Ln(NCS)_3 \cdot (THF)_4$ (Ln = Nd, Eu and Er) have been prepared and their structure was studied in the solid state by X-ray diffractometric methods. They crystallize in the monoclinic space group $P2_1/a$ with a ranging from 19.279(9) for Nd to 18.980(9) Å for Er; b, c and β have almost constant values: $b = 8.11 \pm 0.01$ Å, $c = 17.68 \pm 0.05$ Å and $\beta = 111.0 \pm 0.03°$. A peculiar feature of these complexes is the octa-coordination, the dimeric nature and the fact that in the molecule the NCS groups are coordinated as mono (Ln—NCS) and bidentate (Ln—NCS—LN) ligands. The structural units assume an almost undistorted square antiprismatic coordination geometry; they are linked through bridges of NCS groups. The Ln···S distances range from 3.10 (Nd) to 3.26 Å (Er); these values correspond to rather weak bond interactions, but are unambiguously recognized as coordinating values in geometrical terms.

The ability of the thiocyanate ion to form complexes with transition elements in a mono (M—NCS, M—SCN) or bidentate (M—NCS—M) ligation mode has been extensively investigated.[1] In the majority of reported complexes the NCS group is coordinated to the metal as a monodentate ligand. Examples of bridging thiocyanate are rather rare[2] and the case in which both ligation modes co-exist in the same molecule is confined to the cobalt compound $Co(NCS)_2 \cdot PPQ$.‡[3] To our knowledge no examples of this type are hitherto known for the f elements.

This paper reports the crystal and molecular structure of the homologous complexes $Ln(NCS)_3(THF)_4$ with Ln = Nd, Eu and Er, in which the unusual dual behaviour of the NCS ligand is found. This study was carried out with the aim of checking the effect of the lanthanide contraction on the ligation mode of the NCS group and understanding the influence of the ionic dimension on the coordination arrangement in the solid state.

EXPERIMENTAL

The reactions, manipulation and preparation of the samples for the X-ray data collection were carried out under nitrogen in a glove-box (oxygen

† On sabbatical leave from Dipartimento di Chimica, Università di Napoli, Italy.
‡ PPQ = 2-(2′-pyridyl)-3-(N-2-picolylimido)-4-oxo-1,2,3,4-tetrahydroquinoline.

content 5 ppm, water content 1 ppm). Anhydrous $LnCl_3$ were prepared according to reported methods.[4] Commercially available potassium thiocyanate was purified according to ref. 5. The solvents (THF and pentane) were purified by distillation from lithium aluminium hydride and potassium-benzophenone under nitrogen. The analyses of the metals were performed according to ref. 6.

Synthesis of the complexes $Ln(NCS)_3 \cdot (THF)_4$

In a typical reaction to $LnCl_3$ (2.8 mmol) suspended in THF (50 cm^3) KNCS (8.4 mmol) was added. The mixture was stirred for 1 day at room temperature and successively refluxed for 3 h in an inert atmosphere. The resulting solution was centrifuged, the solid (KCl) removed and the crude product isolated by evaporation of the solvent under reduced pressure. The $Ln(NCS)_3 \cdot (THF)_4$ complexes were recrystallized by adding pentane to their THF solutions. Found: Nd, 23.1; Eu, 24.5; Gd, 25.1; Er, 26.2. Calc. for $C_{19}H_{32}LnN_3O_4S_3$: Nd, 23.8; Eu, 24.7; Gd, 25.4; Er, 26.5%.

Crystallography: crystal data

Single crystals of the complexes $Er(NCS)_3(THF)_4$, $Eu(NCS)_3(THF)_4$ and $Nd(NCS)_3(THF)_4$ were sealed under nitrogen in Lindeman capillaries. Suitable crystals for X-ray analysis were mounted on a Philips PW-100 computer-controlled four-circle diffractometer with a graphite monochromator. Standard centring and auto-indexing procedures indicated the primitive monoclinic lattices $P2_1/a$ for **A**, **B** and **C**. The orientation matrix and accurate unit cell dimensions were determined from a least-squares fit of 25 symmetry-related reflections. Intensity data were collected at 25° using the θ–2θ scan method; two standard reflections, monitored every 150 reflection measurements, fluctuated within 2–3% of their mean value. The intensities were corrected for Lorentz and polarization effects but not for absorption owing to the relatively low values of μ. Crystal data and details of intensity collection are reported in Table 1.

Solution and refinement of the structures

The positions of the lanthanide atoms were determined from three-dimensional Patterson syntheses. The light atoms were located from subsequent Fourier maps. The positions of the hydrogen atoms were geometrically calculated, assigned isotropic thermal parameters [with $U(H) = 1.2\ U_{eq}(C)$] and allowed to ride on their parent carbon atom. They were included in the final calculations but not refined. Anisotropic thermal parameters were used for all the non-hydrogen atoms. Blocked-cascade least-squares refinements were used: they converged to the conventional R indexes reported in Table 1. A unitary weighting scheme was used. Scattering

factors for the atoms were taken from Cromer and Weber;[7] the scattering factors for the lanthanide atoms were corrected for the real and imaginary parts of anomalous dispersion using Cromer's values.[8] All computations were carried out on a Cyber-76 computer using the SHELX-76 program.[9] Full details of the analysis are available in the additional material deposited with the Cambridge Crystallographic Data Centre.

DISCUSSION

By reacting anhydrous lanthanide(III) chlorides with potassium thiocyanate at room temperature according to the equation:

$$LnCl_3 + 3KNCS \xrightarrow[\text{room temperature}]{THF} Ln(NCS)_3 \cdot (THF)_4 + 3KCl,$$

two homologous series of compounds have been obtained. We reported here the results concerning the first series, which includes the lanthanide elements to erbium; crystals suitable for X-ray analysis could be obtained only for Ln ranging from Nd to Er. Preliminary crystallographic data showed that all these crystals belong to the monoclinic space group $P2_1/a$ and have almost constant values of the unit cell parameters b (8.11 ± 0.01 Å), c (17.68 ± 0.05 Å) and β (111.0 ± 0.03°), while a decreases linearly with atomic number from 19.279 for Ln = Nd to 18.980 Å for Ln = Er (Table 2). On account of this we restricted the full crystallographic analysis to only the three complexes having Ln = Nd, Eu and Er. The structural features of these compounds are basically determined by two distinctive perculiarities; the expected lanthanide contraction and the quite rare behaviour of NCS groups as bidentate and monodentate ligands in the same molecule.

The molecular structures can be described in terms of slightly distorted square antiprismatic octa-coordination.[10]

Except for the eighth coordination site, almost in the theoretical direction and occupied by the sulphur atom of one of the NCS groups of the adjacent centrosymmetrical unit, all the stereochemical parameters correspond to predictable values for such geometry; we report for instance the α angles[11] between each metal–ligand bond with the pseudo-eight-fold inversion axis of the molecular unit (Table 3).*

These values can be considered to be in good agreement with the theoretical value of 59.26° for octa (unidentate ligand) complexes,[10] if one realistically takes into account the approximate location of the eight-fold inversion axis and possible distortions due to steric constraints between the non-identical eight ligands. Figure 1 shows a projection of the resulting square antiprism as viewed parallel and normal to the eight-fold inversion axis.

The metal–ligand distances decrease regularly in the order Nd to Er (Table 4), according to the

Table 3. α angle (°) made by the metal–ligand bond with the pseudo-eight-fold inversion axis passing through the metal atom Ln

Bond	Er	Eu	Nd

Ln—O(2)	48.9	51.1	51.1
Ln—O(3)	61.3	61.2	61.6
Ln—O(4)	69.7	67.1	66.0
Ln—S(1)′	52.7	54.1	54.8

* This axis refers to the eight atoms directly bonded to the metal atom.

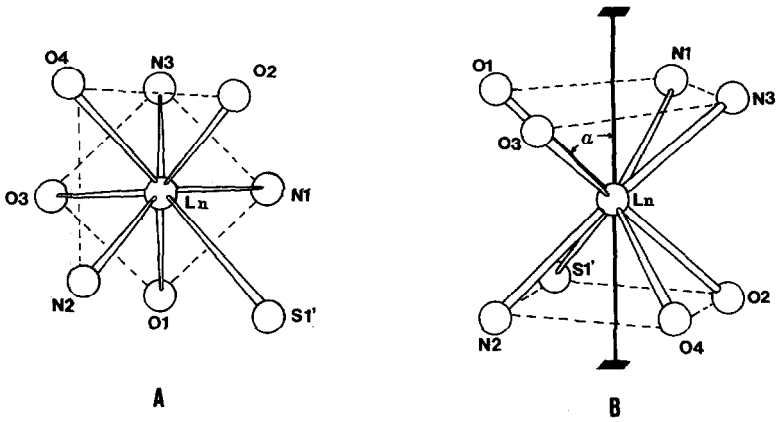

Fig. 1. Schematic perspective of the square antiprism as viewed: (A) parallel and (B) normal to the pseudo-eight-fold inversion axis; only the atoms directly bonded to Ln are drawn.

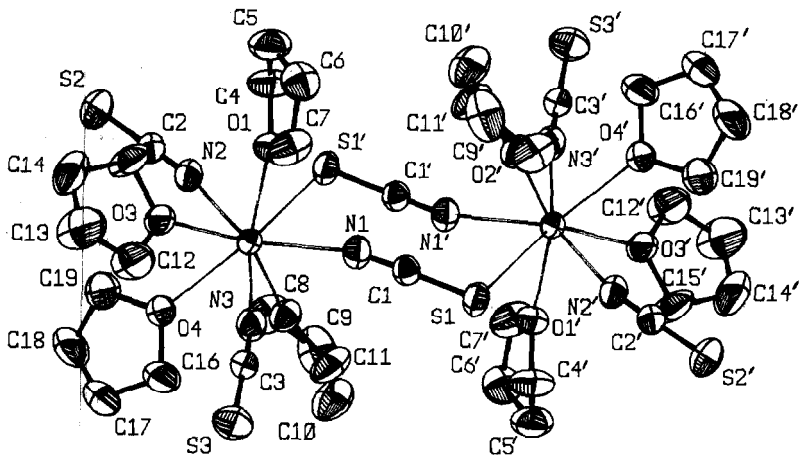

Fig. 2. Projection of the dimer of $Ln(NCS)_3(THF)_4$ down the *b*-axis. The atoms are labelled according to Table 2.

lanthanide contraction. Moreover, the mean variation of these distances (0.054 from Nd to Eu and 0.062 Å from Eu to Er) is almost the same as the corresponding variation of the 3+ ionic radium of the element (0.045 and 0.062 Å, respectively).[12] The large values of Ln—O(3) and Ln—O(4) are likely due to repulsive interactions between bulky groups in the more over-crowded regions of the coordination sphere of the metal; however, they could also be an indication of some amount of *trans* influence of the S-bonded NCS group.[13]

The eighth coordination site is the result of an association through NCS bridges of two $Ln(NCS)_3(THF)_4$ units located about inversion centres (Fig. 2). The metal–metal vector of the dimers is nearly parallel to the *c*-axis. The metal–sulphur distances range from 3.28 for Er to 3.10 Å for Nd; albeit remarkably larger than theoretically evaluable bond lengths, i.e. *ca* 2.84 for Er and up to 2.96 Å for Nd, respectively.* We believe that they can be interpreted with confidence as bond distances. As a matter of fact, these data are in evident contrast with the increasing ionic radius of the metal for Er to Nd and can only be explained in terms of stronger and stronger metal–sulphur bond interactions in the same order. Therefore, the shortening of this bond from 3.28 for Er to 3.10 Å for Nd arises from a gradually expanding coordination sphere of the metal and thus from less and

*These values are calculated from the relation $r_{AB} = r_A + r_B - 0.09D_{AB}$, where r_A and r_B are the ionic radii of the bonded elements and D_{AB} the differences in their electronegativity. The *r* values are taken from Shannon[12] and the D_{AB} values from Allred-Rochow.[14]

less hindered insertion of the sulphur atom therein. Moreover, this analysis shows that the value of *ca* 3.10 Å seems to be a lower limit for the metal–sulphur bond in these complexes; it almost does not change from Eu to Nd (Table 3), in spite of the relatively large increase of the metal–ligand distances which would likely produce unbearable molecular constraints within the dimers. This fact probably explains the instability of the derivatives of Ce and Pr. On the other hand, the value of *ca* 3.28 Å for Er seems to be the upper limit; beyond this value the metal–sulphur bond would be too weak to allow an eight-coordination, so that the next $Ln(NCS)_3 \cdot (THF)_4$ complexes change their molecular configuration.[15] It is to be noted that data on Ln···S bond distances are quite rare; so far we know that they are mostly confined to lanthanum(III) complexes.[16,17] The other conformational parameters of the structural unit are quite normal and do not need any particular comment (see Table 4).

Figure 3 shows the mode of packing which is almost identical for all these complexes as viewed down the *b*-axis. In the *a*-direction the packing is mainly controlled by intermolecular contact distances about two-fold screw axes at (1/4, *y*, 0). These distances are supposed to decrease with increasing metal–ligand bond lengths from Er to Nd, but are instead preserved at constant values by increasing the *a*-axis in an almost equal amount (Table 5). In the *c*-direction the packing is characterized by a stacking of the outermost THF centrosymmetrical units [O(3), C(12), C(14), C(15)], located at *ca* 1/4 and 3/4 of *b* between inversion centres at distances of *ca* 4.0 Å. To a small increase in the metal–ligand distances follows a small slippage of the THF units amidst one another, without appreciable effects on the dimensions of *b* and *c*.

Abstract—Single crystals of $(Cp_2HoCl)_2$ ($Cp = C_5H_5$) were grown from CH_2Cl_2 solution and studied by X-ray crystallography. The molecule of the title compound is a centrosymmetric dimer with two chloride atoms bridging. The holmium atom is coordinated by two Cp ring centroids and two chloride atoms to form a distorted tetrahedral geometry. The average Ho—Cl and Ho—C(Cp) bond distances are 2.674(5) and 2.60(2) Å, respectively. A comparison of some significant structural parameters along the structural series Cp_2MCl_2 (M = Sc, Ho, Er and Yb) with metal ionic radii was made. The magnetic susceptibility of the title compound has been measured in the range 74–300 K and shows linear Curie–Weiss behaviour with $C = 14.3$, $\theta = 1.2$ K and $\mu_{eff} = 10.77$ B.M. There is no evidence of any magnetic interaction between metal centres.

Recently, studies on the magnetic properties of coordination and organometallic compounds of the *d*-block elements have been widely reported.[1] The magnetic properties of organolanthanide polynuclear compounds, however, are rarely studied.[2–4] Compounds of the type Cp_2LnCl would appear to be relevant to these investigations because of their polymeric nature.[3–11] Recent studies have shown that the crystal structures of the Cp_2LnCl-type compounds are dependent on both the conditions of crystal growth and metallic ionic radii.[5,10–12] We are interested in the influence of the conditions of crystal growth and metallic ionic radii on the crystal structures of the Cp_2LnCl-type compounds and their magnetic properties. In order to investigate the crystal structure and magnetic properties of the Cp_2HoCl compound, we herein report the X-ray crystal structure and magnetic properties of $(Cp_2HoCl)_2$ by growing single crystals of the compound from CH_2Cl_2 solution. At the same time we discuss the comparison of some significant structural parameters along the structural series Cp_2LnCl (Ln = Sc, Ho, Er and Yb).

RESULTS AND DISCUSSION

Description and discussion of the crystal structure

The crystal structure of the title compound consists of discrete dimers. The molecular structure of the compound $(Cp_2HoCl)_2$ is shown in Fig. 1. Selected bond lengths and angles are listed in Table 1. The molecular structure contains two holmium atoms, each with two η^5-bonded Cp groups, which are centrosymmetrically bridged by two chlorine atoms. The Ho—Cl bond lengths are 2.676(4) and 2.671(5) Å, respectively, averaging 2.674(5) Å. The Cp rings are almost symmetrically bonded to the holmium atoms with Ho—C bond distances ranging from 2.53(3) to 2.67(3) Å and averaging 2.60(5) Å. The bridging unit Ho_2Cl_2 is almost square, with Ho—Cl—Ho and Cl—Ho—Cl angles of 97.9(2)° and 82.1(1)°, respectively.

The coordination of the holmium atom in this

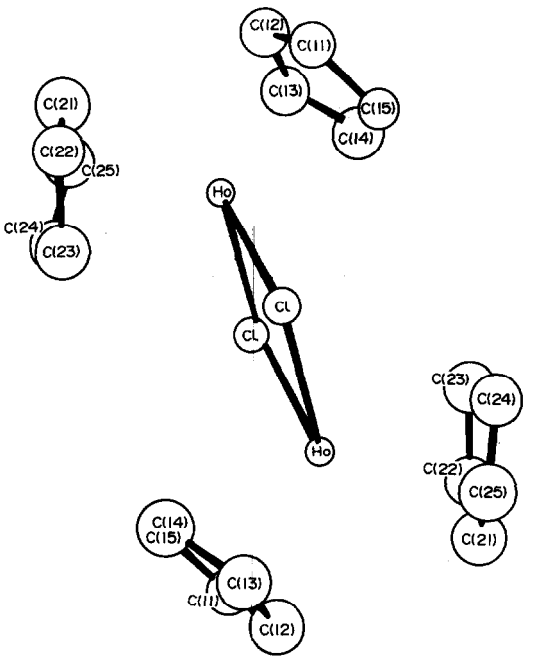

Fig. 1. The molecular structure of the compound $(Cp_2HoCl)_2$ with hydrogen atoms omitted for clarity.

structure can be described as slightly distorted tetrahedral, with the centroids of the two Cp rings and two chlorine atoms forming the apices of the tetrahedron. The vectors from the centroid of each Cp ring to the holmium atoms and from either chlorine to the holmium atoms form two angles (108.5° and 112.3°; 106.4° and 107.9°), which are similar to those reported for the corresponding dimeric compound $[(MeCp)_2YbCl]_2$.[7] The vectors from the centre of either Cp ring to the holmium form an angle of 129.3°, which is similar to that found in the compound $(Cp_2YbCl)_2$ (130.1°),[12] but 2.6° larger than that in compound $(MeCp_2YbCl)_2$. This deviation can be attributed to the difference in the organic ligands. Due to the large steric volume of the MeCp group relative to the Cp group, the steric repulsion existing between two bent metallocene Cp_2Yb subunits should be greater than that in the corresponding compounds $(Cp_2HoCl)_2$ and $(Cp_2YbCl)_2$, thus leading to shortening of the Cent—Yb—Cent angle.

The very fact that there are 15 lanthanide elements which have such a close mutual resemblance means that we can study fairly closely the influence of metal ionic radius on crystal structure. Table 2 compares some significant structural parameters along the structural series $(Cp_2LnCl)_2$ (Ln = Ho, Er, Yb and Sc). It is interesting to note that the bond lengths of Ln—C and Ln—Cl and non-bonded lengths of Cl—Cl and Ln—Ln present a decreasing trend as metal ionic radii decrease. This result is in agreement with the effect of the "lanthanide contraction". In view of the data in

Table 2, however, we found that the angles of Ln—Cl—Ln and Cl—Ln—Cl are similar, despite the different metal ionic radius.

A recent study has shown that the compound $(Cp_2YbCl)_2$ can crystallize as in both its Sc ($Z = 6$)[6] and Er ($Z = 2$)[5] analogues (the former obtained by sublimation, the latter from solution). In order to investigate the influence of conditions of crystal growth on crystal structure of the compound Cp_2HoCl, we have grown single crystals of this compound from CH_2Cl_2 solution. However, the single-crystal diffraction study indicates that Cp_2HoCl is isostructural to the compound Cp_2ErCl.[5] A comparison of the conditions of crystal growth and some important crystallographic parameters (Table 2) revealed also that although the conditions of crystal growth are different, the structures of Ho, Er, Yb and Sc compounds are all dimeric, whereas the structures of Gd and Dy compounds are tetrameric and one-dimensional infinite polymeric, respectively.[10,11] The main variable factor between these compounds is the metal ionic radii. Therefore, we postulated that this result is due to "lanthanide contraction", Gd^{3+} and Dy^{3+} ions having larger ionic radii than Ho^{3+}, Er^{3+} and Yb^{3+} ions; Gd and Dy compounds should have much greater steric and coordination unsaturation than Ho, Er and Yb compounds, thus leading to the polymeric structures. In view of the above result, we deduce that the structures of Cp_2LnCl-type compounds with larger metal ionic radii than the Gd^{3+} ion may be polymeric.

Investigation of the magnetic properties of the compound $(Cp_2HoCl)_2$

The magnetic susceptibility of the title compound as a function of temperature is shown in Fig. 2. The

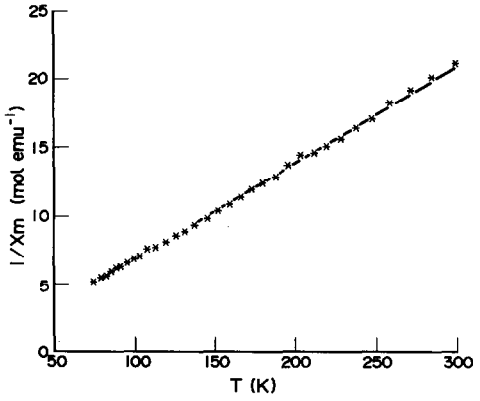

Fig. 2. Inverse molar susceptibility vs temperature for $(Cp_2HoCl)_2$ in the range 74–300 K. The straight line is a least-squares fit to the data

straight line is a least-squares fit to the data. The compound exhibits simple Curie–Weiss behaviour, with $\chi = C/T-\theta$ ($C = 14.3$ and $\theta = 1.2$ K, derived from the straight line). The corresponding value of μ_{eff}, calculated from the slope, is 10.77 B.M. This value is close to those reported for the free ion (10.58 B.M.) and room-temperature magnetic moment (10.3 B.M.) of $(Cp_2HoCl)_2$.[13,14] This result is consistent with those found in the compounds $(Cp_2LnBr)_2$ (Ln = Dy, Er), $(Cp_3Yb)_2C_4H_4N_2$ and $(Cp_2YbX)_2$ (X = Cl, Br).[2-4] Thus, the variable-temperature magnetic susceptibility (74–300 K) of the compound $(Cp_2HoCl)_2$ shows no magnetic interaction between metal centres.

EXPERIMENTAL

Preparation

Due to the extreme sensitivity of the compound to air and moisture, all reactions and handling were facilitated using Schlenk techniques or in a glove-box under dried oxygen-free argon. Tetrahydrofuran was dried over anhydrous $MgSO_4$ and refluxed over sodium-benzophenone ketyl. CH_2Cl_2 was dried and distilled over $LiAlH_4$. All solvents were distilled immediately prior to use.

Anhydrous $HoCl_3$ was prepared according to the literature method.[15] The title compound was pro-

duced by the room temperature reaction of a 1:2:5 molar ratio of $HoCl_3$, Na and C_5H_6 in tetrahydrofuran for 24 h and purified by vacuum sublimation at 200°C/10^{-3} Torr. The yellow sublimate was dissolved in CH_2Cl_2 at room temperature. Crystals suitable for the X-ray diffraction experiment were grown by slow cooling of the saturated CH_2Cl_2 solution.

Structure investigation

Intensities for structure determination were collected on an Enraf–Nonius CAD4 automatic diffractometer using graphite monochromated Mo-K_α radiation at room temperature. Lattice parameters were determined by the least-squares refinement of the setting angles of 25 computer-centred reflections in the range $10° \leqslant \theta \leqslant 15°$. Three standard reflections were monitored every 200 reflections to check crystal stability. No decrease in intensity during data collection was observed. A summary of crystallographic data is listed in Table 3. The calculations were performed on a PDP 11/44 computer (Digital Equipment Corporation) using the SDP programme system. Scattering factors for neutral atoms were taken from the international Tables for crystallography.[16]

The intensity data were corrected for Lorentz–polarization and absorption. The structure was solved by direct methods and refined by full-matrix least-squares techniques, converged to a conventional R factor of 0.055 using 1123 reflections with $I \geqslant 3\sigma(I)$. The positions of the hydrogen atoms were calculated with a C—H bond length of 0.95 Å. In the final calculations the hydrogen atoms ride on the external bisectors of the C—C—C angles. Non-hydrogen atoms were refined using anisotropic temperature factors and hydrogen atoms using isotropic temperature factors. Tables of atomic coordinates, thermal parameters, bond lengths and angles have been deposited at the Cambridge Crystallographic Data Center.

Magnetic susceptibility measurements

Variable-temperature (74–300 K) magnetic susceptibility measurements of crystal samples of the title compound (weighted 0.81 mg) were carried out on a CAHN-2000 Faraday balance with $Ni(en)_3S_2O_3$ as a standard[17] at 6000 G magnetic field. The resulting susceptibility was corrected for underlying diamagnetism.[18]

Acknowledgements—We would like to thank Dr Yunjiang Liu for experimental assistance with the magnetic susceptibility. This research was supported by the National Natural Science Foundation.

FIRST ELECTROSYNTHESIS OF TRANSITION METAL PEROXOFLUORO COMPLEXES. SYNTHESIS, CHARACTERIZATION AND REACTIVITY OF SOME PEROXOFLUORO COMPLEXES

M. C. CHAKRAVORTI,* SOMENATH GANGULY, G. V. B. SUBRAHMANYAM and MANISH BHATTACHARJEE

Department of Chemistry, Indian Institute of Technology, Kharagpur 721 302, India

(*Received* 8 *October* 1992; *accepted* 15 *October* 1992)

Abstract—Peroxofluoro complexes of the transition metals, viz. V, Nb, Ta, Mo and W, have been synthesized electrochemically using the sacrificial metal anodes in the presence of hydrogen peroxide (15%) and hydrofluoric acid (10%). These complexes have also been prepared by the dissolution of the metal powders in a mixture of hydrogen peroxide and hydrofluoric acid. While the monoperoxo complexes are formed at lower pH, higher pH is conducive to the formation of diperoxo complexes. The compounds have been characterized by elemental analysis and vibrational spectral studies. $K_2[MoO(O_2)F_4]\cdot H_2O$ and $K_2[WO(O_2)F_4]\cdot H_2O$ can oxidize triphenylphosphine to triphenylphosphine oxide in high yield.

Previous communications from this laboratory reported that many transition metals when used as anodes readily go into solution in the presence of aqueous hydrofluoric acid or hydrogen peroxide, giving rise to fluoro and peroxo complexes.[1–3] It is expected that mixed-ligand peroxofluoro complexes may result from an electrolyte containing a mixture of the two and different species may be isolated by the appropriate adjustment of pH. The importance of the latter in the synthesis of peroxo complexes has already been emphasized in the literature.[4,5] Fluoride is known to stabilize transition metal peroxo complexes[6,7] and a number of peroxofluoro complexes of various metals, viz. $[Ti(O_2)F_5]^{3-}$,[6] $[Ti(O_2)_2F_2]^{2-}$,[8] $[VO(O_2)_2F]^{2-}$,[9] $[M(O_2)F_5]^{2-}$,[6] $[M(O_2)_2F_4]^{3-}$ (M = Nb or Ta),[10] $[MO(O_2)F_4]^{2-}$ (M = Mo or W),[6] $[MoO(O_2)_2F_2]^{2-}$,[11] etc., have been prepared. Some of their structures have been studied by X-ray spectroscopy. Peroxo complexes are of considerable interest because of their involvement in catalytic and biological oxidation reactions.[12] The present work deals with the first electrosynthesis of peroxofluoro complexes of vanadium, niobium, tantalum, molybdenum and tungsten. A few complexes have also been synthesized chemically by dissolving the metal powders in hydrofluoric acid and hydrogen peroxide mixture. The paper also deals with the studies on the reactivity of some of the synthesized peroxofluoro complexes.

[a] Voltage was adjusted occasionally to keep the current constant.

appropriate metal rods which formed the anode were inserted through a hole. In all cases a platinum foil (1 × 1 × 0.05 cm) served as the cathode and was inserted through the second hole.

Peroxide was determined iodometrically. Fluoride was determined by titration with $Th(NO_3)_4$ after steam distillation of $H_2[SiF_6]$. Metals were analysed by standard methods. IR spectra were recorded in KBr pellets and Nujol mulls using a Perkin–Elmer (model 883) spectrophotometer. Raman spectra were recorded using a DILOR Z24 Raman spectrometer (exciting line 488.0 nm). Molar conductance measurements were performed in conductivity grade water using a direct-reading conductivity meter from Systronics, India. Magnetic susceptibility was measured by the Gouy method.

Preparation of the complexes

Method A. Electrochemical synthesis. $K_2[M(O_2)F_5]\cdot H_2O$ (M = Nb or Ta) and $K_2[MO(O_2)F_4]\cdot H_2O$ (M = Mo or W): Hydrogen peroxide (30%, 5 cm^3) and hydrofluoric acid (20%, 5 cm^3) were taken in the beaker. The metal rod and the platinum foil each joined to the platinum wire were connected to positive and negative terminals of the d.c. power supply, respectively, and were dipped in the electrolyte. The voltage was adjusted to give a current of 0.05 or 0.1 A and the electrolysis was carried out for 2–3 h. The details of the experimental conditions and E_F values are given in Table 1. The temperature of the electrolyte was maintained at 0–5°C throughout the electrolysis. Gradually the solution became yellow in the case of molybdenum, while it remained colourless in the other cases. After electrolysis the solution was filtered to remove any disintegrated metal particle. To the filtrate a solution of KF (2 g) in a minimum volume of HF (20%) was added, whereupon niobium and tantalum complexes of the type $K_2[M(O_2)F_5]\cdot H_2O$ and molybdenum and tungsten complexes of the type $K_2[MO(O_2)F_4]\cdot H_2O$ were precipitated. These were then filtered, washed with ethanol and dried over KOH. The yield is given in Table 1.

$K_2[VO(O_2)_2F]$ and $K_3[M(O_2)_2F_4]$ (M = Nb or Ta): These were prepared in a manner analogous to that described above, except that instead of adding a solution of KF the pH of the electrolysed solution was adjusted by the addition of 30% KOH solution. At pH 5 $K_2[VO(O_2)_2F]$ was precipitated out by the addition of ethanol. $K_3[M(O_2)_2F_4]$ (M = Nb or Ta) precipitated out when the pH of the electrolysed solution was raised to 7.

$K_2[MoO(O_2)_2F_2]$: The electrolyte used was a solution of KF (2 g) in H_2O_2 (30%, 10 cm^3). The details of the experimental conditions are given in Table 1. After the electrolysis the solution was filtered and the filtrate was allowed to stand for *ca* 2 h over concentrated H_2SO_4 in a desiccator, whereupon the complex precipitated out in a microcrystalline state.

Method B. Chemical method. $K_3[Ti(O_2)F_5]\cdot H_2O$, $K_2[Ti(O_2)_2F_2]$, $K_2[VO(O_2)_2F]$ and $K_2[MO(O_2)F_4]\cdot H_2O$ (M = Mo or W): Metal powder (0.25 g*) was dissolved in a mixture of hydrofluoric acid (20%, 5 cm^3) and hydrogen peroxide (30%, 5 cm^3) with stirring. The temperature of the reaction medium was maintained below 10°C. After dissolution of the metal the solution was filtered to remove any fine particles. $K_3[Ti(O_2)F_5]\cdot H_2O$, $K_2[Ti(O_2)_2F_2]$ and $K_2[VO(O_2)_2F]$ were obtained by raising the pH of the solution to 4–5, 8–9 and 4–5, respectively, by adding 30% KOH solution followed by the addition of ethanol. The other two complexes, viz. $K_2[MO(O_2)F_4]\cdot H_2O$ (M = Mo or W), were precipitated out by the addition of KF (1 g) dissolved in hydrofluoric acid (20%, 3 cm^3). All the

* In the case of titanium 1 g of metal was used.

complexes were separated and dried as described before. The yields were 60–70%.

Studies on the reactivity of $K_2[MO(O_2)F_4]\cdot H_2O$ (M = Mo *or* W)

Since the method is a general one, only a representative procedure is given. To a solution of triphenylphosphine (1 mmol) in dimethylsulphoxide (10 cm^3) was added $K_2[MO(O_2)F_4]\cdot H_2O$ (M = Mo or W) (1 mmol) and the mixture was heated under reflux for *ca* 5 h. The reaction mixture was then cooled and filtered to remove any residual inorganic compound and the filtrate was treated with water (15 cm^3), whereupon a dirty white product was precipitated. This was filtered, washed with water and recrystallized from ethanol to yield a light yellowish-white compound, identified as triphenylphosphine oxide by melting point determination (154–156°C). The IR spectrum was identical with that of an authentic sample. The yield of triphenylphosphine oxide was *ca* 80%.

RESULTS AND DISCUSSION

When electrolysis is carried out in a cell depicted as:

$$Pt(-)/H_2O_2(15\%)+HF(10\%)/M(+),$$

the metals (Mo, W, V, Nb and Ta) smoothly go into solution. The reaction at the anode may be represented by the equation:

$$M - ne \longrightarrow M^{n+},$$

where $n = 6$ for Mo and W and 5 for V, Nb and Ta (instead of M^{n+}, an oxo metal ion is more probable). This is evident from the observed electrochemical efficiency (defined as the number of moles of metal oxidized per Faraday), which is close to $1/n$ mol F^{-1} (see Table 1). The most probable reaction at the cathode is:

$$H_2O_2+2H^+ + 2e \longrightarrow 2H_2O,$$

which is proposed in view of the very high (1.77 V) standard reduction potential of the above redox system.[13] Thus, it is expected that hydrogen peroxide will be reduced at the cathode in preference to protons. This is also supported by the fact that in the above electrochemical cell the slight liberation of gas (presumably oxygen) occurs on the platinum surface in the absence of applied voltage, and the rate of gas evolution does not increase during the course of electrolysis. The metal ion liberated in solution then reacts with excess H_2O_2 and HF to produce peroxofluorometallates. At the prevailing low pH (1–2) monoperoxo species, viz. $[MO(O_2)F_4]^{2-}$ (M = Mo or W) and $[M(O_2)F_5]^{2-}$ (M = Nb or Ta), are formed which are precipitated as their potassium salts (monohydrate) on the addition of potassium fluoride dissolved in aqueous hydrofluoric acid. If the pH of the solution left after electrolysis using niobium and tantalum anode is raised to about 7 by the addition of potassium hydroxide, diperoxo species, viz. $[M(O_2)_2F_4]^{3-}$, are formed. This is in conformity with the previous observation[4,5] that a higher pH is conducive to the formation of diperoxo species. Electrolysis of a solution containing potassium fluoride and hydrogen peroxide using a molybdenum anode and a platinum cathode gives a red solution having a pH of *ca* 7, from which the diperoxo complex $K_2[MoO(O_2)_2F_2]$ can be crystallized. No diperoxo compound of tungsten could be prepared by either of the methods described above.

Finely divided titanium or vanadium readily dissolves in a mixture containing equal volumes of 20% HF and 30% H_2O_2 and the solution when treated with KOH solution gives $K_3[Ti(O_2)F_5]\cdot H_2O$ at pH 5 and $K_2[Ti(O_2)_2F_2]$ at pH 9 in the case of titanium. In the case of vanadium $K_2[VO(O_2)_2F]$ is formed at pH 4–5. Molybdenum and tungsten powder also dissolve in the HF and H_2O_2 mixture, from which the monoperoxo complexes, viz. $K_2[MO(O_2)F_4]\cdot H_2O$ (M = Mo or W), are precipitated out by the addition of KF dissolved in aqueous HF. No diperoxo complex could be prepared starting from molybdenum or tungsten powder.

Molybdenum, titanium and vanadium complexes are yellow, whereas niobium, tantalum and tungsten complexes are colourless. All the complexes are soluble in water but insoluble in common organic solvents. Molar conductivity measurements carried out in conductivity grade water agree with their electrolytic nature and also show that the compounds are fairly stable in aqueous solution. However, in acidic solution they decompose rendering it easy to determine the peroxide contents by standard iodometric methods. The results of the analysis of peroxide, fluoride and metal contents agree well with the formulae of the compounds (see Table 2). They are all diamagnetic. The hydrated compounds lose the water molecule on heating at 120°C (Table 2) and the chemical analysis of the residue is compatible with the formulation of the anhydrous compounds.

The common features of the IR and Raman spectra of all the complexes (see Table 2) are the vibrational modes due to bonded peroxide, viz. ν(O—O), ν_s(M—O_2) and ν_{as}(M—O_2), which appear in the regions 900–800 and 630–530 cm^{-1}, respectively, as observed earlier.[14] Another common fea-

[a] Values in parentheses indicate the calculated ones.
[b] Raman spectral data.

ture of the vibrational spectra is the metal–fluorine stretching mode which appears around 500 cm^{-1} and shows the presence of terminal fluoride.[15] Of course, the M—F band may also be overlapped with the symmetric (M—O_2) vibration. Apart from these bands vanadium, molybdenum and tungsten fluoroperoxo complexes show strong absorptions in the region 960–980 cm^{-1}, which can be assigned to terminal ν(M=O) vibrations. The hydrated compounds also give additional bands due to water. The vibrational spectral bands of all the complexes (except the Raman spectra of $K_2[VO(O_2)_2F]$, $K_3[Nb(O_2)_2F_4]$ and $K_3[Ta(O_2)_2F_4]$) are available in the literature.[5,6–11,14] Our data are in agreement with the reported values for the corresponding compounds.

Having achieved the synthesis of the compounds, we were interested in studying their reactivity, especially in terms of oxygen transfer reactions. It should be mentioned here that although all the complexes are reported, no information is available regarding their reactivity. A solution of triphenylphosphine in dimethylsulphoxide when heated under reflux with $K_2[MO(O_2)F_4]\cdot H_2O$ (M = Mo or W) afforded triphenylphosphine oxide in high yield (*ca* 80%).

CONCLUSION

The existing methods[16] for the synthesis of the peroxo complexes are the reactions between the oxides or oxo anions of the metal with hydrogen peroxide or the interaction of dioxygen with metal complexes. The present paper provides a general method for electrochemical as well as chemical synthesis of transition metal peroxofluoro complexes starting directly from metals. Coupled with our previous communication[3] on the synthesis of other heteroligand peroxo complexes of molybdenum and tungsten by a similar method, this opens up a completely new route to the synthesis of peroxo complexes.

Abstract—The addition of aniline ($PhNH_2 \geqslant 2$ equivalents) to the organometallic compounds $[Ti(OC_6H_3Pr^i_2\text{-}2,6)_2(\eta^2\text{-}Bu^tNCCH_2Ph)(CH_2Ph)]$, $[Ti(OC_6H_3Ph_2\text{-}2,6)_2(C_4Et_4)]$ and $[Zr(OC_6H_3Bu^t_2\text{-}2,6)_2(CH_3)_2]$ in hydrocarbon solvents leads to the formation of the mononuclear bis(phenylamido) derivatives $[M(OAr)_2(NHPh)_2]$ [M = Ti, OAr = $OC_6H_3Pr^i_2$-2,6 (**1**); M = Ti, OAr = $OC_6H_3Ph_2$-2,6 (**2**); M = Zr, OAr = $OC_6H_3Bu^t_2$-2,6 (**3**)]. Treatment of $[Hf(CH_2Ph)_4]$ first with $PhNH_2$ (4 equivalents), followed by $HOC_6H_3Bu^t_2$-2,6 (2 equivalents), leads to the related bis(phenylamido) compound **4** (M = Hf; OAr = $OC_6H_3Bu^t_2$-2,6). The two homoleptic aryl amido compounds $[M(NHC_6H_3Pr^i_2\text{-}2,6)_4]$ [M = Zr (**5**); Hf (**6**)] have also been obtained by addition of 2,6-diisopropylaniline to the tetra-benzyl compounds $[M(CH_2Ph)_4]$ (M = Zr, Hf). The addition of 4-pyrrolidinopyridine (py′) to all of the aryl amido compounds except **4** leads to elimination of 1 equivalent of aryl amine and the formation of a series of five-coordinate aryl imido derivatives of the general formula $[M(OAr)_2(=NPh)(py')_2]$ [M = Ti, OAr = $OC_6H_3Pr^i_2$-2,6 (**7**); M = Ti, OAr = $OC_6H_3Ph_2$-2,6 (**8**); M = Zr, OAr = $OC_6H_3Bu^t_2$-2,6 (**9**); and $[M(NHAr)_2(=NAr)(py')_2]$; M = Zr, Ar = $C_6H_3Pr^i_2$-2,6 (**10**); M = Hf, Ar = $C_6H_3Pr^i_2$-2,6 (**11**)]. In the case of the hafnium bis(phenylamido) complex **4**, addition of 4-pyrrolidinopyridine resulted in the formation of a simple adduct, $[Hf(OC_6H_3Bu^t_2\text{-}2,6)_2(NHPh)_2(py')]$, [**4**·py′]. (A similar adduct, [**3**·py′], was detected in the conversion of **3**–**9**.) No elimination of aniline from [**4**·py′] and formation of a phenylimido derivative were observed. Both 2,2′-bipyridine and 1,10-phenanthroline were found to eliminate aniline from compounds **1**–**3** to produce insoluble products. Addition of 3,4,7,8-tetramethyl-1,10-phenanthroline to **2**, however, yielded a soluble phenylimido derivative (**12**). The four-coordinate aryl amido compounds **2**, **3** and **5** were found to be pseudo-tetrahedral in the solid state, while the five-coordinate aryl imido compounds **7**, **9**, **10** and **11** are best described as distorted trigonal-bipyramidal with *trans*-axial pyridine ligands. In the phenanthroline derivative **12** a distorted trigonal-bipyramidal geometry exists about the titanium atom with an aryloxide oxygen atom *trans* to a phenanthroline nitrogen. The bonding of the aryl imido, aryl amido and pyridine groups is discussed. A detailed study of the reaction of a series of bis(aryl amido) complexes, $[Zr(OAr)_2(NHC_6H_4\text{-}4X)_2]$ $(\mathbf{3})^X$ (X = H, F, CH_3, OMe, Br), with a variety of pyridine ligands was undertaken. The mono-pyridine adduct $[\mathbf{3}^X \cdot py]$ is rapidly formed, followed by the slow formation of the corresponding aryl imido complex $[Zr(OAr)_2(=NHC_6H_4\text{-}4X)(py)_2]$ $[\mathbf{9}^X]$ and an equivalent of substituted aniline. Equilibrium constants for the reaction $[\mathbf{3}^X py] + py = [\mathbf{9}^X] + ArNH_2$ were measured. Formation of the aryl imido ligand was found to be favoured by a more basic pyridine ligand and by electron-withdrawing substituents on the aryl ring of the initial aryl amido group. The rate of attainment of the equilibrium situation from [**3**] and py was investigated and various pathways for the reaction are considered. X-ray crystal structures were determined for **2**, **3**, **5**, **7**, **9**, **10**, **11** and **12**.

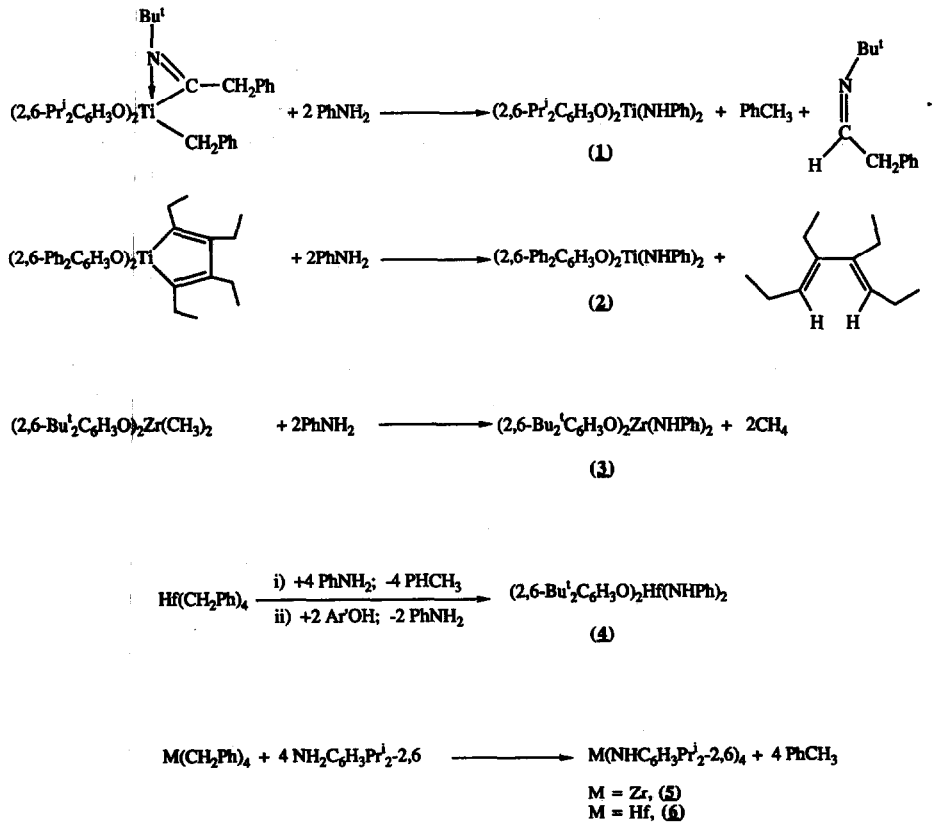
The last two decades have seen a growth both in the scope and importance of the chemistry of transition metal compounds containing multiple metal–ligand bonds.[1] In particular, M=CR$_2$,[2] M≡CR,[3] M=NR[4] and M=O[5] functional groups have been shown to be important in various stoichiometric and catalytic reactions. Until very recently a major gap in this area of chemistry had been the dearth of group 4 metal derivatives containing these functional groups. Recent work by a number of research groups has now shown that such ligands can demonstrate a high degree of reactivity when attached to these early *d*-block metals.[6–9] In particular, both titanium and zirconium imido linkages (typically generated *in situ*) have the ability to activate carbon–hydrogen bonds.[6,7] This reactivity combined with the scarcity of group 4 metal imido compounds highlights the importance of studying the structure and bonding of such compounds as well as investigating the mechanistic pathways whereby they are produced. In this paper we report on the synthesis of a series of aryl imido derivatives of titanium, zirconium and hafnium. The structure and bonding in these compounds is discussed as well as the results of a mechanistic study of their formation by ligand-induced elimination of aryl amines from bis(aryl amido) precursors.

RESULTS AND DISCUSSION

Synthesis of aryl amido compounds

Early transition metal dialkylamido compounds represent an important class of starting materials in inorganic chemistry.[10] Over the years many methods for the synthesis of such compounds have been devised with by far the most common involving the reaction of the metal halide with either an amine/base mixture or with an alkaline metal amide salt. In the area of metal aryloxide chemistry our group has demonstrated the utility of organometallic compounds as starting points for the introduction of aryloxide ligands by reaction with the parent phenol.[11] We have investigated the same synthetic method for the synthesis of aryl amido derivatives of the group 4 metals (Scheme 1). The organometallic bis(aryloxide) compounds [Ti(OC$_6$H$_3$Pr$^i_2$-2,6)$_2$(η^2-Bu^{t}NCCH$_2$Ph)(CH$_2$Ph)],[12] [Ti(OC$_6$H$_3$Ph$_2$-2,6)$_2$(C$_4$Et$_4$)][13] and [Zr(OC$_6$H$_3$Bu$^t_2$-2,6)$_2$(CH$_3$)$_2$][14,15] react slowly with aniline (≥ 2 equivalents) in hydrocarbon solvents to produce the corresponding bis(phenyl amido) compounds along with two equivalents of alkane (Scheme 1). In contrast, the hafnium bis(benzyl) compound [Hf(OC$_6$H$_3$Bu$^t_2$-2,6)$_2$(CH$_2$Ph)$_2$] failed to react



Scheme 1.

(NMR) with aniline over 2 weeks in benzene solution. However, the hafnium bis(phenyl amido) compound $[Hf(OC_6H_3Bu^t_2\text{-}2,6)_2(NHPh)_2]$ (**4**) was obtained by treating $[Hf(CH_2Ph)_4]$ first with aniline (4 equivalents) followed by 2,6-di-tert-butylphenol (2 equivalents, Scheme 1). The homoleptic aryl amido compounds $[M(NHC_6H_3Pr^i_2\text{-}2,6)_4]$ [M = Zr (**5**); Hf (**6**)] can also be obtained by stirring a mixture of 2,6-diisopropylaniline and the corresponding $[M(CH_2Ph)_4]$[16] substrate. The spectroscopic properties of compounds **1–6** are consistent with their formulation as aryl amido compounds and not aryl imido, aniline complexes. In the ^1H NMR spectra of **1–6** the positions and intensities of the aliphatic and aromatic protons appear as expected. An interesting feature of these spectra is the position of the M—N*H*Ar proton. These protons are found to resonate downfield close to the aromatic region of the spectrum and to be sensitive to the metal centre. Progressing down the group 4 triad, from titanium through zirconium to hafnium, this proton resonates to higher field, cf. δ(N*H*) values of 8.22, 7.38 and 6.63 ppm for compounds **1**, **3** and **4**, respectively. A similar upfield shift of the M—N*H* proton is observed between the zirconium compound (**5**), 6.98 δ ppm, and its hafnium analogue (**6**), 6.16 δ ppm.[11,12] An upfield shifting of α-protons is observed for the compounds $[M(OC_6H_3Bu^t_2\text{-}2,6)_2(CH_2Ph)_2]$ on moving from M = titanium, δ 3.19 ppm, to zirconium, δ 2.84 ppm, to hafnium, δ 2.65 ppm. A rationale for this behaviour involves an increase in diamagnetic shielding of adjacent nuclei by the metal centre as the number of core electrons increases.[17]

In order to gain more insight into the bonding in these aryl amido and related aryl imido (*vide infra*) derivatives, compounds **2**, **3** and **5** were subjected to single-crystal X-ray diffraction analyses. Selected bond distances and angles are contained in Tables 1–3 while ORTEP views of the molecules are shown in Figs 1–3. The relevance of the metal–ligand bond distances in these molecules is discussed below. The pair of bis(phenyl amido) compounds **2** and **3** have certain features in common. Within the pseudo-tetrahedral environment about the metal centre the O—M—O angles are larger, 120.1(1)° and 119.8(3)° for **2** and **3**, than the corresponding N—M—N angles, 105.2(1)° and 104.4(4)°. This effect is also seen in other bis(aryloxide), bis(amido) compounds of titanium, cf. O—Ti—O and N—Ti—N angles of 115.2(2)° and 98.6(2)° in $[Ti(OC_6H_2Bu^t_3\text{-}2,4,6)_2(NMe_2)_2]$,[18] 118.5(2)° and 103.8(3)° in $[Ti(OC_6H_2Bu^t_2\text{-}2,6\text{-}Ph\text{-}4)_2(NMe_2)_2]$[19] and 113.1(1)° and 98.5(1)° in $[Ti(OC_6H_3Bu^t_2\text{-}2,6)_2(NMe_2)_2]$.[19] In contrast to this behaviour the O—M—O angles are *smaller* than the N—M—N angles in related group 14 metal derivatives, cf. corresponding angles of 99.8(2)° and 111.9(3)° for $[Ge(OC_6H_3Ph_2\text{-}2,6)_2(NMe_2)_2]$ and 104.5(1)° and 109.6(2)° in $[Sn(OC_6H_3Bu^t_2\text{-}2,6)_2(NMe_2)_2]$.[20] There is also a dis-

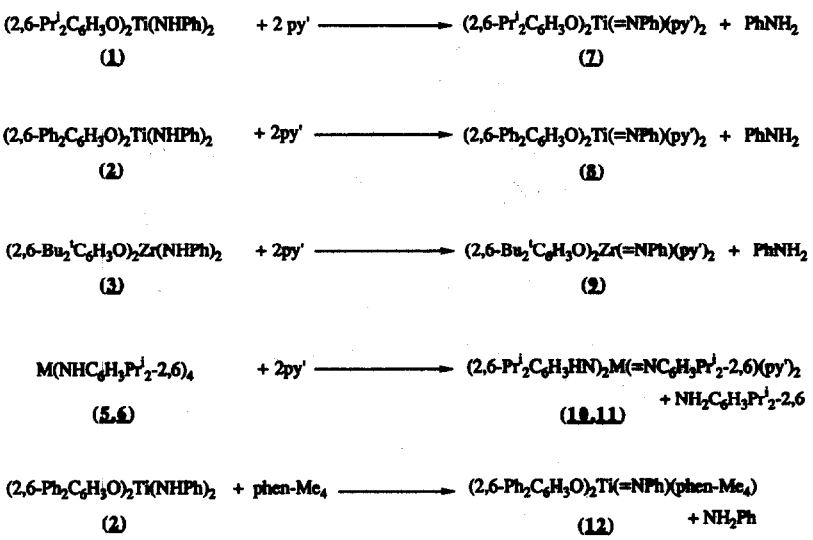
tortion away from tetrahedral geometry in the tetra(aryl amido) compound **5** with N—Zr—N angles varying from 99.7(3)° to 116.8(3)°. Another interesting feature of these molecules are the M—NH—Ar angles. In the more extensively studied, symmetrical dialkylamido derivatives of the early *d*-block metals the two M—N—C angles are typically close to 120°, rarely exceeding 130°.[10] The nitrogen atom is normally described as being sp^2-hybridized with N-*p*-to-M-*d* π-bonding occurring from a filled p_z orbital on nitrogen into any empty metal *d*-orbitals of the correct symmetry. The structural database for mono-alkyl or aryl amido compounds of the early *d*-block metals is much smaller.[10] However, there is much more variation beyond 120° for the M—NH—C angles. Large M—NH—Si angles have been reported for group 4 metal silyl amido complexes.[7] In the bis(phenyl amido) compounds **2** and **3** the M—NH—Ph angles lie in the narrow range 130–135°, while for the bulkier 2,6-diisopropylphenylamido compound **5** the angles vary from 131.9(6)° to 149.3(7)°.

Synthesis of aryl imido complexes

There is no evidence that the aryl amido compounds **1–6** undergo spontaneous proton transfer to produce aryl imido ligands and aryl amines (either free or bound). Addition of aniline ($PhNH_2$) to C_6D_6 solutions of the zirconium bis(phenyl amido) complex (**3**) did not lead to the formation of any new complexes or adducts, as judged by ^1H NMR spectroscopy. Two sharp, distinct sets of N—*H* and N—*Ph* resonances are observed for free $PhNH_2$ and the aryl amido resonances of **3** for this mixture. The addition of aniline-d_7 (excess) to a C_6D_6 solution of **3** was found to produce only small quantities of protio-aniline after 15 min at 25°C. However, monitoring the solution by ^1H NMR showed the liberation of free $C_6H_5NH_2$(NHD) over hours. Hence, exchange of free aniline and the coordinated phenyl amido groups in **3** can occur over hours at ambient temperatures. Furthermore, exchange of ND_2 (aniline) and NH (amido) protons is not rapid. Based upon the results obtained with pyridine ligands we believe this exchange occurs via an undetected five-coordinate adduct of the formula $[(ArO)_2Zr(NHPh)_2(NH_2Ph)]$; intramolecular transfer of protons within the complex then leading to exchange of initially bound phenyl amido groups and free aniline.

We have also investigated the reaction of these aryl amido compounds with pyridine ligands. In previous work we have found the base 4-pyrrolidinopyridine (py′) to be a good ligand of choice due to its high basicity and tendency to help derivatives crystallize from solution. The addition of py′ (2 equivalents) to solutions of compounds **1–3** and **5–6** was found to generate a series of aryl imido compounds with the elimination of 1 equivalent of aryl amine (Scheme 2). The displacement of aniline from the titanium compounds **1** and **2** and 2,6-diisopropylaniline from **5** and **6** was found to occur with no detectable (^1H NMR) intermediates. In the case of the zirconium bis(phenyl amido) compound (**3**) an intermediate pyridine adduct, [**3**·py′], was



Scheme 2.

detected by ^{1}H NMR. In the case of the hafnium analogue (**4**) the corresponding adduct [**4**·py'] was formed and found to be stable, no aniline being displaced even in the presence of a large excess (> 30 equivalents) of py'. The structure and reactivity of the adducts [**3**·py'] and [**4**·py'] are discussed in the mechanistic section below.

The spectroscopic properties of the aryl imido compounds **7**–**11** are consistent with their formulation. In the ^{1}H NMR spectrum of the phenyl imido compounds **7**, **8** and **9** there are the expected resonances for the aryloxide and 4-pyrrolidinopyridine ligands. The *ortho* and *meta* protons on the pyridine rings are well resolved, appearing as multiplets respectively downfield and upfield of the normal aromatic region. In the case of the mixed aryl imido, aryl amido compounds **10** and **11** the ^{1}H and ^{13}C NMR spectra show two well resolved sets of 2,6-diisopropylphenyl resonances in the ratio 2:1. Hence, exchange of aryl amido and aryl imido ligands by proton transfer between nitrogen atoms is slow on the NMR time-scale. The protons attached to the amido nitrogen atoms are observed at δ 6.90 and 6.28 ppm for **10** and **11**, respectively.

At the present time the number of structurally characterized terminal imido derivatives of the group 4 metals is small but growing steadily. Because of this scarcity of structural data we have subjected the titanium, zirconium and hafnium aryl imido compounds **7**, **9**, **10** and **11** to single-crystal X-ray diffraction analysis. Selected bond distances and angles are collected in Tables 4–7 while ORTEP drawings are shown in Figs 4–7, emphasizing the central coordination sphere. All four compounds can be seen to be structurally related, lying somewhere between trigonal-bipyramidal and square-pyramidal geometries (*vide infra*). The pyridine donor ligands are arranged mutually *trans*, consistent with the lack of diastereotopic isopropylmethyl groups in solution ^{1}H NMR spectra, either for the aryl oxide ligands in **7** or the aryl amido

ligands in **10** and **11**. In order to generate an aryl imido compound with a different geometry we investigated the reaction of bidentate ligands such as 2,2′-bipyridine and 1,10-phenanthroline with aryl amido compounds **1**–**6**. Although addition of these ligands was found to lead to the elimination of aniline, the resulting transition metal compounds were found to be only sparingly soluble. The addition of 3,4,7,8-tetramethyl-1,10-phenanthroline (phen-Me_4) to the bis(phenyl amido) complex (**2**) did yield a soluble phenyl imido complex (**12**) and it was structurally characterized (Scheme 2, Table 8, Fig. 8).

Discussion of the structure and bonding in the aryl imido compounds

In discussing the structure of five-coordinate compounds two idealized geometries, the trigonal-bipyramid (D_{3h}) and square-pyramid (C_{4v}) are typ-

ically invoked. A thorough theoretical analysis of transition metal penta-coordination has been published by Rossi and Hoffmann.[21] They have considered these two geometries and the site preference of strong/weak σ-donor ligands as well as the impact of π-donor/acceptor orbitals on the ligands. The five-coordinate aryl imido compounds **7**, **9**, **10** and **11** have a general formula, $[M(=NAr)(X)_2(py')_2]$, where X = aryl oxide or aryl amide. In Table 9 are listed the important angles about the metal centre that help describe the coordination geometry. In the titanium complex **7** the py′—Ti—py′ angle of 165.8(1)° and ArO—Ti—OAr angle of 133.2(1)° are close to the angles (180°, 120°) expected for a trigonal-bipyramidal structure with *trans*-axial py′ groups, but

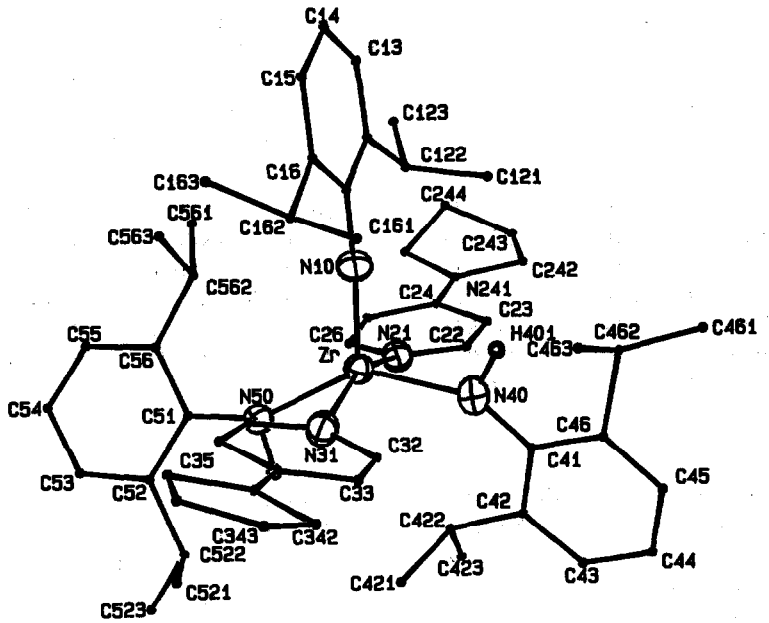

Fig. 6. ORTEP view of $[Zr(NHC_6H_3Pr^i_2\text{-}2,6)_2(=NC_6H_3Pr^i_2\text{-}2,6)(py')_2]$ (**10**).

with a definite distortion towards a square-pyramidal geometry. This distortion is much more evident in the zirconium aryl imido compound (**9**), where the PhN—Zr—py′ and PhN—Zr—OAr angles are approaching one another; 97.1(4)–108.4(3)°. In the mixed aryl amido, aryl imido compounds **10** and **11** the mutually *trans*, aryl amido ligands adopt a conformation in which the planar *ipso*-carbon–N—H propellers lie almost parallel with the M=N—Ar group. One of these groups has the N—H bond pointing towards the imido nitrogen, while the other points away. The difference in the ArN—M—NHAr angles; 100.9(1), 117.7(1)° for **10** and 103.1(1), 113.9(1)° for **11** is almost certainly a reflection of steric repulsion between these groups. We, therefore, conclude that molecules **7** and **9**–**11** adopt structures that lie between a trigonal-bipyramid (with axial py′

ligands) and a square-pyramid (with apical aryl imido group). In their analysis of the bonding in five-coordinate transition metal compounds, Rossi and Hoffman reached a number of conclusions for a d^0-metal configuration. In the case of only σ-bonding they found that the axial bonds should be weaker in a trigonal-pyramidal structure with stronger σ-donor ligands preferring equatorial positions. In the case of a square-pyramid the preferred position for a stronger σ-donor is apical. In the case of ligands containing cylindrical π-donor orbitals (cf. aryloxide groups), the preference is for an equatorial position in a trigonal-bipyramid and in the basal site of a nearly flat square-pyramid. An increase in the pyramidality of a square-pyramid beyond 90° makes the apical position the most favourable. The authors also point out "a general problem for many of the complexes under consideration is that it is difficult to determine what part of an observed conformational preference is due to the electronic effects, and what part is set by the often large steric requirements of the coordinated ligands". The geometries adopted by the molecules in Table 9 clearly are a compromise between these two forces.

Of particular importance to this work is the bonding of the aryl imido ligand to these group 4 metals and the values of the associated metal–nitrogen bond lengths. To begin this discussion a fully formed triple bond between an aryl or alkyl imido nitrogen and a metal centre would occur in a square-pyramidal compound, [(ArN)MX_4], where the aryl imido group occupied the apical site, the ligands X undergo purely σ-bonding with M and the electron configuration of the metal was d^n, $n \leqslant 2$. In this case, the *sp* hybridized imido nitrogen would be

able to form two π-bonds to M, utilizing its p_x and p_y orbitals and the d_{xz} and d_{yz} (e symmetry) metal atomic orbitals. Any electron density on the metal, d^1 and d^2, would reside in the essentially non-bonding d_{xy} metal orbital. The molecules **7** and **9–11** contain two types of ligands besides the aryl imido function. The 4-pyrrolidinopyridine groups can be considered as simple donor ligands that will interact with the metal in a σ-fashion. The aryl oxide and aryl amido ligands, however, bear cylindrical and single-faced π-donor orbitals, respectively. The aryl oxide ligands in compounds **7** and **9** possess almost linear M—O—Ar angles of 172.0(2) and 173.8(3)° for the titanium complex and 173.7(7) and 174.4(7)° for the zirconium complex. Hence, the mutually *trans*-aryl oxide oxygen atoms will compete with each other in π-donating into the empty d_{xy} orbital, as well as competing with the aryl imido nitrogen atom for the d_{xz} orbital. In the case of the compounds **10** and **11** that contain *trans*-aryl amido ligands in the basal plane, their conformation is such that their π-orbitals are both oriented perpendicular to the M—N(imido) axis. They are, therefore, both competing with each other for the empty d_{xy} orbital and are oriented such that they cannot interfere with the metal–imido triple bond. A theoretical (EHMO) analysis of the model compounds $[Zr(NH)(NH_2)_2(NH_3)_2]$ using both the structural parameters for **10** as well as idealized geometries confirmed these ideas. The HOMO was found to be a non-bonding molecular orbital localized on the amido nitrogen atoms, followed first in energy by the amido–metal–amido π-bond and then the two, almost degenerate imido–metal π-bonds (Fig. 9).

We, therefore, conclude that the geometry adopted by the five-coordinate aryl imido compounds **7** and **9–11** does not inhibit, in itself, π-bonding between the aryl imido nitrogen and the metal centre. The geometry is expected, however, to result in decreased π-bonding between the metal centre and aryloxide oxygen atoms in **7** and **9** or the aryl amido nitrogen atoms in **10** and **11**. This is born out by a comparison of the M—O and M—N bond lengths found in the aryl amido compounds **2**, **3** and **5** and the aryl imido compounds **7**, **9** and **10** (Tables 2, 3, 5, 7, 9 and 10). The Ti—OAr bond lengths are 1.789(2) and 1.786(2) Å in tetrahedral **2**, while in the aryl imido complex **7** they are 1.880(3) and 1.867(3) Å. A comparable elongation in Zr—OAr lengths is seen moving from **5** [1.893(7), 1.941(7) Å], to **9** [2.030(6), 2.047(7) Å]. The six Ar—N(amido) distances in compounds **3** and **5** lie in the narrow range 2.027(7)–2.06(1) Å, but are longer in five-coordinate **10**, 2.159(3) and 2.134(4) Å.

In Table 10 are listed the Ti—N distances for

terminal imido derivatives of titanium(IV) reported in the literature. The aryl imido compounds synthesized in this laboratory have Ti—N (imido) distances in the range 1.708(5)–1.723(4) Å. This is comparable to the distance of 1.720(4) Å reported by Roesky *et al.* for six-coordinate $[TiCl_2(py)_3\{NP(S)Ph_2\}]$. However, these distances are *ca* 0.04 Å longer than found for the tert-butyl imido complex $[TiCl_2(O{=}PPh_3)_2(NBu^t)]$, 1.672(7) Å. The shorter distance for the latter compound may reflect the electronic nature of the nitrogen substituent. It has been shown that M—OR (alkoxide) distances are slightly smaller than M—OAr (aryl oxide) bond distances for these ligands bound to the same metal centre.[22] The presence of the aryl substituent in aryl oxide ligands has been shown to decrease the amount of oxygen-*p* to metal-*d* π-donation compared to their saturated alkoxide counterparts.[23]

There are four terminal imido derivatives of zirconium, including **9** and **10**. In this case the Zr—N distances vary considerably from 1.826(4) in $[Cp_2Zr(thf)(NBu^t)]$ to 1.974(6) Å in the silyl imido complex $[(Bu^t_3SiNH)_2Zr(NSiBu^t_3)(thf)]$. In the zirconocene compound the π-donation of all of the cylindrical π-density on nitrogen would be expected to be destabilizing, leading to a formal 20-electron compound. A long Zr—NBu^t distance is, therefore, to be expected. However, this is the shortest distance so far reported. If we use the contraction observed for titanium of 0.04 Å on moving from an aryl imido ligand to a tert-butyl imido ligand then a distance of *ca* 1.8 Å would seem reasonable. In the case of the silyl imido derivative prepared by Wolczanski *et al.* the long Zr—N bond distance may be a consequence of the silicon substituent on the nitrogen. This remarkably long distance may also explain the high reactivity of this and related silyl imido bonds.[7,8]

Mechanistic study of metal–imido bond formation from bis(aryl amido) precursors

Equilibrium studies. The new group 4 metal aryl imido compounds obtained in this study are formed by the ligand-induced elimination of an aryl amine from a bis(aryl amido) precursor. This process has certain similarities to the α-hydrogen abstraction process that generates metal alkylidene functionalities.[2] In order to gain more insight into this process the elimination of aniline from the zirconium bis(phenylamido) compound (**3**) upon addition of 4-pyrrolidinopyridine (py′) was examined in detail. As noted previously, the careful addition of ⩽ 1 equivalent of py′ to a solution of **3** in C_6D_6 was found to lead to the rapid formation of an adduct, [**3**·py′], as detected by ^1H NMR spectroscopy. Both the aryloxide Bu^t groups and phenyl amido N*H* protons undergo significant chemical shift changes upon adduct formation.

Addition of further equivalents of py′ to solutions of the adduct was found (^{1}H NMR) to *slowly* (hours, at 30°C) lead to the formation of an *equilibrium mixture* of the adduct [**3** · py′] and the phenyl imido derivative **9**. As more ligand py′ was added the equilibrium was found to slowly shift in favour of the phenyl imido compound. Removal of solvent from these mixtures ($\leqslant$ 2 equivalents of py′) led to isolation of only **9** presumably due to the removal of volatile aniline from the mixture. The addition of aniline to solutions of the phenyl imido **9** again led (^{1}H NMR) to a mixture of [**3** · py′], free py′ and **9**. Analysis of various (equilibrated) mixtures of **3** plus py′ (2–30 equivalents), sometimes in the presence of added $PhNH_2$ (1–5 equivalents), yielded consistent values for an equilibrium constant derived from the expression $k = [\mathbf{9}][PhNH_2]/[\mathbf{3} \cdot py'][py']$.

This study was then extended in the following manner. (a) The use of unsubstituted pyridine (py) and 4-methyl-pyridine (py-4Me), instead of 4-pyrrolidinopyridine (py′), was found to also lead to equilibrium mixtures of adduct and phenyl imido derivatives. The equilibrium constants were again measured by NMR methods (Table 11). (b) By using various 4-substituted anilines the corresponding bis(aryl amido) compounds $\mathbf{3}^X$ (X = H, F, CH_3, OMe, Br) of zirconium were isolated. The position of equilibrium upon addition of py, py-4Me and py′ was again measured (^{1}H NMR) (Table 11).

Some conclusions can be drawn from the list of equilibrium constants obtained in this study (Table 11). The degree of formation of any given aryl imido compound increases as the basicity of the pyridine ligand is increased. This is seen on moving from pyridine to 4-methyl-pyridine and is dramatically illustrated for the highly basic 4-pyrrolidinopyridine, where the equilibrium constant (for aryl imido formation) is approximately two orders of magnitude larger. This trend is reasonable given the nature of the final aryl imido products. However, an interpretation of the effect of substituents within the aromatic ring of the bis(aryl amido) precursor is not as straightforward. It can be seen that for any given pyridine, formation of the aryl imido complex (elimination of substituted aniline) is favoured by electron-withdrawing groups (4-Br) and disfavoured by electron-donating groups (4-CH_3, 4-OCH_3). Substituents at this position will simultaneously affect a number of parts of the equilibrium. An important impact will be on the electron donating ability of the aryl amido ligands in $\mathbf{3}^X$ and the aryl imido ligand in $\mathbf{9}^X$. Electron-withdrawing substituents should have the effect of slightly increasing the Lewis acidity of the metal centre and hence increase the binding of the pyridine ligands, therefore, making formation of the aryl imido complex more favourable.

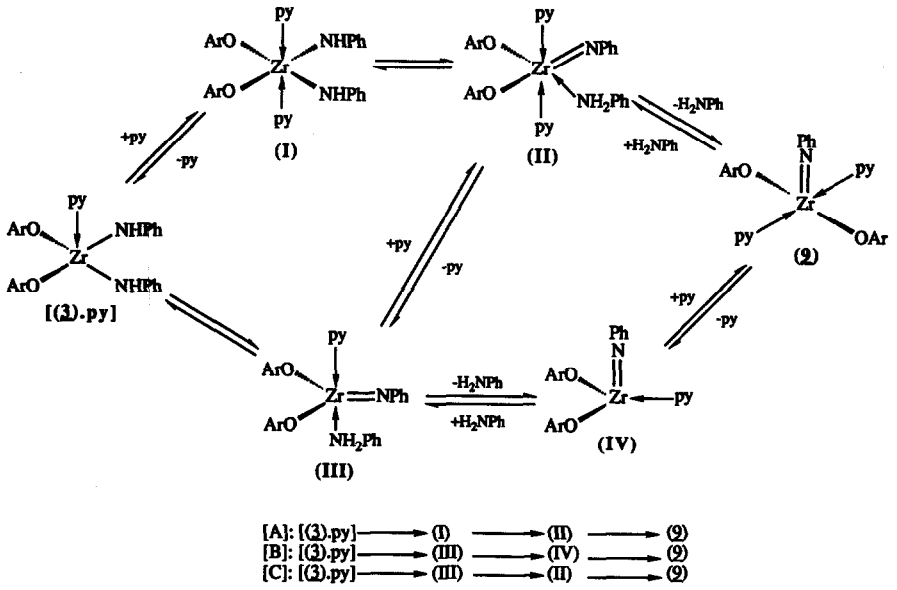
Kinetic studies. A mechanistic investigation by Wolczanski *et al.* of the elimination of $Bu^t_3SiNH_2$ from $[(Bu^t_3SiNH)_3TiCl]$ to form $[(Bu^t_3SiNH)(thf)ClTi{=}NSiBu^t_3]$ in the presence of added thf showed a zero-order dependence on the [thf]. This and other observations, along with a significant primary kinetic isotope effect of 5.9(6) at 90.4°C, were taken as indicative of hydrogen transfer and amine elimination occurring prior to association of the thf. We have considered a number of pathways for the conversion of the mono-pyridine adduct [**3** · py] into the corresponding phenyl imido compound **9** (Scheme 3). The various pathways can be broken down into two groups by focusing upon the important hydrogen transfer step whereby the zirconium imido function is generated. In the first pathway [A] the proton transfer occurs in a six-coordinate complex (**I**) formed by the addition of a second equivalent of pyridine to [**3** · py]. Proton transfer then leads to a six-coordinate phenyl imido complex (**II**), which dissociates aniline to form the product. The other two viable pathways [B] and [C] involve hydrogen transfer occurring within [**3** · py] to generate the five-coordinate phenyl imido complex (**III**). Exchange of pyridine for aniline to produce the product may then occur via a dissociative step through **IV** or an associate exchange process via **II**. The highly circuitous pathway [**3** · py] → **I** → **II** → **III** → **IV** → **9** has also been considered and ruled highly unlikely. Some comments upon the lability of the adduct [**3** · py] and the phenyl imido product **9** are necessary. As pointed out previously the addition of pyridine (py) to the bis(phenyl amido) complex **3** leads to rapid formation of [**3** · py] in solution. It is not possible at room temperature to distinguish (^{1}H NMR) between free and coordinated pyridine in these solutions. Only one set of pyridine resonances is observed at a weighted



Scheme 3.

average position. Hence, exchange of the pyridine ligand in [**3**·py] occurs rapidly on the NMR time-scale with free py in solution. A dissociative pathway for the rapid exchange seems likely given the fact that upon addition of py (< 1 equivalent) to **3** only one set of ligand resonances are observed, indicating that exchange between **3** and [**3**·py] is also rapid on the NMR time-scale. For all of the five-coordinate aryl imido ligands obtained in this study, exchange of coordinated and free pyridine ligands is slow on the ^{1}H NMR time scale. A sharp, well resolved set of coordinated pyridine ligands is observed even in the presence of a large excess of free pyridine in solution.

The fact that the bis(phenyl amido) complexes react with pyridine ligands to produce an equilibrium mixture of the corresponding phenyl imido complex and aniline and the reversibility of the reaction complicates a kinetic analysis. Initial kinetic experiments involved observing the approach to equilibrium of the pyridine adduct [**3**·py] in the presence of both excess pyridine (30 equivalents) and aniline (5 equivalents) in C_6D_6 solution by ^{1}H NMR methods. A kinetic analysis of this data using a model of two reversible first-order (or pseudo-first-order) reactions gave reasonable linear plots.[24] However, when the kinetic runs were carried out only in the presence of excess pyridine (no added aniline) the resulting data was found to lead to curvature when plotted according to a kinetic model involving a (pseudo-) first-order forward reaction and second-order reverse reaction. The addition of 30 equivalents of pyridine to a known concentration of **3** was found to lead to the more favourable equilibrium faster than when only 15 equivalents of pyridine were used. This implies that the rate of formation of the phenyl imido complex from the adduct is pyridine concentration dependent. However, the inability to fit this data to kinetic models involving reversible first- or second-order reactions is unsettling. Furthermore, the possibility that added pyridine acts as a catalyst for hydrogen (proton) transfer between aryl amido groups complicates the picture even more. In the absence of a system more amenable to kinetic study the detailed mechanism of formation of these aryl imido complexes is still uncertain.

It is interesting to speculate on the lack of observed elimination of aniline from the hafnium compound **4**. The addition of 4-pyrrolidinopyridine (1 equivalent) to solutions of **4** results in rapid and complete formation of an adduct [**4**·py′]. However, addition of even a large excess of py′ does not lead to detectable (^{1}H NMR) amounts of the corresponding hafnium phenyl imido complex. The lack of ligand induced elimination of aniline from [**4**·py′] may be kinetic or thermodynamic in origin. The fact that the hafnium 2,6-diisopropylphenylimido complex (**11**) can be obtained by elimination of 2,6-diisopropyl aniline upon addition of py′ lends support for a kinetic effect. One possible explanation would involve a strong reluctance on the part of hafnium to form a bis-pyridine intermediate, [**4**·(py)$_2$], from which aniline can be eliminated. The reason for the lack of expansion of the coordination sphere may be due to steric effects. X-ray diffraction studies of isomorphous zirconium and hafnium compounds typically show

the hafnium–ligand distances to be slightly smaller than the corresponding zirconium–ligand distances. This can be clearly seen for the isostructural aryl imido complexes **10** and **11**. The Hf—N distances in **11** are consistently shorter than the corresponding Zr—N distance by *ca* 0.02 Å. On this basis the mono-pyridine adduct [**4** · py′] is less likely to associate a second py′ on steric grounds compared to [**3** · py′].

EXPERIMENTAL

All operations were carried out under dry nitrogen, either in a Vacuum Atmospheres Drilab or by standard Schlenck techniques. Hydrocarbon solvents were dried by distillation from sodium benzophenone under nitrogen. The compounds $[M(CH_2Ph)_4]$ (M = Zr, Hf),[16] $[Ti(OC_6H_3Pr^i_2\text{-}2,6)_2(\eta^2\text{-}Bu^tNCCH_2Ph)(CH_2Ph)]$,[12] $[Ti(OC_6H_3Ph_2\text{-}2,6)_2(C_4Et_4)]$,[13] $[Zr(OC_6H_3Bu^t_2\text{-}2,6)_2(CH_2Ph)_2]$, $[Zr(OC_6H_3Bu^t_2\text{-}2,6)_2(CH_3)_2]$ and $[Hf(OC_6H_3Bu^t_2\text{-}2,6)_2(CH_2Ph)_2]$[14,15] were synthesized by previously reported methods. Pyridine (py), 4-methylpyridine (py-4Me) and 4-pyrrolidinopyridine (py′) and substituted anilines were obtained commercially (Aldrich). Pyridine and 4-methylpyridine were dried over NaOH pellets and molecular sieves prior to use. ^1H and ^{13}C NMR were recorded on a Varian Associates Gemini-200 spectrometer and selected spectroscopic data are reported. A Perkin–Elmer 1800 spectrophotometer was used to record IR spectra of compounds as mineral oil (Nujol) mulls, supported on CsI plates in the 4000–150 cm^{-1} region.

Synthesis of $[Ti(OC_6H_3Pr^i_2\text{-}2,6)_2(NHPh)_2]$ (**1**)

To a benzene (25 cm^3) solution of $[Ti(OC_6H_3Pr^i_2\text{-}2,6)_2(\eta^2\text{-}Bu^tNCCH_2Ph)(CH_2Ph)]$ (0.5 g, 0.75 mmol) was added aniline (0.14 g, 2 equivalents). The reaction was heated in a sealed flask for 24 h at 100°C. The solvent and other volatiles were removed *in vacuo* leaving the products as a dark red oil. ^1H NMR (C_6D_6, 30°C): δ 9.29 (s, N*H*Ph); 6.6–7.2 (m, phenyl protons); 3.63 [septet, C*H*$(CH_3)_2$]; 1.12 [d, CH(C*H*$_3)_2$].

Synthesis of $[Ti(OC_6H_3Ph_2\text{-}2,6)_2(NHPh)_2]$ (**2**)

To a 50 : 50 hexane/benzene (25 cm^3) solution of $[Ti(OC_6H_3Ph_2\text{-}2,6)_2(C_4Et_4)]$ (0.5 g, 0.72 mmol) was added aniline (9.13 g, 2 equivalents). After 14 h, large red crystals of the product precipitated out of solution. The product was washed with hexane and dried *in vacuo*. Found: C, 80.3; H, 5.4; N, 5.3. Calc. for $TiC_{48}H_{38}N_2O_2$: C, 79.8; H, 5.3; N, 3.9%. ^1H NMR (C_6D_6, 30°C): δ 8.22 (s, N*H*Ph); 6.44 (dd, *ortho*-NH*Ph*); 6.60 (tt, *para*-NH*Ph*); 6.77–7.42 (m, aromatics). ^{13}C NMR (C_6D_6, 30°C): δ 159.9 (*ipso*-$OC_6H_3Ph_2$-2,6); 152.3 (*ipso*-NHC_6H_5); 129.5 (*meta*-NHC_6H_5); 122.7 (*para*-NHC_6H_5); 116.9 (*ortho*-NHC_6H_5); 140.0 (*ortho*-OC_6H_5); 133.0 (*ipso*-$OC_6H_3Ph_2$-2,6). IR spectrum (Nujol mull): 3300 cm^{-1} (w) $\bar{\nu}$ (NH).

Synthesis of $[Zr(OC_6H_3Bu^t_2\text{-}2,6)_2(NHPh)_2]$ (**3**)

To a benzene (30 cm^3) solution of $[(ArO)_2Zr(CH_3)_2]$ (ArO = 2,6-di-*tert*-butylphenoxide) (1.24 g, 2.33 mmol) was added aniline (0.43 g, 2 equivalents). Stirring was carried out overnight before removal of the solvent *in vacuo*. The solid residue was recrystallized from hot toluene to yield 0.47 g of pale yellow crystals (30% yield based on zirconium). Found: C, 69.0; H, 8.4; N, 3.9. Calc. for $ZrN_2O_2C_{40}H_{54}$: C, 70.0; H, 7.9; N, 4.1%. ^1H NMR (C_6D_6, 30°C): δ 7.37 (s, Zr-*N*H); 1.47 (s, $OC_6H_3Bu^t_2$-2,6); 7.22 (d, *meta*-$OC_6H_3Bu^t_2$-2,6); 6.8–7.2 (m, aromatics). ^{13}C NMR (C_6D_6, 30°C): δ 31.7 (CMe_3); 35.2 (CMe_3); 151.0 (*ipso*-NHC_6H_5); 161.3 (*ipso*-$OC_6H_3Bu^t_2$-2,6). IR spectrum (Nujol mull): 3344 (w) and 3262 cm^{-1} (w), $\bar{\nu}$(NH).

Synthesis of $[Hf(OC_6H_3Bu^t_2\text{-}2,6)_2(NHPh)_2]$ (**4**)

To a benzene (50 cm^3) solution of $Hf(CH_2Ph)_4$ (3.07 g, 5.66 mmol) was added aniline (2.11 g, 4 equivalents). Stirring for 2 days, followed by removal of the solvent *in vacuo* left an insoluble precipitate. To a benzene (25 cm^3) suspension of this precipitate was added 2,6-di-tertbutylphenol (2.33 g, 2 equivalents) and the solution allowed to stir for 4 days. Removal of the solvent left a pale white solid which was washed with hexane to yield 2.35 g of product (54% based upon hafnium). ^1H NMR (C_6D_6, 30°C): δ 6.63 (s, N—*H*); 1.46 (s, $OC_6H_3Bu^t_2$-2,6); 7.21 (d, *meta*-$OC_6H_3Bu^t_2$-2,6); 6.8–7.1 (m, aromatics). ^{13}C NMR (C_6D_6, 30°C): δ 31.7 (CMe_3); 35.1 (CMe_3); 150.7 (*ipso*-NC_6H_5); 161.2 (*ipso*-$OC_6H_3Bu^t_2$-2,6). IR spectrum (Nujol mull): 3324 (w) and 3258 cm^{-1} (w), ν(NH).

Synthesis of $[Zr(NHC_6H_3Pr^i_2\text{-}2,6)_4]$ (**5**)

To a benzene solution (10 cm^3) of $[Zr(CH_2Ph)_4]$ (1.95 g, 4.3 mmol) was added 2,6-diisopropylaniline (3.03 g, $\geqslant$ 4 equivalents). After the reaction mixture had been stirred at room temperature for 24 h, the solvent was removed *in vacuo* to leave the crude product as a yellow solid. The product was recrystallized from cold hexane. Yields were typically 60–70%. Found: C, 72.1; H, 9.4; N, 7.4. Calc. for

$ZrN_4C_{48}H_{72}$: C, 72.4; H, 9.1; N, 7.0%. ^{1}H NMR (C_6D_6, 30°C): δ 6.98 (s, Zr—N*H*); 3.26 (septet, C*H*Me$_2$); 1.18 (d, CH*Me*$_2$). ^{13}C NMR (C_6D_6, 30°C): δ 23.8 [CH(*C*H$_3$)$_2$; 31.1 (*C*HMe$_2$)]; 148.0 (*ipso*-NH*C*$_6$H$_5$). IR spectrum (Nujol mull): 3326, 3294, 3248 and 3278 cm^{-1} (w). $\bar{\nu}$ NH bands.

Synthesis of [Hf(NHC$_6$H$_3$Pr$^i_2$-2,6)$_4$] (**6**)

To a benzene solution (10 cm^3) of Hf(CH$_2$Ph)$_4$ (0.349 g, 0.064 mmol) was added 2,6-diisopropylaniline (4.60 g, $\geqslant$ 4 equivalents). After the reaction mixture had stirred for 72 h at room temperature the solvent was removed *in vacuo* to leave the product as a pale yellow solid. The product was recrystallized from cold hexane. Yields were typically 40–50%. Found: C, 65.6; H, 8.4; N, 5.6. Calc. for $HfN_4C_{48}H_{72}$: C, 65.2; H, 8.2; N, 6.3%. ^{1}H NMR (C_6D_6, 30°C): δ 6.16 (s, Hf—N*H*); 3.32 (septet, C*H*Me$_2$); 1.18 (d, CH*Me*$_2$). ^{13}C NMR (C_6D_6, 30°C): δ 23.9 [CH(*C*H$_3$)$_2$]; 31.0 (*C*HMe$_2$); 148.0 (*ipso*-NH*C*$_6$H$_5$).

Synthesis of [Ti(OC$_6$H$_3$Pr$^i_2$-2,6)$_2$(=NPh)(py′)$_2$] (**7**)

To a benzene (25 cm^3) solution of [Ti(OC$_6$H$_3$Pr$^i_2$-2,6)$_2$(η-Bu^{t}NCCH$_2$Ph)(CH$_2$Ph)] (0.5 g, 0.75 mol) was added 4-pyrrolidinopyridine (0.22 g, 2 equivalents). This was followed by the addition of aniline (0.069 g, 1 equivalent) and the solution was allowed to stir for 14 h. The solvent was removed *in vacuo* and the resulting residue redissolved in a minimum of toluene. Slow diffusion of hexane into the toluene solution produced orange–red crystals of the desired product. Found: C, 72.4; H, 8.5; N, 8.5. Calc. for $TiC_{48}H_{63}N_5O_2$: C, 73.0; H, 8.0; N, 8.9%. ^{1}H NMR (C_6D_6, 30°C): δ 8.79 (d, *ortho*-py′); 6.69–7.35 (m, aromatics); 5.67 (d, *meta*-py′); 4.57 [septet, C*H*(CH$_3$)$_2$]; 2.31 (m, α-CH$_2$—py′); 1.13 (m, β-CH$_2$—py′); 1.49 [d, CH(C*H*$_3$)$_2$]. ^{13}C NMR (C_6D_6, 30°C): δ 161.7 (*ipso*-N*C*$_6$H$_5$); 159.8 (*ipso*-O*C*$_6$H$_3$Pr$^i_2$-2,6); 137.7 (*ortho*-O*C*$_6$H$_3$Pr$^i_2$-2,6); 152.0 (*para*-py′); 149.8 (*ortho*-py′); 106.7 (*meta*-py′); 46.2 (α-*C*H$_2$-py′); 24.5 (β-*C*H$_2$-py′); 26.4 [*C*H(CH$_3$)$_2$]; 24.1 [CH(*C*H$_3$)$_2$].

Synthesis of [Ti(OC$_6$H$_3$Ph$_2$-2,6)$_2$(=NPh)(py′)$_2$] (**8**)

(a) To a benzene (25 cm^3) solution of **2** (0.5 g, 0.69 mmol) was added 4-pyrrolidinopyridine (0.21 g, 1.38 mmol). Slow diffusion of hexane induced the formation of yellow–orange crystals of the desired product. The product was washed with hexane and dried *in vacuo*. (b) To a benzene (20 cm^3) solution of Ti(OC$_6$H$_3$Ph$_2$-2,6)$_2$(Ph$_2$) (0.34 g, 0.5 mmols) was added 2 equivalents of aniline. The red solution was allowed to stir for 36 h. The solvent was removed *in vacuo* to give [Ti(OC$_6$H$_3$Ph$_2$-2,6)(NHPh)$_2$]. The subsequent addition of 2 equivalents of 4-pyrrolidinopyridine (py′) to a benzene solution of [Ti(OC$_6$H$_3$Ph$_2$-2,6)$_2$(NHPh)$_2$] yielded, after stirring and removal of solvent, [Ti(OC$_6$H$_3$Ph$_2$-2,6)(=NPh)(py′)$_2$]. Found: C, 72.5; H, 6.1; N, 7.0. Calc. for $TiC_{60}H_{55}N_5O_2$: C, 72.8; H, 6.0; N, 7.6%. ^{1}H NMR (C_6D_6, 30°C): δ 8.06 (broad s, *ortho*-py′); 6.53–7.76 (m, aromatics); 5.48 (broad, *meta*-py′); 2.59 (m, α-CH$_2$—py′); 1.56 (β-CH$_2$—py′). ^{13}C NMR (C_6D_6, 30°C): δ 161.4 (*ipso*-N*C*$_6$H$_5$); 161.3 (*ipso*-O*C*$_6$H$_3$Ph$_2$-2,6)$_2$; 151.9 (*para*-py′); 149.8 (*ortho*-py′); 142.5 (*ortho*-O*C*$_6$H$_3$Ph$_2$-2,6); 133.6 (*ipso*-OC$_6$H$_3$*Ph*$_2$-2,6); 129.0 (*para*-N*C*$_6$H$_5$); 122.7 (*ortho*-N*C*$_6$H$_5$); 118.7 (*meta*-N*C*$_6$H$_5$); 106.8 (*meta*-py′); 46.8 (α-*C*H$_2$—py′); 25.3 (β-*C*H$_2$—py′).

Synthesis of [Zr(OC$_6$H$_3$Bu$^t_2$-2,6)$_2$(=NPh)(py′)$_2$] (**9**)

A benzene (25 cm^3) solution of Zr(OC$_6$H$_3$Bu$^t_2$-2,6)$_2$ (2.36 g, 3.46 mmol) was reacted with 4-pyrrolidinopyridine (1.02 g, 2 equivalents). After overnight stirring the solvent and generated aniline were removed *in vacuo*. Recrystallization of the crude product from hot toluene yielded 1.22 g of product (40% yield based upon zirconium). Found: C, 70.3; H, 8.5; N, 7.5. Calc. for $ZrC_{52}H_{71}O_2N_5$: C, 70.2; H, 8.0; N, 7.9%. ^{1}H NMR (C_6D_6, 30°C): δ 1.86 (s, OC$_6$H$_3$*Bu*$^t_2$-2,6); 7.65 (d, *meta*-OC$_6$*H*$_3$Bu$^t_2$-2,6). ^{13}C NMR (C_6D_6, 30°C): 32.1 (*CMe*); 36.5 (*C*Me$_3$); 160.0 (*ipso*-O*C*$_6$H$_3$Bu$^t_2$-2,6); 163.8 (*ipso*-N*C*$_6$H$_5$).

Synthesis of [Zr(HNC$_6$H$_3$Pr$^i_2$-2,6)$_2$(=NC$_6$H$_3$Pr$^i_2$-2,6)(py′)$_2$] (**10**)

To a solution of **5** (0.67 g, 0.8 mmol) in benzene (10 cm^3) was added 4-pyrrolidinopyridine (0.26 g, 1.7 mmol). The solution was allowed to stir for 9 h at room temperature. The solvent was removed *in vacuo* to give a yellow–brown solid. The solid was washed with hexane to remove the 2,6-diisopropylaniline produced in the reaction. The resulting crude product was crystallized from hot toluene. Yields were typically 50–70%. Found: C, 70.4; H, 8.6; N, 10.3. Calc. for $ZrC_{54}H_{77}N_7$: C, 70.8; H, 8.5; N, 10.7%. ^{1}H NMR (C_6D_6, 30°C): δ 6.90 (s, Zr—N*H*); 3.92 (septet, imido-C*H*Me$_2$); 3.77 (septet, amido-C*H*Me$_2$); 1.29 (d, imido–CH*Me*$_2$); 1.43 (d, amido-CH*Me*$_2$); 8.87 (d, *ortho*-py′); 5.62 (d, *meta*-py′); 2.32 (m, α-CH$_2$—py′); 1.07 (m, β-CH$_2$—py′). ^{13}C NMR (C_6D_6, 30°C): δ 24.2 [imido-CH(*C*H$_3$)$_2$]; 30.4 [amido *C*H(CH$_3$)$_2$]; 156.1 (*ipso*-N*C*$_6$H$_5$); 151.3 (*ipso*-NH*C*$_6$H$_5$). IR spectrum

(Nujol mull): four bands at 3489, 3403, 3330 and 3269 cm^{-1}.

Synthesis of [Hf(NHC$_6$H$_3$Pr$^i_2$-2,6)$_2$(=NC$_6$H$_3$Pr$^i_2$-2,6)(py′)$_2$] (**11**)

To a solution of **6** (1.12 g, 1.3 mmol) in benzene (10 cm^3) was added 4-pyrrolidinopyridine (0.39 g, 2.7 mmol). The solution was allowed to stir for 72 h at room temperature. The solvent was removed *in vacuo* to give a yellow solid. The solid was washed with hexane to remove the 2,6-diisopropylaniline produced in the reaction and the resulting crude product was recrystrallized from hot toluene. Yields were typically 40–50%. ^{1}H NMR (C_6D_6, 30°C): δ 6.28 (s, Hf—N*H*); 3.84 (septet, imido-C*H*Me$_2$); 3.78 (septet, amido-C*H*Me$_2$); 1.29 (d, imido-CH*Me*$_2$); 1.40 (d, amido-CH*Me*$_2$); 8.91 (d, *ortho*-py′); 5.62 (d, *meta*-py′); 2.30 (m, α-CH$_2$—py′); 1.03 (m, β-CH$_2$—py′). ^{13}C NMR (C_6D_6, 30°C): δ 24.2 [imido CH(*C*H$_3$)$_2$]; 24.6 [amido CH(*C*H$_3$)$_2$]; 28.8 [imido *C*H(CH$_3$)$_2$]; 30.3 [amido-*C*H(CH$_3$)$_2$]; 157.7 (*ipso*-N*C*$_6$H$_5$); 152.0 (*ipso*-NH*C*$_6$H$_5$).

Synthesis of [Ti(OC$_6$H$_3$Ph$_2$-2,6)$_2$(=NPh)(phen-Me$_4$)] (**12**)

To a benzene solution (25 cm^3) of **2** (0.25 g, 0.35 mmol) was added 3,4,7,8-tetramethyl-1,10-phenanthroline (phen-Me$_4$) (0.08 g, 1 equivalent). The reaction was heated for 14 h at 110°C in a sealed flask, then allowed to cool slowly to room temperature. The bright red crystals which formed from the solution were washed with hexane and dried *in vacuo*. Found: C, 81.5; H, 5.7; N, 4.8. Calc. for TiC$_{58}$H$_{47}$N$_3$O$_2$·C$_6$H$_6$: C, 81.4; H, 5.7; N, 4.4%. ^{1}H NMR (C_6D_6, 30°C): δ 8.78 (s, *ortho*-phen); 7.75 (d, *ortho*-OC$_6$H$_3$*Ph*$_2$-2,6); 6.53–7.44 (m, aromatics); 6.09 (d, *ortho*-NC$_6$*H*$_5$); 1.82, 1.68 (2s, C*H*$_3$).

Equilibrium studies

The equilibrium constants (Table 11) for reaction of py, py-4Me and py′ with the various bis(phenylamido) complexes **3**^{X} (X = H, F, CH$_3$, OMe, Br) to produce the corresponding imido derivatives were measured by ^{1}H NMR methods. A C_6D_6 solution of the bis(phenylamido) complex of known concentrated was reacted with various amounts of pyridine ligand. The resulting mixture was allowed to reach equilibrium and the concentration of the adduct [**3** · py] and the resulting imido complex were determined by integrations. In all cases the equilibrium constant was determined using at least two different concentrations of pyridine ligand. The results are collected in Table 11. Selected spectroscopic data for the various substituted phenyl amido derivatives are given below. Selected spectroscopic data for the zirconium imido compounds is contained in Table 12.

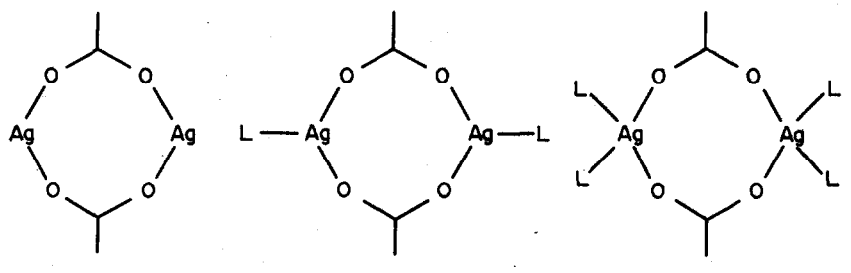
(*Received* 13 *August* 1992; *accepted* 20 *August* 1992)

Abstract—The polymeric silver(I) citrate complex $\{NH_4[Ag_2(C_6H_5O_7)(H_2O)]\}_n$ has been synthesized and its structure determined by X-ray diffraction methods and refined to $R = 0.046$ for 2520 observed reflections. This compound represents the first reported complexes of a silver(I) citrate. In the structural repeating unit there are two independent but different carboxylato(O,O′) bridged silver dimers [Ag—Ag, 2.845, 2.846(1) Å] linked into infinite linear chains by the terminal carboxyl groups of the citrato(3−) ligands. With one dimer, the Ag—O (axial) bonds are to oxygens from the sub-terminal carboxylate groups of two independent silver citrate chains. The second silver dimer also forms links with adjacent chains via axial Ag—O(carboxylate) bonds, while in the remaining axial sites are water molecules. The mean Ag—O distance is 2.377(4) Å. The result is a novel convoluted anionic chain sheet structure.

As a program of investigation in our laboratories into the mode of interaction of silver(I) with carboxylic acids, particularly the phenoxyalkanoic acids [which include a number of herbicidally active commercial members, e.g. 2,4-D (2,4-dichlorophenoxyacetic acid), 2,4,5-T (2,4,5-trichlorophenoxyacetic acid) and MCPA (4-chloro-2-methylphenoxyacetic acid)[1]], a number of structures have been determined and general structural systematics described.[2] The basic structural unit found for the majority of silver(I) carboxylates is a bis(carboxylato-O,O′) dimer, which involves each carboxyl group in a *syn–syn* mode.



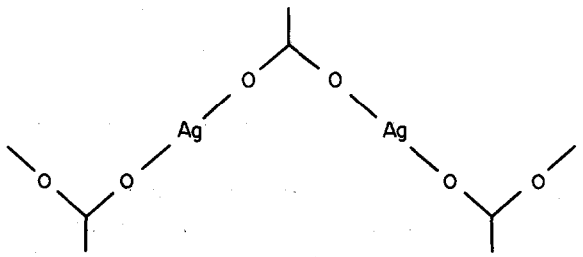
Type 1 Type 2 Type 3

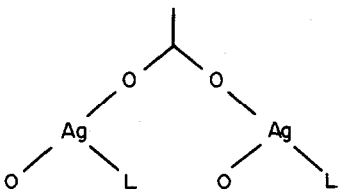
These are classified as Type 1 dimers,[2] such as is found in silver(I) benzoate,[3] silver(I) 4-hydroxy-

* Author to whom correspondence should be addressed.

benzoate hemihydrate,[3] silver(I) 2-hydroxybenzoate,[4] silver(I) 2,6-dihydroxybenzoate,[4] silver(I) pentafluorophenoxyacetate[5] and silver(I) glycylglycine nitrate.[6] Alternatively, the dimer may be extended into a tetramer [bis{bis-μ-(4-fluorophenoxyacetato-O,O′)-bis{aquasilver(I)}}][7] or a polymer (types 2 and 3) via one or two additional terminal oxygens, completing either three- or four-coordinate centres about silver. Examples of the polymeric types among the phenoxyacid complexes are silver(I) phenoxyacetate[7] and silver(I) 2-carbamoylphenoxyacetate.[2] Often terminal positions may be occupied by non-bridging oxygen donor groups, such as H_2O[7] or ClO_4^- [in silver(I) 2-chlorophenoxyacetate-silver(I) perchlorate[8]]. Among all of these types, the Ag—Ag separation ranges from 2.78 [silver(I) 3-hydroxy-2,2,3-trimethylcyclohexanecarboxylate[9]] to 3.00 Å [silver(I) 2-carbamoylphenoxyacetate[2]].

Only two examples are known which are not based on the dimer motif; both are one-dimensional polymers. The first, the isomorphous silver(I) 2,4-dichlorophenoxyacetate and silver(I) 4-chloro-2-methylphenoxyacetate polytypes,[8] form zig-zag polymer chains through *anti–syn* carboxylate linkages. The second, silver(I) pyridinebetaine nitrate, is the only known example of a *syn–syn* bridged one-dimensional polymer.[10]





However, when considering the interaction of silver(I) with hydroxy acids, little information is available,[11] with only a few stability constants reported. Generally, only weak complexes are formed, with a tendency to undergo reduction to silver in aqueous solution. This is the case with ascorbate and tartrate and provides a qualitative basis for distinguishing between tartaric and citric acid.[12] Despite the resistance of citrate to oxidation by silver(I), and the availability of silver citrate as a commercial chemical, no structure of a silver citrate compound has previously been reported. Crystals of the title compound, ammonium silver(I) citrate, $\{NH_4[Ag_2(C_6H_5O_7)(H_2O)]\}_n$, were successfully grown from an aqueous ammoniacal solution containing silver nitrate and citric acid. Preliminary qualitative tests and IR spectra indicated the presence of an ammonium ion. Subsequently, the crystal structure was determined by X-ray diffraction.

EXPERIMENTAL

Preparation

The compound was prepared by adding ammonia solution to an aqueous solution containing 2 : 1 stoichiometric amounts of silver nitrate and citric acid. Allowing the resultant solution to partially evaporate at room temperature yielded large colourlesss crystals after several weeks.

Crystal data

$C_6H_{11}Ag_2NO_8$: $Mr = 440.9$; space group $P\bar{1}$, $a = 6.435(1)$, $b = 7.610(1)$, $c = 11.744(2)$ Å, $\alpha = 71.75(1)$, $\beta = 79.74(1)$, $\gamma = 74.87(1)°$, $V = 524.3(1)$ Å^3, $Z = 2$, $D_{calc} = 2.791$ g cm^{-3}, $D_{obs} = 2.83$ g cm^{-3}, $F(000) = 424$, μ(Mo-K_α) = 37.2 cm^{-1}, $T = 298$ K.

Data collection, structure solution and refinement

X-ray diffraction data were collected from a crystal of dimensions $0.26 \times 0.20 \times 0.05$ mm mounted on an Enraf–Nonius CAD-4 diffractometer using graphite-crystal monochromatized Mo-K_α X-radiation ($\lambda = 0.71073$ Å). Of 2915 reflections collected up to $2\theta_{max} = 50°$, 2680 were unique ($R_{int} = 0.008$) while 2520 with $I > 2.5\sigma(I)$ were considered observed and used in structure refinement. Collection range was h, -8 to 8; k -10 to 10; l, 0 to 16. The data were corrected for Lorentz and polarization effects and for absorption (empirical corrections: maximum and minimum transmission factors: 1.00, 0.72). An average loss of 2.1% in the intensities of three standards monitored over the 34 h data collection period indicates negligible crystal decay. The structure was solved using direct methods (SHELXS-86[13]) and refined to residuals $R = 0.046$ and $R_w = 0.052$ ($s = 3.95$) (SHELX 76[14]) using blocked-matrix least-squares, with anisotropic thermal parameters for all non-

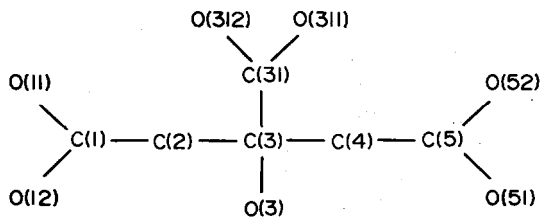
Symmetry operations: [a] $= 1-x, 1-y, 1-z$; [b] $= 1+x, y, z$; [c] $= -x, 2-y, 1-z$; [d] $= -1+x, 1+y, z$; [e] $= -1-x, 3-y, -z$; [f] $= 1+x, -1+y, z$.

hydrogen atoms. A weighting scheme with $w = [\sigma^2(F_o)+8.0\times10^{-5}(F_o)^2]^{-1}$ was used. Hydrogens were located by difference methods and were included in the refinement with coordinates refined but with isotropic U values invariant at 0.5 Å^2.

Atomic coordinates, anisotropic thermal parameters, observed and calculated structure factors and intraligand bond distances and angles have been deposited with the Editor as supplementary material; copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre. Bond distances and angles are given in Table 1. The atom numbering scheme follows the convention used for previous structures of this series determined in our laboratories.[15]



DISCUSSION

The structure determination has revealed a unique sheet polymer structure (Fig. 1), based upon two independent and different bis(carboxylato-O,O′) dimers (**1** and **2**). Both are Type 3 centrosymmetric dimers[2] with Ag—Ag′ separations of 2.845 and 2.846(1) Å for **1** and **2**, respectively. All silver centres are four-coordinate with the terminal O—Ag—O angles close to 90°. In the first dimer, silver is bonded to one terminal carboxylate group of the citrate residue [Ag(1)—O(11), 2.258(4), Ag(1)[a]—O(12). 2.246(4) Å ([a] $= 1-x, 1-y, 1-z$)], while the second silver is bonded to the other terminal carboxylate [Ag(2)—O(52), 2.242(4), Ag(2)[e]—O(51), 2.203(4) Å ([e] $= -1-x, 3-y, -z$)]. The coordination about Ag(1) is completed by bonds to two oxygens from different central citrate

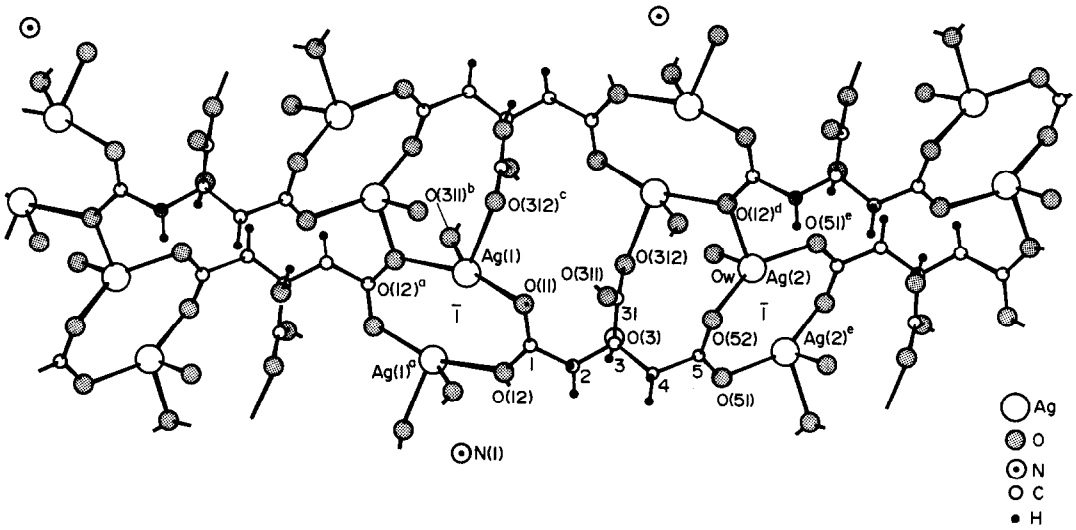


Fig. 1. The structure of $\{NH_4[Ag_2(C_6H_5O_7)(H_2O)]\}_n$. Unless otherwise indicated, atoms are carbons.

carboxylate groups [Ag—O(311)^b, 2.455(4) ($^b = 1+x, y, z$); Ag—O(312)^c, 2.398(4) Å ($^c = -x, 2-y, 1-z$)]. These form links both within and between the polymer sheets. About Ag(2), the terminal coordination comprises a bridging link to a carboxyl oxygen of an adjacent citrate residue [Ag(2)—O(12)^d, 2.486(4) ($^d = -1+x, 1+y, z$)] and a water molecule [Ag(2)—Ow, 2.731(4) Å]. The hydroxyl oxygens are not involved in any direct bonding to the metals but are hydrogen bonded to a carboxyl oxygen [O(51), 2.72(1); $-x, 2-y, -z$] and the coordinated water [2.89(1) Å; $-1-x, 3-y, -z$]. This water is in turn associated with a symmetry generated water [2.92(a) Å; $-2-x, 3-y, -z$]. The ammonium ions are also associated with the coordinated carboxyl oxygens, O(311) [2.80(1) Å; $1+x, y, z$], O(312) [2.77(1) Å; x, y, z] and O(52) [2.91(1) Å; $1+x, y, z$].

Considerable data appears in the literature on the structural systematics of citrates.[16] In the present example, the citrate residue has the extended conformation with the terminal carboxylate groups asymmetrically rotated [torsion angles: C(3)—C(2)—C(1)—O(12), $-131.1(6)°$ and C(3)—C(4)—C(5)—O(51), $+110.8(6)°$]. The central carboxylate group lies essentially perpendicular to the main citrate chain.

Abstract—Reduction of [Mo(NO)L*Cl_2] [L* = HB(3,5-$Me_2C_3HN_2)_3$] with n-butyl lithium in the presence of $SnBu^n_3Cl$ afforded the paramagnetic (17-electron) [Mo(NO)L*Cl(3,5-$Me_2C_3HN_2H$)] (**1**). Related compounds, [Mo(NO)L*XQ] (Q = pyrazole, 3,5-dimethylpyrazole, 4-bromopyrazole and 4-bromo-3,5-dimethylpyrazole; X = Cl or I), were prepared by the reduction of [Mo(NO)L*X_2] by Q (X = I) or by n-butyl lithium in the presence of Q (X = Cl). IR and EPR spectroscopic characterization of these species is reported and the X-ray structure of [Mo(NO)L*Cl(3,5-$Me_2C_3HN_2H$)]·1/2CH_2Cl_2, in which the molybdenum atom has octahedral coordination with disordered Cl and NO ligands, is described.

In an attempt to functionalize the pyrazolyl rings of the tris(3,5-dimethylpyrazolyl)borato ligand HB(3,5-$Me_2C_3HN_2)_3$ (L*) at the 4-positions we have investigated the reactions of [Mo(NO)L*Cl_2] with $LiBu^n$ and $SnBu^n_3Cl$, our intention being to introduce the $SnBu^n_3$ group onto at least one pyrazole ring in the coordinated tripodal ligand. In previous studies of the reactions of [Mo(NO)L*I_2] with organo-lithium reagents we had observed that the reduction of the metal complex rather than displacement of I^- by a carbanion was the dominant reaction.[1] This we could rationalize in terms of the reducing nature of the lithium organyl and the particularly accessible reduction potential of the molybdenum di-iodide (+0.33 V vs S.C.E. in CH_3CN) and also in terms of the apparent steric difficulty in generating a potential four-centred intermediate or transition state necessary to effect interchange of I by an organic group at the metal in the hindered {Mo(NO)L*I} entity. Indeed, treatment of [Mo(NO)L*I_2] with tolyl lithium in ether afforded [Mo(NO)L*$I_2Li(OEt_2)_2$], which contains the paramagnetic [Mo(NO)L*I_2]$^-$ centre stabilized by the $\{Li(OEt_2)_2\}^+$ fragment. However, the reduction potential of [Mo(NO)L*Cl_2] is significantly more anodic (−0.01 V vs S.C.E. in CH_3CN) than that of its iodo-analogue, and we reasoned that, because of this and the well-understood steric protection afforded by L* at the Mo centre,[2] reactivity might be diverted preferentially to the pyrazolyl rings of L*.

In this paper we describe the reactions of [Mo(NO)L*X_2] (X = Cl or I) with n-butyl lithium and $SnBu^n_3Cl$, in which partial decomposition of the nitrosyl complex with disruption of the tris(pyrazolyl)borato ligand and reduction of the basic halide

system occurred, and we report on the consequent formation of the paramagnetic 3,5-dimethylpyrazole complex [Mo(NO)L*X(3,5-$Me_2C_3HN_2H$)] (**1**). Using reductive procedures we have also prepared related complexes containing pyrazole ($C_3H_3N_2H$), 4-bromo-(4-$BrC_3H_2N_2H$) and 4-bromo-3,5-dimethylpyrazole (3,5-Me_2-4-BrC_3N_2H). These paramagnetic pyrazole complexes are closely related to the pyridine and 4,4′-bipyridyl complexes [Mo(NO)L*Cl(py)] and [Mo(NO)L*Cl(NC_5H_4—C_5H_4N)], which have been briefly described elsewhere.[3]

EXPERIMENTAL

Synthetic studies

All reactions were carried out in an atmosphere of dry nitrogen. Toluene was redistilled from sodium benzophenone before use. [Mo(NO)L*Cl_2] was prepared as described elsewhere,[4] butyl lithium was used as a 1.6 M solution in hexane and other reagents were used as received. Column chromatography was carried out using 70–230 mesh silica gel. IR spectra were recorded in KBr discs using a PE 1600 FTIR spectrometer and EPR spectra were recorded in dichloromethane using a Bruker ESP 300E instrument.

General procedure for the synthesis of [Mo(NO)L*IQ] (Q = $C_3H_3N_2H$, 4-BrC_3HN_2H, 3,5-$Me_2C_3H_2H$ *and* 3,5-Me_2-4-BrC_3N_2H)

A solution of [Mo(NO)L*I_2] (0.3 g) and pyrazole (0.09 g) or substituted pyrazole (1 : 2 mole ratio) in toluene (30 cm^3) was stirred at 80–90°C for 15–60 min, depending on the kind of pyrazole. The solution became deep green and the solvent was removed *in vacuo*, the residue being redissolved in dichloromethane. The solution was chromatographed on silica gel, using dichloromethane as an eluant, and the main green fraction was collected. The solvent was evaporated and the residue recrystallized from dichloromethane/petroleum ether (b.p. 40–60°C), affording green crystals. The yields were variable (30–50%).

General procedure for the synthesis of [Mo(NO)L*ClQ] (Q = $C_3H_3N_2H$ *and* 3,5-$Me_2C_3HN_2H$]

A solution of [Mo(NO)L*Cl_2] (0.3 g) and the appropriate pyrazole (2 moles per mole of molybdenum complex) was warmed to facilitate dissolution of the molybdenum complex and then cooled to *ca* 60°C. Butyl lithium in hexane (0.8 cm^3) was added and the reaction mixture stirred for 1 h, during which time the solution became grey–green in colour. Petroleum ether (b.p. 40–60°C) was added to precipitate salts and the solution was filtered, evaporated to dryness *in vacuo* and redissolved in the minimum volume of dichloromethane. The product was then obtained in the same way as the corresponding iodo complex and was isolated as green crystals (yields variable, 25–35%).

Crystal structure determination of [Mo(NO)L*Cl(3,5-$Me_2C_3HN_2H$)] (**1**)

A suitable crystal of the compound (a green plate sized $0.25 \times 0.35 \times 0.40$ mm) was grown from dichloromethane/petroleum ether (b.p. 60–80°C).

Crystal data. $C_{20}H_{30}N_9OBClMo \cdot 1/2CH_2Cl_2$, $M = 597.2$, monoclinic, space group $C2/c$, $a = 20.625(5)$, $b = 10.858(2)$, $c = 24.413(6)$ Å, $\beta = 96.23(2)°$, $U = 5.435(2)$ $Å^3$, $Z = 8$, $D_c = 1.46$ g cm^{-3}, $F(000) = 2.448$, graphite-monochromated Mo-K_α radiation, $\lambda = 0.71069$ Å, $\mu = 7.1$ cm^{-1}.

A total of 4000 independent reflections with $2\theta < 47°$ were collected in the Wyckoff (limited ω) scan mode. The reflection intensities were corrected for absorption, using the semi-empirical method,[5] based on 396 azimuthal scans of 11 reflections (min. and max. transmission coefficients 0.5524 and 0.5744, respectively). The structure was solved by Patterson and Fourier methods and refined by full-matrix least-squares using SHELXTLPLUS[6] programs. Difference-Fourier maps revealed a disorder in the coordination sphere of the molybdenum atom, the Cl and NO ligands mixing at each site. Their occupancy factors were refined, yielding 0.65(2) for positions A and 0.35(2) for B (of both ligands). In the final refinement these atoms were treated in isotropic approximation, while all other non-hydrogen atoms were refined with anisotropic displacement parameters. Most of the hydrogen atoms were revealed by difference-Fourier syntheses, but all of them were included in the refinement in riding model in idealized positions, with the distances C—H 0.96, N—H 0.90 and B—H (from Fourier map) 1.07 Å. The refinement of 310 variables converged at $R = 0.041$ and $R' = 0.052$ for 3298 reflections with $I > 2\sigma(I)$. The weighting scheme $w^{-1} = \sigma^2(F) + 0.002F^2$ was used; goodness of fit was 2.22. The maximum and minimum residuals in the final ΔF map were 0.56 and -0.42 e $Å^{-3}$ (around the disordered atoms).

Selected bond lengths and angles are given in Table 1. Additional data (atom coordinates, thermal parameters and remaining bond lengths and angles) are available from the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

Synthetic and spectral studies

On addition of n-butyl lithium to [Mo(NO)L*Cl_2] partially dissolved in toluene, in a mole ratio of 2 : 1, a red colour developed, but further addition of $LiBu^n$ was necessary to complete dissolution of the molybdenum chloride and generate a homogeneous deep red solution. On addition of $SnBu^n_3Cl$ the solution darkened and on work-up, which involved chromatography over silica, paramagnetic **1** was formed as green crystals. This species was characterized by elemental analysis (Table 2) and by IR and EPR spectroscopy. The yield of the species was of the order 20% and it is clear that the generation of this 17-electron 3,5-dimethylpyrazole species must occur via decomposition of the starting material, possibly via the reduced, 17-electron species [Mo(NO)L*Cl_2]$^-$. Furthermore, we had also previously observed that in reaction of [Mo(NO)L*I_2] with oxacyclohexane[7] reduction of the molybdenum species and formation of the 3,5-dimethylpyrazole adduct, [Mo(NO)L*I(3,5-$Me_2C_3HN_2H$)], occurred.

In a similar reaction with [Mo(NO)L*I_2] **1** was again formed, probably because of the inclusion of $SnBu^n_3Cl$ in the reaction mixture. We have observed on numerous occasions that iodine may be replaced by chlorine in reaction systems derived from [Mo(NO)L*I_2] in the presence of chlorinated hydrocarbons.[8] The yield of the pyrazole complexes was *ca* 20%.

In a modification of the route to these 17-electron heterocycle complexes [Mo(NO)L*Cl_2] was reduced by $LiBu^n$ in the presence of a suitable

pyrazole Q ($C_3H_3N_2H$, 3,5-$Me_2C_3HN_2H$, 4-$BrC_3H_2N_2H$), the desired complex [Mo(NO)L*ClQ] being isolated in yields varying from 25 to 35%. However, [Mo(NO)L*I_2] reacted directly with the pyrazoles Q ($C_3H_3N_2H$, 3,5-$Me_2C_3HN_2H$, 4-$BrC_3H_2N_2H$ and 4-Br-3,5-$Me_2C_3N_2H$), without the necessity of the lithium organyl, affording modest yields of the 17-electron [Mo(NO)L*IQ]. This last reaction may be compared with our earlier observations[9] that the di-iodide reacted with an excess of pyrazole Q ($C_3H_3N_2H$, 3,5-$Me_2C_3HN_2H$), affording the *cationic* 17-electron species $[Mo(NO)L^*Q_2]^+$.

The IR spectra of the new compounds are entirely consistent with our formulations. In addition to exhibiting the normal stretching modes associated with L* [e.g. ν(BH) at *ca* 2550 cm^{-1}] they show an NO stretching frequency in the range 1610–1618 cm^{-1}, which is broadly comparable to the position in the related pyridine species [Mo(NO)L*Cl(py)],[3] but significantly lower than the corresponding bis(pyrazole) species $[Mo(NO)L^*Q_2]^+$,[9] as would be expected on the grounds of the nature of the ligands and positive charge.

The complexes [Mo(NO)L*XQ] (X = Cl, Q = $C_3H_3N_2H$ and 3,5-$Me_2C_3HN_2H$; X = I, Q = $C_3H_3N_2H$) exhibit EPR spectra (Table 3) containing a signal at g_{iso} close to 1.976, with additional hyperfine coupling, $A_{av.}$, of *ca* 46×10^{-4} cm^{-1}, due to the $I = 5/2$ isotopes [^{95}Mo (15.9%) and ^{97}Mo (9.6%)]. These spectral parameters are similar to those obtained from [Mo(NO)L*Cl(py)] (g_{iso} 1.970, $A_{av.}$ 45.7×10^{-4} cm^{-1})[3] and [Mo(NO)L*(pyrazole)$_2$]$^+$ (g_{iso} 1.973–1.977, A_{Mo} 43.8–46.0 $\times 10^{-4}$ cm^{-1}).[9] The data are broadly consistent with localization of the unpaired electron on the metal centre. However, the EPR spectrum of [Mo(NO)L*I(3,5-$Me_2C_3HN_2H$)] shows $g_{iso} = 2.0036$ and $A_{av.} = 43.2 \times 10^{-4}$ cm^{-1}, which differs significantly from the other three species. We have no simple explanation for this observation, but it may arise from some form of distortion in the molecule.

Crystal structure of [Mo(NO)L*Cl(3,5-$Me_2C_3HN_2H$)] (**1**)

The asymmetric unit of the structure contains one molecule of **1** in a general position and half of a CH_2Cl_2 molecule, whose carbon atom is situated on a two-fold axis, thus corresponding to the stoichiometry [Mo(NO)L*Cl(3,5-$Me_2C_3HN_2H$)]·$1/2CH_2Cl_2$.

The molybdenum atom has distorted octahedral coordination, with one chlorine and five nitrogen atoms. The disorder (mixing) of Cl and NO ligands can be explained in terms of both *R* and *S* enantiomers of **1** occupying statistically the same crystallographic position (the crystal itself being centrosymmetric and racemic).

The Mo—N bond lengths associated with the tris(pyrazolyl)borate and the 3,5-dimethylpyrazole ligands are similar (average 2.20 Å) and reveal little difference in *trans* influence due to the Cl and NO groups (this also being a result of the nature of the disorder). As expected the Mo—N—O bond angle is essentially linear and the Mo—N(O) distance (mean 1.79 Å) is close to the usual (1.76–1.80 Å).[10]

In nitrosyl complexes of molybdenum with filled d_{xz} and d_{yz} orbitals, other ligands having filled p_π-orbitals or lone electron pairs tend to adopt the orientation with these orbitals approximately

Table 3. EPR spectral data obtained from [Mo(NO)L*XQ]

X	Q	g_{iso}	$A_{av.} \times 10^4$ (cm^{-1})
Cl	$C_3H_3N_2H$	1.9768	46.2
Cl	3,5-$Me_2C_3HN_2H$	1.9768	46.1
I	$C_3H_3N_2H$	1.9760	45.34
I	3,5-$Me_2C_3HN_2H$	2.0036	43.22

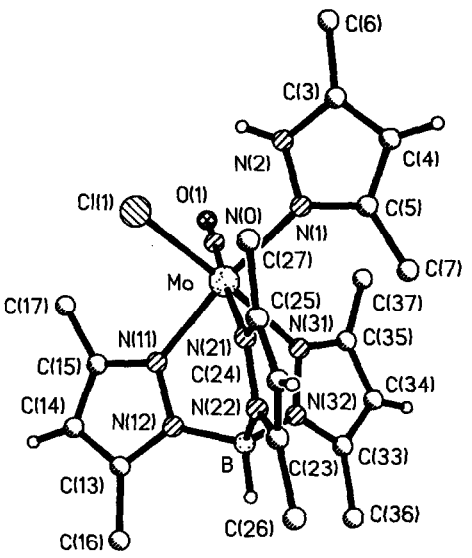

Fig. 1. Molecular structure of [Mo(NO)L*Cl(3,5-$Me_2C_3HN_2H$] (**1**). For clarity, only the major (A) positions of Cl and NO ligands are shown (in B positions these ligands are interconverted), and all methyl hydrogens are omitted.

orthogonal to the NO group, thereby maximizing the d_{xy}–p overlap.[11] In **1** such an orientation is impossible due to the steric hindrance imposed by the methyl substituents of the pyrazolyl rings; torsion angles N(OA)—Mo—N(1)—N(2) and N(OB)—Mo—N(1)—N(2) are 53.6° and −37.3°, respectively. The pyrazole ring C (Fig. 1) is aligned approximately along the bisectral plane between rings E and F, whose interplanar angle of 117.3° is perhaps surprisingly the smallest of the three interplanar angles with L*, viz. D to E 120.3° and D to F 120.5°.

The only active hydrogen atom, at N(2), does not participate in hydrogen bonding.

(*Received* 1 *October* 1992; *accepted* 2 *December* 1992)

Abstract—A range of mixed biphosphine complexes of palladium(0) has been prepared and characterized by ^{31}P NMR spectroscopy. The complexes disproportionate in solution at rates which depend on the nature of the ligands. The structure of [Pd(dcpe)(dppe)] has been established in an X-ray diffraction study.

Studies of the palladium(0) oxidation state have been dominated by investigations of phosphine complexes. Their most significant reactivity involves dissociation and oxidative addition. The complexes are generally prepared by reduction of palladium(II) complexes and a wide variety of reducing agents have been employed. However, most of the simple complexes studied, whether two-, three- or four-coordinate, have contained a single type of phosphine ligand. In this work we report the preparation of mixed biphosphine complexes, their characterization by ^{31}P NMR spectroscopy, their stability with respect to exchange or disproportionation and the determination of the crystal structure of one example in the series. Related mixed chelating biphosphine complexes of platinum have been prepared,[1] by reduction of $[PtCl_2L]$ with $Na[BH_4]$ in the presence of L′. In this case the first product is $[PtLL']^{2+}$, which is then reduced by the borohydride.

RESULTS AND DISCUSSION

Reactions of $[Pd(C_2H_4)(dppe)]$ *with biphosphines*

The complex $[Pd(C_2H_4)(dppe)]$ [dppe = 1,2-bis(diphenylphosphino)ethane], in common with other palladium ethene complexes, is relatively unstable. The synthesis of $[Pd(C_2H_4)(PR_3)_2]$ by reduction of $[Pd(acac)_2]$ (acacH = pentane-2,4-dione) by $AlEt_2OEt$ in the presence of PR_3 and ethene has previously been reported.[2] However, we found it more convenient to prepare $[Pd(C_2H_4)(dppe)]$ *in situ* by the reduction of $[PdCl_2(dppe)]$ with $Li[Et_3BH]$ in the presence of excess ethene. The complex could be characterized spectroscopically at low temperature and ^{31}P NMR spectroscopic data for the phosphine ligand, $[PdCl_2(LL)]$, $[Pd(C_2H_4)(LL)]$ and $[Pd(LL)_2]$ (these complexes were prepared independently from $[Pd(C_2H_4)(LL)]$ and LL for comparison), are collected in Table 1.

Reaction of $[Pd(C_2H_4)(dppe)]$ with dppp [dppp = 1,3-bis(diphenylphosphino)propane] at room temperature gave a solution containing four complexes, identified by ^{31}P NMR spectroscopy as $[Pd(dppe)_2]$, $[Pd(dppp)_2]$, $[Pd(C_2H_4)(dppe)]$ and $[Pd(C_2H_4)(dppp)]$. This suggests that extensive disproportionation had occurred. The presence of $[Pd(C_2H_4)(dppp)]$ and $[Pd(dppp)_2]$ is surprising, since it suggests that dppp is able to displace dppe, which is normally considered to be a much more tightly binding chelating ligand. Even more surprising is the observation that ethene seems to be preferred as a ligand over a chelating biphosphine. The mechanism of formation of $[Pd(C_2H_4)(dppp)]$ is not clear, but two pathways may be envisaged. Either dppp displaces dppe from $[Pd(C_2H_4)(dppe)]$ or ethene displaces one of the biphosphines in $[Pd(dppe)(dppp)]$ or $[Pd(dppp)_2]$. Neither option would have been predicted from conventional wisdom concerning the relative binding abilities of the

ligands involved. When the reaction was repeated at 203 K the mixed complex [Pd(dppe)(dppp)] was formed, as essentially the sole product. The ^{31}P NMR spectrum (Table 2) could be readily assigned by comparison with the chemical shifts for $[Pd(dppe)_2]$ and $[Pd(dppp)_2]$. When the temperature was raised to 283 K intense signals for the two ethene complexes were observed, this change being

partially reversible when the solution was recooled.

Reaction of $[Pd(C_2H_4)(dppe)]$ with dppb [dppb = 1,4-bis(diphenylphosphin)butane] at 203 K gave $[Pd(dppe)(dppb)]$ and $[Pd(dppe)_2]$. No signals due to $[Pd(dppb)_2]$ or free dppb could be observed, possibly because they are rather insoluble at this temperature. Above 263 K the spectrum was appreciably broadened by a dynamic process.

The reaction of $[Pd(C_2H_4)(dppe)]$ with dcpe [dcpe = 1,2-bis(dicyclohexylphosphino)ethane] at 203 K was clean and practically instantaneous. No disproportionation or fluxional processes were noted, even at room temperature, and large bright yellow crystals of [Pd(dcpe)(dppe)] were deposited slowly from solution in the absence of light.

With dppf [dppf = 1,1′-bis(diphenylphosphino)-ferrocene] as the added phosphine the products formed were [Pd(dppe)(dppf)], $[Pd(dppf)_2]$ and $[Pd(dppe)_2]$. On warming the mixed complex became the dominant species and this was stable towards disproportionation at 243 K for several weeks. By contrast, although the reaction with dmpe [dmpe = 1,2-bis(dimethylphosphino)ethane] gave the mixed complex [Pd(dppe)(dmpe)] as the initial product at 203 K, this disproportionated in solution at 243 K over a few days.

Reaction of $[Pd(C_2H_4)(dppe)]$ with the unsymmetrical biphosphine 1-dimethylphosphino-3-diphenylphosphinopropane (dmpp)[3,4] gave a mixture of $[Pd(dppe)_2]$, $[Pd(dmpp)_2]$ and the mixed complex [Pd(dmpp)(dppe)]. Computer simulation allowed the calculation of chemical shifts and coupling constants for the three distinct phosphorus atoms.

Reactions of $[Pd(C_2H_4)(dppp)]$ *with biphosphines*

The addition of 1 molar equivalent of dcpe to $[Pd(C_2H_4)(dppp)]$ at 203 K gave mainly $[Pd(dcpe)_2]$ and $[Pd(dppp)_2]$. On warming to 263 K signals due to a small amount of the mixed species could be seen in the ^{31}P NMR spectrum. Recooling the sample to 203 K resulted in the crystallization of $[Pd(dcpe)_2]$ as a bright yellow microcrystalline solid. Even at low temperature the ^{31}P NMR signal assigned to $[Pd(dppp)_2]$ remained a singlet. This is in contrast to $[Pt(dppp)_2]$ which gives rise to an A_2B_2 pattern in its ^{31}P NMR spectrum at low temperature.[5] At 183 K the signal had broadened slightly, but practical considerations precluded further cooling.

Reaction of $[Pd(C_2H_4)(dppp)]$ with dmpe at 203 K gave a solution containing, as well as the starting material, $[Pd(dppp)_2]$, $[Pd(C_2H_4)(dmpe)]$ and $[Pd(dmpe)_2]$ (Fig. 1). On warming to 253 K the mixed complex [Pd(dmpe)(dppp)] was observed as the predominant component of the mixture, although $[Pd(dmpe)_2]$ and $[Pd(dppp)_2]$ were also present. The mixed complex was stable in THF solution at 243 K for several days.

At 203 K dppf reacted with $[Pd(C_2H_4)(dppp)]$ to give [Pd(dppf)(dppp)] as the main product, together with $[Pd(dppp)_2]$ and $[Pd(C_2H_4)(dppf)]$. At 273 K there was more $[Pd(dppp)_2]$, but the change was reversed on cooling.

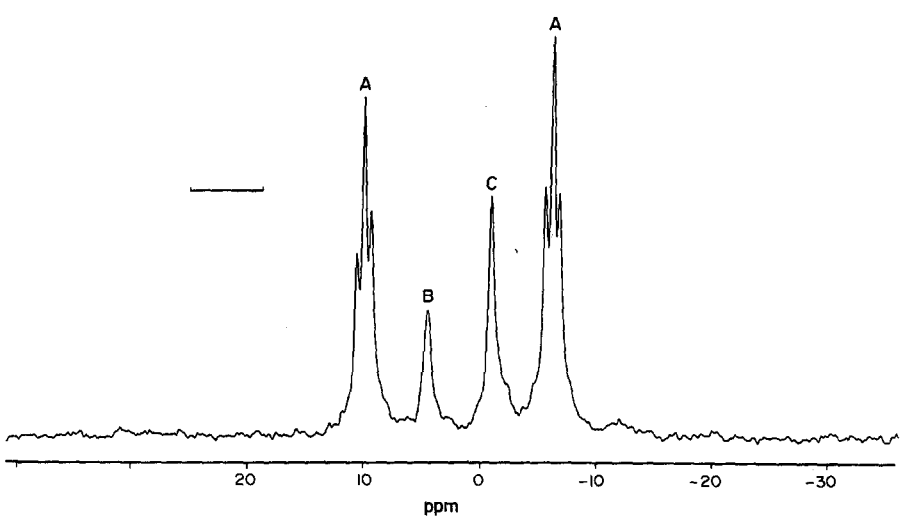

Fig. 1. ^{31}P (32.44 MHz) NMR spectrum of the product obtained on reacting $[Pd(C_2H_4)(dppp)]$ with dmpe in THF at 213 K. (A) [Pd(dmpe)(dppp)]; (B) $[Pd(dppp)_2]$; and (C) $[Pd(dmpe)_2]$. The bar represents 200 Hz.

Reactions of $[Pd(C_2H_4)(dppb)]$ *with biphosphines*

The addition of 1 molar equivalent of dppp to $[Pd(C_2H_4)(dppb)]$ at 203 K gave a mixture with a ^{31}P NMR spectrum showing a signal only for $[Pd(dppp)_2]$. Free dppb is rather insoluble in THF at this temperature, but the appropriate signal was observed on warming. No mixed complex was obtained, in contrast with the reaction in the platinum series.[1] In that case disproportionation was significant, but some [Pt(dppb)(dppp)] could be observed. Complete disproportionation was also noted in the reaction of $[Pd(C_2H_4)(dppb)]$ with dcpe.

Reactions of $[Pd(C_2H_4)(dppf)]$ *with biphosphines*

The addition of 1 molar equivalent of dcpe to $[Pd(C_2H_4)(dppf)]$ at 203 K resulted in the formation of $[Pd(dcpe)_2]$ as the major product, although some [Pd(dcpe)(dppf)] and $[Pd(dppf)_2]$ were also present. The proportions of the components of the mixture did not vary significantly with temperature and at 263 K the signals due to $[Pd(dppf)_2]$ and dppf were broadened by an exchange process. At 283 K there was also evidence that the dppf ligand in the mixed complex is in exchange with free dppf.

The reaction of $[Pd(C_2H_4)(dppf)]$ with dppb gave only $[Pd(dppf)_2]$ and $[Pd(dppb)_2]$.

Reactions to form dmpe complexes

The reactions of $[Pd(C_2H_4)(dppe)]$ and $[Pd(C_2H_4)(dppp)]$ with dmpe gave the expected mixed complexes, together with disproportionation products, as previously noted. The mixed complex [Pd(dmpe)(dppf)] is also a significant product in the reaction of $[Pd(C_2H_4)(dppf)]$ with dmpe (Fig. 2). Signals in the ^{31}P NMR spectrum due to both free phosphines were readily assigned, but assignment of two doublets [δ 0.0, -46.0, $J(PP) = 25$ Hz] was more problematic. That the signals might be due to partial oxidation of dmpe to $Me_2P(=O)CH_2CH_2PMe_2$ was ruled out by the independent preparation (*in situ*, by addition of H_2O_2 to a THF solution of dmpe in an NMR tube) of this monoxide [δ -47.7, 38.5, $^3J(PP) = 38.2$ Hz]. It was noted that the chemical shift of one of the signals from the unknown complex was similar to that for free dmpe and the other similar to $[Pd(dmpe)_2]$. We therefore suggest that the unknown material is $[Pd(\eta^1\text{-dmpe})_n]$. This is supported by NMR spectroscopic studies from the work of Connor on $[M(CO)_5(dmpe)]$ (M = Cr, Mo or W).[6] On warming the sample to 243 K disproportionation of the mixed complex leads to an increase in the concentration of $[Pd(\eta^1\text{-dmpe})_n]$ and at 263 K broadening of the signals gives evidence for an exchange process between free and coordinated dmpe.

Addition of $Li[Et_3BH]$ to a mixture of palladium (II) chloride and dmpe in THF gave a pale yellow solution, the ^{31}P NMR spectrum of which showed two doublets at δ 0 and -46 ppm [$^3J(PP) = 25$ Hz], assigned to $[Pd(\eta^1\text{-dmpe})_n]$, a singlet for $[Pd(dmpe)_2]$ and two triplets centred at δ -3.0 and -10.0 ppm ($^2J = 30$ Hz). We tentatively propose structure **1a** to account for the latter signals, in which there are two non-equivalent sets of phos-

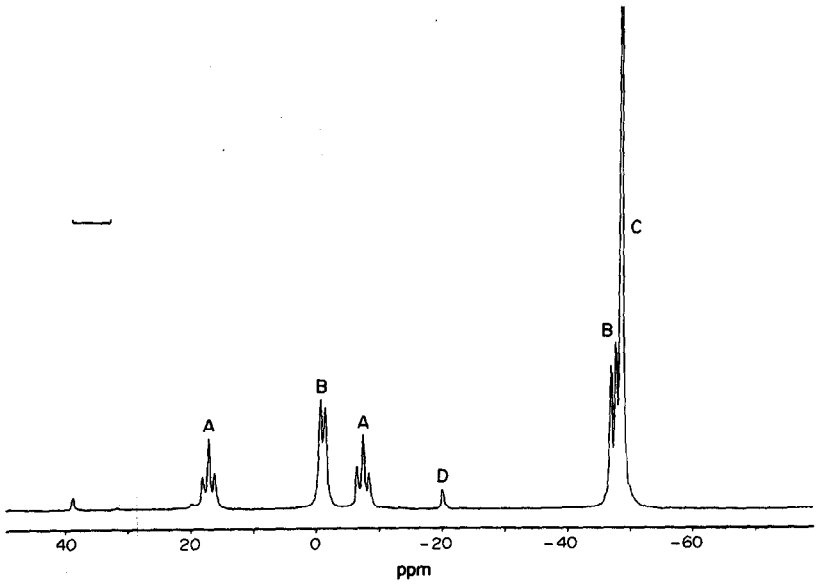

Fig. 2. ^{31}P (32.44 MHz) NMR spectrum of the products from reacting $[Pd(C_2H_4)(dppf)]$ with dmpe in THF at 203 K. (A) [Pd(dmpe)(dppf)]; (B) $[Pd(\eta^1\text{-dmpe})_n]$; (C) dmpe; and (D) dppf. The bar represents 200 Hz.

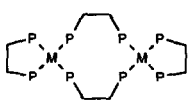
phorus atoms. The addition of dmpe to $[PtCl_2(dmpe)]$ in the presence of $Li[Et_3BH]$ also gave a pale yellow solution. The ^{31}P NMR spectrum of the mixture showed an intense singlet assigned to $[Pt(dmpe)_2]$ [$\delta = -7.0$, $^1J(PPt) = 3710$ Hz]. A pair of doublets [$\delta = 0.0, -46.0$, $^3J(PP) = 26$ Hz] was assigned to $[Pt(\eta^1\text{-dmpe})_n]$. No platinum satellites were observed. They would not be expected for the pendant phosphines and we may postulate that the two phosphorus sites are in rapid exchange on the NMR spectroscopic time scale. A pair of triplets [$\delta = -11.0$, $^1J(PPt) = 3412$ Hz; $\delta = -28.0$, $^1J(PPt) = 4110$ Hz, $^2J(PP) = 60$ Hz] were assigned to **1b**. On warming the signals assigned to $[Pt(dmpe)_2]$ remained sharp, but those due to $[Pt(\eta^1\text{-dmpe})_n]$ were broadened by exchange. We are investigating conditions for the isolation of **1** or of $[M(\eta^1\text{-dmpe})_n]$.



1a M = Pd
1b M = Pt

Reaction of $[Pd(C_2H_4)(dcpe)]$ with dmpe at 203 K gave a mixture of [Pd(dcpe)(dmpe)], $[Pd(\eta^1\text{-dmpe})_n]$ and $[Pd(dmpe)_2]$. On warming there is exchange between free dmpe and $[Pd(\eta^1\text{-dmpe})_n]$ and $[Pd(dcpe)_2]$ is formed by disproportionation.

When $[Pd(C_2H_4)(dppb)]$ was reacted with dmpe at 203 K, the main products were **1a** and $[Pd(\eta^1\text{-dmpe})_n]$, together with a very small amount of the mixed complex. Further evidence for the formation of the mixed complex was obtained by FAB mass spectrometry (*vide infra*).

Reaction of $[Pd(C_2H_4)(dcpe)]$ *with dppm*

Reaction of $[Pd(C_2H_4)(dcpe)]$ with 1 molar equivalent of dppm [dppm = 1,1-bis(diphenylphosphino)methane] at 203 K gave [Pd(dcpe)(dppm)] and a species which we postulate to be $[Pd(\eta^1\text{-dppm})_2]$ [$\delta = 35.0, -29.0$ ppm; $^2J(PP) = 56$ Hz]. We confirmed that the latter signals were not attributable to partially oxidized dppm by independent synthesis (*in situ*, by addition of H_2O_2 to a THF solution of dppm in an NMR tube) of $Ph_2PCH_2P(=O)Ph_2$ [$\delta = 24.2, -27.0$ ppm; $^2J(PP) = 51.8$ Hz]. It could also not be due to the known compound $[Pd_2(\mu\text{-dppm})_3]$, since this has high symmetry and its ^{31}P NMR spectrum shows only a singlet at δ 12.4.[7] As with the derivatives of dmpe, the chemical shift of the phosphine, which we suppose to be pendant, is similar to that of the free ligand and the data are quite similar to those reported for chromium, molybdenum or tungsten complexes of monodentate dppm.[6] Disproportionation of the mixed complex occurred irreversibly on warming.

Reactions involving triphos, $[MeC(CH_2CH_2PPh_2)_3]$

Reaction of $[Pd(C_2H_4)(dppe)]$ with triphos at 203 K gave the mixed complex [Pd(dppe)(triphos)], together with substantial amounts of $[Pd(dppe)_2]$ and $[Pd(triphos)_2]$ (**2**). The complex $[Pd(triphos)_2]$ was identified by independent preparation from $[Pd(C_2H_4)(triphos)]$ and triphos. The resonance due to the uncoordinated phosphine was observed with δ −27.0, essentially the same as for the free phosphine. The coordinated phosphines give rise to an AA′BB′ system (all the AA′BB″ systems approximate to A_2B_2, as the couplings are very similar), which could be readily simulated. This lack of symmetry is not unexpected and mirrors the data reported for $[Pt(triphos)_2]$, for which the structure has been determined.[6] The ^{31}P NMR spectrum of [Pd(dppe)(triphos)] showed a singlet assigned to the pendant phosphine ($\delta = -25.0$) and an AA′BB′ multiplet for the coordinated phosphines [$\delta = 3.0, -6.5$ ppm; $^2J(PP) = 14$ Hz].

The reaction of triphos with $[Pd(C_2H_4)(dcpe)]$ at 203 K gave only disproportionation products.

Crystal and molecular structure of [Pd(dcpe)(dppe)]

Relatively few palladium(0) complexes have been characterized crystallographically. The monomeric two-coordinated complexes $[PdL_2]$ (L = PCy_3[9] or PBu^t_2Ph[10]) both exhibit C_2 symmetry, but the tricyclohexylphosphine complex is bent whilst the derivative of PBu^t_2Ph is almost linear. Two three-coordinate palladium(0) phosphine complexes, $[Pd(PPh_3)_3]$[11] and $[Pd\{Ph_2P(C_6H_4\text{-}3\text{-}SO_3K)\}_3]$,[12] have been characterized, as have the four-coordinate species $[Pd(PPh_3)_4]\cdot 0.5C_6H_6$,[13] $[Pd(PCH_2OH)_4]\cdot MeOH$[14] and $[Pd\{P(C{\equiv}CPh)_3\}_4]$.[15] Related structurally characterized platinum complexes include $[Pt\{P(CMe_3)_3\}_2]$.[16] $[Pt\{PPh(CMe_3)_2\}_2]$,[10] $[Pt(PCy_3)_2]$,[17] $[Pt(PCy_3)_3]$,[18] $[Pt(PPh_3)_3]$[19,20] and $[Pt_2(\mu\text{-dppm})_3]$.[21] Two platinum derivatives of chelating phosphines have been studied. $[Pt(triphos)_2]$ is four-coordinate at platinum, with two pendant phosphines.[8] There have been two reports on the structure of $[Pt(dppp)_2]$, but in one of these the space group is wrongly assigned,[22] giving rise to some anomalies in the bond length and angle data. The correctly refined structure[23] is rather more symmetrical, which

is slightly surprising in view of the non-equivalence of the phosphines in the low-temperature NMR spectrum. The structure of [Pd(dcpe)(dppe)] is the first example of a mixed biphosphine complex of either platinum or palladium to be structurally characterized.

The crystal was monoclinic, space group $P2_1/n$, $Mr = 923.4$, $a = 20.138(4)$, $b = 11.901(2)$, $c = 22.515(5)$ Å, $\beta = 114.37(2)°$, $U = 4915.1$ Å, $Z = 4$, $D_{calc} = 1.25$ g cm^{-1}, $F(000) = 1944$. Selected bond lengths and angles are given in Table 3 and the structure is shown in Fig. 3. The geometry at palladium is approximately tetrahedral, but the distortions are quite large. The angles P(1)—Pd—P(2) (85.7°) and P(3)—Pd—P(4) (86.9°), within each phosphine chelate, are considerably reduced from tetrahedral, whilst the others range from 119.1(2) to 124.8(2)°. The Pd—P bond lengths are slightly longer for the phosphorus atoms of the dcpe ligand [2.352(5), 2.360 Å] than for the dppe [2.324(5), 2.334(5) Å], but the difference is barely statistically significant. These may be compared with a mean Pd—P distance of 2.451(5) Å for $[Pd(PPh_3)_4]$ and 2.319(2) Å for $[Pd\{P(CH_2OH)_3\}_4]$, suggesting that steric demand has some influence on bond length. There is little evidence for the high steric demand of the cyclohexyl rings from the angles at phosphorus with C(33)—P(3)—C(27) = 99.9(8)° and C(41)—P(4)—C(47) = 103.9°. The related angles for the phenyl bearing phosphorus atoms are 100.2(8)° and 102.5(8)°. The P—C_{aryl} and P—C_{alkyl} bond lengths differ a little.

FAB mass spectra of $[Pd(LL)_2]$

FAB mass spectrometry has, over the last decade, proved to be an invaluable tool in the characterization of organometallic and coordination complexes.[24,25] It is especially valuable for species which are not particularly stable, because it is not necessary to subject the complex to thermal shock.[26] FAB mass spectra were obtained for the complexes $[Pd(LL)_2]$ (LL = dppe, dcpe, or dppf) and the mixed complexes [Pd(dcpe)(dppe)] and [Pd(dmpe)(dppb)]. Palladium has several naturally occurring isotopes of rather similar abundance and for the purposes of this discussion we will consider only the peaks arising from ^{106}Pd. In all cases the isotope pattern observed could be correctly simulated and remained essentially unchanged throughout the fragmentation.

The first fragmentation from the molecular ion observed for $[Pd(dppe)_2]^+$ ($m/z = 902$) was a loss of $\{Ph_2PCH_2CH_2\}$ to give a peak at m/z 689. A

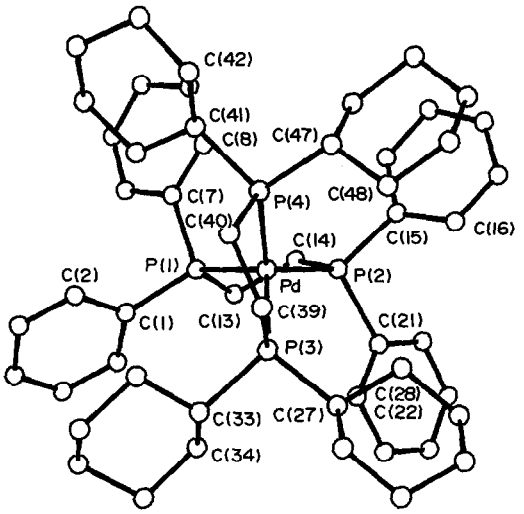

Fig. 3. Structure of [Pd(dcpe)(dppe)] showing atom numbering scheme.

further loss of $\{PPh_2\}$ gives a peak at m/z 504, for $\{Pd(dppe)\}^+$. Loss of a further $\{Ph_2PCH_2CH_2\}$ fragment gave a peak at m/z 291. By contrast, the mass spectrum of $[Pd(dcpe)_2]$ is characterized by the loss of cyclohexyl groups. The first fragmentation of the molecular ion ($m/z = 950$) is the loss of C_6H_{11} to give a peak at m/z 867. Loss of successive C_6H_{12} and C_6H_{11} units gave peaks at m/z 783 and 701, respectively. A strong peak at m/z 590 is difficult to assign. The mass would correspond to $\{Pd(dcpe)P_2\}^+$. Whilst it is possible to envisage a rearrangement which might give rise to this, we are aware of no precedents. An alternative possibility is $\{Pd(dcpe)(PH_2CH_2CH_3)\}^+$. This seems a bit more likely, although it is difficult to envisage the source of the hydrogen atoms. There is also a peak at m/z 528 for the fragment $\{Pd(dcpe)\}^+$.

In the FAB mass spectrum of $[Pd(dppf)_2]$ there is no peak corresponding to the molecular ion at m/z 1214, but the peak for $\{Pd(dppf)\}^+$ (m/z 660) is quite clear.

The spectrum of [Pd(dcpe)(dppe)] ($m/z = 926$) shows the features which one might have expected from those of the homoleptic complexes. The fragments $\{Pd(dppe)\}^+$ and $\{Pd(dcpe)\}^+$ are prominent, as are peaks arising from the loss of either a cyclohexyl group or a $Ph_2CH_2CH_2$ unit.

The FAB mass spectrum was obtained for the mixture obtained on reacting $[Pd(C_2H_4)(dppb)]$ with dmpe. The molecular ion for the mixed complex (m/z 682) was observed, confirming its presence in the reaction mixture. There was also a strong peak for $\{Pd(dppb)\}^+$, presumably formed by loss of dmpe from the mixed complex or dppb from $[Pd(dppb)_2]$. We believe that FAB mass spectrometry may have considerable potential for establishing the composition of such mixtures under ambient conditions. ^{31}P NMR spectroscopy of these species is not generally useful at room temperature, since many of the complexes show dynamic behaviour.

CONCLUSIONS

Complexes of the type [Pd(LL)(LL′)], where LL and LL′ are bidentate chelating phosphines, may generally be prepared by the reaction of LL′ with $[Pd(C_2H_4)(LL)]$ at low temperature. On warming disproportionation occurs in many cases, especially when one of the products, $[Pd(LL)_2]$, has LL as a biphosphine which forms a five-membered chelate ring. Rather few of the complexes are stable towards disproportionation at room temperature, and a number also display exchange processes involving the free phosphine. It is noteworthy that replacement of ethene is not as facile as has been previously assumed; a number of ethene complexes have been observed as stable species, even in the presence of uncoordinated chelating biphosphines. Complexes of dmpe and dppm were anomalous and it is believed that some monodentate and/or bimetallic species were involved in the equilibria. It is intended to study these reactions further. Preliminary experiments by FAB mass spectrometry indicated that this will prove a useful method of complex characterization.

EXPERIMENTAL

Apparatus

All manipulations involving air-sensitive complexes were carried out under dry nitrogen using standard Schlenk-line techniques. ^{31}P NMR spectra were recorded on a Bruker WM360 or Bruker WP80SY spectrometer and are referenced to external 85% H_3PO_4. Mass spectra were recorded using a Kratos MS80RF double focussing spectrometer using a Kratos DS55M data system.

Reagents

Cyclooctadiene palladium(II) dichloride was prepared as described by Frye and co-workers.[27] Biphosphines were purchased from Aldrich and were used as received.

Preparation of $[PdCl_2(dppe)]$

To a solution of dppe (0.721 g, 1.81 mmol) in CH_2Cl_2 (10 cm^3) was added a solution of

$[PdCl_2(cod)]$ (0.491 g, 1.72 mmol) in CH_2Cl_2. After stirring at 25°C for 2 h a white precipitate was formed and the solvent was removed under reduced pressure. Toluene was added to the off-white solid and the mixture heated under reflux for 4 h. On cooling a pale yellow solid was precipitated, collected by filtration and dried *in vacuo* to give $[PdCl_2(dppe)]$ as a pale yellow powder (0.8 g, 86%). The complexes $[PdCl_2(dppp)]$, $[PdCl_2(dppb)]$, $[PdCl_2(dppm)]$ and $[PdCl_2(dppf)]$ were prepared similarly.

Preparation of [Pd(dppe)(dppp)]

$[PdCl_2(dppe)]$ (0.053 g, 0.092 mmol) was weighed into an 8 mm NMR tube, which was evacuated and flushed with dry nitrogen. The solid was dissolved in THF (1 cm^3) and ethene was bubbled through the solution until the mixture was saturated. An excess of $Li[Et_3BH]$ (0.5 cm^3) was transferred to the tube by syringe and the mixture became deep red in colour. Ethene was bubbled through the mixture for a further 5 min. The tube was cooled to −78°C and dppp (0.038 g, 0.092 mmol) was added as a solid. The tube was gently warmed by hand until the solid dissolved and the solution became yellow–brown in colour. ^{31}P NMR spectra were recorded at various temperatures.

A range of mixed-chelating bisphosphine complexes were similarly prepared and their spectra recorded.

Structure of [Pd(dcpe)(dppe)]

Suitable crystals were obtained by slow evaporation of a THF solution and are stable in air. A crystal of dimensions 0.30 × 0.20 × 0.08 mm was used for data collection. Enraf–Nonius CAD-4 diffractometer, graphite monochromated Mo-K_α radiation, $\lambda = 0.71069$ Å, $\mu = 5.3$ cm^{-1}, θ–2θ scan, $\Delta\theta = (0.8 + 0.35 \tan\theta)°$, maximum scan time 1 min, 6379 unique measured reflections for $2 < \theta < 22°$ and $h\ 0 \rightarrow 21$, $k\ 0 \rightarrow 12$, $l\ -23 \rightarrow 23$, 3742 observed reflections with $|F^2| > \sigma(F^2)$, $\sigma(F^2) = \{\sigma^2(I) + (0.04I)^2\}^{1/2}/Lp$. There was no crystal decay. Lorentz and polarization corrections, no absorption or extinction corrections. The structure was solved by routine heavy-atom methods with non-hydrogen atoms refined anisotropically by full-matrix least-squares. Hydrogen atoms were held fixed at calculated positions with $U_{iso} = 1.3U_{eq}$ for the parent atom. Within the ring C(33)–C(38) the carbon atom temperature factors were high, with C(35) non-positive definite, suggestive of partial disorder, although no alternative atom sites were identifiable. With a weighting scheme of $w = 1/\sigma^2(F)$, $\Sigma w(|F_o| - |F_c|)^2$ minimized, the final residuals were $R = 0.079$, $wR = 0.142$ for 514 variables, $S = 3.9$, $(\Delta/\sigma)_{max} = 0.01$, $(\Delta\rho)_{max,min} = +1.1, -1.6$ e Å^{-3} on a final difference map. Programs from the Enraf–Nonius SDP-Plus package (Frenz, 1984) were run on a microVAX II computer. Atomic scattering factors were from the International Tables for X-ray Crystallography (1974). Drawings were by PLUTO.[28]

(*Received* 1 *October* 1991; *accepted* 2 *December* 1992)

Abstract—The reactions of bis(dialkylamino)magnesium [$Mg(NR_2)_2$; R = C_2H_5, $C^i{}_3H_7$] with either diethylaluminum chloride or aluminum bromide yielded the following compounds: $Me_4Al_2[\mu\text{-}N(C^i{}_3H_7)_2]_2$ (**1**), $Et_4Al_2[\mu\text{-}N(Et)_2]_2$ (**2**), $Et_4Al_2[\mu\text{-}N(C^i{}_3H_7)_2]_2$ (**3**) and $Br_4Al_2[\mu\text{-}N(Et)_2]_2$ (**4**). The products were characterized on the basis of their elemental analyses, mass spectra, IR spectra and ^1H, ^{13}C and ^{27}Al nuclear magnetic resonance spectra. The X-ray crystal structures of compounds **3** and **4** were also determined. In addition, ^1H NMR studies of the solvent effect on the dialuminum complexes were explored and a spectroscopic investigation of benzene interaction with these dialuminum complexes was undertaken.

The reactions of organoaluminum compounds with reagents containing one acidic hydrogen may lead to the formation of dimeric or trimeric species.[1–7] Coates assessed the relative importance of entropy, ring strain and steric hindrance on the formation of these dimeric and trimeric molecules.[2a,8] Smith also found that the degree of aggregation of the isopropylimido compound ($[AlMe_2(NH(C^i{}_3H_7))]_2$) depended on the preparation route.[3] Recently, Interrante and co-workers reported that the Me_2AlNH_2 trimer is thermodynamically favoured in the following equilibrium:[4]

$$2(Me_2AlNH_2)_3 \underset{T=40\text{–}800^\circ C,\ \Delta H=38\ Kj}{\overset{K=1\times10^{-5}}{\rightleftharpoons}} 3(Me_2AlNH_2)_2 \quad (1)$$

The area of organoaluminum compounds possessing Al_2N_2 fragments has attracted considerable attention.[1] Furthermore, aluminum nitride has

* Author to whom correspondence should be addressed.

found application as a ceramic material,[4,9] resulting in increased attention being paid to the syntheses of the precursors $R_4Al_2(NR_2)_2$ and $X_4Al_2(NR_2)_2$ in high yield.

In our laboratory, the reactions of aluminum alkyl with bis(dialkylamino)magnesium in a 1:1 molar ratio produced the following aluminum–magnesium complexes: $[(CH_3)_2Al(\mu\text{-}NR_2)_2Mg(CH_3)]_n$ [$R = C_2H_5$, $n = 2$; $R = C^iH_7$, $n = 4$] and $(CH_3)_4Al_2(\mu\text{-}NR_2)_2$ [$R = C_2H_5$, C^iH_7].[10] This paper reports the formation of organoaluminum dimers in quantitative yield from the reaction of bis(dialkylamino)magnesium with either dialkylaluminum chloride or aluminum bromide. Crystal data and solvent effects of these products are also presented.

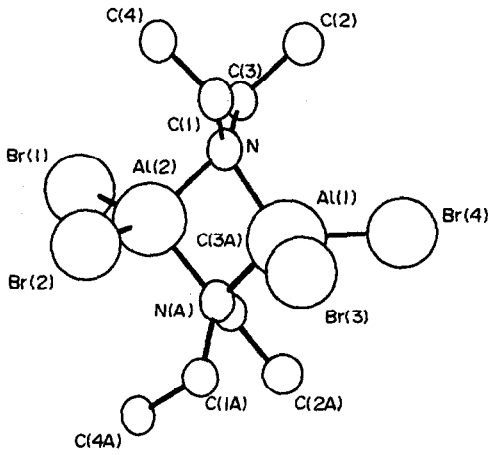

Fig. 2. Molecular structure of $Br_4Al_2[\mu\text{-}N(C_2H_5)_2]_2$.

RESULTS AND DISCUSSION

X-ray structural data

The reactions of bis(dialkylamino)magnesium with either dialkylaluminum chloride or aluminum bromide in diethyl ether gave $X_4Al_2(\mu\text{-}NR_2)_2$, according to the following equation:

$$2AlX_2Y + Mg(NR_2)_2 \xrightarrow{\text{diethyl ether}} X_4Al_2(\mu\text{-}NR_2)_2 + MgY_2. \quad (2)$$

The products were purified by sublimation or crystallization from hexane.

The X-ray crystal structures of compounds **3** and **4** are shown in Figs 1 and 2, respectively; selected bond distances and angles are listed in Table 1. Note that in compound **3** the central Al_2N_2 moiety is non-planar, with the following distorted tetrahedral coordination geometry existing about the aluminum atoms: N(1a)—Al(1)—N(1) = 88.0(1)°, N(1a)—Al(1)—C(1) = 110.2(2)°, N(1a)—Al(1)—C(3) = 119.9(2)° and C(1)—Al(1)—C(3) = 109.7(2)°. The distance between the aluminum atoms [Al···Al distance; 2.784(2) Å] is much shorter than the sum of their van der Waals radii. A comparison of the bridging ligands of $Al_2(CH_3)_6$ and compound **3** reveals that, not surprisingly, since the nitrogen atom in an NR_2 group possesses a lone pair, it differs from a CH_3 group. According to Mason and Mingos,[11] since the NR_2 bridging ligand possesses a filled *p* orbital parallel to the metal–metal vector, it can overlap with antibonding metal orbital combinations, whereas the CH_3 bridging ligand's filled σ-bonding orbitals cannot. Furthermore, metal–metal bond order decreases as orbitals in electron-precise bridged compounds become filled. With the above in mind, the relatively short distance between the two aluminum atoms is mostly likely attributable to $d\pi$–$p\pi$ interactions between aluminum and nitrogen atoms, i.e. overlap between the metal and bridging ligand orbitals. The Al—N distance [1.996(3) Å] is slightly longer than in other amino-bridged aluminum

dimers and it may be due to steric hindrance imposed by the isopropyl group. In compound **4** the Al_2N_2 core is similar to that in $Et_4Al_2[\mu\text{-}N(C^i{}_3H_7)_2]_2$. Note that the Al—Br distance [2.259(4) Å] is shorter than the bridged Al—Br bond in $AlBr_3$, but longer than the terminal Al—Br bond in $AlBr_3$.

A comparison of the X-ray structural data of $Al_2(CH_3)_6$, $(CH_3)_5Al_2NPh_2$ and $[(CH_3)_2AlN(CH_3)_2]_2$ reveals that the Al···Al distance as well as the Al—N—Al angle increases as the number of bridging amino groups increase.[1,2b,5,12] The stability of these compounds had been previously studied and it was suggested that an increase in the metal–metal distance across the $(AlX)_2$ or $(AlY)_2$ rings does not necessarily imply that the bridge itself progressively weakens. The propensity for these compounds to dissociate into monomers increases according to the following sequence: $Al_2(CH_3)_6 < Al_2(CH_3)_5(NPh_2) < Al_2(CH_3)_4[N(CH_3)_2]_2$. At this point it is interesting to compare the structural data of $[(CH_3)_2AlN(CH_3)_2]_2$, $[Cl_2AlN(C_2H_5)_2]_2$,[13] $[Br_2AlN(C_2H_5)_2]_2$ and $[(C_2H_5)_2AlN(C^i{}_3H_7)_2]_2$, in which $[Cl_2AlN(C_2H_5)_2]_2$ and $[Br_2AlN(C_2H_5)_2]_2$ have almost the same structural parameters. The Al···Al distances are 2.700(3) Å in $[Cl_2AlN(C_2H_5)_2]_2$, 2.709(6) Å in $[Br_2AlN(C_2H_5)_2]_2$ and 2.784(2) Å in $[(C_2H_5)_2AlN(C^i{}_3H_7)_2]_2$. They are shorter than the Al···Al distance (2.815 Å) in $[(CH_3)_2AlN(CH_3)_2]_2$; the expected tendency is due to the bulky amino groups. However, the angle Al—N—Al did not

correlate with the Al···Al distance, which is not an unreasonable result because the Al(1), N(1), Al(1a) and N(1a) atoms do not remain in a plane as in $[(CH_3)_2AlN(CH_3)_2]_2$. The deviations from the best plane of these four atoms in $[(C_2H_5)_2AlN(C^iH_7)_2]_2$ are 0.1922, −0.1921, 0.1921 and −0.1922 Å, respectively, so the Al_2N_2 ring in $[(C_2H_5)_2AlN(C^iH_7)_2]_2$ has the cyclobutane-like structure. Similarly, the Al(1), N, Al(2) and N(a) atoms of $[Br_2AlN(C_2H_5)_2]_2$ do not remain in the plane; the deviations from the best plane of these four atoms in $[Br_2AlN(C_2H_5)_2]_2$ are −0.055(5), 0.196(9), −0.064(6) and 0.21(1) Å.

The X-ray structural data of $In_2(CH_3)_4[NR_2]_2$ (R = Me, Et and C^iH_7)[14] and $Al_2(CH_3)_4[N(CH_3)_2]_2$ reveals that all the In_2N_2 and Al_2N_2 rings are planar; however, compound **3** has a cyclobutane-like structure. This is an unusual and interesting result. It is reasonable to believe that the aluminum atom is smaller than the indium atom, so the aluminum cannot accept more steric hindrance of the isopropyl group, such as the indium, to keep in the plane.

Spectroscopic studies

The ^1H NMR spectra of $(C_2H_5)_4Al_2[\mu\text{-}N(C^iH_7)_2]_2$ in $CDCl_3$ show the chemical shift of methyl in the ethyl group is upfield from the methyl in the isopropyl group; however, in benzene-d_6 the chemical shift of methyl in the ethyl group is downfield from the methyl of the isopropyl group.[15] According to these results a strong solvation effect between benzene and the dimer was suspected. In the course of investigating this effect, several solvents were used to determine the solvent effect, as shown in Table 2. It was found that the specific aromatic solvation effect does indeed exist. It depends on the orientation of approach of the aromatic solvent molecules on solute molecules. The solvent molecules' ring current induces a strong anisotropic effect which affects the chemical shift of the solute.

EXPERIMENTAL

Apparatus and materials

All operations were carried out in a nitrogen-flushed glove-bag, dry-box or vacuum system. All solvents were distilled prior to use. IR, mass, nuclear magnetic resonance, electronic absorption and X-ray single-crystal spectral data were obtained using a Perkin–Elmer 1320 IR spectrophotometer, VG 70-250S GC/MS spectrophotometer, Varian VXR-300 MHz FT-NMR spectrometer, Perkin–Elmer Lambda 3B UV spectrophotometer and an Enraf–Nonius CAD-4 automatic diffractometer, respectively. Elemental analyses were carried out at the Galbraith Laboratory, U.S.A.

Reaction of bis(dialkylamino)magnesium (R = C_2H_5, C^iH_7) *with dialkylaluminum chloride* (R = CH_3, C_2H_5)

Bis(dialkylamino)magnesium was prepared by following the literature method.[16] Dialkylaluminum chloride (0.090 mol) in 2 M toluene solution was added to a round-bottomed flask containing bis(dialkylamino) magnesium (0.045 mol) in ether solution (100 cm^3) under nitrogen. The reaction mixture was stirred for 12 h at room temperature and the magnesium chloride precipitate was isolated by centrifuging. The filtrate was evaporated *in vacuo* to give the product, $R_4Al_2(NR_2)_2$.

(1) $(C_2H_5)_4Al_2[\mu\text{-}N(C_2H_5)_2]_2$ (liquid) was purified by distillation at *ca* 140°C. ^1H NMR (C_6D_6): δ 2.614 (q, 8H, CH_2), 1.267 (t, 12H, CH_3), 0.865 (t, 12H, CH_3), 0.444 (q, 8H, CH_2). ^{13}C NMR (C_6D_6): δ 39.541, 12.244, 9.666, 0.532. ^{27}Al NMR (C_6D_6): δ 156. Mass spectrum (EI, 70 eV): the 10 most intense *m/z* peaks at 285 (base peak), 199, 156, 128, 100, 286, 257, 98, 57, 313 ($M^+ - 1$). Found: C, 60.3; H, 12.4; N, 9.9. Calc.: C, 61.1; H, 12.7; N, 8.9%. Note that this is a known compound and the above data is consistent with that in the literature.[1f]

Table 2. ^1H NMR chemical shifts for $Et_4Al_2[\mu\text{-}N(C^iH_7)_2]_2$ in different solvents

Solvent	Heptet	Triplet	Doublet	Quartet	Standard (TMS)

(2) $(CH_3)_4Al_2[\mu\text{-}N(C^iH_7)_2]_2$ (solid) was purified by sublimation at 60°C. M.p. 125–128°C. ^{1}H NMR (C_6D_6): δ 3.632 (sept, 4H, CH), 1.194 (d, 24H, CH_3), −0.260 (s, 12H, CH_3). ^{13}C NMR (C_6D_6): δ 51.194, 26.898, −4.0. ^{27}Al NMR (C_6D_6): δ 160. IR (Nujol): 3020(w), 3000(m), 2965(s), 2922(s), 2855(s), 1460(s), 1408(s), 1378(s), 1305(w), 1260(w), 1202(s), 1165(s), 1135(s), 960(s), 920(m), 840(m), 764(s), 685(s), 648(w), 578(m), 447(w), 410(w). Mass spectrum (EI, 70 eV): the 10 most intense m/z peaks at 142 (base peak), 299, 214, 86, 57, 314 (M^+), 156, 98, 126, 241. Found: C, 62.0; H, 13.1; N, 9.3. Calc.: C, 61.1; H, 12.8; N, 8.9%.

(3) $(C_2H_5)_4Al_2[\mu\text{-}N(C^iH_7)_2]_2$ (solid) was obtained by crystallization from hexane. M.p.$_{dec}$ > 100°C. ^{1}H NMR (C_6D_6): δ 3.575 (sept, 4H, CH), 1.371 (t, 12H, CH_3), 1.214 (d, 24H, CH_3), 0.337 (q, 8H, CH_2). ^{13}C NMR (C_6D_6): δ 51.165, 27.085, 10.293, −4.451. ^{27}Al NMR (C_6D_6): δ 152. IR (KBr): 2990(w), 2940(s), 2910(s), 2880(s), 2840(s), 2780(w), 1445(m), 1405(w), 1390(m), 1380(m), 1360(m), 1320(w), 1295(w), 1250(m), 1225(w), 1185(w), 1165(w), 1150(m), 1120(m), 1090(w), 1010(w), 975(m), 945(m), 900(m), 825(m), 790(m), 765(w), 745(s), 630(s), 585(m), 550(w), 515(m), 435(m), 320(s). Mass spectrum (EI, 70 eV): the 10 most intense m/z peaks at 86 (base peak), 58, 341 ($M^+ - 29$), 156, 101, 128, 70, 170, 227, 269. Found: C, 62.6; H, 12.8; N, 7.8. Calc.: C, 64.8; H, 13.0; N, 7.6%.

*Crystallographic structure determination.** Single crystals were grown by crystallization from hexane. A colourless $Et_4Al_2[\mu\text{-}N(C^iH_7)_2]_2$ crystal with the dimensions 0.65 × 0.52 × 0.45 mm was sealed into a glass capillary for X-ray measurements. During data collection, three standard reflections, $0\bar{4}2$, $04\bar{2}$ and $1\bar{2}7$, were measured every 7200 s; their intensities dropped gradually by 21% at the end of measurement. A decay correction was applied. The correction factors on the intensities of the measured reflections ranged from 1.000 to 1.2075 with an average value of 1.0985. The crystallographic data and refinement details are listed in Table 3. The structure was solved by direct methods. The hydrogen atoms were located from a difference Fourier synthesis. The positional parameters of all hydro-

gen atoms were constrained during the refinement to those of the carbon atoms to which they were bonded [d(C—H) = 0.95 Å]. Full matrix least-squares refinement with anisotropic temperature factors for non-hydrogen atoms and with isotropic temperature factors for hydrogen atoms gave final $R = 0.081$ and $Rw = 0.108$ with $w = 1.0/[\sigma^2(F_o)+0.0254F_o^2]$ for all the observed reflections. The relatively high R values are attributed to the crystal property which is extremely hygroscopic and air-sensitive. During data collection the intensities dropped gradually. Atomic scattering factors were taken from the International Tables for X-ray Crystallography (1974). All crystallographic computations were performed on a VAX 11/780 computer using the SHELX76, MULTAN77 and GEOM78 programs.[17–19]

Synthesis of $Br_4Al_2[\mu\text{-}N(C_2H_5)_2]_2$

The reaction of bis(diethylamino)magnesium with aluminum bromide was carried out by the same procedure as described previously. The compound was purified by sublimation at 72°C in a vacuum system. M.p. 61–62°C. ^{1}H NMR (C_6D_6): δ 2.978 (q, 8H, CH_2), 0.817 (t, 12H, CH_3). ^{13}C NMR (C_6D_6): δ 42.674, 12.426. ^{27}Al NMR (C_6D_6): δ 115.631. IR (KBr): 2970(s), 1470(s), 1380(s), 1310(m), 1285(m), 1220(m), 1168(s), 1120(w), 1090(m), 1032(m), 993(w), 895(m), 880(m), 780(m), 723(w), 620(w). Mass spectrum (EI, 70 eV): the 10 most intense m/z peaks at 244 (base peak), 502, 72, 235, 58, 504, 237, 178, 180, 56. Found: C, 18.2; H, 4.1. Calc.: C, 18.4; H, 3.9%.

*Crystallographic structure determination.** Single crystals were grown by sublimation. A colourless $Br_4Al_2[\mu\text{-}N(Et)_2]_2$ crystal with the dimensions $0.50 \times 0.19 \times 0.26$ mm was sealed into a glass capillary for X-ray measurements. During data collection, three standard reflections, $0.3\bar{5}$, 024 and 060, were measured every 7200 s; their intensities dropped gradually by 20% at the end of measurement. A decay correction was applied. The correction factors on the intensities of the measured reflections ranged from 1.000 to 1.2048 with average value of refinement listed in Table 3. The structure was solved by direct methods. The hydrogen atoms were calculated at anisotropic convergence. The positional parameters of all hydrogen atoms were constrained during the refinement to those of the carbon atoms to which they were bonded [d(C—H) = 1.00 Å]. Full-matrix least-squares refinement with anisotropic temperature factors for non-hydrogen atoms gave final $R = 0.040$ and $Rw = 0.041$ with $w = 1.0/[\sigma^2(F_o)+0.00015F_o^2]$ for all the observed reflections. Atomic scattering factors were taken from the International Tables for X-ray Crystallography (1974). All crystallographic computations were performed on the Micro VAX 3600 computers using the NRCC package programs.[20]

Spectroscopic studies

The chemical shifts of the NMR spectral data of dialuminum complexes were measured in different deuterated solvents, listed in Table 1, and the chemical shifts of $(C_2H_5)_4Al_2[\mu\text{-}N(C^i{}_3H_7)_2]_2$ were observed in different molar ratios between benzene(d_6) and cyclohexane(d_{12}).

(*Received* 30 *September* 1992; *accepted* 30 *November* 1992)

Abstract—The molecular orbitals of a non-planar side-on bound μ-η^2:η^2-peroxodi-(diamminecopper(II))$^{2+}$ model of the active site of oxyhaemocyanin have been calculated. The σ_{O-O} orbital, the two σ_{Cu-O} orbitals, a bonding and a non-bonding π_V orbital were assigned to −4.693, −4.215, −5.183, −4.849 and −1.505 eV, respectively. The absorption bands which were observed in the absorption or CD spectra of oxyhaemocyanin appear to be transitions from molecular orbitals with large 3*d*(Cu) character to the LUMO orbital, which has *ca* 30.4% $3d_{xy}$(Cu) and 55.6% $2p_x$(O) character. The oscillator strengths of the transitions allowed in the C_{2v} point group were calculated. The singlet–triplet separation corresponds to the difference in energy of the asymmetric and symmetric combinations of the $3d_{xy}$(Cu) atomic orbitals and is large (2.060 eV). These molecular orbitals have B_2 and A_1 symmetry, respectively, and, therefore, the electronic transition is allowed in the model compound. The singlet–triplet transition may not be spin-forbidden in all molecules.

Haemocyanin is an oxygen-carrying copper protein which is found in arthropods and molluscs.[1] Each subunit of haemocyanin has a dicopper(I) site in the deoxy form of the protein which, when the protein binds dioxygen, is transformed into a μ-peroxo-bound dicopper(II) site with a very strong absorption band at $\sim$ 350 nm (ε = 20,000 M^{-1} cm^{-1}) and a less intense absorption band at $\sim$ 580 nm (ε = 1000 M^{-1} cm^{-1}).[2] These absorption bands, which are also found in the CD spectrum of oxyhaemocyanin, are explained as two $\pi_V \rightarrow 3d$(Cu) ligand-to-metal charge-transfer bands from the anti-bonding π lone-pair orbitals on the peroxide, which are no longer degenerate to the $3d_{xy}$ (or $3d_{x^2-y^2}$) orbitals on the copper(II) ions which have formed an empty molecular orbital in this strongly anti-ferromagnetically-coupled dicopper(II) site.[2] Various geometries have been considered for this dicopper(II) site bridged by a peroxide ligand: (1) an end-on bound symmetric planar *trans*-μ-peroxodicopper(II) site; (2) an end-on bound symmetric non-planar *trans*-μ-peroxodicopper(II) site; (3) an end-on bound symmetric planar *cis*-μ-peroxodicopper(II) site, which has an endogenous bridging ligand in addition to the peroxo bridge; (4) a side-on bound planar μ-η^2:η^2-peroxodicopper(II) site; and (5) an end-on bound μ-O,O-peroxodicopper(II) site which may have a non-planar dangling oxygen atom. The copper–oxygen bonds in these geometries have been discussed by Freedman, Loehr and Loehr[3] and by Ross and Solomon.[4] This paper is a report of the calculated molecular orbitals of a non-planar side-on bound symmetric μ-η^2:η^2-peroxodi(diamminecopper(II))$^{2+}$ site, in which the oxygen atoms of the peroxo ligand are about 18° above and below the *xy*-equatorial plane which contains $Cu_A(\uparrow)$ and $Cu_B(\downarrow)$ along the axis.

EXPERIMENTAL

The method of calculation was the semi-empirical "Atom Superposition and Electron Delocalization Molecular Orbital Method" (ASED-MO), which has been described previously.[5,6] The atomic parameters which were used in the calculation were taken from Mehandru and Anderson[7] and Anderson *et al.*[8] 3*d* orbital exponents were used only for the copper atom.[7,8]

RESULTS AND DISCUSSION

The absorption bands of oxyhaemocyanin consist of two major bands in the near-UV to near-IR region and are noticeably intense.[1,2] Two intense absorption bands are found in this region in models of oxyhaemocyanin also,[9–16] but some models have a third major band which also occurs in the spectrum of the non-oxygenated compound.[12–16]

The compound chosen for this study as a model of oxyhaemocyanin is very similar to the planar μ-η^2:η^2-peroxo-bridged side-on bound dimer compound (**5**) of Ross and Solomon,[4] but the oxygen atoms of the peroxo ligand have been lifted and lowered symmetrically *ca* 18° off the equatorial plane of the two copper(II) ions (Fig. 1). Thus, this non-planar side-on bound model compound bears a resemblance to the non-planar symmetric *trans*-μ-O,O′-peroxo-bridged dicopper(II) model of Freedman *et al.*[3] and to a proposed more or less planar side-on bound dimer model by Larrabee and Spiro,[17] which has no endogenous bridging ligand. Very briefly, the model compound has two nitrogen donors at the bond length of 1.997 Å per copper(II) ion. There are two symmetric and equal copper–oxygen bonds to each oxygen of the peroxo group at 1.914 Å. The oxygen–oxygen bond length is 1.410 Å and the copper(II)–copper(II) distance is 3.560 Å

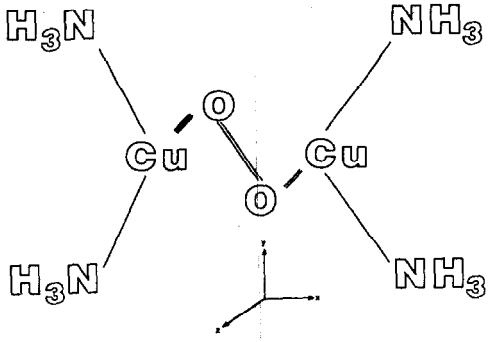

Fig. 1. The model of a peroxodicopper site which may be found in haemocyanin: μ-η^2:η^2-peroxodi(diamminecopper(II))$^{2+}$.

in the model. These distances are similar to the observed bond lengths and copper(I)–copper(I) distances in the structures of the six subunits of *Panulirus interruptus* haemocyanin in the crystal structure reported by Volbeda and Hol[18,19] and are also similar to the reported copper–nitrogen and copper–copper distances in the structures of deoxy- and oxyhaemocyanin determined by the EXAFS method.[20] The non-planar side-on bound model leaves out the two nitrogen donors at long bond distances of 2.77 and 2.66 Å, respectively, each of which is bound to a different copper(II) ion.[18,19]

The molecular orbitals of the model which are shown in Table 1 are for 15 higher-energy orbitals. The symmetry was assigned as the C_{2v} point group (which has a C_2 axis, two symmetry planes, σ_{xz} and σ_{yz}, and no inversion symmetry) rather than the C_{2h} point group (which has a C_2 axis, the inversion operator, and a σ_h plane).[21] At first glance C_{2h} might appear to be the appropriate point group as the geometry of the model has an inversion centre, an equatorial symmetry plane (xy) about the copper(II) ions and a $C_2(z)$ axis. However, if this point group is used, all magnetic dipole-allowed electronic transitions are expected to show resonance enhancement of Raman bands and each electronic transition is allowed by either the magnetic dipole mechanism or the electric dipole mechanism.[22] The assumption was made that the portion of the geometry of the model which might be most useful in determining which electronic transitions are allowed was the central Cu_2O_2 chromophore. The Cu_2O_2 chromophore can be assigned the C_{2v} point group [or, if the model and the dicopper(II) site of haemocyanin are considered to be not strictly planar, the D_2 point group is satisfactory].

The lowest energy unoccupied molecular orbital, assigned zero energy arbitrarily, is a molecular orbital which has mostly $3d_{xy}$(Cu) character and some $3d_{xz}$, $4p_y$ and $4p_z$(Cu) character (Fig. 2). This orbital has a larger percentage of $2p_x$(O) character than copper atomic orbital character and shows antibonding sigma interactions of the $2p_x$(O) atomic orbitals with the $3d_{xy}$ and $3d_{xz}$ atomic orbitals on the copper(II) ions. The symmetry of this orbital is A_1. It is 1.505 eV above the doubly filled HOMO orbital, which is a lone-pair molecular orbital π_V* of the peroxo ligand which has 96.2% oxygen character and some copper character. This molecular orbital has A_2 symmetry and a transition from this orbital, which is non-bonding towards the copper(II) ions, is allowed in the CD spectrum but not in the absorption spectrum.[22] This transition would occur at 824 nm and is close in location to the 930 nm electronic Raman band in oxyhaemocyanin, which was thought to correspond to the singlet–

Table 1. The molecular orbitals of the non-planar side-on bound μ-η^2:η^2-peroxodi(diammine-copper(II))$^{2+}$ model compound calculated by the ASED-MO program are shown. The last column shows the calculated oscillator strength, f, of an electronic transition to the LUMO (top orbital)

triplet transition by Larrabee and Spiro.[17] The oxyhaemocyanin molecule is known to exhibit strong antiferromagnetism and the value of $-2J$ has been estimated to be 550 cm^{-1} for *Limulus polyphemus* haemocyanin.[23] The reported minimum value of $-2J$ would correspond to a separation of 0.068 eV between the singlet and triplet states and no molecular orbital was calculated at this distance from the lowest unoccupied molecular orbital. However, if the value of $-2J$ can be much larger than the reported minimum value, the molecular orbital, which is below the HOMO orbital which was identified as a π_V*(peroxo) orbital above and which has B_2 symmetry, can give an electric dipole allowed transition to the LUMO orbital. This molecular orbital has 64.5% $3d_{xy}$(Cu) and some $3d_{xz}$, $4p_y$ and $4p_z$(Cu) character and it corresponds to the asymmetric combination of the $3d_{xy}$(Cu) atomic orbitals (Fig. 3). The singlet–triplet transition may not be spin-forbidden in a dimeric molecule such as the present non-planar side-on bound model of the active site of oxyhaemocyanin. The electronic transition from the molecular orbital, which has the asymmetric combination of the $3d_{xy}$(Cu) atomic orbitals, to the LUMO orbital, which has the symmetric combination of the $3d_{xy}$(Cu) atomic orbitals, is expected to occur at 601 nm based on Koopman's theorem[24] and, therefore, this transition appears to correspond to the

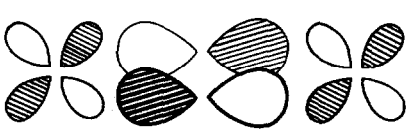

Fig. 2. A schematic diagram of the LUMO of the side-on bound peroxodicopper(II) compound shown in Fig. 1, which has mostly $3d_{xy}$(Cu) and $2p_x$(O) atomic orbital character. The composition of the LUMO is: 30.4% $3d_{xy}$(Cu), 2.0% $4p_z$(Cu), 1.4% $3d_{xz}$(Cu), $\approx$ 0.04% $4p_y$(Cu) and 55.6% $2p_x$(O).

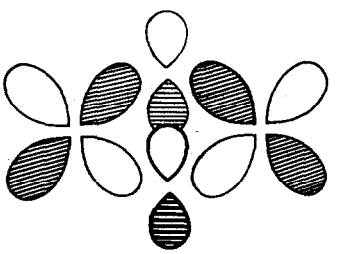

Fig. 3. A schematic diagram of the highest occupied molecular orbital of the side-on bound peroxodicopper(II) compound shown in Fig. 1, which has mostly 3*d*(Cu) atomic orbital character. The composition of this molecular orbital is: 64.5% $3d_{xy}$(Cu), 0.9% $4p_y$(Cu), 0.3% $4p_z$(Cu), $\approx$ 0.4% $3d_{xz}$(Cu), 10.0% $2p_y$(O), 2.1% $2s$(O) and 0.8% $2p_z$(O) atomic orbital character. This molecular orbital is just below the HOMO which has: 87.3% $2p_z$(O), 8.9% $2p_y$(O), $\approx$ 0.001% $2s$(O), 2.4% $3d_{yz}$(Cu), 0.9% $3d_{z^2}$(Cu), 0.4% $3d_{x^2-y^2}$(Cu), 0.03% $4s$(Cu) and $\approx$ 0.01% $4p_x$(Cu).

observed 580 nm absorption band in oxyhaemocyanin, which has an extinction coefficient of *ca* 1000 M^{-1} cm^{-1} and which had been assigned previously as the $\pi_V^* \rightarrow Cu^{2+}$ charge transfer band.[1-4,17] Similar bands were observed in the visible region of the absorption spectrum of model compounds and these bands were also assigned as ligand-to-metal charge-transfer bands from the peroxo ligand to the copper(II) ions.[9-11,13-16] The nature of the absorption band, which is at about 350 nm and which exists in the deoxygenated model compounds, was left unexplained by the authors.[13-16] If the $4p_z$ and $4p_x$ atomic orbitals on the coppers are considered to be distorting portions of a total $3d$ wavefunction f in the formulation of Griffith[25] so that $f = f_g + f_u$, and if approximate molecular orbitals consisting of the $2p_z$ atomic orbitals on the oxygens and the $4p_z$ or $4p_x$ atomic orbitals on the coppers are employed, the oscillator strength, f, of an electronic transition which is electric dipole allowed may be calculated. The value of f is 2.3×10^{-2} for the electronic transition expected at 601 nm. This transition is allowed by the magnetic dipole mechanism as well. Its intensity may be due to the presence of σ Cu—O character in the lower-energy orbital and σ^* Cu—O character in the higher-energy orbital.

The remaining eight $3d$ atomic orbitals of the two copper(II) ions make large contributions to the eight molecular orbitals which follow the top two doubly filled molecular orbitals. The first of these is a mostly $3d_{xz}$(Cu) orbital which has large π_V lone-pair contributions in it. This molecular orbital is the asymmetric combination of the $3d_{xz}$(Cu) atomic orbitals and, although it is calculated to have high oscillator strength, it has A_2 symmetry and a transition from this orbital to the LUMO orbital is expected to be observed in the CD spectrum in the C_{2v} point group. In fact, the CD spectrum of oxyhaemocyanin has a band at *ca* 480 nm, which is not observed in the absorption spectrum.[2]

The region in oxyhaemocyanin in the neighbourhood of 350 nm has very intense absorptions, which are also seen in the CD spectrum.[2] Molecular orbitals which may give rise to transitions in this region appear to have mostly $3d_{x^2-y^2}$(Cu) but also some $3d_{z^2}$(Cu) and $3d_{yz}$(Cu) atomic orbital character, in addition to σ_{O-O} and π_V^* lone-pair character from the π_V^* orbitals which were degenerate in the peroxo ligand. Electronic transitions from the higher-energy molecular orbital, which has the symmetric combination of the $3d_{x^2-y^2}$(Cu) atomic orbitals to the LUMO orbital, are calculated to have low oscillator strength ($f = 5.2 \times 10^{-7}$).

Very high oscillator strength is calculated for an electronic transition from a lower-energy molecular orbital which is mostly made up of the symmetric combination of the $3d_{z^2}$(Cu) atomic orbitals. This molecular orbital includes considerable amounts of $3d_{x^2-y^2}$, $3d_{yz}$ and $4s$(Cu) atomic orbitals, in addition to $3d_{z^2}$ character, and is calculated to give an electronic transition to the LUMO orbital at 317 nm ($f = 0.159$).

Similarly, only one combination of the $3d_{yz}$(Cu) atomic orbitals which follow the symmetric combination, is expected to show an electronic transition to the LUMO orbital in the C_{2v} point group ($f = 2.6 \times 10^{-3}$ for this transition).

The molecular orbital which is next may be described as a σ copper–oxygen orbital. An electronic transition to the LUMO orbital is expected at 294 nm ($f = 6 \times 10^{-4}$). The molecular orbital below it has σ_{O-O} character. An electronic transition from this molecular orbital to the LUMO orbital is calculated to occur at 264 nm and to have much higher oscillator strength ($f = 2.87 \times 10^{-2}$). The π_{Cu-O} molecular orbital follows this orbital and it is followed by the second σ_{Cu-O} molecular orbital. A transition from this σ_{Cu-O} molecular orbital to the LUMO orbital is calculated to have high oscillator strength ($f = 1.05 \times 10^{-2}$).

Molecular orbitals of σ_{Cu-N} character are calculated to give rise to electronic transitions below 200 nm in this calculation. However, contributions from atomic orbitals on the nitrogen donors appear to enter into the σ_{Cu-O} molecular orbitals, which have been assigned B_1 and A_1 symmetry. Thus, these σ_{Cu-O} molecular orbitals may have electric dipole allowed electronic transitions, which are x-polarized and z-polarized, respectively. These electronic transitions to the LUMO orbital are calculated to occur at 294 and 239 nm, respectively, and are expected to show resonance-enhanced-Raman lines in the C_{2v} point group.[22]

CONCLUSIONS

The allowed electronic transitions at *ca* 600 nm and 370 nm in the non-planar side-on bound peroxodi(diamminecopper(II))$^{2+}$ model are calculated to have high oscillator strengths. These electronic transitions may correspond to the major absorption bands observed in oxyhaemocyanin at *ca* 580 and 350 nm. These molecular orbitals appear to contain a great deal of $3d$(Cu) atomic orbital character in addition to lone-pair character from the peroxo ligand. Thus, this description differs substantially from the description given by Ross and Solomon,[4] Solomon *et al.*,[2] Freedman *et al.*[3] and Larrabee and Spiro.[17] Of the 15 molecular orbitals which are reported in Table 1, only the HOMO level and four others have essentially lone-pair character or may

be considered to be a peroxo ligand bond orbital. The calculation appears to explain the intensities of the observed electronic transitions in oxyhaemocyanin satisfactorily in a semi-quantitative way.

The singlet–triplet transition in the model is calculated to correspond to more than 2 eV and to occur at about 600 nm. A singlet–triplet transition is spin-forbidden in a compound,[26] but it may not be forbidden in the antiferromagnetically coupled ground state of the dicopper(II) site in the model.

PREPARATION AND CHARACTERIZATION OF Mn^{II}, Co^{II}, Ni^{II}, Cu^{II} AND Zn^{II} KANAMYCIN COMPLEXES

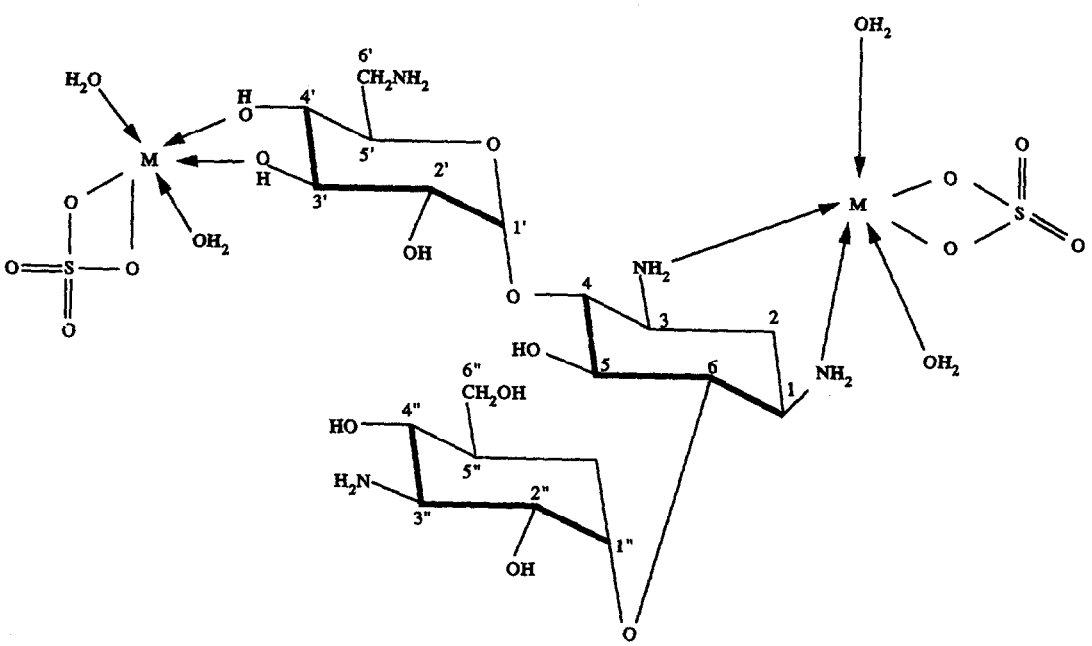
A. MASHALY

Chemistry Department, Faculty of Science, Menoufia University, Shebin El-Kom, Egypt

(*Received* 13 *July* 1992; *accepted* 25 *November* 1992)

Abstract—Binuclear complexes of manganese(II), cobalt(II), nickel(II), copper(II) and zinc(II) with kanamycin sulphate have been synthesized and characterized by elemental analysis, IR, ^{1}H NMR, electronic and ESR spectra in order to throw more light on their structures. The spectral results obtained indicate octahedral geometry around manganese(II), cobalt(II) and nickel(II), distorted octahedral geometry around copper(II) and tetrahedral geometry around zinc (II) ions.

Kanamycin, 0-(3-amino-3-deoxy-α-D-glucopyranosyl)-(1→6)-0-(6-amino-6-deoxy-α-D-glucopyranosyl)-(1→4)-2-deoxy-D-streptamine,[1] has found worldwide use in the treatment of serious gram-negative infections.[2] Despite the importance of aminoglucosides and their metal chelates, little attention has been paid to them by previous authors.[3–6] In addition, no systematic studies are present in the literature concerning complex formation between kanamycin and transition metal ions. The aim of the present investigation was to synthesize the complexes of manganese(II), cobalt (II), nickel(II), copper(II) and zinc(II) with kanamycin and to characterize them in a systematic way using elemental analysis, IR, electronic, ^{1}H NMR and ESR spectra and magnetic moments in order to throw more light on their structure.



I

where M = Mn^{II}, Co^{II}, Ni^{II}, Cu^{II}, in Zn^{II}. Axial water molecules are absent.

EXPERIMENTAL

All the compounds used in the present investigation were pure laboratory grade chemicals from BDH. Kanamycin sulphate was an A.R. product supplied by the Memphies Company, Egypt.

Preparation of the complexes

Kanamycin sulphate (0.001 mol) was dissolved in twice distilled water (10 cm^3). After complete dissolution of the ligand an ethanolic solution of the metal chloride (0.001 mol dissolved in 15 cm^3 of ethanol) was added dropwise. The addition of KOH (0.0019 mol) dissolved in ethanol (75 cm^3) to the solution mixture caused various colour changes and the formation of coloured precipitates, the colours depending on the nature of the metal(II) ion used; buff in the case of manganese(II), pink for cobalt(II), blue–grey for nickel(II), blue for copper(II) and white for zinc(II). After stirring the reaction mixture for 6 h the complexes thus obtained were separated by centrifugation, washed with ethanol and then ether and dried *in vacuo*. The apparatus and working procedures were as described previously.[7,8]

RESULTS AND DISCUSSION

On the basis of the analytical data obtained (Table 1) the complexes prepared can be formulated as $[M_2(Kan.)(H_2O)_n(SO_4)_2]$, where M = Mn, Co, Ni, Cu, and Zn; n = 0–4 and Kan. is kanamycin. The molar conductances of all complexes in DMF were less than 12 Ω^{-1} cm^2 mol^{-1}, indicating that they are non-electrolytes.[9] This indicates the coordinated nature of $[SO_4]^{2-}$ and also that kanamycin behaves as a neutral ligand. The mode of bonding between kanamycin and the metal ions was deduced from the results of the following investigations (Table 2).

(a) On comparing the IR spectra of the solid complexes with that of kanamycin sulphate, the following can be pointed out. The existence of water molecules (lattice or coordinated) in the complexes is gathered from the appearance of the new broad band at 3450–3420 cm^{-1}, corresponding to γ_{sym} of coordinated water. The presence of a new band at 805–810 cm^{-1}, especially in the spectra of copper(II) and manganese(II) complexes, not present in the spectra of free kanamycin, can be assigned to the out-of-plane deformation vibrations of coordinated water[10,11] and supports the presence of coordinated water molecules in copper(II) and manganese(II) complexes. The IR spectra of metal (II)-kanamycin complexes display interesting changes in comparison to that of the free kanamycin molecule.

The bands observed at 3320 and 3200 cm^{-1} in the spectra of the free ligand due to ν(OH) and ν(NH), respectively, are shifted by 100–150 cm^{-1} to lower wave numbers in the spectra of the metal(II)-kanamycin complexes with the same intensity. This denotes that two NH_2 and two OH alcoholic groups contribute to chelation, which is in accordance with the results of conductance measurements. Based on the information gained, kanamycin behaves as a neutral bidentate chelate ligand on reaction with metal(II) ions.

The presence of ν_3(S—O) and ν_1(S—O) in the spectra of kanamycin complexes, not present in the spectra of the free kanamycin located at 1080–1070

and 980–950 cm^{-1}, indicates the chelating bidentate nature of the $[SO_4]^{2-}$ ion. This is in line with earlier studies on the coordinated nature of sulphate complexes.[10,12,13] The two new bands observed at 490–480 and 390–375 cm^{-1} in the spectra of the kanamycin complexes can be assigned to ν(M—O) and ν(M—N), respectively, hence confirming the mode of bonding suggested through the oxygen of the —OH and nitrogen of the NH groups.

(b) The ^1H NMR spectra for nickel(II) and zinc (II) complexes in DMSO (d_6) display a shift of 0.6–0.8 ppm downfield in the spectra of the complexes: δ(2-Ha) (1.65), δ(2-He) (2.45), δ(3″-H) (3.50), δ(2″-H) (3.89), δ(2′-H) (4.20), δ(3′-H) (4.50) and δ(1′-H) (6.20 ppm).

The shift of the signals downfield is due to the deshielding effect of the central metal ion on the kanamycin protons as a result of coordination. The presence of a new signal at $\delta(H_2O)$ (4.0 ppm) in the spectra of these complexes, not present in the spectrum of free kanamycin, can be assigned to H_2O and supports the coordinated nature of the water molecules in these complexes.

The bulk magnetic susceptibility measurements for all the solid complexes under investigation at room temperature, 300 K, are indicative of: five unpaired electrons per manganese(II) ion, $\mu_{eff} = 5.8$, three unpaired electrons per cobalt(II) ion, $\mu_{eff} = 4.04$, two unpaired electrons per nickel (II) ion, $\mu_{eff} = 3.21$ and one unpaired electron per copper(II) ion, $\mu_{eff} = 1.7$ B.M. (Table 2). The magnetic moments are close to the spin-only moments of the free ions, which indicates the absence of metal–metal interactions within the binuclear complexes under investigation.

(c) The reflectance spectra of the complexes under investigation exhibit broad maxima with λ_{max} at 510 and 460 nm for manganese(II), 530 and 960 nm for cobalt(II), 415, 620 and 1135 nm for nickel(II), 810 and 650 nm for copper(II) and 380 nm for zinc(II) complexes. These bands can be assigned to: $^6A_{1g} \rightarrow {}^4T_{2g}(G)$, $^6A_{1g} \rightarrow {}^4T_{1g}(G)$; $^4T_{1g} \rightarrow {}^4T_{1g}(P)$, $^4T_{1g} \rightarrow {}^4T_{2g}$; $^3A_{2g} \rightarrow {}^3T_{1g}(P)(\nu_3)$, $^3A_{2g} \rightarrow {}^3T_{1g}(\nu_2)$, $^3A_{2g} \rightarrow {}^3T_{2g}(\nu_1)$, $^2B_{1g} \rightarrow {}^2B_{2g}$; $^2B_{1g} \rightarrow {}^2E_g$ transitions, as well as charge-transfer interactions within the whole molecule, respectively. These spectral patterns are characteristic of octahedral geometry around manganese(II), cobalt(II) and nickel(III) ions, distorted octahedral geometry around copper(II) ions and tetrahedral symmetry around zinc(II) ions.[14]

(d) *X*-band ESR spectra of the manganese(II)- and copper(II)-kanamycin complexes under investigation (Fig. 1) were measured at room temperature in order to elucidate the nature of the coordination around the manganese(II) and copper(II) ions. The spectra show an intense broad signal and no obvious hyperfine splitting for manganese(II), $g_{eff} = 1.9417$; the pattern of the g_{eff} value, together with the shape of the ESR spectra, indicate octahedral geometry around the manganese(II) ion. For the copper(II)-kanamycin complex the spectrum exhibits an intense broad signal with two lines at $g_{\parallel} = 2.1217$ and $g_{\perp} = 2.0954$, with no obvious hyperfine structure. The calculated value $[g_{iso} = 1/3(2g_{\perp} + g_{\parallel})]$ for the copper-kanamycin com-

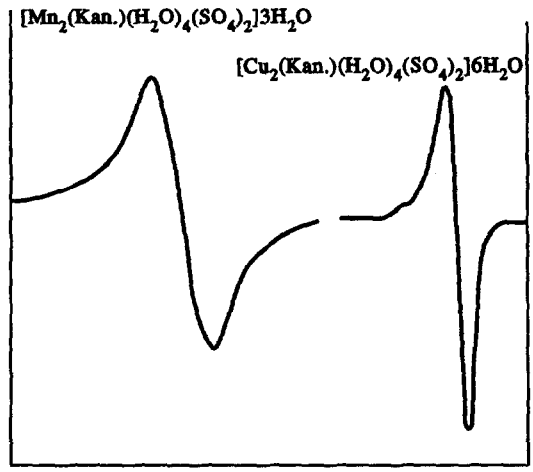

Fig. 1. *X*-band ESR spectra of copper(II)- and manganese(II)-kanamycin complexes at 298 K.

plex amounts to 2.1058, which is in reasonable agreement with the observed value for g_{iso} of copper(II) in similar axial symmetry.[15,16] The values of $G = (g_{\parallel}^{-2}/g_{\perp}^{-2}) < 4$ reveal that exchange is taking place and the local tetragonal axes are misaligned.[17,18]

Based on the knowledge gained from the present investigation, the bonding of metal(II) ions to kanamycin can be formulated as shown in **I**.

(*Received* 27 *August* 1992; *accepted* 23 *November* 1992)

Abstract—Dithiocarbamates react with excess 1,2-bis(dimethylphosphino)ethane (DMPE) in acid conditions in the presence of $[Tc(OH)(O)(DMPE)_2]^{2+}$ to generate the novel zwitter-ionic ligand $^-SCH_2P^+(CH_3)_2(CH_2)_2P(S)(CH_3)_2$ (abbreviated SCP). The technetium(III) complex $[Tc(SCP)_2(DMPE)_2](PF_6)_3$ has been isolated and characterized by elemental analysis, UV–vis spectroscopy and X-ray crystallography. Bond lengths around the octahedrally coordinated technetium(III) ion are Tc—S = 2.299(2) and Tc—P (average) = 2.437(8) Å. Electrochemical and spectroelectrochemical measurements are reported for the reversible technetium(III/II) couple; $E^{0\prime}$ has been determined to be −0.113 V vs Ag/AgCl (0.5 M TEAP/DMF). In addition, a chemically irreversible technetium(II/I) couple is observed at −1.310 V. The properties of $[Tc^{III/II}(SCP)_2(DMPE)_2]^{3+/2+}$ are compared to those observed previously for the related *cis*- and *trans*-$[Tc^{III/II}(SR)_2(DMPE)_2]^{+/0}$ complexes.

We[1–4] and others[5] are currently engaged in the exploration of six-coordinate cationic technetium-bis(thiolato) complexes with bidentate phosphine ligands. The technetium 3+ oxidation state is most stable in this series of compounds, although solids containing technetium in the 2+ oxidation state can be isolated. Technetium(III)/(II) redox potentials span a range of values (~ −0.2 to −0.6 V vs Ag/AgCl) as a result of manipulation of the R group on the thiolato ligand. A study of *cis* vs *trans* isomer formation in these complexes has been evolving and a reasonable explanation for observed isomer ratios has recently been proposed.[6] A number of crystallographic studies have shown little variability within a specific technetium oxidation state, i.e. all the technetium(III) complexes tend to have identical structural parameters and likewise for the technetium(II) complexes. The visible absorption spectra of these complexes contain sulphur-to-technetium charge-transfer bands and the energies of these bands can be related to their reduction potentials. In turn, the reduction potentials are related to the nucleophilicity of the thiolato ligand.

Most recently, the tris chelate complex [Tc(tdt)

Kirchhoff, Department of Chemistry, University of Toledo, Toledo, OH 43606, U.S.A. Dr Edward Deutsch, Mallinckrodt Medical, Inc., 675 McDonnell Blvd, P.O. Box 5840, St Louis, MO 63134, U.S.A.

‡ Authors to whom correspondence should be addressed.

$(DMPE)_2]^+$ [where tdt is 3,4-toluenedithiolate and DMPE is 1,2-bis(dimethylphosphino)ethane] has been prepared and examined.[7] The trigonal prismatic distortion induced by the tdt ligand is accompanied by unusual properties which suggest that the technetium(III) centre in $[Tc(tdt)(DMPE)_2]^+$ is displaying some "technetium(II) character". This has encouraged further studies of other complexes containing bidentate sulphur ligands.

Dithiocarbamates are an interesting group of ligands that can stabilize unusual oxidation states, have multiple bonding properties and bridging modes of coordination.[8] The preparation and study of technetium complexes of dithiocarbamates, also known as 1,1-dithiolato ligands,† would allow important comparisons to $[Tc(tdt)(DMPE)_2]^+$ since tdt is a member of the class of 1,2-dithiolato ligands. The following is a preliminary report of our dithiocarbamate studies, wherein under the reaction conditions utilized the intact dithiocarbamate anion does not function as a ligand to technetium. Rather, a novel zwitter-ionic thiolato ligand is formed by the reaction of dithiocarbamate with DMPE. Since the product so formed contains a new thiolato ligand, we have characterized it fully and have related it to previously studied $[Tc(SR)_2(DMPE)_2]^{+/0}$ complexes.

EXPERIMENTAL

CAUTION! Technetium-99 emits a low energy (0.292 MeV) β particle with a half-life of 2.12×10^5 years. When handled in milligram amounts ^{99}Tc does not present a serious health hazard since common laboratory materials provide adequate shielding. Bremsstrahlung is not a significant problem due to the low energy of the β particle emission, but normal radiation safety procedures must be used at all times, especially when dealing with solid samples, to prevent contamination and inadvertent inhalation. In this paper the symbol Tc refers only to technetium-99; the metastable isotope ^{99m}Tc was not used in these studies.

