(*Received* 2 *June* 1992; *accepted* 10 *September* 1992)

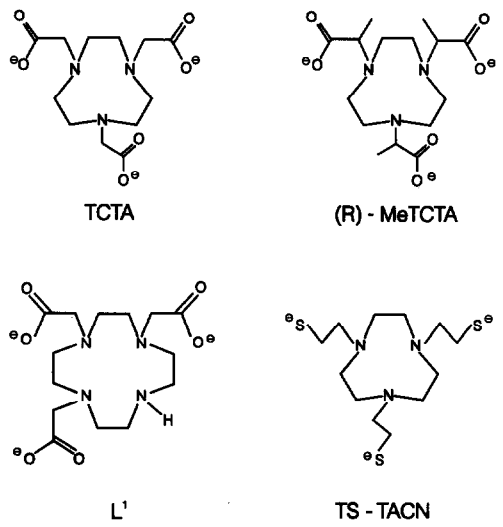
Abstract—Complexes of Al^{3+} and In^{3+} containing the pendent arm macrocycles 1,4,7-tris(acetato)-1,4,7-triazacyclononane (TCTA) and 1,4,7-tris(2-mercaptoethyl)-1,4,7-triazacyclononane (TS-TACN), respectively, have been synthesized and their crystal structures determined. Al(TCTA) contains an octahedral *fac*-N_3O_3 donor set, whereas In(TS-TACN) has an octahedral *fac*-N_3S_3 donor set. Average Al—O and In—S distances are 1.846 and 2.397 Å, respectively.

The coordination chemistry of trivalent group 13 metal ions with trianionic pendent-arm macrocyclic ligands (Scheme I) has attracted considerable interest in recent years as potential diagnostic radiopharmaceuticals (Ga, In).[1,2] Their use *in vivo* in nuclear medicine requires kinetic inertness and, in addition, it appears to be desirable that such complexes are electroneutral, have a low molecular weight and are lipophilic in order to cross the blood–brain barrier. Aluminium complexes of this type are also of interest due to the possible involvement of this element in Alzheimer's disease[3] and removal of Al^{3+} from the body. Parker *et al.* and Kaden *et al.* have recently published the synthesis and crystal structures of Ga(TCTA),[4,5] In(R-MeTCTA),[6] In(TCTA-H)Cl[7] and InL[1,8] and tested their utility as radiopharmaceuticals.

Clarke and Martell[9] have established that Ga^{III} and In^{III} bind very strongly to TCTA and noted in accord with Hancock *et al.*'s[10,11] molecular mechanics calculations that this ligand preferentially binds to *small* metal ions. Stability constants ($K_{ML} = [ML]/[L^{3-}][M^{3+}]$) of Ga^{3+} and In^{3+} are $10^{30.98}$ and $10^{26.2}$, respectively. It is to be expected from these studies that Al(TCTA) is even more stable.

Fanwick *et al.*,[5] on the other hand, have introduced a macrocycle with a 1,4,7-triazacyclononane backbone and three 2-mercaptoethyl pendent arms and have reported the structure of Ga(TS-TACN).

In 1982 we reported the synthesis of Al(TCTA),[12]



Scheme I.

* Author to whom correspondence should be addressed.

which is extremely stable in aqueous solution over a wide range of pH (0–13) for many days at ambient temperature. We have now determined the crystal structure of this complex. The structure has been briefly reported previously.[13] Since the quality of our structure determination is better we decided to publish our data. Independently of Moore's work,[5] we have prepared the neutral complex In(TS-TACN), the structure of which we also report here.

RESULTS AND DISCUSSION

Colourless crystals suitable for the X-ray crystallography of Al(TCTA) were obtained from the reaction of an aqueous solution of the hexadentate ligand and $AlCl_3 \cdot 6H_2O$, as described in ref. 12. Figure 1 shows the structure; important bond distances and angles are summarized in Table 1. Table 2 gives selected bond lengths and angles of the corresponding complexes of Ga^{III}, In^{III} and Fe^{III}.

As Hancock *et al.*[10] pointed out there are two possible arrangements for the coordinated acetate groups on the pseudo-octahedral complexes of TCTA. The bound base fragment 1,4,7-triazacyclononane is chiral. For a given arrangement of the base fragment, ($\lambda\lambda\lambda$) or ($\delta\delta\delta$) conformation

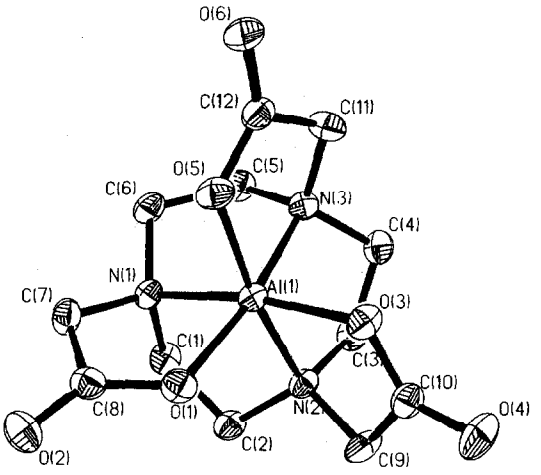


Fig. 1. The structure of Al(TCTA).

of the five-membered M—N—C—C—N chelate rings, the acetate goups may be oriented in a clockwise or anticlockwise fashion (Δ, Λ configuration). The change from type I [Δ($\lambda\lambda\lambda$), Λ($\delta\delta\delta$) enantiomers] to type II [Δ($\delta\delta\delta$), Λ($\lambda\lambda\lambda$) enantiomers][5,9] is a consequence of the increasing M—N bond distance, which forces the metal ion up out of the nine-mem-

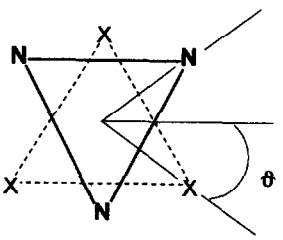
Ligand abbreviations are as in Scheme I.
[a] C.N. = coordination number.
[b] Twist angle as defined in the text.

bered 1,4,7-triazacyclononane ring which causes a strain on the M—O bond. This tension may then be somewhat relieved by switching to the type II structure.[5,9] The twist angle θ is defined as shown below.



It is 30° for a perfect octahedron and 0° for a trigonal prism. It is clearly seen from the compilation of θ values in Table 2 that Al(TCTA) and Ga(TCTA) have slightly distorted octahedral geometry, whereas for In((R)-MeTCTA) a trigonal prism prevails. This switch from an octahedral to a trigonal prismatic polyhedron relieves the above mentioned strain which is imposed on the ligand by increasing M—N and M—O distances. It is interesting that Ga(TCTA) is octahedral whereas Fe(TCTA) is trigonal prismatic, although the effective ionic radii of six-coordinate Ga^{3+} of 0.76 Å and of high-spin Fe^{3+} of 0.785 Å are actually quite similar.[14] It appears that the configurational switch is triggered within a narrow range of M—N and M—O distances and does not occur gradually.

Not surprisingly, in Al(TCTA) the shortest M—N and M—O distances are observed as compared to those in Ga(TCTA)[4,5] and In((R)-MeTCTA).[6] Consequently, Al(TCTA) and Ga(TCTA) are octahedral (type I), whereas In((R)-MeTCTA) is more trigonal prismatic (type II). The average Al—O distance in Al(TCTA) is very short at 1.846(2) Å and may be compared with the corresponding distance in $[Al(OH_2)_6](NO_3)_3 \cdot 3H_2O$ of 1.877(2) Å.[15]

The reaction of $InBr_3$ dissolved in a sodium methanolate/methanol mixture with the ligand 1,4,7-tris(2-mercaptoethyl)-1,4,7-triazacyclononane at 20°C produced colourless microcrystals of In(TS-TACN). Single crystals were obtained from a hot aqueous solution upon slow cooling. Figure 2 shows the structure, Table 1 summarizes selected bond distances and angles. The ligand is hexadentate providing a *fac*-N_3S_3 donor set around the indium(III) metal ion. As Moore *et al.* have discussed for Ga(TS-TACN) the coordinated ligand TS-TACN has three different sources of chirality. The 1,4,7-triazacyclononane backbone adopts either a $(\delta\delta\delta)_m$ or $(\lambda\lambda\lambda)_m$ conformation, the three pendent arms have either $(\delta\delta\delta)_m$ or $(\lambda\lambda\lambda)_m$ configuration and, in addition, may adopt $(\lambda\lambda\lambda)_p$ or $(\delta\delta\delta)_p$ conformation in either configuration.

In crystals of Ga(TS-TACN)$\cdot 2CH_2Cl_2$ both enantiomeric forms of the neutral complex $\Delta(\lambda\lambda\lambda)_m(\delta\delta\delta)_p$ and $\Lambda(\delta\delta\delta)_m(\lambda\lambda\lambda)_p$ are present in the centric unit cell of the space group $P2_1/n$. In(TS-TACN) crystallizes in the same space group and the same enantiomers are present [$\Delta(\lambda\lambda\lambda)_m(\delta\delta\delta)_p$ and $\Lambda(\delta\delta\delta)_m(\lambda\lambda\lambda)_p$], despite the fact that the M—N and M—S bond distances increase by 0.189 and 0.172 Å, respectively, on going from Ga^{3+} to In^{3+}. These differences reflect quite accurately the enormous difference of effective ionic radii of 0.18 Å between six-coordinate Ga^{3+} and In^{3+}.

We conclude from these observations that the ligand TS-TACN exhibits more flexibility towards

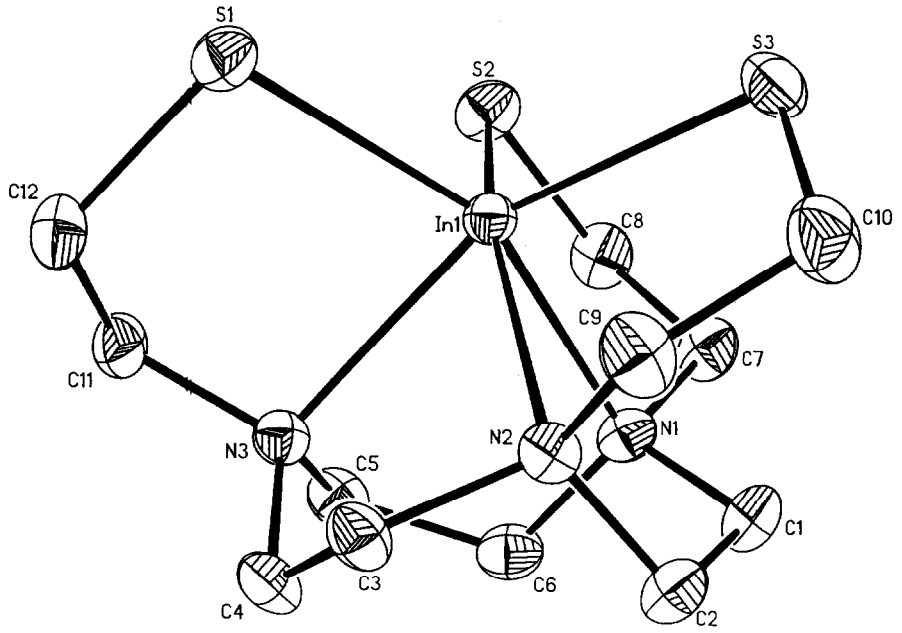


Fig. 2. The structure of In(TS-TACN).

binding of small *and* large metal ions than its counterpart TCTA with three acetate pendent arms.

EXPERIMENTAL

The compound Al(TCTA) and the ligand 1,4,7-tris(2-mercaptoethyl)-1,4,7-triazacyclononane (TS-TACN) were synthesized according to published procedures.[5,12]

Synthesis of In(TS-TACN)

Sodium metal (0.15 g) was carefully dissolved in dry ethanol (25 cm^3) and $InBr_3$ (0.35 g, 1.0 mmol) was added to this solution. To the clear solution the ligand TS-TACN (0.34 g, 1.0 mmol) was added dropwise with stirring at ambient temperature. After 2–3 h a colourless precipitate of In(TS-TACN) formed, which was collected by filtration, washed with ethanol and diethylether and air-dried. Needle shaped, colourless crystals suitable for X-ray crystallography were obtained from recrystallization from a hot water solution (95°C) which was allowed to slowly cool to 20°C (yield: 0.18 g, 43%). Found: C, 34.4; H, 5.8; N, 9.8; S, 22.6. Calc. for $C_{12}H_{24}N_3S_3In$: C, 34.2; H, 5.7; N, 10.0; S, 22.8%.

Crystal structure determinations

Crystal data. $[C_{12}H_{18}N_3O_6Al]$, $M = 327.27$, monoclinic, space group $P2_1/n$, $a = 8.803(6)$, $b = 13.526(9)$, $c = 11.983(6)$ Å, $\beta = 105.43(5)°$, $U = 1375.4$ Å^3 (from 2θ values for 25 reflections measured at $15° < 2\theta < 37°$), $\lambda = 0.71073$ Å, $T = 298$ K, $Z = 4$, $D_c = 1.58$ g cm^{-3}, μ(Mo-K_α) = 0.18 mm^{-1}.

$[C_{12}H_{24}N_3S_3In]$, $M = 421.35$, monoclinic, space group $P2_1/n$, $a = 7.292(1)$, $b = 16.807(4)$, $c = 13.107(2)$ Å, $\beta = 93.69(2)°$, $U = 1603.0$ Å^3 (from 2θ values for 25 reflections measured at $22 < 2\theta < 40°$), $\lambda = 0.71073$ Å, $T = 298$ K, $Z = 4$, $D_c = 1.75$ g cm^{-3}, μ(Mo-K_α) = 1.82 mm^{-1}.

Data processing and structure solution. Intensity data were collected using a Syntex R3 diffractometer, equipped with a graphite monochromator and an Mo-K_α radiation source (ψ-scans). Data were corrected for Lorentz and polarization effects in the usual manner and absorption corrections (ψ-scans of seven reflections) were also carried out in both cases. For Al(TCTA) 4500 reflections were measured ($2\theta_{max} = 60°$, h −11–+8, k 0–16, l 0–16) yielding 2694 with $I \geqslant 2.5\sigma(I)$; for In(TS-TACN) 5144 reflections were measured ($2\theta_{max} = 60°$, h −10–11, k 0–20, l 0–+18) yielding 3809 with $I \geqslant 2.5\sigma(I)$. Both structures were solved by Patterson and difference-Fourier methods, and refined by standard least-squares techniques (SHELXTL PLUS program system). The positions of the hydrogen atoms were calculated and included in the refinement with a common isotropic thermal parameter ($U_{iso} = 0.080$ Å^2); all other atoms were refined with anisotropic thermal parameters. The weighting scheme $w^{-1} = \sigma^2(F)$ was used throughout. For Al(TCTA) refine-

ment converged with $R = 0.049$, $R_w = 0.048$ and for In(TS-TACN) with $R = 0.032$, $R_w = 0.029$. Neutral atom scattering factors and anomalous dispersion data were taken from ref. 16. Final difference maps had no chemically significant maxima.

Thermal parameters, fractional atom coordinates, listings of observed and calculated structure factors have been deposited with the Editor, from whom copies are available on request. Atom coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

AXIAL VERSUS EQUATORIAL METAL–LIGAND DISTANCES IN SQUARE-PYRAMIDAL NICKEL(II) COMPLEXES*

EUGEN JÓNA,† MARIÁN KOMAN and ROMAN BOČA

Department of Inorganic Chemistry, Slovak Technical University,
CS-812 37 Bratislava, Czechoslovakia

(*Received* 13 *May* 1992; *accepted* 10 *September* 1992)

Abstract—The integral stereospecific influences in metal complexes have been analysed, namely the equatorial–axial and angular interactions. These concepts have been extended to five-coordinate complexes, in particular to nickel(II) complexes. The experimental findings are supported by the molecular orbital calculations on model complexes.

A few years ago a concept of the equatorial–axial (shortly equ–ax) interactions was proposed on the basis of both the experimental data and theoretical calculations.[1,2] This was motivated by the works of Hathaway[3] and Gažo *et al.*[4] on correlations among structural parameters within square-bipyramidal copper(II) complexes. Later extensions to nickel(II) complexes,[5] as well as to hexafluoro, hexachloro, hexanitro and hexaaqua complexes of the first row transition metals,[6–8] showed a more general validity of structural correlations abbreviated as R_a vs R_e dependences. These dependences manifest themselves in the fact that increasing axial metal–ligand distances (R_a, 2×) decrease the equatorial distances (R_e, 4×) and *vice versa*. Also, other groups[9,10] closely followed our approach and analogous correlations have been reported for cobalt(III), nickel(II) and zinc(II) complexes of the *trans*-$[MX_2(L_N)_4]$ type, $(L_N)_4$ being an N-donor macrocyclic ligand. Recently we found well-defined R_a vs R_e correlations in complexes of the *trans*-$[Ni(NCS)_2(L_N)_4]\cdot nG$ type, G being a guest molecule.[11]

The aim of the present work is to document structural correlations in square-pyramidal nickel(II) complexes. This allows an extension of the equatorial–axial interaction concept to other than square-bipyramidal complexes. The chromophores to be analysed span two classes: $\{NiN_5\}$ and *trans*-$\{NiXL_4\}$, L being an N- or O-donor ligand, X = Cl, Br and I.

In addition, the molecular structure of $[Ni(NCS)_2(3,5\text{-}Me_2pip)_3]$ is reported here. This was motivated by the fact that its coordination polyhedron may be either square-pyramidal or trigonal bipyramidal, and eventually an intermediate between these limiting cases; its position on the R_a vs R_e correlation curve is under question.

ANALYSIS OF STRUCTURAL DATA

Penta-coordinate complexes with square-pyramidal geometry for the chromophore may be characterized by a couple of basal angles, α and β, which for the ideal square-pyramidal system of C_{4v} symmetry adopt values of 180° (Fig. 1). The apical ligand is denoted as X and $\beta \geqslant \alpha$ usually holds. In the majority of square-pyramidal complexes the central atom M shows a displacement out of the basal plane and thus $\alpha = \beta < 180°$. On the contrary,

[a] Distances in pm, angles in °.

for the ideal trigonal-bipyramidal geometry (D_{3h} symmetry) the angle α becomes 120°. An intermediate geometry may be characterized by the difference $(\beta-\alpha)$, which for C_{4v} symmetry equals 0° and for D_{3h} symmetry equals 60°. Thus, a distortion parameter $\tau = (\alpha-\beta)/60$ has been introduced[12] for the penta-coordinate systems, which expresses the degree of trigonality as $\tau = 0$ for C_{4v} and $\tau = 1$ for D_{3h} geometries, respectively. Other alternatives for expressing the degree of trigonality have also been reported.[13,14]

A set of X-ray structural data on square-pyramidal nickel(II) complexes has been abstracted from the structural data bases. Only the complexes having {NiN_5} (group A) and {NiL_4X} (group B) chromophores (X = Cl, Br, I, L = N, O) have been subjected to analysis. The relevant data (for $\tau < 0.15$) are collected in Table 1. Of interest are the R_a (1×) and R_e (4×) metal–ligand distances, the degree of tetragonal distortion $\delta = R_a - R_e$, the tetragonality parameter $T = R_e/R_a$, the trigonality parameter $\tau = (\alpha-\beta)/60$ and the mean bonding angle $v_e(L_a—Ni—L_e)$.

MOLECULAR ORBITAL CALCULATIONS

The molecular orbital calculations have been performed by the quasi-relativistic INDO/1 method.[31,32] This method spans the class of all valence, and non-empirical calculations which also account for dominant relativistic effects (*s*- and *p*-orbital contraction side-by-side with *d*-orbital expansion). The geometry optimization has been performed for selected bonding coordinates, keeping the rest of the geometrical degrees of freedom unchanged.

EQU–AX INTERACTIONS IN PENTA-COORDINATE COMPLEXES

The experimental R_a values have been plotted vs R_e and the corresponding dependences are shown in Fig. 2. The linear relationship arises from the least-squares fitting. The nearly linear correlation can be considered significant as the correlation coefficients fulfil the relationship $|r| > r_{crit}$ at the 0.01 and 0.05 levels of significance for groups A and B, respectively. Thus, it may be concluded that an R_a vs R_e correlation with the negative slope exists: with increasing R_a values the mean R_e values decrease and *vice versa*. This finding may be interpreted in terms of equatorial–axial interactions: the weakening of the axial (apical) metal–ligand bond is accompanied by the strengthening of the equatorial (basal) metal–ligand bonds so that the total bonding capacity remains almost constant and it is only redistributed among the existing bonds. However, other, mostly steric, effects exist which apply sim-

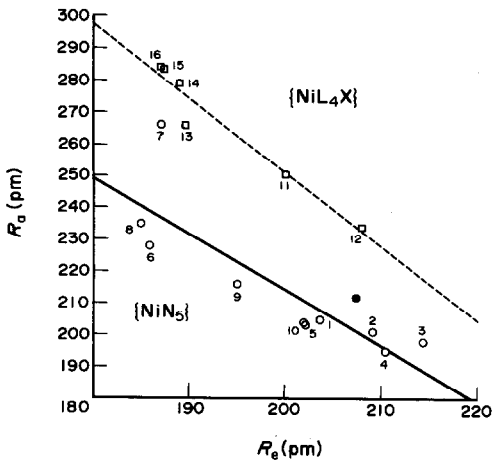

Fig. 2. R_e vs R_e dependences for $\{NiN_5\}$ (group A, hollow circles) and $\{NiL_4X\}$ (group B, hollow squares) chromophores. Filled circle = theoretical result for the $[Ni(NH_3)_3(NCS)_2]$ complex. Numbering according to Table 1.

ultaneously electronic in origin effects and may lead to higher deviations from the ideal (smooth) correlation curve.

The coordination polyhedra of group A prefer an elongated form of the tetragonal pyramid, with tetragonality $T = 0.702$–0.994. Three complexes, however, prefer the slightly compressed tetragonal pyramid. The latter class is less numerous and it covers complexes of the macrocyclic ligands (derivatives of tetramethylcyclam) in the equatorial plane with a monodentate ligand (acetonitrile, azide) occupying the axial position. This finding is contradictory to the behaviour of hexa-coordinate *trans*-$[Ni(L_N)_4(NCS)_2]$ complexes where the macrocycle ligands with a smaller central "hole" prefer an elongated form of the tetragonal bipyramid.[11] Within group A the parameter δ varies from -16.3 to 79.2 pm so that the "length" of the correlation is considerable. The greatest values of δ appear for the bis(difluoroboratodimethylglyoximato) nickel(II) complexes (**6**, **7** and **8**). The molecular geometry of the benzylamine adduct (**6**) closely parallels that of the 4,4′-bipyridine adduct (**7**), but it is markedly in contrast to that of the aniline adduct (**8**). In particular, the plane of the phenyl ring is perpendicular to the macrocycle plane so that a π-interaction between them is impossible. A long axial Ni—N distance in the aniline adduct has been discussed in connection with steric effects.[20]

The $[Ni(3,5\text{-}Me_2pip)_3(NCS)_2]$ complex shows electronic absorption bands and magnetic moment characteristic for penta-coordinate nickel(II) complexes,[33] but these data cannot be used to differentiate between the C_{4v} and D_{3h} symmetry of the $[NiN_5]$ chromophore. According to X-ray data,[24] presented in Fig. 3, the coordination polyhedron is close to a regular tetragonal pyramid, as $\tau = 0.005$. One of the 3,5-Me_2pip ligands occupies the axial position and the remaining ligands (two 3,5-Me_2pip and two NCS ligands) form the equatorial plane. The corresponding R_a and R_e parameters obey the

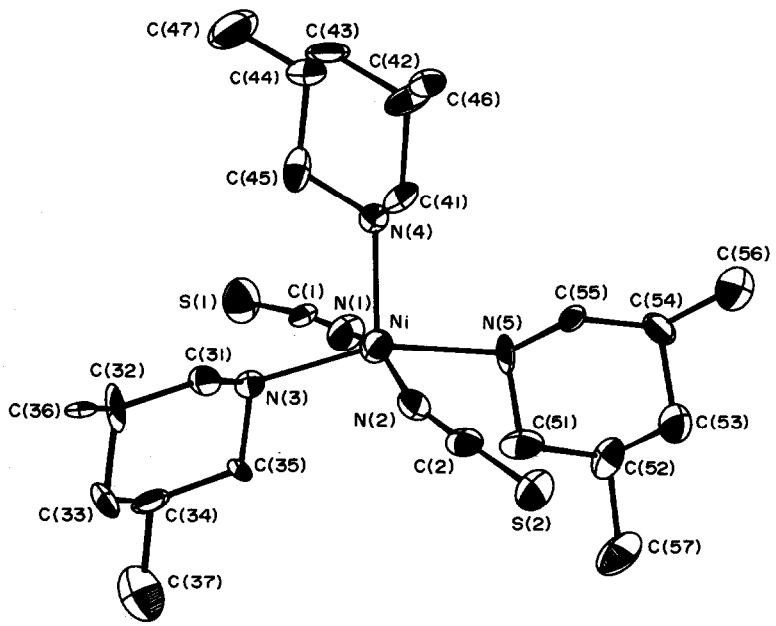

Fig. 3. Molecular structure of the $[Ni(3,5\text{-}Me_2pip)_3(NCS)_2]$ complex.

correlation curve found for the square-pyramidal $\{NiN_5\}$ chromophore (Fig. 2).

The unusual structure of the $[Ni(3,5\text{-}Me_2pip)_3(NCS)_2]$ complex has been subjected to theoretical analysis. Actually, the geometry optimization of the $[Ni(NH_3)_3(NCS)_2]$ complex has been performed with respect to 11 degrees of freedom. The resulting values are: $R_a(Ni—N_a) = 211.9$ (204), $R(N_a—H) = 103.6$, $\nu(Ni—N_a—H) = 107.2$, $R_e(Ni—N_e) = 213.8$ (210, 205), $\nu_e(N_a—Ni—N_e) = 113.1$ (98.9, 102.1), $R(N_e—H) = 103.3$, $\nu(Ni—N_e—H) = 107.7$, $R(Ni—NCS) = 200.9$ (197, 195), $\nu(N_a—Ni—NCS) = 95.5$ (87.4, 104.1), $R(N—C) = 122.2$ (115, 116) and $R(C—S) = 159.4$ (161, 156), where the experimental data are in parentheses (distances in pm, angles in °). The position of this complex within the R_a vs R_e plot is also shown in Fig. 2 (filled circle) and it may be concluded that it spans the range of experimental data.

For group B the tetragonality parameter varies as $T = 0.658$–0.889 and the distortion degree is $\delta = 25.9$–96.0 pm. The greatest degree of distortion is observed for bromine and iodine derivatives. For example, the Ni—Br distance in complex **14** is 279.1 pm, which is significantly longer than that found in hexa-coordinate $[Ni(py)_4Br_2]$ where $R(Ni—Br) = 258$ pm.[34] Thus, the axial nickel–bromine and nickel–iodine interactions in five-coordinate complexes are far weaker than normally observed.

In order to place groups A and B into a common set, a correction for the $R_a(Ni—X)$ value of the differing covalent radii of the halide ions, r_X, has been made: $R_a(cor) = R_a - (r_X - r_N)$. The $R_a(cor)$ vs R_e correlation is shown in Fig. 4, alongside the 99% confidence interval. As the correlation coefficient is $\rho = 0.84$, the correlation is fairly good.

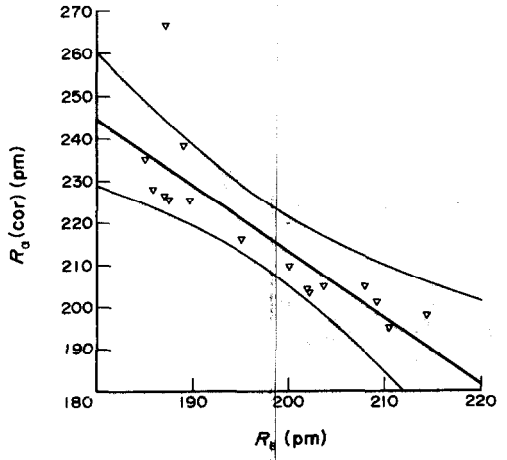

Fig. 4. $R_a(cor)$ vs R_e correlation in penta-coordinate nickel(II) complexes (group A+B). Correlation coefficient $\rho = 0.84$; 99% confidence interval is shown.

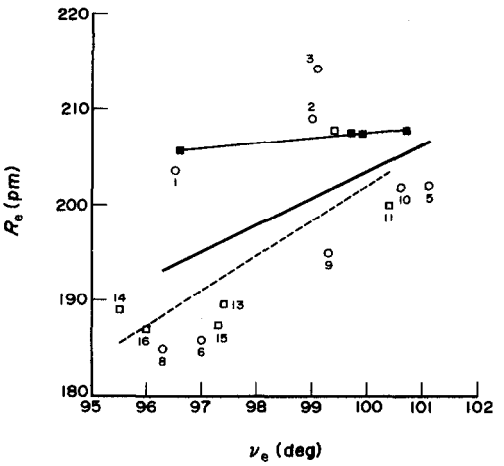

Fig. 5. R_e vs ν_e dependences for $\{NiN_5\}$ (group A, hollow circles) and $\{NiL_4X\}$ (group B, hollow squares) chromophores. Filled squares = theoretical results for $[Ni(NH_3)_4X]^+$ complexes. Numbering according to Table 1.

ANGULAR DEPENDENCE IN PENTA-COORDINATE COMPLEXES

In addition to the R_a vs R_e dependence classified as a manifestation of the equatorial–axial interactions in complexes, another structural correlation has been observed. The bond length R_e is interrelated to the bond angle $\nu_e(X—Ni—N)$ and the corresponding plot is shown in Fig. 5. The R_e vs ν_e dependence is approximated by a straight line and again a significant correlation is proven. Thus, it may be concluded that with increasing R_e values the bond angle ν_e increases. This behaviour may be considered as a new type of integral stereospecific influence in metal complexes, termed hereafter as the "angular dependence".

A common R_e vs ν_e correlation for groups A and B again exists (Fig. 6) with the correlation coefficient $\rho = 0.65$.

The geometry optimization for low-spin $^1[Ni(NH_3)_4X]^+$ complexes has been performed, X being F, Cl, Br and I. Within the square-pyramidal structure of C_{4v} (exactly C_4) symmetry five geometry parameters are independent: distances $R_a(Ni—X)$, $R_e(Ni—N)$ and $R_3(N—H)$ and angles $\nu_e(X—Ni—N)$ and $\nu_1(Ni—N—H)$, or, alternatively, $R_a(N—X)$, $R_1(o\text{-}Ni)$, $R_2(o\text{-}N)$, $R_3(N—H)$ and $\nu_2(o\text{-}N—H)$, where o is the centre of the square defined by four NH_3 groups. As a result of the geometry optimization, the total energy function $E_T = f(R_a, R_e, R_3, \nu_e, \nu_1)$ or $E_T = f(R_a, R_1, R_2, R_3, \nu_2)$ adopts a minimum value.