Reagents

Unless otherwise noted, all chemicals were of reagent grade. Technetium-99, in the form of solid ammonium pertechnetate, was obtained from Oak Ridge National Laboratory and purified.[9] The DMPE ligand was purchased from Strem Chemical Co. and used without further purification. DMF and propylene carbonate were obtained from Burdick and Jackson Lab., Inc. Polarographic grade TEAP from G. F. Smith Chemicals was used in the electrochemical measurements. Prior to use the TEAP was dried at 60°C *in vacuo* over P_2O_5. No significant electroactive impurities were detected in either the solvent or supporting electrolyte. Na(dedc)·$3H_2O$ was purchased from Fisher Scientific and Na(dmdc)·$2H_2O$ from Aldrich Chemicals.

Synthesis of $[Tc(SCP)_2(DMPE)_2](PF_6)_3$

The starting complex, *trans*-$[Tc(OH)(O)(DMPE)_2](PF_6)_2$, was prepared by a method similar to that described in a previous paper,[1] using NH_4TcO_4 (200 mg, 1.1×10^{-3} mol) and DMPE (0.8 cm^3, 4.8×10^{-3} mol). To the orange–brown reaction mixture was added dropwise a solution of NH_4PF_6 (4 g) dissolved in a small amount of 1:1 methanol–water (v/v). The brown precipitate which appeared was kept at room temperature for 1 h and then refrigerated overnight. The precipitate was collected by filtration, washed with a methanol–water (1:1) solution, washed with pure water and then dried in air. Yield: 1.34 g. This material is a mixture of *trans*-$[Tc(OH)(O)(DMPE)_2](PF_6)_2$ and $H_2DMPE \cdot 2PF_6$.

To a suspension containing the above material (150 mg) in degassed ethanol (5 cm^3) was added Na(dedc)·H_2O (340 mg) in degassed ethanol (10 cm^3). This mixture was stirred at *ca* 50°C for 10 min, whereupon it became deep brown in colour. To this solution was added concentrated CF_3SO_3H (0.4 cm^3). The solution was kept at 50°C and continuously stirred for 40 min. The colour of the solution changed gradually from deep brown to dark brown to dark yellowish green and then to deep bluish green. The solution was then cooled to *ca* 30°C and solid NH_4PF_6 (0.2 g) was added. After standing at room temperature for *ca* 30 min a blue precipitate appeared which was collected by filtration, washed with ethanol and dried in a vacuum desiccator. Yield: 15–17 mg. This blue product was recrystallized as a powder from propylene carbonate/ethanol. Found: C, 26.2; H, 5.4; N,

† Acronyms and abbreviations: The following acronyms and abbreviations are used in this article: tdt = 3,4-toluenedithiolate; dedc = diethyldithiocarbamate; DEPE = 1,2-bis(diethylphosphino)ethane; dmdc = dimethyldithiocarbamate; DMF = N,N-dimethylformamide; DMPE = 1,2-bis(dimethylphosphino)ethane; DMSO = dimethylsulphoxide; OTTLE = optically transparent thin-layer electrode; PDE = platinum disk electrode; Ph = phenyl; pmdc = pentamethylenedithiocarbamate; ppmdc = 3-piperidino-pentamethylenedithiocarbamate; SCP = $^-SCH_2P^+(CH_3)_2(CH_2)_2P(S)(CH_3)_2$; STTCT = sulphur-to-technetium charge transfer; TEAP = tetraethylammonium perchlorate.

< 0.1; F, 24.2; P, 24.1; S, 7.7. Calc. for $[Tc(SCH_2P(CH_3)_2CH_2CH_2P(CH_3)_2S_{0.71})_2(DMPE)_2](PF_6)_3 \cdot 1.75(C_4H_6O_3) = C_{33}H_{78.5}O_{4.75}F_{18}P_{11}S_{3.4}Tc$: C, 26.6; H, 5.4; F, 24.4; P, 24.4; S, 7.8%. The non-stoichiometric amount of sulphur in the formulation is discussed in the crystallography sections below.

Single crystals suitable for X-ray analysis were obtained by dissolving the blue product at *ca* 38°C in a solution of 1:7 (v/v) propylene carbonate/ethanol. The solution was filtered to remove insoluble materials. The filtrate, which was preserved under an argon atmosphere, was held at room temperature for 4 h and then placed in a refrigerator for 4 days. The deep blue–black, diamond-plate shaped crystals which appeared were collected by filtration, washed with ethanol and dried in air.

Similar blue products were obtained by the above procedure using dmdc, pmdc and ppmdc instead of the dedc. The pmdc and ppmdc ligands were prepared by literature methods.[10]

Measurements

Elemental analysis was performed by Galbraith Laboratories, Knoxville, TN, U.S.A. UV–vis spectra were recorded in acetonitrile on a Cary 210 spectrophotometer (Varian) at ambient temperature. Electrochemical measurements were made with a Bioanalytical Systems, Inc. (BAS) CV-1B voltammograph. Potentials were monitored with a Keithley 178 digital multimeter and voltammograms were recorded on a Hewlett–Packard 7015B *X–Y* recorder. The visible spectra in the spectroelectrochemical experiment were also recorded on a Cary 210 spectrophotometer; the cell compartment was modified to accommodate electrical leads and an inert gas inlet. The working electrode for conventional cyclic voltammetry was a PDE (BAS). OTTLEs were constructed as previously described with 100 wires per inch gold minigrid.[11] An aqueous Ag/AgCl (3 M NaCl) electrode (BAS) and a platinum wire were used as reference and auxiliary electrodes, respectively. The reference electrode was isolated from the solution by a porous Vycor plug. All potentials are reported vs the Ag/AgCl (3 M NaCl) electrode.[12] In general, electrochemical experiments were performed as previously described.[13–17]

Crystallography. Single-crystal X-ray diffraction experiments were performed on a Nicolet R3 automated diffractometer with a graphite monochromator. Data are summarized in Table 1. All non-hydrogen atoms are refined anisotropically. Hydrogen atoms are placed in calculated positions with U defined as $\sim$ 1.5 times the equivalent isotropic U of the carbon atom to which they are bound. Absorption corrections were empirically derived from psi scans with the program SHELXTL.[18] Structure solutions by Patterson methods and refinements used the programs of SHELX-76.[19] Neutral atom scattering factors and corrections for anomalous dispersion were from the International Tables for X-ray Crystallography, Vol. 4.[20]

RESULTS AND DISCUSSION

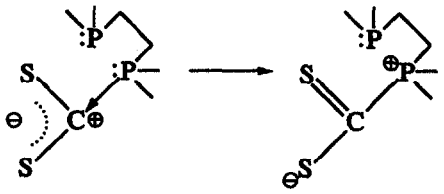
Synthesis

Excess amounts of a dithiocarbamate, such as dmdc, dedc, pmdc or ppmdc, added to a suspension of *trans*-$[Tc(OH)(O)(DMPE)_2](PF_6)_2$ and $H_2DMPE \cdot 2PF_6$ under anaerobic conditions yield deep brown solutions. Acidification of these solutions produces gradual colour changes through dark brown to dark yellowish green and finally to a deep bluish green, ultimately yielding the title complex. These reactions do not proceed without the dithiocarbamate. Dithiocarbamates are known[8,10,21] to undergo an acid induced C—N cleavage to produce an amine and carbon disulphide.

$$H^+ + R_2NCS_2^- \rightleftharpoons HNR_2 + CS_2$$

The carbon atom of CS_2 is susceptible to nucleophilic attack by the DMPE phosphorus lone pair,

yielding a positively charged phosphonium ion and a negatively charged thiol:



The final step in the formation of SCP involves a two-equivalent oxidation and the transfer of a sulphido group to the terminal phosphine. This process may or may not be assisted by coordination to technetium; it is unclear at what stage in the reaction sequence the thiol ligates to technetium. Reduction of the technetium(V) ion can be accomplished by excess dithiocarbamate or excess DMPE.

Under anaerobic conditions, a small amount of 1 M NaOH aqueous solution added to an aqueous solution of *trans*-$[Tc(SCP)_2(DMPE)_2]^{3+}$ yields a brown precipitate. When dissolved in acetonitrile this brown precipitate exhibits the identical absorption spectrum as that obtained at −0.500 V in the spectroelectrochemistry experiment (*vide infra*, spectrum B in Fig. 4). This suggests that the brown precipitate is the technetium(II) complex *trans*-$[Tc(SCP)_2(DMPE)_2]^{2+}$. When a small amount of concentrated HCl is added to an acetonitrile solution of the brown precipitate under an argon atmosphere, the colour of the solution changes to greenish blue and its spectrum coincides with that of the starting technetium(III) complex. Apparently the pH controlled interconversion between the technetium(III) and (II) complexes *trans*-$[Tc(SCP)_2(DMPE)_2]^{2+/3+}$ under anaerobic conditions is reversible; this pH induced redox interconversion is a general feature of *trans*-$[Tc^{III}(SR)_2(DMPE)_2]^{+/0}$ (R = alkyl or benzyl) complexes.[1,2]

The *trans*-$[Tc(SCP)_2(DMPE)_2](PF_6)_3$ salt is soluble in water, methanol, acetone, acetonitrile, propylene carbonate, DMF and DMSO, but is insoluble in 2-propanol, dichloromethane, chloroform, carbon tetrachloride and hexane. The complex is slightly soluble in ethanol and *p*-dioxane. These observations are consistent with the presence of a 3+ charged cation.

The synthesis of the novel ligand SCP has its basis in the acid induced C—N cleavage of dithiocarbamates. Consequently, reactions intending to preserve the dithiocarbamate ligand for intact coordination to technetium must be conducted in alkaline conditions. Even so, the zwitter-ionic ligand SCP is interesting in its own right. For one thing, the negatively charged ligating thiol is α to a positively charged phosphonium group and this is expected to significantly decrease the nucleophilicity of the thiol. Nucleophilicity, or σ-donating ability, of the thiol has been one of the properties we have been tracking through a series of technetium and rhenium thiolato complexes, in order to explore how changes in R are expressed in the redox potentials and spectral energies of the complexes.[1-4,6,22,23] Further interest in SCP might come from its potential use for bidentate coordination. In addition, modification of the terminal sulphido group could make SCP a valuable starting material.

UV–vis spectrum

The absorption spectrum of *trans*-$[Tc(SCP)_2(DMPE)_2]^{3+}$ exhibits three bands at 15.88 ($\varepsilon = 15.8 \times 10^3$ M^{-1} cm^{-1}), 26.60 ($\varepsilon = 4.6 \times 10^3$ M^{-1} cm^{-1}) and 36.90 kK ($\varepsilon = 7.2 \times 10^3$ M^{-1} cm^{-1}). The spectrum of the complex in acetonitrile is shown in Fig. 1. The absorption pattern over the entire region is similar to those of the corresponding bis-thiolato-DMPE complexes, *trans*-$[Tc(SR)_2(DMPE)_2]^+$, where R = methyl, ethyl, n-propyl, benzyl and *p*-methoxybenzyl.[2] By analogy,[4] the two lower energy bands are assigned to be sulphur (π) → Tc(π*) transitions. The higher energy UV absorption at 36.9 kK represents a P → Tc charge transfer band arising from the DMPE ligand.

Crystallography of trans-$[Tc(SCP)_2(DMPE)_2](PF_6)_3 \cdot 2(C_4H_6O_3)$

The independent portion of the structure consists of a half-cation, half-anion, complete PF_6 anion and a loosely held solvent molecule. The technetium atom and the phosphorus atom [P(5)] from the half-anion each occupy crystallographic inversion

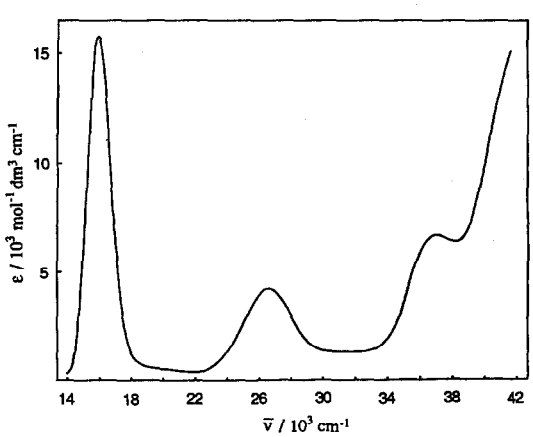


Fig. 1. The absorption spectrum of *trans*-$[Tc(SCP)_2(DMPE)_2]^{3+}$ recorded in acetonitrile.

centres. The general position PF_6 anion shows obvious disorder, so the six fluorine atoms around P(6) are described by 12 partial fluorine atoms. F(4)–F(9) are at 0.65 occupancy and F(10)–F(15) are at 0.35 occupancy. The assignment of these partial fluorine atoms makes little difference in the *R* value, but does improve the final ΔF map. Bond lengths and angles for the cation are presented in Table 2. Figure 2 illustrates the geometry and assigned labelling scheme for the cation.

The technetium atom is coordinated in *trans* octahedral geometry. The DMPE ligand bite angle is the largest distortion from ideal geometry and is normal for this ligand; P(3)—Tc—P(4) = 80.81(7)°. The zwitter-ionic ligand SCP is formally neutral, carrying a formal negative charge on the coordinated sulphur atom [S(1)] and a formal positive charge on the atom P(1). The terminal $R_3P{=}S$ fragment is neutral since the phosphorus–sulphur bond is best described as a double bond [S(2)—P(2) = 1.920(4) Å]. For comparison, the molecule $(2,4,6\text{-}Me_3C_6H_2PS_2)_2$ has a terminal P=S length of 1.917(1) Å.[24] P—S linkages are often found in dithiophosphate molecules wherein the phosphorus atom binds to two terminal sulphur atoms, theoretically in one double bond and one single bond. In these dithiophosphate molecules there is some delocalization and the average P—S length is approximately 1.97 Å,[25] significantly longer than that observed in the title complex.

The terminal sulphur atom [S(2)] has been assigned an occupancy factor less than unity (0.71) based on a comparison of thermal parameters with the other terminal atoms [C(6) and C(7)] and based on the knowledge that the elemental analysis implies the presence of a sulphur atom in about 71% of these sites in a bulk sample. The remaining sites might be occupied by either the phosphorus lone pair electrons or possibly a doubly-bound oxygen atom, neither of which would disturb the overall charge of the complex or lead to serious lattice disruptions. Disorders of the sulphido/oxo type have been noted in other structures.[26]

The solvated propylene carbonate molecule is disordered and probably exists at partial occupancy in the crystal lattice, although the solvent was assigned full occupancy in the model leading to a technetium/solvent ratio of 1/2. In fact, the elemental analysis results agree best with 1.75 solvent molecules per technetium (*vide supra*).

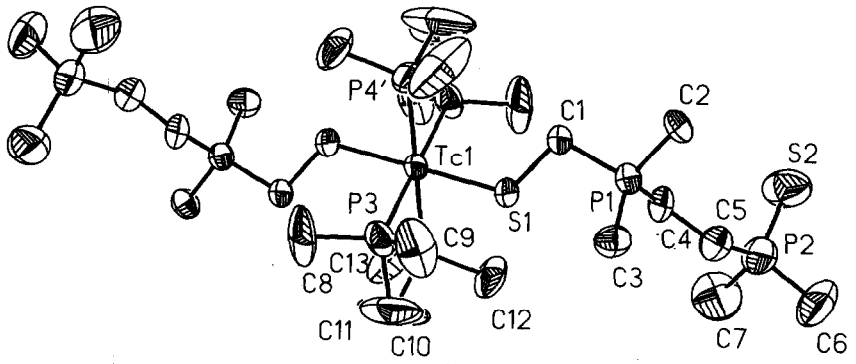

Fig. 2. A perspective view of *trans*-$[Tc(SCP)_2(DMPE)_2]^{3+}$ showing the assigned atom labels. The technetium atom occupies a crystallographic inversion centre. Ellipsoids represent 50% probability.

Structural analyses have been published previously for *trans*-$[Tc^{III}(SCH_3)_2(D)_2]^+$, where D = DMPE and DEPE,[1] and correspond closely with the structural parameters measured herein, cf. Tc—P = 2.428(6), Tc—S = 2.300(3) Å, Tc—S—C = 122.3(8)° and S—C = 1.842(7) Å for *trans*-$[Tc^{III}(SCH_3)_2(DMPE)_2]^+$; Tc—P = 2.45(1), Tc—S = 2.3025(5) Å, Tc—S—C = 121.2(1)° and S—C = 1.821(4) Å for *trans*-$[Tc^{III}(SCH_3)_2(DEPE)_2]^+$; and Tc—P = 2.437(8), Tc—S = 2.299(2) Å, Tc—S—C = 122.7(2)° and S—C = 1.842(7) Å for *trans*-$[Tc^{III}(SCP)_2(DMPE)_2]^{3+}$. Both Tc—S and Tc—P lengths in these complexes are sensitive to the technetium oxidation state and support the assignment of technetium(III) in the title complex. It should be noted that there is a substantial formal charge difference between the +1 complex $[Tc(SCH_3)_2(DMPE)_2]^+$ and the +3 complex $[Tc(SCP)_2(DMPE)_2]^{3+}$, but the coordination distances around technetium remain constant. A summary table presented previously[4] shows that Tc^{III}—SR distances are relatively insensitive to the nature of the R group.

Cyclic voltammetry

Figure 3 shows the cyclic voltammogram at a PDE for a 0.6 mM solution of *trans*-$[Tc(SCP)_2(DMPE)_2]^{3+}$, wherein two major redox couples are observed. A negative potential scan initiated at +0.400 V gives a reduction wave with a peak potential (E_{pc}) at −0.150 V, and upon switching the potential at −0.500 V the coupled oxidation wave (E_{pa}) is observed at −0.076 V on the positive scan. The separation between the cathodic and anodic peaks is 74 mV, which is typical for the one-electron reduction of *trans*-$[Tc(SR)_2(DMPE)_2]^{+/0}$ complexes[1] in TEAP/DMF. The ratio of the anodic/cathodic peak current is nearly unity. These facts indicate that the redox couple can be identified with the following one-electron reversible reaction:

$$trans\text{-}[Tc^{III}(SCP)_2(DMPE)_2]^{3+} + e^- \rightleftharpoons trans\text{-}[Tc^{II}(SCP)_2(DMPE)_2]^{2+}.$$

The formal reduction potential, $E^{0\prime}$, is determined to be −0.113 V and is recorded in Table 3. If the voltammogram is continued for a second cycle with an extension of the negative potential window to −1.55 V, a second reduction wave is observed with E_{pc} = −1.345 V. On the subsequent positive scan the corresponding oxidation is observed at E_{pa} = −1.275 V ($E^{0\prime}$ = −1.310 V). The second process is attributed to the technetium(II/I) redox couple. A close examination of the second cyclic voltammogram indicates that i_{pa} for the oxidation of technetium(II) to technetium(III) is reduced relative to i_{pc} for the reduction of technetium(III) to technetium(II) (i_{pc}/i_{pa} is approximately 1.85) and i_{pa} for the oxidation peak at +0.28 V is increased. This behaviour in the cyclic voltammogram can

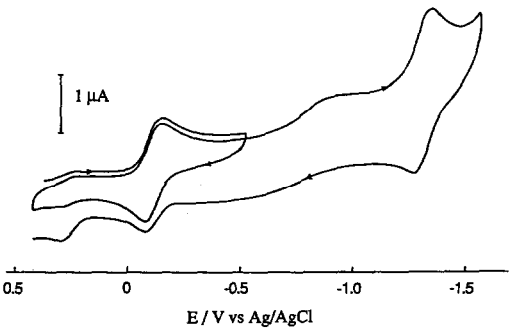

Fig. 3. Cyclic voltammograms of 0.6 mM *trans*-$[Tc(SCP)_2(DMPE)_2]^{3+}$ in 0.5 M TEAP/DMF at a PDE and room temperature; scan rate = 100 mV s^{-1}.

Table 3. Comparison redox potentials[a,b]

	Technetium(III/II), $E^{0\prime}$	Technetium(II/I), E^c
Trans-$[Tc(SCP)_2(DMPE)_2]^{3+}$	−0.113	−1.31[d]
Trans-$[Tc(SCH_3)_2(DMPE)_2]^{+}$ [1]	−0.550	−1.72
Cis-$[Tc(SPh)_2(DMPE)_2]^{+}$ [4]	−0.299	−1.11[d]
Trans-$[Tc(Cl)_2(DMPE)_2]^{+}$ [13]	−0.231	−1.41
Trans-$[Tc(Br)_2(DMPE)_2]^{+}$ [13]	−0.098	−1.27

[a] 25°C; PDE working electrode; scan rate 100 mV s^{-1}; 0.5 M TEAP/DMF; all values in V.
[b] $E^{0\prime} = (E_{pc}+E_{pa})/2$ vs Ag/AgCl (3 M NaCl) from cyclic voltammetry.
[c] Either E_p or $E^{0\prime}$, as specified.
[d] Irreversible at 25°C.

be ascribed to the instability of the technetium(I) species on the cyclic voltammetry time-scale, which results in a chemically irreversible technetium(II/I) redox couple.

Spectroelectrochemistry

In the thin-layer cyclic voltammogram in propylene carbonate *trans*-$[Tc^{III}(SCP)_2(DMPE)_2]^{3+}$ exhibits a reduction wave at −0.250 V and a coupled oxidation wave at −0.106 V ($E^{0\prime} = -0.178$ V). The large peak separation, $E_{pc} - E_{pa} = 0.144$ V, is typical for OTTLEs used with non-aqueous solvents, because of the large solution resistance inherent to the cell arrangement.[14,15] A similar thin-layer cyclic voltammogram was observed in DMF ($E^{0\prime} = -0.138$ V), but spectra could not be recorded because the complex decomposes in DMF on the time-scale of the OTTLE spectroelectrochemical experiment.

The spectra recorded for the technetium(III)/(II) couple during a potential step experiment are shown in Fig. 4. The initial spectrum recorded in the OTTLE after a potential application of +0.400 or +0.075 V is identical with that of the conventional UV–vis measurement for *trans*-$[Tc^{III}(SCP)_2(DMPE)_2]^{3+}$ (*vide supra*). The potential was subsequently moved in the negative direction from +0.075 to −0.500 V. In the spectrum recorded at −0.500 V a new absorption band appears at 513 nm and the band at 630 nm disappears, i.e. the reduction of technetium(III) to technetium(II) causes a large blue shift, consistent with its assignment as an S → Tc CT band. The spectrum at −0.500 V does not change for 2 h in propylene carbonate under these conditions. This supports the synthetic observation that the brown technetium(II) complex obtained from alkaline solution is stable over several hours in polar or non-polar solvents under argon. Apparently the technetium(II) complex is stable under anaerobic conditions. The potential was then moved in the positive direction from −0.500 to +0.075 V and the spectrum was scanned again. In this spectrum, a new absorption band appears at 497 nm along with the original band of the technetium(III) complex at 630 nm, although the band at 630 nm has only 30% of the initial absorbance. The spectrum at +0.400 V shows an increase in intensity of the band at 630 nm and a decrease in intensity of the band at 497 nm.

Similar spectral changes were observed during aerobic oxidation of bulk amounts of the brown technetium(II) complex obtained from the alkaline solution. That is, when the acetonitrile solution of

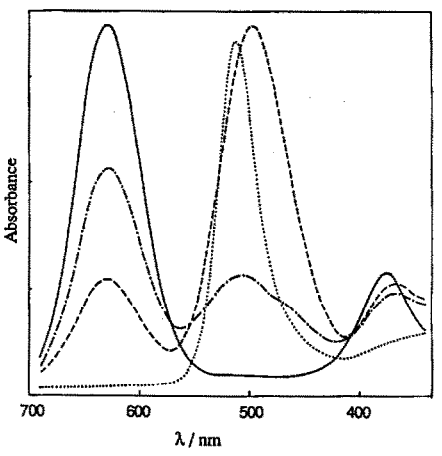

Fig. 4. The absorption spectra obtained during an OTTLE potential step experiment of 0.6 mM *trans*-$[Tc(SCP)_2(DMPE)_2]^{3+}$ in 0.5 M TEAP/propylene carbonate. Applied potentials vs Ag/AgCl are: original, −0.400 and +0.075 V (——); −0.500 V (· · ·); +0.075 V (– – –); and final scan +0.400 V (– · –).

the technetium(II) complex stands in air, it changes to the technetium(III) complex plus some other species; the spectrum of this solution is similar to that of the final scan in Fig. 4 in that it contains the additional peak at 497 nm which is not present in the original technetium(III) solution. Taking the stability of the technetium(II) species into consideration, these facts suggest that part of the *trans*-$[Tc^{II}(SCP)_2(DMPE)_2]^{2+}$ complex reverts to the original technetium(III) complex, but another fraction converts to a different species during oxidation.

The technetium(III/II) $E^{0\prime}$ values are solvent dependent, *viz.* the value obtained in propylene carbonate is more negative than that obtained in DMF. A similar trend was also observed for the technetium(II/I) couple of $[Tc(DMPE)_3]^{2+/+}$.[13] These data suggest that the variation of $E^{0\prime}$ in DMF and propylene carbonate follows the basicity of these solvents.

Electronic properties

The bis(thiolato)-bis(DMPE)-technetium(III) complexes hitherto examined have naturally separated into two classes. When the carbon atom bound to sulphur is saturated, $[Tc^{III}(SR)_2(DMPE)_2]^+$ (R = alkyl or benzyl) complexes have the following characteristics: (1) their geometry tends to be *trans*, (2) reversible couples are observed at *ca* −0.5 to −0.6 V for technetium (III/II) in TEAP/DMF vs Ag/AgCl, and (3) there are two visible STTCT bands *ca* 17 and 28 kK in acetonitrile. When the R group in $[Tc^{III}(SR)_2(DMPE)_2]^+$ is phenyl or a phenyl derivative the following characteristics are observed: (1) the geometry tends to be *cis*, (2) reversible technetium(III/II) couples are in the range −0.19 to −0.38 V, and (3) there are three visible STTCT bands at *ca* 17, 22 and 29 kK. The complex $[Tc(SCP)_2(DMPE)_2]^{3+}$ newly presented here has properties that transcend those of the two classes outlined above. As with an alkylthiolato complex it has *trans* geometry and this is expected since it is thought that the driving force which determines *cis*/*trans* isomerism in these complexes is primarily steric. However, unlike the other alkylthiolato complexes $[Tc(SCP)_2(DMPE)_2]^{3+}$ exhibits an uncommon ease of reduction. The technetium(III/II) reduction potential of this complex is −0.113 V, which is 437 mV more positive than that of *trans*-$[Tc(SCH_3)_2(DMPE)_2]^+$ and even 186 mV more positive than that of *cis*-$[Tc(SPh)_2(DMPE)_2]^+$ (see Table 3). The technetium(III/II) redox potential is strongly linked to the nature of the thiolato R group and as such is inversely related to the σ-donor ability at the thiol.[4] This suggests that the nucleophilicity of the SCP ligand is weaker than those of the other thiolato ligands examined since this complex is the easiest to reduce. Apparently this arises from the positively charged phosphonium group α to the sulphur donor atom in SCP. Orbital mixing between the sulphur donor and the P^+ atoms is also implied by the energies of the two STTCT bands, which are substantially lower than those found in *trans*-$[Tc(SCH_3)_2(DMPE)_2]^+$.

Speculation as to the identity of the intermediate species in the spectroelectrochemical reoxidation experiment leads to the possibility that the electron may be lost first from the terminal sulphido atom, temporarily forming an $S^\bullet$ radical or a disulphide linked dinuclear technetium(II) species. Internal reorganization could then restore the SCP ligand and yield the original technetium(III) species.

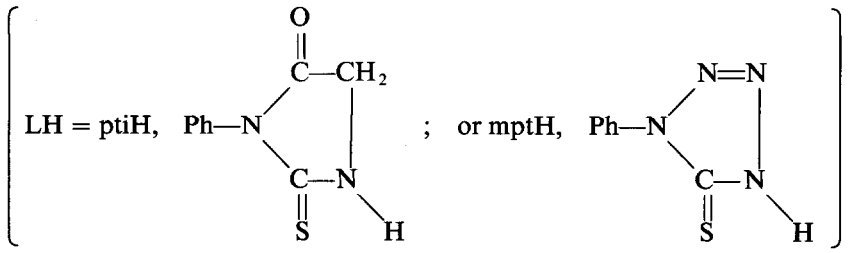
(*Received* 10 *August* 1992; *accepted* 20 *November* 1992)

Abstract—Reactions of $[Cu(AsPh_3)_3X]$ with the title ligands yield $[Cu(AsPh_3)_2(LH)X]$



These complexes have been characterized on the basis of analytical, IR, electronic (UV–vis), ^1H NMR, conductivity and magnetic measurements. In all cases there is a distorted tetrahedral environment around copper(I), and the ligands (LH) bind through the thione sulphur atom to copper(I).

The application of heterocyclic thioamides in corrosion protection[1] and the biological importance of copper–sulphur interactions[2,3] have stimulated much of the research efforts exemplified by reports on the ligating behaviour of heterocyclic thiones.[4–16] Moreover, the copper(I) complexes may adopt di-,[17] tri-,[18] tetra-[2,19] and penta-coordination,[20] which basically depends upon the bulk as well as the electronic properties of the ligands. This has stimulated many workers to study the ligating behaviour of heterocyclic thiones, possessing an α-nitrogen heteroatom. Specifically, in this field of research the group of Karagiannidis has characterized structurally a number of mixed-ligand coordination compounds of copper(I) with heterocyclic thiones, possessing an α-nitrogen heteroatom and triaryl-phosphines[7–14] and -arsines.[15,16] The properties of triphenylphosphine, heterocyclic thione mixed-ligand complexes are fairly well known, but their arsine, stibine and bismuthine analogues are not well studied.

Following our interest in coordination properties of the ligands having the H—N—C=S group,[5,6,21–23] we have recently reported the phosphine counterpart[6] of the complexes. For the sake of comparison and in view of the unique properties of copper coordinated triphenylarsine,[24,25] we describe the syntheses and characterization of novel copper(I) distorted tetrahedral complexes, $[Cu(AsPh_3)_2(LH)X]$, with the title ligands, which behave as monodentate thione sulphur donors.

EXPERIMENTAL

Starting materials

All the chemicals used were either of Analar or chemically pure grade. Complexes of the type $[Cu(AsPh_3)_3X]$,[26] (X = Cl, Br or I) and the ligands 3-phenyl-2-thioxoimidazolidin-4-one[6] (ptiH) and 5-mercapto-1-phenyl-1,2,3,4-tetrazole[6] (mptH) were prepared by literature methods.

Physical methods

Sulphur, halide and copper were determined gravimetrically. The carbon, hydrogen and nitrogen analyses were performed at the Microanalytical

Laboratory, I.I.T. Kanpur, India. The IR spectra were recorded in KBr in the range 4000–400 cm^{-1} on Perkin–Elmer and Shimadzu IR-420 spectrophotometers. The electronic (UV–vis) spectra were recorded on a Shimadzu double beam UV-160 spectrophotometer. The ^1H NMR spectra were recorded on a JEOL JNM-PMX 60 SI NMR spectrometer in the range 0–20 ppm in $CDCl_3$ using TMS as an internal calibrant at room temperature. Conductivity measurements were performed on an Elico conductivity bridge type CM 82T in acetonitrile solution. Magnetic measurements were performed using a parallel-field vibrating sample magnetometer (VSM), model-150A (Princeton Applied Research Corporation, Princeton, NJ). Melting points of the complexes were recorded on a Fisher–John melting point apparatus and are uncorrected.

Preparation of compounds

Preparation of $[Cu(AsPh_3)_2(ptiH)X]$. To a benzene solution (30 cm^3) of the air-stable compound $[Cu(AsPh_3)_3X]$ (0.2 mmol) was added an equivalent amount (0.2 mmol) of the ligand ptiH and the solution/suspension was heated under reflux for *ca* 2 h. During refluxing the reaction mixture became almost clear. After cooling, the solution was filtered through a Whatman No. 1 filter paper to remove any insoluble particles. The resulting solution was concentrated under reduced pressure to half its volume. The addition of petroleum ether (60–80°C) (50 cm^3) resulted in the precipitation of the microcrystalline products on standing for 2–3 h. The complexes were centrifuged and washed several times with petroleum ether and dried *in vacuo*.

Preparation of $[Cu(AsPh_3)_2(mptH)X]$. To a benzene solution (30 cm^3) of $[Cu(AsPh_3)_3X]$ (0.2 mmol) was added an equivalent amount (0.2 mmol) of the ligand mptH and the resulting clear solution was stirred for *ca* 3 h. During the stirring some crystals of the complex were separated. The volume of the reaction mixture was reduced to *ca* 5 cm^3 under vacuum and excess petroleum ether (60–80°C) (50 cm^3) was added to ensure the maximum precipitation of the complexes. These complexes were centrifuged and washed several times with petroleum ether and dried *in vacuo*.

All these compounds are stable in air for several days but a few complexes are susceptible to air oxidation when left in air for more than a week. The air-oxidized products were not further studied. Melting points, yields and colours of the complexes are given in Table 1 along with the analytical data.

RESULTS AND DISCUSSION

The analytical data are in good agreement with the stoichiometry proposed as $[Cu(AsPh_3)_2(LH)X]$ (Table 1). These compounds are soluble in most of the organic solvents like C_6H_6, $CHCl_3$, CH_2Cl_2, DMSO, DMF, CH_3CN, etc. All the compounds are diamagnetic at room temperature. The conductivity of the complexes was found in the range 50–65 Ω^{-1} cm^2 mol^{-1} in acetonitrile and, consequently, were interpreted according to Geary[27] as being non-electrolytes.

The IR spectra of the ligands and complexes are summarized in Table 2. All the ligands adopt the thione form both in the free state and in their complexes. This is evident by the absence of the ν(SH) band in the 2500 cm^{-1} region in each, and by

sh = shoulder.

the presence of ν(NH) in the 2900–3300 cm^{-1} region.[28] The ligands contain a thioamide group (H—N—C=S) and give rise to four characteristic thioamide bands, namely, I, II, III and IV, in the regions 1500, 1300, 1000 and 800 cm^{-1} and have contributions from δ(N—H)+ν(C—N), ν(C=S)+ν(C=N)+ν(C—H), ν(C—N)+ν(C—S) and ν(C—S) modes of vibrations, respectively[6,29–31] (Table 2).

All complexes exhibited the characteristic bands of triphenylarsine.[32] In the case of coordination of the ligand with a carbonyl group, namely ptiH, through the carbonyl oxygen atom the ν(C=O) band should shift to a lower wave number and the thioamide band I [δ(N—H)+ν(C—N)] should shift to a higher wave number. However, if coordination is through the nitrogen atom the thioamide band I will shift to a lower wave number. However, the position of the band at *ca* 1770 cm^{-1}, assigned to ν(C=O), remains almost unaffected or slightly shifts to the higher wave number (*ca* $\Delta\nu = 1$–6 cm^{-1}) in the complexes, ruling out coordination through the carbonyl group. The band at *ca* 1165 cm^{-1}, assigned to ν(C=S) in the spectra of the ligand ptiH, either splits or shifts to a lower wave number (*ca* $\Delta\nu = 10$–15 cm^{-1}) on coordination. The thioamide band IV, which contains a major contribution from ν(C=S), splits or shifts to the lower region by *ca* $\Delta\nu = 41$–42 cm^{-1}, which indicates the involvement of the C=S group in the coordination (Fig. 1).

On complexation ν(C=S) of the ligand mptH (Fig. 2) at 1050 cm^{-1} splits. The thioamide band I at 1492 cm^{-1} undergoes a blue shift by 3–16 cm^{-1}. The thioamide band IV at 793 cm^{-1} undergoes a red shift (lit.[33] value 785 cm^{-1}). These observations support the bond formation between the metal and thione sulphur.

The band at 3180 cm^{-1}, assigned to ν(N—H), for the ligand ptiH becomes weak in the IR spectra of the complexes. The discernible ν(N—H) bands of the ligand mptH (Table 2) shift a little on complexation, indicating the non-involvement of the N—H group in the coordination.

Bonding via sulphur is also favoured in the complexes because copper(I), being a soft acid, should prefer to interact with a soft base such as sulphur and, indeed, the presence of a sulphur–copper(I) bond was confirmed by X-ray single-crystal structure of many complexes having a heterocyclic thione ligand possessing an α-nitrogen heteroatom.[7–16,34] Very recently the mixed-ligand coordination compounds of copper(I) with heterocyclic thiones and triphenylarsine[19] have been synthesized and their X-ray crystal structural characterization

proton of the complexes appeared as a broad signal. The broadening of the signals may be due to hydrogen bonding.[8,15,16] The δ values become lower as the halogen atomic radius increases (10.27 and 9.47 in the bromine and iodine complexes of the ligand ptiH, respectively).[16] The proportions of the protons, observed by integration, exactly match the proposed stoichiometry of the complexes. As expected, only UV absorption bands are observed, which are assigned as intraligand (IL) transitions (Figs 3 and 4).

(*Received* 31 *July* 1992; *accepted* 20 *November* 1992)

Abstract—The isomeric cationic derivatives of niobocene, $[Cp_2Nb(NCMe)_2][BF_4]_2$ and $[Cp_2Nb(CNMe)_2][BF_4]_2$, were prepared from $[Cp_2NbCl_2]$ and the ligands in the presence of $TlBF_4$. The crystal structure determination made on both complexes shows that the cations are isostructural, with pseudo-tetrahedral symmetry and linear ligands. Although the C≡N distances are normal, the Nb—N and Nb—C distances are at the short end of the range found for niobium complexes of these ligands.

In the course of our work on group 6 metallocene chemistry we have prepared a number of d^2 cationic complexes of types $[Cp_2MXL]^+$ and $[Cp_2ML_2]^{2+}$ (M = Mo, W; L = two-electron donor). Some of these 18-electron cations are rather stable to substitution and addition of nucleophiles at the η^5-Cp ring[1] or at the unsaturated ligand L. In the case where L = NCR or CNR, amidines[2] or the iminocarbenes[3] are formed.

No similar chemistry has been performed for the group 5 metallocene complexes and very few cationic complexes of these metallocenes have been reported.[4] In this group three consecutive oxidation states (+3, +4, +5) are easily available and, therefore, the possibility of tuning ligand reactivity by changes in complex charge and electronic configuration (d^2, d^1, d^0) is to be expected.

As an entry into this field resulting from our interest in nitrile and isonitrile activation, we describe, in this paper, the preparation and structural characterization of the isomeric complexes $[Cp_2NbL_2][BF_4]_2$ (L = NCMe, CNMe).

RESULTS AND DISCUSSION

Chemical studies

Treatment of a suspension of $[Cp_2NbCl_2]$ with $TlBF_4$ in acetonitrile gives a smooth reaction and a red–brown solution. After filtration, concentration and addition of diethyl ether a crystalline orange precipitate of $[Cp_2Nb(NCMe)_2][BF_4]_2$ (**1**) is isolated in 80% yield. When the same reaction is performed in the presence of excess CNMe, also in acetonitrile solvent, the yellow complex $[Cp_2Nb(CNMe)_2][BF_4]_2$ (**2**) is isolated in 70% yield.

Both complexes **1** and **2** are very air-sensitive and the analytical results obtained were rather poor. Their paramagnetism precluded NMR measurements and, therefore, the characterization is based on IR and single-crystal X-ray diffraction analysis (see below). The IR spectrum of **1**, in KBr pellets prepared and measured under an argon atmosphere, shows two weak absorptions at 2280 and 2245 cm^{-1}, assignable to the NCMe ligands. These values are shifted *ca* 50 cm^{-1} to lower wave numbers relative to the isostructural $[Cp_2Mo(NCMe)_2][PF_6]_2$,[1] but still have a positive shift relative to free NCMe (2220 cm^{-1}).

The values of the ν(C≡NMe) stretching vibrations in **2** appear at 2250 and 2240 cm^{-1}, which is the same value observed for the isostructural $[Cp_2Mo(CNMe)_2][PF_6]_2$.[3]

Attempts to produce the d^0 cation $[Cp_2Nb(NCMe)_3]^{3+}$ through reaction of $[Cp_2NbCl_2]^{2+}$[5] with $TlBF_4$ were unsuccessful and, even in refluxing acetonitrile, no reaction was observed.

Preliminary reactions show that the dications **1** and **2** are very reactive towards nucleophiles, but the paramagnetic products have not yet been unequivocally characterized. Nevertheless, **1** does not undergo simple nitrile substitution with bipyridyl since the known $[Cp_2Nb(bipy)]^{2+}$[4c] complex is not formed in the reaction of **1** with this chelating ligand.

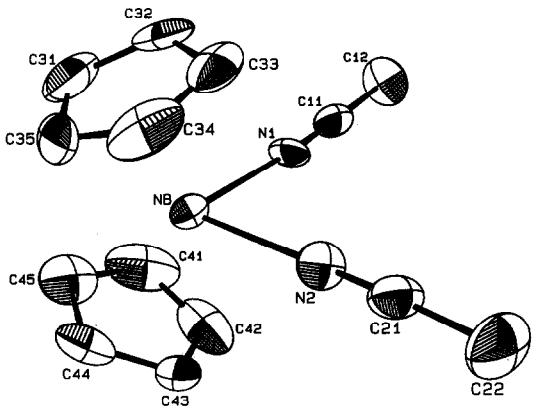

Fig. 1. ORTEP diagram of $[Cp_2Nb(NCMe)_2][BF_4]_2$ showing 30% thermal ellipsoids.

Crystallographic studies

Complexes **1** and **2** are isostructural; molecular diagrams with atom numbering schemes are represented in Figs 1 and 2, respectively. Bond lengths and angles are given in Tables 1 and 2, respectively. The crystal structures consist of discrete $[Cp_2Nb(NCMe)_2]^{2+}$ and $[Cp_2Nb(CNMe)_2]^{2+}$ cations and two $[BF_4]^-$ anions in each case. The cations show the usual bent metallocene coordination with a pseudo-tetrahedral arrangement about the metal atom, if the coordination is considered to the centre of the η^5-cyclopentadienyl rings. However, this type of ligand can also be described as occupying three coordination positions, giving the central metal atom a formal eight-fold coordination.[6] The Cp—Nb—Cp angles defined by the ring normals are 136.6(6)° for **1** and 139.2(5)° for **2**. The bonding angles at the metal atom, N(1)—Nb—N(2)

83.8(2)° and C(11)—Nb—C(21) 84.6(2)°, are comparable to the theoretical value 85°, calculated by Lauher and Hoffmann[7] for bis-cyclopentadienyl d^1 complexes.

The Nb—N bond distances are 2.165(5) and 2.159(4) Å in **1** and the Nb—C bond distances are 2.164(6) and 2.179(5) Å in **2**. The C≡N bond distances are comparable in both complexes (see Table 3) and the acetonitrile and methyl-isonitrile ligands are both linear.

Most of the structurally characterized niobium complexes with nitrile and isonitrile ligands have octahedral and pentagonal bipyramidal coordinations with linear terminal ligands. A comparison between Nb—N, Nb—C and C≡N bond lengths in some of these and the title complexes is presented in Table 3. From these data it is clear that the metal–ligand bonds in complexes **1** and **2** lie in the short range of distances normally observed. A similar shortened W—CNMe bond [1.15(3) Å] is observed in the related cation $[Cp_2WBr(CNMe)]^+$, which shows ν(C≡N) at wavelengths similar to **2** (2210 cm^{-1}).[3]

This effect cannot be rationalized on the basis of back-donation from the metal to the ligands, as this would imply longer C≡N distances and bent ligands as reported for the strongly bent CN^{t}Bu ligand of complex $[Cp_2MoCN^tBu]$, which has a C≡N distance of 1.193(4) Å and shows ν(C≡N) at very low wave numbers in the IR spectrum.[12]

$[\{NbCl_2S(NCMe)_2\}_2]\cdot 2CH_3CN$		2.312(12) 2.322(16)	1.12(2) 1.13(2)	11
$[\{NbCl_2S(NCMe)_2\}_2]\cdot CH_3CN$		2.286(26)–2.334(22)	1.10(4)–1.15(4)	11

Furthermore, according to EHMO calculations, π-back-donation from the Cp_2Mo^{IV} fragment to nitriles is negligible.[2] Thus, the observed contraction of the M—NCMe and M—CNMe bonds in metallocene cationic derivatives probably results from a set of circumstances: namely (1) a very favourable σ-donation overlap between these ligands and the cationic $[Cp_2M]^{n+}$ fragment and (2) a rather sterically undemanding coordination environment on the C—M—C plane.

CONCLUSIONS

From the IR and structural data reported, both nitrile and isonitrile ligands seem to be activated towards nucleophilic addition reactions in the complexes $[Cp_2Nb(NCMe)_2][BF_4]_2$ (**1**) and $[Cp_2Nb(CNMe)_2][BF_4]_2$ (**2**). Failure to observe the simple substitution reaction of bipy for NCMe in complex **1** supports this suggestion, which is currently under investigation.

EXPERIMENTAL

All preparations and manipulations were performed under argon, using standard Schlenk techniques and an MBraun glove-box. Acetonitrile was dried by refluxing CaH_2, followed by distillation and was kept over 3 Å molecular sieves. Et_2O was distilled over Na/benzophenone and kept over 4 Å molecular sieves. IR samples were prepared in a glove-box and measured in an argon purged compartment of a Mattson Polaris FTIR spectrometer. Literature procedures were followed for the preparation of Cp_2NbCl_2[13] and CNMe.[14]

Preparation of **1**

A suspension of Cp_2NbCl_2 (0.120 g, 0.41 mmol) in dry acetonitrile (15 cm^3) was treated with $TlBF_4$ (0.262 g, 0.90 mmol) with rapid magnetic stirring at room temperature. After 2 h the mixture was filtered and the red–brown solution concentrated. Addition of Et_2O gave an orange precipitate, which was collected by filtration and recrystallized from acetonitrile/Et_2O. Yield 151 mg, 80%. IR (cm^{-1}; KBr): 2280 (vw); 2245 (w).

Preparation of **2**

A suspension of Cp_2NbCl_2 (0.280 g, 0.98 mmol) in dry acetonitrile (15 cm^3) was successively treated with excess CNMe (0.1 cm^3) and $TlBF_4$ (0.584 g, 2.00 mmol). A red solution and a white suspension were promptly formed and after 2 h stirring at room temperature the mixture was filtered and the resulting red solution concentrated. The slow addition of Et_2O formed yellow needles of **2**, which were collected by filtration and dried *in vacuo*. Yield 328 mg, 70%. IR (cm^{-1}; Nujol mull): 2250 (m); 2240 (m).

X-ray data of **1** *and* **2**

Suitable crystals of the complexes were obtained by slow diffusion of Et_2O in concentrated solutions of the complexes in NCMe. A single crystal of each compound was mounted in Lindemann capillaries under an argon atmosphere and the intensity data were measured on an Enraf–Nonius CAD-4 diffractometer using graphite monochromatized Mo-K_α radiation ($\lambda = 0.71069$ Å). Cell dimensions and an orientation matrix were obtained by least-squares refinement of setting angles for 25 automatically centred reflections, in the range $13.0° < \theta < 16.0°$ for **1** and $10.4° < \theta < 15.3°$ for **2**. Crystallographic and data collection parameters are presented in Table 4.

Structure determination and refinement

The structures were solved by a combination of Patterson and electron density difference-Fourier syntheses. From the systematic absences, both space groups *Pnma* (No. 62) and $Pna2_1$ (No. 33) were possible. Refinement on each structure was performed in both space groups up to a complete isotropic model. In the space group *Pnma* both ligands L and the metal atom were sitting in crystallographic mirror planes, but disordered models with constrained distances had to be considered for the BF_4^- anions. However, while in the acentric space group a reasonable geometric definition with inverted tetrahedra could be achieved for each structure, in the centric space group this was only possible for one of the anionic positions. Consequently, the R factors were not so good, $R = 0.12$ and $R = 0.11$ for **1** and **2** in space group *Pnma*, while in the space group $Pna2_1$, R was 0.09 for **1** and 0.08 for **2**. Refinement was thus continued in $Pna2_1$, for both structures, and constraints were applied to the C—C bonds in the Cp rings.

As compound **2** was prepared and crystallized in the presence of acetonitrile the correct assignment of the type of atom bonded to the metal had to be confirmed. When both ligands were considered as isonitriles the isotropic thermal parameters gradually increased from the niobium atom to the methyl group. However, when carbon and nitrogen atoms from the C≡N moiety were interchanged abnormal thermal parameters resulted, indicating that the initial assignment was the correct one.

R	0.039	0.038
Rw[a]	0.039	0.035

[a] $Rw = (\Sigma w|F_o - F_c|^2/\Sigma wF_o^2)^{1/2}$; with $w = 1.8907/\sigma^2(F)+0.000319F^2$ for **1** and $w = 1.5880/\sigma^2(F)+0.000202F^2$ for **2**.

Anisotropic refinement for all the non-hydrogen atoms gave $R = 0.043$ for **1** and $R = 0.046$ for **2**. Subsequent difference-Fourier syntheses revealed the positions of three methyl hydrogen atoms for both compounds; all other hydrogen atoms were included at calculated positions. Further refinement was continued keeping the hydrogen atoms at a fixed distance to the parent carbon atoms, but allowing individual refinement of the thermal parameters.

Some of the Cp ring carbon atoms show, for both compounds, high thermal ellipsoids; attempts were made to find a disordered model for the rings, but did not lead to any reasonable solution. The Cp rings adopt an almost eclipsed configuration in both complexes. A weighting scheme was introduced to give final $R = 0.039$ and $Rw = 0.039$ for **1** and $R = 0.038$ and $Rw = 0.035$ for **2**.

Final atomic coordinates and anisotropic thermal parameters for non-hydrogen atoms, hydrogen atomic coordinates and isotropic thermal parameters are available from the Cambridge Crystallographic Data Centre. Lists of observed and calculated structure factors have been submitted as supplementary material. All computations required to solve and refine the structures were made with SHELX76,[15] while drawings were made with ORTEP.[16] Atomic scattering values were taken from the International Tables.[17]

CHARACTERIZATION OF VAPOUR COMPLEXES OVER MOLTEN $POCl_3$–MCl_3 (M = Al, Ga) MIXTURES: RAMAN SPECTRA AND THERMODYNAMICS

S. BOGHOSIAN,* D. A. KARYDIS and G. A. VOYIATZIS

Institute of Chemical Engineering and High Temperature Chemical Processes and Department of Chemical Engineering, University of Patras, GR-26110 Patras, Greece

(*Received* 1 *October* 1992; *accepted* 16 *November* 1992)

Abstract—Raman spectra were obtained at temperatures up to 800 K and pressures up to 6 atm. for vapours over $POCl_3$–$AlCl_3$ and $POCl_3$–$GaCl_3$ molten mixtures under static equilibrium conditions. Spectra are also measured for molten $POCl_3$–$AlCl_3$ and $POCl_3$–$GaCl_3$ salt mixtures. A comparison of the spectral features in the $POCl_3$–MCl_3 (M = Al, Ga) vapours with the spectra of the 1 : 1 and 1 : 2 $POCl_3$–MCl_3 molten mixtures indicates that the vapour complexes have a 1 : 1 stoichiometry and that complexing occurs through oxygen bridging. Gaseous $POCl_3 \cdot AlCl_3$ remains stable with no sign of decomposition at temperatures up to 825 K, while the $POCl_3 \cdot GaCl_3$ vapour complex vaporizes dissociatively. The spectra are interpreted in terms of a C_s symmetry for $POCl_3 \cdot AlCl_3$ with a bent P—O—Al bridge (nine polarized and eight depolarized bands assigned) and C_{3v} symmetry for $POCl_3 \cdot GaCl_3$, with a straight P—O—Ga bridge (five polarized and six depolarized bands assigned). In the spectra of $POCl_3$–MCl_3 (M = Al, Ga) melts several bands are interpreted to account for $POCl_3(AlCl_3)_2$(l) (four polarized and six depolarized bands assigned) and $POCl_3(GaCl_3)_2$(l) (two polarized and three depolarized bands assigned) species. Accurate relative Raman intensity measurements are used for determining the thermodynamic functions of the reactions: (a) $POCl_3(g)+nGa_2Cl_6(g) = POCl_3(GaCl_3)_{2n}(g)$, in the temperature range 600–800 K and pressures up to 6 atm.; it is shown that the predominant vapour complex formed has $n = 0.5$ ($POCl_3 \cdot GaCl_3$) and the thermodynamic functions according to this reaction ($n = 0.5$) are determined from the Raman experiments as $\Delta H^\circ = -37 \pm 0.8$ kJ mol^{-1} and $\Delta S^\circ = -44 \pm 1.1$ J mol^{-1} K^{-1}. (b) $Ga_2Cl_6(g) = 2GaCl_3(g)$ in the temperature range 400–800 K and pressures up to 2.5 atm., where the thermodynamic functions are determined as $\Delta H^\circ = 83 \pm 1.3$ kJ mol^{-1} and $\Delta S^\circ = 131 \pm 2.2$ J mol^{-1} K^{-1}.

A wide range of liquid complex compounds with low melting points, in which phosphoryl chloride acts as a donor molecule towards other inorganic metal halides, has been studied and a detailed summary of their chemistry is available.[1] The chlorides of aluminium and gallium as Lewis acids undergo complex formation with $POCl_3$ and such a complexation has been proposed a few decades ago for the removal of aluminium chloride from Friedel Crafts mixtures.[1].

The phase diagram of the $POCl_3$–$AlCl_3$ system[2] shows a clear and sharp maximum at 186.5°C, corresponding to the 1 : 1 compound and a second compound, $AlCl_3 \cdot 2POCl_3$, with m.p. 164°C (or $2AlCl_3 \cdot 3POCl_3$ with m.p. 166°C[3]) very close to a eutectic at 160°C with 64 mol% $POCl_3$. A mass spectrometric investigation[4] of the vapours over the $POCl_3 \cdot AlCl_3$ compound showed a high stability of this complex and provides confirmation of a bond through the oxygen atom of $POCl_3$ (P—O—Al bridge), as also indicated from a Raman study of the compounds $POCl_3 \cdot AlCl_3$ and $POCl_3 \cdot GaCl_3$ in the liquid state.[5] Results of a vapour pressure study of the $POCl_3$–$AlCl_3$ system in the range 50–64 mol% $AlCl_3$ indicate the formation of

$POCl_3 \cdot AlCl_3$ and $POCl_3 \cdot 2AlCl_3$ in the liquid state and point to $POCl_3 \cdot AlCl_3$ as the stable and predominant vapour species.[6] In the $POCl_3$–$GaCl_3$ system 1 : 1 and 2 : 1 compounds (m.p.s 185°C and 77°C, respectively) occur[7] and a high percentage of adduct in the vapour is reported as a result of sublimation of the $POCl_3 \cdot GaCl_3$ compound.[8]

The aim of the present work is to characterize the vapour complexes over molten mixtures of $POCl_3$ and MCl_3 (M = Al, Ga) under equilibrium conditions by Raman spectroscopy. It has been demonstrated that in certain cases Raman spectroscopy can be used to study the vibrational and structural properties of vapour complexes[9,10] and "adduct" vapour compounds,[11,12] as well as for establishing the stoichiometry and thermodynamics of formation of gas phase reactions.[13] In the present work the vapours over molten $POCl_3$–MCl_3 (M = Al, Ga) mixtures are studied by Raman spectroscopy at temperatures up to 800 K. The vibrational band frequencies of the complexes formed in the vapour as well as in the liquid state are determined and possible complex structures are considered and discussed. Finally, for the $POCl_3$–$GaCl_3$ system the data obtained are shown to be capable for an accurate determination of the stoichiometry, n, and of the thermodynamic functions ($\Delta H°$, $\Delta S°$) of the reaction:

$$POCl_3(g) + nGa_2Cl_6(g) \rightleftharpoons POCl_3 \cdot (GaCl_3)_{2n}(g) \quad 600\,K < T < 800\,K, \quad 2\,atm. < P < 6\,atm. \tag{1}$$

EXPERIMENTAL

High purity anhydrous $AlCl_3$ and $GaCl_3$ were prepared from the corresponding Cerac/Pure Inc. reagents by repeated slow sublimations in fused silica tubes under vacuum. All handling of these chemicals took place in a nitrogen-filled glove-box with a water vapour content of less than 1 ppm. Liquid $POCl_3$ was purchased from Fluka.

The Raman (optical) cells containing the salt vapours consisted of fused silica tubing (20 ± 0.2 mm o.d., 18 ± 0.2 mm i.d., 3–4 cm long). In the case of melts containing molten salt mixtures silica tubing with 4 ± 0.1 mm o.d. and 2 ± 0.1 mm i.d. was used. Preweighed amounts of $AlCl_3$ or $GaCl_3$ were transferred into a clean, dry, flamed and degassed optical cell of known volume, which was attached to an all-glass vacuum line for feeding the $POCl_3$. In the same line a container with $POCl_3$ was attached. Phosphoryl chloride was then allowed to vaporize and occupy a confined bulb of known volume and it was afterwards transferred by distillation and condensed in the bottom of the optical cell which was immersed in liquid nitrogen. The optical cell was then sealed off, the salt mixtures were reacted inside a side tube (6 ± 0.1 mm o.d., 4 ± 0.1 mm i.d.), vapour transported into the main cell compartment and finally the side tube was sealed off. In this way transparent liquids and colourless vapours could be obtained, indicating a high degree of sample purity.

For the study of the $POCl_3$–$AlCl_3$ system stoichiometric amounts of the two components were heated carefully, yielding a clear colourless liquid with m.p. ~185°C, which could be vapour transported over a temperature gradient with no sign of decomposition. Mixtures having excess $POCl_3$ or $AlCl_3$ showed similar behaviour and the distillate could be isolated by sealing away (into the side tube) the excess chemicals. The so-collected 1 : 1 mixture was transferred into optical cells and the vapour Raman spectra recorded thereafter showed no bands due to $POCl_3$ or $Al_2Cl_6/AlCl_3$, even at temperatures up to 800 K, indicating a high thermal stability of the formed complex. During cooling in ice-water or liquid nitrogen no glass formation could be observed.

In the $POCl_3$–$GaCl_3$ system the two components in stoichiometric amounts were mixed as described before at 77 K and while attaining room temperature reacted vigorously, yielding a white solid which gave a clear colourless liquid upon melting at *ca* 120°C. The solid could be sublimed giving needle-shape crystals and preliminary studies of the temperature dependence of its vapour Raman spectra indicated a decomposition to $POCl_3$ and $Ga_2Cl_6/GaCl_3$. Thus, in this system the procedure and method described in ref. 13 could be applied for establishing the stoichiometry and thermodynamics of the vapour complex formed. The "ideal gas" pressure ($P_{0,D}$) of undissociated and non-reacted Ga_2Cl_6 at temperature t was calculated from the number of moles (n_D) added to the cell. Three different cells were made for studying the Ga_2Cl_6–$GaCl_3$ system. The first column in Table A (supplementary material, deposited with the Editor) gives the characteristics of each cell. Measurements from these cells were used to establish the thermodynamics of the Ga_2Cl_6 dissociation and to calculate the equilibrium partial pressures of Ga_2Cl_6, P_D, in $POCl_3$–$GaCl_3$ vapours. Furthermore, seven different cells for the study of the $POCl_3$–$GaCl_3$ system were prepared. The characteristics of these cells are listed in the first column of Table B (supplementary material). An additional cell containing pure $POCl_3$ was prepared and used as a reference standard for calculating the equilibrium partial pressures of $POCl_3$, P_P, in the $POCl_3$–$GaCl_3$ vapour system. The first column in Table B (supplementary material) shows the characteristics of the $POCl_3$ reference cell.

Raman spectra were excited with the 514.5 and/or 488.0 nm lines of a 4 W Spectra Physics argon laser. The scattered light was collected at an angle of 90° (vertical scattering plane) and analysed with a Spex 1403, 0.85-m double monochromator equipped with a −20°C cooled RCA photomultiplier and Eg & G/ORTEC rate meter and photon counting electronics. The optical furnace for obtaining the high-temperature Raman spectra was similar to that described in detail elsewhere.[14]

During the present investigation, the optical geometry, the spectral slit width and the laser power measured before and after the entrance and exit windows of the furnace were maintained constant. The Raman cells were placed inside the mechanically stable metal core of the furnace and were always in a fixed position relative to the collecting lens and entrance slit. The intensity of the scattered light was "maximized" by positioning the focusing and collecting lenses with two x, y, z micropositioners. After the spectra were obtained the cell could be removed and cooled to room temperature and then reintroduced into the optical furnace, yielding always with no further micropositioner adjustments the same Raman intensities. Thus, by the use of the same experimental conditions the Raman intensities could be reproduced to within less than 2% and the relative Raman intensities of gases at different temperatures and pressures could be obtained within the same error.

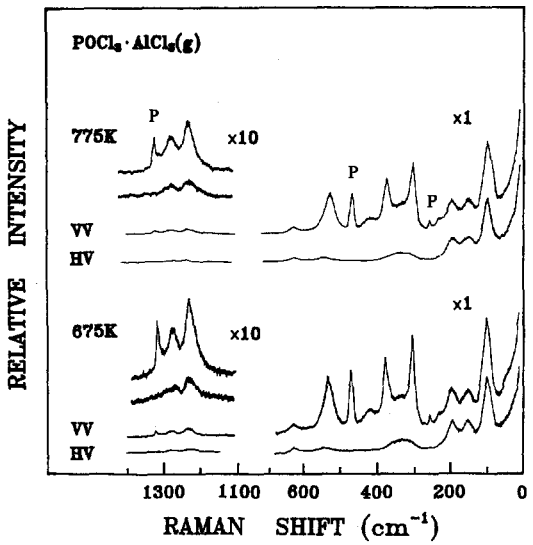

Fig. 1. Raman spectra of $POCl_3 \cdot AlCl_3$(g) at 675 and 775 K. Bands due to $POCl_3$(g) are marked by "P". $\lambda_o = 488$ nm; laser power, w = 280 mW; spectral slit width, ssw = 6 cm^{-1}; time constant, $\tau = 0.3$ s; scan speed, ss = 60 cm^{-1} min^{-1}. Inserts show the high frequency bands; $\tau = 3$ s; ss = 10 cm^{-1} min^{-1}.

RESULTS AND DISCUSSION

The $POCl_3$–$AlCl_3$ *system*

Figure 1 shows representative Raman spectra of $POCl_3$–Al_2Cl_6 vapours at 675 and 775 K. Identical spectra were obtained from samples prepared by either reacting stoichiometric amounts of $POCl_3$ and $AlCl_3$ or reacting aluminium chloride with excess $POCl_3$ and sealing away the excess $POCl_3$ vapours after condensing them in a side-tube by cooling in liquid nitrogen. None of the well-known[15] characteristic Al_2Cl_6(g) bands can be observed in Fig. 1, while three out of 16 totally observed bands can be assigned as the $\nu_1(A_1)$, $\nu_2(A_1)$ and $\nu_3(A_1)$ $POCl_3$(g) bands[16] (see bands in Fig. 1 marked by "P"). These bands could be either due to a slight dissociation of a vapour complex or due to the dissociative vaporization of initially formed $2AlCl_3 \cdot 3POCl_3$ compound.[3] Thus, seven polarized and six depolarized bands (see Table 1 for wave numbers and polarization characteristics) were assigned to the 1 : 1 $POCl_3 \cdot AlCl_3$ vapour complex, which seems to be the one and only stable vapour complex over $POCl_3$–$AlCl_3$ molten mixtures. This is in agreement with Brockner *et al.*,[6] who from vapour pressure measurements deduced that $POCl_3 \cdot AlCl_3$ was the predominant vapour species. The temperature dependence of the spectra in Fig. 1 shows that $POCl_3 \cdot AlCl_3$(g) exhibits a high thermal stability, as postulated earlier.[4] No sign of decomposition could be observed at temperatures up to 800 K. This is quite unusual behaviour, since around this temperature most of the to-date studied inorganic halide vapour complexes[9,10,12–14,16–18] are present in low percentages in equilibrium with the vapours of their component gases.

The structural properties of the vapour complex are better clarified by also studying the Raman spectra of some $POCl_3$–$AlCl_3$ melt mixtures. Figure 2 shows Raman spectra from melts with 1 : 1 ($X_{AlCl_3} = 0.50$) and 1 : 2 ($X_{AlCl_3} = 0.67$) compositions at 500 K. In the case of the 1 : 1 composition none of the 17 observed bands could be assigned to $POCl_3$(l)[19] or Al_2Cl_6(l).[15] Furthermore, the spectrum resembles closely the vapour Raman spectrum of Fig. 1. All 17 bands (nine polarized and eight depolarized) are assigned to the liquid $POCl_3 \cdot AlCl_3$ compound. The observed wave numbers due to $POCl_3 \cdot AlCl_3$(l) are listed in Table 1 and compare well with those of the vapour molecule. Four weak extra bands due to the liquid compound at wave numbers 130, 349, 457 and 480 could not be observed in the vapour Raman spectrum, presumably due to their low intensities. Wave numbers

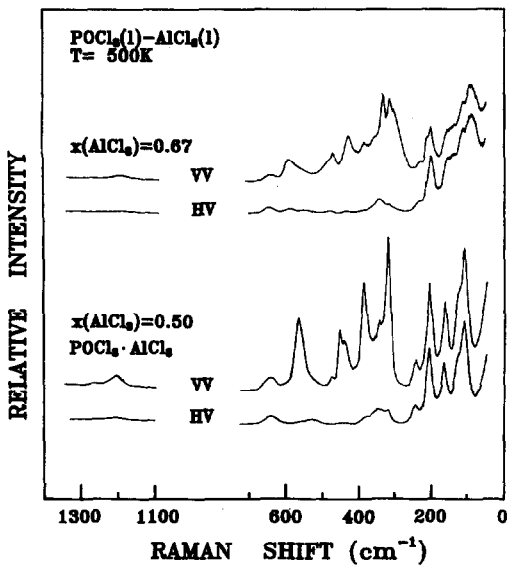

Fig. 2. Raman spectra of molten $POCl_3 \cdot AlCl_3$ mixtures with $X_{AlCl_3} = 0.50$ [i.e. $POCl_3 \cdot AlCl_3$(l)] and $X_{AlCl_3} = 0.67$ at 500 K. $\lambda_o = 488$ nm; w = 250 mW; ssw = 4 cm^{-1}; $\tau = 0.03$ s; ss = 60 cm^{-1} min^{-1}.

reported in ref. 5 for $POCl_3 \cdot AlCl_3$(l) are also included in Table 1 for comparison.

Bonding in the vapour and liquid $POCl_3 \cdot AlCl_3$ complex presumably occurs by bridging the oxygen from $POCl_3$ with the aluminium atom to form a P—O—Al bridge, as in a series of known $POCl_3$ addition compounds.[1] Figure 3 shows two possible structures for the $POCl_3 \cdot AlCl_3$ complex in the vapour or in the liquid state. Structure **A** possesses a three-fold axis along a straight P—O—Al bridge and three vertical symmetry planes (C_{3v} symmetry),

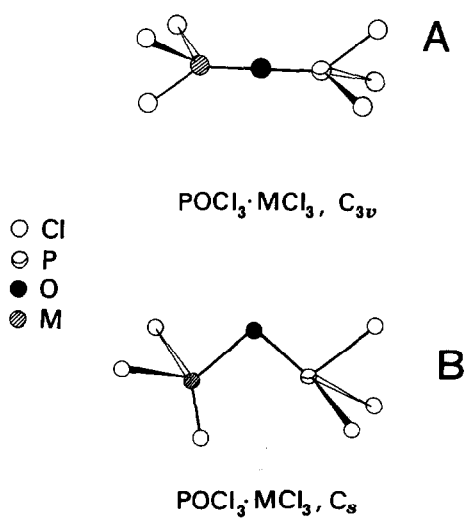

Fig. 3. Molecular models for $POCl_3 \cdot MCl_3$ (M = Al or Ga) vapour complexes with C_{3v} (**A**) and C_s (**B**) symmetry.

while structure **B** possesses a single symmetry plane containing a bent P—O—Al bridge (C_s symmetry). The 21 vibrational modes of the complex for the molecular configurations shown in Fig. 3 can be classified as follows:

$$\Gamma_{C_{3v}} = 6A_1(\mathrm{R,IR}) + A_2 + 7E(\mathrm{R,IR}) \quad (2)$$

$$\Gamma_{C_s} = 13A'(\mathrm{R,IR}) + 8A''(\mathrm{R,IR}) \quad (3)$$

One can exclude the C_{3v} structure on the basis of the nine polarized and eight depolarized Raman bands observed (see Table 1) and thus C_s remains as the most probable structure, but no definite conclusion can be made on this basis. It is assumed here that all the symmetric vibrational modes observed (assigned as A' in Table 1) are fundamentals. Simple combinations and/or first overtones of antisymmetric or symmetric fundamentals do not seem to give rise to any of the nine totally symmetric vibrations observed. The only exception is the 457 cm^{-1} polarized band which may arise from a combination between the 207 and 244 cm^{-1} depolarized bands. However, it is quite unusual for the intensity of a combination band to be so strong and not even a Fermi resonance with a neighbouring symmetric mode (i.e. 445 cm^{-1}) could account for such a high intensity (Fig. 2). Therefore, all bands are assigned in Table 1 as due to fundamentals.

The formation of the ionic $POCl_2^+AlCl_4^-$ liquid compound by chlorine ion transfer from $POCl_3$ to the acceptor molecule "$AlCl_3$" is excluded on the basis of the observed 17 Raman bands due to $POCl_3 \cdot AlCl_3$(l), contrary to the totally expected 10 bands if $POCl_2^+$ (plane symmetry, C_{2v} with six bands) and $AlCl_4^-$ (T_d symmetry with four bands) moities were formed. Furthermore, no observation of the characteristic $AlCl_4^-$ band at 351 cm^{-1} [20] was made.

Addition of aluminium chloride up to $X_{AlCl_3} = 0.67$ causes drastic changes in the liquid Raman spectra (see the upper part of Fig. 2 and list of observed wave numbers, Table 1). The following observations can be made: (1) Six bands emerge at wave numbers 103, 120, 165, 219, 342, 510 and maybe a shoulder at 606 cm^{-1} with relative intensities and polarization characteristics as expected for Al_2Cl_6(l);[15] (2) four of the more characteristic bands due to $POCl_3 \cdot AlCl_3$(l) at wave numbers 324, 391, 573 and 1208 can still be observed indicating the presence of this compound in mixtures with 67 mol% $AlCl_3$; (3) no bands of the spectrum with 50 mol% $AlCl_3$ (Fig. 3, lower part), previously assigned to $POCl_3 \cdot AlCl_3$(l), appear to grow; and (4) 10 new bands (four polarized and six depolarized) appear and are assigned to a higher species [presumably $POCl_3(AlCl_3)_2$[6]].

Thus, while at 50 mol% $AlCl_3$ the mixture can be looked upon as a molecular compound, $POCl_3 \cdot AlCl_3$, at 67 mol% $AlCl_3$ composition the system can most probably be considered as a molecular liquid mixture consisting of Al_2Cl_6(l), $POCl_3 \cdot AlCl_3$(l) and $POCl_3(AlCl_3)_2$(l) participating in the equilibrium:

$$POCl_3 \cdot AlCl_3(l) + \tfrac{1}{2}Al_2Cl_6(l) \Leftrightarrow POCl_3(AlCl_3)_2(l).$$

This statement confirms a recent observation reported in ref. 6. From a structural point of view the $POCl_3(AlCl_3)_2$ liquid complex probably possesses a single symmetry plane with the oxygen coordinated three-fold (C_s symmetry). Such a configuration was also essentially proposed by Brockner *et al.*[6]

The $POCl_3$–$GaCl_3$ *system*

Figure 4 shows representative vapour Raman spectra obtained for $POCl_3$(g) ($POCl_3$ reference cell), for gallium chloride vapours (Cell G3) at 635 K and for vapour mixtures from cell I at 635 and 790 K. Spectral band positions and polarization properties for gaseous phosphorus oxychloride and gallium chloride vapours were in agreement with those previously reported in refs 16 and 21. The spectra of the vapour mixtures consist of superpositions of bands due to the component gases plus eight new bands at wave numbers listed in Table 2 (first column), which are attributed to a vapour complex formed according to reaction (1). The intensities of the bands assigned to the vapour complex are decreasing with increasing temperature, probably due to thermal decomposition. It should be pointed out here that a temperature rise shifts the dissociation equilibrium

$$Ga_2Cl_6(g) \Leftrightarrow 2GaCl_3(g) \qquad (4)$$

to the right. This is illustrated in Fig. 5, which shows the temperature-dependent features of the gallium chloride vapour Raman spectra. Bands due to the dimer (marked by D in Fig. 5) lose intensity with increasing temperature, while bands due to the monomer (marked by M) become progressively stronger.

Consequently, several bands due to the vapour

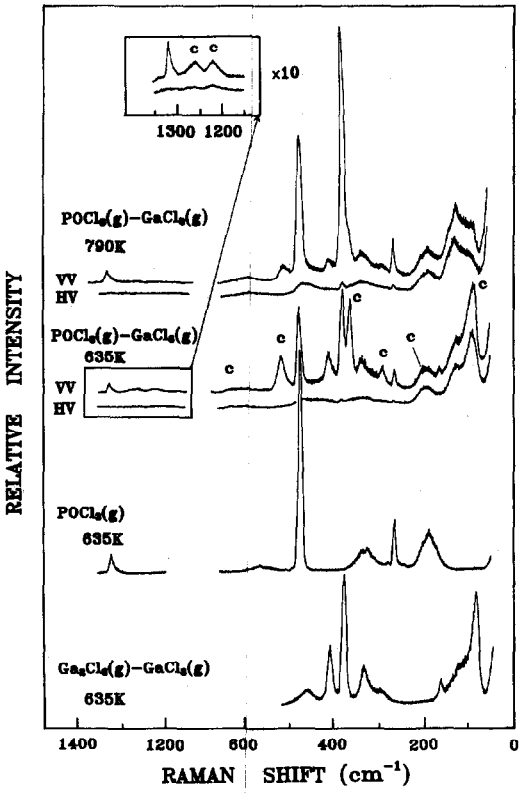

Fig. 4. Raman spectra of Ga_2Cl_6–$GaCl_3$ vapours from cell G3, $POCl_3$(g) from the $POCl_3$ reference cell at 635 K and mixtures from cell I at 635 and 790 K. Bands due to the vapour complex are marked by "c". $\lambda_o = 488$ nm; w = 220 mW; ssw = 6 cm^{-1}; $\tau = 0.2$ s; ss = 15 cm^{-1} min^{-1}.

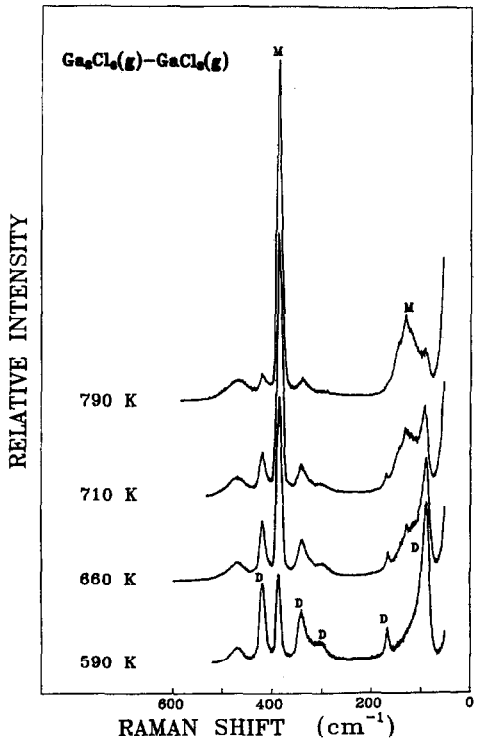

Fig. 5. Temperature dependence of the Raman spectra of Ga_2Cl_6–$GaCl_3$ vapours from cell G3. Bands due to Ga_2Cl_6 and $GaCl_3$ are marked by "D" and "M", respectively. $\lambda_o = 488$ nm; w = 220 mW; ssw = 6 cm^{-1}; $\tau = 0.2$ s; ss = 15 cm^{-1} min^{-1}.

complex might have been obscured by bands due to $POCl_3$(g) and Ga_2Cl_6–$GaCl_3$ vapours in the vapour Raman spectra (Fig. 4). More information about the number of bands due to the complex can be obtained by also considering some liquid state spectra.

Figure 6 shows Raman spectra from melts with 1:1 ($x_{GaCl_3} = 0.50$) and 1:2 ($x_{GaCl_3} = 0.66$) compositions at 500 K. There are 13 bands appearing in the lower spectrum with $x_{GaCl_3} = 0.50$ that *cannot* be assigned to $POCl_3$(l) or Ga_2Cl_6(l). Nevertheless, the strongest Raman line of $POCl_3$(l)[17] at 485 cm^{-1} is observed as a weak polarized band, a fact excluding the possibility of any other band to be assigned as due to $POCl_3$(l). An increase in the $GaCl_3$ concentration to $x_{GaCl_3} = 0.66$ results in the disappearance of this band. Furthermore, two bands in the spectrum with $X_{GaCl_3} = 0.50$ at 165 and 410 cm^{-1} can be assigned as due to Ga_2Cl_6(l). Increasing the $GaCl_3$ concentration results in an intensity increase of these two bands and the appearance of two more bands due to Ga_2Cl_6(l) at 96 and 462 cm^{-1}. All four bands behave as expected for Ga_2Cl_6(l)[22] in terms of positions in the spectrum, relative intensities and polarization properties. The 11 bands dominating the spectrum with $x_{GaCl_3} = 0.50$ (see Table 2 for a list of their wave numbers) can be assigned to a single species, most probably $POCl_3 \cdot GaCl_3$ attaining its maximum concentration at $x_{GaCl_3} = 0.50$, while two shoulder bands at 129 and 400 cm^{-1} probably have to be assigned to a higher complex. The intensities of these two bands increase drastically on going from $x_{GaCl_3} = 0.50$ to 0.66, while the 11 bands assigned to 1:1 $POCl_3 \cdot GaCl_3$ become weaker and four of them even disappear, being obscured by other bands. Moreover, three more bands appear in the spectrum with $x_{GaCl_3} = 0.66$ and are assigned to the higher complex, which could probably be the $POCl_3(GaCl_3)_2$ compound although no definite conclusion can be made on this issue. Table 2 summarizes the vibrational wave numbers of all the bands resolved in the spectra of Fig. 6. Wave numbers reported in ref. 5 for $POCl_3 \cdot GaCl_3$(l) are also included for comparison. Bands assigned as due to the vapour complex in the spectra of $POCl_3$–$GaCl_3$ vapours (Fig. 4) are closely related to certain respective bands in the 1:1 molten mixture (Fig. 5), a fact indicating that the predominant vapour complex species is 1:1 $POCl_3 \cdot GaCl_3$. The determination of the stoichiometric coefficient, n, of reaction (1) which is presented in the next section will show that this is indeed the case.

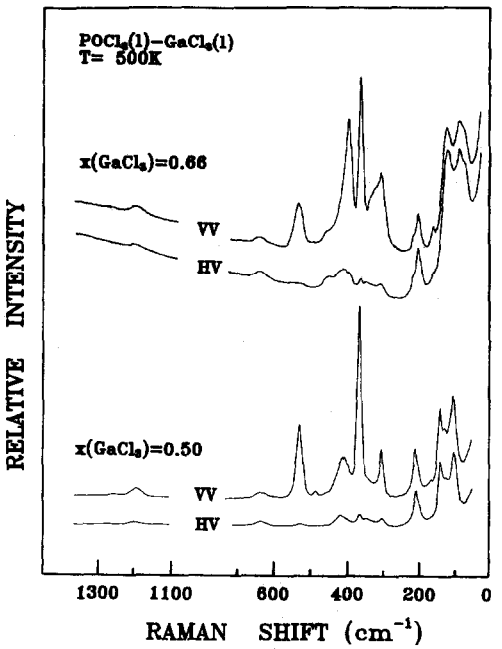

Fig. 6. Raman spectra of molten $POCl_3$–$GaCl_3$ mixtures with $X_{GaCl_3} = 0.50$ and 0.66. $\lambda_o = 488$ nm; w = 250 mW; ssw = 6 cm^{-1}; $\tau = 0.03$ s; ss = 180 cm^{-1} min^{-1}.

The bonding in the vapour and liquid adduct $POCl_3 \cdot GaCl_3$ complex presumably occurs by coordination of the oxygen with the gallium atom, leading to $Cl_3POGaCl_3$. In this way deformation of the $GaCl_3$ group from planar to pyramidal occurs through the addition of an oxygen to the gallium atom, giving rise to four-coordination for both gallium and phosphorus atoms, in agreement with the coordination generally found for these atoms.

Figure 3 shows the possible structures for the vapour or liquid $POCl_3 \cdot GaCl_3$ complex, while relations (2) and (3) represent the classification of the 21 vibrational degrees of freedom for the C_{3v} and C_s configurations. Assignment of five polarized and six depolarized bands to $POCl_3 \cdot GaCl_3$ (see Table 2) points to C_{3v} rather than C_s as the most plausible structure. None of the bands seems to be due to simple combinations or first overtones of other states.

Based on the same arguments put forward in the above discussion concerning the $POCl_3$–$AlCl_3$ molten mixtures one can exclude the formation of the ionic $POCl_2^+GaCl_4^-$ liquid compound by chloride atom transfer. Consequently, the molten $POCl_3$–$GaCl_3$ mixtures in the composition range studied can be considered as molecular liquids consisting of $POCl_3 \cdot GaCl_3$, $POCl_3$, Ga_2Cl_6 and probably $POCl_3(GaCl_3)_2$ linked by the equilibria:

$$POCl_3 \cdot GaCl_3(l) + \tfrac{1}{2}Ga_2Cl_6(l) = POCl_3(GaCl_3)_2(l)$$

$$2POCl_3 \cdot GaCl_3(l) = POCl_3(GaCl_3)_2(l) + POCl_3(l).$$

[b] Assignments based on C_{3v} symmetry for $POCl_3 \cdot GaCl_3$ and C_s for $POCl_3(GaCl_3)_2$ (see text).

Considering the second complex formed in $GaCl_3$-rich melts no definite suggestions can be made from a structural point of view, due to the small number of bands (five) assigned to this species. Nevertheless, as for the $POCl_3$–$AlCl_3$ system a C_s configuration with three-fold coordination for the oxygen atom is possible for a $POCl_3(GaCl_3)_2$ compound.

Stoichiometry and thermodynamics of the vapour complex in the $POCl_3$–$GaCl_3$ *system*

Recently it has been pointed out[13] that the correct formalism for correlating Raman band intensities with equilibrium constants of gaseous reactions should include a temperature factor which depends on the stoichiometric coefficients. Following the procedure derived in ref. 13 the stoichiometry and thermodynamic functions ($\Delta H°$, $\Delta S°$) of reaction (1) are established as follows. (For further details concerning limitations, breadth of applicability and derivation of the procedure, see ref. 13.)

Determination of stoichiometry. This requires measurements at the same temperature from two Raman cells, *a* and *b*, containing the reacting gases at different pressures. If the experiments are conducted with "identical" cells maintaining the optical geometry and the laser power constant, then the following relation can be used for calculating the stoichiometric coefficient, *n*, of reaction (1)

$$\left.\frac{I_C}{I_P I_D^n}\right|_a = \left.\frac{I_C}{I_P I_D^n}\right|_b \quad \text{at constant } T, \tag{5}$$

where I_C, I_P and I_D are the integrated Raman intensities of representative bands due to the vapour complex, phosphoryl chloride and gallium chloride dimer, respectively.

Table B lists the relative integrated Raman intensities of the 265 cm^{-1} $POCl_3$ band (I_P), the 413 cm^{-1} Ga_2Cl_6 band (I_D) and the 512 cm^{-1} complex

Table 2.—*continued*

band (I_C), measured from the different cells used. The stoichiometry of reaction (1) is calculated from eq. (5) and the Raman intensities I_P, I_D and I_C listed in Table B. Combinations of measurements from the seven different cells constructed allowed for 104 calculations of n over the studied temperature range, 610–789 K, with an average value

$$n_{\text{av., reaction (1)}} = 0.54 \pm 0.06,$$

which shows that the predominant vapour complex formed is 1:1 $POCl_3 \cdot GaCl_3$. Thus, the temperature-dependent features of the spectra (e.g. Fig. 4) can be interpreted in terms of shifts in the equilibria:

$$POCl_3 \cdot GaCl_3(g) \Leftrightarrow POCl_3(g) + \tfrac{1}{2}Ga_2Cl_6(g)$$

$$Ga_2Cl_6(g) \Leftrightarrow 2GaCl_3(g).$$

Enthalpy. The calculation of the "second law" enthalpy is based on the following equation:[13]

$$R \ln K = R \ln [T^{\Delta n} K_f K_I]$$

$$= -\Delta H^\circ (1/T) + (\Delta S^\circ - R \ln K_L), \quad (6)$$

where K_I is the quotient of the terms $I_i(\nu_i)$ (with ν_i being the vibrational wave number) due to the gaseous species participating in reaction (1), K_f is the quotient of the terms $1 - \exp(-hc\nu_i/kT)$ and K_L is a temperature-independent parameter involving the intensity of the excitation laser line, the molecular scattering properties and the sensitivity of the spectrometric system used.[13]

For the enthalpy of reaction (1) ($n = 0.5$) a plot [Fig. 7(a)] of $R \ln K$, where $K = 1/T^{0.5} K_f K_I$ vs $1/T$ [i.e. eq. (4), $\Delta n = -0.5$], for all seven cells used gives:

$$\Delta H^\circ_{1, n=0.5} = -36.7 \pm 0.8 \text{ kJ mol}^{-1}.$$

Entropy. The entropy ΔS° is determined from the intercept of an $R \ln K_P$ vs $1/T$ plot. This requires measurements of the partial pressures and the equi-

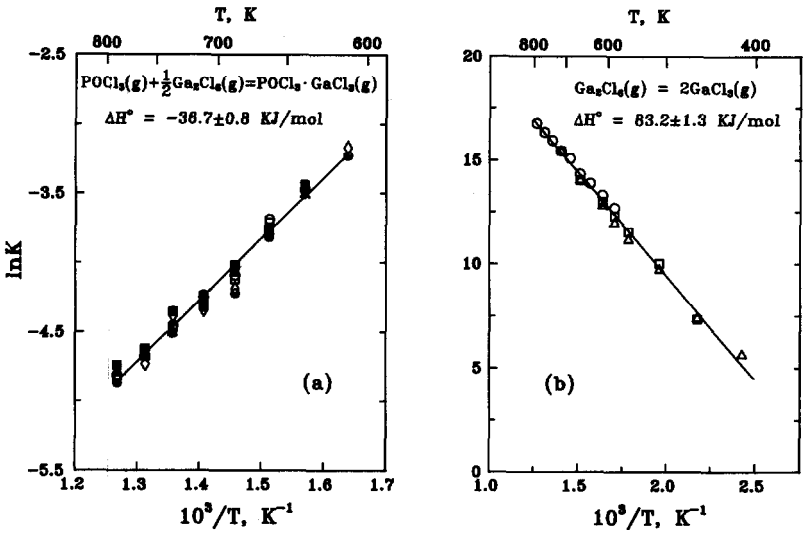

Fig. 7. Plots of $\ln K$ vs $1/T$ for the reactions: (a) $POCl_3(g)+\frac{1}{2}Ga_2Cl_6(g) \Leftrightarrow POCl_3\cdot GaCl_3(g)$, $K=(1/T^{0.5})K_fK_I$ and (b) $Ga_2Cl_6(g) \Leftrightarrow 2GaCl_3(g)$, $K=TK_fK_I$. Points indicate measurements from the different cells as follows: (a) cell I, ○; cell II, ◒; cell III, ●; cell IV, □; cell V, ▲; cell VI, ◇; cell VII, ■. (b) Cell G1, △; cell G2, □; cell G3, ○.

librium constants for the gaseous reaction at different temperatures. Raman experiments can be used for measuring partial pressures by comparing the Raman intensity I_i of a representative band of a species in the reacting mixture in a cell x at temperature T_x, with the Raman intensity of the same band in a reference cell R containing only this species with a known pressure P_R at temperature T_R. If cells x and R are "identical" and if the spectra are obtained under identical conditions, then the unknown partial pressure P_i in cell x is determined[13] by:

$$[P_i]_{\text{cell x}} = [I_i]_{\text{cell x}} \frac{[P_i]_{\text{cell R}}}{[I_i]_{\text{cell R}}} \frac{T_x}{T_R} \frac{f_i(v_i, T_x)}{f_i(v_i, T_R)}. \qquad (7)$$

The partial pressures determined according to the above equation are subject to uncertainties, which are related to the error associated with the measurements of the Raman intensities $[I_i]_{\text{cell x}}$ and $[I_i]_{\text{cell R}}$ (i.e. ±2%, see Experimental). The calculation of the equilibrium partial pressures of $POCl_3$ (P_P) and Ga_2Cl_6 (P_D) in cells I–VII is based on eq. (7) using the pure substance reference cells. An internal reference standard for the complex could be established by considering the gallium mole balance equation $P_C = 2(P_{0,D} - P_D) - P_M$, where $P_{0,D}$ is the expected pressure from the moles of undissociated and unreacted Ga_2Cl_6 added originally in each cell and P_M is the equilibrium partial pressure of the $GaCl_3$ monomer. The intensity of the complex band at 762 K from cell I was selected arbitrarily as a reference standard. The reference state was chosen from high temperature measurements so as to ensure that no other (higher) complexes should be involved in the gallium mole balance equation. Values of P_C listed in Table B are thus calculated using eq. (7) and the complex reference standard.

The last column of Table B lists the equilibrium constants calculated from the P_P, P_D and P_C values. The entropy is calculated from the intercept of a $R\ln K_P$ vs $1/T$ plot, where the slope of the least-squares line corresponds to the $\Delta H^\circ_{1,n=0.5}$ value given above. The result is:

$$\Delta S^\circ_{1,n=0.5} = -43.6 \pm 1.1\ \text{J mol}^{-1}\ \text{K}^{-1}.$$

Furthermore, the data obtained from the cells containing pure gallium chloride (e.g. Fig. 5, Table A) are adequate for establishing the thermodynamics of reaction (4). Table A lists the relative integrated Raman intensities of the 382 cm^{-1} monomer band, I_M, and the 413 cm^{-1} dimer band, I_D. The second law enthalpy, ΔH°, for reaction (4) ($\Delta n = 1$) can be calculated from the data I_M, I_D (Table A) and eq. (6). A linear least-squares fitting of $R\ln K$ ($K = TK_fK_I$) vs $1/T$ for all three cells used determines the enthalpy as the slope of the line shown in Fig. 7b. The measured value is:

$$\Delta H^\circ_4 = 83.2 \pm 1.3\ \text{kJ mol}^{-1}.$$

The calculation of the partial pressures of $GaCl_3$, P_M, is based on eq. (7) using as a reference standard the I_M value from cell G1 at 737 K. An internal reference standard for the dimer was established (cell G1, 510 K) by considering the mole balance

equation $P_D = P_0 - 1/2P_M$. Thus, the calculation of the partial pressures of Ga_2Cl_6, P_D, is based on eq. (7) using as a reference standard the I_D value from cell G1 at 510 K. The last column of Table A lists the equilibrium constants calculated from the P_M and P_D values. As in the case of the vapour complex the entropy was determined from the intercept of a $R\ln K_P$ vs $1/T$ plot, where the slope of the least-squares line corresponds to the ΔH_4° value calculated above. The result is:

$$\Delta S_4^\circ = 130.6 \pm 2.2\,\text{J mol}^{-1}\,\text{K}^{-1}.$$

By combining the thermodynamic functions of reactions (1) and (4) one obtains values for ΔH° and ΔS° for the following reaction:

$$POCl_3(g) + GaCl_3(g) \Leftrightarrow POCl_3 \cdot GaCl_3(g) \quad (8)$$

$$\Delta H_8^\circ = -73.8 \pm 0.8\,\text{kJ mol}^{-1}$$

$$\Delta S_8^\circ = -108.9 \pm 1.1\,\text{J mol}^{-1}\,\text{K}^{-1}.$$

Table 3 summarizes the thermodynamic functions calculated in this work from Raman spectral data. In the case of reaction (4) the measured ΔH° and ΔS° values are in good agreement with earlier reported values.[23,24]

ISOMERIC DITHIOCYANATE COMPLEXES OF RUTHENIUM(II), SYNTHESIS, CHARACTERIZATION OF ALL POSSIBLE BOND ISOMERS OF *TRANS,CIS*-$Ru(CNS)_2L_2$ [L = 2-(ARYLAZO)PYRIDINE] AND STUDIES OF ISOMERIZATION

(*Received* 10 *November* 1992; *accepted* 16 *November* 1992)

Abstract—A series of isomeric new dithiocyanate ruthenium(II) complexes of the type *trans,cis*-$Ru(CNS)_2L_2$ [L = 2-(arylazo)pyridine] have been synthesized by a stereoretentive substitution reaction from the known diaquo cationic complex *trans,cis*-$[Ru(OH_2)_2L_2]^{2+}$. All possible linkage isomers have been separated on a silica gel column and investigated for linkage isomerism. These isomers have been thoroughly characterized from physical properties, ^1H NMR, IR and UV–vis spectroscopy. It has been shown that the most stable linkage isomer in this case is S,S bonded. Two (S,N and N,N) out of three isomers of *trans,cis*-$Ru(CNS)_2L_2$ are converted into the third (S,S) isomer on boiling in xylene. Similar transformations have also been observed in the solid state. Factors influencing the population of the various isomers are noted.

Thiocyanate (SCN^-) is a potential ambidentate[1–5] ligand for metal ions. Much effort has been expanded towards understanding the role of co-ligands[2,6–13] in relation to the thiocyanate bonding mode in mixed-ligand transition metal thiocyanate complexes. It has now been established that both electronic as well as steric factors in metal thiocyanates largely influence the bonding modes of the pseudo-halide. In an attempt to sort out the effect of a strong π-acceptor co-ligand on the bonding mode of the thiocyanate ion to a ruthenium(II) centre we report here the synthesis, characterization and isomerization of isomeric dithiocyanates of the type *trans,cis*-$Ru(CNS)_2L_2$ [L = 2-(arylazo)-pyridine]. The *trans,cis* designation refers to the relative positions of the coordinated pyridine and azo nitrogens of the ligand L, respectively. Besides the fact that examples of ruthenium(II) thiocyanates are scarce,[14–20] no systematic approach on the isomerization of such complexes have been reported. It may be relevant to add here that in most cases only one (most stable) of the possible isomers is formed, which probably precludes the possible studies on the isomerization in such complexes. The two ligands used are abbreviated as L^1 and L^2.

RESULTS AND DISCUSSION

Stereochemistry of the starting material and synthesis

The cationic diaquo complex $[Ru(OH_2)_2L_2]^{2+}$ exists[21] in two geometrical isomeric forms; both have the *cis*-$Ru(OH_2)_2$ moiety. The stereochemistries of isomers having the RuL_2 moiety have been defined.[22] Thus, isomer **1** of $[Ru(OH_2)_2L_2]^{2+}$ is *trans,cis* or simply *t,c*. This diaquo complex (**1**) was used as the starting material for the synthesis of the desired dithiocyanate complex.

An ethanolic solution of **1** reacts smoothly with a large excess of aqueous NH_4SCN (1:>20) to yield [eq. (1)] an isomeric mixture of $Ru(CNS)_2L_2$ (CNS does not imply the bonding mode).

$$t,c\text{-}Ru(H_2O)_2L_2^{2+} \xrightarrow[C_2H_5OH/H_2O]{NH_4SCN} t,c\text{-}Ru(CNS)_2L_2 \quad (1)$$

† Author to whom correspondence should be addressed.

The compound is moderately soluble in the reaction mixture. On concentration of the solution, followed by cooling to 273 K, the crystalline product precipitates. The crude product was then subjected to column chromatography for isomer purification. Three pure isomers were eluted from the column, which on evaporation and further crystallization yielded crystalline compounds. Formulations of the compounds are made on the basis of elemental analyses (Table 1). The solution colours of the three isomers are: first band, greenish blue (**2**); second band, blue (**3**); and third band, violet (**4**). The overall yield of $Ru(CNS)_2L_2$ is quite high (>80%). The relative yields of the isomers vary with the temperature of the reaction. If the anation reaction is performed by boiling the reaction mixture the relative yields of the three isomers **2**:**3**:**4** are 6:3:1, and when the reaction is carried out at room temperature (300 K) the observed relative yields of **2**:**3**:**4** are 3:3:1. Furthermore, we note here that in refluxing xylene (1) both **3** and **4** or a mixture of **3** and **4** isomerizes to **2** and (2) **4** isomerizes to **3**. Similar transformations have also been observed in the solid state. From the above observations it may be concluded that of the three isomers, bluish green **2** is thermally the most stable. It may also be noted here that a very large excess of NH_4SCN is required for the completion of reaction (1). At a lower concentration of NH_4SCN the reaction was incomplete, even after 20 h boiling of the reaction mixture.

Geometry of $Ru(CNS)_2L_2$

It has now been well established that the *t,c* geometry of the RuL_2^{n+} moiety is thermally the most stable[23–25] and **1** undergoes[26,27] stereoretentive nucleophilic substitution reactions with several monodentate and bidentate ligands. Thus, it is reasonable to assume that the anation reaction under consideration occurs without change in the RuL_2 moiety. This assumption is further strengthened by the product of the reaction of crude

$$t,c\text{-}Ru(OH_2)_2L_2^{2+} \underset{Ag^+}{\overset{SCN^-}{\rightleftharpoons}} t,c\text{-}Ru(CNS)_2L_2$$

Scheme 1.

$Ru(CNS)_2L_2$ with 2 mol of $AgNO_3$. The optical spectra of the diaquo compound obtained from the above reaction were indistinguishable from those of authentic $t,c\text{-}Ru(OH_2)_2L_2^{2+}$. Thus, we have the stereoretentive interconversion Scheme 1.

Spectra and identification of linkage isomers of t,c-$Ru(CNS)_2L_2$

The stereoretentive anation reaction of **1** should in principle produce three linkage isomers of *t,c*-$Ru(CNS)_2L_2$ (Scheme 2). Of the three possible isomers two (S,S and N,N) are symmetrical, whereas S,N is unsymmetrical. The geometry and bonding mode of the thiocyanates have been clearly revealed by ^1H NMR and optical spectral data.

^1H *NMR spectra.* The ^1H NMR spectral data of the complexes were used to determine the symmetry of the complexes and thus the bonding mode of CNS in the isomers. Assignment of individual pyridyl proton resonances was made[28,29] on the basis of relative intensity, chemical shifts and by comparison of the spectra with those of analogous complexes of L. Unfortunately, we could not obtain resolvable signals for aryl protons under our experimental conditions. Chemical shifts, along with the *J* values of the proton resonances in the complexes, are listed in Table 2 and a set of representative spectra are displayed in Fig. 1.

Examination of the data in Table 2 reveals that: (1) the methyl and pyridyl proton resonances of **4** are in general upfield to those of **3** and **2**, (2) two (**2** and **4**) of the three isomers exhibited only one signal (singlet or multiplet) both for the pyridyl and methyl protons, whereas the same signals split in the case of the blue isomer (**3**) (Fig. 1). Therefore,

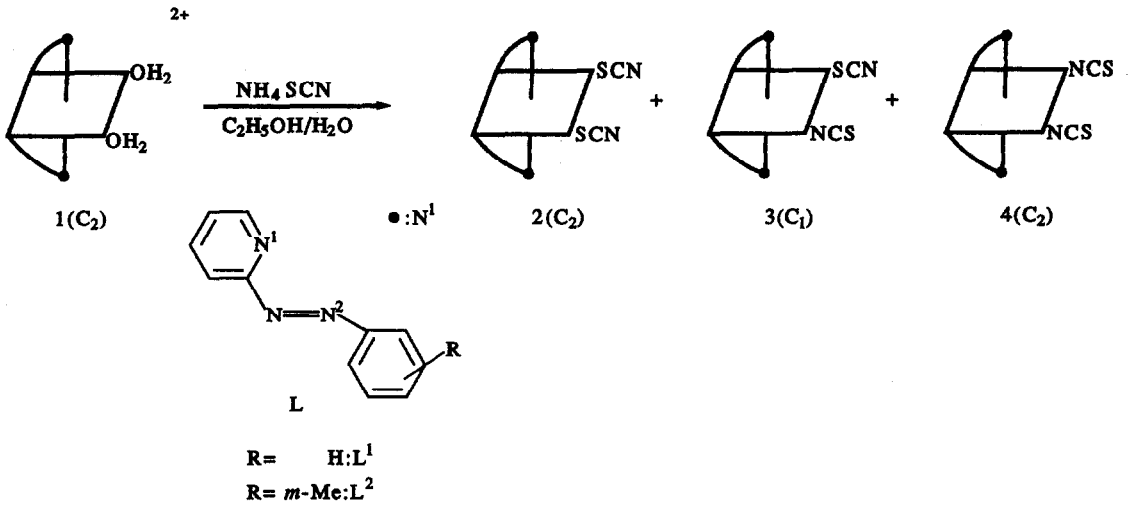

Scheme 2.

in isomer **3** two ligands are magnetically inequivalent and the other two isomers are symmetrical. It has already been noted that the t,c geometry of the RuL_2 moiety is symmetrical and the loss of symmetry in **3** must arise from the unsymmetrical coordination of the two CNS groups. Clearly, isomer **3** is S,N bonded, t,c-$Ru(SCN)(NCS)L_2$. The other two isomers are S,S and N,N bonded and each of them retains the symmetry axis as expected. This ambiguity regarding the S,S and N,N coordination modes could not be settled by ^1H NMR data, however, this problem has been solved by the use of optical spectral data (*vide infra*). (3) Each of the three isomers exhibit resonance(s) due to the orthopyridyl proton at *ca* 9.15 ppm. We note that this proton is shielded in *trans* geometry and the resonance appears at a higher field[28] in the analogous complexes. This further confirms the *cis* geometry of $Ru(CNS)_2L_2$ complexes.

UV–vis spectra. The solution spectra of all three isomers, t,c-$Ru(CNS)_2L_2$, show highly intense allowed transitions in the visible region. UV–vis spectral data of the complexes are collected in Table 3 and representative spectra are displayed in Fig. 2. The lowest energy transition in each case has been attributed[21–27] to metal-to-ligand charge transfer [$Ru(t_2) \rightarrow \pi^*(L)$] MLCT transitions. We note here that the MLCT transition in each case is associated with a shoulder at a higher energy. This spectral

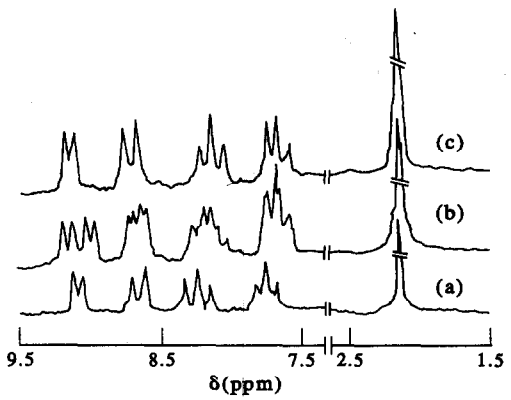

Fig. 1. Segmented ^{1}H NMR spectra of (a) *t,c*-Ru(SCN)$_2$(L^2)$_2$ (**2**), (b) *t,c*-Ru(SCN)(NCS)(L^2)$_2$ (**3**), and (c) *t,c*-Ru(NCS)$_2$(L^2)$_2$ (**4**) in $CDCl_3$.

feature has only been observed[22,30] in the *cis* geometry of bis-ligated ruthenium(II) complexes of L. It is significant to note that the trend of MLCT energies in this triad (**2**–**4**) is mutually consistent with the shift of ν(N=N) of coordinated L. In the spectrochemical series the position of isothiocyanate (N-bonded) is higher[31] than that of the thiocyanate (S-bonded) ligand. Thus, it is expected that N-coordination would stabilize the Ru(t_2) level better than that in the case of S-coordination. If it is assumed that the energies of the acceptor π^* (L) levels are more or less unaffected by a change in the coordination mode of CNS, the order of ν(MLCT) would be S,S < S,N < N,N and a parallel shift of ν(N=N) is also expected. This is exactly what is observed in the spectra of the three-bond isomers of *t,c*-Ru(CNS)$_2$L$_2$. Therefore, based on the spectral data it may be concluded with certainty that the greenish-blue isomer (**2**) is S,S-bonded *t,c*-Ru(SCN)$_2$L$_2$, the blue isomer (**3**) is S,N-bonded *t,c*-Ru(SCN)(NCS)L$_2$ and the violet isomer (**4**) is N,N-bonded *t,c*-Ru(NCS)$_2$L$_2$. This conclusion has been further proven by the examination of IR data.

IR spectra. IR spectral data were collected in the range 4000–250 cm^{-1} using KBr discs. Characteristic group frequencies are given in Table 3.

One of the significant observations in the IR spectrum of each of the isomers of *t,c*-Ru(CNS)$_2$L$_2$ is the consistent and systematic appearance of a strong band at *ca* 2100 cm^{-1}, which was assigned[6,16,31,32] to ν(CN) of coordinated CNS. Interestingly, the intensity of this band of **4** in DMF solution (0.011 g cm^{-3} of DMF) is most intense in this triad (**2**–**4**).

The three isomers of L^1 were chosen for the examination of IR spectra in the range 500–250 cm^{-1}. The violet isomer (**4**) showed two absorptions of almost equal intensity at 330 and 320 cm^{-1}. These bands are absent in the greenish-blue isomer (**2**)—

instead, a two-band structure (relatively weak) at 305 and 298 cm^{-1} was observed. The blue isomer (**3**) showed a moderately strong absorption at 320 cm^{-1}, together with a weak absorption at 305 cm^{-1}. To explain the origin of these bands (500–250 cm^{-1}) in our complexes we note that M—NCS complexes give rise to strong bands at values comparable to M—Cl stretches of the corresponding chloro complexes, whereas thiocyanate linkages (M—SCN) give weaker bands occurring[33] inbetween the metal halide stretches of the corresponding chloro and bromo complexes. In the spectra[30] of the dichloride and dibromide analogues of the present complexes the frequencies corresponding to valence vibrations at ν(Ru—Cl), 336 and 310, and ν(Ru—Br), 275 and 250 cm^{-1}, were observed. Thus, we conclude that the absorptions at 330 and 320 cm^{-1} in isomer **4** are due to ν(Ru—NCS); the absorptions at 320 and 305 cm^{-1} in **3** are respectively due to ν(Ru—NCS) and ν(Ru—SCN); and the absorptions at 305 and 298 cm^{-1} are due to ν(Ru—SCN). The two-band structure of ν(Ru—NCS) in **4** and ν(Ru—SCN) in **2** once again confirms[23] the *cis* coordination of the two CNS ligands.

The IR spectral data of the complexes strengthen our conclusion regarding the modes of bonding of the pseudo-halide in the three linkage isomers of *t,c*-$Ru(CNS)_2L_2$ (**2–4**).

CONCLUSIONS

The spectral properties of the complexes, discussed above, clearly establish the bonding mode of the coordinated thiocyanate ligands in all three isomers, *t,c*-$Ru(CNS)_2L_2$. From statistical considerations the distribution of isomers in *t,c*-$Ru(CNS)_2L_2$ should be S,S (**2**): S,N (**3**): N,N (**4**) = 1 : 2 : 1. We find that the relative populations of **4** and **3** decrease with a rise in temperature of the reaction mixture. Thus, in boiling ethanol the yield of **4** is very poor. This result, together with the results of the thermal isomerizations of **4** → **3** and **3** → **2**, suggest that isomer **2** of the present complex is thermally the most stable. The isomerizations in the present case are surely controlled by the electronic factor alone, since the geometry and thus the steric factor arising from the two L ligands in the RuL_2 framework in all three linkage isomers remain identical. It may be relevant to mention here that the 2,2′-bipyridine (bpy) analogue of *t,c*-$Ru(CNS)_2L_2$ exists only as an N,N isomer, *cis*-$Ru(NCS)_2(bpy)_2$. These results may be interpreted as indicating that —SCN acts[31] as both a σ- and π-donor but a poor π-acceptor. In the present complex two azo groups, which are much better π-acceptors than the two pyridines, are *trans* to two thiocyanate ligands and thus promote S-bonding. In other words the symbiotic theory proposed by Jørgensen[34] is applicable in explaining the linkage preference of —SCN in the present case.

EXPERIMENTAL

Materials

The complexes *t,c*-$[Ru(OH_2)_2L_2](ClO_4)_2 \cdot H_2O$ were prepared as before.[21] Ammonium thiocyanate was obtained from Sarabhai M. Chemicals, Baroda. Spectrograde solvents were used for spectrochemical work. All other chemicals and solvents for preparative work were of reagent grade and used without further purification.

Measurements

Electronic spectra were recorded with a Hitachi 330 spectrophotometer; IR spectra (KBr disc, 4000–250 cm^{-1}) were obtained with a Perkin–Elmer 983 spectrophotometer; and solution IR spectra were measured using DMF solutions. ^1H NMR data were collected in $CDCl_3$ solvent with a Varian EM 390 spectrometer and chemical shifts were referenced to tetramethylsilane.

Preparation of the complexes

t, c- *Dithiocyanatobis* [2- (*arylazo*) *pyridine*] *ruthenium*(II), t,c-$Ru(CNS)_2L_2$. The complexes are prepared by following a general procedure. Specific details are given for *t,c*-$Ru(CNS)_2(L^1)_2$:

A sample of *t,c*-$[Ru(OH_2)_2(L^1)_2](ClO_4)_2 \cdot H_2O$ (0.720 g, 1 mmol) was dissolved in ethanol (25 cm^3) and to it an aqueous solution of NH_4SCN (1.5 g, 20 mmol) in water (5 cm^3) was added and stirred at room temperature (300 K) for 10 h. The ethanolic solution was concentrated *in vacuo* when a dark crystalline compound was obtained. It was filtered, dried and subjected to column chromatography on a silica gel column (60–120 mesh). The first moving greenish-blue band was eluted with a 1:50 acetonitrile: chloroform mixture. Two other fractions, viz. blue and violet bands, were eluted with 1:20 and 1:10 acetonitrile: chloroform mixtures, respectively. The solution of each fraction was evaporated *in vacuo*, each were crystallized from a 1:1 chloroform: hexane mixture. Yields are as follows: First band: *t,c*-$Ru(SCN)_2(L^1)_2$, bluish-green (**2**), 0.200 g (34%); second band: *t,c*-$Ru(SCN)(NCS)(L^1)_2$, blue (**3**), 0.200 g (34%); third band: *t,c*-$Ru(NCS)_2(L^1)_2$, violet (**4**), 0.067 g (12%).

A similar reaction was performed in boiling ethanol. The yields of the three isomers in this case are as follows: **2**, 0.300 g (51%); **3**, 0.150 g (25%); **4**, 0.050 g (9%). Yields of the analogous complexes of L^2: Room temperature (295 K): **2**, 0.205 g (34%); **3**, 0.200 g (33%); **4**, 0.070 g (12%). Boiling ethanol: **2**, 0.330 g (54%); **3**, 0.170 g (27%); **4**, 0.060g (10%).

Conversion of t,c-$Ru(SCN)(NCS)(L^1)_2$ (**3**) *to* t,c-$Ru(SCN)_2(L^1)_2$ (**2**). A solution of **3** (0.583 g, 1 mmol) was suspended in xylene (500 cm^3) and heated to reflux for 12 h. TLC showed only one spot due to the bluish-green isomer (**2**). The solution was concentrated to half volume and the bluish-green crystalline compound was obtained. It was filtered and dried *in vacuo*. Yield, 90%.

Conversion of t,c-$Ru(NCS)_2(L^1)_2$ (**4**) *to* t,c-$Ru(SCN)_2(L^1)_2$ (**2**). This was done similarly to above with the exception that **4** was heated to reflux for 20 h. The solution colour gradually turned blue due to the formation of the second isomer (**3**), and finally it became bluish-green (isomer **2**). Yield, 90%.

Solid-state thermal isomerization

$[t,c\text{-}Ru(SCN)(NCS)(L^2)_2]$ (**3**)→t,c-$Ru(SCN)(L^2)_2$ (**2**). A sample of **3** (0.583 g, 1 mmol) was heated slowly using an oil-bath. The temperature was raised to 150°C and maintained for 5 min. The solid mass was extracted with $CHCl_3$ (50 cm^3). The volume was then reduced to 25 cm^3 and on the addition of hexane dark crystals were obtained. On the TLC plate it showed only one spot due to isomer (**2**). The crystals were collected by filtration and dried *in vacuo*. Yield, 80%. The conversion process **4** → **2** was performed similarly. The temperature required for this transformation was *ca* 200°C. Yield, 80%.

Abstract—The equilibrium isotope effect in tin(II)–tin(IV) electron-exchange systems has been studied by a redox chromatography method using an anion-exchange resin. It was shown that the light isotopes are concentrated in tin(II) preferably. The values of the isotope separation coefficient (α) for ^{112}Sn and heavy isotopes were determined at 82°C and 5.5 mol dm^{-3} HCl. The dependence of α on isotopic mass ratio was found to be defined by the curve reaching top values of α for isotopes heavier than ^{120}Sn.

Redox chromatography in adsorption columns has been used successfully for the separation of uranium isotopes.[1,2] The same approach seems to be available for isotope fractionation of other elements. The aim of our work was to study the isotope effect in tin(II)–tin(IV) electron-exchange systems by means of redox ion-exchange chromatography. The isotope separation was accomplished through the isotopic exchange between tin(IV) adsorbed by a strongly basic anion-exchange resin and tin(II) in hydrochloric acid solution. Iron(III) adsorbed by anion-exchange resin was used as the oxidizing agent for tin(II).

EXPERIMENTAL

All the chemicals used were analytical grade reagents. Solutions were prepared with de-ionized distilled water. The anion-exchange resin Dowex 2 (50–100 mesh, Cl^- form, supplied by Fluka AG) was pretreated with HCl (5.5 mol dm^{-3}) in a hot water bath and packed in a water-jacket glass column (1.6 cm I.D. and 115 cm long). A solution of $FeCl_3$ (0.5 mol dm^{-3}) in HCl (5.5 mol dm^{-3}) at 82 ± 2°C was fed into the column until the resin was saturated by iron(III). The adsorbed iron(III) was then eluted by tin(II) (0.44 mol dm^{-3}) in HCl (5.5 mol dm^{-3}) at the same temperature. Tin(IV), produced by a redox reaction, was adsorbed by the anion-exchange resin.

The temperature of the column was controlled by a LKB 2209 thermostat. The eluant was fed into the column from the thermostated closed vessel to prevent contact with air. The effluent, which emerged from the column, was sampled and iron(III), iron(II) and tin(II) concentrations were then determined.

The concentration of iron(III) was determined spectrophotometrically with potassium thiocyanate.[3] Iron(II) was oxidized with a small excess of H_2O_2 and determined as iron(III). The concentration of tin(II) was determined by iodometric titration.[3]

After the determination of concentrations the samples which were to be analysed mass spectrometrically were treated to separate tin and iron. The separation was carried out by solvent extraction using 30% tri-n-butylphosphate solution in dodecane as an extractant.[4] Tin(II) and tin(IV) in the effluent were oxidized by H_2O_2 and then tin(IV) was extracted from HCl (3 mol dm^{-3}). Equal vol-

* Author to whom correspondence should be addressed.

umes of water and organic phases were shaken mechanically in stoppered glass tubes over 5 min and subsequently the tubes were centrifuged. Tin(IV) in the organic phase was stripped from an aliquot by HCl (0.1 mol dm^{-3}) and used for mass spectrometric analysis.

The abundances of the tin isotopes were measured using an MI-1201 mass spectrometer. The mass range from 112 to 124 was repeatedly scanned and the isotopic abundances were determined from the heights of the corresponding peaks. The statistical error of ^{112}Sn, ^{116}Sn, ^{117}Sn, ^{118}Sn, ^{119}Sn, ^{120}Sn, ^{122}Sn and ^{124}Sn abundance determination was found to be 4–6%. The absolute error for natural tin determination did not exceed the statistical error. For ^{114}Sn and ^{115}Sn the statistical error was found to be more than 15% and satisfactory accuracy (error *ca* 10–15%) of isotope separation coefficient values for these isotopes could not be provided. For this reason ^{114}Sn and ^{115}Sn were excluded from further consideration.

RESULTS AND DISCUSSION

It is known[5] that in hydrochloric acid solutions tin(II) is oxidized rapidly by iron(III). However, in our preliminary experiments it was found that iron(III) adsorbed by Dowex 2 resin can react with tin(II) rapidly only when the temperature is more than 70°C. In order to provide high rates of tin(II) oxidation and tin(II)–tin(IV) isotopic exchange the redox chromatographic experiment was performed at temperatures above 80°C.

In passing through the iron(III) adsorption zone tin(II) is oxidized in accordance with the following scheme:

$$Sn^{II}_{sol} + 2Fe^{III}_{res} \rightarrow Sn^{IV}_{res} + 2Fe^{II}_{sol}, \quad (1)$$

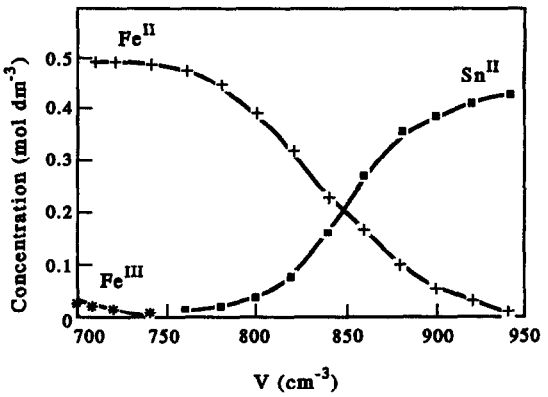

Fig. 1. Concentration profiles of tin(II), iron(II) and iron(III) at the rear boundary of the iron elution zone. Elution rate = 5 $cm^3\ h^{-1}\ cm^{-2}$.

where the terms "sol" and "res" refer to solution and resin, respectively. Since in our experimental conditions tin(II) and iron(II) are adsorbed by the anion-exchange resin more weakly than tin(IV) and iron(III), most of the iron(III) adsorbed by resin was eluted and replaced by tin(IV).

The concentration profiles of tin and iron chromatograms obtained are shown in Fig. 1. The concentration of tin(IV) in the first fractions of effluent did not exceed 5×10^{-4} mol dm^{-3}.

The values of tin isotopic abundances in samples at the front boundary of the tin(II) elution zone are presented in Fig. 2 and Table 1.

The results obtained show that the first portions of tin(II) emerged from the column are enriched by light isotopes. The values of the single stage separation coefficient (α), calculated by the Spedding method,[6] for ^{112}Sn and heavy tin isotopes are presented in Table 2. The values of α are expected

R_0[a]	0.0096	0.141	0.0739	0.244	0.0861	0.329	0.0472	0.0594

[a] Values of standard deviation (σ) were found to be in the limits 4–6%.

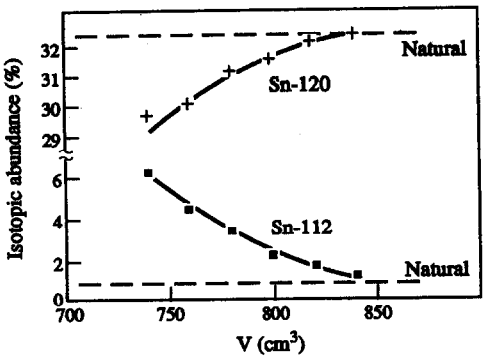

Fig. 2. Isotopic abundances of ^{112}Sn and ^{120}Sn at the front boundary of the tin elution zone.

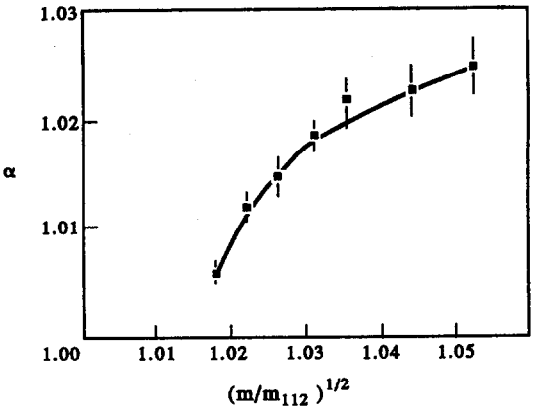

Fig. 3. Values of α plotted as a function of $(m/m_{112})^{1/2}$.

to be linearly proportional to $(m/m_{112})^{1/2}$, where m refers to the masses of the considered tin isotopes, as a first approximation. However, as shown in Fig. 3, such dependence is defined by the curve, reaching top values of α at $m > 120$.

It can be assumed that the magnitude of the isotope separation coefficient is determined by the fine structure of the complexes involved in the isotopic exchange. When tin(II) solution passes through the tin(IV) adsorption zone the following sorption–desorption and isotopic exchange processes are possible:

$$Sn^{IV}_{res} \rightarrow Sn^{IV}_{sol} \quad (2)$$

$$Sn^{II}_{sol} \rightarrow Sn^{II}_{res} \quad (3)$$

$$*Sn^{II}_{sol} + **Sn^{IV}_{res} \rightarrow **Sn^{II}_{sol} + *Sn^{IV}_{res} \quad (4)$$

$$*Sn^{II}_{res} + **Sn^{IV}_{res} \rightarrow **Sn^{II}_{res} + *Sn^{IV}_{res} \quad (5)$$

$$*Sn^{II}_{sol} + **Sn^{IV}_{sol} \rightarrow **Sn^{II}_{sol} + *Sn^{IV}_{sol} \quad (6)$$

$$*Sn^{II}_{res} + **Sn^{IV}_{sol} \rightarrow **Sn^{II}_{res} + *Sn^{IV}_{sol}, \quad (7)$$

where *Sn and **Sn refer to any pair of tin isotopes. During reactions (2)–(7) a little of one tin isotope is transferred from the solution to the resin and other isotopes from the resin to the solution. If isotopic exchange between the different chemical species of tin(II) and tin(IV) is sufficiently fast the multistage separation of tin isotopes occurs.

As predicted from the theoretical treatments[7] the equilibrium isotope effects in the exchange processes of mass transfer are significantly smaller than in the reactions of electron transfer. For this reason the observed isotope effect can be defined by reactions (2) or (3). Since the concentration of tin(IV) in the aqueous phase is sufficiently low the contribution of isotope effects on states (6) and (7) is supposed to be neglected. Thus, the observed isotope effect may be assigned to the isotopic exchange processes in accordance with eqs (4) and (5).

Under our experimental conditions tin(II) and tin(IV) in the resin phase and in the aqueous phase are known[8] to exist in the forms of $SnCl_3^-$ and $SnCl_6^{2-}$ complexes, respectively. Therefore, in order to explain the dependence of α on isotopic mass ratio a detailed investigation of tin isotopic mass influence on zero-point energies of Sn–Cl bond vibrations in $SnCl_3^-$ and $SnCl_6^{2-}$ complexes is required.

Abstract—The one-pot reaction of $HoCl_3$ with C_5H_6 and sodium (1 : 5 : 1 molar ratio) in THF resulted in the formation of the compound η^5-$CpHoCl_2 \cdot 3THF$ ($Cp = C_5H_5$), which was characterized by elemental analysis, IR and MS spectra, and X-ray crystallography, showing that it is monomeric in both the vapour and solid states. The holmium atom has a distorted octahedral geometry coordinated by one Cp ring centroid, three THF molecules and two chloride atoms. The Ho—C(Cp) bond lengths range from 2.656(11) to 2.674(11) Å and average 2.668(11) Å. The three THF molecules coordinate to the holmium atom at the Ho—O bond distances of 2.366(6), 2.376(6) and 2.454(7) Å, respectively. A comparison of some significant structural parameters along with the isostructural series $CpLnCl_2 \cdot 3THF$ (Ln = Nd, Gd, Ho, Er and Yb) was made.

The investigation of the structures of organolanthanide compounds has been of interest for many years, because it is important to interpret the bond nature and chemical properties of lanthanide compounds. Crystal structures of monocyclopentadienyl lanthanide dichlorides, such as $CpNdCl_2 \cdot 3THF$,[1] $CpErCl_2 \cdot 3THF$,[2] $CpGdCl_2 \cdot 3THF$[3] and $CpYbCl_2 \cdot 3THF$,[4] have been reported. To our knowledge, however, the study of the crystal structure of $CpHoCl_2 \cdot 3THF$ has not yet been reported. In order to characterize the Ho—C bond and to learn about the strength of coordination of the THF molecules, we herein report the synthesis of $CpHoCl_2 \cdot 3THF$ by using a one-pot method and its crystal structure by single-crystal X-ray diffraction investigations. At the same time we compare some significant structural parameters along the isostructural series $CpLnCl_2 \cdot 3THF$ (Ln = Nd, Gd, Ho, Er and Yb).

EXPERIMENTAL

General

The title compound is extremely air- and moisture-sensitive. Therefore, both the synthesis and subsequent manipulations of the compound were conducted under purified argon with rigorous exclusion of air and water using Schlenk or glovebox techniques. THF and n-hexane solvents were refluxed and distilled over fine $LiAlH_4$ or the sodium ketyl of benzophenone under argon immediately before use. Anhydrous $HoCl_3$ was prepared according to the literature method.[5]

* Author to whom correspondence should be addressed.

Measurements

Carbon and hydrogen analyses were performed on a Perkin–Elmer 240C microanalyser. The IR spectra were recorded over the 200–4000 cm^{-1} range on a Perkin–Elmer 983G spectrometer using Nujol and fluorolobe mulls and examined between disc-shaped CsI crystals. Mass spectra were recorded on a Shimadzu QP-1000A spectrometer using crystal samples; EI mode; the sample was introduced by direct inlet techniques. Mass data are based on ^{165}Ho, ^{35}Cl, ^{16}O, ^{12}C and ^{1}H. The analysis of holmium was accomplished using a literature procedure with disodium EDTA.[6]

Preparation of $CpHoCl_2 \cdot 3THF$, Cp_2HoCl *and* Cp_3Ho *by the one-pot method*

$CpHoCl_2 \cdot 3THF$. Freshly distilled cyclopentadiene (1.7 cm^3, 20 mmol) and anhydrous $HoCl_3$ (1.1 g, 4 mmol) were dissolved together in THF (40 cm^3). To this suspension was added dispersed sodium metal (0.1 g, 4 mmol) and the reaction mixture was allowed to stir overnight. After the reaction was complete the solution/suspension was centrifuged to remove the precipitate. The solution thus separated out was concentrated by reducing the pressure to *ca* 10 cm^3. n-Hexane (30 cm^3) was then added and a yellow solid was precipitated out, which was purified by recrystallization from THF/n-hexane. Crystals suitable for X-ray diffraction were grown by cooling the saturated THF solution at −25°C for 2 weeks. Yield: 65.3%. Found: C, 39.1; H, 5.4; Ho, 32.2. Calc. for $CpHoCl_2 \cdot 3THF$ ($C_{17}H_{29}O_3Cl_2Ho$): C, 39.5; H, 5.6; Ho, 31.9%. IR (cm^{-1}): 3081m, 2953s, 2878m, 1602s, 1443s, 1046s, 1012s, 914s, 862m, 780s, 762s, 438s, 365m, 238s, 212s. MS: *m/z* (relative intensity %) and fragment: 516(11.2), M; 481(2.5), M−Cl; 451(43.5), M−Cp; 416(8.9), M−Cp−Cl; 381(5.6), M−Cp−2Cl; 66(100.0), HCp; 65(42.3), Cp.

Cp_2HoCl. Freshly distilled cyclopentadiene (3.0 cm^3, 36 mmol) and anhydrous $HoCl_3$ (1.1 g, 4 mmol) were dissolved in THF (40 cm^3). To this suspension was added dispersed sodium metal (0.18 g, 8 mmol) and the reaction mixture was allowed to stir overnight. After the reaction was complete the resulting mixture was dried by reduced pressure. The dried mixture was purified by vacuum sublimation above 160°C, 10^{-3} torr, to afford a yellow crystal product. Yield: 78.3%. The results of elemental, IR and MS spectra are consistent with those reported for Cp_2HoCl in the literature.[7]

Cp_3Ho can be obtained by a procedure similar to that for Cp_2HoCl, using the molar ratio of C_5H_6 : $HoCl_3$: Na as 5 : 1 : 3.

Crystal structure determination

A yellow crystal of the title compound was sealed in a thin-walled glass capillary under argon for X-ray diffraction determination. Intensities were collected on an Enraf–Nonius CAD4 four-circle diffractometer using graphite monochromated Mo-K_α radiation at room temperature and ω–2θ techniques. Lattice parameters were determined by the least-squares refinement of setting angles of 25 computer-centred reflections in the range $10° \leqslant \theta \leqslant 15°$. Three standard reflections were monitored every 200 reflections to check crystal stability. No decrease of intensity during data collection was observed. The intensities were corrected for Lorentz–polarization effects and empirical absorption. A summary of crystallographic data is given in Table 1.

The structure was solved by direct methods and Fourier syntheses using the MULTAN system. Refinement was performed by blocked full-matrix least-squares techniques, converged to a conventional R factor of 0.036 using 2242 reflections with $I \geqslant 3\sigma(I)$. The positions of the hydrogen atoms were calculated with a C—H bond length of 0.95 Å. Non-hydrogen atoms were refined using anisotropic temperature factors and hydrogen atoms isotropic temperature factors. All calculations were performed on a PDP 11/44 computer (Digital Equipment Corporation) using the SDP program system. Atom scattering factors were taken from the International Tables for X-ray Crystallography.[8] Fractional atomic coordinates and thermal parameters, together with observed and calculated structure factors, have been deposited with the Editor.

RESULTS AND DISCUSSION

Discussion of the one-pot reaction for the preparation of cyclopentadienyl lanthanide derivatives

The previous method for preparing the cyclopentadienyl lanthanide derivatives, such as $CpLnCl_2 \cdot 3THF$, Cp_2LnCl and Cp_3Ln (Ln = La − Lu), involves two steps, as shown in the following equations.[7,9–11]

$$2C_5H_6 + 2Na \xrightarrow{THF} 2NaC_5H_5 + H_2 \quad (1)$$

$$LnCl_3 + nNaC_5H_5 \xrightarrow{THF} Cp_nLnCl_{3-n} + NaCl$$
$$n = 1, 2 \text{ or } 3. \quad (2)$$

Due to NaCp being extremely sensitive to air and moisture, the preparation of a good quality solution of NaCp is usually difficult. Therefore, this method

[b] $R = \Sigma \| F_o | - | F_c \| / \Sigma F_o$.

[c] $Rw = [w(F_o - |F_c|)^2 / \Sigma w(F_o)^2]^{1/2}$.

[d] $GOF = [\Sigma w(F_o - |F_c|)^2 / (N_o - N_v)]^{1/2}$ (N_o, N_v are the number of observations and variables, respectively).

is not convenient due to the overelaborate procedure of the preparation and purification of NaCp. Thus, we suggest a modified procedure, namely, the one-pot method for the preparation of lanthanide metallocenes, as shown in the following equation:

$$n C_5H_6 + n Na + LnCl_3 \xrightarrow{THF} (C_5H_5)_n LnCl_{3-n} + NaCl + H_2$$

$$n = 1, 2 \text{ or } 3.$$

The above one-pot reaction is suitable for preparing Cp_3Ln, Cp_2LnCl and $CpLnCl_2 \cdot 3THF$ (see Experimental). However, it must be noted that compounds of Eu^{3+}, Sm^{3+} and Yb^{3+} could not be prepared using the one-pot reaction because of the formation of divalent compounds at the same time. Due to omitting the preparation of NaCp, our new method for the syntheses of cyclopentadienyl lanthanide derivatives is simple and economical compared to the traditional method.

Spectroscopic characterization of $CpHoCl_2 \cdot 3THF$

The compound $CpHoCl_2 \cdot 3THF$ was characterized by elemental analysis, IR and MS spectra. The IR spectra show characteristic absorptions of the η^5-Cp group at *ca* 250, 780, 1010, 1440 and 3080 cm^{-1} and the coordinated THF molecule near 890

and 1046 cm^{-1}.[12-14] The ν(Ho—O) and ν(Ho—Cl) vibrations appear at 438 and 365 cm^{-1}, respectively.[15,16] Mass spectra clearly show the molecular ion and main fragments of the compound $CpHoCl_2 \cdot 3THF$. The molecular ion is characterized by the ready loss of a Cp group with a strong peak, $[M—Cp]^+$, in the spectra. It is interesting to note that in the mass spectra the ion peak of $[M—Cl]^+$ is weaker than that of $[M—Cp]^+$, and no ion peak due to $[M—THF]^+$ formed by the direct loss of coordinated THF from the molecular ion. This indicates that the bond strength is of the order Ho—C < Ho—Cl < Ho—O, the Ho—C bond easily breaking under electron impact.

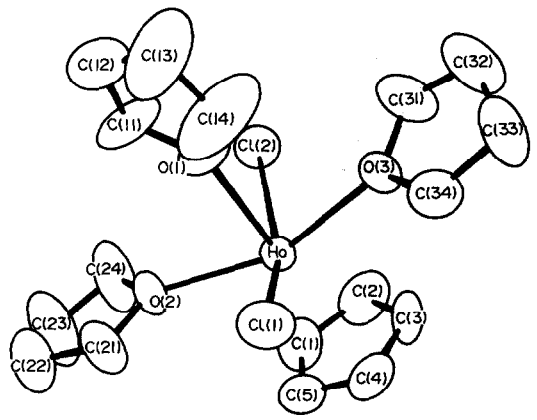

Fig. 1. The structure of the compound $CpHoCl_2 \cdot 3THF$ with the hydrogen atoms omitted for clarity.

Description of the stucture of $CpHoCl_2 \cdot 3THF$

The molecular structure with atomic numbering scheme is shown in Fig. 1. Selected bond distances and angles are listed in Table 2. The compound is monomeric and isostructural with the known

derivatives of Nd, Gd, Er and Yb.[1–4] The holmium atom is coordinated by a η^5-Cp ring centroid, three THF molecules and two chloride atoms to form distorted octahedral geometry.

The Ho—C(Cp) bond distances range from 2.656(11) to 2.674(11) Å, and average 2.668(11) Å. The Ho—O(2) and Ho—O(3) bond lengths are similar, which are 2.367(6) and 2.366(6) Å, respectively. The Ho—O(1) bond distance of 2.454(7) Å is significantly longer than both Ho—O(2) and Ho—O(3) bonds. This deviation indicates that the steric repulsion around the THF1 ring [O(1)–C(14)] is larger than that existing about THF(2) [O(2)–C(22)] and THF(3) [O(3)–C(33)] rings. The Ho—Cl(1) and Ho—Cl(2) bond distances are also similar, which are 2.618(3) and 2.623(3) Å, respectively. The average Ho—Cl bond length [2.621(5) Å] is shorter than that found in the corresponding dimeric compound $[Cp_2HoCl]_2$ [2.674(5) Å].[17] This difference is normal for monomeric and dimeric compounds and is in agreement with the results reported for organolanthanide alkoxides.[18–20] This correlation is especially evident in the compound $(C_5Me_5)_2Y(\mu\text{-Cl})ClY(C_5Me_5)_2$,[21] which contains both bridging and terminal chloride atoms. The bond angle of O(1)—Ho—Cent [179.1(3)°] indicates that the O(1), Ho and the centroid of the Cp ring are almost on one line. The O(2)—Ho—Cent, O(3)—Ho—Cent, Cl(1)—Ho—Cent and Cl(2)—Ho—Cent angles are almost same and are *ca* 102°, which is larger than that (90°) in an octahedron, due to the steric repulsion of the Cp group. It was also found that the order of Ho—C, Ho—Cl and Ho—O bond distances was Ho—C > Ho—Cl > Ho—O.

All the bond distances in the title compound are reasonable in comparison with the corresponding values in the isostructural compounds $CpLnCl_2 \cdot 3THF$ (Ln = Nd, Gd, Er and Yb) (see Table 3).[1–4] It is obvious that all the bond lengths of Ln—C(Cp), Ln—O(THF), Ln—Cl and Ln—Cent(Cp) decrease with increasing atomic numbers of the lanthanide elements. This result is in agreement with the effect of the "lanthanide contraction". The "gadolinium break" phenomenon reported in the structural series $Cp_3Ln \cdot THF$[23] does not occur in the structural series $CpLnCl_2 \cdot 3THF$.

(*Received* 30 *June* 1992; *accepted* 22 *October* 1992)

Abstract—The title compounds were obtained by reacting $(NH_4)_2MS_4$ (M = Mo, W) and AgI with excess α-methylpyridine or γ-methylpyridine. The structures can be described as extended networks of —AgS_2M— (M = Mo, W) as four-membered rhombs which are alternately parallel and perpendicular all along the polymer chain composed of continuous metal–metal bonds.

It is still a challenge to prepare polymeric species containing different metals. One elegant method is the use of thiometallates as adducts. The number of species of this type is still small and those reported are mostly copper containing compounds of thiometallates, such as MoS_4^{2-}, WS_4^{2-} and ReS_4^{1-}.[1–6] Early in 1982 Müller *et al.* discovered that there was a strong absorption in the Mo—S absorption bands from the resonance Raman spectrum of $[(C_6H_5)_4P]AgMoS_4$, and supposed that it may have a polymeric structure.[7,8] However, no report on the crystal structure of such a compound has been published so far. In this context we report the syntheses and crystal structures of the title compounds. In addition, a comparison is given on the generation of different types of polynuclear compounds by thiometallates containing Cu^+ and Ag^+ in the presence of basic ligands such as pyridine and its derivatives.

EXPERIMENTAL

All manipulations were carried out in air. IR spectra (KBr discs) between 4000 and 400 cm^{-1} were recorded on a Nicolet FT-170SX spectrophotometer. Carbon, hydrogen and nitrogen analyses were performed on a PE-240C elemental analyser. Molybdenum, tungsten and silver analyses were performed on a JA-1100 ICP spectrophotometer. $(NH_4)_2MS_4$ (M = Mo, W) was prepared by literature methods.[9] The other chemicals were used as purchased.

Preparation of $+AgMoS_4 \cdot \alpha$-MePyH$+_n$ (1)

To α-methylpyridine (60 cm^3) were added $(NH_4)_2MoS_4$ (0.26 g, 1.0 mmol) and AgI (0.94 g, 4.0 mmol). The mixture was stirred for 1 h at room temperature and then filtered. The resultant filtrate was allowed to stand at ambient temperature for 4 days whereupon dark red crystals of **1** formed, which were filtered off and washed with a mixture (20 cm^3) of acetone and α-methylpyridine (4:1). Yield: 0.20 g (46.93%). In the course of crystal growth a silver mirror appeared on the surface of the glass vessel. Found: C, 16.8; H, 1.8; N, 3.4; Ag, 25.6; Mo, 22.0. Calc. for $C_6H_8NS_4AgMo$: C, 16.9; H, 1.9; N, 3.3; Ag, 25.3; Mo, 22.5%. IR spectrum: ν(Mo—S_{br}) 439.0 cm^{-1}.

Preparation of $+AgWS_4 \cdot \alpha$-MePyH$+_n$ (2)

Compound **2** was prepared as above starting from $(NH_4)_2WS_4$ (0.35 g, 1.0 mmol). Yield: 0.18 g

* Author to whom correspondence should be addressed.

(35.01%) of yellow crystals of **2**. Found: C, 14.0; H, 1.5; N, 2.8; Ag, 21.1; W, 35.0. Calc. for $C_6H_8NS_4AgW$: C, 14.0; H, 1.6; N, 2.7; Ag, 21.0; W, 35.8%. IR spectrum: ν(W—S_{br}), 430.0 cm^{-1}.

Preparation of $+AgMoS_4 \cdot \gamma\text{-MePyH}+_n$ (**3**)

Compound **3** was prepared in the same way as **1** with excess γ-methylpyridine instead of α-methylpyridine. Yield: 0.29 g (68.04%) of dark red crystals of **3**. Found: C, 16.9; H, 1.9; N, 3.3; Ag, 25.5; Mo, 22.1. Calc. for $C_6H_8NS_4AgMo$: C, 16.9; H, 1.9; N, 3.3; Ag, 25.3; Mo, 22.5%. IR spectrum: ν(Mo—S_{br}) 445.0 cm^{-1}.

Preparation of $+AgWS_4 \cdot \gamma\text{-MePyH}+_n$ (**4**)

Compound **4** was prepared by the same route as **3** with $(NH_4)_2WS_4$ (0.36 g, 1.0 mmol). Yield: 0.39 g (75.86%) of yellow crystals of **4**. Found: C, 14.0; H, 1.6; N, 2.8; Ag, 21.1; W, 35.3. Calc. for $C_6H_8NS_4AgW$: C, 14.0; H, 1.6; N, 2.7; Ag, 21.0; W, 35.8%. IR spectrum: ν(W—S_{br}) 437.3 cm^{-1}.

X-ray crystallography

The crystals obtained directly from the preparations were suitable for single-crystal X-ray work. All measurements were made on samples mounted on the tip of a glass fibre with epoxy resin using a Nicolet R3m four-circle diffractometer operating in the θ–2θ scan mode with graphite monochromated Mo-K_α radiation source at 293 K. The cell constants and orientation matrix for the data collection of the three compounds were based on 25 carefully centred reflections in the range $7° < 2\theta < 24°$ for **1** and **4** and $6° < 2\theta < 24°$ for **3**. Data were corrected for Lorentz–polarization effects and an empirical absorption correction (except for **3**) was applied. Structures were solved by a combination of direct methods and the heavy-atom Fourier technique. Full-matrix least-squares refinement was carried out with anisotropic thermal parameters for all the non-hydrogen atoms. Hydrogen atoms were not included in the calculations. Scattering factors with anomalous-dispersion corrections were taken from ref. 10. All calculations for the solution and refinement of the structures were performed on an Eclipse S/140 computer using the SHELXTL program package (Nicolet corporation, 1986). Specific parameters to the data collections are reported in Table 1. Selected bond lengths and angles are listed in Tables 2, 3 and 4, respectively.

RESULTS AND DISCUSSION

The reaction of MS_4^{2-} (M = Mo, W) with Cu^+ in the presence of basic ligands such as pyridine and its derivatives leads to the formation of two types of polynuclear compounds: (1) trinuclear cluster compounds, $(Py)_4Cu_2MS_4$ (M = Mo, W);[11,12] and (2) species with the formula $[Cu_4MS_4X_2Y_6]$ (M = Mo, W; X = Cl, Br, I, CN, SCN; Y = pyridine and its derivatives).[13,14] The similar reaction of MS_4^{2-} and Ag^+ only produces the polymeric cluster compounds with the formula $[AgMS_4 \cdot RPyH]_n$ (M = Mo, W; R = H, α-Me, β-Me, γ-Me). The different reactions between these two metal ions may be explained by the fact that the soft acid Ag^+ has more difficulty accepting the electrons donated from the harder basic ligands such as pyridine than Cu^+, therefore, it preferably accepts electrons from the soft basic ligand MS_4^{2-}. The following reaction may partly reflect this difference:

$$(NH_4)_2WS_4 + CuBr + AgBr + \gamma\text{-MePy} \longrightarrow [Cu_4WS_4(\gamma\text{-MePy})_8][W_6O_{19}].^{15}$$

Although the formation mechanism of this compound and the role of Ag^+ are unclear, the formation of the cation $[Cu_4WS_4(\gamma\text{-MePy})_8]^{2+}$ shows that Cu^+ prefers to form compounds of the type **2**.

Figure 1 shows a view of a short section of $[MoS_2AgS_2]_2$ and the cell packing of $[AgMoS_4 \cdot \alpha\text{-MePyH}]_n$. Figure 2 shows a view of the fragment $[MoS_2AgS_2]_2$ and the cell packing of $[AgMoS_4 \cdot \gamma\text{-MePyH}]_n$. Evidently, compound **1** is crystallographically different from the isomorphous **3** and **4**. From Figs 1(b) and 2(b) it can be found that because of the C_2 axis running along a direction parallel to b in the cell packing of crystals **3** and **4**, they have higher symmetry than **1**. However, in terms of the coordination mode the structures of the three compounds are remarkably similar. In the structures of **1**, **3** and **4** the asymmetric unit contains one $[AgMS_4]^-$ and one $[RPyH]^+$ unit (**1**: M = Mo, R = α-Me; **3**: M = Mo, R = γ-Me; **4**: M = W, R = γ-Me) [see Figs 1(a) and 2(a)]. The nearest four-membered MS_2Ag rings are not quite planar, but are essentially perpendicular to each other. The $MS_2Ag_2M(a)S_2Ag(a)$ moiety approaches linearity with M—Ag—M(a) and Ag—M(a)—Ag(a) close to 180°. The structures can be described as extended networks of AgS_2Mo rhombs, which are alternately parallel and perpendicular all along the polymer chain. In the anion $[AgMS_4]^-$ (M = Mo or W) the geometry of the molybdenum or tungsten atom displays a slightly distorted tetrahedron. The lengthening of the M—S bonds, from 2.178 Å in

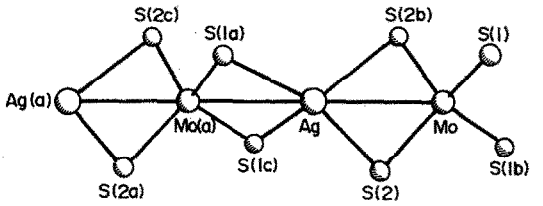

Fig. 2(a). View of a short section of $[MoS_2AgS_2]_2$.

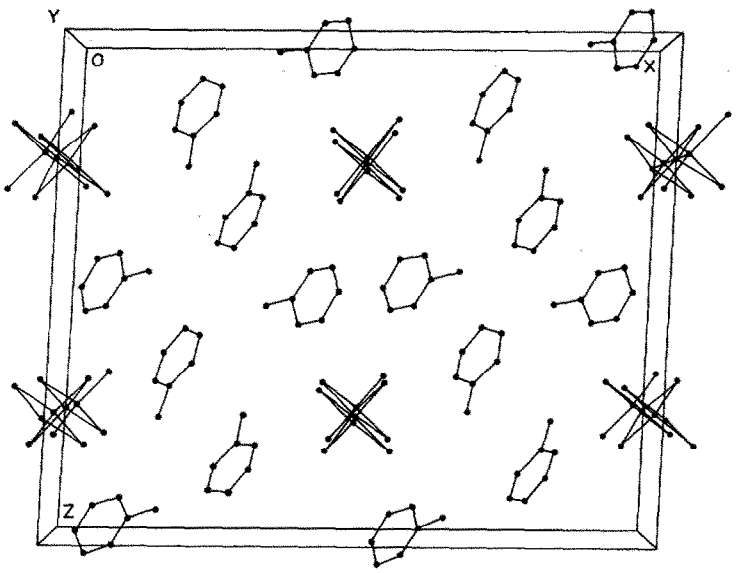

Fig. 2(b). Cell packing of $[AgMoS_4 \cdot \gamma\text{-MePyH}]_n$ viewed down *b*.

$[MoS_4]^{2-}$ to 2.187(5)–2.225(5) Å in **1**, or to 2.200(3)–2.204(3) Å in **3**, or from 2.165 Å in $[WS_4]^{2-}$ to 2.203(4)–2.209(4) Å in **4**, is due to the sulphur-coordinated silver and is reflected in the change of the $\nu(M—S_{br})$ IR stretching frequency from 472 cm^{-1} in $[MoS_4]^{2-}$ to 439 cm^{-1} in **1** or to 445 cm^{-1} in **3**, or from 455 cm^{-1} in $[WS_4]^{2-}$ to 437 cm^{-1} in **4**. The silver ion is also four-coordinated with approximate tetrahedral coordination geometry. The mean Ag—S distance (2.526 Å in **1**, 2.520 Å in **3**, 2.533 Å in **4**) is of the same order of magnitude as those observed in compounds containing tetrahedrally coordinated silver [e.g. in $[Ag_2MoS_4](PPh_3)_3 \cdot 0.8CH_2Cl_2$ ($Ag—S_{av} = 2.515$ Å)[16] or $[Ag_2WS_4](PPh_3)_3 \cdot 0.8CH_2Cl_2$ ($Ag—S_{av} = 2.624$ Å)[17]]. The M—Ag distances [2.908(1)–2.911(1) Å in **1**, 2.915(1)–2.920(1) Å in **3** and 2.946(1)–2.951(1) Å in **4**] are much shorter than the values found in other M—Ag—S compounds (e.g. 2.945 Å in $[(PPh_3)_3Ag_2MoS_4 \cdot 0.8CH_2Cl_2]$,[16] 2.975 Å in $[Ag_4Mo_2S_6](PPh_3)_4S_2$,[18] 2.971 Å in $[(PPh_3)_3Ag_2WS_4 \cdot 0.8CH_2Cl_2]$[17] or 2.997 Å in $[Ag_4W_2S_6](PPh_3)_4S_2$).[19] Although these lengths are only slightly greater (*ca* 0.1–0.15 Å) than the sum of reasonable estimates of the atomic radii of M (Mo or W) and Ag in these environments, significant M—Ag bonding [$Ag^I(d^{10}) \rightarrow M^{VI}(d^0)$ charge delocalization] is a possibility. Because of the continuous metal–metal interaction in this type of polymeric heterometallic compound, they may display some potentially unusual electrical properties. This aspect of the work is worth further investigation.

INVESTIGATION OF THE INTERMEDIATES IN THE OXIDATION OF A BULKY ARYLPHOSPHINE LIGAND WITH FERRIC CHLORIDE

KIM R. DUNBAR*† and ANNE QUILLEVÉRÉ

Department of Chemistry, Michigan State University, East Lansing, MI 48824, U.S.A.

(*Received* 10 *July* 1992; *accepted* 22 *October* 1992)

Abstract—The syntheses, spectroscopic properties and structures of iron(II) and iron(III) complexes prepared by reactions of ferric chloride with the tertiary phosphine ligand tris(2,4,6-trimethoxyphenyl)phosphine (TMPP) are described. The novel diferrous chloride salt $[H\text{-}TMPP]_2[Fe_2Cl_6]$ (**1**) was prepared by the reaction of anhydrous ferric chloride with 1 equivalent of TMPP in benzene or diethyl ether. This redox reaction also produces $[TMPP\text{-}Cl][FeCl_4]$ (**2**) as the oxidized by-product. The structure of **1**, determined by single-crystal X-ray diffraction, revealed that the $[Fe_2Cl_6]^{2-}$ anion consists of two edge-sharing tetrahedra with two terminal and two bridging chlorides per metal atom. Dissolution of complex **1** in ethanol produces $[H\text{-}TMPP]_2[Fe^{II}Cl_4]$ (**3**), which was identified on the basis of a preliminary X-ray investigation. Compound **3**, independently prepared by the reaction of $[Fe(NCCH_3)_6][AlCl_4]_2$ with 2 equivalents of TMPP in methanol, reacts with molecular oxygen to initially form $[H\text{-}TMPP][Fe^{III}Cl_4]$ (**4**) and finally the phosphine oxide species $FeCl_3$(O=TMPP) (**5**). The structure of **4** was determined by single-crystal X-ray diffraction. To test the importance of compound **4** as an intermediate in the production of TMPP=O, it was prepared directly by reaction of $[Fe(NCCH_3)_6][SbCl_6]_2$ with 2 equivalents of TMPP in methanol and reacted with oxygen to give **5** in high yield. Compounds **1–5** were further characterized by IR and electronic spectroscopies, as well as by elemental analyses. The reactions of the salts **1**, **3** and **4** suggest that the oxidation of tertiary arylphosphines with $FeCl_3$ in alcohols does not proceed via the formation of dioxygen complexes, but rather via quaternarization of the phosphine ligand.

Phosphine oxides are important reagents for a variety of applications, including the extraction of transition elements and lanthanides from acidic solutions.[1] A considerable body of research has been devoted to the study of the catalytic oxidation of triphenylphosphine to triphenylphosphine oxide by a variety of transition metal complexes including those containing iron, ruthenium, cobalt, iridium, nickel and palladium.[2–7] Recently, Ondrejovic and co-workers investigated the catalytic oxidation of triphenylphosphine by $FeCl_3$ and the phosphine complex $FeCl_3(PPh_3)_2$, and in the course of their investigation isolated bis-phosphine oxide adducts of the type $FeX_3(Ph_3P{=}O)_2$ (X = Br, Cl, NCS), which are themselves catalysts for the reaction.[8] The reaction proceeds too rapidly to allow for the detection of intermediates, thus it is not possible to obtain detailed mechanistic information. One way to approach this dilemma is to use bulkier arylphosphine ligands to lend kinetic stability to compounds along the reaction pathway. To this end, we undertook an investigation of the ferric chloride chemistry of the bulky triphenylphosphine derivative tris(2,4,6-trimethoxyphenyl)phosphine (TMPP).[9] This phosphine ligand has a cone angle of 184° as compared to that of 145° for triphenylphosphine. In the course of this work we were successful at isolating three key intermediates in the pathway leading to the thermodynamically stable product $FeCl_3$(O=TMPP), which is a catalyst for the production of O=TMPP. Our results suggest that O_2 adducts of transition metal phosphine complexes are not responsible for catalytic oxidation of

this particular phosphine ligand. A portion of this work was the subject of a previous report.[10]

EXPERIMENTAL

Starting materials

Anhydrous $FeCl_3$ was purchased from Strem Chemicals and used as received. The starting materials $[Fe(NCCH_3)_6][AlCl_4]_2$ and $[Fe(NCCH_3)_6][SbCl_6]_2$ were prepared as described in the literature.[11] Tris(2,4,6-trimethoxyphenyl)phosphine (TMPP) was prepared by a modification of the reported method; the corresponding phosphine oxide was synthesized in our laboratories.[12] All solvents were dried over 4 Å molecular sieves. Benzene, diethyl ether and THF were distilled from sodium/potassium benzophenone ketyl radical, whereas methylene chloride, acetonitrile and methanol were distilled under nitrogen from P_2O_5, CaH_2 and $Mg(OCH_3)_2$, respectively.

Reaction procedures

All reactions were carried out under argon using standard Schlenk and dry-box techniques, unless otherwise specified.

(a) *Preparation of* $[H\text{-}TMPP]_2[Fe_2^{II,II}Cl_6]$ (**1**).

(i) Preparation of $[H\text{-}TMPP]_2[Fe_2^{II,II}Cl_6]$ (**1**) in benzene. A quantity (0.162 g, 0.999 mmol) of anhydrous $FeCl_3$ was added to 1 equivalent of TMPP (0.532 g, 0.999 mmol) in deoxygenated benzene (30 cm^3). The resulting suspension was stirred at room temperature for 24 h, after which time the solvent was decanted from a yellow solid. The product was washed with several aliquots of benzene (3×10 cm^3) and THF (3×10 cm^3) until the washings were colourless. The resulting pale yellow product was dried *in vacuo*; yield: 0.456 g (65% relative to $FeCl_3$). Found: Cl, 15.3; C, 46.0; H, 4.9. Calc. for $Fe_2Cl_6PC_{54}O_{18}H_{68}$: Cl, 15.3; C, 46.6; H, 4.9%. Slow diffusion of hexanes into an acetone solution of **1** resulted in the formation of X-ray quality yellow crystals of **1**. Four ν(Fe—Cl) stretches were observed in the far-IR spectrum at 360(s), 300(m), 280(m) and 230(w) cm^{-1}. The ^1H NMR spectrum exhibited the characteristic resonances attributed to the protonated phosphine ligand $[H\text{-}TMPP]^+$ (CD_3CN, δ ppm): 3.67 (s, 18, *o*-OCH_3), 3.85 (s, 9, *p*-OCH_3), 6.24 (d, 6, *m*-*H*), 8.37 (d, 1, P—*H*). The electronic spectrum consists of three features [$CHCl_3$, λ_{max} (nm); ε M^{-1} cm^{-1}]: 377(1.80×10^3), 287(sh) and 260(6.80×10^4). The decanted brown–red reaction solution was evaporated to dryness; yield of $[TMPP\text{-}Cl][FeCl_4]$ (**2**): 0.078 g (11% relative to $FeCl_3$). ^1H NMR (CD_3CN, δ ppm): 3.35 (s, 18H), 3.64 (s, 9H), 5.95 (d, 6H). ^{31}P NMR (CD_3CN, δ ppm): −1.56. IR (CsI, Nujol): ν(Fe—Cl) = 380 cm^{-1}. FAB mass spectrum: m/z = 567 (corresponding to $[TMPP\text{-}Cl]^+$).

(ii) Preparation of $[H\text{-}TMPP]_2[Fe_2^{II,II}Cl_6]$ (**1**) in diethyl ether. A quantity of $FeCl_3$ (0.062 g, 0.380 mmol) was dissolved in diethyl ether (15 cm^3) and filtered into a diethyl ether solution (25 cm^3) of TMPP (0.203 g, 0.380 mmol). The resulting yellow suspension was stirred at room temperature for 24 h. The reaction was treated in a manner identical to that described in (i) above; yield: 0.148 g (56%).

(b) *Preparation of* $[H\text{-}TMPP]_2[Fe^{II}Cl_4]$ (**3**).

(i) From decomposition of $[H\text{-}TMPP]_2[Fe_2Cl_6]$ (**1**) in alcohols. An amount of **1** (0.050 g, 0.036 mmol) was dissolved in EtOH or MeOH (40 cm^3). The resulting yellow solution slowly became colourless over the period of 1 week under an argon atmosphere. Careful evaporation of the solvent by purging the solution with a strong flow of argon yielded a crop of pale yellow crystals suitable for a single-crystal X-ray study.

(ii) From reaction of $[Fe^{II}(NCCH_3)_6][AlCl_4]_2$ with TMPP. An amount of $[Fe(NCCH_3)_6][AlCl_4]_2$ (0.303 g, 0.474 mmol) was reacted with 2 equivalents of TMPP (0.505 g, 0.949 mmol) in MeOH (20 cm^3). The bright yellow solution was stirred at room temperature for 0.5 h. A pale yellow solid, isolated after reduction of the volume, was dried under a dynamic vacuum and recrystallized from an acetone/hexanes mixture (v/v 1 : 1); yield: 0.240 g (40%). Found: C, 51.9; H, 4.9. Calc. for $FeCl_4P_2C_{54}O_{18}H_{68}$: C, 51.3; H, 5.4%. Pale yellow microcrystals were grown by slow diffusion of diethyl ether into a THF solution of **3**, or by diffusion of toluene into a CH_2Cl_2 solution. IR (CsI, Nujol, cm^{-1}): ν(Fe—Cl) = 280(s). UV–vis [$CHCl_3$, λ_{max} (nm); ε (M^{-1} cm^{-1})]: 361(4.6×10^3), 309(4.9×10^3), 287(sh), 261(7.2×10^4). ^1H NMR (CD_3CN, δ ppm): 3.68(s, 18), 3.88(s, 9), 6.25(d, 6), 8.40(d, 1). Cyclic voltammetry: $(E_{1/2})_{ox}$ = +0.04 V; μ_{eff} = 5.29 μ_B.

(c) *Preparation of* $[H\text{-}TMPP][Fe^{III}Cl_4]$ (**4**).

(i) From oxidation of $[H\text{-}TMPP]_2[Fe^{II}Cl_4]$ (**3**) with molecular oxygen. An amount of **3** (0.050 g, 0.039 mmol) was dissolved in MeOH (20 cm^3). Upon bubbling dry oxygen into the solution the colour changed from yellow to orange. Evaporation of the solution produced long orange needles that were of a quality suitable for an X-ray study. Found: C, 44.3; H, 4.7. Calc. for $FeCl_4PC_{27}O_9H_{34}$: C, 44.3; H, 4.6%. IR (CsI, Nujol, cm^{-1}): ν(Fe—Cl) = 380(s). ^1H NMR (CD_3CN, δ ppm): 3.70(s, 18), 3.88(s, 9), 6.26(d, 6), 8.38(d, 1). UV–vis [$CHCl_3$, λ_{max} (nm); ε (M^{-1} cm^{-1})]: 365(5.05×10^3), 315(4.9×10^3), 289(sh) and 261(7.54×10^4). Cyclic voltammetry: $(E_{1/2})_{red}$ = +0.03 V; μ_{eff} = 6.11 μ_B.

(ii) From reaction of $[Fe^{II}(NCCH_3)_6][SbCl_6]_2$ with TMPP. A quantity of $[Fe(NCCH_3)_6][SbCl_6]_2$ (0.173 g, 0.179 mmol) was added to 2 equivalents of TMPP (0.190 g, 0.357 mmol) in MeOH (10 cm^3). Upon addition of the solvent a bright yellow solid rapidly precipitated from an orange solution. The orange filtrate was decanted from the solid and subjected to a dynamic vacuum to yield a residue which was washed with diethyl ether (2×10 cm^3) and dried *in vacuo*; yield: 0.0642 g (51% relative to Fe^{2+}). The resulting orange compound was identified by a comparison of its IR and ^1H NMR properties to those of an authentic, structurally characterized sample of $[H\text{-}TMPP][Fe^{III}Cl_4]$. The yellow solid was characterized as $[H\text{-}TMPP][SbCl_6]$; yield: 0.089 g (40% relative to TMPP). Found: Cl, 24.5; C, 37.3; H, 3.9. Calc. for $SbCl_6P C_{27}O_9H_{34}$: Cl, 24.1; C, 36.7; H, 3.9%. IR (CsI, Nujol): ν(Sb—Cl) = 345 cm^{-1}. ^1H NMR ($CDCl_3$, δ ppm): 3.69(s, 18), 3.87(s, 9), 6.11(d, 6) and 8.33(d, 1). The identical compound was independently prepared from the reaction of $Na^+SbCl_6^-$ with 1 equivalent of TMPP in MeOH.

(d) *Oxygen reactions to yield* $Fe^{III}Cl_3$(O=TMPP) (**5**).

(i) From $[H\text{-}TMPP]_2[Fe_2Cl_6]$ (**1**). An amount of **1** (0.050 g, 0.036 mmol) was dissolved in EtOH (30 cm^3). The resulting yellow solution was bubbled with dry oxygen for 10 min, during which time it turned to a dark orange colour. The reaction solution was then left to evaporate under a purge of oxygen gas which produced red–orange crystals of **5**; yield: 0.041 g (80% relative to **1**). Found: C, 45.9; H, 4.7. Calc. for $FeCl_3PO_{10}C_{27}H_{33}$: C, 45.6; H, 4.6%. IR (CsI, Nujol, cm^{-1}): 380(s) and 320(w). Electronic spectrum [$CHCl_3$, λ_{max} (nm); ε (M^{-1} cm^{-1})]: 342(4.3×10^3), 287(sh), 258(4.0×10^4). FAB-mass spectrum: m/z = 548 (corresponding to TMPP=O); ^1H NMR (CD_3CN): very broad. Cyclic voltammetry: $(E_{1/2})_{red} = -0.02$ V, $\mu_{eff} = 6.31$ μ_B.

An anaerobic EtOH solution of **1**, as described above, became colourless during a period of standing for 1 week. After bubbling oxygen through this solution for 5 min, a yellow colour ensued, which converted to dark orange within 10 min. Red–orange crystals of **5** formed under an oxygen atmosphere after several days.

An amount of **1** (0.050 g, 0.036 mmol) was dissolved in acetonitrile (20 cm^3) and a stream of oxygen gas was passed through the solution for *ca* 1 h. The resulting orange solution was layered with hexanes and diethyl ether. Crystals of **5** were isolated from this solvent mixture after 1 day; yield 0.040 g (78% relative to **1**).

(ii) From $[H\text{-}TMPP]_2[Fe^{II}Cl_4]$ (**3**) with molecular oxygen. An amount of **3** (0.100 g, 0.079 mmol) was dissolved in MeOH (20 cm^3), treated with oxygen for 4 h and layered with hexanes and diethyl ether. Red–orange crystals of **5** were isolated after 1 day; yield: 0.030 g (53% relative to **3**).

(iii) From $[H\text{-}TMPP][Fe^{III}Cl_4]$ (**4**). A quantity of **4** (0.100 g, 0.137 mmol) was dissolved in MeOH (30 cm^3), whereupon the solution was bubbled with oxygen for 3–4 days. During this time, the solvent was replenished regularly to avoid complete evaporation. Red–orange crystals of **5** were eventually deposited at the bottom of the flask; yield: 0.058 g (60% relative to **4**).

(iv) From $FeCl_3$, TMPP and O_2 mixtures. An amount of $FeCl_3$ (0.142 g, 0.874 mmol) was treated with 1 equivalent of TMPP (0.465 g, 0.874 mmol) in EtOH (20 cm^3) under a slow stream of oxygen for 3 h. The resulting orange solution was evaporated under reduced pressure to yield a dark orange solid, which was then recrystallized from EtOH and diethyl ether; yield: 0.345 g (54%).

(v) From $FeCl_3$ and TMPP=O. A quantity of $FeCl_3$ (0.119 g, 0.736 mmol) was treated with 1 equivalent of TMPP oxide (0.404 g, 0.736 mmol) in EtOH (12 cm^3). The resulting orange suspension was stirred at room temperature for *ca* 1 h until all of the $FeCl_3$ had dissolved. The suspension was then filtered in air and washed with EtOH (3×10 cm^3), followed by diethyl ether (1×10 cm^3) and finally dried *in vacuo*; yield: 0.423 g (81% relative to $FeCl_3$).

(e) *Preparation of* TMPP=O. A quantity of $FeCl_3$(O=TMPP) (**5**) (0.067 g, 0.094 mmol) was reacted with a 10-fold excess of TMPP (0.500 g, 0.939 mmol) in acetone (20 cm^3) under a stream of dry oxygen. The solution was stirred at room temperature for 1–2 h, during which time a significant quantity of white solid precipitated from solution. The orange solution was decanted from the solid, which was washed with diethyl ether (3×10 cm^3) and dried *in vacuo*. Chilling the orange filtrate produced more white product, characterized as TMPP=O; yield: 0.325 g (63% relative to TMPP). Work-up of the remaining orange solution consisted of successive extractions by CH_2Cl_2 and EtOH, which yielded crystals of $FeCl_3$(O=TMPP); total recovered yield: 0.062 g (93% of the initial mass). ^1H NMR of TMPP=O (CD_3CN, δ ppm): 3.48(s, 18), 3.79(s, 9), 6.10(d, 6).

(f) *Reaction of* [TMPP-Cl]Cl *with* $FeCl_3$. A solution of TMPP (0.461 g, 0.867 mmol) in benzene (20 cm^3) was bubbled with chlorine gas for 1–2 min until it had turned bright yellow, thereby signifying the formation of the oxidized compound TMPP-Cl^+Cl^-. The reaction solution was then pumped down to a sticky residue, but since no solid could be isolated it was redissolved in benzene (20 cm^3)

and added to $FeCl_3$ (0.141 g, 0.867 mmol). A colour change from yellow to dark brown–red immediately ensued. The solvent was removed under dynamic vacuum to produce a brown residue that was recrystallized from an acetone/hexanes mixture (v/v 1:1); yield: 0.020 g. The properties of this solid were identical to those described for [TMPP-Cl][$FeCl_4$] (**2**) (*vide supra*).

Physical measurements

IR spectra were recorded on a Perkin–Elmer 599 or a Nicolet 740 FT-IR spectrophotometer. ^{1}H NMR spectra were measured on a Varian–Gemini 300 MHz spectrometer. Chemical shifts were referenced relative to the residual proton impurity of d_3-acetonitrile (1.93 ppm with respect to TMS). Electronic absorption spectra were measured on a Hitachi U-2000 spectrophotometer. Electrochemical measurements were performed using an EG&G Princeton Applied Research Model 362 scanning potentiostat in conjunction with a BAS Model RXY recorder. Cyclic voltammetry experiments were carried out at 22 ± 2°C in methylene chloride containing 0.1 M tetra-*n*-butylammonium tetrafluoroborate ($TBABF_4$) as the supporting electrolyte. $E_{1/2}$ values, determined as $(E_{p,a}+E_{p,c})/2$, were referenced to the Ag/AgCl electrode and are uncorrected for junction potentials. The Cp_2Fe/Cp_2Fe^+ couple occurs at $E_{1/2} = +0.51$ V under the same experimental conditions. Variable-temperature magnetic susceptibility measurements were carried out on a Quantum Design MPMS susceptometer in the Physics and Astronomy Department at Michigan State University. Data points were collected over a temperature range from 5 to 300 K at 20° intervals in a field of 500 G. Elemental analyses were performed at Galbraith Laboratories, Inc.

X-ray crystallographic procedures

The structures of complexes **1**, **3** and **4** were determined by applications of general procedures described elsewhere.[13] Geometric and intensity data were collected on a Nicolet P3/F diffractometer for **3** and on a Rigaku AFC6S diffractometer for **1** and **4**; both instruments were equipped with graphite monochromated Mo-K_α ($\lambda_{\bar{\alpha}} = 0.71073$ and 0.71069 Å, respectively) radiation. The data were corrected for Lorentz and polarization effects. Calculations for **1**, **3** and **4** were performed on a VAXSTATION 2000 computer using programs from the TEXSAN Crystallographic Package of the Molecular Structure Corporation.[14] A summary of crystallographic data for compounds **1** and **4** is listed in Table 1, whereas data for compound **3** have been deposited as supplementary material.

[H-TMPP]$_2$[Fe_2Cl_6] (**1**). A yellow parallelepiped of approximate dimensions $0.31\times0.47\times0.52$ mm^3 was mounted at the end of a glass fibre with Dow Corning silicone grease and placed into a nitrogen cold stream at -100 ± 2°C. A preliminary monoclinic cell was determined by centring and indexing 20 reflections. The cell was then refined by a least-squares fit of 21 reflections in the range $23 \leqslant 2\theta \leqslant 30°$. Intensity data were collected from 4 to 47° in 2θ, by using the θ–2θ scan mode. Three standard reflections were measured at regular intervals during data collection and showed no significant decay in crystal quality. After averaging equivalent reflections, 4952 unique data remained, of which 3440 were observed with $F_o^2 \geqslant 3\sigma(F_o)^2$.

The position of the metal atom was determined by a solution provided by the direct methods program in SHELXS-86.[15] The positions of the remaining non-hydrogen atoms and of H(1) bound to the phosphorus atom were located by use of the program DIRDIF.[16] An empirical absorption correction based on the program DIFABS was applied after isotropic convergence had been achieved.[17] The positions of the hydrogen atoms that were not directly located were generated by a program in the TEXSAN package. These were included in the structure factor calculation but not refined. The final full-matrix refinement involved 3440 data and 370 parameters and converged with residuals $R(R_w) = 0.046(0.079)$ and a quality-of-fit of 2.84. The final difference-Fourier map showed a highest peak of 0.96 e Å^{-3}.

[H-TMPP]$_2$[$Fe^{II}Cl_4$] (**3**). The structure of this compound is of a poor quality and is mentioned only in a preliminary form to confirm the identity of the salt as an intermediate in the chemistry of $FeCl_3$ with TMPP. Lack of data and problems with refining the solvent molecule precluded a full refinement of the structure to a satisfactory point. A full listing of data and a description of the structure solution have been deposited in the supplementary material.

[H-TMPP][$Fe^{III}Cl_4$] (**4**). An orange platelet of approximate dimensions $0.10\times0.21\times0.52$ mm^3 was selected and mounted on the end of a glass fibre with epoxy cement. Intensity and geometric data were collected at room temperature. A preliminary orthorhombic unit cell was determined by centring and indexing on 20 reflections. The cell was then refined by a least-squares determination of 24 reflections with $9 \leqslant 2\theta \leqslant 23$. Intensity data were collected by the θ–2θ scan mode over the range 4–45° in 2θ. Three standard reflections were measured at regular intervals during data collection and

showed no decay over time. An empirical absorption correction was applied using the PSI-scan program within the TEXSAN package. After averaging equivalent reflections 3612 unique data remained, of which 1472 were observed with $F_o^2 \geqslant 3\sigma(F_o)^2$. The position of the metal atom was determined from a solution provided by the direct methods program MITHRIL.[18] The positions of the remaining non-hydrogen atoms and of H(1) were located by the program DIRDIF. All of the non-hydrogen atoms were refined anisotropically. The hydrogen atoms were placed in calculated positions and were included in the structure factor calculations, but not refined. The final full-matrix refinement involved 1472 data and 379 parameters. The refinement converged with residuals R and R_w of 0.051 and 0.066, respectively, and a quality-of-fit indicator of 1.457. The final difference-Fourier map showed a highest peak of 0.49 e Å^{-3}.

RESULTS

Synthesis

Several years ago we reported that the reaction of anhydrous $FeCl_3$ with 1 equivalent of tris(2,4,6-trimethoxyphenyl)phosphine in benzene yields a pale yellow compound, formulated as $Fe^{III}Cl_3(\eta^3\text{-TMPP})$ on the basis of elemental analyses. Although no X-ray study of the compound was available at the time, its structure was proposed to be octahedral from the number of observed ν(Fe—Cl) modes in the IR spectrum.[10] Although we realized that hard first-row transition metals are not particularly compatible with a soft donor atom such as phosphorus,[19] we argued that this particular phosphine would be rendered more compatible with a hard Lewis acid such as $FeCl_3$ by the presence of the oxygen donors, which we expected to participate

in the bonding to the iron centre. Precedence for the assignment of a tridentate mode for the phosphine (i.e. η^3-TMPP) existed in the form of the structurally characterized species $Mo(CO)_3(\eta^3$-TMPP)[9c] and $[Rh(\eta^3\text{-TMPP})_2][BF_4]_x$ ($x = 2, 3$),[9a,b] wherein the ligand is coordinated to the metal centre through the phosphorus atom and two oxygen atoms from the pendent methoxy groups on the phenyl rings. At the time, this picture was the most reasonable structure that fit the available data for the iron compound.

Since the earlier report Mössbauer and EPR studies were performed, the results of which did not support this formulation.[20] Most importantly, we finally managed to crystallize compound **1** from acetone and the single-crystal X-ray study revealed that the complex is actually $[H\text{-TMPP}]_2[Fe_2Cl_6]$, in which Fe^{III} has been reduced to Fe^{II} and the tertiary phosphine has become protonated. The empirical formula for this salt differs by only one H^+ from the earlier molecule, thus it was not possible to distinguish between the two designations on the basis of elemental composition. Three ν(Fe—Cl) bands are observed in the IR spectrum of $[H\text{-TMPP}]_2[Fe_2Cl_6]$, one of which is split which accounts for the four bands expected for a D_{2h} symmetry.

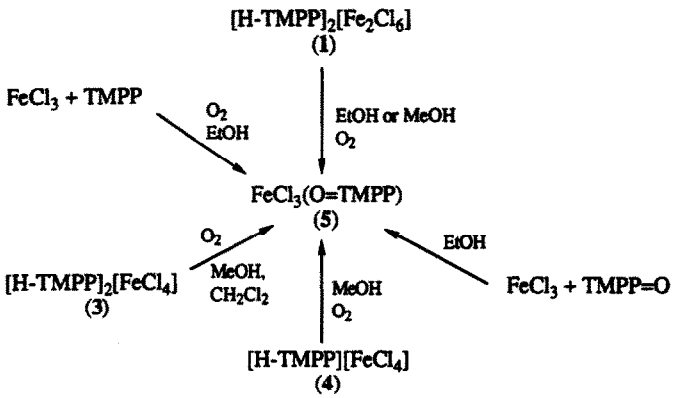
Facile reduction of $FeCl_3$ is not uncommon, as in the synthesis of $Fe^{II}Cl_2(HPyS)_2$ from the reaction of $FeCl_3$ and HPyS (HPyS = 2-mercaptopyridine),[21] furthermore, TMPP is known to be quite sensitive to quaternarization in the presence of metal halides. In fact, similar chemistry was seen to occur earlier, with alcoholic cobalt(II) solutions giving rise to $[H\text{-TMPP}]_2[Co^{II}Cl_4]$ and TMPP reactions of $CoCl_2$ in benzene yielding $[CH_3\text{-TMPP}]_2[Co_2Cl_6]$.[22a,b] To our knowledge, however, there is no documentation in the literature of the $[Fe_2Cl_6]^{2-}$ moiety,[22d] although the cobalt(II) and copper(II) analogues are known and $[Fe_2I_6]^{2-}$ has been documented.[22b,c] It is interesting to note that when the reaction is carried out in acetonitrile small amounts of **1** are isolated, but if other solvents such as chloroform or ethanol are used $[H\text{-TMPP}][FeCl_4]$ is obtained, indicating that no reduction of the metal centre occurs in these solvents.

Upon slow dissolution of $[H\text{-TMPP}]_2[Fe_2Cl_6]$ in ethanol under anaerobic conditions, the phosphonium salt $[H\text{-TMPP}]_2[Fe^{II}Cl_4]$ (**3**) is observed to form. In an effort to study the reactions of this salt as they pertain to the overall reaction to form TMPP=O, the compound was prepared deliberately by the reaction of $[Fe^{II}(NCCH_3)_6][AlCl_4]_2$ with 2 equivalents of TMPP in methanol. Redissolution of **3** in methanol followed by rapid evaporation in air or treatment with a stream of oxygen gas yields the oxidized form of the anion, viz. $[H\text{-TMPP}][Fe^{III}Cl_4]$ (**4**). The conversion of Fe^{II} to Fe^{III} was monitored by IR spectroscopy in the far-IR region, according to the Fe—Cl stretching frequency which occurs at 280 cm^{-1} for $\nu(Fe^{II}$—Cl) and 380 cm^{-1} for $\nu(Fe^{III}$—Cl). Compound **4** was, in turn, independently prepared by the reaction of $[Fe^{II}(NCCH_3)_6][SbCl_6]_2$ with 2 equivalents of TMPP in methanol. Approximately 50% of the original phosphine is consumed to form $[H\text{-TMPP}][SbCl_6]$, as determined by NMR and IR spectroscopies as well as elemental analysis. Antimony(V) is a good oxidizing agent[23] and, therefore, it is not surprising to observe a conversion from Fe^{II} to Fe^{III} in this reaction. In a similar fashion as for **3** protonation of the phosphine occurs with the formation of the very stable $[Fe^{III}Cl_4]^-$ anion, which is quite a common phenomenon.[24,25] The spectroscopic and electrochemical properties of **3** and **4** are in excellent agreement with the reported literature values for various salts of $[Fe^{III}Cl_4]^-$ and $[Fe^{II}Cl_4]^{2-}$.[26]

Lastly, $FeCl_3$(O=TMPP) (**5**) can be obtained quantitatively, *inter alia*, from the reaction of **4** with oxygen in methanol over a period of 1–2 days. The stability of $FeCl_3$(O=TMPP) is evidenced by the extreme facility with which this compound is formed from **1**, **3** or **4**. Scheme 1 summarizes the different synthetic routes to **5** that we have encountered in this work.

Molecular structures

$[H\text{-TMPP}]_2[Fe_2Cl_6]$ (**1**). The X-ray structure unequivocally established the identity of **1** as an $[Fe_2Cl_6]^{2-}$ salt, for which two protonated phosphines serve as counter-ions. An ORTEP representation of $[H\text{-TMPP}]_2[Fe_2Cl_6]$ is shown in Fig. 1, while pertinent bond distances and angles are summarized in Table 2. The $[Fe_2Cl_6]^{2-}$ anion consists of two edge-sharing tetrahedra, with two bridging and two terminal chlorides per metal atom, and an inversion centre situated at the mid-point of the $Fe(1)\cdots Fe(1)'$ axis, as was previously observed in the isomorphous structure of $[CH_3\text{-TMPP}]_2[Co_2Cl_6]$.[22b] The $Fe(1)\cdots Fe(1)'$ separation of 3.350(4) Å, much larger than the sum of the covalent radii, precludes the assignment of a direct metal–metal bond, and is comparable to the distances of 3.32 Å found in $[Fe_2(\mu\text{-OH})(OAc)_2(Me_3TACN)_2](ClO_4)$[27] and 3.35 Å in $[Fe_2(BPMP)_2]$ (BPh_4),[28] but considerably longer than the corresponding distances reported for the two closely related structures $[Fe_2(SEt)_6]^{2-}$ and $[Fe_2Cl_4(OPh)_2]^{2-}$, these being 2.978(1) and 3.177(3) Å, respectively.[29] The average Fe^{II}—Cl bond distance for the terminal chloride



Scheme 1. Synthetic routes to $FeCl_3$(O=TMPP) (**5**).

[2.231(2) Å] is somewhat intermediate between the reported range for Fe^{II}—Cl (2.25–2.35 Å)[30] and Fe^{III}—Cl (2.15–2.20 Å).[31] As expected, the average distance for the bridging chlorides is longer [2.397(2) Å] than the terminal chlorides. The Cl—Fe—Cl bond angles fall in the range expected for tetrahedral geometry [108.02(9)–120.5(1)°], but the Cl(2)—Fe(1)—Cl(2)′ and the Fe(1)—Cl(2)—Fe(1)′ angles of 91.36(8) and 88.64(8)°, respectively, are considerably distorted from ideal geometry. A three-dimensional packing diagram of $[H\text{-}TMPP]_2[Fe_2Cl_6]$ is presented in Fig. 2 and clearly shows the segregated packing of cations and anions when viewed down the *b*-axis. The structural features of the protonated phosphine are similar to those of previously reported examples. Related polynuclear iron chloride salts are $[Fe_2Cl_9]^{3-}$, $[Fe_2Cl_6(\mu\text{-}O)]^{2-}$, $[Fe_2Cl_6(\mu\text{-}OR)_2]^{2-}$ and $Fe_4Cl_8(THF)_6$.[26,32]

$[H\text{-}TMPP]_2[Fe^{II}Cl_4]$ (**3**). The structure of this salt is reported only for the purpose of positively identifying the species and is without remarkable

features. The metal atom lies on a two-fold axis and is ligated by four chlorine atoms to form the $[FeCl_4]^{2-}$ anion. Two protonated phosphines, [H-TMPP]$^+$, serve as the cations in this structure. The structural features of the cation are similar to those of the free phosphine and other phosphonium salts.[24] It is noteworthy that the $[FeCl_4]^{2-}$ anion has been observed to crystallize only with very large cations, such as quaternary ammonium or phosphonium ions.[26]

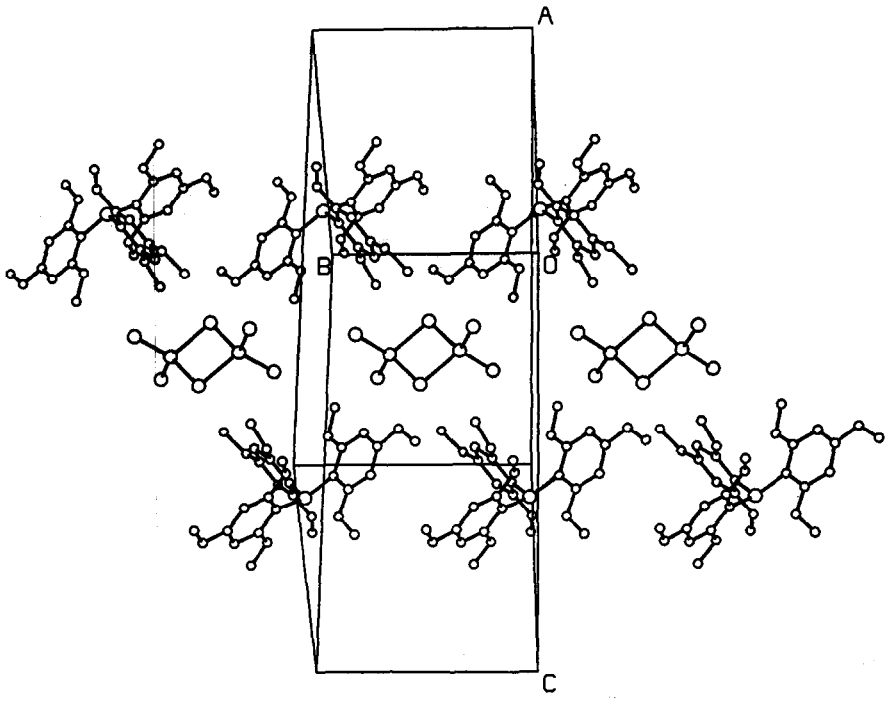

Fig. 2. Packing diagram of $[H\text{-}TMPP]_2[Fe_2Cl_6]$ (**1**) viewed down the *b*-axis.

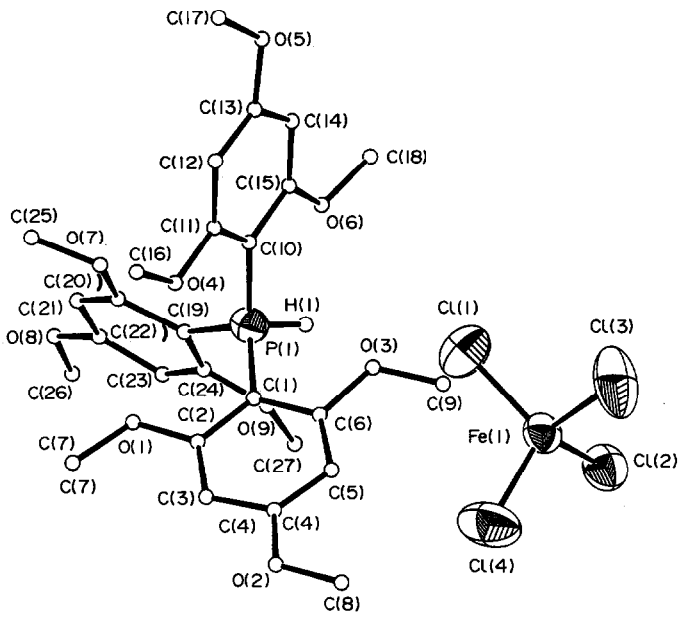

Fig. 3. ORTEP diagram for [H-TMPP][$FeCl_4$] (**4**). Phenyl group atoms are represented as small circles for clarity, whereas all other atoms are represented as their 50% probability thermal ellipsoids.

[H-TMPP][$Fe^{III}Cl_4$] (**4**). An ORTEP diagram of the two constituent ions in the asymmetric unit of **3** is shown in Fig. 3. Pertinent bond angles and distances are summarized in Table 2. The metal atom is surrounded by four chlorine atoms to form the well-known [$FeCl_4$]$^-$ anion. The Fe—Cl bond distances are in the range 2.161(4)–2.182(5) Å, which is in excellent agreement with the literature.[31,32] The Cl—Fe—Cl bond angles fall between 106.2(2) and 112.6(2)°, which deviates very little from ideal tetrahedral geometry. The phosphonium cation is similar to that found in other structures.[24]

DISCUSSION

Chemistry of $FeCl_3$ *with* TMPP.

The compound [H-TMPP]$_2$[Fe_2Cl_6] is the first reported example of a compound containing the unit [Fe_2Cl_6]$^{2-}$.[22d,33] Whereas the molecule Fe_2Cl_6 is known to be the stable form of $FeCl_3$ in the gas phase, and similar di-Fe^{III} compounds of the type [Fe_2Cl_9]$^{3-}$ or [$Fe_2Cl_6(\mu$-O)]$^{2-}$, [$Fe_2Cl_6(\mu$-OEt)$_2$]$^{2-}$ and $Fe_4Cl_8(THF)_6$ have been structurally characterized,[26,32] no such analogous di-ferrous chloride complexes have been reported. There are more examples of the [M_2X_6]$^{2-}$ unit with the heavier halogens, for example the anions [Fe_2I_6]$^{2-}$ and [Mn_2X_6]$^{2-}$ (X = Br, I) are known.[34] The isolation of [H-TMPP]$_2$[Fe_2Cl_6] from the 1 : 1 stoichiometric reaction of $FeCl_3$ with TMPP casts some doubt on the proposed formulations of stable *yellow* compounds, such as $FeCl_3(PCy_3)$[35] and $FeCl_3(PPh_3)$.[36] Actually, neutral four-coordinate adducts of $FeCl_3$ are quite rare in general; among them only $FeCl_3(S_4N_4)$[37] and $FeCl_3(THF)$[31d] have been structurally characterized. Most neutral "FeX_3L" species have actually proven to be of the type [$FeCl_4$][$FeCl_2L_2$]. A more common stoichiometry for this type of complex is $FeCl_3(PR_3)_2$ (R = Me, Ph),[38] as in the recently reported $FeBr_3(PMePh_2)_2$.[39] Further supporting our contention that the mono-adducts $FeCl_3(PR_3)$ are not likely to be particularly stable is the work of Poli *et al.*, who report the synthesis and isolation of $FeCl_3(PCy_3)$ and crystallization of $FeCl_3(PBu^t_3)$,[32a] but only the detection of $FeCl_3(PMe_3)$ and $FeCl_3(PPh_3)$ as elusive dark *red* species by low-temperature EPR experiments.[38] In the same work, the eventual formation of unidentified iron(II) species from the $FeCl_3/PPh_3$ reaction in toluene was noted, along with the concomitant production of chloro-substituted toluene as the oxidized by-product. In the present case, work-up of the benzene reaction filtrate produced a red–brown solid, whose mass-spectrometry, ^{1}H and ^{31}P NMR and IR data collectively point to the salt [Cl-TMPP][$FeCl_4$]. A rational synthesis of this species involved the use of [Cl-TMPP]$^+Cl^-$, prepared by reacting TMPP with chlorine gas in benzene, which was then reacted with $FeCl_3$ to give a compound whose properties are in agreement with those of the by-product. Consequently, we propose the following mechanism for the formation of **1**:

$$3FeCl_3 + 3TMPP \xrightarrow{2HCl} [H\text{-}TMPP]_2[Fe_2Cl_6] + [Cl\text{-}TMPP][FeCl_4]$$

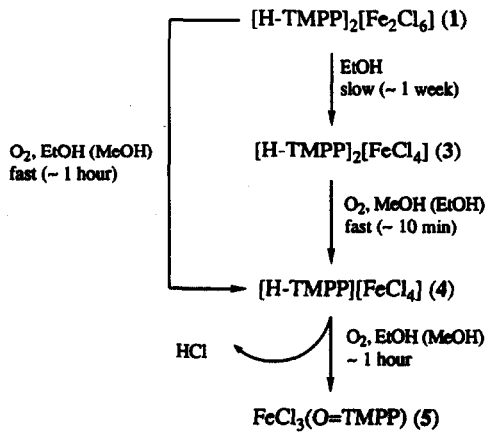
Fe^{III} P^{III} Fe^{II}, P^{III} Fe^{III}, P^{V}

As the equation clearly indicates, the source of the protons and the extra chloride ions is postulated to be adventitious HCl, which is a ubiquitous contaminant in metal halides. In order to test the general nature of this reaction, and to isolate the iron(II) species previously mentioned by Poli *et al.*, we set out to re-investigate the chemistry of PPh_3 and $FeCl_3$. The reactions of $FeCl_3$ with 1 equivalent of PR_3(R = Cy, Ph) in benzene produce dark red solutions instantaneously, from which red solids can be isolated. The spectroscopic properties of the products are in agreement with those of the reported mononuclear $FeCl_3(PR_3)$ complexes.[32a,38] However, if the reaction is allowed to progress further, the solution turns yellow. The yellow solids isolated from these solutions exhibit far-IR spectra that are very similar to that of **1** [ν(Fe—Cl) = 380(s), 360(m), 315(m), 300(w) cm^{-1} for R = Cy and 380(s), 330(m), 320(m), 300(w) cm^{-1} for R = Ph]. In addition, the highest peaks in the FAB mass spectrum of these complexes are $m/z = 281$ and $m/z = 263$, corresponding to $[H\text{-}PCy_3]^+$ and $[H\text{-}PPh_3]^+$, respectively, and in the case of the tricyclohexylphosphonium compound, the characteristic P—H stretch at 2400 cm^{-1} was observed in the IR spectrum.

The final oxidized product $FeCl_3$(O=TMPP) (**5**) is a very stable compound and quite unique in itself, since it is atypical for a mono-phosphine oxide adduct of $FeCl_3$ to be more stable than the corresponding bis-adduct. To date, only two analogous compounds have been reported to our knowledge; these are $FeCl_3(O{=}PPh_3)$ by Lindner *et al.* in 1967[40] and $FeCl_3(O{=}PCy_3)$ by Issleib *et al.* in 1954,[35] but neither have been structurally characterized. A much more commonly encountered stoichiometry is FeX_3L_2 or FeL_4^{n+}, where L is a phosphine oxide ligand.[41]

Oxidation chemistry of $[Fe_2Cl_6]^{2-}$

We now discuss the reaction pathway that leads to the formation of complex **5**, summarized in Scheme 2. In order to understand the present results, one must first take note of previous work in this area, particularly with respect to the solvent dependence of this chemistry. Let us first consider the reactions of $FeCl_3$ and PR_3 ligands that have been performed in CH_3CN. In this solvent the oxidation of triphenylphosphine to triphenylphosphine oxide by iron(III) complexes in the presence of molecular oxygen was reported by Ondrejovic and co-workers to yield complexes of empirical formula $FeX_3(O{=}PPh_3)_2$ (X = Cl, NCS, Br),[8a] among which "$FeCl_3(O{=}PPh_3)_2$" was structurally characterized and proven to actually be $[FeCl_4][FeCl_2(O{=}PPh_3)_4]$.[42] When identical chemistry was performed in a protic solvent such as methanol, the compound $[CH_3\text{-}PPh_3][FeCl_4]$ was isolated.[31a] Ondrejovic proposes that protic solvents induce the quaternarization of the phosphine, by methylation in this case, which is then oxidized to $Ph_3P{=}O$.[31a] In the 1970s Sutin *et al.* also investigated the oxidation of PPh_3 in the presence of iron(III) and iron(IV) dithiolate complexes of the type $[Fe(mnt)_2]^-$, where $[mnt]^{2-}$ is maleonitriledithiolate.[43] In this work, only the stable bis-phosphine oxide complex $[Fe(mnt)_2(O{=}PPh_3)_2]^-$ was observed, however, with no evidence of intermediate species such as the previously postulated dioxygen adducts.[5,44] Recently, McAuliffe and coworkers reported that oxygen decomposes $FeBr_3(PMePh_2)_2$ to an orange product that exhibits a strong P=O stretching frequency in the IR spectrum, but no molecular oxygen species were detected or isolated. These results, like ours, disfavour the hypothesis that stable dioxygen complexes are important intermediates in the oxidation of PR_3 to $O{=}PR_3$.[39]



Scheme 2. Major products isolated from the reaction of $[H\text{-}TMPP]_2[Fe_2Cl_6]$ with O_2 in alcohols.

As in the aforementioned chemistry, the reaction between $FeCl_3$/TMPP and oxygen is also solvent-dependent. The reaction of $[H\text{-}TMPP]_2[Fe_2Cl_6]$ (**1**) with oxygen in CH_3CN leads to the rapid formation of $FeCl_3$(O=TMPP) (**5**) with no detection of phosphonium intermediates. The reaction pathway is dramatically different in alcohol solvents in which protic phosphonium salts of tetrachloroferrate(II)

and (III) are formed. A suspension of $[H\text{-}TMPP]_2[Fe_2Cl_6]$ (**1**) reacts with molecular oxygen in ethanol or methanol to form [H-TMPP][$FeCl_4$] (**4**), as determined by IR spectroscopy and confirmed by X-ray crystallography. One must bear in mind, however, that this reaction is not quantitative, since some $[H\text{-}TMPP]_2[Fe_2Cl_6]$ must be sacrificed to yield extra chloride ions for $[FeCl_4]^-$. The salt [H-TMPP][$FeCl_4$] further reacts with oxygen in alcohols to form $FeCl_3$(O=TMPP) (**5**). Scheme 2 also points out that if $[H\text{-}TMPP]_2[Fe_2Cl_6]$ is suspended in ethanol (but without the addition of oxygen) for a period of time in excess of 1 week, the compound eventually dissolves, with reaction, to yield the iron(II) species $[H\text{-}TMPP]_2[FeCl_4]$ (**3**). Compound **3** can, in turn, be reacted with oxygen in methanol or ethanol to form compound **4**, and subsequently, compound **5**. We have independently prepared complexes **3** and **4** and demonstrated that they indeed react as proposed in the scheme.

Two years ago we reported the formation of a green intermediate during the reaction of $[H\text{-}TMPP]_2[Fe_2Cl_6]$ (**1**) with molecular oxygen in CH_2Cl_2.[10] At that time we hypothesized that the species was a dioxygen adduct, but subsequent IR studies of the behaviour of **1** in CH_2Cl_2 revealed only the appearance of $[FeCl_4]^-$ and $[ClCH_2\text{-}TMPP]^+$ ions over time. Facile decomposition of free TMPP in CH_2Cl_2 to give $[ClCH_2\text{-}TMPP]Cl$ is well-known.[12a] Thus, we conclude that the TMPP ligand in $[H\text{-}TMPP]_2[Fe_2Cl_6]$ is reacting with CH_2Cl_2. We note that photochemically induced reactions of similar $FeCl_3/PR_3$ compounds in chlorinated solvents are documented as in the formation of $[FeCl_4][FeCl_2(dmpe)_2]$ from the photochemical oxidation of $FeCl_2(dmpe)_2$ in chlorinated solvents such as CH_2Cl_2, $CHCl_3$ or CCl_4.[45]

Catalytic formation of TMPP=O

Finally, in view of Ondrejovic's work and the demonstrated catalytic nature of the $FeCl_3/PR_3/O_2$ systems, it was relevant to ask whether $FeCl_3$ (O=TMPP) (**5**) could act as a catalyst for the oxidation of TMPP to TMPP=O. Indeed, when $FeCl_3$(O=TMPP) is reacted with an excess of the phosphine (from 10- to 100-fold) in acetone, acetonitrile or ethanol in the presence of oxygen, TMPP=O is formed in high yield with essentially complete recovery of $FeCl_3$(O=TMPP).

CONCLUSIONS

In summary, the chemistry of 1:1 mixtures of $FeCl_3$/TMPP with oxygen appears to be dominated by the formation of $[Fe^{II}Cl_4]^{2-}$, $[Fe^{III}Cl_4]^-$ and $[H\text{-}TMPP]^+$ species. In accord with this observation is the demonstrated role of quaternary onium tetrachloroferrate salts in numerous catalysed reactions such as hydrosilylation,[46] polymerization of ε-caprolactone[47] and polymerization of α-oxides.[48] The present work has also established the existence of a hitherto unknown di-ferrous chloride, namely $[Fe_2Cl_6]^{2-}$.[22d] Collectively, the results of this investigation support the conclusion that the stable and unprecedented mono-phosphine oxide adduct $FeCl_3$(O=TMPP) does not form via the formation of metal–oxygen adducts, but via quaternarization of the phosphine. Finally, we did not observe the formation of bis-phosphine oxide complexes, a result that is in contrast to previously reported work.

SYNTHESIS, CHARACTERIZATION AND REACTIVITY OF RUTHENIUM TETRAPHENYLPORPHYRIN COMPLEXES CONTAINING THE THIOCARBONYL LIGANDS

KRYSTYNA RACHLEWICZ, MARIA GRZESZCZUK and LECHOSŁAW LATOS-GRAŻYŃSKI*

Institute of Chemistry, University of Wrocław, 14 F. Joliot-Curie St, Wrocław 50 383, Poland

(*Received* 10 *August* 1992; *accepted* 12 *October* 1992

Abstract—A new synthetic route to generate tetraphenylporphyrin ruthenium(II) thiocarbonyl complexes of the general formula Ru^{II}(Por)(CS)L has been developed and the chemistry and electrochemistry of these complexes have been studied. $[Ru^{IV}(Por)(EtO)]_2O$ has been applied as a convenient starting material for ligand incorporation using carbon disulphide, thiophosgene and benzyl trichloromethyl thioether as thiocarbonyl precursors in the reducing medium. The Ru—CS bond is very strong and resistant to nucleophilic replacement. Thiocarbonyl and carbonyl ruthenium(II) porphyrin complexes reveal essential similarity as far as chemical and electrochemical properties are concerned, with the exception of the internal reactivity of the thiocarbonyl ligand. One-electron oxidation of [Ru(Por)(CS)(EtOH)] led to the formation of the respective π-cation radical characterized by visible, IR and ^{1}H NMR spectroscopy.

The novel features of ruthenium porphyrins, including their versatile redox behaviour,[1] the formation of the reactive Ru=O,[2] Ru—H_2,[3] Ru—N_2,[4] Ru—C,[5] Ru=C[6] and Ru—Ru[7] bonds and their relation to naturally occurring metalloporphyrins, have attracted considerable attention. In particular, high-valent oxoruthenium porphyrin complexes have been established to be competent catalysts for the aerobic expoxidation of olefins.[2a] Unusual rupture and repair of the porphyrin inner core in ruthenium complexes of a N,N′-bridged porphyrin have been also described.[8]

Ruthenium organometallic chemistry seems to be of special interest in light of the implication of metal–carbon species in reactions of cytochrome P-450 with polyhalogenated compounds, widely used as solvents, insecticides and fungicides.[9] Various organic compounds containing the SCl_3 moiety display fungicidal activity.[10a] The SCl_3 group can be metabolized into thiophosgene and carbon disulphide, which may account for the activity.[10] Iron porphyrin thiocarbonyl complexes can also be formed in the course of biochemical processes.[11b]

Chemical and electrochemical properties of iron porphyrin thiocarbonyl complexes have been studied in detail.[11,12] The studies on ruthenium porphyrin thiocarbonyl complexes have been limited to the particular case of [Ru(OP)(CS)(py)] species.[13] The similarity of carbon monosulphide (CS) to carbon monoxide has stimulated much interest in the synthesis and reactivity of thiocarbonyl complexes in general.[14] The crucial step of the synthetic route to the thiocarbonyl system elaborated by James and Dolphin[13] involves an oxidative decarbonylation of [Ru(OEP)(CO)(py)] by bromine in the presence of excess cyanide to produce $[Ru^{III}(OEP)(CN)_2]^-$, which is treated with pyridine to give [Ru^{III}(OEP)(CN)(py)]. Reduction of this species in the presence of thiophosgene gives the thiocarbonyl complex $[Ru^{II}(OEP)(CS)(py)]$. Because of the reaction procedure the pyridine ligand occupies one of the axial positions.

In order to probe the influence of axial ligation we have developed a new synthetic route to general ruthenium thiocarbonyl complexes of the general formula $[Ru^{II}(TPP)(CS)L]$, where L is a ligand of choice. $[Ru^{IV}(TPP)(EtO)]_2O$ has been used as a convenient, already decarbonylated starting material to form $[Ru^{II}(TPP)(CS)(EtOH)]$. Here we report on

* Author to whom correspondence should be addressed.

the synthesis and properties of ruthenium porphyrin thiocarbonyl complexes. In particular, the paper extends our previous effort[15] to describe the spectroscopy and reactivity of ruthenium porphyrin cation radicals.

EXPERIMENTAL

Materials

Carbon disulphide (Fluka) and thiophosgene (Aldrich) were used as received. Tetraphenylporphyrin ($TPPH_2$), tetra-*p*-tolylporphyrin (TT PH_2),[16] pyrrole-d_8-tetra-*p*-tolylporphyrin (d_8-TT PH_2)[17] and [Ru^{II}(TPP)(CO)(EtOH)][18] were prepared by reported procedures.

Synthesis of the compounds

μ-oxo-bis(ethoxo)(tetraphenylporphyrinato)ruthenium(IV), [Ru^{IV}(TPP)(OEt)]$_2$O·2H_2O. Ru^{II}(TPP)(CO)(EtOH) (100 mg, 0.12 mmol) was dissolved in dichloromethane–ethanol (100 cm^3, 1:1 vv), vigorously stirred and 30% H_2O_2 (3 cm^3) was added gradually. When the starting material was totally consumed in the reaction, as determined by the disappearance of the ν(C=O) band at the IR spectrum, a 5% solution of sodium cyanate in water was added to precipitate the product. The solid material was collected, dried and purified by column chromatography (neutral alumina, dichloromethane as an eluant). The electronic and ^{1}H NMR spectra of [Ru^{IV}(TPP)(OEt)]$_2$O·2H_2O corresponded to those previously reported.[2,19] This product was used to synthesize the thiocarbonyl complexes. Benzyl trichloromethyl thioether was prepared from benzyl thiocyanates by Makosza's procedure.[20]

Synthesis of ruthenium(II) *porphyrin thiocarbonyl complexes*

Method A. Direct reduction of thiophosgene: [Ru^{IV}(TPP)(OEt)]$_2$O·2H_2O (100 mg, 0.06 mmol) was dissolved in dry dichloromethane (60 cm^3; purged with nitrogen for 10 min) and zinc amalgam (100 mg) was added as a powder at 298 K. The solution was energetically stirred for 30 min and a degassed solution of thiophosgene (0.12 mol) in dichloromethane was added. The reaction mixture was stirred for 4 h. The solution was then filtered to remove an excess of zinc amalgam, ethyl alcohol (10 cm^3) was added and the solution was evaporated to dryness on the rotary evaporator. The progress of the reaction was monitored by product electronic (530 nm) and IR [ν(C=S) band at 1295 cm^{-1}] spectra. The sample was subjected to column chromatography (neutral alumina). The red band of the thiocarbonyl complex was eluted with a mixture of dichloromethane and carbon tetrachloride (2:98 vv). The solution of [Ru^{II}(TPP)(CS)(EtOH)] was evaporated to dryness and crystallized from the dichloromethane/ethanol/n-hexane mixture (1:1:10). Yield 90%.

Method B. Sulphur abstraction from carbon disulphide: [Ru^{IV}(TPP)(OEt)]$_2$O·2H_2O (100 mg, 0.06 mmol) was dissolved in dried THF (60 cm^3; purged with nitrogen for 15 min). The sodium amalgam was added. The solution was stirred for 30 min and degassed carbon disulphide (0.2 cm^3) was added. The reaction mixture was stirred under nitrogen for 48 h and the solution was then filtered through Celite. The volume was reduced on a rotary evaporator and the sample was subjected to chromatography on a 5 × 30 cm column of neutral alumina. The thiocarbonyl complex was then eluted with toluene. The chromatography was repeated to remove the side-products of the reactions. Yield 30%.

Method C. Reductive dehalogenation of benzyl trichloromethyl thioether: [Ru^{IV}(TPP)(OEt)]$_2$O·2H_2O (100 mg, 0.06 mmol) in toluene (100 cm^3) under nitrogen was reduced for 30 min. Benzyl trichloromethyl thioether in toluene (0.02 mg, 0.12 mmol) was then added. The progress of the reaction was followed by absorption spectroscopy. The Q band at 520 nm and the Soret band at 430 nm were tentatively assigned to the intermediate, i.e. the ruthenium porphyrin carbene compound [Ru(TPP)(C(Cl)(SR))]. A solution of $FeCl_2$ in ethanol (2 cm^3) was added to catalyse the decomposition of the intermediate carbene complex and to form the ruthenium tetraphenylporphyrin thiocarbonyl complex (530 and 410 nm). Usually this step required 48 h. The reaction mixture was filtered through Celite and dried on a rotary evaporator. Further purification as in Method A. Yield 60%. Each method gave identical products after recrystallization. Found: C, 69.8; H, 3.5; N, 6.8. Calc. for [Ru^{II}(TPP)(CS)(EtOH)] ($C_{47}H_{30}N_4OSRu$): C, 70.6; H, 3.7; N, 7.0%. Found: C, 70.7; H, 4.7; N, 6.3. Calc. for [Ru^{II}(TTP)(CS)(EtOH)]($C_{51}H_{42}N_4OSRu$): C, 71.2; H, 4.9; N, 6.51.

Hexa-coordinate ruthenium(II) *tetraphenylporphyrin thiocarbonyl complexes*, [Ru^{II}(TPP)(CS)L]

A general procedure was used to generate [Ru^{II}(TPP)(CS)L] in solutions.

[Ru^{II}(TPP)(CS)(EtOH)] was dissolved in dichloromethane and the ligand of interest was added (1:1.5 molar ratio). The coordination of axial ligands was followed by electronic and IR spectra.

Pyridine, chloropyridine, bromopyridine, 4,3-phenylpropylpyridine, 4-methylpyridine, imidazole, 1-methyimidazole, 1-benzylimidazole, triphenylphosphine, toluidine and acetonitrile was used as received. The cyanide source was bis(triphenylphosphine)imminium cyanide. The samples for IR spectra were prepared as a film on KBr or CaF_2 plates.

Chemical oxidation of $[Ru^{II}(TTP)(CS)(EtOH)]$ *and* $[Ru^{II}(TTP)(CO)(EtOH)]$

Method A. $[Ru^{II}(TTP)(CS)(EtOH)]$ (20 mg, 0.023 mmol) was dissolved in dichloromethane (10 cm^3) and 1.5 equivalents of phenoxanthiinylium hexachloroantimonate were added. The solution was stirred for 30 min until the red solution turned green. π-Cation radical formation was followed by electronic and ^1H NMR spectra.[21] The π-cation radical was precipitated with n-hexane. Phenoxanthiinylium hexachloroantimonate was obtained from phenoxanthiin and antimony pentachloride as previously described.[21g]

Method B. $[Ru^{II}(TTP)(CS)(EtOH)]$ in dichloromethane was stirred with a four-fold excess of $Fe(ClO_4)_3 \cdot 9H_2O$ until the colour changed from red to green. π-Cation radical formation was followed by electronic and NMR spectra.[21] After filtration, the π-cation radical $[Ru^{II}(TTP^{+\bullet})(CS)(ClO_4)]$ was used for further investigation. The same procedures were used to generate the π-cation radical of carbonyl tetratolylporphyrin ruthenium(II).

Method C. The oxidation of $[Ru^{II}(TTP)(EtOH)]$ to the π-cation radical was also performed by NMR titration with Br_2 in $CDCl_3$. The titration was stopped before bromination of the pyrrole or the phenyl positions could be observed in the respective ^1H NMR spectrum.[15]

Instrumentation

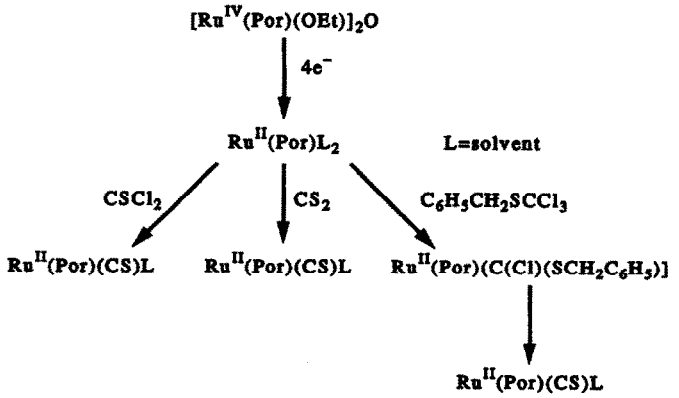
^1H NMR spectra were recorded on Bruker AMX 300 MHz and Tesla 100 MHz spectrometers. UV–vis spectra in dichloromethane, chloroform and toluene solutions were recorded on a Specord M40 and IR on a Specord M42 spectrophotometer, respectively. The samples for IR measurements were prepared as films on CaF_2 or KBr plates, or as chloroform solution KBr cells. Cyclic voltammetry measurements were carried out as previously described.[22]

RESULTS AND DISCUSSION

Properties and characterization of ruthenium porphyrinthiocarbonyl complexes

Three synthetic routes have been established for the incorporation of the thiocarbonyl ligand into metalloporphyrins: (1) reduction of thiophosgene,[23] (2) sulphur abstraction from carbon disulphide,[24] and (3) conversion of CCl(SR) carbene complexes to thiocarbonyl[16] complexes.

Each method requires metalloporphyrin reduction as a prerequisite condition of the reaction. The dinuclear μ-oxo ruthenium(IV) porphyrin complex $[Ru^{IV}(Por)(OEt)]_2O$ can be reduced to monomeric ruthenium(II) porphyrins.[19] This seems to be the most convenient route to generate ruthenium (II) porphyrins bearing a wide variety of axial ligands. We have established that it is convenient to form thiocarbonyl complexes as well. The three routes listed above have been explored (Scheme 1). The best results have been obtained in the case of thiophosgene reduction. The catalytic decomposition of the ruthenium carbene intermediate is



Scheme 1.

Table 1. ν(C=S) frequency for [Ru(TTP)(CS)L] complexes

Ligand L	ν(C=S) (cm^{-1})

Triphenylphosphine	1286
2-Chloropyridine	1288
5,5-Diacyanoimidazole	1290

slow and not quantitative. The [Ru^{II}(Por)(C(Cl)($SCH_2C_6H_5$))] intermediate can be postulated based upon the characteristic changes observed in the electronic spectra and by analogy with the formation of the corresponding iron analogues.[11b]

As determined by electronic and IR spectrocopy the product, [Ru^{II}(Por)(CS)(EtOH)], can be converted into derivatives containing strongly coordinating ligands, e.g. pyridine, imidazole, cyanide or phosphine. The electronic spectra of [Ru^{II}(TTP)(CS)(EtOH)] and [Ru^{II}(TTP)(CO)(EtOH)] are almost superimposable with a small bathochromic shift determined for the Soret band, in spite of the greater π-acceptor capacity of the thiocarbonyl ligand. It has been shown that the C=S stretching frequency for [Ru^{II}(TTP)(CS)L] is dependent upon the identity of the axial ligand L (Table 1). Generally, the frequency shifts to a lower wave number as the basicity of the ligand increases. However, all frequencies observed are higher than those of the CS molecule in the carbon disulphide matrix,[25] which occurs at 1274 cm^{-1}. One has to consider the fact that the CS stretching mode is considerably mixed with the M—C(S) mode.[26] The observed dependency is not interpreted in a straightforward manner in terms of π-back bonding.[27] Iron porphyrin thiocarbonyl complexes demonstrate a similar relationship.[11,12]

Reactivity of [Ru^{II}(TPP)(CS)L]

The [Ru^{II}(TPP)(CS)L] complexes are stable in the presence of dioxygen and all operations including chromatography could be carried out in the presence of air. The Ru—CS bond has not dissociated in diluted solution or during heating at 180°C. The thiocarbonyl complex is resistant to the nucleophilic replacement by pyridine or benzonitrile, even after refluxing for 60 h. However, triphenylphosphine refluxed in toluene (10-fold excess) reacted with [Ru^{II}(TPP)(CS)(EtOH)] to form the previously characterized [Ru^{II}(TPP)(PPh_3)$_2$], as confirmed by IR and ^{1}H NMR spectra.[28] [Ru^{II}(TTP)(CS)] reacted with butylamine to form the isocyanide complex. The formation of the isocyanide ligand was easy followed by IR spectra, where the disappearance of the ν(C—S) band at 1295 cm^{-1} was accompanied by an increase in intensity of ν(C—N) at 2050 cm^{-1}, which is typical for the isocyanide group. The formation of isocyanide-metal complexes from thiocarbonyl complexes has been established for the thiocarbonyl iron porphyrins[11b] and for other non-porphyrin transition metal complexes.[29]

One-electron chemical oxidation of [Ru^{II}(TTP)(CS)(EtOH)] with phenoxanthiinylium hexachloroantimonate leads to the formation of the respective cation radical [Ru^{II}($TTP^{+\cdot}$)(CS)]($SbCl_6$). Other oxidants such as $Fe(ClO_4)_3$ or Br_2 have also been applied. The coordination of thiocarbonyl in the cation radical form has been confirmed by the characteristic frequency of the CS stretching, ν(CS) = 1295.4 cm^{-1}, which is very close to that established for [Ru^{II}(TTP)(CS)(EtOH)]. This fact clearly confirms that the oxidation state of ruthenium is not changed in the course of the oxidation. The electronic and NMR spectra of the cation radical are presented in Figs 1 and 2, respectively.

The assignment of porphyrin resonances in the ^{1}H NMR spectrum has been carried out based upon selective methyl and deuterium substitution. The respective data are collected in Table 2. The pattern of tetraphenylporphyrin resonances can be used as a well-accepted criterion of paramagnetic metalloporphyrin electronic structure. In particular, clear distinction between metal- and ligand-centred oxidation can be made.[15,21] The pattern of phenyl resonances (*p*-methyl, *meta* proton downfield, *ortho*, *para* protons upfield) is expected for the cation radical in the electronic ground state dominated by the A_{2u} molecular orbital of the porphyrin ligand. In this structure the spin density is located to a large extent at the *meso* carbons, which is reflected in the considerable π-spin density delocalization on phenyl rings.[21f].

The [Ru^{II}($TTP^{+\cdot}$)(CS)]($SbCl_6$) cation radical undergoes a one-electron reduction in the presence of excess zinc powder, pyridine or triphenylphosphine. The [Ru^{II}(TTP)(CS)(EtOH)] complex is

recovered in the case of the zinc reduction, as confirmed by ^{1}H NMR and electronic spectra. Two other reagents generate the starting compound and β-substituted derivatives analogously as other diamagnetic[30a] and paramagnetic cation radicals.[30b]

The reaction of [Ru^{II}(TTP$^{+\cdot}$)(CS)]($SbCl_6$) with pyridine and triphenylphosphine has been followed by ^{1}H NMR. The conversion of the paramagnetic π-cation radical into the diamagnetic compound has been determined. The complex resonance pattern at the pyrrole region has been established as the β-substitution markedly lowers the symmetry of the ruthenium tetraphenylporphyrin. A number of organic cation radicals react with pyridine forming pyridinium analogues.[31] ^{1}H NMR investigation on the reaction of [(TTP$^{+\cdot}$)Fe^{III}](ClO_4)$_2$ with pyridine showed also the nucleophilic attack and β-pyridinium derivative formation.[32]

Electrochemistry of [Ru^{II}(TTP)(CS)(EtOH)]

The electrochemistry of [Ru^{II}(TTP)(CS)(EtOH)] was studied with a platinum electrode in dichloroethane (DCE) or dimethylformamide (DMF). The cyclic voltammetric response of [Ru^{II}(TTP)(CS(DMF)] is shown in Fig. 3 (for the sake of simplicity the coordinated DMF molecule is not presented directly in Scheme 2). Two separate quasi-reversible electron-transfer processes were observed during the reduction of [Ru^{II}(TTP)(CS)(DMF)] in DMF solution. The proposed mechanism of reduction is described in Scheme 2.

The reaction mechanism involves the conversion of the initial ruthenium thiocarbonyl complex into a thioformyl [Ru^{II}(TTP)(CHS)]$^-$ complex by a $2e^- + H^+$ process as the second reduction step presents characteristic features of a follow-up chemical reaction. The protonation of [Ru(TTP)(CS)]$^{2-}$ is apparent in Fig. 3. The stability of the dianion decreased as the water concentration has been gradually increased. The reversibility is smaller even for sweep rates five times higher in the second case than in the first one. The irreversible oxidation of [Ru(TTP)(CHS)] occurs at a potential more positive than that of the first reduction potential of the parent thiocarbonyl complex according to eq. (1):

$$[Ru(TTP)(CS)] \underset{-e^-,\,-H^+,\,-e^-}{\overset{e^-,e^-,H^+}{\rightleftharpoons}} [Ru(TTP)(CHS)]^- . \quad (1)$$

The thioformyl species undergoes one electron reduction at potentials of its generation. Its re-

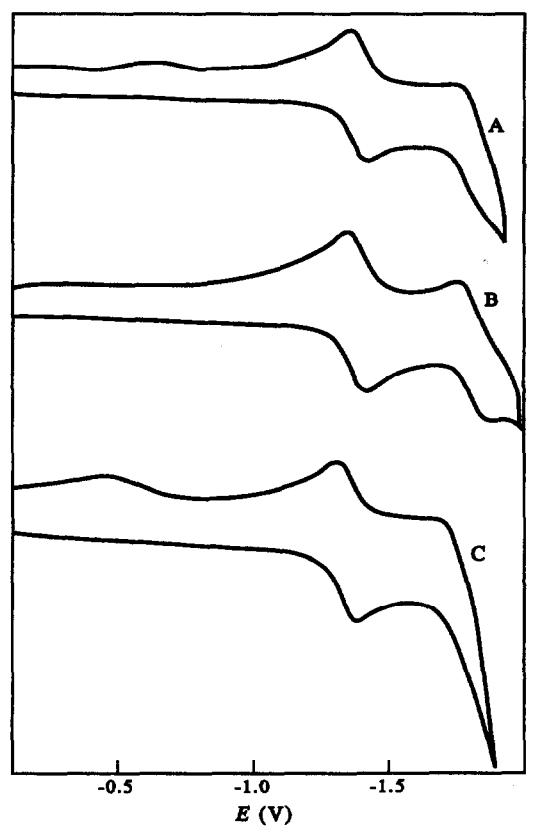

Fig. 3. Cyclic voltammograms of [Ru(TTP)(CS)] in 0.1 M TBAP–DMF; (A) V = 100 (DMF), (B) V = 500 (DMF), and (C) V = 500 mV s^{-1} (DMF with water added).

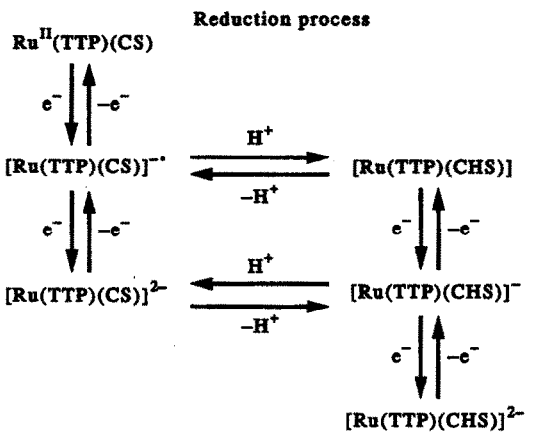

Scheme 2.

oxidation wave ($[Ru(TTP)(CHS)]^{-\cdot}/[Ru(TTP)(CHS)]^{2-}$) is visible at potentials positive to the second electron transfer of the thiocarbonyl species. Potentials for the reduction process of [Ru^{II}(TTP)(CS)(DMF)] and the related complexes are displayed in Table 3. The dependence of the first reduction potential on the nature of the axial ligand (C_2H_5OH, CN^-, pyridine) is presented in Table 4.

Cyclic voltammetry reveals that the reduction mechanism of [Ru(TTP)(CS)] is similar to that of [Fe(TPP)(CS)].[12] It was established that divalent metals present a linear relationship between either the first oxidation or first reduction potential at the ring and the electronegativity of the central metal ion.[33] Since electronegativities of iron and ruthenium are quite close the half-wave potentials for the ring centred process should be the same within 0.1 V for the ruthenium and iron species, as observed. The porphyrin macrocycle of [Ru(TPP)(CS)] is the centre of the first electron addition.

Table 3. Characteristic potentials for the reduction processes in DMF (0.1 TBAP)[a]

[e] The cathodic peak potential at $V = 100$ mV s^{-1}.

Table 4. Characteristic potentials of [Ru^{II}(TTP)(CS)L][a]

	Reduction step I	Oxidation step I	Oxidation step II
[Ru^{II}(TTP)(CS)(EtOH)]	−1.40	0.85	1.22
[Ru^{II}(TTP)(CS)(CN)]$^-$	−1.43	0.66	1.12[b]
			1.36[b]
[Ru^{II}(TTP)(CS)(Im)]	−1.47	0.78	1.23[b]
[Ru^{II}(TTP)(CS)(py)]	−1.52	0.82	1.32[b]
[Ru^{II}(TTP)(CO)(EtOH)]	−1.44	0.78	1.19

[a] $E_{1/2}$, in D.C.E. (0.1 M TBAP) vs S.C.E.
[b] Irreversible, $E_{p/2}$ given.

[Ru^{II}(TTP)(CS)] is oxidized in two well separated quasi-reversible electron-transfer steps (Table 4). The product of the first oxidation, [Ru^{II}($TTP^{+\cdot}$)(CS)], is stable and has been characterized chemically and spectroscopically in this paper as the π-cation radical. The mechanism of the oxidation is proposed in the following equations:

$$[Ru^{II}(TTP)(CS)L] \underset{e^-}{\rightleftharpoons} [Ru^{II}(TTP^{+\cdot})(CS)L] \quad (2)$$

$$[Ru^{II}(TTP^{+\cdot})(CS)L] \underset{-e^-}{\overset{e^-}{\rightleftharpoons}}$$

$$[Ru^{III}(TTP^{+\cdot})(CS)L]\{Ru^{II}(TTP^{2+})(CS)L\}. \quad (3)$$

The second oxidation step is chemically irreversible in the presence of CN^-, pyridine or imidazole. The follow-up chemical reaction results in the appearance of an irreversible reduction wave at potentials (0.5–0 V) depending on the ligand. The formation of β-substituted forms or isoporphyrins can be considered to account for this phenomenon[30,34] as typical for porphyrin dications.

As established by Fuhrop *et al.*[35] the difference in $E_{1/2}$ potentials between the first ring oxidation and the first ring reduction is always equal to 2.25 ∓ 0.15 V. The corresponding values for [Ru^{II}(TTP)(CS)L] systems presented in Table 4 are entirely consistent with the proposed electronic structure of the one-electron reduction and one-electron oxidation products, i.e. [Ru^{II}($TTP^{+\cdot}$)(CS)L] and [Ru^{II}($TTP^{-\cdot}$)(CS)L], respectively.

CONCLUSION

Thiocarbonyl and carbonyl ruthenium(II) porphyrin complexes reveal essential similarity as far as chemical and electrochemical properties are concerned, with the exception of internal reactivity of

the thiocarbonyl ligand. We intend to probe the influence of the thiocarbonyl ligand on the formation of highly-oxidized ruthenium porphyrins.

(*Received* 5 *April* 1991; *accepted* 12 *October* 1992)

Abstract—The molecular structure of the copper complex with title ligand has been determined by X-ray diffraction. It shows a slightly distorted tetragonal bipyramidal coordination of the copper ion. The macrocycle is coordinated in a planar configuration and two carboxylic groups are in a *trans* arrangement. The unusually high activation energy (*ca* 200 kJ mol^{-1}) was measured for second-order complex formation reactions in aqueous solution.

In recent years the metal ion reactions with macrocyclic ligands containing additional ligating groups have been widely studied.[1–5] The kinetics of metal complex formation with such ligands have also been measured.[3–5] Nevertheless, the rate constants and activation energies are known only for a few complexes. The goal of this work is the study of the structure and kinetics of the synthesis of a copper complex with disubstituted tetraazacycloalkane-5,5,7,12,12,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane-1,8-diacetatic acid (H_2TEDA). Metal complexes of TEDA with Cu^{2+}, Co^{2+} and Ni^{2+} solvated with HBr molecules were synthesized and the structure of the NiTEDA · HBr · H_2O complex has been investigated by X-ray diffractometry.[6]

EXPERIMENTAL

IR spectra were recorded as Nujol mulls or potassium bromide pellets on a UR-10 spectrometer. Magnetic susceptibility was measured by Gouy's method.

The free ligand was prepared by standard procedures[6] as H_2TEDA · 2HBr · $8H_2O$ and characterized using IR and NMR spectra.

* Author to whom correspondence should be addressed.

Preparation of CuTEDA · $4H_2O$

Copper acetate, $Cu(CH_3COO)_2 \cdot 2H_2O$ (0.185 g, 1.3 mmol) and H_2TEDA · 2HBr · $8H_2O$ (0.708 g, 1.0 mmol) were dissolved in methanol. The pH was increased to 3 by the addition of sodium acetate and the solution was heated for 2–3 h under reflux. The dark blue solution was acidified by the dropwise addition of trichloroacetic acid until the light blue precipitate appeared. The resulting blue crystals were crystallized from methanol (IR: 1705 cm^{-1}). After heating under reflux for 5 h in ethanol–water solution, for the decomposition of the trichloroacetic acid, blue crystals of tetrahydrate were obtained (IR: 1608 cm^{-1}). Found: Cu, 12.8; N, 11.1. Calc. for $CuC_{20}H_{38}N_4O_4 \cdot 4H_2O$: Cu, 12.8; N, 11.2%. μ_{eff} = 1.93 B.M.

Preparation of CuTEDA · $2CCl_3COOH$

This compound was prepared using the procedure above, but in aqueous solution. A light blue precipitate formed after trichloroacetic acid addition and was filtered and dried in air. Found: Cu, 8.4; N, 7.4; Cl, 28.1. Calc. for $CuC_{20}H_{38}N_4O_4 \cdot 2CCl_3COOH$: Cu, 8.1; N, 7.1; Cl, 27.1%.

Kinetic measurements

The kinetics of H_2TEDA reaction with Cu^{2+} ions were measured spectrophotometrically ($\lambda = 602$ nm) in a thermostated cell. Sodium acetate buffer solutions (pH = 5–6.8) were used. The reactions were made with equal initial concentrations of copper ions and ligand (C = 3–6 mM).

Crystallography

A blue crystal suitable for X-ray study was grown from acetonitrile–ethanol. The complex crystallizes in the triclinic space group with the unit cell parameters $a = 9.009(2)$, $b = 8.936(2)$, $c = 9.846(2)$ Å, $\alpha = 101.86(2)$, $\beta = 101.86(2)$, $\gamma = 116.63(2)°$; $V = 629.1(4)$ Å^3; $\rho_{calc} = 1.40$ g cm^{-3}; structural class $\bar{P}_1$, $z = 1$ ($\bar{1}$; 1; 1).

Experimenal data were collected on a four-circle Nicolet P3 diffractometer using Mo-K_α radiation with a β-filter and θ–2θ scan technique. 1628 independent reflections were collected to $2\theta_{max} = 45°$. No absorption correction was made ($\mu = 9.6$ cm^{-1}). The structure was solved by the heavy-atom method with further refinement using full-matrix least-squares using 1511 reflections with $I \geqslant 3\sigma(I)$. All non-hydrogen atom positions were refined in the anisotropic approximation. Hydrogen atoms of the macrocycle and water molecules were localized from the difference-Fourier map and refined in the isotropic approximation. The final values of R factors are $R = 0.029$, $R_w = 0.033$ ($S = 1.97$).

RESULTS AND DISCUSSION

Formation of CuTEDA *complexes*

The experimental data confirm the second-order rate equation:

$$\frac{d[CuTEDA]}{dt} = k_{eff}[Cu][TEDA];$$

where k_{eff} is an effective rate constant (Fig. 1). The k_{eff} value slightly increases with pH over the range 5–7. The observed k_{eff} values (*ca* 3×10^{-3} M^{-1} s^{-1}, 25°C, pH 6) are much lower than those for *meso*-Me_6[14]aneN$_4$ under similar conditions (2×10^{-2} M^{-1} s^{-1}, 25°C, pH 4.7[7]). This observation contradicts the previously observed phenomenon[1,5] that the rate constants of functionalized macrocycles are 10^3–10^4 times larger than those of the unsubstituted macrocycles.

The temperature dependence of the effective rate constants is shown in Fig. 2 as an Arrhenius plot. The activation energy calculated from the least-squares fit to the data is 200 kJ mol^{-1}. This value

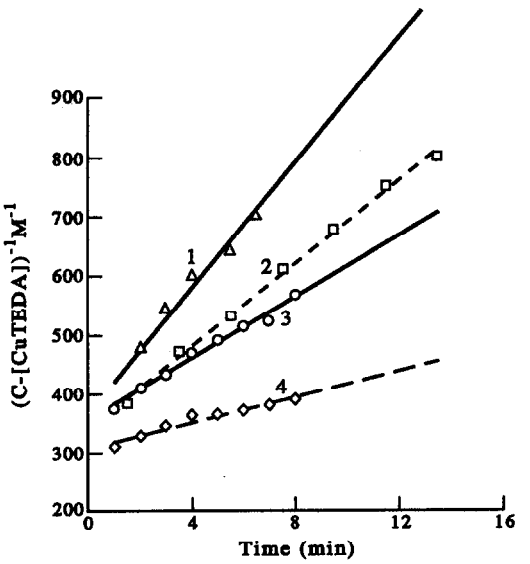

Fig. 1. The typical kinetic data. $C_{Cu} = C_{TEDA} = 3.35$ mM. (1) pH = 6.3, T = 48°C; (2) pH = 6.4, T = 40°C; (3) pH = 5.4, T = 40°C; and (4) pH = 5.1, T = 38°C.

is twice as high as that for the *meso*-Me_6[14]aneN$_4$ complex (93 kJ mol^{-1}).[8] An unusually high activation energy may be explained by the superposition of several effects: (1) The multistage nature of the complex formation reaction. The total activation energy is the sum of several contributions. (2) The ligand deprotonation reaction. An active form of the ligand is probably partly deprotonated (ΔH value for the deprotonation reaction is *ca* 30–50 kJ mol^{-1}). (3) The significant steric effects: the distortion of ligand geometry increases the energy of the transition state for the ligands with a large number of substituents.

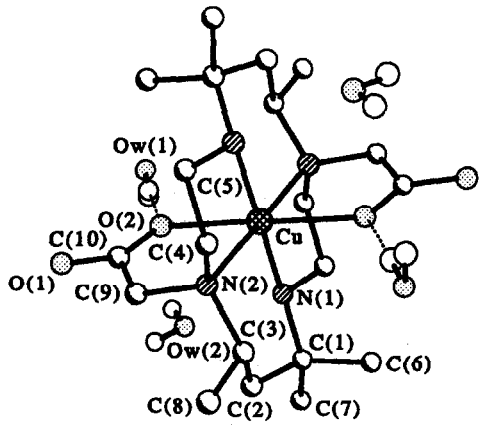

Fig. 3. The molecular structure of the copper complex with 5,5,7,12,12,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane-1,8-diacetic acid.

Description of the structure

In the crystal cell the molecular complex CuTEDA is connected by a system of hydrogen bonds via water molecules. The hydrogen bond parameters are collected in Table 1.

The copper ion has a slightly distorted tetragonal bipyramidal coordination (Fig. 3). Unlike the nickel complex with the same ligand, the carboxylic groups are coordinated in a *trans* arrangement. This fact contradicts the suggestion[6] that the *cis* structure is attributed to the stereochemical pattern of the ligand. The Cu—N distances (Table 2) are typical for copper complexes with secondary (2.00–2.05) and tertiary (2.05–2.10) amines.[9] The Cu—N (secondary) distance is shorter than that of Cu—N (tertiary), unlike the NiTEDA complex. The Jahn–

C(3)—C(2)—C(1)—N(1)	−65.2	C(2)—C(1)—N(1)—C(5a)	179.2
C(1)—N(1)—C(5a)—C(4a)	173.0		

Teller effect probably causes the increase in the Cu—O distance to 2.31 Å; Ni—O distances in the same complex are 2.19 and 2.07 Å. The *d*(Cu—O) value is consistent with those observed for copper alkylcarboxylates with "long" Cu—O bonds (2.30–2.40 Å).[9] The average interatomic distances and angles in the macrocycle ring are also similar to those for copper macrocyclic complexes:[10–12] *d*(C—C) = 1.526, *d*(C—N) = 1.513 Å.

The torsion angles of the C—C bonds correspond to a *gauche* conformation and C—N bonds to *trans* (Table 3).

The five-membered ring formed by the ethylenediamine residue and the copper atom has an envelope conformation with a C_4 atom in the flap and with a flap angle equal to 51° ($\Delta_{max} = \pm 0.05$ Å, $\Delta C_4 = -0.66$ Å). The six-membered ring $CuN_1N_2C_1C_2C_3$ has a chair conformation. The maximum deviation of atoms from the plane $N_1N_2C_1C_3$ is 0.05 Å, while the deviations of Cu and C_2 atoms are −0.83 and 0.69 Å, respectively. The C—O bond lengths in the acetate fragment are the same within experimental error. The aminoacetate five-membered chelate ring is nearly planar, the maximum deviation of atoms from the plane is less than 0.04 Å.

IR spectra

The *v*(C=O) band position is similar to those in copper glycinate (1593 and 1607 cm^{-1}).[13] The hydrogen bonding N—H···O causes a slight shift of the N—H band (3190 cm^{-1}) from the usual position for *meso*-Me_6[14]aneN_4 complexes (*ca* 3200 cm^{-1}).

REACTIONS OF A DINUCLEAR COPPER(I) COMPLEX DERIVED FROM A HEXADENTATE LIGAND HAVING N_2As_4 DONOR SITES. CRYSTAL STRUCTURE OF $[Cu_2(BDAE)(PPh_3)_2Cl_2]$

PARIMAL PAUL* and K. VENKATASUBRAMANIAN

Discipline of Coordination Chemistry and Homogeneous Catalysis,
Central Salt and Marine Chemicals Research Institute, Bhavnagar 364 002, India

(*Received* 11 *June* 1992; *accepted* 1 *October* 1992)

Abstract—The reactions of a tri-coordinate dinuclear copper(I) complex of the composition $[Cu_2(BDAE)](ClO_4)_2$ (where BDAE = α,α′-bis{bis[2-(diphenylarsino)ethyl]amino}ethane) with some mono- and bidentate species having different donor atoms were studied. The reaction of the complex with anionic species such as LiCl, NaN_3, NH_4NCS and $NaBH_4$ resulted in the formation of tetra-coordinate complexes of compositions $[Cu_2(BDAE)Cl_2]$, $[Cu_2(BDAE)(N_3)](ClO_4)$, $[Cu_2(BDAE)(NCS)](ClO_4)$ and $[Cu_2(BDAE)(BH_4)_2]$, respectively. The reactions of CS_2 and thiourea gave the products $[Cu_2(BDAE)(CS_2)_2](ClO_4)_2$ and $[Cu_2(BDAE)(H_2NCSNH_2)_2](ClO_2)_2$, respectively. The reactions of monodentate neutral molecules B (B = PPh_3, $AsPh_3$ and imidazole) yielded complexes of the composition $[Cu_2(BDAE)(B)_2](ClO_4)_2$. The reaction with pyridine in a 1:4 molar ratio gave a complex of composition $[Cu_2(BDAE)(C_5H_5N)_4](ClO_4)_2$. The bidentate ligands 1,2-bis(diphenylphosphino)methane/ethane (dppm/dppe) react with the complex to yield complexes of the composition $[Cu_2(BDAE)(dppm)](ClO_4)_2$/$[Cu_2(BDAE)(dppe)](ClO_4)_2$, in which dppm/dppe acts as a bridge between two metal centres. The reaction with bipyridine gave a tetra-coordinate complex of the composition $[Cu_2(BDAE)(C_{10}H_8N_2)_2](ClO_4)_2$. The molecular structure of the complex $[Cu_2(BDAE)(PPh_3)_2Cl_2]$ was established by single-crystal X-ray diffraction. The cyclic voltammetric behaviour of all of these complexes was investigated.

The chemistry of copper(I) with tertiary phosphine and arsine donors has gained much importance because of their interesting structural properties,[1–5] photochemistry,[6–8] reactions with small molecules[9–11] and catalytic activity.[12–14] In most of these studies tertiary phosphine is mainly used as the ligand, whereas the chemistry of copper(I) with tertiary arsine is less extensive. Although some examples are available in the literature,[1,15–18] they are mainly concerned with monodentate tertiary arsine and their chemistry is restricted to structural investigation.

We were interested to explore copper(I) chemistry with binucleating ligands having tertiary phosphine and arsine donors and some of these studies have been reported recently.[19–22] These ligands have some advantages: due to the π-acidic nature of the donors stable complexes with copper(I) can be formed, and because of the chelating effect they prevent the dissociation of the M—P/As bonds thus limiting the number of available coordination sites for reactivity studies.

We report herein the reactions of a tri-coordinate dinuclear copper(I) complex of the ligand α,α′-bis{bis[2-(diphenylarsino)ethyl]amino}ethane (BDAE) with a variety of mono- and bidentate nucleophiles, which resulted in the formation of tetra-coordinate mixed-ligand dinuclear complexes. The crystal structure of the complex $[Cu_2(BDAE)(PPh_3)_2Cl_2]$ is reported. The cyclic voltammetric behaviour of these complexes is also reported.

EXPERIMENTAL

Physical measurements

Elemental analyses were performed on a Carlo-Erba Elemental Analyser Model 1106. A digisun

* Author to whom correspondence should be addressed.

electronics digital conductivity meter model D1-909 was used for the conductivity measurements. IR spectra were recorded on a Carl Zeiss Specord M80 spectrometer as KBr pellets. ^1H and $^{31}P\{^1H\}$ NMR spectra were recorded on a Jeol FX-100 FT NMR spectrometer. For ^1H tetramethylsilane was used as an external reference and the instrument operated at 99.55 MHz. The $^{31}P\{^1H\}$ NMR spectra were recorded at 40.27 MHz using 10 mm tubes with a capillary of deuterium oxide for the internal lock and 85% H_3PO_4 as an external standard. A Princeton Applied Research (PAR) electrochemical instrument equipped with a precision *X–Y* recorder and a PAR-175 universal programmer coupled with the PAR-174A analyser was used along with a glassy carbon working electrode for recording the cyclic voltammograms. All potentials were measured against a standard calomel electrode (S.C.E.) at 25 ± 1°C using tetrabutylammoniumperchlorate as the supporting electrolyte with scan rates from 50 to 200 mV s^{-1}.

Materials

The ligand BDAE was synthesized by a procedure described previously.[19] The compounds $[Cu(PPh_3)_3Cl]$[23] and $[Cu(NCCH_3)_4](ClO_4)$[24] were prepared by published procedures. Lithium chloride, sodium azide, ammonium thiocyanate, sodium tetrahydroborate, triphenylphosphine, triphenylarsine, 1,2-bis(diphenylphosphino)ethane/methane, bipyridine and imidazole were obtained from Aldrich Chemical Co. Pyridine and carbon disulphide were purchased from S.D. Fine Chemicals and thiourea from Sarabhai M. Chemicals (India).

All organic solvents used were of reagent grade and were purified and dried before use. All the preparations were carried out under dry nitrogen or argon.

Synthesis of the complexes

$[Cu_2(BDAE)(PPh_3)_2Cl_2]$ (**1**). To a boiling solution of $[Cu(PPh_3)_3Cl]$ (0.5 mmol) in dry acetone (40 cm^3) BDAE (0.25 mmol) dissolved in benzene (10 cm^3) was added dropwise and refluxing continued for 4 h. The white compound which separated during reflux was isolated by filtration, washed with benzene and acetone and recrystallized from a chloroform–ethanol (2 : 1) mixture; yield 75%.

$[Cu_2(BDAE)](ClO_4)_2$ (**2**). To a refluxing solution of $[Cu(NCCH_3)_4]$ (0.5 mmol) in acetone (25 cm^3) BDAE (0.25 mmol) dissolved in benzene (5 cm^3) was added dropwise and refluxing continued for 3 h. The volume of the solution thus obtained was reduced to *ca* 10 cm^3 by rotary evaporation and after adding diethyl ether (15 cm^3) the white compound which precipitated was isolated by filtration and recrystallized from acetonitrile–ethanol (2 : 1); yield 70%.

$[Cu_2(BDAE)Cl_2]$ (**3**), $[Cu_2(BDAE)(N_3)](ClO_4)$ (**4**), $[Cu_2(BDAE)(NCS)](ClO_4)$ (**5**) *and* $[Cu_2(BDAE)(BH_4)_2]$ (**6**). To a solution of complex **2** (0.62 g, 0.5 mmol) in acetone (30 cm^3) was added solid LiCl (0.085 g, 2 mmol)/NaN_3 (0.033 g, 0.5 mmol)/NH_4NCS (0.038 g, 0.5 mmol), or an ethanolic solution (5 cm^3) of $NaBH_4$ (0.15 g, 4 mmol), and the reaction mixture was refluxed for 4 h, except in the case of $NaBH_4$ where it was stirred for 2 h at room temperature. For complexes **3** and **6** during the reactions the white compounds were precipitated and were isolated by filtration, washed with water and acetone. For complexes **4** and **5** the volume of the solution was reduced to 10 cm^3 and white compounds separated after the addition of diethyl ether. Compounds **3** and **6** were recrystallized from DMF–ethanol (1 : 5) and **4** and **5** from a dichloromethane–ethanol (3 : 1) mixture; yield 70–80%.

$[Cu_2(BDAE)(CS_2)_2](ClO_4)_2$ (**7**). To a solution of complex **2** (0.62 g, 0.5 mmol) in acetone (30 cm^3) was added carbon disulphide (5 cm^3) and the mixture stirred for 10 h at room temperature. The solution was then concentrated to 0.5 cm^3 and diethyl ether was added. The light yellow solid which separated was isolated by filtration and recrystallized from dichloromethane–n-hexane; yield 90%.

$[Cu_2(BDAE)(H_2NCSNH_2)_2](ClO_4)_2$ (**8**). An aqueous solution (2 cm^3) of thiourea (0.11 g, 1.5 mmol) was added dropwise to a solution of complex **2** (0.62 g, 0.5 mmol) in acetone (30 cm^3) with stirring at room temperature. After complete addition stirring was continued for 2 h, during which time a white compound was deposited. The compound was isolated by filtration, washed with water and acetone and finally recrystallized from hot DMF; yield 75%.

$[Cu_2(BDAE)(PPh_3)_2](ClO_4)_2$ (**9**), $[Cu_2(BDAE)(AsPh_3)_2](ClO_4)_2$ (**10**), $[Cu_2(BDAE)(dppm)](ClO_4)_2$ (**11**) *and* $[Cu_2(BDAE)(dppe)](ClO_4)_2$ (**12**). To a solution of complex **2** (0.31 g, 0.25 mmol) in acetone (20 cm^3) was slowly added $PPh_3/AsPh_3$ (0.5 mmol) or dppm/dppe (0.25 mmol) dissolved in dichloromethane (10 cm^3) through a pressure equalizer and the solution was refluxed for 4 h. The solvent of the reaction mixture was removed by rotary evaporation and the white solid washed with diethyl ether, dissolved in dichloromethane (5 cm^3), filtered and to the filtrate n-hexane was added slowly with stirring. The white compound which deposited was

isolated by filtration and dried *in vacuo*; yield 75–80%.

$[Cu_2(BDAE)(C_3H_4N_2)_2](ClO_4)_2$ (**13**) *and* $[Cu_2(BDAE)(C_{10}H_8N_2)_2](ClO_4)_2$ (**14**). Complexes **13** and **14** were prepared following the same procedures as described for complexes **9–12**. In this case complexes were recrystallized from dichloromethane–ethanol; yield 80–85%.

$[Cu_2(BDAE)(C_5H_5N)_4](ClO_4)_2$ (**15**). An alcoholic solution (10 cm^3) of pyridine (0.24 g, 3 mmol, obtained by dilution of a concentrate solution) was added slowly through a pressure equalizer to a solution of **2** (0.62 g, 0.5 mmol) in acetone (25 cm^3) and the solution was refluxed for 2 h. The assembly was then connected to a vacuum line and the solution was concentrated to *ca* 5 cm^3, allowed to reach room temperature and then deaerated diethyl ether (25 cm^3) was added slowly with stirring. The pale yellow compound which separated was isolated by filtration, washed with diethyl ether and dried *in vacuo*; yield 70%.

X-ray structure determination of $[Cu_2(BDAE)(PPh_3)_2Cl_2]$ (**1**)

Preliminary data on space group and unit cell dimensions, as well as intensity data, were collected using a crystal of suitable size on an Enraf–Nonius CAD4/PDP-11/73 system with graphite monochromatized Cu-K_α radiation in the 2θ range 4–130°. Accurate cell dimensions were obtained by a least-squares fit of 25 arbitrarily chosen higher-order reflections ($30° \leqslant 2\theta \leqslant 32°$). Data were collected using the $\omega/2\theta$ scan method and monitoring two sets of three control reflections to correct for decay and alignment during the entire data collection process. The intensities were corrected for Lorentz and polarization factors. An empirical absorption correction method[25] was employed using three reflections near $\chi = 90°$. The structure was solved by the heavy atom method. An origin-removed sharpened three-dimensional Patterson map gave the positions of both the arsenic atoms in the molecule. The cycle of isotropic least-squares refinement, followed by a difference map gave the locations of the copper, chlorine and phosphorus atoms. All the non-hydrogen atoms could be located from a difference map, phased on the other heavy-atoms. Hydrogen atoms were either generated by stereochemical constraints or from a difference map, after the complete convergence of anisotropic refinement of non-hydrogen atoms. Anisotropic refinement of the non-hydrogen atoms was by full-matrix refinement using ORFLS with two blocks with hydrogen fixed. A unit-weighting scheme with a Dunitz–Seiler factor[26] resulted in convergence. At the end of the refinement the shifts-to-error ratio was less than 0.10. The scattering factors for copper, arsenic, chlorine, phosphorus, oxygen, carbon and nitrogen were taken from the International Tables of Crystallography[27] while those of hydrogen were from Stewart *et al.*[28] All the computations were carried out using the SDP package of the Enraf–Nonius system with a PDP-11/73.[29] The final R and Rw values were calculated using the equations $R = \Sigma||F_o|-|F_c||/|F_o|$ and $Rw = [\Sigma w(|F_o|-|F_c|)^2/wF_o^2]^{1/2}$. For relevant crystallographic data and structure solution parameters, see later.

RESULTS AND DISCUSSION

Complex **1**, $[Cu_2(BDAE)(PPh_3)_2Cl_2]$, obtained by the reaction of $Cu(PPh_3)_3Cl$ with BDAE was characterized by single-crystal X-ray diffraction (discussed later). The reaction of $[Cu(NCCH_3)_4](ClO_4)$ with BDAE resulted in the formation of a dinuclear complex of composition $[Cu_2(BDAE)](ClO_4)_2$ (**2**), in which copper(I) is tricoordinate with ligation to two arsine and a nitrogen of the ligand (Scheme 1).[19] The reactions of this coordinately unsaturated complex (**2**) were studied with various nucleophiles in different molar ratios.

The reactions of complex **2** with LiCl and $NaBH_4$ in a 1:2 molar ratio resulted in the complete displacement of perchlorate with the formation of tetra-coordinate dinuclear complexes of compositions $[Cu_2(BDAE)Cl_2]$ (**3**) and $[Cu_2(BDAE)(BH_4)_2]$ (**6**), respectively. The reactions of **2** with NaN_3 and NH_4NCS in a 1:1 molar ratio gave the products $[Cu_2(BDAE)(X)](ClO_4)$ [X = N_3 (**4**) and NCS (**5**)]. The reaction of **2** with excess CS_2 yielded a complex of composition $[Cu_2(BDAE)(CS_2)_2](ClO_4)_2$ (**7**). The reaction of thiourea, PPh_3, $AsPh_3$, imidazole and bipyridine (B) with **2** in the 1:2 molar ratio yielded complexes of the composition $[Cu_2(BDAE)(B)](ClO_4)_2$ (**8–10**, **13** and **14**). The reactions with the bidentate ligands dppm and dppe in a 1:2 molar ratio resulted in the partial displacement of the ligand DBAE, but with a 1:1 molar ratio yielded complexes of composition $[Cu_2(BDAE)(Z)](ClO_4)_2$ [where Z = dppm (**11**) and dppe (**12**)]. This difference can be attributed to the steric effect; with a 1:2 molar ratio two PPh_2 groups of dppm/dppe have to coordinate to a single copper(I) atom and such a situation creates severe steric overcrowding with either phenyl rings of the two AsP_2 and two PPh_2 groups around the metal ion. Therefore, Cu—As bond dissociation takes place as the Cu—P bond is stronger than the Cu—As bond. In the case of a 1:1 molar ratio dppm/dppe can act as a bridge between two

copper(I) centres, as found in many other cases.[30,31] Here, only one PPh_2 of dppm/dppe coordinates to copper(I), which decreases steric overcrowding and stable complexes are formed. In the case of pyridine with a 1 : 2 molar ratio a pure compound could not be isolated, but with a 1 : 4 molar ratio the complex $[Cu_2(BDAE)(C_5H_5N)_4](ClO_4)_2$ was obtained. All these reactions are summarized in Scheme 1. The compositions of all the complexes were confirmed by elemental analyses (Table 1). They are dia-

[a] Complexes **2**, **4**, **5** and **7–15** exhibit a broad band centring at 1100 cm^{-1} and a sharp band at 620 cm^{-1} due to ν_3 and ν_4 frequencies of ClO_4^-.

[b] KBr pellets.

magnetic and show no *d–d* bands in the visible region of their electronic spectra.

Conductivity measurements in DMF show that complexes **2** and **7–15** correspond to 1:2 electrolytes (Table 2), **4** and **5** correspond to 1:1 electrolytes and complexes **1**, **3** and **6** are non-electrolytes. This shows that the perchlorate anion in all of these complexes is not coordinated to the metal ion, but other anionic species (Cl^-, N_3^-, NCS^- and BH_4^-) do coordinate to copper(I).

Some selected IR bands of the complexes are shown in Table 2. The IR spectra of all the complexes containing the perchlorate anion exhibit a broad band centring at 1100 cm^{-1} and a sharp band at 620 cm^{-1} due to ν_3 and ν_4 frequencies, respectively, for the isolated ClO_4^-.[32] Complex **4** exhibits $\nu_{as}(N_3)$ at 2085 cm^{-1}, shifted to a higher frequency by 35 cm^{-1} compared to that of other azido complexes of copper(I) with similar ligands (2050 cm^{-1}).[19] The $\nu_s(N_3)$ band which is expected to appear around 1350 cm^{-1} [33] could not be observed. It has been reported that $\nu_s(N_3)$ in 1,3-bridged azides is either IR inactive or of low intensity.[33] These data, therefore, suggest that the azide in complex **4** is bridged between two copper(I) centres.[34] A similar observation has also been noted in **5** where a ν_{as}(NCS) band appears at 2110 cm^{-1}, a higher frequency shift by 30 cm^{-1} compared to that of monodentate thiocyanato complexes of copper(I) with similar ligands, indicating that thiocyanate has formed a bridge between the two metal centres. The IR spectrum of **6** shows two broad bands at 2370 and 1990 cm^{-1} and a sharp band at 1125 cm^{-1}, which are assigned to ν(B—H_t), ν(B—H_b) and BH_2 deformations, respectively, of bidentate BH_4^- [19,21,35] (H_b = hydrogen bonded to copper and H_t = hydrogen not bonded to copper). The IR spectrum of **7** exhibits two new bands at 1160 and 630 cm^{-1}, which can be assigned to ν(C=S) (out-of-ring) and ν(C—S) (in-ring), respectively, for bidentate CS_2 (bonding through carbon and one of the sulphur atoms as shown in Scheme 1).[36,37] Complex **8** shows new bands at 3405, 3300 and 3200 cm^{-1} due to NH_2 groups of coordinated thiourea. Complex **8** also exhibits a strong band at 1610 cm^{-1} and a medium intensity band at 355 cm^{-1}, which can be assigned to $\delta(NH_2)$ and ν(Cu—S), respectively. Complexes **13** and **14** exhibit a number of new bands in the range 1600–600 cm^{-1} due to the coordination of imidazole, bipyridine and pyridine to the metal ion.

The ^1H and $^{31}P\{^1H\}$ NMR data of the complexes are shown in Table 3. All the ^1H NMR spectra exhibit distinct resonances due to the principal ligand BDAE. The aromatic protons appear in the range 7.17–7.30 ppm. The *x*-, *y*- and *z*-CH_2 (see footnote to Table 3 for labelling) of the ligand BDAE appeared in the ranges 2.09–2.29, 2.62–2.81 and 2.32–2.58 ppm, respectively. The resonances of *x*-CH_2 and *y*-CH_2 were deshielded significantly

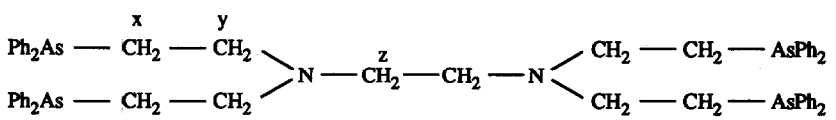
[g] Due to CH_2 of dppe.
[h] Due to NH of imidazole.



(BDAE)

compared with that of the free ligand due to the coordination of $AsPh_2$ to copper(I). In the case of z-CH_2 deshielding is significant in the complexes where the nitrogen atom is coordinated to the metal ion, otherwise it appears very close to the position found for the free ligand. Complexes **6**, **8** and **11**–**13** show an addition signal at 1.15, 2.89, 3.20, 2.45 and 14.30 ppm, respectively. This additional peak can be attributed to protons of BH_4^- (**6**),[38] NH_2 of thiourea (**8**), CH_2 of dppm (**11**), and dppe (**12**) and NH of imidazole (**13**). The resonances due to the CH_2 of dppm/dppe are shifted significantly downfield compared to that of free dppm (2.82 ppm) and dppe (2.11 ppm) and are definitely due to the coordination of PPh_2 to copper(I). However, the resonances of NH_2 and NH of thiourea and imidazole in complexes **8** and **13**, respectively, appear almost at the same positions as found for the free moieties in the same solvent, indicating that the NH_2 of thiourea and NH of imidazole are not involved in coordination. Complexes **14** and **15** show resonances at 8.66 and 8.70 ppm, due in part to the protons of coordinated bipyridine and pyridine molecules, respectively.

Structures

Complex **I** is tetra-coordinate and shows distorted tetrahedral geometry around copper, as established from single-crystal X-ray data. The copper atom in complex **2** is tri-coordinate with a trigonal-planar geometry.[19] In complex **3**, as Cl^- is coordinated to copper(I), a tetrahedral geometry is therefore proposed; however, a significant distortion cannot be ruled out due to different coordinating atoms (As, N, Cl) around copper(I). For complexes **4** and **5** as conductivity measurements show perchlorate is not involved in coordination and IR data indicates that N_3^- (**4**) and NCS^- (**5**) form bridges between two copper(I) centres, there-

fore, a distorted tetrahedral geometry around each copper as shown in Scheme 1 (**4** and **5**) is proposed. In the case of complex **6** it is clear from the IR data that two hydrogen atoms of BH_4^- interact with the copper, therefore, a tetrahedral geometry with an As_2H_2 core is suggested. The geometry of a similar compound with the phosphine analogue of BDAE was established by single-crystal X-ray study and reported recently.[21] For complex **7**, on the basis of IR absorption bands due to CS_2 and comparing with others reported with metal ion d^{10} configuration,[36,37] a triangular bonding of CS_2 with copper(I) (**7**, Scheme 1) is proposed. In the case of **8** from IR and NMR data it is clear that the NH_2 of thiourea is not involved in bonding, consistent with other reports of crystal structures for copper(I);[39,40] therefore, a tetrahedral geometry of the metal ion with ligation to two arsene, nitrogen and sulphur atoms of thiourea is suggested. For complex **9** $^{31}P\{^1H\}$ NMR data exhibit a singlet at 1.45 ppm, indicating that both the PPh_3 molecules are magnetically equivalent and coordinated to copper(I). Therefore, a tetrahedral geometry is expected. However, due to steric overcrowding of a number of phenyl rings around copper, there is the possibility of the elongation of the copper–nitrogen distance. For complex **10**, where $AsPh_3$ is coordinated, a similar geometry to that assigned for **9** is proposed. $^{31}P\{^1H\}$ NMR spectra of complexes **11** and **12** show a singlet at −16.71 (**11**) and −2.78 (**12**), respectively, indicating that in each compound both the phosphorus atoms of dppm/dppe are bound symmetrically to the copper, and presumably the dppm/dppe ligands form bridges between the copper centres, as shown in Scheme 1 (**11** and **12**). In this case, also due to the steric overcrowding of phenyl groups, elongation of the Cu—N distance is possible. For complex **13** IR and ^1H NMR data indicate that the NH of imidazole is not involved in coordination and, therefore, a tetrahedral geometry of copper with the coordination of nitrogen atoms of imidazole is suggested. In the case of **14** two nitrogen atoms of the bipyridine molecule are bonded to copper(I), resulting in a tetrahedral geometry with an As_2N_2 core. For complex **15** a similar geometry is expected with the coordination of two pyridine molecules to each copper(I), as shown in Scheme 1.

Structure of complex **1**

An ORTEP[41] view of complex **1** is shown in Fig. 1. A summary of crystal and refinement data is given in Table 4. Some selected bond lengths and angles are presented in Table 5.

The crystal structure of **1** contains a crystallographic centre of inversion, located at the midpoint of the C(34)—C(34*) bond, thus dividing the molecule into identical halves. The copper atom is ligated to two arsine atoms of the $AsPh_2$ groups,

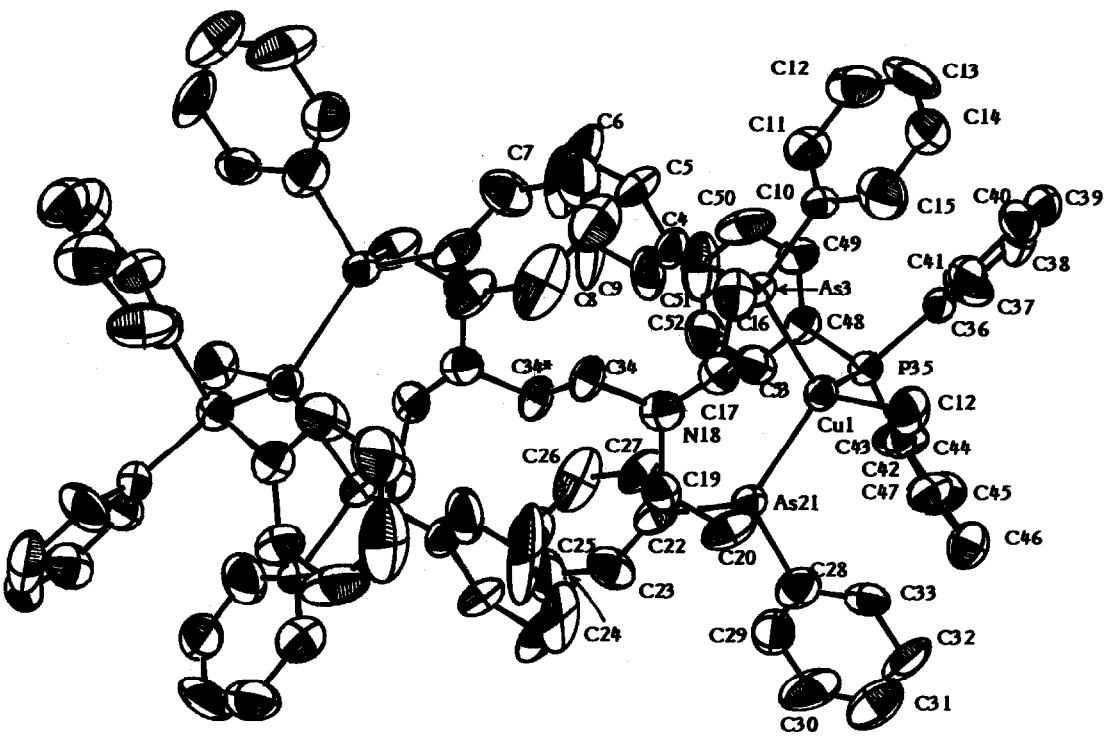


Fig. 1. ORTEP diagram of complex **1**, $[Cu_2(BDAE)(PPh_3)_2Cl_2]$, showing the atom labelling scheme.

phosphorus atom of PPh_3 and a chloride ion and shows a distorted tetrahedral geometry. The angles in the coordination sphere involving the metal are in the range 97.3(2)–120.04(9)° (Table 5), a notable deviation from the idealized value of 109.5°, indicating distortion is significant. This distortion is a consequence of the differing Cu—As, Cu—P and Cu—Cl bond lengths (Table 5) as well as steric overcrowding of seven phenyl rings around each copper atom. The dihedral angles in the coordination sphere are Cu(1)—As(3)—As(21)/Cu(1)—P(35)—Cl(2), 89.75(9); Cu(1)—As(21)—P(35)/Cu(1)—As(3)—Cl(2), 84.46(8); and Cu(1)—As(3)—P(35)/Cu(1)—As(21)—Cl(2), 85.02(9)°. The copper atom lies 0.810(1) Å above the As(3)—P(35)—Cl(2) plane, 0.690(1) Å above the As(21)—P(35)—Cl(2) plane and 0.586(1) Å below the As(3)—As(21)—P(35) plane. The Cu···N distance is 3.840(3) Å and the Cu···Cu separation is 9.680(1) Å.

The Cu—As distances of 2.431(2) and 2.426(2) Å, Cu—P distance of 2.262(3) Å and Cu—Cl distance of 2.328(3) Å compare well with other reported values for tetra-coordinate copper(I).[1,15–18] An inspectrion of the intermolecular distances between the phenyl rings show that they tend to pack in a random fashion. The molecule has no intermolecular short contact less than 3.745 Å and hence the structure is held in space by van der Waals contacts.

Electrochemical study

The cyclic voltammograms of all these copper(I) complexes were studied in DMF in the potential range −0.4 to +1.6 V (vs SCE), in which the free ligand does not show any electrochemical response. The cyclic voltammograms of $[Cu_2(BDAE)(PPh_3)_2](ClO_4)_2$ (**9**) and $[Cu_2(BDAE)(C_5H_5N)_4](ClO_4)_2$ (**15**) are shown in Figs 2 and 3, respectively. The electrochemical data are presented in Table 6. The electrochemical behaviour of the complexes **1–6** and **9–12** are similar and exhibited two quasi-reversible oxidation–reduction couples in the ranges +0.40 to +0.70 V and +0.85 to +1.08 V. For complexes **7** and **13–15** the first couple, however, shifted significantly towards the negative side (+0.15 to +0.06 V) and the second couples are in the range +0.80 to +0.84 V. Complex **8** shows two couples at +0.26 and +0.76 V. The notable points in these experiments are the facts that the $E_{1/2}$ values were independent of scan rates (50 to 200 mV s^{-1}), the ratio of the peak currents due to cathodic and anodic sweeps were close to unity at different scan rates and the difference in potential due to anodic and cathodic peaks (ΔE_p) are in the range 80–120 mV. The above observations are consistent with a quasi-reversible one-electron transfer process. The observed two couples, therefore, can be attributed to the sequential one-electron transfer reactions. Similar observations have also been noted for a series of dinuclear copper(I)[22] and ruthenium(II)[42] complexes of hexadentate ligands having N_2P_4 donor sites and also dinuclear complexes of different transition metal ions with various ligands.[43–47] This type of stepwise electron transfer process for a dinuclear system is often used for determining the stabilities of the mixed-valence intermediate species.[43–47] Thus, the stabilities of the mixed-valence copper(II)–copper(I) species can be expressed in terms of the comproportionation constant (K_{com}) as:

Table 5. Bond distances (Å) and angles (°) in the coordination sphere of complex **1**

Cu(I)—As(3)	2.431(2)	Cu(I)—P(35)	2.262(3)

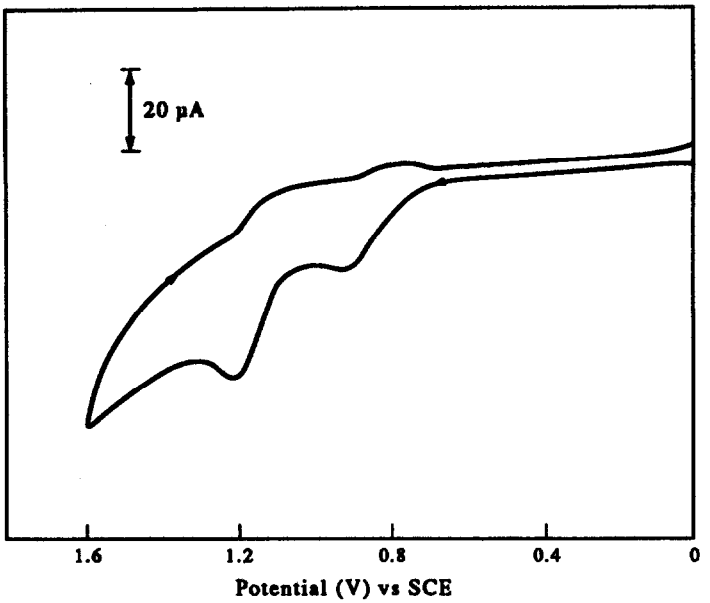

Fig. 2. Cyclic voltammogram of $[Cu_2(BDAE)(PPh_3)_2](ClO_4)_2$, 2.4×10^{-3} M solution in DMF at 25 ± 1°C.

$$K_{com} = \exp(nF\Delta E/RT);$$

where ΔE is the difference between the $E_{1/2}$ values of two oxidation–reduction couples in volts. The K_{com} values thus calculated are given in Table 6.

The K_{com} values found in the range 1.19×10^{5}–3.32×10^{12} indicate that the intermediate species are moderately stable. The interesting observation noted in this study is that in complexes **7** and **13**–**15**, where CS_2, imidazole, bipyridine and pyridine molecules are coordinated to copper(I), the first $E_{1/2}$ values decrease significantly and the K_{com} values are considerably higher compared with those of other compounds. This is definitely due to the fact that the attachment of the σ-donor moiety to copper(I) increases the electron density on the metal ion which caused easy removal of an electron from copper(I) to form copper(II). Secondly, the presence of both a σ-donor and π-acceptor in the coordination sphere provides a balanced electron density on the metal ion, which resulted in extra stability of the mixed-valence intermediate species.

^{183}W NUCLEAR MAGNETIC RESONANCE OF α-$[H_2W_{11}VO_{40}]^{7-}$ AND α-$[H_2W_{11}MoO_{40}]^{6-}$

J. J. HASTINGS and O. W. HOWARTH*

Department of Chemistry, University of Warwick, Coventry CV4 7AL, U.K.

(*Received* 4 *December* 1992; *accepted* 4 *January* 1993)

Abstract—The anions $[H_2W_{11}VO_{40}]^{7-}$ and $[H_2W_{11}MoO_{40}]^{6-}$ have been identified in aqueous solution by ^{183}W, ^{51}V and ^{1}H NMR. They almost certainly both have the α-Keggin structure.

Although many examples are known of the substitution of metal atoms such as vanadium into heteropolytungstates, there is at present only one known case of such substitution into isopolytungstates with the Keggin structure. Pope[1] has reported the substitution of a vanadium(V) atom into α-$[H_2W_{12}O_{40}]^{6-}$ and he argues from both the single, broad vanadium resonance and the proton shift of the two encapsulated protons that this yields $[H_2W_{11}VO_{40}]^{7-}$. The proposed 7- anionic charge is consistent with the observation that this anion has its maximum stability at somewhat higher pH than the α-Keggin species.[2,3] We now confirm Pope's proposal and also report the corresponding molybdenum-substituted anion, $[H_2W_{11}MoO_{40}]^{6-}$.

The $W_{11}V$ anion was prepared between pH 2.5 and 5 in aqueous solution typically containing vanadate (0.333 mol dm^{-3}) and tungstate (1.667 mol dm^{-3}). These solutions typically take several weeks to reach equilibrium. The $W_{11}V$ anion is present at *ca* 0.026 mol dm^{-3}, along with paratungstate B (0.0485 mol dm^{-3})[3] and the dominant $[W_4V_2O_{19}]^{4-}$ species.[1] Other anions are also present in smaller quantities, but have not yet been fully analysed. The ^{51}V and ^{1}H NMR shifts of $W_{11}V$ are -543 and 6.05 ppm, respectively. These agree with Pope's report.[1] A ^{183}W NMR spectrum [Fig. 1(a)] showed six resonances that correspond to $W_{11}V$ by having the correct relative area both to each other and to $[W_4V_2O_{19}]^{4-}$, as predicted from the areas in the ^{51}V spectrum. The peaks are in the area ratio 2:2:(2+1):2:2, where the + sign indicates partial overlap. These ratios show that the anion retains a plane of symmetry. The shifts are listed in Table 1. No broadenings are apparent from coupling to V, but these would not in fact be expected with such a broad V resonance. The peak ratios probably show that the species retains the α-Keggin structure, because the β-isomer would have to be substituted solely at just one of its two sets of three equivalent tungsten atoms, in order to retain a plane of symmetry and also to remain a single species. Even if it did this, rather different tungsten shifts would be expected, for the shifts in the mixed-metal species range from -114.1 to -127.6 ppm (the unsubstituted α-Keggin resonates at -123 ppm), whereas the unsubstituted β-Keggin anion has resonances between -112 and -136 ppm.[3] One would expect a substituted β-Keggin anion to have a larger shift range than an unsubstituted one.

The above range of shifts is surprisingly small in comparison with the corresponding shifts reported by Domaille[4] for mono-substituted heteropolytungstates with the α-Keggin structure. These typically extend from -70 to -140 ppm, with the tungsten nearest to vanadium often having the highest shift. One possible reason for this difference is that the present species have two internal protons. These may move so as to correct any imbalance of charge resulting from the metal substitution. Internal protonation certainly affects the tungsten shifts. We have already shown that the removal of just one internal proton decreases the isopolytungstate shift by 21 ppm.[3]

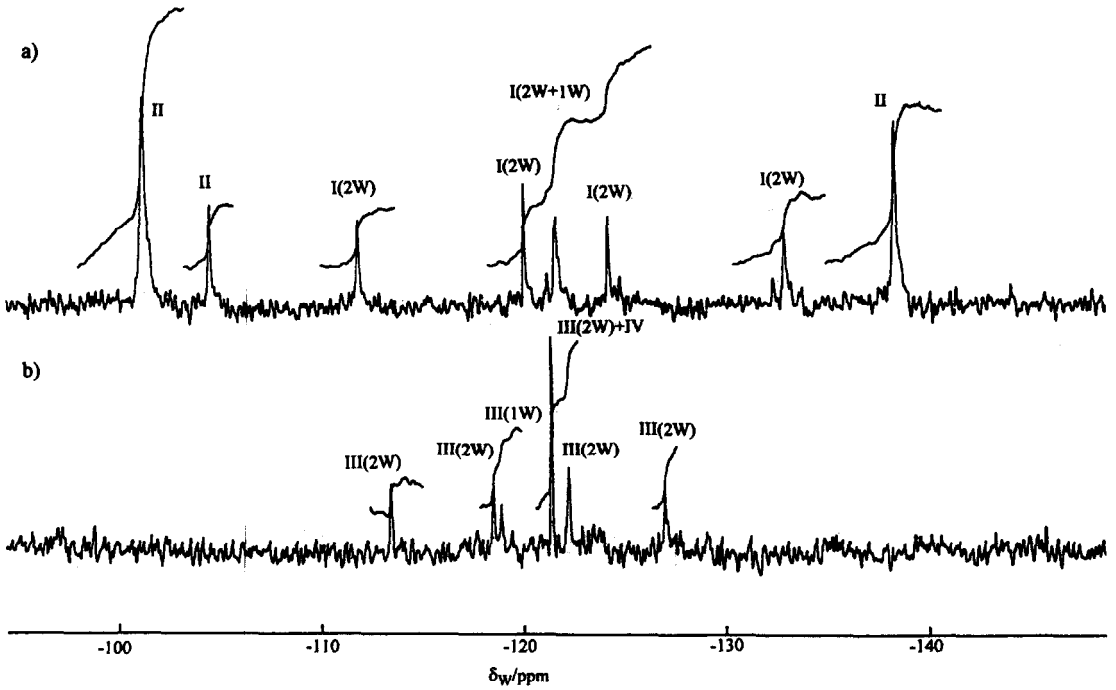

Fig. 1. (a) 16.65 MHz ^{183}W NMR spectrum of 0.333 mol dm^{-3} [V], 1.667 mol dm^{-3} [W] aqueous solution at 295 K, pH 4.9. Species I α-$[H_2W_{11}VO_{40}]^{7-}$, II paratungstate-B $[H_2W_{12}O_{42}]^{10-}$ (with two peaks 2W+4W overlapping at −101 ppm). (b) 16.65 MHz ^{183}W NMR spectrum of 0.1667 mol dm^{-3} [Mo], 1.833 mol dm^{-3} [W] aqueous solution at 295 K, pH 2.2. Species III α-$[H_2W_{11}MoO_{40}]^{6-}$, IV α-$[H_2W_{12}O_{40}]^{6-}$ overlapping one of the 2W resonances of α-$[H_2W_{11}MoO_{40}]^{6-}$.

The corresponding tungstomolybdate species $[H_2W_{11}MoO_{40}]^{6-}$ was prepared in aqueous solution at pH 2–4, with [Mo] = 0.1667 and [W] = 1.833 mol dm^{-3}, along with a complex range of heptametallate species that will be reported separately. It is present at *ca* 0.132 mol dm^{-3}. Its spectrum is shown in Fig. 1(b), and its shifts are also listed in Table 1. They show a close correspondence with those of the $W_{11}V$ anion, but although they also centre approximately at the shift of the unsubstituted α-Keggin isopolytungstate, their spread of shifts is only *ca* 60% of $W_{11}V$. One may deduce that the structure of the $W_{11}Mo$ anion is also probably α-Keggin, and that the substitution of molybdenum perturbs the remaining tungsten atoms even less than does that of vanadium. However, we

have so far been unable to detect the resonances of the presumed central protons or to perform the tungsten homonuclear shift correlation experiments[4] that could in principle permit a more detailed assignment of the resonances. We also have no evidence at present for the substitution of more than one molybdenum or vanadium atom into the isopolytungstate.

METAL-DIRECTED SYNTHESIS OF A PENDENT-ARM N_2S_2-MACROCYCLE INCORPORATING AN *ORTHO*-XYLENE UNIT

ANTHONY J. ELLIOTT, GEOFFREY A. LAWRANCE* and GANG WEI

Department of Chemistry, The University of Newcastle, Callaghan 2308, Australia

(*Received* 27 *October* 1992; *accepted* 21 *December* 1992)

Abstract—Reaction of (2,2′-[*o*-phenylenebis(methylenethio)]bis[ethanamine])copper(II) in alcoholic base with formaldehyde and nitroethane yields the macrocycle (8-methyl-8-nitro-6,10-diaza-3,13-dithia-1,15,16,17,18,19-dehydrobicyclo[13.4.0]nonadecane)copper (II), which incorporates an *ortho*-xylene unit as part of a 15-membered macrocylic ring with *cis*-N_2S_2 donors which also carry pendent nitro and methyl groups. Zinc–acid reduction of the complex permits isolation of a potentially quinquedentate N_3S_2-donor ligand.

Despite the fairly detailed study of the metal-directed reaction involving copper(II) complexes with *cis*-disposed primary amines, formaldehyde and the carbon acid nitroethane,[1,2] only one example of a simple mononuclear macrocyclic complex with mixed nitrogen and sulphur donors has been reported to date[3] and, in general, the study of mixed-donor ligands resulting from this reaction has been neglected. Further, all metal-directed nitroethane/formaldehyde condensation reactions reported to date have involved the synthesis of fully saturated molecules, with the incorporation of aromatic groups in the resultant macrocyclic compounds not attempted previously. To explore some aspects of both the above areas we have examined the facility of a nitroethane/formaldehyde condensation reaction involving the copper(II) complex of **1**. This reaction is directed towards the synthesis of **2**, which incorporates an *ortho*-xylene unit in the macrocycle skeleton. Reduction of the nitro group in **2** yields **3**, which carries an additional potential donor pendent to the macrocycle ring. Details of this chemistry are described herein.

anol (100 cm^3) with stirring. The dark purple solution was allowed to stand overnight and the dark purple solid was collected and air dried (39 g, 67%). Part was reprecipitated from a minimum volume of warm water by the addition of solid $NaClO_4$ in excess. The purple product was collected from the chilled solution, washed well with ethanol and air dried. Found: C, 26.9; H, 4.1; N, 5.6. Calc. for $C_{12}H_{20}Cl_2CuN_2O_8S_2 \cdot H_2O$: C, 26.8; H, 4.1; N, 5.2%. Electronic spectrum (water): λ_{max} 570 (ε 325), 320 nm (ε 3740 M^{-1} cm^{-1}). IR spectrum (KBr disc): 3240, 3115, 1588 (—NH_2), 780 (*ortho*-Ar), 1115, 620 cm^{-1} (ClO_4^-).

(8 - *Methyl* - 8 - *nitro* - 6,10 - *diaza* - 3,13 - *dithia* - 1,15,16,17,18,19 - *dehydrobicyclo*[13.4.0]*nonadecane*) *copper*(II) *perchlorate*, [Cu(**2**)]$(ClO_4)_2$. To a warm solution of [Cu(**1**)]$(NO_3)_2$ (5.1 g) in a mixture of ethanol (50 cm^3) and water (350 cm^3) were added, with stirring, triethylamine (3 cm^3), nitroethane (5 cm^3) and formaldehyde (37% aq., 11 cm^3). The mixture was heated at 60°C for 2 h and then stirred at room temperature for 1 day. The filtered solution was treated with $HClO_4$ (10 cm^3, conc.) and solid $NaClO_4$ (2 g) and the pink–purple solution was chilled to produce a pink precipitate, which was collected, washed with ethanol and air dried (1.1 g, 15%). Further crops were collected after extended standing. Found: C, 28.5; H, 3.7; N, 6.1. Calc. for $C_{16}H_{25}Cl_2CuN_3O_{10}S_2 \cdot 0.5NaClO_4$: C, 28.3; H, 3.7; N, 6.2%. Electronic spectrum (water): λ_{max} 560 (ε 490), 339 (ε 4860), 262 cm^{-1} (ε 3060 M^{-1} cm^{-1}). Magnetic moment (300 K): 1.7 μ_B (d^9 spin-only value is 1.73). IR spectrum (KBr disc): 1540, 1340 (—NO_2), 770 (*ortho*-Ar), 1115, 620 cm^{-1} (ClO_4^-).

8 - *Methyl* - 6,10 - *diaza* - 3,13 - *dithia* - 1,15,16,17,18,19 - *dehydrobicyclo*[13.4.0]*nonadecan* - 8 - *amine hydrochloride*, (**3**)·3HCl. Equal volumes of [Cu(**2**)]$(ClO_4)_2$ (2.0 g) dissolved in water and 3 M HCl were added dropwise at equal rates to constantly stirred excess zinc dust, with the temperature of the mixture adjusted to *ca* 50°C. The final colourless solution was filtered to remove excess zinc dust and copper metal, diluted eight-fold with water and loaded onto a column (20 × 4 cm) of Dowex 50W × 2 (H^+-form) cation exchange resin. The column was washed with 1 M HCl to remove the zinc ions and then eluted with 5 M HCl. The eluate was taken to dryness, twice stirred with a small volume of ethanol and taken to dryness to yield an off-white powder (1.2 g, 85%). Found: C, 37.6; H, 6.9; N, 8.15. Calc. for $C_{16}H_{30}Cl_3N_3S_2 \cdot 4H_2O$: C, 37.9; H, 7.5; N, 8.3%. ^1H NMR spectrum (D_2O): δ 1.35 (s, —CH_3), 2.7–3.4 (m, —CH_2—), 4.1 (s, Ar—CH_2—S), 7.4 (m, Ar—) ppm. ^{13}C NMR spectrum (D_2O): δ 22.5 (—CH_3), 32.4, 35.7 (—NH—CH_2—), 41.3 (tert. C), 50.6, 56.5 (—S—CH_2—), 130.9, 133.7 (Ar—) ppm.

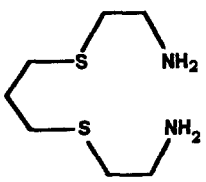
Physical methods

Electronic (in water), IR (KBr discs) and NMR spectra (in D_2O) and cyclic voltammetry (aqueous 0.1 M $NaClO_4$ solution, glassy carbon working electrode) were performed as previously described.[3,5] Magnetic moments were determined by the Evans method.[6]

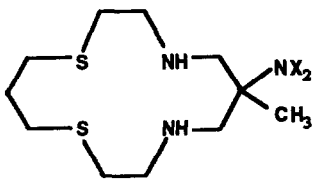
RESULTS AND DISCUSSION

The metal-directed synthesis of the macrocycle **2** proceeds with reasonable facility in a one-step process, the mechanism of which has been described previously.[2] The macrocycle is characterized readily by a number of physical properties: the introduced nitro group is readily identified by IR spectroscopy (asymmetric and symmetric stretching vibrations at 1540 and 1340 cm^{-1}) and voltammetry (irreversible multielectron reduction at −1.08 V vs Ag/AgCl), while the resistance of the product to dissociation even in strong acid is indicative of macrocyclization. The strong primary amine bands (3240, 3115 and 1588 cm^{-1}) in the IR spectrum of the open-chain precursor are replaced by weaker secondary amine resonances (3227, 3181 and 1600 cm^{-1}) in the macrocycle, whereas a vibration associated with the characteristic *ortho*-disubstituted benzene ring near 770 cm^{-1} is preserved.

The copper(II)/(I) couple for $[Cu(2)]^{2+}$ is observed at −0.20 V vs Ag/AgCl and is quasi-reversible (ΔE 80 mV at 100 mV s^{-1} scan rate, i_{pc}/i_{pa} 1.05). The shift to more negative potential vs the precursor $[Cu(1)]^{2+}$ ($E_{1/2}$ −0.04 V, ΔE 70 mV) is the same as that observed with the saturated analogues **4** and **5**,[3] where a shift from $E_{1/2}$ −0.09 (ΔE 138 mV) to −0.245 V (ΔE 140 mV) is observed. A more negative potential for the macrocycle compared with the acycle for tetraamine analogues is ascribed to the reduced flexibility in the former case,[7] with the macrocycle less able to accommodate the larger copper(I) ion and its preferred tetrahedral geometry, but this is relaxed somewhat in the case of the N_2S_2 system as a result of the longer C—S and Cu—S bond lengths. The relatively large chelate ring incorporating the benzene unit in $[Cu(2)]^{2+}$ does not appear to influence accommodation of the change in ion size and geometry upon reduction compared with $[Cu(5)]^{2+}$, as $E_{1/2}$ values are very similar. However, electronic effects from the incorporation of the aromatic group may play some role in the present case.



(4)



(5) X=O

(6) X=H

Reversibility of the couple is enhanced in $[Cu(2)]^{2+}$ compared with $[Cu(5)]^{2+}$.

The electronic spectra of all acyclic and cyclic species are similar, with an absorbance near 330 nm characteristic of the presence of thioether donors.[8] An additional absorbance at 262 nm in the case of the macrocyclic complex can be assigned to the nitro group. A number of CuN_2S_2 complexes with different macrocycle ring sizes have been reported, the *d–d* transition varying with the 12-membered (620 nm), 14-membered (534 nm) and 16-membered (607 nm) ring size.[3,8] The maximum in the present case, which is a 15-membered ring, is observed at 560 nm. This fits into the general trend with ring size, suggesting that $[Cu(2)]^{2+}$ adopts the approximately square-planar geometry of the 14- and 16-membered analogues, despite the incorporation of the benzene ring in the framework.

The present example, $[Cu(2)]^{2+}$, is the first of a macrocycle incorporating an aromatic ring produced by the metal-directed carbon acid/formaldehyde process. Other examples of N_2S_2-macrocycles with benzene rings in the framework have been produced by condensations of dialdehydes and diamines followed by borohydride reduction of the cyclic diimine intermediate,[9] or by condensation of the nickel(II) complex of **1** with acetone.[10] Reduction of $[Cu(2)]^{2+}$ with Zn/HCl produces a macrocycle (**3**) with a pendent primary amine capable of coordination, and the chemistry of this potential N_3S_2-ligand, analogous to the known **6**,[11] is being pursued.

Abstract—The 365 nm continuous irradiation of acidic aqueous solutions of $Cr(bpy)_3^{3+}$ and acrylamide yields polyacrylamide; the $Cr(bpy)_2(OH_2)_2^{3+}$ aquation product is also produced. Upon pulsed-laser excitation, no chromium(II) product is observed, likely due to the low rate constant for the quenching of thermally-equilibrated $^2T_1/^2E$ excited states of the photosensitizer by acrylamide and the low-cage escape yield of redox products. Nevertheless, $Cr(bpy)_3^{3+}$ is a suitable photosensitizer even for excitation with visible light up to 450 nm. The positive dependence of the rate of polymerization on the intensity of absorbed light and [monomer]^2 and the inverse dependence on $[Cr(bpy)_3^{3+}]$ suggest that the termination step of the chain reaction involves the oxidative scavenging of the macroradicals by the photosensitizer.

The use of light to initiate the generation of free radicals has been extensively used in polymerization processes. In addition to providing on–off control at ambient temperature, the photochemical method permits the selection of the wavelength of light, and thus the nature of the excited states and radicals to be generated. Unfortunately, monomeric species generally absorb at short wavelengths and their polymerizations only occur with the excitation of high energy ($\lambda < 270$ nm). Through the use of a photosensitizer the selective formation of radicals can be achieved with light of lower energy.

The polymerizations of vinyl monomers photoinitiated by coordination complexes, such as those of iron(III),[1,2] cobalt(III),[3–6] ruthenium(II)[7] and chromium(VI),[8–10] have already been reported. Chromium(III) as $Cr(H_2O)_6^{3+}$ also appears to be an efficient photoinitiator of vinyl monomer polymerization.[11] In order to elucidate the mechanism of the photoinitiation process, and because of our previous work on the photochemistry and photophysics of polypyridyl complexes of chromium (III),[12] we chose to investigate the polymerization of acrylamide (AA) photosensitized by $Cr(bpy)_3^{3+}$ (bpy = 2,2′-bipyridine), the thermally-equilibrated $^2T_1/^2E$ excited states of which are luminescent, long-lived ($\tau = 70$ μs) in the absence of O_2 and strongly oxidizing ($^*E^\circ = 1.44$ V).[13]

EXPERIMENTAL

Materials

$Cr(bpy)_3^{3+}$ (as the ClO_4^- salt) was synthesized according to literature procedures.[14] Acrylamide (Fluka puriss) was used without further purification. The solutions were prepared with doubly-

† Author to whom correspondence should be addressed.

distilled water and deaerated by bubbling with argon for 45 min. The pH of the solutions was adjusted with HCIO4 to +0.02 units; the ionic strength was not controlled.

Procedures

The irradiations at 365 nm were performed with a high pressure mercury lamp (Osram HBO 200W) equipped with a grating monochromator (Bausch and Lomb). The beam was parallel and the reactor was a square cuvette with a 1 cm pathlength. The incident light intensity was determined by ferrioxalate actinometry (Io~ 1-2x1015 photon cm 2 s--l). In order to study the effect of the absorbed light intensity on the polymerization rate neutral density filters were placed in front of the cell.

Absorption spectra were recorded on a Cary 118C spectrophotometer; emission spectra were obtained with a Jobin Yvon JY 3C spectrofluorimeter equipped with a red-sensitive Hamamatsu detector. The extent of quenching of *Cr(bpy)33+ by acrylamide was determined by monitoring the emission intensity at 727 nm as a function of *[AA]*. The polymer was precipitated by pouring the irradiated solution into methanol; the polymer was separated and weighed, which offered a measure of the fractional conversion of acrylamide into polymer. The rate of polymerization, Rp, was taken from the slope of the linear part of the plot of per cent of monomer conversion vs irradiation time ; the precision of the values of Rp is estimated to be _ 10%.

RESULTS

Quenching and photochemistry

A linear Stern-Volmer plot from emission intensity measurements *(Io/Ivs* [AA]) yields kq = 3 × 103 M-~ s-1 in the presence and absence of air. Irradiation of a deaerated solution at 365 nm, containing 0.11 mM Cr(bpy)33+ and 1 M AA at pH 2.24, resulted in spectral changes that indicated the formation of the aquation product Cr(bpy)2 (OH2)23+ (Fig. 1). The quantum yields of photoaquation (~pa) were virtually the same in the absence (7.0x 10-4) and presence (8.0x 10-4) of 1 MAA.

Rate of polymerization

All experiments were performed on carefully deaerated solutions ; in aerated solutions only traces of polymer were observed. Figure 2 shows a plot of the per cent of monomer conversion vs irradiation

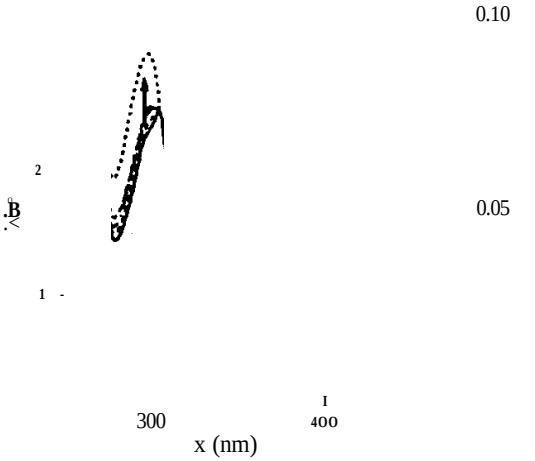

Fig. 1. Spectral changes upon irradiation at 365 nm m the absence of air at pH 2.24. [Cr(bpy)33+] = 0.11 raM; [AA] = 1 M.

time; a steady state was attained without any detectable induction period and the polymerization rate was constant over a large extent of the photoreaction. Since the formation of a gel at high conversion (> 50%) made the solution difficult to handle, the influence of the various parameters on Rp was studied at conversions usually lower than 25%.

Influence of [Cr(bpy)33+]. The variation of Rp as a function of [Cr(bpy)33+] is shown in Fig. 3. In the studied domain the rate of polymerization decreased with an increase in the concentration of the complex.

Influence of pH. The variation of Rp with pH is complex (Fig. 4), with Rp first rising to a plateau with increasing pH, then falling off around pH 4. Due to the pH dependence all other experiments were performed at a pH in the plateau range.

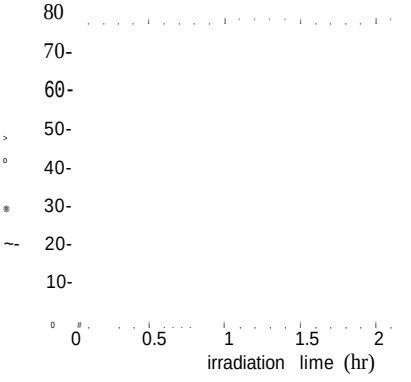

Fig. 2. Plot of per cent conversion of monomer vs irradiation time in the absence of air at pH 2.70. [Cr(bpy)33+1 = 0.12 mM ; [AA] = 1 M.

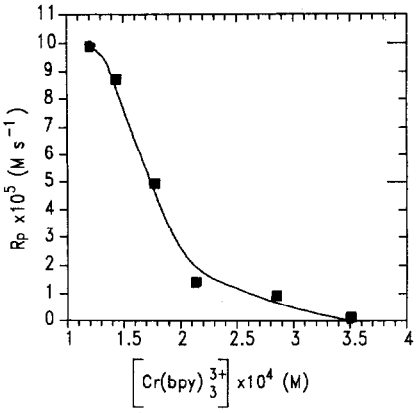

Fig. 3. Plot of R_p vs $[Cr(bpy)_3^{3+}]$ at pH 2.75. [AA] = 1 M.

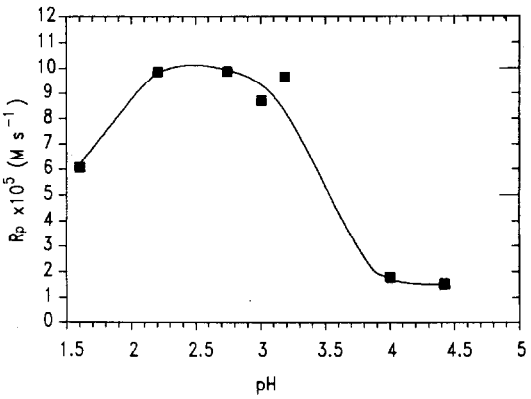

Fig. 4. Plot of R_p vs pH. $[Cr(bpy)_3^{3+}] = 0.12$ mM; [AA] = 1 M.

Influence of absorbed light intensity and [AA]. R_p is directly proportional to I_a (Fig. 5) and shows a square dependence on [AA] (Fig. 6).

Influence of excitation wavelength. A few experiments were performed at 400, 425 and 450 nm. Polymerization was observed with values of R_p of the order 10^{-5} mol dm^{-3} s^{-1}.

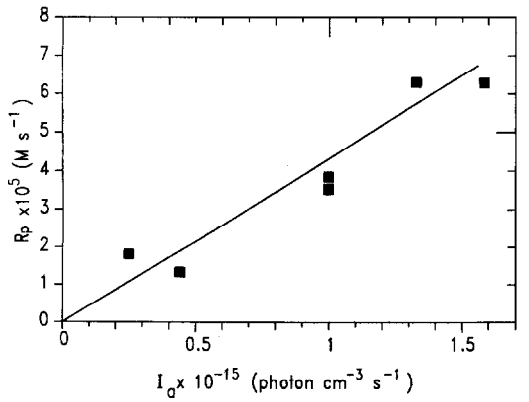

Fig. 5. Plot of R_p vs I_o at pH 2.93. $[Cr(bpy)_3^{3+}]$ = 0.14 mM; [AA] = 1 M.

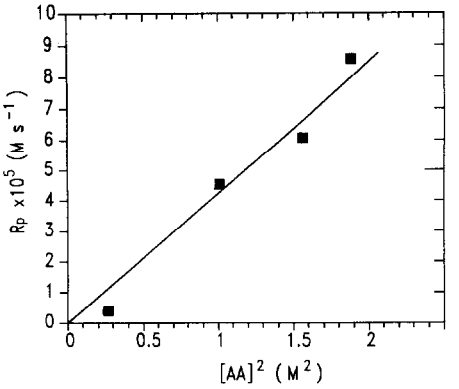

Fig. 6. Plot of R_p vs $[AA]^2$ at pH 2.20. $[Cr(bpy)_3^{3+}]$ = 0.14 mM.

DISCUSSION

From the results we can propose the following simplified scheme of acrylamide polymerization photosensitized by $Cr(bpy)_3^{3+}$.

(1) *Photophysics and photochemistry*

Reactions (1)–(3) describe the formation and disappearance of $*Cr(bpy)_3^{3+}$. The lifetime of the excited state in the absence of quencher is determined by the rates of the various decay modes; $\tau_o = 1/(k_o + k_{pa})$. Reaction (3) is a complex multistep process, presumably involving the formation of a seven-coordinate intermediate from the attack of H_2O at the metal centre and subsequent ligand loss and solvent substitution.

$$Cr(bpy)_3^{3+} \xrightarrow{h\nu} *Cr(bpy)_3^{3+} \quad (1)$$

$$*Cr(bpy)_3^{3+} \xrightarrow{k_o} Cr(bpy)_3^{3+} (+h\nu') \quad (2)$$

$$*Cr(bpy)_3^{3+} + 2H_2O \xrightarrow{k_{pa}} Cr(bpy)_2(OH_2)_2^{3+} + bpy \quad (3)$$

(2) *Initiation*

Reaction (4) describes the electron-transfer quenching of $*Cr(bpy)_3^{3+}$ by acrylamide:

$$*Cr(bpy)_3^{3+} + AA \xrightarrow{k_q} Cr(bpy)_3^{2+} + M^{\cdot}, \quad (4)$$

where $M^{\cdot}$ is the radical arising from the oxidation of the monomer. Due to the value of k_q, the extent of quenching, even with 1 M AA, is quite low. Furthermore, the formation of $Cr(bpy)_3^{2+}$ is not observed in pulsed-laser flash photolysis; the quantum yield of redox products is estimated to be <0.01.

The rate of initiation (R_i) is equal to ΦI_a, where

@ is the quantum yield of M" formation in reaction (4); qb is given as $kq[AA]/(ka+kq[AA])$ with kd = ko+kp~. Due to the low extent of quenching and the low value of ~p,, Ri = $(kq/ko)[AA]Ia$.

(3) *Propagation*

$$M'+AA \xrightarrow{k1} M2"$$

$$M2"+AA \xrightarrow{k2} M3"$$

$$M._{}l"+AA \xrightarrow{4r,} M,"$$

The rate of propagation (Rpr) is equal to kpr[P'][AA], where [P'] is the total concentration of radicals.

(4) *Termination*

It is proposed that in the presence of the photosensitizer the radicals (probably carbon-centred radicals adjacent to an amide moiety) react with Cr(bpy)33+ ($E°= -0.25$ V), according to redox reaction (5); the rate of termination (Rt) is equal to kt[P'][Cr(bpy)33+].

$$p.+Cr(bpy)33+ \xrightarrow{k,} polymer+Cr(bpy)32+ \quad (5)$$

(5) *Overall kinetics*

For the overall process, [P'] = $(kq/kokt)[AA]I~/$ [Cr(bpy)33+]; the rate of polymerization is given by equation (6), where Rp = Rpr.

$$Rp = \frac{Fkqkpr]\ [nA]2Ia}{L\ kokt\ _][Cr(bpy)33+]} \quad (6)$$

Thus, the proposed mechanism accounts for a first-order dependence of Rp on/~ (Fig. 5), a second-order dependence on [AA] (Fig. 6) and predicts an inverse first-order dependence on Cr(bpy)33+ at constant [AA] and Ia.

Inasmuch as Ia is a function of [Cr(bpy)33+] via Beer's Law, a plot of *Rp/I*, vs 1/[Cr(bpy)33+] from the data in Fig. 3 should be linear with a y-intercept of zero. Such a plot is shown in Fig. 7, although we are at a loss to account for the non-zero intercept. Nevertheless, we feel that linear behavior demonstrates, in a general way, the efficacy of the mechanism.

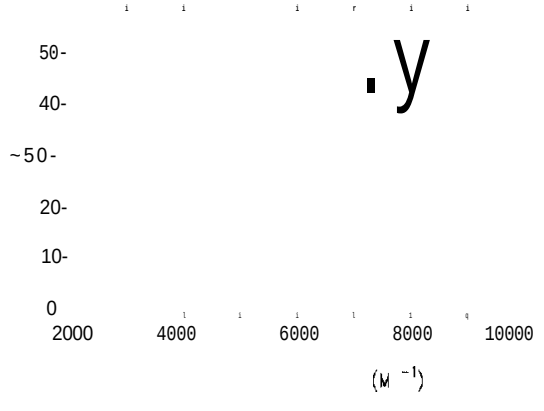

Fig. 7. Plot of *Rp/I~* vs 1/[Cr(bpy)33+].

CONCLUSION

Cr(bpy)3 3+ is a suitable photosensitizer for the polymerization of acrylamide in acidic aqueous solution by near-UV and visible light. However, the low value of the rate constant for the quenching of *Cr(bpy)33+ by acrylamide and the low cage escape of the redox products are features that severely limit the overall efficiency of the process.

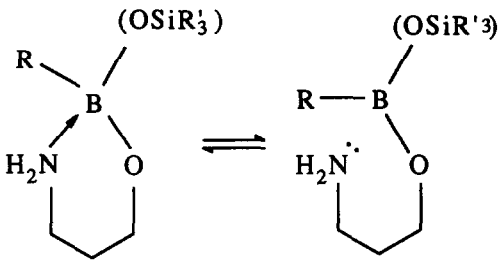
(*Received* 11 *November* 1992; *accepted* 18 *December* 1992)

Abstract—The syntheses of compounds of the types $H_2N(CH_2)_3OB(Ph)(OSiR'_3)$ [$R'_3 = Me_3$ (**1**), Me_2Ph (**2**), $MePh_2$ (**3**), Ph_3 (**4**)] and $H_2N(CH_2)_3OB(Bu)(OSiR'_3)$ [$R'_3 = Me_2Ph$ (**5**), $MePh_2$ (**6**), Ph_3 (**7**)] are reported. The structure of **2** was determined by X-ray crystallography. There are two independent molecules in the unit cell. Both molecules contain tetrahedral $BCNO_2$— and SiC_3O— units joined by B—O—Si bridges with angles of 145.7(3)° and 150.5(3)°, respectively. In solution compounds **1–7** are involved in intramolecular equilibrium reactions between four- and three-coordinate boron species with the latter formed by scission of the B—N bond.

The work described in this paper continues our studies on borosilicate chemistry.[1,2] Previously we have reported the solid state structure of $H_2N(CH_2)_3OB(Ph)(OSiMePh_2)$ (**3**),[1] which contained two tetrahedrally coordinated $BCNO_2$— and R_3SiO— units linked through an oxygen atom. Notable features in the structure of **3** included the large B—O—Si angle, 152.2(2)°, and short Si—O bond length, 1.585(2) Å.[1] In chloroform solution the ^{11}B NMR spectrum of **3** contained two peaks at 28.7 and 2.5 ppm in the ratio of 1 : 2.5.[2] Compound **1** was also reported to exhibit two peaks in its ^{11}B spectrum, at 28.9 and 3.5 ppm, in the ratio of 1 : 1.3.[2] The peaks at *ca* 29 ppm are consistent with a trigonally coordinated boron atom, while those at *ca* 3 ppm correspond to a tetrahedrally coordinated boron.[3] Hence, it was suggested that an equilibrium reaction involving the cleavage of the intramolecular B—N bond occurs in solution, eq. (1).[2]



RESULTS AND DISCUSSION

Compounds **1–7** were obtained from the reactions between $PhB(OSiR'_3)_2$ or $BuB(OSiR'_3)_2$ and $NH_2(CH_2)_3OH$ in dichloromethane at room temperature. Reaction times were either 0.5 h (**1** and **3** only) or 24 h and yields varied between 27% (**3**) and 76% (**2**). These borosilicate compounds are relatively stable in air in the solid state and dissolve readily in non-reacting organic solvents. We decided to determine the solid state structure of a typical member of the series and chose compound **2**, 2-(dimethylphenylsiloxy)-2-phenyl-1,3,2-oxazaborinane.

* Authors to whom correspondence should be addressed.

Crystals of **2** suitable for X-ray crystallographic analysis were grown from a toluene/heptane solution. The unit cell of **2** contains two independent molecules [(A) and (B)] with very similar geometries and conformations. Fig. 1 is a view of molecule (A). Selected bond angles and distances for both (A) and (B) are listed in Table 1. Each molecule contains tetrahedral $BCNO_2$— and Me_2PhSiO— units. The boron atom is part of a six-membered BOC_3N ring which has a chair conformation. The deviation of the atoms C(3) and B from the O(1), N(1), C(2), C(4)-containing mean-plane for molecule (A) are −0.684(7) and 0.637(6) Å, and for molecule (B), −0.689(7) and 0.656(6) Å, respectively.

As can be seen from Table 1 there are only small differences between the two molecules. The largest difference between them is the difference of 4.8° in the B—O—Si angles, which are 145.7(3)° and 150.5(3)° in (A) and (B), respectively. In the compound $H_2\overline{N(CH_2)_3OB(Ph)(OSiMePh_2)}$ (**3**) the B—O—Si angle was 152.2(3)°.[2] For comparison the mean value of the B—O—Si angle in the borosilicate mineral datolite, $CaBSiO_4(OH)$,[4] which contains BO_3OH sites, is 124.3°. In the mineral homilite $Ca_{2.00}(Fe_{0.90}Mn_{0.03})B_{2.0}Si_{2.0}O_{9.86}(OH)_{0.14}$, which also contains tetrahedral boron sites, there are three independent B—O—Si angles which are between 119.2(1)° and 125.7(1)°.[5]

The mean Si—O bond length in **2** is 1.601(2) Å, significantly shorter than the value in $(Ph_3Si)_2O$, 1.616(1) Å,[6] but longer than that in **3**, 1.585(2) Å. The mean B—O(1) and B—O(2) bond lengths in **2** are 1.454 and 1.443 Å, respectively, which may be compared with the B—O(1) and B—O(2) distances in **3** of 1.461(3) and 1.439(4) Å, respectively.[1,2]

The mean B—N bond length of 1.641(6) Å in **2** is comparable with B—N distances of 1.639(4) in **3** and 1.638(3) Å in $Ph_2\overline{BO(CH_2)_3N}H_2$.[7(a)]

None of the B—C, C—O, C—N and C—C bond lengths in **2** are unusual. For each molecule there is an intermolecular hydrogen bond between one of the N—H hydrogens and the oxygen atom in the BOC_3N ring of an adjacent molecule [see Fig. 2, NA···OA 2.883(4) and NB···OB 2.927(4) Å], which leads to infinite hydrogen bonded chains of (A) and (B) molecules. Similar hydrogen bonding occurs in compound **3**.[1,2]

either chloroform or dichloromethane at ambient temperature contain two broad singlet peaks (Table 2). Generally, it can be seen that for each set of compounds (R = Ph or Bu) the tetrahedral species becomes more favourable with increasing number of phenyl groups on the silicon atom; compound **2** is the only exception.

The tetrahedrally coordinated phenylboron compounds are relatively more stable than the corresponding butylboron compounds. Indeed, it is noteworthy that for $H_2N(CH_2)_3OB(Bu)(OSiMe_2Ph)$ the trigonally coordinated boron species is more stable in solution at ambient temperature. The underlying causes of the observed sequence are not clear at this time and we are continuing our study of this phenomenon with a view to determining if it can be rationalized on the basis of electronic and/or steric arguments.

There appear to be no previous reports in the literature of any reactions such as (1) which involve boron-containing compounds analogous to **1**–**7**. Rettig and Trotter have determined the structures (by X-ray analysis) of compounds such as $H_2N(CH_2)_3OBPh_2$ and $H_2N(CH_2)_2OBR_2$ (R = Ph, MeC_6H_4, FC_6H_4),[7] which contain intramolecular B—N bonds and are broadly similar to **1**–**7**, but they did not report any ^{11}B NMR data. However, ring rearrangement–isomerization reactions of compounds of the types **8** and **9**, which occur with the cleavage of the B—N bonds, have been studied by Contreras, Wrackmeyer and coworkers using ^{11}B, ^1H and ^{13}C NMR techniques.[8a,b] Activation energies for the ring inversion reactions of **8a** and **b** were 59.6 ± 1 and 49.2 ± 1 kJ M^{-1}, respectively, and for isomerization reactions which occur at the nitrogen atom in four compounds of type **9** the activation energies ranged from 61 ± 4 to > 80 kJ M^{-1}.

Table 2. ^{11}B NMR data on compounds of the type $H_2N(CH_2)_3OB(R)(OSiR'_3)$

EXPERIMENTAL

General

Elemental analyses were carried out at UCC. Melting points are uncorrected. IR spectra were recorded, as KBr discs, on a Perkin–Elmer 682 IR spectrometer. The ^{1}H NMR spectra were recorded on a JEOL FX60 FT NMR spectrometer operating at 33°C, while the ^{11}B NMR spectra were recorded on a JEOL FT GSX-270 series NMR spectrometer at 25°C. Chemical shifts, δ ppm, are reported relative to $SiMe_4$ (^{1}H) and BF_3OEt_2 (external) (^{11}B) and positive values represent shifts to higher frequencies of the standards. All reactions were carried out under inert atmospheres. Solvents were distilled under an inert atmosphere from the appropriate drying agents prior to use.

The 3-aminopropanol was used as supplied by Aldrich, $PhB(OSiPh_3)_2$ was synthesized by reacting 2 equivalents of Ph_3SiOH with 1 equivalent of $PhB(OH)_2$ in refluxing toluene.[1] The water produced was removed azeotropically and collected in a Dean–Stark apparatus. The compounds $PhB(OSiR'_3)_2$ ($R = Me_3$, Me_2Ph, $MePh_2$) and $BuB(OSiR'_3)_2$ ($R = Me_2Ph$, $MePh_2$, Ph_3) were synthesized by reacting $PhB(OH)_2$ or $BuB(OH)_2$ with the appropriate organosilylchloride in the presence of base (Et_3N).[1]

Preparation of compounds **1–7**

1 - (*Trimethylsiloxy*) - 2 - *phenyl* - 1,3,2 - *oxazaborinane* (**1**). To a dichloromethane solution (20 cm^3) of $PhB(OSiMe_3)_2$ (0.810 g, 3.042 mmol) was added dropwise a dichloromethane solution (20 cm^3) of $NH_2(CH_2)_3OH$ (0.233 cm^3, 3.042 mmol) at room temperature. The clear solution was stirred for 0.5 h, after which time the solvent was removed under reduced pressure to leave a white solid. Recrystallization from dichloromethane/heptane solution afforded colourless microcrystals of **1** in 34% yield (0.260 g, 1.034 mmol); m.p. = 80–81°C. Found: C, 57.6; H, 8.4; N, 6.3. Calc. for $C_{12}H_{22}BNO_2Si$: C, 57.4; H, 8.8; N, 5.6%. ^{1}H NMR ($CDCl_3$): 7.54–7.06 (m, 5H, C_6H_5), 3.80 (t, 2H, CH_2O), 3.22 (s, 2H, NH_2), 2.86 (t, 2H, CH_2N), 1.54 (m, 2H, CH_2—CH_2—CH_2—), 0.26 [s, 9H, $(CH_3)_3$—Si]. IR, ν_{max} cm^{-1}: 3318m, 3282m, 3046s, 3020s, 2962s, 2925m, 2858s, 1615s, 1432m, 1406m, 1376m, 1335s, 1310m, 1276m, 1242s, 1266vs, 1195vs, 1114s, 1102vs, 1081s, 1072vs, 1064s, 1050m, 1005s, 1005s, 954m, 948m, 903s, 891m, 857m, 835s, 802m, 752s, 723s, 706vs.

2-(*Dimethylphenylsiloxy*)-2-*phenyl*-1,3,2-*oxazaborinane* (**2**) $PhB(OSiMe_2Ph)_2$ (0.677 g, 1.774 mmol) and $NH_2(CH_2)_3OH$ (0.133 cm^3, 1.774 mmol) were reacted as dichloromethane solutions in a procedure similar to the preparation of **1** for 24 h. Compound **2** was obtained in 76% yield (0.413 g, 1.319 mmol), m.p. = 101–102°C, on recrystallization from dichloromethane/heptane solution. Found: C, 65.2; H, 7.8; N, 4.0. Calc. for $C_{17}H_{24}BNO_2Si$: C, 65.2; H, 7.7; N, 4.5%. ^1H NMR ($CDCl_3$): 7.88–7.10 (m, 10H, BC_6H_5 and SiC_6H_5), 3.76 (t, 2H, CH_2O), 3.28–2.60 (m, 4H, H_2NCH_2), 2.10–1.30 (m, 2H, CH_2—CH_2—CH_2), 0.23 [s, 6H, $Si(CH_3)_2$]. IR, ν_{max} cm^{-1}: 3260m, 3060m, 3045m, 3000m, 2985m, 2965m, 2935m, 2910m, 1422m, 1415m, 1365m, 1338m, 1325m, 1245m, 1235m, 1223m, 1190m, 1110vs, 1090m, 1066s, 1054m, 1038m, 995m, 948m, 890m, 815m, 790m, 768m, 735m, 720s, 695s, 648s, 635m.

Structural analysis of **2**. Table 3 gives a concise summary of data collection, structure solution and refinement details of the X-ray analysis of **2**. Selected bond lengths and angles are given in Table 1. Figures 1 and 2 are views of a molecule prepared using ORTEP II.[9] A complete list of final fractional coordinates, dimensions, thermal parameters and structure factors has been deposited as supplementary material with the Editor, from whom copies are available on request.

2-(*Diphenylmethylsiloxy*)-2-*phenyl*-1,3,2-*oxazaborinane* (**3**). $PhB(OSiMePh_2)_2$ (1.089 g, 2.099 mmol) and $NH_2(CH_2)_3OH$ (0.161 cm^3, 2.099 mmol) were reacted as dichloromethane solutions using the procedure employed in the preparation of **1**. Compound **3** was obtained in 27% yield (0.210 g, 0.567 mmol); m.p. = 108–111.5°C. Found: C, 70.5; H, 6.7; N, 3.6. Calc. for $C_{22}H_{26}BNO_2Si$: C, 70.4; H, 7.0; N, 3.7%. ^1H NMR ($CDCl_3$): 7.65–6.98 [m, 15H, BC_6H_5 and $Si(C_6H_5)_2$], 3.64 (t, 2H, OCH_2), 3.29 (s, 2H, NH_2), 2.82 (t, 2H, NCH_2), 1.47 (m, 2H, CH_2—CH_2—CH_2), 0.40 (s, 3H, CH_3Si). IR, ν_{max} cm^{-1}: 3286m, 3076s, 3054m, 3001m, 2867m, 1594m, 1432m, 1334m, 1252m, 1233s, 1198s, 1125vs, 1118vs, 1096s, 1078s, 1064s, 1032w, 998m, 897m, 786s, 759m, 730vs, 712s, 704s.

2-(*Triphenylsiloxy*)-2-*phenyl*-1,3,2-*oxazaborinane* (**4**). $PhB(OSiPh_3)_2$ (2.000 g, 3.131 mmol) and $NH_2(CH_2)_3OH$ (0.234 cm^3, 3.131 mmol) were reacted as dichloromethane solutions using the procedure employed in the preparation of **2**. Compound **4** was obtained in 74% yield (1.048 g, 2.396 mmol), m.p. = 138–140°C, on recrystallization from dichloromethane/heptane solution. Found: C, 73.9; H, 6.2; N, 3.1. Calc. for $C_{27}H_{28}BNO_2Si$: C, 74.1; H, 6.5; N, 3.2%. ^1H NMR ($CDCl_3$): 7.80–7.03 [m, 20H, BC_6H_5 and $Si(C_6H_3)_3$], 3.78 (t, 2H, OCH_2), 3.20 (s, 2H, NH_2), 2.87 (t, 2H, NCH_2), 1.55–1.22 (m, 2H, CH_2—CH_2—CH_2). IR, ν_{max} cm^{-1}: 3040m, 3020m, 2970m, 2940m, 1586m, 1419s, 1324m, 1239m, 1190m, 1110vs, 1072m, 1060m, 890m, 740m, 730m, 698vs.

2-(*Dimethylphenylsiloxy*)-2-*butyl*-1,3,2-*oxazaborinane* (**5**). $BuB(OSiMe_2Ph)_2$ (1.142 g, 3.082 mmol) and $NH_2(CH_2)_3OH$ (0.236 cm^3, 3.082 mmol) were reacted as dichloromethane solutions using the procedure employed in the preparation of **2**. On evaporation of the solvent under reduced pressure a liquid was obtained, which became an oil after being pumped *in vacuo* overnight. On the addition of ice-cold heptane (20 cm^3) compound **5** was produced as a colourless solid in 33% yield (0.296 g, 1.009 mmol); m.p. = 62–64°C. Found: C, 61.1; H, 9.6; N, 4.3. Calc. for $C_{15}H_{28}BNO_2Si$: C, 61.4; H, 9.6; N, 4.8%. ^1H NMR ($CDCl_3$): 7.70–

EFFECT OF COPPER(II), NICKEL(II) AND ALUMINUM(III) IONS ON THE HYDROLYSIS RATES OF INORGANIC CONDENSED PHOSPHATE OLIGOMERS

GENICHIRO KURA* and TOMOKI TSUKUDA

Department of Chemistry, Fukuoka University of Education, Akama, Munakata, Fukuoka 811-41, Japan

(*Received* 27 *October* 1992; *accepted* 18 *December* 1992)

Abstract—The effects of Cu^{2+}, Ni^{2+} and Al^{3+} on the hydrolysis rates of cyclic and linear condensed phosphate oligomers have been investigated. Al^{3+} ions affected the hydrolysis rate most strongly, except for the Al^{3+}-cyclo-octaphosphate system at pH 3. Cu^{2+} ions accelerated the rate more strongly than Ni^{2+} ions. The hydrolysis rate is influenced not only by the degree of complex formation with the cations, but also by the nature of the cation bonding in the complexes.

As the major components of condensed phosphates produced by the dehydration of the oxoacid of phosphorus(V), linear phosphates with linear chain structures and cyclophosphates with cyclic structures are well known. They have the general formula $M^{I}_{2n+1}P_nO_{3n+1}$ and $M^{I}_n(PO_3)_n$, respectively. The chemical properties of condensed phosphates having a relatively low degree of polymerization have been investigated because of the biochemical importance of ATP and ADP; however, the properties of the phosphates above the tetramer have not been studied because of the difficulty involved in their preparation and isolation. These oligomers are very important and interesting materials for electrolyte solution chemistry.[1]

When using these compounds for various purposes, for example, as water conditioners, detergent builders, food additives, etc., their hydrolysis properties must be known clearly. Cyclic phosphates are degraded to linear phosphates with the same degree of polymerization and they are also hydrolysed to linear and cyclic phosphates. It has been reported that the hydrolysis rate is significantly affected by experimental conditions such as temperature, H^+ and OH^- ion concentration and the presence of other cations.[2,3]

In this study, the effects of copper(II), nickel(II) and aluminum(III) ions on the hydrolysis reactions of the condensed phosphate oligomers with degrees of polymerization between 3 and 8 have been investigated. These three cations are known to have different rate constants for solvent exchange: the exchange rate for Cu^{2+} is fastest, for Ni^{2+} moderately slow and for Al^{3+} very slow, therefore, different catalytic effects can be expected. Moreover, for the Al^{3+} systems the investigation of the interaction with the phosphate anions is made possible by the ^{31}P and ^{27}Al NMR measurements and the effect of complexation on the hydrolysis rates can be discussed.

Aluminum(III) ions affected most strongly the degradation rate of the phosphates and copper(II) ions catalysed hydrolysis more strongly than nickel (II) ions.

In this paper cyclic and linear oligomers are abbreviated as P_{nm} and P_n, respectively; in both cases n indicates the degree of polymerization.

EXPERIMENTAL

Chemicals

Sodium salts of cyclo-tri-($Na_3P_3O_9 \cdot 6H_2O$), cyclo-tetra-($Na_4P_4O_{12} \cdot 4H_2O$) and cyclo-hexaphosphate ($Na_6P_6O_{18} \cdot 6H_2O$) were prepared following the methods described in the literature.[1,4,5] Sodium cyclo-octaphosphate ($Na_8P_8O_{24} \cdot 6H_2O$) and guanidinium tetraphosphate ($[NH_2]_2[C{=}NH_2]_6P_4O_{13} \cdot H_2O$) were prepared using modified methods of Schülke and Quimby, respectively.[6,7] Cyclo-penta- and -heptaphos-

phate were isolated from the fractionated solution of Graham's salts, a high molecular weight polyphosphate [(NaPO3),, r7 = 100], using a QAE-Sephadex A-25 column. 8 Aluminum chloride, nickel nitrate and cupric perchlorate were used as metal ions. Cupric perchlorate was prepared by mixing perchloric acid and cupric carbonate. Other chemicals were reagent grade and commercially available.

The concentrations of metal ions were determined complexiметrically. The concentration of AI3+ was also determined by spectrophotometry with 5-sulpho-4'-diethylamino-2',-2-dihydroxyazobenzene (DDB). 9 The acidity of cupric perchlorate and aluminum chloride stock solutions was maintained at 0.1 M with perchloric acid and hydrochloric acid, respectively, to prevent hydrolysis.

Hydrolysis

The concentrations of condensed phosphate oligomers to be hydrolysed were 10-4-2.5 × 10-3 M and those of the metal ions added were 2.5 × 10 4_ 2.5 x 10 3 M. The pH of the test solutions was adjusted to pH 5 for the Ni 2÷ and Cu 2+ systems and to pH 3 for the A13+ systems with HNO3, HC104, HC1 or (CH3)4NOH. The pH of the test solutions was measured with a Horiba pH meter M8-S. The hydrolysis reaction was performed in an oil bath, whose temperature was maintained within _ 0.1°C. The phosphates were degraded at 50, 60 or 70°C. However, for the very slow rate systems, the hydrolysis temperature was increased to 90°C. At measured time intervals an aliquot of the test solutions was withdrawn and the reaction was stopped by a rapid neutralization or by the addition of EDTA, followed in either case by cooling.

Hydrolysis products were analysed with a Hitachi high-performance liquid chromatograph. 10

RESULTS AND DISCUSSION

Cyclic oligomers can be hydrolysed to linear oligomers having the same degree of polymerization and the linear oligomers can be similarly hydrolysed to lower linear and cyclic oligomers. The degradation rate constants are defined as :

$$P,m \quad km\ p, \quad k.\ pn_l,pn_2,...,p1,P3m.$$

The hydrolysis reactions of the condensed phosphates are known to be first-order under various experimental conditions and, therefore, if the concentration of cyclic and linear phosphates with the same degree of polymerization at time t are denoted as x and y, the rate can be expressed as :

$$-\frac{dx}{dt} = k,.x \qquad (1)$$

$$\frac{dy}{dt} - k, y-- kmx. \qquad (2)$$

Solving these differential equations by substituting a and b for the initial concentration of the cyclic and linear oligomers, respectively, yields the following equations :

$$x = a \exp(-kmt) \qquad (3)$$

$$Y - \left(k2\sim,,\right)^{kma} \exp(- kmt)$$

$$+\{b \quad (k-\sim m)^{kma}\}exp(-knt). \qquad (4)$$

The value of km was determined by the time dependence of the cyclic oligomer concentration and kn was calculated by the least-squares procedure substituting x, y and k,,, which are experimentally determined from the chromatograms of hydrolysis samples, for eq. (4).

In order to investigate the effect of metal ions on the hydrolysis reaction of condensed phosphates Ni 2+, Cu 2+ and A13+ were added to each phosphate solution and then the respective rates were determined. The pH of the solutions was adjusted to pH 5 for the Ni 2÷ and Cu e+ systems and to pH 3 for the A13÷ systems to avoid the hydrolysis of the metal ions. For the A13+ systems the concentration of H ÷ had to be kept relatively high and thus the effect of H ÷ on the hydrolysis rate was not negligible.

The rate constants determined for Ni 2– systems are summarized in Table 1. The rate constant for the Ni2+-Ps,, system at 90°C was calculated from its Arrhenius plots. The rate constants for these systems are also illustrated in Fig. 1. The rate constants of cyclic oligomers decreased with the degree of polymerization from 3 to 5 and then increased again. This trend can be explained in a similar manner to their hydrolysis in acidic solutions. 2'll The increasing flexibility in the ring structure of larger cyclic phosphates caused a strong affinity for Ni 2+, while the rate constant of linear oligomers slightly increased with the degree of polymerization, which is also similar to their behaviour in acidic media.

In the case of the Cu 2+ systems the rate data are shown in Fig. 2. The rate constants at 90°C for cyclo-tri-, tri- and tetraphosphate were obtained from their Arrhenius plots. The rates were extremely enhanced by the addition of Cu 2+ and the rate constants for cyclic oligomers had a minimum at a degree of polymerization near 5. For

the linear oligomers, the rate constants gradually increased with the degree of polymerization.

The rate constants determined for the Al^{3+} systems are summarized in Table 2 and are also illustrated in Figs 3 and 4. Aluminum(III) ions also accelerated the hydrolysis rate of the oligomers, except for cyclo-octaphosphate. The reason why the rate did not change so much for cyclo-octaphosphate can be explained by a substitution reaction of Al^{3+} with H^+, which strongly affects the hydrolysis rate. At higher pH the enhancement of the rate of cyclo-octaphosphate by Al^{3+} might be expected. The degradation rates of linear oligomers were only slightly affected by Al^{3+}, probably because of the disturbance of bond formation of H^+ with terminal PO^- groups caused by the substitution of Al^{3+}.

The catalytic effect increased in the order: $Ni^{2+} < Cu^{2+} < Al^{3+} \ll H^+$. The hydrolysis reactions of condensed phosphate oligomers depended strongly on the cations present.[12] The catalytic effect of Al^{3+}, stronger than that of Ni^{2+} and Cu^{2+}, might be due to its stronger complex formation with the oligomers.[13,14] Ni^{2+} and Cu^{2+} complexes with cyclic phosphate anions were expected to have the same degree of stability constants;[13,15] therefore,

	Linear	11.8	13.0	195	388	617	269

the stronger catalytic effect of Cu^{2+} observed is presumed to be due to the difference in the M^{2+}—$^{-}$OP bond length in the complexes.

The activation energies of cyclic and linear oligomers in the presence of Al^{3+} were determined. Typical Arrhenius plots are shown in Fig. 5. Good linear relations were obtained and the activation energies are given in Table 3. The activation energies of cyclo-tri- and -tetraphosphate, which have a weak affinity with H^+, were decreased by *ca* 6–9 kcal mol^{-1} by the addition of Al^{3+}. However, a significant decrease in the activation energy for the other cyclic oligomers was not observed. The decrease in activation energies for linear hexa-, hepta- and octaphosphate systems can be also explained by their relatively weak affinity for H^+.

The rate depends not only on the type of cations present but also on their concentration. It has been thought that the rate acceleration in the presence of the cations might be due to complex formation between the cations and phosphate anions. If so, the rate equation, when complex forming cations are present, can be expressed as:

$$-\frac{dc}{dt} = k_0[P]+k_1[MP]+k_2[M_2P]+\cdots \quad (5)$$

where M and P denote cation and phosphate, respectively, and k_0, k_1 and k_2 denote the individual rate constants of the free phosphate, the 1 : 1 (M : P) complex and the 2 : 1 complex, respectively. If the formation of only the 1 : 1 and 2 : 1 complexes (or

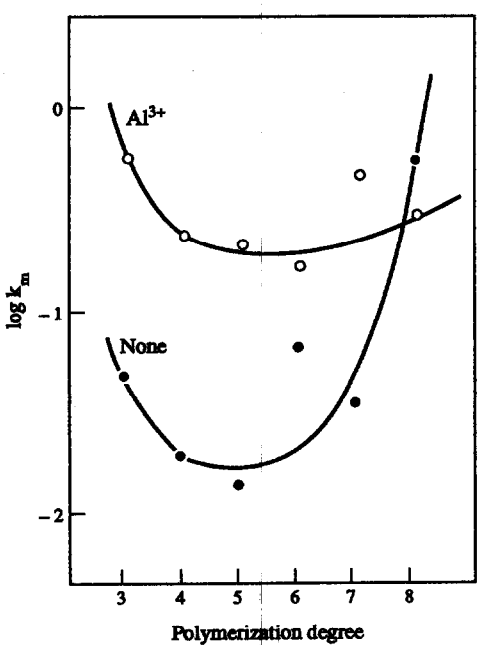

Fig. 3. Hydrolysis rate constants of the cyclic phosphate oligomers in the presence and absence of Al^{3+} at 70°C.

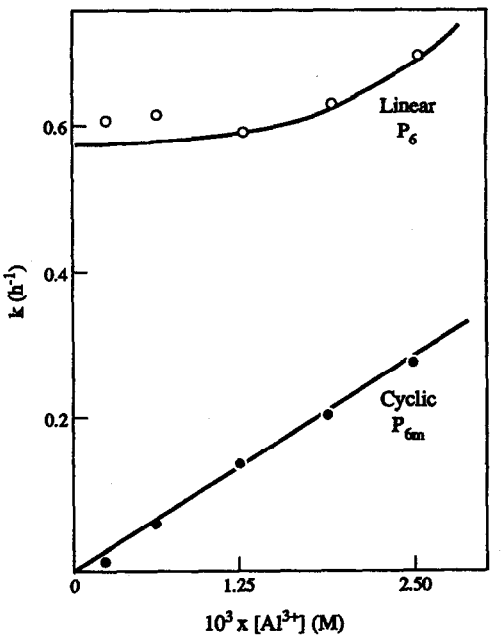

Fig. 6. Effect of Al^{3+} concentration on the rate constants of cyclo-hexa- and linear hexaphosphate at 50°C.

ion pairs) can be assumed and their stability constants are defined as:

$$\beta_1 = \frac{[MP]}{[M][P]} \quad \text{and} \quad \beta_2 = \frac{[M_2P]}{[M]^2[P]},$$

respectively, eq. (5) can be written as:

$$-\frac{dc}{dt} = k_0[P] + k_1\beta_1[M][P] + k_2\beta_2[M]^2[P] + \cdots. \tag{6}$$

The molar fraction of the free phosphate against the total phosphate concentration c can be written as:

$$\frac{[P]}{c} = \frac{1}{1+\beta_1[M]+\beta_2[M]^2},$$

and eq. (7) can be rewritten as:

$$-\frac{dc}{dt} = \frac{k_0 + k_1\beta_1[M] + k_2\beta_2[M]^2}{1+\beta_1[M]+\beta_2[M]^2}c. \tag{7}$$

The apparent rate constants can be expressed as:

$$k_{obs} = \frac{k_0 + k_1\beta_1[M] + k_2\beta_2[M]^2}{1+\beta_1[M]+\beta_2[M]^2}. \tag{8}$$

This concentration dependence of the rate was investigated for the Al^{3+}-cyclo-hexaphosphate system. The concentration of cyclo-hexaphosphate had to be fixed at 1.25×10^{-4} M to prevent precipitate formation, and the Al^{3+} concentration was varied from 2.5×10^{-4} to 2.5×10^{-3} M. The rate constant variation with the concentration of Al^{3+} for cyclo-hexa- and hexaphosphate is shown in Fig. 6. The rate constant for the cyclic hexamer nearly

Table 3. Activation energies (kcal mol^{-1}) of cyclic and linear phosphate oligomers in the presence and absence of Al^{3+}

	n	3	4	5	6	7	8
Cyclic	no M^{3+}	24.1	27.4	28.4	24.6	25.1	25.3
	Al^{3+}	18.7	18.6	27.3	25.4	23.9	22.5
Linear	no M^{3+}	25.8	26.3	24.0	26.6	21.9	22.9
	Al^{3+}	23.6	21.8	23.6	17.6	17.9	18.3

linearly varied with the Al^{3+} concentration. Assuming that $\beta_1[M] \gg \beta_2[M]^2$, 1 and $k_1\beta_1[M]$, $k_2\beta_2[M]^2 \gg k_0$, eq. (8) can be rewritten as:

$$k_{obs} = k_1 + \frac{k_2\beta_2}{\beta_1}[M]. \quad (9)$$

The linear relation between the rate constant observed and Al^{3+} ion concentration can be qualitatively explained by these assumptions. By contrast the rate for linear hexaphosphate did not vary much with Al^{3+} concentration. In an acidic solution, such as pH 3 for example, the complex formation between Al^{3+} and terminal PO^- groups may be difficult.

(*Received* 1 *October* 1992; *accepted* 18 *December* 1992)

Abstract—Mixed pnicogen and thiolato mononuclear cobalt complexes, $Co(SR)_2(PBu^n_3)_2$ [R = Ph (**1**); R = Stolyl-*p* (**2**)] and $Co(mpo)_2L$ [L = PBu^n_3 (**3**); L = Py (**4**)], have been synthesized and studied spectroscopically. The complexes **1** and **2** are tetrahedral, as determined by magnetic susceptibility studies. The structures of **3** and **4** were determined by X-ray diffraction. The cobalt(II) ions in both **3** and **4** are in a square-pyramidal environment with the two *trans*-oriented mpo ligands in the basal plane and the pnicogen group in the axial position.

Cobalt complexes with mixed pnicogen (phosphine or pyridine) and dithiolene ligands were studied 20 years ago for their interesting spectroscopic features and electron transfer properties.[1–5] Balch[3,4] and Schrauzer[5] have studied the magnetic, electronic and ligand exchange properties of a series of mononuclear dithiolene cobalt complexes containing phosphine ligands PPh_3, PBu^n_3 or $P(OEt)_3$. Some cobalt complexes with a combination of mono-, bi- or tridentate phosphine and mono- or bidentate thiolate ligands have been identified structurally, such as mononuclear $[Co(SPh)_3(PPh_3)]^-$ and $[Co(Stolyl\text{-}m)_2(dppep)]$,[6] $[Co(SPh)_2(dppp)]$ and $[Co(SPh)_2(dppep)]$,[7] $[Co(bdt)_2(PBu^n_3)]^-$,[8] binuclear $[Co_2(SR)_2(\mu\text{-}SR)_2(dppm)]$[9] (R = Ph, tolyl-*m*, -*p*, $C_6H_4Bu^t$-*p*) and $[Co_2(SPh)(\mu\text{-}SPh)_3(dppe)]$,[9,10] and trinuclear $[Co_3(bdt)_3(PBu^n_3)_3]$.[8] In our continuing investigation on the coordination chemistry of cobalt complexes containing mono- or bidentate thiolate and monodentate phosphine ligands, a series of mononuclear complexes (**1–3**) was obtained and the X-ray structure, magnetic and electrochemical properties and ^1H NMR spectra studied. The isolation of complex **4** is an indication that pyridine is a much stronger coordinating ligand than phosphine.

EXPERIMENTAL

Materials and methods

All reactions were performed under an atmosphere of dinitrogen in Schlenk-type apparatus on a vacuum-line. Solvents were dried over molecular sieves, distilled and degassed before use. The reagents $CoCl_2$ (Merck), $Co(OAc)_2 \cdot 4H_2O$ (Merck), PBu^n_3 (Merck), sodium *o*-mercaptopyridine N-oxide (Nampo, Aldrich), PhSH (Fluka) and HStolyl-*p* (Merck) are commercially available. Sodium thiolates were prepared by mixing sodium metal and thiol in dry benzene and isolating the white powder obtained.

Physical measurements were performed on the following instruments: IR, Digilab FTS40 spectrophotometer; ^1H NMR, Varian FT-80A spectrometer; magnetic susceptibility, Gouy-Faraday magnetic balance by the Faraday method; CV, Longjin Model 8511B potentiostat (a platinum-inlay working electrode, platinum-wire auxiliary electrode, S.C.E. reference electrode).

* Author to whom correspondence should be addressed.

Abbreviations: Hmpo: *o*-mercaptopyridine N-oxide; dtpo: 2,2′-dithiobis(pyridine N-oxide); dppep: $\{Ph_2P(CH_2)_2\}_2PPh$; dppp: $Ph_2P(CH_2)_3PPh_2$; dppe: $Ph_2P(CH_2)_2PPh_2$; dppm: $Ph_2PCH_2PPh_2$; H_2bdt: *o*-benzenedithiol; H_2mnt: maleonitriledithiol.

Preparations

Co(SPh)z(PBun3)2 (1). To an MeCN (50 cm3) solution of CoC12 (0.82 g, 6.32 mmol) and NaSPh (1.67 g, 12.64 mmol) was added PBun3 (3 cm3, 12.64 mmol, d = 0.85 g cm- 3) with stirring at room temperature. After 20 h the solution was filtered and the purple filtrate gave 2.3 g (53%) of dark crystals of 1 on standing at 5°C overnight. Found : C, 61.3 ; H, 9.6; Co, 8.5; P, 9.6; S, 9.8. Calc. for C36H64CoP2S2 : C, 63.4; H, 9.4; Co, 8.7; P, 9.1 ; S, 9.4%. IR (KBr): 3050, 2960, 2940, 2870, 1575, 1465, 1080, 1025, 970, 910, 740, 695, 480, 425, 360 cm- 1.

Co(Stolyl-p)2(PBun3)2 (2). To an MeCN (50 cm3) solution of COC12 (0.82 g, 6.32 mmol) and NaStolyl-p (1.83 g, 12.64 mmol) was added PBun3 (3 cm3, 12.64 mmol) slowly with stirring at room temperature. After stirring for 20 h and filtration the purple solution gave 2.1 g (46.9%) of dark crystals of 2 on standing at 5°C overnight. Found : C, 64.3 ; H, 9.8; Co, 8.0; P, 8.8; S, 9.8. Calc. for C38H68CoP252 : C, 64.3 ; H, 9.7 ; Co, 8.3 ; P, 8.7 ; S, 9.0%. IR (KBr): 3040, 2960, 2940, 2870, 1590, 1485, 1460, 1090, 1020, 970, 910, 810, 720, 630, 490, 395, 340 cm- 1.

Co(mpo)EPBun3 (3). To an EtOH (40 cm3) solution of COC12 (0.09 g, 0.69 mmol) was added, with stirring at room temperature, a mixture of dtpo (0.175 g, 0.69 mmol), sodium metal (0.032 g, 1.39 mmol) and PBun3 (0.32 cm3, 1.28 mmol) in EtOH (10 cm3). The solution turned reddish-brown immediately, which was filtered and the filtrate gave block-shaped dark crystals of 3 (yield 63%) on standing at 5QC for several days. After isolation of 3 the mother liquor on prolonged standing gave plate-shaped dark red crystals of Co(mpo)3, which was identified by comparison of its IR spectrum with the known compound, 11 showing the oxidation ofcobalt(II) to cobalt(III). Found: C, 50.9 ; H, 7.1; Co, 11.5; N, 5.3; P, 6.1. Calc. for C22H35CoNzO2PS2: C, 51.5 ; H, 6.9; Co, 11.5 ; N, 5.5; P, 6.0%. IR (KBr): 3089, 3066, 3022, 2955, 2928, 2866, 1598, 1538, 1455, 1414, 1187, 1156, 1144, 1086, 824, 781,705,602, 569, 457, 350 cm-1.

Co(mpo)aPy (4). To a stirred MeCN (40 cm3) solution of Co(OAc)2 •4H20 (0.25 g, 1.0 mmol) was added first pyridine (0.08 cm3, 1.0 mmol) and then an MeOH (10 cm3) solution of Nampo (0.30 g, 2.0 mmol) at room temperature. After standing at 5°C for 2 weeks the dark plate-like crystalline product of 4 separated, together with some unreacted Co(OAc)2 which was detected from its red colour. This crude product was filtered and washed with MeOH twice (10 cm3) to give the pure complex 4 (yield 10%). Found: C, 45.9; H, 2.9; Co, 15.7; N, 10.0. Calc. for C15H13CoN3OzS2: C, 46.2; H, 3.4; Co, 15.1; N, 10.8%. IR (KBr): 3097-3012 (six peaks), 1596, 1538, 1456, 1441, 1411, 1216, 1182, 1159, 1136, 1088, 1066, 824, 767, 748, 705,635,611, 571,520, 447, 429, 353 cm- 1.

Crystal structure determinations

The crystallographic data and data collection parameters for complexes 3 and 4 are summarized in Table 1. Single crystals were coated with epoxy resin and mounted on the Rigaku AFC5R diffractometer for data collection with Mo-K, radiation. After data reduction, including correction for Lorentz and polarization effects, the remaining unique reflections with I > 3o-(1)were used for subsequent structure solution and refinement. The structures were solved by direct methods and successive Fourier syntheses and refined by full-matrix least-squares procedures with anisotropic thermal parameters for all the non-hydrogen atoms. The hydrogen atoms were added only to the structure-factor calculations but not refined. All calculations were performed on a VAX 11/785 computer with the SDP program package.

RESULTS AND DISCUSSION

Synthesis

It was found that monodentate thiolate substituted mononuclear cobalt(II) complexes with bi- or tridentate phosphine ligands are more stable than those with monodentate phosphines, since many complexes6.7.9,10 of the former type have been characterized structurally while only one complex of the latter type has been reported. 6This unique complex, (Et4N)[Co(SPh)3(PPh3)], was obtained by reaction of CoC12 with NaSPh and PPh3 in the ratio 1 : 3 : 1.6 When a ratio of 1:2:2 for CoC12:NaSPh (or NaStolyl-p) :PBun3 was employed the reaction in MeCN led to the complex Co(SPh)2(PBun3)2 (1) or Co(Stolyl-p)ffPBun3)2 (2), which was identified by elemental analysis, IR and 1H NMR. Due to the extreme air-sensitivity of the single crystals of 1 and 2 for X-ray diffraction study the bidentate ligalad o-mercaptopyridine-N-oxide was employed and complexes ofpenta-coordination can be obtained which are much more stable than the tetra-coordinated ones. With a molar ratio of 1: 1:2 for the starting materials Co2+:dtpo:PBun3 the complex Co(mpo)aPBun3 (3) was obtained, where dtpo was decomposed heterolytically by the neocleophilic attack of the methoxide ion present in solution on the S--S bond to give the anionic ligand mpo-. The complex Co(mpo)2Py (4) was isolated instead when

under the same reaction conditions a trace of pyridine was added, showing the stronger coordination ability of the pyridine molecule. Complex 4 can also be prepared with a Co 2+ : dtpo : Py ratio of 1 : 2 : 1. The amount ofpyridine has to be limited to less than 1mol since if an excess ofpyridine was employed the complex Co(mpo)2Py2 forms immediately, which can be identified by the appearance of proton peaks corresponding to mpo and py in the ratio of 1 : **1 in** the ~H NMR spectrum. Facile formation of the mono- and bis-pyridine adducts of [Co(mnt)2] 1 ,2 has been reported.

Structure

Single-crystal X-ray diffraction studies have been performed on complexes 3 and 4. Tables 2 and 3 give the selected atomic distances and bond angles for complexes 3 and 4, respectively. Figures 1 and 2 depict the ORTEP structures of 3 and 4, respectively. A comparison of related structural data with other mpo substituted complexes ~-~3 is shown in Table 4. There are two discrete molecules of 4 in an asymmetric unit.

Molecules of both 3 and 4 contain a square-pyramidally coordinated cobalt atom chelated by two *trans-oriented* mpo ligands in the basal plane and a neutral pnicogen molecule, PBUn3 or Py, in the axial position. The Co--S and Co--O bonds in both complexes 3 and 4 are in the ranges 2.36-2.40 and 1.96-2.02 ~, respectively, which are all longer than those in the six-coordinate Co(mpo)3 (average 2.194 and 1.933 /~).11 The N--O bond changes neither with the coordination number nor with the type of central atom of the complexes and is maintained in the range 1.34-1.35 ~, whilst the average S--C bonds are in the range 1.70-1.72/~ for the complexes listed in Table 4 with the shortest values for complexes 3 and 4, agreeing with the fact that the thione form is the predominant coordination mode of mpo :~3

0 **OH**

Thiol **Thione**

Thus, this results in the shortening of the C--S bond compared to the normal covalent distance (1.81 /~)14 for a single bond. The Co--P distance of 2.424 A in 3 is so far the longest observed in cobalt-phosphine complexes,6-10,~5,~6 implying the weak bonding and easy dissociation of PBun3,

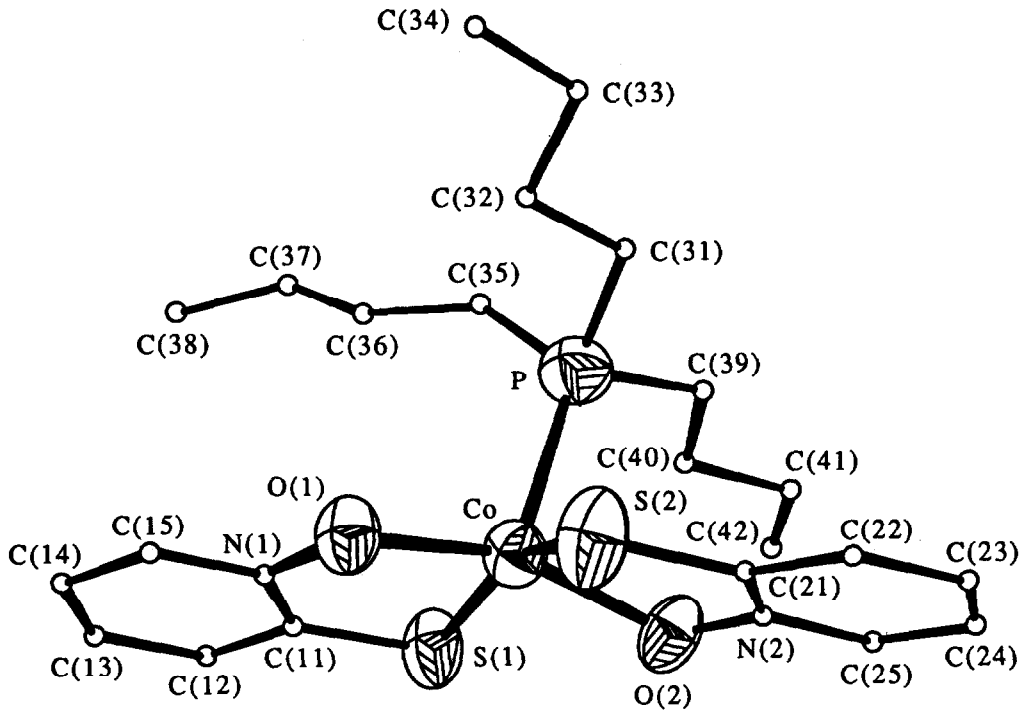

Fig. 1. ORTEP structure of the complex $Co(mpo)_2PBu^n_3$ (**3**) with the carbon atoms represented by arbitrary spheres for clarity.

which agrees well with the ^1H NMR data (see below).

The bite angles S_n—Co—O_n (average 83.2°) for the *trans*-coordinated mpo ligands in complexes **3** and **4** are obviously smaller than those in $Co(mpo)_3$[11] (88.0°) or $Ni(mpo)_2$[13] (89.6°), where the mpos are in *facial* (S_n—Co—S_m 91.2°) or *cis* conformations (S_n—Co—S_m 92.8°), respectively, but comparable to that in $Fe(mpo)_3$[12] (S_n—Co—O_n 81.1°; S_n—Co—S_m 167.7°) in which the mpo ligands are *meridionally* oriented. This result may indicate the fact that the S···S interaction, when

the sulphur atoms are in nearby positions, expands the bite angle by drawing electrons away from the chelate ring. Both Co--S--C (average 95.6°) and Co--O--N (average 118.7°) angles within the five-membered chelate ring Co--O--N--C--S are within the normal ranges 13for the sulphur and oxygen donor atoms to employ mainly p and *sp2*hybrid orbitals for bonding, respectively.

Spectroscopic studies

The IR spectra of complexes 1 and 2 are quite similar to each other, except for the C--H out-of-plane bending absorptions of the benzene ring. Two peaks at 740 and 698 cm- ~are characteristic for the mono-substituted phenyl group in complex 1, while the p-tolyl group in complex 2 gave only one absorption at 810 cm ~for the 1,4-disubstituted phenyl ring. Complex 3 showed an absorption at 1144 cm- ~with a shoulder at 1156 cm- ~for S--C bonds, which appeared as two strong bands at 1136 and 1159 cm-1 for complex 4. These absorptions are indications of partial kS double bond character, as compared with the free ligand Hmpo (1142 cm-1) which has been established by Jones t7 to be predominantly in the thione form. The appearance of a set of three peaks in the region 2960-2870 cm- in complexes 1-3 is a clear indication of the presence of the PBun3 group. The C--H stretching vibrations of the mpo ligand appear in the range 3100-3020 cm- ~in complexes 3 and 4 and the Co--S absorptions appear at 457 and 350 cm- ~(3) and 447 and 353 cm i (4).

The 1H NMR data at room temperature of complexes 1~4 are listed in Table 5, where the paramagnetism of the complexes is clearly shown by the large chemical shifts. Contact contributions to the chemical shifts are shown by signals with alternating signs for the *meta-* and *para-protons* of the phenyl groups: 29.74 and -48.88 ppm, respectively, in the ratio 2:1 for complex 1, while the *ortho-proton* signals are too broad to be detected. In the meantime, complex 2 showed the same result of contact interaction where methyl substitution in the *para-position* for the tolyl-p group alternates the sign of the p-proton to give a signal at 52.92 ppm, with the m-protons appearing at 29.89 ppm. Complexes 3 and 4 showed very similar chemical shifts for the mpo ligands, yet the fate of the pnicogen ligands is quite different in the solvent DMSO. The spectrum showed the dissociation of PBun3 for 3 as the chemical shifts of 0.98 and 1.50 ppm are close to those for the free ligand. 8 The pyridine ligand in 4 showed completely different chemical shifts as compared with the free molecule (8.5, 7.35 and 7.0 for ~-, r- and ~-H, respectively)~ 18 with the signal for a-protons near 20 ppm buried under the peaks of Hc of mpo (see Table 5 for proton assignment). These data indicate the strong affinity of pyridine with the central Co 2÷ ion as compared to phosphine.

Physical-chemical properties

All the complexes are paramagnetic. The magnetic moments of I and 2 at room temperature are

4.40 and 4.54 μ_B, respectively. These values being higher than the calculated spin-only value of 3.87 μ_B for a high spin state $S = 3/2$ for cobalt(II) show that there is a certain degree of orbital contribution to the magnetic moment.[19–21] Knowing that tetrahedral $[Co(SR)_4]^{2-}$[22] possesses a solid moment of 4.6 μ_B[23] and comparing with a series of reported phosphine substituted cobalt(II) complexes with tetrahedral structures and magnetic moments in the range 4.41–4.63 μB,[21] the tetrahedral geometry

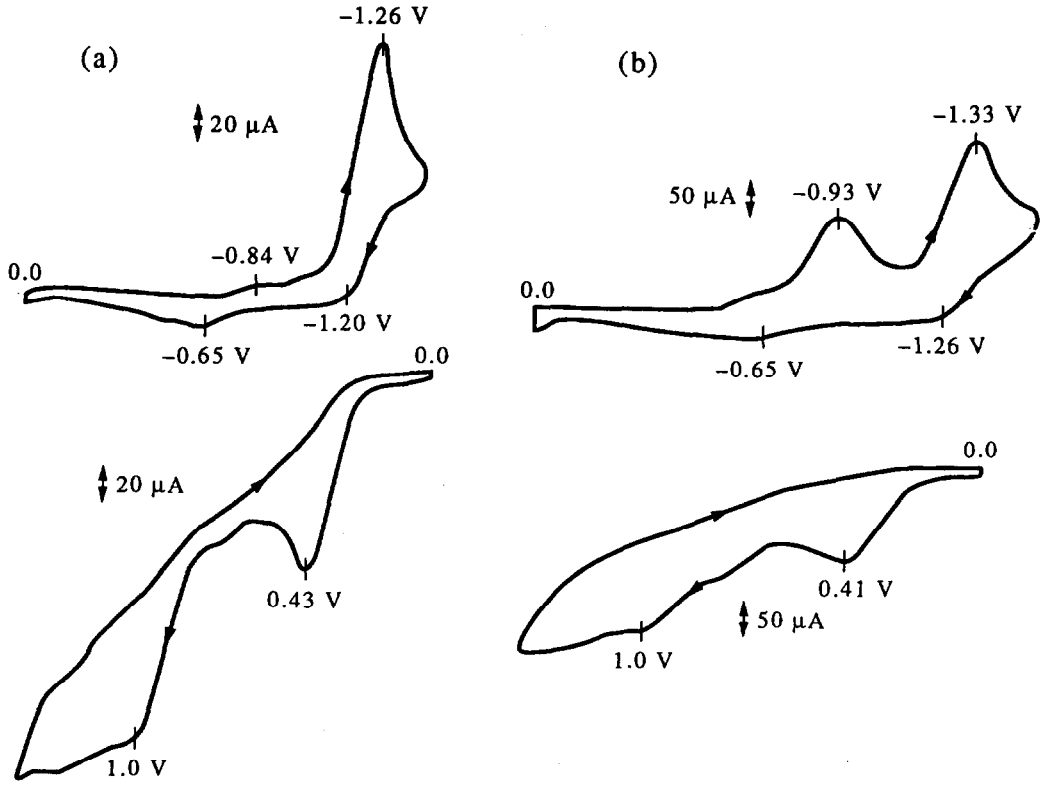

Fig. 3. Cyclic voltammograms of (a) complex **1** and (b) complex **2** in MeCN vs S.C.E. at a scan rate of 100 mV s^{-1} at room temperature.

of the cobalt atom in complexes 1 and 2 can be deduced. Their X-ray single-crystal structure determinations await low temperature facilities. The effective magnetic moment of 3.77 #~ for complex 3 corresponds to a spin-only state of S = 3/2 for the cobalt(II) ion.

The cyclic voltammograms of complexes 1 and 2 were measured in MeCN in the range 1.5 to - 1.5 V, either reductively or oxidatively. Both complexes showed two quasi-reversible reduction waves and two irreversible oxidation waves, as shown in Fig. 3. It is believed that in addition to the reduction (- 1.26 and - 1.33 V) or oxidation (0.43 and 0.41 V) of the complexes (3 and 4, respectively), the ligands also engaged in redox processes within the applied potentials. The waves near 1.0 V account for the oxidation of the thiolates.

(*Received* 30 *September* 1992; *accepted* 18 *December* 1992)

Abstract—The complexes Li(1-nqo)·1/2EtOH, Li(1-nqo)(1-nqoH)·EtOH (1-nqoH = 1,2-naphthaquinone-1-oxime), and Li(2-nqo)·1/2EtOH, Li(2-nqo)(2-nqoH)·EtOH (2-nqoH = 1,2-naphthaquinone-2-oxime), were prepared by the interaction of the quinone oxime with lithium hydroxide. The structure of Li(1-nqo)(1-nqoH)·EtOH was determined by single-crystal X-ray diffraction techniques. The lithium atom is penta-coordinated in a distorted square pyramidal environment.

The study of the synthesis, structure and applications of transition and actinide metal complexes derived from the mono-oximes of 1,2-naphthaquinone and several 1,2-benzoquinone mono-oximes has attracted considerable attention.[1–7] The preparation of the complexes Li(1-nqo) (1-nqoH = 1,2-naphthaquinone-1-oxime), Li(2-nqo)(2-nqoH) (2-nqoH = 1,2-naphthaquinone-2-oxime) and of related sodium, potassium, caesium and rubidium complexes has been described, but there is only limited information on their properties and structure.[8–11] As a continuation of our interest in quinoneoximato complexes we now report on the synthesis, properties and structure of several naphthaquinoneoximato complexes of lithium and on the X-ray crystallographic study of Li(1-nqo)(1-nqoH)·EtOH.

EXPERIMENTAL

Elemental analyses were performed by the Microanalytical Laboratory of the University of North London. IR spectra were recorded as KBr discs on a Perkin–Elmer 781 spectrophotometer.

Preparation of the lithium complexes

[Li(1-nqo)·1/2EtOH]. To a suspension of $LiOH \cdot H_2O$ (1.30 g, 31.0 mmol) in ethanol (40 cm^3) was added a solution of 1-nqoH (5.35 g, 31.0 mmol) in ethanol (125 cm^3) portionwise. The reaction mixture was heated on a water bath for 0.5 h and then filtered hot. After slow evaporation of the filtrate the dark green crystalline product was filtered off, washed with ethanol and light petroleum and dried at 40°C/1.0 mm Hg. Yield: 5.15 g, 82%. Found: C, 64.9; H, 5.1; Li, 3.6; N, 6.7. Calc. for $C_{22}H_{18}Li_2N_2O_5$: C, 65.4; H, 4.5; Li, 3.4; N, 6.9%.

[Li(2-nqo)·1/2EtOH]. Similarly, and by using 2-nqoH, the brown complex resulted in 93% yield. Found: C, 64.8; H, 5.0; Li, 3.5; N, 6.2. Calc. for $C_{22}H_{18}Li_2N_2O_5$: C, 65.4; H, 4.5; Li, 3.4; N, 6.9%.

[Li(1-nqo)(1-nqoH)·EtOH]. To a suspension of LiOH (0.30 g, 12.5 mmol) in ethanol (45 cm^3) was added solid 1-nqoH (4.30 g, 25 mmol) portionwise and the resultant mixture was heated on a water bath for 0.5 h and then filtered hot. After slow evaporation of the filtrate the green crystalline product was filtered off, washed with ethanol and dried at 40°C/1.0 mm Hg. Yield: 2.27 g, 45%. Found: C, 65.9; H, 5.0; Li, 1.8; N, 7.4. Calc. for $C_{22}H_{19}LiN_2O_5$: C, 66.3; H, 4.8; Li, 1.7; N, 7.0%.

[Li(2-nqo)(2-nqoH)·EtOH]. Similarly and by using 2-nqoH the light brown complex resulted in 78% yield and was recrystallized from methanol. Found: C, 66.3; H, 4.2; Li, 1.8; N, 7.4. Calc. for $C_{22}H_{19}LiN_2O_5$: C, 66.3; H, 4.8; Li, 1.7; N, 7.0%.

Pyrolysis of the lithium complexes

Li(1-nqo)·1/2EtOH (4.0814 g) was heated at 110–120°C/1.0 mm Hg for 30 h to give green Li(1-nqo) (3.5603 g, 98%). Found: C, 66.9; H, 3.8; Li, 3.9; N, 7.5. Calc. for $C_{10}H_6LiNO_2$: C, 66.1; H, 3.4; Li, 3.9; N, 7.8%. Using the same method Li(2-nqo)·1/2EtOH (6.1440 g) gave light brown Li(2-nqo) (5.3849 g, 99%). Found: C, 66.8; H, 3.7; Li, 3.7; N, 7.6. Calc. for $C_{10}H_6LiNO_2$: C, 67.1; H, 3.4; Li, 3.9; N, 7.8%. Similarly Li(1-nqo)(1-nqoH)·EtOH (4.9929 g) gave light green Li(1-nqo)(1-nqoH) (4.4020 g, 99%). Found: C, 68.4; H, 4.0; Li, 1.9; N, 7.5. Calc. for $C_{20}H_{13}LiN_2O_4$: C, 68.2; H, 3.4; Li, 2.0; N, 7.9%. Li(2-nqo)(2-nqoH)·EtOH (6.3449 g) gave brown Li(2-nqo)(2-nqoH) (5.5784 g, 99%). Found: C, 68.0; H, 4.0; Li, 1.8; N, 7.6. Calc. for $C_{20}H_{13}LiN_2O_4$: C, 68.2; H, 3.4; Li, 1.9; N, 7.9%.

Crystal data

$C_{22}H_{19}LiN_2O_5$, $M = 398.35$. Orthorhombic, $a = 18.839(3)$, $b = 14.170(3)$, $c = 7.390(2)$ Å, $\alpha = \beta = \gamma = 90°$, $V = 1972.75$ cm^3, $\lambda = 0.71069$ Å, space group $P2_12_12_1$, $Z = 4$, $D_c = 1.34$ g cm^{-3}. Green, rhombic-like crystals. Crystal dimensions $0.32 \times 0.12 \times 0.12$ mm, μ(Mo-K_α) = 0.50 cm^{-1}.

Data collection and processing

A Phillips PW1100 four-circle diffractometer with a graphite monochromator, using Mo-K_α radiation, was employed; θ–2θ scan, 0.05° s^{-1}, $2\theta_{max} = 50°$ for the range $0 \leqslant h \leqslant 24$, $0 \leqslant k \leqslant 18$, $0 \leqslant l \leqslant 10$; three reflections monitored every 200 min with no significant variation. 1998 unique reflections, 716 observed with $I > 3\sigma(I)$. Corrections were made for Lorentz–polarization factors, but not for absorption.

Structure analysis and refinement

The structure was solved by direct methods and all non-hydrogen atoms were located. All the hydrogen atoms were included in structure-factor calculations with fixed isotropic thermal parameters of 0.08 Å^2, but were not refined. The nitrogen and oxygen atoms were assigned anisotropic thermal parameters in the refinement of the structure by a full-matrix least-squares procedure, which converged to $R = 0.056$ ($R = \Sigma|F_o - F_c|/\Sigma|F_o|$). $R_w = 0.053$ ($R_w = \Sigma|F_o - F_c|w^{1/2}/\Sigma|F_o|w^{1/2}$), with a weight of $w = 1/\sigma^2(F_o)$, applied to individual reflections. A final difference-Fourier showed a maximum height of 0.18 e Å^{-3}. Neutral atomic scattering factors and anomalous dispersion corrections were from the International Tables for X-ray Crystallography (1974); all calculations were performed using the SHELX76 Crystallographic Package (Sheldrick 1976).

RESULTS AND DISCUSSION

The reactions of 1,2-naphthaquinone-1-oxime with lithium hydroxide in 1 : 1 and 2 : 1 molar ratios were investigated in ethanol under reflux. The 1 : 1 reaction afforded the complex Li(1-nqo)·1/2EtOH, while the 2 : 1 reaction gave Li(1-nqo)(1-nqoH)·EtOH. Similarly, the reactions of 1,2-naphthaquinone-2-oxime with lithium hydroxide in 1 : 1 and 2 : 1 molar ratios gave Li(2-nqo)·1/2EtOH and Li(2-nqo)(2-nqoH)·EtOH, respectively.

Macro-scale pyrolysis showed that ethanol (1/2 mol mol^{-1} adduct; 1 mol mol^{-1} adduct) was lost between 80 and 130°C for the complexes Li(1-nqo)·1/2EtOH and Li(1-nqo)(1-nqoH)·EtOH, respectively, to give the unsolvated species Li(1-nqo) and Li(1-nqo)(1-nqoH).

All the complexes are highly coloured, involatile solids, fairly soluble in acetone, pyridine and ethanol but insoluble in toluene. They are stable in air, in the solid state and in solution (both in water and organic solvents), but decompose in aqueous acids.

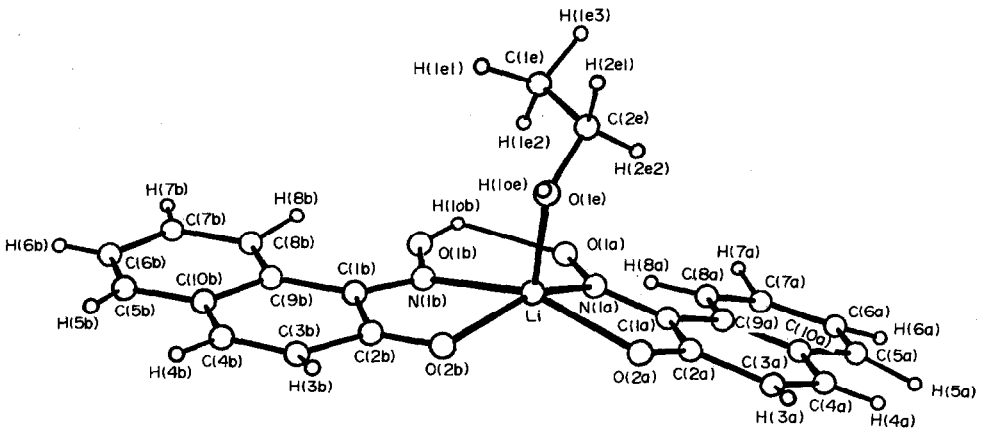

Fig. 1. A view of Li(1-nqo)(1-nqoH)·EtOH, with the atomic numbering scheme.

In all cases the IR spectra exhibit strong bands at 1618–1500 cm^{-1}, which are characteristic of chelated quinoneoximato ligands. Conductance measurements at 25°C in ethanol indicate that dissociation is inappreciable and suggest covalent character. In the case of Li(1-nqo)(1-nqoH)·EtOH the suggested covalent character and the mode of bonding in the ligands has been confirmed by an X-ray crystallographic study.

Crystal structure of Li(1-nqo)(1-nqoH)·EtOH

The lithium atom is penta-coordinated in a distorted square-pyramidal environment with two chelating ligands at the base and an ethanol molecule at the apex. A view of the molecule with the atomic numbering scheme is shown in Fig. 1. Selected bond lengths and angles are given in Tables 1 and 2, respectively.

In this complex both the 1-nqo and protonated 1-nqoH ligands are quinoneoximic in character and are chelated to the metal via the NO and CO groups. The quinoneoximic character of these ligands is indicated by the short C(3)—C(4) and long C(1)—C(2) bond distances. An analogous situation has been found in the free 1,2-naphthaquinone-2-oxime [C(3)—C(4) 1.327(6), C(1)—C(2) 1.484(6) Å][12] and in transition metal quinone-oximato complexes in general.[1,2,5] As in the case of transition complexes the chelate ring is five-membered and the NO group is bonded to the metal via the nitrogen. Both the metal–oxygen and metal–nitrogen bond lengths in Li(1-nqo)(1-nqoH)·EtOH are short [2.033(22)–2.198(23) Å] and compare well to those found in other covalently chelated transition metal complexes [1.951(4)–2.100(3) Å].[1,2,5] In contrast, in K(Clqo)·1/2H_2O (ClqoH = 4-chloro-1,2-benzoquinone-2-oxime) the ligand is bidentate but non-chelating and the NO group bonds to the metal via the oxygen atom.[11] In this compound the metal–

		C(2b)—O(2b)—Li	116(1)

oxygen bond lengths are rather long [2.728(4)-2.859(3) A] and it has been suggested that this is due to the presence of considerable ionic character.

In Li(1-nqo)(1-nqoH)-EtOH the NO groups of the two chelating ligands are in a *cis* arrangement. This contrasts the *trans* arrangement, which is shown by other chelated quinoneoximato complexes, 13,14 and can be correlated to the formation of an asymmetrical hydrogen bond between the neutral and anionic ligands of the lithium complex. The hydrogen atom is positioned 0.84 ~ from the oxygen of the neutral ligand and 1.90 A from the oxygen of the formally anionic ligand. Such an asymmetrical hydrogen bridge at 0.72(6) ,~ from the NO oxygen and at 1.88(6)/~ from the carbonyl oxygen is also found in the protonated free ligand. ~2 A similar hydrogen bridge has also been suggested for bis(salicylaldoximato)nickel(II). 15

In Li(1-nqo)(1-nqoH)" EtOH the ~netal attains a coordination number of five and a distorted square-pyramidal geometry through the attachment of an ethanol molecule. Penta-coordinated lithium has been found in several other complexes, mainly those of crown ethers. 16In Li(1-nqo)(1-nqoH) •EtOH the distance of lithium from the oxygen atom of the ethanol molecule is 1.923(24) ~ and compares well with those found in other penta-coordinate/square-pyramidal lithium solvated complexes *(ca* 1.91-1.96 **A). 16**

(*Received* 23 *November* 1992; *accepted* 30 *November* 1992)

Abstract—Nitrosation of 3-acetylaminophenol in the presence of the appropriate metal(II) chloride or $Na_3[Co(NO_2)_6]$ has led to the complexes $M(5\text{-Acqo})_2 \cdot nH_2O$ (M = Ni, $n = 6$; Cu, $n = 0$), $Mn(5\text{-Acqo})_3 \cdot H_2O$, $Na[Fe(5\text{-Acqo})_3]$ and $Na[Co(5\text{-Acqo})_2(NO_2)_2]$ (AcqoH = 5-acetylamino-1,2-benzoquinone-2-oxime). $Co(5\text{-Acqo})_3$ resulted from the reaction of 5-AcqoH with $CoCl_2 \cdot 6H_2O$. The reaction of $M(5\text{-Acqo})_2$ with pyridine and 2,2′-dipyridine afforded the adducts $M(5\text{-Acqo})_2(py)_2$ and $M(5\text{-Acqo})_2(dipy)$, respectively. Solution electronic spectra and magnetochemical studies indicated octahedral geometries for all complexes prepared, except $Cu(5\text{-Acqo})_2$. ^1H NMR and/or ^{13}C NMR studies indicated that $Co(5\text{-Acqo})_3$ exists as a mixture of the *meridional* and *facial* isomers, whereas the anion in $Na[Fe(5\text{-Acqo})_3]$ is entirely in the *meridional* form.

The study of quinone mono-oximes and especially of their metal complexes is currently receiving much attention.[1–3] Our continuing interest in such compounds is related to their potential in organic synthesis and their application in metal extraction and the treatment of metal overload. Here we report on the preparation and characterization of copper(II), nickel(II), iron(II), cobalt(III) and manganese(III) complexes of 5-acetylamino-1,2-benzoquinone-2-oxime.

EXPERIMENTAL

Elemental analyses were performed on a Carlo–Erba 1106 microanalytical instrument at the Polytechnic of North London. Metals were determined by atomic absorption using a Pye–Unicam SP9 atomic absorption spectrometer. Wet oxidation of the complex was achieved by heating the complex in concentrated nitric acid and 30% hydrogen peroxide. IR spectra in the 4000–400 cm^{-1} region were recorded on a BIO-RAD FTS40 spectrometer and the samples were prepared as pressed potassium discs. Fourier-transform ^1H and ^{13}C NMR spectra were recorded on a Bruker AM250 or a Joel 270 and 500 MHz spectrometer. Trimethylsilane was used as a reference standard for the spectra recorded in d_6-dimethylsulphoxide. UV–vis spectra in the 900–190 nm region were obtained using a Shimadzu UV-2100 spectrometer. Magnetic susceptibilities were recorded at room temperature using a Johnson–Matthey magnetic susceptibility balance. The instrument was calibrated using a solution of manganese(II) chloride. The magnetic susceptibility values were corrected for the diamagnetic effects of the metal and the ligands. A thermal gravimetric analysis was carried out on a Stanton HT-SM thermobalance. The mass spectra were obtained using a Kratos Profile spectrometer.

Preparation of copper(II), *nickel*(II), *manganese*(III) *and cobalt*(III) *complexes of 5-acetylamino*-1,2-*benzoquinone 2-oxime by nitrosation of 3-acetylaminophenol*

3-Acetylaminophenol (8 g, 50 mmol) in methanol (50 cm^3) was added to a solution of the hydrated metal(II) chloride or sodium hexanitrocobaltate (III) (25 mmol), acetic acid (15 cm^3) and sodium acetate trihydrate (15.0 g) in water (75 cm^3).

Pyrolysis of bis(5-acetylarnino-1,2-benzoquinone-2-oximato)nickel(II) hexahydrate

Bis(5-acetylamino-1,2-benzoquinone-2-oximato)nickel(II) hexahydrate (1.1176 g) was heated at 0.1 mm/100-120°C (2 h) to give bis(5-acetylamino-1,2-benzoquinone-2-oximato)nickel (II) (0.8876 g, 100%); m.p. 250-260°C (decomposition). Found: C, 45.5; H, 4.0; N, 14.0; Ni, 14.1. Calc. for CI6HlaNaNiO6 : C, 46.0; H, 3.4; Ni, 14.0; N, 13.5%.

Nitrosation of 3-acetylaminophenol in the presence of ammonium iron(II) sulphate hexahydrate

Sodium nitrite (1.4 g, 20 mmol) in water (20 cm3) was added dropwise with stirring to a solution of ammonium iron(ll) sulphate hexahydrate (3.0 g, 7.5 mmol), 3-acetylaminophenol (2.3 g, 15 mmol), acetic acid (4.5 cm3) and sodium acetate in ethanol/water (1:1) (60 cm3) at 0°C. The mixture was set aside at 20°C for 72 h and then filtered to obtain a dark green solid (2.5 g), which was chromatographed on silica gel. Elution with ethyl acetate gave 3-acetylamino-l,4-benzoquinone-4-oxime (0.3 g, 10%). Elution with methanol gave sodium tris(5-acetylamino-1,2-benzoquinone-2-oximato)-ferrate(II) tetrahydrate (1.4 g, 50%). Found: C, 41.7; H, 4.3; Fe, 8.2; Na, 3.1; N, 12.0. Calc. for C24H29FeNaN6OI3 : C, 41.9; H, 4.2; Fe, 8.1 ; Na, 3.3; N, 12.2%. Pyridine was then added to the chromatography column. Elution with methanol after 1 h yielded bis(5-acetylamino-l,2-benzoquinone-2-oximato)(dipyridine)iron(II) (0.7 g, 20%). Found: C, 54.9; H, 4.3; Fe, 9.6; N, 14.7. Calc. for C26H24FeN606 : C, 54.6 ; H, 4.2 ; Fe, 9.8 ; N, 14.7%.

Direct reaction of 5-acetylamino-l,2-benzoquinone-2-oxime with cobalt(II) chloride hexahydrate in aqueous acetic acid

To a solution of cobalt(II) chloride hexahydrate (1.6 g, 5 mmol) in acetic acid-water (50 cm3, 1 : 1) was added 5-acetylamino-l,2-benzoquinone-2-oxime (3.2 g, 18 mmol) with stirring (3 h). Filtration of the mixture afforded red tris(5-acetylamino-1,2-benzoquinone-2-oximato)cobalt(III) (2.5 g, 85%);

Table 2. Analytical data and yields for pyridine and 2,2′-dipyridine adducts

Adduct	Yield (%)	Found (%) (Calc.) C	H	M	N
$Ni(5\text{-}Acqo)_2(py)_2$	90	54.2 (54.3)	4.3 (4.2)	9.8 (10.3)	14.5 (14.6)
$Ni(5\text{-}Acqo)_2(dipy)$	95	54.7 (54.5)	3.9 (3.8)	10.1 (10.3)	14.7 (14.7)
$Cu(5\text{-}Acqo)_2(py)_2$	90	53.9 (53.8)	4.1 (4.1)	10.8 (11.0)	14.8 (14.5)
$Cu(5\text{-}Acqo)(dipy)_2$	95	54.0 (54.0)	3.8 (3.8)	10.4 (11.1)	14.6 (14.6)

m.p. 290–300°C (decomposition). Found: M^+, 597; C, 47.9; H, 3.9; Co, 9.9; N, 14.0. Calc. for $C_{24}H_{21}CoN_6O_9$: M, 597; C, 48.3; H, 3.5; Co, 9.9; N, 14.1%. The filtrate was washed with water (4×100 cm^3), diethyl ether (4×100 cm^3) and then dried at 0.1 mm/20°C.

Interaction of $M(5\text{-}Acqo)_2 \cdot nH_2O$ *with pyridine*

$M(5\text{-}Acqo)_2 \cdot nH_2O$ (M = Ni, $n = 6$; M = Cu, $n = 0$) (1.2 mmol) and pyridine (0.6 mmol) were stirred in acetone (40 cm^3) (24 h). Dropwise addition of the resultant viscous solution to light petroleum (b.p. 30–40°C; 100 cm^3), followed by filtration gave bis(5-acetylamino-1,2-benzoquinone-2-oximato)bis(pyridine)metal(II), which was washed with light petroleum (b.p. 30–40°C; 3×50 cm^3) and dried at 20°C/0.1 mm (see Table 2 for yield and analytical data).

Interaction of $M(5\text{-}Acqo)_2 \cdot nH_2O$ *with 2,2′-dipyridine*

$M(5\text{-}Acqo)_2O \cdot nH_2O$ (M = Ni, $n = 6$; M = Cu, $n = 0$) (10 mmol) and 2,2′-dipyridine (5 mmol) were stirred in acetone (70 cm^3) (24 h). Filtration gave a solid residue, which was washed with acetone (3×25 cm^3) and dried at 0.1 mm/20°C to give bis-(5-acetylamino-1,2-benzoquinone-2-oximato)(2,2′-dipyridine)metal(II) (see Table 2 for yield and analytical data).

RESULTS AND DISCUSSION

The complexes $M(5\text{-}Acqo)_2 \cdot nH_2O$ (M = Cu, $n = 0$; Ni, $n = 6$) listed in Table 1 have been obtained in high yield by nitrosating 3-acetylaminophenol with sodium nitrite/acetic acid in the presence of the respective metal chloride. The analogous reaction involving manganese(II) chloride afforded the manganese(III) complex $Mn(5\text{-}Acqo)_3 \cdot H_2O$. Nitrosation reactions performed in the presence of ammonium iron(II) sulphate led to the formation of a mixture of the iron(II) complexes, $Fe(5\text{-}Acqo)_2$ and $Na[Fe(5\text{-}Acqo)_3]$, the former of which was separated from the mixture in the form of its dipyridine adduct $Fe(5\text{-}Acqo)_2(py)_2$.

Previous studies have indicated that nitrosation of 1-naphthol or 2-naphthol in the presence of cobalt(II) chloride leads to the formation of a mixture of cobalt(III) complexes of the type $Co(nqo)_3$ and $Na[Co(nqo)_2(NO_2)_2]$ [nqoH = 1-nqoH (1,2-naphthoquinone-1-oxime) or 2-nqoH (1,2-naphthoquinone-2-oxime)].[4] In contrast this study has shown that the analogous reaction with 3-acetylaminophenol leads to a mixture of 3-acetylamino-1,4-benzoquinone-4-oxime and a black diamagnetic cobalt containing product which could not be characterized. However, the complex $Co(5\text{-}Acqo)_3$ was successfully prepared by the direct reaction of 5-acetylamino-1,2-benzoquinone-2-oxime with cobalt(II) chloride hexahydrate in aqueous acetic acid. The synthesis of $Na[Co(5\text{-}Acqo)_2(NO_2)_2]$ was achieved by the nitrosation of 3-acetylaminophenol in the presence of sodium hexanitrocobaltate(III).

The complexes $Cu(5\text{-}Acqo)_2$ and $Ni(5\text{-}Acqo)_2 \cdot 6H_2O$ reacted readily with pyridine to give adducts of the type $M(5\text{-}Acqo)_2(py)_2$ (Table 2). In the case of the copper complex the formation of the di-adduct is novel, as in all previous reactions involving complexes of the type $Cu(qo)_2$ and pyridine only the formation of the monoadduct has been reported.[5] The complexes also reacted readily with 2,2′-dipyridine to give adducts of the type $M(5\text{-}Acqo)_2(dipy)$ (Table 2).

Thermal gravimetric analyses (Table 3) of $Ni(5\text{-}Acqo)_2 \cdot 6H_2O$ and $M(5\text{-}Acqo)_2(py)_2$ (M = Cu or Ni) and macroscale pyrolysis of the former showed that quantitative loss of water or pyridine occurs

below 200°C, followed by decomposition of the resultant M(5-Acqo)2 at *ca* 250°C.

In the protonated ligand, 5-AcqoH, v(CO) of the ring quinone group appears at *ca* 1640 cm-t whereas a strong band at *ca* 1600 cm- 1, assignable to v(CO) of the ring quinone group, is shown by all complexes (Table 4). The observed shift to lower frequency in the complexes suggests that the ring CO group is involved in bonding to the metal.

The solution electronic spectra of all complexes reported are similar and as with other quinone oximic complexes show intense ~tbsorptions in the UV region, which tail into the visible region (Table 4). 6As a consequence bands due to *d-d* transitions appear as broad shoulders and their unambiguous assignment is not always possible. For the nickel(II) and cobalt(III) complexes some assignments indicative of octahedral geometry can be made. The spectra of the cobalt complex show two bands in the 17,000-18,000 and 24,300-24,700 cm-J ranges, as expected for low-spin six-coordinated cobalt(III) complexes. 7 The first band can be assigned to a lT~g~ lAlg transition and the other to a IT2g-"~ 'A lg transition. All nickel(II) complexes show two bands in the 20,000-21,500 and 26,000-27,000 cm- 1ranges, which are assignable to the transitions 3Tlg(F) --o 3A2g(F) and 3TI#(P) --~ 3A2a(F), respectively. 7 In addition in the case of Ni(5-Acqo)2"6H20 a band is observed at *ca* 11,000 cm-~, which is assignable to the transition 3T2g(F) ~ 3A2g(F).7

The proposed octahedral geometry of the nickel (II) complexes Ni(5-Acqo)2"6H20, Ni(5-Acqo)z (PY)2 and Ni(5-Acqo)2(dipy) is further supported by room-temperature magnetic moments, which, as expected for such geometry, are in the range 3.0-3.3/lB.

The room-temperature magnetic moment of the complex Mn(5-Acqo)3"H20 was found to be 2.88 #B, which is close to the spin-only magnetic

Ring carbonyl group.

moment expected for spin-paired manganese(III) in an octahedral environment. So far only a few examples of spin-paired manganese(III) complexes have been reported. These include $Mn(1\text{-nqo})_3$, $Mn(2\text{-nqo})_3$[8] and tris(dimethylaminotroponiminato) manganese(III).[9]

The complexes $Co(5\text{-Acqo})_3$, $Na[Co(5\text{-Acqo})_3(NO_2)_2]$, $Na[Fe(5\text{-Acqo})_3]$ and $Fe(5\text{-Acqo})_2(py)_2$ were found to be diamagnetic, which is in accordance with octahedral geometry and spin-paired configurations. The Mössbauer parameters for the iron complexes $Na[Fe(5\text{-Acqo})_3]\cdot 4H_2O$ ($\delta = 0.10$ mm s^{-1}, $\Delta = 0.67$ mm s^{-1}) and $Fe(5\text{-Acqo})_2(py)_2$ ($\delta = 0.22$ mm s^{-1}, $\Delta = 0.62$ mm s^{-1}) are similar to those reported for other octahedral quinone oximato iron(II) complexes.[6,10] The diamagnetism of these complexes, as well as the low-spin d^4 configuration of $Mn(5\text{-Acqo})_3$, are indicative of the strong field character of the 5-acetylamino-1,2-benzoquinone 2-oximato ligand, a feature which has also been observed for other quinone oximic ligands.[4,6]

The room-temperature magnetic moments of the complex $Cu(5\text{-Acqo})_2$ and its adducts were found to be in the range 1.79–1.94 μ_B, which indicates that the compounds are magnetically dilute and hence monomeric. Previously, similar magnetic moments have been obtained for other copper(II) quinone oximic complexes.[5]

The magnetic moment of the anhydrous complex, $Ni(5\text{-Acqo})_2$, was found to be 1.1 μ_B. The subnormal magnetic moment of the complex can be accounted for in terms of association and antiferromagnetic interaction between adjacent nickel atoms, as suggested previously for the related complexes $Ni(1\text{-nqo})_2$ and $Ni(2\text{-nqo})_2$.[11]

Previous studies of the complexes $Co(1\text{-nqo})_3$ and $Co(2\text{-nqo})_3$ have indicated that the compounds exist as a mixture of isomers.[12] The isomeric forms were subsequently separated by chromatography and characterized as *facial* and *meridional* geometric isomers by NMR studies.[12] Their formation reflects the unsymmetric nature of the ligand and as expected the *facial* isomer, which has a three-fold rotation axis, showed a simpler spectrum than the *meridional* isomer, which has no symmetry. Due to the unsymmetrical nature of the 5-Acqo^- ligand in the complexes $Co(5\text{-Acqo})_3$ and $[Fe(5\text{-Acqo})_3]^-$ a similar type of isomerism could also be exhibited. The ^1H NMR spectra of both $Co(5\text{-Acqo})_3$ and $Na[Fe(5\text{-Acqo})_3]\cdot 4H_2O$ in d_6-dimethylsulphoxide were recorded. At 270 MHz the spectrum of the iron complex (Fig. 1) indicated the presence of three aromatic proton environments. Each signal inte-

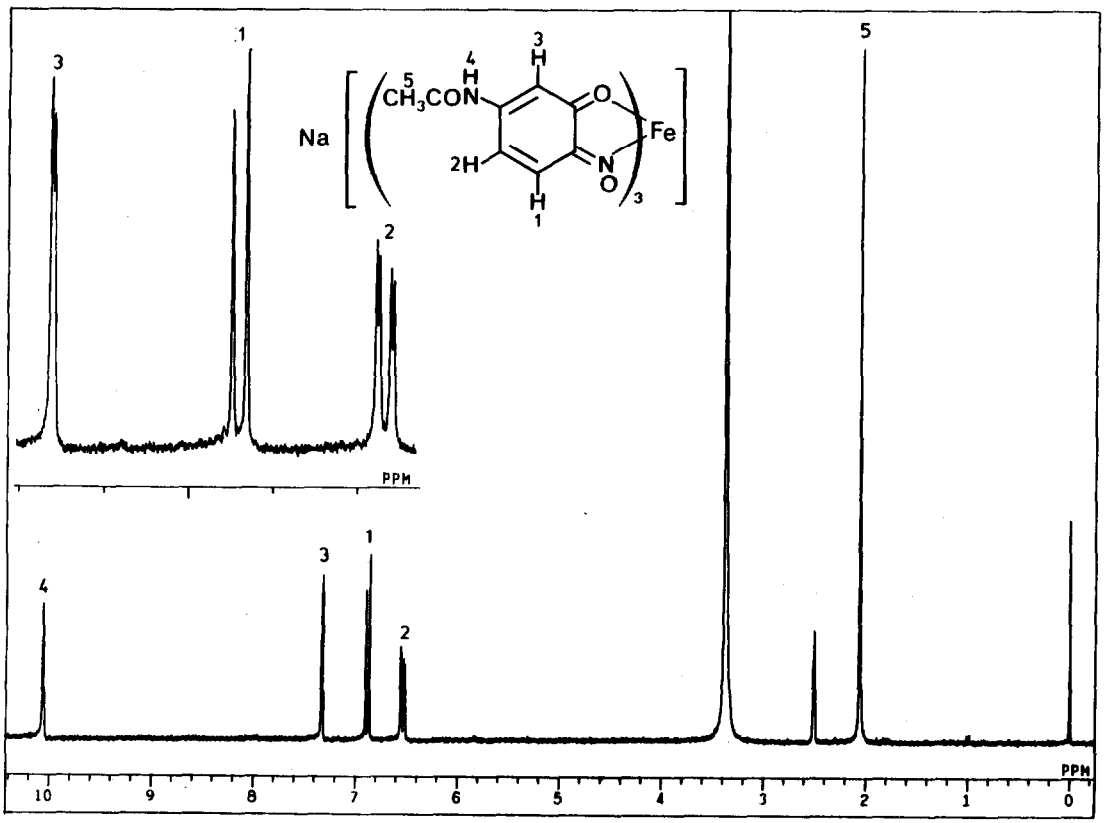

Fig. 1. ^1H NMR spectrum of $Na[Fe(5\text{-Acqo})_3]$ in d_6-DMSO at 270 MHz.

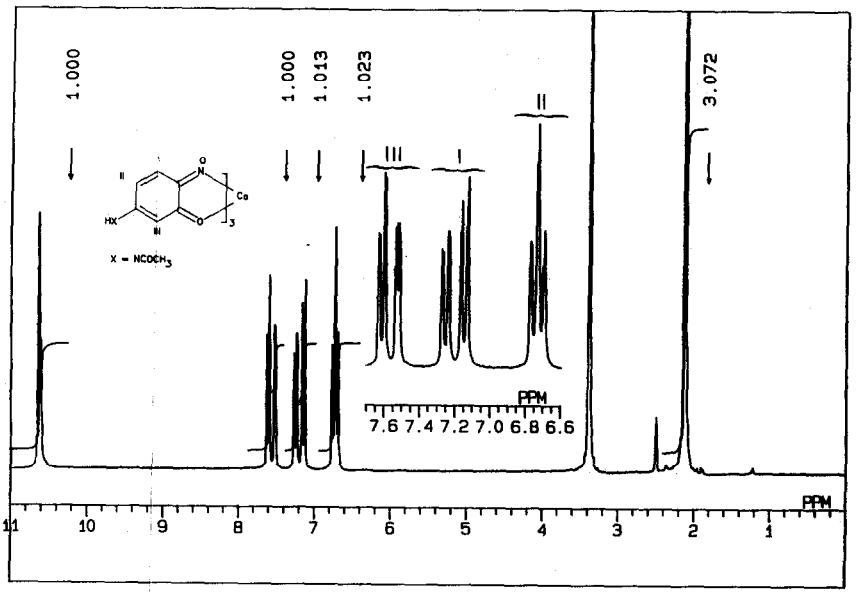

Fig. 2. ^{1}H NMR spectrum of Co(5-Acqo)$_3$ in d_6-DMSO at 270 MHz.

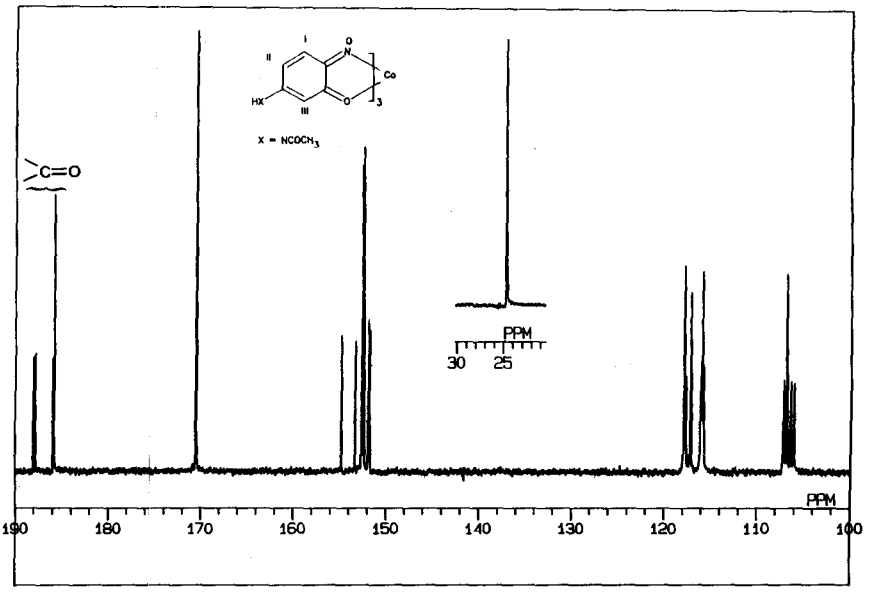

Fig. 3. ^{13}C NMR spectrum of Co(5-Acqo)$_3$ in d_6-DMSO at 270 MHz.

grated for three equivalent protons and showed the expected *ortho* and *meta* couplings, thus indicating the presence of the *facial* isomer only. The ^{1}H NMR spectrum of Co(5-Acqo)$_3$ (Fig. 2) measured at 270 MHz was not well defined, although the presence of four different aromatic proton environments was observed. This suggested that the complex was a mixture of *facial* and *meridional* isomers.

The broad-band decoupled ^{13}C NMR of Co(5-Acqo)$_3$ (Fig. 3) also confirms the presence of *facial* and *meridional* isomers, as it shows peaks corresponding to four different quinonoid (>C=O) carbons. The peaks for the quinonoid carbons were assigned by comparison with chemical shift data for similar compounds.[13]

CRYSTAL AND MOLECULAR STRUCTURE AND SPECTRAL PROPERTIES OF DIISOTHIOCYANATO-(1,10-PHENANTHROLINE)COPPER(II)

GARY L. BRENEMAN and O. JERRY PARKER*

Department of Chemistry and Biochemistry, Eastern Washington University, Cheney, WA 99004, U.S.A.

(*Received* 5 *October* 1992; *accepted* 11 *December* 1992)

Abstract—Adding solid NH_4SCN to a light blue solution which contains a pale green precipitate of $Cu(phen)Cl_2$ produces a green solid that can be recrystallized to produce single crystals. The IR spectrum indicates that both ends of the thiocyanate ion bond to the copper. An X-ray structure determination verifies this conclusion. The structure of this complex has a four-coordinated distorted square-planar arrangement of nitrogen atoms with one nitrogen-bonded thiocyanate twisted above the plane described by copper and phen, and another thiocyanate twisted below the plane. The sulphur ends of the two thiocyanates form longer fifth and sixth bonds to copper atoms in adjacent molecules, forming a linear infinite chain of SCN^- bridged copper atoms. The copper is thus six-coordinated with distorted tetragonal symmetry.

The composition of complexes formed from copper(II), 1,10-phenanthroline and thiocyanate is very sensitive to the nature of the solvent system. The compound $Cu(phen)_2(NCS)_2$ can be prepared from a pyridine solution,[1] which contains phenanthroline, thiocyanate and copper(II) in the appropriate ratios. The five-coordinate compound $[Cu(phen)_2(NCS)]NCS$ can be prepared in aqueous acetone solutions.[2] The addition of this compound to nitrobenzene[2] produces $Cu(phen)(NCS)_2$. The IR and electronic spectra suggested that this complex[3] has a distorted planar or distorted octahedral stereochemistry in the solid state. Previous work on the interpretation of IR data has suggested that $Cu(phen)(NCS)_2$ contains nitrogen-bonded bridging thiocyanate ligands.[3] Copper as a borderline class b metal[4] has the possibility of bonding with either end of the ambidentate thiocyanate ligand. It is difficult to predict whether the electronic factor or the steric factor associated with this ambidentate ligand will predominate. It has been suggested that steric pressure produces a conjunctive response which mandates both a nitrogen- and a sulphur-bonded thiocyanate when two ambidentate ligands reside in a complex that provides steric pressure.[5] We have determined the crystal structure of this complex in order to understand the nature of the thiocyanate linkage.

RESULTS AND DISCUSSION

Synthesis

The procedure for the preparation of the 2,2′-bipyridine complex[3] was slightly modified for the synthesis of $Cu(phen)(NCS)_2$. The compound is extremely insoluble in water and ethanol. The complex is soluble in dimethylsulphoxide and this solubility is very temperature dependent. Dark green crystals were produced when the light green complex was recrystallized in DMSO. A single parallelepiped crystal was selected for the crystal structure determination.

Crystal and molecular structure of $Cu(phen)(NCS)_2$

A summary of crystal data is given in Table 1.

A drawing of the $Cu(phen)(NCS)_2$ molecule, showing thermal ellipsoids, is shown in Fig. 1. Another angle is presented in Fig. 2, showing the lack of planarity of the nitrogen atoms coordinated

to the copper atom. Also shown are the sulphur atoms on other molecules weakly coordinated to the copper in the fifth and sixth positions. Bond distances and angles are given in Tables 2 and 3.

The structure consists of one 1,10-phenanthroline molecule and two thiocyanate ions coordinated to a copper(II) ion, all through nitrogen atoms. The resulting four-coordinate geometry is not square planar, as can be clearly seen in Fig. 2 looking edge on to the 1,10-phenanthroline. The thiocyanate ions are clearly splayed out at a significant angle. The N(1)—Cu—N(2)—C(2) torsion angle is 21.9(4)°. This distortion, from more nearly square-planar geometry, appears to be due to the significant bridging interactions of the sulphur atoms on the ends of the SCN$^-$ ions with neighbouring copper atoms, forming an infinite linear chain along the c-axis. Figure 3 shows a stereoscopic drawing of the unit cell packing in this compound, including the sulphur interactions with the copper atoms. This Cu—S(SCN) distance is 3.163(2) Å. The sulphur atoms are in the fifth and sixth positions of a fairly distorted octahedral geometry. The angles around the copper atom vary from 73.8(1)° to 99.1(1)°. The SCN$^-$ ions are essentially linear [178.5(4)°], but are not quite co-linear with the copper atom [the

Cu—N(1)—C(1) angle is 168.1(5)°] apparently also from the distortion caused by the Cu—S(SCN) interactions. The Cu—S—C(1) angle between molecules is 103.3(2)°.

UV–vis spectroscopy

The absorption spectrum of $Cu(phen)(NCS)_2$ in dimethylsulphoxide displayed two maxima with a molar absorptivity that agreed with previous work.[3] Our work: 373 ($\varepsilon = 689\ M^{-1}\ cm^{-1}$) and 704 nm ($\varepsilon = 61.8\ M^{-1}\ cm^{-1}$); ref. 3: 370–380 ($\varepsilon = 704\ M^{-1}\ cm^{-1}$) and 690–710 nm ($\varepsilon = 76.5\ M^{-1}\ cm^{-1}$).

IR spectroscopy

The diffuse reflectance spectra of Cu(phen) $(NCS)_2$ shows two very strong bands at 2094 and 2118 cm^{-1}. The conventional interpretation of ν(C—N) at 2094 cm^{-1} is that the thiocyanate ligand is sulphur-bonded, but exceptions to this [chromium(III) near 2090 cm^{-1}] are known.[6] The band at 2118 cm^{-1} is usually indicative of thiocyanate bridging. The presence of 1,10-phenanthroline produces medium bands at 718 and 852 cm^{-1}, which precludes the use of ν(C—S) for structural diagnosis. There are weak bands at 424 and 476 cm^{-1} in the spectrum of 1,10-phenanthroline, but the complex shows a very strong band at 424 and a strong band at 474 cm^{-1}. These δ(N—C—S) bands, respectively, would imply a sulphur-bonded and nitrogen-bonded thiocyanate.

Concluding remarks

The IR diffuse reflectance spectra of Cu $(phen)(NCS)_2$ indicates a bridged thiocyanate ligand and a subtle suggestion of both nitrogen- and sulphur-bonded thiocyanate from the δ(N—C—S) bands. Neither provide a clear indication of the polymeric nature of the crystalline solid. The low solubility of the solid in several solvents is the clearest indication of the nature of the linkage in the crystal. The solubility of the compound in DMSO and its temperature dependence is likely the result of the fifth- and six-coordination positions of copper being occupied by the solvent, DMSO.

Bonding distances of 1.945(4) for Cu—N(phen) and 2.011(4) Å for Cu—N(NCS) in Cu(phen) $(NCS)_2$ are normal distances for the short bonds with copper(II) ions. An average bond distance of 2.041 Å for Cu—N(phen) has been observed in $Cu(phen)Br_2$.[7] Bond distances of 1.99 and 2.00 Å have been reported for Cu—N(NCS) in [Cu(bimtp)$(NCS)_2$], where bimtp = (1,5-bis(4-imidazolyl)-3-thiapentane).[8] A distance of 2.60

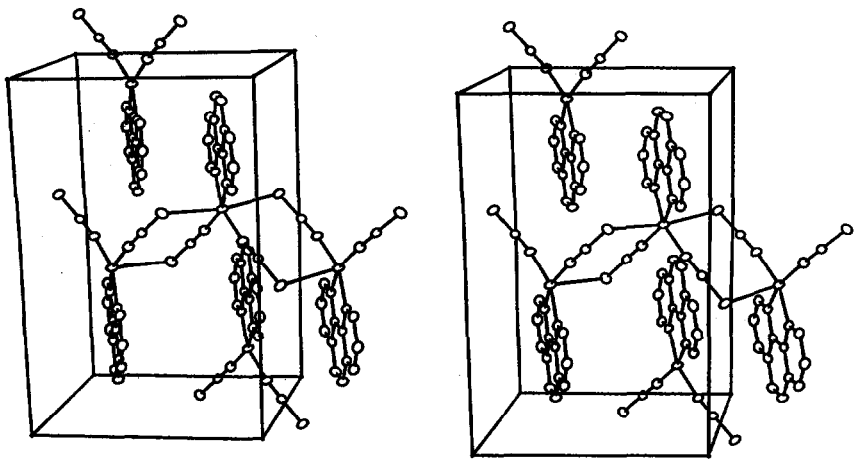

Fig. 3. Stereoscopic picture of the unit cell looking down the *a*-axis with the *b*-axis vertical and the *c*-axis horizontal, showing the linear chain of weakly bridged copper atoms.

/~ has been reported 8 for Cu--S(bimtp) in [Cu(bimtp)(NCS)2], which is representative of a short bond distance in a copper(II) ion. A bonding distance of 3.163(2) /~ for Cu--S(SCN) in Cu (phen)(NCS): is indicative of a long bond distance in copper(II) complexes. Using 2.07 and 2.62 .~ for the short and long bonds 9in Cu(NH 3)6C12and 0.71 ,~ for the ionic radius ~° of the short distance in copper(II) predicts a value of 1.26 A for the ionic radius of the long distance in copper(II). The value of 1.26 A in conjunction with the calculated ionic radius of 1.89 ,~ for sulphur from the Cu--S (bimtp) distance of 2.60/~ estimates a value of 3.15

for Cu--S(SCN), the long distance in the crystal lattice of Cu(phen)(NCS)2. This is in close agreement with the observed value of 3.163(2) ,~. The reported Cu--S(SCN) distance is 3.27 /~ in Cu (en) 2(SCN) 2.1l

The nitrogen-bonded thiocyanate ligands are not coordinated linearly to the central copper(II) ion. The Cu--N(1)--C(1) angle is 168.1 (5)°, which may be a result of the sulphur end of the ligand interacting with a neighbouring copper or it may just represent the normal bonding pattern for thiocyanate. This deviation from 180° is very common with angles of 161.8° and 152.6° observed in [Cu(bimtp)(NCS)2]. 8 The sulphur end of the thiocyanate ion forms a bond with a neighbouring copper(II) at an angle of 103.3(2)°, which is approximately the usual tetrahedral angle. The crystal packing of Cu(phen)(NCS)2 shows that both the nitrogen and sulphur ends of the thiocyanate ligand interact with copper(II) ions and the atoms that surround copper approximate tetragonal coordination. The fact that the thiocyanate ligands are splayed out at a significant angle may vitiate a conjunctive response from the pair of thiocyanate ligands, with the result that both are nitrogen-bonded. 5The smaller size ofcopper(II) as compared to palladium(II) would presumably produce more steric pressure in the copper(II) complex, but this may be effectivelyrelieved by the twisting of the two thiocyanate ligands which significantly removes these ligands from the plane of the complex which is occupied by copper(II) and the phenanthroline ligand.

EXPERIMENTAL

General procedures for the preparation of 1,10-phenanthroline and 2,2'-bipyridine complexes of copper(II) have been described. 3

Preparation of Cu(phen)(NCS) 2

A solution (25 cm 3) of 1,10-phenanthroline monohydrate (1.98 g, 10.0 mmol) in ethanol was slowly added to a 20 cm 3 solution of CuC12" 2H20 (1.71 g, 10.0 mmol) dissolved in water. To the resulting light blue solution which contained a pale green precipitate of Cu(phen)C12, solid NH4SCN (1.52 g, 20.0 mmol) was slowly added with continuous stirring. The product was a very light green solid, which was washed with a small volume of ethanol and anhydrous ether. The light green solid was dissolved in DMSO at *ca* 40°C and allowed to stand overnight. A single crop of dark green crystals was filtered and air-dried.

Single-crystal X-ray determination

Cu(phen)(NCS)2. A summary of crystal data is given in Table 1. The unit cell was determined on an Enraf-Nonius CAD4-diffractometer using Mo-K~ radiation. Symmetry and systematic extinctions *(hkl, h + k* odd and *hOl, l* odd) indicated monoclinic *Cc* or *C2/c* as the choices for the space group. Successful refinement in the centrosymmetric *C2/c* proved this to be the correct space group. An approximate 0.12x0.12x0.30 mm crystal was mounted with epoxy cement on a glass fibre for data collection on the CAD4 diffractometer using a 1.6° 0-20 scan with monochromated Mo-K, radiation. Cell dimensions were determined by least-squares refinement of 25 reflections in the range $34 < 20 < 43°$. One standard reflection was monitored periodically and showed no systematic variation. Psi scan absorption corrections were made. The structure was solved using direct methods and subsequent cycles of structure-factor calculations and difference synthesis. The non-hydrogen atoms were refined anisotropically. Hydrogen atom positions were calculated and refined isotropically to R=0.041 and wR=0.046 using w-1= ~rffFo)+0.00041Fol^2, Yw(IFol- IFcl)2 minimized. All data reduction, structure solution, refinement and graphics were executed using MolEN 12 on a VAX 6410 computer.

Supplementary data. Final values of all refined atomic coordinates, thermal parameters, bond lengths and angles have been deposited.

STEREOCHEMICAL CHANGES IN MONONUCLEAR COMPLEXES ML_n ($n = 10$–12)

BRIAN F. G. JOHNSON,* RUTH MALLORS, EMILIO PARISINI† and YVONNE V. ROBERTS

(*Received* 2 *December* 1992; *accepted* 11 *December* 1992)

Abstract—The process of edge-cleavage (simple and multiple), recently applied to generate complementary geometries for complexes ML_n ($n = 4$–9), has been extended to include values of $n = 10$–12.

Molecules are not rigid, even in the solid state. If a species has a low frequency vibrational mode (i.e. one with a large amplitude) it is likely that any structural distortion will occur along the pathway described by that vibration. In an earlier paper[1] we explored the possibility of a unifying approach to the many mechanisms of fluxionality and isomerization that coordination complexes of the generic formula ML_n might undergo. In that work, because of the more complex nature of polyhedra with greater than 10 vertices, we restricted our attention to values of n from 4 to 9. We concluded that such processes could be *systematized* and that, irrespective of the coordination number, the mechanism of polyhedral interconversion *may* be viewed as being essentially the same, corresponding to the sequential edge-breaking in the parent or ground-state polyhedron until an appropriate complementary polyhedron for the transformation is produced. For coordination numbers 4–9 at least, this process corresponded to the pathway of low frequency, edge-breaking modes and thus Scheme 1 was derived.

In this paper we report the results of our investigations of the sequential formation of polyhedra for coordination numbers 10–12 via the same edge-breaking procedure. These coordination numbers do not appear to have been explored in such detail previously and the geometries associated with them are of relevance mainly for complexes of the heaviest transition metals, e.g. the lanthanide elements.

Rearrangement of the 10*-vertex polyhedron*

The minimum energy polyhedron for 10-coordination is generally accepted as being the bicapped square antiprism, {10},‡ which in Föppl notation corresponds to the 1 : 4 : (4) : 1 arrangement. This is shown in Fig. 1. Apart from this well-established form the only other 10-vertex polyhedron commonly described is the close relative, the bicapped square prism 1 : 4 : 4 : 1, {14−4}.

Within the bicapped square antiprism are edges of three different types: a, b and c. Edge a is associated with the two caps and links vertices with connectivities of four and five, whereas both edges b and c link vertices with the same connectivity of five. Following the rule established previously[1] that edges connecting vertices of maximum connectivity are preferentially broken,§ we shall consider the cleavage of edges b or c only. Thus, in our consideration of polyhedral expansion by sequential cleavage, we have for the first time a polyhedron which offers a choice of two distinct possibilities.

(1) Cleavage of the single edge 2–3 leads directly to the *nido*-undecahedron {11−1}. This is not a

‡ Throughout this paper {n} denotes the most commonly observed n-vertex polyhedron, while {$n-x$} denotes the same polyhedron with x vertices missing.

§ For example, in the trigonal bipyramid {5} edges connecting vertices of four in the equatorial plane are broken, and in the pentagonal bipyramid {7} edges connecting vertices with connectivities of four and five.

$\{5\} \rightleftarrows \{6-1\}$

$\{6\} \rightleftarrows \{7-1\} \rightleftarrows \{8-2\} \rightleftarrows \{9-3\}$

$\{7\} \rightleftarrows \{8-1\} \rightleftarrows \{9-2\}$

$\{8\} \rightleftarrows \{9-1\}$

$\{9\} \rightleftarrows \{10-1\}$

{n} denotes a *closo*–polyhedron with n vertices

{n–1} denotes a *nido* n–polyhedron with n–1 vertices

{n–2} denotes an *arachno* n–polyhedron with n–2 vertices

{n–3} denotes a *hypo* n–polyhedron with n–3 vertices

Scheme 1. The postulated general mechanism for structural variation in polyhedra ML_n (n = 4–9).

suitable complementary geometry for the interconversion process since a diamond → square → diamond operation does not lead to a "new" bicapped square antiprism (see Scheme 2), but rather to a close-packed, polytetrahedral arrangement corresponding to a 3 : 7 Föppl arrangement (Fig. 2). If the edge cleavage process is continued, however, with the cleavage of a second edge 6–7, a $\{12^A-2\}$* polyhedron is produced. This is a perfectly satisfactory complementary geometry and the formation of a "new" bicapped square antiprism follows from the reformation of two "new" edges following typical diamond → square → diamond operations by closing 1–7 and 2–10. Thus, interconversion of the bicapped square antiprism may follow the four-step process in which two square faces are generated in the complementary polyhedron $\{12^A-2\}$. This is shown in Scheme 2(A).

$$\{10\} \rightarrow \{11-1\} \rightarrow \{12^A-2\} \rightarrow \{11^A-1\}' \rightarrow \{10\}'.$$

The collapse of the bicapped square antiprism to the 3 : 7 close-packed arrangement is clearly of some significance. Although unsuitable for a ligated system of the type ML_{10} and of no immediate interest in the context of this paper, it is of some importance in consideration of M_{10} cluster systems (M = metal ion), indicating a surprisingly simple and direct transfer from a polyhedral to close-packed form. The 3 : 7 arrangement here corresponds to a fragment of ptcp (3 : 7 : 3).

(2) In contrast, cleavage of an edge of type c leads to a different process [see Scheme 2(B)]. In this case sequential cleavage of four edges, 2–6, 3–7, 4–8 and 5–9, must occur before a suitable complementary geometry, viz. the bicapped cube (1 : 4 : 4 : 1), is produced. This corresponds to the overall process:

$$\{10\} \rightarrow \{11^B-1\} \rightarrow \{12^B-2\} \rightarrow \{13^B-3\} \rightarrow \{14^B-4\} \rightarrow \{13^B-3\}' \rightarrow \{12^B-2\}' \rightarrow \{11^B-1\}' \rightarrow \{10\}'.$$

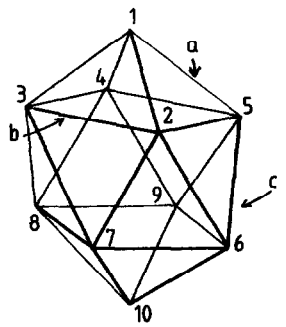

Fig. 1. The bicapped square antiprism.

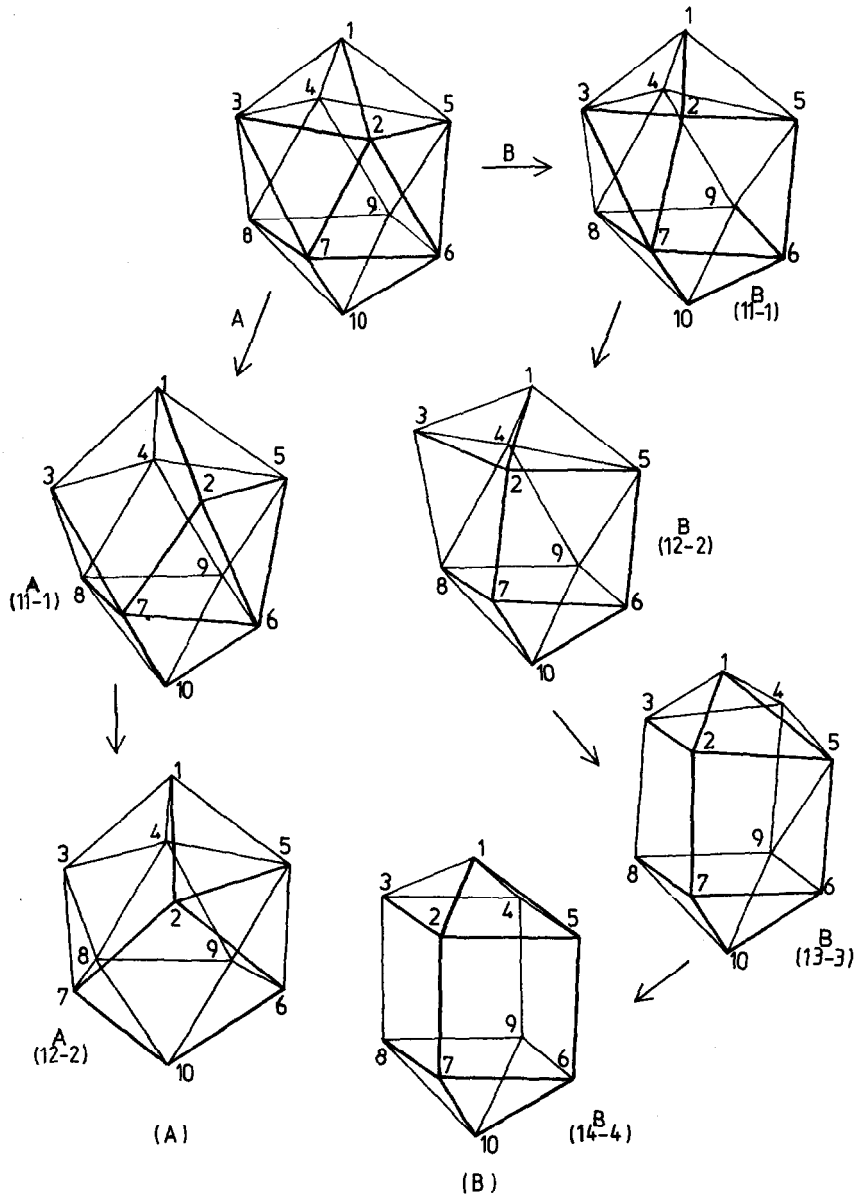
* The icosahedron is deemed to be {12}; the bicapped cuneane arrangement 12^A.



Scheme 2. Sequential edge-cleavage mechanisms for a bicapped square antiprism.

This process, with eight steps, would appear to be less favourable than that given in Scheme 2(A), which requires four steps. Within this sequence, the first intermediate polyhedron, $\{11^{B}-1\}$, appears to be very strained and moving towards a close-packed array of ligands, but beyond that surprisingly reasonable polyhedral forms appear, formally corresponding to the gradual conversion of the central unit from a square antiprism to a cube. Thus, as the process is continued more and more square faces are generated, from one initially to a maximum of four in $\{14-4\}$.

In the above rearrangements, Schemes 2(A) and 2(B), we have chosen the most reasonable of several alternatives. It is important to note that neither process (A) nor (B) (Scheme 2) leads to an *arachno*-icosahedron $\{12-2\}$. However, in process (A) the cuneane complementary geometry may be easily converted to the *arachno*-icosahedron $\{12-2\}$ form by the migration of a single edge.

Rearrangement of an 11*-vertex polyhedron*

It follows from our discussion of the bicapped square antiprism that the rearrangement of the undecahedron $\{11\}$ may be expected to proceed via a monocapped cuneane complementary geometry with a single edge cleavage [see Scheme 3(A)] in two

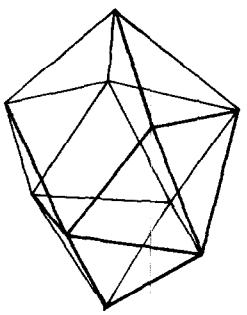


Fig. 2. The polytetrahedral 3 : 7 fragment.

steps:

$$\{11\} \rightarrow \{12^{A}-1\} \rightarrow \{11\}'.$$

Similarly, rearrangement of the alternative 11-vertex polyhedron, related to that established in Scheme 2(B), proceeds via a tricapped cube complementary geometry, viz.

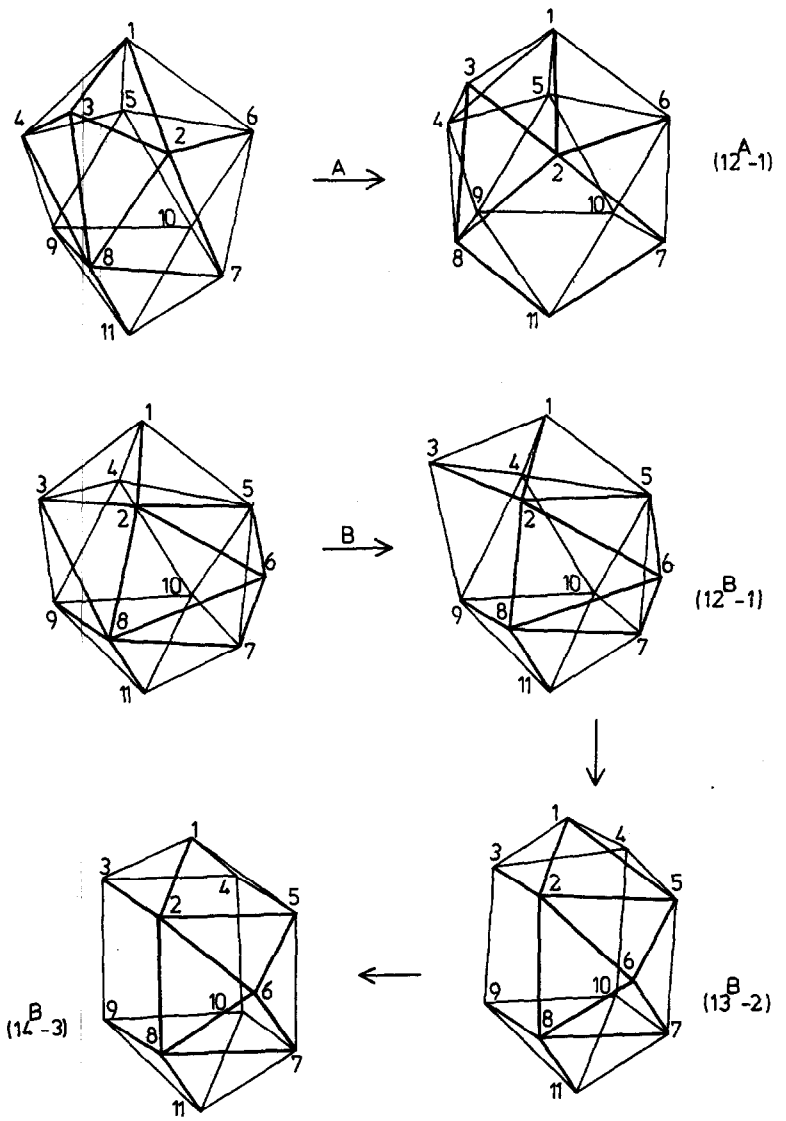
$$\{11^{B}\} \rightarrow \{12^{B}-1\} \rightarrow \{13^{B}-2\} \rightarrow \{14-3\} \rightarrow$$

$$\{13^{B}-2\}' \rightarrow \{12^{B}-1\}' \rightarrow \{11^{B}\}' \text{ [see Scheme 3(B)]}.$$

Clearly, since there is a large increase in the number of steps involved, the former two-step process is expected to be preferable.

Rearrangement of the 12*-vertex polyhedron*

For the "best" 12-vertex polyhedron, viz. the icosahedron {12}, the process of rearrangement is not simple and has been examined extensively.[2-7] A suitable complementary geometry is not found until at least five edges have been broken and the bicapped right pentagonal prism, strictly {17−5},



Scheme 3. Sequential edge-cleavage mechanisms for 11-vertex polyhedra.

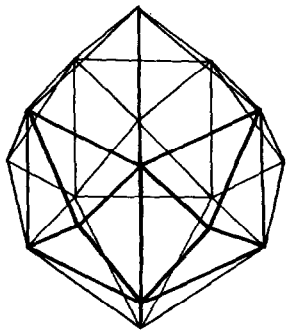


Fig. 3. A 17-vertex polyhedron.

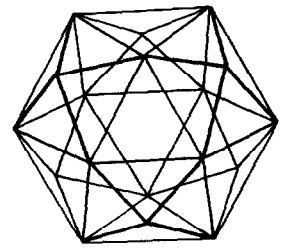

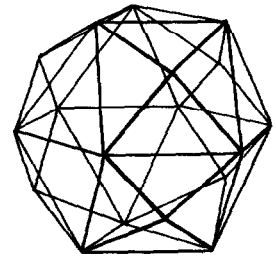

Fig. 4. 18-vertex polyhedra derived from both cubeoctahedron and anticubeoctahedron forms.

has been produced (see Fig. 3):

$$\{12\} \rightarrow \{13-1\} \rightarrow \{14-2\} \rightarrow \{15-3\} \rightarrow$$
$$\{16-4\} \rightarrow \{17-5\} \rightarrow \{16-4\}' \rightarrow \{15-3\}' \rightarrow$$
$$\{14-2\}' \rightarrow \{13-1\}' \rightarrow \{12\}'.$$

Cleavage of six edges leads to either the cubeoctahedron or the anticubeoctahedron $\{18-6\}$ (see Fig. 4) and provides a 12-step interconversion process.

$$\{12\} \rightarrow \{13-1\} \rightarrow \{14-2\} \rightarrow \{15-3\} \rightarrow$$
$$\{16-4\} \rightarrow \{17-5\} \rightarrow \{18-6\} \rightarrow \{17-5\}' \rightarrow$$
$$\{16-4\}' \rightarrow \{15-3\}' \rightarrow \{14-2\}' \rightarrow$$
$$\{13-1\}' \rightarrow \{12\}'.$$

Nevertheless, the same process is adopted, viz. the sequential cleavage of edges to provide complementary geometries. It is interesting to note, however, that the icosahedron is unique amongst the low energy polyhedra studied, which have been grown from forms with 4–10 vertices. Neither the icosahedron itself nor any of its derivatives can be directly produced from the edge-cleavage processes described earlier. If the usual method of polyhedral growth is applied, i.e. edge cleavage, followed by the capping of the square face so produced, the ultimate low energy shape produced is $\{14\}$, the omni-capped cube. The 12-vertex polyhedron derived by this route is the bicapped cuneane form, i.e. the growth sequence follows the path to cubic or hexagonal packing and not pentagonal symmetry, as found in the isosahedron.