The relevant equilibrium coordinates are listed in Table 2. The geometry of the NH_3 group is almost

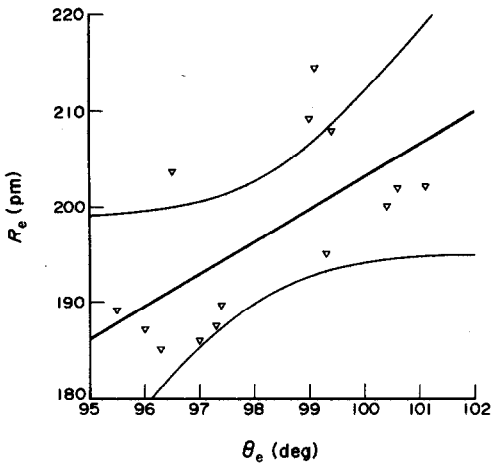

Fig. 6. R_e vs ν_e correlation in penta-coordinate nickel(II) complexes (group A+B). Correlation coefficient $\rho = 0.65$; 99% confidence interval is shown.

constant within the series under study: the angle ν_2(o-N—H) spans the range 108.2–108.7° and the distance keeps the value R_3 = 103.9 pm. The only remarkable change is represented by the out-of-plane displacement of the nickel atom: R_1(o-Ni) = 23.5, 35.7, 35.7 and 38.5 pm. This is the raison d'etre of the bond angle variation ν_e(X—Ni—N) = 96.6, 99.9, 99.9 and 100.7°. It may be concluded that with the decreasing polarity of the apical R_a(Ni—X) bond the out-of-plane displacement R_1(o-Ni) of the nickel atom increases, the ν_e(X—Ni—N) bond angle simultaneously increases and the R_e(Ni—N) bond length also increases. Thus, an R_e vs ν_e correlation is predicted according to an ascending line. The last finding may be rationalized in terms of the extended electron-pair repulsion theory.[35] As far as the iodine atom allows a localization of the bonding electron pair closest to the nickel atom, it repels more effectively the remaining electron pairs at the Ni—N bonds, then the R_e(Ni—N) bond length and the ν_e(X—Ni—N) bond angle increases.

CONCLUSIONS

The bonding capacity of the central atom obeys an integral redistribution among ligands present in the coordination sphere. The integral stereospecific influences may be documented by the equatorial–axial and angular interactions, respectively. They manifest themselves in correlations among structural parameters, namely the R_a vs R_e and R_e vs ν_e dependences.

Table 2. Calculated geometry of $[Ni(NH_3)_4X]^{+1}$ complexes

Geometry parameter	X F	Cl	Br	I
R_a(Ni—X) (pm)	210.4	229.8	239.2	253.3

SYNTHESIS OF A RHODIUM METHYLTHIOLATE AND INSERTION OF CS_2 INTO THE Rh—SCH_3 BOND. STRUCTURE OF THE THIOXANTHATE [$(pp_3)RhSC(S)SCH_3$] [pp_3 = TRIS(2-(DIPHENYLPHOSPHINO)ETHYL)PHOSPHINE]

(*Received* 31 *July* 1992; *accepted* 3 *September* 1992)

Abstract—The reaction between the $(pp_3)Rh^I$ fragment [pp_3 = tris(2-(diphenylphosphino)-ethyl)phosphine, $P(CH_2CH_2PPh_2)_3$] and $NaSCH_3$ readily yields the methylthiolate derivative [$(pp_3)RhSCH_3$]. The sulphur atom of this compound is attacked by the electrophile $CF_3SO_3CH_3$ to yield the stable dimethylsulphide complex [$(pp_3)RhS(CH_3)_2]CF_3SO_3$. Furthermore, the rhodium methylthiolate undergoes CS_2 insertion to form the thioxanthate [$(pp_3)RhSC(S)SCH_3$], which has been characterized by a complete X-ray crystallographic analysis.

Recently, there has been growing interest in mononuclear complexes with the thiolate (M-SR) and hydrosulphide (M-SH) groups, because of the reactivity exhibited by such ligands towards organic substrates.[1] We have recently reported about a family of hydrochalcogenide rhodium derivatives formed by the tripodal polyphosphine tris(2-(diphenylphosphino)ethyl)phosphine, pp_3, and described their reactivity towards electrophiles (H^+, CH_3^+).[2] The chalcogen atom in such compounds appears to be the site for the electrophilic attack, which yields the hydride methyl- or hydro-chalcogenide derivatives of rhodium(III) through a stereospecific internal oxidative addition involving the acidic X—H bond.[3] It has been shown that processes of this type are controlled by the tripodal polyphosphine pp_3, which favours smoother reactions at the metal centre.[4]

With the aim of investigating further the chalcogenide chemistry at the $(pp_3)Rh^I$ fragment, however, avoiding the labile X—H bond, we have undertaken the synthesis of alkylchalcogenolate complexes and the study of their reactivity. Here we report on the isolation and structure determination of a mononuclear rhodium(I) methylthiolate stabilized by the pp_3 ligand and some aspects of its reactivity.

EXPERIMENTAL

All reactions and manipulations were performed under an atmosphere of oxygen-free nitrogen. Solvents were freshly distilled under nitrogen from the appropriate drying agents immediately before use. The ^{31}P and ^1H NMR spectra were obtained in CD_2Cl_2 using a Varian VXR 300 spectrometer operating at 121.4 and 300.1 MHz and are referred to external 85% H_3PO_4 and internal TMS, respectively.

Synthetic procedures

Synthesis of the compounds. [$(pp_3)RhSCH_3$]: $NaSCH_3$ (0.21 g, 3 mmol) dissolved in methanol (10 cm^3) was added to a THF (40 cm^3) solution of $[(pp_3)Rh(cod)]^+$ (1 mmol), generated *in situ*.[5] Orange needles of [$(pp_3)RhSCH_3$] were obtained on leaving the resulting solution overnight (yield 85%). Found: C, 62.7; H, 5.6; S, 3.8. Calc. for [$(pp_3)RhSCH_3$], $C_{43}H_{45}P_4RhS$: C, 62.9; H, 5.5; S, 3.9%. NMR data in CD_2Cl_2: ^1H: δ 2.19 (3H, s, SCH_3). ^{31}P: δ 146.3 [1P, dq, $^1J(P_ARh)$ = 126.9 Hz, $^2J(P_AP_M)$ = 17.3 Hz, P_{apical}], 40.3 [3P, dd, $^1J(P_MRh)$ = 147.6 Hz, $P_{meridional}$].

[$(pp_3)RhS(CH_3)_2]CF_3SO_3$: Neat $CF_3SO_3CH_3$ (0.37 mmol) was added to a suspension of [(pp_3) $RhSCH_3$] (0.3 g, 0.37 mmol) in THF (30 cm^3) at 0°C. The complex dissolved in 30 min and red

crystals of $[(pp_3)RhS(CH_3)_2]CF_3SO_3$ were obtained by the addition of benzene (30 cm^3). Yield 80%. Found: C, 54.7; H, 5.0; S, 6.4. Calc. for $[(pp_3)RhS(CH_3)_2]CF_3SO_3$, $C_{45}H_{48}F_3O_3P_4RhS_2$: C, 54.9; H, 4.9; S, 6.5%. NMR data in $(CD_3)_2CO$: ^1H: δ 1.77 [6H, d, $^3J(HRh) = 2.9$ Hz, $S(CH_3)_2$]. ^{31}P: δ 145.2 [1P, dq, $^1J(P_ARh) = 109.1$ Hz, $^2J(P_AP_M) = 17.0$ Hz, P_{apical}], 47.2 [3P, dd, $^1J(P_MRh) = 143.2$ Hz, $P_{meridional}$].

$[(pp_3)RhSC(S)SCH_3]$: Neat CS_2 (0.6 mmol) was added to a suspension of $[(pp_3)RhSCH_3]$ (0.3 g, 0.37 mmol) in THF (30 cm^3) at room temperature. The complex dissolved in 24 h and red crystals of $[(pp_3)RhSC(S)SCH_3]$ were obtained by adding methanol (20 cm^3). Yield 55%. Found: C, 58.9; H, 5.1; S, 10.6. Calc. for $[(pp_3)RhSC(S)SCH_3]$, $C_{44}H_{45}P_4RhS_3$: C, 58.9; H, 5.1; S, 10.7%. NMR data in CD_2Cl_2: ^1H: δ 2.02 (3H, s, SCH_3). ^{31}P: δ 146.7 [1P, dq, $^1J(P_ARh) = 127.0$ Hz, $^2J(P_AP_M) = 17.1$ Hz, P_{apical}], 40.3 [3P, dd, $^1J(P_MRh) = 148.2$ Hz, $P_{meridional}$].

X-ray crystallographic studies

All measurements were carried out at room temperature on an Enraf–Nonius CAD4 diffractometer using graphite-monochromated Mo-K_α radiation ($\lambda = 0.71069$ Å). The crystal used had the dimensions $0.20 \times 0.20 \times 0.25$ mm. Cell constants were obtained from least-squares refinement of the setting angles of 24 reflections ($14 < \theta < 18°$).

Crystal data. $C_{44}H_{45}P_4RhS_3$, $M = 896.84$, trigonal, space group $P3_2$ (No. 145), $a = 17.360(4)$, $c = 11.702(3)$ Å, $V = 3054(1)$ Å^3, $Z = 3$, $D_{calc} = 1.462$ g cm^{-3}, μ(Mo-K_α) = 7.46 cm^{-1}, $F(000) = 1386$.

Data were collected for $2 \leqslant \theta \leqslant 23°$ by ω–2θ scans with $(0.90 + 0.34 \tan\theta)°$ scan width and 1–5° min^{-1} scan speed. No crystal movement or decay was detected over the data collection. Of 3122 independent reflections measured 1788 having $I > 3\sigma(I)$ were used for structure solution and refinement. An empirical absorption correction was applied after the structure had been solved.[6]

The structure was solved by heavy-atom methods and refined by full-matrix least-squares. The principal computer programs used in the crystallographic calculations are listed in refs 6 and 7. The rhodium, phosphorus, sulphur and the carbon atoms of the thioxanthate ligand were refined anisotropically, whereas the other carbon and hydrogen atoms were assigned isotropic temperature factors. The hydrogen atoms were in calculated positions (C—H = 0.96 Å, $U_H = 1.2U_C$) and phenyl groups were refined as rigid bodies with idealized geometry. The z coordinate of rhodium was fixed during refinement due to the polar nature of the space group. The alternative choice of the $P3_1$ space group was rejected on the basis of the R ratio test.[8] Data were weighted according to $w^{-1} = [\sigma^2(F) + 0.0010F^2]$. Refinement converged at $R = \Sigma ||F_o| - |F_c|| / \Sigma |F_o| = 0.054$ and $R_w = [\Sigma (|F_o| - |F_c|)^2 / \Sigma w(F_o)^2]^{1/2} = 0.057$ for 189 parameters. The extreme values of residual electron density in the final ΔF synthesis were 0.65 (on proximity of the rhodium position, without any chemical meaning) and -0.38 e Å^{-3}. Scattering factors were from refs 7 (carbon, hydrogen, phosphorus and sulphur) and 9a (rhodium), those for rhodium being corrected for anomalous dispersion.[9b] Values of selected bond distances and angles are given in Table 1. Tables of final atomic positional and thermal parameters, full lists of bond lengths and angles, tables of hydrogen atoms positions and a list of observed and calculated structure factors have been deposited as supplementary material.

RESULTS AND DISCUSSION

The methylthiolate $[(pp_3)RhSCH_3]$ derivative was obtained in high yield when a three-fold excess of $NaSCH_3$ was reacted with $[(pp_3)Rh(cod)]^+$, generated *in situ*. The compound was poorly soluble in THF and in chlorinated solvents like $CHCl_3$ and CH_2Cl_2. In the latter solvents it slowly reacted to give chloro complexes. Such sensitivity of metal thiolates to chlorinated hydrocarbon solvents has been observed previously and has been ascribed to the nucleophilicity of the coordinated sulphur atom.[10] Highly diagnostic for the solution stereochemistry of the compound is its $^{31}P\{^1H\}$ NMR spectrum, exhibiting a first-order AM_3X spin system consistent with a trigonal bipyramidal geometry around the metal, with the peripheral phosphorus atoms of the polydentate ligand in the equatorial plane and the central pp_3 phosphorus and the sulphur atom in the axial positions. Both the coupling constants and chemical shifts are in the expected ranges for trigonal bipyramidal compounds of rhodium(I) with tripodal polyphosphines.[11] The proton spectrum of the compound exhibits, in addition to the usual uninformative pattern due to the protons of the pp_3 ligand, a signal whose intensity and chemical shift are consistent with those expected for the group SCH_3.[2]

The methylthiolate derivative suspended in THF readily reacted with a stoichiometric amount of $CF_3SO_3CH_3$ to give the compound $[(pp_3)RhS(CH_3)_2]CF_3SO_3$. The dimethylsulphide derivative was soluble in THF, acetone, CH_2Cl_2 and $CHCl_3$ and its solutions were stable under nitrogen. The $^{31}P\{^1H\}$ NMR spectrum, showing an AM_3X spin system, is consistent with a trigonal bipyramidal arrangement about the metal, similar to that of the parent methylthiolate, and the ^1H NMR spectrum exhibits a resonance whose intensity is in accordance with the proposed formula.

The methylthiolate derivative $[(pp_3)RhSCH_3]$ suspended in THF slowly reacted with carbon disulphide to yield a compound of the formula $[(pp_3)RhSC(S)SCH_3]$. The strong IR band at 995 cm^{-1} is typical for the thioxanthate group.[12] The $^{31}P\{^1H\}$ NMR spectrum of the compound, which consists of a first-order AM_3X spin system, is in agreement with a trigonal bipyramidal geometry around the metal, with the apical phosphorus atom of the ligand in the axial position and the terminal phosphorus atoms in equatorial positions.

Previous studies on thioxanthate complexes, which have been obtained either by reaction of the metal halide with $M(S_2CSR)$, where M is an alkali metal ion,[12,13] or through the less common route of CS_2 insertion into transition metal–thiolate bonds,[14] have shown that the S_2CSR group is bound to the metal centre with two sulphur atoms. Such a feature of the thioxanthate ligand contrasts with the electronic requirements of the $(pp_3)Rh^I$ fragment, which accommodates two-electron donors.[4] In order to ascertain the coordination

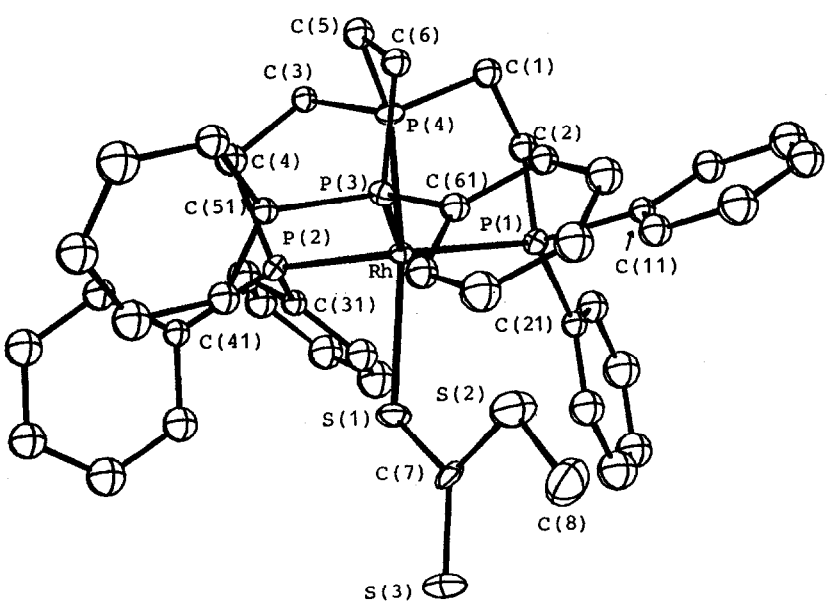

Fig. 1. Perspective view of the $[(pp_3)RhSC(S)SCH_3]$ molecule, with 20% probability ellipsoids. Only the first carbon atom of each phenyl group is labelled for clarity.

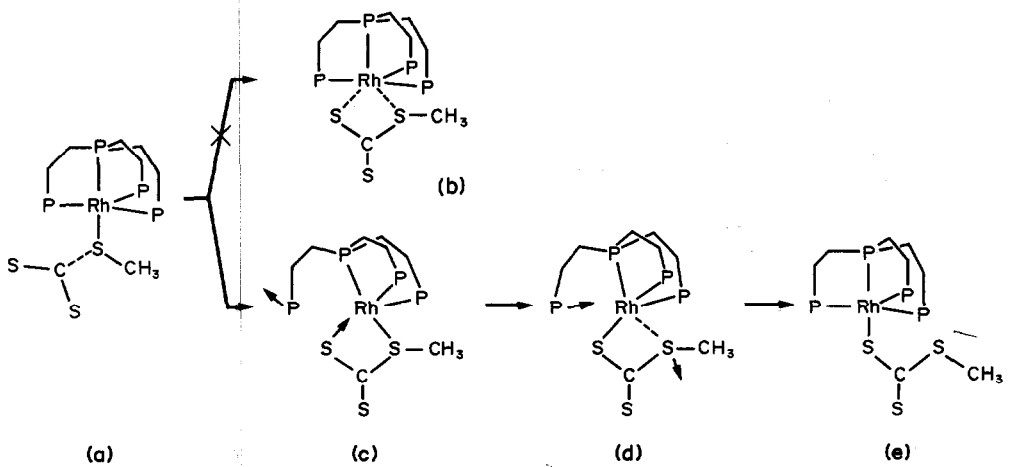
mode of the thioxanthate in the present [(pp_3)RhSC(S)SCH_3] compound, its crystal structure was determined by a single crystal X-ray analysis.

The structure of the compound is formed by isolated [(pp_3)RhSC(S)SCH_3] molecules (Fig. 1), in which the metal atom is coordinated by the four phosphorus atoms of the phosphine ligand and one sulphur atom of the thioxanthate group with essentially trigonal bipyramidal geometry. The central phosphorus atom of the pp_3 ligand and the sulphur donor, occupying the axial positions, form with the metal atom an angle [P(4)—Rh—S(1) = 168.3(2)°] which deviates from the idealized 180° value, probably as a consequence of non-bonded interactions between the thioxanthate group and phenyl rings. The metal atom lies 0.27 Å away from the plane through the equatorial phosphorus atoms towards the sulphur donor. The Rh—P distances are comparable to those existing in the [(pp_3)Rh(SH)] complex,[2] and the Rh—S distance is 0.04 Å shorter than in the latter compound. The C—S distances within the thioxanthate ligand are grossly comparable to each other, presumably due to extensive delocalization,[15] and their mean, of 1.66(1) Å, is slightly smaller than the values, in the range 1.67–1.74 Å, reported for the C—S distances in bidentate thioxanthate ligands.[14,15] We are not aware of other structures of metal compounds containing monodentate thioxanthate ligands which might be referred to for better comparisons.

Insertion of CS_2 into transition-metal thiolates has been reported. However, there has been little investigation on the mechanism of CS_2 insertion into metal–thiolate bonds; it has been recently suggested[14] that at least two extremes can be envisioned regarding the initial interaction of the metal complex with the incoming carbon disulphide: (1) pre-coordination of CS_2 at the metal centre; or (2) attack by free CS_2 on the sulphur atom of the thiolate ligand. Qualitative observations on CS_2 insertion into the M—S bonds in the complexes $CpW(CO)_2(PPh_3)SR$[16] and $CpRu(PPh_3)_2SR$[14] suggested pre-coordinated insertion in those cases. On the other hand, the present results seem to favour the second hypothesis. In particular, the straightforward formation of the dimethylsulphide [(pp_3)RhS$(CH_3)_2$]CF_3SO_3 by electrophilic attack clearly shows that the sulphur atom is preferred as a nucleophilic site with respect to the metal atom. Moreover, the structural results showing that the thioxanthate group acts as a monodentate ligand prove that the tripodal pp_3 ligand is tightly bound to the metal. This opposes pre-coordination by CS_2, thus disfavouring the above route (1) in the present case.

We have attempted to rationalize some aspects of the formation of [(pp_3)RhSC(S)SCH_3] by attack of CS_2 on [(pp_3)RhSCH_3] by means of extended Hückel calculations[17,18] using the program CACAO[19] and, in part, by Fenske–Hall calculations[20] on model systems, with atomic parameter data from the literature[18] or as provided with the package.[20] According to the previous considerations and to views presented for similar processes[21] we have considered as the most probable first step the facile attack [Scheme 1, (a)] of the bent CS_2 electrophile on the sulphur nucleophilic site of the parent rhodium complex. This step should be followed by rotation of the S_2CSCH_3 group thus formed, in the course of which the methyl-substituted sulphur atom should be displaced from the metal environment by one of the unsubstituted sulphur atoms. However, a four-centred transition state as shown in (b), with the undeformed (PP_3)Rh moiety, is unlikely as it would imply a high energy barrier. A transition state of this type, not requiring



Scheme 1.

an open coordination site, has been proposed for COS or CS_2 attack on the W—O bond of $W(CO)_5OR$ systems on the basis of experimental data.[21] Actually, we find that in the latter systems a set of metal-based low-energy empty orbitals may assist in the course of the process, keeping the energy barrier comparatively low. On the other hand, only one σ-type empty hybrid is available in the $(pp_3)Rh$ moiety, the other virtual orbitals being contracted and at high energies. We suggest that in the present case the rearrangement of the S_2CSCH_3 group should be accompanied by detachment of one arm of the pp_3 ligand. Although, as stated above, the ligand appears to be tightly bound, such a detachment has already been found to occur in solution in the presence of strong incoming ligands.[22] A concerted process, such as that schematized in (c), may sensibly reduce the energy barrier preserving orbital symmetry. Finally, detachment from rhodium of the substituted sulphur atom accompanied by approach to the metal by the phosphorus atom of the uncoordinated arm (d) is an easy process leading to the final product (e).

The overlap populations of both Rh—S bonds in the proposed five-coordinate intermediate, between (c) and (d), may vary considerably with the assumed mutual orientation of the two ligands, although significant energy barriers for rearrangements from the geometry shown in (d) exist. Taking all this into consideration, we find no clear evidence for electronic factors strongly favouring detachment of a specific sulphur atom. The steric hindrance due to the CH_3 group may be the factor disfavouring coordination by the substituted sulphur atom. It could also prevent it from bonding again to the metal through possible iterations in solution of the process described above. On the other hand, exchange occurring in solution between the two unsubstituted sulphur atoms, in the bonding position to the metal atom, cannot be ruled out.

Abstract—Bis(η^5-phospholyl) or bis(η^5-arsolyl)M(THF)$_2$ complexes, where M = Sm or Yb, can be obtained either by reaction of potassium phospholides or arsolides with $MI_2(THF)_2$ or by cleavage of the P—P or As—As bond of a biphospholyl or biarsolyl by ytterbium or samarium metal powders. The THF molecules that coordinate to the metal are labile when the ligands are 2,3,4,5-tetramethylphospholyl or arsolyl, but not when they are 2,5-diphenylphospholyl. An X-ray crystal structure of bis(η^5-2,5-diphenylphospholyl)Yb(THF)$_2$ is presented. ^{171}Yb and ^{31}P NMR studies reveal that exchange of ligands is occurring in bis(η^5-2,3,4,5-tetramethylphospholyl)Yb(THF)$_2$; this exchange is slow at room temperature and frozen at −20°C. For bis(η^5-2,5-phenyldiphenylphospholyl)Yb(THF)$_2$ ^{31}P NMR data suggest that no exchange is occurring at room temperature.

In a recent communication[1] we briefly described the synthesis of bis(η^5-2,3,4,5-tetramethylphospholyl) complexes of samarium(II) and ytterbium(II), $L_2M(THF)_2$ (**1**·2THF and **2**·2THF, respectively) by two methods: (a) reaction of an anionic precursor such as L^-K^+ with the lanthanide(II) iodides; or (b) direct reaction of the biphospholyl L—L with ytterbium or samarium as metallic powders (Scheme 1).

At this point, we wanted to check if we could apply these methods to the synthesis of other heterocyclopentadienyl compounds; this led us to develop the use of the η^5-2,3,4,5-tetramethylarsolyl ligand. We also wanted to see whether one could synthesize π-heterocyclopentadienyl compounds, where electron-withdrawing substituents were present on the ring; for this purpose, we used the η^5-2,5-diphenylphospholyl ligand.

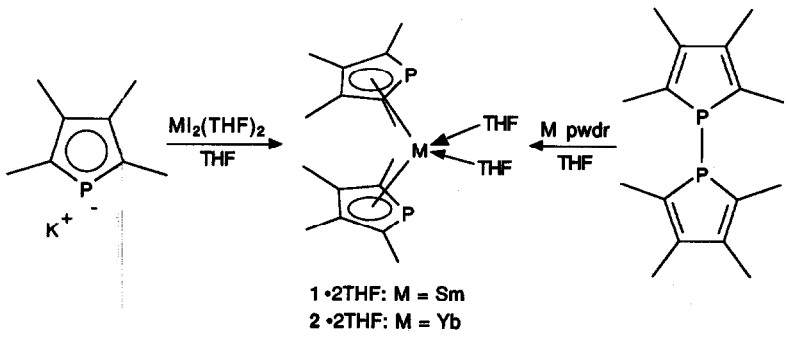
RESULTS AND DISCUSSION

Arsolyl complexes

The synthesis of the 2,3,4,5-tetramethylarsole ring system has recently been described by Fagan *et al.*,[2] by reaction of $PhAsCl_2$ with zirconacyclopentadienes. Instead of using $PhAsCl_2$, we reacted the zirconacyclopentadiene with $AsCl_3$, thus obtaining a chloroarsole. However, in our hands, this chloroarsole was rather unstable, and, although we were able to successfully transform it into the desired 2,3,4,5,2′,3′,4′,5′-octamethyl-1,1′-biarsolyl (**6**), we chose another route: reaction of zirconacyclopentadiene (**3**) with $PhAsCl_2$ gave 1-phenyl-2,3,4,5-tetramethylarsole **4** in good yield as a reasonably stable yellow oil, as described.[2] Potassium cleavage of **4** yielded potassium 2,3,4,5-tetramethylarsolide (**5**) as an unsolvated stable white salt, which could be coupled with $Bu^n_4N^+Br_3^-$ to give **6** (Scheme 2).



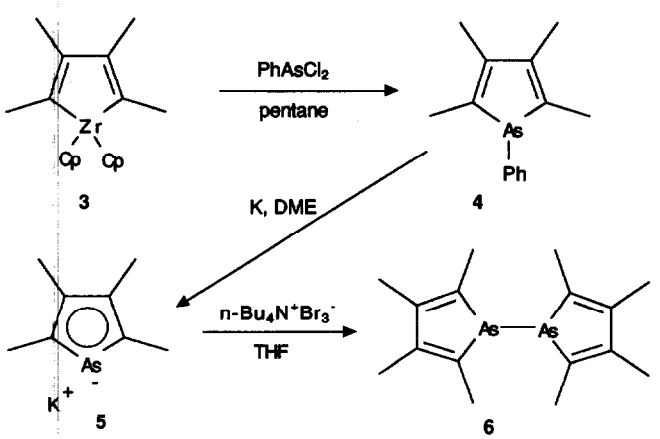
Scheme 1.

Interaction of potassium arsolide (**5**) with YbI_2 and SmI_2 in THF resulted in an immediate colour change, to dark reddish-brown for samarium and to dark red for ytterbium. Evaporation of the solvents led to desolvation of THF and obtention of amorphous powders (**7**: M = Sm, black; **8**: M = Yb, green), of the composition L_2M, as shown by ^1H NMR; the spectra in d_8-THF did not reveal the presence of non-deuterated THF. d_8-THF coordinates to **7** and **8** upon dissolution, as shown by the colour change back to dark reddish-brown for samarium and dark red for ytterbium. With M = Yb, careful evaporation of THF yielded $(C_4Me_4As)_2Yb(THF)_2$(**8**·2THF), as shown by ^1H NMR, but attempted recrystallization of this material led to desolvation and elemental analysis of all arsenic complexes was poor. Complexes **7** and **8** could also be made by the direct interaction of biarsolyl (**6**) with samarium and ytterbium as elements. Thus, overnight stirring of a THF solution of **6** with commercial samarium and ytterbium powders resulted in complete transformation into **7** and **8** respectively. In this way, similar to the previously described synthesis of complexes **1** and **2** from a biphospholyl,[1] the metals samarium and ytterbium are electropositive enough to be able to transfer electrons to the As—As bond of **6**, resulting in cleavage of this bond and stabilization by π-complexation (Scheme 3).

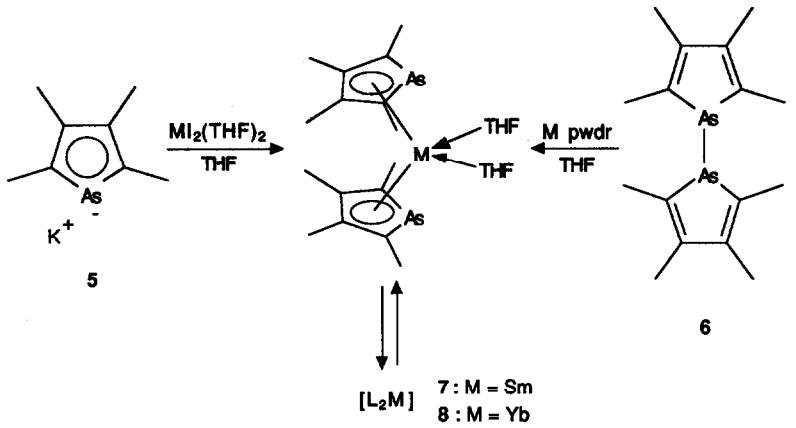
The NMR characteristics of **7**·2THF and **8**·2THF are very similar to those of **1**·2THF and **2**·2THF, respectively, as far as chemical shifts are concerned. One also observes, in **7**·2THF, the paramagnetic shift of the arsolyl ring carbons at high field and that of the methyl groups at low field.

2,5-*Diphenylphospholyl complexes*

A number of published studies in the field of divalent lanthanide π-complexes have used pentamethylcyclopentadienyl (C_5Me_5 or Cp*) as the π-ligand.[3] This ligand increases the solubility and enhances the reactivity of the electron-rich metal in the lower oxidation state. A five-electron π-ligand bearing electron-withdrawing substituent, on the other hand, should stabilize the +II vs the +III oxidation state more than the Cp* ligand. There are few examples of such complexes in the



Scheme 2.



Scheme 3.

literature; one can note the preparation of complexes with silyl-[4] and phosphinyl-substituted[5] cyclopentadienes and also that of indenyl[6] complexes. We, therefore, wanted to devise the synthesis of complexes of samarium and ytterbium with phenyl substituents on the phospholyl rings.

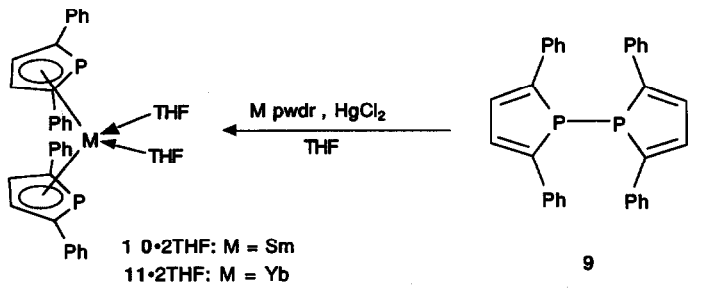
Some time ago, Charrier successfully prepared 2,5,2′,5′-tetraphenyl-1,1′-biphospholyl (**9**).[7] We thought that in order to prepare π-complexes of the 2,5-dimethylphospholyl ligand, the most suitable method would be method (b), which uses the direct interaction of the zero-valent metal with the P—P bond, because in this case no inorganic salt (KI) would interfere with the isolation of the products which are expected to be of low solubility.