CONCLUSIONS

This work has revealed that, as with lower coordination numbers (4–9), the process of sequential edge-cleavage provides a convenient mechanism to suitable complementary geometries for polyhedral interconversion. However, in contrast to those lower coordination numbers for which the process generates only one possible complementary geometry, for coordination numbers 10–12 at least two complementary geometries are available. Significantly, no complementary geometries based on the icosahedron may be derived by this route. Of considerable significance is the observation that cleavage of the appropriate adjacent edges of the bicapped square antiprism leads to a close-packed arrangement of ligands. This is of no use in the ligated systems, but clearly of importance when applied to polyhedra of metal atoms, since it demonstrates a facile movement from polyhedral to close-packed arrays of metal atoms.

Abstract—The reaction of $Ru_2Cl(\mu\text{-}O_2CCH_3)_4$ with bbtp [bbtp = tert-butylbis(2-thienyl)-phosphine] in methanol under nitrogen leads to a disproportionation process with the formation of $Ru_2(\mu\text{-}O)(\mu\text{-}O_2CCH_3)_2(O_2CCH_3)_2(bbtp)_2$ (**1**) and *cis*-$Ru(O_2CCH_3)_2(bbtp)_2$ (**2**). In the presence of air compound **2** is very unstable in solution, giving compound **1**. The X-ray crystal structures of **1** and the CH_2Cl_2 solvate of **2** have been determined. Compound **1** contains two ruthenium(III) atoms linked by two bridging acetate groups and one bridging oxo ligand; the pseudo-octahedral environment of each ruthenium atom is completed by one bidentate chelating acetate and one monodentate phosphine ligand. Compound $\mathbf{2} \cdot CH_2Cl_2$ also has a pseudo-octahedral environment, with two monodentate bbtp ligands and two bidentate chelating acetate ligands giving a *cis* arrangement.

The reactions of $Ru_2Cl(\mu\text{-}O_2CR)_4$ (R = alkyl or aryl) with phosphines have attracted much interest in recent years.[1–14] Earlier studies,[4] performed on the reactivity of $Ru_2Cl(\mu\text{-}O_2CCH_3)_4$ with PPh_3, have shown that in methanol the compound $Ru_2(\mu\text{-}O)(\mu\text{-}O_2CCH_3)_2(O_2CCH_3)_2(PPh_3)_2$ is obtained in a yield of *ca* 100%. More recently,[5,6] it has been described that the reactions of $Ru_2Cl(\mu\text{-}O_2CR)_4$ (R = Ph, *p*-C_6H_4—OMe) with PPh_3 in acetonitrile also lead to the formation of similar oxodimer compounds. In all these reactions the initial ruthenium(II)–ruthenium(III) complex gives only ruthenium(III) compounds, indicating that some oxidation process has occurred. Although in these reactions the oxidizing agent was not mentioned, atmospheric oxygen is the most probable agent.

In some cases only ruthenium(II) complexes were obtained from $Ru_2Cl(\mu\text{-}O_2CCH_3)_4$.[7–10] For example, in the reaction with chelating diphosphines, $Ph_2P(CH_2)_nPPh_2$ (n = 1–3), in cold or refluxing benzene, *cis*- and *trans*-$Ru(O_2CCH_3)_2[PPh_2(CH_2)_nPPh_2]_2$ were obtained. In these cases the phosphine is the most likely reducing agent, which is very usual in the synthesis of phosphine complexes of ruthenium(II) from ruthenium (III).[15]

In contrast to the results described for $Ru_2Cl(\mu\text{-}O_2CCH_3)_4$, we have found previously[11,12] that the reaction of $[Ru_2(\mu\text{-}O_2CCH_3)_4(thf)_2]BF_4$ with PPh_3 leads to a disproportionation process in which, in addition to an oxodimer of ruthenium(III), a yellow ruthenium(II) compound was obtained. Furthermore, in the reactions of $Ru_2Cl(\mu\text{-}O_2CR)_4$ (R = Me, Et, *cyclo*-C_6H_{11}, Ph, *o*-C_6H_4OH) with PPh_3 in 2-methoxyethanol only ruthenium(II) compounds have been obtained, but the existence of a previous disproportionation process has been proposed.[13]

* Author to whom correspondence should be addressed.

Due to the differences observed in the reactivity of Rtl2CI(#-O2CCH3) 4 and [Ru2(I/-O2CCH3) 4 (thf) 2]BF4, and because we think that many of these reactions occur via a disproportionation process, we have decided to investigate the reaction of Ru2CI(#-O2CCH3) 4 with bbtp [bbtp = tert-butyl-bis(2-thienyl)phosphine]. This new ligand is a functional tertiary phosphine containing two different donor centres, separated by a single atom bridge, and is supposed to be able to stabilize some intermediate compounds. However, previous investigations of mercury(II), palladium(II), platinum(II) and rhodium(I) complexes of tris(2-thienyl)phosphines and aryl(2-thienyl)phosphines have shown only a monodentate coordination of the phosphines via the phosphorus atom.16]9

I

RESULTS AND DISCUSSION

Under an atmosphere of dinitrogen the reaction of Ru2CI(#-O 2CCH 3)4with bbtp in methanol leads to the formation of Ru2(#-O)(~-O2CCH3) 2 (OzCCH3)2(bbtp)2 (1) and Ru(OzCCH3)2(bbtp)2 (2). Compound 1 is stable to air and moisture in the solid state and is soluble with a violet colour in most of the usual organic solvents like CHC13, tetrahydrofuran and toluene. Compound 2 has been obtained from CH2C12/petroleum ether (40-60°C) as dichloromethanc solvate, which is only stable in a dichloromethane atmosphere. Compound 2 is soluble with a brown colour in CH2C12, toluene, tetrahydrofuran and other polar organic solvents and the colour of its solutions changes in air to violet, giving the oxodimer 1. In accordance with these results, in the presence of air the reaction of RuzCI(#-O2CCH3)4 with bbtp yields only 1 (Scheme 1). The similar oxidation of Ru(O2CCHa)2(PPh3)2 with oxygen to give Ru2(#-O)(#-OzCCH3)2 (O2CCHa)E(PPh3) 2 has also been previously observed. 4

IR, IH and 31p(1H} NMR spectroscopic data for 1 are listed in Table 1.

The IH NMR spectrum shows only one doublet for the tert-butyl groups, but two singlets for the methyl groups, in accordance with two types of acetate groups. In contrast to Ru2(/~-O)(#-O2CCH3)a(O2CCHa)2(PPh3)2 (A6 0.05 ppm) 12 the A6 separation between the signals corresponding to the acetate methyl groups of 1 (A6 0.199 ppm) is greater.

The region of the thienyl protons (6-8 ppm) shows six groups of signals, indicating two different types of thienyl groups (Table 2).

The reason for the pronounced downfield shift for H' may be a certain type of interaction between these protons and the metal caused by the spatial proximity, as seen in the crystal structure (see Fig. 1).

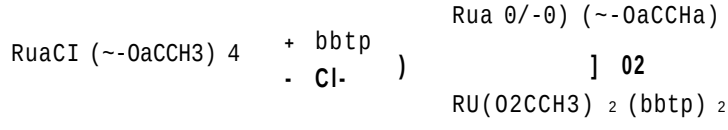
The 31p{~H} NMR spectrum only shows a singlet at 52.14 ppm, indicating that the two phosphine ligands are in equivalent positions.

The IR spectra of 1 in trichloromethane solution and in the solid state are very similar in the carboxylate region. The marked differences between the spectrum of 1 in the solid state and in CHCI3 solution in the region of the v(C--H) stretching vibrations may be rationalized in terms of different rotational conformers caused by the positions of the tert-butyl and thienyl groups of the phosphine ligands. Thus, the observed pronounced separation, A6, of the ~H NMR signals of the acetate methyl groups of 1 also must be due to the nature of the phosphine.

A PLUTON view of 1 is shown in Fig. 1. The most important distances and angles are summarized in Table 3. The Ru2(#-O)(p-O2CCH3)2 (O2CCH3)2(bbtp)2 molecule is formed by two ruthenium(Ill) atoms finked by two bridging acetate ligands and a bridging oxo group; the hexa-coordination of each ruthenium atom is completed by a chelating bidentate acetate group and a monodentate bbtp ligand which coordinates via the phosphorus atom in the *trans* position to one of the bridging acetates. The structure of this compound is very similar to that found in Ru2(g-O)(#-O 2CCH 3)2(O 2CCH 3)2(PPh 3)2.~2The Ru--Ooxo distances and the Ru--O--Ru angle are similar to those found for other oxodimer compounds.6122w23

IR, IH and 31p{ill} NMR spectroscopic data for 2 are summarized in Table 1.

The existence of only one singlet for the methyl protons and only three groups of signals for the thienyl protons in the IH NMR spectrum of 2 indicates the equivalence of the two acetate groups, as well as of the two phosphine ligands. In accordance with this the 31p{IH} NMR spectrum only shows



Scheme I.

one singlet at 67.83 ppm, indicating that only one isomer exists in solution. The spectral data alone are not sufficient to decide whether this is the *cis* or the *trans* isomer. Therefore, we have undertaken a single-crystal X-ray diffraction analysis of $\mathbf{2}\cdot CH_2Cl_2$, showing that the *cis* isomer is formed. A PLUTON view of $\mathbf{2}\cdot CH_2Cl_2$ is shown in Fig. 2. Selected bond lengths and angles are given in Table 4. In the crystal molecules of complex **2** and dichloromethane molecules of solvation are present and linked by van der Waals forces. The ruthenium atom is six-coordinated in a distorted octahedral geometry by two chelating acetate groups and two monodentate phosphine ligands in *cis* positions to each other. The Ru—O(2) and Ru—O(4) bond lengths, which are *trans* to the phosphine ligands, are longer than the Ru—O(1) and Ru—O(3) bond distances. The differences in these bond lengths are probably a consequence of the high *trans*-influence of the phosphine ligand. The Ru—P distances are similar to those found for other *cis*-phosphine complexes.[24,25]

Since the starting material, $Ru_2Cl(\mu\text{-}O_2CCH_3)_4$, is a diruthenium(II,III) compound and the reaction products are **1** and **2**, which are ruthenium(III) and ruthenium(II) compounds, respectively, a disproportionation process has been produced. Some disproportionation reactions of the $[Ru_2(\mu\text{-}O_2CCH_3)_4]^+$ unit have been previously observed.[12,26-28] Thus, the results obtained in the reaction of $Ru_2Cl(\mu\text{-}O_2CCH_3)_4$ with bbtp are con-

sistent with those observed in the reaction of $[Ru_2(O_2CCH_3)_4(thf)_2]BF_4$ with PPh_3[12] and with the proposed disproportionations in the reactions of $Ru_2Cl(O_2CR)_4$ (R = Me, Et, Ph, *cyclo*-C_6H_{11}, *o*-C_6H_4OH) with PPh_3 in 2-methoxyethanol.[13] However, these results are in contrast to the reactions of $Ru_2Cl(O_2CR)_4$ (R = Me, Ph, *p*-C_6H_4—OMe) with PPh_3 in MeOH[4] or MeCN,[5,6] which give only ruthenium(III) complexes. The ease of oxidation of $Ru(O_2CR)_2(PPh_3)_2$ in air could explain why in these last mentioned reactions, which are carried out in air, ruthenium(III) compounds were obtained.

In conclusion, the results obtained in the reaction of $Ru_2Cl(\mu\text{-}O_2CCH_3)_4$ with bbtp show that in an atmosphere of dinitrogen a disproportionation process has occurred with the formation of **1** and **2**, whereas in air only **1** is formed. Thus, we believe that other similar reactions, described in the literature as oxidation reactions of the Ru_2^{5+} unit to give the unstable Ru_2^{6+} unit, are better described as reactions of disproportionation with posterior oxidation of the ruthenium(II) compound. Finally, the presence of a sulphur atom in the bbtp ligand does not have any important influence in the reactivity towards $Ru_2Cl(\mu\text{-}O_2CCH_3)_4$.

EXPERIMENTAL

All manipulations were carried out in an inert atmosphere of dinitrogen, using standard Schlenk techniques. $RuCl_3 \cdot 3H_2O$ (Engelhard) was purchased from commercial sources; $Ru_2Cl(\mu\text{-}O_2CCH_3)_4$ was prepared by the literature procedure;[4] bbtp was synthesized in analogy to the method of Allen and Ashford.[29] The exact procedure will be published elsewhere.[30]

The ^1H and $^{31}P\{^1H\}$ NMR spectra were recorded with a Varian VXR-300 or a WP 80 Fa.Bruker spectrophotometer using $CDCl_3$ as the solvent; ^1H chemical shifts are relative to $SiMe_4$; ^{31}P chemical shifts are relative to external 85% H_3PO_4 (positive values = downfield shifts). IR spectra were recorded on a Philips PU 9712 spectrophotometer or a Perkin–Elmer 1720 FT-IR spectrometer. Elemental analyses were performed by the Analytical Service of the Complutense University of Madrid.

Synthesis of $Ru_2(\mu\text{-}O)(\mu\text{-}O_2CCH_3)_2(O_2CCH_3)_2(bbtp)_2$ *and* cis-$Ru(O_2CCH_3)_2(bbtp)_2$

To the red solution of $Ru_2Cl(\mu\text{-}O_2CCH_3)_4$ (0.50 g, 1.05 mmol) in methanol (15 cm^3) was added a solution of bbtp (0.55 g, 2.1 mmol) in methanol (15 cm^3) with stirring. The mixture was stirred for 5 h at room temperature. During this time the colour of the solution changed to violet and compound **2** deposited as a brown precipitate, which was filtered off, washed with methanol and reprecipitated by dissolving in dichloromethane (1 cm^3) and adding petroleum ether (30 cm^3; b.p. 40–60°C). A brown power was obtained (**2**) (yield: 0.17 g,

22%). Found: C, 45.7; H, 4.9. Calc. for $C_{28}H_{36}O_4P_2RuS_4$: C, 46.2; H, 5.0%.

A dichloromethane solvate of **2** can be obtained by dissolving the powder in dichloromethane, followed by layering with petroleum ether.

Compound **1** was obtained from the violet filtrate by removing the solvent *in vacuo* and by reprecipitating the residue from dichloromethane/petroleum ether (b.p. 40–60°C). A violet powder was obtained (**1**) (yield: 0.54 g, 53%); m.p. 228°C. Found: C, 40.2; H, 4.5. Calc. for $C_{32}H_{42}O_9P_2Ru_2S_4$: C, 39.9; H, 4.4%.

Crystal structure determination of complexes **1** *and* $2 \cdot CH_2Cl_2$

Suitable crystals of complexes **1** and $2 \cdot CH_2Cl_2$ were grown from dichloromethane–petroleum ether by slow layer diffusion at room temperature.

Crystal data. **1**: $C_{32}H_{42}O_9P_2Ru_2S_4$, $M = 963.0$, monoclinic, space group $I2/a$, $a = 20.485(3)$, $b = 9.947(1)$, $c = 21.016(2)$ Å, $\beta = 108.15(1)°$, $U = 4069.2(9)$ Å^3, $Z = 4$, $D_c = 1.562$ g cm^{-3}, $F(000) = 1928$, μ(Mo-K_α) = 10.5 cm^{-1}.

$2 \cdot CH_2Cl_2$: $C_{28}H_{36}O_4P_2RuS_4 \cdot CH_2Cl_2$, $M = 812.8$, monoclinic, space group $P2_1/c$, $a = 11.411(1)$, $b = 10.029(1)$, $c = 31.157(5)$ Å, $\beta = 93.39(1)°$, $U = 3559(1)$ Å^3, $Z = 4$, $D_c = 1.507$ g cm^{-3}, $F(000) = 1644$, μ(Mo-K_α) = 9.3 cm^{-1}.

Data collection. Unique data sets were measured within the limit $2\theta_{max} = 55°$ using a four-circle diffractometer (Syntex $P2_1$) by the $2\theta/\omega$-scan technique; monochromatic Mo-K_α radiation, $\lambda = 0.71069$ Å.

For crystal **1** of the approximate dimensions $0.2 \times 0.3 \times 0.4$ mm 5210 reflections were collected, of which 4330 symmetry-independent reflections

were recorded and 3456 had $F_o > 5\sigma(F_o)$. For crystal $2 \cdot CH_2Cl_2$ (dimensions $0.1 \times 0.2 \times 0.4$ mm) 7288 reflections were collected, of which 5333 symmetry-independent reflections were recorded and 3227 had $F_o > 5\sigma(F_o)$. Both data sets were corrected for Lorentz–polarization effects and absorption (empirical absorption correction).

Determination and refinement of the structure. The structures were solved by the Patterson method[31–33] and refined by full-matrix least-squares calculations.[34]

In **1** the bridging oxygen atom occupies a special position (1/4, y, 1/2) and, therefore, the asymmetric unit consists only of half a molecule.

One of two 2-thienyl units shows disorder by rotation around a two-fold axis defined by the P—C(11) bond. The disordered 2-thienyl entity was given ideal geometry and included in the least-squares refinement with common isotropic temperature factors applied to atoms related by pseudo-symmetry. The population parameters applied to each pair of thienyl units were refined, the final values giving occupancies of 45% [C(111), C(121), C(131), C(141), S(11)] and 55% [C(112), C(122), C(132), C(142), S(12)]. Hydrogen atoms were introduced at idealized positions with fixed thermal parameters only for the ordered 2-thienyl group and the methyl groups. All non-hydrogen atoms were given anisotropic temperature factors and refinement converged at $R = 0.053$, $R_w = 0.043$. A weighting scheme, $w = 1/[\sigma^2(F_o)]$, was adopted. Selected bond distances and angles are given in Table 3 (taken from the program PLATON[35]).

In $2 \cdot CH_2Cl_2$ the S(3) atom had very large temperature factors, while those for C(42) were very small. This suggests that there also is a disorder about the P—C bond. The site occupation factor for position 1 is 0.70 and for position 2 0.30. The refinement was carried out by the same procedure as for **1**. In the final cycles of refinement the weighting scheme $w = 1/[\sigma^2(F_o) + 0.0001(F_o)^2]$ was adopted. The final value of R (R_w) was 0.063 (0.053). Selected bond lengths and angles are listed in Table 4 (taken from the program PLATON[35]).

(*Received* 14 *April* 1992; *accepted* 9 *December* 1992)

Abstract—X-ray absorption spectra for molybdenum(VI) in acidic solutions were measured and their XANES and EXAFS were analysed. The cationic monomer MoO_2^{2+} is present in $HClO_4$, H_2SO_4 and HNO_3. In HCl the coordination of chloride ions to MoO_2^{2+} was observed. Diethyl ether extracts MoO_2Cl_2 selectively from a HCl solution of molybdenum(VI).

Hexavalent molybdenum exists in the monomeric form of MoO_4^{2-} in neutral or alkaline solution, while in weakly acidic solutions polymeric anions such as $Mo_7O_{24}^{6-}$, $Mo_8O_{26}^{4-}$ and $Mo_6O_{19}^{2-}$ are present.[1–3] A previous spectroscopic investigation has clarified the structures of these anions.[3] In strongly acidic solutions cationic monomers and dimers are present,[4,5] however, their structures have not been elucidated [for example, Cruywagen *et al.*[4] have considered the existence of $Mo(OH)_5H_2O^+$ and Burclova *et al.*[5] proposed MoO_2^{2+}].

In recent years XANES (X-ray absorption near edge structure) and EXAFS (extended X-ray absorption fine structure) have been proved to be useful for the study of the short range order of atoms

* Author to whom correspondence should be addressed.

in polynuclear compounds.[6-10] In our previous paper[7] the structure of the μ-oxo dimeric cation, $Mo_2O_5^{2+}$, in acid solution (2 M) was studied and it was shown that its Mo—O—Mo bond angle is *ca* 125° by analysing XANES and EXAFS. In this work the structure of molybdenum(VI) in further acidic solutions and of the species extracted by ether are investigated.

EXPERIMENTAL

Molybdenum(VI) solutions were prepared from $Na_2MoO_4 \cdot 2H_2O$ and their concentrations were determined gravimetrically with 8-hydroxyquinoline and volumetrically with lead nitrate.[11] The concentration of molybdenum(VI) was adjusted to 0.1 M unless otherwise noted. Other chemicals were of guaranteed reagent grade and were used without further purification. X-ray absorption spectra were obtained with the EXAFS apparatus at beam line 10B of the 2.5 GeV storage ring from the Photon Factory at Tsukuba. Photon energy was calibrated by using the pre-edge peak of sodium molybdate, $Na_2MoO_4 \cdot 2H_2O$, at 20,007 eV. Other conditions were the same as those reported previously.[7]

RESULTS AND DISCUSSION

K-edge XANES spectra of molybdenum(VI) taken in hydrochloric acid solutions are shown in Fig. 1. When c_{HCl}, the concentration of HCl, is less than 3 M a pre-edge peak is observed clearly at *ca* 20,008.8 eV, while in further acidic solutions the peak is obscured by the red shift of the absorption edge. This pre-edge peak is assigned to the $1s$–$4d$ transition.[12] It is known that the intensity of the peak correlates with the number of Mo=O bonds per molybdenum atom,[7,12] and in HCl solution of less than 3 M the intensity corresponds to two Mo=O bonds. This is in agreement with the structure of MoO_2^{2+}, proposed by Burclova.[5] The intensity of the pre-edge peak is slightly decreased in HCl solutions of more than 3 M. The coordination of chloride ion may cause the shift of the edge, which is shown by the result of EXAFS analysis described later in this paper. The threshold energy, E_0 (which was determined from the position of the half height of the absorption edge at around 20040 eV; in this method experimental errors for E_0 are within about ± 0.2 eV), for various molybdenum(VI) samples are listed in Table 1. The spectra and E_0 obtained for 1–6 M perchloric, 1–3 M sulphuric and 1–8 M nitric acid solutions are almost the same as those obtained in less than 3 M HCl. This means that the coordination of perchlorate, sulphate and nitrate is not important.

EXAFS Fourier transforms for molybdenum(VI) in HCl solutions are shown in Fig. 2. In the Fourier transforms the corrections for the phase shift and the backscattering amplitude were performed using the theoretical parameters for the Mo—O bond, given by Teo and Lee[13] (in this method experimental errors for bond distances are

[a] The R and N values are for molybdenum(VI) complexes extracted into diethyl ether from HCl aqueous solutions.

within *ca* ±0.02 Å). In HCl solutions of less than 3 M only one distinct peak is observed around 1.7 Å, corresponding to the distance of the Mo=O bond, and no peak due to the Mo—O bond (*ca* 1.9 Å) is observed. For the monomeric cation of molybdenum(VI) Cruywagen *et al.*[4] have considered the existence of $Mo(OH)_5H_2O^+$ and Burclova *et al.*[5] proposed the presence of MoO_2^{2+}. As described above the results of XANES support the existence of MoO_2^{2+} and the results of EXAFS Fourier transforms are also in agreement with this conclusion. This species must be hydrated, such as $MoO_2(H_2O)_4^{2+}$ (molybdenum centre should be coordinated octahedrally because the pre-edge peak is observed at 20,008.8 eV in XANES spectra; if it is surrounded tetrahedrally the peak should be at 20,007 eV[7]), however, coordinated oxygen atoms of water molecules which should appear at *ca* 2.2–2.3 Å in Fourier transforms could not be observed clearly. This may be due to rapid exchange of coordinated water molecules, i.e. the labile character of molybdenum(VI).[14] For 0.4 M molybdenum(VI) solutions a dimeric cation can be detected by EXAFS (the peak at 3.37 Å corresponding to Mo—Mo was observed[7]), while for 0.1 M molybdenum(VI) solutions the dimeric cation cannot be detected clearly. In HCl solutions of more than 3 M the peak at *ca* 2.3 Å, corresponding to the distance of the Mo—Cl bond, increases with c_{HCl}, indicating that the number of coordinated chloride ions increases. The numbers of coordinating oxygen and chlorine atoms, N_O and N_{Cl}, in the cationic species of molybdenum(VI) are estimated using the relation $hR^2 = PN$, where h is the peak height in Fourier transform, R is the bond length and P is the proportional constant. In this case the root-mean-square relative deviation (RMSRD) of R is assumed to be constant.[7,15] This assumption leads to the experimental errors for N within *ca* ±7%. The reference samples used to determine the value of P were MoO_4^{2-} (in pH 7.28) for N_O and $MoOCl_5^{2-}$ (in 8 M HCl) for N_{Cl}.[16] The values of R_O, N_O, R_{Cl} and N_{Cl} determined are listed in Table 1 (in these analyses values for N are averaged ones for each molybdenum atom and, therefore, not for each species). In perchloric, sulphuric and nitric acid solutions the values of R_O are almost constant and N_O values are around two, and no coordination of the anion is observed. The structure of the cationic species MoO_2^{2+} seems to be the same in these acid solutions, which is also in agreement with the results of XANES. In HCl solution of less than 3 M coordination of the chloride ion is not observed clearly. Above 3 M N_{Cl} increases steadily, while N_O remains almost two. Thus, the unit of MoO_2^{2+} does not change when the chlorine atom coordinates.

It is well known that molybdenum(VI) is extracted into diethyl ether from 6 M HCl solution. Nelidow and Diamond[17] concluded from chemical analysis that the extracted species in diethyl ether is MoO_2Cl_2, while Zharovskii[18] and others[19] claimed that $HMoO_2Cl_3$ was extracted. EXAFS results are listed in Table 1 for the organic phase after extraction from HCl solution. While N_{Cl} in aqueous solution depends on c_{HCl}, both N_O and N_{Cl} for the organic phase are constantly two, indicating that the species extracted is MoO_2Cl_2. N_{Cl} in diethyl ether is somewhat larger than in aqueous solutions, which is probably due to the small RMSRD resulting from solvation by ether molecules to produce the stable structure of MoO_2Cl_2. The result in Table 1 indicates that the composition of the molyb-

denum(VI) species in 6 M HCl solution is almost the same as that in the organic phase. This result is in agreement with that reported by Griffith and Wickins[20] that the Raman spectrum of an ether solution of $MoO_2Cl_2(OEt_2)_2$ is very similar to that of molybdate in 6 M HCl solution. The distribution ratio, D_{Mo}, is largest at *ca* 6 M HCl[13] (D_{Mo} determined in this work was 0.50, 1.62, 2.15 and 1.88 in 4, 5, 6 and 7 M HCl, respectively). Further, even if c_{HCl} for aqueous solutions are different (4–7 M) E_0 values for the organic phase after extraction are almost the same as those in 6 M HCl aqueous solution. That is, a few kinds of species having the same MoO_2^{2+} unit but having different numbers of coordinating chlorine atom, such as MoO_2Cl^+, MoO_2Cl_2 and $MoO_2Cl_3^-$, are present in aqueous HCl solutions.[17,21] However, the species of MoO_2Cl_2 seems to be extracted selectively into diethyl ether.

Recently, Coddington and Taylor[22] reported a ^{95}Mo NMR investigation and concluded that MoO_2Cl_2 is present in HCl solution and is extracted into the ether phase. These observations are in agreement with the results of our work.

THE REACTIONS OF $[WI_2(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$ (R = Me OR Ph) WITH $OPPh_3$ AND $SPPh_3$

PAUL K. BAKER* and STEPHEN D. RIDYARD

Department of Chemistry, University of Wales, Bangor, Gwynedd LL57 2UW, U.K.

(*Received* 30 *September* 1992; *accepted* 4 *December* 1992)

Abstract—Equimolar quantities of $[WI_2(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$ (R = Me or Ph) and L (L = $OPPh_3$ or $SPPh_3$) react in CH_2Cl_2 at room temperature to give $[WI_2(CO)L(\eta^2\text{-}RC_2R)_2]$ (**1–4**). The reaction of $[WI_2(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$ (R = Me or Ph) with 2 equivalents of L (L = $OPPh_3$ or $SPPh_3$) eventually affords the cationic complexes $[WI(CO)L_2(\eta^2\text{-}RC_2R)_2]I$ (**5–8**). The complexes $[WI_2(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$ (R = Me or Ph) react with 3 equivalents of L (L = $OPPh_3$ or $SPPh_3$) to yield the dicationic complexes $[W(CO)L_3(\eta^2\text{-}RC_2R)_2]2I$ (**9–12**). The mono- and dicationic nature of **5–8** and **9–12** was established by preparing the tetraphenylborate complexes $[WI(CO)(OPPh_3)_2(\eta^2\text{-}MeC_2Me)_2][BPh_4]$ (**13**) and $[W(CO)(OPPh_3)_3(\eta^2\text{-}MeC_2Me)_2][BPh_4]_2$ (**14**), respectively.

Since the discovery of the tris(alkyne) tungsten complex $[W(CO)(\eta^2\text{-hex-3-yne})_3]$ in 1963,[1] a considerable number of alkyne complexes of molybdenum and tungsten have been reported.[2] Although a large number of alkyne complexes of molybdenum or tungsten containing neutral phosphorus donor ligands have been reported,[2–9] hitherto very few alkyne complexes containing neutral oxygen or sulphur donor ligands have been made. We have previously described the reactions of $[WI_2(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$ (R = Me or Ph)[10] or $[WI(CO)(NCMe)(dppm)(\eta^2\text{-}MeC_2Me)][BF_4]$[11] with thiourea and related ligands. In this paper we describe the reactions of $[WI_2(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$ (R = Me or Ph) with $OPPh_3$ or $SPPh_3$.

EXPERIMENTAL

All the new complexes described in this paper were prepared using standard Schlenk-line techniques. The starting materials, $[WI_2(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$ (R = Me or Ph), were prepared by the published method.[12] All chemicals used were purchased from commercial sources. The solvent CH_2Cl_2 was dried and distilled before use.

Elemental analyses (carbon, hydrogen and nitrogen) were determined using a Carlo–Erba Elemental Analyser MOD 1106 (using helium as a carrier gas). IR spectra were recorded on a Perkin–Elmer 1430 ratio recording IR spectrophotometer. The ^1H NMR spectra reported in this paper were recorded on either a Bruker AC 250 CP/MAS NMR spectrometer or a Bruker WH 400 MHz NMR spectrometer. All spectra were referenced to tetramethylsilane.

Preparation of $[WI_2(CO)(OPPh_3)(\eta^2\text{-}MeC_2Me)_2]$ (**1**)

To $[WI_2(CO)(NCMe)(\eta^2\text{-}MeC_2Me)_2]$ (0.5 g, 0.813 mmol) dissolved in CH_2Cl_2 under a stream of dry nitrogen with continuous stirring was added $OPPh_3$ (0.23 g, 0.813 mmol). After stirring the solution for 3 h, filtration followed by removal of the solvent *in vacuo* gave yellow crystals of $[WI_2(CO)(OPPh_3)(\eta^2\text{-}MeC_2Me)_2]$ (**1**), which were recrystallized from CH_2Cl_2/Et_2O; yield = 0.56 g, 81%.

Similar reactions of $[WI_2(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$ (R = Me or Ph) with an equimolar quantity of L (L = $OPPh_3$ or $SPPh_3$) gave $[WI_2(CO)L(\eta^2\text{-}RC_2R)_2]$ (**2–4**) (see Table 1 for physical and analytical data).

Preparation of $[WI(CO)(OPPh_3)_2(\eta^2\text{-}MeC_2Me)_2]I$ **(5)**

To $[WI_2(CO)(NCMe)(\eta^2\text{-}MeC_2Me)_2]$ (0.5 g, 0.813 mmol) dissolved in CH_2Cl_2 (20 cm^3) under a stream of dry nitrogen with continuous stirring was added $OPPh_3$ (0.45 g, 1.626 mmol). After stirring the solution for 4 h, filtration followed by removal of the solvent *in vacuo* gave orange/yellow crystals of $[WI(CO)(OPPh_3)_2(\eta^2\text{-}MeC_2Me)_2]I$ **(5)**, which were recrystallized from CH_2Cl_2/Et_2O; yield = 0.86 g, 94%.

Similar reactions of $[WI_2(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$ (R = Me or Ph) with 2 equivalents of L (L = $OPPh_3$ or $SPPh_3$) gave $[WI(CO)L_2(\eta^2\text{-}RC_2R)_2]I$ **(6–8)** (see Table 1 for physical and analytical data).

Preparation of $[W(CO)(SPPh_3)_3(\eta^2\text{-}MeC_2Me)_2]2I$ **(11)**

To $[WI_2(CO)(NCMe)(\eta^2\text{-}MeC_2Me)_2]$ (0.5 g, 0.813 mmol) dissolved in CH_2Cl_2 (20 cm^3) under a stream of dry nitrogen with continuous stirring was added $SPPh_3$ (0.72 g, 2.439 mmol). After stirring the solution for 18 h, filtration followed by removal of the solvent *in vacuo* gave yellow/brown crystals of $[W(CO)(SPPh_3)_3(\eta^2\text{-}MeC_2Me)_2]2I$ **(11)**, which were recrystallized from CH_2Cl_2/Et_2O; yield = 0.94 g, 80%.

Similar reactions of $[WI_2(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$ with 3 equivalents of L (L = $OPPh_3$ or $SPPh_3$) gave $[W(CO)L_3(\eta^2\text{-}RC_2R)_2]2I$ **(9, 10, 12)** (see Table 1 for physical and analytical data).

Preparation of $[WI(CO)(OPPh_3)_2(\eta^2\text{-}MeC_2Me)_2][BPh_4]$ **(13)**

To $[WI_2(CO)(NCMe)(\eta^2\text{-}MeC_2Me)_2]$ (0.5 g, 0.813 mmol) suspended in acetonitrile (25 cm^3) was added $OPPh_3$ (0.45 g, 1.626 mmol), followed by $Na[BPh_4]$ (0.28 g, 0.813 mmol) under a stream of dry nitrogen. After stirring the solution at room temperature for 18 h removal of the solvent *in vacuo* afforded an orange/white slurry, which was redis-

solved in CH_2Cl_2 (20 cm^3) and filtered twice. Removal of the solvent *in vacuo* gave orange crystals of $[WI(CO)(OPPh_3)_2(\eta^2\text{-}MeC_2Me)_2][BPh_4]$ (**13**), which were recrystallized from CH_2Cl_2/Et_2O; yield = 0.49 g, 46%.

Preparation of $[W(CO)(OPPh_3)_3(\eta^2\text{-}MeC_2Me)_2][BPh_4]_2$ (**14**)

To $[WI_2(CO)(NCMe)(\eta^2\text{-}MeC_2Me)_2]$ (0.5 g, 0.813 mmol) suspended in acetonitrile (25 cm^3) was added $OPPh_3$ (0.68 g, 2.439 mmol) followed by $Na[BPh_4]$ (0.56 g, 1.626 mmol) under a stream of nitrogen. After stirring at room temperature for 18 h removal of the solvent *in vacuo* afforded an orange/white slurry, which was redissolved in CH_2Cl_2 (20 cm^3) and filtered twice. Removal of the solvent *in vacuo* afforded orange crystals of $[W(CO)(OPPh_3)_3(\eta^2\text{-}MeC_2Me)_2][BPh_4]_2$ (**14**), which were recrystallized from CH_2Cl_2/Et_2O; yield = 0.43 g, 30%.

RESULTS AND DISCUSSION

The starting materials used in this research, namely $[WI_2(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$ (R = Me or Ph), were prepared by reacting the seven-coordinate complex $[WI_2(CO)_3(NCMe)_2]$ with an excess of RC_2R in CH_2Cl_2 at 0°C.[12] The reactions of $[WI_2(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$ (R = Me or Ph) with 1, 2 or 3 equivalents of L (L = $OPPh_3$ or $SPPh_3$) in CH_2Cl_2 at room temperature afford the new alkyne complexes $[WI_2(CO)L(\eta^2\text{-}RC_2R)_2]$ (**1–4**), $[WI(CO)L_2(\eta^2\text{-}RC_2R)_2]I$ (**5–8**) and $[W(CO)L_3(\eta^2\text{-}RC_2R)_2]2I$ (**9–12**), respectively. The cationic nature of complexes **5–8** was confirmed by reacting $[WI(CO)(OPPh_3)_2(\eta^2\text{-}MeC_2Me)_2]I$ (**5**) with 1 equivalent of $Na[BPh_4]$ in acetonitrile, which gave the iodide exchanged product $[WI(CO)(OPPh_3)_2(\eta^2\text{-}MeC_2Me)_2][BPh_4]$ (**13**). Similarly, the dicationic nature of **9–12** was established by treating $[W(CO)(OPPh_3)_3(\eta^2\text{-}MeC_2Me)_2]2I$ with 2 equivalents of $Na[BPh_4]$ in acetonitrile to yield the bis(tetraphenylborate) product $[W(CO)(OPPh_3)_3(\eta^2\text{-}MeC_2Me)_2][BPh_4]_2$ (**14**). Complexes **1–14** have all been characterized by elemental analysis (carbon, hydrogen and nitrogen) (Table 1) and IR and ^1H NMR spectroscopy (Table 2). All the complexes (**1–14**) are soluble in chlorinated solvents such as CH_2Cl_2 and $CHCl_3$ and also in acetone. However, they are only partially soluble (**1–4**) or totally insoluble in hydrocarbon solvents and diethyl ether. The complexes (**1–14**) are all air-sensitive in the solid state and very air-sensitive in solution. The more L (L = $OPPh_3$ or $SPPh_3$) groups which are attached to the metal, the more sensitive and less stable the complexes were found to be.

[a] Spectra recorded in $CHCl_3$ as thin films between NaCl plates; s, strong.

[b] Spectra recorded in $CDCl_3$ (+25°C) on a Bruker AC250 CP/MAS NMR spectrometer and referenced to Me_4Si.

[c] Spectra recorded in CD_2Cl_2 (+32°C) on a Bruker WH 400 NMR spectrometer and referenced to Me_4Si.

It is likely that the reactions of $[WI_2(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$ with 1 equivalent of L (L = $OPPh_3$ or $SPPh_3$) to give the acetonitrile displaced products $[WI_2(CO)L(\eta^2\text{-}RC_2R)_2]$ (**1–4**) proceed via an associative mechanism, since alkyne ligands can rearrange their mode of bonding from a "three-electron" donor to a two-electron donor and hence incorporate the donor ligand, L, before expelling the acetonitrile and reverting to being a four-electron donor. Other workers[3,13] have proposed these associative mechanisms for reactions of neutral donor ligands with alkyne complexes of molybdenum(II) and tungsten(II). It is interesting to note that the IR spectra of **1–4** all show carbonyl bands at similar wave-numbers compared with the starting materials $[WI_2(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$ [for R = Me, $\nu(CO)$ = 2050; for R = Ph, $\nu(CO)$ = 2090 cm^{-1}],[12] hence it is likely that $OPPh_3$ and

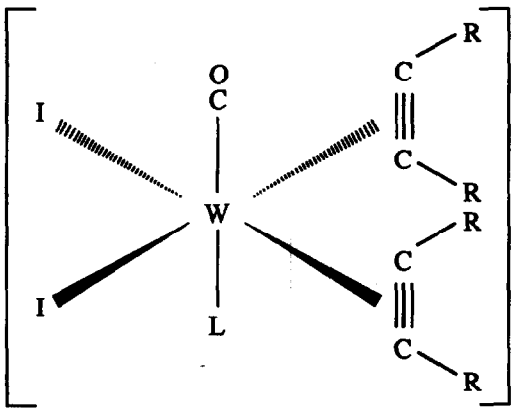

Fig. 1. Proposed structure for $[WI_2(CO)L(\eta^2\text{-}RC_2R)_2]$ (**1–4**).

$SPPh_3$ are acting mainly as σ-donor ligands in these complexes. Unfortunately, the $\nu(C{\equiv}C)$ bands were masked by the phenyl overtones in complexes **1–14**. Since the molecular structures of $[WI_2(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$ (R = Me or Ph),[12] $[WI_2(CO)_2(\eta^2\text{-}MeC_2Me)_2]$[14] and $[WI_2(CO)\{NCCH_2(C_4H_3S)\}(\eta^2\text{-}MeC_2Me)_2][NCCH_2(C_4H_3S)$ = thiophene-3-acetonitrile][15] have been determined crystallographically, it is likely that complexes **1–4** will have a similar structure, as shown in Fig. 1. The ^1H NMR data (Table 2) conform with the structure shown in Fig. 1.

The reaction of $[WI_2(CO)(NCMe)(\eta^2\text{-}PhC_2Ph)_2]$ with 2 equivalents of $OPPh_3$ in $CHCl_3$ was followed by IR spectroscopy. After 1 h the spectrum showed a broad band at 2085 cm^{-1} due to $[WI_2(CO)(NCMe)(\eta^2\text{-}PhC_2Ph)_2]$ and **2**, and a very weak band at 1970 cm^{-1} which is likely to be due to the mono(diphenylacetylene) complex $[WI_2(CO)(OPPh_3)_2(\eta^2\text{-}PhC_2Ph)]$. After 2 h the solution became darker green and the band at 1970 cm^{-1} had reached a maximum intensity. We have previously reported the preparation of bis(phosphine) complexes of the type $[WI_2(CO)L'_2(\eta^2\text{-}MeC_2Me)]$ (L′ = monodentate phosphine),[7] and many of these four-electron alkyne complexes are dark green in colour. After 4 h the colour of the solution became orange/yellow and the band at 1970 cm^{-1} had disappeared in the IR spectrum, leaving only a band at 2080 cm^{-1} due to $[WI(CO)(OPPh_3)_2(\eta^2\text{-}PhC_2Ph)_2]I$ (**6**). Many unsuccessful attempts were made to isolate the dark green intermediate $[WI_2(CO)(OPPh_3)_2(\eta^2\text{-}PhC_2Ph)]$ and also the analogous $SPPh_3$ complex. The proposed mechanism of the reaction of $[WI_2(CO)(NCMe)(\eta^2\text{-}PhC_2Ph)_2]$ with 2 equivalents of $OPPh_3$ is shown in Scheme 1. Further evidence to support this proposed mechanism comes from the reaction of $[WI_2(CO)(OPPh_3)(\eta^2\text{-}PhC_2Ph)_2]$ (**2**) with an equimolar amount of $OPPh_3$ in CH_2Cl_2 at room temperature, which eventually gives the cationic complex $[WI(CO)(OPPh_3)_2(\eta^2\text{-}PhC_2Ph)_2]I$ (**6**). It is interesting to note that the reaction of $[WI_2(CO)(NCMe)(\eta^2\text{-}MeC_2Me)_2]$ with 2 equivalents of L [L = $SC(NH_2)_2$ or $SC(NMe_2)_2$] in acetone gave the purple mono(but-2-yne) complexes $[WI_2(CO)L_2(\eta^2\text{-}MeC_2Me)]$.[10] This behaviour is likely to be due to the stronger π-acceptor properties of $SC(NH_2)_2$ and $SC(NMe_2)_2$ compared to $OPPh_3$ and $SPPh_3$.

The X-ray crystal structure of the 2,2-bipyridyl complex $[WI(CO)(2,2'\text{-bipy})(\eta^2\text{-}MeC_2Me)_2][BPh_4]$ has been determined[16] and shows the two *cis*-but-2-yne ligands are parallel and have the 2,2′-bipyridyl ligand in the equatorial plane with the carbonyl and iodide ligands in the axial positions. Hence, it is very likely that the structure of **5–8** will be similar and as shown in Fig. 2. The ^1H NMR data (Table 2) of **5–8** conform with the structure which is shown in Fig. 2.

Surprisingly, the reactions of $[WI_2(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$ with 3 equivalents of L (L = $OPPh_3$ or $SPPh_3$) apparently give the bis(alkyne) complexes $[W(CO)L_3(\eta^2\text{-}RC_2R)_2]2I$ (**9–12**) rather than the mono(alkyne) complexes $[WI(CO)L_3(\eta^2\text{-}RC_2R)]I$. This may be due to the electron-rich nature of $OPPh_3$ and $SPPh_3$. It should also be noted that reaction of $[WI(CO)(OPPh_3)_2(\eta^2\text{-}PhC_2Ph)_2]I$ (**6**) with an equimolar quantity of $OPPh_3$ in CH_2Cl_2 at room temperature affords the expected dicationic complex $[W(CO)(OPPh_3)_3(\eta^2\text{-}PhC_2Ph)_2]2I$ (**10**).

In summary, the reactions of $[WI_2(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$ with 1 equivalent of $OPPh_3$ or $SPPh_3$ are similar to other reactions with electron-rich neutral nitrogen, oxygen and sulphur donor ligands. However, for reactions with 2 or more

(i) $[WI_2(CO)(NCMe)(\eta^2\text{-}PhC_2Ph)_2] \xrightarrow{OPPh_3} [WI_2(CO)(OPPh_3)(\eta^2\text{-}PhC_2Ph)_2] + NCMe$

(ii) $[WI_2(CO)(OPPh_3)(\eta^2\text{-}PhC_2Ph)_2] \xrightarrow{OPPh_3} [WI_2(CO)(OPPh_3)_2(\eta^2\text{-}PhC_2Ph)] + PhC_2Ph$

(iii) $[WI_2(CO)(OPPh_3)_2(\eta^2\text{-}PhC_2Ph)] \xrightarrow{PhC_2Ph} [WI(CO)(OPPh_3)_2(\eta^2\text{-}PhC_2Ph)_2]I$

Scheme 1.

Abstract—The first chain copper(I) complex with 4,4′-bipyridine as the bridging ligand, of the formula $[\mu$-4,4′-bipy-Cu(TTA)$]_n$ (TTA = 2-thienoyltrifluoroacetone), has been prepared and characterized by elemental analysis, IR and FAB mass spectra. Its X-ray crystal structure determination reveals that the local coordination geometry around copper(I) is a distorted tetrahedron. Cu(TTA) units are bridged by 4,4′-bipyridine to form an infinite zigzag chain with an N—Cu—N angle of 143.3(7)°. The short Cu—N distance (1.98 Å) indicates that quite strong molecular chains have been formed in the crystal.

One-dimensional transition metal complexes bridged by bidentate π-electron-containing ligands, such as pyrazine and 4,4′-bipyridine, have gained more importance with respect to their properties as organic conductors. Many polymers, most containing metallomacrocycles, have been synthesized and extensively investigated.[1–3] After partial oxidation or reduction of the polymers mixed-valence solids can be obtained and show good conducting or semiconducting properties. Recently we have reported a one-dimensional β-diketonate complex with copper(II) as the central metal ion and 4,4′-bipyridine as the bridging ligand.[4] In the partial reduction process of the copper(II) complex with ascorbic acid a novel copper(I) complex with an infinite zigzag chain structure appeared unexpectedly. Although copper(II) complexes of β-diketonate have been extensively investigated, there are few reports of copper(I) β-diketonate compounds.[5] To our knowledge, the title complex is the first structurally characterized copper(I) complex with a chain arrangement. Here we report the synthesis, mass spectra and X-ray single crystal structure of the copper(I) complex, $[\mu$-4,4′-bipy-Cu(TTA)$]_n$.

EXPERIMENTAL

Synthesis

Analytical grade copper(II) chloride, 2-thienoyltrifluoroacetone, 4,4′-bipyridine and ascorbic acid were used without further purification. Solvents were refluxed and distilled over $MgSO_4$ for DMF and NaH for methanol under nitrogen. $Cu(TTA)_2$ was prepared according to the literature method.[6] The title complex was prepared by mixing ascorbic acid (1 mmol), 4,4′-bipyridine (2 mmol) and $Cu(TTA)_2$ (0.5 mmol) in DMF (10 cm^3). The solution was stirred for 2 h at room temperature and filtered to leave a red–brown filtrate. The filtrate was then poured into methanol (50 cm^3) and red crystals precipitated out. The crystals were collected by filtration, washed with methanol and dried *in vacuo*; yield 0.10 g (45%). Found: C, 49.2; H, 2.7; N, 6.3. Calc. for $C_{18}H_{12}N_2F_3O_2SCu$: C, 49.0; H, 2.7; N, 6.3%. The red plate-like crystals suitable for X-ray structure analysis were grown from the

* Author to whom correspondence should be addressed.

filtrate by diffusion with methanol vapour for 2 weeks. Each process was performed under nitrogen. The pure solid complex is relatively stable in dry air, but the copper(I) can be oxidized slowly in moist air.

Physical measurements

Elemental analyses for carbon, hydrogen and nitrogen were performed on a Perkin–Elmer 240C analyser. IR spectra were obtained with KBr pellets in the 4000–400 cm^{-1} region, using a Nicolet 170SX FTIR spectrophotometer. Fast atom bombardment (FAB) mass spectra were obtained on a VG-ZAB-HS spectrometer with thioglycerol as a matrix. Xenon was used to produce the primary beam. A primary current of 1 mA at an energy of 8 KeV provided good sample ion intensities.

Crystallographic structure determination

A single crystal with the dimensions $0.1 \times 0.2 \times 0.2$ mm was selected for X-ray diffraction analysis. Diffraction data were collected on a Rigaku AFC5R diffractometer using graphite-monochromated Mo-K_α ($\lambda = 0.71069$ Å) radiation. During the course of the intensity data collection the crystal showed no loss in intensity. A summary of crystallographic data is given in Table 1. The crystal structure was solved using direct methods and difference-Fourier syntheses, and refined by the full-matrix least-squares technique using anisotropic temperature factors. Hydrogen atoms were calculated as riding on carbon atoms at 0.95 Å and refined using isotropic temperature factors. The intensity data were corrected for Lorentz–polarization effects and empirical absorption. All the calculations were performed on a micro VAXII computer using the TEXSAN program system. Complete tables of atomic coordinates and thermal parameters, together with observed and calculated structure factors, have been deposited with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Center.

RESULTS AND DISCUSSION

By reaction of $Cu(TTA)_2$ and 4,4′-bipyridine with ascorbic acid, we have synthesized a novel copper(I) complex. Elemental analysis has confirmed the formula $[Cu(C_8H_4F_3O_2S)(C_{10}H_8N_2)]_n$.

When 4,4′-bipyridine is the bridging ligand IR spectroscopy is a useful tool for distinguishing monomers from polymers.[7] The monomeric derivatives give rise to new bands at 800, 1070, 1215, 1402, 1483 and 1589 cm^{-1}. These absorptions are caused by the ligand and agree with the bands exhibited by the free 4,4′-bipyridine. The predominant spectral difference observed for the 4,4′-bipyridine bridging compounds, compared with monomeric compounds containing terminal 4,4′-bipyridine, is the disappearance of absorptions at *ca* 1215, 1402 and 1589 cm^{-1}. The IR spectra of the title complex display three characteristic absorptions of 4,4′-bipyridine at 808, 1055 and 1470 cm^{-1}. The disappearance of in-plane vibrations around 1215, 1402 and 1589 cm^{-1} indicates that the copper(I) complex is a polymer with 4,4′-bipyridine as the bridging group.

FAB mass spectra, developed rapidly during the last few years, promise to be extremely valuable in characterizing polar involatile compounds. Table 2 summarizes the results obtained for the FAB-MS analysis on the copper(I) complex. The most intense peak corresponds to the fragment ion $(4,4'\text{-bipy}+H)^+$. Every original cation peak is bound with two peaks corresponding to the addition of one and two hydrogen atoms.[8] Peak a is assigned to two fragment ions, $[(C_4H_3S)CO]^+$ ($m/z = 111$) and $(CH_2COCF_3)^+$ ($m/z = 111$), due to the cleavage of the TTA ligand at the carbonyl carbon.[9] The

Table 3. Selected bond distances (Å) and angles (°) in [μ-4,4′-bipy-Cu(TTA)]$_n$

Cu—N(1)	1.98(2)	Cu—N(2)	1.97(2)
Cu—O(1)	2.20(1)	Cu—O(2)	2.15(2)
O(1)—C(13)	1.29(2)	O(2)—C(11)	1.23(3)
C(3)—C(8)	1.50(3)	C(11)—C(12)	1.40(3)
C(12)—C(13)	1.35(3)	C(13)—C(14)	1.44(3)
N(1)—Cu—N(2)	143.3(7)	O(1)—Cu—O(2)	83.3(6)
N(1)—Cu—O(1)	100.6(7)	N(1)—Cu—O(2)	107.9(7)
N(2)—Cu—O(1)	104.5(7)	N(2)—Cu—O(2)	101.4(7)

presence of peak e indicates that the complex is polymeric with 4,4′-bipyridine as bridging groups. According to the relative intensity I the ligand ratio of TTA and 4,4′-bipyridine can be calculated. $I_{4,4'\text{-bipy}} = I_b+I_d+I_e+2I_f = 169.7\, I_{TTA} = I_c+1/2(I_a+I_d+I_e+I_f) = 162.1$ $I_{4,4'\text{-bipy}}$ is nearly equal to I_{TTA}, indicating that the ligand ratio is 1 : 1. This is exactly in agreement with the result of elemental analysis.

The molecular structure of the copper(I) complex is shown in Fig. 1. Selected bond distances and angles are listed in Table 3. The local coordination geometry around the copper(I) ion is distorted tetrahedral. Cu(TTA) units are linked by 4,4′-bipyridine in a zigzag fashion with an N(1)—Cu—N(2) angle of 143.3(7)°, forming an infinite chain in the crystal. Eight of these chains pass through a cell in a parallel fashion.

The average Cu—O bond length (2.18 Å) is longer, whereas Cu—N (1.98 Å) is shorter than those found in the related known β-diketonate complexes, such as trigonal planar Cu^{I}(tfacac)(PMe_3), Cu—O 1.986;[5] square planar Cu^{II}(TTA)$_2$, Cu—O 1.914;[10] square-pyramidal μ-4,4′-bipy-

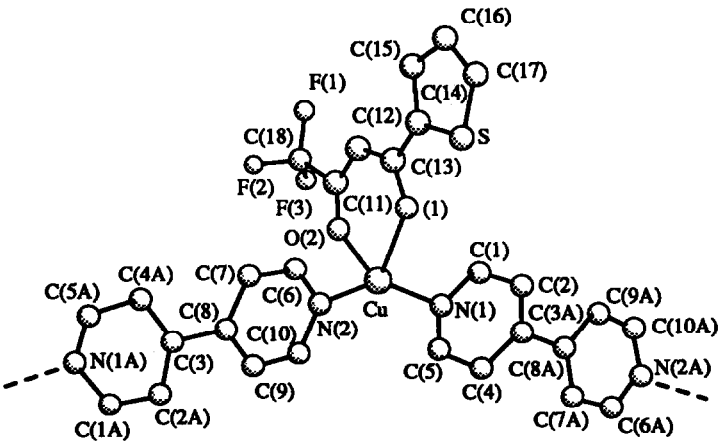

Fig. 1. Structure of the complex [μ-4,4′-bipy-Cu(TTA)]$_n$.

cun2(TTA)4, Cu--O 1.934, Cu--N 2.262; 11 and octahedral [#-4,4'-bipy-Cu~(TTA)2]n,Cu--O 2.039, Cu--N 2.201/~.4 The unusually short Cu--N distance, taking into consideration the difference in metallic ion radii (Cu ÷ 0.96, Cu 2÷ 0.72 A), indicates that strong bonds and quite firm molecular chains have been formed. The bond angle of O(1)---Cu--O(2) is 83.3°. The chelate ring between O(1) and 0(2) with the copper atom is basically planar. The dihedral angle between the thiophene ring and the chelate ring is rather small (4.47°), indicating some kind of conjugation effect. This leads to the fact that the bond length of 1.44 /~ between C(13) and C(14) is shorter than the usual *sp2-sp 2* C--C single bond length of 1.50 ~.

SYNTHESIS AND STRUCTURAL CHARACTERIZATION OF DIMERIC DIORGANOTIN(IV) N-2-HYDROXYNAPHTHALIDENE-β-AMINO ACID COMPLEXES: X-RAY STRUCTURE OF $[Me_2Sn(OC_{10}H_6CH{=}NCH_2CH_2COO)]_2$

(*Received* 8 *October* 1992; *accepted* 2 *December* 1992)

Abstract—Two new compounds with the formula $[R_2Sn(OC_{10}H_6CH{=}NCH_2CH_2COO)]_2$ where R = CH_3 or n-C_4H_9, have been synthesized. The crystal structure of the dimethyltin compound is reported along with ^1H, ^{13}C and IR spectroscopic data for both compounds. The centrosymmetric dimethyltin complex exhibits octahedral coordination for each tin atom. The tridentate ligand chelates meridionally via the phenolate oxygen, the imino nitrogen and one carboxylate oxygen atom. Two further *trans* positions in the tin coordination sphere are taken up by the two methyl groups while the apical (sixth) position is filled by a shared carboxylate oxygen atom from the other organotin unit.

Many organotin compounds are active *in vitro* and *in vivo* against P388 leukemia.[1,2] Some are characterized by a bicyclic structure such as the dibutyltin derivative of glycylglycine[3] and the diorganotin 2,6-pyridine dicarboxylates.[4] Although extensive biological[5] and structural[6,7] studies have been conducted on these eight- and nine-membered bicyclic compounds, there is to-date no structural characterization of 10-membered bicyclic diorganotin complexes with two six-membered chelate rings resulting from a 1,6-intramolecular Sn—N interaction. As a continuation of our studies on the eight- and nine-membered bicyclic diorganotin compounds,[8,9] we now report the results of our investigation into the synthesis and characterization of diorganotin(IV) N-2-hydroxynaphthalidene-β-amino acid complexes: $R_2Sn(OC_{10}H_6CH{=}NCH_2CH_2COO)$ (R = CH_3 and Bu^n). A full X-ray structural analysis of the dimethyltin complex of the N-2-hydroxynaphthalidene-β-alanine ligand has been performed and the results are reported along with a variety of spectroscopic data for both the dimethyltin and dibutyltin derivatives of the ligand.

* Authors to whom correspondence should be addressed.

RESULTS AND DISCUSSION

Diorganotin complexes of bis-chelating tridentate ligands capable of forming two chelate rings frequently have trigonal bipyramidal geometry with the ligand occupying the axial–equatorial–axial sites.[6,9] It was anticipated that the ligand, 2-$HOC_{10}H_6CH{=}NCH_2CH_2COOH$, which forms two six-membered chelate rings upon complexation, would behave likewise. However, the X-ray structural investigation of $Me_2Sn(OC_{10}H_6CH{=}NCH_2CH_2COO)$ confirms that the complex crystallized as a centrosymmetric dimer. The six-coordinate geometry of the complex organotin moiety and the atomic numbering scheme are shown in

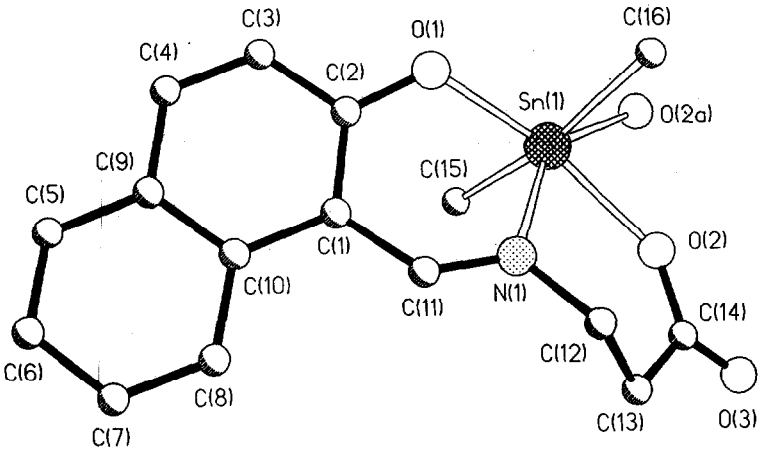

Fig. 1. Molecular structure and crystallographic numbering scheme employed for $[Me_2Sn(OC_{10}H_6CH{=}NCH_2CH_2COO)]_2$.

Fig. 1, while packing of the dimeric units is illustrated in Fig. 2. Table 1 lists the bond distances and bond angles. The ^1H and ^{13}C NMR data for both the dimethyl and di-n-butyl compounds are listed in Table 2, together with those of the ligand, while the IR, physical and analytical data are included in the Experimental.

Each tin atom is in a distorted octahedral environment and coordinated meridionally by the tridentate ligand via the phenolate oxygen, imino nitrogen and one-carboxylate oxygen atom. Two further *trans* positions in the coordination sphere are taken up by the two methyl groups, while the apical (sixth) position is filled by a shared carboxylate oxygen (O2a) from the other organotin unit, resulting in a dimer consolidated by a centrosymmetric, planar, four-membered Sn_2O_2 ring (Fig. 2).

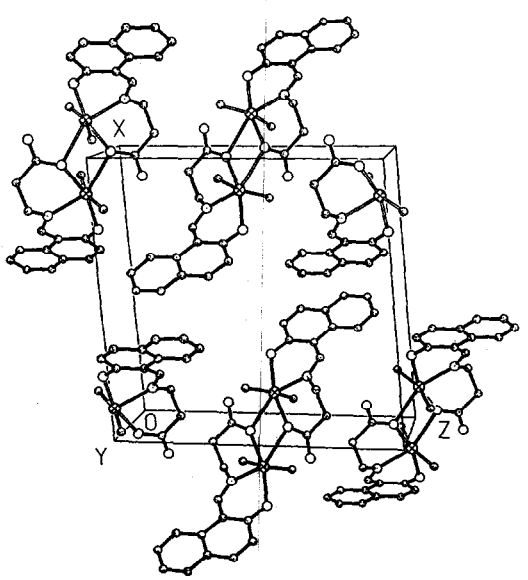

Fig. 2. Molecular packing in the dimeric crystal structure of $[Me_2Sn(OC_{10}H_6CH{=}NCH_2CH_2COO)]_2$.

In this configuration the three *trans* angles around the tin atom, 163.2° [C(15)—Sn—C(16)], 161.6° [O(1)—Sn—O(2)] and 146.9° [N(1)—Sn—O(2a)], are normal for octahedral tin(IV) complexes.[10,11] However, the *trans* angle of 161.6°, formed between the two terminal oxygen donors of the ligand and the tin atom, [O(1)—Sn—O(2)], is 5.7° wider than that reported for the pentacoordinate dibutyltin complex[9] $Bu_2Sn[OC_6H_4CH{=}NCH(Pr^i)COO]$, which contained a six-membered and a five-membered chelate ring. This is further reflected by the lengthening of the intramolecular Sn—N bond from 2.158 Å for $Bu_2Sn[OC_6H_4CH{=}NCH(Pr^i)COO]$ to 2.224 Å in the title complex, which now has two six-membered chelate rings. In spite of this, the two six-membered chelate rings are puckered into a boat and a half-chair conformation. The atoms forming the floor of the boat, Sn, N(1), C(13) and C(14), are co-planar to within 0.022 Å, while the prow atoms, O(2) and C(12), are displaced from this plane in the same direction by 0.087 amnd 0.672 Å, respectively. In the half-chair conformation N(1), C(11), C(1), C(2) and O(1) are co-planar to within 0.121 Å, while the remaining tin atom is displaced from this plane by a distance of 1.006 Å.

The similarities of the spectroscopic data indicate that the six-coordinate dimeric structure should be proposed for the dibutyltin derivative. The IR carbonyl stretching vibrations for the two diorganotin derivatives are normal in the range 1630–1610 cm^{-1}. However, the absence of a symmetric and the presence of an asymmetric Sn—Me stretching vibration at 580 cm^{-1} indicate a linear C—Sn—C

Symmetry transformation: a $(-x, -y, -z)$.

moiety in the methyl groups. This would be consistent with an octahedral configuration for the tin atom with the methyl groups in the *trans* positions. Table 2 gives the proton and ^{13}C NMR data for the complexes and the ligand. A downfield shift for the proton and ^{13}C signals was observed for the ligand upon complexation. This downfield shift was also observed in the diorganotin complex formed with 2-hydroxynaphthalidene-α-amino acid.[9] The spin–spin coupling between the azomethine proton and the tin nucleus, ^3J(SnN=CH), was detected in the two complexes. This type of spin–spin coupling, where the tin nuclei are located in a *trans* position to the azomethine proton, has previously been reported.[12,13] It thus confirms the presence of nitrogen–tin coordination in the complexes. In addition the values of the coupling constant (50–54 Hz) for ^3J(SnN=CH) (Table 2) are smaller than those (53–58 Hz) reported for the $[R_2Sn(OC_{10}H_6CH{=}NCH_2COO)]$ complexes.[9] This is attributed to the longer bond distance of the intramolecular Sn—N interaction in the present complexes.

from the Aldrich Chemical Company. All were used without further purification, except salicylaldehyde which was distilled before use.

Microanalyses were performed at the School of Chemical Sciences, Universiti Sains Malaysia, using an elemental analyser (Model 240-XA).

NMR spectra

The proton and ^{13}C NMR spectra were recorded in $CDCl_3$:DMSO-d_6 on a CFT-20 Varian or Bruker AC-P300 spectrometer. NMR results are summarized in Table 2.

IR spectra

These were obtained on a Nicolet 5MX instrument with the samples as Nujol mulls or in KBr discs.

Preparation of diorganotin N-2-hydroxynaphthalidene-β-amino acid complexes

To a suspension of β-alanine (20 mmol) in absolute ethanol (120 cm^3) was added R_2SnO (20 mmol) (R = CH_3; Bu^n), followed by 2-hydroxynaphthaldehyde (3.4 g, 20 mmol). The mixture was stirred under nitrogen and refluxed for 10–12 h. After cooling in the refrigerator a crystalline precipitate formed, which was filtered, dried and recrystallized from methanol to give the pure product. Analytical data, melting points, along with the yields obtained, and the IR stretching vibrations data are as follows:

(a) $Me_2Sn(OC_{10}H_6CH{=}NCH_2CH_2COO)$: m.p. 232–234°C; yield 72%. Found: C, 49.1; H, 4.5; N, 3.4. Calc. for $C_{16}H_{17}NO_3Sn$: C, 49.3; H, 4.4; N, 3.6%. IR (cm^{-1}): ν(C=O): 1610; $\nu(Sn{-}Me)_{asym}$: 580. (b) $Bu_2Sn(OC_{10}H_6CH{=}NCH_2CH_2COO)$: m.p. 138–140°C; yield 88%. Found: C, 54.4; H, 6.5; N, 2.7. Calc. for $C_{22}H_{29}NO_3Sn$: C, 55.7; H, 6.2; N, 2.9%. IR (cm^{-1}): ν(C=O): 1630.

X-ray crystallography

$(C_{16}H_{17}NO_3Sn)_2$, $M_r = 780$, monoclinic, space group $P2_1/c$ (No. 14), $a = 14.891(4)$, $b = 6.764(1)$, $c = 15.070(3)$ Å, $\beta = 94.01(2)°$, $V = 1514.2(6)$ $Å^3$, $Z = 2$, $F(000) = 776$, $\lambda = 0.71073$ Å, $\mu(Mo\text{-}K_\alpha) = 1.70$ mm^{-1}.

A selected crystal of the dimensions $0.10 \times 0.16 \times 0.28$ mm was used. Diffraction data (2771 unique reflections) were collected up to $2\theta_{max} = 50°$ on Siemens P4 diffractometer using the ω-scan mode (2.96–15.64° min^{-1}), processed with a profile-fitting procedure[14] and corrected for absorption using ψ-scan data ($\mu r = 0.10$, transmission factors 0.751–0.812).[15] A total of 2215 independent reflections with $I > 3\sigma(I)$ were considered as observed data and used in the structure analysis. The structure was solved by Patterson superposition and subsequent Fourier synthesis. Non-hydrogen atoms were refined anisotropically. All hydrogen atoms were generated geometrically (C—H = 0.96 Å) and included in structure–factor calculations with assigned isotropic thermal parameters. Final R_F and R_{WF_2} values are 0.028 and 0.030 for 190 variables with the weighting scheme $w = [\sigma^2(|F^0|) + 0.00002|F^0|^2]^{-1}$. The residual extrema in the final difference map are in the range +0.37 to −0.52 e $Å^{-3}$. Computations were performed using the SHELXTL-PC program package.[16] Analytical expressions of neutral atomic scattering factors were used and anomalous dispersion corrections were incorporated.[17]

(*Received* 1 *October* 1992; *accepted* 30 *November* 1992)

Abstract—Reaction of $HgCl_2$, in slight excess of 1 molar equivalent of the ligand ([18]aneN$_6$) in water, produces a colourless solution containing [Hg([18]aneN$_6$)](HgCl$_4$). The X-ray structure of this complex shows that the six nitrogen donor atoms of the macrocycle surround the mercury(II) atom in a distorted trigonal prismatic coordination. Cyclic voltammetry of [Hg([18]ane)]$^{2+}$ shows a chemically reversible reduction at a HDM electrode, with $E_{1/2} = -0.293$ V vs S.C.E. at pH 9.37 and a scan rate of 200 mV s^{-1}. The global oxidation–reduction process involves two electrons and two protons.

The coordination chemistry of potentially hexadentate macrocycles containing 18-membered rings (namely [18]aneX$_m$Y$_n$; X,Y = O,N,S; $m+n = 6$) is of particular interest, since these large ring systems have high flexibility and, therefore, can encapsulate and readily bind to a range of transition metal atoms, with the resulting complexes adopting different geometries.[1,2]

The macrocycle 1,4,7,10,13,16-hexaazacyclooctadecane (18-azacrown-6 or [18]aneN$_6$) is a ligand known to have great ability to form 1:1 complexes with several different metal cations, such as Co^{3+}, Ni^{2+}, Cu^{2+}, Cd^{2+}, Hg^{2+}, Pb^{2+}, Ca^{2+}, Sr^{2+}, La^{3+} and K^+ (as has been demonstrated by potentiometric techniques[3]), and also, as a triprotonated species, with some anions.[4] However, only two metal complexes with this ligand have been characterized by single-crystal X-ray analysis, *meso*-[Co([18]aneN$_6$)]Cl$_3$[5] and *rac*-[Co([18]aneN$_6$)](ClO$_4$)$_3$.[6] They both present an octahedral coordination involving all six nitrogen atoms of the ligand, but adopt different configurations.

Most properties exhibited by macrocyclic complexes appear to be controlled by the size of the cavity of the ligand.[7] According to previous molecular mechanics calculations[8] on metal 18-azacrown-6 complexes, it was concluded that for small metal ions (M—N ≈ 2.1, 2.2 Å) an octahedral geometry in two different isomeric structures, *rac* and *meso* (**I** and **II** on diagram), was preferred, while for larger metal ions (M—N ≈ 3.1 Å) a hexagonal bipyramidal geometry (**III**) was more probable.

Studies of the stability constants of different metal complexes with this ligand have shown that the highest values found were for copper [log K(CuL) = 21.6] and mercury [log K(HgL) = 29.1] complexes.[3]

We thus decided to synthesize both complexes. However, crystals of good quality were only obtained for the mercury complex. We report here the synthesis, characterization, electrochemical behaviour and crystal structure of the [Hg(18-azacrown-6)](HgCl$_4$) complex.

RESULTS AND DISCUSSION

Synthesis and characterization

Reaction of $HgCl_2$ with 1 molar equivalent of [18]aneN$_6$·HCl and an equivalent amount of base gave a colourless solution, which upon slow evaporation afforded white crystals of a mercury complex. Spectroscopic data and elemental analysis are indicative of the compound [Hg([18]aneN$_6$)] ($HgCl_4$). IR spectra showed peaks at *ca* 3400 and 1630 cm^{-1}, corresponding to N—H stretching and bending vibrations, respectively. The absence of any amine salt stretching vibration band, as has been found for the corresponding hexaamine ligand [as its 6 HCl adduct, ν(NH) $\approx$ 2700 cm^{-1}], was noticed. A strong sharp band was also observed at $\nu = 570$ cm^{-1}, which was attributed to the ν(Hg—N) stretching vibration. According to Adams[9] ν(M—N) in ethylenediamine metal complexes appears in the range 590–606 cm^{-1}; also, the IR frequency of ν(Hg—N) in amidomercury(II) chlorides is 573 cm^{-1}. The band corresponding to ν(Hg—Cl) stretching may be present in the far-IR regions [$(HgCl_4)^{2-}$, as a mull of NEt_4N^+ salts, presents $\nu = 223$ cm^{-1}], but the weakness of all far-IR bands makes it impossible to identify that vibration.

The ^{1}H NMR spectrum of [Hg([18]aneN$_6$)] ($HgCl_4$) showed a very thin multiplet at 2.61–2.63 ppm, which is characteristic of methylene protons, but it is shifted to a higher field relative to the free ligand ($\delta = 3.59$ ppm), as a consequence of the electrophilic character of the bonded Hg^{2+} ion. Moreover, an identical behaviour was observed for the ^{13}C NMR spectra of the complex and ligand, both presenting only one single resonance at $\delta = 43.22$ and $\delta = 44.39$ ppm, respectively. These data probably indicate the presence of a single product in solution, all the protons and carbons being magnetically equivalent but quite different from the free ligand.

The cyclic voltammetric behaviour observed for [Hg([18]aneN$_6$)]$^{2+}$ in water (0.1 M KNO_3 supporting electrolyte) is consistent with that expected for a reversible redox process,[10] namely $ip^c/ip^a \approx 1$ for all ranges of scan rates (v = 200–1000 mV s^{-1}), Ep^c and Ep^a are independent of scan rate and the plot of ip^c against $v^{1/2}$ gave a straight line. A peak potential separation of 30 mV is indicative of a two-electron transfer process, where $\Delta E_p = 59/n$ mV is expected for a reversible n-electron couple.

The half-wave potential, $E_{1/2}$, is -0.293 V vs S.C.E. at pH = 9.37 and a scan rate $v = 200$ mV s^{-1} (Fig. 1). No other waves appear within the limits of the solvent.

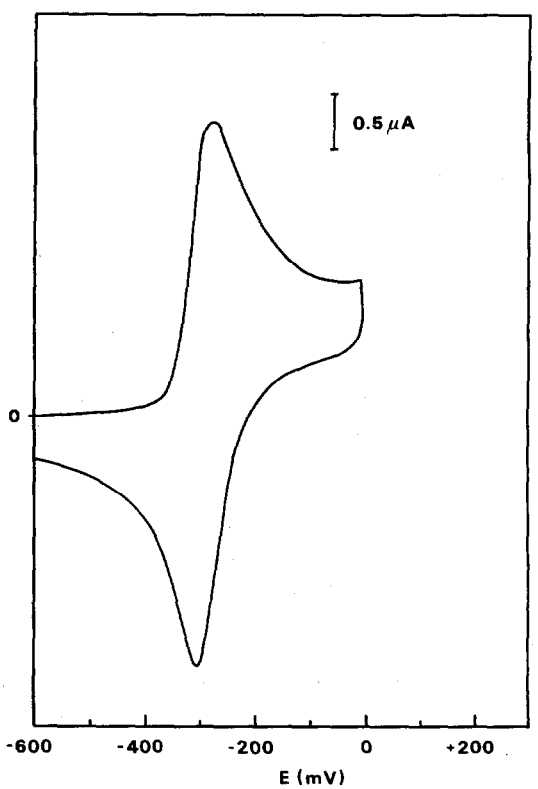

Fig. 1. Cyclic voltammogram of [Hg([18]aneN$_6$)]$^{2+}$ in water (0.1 M KNO_3) at HME. Scan rate = 200 mV s^{-1}, $T = 25 \pm 1$°C, pH = 9.37, $C_L = 5 \times 10^{-4}$ M.

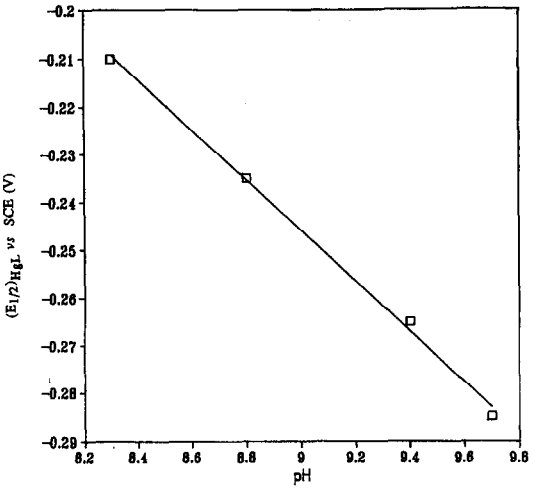

Fig. 2. Effect of pH on $(E_{1/2})_{HgL}$ at $I = 0.1$ M (KNO_3), 25°C, $C_L = 5 \times 10^{-4}$ M.

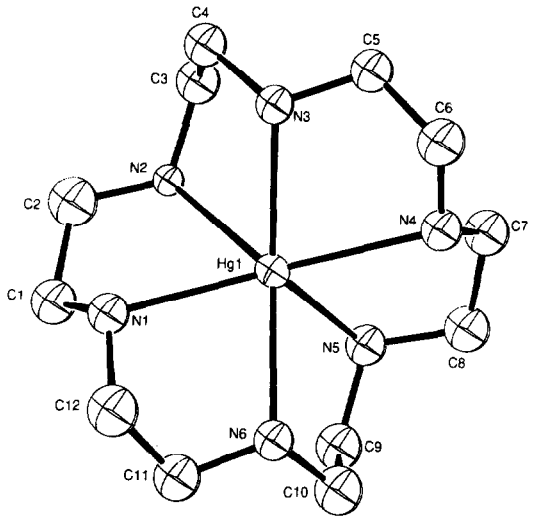

Fig. 3. Molecular structure of $[Hg([18]aneN_6)]^{2+}$ with 30% probability thermal ellipsoids showing the atom labelling scheme.

$E_{1/2}$ is independent of the macrocycle concentration in solution, but shifted linearly to a more negative value, with an increase in pH and a slope of $\Delta E_{1/2}/\Delta pH = -53$ mV (Fig. 2). These findings suggest that in the experimental conditions used in this work Hg^{2+} forms a 1:1 complex with the macrocycle ligand $[18]aneN_6$, the oxidation being easier in less acidic conditions. In the pH range studied (pH = 8.0–9.7) the global oxi-reduction process should involve two electrons and two protons, as expressed by eq. (1):

$$Hg + H_2L^{2+} \rightleftharpoons [HgL]^{2+} + 2H^+ + 2e^- \quad (1)$$

These results seem to indicate that the only complex formed in solution is $[Hg^{II}L]^{2+}$. The corresponding mercury(I) complex has not been found in the time scale of our experiment (0.025–0.25 s).[11]

The Ep^a value now determined (−0.235 V, at pH 8.8) is comparable to that found in the literature[12] for the half-wave potential, $E_{1/2}$, for the DC polarographic anodic wave of a solution of the same polyamine at D.M.E. (dropping mercury electrode).

Further comparisons of redox potentials with values from related azacrown complexes[13] (namely, *rac*-$[Hg([18]aneN_2S_4)]^{2+}$, $Ep^c = -0.85$ V at a platinum electrode in acetonitrile) are not valid because different solvents and different working and reference electrodes have been used. Furthermore, the effect of donor atom substitution on the macrocycle[14] and other structural effects can, in some way, influence the ratio of stability for oxidized and reduced species, and consequently the peak potentials. Also, in contrast to azacrown complexes thio-aza analogues present irreversible reductions, which might be indicative of a slow large stereochemical change occurring at the metal centre.

X-ray structural analysis

A molecular diagram presenting the numbering scheme is shown in Fig. 3. Relevant bond lengths and angles are listed in Tables 1 and 2, respectively.

The metal atom is coordinated to the six nitrogen donor atoms of the macrocycle, with an average Hg—N bonding distance of 2.44(2) Å. Other complexes also containing a HgN_6 central core have similar Hg—N bond lengths, 2.46(2) Å in $[Hg(pyridine)_6]^{2+}$[15] and 2.400(6) Å in $[Hg(1,10\text{-phenanthroline})_3]^{2+}$.[16] Complexes with related macrocyclic ligands show comparable metal-to-nitrogen distances, e.g. 2.47(1) Å in $[Hg([18]aneN_2S_4)]$.[13]

The C—N and C—C bonding distances, within the macrocycle skeleton, ranging from 1.37(3) to

1.48(3) and 1.41(4) to 1.55(4) Å, respectively, are close to the values found in the cobalt complexes of the same ligand. In the *meso* cobalt complex[5] the average distances are 1.498(2) and 1.515(2) Å, while in the *rac* isomer[6] they are 1.47(2) and 1.47(3) Å, respectively.

The geometry of the $(HgCl_4)^{2-}$ anion is a distorted tetrahedron, with Hg—Cl distances ranging from 2.447(9) to 2.518(9) Å and Cl—Hg—Cl angles between 99.5(3) and 116.9(4)°. The overall geometry of this anion is comparable to that observed in the complex $[Hg([14]aneN_4)Cl]_2(HgCl_4)$.[17]

In a survey of the CSD Cambridge Crystallographic Database,[18] on macrocyclic complexes of the type (M([18]aneX$_m$X$_n$), with M = transition metal and X = O, S, N, $m+n=6$, the coordination geometry found for the MX$_m$X$_n$ centre is mainly octahedral in *meso* and *rac* isomers.[19,20]

There are, however, some exceptions, e.g. the hexagonal bipyramidal geometry in some [M([18]aneO$_6$)X$_2$] (M = Cd, X = Cl, Br; M = Hg, X = Cl, SCN)[21] and [M([18]aneN$_2$O$_4$)I$_2$] (M = Hg, Cd)[22] complexes and the square planar geometry in the N-methylated [18]aneN$_2$S$_4$ complex of palladium.[23]

The coordination geometry obtained for the title complex is of a different type: a distorted trigonal prism, with the two bases of the prism defined by the nitrogen atoms N(1), N(2), N(3) and N(4), N(5), N(6), respectively. The different N···N intramolecular distances [2.88(2)–3.75(3) Å] between the nitrogen atoms on the triangular bases and the values of the angles made between the planes defined by the metal atom and the lateral edges of the prism, 107.1(6), 108.1(5) and 144.1(5)°, are a measure of the distortion on the trigonal prism. Additionally, a third criterion based on the angle of rotation, θ, of one triangular base relative to the other has been used to quantify this distortion.[23] It is 0° for an ideal trigonal prism and at the other extreme 30° for an ideal octahedron. In the title complex this parameter is 11.5(2)°.

Recent molecular mechanics calculations[2] performed for a trigonal prismatic configuration of M[18]aneN$_6$ complexes indicated an ideal M—N distance of 2.4 Å, with a minimized steric energy 20.8 kcal mol^{-1} lower than the *meso* and 22.4 kcal mol^{-1} lower than the *rac* octahedral configurations. These calculations are, therefore, in agreement with the observed coordination geometry now reported for the $[Hg([18]aneN_6)]^{2+}$ complex. Additionally, the molecular parameters in the metal coordination sphere obtained with this conformational analysis,

Table 3. Comparison between structural parameters obtained by X-ray diffraction and calculated by molecular mechanics[2] for the coordination sphere of the $[Hg([18]aneN_6)]^{2+}$ complex

	Observed values[a]	Calculated values[a]
Bond distances (Å)		
Hg—N	2.44(2)	2.44
Bonding angles (°)		
	72.8(7)	74.3
	128.5(7)	130.5
N—Hg—N	99.5(8)	96.9
	152.1(7)	146.3

[a] Mean values.

listed in Table 3, show a reasonable agreement with those found in the X-ray determination.

It is noteworthy that the geometry adopted by the $[(Hg[18]aneO_6)Cl_2]$[21b] complex is hexagonal bipyramidal, which also agrees with theoretical calculations. In fact the best hole size for this geometry (ideal M—O = 2.85 Å)[24] is very close to the Hg—O bond distance observed in the X-ray analysis, 2.825(4) Å. Therefore, the coordination geometries preferred for the two $[Hg([18]aneX_6)]$, X = N, O, complexes seem to result mainly from the ligand preferences, in particular the fit of the metal ion into the cavity of the macrocycle.

EXPERIMENTAL

Materials and synthesis

All chemical reagents were analytical grade and used as supplied.

1,4,7,10,13,16-*Hexaazacyclooctadecane hexahydrochloride*. A suspension of commercial 1,4,7,10,13,16-hexaazacyclooctadecane trisulphate salt, purchased from Aldrich (2.763 g, 5 mmol), in water (100 cm^3) was treated with an equivalent amount of $BaCO_3$. After the resulting slurry was kept at 80°C with stirring for 2 h, the filtered solution was concentrated with a rotary evaporator. The addition of a large excess of hydrochloric acid and concentration of the resulting solution gave a white solid. Recrystallization from 6 M hydrochloric acid/methanol and vacuum drying gave 1.884 g (79%) of white crystals; m.p. 309–311°C (dec). ^1H NMR (D_2O) δ: 3.59 (s). ^{13}C NMR (D_2O) δ: 44.39. IR ν(KBr, cm^{-1}): 3360–3540 (N—H); 2600–2750 (N—H). Found: C, 30.3; H, 7.6; N, 17.4. Calc. for $C_{12}N_6H_{36}Cl_6$: C, 30.2; H, 7.5; N, 17.6%.

$[Hg(18\text{-azacrown-}6)](HgCl_4)$ *complex*. To a solution of 18-azacrown-6·6HCl (111 mg, 0.25 mmol) in water (20 cm^3) was added a solution of $HgCl_2$ in a slight excess (80 mg, 0.29 mmol) in water (20 cm^3). After adjustment of pH at 6 with 1 M sodium hydroxide solution, this reaction mixture was kept at 60°C with stirring for 2 h. This solution was then concentrated until about one fifth of the initial volume and left in the cool for several days. Slow evaporation gave colourless crystals that were air-dried. ^1H NMR (D_2O) δ: 2.62 (m). ^{13}C NMR (D_2O) δ: 43.22 (s). Found: C, 16.0; H, 4.3; N, 9.3. Calc. for $[(HgC_{12}N_6H_{30})(HgCl_4)]\cdot 2H_2O$: C, 16.5; H, 4.4; N, 9.6%.

Measurements

Melting points were taken on a Buchi 530 apparatus. IR spectra were measured as KBr pellets using a Perkin–Elmer 683 spectrometer over the range 200–400 cm^{-1}. ^1H NMR and ^{13}C NMR spectra were measured on a Varian–Unity 300 spectrophotometer. Elemental analyses were obtained using a Perkin–Elmer 240B elemental analyser.

The electrochemical measurements were performed with a Princeton Applied Research PAR 173 potentiostat coupled with the universal programmer PAR 175. Cyclic voltammetry was conducted at a hanging mercury-drop working electrode (H.M.E.) with a platinum auxiliary electrode and a saturated calomel electrode (S.C.E.) as references. All potentials were referred to the saturated calomel electrode. The supporting electrolyte was KNO_3 (0.1 M). All solutions were thermostated at 25±1°C and degassed with nitrogen.

X-ray analysis

Crystal data. $[Hg([18]aneN_6)](HgCl_4)$, $C_{12}H_{30}Cl_4Hg_2N_6$, $M = 801.4$, orthorhombic system, space group *Pbca* (No. 61), $a = 14.20(1)$, $b = 14.37(2)$, $c = 21.323(9)$ Å, $V = 4.352(6)$ $Å^3$, $Z = 8$, $D_c = 2.45$ g cm^{-3}, $F(000) = 2976$, λ(Mo-K_α) = 0.71069 Å, mosaic spread = 0.61(4)°, μ(Mo-K_α) = 145.98 cm^{-1}.

Data was collected "on line" at 273 K on an Enraf–Nonius FAST diffractometer equipped with a molybdenum rotating anode using SADNESS, a modified version of MADNESS,[25] for small molecule data collection. The detector was kept at a distance of 40 mm from the crystal and at a θ angle of 25°.

Unit cell parameters and orientation matrix were

obtained by auto-indexing 50 intense reflections collected by the ω-scan mode in two narrow ($\approx 5°$), almost orthogonal zones in reciprocal space. Both the cell parameters and orientation matrix were refined every 10° of measured data.

PROCOR[26] was used in the data reduction of the measured intensities applying the Kabsch method of profile fitting. Data was corrected from polarization and Lorentz effects and then it was merged using SHELX76,[27] with $R_{merge} = 0.074$.

Structure analysis and refinement

The positions of the heavy atoms were obtained from a three-dimensional Patterson map, while the positions for the remaining non-hydrogen atoms were obtained from successive difference-Fourier syntheses.

The isotropic refinement (without hydrogen atoms) converged to $R = 0.1103$. At this point an absorption correction was applied using a version of DIFABS,[28] modified for the FAST geometry. The maximum and minimum correction factors applied were 1.030 and 0.440, respectively, and the R factor then lowered to 0.1022.

The anisotropic refinement of the mercury and chlorine atoms lowered the final R value that converged to 0.0739.

No weighting scheme was used in the final refinement of 127 parameters with 5953 unique reflections with $|F_o| > 3\sigma|F_o|$.

The final electron density in the difference Fourier map was -1.08 and 3.36 e $Å^{-3}$, situated near the mercury atom of the cation.

A drawing was made with the ORTEP-II program.[29] Atomic scattering factors were taken from the international tables.[30]

Tables listing fractional atomic coordinates and anisotropic displacement parameters and tables of observed and calculated structure factors have been deposited as supplementary material.

(*Received* 9 *April* 1992; *accepted* 25 *November* 1992)

Abstract—The crystalline compound $[La(C_{30}H_{28}N_2O_4)_2(H_2O)_2][La(NO_3)_6]\cdot 2H_2O\cdot 2CH_3CN$ has been structurally characterized by X-ray crystallography. The compound contains a complex cation, $[La(C_{30}H_{28}N_2O_4)_2(H_2O)_2]^{3+}$, with a 10-coordinate lanthanum ion and a hexanitrato anion, $[La(NO_3)_6]^{3-}$, with a 12-coordinate lanthanum(III) ion. The coordination polyhedra of lanthanum in the cation and anion are distorted bicapped dodecahedron and eicosahedron, respectively. The La—O bond lengths in the cation lie in the range 2.503(3)–2.771(3) Å and the ether oxygens have weaker bonding than the amide oxygens; La—O distances in the anion range between 2.618(4) and 2.749(4) Å. There are also two lattice water molecules and two acetonitrile solvent molecules in the asymmetric unit cell, which form hydrogen bonds with the complex cations and anions.

Although macrocyclic and non-cyclic polyethers, especially those containing CH_2CH_2O units, can react with rare earths to form stable solid complexes, the ligands which are composed of CH_2CH_2O and amide oxygens are superior. Previous research work has mainly focused on the polyethylene glycols,[1–7] while rare earth complexes with derivatives of glycol-O,O′-diacetoamide have been little reported. We report here the synthesis of the lanthanum complex with the ligand N,N,N′,N′-tetraphenyl-3,6-dioxaoctanedioic diamide and an investigation of the crystal structure of this new lanthanum complex. As previously reported, rare earth salts react with crown ethers in organic solvents to yield stable complexes with different metal/ligand ratios, both 1:1 and 4:3 complexes form with lanthanide nitrates. The present complex is an example of a 1:1 complex with lanthanide nitrate.

EXPERIMENTAL

Preparation

A solution of lanthanum nitrate (0.5 mmol) in anhydrous ethanol (20 cm^3) was added dropwise to a solution of N,N,N′,N′-tetraphenyl-3,6-dioxaoctanedioic diamide[8] (0.5 mmol) in chloroform (15 cm^3). The mixture was stirred at room temperature for 24 h and the solution was then partially evaporated. The precipitated solid complex was filtered, washed with anhydrous ethanol and ether and dried

* Author to whom correspondence should be addressed.

in a desiccator (0.1 mm Hg) over P_4O_{10}. The single crystals for the X-ray study were prepared by dissolving the solid complex in acetonitrile and by allowing the resulting solution to stand for 4 weeks.

Crystal structure determination

Crystal data. $[C_{30}H_{32}N_2O_6La][N_6O_{18}La]\cdot 2[H_2O]\cdot 2[C_2H_3N]$, $Mr = 1765.15$, monoclinic, $a = 16.463(2)$, $b = 23.231(4)$, $c = 19.914(2)$ Å, $\beta = 96.58(1)°$, $V = 7566$ Å^3, space group $P2_1/n$, $Z = 4$, $D_c = 1.55$ g cm^{-3}, μ(Mo-K_α) = 12.04 cm^{-1}. A crystal of the dimensions $0.5 \times 0.5 \times 0.8$ mm^3 was sealed with some mother liquor in a capillary tube and mounted on an Enraf–Nonius CAD4 diffractometer. The unit-cell parameters were determined by least-squares calculations based on the angular setting of 25 automatically centred reflections with 2θ between 24° and 34°. Intensities were measured in the ω–2θ scan mode (scan width: $0.6+0.35\tan\theta$) with graphite-monochromated Mo-K_α radiation, θ range $1 \leqslant \theta \leqslant 24°$ ($h = -18$ to 18; $k = 0$–26; $l = 0$–22). 13,957 reflections were collected, 13,109 independent reflections ($R_{int} = 0.017$), of which 11,004 were considered observed [$I > 3\sigma(I)$]. Lorentz and polarization, but no absorption, corrections were made.

Two lanthanum atoms were located from a Patterson synthesis and the remaining non-hydrogen atoms from Fourier syntheses. 108 Non-hydrogen atoms were refined anisotropically by full-matrix least-squares. The function minimized was $\Sigma w(|F_o|-|F_c|)^2$, where w = 1. All hydrogen atoms were located from a difference synthesis and were included in the structure–factor calculation, but not refined. The final R factor was 0.040 ($R_w = 0.042$), $(\Delta/\sigma)_{max} = 0.37$ and the final difference synthesis-Fourier map showed peaks less than 0.631 e Å^{-3}.

Atomic scattering factors were taken from ref. 9. All calculations were performed on an PDP 11/44 computer using the SDP package.[10]

RESULTS AND DISCUSSION

As shown in Figs 1 and 2 the crystal structure of this lanthanum complex is composed of a complex cation, $[La(A)(C_{30}H_{28}N_2O_4)_2(H_2O_2)_2]^{3+}$, and a hexanitrato anion, $[La(B)(NO_3)_6]^{3-}$, and the two different moieties are found in the ratio 1 : 1. Lattice water molecules and two acetonitrile solvent molecules are also found in the asymmetric unit. Selected bond distances and angles for $[La(C_{30}O_{28}N_2O_4)(H_2O)_2]^{3+}$ and $[La(NO_3)_6]^{3-}$ are listed in Tables 1 and 2, respectively.

The lanthanum ion is 10-coordinate being

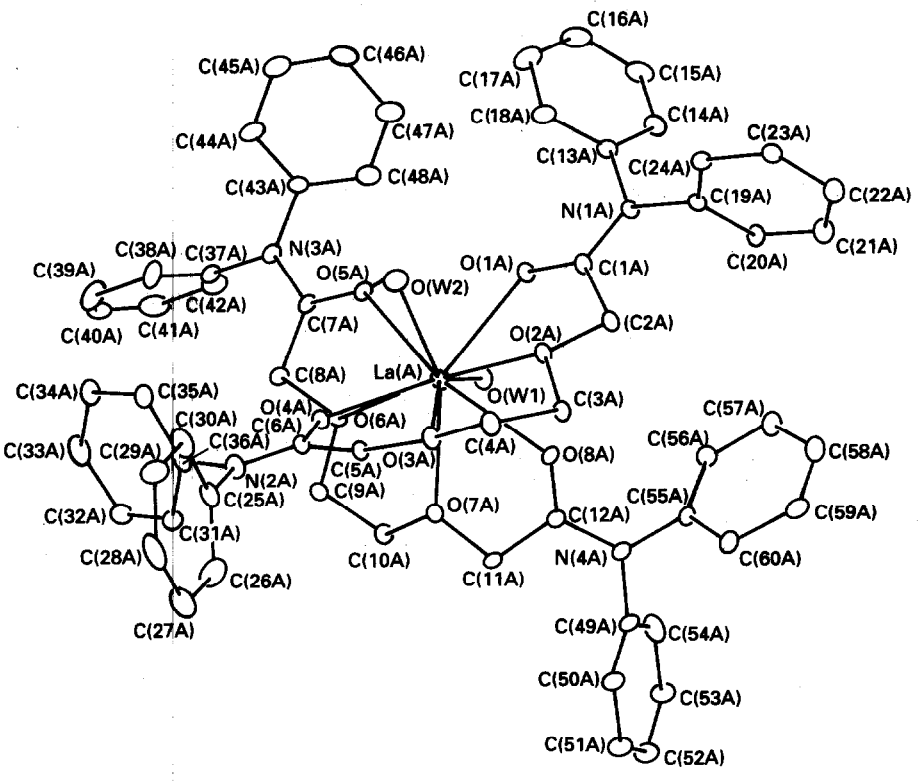

Fig. 1. View of the $[La(C_{30}H_{28}N_2O_4)_2(H_2O)_2]^{3+}$ cation.

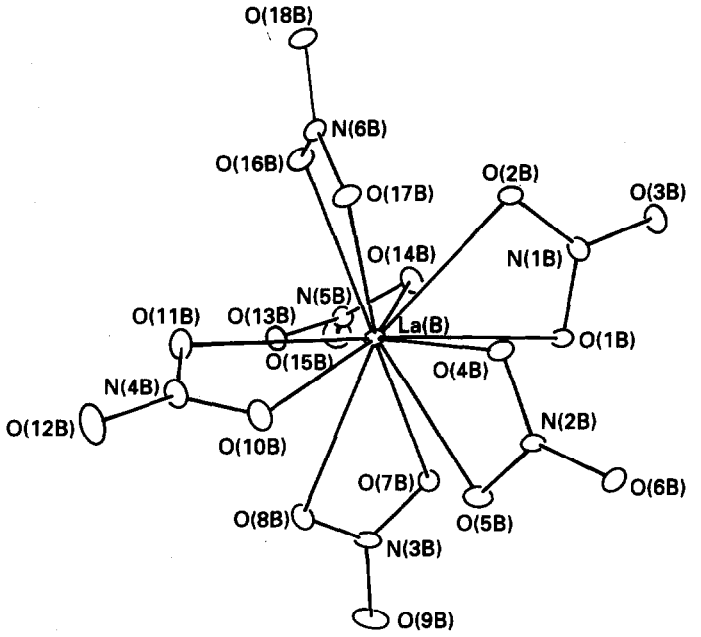

Fig. 2. View of the $[La(NO_3)_6]^{3-}$ anion.

bonded to oxygen atoms of two water molecules and to the eight oxygen atoms of two ligands in the cation. The coordination polyhedron is a bicapped dodecahedron (BCDod) with D_2 symmetry.[12-14] The framework diagram illustrating the coordination polyhedron in the lanthanum(A) complex cation described here is given in Fig. 3. For the D_2 polyhedron atoms O(W1), O(8A), O(5A) and O(3A) would define the first trapezoidal plane, then O(W2), O(4A), O(1A) and O(7A) the second. The two planes are no longer perpendicular; the dihedral angle listed in Table 5 is 74.86°. Atoms O(W1), O(8A), O(W2) and O(4A) are (A) type atoms and O(1A), O(7A), O(5A) and O(3A) are (B) type. The two capping atoms, O(2A) and O(6A), occupy ligand sites (C) and O(2A)—La(A)—O(6A) is 172.34(9)°. The angular parameters θ_A and θ_B are 36.2(2) and 67.5(1)°, respectively, which are similar to those structure parameters in the compounds with BCDod reported in the literature.[12,13] There are seven types of edges in BCDod and the values of these edges in the polyhedron of the complex cation are listed in Table 3. The La(A)—O(water) bond lengths are 2.522(3) and 2.541(3) Å. The La(A)—O(L) distances are of two types: as expected, the four La(A)—O(ether) distances [mean 2.729(3) Å] are significantly longer than the four La(A)—O(amide) distances [mean 2.546(3) Å]. The

Symmetry codes:

[a] $1-x, 1-y, 1-z$.

[b] $\frac{1}{2}+x, 1\frac{1}{2}-y, \frac{1}{2}+z$.

[c] x, y, z.

former are close to the value in another open-chain crown ether complex of lanthanum, $[La(NO_3)_3(C_8H_{18}O_5)]$, La—O(ether) 2.70 Å, where La—O (alcohol) = 2.58 Å.[7] According to expectations the latter are longer than the distances of La—O (ketonic), 2.473 Å.[15] The data of bond distances in two types of oxygens show that amide oxygens are more strongly bonded than ether oxygens.

The N,N,N′,N′-tetraphenyl-3,6-dioxaoctanedioic diamide ligand coordinated to lanthanum is a type of open-chain crown ether. The co-planarity of O(1A), O(2A), O(3A) and O(4A) atoms in one ligand is better than that of O(5A), O(6A), O(7A) and O(8A) atoms in the other ligand (see Table 4). The N—C bond distances [mean 1.343(6) Å] connected with the ketone group are shorter than that [mean 1.449(6) Å] connected to the phenyl rings. The phenyl rings and planes containing nitrogen atoms have dihedral angles which are listed in Table 4.

The lanthanum(B) ion is 12-coordinate surrounded by six bidentate nitrate ions (Fig. 2). The geometry of the hexanitratolanthanate ion is a distorted eicosahedron and is similar to that previously found.[7,14,16] The coordination polyhedron of lanthanum (B) is shown in Fig. 4.

As shown in Table 5 four water molecules form hydrogen bonds with the oxygen atoms in the hexanitrato lanthanum ion and the nitrogen atom in one acetonitrile solvent molecule, just as the complex cation and the anion are interconnected with lattice water and solvent molecules by hydrogen bonds.

Additional crystallographic data, bond lengths and angles are available from the Editor on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

SYNTHESIS AND CHARACTERIZATION OF LIGHT LANTHANIDE PIPERIDINOCARBODITHIOATE COMPLEXES

ZHU HAILIANG, TANG NING,† GAN XINMIN, ZHANG WEIGUANG, TAN MINYU and WANG AILI

Department of Chemistry, Lanzhou University, Lanzhou 730000, China

(*Received* 10 *September* 1992; *accepted* 20 *November* 1992)

Abstract—The light lanthanide piperidinocarbodithioate complexes with the general formula $(PipH_2)[Ln(PipCS_2)_4]$ (Pip = piperidino, Ln = La, Pr, Nd, Sm, Eu and Gd) have been prepared using anhydrous lanthanide chloride and piperidinium piperidinocarbodithioate as reactants. They have been characterized by chemical analyses, IR spectra, electronic spectra, conductivity measurement and TG–DTA techniques. In all the complexes the carbodithioate ligands show bidentate behaviour.

In recent years complexes of transition metal elements with dithiocarbamates have not only been studied thoroughly, but also have been widely used in the rubber industry, inorganic analyses and agriculture.[1] However, much less has been reported on similar complexes of the lanthanides. As an extension of our previous research studies on the complexes of lanthanides with sulphur containing ligands,[2,3] we have recently synthesized the solid complexes of light lanthanides with piperidinocarbodithioate and investigated the composition and properties of these new complexes.

EXPERIMENTAL

Preparation of anhydrous lanthanide chlorides

Anhydrous lanthanide chlorides were prepared by the literature[4] method with sulphinyl chloride as the dehydrating agent.

Preparation of the ligand

Piperidinium piperidinocarbodithioate ($[\overline{CH_2CH_2CH_2CH_2CH_2}\overline{NH_2}]\cdot[\overline{CH_2CH_2CH_2CH_2CH_2}\overline{NCS_2}]$) was obtained according to the literature[5] by the reaction of piperidine and carbon disulphide (molar ratio 2 : 1) in petroleum ether medium. The product was purified by sublimation and then verified by elemental analysis, IR and ^1H NMR spectroscopy.

Preparation of the complexes

Piperidinium piperidinocarbodithioate (0.4 mmol) was dissolved in absolute ethanol (10 cm^3). To this solution was slowly added a solution (10 cm^3) of anhydrous lanthanide chloride (0.1 mmol) in absolute ethanol. The complex precipitated slowly. Prior to isolating the complex by filtration, the solution was continually stirred at room temperature for 10 h. The product was washed with anhydrous ethyl ether and dried *in vacuo* with P_4O_{10} for 1 week. All the complexes obtained were solid yellow powders and unstable in moist air. The whole process of synthesis of the complexes was carried out in a glove-box filled with dry nitrogen gas.

Analyses

The metal ions were determined by EDTA titration using xylenol-orange as an indicator. Carbon, nitrogen and hydrogen were determined using a Carlo–Erba 1106 elemental analyser.

IR measurements

The IR spectra were recorded on a 170 SX FTIR spectrometer in the 4000–200 cm^{-1} region using KBr pellets.

[a] Pip = piperidino ($\overline{CH_2CH_2CH_2CH_2CH_2N}$—).

Electronic spectra

The electronic spectra were recorded with a Shimadzu UV-240 spectrophotometer in the acetonitrile solution in the 190–400 nm range.

Thermal analyses

Thermal analyses (TG and DTA) were performed on a Dupont 1090 thermobalance. The heating rate was 10°C min^{-1}.

Conductivity measurements

These measurements were performed with a DDS-11A type conductivity bridge for freshly prepared solutions in acetonitrile at 25°C.

RESULTS AND DISCUSSION

The composition of the complexes

The analytical data for the newly synthesized complexes listed in Table 1 indicate that there are one piperidinium ion, one lanthanide ion and four piperidinocarbodithioate groups in each of the complex molecules.

IR spectra

The most important IR peaks of the ligand salt and of the complexes are reported in Table 2. The presence of a single strong band due to a ν(CSS) mode in the range 984–996 cm^{-1} in the spectra of the complexes is strongly indicative of the bidentate behaviour of the dithio ligand in the complexes,[6,7] otherwise a doublet is expected in the 1000 ± 70 cm^{-1} region in the case of monodentate coordination.[8,9] The analysis of the position of the ν(C···N) mode, in the range 1469–1476 cm^{-1}, gives further confirmation of the above suggested behaviour: this band, in fact, undergoes a blue shift in all the complexes, while for unidentate coordination this stretching mode would be shifted towards lower wave numbers or would remain unchanged at the value of the free carbodithioate sodium salt.[10]

In the far-IR region the bands of the ligand

$PipH_2[Gd(PipCS_2)_4]$	218	241	274

appear unchanged in the spectra of the complexes; in addition, new bands, absent in the spectra of the starting material, are present in the 330–336 cm^{-1} range, which may be assigned as the ν(M—S) stretching frequency.[6,11]

Electronic spectra

The electronic spectra are given in Table 3. All the complexes show three absorption bands due to the chromophore group NCS_2[12] (these absorptions are indicated as Band 1, Band 2 and Band 3).

Band 1 is assigned to an intramolecular charge transfer in the ligand, i.e. a $\pi \rightarrow \pi^*$ transition located mainly in the N···C···S group.[13,14] Band 2 is attributed to the $\pi \rightarrow \pi^*$ transition of the S···C···S group.[15] This band does not undergo splitting and this fact clearly indicates the equivalence of the C···S bonds in the complexes. Band 3 is a low-intensity band assigned to an $n \rightarrow \pi^*$ transition, i.e. the transition of an electron of the lone pair on the sulphur atom to an antibonding π-orbital.[16] It can be seen from Table 3 that Bands 2 and 3, not Band 1, undergo a considerable violent shift upon complexation. This change can be attributed to the formation of M—S bonds and the deviation of the electron cloud around the sulphur atoms, the electron donors, towards the lanthanide ions, which is bound to decrease the π–π and p–π conjugate effects in the chromophore group and to increase the energy needed for the $\pi \rightarrow \pi^*$ and $n \rightarrow \pi^*$ transition, and results in the absorption bands to shift towards the short wavelength direction.

Thermal analyses

The thermal analyses studies were performed by means of TG and DTA techniques.

The processes of thermal decomposition for all the complexes were almost the same. The complexes decomposed very rapidly in the 206–213°C range. Continuous weight loss was then detected up to 850°C. At this temperature Ln_2O_3 (Pr_6O_{11} for the praseodymium complex) was formed.

Solubility and molar conductance

All the complexes are sparingly soluble in ethyl ether and cyclohexane, but are soluble in methanol, ethanol, acetone and THF and readily soluble in acetonitrile and methylene dichloride. The molar conductance values of the complexes measured in acetonitrile at 25°C lie in the range 146.7–152.8 Ω^{-1} cm^2 mol^{-1}, which indicates that all the complexes are 1 : 1 electrolytes and denotes that each of the complex molecules dissociate as one cation and one anion in the solution.[17]

From the above discussion it can be concluded that the new complexes reported in this paper are ion-association type coordination compounds. In

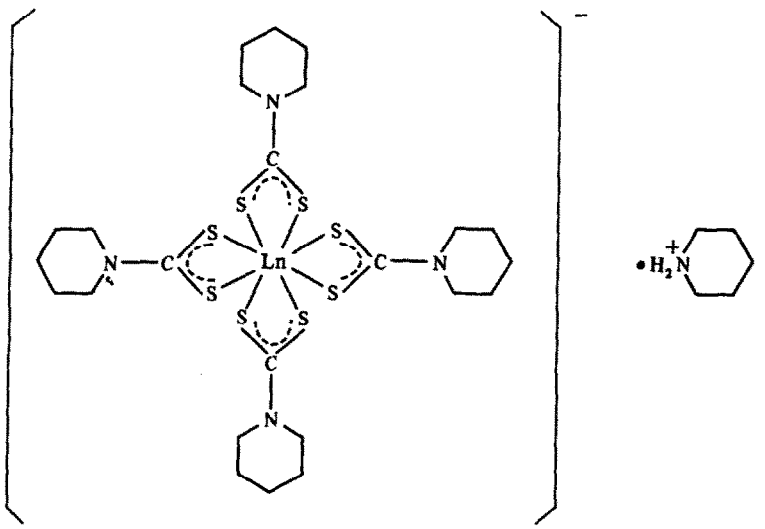

Fig. 1. Proposed structure of the complexes.

each of the complex molecules four carbodithioate groups, as uninegative bidentate ligands, are coordinated to a lanthanide ion through eight sulphur atoms to form a complex anion, and a cation, piperidinium, lies out of the coordination shell (see Fig. 1). This coordination state was also found in some other types of lanthanide carbodithioate complexes.[18–20]

Abstract—Heterobimetallic complexes of the type $[Cu(TETA)Cl_2MCl_2]$ (M = Si, Ge, Sn, Ti and Zr; TETA = triethylene tetramine) have been synthesized and characterized by elemental analyses, ESR, electronic and IR spectra and conductivity measurements. The complex $[Cu(TETA)Cl_2SnPh_2]$ has also been prepared. The results indicate that $[Cu(TETA)]Cl_2$ is square planar and ionic in nature, while its bimetallic complexes, $[Cu(TETA)Cl_2MCl_2]$ and $[Cu(TETA)Cl_2SnPh_2]$, are covalent with an octahedral environment around the copper(II) ion.

The development of binuclear systems has arisen from the idea that two metal atoms in close proximity could react in a cooperative manner with substrate molecules.[1,2] A major role in the building of binuclear complexes has been played by tertiary diphosphines, bis(diphenylphosphino)methane (dppm) being particularly efficient for this purpose.[3,4] Substitution of one of the donor atoms in the dppm skeleton for a softer (As) or harder (N) centre has been introduced to create heterobinuclear complexes of the platinum group metals. Such ligand systems studied by Balch are (diphenylarsino)(diphenylphosphino)methane (dapm)[5,6] and 2-(diphenylphosphino)pyridine (Ph_2PPY),[7–15] which have led to a controlled synthesis of platinum–rhodium complexes having two bridging ligands.[16]

The growing interest in electrochemical, magnetic and spectroscopic studies on multimetallic complexes is due to their great importance in biology.[17–24] They are ubiquitous in nature as active sites in a variety of metalloenzymes and are playing a significant role in industrial catalysis. Furthermore, they provide interesting cases for the study of magnetic interaction and may also serve as models in certain cases for some metalloproteins, for which the biological function is associated with the occurrence of metals centres in pairs.

By a judicious choice of the two metals, it is possible to synthesize a large number of multimetallic compounds. Since the heterobimetallic chelates containing group (IV) elements seem to be scarce, it was considered worthwhile to synthesize a number of new heterobimetallic complexes of the type $[Cu(TETA)Cl_2MCl_2]$ (M = Si, Ge, Sn, Ti and Zr).

EXPERIMENTAL

Triethylene tetramine (Koch Light), cupric chloride, $SiCl_4$, $GeCl_4$, $SnCl_4$, $TiCl_4$, $ZrCl_4$ (BDH) and Ph_2SnCl_2 (Fluka) were used as received. Ethanol and DMSO were distilled before use. Microanalyses of the complexes were obtained on a Carlo–Erba Analyser Model 1106. Molar conductance was measured at room temperature on a Digisun electronic conductivity bridge. The IR spectra (200–4000 cm^{-1}) were recorded on a Carl–Zeiss Specord M-80 spectrophotometer in Nujol mulls. The electronic spectra were recorded on a Shimadzu UV–vis recording spectrophotometer Model 60. The EPR spectrum was recorded on a Bruker Scientific *X*-band spectrometer (ESP-300) using a 100 kHz field modulation and quartz sample tubes and the values determined calibrated with DPPA powder, $g = 2.0036$. The estimation of chlorine was determined by the usual gravimetric method.

Synthesis of $[Cu(TETA)]Cl_2$

This complex was prepared by dissolving cupric chloride (0.01 mol, 2.42 g) in ethanol (30 cm^3) with dropwise addition of triethylene tetramine (0.01 mol, 1.46 cm^3). The dark blue product was formed after keeping the mixture overnight and was washed, recrystallized from ethanol and dried *in vacuo*.

Synthesis of $[Cu(TETA)Cl_2MCl_2]$ *and* $[Cu(TETA)Cl_2SnPh_2]$

A hot ethanolic solution (15 cm^3) of $[Cu(TETA)]Cl_2$ (0.01 mol, 2.8 g) was treated with group (IV) metal tetrachlorides or diphenyltindichloride (0.01 mol). In each case an immediate precipitate appeared, which was washed with ethanol and dried *in vacuo*. All the synthesized complexes are soluble only in DMSO.

RESULTS AND DISCUSSION

The analytical data (Table 1) conform to the compositions $[Cu(TETA)]Cl_2$, $[Cu(TETA)Cl_2MCl_2]$ and $[Cu(TETA)Cl_2SnPh_2]$ (M = Si, Ge, Sn, Ti and Zr; TETA = triethylenetetramine). The reaction of copper(II) chloride with TETA in ethanol yields $[Cu(TETA)]Cl_2$. Further reaction of this complex with group(IV) metal tetrachlorides and diphenyltin(IV) dichloride gives high yields of the heterobimetallic chelates $[Cu(TETA)Cl_2MCl_2]$ and $[Cu(TETA)Cl_2SnPh_2]$, respectively. The conductivity measurements in DMSO[25] show that the ligand $[Cu(TETA)]Cl_2$ is ionic, while the heterobimetallic chelates are covalent. Therefore, the complexes are formed by the replacement of amine hydrogens by group (IV) metals and the removal of 2HCl molecules, which has also been confirmed by the quantitative estimation of chlorine as AgCl. The reactions followed are represented in Scheme 1.

A room-temperature ESR spectrum of the powdered sample of $[Cu(TETA)]Cl_2$ gives approximate g values with $g_{\parallel} = 2.09$ and $g_{\perp} = 2.06$, which favours the square planar geometry around the copper(II) ion.[26,27] The apparent g values of the bimetallic polycrystalline samples are $g_{\parallel} = 1.99$ and $g_{\perp} = 2.07$, with the average g values $\langle g \rangle = (2g_{\parallel} + g_{\perp}/3 = 2.04)$ being in accordance with those

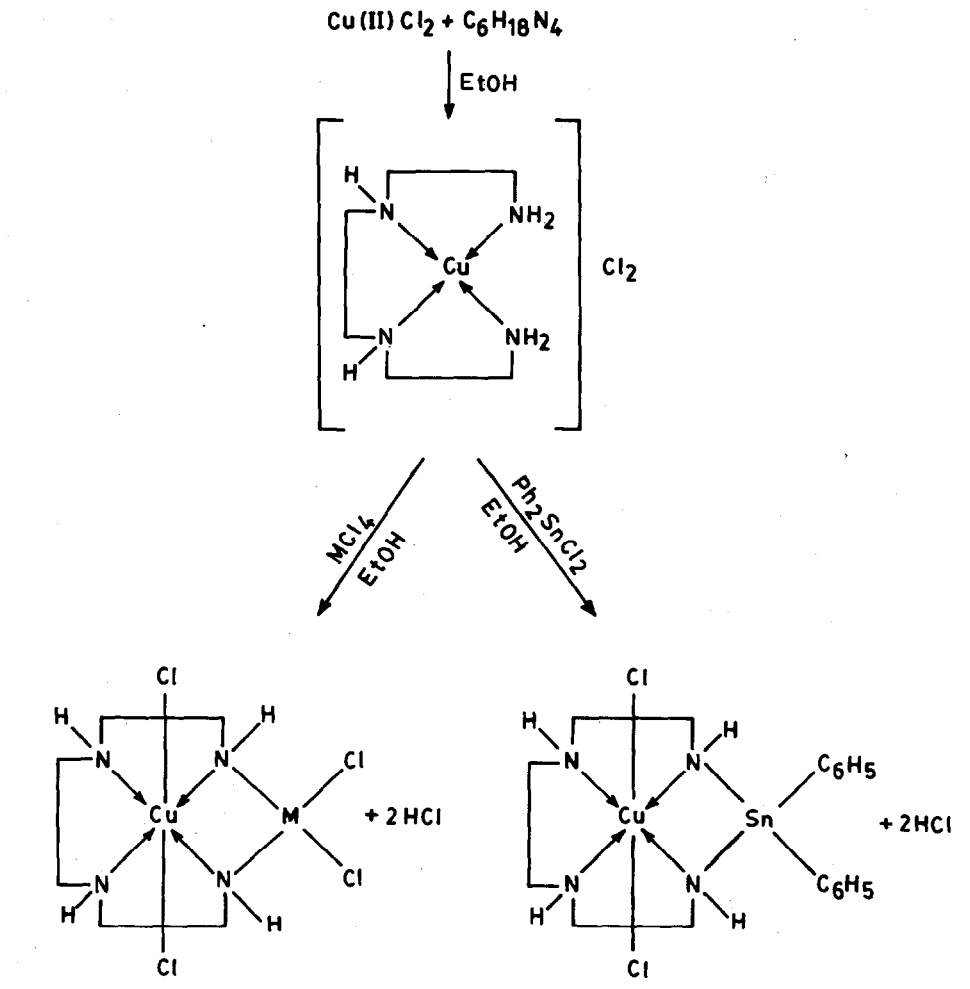

Scheme 1.

of typical octahedral copper(II) complexes.[28] On this basis we suggest that the chloride ions present in $[Cu(TETA)]Cl_2$ coordinate with copper(II) ions upon complexation with group(IV) metal tetrachlorides to produce an octahedral environment around the copper(II) ion. It is to be noted that the chloride ions present in $[Cu(TETA)]Cl_2$ coordinate to the copper(II) ion and not the group (IV) metal chlorine. This may be due to (a) the easy availability of the anionic chlorine of $[Cu(TETA)]Cl_2$, which should in any case be a better ligand than the covalently bonded chlorine of group (IV) metals and (b) since copper(II) achieves an octahedral geometry only after complexation with MCl_4, it is thought that the removal of aminohydrogen occurs due to the group (IV) metal chlorine. Otherwise, the chloride ions present in $[Cu(TETA)]Cl_2$ would have gone as HCl before its reaction with MCl_4.

The electronic spectra of the mononuclear complex in methanol, $[Cu(TETA)]Cl_2$, shows a high intensity charge-transfer band at 247 nm, along with the ligand–metal charge-transfer band at 304 nm. A strong *d–d* band at 596 nm is also observed, which is characteristic of square planar complexes.[29] The bimetallic complexes in DMSO also show strong bands at 275 nm, along with the shoulders assignable to intra-ligand transitions and ligand–metal charge-transfer, which is in agreement with the observation reported.[30,31] The *d–d* band maxima, one at 930 and another at 882 nm, are due to octahedral bimetallic copper(II) complexes. It is known that octahedral distortion in copper(II) complexes leads to the displacement of *d–d* bands to lower energies.[32]

It is possible to assign some of the important IR bands which are helpful in determining the structures of the synthesized complexes. In $[Cu(TETA)]Cl_2$ the band at 3270 cm^{-1} is characteristic of the N—H stretching frequency, while the peak at 1584 cm^{-1} is assigned to δ(N—H). In the bimetallic

Table 2. IR and far-IR absorption bands of the ligand, $[Cu(TETA)]Cl_2$, and its heterobimetallic complexes

Complex	Peak positions (cm^{-1})				
	ν(N—H)	ν(Cu—N)	ν(Cu—Cl)	ν(M—N)	ν(M—Cl)
$[C_6H_{18}N_4CuCl_2]$	3270m	405s	—	—	—
$[C_6H_{16}N_4CuSiCl_4]$	3110m	403s	315m	430s	300s
$[C_6H_{16}N_4CuGeCl_4]$	3112m	403s	315m	485s	305s
$[C_6H_{16}N_4CuSnCl_4]$	3112m	403s	315m	455s	300s
$[C_6H_{16}N_4CuTiCl_4]$	3110m	403s	315m	520s	290s
$[C_6H_{16}N_4CuZrCl_4]$	3110m	403s	315m	525s	290s
$[C_6H_{16}N_4CuSnCl_2(C_6H_5)_2]$	3108m	403s	310m	472s	300s

chelates ν(N—H) appears at a lower wave number (3110 cm^{-1}), suggesting the formation of a group (IV) metal–nitrogen covalent bond, and δ(N—H) remains unaffected. Two sharp absorption bands appear at 1060 and 1384 cm^{-1} in both the mono- and binuclear complexes, assigned to ν(C—C) and ν(C—N) modes, respectively. Another two distinct bands appear at 2962 and 751 cm^{-1}, assigned to ν(C—H) and CH_2 rocking modes, respectively.

The far-IR region of the spectra is very significant as it includes the M—N and M—X stretches. The M—X absorption bands are stronger and appear at lower wave numbers compared to M—N absorption bands. New bands of medium intensity in the range 430–525 cm^{-1} in the complexes have been assigned to ν(M—N). A distinct band appeared in the ligand and the heterobimetallic complexes at 405 cm^{-1}, assigned to a Cu—N stretching frequency. A band appeared in the complexes at 315 cm^{-1}, assigned to ν(Cu—Cl), which was absent in the spectra of the free ligand, $[Cu(TETA)]Cl_2$. Sharp bands appeared in the complexes in the range 290–305 cm^{-1} and are attributed to ν(M—Cl). The characteristic IR bands are given in Table 2.

In further communications our interest lies in reporting the results of the reaction between $[Cu(TETA)](BF_4)_2$ and $[Cu(TETA)]Br_2$ with group (IV) metal tetrachlorides and organotin(IV) chlorides.

CYANO-BRIDGED COMPLEXES OF BIS(2,2′-BIPYRIDINE)(PYRIDINE)RUTHENIUM(II)†

EDGARDO H. CUTIN and NÉSTOR E. KATZ‡

Instituto de Química Física, Facultad de Bioquímica, Química y Farmacia, Universidad Nacional de Tucumán, Ayacucho 491, 4000 San Miguel de Tucumán, Argentina

(*Received* 30 *September* 1992; *accepted* 20 *November* 1992)

Abstract—New complexes with the $Ru(bpy)_2(py)^{2+}$ moiety (bpy = 2,2′-bipyridine, py = pyridine) connected through a cyano group to $Ru(NH_3)_5^{3+}$ and $Fe(CN)_5^{2-}$ as electron acceptors have been prepared and their spectroscopic, electrochemical and photophysical properties investigated. Cyano-bridging is disclosed by changes in the shape and position of the cyanide stretching vibration, $\nu(C{\equiv}N)$, in the IR spectrum of the dinuclear ruthenium species, as compared with the mononuclear parent complex. Blue shifts in the lowest energy $d_\pi \rightarrow \pi^*$ (Ru → bpy) metal-to-ligand charge transfer (MLCT) transition occur when going from $[Ru(bpy)_2(py)(CN)]^+$ (**A**) to $[(bpy)_2(py)Ru^{II}{-}CN{-}Ru^{III}(NH_3)_5]^{4+}$ (**B**) and to $[(bpy)_2(py)Ru^{II}{-}CN{-}Fe^{III}(CN)_5]^-$ (**C**), thus pointing to the existence of nitrile-bound pentaammineruthenium(III) and pentacyanoferrate(II) capping groups in the mixed-valence species **B** and **C**. Besides, new intense and broad absorptions at 697 (in HCl 0.01 M) and 700 nm (in H_2O/Me_2CO, 1 : 1 v/v) appear in **B** and **C**, respectively, and can be assigned to metal-to-metal charge transfer (MMCT) or "intervalence" transitions. The luminescence of **A** is completely quenched in **B**, even at 77 K, a fact which can be explained on the basis of efficient excited-state electron transfer to form the electronic mixed-valence isomer of **B**. The strong asymmetric nature of **B**, as deduced from cyclic voltammetry data (the difference in redox potentials between both ruthenium sites amounts to 1.30 V), together with a strong electronic coupling [$H_{AB} = 2200\ cm^{-1}$, calculated from the "intervalence" absorption data] indicate that the back electron transfer (or charge recombination) from the MMCT excited state of **B** probably lies in the "inverted" region.

Cyano-bridged transition metal complexes are interesting systems in the field of mixed-valence chemistry,[1] because of the relatively strong metal–metal interaction mediated by the short cyanide group, which gives rise to intense metal-to-metal charge transfer (MMCT) or "intervalence" transitions in the visible or near-IR spectra. We have recently reported[2–5] a new series of asymmetric mixed-valence complexes with $Ru(bpy)_2(py)^{2+}$ and $Ru(trpy)(bpy)^{2+}$ (bpy = 2,2′-bipyridine, trpy = 2,2′:6′,2″-terpyridine) as photosensitizing moieties connected through different bridging ligands to $Ru(NH_3)_5^{2+/3+}$ and $Fe(CN)_5^{3-/2-}$ groups that can act as electron "relays". These dinuclear compounds can be useful as models for energy conversion devices and molecular electronics.[6]

We report here the syntheses and spectroscopic, electrochemical and photophysical properties of new dinuclear complexes derived from the mononuclear species $[Ru(bpy)_2(py)(CN)]^+$ (**A**), first reported by Calvert and Meyer,[7] and which has been separated in this work from its main impurity, $Ru(bpy)_2(CN)_2$, using a chromatographic procedure. The new species, $[(bpy)_2(py)Ru^{II}{-}CN{-}Ru^{III}(NH_3)_5]^{4+}$ (**B**) and $[(bpy)_2(py)Ru^{II}{-}CN{-}Fe^{III}(CN)_5]^-$ (**C**), have been characterized in the solid state and in solution. Intense MMCT tran-

sitions have been detected in the visible region for both mixed-valence ions. In contrast to **A** complex **B** does not emit, even at 77 K, thus evidencing an efficient oxidative quenching process, probably due to the presence of low-lying MMCT excited states.

EXPERIMENTAL

Syntheses

$[Ru(bpy)_2(py)(CN)](PF_6)\cdot 11H_2O$. $[Ru(bpy)_2(py)Cl]Cl$ (0.60 g, 1.1 mmol), prepared as in ref. 8, and KCN (0.07 g, 1.1 mmol) were refluxed for 2 h in a solution of water (8 cm^3) and ethanol (2 cm^3). After filtering and evaporating to a volume of 5 cm^3 the solution was sorbed onto a CM-Sephadex C-25 column. Elution with pure H_2O was performed first in order to remove the undesired complex $Ru(bpy)_2(CN)_2$. Then, 0.1 M LiCl was used to elute a second orange fraction containing the ion **A**. This fraction was rotoevaporated to a minimum volume and precipitation was achieved by adding a concentrated aqueous solution of NH_4PF_6. The solid was filtered, washed with cold water and ether and dried *in vacuo* over KOH. Yield: 15%. Found: C, 36.4; H, 3.3; N, 9.1. Calc.: C, 36.5; H, 4.1; N, 9.8%.

$[(bpy)_2(py)Ru^{II}—CN—Ru^{III}(NH_3)_5](PF_6)_4\cdot 12H_2O$. $[Ru(NH_3)_5Cl]Cl_2$ (20 mg, 0.07 mmol) dissolved in 0.01 M HCl (6 cm^3) was added to $[Ru(bpy)_2(py)(CN)](PF_6)\cdot 11H_2O$ (50 mg, 0.05 mmol) in an H_2O/Me_2CO (5 cm^3; 1:1 v/v) solution under argon. After 0.5 h Zn(Hg) was added and the mixture was stirred for 5 h with continuous argon bubbling at room temperature. After removal of the Zn(Hg) a few drops of H_2O_2 35% were added. The colour of the solution changed from red to green after a few minutes. After evaporating to a minimum volume, the solution was sorbed onto an SP-Sephadex C-25 column (3 × 50 cm). After eluting with 0.3 M HCl to remove unreacted species a dark green solution was collected with 0.5 M HCl as an eluant. This solution was rotoevaporated to a small volume, and excess NH_4PF_6 was added to precipitate the product, which was redissolved in H_2O and reprecipitated with NH_4PF_6, washed with cold water and ether and dried *in vacuo*. Yield: 39%. Found. C, 19.1; H, 3.3; N, 11.0. Calc.: C, 20.9; H, 3.5; N, 10.3%.

$[(bpy)_2(py)Ru^{II}—CN—Fe^{III}(CN)_5]^-$. This complex was prepared in solution by mixing stoichiometric amounts of $[Ru(bpy)_2(py)(CN)](PF_6)\cdot 11H_2O$ and $Na_3[Fe(CN)_5(NH_3)]\cdot 3H_2O$ in H_2O/Me_2CO (10 cm^3; 1:1 v/v). After stirring under argon for 1 h Br_2 vapour was added and visible spectra were recorded.

Instrumentation and techniques

Analytical reagent chemicals were used throughout this work. IR spectra were recorded (as KBr pellets) on a Perkin–Elmer 983G spectrophotometer (wave-number precision: ± 2 cm^{-1}). UV–vis spectra were obtained with Perkin–Elmer Coleman 124 and Shimadzu UV-160A spectrophotometers at 22°C (errors in λ_{max} and ε_{max} were ± 2 nm and $\pm 5\%$, respectively). Cyclic voltammetry data were obtained as described before.[3] Luminescence measurements were performed on a Perkin–Elmer LS5 spectrophotometer at room temperature and 77 K. Microanalyses were performed at UMYMFOR, Universidad de Buenos Aires, Argentina.

RESULTS AND DISCUSSION

Syntheses

The mononuclear complex **A** can be separated from its main impurity, $Ru(bpy)_2(CN)_2$ (cf. ref. 7), by a chromatographic exchange on a Sephadex C-25 column. The dinuclear mixed-valence species **B** has been prepared as a solid PF_6^- salt using a method similar to that reported[9] for the dinuclear compound $[(NH_3)_5Ru^{III}—NC—Ru^{II}(bpy)_2(CN)](PF_6)_3$. The corresponding dinuclear iron species **C** can be detected in an H_2O/Me_2CO (1:1 v/v) solution.

IR spectra

Figure 1 shows the IR spectra (as KBr pellets) of the PF_6^- salts of **A** and **B**. Assignments can be made by comparison to analogous complexes.[2] For the mononuclear species **A**, the sharp absorption at 2071 cm^{-1} can be attributed to the cyanide stretching vibration $\nu(C\equiv N)$. In the dinuclear mixed-valence complex **B** this band is much broader and appears at 2024 cm^{-1}. The broadening effect in $\nu(C\equiv N)$ has already been observed in the mixed-valence species $(NH_3)_5Ru—NC—Ru(CN)_5$ when compared to $Ru(CN)_6^{4-}$.[10] The negative shift in $\nu(C\equiv N)$ of **B** with respect to **A** contrasts to the increase observed in $[(trpy)(bpy)Ru^{II}—CN—Ru^{II}(NH_3)_5](PF_6)_3\cdot 3Me_2CO$,[4] when compared with the mononuclear parent complex. This difference can be accounted for by the different inductive effects of a capping pentaammineruthenium group when the oxidation state of ruthenium is changed from (II) to (III). The wave-numbers of the ammonia stretching and deformation vibrations in the PF_6^- salt of **B** [$\nu(N—H) = 3300–3150$ cm^{-1}

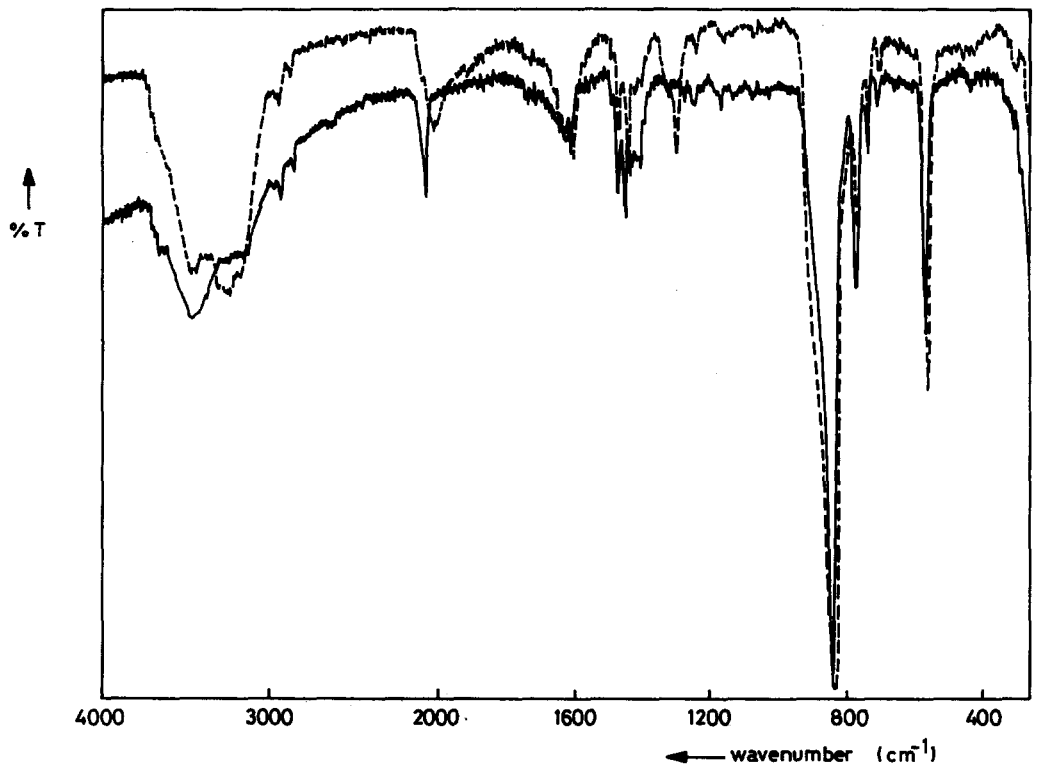

Fig. 1. IR spectra (as KBr pellets) of: (——) $[Ru(bpy)_2(py)(CN)](PF_6)\cdot 11H_2O$ and (– – –) $[(bpy)_2(py)Ru—CN—Ru(NH_3)_5](PF_6)_4\cdot 12H_2O$.

and $\delta(NH_3) = 1312\ cm^{-1}$] are typical of pentaammineruthenium(III) moieties.[11]

UV–vis spectra

Table 1 shows the observed absorption maxima in the UV–vis region for complexes **A** (in CH_3CN) and **B** (in 0.01 M HCl). For the former ion the lowest-energy band appears at $\lambda_{max} = 470$ nm, in agreement with the value previously reported,[7] and can be assigned to the metal-to-ligand charge transfer (MLCT) transition $d_\pi(Ru) \rightarrow \pi_1^*(bpy)$. The following absorption band at $\lambda_{max} = 346$ nm has contributions from $d_\pi(Ru) \rightarrow \pi_2^*(bpy)$ and $d_\pi(Ru) \rightarrow \pi^*(py)$ MLCT transitions, as discussed before.[12] These two low-energy bands are shifted in H_2O to 442 and 330 nm, respectively, as shown in Fig. 2. This strong solvatochromic effect can be explained by considering the higher electron-accepting abilities of H_2O with respect to CH_3CN.[13] When comparing the lowest-energy absorption maximum of this ion in aqueous solution to the corresponding values of $Ru(bpy)_2(CN)_2$ ($\lambda_{max} = 431$ nm)[14] and $[Ru(bpy)_2(py)_2]^{2+}$ ($\lambda_{max} = 455$ nm),[14] we infer that increasing the number of CN^- ligands attached to a ruthenium bipyridil moiety causes a noticeable

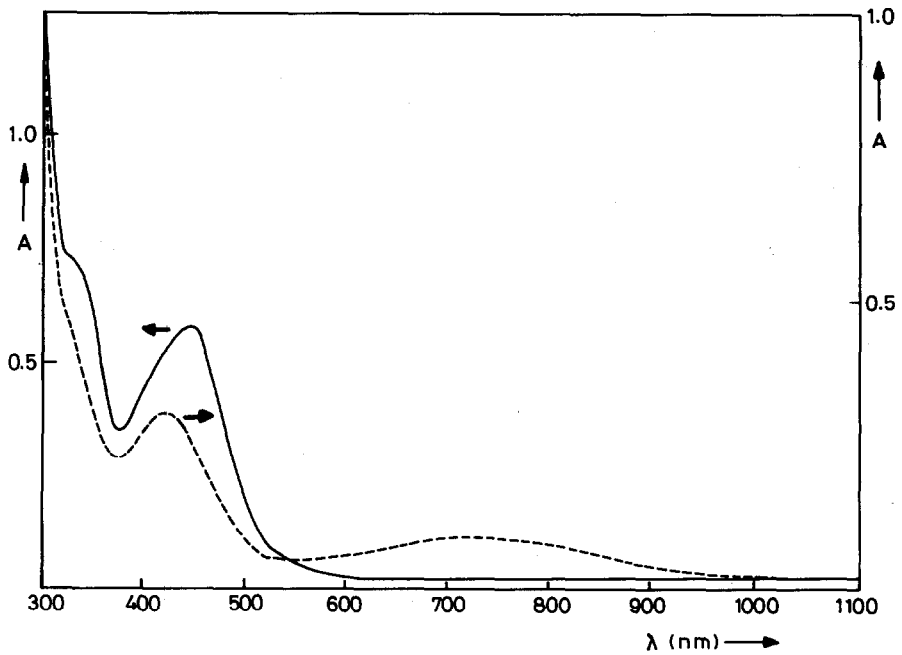

Fig. 2. Visible spectra in aqueous solutions of: (——) $[Ru(bpy)_2(py)(CN)]^+$ ($C = 9 \times 10^{-5}$ M) and (– – –) $[(bpy)_2(py)Ru^{II}—CN—Ru^{III}(NH_3)_5]^{4+}$ ($C = 4.8 \times 10^{-5}$ M).

decrease in Ru → bpy π-backbonding, with a concomitant increase in the energy of the MLCT band. The bands at 288 and 244 nm in **A** are assigned to $\pi \rightarrow \pi^*$ intraligand transitions, while the band at 208 nm is due to a $d_\pi(Ru) \rightarrow \pi^*(CN^-)$ MLCT transition.

The UV–vis absorption spectrum of **B** in aqueous solution is also shown in Fig. 2. The bands at 285 and 243 nm are again assigned to $\pi \rightarrow \pi^*$ intraligand transitions. The $d \rightarrow \pi^*$ ($Ru^{II} \rightarrow$ bpy) CT band at 442 nm in **A** is shifted to 423 nm in **B**, as expected for dinuclear complexes with metal binding through cyanide bridges.[9] A new intense and broad absorption band at $\lambda_{max} = 697$ nm can be confidently assigned to an MMCT transition, $Ru_b^{II} \rightarrow Ru_a^{III}$ (Ru_b = Ru bonded to bpy, Ru_a = Ru bonded to NH_3), since it disappears in the corresponding $Ru_b^{II}—CN—Ru_a^{II}$ and $Ru_b^{III}—CN—Ru_a^{III}$ species (obtained by adding solid $S_2O_4^{2-}$ and Ce^{IV} salts, respectively, to aqueous solutions of **B**). This band is shifted to 690 nm in CH_3CN, typical of this type of asymmetric system.[9] Besides, it compares reasonably well in shape and position to the MMCT bands of the complexes $[(trpy)(bpy)Ru^{II}—CN—Ru^{III}(NH_3)_5]^{4+}$ ($\lambda_{max} = 700$ nm in CH_3CN)[4] and $[(NH_3)_5Ru^{III}—NC—Ru^{II}(bpy)_2(CN)]^{3+}$ ($\lambda_{max} = 694$ nm in H_2O).[9] For the $Ru^{II}—CN—Fe^{III}$ complex **C** the MMCT band is observed at 700 nm in H_2O/Me_2CO (1 : 1 v/v) solution.

Electrochemistry

The redox potentials for the ruthenium-based and two bpy-based couples have already been determined for complex **A**: 1.04, −1.48 and −1.72 V, respectively, in CH_3CN, vs S.C.E.[15] In complex **B** $E_{1/2}$ (Ru_b^{III}/Ru_b^{II}), as determined by cyclic voltammetry, appears at 1.28 V (in CH_3CN, vs S.C.E.), as expected for its higher charge with respect to **A**. The value for $E_{1/2}$ (Ru_a^{III}/Ru_a^{II}) = −0.02 V (in CH_3CN, vs S.C.E.) is consistent with those values observed for nitrile-bound pentaammineruthenium complexes.[9] The energy difference between both mixed-valence isomers of **B** thus amounts to 1.30 eV. The reduction waves were somewhat irreversible, with peak potentials at −1.46 and −1.74 V due to bpy reduction processes. Due to the narrow electrochemical window for aqueous solutions, $E_{1/2}$ values for both metallic couples could not be determined for the ion **C**, but we expect them to be very similar to **B**, the ruthenium analogue.

Luminescence

Complex **A** emits at room temperature ($\lambda_{em} = 620$ nm in H_2O).[7] Figure 3 shows the emission spectrum of **A** at 77 K as an EtOH/MeOH glass (4 : 1 v/v; the solution had to be filtered). At $\lambda_{ex} = 466$ nm there is an emission maximum at 585

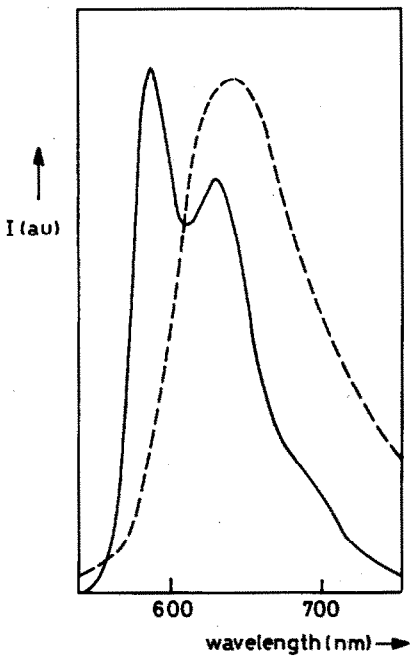

Fig. 3. Emission spectrum ($\lambda_{ex} = 466$ nm) of $[Ru(bpy)_2(py)(CN)]^+$ in EtOH/MeOH (4:1 v/v): (——) at 77 K and (– – –) at room temperature.

nm and a shoulder at 623 nm, characteristic of $Ru(bpy)_2(L)_2^{n+}$ complexes which decay from an ^{3}MLCT excited state.[16] The excitation and absorption spectra were almost identical. At room temperature this alcoholic solution emits at 636 nm, as also shown in Fig. 3. Complex **B** does not emit at room temperature or 77 K. This lack of emission may be due to an efficient oxidative quenching process, such as those proposed[17] for similar cyano-bridged systems:

$$[(bpy)_2(py)Ru^{II}CNRu^{III}(NH_3)_5]^{4+} \xrightarrow{h\nu} [(bpy)(bpy^-)(py)Ru^{III}CNRu^{III}(NH_3)_5]^{4+}$$

$$[(bpy)(bpy^-)(py)Ru^{III}CNRu^{III}(NH_3)_5]^{4+} \xrightarrow{k_q} [(bpy)_2(py)Ru^{III}CNRu^{II}(NH_3)_5]^{4+*}$$

$$[(bpy)_2(py)Ru^{III}CNRu^{II}(NH_3)_5]^{4+*} \xrightarrow{k_b} [(bpy)_2(py)Ru^{II}CNRu^{III}(NH_3)_5]^{4+}.$$

The "unstable" isomer of **B** is involved in the quenching step k_q, i.e. the MMCT excited state can quench the radiative decay from the ^{3}MLCT excited state.

Electronic coupling

By using the Marcus–Hush formalism[1] it is possible to calculate the electronic metal-to-metal coupling in the mixed-valence species **B** from spectroscopic data. Indeed, from values of $\nu_{max} = 1.45 \times 10^4$ cm^{-1}, $\varepsilon_{max} = 3.4 \times 10^3$ M^{-1} cm^{-1} and $\Delta\nu_{1/2} = 6.0 \times 10^3$ cm^{-1}, obtained by analysing the MMCT band of **B**, a value of $H_{AB} = 2200$ cm^{-1} (0.27 eV) results, typical for cyano-bridged mixed-valence complexes.[9,18]

The reorganization barrier for the optical electron transfer, λ, can be calculated from the following equation:[16]

$$E_{op} = \lambda + \Delta G^0 + \Delta E_{ex},$$

where E_{op} is the maximum of the MMCT band, ΔG^0 is the free energy difference between both metal sites and ΔE_{ex} is a correction for excited state/ground state differences. Since, for ion **B**, $E_{op} = 1.80$ eV, $\Delta G^0 = 1.30$ eV and $\Delta E_{ex} = 0.15$ eV,[19] a value of $\lambda = 0.35$ eV is obtained. For the ion $[(py)(NH_3)_5 Ru^{III}—NC—Ru^{II}(bpy)_2(CN)]^{3+}$, for which ΔG^0 is lower by $\cong 0.3$ eV, a concomitant decrease of $\cong 0.2$ eV in E_{op} is observed.[20] Values for λ and ΔG^0 are very similar for analogous cyano-bridged complexes[4,9] and thus E_{op} appears at almost the same value ($\cong 1.8$ eV). For the thermal back electron transfer $Ru_b^{III} \rightarrow Ru_a^{II}$ $\Delta G^0 = -1.30$ eV and $\lambda < -\Delta G^0$, so that an "inverted" behaviour is predicted.[4] A non-adiabatic treatment[21] gives the reverse rate constant $k_{th,r} \cong 7 \times 10^8$ s^{-1}. However, recent picosecond IR experiments[22] performed on the mixed-valence dimer $[(NC)_5Ru^{II}—CN—Ru^{III}(NH_3)_5]^{-*}$ have shown that an ultrafast ($\tau < 0.5$ ps) back electron transfer, followed by vibrational relaxation, occurs in this system from the MMCT excited state, suggesting that a theory considering vibrational equilibrium is not adequate for this process. Besides, it has been pointed out that electronic coupling elements for optical electron transfers are not necessarily equal to those for thermal electron transfers.[23]

To conclude, strong coupling in cyano-bridged asymmetric mixed-valence complexes, such as **B** or **C**, gives rise to intense MMCT bands in the visible region. The complete lack of emission, even at 77 K, of dimer **B** points to efficient quenching of the MLCT (Ru → bpy) excited state, probably through crossing to the MMCT excited state. Increasing the metal-to-metal separation, such as in the complex $[(trpy)(bpy)Ru^{II}(4,4'\text{-bpy})Ru^{III}(NH_3)_5]^{5+}$ (with 4,4′-bpy = 4,4′-bipyridine),[5] causes a higher reorganization barrier λ, which may result in longer-lived MMCT excited states.

SYNTHESIS AND CHARACTERIZATION OF $M_2(EPh_3)_2(NMe_2)_4$ COMPOUNDS (E = C, Si, Ge, Sn; M = Mo, W)

MALCOLM H. CHISHOLM,* GENNARO J. GAMA and IVAN P. PARKIN

Department of Chemistry, Indiana University, Bloomington, IN 47405, U.S.A.

(*Received* 10 *November* 1992; *accepted* 16 *November* 1992)

Abstract—The reaction between $M_2Cl_2(NMe_2)_4$ and $LiEPh_3$ (2 equivalents) (M = W; E = C, Si, Ge, Sn; M = Mo; E = Si, Ge, Sn) in toluene/THF at room temperature produces a precipitate of $M_2(EPh_3)_2(NMe_2)_4$ in 35–65% isolated yield. The compounds are air-, water- and light-stable for prolonged periods in the solid state (except when E = C). All are soluble in aromatic hydrocarbon solvents and decompose on heating at 161–270°C. They were characterized by IR, UV, mass spectrometry and VT ^{1}H NMR. The latter revealed only the *anti* isomer in solution with $T_c \geqslant 115$°C and $\Delta G^{\dagger} \geqslant 74$ kJ mol^{-1} for the amide rotation (M = W, Mo; E = Si, Ge). For $W_2(SnPh_3)_2(NMe_2)_4$ a coalescence point of $T_c = 75$°C ($\Delta G^{\dagger} = 70$ kJ mol^{-1}) was observed and the compound slowly isomerizes to a mixture of the *gauche* and *anti* configurations.

Compounds of the type $M(R)_2(NMe_2)_4$ [M = Mo, W; R = Cl, $Si(SiMe_3)_3$, CR'_3, $Sn(SnMe_3)_3$, $SeC_6H_2Me_3$, PR'_2][1] have been synthesized by metathesis reactions involving LiR and substitutionally labile $M_2Cl_2(NMe_2)_4$ compounds.[2] More recently compounds of the formula $W_2(OCPh_3)_2(NMe_2)_4$,[3] $W_2(OSiPh_3)_2(NMe_2)_4$[3] and $W_2(OC(CF_3)_2NMe_2)_2(NMe_2)_4$[4] has been formed by reaction of $W_2(NMe_2)_6$ with the appropriate alcohol. Presumably steric hindrance prevents further substitution. Despite the synthesis of a number of $W_2(ER_3)_2(NMe_2)_4$ complexes, where E is a group 14 element, no systematic synthesis for the same R group has been obtained. This is important as it may give information about trends and reactivity within the homologous series.[5] Here we describe the formation of complexes of the form $M_2(EPh_3)_2(NMe_2)_4$ (E is a group 14 element and M = Mo, W).[6]

EXPERIMENTAL

All reactions were performed in oven-dried glassware, under dry nirogen, by Schlenk or glove-box techniques. All non-deuterated solvents were distilled from Na/benzophenone ketyl and stored over molecular sieves or metallic sodium, under dry nitrogen. ^{1}H NMR spectra were recorded on a Varian XL 300 spectrometer at 299.66 MHz in C_6D_6 or $C_6D_5CD_3$ and referenced to residual proton impurities at 7.16 and 2.09 ppm, respectively. Variable-temperature ^{1}H NMR were calibrated by an external methanol curve. IR spectra were obtained on a Perkin–Elmer PE 283B spectrophotometer as pressed KBr pellets. Ditungsten dichloride tetrakis(dimethylamide) and the dimolybdenum analogue were made by standard procedures.[2] Lithium powder, sodium and Ph_3ECl were purchased from Aldrich Chemical Co. and used as supplied.

Synthesis of Ph_3ELi *compounds*[7]

A solution of Ph_3ECl (1.66×10^{-3} mol) in THF (5 cm^3) was added to an eight-fold excess of lithium powder (containing 2% of Na) (0.090 g, 1.30×10^{-2} mol) and vigorously stirred in THF (5 cm^3). During the addition the original solution changed colour from colourless to pale yellow and to deep green after all the Ph_3ECl had been added. The only exception was the compound where E = carbon, whose solution turned brownish-red. The reaction was allowed to stand for 3 h and the volume reduced *in vacuo* to precipitate LiCl. The resulting solution was filtered through a fine glass frit and used directly in the subsequent reactions.

The lead congener was prepared according to the procedures below: (a) From the reaction between Ph_3PbCl and lithium (containing from 5 up to 10%

* Author to whom correspondence should be addressed.

of sodium) in THF, which resulted in a canary green solution of the salt; (b) from the reaction between the Pb_2Ph_6 dimer and lithium in liquid ammonia, which resulted in a bright yellow solution which was evaporated under vacuum and the yellow solid redissolved in THF.

Preparation of $M_2(EPh_3)_2(NMe_2)_4$ (M = Mo; E = Si, Ge, Sn; M = W, E = C, Si, Fe, Sn)

To $M_2Cl_2(NMe_2)_4$ (7.20×10^{-4} mol) in toluene (5 cm^3) was added Ph_3ELi (1.66×10^{-3} mol) in THF (3 cm^3) at room temperature. The resulting solution was vigorously stirred for 30 min with the generation of a white precipitate. The precipitate was removed by filtration and the resulting filtrate was reduced to 1/4 of the volume *in vacuo*. The resulting solution precipitated an orange solid. The solvent was filtered off and the solid washed with toluene (1 cm^3) and THF (1 cm^3) and dried for 7 h *in vacuo*. The physical characterization data and yields of the solids obtained are given in Table 1. All solids were air stable for prolonged periods, but their solutions quickly showed some decomposition after a few seconds of exposure to air. The tin derivatives decompose, in the solid state, after 2–3 h. Attempts to prepare the lead derivatives, following the same procedures, led always to the formation of a black intractable precipitate upon addition of the Ph_3PbLi solution to Mo or the W substrate solution in toluene.

The IR spectra for all the $M_2(EPh_3)_2(NMe_2)_4$ compounds were similar with the following main bands (cm^{-1}): 3040, 2980, 2840, 2790, 1570, 1430, 1410, 1245, 1145, 845, 720, 685, 475, 315.

RESULTS AND DISCUSSION

Synthesis

Reaction of $LiEPh_3$ with $M_2Cl_2(NMe_2)_4$ in toluene/THF produces $M_2(EPh_3)_2(NMe_2)_4$ in reasonable yields (35–65%), according to eq. (1).

$$M_2Cl_2(NMe_2)_4 + 2LiEPh_3 \longrightarrow M_2(EPh_3)_2(NMe_2)_4 + 2LiCl \quad (1)$$

The reactions were extremely rapid with LiCl being immediately precipitated on mixing the reagents. This precluded monitoring the reaction by ^1H NMR. The $M_2(EPh_3)_2(NMe_2)_4$ compounds precipitated from the reaction solution after reducing the volume of the solution to between a quarter or half of its original amount. A constant problem in the isolation of the $M_2(EPh_3)_2(NMe_2)_4$ compounds is the removal of the remaining LiCl, which co-precipitates with the product. Washing the final product with THF, or extracting the product with a benzene/hexane mixture or washing the solid with small amounts of degassed water (followed by washing with small amounts of THF) and drying the product for several hours helps to remove the LiCl contaminant. $Mo_2(SiPh_3)_2(NMe_2)_4$ was washed with degassed water (1.5 cm^3) at 10°C for approximately 30 s and then washed with THF (1 cm^3). Only a small decomposition was observed. The yields obtained in these reactions were comparable to other alkylation reactions of $M_2Cl_2(NMe_2)_4$.

It is not clear whether our failure to obtain the lead containing compound is a reflection of thermodynamic factors (weak W—Pb bonds) or is

merely a kinetic problem in that $LiPbPh_3$ is highly reducing.

Characterization

All the $M_2(EPh_3)_2(NMe_2)_4$ compounds are air-stable, relatively inert to alcoholysis by PrOH, EtOH and MeOH, and in the case of the germanium derivatives, the compounds are inert to 6 M KOH in EtOH and react only slowly with 1 M HNO_3. These remarkable properties are likely steric in origin as $M_2R_2(NMe_2)_4$ (M = Mo, W; R = alkyl or aryl) undergo ready alcoholysis to form $M_2R_2(OR)_4$ compounds.[8] The steric protection is almost certainly afforded by the large "propeller-like" hydrophobic EPh_3 groups. The $M_2(EPh_3)_2$ containing complexes are all orange or orange–red in colour and have decomposition points in the range 161–270°C, dependent on the nature of E.

The IR spectra of $M_2(EPh_3)_2(NMe_2)_4$ are all virtually identical within the range 3000–300 cm^{-1}, with the same general shape and shift of individual bands by no more than 5–15 cm^{-1}, dependent on the sample. No M—E vibrations were identified; for E = Si, Ge and Sn they likely occur below 300 cm^{-1}. The C—E vibrations in the EPh_3 groups are weak and no definitive assignment was possible.

The ^1H NMR spectra of the $M_2(EPh_3)_2(NMe_2)_4$ complexes at room temperature showed only two resonances in the amide region. This observation is consistent with the *anti*-isomer in solution. The observed spectra show two types of dimethylamide resonances at room temperature and below, both with equal intensities. It is in agreement with the staggered ethane-like geometry adopted. For $M_2(R)_2(NMe_2)_4$ complexes, the R groups can be oriented in a *gauche* or *anti* fashion. For the *anti* isomer all the dimethylamide groups are equivalent, being related by a mirror plane and a C_2 axis, however, the methyl groups on each dimethylamido ligand are proximal and distal with respect to the metal–metal multiple bond.[9] The M—N bond is formally a multiple bond in the $M_2(EPh_3)_2(NMe_2)_4$ complexes. The barrier to free rotation about the M—N bond can be observed in the NMR timescale by measuring the coalescence of the proximal and distal resonances. In the *gauche* isomer either two or four resonances are observed, depending on the temperature, as two sets of dimethylamide groups are present.

In the series $M_2(EPh_3)_2(NMe_2)_4$ all the compounds showed only two resonances in the amide region from −70 to 25°C in d_8-toluene, indicating that only the anti-isomer is formed in the reaction. Heating the solutions of $M_2(EPh_3)_2(NMe_2)_4$ up to 105°C in d_8-toluene showed a marked broadening of the amide resonances for M = Mo, W, E = C, Si, Ge, but no coalescence. The estimated coalescence temperature for these compounds is above 120°C. For M = Mo, W; E = Sn, a coalescence point at 70°C is observed for the free amide rotation. Further in this case the appearance of the gauche isomer occurs at $T \geqslant 65$°C, until the equilibrium distribution of rotamers (66.7% *gauche*: 33.3% *anti*) is obtained after prolonged heating. This indicates that the *anti* rotamer is the kinetic product in eq. (1). Figure 1 shows the spectra of $W_2(NMe_2)_4(CPh_3)_2$. Pertinent ^1H NMR data are presented in Table 2.

At high temperatures ($T \geqslant 65$°C) $W_2(SnPh_3)_2(NMe_2)_4$ rotation about the metal–metal bond occurs at a significant rate, such that on cooling a sample heated to 75°C for 15 min six resonances of equal intensity are observed in the amide region, indicative of a statistical distribution of *anti* and *gauche* rotamers. In the case of the latter compound the estimated M—E distance, based on the atomic radii, is the largest for the homologous series, thus restriction of rotation about the M—M bond due to the cogging of the EPh_3 group is lower in energy than in the other compounds.

The structure of *anti*-$W_2(GePh_3)_2(NMe_2)_4$ has been previously reported, but is shown again here in Fig. 2 since it is instructive to consider the consequences of the M—E distances within this series.

The freedom of the amide rotation in W_2^{6+} complexes has been ascribed to electronic and steric contributions. In the $M_2(EPh_3)_2(NMe_2)_4$ series the electronic nature of the ligands is almost constant as there is little change in the electronegativity between silicon and tin; however, the steric effects change

Table 2. ^1H NMR data (δ) and coalescence temperature for amide rotation in $M_2(EPh_3)_2(NMe_2)_4$ compounds

M	E	Me_d[a] (ppm)	Me_p[a] (ppm)	T_c[b] (°C)	$\Delta G^{\dagger}$[c] (kJ mol^{-1})
W	C	1.37	3.36	> 150	> 81
W	Si	2.11	3.63	125	77
W	Ge	2.18	3.73	115	74
W	Sn	2.37	3.87	75	67[d]
Mo	Si	2.22	3.64	125	77
Mo	Ge	2.28	3.73	120	77
Mo	Sn	2.40	3.86	105	73[d]

[a] $Me_{p,d}$ denote the proximal and distal Me groups, respectively.

[b] Values for T_c were estimated by line shape analysis for free amide rotation.

[c] $\Delta G^{\dagger}$ values calculated by $\Delta G^{\dagger} = -\ln(K_{ex}h/KT_c)RT_c$.

[d] Equilibrium between the *anti* and *gauche* rotamers was observed.

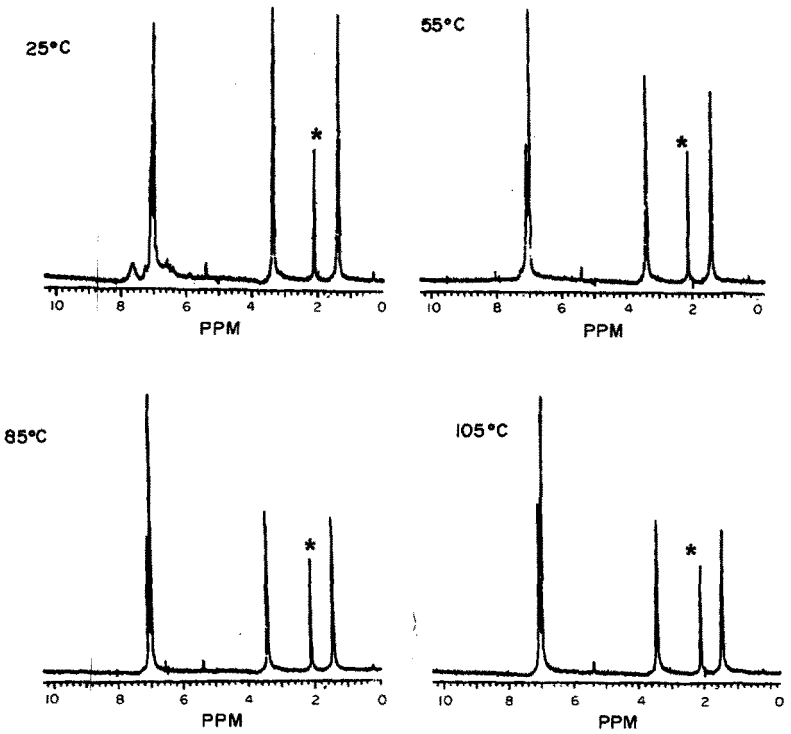

Fig. 1. Variable-temperature ^1H NMR spectra for $W_2(CPh_3)_2(NMe_2)_4$ in d_8-toluene. * = protio-toluene.

quite dramatically ($\simeq$ 2.20 for W—C and $\simeq$ 2.70 Å for W—Sn). Here we observe the estimated coalescence temperature for the free amide rotation following the order C $\gg$ Si > Ge > Sn. This indicates that the steric interaction between the EPh_3 and NMe_2 groups across the M—M bond decreases as the M—E bond increases. A small electronic component to the amide rotation barrier caused by differences in electronegativity of E would work in parallel with the steric effects. The higher the electronegativity of E, the stronger the $M_{d\pi}$–$N_{p\pi}$ interaction and the higher the rotational energy.

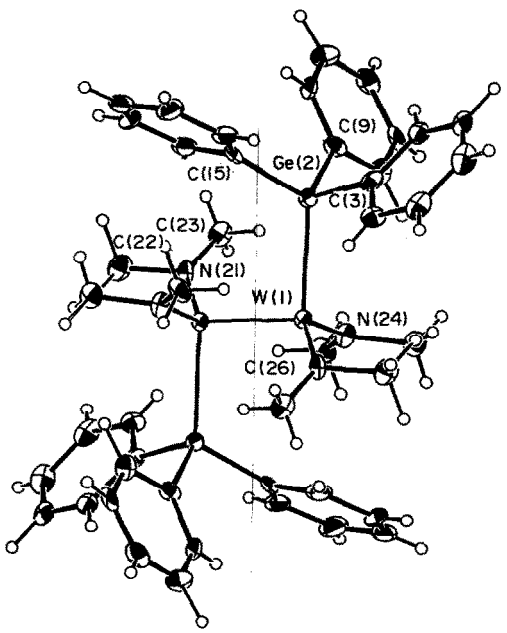

Fig. 2. An ORTEP view of the centrosymmetry *anti*-$W_2(GePh_3)_2(NMe_2)_4$. Pertinent distances (Å) and angles (°) are W—W = 2.297(1), W—Ge = 2.625(1), W—N = 1.95(1), W—W—Ge = 95.9(1), W—W—N = 106.9(1).

CONCLUSIONS

The analysis of the ^1H NMR data suggests that the $M_2(EPh_3)_2(NMe_2)_4$ compounds form a structurally homologous series with an *anti* ethane-like staggered configuration. The rotational barrier for M—N free rotation depends on the steric hindrance afforded by the EPh_3 groups which decrease with the length of the M—E bond. An electronic component due to the electronegativity of the EPh_3 groups plays a minor role in the rotational process. The partial conversion of the kinetically formed *anti* isomer to the *gauche* form is facilitated at high temperatures ($T > 75$°C), only for E = Sn. This is mainly a consequence of the lower barrier to rotation about the W≡W bond afforded by the longer M—E bond.

SYNTHESIS OF (3-METHOXYPROPYL)-CYCLOPENTADIENYLTITANIUM AND ZIRCONIUM COMPLEXES

YANLONG QIAN* and GUISHENG LI

Shanghai Institute of Organic Chemistry, Academia Sinica, 345 Lingling Lu, Shanghai 200032, China

(*Received* 4 *November* 1992; *accepted* 13 *November* 1992)

Abstract—Four titanium and zirconium complexes of (3-methoxypropyl)cyclopentadienyl, Cp'_2MCl_2 (M = Ti, Zr), $Cp'CpTiCl_2$ and $Cp'Cp''TiCl_2$ (Cp = C_5H_5, Cp′ = $MeOCH_2CH_2C_5H_4$, Cp″ = $MeOCH_2CH_2C_5H_4$), have been synthesized in good yields by reacting the potassium salt Cp′K with MCl_4 (M = Ti, Zr), $CpTiCl_3$ and $Cp''TiCl_3$, respectively. Their IR spectra show that the oxygen atom in the side-chain does not coordinate with the central metals, while mass specta imply the coordination of oxygen with the metals is possible, in particular in some low-valent species.

Investigation of synthesis, structure and reactivity of metal complexes with cyclopentadienyl ligands remains an active research field in organometallic chemistry. A number of interests are related to the introduction of various kinds of substituents onto the cyclopentadienyl ligand, aimed at studying the structures of metal complexes and adjusting their properties.[1] Among them, great attention has been paid to group IV element complexes.[2–6] We have synthesized several kinds of ring-substituted cyclopentadienyl titanium and zirconium complexes[7–11] and found remarkable substituent effects upon the catalytic properties of the titanium complexes toward olefin isomerizations.[12–14] For example, the isomerization of 1,5-hexadiene catalysed by $(RC_5H_4)_2TiCl_2/Pr^iMgBr$ afforded 90% methylenecyclopentane, when R is 2-methoxyethyl, while 95% 2,4-hexadiene was obtained, when R is an allyl.[13] We recognized and confirmed that the methoxy in the side-chain on the cyclopentadienyl ring can chelate with titanium, thus regulating the structure and reactivity of the complex. In this paper we further present the synthesis of the 3-methoxypropylcyclopentadienyl ligand and its titanium and zirconium complexes.

RESULTS AND DISCUSSION

3-Methoxypropylcyclopentadiene (**1**), prepared from 3-methoxypropyl chloride and sodium cyclopentadienide in THF, was converted immediately into the corresponding potassium salt in 86% yield on treatment with metal potassium in THF.

$Cp'H$ $Cp'K$ Cp'_2TiCl_2
(**1**) (**2**) (**3**)

Cp'_2ZrCl_2 $Cp'CpTiCl_2$ $Cp'Cp''TiCl_2$
(**4**) (**5**) (**6**)

(Cp = C_5H_5, Cp′ = $MeOCH_2CH_2CH_2C_5H_4$,
Cp″ = $MeOCH_2CCH_2C_5H_4$)

The potassium salt of 3-methoxypropylcyclopentadiene (**2**) reacted with $TiCl_4$, giving rise to bis(3-methoxypropyl-cyclopentadienyl)titanium dichloride (**3**) as purple needle crystals in 71% yield. A similar reaction between **2** and $ZrCl_4$ afforded bis-(3-methoxypropyl-cyclopentadienyl)zirconium dichloride (**4**) in 87% yield. The mono-substituted cyclopentadienyl titanium complex (**5**) was obtained in 88% yield by reacting **2** with cyclopentadienyltitanium trichloride. In order to compare the effect of different lengths of the side-chain, with 2-methoxyethyl on one cyclopentadienyl and 3-methoxypropyl on another, complex **6**

was also successfully synthesized from the reaction of **2** with (2-methoxyethyl-cyclopentadienyl)-titanium trichloride ($Cp''TiCl_3$). Complex **6** is much more soluble than complexes **3** and **5** in ordinary organic solvents, such as ether, acetone, THF, etc. Attempts to synthesize bis(3-methoxypropyl-cyclopentadienyl)titanium chloride (Cp'_2TiCl) via reaction between **2** and $TiCl_3 \cdot 3THF$ or reduction of **3** by aluminium foil were unsuccessful. The target compound should be a solid, but these two synthetic routes led to a green viscous oily substance, which could not be crystallized or solidified by the usual methods available.

Introduction of 3-methoxypropyl and 2-methoxyethyl into the cyclopentadienyl rings caused the ^1H NMR signals of the ring hydrogens to move towards a higher magnetic field in comparison with that of dicyclopentadienyltitanium dichloride. The ring protons on the Cp′ moiety are split into two groups of muliplets, with an equal integrated area, centred at 6.40 and 6.33 ppm, respectively, for complexes **3**, **5** and **6**. The ring protons of Cp″ appeared as a broad singlet, falling into the multiplet around 6.40 of Cp′. The ring protons in the zirconium complex were also found to be two groups of multiplets, centred at 6.30 and 6.22 ppm, approximately 0.1 ppm higher field than those in the corresponding titanium complexes.

In the IR spectra the stretching vibration frequencies of C—O in these complexes are around 1120 cm^{-1}, almost identical to that in the ligand (**1**). This fact indicates that the oxygen atom is not coordinated with the metals in these quadrivalent metal complexes. The mass spectra of these complexes have regular types of fragmentation. The molecular ion peaks are usually weak and the main fragments are M—Cl, M—Cp′ and M—Cp″, etc. For complexes **3** and **4** the base peaks are attributed to M—Cp′ species. In the case of complex **5** the peak of M—Cp ($Cp'TiCl_2$) is much stronger than that of M—Cp′ ($CpTiCl_2$), indicating that the M—Cp species is more stable than M—Cp′ species under gas phase conditions, possibly due to intramolecular coordination between the oxygen and titanium in M—Cp species. For complex **6**, with two different oxygen-containing substituents on the cyclopentadienyls, the relative intensity for the peak due to M—Cp″ is only 35% of that for M—Cp′. A similar case is found for the peaks of M—Cp″—HCl and M—Cp′—HCl. These results reveal that the oxygen atom in 2-methoxyethyl is more favourable towards chelation to the titanium than for the 3-methoxypropyl analogue. This kind of interaction between the substituent and the central metal may be an important factor in controlling the structure and reactivity of the metal complex.

EXPERIMENTAL

All experiments were carried out under purified argon using standard Schlenk techniques. Melting points were not corrected. Solvents (THF, Et_2O, n-hexane and toluene) were refluxed over sodium Ph_2CO and distilled prior to use. The ^1H NMR spectra of **1** and **3–6** were recorded on Varian 360A and Varian XL-200 NMR spectrometers, respectively. IR were measured on a Shimadzu IR-40 spectrometer and MS were obtained on a Finnigan 4021 mass spectrometer. Compound $Cp''TiCl_3$ was prepared according to ref. 10. Commercially available $ZrCl_4$ was purified by sublimation before use.

Synthesis of **1**

Sodium cyclopentadienide, prepared from sodium sand (3.0 g, 0.13 mol), cyclopentadiene (18 cm^3, 0.22 mol) and THF (150 cm^3), was added to $CH_3OCH_2CH_2CH_2Cl$ (14.0 g, 0.13 mol) under magnetic stirring. The mixture was stirred at room temperature overnight, accompanied by the formation of a white solid (NaCl) precipitate. Solvents were removed under reduced pressure, and then the solid was dissolved with water. The organic layer was separated and the water-phase was extracted with petroleum ether (30–60°C) (3×30 cm^3). The combined organic phase was washed with saturated NaCl solution until neutral and dried over $CaCl_2$ for 2 h. After filtration and removal of the solvents, the residue was distilled. A colourless liquid (12.8 g, b.p. 34–36°C/1.0 mmHg) was obtained in 71% yield. Found: C, 78.3; H, 9.7. Calc. for $C_9H_{14}O$: C, 78.2; H, 10.2%. ^1H NMR (CCl_4, ppm): 6.0 (m, 3H), 3.06 (m, 5H), 2.68 (m, 2H), 2.26 (m, 2H), 1.60 (m, 2H). IR (neat, cm^{-1}): 3080m, 1618m, 1605m, 1120s, 900s, 680s.

Synthesis of **2**

3-Methoxypropylcyclopentadiene (**1**) (12 g, 87 mmol) was added to metal potassium (3.6 g, 92 mmol) in THF (190 cm^3). The mixture was stirred until almost no hydrogen was released (*ca* 12 h). The reddish solution was transferred through a stainless steel tube and washed twice with THF (60 cm^3). The concentration of the combined THF solution (*ca* 250 cm^3) was determined by titration with standard HCl solution to be 0.2985 mmol cm^{-3}, corresponding to approximately 86% yield based on **1**.

Synthesis of **3**

A solution of $MeOCH_2CH_2CH_2C_5H_4K$ in THF (134 cm^3, 40.0 mmol) was added dropwise to $TiCl_4$

(2.19 cm^3, 20.0 mmol) with stirring. After completing the addition, the reaction mixture was stirred for another 5 h. Removal of the solvents gave a red solid, which was extracted in a Soxhlet extractor with Et_2O and purple needles (5.56 g) were isolated in 71%; m.p. 92–93°C. Found: C, 54.8; H, 6.6; Ti, 12.1. Calc. for $C_{18}H_{26}Cl_2O_2Ti$: C, 5.5; H, 6.7; Ti, 12.2%. ^1H NMR ($CDCl_3$, ppm): 6.40 (m, 1H), 6.33 (m, 1H), 3.39 (t, 2H, $J = 6.4$ Hz), 3.33 (s, 3H), 2.78 (t, 2H, $J = 8.0$ Hz), 1.86 (m, 2H). IR (KBr, cm^{-1}): 3100m, 1500m, 1460m, 1440m, 1385m, 1215w, 1150m, 1118s, 1010m, 840s. MS (*m/z*, %): 357 (M—Cl, 2), 255 (M—Cp′, 100), 219 (M − Cp′ − HCl, 28), 187 (M − Cp′ − HCl − MeOH, 15), 105 (Cp′ − MeOH, 11), 91 (Cp′ − MeOME, 22), 78 ($CH_2C_5H_4$, 25), 45 ($MeOCH_2$, 59).

Synthesis of **4**

A solution of $MeOCH_2CH_2CH_2C_5H_4K$ in THF (40 cm^3, 12 mmol) was added to a mixture of sublimated $ZrCl_4$ (1.405 g, 6 mmol) and THF (15 cm^3) with stirring for 0.5 h. A yellowish solution was obtained and stirred overnight. KCl formed in the reaction was separated by centrifuging. The clear solution was transferred and concentrated, followed by the addition of n-hexane. A white solid (2.28 g) (**4**) was obtained in 87%. Sublimation at 90°C (oil bath)/3×10^{-4} mmHg) gave an analytical sample; m.p. 94°C. Found: C, 49.1; H, 5.9; Zr, 20.5. Calc. for $C_{18}H_{26}Cl_2O_2Zr$: C, 49.5; H, 6.0; Zr, 20.9%. ^1H NMR ($CDCl_3$, ppm): 6.30 (m, 1H), 6.22 (m, 1H), 3.38 (t, 2H, $J = 6.5$ Hz), 3.30 (s, 3H), 2.71 (t, 2H, $J = 7.4$ Hz), 1.83 (m, 2H). IR (KBr, cm^{-1}): 3100m, 1496m, 1480m, 1455s, 1390s, 1210m, 1135m, 1120s, 1010s, 810s. MS (*m/z*, %): 399 (M − Cl), 297 (M − Cp′, 95), 261 (M − Cp′ − HCl, 41), 91 (Cp′ − MeOMe, 49), 57 (C_3H_6O, 100), 42 (C_2H_4O, 82).

Synthesis of **5**

A solution of $MeOCH_2CH_2CH_2C_5H_4K$ in THF (38.15 cm^3, 11.4 mmol) was added to $CpTiCl_3$ (2.498 g, 11.4 mmol) in THF (20 cm^3). The reaction mixture was stirred at room temperature for 5 h. The red solid remaining after removal of the solvent was extracted in a Soxhlet extractor with Et_2O. The crude product **5** (3.22 g, 88%) was obtained. Recrystallization from PhMe–n-hexane provided an analytical sample; m.p. 78–79°C. Found: C, 51.9; H, 5.4; Ti, 15.3. Calc. for $C_{14}H_{18}Cl_2OTi$: C, 52.4; H, 5.6; Ti, 14.9%. ^1H NMR ($CDCl_3$, ppm): 6.55 (s, 5H), 6.33–6.44 (m, 4H), 3.39 (t, 2H, $J = 6.5$ Hz), 3.33 (s, 3H), 2.78 (m, 2H), 1.85 (m, 2H). IR (KBr, cm^{-1}): 3150m, 1460s, 1125s, 1030m, 840s. MS (*m/z*, %): 285 (M − Cl, 5), 255 (M − Cp, 100), 219 (M − Cp − HCl, 39), 187 (M − Cp′, 16), 151 (M − Cp′ − HCl, 2), 105 (Cp′ − MeOH, 20), 91 ($CH_2{=}CHC_5H_4$, 26), 78 ($CH_2C_5H_4$, 34), 45 ($MeOCH_2$, 77).

Synthesis of **6**

A solution of $MeOCH_2CH_2CH_2C_5H_4K$ in THF (31.4 cm^3, 9.38 mmol) was added to $MeOCH_2CH_2C_5H_4TiCl_3$ (2.60 g, 9.38 mmol) with stirring for 20 min. The resulting red solution was stirred for another 5 h. The solvent was then removed and the residue was extracted in a Soxhlet extractor with Et_2O. Concentration of the extract and washing with petroleum ether gave a red solid (3.25 g) in 91% yield; m.p. 48–50°C. Found: C, 53.8; H, 6.0; Ti, 12.7. Calc. for $C_{17}H_{24}Cl_2O_2Ti$: C, 53.8; H, 6.4; Ti, 12.6%. ^1H NMR ($CDCl_3$, ppm): 6.40 (m, 6H), 6.34 (m, 2H), 3.62 (t, 2H, $J = 6.0$ Hz), 3.39 (t, 2H, $J = 6.4$ Hz), 3.35 (s, 3H), 3.33 (s, 3H), 2.99 (t, 2H, $J = 6.0$ Hz), 2.78 (t, 2H), 1.86 (m, 2H, $J = 7.8$ Hz). IR (KBr, cm^{-1}): 3100m, 1500m, 1120s, 840s. MS (*m/z*, %): 343 (M − Cl, 22), 255 (M − Cp″, 35), 241 (M − Cp′, 100), 219 (M − Cp″ − HCl, 13), 205 (M − Cp′ − HCl, 39), 91 ($CH_2{=}CHC_5H_4$, 37), 78 ($CH_2C_5H_4$, 28), 45 ($MeOCH_2$, 69).

SYNTHESIS, CHARACTERIZATION AND REACTIVITY OF *TRANS*-$[Ru(NH_3)_4\{P(OEt)_3\}_2]^{3+}$ IONS

S. E. MAZZETTO, E. RODRIGUES and D. W. FRANCO*

Universidade de São Paulo, Instituto de Física e Química de São Carlos, Cx. Postal 369, 13560-970 São Carlos, SP, Brazil

(*Received* 18 *August* 1992; *accepted* 2 *November* 1992)

Abstract—*Trans*-$[Ru(NH_3)_4\{P(OEt)_3\}_2]^{3+}$ ions were generated by electrochemical oxidation of the corresponding *trans*-$[Ru(NH_3)_4\{P(OEt)_3\}_2]^{2+}$ ions. The oxidation is quantitative and reversible and the resulting complex absorbs at 292 nm ($\varepsilon = 5.9 \times 10^2$ M^{-1} cm^{-1}). ESR spectra of frozen solutions are compatible with axial symmetry D_{4h}, with $g_{\parallel} = 1.83$ and $g_{\perp} = 2.36$. Aqueous solutions of the ruthenium(III) complex yield *trans*-$[Ru(NH_3)_4\{P(OEt)_3\}(H_2O)]^{2+}$ as the main product upon ageing.

The chemistry of phosphite complexes of ruthenium(II) tetraamines has been the subject of research in our laboratory for many years.[1–6]

The synthesis, characterization and reactivity of *trans*-$[Ru(NH_3)_4\{P(OR)_3\}(H_2O)]^{2+}$ type complexes have been reported,[1–6] and provide information regarding the degree of back-bonding in $Ru^{II} \rightarrow P^{III}$ and the influence on the chemical properties of the metal centre and the ligand upon coordination. Extending our investigation to d^5 low-spin systems, we recently reported similar results for the *trans*-$[Ru(NH_3)_4\{P(OEt)_3\}(H_2O)]^{3+}$ system.[7]

In the present paper we describe the synthesis, characterization and stability of the *trans*-$[Ru(NH_3)_4\{P(OEt)_3\}_2]^{3+}$ ion in aqueous solution.

EXPERIMENTAL

Reagents

Doubly distilled water was used throughout. All reagents were of analytical grade purity. Ethanol, acetone and diethyl ether were purified as described in the literature.[8]

The ruthenium compounds $[Ru(NH_3)_5Cl]Cl_2$, $[Ru(NH_3)_5(H_2O)](PF_6)_2$ and *trans*-$[Ru(NH_3)_4\{P(OEt)_3\}_2](PF_6)_2$ were prepared and characterized as described in the literature.[1,9,10]

The ruthenium(III) compound was generated in solution by the electrochemical oxidation of the corresponding ruthenium(II) salt. In a typical preparation *trans*-$[Ru(NH_3)_4\{P(OEt)_3\}_2]^{2+}$ was dissolved in a 1.0×10^{-3} M aqueous solution of trifluoroacetic acid. Electrochemical oxidation was performed at +0.85 V (vs S.C.E.) and the oxidation was monitored through coulometric and spectrophotometric measurements.

Apparatus and techniques

All manipulations were performed under pure argon. All the complexes were stored *in vacuo* and protected from light. The purity of the complexes was always checked by means of cyclic voltammetry and spectrophotometric measurements. CF_3COONa/CF_3COOH aqueous solutions were used to control the ionic strength. During the spectrophotometric and electrochemical measurements the temperature was controlled at 25.0± 0.2°C using a Superohm thermostat.

The controlled potential electrolysis, coulometric and cyclic voltammetric measurements were performed in a multifunctional PARC system consisting of a model 175 Universal Programmer, a model 173 potentiostat–galvanostat, a model 379 digital coulometer, a model 376 voltage-current convertor and a model Re-0074 *X–Y* recorder.

For cyclic voltammetric measurements a glassy carbon, platinum wire and S.C.E. were used as the working, auxiliary and reference electrodes, respectively. During the electrolysis a platinum net (area 13.6 cm^2) was used as the working electrode.

All absorbance measurements were performed

* Author to whom correspondence should be addressed.

using a Hewlett–Packard 8450A diode-array spectrophotometer and the λ_{max} values found in the electronic spectra were determined by deconvolution.

Frozen solutions of the *trans*-$[Ru(NH_3)_4\{P(OEt)_3\}_2]^{3+}$ salt in aqueous medium, produced immediately after electrolysis, were used for ESR measurements on a Varian E-109 spectrometer at (153 ± 5 K).

Kinetic measurements

The decay of the *trans*-$[Ru(NH_3)_4\{P(OEt)_3\}_2]^{3+}$ species was monitored following the changes in absorbance at 316 nm and changes in peak current (i_{pa}) at 0.54 and 0.50 V, respectively.

Good agreement was observed for first-order rate constants, determined graphically from plots of $\log(A_\infty - A_t)$ vs t, and those obtained from the electrochemical measurements.

RESULTS AND DISCUSSION

Two absorption bands can be observed in the electronic spectra of solutions containing *trans*-$[Ru(NH_3)_4\{P(OEt)_3\}_2]^{2+}$, $\lambda_1 = 262\ M^{-1}\ cm^{-1}$ ($\varepsilon_1 = 4.3 \times 10^2$) and $\lambda_2 = 294$ nm ($\varepsilon_2 = 2.3 \times 10^2\ M^{-1}\ cm^{-1}$), both attributed to *d–d* transitions.

During oxidation of the metal centre in acidic medium, $C_{H^+} = 10^{-3}$ M, the resulting solutions strongly absorb light below 260 nm, without defining a peak or shoulder in this region, whereas a shoulder can be observed at 292 nm ($\varepsilon = 5.9 \times 10^2\ M^{-1}\ cm^{-1}$) which we attribute tentatively to a ligand field transition (see Fig. 1). As expected the voltammetric spectra did not change during the oxidation, since the coordination sphere was not altered. The coulometric measurements indicate that in acidic media, C_{H^+}, the electrochemical oxidation:

$$trans\text{-}[Ru(NH_3)_4\{P(OEt)_3\}_2]^{2+} \longrightarrow trans\text{-}[Ru(NH_3)_4\{P(OEt)_3\}_2]^{3+} + e^-$$

occurs quantitatively and is reversible.

The number of electrons per *trans*-$[Ru(NH_3)_4\{P(OEt)_3\}_2]^{2+}$ ion becomes significantly higher than 1 as the hydrogen ion concentration of the medium decreases. Furthermore, the solution develops a blue colour and the original *trans*-$[Ru(NH_3)_3\{P(OEt)_3\}_2]^{2+}$ species are not regenerated by reversion of the current direction or by addition of a chemical reductor.

The thermal decay of the *trans*-$[Ru(NH_3)_4\{P(OEt)_3\}_2]^{3+}$ species was followed using UV–vis and ESR spectroscopy and cyclic voltammetry.

As shown in Fig. 2(a) only two systems can be observed in the voltammetric spectra of the aged acidic solutions originally containing the *trans*-$[Ru(NH_3)_4\{P(OEt)_3\}_2]^{3+}$ species. The couple whose peak current decreases with time, $E_{1/2} = +0.64$ V, corresponds to the *trans*-$[Ru(NH_3)_4\{P(OEt)_3\}_2]^{3+/2+}$ system. The second process exhibits $E_{1/2} = +0.50$ V and its peak currents (i_{pa} and I_{pc}) increase as the peak currents for the first process decrease. The process with $E_{1/2} = +0.50$ V has been assigned to the Ru^{III}/Ru^{II} couple in the *trans*-$[Ru(NH_3)_4\{P(OEt)_3\}(H_2O)]^{3+/2+}$ system and is the only one present in the voltammogram of the ruthenium(III) solution following 70 h of storage, see curve (b) in Fig. 2.

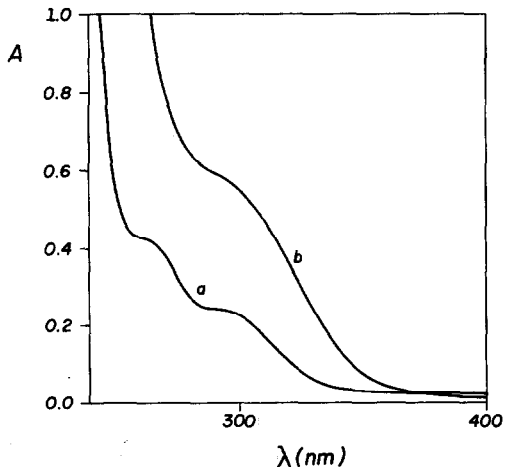

Fig. 1. Changes in electronic spectra associated with the oxidation in aqueous solutions of the ion *trans*-$[Ru(NH_3)_4\{P(OEt)_3\}_2]^{2+}$: (a) before oxidation and (b) after oxidation is completed. $C_{Ru} = 1.0 \times 10^{-3}$ M, $\mu = 0.10$ $NaCF_3COO$; pH = 3.0.

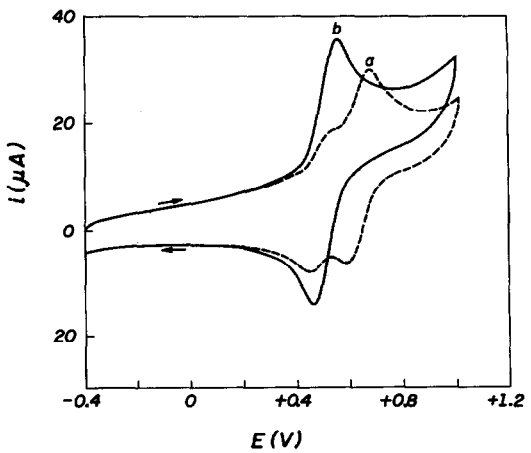

Fig. 2. Cyclic voltammogram containing the complex ions *rans*-$[Ru(NH_3)_4\{P(OEt)_3\}_2]^{2+}$: (a) 6 h after the oxidation and (b) after 70 h. $C_{Ru} = 1.0 \times 10^{-3}$ M, $\mu = 0.10$ $NaCF_3COO$, 25°C, scan rate = 200 mV s^{-1}.

From i_{pa} and i_{pc} data obtained from the voltammogram of the starting ruthenium(III) solution and the same solution after ageing for 50 h, it is possible to estimate that *ca* 80% of the original ruthenium(III) complex is still present in the mixture of the *trans*-$[Ru(NH_3)_4\{P(OEt)_3\}[H_2O)]^{3+/2+}$ ions.

From potentiometric measurements it was possible to estimate that the concentration of *trans*-$[Ru(NH_3)_4\{P(OEt)_3\}(H_2O)]^{3+}$ is less than 10% of the total ruthenium monophosphite complex present.

Similarly to the voltammetry, the electronic spectra of acidic solutions containing the *trans*-$[Ru(NH_3)_4\{P(OEt)_3\}_2]^{3+}$ complex ions also change with time. The absorbance at 292 nm decreases with the simultaneous increase of absorbance at 265 and 316 nm. After ageing for 70 h only one absorption maximum at 316 nm can be observed in the electronic spectrum. Therefore, in agreement with the voltammetric and potentiometric data the electronic spectra strongly suggest that *trans*-$[Ru(NH_3)_4\{P(OEt)_3\}(H_2O)]^{2+}$ is the final product.

Additional support for the above hypothesis was obtained by monitoring the decay of the *trans*-$[Ru(NH_3)_4\{P(OEt)_3\}_2]^{3+}$ species through ESR spectroscopy.

Frozen aqueous solutions of *trans*-$[Ru(NH_3)_4\{P(OEt)_3\}_2](PF_6)_3$ exhibit well-defined axial spectra with $g_\perp = 2.36$ and $g_\parallel = 1.83$ and without any hyperfine interaction (see Fig. 3).

Considering that ruthenium(III) is a low-spin $4d^5$ ion and that the experimental g-factors found are far from spin-only values and such that $g_\perp > g_\parallel$, we suppose the ion is subjected to a strong octahedral crystal field with tetragonal distortion. This is consistent with the observed absorption band at 292 nm, which points to a crystal field splitting of *ca* 34,000 cm^{-1} for the ^2D level. A low-spin $4d^5$ ion may be regarded as having a hole in the t_{2g} shell and an effective spin of $S = 1/2$. As a consequence we have an orbital triplet for the ground state and a negative spin orbit coupling constant. Under the combined action of the spin-orbit interaction and the crystal field distortion three Kramers' doublets may be considered.

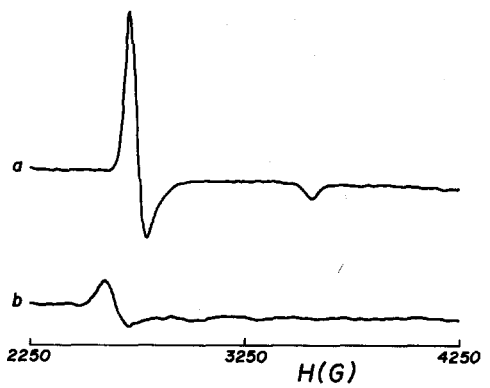

Fig. 3. EPR spectra of frozen solutions containing the complex ions *trans*-$[Ru(NH_3)_4\{P(OEt)_3\}_2]^{3+}$: (a) immediately after electrolysis and (b) 50 h after electrolysis. $C_{Ru} = 1.0\times10^{-3}$ M, $\mu = 0.10$ $NaCF_3COO$; gain = 5×10^3; scan time 2 min; scan range 2000 G; $t = 153$ K.

For the ground doublet the g values are given by the following expressions.[11-14]

$$g_\parallel = |(2+k)\cos 2\alpha + k| \quad (1)$$

$$g_\perp = |1+\sqrt{2}k\sin 2\alpha - \cos 2\alpha|, \quad (2)$$

where k is the orbital reduction factor for the magnetic electron and α is a parameter connected to the states of the ground doublet.

The axial splitting of the energy levels, δ, and the spin-orbit coupling parameter λ are related by the expression

$$\delta/\lambda = \sqrt{2}\cot 2\alpha - 1/2. \quad (3)$$

An exact fit to the experimental g values is obtained from eqs (1) and (2) with $k = 0.875$ and $\alpha = 1.398$. For a hole in the t_{2g} shell we take a value of $\lambda = -1000$ cm^{-1} for Ru^{3+} complexes,[15] which when taken in eq. (3) results in a value of $\delta = 4428$ cm^{-1}.

These results are similar to those found in a number of Ru^{3+} complexes studied in ESR experiments.[16-18]

After 50 h of ageing only a small concentration of paramagnetic species could be detected. This remaining paramagnetic species exhibited $g_\perp = 2.44$, a value very close to that of 2.429 reported for the *trans*-$[Ru(NH_3)_4\{P(OEt)_3\}(H_2O)]^{3+}$ ions.

As reported[7] for the *trans*-$[Ru(NH_3)_4\{P(OEt)_3\}(H_2O)]^{3+}$ ion, the stability of the *trans*-$[Ru(NH_3)_4\{P(OEt)_3\}_2]^{3+}$ species also depends on the hydrogen ion concentration of the solution. Table 1 summarizes the kinetic data for the *trans*-$[Ru(NH_3)_4\{P(OEt)_3\}_2]^{3+}$ ion decay in acidic media.

Table 1. Kinetic data for the *trans*-$[Ru(NH_3)_4\{P(OEt)_3\}_2]^{3+}$ ion decay

C_{H^+} (M)	k_{obs} (s^{-1})
0.0	2.3×10^{-5}
1.0	6.9×10^{-5}
2.0	1.1×10^{-4}
3.0	1.5×10^{-4}

Each value is the mean of at least three independent determinations with better than 90% agreement. $\mu = 0.1$ ($NaCF_3COO$), $C_{Ru} = 1.0\times10^{-3}$ M (25.0±0.2°C).

For the decay of *trans*-$[Ru(NH_3)_4\{P(OEt)_3\}(H_2O)]^{3+}$ experimental evidence supports[7] the disproportionation of the ruthenium(III) species, yielding ruthenium(II) and the mixture of ruthenium(IV) and ruthenium(VI) with a predominance of the latter. However, for the *trans*-$[Ru(NH_3)_4\{P(OEt)_3\}_2]^{3+}$ complex ions, as far as our experiments in acidic media are concerned, it is unlikely that a disproportionation reaction takes place.

Based on the experimental data and accumulated experience[1-7] in the chemistry of phosphorus as the ligand in ruthenium(II) and ruthenium(III) complexes, the tentative scheme below was suggested to explain the conversion of the *trans*-$[Ru(NH_3)_4\{P(OEt)_3\}_2]^{3+}$ ions into the *trans*-$[Ru(NH_3)_4\{P(OEt)_3\}_2]^{3+/2+}$ mixture.

$$\textit{trans}\text{-}[Ru(NH_3)_4\{P(OEt)_3\}_2]^{3+} \xrightarrow{\text{slow}} \textit{trans}\text{-}[Ru(NH_3)_4\{P(OEt)_3 \ldots P(OEt)_3\}]^{3+}$$

$$\textit{trans}\text{-}[Ru(NH_3)_4\{P(OEt)_3\}_2]^{3+} + \textit{trans}\text{-}[Ru(NH_3)_4\{P(OEt)_3 \ldots P(OEt)_3\}]^{3+} + H_2O \longrightarrow$$
$$\textit{trans}\text{-}[Ru(NH_3)_4\{P(OEt)_3\}(H_2O)]^{2+} + \textit{trans}\text{-}[Ru(NH_3)_4\{P(PEt)_3\}_2]^{2+} + (O)P(OEt)_3 + 2H^+$$

$$\textit{trans}\text{-}[Ru(NH_3)_4\{P(OEt)_3\}_2]^{2+} + H_2O \longrightarrow \textit{trans}\text{-}[Ru(NH_3)_4\{P(OEt)_3\}(H_2O)]^{2+} + P(OEt)_3$$

$$2\,\textit{trans}\text{-}[Ru(NH_3)_4\{P(OEt)_3\}(H_2O)]^{3+} + P(OEt)_3 + H_2O \longrightarrow$$
$$2\,\textit{trans}\text{-}[Ru(NH_3)_4\{P(OEt)_3\}(H_2O)]^{2+} + (O)P(OEt)_2 + 2H^+$$

$$\textit{trans}\text{-}[Ru(NH_3)_4\{P(OEt)_3\}_2]^{3+} + \textit{trans}\text{-}[Ru(NH_3)_4\{P(OEt)_3\}(H_2O)]^{2+} \longrightarrow$$
$$\textit{trans}\text{-}[Ru(NH_3)_4\{P(OEt)_3\}_2]^{2+} + \textit{trans}\text{-}[Ru(NH_3)_4\{P(OEt)_3\}(H_2O)]^{3+}$$

It is well known that the $P(OEt)_3$ molecule in acidic solution hydrolyses fast yielding $P(O)(H)(OEt)_2$, which is quite resistant to oxidation under these experimental conditions. On the other hand, it has been shown[1,3,7] that the coordinated phosphite molecule does not hydrolyse nor undergo oxidation as long as it is coordinated to a ruthenium(II) or ruthenium(III) centre.

Therefore, the $P(OEt)_3$ ligand needs to be activated to become reactive. This activation could be achieved when the phosphite molecule is in a semi-coordination position. In such a situation the $P(OEt)_3$ ligand would be positioned far from the ruthenium(III) centre at a distance between that of the coordinated phosphite and that of the free $P(OEt)_3$ molecule. Under these conditions the Ru^{III}—P^{III} bond is weakened and the ester becomes susceptible to oxidation by the collision of these excited ruthenium(III) complexes with other ruthenium(III) species.

Work is in progress in this laboratory aiming at improving the understanding of the mechanism of *trans*-$[Ru(NH_3)_4\{P(OEt)_3\}_2]^{3+}$ and *trans*-$[Ru(NH_3)_4\{P(OEt)_3\}(H_2O)]^{2+}$ decays. Results on this subject will be reported soon.

1. INTRODUCTION

This review gives an up-to-date account of the ligand polyhedral model (LPM) and its application to the binary carbonyls. The model not only offers a satisfactory explanation of the wide variety of structures observed for the binary carbonyls, but also offers an alternative view of their fluxionality and chemical reactivity.

Following the initial discovery of binary carbonyls[1] much effort, inspired by the pioneering work of Hieber,[2] was put into establishing and rationalizing their structures. For simple monometal systems, such as $Cr(CO)_6$, $Fe(CO)_5$ and $Ni(CO)_4$, this proved to be a relatively straightforward matter. Following the ideas of Sidgewick[3] on the effective atomic number (or 18-electron rule) led to a simple understanding of the metal : CO ratios and furthermore, the valence bond approach provided a clear understanding of the geometries of octahedral $Cr(CO)_6$ (d^2sp^3), trigonal bipyramidal $Fe(CO)_5$ (dsp^3) and tetrahedral $Ni(CO)_4$ (sp^3) (Fig. 1). Although the basic tenets of Gillespie and

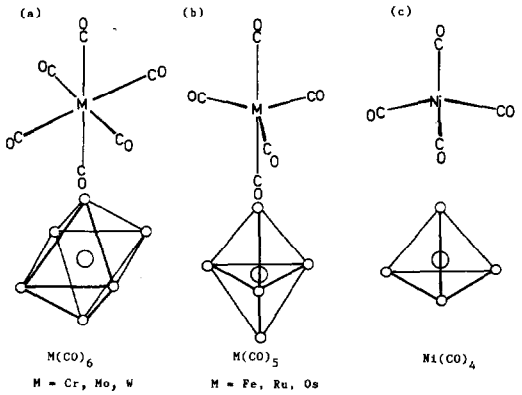

Fig. 1. The molecular structures of the simple mononuclear binary carbonyls.

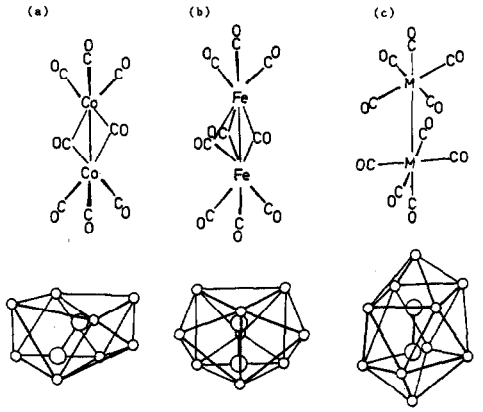

Fig. 2. The molecular structures of the binuclear carbonyls: (a) $Co_2(CO)_8$, (b) $Fe_2(CO)_9$ and (c) $M_2(CO)_{10}$ (M = Mn, Tc or Re).

Nyholm[4] are not strictly applicable to transition metal complexes, because of problems in deciding upon the location or effect of lone pairs in such systems, the observed geometrical forms fitted nicely with the overall picture of coordination geometry at that time.

Nor did the elucidation of the structures of $Co_2(CO)_8$,[5] $Fe_2(CO)_9$[6] and $Mn_2(CO)_{10}$[7] by X-ray diffraction present any major problems and, indeed, $Co_2(CO)_8$ [Fig. 2(a)] provided an early but classic illustration of the enormous value of X-ray diffraction methods in structural chemistry. Here was a structure which was special in that the molecule appeared bent or "book-shaped"; a description which persists to this day. It presented an early example of both μ_2-bridging CO ligands (i.e. one CO ligand bridging two metal atoms) and a "bent" or "banana-shaped" metal–metal bond. Equally intriguing was di-iron nonacarbonyl, $Fe_2(CO)_9$ [Fig. 2(b)], providing the first and only example of a dinuclear compound spanned by three CO bridges. This led to much speculation about whether or not an Fe—Fe bond was present in the molecule. As far as electron counting goes we assume there is, and this is supported by the observed diamagnetism and the Fe—Fe distance (2.56 Å) in the crystal state.

Dimanganese dodecacarbonyl was synthesized much later, but again its structure elucidation posed no major experimental problem and in another classic paper Dahl and Rundle described the structure shown in Fig. 2(c). The structure of $Mn_2(CO)_{12}$ was considered to be unusual in that the Mn—Mn bond was found to be considerably longer than anticipated (3.02 Å). No CO bridges were located and the 10 carbonyl ligands were shown to adopt a bicapped square-bipyramidal arrangement. Other binary carbonyls such as $Fe_3(CO)_{12}$[8] and $Co_4(CO)_{12}$[9] provided far more serious experimental difficulties but, after considerable effort, their molecular structures were also established. Tri-iron dodecacarbonyl, $Fe_3(CO)_{12}$, was considered extremely unusual in that it adopted

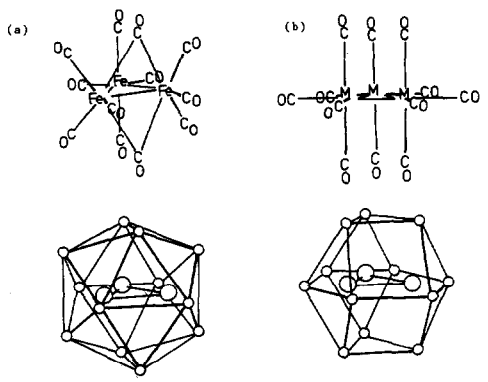

Fig. 3. The molecular structures of the trinuclear carbonyls: (a) $Fe_2(CO)_{12}$ and (b) $M_3(CO)_{12}$ (M = Ru or Os).

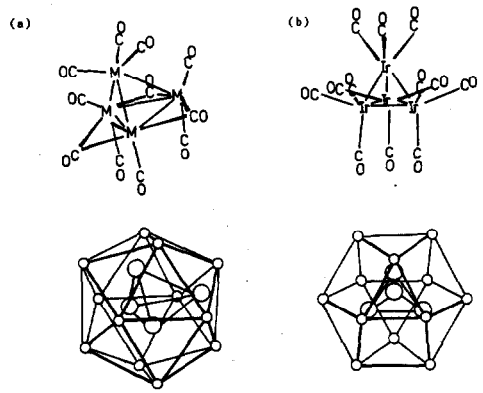

Fig. 4. The molecular structures of the tetranuclear carbonyls: (a) $M_4(CO)_{12}$ (M = Co or Rh) and (b) $Ir_4(CO)_{12}$.

what appeared to be a highly asymmetric structure, which resembled $Fe_2(CO)_9$ with one carbonyl bridge replaced by an $Fe(CO)_4$ unit [Fig. 3(a)]. In the paper reporting the correct structure of $Fe_3(CO)_{12}$, which had followed a series of erroneous predictions, Dahl commented on the apparent icosahedral arrangement of the 12 carbonyl ligands. The structural history of $Co_4(CO)_{12}$ closely paralleled that of $Fe_3(CO)_{12}$. Despite the employment of a wide range of physicochemical techniques, the correct structure was finally established much later and again by single-crystal X-ray diffraction analysis. The structure of $Co_4(CO)_{12}$ is remarkable in that, contrary to expectation, it is asymmetric with one unique cobalt atom [Fig. 4(a)]. The completion of the X-ray diffraction analysis of both $Fe_3(CO)_{12}$ and $Co_4(CO)_{12}$ was, and remains, a triumph for Dahl and his co-workers. The two structures show certain similarities. Both are more asymmetric than expected and both contain CO bridges supporting some (but not all) metal–metal vectors. In each case the 12 CO ligands adopt the same highly symmetric icosahedral form and this accounts for some of the problems encountered in the X-ray diffraction analysis.

The close relatives of $Fe_3(CO)_{12}$, viz. $Ru_3(CO)_{12}$ and $Os_3(CO)_{12}$, are quite different from $Fe_3(CO)_{12}$ itself. Both have virtually identical structures [Fig. 3(b)]. Triruthenium dodecacarbonyl shows a slight but significant distortion of carbonyl ligands, which may be taken as indicating a shift from an icosahedral towards an anticubeoctahedral arrangement,[10] whereas $Os_3(CO)_{12}$ adopts a more regular D_{3h} symmetry.[11] There are no bridges in either case and whereas there is considerable evidence to support a second, non-carbonyl bridged isomer of $Fe_3(CO)_{12}$,[12] no evidence for a bridged form of either $Ru_3(CO)_{12}$ or $Os_3(CO)_{12}$ exists.

In the cobalt series $Rh_4(CO)_{12}$ is very similar to the cobalt compound, although the X-ray data is not totally reliable because of the difficulties in growing a crystal suitable for analysis,[9,13] but $Ir_4(CO)_{12}$[14] has a tetrahedral M_4 core, with 12 terminally bonded CO ligands [Fig. 4(b)] forming a cubeoctahedron. With all these molecules the 18-electron rule may be applied satisfactorily, but beyond four metals the rule fails to reliably rationalize the observed cluster geometries and alternative methods of electron-counting must be applied.

Thus, the carbonyls have provided a remarkably interesting area for study. Many have highly useful catalytic activity[15] and all have proved to be invaluable precursors in organometallic chemistry.[15–17] Their physicochemical properties have proved an exceptionally fertile area of study and the fundamental questions raised by their unpredictable structures have provoked much theoretical debate.[17] Many are photosensitive[18] and the mechanism by which they undergo chemical reactions continues to provide a substantial challenge to chemists.

Several years ago[19] we developed ideas which we believe have been successful in permitting a better understanding of the structures and chemical behaviour of these apparently complicated compounds. These ideas also go a long way towards rationalizing the variety of isomeric forms and fluxional behaviour they frequently exhibit and help to explain the substitution chemistry they undergo. These ideas and, more especially, the development of the ligand polyhedral model (LPM) over the last 5 years[20] form the basis of this article.

2. THE LIGAND POLYHEDRAL MODEL

As we mentioned in the introduction workers in the area of cluster chemistry have often commented on the structural form or ligand geometry that the binary carbonyls adopt. For coordination compounds Gillespie, Nyholm and others regard the minimum energy ligand polyhedra as being the tetrahedron ($n = 4$), trigonal bipyramid ($n = 5$), octahedron ($n = 6$), pentagonal bipyramid ($n = 7$), square antiprism (or possibly dodecahedron) ($n = 8$), tricapped trigonal prism ($n = 9$), bicapped square antiprism ($n = 10$) and for 12-coordination the icosahedron (Fig. 5). In the main, but with notable exceptions for $n = 7$ or 8, these correspond to the polyhedra found for $Ni(CO)_4$, $Fe(CO)_5$, $Co(CO)_6$, $Fe_2(CO)_9$, $Mn_2(CO)_{10}$, $Fe_3(CO)_{12}$ and $Co_4(CO)_{12}$. These observations led us to consider the possibility that, just as in mononuclear coordination complexes, the geometry of the ligand shell in metal carbonyl clusters is determined not by the major bonding forces, but rather by the interaction between the ligands themselves. We argued that, at least for moderately spherical metal cluster units, such as the triangle or tetrahedron, the same principles employed for mononuclear systems might be extended to include the carbonyl clusters. This model, when applied to mononuclear systems, is frequently referred to as a ligand repulsion model,[21] a term we do not fully accept but which does give a reliable guide to ligand geometries. If our proposals are valid then we might expect the same regular or semi-regular geometries to be found in cluster systems. We further postulated that the number and type of CO ligands (i.e. terminal or bridging) present would then depend upon the possible arrangements of one polyhedron or polygon (the metal cluster unit) within the other (the CO envelope). Thus, for the 12 CO ligands of $Fe_3(CO)_{12}$ we predicted that optimum geometry to be an icosahedron and that the formation of two CO bridges along one Fe—Fe vector would be a direct result of packing an Fe_3 triangle within that CO icosahedron. This corresponds exactly with the observed structure. The icosahedron is also observed for $Co_4(CO)_{12}$ and $Rh_4(CO)_{12}$ and the three O bridges spanning the basal M—M vectors are again a consequence of inserting the M_4 tetrahedron into that icosahedron. Thus, our argument is based purely on geometric arrangements and there is no need to consider directed valence bonds.

The same logic clearly applies to $Fe_2(CO)_9$ and $Mn_2(CO)_{10}$. In each case the optimum CO geometry, viz. the tricapped trigonal prism and the bicapped square antiprism, respectively, are found. The insertion of the linear M—M unit into the tricapped trigonal bipyramid naturally leads to a structure with three CO bridges, where insertion into a bicapped square antiprism leads to a form in which no bridges are generated. Thus, for many of the simpler binary carbonyls, their structures are readily understood on a straightforward geometric basis.

Problems arise, however, when we consider $Co_2(CO)_8$, $Ru_3(CO)_{12}$, $Os_3(CO)_{12}$ or $Ir_4(CO)_{12}$. Here the *optimum* CO geometry is not found. Again, the problem may be resolved within the terms of the ligand polyhedral model. If we assume that the CO ligand is *quasi*-spherical with a centre

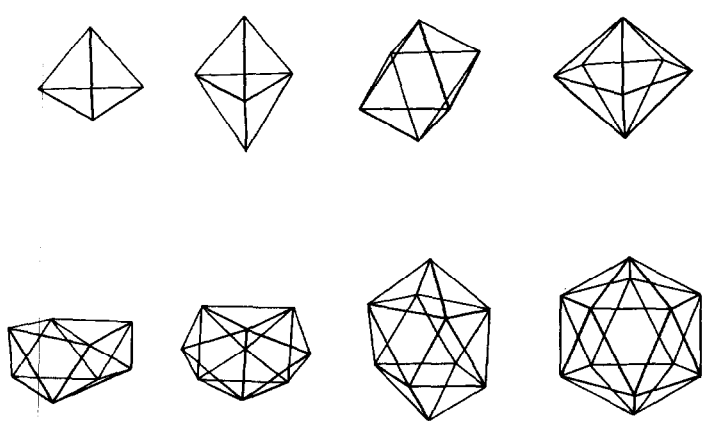

Fig. 5. The "low energy" polyhedral forms found in coordination compounds ML_n (for $n = 4$–10 and 12).

localized on the oxygen atom, then a radius of 3.0 Å may be estimated (or derived empirically)[19] and stems from the synergic nature of the M—C—O bond. As the M—C bond strengthens (or shortens) the C—O bond weakens (or lengthens), hence the M···O distance remains more-or-less constant. This is fortunate since it allows the estimated radius of the CO to be transferred from one binary carbonyl to another, almost irrespective of the metal concerned. However, it must be remembered that this is an estimated value (although it may be derived empirically from a study of the multitude of structures now available) and puts a severe limitation on the model. Taking this value of *ca* 3.0 Å we can, using the sample radius ratio ideas applied to infinite solid-state structures (especially ionic solids), compute the size of the interstitial holes within the polyhedra described by the CO ligands. Thus, for eight CO ligands we can easily establish that a dodecahedron has a hole of radius 2.4 Å. This is too small for a Co_2 unit with a predicted bond length of 2.5 Å and a square antiprism would lead to a Co—Co distance of *ca* 3.0 Å [cf. $Mn_2(CO)_{10}$], which is too long. However, for the intermediate polyhedron, the tricapped trigonal prism, a Co—Co bond length of 2.50 Å is generated, in line with the predicted requirements. Hence, for $Co_2(CO)_8$ the second most favourable geometry, viz. the bicapped trigonal bipyramid, is observed. It is now easier to appreciate the unusual bent-shape of the molecule. The "hole" in the structure corresponds to the missing vertex of a tricapped trigonal prism [i.e. $Co_2(CO)_8$ has an *arachno* nine-vertex structure]. Nevertheless, we must expect that closely related structures based on a dodecahedron or square antiprismatic arrangement of CO groups will lie in additional potential energy wells. Thus, we might anticipate that under the right conditions (e.g. on interaction with solvent) these alternative forms might also exist and it is noteworthy that several isomeric forms of $Co_2(CO)_8$ have been reported. We would argue that these isomers correspond (in part) to the different geometries available for eight carbonyl ligands.

The same explanation may be used to account for the change in structure observed in going from $Fe_3(CO)_{12}$ to $Ru_3(CO)_{12}$ or $Os_3(CO)_{12}$. For a CO icosahedron with a radius ratio of 0.95 Å it can be shown that an Fe_3 triangle with Fe—Fe bond lengths similar to those found in the bulk metal (2.5 Å) can be accommodated, whereas the larger Ru_3 or Os_3 unit (Ru—Ru 2.75, Os—Os 2.75 Å) cannot. These larger triangles will, however, fit into an anticubeoctahedron with a radius ratio of 1.00 Å and consequently a larger interstitial site. Placement of an M_3 triangle within an anticubeoctahedron leads to the observed all-terminal structure. Precisely the same arguments may be applied to the change in structure (or polyhedral form) on going from $Co_4(CO)_{12}$ (icosahedron) to $Ir_4(CO)_{12}$ (cubeoctahedron).

Thus, the model works well in attempts to rationalize the structures of the simpler binary carbonyls. It may be easily extended to embrace more complicated systems such as $Rh_6(CO)_{16}$ (an Rh_6 octahedron within the best 16-vertex polyhedron; the tetracapped truncated tetrahedron)[22] or $Co_6(CO)_{14}^{4-}$ (a Co_6 octahedron within the optimum 14-vertex polyhedron; the *omni*-capped cube).[23] These structures are illustrated in Fig. 6.

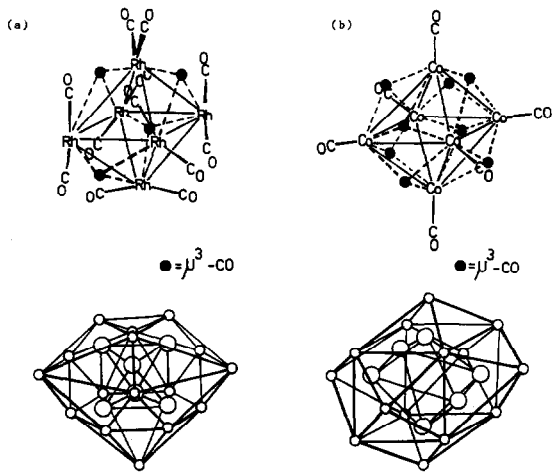

Fig. 6. The molecular structures of: (a) $Rh_6(CO)_{16}$ and (b) $Co_6(CO)_{14}^{4-}$.

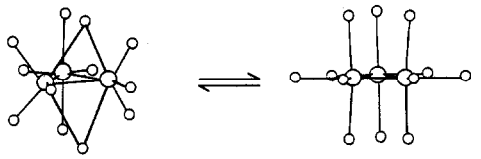

Fig. 7. A postulated rearrangement for the interconversion of the bridged form (C_{2v}) and the non-bridged (D_{3h}) form of $Fe_3(CO)_{12}$.

3. ISOMERS

A common feature of many of these compounds is the apparent ease with which they undergo structural change with a change in the environment. The classic example in this regard must be $Fe_3(CO)_{12}$, which in solvents changes structure from the bis-μ_2 form (C_{2v}) to a non-bridged form (D_3).[24] At one time it was assumed, for obvious reasons, that this non-bridged form corresponded to an $Ru_3(CO)_{12}$ structural type.[25] It has been argued that the two CO bridges simply opened out to give the non-bridged $Ru_3(CO)_{12}$ form (see Fig. 7). However, detailed examination of the observed IR spectrum of the new species [in the ν(CO) stretching region] revealed that the spectrum is not compatible with a *pseudo*-$Ru_3(CO)_{12}$ arrangement.[19]

In 1976 we offered an alternative view. Given that the 12 CO ligands adopted an icosahedral arrangement, we recognized that within this polyhedron three orientations of the Fe_3 triangle were possible and that they were related by a simple librational motion. These orientations correspond to the solid state (C_{2v}) μ_2-bridged form [Fig. 8(a)], a new all-terminal form (D_3) [Fig. 8(b)] and a C_2 μ_3-bridged form [Fig. 8(c)]. The ease by which interconversion might occur, combined with the observation that the IR spectrum of a D_3-form corresponded closely to that recorded, led us to suggest that the existence of a second isomeric form based on the same icosahedron of carbonyl ligands was preferable to the D_{3h} anticubeoctahedral form.[19] Nevertheless, we would emphasize that the possibility of conversion to an anticubeoctahedral or cubeoctahedral ligand envelope, both of which are expected to occupy potential energy wells, cannot be entirely discounted.

Similar arguments have also been applied to explain the several isomers of $Co_2(CO)_8$ which apparently exist.[26] In our discussion of this molecule above, we pointed out that several closely related carbonyl polyhedra could exist and that interconversion between these forms would be a relatively facile process. This process is illustrated in Fig. 9, where it can be seen that the sequential cleavage of single polyhedral edges would lead progressively from the dodecahedron [Fig. 9(a)], through the bicapped trigonal prism observed in the solid [Fig. 9(b)] to the square antiprism, which is clearly based on the non-bridged arrangement of carbonyls found for $Mn_2(CO)_{10}$ [Fig. 9(c)].

In addition, and just as with $Fe_3(CO)_{12}$, we might anticipate that the Co—Co dimer will undergo libration within the various carbonyl polyhedra. This librational motion, which will be synchronized with a Co—Co bond stretch, will not be independent of the polyhedral interconversion. Indeed, the

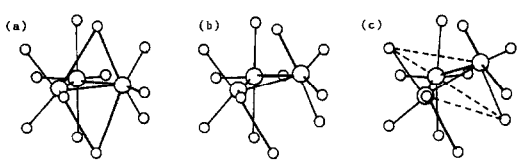

Fig. 8. The three isomeric forms of $Fe_3(CO)_{12}$, based on the icosahedral distribution of carbonyl ligands: (a) C_{2v}, (b) D_3 and (c) $C_{2v}(2)$.

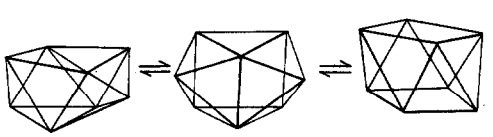

Fig. 9. The carbonyl polyhedra expected for $Co_2(O)_8$.

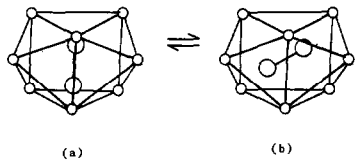

Fig. 10. The interconversion of two possible isomeric forms of $Co_2(CO)_8$ by libration of the Co—Co vector through a two-fold axis within the bicapped trigonal prism and carbonyl ligands.

two processes will occur simultaneously, although the contribution of each to the rearrangement will be dependent on phase and temperature. It is apparent that the same librational motion can occur within the dodecahedron or square antiprism, as in Fig. 10, leading to a variety of bridged and non-bridged isomeric forms of $Co_2(CO)_8$, or indeed any $M_2(CO)_8$ species.

Related to these observations are the isomeric forms observed for $Ir_6(CO)_{16}$.[22] We have commented on the molecular structure of $Rh_6(CO)_{16}$ above. One form of $Ir_6(CO)_{16}$ is isostructural with the Rh_6 analogue, with two terminal CO groups per metal atom and four face-bridging CO groups occupying the corners of a tetrahedron (corresponding to the four caps of the tetracapped truncated tetrahedron). The second isomeric form has a very similar structure, except that the four bridges now span four metal–metal edges of the Ir_6 octahedron but still occupy the four corners of a tetrahedron within the same tetracapped truncated tetrahedron. In other words, the CO polyhedron is the same in each case. The two isomers are related by the simple rotation of the metal octahedron about an octahedral (Ir_6) C_4 axis. This rotation simply changes μ_3-bridges into μ_2-bridges and back again. These observations emphasize the importance of similar motions to those employed to account for the formation of different isomers of $Fe_3(CO)_{12}$, except in that case they cannot be characterized independently in the solid.

Similar arguments can be applied to $Co_4(CO)_{12}$. Again, there is more than one orientation of the metal tetrahedron within the icosahedron. The two most obvious possibilities are shown in Fig. 11 and are related by rotation about the C_3 axis through the unique cobalt atom in this Co_4 tetrahedron. Other possibilities exist. These are derived either by rotation about the other available *pseudo*-C_3 axis (of the Co_4 tetrahedron) through a basal cobalt atom or by rotation through a *pseudo*-C_2 axis of the Co_4 tetrahedron. Circumstantial evidence derived from an examination of the a.d.p.s[19] would favour rotation about the primary C_2 axis, according to Fig. 11.

Further possibilities exist. Given that $Ir_4(CO)_{12}$ adopts a cubeoctahedral distribution of carbonyl groups, $Co_4(CO)_{12}$ could do the same. However, another possibility is that the CO groups could rearrange into another closely related polyhedron, viz. the anticubeoctahedron, as observed with $Ru_3(CO)_{12}$ (see Fig. 12). All are related by a comparatively small motion, either of the Co_4 tetrahedron by libration or the polyhedral rearrangement of the carbonyl envelope.

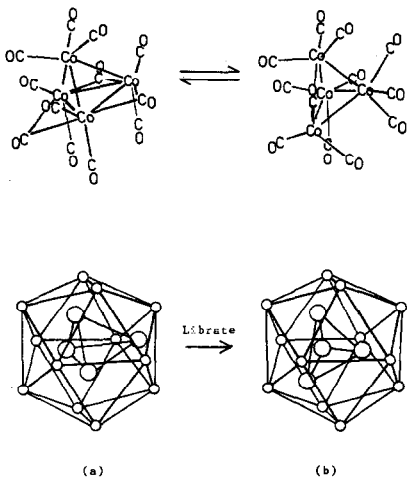

Fig. 11. Interconversion of C_{3v} and T forms of $Co_4(CO)_{12}$ by libration about the unique C_3 axis of the Co_4 tetrahedron in the $(CO)_{12}$ icosahedron.

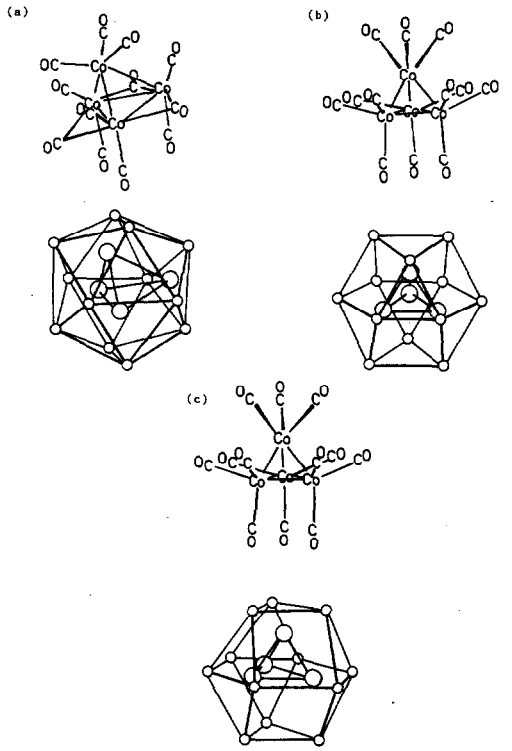

Fig. 12. The three possible polyhedral forms for $M_4(CO)_{12}$ (M = Co, Rh or Ir): (a) icosahedron, (b) cubeoctahedron and (c) anticubeoctahedron.

There has been some confusion as to the true nature of these librational motions. First, it is difficult to obtain direct evidence for such movement, but examination of the a.d.p.s in both $Fe_3(CO)_{12}$[19] and $Co_4(CO)_{12}$ provides some support for the proposals offered. However, it must be appreciated that such evidence must, at best, be tentative given the unreliability of the structural data currently available. Secondly, there has been some confusion with regard to the motion itself. Clearly, in solution it does not matter whether the motion is regarded as that of the metal unit with a stationary carbonyl polyhedron or *vice versa*. In the solid the movement of the metal unit must dominate. Obviously, movement of the carbonyls within a crystalline lattice will be severely restricted unless there are special circumstances as with $Co_2(CO)_8$. Major movement will lead first to phase transition and ultimately to the complete degradation of the lattice. It is important to appreciate that the relative masses of the cluster units and CO polyhedra in question are not that different, e.g. Fe_3 168, Co_4 236, $(CO)_{12}$ 336. As the relative mass increases (as, for example, with Os_3 588), then librational motion of the metal unit will be restricted accordingly and here it is more reasonable to consider that the motion corresponds to that of the CO polyhedron about the metal unit. This will be discussed in more detail in the section below devoted to fluxional behaviour.

The main advantages of the approach offered here are clear to see. First, the frequent observation of isomeric forms of many of the binary carbonyls is easily understood. The model allows us to appreciate more fully how these different forms or isomers might arise. In this sense it is no different from mononuclear coordination chemistry where such phenomena are frequently encountered as, for example, with five-coordinate species which exhibit both trigonal bipyramidal and square-based pyramidal forms and seven-coordinate complexes with bicapped pentagonal and monocapped octahedral geometries. The ideas put forward here are a natural extension of the geometric isomers observed in monometal coordination systems.

4. FLUXIONAL BEHAVIOUR

The carbonyls have a unique place in studies of fluxional behaviour.[25,27] The observation that they are able to undergo structural rearrangement on the NMR timescale, combined with their

relative ease of study, has made them ideal examples of this fundamentally important and interesting phenomenon. Fluxional behaviour simply tells us that the molecule has a number of closely related structures accessible by relatively low energy barriers. In that sense it is immediately clear why the LPM may be so easily applied. Fluxional behaviour also tells us that the precise direction of the chemical bonds coming out of the central cluster unit is not important (just as with mononuclear systems). In mononuclear systems it is usual to describe intermolecular rearrangements in terms of polyhedral interconversions. The classic example must be the Berry *pseudo*-rotation mechanism[28] for the fluxional behaviour exhibited by five-coordinate ML_5 systems, in which the scrambling of the five ligands (two axial, three equatorial) is envisaged as occurring through a square-pyramidal *complementary geometry*. This view is widely taught at the undergraduate level. This approach is easily extendable to higher polyhedra and we have suggested that a simple methodology involving successive edge cleavage may be applied in order to understand the motion of ML_n ligand polyhedra for values of n from 4 to 12. It may also be extended to embrace clusters. Provided that the central cluster unit is spherical (or nearly so), there is little difference between mononuclear systems of the type ML_n and polynuclear systems of the type M_mL_n. For carbonyl clusters with two to four metal atoms the problem is slightly more complicated because of the larger values of n involved and less is known of the rearrangement patterns of these larger polyhedra ($n > 12$). Nevertheless, in principle, the same rules apply and the only difficulty lies in establishing or deciding upon the correct complementary geometry. This is an alternative way of looking at carbonyl fluxionality and differs from that developed historically[29] (and still widely applied) which considers only localized carbonyl migrations. We believe this localized view cannot be correct and believe that the motion of carbonyl ligands about a central metal unit must be concerted.

Unlike the mononuclear systems, however, there is a further contribution to fluxionality which is extremely important and certainly of great significance to motion in the solid state. This is the idea that the cluster metal core may librate without the motion of the carbonyl polyhedron and *vice versa*. In this case the carbonyl polyhedron retains its integrity throughout and individual CO ligands do not undergo interchange within the total polyhedron. Thus, for an icosahedral arrangement, the antipodal relationships are constant, no matter how the relationship they have with the internal metal unit may change (terminal, edge-bridging-μ_2 or face-bridging-μ_3).

If we consider, for example, the fluxional behaviour of $Fe_3(CO)_{12}$. This is a particularly surprizing example in that even at the very lowest accessible temperatures the process cannot be stopped and the ground-state structure revealed by ^{13}CO NMR spectroscopy. The conventional explanation has been a bridge open $\rightleftarrows$ close motion of the sort outlined in Fig. 7. More recently, it has been suggested that this is incorrect and that the motion may be viewed as being totally concerted,[30,33] and as bridges open along one edge bridges close along another. In our view, as expressed in 1976, the low energy fluxional pathway exhibited by $Fe_3(CO)_{12}$ involves the simple libration of the Fe_3 triangle about its unique C_2 axis in the carbonyl icosahedron; or, as an alternative which we gave at the time, the motion of the "totally preserved" icosahedron about the central metal triangular unit (Fig. 13). This we believe to be exactly the same as the concerted motion discussed above.[30,33]

Very similar arguments may be applied to $Co_4(CO)_{12}$ or $Rh_4(CO)_{12}$. Again, migration of the "preserved icosahedron" about the central metal tetrahedron is exactly the same as saying that as one set of bridges open a new set are formed. There is no difference in outcome.

So much for the lowest energy process. For higher energy processes we must now invoke, in addition to metal libration, the idea of polyhderal interconversion of the type outlined above. However, it is important to reiterate at the outset that the two motions, libration and polyhedral interconversion, are not independent but are closely related. The contribution each makes to the

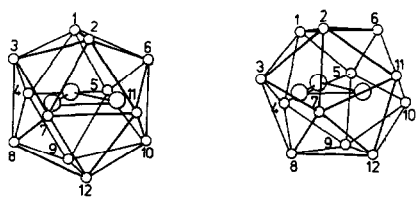

Fig. 13. Rotation of CO icosahedron about the internal Fe_3 triangle.

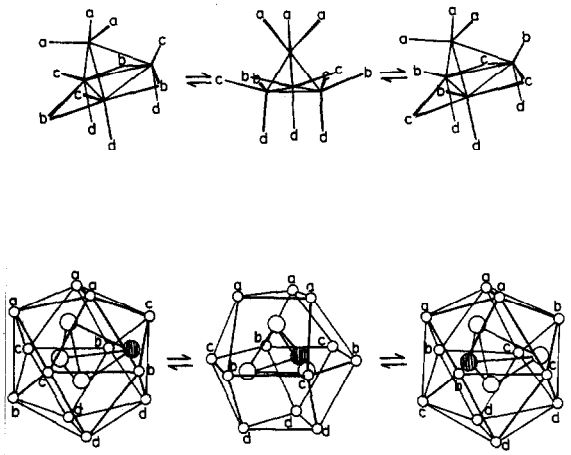

Fig. 14. (a) One of the five modes of polyhedral interconversion for $M_4(CO)_{12}$. The three original bridges (b) move to basal axial positions (c).

overall fluxional process will depend not only on the phase and temperature but also, as we indicated above, on the relative masses of the M_m and $(CO)_n$ units. Thus, libration may be more important in one instance and polyhedral interconversion in another. Irrespective of the circumstances, we would argue that the motions will be *symmetry controlled* and, as such, generally predictable.

If we apply these arguments to $Fe_3(CO)_{12}$ and its derivatives we would expect librational motion to dominate any fluxionality observed in the solid, while a combination of libration and polyhedral interconversion would take place in solution. Following the procedures laid down by Dunitz and Burgi[31] it has been possible to show, from an examination of a number of crystallographic structure determinations for a wide range of $M_3(CO)_{12-n}L_n$ systems (M = Fe, Ru, Os; L = ligand), that the most likely complementary geometry for the fluxional process is the anticubeoctahedron[32] and that libration or reorientation of the M_m and $(CO)_n$ polyhedra does occur.

Similarly, the same ideas may be applied to $M_4(CO)_{12}$ compounds and their derivatives. Again, the rotation of one polyhedron relative to the other is sufficient to bring about the observed low energy process and similar polyhedral conversion will apply to additional processes at higher temperatures. It is difficult to establish these processes by direct experimental means, but examination of the molecular structures of substituted derivatives of the type $M_4(CO)_{11}L$ and $RhCo_3(CO)_{12}$ has given support to the overall mechanism suggested. A special advantage of the LPM, and the fact that it is symmetry governed, is that the number of potential (although not necessarily observable) mechanistic pathways may be predicted. Put simply, for the icosahedron there are five degenerate pathways to the cubeoctahedron or the anticubeoctahedron. Substitution of a carbonyl group in the CO polyhedron by, for example, a tertiary phosphine ligand L will remove this degeneracy in a manner totally predictable from symmetry arguments. Similarly, exchange of one metal within the tetrahedron, for example forming $RhCo_3(CO)_{12}$, will also lift the degeneracy in a predictable way. By this means both the number and type of fluxional processes may be predicted.

A feature of the polyhedron interconversion process is that it does not exclude the conventional terminal $\rightleftarrows$ bridge mechanisms previously suggested, but argues that these correspond to one of the five degenerate modes. This is illustrated in Fig. 14 for $Co_4(CO)_{12}$. Other modes lead to movements which involve, apparently, highly unusual migration. Thus, for $M_4(CO)_{12}$ one mode leads to the prediction that a μ_2-CO bridge around the basal plane migrates to the apical metal atom across a tetrahedral face. This is in accord with recent suggestions based on detailed NMR structures of $Ir_4(CO)_{10}$(diars).[33]

5. CARBONYL SUBSTITUTION

The application of the LPM relies upon the use of a CO radius of *ca* 3.0 Å. Clearly, if a CO ligand is replaced by a ligand L, with a different cone angle, then the radius ratio will change and the size of the interstitial hole will vary accordingly. Thus, substitution of CO by large, bulky

phosphines will lead to larger interstitial holes for the ligand polyhedron. As a consequence, conversion of the polyhedron from a less favourable to a more favourable geometry may occur. This is best illustrated by the series of substituted derivatives of $Ir_4(CO)_{12}$, viz. $Ir_4(CO)_{12-n}L_n$ (n = 1–3).[34] As the larger ligand L is inserted into the molecule the ligand arrangement is modified from the less favourable cubeoctahedron towards the lower energy and thus more favourable icosahedron. This change will bring about the modification of the structure from the T_d ground state to the C_{3v} ground state and the formation of three basal bridging ligands, as is observed experimentally.

For those systems for which the minimum energy polyhedron, e.g. the icosahedron, is already present, as in $Fe_3(CO)_{12}$, the insertion of bulkier ligands will bring about a lengthening and hence weakening of the M—M bond. Thus, rather than simple structural modification, the tendency to undergo fragmentation will be enhanced.

Since the lowest energy polyhedron is more readily accessible to the smaller metal ions of the first transition metal series, which are known to have the lowest metal–metal bond energies, it follows that the first series are the most susceptible to fragmentation. Although, for all metal cluster compounds, the insertion of several bulky ligands will lead first to the lower energy polyhedron and then subsequently to fragmentation.

The substitution reactions of the cluster carbonyls of the iron and cobalt triads have been explored in some detail, but the mechanism(s) by which these reactions occur remains a matter of some debate.[35] The higher cluster carbonyls containing greater than four metal atoms have been investigated far less extensively. In general, two mechanisms have emerged for the fragmentation of small clusters. The original proposal considered that the reaction of, for example, $Ru_3(CO)_{12}$ with PBu^n_3 occurs via a radical pathway in which the triangular metal unit undergoes complete fragmentation into three radical species. These 17-electron radicals are then considered to undergo substitution, followed by recombination to produce the substituted trimer.

The alternative suggestion, that the important step is CO-dissociation generating the coordinatively unsaturated (46-electron) system $M_3(CO)_{11}$, is very attractive, especially when one recalls the similar behaviour shown by a range of the simpler carbonyl systems.[36] Certainly, it ties in well with much of the reported kinetic data. Nevertheless, it fails to explain much of the more detailed aspects of the substitution reactions described by several groups of independent workers (see ref. 35). If we consider this approach in detail we must also examine the geometrical implications of the carbonyl envelope or polyhedron. It is interesting to note in this connection that whereas the geometry of the complex is regarded as important in kinetic studies of mononuclear systems, as far as we are aware the implications of ligand geometry are completely ignored in considerations of cluster systems. As described above, in the parent molecule, $Fe_3(CO)_{12}$, the carbonyl ligands described an icosahedron, whereas in both $Ru_3(CO)_{12}$ and $Os_3(CO)_{12}$ the polyhedron is found to be the less favourable anticubeoctahedron. The dissociation of CO from $Fe_3(CO)_{12}$ would lead therefore to a *nido*-icosahedral array, which, contrary to current opinion, leads to a remarkably open array of CO groups with a very spacious pentagonal face open to incoming substrate (Fig. 15). In this case steric effects, i.e. the bulk of the entering nucleophile, would be minimized and less restrictive than an attack on, for example, a square pyramidal intermediate in the substitution of an octahedral complex. With the corresponding derivatives of ruthenium and osmium, CO dissociation would lead to an even more open polyhedron of CO ligands in the *nido*-anticubeoctahedron. On these grounds it is difficult to understand the observed change in the k_2 term and particularly difficult to appreciate the main difference in behaviour between the compounds of ruthenium and osmium, given the similarity of both their ligand polyhedral shells and the metal–metal bond distance, for the dissociative process.

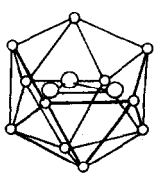

Fig. 15. The *nido*-icosahedral array of 11 ligands in the intermediate $M_3(CO)_{11}$ (M = Fe, Ru or Os).

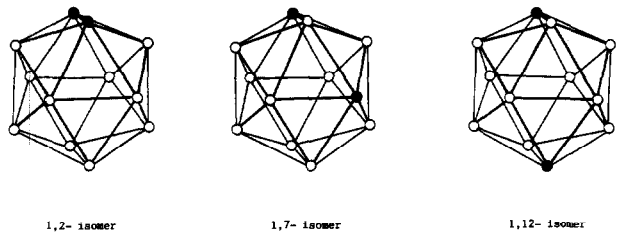

Fig. 16. Icosahedral 1,2-, 1,7- and 1,12-isomers.

Further substitution of CO by L in $M_3(CO)_{11}L$ to give first $M_3(CO)_{10}L_2$ and eventually $M_3(CO)_9L_3$ also requires a more detailed assessment. Firstly, we must again consider the geometry of the ligand envelope and take note of the fact that as substitution of CO by L occurs (for Ru and Os), there is a concomitant change in the geometry of the ligand shell from basically anticubeoctahedron towards quasi-icosahedral. The reasons for this fundamental change have been discussed in detail above, but the important point as far as we are concerned here is that in our consideration of the substitution reactions of $M_3(CO)_{12}$ and $M_3(CO)_{12-n}L_n$ we must remember that we are not strictly comparing substitution patterns of compounds with the same ligand geometry.

Consideration of the ligand polyhedral shell also reveals that for the bis-substituted derivatives, $Fe_3(CO)_{10}L_2$, we have three potential ligand distributions within the icosahedron, viz. the 1,2-, 1,7- and 1,12- forms (Fig. 16). Clearly the 1,2-disubstituted form requires the two ligands L to occupy adjacent positions and unless these ligands are smaller than CO, on steric grounds this will be unfavourable. The 1,7-form is more desirable since the two ligands will not be isolated from each other and, finally, in the 1,12-form we might argue that we have the most favourable arrangement, which minimizes any L—L interaction.

Finally, for the tris-substituted complex a 1,7,9-tri-substituted ligand icosahedron is expected if all ligands L are to occupy positions which minimize their interaction. If we accept the CO-

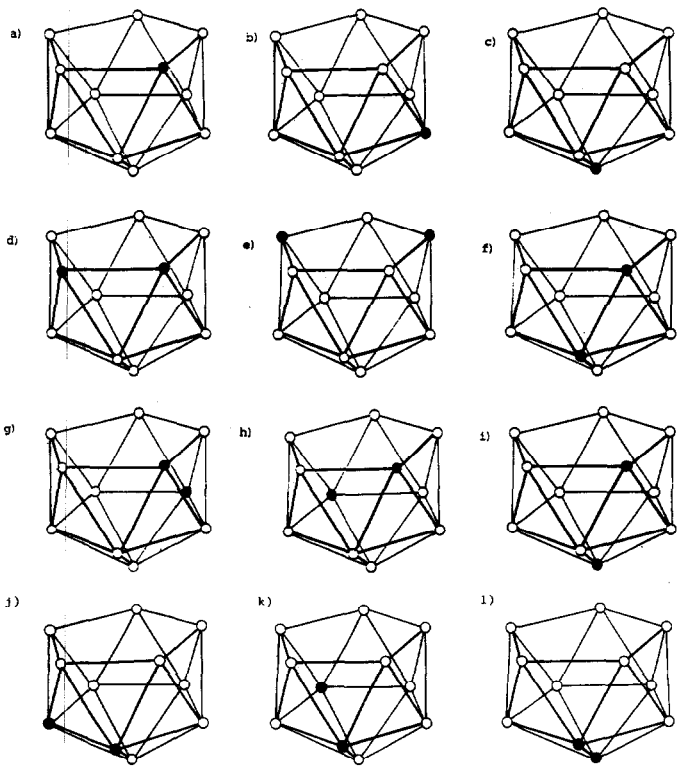

Fig. 17. The various isomeric forms of the *nido*-icosahedral ligand shell in $Fe(CO)_{10}L$ and $Fe_3(CO)_9L_2$.

dissociation mechanism we can imagine that dissociation of CO from $Fe_3(CO)_{11}L$ to produce the reactive intermediate $Fe_3(CO)_{10}L$ may occur in at least two distinct ways. First to produce a pentagonal ligand face containing L as in Fig. 17(a), or without L as in Figs 17(b) or (c). Further substitution to generate $M_3(CO)_9L_3$ would require L addition to the unsaturated intermediate $M_3(CO)_9L_2$, for which it is also possible to present vacant or occupied pentagonal faces [Figs 17(d)–(l)]. The presentation of L onto the open face (17k) would appear to present the least steric problems and would lead to the tris-substituted product, with significantly an equally disposed set of three L ligands (1,7,9).

Thus, we must conclude that although the CO dissociation mechanism is clearly attractive, little attention appears to have been paid to the more detailed geometric aspects of this route. It certainly fits the data far better than complete homolytic fission and is in line with current thought on simpler carbonyl systems. Neverthelesss, we have recently put forward another and, to us, more attractive explanation, which we have described elsewhere[37–39] and which we believe accounts more satisfactorily for the diverse set of observations made on these systems and outlined above. This approach differs from those described above in that the process of substitution is regarded as associative and requires the initial fragmentation of the metal–metal bond. Since our original suggestion,[37] similar ideas have been proposed[38] and a variety of structures having a cleaved metal–metal bond have been proposed to describe possible intermediates formed by ligand addition. Significantly, the cleavage and re-formation of metal–metal bonds by the addition and elimination of nucleophiles has been observed for some high nuclearity clusters and for other small clusters with bridging ligands.[40–46] Very recently, Adams and his co-workers have observed the formation of the two addition products $Os_3(CO)_{11}(\mu\text{-}CNCF_3)_2$ and $Os_3(CO)_{10}(NCMe)(\mu\text{-}CNCF_3)_2$ as the products of the reaction of $Os_3(CO)_{12-n}(NCMe)_n$ ($n = 1$ or 2) with $CNCF_3$. These may be regarded as stabilized derivatives of the unknown binary carbonyl $Os_3(CO)_{13}$ and a possible structural model for the intermediate addition product of the type described above. Thus, direct evidence for the cleavage of a metal–metal bond during the reaction sequence leading to a bis-substituted derivative has been found, providing direct experimental support for this new approach.[47]

6. CONCLUSIONS

In this account we have attempted to illustrate the usefulness of the ligand polyhedral model in the rationalization of cluster carbonyl structures. We hope we have also demonstrated its versatility in its application to the fluxional behaviour, isomeric formation and reaction mechanisms and kinetics of these fascinating systems. It is clear that there remains much more to do. More experimental evidence is required to support much of the work reported here and we are aware of some of the criticism levelled at this approach. Nevertheless, we are convinced that this method, which considers the molecular structure as a whole, offers a more understandable and more general view of these truly beautiful compounds.

Acknowledgements—We wish to thank our colleagues at Cambridge and elsewhere for their many helpful comments over the years. We would especially like to acknowledge our many helpful and vigorous discussions with Professor Lord Lewis (Cambridge), Professor Ken Wade (Durham) and our energetic co-workers Professor Dario Braga and Fabrizia Grepioni (Bologna).

(*Received* 11 *December* 1992; *accepted* 27 *January* 1993)

Abstract—The complexes $[Cu(PPh_3)_n(MeCN)_{4-n}]BF_4$ (n = 0, 2–3), $[Cu(F—BF_3)(PCy_3)_2]$, $[Cu(MeCN)_2\{1,2\text{-}C_6H_4CH_2NMe_2(PPh_2)\}]BF_4$ and species formed by *in situ* addition of various ligands to $[Cu(MeCN)_4]BF_4$ are all active catalysts for cyclopropanation reactions using N_2=CH(CO_2Et). With styrene as a substrate the *trans/cis* selectivity in the product cyclopropane may be somewhat controlled by the appropriate choice of phosphine ligand. Catalysis by $[Cu(MeCN)_2(PPh_3)_2]BF_4$ and $[Cu(MeCN)_2\{1,2\text{-}C_6H_4CH_2NMe_2(PPh_2)\}]BF_4$ is proposed to involve alkene coordination, while that by $[Cu(MeCN)(PPh_3)_3]BF_4$ and $[Cu(F—BF_3)(PCy_3)_2]$ is not. The structures of the catalysts showing the highest selectivity have been determined. For monoclinic $[Cu(F—BF_3)(PCy_3)_2]$ the molecule contains an unusually large P—Cu—P angle (*ca* 160°).

Cyclopropanes constitute important structural fragments in many pharmaceutical and insecticidal molecules of economic importance.[1] One attractive cyclopropanation route to these targets is the decomposition of a diazo compound in the presence of an alkene.[2,3] Although many transition metals, in one form or another, show activity for this reaction, traditionally copper species are recognized as pre-eminent catalysts. A wide variety of copper sources, including activated copper powders,[4] simple copper(I) or copper(II) salts[5] and complexes such as $[CuCl\{P(OR)_3\}]_4$ (R = alkyl),[6,7] are active pre-catalysts. Recent studies have concentrated on reactions employing chiral ligands in the presence of labile copper(I) sources to fashion highly enantioselective (> 95% enantiomeric excess, e.e.) cyclopropanation reactions.[8–10]

It is popularly assumed, generally without proof, that in all these reactions unstable copper(I) carbenoid intermediates form and that these are trapped by substrate alkene resulting in cyclopropanation (Scheme 1). Alternatively, two carbene complexes may undergo binuclear C—C coupling to yield a substituted alkene, a commonly observed reaction by-product in catalytic cyclopropanation reactions. One reason for assuming copper(I) intermediates is that many diazo compounds show appreciable reductive ability and reduction of copper(II) sources to the lower oxidation state is facile under these conditions. Relatively few mechanistic studies in copper(I) catalysed cyclopropanation have been reported.[5,11] Whether a single reaction coordinate and set of common intermediates is responsible is unclear. These vagaries piqued our interest in the mechanism of catalytic cyclopropanation and led us to begin an investigation into the possibility of designing a cyclo-

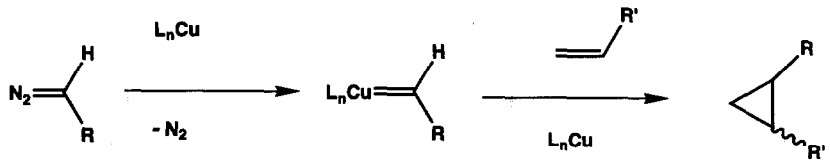


Scheme 1.

propanation reaction with well-defined catalytic intermediates, the preliminary results of which are the subject of this paper.

We selected the complex $[Cu(MeCN)_4]BF_4$ (**1**) as a versatile candidate with which to probe catalytic cyclopropanation for a number of reasons: complex **I** is easily prepared, fairly air-stable and the $[BF_4]^-$ anion can be systematically varied if necessary.[12] The cations $[Cu(MeCN)_4]^+$ are known to be active cyclopropanation catalysts.[10] The acetonitrile ligands in **1** are rather labile. For example, partial displacement with EPh_3 (E = P, Sb) forms the family of complexes $[Cu(MeCN)_{4-n}(EPh_3)_n]^+$ (n = 2–4).[13] Thus, steric and electronic modification of the copper(I) environment is possible. The presence of phosphine ligands also allows ^{31}P NMR reaction monitoring of such species on exposure to the catalytic reaction conditions.

RESULTS AND DISCUSSION

Preparation of the copper complexes

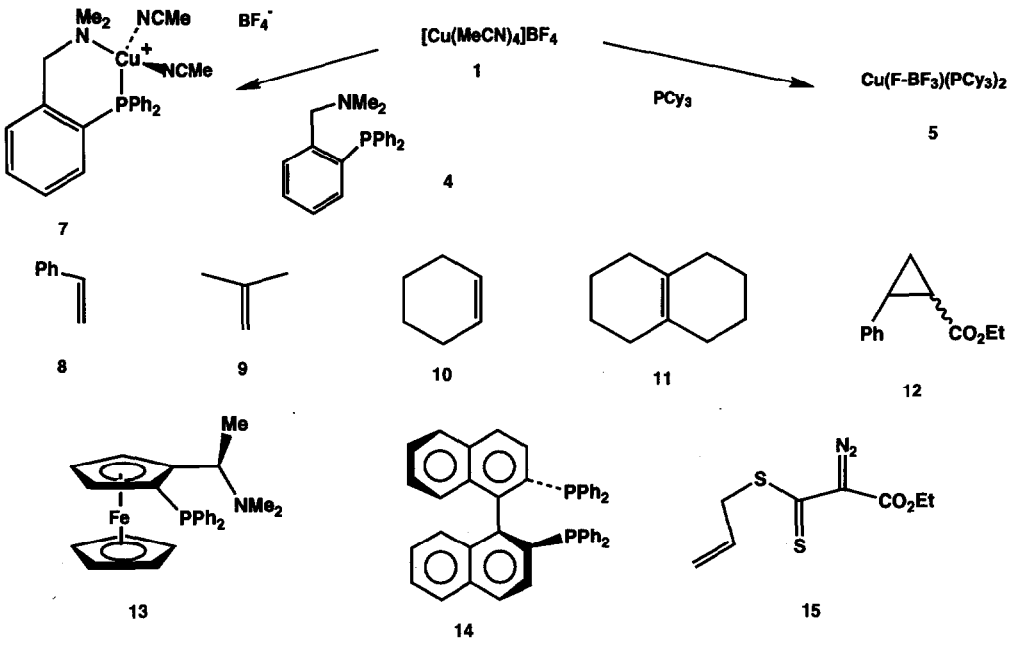
The preparation of $[Cu(MeCN)_4]BF_4$ (**1**), $[Cu(MeCN)_2(PPh_3)_2]BF_4$ (**2**) and $[Cu(MeCN)(PPh_3)_3]BF_4$ (**3**) follows the routine literature preparations used for the related ClO_4 and PF_6 salts.[12,13] Attempts to prepare $[Cu(MeCN)_3(PPh_3)]BF_4$ deserve special comment. Addition of 1 equivalent of PPh_3 to **1** results in mixtures containing variable Cu:PPh_3 ratios. Fractional crystallization of the mixture from CH_2Cl_2–Et_2O leads to well-formed needles with a PPh_3:MeCN ratio of 3:5, as judged by ^1H NMR spectroscopy. However, crystallographic investigation of these needles reveal them to be $[Cu(MeCN)_2(PPh_3)_2]BF_4$ (**2**).* The hexafluorophosphate salt $[Cu(MeCN)_3(PPh_3)]PF_6$ is suggested on the basis of ^{31}P NMR spectroscopic evidence, but these claims are not yet substantiated crystallographically.[14] The versatility of acetonitrile replacement in **1** is further demonstrated by its reactions with PCy_3 (Cy = cyclo-C_6H_{11}), the nitrogen–phosphorus chelate **4** and other ligands in Scheme 2.

Reaction of PCy_3 and **1** in a 2:1 ratio affords colourless crystals. The toluene solubility of this material is inconsistent with the properties of a salt, suggesting the formula $[Cu(F—BF_3)(PCy_3)_2]$ (**5**). Consistent with this idea the ν(B—F) stretch observed in the solid-state IR spectrum is sharper than that observed for $[Cu(MeCN)_2(PPh_3)_2]BF_4$ (**2**) and $[Cu(MeCN)(PPh_3)_3]BF_4$ (**3**) but different from that of $[Cu(F—BF_3)(PPh_3)_3]$ (**6**) prepared by pyrolysis of **3** under vacuum and subsequent recrystallization. The formation of **5** is confirmed by the absence of an MeCN signal in the ^1H NMR spectrum and by the results of an X-ray crystallographic study (see later).

The nature of tetrafluoroborate coordination in solutions of **5** is apparent from ^{19}F NMR studies. Two signals are seen for solutions of **5** in C_6D_6, acetone-d_6 or DMSO-d_6 in the range δ_F −145 to −150. The exact chemical shifts depend on the solvent, however, the integral ratio of the two signals shows the larger signal to be due to ^{10}B—F environments while the smaller signal represents ^{11}B—F. While the smaller signal remains a featureless envelope in all solvents the larger signal, in DMSO-d_6, shows the four-line multiplet [$J(^{10}BF)$ = 1.2 Hz] expected for an uncoordinated $[BF_4]^-$ anion. For comparison, the $J(^{10}BF)$ coupling for $NaBF_4$ (δ_F −152.10) in D_2O is 2.2 Hz. These results indicate that the salt $[Cu(PCy_3)_2]BF_4$ is exclusively present in DMSO-d_6. In less polar solvents an equilibrium between **5** and $[Cu(PCy_3)_2]BF_4$ probably exists. A related anion exchange process has recently been characterized by ^{27}Al NMR spectroscopy for the complex Ti$(CH_2SiMe_3)(Cl—AlCl_3)(\eta$-$C_5H_5)_2$.[15]

The reaction of **4** with $[Cu(MeCN)_4]BF_4$ (**1**) affords a moderate yield (66%) of the complex $[Cu(MeCN)_2\{1,2\text{-}(Me_2NCH_2)(PPh_2)C_6H_4\}]BF_4$ (**7**) (Scheme 2). The purification procedure is complicated by the presence of yellow impurities and by the higher air-sensitivity of **7** compared to the bis-

* $[Cu(MeCN)_2(PPh_3)_2]BF_4$ crystallizes from CH_2Cl_2–Et_2O as monoclinic colourless prisms. Space group $P2_1/n$, a = 9.211(3), b = 26.864(9), c = 15.397(4) Å, β = 94.60(2)°, V = 3798(2) Å^3, Z = 8. Full details are deposited in the Cambridge crystallographic database. The structure of the copper cation is essentially identical to the known perchlorate salt. See also ref. 20.



Scheme 2.

phosphine complexes. The spectroscopic properties of **7** and the results of a crystallographic study (see later) are fully consistent with the formula proposed.

Catalytic and mechanistic studies

At the outset of this project information regarding cyclopropanation reactions using **1** was rather limited. We, therefore, undertook some initial screening reactions to identify the catalytic activity of **1** and the related phosphine complexes **2**, **3**, **5** and **7** for cyclopropanations using ethyl diazoacetate and the alkenes **8**–**11** (Scheme 2). In addition cyclopropanation reactions of **1** in the presence of added ligands were performed. Ethyl diazoacetate is an excellent test compound as known literature compounds are formed in most cases. In all cases, after a short induction period (*ca* 10–30 s), prompt decomposition of N_2=CH(CO_2Et) at room temperature is observed (Table 1). The complexes are highly active compared to traditional catalysts.

Table 1. Catalytic cyclopropanation results

Catalyst[a]	Alkene [Conc.]	Reaction time	Cyclopropane[b] yield	Isomer[c] ratio	Alkene[b] yield	*E*/*Z*[c] ratio
$[Cu(MeCN)_4]^+$	**8** [1.5 M]	10 min	60%	1.65	30%	1.35
$[Cu(MeCN)_4]^+$	**8** [0.35 M]	20 min	34%	1.95	43%	1.55
$[Cu(MeCN)_2(PPh_3)_2]^+$	**8** [1.5 M]	2.25 h	55%	2.50	31%	1.80
$[Cu(MeCN)(PPh_3)_3]^+$	**8** [1.5 M]	16 h	27%	2.38	34%	1.75
$[Cu(MeCN)_2(\mathbf{4})]^+$	**8** [1.5 M]	15 h (at 4°C)	65%	2.75	32%	1.60
$[Cu(MeCN)_2(\mathbf{13})]^+$[d]	**8** [1.3 M]	45 min	47%	2.50	34%	4.10
$[Cu(F{-}BF_3)(PCy_3)_2]$	**8** [1.5 M]	4.5 h	29%	4.00	49%	4.20
$[Cu(MeCN)_4]^+$	**9** [3.5 M]	20 min	71%	—	30%	1.25
$[Cu(MeCN)_4]^+$	**10** [1.5 M]	10 min	30%	5.50[e]	44%	3.90
$[Cu(MeCN)_4]^+$	**11** [1.5 M]	10 min	7%	—	46%	1.35

[a] Reactions performed on a 1–2 mmol scale in CH_2Cl_2 using 2 mol% catalyst ($[BF_4]^-$ counter-anion) at ambient temperature.

[b] Isolated by column or preparative TLC.

[c] *Trans*/*cis* ratio (cyclopropane) or *E*/*Z* ratio (alkene) determined by GC on the crude reaction mixture, error ±0.05.

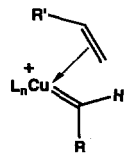
[d] Prepared *in situ*.

[e] *Exo*/*endo* value.

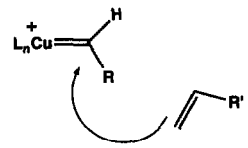
However, for high yields of cyclopropanes the effective concentration of the alkene must be above 1.0 molar. Terminal alkenes, especially styrene, are the most reactive. Although various enantioselective routes to the styrene derived product **12** are available, catalyst control of the relative *trans*/*cis* stereochemistry by a family of complexes is rarely demonstrated. Selective formation of cyclopropanes related to *trans*-**12** using sterically hindered diazoacetates is known,[16] but catalyst-based *trans*/*cis* control is rare.

In the PPh_3 substituted catalysts the *trans*/*cis*-**12** selectivity and rate is influenced by the number of phosphine ligands coordinated to the catalyst, maximizing for $[Cu(MeCN)_2(PPh_3)_2]BF_4$ (**2**). Different PPh_3:Cu ratios result in inferior selectivity and rates, the 3 : 1 ratio of **3** gives a *trans*/*cis* value of 2.38 after 16 h, while the complex $[Cu(PPh_3)_4]BF_4$ shows only feeble catalytic activity. Complex **5** catalyses the reaction rather slowly, but in this case with high *trans*/*cis*-**12** selectivity (4.00). Crystallographic studies show that $M(PCy_3)_2$ (M = Cu, Ag) based complexes often attain a maximum coordination number of only three.[17] The above results indicate although only one free coordination site is required for these catalysts, significant rate enhancements are attained where at least two are present. In support of this notion is the observation that the rate of $N_2{=}CH(CO_2Et)$ decomposition by **2** is faster in the presence of styrene than in its absence. The *trans*/*cis*-**12** selectivity of the nitrogen–phosphorus chelate complex **7** is also relatively high (2.75), but the reaction proceeds much faster than that catalysed by **5**. Attempts at chiral catalysis using the *in situ* complex $[Cu(MeCN)_2(\mathbf{13})]BF_4$ results in a modest yield of essentially racemic **12**. Similarly, racemic **12** is isolated from very low activity catalysts prepared by (*S*)-BINAP (**14**) addition to $[Cu(MeCN)_4]BF_4$ (**1**) in a 1 : 1 ratio. The low cyclopropane yields obtained from **11** are due to steric factors. Attempts at intramolecular cyclopropanation using **15** are unsuccessful due to the high stability of the diazo-species.

Mechanistically the two most probable transition states for copper-catalysed cyclopropanation involve alkene coordination (**16**) or attack on the coordinated carbene ligand by an outer-sphere alkene (**17**) (Scheme 3). As kinetic regimes often cannot distinguish between these two possibilities[5] we sought for alternative evidence for alkene and carbene coordination. No MeCN exchange with



16



17

Scheme 3.

styrene in **2** could be detected by ^{31}P NMR spectroscopy at room temperature or −30°C. Further, no MeCN liberation from **2** is detected by IR or ^{31}P NMR spectroscopy for the related π-acid CO. These results suggest rather small equilibrium constants for MeCN dissociation. In the catalytic systems MeCN is removed by degradation with ethyl diazoacetate during the short induction period, thus preventing equilibrium back reactions. Supporting this idea reactions in acetonitrile alone give small variable yields of $MeC{=}NCH(CO_2Et)$, together with *E*/*Z* alkene and polymeric material. The catalytic species *do* coordinate π-acids, admission of CO totally inhibits the catalysis but the activity returns once a nitrogen atmosphere is readmitted. The lowest temperature at which our catalysts are active is *ca* 4°C, precluding NMR investigations by low-temperature mixing. However, prompt cooling of the active reaction mixtures using a $[Cu(MeCN)_2(PPh_3)_2]BF_4$ (**2**) pre-catalyst allows the catalytic rest state to be interrogated by ^{31}P NMR spectroscopy. Under these conditions the signal for the starting material [δ_P (109.25 MHz, $CDCl_3$, −30°C) −0.3 ($W_{1/2}$ = 48 Hz)] is replaced by a broad resonance at δ_P −0.8 ($W_{1/2}$ = 180 Hz) and a smaller sharp signal at δ_P 20.7. This signal is identified as $Ph_3P{-}N_2{=}CHCO_2Et$ by comparison with an authentic sample.[18] However, attempts to probe the structure of the active copper species are thwarted by the quadrupolar nature of copper (I = 3/2 for both ^{63}Cu and ^{65}Cu).

Crystallographic studies

In order to gain some further insights into the origins of the higher *trans*/*cis* selectivity shown by complexes **5** and **7** the crystal structures of these molecules were investigated.* ORTEP views of the molecules are shown in Figs 1 and 2, while selected bond length and angle data are presented in Tables 2 and 3. Details of the crystal and structure refinement data for both compounds are summarized in Table 4.

The $[Cu(F{-}BF_3)(PCy_3)_2]$ (**5**) molecule exhibits positional disorder in one of the cyclohexyl groups (designated "6") and in the three BF_4 fluorine atoms

* Full details for **5** and **7** are deposited at the Cambridge Crystallographic database.

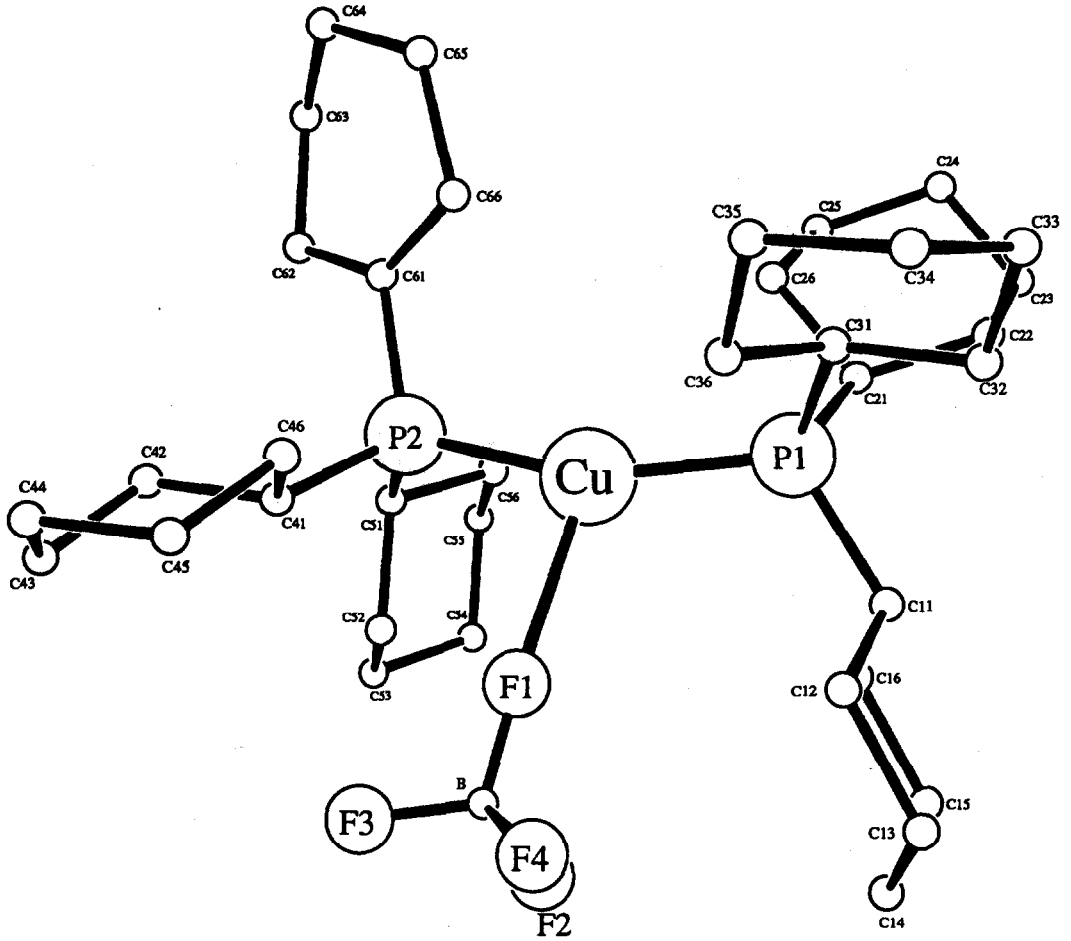


Fig. 1. An ORTEP view of $Cu(F—BF_3)(PCy_3)_2$ (**5**); hydrogen atoms are omitted for clarity.

which are not coordinated to the metal. However, the disorder is not of great consequence to the discussion and for this reason and to eliminate clutter the multiple occupancy positions are not shown; the figure shows the primary fluorine atom positions. The semi-coordinated BF_4 group is anchored at the coordinated fluorine atom, which is uniquely positioned and shows no disorder. Overall three-coordinate copper is observed in **5** with a Cu—F contact distance of 2.420(6) Å. The second nearest fluorine of the coordinated BF_4 group [F(2), 70% occupancy] at *ca* 4.2 Å is effectively non-bonded. Coordination of the anion results in a slight shortening of the coordinated B—F bond B—F(1) to 1.29(2) Å, while the uncoordinated B—F bonds are in the range expected [1.33(2)–1.39(2) Å]. Similar features are seen in the structure of $Cu(F—BF_3)(PPh_3)_3$ (**6**), where the principal Cu—F contact is 2.306 Å,[19] but in this case no B—F contraction is observed. Commensurate with the high steric bulk of PCy_3, a large P—Cu—P angle of 159.98(8)° is observed. This is the largest angle observed in $M(PR_3)_2$ (M = Cu, Ag) systems, some 13–15° greater than those in $M(X)(PCy_3)_2$ (M = Cu, Ag; X = NO_3, ClO_4)[17] at 139.0–147.3° and considerably greater than those at 127.6(1)° and 127.1(1)° in the structures $[Cu(MeCN)_2(PPh_3)_2]X$ (X = ClO_4, BF_4).[20] The bulky phosphines offer considerable steric protection to the metal, however, due to disorder in one of the cyclohexyl rings extensive discussion of the ring geometries is not profitable.

The coordination geometry about copper in **7** is approximately tetrahedral. The most significant deviation is the P—Cu—N angle of 98.3(1)° due to the chelate ligand. Direct comparison with related phosphorus nitrogen chelates on copper(I) is difficult as apparently no other is crystallographically characterized. The Cu—P distance at 2.195(2) Å is in the range expected by comparison with the structures of $Cu(MeCN)_n(PPh_3)_{4-n}$ (n = 0–2).[13] The Cu—NMe_2 distance at 2.179 Å is somewhat longer than Cu^I—N bond distances observed in coordinated acetonitrile complexes,

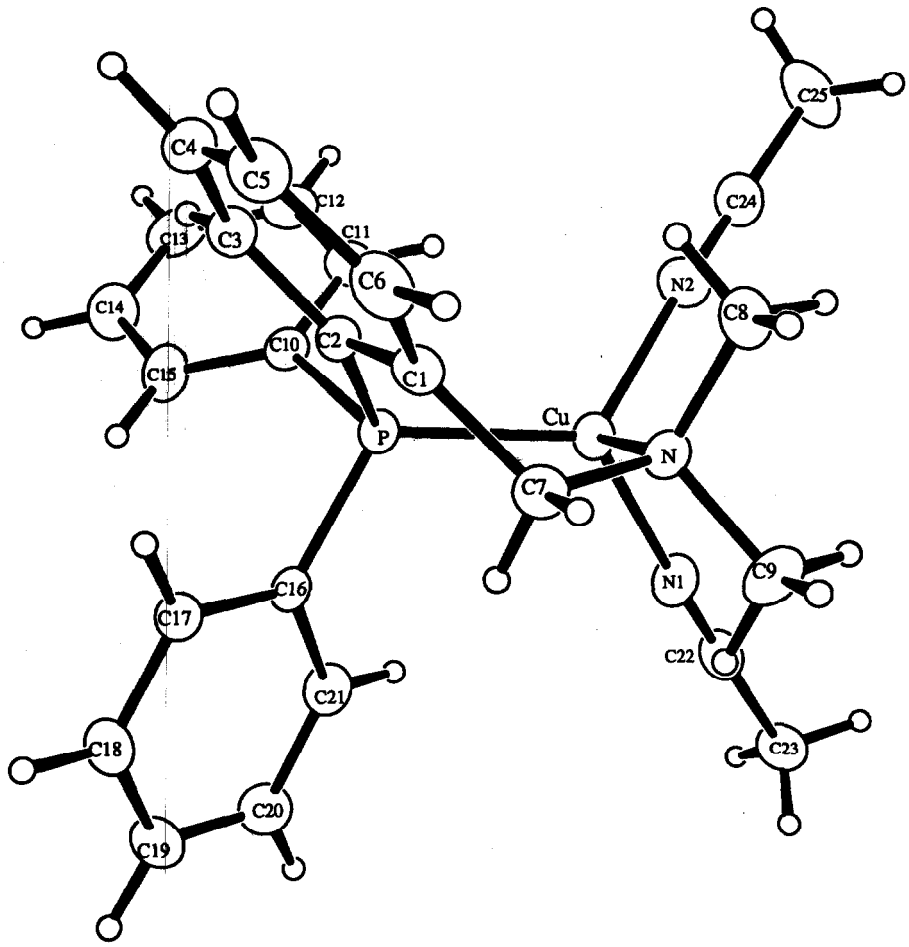

Fig. 2. An ORTEP view of $[Cu(MeCN)_2\{1,2\text{-}(Me_2NCH_2)(PPh_2)C_6H_4\}]BF_4$ (**7**).

2.02–2.12 Å.[13] Solution ^1H NMR studies suggest that the chelate ring is flat, but in the solid state the ring is kinked about the methylene linkage of the chelate ligand. This is most clearly seen in the N—C(7)—C(1) and Cu—P—C(2) angles, which are 114.9(5)° and 105.7(2)°, respectively. Rapid ring deformation must occur in solution rendering the CH_2 and NMe_2 groups equivalent in the ^1H NMR spectra. The $[BF_4]^-$ counter-anion in $[Cu(MeCN)_2\{1,2\text{-}(Me_2NCH_2)(PPh_2)C_6H_4\}]BF_4$ (**7**) exhibits positional disorder, hence, additional positions are tabulated with the other data.

CONCLUSIONS

The observed rate differences and selectivities shown by these complexes indicate that alkene coordination and a transition state similar to **16** is important in cyclopropanation catalysis by **2**, **7** and related sterically unencumbering ligands. For the species **3** and **5** no alkene coordination is proposed to occur due to steric blocking of the fourth coordination site at the copper. In these cases direct attack on the coordinated carbene $[L_nCu{=}CH(CO_2Et)]$ (viz. **17**) is likely.

EXPERIMENTAL

General

All manipulations involving nitrogen ligated copper complexes, together with catalytic reactions, were performed under nitrogen atmospheres using standard Schlenk techniques. All alkenes and ethyl diazoacetate were commercial products (Aldrich), used after drying over 4 Å molecular sieves. Commercial PCy_3 was used as supplied. Carbon disulphide and dichloromethane were distilled from CaH_2 immediately prior to use; hexane, light petroleum (b.p. 40–60°C) and Et_2O were dried

over sodium wire. Column chromatography and preparative TLC were run on activated silica gel; Fisons S/0780/60 and Merck Kieselgel 60 $HF_{254+366}$, respectively. IR spectra were recorded using a Perkin–Elmer 983G instrument. Proton NMR spectra were recorded on Jeol-270 (270 MHz) or Bruker WH-400 (400 MHz) spectrometers. ^{13}C NMR (67.8 MHz), ^{31}P NMR (109.3 MHz) and ^{19}F NMR (254.1 MHz) spectra were recorded on the Jeol-270. Mass spectra were obtained on Finnigan 1020 (electron impact ionization, EI) or VG–ZAB (fast atom bombardment ionization, FAB) machines. Optical activities were assayed by polarimetry on a Optical Activity Ltd AA-10 instrument. Catalytic reaction mixtures were investigated with a Sigma-3 GC using a Carbowax-20M column, a carrier gas flow of 30 $cm^3\ min^{-1}$ (N_2) and either a temperature program (8 min at

145°C/ramp to 185°C over 5 min/12 min at 185°C) or an isothermal run at 100°C. The complex $[Cu(MeCN)_4]BF_4$ (**1**) was prepared in an identical manner to $[Cu(MeCN)_4]PF_6$ using HBF_4 (48%wt in water) and recrystallized from MeCN before use.[12] The species $[Cu(MeCN)_2(PPh_3)_2]BF_4$ (**2**)[13] and the ligand **4**[21] are literature compounds.

Preparations and catalysis

Preparation of $Cu(F{-}BF_3)(PCy_3)_2$ (**5**). Solid PCy_3 (0.60 g, 2.14 mmol) was added to a suspension of $[Cu(MeCN)_4]BF_4$ (**1**) (0.33 g, 1.07 mmol) in CH_2Cl_2 (30 cm^3) at room temperature. The reaction was stirred for 1 h, during which time the mixture became homogeneous. The colourless solution was filtered, concentrated to a minimal volume and crystallized by addition of Et_2O and cooling, resulting in two crops of colourless plates; 0.57 g (75%); m.p. 218–219°C. Found: C, 60.5; H, 9.1; M(cation)$^+$, 623. Calc. for $C_{36}H_{66}BCuF_4P_2$: C, 60.8; H, 9.35%; M(cation), 623. ν_{max} (cm^{-1}) (KBr disc): 2919s, 2842s (CH) and 1080s (BF). δ_H (400 MHz, $CDCl_3$): 1.13–1.46 (30 H, m, axial H), 1.68–1.95 (30 H, m, equatorial H) and 1.95–2.06 [6 H, m, H—C(1)]; δ_C (67.8 MHz, $CDCl_3$): 25.9 [6 C, s, C(4)], 27.0 [12 C, t, J(PC) = 6 Hz, C(2)], 31.0 [12 C, s, C(3)] and 31.6 [6 C, t, J(PC) = 11 Hz, C(1)]; δ_P (109.3 MHz, $CDCl_3$): 21.3 (PCy_3); δ_F (254.1 MHz, C_6D_6): 148.96, 149.00; δ_F (254.1 MHz, acetone-d_6): 149.47, 149.51; δ_F (254.1 MHz, DMSO-d_6): 146.80, 146.85.

Preparation of $[Cu(F{-}BF_3)(PPh_3)_3]$ (**6**). Addition of PPh_3 (0.62 g, 2.40 mmol) to $[Cu(MeCN)_4]BF_4$ (**1**) (0.25 g, 0.80 mmol) in CH_2Cl_2 (50 cm^3), followed by crystallization from CH_2Cl_2–Et_2O afforded colourless cubes of $[Cu(MeCN)(PPh_3)_3]BF_4$ (**3**); 0.72 g (92%). The complex had properties closely related to the known ClO_4 salts;[13] m.p. 225–226°C. Found: C, 68.3; H, 4.8; N, 1.7; M(cation-MeCN)$^+$, 849. Calc. for $C_{56}H_{48}BCuF_4NP_3$: C, 68.8; H, 4.95; N, 1.4%; M(cation), 890. ν_{max} (cm^{-1}) (KBr disc): 3062m (CH), 2282w, 2244w (CN), 1485s, 1434s (CC) and 1050s br (BF). δ_H (270 MHz, $CDCl_3$): 2.03 (3 H, s, Me), 7.00–7.12 (18 H, m, Ph-*o*), 7.12–7.23 (18 H, m, Ph-*m*) and 7.32–7.41 [9 H, m, Ph-*p*]; δ_P (109.3 MHz, $CDCl_3$): 1.4 (PPh_3). Heating the solid under vacuum (0.05 mm Hg) at 90°C (2 h) followed by recrystallization from CH_2Cl_2–Et_2O yielded colourless needles of $[Cu(F{-}BF_3)(PPh_3)_3]$, 0.57 g (82%), with literature properties;[19] m.p. 219–220°C. Found: C, 68.9; H, 4.75. Calc. for $C_{54}H_{45}BCuF_4P_3$: C, 69.2; H, 4.8. ν_{max} (cm^{-1}) (KBr disc): 3062m (CH), 1482s, 1437s (CC) and 1060s br (BF). δ_H (270 MHz, $CDCl_3$): 6.95–7.10 (18 H, m, Ph-*o*), 7.10–7.23 (18 H, m, Ph-*m*) and 7.32–7.42 [9 H, m, Ph-*p*]; δ_P (109.3 MHz, $CDCl_3$): 1.8 (PPh_3).

Preparation of $[Cu(MeCN)_2\{1,2\text{-}(Me_2NCH_2)$

$(PPh_2)C_6H_4\}]BF_4$ (**7**). A degassed solution of 1,2-$(Me_2NCH_2)(PPh_2)C_6H_4$ (**4**) (0.34 g, 1.05 mmol) in CH_2Cl_2 (5 cm^3) was added by cannula to a suspension of $[Cu(MeCN)_4]BF_4$ (**1**) (0.33 g, 1.03 mmol) in CH_2Cl_2 (10 cm^3) at ambient temperature and stirred (30 min). The resulting deep yellow solution was filtered under nitrogen and concentrated to *ca* 4 cm^3. An equal volume of degassed Et_2O was added and the yellow by-products removed by filtration under nitrogen. Further Et_2O addition and slow cooling afforded two crops of colourless rhomboid crystals; 0.37 g (66%); m.p. 128–130°C (dec.). Found: C, 54.1; H, 5.0; N, 7.2; M(cation)$^+$, 464. Calc. for $C_{25}H_{28}BCuF_4N_3P$: C, 54.1; H, 5.1; N, 7.6%; M(cation), 464. ν_{max} (cm^{-1}) (KBr disc): 3044w, 2999w, 2960w, 2940w, 2875w, 2837w, 2795w (CH), 2300w, 2267w, 2243w (CN), 1478m, 1454m, 1430m (CC), and 1060s br (BF); δ_H (270 MHz, $CDCl_3$): 2.28 (6 H, s, MeCN), 2.44 (6 H, s, NMe_2), 6.84–6.90 (1 H, m, phenylene), 7.26–7.59 (13 H, m, Ph + phenylene); δ_P (109.3 MHz, $CDCl_3$): 1.3 (PPh_2).

Typical procedure for catalytic cyclopropanation. Neat N_2=CH(CO_2Et) (0.2 cm^3, 1.90 mmol) was added by microlitre syringe to a solution containing styrene (1.1 cm^3, 9.5 mmol) and $[Cu(MeCN)_4]BF_4$ (**1**) (12 mg, 0.04 mmol, 2 mol%) in CH_2Cl_2 (5 cm^3) and the reaction stirred at room temperature until nitrogen evolution ceased. The cyclopropane *trans/cis* and alkene *E/Z* ratios were determined by GC; the relevant response factors were checked at regular intervals. Chromatography in 1:1 CH_2Cl_2: light petroleum afforded styrene followed by the cyclopropane *trans/cis*-**12**.[10] *Trans*-**12**: TLC (1:1 CH_2Cl_2: hexane), $R_f = 0.57$; GC retention time = 18.7 min (program). δ_H (400 MHz, $CDCl_3$): 1.23 [3 H, t, J(HH) = 7.2 Hz, Me], 1.30 [1 H, ddd, J(HH) = 8.4, 6.5, 4.5 Hz, H—C(3)], 1.59 [1 H, ddd, J(HH) = 9.2, 5.4, 4.5 Hz, H—C(3)], 1.89 [1 H, ddd, J(HH) = 8.4, 5.4, 4.2 Hz, H—C(1)], 2.51 [1 H, ddd, J(HH) = 9.2, 6.5, 4.2 Hz + unresolved long range couplings to Ph, H—C(2)], 4.16 [2 H, q, J(HH) = 7.2 Hz, OCH_2], 7.08–7.10 (2 H, m, Ph-*o*) and 7.10–7.29 (3 H, m, Ph-*m* + *p*). *Cis*-**12**: TLC (1:1 CH_2Cl_2: hexane), $R_f = 0.35$; GC retention time = 16.9 min (program). δ_H (400 MHz, $CDCl_3$): 0.96 [3 H, t, J(HH) = 7.2 Hz, Me], 1.32 [1 H, ddd, J(HH) = 9.1, 7.8, 5.1 Hz, H—C(3)], 2.07 [1 H, ddd, J(HH) = 9.1, 7.8, 5.6 Hz, H—C(1)], 2.57 [1 H, dt, J(HH) = 9.1, 9.1, 7.5 Hz + unresolved long range couplings to Ph, H—C(2)], 3.86 [2 H, q, J(HH) = 7.2 Hz, OCH_2] and 7.10–7.29 (5 H, m, Ph). The diastereomers could be separated by preparative TLC (10:1 light petroleum: EtOAc); complete resolution was only achieved at low plate loadings. Optical activities were assessed by use of literature optical rotations.[22] Continued elution with 1:1 CH_2Cl_2: EtOAc afforded a mixture of diethyl fumarate/maleate. Fumarate (*E*-alkene): TLC (1:1 CH_2Cl_2: hexane), $R_f = 0.11$–0.28; GC retention time = 8.2 min (program). δ_H (270 MHz, $CDCl_3$): 1.30 [3 H, t, J(HH) = 7.2 Hz, Me], 4.23 [2 H, q, J(HH) = 7.2 Hz, OCH_2] and 6.80 (2 H, s, =CH). Maleate (*Z*-alkene): TLC (1:1 CH_2Cl_2: hexane), $R_f = 0.11$–0.28; GC retention time = 10.3 min (program). δ_H (270 MHz, $CDCl_3$): 1.29 [3 H, t, J(HH) = 7.2 Hz, Me], 4.23 [2 H, q, J(HH) = 7.2 Hz, OCH_2] and 6.42 (2 H, s, =CH).

Cyclopropanation of 1,1-*dimethylethene* (**9**). Application of the above procedure afforded the cyclopropane having literature properties.[8] TLC (1:1 CH_2Cl_2: hexane): $R_f = 0.37$; GC retention time = 4.9 min (100°C). ν_{max} (cm^{-1}) (thin film): 2960s, 2925s, 2858m (CH) and 1732s (CO). δ_H (270 MHz, $CDCl_3$): 0.84 [1 H, dd, J(HH) = 8, 4 Hz, H—C(3)], 1.08 [1 H, dd, J(HH) = 5, 4 Hz, H—C(3)], 1.15 (3H, s, Me), 1.21 (3 H, s, Me), 1.27 [3 H, t, J(HH) = 7 Hz, OCH_2*Me*), 1.48 [1 H, dd, J(HH) = 8, 5 Hz, H—C(1)] and 4.07–4.19 (2 H, m, OCH_2). MS (EI): 142 (M^+).

Cyclopropanation of cyclohexane (**10**). Using the standard method afforded the cyclopropane having literature properties.[6] TLC (1:1 CH_2Cl_2: hexane), $R_f = 0.44$; GC retention time = 9.3 min (program). ν_{max} (cm^{-1}) (thin film): 2930s, 2861s (CH) and 1725s (CO). δ_H (270 MHz, $CDCl_3$): 1.28 [3 H, t, J(HH) = 7 Hz, Me-*exo*], 1.29 [3 H, t, J(HH) = 7 Hz, Me-*endo*], 1.20–1.99 (11 H, m, ring protons), 4.10 [2 H, q, J(HH) = 7 Hz, OCH_2-*exo*] and 4.12 [2 H, q, J(HH) = 7 Hz, OCH_2-*endo*]. MS (EI): 168 (M^+).

Cyclopropanation of 1,2,3,4,5,6,7,8-*octahydronaphthylene* (**11**). Using the above protocol yielded the cyclopropane as a clear oil. TLC (1:1 CH_2Cl_2: hexane), $R_f = 0.50$; GC retention time = 17.9 min (program). ν_{max} (cm^{-1}) (thin film): 2920s, 2849s, (CH) and 1725s (CO). δ_H (270 MHz, $CDCl_3$): 1.28 [3 H, t, J(HH) = 7 Hz, Me], 1.30–2.28 (17 H, m, ring protons) and 4.13 [2 H, q, J(HH) = 7 Hz, OCH_2]. MS (EI): 222 (M^+).

Decomposition of N_2=CH(CO_2Et) *in* MeCN. A solution of N_2=CH(CO_2Et) (0.2 cm^3, 1.90 mmol) in MeCN (1 cm^3) was decomposed by $[Cu(MeCN)_4]BF_4$ (**1**) (12 mg, 0.04 mmol, 2 mol%) over 3 h. Preparative TLC afforded 39 mg (23%) of *E/Z*-(EtO_2C)CH=CH(CO_2Et), $R_f = 0.20$–0.40, and a slow moving band, $R_f = 0.09$–0.16, containing variable amounts of MeC=NCH(CO_2Et), *ca* 11 mg (9%) as a yellow oil with literature properties.[23] TLC (3:2 hexane: EtOAc), $R_f = 0.35$. ν_{max} (cm^{-1}) (thin film): 1784s (C=N) and 1709s (CO). δ_H (270 MHz, $CDCl_3$): 1.41 [3 H, t, J(HH) = 7 Hz,

CH_2Me), 2.34 (3 H, s, CMe), 4.08 [2 H, q, J(HH) = 7 Hz, OCH_2]. MS (EI): 127 (M^+).

Preparation of $N_2{=}C(CO_2Et)(CS_2CH_2CH{=}CH_2)$ **(15)** *and attempted intramolecular cyclopropanation.* Freshly prepared $LiNPr^i_2$ (LDA) (10.00 mmol) in THF (10 cm^3) was added slowly by cannula to a mixture of $N_2{=}CH(CO_2Et)$ (1.09 g, 9.51 mmol) and CS_2 (0.76 g, 9.98 mmol) in THF (40 cm^3) at −78°C, causing a darkening to orange. Allyl bromide (0.85 cm^3, 1.19 g, 9.82 mmol) was then added by syringe. The solution was allowed to come to room temperature (2 h), during which time its colour darkened to brown. The solution was stirred at ambient temperature, concentrated and quenched (NH_4Cl solution, 20 cm^3). Extraction with CH_2Cl_2 and water afforded on drying (Na_2SO_4) a yellow oil. Chromatography on SiO_2 (115 × 30 mm), eluting with 10:1 (light petroleum:CH_2Cl_2), afforded small amounts of an uncharacterized species. TLC (4:1 hexane:CH_2Cl_2), R_f = 0.75. Continued elution with 4:1 (light petroleum:CH_2Cl_2) yielded **15** as a yellow oil, 0.53 g (24%). TLC (4:1 hexane:CH_2Cl_2), R_f = 0.38. ν_{max} (cm^{-1}) (thin film): 2985m, 2938w, 2910w (CH), 2105w, (NN), 1706s (CO) and 1063s (CS). δ_H (270 MHz, $CDCl_3$): 1.47 [3 H, t, J(HH) = 7.1 Hz, Me], 3.72 [2 H, dt, J(HH) = 6.6, 1.3, 1.3 Hz, CH_2CH], 4.52 [2 H, q, J(HH) = 7.1 Hz, OCH_2], 5.38 [1 H, ddt, J(HH) = 10.0, 1.3, 1.3, 1.0 Hz, $=CH_2$], 5.50 [1 H, ddt, J(HH) = 16.9, 1.3, 1.3, 1.0 Hz, $=CH_2$] and 5.90 [1 H, m, J(HH) = 16.9, 10.0, 6.6, 6.6 Hz, =CH]. δ_C (67.8 MHz, $CDCl_3$): 14.1 (Me), 40.3 (OCH_2), 61.9 (SCH_2), 121.4 (=CH), 129.7 ($=CH_2$), 146.4, 160.5, 164.2 ($C{=}N_2$, C=O, C=S). MS (EI): 230 (M^+). Attempted intramolecular cyclopropanation using **1** in CH_2Cl_2 at ambient temperature or 1,2-dichloroethane at 65°C led only to the recovery of the starting material.

Crystallographic studies

Colourless crystals of $Cu(F{-}BF_3)(PCy_3)_2$ **(5)** were grown from an Et_2O solution containing traces of CH_2Cl_2 at −20°C. Greenish tinged crystals of $[Cu(MeCN)_2\{1,2\text{-}(Me_2NCH_2)(PPh_2)C_6H_4\}]BF_4$ **(7)** were grown from a CH_2Cl_2–Et_2O mixture at 0°C. For each complex a colourless crystal was mounted on a glass fibre with epoxy resin. In each case cell dimensions and space group data were obtained by standard methods on an Enraf–Nonius CAD4 four-circle diffractometer with graphite-monochromated Mo-K_α radiation. The θ–2θ technique was used, as previously described,[24] to record the intensities of all non-equivalent reflections, for which $3° < 2\theta < 50°$. Scan widths were calculated as $A + B \tan\theta$, where A is estimated from the mosaicity of the crystal and B allows for the increase in peak width due to $K\alpha_1$–$K\alpha_2$ splitting. Scan speeds were varied depending on the prescan reflection intensity. Data were collected as previously described on the Enraf–Nonius CAD4 diffractometer.[24]

Solution and refinement of the structures. Computations were carried out using the data with $F^2_o > 3\sigma(F^2_o)$, where $\sigma(F^2_o)$ was estimated from counting statistics.[25] Corrections were applied for Lorentz and polarization effects and for absorption.[26] In each case the positions of the metal and one phosphorus atom were determined using a Patterson map. Other atoms were located from Fourier-difference syntheses. The initial calculations were made with the MolEN program set,[27] while the final full-matrix least-squares refinement was performed using the TEXRAY program set.[28] Full-matrix least-squares refinement was based on F. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, where $w = 4F_o^2/\sigma^2(F_o^2)$, $\sigma^2(F_o^2) = [S^2\{(C + R^2B) + 0.03F_o^2\}^2]/Lp^2$; S = scan rate, C = total integrated peak count, R = ratio of scan time to background counting time, B = total background count and Lp = Lorentz polarization factor. Atomic scattering factors for both non-hydrogen[29] and hydrogen[30] atoms were taken from literature values. The effects of anomalous dispersion were included using literature values for $\Delta f'$ and $\Delta f''$.[31]

BIS-AMINOPHENYLFERROCENES: SYNTHESIS AND ELECTROCHEMISTRY

IAN R. BUTLER,* MAHER KALAJI,* LOUISE NEHRLICH and DENIS J. WILLIAMS

Chemistry Department, University of Wales, Bangor, Gwynedd LL57 2UW, U.K.

(*Received* 27 *November* 1992; *accepted* 26 *January* 1993)

Abstract—The synthesis and electrochemistry of bis-2-aminophenylferrocene is described and the synthesis and characterization of the co-polymer formed by reaction of bis-2-aminophenylferrocene with *p*-terephthaloyl chloride is discussed.

There is currently an enormous interest in the synthesis of redox active polymers in the general area of new material science.[1] A large proportion of the work in this area has focussed on the polyaniline system, which is one of the most promising as far as material development in electrochromic applications is concerned.[2] Coupled with this is a resurgence in the similar area of metallocene chemistry because of the ability to use the fine tuning of the redox couple of the metal centre in a metallocene as a probe for chemical sensing.[3] It was decided to examine the electrochemical behaviour of bis-2-aminophenylferrocene to see if the combination of the two redox active systems might be useful in material development.

EXPERIMENTAL

All reaction organic solvents were distilled prior to use. ^{1}H NMR spectra were recorded using either a Bruker WH-250 or a WH-400 instrument, in $CDCl_3$ unless otherwise stated. Sulphuric acid was reagent grade and was used as supplied.

Preparation of bis-4-nitrophenylferrocene,[4] *general procedure*

Ferrocene (50.0 g, 0.27 mol) was added to 96% sulphuric acid (250 cm^3), while allowing the temperature to rise to 50°C. The solution was then stirred at room temperature overnight and then poured into an ice/water mixture. 4-Nitroaniline was diazotised as follows: 4-nitroaniline (80.0 g, 0.59 mol) was dissolved in 20% v/v H_2SO_4 (250 cm^3) solution and the mixture cooled to < 4°C. This solution was then added slowly to a solution of sodium nitrite (40 g, 0.58 mol) in water (250 cm^3), maintaining the temperature below 4°C throughout. The diazonium salt was then added to the ferrocenium solution and foaming began with the concomitant formation of a finely divided precipitate. The reaction was allowed to proceed for a further 20 h. The reaction mixture was then filtered and the filtrate extracted several times with dichloromethane. The combined dichloromethane fractions were then evaporated to dryness and the solid residue was extracted in a Soxhlet with the following solvents: (1) petroleum ether (b.p. 40–60°C): evaporation of the extract and crystallization gives pure mono 4-nitrophenylferrocene; (2) dichloromethane: evaporation gives a red oil, which on crystallization gives pure bis-4-nitrophenylferrocene (**1**); and (3) acetone: evaporation of the solvent gives a brown powder, identified by ^{1}H NMR to be primarily a tri-substituted ferrocene compound. An insoluble (organic solvents) residue remained, which was bright purple. Found: C, 46.7; H, 4.2; N, 8.4%. The latter material dissolves in concentrated sulphuric acid to give a pink solution which turns blue on neutralization with sodium hydroxide solution.

4-Nitrophenylferrocene:[4] ^{1}H NMR ($CDCl_3$), 250 MHz: 4.08 (s, 5H), 4.50 (t, 2H), 4.70 (t, 2H), 7.51 (d, 2H), 8.13 (d, 2H); yield 6.4 g, 7.7%.

Bis-4-nitrophenylferrocene: ^{1}H NMR ($CDCl_3$), 250 MHz: 4.03 (t, 4H), 4.63 (t, 4H), 7.34 (d, 4H), 8.01 (d, 4H); yield 28.6 g, 24.7%.

Tris-1,3,1′-(4-*nitrophenyl*)*ferrocene*: ^{1}H NMR ($CDCl_3$), 250 MHz: 4.26 (bs, 2H), 4.6 (bs, 2H), 4.96 (bs, 2H), 5.19 (bs, 1H), 8.14 (m, 4H), 7.90 (bm, 2H), 7.45 (m, 4H), 7.07–7.26 (ms, 2H). Combined yield for trisubstituted derivatives 4 g.

Preparation of bis-2-nitrophenylferrocene (**1**)

An identical procedure to that for 4-nitrophenylferrocene was followed using petroleum ether and diethyl ether for the product extraction. Only two fractions were crystallized, the mono-substituted ferrocene from the petroleum ether fraction (4.3 g, 5.2%) and the di-substituted derivative from the ether fraction (36.1 g, 31.2%).

Bis-2-nitrophenylferrocene (**1**). Found: C, 61.6; H, 3.8; N, 7.2. Calc. for $C_{22}H_{16}FeN_2O_4$: C, 61.7; H, 3.7; N, 6.5. ^{1}H NMR ($CDCl_3$), 250 MHz: 4.35 (t, 4H), 4.50 (t, 4H), 7.25 (td, 2H), 7.33 (td, 2H), 7.45 (dd, 2H), 7.51 (dd, 2H). Mass spectrum, *m/z* (rel. intensity): 428(100), M^+, 412(6), 224(12), 212(13), 184(20), 170(15), 158(16), 139(27), 130(32). IR: 3054 (aryl C—H str.), 2986 (Fc C—H str.), 1526 (asymm. N=O str.), 14,222 (symm. N=O str.), 896 cm^{-1} (aryl deform.).

Compound **1** was reduced almost quantitatively using Zn/HCl using standard methodology to give the product amine **2**.

Bis-2-aminophenylferrocene (**2**). Found: C, 69.2; H, 5.3; N, 7.3. Calc. for $C_{22}H_{20}FeN_2$: C, 71.7; H, 5.4; N, 7.6. ^{1}H NMR ($CDCl_3$), 250 MHz: 4.14 (bs, 4H, N*H*), 4.32 (t, 4H, C_5H_4—β-H), 4.55 (t, 4H, C_5H_4—α-H), 6.57 (d, 2H), 6.65 (t, 2H), 7.02 (t, 2H), 7.21 (d, 2H). Mass spectrum, *m/z* (rel. intensity): 368(86), M^+, 211(100), 184(9), 156(15), 155(33), 154(40), 139(9), 130(13), 129(26), 128(23), 126(20). 121(24). IR: 3045 (C—H str.), 2986 (Fc C—H str.).

Preparation of the polymer from **2** *and* p-*terephthaloyl chloride*

Bis-2-aminophenylferrocene and *p*-terephthaloyl chloride were reacted in equimolar quantities with stirring in dry diethyl ether. The polymeric product which precipitated was filtered off and washed with acetone and vacuum dried. ^{1}H NMR (d^6-DMSO): (a) 4.12 (t), (b) 4.37 (t), ratio (a):(b) $\cong$ 1:7, total integral 4H, (c) 4.48 (t), (d) 4.94 (t), ratio (c):(d) $\cong$ 1:7, total integral 4H, 7.10–7.40 (2 ms, 3H), 7.68 (bd, 1H), 8.01–8.08 (2bs, 4H), 9.93 (bs, 1H).

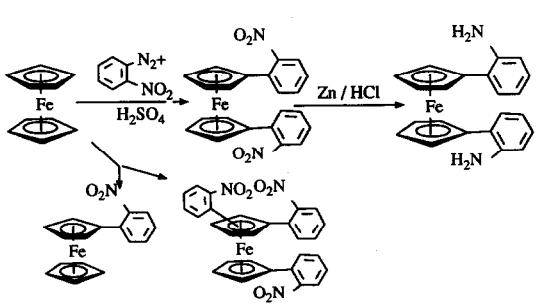
Electrochemical characterization

Cyclic voltammetry experiments were performed using a Hi-Tek potentiostat (type DT2101) and waveform generator (type PPR1). The working electrode was a platinum disc (2 mm diameter) polished to a mirror finish on successively finer grade alumina (Buehler 3.0, 0.3 and 0.05 μm). A platinum mesh served as a counter electrode. All potentials are quoted with respect to the saturated calomel electrode (S.C.E.). The measurements were performed in either aqueous solutions containing HCl (1 mol dm^{-3}) or acetonitrile solutions containing tetrabutylammonium tetrafluoroborate (0.1 mol dm^{-3}) (Aldrich). All solutions were degassed with nitrogen prior to any measurement.

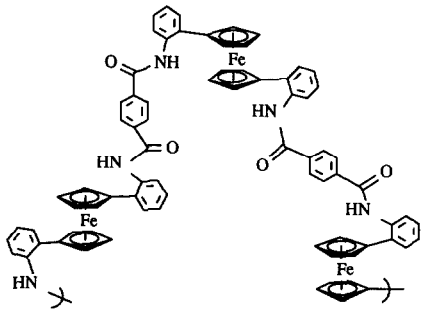
RESULTS AND DISCUSSION

There are a variety of different synthetic routes which would give the desired ferrocenylaniline compounds, such as Heck coupling of a haloferrocene with iodoaniline or nickel or palladium catalysed arylation; however, we decided to adopt the simplest approach possible using a diazonium salt coupling reaction.

The reaction of aryldiazonium salts with ferrocenium ion in the presence of ferrocene in acidic media is one of the oldest established reactions of ferrocene.[5–8] The mechanism of this reaction has not been fully elucidated, but has been the subject of intense scrutiny and free aryl radicals are known to be key intermediates in the reaction.[9] As a test the diazonium salt of *p*-nitroaniline was reacted initially with the ferrocenium salt derived from the reaction of ferrocene with sulphuric acid to prepare the known *p*-nitrophenylferrocene. In this reaction a complex mixture of ferrocenyl products was obtained including mono-, di-, tri- and tetra-substituted ferrocenes. In all 10 products were observed by TLC, however, the major components identified by NMR were the known mono- and di-substituted ferrocene derivatives. When the reaction was repeated with *o*-nitroaniline only two predominant products were obtained, the mono- and di-substituted products. The desired di-substituted compound, bis-2-nitrophenylferrocene (**1**), was then reduced with zinc in aqueous HCl to give the bis-2-aminophenylferrocene (**2**).



The reaction of bis-2-aminophenylferrocene with *p*-terephthaloyl chloride results in the formation of a polymer (**3**), which is soluble in DMSO. The ^1H NMR spectrum is surprisingly simple with only two predominantly different ferrocenyl environments discernable. The ratio of these is approximately 1:7, with the low intensity cyclopentadienyl resonances lying downfield of the higher intensity resonances by 0.25 and 0.43 ppm, respectively, which would indicate that the latter resonances may be associated with ferrocenyl carboxylic acid termini. This and similar polymers may be useful in the development of redox active polymers in their own right. The electrochemistry of the monomeric pro-



ducts was then investigated. Table 1 shows a summary of the results obtained. Compound **2** exhibits similar electrochemical behaviour to ferrocene. However, $E_{1/2}$ is shifted anodically by 71 mV ($E_{1/2}$ for ferrocene is 435 mV vs S.C.E.) (Fig. 1). The nitro substitution (compound **1**) results in an even bigger shift ($E_{1/2}$ = 575 mV), indicating the presence of the electron withdrawing group with ΔE = 150 mV. The dianilinium tetrafluoroborate salt (**4**) exhibits an even larger anodic shift. However, when the dianilinium hydrochloride salt **5** was studied in aqueous HCl the oxidation and reduction potentials were very similar to that of ferrocene.

Attempts were made to electropolymerize the bis-2-aminophenylferrocene and its dihydrochloride salt potentiodynamically[10] to form the equivalent polyaniline (Fig. 2). However, as the anodic limit was increased above that of the first oxidation the

Table 1.

Compound	E_{ox} (mV)	E_{red} (mV)	ΔE (mV)	$E_{1/2}$ (mV)
Ferrocene	465	405	60	435
1	650	500	150	575
2	552	460	92	506
4	690	560	130	625
5	443	378	65	410

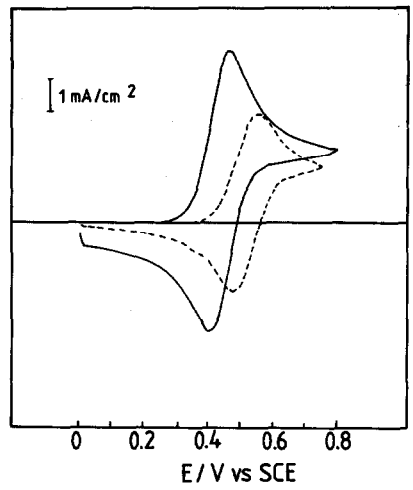


Fig. 1. Cyclic voltammograms for solutions (0.01 mol dm^{-3}) of —— ferrocene and ---- bis-2-aminophenylferrocene in tetrabutylammonium tetrafluoroborate (0.1 mol dm^{-3}) in MeCN on a platinum disc. Note that the latter is for the unprotonated form of compound **4**.

peak heights decreased and the peak separation increased on every cycle until eventually no peaks were observed. It is clear that an insulating layer forms on the surface. If the electrode is polished then the peaks appear again. The insulating film is transparent even though a species with a deep-red colour diffuses away from the electrode at the high anodic limits. Such behaviour has recently been observed for ferrocenylpyrrole.[11,12]

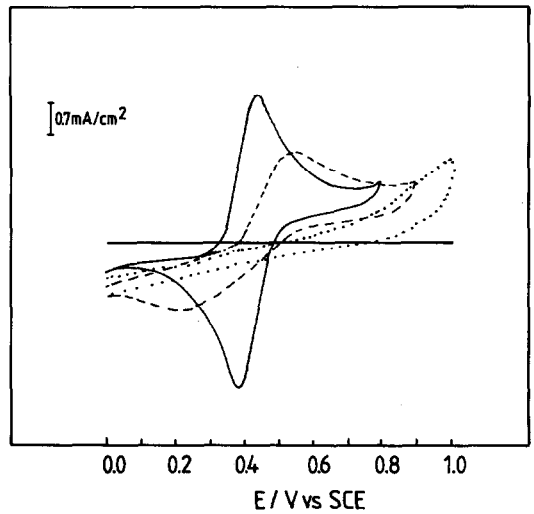

Fig. 2. Cyclic voltammograms for a solution of bis-2-aminophenylferrocene (0.01 mol dm^{-3}) in HCl (1 M) on a platinum disc electrode. Each CV is the second cycle taken at increasing anodic limits.

Our investigations are continuing into the nature of the thin insulating film deposited on the electrode surface and we are currently investigating the effect of a range of spacers between the ferrocene and the anilinium group. It should be noticed that Horowitz and Dailey has previously investigated the complementary system[13] with a methylene space. Our results in this area will be published in due course.

A MECHANISM OF HYDROXYALUMINOSILICATE FORMATION

C. EXLEY* and J. D. BIRCHALL

Unit for Inorganic Chemistry and Materials Science, Department of Chemistry, Keele University, Staffordshire ST5 5BG, U.K.

(*Received* 17 *November* 1992; *accepted* 26 *January* 1993)

Abstract—The simple fractionation procedure membrane filtration was successfully applied to the identification of the formation of hydroxyaluminosilicates. The mechanism of formation was shown to proceed through the inhibition of the nucleation of aluminium hydroxide. The inhibition was the result of silicic acid replacing hydroxylated aluminium at growth sites on aluminium hydroxide lattices. The ability of silicic acid to poison the growth of aluminium hydroxide lattices was dependent upon solution pH and the silicic acid concentration. This may be the first fully supported observation of a reaction of this ilk involving the neutral silicic acid molecule.

The biological availability and toxicity of aluminium is of increasing concern in biology and medicine.[1] The observation that silicic acid protected against the toxicity of aluminium in fish[2] was explained as being due to the reduction in the biological availability of aluminium through the formation of stable hydroxyaluminosilicates (HAS).[3] A recent experiment has confirmed the formation of HAS in solutions containing a "biologically relevant" total aluminium concentration and a mechanism to describe their formation was proposed.[4] Silicic acid was suggested to poison the nucleation of aluminium hydroxide, an effect which could be observed in solution by determining the size distribution profile (SDP) of aluminium particles using membrane filtration. In the experiments described herein the proposed mechanism of HAS formation was thoroughly tested using membrane filtration and an additional technique in which the base neutralizing capacities (BNC) of aluminium hydroxide and HAS solutions were compared.

EXPERIMENTAL

Materials and method

Membrane filtration was used to investigate changes in the size distribution profile of aluminium particles in solutions of known silicic acid concentration. In an additional experiment solutions of aluminium and aluminium and silicic acid were titrated against a base and their pH response recorded. Solutions were prepared in a medium of $NaHCO_3$ (10 mmol dm^{-3}; Sigma Chem. Co.) with the exception of the titration studies when solutions were additionally made up in ultra-pure water, the conductivity of which was consistently below 0.5 μS cm^{-1} (Russel CD800). Solution pH values in the range 3.0–9.0 were measured using a laboratory pH meter (Phillips PW 9420) and any pH adjustments were achieved through manual additions of microlitre aliquots of 0.1 M NaOH or HNO_3 (both BDH Aristar). Magnetic stirrers set at a constant speed were used to agitate the solution both during pH adjustment and final measurement. Aluminium was added to treatments from a stock solution (2 mmol dm^{-3}) of $Al(NO_3)_3 \cdot 9H_2O$ (Aldrich Chem. Co.) to give a nominal concentration in the treatment solutions of 4 μmol dm^{-3}. Silicic acid was used in the concentration range 0–2000 μmol dm^{-3} and was added as a stock solution (2 mmol dm^{-3}) of $Si(OH)_4$, prepared freshly as required using Na_4SiO_4 (Alfa Prod.). The contamination of solutions was reduced through the use of polypropylene, polythene and polycarbonate laboratoryware pre-washed in 5% nitric acid solution and rinsed in ultra-pure water for 24 h prior to use. All experiments were performed at a laboratory temperature recorded as 20 ± 2°C.

* Author to whom correspondence should be addressed.

The method of preparation of treatment solutions is critical to the efficacy with which membrane filtration can be used to discriminate changes in the size distribution profile of aluminium particles.[4] With this in mind the following experimental protocol was adopted for all preparations of treatment solutions unless otherwise specifically stated.

(1) The required silicic acid solution was made up in the appropriate medium (either 10 mmol dm^{-3} $NaHCO_3$ or ultra-pure water) and the solution pH adjusted to 3.0.
(2) Aluminium was added from the stock solution to give a treatment solution of 4 μmol dm^{-3} and, if necessary, the solution pH readjusted to 3.0.
(3) The treatment solution was then left to equilibrate for 24 h.
(4) If necessary the treatment solution pH was readjusted to 3.0 and thereafter base was added to effect the required treatment solution pH.
(5) The treatment solution was then left to equilibrate for a pre-determined time; in these studies anything from 300 s to 12 weeks.

At the appropriate time solutions were filtered under reduced pressure through 0.04 μm membrane filters (Ultipor, Pall UK Ltd.) in closed polycarbonate filtration vessels (Sterifil, 47 mm, Millipore) using protocol described in detail elsewhere.[4]

Four separate experiments comprized the present study.

(i) *The influence of* $[Si(OH)_4]$ *on HAS formation.* Treatment solutions containing silicic acid (0, 50, 100, 1000 and 2000 μmol dm^{-3}) and Al (4 μmol dm^{-3}) were adjusted to pH in the range 3.0–9.0 and thereafter equilibrated for 24 h before filtation. The total aluminium concentration ($[Al_t]$) in the filrate was expressed as a proportion of the total aluminium in solution at each recorded pH.

(ii) *Solution age and the size distribution profile of aluminium particles.* Solutions containing $Si(OH)_4$ (0 or 2000 μmol dm^{-3}) and Al (4 μmol dm^{-3}) were adjusted to pH in the range 5.0–9.0 and thereafter equilibrated for 300 s, 24 h, 1, 2, 3, 4 or 12 weeks, at which point the solutions were filtered and the total aluminium ($[Al_t]$) in the filtrate determined. Any change in the pH of solutions during their equilibration was not adjusted and the recorded pH values refer to solution pH immediately prior to their filtration. Results were plotted as $-\log_{10}[Al_t]$ against the solution pH.

(iii) *The effect of initial solution pH on the size distribution profile of aluminium particles in pH-adjusted solutions.* In this experiment modifications to the protocol of solution preparation were made. Solutions containing $Si(OH)_4$ (0 or 2000 μmol dm^{-3}) and Al (4 μmol dm^{-3}) were made up as detailed above, except that they were initially adjusted to either pH 3.0, 6.0 or 9.0. After the initial aging for 24 h the solution pH values were then adjusted, using microlitre additions of acid or base as appropriate, in the range 3.0–9.0 and then left to equilibrate for a further 24 h at their adjusted pH. Solutions were then filtered and $[Al_t]$ in the filtrate determined. Again, $[At_t]$ was expressed as a proportion of the total aluminium in solution at each recorded pH.

(iv) *The influence of silicic acid on the base neutralizing capacity (BNC) of aluminium solutions.* Four treatment solutions were prepared, as in the general solution preparation protocol, in both $NaHCO_3$ (10 mmol dm^{-3}) and ultra-pure water only.

1. Medium only, i.e. $NaHCO_3$ (10 mmol dm^{-3}) or ultra-pure water.
2. Medium + $Si(OH)_4$ (2000 μmol dm^{-3}).
3. Medium + $Si(OH)_4$ (2000 μmol dm^{-3}) + Al (4 μmol dm^{-3}).

Each treatment solution was equilibrated for 24 h at pH 3.0 before known volumes of NaOH (0.1 M) were added to 100 cm^3 aliquots of each. These aliquots were then left to equilibrate for either 24 h or 2 weeks, at which time their solution pH values were recorded. The results for each treatment solution in each medium were recorded as a final pH for each discrete volume of base added.

Total aluminium and total silicon were measured by graphite furnace atomic absorption spectroscopy (Perkin–Elmer 2280, HGA 400) using previously developed programmes.[5]

RESULTS AND DISCUSSION

The experiments were designed to test the hypothesis that hydroxyaluminosilicate (HAS) formation, as identified by changes in the size distribution profile (SDP) of aluminium-containing particles, was dependent upon the interaction of silicic acid ($Si(OH)_4$) with polymers of aluminium hydroxide ($\{Al(OH)_3\}_n$). Membrane filtration was the chosen method of fractionation, whilst the additional method of titration was used to elucidate further on the chemical nature of HAS in solution.

1. *The influence of* $[Si(OH)_4]$ *on HAS formation*

In the first experiment the fractionation procedure, membrane filtration, was evaluated. It was important to determine the $[Si(OH)_4]$ that in comparatively young (24 h) solutions would effect an observable change in the SDP of aluminium

particles. The SDP of aluminium particles formed in solutions aged for 24 h and containing $Si(OH)_4$ (0, 50, 100, 1000 and 2000 μmol dm^{-3}) were compared in the pH range 3.0–9.0. The results are shown in Figs 1(a)–(f). In the absence of silicic acid the SDP of aluminium particles assumed a characteristic V-shaped curve with the maximum growth and aggregation of particles to a filterable size occurring at *ca* pH 6.5 [Fig. 1(a)]. This profile remained largely unchanged for 50, 100 and 500 μmol dm^{-3} [Figs 1(b), (c) and (d)], except for a gradual widening, with increasing $[Si(OH)_4]$, of the pH regime in which these effects on aluminium particle size were enhanced. A more definitive response to the presence of silicic acid was seen in solutions containing 1000 and 2000 μmol dm^{-3} $Si(OH)_4$ [Figs 1(e) and (f)]. The mean particle size (MPS) was significantly reduced in the pH regime 5.5–7.5 and the pH at which the maximal growth and aggregation of particles to a filterable size occurred had moved from 6.5 to 5.5.

These results confirm silicic acid as a poison of the growth and aggregation of aluminium hydroxide. The kinetics were dependent upon both the pH ($5.5 < pH < 7.5$) and the silicic acid concentration ($[Si(OH)_4] > 500$ μmol dm^{-3}) in solution. The results do not preclude the possibility that HAS were formed in solutions of pH and $[Si(OH)_4]$ outside these limits (both chemical[4] and biological studies[2,6,7] have either identified or implied the formation of HAS at $[Si(OH)_4] \leqslant 500$ μmol dm^{-3}), only that their growth and aggregation to a filterable size (> 40 nm) could not be distinguished from that of aluminium hydroxide alone. If the size distribution profiles shown in Figs 1(a)–(f) were inverted they might be re-interpreted as the influence of solution pH on the tendency of aluminium particles to reach a filterable size, which in these experiments was *ca* 40 nm. The processes that contributed towards these tendencies were (1) the attainment of a critical nucleus, (2) the growth of critical nuclei of aluminium atoms, and (3) the aggregation of these growing nuclei. Which of these events were influenced by the formation of HAS cannot be easily determined from the results of these experiments. At the lower silicic acid concentrations ($[Si(OH)_4] \leqslant 500$ μmol dm^{-3}) the reaction kinetics of HAS formation were not sufficiently rapid in the time-scale available (24 h) to affect any of these processes relative to those of aluminium hydroxide alone; however, the higher concentrations of silicic acid ($[Si(OH)_4] \geqslant 1000$ μmol dm^{-3}) might alternatively be interpreted as influencing each of these mechanisms. (The identification in a previous study[4] of HAS $\leqslant$ 14 Å in size might lend support towards the formation of HAS involving critical nuclei containing fewer aluminium atoms than for aluminium hydroxide alone.) Certainly the tendency for HAS to form more easily at pH 5.5 than 6.5 was evidence of competition between silicic acid and hydroxylated aluminium for addition onto critical nuclei.

The influence of the aging of solutions might help to clarify which of the processes that determine the size distribution profiles of aluminium particles were in fact influenced by HAS formation. This was tested in the next experiment.

To make the most of the method of membrane filtration to identify the formation of HAS a silicic acid concentration of 2000 μmol dm^{-3} was used in all the remaining experiments.

2. *Solution age and the size distribution profile of aluminium particles*

HAS formation in young solutions changed the tendancy of aluminium particles to achieve a filterable size. Whether this was an effect on particle growth, aggregation or both was not clear. In this experiment the contribution of the age of the solution to the SDP of aluminium particles was determined.

The influence of equilibration time or solution age on the SDP of aluminium particles was ascertained for solutions of initial pH between 5.0 and 7.0 and containing $Si(OH)_4$ (0 or 2000 μmol dm^{-3}). Solutions were aged for up to 12 weeks, at which time their aluminium particle SDP was determined by membrane filtration. The results are shown in Figs 2(a)–(g).

The influence of silicic acid was immediate with an inhibition of nucleation, relative to aluminium hydroxide alone, occurring within 300 s of equilibration [Fig. 2(a)]. The further aging of the solutions produced the now characteristic V-shaped SDP of both aluminium hydroxide and HAS. In solutions aged for 12 weeks the growth and aggregation of particles in both aluminium only and HAS solutions reached an apparent steady-state [Fig. 2(g)]. At the respective solution pH where the growth of aluminium particles to a filterable size was greatest the concentration of aluminium particles not retained by membrane filtration was reduced, relative to the 24 h solutions, for both the aluminium only (*ca* 0.6–0.1 μmol dm^{-3}) and the HAS (*ca* 1.6–0.6 μmol dm^{-3}) treatments. Thus, aggregation of aluminium particles was occurring in both aluminium hydroxide and HAS solutions. The extent, however, to which aggregation occurred was reduced by HAS formation and this might be explained as a difference between the surface properties of HAS and aluminium hydroxide.

These results further support the hypothesis of silicic acid poisoning the nucleation of aluminium hydroxide through the substitution of silicic acid for hydroxylated aluminium at growth points on an aluminium hydroxide lattice. This hypothesis was further tested in the following experiment.

3. *The effect of the initial solution pH on the SDP of aluminium particles in pH-adjusted solutions*

In the aforementioned experiments all solutions were made up via the pH adjustment of solutions that had been previously equilibrated for 24 h at pH 3.0. In this way silicic acid would be able to influence the critical nucleus size and both the growth and subsequent aggregation of the critical nuclei of aluminium particles. How then might silicic acid influence the SDP of aluminium particles in solutions in which either (1) a variety of aluminium hydroxide lattices were preformed or (2) the tendancy to form aluminium hydroxide lattices was aproached from solutions containing predominantly tetrahedral anionic aluminium, i.e. the aluminate anion, $Al(OH)_4^-$. The effect of these

differences in treatment solution preparation and the species composition of the solutions prior to pH adjustments on the SDP of aluminium particles was tested in young solutions in which pH adjustments were made in the range 3.0–9.0. The results are shown in Figs 3(a)–(c). The SDP of aluminium particles originally equilibrated at pH 3.0 [cf. Figs 1(a) and (f)] is shown in Fig. 3(a) for comparison. For solutions originally equilibrated at pH 6.0 the SDPs of aluminium hydroxide and HAS were only marginally different [Fig. 3(b)]. The MPS for HAS solutions was reduced slightly in the circumneutral pH regime and the pH at which the maximum particle size occurred had moved from 6.5 to 5.5. These effects, however, were much reduced when compared to the solutions that had been prepared from an original pH of 3.0 [cf. Figs 3(a) and (b)]. In this experiment the influence of HAS formation on the size stability of preformed aluminium hydroxide lattices was tested. The subsequent adjustments in solution pH from 6.0 towards both 3.0 and 9.0 tested the further stabilities of the complexes formed at pH 6.0 to both acid and base attack. The results confirmed an interaction between silicic acid

and the preformed aluminium hydroxide polymers with the formation of HAS producing a diminution of their size in the expected pH range 5.5–7.5. These changes might be interpreted as HAS solutions approaching the steady-state characteristics of particle size distribution seen in aged solutions [Fig. 2(g)], although in the present experimental conditions the solutions were undersaturated (as opposed to oversaturated for solutions originally equilibrated at pH 3.0) with respect to their SDP of HAS. Thus, the extended HAS lattices formed at pH 6.0 were subject to pH-induced changes in their size. The response to pH changes of solutions of aluminium and silicic acid originally equilibrated at pH 9.0 was again different, although the final SDP was similar to that of solutions of an initial pH of

3.0 [Fig. 3(c)]. The SDP was largely ambiguous, although it gave some indication that HAS were formed at and around pH 9.0 and that the growth and aggregation of these HAS was relatively insensitive to pH adjustments in alkaline solution. Whether these HAS formed in alkaline solution were of similar structure and stoichiometry to those identified in acidic milieu cannot be ascertained from these results. There is evidence, although not from comparative studies in the laboratory, that they may not be.[8–11] Our own studies have indicated an increased silicon content of HAS formed in alkaline solutions.[4]

The results to-date suggest that HAS formation and the subsequent poisoning of the growth and aggregation of aluminium hydroxide may influence the hydrolytic reactions of aluminium in solution. In a final experiment the influence of silicic acid on the base neutralizing capacity (BNC) of aluminium solutions was determined.

4. *The influence of silicic acid on the BNC of aluminium solutions*

The change in pH of solutions of aluminium only and aluminium and silicic acid, which had previously been equilibrated for 24 h at pH 3.0, after the addition of known volumes of NaOH (0.1 M) were measured after either 24 h or 14 days equilibration. The experiment was first conducted using the standard bicarbonate medium [Fig. 4(a) and (b)]. Equilibrium with respect to the solution pH was aproached only very slowly and this phenomenon was directly attributable to the effect of bicarbonate *per se*. For this reason the pH response of the younger solutions (although largely vindicating the effects seen in the aged solutions) were largely discounted. Aluminium improved the BNC of solutions relative to bicarbonate alone only within the pH regime 4.0–7.0. The presence of silicic acid reduced this improvement of BNC. A closer examination of the results revealed that aluminium could be discerned as a contributor to the BNC in the pH range 4.1–5.9, whilst in the presence of silicic acid its efficacy was only evident up to a pH of 5.2. Below pH 4.0 and above pH 7.0 any effect of aluminium on BNC was not discernable from the effect of bicarbonate alone. The response of solution BNC to the presence of silicic acid corresponded closely to the pH regime in which the formation of HAS produced identifiable changes in the SDP of aluminium particles. For solutions of pH above *ca* 5.2 (the approximate pH range in which the MPS of aluminium particles was reduced in the presence of silicic acid) the presence of silicic acid abolished any significant addition of the presence of aluminium to the BNC of solutions. Whilst these results suggest that HAS formed at pH 5.2 and above were stable towards further hydrolysis they cannot totally preclude the possibility that further proton release was occurring, but that any effects of such on solution pH were masked by the burgeoning buffering potential of bicarbonate at these circumneutral pH. To look at the possible effects of bicarbonate on these results the experiment was repeated, making up the solutions in pure water as opposed to $NaHCO_3$ (10 mmol dm^{-3}). The results are shown in Figs 4(c) and (d). The results were surprizing and apparently contrary to those found for the bicarbonate medium. Above pH 4.0 aluminium significantly improved the BNC of the pure water medium. This was most significant in the pH range 4.2–6.6 and was evident in both young and aged solutions. The presence of silicic acid did not reduce aluminium's contribution to the BNC of solutions, as might have been predicted from the previous experiment, but actually increased the BNC over the entire pH range at which aluminium *per se* was effective. Although only preliminary and prone to the vagaries of pH measurements in solutions of different ionic potential these results were indicative of the possible influence of media on the fate of chemical reactions. Bicarbonate will bind aluminium[12] and bicarbonate was implicated in the reaction of aluminium with silicic acid in a previous experiment.[13] The importance of any such interactions of bicarbonate with aluminium on HAS formation will be investigated in future experiments.

CONCLUSIONS

Membrane filtration was successfully applied to the identification of HAS formation in solutions of low total aluminium concentration. The formation of hydroxyaluminosilicates was identified as changes in the tendancy of aluminium-containing particles to achieve a filterable size. The pH-dependency of these changes in SDP of aluminium-containing particles supported the interaction of silicic acid with both the growth and aggregation of critical nuclei of aluminium atoms. The mechanism of HAS formation and thus the inhibition of the nucleation of aluminium hydroxide included both steric and kinetic components. Silicic acid blocked growth sites on aluminium hydroxide lattices, possibly in the same way as the dimeric silicate anion inhibits the growth of calcium hydroxide crystals.[14] The rate of HAS formation was dependent upon both the solution pH and the silicic acid concentration. The poisoning of the nucleation of aluminium hydroxide was rapid at high silicic acid concentrations (> 500 μmol dm^{-3}) and was iden-

tified by membrane filtration. At lower concentrations of silicic acid the formation of HAS has been observed,[4] although in these studies, as in the previous study, it was not identified by membrane filtration. These experiments do not preclude the existence of soluble aluminosilicates such as those postulated in a recent publication.[15] The formation of HAS of this type through the substitution of silicic acid for water in the inner coordination sphere of the hexa-aqua aluminium species has a precedent, although unproven, in iron–silicon chemistry.[16] If such species do form they are, how-

(*Received* 14 *August* 1992; *accepted* 19 *January* 1993)

Abstract—Reaction of $Cu(ClO_4)_2$ with 2-methylpyrazine (mepz), 2,5-dimethylpyrazine (2,5-dmpz) or 2,6-dimethylpyrazine (2,6-dmpz) in aqueous solution yields the corresponding $CuL_n(ClO_4)_2(H_2O)_m$ ($n = 2,4$; $m = 1,2,4$). Single-crystal X-ray diffraction of $Cu(mepz)_2(ClO_4)_2(H_2O)_2$ (**1**) reveals a roughly octahedral geometry with all ligands *trans*. Similarly, $Cu(mepz)_4(ClO_4)_2(H_2O)$ (**2**) is pseudo-octahedral with one coordinated perchlorate and one H_2O in the axial sites. The pyrazines are coordinated through the N(4) nitrogen atom in both **1** and **2**. The magnetic susceptibilities of these compounds have been measured in the range 2–300 K. All the compounds behave as paramagnets. Conversely, reaction of $Cu(ClO_4)_2$ with 2,3-dimethylpyrazine in aqueous solution, or with mepz, 2,3-dmpz or 2,5-dmpz and $NaBH_4$ or NaSCN in aqueous solution yields complexes of the type $Cu_2(L)_3(ClO_4)_2$ or $Cu_2(L)(SCN)_2$, respectively. IR analysis suggests that the complexes are polymeric lattices of tri-coordinate copper(I) atoms bridged by the pyrazine ligands or the pyrazine and thiocyanate ligands, similar to the known structure of Cu_2(2,3-dimethylpyrazine)$_3(ClO_4)_2$.

Through our interest in magnetic interactions between metals mediated by organic ligands we began a study of complexes of bidentate heterocyclic ligands. Pyrazine is known to bridge metal ions and form coordination polymers such as the 2D-Heisenberg antiferromagnetic system $Cu(pz)_2(ClO_4)_2$ (pz = pyrazine).[1] In the crystalline state this complex is described as a two-dimensional array of Cu^{2+} atoms with bridging pyrazines, such that each copper atom is bonded to four pyrazine molecules in a pseudo-square planar array (the perchlorate ions are loosely coordinated in the axial sites). The material exhibits typical antiferromagnetic behaviour with a rounded maximum in the magnetic susceptibility versus temperature curve around 12 K.[1a] The pyrazine rings are rotated out of the plane described by the copper and nitrogen atoms by 66°, presumably to relieve steric crowding. We hoped that modification of the pyrazine ligand to increase the steric interactions between the rings would increase the angle between the pyrazine rings and the coordination plane and so examined the effect of methyl substitution on the structure and magnetism of the compounds in the series $Cu(mepz)_n^{2+}$, $Cu(2,3\text{-dmpz})_n^{2+}$, Cu(2,5-

dmpz)$_n^{2+}$ and Cu(2,6-dmpz)$_n^{2+}$, along with their related diamagnetic Cu^+ equivalents (2-methylpyrazine = *mepz*; 2,3-dimethylpyrazine = 2,3-dmpz; 2,5-dimethylpyrazine = 2,5-dmpz and 2,6-dimethylpyrazine = 2,6-dmpz; $n = 2, 4$). Under the synthetic conditions employed, only the copper(I) compounds proved to be coordination polymers.

RESULTS

Synthesis and structure of copper(II) *complexes*

Addition of one or more methyl substituents to the pyrazine ring disrupted the two-dimensional lattice and no Cu^{2+} coordination polymers were isolated. Two Cu^{2+} complexes of 2-methylpyrazine were isolated with the formulae $Cu(mepz)_2(ClO_4)_2(H_2O)_2$ (**1**) and $Cu(mepz)_4(ClO_4)_2(H_2O)$ (**2**).

The major product of the reaction between $Cu(ClO_4)_2$ and 2,3-dimethylpyrazine was the previously reported Cu^+ complex $Cu_2(2,3\text{-dmpz})_3(ClO_4)_2$ (**10**).[2] Only one Cu^{2+} complex of 2,5-dimethylpyrazine was obtained, $[Cu(2,5\text{-dmpz})_2(H_2O)_4](ClO_4)_2$ (**3**). Trace amounts of minute yellow crystals were also recovered and characterized as $Cu_2(2,5\text{-dmpz})_3(ClO_4)_2$ (**11**) by combustion analysis.

Similar to mepz, reaction of Cu^{2+} with 2,6-dimethylpyrazine gave two Cu^{2+} complexes, $Cu(2,6\text{-dmpz})_2(ClO_4)_2(H_2O)_2$ (**4**), as the major product and trace amounts of $Cu(2,6\text{-dmpz})_4(ClO_4)_2(H_2O)$ (**5**). Compound **5** co-crystallized with **4** and could be recovered only in trace amounts by physical separation under a stereomicroscope. Sufficient material for IR, EPR and combustion analysis was obtained. Magnetic susceptibility data were not collected.

Single-crystal X-ray diffraction studies of compounds **1** and **2** were completed. Figures 1 and 2 show ORTEP drawings of **1** and **2**, respectively. Compound **1** crystallizes in the orthorhombic space group $Pna2_1$. The geometry about the metal ion is roughly octahedral with the ligated pairs of mepz, H_2O and ClO_4 groups mutually *trans* (L—Cu—L bond angles 175–180°). The mepz rings are coordinated through the nitrogen atom distal to the methyl substituent and the rings are nearly coplanar with the methyl groups oriented *anti* to each other. Compound **2** occurs as triclinic crystals, space group $P\bar{1}$. The metal coordination sphere is again roughly octahedral with the four mepz ligands occupying the equatorial positions and a water molecule and one of the perchlorate ions in the axial sites. The CuL_4 species assumes a propellor structure with the pyrazine rings twisted out of the CuN_4 plane by an average of 53° (range 46.6–56.5°).

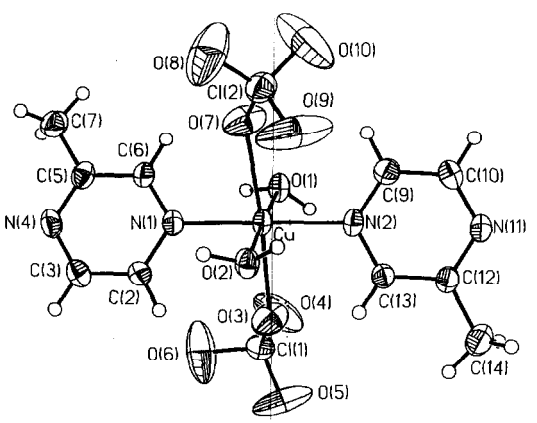

Fig. 1. ORTEP picture of Cu(2-methylpyrazine)$_2$ $(H_2O)_2(ClO_4)_2$ (**1**).

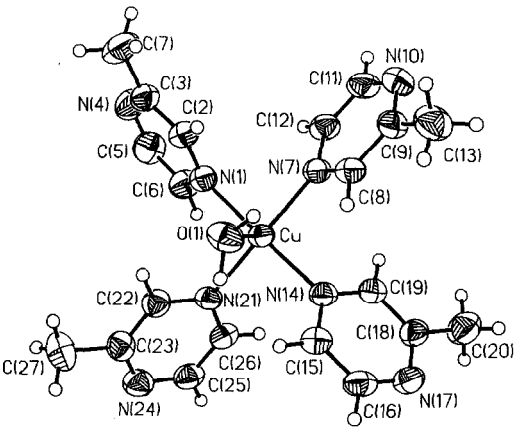

Fig. 2. ORTEP picture of [Cu(2-methylpyrazine)$_4$ $(H_2O)(ClO_4)]ClO_4$ (**2**) (ClO_4 ions have been removed for clarity).

EPR and magnetic data for copper(II) *complexes*

The magnetic susceptibility data of polycrystalline samples of compounds **1**–**4** have been measured between 2 and 300 K. All four of the data sets are similar with temperature intercepts close to zero, indicating the absence of any significant interactions. Least-squares fits to the data have been made to the Curie–Weiss equation $\chi^{-1} = (T-\theta)/C$, where C is the Curie constant $= Ng^2mb2S(S+1)/3kB = 0.375(g/2)^2$ cgs K mol^{-1} for the $S = 1/2$ Cu^{2+} ion. Both C and the Weiss parameter θ were adjusted for the best fit. The parameters (C, θ) were found to be **1**: 0.42(1) emu K mol^{-1}; −0.3(1) K; **2**: 0.43(1) emu K mol^{-1}; −0.2(1) K; **3**: 0.43(1) emu K mol^{-1}; −0.2(1) K; **4**: 0.42(1) emu K mol^{-1}; −0.3(1) K.

EPR spectra of samples **1**–**5** were collected at room temperature. The average g values (and the

corresponding Curie constant) for each compound were determined to be: **1** and **2**: 2.067 (0.40 emu K mol^{-1}, line width = 49.5 and 47.5 G, respectively); **3**: 2.084 (0.41 emu K mol^{-1}, line width = 47.5 G); **4**: 2.085 (0.41 emu K mol^{-1}, line width = 35.1 G); **5**: 2.065 (0.41 emu K mol^{-1}, linewidth = 80.5 G). Although the Curie constants determined by magnetic susceptibilities are higher than those determined by the EPR measurements, the differences are within experimental error.

Synthesis of copper(I) complexes

We recently reported the serendipitous preparation of $Cu_2(2,3\text{-dmpz})_3(ClO_4)_2$ (**10**)[2] and a related report appeared shortly thereafter.[3] Compound **10** formed spontaneously from an aqueous solution of $Cu(ClO_4)_2$ and 2,3-dmpz. Single-crystal X-ray diffraction showed the material to be a polymeric sheet of tri-coordinate copper(I) ions, bridged by the 2,3-dmpz ligands. Reaction with other pz ligands gave no copper(I) products under these conditions.

Previous work by Davies[4] showed that $Cu^{I}L_nClO_4$ complexes could be prepared by treatment of the corresponding copper(II) compounds with SCN^- ions in aqueous solution. Reaction of mepz, 2,3-dmpz or 2,5-dmpz with NaSCN in aqueous solution gave good yields of $Cu_2(mepz)(SCN)_2$ (**6**), $Cu_2(2,3\text{-dmpz})(SCN)_2$ (**7**) and $Cu_2(2,5\text{-dmpz})(SCN)_2$ (**8**). Under the same reaction conditions 2,6-dmpz and tetramethylpyrazine gave CuSCN in nearly quantitative yield.

A second attempt to prepare the complexes $Cu_2(L)_3(ClO_4)_2$ was made using $NaBH_4$ as the reducing agent. $Cu_2(mepz)_3(ClO_4)_2$ (**9**), $Cu_2(2,3\text{-dmpz})_3(ClO_4)_2$ (**10**) and $Cu_2(2,5\text{-dmpz})_3(ClO_4)_2$ (**11**) were recovered in good yields and $Cu_2(2,6\text{-dmpz})_3(ClO_4)_2$ (**12**) was recovered in trace amounts when excess $NaBH_4$ was used. All the copper(I) complexes appear to be stable to air indefinitely in the solid state.

DISCUSSION

Structure of the ligands and reactions with copper(II)

The stoichiometry and stability of the complexes varied substantially with the ligand. 2-Mepz and 2,6-dmpz are similar in differentiating the ring nitrogens based on steric effects. The difference between 2,3-dmpz and 2,5-dmpz is more subtle and is best seen by looking at 2,3-dmpz. The adjacent methyl groups on C(2) and C(3) will exert a steric pressure on each other, bending them towards the nitrogens. Thus, there should be slightly more steric crowding around the nitrogens in 2,3-dmpz than in 2,5-dmpz. Molecular mechanics calculations[5] show the N(1)—C(2)—CH^3 bond angle in 2,3-dmpz (116.3°) to be *ca* 3° smaller than the equivalent angle in 2,5-dmpz (119.3°).

In the copper complexes these steric differences are obvious. Both isolated complexes of mepz, **1** and **2**, show coordination of the Cu^{2+} ion only to the distal nitrogen. Combustion analysis of **4** and **5**, the two complexes of 2,6-dmpz, indicates that they have the same composition as the mepz compounds **1** and **2**, respectively.

In the case of the 2,3- and 2,5-dimethylpyrazines the difference in reactivity with copper(II) is much more dramatic. Reaction of 2,3-dmpz with $Cu(ClO_4)_2$, even in the absence of an added reducing agent, gave the copper(I) complex $Cu_2(2,3\text{-dmpz})_3(ClO_4)_2$ (**10**) as the major product. Traces (20 mg) of an unidentified Cu^{2+} complex were isolated during one attempt, but this could not be reproduced. Conversely, reaction of 2,5-dmpz with $Cu(ClO_4)_2$ produced $[Cu(2,5\text{-dmpz})_2(H_2O)_4](ClO_4)_2$ (**3**) in 69% yield and only traces of **11**, the copper(I) complex analogous to **10**.

For both of these ligands coordination can only occur through a nitrogen adjacent to a methyl substituent. The slight increase in crowding provided by the 2,3-dmpz ligand, relative to 2,5-dmpz, is sufficient to dissociate the perchlorate groups and distort the geometry of the complex towards tetrahedral, whereupon it is reduced to copper(I) and **10** forms. Copper reductions of this type are well documented.[6] For 2,5-dmpz the crowding of the methyl substituents appears to be sufficient to dissociate the perchlorates and replace them with water molecules, but must not cause the degree of distortion that 2,3-dmpz does, as evidenced by the minute amounts of **11** recovered. We note that we are presuming the structure of **3** is $[Cu(2,5\text{-dmpz})_2(H_2O)_4](ClO_4)_2$. The alternative structure $[Cu(2,5\text{-dmpz})_2(H_2O)_2(ClO_4)_2]\cdot 2H_2O$, where the coordination sphere about the metal is similar to **1**, would have the same composition and would also contain only unidentate pyrazine ligands.

IR spectra and structure of the copper(I) complexes

Work by Lever[7] and Ahuja[8] has shown that IR spectra are useful in determining the coordination mode, bridging or unidentate, of pyrazines. Compounds **1**, **2**, **4** and **5** all exhibit the characteristic IR absorbances for unidentate pyrazines. These bands occur at 1256 cm^{-1} in the bis-methylpyrazine complex **1** and as a doublet (1258 and 1250 cm^{-1}) in the tetrakismethylpyrazine complex **2**.[9] This method for determining the coordination mode of

the methylpyrazine ligand may also be demonstrated in the related $Mn(mepz)Cl_2$ (**13**) and $Zn(mepz)_2Br_2$ (**14**) compounds. Compound **13** does not exhibit an absorbance near 1250 cm^{-1}, in agreement with a structure similar to the analogous cobalt(II)[7a] and nickel(II)[7c] complexes, while **14** shows a medium intensity band at 1254 cm^{-1}, suggesting unidentate coordination as is observed for $Zn(mepz)_2Cl_2$ and $Zn(mepz)_2I_2$.[8] For 2,6-dimethylpyrazine compounds the band that characterizes unidentate coordination occurs near 1160 cm^{-1}. Bands are observed at 1165 and 1164 cm^{-1} for **4** and **5**, respectively, but not for the copper(I) complex **12**. All are in agreement with monomeric copper(II) compounds and bridged copper(I) compounds.

The steric differences between 2-methylpyrazine and 2,6-dimethylpyrazine are more pronounced in the copper(I) complexes. 2-Methylpyrazine forms bridging complexes with copper(I) in both the SCN complex **6** and the perchlorate **10**. No IR absorption is seen near 1250 cm^{-1} for either compound. In the thiocyanate complex (**6**) the SCN absorbances at 2110 and 770 cm^{-1} are indicative of bridging SCN groups as well,[6c,7,10] suggesting that these complexes have structures similar to **10** with trigonal coordination spheres for the copper(I) ions. The coordination geometry about the copper atoms in $KCu_2(CN)_3 \cdot H_2O$ is similar.[11]

Reaction of 2,6-dmpz with $Cu(ClO_4)_2$ and $NaBH_4$ gave poor yields of $Cu_2(2,6\text{-dmpz})_3(ClO_4)_2$ (**12**). No absorbance was observed in the IR spectrum of **12** near 1160 cm^{-1}, suggesting bridging pyrazines. As seen in **4** this ligand does form stable complexes in less crowded systems such as $Zn(2,6\text{-dmpz})_2Br_2$ (**15**), where bridging is not required. The strong absorbance at 1162 cm^{-1} in the IR spectrum of **15** confirms the unidentate nature of the 2,6-dmpz.

Only copper(I) complexes of 2,3-dmpz were obtained. In **7** the SCN bands appear at 2100 and 770 cm^{-1}, indicating bridging thiocyanates. The IR bands arising from the ligand resemble those of the crystals of **10**, which contains bridging 2,3-dmpzs and thus we conclude the ligand is bridging in **7** as well. A weak IR band is observed at 1250 cm^{-1} in all our 2,3-dmpz compounds, indicating that although the absence of this band may characterize a bridging 2,3-dmpz, its presence does not exclude bridging, as suggested earlier.[12]

Of greater interest is the observation that the IR spectrum of **10**, as prepared via addition of $NaBH_4$, does not match the spectrum of the crystals of **10** that grew spontaneously, although they have the same composition according to combustion analysis. The differences are most obviously in the perchlorate regions where the hydride reduction product shows bands at 1140s, 1110s, 1080s, 632mw, 622m cm^{-1}, while the spontaneously generated material shows only two bands, a strong broad absorbance centred at 1090 cm^{-1} and a sharp medium intensity peak at 622 cm^{-1}. The existence of two phases of this material was confirmed by powder X-ray diffraction. The observed low-angle lines in a powder spectrum of **10**, from hydride reduction, did not match the values calculated based on the crystal structure of the spontaneous product.[13]

The copper(I) thiocyanate of 2,5-dmpz (**8**) also contains bridging thiocyanate groups, as indicated by the IR spectrum (2105 and 765 cm^{-1}). The presence of a bridging 2,5-dmpz in **8** is also indicated by the presence of only a single absorbance (at 1068 cm^{-1}) in the 1050–1080 cm^{-1} range.[7] In the perchlorate complex (**11**) it also appears that only one absorbance is presented (at 1060 cm^{-1}), but a second band could be obscured by the strong ClO_4 peak at 1090 cm^{-1}. This is also true for $[Cu(2,5\text{-dmpz})(H_2O)_4](ClO_4)_2$ (**3**). However, a different change in the IR spectrum is readily detected. A single peak is observed in both **8** and **11** at 1375 and 1382 cm^{-1}, respectively, which we assign to the symmetric bending mode of the methyl C—H bonds. In **3** this band is split into two peaks at 1372 and 1382 cm^{-1}. If the 2,5-dmpz is indeed unidentate in **3**, then the two methyl groups would be inequivalent and two absorbances would be expected. Unfortunately, the absorbances in this region for the tetrahedral zinc compound $Zn(2,5\text{-dmpz})_2Br_2$ (**16**) do not resemble those of the copper complexes and cannot be used to confirm or deny this means of distinguishing the unidentate and bridging modes of 2,5-dmpz.

Magnetic properties

The magnetic susceptibility data for the copper(II) compounds show the absence of significant magnetic interactions. This result is not unexpected, given the known structures. The closest metal–metal distances in **1** and **2** correspond to unit cell translations of 4.8 and 10.1 Å, respectively. Long metal–metal distances by themselves do not imply weak magnetic interactions. A copper dimer has recently been reported in which the exchange interaction has a strength of 70 cm^{-1}, although the copper ions are separated by 11.3 Å.[14] The extended conjugated network provided excellent overlap between the magnetic *d*-orbitals. In the present compounds the only possible conjugated pathways would be through the methyl-substituted pyrazines. The copper ions are monomeric units, with only weak dipolar interactions to couple them.

CONCLUSIONS

Addition of one or more methyl group to the pyrazine ring provides sufficient steric hindrance to prevent formation of the desired two-dimensional copper(II) coordination polymer when isolated from aqueous solution. A variety of monomeric compounds are formed containing either two or four pyrazine ligands and all are paramagnetic. The methylpyrazines do form bridging coordination polymers with copper(I) ions and these compounds may be readily produced by the addition of reducing agents such as SCN^- or H^-. The bridged complexes most likely result from the reduced steric requirements of the tri-coordinate copper(I) ions. Further work in this area is in progress involving the use of anhydrous conditions and alternate geganions.

EXPERIMENTAL

2-Methylpyrazine, 2,5-dimethylpyrazine, 2,6-dimethylpyrazine and 2,3,5,6-tetramethylpyrazine were purchased from Aldrich Co. and used without further purification. $Cu(ClO_4)_2 \cdot 6H_2O$ was purchased from Aesar and dried under vacuum prior to use. IR spectra were taken on a Perkin–Elmer 467 spectrophotometer in a KBr or KCl matrix[15] and calibrated against polystyrene (br = broad, sh = shoulder, d = doublet, s = strong, w = weak). Elemental analyses were performed by the University Instrumentation Centre, University of New Hampshire, Durham, NH. All compounds gave acceptable analyses ($\pm 0.4\%$).

Diaquobis(2-methylpyrazine)bisperchloratocopper(II) (**1**)

$Cu(ClO_4)_2 \cdot 6H_2O$ (3.70 g, 10 mmol) was dissolved in H_2O (8 cm^3) and added to a solution of 2-methylpyrazine (1.88 g, 20 mmol) dissolved in H_2O (5 cm^3). The mixture was allowed to stand at room temperature. After 1–2 days blue crystals formed, which were collected by filtration, washed briefly with cold H_2O, followed by acetone and air-dried to give 0.82 g of compound **2** (25%). Further evaporation at room temperature over 2 weeks gave blue crystals of **1**, which were isolated as above to give 1.46 g (55%, corrected for isolated **2**). IR (KCl): 3400m br, 1592m, 1520w br, 1480m, 1440m, 1400m, 1375w, 1300m, 1256w, 1175s, 1110vs br, 1025s, 940w, 910w, 830s, 735m, 625s, 445w, 415m cm^{-1}.

Aquotetrakis(2-methylpyrazine)perchloratocopper(II) *perchlorate* (**2**)

$Cu(ClO_4)_2 \cdot 6H_2O$ (1.85 g, 5.0 mmol) was dissolved in H_2O (10 cm^3) and added to a solution of 2-methylpyrazine (1.88 g, 20 mmol) dissolved in H_2O (5 cm^3). After standing at room temperature for 10 days, blue crystals of **2** were recovered, as described above; yield 1.2 g (37%). Further evaporation gave an additional 1.6 g (49%) of somewhat less pure material. IR (KCl): 3400m br, 1650vw br, 1595w, 1525w, 1480m, 1445m, 1400m, 1375w, 1300m, 1260w, 1250w, 1175m-s, 1140s, 1100vs br, 1080sh, 1025m, 940w, 910w, 830s, 735m-w, 635sh, 625s, 495w, 415m, 400m cm^{-1}.

Tetraaquobis(2,5-dimethylpyrazine)copper(II) *bisperchlorate* (**3**) *and tris(2,5-dimethylpyrazine)-dicopper*(II) *bisperchlorate* (**11**)

$Cu(ClO_4)_2 \cdot 6H_2O$ (3.70 g, 10.0 mmol) was dissolved in H_2O (5 cm^3) and added to a solution of 2,5-dimethylpyrazine (2.16 g, 20 mmol) dissolved in H_2O (5 cm^3). After standing at room temperature for 2 weeks large blue crystals were deposited on the bottom of the beaker and trace amounts of tiny yellow crystals were observed floating in the supernatant liquid. The supernate was decanted away from the blue solid and filtered to give a yellow solid (**11**); yield 0.018 g (< 1%), which will be described below. The blue crystals of **4** were recorded as described above; yield 3.82 g (69%). IR (KCl): 3400w br, 3040w, 1500m, 1480sh, 1460w, 1435w, 1382w, 1372w, 1350m, 1140–1080vs br, 1040m, 990m, 940w, 878m, 622s, 435m cm^{-1}

Diaquobis(2,6-dimethylpyrazine)bisperchloratocopper(II) (**4**) *and aquotetrakis(2,6-di-methylpyrazine)-perchloroatecopper*(II) *perchlorate* (**5**)

$Cu(ClO_4)_2 \cdot 6H_2O$ (3.70 g, 10.0 mmol) was dissolved in H_2O (5 cm^3) and added to a solution of 2,6-dimethylpyrazine (2.16 g, 20 mmol) dissolved in H_2O (10 cm^3) The solution immediately became a very dark blue and crystals formed within 7 min after the addition was complete. After 10 min the solution was filtered and the precipitate was washed with cold water, followed by acetone and allowed to air dry to give **4** as a blue solid; yield 1.31 g (25%). The filtrate and the aqueous wash were combined and left to evaporate. After standing at room temperature for 1 week blue crystals were recovered as described above; yield 2.91 g (57%, based on **4**). Upon examination under a stereomicroscope, this material proved to be a mixture of two different substances, greater than 95% (estimated visually), blue crystals of **4** and deep violet crystals of **5**. Sufficient crystals of **5** for IR and combustion analysis were carefully separated by hand under the microscope. Data for **4**: IR (KBr): 3450br, 3090w, 1600w, 1530m, 1460sh, 1450m, 1425m, 1410m,

1380m, 1290w, 1255m, 1165s, 1125s br, 1100sh, 1050m-s, 1035m-s, 950w, 932w, 927w, 875w, 868m, 760w, 735m, 635sh, 625m-s, 490m cm^{-1}. For **5**: IR (KBr): 3450br w, 3090w, 1590w, 1530m, 1455m br, 1425m, 1410m, 1380m, 1365w, 1290w, 1255m, 1165s, 1140s, 1100vs br, 1025m, 940w d, 865m, 760w, 735m-w, 635sh, 625m-s, 490m-w cm^{-1}.

2-*Methylpyrazinobisthiocyanatodicopper*(I) (**6**)

$Cu(ClO_4)_2 \cdot 6H_2O$ (1.85 g, 5.00 mmol) was dissolved in H_2O (5.0 cm^3) and added to a stirred solution of 2-methylpyrazine (1.88 g, 20.0 mmol) in H_2O (5.0 cm^3). A solution of NaSCN (0.40 g, 5.0 mmol) in H_2O (5 cm^3) was then added, generating an immediate dark green–brown precipitate. The mixture was stirred for 2 h and then filtered to yield a dirty brown solid. Repeated washing with water and acetone gave an orange–red solid; yield 0.65 g (77%). IR (KBr): 2110vs, 1510w, 1470m, 1442m, 1385w, 1300m, 1175m, 1150m, 1110m, 1080m-s, 1035m, 990w, 960w, 835m, 770w, 625w, 500w, 420m cm^{-1}.

2,3-*Dimethylpyrazinobisthiocyanatodicopper*(I) (**7**)

Prepared as in **6** to give a dark yellow solid; yield 0.80 g (91%). IR (KBr): 2100vs, 1465w, 1432w, 1402m, 1372w, 1257w, 1190m, 1182m, 1012w, 972w, 812w, 770m, 485m cm^{-1}.

2,5-*Dimethylpyrazinobisthiocyanatodicopper*(I) (**8**)

Prepared as in **6** to give a yellow solid; yield 0.77 g (87%). IR (KBr): 2105s, 1480m, 1430w br, 1375w, 1330w, 1160w, 1068w, 1035vw, 765m-w, 430w cm^{-1}

Tris(2-*methylpyrazino*)*dicopper*(I) *perchlorate* (**9**)

$Cu(ClO_4)_2 \cdot 6H_2O$ (1.85 g, 5.00 mmol) was dissolved in H_2O (5.0 cm^3) and added to a stirred solution of 2-methylpyrazine (0.70 g, 7.5 mmol) in H_2O (5.0 cm^3). $NaBH_4$ (0.19 g, 5.0 mmol) was added in portions to the mixture. The originally green mixture turned brown and a precipitate formed. The mixture was stirred overnight and the resulting solid was collected by vacuum filtration, washed with H_2O and acetone and then air-dried to give a yellow solid; yield 0.84 g (62%). IR (KBr): 3115vw, 3080vw, 3045vw, 1605w, 1510w, 1485m, 1480sh, 1450m, 1402m, 1380w, 1310m, 1180m, 1167m, 1155m, 1100vs br, 1050s br, 925w, 845w, 830w, 730vw, 620s, 695vw, 475vw, 437m, 412w cm^{-1}.

Tris(2,3-*dimethylpyrazino*)*dicopper*(I) *perchlorate* (**10**)

Prepared as in **9** to give a yellow solid; yield 0.79 g (54%). IR (KBr): 3080w, 1435m br, 1405s, 1255w, 1175m-s, 1142s, 1100vs br, 1018m, 990m, 972m, 942w, 862w, 638m, 630s, 480w, 440w cm^{-1}. IR of spontaneously formed product (KBr): 3080w, 1437s, 1408s, 1262w, 1255w, 1190sh, 1180s, 1090vs br, 1010m-s br, 675s, 858m, 840m, 750w br, 620s, 490m, 470w cm^{-1}.

Tris(2,5-*dimethylpyrazino*)*dicopper*(I) *perchlorate* (**11**)

Prepared as in **9** to give a yellow solid; yield 0.34 g (23%). This compound also crystallizes in very low yield as a by-product in the synthesis of **3**. IR (KBr): 1500m, 1490sh, 1440w br, 1382w, 1340w, 1162m, 1140m, 1105s, 1095s, 1060m-s, 1045m, 970w, 930w, 620m, 420w br cm^{-1}. Found: C, 33.23; H, 3.71; N, 13.08%.

Tris(2,6-*dimethylpyrazino*)*dicopper*(I) *perchlorate* (**12**)

Prepared as in **9**. A substantial amount of the material dissolved in the H_2O wash and only traces of the product were recovered. IR (KBr): 1535m, 1450w br, 1412m, 1380w, 1280vw, 1250m, 1140m-s, 1105s, 1095s, 1020m-w, 940w, 870w, 735w, 632w, 625m, 462w cm^{-1}.

Dichloro(2-*methylpyrazine*)*manganese*(II) (**13**)

$MnCl_2 \cdot 4H_2O$ (2.69 g, 10.0 mmol) was dissolved in absolute ethanol (13 cm^3) and added to a stirred solution of 2-methylpyrazine (1.88 g, 20.0 mmol) in absolute ethanol (3.0 cm^3) generating an immediate precipitate. The mixture was filtered, the precipitate was washed with ethanol and air dried to give a white solid; yield 2.57 g (36%). IR: 3100w, 1600w, 1510w, 1475m, 1440m, 1405m, 1385m, 1305w, 1180m, 1160s, 1080s, 1035s, 820s, 740w, 480m, 420s cm^{-1}. Found: C, 27.50; H, 2.78; N, 12.69%.

Dibromobis(2-*methylpyrazine*)*zinc*(II) (**14**)

Prepared as in **13** and recrystallized from THF/Et_2O to give a white solid; yield 0.30 g (36%). IR: 3050w br, 1595w, 1515m br, 1477s, 1440s, 1490s, 1375s, 1297m, 1254m, 1165s br, 1077s, 1040sh, 1022s, 980m, 920w, 835s, 737m, 660w, 495w, 475m, 405s br cm^{-1}.

Dibromobis(2,6-*dimethylpyrazine*)*zinc*(II) (**15**)

Prepared as in **13** to give a white solid; yield 0.125 g (14%). Additional material of slightly lower purity can be recovered by further evaporation of the filtrate. IR: 3050w, 2960w, 2920w, 1530m, 1420s br, 1400sh, 1370m, 1288m, 1255m, 1175sh, 1162vs, 1020s, 942w, 870m, 755m, 735m, 555w, 470m, 460m cm^{-1}.

Dibromobis(2,5-*dimethylpyrazine*)*zinc*(II) (**16**)

Prepared as in **13** to give a white solid; yield 0.248 g (27%). IR: 1645m, 1585m, 1535sh, 1525w, 1485s, 1415m, 1305m, 1222s, 1180m, 1040w, 665w, 652w, 580m, 565m, 480w br cm^{-1}.

Magnetic data collection

Measurements of magnetic susceptibility were made using a Foner-type vibrating sample magnetometer (EG&G PAR Model 155) using a custom Helium cryostat.[16] Temperatures were measured with a Ga—Al—As diode, which had been calibrated *in situ* against magnetic standards. Magnetic field measurements were performed with a calibrated Hall probe. All data were corrected for diamagnetism and the temperature-independent paramagnetism of copper(II), taken as 60×10^{-6} cgs mol^{-1}. The EPR spectra were performed using a Varian E-9 spectrometer operating at 9.3 GHz. DPPH was used as an internal standard.

X-ray structure determination

The data collections were performed on an upgraded Syntex $P2_1$ diffractometer, employing Mo-K_α radiation ($\lambda = 0.71069$) and a graphite monochromator. The orientation matrix and lattice parameters were optimized from a least-squares calculation on 25 centred reflections with high Bragg angles (35–40° (**1**), 33–35° for **2**). Two standard reflections were monitored every 96 reflections. All data reduction, structure solution and refinement and graphics were performed using SHELXTL 5.1 software.[17] Crystallographic data may be found in Table 1. Selected bond distances and angles are given in Table 2. Additional structural details may be found in the supplementary material and details of the refinement procedure are available from the authors.

CHARACTERIZATION OF REACTION PRODUCTS OF 2-THIENYLAMINE AND 2-FURFURYLAMINE WITH BIS(ACETYLACETONATO)PALLADIUM(II)

MASAKAZU KITA and MATSUO NONOYAMA*

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464-01, Japan

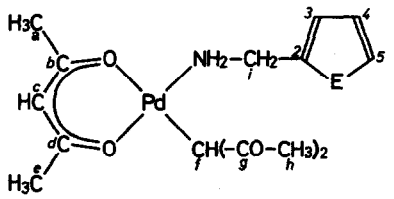
(*Received* 11 *December* 1992; *accepted* 8 *January* 1993)

Abstract—2-Thienylamine (Hata) and 2-furfurylamine (Hafa) reacted with bis(acetylacetonato)palladium(II) [Pd(acac)$_2$] in dichloromethane at room temperature to give Pd(acac)$_2$(Hata) and Pd(acac)$_2$(Hafa), respectively. In refluxing toluene the former amine gave [Pd(acac)(ata)]$_2$, while with the latter no further reaction took place. In Pd(acac)$_2$(Hata) and Pd(acac)$_2$(Hafa) the amines were coordinated through the amino group, with one acac ligand as an O—O chelate and the other γ-carbon bonded. X-ray analysis revealed that [Pd(acac)(ata)]$_2$ was a dimer where the palladium atoms were bridged by deprotonated amino groups and coordinated with O—O chelating acac ligands.

A large number of cyclometallated benzene derivatives have been reported.[1] Benzene derivatives containing a tertiary amino group are easily cyclopalladated, but those containing a primary amino group are far more difficult.[1] Bis(acetylacetonato)-palladium(II) [Pd(acac)$_2$] has been reported[2] to be capable of cyclopalladating a primary amine, benzylamine, which is not cyclopalladated with palladium(II) chloride. This fact stimulated us to attempt the cyclopalladation of 2-thienylamine (abbreviated as Hata) and 2-furfurylamine (Hafa), which are the heteroaromatic equivalents of benzylamine, since we have been interested in cyclometallation of heteroaromatic compounds.[3] The two heteroaromatic amines are not cyclopalladated, contrary to our expectation, coordinating only through amino groups. Cyclopalladation of Hafa and Hata with Pd(acac)$_2$ is hence more difficult than that of benzylamine.

RESULTS AND DISCUSSION

Pd(acac)$_2$ reacted with Hata and Hafa at room temperature to give Pd(acac)$_2$(Hata) and Pd(acac)$_2$(Hafa), respectively. The IR spectra show the presence of O—O chelated acac and γ-carbon bonded acac ligands: 1517, 1551, 1675 cm^{-1} for the former complex and 1518, 1565, 1673 cm^{-1} for the latter. The bands of the amino group are at 3225, 3145 [ν(NH)], 1633 [$\delta(NH_2)$] for the former and 3217, 3150, 1620 cm^{-1} for the latter. These bands are close to those of Pd(acac)$_2$(Hbza) (Hbza = benzylamine).[4] Structure **I** is thus proposed (E = S and O), where one acac is O—O chelated and the other γ-carbon bonded. The ^{1}H and ^{13}C NMR spectra of the two complexes (Table 1) are reasonably explained on the basis of structure **I**: the signals of



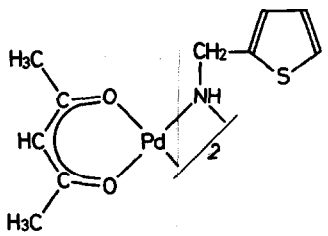
I(E = O, S)

both O—O chelated and γ-carbon bonded acacs are observed and their chemical shifts similar to those of the corresponding signals of Pd(acac)$_2$(Hbza). All the signals of the heteroaromatic amines remain intact with changes in chemical shift.

The reaction of Pd(acac)$_2$ with Hata in refluxing toluene gave [Pd(acac)(ata)]$_2$, in which Hata was deprotonated but the reaction with Hafa did not lead to deprotonation. Under these reaction con-

* Author to whom correspondence should be addressed.

ditions benzylamine (Hbza) was reported to be cyclopalladated to form Pd(acac)(bza)[2]. No ^{13}C NMR spectrum of $[Pd(acac)(ata)]_2$ was available because of its low solubility. The IR spectrum reveals the presence of only an O—O chelated acac (1510, 1570 cm^{-1}) and an N—H group (3210 cm^{-1}). The ^1H NMR spectrum (Table 1) is consistent with the result, but no N—H signal is detected. The doublet of the CH_2 signal ($J = 4.4$ Hz) may result from coupling with the N—H group. All the thiophene ring signals remain: there is no possibility of thiophene-ring cyclopalladation. Structure **II** was proposed and confirmed by X-ray analsyis: the conformation (*syn* or *anti*) of the bridging part, $Pd_2(\mu\text{-}NHR)_2$, was determined (R = 2-thienyl). A similar dimer has been obtained by the reaction of $Pd(acac)_2$ with aniline, but no structural details were reported.[5]



II

The bond distances and angles of $[Pd(acac)(ata)]_2$ are given in Table 2 and the molecular structure, with atom-numbering scheme, is shown in Fig. 1. Two square-planar four-coordinated palladium atoms are bridged by deprotonated amino groups and the mid-point of the two palladium atoms is a centre of symmetry. There is nothing unusual on coordination of the acac ligands (Table 2). The bridging nitrogen atom is significantly flattened [Pd—N—C(5) angles, 119.6(6) and 118.5(5)°, are larger than the tetrahedral angle 109.5°] and the conformation of the $Pd_2(NHR)_2$ ring is *anti*: the two R groups are on different sides of the rhombic Pd_2N_2 plane (R = 2-thienyl group). The Pd—N bond distances are in the normal range found for aliphatic amine palladium(II) complexes.[6] The dihedral angle of the thiophene ring with respect to

the coordination plane is 77.8(3)° and there is no interaction between the palladium and sulphur atoms [the distance is 3.641(6) Å]. The Pd—Pd separation is 3.0633(9) Å, suggesting no bonding between the two palladium atoms.

EXPERIMENTAL

Measurements

Measurements were performed using the methods reported previously.[3]

Preparation

Pd(acac)$_2$(Hafa) *and* Pd(acac)$_2$(Hata). A mixture of Pd(acac)$_2$(305 mg, 1 mmol) and Hafa (117 mg, 1.2 mmol) or Hata (136 mg) in dichloromethane (20 cm^3) was stirred for a few hours at room temperature and mixed with hexane (30 cm^3). The filtered mixture was evaporated to a small volume to precipitate yellow crystals, which were collected, washed with hexane and dried in air. Pd(acac)$_2$(Hafa): yield 85% and m.p. 123°C (decomposed). Found: C, 44.7; H, 5.3; N, 3.4. Calc. for $C_{15}H_{21}NO_5Pd$: C, 44.8; H, 5.3; N, 3.5%. Pd(acac)$_2$(Hata): yield 60% and m.p. 133°C (decomposed). Found: C, 43.0; H, 5.0; N, 3.2. Calc. for $C_{15}H_{21}NO_4SPd$: C, 43.1; H, 5.1; N, 3.4%.

Pd(acac)(ata). A mixture of Pd(acac)$_2$ (305 mg, 1 mmol) and Hata (113 mg, 1 mmol) in toluene (15 cm^3) was refluxed for 5 h with stirring and allowed to cool. A yellow product crystallized, which was collected, washed with toluene and dried in air. The product was recrystallized from dichloromethane. Crystals suitable for X-ray diffraction were obtained upon slow evaporation of a dichloromethane solution. Yield 38% and m.p. 179°C (decomposed). Found: C, 37.8; H, 4.1; N, 4.3. Calc. for $C_{10}H_{13}NO_2SPd$: C, 37.8; H, 4.1; N, 4.4%.

X-ray analysis of [Pd(acac)(ata)]$_2$

Diffraction data of a crystal with approximate dimensions 0.1 × 0.2 × 0.3 mm^3 were collected on a Rigaku AFC-5R diffractometer with graphite Mo-K_α radiation (λ = 0.71069 Å). Crystal data: monoclinic, $P2_1/n$, a = 10.934(2), b = 5.611(1), c = 19.565(2) Å, β = 95.99(1)°, V = 1193.8(3) Å^3, Z = 2, D_x = 1.77 g cm^{-3}, μ(Mo-K_α) = 16.8 cm^{-1}. Within the range $2\theta < 60°$, 2341 independent reflections with $|F_o| > 3\sigma(|F_o|)$ were obtained. A ψ scan empirical absorption correction was applied. All the computations were performed on a HITAC M-680H computer at the Computer Center of the Institute for Molecular Science, using the Universal Crystallographic Computation Program System UNICS III.[7] The structure was solved by the usual heavy-atom method. The positions of all the non-hydrogen atoms were identified in subsequent Fourier maps. The hydrogen atoms could not be located by the difference Fourier synthesis. The final R was 0.051 for 1496 unique reflections. The bond lengths and angles, atomic parameters and anisotropic tem-

perature factors are given as supplementary material.

Acknowledgement—We wish to thank the Institute for Molecular Science (Okazaki) for the use of X-ray measurement and computation facilities.

(*Received* 27 *November* 1992; *accepted* 8 *January* 1993)

Abstract—The crystal structure of the complex $Li_4[Fe(C_2O_4)_3]Cl \cdot 9H_2O$ has been determined by X-ray diffraction analysis. It is composed of sheets perpendicular to the *c*-axis of the hexagonal cell. In the direction of *c*, short and long intervals, occupied by hydrated lithium ions, alternate between the sheets. The coordination is distorted octahedral for the iron ion, the chlorine ion and one of the lithium ions. It is nearly tetrahedral for the other lithium ions. The Mössbauer spectra are characterized by an asymmetric quadrupole doublet arising from a local distorsion of the iron octahedral coordination and the presence of a relatively fast spin–spin relaxation process.

The tris oxalato complexes, $[M(C_2O_4)_3]^{3-}$ (M = Al, Fe, Cr, Co, Rh, Ir), have played an important role in coordination chemistry for a long time. Since the discovery of the Mössbauer effect, particular interest has been devoted to tris(oxalato)ferrate(III) complexes, but, although Mössbauer spectroscopy has been widely applied in numerous radiolysis, photolysis and thermal decomposition studies,[1–14] little attention has been paid to chemical bond and structural problems. This is presumably due to the fact that the spectra of these complexes are subject to electronic paramagnetic relaxation[15–17] and need, therefore, for their interpretation knowledge of the iron interionic distances, which are well established only for few compounds.[18,19]

In this paper the detailed crystallographic structure of a novel tris(oxalato)ferrate(III) complex, $Li_4[Fe(Ox)_3]Cl \cdot 9H_2O$, is determined by X-ray diffraction analysis (XRD) and the Mössbauer absorption spectra of ^{57}Fe in this compound are interpreted in connection with the crystallographic data.

EXPERIMENTAL

Synthesis and chemical analysis

The green complex of lithium tris(oxalato) ferrate(III) has been prepared by mixing equal volumes of a 3 M lithium oxalate solution and 1 M iron(III) chloride solution. The slow evaporation of this solution in the dark gives rise to the formation of two different hydrates of the complex $Li_4[Fe(Ox)_3]Cl$, depending on the crystallization temperature. A dodecahydrate crystallizes below 18°C, whereas the nonahydrate is formed at *ca* 28°C. The crystals of both compounds are emerald green and present a triangular prismatic shape. The dodecahydrated crystals are not stable at room temperature and transform readily in a few days into the nonahydrate, without apparent change of external morphology, but an apparition of opacity. The crystals of nonahydrate obtained in this way present

* Author to whom correspondence should be addressed.

a flake-like texture parallel to the triangular plane and become very easy to cleave along this direction. As a result of this transformation very thin single crystals can be obtained, which are suitable for XRD and Mössbauer measurements.

The chemical composition of $Li_4[Fe(Ox)_3]Cl \cdot 9H_2O$ was determined by elemental analysis of iron, oxalate and chloride ions and are in good agreement with the above formula (W%, Fe, Cl^-, $C_2O_4^{2-}$; th. 10.2, 6.5 and 48.4; obs. 10.1, 6.6 and 47.9).

The water of crystallization was determined by thermogravimetric analysis and the observed weight loss corresponding to the dehydration (29.5%) is consistent with the theoretical value (29.7%).

Crystal structure determination of $Li_4[Fe(C_2O_4)_3]Cl \cdot 9H_2O$

The crystal used had the shape of a triangular base prism with the dimensions 0.65 (edge of the triangle) × 0.2 mm (height of the prism). Lattice parameters were refined using 16 reflections in the range $9° \leqslant 2\theta \leqslant 28°$. Intensity data were collected at room temperature on a Huber four-circle diffractometer, using graphite monochromatized Mo-K_α radiation ($\lambda = 0.71069$ Å). A standard reflection (4, 1, 6) was checked every 50 reflections and showed no significant deviation. 2918 reflections were collected with $\sin\theta/\lambda \leqslant 0.617$ Å^{-1}, providing 1616 unique reflections ($R_{merge} = 0.023$), of which 1360 with $I \geqslant 2.5\sigma(I)$ were considered as observed and used in further calculations. The crystal data are given in Table 1.

It is worth remarking that according to the compilation of Padmaja *et al.*,[20] this is a unique occurrence of the space group (*P*-6*c*2) among organo carbon compounds. It appears that in the meantime the 1992 release of the Cambridge Structural Database[21] contains only two structures belonging to this space group.

The structure was solved by heavy atom and Patterson methods using SHELXS86.[22] An anisotropic least-squares refinement (SHELX76[23]) using *F* converged to $R = 0.046$, $Rw = 0.052$ for 1360 observed reflections. The maximum and minimum heights in final difference-Fourier synthesis are 1.04 (close to Cl^- ion) and −0.53 e Å^{-3}. The atomic scattering factors are from the International Tables for X-ray Crystallography (1974, Vol. IV). The atomic parameters, lists of anisotropic thermal parameters and observed and calculated structure factors have been deposited as supplementary material with the Editor, from whom copies are available on request.

Table 1. Crystal data and structure refinement of $Li_4[Fe(C_2O_4)_3]Cl \cdot 9H_2O$

Formula	$C_6H_{18}O_{21}Li_4FeCl$

Mössbauer measurements

Mössbauer spectra of $Li_4[Fe(OX)_3]Cl \cdot 9H_2O$ were obtained with a polycrystalline sample, as well as with single crystals and in the latter case they were recorded as a function of the angle θ between the gamma ray beam and the principal crystallographic axis *c*. The thickness of the samples was of the order 0.5 mm in order to have an effective thickness of 9 mg of natural iron per square centimeter. The measurements were performed at room temperature with an ordinary constant-acceleration spectrometer using a ^{57}Co(Rh) source. Experimental data were resolved into Lorentzian lines using a conventional iterative least-square fit program.

RESULTS AND DISCUSSION

Description of the structure

The structure can be described as a succession along the *c*-axis of two-dimensional sheets extending infinitely in the *a*,*b*-plane. The approximate *z*-coordinate of the sheets in one unit-cell are successively 0.10, 0.40, 0.60 and 0.90. The separations between the sheets alternate between a short distance (*ca* $0.2 \times c \approx 5.3$ Å) and a long distance (*ca* $0.3 \times c \approx 8.0$ Å).

Each sheet corresponds to the chemical com-

position $Li^+[Fe(C_2O_4)_3]^{3-}Cl^- \cdot 6H_2O$. The Fe^{3+}, Li^+(1) and Cl^- ions lie on the three different three-fold axes present in the space group, respectively, at (1/3,2/3,z), (0,0,z) and (2/3,1/3,z). The cohesion inside the sheets is principally secured by the oxalate ions. For each of them two oxygen atoms belonging to two different carboxylate groups are bound to the iron ion, and the two remaining ones to the lithium ion. Schematically this could be compared to an assembly of hexagonal tiles in which the vertices are alternatively occupied by iron and lithium ions and the edges by the oxalate ions. A hexahydrated chlorine atom lies on the centre of the hexagon according to the following scheme.

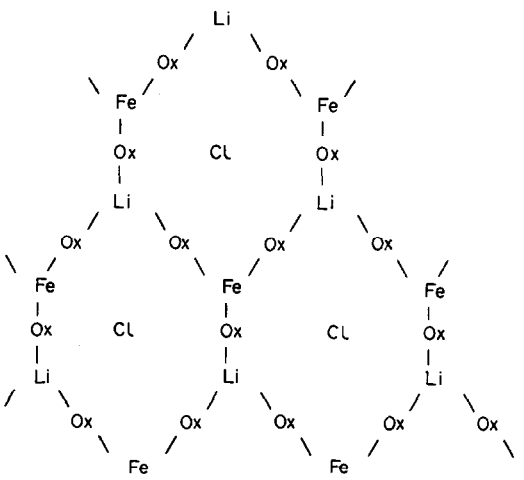

Fig. 1. presents one of these sheets with the numbering of the atoms (Program ORTEP[24]).

Such an arrangement in two-dimensional sheets has been described, for example in hexaaquatris(oxalato)dipraseodymium(III) pentahydrate[25] and in hexaaquatris(oxalato)dineodymium(III) 4.5 hydrate,[26] where both sides of the oxalate ions are bound to the same metal. It differs markedly from the situation observed in other tris(oxalato)ferrate (III) compounds of monovalent cations, $(NH_4)_3[Fe(C_2O_4)_3]3H_2O$[19] and $K_3[Fe(C_2O_4)_3]3H_2O$,[18] where discrete complex anions, $[Fe(C_2O_4)_3]^{-3}$, are observed. The latter situation is also usually found in similar complexes with other M^{III} atoms such as Cr,[27-29] Mn,[30] Al[29] and Ti.[31]

The coordination of Fe^{3+} is a distorded octahedron composed of the oxygen atoms O(1) and O(4) of three oxalate ions related by a three-fold axis through the central ion. A very similar coordination is observed around Li^+(1) with the two other oxygen atoms of the oxalate ion O(2) and O(3). The distances and angles are given in Table 2. It is worth noting that the two oxygen atoms coordinating the iron ion correspond to the longest C—O bonds in the oxalate ion. The oxalate ions are planar within experimental error (largest deviation from mean plane < 0.008 Å). The Fe^{3+}—O values (2.020 and 2.023 Å) are comparable to the mean distance observed in potassium tris(oxalato)ferrate trihydrate (2.037 Å) by Herpin[18] and in ammonium tris(oxalato)ferrate trihydrate (2.002 Å) by Merrachi *et al.*[19] The deformation of the octahedra can be related to the constraints imposed on the distance between the two oxygen atoms belonging to the same oxalate ion. In a regular octahedron the length of the edges should be the mean metal–oxygen dis-

tance multiplied by $\sqrt{2}$, i.e. 2.86 and 3.05 Å for the iron and lithium ions, respectively. The corresponding observed distances are O(1)···O(4) 2.61 and O(2)···O(3) 2.73 Å. The coordination of the chloride ions is also octahedral, composed of the water molecules O(5) and O(6) and four symmetry-related water molecules. Hydrogen bonds exist between these water molecules and the oxalate oxygens: O(5)—O(1) = 2.99, O(5)—O(2) = 3.01 and O(6)—O(3) = 2.82 Å, improving the intra-sheet cohesion. As will be described in the next paragraphs, these water molecules also take part in the connections between the sheets.

A quantitative description of the deformation of the octahedra has been proposed by Muetterties and Guggenberger.[32] As shown in Table 3 this description includes a dihedral angle (ϕ), describing the relative twist of opposed triangular faces of the octahedron and angles (δ) between the normal to the faces. In this way the coordination figure is described as an intermediate between $O_h(D_{3d})$ and D_{3h}. The values describing the polyhedron around the iron atom can be compared to the values computed by Merrachi *et al.*[28] in tris(oxalato)-ferrate(III) and -chromate(III) of monovalent cations. Interestingly, the values observed by these authors around chromium [$48 \leqslant \phi \leqslant 50$; $60 \leqslant \delta(b_1) \leqslant 63$; $78 \leqslant \delta(b_2) \leqslant 81$] resemble much more our observations than the values given around iron [$\phi = 40$; $51 \leqslant \delta(b_1) \leqslant 53$; $85 \leqslant \delta(b_2) \leqslant 86$].

Table 3. Description of the deformations of (a) the octahedra and (b) the tetrahedra using the symbolism proposed by Muetterties and Guggenberger.[32] For comparison, the extreme situations, regular octahedron (O_h) and trigonal prism (D_{3h}) for (a), regular tetrahedron (T_d) and square planar (D_{4h}) for (b), are indicated

(a)	Φ	$\delta(b1)$	$\delta(b2)$	δ(remaining)
O_h	60.0	70.5	70.5	70.5
Fe	46.0	59.3	82.2	70.5; 71.0

Li(3)	81.9; 86.0			115.0; 115.0; 118.1; 118.1
D_{4h}	0			180

The space between two adjacent sheets corresponding to a short distance (5.3 Å) is occupied by a lithium ion, $Li^+(2)$, lying on a two-fold axis $(x,-x,0)$, The distorted tetrahedral coordination (see Table 3) of this ion includes O(2), an oxygen atom of the oxalate ion, O(5), a water molecule around the chlorine ion, and two symmetry related oxygen atoms. This lithium ion is thus directly bound to four oxygen atoms belonging to two different sheets, justifying the short distance observed.

The remaining lithium ion, $Li^+(3)$, is located in the gap corresponding to a long distance between sheets (8.0 Å), lying on a mirror plane at $z = 1/4$. Its coordination is also approximately tetrahedral (Table 3): two symmetry related oxygen atoms [O(6)] belonging to the hydration sphere of the chlorine ions in two different sheets and two additional water molecules, O(7) and O(8), in the mirror plane. There is only one direct bond with the adjacent sheets and some hydrogen bonds, including the water molecules: O(7)—O(3) = 2.93 and O(8)—O(4) = 3.05 Å.

Figure 2 is a schematic representation of the stacking of the sheets in the unit cell.

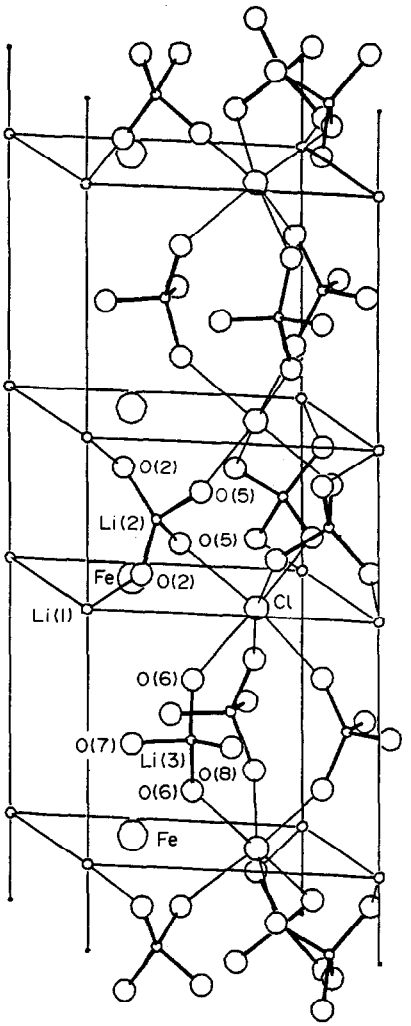

Fig. 2. Schematic representation of the stacking of the sheets in the unit cell. Horizontal planes are drawn at the positions of the sheets. The short gaps contain $Li^+(2)$ and the long ones $Li^+(3)$, both with a tetrahedral coordination.

Mössbauer spectroscopy

Figure 3 shows the Mössbauer spectrum of a polycrystalline sample [Fig. 3(a)], as well as the spectra obtained with single crystals for different values of the angle θ between the gamma ray beam and the crystallographic axis c [Fig. 3(b), $\Theta = 0°$; Fig. 3(c), $\Theta = 54.73°$; Fig. 3(d), $\Theta = 90°$].

All these spectra exhibit a badly resolved and asymmetric quadrupole pattern consisting of two lines with different line-widths and different relative areas (intensities). The apparent quadrupole splitting is 0.60 ± 0.05 mm s^{-1} and the centre of the lines indicates an isomer shift of 0.33 ± 0.05 mm s^{-1} relative to natural iron. Both values are characteristic of a high spin Fe^{3+} ion in a non-cubic environment. The presence of a quadrupolar interaction is consistent with the above described deformation of the octahedral coordination of the iron atom from O_h to D_{3h} symmetry. Furthermore, as the ternary symmetry axis of the distorted octahedra is parallel to the c-axis, one can assume that the quadrupole interaction results from an axially symmetric electric field gradient (EFG) oriented in the

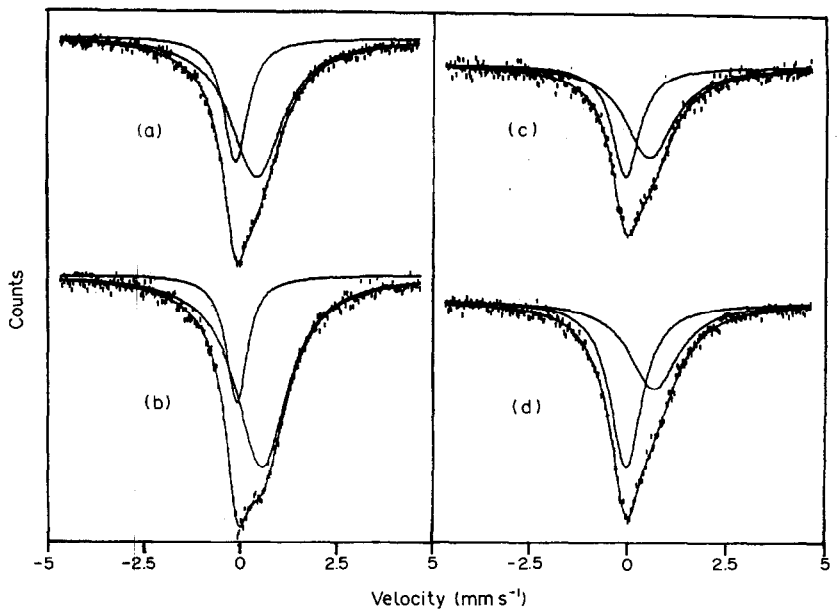

Fig. 3. Mössbauer spectra at room temperature of (a) a polycrystalline sample and of a single crystal with the *c*-axis oriented at (b) 0°, (c) 54.73° and (d) 90°, with respect to the gamma ray beam.

same direction. Neglecting for the moment the problem of the origin of the line-width asymmetry, this result seems in relatively good agreement with the observed values of the intensities ratio of the two lines for the different orientations of the single crystal with respect to the gamma ray beam.

The intensities ratios I^+/I^- of the highest energy line (I^+) to the lowest energy one (I^-) were found to be equal to 3.46 ± 0.3, 1.42 ± 0.2 and 0.78 ± 0.1 for $\Theta = 0°$, 54.73° and 90°, respectively. These values are indeed close to the corresponding theoretical values 3, 1 and 0.66 calculated from the formula $I^+/I^- = 3(1+\cos^2\Theta)/(5-3\cos^2\Theta)$, considering that the highest energy line corresponds to the $|\pm3/2\rangle \rightarrow |\pm1/2\rangle$ nuclear transition and that the EFG is parallel to the *c*-axis.

In the case of a randomly distributed polycrystalline sample this ratio should also be equal to one, but the observed value is larger: 2.2 ± 0.3. The asymmetry observed here could be due to a Goldanskii–Karyagin effect, which is based on the anisotropy of the Debye–Waller factor *f* in connection with the angular distribution of the gamma radiation, but this effect is usually small. The *f* factor can be related to the mean square vibrational amplitudes of the nucleus in the direction of the gamma rays. From XRD analysis we find that the root mean square amplitudes of the iron atoms along the principal axes *x,y,z* of the thermal vibration ellipsoid are 0.129, 0.129 and 0.179 Å, respectively, and that the *z*-axis of the ellipsoid coincides with the crystallographic *c*-axis. This result is of course in agreement with an axially symmetric EFG along this direction. This means that, at room temperature, the Debye–Waller factors in the *a,b*-plane and along the *c*-axis are 0.71 and 0.52, respectively. These values correspond (according to ref. 33) to an intensity ratio I^+/I^- of only 0.96, which cannot explain the observed difference. It is likely that this difference is to be attributed to a residual orientation of the crystallites with respect to the gamma ray beam, an effect which can be quite large and difficult to eliminate in plate-like materials.

The asymmetry in the line-width of the lines can be attributed to relaxation of paramagnetic ions, causing fluctuating magnetic fields, rather than to a Goldanskii–Karyagin effect because the former effect gave lines with different shapes and equal areas while the latter results in lines with different areas and equal shapes.

A broadening of a line will result when the relaxation time of the magnetic field is comparable to or larger than the nuclear Larmor period. For *S*-state ions such as high spin Fe^{3+} the orbital angular momentum is rigorously zero and the spin-lattice mechanism is, therefore, negligible compared to the spin–spin relaxation process, which depends on the distance *r* between the dipoles as $\langle r^{-3}\rangle$. Hence, in iron(III) compounds with a small Fe—Fe distance ($\sim$ 5 Å) the relaxation is fast and the lines are comparatively sharp, whereas compounds with larger iron interionic distances ($\sim$ 10 Å) tend to show definite magnetic structure.

According to the structure of $Li_4[Fe(Ox)_3]$

$Cl \cdot 9H_2O$, each iron ion has at least one nearest neighbour iron located (on the *c*-axis) at a considerably shorter distance (5.356 Å) than the other adjacent ions (8.004 Å on the *c*-axis, 9.465 Å in the *a*,*b*-plane) and, therefore, the spin–spin relaxation between the closest iron ions will be predominant and relatively fast. If the fluctuating magnetic field is parallel to the electric field gradient Blume and Tjon[34] have shown that the $|\pm 3/2\rangle \rightarrow |\pm 1/2\rangle$ nuclear transitions, which make up one of the lines (I^+) of the quadrupole doublet, have a larger splitting than do the $|\pm 1/2 \rightarrow |\pm 1/2\rangle$ transitions, which make up the other line (I^-). This is in agreement with the observation that the line-width of the highest energy line (I^+) is larger (1.58 ± 0.07 mm s^{-1}) than that of the lowest one (I^-) (0.80 ± 0.15 mm s^{-1}). In this particular compound we may expect to find, as in the case of $FeCl_3 \cdot 6H_2O$,[35] a relaxation time for which the I^- line is narrowed while the I^+ line is still broad. Furthermore, the temperature and the external magnetic field dependences of the Mössbauer spectra of both compounds should be similar, but these results will be presented separately.

A CONVENIENT METHOD FOR THE SYNTHESIS OF DINITROSYLMOLYBDENUM(0) COMPLEXES OF HETEROCYCLIC ACIDS†

MANNAR R. MAURYA‡ and C. GOPINATHAN

Inorganic Chemistry Division, National Chemical Laboratory, Pune 411 008, India

(*Received* 21 *October* 1992; *accepted* 7 *January* 1993)

Abstract—A simple procedure is described for the synthesis of dinitrosylmolybdenum(0) complexes of picolinic acid and its derivatives by the reaction of $Mo(NO)_2(acac)_2$ (where acacH = acetylacetone) with the respective ligand in methanol under aerobic conditions.

Ligand exchange reactions are a very common method in coordination chemistry to design and synthesize metal complexes with deliberately tailored properties. In the chemistry of dioxo-metal cations, such as dioxomolybdenum(VI),[1] dioxotungsten(VI),[2] dioxouranium(VI),[3] etc., such reactions have been studied extensively using $MO_2(acac)_2$ (where M = Mo, W or U) as a starting precursor. Only acetylacetone exchanges with the ligand during the chemical reaction and the strongly bound oxygens of the oxometal group remain intact. With this background we have recently studied the exchange ability of the acetylacetone group in $Mo(NO)_2(acac)_2$ with the Schiff bases and have shown that similar dinitrosylmolybdenum(0) complexes can be prepared in aerobic conditions using $Mo(NO)_2(acac)_2$ as a starting precursor.[4] We have now extended the reactivity of this precursor towards simple heterocylic acids (**1**), where X = H, 3-COOH or 5-COOH, and report that $Mo(NO)_2(acac)_2$ can be readily used to prepare dinitrosylmolybdenum(0) complexes of these ligands.

EXPERIMENTAL

Reagents

All chemicals used were of analytical grade. $Mo(NO)_2(acac)_2$ was prepared following the method described by Sarkar and Subramanian.[5]

Preparation of the complexes

$Mo(NO)(2\text{-pic})_3$ (**1**) *and* $Mo(NO)_2(2\text{-pic})_2$ (**2**). A mixture of $Mo(NO)_2(acac)_2$ (0.354 g, 0.001 mol) and 2-picolinic acid (0.246 g, 0.002 mol) in methanol (15 cm^3) was refluxed on a water bath for 15 h. After cooling the reaction mixture for 2 h the yellow complex (**1**) separated was filtered, washed with methanol and dried *in vacuo*. The combined washings and filtrate were evaporated to *ca* 3 cm^3 under a current of air. The green complex (**2**) separated was filtered, washed with cold methanol and dried. Finally compound **2** was recrystallized from CH_2Cl_2. Yield: $Mo(NO)(2\text{-pic})_3$ = 0.025 g (7.6%); $Mo(NO)_2(2\text{-pic})_2$ = 0.21 g (52.5%).

$Mo(NO)_2(2,3\text{-pydc})_2$(**3**) *and* $Mo(NO)_2(2,5\text{-pydc})_2$ (**4**). 2,3-Pyridine dicarboxylic acid or 2,5-pyridine dicarboxylic acid (0.334 g, 0.002 mol) was added to a methanolic solution of $Mo(NO)_2(acac)_2$ (0.354 g, 0.001 mol in 15 cm^3) and the reaction mixture was refluxed on a water bath for 15 h. After removal of the solvent under reduced pressure the crude product was suspended in methanol (5 cm^3) and heated at reflux for 5 min. The green solid was filtered after cooling, washed with methanol and dried *in vacuo*. Yield: $Mo(NO)_2(2,3\text{-pydc})_2$ = 0.19 g (39%); $Mo(NO)_2(2,5\text{-pydc})_2$ = 0.22 g (43%).

[a] ε in $dm^3\ mol^{-1}\ cm^{-1}$.

The analytical and physicochemical data of the complexes are presented in Table 1.

Measurements

Molybdenum was estimated gravimetrically as bis(8-hydroxyquinolinato)dioxomolybdenum(VI) after decomposing the complexes with concentrated HNO_3. Other elemental analyses were performed by the microanalytical section of this laboratory. The electrical conductance measurements were performed in 1×10^{-3} M DMF solutions using a Toshniwal conductivity bridge (Type CLO1-02A) and a dip-type cell calibrated with KCl solution. IR spectra were recorded as KBr discs on a Perkin–Elmer model 1620 FT-IR spectrophotometer. Electronic spectra were recorded in DMF on a Shimadzu UV-160A UV–vis spectrophotometer.

RESULTS AND DISCUSSION

Although $Mo(NO)_2(2\text{-pic})_2$ and $Mo(NO)(2\text{-pic})_3$ have already been reported by reductive nitrosylation of dioxomolybdenum(VI) by hydroxylamine hydrochloride in the presence of 2-picolinic acid under aqueous-aerobic conditions,[6] all the complexes reported here have been prepared by a single-step ligand exchange process using $Mo(NO)_2(acac)_2$ as the starting material. Thus, $Mo(NO)_2(acac)_2$ undergoes ligand exchange reactions with **1** in methanol to give complexes of the type $Mo(NO)_2L_2$ (where LH = **1**; R = H, 3-COOH and 5-COOH). Under the reaction conditions both molecules of acetylacetone are replaced by the heterocyclic acids as follows:

$$Mo(NO)_2(acac)_2 + 2LH \xrightarrow{MeOH} Mo(NO)_2L_2 + 2acacH.$$

Analytical data support the above formulation of the complexes. Some unidentified minor secondary products were also formed which were neglected. Only in the case of 2-picolinic acid was a secondary product of the composition $Mo(NO)(2\text{-pic})_3$ isolated in reasonably good yield (see Experimental) and characterized. Perpinan *et al.*[6] have also noticed the formation of such minor secondary products in the case of some bidentate ligands. However, they were also unable to characterize these, except that obtained by us in the case of 2-picolinic acid.

All the dinitrosyl complexes are non-electrolytes ($\Lambda_M = 3.5-7.8\ \Omega\ mol^{-1}\ cm^2$) in DMF. They are soluble in coordinating solvents like pyridine, DMF and DMSO, but $Mo(NO)(2\text{-pic})_3$ is insoluble in most solvents. The high decomposition temperature (>250°C) indicates the increased stability of the complexes.

IR spectra

The IR spectra of the dinitrosyl complexes exhibit two well-separated bands in the 1800 and 1650 cm^{-1} regions, indicating the presence of a *cis*-$Mo(NO)_2$ structure; the *trans*-$Mo(NO)_2$ structure would only show one band. The frequencies of the bands suggest that NO is coordinated as NO^+. In fact, the NO^+ character of the nitrosyl group in the complex $Mo(NO)_2(2\text{-pic})_2$ has been confirmed by X-ray crystal study, in which the Mo—N—O bond angles of 173.9° and 194.9° are characteristic of linear coordination of the NO^+ group.[6] The mononitrosyl complex $Mo(NO)(2\text{-pic})_3$ shows only one band at 1655 cm^{-1}.

The $\nu_a(COO^-)$ and $\nu_s(COO^-)$ bands of free 2,3-pydc and 2,5-pydc appear at 1670 and 1469, and

1694 and 1492 cm^{-1}, respectively. These bands are still present in the complexes together with two new bands. In complex **3** these new bands are at 1693 and 1455 cm^{-1}, whereas in **4** they are at 1731 and 1460 cm^{-1} and are assigned to ν(C=O) and ν(C—O) modes, respectively. The mode of shifting and magnitude of separation between the two ν(CO) bands clearly indicate the unidentate coordination of the carboxylate ion.[7] The other two bands which are present in the ligands and the complexes suggest the non-participation of the other carboxylic acid group. The position of the ν(C=O) and ν(C—O) bands in **1** and **2** are also in-line with the unidentate coordination of the carboxylate ion. The ν(C=N) bands due to coordinated nitrogen could not be located unequivocally due to complexity of the spectra. However, in the light of the X-ray crystal structure of $Mo(NO)_2(2\text{-pic})_2$[6] it is suggested that pyridinic nitrogen is coordinated to molybdenum in all complexes.

Electronic spectra

The electronic spectra of the dinitrosyl complexes are dominated by two strong bands centred at *ca* 657 and 440 nm. These bands are tentatively assigned to the transitions from a_2 [d_{xy}, π^*(NO)] or b_2 [d_{yz}, π^*(NO)] to the lowest empty molecular orbital b_1 [π^*(NO)] and a_1 [d_{z^2}, π^*(NO)] to b_1 [π^*(NO)] within the $\{Mo(NO)_2\}^6$ group. The values obtained here agree well with the values reported for the majority of the *cis*-dinitrosylmolybdenum(0) complexes.[6,8]

CONCLUSION

On the basis of physicochemical and spectroscopic results an octahedral structure has been suggested for the dinitrosyl complexes, in which the two nitrosyl groups are *cis* to each other. We believe that the synthetic route described here can be generalized to the other dinitrosylmolybdenum(0) complexes.

(*Received* 4 *November* 1992; *accepted* 4 *January* 1993)

Abstract—The chelates $Na_2[Ln(C_{34}H_{28}N_8O_8)Cl]\cdot nH_2O$ of the malonyl dihydrazone of salicylaldehyde with the lanthanides have been prepared and characterized by elemental analysis, IR, UV, molar conductance and TGA. It is shown that the ligand coordinates to the central ion with one hydrazone unit in the keto form and one chloride ion participates in coordination to the metal ion. These chelates are 1 : 2 electrolytes in DMF and are more thermostable than their ligand due to the formation of chelate rings.

Since Sacconi[1] first reported the complexes of nickel (II) with dihydrazones a large number of transition metal complexes of acid dihydrazides have been studied.[2–4] However, no work has been performed on the complexes of the lanthanides with dihydrazones. In the present work the reaction of N-salicylidene derivatives of malonic dihydrazides (H_2L) with 11 lanthanide(III) chlorides in anhydrous ethanol in the presence of sodium hydroxide have been investigated, and the IR, UV, molar conductance and thermal analysis (TGA) of the complexes are discussed.

EXPERIMENTAL

All the solvents were dried by the reported method.[5] Lanthanide(III) chlorides were prepared from their oxides and hydrochloric acid. The ligand was prepared by the literature method.[6]

Preparation of the lanthanide chelates

H_2L (1 mmol) was dissolved in warm ethanol (25 cm^3) containing NaOH (2 mmol). This solution was added to the hydrated lanthanide(III) chloride (0.5 mmol) in anhydrous ethanol (20 cm^3). The mixture was refluxed for 2–3 h until the reaction was complete. The product was separated, washed with warm water, ethanol and diethyl ether, respectively, and dried *in vacuo*. Yields were 75%. Elemental analyses and some physical properties of the products obtained are listed in Table 1.

Measurements

The IR spectra were obtained with a Nicolet 5-DX spectrophotometer using KBr discs in the 4000–400 cm^{-1} region. UV spectra were recorded on a UV-240 spectrometer in the 190–600 nm region using a solution in DMF. Electrolytic conductivities were obtained using a DDS-II A molar conductometer and DMF as the solvent at room temperature. TGA analyses were carried out with a thermal analyser (Japan) between room temperature and 850°C in a nitrogen atmosphere.

RESULTS AND DISCUSSION

These chelates of malonyl dihydrazone of salicylaldehyde with lanthanide are insoluble in non-polar

[a] Calculated values are given in parentheses.

solvents, such as pentane and benzene, but soluble in DMF, warm methanol, warm ethanol and hot water. These chelates are hygroscopic. Their elemental analyses, molar conductance, IR and UV spectra and TGA measurements show that $LnCl_3\cdot nH_2O$ (Ln = lanthanide) forms chelates with the loss of two chloride ions and they conform to the formula $Ln(NaL)_2Cl\cdot nH_2O$.

IR spectra

The IR spectra of the ligand and its complexes are shown in Table 2. The IR spectra of H_2L show bands at 3283, 1679, 1602, 969 and 2700–2800 cm^{-1}, assigned to ν(N—H), ν(C=O), ν(C=N), ν(N—N) and ν(O—H) (phenolic), respectively.[7] In contrast to the parent ligand the IR spectra of these complexes, $Ln(NaL)_2Cl\cdot nH_2O$, show two bands at *ca* 1673 and 1630 cm^{-1} due to uncoordinated and coordinated ν(C=O). In addition, the corresponding band of ν(C=N) appears at 1609 and 1560 cm^{-1} and that of ν(N—N) at 1011 and 969 cm^{-1}, respectively. The presence of both the free and coordinated ν(C=O), ν(C=N) and ν(N—N), and also a band due to ν(N—H) at *ca* 3250 cm^{-1}, suggests that only one of the hydrazone units is coordinated to the lanthanide(III) ion in the keto form.[4] A broad medium band in the region 2700–2800 cm^{-1} of the ligand, assigned to ν(O—H) of salicylaldehyde, disappeared in the complexes. This suggests that one of the hydrogens is replaced by a sodium ion and another by a lanthanide ion, which was confirmed by a new single band at 589 cm^{-1} due to ν(M—O).[8]

Electrolytic conductance

Dissolving the lanthanide chelates in DMF obtained a light yellow to red–brown solution. The molar conductances (Table 3) of these solutions

Table 4. TGA data of the ligand and its complexes

Compound	Temperature (°C)	Loss of groups	Loss of weight (%)[a]

	322.3–459.7	$—OC_6H_4—CH{=}NNH—COCh_2—C—ONH—$, Cl	48.5 (49.8)
	459.7–576.2	2-$C_6H_4—CH{=}N—$	20.6 (21.7)
	Up to 850	Residue, $\frac{1}{2}La_2O_3+Na_2O$	23.7 (23.6)
$Na_2[Pr(C_{34}H_{28}N_8O_8)Cl]\cdot 3H_2O$	86.1	$4H_2O$	7.95 (7.56)
	311.9–494.5	$—OC_6H_4—CH{=}NNHCOCH_2CO—NH—$, Cl	49.36 (49.72)
	494.5–541.5	2-$C_6H_4—CH{=}N—$	20.08 (21.63)
	Up to 850	Residue, $\frac{1}{2}Pr_2O_3+Na_2O$	23.95 (23.80)

[a] Calculated values are given in parentheses.

approach those reported for 1:2 electrolytes,[9] showing that the chloride ion participates in coordination. The complexes are, therefore, formulated as $Na_2[Ln(C_{34}H_{28}N_8O_8)Cl]\cdot nH_2O$.

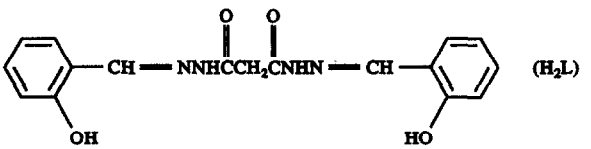
UV spectra

Important bands in the UV spectra of the ligand and its complexes in DMF are shown in Table 3. It can be seen that the K absorption band ($\pi \rightarrow \pi^*$ transition) of the ligand appears at 280 nm, but is shifted to a longer wavelength by 6–12 nm in the complexes. This may be attributed to the interaction between ligands and metal ions when complexing. The absorption band at 322 nm in the ligand is shifted to a lower wavelength, 315–321 nm, after chelating, which can be assignable to the $\pi \rightarrow \pi^*$ transition on azomethine. This indicates that in the complexes the nitrogen in the imino group participated in coordination to the metal ion. In addition, there is a new broad band at *ca* 372 nm, which is due to the ligand–metal charge-transfer band.[3]

Thermal analysis

The thermal analysis data of the ligand and its complexes are listed in Table 4; thermal analyses shows that the ligand decomposes exothermically at 242.3–271.2°C and loses *ca* 78.1% of its weight. Perhaps this is due to two $HOC_6H_4CH{=}NNH$— groups breaking away from the molecule. The exothermic peak at 427.4°C is due to the loss of another part of the molecule. The decomposition of the ligand is complete and there is no residue. The thermal analysis diagrams of all complexes are different from that of the ligand. The diagram of $Na_2[PrL_2Cl]\cdot 3H_2O$ shows that it loses water at 86.1°C, but the water content is more than that resulting from the elemental analysis which can be due to their hygroscopic properties. Two $-OC_6H_4CH{=}NNHCOCH_2CONH-$ groups and two $-C_6H_4CH{=}N-$ groups are then released at 311.9–494.5°C and 494.5–541.5°C, respectively. It seems the molecules of the chelates are thermally more stable than its ligand.

These results show that the ligand has the following structure:



(H_2L)

and forms the complexes with some lanthanide ions, $Na_2[LnL_2Cl]\cdot nH_2O$.

Abstract—The interaction of $C_7H_8M(CO)_4$ (M = Cr, Mo) with half an equivalent of P_2N_2 (P_2N_2 = N,N′-bis[*o*-(diphenylphosphino)benzylidene]ethylenediamine) in THF at ambient temperature gives [*cis*-$(CO)_4M]_2(P_2N_2)$ (**I**, M = Cr; **II**, M = Mo) in high yield. The interaction of $C_7H_8M(CO)_4$ with 1 equivalent of P_2N_2 in refluxed THF gives [*cis*-$(CO)_4M]_2(P_2N_2)$, *fac*-$(CO)_3M(PN_2P)$ (**III**, M = Cr; **IV**, M = Mo) and *fac*-$(CO)_3M[PN_2P(O)]$ (**V**, M = Mo). The yield of the products depends on the length of the reaction time. For a short reaction time the major product is [*cis*-$(CO)_4M]_2(P_2N_2)$, whereas for a long reaction time *fac*-$(CO)_3M(PN_2P)$ is the major product. However, the interaction of $C_7H_8Cr(CO)_4$ with 1 equivalent of $P_2N_2H_4$ ($P_2N_2H_4$ = N,N′-bis[*o*-(diphenylphosphino)benzyl]ethylenediamine) in refluxed THF produces [*cis*-$(CO)_4Cr]_2(P_2N_2H_4)$ (**VI**) as the only isolated product in high yield. Prolonged refluxing of [*cis*-$(CO)_4M]_2(P_2N_2)$ with P_2N_2 in THF does not give *fac*-$(CO)_3M(PN_2P)$. In solution **IV** slowly oxidizes to **V**, whose structure has been determined by X-ray crystallography.

The potential of polydentate ligands having both soft and hard base donor atoms as good bridging ligands for the preparation of heterobimetallic complexes containing an oxophilic metal and a late transition metal has led to extensive studies on the synthesis and reactivities of polydentate ligands containing both phosphine and nitrogen donor groups.[1–3] N-N′-bis[*o*-(diphenylphosphino)benzylidene]ethylenediamine (P_2N_2), a tetradentate ligand containing both imino and phosphino groups, has been synthesized for some time; however, its reactivity towards transition metals has only been briefly explored.[4] We are interested in examining whether transition metals of low oxidation state will preferentially interact with the phosphino groups of the P_2N_2 ligand, leaving the imino groups uncoordinated. Recently, we have briefly described the interaction of P_2N_2 with $C_7H_8Cr(CO)_4$, which gave the centrosymmetric dimeric species [*cis*-$(CO)_4Cr]_2(P_2N_2)$ in high yield.[5] In this paper we report the detailed study of the reactivity of P_2N_2 towards $C_7H_8M(CO)_4$ (M = Cr, Mo) and the X-ray diffraction analysis of the complex *fac*-$(CO)_3Mo[PN_2P(O)]$.

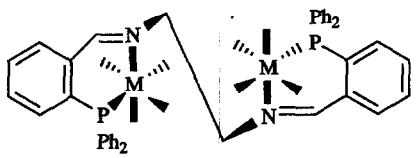
RESULTS AND DISCUSSION

Preparation of $[cis\text{-}(CO)_4M]_2(P_2N_2)$ (M = Cr, Mo)

(1) M = Cr (**I**). When $C_7H_8Cr(CO)_4$ was treated with half an equivalent of P_2N_2 in THF at ambient temperature for 16 h dark orange crystals of stoichiometry $[(CO)_4Cr]_2(P_2N_2)$ (**I**) were isolated in high yield (90%). The IR spectrum (KBr) of **I** exhibits three absorptions at 1996m, 1876vs and 1832s cm^{-1}. The absorption pattern is indicative of a *cis* configuration for the four terminal carbonyl groups of the two $Cr(CO)_4$ moieties. The $^{31}P\{^1H\}$ NMR spectrum of **I** exhibits only a singlet at δ50.3 ppm. This suggests that the two phosphorus centres of the P_2N_2 ligand were coordinated and equivalent. The ^1H NMR spectrum of **I** exhibits a broad singlet, a broad multiplet and a singlet of relative intensity 1/14/2 at δ8.26, 7.45 and 4.04 ppm, respectively. The spectroscopic data suggest that the dimeric species should be symmetrical and that an imino group and a phosphino group of the P_2N_2 ligand should be coordinated to each individual $Cr(CO)_4$ moiety. This is confirmed by an X-ray diffraction study[5] which shows that the P_2N_2 ligand acts as a bidentate ligand with an imino group and a phosphino group coordinated to each of the two $Cr(CO)_4$ moieties, which adopt a *cis* configuration for the four terminal carbonyl groups, and the dimeric species has a centro-symmetrical structure (**A**).



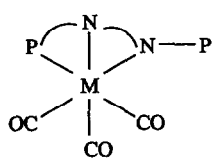
A

(2) M = Mo (**II**). Similar to chromium orange crystals of stoichiometry $[(CO)_4Mo]_2(P_2N_2)$ (**II**) were isolated in high yield (90%) when $C_7H_8Mo(CO)_4$ was treated with half an equivalent of P_2N_2 in THF at ambient temperature for 16 h. The IR spectrum (KBr) of **II** exhibits three absorptions at 2000m, 1878vs and 1838s cm^{-1}. The absorption pattern is indicative of a *cis* configuration for the four terminal carbonyl groups of the two $Mo(CO)_4$ moieties. The $^{31}P\{^1H\}$ NMR spectrum of **II** exhibits only a singlet at δ32.5 ppm. This suggests that the two phosphorus centres of the P_2N_2 ligand were coordinated and equivalent. The ^1H NMR spectrum of **II** exhibits a broad singlet, a broad multiplet and a singlet of relative intensities 1/14/2 at δ8.15, 7.49 and 4.13 ppm, respectively. The spectroscopic data of **II** are very similr to **I**. This suggest that the structure of **II** is similar to that of **I** and thus, structure **A** is assigned to **II**.

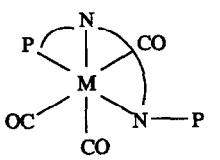
Compound **II** can also be prepared in good yield (72%) by the interaction of $(CO)_3Mo(CH_3CN)_3$ with 1 equivalent of P_2N_2 in THF at ambient temperature for 4–5 h.

Interaction of $C_7H_8M(CO)_4$ *with* 1 *equivalent of* P_2N_2

(1) M = Cr. When $C_7H_8Cr(CO)_4$ was treated with 1 equivalent of P_2N_2 in refluxing THF **I** and dark red crystals of stoichiometry $[(CO)_3Cr](PN_2P)$ (**III**) were isolated. The yields of **I** and **III** depended on the length of the reaction time. When refluxed for 4 h **I** and **III** were isolated in 86 and 5% yields, respectively. However, when the reaction was refluxed for 16 h **I** and **III** were isolated in 12 and 76% yields, respectively. The $^{31}P\{^1H\}$ NMR spectrum of **III** exhibits two singlets of relative intensities 1/1 at δ49.5 and -17.0 ppm, respectively. The resonance at δ49.5 ppm corresponds to a coordinated phosphorus and the resonance at $\delta -17.0$ ppm corresponds to an uncoordinated phosphorus. This suggests that the P_2N_2 ligand acts as a tridentate ligand with one of its phosphino groups remaining uncoordinated. This is further supported by the ^1H NMR spectrum which exhibits a broad singlet at δ9.3 ppm, which corresponds to the proton of the uncoordinated benzylidene, and a broad multiplet at δ8.4 ppm, which corresponds to the proton of the coordinated benzylidene. There are two possible structures for **III**. These are the *fac* and *mer* isomers as shown below.



fac
B



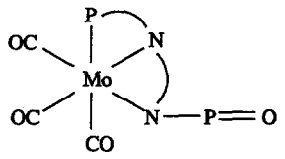
mer
C

The IR spectrum (KBr) of **III** exhibits two absorptions at 1900s and 1780vs cm^{-1}, which is indicative of a *fac* configuration for the three terminal carbonyl groups.[6] Thus, structure **B**, the *fac* isomer, is assigned to **III**.

(2) M = Mo. Similar to chromium **II** and dark red crystals of stoichiometry $[(CO)_3Mo](PN_2P)$ (**IV**) and $[(CO)_3Mo][PN_2P(O)]$ (**V**) were isolated when $C_7H_8Mo(CO)_4$ was treated with 1 equivalent of P_2N_2 in refluxing THF. The yields of **II**, **IV** and **V** depended on the length of the reaction time. When refluxed for 4 h **II** and **IV** were the products isolated in 85 and 5% yields, respectively. However, when the reaction was refluxed for 24 h **II**, **IV** and **V** were isolated in 13, 45 and 15% yields, respectively. The $^{31}P\{^1H\}$ NMR spectrum of **IV** exhibits

two singlets of relative intensities 1/1 at δ34.1 and -17.4 ppm, respectively. The resonance at δ34.1 ppm corresponds to a coordinated phosphorus and the resonance at $\delta-17.4$ ppm corresponds to an uncoordinated phosphorus. This suggests that the P_2N_2 ligand acts as a tridentate ligand with one of its phosphino groups remaining uncoordinated. This is further supported by the ^1H NMR spectrum which exhibits a broad singlet at δ9.5 ppm, which corresponds to the proton of the uncoordinated benzylidene, and a broad multiplet at δ8.5 ppm which corresponds to the proton of the coordinated benzylidene. The IR spectrum (KBr) of **IV** exhibits two absorptions at 1902s and 1778vs cm^{-1}, which is indicative of a *fac* configuration for the three terminal carbonyl groups. Thus, structure **B** is assigned to **IV** as well.

The IR spectrum (KBr) of **V** exhibits two absorptions at 1902s and 1778vs cm^{-1}, which is indicative of a *fac* configuration for the three terminal carbonyl groups. The $^{31}P\{^1H\}$ NMR spectrum exhibits two singlets of relative intensities 1/1 at δ33.3 and 31.9 ppm, respectively. The chemical shift of the resonance at δ33.3 ppm corresponds to that of coordinated phosphorus as in **II** and **IV**, and the resonance at δ31.9 ppm corresponds to that of phosphine oxides.[7] This suggests that the uncoordinated phosphorus of **IV** has been oxidized to phosphine oxide. Thus, based on the spectroscopic data, structure **D** is assigned to **V**.



D

The structure of **V** was confirmed by X-ray crystallography. Crystals suitable for the diffraction study were grown from a mixture of CH_2Cl_2/hexane. The structure consists of two independent but structurally very similar molecules of **V** and a partially occupying molecule of dichloromethane, all separated by normal van der Waals distances. There are only small conformational differences between the two chelated ring systems. A perspective drawing of **V** is shown in Fig. 1. Selected bond lengths and angles are listed in Table 1. The structure can be described as a distorted octahedral with the three carbonyl groups in a *fac* configuration and the uncoordinated phosphine oxidized to the corresponding phosphine oxide.

In solution **IV** was slowly oxidized to **V** when exposed to air. The oxidation process is conveniently monitored by $^{31}P\{^1H\}$ NMR spectroscopy. $^{31}P\{^1H\}$ NMR study shows that **IV**, when dissolved in an undeaerated solution of $CDCl_3$, decomposed completely within 6 h to give a complex mixture from which the oxidized product **V** was observed in 30% yield. Unlike **IV** the chromium analogue (**III**) did not undergo oxidation as readily as **IV**. In a similar study **III** was found to be unchanged after leaving it in an undeaerated solution of $CDCl_3$ for 48 h.

Attempts to synthesize *fac*-$(CO)_3M(P_2N_2)$ via the interaction of $(CO)_3M(CH_3CN)_3$ with 1 equivalent of P_2N_2 were unsuccessful. The interaction of $(CO)_3M(CH_3CN)_3$ with 1 equivalent of P_2N_2 gave [*cis*-$(CO)_4M]_2(P_2N_2)$ as the only isolated product in 75% yield.

Interaction of [cis-$(CO)_4M]_2(P_2N_2)$ *with* P_2N_2 (M = Cr, Mo)

Attempts to synthesize *fac*-$(CO)_3M(P_2N_2)$ from the dimeric species [*cis*-$(CO)_4M](P_2N_2)$ were unsuccessful. When [*cis*-$(CO)_4M]_2(P_2N_2)$ (**I**, M = Cr; **II**, M = Mo) was treated with excess P_2N_2 in refluxed THF for 24 h [*cis*-$(CO)_4M](P_2N_2)$ was recovered almost quantitatively. The formation of *fac*-$(CO)_3M(P_2N_2)$ was not observed. This suggests that the formation of *fac*-$(CO)_3M(P_2N_2)$ is not derived

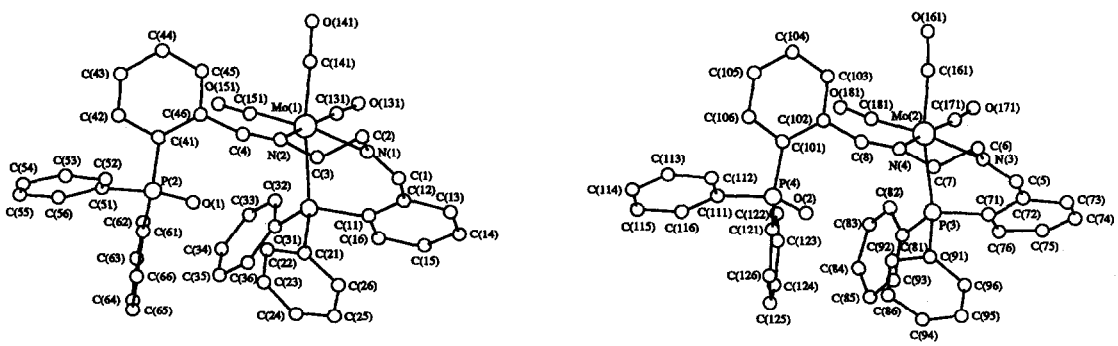


Fig. 1. A perspective view of the molecular structure of **V**. Both independent molecules are shown.