When a solution of **9** was stirred in the presence of samarium or ytterbium metal no reaction took place after 24 h at room temperature. If a small (*ca* 20 mg) amount of $HgCl_2$ was added to the reaction mixture, activation of the metals occurred and the reaction proceeded to yield reasonable yields of **10**·2THF and **11**·2THF, respectively, after 16 h (Scheme 4).

These compounds are only slightly soluble in THF and almost totally insoluble in toluene or hexane, and the THF which is coordinated to the metal shows no sign of lability; overnight pumping of the solids did not lead to partial desolvation. **11**·2THF gave a correct microanalysis. The spectral characteristics of **10**·2THF and **11**·2THF fully support their structure. All ^1H and ^{13}C NMR resonances could be resolved and attributed. In **10**·2THF one observes an upfield paramagnetic shift of the heterocyclic ring ^{31}P and ^{13}C atom resonances, and a downfield shift of the H3 proton ($\approx$20 ppm).

Crystal structure of **11**·2*THF*

A suitable crystal of **11**·2THF could be obtained by slow cooling of a warm saturated THF solution. Crystal data and data collection parameters are listed in Table 1. Table 2 lists selected bond lengths and angles for **11**·2THF. There are two nearly identical but independent molecules in the unit cell, and Fig. 1 presents an ORTEP plot of one molecule of **11**·2THF. This structure shows the pseudo-tetrahedral coordination geometry around the ytterbium atom, if one considers the values of the centroid—Yb—centroid and O—Yb—O angles (129° and 82°, respectively). The former angle is slightly smaller than that found in other L_2Yb



Scheme 4.

$(THF)_2$ compounds: 133°, 134° and 134°, respectively, in $(Me_3SiC_5H_4)_2Yb(THF)_2$,[4] $(Me_3CC_5H_4)_2Yb(THF)_2$[8] and $[Me_2Pt(Ph_2PC_5H_4)_2Yb(THF)_2]THF$;[5] whereas the O—Yb—O angle is similar to those described. The Yb—O, Yb—C and Yb—P[9] bonds are also quite similar to those already mentioned. The heterocyclic bond angles and distances are not significantly different from those of other π-phospholyl complexes, the most noteworthy feature being the partial double-bond character of the P—C bond (1.77 Å). The phospholyl and the phenyl rings of **11**·2THF are almost planar. The molecule is rather asymmetrical: one of the phenyl rings is almost co-planar to a phospholyl ring (dihedral angle = 5°), and the other phospholyl–phenyl dihedral angles range from 25° to 80°. Furthermore, in the same molecule the phenyl ring *ipso*-carbons of one ligand bend towards the ytterbium atom, whereas for the other ligand the *ipso* carbons bend away from the metal. Packing forces might be responsible for these irregularities.

^{171}Yb and ^{31}P NMR spectra

^{171}Yb NMR has recently been introduced as an additional tool in the study of ytterbium(II) organometallic compounds.[10] A range of chemical shifts and heteronuclear coupling constants is already available.[11] However, no ^{31}P–^{171}Yb coupling constants have ever been reported; fast chemical exchange of the dmpe ligand in $Yb[N(SiMe_3)_2]$(dmpe) precluded the observation of any P—Yb coupling.[10]

In the ^{31}P spectrum of **2**·2THF at room temperature a singlet is observed at 81.2 ppm, with broad humps symmetrically disposed on both sides of the peak. As the temperature is gradually lowered these humps sharpen and at −20°C, their width at half height ($w_{1/2}$) becomes equal to the central peak. For **11**·2THF satellite peaks can be seen at room

temperature (Fig. 2). The separation between the satellite lines is 100 Hz for **2**·2THF and 50 Hz for **11**·2THF. We successfully obtained, at 70 MHz, ^{171}Yb NMR spectra of **2**·2THF and **8**·2THF. Unfortunately, we could not detect the resonance of **11**·2THF, presumably because of the very low solubility of this compound. At −30°C, the resonance of **8**·2THF is a broad ($w_{1/2} \approx 50$ Hz) peak at 316 ppm [downfield from the resonance of $Cp^*_2Yb(THF)_2$ at 0 ppm] and that of **2**·2THF is a reasonably well-resolved 1/2/1 triplet at 242 ppm; the separation between the lines is 100 Hz (Fig. 3). At room temperature, this triplet collapses into a broad ($w_{1/2} \approx 100$ Hz) signal at 185 ppm, where a triplet structure is barely noticeable. These results indicate that: (a) the satellites in the ^{31}P spectra are ^{171}Yb satellites, the measured separation is the ^{31}P–^{171}Yb coupling constant and for **11**·2THF we verified that the separation was the same at different field strengths, thus indicating a coupling constant; (b) that the stoichiometry in solution is indeed $L_2M(THF)_2$, as indicated by the triplet with $J = 100$ Hz in the ^{171}Yb spectrum of **2**·2THF. Temperature dependence of the chemical shift had already been noted;[10] and (c) that an exchange process, slow at room temperature and frozen at −20°C, is occurring for the phospholyl ligands of **2**·2THF in THF solution. The sharp appearance of the ^{171}Yb satellites at 20°C suggests that for this compound, no exchange takes place at this temperature.

Our future goals include the investigation of the

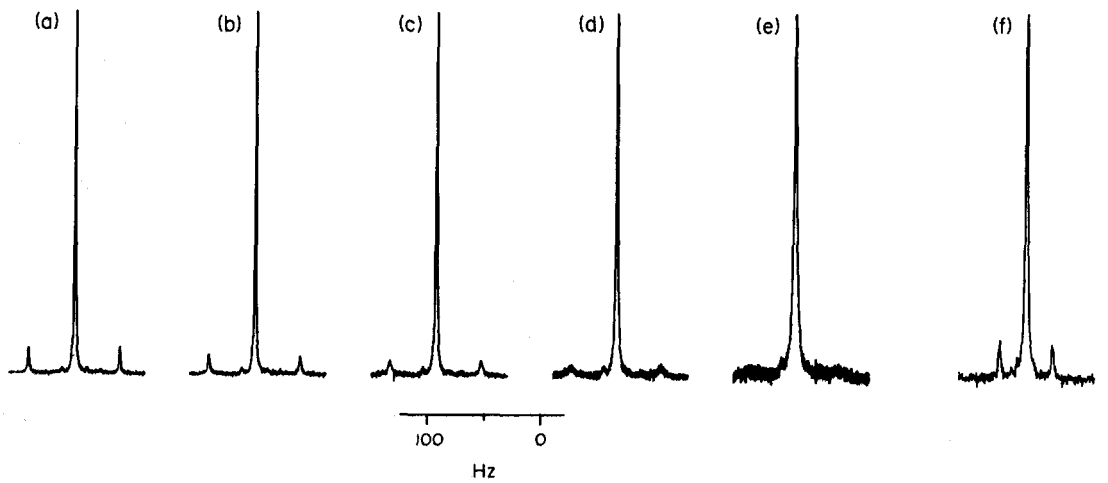

Fig. 2. (a)–(e) ^{31}P NMR spectra of **2**·2THF at different temperatures: (a) −20°C, (b) −10°C, (c) 0°C, (d) +10°C, (e) +20°C; (f) ^{31}P NMR spectrum of **11**·2THF at +20°C.

samarium and ytterbium P—P bond cleavage reaction with simple biphosphines and also the chemistry of the isolated ytterbium and samarium complexes.

EXPERIMENTAL

Due to the extreme air sensitivity of the complexes, all operations were performed under nitrogen with the use of a vacuum-line and dry-box, with dry, carefully degassed solvents. $SmI_2(THF)_2$, $YbI_2(THF)_2$,[12] potassium 2,3,4,5-tetramethylphospholide,[13] 2,3,4,5,2′,3′,4′,5′-octamethyl-1,1′-biphospholyl,[14] $PhAsCl_2$[15] and 2,5,2′,5′-tetraphenyl-1,1′-biphospholyl[7] were prepared as previously described. Tetrabutylammonium tribromide was recrystallized in ethyl acetate. All other reagents were used as received from the commercial suppliers. NMR (^{1}H, ^{13}C, ^{31}P) spectra were measured on Bruker AC 200 or AM 400 instruments. ^{171}Yb spectra were measured at 70 MHz on the AM 400 instrument with a 5 mm multinuclear probe. Elemental microanalyses were obtained at the Centre de Microanalyse du CNRS, Gif-sur-Yvette, France. Mass spectra were obtained on a Shimadzu GC-MS 1000.

1-*Phenyl*-2,3,4,5-*tetramethylarsole* (**4**)[2]

In a 1 dm^3 screw-capped vessel were placed magnesium (8 g, 0.33 g-atom), $HgCl_2$ (9 g, 0.033 mol) and THF (250 cm^3). The magnesium was activated by stirring for 10 min and then a solution of Cp_2ZrCl_2 (17.8 g, 0.061 mol) and 2-butyne (7 g, 0.130 mol) in THF (250 cm^3) was added to the flask. The vessel was stoppered and its contents stirred overnight. The reaction mixture was then filtered and evaporated to dryness. The resulting residue was taken up in n-pentane (500 cm^3) and filtered again. To the dark-red pentane solution cooled to 0°C was added dropwise a pentane (50 cm^3) solution of $PhAsCl_2$ (13 g, 0.058 mol). The reaction mixture was filtered, evaporated to dryness and the residue bulb-to-bulb distilled at 150–160°C/1 mm Hg. 13.05 g (0.050 mol, 86%) of **4** were obtained as a yellow oil. NMR ($CDCl_3$): ^{1}H: 1.87 (Me), 1.98 (Me), 7.24 (Ph). ^{13}C: 14.45 (Me), 14.65 (Me), 128.12 (C *para*), 128.45 (C *ortho*), 132.77 (C *meta*), 137.72 (C *ipso*), 140.99 (C3), 143.42 (C2). Mass spec.: *m/z* 260 (M^+, 100%).

Potassium 2,3,4,5-*tetramethylarsolide* (**5**)

To a solution of **4** (2.68 g, 10.30 mmol) in dimethoxyethane (25 cm^3) was added potassium metal in small lumps (1.0 g, 25 mmol). The reaction mixture was heated at 70°C with vigorous stirring for 2 h. The dark-brown reaction mixture was then filtered on a 5 mm layer of celite and evaporated to dryness. The residue was redissolved in boiling THF (30 cm^3) and slowly cooled to room temperature. The white precipitate which resulted was filtered and rinsed with cold THF (5 cm^3), 1/1 THF/n-pentane (5 cm^3) and n-pentane (10 cm^3) and then dried *in vacuo*. 1.85 g of **5** were obtained as a white powder (8.33 mmol, 81%). NMR (C_4D_8O): ^{1}H: 1.93 (Me), 2.32 (Me). ^{13}C: 14.87 (Me), 18.23 (Me), 126.13 (C3), 145.96 (C2). Found: C, 42.6; H, 5.5. Calc. for $C_8H_{12}AsK$: C, 43.2; H, 5.4%.

2,3,4,5,2′,3′,4′,5′-*Octamethyl*-1,1′-*biarsolyl* (**6**)

$Bu^n{}_4N^+Br_3^-$ (480 mg, 1 mmol) was added to a slurry of **5** (440 mg, 2 mmol) in THF (10 cm^3). After stirring at room temperature for 10 min the reaction mixture was evaporated to dryness. The residue was taken up in n-pentane (20 cm^3), filtered and evaporated to dryness, yielding **6** as a yellow semi-solid (310 mg, 0.84 mmol, 84%) that darkens on standing. NMR (C_6D_6): ^{1}H: 1.72 (Me), 1.86 (Me). ^{13}C: 15.27 (Me), 16.17 (Me), 140.12 (C3 or C2), 143.56 (C2 or C3). Mass spec.: *m/z* 366 (M^+, 75%), 183 (M/2, 100%).

General procedure for the synthesis of bis(heterocyclopentadienyl)lanthanide(II) *complexes*

Method A. To a mixture of one equivalent of solid $MI_2(THF)_2$ (M = Sm, Yb) and two equivalents of

L^-K^+ was added THF (10 to 20 cm^3). The reaction mixtures were stirred for 10 min at room temperature, evaporated to dryness and the residues were repeatedly extracted with toluene until the filtrates were colourless. The combined extracts were then evaporated to dryness and the residues stirred in toluene and filtered.

Method B. To a mixture of the metallic powders (samarium or ytterbium) in a slight excess and the biphospholyl or biarsolyl was added THF (10 cm^3). The reaction mixtures were stirred overnight, evaporated to dryness and usually worked up as described in method A, unless otherwise specified.

Bis(2,3,4,5-*tetramethylphospholyl*)*samarium* (**1**)

Method A. From potassium 2,3,4,5-tetramethylphospholide (400 mg, 2.2 mmol) and $SmI_2(THF)_2$ (620 mg, 1.1 mmol) **1** was obtained as a black powder (265 mg, 0.65 mmol, 58%).

Method B. From 2,3,4,5,2′,3′,4′,5′-octamethyl-1,1′-biphospholyl (500 mg, 1.8 mmol) and samarium (300 mg, 2 mmol) **1** was obtained (400 mg, 0.93 mmol, 50%). NMR data are described in ref. 1. Found: C, 44.7; H, 5.5. Calc. for $C_{16}H_{24}P_2Sm$: C, 44.8; H, 5.6%.

Bis(2,3,4,5-*tetramethylphospholyl*)*ytterbium* (**2**)

Method A. From potassium 2,3,4,5-tetramethylphospholide (400 mg, 2.2 mmol) and $YbI_2(THF)_2$ (640 mg, 1.1 mmol) **2** was obtained as a green powder (310 mg, 0.69 mmol, 61%).

Method B. From 2,3,4,5,2′,3′,4′,5-octamethyl-1,1′-biphospholyl (500 mg, 1.8 mmol) and ytterbium (350 mg, 2 mmol) **1** was obtained (450 mg, 1.1 mmol, 55%). NMR data are described in ref. 1.

Bis(2,3,4,5-*tetramethylarsolyl*)*samarium* (**7**)

Method A. From tetramethylarsolide (**5**) (440 mg, 2 mmol) and $SmI_2(THF)_2$ (550 mg, 1 mmol) **7** was obtained as a black powder (310 mg, 0.60 mmol, 60%).

Method B. From biarsolyl (**6**) (250 mg, 0.68 mmol) and samarium (130 mg, 0.87 mmol) **7** was obtained (200 mg, 0.38 mmol, 57%). NMR (C_4D_8O): ^1H: 3.67 ($w_{1/2} \approx 5$ Hz, Me), 5.64 ($w_{1/2} \approx 5$ Hz, Me). ^{13}C: 0.17 ($w_{1/2} \approx 15$ Hz, C2 or C3), 15.93 ($w_{1/2} \approx 15$ Hz, C3 or C2), 73.12 ($w_{1/2} \approx 6$ Hz, Me), 78.80 ($w_{1/2} \approx 6$ Hz, Me).

Bis(2,3,4,5-*tetramethylarsolyl*)*ytterbium* (**8**)

Method A. From tetramethylarsolide (**5**) (440 mg, 2 mmol) and $YbI_2(THF)_2$ (570 mg, 1 mmol) **8** was obtained as a green powder (300 mg, 0.48 mmol, 48%).

Method B. From biarsolyl (**6**) (300 mg, 0.82 mmol) and ytterbium (170 mg, 1 mmol) **8** was obtained (270 mg, 0.51 mmol, 50%). NMR (C_4D_8O): ^1H: 1.93 (Me), 2.31 (Me). ^{13}C: 15.48 (Me), 18.75 (Me), 131.12 (C3), 150.12 (C2).

Bis(η^5-2,5-*diphenylphospholyl*)*samarium bis*(*tetrahydrofuran*) **10**·2THF

Method B. To biphospholyl (**9**) (470 mg, 1 mmol) and samarium (180 mg, 1.2 mmol) $HgCl_2$ was added ($\approx$20 mg) and the reaction mixture was stirred overnight. The resulting chocolate brown solution was then filtered and the residue was repeatedly extracted with THF until the filtrate was colourless. The filtrate was then reduced to 5 cm^3 and the resulting crystalline precipitate filtered, rinsed with cold THF (2 cm^3) and dried. **10**·2THF was obtained as a chocolate brown microcrystalline powder (500 mg, 0.65 mmol, 65%). NMR (C_4D_8O): ^1H: 1.76 (THF), 3.62 (THF), 7.48 (ps. t., $J_{app.} = 8$, H *para*), 9.44 (ps. t., $J_{app.} = 8$, H *meta*), 9.67 (ps. d., $J_{app.} = 8$, H *ortho*), 19.4 ($w_{1/2} \approx 10$ Hz, H3). ^{13}C: −9 ($w_{1/2} \approx 10$ Hz, C3), 57.5 [d, $w_{1/2} \approx 25$ Hz, J(PC) $\approx$ 40, C2], 128.62 (C *meta*), 134.80 (C *para*), 143.82 [d, J(PC) = 12, C *ortho*], 181.80 [d, J(PC) = 17.5, C *ipso*]. ^{31}P: −417 ($w_{1/2} \approx 25$ Hz).

Bis(η^5-2,5-*diphenylphospholyl*)*ytterbium bis*(*tetrahydrofuran*) **11**·2THF

Method B. From biphospholyl (**9**) (470 mg, 1 mmol) and ytterbium (210 mg, 1.2 mmol) $HgCl_2$ ($\approx$20 mg) was added and the reaction mixture was stirred overnight. The resulting dark purple solution was then worked up as described above to **10**·2THF. Yield: 560 mg (0.71 mmol, 71%) of **11**·2THF as a purple microcrystalline powder. NMR (C_4D_8O): ^1H: 1.77 (THF), 3.61 (THF), 7.07 (ps. d., $J_{app.} = 8$, H *para*), 7.23 (ps. t., $J_{app.} = 8$, H *meta*), 7.26 [d, J(PH) 3.5, H3], 7.67 (ps. t., $J_{app.} = 8$, H *ortho*). ^{13}C: 120.25 (C3), 125.72 (C *para*), 125.84 [d, J(PC) = 12.5, C *ortho*], 129.04 (C meta), 141.13 [d, J(PC) = 19, C *ipso*], 151.93 [d, J(PC) = 46, C2]. ^{31}P: 74.7. Found: C, 61.0; H, 5.0. Calc. for $C_{40}H_{40}O_2P_2Yb$: C, 61.0; H, 5.1%.

X-ray structure determination of **11**·2THF

Data were collected on an Enraf–Nonius CAD4 diffractometer with graphite-monochromated Mo-K_α radiation ($\lambda = 0.71073$ Å, $\mu = 29.0\ cm^{-1}$), using the Enraf–Nonius supplied SDP package. The intensities were corrected for Lorentz–polarization

effects and the structure was solved by the Patterson method. The crystal structure consists of two nearly identical independent molecules. In each molecule one carbon atom of a THF ligand is disordered; refinement of the multiplicity of these atoms showed that the occupancy of each site was equal. The hydrogen atoms were included as fixed contributions in the final stages of least-squares refinement while using anisotropic temperature factors for all the other atoms. A non-Poisson weighting scheme was applied with a p factor equal to 0.05. The final agreement factors were $R = 0.026$, $R_w = 0.036$, G.O.F. = 1.05.

SYNTHESIS OF MONO- AND BINUCLEAR [{Mo(CO)$_3$L}$_n$(dpq)] [n = 1,2; L = CO, MeCN, PPh$_3$; dpq = 2,3-BIS(2-PYRIDYL)QUINOXALINE] COMPLEXES AND HETEROBIMETALLIC ADDUCT FORMATION WITH HEXAFLUOROACETYLACETONATECOBALT(II)

J. GRANIFO

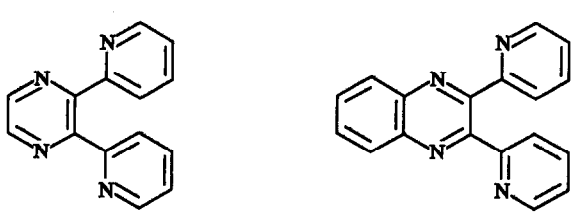
(*Received* 17 *July* 1992; *accepted* 3 *September* 1992)

Abstract—The new compounds [{Mo(CO)$_4$}$_n$(dpq)] [n = 1,2; dpq = 2,3-bis(2-pyridyl) quinoxaline] on refluxing in MeCN produce the acetonitrile complexes [{Mo(CO)$_3$(NCMe)}$_n$(dpq)] (n = 1,2). These acetonitrile derivatives behave as precursors for the tricarbonyl-based fragments [{Mo(CO)$_3$}$_n$(dpq)] (n = 1,2); they react in CH_2Cl_2 at room temperature with PPh$_3$ to afford the [{Mo(CO)$_3$(PPh$_3$)}$_n$(dpq)] (n = 1,2) complexes. In addition, the ligating properties of the novel mononuclear products [Mo(CO)$_4$(dpq)] and [Mo(CO)$_3$(PPh$_3$)(dpq)] towards [Co(hfacac)$_2$] are also reported. The new substances were characterized by IR and electronic spectroscopy.

In previous work,[1] the acetonitrile derivatives [Mo(CO)$_3$(NCMe)(NN)] (NN = bipy, phen), obtained by refluxing [Mo(CO)$_4$(NN)] in MeCN,[2] have been used as precursors for the tricarbonyl complexes *fac*-[Mo(CO)$_3$(L)(NN)] (L = P donor ligand) through the replacement of MeCN by the L ligand. Now, as an extension of this synthetic procedure, we are interested in obtaining acetonitrile precursors containing bis(diimine) ligands instead of the diimine ligands NN.

Recently, Ruminski and Johnson[3] have reported that the molybdenum complexes [{Mo(CO)$_4$}$_n$(dpp)] [n = 1,2; dpp = 2,3-bis(2-pyridyl)pyrazine, Fig. 1] suffer thermal decomposition in MeCN. The binuclear complex [{Mo(CO)$_4$}$_2$(dpp)] derives to the mononuclear [Mo(CO)$_4$(dpp)]; the final products of the monometallic [Mo(CO)$_4$(dpp)] compound were not identified. In this work we report different behaviour in the above molybdenum complexes when the 2,3-bis(2-pyridyl)pyrazine ligand is replaced by the closely related ligand 2,3-bis (pyridyl)quinoxaline (dpq, Fig. 1). Therefore, the [{Mo(CO)$_3$(NCMe)}$_n$(dpq)] (n = 1,2) compounds are obtained by refluxing the [{Mo(CO)$_4$}$_n$(dpq)] (n = 1,2) complexes with MeCN. These acetonitrile derivatives show a high reactivity evidenced through the easy displacement of the MeCN ligand by PPh$_3$ to give the [{Mo(CO)$_3$(PPh$_3$)}$_n$(dpq)] (n = 1,2) complexes.



dpp dpq

Fig. 1. Structure of the ligands dpp and dpq.

In addition, we report here the coordinating properties of the above novel and stable mononuclear complexes [Mo(CO)$_4$(dpq)] and [Mo(CO)$_3$(PPh$_3$)(dpq)]. They react with the hexafluoroacetylacetonatecobalt(II) complex [Co(hfacac)$_2$] to yield heterobinuclear complexes with Mo—dpq—Co arrays. The chelating aptitude of the dpq ligand towards [Co(hfacac)$_2$] has been reported recently by Escuer *et al.*[4] by isolating the [Co(dpq)(hfacac)$_2$] complex.

RESULTS AND DISCUSSION

The carbonyl stretching frequencies of the new dpq complexes [{Mo(CO)$_4$}$_n$(dpq)] (n = 1,2) (Table 1) are typical of the *cis*-[Mo(CO)$_4$(NN-donor)]

Table 1. Analytical and IR spectra for the complexes $[\{Mo(CO)_3L\}_n(dpq)]$ (n = 1,2; L = CO, MeCN, PPh_3) and $[(CO)_3(L)Mo(dpq)Co(hfacac)_2]$ (L = CO, PPh_3)

[c] Broad.

species.[5] The visible absorption spectra of these mono- and bimetallic compounds are dominated by an intense solvatochromic band (Table 2). On the basis of the similarity to results previously published on related complexes,[3] these solvatochromic bands are assigned to metal-to-ligand charge-transfer (MLCT) transitions dpq(π^*) ← Mo(4d). In the analogous $[\{Mo(CO)_4\}_n(dpp)]$ (n = 1,2) complexes[3] these absorptions are shifted towards the blue region, indicating an increase of the electron-withdrawing ability of the LUMO of dpq in comparison with dpp.

Refluxing the above mono- and binuclear $[\{Mo(CO)_4\}_n(dpq)]$ (n = 1,2) complexes in MeCN results in the formation of the acetonitrile derivatives $[\{Mo(CO)_3(NCMe)\}_n(dpq)]$ (n = 1,2), respectively. The $[\{Mo(CO)_3(NCMe)\}_n(dpq)]$ (n = 1,2) complexes are air-sensitive in the solid state and extremely air-sensitive in solution. Their structures are likely to have a facial tricarbonyl geometry, since the IR spectra in the ν(CO) region (Table 1) have a similar pattern to that from the tricarbonyl complexes *fac*-$[Mo(CO)_3(NCMe)(NN\text{-donor})]$.[2]

Considering the labile character of the MeCN ligand, the novel acetonitrile compounds $[\{Mo(CO)_3(NCMe)\}_n(dpq)]$ (n = 1,2) are expected to act as potential precursors of the $[\{Mo(CO)_3\}_n(dpq)]$ (n = 1,2) fragments. In fact, treatment at room temperature of CH_2Cl_2 solutions of $[\{Mo(CO)_3(NCMe)\}_n(dpq)]$ (n = 1,2) in the presence of PPh_3 gave the crystalline $[\{Mo(CO)_3(PPh_3)\}_n(dpq)]$ (n = 1,2) complexes. These products are air stable and soluble in common organic solvents.

Likewise with the starting $[\{Mo(CO)_3(NCMe)\}_n(dpq)]$ (n = 1,2) complexes, the new mixed derivatives $[\{Mo(CO)_3(PPh_3)\}_n(dpq)]$ (n = 1,2) have the facial structure of the carbonyl groups. In particular, the IR spectra of the $[\{Mo(CO)_3(PPh_3)\}_n(dpq)]$ (n = 1,2) compounds display two strong carbonyl stretching bands (Table 1). The lower frequency band is split into two. The same pattern has been observed in the complexes *fac*-$[Mo(CO)_3(L)(NN\text{-donor})]$, L being a phosphorus donor ligand.[1]

The electronic spectra in the visible region of the triphenylphosphine $[\{Mo(CO)_3(PPh_3)\}_n(dpq)]$ (n =

Table 2. Visible absorption maxima (nm) of the complexes $[\{Mo(CO)_4\}_n(dpq)]$ (n = 1,2) and $[\{Mo(CO)_3(PPh_3)\}_n(dpq)]$ (n = 1,2) in several solvents

[a] ε = 13,965 M^{-1} cm^{-1}.
[b] ε = 4886 M^{-1} cm^{-1}.
[c] ε = 18,140 M^{-1} cm^{-1}.
[d] ε = 4221 M^{-1} cm^{-1}.

1,2) complexes consist of one broad and strong solvent sensitive band (Table 2). These bands appear at a lower energy than those of their respective parent complexes [{Mo(CO)$_4$}$_n$(dpq)] (n = 1,2). These results suggest that the observed absorptions in both systems are of the same nature, i.e. MLCT dpq(π^*) ← Mo(4d) transitions. Indeed, when one carbonyl group is substituted by a phosphorus-donor ligand the metal orbitals are destabilized,[1] then a lower dpq(π^*)/Mo(4d) gap for the PPh_3 complexes should occur.

Finally, the capacity of adduct formation of the mononuclear dpq complexes [Mo(CO)$_4$(dpq)] and [Mo(CO)$_3$(PPh$_3$)(dpq)] was demonstrated. Thus, the reaction of an equimolar amount of the mononuclear [Mo(CO)$_4$(dpq)] or [Mo(CO)$_3$(PPh$_3$)(dpq)] complexes with [Co(hfacac)$_2$] in CH_2Cl_2 affords the heterobinuclear adducts [(CO)$_4$Mo(dpq)Co(hfacac)$_2$] or [(CO)$_3$(PPh$_3$)Mo(dpq)Co(hfacac)$_2$]. Both bimetallic compounds are soluble and stable in non-coordinating solvents such as dichloromethane or benzene; nevertheless, in acetone they dissociate into the original [Mo(CO)$_4$(dpq)] or [Mo(CO)$_3$(PPh$_3$)(dpq)] and [Co(hfacac)$_2$] complexes as evidenced by the electronic spectra. The new adducts have ν(CO) modes in their IR spectra that are in close agreement with those which are exhibited by their precedent mononuclear [Mo(CO)$_4$(dpq)] and [Mo(CO)$_3$(PPh$_3$)(dpq)] species (Table 1). Furthermore, in CH_2Cl_2 solutions a pronounced red shift of the MLCT dpq(π^*) ← Mo(4d) transition of the heterometallic [(CO)$_4$Mo(dpq)Co(hfacac)$_2$] (λ_{max} = 643 nm) and [(CO)$_3$(PPh$_3$)Mo(dpq)Co(hfacac)$_2$] (λ_{max} = 777 nm) species vs their respective monometallic components, [Mo(CO)$_4$(dpq)] (λ_{max} = 562 nm) and [Mo(CO)$_3$(PPh$_3$)(dpq)] (λ_{max} = 680 nm), was observed. These shifts in dpq-based complexes[6,7] have been rationalized in terms of a stabilization of the π^*dpq orbital of the monometallic chromophore upon attachment of a second metal centre. On the other hand, the magnetic moments of the complexes [(CO)$_4$Mo(dpq)Co(hfacac)$_2$] (μ_{eff} = 4.8 B.M.) and [(CO)$_3$(PPh$_3$)Mo(dpq)Co(hfacac)$_2$] (μ_{eff} = 4.3 B.M.) are in the range observed by Escuer *et al.*[4] for the six-coordinated cobalt(II) complexes [Co(L)(hfacac)$_2$] [L = bis(diimine) ligand]. However, we failed to determine the ligand field (d–d) transitions of the cobalt(II) centre[4] in the visible region, since they are masked by the more intense MLCT dpq(π^*) ← Mo(4d) transitions.

EXPERIMENTAL

All solvents used in preparing the complexes were reagent grade and used without further purification. [Mo(CO)$_6$] and [Co(hfacac)$_2$]·3H$_2$O were purchased from Aldrich Chemical Company. 2,3-Bis(2-pyridyl)quinoxaline (dpq)[8] and [Mo(CO)$_4$(piperidine)$_2$][9] were prepared by similar methods to those described in the literature. The IR spectra were recorded on a Perkin–Elmer 577 spectrophotometer. The electronic spectra were registered on a Spectronic 3000 diode array spectrophotometer. Magnetic susceptibilities at room temperature were measured by the Faraday method using a Cahn 7600-RTL balance.

Synthesis of [Mo(CO)$_4$(dpq)]

A mixture of dpq (0.300 g, 1.057 mmol) and freshly prepared [Mo(CO)$_4$(piperidine)$_2$] (0.400 g, 1.057 mmol) was stirred in methanol (15 cm^3) for 2 h. The bright black precipitate was filtered and washed three times with 3 cm^3 portions of methanol and dried *in vacuo*. 0.365 g (70% yield) of the crystalline compound were obtained. The results of the elemental analysis are presented in Table 1.

Synthesis of [{Mo(CO)$_4$}$_2$(dpq)]

A mixture of dpq (0.350 g, 1.231 mmol) and [Mo(CO)$_6$] (0.780 g, 2.954 mmol) in benzene (15 cm^3) was heated at reflux for 16 h under nitrogen. The solid was collected by filtration, washed with benzene (10 cm^3), dissolved in CH_2Cl_2 (100 cm^3), filtered and then reprecipitated by the addition of petroleum ether (150 cm^3, 40–60° fraction). The black needle-like crystals were washed with a mixture of CH_2Cl_2 and petroleum ether (30 cm^3, 1 : 2). Yield: 0.700 g (81%). The results of the elemental analysis are presented in Table 1.

Synthesis of [{Mo(CO)$_3$(PPh$_3$)}$_n$(dpq)] (n = 1,2)

These complexes were prepared by an analogous method using fresh samples of [{Mo(CO)$_3$(NCMe)}$_n$(dpq)] (n = 1,2) as the starting material. The following procedure is typical.

[{Mo(CO)$_3$(PPh$_3$)}$_2$(dpq)]. [{Mo(CO)$_4$}$_2$(dpq)] (0.1 g, 0.143 mmol) in MeCN (10 cm^3) was refluxed for 2 h under nitrogen. The green solution was evaporated to dryness to give the black acetonitrile complex [{Mo(CO)$_3$(NCMe)}$_2$(dpq)] and PPh_3 (0.075 g, 0.286 mmol) and CH_2Cl_2 (10 cm^3) were added. The resultant green mixture was stirred at room temperature for 0.5 h, filtered and concentrated to 3–4 cm^3 volume. A very dark green crystalline precipitate was formed on slow addition of MeOH (10 cm^3). The material was separated and washed with MeOH (3 × 4 cm^3).

Yield: 0.130 g (78%). The results of the elemental analyses are presented in Table 1.

Synthesis of $[(CO)_4Mo(dpq)Co(hfacac)_2]$ *and* $[(CO)_3(PPh_3)Mo(dpq)Co(hfacac)_2]$

Both adducts were obtained by direct reaction at room temperature of a mixture of equimolar amounts of $[Mo(CO)_4(dpq)]$ or $[Mo(CO)_3(PPh_3)(dpq)]$ and $[Co(hfacac)_2]\cdot 3H_2O$ in CH_2Cl_2; a typical reaction runs as follows.

$[(CO)_3(PPh_3)Mo(dpq)Co(hfacac)_2]$. To a solution of $[Mo(CO)_3(PPh_3)(dpq)]$ (0.070 g, 0.096 mmol) in CH_2Cl_2 (15 cm^3) was added $[Co(hfacac)_2]\cdot 3H_2O$ (0.051 g, 0.096 mmol). The green solution was stirred for 0.5 h, filtered and then concentrated to 3–4 cm^3 volume. To the concentrate was added petroleum ether (30 cm^3, 40–60° fraction). A black crystalline solid precipitated after 30 min, which was washed with a mixture of CH_2Cl_2/petroleum ether (10 cm^3, 1:10). Yield: 0.052 g (45%). The elemental analyses are presented in Table 1.

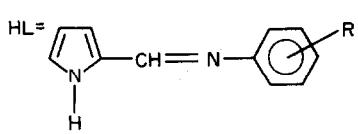
(*Received* 13 *July* 1992; *accepted* 3 *September* 1992)

Abstract—The electrochemical oxidation of anodic cadmium in acetonitrile containing both a Schiff base, HL (derived from H-pyrrole-2-carbaldehyde and a substituted aniline), and a nitrogen donor ligand [1,10-phenanthroline(phen) or 2,2′-bipyridine(bipy)] yielded the mixed complexes $CdL_2 \cdot phen$ and $CdL_2 \cdot bipy$. The crystal structure of 2,2′-bipyridine bis{2-[(2-methoxyphenyl)iminomethyl]pyrrolato}cadmium(II) was determined by X ray diffraction.

The synthesis of mixed complexes of nickel and cobalt with pyrrolaldimines and additional ligands by electrolysis of the metal in a solution of the ligands has been the subject of several recent papers from our laboratory.[1,2] In continuation of this series, this paper describes the successful application of the above method to the synthesis of mixed complexes of cadmium(II) with arylpyrrolaldimines (HL) and bidentate nitrogen ligands, such as 2,2′-bipyridine or 1,10-phenanthroline.

The crystal structure of 2,2′-bipyridine bis{2-[(2-methoxyphenyl)iminomethyl]pyrrolato}cadmium(II) is also reported.



where R = H (HL^1); 4-CH_3 (HL^2); 4-Cl (HL^3); 2-OCH_3 (HL^4) or 4-OCH_3 (HL^5).

EXPERIMENTAL

Acetonitrile, pyrrole-2-aldehyde, 1,10-phenanthroline(phen), 2,2′-bipyridine(bipy) and all other reagents were commercial products and were used as supplied. Cadmium (Ega Chemie) was used as *ca* 2 × 2 cm plates.

The ligands were prepared by standard methods by direct reaction of equimolar amounts of the aldehyde and the amine in chloroform, using a Dean–Stark trap. After removal of the water produced in the reaction, the solution was concentrated and the isolated solid was washed with diethyl ether and dried *in vacuo*. Its purity was checked by recording its IR and ^1H NMR spectra.

Electrochemical synthesis

The electrochemical method used was similar to that described by Tuck.[3] The cell was a 100 cm^3 tall-form beaker fitted with a rubber bung, through which the electrochemical leads entered. The anode was suspended from a platinum wire and the cathode was also a platinum wire. The Schiff base and

[b] Voltage to produce a current of 20 mA.

the additional ligand (1,10-phenanthroline or 2,2′-bipyridine) were dissolved in acetonitrile and a small amount of tetraethylammonium perchlorate was added to the solution as a current carrier. A direct current was obtained from a purpose-built d.c. power supply. Applied voltages of 15–30 V allowed sufficient current flow for smooth solution of the metal. In all cases, hydrogen was evolved at the cathode. These cells can be summarized as:

$$Pt(-)/CH_3CN + HL + L'/Cd(+),$$

where L′ is phenanthroline or bipyridine.

At the end of electrolysis, the clear solutions were filtered to remove any particles of metal and then left to concentrate, yielding crystalline products. The solids were washed with acetonitrile and diethyl ether and dried at room temperature.

The solution compositions and experimental conditions are set out in Table 1.

Physical measurements

The carbon, nitrogen and hydrogen contents of the complexes (Table 2) were determined on a Carlo–Erba EA1108 microanalyser. IR spectra were recorded in KBr mulls on a Perkin–Elmer 180 spectrophotometer. Proton NMR spectra were recorded on a Bruker WM 250 MHz spectrometer using DMSO as the solvent; chemical shifts were referred to TMS as the internal standard.

Crystal structure determination

Crystal data. $C_{36}CdH_{33}N_7O_2$; $M = 708.11$, orthorhombic, $a = 11.0362(6)$, $b = 17.0351(7)$, $c = 17.6012(7)$ Å, $U = 3309.1(4)$ Å^3 (by least-squares refinement on diffractometer angles for 25 automatically centred reflections, $19 < \theta < 56°$, $\lambda = 1.54184$ Å), space group *Pccn* (No. 56), $Z = 4$, $D_c = 1.421$ g cm^{-3}. Irregular shaped crystals of maximum and minimum linear dimension 0.25 and 0.35 mm were used; μ(Mo-K_α) = 57.53 mm^{-1}.

Data collection and processing

CAD4 diffractometer, $\omega/2\theta$ mode with ω scan width = 0.85+0.15 tan θ, graphite monochromated Cu-K_α radiation, 2845 reflections measured ($0 < \theta < 60°$, $-2 \leqslant h \leqslant 12$, $0 \leqslant l \leqslant 19$), 2313 unique (merging $R = 0.027$), 1842 with $I > 3\sigma(I)$; Lorentz and polarization corrections. Absorption corrections were applied at a later stage in the refinement[4] (max., min. transmission factors = 1.48, 0.46). The intensities of two standard reflections were essentially constant throughout the experiment.

Structure analysis and refinement

Standard direct methods were followed by normal difference Fourier techniques. Blocked-matrix least-squares refinement with all non-hydrogen atoms anisotropic; hydrogens included as fixed contributors were those found in difference syntheses, with an overall isotropic temperature factor of $U_{iso} = 0.08$ Å^2. The function which minimized $\Sigma w(|F_o| - |F_c|)^2$ with the weighting scheme $w = 1/[\sigma^2(F_o) + 0.0002F_o^2]$ gave final $R[= \Sigma w(|F_o| - |F_c|)/\Sigma w(|F_o|]$ and $R'\{= [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2}\}$ values of 0.044 and 0.048, respectively. Programs used: SHELX76[5] and ORTEP;[6] scattering factors for non-hydrogen atoms from Cromer and Mann[7] with corrections for anomalous dispersion from Cromer and Liberman,[8] for hydrogen from Stewart *et al.*[9] These and other crystallographic data have been deposited as supplementary material (No. CSD 56421). Copies can be obtained through the Fachinformationszentrum Energie, Physik, Mathematik D-7514 Eggenstein-Leopoldshafen.

RESULTS AND DISCUSSION

The oxidation of metallic cadmium as the anode of an electrochemical cell containing an acetonitrile solution of the appropriate Schiff base HL and 1,10-phenanthroline or 2,2′-bipyridine as additional ligands was a simple direct route to CdL_2L'. The compounds obtained were yellow crystalline solids that were insoluble in common non-polar solvents, but soluble in polar solvents such as acetonitrile or dimethylsulphoxide.

As in the synthesis of other cadmium complexes, the electrochemical efficiency, E_f, defined as the number of moles of metal dissolved per Faraday of charge (mol F^{-1}), was always close to 0.5. This, and the formation of hydrogen at the cathode, are in keeping with the following mechanism:

$$\text{Cathode: } 2HL + 2e^- \longrightarrow H_{2(g)} + 2L^-$$

$$\text{Anode: } Cd + L' + 2L^- \longrightarrow CdL_2L' + 2e^-$$

$$L' = \text{bipy or phen.}$$

An ORTEP view of the structure of 2,2′-bipyridine bis{2-[(2-methoxyphenyl)iminomethyl]pyrrolato}cadmium(II) is shown in Fig. 1. Bond distances and angles are listed in Table 3. The complex has crystallographic C_2 symmetry, with the cadmium atom located on the two-fold axis and coordinated to the N(1) and N(2) nitrogen atoms of two symmetry-related Schiff bases and to the two nitrogen atoms of the bipyridine moiety, which are also symmetry related by the two-fold axis.

The coordination polyhedron is best described as a distorted trigonal prism in which the bases, formed by atoms N(1), N(2) and N(3), are related by the crystallographic two-fold axis, with a dihedral angle of 171(1)° between them.

The Cd—$N_{(pyrrole)}$ bond length, 2.242(4) Å, is similar to the 2.266(4) Å found in the bis{2-[[2(N,N-dimethyl)aminoethyl]iminomethyl]pyrrolato}cadmium(II), a compound with a CdN_4 core and only a very weak interaction with the tertiary amine nitrogen.[10] The Cd—$N_{(azomethine)}$ distance, 2.524(5) Å, is considerably longer than those found in the above-mentioned complex, 2.277(5) Å,[10] and those found in the hexa-coordinate [(1,2-benzenediamine-N)][N,N″-(2,6-pyridinediyldimethylidene)bis[1,2-benzenediamine]diperchlorate]cadmium(II), 2.377(10) Å.[11] The Cd—$N_{(bipyridine)}$ bond lengths, 2.371(4) Å, are very similar to that found in $Cd(S_2CSC_4H_{9-n})_2 \cdot$ bipy, 2.363(3) Å,[12] and not very different to those found in [(2,2′-bipyridine)bis-(diethyldithiocarbamato)]cadmium(II), 2.430(3) Å.[13] Likewise, the N—Cd—N bite angle, 68.4(2)°, is similar to those reported for the latter complexes, 69.0(1)° and 67.6(3)°, respectively.

The average value of the C—N bond lengths, 1.287(7) Å, is very close to the reported norm for C=N bonds, 1.30 Å.[14] The bond lengths and angles in the pyrrole ring are very similar to those of the free pyrrole molecule. An acetonitrile molecule completes the crystal structure with its two carbon atoms on a crystallographic two-fold axis.

The IR spectra of the complexes (Table 4) are consistent with the structural data presented above. The ν(N—H) band of the free bases at 3300 cm^{-1} is absent in the spectra of the complexes, confirming that it is the deprotonated ligand that is present in the latter. The band which appears in the free ligand at 1630–1615 cm^{-1} is shifted to lower frequencies as a consequence of coordination to the imino nitrogen.[15]

In addition, bands at *ca* 1510, 850 and 730 cm^{-1} in the compounds containing 1,10-phenanthroline and at *ca* 760 and 760 cm^{-1} in the 2,2'-bipyridine derivatives confirm the presence of these ligands in the coordination sphere of the metal[16] and hence that cadmium is hexa-coordinate in all these compounds.

The ^1H NMR spectra reinforce the above conclusions. The signal attributed to N—H which appears at 11.8 ppm in the ligand (Table 5) is absent in the complexes, confirming that in the latter the ligand is deprotonated. The azomethine signal (at 8.3–8.6 ppm in the complexes) was slightly shifted downfield from its position in the free ligands. The spectra also show the signals of the additional

Abstract—$[Mo(NO)L^*Cl_2]$ [L* = hydrotris(3,5-dimethylpyrazol-1-yl)borate] reacted with $S(SnPh_3)_2$ to give $[\{Mo(NO)L^*Cl\}_2(\mu\text{-}S_2)]$ in low yield. The reaction between $[Et_3NH][Mo(NO)L^*Cl_2]$ and elemental sulphur afforded $[\{Mo(NO)L^*\}_2(\mu\text{-}S)_2]$ and $[\{Mo(NO)L^*Cl\}_2(\mu\text{-}S_2)]$. Both compounds undergo reversible one-electron reductions. The molecular structure of one isomer of $[\{Mo(NO)L^*Cl\}_2(\mu\text{-}S_2)]$ was determined crystallographically and the compound contains an Mo—S—S—Mo core with short Mo—S distances of 2.310 Å, but no direct metal–metal bond.

In our studies of bimetallic redox-active molybdenum and tungsten nitrosyl complexes, in which the two metals are bridged by aromatic and aliphatic groups, we have observed[1–3] that the interaction between the two metal centres is, as expected, strongly dependent on the nature of the bridging ligand, i.e. whether it is conjugated or non-conjugated in nature, and on the distance between the two metal centres. The mono-reduced species derived from the general system [M(NO)L*X—Q—M′(NO)L*X] [L* = tris(3,5-dimethylpyrazolyl)borate; X = Cl, I], which are paramagnetic and have one unpaired electron per bimetallic, exhibit the full range of mixed-valence behaviour. That is, the unpaired electron in the species $[M(NO)L^*X—Q—M'(NO)L^*X]^-$ may be localized on one metal ("valence-trapped"), partially localized ("hopping" between metal centres) or fully delocalized, depending on the electronic structure and geometry of Q.[1,3,4–7]

During our synthetic studies of the [M(NO)L*XY] system we have frequently obtained the bimetallic μ-oxo species $[\{M(NO)L^*X\}_2O]$.[5,8] These compounds both contain inequivalent metal sites as shown by ^1H NMR spectroscopy, an observation which was confirmed in $[Mo(NO)L^*I]_2(\mu\text{-}O)$ by an X-ray crystal structure determination.[8] It was expected that the electrochemical interaction between the two metal centres in this type of complex would be very strong and so we would have anticipated two well-separated one-electron reduction processes. However, we have so far detected only one one-electron electrochemical reduction process, although it is possible that the second reduction occurs very close to the potentials for the decomposition processes of the solvent and base electrolyte. Spectroelectrochemical studies of $[\{Mo(NO)L^*Cl\}_2O]^-$ suggest that the unpaired electron is delocalized over the Mo—O—Mo unit.[5]

The closely related μ-sulphido complexes [{Mo(NO)L*X}$_2$S] would clearly be of interest in further exploring the electronic properties of such single-atom bridged systems. The reactions between elemental sulphur and [Mo(CO)$_3$LH] or [Mo(CO)$_3$L*H] [L = hydrotris(pyrazol-1-yl)borate] have afforded [{Mo(CO)$_2$L}$_2$(μ-S)] and [{Mo(CO)$_2$L*}$_2$(μ-S)], respectively,[9] both of which contain a linear [Mo—S—Mo]$^{2+}$ unit. This contrasts with the more general observation that μ-sulphido molybdenum complexes show acute Mo—S—Mo angles (75°).[10] The apparently straightforward synthesis of such μ-sulphido carbonyl species encouraged us initially to investigate the reactions between [Mo(NO)L*I$_2$] and either H_2S or Na_2S, since the reactive di-iodide was readily converted into [{Mo(NO)L*I}$_2$O] on treatment with water. However, although reactions with H_2S and Na_2S undoubtedly occurred, we were unable to isolate characterizeable products.

In contrast, the reactions between [Mo(NO)L*Cl$_2$] and S(SnPh$_3$)$_2$, and between [Et$_3$NH][Mo(NO)L*Cl$_2$] and S_8, have afforded isolable products and in this paper we describe the nature of the products isolated and their characterization.

EXPERIMENTAL

The complexes [Mo(NO)L*Cl$_2$] and [NHEt$_3$][Mo(NO)L*Cl$_2$] were prepared by previously described methods.[11,12] Other reagents were used as supplied and reaction solvents were redistilled from drying agents according to standard methods. All reactions were performed under an atmosphere of dry nitrogen, but most of the reaction products were air-stable. Column chromatography was carried out using silica gel (Merck 70-230 ASTM) columns.

IR spectra were recorded in KBr discs using a PE 297 spectrophotometer and ^{1}H NMR spectra were obtained using Jeol GX270 and Bruker WH400 instruments. Electronic spectra were recorded in dichloromethane solution using a Shimadzu UV-240 spectrometer. Mass spectra were obtained using a Kratos MS80 instrument under EI conditions.

Electrochemical measurements were made using an in-house designed three-electrode cell which incorporated a saturated calomel electrode (SCE), a platinum wire auxiliary electrode and a platinum-bead working electrode. Cyclic voltammetry and differential pulse voltammetry measurements were made at 20 ± 1°C with a PAR 174A potentiostat and a Philips *X–Y* recorder. Cyclic voltammetry measurements for Condecon electrochemical analysis were made over three or four scan rates between 100 and 1000 mV s^{-1} using a PAR 360 potentiostat with an analogue-digital convertor and the data were collected using an Amstrad PC1512 computer. The Condecon software, available from E.G. & G, uses convolutions and deconvolutions in the treatment of digitalized data from cyclic voltammetric experiments. An iterative approach is used to enable modelling of experimental data and, hence, mechanistic details can be deduced. All the electrochemical results were obtained from solutions containing [NBu$_4$]BF$_4$ (*ca* 0.2 mol dm^{-3}) as the supporting electrolyte and the potentials are reported vs SCE, but were calibrated using ferrocene as an internal reference couple.

Synthesis of S(SnPh$_3$)$_2$

SnClPh$_3$ (5.46 g, 14.2 mmol) and Na_2S (0.81 g) in water (100 cm^3) were refluxed for 2 days. The water was then distilled off, acetone was added to dissolve the solid and the solution was filtered. The bulk of the solution was reduced *in vacuo* and the addition of water gave a crystalline white precipitate. The solid was collected by filtration and dried *in vacuo* over P_2O_5 (yield: 2.78 g, 53%). The product was characterized by ^{1}H NMR spectroscopy and by elemental analysis. The presence of sulphur was ascertained by adding acid to an acetone solution of the product and monitoring the evolved gas with lead acetate paper, which turned black.

Reaction of S(SnPh$_3$)$_2$ *with* [Mo(NO)L*Cl$_2$], *isolation of* [{Mo(NO)L*Cl}$_2$(μ-S$_2$)] (1)

[Mo(NO)L*Cl$_2$] (0.203 g, 41 mmol) was refluxed for 5 days in toluene (75 cm^3) containing S(SnPh$_3$)$_2$ (0.133 g, 0.18 mmol). The solution, which had become very dark brown, was cooled and filtered. The filtrate was evaporated to dryness and purified by column chromatography (column dimensions 40 × 4 cm, eluant dichloromethane/hexane, 70/30 v/v). Five fractions were collected, but only the blue second fraction, compound **1**, afforded a solid in a pure form. This compound was identified as [{Mo(NO)L*Cl}$_2$(μ-S$_2$)] from the X-ray study (yield: 7 mg, 3%). Found: C, 38.9; H, 4.6; N, 19.3. Calc. for **1**: C, 38.0; H, 4.7; N, 20.7%. IR (cm^{-1}, KBr disc): ν(BH) 2545, ν(NO) 1685. ^{1}H NMR spectrum [ppm, 270 MHz, $CDCl_3$ (relative area, multiplicity)]: 5.95(2s), 5.87(2s), 5.83(2s), 2.66(6s). 2.47(6s), 2.41(6s), 2.38(6s) and 2.31(6s). Mass spectrum: m/z = 947 ([Mo$_2$(NO)$_2$L*$_2$Cl$_2$S − 1]$^+$), 932 ([Mo$_2$(NO)NL*$_2$Cl$_2$S]$^+$), 493 ([Mo(NO)L*ClS + 1]$^+$), 465 ([Mo(NO)L*Cl]$^+$). Electronic spectrum {λ_{max} [nm, ε (dm^3 mol^{-1} cm^{-1}; $CHCl_3$)]}: 586 (17,250), 410 (67,000), 342 (11,940), 232 (45,240). Electrochemical data (CH_2Cl_2; vs SCE): $E_{1/2}$ =

-0.073 ± 0.005 V, $\Delta E_p = 85\pm10$ mV (ferrocene, $E_{1/2} = +0.555\pm0.005$ V, $\Delta E_p = 100\pm10$ mV). Condecon analysis in dichloromethane showed a one-electron fast transfer process. This process was not fully reversible, with a decomposition rate of *ca* 0.2 s^{-1}.

Reaction of [NHEt$_3$][Mo(NO)L*Cl$_2$] *with elemental sulphur; attempted isolation of* [{Mo(NO)L*S}$_2$] (3)

[NHEt$_3$][Mo(NO)L*Cl$_2$] (250 mg, 0.42 mM) was refluxed with elemental sulphur (125 mg, 3.90 mM) in toluene (50 cm^3). The solution began to darken immediately, but heating was continued for 16 h. The solution was cooled, filtered and evaporated to dryness. Purification was carried out by column chromatography (column dimensions 50×2 cm, eluant 80% dichloromethane/20% hexane) and four fractions (brown, red, blue and purple in order of elution) were isolated. The first fraction was brown (3) and was identified tentatively by ^{1}H NMR and mass spectrometry as [{Mo(NO)L*Cl}$_2$(μ-S)$_2$] contaminated with elemental sulphur, which could not be removed (yield: 13 mg of the impure product). IR spectrum (cm^{-1}, KBr disc): ν(BH) 2555, ν(NO) 1685. ^{1}H NMR spectrum [ppm, 400 MHz, $CDCl_3$ (relative area, multiplicity)]: 5.90(1s), 5.85(2s), 2.50(3s), 2.39(6s), 2.33(6s) and 2.18(3s). Mass spectrum: $m/z = 910$ ([M]$^+$), 489 ([Mo(NO)L*S$_2$]$^+$), 457 ([Mo(NO)L*S]$^+$), 427 ([MoL*S]$^+$). Electronic spectrum {λ_{max} [nm, ε ($dm^3\ mol^{-1}\ cm^{-1}$; $CHCl_3$)]}: 535 (4890), 413 (17,870), 233 (66,400). Electrochemical data (CH_2Cl_2; vs SCE): $E_{1/2} = -0.360\pm0.005$ V, $\Delta E_p = 105\pm10$ mV (ferrocene, $E_{1/2} = +0.555\pm0.005$ V; $\Delta E_p = 95\pm10$ mV). Condecon analysis showed a fast one-electron transfer with a small decomposition process with a rate constant <0.05 s^{-1}.

The remaining fractions were obtained in yields of 3% or less, in insufficient quantities for adequate characterization. However, from mass and IR spectral comparisons the third blue fraction seems to be very similar, if not identical, to **1**.

X-ray crystallographic data obtained from compound **1**

$C_{30}H_{44}B_2Cl_2Mo_2N_{14}O_2S_2$, $M = 981.3$, monoclinic, space group $P2_1$, $a = 10.205(4)$, $b = 16.958(9)$, $c = 12.701(3)$ Å, $\beta = 106.38(3)°$, $V = 2108.8$ Å^3, $Z = 2$, $D_c = 1.545$ g cm^{-3}, $F(000) = 996$, μ(Mo-K_α) = 0.844 mm^{-1}, $\lambda = 0.71069$ Å.

A plate-shaped crystal ($0.3\times0.25\times0.1$ mm) was mounted on an Enraf–Nonius CAD-4 diffractometer, cell dimensions and intensities were measured by $\omega/2\theta$ scans with graphite-monochromated Mo-K_α radiation and scan range (θ) = (1.1+0.35 tan θ)°. 4367 reflections were scanned in the range $2 < \theta < 25°$, of which 3838 were unique ($R_i = 0.04$), and of these 2378 having $I > 2.5\sigma(I)$ were considered observed and used in the analysis. Three standard reflections measured every 2 h showed no significant variation in intensity.

The structure was determined by Patterson and Fourier methods. It was obvious as this stage that the overall molecular conformation approximated closely $\bar{1}$ (C_i) symmetry. It had been noted that the hol reflections having $h+1$ odd were significantly weaker than those having $h+1$ even. The space group thus approximates to the centrosymmetric $P2_1/n$. To overcome the difficulties inherent in refining by least-squares a pseudo-centrosymmetric structure in a non-centrosymmetric space group, a damping factor[13] was included in the calculations and the two halves of the molecules related by the pseudo-centre were refined in separate blocks. Anisotropic thermal parameters were used for the non-hydrogen atoms. Hydrogen atoms were placed in calculated positions. Weights, $w = 1/[\sigma^2(F)+0.001F^2]$, which resulted in a satisfactory weighting analysis, were used in the least-squares refinement. The calculations were terminated when all shift/error ratios were less than 0.35 and R = 0.0477, $R_w = 0.0564$ for 2378 observed reflections. The residual electron density in a final difference map was within the range -0.73 to $+0.91$ e Å^{-3}.

Complex neutral-atom scattering factors were employed. Computations were carried out largely on the University of Birmingham IBM 3090 computer with SHELX 76.[13] The molecular diagram was drawn using PLUTO.[14]

Additional material available from the Cambridge Crystallographic Data Centre comprises atomic coordinates, thermal parameters and the full set of bond lengths and angles.

RESULTS AND DISCUSSION

Synthetic and spectral studies

Because of earlier difficulties in obtaining isolable products from the reactions between H_2S and Na_2S and the labile [Mo(NO)L*I$_2$], we have investigated reactions between [Mo(NO)L*Cl$_2$] and S(SnPh$_3$)$_2$. The tin-containing reagent appeared to be particularly useful for introducing S^{2-} into the molybdenum nitrosyl system because of the very high stability of the Sn—Cl bonds in the $SnClPh_3$ by-product. We have also investigated the reaction between [Mo(NO)L*Cl$_2$]$^-$ and S_8. The reduced molybdenum nitrosyl chloride has proved to be a

most useful intermediate for the introduction of neutral nucleophiles into the molybdenum nitrosyl system, affording species of the type [Mo(NO)L*ClQ].

The reaction between $[Mo(NO)L^*Cl_2]$ and $[Ph_3Sn]_2S$ was carried out in refluxing toluene for several days in order to drive the reaction to near-completion. Five fractions, excluding the starting material, were separated by column chromatography, the first fraction being red, the second dark blue (**1**), the third green, the fourth purple and the fifth dark green (**2**). Of these, we were only able to satisfactorily separate and purify the second and fifth fractions. Among the other compounds which could occasionally be isolated from the reaction mixture during work-up, one white crystalline material was identified as $Ph_3SnSnPh_3$ on the basis of mass spectral measurements.

The fifth fraction yielded compound **2**, identified as $[\{Mo(NO)L^*Cl\}_2(\mu\text{-}O)]$ by ^1H NMR spectroscopy and by comparison with an authentic sample.[5,8] The first fraction could not be identified. However, the IR spectrum of the dark blue second fraction (**1**) contained a single nitrosyl stretch, the ^1H NMR spectrum contained only a single set of signals attributable to L* and the mass spectrum contained a peak assigned to $[Mo_2(NO)_2L^*_2Cl_2S-H]^+$. It was possible to obtain crystals of this compound by slow evaporation of a dichloromethane solution, and an X-ray analysis established that the compound is $[\{Mo(NO)L^*Cl\}_2(\mu\text{-}S_2)]$. Although the yield of the product was very low, the reaction was reproducible. The observation of **1** as a product of the reaction between $[Mo(NO)L^*Cl_2]$ and $S(SnPh_3)_2$ possibly explains the occurrence of $[\{SnPh_3\}_2]$, perhaps formed by reaction of two molecules of the putative intermediate [Mo(NO)L*Cl(SSnPh$_3$)].

The reaction between $[NHEt_3][Mo(NO)L^*Cl_2]$ and an excess of S_8 in refluxing toluene afforded, after cooling, reduction of the solvent and column chromatography gave four fractions, the first being brown (**3**), the second red, the third dark blue (probably **1**) and the fourth purple. All four fractions were separated by column chromatography.

The brown fraction afforded compound **3**, but this was difficult to obtain in pure form as it travelled down the column with elemental sulphur. The sulphur was observed to preferentially precipitate from a dichloromethane/hexane mixture, but it could not be completely removed from the fraction. Attempts were made to sublime the element from the compound mixture, but even this failed to fully purify the compound and thus elemental analysis was precluded. The mass spectrum of this material contained a molecular ion at $m/z = 910$ which corresponds to the formulation $[\{Mo(NO)L^*S\}_2]^+$. The ^1H NMR spectrum of this species was also consistent with this formulation, showing one set of signals assigned to L*, viz. two signals due to the hydrogen atom attached to C(4) of the pyrazolyl ring and four methyl signals, of relative areas 1:2:3:6:6:3. This indicates that the molecule has a plane of symmetry through one pyrazole ring of each L* ligand and this could be consistent with a formulation as $[\{Mo(NO)L^*\}_2(\mu\text{-}S)_2]$, which could exist as two isomers, *cis* and *trans* with respect to the nitrosyl groups (Fig. 1). However, the compound exhibits only one NO stretching frequency and so we conclude that the species may have the *trans* (C_{2h}) form. NOE studies failed to reveal any signal enhancements and so did not distinguish the possibilities.

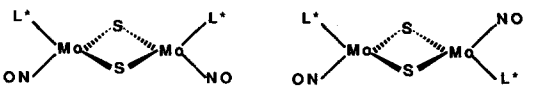

Fig. 1. *Cis* and *Trans* isomers of $[\{Mo(NO)L^*\}(\mu\text{-}S)_2]$ (**3**).