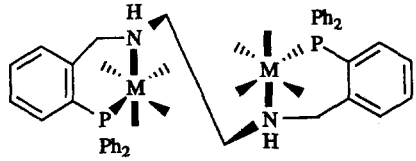
from [*cis*-$(CO)_4M](P_2N_2)$. The origin of the formation of the monomeric species *fac*-$(CO)_3M(P_2N_2)$ is still unknown.

Preparation of [cis-$(CO)_4Cr]_2(P_2N_2H_4)$ **(VI)**

When $C_7H_8Cr(CO)_4$ was treated with 1 equivalent of $P_2N_2H_4$ in refluxed THF overnight yellow crystals of stoichiometry $[(CO)_4Cr]_2(P_2N_2H_4)$ **(VI)** were isolated in good yield (78%). Compound **VI** exhibits three absorptions at 1992w, 1856s and 1832vs cm^{-1} in the IR spectrum (KBr), indicative of a *cis* configuration for the four terminal carbonyl groups and a singlet at δ43.2 ppm in the $^{31}P\{^1H\}$ NMR spectrum, indicating that the two phosphorus atoms of the $P_2N_2H_4$ ligand are coordinated and equivalent. The absorption pattern of the IR and $^{31}P\{^1H\}$ spectra of **VI** is very similar to that of **I**, indicating that **I** and **VI** have similar structures. Thus, based on the above spectroscopic data, structure **E**, shown below, is assigned to **VI**.



E

EXPERIMENTAL

Microanalysis were performed by the Shanghai Institute of Organic Chemistry, Chinese Academy of Sciences, China. IR spectra (KBr pellets) were recorded on a Hitachi 270-30 IR spectrometer; data are given in cm^{-1}. NMR spectra were recorded on a JEOL FX90Q spectrometer. Chemical shifts of ^1H NMR spectra were referenced to internal deuterated solvents and then recalculated to TMS = δ0.0 ppm. ^{31}P NMR spectra were referenced to external 85% H_3PO_4.

All operations were performed under nitrogen or *in vacuo*. All chemicals used were of reagent grade. Solvents were dried by standard procedures, distilled and deaerated prior to use. Melting points were taken in sealed capillaries and are uncorrected.

$C_7H_8Cr(CO)_4$,[8] $C_7H_8Mo(CO)_4$,[8] $Mo(CO)_3(CH_3CN)_3$,[8] P_2N_2[4] and $P_2N_2H_4$[4] were prepared according to literature methods. ^1H and $^{31}P\{^1H\}$ NMR data are given in Table 2.

Preparation of [cis-$(CO)_4M](P_2N_2)$ (M = Cr, Mo)

(1) M = Cr **(I)**. A solution of $C_7H_8Cr(CO)_4$ (0.13 g, 0.5 mmol) and P_2N_2 (0.15 g, 0.25 mmol) in THF (15 cm^3) was stirred at room temperature for 16 h. A deep red colour solution was obtained. The solvent was removed *in vacuo* to give a dark red residue. The residue was redissolved in a minimum amount of CH_2Cl_2 and chromatographed on a silica gel column (2 × 15 cm) using CH_2Cl_2 as an eluant. The orange–red band obtained was concentrated to *ca* 5 cm^3 and then diethyl ether was added until the solution turned cloudy. The CH_2Cl_2/diethyl ether mixture was then cooled to −20°C to give orange–red crystals, which were filtered and dried *in vacuo*. Yield: 0.21 g, 90%; m.p. 192–195°C (decomposed). Found: C, 60.1; H, 3.3; N, 2.9. Calc. for $C_{48}H_{34}O_8N_2P_2Cr_2 \cdot \frac{1}{2}CH_2Cl_2$: C, 59.7; H, 3.6; N, 2.9%. IR (KBr): ν(CO): 1996m, 1876vs, 1832s cm^{-1}.

(2) M = Mo **(II)**. The procedure was similar to that of **I**, except $C_7H_8Mo(CO)_4$ (0.15 g, 0.5 mmol) and P_2N_2 (0.15 g, 0.25 mmol) were used. An orange

band was obtained using CH_2Cl_2 as an eluant. Orange crystals were obtained from a mixture of CH_2Cl_2/diethyl ether. Yield: 0.23 g, 90%; m.p. 203–206°C (decomposed). Found: C, 49.1; H, 3.1; N, 2.3. Calc. for $C_{48}H_{34}O_8N_2P_2Mo_2 \cdot 2CH_2Cl_2$: C, 50.4; H, 3.2; N, 2.4%. IR (KBr): ν(CO): 2000m, 1878vs, 1838vs cm^{-1}.

Interaction of $C_7H_8M(CO)_4$ *with* 1 *equivalent of* P_2N_2

(1) M = Cr. A solution of $C_7H_8Cr(CO)_4$ (0.13 g, 0.5 mmol) and P_2N_2 (0.32 g, 0.53 mmol) in THF (15 cm^3) was refluxed for 16 h. A violet–red coloured solution was obtained. The solvent was removed *in vacuo* to give a dark purple residue. The residue was redissolved in a minimum amount of CH_2Cl_2 and chromatographed on a silica gel column (2 × 15 cm). An orange–red band and a violet–red band were obtained when the column was eluted with CH_2Cl_2 and CH_2Cl_2/acetone (1 : 1) solutions, respectively. Work-up of the orange–red band gave orange–red crystals, which were identical to the dimeric species **I**. Yield: 0.03 g, 12%. The violet–red band was evaporated to dryness *in vacuo* and redissolved in *ca* 5 cm^3 of CH_2Cl_2. Diethyl ether was added slowly to the CH_2Cl_2 solution until it turned cloudy. The CH_2Cl_2/diethyl ether mixture was then cooled to −20°C to give violet–red crystals of stoichiometry $(CO)_3Cr(P_2N_2) \cdot H_2O$ (**III**). Yield: 0.28 g, 76%; m.p. 175–178°C (decomposed). Found: C, 67.9; H, 4.9; N, 3.6. Calc. for $C_{43}H_{34}O_3N_2P_2Cr \cdot H_2O$: C, 68.1; H, 4.8; N, 3.7%. IR (KBr): ν(CO): 1900s, 1780vs cm^{-1}.

When a solution of $C_7H_8Cr(CO)_4$ (0.13 g, 0.5 mmol) and P_2N_2 (0.32 g, 0.53 mmol) in THF (15 cm^3) was refluxed for 4 h, work-up of the solution following the above procedure gave **I** and **III** in

86% (0.22 g) and 5% (0.02 g) yields, respectively.

(2) M = Mo. A solution of $C_7H_8Mo(CO)_4$ (0.09 g, 0.3 mmol) and P_2N_2 (0.19 g, 0.3 mmol) in THF (15 cm^3) was refluxed for 16 h. A deep red solution was obtained. The solvent was removed *in vacuo* to give a dark red residue. The residue was redissolved in a minimum amount of CH_2Cl_2 and chromatographed on a silica gel column (2 × 15 cm). An orange band and a deep red band were obtained when the column was eluted with CH_2Cl_2 and acetone solution, respectively. Work-up of the orange band gave orange crystals, whose IR, ^1H and $^{31}P\{^1H\}$ spectra were identical to that of **II**. Yield: 0.02 g, 13%. Removal of the solvent from the deep red band gave a deep red residue, which was redissolved in *ca* 5 cm^3 of CH_2Cl_2. Diethyl ether was added to the CH_2Cl_2 solution slowly until it turned cloudy. The CH_2Cl_2/diethyl ether mixture was then cooled to −20°C to give 0.15 g deep red crystals. The $^{31}P\{^1H\}$ NMR spectrum of the red crystals indicated that they were a 3:1 mixture of $(CO)_3Mo(P_2N_2)\cdot H_2O$ (**IV**) and $(CO)_3Mo[PN_2P(O)]\cdot \frac{1}{2}CH_2Cl_2$ (**V**). Recrystallization of the crude mixture in CH_2Cl_2/diethyl ether solution gave **V** first then **IV**. Yield of **IV** (based on the $^{31}P\{^{31}H\}$ spectrum of the crude mixture): 0.11 g, 45%; m.p. 173–176°C (decomposed). Found: C, 64.2; H, 4.4; N, 3.4. Calc. for $C_{43}H_{34}O_3N_2P_2Mo\cdot H_2O$: C, 64.3; H, 4.5; N, 3.5%. IR (KBr): ν(CO): 1900s, 1780vs cm^{-1}. Yield of **V** (based on $^{31}P\{^1H\}$ spectrum of the crude mixture): 0.04 g, 15%; m.p. 180–184°C (decomposed). Found: C, 61.7; H, 4.4; N, 3.2. Calc. for $C_{43}H_{34}O_4N_2P_2Mo\cdot \frac{1}{2}CH_2Cl_2$: C, 62.0; H, 4.2; N, 3.3%. IR (KBr): ν(CO): 1900s, 1780vs cm^{-1}.

Preparation of $[cis\text{-}(CO)_4Cr]_2(P_2N_2)$ **(VI)**

A solution of $C_7H_8Cr(CO)_4$ (0.26 g, 1.0 mmol) and P_2N_2 (0.64 g, 1.06 mmol) in THF (20 cm^3) was refluxed for 20 h. A yellow solid precipitate was obtained. The precipitate was filtered, washed with hexane (2 × 10 cm^3) and redissolved in CH_2Cl_2 (20 cm^3) to give a yellow solution. Hexane was added slowly to the CH_2Cl_2 solution until it turned cloudy. The CH_2Cl_2/hexane mixture was then cooled to −20°C to give yellow crystals of stoichiometry $[(CO)_4Cr]_2(P_2N_2)$ (**VI**). Yield: 0.36 g, 77%; m.p. 207–210°C (decomposed). Found: C, 61.4; H, 4.3; N, 2.8. Calc. for $C_{48}H_{38}O_8N_2P_2Cr_2$: C, 61.5; H, 4.1; N, 3.0%. IR (KBr): ν(CO): 1992w, 1856s, 1832vs cm^{-1}.

Interaction of **I** *with* P_2N_2

A solution of **I** (0.1 g, 0.1 mmol) and P_2N_2 (0.08 g, 0.13 mmol) was stirred and refluxed in THF (15 cm^3) for 20 h. The resultant solution was evaporated to dryness, redissolved in a minimum amount of CH_2Cl_2 and chromatographed on a silica gel column (2 × 15 cm). An orange–red band was obtained using CH_2Cl_2 as an eluant. No other colour band was obtained. Removal of the solvent from the orange–red band gave an orange–red residue, whose IR spectrum was identical to that of **I**.

Interaction of $(CO)_3Mo(CH_3CN)_3$ *with* P_2N_2

A solution of $(CO)_3Mo(CH_3CN)_3$ (0.23 g, 0.76 mmol) and P_2N_2 (0.46 g, 0.76 mmol) in THF (15 cm^{-1}) was stirred at room temperature for 4 h. A red solution was obtained. The solution was evaporated to dryness *in vacuo*, redissolved in a minimum amount of CH_2Cl_2 and chromatographed on a silica gel column (2 × 15 cm) using CH_2Cl_2 as an eluant. The orange band obtained was concentrated to *ca* 5 cm^3 and then diethyl ether was added until the solution turned cloudy. The CH_2Cl_2/diethyl ether mixture was then cooled to −20°C to give orange crystals, whose IR spectrum was identical to that of **II**. Yield: 0.29 g, 75%.

X-ray diffraction studies

Crystals of **V** suitable for X-ray diffraction study were grown from CH_2Cl_2/n-hexane as a solvate of stoichiometry $\mathbf{V}\cdot\frac{1}{4}CH_2Cl_2$. A dark red crystal of dimensions 0.17 × 0.22 × 0.25 mm^3 was mounted on a glass fibre with an epoxy resin. Intensity data were collected on an Enraf–Nonius CAD-4 diffractometer at room temperature, using graphite monochromated Mo-K_α radiation (λ = 0.71073 Å). 11,385 reflections ($2\theta \leqslant 45°$) were measured; 10,993 were unique, R_{int} = 0.024, and of these 7406 had $I \geqslant 3\sigma(I)$ and were considered to be observed. The data were collected for Lorentz and polarization factors, but no absorption correction was applied. Crystal data, data collection parameters and results of the analysis are given in Table 3. The structure was solved by a combination of Patterson and direct methods (DIRDIF).[9] Two crystallographic independent molecules of **V** and a partially occupying solvent molecule of CH_2Cl_2 were located in the asymmetric unit. All non-carbon, non-hydrogen atoms, except for the solvent molecule, were refined anisotropically. The hydrogen atoms were generated in their idealized positions (C—H bond fixed at 0.96 Å) and included in structure-factor calculations, but not in refinement. Refinement was by full-matrix least-squares. All calculations were carried out on a MicroVAC-II computer using the Enraf–Nonius SDP program.[10] Final atomic coordinates, thermal parameters and structure factors

(*Received* 10 *September* 1992; *accepted* 18 *December* 1992)

Abstract—The lanthanide isothiocyanate complexes with 13C4 have been prepared in ethyl acetate medium. These new complexes with the general formula $[Ln(NCS)_3(13C4)2H_2O]$ (Ln = La, Pr–Tb, Er–Yb) have been characterized by elemental analysis, IR spectra, *f–f* hypersensitive transitions spectra, ^1H NMR spectra, conductivity measurements and TG–DTA techniques. In the complexes the ligand 13C4, isothiocyanate groups and water molecules are all coordinated to the metal ions.

Many lanthanide-crown ether complexes have been investigated in recent years.[1,2] Most attention has been concentrated on the crown ethers containing ethylene groups, while the lanthanide complexes with the crown ethers containing a trimethylene unit have been studied less. Recent studies have demonstrated that the crown ethers containing trimethylene units have a lower coordination power towards most metal ions, but they have a selectivity to the best-fit metal ions[3,4] due to their enlarged cavity size and the favourable orientation of donor atoms. In order to study more deeply the selectivity and coordination pattern of these crown ethers to lanthanide ions, we have synthesized the solid complexes of 13C4 with lanthanide isothiocyanates in anhydrous medium and investigated the composition and properties of these new complexes.

EXPERIMENTAL

Reagents

Hydrated lanthanide isothiocyanates were prepared as follows:[5] NH_4SCN (0.5 mol) was added to a solution of $LnCl_3 \cdot nH_2O$ (0.04 mol) in water (1000 cm^3). The mixture was shaken with TBP (500 cm^3) for 20 min and then separated. The organic phase was then washed twice with cold water (15°C). The product was obtained by extracting the TBP solution with hot water (40–50°C) three times. After moving the water under reduced pressure the pure product was obtained as crystals in 35% yield.

The ligand 13C4 was prepared as reported previously.[3] All other chemicals used were AnalaR grade.

Chemical and physical measurements

The metal ion contents were determined by EDTA titration using Xylenol orange as an indi-

* Author to whom correspondence should be addressed.

cator. Carbon, nitrogen and hydrogen contents were determined using a Carlo–Erba 1106 elemental analyser. The IR spectra were recorded in the 4000–200 cm^{-1} region using KBr pellets and a 170SX FTIR spectrometer. A Shimadzu UV-240 spectrophotometer was used to obtain the electronic absorption spectra. The ^1H NMR spectra were recorded on a FT-80A spectrophotometer using acetone-d_6 as a solvent and TMS as an internal standard. Thermal analyses (TG and DTA) were performed on a Beijing PcT-2 thermobalance. The heating rate was 10°C min^{-1}. Conductivity measurements were carried out with a DDS-11A type conductivity bridge for a freshly prepared solution in acetone at 25°C.

Preparation of the complexes

A solution of lanthanide isothiocyanate (0.2 mmol) in ethyl acetate (2 cm^3) was added dropwise to a solution of the ligand (0.2 mmol) in ethyl acetate (2 cm^3). The mixture was stirred at room temperature for over 24 h. The precipitated solid complex was filtered, washed with ethyl acetate and dried in a desiccator (0.1 mm Hg) over P_4O_{10} for 2 days. All the complexes are powdered solids and air stable with the characteristic colour of the corresponding lanthanide isothiocyanates.

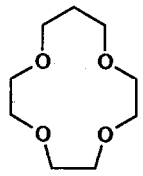

Fig. 1. The structure of the ligand.

RESULTS AND DISCUSSION

The composition of the complexes

The analytical data for the newly synthesized complexes, listed in Table 1, indicate that all of the complexes conform to a 1 : 1 stoichiometry of the metal ion and crown ether.

IR spectra

The most important IR peaks of the ligand and the complexes are reported in Table 2.

Compared with those of the free ligand, the absorptions of ν(R—O—R) of the complexes showed shifts of 64–76 cm^{-1} towards lower wave numbers. This provides evidence for the coordination of the crown ether with the metal ions. In addition, in the far-IR region new bands, absent in the spectrum of the free ligand, are found in the

373–388 cm^{-1} region, which may be assigned to the $\nu(Ln—O_{crown})$ stretching frequency.[6] The wave numbers of the $\nu(Ln—O_{crown})$ stretching frequency rise with increasing atomic number due to the lanthanide contraction.

The IR absorptions of ν(CN), ν(CS) and δ(NCS) of the isothiocyanate groups are present in the 2030–2082, 835–845 and 480–484 cm^{-1} regions, respectively, which suggests that the isothiocyanate groups in the complexes are coordinated to the metal ions through the nitrogen atoms,[7] while the absence of absorptions near 2100, 700 and 420 cm^{-1} indicates that the sulphur atoms in the isothiocyanate groups are not bonded to the metal ions. Moreover, weak bands assigned to $\nu(Ln—N_{NCS})$[8] are found in the 324–349 cm^{-1} region, further supporting the above assignment.

^{1}H *NMR spectra*

After formation of the lanthanum complex the proton chemical shifts of $\delta(—CH_2—O)$ (3.45–3.66, 16H, m) and $\delta(R—CH_2—R)$ (1.58–1.71 ppm, 2H, m) of the ligand show significant downfield shifts [$\Delta\ \delta(CH_2—O) = 0.12$, $\Delta\ \delta(R—CH_2—R) = 0.15$ ppm], indicating metal–ligand complex formation. Moreover, the chemical shift of water, which appears at 3.08 ppm, suggests that water molecules exist in the lanthanum complex. This result agrees with those of the elemental analysis and IR spectra.

Electronic absorption spectra

The electronic absorption spectra of lanthanide ions have been the subject of several investigations.[9] We measured the *f–f* electronic hypersensitive transitions of Pr^{III}, Nd^{III} and Er^{III} isothiocyanates and their corresponding complexes in acetone. The spectral data along with various calculated parameters are given in Table 3. The nephelauxetic ratio β, the Sinha's covalency parameter δ and the bonding parameter $b^{1/2}$ are expressed as follows:[10,11]

$$\beta = n^{-1}\sum_{1}^{n} \nu_{comp}/\nu_{aq}, \quad \delta(\%) = [(1-\beta)/\beta] \times 100,$$

$$b^{1/2} = [1/2(1-\beta)]^{1/2}.$$

The positive and negative values of δ and $b^{1/2}$ for a complex correspond to covalent and ionic characters, respectively.

From Table 3 it can be found that the positive values of $\delta(\%)$ and $b^{1/2}$ indicate the covalency existing in the metal–ligand bonding, and the small $\delta(\%)$ values of the complexes indicate weak covalent bonding in the complexes.

Thermal analyses

The thermal analyses studies were performed by means of TG and DTA techniques. The thermal analytical data for the ligand and some of the complexes are summarized in Table 4.

The DTA curve of the ligand shows an exothermic peak at 186°C, then an endothermic peak appears at 312°C. The ligand decomposes completely when heated up to 630°C.

The processes of thermal decomposition for all the complexes are almost the same and are different from that of the ligand. For example, the lanthanum complex loses two water molecules when heated to 223°C; the weight loss found in this process is 7.14% (calc. 6.68%). After the loss of two water molecules the lanthanum complex decomposes exo-

Eu	184	276, 487, 501, 510	62.37	60.87

[a] Calculated weight loss for the change from the complexes to $Ln_2O_2SO_4$.

thermically at 297°C. After this other exothermic peaks and continuous weight loss are detected up to 850°C. At this temperature $La_2O_2SO_4$ is formed.[6] The total weight loss found was approximately consistent with that calculated (Table 4).

By comparing the first exothermic peaks of the $Ln(NCS)_3(13C4)2H_2O$ complexes with those of $Ln(NO_3)_3(12C4)$ complexes[1] we find that the $[Ln(NCS)_3(13C4)2H_2O]$ complexes are thermally less stable than the $Ln(NO_3)_3(12C4)$ complexes due to the existence of trimethylene units, indicating that the lanthanide ions are bound more weakly with less symmetrical 13C4.

Solubility and molar conductance

All the complexes are sparingly soluble in diethyl ether and benzene, slightly soluble in acetonitrile, ethyl acetate and THF and much more soluble in acetone, methanol and dimethyl sulphoxide. The molar conductance values of the complexes measured in acetone at 25°C lie in the range 7.4–19.5 Ω^{-1} cm^2 mol^{-1} (Table 1), indicating that all the complexes are non-electrolytes.[12] This indicates that all the isothiocyanate groups in the complexes are coordinated to the metal ions.

Abstract—The cyclohexylimido complex of tungsten(VI), $[W(NCy)Cl_4]_2$ (**1**), is reduced by Na/Hg in the presence of PMe_3 to give *cis,mer*-$W^{IV}(NCy)Cl_2(PMe_3)_3$ (**2**). Interaction of **2** with AgO_3SCF_3 in THF gives the tungsten(V) complex $[W(NCy)Cl_2(PMe_3)_3]O_3SCF_3$ (**3**); with $NaBPh_4$ in the presence of PMe_3 $[W(NCy)Cl(PMe_3)_4]BPh_4$ (**4**) is obtained. Interaction of $WCl_2(PMe_3)_4$ with the new organoazide $(o\text{-tolyl})_3Si(N_3)$ produced $W[NSi(o\text{-tolyl})_3]Cl_2(PMe_3)_3$ (**5**), while with $(mesityl)_2B(N_3)$, *cis,cis,trans*-$W[NB(mes)_2]_2Cl_2(PMe_3)_2$ (**6**) is obtained. Interaction of $[W(NPh)Cl_4]_2$ with dilithium perfluoropinacolate gives $Li\{W(NPh)Cl[O_2C_2(CF_3)_4]_2\}$ (**7**). The structures listed in the title have been determined by X-ray crystallographic study. In complexes **2**–**7** the metal has octahedral geometry. The W—N(imido) distances vary from 1.69(1) Å in complex **4**, a tungsten(IV) species, to 1.78(1) Å in the tungsten(VI) bis-imido complex **6**, with no simple correlation with the oxidation state of the metal. The *trans*-lengthening effect of the imido function also varies, with the greatest effect generally in the tungsten(V) complex **3**. No lengthening seems to occur in the tungsten(IV) complexes **2** and **4**, but there is a slight effect in complex **5**. The complex $WCl_4(PMe_2Ph)_3$ has a capped octahedral geometry.

The synthesis of several new organoimido complexes of tungsten in oxidation states IV, V and VI together with their X-ray crystal structures are reported.

Analytical and physical data for new compounds are collected in Table 1.

RESULTS AND DISCUSSION

Cyclohexylimido compounds

The starting material, $WOCl_4$, has been previously used for the synthesis of organoimido compounds.[1] While some examples are known,[2] the use of the cyclohexyl group is not common; cyclohexylimido species can often be more easily isolated and crystallized than other imido species with e.g. NBu^t groups.

The interaction of CyNCO and $WOCl_4$ in refluxing toluene readily gives multigram quantities of $[W(NCy)Cl_4]_2$ (**1**) as orange–red needles. The compound doubtless has the same chlorine-bridged structure as in similar compounds where other imido groups (e.g. NEt) are present.[3] The reduction of **1** with sodium amalgam or sodium naphthalenide in toluene in the presence of excess PMe_3 gives red–purple crystals of the diamagnetic tungsten(IV)

complex, $W(NCy)Cl_2(PMe_3)_3$ (**2**), in high yield. The structure of **2** is shown in Fig. 1; selected bond lengths and angles are given in Table 2. The molecule has approximate octahedral geometry with a *mer* arrangement of PMe_3 ligands that are *cis* to the near-linear imido function [$\angle WNC = 172.5(8)°$]. A similar *cis,mer* configuration was found for the analogous $Mo(N\text{-}p\text{-tolyl})Cl_2(PMe_3)_3$[4] and for $W(NPh)Cl_2(PMe_3)_3$.[1a] The ^1H NMR data show the presence of two magnetically inequivalent PMe_3 groups in a 1 : 2 ratio coupled to each other and one C_6H_{11} group. The $^{31}P\{^1H\}$ spectrum (100 MHz) consists of a singlet, which suggests coincidence of the two types of PMe_3 groups, a fact supported by the presence of two pairs of tungsten–phosphorus satellites, $^1J(W—P) = 20.0$ Hz (*trans* to Cl), $^1J(W—P) = 152.6$ Hz. The data favour *cis*-chlorine atoms, but the distinction between *mer* and *fac* arrangements of PMe_3 groups it not unequivocal on spectroscopic data.

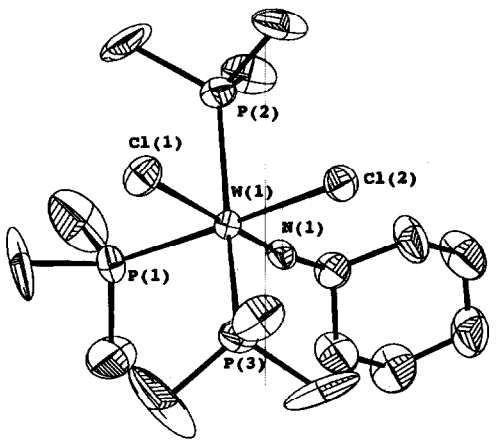

Fig. 1. The structure of $W(NC_6H_{11})Cl_2(PMe_3)_3$ (**2**).

Complex **2** is oxidized by silver trifluoromethanesulphonate in THF to give the W^V complex $[W(NCy)Cl_2(PMe_3)_3]CF_3SO_3$ (**3**), which is paramagnetic (d^1) but which gives only slightly broadened ^1H NMR spectra. These have a C_6H_{11} peak and two singlets (1 : 2) for the inequivalent PMe_3 ligands [$^2J(P—H)$ or $^4J(P—H)$ coupling is not resolved]. The $^{31}P\{^1H\}$ spectrum has a sharp singlet [−28 ppm, $^1J(W—P) = 142.4$ Hz] assigned to the *trans*-equatorial phosphines, while the third PMe_3 resonance is broad (*ca* 0 ppm: no coupling was observed). NMR data on paramagnetic W^V compounds have been obtained previously, e.g. for Cp^*WMe_4.[5a] Cationic tungsten(V) compounds are quite rare.[5b] The spectroscopic data is consistent with a *cis,mer* arrangement of Cl and PMe_3 groups, as found via an X-ray structure determination. A diagram of cation **3** is shown in Fig. 2; bond lengths and angles are given in Table 3.

Complexes **2** and **3** thus have the same structural configuration, but bond length and angle differences are more complex than would be expected from the simple difference in the metal oxidation state. In complex **3** the W—Cl bond *trans* to the imido function is *ca* 0.07 Å longer than that which is *trans* to one of the phosphines. The W—P distances are very similar, but with that *trans* to the chlorine the shorter of the three. In the W^{IV} d^2 complex **2** the imido function seems to exert little

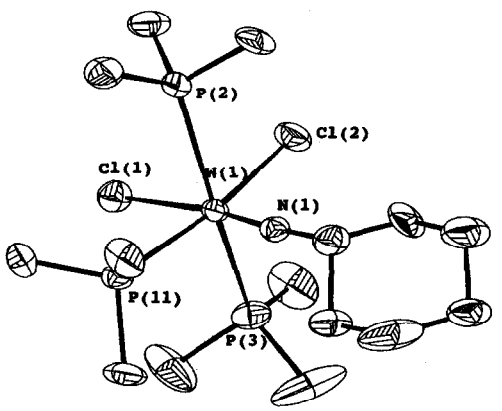

Fig. 2. The structure of the cation $[W(NC_6H_{11})Cl_2(PMe_3)_3]^+$ in the trifluoromethanesulphonate (**3**).

trans influence, and indeed, the *trans*-W—Cl bond is actually shorter, by 0.015 Å, than the W—Cl bond *trans* to a phosphine. This phosphine has a W—P bond *ca* 0.05 Å shorter than the other two, which are mutually *trans*. It is also surprising to find that the W—N (imido) bond in the W^V complex (**3**), at 1.73(1) Å, is slightly longer than that in the W^{IV} complex (**2**), which is 1.70(1) Å.

However, the results found for the molecule of **2** are very similar to those previously found for the phenylimido complex $WCl_2(PMe_3)_3(NPh)$.[1a] Although a configuration analogous to the W^V complex **3** has not previously been structurally characterized, a strong imido *trans* influence has in fact been noted for another W^V complex, WCl_3

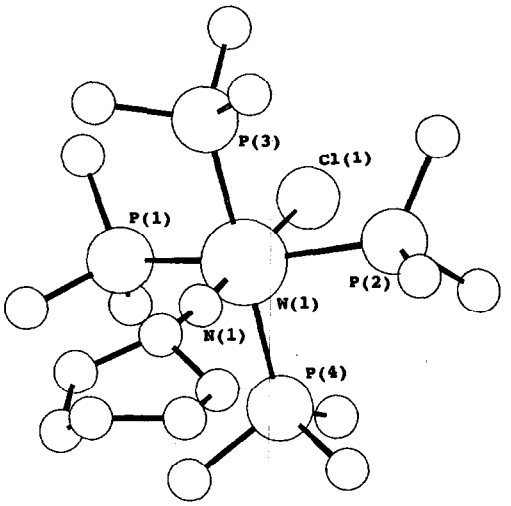

Fig. 3. The structure of the cation $[W(NC_6H_{11})Cl(PMe_3)_4]^+$ in the tetraphenylborate (**4**).

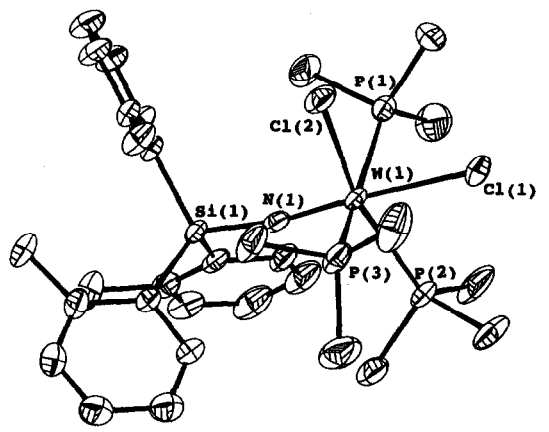

Fig. 4. The structure of $W[NSi(o\text{-tol})_3]Cl_2(PMe_3)_3$ (**5**).

$(PMe_3)_2NPh$,[1a] where the *trans* bond length is 2.443(7) and the *cis* lengths are 2.368–2.405(3) Å.

The interaction of **2** with the $NaBPh_4$ in THF containing PMe_3 gives a tungsten(IV) cation, $[W(NCy)Cl(PMe_3)_4]^+$, as the BPh_4^- salt **4**, whose structure is shown in Fig. 3; bond lengths and angles are in Table 4.

In this W^{IV} complex the single Cl atom is *trans* to the imido function and gives a similar W—Cl distance to that in complex **2**. The four W—P bonds, which form an "equatorial" plane are, not unexpectedly, all very similar. The W—N distance, at 1.69(1) Å, is short, as in complex **2**.

The cyclohexyl groups in all three complexes show varying degrees of conformational thermal motion/disorder, most extreme in the last structure.

The ^1H and $^{31}P\{^1H\}$ NMR spectra of **4** show the presence of a single type of PMe_3 group, showing that in solution the structure formed in the solid is maintained.

Triarylsilyl- and bis(aryl)boryl-imido species

The interaction of $Me_3Si(N_3)$ with $WCl_2(PR_3)_4$, R = Me and Me_2Ph, gives the corresponding tungsten(IV) species, $W(NSiMe_3)Cl_2(PR_3)_3$,[6] in oxidative-addition reactions.

The interaction of $WCl_2(PMe_3)_4$ with the new azide $(2\text{-}MeC_6H_4)_3Si(N_3)$ leads to the similar air-stable, crystalline $W[NSi(o\text{-tol})_3]Cl_2(PMe_3)_3$ (**5**). Both NMR and X-ray data indicate again the *cis,mer* configuration; the structure is shown in Fig. 4 with bond lengths and angles in Table 5. In this

complex the W—Cl bond *trans* to the imido group is the longer of the two and the W—P bonds *trans* to chlorine is again the shortest of the three. The W—N (imido) bond length at 1.758(6) Å is longer than any of these in the three complexes described above. An additional factor here is the presence of the Ar_3Si group on the imide. The Si—N distance of 1.766(6) Å indicates some π-interaction between these two atoms, which could weaken the W—N interaction.

Interaction of $WCl_2(PMe_3)_4$ with $mes_2B(N_3)$ at 60° leads to the relatively air stable 4e tungsten (VI) oxidative-addition, bis-imido product, $W[NB(mes)_2]_2Cl_2(PMe_3)_2$ (**6**). The ^1H NMR spectrum indicates the presence of two equivalent *trans*-PMe_3 groups and two borylimido groups, each possessing magnetically inequivalent mesityls at 25°C. On heating the four upfield *o*-methyl bands start to broaden at 55°C and collapse to a single band at 70°C, while the two downfield *p*-methyls start to broaden at 65°C and collapse at 90°C. The fast exchange limit could not be reached at 120°C. The inequivalence of mesityl groups is a result of hindered rotation around aryl—B, B—N and N—W bonds. Collapse of the *o*-methyls at 70°C reveals the first dynamic process ($\sim$ 68 kJ mol^{-1}), rotation around the B—aryl bond, while collapse of *p*-methyls a second one (140 kJ mol^{-1}), e.g. rotation around B—N and/or W—N bonds, although we consider that W—N rotation is less likely than B—N in view of the high π-bond character of W—N.

The solid state structure of **6** is given in Fig. 5; important bond lengths and angles are given in Table 6. The molecular geometry is octahedral with *trans* phosphines, but *cis* chloride and *cis* imido groups. The N—W—N angle has opened up to 100.0(4)° and the Cl—W—Cl angle has reduced to 79.9(2)°. The *cis*-P—W—Cl and *trans*-P—W—P angles are also all less than the ideal 90° or 180°. The W—N distances are equal within the limits of error at 1.78(1) Å, but the pairs of formally chemically equivalent W—P and W—Cl bonds each show small differences. It would seem that steric

factors may be affecting bond lengths, as well as angles. The W—N(imido) lengths of 1.78(1) Å are long, but a similar value was found for the anionic W^{VI} species $[WCl_5(NPr^i)]^-$,[1b] where the distance is 1.76(2) Å.

The geometries of the compounds described above show that the origins of a structural *trans* effect, generally quite common in octahedral or other "axial" stereochemistries, containing multiply bonded ligands such as imide, nitride or oxide, are complex. Previous discussions[1a,b] have considered the possibility that steric effects may be partly responsible, with compression from the equatorial ligands which are repelled by the high concentration of charge in the M—L multiple bond "squeezing out" the *trans* ligand. The results obtained for the structurally analogous complexes **2** and **3** do not agree with this model. An electronic explanation is also possible, with the strongly multiply-bonding ligand causing a weakening of the bonding to the *trans* ligand. A recent *ab initio* study of transition metal–imido bonding, in which mainly tetrahedral complexes are studied,[7] showed that a number of canonicals contribute to the M—N bonding. However, the study did not seem to model experimentally found structural *trans* effects for the only octahedral complexes investigated, of rhenium and technetium.

It may be noted that while the octahedral *bis* imido compound **6** is obtained with the borylimido group, Doherty *et al.*[6] found that $WCl_2(PMePh_2)_4$ with 2 equivalents of $Me_3Si(N_3)$ gave the five-coordinate $W(NSiMe_3)_2Cl_2(PMePh_2)$; they also reported that with excess $Me_3Si(N_3)$ at elevated temperature $W(NSiMe_3)Cl_2(PMe_3)_3$ underwent elimination of Me_3SiCl. The reluctance of $W(NSiMe_3)Cl_2(PMe_3)_3$ to be oxidized to tungsten(VI) is ascribed to the non-lability of PMe_3 ligands, making Me_3SiCl elimination competitive.

The different behaviour of the $(mes)_2BN$ system can be attributed to (a) the greater electrophilic nature of the nitrogen atom in $(mes)_2B(N_3)$ and the greater reactivity due to the presence of the electron-withdrawing B atom in the α-position, (b) the fact that mes_2BCl will be a poorer leaving group than Me_3SiCl. We have been unable to observe any tungsten(IV) monoimido intermediate, even when using a deficiency of $mes_2B(N_3)$.

Phenylimido species

Interaction of $[W(NCy)Cl_4]_2$ with lithium perfluoropinacolate gave intractable mixtures, but using $[W(NPh)Cl_4]_2$ in Et_2O gave red prisms of what proved to be the salt $Li[W(NPh)Cl\{OC(CF_3)_2C(CF_3)_2O\}_2]$ (**7**) which is a 1:1 electrolyte in THF. The anion is shown in Fig. 6; bond lengths and angles are given in Table 7. The tungsten has close to octahedral coordination with a bent WNPh group, ∠W—N—C = 158.5°. This angle is slightly smaller than the angles found in the related monomeric pinacolato (L) tungsten(VI) complexes[8] $W(NBu^t)_2(L)(NH_2Bu^t)$ and $W(NBu^t)(L)(NH_2Bu^t)_2$ of 161–166°; other bond distances and angles are similar. The Cl atom is *cis* to NPh, with the shortest W—Cl bond found in any of the complexes described here. The distance is 2.22(1) Å and compares with a value of 2.24 Å in WCl_6.[9] The Li^+ atom has close contacts with CF_3 fluorine atoms and with the phenyl group on the imido ligand. Unlike other reactions involving replacement of Cl by LiOR (R = ^{i}Pr, Cy),[10] lithium chloride does not appear in the crystals.

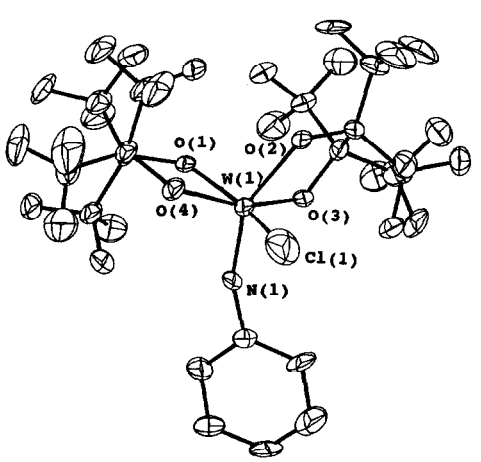

Fig. 6. The structure of Li[W(NPh)Cl{OC(CF_3)$_2$C(CF_3)$_2$O}$_2$] (7).

Other tungsten(IV) *species*

The paucity of X-ray structural information for seven-coordinate W^{IV} complexes, available only for $WCl_4(PMe_3)_3$,[11] prompted the study of compounds with bulkier PR_3 groups, since considerable variation of stereochemistry has been observed for tertiary phosphine adducts of Nb^{IV} and Ta^{V} chlorides.[12]

The structure of $WCl_4(PMe_2Ph)_3$[13] is shown in Fig. 7; bond lengths and angles are given in Table 8. The molecule has a capped octahedral geometry with C_{3v} symmetry: thus Cl(1) occupies the unique capping position surrounded by the more sterically demanding phosphorus ligands and gives the shortest W—Cl bond. The atoms Cl(1), (3) and (4) form the non-capped face. There is no distortion in the

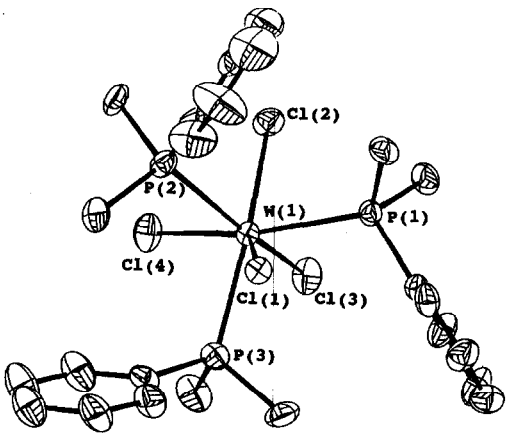

Fig. 7. The structure of $WCl_4(PMe_2Ph)_3$.

uncapped face as was reported for $WCl_4(PMe_3)_3$. Otherwise, there are no marked structural differences. The W—P bond lengths [2.554(6)–2.561(6) Å] are closer together and similar to the longer bonds in $WCl_3(PMe_2Ph)_3$[14a] [2.514(1)–2.555(1) Å] and the facial W—Cl bonds [2.433(5)–2.435(5) Å] are also similar to two of those in $WCl_3(PMe_2Ph)_3$ [2.437(1) and 2.441(1) Å]; the third W—Cl bond was somewhat shorter [2.295(2) Å], a fact suggested[14b] as being due to co-crystallization with $WOCl_2(PMe_2Ph)_3$.

EXPERIMENTAL

Microanalyses were performed by MEDAC Ltd, Brunel University, and Imperial College laboratories. The general techniques and instrumentation have been described.[15] NMR: JEOL EX-270 (270 MHz, ^1H; 100 MHz, ^{31}P); δ ppm (vs Me_4Si); referenced internally on residual proton impurity in the solvent (7.15 ppm, C_6D_6; 7.26 ppm, $CDCl_3$) and external H_3PO_4. IR spectra were obtained (cm^{-1}) in Nujol mulls unless otherwise specified. Commercial chemicals were from Aldrich. Published procedures were used for $WCl_2(PMe_3)_4$,[16] $LiO_2C_2(CF_3)_4$,[17] (*o*-tolyl)$_3$SiCl[18] and (mesityl)$_2$B(N_3).[19]

Tris(2-methylphenyl)silylazide

Tris(2-methylphenyl)silylchloride (3.3 g, 9.9 mmol) and a 10-fold excess of NaN_3 (6.5 g, 99 mmol) in MeCN (50 cm^3) were refluxed for 24 h, when the solution was evaporated in vacuum. The residue was extracted with toluene (3×50 cm^3) and the solution filtered and evaporated under reduced pressure, affording a white powder which is sufficiently pure to use in syntheses. Yield: 2.2 g, 65%; 105–108°C. IR: 2145 (N_3). ^1H NMR ($CDCl_3$): δ 7.45–7.05 (m, 12H, aromatic); 2.35 ppm (s, 9H, *o*-$CH_3C_6H_4$).

Tetrachloro(cyclohexylimido)tungsten(VI) (**1**)

To $WOCl_4$ (6.2 g, 18.2 mmol) in toluene (80 cm^3) was added CyNCO (2.5 cm^3, 19.6 mmol). After refluxing (*ca* 12 h) and cooling (−20°C) the orange precipitate was washed with hexane (2×20 cm^3) and dried *in vacuo*. Yield: typically 70–80%. IR: 2662w, 2195w, 1668m, 1593m, 1558w, 1346s, 1306s, 1281s, 1261s, 1144s, 1108s, 1030m, 1009s, 924s, 891m, 862s, 856s, 815m, 799s, 777m, 723s, 715s, 570s, 537w, 479w, 422w, 390s, 341bs, 284s, 233m. ^{13}C NMR (CD_2Cl_2): δ_α 78.7, δ_β 33.8 ($\Delta = 45$, cf. 48.4 for $[W(NPr^i)Cl_4]_2$.[20]

Cis-*dichloro(cyclohexylimido)*mer-*tris(trimethylphosphine)tungsten*(IV) (**2**)

(a) *By sodium naphthalenide reaction.* To a solution of **1** (1.05 g, 2.45 mmol) and PMe_3 (1.3 cm^3, 14.6 mmol) in THF (40 cm^3) at −78°C was added a solution of $NaC_{10}H_8$ in THF (37 cm^3 of 0.265 M solution; 9.85 mmol). After stirring for 12 h the volatiles were removed in vacuum, the residue washed with hexane (30 cm^3) and extracted into toluene (40 cm^3). Filtration, concentration (to *ca* 20 cm^3) and cooling (−20°C, 12 h) gave red crystals. Yield: *ca* 20%.

(b) *By Na/Hg reduction.* A solution of **1** (2.0 g, 4.75 mmol) in toluene (50 cm^3) was added to toluene

($30\ cm^3$) at 0°C containing PMe_3 (2 cm^3, 20 mmol) and Na/Hg (1.0 g Na and 60 g Hg). On stirring, the colour changed to orange, then green, blue and finally purple: after 24 h the mercury was separated and the mixture worked up as above. Yield: 1.7 g, 62% in two crops. ^1H NMR (C_6D_6): δ 1.5 [t, 18H, P_AMe_3]; 1.4 [d, 9H, P_BMe_3]; 2.4, 1.8, 1.2–0.8 [m, 11H, $C_6H_{11}N$]. $^{31}P\{^1H\}$ NMR: −23.2 [s, $^1J(W—P_A) = 152.6$ Hz, $J(W—P_B) = 200$ Hz].

Cis-*dichloro*(*cyclohexylimido*)mer-*tris*(*trimethylphosphine*)*tungsten*(V)*trifluoromethanesulphonate* (**3**)

To a solution of **2** (0.57 g, 0.98 mmol) in THF ($20\ cm^3$) was added AgO_3SCF_3 (0.26 g, *ca* 1 mmol) when a black precipitate of silver appeared. After stirring (2 h) the solution was filtered, evaporated and the residue washed with toluene ($2 \times 20\ cm^3$): this was then dissolved in THF ($20\ cm^3$) and the filtered solution layered with hexane. After 3–4 days the orange crystals were collected. Yield: 0.6 g, 85%. ^1H NMR (CD_2Cl_2): δ 1.7 (s, 18H, $w_{1/2} = 15$ Hz, PMe_3); 1.6 (s, 9H, $w_{1/2} = 10$ Hz, PMe_3); 2.0–2.2 and 0.8–1.2 (br.m., $C_6H_{11}N$). $^{31}P\{^1H\}$: δ −28.2 [s, $J(W—P) = 142.5$ Hz]; *ca* 0 (br.s., $w_{1/2} = 450$ Hz). No ^{19}F NMR spectrum could be obtained.

Chloro(*cyclohexylimido*)*tetrakis*(*trimethylphosphine*)-*tungsten*(IV) *tetraphenylborate* (**4**)

Solid **2** (0.56 g, 1 mmol) was added to a THF (30 cm^3) solution of $NaBPh_4$ (0.37 g, 1.1 mmol). The mixture was stirred for 5 h, filtered, the solution concentrated (*ca* 15 cm^3) and layered with hexane. After several hours the yellow–orange, moisture-sensitive crystals were collected. Yield: *ca* 55%. IR: 1579m, 1287m, 1263m, 946s, 851m, 614m. ^1H NMR (CD_2Cl_2): δ 6.95–7.22 [m, 20H, $B(C_6H_5)_4$]; 1.7 [s, 36H, PMe_3]; 0.9–1.15 (m, 11H, $C_6H_{11}N$). ^{31}P NMR: δ −28.6, $^1J(W—P) = 142.6$ Hz.

Cis-*dichloro*[*tris*(2-*methylphenyl*)*silylimido*]mer-*tris*(*trimethylphosphine*)*tungsten*(IV) (**5**)

$WCl_2(PMe_3)_4$ (0.56 g, 1 mmol) and tritolylsilylazide (0.4 g, 1.17 mmol) were mixed in the dry box, then dissolved in toluene ($30\ cm^3$) and stirred for 24 h at 45–50°C. The green–brown mixture was filtered and layered with hexane to give purple–blue crystals after 2 days. Yield: 0.15 g, *ca* 20%. ^1H NMR (C_6D_6): δ 6.95–7.95 (m, 12H, C_6H_4Me); 2.2 (s, 9H, *o*-MeC_6H_4); 1.4 [virtual t, 27H, PMe_3]. $^{31}P\{^1H\}$ NMR: δ −26 [$^1J(W—P) = 156$ Hz, *trans*-PMe_3]; −29.4 [$^1J(W—P) = 204$ Hz].

Cis,cis,trans-*dichlorobis*[*bis*(2,4,6-*trimethylphenyl*)-*borylimido*]*bis*(*trimethylphosphine*)*tungsten*(VI) (**6**)

To a mixture of $WCl_2(PMe_3)_4$ (0.59 g, 0.9 mmol) and $(mes)_2B(N_3)$ (0.53 g, 1.8 mmol) was added toluene ($30\ cm^3$); after 12 h at 55–60°C volatiles were removed and the residue crystallized from Et_2O as yellow plates. Yield: 0.21 g, 25%. X-ray quality crystals were grown from Bu^n_2O. ^1H NMR (C_6D_6): δ 6.8–7.1 (4s, 8H, $C_6H_2Me_3$); 3.15, 2.75, 2.3, 2.2, 2.12, 2.0 (s, each 6H, $C_6H_2Me_3$); 1.1 (t, 18H, PMe_3). ^{31}P NMR: −8.7 [s, $^1J(W—P) = 152$ Hz].

Lithiumchlorobis(*perfluoropinacolato*)*phenylimido-tungstate*(VI) (**7**)

To $W(NPh)Cl_4 \cdot OEt_2$ (0.86 g, 1.75 mmol) in Et_2O ($30\ cm^3$) at −78°C was added dropwise a solution of $LiO_2C_2(CF_3)_4$ (1.21 g, 3.5 mmol) in Et_2O (30 cm^3). After warming and stirring for 12 h volatiles were removed and the residue extracted with toluene ($30\ cm^3$), which was concentrated (to $20\ cm^3$) and cooled (−20°C) to give red prisms. Yield: *ca* 30%. Λ_M (THF, 21°C) = 70.7 $\Omega^{-1}\ cm^2\ mol^{-1}$. ^1H NMR (d_6-acetone): 7.59–7.65 (m, 5H, aromatic); additional bands due to *ca* 0.1 and 0.2 molecules of toluene and Et_2O of solvation. X-ray quality crystals with 0.5 toluene per W were grown from toluene.

X-ray crystallography

Crystals of all complexes were sealed under argon in thin-walled glass capillaries. Cell dimensions and intensity data were recorded using a FAST TV area detector diffractometer as previously described.[21] The structures were solved and developed via the heavy atom method and refined via full-matrix least-squares. An absorption correction was applied in each case using the DIFABS method. Most non-hydrogen atoms were refined anisotropically and hydrogens included in idealized positions and refined in the "riding" mode. However, for complex **4** the carbons of the cyclohexyl ligand were refined isotropically and hydrogens in this group were not included. Crystal data and experimental details are given in Table 9. Tables of atomic coordinates and other data have been deposited as supplementary material with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic data centre.

Acknowledgements—We thank the SERC for support and provision of X-ray facilities.

SYNTHESIS AND CHARACTERIZATION OF THE FIRST HETEROLEPTIC TIN(II) ISOPROPOXOMETALLATES

SANJAY MATHUR, ANIRUDH SINGH* and RAM C. MEHROTRA†

Department of Chemistry, University of Rajasthan, Jaipur 302004, India

(*Received* 10 *September* 1992; *accepted* 9 *December* 1992)

Abstract—Tin(II) isopropoxometallates of the types $XSn\{Al(OPr^i)_4\}$, $XSn\{Zr_2(OPr^i)_9\}$, $XSn\{M(OPr^i)_6\}$, $\{Al(OPr^i)_4\}Sn\{Zr_2(OPr^i)_9\}$ and $\{Nb(OPr^i)_6\}Sn\{Ta(OPr^i)_6\}$ (where X = Cl, OPr^i/OBu^t; M = Nb/Ta) have been synthesized and characterized by elemental analyses, molecular weight measurements and multinuclear (^1H, ^{13}C, ^{27}Al and ^{119}Sn) NMR studies.

Although the chemistry of organic compounds of subvalent group 14 elements[1–10] has been extensively investigated during the last two decades, comparatively scant attention has been focused on the development[5,11–13] of the chemistry of compounds with M—O—C functionalities. Amongst the latter classes of compounds examples of heterometal alkoxide systems[14–17] are limited to $Sn\{Al(OPr^i)_4\}_2$, $Sb\{Sn(OR)_3\}_3$, $Tl\{Sn(OBu^t)_3\}$ and $Sr\{Sn(OBu^t)_3\}_2$. In this paper we report the synthesis of novel alkoxo- and (chloro)isopropoxometallatotin(II) complexes, of which the latter complexes have been used as starting materials for the preparation of two trimetallic alkoxides of tin(II) for the first time.

EXPERIMENTAL

All manipulations have been performed under a dry and oxygen-free nitrogen atmosphere. The glass apparatus used was oven-dried (140–150°C) after rinsing with ethyl alcohol and cooled in dry nitrogen prior to use.

Aluminium, zirconium, niobium and tantalum alkoxides were prepared by the literature methods.[18] Anhydrous tin(II) chloride was prepared by the interaction of $SnCl_2 \cdot 2H_2O$(BDH) with acetic anhydride, followed by washing of the solid product with n-hexane and drying under reduced pressure (~ 1 mm). Found: Sn, 62.5; Cl, 37.1. Calc. for $SnCl_2$: Sn, 62.6; Cl, 37.4%.

Tin was determined as SnO_2 after precipitation as cupferrate followed by ignition. The aluminium content in the filtrate was determined gravimetrically as oxinate. Niobium and tantalum were estimated as oxides. In the case of zirconium-containing derivatives tin was determined as cupferrate in the filtrate obtained after the removal of zirconium as mandelate. Isopropoxy contents in isopropoxide derivatives were estimated by an oxidimetric method,[19] using M/6 $K_2Cr_2O_7$ solution in 12.5% H_2SO_4. Chloride was estimated volumetrically by Volhard's method.[20]

IR (4000–200 cm^{-1}) spectra were recorded as Nujol mulls on a Carl Zeiss Jena specord M-80 spectrophotometer. Multinuclear NMR studies were performed on a JEOL FX 90Q spectrometer. ^{27}Al and ^{119}Sn NMR chemical shifts were measured using $Al(NO_3)_3 \cdot xH_2O$ and $SnMe_4$ as external references, respectively. ^1H and ^{13}C NMR chemical shifts were measured using $SiMe_4$ as an internal reference.

Molecular weights were determined ebullioscopically in benzene using a Gallenkamp ebulliometer with a thermistor sensing device.

Preparation of heterometal isopropoxides of tin(II)

In view of the similarity of the procedures for the syntheses of a number of derivatives, only typical preparations are described below:

(1) $ClSn\{Al(OPr^i)_4\}$ (**Ia**). A solution of $K\{Al(OPr^i)_4\}$ [freshly prepared by the reaction of potassium (0.94 g, 24.23 mmol) and $Al(OPr^i)_3$ (4.95 g, 24.24 mmol) with isopropyl alcohol (~ 5 cm^3) in benzene

* Author to whom correspondence should be addressed.
† Present address: Vice-Chancellor, University of Allahabad, Allahabad 211002 (U.P.), India.

($\sim$ 15 cm^3)] was slowly added to $SnCl_2$(4.59 g, 24.23 mmol) dispersed as a suspension in benzene ($\sim$ 15 cm^3). After the addition was complete the reaction mixture was stirred for $\sim$ 4 h at room temperature. The precipitated KCl (1.78 g, 23.86 mmol) was filtered; removal of volatiles from the filtrate under reduced pressure ($\sim$ 1 mm) at room temperature (33°C) yielded the viscous product $ClSn\{Al(OPr^i)_4\}$ (9.88 g, 98%), which on heating under reduced pressure (0.1 mm) disproportionated, giving a volatile product which closely corresponded to the composition $Sn\{Al(OPr^i)_4\}_2$ (b.p. 140°C/0.1 mm).

A similar procedure was followed to prepare **1c** and **1d** in quantitative yields by the equimolar reactions of $SnCl_2$ with $KNb(OPr^i)_6$ and $KTa(OPr^i)_6$, respectively.

(2) $ClSn\{Zr_2(OPr^i)_9\}$ (**1b**). The method was slightly modified in the synthesis of $ClSn\{Zr_2(OPr^i)_9\}$ as the reaction of a solution of $KZr_2(OPr^i)_9$ in isopropyl alcohol with $SnCl_2$ led to partial crystallization of $Zr(OPr^i)_4 \cdot Pr^iOH$. However, the reaction went smoothly as in the above case when a benzene solution of $KZr_2(OPr^i)_9$ [obtained by reacting potassium (0.16 g, 4.12 mmol) with $Zr(OPr^i)_4 \cdot Pr^iOH$ (3.21 g, 4.14 mmol) in a mixture of isopropyl alcohol ($\sim$ 5 cm^3) and benzene ($\sim$ 15 cm^3), followed by removal of volatiles] was added slowly to a suspension of $SnCl_2$ (0.79 g, 4.16 mmol) in benzene ($\sim$ 15 cm^3). After stirring the reaction mixture for 4 h the precipitated KCl (0.29 g, 3.99 mmol) was filtered off. Removal of volatiles from the filtrate under reduced pressure yielded a white sticky solid, $ClSn\{Zr_2(OPr^i)_9\}$ (3.51 g, 97%). The compound was purified by sublimation (140°/0.1 mm) in 70% yield.

(3) $(Pr^iO)Sn\{Zr_2(OPr^i)_9\}$ (**3a**). To a benzene ($\sim$ 20 cm^3) solution of $ClSn\{Zr_2(OPr^i)_9\}$ (3.9 g, 4.38 mmol) was added slowly a suspension of $KOPr^i$ [prepared by reacting potassium (0.17 g, 4.40 mmol) with isopropyl alcohol ($\sim$ 5 cm^3), followed by removal of volatiles]. The reaction mixture was stirred at 70°C for $\sim$ 4 h. The precipitated KCl (0.31 g, 4.15 mmol) was removed by filtration. The volatiles were stripped from the filtrate under reduced pressure ($\sim$ 1 mm) to yield the title product (3.95 g, 96%) as a sticky solid, which was purified by sublimation at 141°C/0.1 mm in 60% yield.

In a similar manner the equimolar reaction of $KOBu^t$ with $ClSn\{Zr_2(OPr^i)_9\}$ afforded $(OBu^t)Sn\{Zr_2(OPr^i)_9\}$ as a sticky solid (b.p. 146°C/0.1 mm).

(4) $\{Al(OPr^i)_4\}Sn\{Zr_2(OPr^i)_9\}$ (**3c**). To a benzene ($\sim$ 20 cm^3) solution of $ClSn\{Zr_2(OPr^i)_9\}$ (7.38 g, 9.79 mmol) was added $KAl(OPr^i)_4$ [freshly pepared from potassium (0.38 g, 9.87 mmol) and $Al(OPr^i)_3$ (2.01 g, 9.86 mmol) in isopropyl alcohol ($\sim$ 5 cm^3) and benzene ($\sim$ 15 cm^3), followed by removal of the volatiles]. The reaction mixture after stirring for $\sim$ 3 h was refluxed for *ca* 1 h. The precipitated KCl (1.40 g, 18.76 mmol) was filtered off. Removal of the volatiles from the filtrate yielded the title product (10.5 g, 97%) as a viscous mass, which could be volatilized at 180°C/0.1 mm, unchanged in 60% yield.

Details of analytical and physical data for all the derivatives are listed in Table 1.

RESULTS AND DISCUSSION

Heterometal chloride alkoxides of tin(II) can be synthesized readily in quantitative yields by the equimolar reaction of the appropriate potassium alkoxometallate with $SnCl_2$ in a suitable solvent, according to the following equation [eq. (1)]:

$$SnCl_2 + KM_x(OR)_y \longrightarrow ClSn(M_x(OPr^i)_y) + KCl\downarrow \quad (1)$$

(**1a**): M = Al, $x = 1, y = 4$

(**1b**): M = Zr, $x = 2, y = 9$

(**1c**): M = Nb, $x = 1, y = 6$

(**1d**): M = Ta, $x = 1, y = 6$.

These chloro derivatives (**1a** and **1b**) have been shown to be convenient precursors for the synthesis of many interesting hetero- (bi- or tri-)metal alkoxides via chloride–alkoxide (or alkoxometallate) exchange reactions [eqs (2)–(4)], as shown below:

$$\mathbf{1a} + Kx \longrightarrow \mathbf{2} + KCl\downarrow \quad (2)$$

2a: x = OPr^i, **2b**: x = OBu^t

$$\mathbf{1b} + Kx \longrightarrow \mathbf{3} + KCl\downarrow \quad (3)$$

3a: x = OPr^i, **3b**: x = OBu^t,
3c: x = $\{Al(OPr^i)_4\}$

$$\mathbf{1c} + Kx \longrightarrow \mathbf{4} + KCl\downarrow \quad (4)$$

4a: x = OPr^i, **4b**: x = OBu^t,
4c: x = $\{Ta(OPr^i)_6\}$.

Most of these derivatives are colourless viscous materials and attain a yellowish tinge on storage. They are highly susceptible to moisture and air. The compounds are readily soluble in common organic solvents and show molecular complexities in the range 1.4–1.7 in boiling benzene, indicating the existence of an equilibrium between monomeric and dimeric species. The derivatives $\{Al(OPr^i)_4\}Sn\{Zr_2(OPr^i)_9\}$ and $\{Nb(OPr^i)_6\}Sn\{Ta(OPr^i)_6\}$ are monomeric.

These derivatives could be volatilized unchanged under reduced pressure, except the compounds containing hexaisopropoxoniobate and -tantalate units

Table 1. Analytical, some physical and NMR (^{27}Al and ^{119}Sn) data for new heterometal alkoxides of tin(II)

[c] Refers to undistilled product.

which disproportionated at higher temperatures into the volatile $[M(OPr^i)_5$ (M = Nb or Ta)] and non-volatile components $[ClSn(OPr^i)]$.

IR spectral studies

Following published data[21–23] on metal alkoxides and metal halide complexes,[24] these new derivatives have been characterized by absorption bands in the region 1170–300 cm^{-1}. The ν(C—O) absorptions due to terminal and bridging isopropoxy groups appear at 1160–950 and 935–900 cm^{-1}, respectively. Absorptions in the range 720–430 cm^{-1} have been observed for ν(Al—O), 750–675, ν(Zr—O), 585–510, and ν(M′—O) [M = Nb or Ta], 610–540 cm^{-1}. The ν(Sn—O) stretching frequencies have been observed in the range 705–535 cm^{-1}. The chloro complexes exhibit additional bands in the 335–305 cm^{-1} region due to Sn—Cl stretching frequencies.

NMR studies

The ^{1}H NMR spectrum of **1a** exhibits two overlapping doublets at δ 1.09 and 1.15 ppm, arising from terminal isopropoxy methyl protons. The two doublets at δ 1.32 (J = 6 Hz) and 1.40 (J = 6 Hz) may be assigned to methyl protons of bridging isopropoxy groups. The integrated intensity ratio of terminal and bridging methyl protons is approximately 1 : 1. The methine protons are observed as overlapping septets at δ 4.44 ppm (J = 6 Hz). The ^{13}C NMR spectrum of **1a** shows peaks at δ 25.27, 26.65, 28.22 and 63.60, 65.49, 66.41 ppm for β- and α-carbon atoms, respectively.

The ^{1}H NMR spectrum of **1b** displays two overlapping doublets at δ 1.27 and 1.18 ppm due to the methyl protons of terminal and bridging isopropoxy groups. The methine protons of terminal and bridging isopropoxy groups appear as a complex multiplet in the range δ 4.62–3.24 ppm (J = 6

Hz), in which 11 peaks can be distinguished. The above observation is supported by ^{13}C NMR data: δ 25.84, 25.05 (β-carbons) and 75.08, 75.57 (α-carbons). It is noteworthy that the nature of the ^{1}H NMR spectrum of **1b** remains unaltered even at $-65°C$.

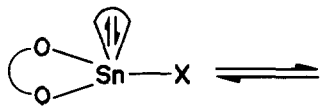
The ^{1}H NMR spectrum of **1d** shows: (1) peaks due to methine protons as two multiplets at δ 3.95 and 4.88 ppm, wherein 10 and seven peaks, respectively, can be distinguished arising from terminal and bridging isopropoxy groups; and (2) two doublets centred at δ 1.37 and 1.44 ppm ($J = 6$ Hz), assignable to bridging isopropoxy groups, while the upfield signals at δ 1.21, 1.26 and 1.32 ppm may be due to two overlapping doublets of terminal isopropoxy groups. Interestingly, the ^{13}C NMR spectrum in benzene exhibits a simpler pattern with peaks at δ 25.13 and 71.56 ppm, ascribable to β- and α-carbons of the isopropoxy groups, respectively.

The ^{1}H NMR spectrum of **4a** shows two overlapping doublets at δ 1.17 and 1.25 ppm, arising from $OCHMe_2$ groups present in bridging and terminal positions. The methine protons appear as an average septet centred at δ 4.53 ppm ($J = 6$ Hz). The derivative **4b** displays four peaks (δ 1.14, 1.23, 1.27 and 1.34 ppm) in the form of two doublets ($J = 6$ Hz) centred at δ 1.19 and 1.31 ppm, due to *gem*-dimethyl protons. Out of the above the peaks at δ 1.34 and 1.27 appear to be mixed respectively with the singlets arising from CH_3 protons of the OBu^t group of the two types, i.e. terminal and bridging in the monomeric and dimeric forms of **4b**.

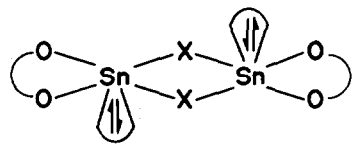
The ^{1}H NMR spectra of the complexes **2a**, **3a**, **3b** and **3c** exhibit doublets ($J = 6$ Hz) centred at δ 1.26, 1.21, 1.21 and 1.21 ppm due to *gem*-dimethyl protons, respectively, while the septets ($J = 6$ Hz) due to methine protons from the corresponding complexes have been observed, respectively, at δ 4.22, 4.46, 4.18 and 4.15 ppm, indicating a rapid interchange between terminal and bridging isopropoxy groups at room temperature. In the case of **3b** the peaks for tert-butoxy protons appear to merge in the peak due to isopropoxy methyl protons at δ 1.24 ppm. The ^{13}C NMR spectrum of **3c** exhibits a single peak at δ 27.34 ppm for β-carbons and two peaks at δ 68.69 and 69.18 ppm for α-carbons. The appearance of two peaks at δ -234.3 and -327.15 ppm in the ^{119}Sn NMR spectrum is indicative of the presence of two species in solution, probably in three- and four-coordinated environments around tin(II). The appearance of a broad signal centred at δ 64.3 ppm in the ^{27}Al NMR spectrum is indicative[25,26] of a pseudo-tetrahedral environment around aluminium. Further, the high-temperature ($+71°C$) ^{119}Sn NMR spectrum shows a relative decrease in intensity of the peak at δ -327.15 ppm, favouring the shifting of the equilibrium towards the formation of species in a lower coordination state.

The ^{1}H NMR spectrum of **4c** displays two doublets ($J = 6$ Hz) in the integrated intensity ratio 1 : 2, centred at δ 1.16 and 1.30 ppm, assignable to bridging and terminal *gem*-dimethyl groups. The methine protons appear as two septets centred at δ 4.20 and 4.70 ppm in the ratio indicated above. The ^{13}C NMR spectrum exhibits resonances at δ 25.11, 25.74 and 73.82, 75.08 ppm due to β- and α-carbons, respectively. The ^{119}Sn NMR spectrum shows a sharp signal at δ -329.75 ppm, possibly due to a tetra-coordinated tin atom with a stereochemically active lone pair.

The ^{119}Sn NMR spectra of chloro- and alkoxo-bimetallic derivatives (**1a**, **1b**, **1c**, **3a**, **3b**, **4a** and **4b**) exhibit two signals in the ranges δ -190 to -236 and -296 to -350 ppm, characteristic of three- and four-coordinated tin atoms, respectively, which could be interpreted in terms of an equilibrium between the three-coordinated monomer and the four-coordinated dimer, as indicated below:



(A)



(B)

where, X = Cl, OPr^i, OBu^t; = $Al(OPr^i)_4$,

$Zr_2(OPr^i)_9$, $M(OPr^i)_6$; M = Nb or Ta.

The above equilibrium is consistent with the observed molecular complexity in benzene (Table 1).

REACTIVITY OF (dtc)$BiCl_2$ (dtc = DIETHYLDITHIOCARBAMATE) TOWARDS PHENYLLITHIUM: SYNTHESIS AND CHARACTERIZATION OF NOVEL ORGANOMETALLIC TETRADENTATE BISMUTH(III) COMPLEXES

R. SHUKLA and P. K. BHARADWAJ*

Department of Chemistry, Indian Institute of Technology, Kanpur 208016, India

(*Received* 10 *September* 1992; *accepted* 9 *December* 1992)

Abstract—Two tetradentate organometallic complexes of bismuth(III) have been synthesized in high yields from the reactions of (dtc)$BiCl_2$ with phenyllithium in 1:1 and 1:2.5 molar ratios. These complexes were characterized by elemental analysis, IR and NMR spectroscopy. In Bi(dtc)PhCl (**1**) the bismuth(III) ion is coordinated to a dtc, a chloride and a phenyl group, thus providing the first example of a bismuth(III) complex having three different types of ligation. The other complex has ligation from two phenyl groups in addition to one dtc.

The dithiocarbamate anion (dtc) can bind strongly to transition as well as non-transition metal ions and a large number of dithiocarbamato complexes are known.[1–3] Our interest in bismuth chemistry stems from the facts that it is a relatively unexplored area and some bismuth compounds are used as heterogeneous catalysts.[4,5] We have initiated[6] a research program to explore the chemistry of bismuth in the +3 oxidation state with the ultimate goal of preparing catalytically active compounds. The difficulty in isolating pure bismuth compounds lies in the facile formation of BiO^+ in the presence of moisture unless the solutions are very acidic.[7] However, bismuth(III) being a heavy metal has a very strong affinity towards sulphur donor ligands. Thus, an aqueous solution of sodium dialkyldithiocarbamate reacts readily with an alcoholic solution of $BiCl_3$ to form $Bi(dtc)_3$ in high yields.[3] Even when BiOCl is allowed to react with an excess of dtc, the $Bi(dtc)_3$ can be isolated in good yields,[8] indicating the high stability of such bonding. In studying the reactivity of (dtc)$BiCl_2$ our assumption was that the bonding between dtc and bismuth(III) being quite stable should remain intact during cleavage of Bi—Cl bonds by various reagents, giving rise to the formation of new compounds.[8] When the (dtc)$BiCl_2$ complex was allowed to react with phenyllithium different bismuth(III) complexes could be isolated, depending upon the ratio of the reactants used. In the present paper we describe the facile syntheses of two such new bismuth(III) complexes and their characterization in the solid state.

EXPERIMENTAL

Materials

Bismuth trichloride and tetraethylthiuram disulphide were purchased from Aldrich, while carbon disulphide, diethylamine, sodium hydroxide, phenyl bromide and the solvents were obtained from SD Fine Chemicals, India. Lithium metal in the form of wire was acquired from Fisher Scientific. All the solvents, phenyl bromide and diethylamine were purified using standard procedures[9] prior to use. The reactions were carried out under dry nitrogen unless otherwise mentioned.

Proton NMR spectra were recorded on a Bruker WP-80 FT instrument using TMS as the internal standard. IR spectra were recorded on an Acculab-10 IR spectrophotometer. Conductivity data in acetonitrile were obtained using an all-glass model 82-CT conductivity bridge. Microanalyses were performed at the Central Drug Research Institute, Lucknow, India.

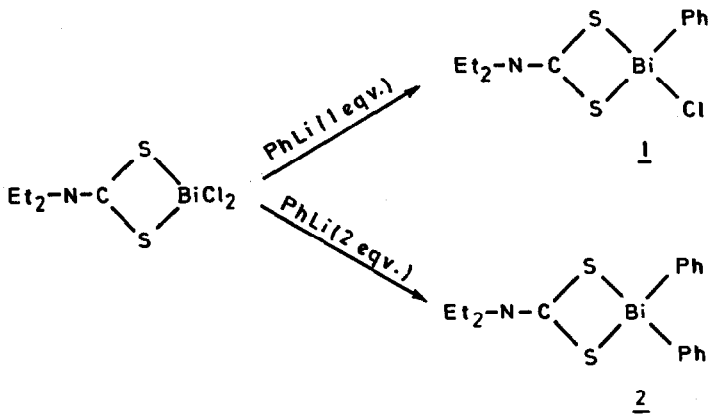

Fig. 1. Synthetic scheme for complexes **1** and **2**.

Synthesis of the complexes

Syntheses of the complexes are shown schematically in Fig. 1.

$Bi(dtc)Cl_2$. This compound was prepared[8] by reacting $BiCl_3$ with $Bi(dtc)_3$ in a 2 : 1 molar ratio in an acetonitrile–chloroform mixed solvent system at room temperature. The crystal structure of this compound has been determined.[10] It forms an extended chloride-bridged species in the solid state.

Bi(dtc)PhCl (**1**). This compound could be prepared by allowing phenyllithium to react with $Bi(dtc)Cl_2$ in a 1 : 1 molar ratio in THF medium at 0°C. Lithium metal (0.16 g, 0.023 mol) was added to THF (50 cm^3), followed by freshly distilled bromobenzene (0.37 g, 0.023 mol) dropwise with constant stirring. All the lithium dissolved in *ca* 1 h. At this point solid $Bi(dtc)Cl_2$ (1.0 g, 0.023 mol) was added to the solution in small portions. After the addition was complete, in 0.5 h, the resulting yellow solution was kept at room temperature for another 2 h and then filtered. The filtrate evaporated to dryness and the yellow residual solid was dissolved in acetone and allowed to evaporate at room temperature. A light yellow microcrystalline solid deposited, which was collected by filtration and air-dried. Yield 52% ; m.p. 125–127°C.

$Bi(dtc)Ph_2$ (**2**). When phenyllithium and $Bi(dtc)Cl_2$ was allowed to react in a 2.5 : 1 molar ratio under warm conditions (50–60°C) both the chloride groups were replaced by the phenyl groups to give the title compound in 66% yield. Elemental analyses and ^1H NMR data for the two complexes are given in Table 1.

RESULTS AND DISCUSSION

Both of the complexes are stable in air in the solid state, as well as in solvents like acetone, acetonitrile, etc. Both behave as non-electrolytes in the above two solvents, signifying that the integrity of the complexes remains intact in these solvents. Selective IR spectral data for **1** and **2** and related complexes are collected in Table 1. Both **1** and **2**, as well as other dithiocarbamato complexes of bismuth(III), show two strong peaks in the region 1450–1550 cm^{-1}. However, triphenyl bismuthine does not absorb appreciably in this region and hence, these two peaks are associated with carbon–nitrogen stretching vibrations. Transition metal complexes of dialkyldithiocarbamato ligands are reported to show absorption in this region due to C—N stretching vibrations.[3] Positions of these absorptions fall between C—N single and C=N double bonds,[11] signifying partial double-bond character for this bond. The 950–1050 cm^{-1} region is associated with ν(CSS) vibrations. However, the phenyl group absorbs strongly in this region and hence, no comment can be made regarding the ν(CSS) vibrations. The complexes $(dtc)BiCl_2$ and **1** show three sharp peaks in the 400–300 cm^{-1} region, which are not present either in the spectrum of **2** or in the spectrum of the $(dtc)_3Bi$ complex. These vibrations are assigned as the Bi—Cl stretching vibrations. Bi—Cl stretching vibrations are reported[12] to occur in this region.

The NMR spectral data for the complexes are also given in Table 1. For complex **1** the ratio of integration of the aliphatic and the aromatic protons is 1 : 1, indicating the formation of the complex as shown in Fig. 1. An alternative structure of **1** can be a chloride-bridged dimer or polymer. However, in the absence of an X-ray structure, it cannot be said with certainty whether the structure is monomeric or dimeric. However, the FAB-mass data showed a peak at 434, which is attributable to the cation $[(Ph)Bi(dtc)]^+$. The NMR spectrum of complex **2** shows the ratio of integration of the aliphatic and aromatic protons as 1 : 2 and it is most likely a discrete monomeric complex, as shown in Fig. 1.

(*Received* 15 *October* 1992; *accepted* 2 *December* 1992)

Abstract—The synthesis and characterization by elemental analyses, mass, IR and electronic spectrometry and conductance and magnetic measurements of compounds with the general formula $Ni(BBDHP)X_2 \cdot n$Solv. is reported [X = Cl, Br, I, ClO_4 or NO_3; Solv. = H_2O, EtOH or Bu^tOH; n = 2–5; BBDHP = 1,7-bis(benzimidazol-2-yl)-2,6-dithiaheptane]. The structures of $[Ni(BBDHP)(\mu\text{-}Cl)]_2Cl_2 \cdot 5H_2O \cdot 2EtOH$ (**II**) and $Ni(BBDHP)Br_2 \cdot EtOH \cdot 1/2Bu^tOH$ (**IV**) were determined by single-crystal X-ray diffraction. A molecule of **II** exhibits a dimeric structure involving two approximately symmetrical chlorine bridges. In both complexes the nickel atom has an octahedral environment with *cis* coordination of the two halide ligands [av. Ni—Cl = 241.6(1), av. Ni—Br = 256.9(9) pm] and the BBDHP in a symmetrical-*cis* arrangement [av. Ni—S = 243.6(2), av. Ni—N = 207.1(4) pm]. In both compounds the crystal packing is governed mainly by hydrogen bonds involving benzimidazole groups, halide atoms and water molecules.

Metal complexes of sulphur–nitrogen chelating ligands have attracted considerable attention because of their interesting physicochemical properties, pronounced biological activities[1–3] and as models of the metalloprotein and metalloenzyme active sites, since it is well known that histidine imidazole nitrogen atoms and methionine thioether sulphur atoms play key roles in the coordination of metals at the active sites of numerous metallobiomolecules,[4] whereby linear tetradentate chelating ligands with an NSSN-donor system are some of the most utilized.[5]

As part of our comprehensive research into compounds formed by transition and post-transition metal(II) ions and polydentate ligands,[6–14] this paper describes the synthesis and structural characterization of nickel(II) complexes of the ligand 1,7-bis(benzimidazole-2-yl)-2,6-dithiaheptane (BBDHP), which also has an N_2S_2 donor system via two benzimidazole nitrogen atoms and two thioether sulphur atoms.[15,16] These complexes, with chlorine and bromine as counter-ions, have already been partially studied,[16] but we have now completed that study and also have determined the crystal and molecular structure.

EXPERIMENTAL

Materials

The ligand BBDHP was prepared according to the method described in the literature.[17] Nickel(II) salts and solvents were reagent-grade chemicals.

Metal complexes

All the complexes were isolated by the following general procedure. To a solution of nickel(II) salt (1 mmol) in a minimum amount of EtOH was added a solution of BBDHP (1 mmol) in hot EtOH and the mixture was left with constant stirring for several days. The solid products were filtered off, washed with EtOH and dried over $CaCl_2$ (yield 60–90%). Crystals of $[Ni(BBDHP)(\mu\text{-}Cl)]_2Cl_2\cdot 5H_2O\cdot 2EtOH$ (**II**) were grown by slow evaporation of the EtOH solution and $Ni(BBDHP)Br_2\cdot EtOH\cdot 1/2Bu^tOH$ (**IV**) crystals were obtained after recrystallization from Bu^tOH. The analytical data are reported in Table 1.

Physical measurements

Microanalyses for carbon, hydrogen and nitrogen were determined on a Perkin–Elmer 240B microanalyser. Positive ion FAB mass spectra were obtained on a Kratos MS-50 mass spectrometer retrofitted with a Kratos FAB source and interfaced to a Kratos DS-90 data system. Xenon was used as the bombarding gas with atom gun energies of 8 kV. The source was operated at 250°C. The liquid matrix used was 3-nitrobenzyl alcohol (NBA). IR spectra in the range 4000–200 cm^{-1} were measured in KBr pellets on a Perkin–Elmer 1330 spectrometer. Conductance measurements in acetonitrile at *ca* 10^3 M were made with a WTW conductivity bridge type LF-3. Magnetic measurements in the temperature range 70–300 K were obtained by the Faraday method with a DSM-5 susceptometer calibrated with $HgCo(NSC)_4$. Diamagnetic corrections were applied using Pascal's constants.[18] Diffuse reflectance spectra were recorded on Perkin–Elmer Lambda 15 and Lambda 9 spectrophotometers equipped with a reflectance accessory, using MgO as the reference.

Data collection and structure analyses for II *and* IV

Prismatic crystals of **II** ($0.55\times0.55\times0.65$ mm) and **IV** ($0.50\times0.40\times0.40$ mm) were mounted on glass fibres and placed on an Enraf–Nonius CAD-4 automatic diffractometer. Cell parameters were determined on the diffractometer and were refined by least-squares fit of the parameters to 25 reflections for both **II** and **IV**. Crystal data are summarized in Table 2.*

Data for both compounds were collected with graphite-monochromatized Mo-K_α radiation ($\lambda = 0.71073$ Å) using the ω/θ scan technique ($3 < \theta < 25°$). 5705 (**II**) and 3517 (**IV**) independent reflections with $I > 3\sigma(I)$ were used for the structure refinement. The intensities were corrected for Lorentz–polarization effects and absorption.[19]

The structures were solved by direct methods,[20] which revealed the positions of all non-hydrogen atoms, and refined by the full-matrix least-squares method based on F with a weighting scheme of $w = 1/\sigma^2(F)$.[21] The positions of the hydrogen atoms were obtained by a difference-Fourier synthesis and included in the structure-factor calculation with B_{iso} fixed, but not refined.

In the last cycle of the refinement, in **II** with anisotropic displacement factors for all non-hydro-

gen atoms and in **IV** with anisotropic displacement factors for nickel, sulphur, bromine and four nitrogen atoms and isotropic factors for the remaining non-hydrogen atoms, including a secondary extinction correction,[22] no parameters shifted by more than 0.001. The final values of R and R_w were 0.050 and 0.054 (**II**) and 0.063 and 0.076 (**IV**), respectively. A final difference-Fourier contained no peak higher than 0.78 for **II** and 0.87 e Å^{-3} for **IV**, respectively. All the calculations were performed on a DEC MicroVAXII. The atomic scattering factors were taken from the International Tables.[23]

RESULTS AND DISCUSSION

The metal complexes are quite stable at room temperature and do not show any decomposition after a long period, but were found to be insoluble in most common polar and non-polar organic solvents. Solutions in acetonitrile (*ca* 10^{-3} M) could only be obtained with the complexes [Ni(BBDHP)I_2] $\cdot$ 2Bu^{t}OH (**V**) and [Ni(BBDHP)$(H_2O)_2$]$(ClO_4)_2$ (**VI**). The molar conductance of 39 Ω^{-1} cm^2 mol^{-1} for complex **V** in acetonitrile is consistent with its non-electrolytic nature,[24] showing that the iodine atom is coordinated to the nickel. The value of 285 Ω^{-1} cm^2 mol^{-1} found for compound **VI** proves this complex to behave as a uni-univalent electrolyte,[24] indicating the dissociation of bonds between nickel and anions and shows the presence of perchlorate anions inside the coordination sphere.

The mass spectra of the complexes, summarized in Table 3, have two peaks. That of greater m/z can be assigned to the $[Ni(BBDHP)X]^+$ species and another of $m/z = 426$ to the $[Ni(BBDHP)]^+$ species. Both these species are common in the mass spectra of similar complexes with the metal in oxidation states of II or III.[14,25,26] The spectra also show some peaks at lower m/z values that are due to the ligand and its fragmentation products. At

higher *m/z* values the spectra of compounds **II** and **IV** contain peaks assigned to the dimeric species $[Ni_2(BBDHP)_2X_2]^+$, which in complex **II** appear with high relative abundance, thus indicating their stability.

Description of the structure of **II**

In this compound the asymmetric unit is formed by an $[Ni_2(BBDHP)_2(\mu\text{-}Cl)_2]^{2+}$ cation, two chloride anions, five water molecules, three of them being disordered, and also two disordered ethanol molecules.

The cation consists of dichloro-bridged dimeric units. A view of a single dimer is given in Fig. 1. The geometry at the nickel(II) centres is octahedral with the BBDHP ligand in a symmetrical-*cis* disposition, in which the axial positions around both metals are occupied by nitrogen donor atoms of the two benzimidazolyl groups and two of the equatorial positions by the thioether sulphur atoms. The remaining equatorial positions are occupied by the two bridging chlorine atoms.

The geometry at the nickel centre is highly distorted. The bond lengths and angles in the coordination sphere are given in Table 4. The *cis* angles in the equatorial planes range from 86.90(5) to 97.73(4)° for Ni(1) and 86.22(4) to 99.95(4)° for Ni(2), while the *trans* angles are between 173.13(4) and 174.44(4)° and the N—Ni—N axial angles are 171.70(1) and 170.30(1)° for Ni(1) and Ni(2), respectively. Some distortion may be introduced because of the four five-membered and two six-membered chelate rings present in the molecule. Least-squares planes were calculated for all four chelate rings, and in all cases the rings were not planar. The deviations from planes range from −27.4 to 24.8 pm.

The nickel–sulphur bond lengths between 240.9(1) and 246.3(1) pm are in the lower range of 240–260 pm, generally observed for Ni—S distances in octahedral molecules. The nickel–nitrogen bond lengths of 205.8(3)–206.2(3) pm are within the range found in other octahedral nickel complexes with NSSN-type ligands and benzimidazolyl groups,[9,16] but significantly different from the nickel to nitro-

gen distances of 210–214 pm found in complexes with similar ligands with pyridyl groups.[27] The question if the difference is related to the basicity of the two types of heterocycle nitrogen atoms cannot be answered at present.

The Ni(1)—Cl—Ni(2) bridges are quite symmetrical and the Ni—Cl distances of 240.9(1)–243.0(1) pm compare well with the mean distance of 243.6 pm, calculated on the basis of the structures of 20 six-coordinate nickel(II) complexes.[28] The angles within the bridge Ni(1)—Cl—Ni(2) of 92.67(3) and 93.04(3)° are also comparable with those in other octahedral dichloro-bridged nickel(II) dimers. The large Ni(1)···Ni(2) distance of 350.08(7) pm indicates the absence of orbital interactions between the metal atoms. The Cl(1)···Cl(2) distance is 332.9(1) pm.

The bond distances and angles in the BBDHP ligand are within the expected range, except the C(10)—C(11) bond which is 137.0(9) pm. This is a result of the disorder of these atoms. The benzimidazolyl rings are planar with deviations from the mean plane less than 5 pm.

The two Cl^- counter-ions are associated with two water molecules (Fig. 2). From the H···Cl and O···Cl distances and O—H···Cl angles there is evidence of hydrogen bond interactions.[29] The resulting $[Cl_2(H_2O)_2]^{2-}$ units also form hydrogen bonds with N—H of the benzimidazolyl groups of neighbouring cations. A summary of the dimensions of the hydrogen bonds is given in Table 5 and a stereoview of the packing of the molecules in the unit cell in Fig. 3.

Discussion of the structure of **IV**

The asymmetric unit consists of two Ni(BBDHP)Br_2 molecules, two ethanol molecules and a disordered n-butanol molecule. The perspective drawing of the two independent [Ni(BBDHP)Br_2] molecules and the numbering scheme of the atoms are shown in Fig. 4. As can be seen in this figure, and as is expected, the complex exhibits an octahedral geometry and the BBDHP ligand molecules have a very similar symmetrical-*cis* arrangement to that of the $[Ni_2(BBDHP)_2(\mu\text{-}Cl)_2]^{2+}$ cation, with Ni—S distances between 240.9(2) and 246.1(2) pm and average Ni—N distances of 208.3(4) pm being also comparable with those of compound **II**. The selected interatomic distances and angles are listed in Table 6.

The observed Ni—Br distances from 254.3(9) to 257.8(9) pm are in the range normally observed for octahedrally coordinated nickel(II)[28] and are similar to those found in Ni(BBDH)Br_2 [BBDH = 1,6-bis(benzimidazol-2-yl)-2,5-dithiahexane].[16]

The most obvious deviations from the ideal octahedral coordination polyhedron are the Br—Ni—N angles between 99.00(1) and 101.60(1)° and the angles N(1)—Ni(1)—N(3) and N(21)—Ni(2)—N(23) of 162.00(2) and 162.20(2)°, respectively.

The geometry of the BBDHP ligand does not

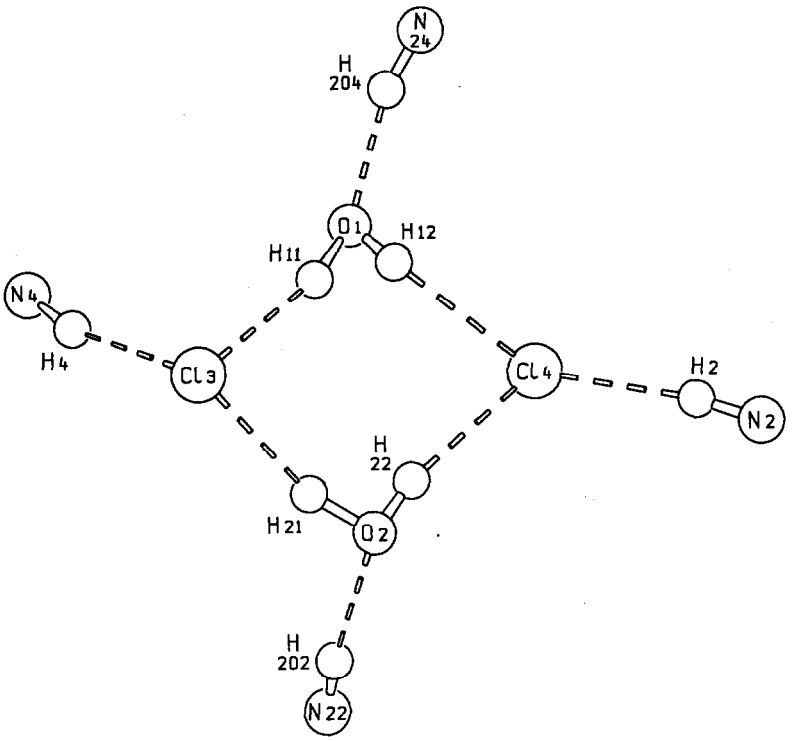

Fig. 2. Perspective drawing of the associated chloride anions in **II** showing the inter- and intramolecular hydrogen bond.

show any dissimilarity with that observed in compound **II**.

The symmetrically independent molecules appear to be joined by a pair of hydrogen bonds between the benzimidazole N—H group of one complex and a bromide ligand of the other complex (Table 5). The N···Br and H···Br distances and associated N—H···Br angles are well within the range observed for other N—H···Br hydrogen bonds.[30] A stereoview of the unit cell is shown in Fig. 5.

IR spectra

The assignments of some of the IR spectral bands of free BBDHP and its nickel(II) complexes are

reported in Table 7. The IR spectra of the compounds are very similar to one another and to BBDHP itself. The most significant differences are in the NH stretching region. The ν(NH) frequency on coordination is raised by *ca* 200 cm^{-1} relative to that of the free ligand, and in the 1450–1400 cm^{-1} region the low frequency shift of the deformations δ(NH) shifts from 1430 cm^{-1} in BBDHP to *ca* 1400 cm^{-1} in the complexes. This indicates that there are direct bonds between the pyridine nitrogen atoms of the benzimidazolyl groups and the nickel atoms. A weak band observed at 690 cm^{-1} is assigned mainly to the ν(CS) stretching vibration[31] and on coordination is irregularly displaced.

The IR spectrum of the nitrate derivative exhibits bands around 1530, 1278 and 1005 cm^{-1}, assigned to ν_4, ν_1 and ν_2 modes associated with a monodentate nitrate group.[32] In the case of the perchlorate derivative strong singlets at 1100 and 625 cm^{-1} are observed, which are assigned to the ν_3 stretching vibration and ν_4 deformations in an ionic perchlorate group.[32]

In the far-IR region the complexes exhibit bands at 320 and 285 cm^{-1}, which are assigned to ν(NiN) and ν(NiS) vibrations, respectively.[33] In compounds **I** and **II** ν(NiCl) appear at 260 (Ni—Cl_t) and 220 cm^{-1} (Ni—Cl_b), and in compounds **VI** and **VII** ν(NiO) appear at *ca* 405 cm^{-1}, which are in good agreement with the reported values.[33]

[a] $B(Ni^{2+}) = 1030\ cm^{-1}$; $\beta = B/1030$.

Electronic spectra

The reflectance spectra of the nickel(II) complexes (Table 8) display three sets of low-intensity absorption bands at 8880–9730 [ν_1, $^3A_{2g}(F) \rightarrow {}^3T_{2g}(F)$], 14,830–16,420 [$\nu_2$, $^3A_{2g}(F) \rightarrow {}^3T_{1g}(F)$] and 24,450–25,700 cm^{-1} [ν_3, $^3A_{2g}(F) \rightarrow {}^3T_{1g}(P)$]. The position of those bands and the calculated $10Dq$, B and β values are analogous to other octahedral nickel(II) complexes.[34]

Magnetic moments

The μ_{eff} values at room temperature and in the range 70–300 K with Curie–Weiss, θ, and Curie, c, constants are reported in Table 9. The magnitude and slight temperature dependence of the μ_{eff} values betweem 2.7 and 3.2 B.M. are in the range expected for distorted octahedral complexes of nickel(II).[35]

(*Received* 1 *October* 1992; *accepted* 20 *November* 1992)

Abstract—Complexes of lanthanide chlorides with pyruvic acid semicarbazone (PASH), having the general formula $Ln(PAS)_3 \cdot nH_2O$ (where Ln = La–Nd, Sm–Dy, Er, Yb; n = 1–3), have been synthesized and characterized on the basis of elemental analyses, IR spectra and thermal analyses. It has been found that the ligand and its complexes possess scavenger effects on OH$^{\cdot}$ and $O_2^{-\cdot}$ radicals.

Thiosemicarbazones, semicarbazones and their metal complexes have aroused great interest due to their possession of a broad spectrum of biological activity.[1–7] Moreover, in many cases it has been suggested that the biological activities of thiosemicarbazones and semicarbazones can be increased on being coordinated or mixed with suitable metal ions.[8–10] This idea led us to prepare thiosemicarbazones[11] and semicarbazone-metal complexes with a view to evaluate their biological properties.

Although some transition metal complexes with pyruvic acid semicarbazone (= PASH) have been reported,[12–14] no paper concerning the study of lanthanide(III) complexes with this ligand has yet appeared. Therefore, we now wish to report the synthesis characterization of lanthanide(III) complexes with PASH and discuss their biological properties.

EXPERIMENTAL

All chemicals used were of reagent grade. All biochemicals were obtained from Sigma Chemical Co. The hydrated lanthanide(III) chlorides were prepared by dissolving the respective oxides (99.95%) in concentrated HCl. The ligand pyruvic acid semicarbazone was prepared according to the literature method.[15] The purity of the ligand was confirmed by elemental analysis and ^{1}H NMR spectroscopy. δH: 2.05 (3H, s, —CH_3), 7.04 (2H, s, —NH_2), 9.92 (1H, s, —NH), 11.15 (1H, s, —COOH).

Preparation of the complexes

A solution of an appropriate lanthanide(III) chloride (1 mmol) in water (20 cm^3) was added dropwise to a solution of NaOH (3 mmol) and PASH (3 mmol) in water (20 cm^3). After stirring for 4 h at room temperature a precipitate was collected by filtration, washed with water until the Cl^- ions disappeared and dried in a vacuum desiccator over P_4O_{10}. The elemental analyses of the complexes are given in Table 1.

Physical measurements

Carbon, hydrogen and nitrogen were determined using a Carlo-Erba 1106 elemental analyser. The metal contents of the complexes were estimated by titration with EDTA. The IR spectra were recorded on a Nicolet-170SX FT-IR spectrophotometer using KBr discs in the range 4000–200 cm^{-1}. ^{1}H NMR spectra were obtained using a

Varian FT-80A spectrometer with $CDCl_3$ as the solvent and TMS as the internal reference. Thermal analyses were performed using a Du Pont 1090 thermal analyser. Gas chromatography was performed using a Shimadzu GC-8A gas chromatograph spectrometer. Absorbances were determined on a 751-spectrophotometer at 560 nm.

Tests for scavenger effects on $OH^{\bullet}$ *and* $O_2^{-\bullet}$

The hydroxyl radicals ($OH^{\bullet}$) were produced by the H_2O_2/Fe^{2+}-EDTA/ascorbic acid[16] system and determined by their reaction with 3-methylthiopropionaldehyde to give ethylene. The reaction mixture (5 cm^3) contained Fe^{2+}-EDTA (0.1 mM), 3-methylthiopropionaldehyde (0.1 mM), L-ascorbic acid (0.20 mM), H_2O_2 (0.40 mM), the tested compound (0.3 mM) and NaH_2PO_4–K_2HPO_4 buffer (0.01 M) (pH = 7.4). The reaction was left for 0.5 h at a constant 37°C. The amount of ethylene produced was detected by gas chromatography. The suppression ratio for $OH^{\bullet}$ was calculated from the following expression:

$$\text{Suppression ratio} = 100 \times \frac{M_0 - M}{M_0},$$

where M = ethylene content in the presence of the ligand or its complexes and M_0 = ethylene content in the absence of the ligand or its complexes.

The superoxide radicals ($O_2^{-\bullet}$) were produced by a system of NADH/PMS (phenazine methosulphate)/NBT (nitro blue tetrazolium)[17] and measured by the amount of NBT reduced by $O_2^{-\bullet}$. The reaction mixture (5 cm^3) contained NADH (79 μM), PMS (30 μM), NBT (75 μM), tris-HCl buffer (0.01 M) (pH = 8.0) and the tested compound (3 μM). The reaction was left for 5 min at room temperature. The amount of reduced NBT was detected by the absorbance at 560 nm, since the reduced product, blue formazan, absorbs at this wavelength. The suppression ratio for $O_2^{-\bullet}$ was calculated from the following expression:

$$\text{Suppression ratio} = 100 \times \frac{A_0 - A}{A_0}$$

where A = the absorbance in the presence of the ligand or its complexes and A_0 = the absorbance in the absence of the ligand or its complexes.

RESULTS AND DISCUSSION

The elemental analyses of the lanthanide(III) complexes (see Table 1) show that the lanthanide(III) ions form 1:3 (metal:ligand) complexes having the general formula $Ln(PAS)_3 \cdot nH_2O$ (where Ln = La–Nd, Sm–Dy, Er, Yb; n = 1–3). These data also show that all the complexes contain water molecules, which was also confirmed by the thermal studies and IR spectra of the complexes. The complexes are stable at room temperature and insoluble in most common organic solvents, but they are slightly soluble in DMF and DMSO.

Thermal analysis

The TG curves of the complexes show a weight loss between 35 and 150°C. The weight loss corresponds to one water molecule for La–Eu (except Pm) complexes; two water molecules for the Yb complex and three water molecules for Gd–Dy and Er complexes. These results are in accordance with the compositions of the complexes determined by elemental analyses. Although the dehydration temperature for some complexes is relatively high (over

Table 2. Thermal studies for dehydration and decomposition process of typical complexes

100°C), it appears that the water molecules in these complexes are present as crystal water, since no characteristic band due to coordinated water is observed in the far-IR spectra of the complexes. The higher dehydration temperature for some complexes may be due to the existence of relatively strong hydrogen bonds between water molecules and the ligand in the complexes in the solid state, as was observed in the manganese complex with PASH whose crystal structure was determined by single-crystal X-ray diffraction.[18] The complexes undergo decomposition over the range 260–710°C. The final products are metal oxides in all cases. The thermal analytical data of typical complexes are given in Table 2.

IR spectra

The important data for the ligand and its complexes are listed in Table 3. In the IR spectra of the complexes the bands at 3567–3518 cm^{-1} assigned to $\nu(OH)(H_2O)$, which are absent in the free ligand, are weak and broad, indicating that the water in all of these complexes is crystal water.[19] This is further supported by the absence of any modes of coordinated water.[20] The strong band at ~ 3440 in the free ligand assigned to $\nu(NH_2)$ vibrations of the terminal $-NH_2$ group is unchanged or slightly shifted towards the higher side in all the complexes, suggesting that the $-NH_2$ group is not involved in bonding. The bands at 1750, 1679 and 1620 cm^{-1} in

the free ligand, assigned to ν(C=O) of the carboxyl group, ν(C=O) of the semicarbazide moiety and ν(C=N) vibrations, respectively, shift towards lower wave numbers in all the complexes. This indicates that the pyruvic acid semicarbazone behaves as a tridentate ligand,[12] i.e. the ligand coordinates to the metal ion through the C=N nitrogen, the oxygen of the semicarbazone and the oxygen of the carboxylic group, forming two five-membered rings around the metal ion. The metal ion seems to be nine-coordinated. On the basis of the above discussion, the probable structure of the complexes is proposed and shown in Fig. 1.

The scavenger effects on $OH^{\cdot}$ *and* $O_2^{-\cdot}$

The suppression ratios of the ligand and its complexes for $OH^{\cdot}$ and $O_2^{-\cdot}$ radicals are summarized in Table 4. The results show that the ligand and its complexes possess scavenging effects on $OH^{\cdot}$ and $O_2^{-\cdot}$.

The suppression ratios of the complexes for $OH^{\cdot}$ and $O_2^{-\cdot}$ are mostly higher than that of the ligand. Also, it has been observed that the scavenging effects on $OH^{\cdot}$ and $O_2^{-\cdot}$ of the cerium complex are stronger than the other complexes. This may be due to the variable valency (III, IV) of the cerium ion.

(*Received* 31 *July* 1992; *accepted* 2 *November* 1992)

Abstract—The title complex pyridine[NN′-ethylenebis(salicylideneiminato)](iso-butyl)-cobalt(III) [$C_4^iH_9Co(salen)(py)$] has been synthesized and characterized and its crystal structure has been determined by X-ray diffraction methods. The crystal consists of discrete molecules with distorted octahedral stereochemistry around the cobalt(III) ion. The tetradentate "salen" ligand is in the equatorial plane and $C_4^iH_9$ and pyridine occupy the two axial positions. The lengths of axial Co—C and Co—N bonds are 2.003(4) and 2.184(3) Å, respectively.

As is well known, co-enzyme B_{12} (5′-deoxyadenosylcobalamin) was the first reported example of a naturally occurring organometallic compound. It serves as a co-factor for various rearrangement reactions in biological systems.[1] It is important to prepare the related organocobalt compounds containing Co—C σ-bonds as co-enzyme B_{12} models and to study the crystal structure of these compounds. Unfortunately, among the number of B_{12} model compounds only a few organocobalt(III) Schiff base complexes have undergone crystal structure determinations and there is a lack of X-ray diffraction data for those salen Schiff base complexes with both secondary alkyl and pyridine axial ligands.[2,3] Recently we prepared a new alkylcobalt(III) Schiff base complex [$C_4^iH_9Co(salen)(py)$] and in this paper we describe its synthesis and structure determination.

EXPERIMENTAL

Preparation

The title complex was prepared by dissolving 60 mg of $C_4^iH_9Co(salen)(H_2O)$[4] in pyridine (10 cm^3), after the addition of light petroleum/ether (5 cm^3), allowing the solvents to evaporate slowly at room temperature. All manipulations were performed in the dark. The purple crystal can be obtained in 15 days. Found: C, 64.8; H, 6.1; N, 9.2; Co, 12.9. Calc. for $C_{25}H_{28}CoN_3O_2$: C, 65.1; H, 6.1; N, 9.1; Co, 12.8%.

Characterization

IR spectra were recorded on a Shimadzu IR-440 spectrophotometer with KBr pellets. UV–vis spectra were performed on a Shimadzu UV-240 spectrophotometer. All manipulations for preparing the solutions were performed in the dark. TG and DTA analyses were determined on a ZRY-1 Thermal Analyser under a nitrogen flow at a heating rate of 10°C min^{-1}.

Crystal data

$C_{25}H_{28}CoN_3O_2$, $M = 461.45$; monoclinic, $a = 9.476(9)$, $b = 19.621(9)$, $c = 12.383(3)$ Å; $\beta = 106.5(4)°$, $V = 2288.6$ Å^3, $Z = 4$, $D_c = 1.339$ g cm^{-3}, Mo-K_α radiation, $\lambda = 0.71073$ Å, μ(Mo-K_α) = 7.7 cm^{-1}, $F(000) = 968e$, space group $P2_1/c$.

Data collection, structure solution and refinement

Data were collected at room temperature from a specimen measuring $0.4 \times 0.3 \times 0.3$ mm^3 on an Enraf–Nonius CAD4 four-circle diffractometer. 4922 reflections were collected by the $\omega/2\theta$ scan mode within the range $2° \leqslant 2\theta \leqslant 50°$, giving 4354 unique reflections, of which 3356 with $I > 3\sigma(I)$ were used in the structure refinement. Crystal monochromatized Mo-K_α radation ($\lambda = 0.71073$ Å) was used. Intensity data were corrected for Lorentz and polarization effects and empirically for absorption. The position of the cobalt atom was found by direct methods. Several cycles of difference-Fourier syntheses revealed all the non-hydrogen atoms. Full-matrix least-squares refined anisotropic thermal parameters on all the non-hydrogen atoms. All hydrogen atoms were located on difference-Fourier maps and refined isotropically. The final R and Rw [$w = 1/\sigma^2(F_o)$] factors are 0.038 and 0.043, respectively. The maximum peak in the final difference-Fourier analysis was 0.212 e Å^{-3}. All calculations were performed on a PDP11/44 computer using the SDP-PLUS program package.

Atomic fractional coordinates, anisotropic thermal parameters, bond lengths and bond angles, important equations of least-square planes and interplanar angles are deposited with the Editor as supplementary material. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

DISCUSSION

The structure of the alkylcobalt(III) complex and the packing diagram of the unit cell are shown in Figs 1 and 2, respectively.

The crystal contains discrete molecules with distorted octahedral stereochemistry around the cobalt(III) ion. The salen ligand occupies the four equatorial positions, whereas the $C_4^iH_9$ group and the pyridine molecule occupy the two axial positions. The structure determination shows that the cobalt atom is almost in the plane of the equatorial donors $N_1N_2O_2O_1$ (which are co-planar within ± 0.080 Å). The two salicylaldimine residues are bent towards the $C_4^iH_9$ group and assume an umbrella shape ($\alpha = 4.1$, $\beta = 12.1$, $\gamma = +16.1°$), with a slight twist between the planes of the aromatic rings. The pyridine plane is nearly perpendicular to the salicylaldimine plane (98.1°). The ethylene bridge atoms were not co-planar with $N_1N_2O_2O_1$ and the carbon atoms are asymmetrically displaced from the coordination plane leading to a "half-chair" (*gauche*) conformation of the ring. This conformation is preferred for asymmetric umbrella-shape molecules of salen derivatives.[2]

Important bond lengths and angles are given in Table 1. The distances for the Co-salen ligand are consistent with the average values reported for a series of salen compounds (Co—N 1.884, Co—O 1.904 Å).[2] The Co—C bond length (2.003 Å) of the title compound is not significantly different compared with the organometallic derivatives, but somewhat longer than in the vinyl analogue. [CH_2=CHCo(salen)py] shows a significantly shorter Co—C bond (1.930 Å), even after correction from an sp^2 to sp^3 carbon σ-covalent radius (1.950 Å).[5] On the other hand the Co—N(31) bond length is 2.184 Å. This is comparable with reported Co—N bond lengths *trans* to —CH=CH_2 (2.190 Å), —CH_2CN (2.092 Å) and —OCH_3 (2.031 Å) in octahedral salen compounds.

A RAPID COBALT CARBONYL MEDIATED CLEAVAGE OF BOTH PHOSPHORUS–CARBON BONDS IN BIS(DIPHENYLPHOSPHINO)METHANE UNDER VERY MILD CONDITIONS: EXTRUSION OF METHYLENE AS KETENE

SHAMSUDDIN AHMED, DAVID G. HOLAH, ALAN N. HUGHES* and ROBERT T. MARKEWICH

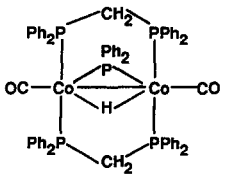
Department of Chemistry, Lakehead University, Thunder Bay, Ontario, Canada P7B 5E1

(*Received* 29 *July* 1992; *accepted* 5 *February* 1993)

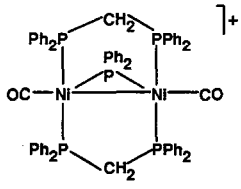
Abstract—In cobalt(II)/{bis(diphenylphosphino)methane}/$NaBH_4$/CO reactions, in which the $NaBH_4$ is added very rapidly, both P—C bonds of the phosphine are cleaved with extrusion of the methylene group as ketene.

It has been established[1] that the ease of transition-metal mediated phosphorus–carbon bond cleavage in tertiary phosphines is in the order P—C_{sp} > P—C_{sp^2} > P—C_{sp^3} and, therefore, the great majority of such reactions in the literature involve phosphorus bound to *sp* or sp^2 carbon.[2] While P—C_{sp^3} cleavage is the least common and normally requires more forcing conditions, several recent reports of this type of bond scission in bis(diphenylphosphino)methane (dppm) in the presence of di-iron,[3] platinum,[4] cobalt[5] or nickel[5] centres under comparatively mild conditions have appeared. These reactions normally result in the formation of products containing both the Ph_2P— and Ph_2PCH_2— fragments (or derivatives thereof) arising from a single P—C cleavage.[3a,4] However, products containing bridging Ph_2P— groups as in **1** and **2**, but with no trace of the Ph_2PCH_2— fragment, have also been reported;[5] there is one very recent report of a product containing both Ph_2P— fragments arising from a double P—C cleavage.[3b] In this last reaction (described as being unprecedented) $[Fe_2(CO)_6(\mu\text{-}CHCO_2Et)(\mu\text{-dppm})]$ under reflux in toluene generates[3b] ethyl acrylate and $[Fe_2(CO)_6(\mu\text{-}PPh_2)_2]$, probably via the formation of an $Fe_2(\mu\text{-}CH_2)$ unit followed by the intramolecular linking of the —CH_2— and —$CHCO_2Et$ bridges in the manner observed[6] for some other di-μ-alkylidene species. We report here evidence for another such double scission which occurs very rapidly under extraordinarily mild conditions and with the extrusion of methylene as ketene.

Examination of the filtrates obtained from reactions in which $NaBH_4$ is added very rapidly (< 1 min) to cobalt(II) and nickel(II) salts in ethanol/benzene under CO in the presence of dppm at room temperature (or below), giving[5] systems of types **1** and **2**, showed no traces of Ph_2PMe or



(1)



(2)

any other derivative of the Ph_2PCH_2— fragment. However, filtrates obtained from the cobalt(II) system (the cleanest of these reactions) always showed

* Author to whom correspondence should be addressed.

(GLC, MS)* the presence of ethyl acetate. Similar reactions performed in the absence of dppm showed no evidence of ethyl acetate formation. The $-CH_2-$ bridge in dppm is therefore extruded, together with CO, as ketene which then reacts[7] with the ethanol in the solvent mixture to give ethyl acetate with the entire reaction, starting from cobalt(II), being complete in *ca* 1 min at room temperature.

Clearly, there are important differences between the di-iron case[3] noted above and the cobalt(II) reactions leading to **1** in that the final product in the di-iron case contains two bridging phosphido units, while for **1** the second bridging species is hydride. Also, in the di-iron case the reaction requires more rigorous conditions (reflux) than pertain in the cobalt case (room temperature) and it is possible that the two reactions are mechanistically quite different. Mechanistic studies are in progress and the results of these studies will be the subject of a separate report.

* In a typical experiment, a solution of $CoCl_2 \cdot 6H_2O$ (0.22 g) and dppm (0.70 g) in degassed $EtOH/C_6H_6$ (1 : 1, 4 cm^3) was saturated with CO for 5 min and solid $NaBH_4$ (0.10 g) was added in one portion. After 1 min the mixture was filtered to remove **1** and some $[Co_2(\mu\text{-dppm})_2(CO)_4]$ and the filtrate was distilled to low volume. The metal- and phosphine-free distillate was examined by GLC on both Poropak Q and Chromosorb 101 columns. In each case ethyl acetate (not present in either of the solvents used for the reaction and not formed if dppm is absent from the reaction mixture) was detected. The retention times observed for each stationary phase were found to be identical to those observed for a standard sample of 1 : 1 $EtOH/C_6H_6$ containing 0.1% ethyl acetate, which, given the quantities of reagents and solvents used and the measured[5] yield of **1**, is representative of the low concentration which should be, and was, observed. Ethyl acetate formation was confirmed by low-voltage electron-impact mass spectrometric studies on the distillate. At 14 eV a weak peak assigned to the low concentration of ethyl acetate was observed at m/z 88. This peak decreased in intensity with increasing voltage, while a new peak at m/z 60 ($M-C_2H_4$, McLafferty elimination of ethylene) grew. This trend is clearer for the solvent system THF/C_6H_6, which, however, is not suitable for GLC studies since THF and ethyl acetate have similar retention times.

THE PREPARATION AND X-RAY STRUCTURE OF A SEVEN-COORDINATE TRIS(CATECHOLAMIDE)NIOBIUM(V) COMPLEX

DENNIS F. EVANS,✠ ALEXANDRA M. Z. SLAWIN, DAVID J. WILLIAMS,* CHIH Y. WONG and J. DEREK WOOLLINS*

The Evans and Chemical Crystallography Laboratories, Department of Chemistry, Imperial College, London SW7 2AY, U.K.

(*Received* 18 *December* 1992; *accepted* 1 *February* 1993)

Abstract—The preparation and crystal structure of the Nb^{V}(Htrencam)·DMSO complex is reported [where H_6trencam is the hexadentate tris(catecholamide) ligand and DMSO is dimethylsulphoxide], revealing a cavitand-like arrangement of the three catecholamide groups with the protonated non-binding nitrogen atom directed inwards to the niobium atom.

Biological metal encapsulation of iron(III) has been dominated by a group of low molecular weight macromolecules, the siderophores.[1] These are complexing agents that have a very high affinity for iron(III) and solubilize this otherwise insoluble ion, facilitating its transport into microbes such as bacteria and fungi. The synthetic analogue, H_6trencam [Fig. 1(a)], described by Raymond and co-workers,[2] has been well characterized for its ability to mimic the naturally occurring siderophore enterobactin [Fig. 1(b)]. The X-ray crystal structures of both K_3[Fe(trencam)]·CH_3OH·H_2O[3] and K_3[V(trencam)]·$4CH_3OH$·$2H_2O$[4] have been recently reported. Both anions show six-coordination by phenolic oxygen donors to form a distorted octahedral environment around the M^{3+} cation (M = Fe or V). An analogous ligand, H_6tripace [Fig. 1(c)], has been reported to chelate to titanium(IV) to form [NEt_3H][Ti(Htripace)], where the hexadentate chelate was protonated at the central nitrogen atom.[5]

Here, we describe the complex formed from the reaction between H_6trencam and $NbCl_5$ in refluxing ethanol, according to eq. (1).† This is the first neutral "trencam"-like bound metal complex.

The X-ray crystal structure‡ of Nb^{V}(Htrencam)·DMSO (Fig. 2) shows the niobium to be seven-coordinate. The "trencam" ligand binds to the niobium atom in a highly symmetric fashion via all six phenolic oxygen atoms. The C_3 sym-

† Preparation of Nb(Htrencam)·DMSO. $NbCl_5$ (0.35 g, 1.30 mmol) was added to H_6trencam·HBr·H_2O (0.85 g, 1.30 mmol) in ethanol (15 cm^3) under argon. The mixture was refluxed for 48 h and the orange solid filtered off. Nb^{V}(Htrencam)·DMSO recrystallized by slow diffusion of a DMSO solution layered with an ethanol/ether mixture. Mass spectrum (FAB$^-$, *m*-nitrobenzyl alcohol matrix): $m/z = 641$, corresponds to [Nb^{V}(trencam)]$^-$.

‡ Crystals of Nb^{V}(Htrencam)·DMSO suitable for X-ray diffraction measurements were obtained by slow diffusion (*ca* 2 months) from a DMSO solution layered with an ethanol/ether mixture. The resulting crystal quality was still extremely poor, the crystals giving diffuse diffraction patterns. Full data sets on two different crystals were obtained and we report that of the better crystal. *Crystal data.* Nb^{V}(Htrencam)·DMSO: $C_{29}H_{31}N_4O_{10}SNb$, $M = 720.6$, triclinic, $a = 9.798(6)$, $b = 12.136(6)$, $c = 12.860(11)$ Å, $\alpha = 91.64(5)$, $\beta = 99.61(6)$, $\gamma = 100.11(5)°$, $U = 1482$ Å^3, space group $P\bar{1}$, $Z = 2$, $D_c = 1.615$ Mg m^{-3}, μ(Mo-K_α) = 0.54 mm^{-1}, $\lambda = 0.71073$ Å, $F(000) = 740$. Siemens P4/PC diffractometer, room temperature, ω-scan method (2θ range 3.0–50.0°), graphite monochromated Mo-K_α radiation; 2955 observed reflections, [$|F_o| > 5.0\sigma(|F_o|)$], corrected for Lorentz and polarization factors. Refinement was by full-matrix least-squares to $R = 0.0765$, $R_w = 0.0744$. Computations were carried out on an IBM 386/70 using SHELXTL PC.[6] Atomic coordinates, and bond lengths and angles have been deposited at the Cambridge Crystallographic Data Centre.

bonding nature of DMSO. The central nitrogen [N(10)] is protonated in the "in" conformation [Nb···N(10) 5.91, Nb···H(10) 4.93 Å and N(10)—H(10)···Nb 176°]. The protonated "in" conformation is probably favoured by the three weak, equidistant (2.45 Å), intramolecular N(10)—H(10)···N(7) interactions. This protonation has not previously been observed for "trencam" complexes derived from vanadium(III) and iron(III), which also possess an "in" conformation.[3,4] The protonation of the central nitrogen may be dependent on a number of factors, including the experimental conditions and the metal ion involved. The structure reported here with protonation within the cavitand-like framework raises the possibility of the formation of bimetallic cavitand systems.

SIMULATION OF COPPER(II) COORDINATION POLYHEDRON DISTORTION: AN IMPROVEMENT OF THE MOLECULAR MECHANICS MODEL BASED ON COULOMBIC INTERACTIONS

J. SABOLOVIĆ*

Chemistry Department A, The Technical University of Denmark,
DK-2800 Lyngby, Denmark

(*Received* 11 *December* 1992; *accepted* 1 *February* 1993)

Abstract—In order to reproduce the shapes of distorted coordination polyhedra of tetra-coordinated copper(II) complexes by means of a molecular mechanics method, an electrostatic model was proposed (J. Sabolović and N. Raos, *Polyhedron* 1990, **9**, 2419). With the model a square-planar complex was defined as an octahedron consisting of four charges situated in the coordination plane, and two charges (denoted as X and X′) above and below the plane. The model proved good in reproducing the geometry of both planar and non-planar copper(II)-aminoacidates. The analysis of the potential energy surface for the coordination polyhedron distortion showed, however, that besides two "real" (*trans*- and *cis*-planar) minima, a large series of "false" minima (distorted pyramids, trigonal bipyramids) appeared with a lower conformational energy than the "real" ones. The reason for their occurrence was the lack of a repulsive potential between apically placed charges, so the system was able to degenerate easily to the "penta-coordinated" complex (X—M—X′ = 0°). The repulsive coulombic interaction between the apically placed charges is now introduced. The empirical parameters used are the same except the bond-stretching parameter $k_{b,MX}$ is chosen in such a way as to give the same M—X value as before. The new model reproduces the copper(II)-aminoacidato geometries in the same manner as the old model or slightly better. From the shape of the potential energy surface in the space of *trans*-valence angles for the "complex" $CuX_2N_2O_2$ it can be concluded that: the degeneracy to the "penta-coordinated" complex is suppressed but three "false" minima that correspond to three distorted pyramids (X—M—X = 105°) are left; while in the previous model the energy difference between the *trans*-planar minimum and the pyramid with the lowest conformational energy was 70.61 kJ mol^{-1}, in the new model the corresponding difference is 0.78 kJ mol^{-1}. Tetrahedral configuration would be possible to achieve only by choosing a very small value of $k_{b,MX}$. The appearance of the distorted pyramid minima opens a possibility of the application of the new model to penta-coordinated copper(II) complexes.

In order to reproduce and predict geometrical and thermodynamical properties of tetra-coordinated copper(II)-aminoacidates three kinds of molecular mechanics models were proposed: a "dummy" atom model,[1,2] models with a distortion potential[3–5] and a model based on coulombic interactions.[6] The models differ with respect to the choice of empirical potentials for the description of interactions inside the copper(II) coordination sphere. The reason for their development was a need for a model that could reproduce, not only the chelate rings geometries, but also the shapes of copper(II) coordination polyhedra (usually an irregular square-planar or a flattened tetrahedron).

* On leave from the Institute for Medical Research and Occupational Health, University of Zagreb, Zagreb, Croatia.

Among the six available models the model based on coulombic interactions, Model 6, gave the best agreement with the X-ray structures of copper(II) complexes with amino acids and their N-alkylated derivatives.[6] Therefore, the electrostatic model was selected for further development in an attempt to determine a force field suitable for dealing with the class of compounds of our interest.

The model was termed electrostatic because of the assumption that repulsive coulombic interactions among the non-bonded atoms of the coordination polyhedron determine its shape.* The coordination polyhedron was defined with five "real" atoms (M, N, N′, O and O′), situated in the plane of the chelate rings, and two "dummy" ligand atoms (denoted as X and X′), imagined to represent an electron pair placed half above and half below the plane. As a counterbalance to these coulombic interactions (between all non-bonded atoms, except between X and X′) only harmonic bond-stretching interactions with the metal atom were calculated.

It was shown,[6] however, that the absence of any interaction between apically placed charges was a short-coming of the model. Namely, the checking of the model on the $CuX_2N_2O_2$ "molecule", in order to analyse its ability to simulate the plasticity† of copper(II) coordination without "additional" sterical influences of the rest of the molecule, showed that besides two "real" (*trans*- and *cis*-planar) minima, a large series of "false" minima (distorted pyramids, trigonal bipyramids, even linear molecules) appeared, some of them with a lower conformational energy than the "real" ones. The model appeared to be reliable for not too great deviations from planarity (15–30° for *trans*-valence angles around copper), otherwise the system could degenerate easily to the "penta-coordinated" complex, i.e. the "dummy" atoms came on top of each other (X—M—X′ = 0°). Since the deviation from planarity in the real molecules was not so high, the model was able to reproduce the geometry of the coordination polyhedra in a proper way. However, the change of coordination from "octahedral" into the "penta-coordinated" complex might cause problems during the process of empirical parameters' optimization with respect to experimental data. Therefore, a repulsive coulombic interaction between the "dummy" atoms has to be introduced.

The influence of this particular interaction on the reproduction of the copper(II)-aminoacidato geometries, as well as on the potential energy surface for coordination polyhedron distortion, in comparison with the results of Model 6, have been investigated. For this reason all the empirical parameter values are left the same as in Model 6, except for the bond-stretching parameter $k_{b,MX}$. The parameter for the M—X bond is calculated in such a way as to give the same b_{MX} distance as before,[6] from the condition that at the distance b_{MX} from the central metal atom there is an equilibrium of attractive bonding (between M and X, $b_{0,MX} = 0$) and the repulsive coulombic forces (between X and other ligated atoms):

$$k_{b,MX} = \frac{qq_X}{\varepsilon_r} k'_b; \qquad (1)$$

where q is the charge parameter for atom O or N (it is taken to be equal), q_X is the charge parameter for the "dummy" atom X, ε_r is the effective dielectric constant and k'_b is a sterical parameter dependent on the geometry of the system (appropriate bond lengths, b, valence angles, θ, and non-bonded distances, r, between atoms in coordination polyhedron). By introducing the interaction between apically placed charge k'_b becomes dependent also on the ratio between two charges' parameters:

$$k'_b = \sum_Y \frac{b_{MX} - b_{MY}\cos\theta_{XMY}}{r^3_{XY} b_{MX}} + \frac{q_X}{q}\frac{b_{MX} - b_{MX'}\cos\theta_{XMX'}}{r^3_{XX'} b_{MX}}; \qquad (2)$$

where Y is O or N. It was shown before[6] that by plotting the dependence of k'_b on b_{MX} for a regular coordination (square-planar, pyramidal and tetrahedral) it was possible to deduce semi-quantitatively the distance from M at which X would be in the equilibrium for a certain k'_b. In order to obtain the same b_{MX} distance as in Model 6, q and q_X values were left the same and the new value of the sterical parameter was calculated (it was assumed that $b_{MX} = b_{MX'}$ and X—M—X′ = 180°) (see Table 1, footnotes d and e).

The first step in checking the new model, Model 7, was the calculation of the root-mean-square deviations between crystal and theoretical structures for all tetra-coordinated copper(II) bis-complexes with α-amino acids and their N-alkylated derivatives, which showed no pronounced intermolecular interactions, and their comparison with the results of Model 6. Calculations were performed with the

* No charge was supposed to reside on the atoms outside the coordination sphere.

† The plasticity means that copper seldom forms "regular" planar, tetrahedral or octahedral coordination polyhedra. Due to plasticity, copper compounds form crystal modifications with differently distorted coordination polyhedra and show less pronounced stereoselectivity effects than corresponding complexes of nickel and cobalt, metals with rigid coordination.

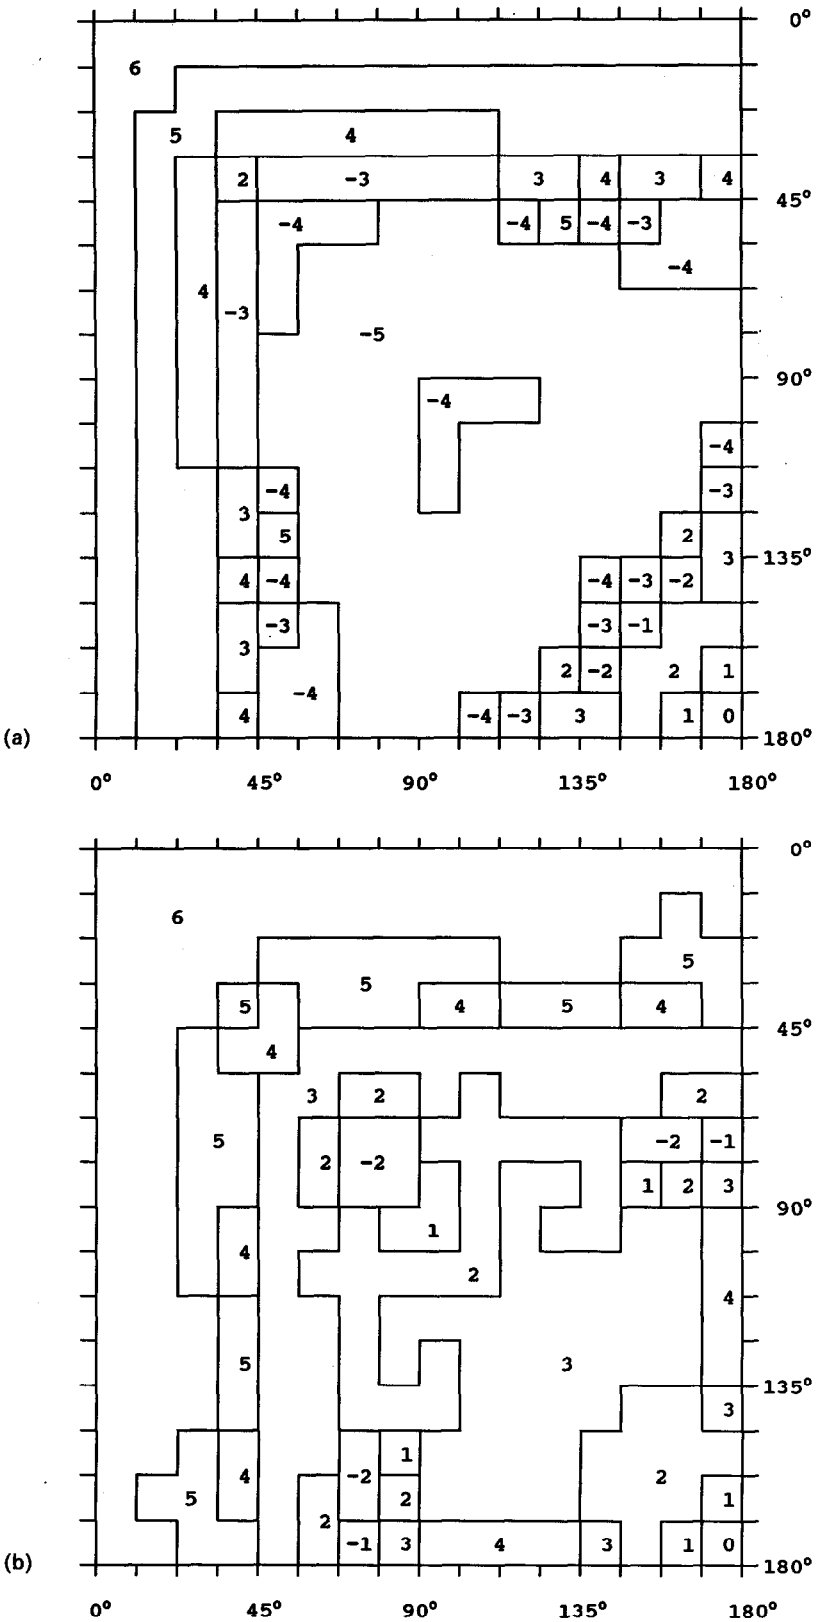

Fig. 1. Diagrams of potential (conformational) energy of the $CuX_2N_2O_2$ "complex" in the frame of coordinates N—M—N′ and O—M—O′ for (a) Model 6 and (b) Model 7. The energy ranges (in kcal mol^{-1}) are expressed by the numbers (absolute values): 0 (< 0.001), 1 (0.001–0.1), 2 (0.1–1), 3 (1–5), 4(5–10), 5 (10–50) and 6 (> 50). Zero values correspond to *trans*-planar minima: (a) $V = 204.298$ kcal mol^{-1} and (b) $V = 236.139$ kcal mol^{-1}.

[a] The root-mean-square deviation was calculated from:

$$\varepsilon_{r.m.s.} = \left(\frac{1}{N}\sum_{i=1}^{N}(\Delta X_i)^2\right)^{1/2};$$

where X are the angles around copper (valence angles θ, "torsional" angle ϕ_{ONNO} and distortion angle β[3,4]) when comparing the copper coordination geometry, or for interatomic distance, r, when comparing the overall similarity (only distances between non-hydrogen atoms were taken into account). The symbol Δ denotes the difference between the values of observable X in two structures.

[b] All angles are expressed in degrees and $\varepsilon_{r.m.s.}(\Delta r)$ values in Å.

[c] References correspond to crystal structures.

[d] Force-field parameters: $q = -0.375$ e, $q_X = -0.750$ e, $\varepsilon_r = 2$, $k'_b = 0.150$ Å^{-3}, $k_{b,MX} = 7.005$ kcal mol^{-1} Å^{-2}, $b_{0,MX} = 0$.

[e] Force-field parameters: $q = -0.375$ e, $q_X = -0.750$ e, $\varepsilon_r = 2$, $k'_b = 0.197$ Å^{-3}, $k_{b,MX} = 9.198$ kcal mol^{-1} Å^{-2}, $b_{0,MX} = 0$.

CFF programme for conformational analysis,[7,8] which was further modified to cope with the electrostatic models. For the planar molecules Model 7 yielded the same values as Model 6.[6] For the distorted non-planar molecules the results were slightly different (Table 1): for the complexes with L-phenylalanine and L-leucine the new electrostatic model gave lower root-mean-square deviations, for (glycinato)(L-serinato)copper(II) the coordination polyhedron geometry was reproduced almost as well as with Model 6, while for the other molecules the results were the same as with the old model. The comparison of the differences between experimental and theoretical values of the individual angles around copper (Table 2) showed that: N—Cu—O, N′—Cu—O′ and O′—N′—N—O angles were equally well reproduced by both models; for O—Cu—O′, N′—Cu—O and β angles Model 7 gave better results than Model 6, while for N—Cu—N′ and N—Cu—O′ angle differences the new model yielded numerically larger mean values but lower standard deviations than the old electrostatic model.

The checking of the new model on the $CuX_2N_2O_2$ "complex" revealed that it yields five minima (Table 3): *trans*- and *cis*-planar and three distorted pyramids (X—M—X′ = 105°), with conformational energy differences lower than 1 kJ mol^{-1}. The degeneracy to a "penta-coordinate" complex was suppressed but three "false" minima were left. These five minima were those which fulfilled the condition of equilibrium of the attractive and repulsive forces (each of them has a C_2-symmetry axis as a bisector of the all valence angles, while in the old model all the minima had a C_2-symmetry axis with X atoms placed on it). The atoms tend to be as far apart as possible and at the same time as close as possible to their equilibrium bond lengths. Our initial intention was to find a model that could give only two minima: a planar and a tetrahedral.[3–6] The tetrahedral configuration would be possible to achieve with the electrostatic models only when the X atoms are so far away that their influence is very weak, i.e. when the value of $k_{b,MX}$ is small enough not to hold the "dummy" atoms close to the central metal atom. Otherwise, the tetrahedral minimum is energetically unfavourable—this configuration imposes too close contacts between real and "dummy" atoms. On the other hand, the appearance of

[a] All angles are expressed in degrees, M—X bond lengths in Å and conformational potential (*V*) in kJ mol^{-1}.

the distorted pyramid minima makes possible the application of Model 7 to penta-coordinated copper(II) complexes too.

The influence of the introduction of the "dummy" atom interaction on the shape of the potential energy surface can be studied by means of the energy diagrams in the frame of *trans*-valence angles (details of their construction were given elsewhere[4,6]) (Figs 1 and 2). Around the planar minimum both models have similar behaviour. That is the reason for essentially the same reproduction of copper(II)-aminoacidato geometries. A very flat region in the vicinity of the planar minimum points out that the $CuX_2N_2O_2$ "molecule" is very flexible there, so the plasticity of the copper(II) coordination sphere is evident. While in Model 6 upon larger distortions (> 15–30° for N—M—N′ and O—M—O′ angles) the $CuX_2N_2O_2$ "complex" was placed in the lower regions of the potential energy surface yielding the "false" minima (the energy difference between the planar minima and the pyramid with the lowest conformational energy is 70.6 kJ mol^{-1}), in Model 7 there is a potential barrier (up to 42 kJ mol^{-1}) that separates the "real" minimum from the "false" minima regions.

As a conclusion it can be stated that Model 7 is an improved version of Model 6 because the new electrostatic model reproduces the geometries of the real molecules in the same manner or better than the old electrostatic model; it does not allow for the "dummy" atoms to fold over and alleviates the "false" minima problem. As such, it is more suitable for further force field development.

Acknowledgements—I would like to thank Professor Kjeld Rasmussen for encouragement and helpful discussion and to the Danish Research Academy for supporting my work in Denmark.

COMMUNICATION

COMPLEXATION OF A TRIS-BIPYRIDINE CRYPTAND WITH AMERICIUM(III)

V. K. MANCHANDA* and P. K. MOHAPATRA

Radiochemistry Division, B.A.R.C., Bombay 400085, India

(*Received* 17 *November* 1992; *accepted* 25 *January* 1993)

Abstract—Extraction studies on the americium(III) tris-bipyridine cryptate revealed acid-assisted slow dissociation of the complex and improved separation from europium(III) under non-equilibrium conditions.

Due to their large hydration energies trivalent actinides and lanthanides form weak complexes with crown ethers[1] and diaza-crown ethers[2] in the aqueous phase. On the other hand the ionizable macrocyclic as well as macrobicyclic ligands (cryptands) form thermodynamically stable and substitutionally inert complexes in aqueous medium.[3–8] The efficiency of these ionophores depends largely on the protection of the encapsulated lanthanide ions from solvent (water) molecules. The hydrophobic nature of the cryptand and the simultaneous decrease in the number of associated water molecules is expected to facilitate the cation transfer towards the organic phase. The present work is the first attempt to understand the complexation behaviour of americium(III) with tris-bipyridine cryptand, L (Fig. 1), employing the solvent extraction tracer technique.

EXPERIMENTAL

Reagents

^{241}Am and $^{152-154}$Eu were used as tracers after ascertaining their purity by alpha and gamma spectrometry, respectively.[9] Dinonylnaphthalenesulphonic acid (HD) was obtained from R. T. Vanderbilt Co., U.S.A. The tris-bipyridyl cryptand in the NaBr form was provided by Prof. J.-M. Lehn. All other reagents are of A.R. Grade.

Procedure

HD solutions were made in toluene and used as the organic phase. For the experiments performed with controlled pH pre-equilibration of the HD solution was done with a 4 M solution of $N(CH_3)_4Cl$ for 24 h to convert it quantitatively into the $N(CH_3)_4D$ form.

The tris-bipyridine cryptate complex of americium was prepared in a 1:1 mixture of CH_3CN and $CHCl_3$ by refluxing the mixture at 70°C for 12 hours[10] ($[L] = 5 \times 10^{-5}$ M). The solvent was then removed at room temperature and the complex extracted into the organic phase containing HD or $N(CH_3)_4D$ as the case may be. Distribution studies were performed by equilibrating the complex-loaded organic phase with dilute HCl solutions of known concentrations. The assays of the two phases were obtained using an 80CC Ge detector coupled to a multichannel analyser by monitoring ^{241}Am at 60 keV and $^{152-154}$Eu at 122 keV.

RESULTS AND DISCUSSION

Experiments in the absence of L

The behaviour of HD depends on the size and composition of the micelle formed on aggregation, which in turn is a function of the nature of the diluent.[11] The variation of log D_o* with log [HD] (in the concentration range 2×10^{-3}–1×10^{-2} M) showed a dependence of 1. Figure 2(a) shows that in the absence of L the slope of the plot of log D_o vs log a_{H^+} is approximately −3. These observations lead to the following two-phase equilibrium:

$$M^{3+}_{(a)} + (HD)_{n(o)} \rightleftharpoons M(H_{3-n}D_n)_{(o)} + 3H^+_{(a)}, \quad (1)$$

where M = Am and $(HD)_n$ represents the micelles of the extractant with n being the aggregation number.

Experiments in the presence of L

As in the above case the complex also extracts by the micelle mechanism in the $[H^+]$ range 0.2–0.5 M as follows:

$$ML^{3+}_{(a)} + (HD)_{n(o)} \rightleftharpoons ML(H_{n-3}D_n)_{(o)} + 3H^+_{(a)}. \quad (2)$$

Figure 2(b) shows that in the presence of L the plot of log D vs log a_{H^+} deviates from linearity beyond 0.5 M. This is explained due to the fact that the D values in the presence of L do not refer to the states of equilibrium, even though the two phases are in contact for 2 h. The enhancement in the D value appears to be due to the increased hydrophobic nature of the cryptate with respect to the uncomplexed metal ion. It is interesting that the enhancement, represented as D/D_o, observed in the present work is much larger at 1 M acidity (14 times) compared with that observed at 0.2 M. This is a consequence of the kinetic inert nature of the cryptate formed. The macrobicyclic complex originally present in the organic phase has to undergo dissociation several folds, more at 1 M $[H^+]$ compared with lower acidities, to attain the blank distribution ratio (D_o) values.

The distribution data at different time intervals are listed in Table 1 up to 1272 h. Data obtained with pH 3.0 and 6.0 are also included for better interpretation of the results. The data indicate that although there is no change in the D values in the pH range studied, an acid-dependent decrease in these values is observed in the HCl concentration range 0.2–1.0 M. It is clearly seen from the last column of Table 1 that whereas the drop in D value

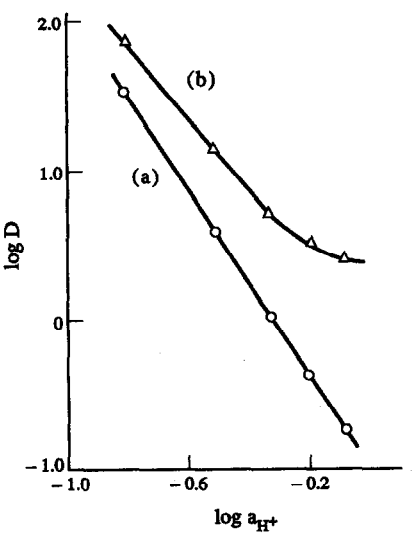

Fig. 2. Variation of log D with log a_{H^+}; (a): [HD] = 5×10^{-3} M; no L present; (b): [HD] = 5×10^{-3} M; [L] = 5×10^{-5} M.

* D_o is the distribution ratio in the absence of L and D is that in the presence of L.

is 5.4 times at 1 M acidity, it is only 2.2 times at 0.2 M $[H^+]$ under identical experimental conditions. It can also be observed from Table 1 that whereas the D value after 912 h has already approached the D_0 value in the case of 0.2 M HCl, the corresponding value is quite close for 0.4 M HCl. In other cases also the D values are expected to drop to their respective D_0 values after prolonged contact periods of the two phases. The continuous drop in D value is related to the dissociation of the cryptate in the presence of $[H^+]$, as shown by the following probable aqueous phase equilibrium:

$$ML^{3+} + 2H^+ \rightleftharpoons M^{3+} + LH_2^{2+}. \quad (3)$$

There is no enhancement in the D value if L is replaced by 18-crown-6, Kryptofix 22 or 2,2′-bipyridyl, even though other experimental conditions are identical. It seems that these ligands interact weakly (outer sphere complexes), as compared with the cryptates by L, with the metal ion and dissociate readily on contact with the aqueous phase (1 M HCl). This is supported by the structural studies on lanthanide-cryptates by Walksman *et al.*[12] and lanthanide-crown ether complexes by Rogers *et al.*[13]

To explore the possible application of cryptands for the separation of lanthanides and actinides experiments were conducted on a synthetic mixture of americium(III) and europium(III). Employing 1 M HCl as the aqueous phase and a phase contact time of 2 h the distribution data were obtained as a function of refluxation time for the two cations. The separation factor of 2.2 ± 0.2 thus obtained was distinctly larger than the corresponding value of 1.1 ± 0.1 in the absence of L. The separation factor was, however, not as high as one expects for a cryptate system. However, a non-equilibrium system like this needs the optimization of the equilibration time which could yield improved results.[14]

Acknowledgements—The authors are grateful to Prof. Jean-Marie Lehn, Institut Le Bel, Université Louis Pasteur, Strasbourg (France), for providing a sample of the tris-bipyridyl cryptand in the NaBr form, which was used throughout this work. Thanks are also due to Dr R. H. Iyer, Head, Radiochemistry Division, for his constant encouragement.

THE PREPARATION AND CRYSTAL STRUCTURE OF μ,μ'-DICHLORO-BIS[(DI-*p*-TOLYLMETHYLAMIDO)-(TRIPHENYLPHOSPHINE)COPPER(II)] FORMED BY AMIDE TRANSFER FROM RHODIUM

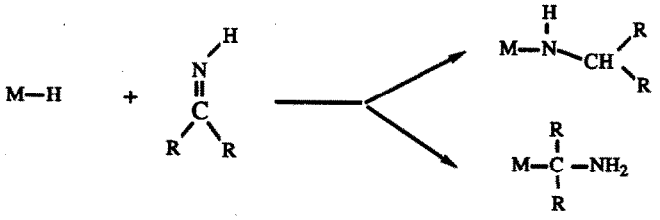
S. C. NYBURG, A. W. PARKINS* and M. SIDI-BOUMEDINE

Department of Chemistry, King's College London, Strand, London WC2R 2LS, U.K.

(*Received* 4 *January* 1993; *accepted* 18 *February* 1993)

Abstract—The addition of $HRh(CO)(PPh_3)_3$ to di-*p*-tolyl ketimine has been shown to give a metal amide rather than a metal alkyl. The initial rhodium amide product could not be characterized, but reaction with CuCl gave the title compound which has been characterized by X-ray crystallography. The copper complex has terminal amide and triphenylphosphine ligands coordinated to a Cu_2Cl_2 core, in which the copper atoms have pseudo-tetrahedral geometry.

There is considerable current interest in the hydrogenation of imines catalysed by homogeneous transition metal catalysts.[1] The mechanism proposed for the reduction involves the addition of a metal hydride to the carbon–nitrogen double bond. In principle this addition could give either a metal amide or a metal alkyl [eq. (1)]:



(1)

Fryzuk and Piers[2] have shown that dinuclear rhodium hydrides add to diphenyl ketimine to give a bridging amide complex, although no crystal structure was reported. We describe here the reaction of the mononuclear hydride $HRh(CO)(PPh_3)_3$ with di-*p*-tolyl ketimine and the structural characterization of a copper amide, obtained by transfer of the amide initially formed on rhodium to copper. The crystal and molecular structures have been established by X-ray diffraction and show unequivocally that the product is an amide, the hydrogen atom of the hydride having become attached to the β-carbon atom.

* Author to whom correspondence should be addressed.

EXPERIMENTAL

Materials and methods

$HRh(CO)(PPh_3)_3$ was prepared by a modification[3] of the procedure described in Inorganic Syntheses.[4] Di-*p*-tolyl ketimine, which has previously been reported by Pickard and Vaughan,[5] was prepared using the procedure described by Pickard and Tolbert[6] for diphenyl ketimine. CuCl was prepared by the method of Keller and Wycoff.[7] The preparation of the amide complex (**I**) was performed under nitrogen.

Rhodium on silica catalyst

Chromatographic silica (Merck 7734) (3 g) was stirred at room temperature in a solution of rhodium trichloride trihydrate (0.25 g) in methanol (50 cm^3). Addition of sodium borohydride (0.2 g) caused immediate reduction to the metal. After 10

min the solid was filtered off, washed with methanol and dried *in vacuo*.

μ,μ′-Dichloro-bis[(di-p-tolylmethylamido)(triphenylphosphine)copper(II)] (I)

$HRh(CO)(PPh_3)_3$ (1.0 g, 1.09 mmol), di-*p*-tolyl ketimine (0.6 g, 2.87 mmol) and rhodium on silica (0.2 g) were heated under reflux in THF (40 cm^3) for 2 h. The mixture was cooled to room temperature and treated with CuCl (0.2 g, 2.02 mmol) and heated under reflux for a further 30 min. The mixture was then cooled, filtered through celite, concentrated to *ca* 10 cm^3 and set aside in the refrigerator (42 h at 5°C). The product was isolated by decanting off the very dark mother liquor and washing the orange solid with THF. Crude yield 0.60 g, 97%. The analytical sample was obtained by recrystallization from THF. As the main impurity is the less soluble $(PPh_3)_2Rh(CO)Cl$ it was found helpful to avoid dissolving up the last few crystals of the crude product, before decantation and cooling; m.p. 164–165°C. Found: C, 69.1; H, 4.9; Cl, 7.1; Cu, 11.2; N, 2.4: Calc. for $C_{66}H_{62}Cl_2Cu_2N_2P_2$: C, 69.3; H, 5.5; Cl, 6.2; Cu, 11.1; N, 2.5%.

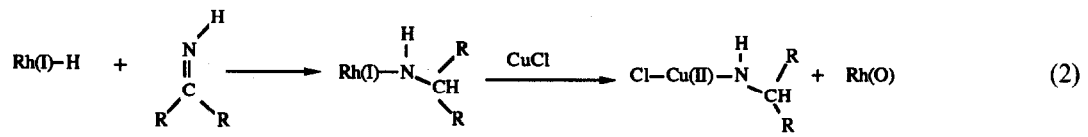
Crystallography

$C_{66}H_{62}Cl_2Cu_2N_2P_2$, $Mr = 1143.20$, triclinic, $P\bar{1}$ $a = 9.395(15)$, $b = 13.587(6)$, $c = 13.659(8)$ Å, $\alpha = 116.07(4)$, $\beta = 70.76(7)$, $\gamma = 106.46(8)°$, $V = 1459(2)$ $Å^3$, $Z = 1$, $D_{calc} = 1.30$ g cm^{-3}, $D_{obs} = 1.28$ g cm^{-3}; $\lambda(Mo\text{-}K_\alpha) = 0.7107$ Å, $\mu = 9.2$ cm^{-1}; $F(000) = 594$. Temperature = 298 K, $R = 0.039$, $Rw = 0.041$, 68 atoms, 346 parameters. Quality-of-fit 2.17 for 3015 reflections with $I_{net} > 2.5\sigma(I_{net})$ out of a total of 3809 reflections in the range $3° < 2\theta < 45°$.

A crystal of **I** (0.65 × 0.38 × 0.22 mm), crystallized from THF was X-ray photographed to establish quality and the cell dimensions were obtained from 24 reflections ($37° < 2\theta < 41°$) on a Picker four-circle diffractometer interfaced to an AT TURBO 286 IBM-compatible micro computer, using Zr-filtered Mo-K_α radiation with pulse height analysis. A standard reflection was measured every 50 reflections and showed no significant change during the data collection. An absorption correction was applied and the maximum and minimum transmission factors were 0.812 and 0.721. The structure was solved by direct methods and difference-Fourier synthesis using the NRCVAX program package.[8] The positions of the amide hydrogen and of two methyl hydrogen atoms were found from the difference map; the remaining hydrogen atoms were placed in calculated positions with temperature factors related to the atoms to which they are attached. The positions of all non-hydrogen atoms and the three experimentally determined hydrogen atoms were refined by full-matrix least-squares, together with anisotropic temperature factors for the non-hydrogen atoms and isotropic temperature factors for the three hydrogens. The refinement was performed with unit weighting of the *F*s and converged to a final *R* of 0.039.

RESULTS AND DISCUSSION

On warming a solution of $HRh(CO)(PPh_3)_3$ with diphenyl or di-*p*-tolyl ketimine in THF a colour change from yellow to deep red occurs within minutes. We were able to isolate a red solid from this reaction, but we were unable to characterize it. As one of the problems appeared to be removing triphenylphosphine from the product, we decided to add CuCl, which is known[9] to form an adduct with triphenylphosphine. The addition of CuCl to the red solution causes the mixture to become brown and allows the isolation of an orange crystalline material, which was shown to contain both copper and chloride. The structural investigation subsequently showed that the rhodium amide intermediate had acted as an amidating agent on the copper producing a copper amide (**I**) [eq. (2)].



(2)

During the development of the preparation it was found that the desired product was not obtained reproducibly and that sometimes the main product was the well known chloride complex, $(PPh_3)_2Rh(CO)Cl$. After considerable experimentation it was found that the formation of $(PPh_3)_2Rh(CO)Cl$ could be minimized if the reaction is performed in the presence of rhodium deposited on silica. The catalysis of the displacement of carbonyl groups by supported transition metals or zero-valent complexes has been reported by several groups,[10] but usually the reactants employed are well-defined compounds rather than the intractable intermediate described here.

The molecular structure of the copper amide is

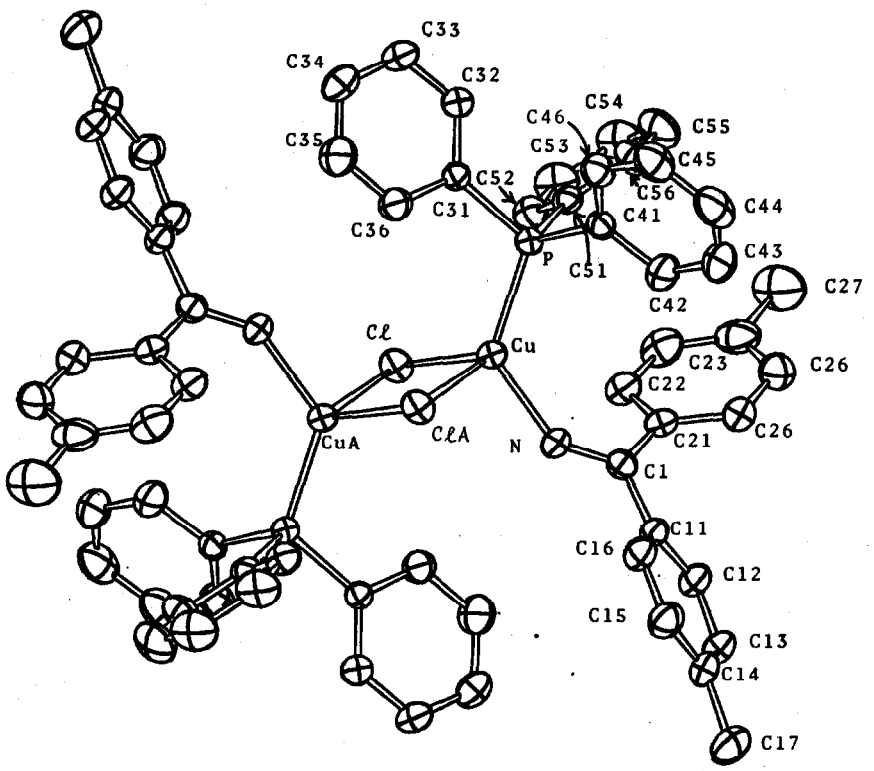


Fig. 1. ORTEP plot of **I**, showing the atomic numbering scheme. The molecule is centrosymmetric and so numbers are not shown for all atoms.

shown in Fig. 1 and selected bond distances and angles are given in Table 1. The molecule consists of two identical pseudo-tetrahedrally coordinated copper atoms linked by a planar Cu_2Cl_2 bridge. This is a common structural unit and compounds of this type have been reviewed recently.[11] The molecule has a crystallographically imposed centre of symmetry and the Cu—Cu distance is 3.268(3) Å. The evidence points clearly to the complex being an amide complex of copper(II), rather than an amine complex of copper(I). Only one hydrogen atom could be seen in the difference map and the N—H stretching vibration is a very sharp peak at 3265 cm^{-1}. Cooper and Downes[12] have previously remarked upon the sharpness of the N—H bands in platinum amides. The sum of the bond angles at the nitrogen atom [139.1(4)+96(4)+124(4)] is 359.1, which indicates planarity at nitrogen as required for an amide. Two recent reports[13] of amide structures have discussed the planarity of the substituents bonded to amide nitrogen atoms. The structure of a compound of similar coordination geometry has been reported by White and coworkers,[14] although the complex they studied, $[(Ph_3P)(py)CuCl_2Cu(py)(PPh_3)]$, has a shorter Cu—Cu distance [2.915(2) Å] and being a complex

of copper(I) is colourless. The amide complex (**I**) is orange and paramagnetic. The Cu—N distance in the amide 1.993(4) Å is slightly longer than the value reported[15] for bridging copper amide [1.904(3) Å] groups, but we were unable to find any report of a terminal copper amide bond. The Cu—P bond length [2.190(2) Å] is shorter than the mean value (2.252 Å) given by Orpen *et al.*[16] but the latter value is derived mainly if not exclusively from complexes of copper(I). The Cu—Cl distances in **I** are slightly longer than average, but White and co-workers have pointed out that there is a large range of distances within Cu_2Cl_2 units.

The results of the magnetic measurements we made were erratic. We attribute this, in view of the method of preparation, to the presence of rhodium metal impurities. We are trying to prepare **I** without the intervention of rhodium, and, if successful, this will enable us to carry out an investigation of the magnetic properties of the copper amide.

Supplementary material available. Tables of positional and thermal parameters for **I** (Table 2), together with all bond distances and angles (Table 3) and listings of observed and calculated structure factors.

Acknowledgement—We thank Johnson Matthey plc for a loan of rhodium trichloride.

(*Received* 10 *November* 1992; *accepted* 10 *February* 1993)

Abstract—A range of primary and secondary amines have been reacted with the dimers [(arene)$RuCl_2]_2$ to give simple adducts [(arene)$RuCl_2(NHRR^1)$]. We have structurally characterized the complexes [(1,3,5-$Me_3C_6H_3$)$RuCl_2(HNC_5H_{10})$] and [(1,3,5-$Me_3C_6H_3$)$RuCl_2(NC_5H_5)$]. Amine exchange reactions have been performed to assess the relative stabilities of these adducts. With certain ligands complex cations, [(1,3,5-$Me_3C_6H_3$)RuCl$(NHRR^1)_2]^+$, can form, although these are more easily prepared by reaction in the presence of $AgBF_4$.

The reactions of the dimers [(arene)$RuCl_2]_2$ with tertiary phosphines, phosphites and nitrogen bases such as pyridine, hydrazines and ammonia have been well studied.[1] However, the reactions with simple amines are much less well investigated and are limited to complexes with primary amines.[2,3] In particular, a previous study using ultrasound promoted reactions found no reactions with secondary or tertiary amines.[3] This is unlikely to be due to steric crowding since tertiary phosphines will coordinate easily.

The recent publication[3] of the use of ultrasound to promote the reactions of the dimers [(arene)$RuCl_2]_2$ with amines prompted us to report our work in this area. We have established that such reactions are just as easily performed thermally. Thus, heating a suspension of [(1,3,5-$Me_3C_6H_3$)$RuCl_2]_2$ with a slight excess of amine in dichloromethane or chloroform leads after a few hours to a red–orange solution from which the adducts [(1,3,5-$Me_3C_6H_3$)$RuCl_2(NHRR^1)$] (**1a–e**) can be isolated. An analogous product (**1f**) can be isolated starting from a solution of [(*p*-cymene)$RuCl_2]_2$ (Scheme 1). Of particular note is the formation of secondary amine adducts **1c–f**.

The complexes were characterized by ^{1}H NMR, microanalysis and FAB mass spectroscopy. In most cases molecular ions were observed in the FAB mass spectra (see Experimental), although in a number of samples ions due to dimeric species were also observed. These may have been formed in the matrix, or possibly by reactions in the spectrometer. All the complexes show the expected signals due to coordinated arene and the amine in their ^{1}H NMR spectra. The coordinated mesitylene signals occur at *ca* δ 2.0–2.2 and δ 4.8–5.0. It is noticeable that for **1c** and **1d** the methylene groups attached to nitrogen contain inequivalent hydrogens, i.e. NCHH,[1] as expected for diastereotopic protons. This shows that dissociation of the amine is slow, at least on the NMR time-scale, since these hydrogens are equivalent in the free amines. However, complexes **1c** and **1d** are unstable in solution with some loss of amine occurring, thus free amine is always observed in the NMR spectra of these products. Complex **1c** also decomposes in the solid state over a period of several days and hence the analysis results are inaccurate.

In the reactions with benzylamine the products formed depend on the reaction time or the solvent used. The adduct **1b** can be made without contamination by the cationic product by reacting [(1,3,5-$Me_3C_6H_3$)$RuCl_2]_2$ with excess benzylamine in refluxing hexane or by using exactly 1 equivalent per ruthenium atom in dichloromethane. If excess benzylamine is used in chloroform then a mixture of the adduct [(1,3,5-$Me_3C_6H_3$)$RuCl_2(NHRR^1)$] and the salt [(1,3,5-$Me_3C_6H_3$)RuCl$(NHRR^1)_2$][Cl] is formed, which cannot be separated easily. This sol-

vent dependence has been observed previously in the reaction of pyrazoles with $[(benzene)RuCl_2]_2$.[4]

Although steric factors do not prevent the formation of complexes of secondary amines they may influence their relative stability. In order to try and assess the degree of steric crowding in these complexes we determined the crystal structure of the piperidine adduct **1e**. For comparison purposes we also determined the structure of the related pyridine complex $[(1,3,5\text{-}Me_3C_6H_3)RuCl_2(NC_5H_5)]$, which has been made previously.[1a] The structures of the complexes are shown in Figs 1 and 2, respectively, and selected bond lengths and angles are listed in Table 1. The most notable feature of the structures is the orientation of the piperidine, with the N—H pointing away from the arene and the sterically more demanding CH_2 groups pointing towards the arene. This may be due to attractive forces between the alkyl groups on the arene and the piperidine ring and also the possibility of hydrogen bonding between the N—H and the two chlorine atoms. The HN–chlorine distances [2.588 to Cl(1) and 2.712 Å to Cl(2)] are consistent with hydrogen bonding, although it should be remembered that this hydrogen atom has been included in a calculated position and was not found in the difference-Fourier map. The Ru—N bond in the piperidine complex, 2.153(4) Å, is longer than in the pyridine complex, 2.127(7) Å, as expected. The average Ru—Cl bond lengths and Cl—Ru—Cl bond angle are the same in the two complexes. The mesitylene ring is essentially planar in both structures and the distances from the ring to the metal are 1.673 and 1.676 Å for the piperidine and pyridine complex, respectively.

We thought it might also be possible to assess the role of steric factors in determining the relative stability of these amine complexes by attempting amine exchange reactions.

$$[(1,3,5\text{-}Me_3C_6H_3)RuCl_2L] + L^1 \rightleftharpoons [(1,3,5\text{-}Me_3C_6H_3)RuCl_2L^1] + L$$

This has resulted in the following series of stabilities: **1e** > **1a** > **1d**. Qualitatively we have observed that the primary amine complexes are more stable than the secondary amine ones, however, piperidine seems to be a special case. The use of this amine exchange reaction is limited by the occurrence of competing side reactions in certain cases. For example, the reaction of the piperidine complex **1e** with

1 equivalent of benzylamine when monitored by ^1H NMR shows the presence of some starting complex **1e**, some **1b** and some species, which judging by the chemical shift of the mesitylene protons are due to cationic species containing two amines. During the course of our work a report has been published on amine exchange reactions of the complex cations $[(dppe)PdMe(NRR'RR'')]^+$, which concluded that both steric and electronic factors were important in determining the relative stability of the various cations.[5]

As mentioned above with benzylamine it is possible to form the cation $[(1,3,5\text{-}Me_3C_6H_3)RuCl(NHRR^1)_2]^+$ by direct reaction of $[(1,3,5\text{-}Me_3C_6H_3)RuCl_2]_2$ with benzylamine. Similar behaviour has been observed previously for aromatic amines.[3] An alternative is to react the amine adducts $[(1,3,5\text{-}Me_3C_6H_3)RuCl_2(NHRR^1)]$ with 1 equivalent of amine and $AgBF_4$. Using this method we have isolated the compounds **2a** and **2b**.

The ^1H NMR spectra of the cations showed peaks in the expected regions. However, the mesitylene signals for **2a** are shifted to higher field than in **1a**, while for **2b** they are to lower field than in **1b**. Since complexes **2** contain cationic ruthenium fragments one might expect a shift to lower field, as is observed with **2b**. Thus, the upfield shift for **2a** may be due to the ring current effects of the phenyl rings. It is noteworthy that for **1a** the methyl groups of the mesitylene ring are *ca* 0.2 ppm upfield from the complexes **1b–e**, which may also be a consequence of a ring current effect.

EXPERIMENTAL

Petroleum ether and diethyl ether were dried by refluxing over purple sodium/benzophenone under nitrogen, while dichloromethane was purified by refluxing over calcium hydride. The compounds $[(p\text{-cymene})RuCl_2]_2$[6] and $[(1,3,5\text{-}Me_3C_6H_3)RuCl_2]_2$[7] were prepared using literature procedures. The reactions described were performed in deoxygenated solvents under nitrogen; however, once isolated as pure solids the compounds are relatively air-stable and precautions for their storage are unnecessary.

^1H NMR spectra were recorded on a Bruker AM300 or a Varian EM390 spectrometer. Microanalyses were performed by Butterworth Labor-

atories Ltd, Middlesex. FAB mass spectra were performed at the SERC Mass Spectroscopy service centre at University College Swansea.

Preparation of [(1,3,5-$Me_3C_6H_3$)$RuCl_2(NH_2Ph)$] (**1a**)

Aniline (114 mg, 1.55 mmol) was added to a suspension of [(1,3,5-$Me_3C_6H_3$)$RuCl_2]_2$ (301 mg, 0.52 mmol) in dichloromethane (50 cm^3) and the mixture was refluxed for 2.5 h. The solvent was removed and the solid was washed with petroleum ether. Recrystallization from dichloromethane/diethyl ether gave [(1,3,5-$Me_3C_6H_3$)$RuCl_2(NH_2$ Ph)] as a yellow solid (338 mg, 85%). Found: C, 47.2; H, 4.8; N, 3.5. Calc. for $C_{15}H_{19}Cl_2NRu$: C, 46.8; H, 5.0; N, 3.6%. ^1H NMR ($CDCl_3$): 2.00 (s, 9H, Me), 4.83 (s, 3H, C_6H_3), 7.25 (m, 5H, Ph).

Preparation of [(1,3,5-$Me_3C_6H_3$)$RuCl_2(NH_2CH_2$ Ph)] (**1b**)

Benzylamine (90 mg, 0.84 mmol) was added to a suspension of [(1,3,5-$Me_3C_6H_3$)$RuCl_2]_2$ (245 mg, 0.42 mmol) in dichloromethane (50 cm^3) and the mixture was refluxed for 2.5 h. The solvent was removed and the solid was washed with petroleum ether. Recrystallization from dichloromethane/diethyl ether gave [(1,3,5-$Me_3C_6H_3$)$RuCl_2(NH_2$ CH_2Ph)] as orange crystals (287 mg, 86%). Found: C, 48.2; H, 5.6; N, 3.4. Calc. for $C_{16}H_{21}Cl_2NRu$: C, 48.1; H, 5.3; N, 3.5%. ^1H NMR ($CDCl_3$): 2.21 (s, 9H, Me), 3.22 (br, 2H, NH), 4.12 (m, 2H, CH_2), 4.92 (s, 3H, C_6H_3), 7.30 (m, 5H, Ph). Mass spectrum: *m/z* 399 $(M)^+$, 364 $(M-Cl)^+$.

Preparation of [(1,3,5-$Me_3C_6H_3$)$RuCl_2(NHEt_2)$] (**1c**)

Diethylamine (94 mg, 1.2 mmol) was added to a suspension of [(1,3,5-$Me_3C_6H_3$)$RuCl_2]_2$ (251 mg, 0.43 mmol) in chloroform (50 cm^3) and the mixture was refluxed for 2 h. The solvent was removed and the solid was washed with petroleum ether to leave [(1,3,5-$Me_3C_6H_3$)$RuCl_2(NHEt_2)$] as a yellow solid (232 mg, 74%). Found: C, 33.4; H, 4.3; N, 1.3. Calc. for $C_{13}H_{23}Cl_2NRu$: C, 42.7; H, 6.3; N, 3.8%. ^1H NMR ($CDCl_3$): 1.22 [t, 6H, CH_3CH_2, *J*(7)], 2.26 (s, 9H, C_6Me_3), 3.13 (m, 2H, CHH^1), 3.63 (m, 2H, CHH^1), 4.91 (s, 3H, C_6H_3). Mass spectrum: *m/z* 378 $(M+H)^+$.

Preparation of [(1,3,5-$Me_3C_6H_3$)$RuCl_2(NHBu_2)$] (**1d**)

Dibutylamine (278 mg, 2.15 mmol) was added to a suspension of [(1,3,5-$Me_3C_6H_3$)$RuCl_2]_2$ (252 mg, 0.43 mmol) in chloroform (75 cm^3) and the mixture was refluxed for 1.5 h. The solvent was removed and the solid was washed with petroleum ether. Recrystallization from dichloromethane/petroleum ether gave [(1,3,5-$Me_3C_6H_3$)$RuCl_2(NHBu_2)$] as a yellow solid (363 mg, 100%). Found: C, 48.6; H, 7.6; N, 3.6. Calc. for $C_{17}H_{31}Cl_2NRu$: C, 48.4; H, 7.4; N, 3.3%. ^1H NMR ($CDCl_3$): 0.90 [t, 6H, CH_3, *J*(7)], 1.28 (m, 4H, CH_2), 1.55 (m, 4H, CH_2), 2.26 (s, 9H, C_6Me_3), 3.01 (m, 2H, $NCHH^1$), 3.47 (m, 2H, $NCHH^1$), 4.90 (s, 3H, C_6H_3). Mass spectrum: *m/z* 422 $(M+H)^+$.

Preparation of [(1,3,5-$Me_3C_6H_3$)$RuCl_2(HNC_5$ H_{10})] (**1e**)

Piperidine (183 mg, 2.15 mmol) was added to a suspension of [(1,3,5-$Me_3C_6H_3$)$RuCl_2]_2$ (252 mg, 0.43 mmol) in chloroform (50 cm^3) and the mixture was refluxed for 3 h. The solvent was removed and the solid was washed with petroleum ether. Recrystallization from dichloromethane/petroleum ether gave [(1,3,5-$Me_3C_6H_3$)$RuCl_2(HNC_5H_{10})$] as an orange solid (281 mg, 86%). Found: C, 44.5; H, 5.9; N, 3.7. Calc. for $C_{14}H_{23}Cl_2NRu$: C, 44.5; H, 6.1; N, 3.7%. ^1H NMR ($CDCl_3$): 1.40–1.90 (m, 6H, various piperidine), 2.26 (s, 9H, C_6Me_3), 2.93 [dt, 2H, NCH, *J*(12,12)], 3.75 [d, 2H, $NCHH^1$, *J*(12)], 4.97 (s, 3H, C_6H_3). Mass spectrum: *m/z* 378 $(M+H)^+$, 342 $(M+H-Cl)^+$.

Preparation of [(p-cymene)$RuCl_2(NHEt_2)$] (**1f**)

Diethylamine (39 mg, 0.53 mmol) was added to a solution of [(*p*-cymene)$RuCl_2]_2$ (108 mg, 0.176 mmol) in chloroform (50 cm^3). The mixture was refluxed for 3 h, during which time the solution became orange. The solvent was removed and the solid was washed with petroleum ether. Recrystallization from dichloromethane/petroleum ether gave [(*p*-cymene)$RuCl_2(NHEt_2)$] as a bright yellow solid (66 mg, 50%). Found: C, 43.6; H, 6.5; N, 3.5. Calc. for $C_{14}H_{25}Cl_2NRu$: C, 44.3; H, 6.6; N, 3.7%. ^1H NMR ($CDCl_3$): 1.22 [t, 6H, CH_2CH_3, *J*(7)], 1.31 [d, 6H, $CHMe_2$, *J*(7)], 2.23 (s, 3H, C_6H_4Me), 3.03 [sep, 1H, $CHMe_2$, *J*(7)], 3.16 (m, 2H, CHH^1), 3.50 (m, 2H, CHH^1), 5.33, 5.38 [$(AB)_2$, 4H, C_6H_4, *J*(AB)6].

Amine exchange reactions

Complex **1d** (250 mg, 0.59 mmol) and aniline (166 mg, 1.78 mmol) were refluxed in chloroform (50 cm^3) for 2.5 h. The solvent was removed and the oily solid was washed with petroleum ether to give

a yellow solid, identified as complex **1a** on the basis of its ^1H NMR spectrum (157 mg, 70%).

The same general procedure was used for the reaction of complex **1a** with piperidine in equimolar amounts to give complex **1e** in 71% yield. Using the same method refluxing of complex **1e** with aniline gave no reaction.

Preparation of [(1,3,5-$Me_3C_6H_3$)$RuCl(NH_2Ph)_2$][BF_4] (**2a**)

Aniline (48 mg, 0.52 mmol) and $AgBF_4$ (101 mg, 0.52 mmol) were added to a solution of [(1,3,5-$Me_3C_6H_3$)$RuCl_2(NH_2Ph)$] (20 mg, 0.52 mmol) in dichloromethane (50 cm^3) and the mixture was stirred for 0.5 h. The AgCl was removed by filtration through celite and the solvent was rotary evaporated. Recrystallization from dichloromethane/diethylether gave [(1,3,5-$Me_3C_6H_3$)$RuCl(NH_2Ph)_2$][BF_4] as an orange crystalline solid (259 mg, 94%). Found: C, 47.2; H, 4.9; N, 5.0. Calc. for $C_{21}H_{26}BClF_4N_2Ru$: C, 47.6; H, 4.9; N, 5.3%. ^1H NMR ($CDCl_3$): 1.69 (s, 9H, C_6Me_3), 4.48 (br, 2H, NH), 4.76 (s, 3H, C_6H_3), 5.83 (br, 2H, NH), 7.35 (m, 10H, Ph).

Preparation of [(1,3,5-$Me_3C_6H_3$)$RuCl(NH_2CH_2Ph)_2$][BF_4] (**2b**)

Benzylamine (47 mg, 0.44 mmol) and $AgBF_4$ (86 mg, 0.44 mmol) were added to a solution of [(1,3,5-$Me_3C_6H_3$)$RuCl_2(NH_2CH_2Ph)$] (177 mg, 0.44 mmol) in dichloromethane (60 cm^3) and the mixture was stirred for 0.5 h. The AgCl was removed by filtration through celite and the solvent was rotary evaporated. Recrystallization from dichloromethane/diethylether gave [(1,3,5-$Me_3C_6H_3$)$RuCl(NH_2CH_2Ph)_2$][BF_4] as an orange crystalline solid (170 mg, 68%). Found: C, 49.7; H, 5.4; N, 4.9. Calc. for $C_{23}H_{30}BClF_4N_2Ru$: C, 49.5; H, 5.4; N, 5.0%. ^1H NMR (CD_2Cl_2): 2.30 (s, 9H, C_6Me_3), 2.50 (br, 2H, NH), 4.01 (m, 4H, CH_2), 4.42 (br, 2H, NH), 5.10 (s, 3H, C_6H_3), 7.34 (m, 10H, Ph). Mass spectrum: m/z 471 $[M]^+$, 364 $[M-NH_2CH_2Ph]^+$ (M refers to the complex cation).

X-ray structure determinations

Crystals of [(1,3,5-$Me_3C_6H_3$)$RuCl_2(HNC_5H_{10})$] were grown from dichloromethane/mesitylene, while those of [(1,3,5-$Me_3C_6H_3$)$RuCl_2(NC_5H_5)$] were grown from dichloromethane/diethylether. The crystals used for data collection were mounted in air and the unit cell parameters were determined by least-squares refinement of ω-measurements of different layers.[8] Data were collected on a Stoe STADI-2 diffractometer with an ω-scan technique in the range $7 < 2\theta < 54°$. Scattering factors were taken from ref. 9.

Crystal data for [$C_{14}H_{23}Cl_2NRu$] (**1e**). $M = 377.3$; monoclinic, space group $P2_1/c$, $a = 11.573(9)$, $b = 9.341(8)$, $c = 15.100(14)$ Å, $\beta = 107.3(1)°$, $U = 1558.3$ Å^3, $Z = 4$, $\mu = 12.09$ cm^{-1}, λ(Mo-K_α) = 0.7107 Å, $F(000) = 768$, $D_c = 1.61$ g cm^{-3}. Crystal dimensions $0.48 \times 0.28 \times 0.155$ mm.

The intensities of 3178 unique reflections were measured and these data were corrected for Lorentz and polarization effects to give 2098 unique reflections with $I > 3\sigma(I)$. The structure was solved using the PATT option of SHELXS-86; all subsequent calculations were performed with the computer programme SHELX-76.[10] All hydrogen atoms were included in calculated positions (C—H = 1.08 Å) and all non-hydrogen atoms were refined anisotropically. Final cycles of least-squares refinement used a weighting parameter $w = 1/(\sigma^2F+gF^2)$, where $g = 0.0007$, and gave final residual indices of $R = 0.038$ and $R_w = 0.041$.

Crystal data for [$C_{14}H_{17}Cl_2NRu$]. $M = 371.3$; orthorhombic space group $P2_12_12_1$, $a = 13.623(14)$, $b = 13.928(14)$, $c = 7.633(2)$ Å, $U = 1448.27$ Å^3, $z = 4$, $\mu = 13.01$ cm^{-1}, λ(Mo-K_α) = 0.7107 Å, $F(000) = 744$, $D_c = 1.70$ g cm^3. Crystal dimensions $0.38 \times 0.12 \times 0.06$ mm.

The intensities of 1740 reflections were measured and these data were corrected for Lorentz and polarization effects to give 1411 unique reflections with $I > 3\sigma(I)$. The structure was solved by direct methods using SHELXS-86; all subsequent calculations were carried out with the computer program SHELX-76.[10] All hydrogen atoms were put in calculated positions (C—H = 1.08 Å) and all non-hydrogen atoms were refined anisotropically. Final cycles of least-squares refinement used a weighting parameter $w = 1.1827/(\sigma^2F+gF^2)$, where $g = 0.0007$, and gave final residual indices of $R = 0.0416$ and $R_w = 0.0422$.

THE REACTIVITY OF Se_4N_4 IN LIQUID AMMONIA

PAUL F. KELLY and J. DEREK WOOLLINS*

Department of Chemistry, Imperial College, London SW7 2AY, U.K.

(*Received* 27 *January* 1993; *accepted* 5 *February* 1993)

Abstract—Tetraselenium-tetranitride, Se_4N_4, dissolves in liquid ammonia at high pressure (*ca* 50 atm.) and reacts with $PtCl_2(PMe_2Ph)_2$ to give $Pt(Se_2N_2)(PMe_2Ph)_2$ in quantitative yield. If the reaction is performed using $Se_4{}^{15}N_4$ the product is obtained with a low (<20%) degree of ^{15}N labelling; in contrast $Se_4{}^{15}N_4$ may be recrystallized from ammonia with no loss of ^{15}N content, indicating that, unlike S_4N_4, it does not react with ammonia as it dissolves.

After many years in the role of "poor-relation" to their sulphur–nitrogen counterparts, selenium–nitrogen compounds have recently become the focus of much attention.[1] One of the main catalysts for this upsurge of interest was the realization that although Se_4N_4 is undoubtedly less reactive (and substantially more hazardous) than S_4N_4, it can, in the right circumstances, act as a source of novel Se—N compounds and ligands. Thus, reaction with $[Se_4]^{2+}$ generates cations of the type $[Se_3N_2]^{n+}$,[2] while a number of different metal species have been shown to react to give complexes of [NSeCl],[3] Se_3N^-,[4] $Se_2N_2{}^{2-}$ [5] and $Se_2N_2N^-$.[6] Although recent work has resulted in a number of less explosive species such as $[Me_3SiN]_4Se$,[7] which clearly have great potential as synthons, it is likely that Se_4N_4 will remain an extremely important source of new Se—N systems.

A major hindrance to the advancement of the chemistry of Se_4N_4 is its extreme insolubility in common solvents. By way of illustration we have found that the solubility in xylene is so low that even at temperatures greater than 150°C there is only a very slight colouration of the solvent; clearly the solubility is many orders of magnitude less than S_4N_4. In contrast, previous work by Street *et al.* revealed that a new phase of Se_4N_4 crystallizes from ammonia after heating to 70°C,[8] implying that the compound has a reasonable solubility at this temperature. Here we report on investigations into the use of ammonia as a solvent for Se_4N_4 reactions.

* Author to whom correspondence should be addressed.

EXPERIMENTAL

High-pressure reactions were performed in a Bergfhof pressure reactor (HR 100) equipped with a 70 cm^3 Teflon insert. The compounds Se_4N_4[9] and $Se_4{}^{15}N_4$[10] were pepared by the literature methods. **NOTE!** Se_4N_4 is a powerful explosive which is extremely shock sensitive and should not be handled with a metal spatula; residues should be destroyed by slurrying with water followed by cautious addition of hypochlorite solution.

Dissolution of $Se_4{}^{15}N_4$ *in ammonia*

A suspension of $Se_4{}^{15}N_4$ (17 mg, 0.045 mmol) in liquid ammonia (50 cm^3) was slowly heated over a period of 30 min until the internal pressure reached 50 atm. (external heating temperature 135°C, internal temperature measured as *ca* 90°C). After 10 min at this pressure the system was cooled and the ammonia decanted from the pressure tube; the latter was thoroughly rinsed with CH_2Cl_2 and these washings added to the ammonia, which was allowed to evaporate. The resulting solid Se_4N_4 was transferred, as a suspension, to a Schlenk tube and allowed to settle. CH_2Cl_2 was decanted and the solid dried *in vacuo*; it was then treated with a solution of $Pt(PPh_3)_3$ (40 mg, 0.04 mmol) in dried, degassed CH_2Cl_2 (20 cm^3) with stirring. The resulting dark solution was allowed to stand for a few hours to precipitate all the resulting insoluble green $[Pt(Se_2N_2)(PPh_3)]_2$ and then filtered. After removal of the solvent *in vacuo* $CDCl_3$ was added to dissolve the $Pt(Se_2N_2)(PPh_3)_2$ present, the resulting solution

treated with a drop of the base DBU (to remove any protonation effects of residual HCl) and the ^{31}P NMR spectrum recorded. The splitting pattern obtained for both phosphorus atoms was identical to that obtained for analogous products formed from unrecrystallized $Se_4{}^{15}N_4$, indicating that no exchange with nitrogen from the ammonia had occurred and that the Se_4N_4 was, therefore, still fully labelled.

Reaction of $PtCl_2(PMe_2Ph)_2$ *with* Se_4N_4

A mixture of Se_4N_4 (46 mg, 0.12 mmol) and $PtCl_2(PMe_2Ph)_2$ (70 mg, 0.13 mmol) in liquid ammonia (50 cm^3) was heated and cooled as above and the ammonia allowed to evaporate. After extraction into CH_2Cl_2 (50 cm^3), filtration and removal of the solvent *in vacuo* the resulting yellow oily residue was dissolved in $CDCl_3$, treated with one drop of DBU and then the ^{31}P NMR spectrum of the solution recorded. This revealed that complete conversion of the starting material to $Pt(Se_2N_2)(PMe_2Ph)_2$ had taken place, the latter being characterized by an AX pair of doublets at δ −2.6 ($^1J\{^{195}Pt—^{31}P\}$ 2814 Hz) and δ −28.4 ($^1J\{^{195}Pt—^{31}P\}$ 2565 Hz).

The reaction involving $Se_4{}^{15}N_4$ was performed in an identical manner using 13 mg (0.03 mmol) of the latter and 20 mg (0.04 mmol) of the platinum complex.

RESULTS AND DISCUSSION

When Se_4N_4 [Fig. 1(a)] is prepared by the action of ammonia gas upon a toluene solution of diethylselenite,[9] $[EtO]_2SeO$, it forms as an amorphous orange solid with no evidence of crystallinity. If this material is then suspended in liquid ammonia in a high-pressure system, the temperature raised (internal temperature *ca* 90°C ≡ 50 atm.), then after 10 min the mixture re-cooled, the resulting Se_4N_4 is obtained as dark-orange, well-formed microcrystals. From this observation it is clear that Se_4N_4 is actually soluble in the ammonia at this temperature.

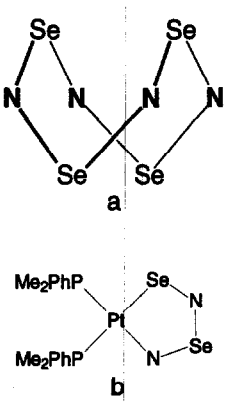

Fig. 1. The structures of (a) Se_4N_4 and (b) $Pt(Se_2N_2)(PMe_2Ph)_2$.

If the above experiment is repeated in the presence of *cis*-$PtCl_2(PMe_2Ph)_2$ and the ammonia removed from the resulting orange solution ^{31}P NMR spectroscopy reveals that complete conversion of the platinum complex to $Pt(Se_2N_2)(PMe_2Ph)_2$ [Fig. 1(b)] takes place. This reaction, therefore, mirrors that of the platinum species with $[S_3N_2Cl]Cl$, $[S_4N_3]Cl$ or S_4N_4 in ammonia (at −78°C), all of which generate $Pt(S_2N_2)(PMe_2Ph)_2$.[11] In the latter cases the reactions proceed via S—N anions such as $[S_3N_3]^-$, which we have observed in solution using ^{14}N NMR. Clearly, it is possible that so-far unknown selenium analogues, such as $[Se_3N_3]^-$, may be responsible for the reactivity of Se_4N_4 in ammonia.

Previous work showed that when a solution of a fully ^{15}N labelled species, such as $[S_4{}^{15}N_3]Cl$, in ammonia is used to generate $Pt(S_2N_2)(PMe_2Ph)_2$ the latter is obtained with a degree of ^{15}N labelling substantially less than 100%. This intermixing with the nitrogens of the ammonia is brought about by two different processes: (1) incorporation of ammoniacal nitrogens into the S—N systems during the initial formation of the reactive anions (e.g. $S_3N_3{}^-$) and (2) a slow exchange between the nitrogens in the latter and those in the ammonia. This was illustrated by analysis of S_4N_4 recovered from ammonia solutions of $[S_4{}^{15}N_3]Cl$; work-up after a few minutes yields the product with a degree of labelling of *ca* 60%—in contrast if the ammoniacal solution is left overnight this figure drops to only 20%.[12]

We have recently reported the preparation of $Se_4{}^{15}N_4$ by reaction of $[EtO]_2SeO$ with stoichiometric amounts of $^{15}NH_3$ in xylene.[12] Access to the labelled compound allows us to use NMR techniques to investigate the Se_4N_4/NH_3 system. If the reaction between $Se_4{}^{15}N_4$ and $PtCl_2(PMe_2Ph)_2$ is performed as above, and the ^{31}P NMR spectrum of the resulting $Pt(Se_2N_2)(PMe_2Ph)_2$ measured (Fig. 2), it indicates that a very large percentage of the ^{15}N has been washed from the system, leaving a degree of labelling of *ca* 20%. There are three possible explanations for this decrease in ^{15}N content: (1) that Se_4N_4 actually reacts with the ammonia as it dissolves, in the same manner as S_4N_4; (2) that Se_4N_4 reacts with the platinum compound to give a species such as $[Se_3N_3]^-$, which then undergoes nitrogen exchange with the ammonia *before* generation of the final complex;

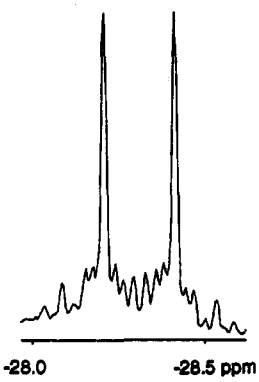

Fig. 2. $^{31}P\{^1H\}$ NMR of the phosphorus *trans* to nitrogen in $Pt(Se_2N_2)(PMe_2Ph)_2$, prepared by the reaction of $Se_4{}^{15}N_4$ with $PtCl_2(PMe_2Ph)_2$ in ammonia. The simplicity of the spectrum shows that there is a low degree of ^{15}N in the product.

or (3) that fully labelled $Pt(Se_2N_2)(PMe_2Ph)_2$ is produced and this then undergoes nitrogen exchange with the ammonia. Obviously a combination of the latter two could occur but the conclusion would still be that there was no initial reaction of Se_4N_4 with ammonia.

Given the fact that the high temperature of the system would undoubtedly increase the rate of the slow exchange between the nitrogen atoms in the ammonia and any Se—N anions present, the degree of labelling in the products obtained in this manner lends credance to explanation (1). In such a situation it is possible that the anions produced would be relatively unstable and would revert to Se_4N_4 upon cooling and evaporation of the ammonia. This would explain why only Se_4N_4 (together with some residual red selenium) is obtained during recrystallization. However, if spontaneous reaction of Se_4N_4 with ammonia, to give reactive anionic species, was occurring then this would mean that the ^{15}N content of a solution of $S_4{}^{15}N_4$ in ammonia would slowly diminish.

Monitoring the decrease in ^{15}N content of Se_4N_4 presents more of a challenge than in the case of S_4N_4. The latter is more amenable to mass spectrometry, both in terms of the ease in obtaining parent ion peaks and in calculating ^{15}N content from such peaks, and to ^{15}N NMR spectroscopy. In the latter case we have found that there is a small but measurable isotope effect giving rise to individual peaks for $S_4{}^{15}N^{14}N_3$, $S_4{}^{15}N_2N_2$, $S_4{}^{15}N_3N$ and $S_4{}^{15}N_4$ separated by *ca* 0.04 ppm. This is illustrated by Fig. 3, which shows the high resolution ^{15}N

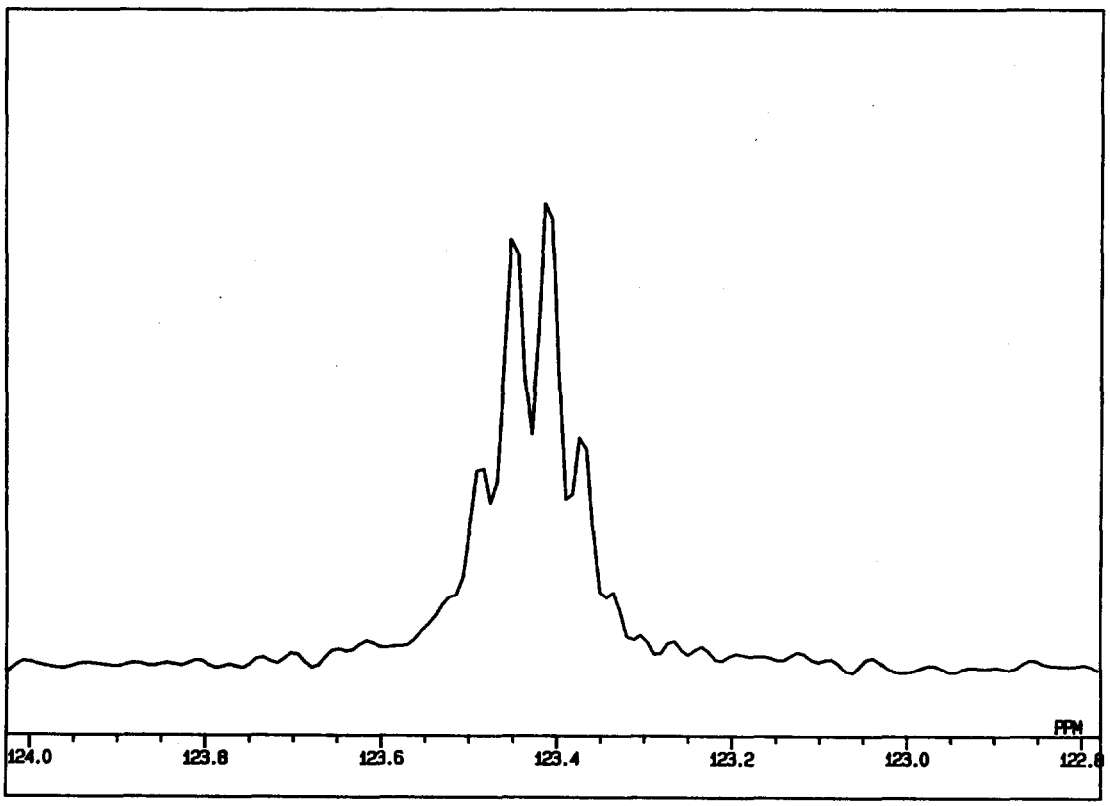

Fig. 3. Resolution-enhanced ^{15}N NMR spectrum of 50% ^{15}N labelled S_4N_4; each resonance is due to a different isotopomer.

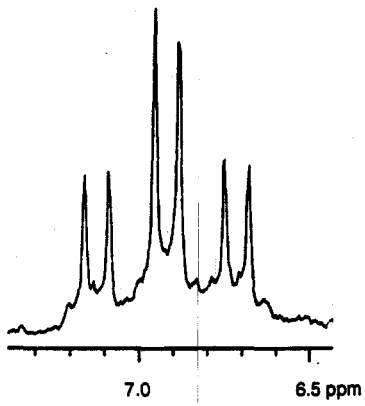

Fig. 4. $^{31}P\{^{1}H\}$ NMR of the phosphorus *trans* to nitrogen in $Pt(Se_2N_2)(PPh_3)_2$ prepared by the reaction of $Se_4{}^{15}N_4$ with $Pt(PPh_3)_3$. An identical spectrum is obtained from the reaction of $Se_4{}^{15}N_4$, which has been recrystallized from liquid ammonia.

NMR spectrum of 50% labelled Se_4N_4; the four lines for the four different isotopomers are seen in the predicted 1:3:3:1 intensity ratio. Obviously the extreme insolubility of Se_4N_4 in common solvents precludes analogous studies; however, a convenient technique which can be employed utilizes its reactivity towards the platinum(0) species $Pt(PPh_3)_3$. This reaction generates $Pt(Se_2N_2)(PPh_3)_2$,[5] which is soluble and shows characteristic splitting patterns in the ^{31}P NMR spectrum, which are indicative of the degree of labelling. Particularly informative is the resonance for phosphorus *trans* to nitrogen, which, in the fully labelled case, shows a pattern due to two $^{15}N—^{31}P$ interactions of magnitude 24 and 8 Hz (Fig. 4). If $Se_4{}^{15}N_4$, which has been recrystallized from ammonia, is used to generate the latter species the splitting pattern obtained is identical to that in Fig. 4. In other words *there is no incorporation of nitrogen from the ammonia into* Se_4N_4 *during recrystallization* and thus we can conclude that, unlike S_4N_4, Se_4N_4 does not spontaneously react with the ammonia.

If fully labelled $Pt(Se_2{}^{15}N_2)(PMe_2Ph)_2$ is dissolved in ammonia and the temperature raised as before the ^{31}P NMR spectrum of the product obtained after cooling is identical to that of the starting material. From this observation we can conclude that the third possibility listed above, namely that there may be slow exchange between the nitrogens of the ammonia and of $Pt(Se_2{}^{15}N_2)(PMe_2Ph)_2$, can be ruled out.

The above results, summarized in Scheme 1, lead to the conclusion that a reactive Se—N intermediate must be the first product of the reaction with the platinum compound and that this intermediate can then undergo nitrogen exchange with ammonia prior to ultimately generating $Pt(Se_2N_2)(PMe_2Ph)_2$. It is difficult to speculate upon the exact nature of this intermediate, especially as we do not know what form the platinum species takes in this situation; preliminary studies indicate that when $PtCl_2(PMe_2Ph)_2$ is dissolved in ammonia under similar conditions to the above reactions there is at least some degree of conversion to substituted species (which we speculate are of the type $[Pt(PMe_2Ph)_2(NH_3)Cl]^+$ and $[Pt(PMe_2Ph)_2(NH_3)_2]^{2+}$). If these solutions are allowed to cool and the ammonia evaporated off under a steam of nitrogen a white solid is left. Extraction of this solid with CH_2Cl_2 yields $PtCl_2(PMe_2Ph)_2$ (as shown by ^{31}P NMR); we have yet to characterize the white, CH_2Cl_2-insoluble residue. Interestingly, if CH_2Cl_2 is added to the ammonia before it has been evaporated then a new soluble product is obtained, which is seen as a singlet in the ^{31}P NMR spectrum (δ −13.9; $^{1}J\{^{195}Pt—^{31}P\}$ 2825 Hz). This product appears to decompose slowly to the dichloride in solution and thus any attempt to crystallize it by slow diffusion simply yields colourless crystals of the latter.

In conclusion it is clear that liquid ammonia at high, but relatively easily handled pressure is an excellent solvent for Se_4N_4. The latter does not appear to undergo significant reaction with the

$$PtCl_2(PMe_2Ph)_2 + Se_4N_4\ (98\%\ {}^{15}N) \xrightarrow[50\ Atm.]{NH_3(liq.)} Pt(Se_2N_2)(PMe_2Ph)_2\ (<20\%\ {}^{15}N)$$

$$Se_4N_4\ (98\%\ {}^{15}N) \xrightarrow[50\ Atm.]{NH_3(liq.)} Se_4N_4\ (98\%\ {}^{15}N)$$

$$Pt(Se_2N_2)(PMe_2Ph)_2\ (98\%\ {}^{15}N) \xrightarrow[50\ Atm.]{NH_3(liq.)} Pt(Se_2N_2)(PMe_2Ph)_2\ (98\%\ {}^{15}N)$$

Scheme 1.

ammonia and should therefore be amenable to reaction with a wide range of species. Of course the latter must be compatible with the ammonia but even allowing for this *caveat* it is likely that this system will be a valuable tool in the advancement of selenium–nitrogen chemistry.

THE PREPARATION AND X-RAY STRUCTURE OF [NBu$_4$][*fac*-PtBr$_3$(S$_4$N$_4$)]

VANESSA C. GINN, PAUL F. KELLY, ALEXANDRA M. Z. SLAWIN, DAVID J. WILLIAMS and J. DEREK WOOLLINS*

Department of Chemistry, Imperial College, London SW7 2AY, U.K.

(*Received* 23 *November* 1992; *accepted* 27 *January* 1993)

Abstract—Reaction of [NBu$_4$][Pt$_2$Br$_6$] with S$_4$N$_4$ gives the title compound, which has been characterized by ^{15}N/^{195}Pt NMR and X-ray crystallography. The anion consists of fused PtS$_2$N$_2$ and PtS$_3$N$_2$ rings with coordination to the platinum via two sulphur atoms and one nitrogen. The five-membered ring is essentially planar, whereas the six-membered ring is planar with the exception of the coordinated sulphur atom which is common to both rings. The N—S—N angles can be related to the magnitude of the $^2J\{^{15}N—^{15}N\}$ coupling constants.

Metalla-sulphur–nitrogen chemistry continues to excite interest,[1,2] in part because of the ability of the metal to stabilize unknown S—N anions and because of the diversity of the structural types which are observed. Thus, although S$_4$N$_4^{2-}$ has not been isolated in any simple salts three configurations have been observed when it behaves as a ligand in metal complexes. Reaction of S$_4$N$_4$ with Ir(CO)Cl(PPh$_3$)$_2$ gives[3,4] *fac*-Ir(CO)Cl(S$_4$N$_4$)(PPh$_3$) (**1**), whereas reaction with [PtCl$_2$(PMe$_2$Ph)]$_2$ gives[5,6] *mer*-PtCl$_2$(PMe$_2$Ph)(S$_4$N$_4$) (**2**), which can (from NMR studies) adopt two different coordination modes. Recently, we have reported on the formation of [PPh$_4$][PtX$_3$(S$_4$N$_4$)] (**3**) from the oxidative addition reaction of S$_4$N$_4$ with [PPh$_4$]$_2$[Pt$_2$X$_6$]. The facial coordination of the S$_4$N$_4^{2-}$ ligand in **3** was postulated[7] on the basis of ^{15}N and ^{195}Pt NMR, but could not be substantiated by X-ray crystallography because of disorder problems. Here we report the preparation and X-ray structure of [Bu$_4$N][PtBr$_3$(S$_4$N$_4$)] (**4**). ^{15}N and ^{195}Pt NMR studies indicate that **4** is isostructural with **3**.

EXPERIMENTAL

[Bu$_4$N]$_2$[Pt$_2$Br$_6$]

To K$_2$PtBr$_4$ (0.49 g, 0.8 mmol) in water (100 cm^3) was added [Bu$_4$N]Br (0.26 g, 0.8 mmol) in water (200 cm^3). The resulting sage green precipitate was filtered off, washed with water (250 cm^3) and Et$_2$O (100 cm^3) and recrystallized from CH$_2$Cl$_2$/toluene (yield 0.13 g, 24%). Found: C, 27.8; H, 5.1; N, 2.0. Calc.: C, 28.4; H, 5.4; N, 2.1%. The ^{195}Pt NMR spectrum consists of a singlet at δ −2293.

[Bu$_4$N][PtBr$_3$(S$_4$N$_4$)] (4)

[Bu$_4$N]$_2$[Pt$_2$Br$_6$] (0.134 g, 0.1 mmol) and S$_4$N$_4$ (37 mg, 0.2 mmol) were dissolved in CH$_2$Cl$_2$ (30 cm^3) and the resulting dark solution stirred for 3 days. The volume of the solution was then reduced to 2–3 cm^3 *in vacuo* and slow diffusion of Et$_2$O resulted in dark crystals. X-ray crystallography showed these to be [Bu$_4$N][PtBr$_3$(S$_4$N$_4$)] (yield 70 mg, 40%). Found: C, 22.3; H, 4.3; N, 7.5. Calc.: C, 22.3; H, 4.2; N, 8.1%. The ^{195}Pt NMR spectrum consisted of a singlet at δ −2272.

For the ^{15}N labelled sample of **4** S$_4$^{15}N$_4$ was prepared by the literature method from 98% ^{15}N enriched NH$_4$Cl (Aldrich). [Bu$_4$N]$_2$[Pt$_2$Br$_6$] (59 mg, 0.04 mmol) with S$_4$^{15}N$_4$ (16 mg, 0.08 mmol) were mixed as solids and then CH$_2$Cl$_2$ (30 cm^3) was added with stirring. After stirring for 4 h the dark red solution was reduced to 2–3 cm^3 in volume and the ^{15}N{^{1}H} and ^{195}Pt NMR spectra (CD$_2$Cl$_2$) of the solution recorded.

Attempted preparation of fac-[PtCl$_2$(PMe$_2$Ph)(S$_4$N$_4$)]

A solution of [PPh$_4$][PtCl$_3$(S$_4$N$_4$)] (0.115 g, 0.14 mmol) in CH$_2$Cl$_2$ (20 cm^3) was placed in an ice bath

* Author to whom correspondence should be addressed.

and treated with a dilute solution of PMe_2Ph (0.02 cm^3, 0.14 mmol) in the same solvent (1.0 cm^3). The orange red solution did not change colour after addition of the phosphine and was maintained at 0°C for $\frac{1}{2}$ h; on warming to room temperature the solution darkened to orange–brown. The volume of the solution was reduced to 3 cm^3 *in vacuo* and its $^{31}P\{^1H\}$ NMR spectrum recorded ($CDCl_3$). This revealed two singlets at δ −14.5 ($^1J\{^{31}P—^{195}Pt\}$ 3550 Hz) [*cis*-$PtCl_2(PR_3)_2$] and δ −21.8, attributable to $PtCl(S_2N_2H)(PMe_2Ph)$; the presence of the latter was further confirmed by TLC, which gave identical results to an authentic sample (yellow spot at $R_f = 0.37$, eluant CH_2Cl_2).

X-ray crystallography

Crystal data. $C_{16}H_{36}Br_3N_5PtS_4$, $M = 861.6$, monoclinic, $a = 11.540(2)$, $b = 11.955(2)$, $c = 21.646(5)$ Å, $\beta = 104.45(2)°$, $U = 2892$ Å^3, space group $P2_1/c$, $Z = 4$, $D_c = 1.979$ g cm^{-3}. Red plates, dimensions $0.025 \times 0.283 \times 0.300$ mm, μ(Mo-K_α) = 93.0 cm^{-1}, $\bar{\lambda} = 0.71073$ Å, $F(000) = 1656$.

Data collection and processing. Siemens *P*4 diffractometer, ω-scan method ($3 \leqslant 2\theta \leqslant 50°$) graphite monochromated Mo-K_α radiation; 4084 independent measured reflections, 1904 observed [$|F_o| > 4\sigma(|F_o|)$], corrected for Lorentz and polarization factors; empirical absorption correction, maximum and minimum transmission factors 0.783 and 0.100, respectively.

Structure analysis and refinement. The structure was solved by the heavy atom method and all the non-hydrogen atoms refined anisotropically. The hydrogen atoms were idealized (C—H = 0.96 Å), assigned isotropic thermal parameters $U(H) = 1.2U_{eq}(C)$ and allowed to ride on their parent carbons. Refinement was by full-matrix least-squares to $R = 0.0552$ ($R = \Sigma[|F_o| - |F_c|]/\Sigma|F_o|$), $R_w = 0.0446$ [$w^{-1} = \sigma^2(F) + 0.0007F^2$]. The maximum and minimum residual electron densities in the final ΔF map were 1.56 and −0.79 e Å^{-3} and the mean and maximum shifts/error in the final refinement cycle were 0.021 and 0.224, respectively. Computations were carried out on an IBM 386 computer using the SHELXTL/PC program system.[8]

RESULTS AND DISCUSSION

Reaction of $[Bu_4N]_2[Pt_2Br_6]$ with S_4N_4 in CH_2Cl_2 proceeds at room temperature according to eq. (1) to give **4** in 40% yield. Compound **4** is air-stable, soluble in common organic solvents and appears to be insensitive to shock or heat.

$$[Bu_4N]_2[Pt_2Br_6] + S_4N_4 \longrightarrow [Bu_4N][PtBr_3(S_4N_4)] \quad (1)$$

After reaction for 3 days the product was crystallized by slow diffusion of Et_2O into a solution in CH_2Cl_2. The resulting species was more amenable to X-ray crystallography than its $[PPh_4]^+$ counterpart. The X-ray structure of $[Bu_4N][PtBr_3(S_4N_4)]$ (Fig. 1, Table 1) reveals that the

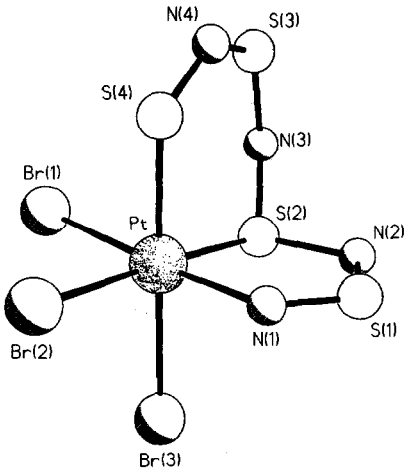

Fig. 1. The X-ray structure of the anion in **4**.

geometry around the platinum in the anion is slightly distorted from octahedral, with angles at platinum in the ranges 83.2(2)–98.8(2)° and 174.5(2)–177.4(2)°. The platinum atom is facially coordinated by three bromine atoms, together with two sulphur atoms and one nitrogen of the $S_4N_4^{2-}$ ligand. The coordination bond lengths are normal and in the range expected for platinum(IV).[9] The PtS_2N_2 ring is essentially planar [maximum deviation from the mean plane 0.04 Å for N(2)], whereas the PtS_3N_2 ring is puckered. Pt, S(4), N(4), S(3) and N(3) are co-planar to within 0.02 Å, with S(2) and Br(3) being 0.49 and 0.11 Å, respectively, from this plane (Fig. 2). The five- and six-membered rings are essentially orthogonal to each other. The gross structure of the MS_4N_4 unit is comparable to that

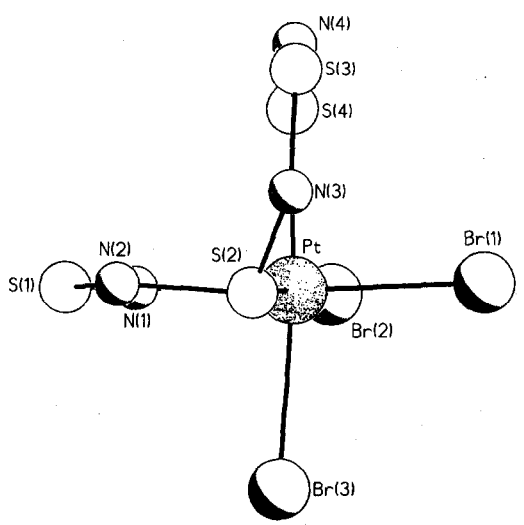

Fig. 2. View of the anion in **4** illustrating the puckering of the PtS_3N_2 ring at S(2) and the orthogonal relationship of the two fused rings.

reported for **1**, the only other structurally characterized *fac*-$S_4N_4^{2-}$ metal complex.

Although there is a superficial similarity between the aforementioned PtS_2N_2/PtS_3N_2 rings in **4** and the rings in the structures of species such as $Pt(S_2N_2)(PR_3)_2$ and $[Pd_2Cl_4(S_3N_2)]^{2-}$, there are also subtle differences between them. In the $S_2N_2^{2-}$ complexes there are two short (*ca* 1.55 Å) and one long (*ca* 1.7 Å) S—N bond lengths, which is mirrored in the PtS_2N_2 unit of $[PtBr_3(S_4N_4)]^-$. However, the planarity of the $S_3N_2^{2-}$ ligand in the binuclear palladium species contrasts with the puckered unit in the $S_4N_4^{2-}$ ligand in **4**. By comparing the geometry of the $S_4N_4^{2-}$ ligand to that of free S_4N_4 it can be seen that the S···S distances S(1)—S(3) and S(2)—S(4) correspond to two of the weak S···S interactions observed in the latter. The distances in the coordinated ligand are much larger, however, at 4.3 and 3.5 Å, respectively (cf. 2.6 Å in S_4N_4).

In **4** there is an absence of significant intermolecular S···S or S···N contacts of the type that have been observed in other S—N systems.[2] The closest inter-anion contact is S(3)···S(3′) (3.8 Å), although there is a fairly short Br(1)···Br(1′) contact of 4.0 Å. The bulk of the $[NBu_4]^+$ cation mitigates against good interanion interactions.

The ^{15}N NMR parameters for **4** are essentially identical (Table 2) to those of **3**, indicating that our previous NMR analysis was correct and that the anions in **3** and **4** are isostructural. The ^{195}Pt NMR spectra of ^{15}N labelled and normal **4** are compared in Fig. 3; the relative magnitudes of the two $\{^{15}N—^{195}Pt\}$ couplings are quite apparent from these spectra. It is possible to relate the geometry within the $S_4N_4^{2-}$ ligand to the $^2J\{^{15}N—^{15}N\}$ coupling constants measured from the ^{15}N NMR spectrum. As noted earlier the largest such interaction is between N(3) and N(4) (5.6 Hz), with a smaller interaction between N(1) and N(2) (3 Hz) and no observable interaction between N(2) and N(3). The angles at the sulphur atoms bridging these pairs of atoms are 119, 120 and 106° at S(3), S(1) and S(2), respectively. Thus, we postulate that the presence of an angle close to tetrahedral at S(2) results in poor orbital overlap (especially via any π-system) and consequent lack of interaction between nitrogen atoms. It should be remembered, however, that the couplings in question are only a few Hz in magnitude and thus any rationalization of their precise magnitude must be treated with some caution.

Mechanistically the formation of **3** and **4** is interesting. During the course of these reactions the halo-bridged dimeric starting materials are, as predicted, acting as a source of the coordinatively unsaturated $[PtX_3]^-$ unit. It is tempting to suggest

Table 2. Comparison of the ^{15}N NMR parameters for $[Bu_4N]^+$ and $[PPh_4]^+$ salts of $[PtBr_3(S_4N_4)]^-$ (* indicates coupling not resolved)

Compound	Nitrogen	δ (ppm)	$^2J\{^{15}N—^{15}N\}$ (Hz)	$^{15}N—^{195}Pt$ (Hz)
$[Bu_4N][PtBr_3(S_4N_4)]$	N(1)	433	2.6	152
	N(2)	284	2.6	*
	N(3)	164	6.0	*
	N(4)	345	6.0	*
$[PPh_4][PtBr_3(S_4N_4)]$	N(1)	433	3.0	150
	N(2)	283	3.0	6
	N(3)	164	5.6	16
	N(4)	343	5.6	*

that the initial stage of the reaction involves the formation of a simple σ-bonded platinum(II) species of the type $PtX_3(S_4N_4)^-$, which then undergoes an internal rearrangement to the final platinum(IV) species. There is, however, no unequivocal evidence for such an intermediate.