Electronic spectral data obtained from the purified complexes are given in the Experimental. The absorption which appears at *ca* 230 nm can be assigned to a π–π^* transition in L* and the other transitions would appear to be charge-transfer in nature, almost certainly ligand-to-metal, as indicated by their intensities. The transition at 410 nm in **1** is very strong ($\varepsilon = 67{,}000$ dm^3 mol^{-1} cm^{-1}), which causes the complex to be intensely dark blue. It is possible that this band is due to a transition associated with the Mo—S—S—Mo chromophore, implying that there is delocalization within the bridge.[5]

Electrochemical studies

Compound **1** displayed an initial reduction process at -0.073 ± 0.005 V in dichloromethane (platinum electrode, vs SCE). Multiple scans around this wave and scan-rate dependence studies indicated that it was very close to being reversible, so we presume that $[\{Mo(NO)L^*Cl\}_2S_2]^-$ has been formed. Condecon™ electrochemical analysis established that the compound exhibited a fast one-electron addition process with only slight decomposition. Species **1** also revealed additional processes as the voltage was scanned to potentials negative of the initial reduction; viz. two waves close together at around -1.05 ± 0.02v V and a third at *ca* -1.6 ± 0.02 V were detected. These three waves all appeared to be slightly smaller than the initial wave, but were at best only quasi-reversible. In addition, scanning out as far as -1.9 V and then

recycling produced a small product wave with its maximum at +0.2 V. Multiple scans around the first wave at −1.05 V showed that it died away rapidly.

The cyclic voltammogram of **3** showed only one reduction process, perhaps due to the formation of $[\{Mo(NO)L^*S\}_2]^-$, but if the voltage scan was continued well past the wave to negative potentials a small irreversible product was observed on the return sweep, with its maximum at $-0.55+/-0.02$ V. Analysis of the reduction wave using Condecon™ procedures established that the electrode reaction was a fully reversible one-electron process.

X-ray structural studies

Selected geometrical parameters are in Table 1. The structure is illustrated in Fig. 2, which also shows the atomic numbering scheme. The molecule is pseudo-centrosymmetric about the mid-point of the S—S′ bond. The Mo—Mo′ distance is 5.686(2) Å, indicating the absence of any direct interaction between the metal centres.

The coordination about molybdenum is essentially octahedral [maximum angular deviation from ideal octahedral 15.9°, angle S(1)—Mo—N(6) and S(1′)—Mo′—N(6′) both 164.1°, mean deviation 6.4°] and is similar to that found in an analogous bimetallic complex,[3] $[\{Mo(NO)L^*Cl\}_2(\mu\text{-}NC_4H_8N)]$, where the mean angular deviation from octahedral is 5.6°.

The Mo—S and S—S bond lengths, 2.308 (mean) and 2.036(5) Å, respectively, are significantly shorter than the corresponding lengths in the oxo-disulphido molybdate(VI) anion $[\{(S_2)_2MoO\}_2S]_2^{2-}$ of 2.418 and 2.083 Å.[15] This appears to be the only example in the literature of two molybdenum atoms bridged by a single disulphide bridge for which structural parameters have been determined. In $[Fe(\eta^5\text{-}C_5H_4S)_2Mo(NO)L^*]$[16] the Mo—S bond distances are also longer at 2.356(2) and 2.375(2) Å. The bonds to the pyrazolyl rings (2.142–2.215 Å) fall within the range of lengths commonly found in this type of complex. As has been noted previously[3,17] the bond *trans* to the nitrosyl group tends to be long [2.205 Å (mean) in the present structure] due to the *trans* influence of the strongly π-accepting nitrosyl group. The shortest Mo—N(pyrazolyl) bond is *trans* to the chloro substituent. This is also a systematic effect and has been described before.[3,17] The Mo—Cl length, 2.389 Å, is similar to those found in two analogous chloro complexes, 2.408(2)[3] and 2.380(3) Å.[18] The Mo—N(nitrosyl) bond, mean 1.744 Å, is the short-

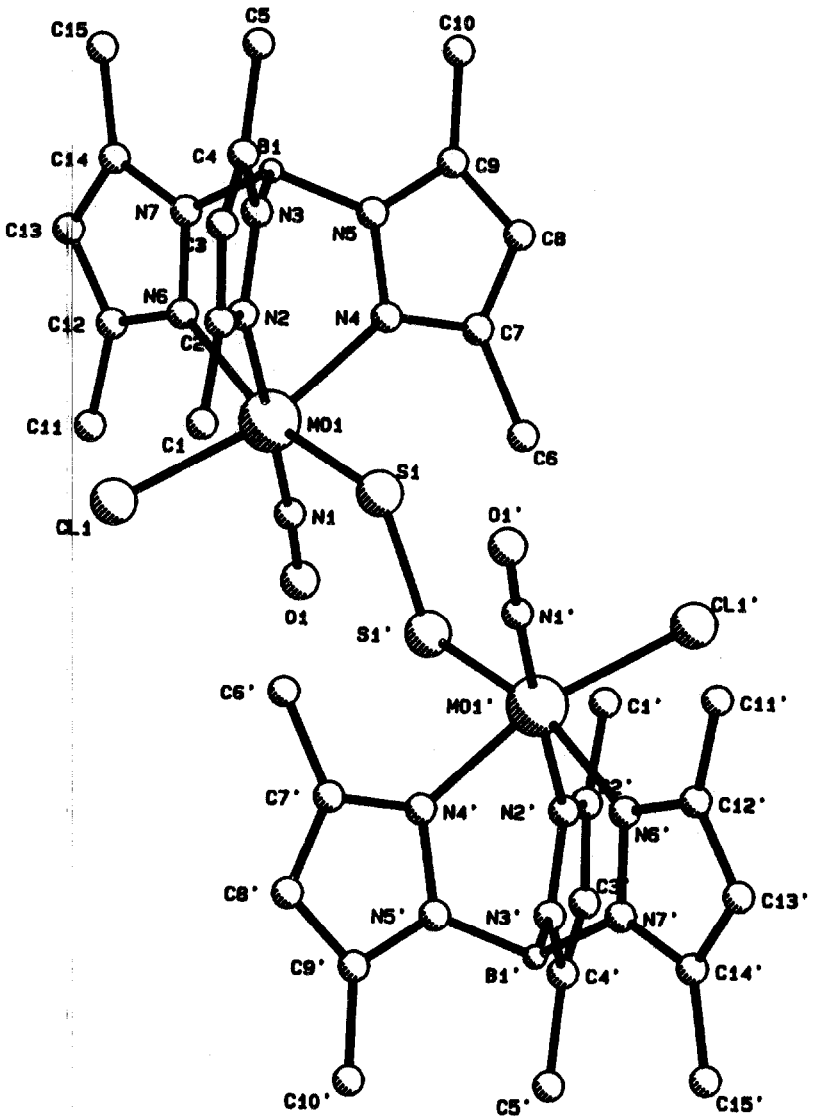

Fig. 2. Structure of [{Mo(NO)L*Cl}(μ-S_2)] (1).

est molybdenum–ligand distance and falls at the lower end of the range (*ca* 1.74–1.80 Å) commonly found[3,17,18] for this bond in complexes containing the $\{Mo(NO)L^*\}^{2+}$ moiety. The slight (mean 4.85°) deviation from linearity of the Mo—N—O grouping is also typical, comparing with deviations ranging from 0.4 to 6.0°, mean 3.0° found in the crystal structures of a number of closely related structures of this type.[16]

Hoffmann has recently described a theoretical investigation into some of the factors effecting bonding in molybdenum sulphur bimetallics.[19] Apparently there are only small energy differences between the various possible bonding alternatives in sulphido bridge molybdenum species and so it is difficult to predict, or even to account for, the structures found in these molecules. Although disulphide links are fairly common in transition metal chemistry,[20] only a few examples of ($\eta^1:\eta^1$-S_2) have been crystallographically characterized, the ($\eta^2:\eta^2$-S_2) bridge being more common. Amongst the examples which have been characterized many contain more than just a single bridge. Examples of other metals bridged by a single S_2 unit include [{Ru$(NH_3)_5$}$_2$(μ-S_2)][21] and [{Co$(CN)_5$}$_2$(μ-S_2)].[22]

(*Received* 13 *August* 1992; *accepted* 20 *August* 1992)

Abstract—The new complexes $[Mo(NO)L(X)(NHC_6H_4CH{=}CHC_6H_4OR\text{-}4,4')]$ ($R = C_6H_{13}$, X = Cl, I, OH; $R = C_8H_{17}$ or $C_{12}H_{25}$ and X = Cl or I) and $[Mo(NO)L(NHC_6H_4CH{=}CHC_6H_4OR\text{-}4,4')_2]$ ($R = C_6H_{13}$, C_8H_{17} or $C_{12}H_{25}$) have been synthesized and characterized by spectroscopic methods. All undergo one-electron reduction processes at potentials ranging from −0.74 to −1.20 V (vs S.C.E.). These new compounds have also been examined by differential scanning calorimetry and polarizing hot-stage microscopy, but do not exhibit any liquid crystalline mesophases.

In recent years a variety of transition metal derivatives has been reported to form liquid crystal phases and there is continuing interest in compounds of this type because of their potential for introducing magnetic, redox and optical properties into liquid crystal materials.[1–5] The molybdenum mononitrosyl derivatives [Mo(NO)L(X)(Y)] [L = hydrotris(3,5-dimethylpyrazol-1-yl)borate, X = Cl, I or Y and Y = phenoxide or arylamide][6] are redox active,[7,8] and can, in certain cases, exhibit non-linear optical properties.[9] In order to discover whether suitably derived complexes of this type might form liquid crystal mesophases, we have previously synthesized derivatives of [Mo(NO)L(X)(Y)] containing anilide or phenolate ligands carrying long-chain alkyl substituents in the 4-position of the aryl ring. Although the alkyl substituents served to reduce the melting points of these complexes, no liquid crystal phases were observed.[10] In a continuation of this study we have used ligands containing alkoxylated stilbenyl groups in an attempt to produce molecules which might give rise to mesophases and which might also, in suitably ordered arrays, exhibit non-linear optical properties. The alkoxystilbenamide ligand was selected since molecules of this structural type are known to form liquid crystals and, when attached to the {Mo(NO)L(X)} moiety, the ferrocenylstilbenamide ligand produces NLO materials. Thus, the new complexes $[Mo(NO)L(X)(NHC_6H_4CH{=}CHC_6H_4OR\text{-}4,4')]$ ($R = C_6H_{13}$, X = Cl, I, OH; $R = C_8H_{17}$ or $C_{12}H_{25}$ and X = Cl or I) and $[Mo(NO)L(NHC_6H_4CH{=}CHC_6H_4OR\text{-}4,4')_2]$ ($R = C_6H_{13}$, C_8H_{17} or $C_{12}H_{25}$) (Fig. 1) have been synthesized and studied by differential scanning calorimetry and polarizing hot-stage microscopy.

EXPERIMENTAL

All reagents were used as supplied. $[Mo(NO)\{HB(3,5\text{-}Me_2C_3N_2H)_3\}I_2]$ and $[Mo(NO)\{HB(3,5\text{-}Me_2C_3N_2H)_3\}Cl_2]$ were prepared according to

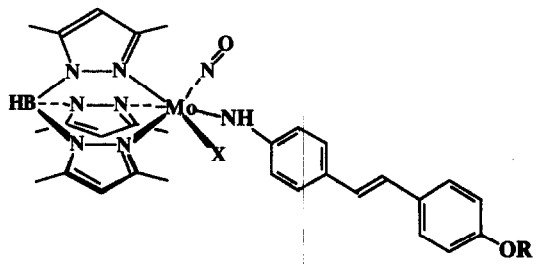

Fig. 1. $[Mo(NO)L(X)(NHC_6H_4CH{=}CHC_6H_4OR)]$ ($R = C_6H_{13}$, C_8H_{17}, $C_{12}H_{25}$; X = Cl, I, $NHC_6H_4CH{=}CHC_6H_4OR$; X = OH, $R = C_6H_{13}$).

previously described methods.[11,12] Solvents used as reaction media were dried according to standard methods and freed of oxygen before use. Silica gel 60 (70–230 mesh) or alumina 90 (70–230 mesh) was used as the stationary phase for column chromatography with column dimensions of 40 × 2 cm unless otherwise specified. Triethylamine was dried over sodium and stored over activated alumina, and hexamine was recrystallized from absolute ethanol and dried under vacuum. Other reagents were used as supplied, and all reaction solvents were redistilled from drying agents according to standard methods prior to use. All reactions were performed under an atmosphere of dry nitrogen but the reaction products were handled in air. Elemental analyses were carried out by the Microanalytical Laboratory, University of Birmingham.

IR spectra were recorded using a PE 297 spectrometer with samples as KBr discs. 270 MHz ^1H NMR spectra were obtained from solutions in $CDCl_3$ using a Jeol GX 270 spectrometer. Cyclic voltammetric measurements were made using a PAR 174A polarograph. Solutions in CH_2Cl_2 were *ca* 10^{-3} mol dm^{-3} in the complex and 0.2 mol dm^{-3} in $[Bu^nN]BF_4$ as the base electrolyte. A platinum bead test electrode was used with a scan rate of 200 mV s^{-1}. An S.C.E. reference electrode was used with ferrocene as an internal standard. Potentials are quoted relative to the S.C.E. and under these conditions E_f for the oxidation of ferrocene was found to be 0.58 V. Differential scanning calorimetry measurements were carried out using a Perkin–Elmer DSC7 instrument with samples (typically 1.4–3 mg) being hermetically sealed in 0.1 cm^3 aluminium pans. In all cases heating and cooling rates of 10 K min^{-1} were used. The microscopy studies were carried out using a CZ Scientific Labpol system equipped with a Link-Am PR600 controller and TH600 hot-stage. Heating rates were 10 K min^{-1} unless otherwise stated.

4-n-*Dodecyloxy-4′-nitrostilbene* (**1**)

A solution of 4-n-dodecyloxybenzaldehyde (4.0 g, 13.8 mmol), 4-nitrophenylacetic acid (2.74 g, 15.1 mmol) and piperidine (10 cm^3) was stirred under reflux in pyridine (50 cm^3) for 22 h. The mixture was cooled and the solvent removed under reduced pressure. The bright yellow product was purified by two recrystallizations from ethanol to yield bright yellow crystals of 4-n-dodecyloxy-4′-nitrostilbene (0.90 g, 16%).

$C_{12}H_{25}OC_6H_4CH{=}CHC_6H_4{-}NO_2$, m.p. 95–113°C. Found: C, 76.5; H, 8.5; N, 3.4. Calc. for $C_{26}H_{35}NO_3$: C, 76.3; H, 8.6; N, 3.4%. $\nu_{max}(NO_2)$: 1500s and 1330s cm^{-1}. $\delta_H(CDCl_3)$: 8.19 and 7.58 [2H, d, J(HH) = 8.8 Hz; 2H, d, J(HH) = 8.8 Hz, $C_6H_4{-}NO_2$], 7.48 and 6.91 [2H, d, J(HH) = 8.8 Hz; 2H, d, J(HH) = 8.8 Hz, $C_6H_4{-}OC_{12}H_{25}$], 7.22 and 6.99 [1H, d, $J(HH)_{trans}$ = 16.3 Hz; 1H, d, $J(HH)_{trans}$ = 16.3 Hz, $CH = CH$], 3.98 [2H, t, J(HH) = 6.6 Hz, $OCH_2{-}C_{11}H_{23}$], 1.80 [2H, qn, $OCH_2{-}CH_2{-}C_{10}H_{21}$], 1.46 [2H, qn, $OCH_2CH_2{-}CH_2{-}C_9H_{19}$], 1.27 [16H, br s, $OC_3H_6{-}C_8H_{16}{-}CH_3$], 0.88 [3H, t, J(HH) = 7.0 Hz, CH_3].

4-n-*Hexyloxy-4′-nitrostilbene* (**2**)

This compound was prepared in an identical manner to **1** using 4-n-hexyloxybenzaldehyde (2.85 g, 13.8 mmol) in place of 4-n-dodecyloxybenzaldehyde. Recrystallization afforded bright yellow crystals of 4-n-hexyloxy-4′-nitrostilbene (0.85 g, 19%).

$C_6H_{13}OC_6H_4CH{=}CHC_6H_4{-}NO_2$, m.p. 99–106°C. Found: C, 73.8; H, 7.0; N, 4.6. Calc. for $C_{20}H_{23}NO_3$: C, 73.8; H, 7.1; N, 4.3%. $\nu_{max}(NO_2)$: 1500s and 1330s cm^{-1}. $\delta_H(CDCl_3)$:* 8.19 and 7.58 [2H, d, J(HH) = 8.8 Hz; 2H, d, J(HH) = 8.8 Hz, $C_6H_4{-}NO_2$], 7.48 and 6.91 [2H, d, J(HH) = 8.8 Hz; 2H, d, J(HH) = 8.8 Hz, $C_6H_4{-}OC_6H_{13}$], 7.22 and 6.99 [1H, d, $J(HH)_{trans}$ = 16.3 Hz; 1H, d, $J(HH)_{trans}$ = 16.3 Hz, $CH = CH$], 3.99 [2H, t, J(HH) = 6.6 Hz, $OCH_2{-}C_5H_{11}$], 1.80 [2H, qn, $OCH_2{-}CH_2{-}C_4H_9$], 1.47 [2H, qn, $OCH_2CH_2{-}CH_2{-}C_3H_7$], 1.37–1.31 [4H, c m, $OC_3H_6{-}C_2H_4{-}CH_3$], 0.91 [3H, t, J(HH) = 7.0 Hz, CH_3].

4-n-*Octyloxy-4′-nitrostilbene* (**3**)

This compound was prepared in an identical manner to **1** using 4-n-octyloxybenzaldehyde (3.23 g, 13.8 mmol) in place of 4-n-dodecyloxybenzaldehyde. Recrystallization afforded bright yellow

* Relative area and multiplicity given in parentheses; s = singlet, d = doublet, t = triplet, m = multiplet with unresolved coupling, b = broad.

needles of 4-n-octyloxy-4′-nitrostilbene (0.98 g, 20%).

$C_8H_{17}OC_6H_4CH{=}CHC_6H_4{-}NO_2$, m.p. 95–109°C. Found: C, 75.1; H, 7.7; N, 4.0. Calc. for $C_{22}H_{27}NO_3$: C, 74.8; H, 7.7; N, 4.0%. $\nu_{max}(NO_2)$: 1500s and 1330s cm^{-1}. $\delta_H(CDCl_3)$: 8.19 and 7.58 [2H, d, J(HH) = 8.8 Hz; 2H, d, J(HH) = 8.8 Hz, $C_6H_4{-}NO_2$], 7.48 and 6.91 [2H, d, J(HH) = 8.8 Hz; 2H, d, J(HH) = 8.8 Hz, $C_6H_4{-}OC_8H_{17}$], 7.22 and 6.99 [1H, d, $J(HH)_{trans}$ = 16.3 Hz; 1H, d, $J(HH)_{trans}$ = 16.3 Hz, $CH = CH$], 3.98 [2H, t, J(HH) = 6.6 Hz, $OCH_2{-}C_7H_{15}$], 1.80 [2H, qn, $OCH_2{-}CH_2{-}C_6H_{13}$], 1.46 [2H, qn, $OCH_2CH_2{-}CH_2{-}C_5H_{11}$], 1.40–1.20 [8H, br m, $OC_3H_6{-}C_4H_8{-}CH_3$], 0.89 [3H, t, J(HH) = 7.0 Hz, CH_3].

4-n-*Hexyloxy-4′-stilbenamine* (**4**)

A solution of **2** (1.1 g, 3.38 mmol) and ammonium chloride (1.1 g, 20.56 mmol) in acetone (100 cm^3) and water (20 cm^3) was heated to reflux. Zinc powder (1.0 g, 15.30 mmol) was added and the mixture stirred under reflux for 1 h. Further ammonium chloride (0.5 g) and zinc powder (0.5 g) were added and the mixture was stirred under reflux for a further 4 h. The colour of the solution changed from yellow to almost colourless during this time. The reaction mixture was cooled and the zinc powder removed by filtration. The acetone was removed *in vacuo* and water (50 cm^3) and dichloromethane (50 cm^3) were added. The pale yellow–orange organic layer was separated and the aqueous layer extracted with further dichloromethane (3 × 20 cm^3). The combined organic extracts were evaporated to yield 4-n-hexyloxy-4′-stilbenamine as a beige powder (0.89 g, 89%).

$C_6H_{13}OC_6H_4CH{=}CHC_6H_4{-}NH_2$. Found: C, 78.7; H, 8.2; N, 4.8. Calc. for $C_{20}H_{25}NO{\cdot}0.13CH_2Cl_2$: C, 78.9; H, 8.3; N, 4.6%. $\nu_{max}(NH_2)$: 3380s and 3315s cm^{-1}. $\delta_H(CDCl_3)$: 7.39 and 6.86 [2H, d, J(HH) = 8.8 Hz; 2H, d, J(HH) = 8.8 Hz, $C_6H_4{-}NH_2$], 7.30 and 6.66 [2H, d, J(HH) = 8.6 Hz; 2H, d, J(HH) = 8.6 Hz, $C_6H_4{-}OC_6H_{13}$], 6.87 [2H, s, $CH{=}CH$], 3.96 [2H, t, J(HH) = 6.6 Hz; $OCH_2{-}C_5H_{11}$], 3.72 [2H, vbr, s, NH_2], 1.78 [2H, qn, $OCH_2{-}CH_2{-}C_4H_9$], 1.45 [2H, qn, $OCH_2CH_2{-}CH_2{-}C_3H_7$], 1.37–1.31 [4H, c m, $OC_3H_6{-}C_2H_4{-}CH_3$], 0.91 [3H, t, J(HH) = 7.0 Hz, CH_3].

4-n-*Octyloxy-4′-stilbenamine* (**5**)

This compound was prepared in an identical manner to **4** using **3** (1.19 g, 3.38 mmol) in place of **2**. Due to lower solubility the reaction was allowed to proceed for a total reflux time of 22 h. This afforded 4-n-octyloxy-4′-stilbenamine as a beige powder (0.69 g, 63%).

$C_8H_{17}OC_6H_4CH{=}CHC_6H_4{-}NH_2$. Found: C, 80.5; H, 8.8; N, 4.5. Calc. for $C_{22}H_{29}NO{\cdot}0.06CH_2Cl_2$: C, 80.6; H, 8.9; N, 4.3%. $\nu_{max}(NH_2)$: 3380s and 3315s cm^{-1}. $\delta_H(CDCl_3)$: 7.39 and 6.86 [2H, d, J(HH) = 8.8 Hz; 2H, d, J(HH) = 8.8 Hz, $C_6H_4{-}NH_2$], 7.30 and 6.66 [2H, d, J(HH) = 8.6 Hz; 2H, d, J(HH) = 8.6 Hz, $C_6H_4{-}OC_8H_{17}$], 6.87 [2H, s, $CH{=}CH$], 3.96 [2H, t, J(HH) = 6.6 Hz; $OCH_2{-}C_7H_{15}$], 3.72 [2H, vbr, s, NH_2], 1.78 [2H, qn, $OCH_2{-}CH_2{-}C_6H_{13}$], 1.45 [2H, qn, $OCH_2CH_2{-}CH_2{-}C_5H_{11}$], 1.40–1.25 [4H, br m, $OC_3H_6{-}C_4H_8{-}CH_3$], 0.89 [3H, t, J(HH) = 7.0 Hz, CH_3].

4-n-*Dodecyloxy-4′-stilbenamine* (**6**)

This compound was prepared in an identical manner to **4** using **1** (1.38 g, 3.38 mmol) in place of **2**. Due to lower solubility the reaction was allowed to proceed for a total reflux time of 22 h. This afforded 4-n-dodecyloxy-4′-stilbenamine as a beige powder (0.62 g, 48%).

$C_{12}H_{25}OC_6H_4CH{=}CHC_6H_4{-}NH_2$. Found: C, 80.6; H, 9.5; N, 3.0. Calc. for $C_{26}H_{37}NO{\cdot}0.11CH_2Cl_2$: C, 80.6; H, 9.6; N, 3.6%. $\nu_{max}(NH_2)$: 3380s and 3315s cm^{-1}. $\delta_H(CDCl_3)$: 7.39 and 6.86 [2H, d, J(HH) = 8.8 Hz; 2H, d, J(HH) = 8.8 Hz, $C_6H_4{-}NH_2$], 7.30 and 6.66 [2H, d, J(HH) = 8.6 Hz; 2H, d, J(HH) = 8.6 Hz, $C_6H_4{-}OC_8H_{17}$], 6.87 [2H, s, $CH{=}CH$], 3.96 [2H, t, J(HH) = 6.6 Hz; $OCH_2{-}C_{11}H_{23}$], 3.72 [2H, vbr, s, NH_2], 1.78 [2H, qn, $OCH_2{-}CH_2{-}C_6H_{13}$], 1.45 [2H, qn, $OCH_2CH_2{-}CH_2{-}C_9H_{19}$], 1.26 [16H, br s, $OC_3H_6{-}C_8H_{16}{-}CH_3$], 0.88 [3H, t, J(HH) = 7.0 Hz, CH_3].

$[Mo(NO)\{HB(3,5\text{-}Me_2C_3N_2H)_3\}Cl(HNC_6H_4CH{=}CHC_6H_4OC_6H_{13})]$ (**7**)

A solution of $Mo(NO)LCl_2$ (0.30 g, 0.61 mmol), 4-hexyloxy-4′-stilbenamine (**4**) (0.22 g, 0.74 mmol) and triethylamine (0.5 cm^3) was stirred under reflux in toluene (20 cm^3) for 2 h. The reaction mixture was cooled and evaporated to dryness under reduced pressure. The resulting solid was purified by column chromatography on silica using 60% dichloromethane/n-hexane as an eluant. The major violet band was collected and the product it contained was recrystallized from dichloromethane/n-hexane to give a deep violet solid (0.32 g, 70%). Found: C, 53.6; H, 6.0; N, 14.5; M^+, 754. Calc. for $C_{35}H_{46}BClMoN_8O_2{\cdot}0.5CH_2Cl_2$: C, 53.6; H, 6.0; N, 14.1%; M, 753. $\nu_{max}(NH)$: 3270w; $\nu_{max}(NO)$: 1655 cm^{-1}. $\delta_H(CDCl_3)$: 12.60 [1H, s, NH], 7.54 and 7.45 [2H, d, J(HH) = 8.7 Hz; 2H, d,

[Mo(NO){HB(3,5-$Me_2C_3N_2H$)$_3$}I(HNC_6H_4CH=$CHC_6H_4OC_6H_{13}$)] (**8**)

This compound was prepared in an identical manner to **7** using [Mo(NO){HB(3,5-$Me_2C_3N_2$ H)$_3$}(I)$_2$]·C_7H_8 (0.40 g, 0.52 mmol) in place of [Mo(NO){HB(3,5-$Me_2C_3N_2H$)$_3$}(Cl)$_2$] and 4-n-hexyloxy-4′-stilbenamine (**4**) (0.20 g, 0.68 mmol). A deep violet solid was obtained (0.33 g, 75%). Found: C, 47.8; H, 5.5; N, 13.5; M^+, 846. Calc. for $C_{35}H_{46}BIMoN_8O_2$·0.5CH_2Cl_2: C, 48.1; H, 5.3; N, 12.6%; M, 844. ν_{max}(NH): 3275w; ν_{max}(NO): 1655 cm^{-1}. δ_H($CDCl_3$): 13.06 [1H, s, NH], 7.61 and 7.46 [2H, d, J(HH) = 8.7 Hz; 2H, d, J(HH) = 8.7 Hz, C_6H_4—OC_6H_{13}], 7.49 and 6.89 [2H, d, J(HH) = 8.7 Hz; 2H, d, J(HH) = 8.7 Hz, C_6H_4—NHMo], 7.18 and 6.94 [1H, d, $J(HH)_{trans}$ = 16.1 Hz; 1H, d, $J(HH)_{trans}$ = 16.1 Hz, CH=CH], 5.93, 5.86 and 5.77 [1H, s; 1H, s; 1H, s, $(Me_2C_3N_2H)_3$], 3.98 [2H, t, J(HH) = 6.7 Hz, C_6H_4—OCH_2—C_5H_{11}], 2.72, 2.48, 2.46, 2.38, 2.37 and 2.00 [3H, s; 3H, s; 3H, s; 3H, s; 3H, s; 3H, s, $(Me_2C_3N_2H)_3$], 1.80 [2H, qn, $C_6H_4OCH_2$—CH_2—C_4H_9], 1.47 [2H, qn, $C_6H_4OC_2H_4$—CH_2—C_3H_7], 1.40–1.30 [4H, c m, OC_3H_6—C_2H_4—CH_3], 0.91 [3H, t, J(HH) = 6.9 Hz, CH_3]. m/z 846 (M^+), 719 (M−125), 295 ($H_2NC_6H_4CH$=$CHC_6H_4OC_6H_{13}$), 211 ($H_2NC_6H_4CH$=CHC_6H_4OH), 128 (I). E_f = −0.78 V, ΔE_p = 125 mV, ΔE_p(Fc) = 100 mV.

[Mo(NO){HB(3,5-$Me_2C_3N_2H$)$_3$}(HNC_6H_4CH=$CHC_6H_4OC_6H_{13}$)$_2$] (**9**)

Sodium (0.1 g, 4.35 mmol) was heated under reflux in dry THF (35 cm^3) for 30 min. Naphthalene (0.1 g, 0.78 mmol) was then added and the mixture stirred for 1 h under reflux, during which time the solution became dark green. The mixture was filtered under dinitrogen to remove excess sodium and 4-n-hexyloxy-4′-stilbenamine (**4**) (0.06 g, 0.20 mmol) was added to the filtrate. After stirring the resulting solution for 30 min at room temperature **8** (0.11 g, 0.13 mmol) was added and the mixture stirred under reflux for a further 2 h. The resulting mixture was cooled and filtered in air and the solvent removed by evaporation under reduced pressure. The crude product was purified by column chromatography on alumina 90 using 40% n-hexane/dichloromethane. This afforded a deep emerald green solid (0.11 g, 84%). Found: C, 63.4; H, 6.9; N, 11.4; M^+, 1013. Calc. for $C_{55}H_{70}BMo$ N_9O_3·0.5CH_2Cl_2: C, 63.2; H, 6.8; N, 12.0%; M, 1012. ν_{max}(NH): 3300m; ν_{max}(NO): 1635 cm^{-1}. δ_H($CDCl_3$): 8.90 [2H, s, 2×NH], 7.40 and 7.27 [4H, d, J(HH) = 8.7 Hz; 4H, d, J(HH) = 8.7 Hz, 2×C_6H_4—OC_6H_{13}], 7.40 and 6.87 [4H, d, J(HH) = 8.7 Hz; 4H, d, J(HH) = 8.7 Hz, 2×C_6H_4—NHMo], 6.93 [4H, s, 2×CH=CH], 5.96 and 5.75 [1H, s; 2H, s, $(Me_2C_3N_2H)_3$], 3.97 [4H, t, J(HH) = 6.6 Hz, 2×C_6H_4—OCH_2—C_5 H_{11}], 2.47, 2.35 and 2.27 [3H, s; 9H, s; 6H, s, $(Me_2C_3N_2H)_3$], 1.78 [4H, qn, 2×$C_6H_4OCH_2$—CH_2—C_4H_9], 1.46 [4H, qn, 2×$C_6H_4OC_2H_4$—CH_2—C_3H_7], 1.40–1.30 [8H, c m, 2×OC_3H_6—C_2H_4—CH_3], 0.91 [6H, t, J(HH) = 6.9 Hz, 2×CH_3]. m/z 1013 (M^+), 989 (M−23), 982 (M−NO), 927 (M−C_6H_{13}), 911 (M−OC_6H_{13}), 295 ($H_2NC_6H_4CH$=$CHC_6H_4OC_6H_{13}$), 211 (H_2NC_6 H_4CH=CHC_6H_4OH). [Mo(NO){HB(3,5-$Me_2C_3N_2H$)$_3$}I(HNC$_6$H$_4$CH=CHC$_6$H$_4$OC$_{12}$H$_{25}$)] (**15**)

This compound was prepared in an identical manner to **14** using [Mo(NO){HB(3,5-$Me_2C_3N_2H$)$_3$}(I)$_2$]·C_7H_8 (0.40 g, 0.52 mmol) and 4-n-dodecyloxy-4′-stilbenamine (**6**) (0.26 g, 0.68 mmol). A deep violet solid was obtained (0.36 g, 75%). Found: C, 50.2; H, 6.0; N, 11.8; M^+, 930. Calc. for $C_{41}H_{58}BIMoN_8O_2 \cdot 0.8CH_2Cl_2$: C, 50.4; H, 6.0; N, 11.2%; M, 929. ν_{max}(NH): 3275w; ν_{max}(NO): 1655 cm^{-1}. δ_H($CDCl_3$): 13.06 [1H, s, N*H*], 7.61 and 7.46 [2H, d, J(HH) = 8.7 Hz; 2H, d, J(HH) = 8.7 Hz, C_6H_4—$OC_{12}H_{25}$], 7.49 and 6.89 [2H, d, J(HH) = 8.7 Hz; 2H, d, J(HH) = 8.7 Hz, C_6H_4—NHMo], 7.18 and 6.94 [1H, d, $J(HH)_{trans}$ = 16.1 Hz; 1H, d, $J(HH)_{trans}$ = 16.1 Hz, C*H*=C*H*], 5.93, 5.86 and 5.77 [1H, s; 1H, s; 1H, s, $(Me_2C_3N_2H)_3$], 3.98 [2H, t, J(HH) = 6.7 Hz, C_6H_4—OCH_2—$C_{11}H_{23}$], 2.72, 2.48, 2.46, 2.38, 2.37 and 2.00 [3H, s; 3H, s; 3H, s; 3H, s; 3H, s; 3H, s, $(Me_2C_3N_2H)_3$], 1.80 [2H, qn, $C_6H_4OCH_2$—CH_2—$C_{10}H_{21}$], 1.47 [2H, qn, $C_6H_4OC_2H_4$—CH_2—C_9H_{19}], 1.40–1.30 [16H, c m, OC_3H_6—C_8H_{16}—CH_3], 0.88 [3H, t, J(HH) = 6.9 Hz, CH_3]. *m/z* 930 (M^+), 803 (M−125), 379 ($H_2NC_6H_4CH$=$CHC_6H_4OC_{12}H_{25}$), 211 ($H_2NC_6H_4CH$=CHC_6H_4OH), 128 (I). E_f = −0.74 V, ΔE_p = 110 mV, ΔE_p(Fc) = 95 mV.

[Mo(NO){HB(3,5-$Me_2C_3N_2H$)$_3$}(HNC$_6$H$_4$CH=CHC$_6$H$_4$OC$_{12}$H$_{25}$)$_2$] (**16**)

This compound was prepared in an identical manner to **9** using **15** (0.12 g, 0.13 mmol) and 4-n-dodecyloxy-4′-stilbenamine (**6**) (0.075 g, 0.20 mmol). Upon the addition of **15** the solution was stirred at reflux for 2 h, and cooled before filtration. The product was purified by column chromatography on alumina 90 using 40% n-hexane in dichloromethane. This afforded a deep emerald green solid (0.070 g, 46%). Found: C, 68.1; H, 8.4; N, 9.4. Calc. for $C_{67}H_{94}BMoN_9O_3$: C, 68.2; H, 8.0; N, 10.7%; M, 1180. ν_{max}(NH): 3300m; ν_{max}(NO): 1635 cm^{-1}. δ_H($CDCl_3$): 8.90 [2H, s, 2×N*H*], 7.40 and 7.27 [4H, d, J(HH) = 8.7 Hz; 4H, d, J(HH) = 8.7 Hz, 2×C_6H_4—$OC_{12}H_{25}$], 7.40 and 6.87 [4H, d, J(HH) = 8.7 Hz; 4H, d, J(HH) = 8.7 Hz, 2×C_6H_4—NHMo], 6.93 [4H, s, 2×C*H*=C*H*], 5.96 and 5.75 [1H, s; 2H, s, $(Me_2C_3N_2H)_3$], 3.97 [4H, t, J(HH) = 6.6 Hz, 2×C_6H_4—OCH_2—$C_{11}H_{23}$], 2.47, 2.35 and 2.27 [3H, s; 9H, s; 6H, s, $(MeC_3N_2H)_3$], 1.78 [4H, qn, 2×$C_6H_4OCH_2$—CH_2—$C_{10}H_{21}$], 1.46 [4H, qn, 2×$C_6H_4OC_2H_4$—CH_2—C_9H_{19}], 1.40–1.30 [32H, c m, 2×OC_3H_6—C_8H_{16}—CH_3], 0.88 [6H, t, J(HH) = 6.9 Hz, 2×CH_3]. *m/z* 1037 (M−NO−C_8H_{17}), 990, 925 (M−$OC_{12}H_{25}$−C_5H_{11}), 895 (M−$OC_{12}H_{25}$−C_5H_{11}−NO), 379 ($H_2NC_6H_4CH$=$CHC_6H_4OC_{12}H_{25}$), 211 ($H_2NC_6H_4CH$=CHC_6H_4OH). E_f = −1.20 V, ΔE_p = 230 mV, ΔE_p(Fc) = 100 mV.

DISCUSSION

Synthetic studies

The new complexes were synthesized according to previously established procedures.[6,13] In the formation of the monoarylamide complexes triethylamine was used to consume the HI or HCl liberated in the halide substitution reactions. In forming the bis-arylamide derivative more forcing conditions involving sodium naphthalenide were used to substitute the remaining iodide in [Mo(NO)LI(NHC$_6$H$_4$CH=CHC$_6$H$_4$OR)].[13]

All the new complexes exhibit ν(BH) at *ca* 2550 cm^{-1} in their IR spectra. In addition, the chloro-monostilbenamide complexes exhibit ν(NH)

at 3270 cm^{-1}, whilst in their iodo containing counterparts this band appears at 3275 cm^{-1} and in [Mo(NO)L(OH)I($NHC_6H_4CH{=}CHC_6H_4OC_6H_{13}$)] it appears at 330 cm^{-1}. The spectra also contain ν(NO) at 1635 cm^{-1} in the cases of the halide complexes and 1640 cm^{-1} in the case of the hydroxy complex. The IR spectra of the bis-stilbenamide complexes contain ν(NH) at 3300 cm^{-1} and ν(NO) at 1635 cm^{-1} in accord with their formulations.[6]

The ^{1}H NMR spectra of the new complexes contain signals from the three pyrazolyl-4-H and six methyl groups in the ligand L, which are indicative of the molecular symmetry. In the absence of overlap nine resonances with the area ratios 1 : 1 : 1 : 3 : 3 : 3 : 3 : 3 : 3 should be present for mono-substituted derivatives, whilst the bis-substituted derivatives should exhibit signals with the area 1 : 2 : 3 : 3 : 6 : 6. The area ratios observed for the new complexes are in all cases in accord with their formulations. The complexes also exhibit signals attributable to the presence of the aryl and alkyl groups in the stilbenamide ligand, which have the appropriate relative areas for mono- or bis-substituted complexes according to their formulations. The ^{1}H NMR spectra of the chloro-mono-stilbenamide complexes contain a broad signal at 12.60 ppm due to the amide proton, whilst in their iodo and hydroxy substituted counterparts this signal appears at 13.06 and 10.46 ppm, respectively. In the bis-stilbenamide complexes this signal appears at 8.90 pm.

Electrochemical studies

The electrochemical properties of the new complexes have been determined by cyclic voltammetry and are in accord with expectations. Previous work has shown that the reduction potentials of the complexes Mo(NO)LXY are highly sensitive to the nature of X and Y. Thus, for X = halide and Y = arylamide a reduction potential of *ca* −0.8 V might be expected, compared to the value *ca* −1.2 V for the bis-arylamide complexes.[7] The ΔE_p values are significantly larger than those of ferrocene, particularly in the case of the bis-stilbenamide complexes, and indicative of kinetically-controlled electron transfer. However, on the cyclic voltammetry time-scale the processes appear to be chemically reversible.

Thermal studies

The nitrostilbene precursors to the stilbenamine ligands used were investigated under the polarizing microscope and the occurrence of extensive fluid birefringence, characteristic of liquid crystalline phases, was observed in all three. Both of the previously reported hexyloxy (**2**) and octyloxy (**3**) derivatives melted at *ca* 100°C and the new dodecyloxy derivative (**4**) at about 80°C. Since their mesogenic properties have already been reported elsewhere,[14] **2** and **3** will not be discussed here. The thermal behaviour of 4-dodecyloxy-4′-nitrostilbene (**1**) has not been described previously and is discussed here; a DSC trace for this compound is shown in Fig. 2.

Under the microscope a crystal-to-fluid transition was observed at about 85°C and the birefringent texture of a smectic A phase was seen until clearing occurred at about 115°C. A DSC study gave more precise evidence for these transitions. On heating at 10 K min^{-1} a minor endo-

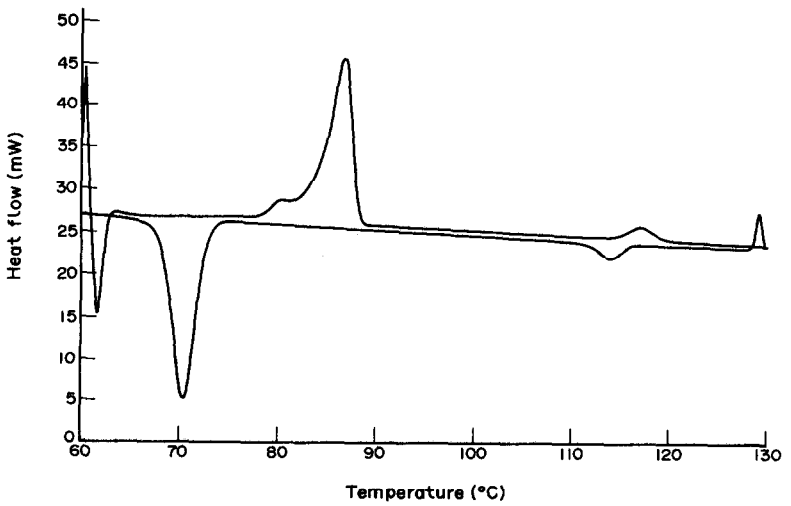

Fig. 2. The DSC trace for 4-dodecyloxy-4′-nitrostilbene. T1 = 77.2°C, T2 = 91.3°C, peak at 86.8°C, area = 406.1 mJ, ΔH = 108.0 J g^{-1}, height = 19.53 mW, onset = 83.5°C.

thermic event peaking at 80.0°C was found before a major event with T_{ON} = 83.5°C (for both events combined ΔH = 108.0 J g^{-1}). The main peak represents the K–S_A (crystal to smectic) transition, but the origin of the small pre-peak is unclear. A second endothermic event corresponding to the S_A–I (smectic to isotropic liquid) transition was detected with T_{ON} = 114.5°C (ΔH = 7.9 J g^{-1}). Upon cooling from 130°C at 10 K min^{-1} both of these events proved to be fully reversible with exothermic events at T_{ON} = 116.1°C (ΔH = −8.0 J g^{-1}) and at T_{ON} = 72.7°C (ΔH = −101.5 J g^{-1}).

The three stilbenamine ligands **4**, **5** and **6** were also investigated. These showed ill-defined behaviour, all melting at *ca* 120°C with no evidence for liquid crystalline phases. This is perhaps unsurprising as terminal amino groups are not generally thought of as desirable for the stabilization of mesophases. The vast majority of known thermotropic organic compounds possess terminal cyano, halo, nitro, alkoxy or alkyl groups,[15] and the absence of mesogenic behaviour in these amines may well reflect the presence of opportunities for hydrogen bonding between the amino hydrogens and the oxygen of the alkoxy function.

DSC and microscopy studies on the new stilbenamide and complexes were carried out, but none revealed signs of any liquid crystalline behaviour. Indeed, under the microscope these compounds were observed to melt over very broad ranges, 10–20°C, and many DSC traces failed to show any detectable events whatsoever. Their extremely strong visible absorptions render even very thin layers highly coloured, and the crystalline samples appeared almost black without the analyser in place. Generally high melting points were observed under the microscope as shown in Table 1. For the octyloxy and dodecyloxy derivatives the iodide complexes melt at considerably lower temperatures than their chloride analogues with the longest chain species having the lowest melting points. However, the hexyloxy/chloride derivative **7** has a far lower melting point than its iodo analogue **8** and than its longer chain homologues **11** and **14**, providing a curious exception to the trends found for other types of complex. The hydroxide derivative **10** is also high melting, with apparent decomposition at 190°C. No evidence for liquid crystalline behaviour was observed in any of these compounds.

The bis-substituted stilbenamide complexes also showed reduced melting points, which were found to decrease with increasing chain length as shown in Table 1. The bis(dodecyloxystilbenamide) complex **16** represents the only compound other than $[Mo(NO)L(OC_6H_4CO_2C_{12}H_{25})_2]$[10] which melts significantly below 100°C. However, these compounds did not show any birefringence under the microscope and DSC study failed to show any features in heating or cooling modes so that again there was no evidence for any liquid crystalline behaviour.

Table 1. Approximate melting points for the stilbenamide complexes $[Mo(NO)L(X)(HNC_6H_4CH{=}CHC_6H_4OC_nH_{2n+1})]$ and $[Mo(NO)L(HNC_6H_4CH{=}CHC_6H_4OC_nH_{2n+1})_2]$

FIRST ELECTROSYNTHESIS OF TRANSITION METAL PEROXO COMPLEXES. SYNTHESIS, CHARACTERIZATION AND REACTIVITY OF MOLYBDENUM AND TUNGSTEN HETEROLIGAND PEROXO COMPLEXES

M. C. CHAKRAVORTI,* SOMENATH GANGULY and MANISH BHATTACHARJEE

Department of Chemistry, Indian Institute of Technology, Kharagpur 721 302, India

(*Received* 26 *May* 1992; *accepted* 3 *September* 1992)

Abstract—Molecular peroxo complexes of molybdenum and tungsten, viz. $[MO(O_2)_2L]$ (M = Mo or W; L = 2,2′-bipyridine, 1,10-phenanthroline or 2,2′-bipyridine-N,N′-dioxide), have been synthesized electrochemically using a sacrificial molybdenum or tungsten anode in the presence of hydrogen peroxide and then precipitating with the corresponding heteroligands. These complexes have also been prepared by the dissolution of metal powders in hydrogen peroxide. They have been characterized by elemental analysis and vibrational spectra. The complexes oxidize triphenylphosphine and triphenylarsine to triphenylphosphine oxide and triphenylarsine oxide, respectively.

Transition metal peroxo compounds play a central role in catalytic and biological oxidation reactions and have generated considerable interest among chemists in recent years.[1–5] The existing methods for the synthesis of peroxo complexes are the reactions between the oxides or oxoanions of the metal with hydrogen peroxide, or the interaction of dioxygen with metal complexes.[6] Until now, there have been no reports on the synthesis of the peroxo complexes by electrochemical or chemical methods starting directly from metals, except for a recent report[7] on the preparation of an ill-characterized peroxopolytungstic acid by the dissolution of tungsten powder in hydrogen peroxide. Electrochemical synthesis provides an easy and direct route to the synthesis of highly pure complexes, starting from sacrificial metal anodes.[8–11] It was thought worthwhile to develop a simple electrosynthetic route for peroxo complexes. A few heteroligand peroxo complexes of molybdenum and tungsten of the type $[MO(O_2)_2L_1L_2]$ and $[MO(O_2)_2L_2]$ have been reported and crystal structures of $[MoO(O_2)_2(HMPA)(H_2O)]$,[12] $[MoO(O_2)_2(bipy)]$,[13] $[MoO(O_2)_2(phen)]$[14] and $[MoO(O_2)_2(glycine)(H_2O)]$[15] have been determined. This paper deals with the first electrosynthesis of molybdenum and tungsten heteroligand peroxo complexes of the type $[MO(O_2)_2L]$ (M = Mo or W; L = 2,2′-bipyridine, 1,10-phenanthroline and 2,2′-bipyridine-N,N′-dioxide). The paper also reports the direct chemical synthesis of these complexes from metal powders. The oxidizing capability of the aforesaid complexes is also determined.

EXPERIMENTAL

Specpure molybdenum and tungsten rods (0.5 cm diameter) were supplied by Johnson Matthey Chemicals Ltd, U.K. Molybdenum powder (4–8 μ), supplied by Koch–Light Laboratories Ltd, U.K., was 99.95% pure. Tungsten powder, supplied by Johnsons of Hendon Ltd, U.K., was 99.0% pure. Other chemicals were of AR/GR quality from reputable manufacturers. The salts $(pyH)_2[Mo_2O_3(O_2)_4(H_2O)_2]$ and $K_2[W_2O_3(O_2)_4(H_2O)_2]\cdot 2H_2O$ were prepared by literature methods.[16,17]

The electric power was supplied by a d.c. power supply (Aplab, India). The electrolytic cell was a tall form beaker (100 cm^3) fitted with a rubber stopper through which two holes were made. The appropriate metal rods which formed the anode

* Author to whom correspondence should be addressed.

were inserted through a hole. In both cases a platinum foil (1 × 1 × 0.15 cm) connected to a platinum wire served as the cathode and was introduced through the second hole.

Peroxide was analysed iodometrically by stirring the aqueous suspensions of the compounds by a magnetic stirrer. Metals were analysed by standard gravimetric methods. Nitrogen was determined by micro Dumas' method. IR spectra were recorded in KBr pellets using a Perkin–Elmer spectrophotometer (No. 883). The laser Raman spectra were recorded on a SPEX Ramalog model 1403 spectrophotometer. The 5145 Å laser line from a Spectra-Physics model 165 argon laser was used as the excitation source. The scattered light at 90° was detected with the help of a cooled RCA 31034 photomultiplier tube, followed by a photon count processing system. The spectra were recorded at ambient temperatures by making pressed pellets of the compounds. Molar conductance was measured using a direct reading conductivity (Systronics, India). Magnetic susceptibility was measured by the Gouy method.

Preparation of the complexes $[MO(O_2)_2L]$ (M = Mo *or* W; L = 2,2′-*bipyridine*; 1,10-*phenanthroline*; 2,2′-*bipyridine-N,N′-dioxide*)

Method A. Hydrogen peroxide (30%, 15 cm^3) was taken in a beaker. The molybdenum or tungsten rod and the platinum foil each connected to platinum wire were dipped in it and connected to the positive and negative terminal of the d.c. power supply, respectively. Electrolysis was carried out at an applied voltage of 15 V for 4 h. Initially the current was very small, but it slowly increased from 0.02 to 0.1 A. The temperature of the reaction medium was maintained at 0–5°C throughout the electrolysis. Gradually, the solution became yellow in the case of molybdenum, while with tungsten the solution remained colourless. After electrolysis, the solution was filtered to remove any disintegrated metal particles. The amount of metal lost was calculated and the ligands 2,2′-bipyridine, 1,10-phenanthroline and 2,2′-bipyridine-N,N′-dioxide (metal : ligand = 1 : 1) dissolved in ethanol (20 cm^3), in the first two cases, and in water (20 cm^3), in the others, were added to the filtrate with stirring. The bipyridine and the phenanthroline complexes precipitated out instantly, while the bipyridine N,N′-dioxide complex was precipitated by adding ethanol (40 cm^3). The complexes were separated by filtration, washed several times with ethanol and dried *in vacuo* over concentrated sulphuric acid. The yields were *ca* 80% and 50% (based on the amount of metal oxidized) for molybdenum and tungsten, respectively.

Method B. Finely powdered molybdenum or tungsten metal (0.25 g) was added to cold hydrogen peroxide (30%, 10 cm^3) and the reaction mixture was allowed to stand for 3 h at 0–5°C, with occasional stirring. Molybdenum dissolved almost completely to form a yellow solution, but a considerable amount of white residue was left with tungsten. The mixture was filtered and the complexes were obtained as described above.

Reactions of $[Mo(O_2)_2L]$ *complexes with triphenylphosphine and triphenylarsine.* $[MO(O_2)_2L]$ (1 mmol) was added to a solution of triphenylphosphine or triphenylarsine (1 mmol) dissolved in acetonitrile (50 cm^3) and the mixture was refluxed for 5 h. The reaction mixture was then filtered and the filtrate was evaporated to dryness. The yellowish white residue was recrystallized from ethanol (yield 70%) and the oxidized products were identified to be triphenylphosphine oxide and triphenylarsine oxide, respectively, by recording their melting points (156–158°C and 188–190°C, respectively) and IR spectra, which were in agreement with those of the authentic samples.

RESULTS AND DISCUSSION

Molybdenum and tungsten powders dissolve readily in cold hydrogen peroxide solution, from which the heteroligand peroxo complexes $[MOO(O_2)_2L]$ can be easily precipitated out by the addition of 2,2′-bipyridine, 1,10-phenanthroline and 2,2′-bipyridine-N,N′-dioxide. While molybdenum dissolves almost completely giving a yellow solution, tungsten gives a colourless solution along with a considerable amount of white residue which does not contain any peroxide. In both cases the solutions are strongly acidic (pH about 1.5). The electronic spectrum of a solution of molybdenum metal in 30% hydrogen peroxide shows a band at 327 nm, which is identical in position to the absorption spectrum of $(pyH)_2[Mo_2O_3(O_2)_4(H_2O)_2]$ in 30% hydrogen peroxide. It is thus believed that molybdenum dissolves in 30% hydrogen peroxide to give the dimeric species $H_2[Mo_2O_3(O_2)_4(H_2O)_2]$ which, however, changes to the monomeric form on addition of the ligands giving the complexes $[MoO(O_2)_2L]$ (L = 2,2′-bipyridine, 1,10-phenanthroline and 2,2′-bipyridine-N,N′-dioxide). This is supported by the fact that the mononuclear complexes $[MO(O_2)_2L]$ (M = Mo or W) are also obtained by the addition of the ligands L to an aqueous solution of the salts $(pyH)_2[Mo_2O_3(O_2)_4(H_2O)_2]$ and $K_2[W_2O_3(O_2)_4(H_2O)_2]\cdot 2H_2O$.

Molybdenum and tungsten rods are unaffected

by 30% hydrogen peroxide in the cold. When platinum foil is dipped in, the evolution of oxygen occurs on the platinum surface at a moderate rate. However, on the application of a voltage molybdenum and tungsten anodes undergo dissolution giving yellow and colourless solutions, respectively. The rate of evolution of oxygen at the platinum cathode is not much affected, but along with dissolution of the metals a slight evolution of oxygen occurs at the tungsten anode, while at the molybdenum anode the evolution of gas is negligible. Initially the current is very small (0.02 A), but with the passage of time it increases steadily with a simultaneous increase in the acidity of the solution, which is ascribed to the formation of $H_2[M_2O_3(O_2)_4]$ (or its hydrated species). The main reaction taking place at the anode may be depicted as follows:

$$2M + 4H_2O_2 + 3H_2O \longrightarrow [M_2O_3(O_2)_4]^{2-} + 14H^+ + 12e,$$

which is evident from the observed electrochemical efficiency (defined as the number of moles of metal oxidized per Faraday) of 0.16 and 0.14 mol F^{-1} for molybdenum and tungsten systems, respectively. The slightly lower value in the latter case may be ascribed to the liberation of oxygen at the anode due to the oxidation of OH^- and/or hydrogen peroxide. Since the rate of liberation of gas at the cathode is not affected by the passage of a current, hydrogen is not liberated at the cathode. The main reaction at the cathode may be as follows:

$$H_2O_2 + 2H^+ + 2e \longrightarrow 2H_2O,$$

which appears highly probable in view of the high value of E^0(1.77 V) in the above redox system.[18]

The complexes $[MO(O_2)_2L]$ can be precipitated out by the addition of the corresponding ligands to the solution remaining after the dissolution of the sacrificial metal anodes. These were identical in all respects to the corresponding complexes formed by the dissolution of metal powders in hydrogen peroxide.

The properties of the complexes are similar to those reported earlier.[16,19] The elemental analyses are satisfactory (Table 1). The molar conductance values measured in dimethylformamide solution

(1.0×10^{-3} M) lie in the range 1–11 Ω^{-1} cm^2 mol^{-1} at 25°C, showing their non-electrolytic nature. All the compounds are diamagnetic and the vibrational spectra are in order[19,20] (Table 1).

Having achieved the direct synthesis of these compounds we were interested in studying their reactivity in terms of their ability to transfer oxygen to other substances. All the complexes were found to oxidize triphenylphosphine and triphenylarsine to their oxides in acetonitrile under reflux conditions in good yields. Reactions of the complexes with unsaturated compounds like styrene, cyclohexene and α,β-unsaturated ketone were carried out with a view to examining the epoxidizing capability of the compounds, but no epoxides or other oxidized products could be isolated. This lack of reactivity may be due to their low or moderate solubility in organic solvents.

CONCLUSIONS

This paper reports the first electrosynthesis of some heteroligand peroxo complexes of molybdenum and tungsten, all of which, except [MO$(O_2)_2$(bipyO_2)] (M = Mo or W), are already known.[13,14,16,20] It appears that the method may be extended to other metals to prepare peroxo and heteroligand peroxo complexes.

PREPARATION AND CHARACTERIZATION OF (ARYLOXY)CHLOROCYCLOTRIPHOSPHAZENES BY PHASE TRANSFER CATALYSIS

Y. W. CHEN-YANG* and B. D. TSAI

Department of Chemistry, Chung Yuan Christian University, Chung Li, Taiwan 32023, R.O.C.

(*Received* 16 *August* 1991; *accepted* 28 *August* 1992)

Abstract—The phase transfer catalysis method (PTC) was used to synthesize seven series of (aryloxy)chlorocyclotriphosphazenes, $N_3P_3Cl_{6-n}(OC_6H_4Y)_n$, n = 1–6, in high yields, where Y = (*o*, *m* and *p*)-Cl, (*o*, *m* and *p*)-Br, *p*-NO_2, and *p*-CH_3. Except for the case with Y = NO_2, all the reactions were successfully carried out in an aqueous/dichloromethane immiscible binary solvent system. Ethylene glycol and benzene were used as solvents for Y = NO_2. It was found that the PTC method is more convenient and efficient for the preparation of the (aryloxy)chlorocyclotriphosphazenes than that reported before. Most of the compounds obtained were isolated by column chromatography and characterized by a combination of IR spectroscopy, elemental analysis, mass spectroscopy and ^{31}P NMR spectroscopy. The distributions of the products are not affected by the side group Y and its position in the lower level of substitution, but are strongly affected by them in the higher level of substitution. The rates of the reactions, with a molar ratio of aryl alcohol and hexachlorocyclotriphosphazene of 2, are all second-order with respect to the concentration of the corresponding aryloxide transferred to the organic phase.

As the application of alkoxy and aryloxy cyclo- and polyphosphazenes is developing rapidly, a large number of these cyclic oligomers and polymers have been synthesized. The synthesis of various (aryloxy)cyclotriphosphazenes has been studied by many groups.[1–13] In these studies the conventional substitution method of the reaction of alkali metal aryloxides with chlorocyclotriphosphazenes in organic media has been used.[1] However, it takes longer, usually about 2 days, to complete the reaction. Therefore, several studies have been reported to improve the preparation.[11,14–17] Most of these studies were concentrated on the preparation of the fully substituted compounds. Nevertheless, as far as the application of the functional phosphazenes is concerned, the preparation of partially substituted derivatives is equally important.[9–18] Hence, a study on preparing partially substituted (phenoxy)cyclotriphosphazenes by the PTC method has been carried out in our laboratory. It was found that the method is not only convenient and economic for preparing hexa(phenoxy)cyclotriphosphazenes, but also efficient for preparing partially substituted derivatives.[19] In this study, the method is further extended to the reaction of hexachlorocyclotriphosphazene (**1**) and some aryl alcohols, YC_6H_4OH, where Y = (*o*, *m* and *p*)-Cl, (*o*, *m* and *p*)-Br, *p*-NO_2 and *p*-CH_3. Five questions are of interest. First, how fast are the reactions by this method? Second, is the reaction mass transfer or kinetically controlled? Third, how is the reaction affected by the side group Y and its position on the benzene ring (*o*-, *m*- *p*-)? Fourth, how does the molar ratio of aryl alcohol and **1**, MR, affect the distribution of the products? Fifth, what is the limitation of the reaction? Therefore, the distributions of the products were measured and the rate constants were determined for the reactions with MR equal to 2 as model reactions. Also discussed is the relation of the chemical shifts and the coupling constants of ^{31}P NMR data to the nucelophilic ability of the aryloxy group and the level of substitution, n.

EXPERIMENTAL

Apparatus and materials

^{31}P NMR spectra (in $CDCl_3$) were recorded on a Bruker AC200 spectrometer. $N_3P_3Cl_6$, assigned as 20 ppm relative to 85% H_3PO_4, was used as an internal reference. The IR spectra were obtained as thin films (KBr disks) on a Jasco Report-100 spectrometer. Mass spectra were recorded on a Jeol JMS-HX 110 spectrometer. Elemental analyses were performed on a Heraius CHN-O-RAPID analyser by the Instrument Center of NSC at Tainan, Taiwan. Differential scanning calorimetry (DSC) data were obtained on a Mettler DSC-30 thermal analyser at a heating rate of 10°C min^{-1} in a nitrogen atmosphere. The concentration of aryloxide derivatives in the aqueous phase was determined with a Shimadzu UV160 spectrometer at fixed wavelengths. An Iwaki Glass PC-351 hot plate with magnetic stirrer was used for the synthesis of the individual derivatives.

Hexachlorocyclotriphosphazene (**1**) was kindly provided by the Nippon Fine Chemical Corporation, Japan. Except sodium hydroxide (Osaka Chemical Co., Japan), all the other reagents and solvents were purchased from Merck Chemical Co. The reagents and solvents were all used as received.

Reaction kinetics of the reaction with MR = 2

In this part, the procedure described previously[19] was followed. Hence, a solution of **1** (3.48 g, 0.01 mol) in chloroform (100 cm^3) was mixed with an aqueous solution (200 cm^3) containing aryloxide (0.02 mol), sodium hydroxide (1.60 g, 0.04 mol) and tetrabutylammonium bromide (TBNB) (0.24 g, 0.75 mmol) as the phase transfer catalyst. The reaction mixture was stirred vigorously and taken out with a 20 cm^3 pipette at time intervals of 3 or 6 min. The reaction mixture collected at each time interval was separated into an organic phase and an aqueous phase. The concentration of aryloxide remaining in the aqueous phase was then determined using the UV spectrometer at the corresponding wavelengths listed in Table 1. The dependence of the absorbance on the concentration of a standard solution of each aryloxide at the corresponding wavelength was made for calibration.

Synthesis of aryloxychlorocyclotriphosphazenes, $N_3P_3Cl_{6-n}(OC_6H_4Y)_n$, Y = Cl(-o, -m, -p), Br(-o, -m, -p), NO_2, H *and* CH_3, n = 1–6.

A typical example with $[HOC_6H_4—Y]/[I] = 2$, Y = Cl—*p* was carried out as follows: An aqueous solution (32 cm^3) containing *p*-chlorophenol (3.70 g, 0.029 mol), sodium hydroxide (1.53 g, 0.038 mol) and TBNB (1.25 g, 0.0039 mol) was prepared. On the other hand, dichloromethane solution (50 cm^3) containing **1** (5 g, 0.014 mol) was prepared in a 250 cm^3 three-necked flask. With stirring, the aqueous solution was added dropwise into the dichloromethane solution in an ice bath was was reacted for 40 min at room temperature. When the reaction was over the solution mixture was separated into water and organic layers. The organic layer was dried by magnesium sulphate and filtered, and then the filtrate was concentrated by vacuum evaporation. The residue was separated by column chromatography with n-hexane/chloroform as the eluant. A similar procedure was used for the other reactions. The conditions for the other reactions are listed in Table 2.

Table 1. The absorption characteristics of various aryloxides ($OC_6H_4Y^-$) in UV spectra

Y	Absorption peak (m)
m-Cl	305.0
p-Cl	297.2
o-Cl	307.0
m-Br	280.0

o-Br	308.0
p-CH_3	294.2
p-NO_2	275.0

Synthesis of $N_3P_3(OC_6H_4Y)_6$, Y = o-NO_2 *or* p-NO_2, *in ethylene glycol/benzene solvent system*

Synthesis of $N_3P_3(p\text{-}OC_6H_4NO_2)_6$ (**50**). A solution of *p*-nitrophenol (9.73 g, 0.07 mol), Na_2CO_3 (8.48 g, 0.14 mol) and methyltrioctylammonium chloride (MRNC) (0.9 g, 0.002 mol) in ethylene glycol (20 cm^3) was added dropwise into a solution of $N_3P_3Cl_6$ in benzene (30 cm^3). The mixture was then refluxed for 3.5 h. When the reaction was over, the solvent was removed by vacuum evaporation. The residue was added to hot DMF, decolourized by activated carbon and then filtered. The product was finally crystallized to yield 8.81 g (91.5%) of **50**.

Synthesis of $N_3P_3(o\text{-}OC_6H_4NO_2)_6$ (**51**). The reaction was carried out as above for compound **50** for 2 h. The reaction product was then purified by column chromatography with THF as the eluant. Yield: 91.9%.

Table 2. The conditions of synthesis of $N_3P_3Cl_{6-n}(OC_6H_4Y)_n$, $n = 1$–6[a]

5	14.4	71.8	9.70	95.6	80	50
7	14.4	100.6	13.60	133.9	112	50

[a] All the reactions were carried out at room temperature for 40–60 min.

RESULTS AND DISCUSSION

The mechanism of the reaction of aryl alcohol with **1** in the aqueous and organic phases can be described as follows:[20]

$$ArOH + NaOH \Leftrightarrow ArO^-_{[aq.]} + Na^+_{[aq.]} + H_2O \quad [aq.\ phase] \quad (1)$$

$$ArO^-_{[aq.]}Q^+X^-_{[aq.]} \Leftrightarrow Q^+ArO^-_{[aq.]} + X^-_{[aq.]} \quad [aq.\ phase] \quad (2)$$

$$Q^+ArO^-_{[aq.]} \Leftrightarrow Q^+ArO^-_{[org.]} \quad [interface] \quad (3)$$

$$Q^+ArO^-_{[org.]} + N_3P_3Cl_x(OAr)_y \Leftrightarrow N_3P_3Cl_{x-1}(OAr)_{y+1} + Q^+Cl^-_{[org.]} \quad [org.\ phase] \quad (4)$$

$$Q^+Cl^-_{[org.]} \Leftrightarrow Q^+Cl^-_{[aq.]} \quad [interface] \quad (5)$$

$$ArO^-_{[aq.]} + Q^+Cl^-_{[aq.]} \Leftrightarrow Q^+ArO^-_{[aq.]} + Cl^-_{[aq.]} \quad [aq.\ phase] \quad (6)$$

then repeat from eq. (2).

QX, representing tetrabutylammonium bromide, was used as a phase transfer catalyst to transfer aryloxide from the aqueous phase to the organic phase, where the reaction occurred.

Kinetic study of the reactions with [*aryloxide*]/[1] = 2

As described in the previous study,[19] in order to understand the possible kinetics and the relative rate of the reaction in the lower level substitution, a milder condition was used for the model reactions with MR equal to 2. Figure 1 shows the relation between the concentration of aryloxide remaining in the aqueous phase, [B], vs the reaction time. Figure 2 shows that all the reactions followed eq. (7) and are second-order. The corresponding rate constants, k, are determined and listed in Table 3, which indicates that most of the rate constants are in the range 10^{-3}–10^{-1} $dm^3\ mol^{-1}\ s^{-1}$ and the rate, varied with Y, is of the order *m*-Br > *m*-Cl > *p*-Br > *p*-Cl > *o*-Br > *o*-Cl > —H > *p*-CH_3 ≫ *p*-NO_2 for the model reactions.

$$1/[B] - 1/[B]_0 = k't \quad (7)$$

Syntheses of (*aryloxy*)*chlorocyclotriphosphazenes*

The products obtained in each run were separated by column chromatography and identified by a combination of IR spectroscopy, elemental analysis, mass spectroscopy and ^{31}P NMR spectroscopy (Tables 4 and 5).

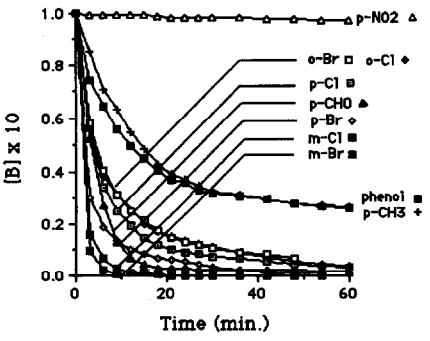

Fig. 1. The effect of various aryl alcohols on the aryloxide concentration transferred from the aqueous phase to the organic phase with the reaction time.

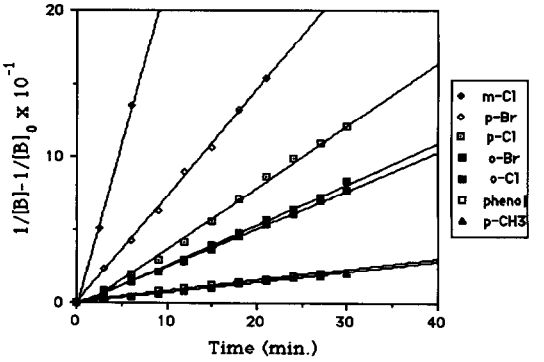

Fig. 2. The effect of various aryl alcohols on the kinetics of the reaction with MR = 2.

Table 3. The effect of Y on the rate constant of the reaction with MR = 2

Y	Reaction order	Rate constant[a] ($dm^3\ mol^{-1}\ S \times 10^3$)
m-Cl	Second	377.2
p-Cl	Second	70.7
o-Cl	Second	43.7
m-Br	Second	Too fast
p-Br	Second	121.7
o-Br	Second	46.6
—H[b]	Second	13.0
p-CH_3	Second	12.0

[a] Unit of the rate constant is S^{-1}.
[b] Recorded from ref. 19 for comparison.

The retention of the cyclic trimeric ring is indicated by the presence of a strong IR absorption at 1100–1300 cm^{-1}. On the other hand, the aromatic nitro groups in **44** and **45** are identified by the absorptions at 1570–1485 and 1370–1320 cm^{-1}.

The assignments of the ^{31}P NMR spectra are based on the simple rule that increasing substitution on a phosphorus atom leads to upfield shifts, viz. $\delta PCl_2 > \delta PCl(OAr) > \delta P(OAr)_2$. Explanations for the spectra are described below.

The mono-substituted derivatives have AX_2 ^{31}P NMR spectra appropriate to their structures. The individual spectrum of the bis derivatives shows a mixture spectrum of two closely spaced AX_2 patterns, representing the *cis* and *trans* isomers, and a low-intensity A_2X pattern, indicating the exis-

[a] Cl was calculated as 35.5 and the found molecular weight was observed directly from the mass spectra.

[b] The parent peak was not observed.

[c] The highest mass ion observed was the parent minus $NP(OC_6H_4CH_3)_2$.

[a] Units of chemical shifts and the coupling constants are ppm and Hz, respectively.

tence of a trace amount of the geminal isomer. Each A_2X spectrum, with A being in the PCl_2 region and X in the general $P(OAr)_2$ region, is consistent only with the corresponding geminal isomer.

The ^{31}P NMR spectra of the tris derivatives mainly show a mixture of non-geminal isomers. A large singlet corresponding to the *cis* isomer and an AB_2 pattern corresponding to the *trans* isomer are indistinguishable in the PCl(OAr) region. A doublet of doublets or triplet (centre lines of doublet of doublets merged) in the PCl_2, PCl(OAr) and $P(OAr)_2$ regions, respectively, is observed in a few cases, indicating the existence of traces of the geminal isomer. A typical spectrum of the tetrakis derivatives again indicates mainly the presence of non-geminal isomers. Two sets of closely spaced A_2X spectra represent the *cis* and *trans* isomers.

Each spectrum of the pentakis derivatives, as expected, exhibits the corresponding AX_2 pattern. A doublet in the $P(OAr)_2$ region and a triplet in PCl(OAr) region are observed. The spectra of the hexakis derivatives have the expected singlet in the $P(OAr)_2$ region.

From the results shown above, it is found that

the non-geminal pathway is favoured in all the reactions. Table 3 lists the chemical shifts and the coupling constants of the compounds isolated. As found for phenoxychlorocyclotriphosphazenes,[21] the chemical shifts and the coupling constants correlate linearly with the level of substitution, n. Furthermore, the chemical shift for $\delta P(OAr)_2$ is generally shifted upfield and that of $\delta PCl(OAr)$ is shifted downfield as the nucleophilic ability of the aryloxide, which is indicated by the K_a value of the corresponding aryl alcohol in Table 4, is increased.

The distributions of the products for the reactions carried out in the aqueous dichloromethane solvent system are listed in Table 6. Except for nitrophenol, the total yields of the other cases were all larger than 85%.

For the reactions with MR < 5 the distributions of the products are similar and the degree of substitution of the major product, yield >60%, is the same as the value of MR, independent of the side

Table 7. The results of the preparation of $N_3P_3(OC_6H_4NO_2)_6$ in the ethylene glycol/benzene (EG/BG) system

Position of Y	MR	Temperature	Solvent	Time (h)	Yield (%)	
p-NO_2	7.0	Reflux	EG/BG	3.5	91.5	This study
o-NO_2	7.0	Reflux	EG/BG	2.0	91.9	This study
p-NO_2	7.5	Reflux	Xylene	28.0	87.0	22
p-NO_2	6.2	Reflux	THF	72.0	81.0	23
p-NO_2	7.0	Reflux	Xylene	14.0	76.0	11

group Y being electron-withdrawing or electron-releasing. This indicates that under the reaction conditions used, the inductive and resonance effects are obviously not present in the formation of the low substituted derivatives, i.e. lower than pentakis derivatives. The reactions were basically mass transfer-controlled in these levels of substitution. Therefore, mono-substituted and tri-substituted derivatives are expected to be obtained predominantly in these cases, if MR equals 1 and 3 are used, respectively, in the reaction. However, it becomes important for the formation of the pentakis and hexakis derivatives due to the increased steric hindrance. The reactions are slowed down and become more kinetically controlled. Hence, for the reactions with Y in the *para* position of aryloxide and MR = 5, the major products are pentakis for those with an electron-withdrawing group, both tetrakis and pentakis for phenol and tetrakis for *p*-creosol, an electron-releasing substituted phenol.

For the reactions with MR = 7 and Y in *para* and *meta* positions, fully substituted derivatives were obtained in high yield for those with electron-withdrawing groups, while a very low yield was obtained for phenol, and none was found for *p*-cresol. On the other hand, for the reaction with Y at the *ortho* position the major product found was pentakis and a low yield of hexakis was obtained due to the steric hindrance effect. These results indicate that the steric hindrance effect enhances the activation energy, and the electron-withdrawing inductive effect and the resonance effect, on the other hand, enhances the reactivity; but, the rate of the reaction depends on the net effect of them.

The extremely low yield for the reaction with nitrophenol, showing a much higher percentage of hydrolysis, is ascribed to the insolubility of nitrophenol in the aqueous alkali solution. In order to overcome this problem, ethylene glycol/benzene, a non-aqueous solvent system, was used. As listed in Table 7 the yield increased remarkably, and the reaction time was much shorter than that reported before.[9,11,22,23] Similar thermal behaviour, reported by Bornstein,[11] is observed for compound **44** by DSC measurement. The compound melted at 248°C and 264°C, indicating two crystalline forms, in the first scan, and mainly at 263°C in the second scan. On the other hand, a single melting point at 158°C is observed in the DSC thermograph, indicating one crystalline form for compound **45**.

CONCLUSION

The results of this study indicate that phase transfer catalysis is a very efficient method for the preparation of the strongly nucleophilic (aryloxy) chlorocyclotriphosphazenes in a suitable binary immiscible solvent system. The partially substituted (aryloxy)chlorocyclotriphosphazenes obtained can be expected to form the basis of the derivation of functional cyclotriphosphazenes. It is also expected that the method can be applied to the successive replacement of chlorine atoms in **1** to prepare mixed substituted aryloxycyclotriphosphazenes. Although the small molecule chemistry of hexachlorocyclotriphosphazene often provides a model for the reactivity of polydichlorophosphazene,[24] the aqueous/organic solvent system will not be suitable for polydichlorophosphazene due to its high sensitivity to water. However, other non-aqueous immiscible binary solvent systems may be applicable. Work concerning this is under investigation in our laboratory.

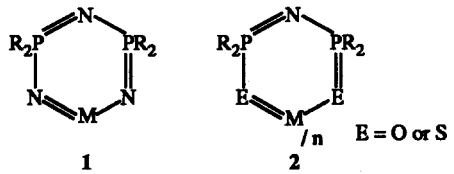
(*Received* 31 *July* 1992; *accepted* 27 *August* 1992)

Abstract—A new inorganic heterocycle is obtained by reacting potassium tetraphenyldithioimidodiphosphinate with trimethyltin and dimethyltin chlorides, in benzene. X-ray diffraction analysis reveals a spirocyclic structure with the dimethyltin moiety as the coordination centre with non-planar six-membered SnS_2P_2N rings. The coordination at tin is nearly perfectly octahedral, with equal Sn—S [273.3(2) and 273.7(2) pm] and P—S bonds [200.9(3) and 201.9(3) pm]. The S—Sn—S and H_3C—Sn—CH_3 units are co-linear.

The most common inorganic heterocycles[1,2] are non-metal rings. Although metal-containing inorganic heterocycles have been known for some time this area has started flourishing in the last 10 years, mainly by incorporation of metal heteroatoms into cyclothiazene[3] and cyclophosphazene[4] rings. Such rings are attractive as precursors for new types of inorganic polymers.[5] A particular class of carbon-free metallocycles includes inorganic chelate rings[6] and this type of compound may add a new dimension to both coordination chemistry and inorganic ring chemistry.

In addition to phosphazene metallocycles (1),[7] chelate rings (**2**), in which an azadiphosphinate group is attached to a metal through oxygen or sulphur, have been reported.[6] The known compounds of type **2**, with E = sulphur, are chelate rings with M = Mn^{II},[8] Fe^{II},[9] Co^{II},[8c,9a,9c] Ni^{II},[9a,10] Pd^{II},[9a] Pt^{II},[9a] Zn^{II},[9a] Cu^{I},[8c,11] Cu^{II},[9c,12] Ag^{I},[13] Au^{I},[13,14] Bi^{III}[15] or Te^{II}.[16] The only derivatives with an organometallic coordination centre reported so far are a dimeric phenyltellurium(II) compound, $[PhTe(SPPh_2NPh_2PS)]_2$,[17] and monomeric diorganogold(III) derivatives, $R_2Au(SPR_2NR_2PS)$.[14,18]

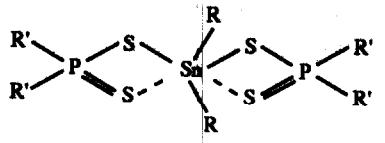


1 **2**

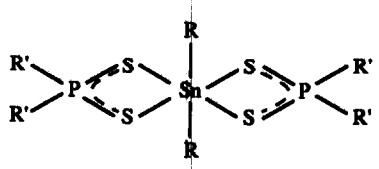
Several years ago one of us reported an organotin derivative, $Me_2Sn(SPPh_2NPh_2PS)_2$, which was not investigated in detail.[19] We now report some spectroscopic properties and a full crystal structure determination of this compound. This was prompted by the renewed interest in this type of chelate ring (e.g. **2**, E = O, M = Al, Ga, In, Sn, Mo, V)[20] and by the possible comparison with organotin dithiophosphates and dithiophosphinates, much investigated in recent years.[21,22] Thus, nearly all diorganotin dithiophosphates and phosphinates whose structures were determined by single-crystal X-ray diffraction show that the ligand is anisobidentate, coordinated to the metal in an unsymmetrical fashion (**3**) and exhibits an intermediate geometry between tetrahedral and octahedral, with

* Author to whom correspondence should be addressed.

short and long Sn—S bonds.[21a,d,e] The only exception known so far in organotin compounds is diphenyltin bis(diisopropyldithiophosphate) (**4**)



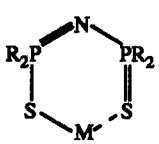
3



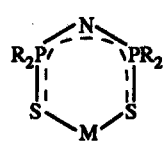
4

(R = Ph, R′ = OPr^i),[23] which exhibits a symmetrical structure with octahedral geometry and identical Sn—S bonds. The fact that the symmetrical structure **4** is the exception rather than the rule makes difficult any prediction. This latter type (isobidentate) of coordination is, however, typical for transition metal dithiophosphates.

In agreement with this data, for an organotin derivative of the dithioimidodiphosphinato ligand either an unsymmetrical structure **5** or a symmetrical structure **6** could be expected (M = Sn).



5



6

The single-crystal X-ray structure determination showed that the symmetrical structure **6** is actually present in the dimethyltin compound.

EXPERIMENTAL

The potassium salt of tetraphenyldithioimidodiphosphinic was prepared from the free acid and Bu^{t}OK.[24] The IR spectra of the starting materials and of the tin compounds were recorded as KBr pellets on a Nicolet 310/320 FT-IR spectrometer. The ^{119m}Sn Mössbauer spectrum of compound **8** was recorded at liquid nitrogen temperature, using $CaCa^{119m}SnO_3$ as a source and standard material for zero velocity.

Preparation of $Me_2Sn[(SPPh_2)_2N]_2$

A solution of Me_2SnCl_2 (0.44 g, 2 mmol) in anhydrous benzene was added to a suspension of $(SPPh_2)_2NK$ (1.95 g, 4 mmol) in the same solvent and the reaction mixture was refluxed for 90 min. The remaining white solid was then filtered off and extracted several times in a Soxhlet apparatus, using acetonitrile as a solvent. Small white–pink crystals of the title compound deposited from the clear acetonitrile solution upon standing for 24 h. Yield: 1.23 g (61%). Found: P, 11.0. Calc for $C_{50}H_{46}N_2P_4S_4Sn$: P, 11.8%.

Preparation of $Me_3Sn(SPPh_2)_2N$

A solution of Me_3SnCl (0.80 g, 4 mmol) in anhydrous benzene was added to a stirred suspension of $(SPPh_2)_2NK$ (1.95 g, 4 mmol) in the same solvent. The mixture was refluxed for 3–4 h and then the resultant KCl was filtered off. The hot, clear solution was allowed to reach room temperature slowly and colourless crystals deposited. Yield: 1.40 g (66%).

Crystallographic data for compound **8**

$C_{50}H_{46}N_2P_4S_4Sn$, $M = 1045.7$, monoclinic, space group $P2_1/n$; $a = 11.099(1)$, $b = 15.551(3)$, $c = 14.442(2)$ Å, $\beta = 103.30(1)°$; $V = 2425.9(6)$ Å^3, $Z = 2$, $d_{calc} = 1.43$ g cm^{-3}, absorption coefficient 0.858 mm^{-1}, $F(000) = 1068$. A colourless crystal of the dimensions $0.3 \times 0.4 \times 0.5$ mm was measured at room temperature on a STOE HED2 (rev. 6.2) four-circle goniometer with graphite monochromatized Mo-K_α radiation in the profile optimizing mode. Within $2\theta < 45°$, 2259 symmetry-independent reflections were collected of which 1678 with $F > 3\sigma(F)$ were used in the least-squares calculations (SHELX-76). The structure was solved by the heavy-atom method implemented in SHELX-86. All non-hydrogen atoms were refined anisotropically and hydrogen atoms positioned geometrically. The final R values are $r = 0.043$ and $Rw = 0.041$ with weights $w^{-1} = \sigma^2(F) + 0.0004\,F^2$. The residual electron density was in the range -0.3 to 0.5 e Å^{-3}. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Informations mbH, W-7514 Eggenstein-Leopoldstr. 2 (FRG), on quoting the deposit number CSD 56534, the names of the authors and the journal citation.

RESULTS AND DISCUSSION

The potassium salt of the tetraphenyldithioimidodiphosphinato ligand reacted with trimethyltin chloride, in benzene, to give a crystalline product; m.p. 135°C.

Table 1. IR data for methyltin(IV) derivatives and related compounds (in cm^{-1})

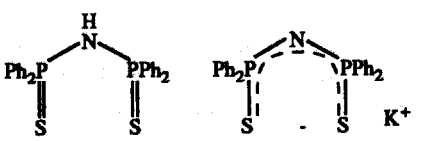
$$Me_3SnCl + K[(SPPh_2)_2N] \longrightarrow Me_3Sn(SPPh_2)_2N + KCl$$
7

Similarly prepared, the dimethyltin derivative was a colourless, crystalline compound; m.p. 265–266°C (from acetonitrile).

$$Me_2SnCl_2 + 2K[(SPPh_2)_2N] \longrightarrow Me_2Sn[(SPPh_2)_2N]_2 + 2KCl$$
8

The IR spectra of the two organotin compounds differ significantly from that of the neutral free ligand. The latter was shown by X-ray diffraction to have the structure of a bis(thiodiphenylphosphinyl)amine (**9**), $Ph_2P(S)NHP(S)Ph_2$.[25] The important bands in the IR spectra of the organotin derivatives are compared with those of the neutral ligand **9** and the potassium salt containing the anion **10** in Table 1.[9c,24] It is quite obvious that in the

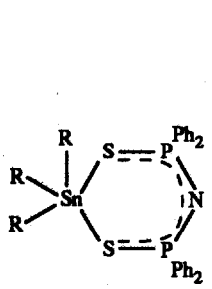


9 **10**

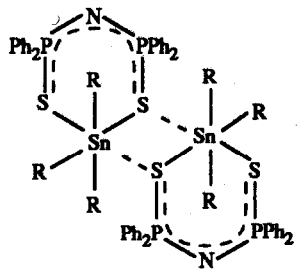
organotin compounds both the ν(PS) and ν(PNP) frequencies are different, due to the delocalization of the negative charge over the whole SPNPS fragment in the anion and changes in the P—S and P—N bond orders, as shown in structures **9** and **10**.

The 1250 and 1217 cm^{-1} bands in $Me_2Sn[(SPPh_2)_2N]_2$ and $Me_3Sn(SPPh_2)_2N$, respectively, were assigned to P···N···P asymmetrical stretching by comparison with a similar band in cyclophosphazenes, $(Ph_2PN)_{3\text{ and }4}$,[26] which exhibit ν_{as}(PNP) in the range 1220–1190 cm^{-1}. The strong bands at 652 and 645 cm^{-1}, characteristic of the P=S double bond in the free ligand **9** and its N-methyl derivative,[24] are replaced by a strong band at 570 and 560 cm^{-1} in the tin compounds, assigned to P···S stretching. This suggests the coordination of all sulphur atoms to tin.

The 535 cm^{-1} band in the diorganotin compound, assigned to SnC_2, indicates a linear arrangement of the two methyl groups in the central $SnMe_2$ moiety. For the trimethyltin(IV) derivative IR data suggest a non-planar orientation of the Sn—C bonds. Since both sulphur atoms seem to be coordinated, its possible solid-state molecular structures could be either monomeric (**11**) [as proposed for $Me_3SnS_2P(OR)_2$, R = Et, Pr^i, on the basis of Mössbauer data[21c]] or dimeric (**12**) with bridging ligands (similar to $Ph_2SbS_2PPh_2$[27]). The coordination geometry of the tin atom would be distorted trigonal bipyramidal in **11**, and octahedral in **12**.



11



12

The Mössbauer spectrum of the dimethyltin compound (IS = 1.63 mm s^{-1} and QS = 3.98 mm s^{-1}) is in agreement with the presence of tin(IV) with a *trans* configuration of the Me—Sn—Me central unit. On the other hand, both the quadrupole splitting and the QS/IS ratio (ρ = 2.44) are consistent with six-coordinate octahedral geometry around tin.[28]

These data were insufficient to distinguish between the chelate ring structure **5** and metallocycle structure **6** of the tin compounds. The X-ray

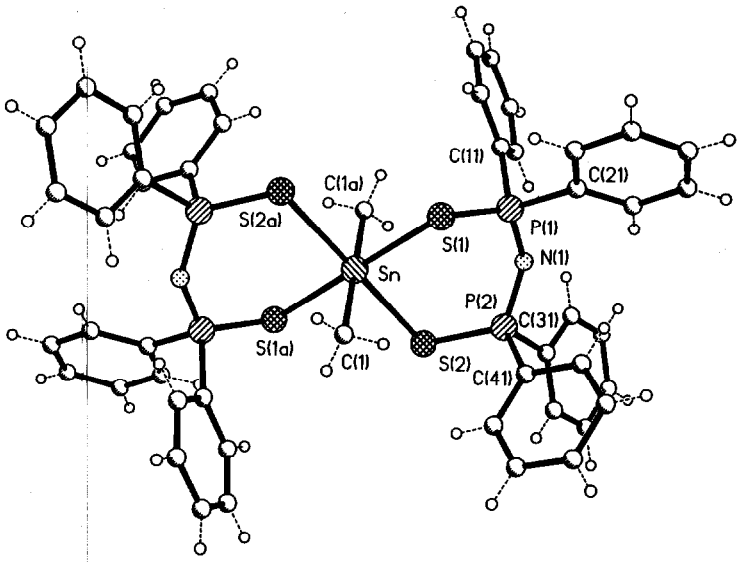


Fig. 1.

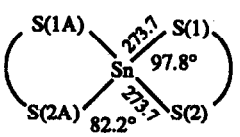
molecular structure determination of the trimethyltin compound **7** was not possible because of disorder, but we were successful with the dimethyltin derivative **8**.

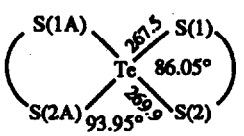
Crystal and molecular structure of $Me_2Sn[(SPPh_2)_2N]_2$ (**8**)

The structure of compound **8** is built up of discrete $Me_2Sn[(SPPh_2)_2N]_2$ molecules. Its molecular structure in the crystal, with the atom numbering scheme, is illustrated in Fig. 1. Selected bond lengths and angles are given in Table 2.

The most unexpected feature of this structure is its high symmetry besides its crystallographic centrosymmetry. Both dithioimidodiphosphinato ligands act as isobidentate moieties forming a symmetrical metallocycle, **6**. All four sulphur atoms lie at equal distances [273.3(2) and 273.7(2) pm, respectively] from the tin atom, which are intermediate between the ester-type bonds (P—)S—Sn (average 248.5 pm) and secondary bonds (P=)S···Sn (average 321.5 pm) in $Ph_2Sn[S_2P(OEt)_2]_2$.[21a] As a result, two six-membered metallocycles, SnS_2P_2N, are formed with tin as the *spiro* atom. Moreover, opposite sulphur atoms belonging to different ligand molecules are co-linear [i.e. S(1)—Sn—S(1A) and S(2)—Sn—S(2A) angles are 180.0(1)°]. This leads to a co-planar SnS_4 system in which the angle between the sulphur atoms of the same ligand is greater [S(1)—Sn—S(2) 97.8(1)°] than that arising between *cis*-sulphur atoms belonging to different ligand moieties [S(1)—Sn—S(1A) 82.2(1)°] (**13**). A similar co-planar MS_4 system with co-linear opposite sulphur atoms was present in the tellurium(II) derivative of the same ligand, i.e. $Te[(SPPh_2)_2N]_2$,[16] but here the Te—S bonds are unequivalent [267.5(2) and 269.9(3) pm] and the intraligand S(1)—Sn—S(2) bond angle [86.05(8)°] is lower than the interligand S(2)—Sn—S(2A) angle [93.95(8)°] (**14**).



13



14

In the central dimethyltin unit the tin–carbon bonds are equal [211.1(8) pm] and co-linear [C(1)—Sn—C(1A) 180.0(1)°]. The axis described by the SnC_2 moiety is almost perpendicular to the SnS_4 plane, as suggested by the C—Sn—S angles (range 86.3–93.7°). As a result the tin atom is placed in the centre of a slightly distorted octahedron.

A comparison with other octahedral compounds containing dithiophosphorus ligands will be useful. Thus, the bismuth(III) complex of tetraphenyldithioimidodiphosphinic acid, $Bi[(SPPh_2)_2N]_3$, contains two sets of short and long Bi—S bonds (average values of 276 and 289 pm, respectively), indicating a structure analogous to **5** (M = Bi). The angles between opposite sulphur atoms are lower than 180° (range 166.3–174.4°). The distorted octahedral geometry around the metal atom was discussed as a result of two concurrent factors, i.e. the electrostatic repulsions between bonded pairs

and the lone pair of the bismuth atom, and the bulky nature of the ligand, respectively.[15b]

The coordination around tin in compound **8** is similar to that found in $Ph_2Sn[S_2P(OPr^i)_2]_2$, with a unique octahedral structure, containing linear Ph—Sn—Ph groups and symmetrically coordinated (isobidentate) dithiophosphato ligands with all four Sn—S bonds identical (average 268.4 pm).[23] In unsymmetrically coordinated (anisobidentate) diethyldithiophosphate, $Ph_2Sn[S_2P(OEt)_2]_2$,[21a] and dimethyltin(IV) bis(dialkyldithiophosphinates), $Me_2Sn(S_2PMe_2)_2$[21d] and $Me_2Sn(S_2PEt_2)_2$,[21e] there are two sets of long and short Sn—S distances (Table 3). The lengths of the P—S bonds also differ in these compounds.

Concerning the tetraphenyldithioimidodiphosphinato ligand, since it is coordinated to tin through both its sulphur atoms, a twist about the P—N bond from the *trans* configuration of the sulphur atoms in the free ligand[25] to the *cis* orientation is required.

Although there are some small differences between the P—S and P—N bond lengths respectively reported in the structure of the free ligand described by different authors,[25] these bonds are of the same magnitude as the P=S double bond in P_4S_{10} (196 pm)[29] and P—N single bonds in $[ClP(S)NMe]_2$ (167 pm)[30] or $(H_2N)_2P(S)$—NMe—$P(S)(NH_2)NHMe$ (173 pm).[31] The isobidentate coordinated ligand in the tin compound **8** has equal phosphorus–sulphur and phosphorus–nitrogen bond lengths, respectively. However, the former are significantly longer and the latter shorter than in the free ligand, thus suggesting a considerable amount of double bond character resulting from the delocalization of the π-electrons on the SnS_2P_2N metallocycle. Moreover, the lengths of the tin–sulphur and phosphorus–sulphur bonds in compound **8** are comparable to those observed in the highly symmetrical molecule of $Ph_2Sn[S_2P(OPr^i)_2]_2$,[23] which also involves an extensive electron delocalization on the SnS_2P ring.

Both S—P—N and P—N—P angles in the dimethyltin(IV) complex are slightly larger than in the free ligand,[25] to permit the symmetrical coordination of the ligand to the metal atom. The electrons of the phosphorus atoms are essentially sp^3 hybridized, resulting in a distorted tetrahedral

Abstract—$NaVO_3$ reacts with guanidine hydrochloride in aqueous solution to afford the title complex. The X-ray single crystal structure of the complex reveals that the molecular structure consists of a $V_{10}O_{28}^{6-}$ polyanion with 10 VO_6 distorted octahedra, which form two octahedra sharing an edge. Six protons of each decavanadic acid are captured by guanidine. In the crystal, the isopolydecavanadate anion, guanidine and the crystal water are linked together by ionic forces and hydrogen bonding.

Vanadium is an element which can form hetero- and isopolyanions. The degree of aggregation and structures of the vanadates are directly dependent upon the acidity of the medium.[1] The isopolyvanadate and the adducts of isopolyvanadic acid with a variety of Lewis bases are the important intermediate products during the wet process of vanadium metallurgy and some of them may be used to separate vanadium from other elements.[2] In addition, polyvanadic acids are polybasic acids, so they can offer several protons and have the ability to combine with various Lewis bases in different proportions. Therefore, it should be worth while systematically studying this kind of addition compound.

Here, we report the synthesis and the crystal structure of the title compound.

EXPERIMENTAL

Preparation

$NaVO_3$ (4.5 g, 37 mmol) was dissolved in water (25 cm^3) and the pH of the orange solution adjusted to 5–6 by nitric acid (3 mol dm^{-3}). An aqueous solution containing guanidine hydrochloride (5.0 g, 52.3 mmol) was then added with stirring. A yellow precipitate immediately formed and was washed several times with ethanol and cold water. Found: C, 5.1; H, 3.3; N, 17.6. Calc. for $(CN_3H_6)_6[V_{10}O_{28}]\cdot 6H_2O$: C, 5.0; H, 3.4; N, 17.7%. The orange-needle single crystals of the title compound were obtained by recrystallization in hot water.

Determination of the crystal structure

A single crystal with the approximate dimensions $0.20 \times 0.20 \times 0.30$ mm was mounted on a glass fibre. All the intensity data were collected on an Enraf–Nonius CAD4 diffractometer using graphite-monochromated Cu-K_α radiation ($\lambda = 1.5418$ Å) with a scan mode of ω–2θ. 3571 independent reflections were collected in the range $2° < 2\theta < 120°$, and 2910 independent reflections with $I > 3\sigma(I)$ were used for further computation. All data were corrected for Lorentz and polarization effects and empirical absorption corrections, based on ψ scans, were applied (max 0.987, min 0.481).

The title compound is monoclinic, space group $P2_1/n$, $Mr = 1353.91$, with the cell dimensions $a = 9.198(2)$, $b = 21.895(2)$, $c = 11.170(3)$ Å, $\beta = 103.92(2)°$, $V = 2183.4$ Å^3, $Z = 2$, $D_{calc} = 2.06$ g cm^{-3}, $F(000) = 1344$, $\mu = 183.8$ cm^{-1}. The structure analysis was performed on a PDP 11/44 com-

* Author to whom correspondence should be addressed.

puter with the SDP program. The positions of all the vanadium atoms were determined by direct methods. The positions of other non-hydrogen atoms were revealed by difference-Fourier syntheses. The hydrogen atoms, located in a difference map and fixed with isotropic $B = 5.0$ Å^2, were included as a fixed contribution. The structure was refined with unit weights by full-matrix least-squares methods with anisotropic thermal factors for all non-hydrogen atoms. Refinement converged to a final $R = 0.074$ for the 2910 observed reflections; $(\Delta/\sigma)_{max} = 0.76$, $\Delta\rho_{max} = 1.86$ e Å^{-3} and $\Delta\rho_{min} = -0.3$ e Å^{-3}. R is high due to the poor quality of the crystal.

RESULTS AND DISCUSSION

Selected bond angles and distances are summarized in Tables 1 and 2, respectively. The final atomic coordinates and the thermal parameters have been deposited as supplementary material with the Editor, from whom copies are available on request.

The decavanadate polyanion shows the same configuration with $K_2Zn_2V_{10}O_{28}\cdot 16H_2O$,[3] $Ca_3V_{10}O_{28}\cdot 17H_2O$,[4] $Na_6V_{10}O_{28}\cdot 18H_2O$,[5] $Nd_2V_{10}O_{28}\cdot 28H_2O$[6] and $(H_3NCH_2CH_2NH_3)_3V_{10}O_{28}\cdot 6H_2O$.[7]

In the crystal, the existence of the decavanadate polyanions has been confirmed by structure analysis. This kind of isopolynuclear complex anion is a highly condensed system of VO_6 octahedra formed by 10 vanadium atoms and 28 oxygen atoms. It therefore has a high molecular weight, 957.4. The stereoconfiguration of the complex and atomic labels are shown in Fig. 1; the 10 vanadium atoms form two octahedra sharing an edge of which the middle point sits on a crystallographic centre of symmetry.

In the decavanadate group there are three kinds of unique vanadium atoms: V(2) and V(5), V(1) and V(4), and V(3). The first two types of vanadium, V(2), V(5), V(1) and V(4), form oxovanadium(V), i.e. VO^{3+}, with O(3), O(4), O(14) and O(13), respectively. The third type of vanadium atom, V(3), has two short V—O bonds with O(1) and O(2) (the lengths of these bonds are 1.679 and 1.691 Å) and the bond angle O(1)—V(3)—O(2) is 106.94°. This group with a bent configuration might be considered as a separate dioxovanadium(V) ion or the pervanadyl ion VO_2^+.

Both in VO^{3+} and VO_2^+ groups V—O bonds possess high multiple bond character due to the participating π-bonds of the d-orbitals.

On the basis of eight VO^{3+} and two VO_2^+ groups the polydecavanadate anion is formed by linking 10 oxovanadium(V) groups together with 16 oxygen

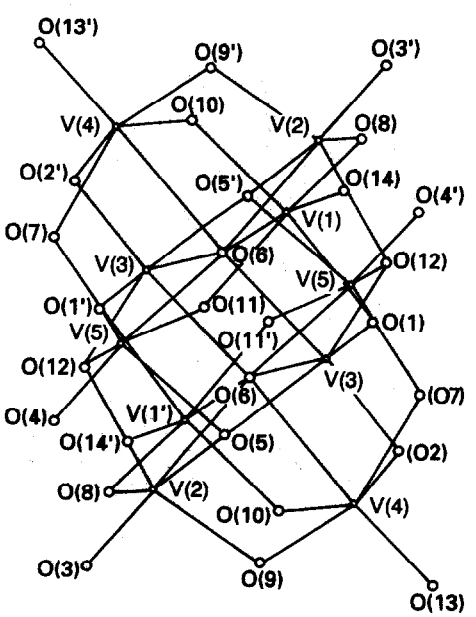

Fig. 1. View of the $V_{10}O_{28}^{6-}$ polyhedron.

atoms. In the polyanion the oxygen atoms may be divided into five classes in which eight oxygen atoms coordinate with only one vanadium atom in each VO^{3+} group; there are four oxygen atoms [O(5), O(5′), O(12) and O(12′)], each coordinates with three vanadium atoms; four bridge atoms involved in VO_2^+ groups coordinate two vanadiums each in an asymmetric way; 10 bridge atoms coordinate two vanadium atoms each and two oxygen atoms lie inside the $V_{10}O_{28}^{6-}$ group and coordinate with six vanadium atoms each.

From Table 2 and Fig. 1 we can recognize that each vanadium atom is coordinated by six oxygen atoms. The characteristic features of the bond type in oxovanadium species are the asymmetry of the V=O multiple bond in the axial direction, with respect to the opposite position, and the coordinate bonds around vanadium may be divided into three distinct classes (strong, medium and weak).

The decavanadic acid is a hexaprotic acid with

(1) $x, y, 1+z$; (2) $1/2-x, 1/2-y, 3/2-z$; (3) $1-x, 1-y, 1-z$; (4) $1/2+x, 1/2-y, 3/2-z$; (5) $1/2-x, -1/2+y, 3/2-z$; (6) $3/2+x, -1/2+y, 1/2+z$; (7) $1+x, y, 1+z$; (8) $1/2+x, 1/2-y, -1/2+z$; (9) $1/2+x, 1/2-y, 1/2+z$; (10) $x, y, -1+z$; (11) $-1/2+x, 1/2-y, -1/2+z$; (12) $3/2-x, 1/2-y, 1/2-z$; (13) x, y, z.

six replaceable hydrogen atoms. Therefore, it may combine with protons or Lewis bases in different ways under varied conditions. In the title complex all the six protons of decavanadic acid are captured by six guanidine molecules so as to yield the bare species of $V_{10}O_{28}^{6-}$.

Table 2 provides a comparison of the V—O bond distances in $(CN_3H_6)_6[V_{10}O_{28}]\cdot 6H_2O$ and $Na_2[(CH_2)_6N_3NH]_2[H_2V_{10}O_{28}]\cdot 8H_2O$.[8] It can be seen from Table 2 that the V—O distances of the title complex (except a few V—O bonds) are shorter than these of $H_2V_{10}O_{28}^{4-}$. As the hydrogen in $H_2V_{10}O_{28}^{4-}$ belonged to O(12) the V(5)—O(12′) and V(4)—O(2) bonds have been shortened significantly from 2.039 and 2.096 Å (the values for $H_2V_{10}O_{28}^{4-}$) to 1.962 and 2.018 Å, respectively. This is a reasonable variation which is associated with a strong O(12)—H bond formation in $H_2V_{10}O_{28}^{4-}$.

As mentioned above, guanidine has a stronger capability of capturing protons than hexamethylenamine.

From Table 3 it can be seen that in directions away from the guanidine groups and the water groups, nitrogen and oxygen atoms of water molecules show close contacts in the ranges 2.906–3.244 and 2.758–2.929 Å, respectively, with oxygen atoms of the anions. The nitrogen atoms make contact with the oxygen atoms of water molecules in the range 2.844–3.075 Å, indicating strong hydrogen bonding to the water molecule. The O(17)···O(16) distance is 2.762 Å, which indicates that there is

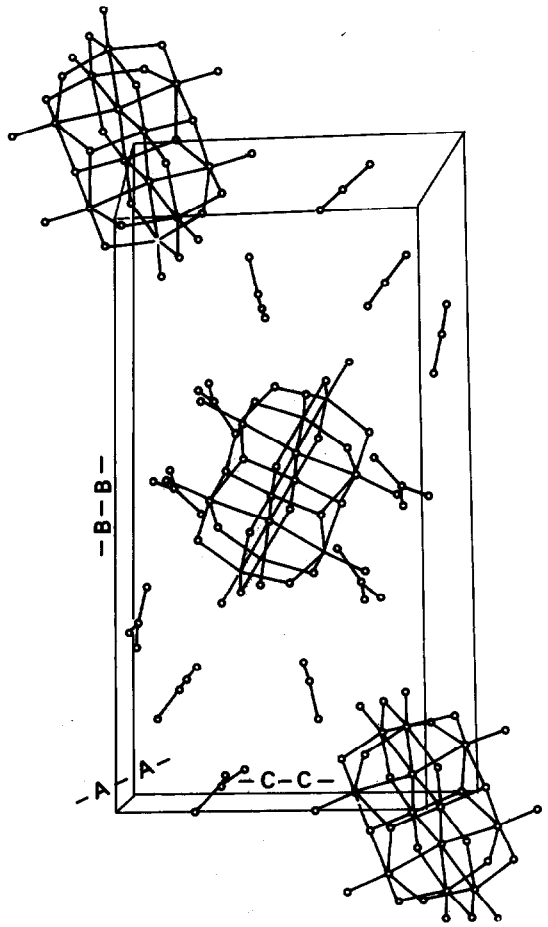

Fig. 2. The unit cell of $(CN_3H_6)_6[V_{10}O_{28}]\cdot 6H_2O$.

strong hydrogen bonding to the water molecules. In the anions all the oxygen atoms show close contacts with the nitrogen atoms of guanidine, except O(6) due to its central position in the polyanion. Therefore, in crystals decavanadate, guanidine and the crystal water are linked together by ionic forces and hydrogen, see Fig. 2.

SYNTHESIS AND CHARACTERIZATION OF COPPER(II) AND NICKEL(II) COMPLEXES WITH LIGANDS HAVING $N_2S_2^*S_2$ (S* = THIOETHER) DONORS: PSEUDO-REVERSIBLE Cu^{III}/Cu^{II} COUPLE

R. SHUKLA, S. MANDAL and P. K. BHARADWAJ†

Department of Chemistry, Indian Institute of Technology, Kanpur 208016, India

(*Received* 2 *June* 1992; *accepted* 27 *August* 1992)

Abstract—Two new hexadentate ligands having thioether and thiolate groups in pairs along with two amide nitrogens have been synthesized. The thiols are protected as their tertiary butyl derivatives. On refluxing the ligands with a copper(II) or a nickel(II) salt in isopropanol, the S-tertiary butyl group was cleaved to form the corresponding hexa-coordinated neutral complex with the chromophore $M^{II}N_2S_2^*S_2$, where the four sulphurs are equatorial and the amide nitrogens are axial. Both the copper(II) complexes show pseudo-reversible responses (ΔE_p = 100 mV) in cyclic voltammograms with $E_{1/2}$ = 0.5 V vs S.C.E. at room temperature in acetonitrile, attributable to a Cu^{III}/Cu^{II} couple. The corresponding nickel(II) complex shows an irreversible response in the region −1.0 to +1.0 V. In their electronic spectra the copper(II) complexes show a strong band near 600 nm, attributable to a σ(thiolate) → Cu^{II} LMCT transition. Each of the copper(II) complexes show ligand field bands typical of a tetragonally distorted octahedral complex. The nickel(II) complexes show three ligand field bands typical of octahedral geometry.

Hexa-coordinated copper(II)-thiolates having the chromophore $CuN_2S_2^*S_2$ (S* = thioether), where the four sulphurs are equatorially bound and the two nitrogens are axially bound, have been reported by us.[1] This arrangement of donor atoms not only lowers the Cu^{II}/Cu^{I} couple, but also makes possible the generation of oxidized copper-thiolate systems electrochemically, which are metastable. Electrochemical studies showed that these oxidized species could be copper(III)-thiolate systems. The importance of these studies lies in the fact that copper(II) has been implicated[2] in the biochemical reactions of some copper proteins. To further probe whether the oxidation is metal centred or ligand based, we have synthesized the two new ligands L_1 and L_2. With copper(II) each forms a hexa-coordinated neutral complex. To identify possible ligand oxidations the corresponding nickel(II) complexes have also been synthesized and probed electrochemically. Besides, nickel has been established as an essential constituent of several hydrogenases.[3,4] Based on physicochemical techniques,[5–8] the nickel site is believed to have the metal ion in a distorted octahedral arrangement with 2/3 sulphur atoms and the rest are nitrogen or oxygen atoms. Nickel bonded to sulphur and nitrogen/oxygen are also present in carbon monoxide dehydrogenases.[9] These findings have stimulated interest in nickel chemistry with mixed sulphur and nitrogen donor ligands.[10–14] Thus, it was considered worthwhile to study nickel(II) complexes having sulphur and nitrogen donor ligands in an octahedral/pseudo-octahedral environment.

EXPERIMENTAL

Materials

Thiosalicylic acid, ethyl chloroformate (Fluka), 1,2-dibromoethane, 1,3-dibromopropane, copper(II) and nickel(II) salts (Aldrich) were reagent grade chemicals and were used as received without further purification. Triethylamine, t-butanol and all solvents were obtained from Glaxo laboratories and purified[15] prior to use. The physical measurements made on the complexes were per-

† Author to whom correspondence should be addressed.

formed as described earlier.[1] Elemental analyses were performed at the Central Drug Research Institute, Lucknow, India.

Syntheses of ligands and complexes

Syntheses of the ligands were achieved as schematically shown in Fig. 1.

S-t-Butylthiosalicylic acid. This was synthesized following a published procedure.[16] A solution of thiosalicylic acid (5 g, 3.2 mmol) in a mixture of 2 (N) hydrochloric acid (15 cm^3) and tertiary butyl alcohol (5 cm^3) was refluxed for 12 h. At the end of reflux excess alcohol and water were removed under reduced pressure. The remaining thick liquid upon cooling to room temperature solidified as a pale yellow solid and was washed several times with water. The solid upon recrystallization from a 1 : 1 ethanol–water mixture gave a pale yellow crystalline solid in 60% yield; m.p. 67–68°C. ^{1}H NMR (80 MHz, d^6-DMSO, δ_{TMS} ppm): 7.4 (m, 4H), aromatic; 1.2 (s, 9H), t-butyl.

1,2-*Bis*(O-*aminophenolthio*)*ethane* (*DAPTE*). The synthesis of this compound was achieved as described earlier.[1]

1,3-*Bis*(O-*aminophenolthio*)*propane*, (*DAPTP*). This compound was synthesized for the first time following the method used for DAPTE, starting with 1,3-dibromopropane and *o*-aminothiophenol.

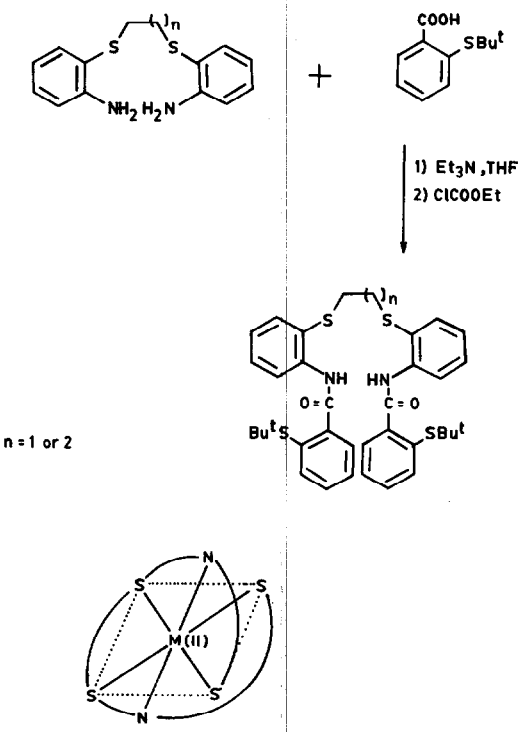

Fig. 1. Synthetic scheme for the ligand syntheses and binding mode of the ligands.

The product was obtained as a semi-solid in a 72% yield. ^{1}H NMR (80 MHz, $CDCl_3$, δ_{TMS} ppm): 7.1 (m, 8H), aromatic; 4.0 (sb, 4H), NH_2; 2.7 (t, 4H), SCH_2; 1.6 (m, 2H), CH_2.

Synthesis of the ligand L_1. This was synthesized by the mixed anhydride method.[1] To an ice cold solution of S-t-butyl thiosalicylic acid (2 g, 9.5 mmol) and triethylamine (0.96 g, 9.5 mmol) was slowly added ethylchloroformate (1.03 g, 9.5 mmol) mixed with THF (30 cm^3). The mixture was allowed to stir at ice cold temperature for 30 min and then allowed to react slowly with a THF solution (40 cm^3) of DAPTE (1.31 g, 4.7 mmol) in an argon atmosphere. The reaction mixture was brought to room temperature after 2 h and allowed to stir for 16 h. The colourless precipitate of triethylamine hydrochloride was filtered off and THF evaporated under reduced pressure to obtain a pale yellow semi-solid. This semi-solid product in $CHCl_3$ was washed several times with H_2O and finally all of the $CHCl_3$ removed in a rotary evaporator to obtain the desired product as a pale yellow semi-solid; yield 78%. ^{1}H NMR (80 MHz, $CDCl_3$, δ_{TMS} ppm): 7.2 (m, 16H), aromatic; 5.5 (sb, 2H), NH; 2.9 (s, 4H), CH_2; 1.3 (s, 18H), t-butyl.

Synthesis of the ligand L_2. The ligand L_2 was synthesized following the same method as used for L_1 using DAPTP and S-tertiary butyl thiosalicyclic acid. The product was obtained as a semi-solid in 75% yield. ^{1}H NMR (80 MHz, $CDCl_3$, δ_{TMS} ppm): 7.3 (m, 16H), aromatic; 6.2 (sb, 2H), NH; 2.8 (t, 4H), SCH_2; 1.6 (m, 2H), CH_2; 1.3 (s, 18H), t-butyl.

Syntheses of thiolato complexes of copper(II) *and nickel*(II). The metal complexes were synthesized by breaking the S-tertiary butyl linkages.[17,18]

Synthesis of **1**. The ligand L_1 (1 g, 1.5 mmol) was dissolved in ethanol (30 cm^3) and a solution of $CuCl_2 \cdot 2H_2O$ (0.26 g, 1.5 mmol) in ethanol (10 cm^3) was added with constant stirring at room temperature. The resulting solution was heated under reflux in a nitrogen atmosphere for 0.5 h until it became deep blue. The deep blue solution was reduced to *ca* 10 cm^3 volume by passing nitrogen through at room temperature. Finally, on keeping at 5°C for 2 h a dark blue powder separated, which was collected by filtration, washed with diethyl ether and dried *in vacuo*; yield 60%.

Synthesis of the copper(II) *complex* **2**. Complex **2** was synthesized by the same method as that adopted for **1**; yield 53%.

Synthesis of the nickel(II) *complex* **3**. $NiCl_2 \cdot 6H_2O$ (0.56 g, 2.3 mmol) and L_1 (1.5 g, 2.3 mmol) were dissolved in iso-butanol and heated under reflux in an argon atmosphere. The colour of the solution changed slowly to dark brown. After refluxing for a total of 2 h the solution was filtered,

[a] The values given are those obtained on the solid samples at room temperature.

concentrated to *ca* 15 cm^3 and cooled to room temperature, whereupon a dark brown crystalline solid separated. The solid was collected by filtration and air-dried; yield 31%.

Synthesis of the nickel(II) *complex* **4**. Complex **4** was synthesized following the same method used for **3**; yield 34%.

All the complexes could be synthesized using other metal salts, such as acetate, nitrate, perchlorate, etc. Analytical data for the complexes are given in Table 1.

RESULTS AND DISCUSSION

The copper(II)-thiolates are air-stable in the solid state. In solution under argon they are stable for days. However, on exposure to air they are stable only for a few hours, after which they decompose slowly. The nickel(II) complexes are stable in the solid state as well as in solution. All the complexes are non-conducting in dichloromethane or in acetonitrile—the two solvents used in the conductivity measurements.

In the solid state as well as in acetonitrile (*ca* 1×10^{-3} M) **1** and **2** gave isotropic EPR spectra with $g_{av} > g_e$ (Table 1), which were not indicative of their structures. The room temperature magnetic moment values for the complexes were found to be within the normal ranges for hexa-coordinated discrete complexes.[19]

The electronic spectral data for the copper(II) complexes are shown in Table 2 while the spectrum of **1** is shown in Fig. 3. In the case of hexa-coordinated copper(II) complexes with moderate Jahn–Teller distortions, the lowest energy transition ($d_{z^2} \rightarrow d_{x^2-y^2}$) occurs[1,20] around 750–900 nm. In **1** and **2** a broad band appears with λ_{max} near 800 nm (Table 2), which is attributed to the lowest energy transition. Transitions from the components of t_{2g} to $d_{x^2-y^2}$ should then occur as a broad band at higher energy. Both **1** and **2** show a very strong band near 615 nm, which is responsible for their blue colour. In other $CuN_2S_2^*S_2$ (S* = thioether) complexes[1] this band is slightly blue shifted and occurs near 600 nm. This band has been identified[1] as due to a σ(thiolate) → copper(II) LMCT transition. The ligand field transition originating from t_{2g} to $d_{x^2-y^2}$ is not seen due to this intense band. The

[a] sh = shoulder.

high intensity (Table 2) of the band is due to a good overlap of the equatorially bound thiolate (Fig. 1) with the $d_{x^2-y^2}$ orbital of the copper(II) ion. Cu(DAPTP)Cl_2 shows only a small absorption around 600 nm. Molecular model studies also indicated that the complex will be least strained in the binding mode illustrated in Fig. 1. In this mode the four sulphurs are equatorially bound, while the two nitrogens are axially bound. An alternative mode of binding will make the thioethers and amide nitrogens equatorial and the thiolates axial. However, in this mode one carbonyl oxygen will come very close to the other. A similar diphenolate[21] also binds as shown in Fig. 1. A shoulder which appears near 525 nm (Table 2) is attributed to the lower energy π(thiolate) → copper(II) LMCT transition.[1,22]

Electronic absorption bands observed for the nickel(II) complexes **3** and **4** are also listed in Table 2 while the spectrum of **3** is shown in Fig. 4. Octahedral nickel(II) complexes show three spin-allowed ligand field transitions[23] corresponding to excitation from the $^3A_{2g}$ ground state to $^3T_{2g}$, $^3T_{1g}$ and $^3T_{1g}$(P) states. For an ideal octahedral coordination the intensities of these *d–d* bands lie below 30 M^{-1} cm^{-1}. As the geometry distorts from ideal centrosymmetric, the intensities of these bands increase and may result in splitting of some of the bands.[24] The intensities of the ligand field bands in **3** and **4** (Table 2) are consistent with their structures, which are almost regular octahedral. For both the nickel(II) complexes the solvent had no effect in the appearance of the electronic spectral bands. This means that the ligands encapsulate the metal ion, leaving no vacant site for possible solvent interactions.

Cyclic voltammograms for the complexes **1** and **2** in acetonitrile (*ca* 1×10^{-3} M) are shown in Figs 2 and 3. Both the copper(II) complexes show quasi-reversible responses with $E_{1/2}$ near +0.53 V vs S.C.E. and $\Delta E_p \simeq 100$ mV. The following characteristics were observed: the ratio $i_{pa}/i_{pc} = 1.0$ within experimental error for different scan rates, the ratio $i_{pc}/v^{1/2}$ is practically constant and the peak separation, ΔE_p, increases slowly with an increase in the scan rate. To identify possible ligand oxidations, the corresponding nickel(II) complexes **3** and **4** were subjected to cyclic voltammetric investigations. None of these complexes showed any well-defined peaks in the region −1.0 to +1.0 V. Only a broad anodic peak appears at *ca* 1.0 V, but on scan reversal no peak appears. This indicates that the oxidized species undergo rapid chemical decomposition once generated electrochemically. We, therefore, assign this quasi-reversible response to the following redox

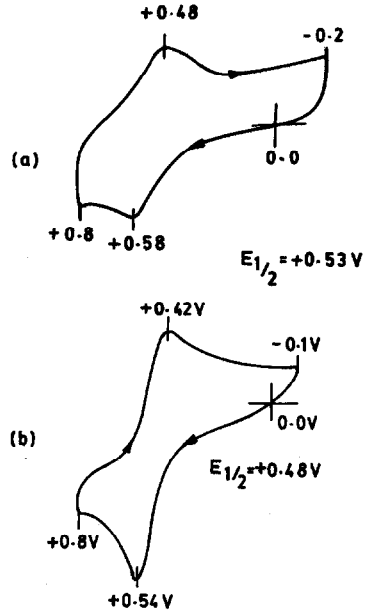

Fig. 2. Cyclic voltammograms for the copper(II) complexes in DMF at the scan rate of 100 mV s^{-1}, using a glassy carbon working electrode and TBAP as the supporting electrolyte: (a) complex **1**, (b) complex **2**.

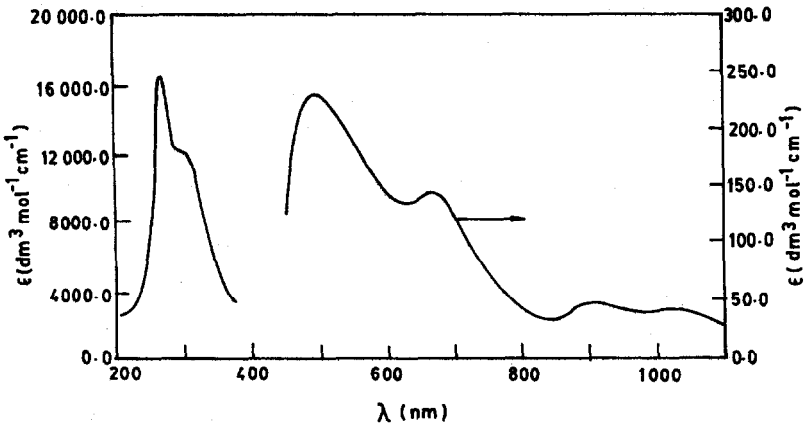

Fig. 4. Electronic spectrum for the nickel(II) complex **3** in DMF.

reactions:

$$1^+ + e^- = 1$$

$$2^+ + e^- = 2.$$

On scanning further on either side, none of the copper(II) complexes showed any well-defined cyclic response. However, when scanned in the negative direction beyond −0.9 V a broad peak appears and on scan reversal an intense peak centring around −0.2 V appears, which is attributable[25] to the oxidation of copper deposited at the electrode. As the data shown in Table 2 indicate, complex **2** is easier to oxidize compared to complex **1**. Both the ligands' donor atoms are somewhat rigid due to the aromatic rings. However, ligand L_2 is less rigid as the thioethers are separated by three carbon atoms, therefore enabling easier self-reorganization upon oxidation, resulting in a lower $E_{1/2}$ value.

CONCLUSION

Hexa-coordinated copper(II) and nickel(II) complexes have been synthesized. The copper complexes are tetragonal and show a quasi-reversible Cu^{III}/Cu^{II} couple while the nickel(II) complexes do not show any well-defined peaks in their cyclic voltammograms. The generation of copper(III) in the cyclic voltammetric time-scale may be associated with the strong equatorial ligation by four sulphur donors, as also observed in the previous cases.[1]

REACTIONS OF $As(NMe_2)_3$ AND $Sb(NMe_2)_3$ WITH ALUMINUM AND MAGNESIUM ALKYLATING AGENTS

C. J. THOMAS, L. K. KRANNICH* and C. L. WATKINS

Department of Chemistry, University of Alabama at Birmingham, AL 35294, U.S.A.

(*