As noted earlier it is possible to prepare *mer*-$PtCl_2(S_4N_4)(PMe_2Ph)$ by reaction of S_4N_4 with $[PtCl_2(PMe_2Ph)]_2$. We attempted to generate its *facial* analogue by addition of a stoichiometric amount of the free phosphine to **3**. An ice-cold solution of $[PPh_4][PtCl_3(S_4N_4)]$ in CH_2Cl_2 was treated with a dilute solution of PMe_2Ph and the resulting orange–red solution maintained at this temperature for $\frac{1}{2}$ h. After warming to room temperature the $^{31}P\{^1H\}$ NMR spectrum of the concentrated solution was recorded. This showed that most of the compound had been converted to $PtCl_2(PMe_2Ph)_2$, together with a small amount of a species characterized by a singlet at δ −22 ppm; this chemical shift is similar to that of $PtCl(S_2N_2H)(PMe_2Ph)$ (reported value[10] −21 ppm), although the spectrum was too weak for $^1J\{^{31}P—^{195}Pt\}$ satellites to be resolved. Confirmation that this was indeed the compound present came from the TLC of the solution (CH_2Cl_2), which revealed a yellow band at $R_f = 0.37$, identical to that for $PtCl(S_2N_2H)(PMe_2Ph)$. Although disappointing this result was not entirely unexpected. Earlier work in our group has shown that any attempts to involve *mer*-$PtCl_2(S_4N_4)(PMe_2Ph)$ in further reactions inevitably result in massive decomposition to mixtures of the two species mentioned above. Thus, despite its relative stability once formed, the $S_4N_4^{2-}$ unit does not appear to be robust enough to be retained during these types of reactions. Further studies into its reactivity (e.g. protonation) are in progress.

Abstract—The compound (3,5-dinitrobenzoate)bis(triphenylphosphine)copper(I) was synthesized and studied by IR spectroscopy and X-ray diffraction techniques. It is monomeric with the carboxylato acting as a monodentate ligand. The copper atom shows a trigonal planar coordination geometry.

The study of copper(I) complexes is a topic currently being investigated in many laboratories. Among the reasons for carrying out the investigation of such species are their structural features,[1,2] the usefulness of copper(I) compounds in organic syntheses[3] and the well-documented importance of copper(I) centres at the active sites of a number of proteins.[4] Concerning copper(I) carboxylates a further interest exists, stemming from their use in homogeneous catalysed hydrogenation.[5] In continuation of our research on copper compounds[2,6–8] we prepared [Cu(3,5-$NO_2C_6H_3CO_2$)(PPh_3)$_2$], which was subjected to a full IR and X-ray crystallographic characterization.

EXPERIMENTAL

Synthesis of [Cu(3,5-$NO_2C_6H_3CO_2$)(PPh_3)$_2$]

All operations described herein, except the weighings, were performed in an atmosphere of purified nitrogen in a Schlenk apparatus. To a solution containing [Cu(BH_4)(PPh_3)$_2$] (0.2 g, 0.33 mmol) in chloroform (10 cm^3) was added a tetrahydrofuran solution (5 cm^3) containing 3,5-dinitrobenzoic acid (0.071 g, 0.33 mmol). The mixture was stirred for 5 h at room temperature. The solution was concentrated under reduced pressure and by adding pentane an orange solid was formed. Recrystallization from ether gave orange crystals suitable for X-ray analysis. The elemental analysis results were in agreement with the proposed formula.

IR spectrum

The IR spectrum was recorded as KBr pellets on a Nicolet 730-FT spectrophotometer.

Crystal structure determination

$C_{43}H_{33}N_2O_6P_2Cu$, *crystal data.* $M = 799.24$, monoclinic, $a = 14.839(2)$, $b = 13.771(2)$, $c = 18.745(3)$ Å, $\beta = 101.21(1)°$, $U = 3757(2)$ Å^3 (by least-squares refinement on diffractometer angles for 25 automatically centred reflections, $9 < \theta < 26°$, $\lambda = 0.71073$ Å), space group $P2_1/n$, $Z = 4$, $D_c = 1.413$ g cm^{-3}. An irregular shaped crystal was used of maximum and minimum linear dimensions 0.55 and 0.25 mm, μ(Mo-K_α) = 7.15 cm^{-1}.

Data collection and processing. CAD4 diffractometer, $\omega/2\theta$ mode with ω scan width = 0.85+0.15 tan θ, graphite monochromated Mo-K_α radiation, 5904 unique reflections measured ($0 < \theta < 25°$, $-17 \leqslant h \leqslant 17$, $0 \leqslant k \leqslant 16$, $0 \leqslant l \leqslant 22$), 4278 with $I > 3\sigma(I)$; Lorentz and polarization corrections were applied. Absorption corrections were applied

* Author to whom correspondence should be addressed.

at a later stage in the refinement[9] (max., min. transmission factors = 1.609, 0.504). The intensity of a standard reflection was essentially constant throughout the experiment.

Structure analysis and refinement. Standard direct methods followed by normal difference Fourier techniques. Blocked-matrix least-squares refinement with all non-hydrogen atoms anisotropic and hydrogens included, as fixed contributors, at positions found in difference synthesis, with one overall isotropic temperature factor which was refined to $U_{iso} = 0.082(2)$ Å^2. The function minimized was $\Sigma w(|F_o|-|F_c|)^2$, with the weighting scheme $w = 1/[\sigma^2(F_o)+0.003F_o^2]$, gave satisfactory agreement analysis. Final $R = [\Sigma(|F_o|-|F_c|)/\Sigma|F_o|]$ and $R' = \{[\Sigma w(|F_o|-|F_c|)^2/\Sigma w|F_o|^2]^{1/2}\}$ values were 0.041 and 0.042, respectively. Programs used: SHELX76,[10] ORTEP;[11] scattering factors for non-hydrogen atoms were from Cromer and Mann[12] (with corrections for anomalous dispersion from Cromer and Liberman)[13] and for hydrogen atoms from Stewart *et al.*[14] The atomic positions, full lists of bond lengths and angles and other crystallographic data have been deposited as supplementary material.

RESULTS AND DISCUSSION

It is a well known fact that cuprous carboxylates, that in general are sensitive to moisture, can be effectively stabilized by ligands such as triphenylphosphine, affording compounds of the type [Cu(RCOO)$(PPh_3)_2$]. These complexes can be synthesized by reducing cupric carboxylates with the phosphorus ligand[15] or through the reaction of tetrahydroborato-bis(triphenylphosphine)copper(I), [Cu$(BH_4)(PPh_3)_2$], with carboxylic acids, as was used to obtain the title compound. The IR spectrum of [Cu(3,5-$NO_2C_6H_3CO_2$)$(PPh_3)_2$] showed a number of absorption bands, but the most characteristic ones[16,17] were those assigned to stretching modes of the carboxylato and nitro groups, respectively, at 1617s, $\nu_{as}(CO_2)$; 1341vs, $\nu_s(CO_2)$; 1537s, $\nu_{as}(NO_2)$; 1374s, $\nu_s(NO_2)$ cm^{-1}.

An important feature to be noted is the separation between the two stretching modes, $\Delta\nu = \nu_{as}(CO_2)-\nu_s(CO_2) = 276$ cm^{-1}, which suggests that the 3,5-dinitrobenzoate acts as a monodentate ligand to the copper atom. Moreover, this conclusion is further supported by the lower differences, 247 and 214 cm^{-1}, respectively, found in similar compounds[18] such as [Cu(2-$NO_2C_6H_4CO_2$)$(PPh_3)_2$] and [Cu(4-$NO_2C_6H_4CO_2$)$(PPh_3)_2$], where the anions are bidentate.

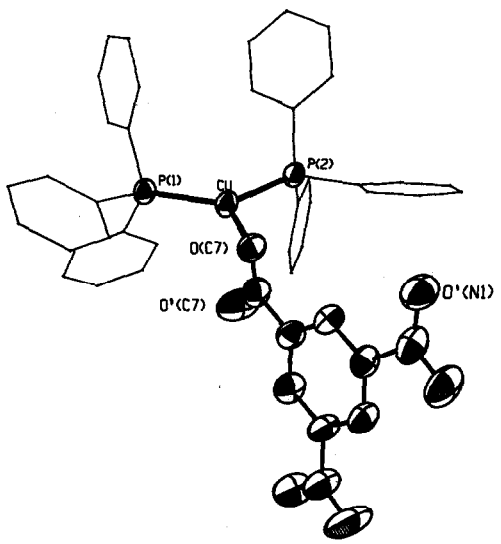

Fig. 1. Molecular structure of [Cu(3,5-$NO_2C_6H_3CO_2$)$(PPh_3)_2$].

The monomeric nature of the compound and the important structural features of the carboxylate group suggested by IR spectroscopy were definitively proved by the crystal and molecular structural X-ray analyses. The structure of the compound with the labelling scheme is presented in Fig. 1. Selected bond lengths and angles are given in Table 1. The molecular structure shows that the copper atom is bonded to the phosphorus atoms of the two triphenylphosphine ligands and to one oxygen atom of the carboxylate group, giving rise to a nearly trigonal planar coordination. In fact the copper atom is only 0.026(3) Å out of the plane through P(1)—P(2)—O(C7). The other copper contacts are: Cu···O'(C7) = 2.643(3), Cu···O'(N1) [$1-x$, $-y$, $1-z$] = 3.009(3) Å.

The 3,5-dinitrobenzoate anion behaves as a monodentate carboxylate ligand making the shortest interaction with the metal atom [Cu—C

Table 1. Selected distances (Å) and angles (°) for [Cu(3,5-$NO_2C_6H_3CO_2$)$(PPh_3)_2$]

Cu—P(1)	2.221(1)	P(1)—Cu—P(2)	129.24(4)
Cu—P(2)	2.243(1)	P(1)—Cu—O(C7)	121.76(8)
Cu—O(C7)	2.051(3)	P(2)—Cu—O(C7)	108.95(8)

(C7) = 2.051(3) Å]. The dihedral angles between the phenyl ring and the carboxylate and nitro groups [N(1) and N(2)] are 16.7(7), 9.0(9) and 8.2(9)°, respectively.

Finally, the important structural differences related to the coordination polyhedra (trigonal planar) and the Cu—O bond length, 2.051(3) Å, for $[Cu(3,5\text{-}NO_2C_6H_3CO_2)(PPh_3)_2]$ and those of the related compounds $[Cu(2\text{-}NO_2C_6H_4CO_2)(PPh_3)_2]$ and $[Cu(4\text{-}NO_2C_6H_4CO_2)(PPh_3)_2]$, both tetrahedral with Cu—O distances in the range 2.145(3)–2.304(3) Å, are probably of electronic origin caused by the presence of two nitro groups in the present compound.

SOLVATION OF INORGANIC COMPLEXES IN OCTANOL-WATER, HEXANOL-WATER, AND RELATED MICROEMULSIONS

SUADA AHMED,* JOHN BURGESS,† GLEN CAPPER, NICOLA C. FELLOWES and MARTTAND S. PATEL

Department of Chemistry, University of Leicester, Leicester LE1 7RH, U.K.

(*Received* 7 *January* 1993; *accepted* 27 *January* 1993)

Abstract—Solubilities of tris(ethylmaltolato)iron(III) have been determined in dry 1-octanol, 1-hexanol and isobutanol and in the limited ranges of alcohol–water binary mixtures accessible for these alcohols. The observed pattern is discussed in terms of particularly favourable synergic solvation in the mixed solvents and is compared with solvation patterns indicated by the solvatochromic iron(II) complex $Fe(CN)_2(bipy)_2$.

Inorganic complexes are becoming increasingly relevant to pharmacology.[1,2] Their solvation properties are important in this connection, especially if they are to be administered orally. There is a requirement for an appropriate hydrophilic–lipophilic balance (HLB)[3] so that they can cross the various membranes and barriers—the gut wall, blood–brain barrier, cell walls—between the dosage site and the site of action. It is conventional to assess the HLB through partition coefficients, generally between water and 1-octanol.[4] Partition coefficients have been obtained for a very large number of organic compounds, but for relatively few inorganic species. The determination of partition coefficients for methylmercury(II)-thiol[5] and methylmercury(II)-antidote[6] complexes provided useful information in relation to the treatment of alkylmercury poisoning, but the determination of reliable partition coefficients for such complexes as tris-maltolatoaluminium(III) proved unexpectedly difficult.[7] The widely-used and valuable partition coefficient approach does not, however, give any indication of possible synergic solvation in a binary medium, of which a membrane/aqueous medium interface may be considered a special case. The process of transport across a membrane may be split into *pre-equilibrium siting of the substrate at* the interface, followed by passage through the membrane.[8] The partition coefficient is the key parameter in relation to the first step, favourable interaction at the interface. It seems likely that a substrate which is favourably solvated *both* by water and by octanol would be most stable at a membrane surface. In a sense the water–octanol partition coefficient is particularly relevant in that the octanol contains up to about 6% water,[9] which limited solubility arises from favourable solvent–solvent hydrogen-bonding interactions.[10] It has long been recognized that the solubility of a species in wet octanol in a partition experiment may be considerably different from its solubility in dry octanol,[11] but quantitative data seem to be sparse. We have recently demonstrated that a number of inorganic complexes of pharmacological relevance, including a number of pyrone (**1**) and pyridinone (**2**)

complexes of iron(III), aluminium(III), gallium(III) and indium(III)[12–14] and classical inorganic complexes, such as $[Fe(bipy)_2(CN)_2]$,[15] are more soluble in alcohol–water mixtures than in either separate component. These results were obtained mainly with methanol or t-butyl alcohol as the co-solvent, so that solubilities could be established over the

† Author to whom correspondence should be addressed.

complete solvent composition range and solubility maxima corresponding to favourable synergic solvation by both components readily identified. We now report an extension of these studies to alcohols which are not fully miscible with water, especially to 1-hexanol and 1-octanol, and to "organized aqueous media" in which the addition of surfactants solubilizes these alcohols in water. The main aim has been to monitor the effects of adding small quantities of water to the organic components. This we have done through solubility measurements, with derived transfer chemical potentials to give an idea of energy changes, and through solvatochromism. This latter phenomenon is valuable in providing an easy indication of preferential solvation, but is restricted to a small number of inorganic compounds, of which ternary iron(II)-diimine-cyanide complexes have suitable sensitivity and solubility characteristics to use here. Solubility determinations are of much more general applicability. Here we have used tris-ethylmaltolatoiron(III) [ethylmaltol = etmaH = pyrone (1) with R = Et] as a typical substrate of pharmacological relevance—pyrones and pyridinones are proving of actual and potential value in the control of iron and aluminium levels in the body,[16] may provide suitable vehicles for the introduction of radioisotopes such as those of gallium, indium, or yttrium into the body for diagnostic or therapeutic purposes,[2,17] or gadolinium for MRI,[2] and, in the form of the maltol-vanadyl complex, may be valuable in the control of diabetes.[18]

The solubility of $Fe(etma)_3$ in dry 1-octanol (4.6×10^{-4} mol dm^{-3}) is only slightly higher than in water (3.7×10^{-4} mol dm^{-3}), but it is over eight times more soluble in 1-octanol containing 6.3% water (solubility 38×10^{-4} mol dm^{-3}) than in 1-octanol itself. The situation is similar with respect to 1-hexanol, where the solubilities of $Fe(etma)_3$ are 8.2×10^{-4}, 36×10^{-4} and 68×10^{-4} mol dm^{-3} in 1-hexanol containing 0%, 3.3% and 9.1% water, respectively. These effects of addition of small amounts of water to these alcohols are shown in terms of transfer chemical potentials [$\delta_m\mu^0$ = (solubility in medium 2)/(solubility in medium 1)] in Fig. 1. This figure also shows the effects on $Fe(etma)_3$ solubility of adding water to isobutanol, and of isobutanol to water, and, for comparison, the transfer chemical potential trend for this complex in methanol–water mixtures.[13] It is interesting that the transfer chemical potential minimum (solubility maximum) is obtained within the limited mutual miscibility range[19] in the case of iso-butanol, and that $Fe(etma)_3$ has a large salting-in effect on the isobutanol (solubility of isobutanol in water is 19%[20]). In this its behaviour parallels that of a

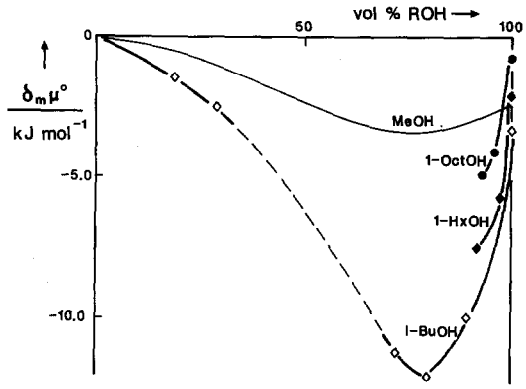

Fig. 1. Transfer chemical potentials for $Fe(etma)_3$ to water–alcohol media, at 298.2 K.

range of organic solutes in water/di-n-butylether[21] and transition metal(II) perchlorates in 1-butanol/water.[22] Figure 1 shows clearly the considerable increase in overall solvation caused by hydration of hydrophilic areas on the periphery of the complex when water is added to 1-octanol, 1-hexanol, isobutanol or methanol.

Our observations in the 1-octanol–water system can be related to the partition coefficient. We have measured this, by the shaking method, finding a value of 8.2. This may be compared with the value of 0.08 reported for the rather more lipophilic tris-maltolatoaluminium(III)[23] and a range of values from 0.03 to 7.7 for tris-pyridinatoiron(III) complexes containing various alkyl substitutents.[24] A partition coefficient of 8.2 corresponds to a chemical potential change of -5.2 kJ mol^{-1} for transfer

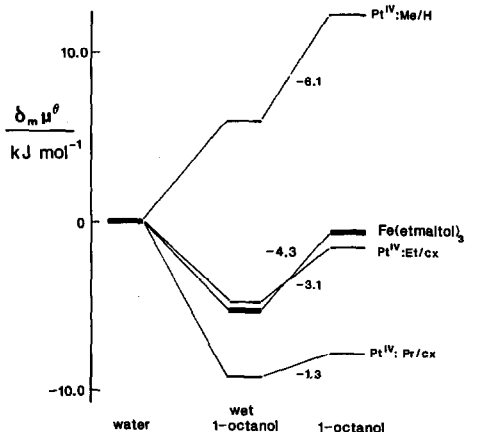

Fig. 2. Chemical potentials for $Fe(etma)_3$ and for three platinum(IV) complexes of formula 3 in water–1-octanol. The values given on the diagram are for transfer from dry 1-octanol to water-saturated 1-octanol, in kJ mol^{-1} at 298.2 K.

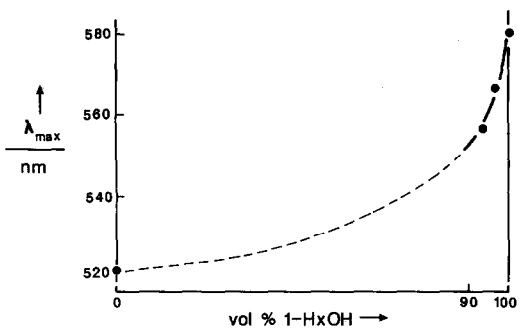

Fig. 3. Solvatochromic behaviour of the MLCT band of $Fe(CN)_2(bipy)_2$ in water–1-hexanol.

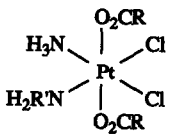
from the water layer into the wet octanol layer. The transfer chemical potential of $Fe(etma)_3$ from water into dry 1-octanol is only -0.7 kJ mol^{-1} from our solubility measurements, but the transfer chemical potential from dry octanol to wet octanol (6.3% water) is -4.3 kJ mol^{-1}. Significant changes in solubility or chemical potential between dry and wet octanol have been noted before,[11] but do not seem to have been systematized and rationalized.[25] A recent inorganic example has been provided by a series of platinum(IV) complexes (**3**). The transfer chemical potentials for such compounds with R = Me, R′ = H; R = Et, R′ = cyclohexyl; R = Pr, R′ = cyclohexyl from dry octanol into water-saturated octanol are -6.1, -3.1 and -1.3 kJ mol^{-1}, respectively.[26] Solvational stabilization decreases as ligand hydrophilicity decreases. These results are included in Fig. 2, where they are compared with our estimates for $Fe(etma)_3$.



3

An alternative approach to demonstrating the importance of hydration of hydrophilic areas on adding a little water to organic solvents is offered by solvatochromism, at least in those few cases where the solute exhibits this phenomenon. Pyrone and pyridinone complexes are only very slightly solvatochromic, so we have had to turn to iron(II) complexes of the $[Fe(CN)_2(bipy)_2]$ and $[Fe(CN)_4(bipy)]^{2-}$ type. Figure 3 shows λ_{max} values for $[Fe(CN)_2(bipy)_2]$ in 1-hexanol–water mixtures, with a rapid decrease in λ_{max} towards the value for pure water on adding relatively small amounts of water to 1-hexanol. Solubilities of 1-hexanol or 1-octanol in water can be significantly increased by the use of appropriate surfactants. Figure 4 shows the dependence of λ_{max} on water content for three such systems. The patterns are similar and indeed are very similar to Fig. 3. In all cases the strong preferential hydration of the cyanide ligands in the

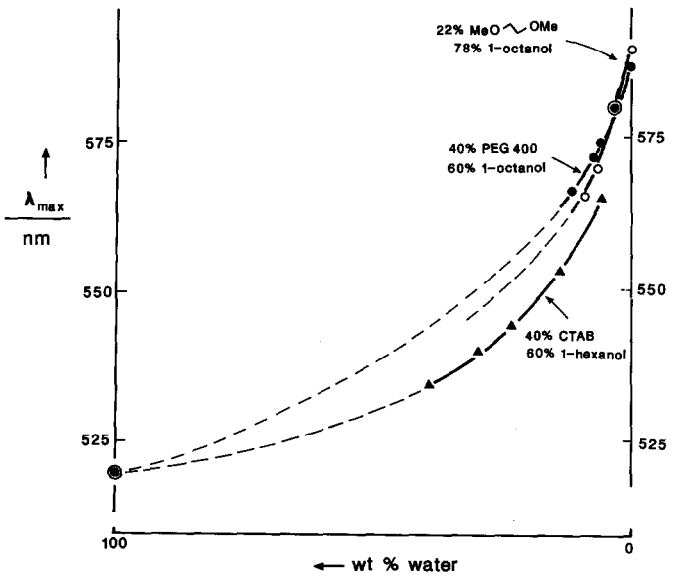


Fig. 4. Solvatochromic behaviour of the MLCT band of $Fe(CN)_2(bipy)_2$ in water–alcohol–surfactant systems. The compositions specified against the three curves are those corresponding to the 0% water axis.

complex by the added water cause marked shifts of λ_{max} towards its value in pure water.

THE PHENOMENON OF CONGLOMERATE CRYSTALLIZATION—XXXII. THE CRYSTALLIZATION BEHAVIOUR OF [*cis*-$Co(en)_2(NO_2)_2$]I (I). COUNTER-ION EFFECTS ON CRYSTALLIZATION PATHWAY OF RACEMATE SOLUTIONS—III

IVAN BERNAL,* JOZEF MYRCZEK†‡ and JIWEN CAI†

Chemistry Department, University of Houston, Houston, TX 77204-5641, U.S.A.

(*Received* 10 *November* 1992; *accepted* 26 *January* 1993)

Abstract—[*Cis*-$Co(en)_2(NO_2)_2$]I (**I**), $ICoO_4N_6C_4H_{16}$, crystallizes from water at 18°C as both a racemate and a conglomerate. The structure of the latter was determined in this study. Unlike its chloride and bromide brethren, which crystallize exclusively as conglomerates, in the space group $P2_1$, the iodide crystallizes in the tetragonal space group $P4_1$ (No. 76). The absolute configuration was determined by comparison with that of the parent compound, $(-)_{589}$-[$\Lambda(\delta\lambda)$-*cis*-$Co(en)_2(NO_2)_2$]Br (**III**), from which it was made by metathesis. Unlike the chloride and parent bromide, whose chiroptical symbols are [*cis*-$(-)_{589}$-$\Lambda(\delta\lambda)$-$Co(en)_2(NO_2)_2$]Cl (**II**) and [*cis*-$(-)_{589}$-$\Lambda(\delta\lambda)$-$Co(en)_2(NO_2)_2$]Br (**III**), in the solid state that of [*cis*-$(-)_{589}$-$Co(en)_2(NO_2)_2$]I (**I**) is $\Lambda(\lambda\lambda)$. The cations of **I** form infinitely hydrogen-bonded, homochiral, helical strings about the four-fold screw axis of the crystals. In turn, adjacent helical strings are held together by hydrogen bonds between the iodides and $-NH_2$ hydrogens of the amine ligands. Such an arrangement is also present in the isomorphous chloride and bromide derivatives; however, in those compounds the infinite spirals are wound about the two-fold screw axis of the space group $P2_1$.

In previous studies[1–9] we reported conglomerate crystallization[10] of Werner coordination compounds belonging to a class characterized by having *clavic* (from the Latin word for paddle or tiller) ligands, such as $-NO_2$, which can be anchored into specific dissymmetric arrangements by hydrogen bonds to adjacent amine ligands, all of which have a pronounced tendency to crystallize as conglomerates—mechanical mixtures of pure homochiral crystals derived from a solution of a racemate. Examples of compounds of such class, crystallizing as conglomerates and whose structures and absolute configurations have been determined, are the series [*cis*-α-$Co(trien)_2(NO_2)_2]\cdot H_2O$ (X = Cl,[1] I[2]), the series [*cis*-$Co(en)_2(NO_2)_2$]X (X = Cl,[1] Br[3]) and [*cis*-$Rh(en)_2(NO_2)_2$]Cl.[4]

We have recently explored[5] in some detail the effect of the counter-ion on the crystallization pathway selected by a series of ionic species in which either the cation or the anion was retained while varying the nature of the counter-ion, a topic which had been mentioned since the beginning of our studies.[1] The conclusions reached[5] were that (a) in substituted cobalt amine series hydrogen bonding plays an important role in selecting the crystallization pathway, (b) in *cis*-dinitro cobalt amines strong intramolecular bonds are formed by the axial amine $-NH_2$ hydrogens with the $-NO_2$ oxygens and the presence of these bonds seems to be a necessary condition for conglomerate crystallization, and (c) that counter-anions capable of forming strong hydrogen bonds with the cation $-NH_2$ hydrogens can often compete for the formation of hydrogen bonds, and, thus, block the formation of intramolecular ones. When this happens cations which crystallize as conglomerates with halide counter-ions now crystallize as racemates. However, anions

* Author to whom correspondence should be addressed.
† Fellow of the Robert A. Welch Foundation.
‡ On leave from the Technical University of Wrocław, 1-5 Wrocław, Poland.

capable of forming strong hydrogen bonds with the metal amine hydrogens can function in different ways depending on the nature of the cation: (1) in a positive manner (conglomerate crystallization results, i.e. in $[Ni(en)_3]NO_3$[6,7]), or (2) in a negative fashion (racemates result, e.g. [*cis*-$Co(en)_2(NO_2)_2]NO_2$).[8] (d) It appears that in the [*cis*-metal $(en)_2(NO_2)_2$] series a sign of the intramolecular hydrogen-bonded interactions is the fact that the two en rings have opposite torsional chirality (e.g. one is δ, the other one λ).[9] For more details the interested reader is directed to our arguments and examples in the published literature.[1-9]

With respect to compounds such as **I** the following information was known prior to this study:

Compound	Space group	Ref.
[*cis*-$Co(en)_2(NO_2)_2$]Cl (**II**)	$P2_1$	1
[*cis*-$Co(en)_2(NO_2)_2$]Br (**III**)	$P2_1$	3
[*cis*-$Co(en)_2(NO_2)_2]NO_3$ (**IV**)	$P2_1/c$	11
[*cis*-$Co(en)_2(NO_2)_2]NO_2$(**V**)	Cc	8

Thus, it seemed interesting to document whether or not the pattern noted in the ethylenediamine derivatives could be observed with additional charge compensating anions. This is particularly interesting for the iodide (**I**) in view of the observation, by Yamanari *et al.*,[12(a)] that **II** and **III** crystallize as conglomerates, whereas **I** crystallizes as both a racemate and a conglomerate. It seems then that the iodide (**I**) provides a golden opportunity for exploring the differences in intra- and intermolecular interactions during the course of one or the other crystallization mode. Our results of such exploration are given below.

EXPERIMENTAL

Preparation of the compounds and crystal growth

Racemic [cis-$Co(en)_2(NO_2)_2$]I (**I**). [*Cis*-$Co(en)_2(NO_2)_2$]Br was prepared as described before.[13] Compound **I** was obtained by the addition of solid NaI to a stirred, warm (60°C), saturated solution of [*cis*-$Co(en)_2(NO_2)_2$]Br until precipitation. We already knew[1,3,12(a)] that in the *cis*-dinitro series (both trien and en) the solubility order is Cl > Br > I. The solution was cooled overnight in a refrigerator and filtered. The dried solid was used to prepare a room-temperature, saturated solution which was allowed to slowly crystallize at room temperature. Crystals obtained in this fashion were completely useless for single-crystal X-ray diffraction work. We tried for 5 years to obtain useful crystals but without success.

Eventually, we decided to use pure, chiral [*cis*-$Co(en)_2(NO_2)_2$]I derived from our previously prepared $(-)_{589}$-[$\Lambda(\delta\lambda)$-*cis*-$Co(en)_2(NO_2)_2$]Br and grow crystals in the dark, since we had observed that $[Co(en)_2$oxalato]I decomposes when in solution and exposed to laboratory lights.[13]

$(-)_{589}$-[*Cis*-$Co(en)_2(NO_2)_2$]I (**I**) was prepared by metathesis with NaI, as described above, but using $(-)_{589}$-{$\Lambda(\delta\lambda)$-*cis*-$Co(en)_2(NO_2)_2$]Br. Crystals grown in the dark are of varying quality. The worst ones are as bad as those obtained from racemic solutions. However, after several crystallization batches were sampled, one produced a very good crystal, which was used in the current study.

Elemental analyses for **I** were unnecessary since this is a known compound [12(a)] prepared from another known compound.[13,2(a)]

Collection of X-ray diffraction data

All data collection and processing were performed with the Molecular Structure Corporation TEXRAY-230 Modification[14] of the SDP-Plus[15] programs. The reader is referred to this manual for the details of the various routines mentioned and for the procedures recommended by them.

Nearly cubic, amber-brown crystals (**I**) were formed on slow evaporation of a water solution (*ca* 18°C) of the optically active compound, kept in the dark. The crystal was mounted on a translation head and onto an Enraf–Nonius CAD-4 diffractometer. A set of 25 reflections were centred and used to define the orientation and Niggli[16] matrices. The cell is primitive, tetragonal; the only systematic absences are those for which $011 \neq 4n$, which suggest the space groups $P4_1$, $P4_3$, $P4_122$ or $P4_322$ since the compound was known to be a pure enantiomorph.

Mo-K_α radiation was used throughout. Data for **I** were collected over the range $4° \leqslant 2\theta \leqslant 60°$. Two reflections were used as intensity standards in order to monitor crystal orientation and electronic stability. Intensity standards were collected every 2 h and an absorption correction was applied to the structure factors. No decay or systematic variation were observed and details of data collection and processing are listed in Table 1. The scattering curves of Cromer and Waber[17] were used throughout.

The phase problem was solved using a Patterson summation, from which the position of **I** was readily extracted. Heavy atoms were refined anisotropically and every five cycles of refinement new positions were calculated for the hydrogen atoms of the cation (C—H = N—H = 0.95 Å), added to the list and the structure refined until convergence.

Table 1. Summary of data collection and processing parameters for $(-)_{589}$-[*cis*-$Co(en)_2(NO_2)_2$]I (I)

Space group	$P4_1$

$R_w = [\Sigma w^2(\|F_o\|-\|F_c\|)^2/\Sigma\|F_o\|^2]^{1/2}$	0.0561
Weights used	$w = [\sigma(F_o)]^{-2}$

Bond lengths, angles, torsional angles and hydrogen bonds for I are listed in Table 2.

The absolute configuration of (I) was determined by refinement of the coordinates of the two enantiomorphs. The original coordinates (space group $P4_1$) gave the known absolute configuration of the cation of the parent bromide, namely Λ; consequently, it was assumed to be the correct one inasmuch as there is no reason to expect inversion at the cobalt centre; moreover, the sign of the rotation (−) of the solution of I used to grow the crystals matches that of the parent bromide.

RESULTS

The absolute configuration of the cation is shown in Fig. 1, which displays the contents of the asymmetric unit. As expected from the prepara-

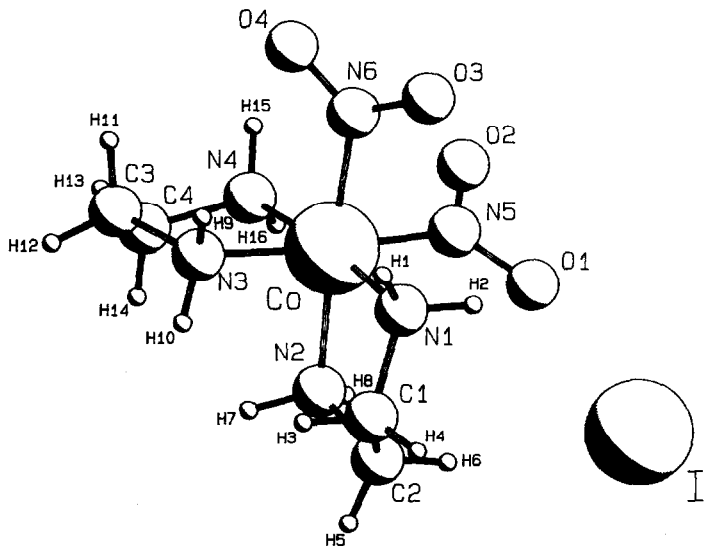

Fig. 1. The contents of the asymmetric unit. Note that the configuration about cobalt is Λ while the conformations of N(1)—C(1)—C(2)—N(2) and N(3)—C(3)—C(4)—N(4) are λ and λ. Also the hydrogen bonds between O(1) and H(2) and between O(4) and H(15) are evident from this view. For details of the bond lengths see Table 2(D).

[a] Estimated errors in distances range from 0.005 to 0.01 Å.

[b] Estimated errors in angles range from 0.02 to 0.05°.

No e.s.d.s are shown since hydrogen atoms were not refined.

Numbers in parentheses are estimated standard deviations in the least significant digits.

tion the cation has the configuration Λ; however, the helical chiralities of the two en rings are λ[<N(1)—C(1)—C(2)—N(2) = −51.6°] and λ[< N(3)—C(3)—C(4)—N(4) = −48.6°], which is an interesting solid state result since that of the bromide **III**, from which **I** was prepared, was Λ($\delta\lambda$), implying that intra- or intermolecular interactions, or both, are responsible for a change which increases the conformational energy of the system.[18]

The packing of the molecules in the unit cell is shown in Fig. 2, which illustrates the fact that the cations form infinite spiral strings, propagating along the four-fold screw axis, and held together by hydrogen bonds between the —NO_2 oxygens and the —NH_2 hydrogens, typical of which are those listed in Table 3(D). The spiral strings are made up of homochiral cations inasmuch as we used a resolved species.

In **I** the helical strings are, in turn, held together by hydrogen bonds between the iodide and hydrogens of the —NH_2 moieties. The strings have the same helical chirality and, in that regard, resemble the helical strings of a polypeptide derived from homochiral amino acids.

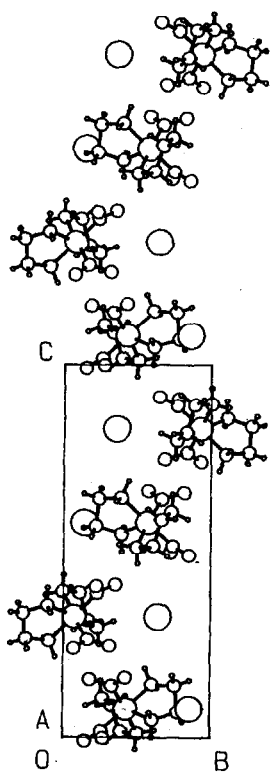

Fig. 2. A portion of the unit cell. Note the infinite spirals of hydrogen-bonded cations into pockets of which fit the iodide anions which link adjacent spiral strings.

Table 3. Torsional angles for [*cis*-Co(en)$_2$(NO$_2$)$_2$]Cl, bromide and iodide (**I**)

[a] Angle labels were rearranged to correspond to those of the lower halides, since in the labelling for the —NO_2 oxygens O(1) and O(2) and O(3) and O(4) for the iodide were reversed compared with the labels for the other two.

DISCUSSION

Racemic [*cis*-Co(en)$_2$(NO$_2$)$_2$]I (**I**) crystallizes either as a racemate[12(a)] or in the enantiomorphic space group $P4_1$, whose contents ($z = 4$) are homochiral, as shown above. Thus far, we have not been able to isolate X-ray quality crystals of the racemate, and, as stated above, the enantiomorphic ones were obtained from pre-resolved material. However, we know that they should be the same as those precipitating during conglomerate crystallization since Aoki *et al.*[19] studied the structure of resolved $(-)_{589}$-[*cis*-[Λ($\delta\lambda$)-Co(en)$_2$oxalato] Br·H_2O while we[5(b)] determined its structure using crystals from a conglomerate crystallization. The results are identical. The interested reader is referred to our previous paper on this subject.[5(b)]

It is noteworthy that the iodide (**I**) is not isomorphous with its chloride (**II**) or bromide (**III**) analogues, which is in line with the observation that it is capable of crystallizing as both a racemate and a conglomerate[12(a)] from the same racemic solution, while **II** and **III** crystallize as conglomerates. The same observations apply to the oxalato series, [*cis*-Co(en)$_2$Ox]X·nH$_2$O (X = Cl, $n = 4$; X = Br, $n = 1$; X = I, $n = 0$). in which the chloride and bromide crystallize as conglomerates, while the iodide crystallizes as both.[5(b),12(b),(c)] In that series one could argue that space group changes would not be surprising inasmuch as the degree of hydration varies; however, such is not the case with the current series. Finally, in the oxalato series similar difficulties arise from the quality of the crystals of the iodide salt, as we have demonstrated earlier.[5(b)]

A pertinent fact is that while **I** winds its cations on a four-fold spiral screw, **II** and **III** crystallize in

the space group $P2_1$ and their cations pack in helical strings also, but the order of the screw axis is two. However, they all wrap themselves about a screw axis, in a helical arrangement internally held by $—NO_2 \cdots H_2N—$ hydrogen bonds. In turn, strings of the same helical chirality are held together in a three-dimensional array by hydrogen bonds between the counter-anion and the $—NH_2$ hydrogens of the cations. This feature is shared by the three homochiral crystalline forms of **I**, **II** and **III**.

The following observations concerning the crystallization characteristics of the three halides of the $[cis\text{-}[Co(en)_2(NO_2)_2]^+$ cation are useful to understand the reasons for their crystallization behaviour:

(1) The ionic radii of six-coordinate Cl^-, Br^- and I^- are, respectively,[20] 1.67, 1.82 and 2.06 Å. Therefore, their respective volumes are 19.41, 25.25 and 36.62 Å^3. The differences between **I** and **III**, between **I** and **II** and between **III** and **II** are, respectively, 17.11, 11.37 and 5.74 Å^3. The experimental volume per molecule of **I** is 299.35 Å^3. The chloride (**II**) is characterized by a molecular volume of 288.17 Å^3, while the molecular volume of the bromide (**III**) is 292.67 Å^3. The experimental volume differences between **I** and **III** and between **I** and **II** are, respectively, 6.68 and 11.18 Å^3; the difference in volume between **II** and **III** is 4.50 Å^3. These differences are too small to be due to the radius differences of the halide counter-anion, which means expansion of the lattices is less than expected from a simple, linear, additive model. Here we note that (see Fig. 2) the anions lie in cages formed by the cationic strings, which it helps stitch together. The same feature has been observed[5(b)] in the packing of **II** and **III**, despite the difference in space groups. Apparently the chloride fits well in the cage, which needs to expand only slightly to accommodate the larger bromide anion. This is not a trivial observation since in the current series, as well as in the series $[Co(en)_2Ox]X$, with X = Cl, Br and I, the radius of the anion plays a crucial role in the crystallization pathway. Shimura *et al.* have shown, from phase diagrams, that *cis*-dinitro[12(a)] and the oxalato chlorides and bromides crystallize as conglomerates, while the iodides can crystallize as both a conglomerate and a racemate.[12(b),(c)] In separate papers of ours,[3,13] we have shown that the reason for this behaviour is that the cations form infinite hydrogen-bonded helical strings which extend throughout the length of the crystal. Between these strings are cavities into which the anions and the waters of crystallization fit; in turn, they link the strings by hydrogen bonds. The iodide anion is apparently large enough to force the cations apart and disrupts, or otherwise modifies, the spiral formation. Furthermore, given the fact[12] that the iodide derivative crystallizes as a racemate as well as a conglomerate, it appears that this anion loses the ability to differentiate between joining homochiral strings vs joining heterochiral strings, which is probably due to (a) the formation of much weaker hydrogen bonds than the chloride and bromide anions due to its inherently lower basicity and (b) its larger radius, which mechanically disrupts the cages formed by the cationic spiral strings present in the lower halides, and the result is apathy to the form of packing of the spiral strings. (c) Finally, when forced to form an enantiomorphic lattice (as happened here) the pitch of the screw axis is changed from 2_1 to 4_1 in order to better accommodate the bulkier iodide anion.

(2) The conformation and configuration of the cation in **I** is $\Lambda(\lambda\lambda)$; e.g. given the conformational symbol Λ both en rings have been coerced into the highest energy conformation ($\lambda\lambda$) in order to form stronger intramolecular hydrogen bonds between the $—NO_2$ oxygen and the $—NH_2$ hydrogens now that in **I** there is a weaker hydrogen bonding network between cations and anions (see Figs 1 and 2). We have pointed out before[1,21-23] that for a $\Lambda(\delta\delta)$-$[cis\text{-}Co(en)_2(NO_2)_2]^+$ cation, if through torsional motion about the $Co—NO_2$ bond one $—NO_2$ orients itself at the most advantageous position for hydrogen bonding with a δ ring, it is impossible for the second $—NO_2$ ligand to achieve an equally effective hydrogen bonding with another δ ring while a proper interligand $O \cdots O$ distance (*ca* 3.1 Å) is achieved. However, if the second en ring acquires the λ conformation, a much more effective intramolecular hydrogen bonding scheme is achieved by the second $—NO_2$ ligand. This appears to be the reason for the occurrence of $\Lambda(\delta\lambda)$, $\Delta(\lambda\delta)$, $\Lambda(\lambda\lambda)$ and $\Delta(\delta\delta)$ $[cis\text{-}Co(en)_2(NO_2)_2]^+$ cations in the crystalline state. This phenomenon can best be demonstrated by comparison of the torsional angles defined by (axial nitrogen)—Co—(NO_2 nitrogen)—(NO_2 oxygen), as listed below (Table 3). For more details of these arguments, the reader is referred to the original papers.[1,21-23]

(3) The energy associated with en ring inversion has been recently measured[24] to be 24.7 ± 4.5 KJ mol^{-1} in the anion $[Fe(CN)_4(en)]^-$, implying that the intramolecular hydrogen bonds present in the cation must exceed that barrier in order to be effective. Thus, we have an appropriate value of the strength of these hydrogen bonds.

(4) Finally, we should point out that the helical nature of the strings is not the result of packing forces in crystals belonging to space groups containing such symmetry elements. We know this

is so because such strings are also found in compounds crystallizing in the space groups $P1$ and $P\bar{1}$, where no such symmetry element is found. The point will be discussed in a separate paper[25] on the structure of K[Co(edda)$(NO_2)_2$] and K[Co(edda)$(NO_2)_2$]·H_2O (edda = ethylenediamine-diacetic acid), which crystallize, respectively, in space groups $P2_12_12_1$ and $P\bar{1}$. Such helical strings are found in both; however, in the latter compound pairs of adjacent strings are of opposite helical chirality, while the anionic members of each string are homochiral.

CONCLUSIONS

We have previously[1,21-23] emphasized that in order for cations of the two series [*cis*-Co$(en)_2$$(NO_2)_2$]X to crystallize as conglomerates the counter-anions (and/or waters of crystallization) must not compete for the hydrogen bonds of the —NH_2 ligands. In the conglomerate halide series the anion is always hydrogen-bonded to the equatorial —NH_2 hydrogens and leaves the —NO_2 oxygens free to form relatively strong hydrogen bonds with axial hydrogens and with the hydrogens of adjacent cations within that string, thus increasing the rigidity of the molecule and destroying the potential two-fold axis which these cations could have if the —NO_2 ligands were properly oriented. We find the current results gratifying since the consistency in crystallization mode indicates our suggestions for the origin of conglomerate crystallization are reasonable and consistent with experimental facts obtained with a wide range of compounds of the *cis*-dinitro and oxalato series.

Supplementary material available. Compound **I**: anisotropic thermal parameters (1 page), structure factor tables (18 pages). The latter are available in PC diskette form from Ivan Bernal.

THE PHENOMENON OF CONGLOMERATE CRYSTALLIZATION—XXXIII. COUNTER-ION EFFECTS ON CRYSTALLIZATION PATHWAY OF RACEMATE SOLUTIONS—IV. THE CRYSTAL AND MOLECULAR STRUCTURE OF RACEMIC $(H_3O^+)[Co(en)_2ox]Cl_2 \cdot H_2O$ (I)

IVAN BERNAL,* JIWEN CAI† and JOZEF MYRCZEK†‡

Chemistry Department, University of Houston, Houston, TX 77024-5641, U.S.A.

(*Received* 10 *November* 1992; *accepted* 27 *January* 1993)

Abstract—$(H_3O^+)[Co(en)_2ox]Cl_2 \cdot H_2O$ (I), $CoCl_2O_6N_4C_6H_{21}$, crystallizes as a racemate in the monoclinic space group $P2_1/c$ (No. 14). Infinitely hydrogen-bonded spiral strings of homochiral $[Co(en)_2ox]^+$ cations are formed which are wrapped about the two-fold screw axis of the crystals. Adjacent spirals are held together by hydrogen bonds between the waters and chlorides and the $—NH_2$ hydrogens of the cations. Such an arrangement is also present in the conglomerate crystals of the $[Co(en)_2ox]Cl \cdot 4H_2O$ (II) and $[Co(en)_2ox]Br \cdot H_2O$ (III) derivatives; however, unlike II and III, which crystallize as conglomerates and all spiral strings are of the same helicity, in I adjacent spirals are of opposite helical chirality and related to one another by the inversion operation of the space group.

It has been known for some time[1–3] that the series $[M(en)_2ox]X$ (M = Co, Cr, Rh; X = Cl^-, Br^-) crystallize as conglomerates, whereas $[Co(en)_2ox]I$ crystallizes both as a conglomerate and as a racemate.[1(c)] In fact, this observation was used by Shimura *et al.*[1(c)] as evidence of the success of the thermodynamic formulation of the condition $S_r > 1.414S_e$ (where S_r is the solubility of the racemate and S_e that of the enantiomer), which defines what crystallization pathway will a given substance prefer—racemate or conglomerate. Relevant crystallization data on these systems are summarized below:

Compound	Space group	Ref.
$[Co(en)_2ox]Cl \cdot 4H_2O$ (III)	$P2_12_12_1$	1(c), 2
$[Co(en)_2ox]Br \cdot H_2O$ (IV)	$P2_12_12_1$	2, 3
$[Co(en)_2ox]I$ (V)	?§	1(c)
$[Cr(en)_2ox]Br$	?§	1(a), 4
$[Rh(en)_2ox]Br$	?§	4
$[Rh(en)_2ox]Cl \cdot H_2O$	?§	4

Our crystallization and structural studies of III[2] and IV[2] demonstrated that, in both compounds, homochiral cations are present in spiral strings linked by hydrogen bonds spanning from the terminal oxalato oxygens of one cation to the basal plane amines of an adjacent one, each string being an infinite polymer running along the length of the *b*-direction of the crystal.[2] Adjacent strings are also homochiral with respect to their helical sense and in III and IV are held together by halide anions which are bonded to hydrogens of an axial $—NH_2$ and to a water of crystallization, the latter being bonded to an axial $—NH_2$ hydrogen of a cation belonging to the adjacent string. This stitching to-

§ These substances were identified as forming conglomerates either from solubility measurements, by seeding experiments or by measuring the CD spectra of resulting crystalline material. No structural data were reported. See refs 1(a), 1(c) and 5 for details of the crystallization, seeding and spectroscopic experiments performed on these compounds.

gether of the strings occurs across the entire length of adjacent spirals.

At the time we published ref. 2 we suggested that anything that interfered with the orderly formation of the spiral string and/or of the stitching pattern found in **III** and **IV** would probably result in the formation of heterochiral crystals (racemates). Sometime later we were able to prepare $NH_4[Cr(en)_2ox]Cl_2 \cdot H_2O$ (**VI**)[5] and found that the ammonium cation hydrogen bonds to the terminal oxalato oxygens and, thus, disrupts the formation of the spiral strings mentioned above. It is, therefore, noteworthy that **VI** crystallizes as a racemate in the space group $P2_1/c$, as suggested earlier.[2] We have been unable to prepare the cobalt analogue to **VI**, despite repeated efforts, as discussed in our report[5] on the crystallization behaviour of **VI**. The similarity of **I** and **VI** suggested they should crystallize similarly and made it possible to, once more, test our hypothesis[2] since it was reasonable to expect that, as in **VI**, the hydronium cation would also alter drastically the hydrogen bond pattern observed in **III** and **IV**.

Finally, **I** was prepared by accident while attempting to grow crystals of $[Co(en)_2ox]Pb_2Cl_5 \cdot 2H_2O$, the analogue of $[Co(N\text{-}Me\text{-}ethylenediamine)_2ox]Pb_2Cl_5 \cdot 2H_2O$—a compound previously studied here.[6] That effort was unsuccessful, but the product obtained easily compensated for our failure to produce the lead compound we were seeking.

EXPERIMENTAL

Synthesis

Compound **I** was prepared as follows: $PbCl_2$ was slurried with distilled water, at 60°C, and concentrated HCl was added until all the solid had dissolved. A solution of $[Co(en)_2ox]Cl \cdot 4H_2O$[2,7,8] in water was stirred at 60°C with enough of the acidified lead chloride so that the Co : Pb ratio was 1 : 2. The solution was allowed to cool, filtered and set aside to crystallize (*ca* 18°C). Approximately equilateral crystals of the reddish-orange substance were formed, filtered and washed with ethanol. One was selected for single-crystal X-ray data collection.

Elemental analysis.[9] For $(H_3O^+)[Co(en)_2ox]Cl_2 \cdot H_2O$, $CoCl_2O_6N_4C_6H_{21}$: Mol. wt = 375.10. Found: C, 19.4; H, 5.6; N, 16.1. Calc.: C, 19.2; H, 5.6; N, 14.9%.

X-ray diffraction

Data for **I** were collected with an Enraf–Nonius CAD-4 diffractometer operating with a Molecular Structure Corporation TEXRAY-230 modification[10] of the SDP-Plus software package (see Table 1).[11] The crystal was centred with data in the $22° \leqslant 2\theta \leqslant 34°$ range and examination of the cell constants and Niggli matrix[12] clearly showed it to crystallize in a primitive, monoclinic lattice whose

Table 1. Summary of data collection and processing parameters for racemic $(H_3O^+)[Co(en)_2ox]Cl_2 \cdot H_2O$

Space group	$P2_1/c$

b (Å)	12.137(3)
c (Å)	17.011(3)
β (°)	100.66(4)
Cell volume (Å^3)	1400.97
Molecular formula	$CoCl_2O_6N_4C_6H_{21}$
Molecular weight (g mol^{-1})	375.10
Density (calc; $z = 4$ mol cell^{-1}) (g cm^{-3})	1.660
Radiation employed	Mo-K_α ($\lambda = 0.71073$ Å)
Absorption coefficient, μ (cm^{-1})	15.237
Transmission coefficients	0.9247–0.9995
Data collection range	$4° \leqslant 2\theta \leqslant 60°$
Scan width	$\Delta\theta = 1.00 + 0.35 \tan\theta$
Total data collected	3139
Data used in refinement	2543
$R = \Sigma\|\|F_o\| - \|F_c\|\|/\Sigma\|F_o\|$	0.0449
$Rw = [\Sigma w^2(\|F_o\| - \|F_c\|)^2/\Sigma\|F_o\|^2]^{1/2}$	0.0458
Weights used	$w = [\sigma(F_o)]^{-2}$

Laue symmetry and systematic absences belong to those of the space group $P2_1/c$ (No. 14). The intensity data set was corrected for absorption using empirical curves derived from Psi scans[10,11] of five reflections. The scattering curves were taken from Cromer and Waber's compilation.[13]

RESULTS

The contents of the asymmetric unit are shown in Fig. 1, which shows that there is a cobalt cation, a hydronium cation and a water of crystallization which is hydrogen bonded to a terminal oxalato oxygen [O(3)] and to the chloride anion [Cl(2)], which in turn is hydrogen bonded to a terminal —NH_2 hydrogen (H1). The hydronium cation is weakly hydrogen bonded to O(4), but it also blocks access to a non-bonded pair of O(4). Finally, Cl(1) is hydrogen bonded to H(8) and H(9), thus blocking some of the hydrogens needed by the terminal oxalato oxygens to form the helical strings observed in the conglomerate crystallization of **III** and **IV**.

Figure 2 is a packing diagram in which the centre of the cell is one of the inversion centres, as readily ascertained by the relationship of the chloride and waters of crystallization clustered about that point. Note also that there are strings of cations running along the *b*-axis, as expected from the space group; however, given the position of the inversion centre, the cations of adjacent strings are of opposite chirality, as is the sense of the helical chirality of adjacent spiral strings. Thus, not only does the lattice contain racemic pairs of $[Co(en)_2ox]^+$ cations, but an enantiomorphic relationship exists also between the helicities of the entire sets of adjacent strings.

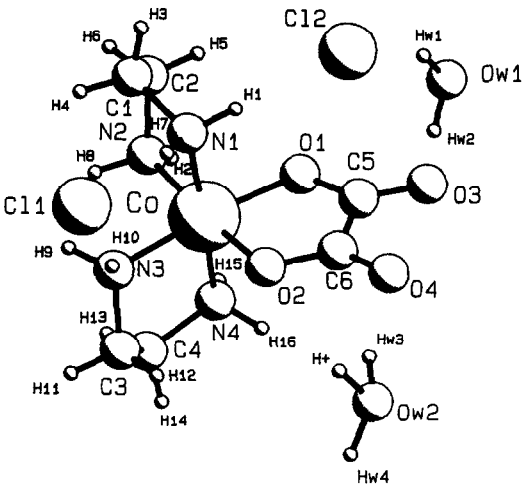

Fig. 1. A view of the contents of the asymmetric unit. Note the position of the (H_3O^+) cation, blocking access to O(4) and of the water of crystallization blocking access to O(3) of the oxalato ligand. Also note the position of the chloride anions, which effectively block access to the —NH_2 hydrogens. These hydrogen-bonded interactions effectively eliminate all chances of forming the spiral strings of cobalt cations found (see refs 2 and 5) in the series of $[Co(en)_2ox]X$ (X = Cl, Br, I) and whose formation was postulated as the origin of conglomerate crystallization.

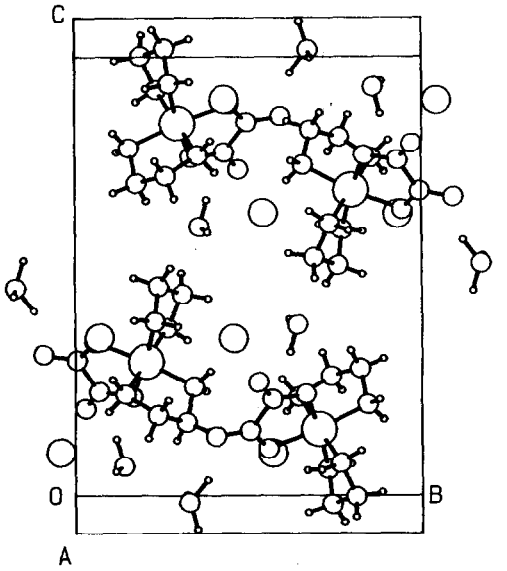

Fig. 2. A view of the unit cell contents. Here, the viewer can see the approach between cobalt cations blocked by the water, the (H_3O^+) cation and the chlorides. Note the inversion centre located at the centre of the cell. This centre relates enantiomorphic pairs of cations as well as spiral strings of opposite helicity.

Table 2(D) shows that the shortest hydrogen bond in the entire lattice is between O(4) and Hw(3) and the next shortest is between O(3) and Hw(2). Therefore, the two terminal oxalato oxygens are engaged in hydrogen bonding which preclude the formation of the spiral strings observed in the case of the chloride (**III**) and the bromide (**IV**). Such was precisely the case with the double salt $NH_4[Cr(en)_2ox]Cl_2 \cdot H_2O$ (**VI**),[5] with which compound **I** is nearly isomorphous. Given that fact, we refer the interested reader to the original paper on **VI**[5] for details of the hydrogen bonding present there.

Finally, the hydronium cation is very far from the water of crystallization (nearest contact, see Table 2(D), is 2.21 Å). Therefore, the correct formulation of this hydrated cation is H_3O^+ and not $H_5O_2^+$.

DISCUSSION

It was our good fortune to accidentally obtain **I** since it is chemically different, yet nearly iso-

Numbers in parentheses are estimated standard deviations in the least significant digits.

morphous with the ammonium salt **VI**[5] and provided us with an additional piece of the puzzle mentioned in the Introduction; namely, the ammonium cation of **VI** was bound to form hydrogen bonds with the oxalato oxygens, with the anions and with the water of crystallization. Therefore, it would be expected to alter the nature of the packing by (a) intercalating between cobalt cations and modifying or destroying the spiral strings, or by (b) upsetting the nature of the bridges between adjacent strings, or both. The same comments would apply to the hydrogen bonding scheme expected for **I** if our previous statements[5] were correct and general.

Figure 1, together with the hydrogen bonding data in Table 2(D), shows that $Cl(1)^-$ and $Cl(2)^-$ are busily enagaged in hydrogen bonds with both axial and equatorial $-NH_2$ hydrogens and that irrespective of the strength or weakness of their hydrogen bonds, they present a steric barrier to the approach of a second cobalt cation. Consequently, the onset of the formation of a spiral string is obviously hopelessly compromised. Second, on the other side of the cobalt cation, terminal oxygens [O(3) and O(4)] are hydrogen bonded to the hydronium cation and to the water of crystallization, Ow(1). Consequently, the presence of such hydrogen bonds would force additional hydrogen bonds between oxalato terminal oxygens and $-NH_2$ hydrogens to be bifurcated bonds insofar as the oxygens are concerned. Such bonds would be expected to be weaker, if they took place. Moreover, the chlorides, waters and hydronium cations are sterically demanding fragments which would effectively hinder access by another cobalt cation to the amino hydrogens. Again, the possibility of retaining the spiral string geometry observed in previous cases is seriously impaired on the both sides of cobalt cation.

These observations strengthen our previously derived conclusions as to why and how the halides of the $[Co(trien)_2(NO_2)_2]^+$, $[Co(en)_2(NO_2)_2]^+$ and $[Co(en)_2ox]^+$ cations undergo conglomerate crystallization.[2,14–17] Therefore, there appears to be consistency in our crystallization mechanistic conclusions, even when we compare members of different series of cations—a fact which is greatly satisfying.

SYNTHESIS OF WATER-SOLUBLE AND ETHER-SOLUBLE TETRA-μ-ACETATODIRUTHENIUM(II,III) COMPLEXES AND X-RAY CRYSTAL STRUCTURE OF $[Ru_2(\mu\text{-}O_2CC_6H_5)_4(C_2H_5OH)_2][Ru_2(\mu\text{-}O_2CC_6H_5)_4(HSO_4)_2]$

(*Received* 27 *October* 1992; *accepted* 26 *January* 1993)

Abstract—$[Ru_2(\mu\text{-}O_2CCH_3)_4Cl]$ reacts readily with aqueous Ag_2SO_4 (2:1 molar ratio) to give the sulphate salt $[Ru_2(\mu\text{-}O_2CCH_3)_4(H_2O)_2]_2(SO_4)$ (**1**). Addition of $NaBPh_4$ to an aqueous solution of **1** produces the ether-soluble tetraphenylborate salt $[Ru_2(\mu\text{-}O_2CCH_3)_4(H_2O)_2][BPh_4]$ (**2**). A methanolic solution of **1** reacts with $Ba(C_6H_5C{\equiv}CCO_2)_2\cdot H_2O$ to give the tetraacetatemonophenylpropynoate complex $[Ru_2(\mu\text{-}O_2CCH_3)_4(O_2CC{\equiv}CC_6H_5)]\cdot H_2O$ (**3**). The reaction of an ethanolic suspension of $[Ru_2(\mu\text{-}O_2CC_6H_5)_4Cl]$ with Ag_2SO_4 and H_2SO_4 (2:1:1 molar ratio) leads to the tetra-μ-benzoatodiruthenium(II,III) double complex salt $[Ru_2(\mu\text{-}O_2CC_6H_5)_4(C_2H_5OH)_2][Ru_2(\mu\text{-}O_2CC_6H_5)_4(HSO_4)_2]$ (**4**). Complex **4** is also obtained by reacting an ethanolic solution of **1** with an excess of benzoic acid in the presence of H_2SO_4. The X-ray crystal structure of **4** shows it to consist of $[Ru_2(\mu\text{-}O_2CC_6H_5)_4(C_2H_5OH)_2]^+$ and $[Ru_2(\mu\text{-}O_2CC_6H_5)_4(HSO_4)_2]^-$ ions, which are linked together by hydrogen bonds into an infinite polymeric chain. The Ru—Ru distances in the cation and anion are very similar [2.265(2) and 2.272(2) Å, respectively]. Spectroscopic, magnetic, conductivity and cyclic voltammetry data are given for the complexes.

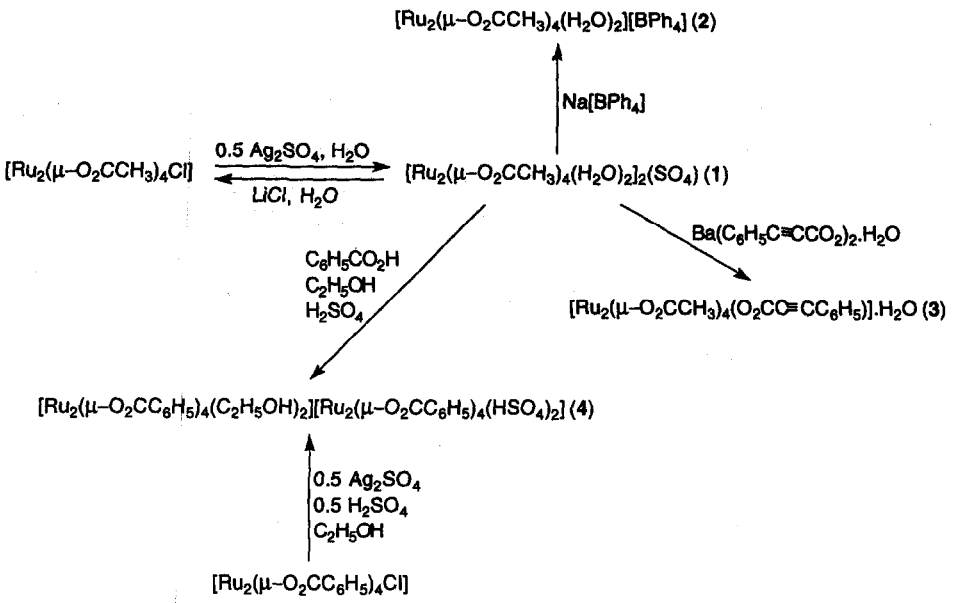
As part of our continuing interest in the synthesis and applications of bimetallic carboxylates[1] we have been seeking to develop complexes with potentially useful solubility properties. Herein, we outline the preparation and properties of water-soluble and ether-soluble tetra-μ-acetatodiruthenium(II,III) complexes. In addition, the synthesis and X-ray crystal structure of a novel tetra-μ-benzoatodiruthenium(II,III) double complex salt is given.

RESULTS AND DISCUSSION

Routes to the four new diruthenium(II,III) complexes are summarized in Scheme 1 and, in general, their spectroscopic and magnetic properties were similar to those reported for other Ru_2^{5+} carboxylates.[2–4] $[Ru_2(\mu\text{-}O_2CCH_3)_4Cl]$ dissolved readily in water containing Ag_2SO_4 (2:1 molar ratio) to give the sulphate salt $[Ru_2(\mu\text{-}O_2CCH_3)_4(H_2O)_2]_2(SO_4)$ (**1**). Complex **1** was very soluble in a wide range of solvents (see Experimental), its extreme solubility in water (it is also slightly hygroscopic) being unique among complexes of the $[Ru_2(\mu\text{-}O_2CCH_3)_4]^+$ cation. The large molar conductivity of an aqueous solution of **1** [Λ_M (H_2O) = 186 S cm^2 mol^{-1}] suggests that the complex behaves as a 2:1-type electrolyte in water.[3]

The water-solubility of **1**, together with the presence of sulphate in the complex, proved useful for synthetic purposes. For example, addition of $NaBPh_4$ to a cooled solution of **1** caused the

* Author to whom correspondence should be addressed.



Scheme 1.

immediate precipitation of the orange–brown solid $[Ru_2(\mu\text{-}O_2CCH_3)_4(H_2O)_2][BPh_4]$ (**2**). This result differs with that reported[2] for the reaction of $[Ru_2(\mu\text{-}O_2CCH_3)_4Cl]$ with $NaBPh_4$ in water, which apparently gave a partially hydrolysed product, formulated as $[Ru_2(\mu\text{-}O_2CCH_3)_3(OH)(H_2O)][BPh_4]$. Like the latter complex **2** decomposed on heating in water and it also slowly darkened in the solid state. Complex **2** was a 1 : 1-type electrolyte in methanol [Λ_M (MeOH) = 59 S cm^2 mol^{-1}].

The presence of the SO_4^{2-} ion in **1** was exploited in order to bring about precipitation reactions in the presence of barium salts, particularly in cases where the corresponding silver salts were unsuitable for reaction with $[Ru_2(\mu\text{-}O_2CR)_4Cl]$ complexes. Thus, on reacting a methanolic solution of **1** with barium phenylpropyonate, $Ba(C_6H_5C{\equiv}CCO_2)_2\cdot H_2O$, a white precipitate of $BaSO_4$ was formed and subsequent concentration of the filtrate gave $[Ru_2(\mu\text{-}O_2CCH_3)_4(O_2CC{\equiv}CC_6H_5)]\cdot H_2O$ (**3**) in high yield. Efforts to prepare **3** by reacting $[Ru_2(\mu\text{-}O_2CCH_3)_4Cl]$ with silver phenylpropynoate were unsuccessful due to the extreme insolubility of the silver salt.

Attempts to prepare a sulphate salt of the tetra-μ-benzoate cation $[Ru_2(\mu\text{-}O_2CC_6H_5)_4]^+$, by the method employed for the synthesis of the acetate **1**, were unsuccessful, presumably because of the extreme insolubility of $[Ru_2(\mu\text{-}O_2CC_6H_5)_4Cl]$ in water, and the insolubility of Ag_2SO_4 in other solvents. On refluxing $[Ru_2(\mu\text{-}O_2CC_6H_5)_4Cl]$ with Ag_2SO_4 (Ag : Cl = 1 : 1) in ethanol dissolution was minimal. However, upon the addition of an equivalent amount of H_2SO_4 to the reaction mixture the complex rapidly dissolved. After removing the AgCl precipitate crystals of $[Ru_2(\mu\text{-}O_2CC_6H_5)_4(C_2H_5OH)_2][Ru_2(\mu\text{-}O_2CC_6H_5)_4(HSO_4)_2]$ (**4**) formed in the filtrate. Thus, the overall stoichiometry of the reaction is:

$$2[Ru_2(\mu\text{-}O_2CC_6H_5)_4Cl] + Ag_2SO_4 + H_2SO_4 + 2C_2H_5OH \rightarrow [Ru_2(\mu\text{-}O_2CC_6H_5)_4(C_2H_5OH)_2][Ru_2(\mu\text{-}O_2CC_6H_5)_4(HSO_4)_2]\ (\mathbf{4}) + 2AgCl.$$

Complex **4** was also prepared by reacting an ethanolic solution of **1** with excess benzoic acid in the presence of H_2SO_4.

The X-ray crystal structure of **4** (Figs 1 and 2) showed that it was a double complex salt of the type $[Ru_2(\mu\text{-}O_2CC_6H_5)_4(C_2H_5OH)_2]^+[Ru_2(\mu\text{-}O_2CC_6H_5)_4(HSO_4)_2]^-$. Although individual cationic $[Ru_2^{5+}]^+$ and anionic $[Ru_2^{5+}]^-$ tetra-μ-carboxylato species have previously been structurally characterized (e.g. $[Ru_2(\mu\text{-}O_2CCH_3)_4(H_2O)_2]^+$ and $[Ru_2(\mu\text{-}O_2CCH_3)_4Cl_2]^-$ ions[5]), complex **4** is the first example in which both ions have formed a single crystalline salt together. However, it should be mentioned that in the course of electrochemical studies on a solution of the butyrate complex $[Ru_2(\mu\text{-}O_2CC_3H_7)_4Cl]$ (discussed below) Cotton and Pedersen[6] detected the presence of both $[Ru_2(\mu\text{-}O_2CC_3H_7)_4]^+$ and $[Ru_2(\mu\text{-}O_2CC_3H_7)_4Cl_n]^{(n-1)-}$ ions.

Figure 2 illustrates how the $[Ru_2(\mu\text{-}O_2CC_6H_5)_4$

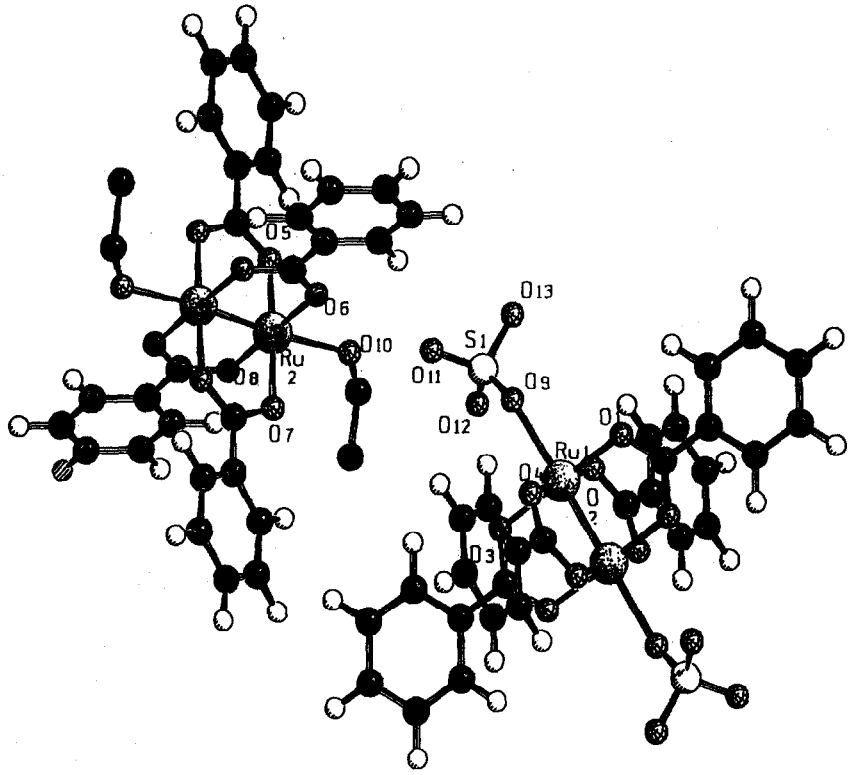


Fig. 1. The $[Ru_2(\mu\text{-}O_2CC_6H_5)_4(C_2H_5OH)_2]^+$ and $[Ru_2(\mu\text{-}O_2CC_6H_5)_4(HSO_4)_2]^-$ ions as they occur in **4**.

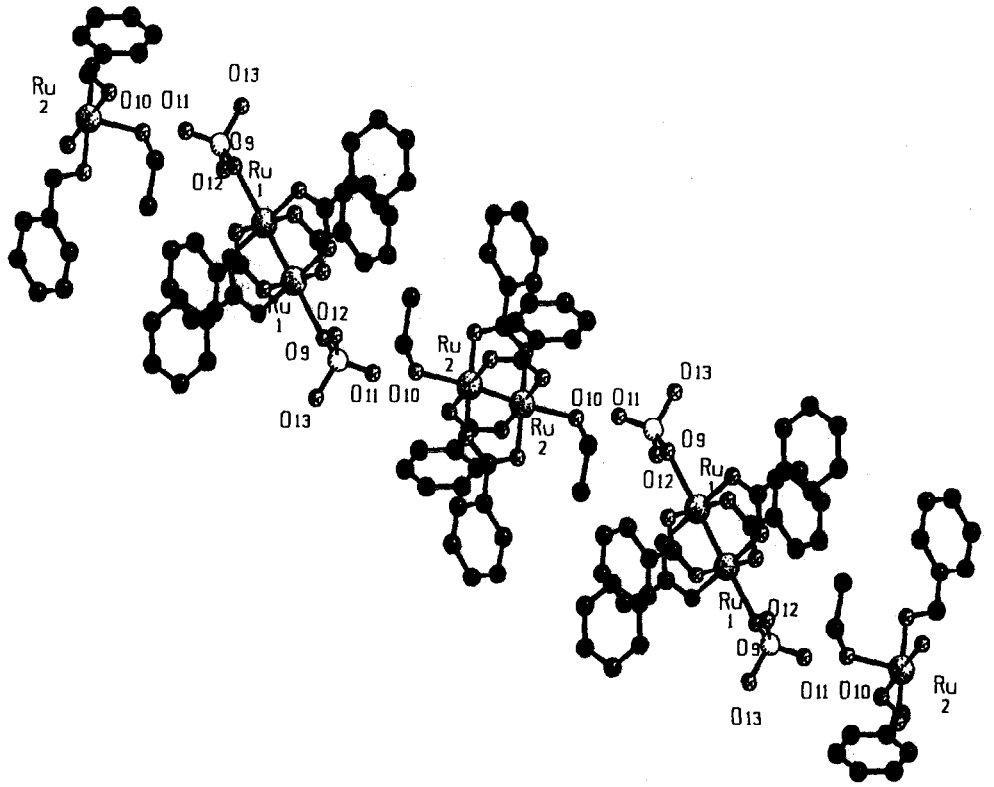

Fig. 2. Infinite chain structure of **4** in the solid state.

$(C_2H_5OH)_2]^+$ cations alternate with the $[Ru_2(\mu\text{-}O_2CC_6H_5)_4(HSO_4)_2]^-$ anions to form extended chains in the solid state. The Ru—Ru distances in the cation and anion (Table 1) are very similar [2.265(2) and 2.272(2) Å, respectively], that in the anion being very slightly longer. These metal–metal distances compare closely with the values found for other Ru_2^{5+} carboxylates[5,7,8] and in particular with the Ru—Ru distance of 2.277(1) Å in the benzoate $[Ru_2(\mu\text{-}O_2CC_6H_5)_4(O_2CC_6H_5)(HO_2CC_6H_5)]$.[9] The Ru—O (bridging benzoate) distances in **4** range from 2.00(1) to 2.014(9) Å in the cation and from 2.005(8) to 2.024(8) Å in the anion. Thus, there is no real distinction between the Ru—O(benzoate) bond lengths in the cation and the anion. The Ru—O(ethanol) bond length [2.234(9) Å] also compares closely with the Ru—O(water) distance [mean = 2.31(1) Å] found in $[Ru_2(\mu\text{-}O_2CCH_3)_4(H_2O)_2][BF_4]$.[5]

The short non-bonded distance (2.77 Å) between the ethanol oxygen O(10) and the hydrogensulphate oxygen O(11) indicates the presence of a hydrogen bond (incorporating the hydroxyl hydrogen of ethanol) between these two atoms. Thus, it appears that in the solid state the alternating anionic and cationic dimeric units are linked together by these hydrogen bonds into infinite linear arrays. This is a similar situation to that found in $[Ru_2(\mu\text{-}O_2CCH_3)_4(O_2CCH_3)_2H]$.[8,10]

The relatively low value obtained for the molar conductivity of **4** in ethanol [Λ_M (EtOH) = 52 S cm^2 mol^{-1}] suggests that the large complex anion and cation are dissociated from each other in solution, and that further dissociation of the hydrogen sulphate ligands from the complex anion $[Ru_2(\mu\text{-}O_2CC_6H_5)_4(HSO_4)_2]^-$ is minimal. This means that the anionic and cationic moieties of **4** retain their identities in solution, instead of the anion dissociating to become equivalent to the cation as follows:

$$[Ru_2(\mu\text{-}O_2CC_6H_5)_4(HSO_4)_2]^- + 2C_2H_5OH \rightarrow [Ru_2(\mu\text{-}O_2CC_6H_5)_4(C_2H_5OH)_2]^+ + 2HSO_4^-.$$

Electrochemistry

The cyclic voltammogram of $[Ru_2(\mu\text{-}O_2CCH_3)_4(H_2O)_2]_2(SO_4)$ (**1**) in aqueous Na_2SO_4 showed a single reversible wave for the Ru_5^{5+}/Ru_2^{4+} couple with $E_{1/2} = +189$ mV [vs Ag/AgCl]. The voltammogram of the tetraphenylborate salt $[Ru_2(\mu\text{-}O_2CCH_3)_4(H_2O)_2][BPh_4]$ (**2**) in methanolic $LiClO_4$ (Fig. 3) contained a reversible Ru_2^{5+}/Ru_2^{4+} couple with $E_{1/2} = +78$ mV, together with an irreversible oxidation wave ($Ea = +810$ mV) for the $[BPh_4]^-$ ion. The potential for the $[BPh_4]^-$ oxidation was close to that found for $Na[BPh_4]$ in methanol/$LiClO_4$. For a solution of the double

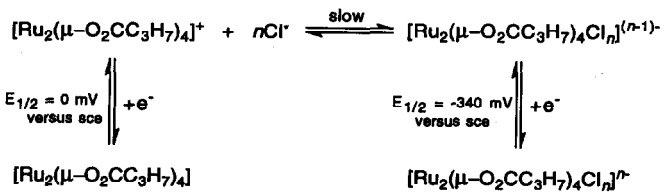
complex salt $[Ru_2(\mu\text{-}O_2CC_6H_5)_4(C_2H_5OH)_2][Ru_2(\mu\text{-}O_2CC_6H_5)_4(HSO_4)_2]$ (**4**) in ethanol/tetrabutylammonium perchlorate (TBAP) only a single, quasi-reversible Ru_2^{5+}/Ru_2^{4+} couple was detected, with $E_{1/2} = +159$ mV. This is somewhat surprising since two separate Ru_2^{5+}/Ru_2^{4+} couples might have been expected, one for the $[Ru_2(\mu\text{-}O_2CC_6H_5)_4(C_2H_5OH)_2]^+$ ion and the other for the $[Ru_2(\mu\text{-}O_2CC_6H_5)_4(HSO_4)_2]^-$ ion, the latter couple occurring at the more negative potential. This indeed is what was found in the voltammogram of $[Ru_2(\mu\text{-}O_2CC_3H_7)_4Cl]$ when the experiment was run in a CH_2Cl_2/TBAP solvent/supporting electrolyte systems.[6] In that particular case separate quasi-reversible Ru_2^{5+}/Ru_2^{4+} couples were observed for the $[Ru_2(\mu\text{-}O_2CC_3H_7)_4]^+$ cation and the $[Ru_2(\mu\text{-}O_2CC_3H_7)_4Cl_n]^{(n-1)-}$ anion, the two ions originating from the equilibrium outlined in Scheme 2. One possible explanation for the presence of only a single Ru_2^{5+}/Ru_2^{4+} couple in the voltammogram of **4** is that there may be a surface effect operating at the platinum working electrode that causes the $[Ru_2(\mu\text{-}O_2CC_6H_5)_4(HSO_4)_2]^-$ ion to dissociate to give a second $[Ru_2(\mu\text{-}O_2CC_6H_5)_4(C_2H_5OH)_2]^+$ ion and two HSO_4^- ions.

EXPERIMENTAL

Literature methods were used to prepare $[Ru_2(\mu\text{-}O_2CCH_3)_4Cl]$[11] and $[Ru_2(\mu\text{-}O_2CC_6H_5)_4Cl]$.[12] $Ba(C_6H_5C{\equiv}CCO_2)_2 \cdot H_2O$ was prepared by reacting phenylpropynoic acid with barium carbonate (2:1 molar ratio) in a mixture of methanol and water. A satisfactory microanalysis was obtained for this compound. IR spectra for the solids (as KBr discs) were recorded in the 4000–200 cm^{-1}



Scheme 2. See ref. 6.

region on a Perkin–Elmer 783 grating spectrometer and UV–vis spectra were run on a Milton Roy spectronic 3000 array. Room-temperature magnetic susceptibility measurements on the solids were made on a Johnson–Matthey magnetic susceptibility balance. Cyclic voltammograms were recorded (*ca* 20°C and under nitrogen) using an EG & G Model 264A polarographic analyser and the data were analysed using the EG & G Condecon software package. A platinum bead and a platinum wire were used as the working and counter electrodes, respectively, and potentials were recorded with respect to a silver–silver chloride (aqueous KCl) reference electrode. Sample concentrations were 8.0×10^{-3} M with respect to ruthenium and the scan rate was 50 mV s^{-1}. For complex **1** the solvent/supporting electrolyte was H_2O/Na_2SO_4 (0.1 M), against which the $[Fe(CN)_6]^{2+}/[Fe(CN)_6]^{3+}$ couple had $E_{1/2} = +329$ mV [vs Ag/AgCl]. For **2** the solvent/supporting electrolyte was $MeOH/LiClO_4$ (0.1 M), against which the ferrocene/ferrocenium(1+) couple (Fc/Fc^+) had $E_{1/2} = +497$ mV [vs Ag/AgCl]. For **3** the solvent/supporting electrolyte was EtOH/TBAP (0.1 M), against which the Fc/Fc^+ couple had $E_{1/2} = +529$ mV [vs Ag/AgCl]. Conductivity readings were taken with an AGB model 10 conductivity meter and elemental analyses were performed by the Microanalytical Laboratory, University College Cork, Ireland.

Crystallography

Crystal data for $[Ru_2(\mu\text{-}O_2CC_6H_5)_4(C_2H_5OH)_2][Ru_2(\mu\text{-}O_2CC_6H_5)_4(HSO_4)_2]$ (**4**). Formula: $C_{30}H_{27}O_{13}Ru_2S_1$, $M_r = 829.733$; triclinic, $P-1$ (no. 2), $a = 10.530(5)$, $b = 11.667(5)$, $c = 13.883(6)$ Å, $\alpha = 80.60(3)$, $\beta = 84.20(3)$, $\gamma = 87.82(3)°$, $U = 1673(1)$ Å^3, $D_c = 1.647$ g cm^{-3}, $Z = 2$, $F(000) = 830$, $\lambda = 0.71069$, $\mu(\text{Mo-}K_\alpha) = 9.73$ cm^{-1}.

A brown crystal was mounted on an Enraf–Nonius CAD4 diffractometer. Accurate cell dimensions were established by refining the setting angles of 25 reflections ($14° < \theta < 16°$). The intensities of 4327 reflections in the range $0° < \theta < 22°$ were measured using graphite monochromated Mo-K_α radiation. These were reduced to give 3759 unique reflections (merging R of 0.0118), of which 3265 had $|F_{obs}| > 4\sigma|F_{obs}|$ and were used in the structure solution and refinement.

The structure was solved by both the Patterson and direct methods of SHELXS and refined by full-matrix least-squares. There were two half molecules in the asymmetric unit, the central ruthenium portion being the same for both, but the coordinated terminal groups being different, one C_2H_5OH and the other HSO_4^-. The non-hydrogen atoms, with the exception of two of the oxygen atoms attached to the sulphur, were refined with anisotropic temperature factors. These two oxygens were found to have high temperature factors and along with the carbons in the ethyl group were thought to be slightly disordered. The hydrogen atoms were placed geometrically and refined with common temperature factors. Due to the short contact distance a hydrogen bond was inferred[8] to exist between the ethanolic hydrogen and one of the oxygens attached to the sulphur (the hydrogen itself could not be located because of the reasons outlined above). The refinement was weighted to give a flat analysis of variance with final $R = 0.0800$ and $R_w = 0.0937$. The final difference-Fourier had highest peaks of 1.9 e Å^{-1}, which were in the areas of disorder of the sulphur oxygens and the ethyl group. SHELXS-86 and SHELX-76 were used by kind permission of G. M. Sheldrick (Universität Göttingen).

$[Ru_2(\mu\text{-}O_2CCH_3)_4(H_2O)_2]_2(SO_4)$ (**1**)

$[Ru_2(\mu\text{-}O_2CCH_3)_4Cl]$ (0.48 g, 1.0 mmol) and silver(I) sulphate (0.16 g, 0.5 mmol) were stirred in water (20 cm^3) at *ca* 40°C for 10 min. The ruthenium complex rapidly dissolved to give a deep orange solution and a white precipitate of AgCl formed. The AgCl was filtered off and the aqueous solution was then evaporated under reduced pressure to give a brown tar. The tar was redissolved by adding methanol (10 cm^3) and ethyl acetate (40 cm^3) was then added. The solution was evaporated to low volume and more ethyl acetate (30 cm^3) was added. When this solution was concentrated to low volume the product precipitated as a yellow–brown solid. The solid was filtered off, washed with dry ethyl acetate (5 cm^3) and then dried *in vacuo*. The complex was slightly hygroscopic and was very soluble in water, methanol and ethanol, slightly soluble in acetone and was insoluble in THF, dichloromethane, ethyl acetate and diethyl ether; yield: 0.36 g (69%). Found: C, 18.7; H, 3.1; S, 2.7. Calc.: C, 18.4; H, 3.1; S, 3.1%. IR: 3440 (OH), 2940 (CH), 1400, 1395 (OCO), 1115 cm^{-1} (SO_4). λ_{max} (H_2O) = 426 nm ($\varepsilon = 1414$ dm^3 mol^{-1} cm^{-1}). $\mu = 4.1$ B.M. per Ru_2.

$[Ru_2(\mu\text{-}O_2CCH_3)_4(H_2O)_2][BPh_4]$ (**2**)

$[Ru_2(\mu\text{-}O_2CCH_3)_4Cl]$ (0.48 g, 1.0 mmol) and silver(I) sulphate (0.16 g, 0.5 mmol) were stirred in water (20 cm^3) at *ca* 40°C for 10 min. The AgCl was filtered off and the solution was chilled to 0°C. An aqueous solution of sodium tetraphenylborate (0.4 g, 1.2 mmol) was added dropwise with stirring

and the orange–brown product precipitated immediately. The solid was filtered off, washed with cold water (3×2 cm^3) and then dried *in vacuo* at 30°C. The complex was *very* soluble in acetone, THF, ethanol and cold methanol (decomposes in hot methanol), soluble in dichloromethane, ethyl acetate and diethyl ether and was slightly soluble in water; yield: 0.67 g (84%). Found: C, 48.3; H, 4.6. Calc.: C, 48.4; H, 4.6%; IR: 3440 (OH), 2930 (CH), 1440, 1395 (OCO), 740, 708 cm^{-1} (BPh_4). λ_{max} (MeOH) = 426 nm (ε = 726 dm^3 mol^{-1} cm^{-1}). μ = 3.9 B.M. per Ru_2.

$[Ru_2(\mu\text{-}O_2CCH_3)_4(O_2CC{\equiv}CC_6H_5)]\cdot H_2O$ (**3**)

Complex **1** (0.12 g, 0.25 mmol) and $Ba(C_6H_5C{\equiv}CCO_2)_2\cdot H_2O$ (0.056 g, 0.125 mmol) were stirred in methanol (20 cm^3) at 20°C for 0.5 h. The fine white precipitate of $BaSO_4$ was removed by centrifugation and the reddish-brown solution was evaporated to low volume under reduced pressure (not heated above 30°C). On addition of ethyl acetate and further evaporation under reduced pressure the product appeared as an orange–brown precipitate. The solid was washed with diethyl ether and dried *in vacuo*; yield: 0.10 g (66%). Found: C, 33.9; H, 3.0. Calc.: C, 33.9; H, 3.2%; IR: 3430 (OH), 2930 (CH), 2210 (C≡C), 1440, 1440 cm^{-1} (OCO). Note: the IR spectrum of $Ba(C_6H_5C{\equiv}CCO_2)_2\cdot H_2O$ had ν(C≡C) at 2210 cm^{-1} and in phenylpropyonic acid there were ν(C≡C) bands at 2200 and 2260 cm^{-1}.

$[Ru_2(\mu\text{-}O_2CC_6H_5)_4(C_2H_5OH)_2][Ru_2(\mu\text{-}O_2CC_6H_5)_4(HSO_4)_2]$ (**4**)

Method (*a*). A suspension of $[Ru_2(\mu\text{-}O_2CC_6H_5)_4Cl]$ (0.29 g, 0.4 mmol), silver(I) sulphate (0.063 g, 0.2 mmol) and H_2SO_4 (0.98 g of a 2% weight solution in ethanol, 0.2 mmol) in ethanol (40 cm^3) was refluxed for 2 h. During this time the ruthenium complex slowly dissolved to give a bright red–brown solution. The AgCl was then filtered off and the filtrate was concentrated *in vacuo* to *ca* 5 cm^3. After standing for several days the product formed as deep red crystals. Addition of ethyl acetate to the mother liquor gave a further crop of microcrystalline product; yield: 0.26 g (78%).

Method (*b*). Complex **1** (0.42 g, 0.4 mmol), benzoic acid (2.44 g, 20 mmol) and H_2SO_4 (0.98 g of a 2% weight solution in ethanol, 0.2 mmol) were dissolved in ethanol (20 cm^3) and the mixture was stirred for 72 h. n-Hexane (20 cm^3) was then added. The solution was filtered and sat aside in a sealed tube for several months, during which time deep-red single crystals of the product formed. Found: C, 43.3; H, 3.6; S, 3.4. Calc.: C, 43.4; H, 3.3; S, 3.9%. IR: 3380, 3220 (OH), 2980 (CH), 1465, 1400 (OCO), 1175 cm^{-1} (SO_4). λ_{max} (EtOH) = 437 nm (ε = 1310 dm^3 mol^{-1} cm^{-1}). μ = 3.8 B.M. per Ru_2.

Acknowledgement—We thank Johnson Matthey plc for the loan of ruthenium trichloride.

SYNTHESIS AND CHARACTERIZATION OF TRIAZENIDO AND AMIDINO COMPLEXES OF NICKEL AND PALLADIUM

MONTSERRAT GÓMEZ, GUILLERMO MULLER* and JOAQUIM SALES*

Departament de Química Inorgànica, Universitat de Barcelona,
Diagonal 647, 08028 Barcelona, Spain

(*Received* 4 *December* 1992; *accepted* 26 *January* 1993)

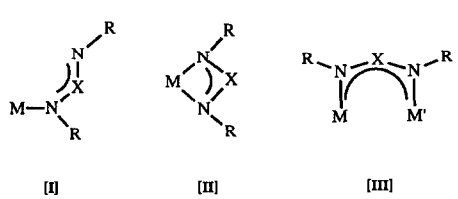
Abstract—The reaction of LiPhN(Y)NPh [Y = N or C(Ph)] with $[MX_2L_2]$ (M = Ni, Pd; X = Cl, Br, mesityl; L = PEt_3, **a**; PMe_2Ph, **b**; PPh_3, **c**; PBz_3, **d**) has been studied. With Y = N complexes containing the triazenido ligand as monodentate $[MX(NNN)L_2]$ (Ni: **1**; Pd: **2**), bidentate [MX(NNN)L] (Ni: **3**; Pd: **4**) and bridging two metal atoms $[M(\mu\text{-}NNN)L_2]_2(ClO_4)_2$ (Ni: **5**; Pd: **6**) have been prepared. However, when Y = C(Ph) only palladium derivatives having the bridging amidino group $[Pd(\mu\text{-}NCN)XL]_2$ (**7**) can be obtained. These complexes have been characterized by IR, ^1H and ^{31}P NMR spectroscopy.

The study of transition metal complexes containing triazenido $[RN{=}N{-}NR]^-$ and amidino $[RN{-}CR'{=}NR]^-$ ligands has increased greatly in the past few years, because of their potential reactivity in relation to their several modes of coordination.[1] As these ligands are isoelectronic with allyl and carboxylato anions, their complexes can be very active catalytic species. Moreover, the nitrogen ligands are more versatile, since the ligating properties are influenced by both the electronic and steric properties of the substituents R and R'.

These anionic ligands (NNN and NCN) may act as a monodentate group [I], a bidentate ligand [II] or a bridging ligand between two metal centres [III], and examples of the three types have been reported[1] (see Fig. 1).

Several complexes, mainly of nickel, palladium and platinum, with monodentate bonded triazenido ligands have been reported.[2] However, no complex derivative of the monodentate amidino group has been prepared so far, although some formamidine complexes are known.[2a,b,f,g] Several years ago[3] it was proposed that 1,3-diphenyltriazenido complexes of nickel contained bidentate triazenido ligands, but subsequent structural studies confirmed that the ligand actually bridges the metal centres.[4] Some complexes containing bridging amidino groups are known.[5] The chelating bonding mode is less common for these ligands than the bridging mode. One factor may be the steric bulk of the ligand, but another is clearly the strain involved in the formation of a four-membered ring, which is clear from the acute NYN angle of *ca* 102–105°. Some structurally characterized complexes with chelating triazenido ligands of several transition metals[5a,6] have been reported, but, to the best of our knowledge no derivative of nickel, palladium or platinum has been obtained. As for amidino derivatives, complexes of these metals are known.[7] Recently, triazenido complexes of indium (chelate ones) and rhodium (bridging ones) have been reported.[8]

We describe here the preparation and structural characterization of a series of nickel and palladium complexes containing 1,3-diphenyltriazenido or 1,3-diphenylbenzamidino ligands. These ligands



(X = CR, N; R = aril, alquil)

Fig. 1.

* Authors to whom correspondence should be addressed.

adopt the three modes of coordination indicated. The catalytic activity of these complexes has also been tested in the oligomerization of ethylene, but in no case have satisfactory results been obtained.

RESULTS AND DISCUSSION

The general method used in the preparation of the new complexes is the reaction of the lithium salts LiNYN (NYN = PhNNNPh or PhNC(Ph)NPh], which were prepared *in situ* from the neutral ligand, with metallic complexes. Depending on the experimental conditions and the metallic complex used, compounds containing the triazenido ligand in the different modes of coordination are obtained (see Scheme 1).

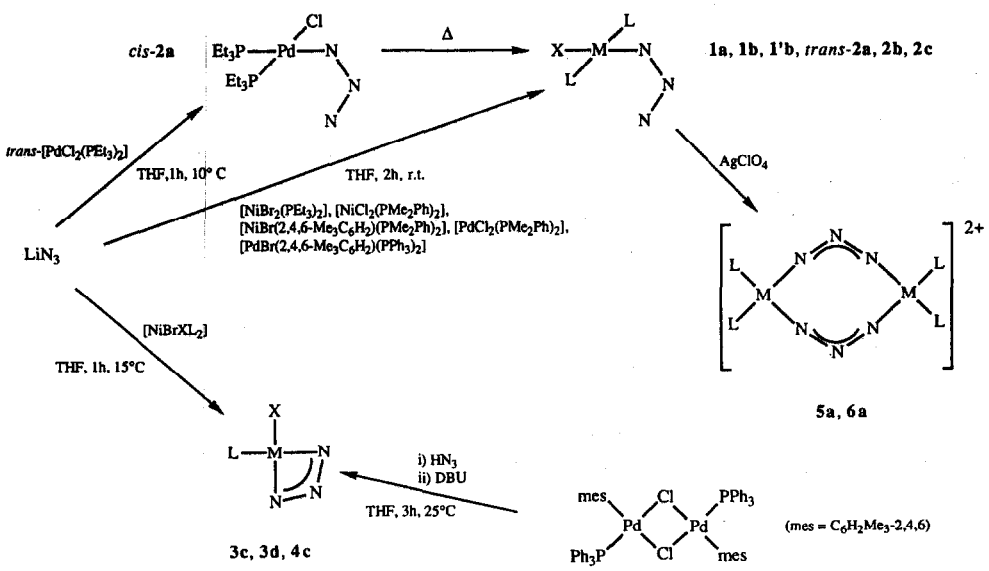
With $[NiX_2L_2]$ (X = Cl, Br) compounds of type [I], containing the monodentate ligand [NiX(NNN)L_2] (**1a**, X = Br, L = PEt_3; **1b**, X = Cl, L = PMe_2Ph), are obtained, but when L = PPh_3 only decomposition is observed. With the organonickel complex [NiX(mesityl)L_2] the compound with the monodentate triazenido [Ni(mesityl)(NNN)$(PMe_2Ph)_2$] (**1'b**) and the complexes with the bidentate ligand [Ni(mesityl)(NNN)L], when L = PPh_3 or PBz_3 (**3c,d**), are obtained. With the bulkier phosphines the M—P bond is weaker and the easy decoordination of the phosphine ligand favours the action of the triazenido ligand as a chelate.

The palladium derivatives of type [I] [PdCl(NNN)L_2] (**2a,b**) and [Pd(mesityl)(NNN)$(PPh_3)_2$] (**2c**) are easily obtained from $[PdCl_2L_2]$ and [PdBr(mesityl)$(PPh_3)_2$], respectively. It should be noted, that the addition of LiNNN, at 10°C, to *trans*-$[PdCl_2(PEt_3)_2]$ gives *cis*-[PdCl(NNN)$(PEt_3)_2$] (*cis*-**2a**); when the solution is heated to 40°C the more stable *trans*-[PdCl(NNN)$(PEt_3)_2$] (*trans*-**2a**) is formed. This *trans*-isomer can be obtained directly by reaction of the neutral ligand and the metallic complex, at 50°C, in the presence of a base such as NaOH.

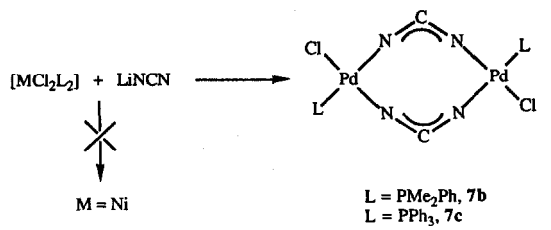
The bidentate [II] complex of palladium, [Pd(mesityl)(NNN)(PPh_3)] (**4c**), has been obtained from the dinuclear compound [Pd(μ-Cl)(mesityl)$(PPh_3)]_2$ by reaction with the neutral ligand (HNNN) and subsequent addition of DBU [1,8-diazabicyclo[5.4.0]undec-7-en(1,5-5)]. Initially the HNNN ligand breaks the chlorine-bridge, giving [PdCl(mesityl)(HNNN)(PPh_3)]. The subsequent addition of DBU deprotonates the ligand and as it is very bulky, does not prevent the coordination of the second nitrogen atom and the triazenido ligand can act as a chelate ligand. The complex **4c** can also be obtained by abstraction of one PPh_3 ligand by silver salts from **2c**. Therefore, it is possible to prepare complexes of type [I] or [II] with the same phosphine ligand.

Complexes of type [III], M = Ni (**5a**) or Pd (**6a**), are obtained by reaction of $[MX(NNN)(PEt_3)_2]$ with silver salts.

With the 1,3-diphenylbenzamidino ligand different results have been obtained and only complexes of palladium of type [III] (**7**), with the ligand as a bridge, have been isolated (see Scheme 2). These compounds, [Pd(μ-NCN)ClL]$_2$ (**7b,c**; L = PMe_2



Scheme 1.



Scheme 2.

Ph, PPh_3), are prepared by the general method from $[PdCl_2L_2]$ and LiNCN. Their insolubility suggests that they are not mononuclear species. The EM–FAB studies show that they are dimeric complexes and that the amidino ligand acts as a bridge between the two palladium atoms. Table 1 shows the fragments detected for the compound **7b**.

The reaction of LiNCN with the nickel complexes $[NiX_2L_2]$, [NiX(mesityl)L_2] or [Ni(mesityl)L_2]$^+$ does not give any isolable complex. The addition of the neutral ligand PhNC(Ph)NPh(H) on nickel(0) complexes, such as $[Ni(cod)_2]$, does not give any complex either. Probably, the amidino group is not able to replace the cod ligand.

It has been reported[9] that complexes of type [I] insert CO, CN^-, etc. giving five-membered metallocycles. However, in our case the action of CO in a solution (at room temperature and 1 atm.) on $[NiCl(NNN)(PMe_2Ph)_2]$ produces only the substitution of one molecule of phosphine, as can be observed by ^{31}P NMR spectroscopy. After concentration of the solution the starting nickel complex was recovered.

Table 1. Mass fragments (FAB) obtained for $[Pd(\mu\text{-NCN})Cl(PMe_2Ph)]_2$ (**7b**)

Ion	*m/z*
$[Pd_2(NCN)_2Cl(PMe_2Ph)_2]^+$	1067
$[Pd_2(NCN)_2(PMe_2Ph)_2]^+$	1030
$[Pd_2(NCN)_2Cl(PMe_2Ph)]^+$	930
$[Pd_2(NCN)(Cl)_2(PMe_2Ph)_2]^+$	831
$[Pd_2(NCN)_2Cl]^+$	795
$[Pd(NCN)(PMe_2Ph)]^+$	788
$[Pd_2(NCN)_2]^+$	757
$[Pd(NCN)_2]^+$	650
$[Pd_2(NCN)(PMe_2Ph)]^+$	623
$[Pd(NCN)Cl(PMe_2Ph)]^+$	552
$[Pd(NCN)(PMe_2Ph)]^+$	516
$[Pd_2(NCN)]^+$	485
$PhNCPh^+$	182
PMe_2Ph^+	138
Pd^+	106

The catalytic activities of the monodentate and bidentate complexes have been tested in the oligomerization of ethylene at 40 bar and 95°C in toluene. The organometallic compounds containing the mesityl group (**1'b**, **2c**, **3c**, **3d** and **4c**) were used solely as precursors, because the insertion of ethylene and subsequent β-elimination produces the hydrido complex that is the catalytic active species. With the other complexes $AlEt_3$ was added ($M/AlEt_3$: 1/2) in order to promote the formation of the hydrido complex, but oligomers were not detected in any case.

These results and those obtained from the analogous nickel and palladium compounds of bis(diphenylphosphino)methanide ($Ph_2PCHPPh_2$ = PCP) and bis(diphenylphosphino)amide (Ph_2PNPPh_2 = PNP) ligands[10] show that the formation of four-membered metallocycle complexes of type [II] depends on the lability of the M–phosphine bond. The nickel compounds and/or the largest phosphines make it easier for the ligand to act as a chelate. On the other hand, the ligands containing one central carbon atom (PCP and NCN) do not stabilize the nickel derivatives, although these derivatives can be obtained when the central atom is nitrogen (PNP and NNN).

Characterization

The new compounds obtained are air-stable solids, but in solution they decompose slowly, even under nitrogen.

Table 2 shows the ^1H and ^{31}P NMR data and Table 3 shows the most significant IR bands. The main stretching bands arising from the triazenido ligand have been classified into three groups. Bands at *ca* 1300–1260 and 1600–1580 cm^{-1} are indicative of the ligand acting as a chelate;[3a,3b,11] in compounds **3** and **4** a very strong band at 1250–1260 cm^{-1} is observed. In compounds **5** and **6** the strong band at 1350–1375 cm^{-1} indicates that the ligand acts as a bridge between the two metal atoms.[12] When the ligand acts as a monodentate ligand the number and intensity of the bands increase. The most significant absorptions are observed at 1190–1210, 1250–1280, 1300–1350 and 1580–1600 cm^{-1}. In contrast, the bands due to the amidino ligands (**7b, c**) do not allow unambiguous deduction of the mode of coordination of the ligand. By comparison with the IR spectrum of *trans*-$[PtCl(NCN)(PPh_3)_2]$ [1370(vs), 1470(vs), 1520(vs) and 1620(s) cm^{-1}] the monodentate coordination can be ruled out. Data obtained from other benzamidino complexes[8] suggest a bidentate form of bonding, but it is not possible to differentiate between chelating and bridging modes. As indicated above the mass spectra con-

firmed that the ligand bridges the two palladium atoms.

EXPERIMENTAL

IR spectra were recorded as KBr pellets on a Perkin–Elmer 1330 spectrophotometer over the range 4000–200 cm^{-1}. $^{31}P\{^1H\}$ NMR spectra were recorded on a Bruker FT-80 SY spectrophotometer at 32.4 MHz with 85% H_3PO_4 as an external standard. ^1H spectra were recorded on a Varian XL-200 or a Varian XL-500 instrument with $SiMe_4$ as an internal standard. Positive chemical shifts indicate shifts to lower fields relative to the standard. Chemical analyses (carbon, hydrogen and nitrogen) were performed at the Institut de Química Biorgànica de Barcelona (C.S.I.C.). FAB (fast atom bombardment) mass spectra were obtained with a HP CG/Ms 5988A instrument.

Materials and syntheses

N,N'-diphenylbenzamidine[13] and diazoaminobenzene[14] were prepared by published methods. The following complexes were prepared by the methods reported: [MX_2L_2] (M = Ni; X = Cl, Br; L = PEt_3, PMe_2Ph, PPh_3, PBz_3;[15] M = Pd; X = Cl; L = PEt_3, PMe_2Ph, PPh_3[16]) and [$MXR(PPh_3)_2$] (M = Ni, R = mesityl;[17] M = Pd, R = mesityl[18]). All new compounds were prepared in a dry nitrogen atmosphere using conventional Schlenk techniques. The solvents used were dried and freshly distilled under nitrogen. Lithiotriazenido, Li^+NNN^-,[11] and lithiobenzamido, Li^+NCN^-,[19] were prepared by reaction of the nitrogenated ligand with Bu^nLi in THF at −15°C for 1 h. These solutions were used immediately after preparation.

Preparation of [MX(NNN)L_2] (M = Ni, Pd; X = Cl, Br, mesityl; L = PEt_3, PMe_2Ph, PPh_3) (**1a,b**; **1'b**; **2a, b, c**)

Li^+NNN^- (1 mmol, 0.20 g of diazoaminobenzene in 10 cm^3 of THF was treated with 0.63 cm^3 of Bu^nLi—*ca* 1.6 M—at −15°C for 1 h) was added to [MX_2L_2] (1 mmol; 0.45 g for [$NiBr_2$(PEt_3)$_2$]; 0.40 g for [$NiCl_2$(PMe_2Ph)$_2$]; 0.53 g for [NiBr(mesityl)(PMe_2Ph)$_2$]; 0.41 g for [$PdCl_2$(PEt_3)$_2$]; 0.45 g for [$PdCl_2$(PMe_2Ph)$_2$]; 0.85 g for [PdBr(mesityl)(PPh_3)$_2$]) in THF (25 cm^3) at −25°C. The mixture was slowly warmed and after 1 h at room temperature (for [PdBr(mesityl)(PPh_3)$_2$] 2 h at room temperature) the orange solid was filtered off and recrystallized from CH_2Cl_2/hexane. Yields: 0.25 g (55%) for [NiBr(NNN)

M.p.s (decomposition): 130, 163, 95, 142, 110 and 95°C, respectively.

Preparation of [M(mesityl)(NNN)L] (M = Ni, Pd)

[Ni(mesityl)(NNN)L] (**3c, d**). Li^+NNN^- (1 mmol) was added to [NiBr(mesityl)L_2] (1 mmol; 0.74 g for [NiBr(mesityl)(PPh_3)$_2$]; 0.86 g for [NiBr(mesityl)(PBz_3)$_2$]) in THF (20 cm^3) at −25°C. The mixture was warmed to −5°C for 1 h and the solvent then removed under reduced pressure. After adding hexane (20 cm^3) an orange solid was obtained, which was recrystallized from toluene/hexane. Yields: 0.41 g (55%) for [Ni(mesityl)(NNN)(PPh_3)] (**3c**); 0.31 g (45%) for [Ni(mesityl)(NNN)(PBz_3)] (**3d**). Found: C, 73.8; H, 5.9; N, 6.3. Calc. for $C_{39}H_{36}N_3PNi$ (**3c**): C, 73.6; H, 5.7; N, 6.6%. Found: C, 74.1; H, 6.1; N, 6.0. Calc. for $C_{42}H_{42}N_3PNi$ (**3d**): C, 74.4; H, 6.2; N, 6.2%. M.p.s (decomposition): 135 and 100°C, respectively.

[Pd(mesityl)(NNN)(PPh_3)] (**4c**).

From [Pd(μ-Cl)(mesityl)(PPh_3)]$_2$. [Pd(μ-Cl)(mesityl)(PPh_3)]$_2$ (1.05 g, 1 mmol) and diazoaminobenzene (0.40 g, 2 mmol) in THF (30 cm^3) were warmed to 50°C for 2 h. The mixture was cooled to room temperature and DBU (0.3 cm^3) (*ca* d = 1.022) was added. The solution was warmed to 50°C for 2 h. The solvent was removed at room temperature under reduced pressure and an orange solid was obtained after the addition of ethanol (20 cm^3). This was filtered off and recrystallized from THF/ethanol. Yield: 0.53 g (50%) (**4c**). Found: C, 68.4; H, 5.3; N, 6.0. Calc. for $C_{39}H_{36}N_3PPd$ (**4c**): C, 68.5; H, 5.3; N, 6.1%. M.p. (decomposition): 105°C.

From [Pd(mesityl)(NNN)(PPh_3)$_2$]. [Pd(mesityl)(NNN)(PPh_3)$_2$] (0.95 g, 1 mmol) in toluene (20 cm^3) was treated with $AgClO_4 \cdot H_2O$ (0.21 g, 1 mmol) at room temperature for 45 min. The mixture was filtered off and the solvent was removed under reduced pressure. The yellow solid obtained (**4c**)

was recrystallized from toluene/hexane. Yield: 0.67 g (70%).

Preparation of $[M(\mu\text{-NNN})(PEt_3)_2]_2(ClO_4)_2$ (M = Ni, Pd) (**5a**, **6a**)

$[MX(NNN)(PEt_3)_2]$ (1 mmol; 0.52 g for $[NiBr(NNN)(PEt_3)_2]$; 0.57 g for $[PdCl(NNN)(PEt_3)_2]$) in THF (40 cm^3) was treated with $AgClO_4 \cdot H_2O$ (0.21 g, 1 mmol) at 0°C for 30 min. The mixture was warmed at room temperature for 30 min more and the solution was then filtered off with celite in order to separate the AgCl formed. The solvent was removed under reduced pressure and the residue was treated with toluene (20 cm^3), giving a yellow precipitate after cooling. Yield: 0.21 g (40%) for (**5a**); 0.31 g (55%) for (**6a**). Found: C, 48.2; H, 6.5; N, 6.9. Calc. for $C_{36}H_{25}ClN_3OPNi$ (**5a**): C, 48.8; H, 6.8; N, 7.1%. Found: C, 45.0; H, 3.8; N, 6.1. Calc. for $C_{36}H_{25}ClN_3OPPd$ (**6a**): C, 45.2; H, 3.9; N, 6.5%. M.p.s (decomposition): 120 and 155°C, respectively.

Preparation of $[Pd(\mu\text{-NCN})ClL]_2$ (L = PMe_2Ph, PPh_3; **7b**, **7c**)

Li^+NCN^- (1 mmol, 0.27 g of N,N′-diphenylbenzamidine in 10 cm^3 of THF was treated with 0.63 cm^3 of Bu^nLi—*ca* 1.6 M—at −15°C for 1.5 h) was added to $[PdCl_2L_2]$ (1 mmol, 0.45 g for L = PMe_2Ph; 0.70 g for L = PPh_3) in THF (25 cm^3) at −30°C. The mixture was warmed to room temperature for 16 h. The solvent was removed under reduced pressure and a red oil was formed, which when treated with hexane gave a very insoluble red solid. The solid was filtered off and washed with THF and ether. Yields: 0.38 g (70%) for $[Pd(\mu\text{-NCN})Cl(PMe_2Ph)]_2$ (**7b**); 0.51 g (75%) for $[Pd(\mu\text{-NCN})Cl(PPh_3)]_2$ (**7c**). Found: C, 59.0; H, 4.9; N, 4.9. Calc. for $C_{54}H_{52}Cl_2N_4P_2Pd_2$ (**7b**): C, 58.8; H, 4.8; N, 5.0%. Found: C, 66.0; H, 4.6; N, 3.9. Calc. for $C_{74}H_{60}Cl_2N_4P_2Pd_2$ (**7c**): C, 68.5; H, 4.5; N, 4.1%. M.p.s (decomposition): 120 and 130°C, respectively.

Preparation of trans-$[PtCl(NCN)(PPh_3)_2]$

N,N′-Diphenylbenzamidine (0.27 g, 1 mmol) in THF (10 cm^3) was treated with Bu^nLi (0.63 cm^3) (*ca* 1.6 M) at −15°C for 1.5 h. To this solution was added *cis*-$PtCl_2(PPh_3)_2$ (0.79 g, 1 mmol) in THF (25 cm^3) at −25°C. The mixture was warmed to room temperature for 2 h. The solvent was removed under reduced pressure. The yellow solid obtained was recrystallized from toluene/hexane. Yield: 0.60 g (58%). Found: C, 64.1; H, 4.2; N, 2.5. Calc. for $C_{55}H_{45}ClN_2P_2Pd$: C, 64.3; H, 4.4; N, 2.7%. M.p. (decomposition): 105°C. $^{31}P\{^1H\}$ NMR: δ = 10.8 ppm; $^1J(^{31}P—^{195}Pt)$ = 1733 Hz.

THE CRYSTAL AND MOLECULAR STRUCTURES OF A TETRAAZAANNULENE AND ITS COBALT(II) COMPLEX AND THE PREPARATION OF THE CHROMIUM(II) COMPLEX

JAYNE JUBB, LESLIE F. LARKWORTHY,* DAVID C. POVEY and GALLIENUS W. SMITH

Department of Chemistry, University of Surrey, Guildford GU2 5XH, U.K.

(*Received* 4 *November* 1992; *accepted* 26 *January* 1993)

Abstract—The structures of the diphenyl-substituted tetraazaannulene dptaaH_2 (**1**) and its cobalt(II) complex Co(dptaa) (**2**) have been determined by X-ray diffraction. The cobalt(II) complex is low spin (μ_{eff} = 2.5 B.M. at 291 K) and except for the two phenyl groups, which are rotated by 30.0° and 38.1° with respect to the CoN_4 plane, the molecule shows less deviation from planarity than the ligand. The chromium(II) complex is low spin (μ_{eff} = 2.85 at 292 K and 2.72 B.M. at 87 K) and could not be obtained as a crystalline form. It is believed to be structurally analogous to Co(dptaa) and not to the related chromium(II) complex Cr_2(tmtaa)$_4$ of the tetramethyldibenzotetraaza[14]annulene tmtaaH_2, which is essentially diamagnetic and contains an unsupported quadruple bond.

The cobalt(II) complexes of the unsaturated diphenyl-substituted tetraazaannulene (**1**), 6,13-diphenyl-1,8-dihydro-2,3:9,10-dibenzo-1,4,8,11-tetraazacyclotetradecane-4,6,11,13-tetraene (dptaa H_2) and various substituted derivatives have been considered as catalysts for the reduction of oxygen in fuel cells.[1] Since absorption of the complex on the cathode surface may be important in the electrochemical process the structures of the cobalt complex and the ligand have been determined by single-crystal X-ray methods. The preparation of the chromium(II) complex Cr(dptaa) is also reported. There are brief accounts of the complexes Ni(dptaa),[2–4] Pd(dptaa),[3] Cu(dptaa)[2] and Zn(dptaa)[2] and of some iron(III) complexes[4] of uncertain structure; when doped with I_2 the nickel and palladium complexes exhibit metallic conductivity.

EXPERIMENTAL

Unless otherwise stated below, the reagents and solvents were obtained from commercial sources and used as received.

Preparation of the ligand

The ligand (**1**) was prepared[1] by heating a solution of α-phenyl-β-dimethylaminoacraldehyde[5] (9.0 g, 0.05 mol) and *o*-phenylenediamine (5.55 g, 0.05 mol) in dimethylformamide (100 cm^3) under reflux for 5 h. The brown needle-like crystals which separated were filtered off, washed with methanol and dried *in vacuo* at 50°C (4.4 g, 40%). Found: C, 81.1; H, 5.7; N, 12.85. Calc. for $C_{30}H_{24}N_4$: C, 81.8; H, 5.5; N, 12.7%. δ_H ($CDCl_3$): 14.27 (2H, t, NH), 8.07, 8.05 (4H, d, CH), 7.40, 7.38 (10H, C_6H_5), 6.97–7.18 (8H, C_6H_4).

Preparation of the cobalt(II) *complex*

The cobalt(II) complex was prepared[1] by a template synthesis. *o*-Phenylenediamine (1.08 g, 0.01 mol) and cobalt(II) acetate tetrahydrate (1.24 g, 0.005 mol) were heated in dimethylformamide (40 cm^3) at 120°C for 4 h, α-phenyl-β-dimethylaminoacraldehyde (1.75 g, 0.01 mol) was added and the mixture was heated under reflux for 3 h. It was then cooled in ice, the dark purple solid filtered off, washed with methanol, air-dried and dried at 50°C *in vacuo*. The complex was recrystallized from dimethylformamide (1.28 g, 52%). Found: C, 71.7; H, 4.6; N, 11.3. Calc. for $C_{30}H_{22}N_4Co$: C, 72.4; H, 4.6; N, 11.3%. The complex was also prepared by heating the ligand (0.39 g, 0.0009 mol) and $Co(O_2CCH_3)_2 \cdot 4H_2O$ (0.23 g, 0.0009 mol) in dimethylformamide (4 cm^3) under reflux for 5 h. The product was treated as above (0.39 g, 87%). Found: C, 72.0; H, 4.5; N, 11.2%. μ_{eff} = 2.5 B.M. at 291 K (Gouy method).

Preparation of the chromium(II) *complex*

The ligand dptaaH_2 (1.05 g, 2.38 mmol) was suspended in freshly distilled THF (50 cm^3) under nitrogen and the solution was cooled to −40°C. Butyllithium in hexane (1.90 cm^3, 4.80 mmol) was added to the vigorously stirred solution to give a solution of Li_2dptaa (2.38 mmol). Anhydrous chromium(II) acetate (0.41 g, 2.38 mmol), prepared by heating the monohydrate[6] at 120°C under oil-pump vacuum, was added to the cold solution. After being stirred and allowed to warm to room temperature overnight the purple–black mixture was taken to dryness, the residue extracted with hot anhydrous toluene (200 cm^3) and filtered while hot to remove the lithium acetate. The filtrate was left at −18°C overnight and the purple–black powder which separated was filtered off and dried *in vacuo*. It could not be recrystallized from dimethylformamide or toluene and the microanalysis indicates the inclusion of toluene. Found: C, 76.3; H, 6.1; N, 8.6. Calc. for $C_{30}H_{22}CrN_4 \cdot 1.5C_7H_8$: C, 77.4; H, 5.5; N, 8.9%. IR spectrum (Nujol): 1580 m, br, 1560 m, br, 1540 sh, 1535 sh, 1310 s, vbr, 1275 s, 1205 m, 1175 m, 1020 w, br, 970 w, 830 w, 765 sh, 760 m, 740 s, 730 m, sh, 700 m, 670 w. Magnetic measurements: μ_{eff} = 2.85 (292 K), μ_{eff} = 2.72 B.M. (87 K), θ = 11° (Gouy method).

X-ray crystal structure analysis of 6,13-*diphenyl*-1,8-*dihydro*-2,3:9,10-*dibenzo*-1,4,8,11-*tetraaza*-*cyclotetradecane*-4,6,11,13-*tetraene*

The crystals prepared as described were suitable for X-ray study and one of approximate dimensions 0.3 × 0.2 × 0.1 mm was mounted on a glass fibre.

Crystal data. $C_{30}H_{24}N_4$, M = 440.55, monoclinic, space group $P2_1/c$, a = 11.402(5), b = 7.088(4), c = 27.069(8) Å, β = 90.24(03)°, U = 2187.6(2.0) Å^3, Z = 4, D_c = 1.338 g cm^{-3}, $F(000)$ = 928, graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å), μ(Mo-K_α) = 0.75 cm^{-1}.

Data collection. Cell parameters were determined on an Enraf–Nonius CAD4 diffractometer by measurement of 25 accurately centred reflections. Intensity data were collected by the ω–2θ scan mode in the range $1° \leqslant \theta \leqslant 22°$ ($0 \leqslant h \leqslant 12$, $0 \leqslant k \leqslant 7$, $-28 \leqslant l \leqslant 28$); in all 3015 reflections were measured, which after the usual Lp correction and removal of systematic absences yielded 873 having $I \geqslant 3\sigma(I)$.

Structure solution and refinement. In the absence of the cobalt complex ready to hand the structure determination of the ligand itself proved difficult. Many runs of the direct methods program MULTAN[7] were made using a wide range of options available. In all cases the top 5–8 solutions were of the chicken-wire type, consistent with a multi-ring system, but in solutions lower down the list there appeared structures containing 29–31 atoms having the desired molecular arrangement. However, none of these trial structures proved correct, R being in the range 0.32–0.38, and none produced the missing atoms in the subsequent electron density maps. The molecule has many atoms lying close to the 0 0 22 and 10 0 $\bar{10}$ planes and it was obvious that the signs of these two reflections were not being correctly determined by MULTAN. Attempts with the four possible sign combinations gave similar results as before. It was surmised that

the orientation of the molecule was probably correct, but that it required small shifts in the *ac* plane to obtain the correct position. The program DIRDIF,[8] which has a translation function as part of its routines, is ideally suited for such a problem. One of the trial structures initially input into DIRDIF did not produce sensible shifts, but a second trial structure produced shifts of 0.029 in the x direction and -0.022 in the z direction. The resulting E map also produced the missing three atoms of the trial structure. Thereafter, refinement went smoothly. Isotropic full-matrix least-squares refinement converged at $R = 0.078$ with hydrogen atoms in fixed calculated positions ($d_H = 1.0$ Å). Anisotropic refinement of non-hydrogen atoms converged at $R = 0.058$ and from a difference map the two hydrogens attached to N(1) and N(3) were found. Including these two hydrogen atoms in the refinement the final value of R was 0.055, $R_w = 0.061$ and $S = 1.045$, using the weighting scheme[9] $w^{-1} = [\sigma(F^2)+0.07F]$. The largest peak in the difference map was 0.2 electrons.

Selected bond distances and angles are given in Table 1, and the atom numbering scheme in Fig. 1. All calculations were performed with the Enraf–Nonius Structure Determination Package.[10]

X-ray crystal structure analysis of Co(dptaa). A crystal of the cobalt(II) complex, obtained by slow recrystallization from hot dimethylformamide and of approximate dimensions $0.4 \times 0.3 \times 0.1$ mm, was mounted on a glass fibre for the crystal structure determination.

Crystal data. $C_{30}H_{22}N_4Co$, $M = 497.5$, monoclinic, space group $P2_1/c$, $a = 11.470(2)$, $b = 7.061(4)$, $c = 27.045(5)$ Å, $\beta = 90.82(01)°$, $U = 2190.1(2.0)$ Å^3, $Z = 4$, $D_c = 1.509$ g cm^{-3}, $F(000) = 1028$, graphite-monochromated Mo-K_α radiation ($\lambda = 0.71073$ Å), μ(Mo-K_α) = 8.08 cm^{-1}.

Data collection. The unit cell was obtained by the measurement of 25 accurately centred reflections on an Enraf–Nonius CAD4 diffractometer. Intensity data were collected by the ω–2θ scan mode in the range $1 \leqslant \theta \leqslant 24°$ ($0 \leqslant h \leqslant 13$, $0 \leqslant k \leqslant 8$, $-31 \leqslant l \leqslant 31$); in all 3954 reflections were measured, which after the usual Lp correction and removal of systematic absences yielded 2256 reflections having $I \geqslant 3\sigma(I)$.

Structure solution and refinement. Comparison of this unit cell with that of the ligand shows that the two compounds are isostructural and that atomic coordinates would be closely similar. The coordinates of the cobalt atom were derived from the Patterson synthesis and were found to be very close to the centre of gravity of the ligand molecule. An F_o map based upon the phases of the cobalt atom revealed all but one atom of the ligand and a subsequent structure–factor/Fourier cycle produced the complete molecule. With the inclusion of hydrogen atoms in fixed calculated positions ($d_H = 1.0$ Å) R fell to 0.061. An absorption correction by the program DIFABS[11] gave maximum and minimum absorption corrections of 0.86 and 1.11. Anisotropic full-matrix refinement, initially with cobalt alone and then with all non-hydrogen atoms, con-

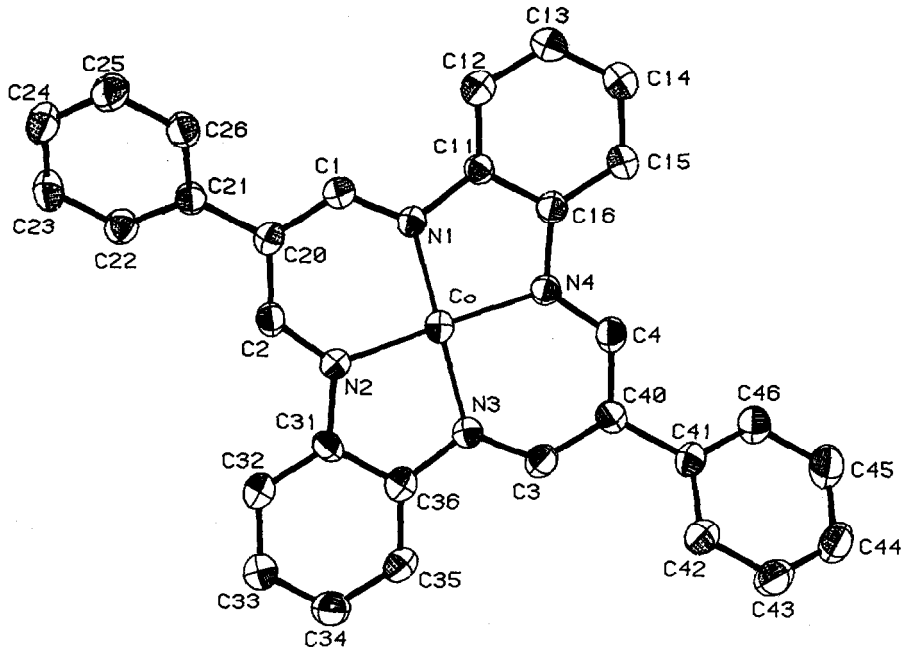

Fig. 2. Atom-numbering scheme for the cobalt(II) complex Co(dptaa).

verged at $R = 0.042$, $R_w = 0.053$ and $S = 1.073$, using the weighting scheme $w^{-1} = [\sigma(F^2) + (0.025F)^2 + 2.5]$. The largest peak in the difference map was 0.3 electrons. Selected bond distances and angles are listed in Table 1 and the atom numbering scheme is given in Fig. 2.

RESULTS AND DISCUSSION

Structure of the ligand

The nitrogen atoms of the ligand are almost coplanar. Atoms N(2) and N(4) (Fig. 1) are, respectively, 0.020 and 0.019 Å above the mean plane of the four nitrogen atoms, whereas N(1) and N(3) lie the same distances below the plane. The two benzenoid rings are at angles of 3.2° [C(11)—C(16)] and 2.3° [C(31)—C(36)] to the plane of the four nitrogen atoms and the phenyl groups are rotated at 29.8° [C(21)—C(22)/C(2)—C(20)] and 38.2° [C(41)—C(42)/C(4)—C(40)] in opposite directions. The sideways representation of the molecule in Fig. 3 shows clearly the planarity of all except the phenyl groups. Hydrogen bonds bridge adjacent nitrogen atoms of the 2-phenyl-1,3-propanediimine bridges.

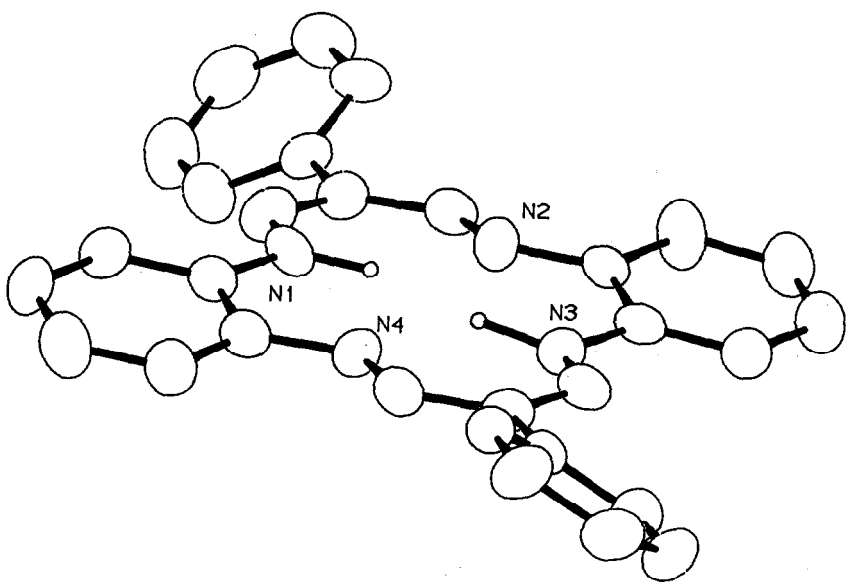

Fig. 3. Sideways representation of the ligand molecule.

The hydrogen bond distances are 1.906 [H(1n)—N(2)] and 1.843 Å [H(3n)—N(4)]. These are much shorter than the non-bonded N—H distances across the *o*-phenylenediamine rings, which average 2.343 Å. There is considerable delocalization in the 2-phenyl-1,3-propenediimine bridges since the C—C distances are similar [1.383(9)–1.406(9) Å] and close to those in benzene (1.39 Å). The N—H bonds lie in the N_4 plane so each nitrogen atom can be considered sp^2-hybridized with a *p*-orbital freed for delocalization. Also, the C—N bonds in the bridges (mean 1.324 Å) are much shorter than the C—N bonds to benzo groups (mean 1.407 Å), which might be considered closer to single C—N bonds. The diagonally opposed nitrogen atoms have separations of 3.852 [N(1)—N(3)] and 3.800 Å [N(2)—N(4)]. Thus, the nitrogen-to-centre distance of the neutral ligand is approximately 1.913 Å. The cavity is, therefore, slightly larger than that of the related neutral ligand tmtaaH_2 (1.902 Å). Consequently, it is not surprising that a cobalt(II) complex can be prepared easily.

Structure of the cobalt(II) *complex*

The structure of the cobalt(II) complex (Figs 2 and 4) is very similar to that of the free ligand, except that the nitrogen atoms in the complex are exactly planar and the cobalt is at the centre equidistant from the four donor atoms (mean Co—N = 1.865 Å). Thus, the nitrogen lone pairs are positioned directly in the plane. As expected for a planar N_4 coordination sphere the cobalt(II) is low spin (μ_{eff} = 2.5 B.M. at 291 K). The radius of low-spin cobalt(II) is estimated to be 0.63 Å[12] so that the macrocycle cavity can clearly accommodate the metal ion without strain in the ligand; in fact, corresponding bond distances in the 14-membered macrocycle are more nearly equal in the complex than in the free ligand, and except for the phenyl groups the molecule is nearly planar and shows less deviation from planarity than the (neutral) uncomplexed ligand. The phenyl groups are rotated with respect to the macrocycle plane (30.0° and 38.1°) as in the free ligand.

Chromium(II) *complex*

The chromium(II) complex is low spin. The magnetic moment is 2.85 B.M. at room temperature, close to the spin-only value for the t_{2g}^4 configuration of 2.83 B.M. The magnetic moment decreases only slightly to 2.72 B.M. at 87 K. The chromium(II) complex Cr_2(tmtaa)$_4$ of the analogous tetraazannulene ligand is dinuclear,[13] with an unsupported metal–metal bond and is only weakly paramagnetic (μ_{eff} = 0.49 B.M.). It is difficult to know whether this weak paramagnetism is due to traces of paramagnetic impurity, temperature-independent paramagnetism, slight population of the triplet state or a combination of all three effects, but the magnetic behaviour is clearly different from that of Cr(dptaa). This suggests that Cr(dptaa) has a planar structure more analogous to that of Co(dptaa).

The radius of low-spin chromium(II) is estimated to be 0.75 Å.[12] This is 0.1 Å greater than the value for low-spin cobalt(II) and since the nitrogen-to-centre distance in the ligand is 1.913 Å and the Co—N distance in the planar Co(dptaa) is 1.86 Å, it is likely that the Cr^{2+} can be accommodated in the ligand cavity without great distortion to give a planar complex (except for the twist of the phenyl substituents).

STRUCTURAL AND ANTITUMOUR STUDIES OF METAL COMPLEXES WITH THIOSEMICARBAZONES OF β-DIKETOESTERS

S. JAYASREE and K. K. ARAVINDAKSHAN*

Department of Chemistry, University of Calicut, Kerala 673 635, India

(*Received* 1 *September* 1992; *accepted* 26 *January* 1993)

Abstract—The reactions of thiosemicarbazones of methyl- and ethylacetoacetates ($MatH_2$ and $EatH_2$, respectively) with the acetates of manganese(II), cobalt(II), nickel(II), copper(II), zinc(II) and cadmium(II) gave solid complexes, which were characterized by various physicochemical methods such as microanalyses, magnetic measurements and ESR, UV–vis, IR and NMR spectral studies. They were found to be of the following general formulae: $[M(LH)_2]$, where M = Mn^{II}, Co^{II}, Ni^{II} or Cd^{II} and LH = monoanions, MatH or EatH; [Cu(L)] and $[Zn(L)(H_2O)]$, where L = dianions, Mat or Eat. The thiosemicarbazones and their cobalt(II) and copper(II) complexes were screened for their possible antitumour activity.

In continuation of our work on biologically important transition metal complexes[1] of thiosemicarbazones derived from β-diketones, we herein report the complexes with methyl- and ethylacetoacetate thiosemicarbazones. Apart from one report[2] on the complexes of certain metal chlorides with $EatH_2$, no systematic investigations have been reported on the donor properties of thiosemicarbazones of β-diketoesters and hence it was considered worthwhile and interesting to investigate the reactions of $MatH_2$ and $EatH_2$ towards various transition metal acetates so as to isolate and characterize the solid complexes formed. The inhibitory activity of these compounds against tumour cells were also studied.

EXPERIMENTAL

Materials

Methyl- and ethylacetoacetates and the metal acetates were bought from BDH. The solvents were of reagent grade and were purified before use by the standard methods.[3] The chemicals used for the antitumour screening tests were of E. Merck's reagent grade. Minimum Essential Medium (MEM) and trypsin were purchased from Hi-Media Laboratories Pvt. Ltd, Bombay. Ehrlich ascites and Chinese Hamster Ovary (CHO) tumour cells were obtained from Tata Memorial Hospital, Bombay, and the National Faculty for Cell and Tissue Culture, Pune, respectively. Swiss Albino mice were bought from C.M.C. Vellore.

Synthetic procedures

(a) *Preparation of ligands.* β-Diketoester (1.17–1.36 g, 0.01 mol) and thiosemicarbazide (0.90 g, 0.01 mol) were mixed in EtOH (25 cm^3) and refluxed on a steam bath for 1 h. Partial evaporation of the solvent yielded the crystalline compound, which was suction filtered, washed with EtOH and dried under reduced pressure over P_4O_{10} [Figs 1(a) and (b)].

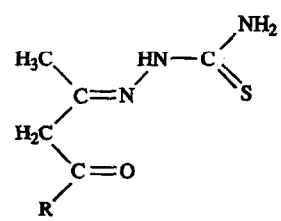

Fig. 1. (a) Where R = OCH_3($MatH_2$) and (b) where R = OC_2H_5($EatH_2$).

*Author to whom correspondence should be addressed.

(b) *Preparation of complexes.* The complexes were prepared by refluxing methanolic solutions of the ligands (0.005 mol in 15 cm^3) and metal acetates (0.005 mol in 20 cm^3) for 2 to 3 h. The solid complexes which separated out on keeping the reaction mixtures overnight were filtered off, washed with methanol and dried under reduced pressure over P_4O_{10}.

Analyses and physical measurements

Metals present in the complexes were estimated as per the standard procedure of Vogel.[3] Microanalyses were performed using a Heraues CHN-O rapid analyser. Magnetic measurements were performed at room temperature using a Gouy type magnetic balance with $Hg[Co(NCS)_4]$ as the calibrant. ESR spectra of the copper(II) complexes were recorded on a Varian E-109 EPR spectrophotometer using DPPH as the internal standard. Electronic spectra of the complexes in the solid state were recorded on a Hitachi 3200 UV–vis spectrophotometer. The IR spectra in the range 4000–200 cm^{-1} were recorded using KBr discs on a Perkin–Elmer 580 IR spectrophotometer. NMR spectra of the ligands and the zinc(II) complexes were recorded on a Bruker ACF 200 MHz NMR spectrometer.

(a) In vitro *cytotoxicity*. The *in vitro* cytotoxicity was performed using Ehrlich ascites tumour cells. The drugs were incubated with 1×10^5 cells at 37°C for 3 h. After incubation the percentage of dead cells was determined by the trypan blue exclusion method.[4]

(b) *Effect on cultured cells.* CHO cells were grown in culture flasks with MEM (10 cm^3) containing 10% heat inactivated serum and some antibiotics. Drugs were added in different concentrations and incubated for 7 days at 37°C. After the incubation period the medium was removed, trypsinized and the number of cells counted using a haemocytometer.

(c) In vivo *experiment.* The tumour cells were transplanted in the peritoneal cavity of 12 female Swiss Albino mice (two groups of six each) so that they may develop ascites tumour. After 24 h 100 μg of the lyposomally encapsulated drug was administered intraperitoneally to one group and continued for 5 alternate days and the survival of the animals was watched. The other group was kept as a control. The percentage increase in life span (ILS) was determined using the formula $(T-C)$ 100/C, where T is the average number of days survived by the test animals and C is the number of days survived by the control animals.

RESULTS AND DISCUSSION

The data obtained from chemical analyses and physicochemical measurements can be correlated so as to explain the properties, structure and geometries of the ligands and the complexes. All the complexes are coloured. They are air and light stable non-hygroscopic amorphous powders and they decompose above 200°C. They are sparingly soluble in common organic solvents, but are appreciably soluble in DMSO. The microanalytical data of the complexes correspond to $[M(LH)_2]$, where M = Mn^{II}, Co^{II}, Ni^{II} or Cd^{II} and LH = monoanions, MatH or EatH, [Cu(L)] and $[Zn(L)(H_2O)]$, where L = dianions, Mat or Eat (Table 1).

Magnetic susceptibility measurements

The room-temperature magnetic moment value of $[Mn(EatH)_2]$ is 5.88 B.M., which suggests octahedral geometry for the manganese(II) complex.[5] $[Co(MatH)_2]$ and $[Co(EatH)_2]$ exhibit μ_{eff} values of 4.98 and 4.86 B.M., respectively, which suggest octahedral coordination around the cobalt(II) ions. The two nickel(II) chelates had magnetic moments of 3.17 and 3.29 B.M., respectively, which are as expected for a nickel(II) complex with octahedral geometry. The copper(II) complexes of $MatH_2$ and $EatH_2$ exhibit magnetic moments of 1.58 and 1.24 B.M., respectively. These values are significantly lower than expected for copper(II) complexes and may be due to some exchange interactions between the neighbouring molecules, as the dibasic tridentate ligand forces the molecule to dimerize or polymerize.

ESR spectra

The ESR spectra of the copper(II) chelates of $MatH_2$ and $EatH_2$ in polycrystalline samples at room temperature and liquid nitrogen temperature show broad intense signals with isotropic g values of 2.12 and 2.13, respectively. These values indicate considerable covalent character of the metal–ligand bonds in the complexes.[6]

Electronic spectra

The manganese(II) complex with a high-spin d^5 state registers no characteristic bands in the visible region. However, in the present complex the two broad bands at 29,500 and 24,200 cm^{-1} are typical charge-transfer transitions, as expected for an octahedral manganese(II) complex[7] (Table 2).

For an octahedral cobalt(II) complex the visible spectrum will be dominated by the highest energy

transition, $^4T_{1g}(F) \rightarrow {}^4T_{2g}(P)$. The next possible transition, $^4T_{1g}(F) \rightarrow {}^4T_{1g}(P)$, which is also spin-allowed, occurs in the near-IR region. The third transition, $^4T_{1g}(F) \rightarrow {}^4A_{2g}(F)$ is a two-electron transition and, therefore, is much weaker than the other two transitions. In the spectra of the present cobalt(II) complexes only the first two bands are present in the expected regions, whereas the third

$[Cd(EatH)_2]$	1695	745	1545	—	

one is absent. Similar situations occur in the electronic spectra of several octahedral cobalt(II) complexes.[7]

[Ni(MatH)$_2$] and [Ni(EatH)$_2$] register bands in the regions 22,880–24,390, 19,283–18,200 and 10,240 cm^{-1}. These may arise from $^3A_{2g} \rightarrow {}^3T_{1g}$(P), $^3A_{2g} \rightarrow {}^3T_{1g}$(F) and $^3A_{2g} \rightarrow {}^3T_{2g}$(F) transitions, respectively, of a six-coordinate octahedral nickel(II) ion.[8]

The bands observed around 19,200 cm^{-1} for the copper(II) chelates may be assigned to the transition $^2B_{1g} \rightarrow {}^2B_{2g}$, typical of square-planar geometry.[8]

IR spectra

The IR spectra of the ligands exhibit bands due to NH vibrations at 3400, 3340, 3200 and 3120 cm^{-1}. Out of these, the first two bands are attributed to the asymmetric stretching modes and the other two are assigned to the symmetric NH of the terminal NH_2 and NH groups.[9] The lower frequency bands suffer a series of changes in the spectra of the complexes. In the spectra of the chelates there are fewer bands in this region and they are found to be broad in nature. This may be due to the participation of the hydrazine nitrogen of the system N—NH—C=S in chelate formation (Table 2).

The absence of bands in the region 2600–2450 cm^{-1} in the spectra of the ligands indicate that there are no S—H groups in these free ligands in the solid state.[10]

The bands of strong intensities in the spectra of the ligands around 1750–1720 cm^{-1} may be attributed to the carbonyl stretching vibration of the ester group.[2] In the spectra of complexes of manganese(II), cobalt(II), nickel(II) and cadmium(II) this band has undergone a shift to a lower frequency region, i.e. 1700–1690 cm^{-1}, which demonstrates the involvement of the carbonyl group in coordination. However, in the spectra of the copper(II) and zinc(II) complexes this ester carbonyl frequency band is absent and a new band is observed around 1000 cm^{-1}, which may be attributed to the enolization and subseqeunt coordination through the deprotonated oxygen atom of the system CH_2—C=O.

The strong bands at 1600–1580 cm^{-1} in the spectra of the ligands are assigned to ν(C=N). In the spectra of all the complexes a shift, by *ca* 30–40 cm^{-1}, for this band indicates the coordination of azomethine nitrogen to the metal ions.

The band of medium intensity at 1070 cm^{-1} in the spectra of all the ligands may be assigned to the (C=S) stretch. In the spectra of the complexes this band disappears and a new band simultaneously appears in the 750–700 cm^{-1} region. All these observations may be attributed to the enolization of C=S and subsequent coordination through the thiolate (S$^-$).[11,12]

The broad bands of medium intensities due to ν(O—H) around 3550 cm^{-1} in the spectra of the zinc(II) complexes indicate the presence of water molecules. In addition, a band of strong intensity at 940–890 cm^{-1} suggests that these water molecules are coordinated.

Further evidence for the nature of the metal–ligand bonding is given by the ν(M—S), ν(M—N) and ν(M—O) bands observed in the spectra of the complexes at 300–270, 390–360 and 450–430 cm^{-1}, respectively.[2]

NMR spectra

The ^{1}H NMR spectra of $MatH_2$ and $EatH_2$ in DMSO-d_6 register signals at 2.13–2.01 and 3.39–3.32 ppm due to CH_3 and CH_2 protons, respectively. The ethoxy group (O—CH_2—CH_3) proton signals of $EatH_2$ are observed as a triplet at 1.31 ppm due to CH_3 and as a quartet at 4.24 ppm due to O—CH_2. The —OCH_3 signal of $MatH_2$ is observed around 3.89 ppm. The NH proton signals are observed at 6.68–6.58 ppm and the broad signal in the range 8.87–8.68 ppm may be attributed to the NH_2 group.

In the spectra of the zinc(II) chelates the CH_2

Table 3. Cytotoxic action of compounds on Ehrlich ascites tumour cells

[Cu(Eat)]	48	93	95	100	100

Table 4. Effect of [Cu(Eat)] in Ehrlich ascites tumour-bearing animals

Compound	Tumour model	Dose and mode of therapy	No. of mice survived after (days) 10	15	20	25	30	% ILS
[Cu(Eat)]	Ehrlich ascites	20 mg kg^{-1} b.wt Intraperitoneally	6	6	6	3	1	61.18
Control			6	6	0	0	0	—

proton signals are not present and new signals are observed at 4.39–4.87 ppm, due to the CH proton. This may be due to the enolization of the CH_2—C=O group to CH=C—OH during coordination. The NH proton signals are also not observed in the spectra of the zinc(II) complexes. This may be as a consequence of enolization of N—NH—C=S to N—N=C—SH. The other main characteristic features in the spectra of the ligands are retained in those of the complexes.

Antitumour studies

Of all the compounds tested *in vitro* (Table 3) $MatH_2$ alone was found to be the least active or effective, while others produced $\geqslant 50\%$ cell death. The more active compounds, namely $EatH_2$ and [Cu(Eat)], were then placed in culture medium. A concentration of 1 $\mu g\ cm^{-3}$ of [Cu(Eat)] produced 100% growth inhibition of CHO cells (Fig. 2), whereas the same concentration of $EatH_2$ produced only 73%. Thus, from the preliminary studies it was found that chelates are more active than their respective free ligands, which is consistent with earlier observations.[13] Further, *in vivo* studies were conducted with [Cu(Eat)], administration of which could considerably delay the onset of tumour development and increase the life-span of the treated animals to 61.18% (Table 4).

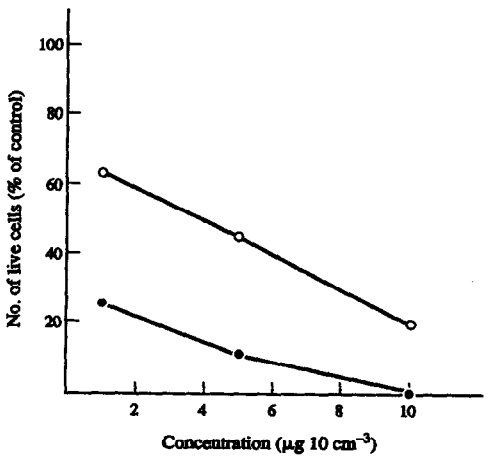

Fig. 2. Effect of ($EatH_2$) and [Cu(Eat)] on tissue cultured cells (CHO): O——O ($EatH_2$); ●——● [Cu(Eat)].

From all these observations it is inferred that [Cu(Eat)] possesses appreciable tumour reducing action. Even though remarkable progress in understanding the antitumour activities of related compounds has been made by biological methods, the chemistry behind them still remains rather obscure. It has been suggested that similar compounds interfere with the incorporation of thymine in DNA and also interact with cellular thiols,[14–16] diminishing their concentration. Metal coordination increases the lipophilicity, which may be a contributing factor to the enhanced activity of the metal chelates. However, it requires more detailed investigation to ascertain their actual mode of action.

Acknowledgement—We wish to thank Dr N. Thankarajan, Head, Department of Chemistry, for facilities, Dr Ramadas Kuttan, Research Director, and Dr Girija Kuttan, Amala Cancer Research Centre, for their help in the antitumour screening tests.

(*Received* 2 *December* 1992; *accepted* 8 *January* 1993)

Abstract—Attempts to prepare 1 : 1 complexes, L*CdX, where L* = hydridotris(3,5-dimethylpyrazolyl)borate and X = Cl, I, met with limited success. Thus, with X = Cl, CdL^*_2 was a usual product, although the reactions were not always clean. An L*CdI compound was prepared. By contrast, reactions of KL* with $HgCl_2$ gave L*HgCl cleanly. The reactions of $[(Ph_3P)_2CdCl_2]$ or [(di-2-pyridylamine)$CdCl_2$] with KL* gave "L*Cd(OH)·H_2O" in alcoholic media, whereas [(1,2-phenylenediamine)CdI_2] on reaction with KL* in CH_2Cl_2 gave CdL^*_2. KL* removed 18-crown-6 from [(18-crown-6)$CdCl_2$] as [(18-crown-6)K]L*. PhHgCl reacted with KL* in THF to give a product of stoichiometry "PhHgL*·0.5KCl". Variable-temperature ^1H and ^{199}Hg NMR studies in $CDCl_3$ gave data consistent with the equilibrium

$$PhHg^+ + L^{*-} \rightleftharpoons PhHgL^*$$

with low temperatures favouring the covalent form. Other NMR data are presented and discussed. The crystal structure of CdL^*_2 is reported, but severe disorder, with the molecule taking up two orientations about a $\bar{3}$ axis, reduced the accuracy of the structure determination. The environment around cadmium is essentially octahedral with a slight trigonal distortion in one molecule (**A**), but not in the other (**B**). The Cd—N distances [2.36(1) in **A**, 2.43(2) Å in **B**] are in good agreement with those found in analogous cadmium complexes.

Since the first report of their use in 1966[1] the pyrazolylborates, $[R_nB(pz)_{4-n}]^-$ (R = H, alkyl or aryl; pz = pyrazolyl),[2,3] and related ligands[3] have established themselves as an important weapon in the armory of the coordination chemist. The hydridotris(pyrazolyl)borate $[HB(pz)_3]^-$[2] in particular is of great interest and the parent ligand readily gives uncharged bis-ligand complexes with bipositive metal ions, e.g. $[ZnL_2]$ and $[CdL_2]$.[4] Modified ligands carrying substituents on the 3- and 5- (or solely 3-) carbon atoms of the pyrazolyl ring are now well known, e.g. [HB(3,5-dimethylpyrazolyl)borate](L*);[3] other examples include the presence of more sterically demanding substituents in the 3-position,[3] e.g. Ph and Bu^t.[5,6] The 3-tertiarybutyl and 3-phenyl derivatives have recently been shown to give monomeric zinc complexes, "L^1ZnX", where X = NO_3, NCS, NCO, N_3[5] or groups such as SEt.[6] The large pendant-like substituents in the 3-position of the ring are considered to form a hydrophobic cage around the metal. Also,

† Author to whom correspondence should be addressed.

in a similar fashion the sterically demanding ligands have been used to prepare important organomagnesium derivatives of the type LMgR where L is the substituted pyrazolylborate and R an organic moiety.[7,8]

Compounds of stoichiometry "LMER" (L = anionic ligand; M = Zn, Cd, Hg; E = Se, Te; R = organic group) may be of interest as semi-conductor precursors in MOCVD experiments and the hydridotris(pyrazolyl)borates are an attractive choice of L for preliminary studies. This paper reports observations made during efforts to obtain monomeric cadmium complexes of the type L*CdX(ligand)$_2$, where L* is hydridotris(3,5-dimethylpyrazolyl)borate and ligand is a nitrogen, oxygen or phosphorus donor. The desired compounds were not in fact formed but some new results were obtained and these are briefly communicated.

EXPERIMENTAL AND RESULTS

Syntheses

Bis[hydrido(3,5 - dimethylpyrazolyl)borate]cadmium(II). A solution of K[HB(3,5-Me$_2$pz)] (0.34 g, 1 mmol) in water (15 cm^3) was added dropwise to a stirred solution of $CdCl_2$ (0.19 g, 1 mmol) in water (20 cm^3). The mixture was stirred for 1 h at room temperature and filtered. The white solid was recrystallized from carbon tetrachloride and dried *in vacuo*; m.p. 350°C (dec.). Found: C, 49.5; H, 6.1; N, 22.9. Calc. for $C_{30}H_{44}B_2CdN_{12}$: C, 50.9; H, 6.2; N, 23.8%.

If the above preparation is performed using $Cd(ClO_4)_2$ in water an impure product was obtained. Contamination of the bis complex with the species L*Cd(OH) (see below) occurred (IR, analysis). Also, the use of ethanol rather than water as the solvent for $CdCl_2$ gave a less pure product. Found: C, 48.6; H, 6.0; N, 22.1%. In this case ^{1}H and ^{13}C NMR showed contamination with a small quantity of another species, but microscopic examination of the material showed that the bulk of the crystals were CdL*$_2$ [L* = hydridotris-(3,5-dimethylpyrazolyl)borate], which could readily be hand separated. Similar problems were found when the corresponding zinc(II) complex was prepared by reaction of KL* (1 mmol) in ethanol (10 cm^3) with $ZnCl_2$ (1 mmol) in ethanol (10 cm^3). The white product obtained after the mixture was stirred for $\frac{1}{2}$ h gave a poor analysis. Found: C, 51.4; H, 6.4; N, 23.8. Calc. for $C_{30}H_{44}B_2N_{12}Zn$: C, 54.6; H, 6.7; N, 25.5%. In this case also crystals of pure ZnL*$_2$ could be hand picked (X-ray crystallography, see below).

Reactions of KL* *with cadmium chloride complexes.* The following complexes were prepared from $CdCl_2$ and the appropriate ligand: (a) [(Et_2N, $CH_2CH_2 \cdot NEt_2$)$CdCl_2$]. Found: C, 33.8; H, 6.90; N, 7.9. Calc. for $C_{10}H_{24}CdCl_2N_2$: C, 33.8; H, 6.7; N, 7.87%. (b) [$(Ph_3P)_2CdCl_2$]. Found: C, 60.7; H, 4.1. Calc. for $C_{36}H_{30}CdCl_2P_2$: C, 61.1; H, 4.3%. (c) [(18-crown-6)$CdCl_2$]. Found: C, 66.2; H, 6.9. Calc. for $C_{12}H_{24}CdCl_2O_6$: C, 66.7; H, 6.7%.

Both [$(Et_2NCH_2CH_2NEt_2)CdCl_2$] and [$(Ph_3P)_2$ $CdCl_2$] gave the same product when reacted with KL* under the following conditions. A solution of KL* (0.334 g, 1 mmol) in acetone (20 cm^3) was added dropwise to a solution of [$(Et_2NCH_2CH_2$ $NEt_2)CdCl_2$] (0.36 g, 1 mmol) in acetone (15 cm^3). The mixture was stirred for 1 h at room temperature, after which a white solid was filtered, washed and dried *in vacuo*. The rather intractable material analysed as L*Cd(OH) $\cdot$ H_2O [m.p. = 320°C (dec), ν(OH) = 3440 cm^{-1}). Found: C, 41.1; H, 5.1; N, 18.5. Calc. for $C_{15}H_{25}BCdN_6O_2$: C, 40.5; H, 5.6; N, 18.9%. The IR spectra showed the absence of N,N'-tetraethyl-1,2-diamine and similarly the absence of Ph_3P when the phosphine complex was used in the synthesis.

Another ligand to be considered was 1,2-phenylenediamine(pd), thus [(pd)CdI_2] was prepared by the direct reaction of CdI_2 and 1,2-phenylenediamine in CH_2Cl_2. When this complex was reacted with KL* in a 1 : 1 mole ratio in CH_2Cl_2, a sample of pure CdL*$_2$ was isolated. Found: C, 50.3; H, 6.2; N, 23.5%.

Different behaviour was observed for [(18-crown-6)]$CdCl_2$, thus, a solution of KL* (0.34 g, 1 mmol) in acetone (20 cm^3) was added dropwise to a stirred solution of [(18-crown-6)$CdCl_2$] (0.45 g, 1 mmol) in acetone (25 cm^3). The mixture was stirred for 5 h at room temperature, over which period a white precipitate shown to be [(18-crown-6)K]L* separated; m.p. = 100°C. Found: C, 54.5; H, 7.1; N, 14.9. Calc. for $C_{27}H_{46}BKN_6O_6$: C, 54.0; H, 7.7; N, 14.0%.

Reaction of KL* *with cadmium*(II) *iodide and mercury*(II) *chloride.* (a) CdI_2: A solution of CdI_2 (3.35 g, 9.2 mmol) in dichloromethane (30 cm^3) was heated under reflux and to the hot solution was added dropwise a solution of KL* (1.54 g, 4.6 mmol) in dichloromethane (60 cm^3). The combined solution was heated under reflux for 1 h and the solid product was filtered hot; m.p. 280°C. Found: C, 33.6; H, 4.1; N, 15.2. Calc. for $C_{15}H_{22}CdIN_6$: C, 33.6; H, 4.1; N, 15.7%.

(b) $HgCl_2$: A solution of KL* (0.34 g, 1 mmol) in acetone (20 cm^3) was added dropwise to a stirred solution of $HgCl_2$ (0.28 g, 1 mmol) in acetone (20 cm^3). The mixture was stirred for 5 h at room tem-

perature, after which the solid product was filtered, washed with acetone and dried *in vacuo*; m.p. = 200°C (dec.). Found: C, 34.0; H, 4.2; N, 15.1. Calc. for $C_{15}H_{22}BClHgN_6$: C, 33.8; H, 4.1; N, 15.8%.

Reaction of PhHgCl *with* KL*. A solution of KL* (0.34 g, 1 mmol) in dry THF (30 cm^3) was added dropwise to a solution of PhHgCl (0.32 g, 1 mmol) in dry THF (30 cm^3). The mixture was stirred for 1.5 h at room temperature and the separated solid was filtered. The material was recrystallized from THF. Found: C, 42.2; H, 4.6; N, 13.5. Calc. for $C_{21}H_{27}BN_6Hg \cdot 0.5KCl$: C, 41.9; H, 4.5; N, 13.9%. A flame test was positive for potassium.

Physical measurements

IR spectra were measured as KBr discs or Nujol mulls with a Perkin–Elmer 1710 FTIR spectrometer. ^1H and ^{13}C NMR spectra were recorded with a Bruker AC(E) 300 MHz spectrometer. Both spectra were referenced to tetramethylsilane. ^{199}Hg spectra were also determined and referenced to aqueous $HgCl_2$. Fast atom bombardment mass spectra (FABMS) were obtained via the SERC service at Swansea.

X-ray crystallography

Cadmium complex—crystal data. $C_{30}H_{44}B_2CdN_{12}$, $M_r = 706.8$, trigonal, space group $R\bar{3}$, $a = 10.423(4)$ Å, $\alpha = 63.71(4)°$, $V = 866.3$ Å^3, $Z = 2$, $D_c = 2.710$ g cm^{-3}, $F(000) = 732$, μ(MO-K_α) = 1.339 mm^{-1}, $\lambda = 0.71069$ Å.

A colourless crystal was mounted on an Enraf–Nonius CAD-4 diffractometer; cell dimensions and intensities were measured by ω–2θ scans with graphite monochromated Mo-K_α radiation. 4212 reflections were scanned in the range $2 < \theta < 27.5°$ and of these 1338 were independent ($R_{int} = 0.034$) and 1206 having $I > 2.5\sigma(I)$ were considered observed and used in the analysis. Three standard reflections measured every 2 h showed no significant variation in intensity.

The structure was determined by Patterson and Fourier methods and refined by least-squares using anisotropic thermal parameters for non-hydrogen atoms. Hydrogen atoms were placed in calculated positions riding on their respective bonded atoms. Weights, $w = 1/[\sigma^2(F) + 0.002F^2)]$, were used in the least-squares refinement. The molecule possesses crystallographic $\bar{3}$ (C_{3i}) symmetry, cadmium and boron lying on special positions with point symmetry $\bar{3}$ (C_{3i}) and 3 (C_3), respectively. The organic ligand is disordered, occupying two sites rotated through *ca* 30° with respect to each other. The two half molecules were refined in separate blocks. The calculations were terminated when all shift/e.s.d. ratios were < 0.1 and $R = 0.0632$, $R_w = 0.0893$ for 1206 observed reflections. The residual electron density in a final difference map was within the range −1.07 to +1.02 e Å^{-3}.

Computations were performed on the IBM 3090 computer at the University of Birmingham and on the Ahdahl 5890 at the Manchester Computing Centre with the SHELXS 86[9] and SHELX 76[10] programs. The molecular diagram was drawn using PLUTO.[11] A crystal of the related zinc(II) complex $C_{30}H_{44}B_2N_{12}Zn$ was shown to be isomorphous (same space group, unit cell). Atomic coordinates and thermal parameters for the cadmium complex have been deposited with the Cambridge Crystallographic Data Centre. Bond lengths and angles are listed in Table 1.

Table 1. Bond lengths (Å) and angles (°) with e.s.d.s in parentheses

N(21) is related to N(1) by symmetry operation z, x, y.

N(31) is related to N(1) by symmetry operation $-z, -x, -y$.

N(22) is related to N(2) by symmetry operation z, x, y.

DISCUSSION

Despite the fact that the ligand [HB(3,5-dimethylpyrazolyl)borate] (L*) may reduce the accessibility of the metal to which it is coordinated[12] (cone angle estimated to be 225°) and that, in consequence, novel molybdenum and tungsten derivatives have been stabilized, e.g. $L^*Mo(NO)X_2$ (X = halogen),[13,14] the readiness with which both zinc(II) and cadmium(II) ions gave bis complexes[4] with $[HB(pz)_3]^-$ made it unlikely that mono-ligand complexes would be easily prepared on reaction of L* with these ions. The reactions between KL* and cadmium(II) salts were, in general, not clean. Similar problems were encountered by Trofimenko *et al.*[15] when hydridotris(3-iso-propylpyrazolyl)-borate, a ligand of intermediate steric demand, was reacted with zinc(II) salts. Even when KL* and cadmium(II) salts were reacted in a 1:1 metal: ligand ratio, the bis complex CdL^*_2 was the dominant product. The best procedure was to use water as a solvent for $CdCl_2$ and to recrystallize the product from CCl_4. Use of ethanol as a solvent for $CdCl_2$ and KL* gave products of variable analysis, microscopic examination of which revealed crystalline CdL^*_2 (X-ray analysis) with small quantities of a second product. When $Cd(ClO_4)_2$ was used there was IR evidence that the contaminant may be a hydroxo species, possibly the intractable material "$L^*Cd(OH)\cdot H_2O$" formed under other circumstances (see below). This material contains strong broad features in the IR spectrum, which are characteristic of strongly hydrogen-bonded species. Confirmation of the preparation of CdL^*_2 (and similarly, ZnL^*_2) was obtained from FABMS which showed the parent ion; the base peak was, however, derived from the loss of one 3,5-dimethylpyrazolyl moiety. Also, the crystal structure was solved by X-ray methods (see below).

It was speculated that other ligands might be able to reduce the Lewis acidity of cadmium(II) and encourage the formation of 1:1 Cd:L* complexes. Thus, as detailed in the Experimental $[Cd(Et_2NCH_2CH_2NEt_2)Cl_2]$, $[Cd(PPh_3)_2Cl_2]$[16] and [Cd(18-crown-6)Cl_2][17] were reacted, in turn, with KL* in a 1:1 molar ratio. The first two complexes afforded the intractable "$L^*Cd(OH)\cdot H_2O$", referred to above. The product which precipitated from the reaction involving the cadmium(II)-crown ether complex was in fact [K(18-crown-6)][L*]. Thus, whilst in two cases the presence of the second ligand has influenced the stoichiometry of the product complex, the material is of limited value for our ultimate purpose. No greater success was achieved using complexes of cadmium(II) iodide. Thus, $[(pd)CdI_2]$ (pd = 1,2-phenylenediamine) in reaction with KL* in CH_2Cl_2 afforded pure CdL^*_2. The problem of hydrolysis had been overcome but six-coordinate cadmium products still resulted.

The failure to obtain clean preparations of 1:1 complexes, L*CdX, with X = Cl led to the consideration of a larger halogen, iodine. A compound of stoichiometry L*CdI was obtained, but in this case also replicate syntheses gave some products of variable (usually high) carbon percentages. ^1H NMR spectroscopy indicated contamination with greater or smaller amounts of CdL^*_2. By contrast, the reaction with $HgCl_2$ to give L*HgCl was clean. An interesting reaction was that of PhHgCl with KL* in THF. The product, on repeated recrystallization, was of stoichiometry "$PhHgL^*\cdot 0.5$ KCl" and gave a positive qualitative test for potassium. The IR spectrum showed L* and Ph to be the only organic moieties present.

The IR spectra of the compounds CdL^*_2, ZnL^*_2, L*CdI, L*HgCl and "$PhHgL^*\cdot 0.5$ KCl" are all extremely similar with respect to the contributions of L*. Given the known (see below) bis-terdentate mode of coordination for the ligands in CdL^*_2, the IR spectra provide circumstantial evidence that the terdentate mode of bonding is adopted for all the listed compounds in the solid state. It is not, however, possible to comment at this juncture on the metal coordination number for L*CdI or L*HgCl.

NMR studies

There is evidence in the literature of fluxional behaviour for complexes of L* with both transition metal[18] and main group[19] elements. It was prudent to explore that possibility for the present compounds, although it is known that ligand exchange reactions may be very rapid for cadmium(II) and mercury(II) species—for example, MeHgL [L = $HB(pz)_3$] underwent such rapid exchange even at −90°C that it was not possible to determine the mode of attachment (mono-, bi- or terdentate) with ^1H NMR spectroscopy.[20] In the case of the complexes studied here the ^1H NMR data showed the three pyrazolyl rings to be equivalent over the temperature range considered (300–220 K), thus a choice between fluxional bidentate and terdentate behaviour is not possible. However, the NMR data which are gathered into Table 2 are useful in other respects and a brief discussion follows.

Whilst ^1H NMR data for CdL^*_2 are certainly consistent with the presence of terdentate ligands the data cannot eliminate the possibility of lower coordination numbers in solution. Cooling a $CDCl_3$ solution of CdL^*_2 to 263 K did allow direct observation of the rarely reported resonance of the pro-

Table 2. ^{1}H and ^{199}Hg NMR data for cadmium and mercury complexes in $CDCl_3$ solution

Compound		^{1}H data[a] Ph	4-H	5-CH_3, 3-CH_3	B—H	^{199}Hg data[b]
CdL^*_2	295 K	—	5.63	2.40, 1.67		—

ton attached to boron as a broad band at $\delta = 4.8$ ppm (N.B. both ^{10}B and ^{11}B are quadrupolar). The spectrum of the product obtained from the reaction of KL* with $CdCl_2$ in ethanol clearly shows the presence of CdL^*_2 and another species, possibly L*CdCl. CdL^*_2 was also detected as a minor contaminant in preparations of L*CdI (see above), the integrals were constant with temperature and hence, the material is an impurity rather than arising from a redistribution reaction of L*CdI in $CDCl_3$. The presence of CdL^*_2 is also apparent in the ^{13}C NMR spectrum, another feature of interest in which is the observation of a 14 Hz coupling of $^{111,113}Cd$ with C(3).

The ^{1}H NMR spectrum of L*HgCl confirms the clean preparation of this compound and also shows a 15 Hz $^{1}H(4)–^{199}Hg$ coupling. Cooling effects produce no spectral changes. The most interesting data were obtained for the material "PhHgL*·0.5 KCl". The ^{1}H data confirmed the 1:1 Ph:L* ratio, but strongly suggested that two phenyl environments were present (overlapping multiplets). The data also suggested that free and coordinated L* co-existed in the solution ($CDCl_3$). The temperature dependence of the ^{199}Hg NMR spectrum was determined (Table 2) and two mercury resonances were observed. At higher temperatures a sharp resonance at 815.8 ppm (278 K) dominated a broad resonance at 614.4 ppm (both relative to aqueous $HgCl_2$). However, on cooling ultimately to the point of freezing (213 K) the broad resonance becomes dominant (622 ppm at 213 K) and the sharp resonance becomes almost vanishingly weak. It is sensible to assign the broad resonance of the mercury species carrying the L* ligand since the quadrupolar ^{14}N ligand atoms are likely to reduce the relaxation time of the ^{199}Hg nucleus. The other resonance does not arise from PhHgCl, which gives a peak at 420.4 ppm at 278 K.

The significant deshielding of the mercury nucleus is consistent with a positively charged species and hence, an explanation which is consistent

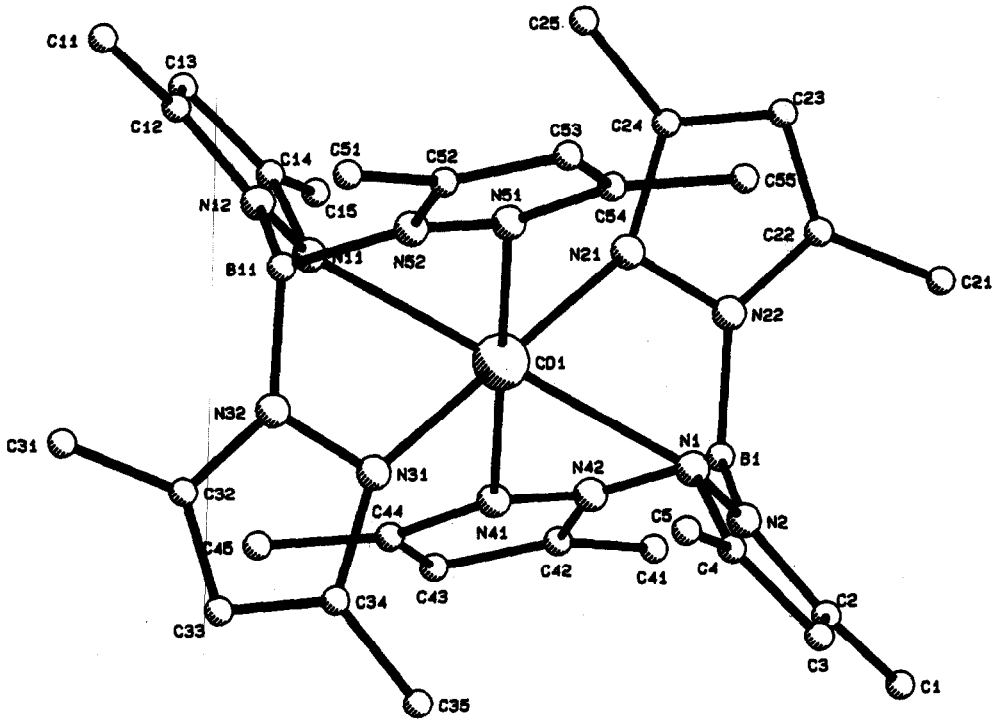

Fig. 1. View of molecule A. Hydrogen atoms have been omitted for the sake of clarity. Atoms labelled 11–15, 21–25, 31–35, 41–45 and 51–55 are related to those labelled 1–5 by the symmetry operations $-x, -y, -z; z, x, y; -z, -x, -y; y, z, x$; and $-y, -z, -x$, respectively.

with all ^{1}H and ^{199}Hg data involves the following equilibrium:

$$\underset{614.4\ \text{ppm (278 K)}}{\text{PhHgL*}} \overset{CDCl_3}{\rightleftharpoons} \underset{815.8\ \text{ppm (278 K)}}{\text{PhHg}^{+}} + \text{L*}^{-}. \quad (1)$$

It seems likely that PhHgL* is present in the solid state also. If $CDCl_3$ solutions of PhHgL*·0.5KCl are allowed to stand overnight some mercury is deposited together with some small quantities of a white solid; however, the ^{1}H and ^{199}Hg spectra of the decanted supernatant solution show the continued presence of the species in eq. (1). If the solution is left several days a very simple ^{1}H NMR spectrum is obtained, which consists of resonances from the phenyl-group, the 4-hydrogen atom of the pyrazolyl ring and a single methyl resonance in the ratio 2.5:1.6. It would seem that the ligand has decomposed with the rupture of B—N bonds by a mechanism as yet unknown.

Structural studies

A view of one of the "half molecules" (molecule **A**) is displayed in Fig. 1. Due to the disorder in the crystal structure accurate molecular parameters could not be obtained. The coordination geometry around cadmium is essentially octahedral with some trigonal distortion in molecule **A**, but not in molecule **B**. The Cd—N bond distances are greater than previously found in analogous complexes. Thus, in the copper,[21] high-spin iron(II)[22] and magnesium[23] analogues metal—N bond distances are in the ranges 2.04–2.32, 2.15–2.19 and 2.17–2.20 Å, respectively. Our results are, however, in good agreement with previous determinations of Cd—N(pyrazolyl) bond distances in complexes of different ligands; 2.43 in dichloro[2,5-dimethyl-1,6-bis(3,5-dimethyl-1-pyrazolyl)-2,5-diazahexane-N,N′,N″,N‴]cadmium(II),[24] 2.35 in Cd_2(bddo)(NCS)$_4$ [bddo = 1,8-bis(3,5-dimethyl-1-pyrazolyl)-3,6-dithiaoctane],[25] 2.26 (mean) in [bis(2-(3,5-dimethyl-1-pyrazolyl)ethyl)oxide]bis(nitrato-O,O′)cadmium (II)[26] and 2.31 Å (mean) in the amine analogue.[26]

(*Received* 11 *December* 1992; *accepted* 8 *January* 1993)

Abstract—Three platinum(II) complexes of biq (biq = 1,1′-biisoquinoline), $[Pt(biq)Cl_2]$, $[Pt(biq)(py)_3](ClO_4)_2$ (py = pyridine) and $[Pt(biq)(dapy)_3](ClO_4)_2$ [dapy = 4-(dimethylamino)pyridine] were prepared. Using ^1H NMR spectroscopy and X-ray crystallography, biq in the former complex was found to be bidentate and in the two latter complexes monodentate. Dihedral angles between the two isoquinoline rings were determined to be 35.18° and 41.12° in $[Pt(biq)Cl_2]$ and 77.61° in $[Pt(biq)(dapy)_3](ClO_4)_2$. The crystal structure of $[Pt(biq)Cl_2]$ is the first example of η^2-μ_1 biq complexes with a five-membered chelating ring. Weak intramolecular π–π stacking occurs in the solid phase of $[Pt(biq)(dapy)_3](ClO_4)_2$.

Ligands incorporating a 1,1′-binaphthyl unit have been receiving current interest because of their application in catalytic asymmetric reactions.[1] In our search for new metal catalysts for asymmetric organic oxidation the ligand 1,1′-biisoquinoline (biq), which possesses the combined structural features of 2,2′-bipyridine (bpy) and 2,2′-bis(diphenylphosphino)-1,1′-binaphthyl, has attracted our interest. Dai *et al.* first reported the X-ray crystal structure of a chiral palladium complex of biq, in which the ligand acts as a bridging ligand.[2] Here we describe three mononuclear platinum(II)-biq complexes, $[Pt(biq)Cl_2]$, $[Pt(biq)(py)_3](ClO_4)_2$ and $[Pt(biq)(dapy)_3](ClO_4)_2$, with the crystal structures of $[Pt(biq)Cl_2]$ and $[Pt(biq)(dapy)_3](ClO_4)_2$ determined.

EXPERIMENTAL

Physical measurements

UV–vis absorption spectra were recorded with a Shimadzu UV-240 spectrophotometer or a Milton Roy Spectronic 3000 Array spectrophotometer in acetonitrile. NMR spectra were run on a Jeol GSX 270 spectrometer. Chemical shifts (δ/ppm) were reported relative to tetramethylsilane (TMS).

X-ray structure determination

Crystals of $[Pt(biq)Cl_2]$ were obtained by the addition of diethyl ether to a dimethyl formamide solution of $[Pt(biq)Cl_2]$. Yellow crystals of $[Pt(dapy)(dapy)_3](ClO_4)_2$ were obtained by diffusion of diethyl ether into acetonitrile solution. X-ray diffraction data were collected on an Enraf–Nonius CAD4 diffractometer with graphite-monochromated Mo-K_α radiation ($\lambda = 0.71069$ Å) using the $\omega/2\theta$ scan mode. Details of crystal parameters, data collection and structure refinement are given in Table 1. Cell dimensions were obtained from 24 reflections with 2θ in the ranges 18.90–23.60° and 18.84–29.16° for $[Pt(biq)Cl_2]$ and $[Pt(biq)(dapy)_3](ClO_4)_2$, respectively. All reflections were corrected for Lorentz, polarization and absorption effects. All data reduction and structure refinement were performed using the NRCC-SDP-VAX packages.[3] The structure was solved by the Patterson method

and refined by least-squares. Selected bond distances and angles for $[Pt(biq)Cl_2]$ and $[Pt(biq)(dapy)_3](ClO_4)_2$ are given in Tables 2 and 3, respectively.

Materials

Potassium tetrachloroplatinate(II) (K_2PtCl_4) and isocarbostyril were purchased from Aldrich Chemical Company, Inc. Nickel chloride (GPR) ($NiCl_2 \cdot 6H_2O$) and zinc powder (LR) were purchased from BDH. 4-(Dimethylamino)pyridine (dapy) and triphenylphosphine (PPh_3) were purchased from Merck. All chemicals and solvents were used without further purification.

Syntheses

The ligand biq was prepared by homo-coupling of 1-bromoisoquinoline catalysed by $NiCl_2$–PPh_3–Zn in 20% yield.[4] 1-Bromoisoquinoline was prepared by bromination of isocarbostyril with phosphorus tribromide (PBr_3).

$[Pt(biq)Cl_2]$ was prepared in a similar manner to [Pt(substituted 2,2′-bipyridine)Cl_2].[5] In a typical reaction a mixture of K_2PtCl_4 (0.10 g) and biq (0.07

g) in water (20 cm^3) was heated to boiling for ½–1 h. The solid precipitate was filtered and washed with dilute hydrochloric acid, water and finally ethanol. The orange solid product yielded 88%. UV–vis spectral data in acetonitrile [λ/nm ($\varepsilon/\times 10^4$ mol^{-1} dm^3 cm^{-1})]: 245 (3.10), 302 (1.20), 385 (1.06), 404 (1.19), 446 (0.50).

The complexes $[Pt(biq)(py)_3](ClO_4)_2$ and $[Pt(biq)(dapy)_3](ClO_4)_2$ were prepared in a similar manner to that for $[Pt(bpy)(py)_2]^{2+}$ by Bielli *et al.*[5] In a typical reaction a mixture of $[Pt(biq)Cl_2]$ (0.13 g) and pyridines (py, dapy; 1 cm^3) in ethanol was warmed at *ca* 50°C for *ca* 10 min until the orange suspension turned to a clear pale-yellow solution. The reaction mixture was filtered and excess $LiClO_4$ was added to the filtrate to give a pale yellow solid, which was filtered and washed with ethanol and diethyl ether. Anal. for $[Pt(biq)(py)_3](ClO_4)_2(PtC_{33}H_{27}N_5O_8Cl_2)$: Found: C, 44.0; H, 2.7; N, 7.8. Calc.: C, 44.7; H, 3.1; N, 7.9%. UV–vis spectral data in acetonitrile [λ/nm ($\varepsilon/\times 10^4$ mol^{-1} dm^3 cm^{-1})]: $[Pt(biq)(py)_3](ClO_4)_2$: 251 (3.02), 325 (2.10), 339 (shoulder); $[Pt(biq)(dapy)_3](ClO_4)_2$: 288 (0.47), 325 (shoulder).

RESULTS AND DISCUSSION

The UV–vis spectral data of $[Pt(biq)(py)_3](ClO_4)_2$ and $[Pt(biq)(dapy)_3](ClO_4)_2$ show two allowed transition bands between 200 and 400 nm, which are assigned to intraligand π–π^* transitions. The UV–vis absorption spectrum of $[Pt(biq)Cl_2]$ is similar to that of $[Pt(LL)Cl_2]$ reported by Gidney *et al.*[6]

Perspective drawings of the molecule and unit cell of $[Pt(biq)Cl_2]$ are given in Figs 1 and 2, respectively. In $[Pt(biq)Cl_2]$ two kinds of configuration were found and they are principally different in the dihedral angles between the two isoquinoline planes. The one with smaller dihedral angle is designated type I (35.18°) and another one type II (41.12°). In both types the platinum atom is in a slightly distorted square-planar coordination geometry. The two isoquinoline moieties are bent away from the coordination plane in opposite directions as a result of mutual repulsion between protons 8 and 8′ on the biq moiety. Similar to $[Pt(bpy)Cl_2]$,[5,7] dimorphism occurs in $[Pt(biq)Cl_2]$. The freshly prepared $[Pt(biq)Cl_2]$ was orange in colour, but after recrystallization from dimethyl formamide dark brown crystals were obtained. An orange solid was precipitated when recrystallization was attempted in a water–acetone mixture. The difference in crystal colour is believed to be due to a change in the degree of hydration. Although $[Pt(biq)Cl_2]$ is similar to $[Pt(bpy)Cl_2]$ in exhibiting dimorphism, no superimposition of molecules is found in the crystal structure of $[Pt(biq)Cl_2]$, as shown in $[Pt(bpy)Cl_2]$.[7] The intermolecular Pt—Pt

distances are 6.221, 5.128 and 6.414 Å for Pt(1)—Pt(1), Pt(2)—Pt(2) and Pt(1)—Pt(2), respectively, indicating no Pt—Pt interaction. The reason why two forms exist in the crystal is not fully understood. From the unit cell diagam (Fig. 2) it can be seen that the twisted biq moiety in the type II complexes is interlocking with other biq units, hence, reasonably giving an enlarged dihedral angle.

A perspective drawing of the $[Pt(biq)(dapy)_3]^{2+}$ cation is given in Fig. 3. The platinum atom is in a distorted square-planar configuration with Pt, N(1), N(21), N(31) and N(41) all on the same plane. Three dapys are more or less perpendicular to the coordination plane. For the coordinated biq ligand the two isoquinoline moieties are almost planar, in which the deviation of atoms from the least-squares planes is within 0.072 Å. The biq ligand is in an η^1 coordination mode, despite it also being a bidentate chelating ligand. The dihedral angle between the two isoquinoline rings is 77.61°, which is substantially larger than the related values of 35.18° and 41.12° for the $[Pt(biq)Cl_2]$ complex described above. The isoquinoline moiety with the non-coordinated nitrogen atom [N(12)] is weakly stacked adjacent to its neighbouring dapy ring. The interplane distance between the isoquinoline and dapy plane is *ca* 3.5 Å. Such intramolecular π–π stacking is absent in solution, as revealed by ^1H NMR study (*vide infra*). The angle C(2)—N(1)—C(10) [119.7(7)°] [N(1) is coordinated to platinum] is greater than the angle C(11)—N(12)—C(13) [116.3(9)°] [N(12) is uncoordinated]. The former value is similar to those in $[Pt(biq)Cl_2]$, while the latter is typical of non-coordinated sp^2-hybridized nitrogen.

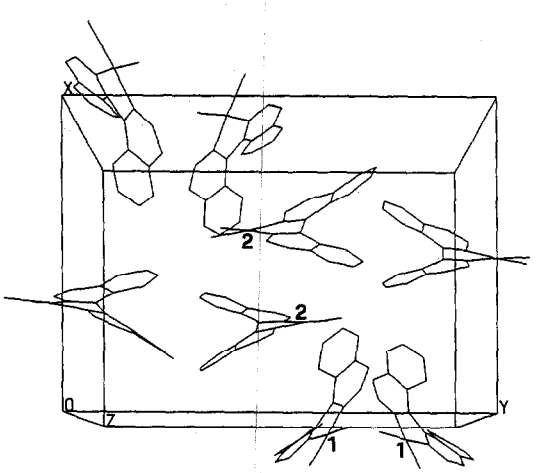

Fig. 2. The unit cell of $[Pt(biq)Cl_2]$.

The ^1H NMR spectroscopic data are listed in Table 4. The ^1H NMR spectrum of $[Pt(biq)Cl_2]$ in $CDCl_3$, with the atomic numbering scheme, is shown in Fig. 4. Figure 5 shows the numbering schemes of $[Pt(biq)(dapy)_3]^{2+}$ and $[Pt(biq)(py)_3]^{2+}$. As discussed above, in the solid form the

Pt—N(biq) bond of $[Pt(biq)(dapy)_3](ClO_4)_2$ is not free to rotate as it is restricted by two dapys *cis* to it and the π–π stacking (*vide supra*). However, the ^{1}H NMR spectrum in acetonitrile solution reveals no π–π stacking in solution. This is evidenced by the magnetic equivalence of two dapys *cis* to the biq ligand. The change in coordination mode of biq from η^2 to η^1 upon treatment of $[Pt(biq)Cl_2]$ with nitrogen base is likely due to the ring strain of the five-membered ring in the η^2-μ_1 coordination mode and the regain of the planarity of the isoquinoline rings in the η^1-μ_1 geometry.

Similar to rhodium(I) and palladium(II), four-coordinated platinum(II)-biq complexes are coordinatively unsaturated. The availability of vacant coordination sites and the C—H bond activating property of platinum(II) should be useful in platinum(II)-biq complexes in asymmetric C—H

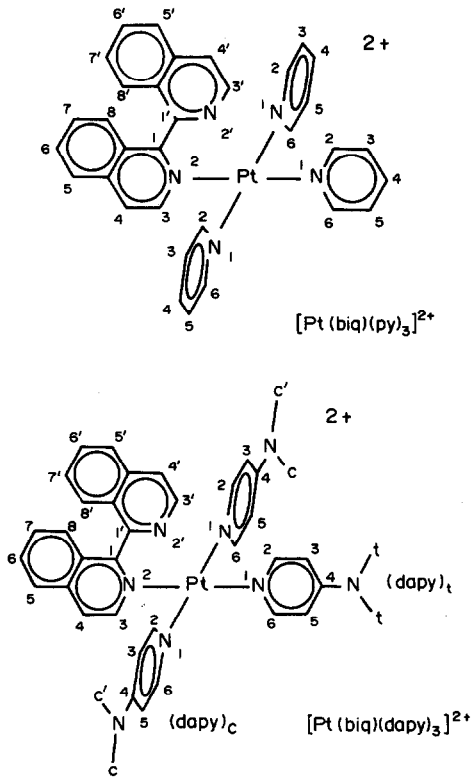

Fig. 5. Numbering schemes of $[Pt(biq)(dapy)_3]^{2+}$ and $[Pt(biq)(py)_3]^{2+}$.

bond oxidation. On the other hand, Calladine's rule is present in DNA. The base pairs have a propeller twist, 11° for dG–DC and 17° for dA–dT pairs.[8] The small twist angles of $[Pt(biq)Cl_2]$ compared with that of Toriumin's complex [77.4(2)°][9] may make chiral recognition binding to DNA possible.

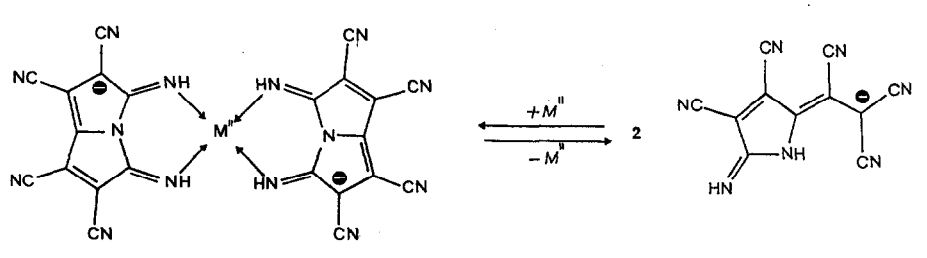
(*Received* 11 *December* 1992; *accepted* 8 *January* 1993)

Abstract—The X-ray crystal structure of the bis(1,2,6,7-tetracyano-3,5-diimino-3,5-dihydro-pyrrolizinido)copper(II) complex, as an adduct with acetonitrile, $CuL_2 \cdot 2CH_3CN$ (**1a**), is described and compared with that of the analogous tetrahydrofuran derivative $CuL_2 \cdot 2THF$ (**1b**), previously reported. The molecular structure of both complexes is almost the same (the copper atom is centrosymmetrically surrounded by four chelating imino groups in a square planar configuration), whereas the spatial arrangement is totally different: in **1a** the molecular units are slipped stacked, while in **1b** they are mutually orthogonal. The results of a number of physical measurements on both **1a** and **1b** are reported and correlated with the structures. The solution electronic spectrum is also reported and compared with that, extraordinarily similar, of copper-phthalocyanine.

Our current investigations are concerned with the bis(1,2,6,7-tetracyano-3,5-diimino-3,5-dihydro-pyrrolizinodo)metal(II), ML_2, complexes (**1**), resulting from a metal-assisted intramolecular cyclization of the corresponding pyrrolenine anion (**2**), as outlined in the scheme below.

We have already reported preliminary information on copper(II)[1] and more extensively discussed nickel(II),[2] iron(II)[3] and cobalt(II)[3] derivatives. The interest in such compounds is due to their electronic structure, which is very similar to that of metal-phthalocyanines (MPc),[4] and, therefore, they might



Scheme 1.

† Authors to whom correspondence should be addressed.

be technologically important as an analogy.[5]

As far as the solid state structure is concerned systems **1** differ considerably from MPc. In fact, while MPc adopt the classical herring-bone structure,[6] **1** display a variety of crystal packing depending on the cystallization solvent, usually laterally adducted to the chelating imino groups in the molecular plane via hydrogen bonds. Sometimes the difference in packing arrangement is remarkable, due to the variation in the crystallization solvent. This is the case for the title complex, which shows either slipped-stacked interacting molecular units when crystallized from acetonitrile, CH_3CN, or mutually orthogonal units when crystallized from tetrahydrofuran. The X-ray crystal structure of $Cu(C_{11}N_7H_2)_2 \cdot 2CH_3CN$ (**1a**) is presented here and compared with that of $Cu(C_{11}N_7H_2)_2 \cdot 2THF$ (**1b**), previously reported;[1] the results of a number of physical measurements on both compounds are also reported and discussed.

EXPERIMENTAL

All manipulations were performed under dinitrogen on a vacuum line using standard Schlenk techniques or in a dry-box; solvents were dried and freshly distilled before use.

Preparations

CuPc was purified by sublimation. $Cu(C_{11}N_7H_2)_2 \cdot 2THF$ (**1b**) was prepared as described previously.[1]

$Cu(C_{11}N_7H_2)_2 \cdot 2CH_3CN$ (**1a**). By solvent substitution: a suspension of **1b** (0.50 g, 0.74 mmol) in CH_3CN (50 cm^3) was refluxed for 3 h. After cooling to room temperature and filtering **1a** was collected in a quantitative yield as bronze microcrystals. Crystals suitable for X-ray determinations were obtained after crystallization of crude **1a** in CH_3CN, as follows: a hot saturated acetonitrile solution was filtered and sealed in a vial under vacuum. On very slow cooling from 80°C to room temperature over 7 days needle-like crystals of **1a** separated. The elemental analysis data of **1a** from several analyses were not reproducible, due to the partial loss of the solvent when **1a** was dried; however, the experimental X-ray powder diffraction pattern from a freshly prepared sample of **1a** was in excellent agreement with the diffraction pattern generated from X-ray diffraction studies of a single crystal sample.[7]

Physical measurements

A Cary 5 instrument was used to record diffuse relectance spectra on MgO-diluted samples. The solution electronic spectra were recorded with a Perkin–Elmer 330 spectrometer. A Biorad FTS40 FTIR spectrometer was used to measure the IR spectra in Nujol mulls; CsI windows were used in the spectral range 4000–180 cm^{-1} and polyethylene windows in the range 500–50 cm^{-1}; the reproducibility was 0.3 cm^{-1} or better. Magnetic measurements were performed on a commercial SQUID magnetometer (Quantum Design, H_{max} = 5 T); molar susceptibilities were corrected for intrinsic diamagnetism, estimated from Pascal's constants.

X-ray analysis

An irregularly shaped crystal of approximate dimensions $0.60 \times 0.25 \times 0.20$ mm was sealed in a capillary in the presence of the mother liquor and used for data collection on a Nicolet $P2_1$ four-circle diffractometer. Unit cell parameters were determined from 25 accurately centred reflections ($23° \leqslant 2\theta \leqslant 37°$). Intensity data were collected at room temperature using graphite crystal monochromated Mo-K_α radiation ($\lambda = 0.71069$ Å) by the θ–2θ scan technique and corrected for Lorentz and polarization effects. No absorption correction was applied, given the low value of μ and the crystal dimensions. Furthermore, a ψ-scan on two reflections showed a maximum deviation of less than 4%.

The structure was solved by conventional Patterson and Fourier methods and refined by full-

matrix least-squares methods, with neutral scattering factors calculated using the data from ref. 8. The final refinements were made with anisotropic temperature factors for non-hydrogen atoms; hydrogens were placed in calculated positions with fixed isotropic thermal parameters.

All calculations were performed using the SIR-CAOS Crystallograhic Program System.[9] Crystallographic and processing data are given in Table 1. Positional and anisotropic thermal parameters, a full list of bond lengths and angles and observed and calculated structure factors have been deposited with the Editor as supplementary material.

RESULTS AND DISCUSSION

Crystal structure of $CuL_2 \cdot 2CH_3CN$ (**1a**)

The molecular geometry and relative orientation of the two symmetry-related formula units, comprised in the unit cell, are shown in Fig. 1. The main interatomic distances and angles are given in Table 2: they are strictly comparable with those found in **1b** which have already been discussed.[1-3] The copper atom is centrosymmetrically surrounded by four chelating imino groups in a square planar arrangement with Cu(1)—N(8) and Cu(1)—N(14) distances of 1.986 and 2.005 Å, respectively, and completes its tetragonally elongated octahedral geometry with two axial cyano groups at 2.900 Å. These latter groups do not belong to almost orthogonal equivalent complex units, as in the case of **1b**,[1,3] but to parallel *a*-shifted units (Fig. 2), giving rise to symmetry-related, differently oriented slipped stacks of planar molecules, with an interplanar distance of 3.09 Å. Although no degree of π-superposition is present within the stack, such packing resembles that of the β-phase of CuPc,[10] thus enhancing its similarity with Mpc discussed below.

The adducted acetonitrile molecules act as bridging groups between the stacks via weak hydrogen interactions (Fig. 1), with the coordinated imino groups on one side and peripheral cyano groups on the other ($N_{acetonitrile}$—N_{imino} and $C_{acetonitrile}$—N_{cyano} mean distances: 3.15 and 3.45 Å, respectively).

In conclusion it is worth noting that, probably owing to its small dimensions and strong polarized character, the acetonitrile molecule causes a Cu $L_2 \cdot 2CH_3CN$ crystal packing completely different from the analogous dimethoxyethane (DME) com-

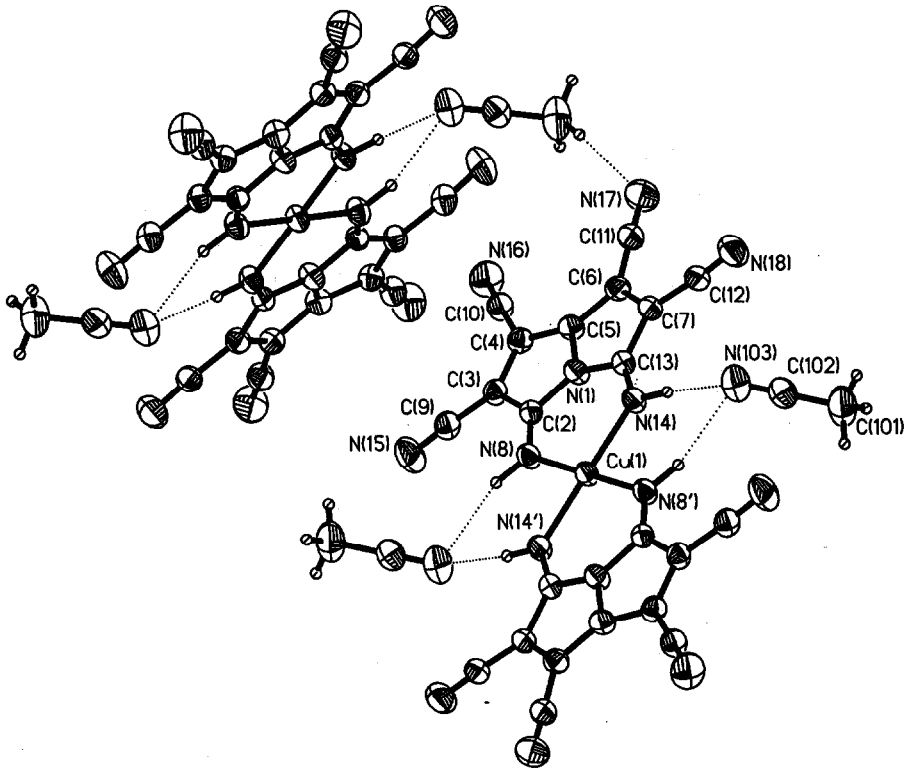

Fig. 1. A perspective view of the unit cell content, showing the two symmetry-related complex molecules and the labelling of the atoms. The laterally adducted acetonitrile solvent molecules act as bridging groups between them via weak hydrogen bonds (dotted lines).

plexes $FeL_2 \cdot 2DME$,[3] $CoL_2 \cdot 2DME$[3] and $CuL_2 \cdot 2THF$,[1] and more similar to that of the β-phase of MPc. Tuning of the metal β-diiminopyrrolizinido solid-state features can, therefore, be envisaged by varying the crystallization solvent and/or the metal atom.

Solution behaviour

The copper complex, like the other first-row transition metal derivatives, is sparingly soluble in donor solvents (solubility in THF $\approx 4.32 \times 10^{-4}$); in solution it does not obey Beer's law; water labilizes the coordination bond, shifting the dissociation equilibrium (see Scheme 1) to the right [ν_{max} (**2**) = 546 nm]. By increasing the amounts of Cu^{2+}, as $CuCl_2 \cdot 2H_2O$, it is possible to reverse the equilibrium to the left so that a large excess (≈ 100 times) is needed in order to observe the intrinsic visible spectrum of the undissociated species. Such a spectrum is reported in Fig. 3, together with that of CuPc for comparison. The spectra in Fig. 3 are very similar, exhibiting two major bands (the characteristic Q and Soret bands of MPc), spaced by a window in the 500 nm region. The key to this extraordinary similarity has been found for the analogous nickel(II) complex, based on semi-empirical MO calculations.[4] It follows from these calculations and the observed overall similarity that also in the copper complex the Q-like band arises from two allowed, accidentally degenerate, electronic $\pi \rightarrow \pi^*$ intraligand transitions between HOMO and LUMO orbitals.

Solid state properties: electronic and IR spectroscopy and magnetic measurements

The reflectance spectrum of **1b** is dominated by the very intense Q-like band centred at 660 nm; in **1a** this band is broadened and split into two components with maxima at 670 and 717 nm. According to the Davydov theory[11] this splitting (≈ 970 cm^{-1}) is caused by the interaction between molecules of differing site symmetry in the unit cell and, as in CuPc,[12] it can be correlated with the interaction between equivalent molecules along the

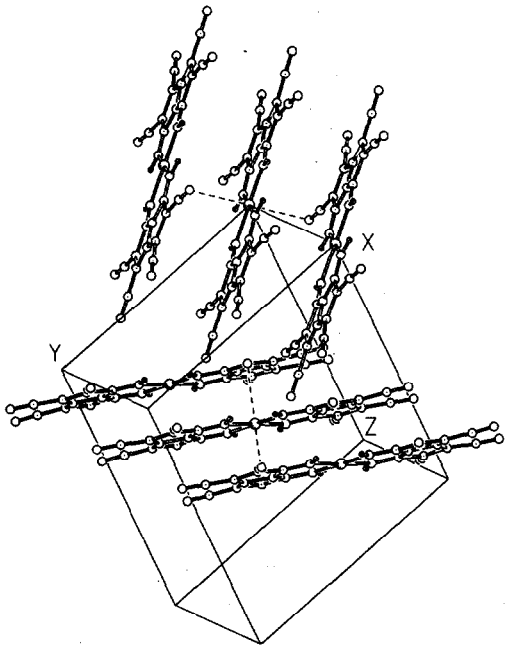

Fig. 2. Crystal packing of **1a**, showing the two differently oriented slipped stacks of *a*-spaced complex molecules. The axial copper–nitrogen interactions within each stack are drawn as dashed lines. Acetonitrile groups have been omitted for clarity.

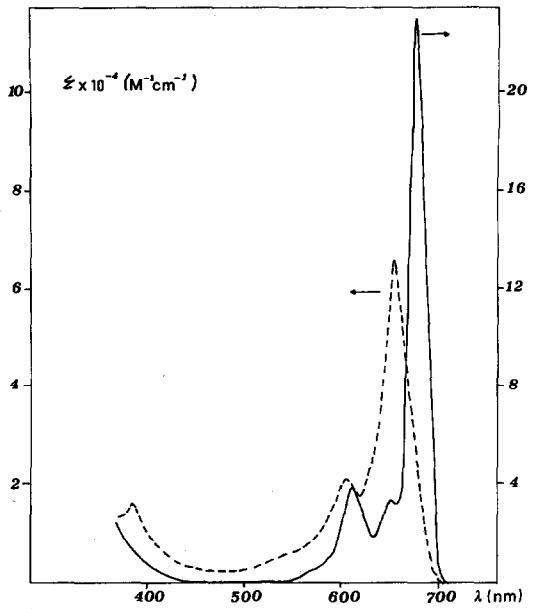

Fig. 3. Solution electronic spectra of CuPc (——) (α-chloro-naphthalene) and CuL_2 (– – – –) (THF+0.11 M $CuCl_2 \cdot 2H_2O$).

stacks. It is worthwhile noting that in CuPc, in spite of a larger intermolecular separation (3.28 Å),[10a] such an interaction appears to be greater than in **1a**, being almost double the size of the Davydov splitting (1890–1960 cm^{-1}).[12] Moreover, both **1a** and **1b** show a weak band at low energy (1070 and 1060 nm, respectively), which can be correlated with the weak intermolecular Cu···N bonds (2.90 and 2.82 Å, respectively) and probably due to the metal $d_{z^2} \rightarrow d_{x^2-y^2}$ electronic transition, confined within the axially distorted octahedral $CuN_4N'_2$ chromophore. The energy of such a band is clearly due to the difference in the out-of-plane bond length.[13] In addition, **1b** shows another band, appearing as a shoulder at 970 nm, probably due to the second metal $d \rightarrow d$ transition, as previously assigned.[1]

As far as the IR spectra are concerned, most interest is associated with the N—H and Cu—N stretching vibrations (Fig. 4); the first giving bands in the higher energy region, diagnostic of the hydrogen bond involving the imino groups. Such bands are in effect red-shifted, split (**1a**) and broadened (**1b**), compared with the band attributable to the imino group, when not involved in a hydrogen bond as in the tetraphenylarsonium salt of the pyrrolenine anion **2** [ν(N—H) = 3360 cm^{-1}].[14] The peak energy values [Fig. 4(a)] in **1a** (3258 and 3295 cm^{-1}) and **1b** (3165 and 3258 cm^{-1}) parallel the corresponding hydrogen bond distances (2.158 and 2.239 Å for **1a** and 1.953 and 2.298 Å for **1b**). The Cu—N stretching absorptions [Fig. 4(b)] fall in the lower energy region. In D_{2h} these IR-allowed vibrations have the symmetry B_{2u} and B_{3u} (in-plane) and A_u (out-of-plane).[15] The first two symmetries can be assigned at 232.5 and 256 cm^{-1} in both materials. Such an assignment is supported by the observation that in the analogous zinc complex, adducted with THF, these bands (224.6 and 200 cm^{-1}) are red-shifted as a consequence of the mass effect and the longer Zn—N bond distance (2.016 Å).[16] However, note that the similarities of the frequencies of the two in-plane Cu—N stretching vibrations in **1a** and in **1b** are consistent with the fact that in-plane distances between copper and nitrogen atoms are almost equal in these materials. The frequency of the A_u mode should fall at lower energy (probably < 200 cm^{-1});[13] unfortunately, this energy region is very rich in weak absorptions so that no reliable assignment can be made at present without further carefully designed IR experiments.

Finally, we wondered whether **1a** exhibits any linear-chain behaviour, given that its intermolecular separation is much lower than the characteristic van der Waals distance (3.4 Å). Surprisingly enough, it does not show any cooperative property: it is an electrical insulator ($\sigma < 10^{-7}$ S) and the temperature dependence of the corrected

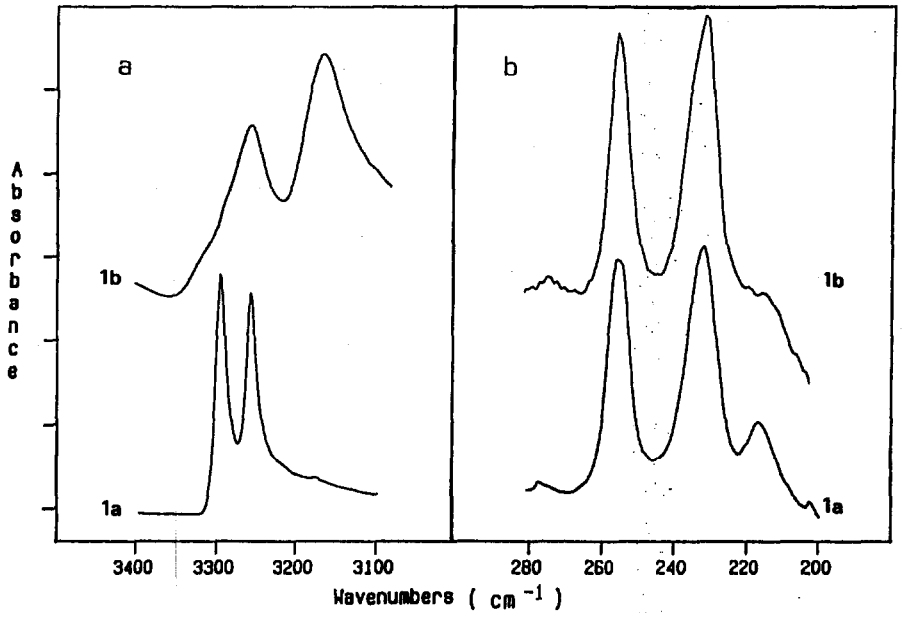

Fig. 4. IR absorption spectra in (a) the 3400–3100 cm^{-1} region and (b) the 280–200 cm^{-1} region. The upper curves are relative to compound **1b**, the bottom ones to **1a**.

molar susceptibility follows the Curie law within the temperature range investigated (6–300 K). The copper ions are magnetically isolated as they are in the compound **1b** (μ_{eff} = 1.73 and 1.77 B.M., respectively).

(*Received* 2 *December* 1992; *accepted* 8 *January* 1993)

Abstract—The reaction between the oxomolybdenum(V) complex $Et_4N[MoOI_4(H_2O)]$ and triphenylphosphine oxide (L = $OPPh_3$) produces the mononuclear complex $[MoOI_3L_2]$ and the dinuclear complex **1** $[Mo_2O_4I_2L_3]$, the crystal structure of which has been studied by X-ray. Each metal centre is bound to a terminal and two bridging oxygen atoms; the Mo_2O_2 central fragment appears slightly disymmetric with a short Mo—Mo distance [2.557(1) Å], in agreement with a single metal–metal bond. The whole structure is strongly asymmetric, with the three phosphorus ligands bound to a first molybdenum atom with a distorted octahedral MoO_6 coordination and the two iodo ligands bound to a second molybdenum atom which has a *cis*-$MoOO_2I_2$ square-pyramidal coordination. Extended Hückel calculations on the model $[Mo_2O_4I_2L_3]$ (L = OPH_3), the structure of which was derived from the averaged structure of **1**, have been performed to understand the structure and bonding in this unsymmetrical dimer. They show a HOMO–LUMO gap of 1.06 eV and indicate that **1** can be considered unambiguously as an Mo^V–Mo^V [and not an Mo^{IV}–Mo^{VI}] dinuclear complex. An orbital explanation is provided to rationalize why the *cis* conformation is generally preferred for Mo^V–Mo^V dinuclear species: such a conformation allows a stronger Mo—Mo bond. Some predictions are made, concerning the reactivity of the Mo—Mo bond with respect to nucleophilic and electrophilic attacks.

At the end of the 70s most of the known dinuclear complexes were symmetrical homodinuclear species, but in the last two decades much attention has been focused upon heterodimetallic complexes.[1,2] Such complexes obviously present a richer reactivity than mono- and homodinuclear complexes and much effort has been particularly directed towards the use of early/late transition metal combinations as catalysts themselves, catalyst precursors or as model compounds for catalytic intermediates.[3] Unsymmetrical homodinuclear complexes con-

* Authors to whom correspondence should be addressed.

stitute an interesting intermediate class which has been relatively little studied up to date; the two metallic centres, of the same chemical nature, differ only in their coordination sphere and the subtle differences in the properties and reactivities of the two metal sites can only arise from the different ligands bound to each of them.

In the specific case of molybdenum, examples of dinuclear compounds with non-equivalent metal sites are very diverse: various oxidation states and various coordination numbers of both metallic cations, as well as various overall geometries and various charges of the complexes are seen. The large range of unambiguously X-ray characterized, unsymmetrical molybdenum complexes includes mono-bridged complexes such as $[O_3Mo^{VI}(\mu\text{-}O)Mo^{VI}O_3(en)]^{2-}$ [4] and $[LCl(O)Mo^{V}(\mu\text{-}O)Mo^{VI}O_2L]$ $[L = \{HB(Me_2pz)_3\}^-]$,[5] doubly-bridged complexes such as $[L_2ClMo^{III}(\mu\text{-}Cl)(\mu\text{-}S)Mo^{III}Cl_2L_n]$ $[L = PMe_3;\ n = 1,2]$,[6] $[(RCp)_2Mo(\mu\text{-}S)_2MoO_2]$[7] and $[L_2Mo(\mu\text{-}OPr^i)_2Mo(OPr^i)_2L]$ (L = 9,10-phenanthrenequinone),[8] and triply-bridged complexes such as $[LX_2Mo^{III}(\mu\text{-}X)_3Mo^{III}L_2X]$ $(X = Cl, Br;\ L = PMe_2Ph)$[9] and $[L(NR)Mo(\mu\text{-}S)_2(\mu\text{-}O_2CR)Mo(NR)L']$ $[L = \{PS_2(OR)_2\}^-;\ L' = dppe]$.[10] It also includes, however, unbridged complexes such as $[L_2Mo{\equiv}Mo(OPr^i)_4]$ (L = dmpe),[11] which contains a triple metal–metal bond associating d^6-Mo^0 and d^2-Mo^{IV} centres.

In the course of our study on iodooxomolybdenum complexes we obtained a dinuclear complex, $[Mo_2O_4I_2L_3]$ $(L = OPPh_3)$, for which a crystal structure determination by X-ray diffraction clearly showed a strongly unsymmetrical structure. This strong asymmetry and the availability of precise structural data prompted us to examine the electronic properties of this compound. The synthesis, structural results and the theoretical calculations are presented in this paper.

EXPERIMENTAL

All reactions were performed in Schlenk tubes in a dry oxygen-free nitrogen atmosphere. Solvents were distilled by standard techniques and thoroughly deoxygenated before use. Elemental analyses were performed by Service Central d'Analyse du CNRS, Vernaison, France. IR spectra were obtained with a Perkin–Elmer 1430 spectrometer (KBr pellets). The starting molybdenum complex $Et_4N[MoOI_4(H_2O)]$ was synthesized as previously described.[12]

Synthesis

$Et_4N[MoOI_4(H_2O)]$ (1 mmol, 0.75 g) was dissolved at room temperature in the minimum amount of acetonitrile. This solution was then transferred into a concentrated solution of $OPPh_3 \cdot 0.5H_2O$ (2 mmol, 0.56 g) in acetonitrile. The solution, which was stirred for *ca* 15 min, became violet. Upon standing a purple precipitate appeared; it was filtered, washed and dried under reduced pressure (yield *ca* 65%). Found: Mo, 8.7; C, 41.7; H, 2.9; I, 35.9; P, 5.8. Calc. for $MoC_{36}H_{30}I_3O_3P_2$: Mo, 9.1; C, 41.2; H, 2.9; I, 36.3; P, 5.9%. IR (KBr, cm^{-1}): 970, ν(MoO). The resulting filtrate was kept under nitrogen at −20°C. The solution slowly became brown and reddish microcrystals of complex **1** precipitated. They were filtered, washed and dried under reduced pressure (yield *ca* 10%). Found: C, 47.8; H, 3.7; I, 19.6; P, 5.8. Calc. for $Mo_2C_{54}H_{45}I_2O_7P_3$: C, 48.5; H, 3.5; I, 18.3; P, 6.7%. IR (KBr, cm^{-1}): 975 and 940, ν(MoO).

Crystal and molecular structure of **1**, $[Mo_2O_4I_2L_3]$ $(L = OPPh_3)$

Crystal data. $Mo_2C_{54}H_{45}I_2O_7P_3$, $M = 1344.6$, triclinic, space group $P\bar{1}$, $a = 10.717(5)$, $b = 11.631(2)$, $c = 12.336(4)$ Å, $\alpha = 69.49(3)$, $\beta = 74.76(3)$, $\gamma = 66.46(4)°$, $V = 1306.8(9)$ Å^3, $Z = 1$, $Dx = 1.708$ g cm^{-3}, $F(000) = 660$, λ(Mo-K_α) = 0.71069 Å, $\mu = 17.76$ cm^{-1}.

A reddish translucent crystal (approximate dimensions $0.20 \times 0.22 \times 0.28$ mm) with well-developed faces was used for the data collection. No problems were encountered collecting the data on an Enraf–Nonius CAD4 four-circle diffractometer at room temperature using graphite-monochromated Mo-K_α radiation (0.71069 Å) and employing the ω–2θ scan technique. There was no decomposition of the sample during the experiment (intensity variation <0.2%). Unit cell parameters were obtained from least-squares refinement on the setting angles of 25 reflections. No symmetry higher than triclinic was found. Of 6002 reflections collected up to $2\theta = 50°$ (hkl range: h 0,13; k −14,14; l −15,15) only 3415 independent reflections ($R_{int} = 0.028$) with $I > 3\sigma(I)$ were used to solve and refine the structure. After Lorentz and polarization corrections the structure was solved with direct methods which reveal the iodine, phosphorus and molybdenum atoms of the asymmetric unit. The remaining non-hydrogen atoms of the structure were found after successive scale factor refinements and Fourier differences. After isotropic refinement an absorption correction was made with Difabs.[13a] The whole structure was refined by the full-matrix least-squares techniques (use of F magnitude; x, y, z, β_{ij} for I, Mo, P, O and C atoms and x, y, z fixed for hydrogen atoms; 611 variables

and 3415 observations; $w = 1/\sigma^2(F_o) = [\sigma^2(I) + (0.04F_o^2)^2]^{-1/2}$) with the resulting $R = 0.031$ and $R_w = 0.029$ and $S_w = 1.32$ (residual $\Delta\rho < 0.32$ e Å^{-3}). The scattering factors were taken from the International Tables.[14] All calculations were made with the MolEN program[13b] using a Digital MicroVAX 3100 computer.

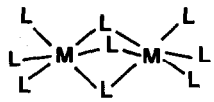
Computational details for MO calculations

All the calculations were made within the extended Hückel formalism,[15] using the weighted H_{ij} formula.[16] The atomic parameters, listed in Table 1, are taken from the literature.[17] A double-ζ expansion was used for the metallic 4*d* AOs. The molecular structures of the models used in the calculations are derived from the averaged idealized experimental structure of **1** with the following bond distances in Å (unless specified in the text): Mo—Mo = 2.56; Mo=O = 1.68; Mo—OPH_3 = 2.19; Mo—O(bridge) = 1.93; Mo—I = 2.77; P—O = 1.49; P—H = 1.42; O—H = 0.96. The C_s symmetry was assumed for **2**, **2′**, **3** and **4**, and the C_{2v} symmetry for **5** and **6**.

RESULTS AND DISCUSSION

Preparation and crystal structure

Reaction of $Et_4N[MoOI_4(H_2O)]$ with 2 mole equivalents of L = $OPPh_3$ in acetonitrile at room temperature quickly resulted in the precipitation of a purple compound. The resulting filtrate, kept under nitrogen at −20°C, slowly gave reproducible reddish microcrystals of complex **1**. The purple compound, formed in *ca* 65% yield, analysed as $[MoOI_3L_2]$ and seemed likely to be a pseudo-octahedral mononuclear oxomolybdenum(V) complex [ν(MoO) = 970 cm^{-1}]. Elemental analyses for complex **1**, which indicated an unusual L/Mo ratio of 3/2, were in agreement with the $[Mo_2O_4I_2L_3]$ stoichiometry, i.e. with the presence of nine ligands for two metallic centres. For such a stoichiometry, and since examples of $OAsPh_3$ bridging ligands have been unambiguously found,[18] the symmetrical confacial bioctahedral structure shown below, in which



the ligand atoms define two octahedra with a common face, as in $[Mo_2Cl_9]^{3-}$ and various other molybdenum complexes,[2,9,19] was possible. However, since a careful examination of the IR spectra showed two absorptions assignable to ν(MoO) (975 and 940 cm^{-1}), in disagreement with such a symmetrical structure, a single-crystal structure determination for complex **1** was performed. This study unequivocally shows that **1** may be formulated as an unsymmetrical dinuclear oxomolybdenum complex (Figs 1 and 2). While the discrete dimeric molecule possesses no crystallographically imposed geometry, it has virtual C_s symmetry with the mirror plane encompassing the two molybdenum and the two terminal oxygen atoms, as well as the oxygen atom O(5) of one of the triphenylphosphine oxide ligands.

The main structural features shown by the structure determination (Figs 1 and 2; Table 2) are the following: (1) the three phosphorus ligands are bound to the first molybdenum atom Mo(1), while the two iodo ligands are coordinated to the second molybdenum atom Mo(2); (2) each metal atom is bound to a terminal oxygen atom [Mo(1)—O(2) = 1.692(8); Mo(2)—O(7) = 1.677(8) Å], in

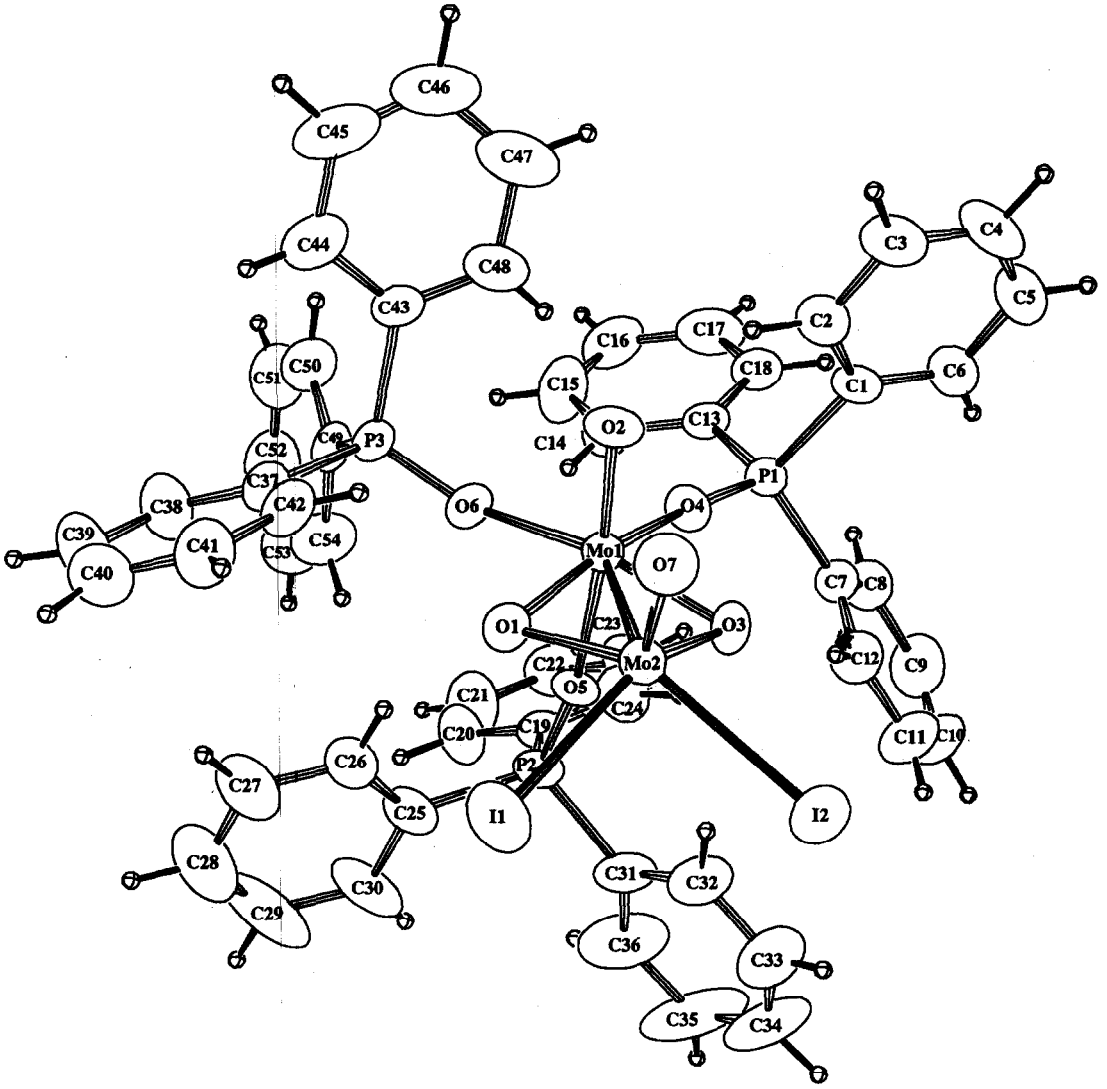


Fig. 1. Structure and labelling of the $[Mo_2O_4I_2L_3]$ complex **1** (L = $OPPh_3$).

agreement with the IR spectra, and also to two bridging oxygen atoms; and (3) the Mo_2O_2 central fragment appears puckered and slightly unsymmetric [Mo(1)—O(1) = 1.888(5); Mo(1)—O(3) = 1.919(5); Mo(2)—O(1) = 1.950(5); Mo(2)—O(3) = 1.956(5) Å] with a short Mo(1)—Mo(2) distance [2.557(1) Å], indicating a single metal–metal bond. Disregarding the metal–metal bond, (1) Mo(1) presents a distorted octahedral MoO_6 coordination with an O(1)O(3)O(4)O(6) fragment planar within ±0.0007 Å and with the metal atom displaced by 0.321 Å from this mean plane, and (2) Mo(2) has a *cis*-$MoOO_2I_2$ square pyramidal coordination with an O(1)O(3)I(1)I(2) fragment planar within ±0.004 Å and the metal atom displaced by 0.646 Å from this mean plane.

It is noteworthy that the terminal oxo groups are located in a *cis* arrangement (*vide infra*) and that, as expected, the terminal oxo group on Mo(1) exerts a *trans* influence on Mo—O(P) bond lengths [2.241(7) for the phosphorus ligand *trans* to the terminal oxo ligand vs 2.155(5) and 2.182(5) Å for the phosphorus ligands *trans* to oxo bridges].

The main structural features of the di-μ-oxo complex **1**, $[X_2MoO(\mu\text{-}O)_2MoOL_3]$, with X = I and L = $OPPh_3$, are similar to those of the recently reported di-μ-sulphido complex $[X_2MoO(\mu\text{-}S)_2MoOL_3]$, with $X_2 = S_2$ and L = DMF.[20]

Theoretical calculations

A question which arises from the dissymmetry of the dinuclear complex **1** concerns the nature of its metal–metal bond: can it be considered as a simple

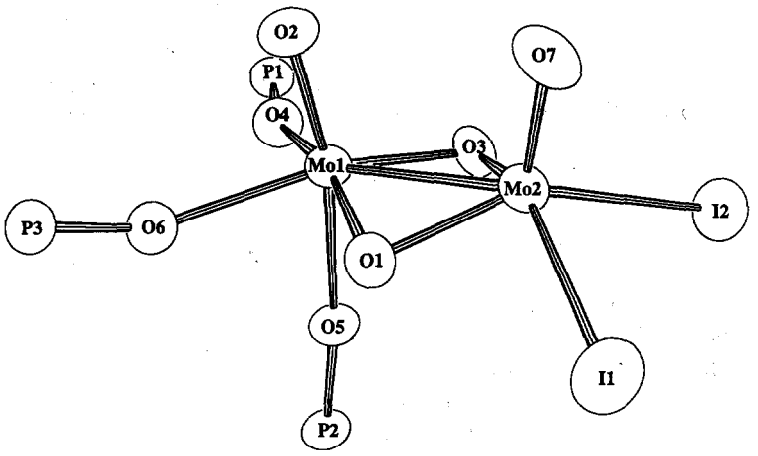

Fig. 2. The $Mo_2O_7I_2$ central unit of the $[Mo_2O_4I_2L_3]$ complex **1** (L = $OPPh_3$).

covalent bond between two Mo^V atoms, or is it better viewed as a dative bond from an Mo^{IV} to an Mo^{VI} centre? In order to answer this question, to understand the general structural features of **I** and to explore the reactivity of the Mo—Mo bond, we have undertaken extended Hückel calculations on the model $Mo_2O_4I_2(OPH_3)_3$ (**2**), the structure of which is derived from the averaged experimental structure of **1**. Other related models were also investigated (*vide infra*). All the structural and computational details are given in the experimental section.

(a) *The nature of the* Mo—Mo *bond.* Conceptually, one can consider the Mo—Mo bonding in

Table 2. Interatomic distances (Å) and bond angles (°) in **1**[a]

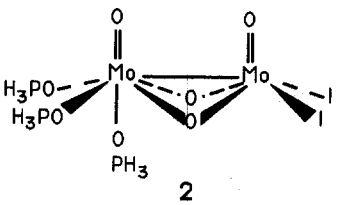
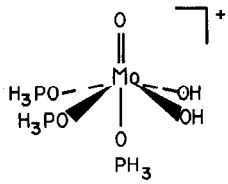
[a] Numbers in parentheses are estimated standard deviations in the least significant digits.

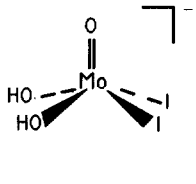


2

2 as resulting from the interaction between two mononuclear units, namely the six-coordinated $MoO(OPH_3)_3(1/2O)_2$ and the five-coordinated $MoOI_2(1/2O)_2$ fragments. Before entering into the bonding analysis of **2**, we shall start by discussing the electronic structure of these two mononuclear subunits. In order to avoid π-type interactions which are not present in the dinuclear species hydrogen atoms have been placed on the two oxygen atoms which are bridging in **2**. The two resulting models considered in the calculations, $[MoO(OPH_3)_3(OH)_2]^+$ and $[MoOI_2(OH)_2]^-$, are shown in **3** and **4**, respectively. Their charges have been chosen in order to have arbitrary Mo^V (d^1) oxidation states on both units.



3



4

To understand simply the MO pattern of fragment **3**, shown on the left-hand side of Fig. 3, it is useful to consider it as a distorted octahedron, i.e. as being, at a zero-order approximation, structurally related to the class of ML_6 complexes of O_h symmetry. It exhibits the general 4*d* splitting of a

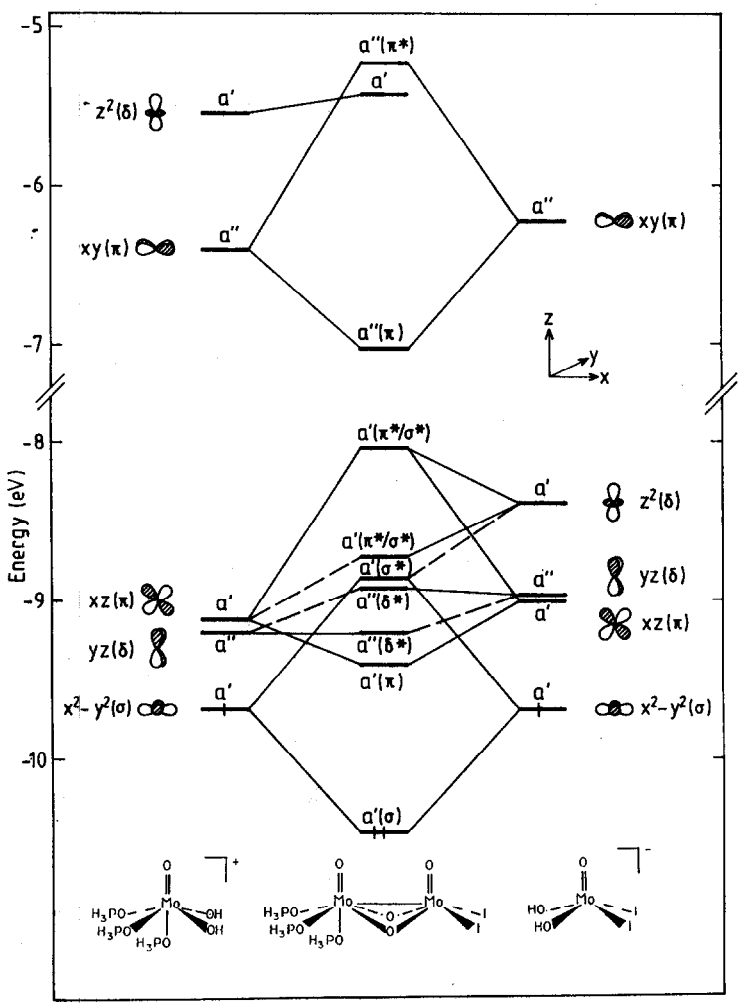


Fig. 3. The metallic MO diagram of the dinuclear compound **2**, based on the interaction of the two mononuclear units **3** and **4**.

group of three low-lying orbitals, the "t_{2g}" set (xz, yz and x^2-y^2 in our coordinate system), lying below two antibonding "e_g" orbitals (xy, z^2). However, one can see that the degeneracy inside each of the so-called "t_{2g}" and "e_g" groups of levels is far from being reached for **3**. This level splitting is principally due to the presence of a metal-oxo formal double bond, which reduces the O_h pseudo-symmetry to four-fold (C_{4v}) pseudo-symmetry. The shorter Mo=O bond induces a destabilization of the metallic levels, which have the proper symmetry to interact with the apical oxo ligand AOs. Indeed, the overlap between the atomic orbitals of the molybdenum and the apical oxygen is larger. As a result, the apical oxygen AOs are stabilized, while their molybdenum counterpart 4*d* AOs are destabilized, becoming somewhat antibonding. This effect is particularly noticeable for the z^2 level, which is much more destabilized by the σ-oxo lone pair than the other component of the "e_g" group (the xy level) by the lone pairs of the equatorial ligands. A similar but weaker destabilization is afforded by the xz and yz MOs, due to their interaction with the π-type oxo lone pairs. This π-type interaction, which splits the "t_{2g}" group, is responsible for the existence of the Mo=O formal double bond.

Another distortion from ideal O_h symmetry is present in fragment **3** (as well as in **1**). The molybdenum atom does not lie exactly in the plane of the four equatorial oxygen atoms, but slightly above, on the same side as the doubly bonded oxygen (*vide supra*). This distortion allows the xz and yz metallic orbitals to mix in a bonding way with the occupied metal–ligand bonding MOs of the same e pseudo-symmetry (assuming a near C_{4v} symmetry group). These levels, which have some molybdenum x and y character, are stabilized upon hybridation with the xz and yz AOs. This interaction, which is not possible when the molybdenum valence bond angles are equal to 90°, contributes to the destabilization of the empty xz and yz levels.

From the above analysis it results that the lowest 4*d* level in **3** is of x^2-y^2 dominant character. This MO, situated at −9.69 eV, has a large metallic character (93%) and is the frontier orbital which will be involved in the building of the Mo—Mo bond in the dinuclear species.

The MO diagram of fragment **4**, shown on the right-hand side of Fig. 3, can be understood in the same way as that used for fragment **3**. At the zero-order approximation it can be considered as belonging to the class of pseudo-octahedral ML_5 units, i.e. deriving from an O_h ML_6 complex by the removal of one ligand. The ordering of the metallic levels in such a fragment is well known.[21] There is a block of three low-lying levels derived from the t_{2g} set of the octahedron, lying below a hybridized z^2-type level which is antibonding with respect to the apical ligand. Significantly above this z^2 level, there is an in-plane antibonding level (xy in our coordinate system).[21] The presence of the metal–oxo double bond slightly perturbes this general MO pattern. The z^2 level appears more antibonding than usually found in related pseudo-octahedral ML_5 fragments because of the dominant interaction with the oxo atom; nevertheless, it remains far below the xy level which is antibonding on four Mo—L bonds. As found for **3**, the oxo π-type lone pairs split the "t_{2g}" set by destabilizing the xz and yz MOs. Similarly, the position of the metal atom above the plane of the equatorial ligands reinforces the four equatorial Mo—L bonds and contributes to the destabilization of the xz and yz levels. As a result, and as for **3**, the lowest metallic level, situated at −9.69 eV, is of x^2-y^2 parentage. Its localization on the metal atom is large (90%). This level can be identified as being the σ-type frontier orbital of **4** responsible for the Mo—Mo bond in the dinuclear species. From the comparison of the nature, energy and occupation of the σ-type frontier orbitals of the two Mo^V units **3** and **4**, it can be concluded that these two units have the same bonding properties and can be considered as being isolobal.[21]

The MO diagram for **2** is represented in the middle of Fig. 3, where it can be seen that each mononuclear level generates in **2** a pair of in-phase and out-of-phase combinations. Although the low symmetry (C_s) of **2** allows some $\sigma/\pi/\delta$ mixing, its HOMO can be clearly identified as being the bonding combination of the x^2-y^2 σ-type frontier orbitals of fragments **3** and **4**. Since these two frontier orbitals are very similar in energy and composition the HOMO of **2** is symmetrically distributed on both metal atoms (46% on the six-coordinated molybdenum and 43% on five-coordinated). A plot of this HOMO is shown in Fig. 4. The Mo—Mo bonding overlap population in this MO is large (0.169), reflecting a strong σ-bond. This value is very close to the total Mo—Mo overlap population (0.173), indicating that the HOMO is the only occupied level of significant metal–metal bonding character. Since the Mo—Mo bonding electron pair is equally shared by the metal atoms, complex **2** can be considered without any ambiguity as an Mo^V–Mo^V compound. However, it should be noted that the net atomic charges of the molybdenum atoms are not strictly equal. They are 2.96 for the six-coordinated atom and 2.48 for five-coordinated. In fact, this difference does not reflect any significant electron transfer between the metal atoms, but different metal–ligand charge polarization inside the mononuclear units. Indeed, the

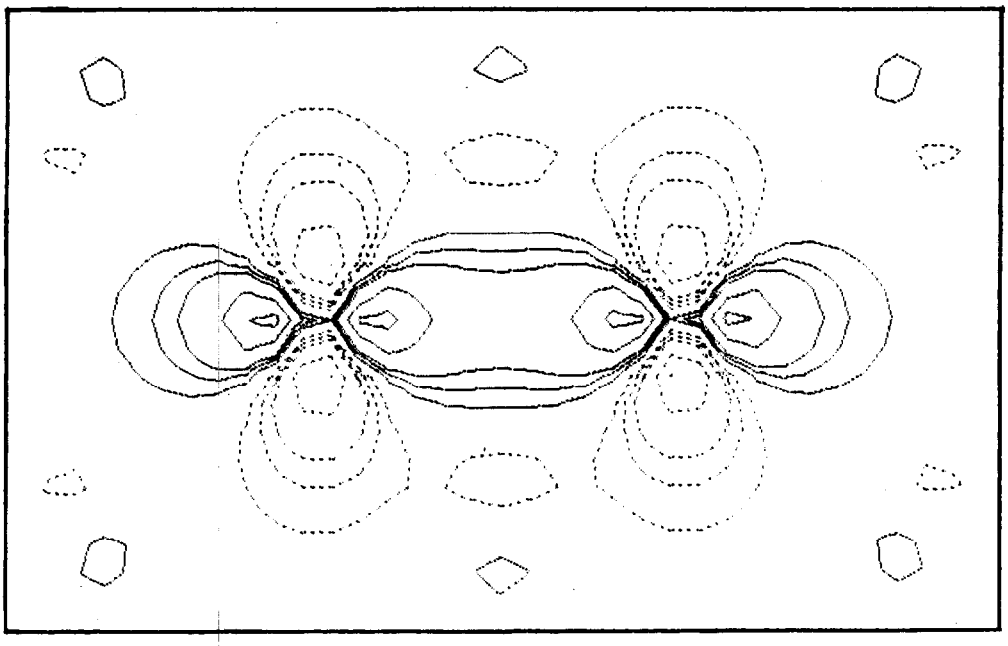

Fig. 4. Contour plots of the HOMO of **2**.

molybdenum net charges calculated for the monomers **3** and **4** (i.e. before the making of the Mo—Mo bond) are very close that found in **2** (3.05 and 2.59, respectively).

The calculated HOMO/LUMO gap is 1.06 eV. This is a rather large value, in full agreement with the stability, colour and diamagnetism of **1**. The LUMO is plotted in Fig. 5. It is a π-type bonding orbital, derived from the xz mononuclear levels. Due to some σ-type molybdenum atomic orbital

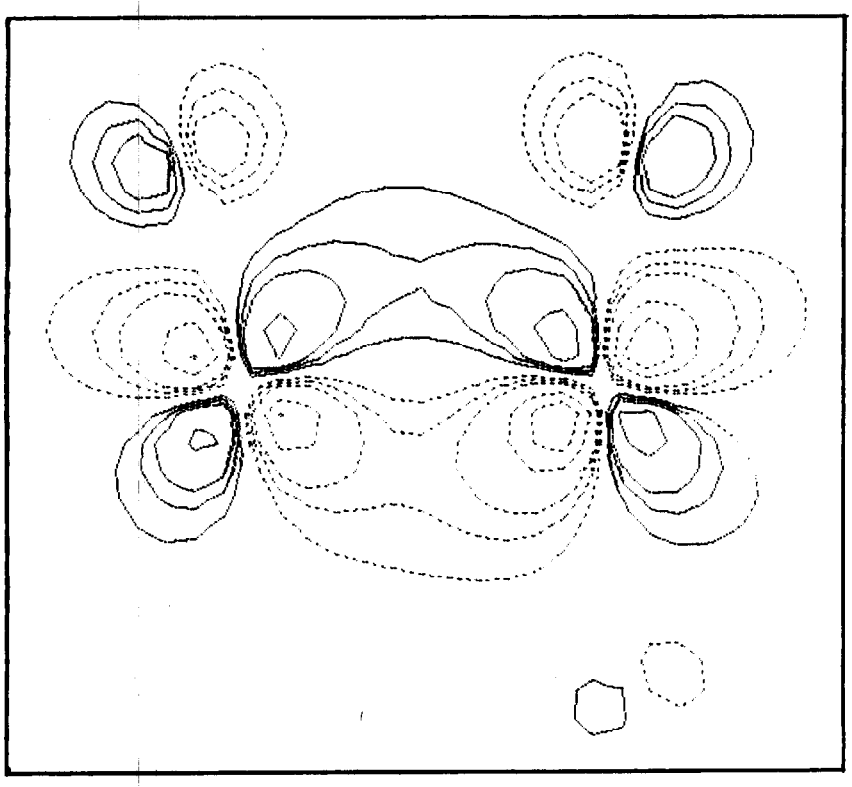

Fig. 5. Contour plots of the LUMO of **2**.

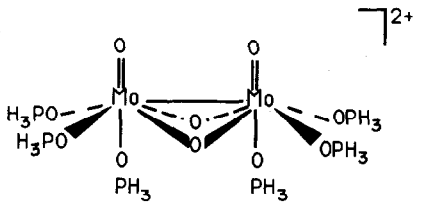
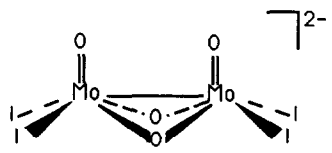
admixture, this level is strongly bonding, as shown in its Mo—Mo overlap population (0.164). Therefore, the reduction of **1** is expected to cause a significant shortening of the Mo—Mo bond.

Another way to show that fragments **3** and **4** have similar bonding abilities is to perform calculations on the hypothetical symmetrical d^1–d^1 dinuclear species **5** and **6**, the structures of which are generated by duplication of **3** and **4**, respectively, with the same metal–ligand environment and the same Mo—Mo bond distance (2.56 Å) as in **2**. Therefore, **5** and **6** can be considered as prototypical models for a number of symmetrical Mo^V μ-oxo dinuclear compounds.[2] Their MO diagrams appear to be very similar to that of **2**, with a σ(Mo—Mo) HOMO and a π(Mo—Mo) LUMO. The HOMO/LUMO gap is 0.99 and 1.14 eV for **5** and **6**, respectively. The Mo—Mo overlap populations in the HOMO are 0.164 and 0.168, respectively. These values compare well with the corresponding values found in **2**. The calculations on **2**, **5** and **6** are in qualitative agreement with previous calculations on related μ-oxo and μ-sulphido molybdenum(V) dinuclear complexes.[22]

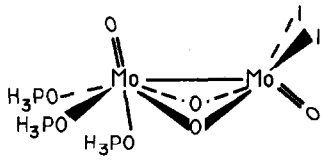


5



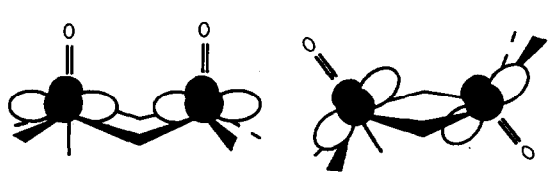
6

(b) Cis/trans *isomerism in dibridged* Mo^V–Mo^V *complexes*. At this stage of the discussion, it is interesting to consider the possibility of the existence of a *trans* isomer of **2**, namely **2′**. It should be noted that most of the dibridged dimolybdenum(V) compounds with an Mo_2O_2 core have been characterized as having the *cis* conformation and only a few examples of *trans* conformers exist.[2] It has been shown by Wieghardt and co-workers,[23] who have structurally characterized two conformers, that the environment of the molybdenum atoms is the same in both isomers. The only significant difference lies in the structure of the Mo_2O_2 ring, which is puckered in the *cis* isomer and planar in the *trans* form.



2′

The structure of **2′** has been modelled using exactly the same metal–ligand environment as in **2**. Keeping this environment frozen, the puckering (and, therefore, the Mo—Mo distance) of the Mo_2O_2 butterfly has been varied. The lowest energy was found for the puckering shown in the diagram of **2′**, the bending angle (Mo—Mo—middle of the O···O vector) is small (10°) and the Mo—Mo distance is 2.61 Å. The energy difference between this energy minimum and the structure corresponding to a planar Mo_2O_2 core is very small (0.02 eV), a value not significant at our level of calculations. The optimized structure of **2′** is found to be less stable than its *cis* conformer **2** by 0.4 eV. Consistently, the Mo—Mo overlap population is lower (0.154). This conformational preference for the *cis* structure can be easily understood if it is assumed that it is driven by the Mo—Mo interaction, i.e. by the overlap between the two σ-type frontier orbitals of the mononuclear units. In the *cis* conformation, the maximum overlap can be reached for the puckered structure which allows both overlapping lobes to be lined up with the Mo—Mo vector, as shown in **7a**. This ideal σ-type overlap cannot be reached for the *trans* conformation, which provides its best (but not so strong) overlap when the Mo_2O_2 core is planar, as shown in **7b**. In that situation, both overlapping lobes are parallel, but not lined up. The fact that the calculations on **2′** very slightly favour a puckered structure arises from some participation of the z^2-type level of the five-coordinated molybdenum atom (see Fig. 3). Indeed, when the Mo_2O_2 core is bent this MO can to a degree overlap and consequently mixes in a bonding fashion with the occupied σ(Mo—Mo) bonding orbital. This mixing is disfavoured when the puckering is made in the other direction. Moreover, steric repulsion between ligands occurs also in that case, causing this puckering to be significantly disfavoured.



7a **7b**

In the absence of steric hindrance, the above results can be generalized to the whole series of

dibridged dimolybdenum(V) compounds with an Mo_2O_2 core. Thus, the preference for the *cis* conformation is rationalized on the basis that this geometry allows a stronger Mo—Mo σ-bond.

(c) MO *investigations of the reactivity of the metal–metal bond in* **1**. In order to model the reactivity of the metal–metal bond of **1** toward acids we have undertaken calculations on the $[2+H^+]$ system, with the proton attacking at different sites. At our level of calculations (which does not consider ionic interactions) the attack of the Mo—Mo bond does not appear strongly disfavoured with respect to attack on oxygen or iodine atoms. The more attractive approach of the bond is when H^+ attacks on the same side as the terminal oxo ligands. The proton 1*s* AO interacts mainly with the HOMO and the LUMO of **2**, so that the $[2+H^+]$ system can be considered as a two-electron three-orbital system. When the Mo—H distances are set to 1.8 Å, the occupation of these two metallic orbitals in the $[2+H^+]$ system is 0.30 and 0.96, respectively. The Mo—H overlap populations are 0.190 for the six-coordinated molybdenum atom and 0.262 for the five-coordinated one. These values indicate a strong bonding interaction. The presence of the bridging proton considerably reduces the Mo—Mo overlap population (0.057), suggesting that the attack of the Mo—Mo bond by H^+ would ultimately lead to the formation of mononuclear species.

Replacing H^+ by H^- provides us with the opportunity to model the reactivity of **1** with respect to a nucleophilic attack. The best site of attack for **2** is found to be the vacant site on the five-coordinated molybdenum atom. Indeed, the unoccupied z^2-type MO of this metal atom (Fig. 3) can overlap significantly with the nucleophile lone pair. The attack of the Mo—Mo bond is found repulsive. This result suggests that a hydride attack of the Mo—Mo bond would better lead to electron transfer rather than to Mo—H bond formation. Indeed, the reduction of **2** is expected to reinforce the metal–metal bond by occupying the Mo—Mo π-bonding LUMO (*vide supra*).

COMPLEXES OF YTTRIUM AND LANTHANIDE NITRATES WITH 4-N-(4′-ANTIPYRYLMETHYLIDENE)AMINOANTIPYRINE

M. K. MURALEEDHARAN NAIR and P. K. RADHAKRISHNAN†

School of Chemical Sciences, Mahatma Gandhi University, Ettumanoor, Kottayam, Kerala 686 631, India

(*Received* 4 *November* 1992; *accepted* 7 *January* 1993)

Abstract—Yttrium and lanthanide nitrate complexes with the Schiff base 4-N-(4′-antipyrylmethylidene)aminoantipyrine (AA) of the composition of $[Ln(AA)_2(NO_3)_2]NO_3$ (where Ln = Y, La, Pr, Nd, Sm, Eu, Gd, Dy, Ho and Er) have been synthesized and characterized by elemental analyses, electrical conductance in non-aqueous solvents, magnetic susceptibility measurements, IR, electronic and proton NMR spectra and thermogravimetric analyses. The Schiff base AA acts as a tridentate ligand in all these complexes, coordinating through the oxygens of both carbonyl groups and the azomethine nitrogen. Only two of the nitrate ions are coordinated monodentately to the central metal ion, while the third remains uncoordinated.

As part of our studies on the Schiff base complexes of yttrium and the lanthanides[1–4] a new series of complexes of the nitrates with AA were synthesized and characterized. The present complexes includes Y^{III} and the lanthanides La^{III}, Pr^{III}, Nd^{III}, Sm^{III}, Eu^{III}, Gd^{III}, Dy^{III}, Ho^{III} and Er^{III}. The ligand possessing two antipyrine groups and an azomethine group may act as a terdentate ligand, forming two chelate rings imparting considerable stability for the resulting complexes. Also, the Schiff base being an antipyrine derivative possessing antibacterial and anti-inflammatory properties,[5] the complexes would be expected to be of physiological importance.

EXPERIMENTAL

Reagents

The Schiff base AA was prepared from 4-aminoantipyrine and 4-antipyrine carboxaldehyde by condensation in ethanolic medium. The nitrates of Y, La, Pr, Nd, Sm, Eu, Gd, Dy, Ho and Er were prepared as reported previously.[3]

Preparation and analysis of the complexes

Solutions of the Schiff base (2.5 mmol) in acetonitrile (100 cm^3) and the metal nitrate (1 mmol) in acetonitrile (20 cm^3) were mixed and refluxed for *ca* 2 h. The resulting mixture was cooled, filtered and evaporated to dryness. The residue obtained was repeatedly washed with hot chloroform to remove excess ligand and finally recrystallized from methanol. The purified complexes were dried *in vacuo* over phosphorus(V) oxide and were analysed for metal content by conventional methods.[6]

Measurements

Molar conductivities of the complexes in DMF and methanol (*ca* 10^{-3} M solution) were measured at room temperature using a Toshniwal conductivity bridge with a dip-type conductance cell and platinum electrode (cell constant = 0.9588 cm^{-1}). Elemental analyses were obtained with a Heraeus CHNO rapid analyser. The IR spectra of the ligand and complexes were recorded in the range 4000–400 cm^{-1} on a Shimadzu IR-470 spectrophotometer using the KBr disc technique. Electronic spectra of the ligand and complexes in acetonitrile (10^{-4} M solution) were recorded in the 200–1100 nm range on a Shimadzu UV-160A spectro-

† Author to whom correspondence should be addressed.

photometer. Proton NMR spectral studies were performed using an NMR-GSX-400 instrument. Thermal studies were performed on a Shimadzu DT-40 thermal analyser (sample: 10 mg; heating rate: 10°C min^{-1}; atmosphere: nitrogen). Magnetic moments were measured at room temperature by the Gouy method using mercury(II) tetrathiocyanatocobaltate(II) as the calibrant.

RESULTS AND DISCUSSION

The analytical data (Table 1) indicate that all the complexes have the general formula $Ln(AA)_2(NO_3)_3$, where Ln = Y, La, Pr, Nd, Sm, Eu, Gd, Dy, Ho and Er. All these complexes are soluble in acetonitrile, DMF, DMSO, ethanol and methanol and insoluble in acetone, benzene, chloroform, ethyl acetate and toluene.

Electrical conductance

The molar conductance data of the complexes are presented in Table 1. The conductance values in DMF and methanol are in the range expected for 1 : 1 electrolytes.[7] Hence, the present complexes may be formulated as $[Ln(AA)_2(NO_3)_2]NO_3$.

Magnetic behaviour

The magnetic susceptibility data given in Table 1 show that all complexes, except those of Y and La, are paramagnetic, as expected. The measured magnetic moments of the complexes agree well with the theoretical values calculated from the Van Vleck formula,[8] which suggest that the 4*f* electrons play a negligible role in bonding.

IR spectra

The important IR frequencies of the Schiff base ligand and the complexes are presented in Table 2. The strong band at 1658 cm^{-1}, due to ν(C=O) in AA, is shifted to 1625 cm^{-1} in the complexes, suggesting that both carbonyl oxygens are coordinated.[4] The IR spectrum of the Schiff base shows a strong band at 1596 cm^{-1}, attributable to the C=N stretching vibration. On complexation this band shifts to the 1586 cm^{-1} region, showing that the nitrogen of the azomethine group is also coordinated to the metal ion.[4] The spectra of the complexes show three bands at *ca* 1425, 1382 and 1320 cm^{-1}, which are not present in the spectrum of AA. These bands are assigned to ν_4(coordinated),

s = strong; m = medium; w = weak.

ν_3(uncoordinated) and ν_1(coordinated) vibrations of the nitrate groups.[9] The magnitude of $\nu_4-\nu_1$ is 105 cm^{-1}, indicating that the nitrate ions are coordinated in a monodentate fashion.[10] This conforms with the conductance data, which shows that only two of the nitrate groups are coordinated. The ν(M—O) and ν(M—N) stretching vibrations are observed at *ca* 540 and 460 cm^{-1}, respectively, in the spectra of the complexes.[11]

Proton NMR spectra

The proton NMR spectrum of the ligand AA shows the —CH=N— proton resonance at 8.35δ and it is shifted to 8.6 and 8.45δ in the yttrium and lanthanum complexes, respectively, with respect to TMS, suggesting coordination of the azomethine nitrogen.[12] The spectra of the ligand and its complexes show the following bands: phenyl multiplet

Table 3. Important *f–f* bands and their tentative assignments

Complex	Band (nm)	Tentative assignments	Covalency parameters calculated
Pr	446	$^3H_4 \rightarrow {}^3P_2$	$\beta = 0.9963$
	471	$^3H_4 \rightarrow {}^3P_1$	$\delta = 0.3714$
	485	$^3H_4 \rightarrow {}^3P_0$	$b^{1/2} = 0.0304$
	592	$^3H_4 \rightarrow {}^1D_2$	$\eta = 0.0019$
Nd	513	$^4I_{9/2} \rightarrow {}^2G_{9/2}$	$\beta = 0.9961$
	525	$^4I_{9/2} \rightarrow {}^2G_{7/2}$	$\delta = 0.3915$
	581	$^4I_{9/2} \rightarrow {}^4G_{5/2}, {}^2G_{7/2}$	
	682	$^4I_{9/2} \rightarrow {}^4F_{9/2}$	$b^{1/2} = 0.0312$
	745	$^4I_{9/2} \rightarrow {}^4F_{7/2}$	$\eta = 0.0020$
	800	$^4I_{9/2} \rightarrow {}^4F_{5/2}$	
	872	$^4I_{9/2} \rightarrow {}^4F_{3/2}$	
Ho	451	$^5I_8 \rightarrow {}^5G_5$	$\beta = 0.9966$
	538	$^5I_8 \rightarrow {}^5S_2, {}^5S_4$	$\delta = 0.3412$
	645	$^5I_8 \rightarrow {}^5F_5$	$b^{1/2} = 0.0292$
			$\eta = 0.0017$
Er	521	$^5I_{15/2} \rightarrow {}^2H_{11/2}$	$\beta = 0.9972$
	543	$^5I_{15/2} \rightarrow {}^5S_{3/2}$	$\delta = 0.2808$
	653	$^4I_{15/2} \rightarrow {}^4F_{9/2}$	$b^{1/2} = 0.0265$
			$\eta = 0.0014$

at 7.52δ, =C—CH_3 at 2.5δ and —N—CH_3 at 2.7 and 3.35δ.

Electronic spectra

The electronic spectrum of the ligand shows the following maxima: $n \rightarrow \pi^*$ transition at 347.9 nm and $\pi \rightarrow \pi^*$ at 247 nm. In the complexes the $n \rightarrow \pi^*$ band is red-shifted to 345–342 nm and $\pi \rightarrow \pi^*$ to 227–222 nm, respectively. The complexes of Pr, Nd, Ho and Er show *f–f* bands, the tentative assignments of which are given[13,14] in Table 3. The inter-electronic repulsion parameter (β), percentage covalency (δ), the bonding parameter ($b^{1/2}$) and the covalency angular overlap parameter (η) calculated[13] for these complexes are also included in Table 3. The values of β are found to be less than unity and also $b^{1/2}$ and η are positive, suggesting covalency in the metal–ligand bonding. The "δ" values less than 1.5 in all these complexes indicate weak covalent character in the metal–ligand bond. Also, from the shape of the hypersensitive $^4I_{9/2} \rightarrow {}^2G_{5/2}$, $^2G_{7/2}$ transition of Nd^{III}, a coordination number of eight may be assigned[14] to the complex $[Nd(AA)_2(NO_3)_2]NO_3$.

Thermal behaviour

The thermogravimetric data of the complexes show that they are stable up to 220°C. The TG and DTG curves do not have stages or peaks up to 220°C, therefore, the complexes do not contain small molecules (water or solvent). The complexes undergo two-stage decomposition with DTG peaks at 275 and 330°C. The complexes undergo complete decomposition in the 800–850°C region, forming the corresponding metal oxides.

Abstract—A vanadium(V) tetramer, $[V_4O_8(CH_3O)_4(bipy)_2]$ (**1**), has been isolated from a solution of $[V^{IV}O(sal\text{-}gly)(H_2O)]$ (**2**) (sal-gly = N-salicylideneglycinate) and bipyridyl. Its structure has been determined by X-ray diffraction analysis. There is one molecule per unit cell and its centre lies at a crystallographic inversion centre. The vanadium atoms lie on the corners of a diamond-shaped planar unit and each of the two independent vanadium atoms V(1) and V(2) are octahedrally coordinated. The tetramer contains a V_4O_8 core, two μ_3-OCH_3, two CH_3O^- and two bipy ligands. The magnetic susceptibility was measured and data could be fitted to a $\chi_p = A + C/T$ function with $A = 9.087 \times 10^{-5}$ emu mol^{-1} and $C = 1.809 \times 10^{-3}$ emu K mol^{-1}.

Vanadium is receiving considerable attention as a biologically important metal since the discovery of the first two vanadoenzymes (bromoperoxidase from marine algae[1,2] and nitrogenase from *Azotobacter vinelandii*[3]). In order to understand how the uptake of vanadium from living organisms occurs and how it might function in a complex biomolecule it is necessary to study its basic coordination chemistry and the oxidation–reduction reactivity of vanadium complexes.

Polynulcear μ-oxo and μ-hydroxo vanadyl (d^0 and/or d^1) are interesting classes of compounds. Decavanadates are perhaps the best characterized and current research interest for these and other polyoxometallates has been increased due to the wide field of applications that has been found for these compounds, including analytical and clinical chemistry, catalysis, biochemistry, medicine and solid-state devices.[4,5] Other types of polyoxovanadates and their structural characteristics were also recently reviewed.[6] Mixed-valence metal oxygen clusters that exist with different electron populations are of importance for understanding electron-transfer and electron-storage systems in nature and in materials science. Mixed-valence vanadium–oxygen clusters have recently received much interest.[5,7,8] The simplest of these involve complexes with the $V_2O_3^{3+}$ unit, whose stability is now quite well established.[9–11]

Several examples of simple organic units incorporated into polyoxovanadate frameworks have

*Author to whom correspondence should be addressed.

been structurally characterized (see, e.g. refs 7, 8 and 12–18). (Alkoxo)oxovanadium complexes ("vanadate esters") are receiving increased attention, on one hand because of their potential in generating thin metal-oxide and -carbide layers by gas-phase deposition[19] and on the other because of the biological importance of vanadium ester compounds.[20] The present paper describes the synthesis, X-ray crystallographic and magnetic characterization of a vanadium tetramer containing a V_4O_8 core, two μ_3-OCH_3 ligands, two CH_3O^- and two bipy ligands.

EXPERIMENTAL

Reagents and apparatus

Reagent grade salicylaldehyde (Carlo Erba), glycine (BDH), vanadium sulphate pentahydrate (Merck), bipyridyl (Merck) and methanol (Merck) were used without further purification.

The IR spectra of KBr discs were recorded on a Perkin–Elmer 683 spectrometer and magnetic susceptibilities were measured using a Faraday balance down to 5 K.

Preparation of complex **1**

[VO(sal-gly)(H_2O)] (**2**) (0.0622 g, 0.24 mmol) was prepared by standard procedures[21,22] and dissolved in methanol (20 cm^3). Bipyridyl (0.0335 g, 0.21 mmol) was dissolved in methanol (5 cm^3) and slowly added to the solution of **2** by diffusion through a strip of filter paper until green/brownish crystals of the title compound were obtained. No recrystallization was needed. The compound is reasonably stable when exposed to the atmosphere.

X-ray crystal structure determination of complex **1**

Crystal data. $V_4O_8(CH_3O)_4(C_{10}H_8N_2)_2$, M_r = 768.27, triclinic, space group $P\bar{1}$, a = 8.1240(7), b = 9.0857(7), c = 11.1945(9) Å, α = 104.83(1), β = 105.78(1), γ = 103.78(1)°, V = 725(3) $Å^3$, Z = 1, $F(000)$ = 388, D_c = 1.76 g cm^{-3}, μ(Mo-K_α) = 2.73 cm^{-1}.

Data collection. X-ray measurements were made with an Enraf–Nonius CAD-4 diffractometer and graphite monochromatized Mo-K_α radiation (λ = 0.71069 Å). Cell dimensions were determined from the measured θ-values for 25 intense reflections with $14 \leqslant \theta \leqslant 16°$. The intensities of 4438 observations of 4347 independent reflections in the range $2.0 \leqslant \theta \leqslant 27.0°$ were measured by the ω–2θ scan mode. Data was corrected for Lorentz, polarization and absorption effects.

Structure determination and refinement. The 3679 reflections with $F_o \geqslant 3\sigma(F_o)$ were used in the structure solution and refinement. The non-hydrogen atomic positions were determined by a direct method with the SHELXS-86 program[23] and refined to convergence with anisotropic thermal motion parameters using the SHELX-76 program.[23] At this stage the positions of the hydrogen atoms were obtained from a difference-Fourier map and were included in the refinement process with isotropic thermal motion parameters. The final refinement was carried out with a weighting scheme of $w = 1/(\sigma^2(F_o)+0.0006F_o^2)$ and converged to $R(F) = 0.038$ and $R_w(F) = 0.040$ for 3783 reflections with $F_o \geqslant 2\sigma(F_o)$ and 255 refined parameters. The largest negative and positive peaks in the final difference map were 0.82 and −0.68 e $Å^{-3}$ and were located near the vanadium atoms. Data for atomic scattering factors were taken from the International Tables.[24]

Additional material is available from the Cambridge Crystallographic Data Centre, which comprises hydrogen atom coordinates, atomic thermal motion parameters, remaining bond lengths and angles and a list of observed and calculated structure factors.

RESULTS AND DISCUSSION

The solid tetramer **1** was isolated from methanolic solutions. The formation of a vanadium(V) compound may be explained by the slow diffusion of atmospheric oxygen into the solution and reaction with oxovanadium(IV).

A molecular diagram[25] presenting the numbering scheme is shown in Fig. 1; bond distances and bond angles are listed in Tables 1 and 2, respectively.

[a] Symmetry related atom by $-x, 1-y, 1-z$.

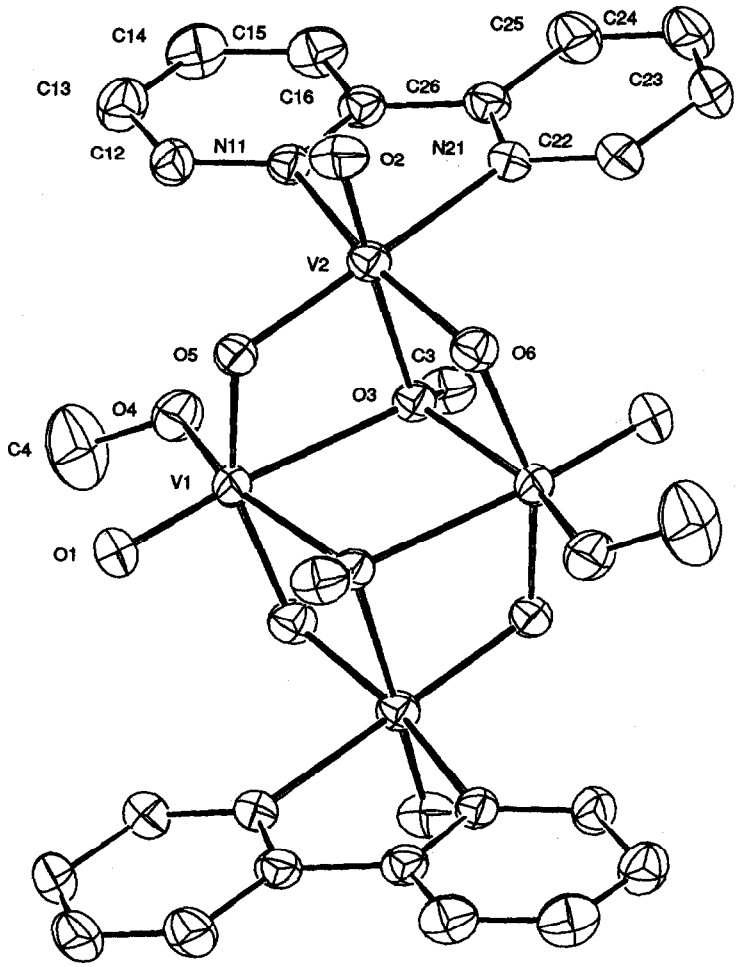

Fig. 1. ORTEP[25] diagram of $[V_4O_8(CH_3O)_4(bipy)_2]$ (1). There are two independent types of vanadium atoms: V(1) and V(2). The four vanadium atoms form a planar unit and its centre lies on a crystallographic inversion centre.

There is one molecule per unit cell and its centre lies at a crystallographic inversion centre. The vanadium atoms lie on the corners of a diamond-shaped planar unit, with nearly identical V(1)—V(2) distances [3.1212(4) and 3.1225(3) Å]. The shortest diagonal is defined by the two V(1) atoms [3.4633(4) Å] and the longest by the two V(2) atoms [5.1951(4) Å]. The μ-oxo groups are alternately above and below the plane of the four vanadium atoms (see Fig. 2) and all coordinated groups above this plane have their symmetry-related counterparts as required by the existence of an inversion centre.

Each of the two independent vanadium atoms V(1) and V(2) are octahedrally coordinated. The V(1) atom is coordinated to vanadyl oxygen (O1) [1.597(1) Å] and there are two other relatively short bonds: to the methoxy oxygen O(4) [1.802(1) Å] and to the bridging oxygen μ_2-O(5) [1.822(1) Å]. The bond distance [2.299(1) Å] between V(1) and the methoxy oxygen O(3), *trans* to the vanadyl bond, is relatively long, as expected, while the V(1)—O(3a) distance [2.039(1) Å] is again in the expected range for an oxygen atom coordinated *cis* to the vanadyl group. The V(2) atom is coordinated to the vanadyl oxygen O(2) [1.610(1) Å] and there are also two other short bonds, namely to the bridging μ_2-oxo atoms O(5) [1.818(1) Å] and O(6) [1.719(1) Å]. The bond distance between V(2) and the methoxy oxygen μ_3-O(3) [2.274(1) Å], *trans* to the vanadyl bond, is also in the expected range. The six-fold coordination of V(2) is completed by the two nitrogen atoms of the bipy moiety [V(2)—N(11), 2.189(1); V(2)—N(21), 2.168(1) Å].

The IR spectrum exhibits two bands at 940 and 955 cm^{-1}, which can be associated with ν(V=O) of the two unequivalent vanadyl groups. A band at 2800 cm^{-1} might be associated with the C—H stretching modes of the methoxy groups. The absorp-

[a] Symmetry related atom by $-x, 1-y, 1-z$.

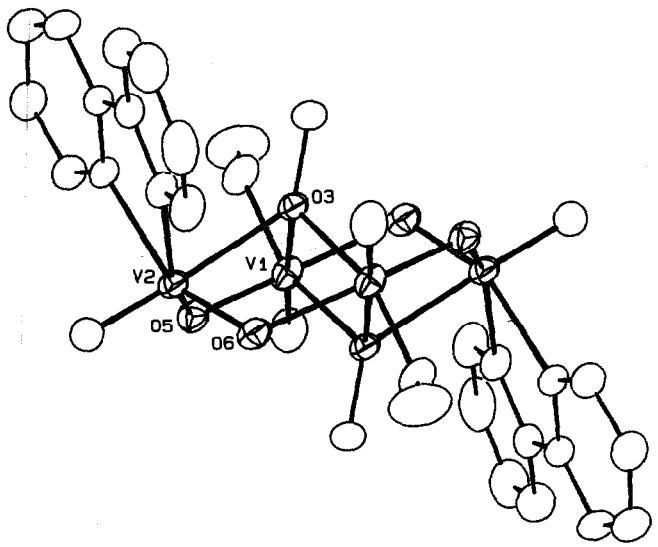

Fig. 2. ORTEP[25] diagram of **1** illustrating the bridging through oxo and alkoxo oxygen atoms and emphasizing the alternating position of the ligands above and below the plane of the four vanadium atoms.

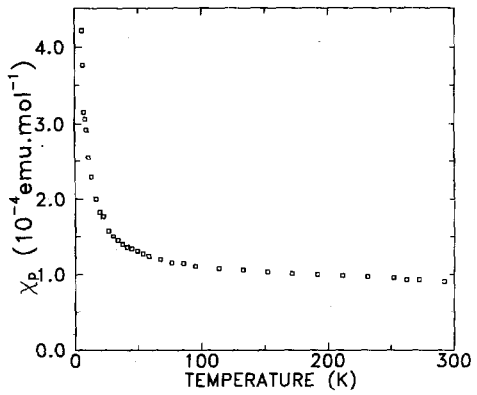

Fig. 3. Temperature dependence of the magnetic susceptibility of **1** per vanadium atom at 5 Tesla. The data were corrected from the diamagnetic contribution ($\chi_d = -9.97 \times 10^{-5}$ emu mol^{-1}).

tions in the 850–900 cm^{-1} range might be associated to bridging oxo groups, as well as some of the more sharp bands in the 650–780 cm^{-1} and 500–580 cm^{-1} range. Some of the bands observed in the 700–770 cm^{-1} range might be associated with the bipy moiety.

Having started with a vanadium(IV) compound, the possibility of tetramer **1** being a mixed-valence product existed; in this case the methoxy oxygens O(4) and/or O(4′) [or bridging oxygens O(5) and/or O(6)] would be protonated. As there is no safe way to assess this from the IR, X-ray or analytical data, the magnetic susceptibility was measured by the Faraday method at 5 Tesla between 5 and 290 K and was corrected for the diamagnetic contribution. Data in Fig. 3 can be fitted to a $\chi_p = A + C/T$ function with $A = 9.087 \times 10^{-5}$ emu mol^{-1} and $C = 1.809 \times 10^{-3}$ emu K mol^{-1}. The C term corresponds to a paramagnetic $S = 1/2$ impurity of $\sim 0.5\%$ per vanadium atom. The temperature-independent paramagnetic term A is within the values commonly found in vanadium(V) compounds (10^{-5}–10^{-4} emu mol^{-1}).[26] Therefore, tetramer **1** is definitely a vanadium(V) cluster.

The bond lengths to vanadium atoms for bridging [O(3)] and non-bridging [O(4)] methoxy oxygens are within the values found in other structurally characterized vanadium complexes (see e.g. refs 8, 12–15, 18, 20 and 27). The μ_2-(V—O) bond lengths are also within the normal range, but they are shorter for the V(2) atoms. The V—N bond lengths are of the order of magnitude (but in the higher range) of the values found in many other vanadium(IV) and (V) complexes containing the bipy moiety (see e.g. refs 28–35). The V—O bond lengths are distributed over a relatively wide range of values. The shortest bonds correspond to the four vanadyl bonds. The bonds corresponding to V—O—V (oxo) bridges lie between 1.719 and 1.822 Å and those corresponding to V—O—V (alkoxo) bridges, including the oxygens located in *trans* positions to vanadyl bonds, vary between 2.039 and 2.299 Å. The presence of differentiated V—O linkages indicates the possibility of a variety of internal vibrations, although some of them could be expected to superimpose or to fall in restricted spectral ranges, as observed.

Cyclic vanadate tetramers containing V_4O_4 rings have been structurally characterized,[16] including the *meta*-vanadates $[N(C_4H_9)_4]_3HV_4O_{12}$[36] and $[HC_4H_{11}N]_4[V_4O_{12}]$,[37] and were suggested as intermediates in water exchange and depolymerization reactions of the polyanion $V_{10}O_{28}^{6-}$,[38] as "constituents" of the decavanadate framework[39] and of clusters $[(C_4H_9)_4N]_2[V_6O_{13}\{(OCH_2)_3CR\}_2]$ (R = NO_2, CH_2OH, CH_3), $[V_6O_{11}(OH)_2\{CH_3C(CH_2O)_3\}_2]$, $[(C_4H_9)_4N]_2[V_4^{IV}V_2^{V}O_9(OH)_4\{(OCH_2)_3CCH_3\}_2]$ and $[(C_4H_9)_4N][V_6^{IV}O_7(OH)_6\{(OCH_2)_3CCH_3\}_2]\cdot 2CH_2Cl_2\cdot 0.5C_6H_5NNC_6H_5$.[18] The observation of the V_4O_4 rings for both coordination complexes and the metavanadate ion suggests that this core may have a relevant role in the chemistry of oxovanadates, and that significant variations in the structural parameters associated with the core may be tolerated.

The vanadium tetramer **1** is structurally similar to $[Mo_4O_8(OPr^i)_4(py)_4]$ (**3**), characterized by Chisholm and co-workers,[40] and to other molybdenum and tungsten compounds containing M_4O_{16} units. It also confirms Chisholm's suggestion[40] of a large class of structurally related compounds of the formula $M_4X_aY_bZ_c$, where $a+b+c = 16$, having 0–12 cluster electrons. Tetramer **1** has zero cluster electrons and to our knowledge the structure of **1** is the first of this type in vanadium chemistry; it is similar to compound **3**,[40] but the triply bridging oxygen atoms are from methoxy groups and not from oxo groups; the μ_2-(OPr^i) groups are here replaced by μ_2-oxo groups and only V(2) atoms are bonded to nitrogens.

Although [VO(sal-gly)(H_2O)] (**2**) can be used as a starting material for the preparation of several monomeric vanadium(IV) complexes,[22,41] we do not expect that we have found a useful general route to substituted vanadium(IV) and/or vanadium(V) clusters when making changes in reagents. In fact when trying the reaction with pyridine we isolated green, brown and pink complexes. The brown complex is [VO(sal-gly)($py)_2$], characterized by X-ray diffraction.[42] Elemental analyses for the pink and green products were not satisfactory, but suggest the presence of the Schiff base ligand and of water,

pyridine and eventually methanol in the compounds. When reacting [VO(sal-ala)(H_2O)] with bipy, crystals of a compound with an elemental analysis consistent with [VO(sal-ala)(bipy)] were easily obtained[43] and we are presently collecting X-ray data for this compound. Nothing similar to Chisholm's complex **3** or our tetramer **1** was isolated in these reactions.

The vanadate tetramer characterized constitutes a remarkable example of a complex containing the bipy moiety, so commonly found in vanadium(IV) and vanadium(V) complexes with known molecular structures. It also constitutes one more example of the incorporation of simple organic units into polyoxovanadate frameworks. When trying to get solids out of solutions containing vanadium salts and organic ligands this phenomenon is probably much more common than one would expect, but the difficulty in obtaining suitable crystals normally precludes their structural characterization.

(*Received* 4 *September* 1992; *accepted* 6 *January* 1993)

Abstract—The higher selectivity towards a thallium(I) ion of dibenzo-22-crown-6 (DB22C6) compared with dibenzo-18-crown-6 (DB18C6) and dibenzo-20-crown-6 (DB20C6) was investigated by ^{1}H and ^{13}C NMR spectroscopy and ^{13}C relaxation time (T_1) measurements. The results indicate that DB22C6 has a much larger cavity than the ionic radii of univalent metal ions such as thallium(I) and potassium(I). Therefore, its conformational change by complexation with the metal ions should be larger than those of DB18C6 and DB20C6, and the conformational change in DB22C6 by complexation with a potassium(I) ion is larger than with a thallium(I) ion.

Crown ethers have been extensively investigated as host compounds in host–guest chemistry and many analogues of various numbers of ring size, donor set and so on have been synthesized.[1] Since these compounds exhibit a high selectivity towards a certain metal ion or cationic compounds, their applications to analytical chemistry fields such as ion-selective electrode,[2] solvent extraction,[3] ion-pair chromatography,[4] etc. have been accomplished. In previous papers[5,6] solvent extraction and ion selective electrode studies revealed that dibenzo-22-crown-6 ether (DB22C6) exhibits higher selectivity for the thallium(I) ion than dibenzo-18-crown-6 ether (DB18C6) and dibenzo-20-crown-6 ether (DB20C6) against other univalent metal ions, such as potassium(I), sodium(I) and lithium(I), although its complexing ability is lower. In this paper we describe the conformational changes of these crown ethers caused by complexation with the above metal ions in acetonitrile-d_3, which were determined by ^{1}H and ^{13}C NMR spectroscopies. In addition, ^{13}C relaxation time (T_1) measurements were obtained to reveal the changes in molecular motion for the dibenzocrown ethers.

EXPERIMENTAL

Materials

DB22C6 and DB20C6 ethers were prepared by literature methods.[5] DB18C6 was obtained from a commercial source.

Measurements

The ^{1}H NMR, ^{13}C NMR and ^{13}C relaxation time (T_1) measurements were recorded on a Bruker CX-600 spectrometer at 600 MHz for ^{1}H and at 150 MHz for ^{13}C nuclei, using TMS as an internal standard. Each sample solution was almost saturated with the respective compounds in CD_3CN.

Metal picrates were used for complexation of the crown ethers with metal ions.

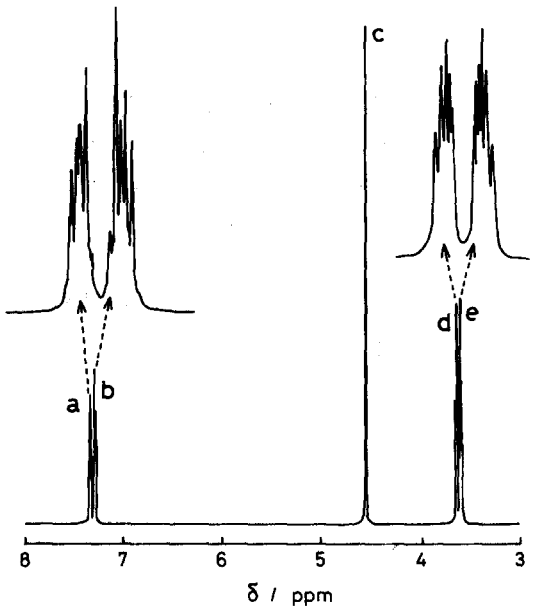

Fig. 2. ^{1}H spectrum of DB22C6 in CD_3CN.

RESULTS AND DISCUSSION

^{1}H *NMR spectra of crown ethers*

Figure 2 shows the ^{1}H NMR spectrum of DB22C6 in CD_3CN. The spectrum has four multiplet resonance peaks centred at 3.605, 3.611, 7.276 and 7.340 ppm and a singlet resonance peak at 4.632 ppm. These resonance peaks can be assigned to methylene protons (e) and (d), phenyl protons (b) and (a) and methylene protons (c) as shown in Fig. 1. Similarly the ^{1}H NMR spectra of DB18C6 and DB20C6 have four and nine resonance peaks, respectively, as shown in Table 1.

^{13}C *NMR spectra of crown ethers*

The ^{13}C NMR spectrum of DB22C6 exhibits six resonance peaks at 70.22, 70.97, 71.09, 128.09, 129.14 and 137.77 ppm due to methylene carbons (e), (d) and (c), phenyl carbons (b) and (a) and quarternary carbons (f), respectively. Similarly the ^{13}C NMR spectra of DB18C6 and DB20C6 have five and 11 resonance peaks, respectively, as shown in Table 1.

Changes in chemical shifts caused by the addition of thallium(I)

Figures 3–5 show the chemical shift changes on ^{1}H and ^{13}C NMR signals of BD18C6, DB20C6 and DB22C6 ligands caused by the addition of thallium(I) picrate, where positive and negative values represent the changes to higher and lower fields, respectively.

As shown in Fig. 3 all ^{1}H NMR signals for DB18C6 shifted to lower fields by the addition of a thallium(I) picrate and the shift values increased with increasing concentrations of thallium(I) ions. This behaviour can be interpreted in terms of a decrease in the electron density on all protons of DB18C6 by the thallium(I) ion. On the other hand the signals of (b), (c) and (e) carbons of DB18C6 are shifted to higher fields, without any significant change in (a) and (d) carbons. By the addition of thallium(I) a conformational change of DB18C6 may occur to allow coordination with the metal ion through six oxygen donor atoms of DB18C6. Thus,

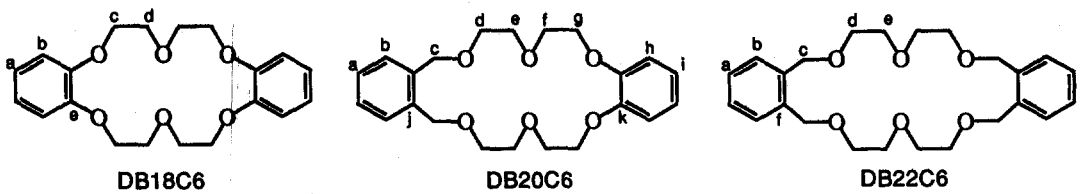

Fig. 1. Chemical structure of dibenzocrown-6-ethers.

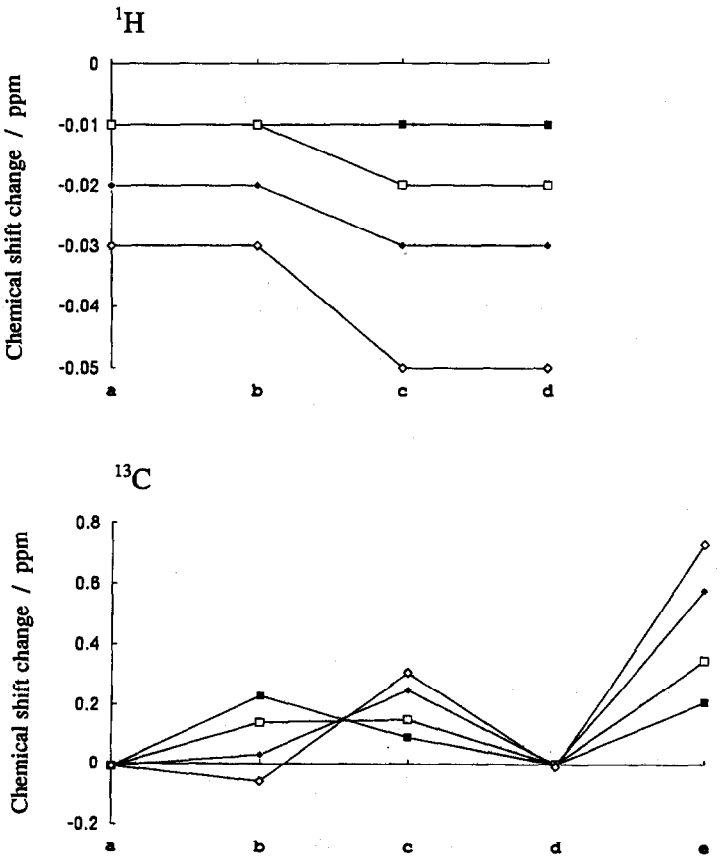

Fig. 3. Chemical shift changes of NMR signals of DB18C6 caused by the addition of thallium(I) ions. The molar ratios of thallium(I)-to-DB18C6 are 0.12 (■), 0.19 (□), 0.30 (◆) and 0.39 (◇).

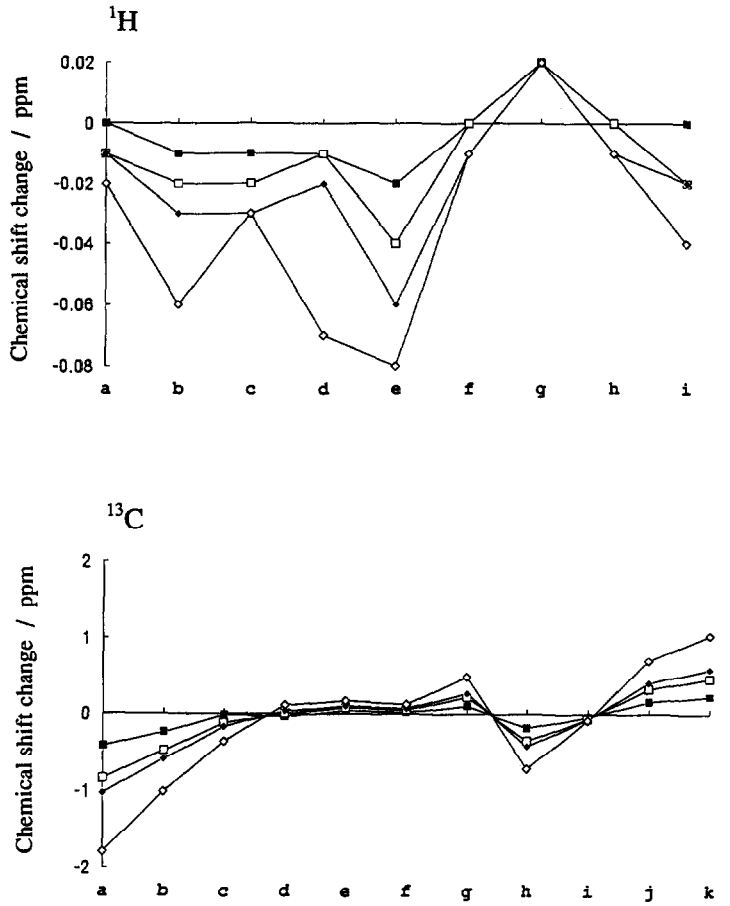

Fig. 4. Chemical shift changes of NMR signals of DB20C6 caused by the addition of thallium(I) ions. The molar ratios of thallium(I)-to-DB18C6 are 0.20 (■), 0.35 (□), 0.44 (◆) and 0.73 (◇).

the C—C and C—O bonds in the DB18C6 molecule should accept distortional stress, compared with those under the metal-free conditions which may shift ^{13}C NMR signals to higher field due to the steric compression effect,[7] especially on the quaternary (e) carbons.

As shown in Fig. 4 all ^{1}H NMR signals for DB20C6 are shifted to lower fields, except (g) protons. These shift values are similar to those observed for the DB18C6 system. However, a very different behaviour was observed for DB22C6, as shown in Fig. 5. The (a) and (c) proton signals are shifted to higher fields by 0.07 ppm at a thallium(I)-to-ligand molar ratio of 0.84; further addition of the thallium(I) salt was not possible due to its poor solubility in CD_3CN. The opposite shifts of the (a) and (c) protons, compared with DB18C6 and DB20C6, can be explained as follows. Since the cavity size of DB22C6 is much larger than the ionic radius of the thallium(I) ion, the ligand molecule must change its conformation in order to coordinate with the metal ion through the oxygen donor atoms. This conformational change may induce the rising of the (c) carbons [with (c) protons] out of the planes of the benzo groups. In such circumstances the (c) protons may suffer a reverse magnetic anisotropic effect from the benzene ring current. Thus, relatively large and higher field shifts on the (c) protons are observed. If this consideration is true a shift value for the (a) protons may reflect the extent of interaction between the metal ion and crown ethers, and a shift value for the (c) protons may reflect the extent of the conformational change of the ligand molecule.

On the other hand, higher field shifts of the (a) and (c) protons of DB22C6 were observed in complexation with potassium(I) ions; at the metal-to-ligand molar ratio of 0.81 the shift values are 0.04 and 0.09 ppm for the (a) and (c) protons, respectively. The shift value for the (c) protons is larger with potassium(I) than with the thallium(I) ion, although that for the (a) protons is smaller, which means that a larger conformational change for DB22C6 may occur in the former case.

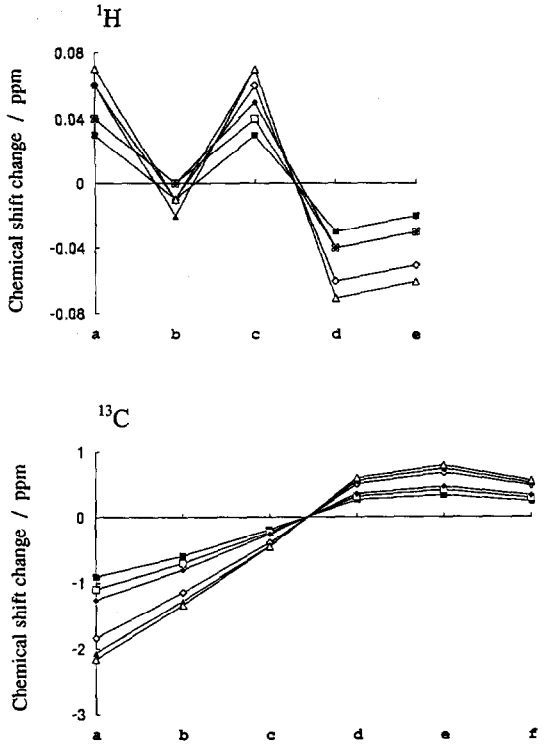

Fig. 5. Chemical shift changes of NMR signals of DB22C6 caused by the addition of thallium(I) ions. The molar ratios of thallium(I)-to-DB18C6 are 0.34 (■), 0.44 (□), 0.51 (◆), 0.72 (◇), 0.75 (▲) and 0.84 (△).

T_1 *measurements*

The T_1 measurements were obtained using the inversion recovery method for DB18C6,[8] DB20C6 and DB22C6 ligands in the presence and absence of thallium(I) in CD_3CN. The T_1 data for three systems are listed in Table 2. From these data only it is difficult to discuss intramolecular motion such as distortion of the ligand, dissociation and formation of the coordination bond between oxygen donor atoms in the ligand molecule and the thallium(I) ion, and conformational changes. However, the relative difference in intramolecular motion between DB18C6, DB20C6 and DB22C6 ligands, or between a ligand and its thallium(I) complex, can be discussed qualitatively based on T_1 data. It can be said that the larger the T_1 value for a ^{13}C atom the faster its motion becomes, if the number of hydrogen atoms bonded to the ^{13}C atom is the same.

For DB18C6 the crown ether ligand has been found to undergo intramolecular motion such as the conversion between the *syn-* and *anti-gauche* rotamers on its ethylene moieties.[9] In the presence of thallium(I) the T_1 values of all the carbon atoms of the DB18C6 molecules were found to decrease, which indicates that the ligand molecule interacts with the metal ion and its molecular motion is restricted considerably. The largest decrease in the T_1 values was observed for the (c) carbon atoms; the ratio of T_1 values on the (c) carbons for Tl^+ complex-to-uncoordinated ligand is 0.57 and those on other carbons are *ca* 0.8. The results may suggest that the oxygen donor atoms interposed between the benzene ring and (c) carbons play an important role in the complexation with metal(I) ions. For the DB20C6 ligand all the T_1 values are larger than for DB18C6, in spite of a large molecular weight. This result can be interpreted as the intramolecular motion in DB20C6, especially the conversion between *syn-* and *anti-gauche* rotamers on its

Table 2. T_1 data for DB18C6, DB20C6 and DB22C6 and their thallium(I) complexes

	DB18C6		DB20C6		DB22C6

(i)			1.9	1.4		
(j)			(8.0)	(5.6)		
(k)			(15.2)	(11.3)		

[a] Molar ratio of thallium(I)-to-ligand is 0.22.
[b] Molar ratio of thallium(I)-to-ligand is 0.63.
[c] Molar ratio of thallium(I)-to-ligand is 0.70.

ethylene moieties, becoming more vigorous due to the increase from an 18- to a 20-membered ring. The interaction of DB20C6 with the thallium(I) ion was also responsible for the decrease in T_1 values of all the carbon atoms in DB20C6, especially those of the ethylene carbons.

Similarly, as mentioned above, all the T_1 values on DB22C6 increase steadily, indicating that its intramolecular movements become most vigorous among three dibenzocrown-6-ethers. By complex formation with the thallium(I) ion each T_1 value for DB22C6 is decreased to approximately one half. Relatively large decreases in the T_1 values on (c) and (d) carbons suggest that the oxygen donor atoms interposed between (c) and (d) carbons play an important role in the complexation with metal(I) ions.

CONCLUSIONS

The results obtained from ^{1}H and ^{13}C NMR spectral data and relaxation time (T_1) measurements for DB18C6, DB20C6 and DB22C6 ligands and their thallium(I) and potassium(I) complexes may clarify the reason why DB22C6 possesses a higher ion-selectivity towards thallium(I) over potassium(I). Since DB22C6 has a much larger cavity than the ionic size of thallium(I) and potassium (I), a considerable conformational change should occur when all the six oxygen donor atoms in DB22C6 interact with the metal(I) ion; that is, DB22C6 should adopt a distorted or strained conformation. The evidence for this can be deduced from large higher field shifts on (c) protons observed only for DB22C6 among the three crown ethers. On the other hand, the effective ionic radii of six-coordinated thallium(I) and potassium(I) ions are 150 and 138 pm, respectively.[10] Therefore, when DB22C6 interacts with potassium(I) to form the complex ion it should adopt a more highly strained form than that with the thallium(I) ion. This consideration is supported by the fact that the higher field shift value for the (c) protons of DB22C6 is much larger with potassium(I) than that with thallium(I). This may be taken into account for the higher ion-selectivity of DB22C6 towards the thallium(I) ion in spite of its lower complexing ability compared with DB18C6 and DB20C6, which is revealed by the solvent extraction and ion-selective electrode studies.

Acknowledgements—The authors thank Professor Yoshikane Kawasaki of Osaka Institute of Technology for his helpful comments and discussion. The authors are also indebted to Professor E. Weber and Dr K. Stobridis of Bonn University for their invaluable assistance on the preparation of dibenzo-20-crown-6 and dibenzo-22-crown-6 ethers.

Abstract—A new synthetic route to prepare mono- and poly-tin(IV) complexes with the oxalate anion is reported. It behaves either as a mono- or bichelating terminal ligand, or as a bi- or tetra-unidentate bridging ligand, according to the experimental conditions. Possible structures for these complexes are proposed on the basis of IR and Mössbauer spectroscopic data.

The coordination ability of the oxalate anion has been widely investigated in the past. X-ray crystal structures of binuclear inorganic tin(IV) adducts with the general formula $(SnX_4)_2C_2O_4(R_4N)_2$ (X = Cl, Br, I; R = Et, Bu) have been reported[1] and a subsequent detailed spectroscopic investigation based on the X-ray results was performed.[2] Bi-, tri- and tetranuclear cobalt(III) complexes have been described[3] and some oxalate amine complexes with transition metals such as nickel(II), copper(II) and zinc(II) have also been reported.[4]

The aim of this paper, that is the continuation of our research on oxyanionic ligands,[5–7] is to describe a new and facile way to synthesize inorganic and metallorganic mono- and poly-tin(IV) adducts with the oxalate anion, to suggest possible structures on the basis of IR and Mössbauer data and to check the influence of the cation dimensions on the products.

EXPERIMENTAL

All the starting materials were used as purchased, without any further purification.

$(R_4N)_2C_2O_4 \cdot nH_2O$ (R = Me, $n = 2$; R = Et, $n = 4$) was prepared by mixing water solutions of the appropriate tetraalkyl ammonium hydroxide with oxalic acid. A white powder was obtained by solvent evaporation; it was recrystallized from absolute ethanol.

All the products were obtained in a similar way: an ethanolic solution of the appropriate oxalate was added to a solution in benzene of SnX_4 (X = Cl or Br), in ethanol of $SnPh_2Cl_2$ or in diethyl ether of $SnPh_3Br$ in the defined metal-to-ligand ratio reported in Table 1. A white solid was immediately formed; however, the suspensions were stirred for several hours. The solid was then filtered off, washed with the solvent and dried *in vacuo*.

The analytical data are reported in Table 1. Elemental analyses were performed by the analytical laboratory of the Department of Inorganic Chemistry (University of Padua, Italy) and the "Service central d'analyses", Vernaison, France. IR spectra were recorded as KBr pellets and Nujol mulls on a 580 Perkin–Elmer or a Bruker FTIR model FS 113 V spectrophotometer. Mössbauer spectra were collected in a liquid nitrogen cryostat at 80.0 K. The $Ca^{119}SnO_3$ source (15 mCi, New England Nuclear) was kept at room temperature and moved at constant acceleration with a triangular wave form. Suitable computer programs have been employed in the fitting procedure of the experimental spectra to Lorentzian line shapes by using standard least-squares computer minimization techniques.

RESULTS AND DISCUSSION

IR study

The most relevant IR absorption bands are listed in Table 2, together with their assignments. The data for compounds **5** and **6** are virtually the same as those already known[2] and so are not reported.

The tetra-halo adducts **1**, **2** and **5**, **6** present in the far-IR region three bands that are attributable to $\nu_{as}(SnX_4)$ $(A_1+B_1+B_2)$; the triplet is indicative of *cis* coordination of the halide within an octahedral environment with C_{2v} symmetry around the tin centre.[8-10] In the two pentahalo complexes **3** and **4** $\nu(SnX_5^-)$ exhibits only two absorption bands; it is important to note the constant value of the halogen shift for the two bands: $335/234 = 302/211 = 1.431$. In all the inorganic derivatives the carboxylate groups present four bands; this set is consistent with a C_{2v}, C_s or C_1 symmetry for the oxalate anion. The presence in the far-IR region of a band due to ν(SnO) indicates an oxygen coordination of the ligand.

In the spectrum of the diphenyl derivative **7** two bands, one at 1630 and the second at 1346 cm^{-1}, are due to $\nu_{as}(COO^-)$ $(B_{1u}$ and $B_{2u})$ and point to a centrosymmetrical geometry for the oxalate anion, which behaves as a bichelating oxygen-donor

ligand. On the basis of the assignments already reported for $SeO_4(Me_4N)_2 \cdot 2SnPh_2Cl_2$,[5] the bands at 316, 289 and 260 cm^{-1} have been attributed to $\nu_{as}(SnC_2)$, $\nu_{as}(SnCl_2)$ and $\nu_s(SnCl_2)$, respectively. This attribution indicates the presence of *cis* coordination geometry for $SnPh_2Cl_2$, with the phenyl groups occupying the apical positions of the octahedron.

The important role of the size of the cation is noteworthy: with large cations such as tetraethyl and tetrabutyl ammonium, the only type of adduct that was obtained with SnX_4 was $(R_4N)_2 \cdot C_2O_4 \cdot (SnX_4)_2$,[1,2] while with a smaller cation such as tetramethyl ammonium new types of adducts have been isolated: $SnX_4 \cdot C_2O_4(Me_4N)_2$ and $(SnX_5)_2 \cdot C_2O_4(Me_4N)_4 \cdot 2H_2O$. This last compound can be considered as $(SnX_4)_2 \cdot C_2O_4(Me_4N)_2$ (that has not yet been isolated probably because of the small size of the cation) reacting with two more Me_4NX molecules. The formation of R_4NX (R = Me, Et) *in situ* in a mixture of ethanolic solutions of tetraalkyl ammonium salts of oxyacids and of metal halides has been reported recently.[11]

The triphenyl compound **8** represents the first adduct of $(SnPh_3)_2C_2O_4$[7] with a polybasic anion. In fact it can be considered as the coordination of an oxalate anion to the triphenyl tin(IV) oxalate derivative. Its IR spectrum exhibits a strong absorption at 1663 cm^{-1} with shoulders at 1680 and 1655 cm^{-1}, all of which are assigned to $\nu_{as}(COO^-)$. The relative symmetric stretching can be found at 1297 and 1248 cm^{-1} with shoulders at 1262 and 1235 cm^{-1}. The presence of several bands due to these stretching vibrations is indicative of the presence of more than one type of oxalate ligand; $\nu_s(SnC_3)$ can be found as a weak band at 224 cm^{-1}, in the same position as in the $(SnPh_3)_2C_2O_4$ derivative,[7] and indicates an almost planar SnC_3 moiety, as in $(SnPh_3)_2SO_4$;[7] the weak intensity of the band is characteristic of a flat SnC_3 group.[12]

Mössbauer study

The Mössbauer effect spectral data are reported in Table 3. The parameters of compounds **1–6** are typical for inorganic tin(IV) derivatives: in fact they present a virtually zero quadrupole splitting, indicating nearly regular geometries around the tin centre. The isomer shift values for all the complexes are lower than for the respective hexahalo compounds, as a consequence of the substitution of one or two halogen atoms with the more electronegative oxygens of the oxalic anion. This effect is much more evident in the bromo than in the chloro complexes, probably because of the much larger difference in the electronegativity values. So, while δ for $SnBr_6^{2-}$ is around 0.87 mm s^{-1},[13] it decreases to 0.71 mm s^{-1} for the $SnBr_5O$ adduct (sample **4** in Table 3) and to 0.58 and 0.34 mm s^{-1} for the two $SnBr_4O_2$ derivatives (samples **2** and **6** in Table 3). The different δ values for compounds **2** and **6** indicate different donating behaviour for the oxalate ligand. In fact the involvement of all the four oxygens in bonding, that is likely to occur in the 2:1 compound **6**, should decrease the electron density on the Sn—O bonds with respect to the 1:1 compound **2**, in which only two oxygens are bonded to the tin centre. As a consequence the δ value for the latter compound should be lower than that for the former one, as is actually the case. As expected, the δ values for the chloro derivatives are generally lower than for the bromo complexes, but are insensitive to the variations in the coordination sphere.

The high value for the quadrupole splitting of the diphenyl derivative **7** is a clear indication of an octahedral coordination with the phenyl groups in apical positions. In the case of the triphenyl tin derivative **8**, the increase in the ΔE_Q value with respect to $SnPh_3Cl$ (2.54 mm s^{-1}), which presents tetrahedral coordination, seems to indicate an increase in the coordination number and so the

presence of a penta-coordinated tin centre. Point charge calculations give a ΔE_Q value of 3.07 mm s^{-1} for a penta-coordinated compound with bridging oxalate anions in apical positions, in good agreement with the experimental value and the δ value reported for $CH_3COOSnPh_3$,[14] for which the same type of coordination around tin is considered.

Proposed structures

From all the above considerations on the IR and the Mössbauer spectroscopic data it is possible to obtain some clues to hypothesize the geometrical structures for these complexes. Therefore, for the 1:1 adducts **1** and **2** a discrete structure can be proposed in which the oxalate anion behaves as a monochelating ligand and the tin atom assumes an octahedral coordination geometry with the oxygen atoms in *cis* positions (see Fig. 1). Also, in the pentahalo complexes **3** and **4** the tin atoms present an octahedral geometry, the sixth position of which is occupied by an oxygen of the oxalate ion which behaves as a bi-unidentate ligand connecting two SnX_5^- moieties (see Fig. 2). The 2:1 tetrahalo derivatives **5** and **6** and the diphenyl tin adduct **7** should present the same structure: the oxalate

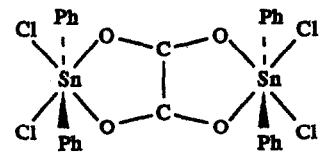

Fig. 3. Proposed schematic structure for the compound $(SnPh_2Cl_2)_2 \cdot C_2O_4(Me_4N)_2$.

anion behaves as a bichelating ligand with all the oxygens involved in bonds to the tin centre, which is octahedrally surrounded by two oxygen atoms in *cis* positions and either by the four halogens or by two apical phenyl groups and the two chlorine atoms again in *cis* positions (see Fig. 3). For the triphenyl tin derivative **8** two structures are equally possible. In both cases the tin atom is penta-coordinated with a trigonal bipyramidal geometry, in which the phenyl groups occupy the three planar positions and two oxygens from the oxalate anion the apical positions. The difference between the two

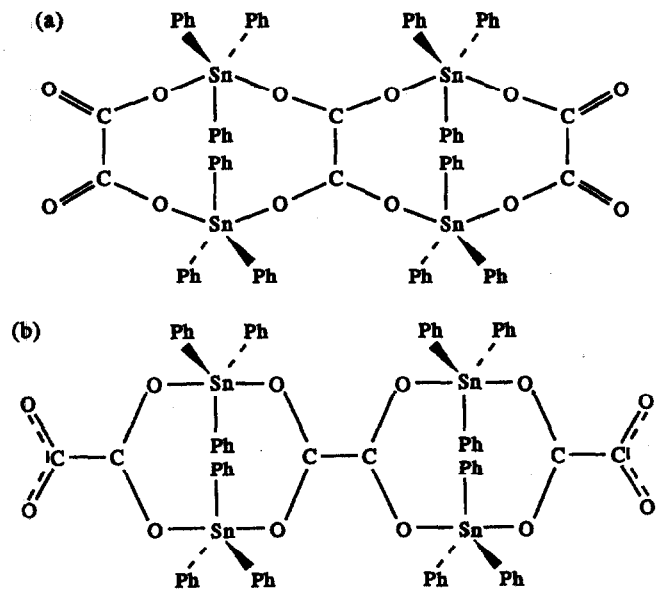

Fig. 4. Proposed schematic structures for the compound $(Et_4N)_2C_2O_4 \cdot 2(SnPh_3)_2C_2O_4$.

structures is due to the different arrangements of the oxalate ions (see Fig. 4).

CONCLUSIONS

In this series of compounds the variety of coordination possibilities typical for the oxalate anion is widely demonstrated. Therefore, compounds in which it behaves as a mono- or bichelating or as a bridging poly-unidentate ligand have been obtained and characterized. The results of Mössbauer and IR spectroscopic techniques allowed the proposal of suitable structures for each compound.

The important role of the size of the cation has been discussed: with large cations such as tetraethyl and tetrabutyl ammonium only a binuclear bichelating oxalate ligand-containing adduct was obtained with SnX_4, while with a smaller cation such as tetramethyl ammonium two new compounds (a mononuclear monochelating oxalate ligand-containing adduct and a binuclear bridging oxalate ligand-containing adduct) were isolated. The first adduct of $(SnPh_3)_2C_2O_4$ has also been reported in this paper.

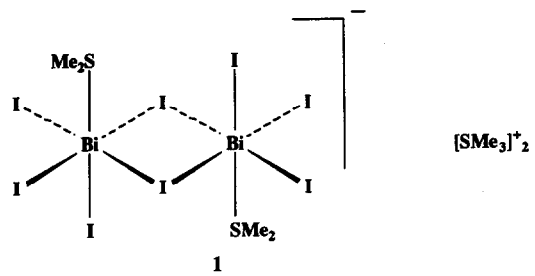
(*Received* 22 *February* 1993; *accepted* 4 *March* 1993)

Abstract—The synthesis and X-ray crystal structure of the ionic compound $[SMe_3]_2[Bi_2I_8(SMe_2)_2]$ is described. The bismuth-containing dianion can be considered as a complex of $[Bi_2I_8]^{2-}$ and two molecules of SMe_2, with an edge-shared bioctahedral structure in which the weakly bound SMe_2 ligands are in axial sites and *trans*.

We have recently described the preparation and structural characterization of some phosphine (PR_3) complexes of bismuth(III) halides and halogenoanions,[1] which were the first such compounds to be described and also the first structurally characterized examples of bismuth–phosphorus bonds. Analogous chemistry with organosulphide ligands (SR_2) is still undeveloped and we report herein the synthesis and X-ray crystal structure of the first compound of this type, namely the ionic species $[SMe_3]_2[Bi_2I_8(SMe_2)_2]$ (**1**), which contains an iodobismuthate anion in which the bismuth centres are each coordinated by a dimethylsulphide (SMe_2) ligand.

Bismuth tri-iodide was found to dissolve readily in SMe_2 to give dark red solutions, but subsequent crystallization procedures (solvent diffusion from an overlayer of hexane) afforded a dark crystalline material which was found to be mostly unsolvated BiI_3.† However, small quantities of dark red crystals were also present and these were examined by X-ray crystallography,‡ the results of which revealed an ionic compound with the formula $[SMe_3]_2[Bi_2I_8(SMe_2)_2]$ (**1**).



1

* Author to whom correspondence should be addressed.

† SMe_2 (20 cm^3) was condensed onto a sample of BiI_3 (0.85 g, 1.44 mmol) in a nitrogen atmosphere and the mixture stirred and allowed to warm to room temperature. Most of the BiI_3 dissolved to give a deep red solution, over which hexane (20 cm^3) was then layered. Solvent diffusion over a period of days resulted in the formation of a crop of dark crystals, most of which were BiI_3 (assumed on the basis of colour and the fact that elemental analysis showed only traces of carbon and hydrogen), but which also included a small yield of red crystals of **1**. These crystals were suitable for X-ray diffraction, but satisfactory microanalytical data could not be obtained since it was not possible to separate a pure sample from an intimate mixture of **1** and BiI_3.

‡ Crystal data for **1**: $C_{10}H_{30}Bi_2I_8S_2$, $M = 1711.74$, monoclinic, $P2_1/c$, $a = 9.403(5)$, $b = 16.177(6)$, $c = 12.884(13)$ Å, $\beta = 106.21°$, $V = 1882(2)$ $Å^3$, $Z = 2$, $D_c = 3.021$ g cm^{-3}, λ(Mo-K_α) = 0.71073 Å, $\mu = 16.12$ mm^{-1}, $F(000) = 1488$, $T = 293$ K. The structure was determined by direct methods and difference syntheses and refined by full-matrix least-squares methods on 3302 unique F^2 values (2θ max 50°) measured on a Stoe–Siemens diffractometer and corrected for 40% intensity decay and for absorption (semi-empirically; transmission 0.058–0.143). Anisotropic displacement parameters were refined; hydrogen atoms were not included; extinction effects were negligible. $R' = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2]^{1/2} = 0.1983$ for all data, conventional $R = 0.0597$ for F values of 1147° "observed" [$F^2 > 2\sigma(F^2)$] reflections only, goodness of fit = 1.028. All features in a final difference map were within the range −0.95–1.11 e $Å^{-3}$. Programs: SHELXS-86 and SHELXL-92 (G. M. Sheldrick, University of Göttingen, Germany). Atomic coordinates, bond lengths and angles and atomic displacement parameters have been deposited as supplementary material at the Cambridge Crystallographic Data Centre.

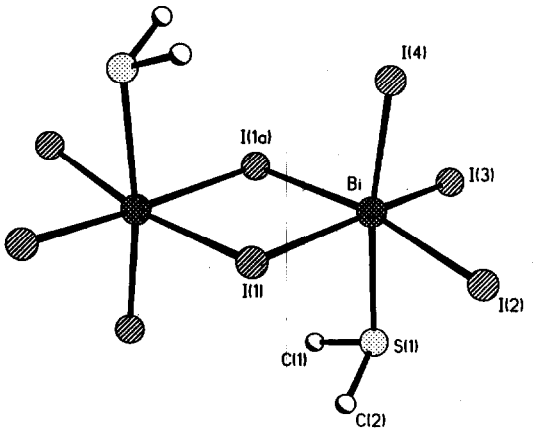


Fig. 1. A view of the anionic part of the structure of **1** showing the atom numbering scheme. Important bond lengths (Å) and angles (°): Bi—I(1) 3.234(3), Bi—I(1a) 3.229(3), Bi—I(2) 2.955(3), Bi—I(3) 2.954(3), Bi—I(4) 2.934(3), Bi—S(1) 3.054(8); I(1)—Bi—I(1a) 84.04(7), I(1)—Bi—I(2) 91.65(9), I(1)—Bi—I(3) 169.79(7), I(1)—Bi—I(4) 92.31(9), I(1)—Bi—S(1) 90.4(2), I(2)—Bi—I(1a) 170.43(7), I(2)—Bi—I(3) 94.95(9), I(2)—Bi—I(4) 93.94(9), I(2)—Bi—S(1) 77.8(2), I(3)—Bi—I(1a) 88.24(8), I(3)—Bi—I(4) 94.98(9), I(3)—Bi—S(1) 83.4(2), I(4)—Bi—I(1a) 94.76(9), I(4)—Bi—S(1) 171.4(2), I(1a)—Bi—S(1) 93.7(2), Bi—I(1)—Bi(a) 95.96(7).

The anionic part of **1** is shown in Fig. 1 and may be viewed as a complex of the dimeric dianion $[Bi_2I_8]^{2-}$ and two SMe_2 ligands with an overall edge-shared, crystallographically centrosymmetric, bioctahedral geometry. Specifically, the SMe_2 ligands are mutually *trans* and occupy axial sites *cis* to both bridging iodides. The terminal Bi—I bond lengths (av. 2.948 Å) and the bond lengths to the two symmetrically bridging iodides [3.234(3) and 3.229(3) Å] are normal and very similar to the corresponding distances found in the dianion $[Bi_2Ph_2I_6]^{2-}$.[2] Bismuth–sulphur bonds, in contrast to those involving phosphorus, are well established and fall within the range 2.6–3.2 Å, as exemplified by a number of bismuth complexes of thioureas,[3] thiosemicarbazides,[4] imidazolidine-2-thiones,[3b,5] xanthates[6] and dithiocarbamates,[7] particular distances depending on the nature of the sulphur donor (e.g. monodentate or bidentate), the nature of the other ligands and the coordination number around the bismuth centre. Complex **1**, however, is the first example of a bismuth complex of a dialkylsulphide and the Bi—S distance [Bi—S(1) 3.054(8) Å] is towards the long end of this range which indicates that the SMe_2 ligand is only weakly bound to the bismuth centre. A further and informative comparison is between **1** and the related ionic phosphine complex $[PMe_3H][Bi_2Br_7(PMe_3)_2]$ (**2**),[1a] which contains a polymeric anion, the essential dibismuth unit of which is very similar to the structure of the dianion in **1**. The Bi—P distance in **2** [2.762(3) Å] is considerably shorter than the Bi—S distance in **1**, indicating that PMe_3 is probably a much better ligand than SMe_2 in this type of complex.

The formation of **1** under the reaction conditions employed is most likely due to a small degree of hydrolysis resulting from adventitious water, as was also considered likely with regard to the formation of **2**,[1a] and it is interesting to note also that whilst a crystalline SMe_2 complex of an iodobismuthate anion is formed we have been unable to isolate a neutral complex.

HYDROGEN BONDING OF H_2O TO THE HYDROXO LIGANDS OF $Cp^*_2Zr(OH)_2$: IMPLICATIONS FOR PROTON AND OXYGEN EXCHANGE PROCESSES. THE CRYSTAL AND MOLECULAR STRUCTURE OF THE HYDRATE $Cp^*_2Zr(OH)_2 \cdot (H_2O)$

WILLIAM A. HOWARD and GERARD PARKIN†

(*Received* 31 *November* 1992; *accepted* 25 *February* 1993)

Abstract—The molecular structure of $Cp^*_2Zr(OH)_2 \cdot (H_2O)$ ($Cp^* = \eta^5$-C_5Me_5) has been determined by single-crystal X-ray diffraction. The asymmetric unit of $Cp^*_2Zr(OH)_2 \cdot (H_2O)$ consists of a hydrogen-bonded dimeric structure in which two water molecules serve to link two $Cp^*_2Zr(OH)_2$ moieties together. The hydrogen bonding of H_2O to the hydroxo ligands of $Cp^*_2Zr(OH)_2$, rather than the direct coordination of H_2O to the zirconium centre, provides support for the mechanisms proposed previously to rationalize the fact that proton exchange between $Cp^*_2Zr(OH)_2$ and labelled H_2O is more facile than that for oxygen exchange.

Monomeric, unbridged terminal metal-hydroxo complexes of the early transition metals are relatively uncommon, possibly due to the tendency of such groups either (1) to bridge two or more metal centres or (2) to eliminate water with the concomitant formation of an oxo derivative.[1] In the course of a study of the reactivity of bis(pentamethylcyclopentadienyl)zirconium complexes towards H_2O, Hillhouse and Bercaw successfully utilized the steric demands of the pentamethylcyclopentadienyl ligand to stabilize $Cp^*_2Zr(OH)_2$ ($Cp^* = \eta^5$-C_5Me_5).[2] $Cp^*_2Zr(OH)_2$ is a rare example of an early transition metal bis(hydroxo) complex and its stability contrasts with that of the corresponding tungsten derivative, $[Cp^*_2W(OH)_2]$, which is unstable with respect to loss of water and formation of the terminal oxo complex $Cp^*_2W{=}O$.[3] In this regard it is also noteworthy that $Cp^*_2Zr(OH)_2$ has been independently synthesized by Carty *et al.* with the aim of utilizing this complex as a precursor for the formation of a monomeric terminal zirconium oxo derivative.[4]

In addition to the synthesis of $Cp^*_2Zr(OH)_2$ Hillhouse and Bercaw also reported that the bis(hydroxo) complex could be isolated as a monohydrate derivative, $Cp^*_2Zr(OH)_2 \cdot (H_2O)$.[2] The structure of the monohydrate derivative is of some interest, especially in view of the role that it may play in both proton and oxygen exchange between $Cp^*_2Zr(OH)_2$ and labelled water ($H_2{}^{17}O$ and D_2O).[2] Here we report (1) the structure of the monohydrate $Cp^*_2Zr(OH)_2 \cdot (H_2O)$, as determined by single-crystal X-ray diffraction, (2) its relationship to the structure of $Cp^*_2Zr(OH)_2$ and (3) the implications for proton and oxygen exchange between $Cp^*_2Zr(OH)_2$ and H_2O.

The molecular structure of $Cp^*_2Zr(OH)_2 \cdot (H_2O)$ was determined by a single-crystal X-ray diffraction study. The asymmetric unit of $Cp^*_2Zr(OH)_2 \cdot (H_2O)$ consists of a hydrogen-bonded dimeric structure in which two water molecules serve to link two $Cp^*_2Zr(OH)_2$ moieties together,

† Author to whom correspondence should be addressed.

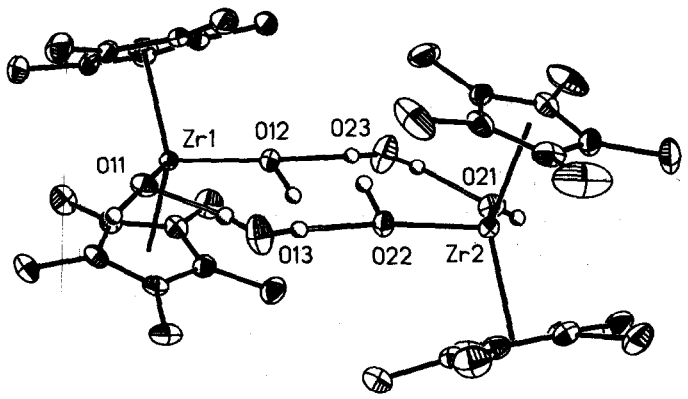

Fig. 1. The asymmetric unit of $Cp^*_2Zr(OH)_2 \cdot (H_2O)$. Hydrogen-bonding interactions are represented by open bonds. Hydrogen-bonding separations (e.s.d.s *ca* 0.005–0.01 Å): O(11)···O(13) 2.828, O(13)···O(22) 2.879, O(21)···O(23) 2.787 and O(23)···O(12) = 2.974 Å. In view of the location of the hydrogen atoms attached to O(12) and O(22) a hydrogen bond is not considered to be present between these atoms, even though the O(12)···O(22) separation is 2.994 Å.

as shown in Fig. 1.† The four O···O separations involved in the hydrogen bonding are in the range 2.79–2.97 Å, so that the interactions are best characterized as weak hydrogen bonds.[5] Furthermore, the hydrogen-bonding network extends beyond this dimeric assembly, so that the units are linked together into an infinite chain-type structure, a portion of which is illustrated in Fig. 2.

The coordination environments about each zirconium centre are very similar, as summarized in Table 1. For comparative purposes Table 1 also includes metrical data for $Cp^*_2Zr(OH)_2$, which indicate that the coordination environment about zirconium in the monohydrate $Cp^*_2Zr(OH)_2 \cdot (H_2O)$ is relatively unperturbed from that observed for $Cp^*_2Zr(OH)_2$. For example, the average Zr—O bond length in $Cp^*_2Zr(OH)_2 \cdot (H_2O)$ is 2.00(2) Å, very similar to that of 1.98(1) Å in $Cp^*_2Zr(OH)_2$.

† Crystal data for $Cp^*_2Zr(OH)_2 \cdot (H_2O)$ at room temperature: Triclinic $P\bar{1}$, $a = 10.501(1)$, $b = 13.160(2)$, $c = 16.927(2)$ Å, $\alpha = 111.58(1)°$, $\beta = 106.86(1)°$, $\gamma = 91.03(1)°$, $V = 2061.2(5)$ Å^3, $Z = 4$, $R = 0.0368$, $R_w = 0.0474$. All hydrogen atoms attached to oxygen atoms were located, but their positional parameters were refined subject to constraints to limit the O—H bond lengths to chemically reasonable values (see refs 5 and 9). A complete set of tables of crystal and intensity collection data, atomic coordinates, bond distances and angles, anisotropic displacement parameters, observed and calculated structure factors and an ORTEP drawing for $Cp^*_2Zr(OH)_2 \cdot (H_2O)$ have been deposited with the Editor as supplementary material. The atomic coordinates have also been deposited with the Cambridge Crystallographic Data Center.

Perhaps the most significant feature of the structure of the monohydrate $Cp^*_2Zr(OH)_2 \cdot (H_2O)$ is that the water molecule is *not* coordinated to the zirconium centre. As such, the structure contrasts with those of the cationic bis(cyclopentadienyl)-zirconium aqua complexes $[Cp_2Zr(H_2O)_3]^{2+}$ and $[Cp_2Zr(H_2O)_2(OTs)]^+$,[6,7] in which there are three substituents in the equatorial plane, compared with two for $Cp^*_2Zr(OH)_2 \cdot (H_2O)$. Moreover, the Zr—O interactions in $Cp^*_2Zr(OH)_2 \cdot (H_2O)$ [see Table 1] are also shorter than those in $[Cp_2Zr(H_2O)_3]^{2+}$ [$d(Zr—OH_2)_{(lateral)} = 2.261(7)$ and 2.239(7), $d(Zr—OH_2)_{(central)} = 2.195(7)$ Å][7] and $[Cp_2Zr(H_2O)_2(OTs)]^+$ [$d(Zr—OH_2)_{(lateral)} = 2.276(5)$ and 2.242(5), $d(Zr—OTs) = 2.169(5)$ Å].[6,8]

Hillhouse and Bercaw's exchange studies between (1) $Cp^*_2Zr(OH)_2$ and D_2O and (2) $Cp^*_2Zr(OH)_2$ and $H_2{}^{17}O$ have elegantly demonstrated that the rate of $^{16}O/^{17}O$ exchange is dramatically slower than the rate of H/D exchange.[2] These results clearly indicated that the two exchange processes do not involve a common mechanism and the two pathways illustrated in Scheme 1 were suggested to account for the results of the exchange studies.[2] $^{16}O/^{17}O$ exchange was proposed to require the presence of an intermediate in which water was bound to the zirconium centre (mechanism A), a pathway that would also result in proton exchange. In contrast, the more facile H/D exchange (to the exclusion of oxygen exchange) could be achieved by an intermediate in which water was *not* involved in the first coordination sphere of the metal, i.e. an intermediate in which the water molecule and the hydroxo ligands of $Cp^*_2Zr(OH)_2$ are involved in hydrogen bonding. Therefore, our observation that the ground state structure of the monohydrate

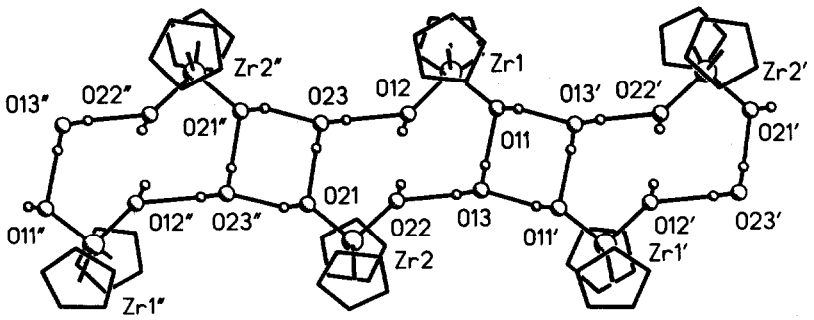

Fig. 2. A portion of the extended chain-type structure of $Cp^*_2Zr(OH)_2 \cdot (H_2O)$. For clarity the Cp* ligands are represented by pentagons. Hydrogen-bonding separations that are not included in Fig. 1 (e.s.d.s *ca* 0.005–0.01 Å): O(11)···O(13′) 2.821 and O(23)···O(21″) 2.800 Å.

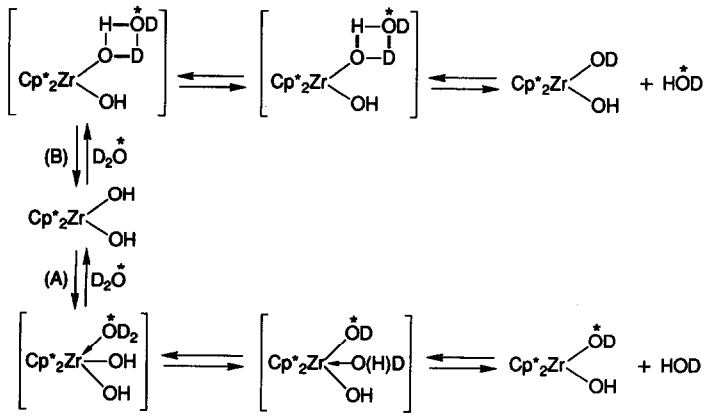
	Zr(1)	Zr(2)	$Cp^*_2Zr(OH)_2$[a]
Zr(X)—O(X1)	1.976(2)	1.978(2)	1.975(8)
Zr(X)—O(X2)	2.028(3)	2.026(3)	1.982(7)
Zr(X)—C $[Cp^*]_{av}$	2.57	2.57	2.55
O(X1)···O(X2)	3.011(5)	3.001(5)	3.025(12)
O(X1)—Zr(X)—O(X2)	97.5(1)	97.1(1)	99.7(3)

[a] Data taken from ref. 4.



Scheme 1. Two pathways for proton and oxygen exchange between $Cp^*_2Zr(OH)_2$ and labelled water ($D_2{}^*O = D_2O$ or $H_2{}^{17}O$). Adapted from ref. 2.

$Cp^*_2Zr(OH)_2 \cdot (H_2O)$ does *not* involve coordination of the water molecule to the zirconium centre provides good support for Hillhouse and Bercaw's mechanistic proposals concerning H/D and $^{16}O/^{17}O$ exchange processes in this system.

STEPWISE SYNTHESIS AND REACTIVITY OF A CHLORINE-FUNCTIONALIZED σ^3,λ^4-PHOSPHANEDIYL COMPLEX; X-RAY CRYSTAL STRUCTURE OF (2,4,6-$Bu^t_3C_6H_2O$)(Cl)P—$MoCp(CO)_3$

MICHAEL LEISE, LASZLO ZSOLNAI and HEINRICH LANG*

Anorganisch-Chemisches Institut der Universität, Im Neuenheimer Feld 270, W-6900 Heidelberg 1, F.R.G.

(*Received* 4 *November* 1992; *accepted* 10 *February* 1993)

Abstract—The stepwise formation of the bifunctional σ^3,λ^4-phosphanediyl complex (2,4,6-$Bu^t_3C_6H_2O$)(Cl)P=$MoCp(CO)_2$ (**4**) (R = 2,4,6-$Bu^t_3C_6H_2O$) is reported. The primary metallo-chlorophosphine (R)(Cl)P—$MoCp(CO)_3$ (**3**) is isolated in almost quantitative yield from the reaction of $RPCl_2$ (**1**) with $Na[MoCp(CO)_3]$ (**2**). Decarbonylation of **3** affords **4**. The reactivity of **4** towards different nucleophiles is discussed. The identities of all new compounds are documented by analytical as well as spectroscopic (IR, MS, ^1H, ^{13}C and ^{31}P NMR) data; the X-ray structure of (R)(Cl)P—$MoCp(CO)_3$ (**3**) is reported.

Complexes of the type (R)(R′)P=ML_n [R,R′ = single-bonded organic ligand; ML_n = $Co(CO)_3$,[1] $Mn(CO)_4$,[2] $MoCp(CO)_2$, $WCp(CO)_2$[3–6]], which each contain an sp^2-hybridized phosphorus atom in a trigonal planar environment, can be prepared either via reductive dehalogenation of (R)(R′)PCl with $Co_2(CO)_8$[1a,c] or dehydrochlorination of R_2XP—$MCp(CO)_2Y$ (M = Mo, W; X = H, Y = Cl; X = Cl, Y = H).[3]

However, another possibility for preparing this type of compound is given in the reaction of (R)(R′)PCl with $Na[ML_{n+1}]$ [ML_{n+1} = $Co(CO)_4$,[1] $Mn(CO)_5$,[2] $MoCp(CO)_3$, $WCp(CO)_3$[3–6]]. The sodium-chloride metathesis reaction affords first the appropriate metallo-phosphine intermediates (R)(R′)P—ML_{n+1}, which then readily eliminate CO to yield (R)(R′)P=ML_n [ML_n = $Co(CO)_3$,[1] Mn $(CO)_4$,[2] $MoCp(CO)_2$, $WCp(CO)_2$[3–6]]. To our knowledge the intermediates (R)(R′)P—ML_{n+1} have never been isolated in crystalline form and converted to neutral phosphenium-ion complexes, which contain a formal phosphorus–metal double bond.

We report here the selective synthesis of the stable metallo-phosphine (R)(Cl)P—$MoCp(CO)_3$ (**3**) and its controlled decarbonylation to the σ^3,λ^4-phosphanediyl complex (R)(Cl)P=$MoCp(CO)_2$ (**4**). Some aspects of the reactivity of **4** are discussed.

RESULTS AND DISCUSSION

The complex (R)(Cl)P—$MoCp(CO)_3$ (R = 2,4,6-$Bu^t_3C_6H_2O$) is easily accessible in high yields via the reaction of equimolar amounts of $RPCl_2$[7] (**1**)

R = 2,4,6-^{t}Bu$_3$C$_6$H$_2$O

* Author to whom correspondence should be addressed.

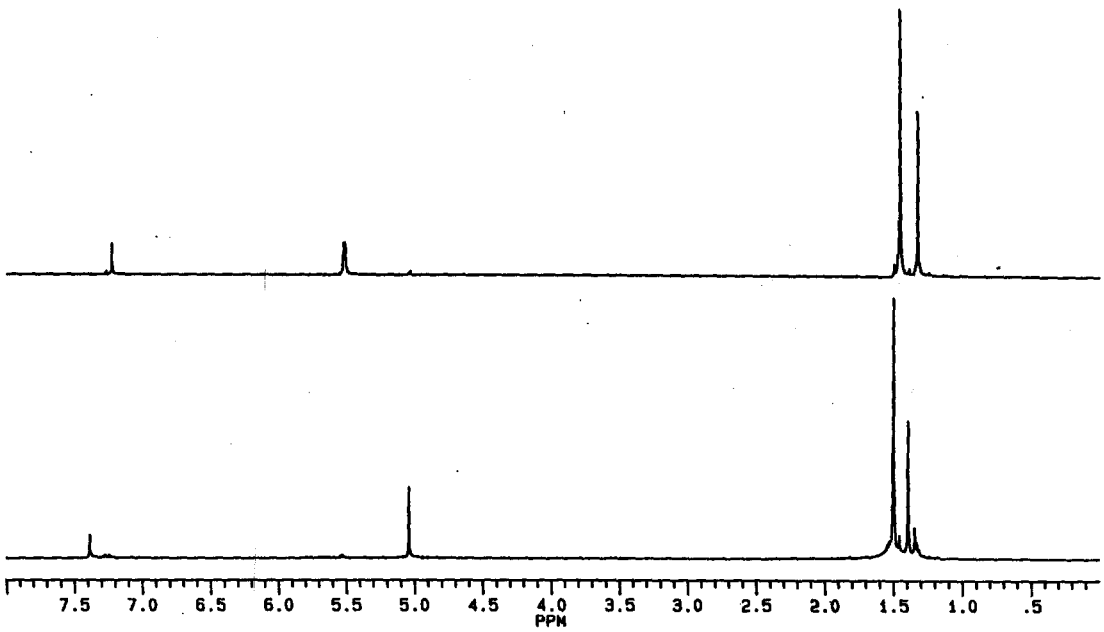

Fig. 1. ^{1}H NMR; thermal conversion of **3** to **4** (**3** top: recorded at −15°C; **4** bottom: same sample recorded after 90 min at 25°C.

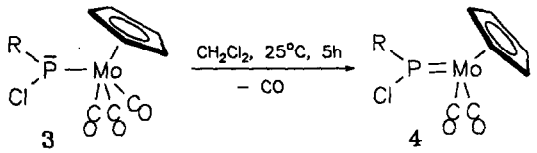
and Na[MoCp(CO)$_3$][8] (**2**) in THF at −20°C.* The yellow metallo-phosphine **3** is best purified by column chromatography at −20°C.*

On warming this compound up to *ca* 25°C in methylenechloride for 5 h decarbonylation occurs and the orange-coloured σ^3,λ^4-phosphanediyl complex (R)(Cl)P=MoCp(CO)$_2$ (**4**) is formed in almost quantitative yields.*



R = 2,4,6-^{t}Bu$_3$C$_6$H$_2$O

Compound **4** is the only isolated product obtained upon extraction of the reaction residue with n-pentane, followed by filration through Celite. Recrystallization from n-pentane yields analytically pure **4**. The most characteristic features in the IR spectrum of **4** is the ν(CO) pattern of the MoCp(CO)$_2$ moiety, with two strong absorption bands at 1975 and 1946 cm^{-1}, which is typical for neutral phosphenium ion complexes containing an MoCp(CO)$_2$ unit.[3-6]

The decarbonylation of **3** to **4** is best followed by ^{31}P and ^{1}H NMR experiments.* The most significant observation in the ^{1}H NMR spectra of **3** and **4** (Fig. 1) is the high-field shift of the cyclopentadienyl resonance signal, which moves from $\delta = 5.5$ (**3**) to $\delta = 5.0$ (**4**). In addition the typical PH coupling constant of J(PC) = 2.6 Hz in **3**, which is typical for this class of compounds,[9] disappears in **4**.

* The composition and constitution of compounds **3** and **4** were given by satisfactory elemental analysis and spectroscopic (IR, MS, ^{1}H, ^{13}C and ^{31}P NMR) data.

3: ^{1}H NMR ($CDCl_3$, −15°C): 1.32 (s, 9H, *p*-Bu^t), 1.45 (s, 18H, *o*-Bu^t), 5.52 [d, J(PH) = 2.6 Hz, 5H, Cp], 7.23 (s, 2H, C_6H_2) ppm. ^{13}C{^{1}H} NMR ($CDCl_3$, −15°C): 31.5 (s, 3C, *p*-Bu^t), 33.3 (s, 3C, *o*-Bu^t), 33.4 (s, 3C, *o*-Bu^t), 34.4 (s, 1C, *p*-C^i/Bu^t), 36.2 (s, 2C, *o*-C^i/Bu^t), 95.4 [d, J(PC) = 6.5 Hz, 5C, Cp], 123.8 (s, 2C, C_6H_2), 141.0 [d, J(PC) = 3.5 Hz, 2C, C_6H_2], 144.4 [d, J(PC) = 2 Hz, 1C, C_6H_2], 152.1 (s, 1C, C_6H_2), 224.0 [d, J(PC) = 6 Hz, 1C, CO], 224.3 [d, J(PC) = 25.5 Hz, 1C, CO], 232.4 [d, J(PC) = 11 Hz, 1C, CO] ppm. ^{31}P{^{1}H} NMR ($CDCl_3$, −15°C): 358.6 (s) ppm. IR (n-pentane; CaF_2 cells): 2022 vs, 1957 s, 1946 s [ν(CO)], 1592 w [ν(C=C)] cm^{-1}. M.p. 112°C (decomposition).

4: ^{1}H NMR ($CDCl_3$): 1.38 (s, 9H, *p*-Bu^t), 1.49 (s, 18H, *o*-Bu^t), 5.03 (s, 5H, Cp), 7.38 (s, 2H, C_6H_2) ppm. ^{13}C{^{1}H} NMR ($CDCl_3$): 31.5 (s, 3C, *p*-Bu^t), 32.7 (s, 6C, *o*-Bu^t), 34.7 (s, 1C, *p*-C^i/Bu^t), 36.0 (s, *o*-C^i/Bu^t, 2C), 91.1 [d, J(PC) = 6.5 Hz, 5C, Cp], 123.9 (s, 2C, C_6H_2), 142.1 [d, J(PC) = 4.5 Hz, 2C, C_6H_2], 147.4 (s, 1C, C_6H_2), 147.5 (s, 1C, C_6H_2), 231.9 [d, J(PC) = 23 Hz, 2C, CO] ppm. ^{31}P{^{1}H} NMR ($CDCl_3$): 197.1 (s), EI MS [m/z (rel. int.)]: M^+ 546(6), $M^+ - 2CO$ 490(25), $M^+ - 2CO - Bu^t$ 433(9), $M^+ - 2CO - Bu^t - Cl$ 398(8), $Bu^t{}_3C_6H_2OH^+$ 262(24), $Bu^t{}_3C_6H_2OH^+ - Me$ 247(100), Bu^{t+} 57(28). IR (n-pentane, CaF_2 cells): 1975 s, 1946 s [ν(CO)], 1592 w [ν(C=C)] cm^{-1}.

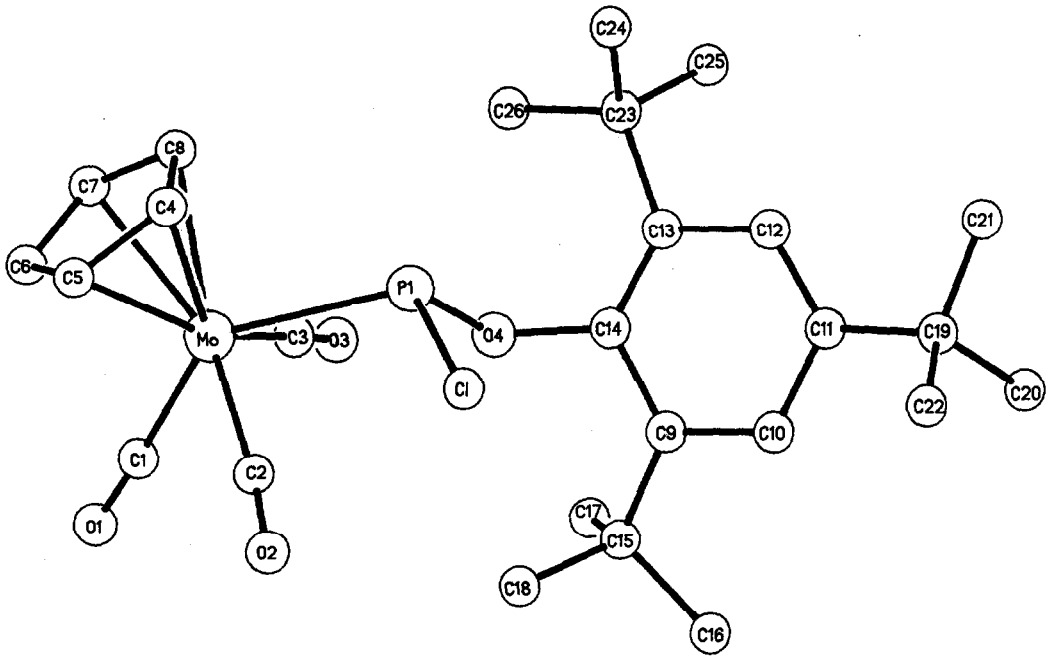


Fig. 2. Molecular geometry and atom labelling scheme for **3**; selected interatomic distances (Å) and angles (°) are: P—Mo 2.584(4), P—O(4) 1.654(6), P—Cl 2.118(4), O(4)—P—Mo 106.4(2), Mo—P—Cl 111.8(1), Cl—P—O(4) 101.1(2).

Conspicuous in the ^{31}P NMR spectra of **3** and **4** is the observed high-field shift of the appropriate resonance signal from $\delta = 359$ (**3**) to $\delta = 197$ (**4**). This shielding is attributed to a change of hybridization of the phosphorus atom (sp^3 (**3**) $\rightarrow sp^2$ (**4**)), as well as to a transfer of electron density from the molybdenum centre to the phosphorus atom in **4**. The spectroscopic data for **4** confirm the notion that the phosphorus atom possesses a trigonal planar environment and is part of a formal phosphorus–molybdenum doubly bonded system.

The structure of **3** is related to structures of other metallo-phosphines, in which the phosphorus atom is σ-bonded to 17-electron complex fragments such as $MoCp(CO)_3$.[10] A representation of the solid state structure of **3**, as determined by single-crystal X-ray diffraction, is shown in Fig. 2.*

The molecule consists of a single molybdenum atom bonded to a cyclopentadienyl group, three terminal carbonyls and a terminal phosphino ligand P(Cl)(R). Figure 2 shows that the phosphorus atom possesses a tetrahedral environment with a chemically reactive lone pair of electrons. Indicative of the absence of π-character between the phosphorus and molybdenum atoms in compound **3**, as compared to compounds of type **4**, is the elongated phosphorus–molybdenum bond length [2.584(4) Å] (Fig. 2). The other interatomic distances and angles are in the range for the usual values.[11]

An overview of the reactivity of **4** is given in Scheme 1. As demonstrated by the reactions depicted in Scheme 1 compound **4** has been shown to be useful for the synthesis of multi-functionalized σ^3,λ^4-phosphanediyl complexes containing a formal phosphorus–molybdenum double bond, as well as an organic π-system. With this in mind **4** is a promising building block for the synthesis of various functionalized complexes of the type (R)(R′)P=$MoCp(CO)_2$ [R = 2,4,6-$Bu^t_3C_6H_2O$; R′ = CH=C(H)(Ph) (**5**), C≡CPh (**6**), $CH_2C{\equiv}CH$ (**7**), NEt_2 (**8**)].[8]

* Crystal data for **3**: $C_{26}H_{34}ClMoO_4P$, $M = 572.9$, monoclinic, space group $P2_1/c$, $a = 11.34(1)$, $b = 11.41(2)$, $c = 20.99(3)$ Å, $\beta = 97.2(1)°$, $V = 2693(2)$ Å^3, $Z = 4$, $D_c = 1.41$ g cm^{-3}.

Diffraction data were collected on a Siemens (Nicolet Syntex) R3m/V diffractometer using the ω-scan technique [2θ limits 2–47°, scan range 0.75°, scan speed $2.3 \leqslant \dot{\omega} \leqslant 29.3°$ min^{-1} (in 2θ)] and Mo-K_α radiation ($\lambda = 0.71069$ Å).

The structure was solved by direct methods [SHELXTL-PLUS on 3386 unique reflections with $F \geqslant 4\sigma(F)$]. An empirical absorption correction was applied. The functional discrepancy indices were $R_F = 0.065$, $R_w = 0.071$.

Atomic coordinates, interatomic distances and angles and atomic thermal parameters have been deposited at the Cambridge Crystallographic Data Center.

COMMUNICATION

FURTHER ON THE CHEMICAL REDUCTION OF $Fe_2(NO)_4(\mu\text{-SR})_2$

CHUNG-NIN CHAU and ANDREW WOJCICKI*

Department of Chemistry, The Ohio State University, Columbus, OH 43210, U.S.A.

(*Received* 27 *January* 1993; *accepted* 5 *February* 1993)

Abstract—Reduction of $Fe_2(NO)_4(\mu\text{-SR})_2$ (R = Me, Et or Bu^t) with 2 equivalents of sodium, KH or MBR_3H (M = Li, Na or K; R = Et or Bu^s) in THF affords $[Fe_2(NO)_4(\mu\text{-SR})_2]^{2-}$, as evidenced by quantitative analysis of evolved hydrogen, conductivity measurements in MeOH and ^1H and ^2H NMR and IR ν(NO) spectroscopic data of the products. In contrast, reduction of $Fe_2(NO)_4(\mu\text{-SR})_2$ with 1 equivalent of MBR_3H yields products that differ from the foregoing dianions by the presence of hydrogen derived from the borohydride. The combined product characterization data do not support the formulation $[Fe_2(NO)_4(\mu\text{-SR})_2]^-$.

For approximately a decade we have been engaged in investigations on the chemical reduction of complexes of the type $M_2L_x(\mu\text{-Y})_2$ (L = CO or NO; L = a three-electron donor ligand) and the chemistry of resultant reduced species.[1,2] Although most of our studies have been concerned with phosphido complexes (Y = PR_2), we have also investigated thiolato complexes (Y = SR) of the composition $Fe_2(NO)_4(\mu\text{-SR})_2$. In a recent paper we reported[3] some details of the previously mentioned by us[4,5] chemical reduction of $Fe_2(NO)_4(\mu\text{-SR})_2$ (R = Me or Et) and of the conversion of the resultant anions by alkyl iodides (R'I) to $Fe_2(NO)_4(\mu\text{-SR})(\mu\text{-NHR}')$. Regrettably, in the preparation of this manuscript we overlooked a relevant publication by Glidewell and co-workers.[6] This omission and our formulation of the products of reduction with 2 equivalents of sodium or hydride as $[Fe_2(NO)_4(\mu\text{-SR})_2]^{2-}$ came under criticism by Glidewell and Lambert,[7] who apparently were unaware of our ongoing researches in this area since the 1980s[4,5] and who have formulated these products as the monoanions $[Fe_2(NO)_4(\mu\text{-SR})_2]^-$.[6] The purpose of the present communication is not only to set straight the chronology of these events, but also to point out that the chemical reduction of $Fe_2(NO)_4(\mu\text{-SR})_2$ is more complex than that which Glidewell and coworkers have reported.

In our hands reduction of $Fe_2(NO)_4(\mu\text{-SR})_2$ (R = Me, Et or Bu^t) with 1 and 2 equivalents of hydride (as MBR_3H: M = Li, Na or K; R = Et or Bu^s) affords different products, **A** and **B**, respectively. [The reaction with 2 equivalents of sodium yields **B**; with 4 equivalents of sodium an uncharacterized product showing no IR ν(NO) bands is obtained.] Compound **B** is formulated as $[Fe_2(NO)_4(\mu\text{-SR})_2]^{2-}$, while **A** may be $[HFe_2(NO)_4(\mu\text{-SR})_2]^-$ on the basis of the following evidence.

(1) Probably the most compelling evidence for the credibility of the proposed formula of **B** comes from quantitative analysis of the gas evolved in the reaction of $Fe_2(NO)_4(\mu\text{-SMe})_2$ with $LiBEt_3H$ in THF. When 2 equivalents of $LiBEt_3H$ were used 92% of all hydrogen derived from the hydridic H in $LiBEt_3H$ was collected. Thus, this reaction proceeds according to the stoichiometry:

$$Fe_2(NO)_4(\mu\text{-SMe})_2 + 2LiBEt_3H \longrightarrow Li_2[Fe_2(NO)_4(\mu\text{-SMe})_2] + 2BEt_3 + H_2.$$

In contrast, when 1 equivalent of $LiBEt_3H$ was employed under similar conditions, only 3% of the hydridic hydrogen was collected. At the conclusion of each experiment the IR ν(NO) spectrum of the reaction solution revealed that all of the $Fe_2(NO)_4(\mu\text{-SMe})_2$ had reacted. Thus, the unex-

* Author to whom correspondence should be addressed.

pelled hydridic hydrogen must be part of the product **A**. In both reactions hydrogen was analysed by mass spectrometry. The presence of BR_3 (R = Et or Bu^s) in solution was observed by ^{11}B NMR spectroscopy at the conclusion of these and related experiments. Apparently the role of the second equivalent of $LiBEt_3H$ is that of a scavenger of the hydrogen (as H^+) acquired as H^- in the formation of **A**, to give **B** and H_2. If $[Fe_2(NO)_4(\mu\text{-SMe})_2]^-$ had formed in these reduction reactions then 50% of the hydridic hydrogen of $LiBEt_3H$ would have been evolved for both 1 : 1 and 1 : 2 ratios of reactants.

(2) The formulation of **B** as $[Fe_2(NO)_4(\mu\text{-SR})_2]^{2-}$ receives further support from a series of conductivity measurements on MeOH solutions of a solid that was isolated from the reaction of $Fe_2(NO)_4(\mu\text{-SMe})_2$ with 2 equivalents of KH in diethyl ether. The resulting Onsager plot[8] is shown in Fig. 1. Also shown, for comparison, is the corresponding plot for the structurally characterized[9] $Na_2[Fe_2(CO)_6(\mu\text{-PPh}_2)_2]$. Clearly, both compounds are of the same electrolyte type (i.e. 2 : 1[8]).

(3) The ^1H NMR spectrum of $K_2[Fe_2(NO)_4(\mu\text{-SEt})_2]$ [isolated from the reaction of $Fe_2(NO)_4(\mu\text{-SEt})_2$ with 2 equivalents of KH in diethyl ether] in acetone-d_6 shows resonances at δ 1.8 (q) and 0.9 (t) ($J = ca$ 7 Hz). These resonances are shifted to higher field compared to those of the uncharged $Fe_2(NO)_4(\mu\text{-SEt})_2$ [δ 3.05 (q) and 1.55 (t)]. Similarly, $Na_2[Fe_2(NO)_4(\mu\text{-SCD}_3)_2]$, from $Fe_2(NO)_4(\mu\text{-SCD}_3)_2$ and 2 equivalents of $LiBEt_3H$ in THF, shows one ^2H NMR resonance at δ 2.57; neutral $Fe_2(NO)_4(\mu\text{-SCD}_3)_2$ gives a signal at δ 3.42. All of these resonances are sharp, occur in the region expected for diamagnetic compounds and experience, as predicted, upfield shifts when compared to those of the uncharged counterparts.

(4) Rather unexpectedly, **A** and **B** exhibit very similar IR spectra in the ν(NO) region: two absorptions at 1670–1675 and 1650–1660 cm^{-1} in THF. Under favourable resolution both bands show shoulders at *ca* 1680 and 1645 cm^{-1}, indicating the presence of another, minor iron nitrosyl species. For comparison, neutral precursors $Fe_2(NO)_4(\mu\text{-SR})_2$ absorb at 1785–1790 and 1750–1760 cm^{-1} in $CHCl_3$. Similar IR ν(NO) spectra of complexes such as **A** and **B** are not unprecedented, however; e.g. $[Fe_2(NO)_3(PPh_2H)(\mu\text{-NO})(\mu\text{-PPh}_2)]^-$ and $[Fe_2(NO)_4(\mu\text{-PPh}_2)_2]^{2-}$ display ν(NO) bands at comparable average frequencies.[10] It is more difficult to reconcile IR ν(NO) spectral trends with the formulation $[Fe_2(NO)_4(\mu\text{-SR})_2]^-$. On going from $Fe_2(NO)_4(\mu\text{-PPh}_2)_2$ [ν(NO) 1762, 1748 cm^{-1}] to $[Fe_2(NO)_4(\mu\text{-PPh}_2)_2]^{2-}$ [ν(NO) 1673 (br, unresolved) cm^{-1}][10] ν(NO) decreases by *ca* 80 cm^{-1}. On this basis the observed decrease in ν(NO) by $\gtrsim$ 100 cm^{-1} upon reduction of $Fe_2(NO)_4(\mu\text{-SR})_2$ to $[Fe_2(NO)_4(\mu\text{-SR})_2]^{n-}$ is more consistent with n being 2 rather than 1.

(5) Complexes **A** and **B** from $Fe_2(NO)_4(\mu\text{-SMe})_2$ and $LiBEt_3H$ also differ in their UV–vis spectra in THF. For example, the former shows an absorption band at 360 nm, which is missing in the spectrum of **B**.

The foregoing results notwithstanding, we do not dispute that Glidewell and co-workers generated and correctly characterized the ESR-active $[Fe_2(NO)_4(\mu\text{-SR})_2]^-$ in their studies. However, evidence obtained in our investigations on *bulk* reaction and product solutions for the reduction of $Fe_2(NO)_4(\mu\text{-SR})_2$ with 2 equivalents of sodium or hydride clearly implicates $[Fe_2(NO)_4(\mu\text{-SR})_2]^{2-}$ as the major species. (In our work freshly opened hydride reagents obtained from Aldrich Chemical Co. were employed, solvents were dried and freshly distilled and experiments were conducted under purified argon by the use of Schlenk, dry-box and vacuum-line techniques.)

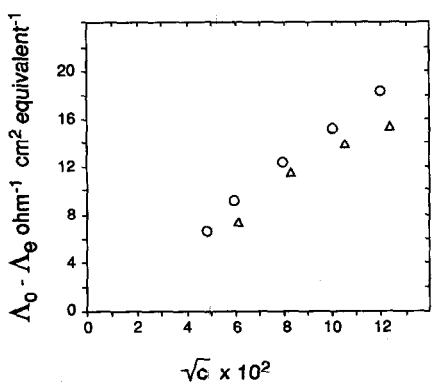

Fig. 1. Onsager plots for solutions of $K_2[Fe_2(NO)_4(\mu\text{-SMe})_2]$ (Δ) and $Na_2[Fe_2(NO)_4(\mu\text{-PPh}_2)_2]$ (○) in MeOH.

REACTIONS OF COORDINATED β-KETOESTERS. A NEW ROUTE FOR THE SYNTHESIS OF 4-SUBSTITUTED-3-METHYL/PHENYL-1-PHENYL PYRAZOL-5-ONES VIA A METAL CHELATED STABLE INTERMEDIATE

S. ABDUL SAMATH,* K. JEYASUBRAMANIAN, S. THAMBIDURAI, S. KAMARDEEN and S. K. RAMALINGAM

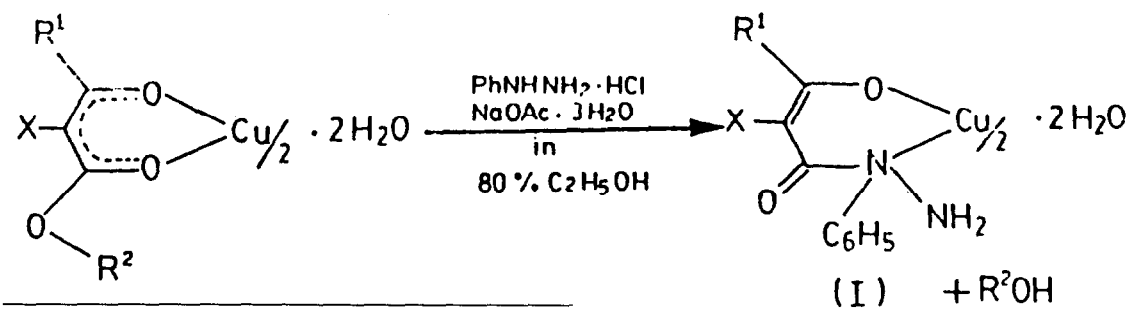
Department of Inorganic Chemistry, School of Chemistry, Madurai Kamaraj University, Madurai 625 021, India

(*Received* 23 *November* 1992; *accepted* 27 *January* 1993)

Abstract—Unsubstituted and γ-substituted copper(II) complexes of β-ketoesters on treatment with phenylhydrazine give ring-rearranged chelate intermediates, which on subsequent demetallation afford the new 4-halo/phenylamido-3-methyl/phenyl-1-phenyl pyrazol-5-ones.

Pyrazolone compounds have a wide variety of applications in biological,[1] clinical,[2] pharmacological[3,4] and analytical areas.[5,6] The synthesis of their 4-substituted derivatives involves more than one reaction step. As part of our interest in the reactions of coordinated β-diketonates,[7] we have investigated the reaction of phenylhydrazine with β-ketoester complexes of copper(II) in an attempt to synthesize 4-substituted pyrazolones in one step. This also serves to test the potential of the reaction for preparing analogous compounds starting from the metal chelates. We briefly report here the reactions involving copper(II) complexes of ethylacetoacetate (EAA), methylacctoacetate (MAA), benzoylacetate ethylester (BZAE) and their 3-bromo and 3-phenylamido products.

Reaction of phenylhydrazine with copper(II) complexes of β-ketoesters gives the ring-rearranged product **I**. The formation of the chelates is indicated by their elemental analyses and their IR spectra which exhibit ring-rearrangement features as reported in our earlier studies.[7–9]



Subsequent demetallation of complex **I** by treatment with H_2S affords 2 mol of 4-X-pyrazolones (X = H, Br or C_6H_5NHCO—) per mole of complex, which on further treatment with dimethyl sulphate gives the corresponding 4-X-3-methyl/phenyl-N-methyl-1-phenyl pyrazolones (**IIIa–f**).

The analytical data (Table 1) along with the spectral features of compounds **II(a–f)** and **III(a–f)** indi-

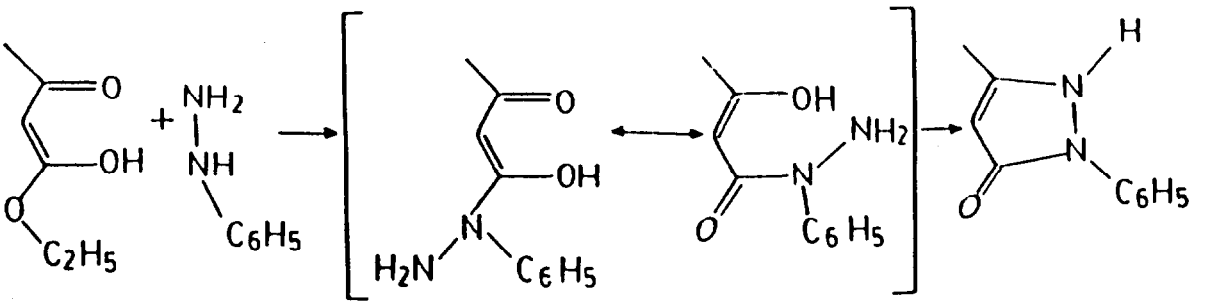
cate that the cyclization has occurred upon demetallation between the $—NH_2$ group (of the phenyl hydrazine) and the carbonyl oxygen (adjacent to the R^1 group). It can, therefore, be inferred that this new ring-rearranged chelate **I** acts as a probable stable intermediate and is vital in the synthesis of the pyrazolone compounds **II** and **III**. In the reported synthesis[10] of such compounds from the direct reaction of β-ketoesters and phenylhydrazine the probable intermediate must be the one represented as below, although it has not been isolated.



Unstable intermediate

The 4-bromo [**II(b,e)** and **III(b,e)**] and 4-phenylamido [**II(c,f)** and **III(c,f)**] pyrazolones and the intermediate complexes [**I(a–f)**] reported in this communication are new. Not only are these intermediates becoming increasingly important in the synthesis of substances of scientific appeal, but they are also significant in the study of new pathways in reaction mechanisms.

EXPERIMENTAL

Action of phenylhydrazine on copper(II) chelates

Phenylhydrazine (10 mmol) and an ethanolic suspension (80%) of copper(X-β-ketoester)$_2 \cdot 2H_2O$ (X = H, Br or $C_6H_5NHCO—$; 5 mmol) were stirred together at 60–80°C for 2 h. The solid intermediate complex **I** was filtered off, washed with ethanol and dried *in vacuo*. IR (KBr): ν(C=O); 1695 and ν(NH)$_2$ 3280–3360 cm^{-1}.

Demetallation and cyclization reactions

A stream of H_2S was bubbled through complex **I** suspended in 50% (v/v) ethanol for 30–45 min. The precipitated CuS was filtered off and excess H_2S was expelled by boiling. The solution on concentration gave the solid 4X-3-methyl/phenyl-1-phenyl pyrazol-5-ones. On further treatment with dimethyl sulphate this yielded the corresponding N-methyl pyrazolones. IR (KBr): ν(C=O) (amide) 1660 and ν(NH) 3130–3210 cm^{-1}. ^1H NMR (δ ppm): 7.36–7.20 (5H, m, C_5H_5), 5.10–5.30 (1H, s, 4-H), 3.12–3.22 (3H, s, N—CH_3), 2.30–2.05 (3H, s, 2-CH_3).

Abstract—Manganese(IV) phosphate was prepared in 3 M phosphoric acid. Ultracentrifugal and electron microscopic studies did not indicate colloid properties. Manganese(IV) phosphate oxidizes mainly oxygen-containing bifunctional substrates in an autocatalytic way. Its reactivity was found to be higher in every case than that of manganese(III) phosphate.

In our investigations performed with dissolved manganese(IV) we had two aims in view. Solid MnO_2 is an oxidant which has been known for a long time and is still used today in some interesting preparation methods.[1] As can be seen, however, the kinetics and mechanism of these reactions have not been satisfactorily clarified, due not only to the heterogeneity of the reactions but also to the fact that the reactivity of MnO_2 is highly affected by precipitation and special pre-treatments. Therefore, we strived to transfer manganese(IV) in the dissolved state in the hope that these questions may be clarified in the homogeneous phase and the results may—at least partly—be applied under heterogeneous conditions.

In the course of permanganate oxidation a soluble brownish-yellow manganese species usually appears,[2–10] with the oxidation state +4, determined iodometrically, and which in many cases accelerates permanganate oxidation autocatalytically.[5–10] For the sake of detailed clarification of the mechanism of permanganate oxidation, it is important to determine what substrates or intermediate products can be attacked by the manganese(IV) intermediate. This was the other goal of our investigations.

Although manganese(IV) forms water soluble complexes with several inorganic[11–15] and organic[16–24] ligands, Perez-Benito[25–27] and recently Freeman[28,29] verified that in the reduction of permanganate at pH 6.8 a fine colloid dispersion of MnO_2 appears, which is stabilized by anions, predominantly by phosphate ions adsorbed on the surface. We performed our kinetic investigations in phosphoric acid since in this case, owing to the lower pH value, there is no danger of disproportionation of manganese(III).

EXPERIMENTAL

The permanganate used was Merck analytical grade, phosphoric acid was Rudipont electronic grade and the substrates were Fluka purest grade products. Special stress was laid on the purity of the water used, which was distilled three times, once from permanganate.

The active MnO_2, which is actually a mixture of oxides and hydroxides containing various amounts of water, was prepared by the reduction of permanganate. The sample taken was dissolved in

* Author to whom correspondence should be addressed.

phosphoric acid of an appropriate concentration, using a shaking device, then the excess was removed by filtration on a filter of G5 porosity. The first filtrate usually shows some Tyndall effect, therefore, the filtration was repeated through the precipitate on the same filter. The solution thus obtained showed no Tyndall effect and lost from its iodometrically determined titre no more than 1% per day.

The reduction of permanganate can be performed most suitably with excess sodium formate, when the permanganate is reduced quantitatively to manganese(IV). Reduction with Mn^{2+} is the least advisable since its excess cannot be removed from the precipitate by washing and when dissolved in phosphoric acid it reduces some of the manganese(IV) immediately into manganese(III). Only freshly prepared MnO_2 stored in an aqueous suspension should be used. The solubility equilibrium is practically established after half an hour's shaking. Figure 1 shows the amount of soluble manganese(IV) against the concentration of phosphoric acid.

Kinetic investigations were performed with a Hewlett–Packard 8432 A type spectrophotometer. For reactions with half-times less than 1 min a stopped-flow stirring system built in our laboratory was used. Manganese(IV) consumption was followed at 390 nm ($\varepsilon_{390} = 2130$) since manganese(III) has practically no absorption here. Manganese(III) consumption, on the other hand, was measured at its absorption maximum, 505 nm ($\varepsilon_{505} = 93$).

Electron microphotographs were taken with a Zeiss EM 902 transmission electron microscope. The sample was placed on the 1 μ density sieve of the microscope and dried for 1 day at room temperature in high vacuum as completely as possible. The ultracentrifuge used was a MOM device, type 3180 (r.p.m.: 45,000).

RESULTS AND DISCUSSION

The experiments were performed in 3 M phosphoric acid. The spectrum of the brown coloured,

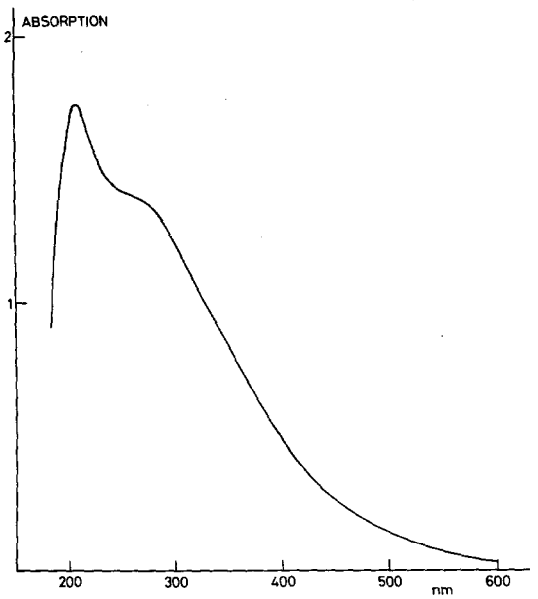

Fig. 2. The spectrum of manganese(IV) phosphate; $[Mn^{IV}] = 1.00 \times 10^{-3}$ M, $[H_3PO_4] = 3.0$ M.

clearly transparent manganese(IV) species is shown in Fig. 2. The characterless, monotonous curve is in agreement with spectra obtained by Selim and Lingane[30] in sulphuric acid and in a phosphate buffer of pH 6.8.[25,28,29] If a solution of a manganese(II) salt is added in excess the brown colour turns immediately into pale pink, but the oxidation titre of the solution does not change. The spectrum of the pink solution is practically identical to that of manganese(III) pyrophosphate.[31] The absorption of both the manganese(IV) and manganese(III) solutions strictly obeys the Beer–Lambert law.

The question is whether manganese(IV) is present in dissolved or in colloidal form. It should be noted that in such a high electrolyte concentration (3 M), generally no stable colloid can be expected, even if the anion happens to be the phosphate ion which can be well adsorbed on the surface of MnO_2. At any rate the investigations performed with an ultracentrifuge and an electron microscope did not indicate any colloid. The solutions containing manganese(IV) in 6×10^{-3} and 10×10^{-3} M concentrations did not show sedimentation in the ultracentrifuge at 45,000 r.p.m. This means that the particle size must be below 50 nm. In the case of electron microscope studies the starting solution was 6×10^{-3} M manganese(IV). This was diluted five times to half its concentration and photographs were taken for each. In no case have we obtained a picture indicating a particle. At the same time, known colloids [SiO_2–sol, FeO(OH)–sol] gave excellent pictures. In our experience,[32,33] particles larger than 2 nm are easily detected by this method.

Thus, in the case of a colloid particle size cannot exceed 2 nm. In any case, our species will be subsequently referred to as manganese(IV) phosphate.

Manganese(IV) phosphate is a strong oxidizing agent. In order to determine what kind of compound or functional group it can attack we performed comparative kinetic measurements under identical reaction conditions. Since the reactions, except in the case of some substrates, do not show simple kinetics, but an accelerating trend, the half-time of consumption of the oxidizing agent was measured and these values are listed in Table 1. Thus, $t_{1/2} = \infty$ indicates that the reduction of manganese(IV) is not much faster than the blind test in the absence of the substrate. In Table 1 virtual reaction rates determined by the tangent-method at half time are also indicated: ($w = \Delta[Mn^{IV}]/\Delta t$).

The intermediate product in the reduction of manganese(IV) is in each case manganese(III). The reduction can proceed in one electron step or in a very rapid

$$Mn^{IV} + Mn^{II} \longrightarrow 2Mn^{III}$$

process following a two-electron step.

The appearance of manganese(III) justified the investigation of its reactivity with the same substrates, in order to obtain at least a qualitative picture of the difference between the reactivities of

[a] First-order related to both manganese(IV) phosphate and the substrate; zero-order to manganese(III).

the two manganese species. As can be seen from the comparison of half-times the reaction of manganese(III) with each substrate studied by us proved to be slower than that of manganese(IV).

Among the substrates listed in Table 1 only formic acid, formaldehyde and α,β-unsaturated alcohols show virtual first-order kinetics; in each other case the reaction was accelerating and a sigmoid-shape kinetic curve was obtained. In the case of the latter substrates, if manganese(III) is added to the system so that $[Mn^{III}]_0 = [Mn^{IV}]_0 = 1 \times 10^{-3}$ M, the induction period is considerably shorter and the sigmoid character decreases. This points to autocatalytic reactions, where manganese(III) plays a decisive role even in the case of substrates which are not oxidized by manganese(III) alone.

The half-times and the reaction rates measured at half-times do not show exactly the same reactivity sequence of substrates, but similar tendencies can be observed in both cases. Due to the kinetic relationships, which are generally not of first-order, this reactivity sequence only presents a rather qualitative picture; nevertheless, certain conclusions may automatically present themselves. Thus, it is at once evident that manganese(IV) attacks mainly those bifunctional substrates which allow the formation of a complex of chelate character. Thus, it practically does not oxidize primary alcohols, but it does oxidize glycols. The vicinal position seems to be somewhat more favourable than the 1,3-position. However, it does not oxidize 1,4-butenediol, presumably because of the great distance no chelate complex can be formed here. The same tendency can be observed with carboxylic acids. Although it undergoes a slow reaction with the markedly reducing formic acid, it cannot attack acetic acid. At the same time it oxidizes oxalic acid and malonic acid rapidly, while succinic acid, presumably again for steric reasons, is oxidized very slowly. The situation is practically the same with carbonyl compounds as well, since although their monofunctional derivatives can be oxidized, bifunctional derivatives show a considerable increase in reactivity. A particularly convincing example, from this aspect, is the weak oxidation tendency of acetone compared with hydroxyacetone. The highest reactivity was observed with compounds having a carbonyl group in the proximity of the carboxyl group (pyruvic acid, glyoxylic acid).

Column B in Table 1 indicates that manganese(III) phosphate also oxidizes those substrates which are capable of chelate complex formation, but its reactivity is much lower than that of the manganese(IV) phosphate, as manifested also by its inactivity towards glycols.

Although it could not be verified unambiguously that the manganese(IV) phosphate prepared by us is a real solution and not a finely dispersed colloid, as with the species observed by Perez-Benito and Freeman under totally different conditions, these investigations may offer some information on its behaviour towards various groups of compounds.

EFFECT OF PHYSICO-CHEMICAL PROPERTIES OF BINARY LIQUID MEMBRANES ON STEADY-STATE TRANSPORT OF COPPER(II) IONS

MARIOLA SZPAKOWSKA

(*Received* 27 *January* 1993; *accepted* 18 *February* 1993)

Abstract—The coupled transport of copper(II) ions by the carrier Acorga P-50 through mono and binary liquid membranes has been analysed in the steady-state approximation. The membranes were composed of C_8–C_{14} normal chain paraffins and their mixtures. It was found that the total ion fluxes are the most appropriate kinetic parameters for asymmetric membranes in the steady-state approximation. The results obtained for single component (mono) membranes have shown the importance of the physicochemical nature of membrane material. In all cases transport rates were diminished by increasing viscosity and by increased copper(II)–carrier-membrane interactions, as governed by general solvent effects (polarity and polarizability). Using binary solvent mixtures as the membrane a surprising variety of substitution profiles have been obtained, despite the very similar chemical character of the membrane components. The regular substitution profile obtained for the n-octane (*S*)–n-tetradecane (*Z*) solvent pair could be analysed successfully by COPS theory. The results confirmed quantitatively the decisive role played by molecular interactions in transport kinetics. A simple molecular model is proposed to explain the dominating role played by membrane polarity in determining transport rates. The general conclusions support fully those obtained previously for non-steady state kinetic conditions.

Liquid membranes represent a very efficient means for the removal of various impurities, including metal ions, from aqueous solutions (e.g. industrial waste waters).[1–4] Therefore, scientific research to obtain more information is important from both the fundamental[1,5] and technological[3,4,6,7] viewpoints. Surprisingly, not many reports have been published which are based on the use of different membrane systems[8] or multicomponent membranes.[9] However, our previous papers[10–13] have shown the importance of the nature of the membrane material and its composition in metal ion transport through liquid membranes. The behaviour of organic solvents belonging to different solvent classes has been examined in detail.[12] It was found that some solvents were very efficient (paraffins), but others have even stopped the transport flux completely. It was also shown that physicochemical properties of membrane material and solute–solvent interactions inside the membrane have substantial influence on process efficiency.[12,13]

In the present paper the influence of the membrane solvent composition (binary mixtures of C_8–C_{14} normal chain paraffins) on process efficiency is investigated in order to check whether binary membranes are more efficient than single component ones. For this purpose the kinetics of coupled transport of copper(II) ions through

* Author to whom correspondence should be addressed.

different pure liquid paraffin membranes and their mixtures of variable compositions are studied in the steady-state approximation. The purpose of using this latter approximation in the present study is to verify the general validity of the conclusions obtained in non-steady-state conditions.[12]

EXPERIMENTAL

Materials

Copper(II) sulphate pentahydrate (Aldrich > 99.999%), acorga P50 (Acorga Ltd, 94% in kerosene) and fresh solvents (Aldrich > 99%) were used without further purification. The aqueous solutions were made up using demineralized water.

Measurement of membrane properties

Viscosity (η), refractive index (n_D^{20}) and dielectric constant (ε) of the various pure paraffins and their mixtures were determined by standard methods.[14]

Kinetic procedure

All transport experiments were conducted at $T = 25 \pm 0.1$°C using an apparatus described previously,[12] containing asymmetric membranes. The ratio of interphase surfaces between donor phase/membrane (S_d) and acceptor phase/membrane (S_a) was $S_d/S_a = 2$. The organic solvents used as membrane material were pure open-chain paraffins (n-octane, n-decane, n-dodecane, n-tetradecane) or their mixtures, immiscible with water (weight % solubilities in water $< 1 \times 10^{-4}$). For every solvent pair (see Tables 1 and 2) the initial compositions of the three phases were as follows: Donor phase: $C_{do}(CuSO_4) = 0.1175$ M, pH = 3.64, in water; membrane: carrier acorga P-50 ($C_{AC} = 0.01$ M) dissolved in pure or binary solvents S–Z of variable compositions; acceptor phase: 2 M H_2SO_4 in water (experimental conditions I). For the n-octane–n-tetradecane system a second series of experiments has also been realized (experimental conditions II): donor phase: $CuSO_4$, $C_{do} = 0.1166$ M, pH = 3.71 in H_2O; membrane: acorga P-50, $C_{AC} = 0.0094$ M; acceptor phase: 1 M H_2SO_4 in H_2O. Stirring speeds for donor, membrane and acceptor phases, 400, 250 and 400 rpm, respectively, were the highest possible ones at which hydrodynamic complications (whirls, interface deformations) were still absent. Samples (0.5 cm^3) were taken from both water phases at regular time intervals and analysed by EDTA titration using murexide as an indicator. Each

experimental result reported is the arithmetic mean of two independent titrations (error < 2%). The reproducibility of the kinetic curves is fairly good.

RESULTS AND DISCUSSION

For the systems investigated using either pure or mixed membranes all kinetic measurements were performed in exactly the same experimental conditions, except for the variable membrane composition (from $Y_Z = 0$ to $Y_Z = 1$, with Y_Z = volume fraction of membrane component Z, see below). Steady-state conditions were established using a large excess of copper in the donor phase (concentration C_{do} in M) compared to the amount of carrier (acorga P-50: AC) in the membrane (concentration C_{AC} in M units): $C_{do}/C_{AC} = 11.75$.[10,22] The change in copper concentration with time was measured directly in both the donor (C_d in M) and acceptor (C_a in M) aqueous phases. The corresponding copper concentration changes in the membrane (C_m in M) were established from material balance. It was found useful to use reduced concentrations in all kinetic analyses: $R_d = C_d/C_{do}$ for the donor phase, $R_m = C_m/C_{do}$ for the membrane and $R_a = C_a/C_{do}$ for the acceptor phase.[12] Obviously, $R_d + R_m + R_a = 1$.

Figure 1 represents typical concentration vs time diagrams obtained for n-octane(S)–n-tetradecane(Z) mixtures used as membranes. It can be seen (see also Tables 1 and 2) that fairly good straight lines have been obtained throughout the full kinetic run with correlation coefficients $r_i > 0.99$ in the majority of cases. Tables 1 and 2 also show that R_m values are rather low and remain fairly constant during the entire transport process time interval, as indicated in Fig. 1. These two important criteria, i.e. linear concentration vs time relationships (zero-order kinetics) and constancy and low levels of copper concentration in the membrane, show that the kinetic behaviour of metal ion transport through liquid membranes described by a general scheme involving two consecutive irreversible first-order reactions[12] can also be analysed in the steady-state approximation. Therefore, the straight lines of Fig. 1 obey the following equations:[12]

$$R_d = -k_o t + R_{do} \quad (1)$$

$$R_a = +k_o t + R_{ao}, \quad (2)$$

with $R_{ao} = 0$ and k_o in time^{-1} units (here h^{-1}). The corresponding copper ion fluxes are:

$$J_d = \frac{dR_d}{dt} C_{do} = -k_o C_{do} \quad (3)$$

and

$$J_a = \frac{dR_a}{dt} C_{do} = +k_o C_{do}. \quad (4)$$

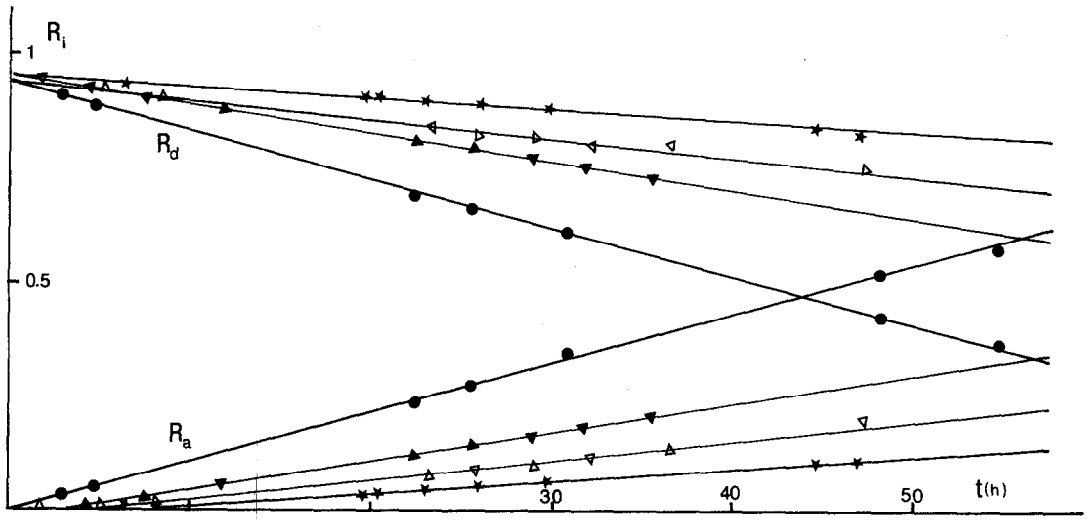

Fig. 1. Steady-state zero-order kinetics of copper(II) ion transport through n-octane(S)–n-tetradecane(Z) binary liquid membranes. R_d and R_a are the relative concentrations of copper(II) ions in the donor and acceptor aqueous phases, respectively. Volume fraction of Z component: $Y_Z = 0$ (●), $Y_Z = 0.3$ (▲), $Y_Z = 0.6$ (△), $Y_Z = 1$ (★).

J_d and J_a are actually the membrane permeation and membrane exit fluxes, respectively. They are given in M h^{-1} units. Since they are standardized to the donor phase volume (V_d), because of the requirements of material balance, they can be obtained also in mol h^{-1} units by simple multiplication by the factor V_d (in L units). Both J_d and J_a are in reality total fluxes crossing the appropriate interface surface area [donor phase/membrane (S_d) and membrane/acceptor phase (S_a), respectively]. Their values in M h^{-1} units are collected in Tables 1 and 2. It can be seen that in each case the two fluxes are identical (i.e. $-J_d = +J_a$) within experimental error, in full agreement with steady-state requirements. It is important to realize that this identity could never have been obtained using the traditional fluxes per unit area (in M h^{-1} cm^{-2} units) on account of the asymmetry of the membranes used (i.e. $S_d \neq S_a$). Fluxes reported to the unit area can satisfy steady-state requirements only in the case of symmetrical membranes.

Tables 1 and 2 also show the relative amounts of copper(II) ions present after 30 h of transport in the donor phase (R_d), membrane phase (R_m) and acceptor phase (R_a). The R_a values show clearly that copper ion transport is rather slow in the investigated systems. In the most favourable cases only *ca* 30% of the copper is transported from the donor to the acceptor phase during the time interval considered. This seems to be due to the high C_{do}/C_{AC} ratio which is necessary to obtain and to maintain zero-order kinetics during the experiments (see above).

(a) *Transport through single component membranes*

Steady-state transport rates were measured through the following pure membranes: n-octane (OC), n-decane (DC), n-dodecane (DD) and n-tetradecane (TD). They are given by the entries of Table 1 corresponding to either $Y_Z = 0$ or $Y_Z = 1$. It can be seen from this table that steady-state fluxes are quite sensitive to the nature of the membrane material, despite the fact that the organic solvents used have similar chemical character. They all belong to the same homologous series of normal chain paraffins.

When the actual flux values in the acceptor phase (J_a) are compared the different solvents can be put into the following order of decreasing transport efficiency: OC > DC > DD > TD. Due to the steady-state conditions the analysis of J_d values leads to the same conclusions as expected. It should be noted that the observed order of transport efficiency is identical to the sequence that was established previously[12] using non-steady-state kinetic analyses. This confirmation raises the question as to the nature of the physicochemical properties which decide transport efficiency. It might be expected that if the rate limiting step of the transport process is diffusion through a thin membrane layer situated between the interface and the bulk of the membrane

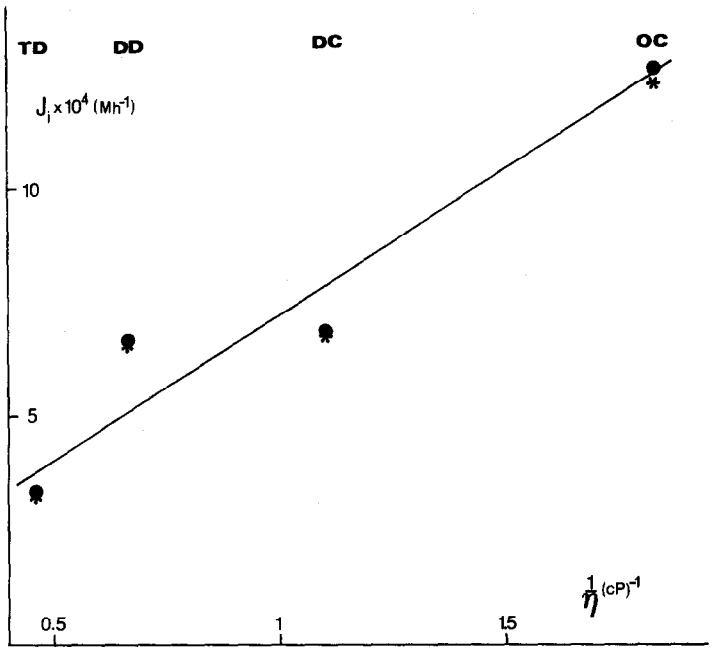

Fig. 2. Variation of membrane permeation, J_d (*), and membrane exit, J_a (●), fluxes with membrane viscosity. OC: n-octane; DC: n-decane; DD: n-dodecane; TD: n-tetradecane.

(as previously, see ref. 12), fluxes should be inversely proportional to the membrane viscosity. Figure 2 shows that this is indeed the case (Tables 1–3). The straight line obtained obeys the following equation:

$$J_a = -(0.077 \pm 0.25)10^{-4} + (0.148 \pm 0.031)10^{-4}\eta^{-1}, \quad (5)$$

with the correlation coefficient $r = 0.9577$ and standard deviation $\sigma = 0.213 \times 10^{-4}$. Therefore, increasing membrane viscosity slows down the transport rate.

Furthermore, molecular interactions between the diffusing metal ion–carrier complex and the membrane molecules, as expressed by membrane material polarity [Kirkwood function $(\varepsilon-1)/(2\varepsilon+1)$] and polarizability $[(n^2-1)/(n^2+2)]$ parameters, should also have a strong influence on transport kinetics. The reason for using the Kirkwood function was explained in a previous paper.[12] When the interaction between the diffusing species and the membrane molecules increases, i.e. when membrane polarity and polarizability increase, the transport rate should decrease if these general solvent effects stabilize the initial state more than the transition state of diffusion. This expectation is fully borne out by the following relationships obtained for the present steady-state kinetics data (Tables 1–3):

$$\ln J_a = (14.242 \pm 1.425) - (0.783 \pm 0.194)[(\varepsilon-1)/(2\varepsilon+1)] \quad (6)$$

with $r = 0.9437$; $\sigma = 0.187$

and

$$\ln J_a = (17.784 \pm 2.78) - (0.979 \pm 0.378)[(n^2-1)/(n^2+2)] \quad (7)$$

with $r = 0.8775$; $\sigma = 0.366$.

However, it should be noted that these relationships are valid only in the first approximation since J_a values are composite quantities[12] and each of their components may be influenced differently by membrane properties.

When the same analysis is made for the permeation flux J_d the same conclusions are obtained as for J_a. This is due, of course, to the steady-state conditions: $|J_d| = |J_a|$ within experimental error.

It is important to emphasize that the conclusions concerning membrane material effects are the same as those obtained for non-steady-state kinetic conditions.[12] This confirms the validity of both approaches to the same transport process. However, non-steady-state analysis appears to be superior to steady-state at the molecular level. As a matter of fact, it was shown previously[12] that permeation rates and membrane exit rates are

influenced differently by membrane material effects. This fact could be exploited as a useful diagnosis for the molecular mechanism of the transport process. The very identity of J_d and J_a in steady-state conditions obviously precludes such a possibility.

(b) *Transport through binary membranes*

By mixing different membrane solvents a great variety of physicochemical conditions could be realized with the aim of optimizing transport efficiency. Namely, when one membrane component is gradually replaced by another one the transport rate can be varied in a systematic way (Fig. 1, Table 1). Figures 3–6 represent the variation of steady-state fluxes in the acceptor phase (J_a) with composition of the binary membrane (Y_Z). The volume fraction of the Z membrane component (Y_Z) was determined by the actual membrane composition used in the various experiments.

It can be seen that when the starting membrane material (S) is gradually replaced by another one (Z), different kinds of substitution or stripping profiles are obtained. Adding n-decane (Z) to n-dodecane (S) (Fig. 3) almost no change of kinetic flux is observed, even at complete substitution

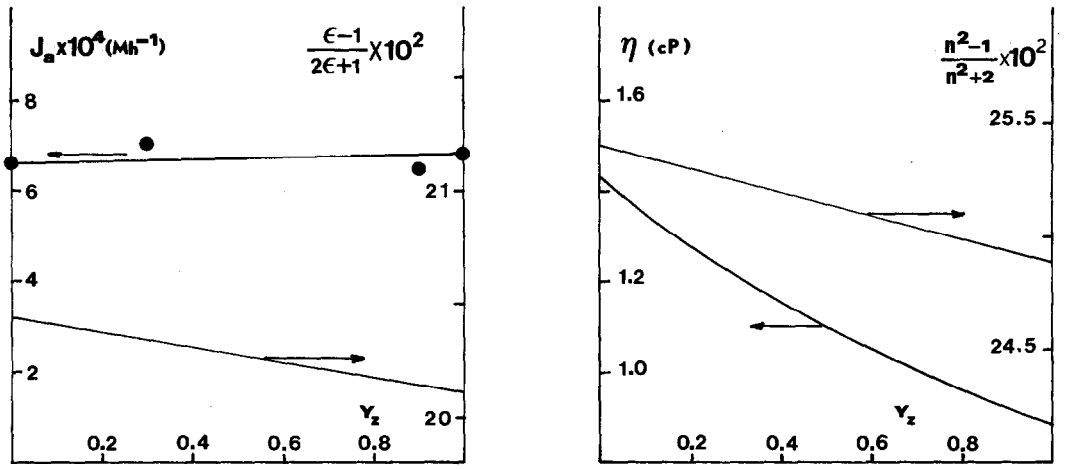

Fig. 3. Stripping profile of membrane exit rate J_a and membrane properties for the system n-dodecane(S)–n-decane(Z).

($Y_Z = 1$). On the other hand, when n-octane is added to the same initial solvent (Fig. 4) a sizeable increase in J_a is observed, while the presence of n-tetradecane brings about a slowing down of the transport process (Fig. 5). In the latter case even a minimum appears on the stripping profile. The greatest decrease of J_a appears when n-octane is substituted by n-tetradecane (Fig. 6).

This great variety of stripping profiles appears rather surprising in the light of the very similar chemical character of the membrane components. It was shown in the case of single component membranes (see above) that increasing membrane viscosity and/or the membrane–metal-carrier complex interactions, as expressed by polarity and polarizability, brings about a decrease in transport rate. Unfortunately, the different linear relationships obtained [eqs (5)–(7)] do not allow us to conclude definitively which property is the dominating factor. In the case of binary membranes the same regularities may be observed. When the stepwise replacement of one membrane component (S) by another (Z) increases the resulting membrane viscosity and the corresponding membrane–metal-carrier interactions, the steady-state fluxes are systematically decreased (Figs 3–6). Furthermore, the comparison of stripping profiles obtained for viscosity, polarizability and polarity (Figs 3–6) shows

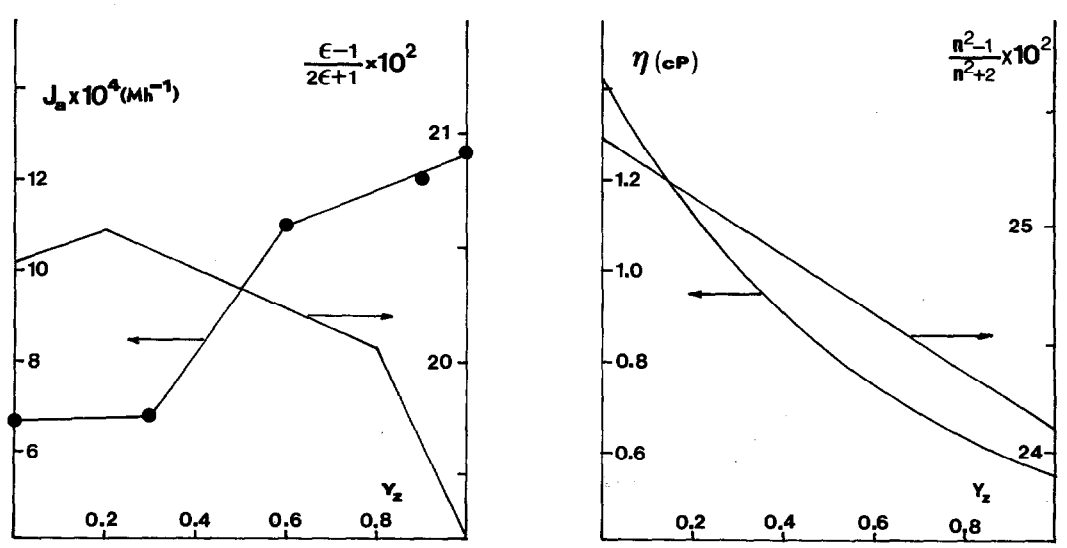

Fig. 4. Stripping profile of membrane exit rate J_a and membrane properties for the system n-dodecane(S)–n-octane(Z).

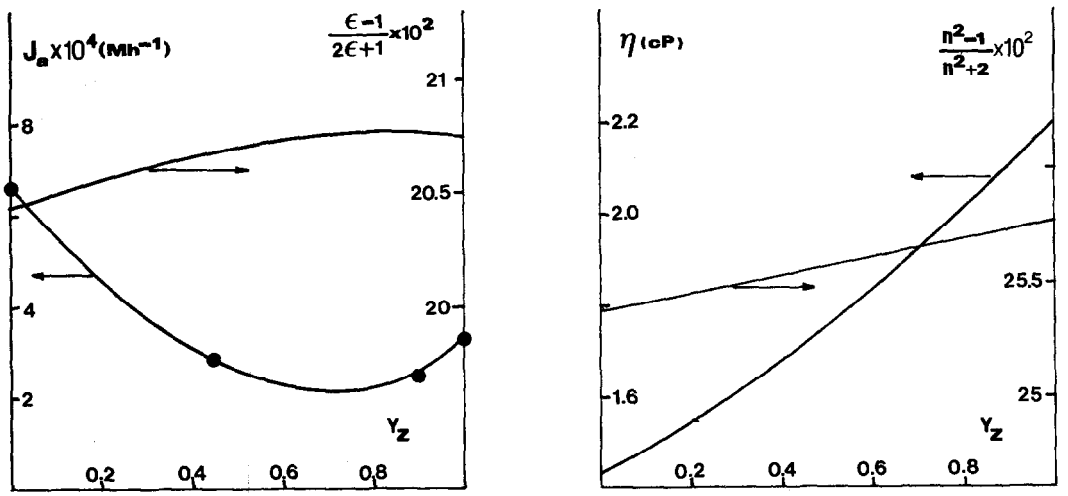

Fig. 5. Stripping profile of membrane exit rate J_a and membrane properties for the system n-dodecane(S)–n-tetradecane(Z).

clearly that only the latter has a profile, the shape of which is roughly the mirror image of the stripping profile obtained for the transport flux J_a. This suggests that the dominating membrane property may be its polarity in determining transport efficiency. This important observation may be interpreted using the following simple model.

It is assumed, in agreement with reaction field theory,[15] that the membrane constitutes a homogeneous, isotropic medium having a bulk dielectric

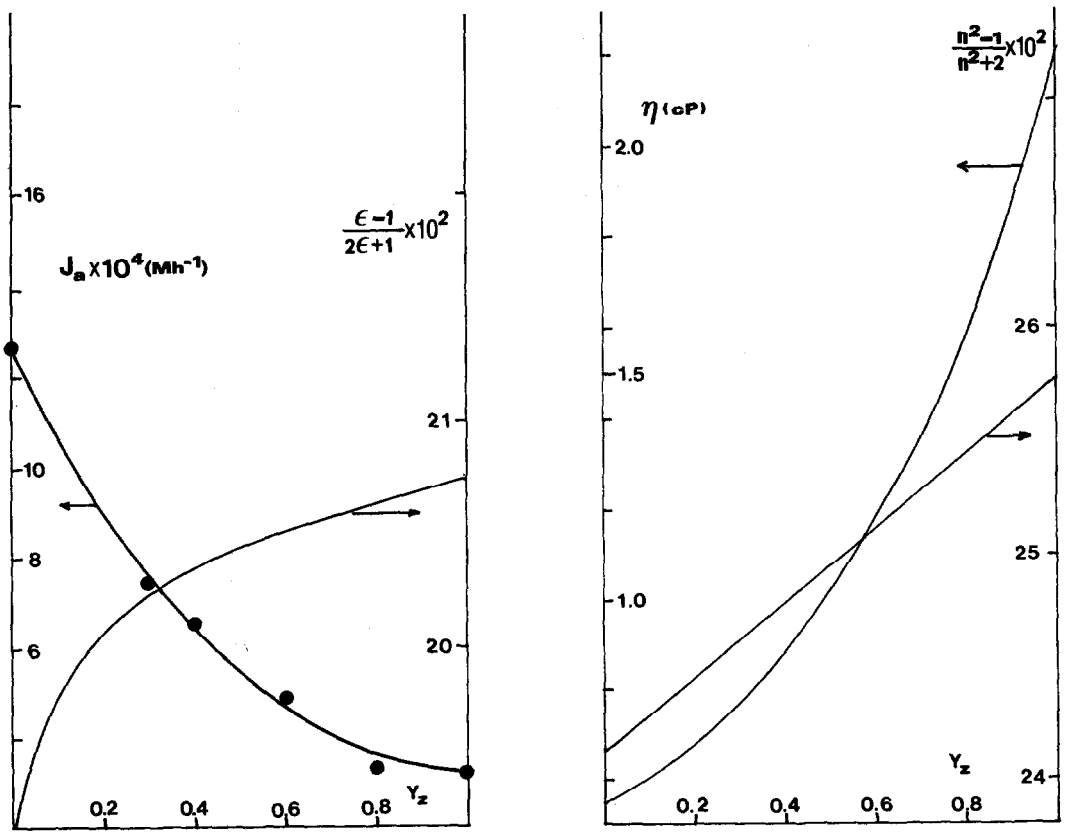

Fig. 6. Stripping profile of membrane exit rate J_a and membrane properties for the system n-octane(S)–n-tetradecane.

constant ε. The solute A, characterized by a permanent (point) dipole μ_A and by a polarizability α_A, sits in the middle of a solvent cavity of radius r. The solute molecule polarizes the solvent cage and as a consequence a reaction field F is produced by the polarized solvent. This reaction field depends directly on solvent polarity through the Kirkwood function (see above). Furthermore, F is composed of an electronic part depending on solvent polarizability[16] and a nuclear part depending on position and orientation of the atoms in the solvent molecules. The actual value of the reaction field is not constant. It is fluctuating in a random way due to the Brownian motion of the solute and solvent molecules. Such a motion may be described by the Langevin equation.[17] When this latter is combined with stochastic considerations (random walk), the following expression may be derived for the translational diffusion coefficient D: $D = kT/f$, where k is the Boltzmann constant, T is the absolute temperature and f represents the so-called friction coefficient opposing the diffusional movement.[18] It can be shown by hydrodynamic considerations[19] that $f = 6\pi r\eta$, where η is the solvent viscosity, leading to the well known Stokes–Einstein formula of the diffusion coefficient: $D = kT/6\pi\eta r$. This formula shows clearly why transport flux diminishes with increasing membrane viscosity. At the molecular level the friction coefficient is nothing other than the time integral of the auto-correlation function of the fluctuating force acting on the solute molecule.[17] We propose that in the present case such a force is created by the fluctuating reaction field F. Recalling that the transport flux J (either steady or non-steady state) is directly proportional to the diffusion coefficient D (Fick's laws), the observed medium dependence of transport fluxes may be easily explained. If the membrane dielectric constant increases the reaction field F also increases and the friction coefficient f becomes greater. However, increasing f decreases the diffusion coefficient D and this brings about a corresponding decrease of the transport flux J in full agreement with the experiment.

Our model also makes clear why polarity is a more important factor than polarizability in defining membrane medium effect on transport rate: polarizability is only part of the total reaction field, determined completely by polarity, and it cannot give a full description of the observed phenomena.

All these considerations confirm our previous hypotheses[12] that the rate determining step of the studied transport kinetics implies a diffusion process across a thin membrane layer situated between the water–membrane interface and the bulk membrane interior.

The regularity of the stripping profile obtained for the n-octane(S)–n-tetradecane(Z) binary membrane system (Fig. 6) suggests that it may be analysed in the light of the competitive preferential solvation (COPS) theory.[10,13,20]

It should be recalled that COPS theory is very useful in evaluating quantitatively solute–solvent interactions.[20] It is based essentially on a virtual microscopic partitioning of the solute in homogeneous media. It is admitted that the components S and Z of a binary solvent mixture compete for solvating the solute A to the extent of their electronic-geometric affinity, $\kappa_{A(S)}$ and $\kappa_{A(Z)}$, respectively. When solvent–solvent interactions may be neglected compared with solute–solvent interactions the solute can be considered as partitioned between the solvent components. Since the latter act independently, the steady-state transport flux J_i through a binary membrane may be written as:

$$J_i = P_{A(S)}J_{i(S)} + P_{A(Z)}J_{i(Z)}. \tag{8}$$

$J_{i(S)}$ and $J_{i(Z)}$ represent membrane permeation (i = d) or membrane exit (i = a) fluxes measured through pure S and pure Z membranes, respectively. $P_{A(S)}$ and $P_{A(Z)}$ are the respective generalized partitioning factors:

$$P_{A(j)} = \frac{\kappa_{A(j)}C_j}{\sum_k \kappa_{A(k)}C_k}, \tag{9}$$

where j = S or Z, k = S and Z, and C_j and C_k are concentrations of components j and k in M units.

Therefore, the COPS equation for the membrane exit flux, J_a, will have the form

$$J_a = \frac{J_{a(S)}\kappa_{A(S)}C_S + J_{a(Z)}\kappa_{A(Z)}C_Z}{\kappa_{A(S)}C_S + \kappa_{A(Z)}C_Z}. \tag{10}$$

Neglecting the eventual volume change of mixing and using the relationship between volume fraction (Y_i) and concentration ($C_i = Y_i v_i^{-1}$, where v_i is the molar volume of component i), the following useful relationship between C_S and C_Z can be obtained:

$$C_S = (1 - v_Z C_Z)/v_S. \tag{11}$$

Substitution of this relationship into eq. (10) leads to the following equation:

$$J_a = \frac{J_{a(S)} + \left[J_{a(Z)}\dfrac{\kappa_{A(Z)}}{\kappa_{A(S)}}v_S - J_{a(S)}v_Z\right]C_Z}{1 + \left[\dfrac{\kappa_{A(Z)}}{\kappa_{A(S)}}v_S - v_Z\right]C_Z}, \tag{12}$$

which may be used to describe the substitution (or stripping) profiles.

The quantity $\kappa_{A(Z)}/\kappa_{A(S)}$ appearing in this equation

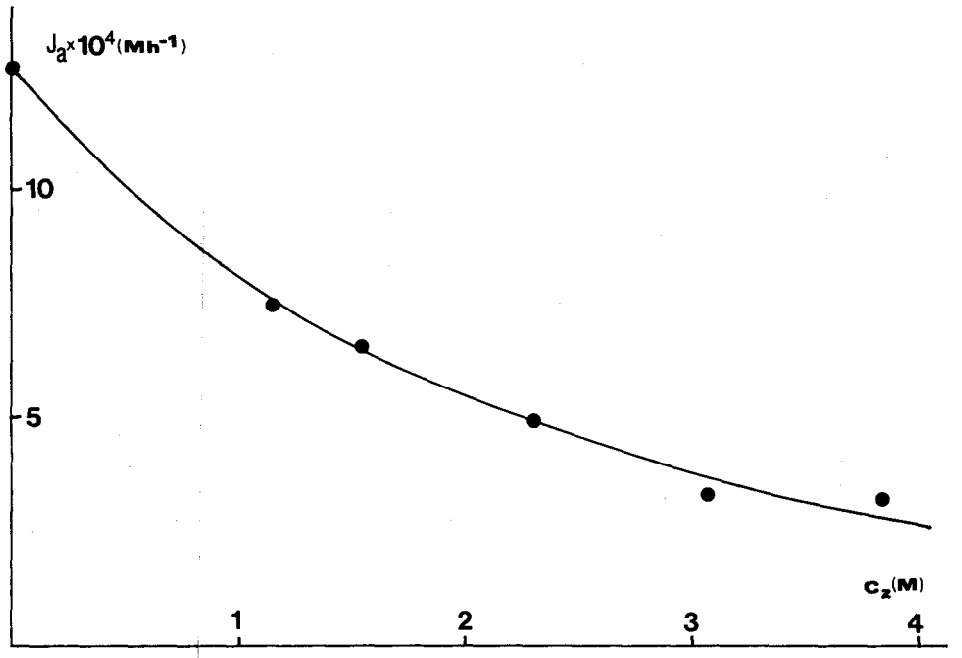

Fig. 7. Stripping profile for membrane exit flux J_a in the case of n-octane(S)–n-tetradecane(Z) binary membrane (experimental conditions I). The theoretical curve was calculated from the data of Tables 2 and 5 using eq. (12).

is the affinity constant ratio.[20] It accounts quantitatively for the solute (A = copper(II)–carrier complex)–solvent (membrane components S and Z) interactions. Its graphical determination may be realized using a Scatchard-type linearized form of eq. (12):

$$\frac{J_{a(S)}-J_a}{C_Z} = (J_{a(S)}-J_{a(Z)})\frac{\kappa_{A(Z)}}{\kappa_{A(S)}}v_S - \left[\frac{\kappa_{A(Z)}}{\kappa_{A(S)}}v_S - v_Z\right](J_{a(S)}-J_a). \quad (13)$$

The results of the stripping experiments realized for the n-octane(S)–n-tetradecane(Z) binary membrane in two different experimental conditions are collected in Table 2 and Fig. 7. Details of COPS theory calculations are given in Table 4. As an example, Table 5 and Fig. 8 show that the linear equation [eq. (13)] is obeyed in the full concentration range, in agreement with all the previous results.[10,13,20] The final results obtained from the COPS theoretical analysis are given in Table 6. It can be seen from the obtained affinity constant ratios that n-tetradecane interacts with the copper(II)–carrier complex about four times stronger than n-octane, independently of the exper-

imental conditions and the transport fluxes (J_d or J_a) used for their determination. This confirms and supports the conclusion above that more strongly interacting membranes slow down the transport rate [eqs (6) and (7)].

The validity of the COPS equation can also be firmly established from the fact that the calculated differences between fluxes characterizing pure membrane components (e.g. $J_{a(S)}-J_{a(Z)}$) are identical, within experimental errors, to the directly measured values. Furthermore, COPS theory can also be used to determine the molar volume of the component $Z(v_Z)$. As a matter of fact, if the linear COPS equation [eq. (13)] is valid the following formula can be used to predict v_Z values:

$$v_Z = \frac{\text{intercept of eq. (13)}}{J_{a(S)}-J_{a(Z)}} - \text{slope of eq. (13)}. \quad (14)$$

Here $(J_{a(S)}-J_{a(Z)})$ represents the directly measured flux difference. Table 6 shows that the calculated v_Z values are in fairly good agreement with the official values reported in the literature. Let us note finally that the coherence of COPS parameters (Table 6) is demonstrated by the fact that when they are substituted into eq. (12) they allow the correct reproduction of the experimental stripping profile (Fig. 7).

CONCLUSIONS

The present study allows us to draw the important conclusion that, notwithstanding the approach (steady state or non-steady state) used to analyse the transport kinetics,[21] the same general conclusions can be obtained for the physicochemical mechanism of action and transport efficiency of mono and binary liquid membranes.

(*Received* 4 *January* 1993; *accepted* 18 *February* 1993)

Abstract—The X-ray crystal structure of $[La(Odpp)_3(THF)_2]\cdot THF$ (Odpp = $OC_6H_3Ph_2$-2,6), prepared by reaction of lanthanum metal, bis(pentafluorophenyl)mercury and 2,6-diphenylphenol in THF, shows distorted trigonal-bipyramidal stereochemistry for lanthanum. A phenolate oxygen [La—O 2.25(1) Å] and a THF oxygen [La—O 2.68(2) Å] occupy apical positions [O—La—O 165.9(4)°], whilst two phenolate oxygens [La—O 2.25(1), 2.234(9) Å] and a THF oxygen [La—O 2.52(1) Å] occupy trigonal positions [O—La—O 122.1(4), 124.8(5), 96.5(6)°]. The apical La—O(THF) distance is exceptionally and unexpectedly long. Unit cell data for $[Nd(Odpp)_3(THF)_2]\cdot THF$ suggest that it is isostructural with the lanthanum compound.

The effect of lanthanide ion contraction (*ca* 0.2 Å from La^{3+} to Lu^{3+})[1] on the coordination number and stereochemistry of lanthanide complexes is of considerable interest.[2] Although the larger lanthanides might be expected to favour higher coordination numbers than the smaller elements, the observed effects are quite variable. Thus, determination of the structures of 10 $LnCp_3(THF)$ ($Cp = \eta^5$-cyclopentadienyl, Ln = Y,[3] La,[3] Ce,[4] Pr,[5] Nd,[5,6] Sm,[7] Gd,[8] Dy,[9] Yb,[10] Lu[11]) complexes has shown all to be isostructural with pseudo-tetrahedral 10-coordination for the lanthanide. By contrast, $LnCp_3$ structures show a gradation from 11-coordination (Ln = La,[12] Pr[13]) through 10-(Ln = Er, Tm[14]) and nine-coordination (Ln = Yb[15]) to eight-coordination (Ln = Lu[16]). We recently reported the structure of $[Yb(Odpp)_3(THF)_2]\cdot THF$ (Odpp = $OC_6H_3Ph_2$-2,6), which shows distorted square pyramidal, five-coordination for ytterbium,[17] the unusually low coordination number for the lanthanide[2] being stabilized by the bulky 2,6-diphenylphenolate ligands. To examine the effect of lanthanide ion size on structures of complexes of this ligand we have now determined the X-ray structure of the THF complex of lanthanum 2,6-diphenylphenolate.

RESULTS AND DISCUSSION

The reaction of lanthanum metal with bis(pentafluorophenyl)mercury and 2,6-diphenylphenol in THF yielded the THF complex of lanthanum 2,6-diphenylphenolate.

$$2La + 3Hg(C_6F_5)_2 + 6HOdpp \longrightarrow 2La(Odpp)_3 + 3Hg\downarrow + 6C_6F_5H \quad (1)$$

This synthetic route has previously been used for heavier lanthanide 2,6-diphenylphenolates.[17] It can be rationalized as a redox transmetallation (2)

* Part VI, *Angew. Chem.*, in press.

† Author to whom correspondence should be addressed.

‡ Present address: Changchun Institute of Applied Chemistry, Chinese Academy of Sciences, Changchun 130022, P.R.C.

between the metal and $Hg(C_6F_5)_2$, giving $La(C_6F_5)_3$ which is trapped by protolytic ligand exchange (3) with the phenol.

$$2La + 3Hg(C_6F_5)_2 \longrightarrow 2La(C_6F_5)_3 + 3Hg\downarrow \quad (2)$$

$$La(C_6F_5)_3 + 3HOdpp \longrightarrow La(Odpp)_3 + 3C_6F_5H \quad (3)$$

Alternatively, initial redox transmetallation giving $La(C_6F_5)$ may be followed by a rapid series of ligand exchange and redox reactions through e.g. La(Odpp), $La(Odpp)C_6F_5$, $La(Odpp)_2$, etc. Protolytic ligand exchange is favoured by the greater acidity of 2,6-diphenylphenol (phenols have pK *ca* 10)[18] than pentafluorobenzene (pK 25.6 in THF, derived[19] from the value in cyclohexylamine[20] by the method of Streitwieser[21]).

The IR spectrum of the product showed no ν(OH) absorptions, consistent with the formation of a phenolato complex, and was similar to spectra of reported 2,6-diphenylphenolates.[17] No unambiguous information concerning coordination of THF can be derived from the IR spectrum owing to significant absorption of the phenolate ligand in the relevant regions. Although single crystals of the complex had the composition $[La(Odpp)_3(THF)_2]\cdot THF$, the ^1H NMR spectrum of the crystals gave a THF:Odpp ratio of 4:3. Preservation of the crystals for X-ray crystallography precluded drying and it is possible that some free THF was retained, and it is of interest that a microanalysis was marginally closer to the calculated figures for $La(Odpp)_3\cdot 4THF$ than $La(Odpp)_3\cdot 3THF$. Alternatively, the use of d_8-toluene as an NMR solvent may have led to the slight precipitation of a species with a THF:Odpp ratio $< 1:1$, leaving a higher ratio in solution. Dissolution of $Yb(C_5H_4PPh_2)_2(THF)_2$ in toluene is followed by deposition of $Yb(C_5H_4PPh_2)_2(THF)$.[22]

X-ray crystal structure

The structure of the complex $[La(Odpp)_3(THF)_2]\cdot THF$ is displayed in Fig. 1. Selected bond distances and angles are given in Table 1, together with analogous data[17] for $[Yb(Odpp)_3(THF)_2]\cdot THF$. Lanthanum is five-coordinate with distorted trigonal bipyramidal stereochemistry, in contrast to the distorted square pyramidal arrangement in the ytterbium complex. In particular, there is only one near linear O—La—O angle [165.9(4)°, next nearest 124.8(5)°], whereas there are O—Yb—O angles of 147.8(3)° and 151.8(3)° for $[Yb(Odpp)_3(THF)_2]\cdot THF$. The lanthanum complex has apical phenolate and THF ligands, with two phenolates and one THF in the trigonal plane (Fig. 1). There is no significant difference in the La—Odpp distances, despite the different environments for the Odpp ligands. By contrast, the apical La—O(THF) distance is appreciably lengthened (0.16 Å) over the equatorial La—O(THF) bond. In the ytterbium complex the O(THF) donor atoms are *trans* and the

[a] Beyond the donor atoms, the numbering scheme is different for the two compounds.

Yb—O(THF) bond lengths are equal, whereas there is some variation (0.07 Å) in the Yb—Odpp lengths (Table 1) with the longer bonds in the square plane. The stereochemical arrangement in $[La(Odpp)_3(THF)_2]\cdot THF$ is similar to that of distorted trigonal bipyramidal $[Ce(OC_6H_3Bu^t_2\text{-}2,6)_3(CNBu^t)_2]$, which has apical aryloxide and t-butyl isocyanide ligands.[23] In particular, the O—Ce—C angle for the apical donor atoms is 161.4(3)°. However, there is much less variation between apical and planar Ce—C distances (0.045 Å) than between corresponding La—O(THF) distances. The average La—O(Ar) distance (2.24 Å) corresponds closely to ⟨Ce—O(Ar)⟩ (2.23 Å). This is consistent with the small difference (0.02 Å)[1] in ionic radii for La^{3+} and Ce^{3+} with the same coordination number. Further, ⟨La—Odpp⟩ exceeds ⟨La—$OCPh_3$⟩ (2.18 Å) for the terminal La—O bonds of $La_2(OCPh_3)_6$[24] by an amount (0.06 Å) reasonable (see ref. 1) for the difference in ionic radii between five- and four-coordinate La^{3+}.

Subtraction of an ionic radius for five-coordinate La^{3+} (0.96 Å) (derived from extrapolation of data for higher coordination numbers[1]) from ⟨La—O(Ar)⟩ gives 1.28 Å, a value consistent with 1.27 Å similarly derived from ⟨Yb—O(Ar)⟩ of $[Yb(Odpp)_3(THF)_2]\cdot THF$,[17] and with values from analogous subtractions for a variety of low-coordinate lanthanide(II or III) aryloxides.[25] The distance (1.56 Å) from subtraction of the lanthanum five-coordinate radius from La—O(5) is much larger than usual values [1.34(5) Å] for lanthanide-ether complexes,[26] but is within the range (1.48–1.59 Å) for THF complexes of bulky lanthanide phenolates.[25] However, a similar subtraction for La—O(4) gives the exceptionally large 1.72 Å, indicating that the apical THF is very weakly bound. Indeed, without this THF ligand there is a plausible distorted tetrahedral $[La(Odpp)_3(THF)]$ species, in which the bond distances are only slightly longer (*ca* 0.03–0.05 Å) than reasonable values for four-coordinate lanthanum. The abnormal length of La—O(4), in contrast to the Yb—O(THF) bonds of $[Yb(Odpp)_3(THF)_2]\cdot THF$, is surprising since steric repulsion should be lower for La^{3+} than the smaller Yb^{3+}. Possibly, the apical 2,6-diphenylphenolate strongly repels (electronically and sterically) the transoid THF ligand, whereas no THF is *trans* to Odpp in the ytterbium complex.[17] It is of interest that the two mutually *trans* Odpp ligands of $[Yb(Odpp)_3(THF)_2]\cdot THF$ are bound more weakly than the apical Odpp (Table 1). In $[Ce(OC_6H_3Bu^t_2\text{-}$

$2,6)_3(CNBu^t)_2]$ elongation of the apical Ce—C bond is far less marked (above). Steric repulsion by THF is likely to be greater than by an isonitrile, even one with a bulky alkyl group, because of the spear-like nature of the latter.

The steric coordination number[27]* of Odpp (1.9), determined from X-ray data for $[Yb(Odpp)_3(THF)_2]\cdot THF$, is intermediate between those of 2,6-di-i-propylphenolate (1.7) and 2,6-di-t-butylphenolate (2.4). Thus, the sum of the steric coordination numbers of the ligands in $[La(Odpp)_3(THF)_2]\cdot THF$ is 8.1, indicative[25] of a high degree of crowding.

The C—O distances of the phenolate ligands are substantially reduced from single bond lengths, reflecting substantial delocalization from oxygen into the aromatic rings; this effect being enhanced by the essentially ionic character of the lanthanum–oxygen bonds. In addition, these bonds are consistently shorter [⟨C—O(Ar)⟩ 1.31 Å], as are those of the Yb analogue [⟨C—O(Ar)⟩ 1.33 Å], than ⟨C—O(Ar)⟩ (1.38 Å) of $[Yb(OC_6H_2Bu^t_3\text{-}2,4,6)_3 THF]$.[17] This can be attributed to the electron-withdrawing effect of the phenyl substituents.

Unit cell data for $[Nd(Odpp)_3(THF)_2]\cdot THF$ (see Experimental) are similar to those of the title lanthanum complex and very different from those of the Yb analogue, hence the Nd and La complexes are probably isostructural. Similarities between the properties of complexes of lighter lanthanides, e.g. La and Nd, are common.[28]

Thus, increasing the lanthanide ion size in $Ln(Odpp)_3(THF)_n$ complexes does not result in an increase in coordination number. Rather, there is a change from square-pyramidal stereochemistry to a trigonal bipyramidal arrangement with one elongated bond.

EXPERIMENTAL

General

The lanthanide phenolates are air- and moisture-sensitive and were handled under purified nitrogen or argon. Handling methods, gas and solvent purification and analytical methods were as reported previously.[19,29–32] IR spectra are of Nujol mulls for the region 4000–650 cm^{-1}. The ^1H NMR spectrum was recorded for a solution in C_7D_8 and chemical shifts are in ppm downfield from internal tetramethylsilane. Lanthanum metal (REACTON Grade) was from Johnson–Matthey Rare Earth Products. Bis(pentafluorophenyl)mercury was obtained by the reported method.[33] 2,6-Diphenylphenol was from Aldrich.

Tris(2,6-diphenylphenolato)bis(tetrahydrofuran)lanthanum(III)-tetrahydrofuran (1/1)

Lanthanum powder (0.52 g, 3.7 mmol), 2,6-diphenylphenol (0.38 g, 1.5 mmol) and bis(pentafluorophenyl)mercury (0.40 g, 0.75 mmol) were stirred in dry THF at room temperature under purified nitrogen. After 1 day, two drops of mercury metal were added to promote the reaction. Following stirring for 4 days the reaction mixture was filtered through a celite pad. The yellow filtrate was concentrated *in vacuo*. Cooling at −20°C for several days gave elongated tubular, light yellow–gold crystals of the title compound (yield 60%). Found: C, 71.5; H, 6.1. Calc. for $C_{66}H_{63}LaO_6$: C, 72.6; H, 5.8%. Calc. for $C_{70}H_{71}LaO_7$ ($La(Odpp)_3(THF)_4$): C, 72.2; H, 6.2%. IR: 1595m, 1495m, 1404m, 1307m, 1281m, 1260s, 1174w, 1086m, 1064m, 1025m, 966w, 914w, 855s, 753s and 703s cm^{-1}. ^1H NMR: 1.13, m, 16H, CH_2C; 3.09, m, 16H, CH_2O; 6.73, m, 11H aromatic; 6.93, m, 22H, aromatic; 7.13, d, 6H, aromatic. Single crystals of the complex were present in the isolated crystalline product. Crystals suitable for X-ray study were sealed in Lindeman glass capillaries under argon in a recirculating atmosphere dry-box.

Tris(2,6-diphenylphenolato)bis(tetrahydrofuran)neodymium(III)-tetrahydrofuran (1/1)

The complex was prepared by the method reported for $[Nd(Odpp)_3(THF)_2]$,[17] but crystals obtained from cooling the filtered, partly evaporated reaction mixture were not dried under vacuum (which gives $[Nd(Odpp)_3(THF)_2]$ as a powder[17]). Suitable crystals were mounted for X-ray examination as for the La analogue.

X-ray crystallography

Intensity data for a multifaceted transparent crystal of $[La(Odpp)_3(THF)_2]\cdot THF$, with the dimensions $0.1\times0.1\times0.3$ mm mounted in a glass capillary, were measured at room temperature on an Enraf–Nonius CAD4F diffractometer fitted with Mo-K_α radiation, $\lambda = 0.7107$ Å (graphite monochromator). The ω–2θ scan technique was employed to measure 4225 data to a maximum Bragg angle of 22.5°. Significant decomposition of the crystal occurred during the data collection, as

* This provides an estimate of the steric demands of a ligand relative to chloride as 1.0, and is based on the solid angle comprising the van der Waals radii of all atoms of the ligand.[27]

evidenced by the linear decrease in the net values (to *ca* 90% of their original values) of two intensity standards monitored every 7600 s of X-ray exposure time. The data set was corrected for this intensity variation, Lorentz and polarization effects, but not for absorption. Of the reflections measured 3994 were unique and 2007 satisfied the $I \geqslant 2.5\sigma(I)$ criterion and were used in the subsequent analysis. $[La(Odpp)_3(THF)_2]\cdot THF$, $C_{66}H_{63}LaO_6$, $M = 1091.1$, monoclinic, space group $P2_1$, $a = 10.231(3)$, $b = 22.000(3)$, $c = 13.390(4)$ Å, $\beta = 100.76(3)°$, $V = 2960.9$ Å^3, $Z = 2$, $D_c = 1.224$ g cm^{-3}, $F(000) = 1128$, $\mu = 7.43$ cm^{-1}.

The structure was solved by the interpretation of the Patterson synthesis and refined by a full-matrix least-squares procedure based on F.[34] The lanthanum and oxygen atoms were refined with anisotropic thermal parameters and the C_6H_5 groups were refined as hexagonal rigid groups; hydrogen atoms were included in the model at their calculated positions (C—H 0.97 Å). After the inclusion of a weighting scheme of the form $w = [\sigma^2(F)+gF^2]^{-1}$ the refinement was continued until convergence, when $R = 0.061$, $g = 0.0093$ and $R_w = 0.063$. The analysis of variance showed no special features and the maximum residual electron density peak in the final difference map was 0.69 e Å^{-3}. The absolute configuration of the structure was determined on the basis of differences in high-angle Friedel pairs included in the data set. The molecular structure and numbering scheme are shown in Fig. 1, which was drawn with ORTEP[35] at 15% probability ellipsoids. Structure solution and refinement were performed with the SHELX76 program installed on a SUN 4/280 computer. Scattering factors (corrected for f' and f'') for neutral lanthanum were from ref. 36 and those for the remaining atoms were as incorporated in SHELX76.[34] Fractional atomic coordinates, complete lists of bond distances, bond angles, thermal parameters, hydrogen atom parameters and structure–factor tables are available from the Editor and the atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

Unit cell data for $[Nd(Odpp)_3(THF)_2]\cdot THF$

$a = 10.149$, $b = 21.839$, $c = 13.192$ Å, $\beta = 100.51°$, measured with a Philips PW1100 diffractometer.

Acknowledgements—We are grateful to the Australian Research Council for support, to the Australian Academy of Science for an exchange visit by Q.S. and to Prof. J. Marçalo, ICEN-LNETI, Portugal, for calculation of the steric coordination number of Odpp.
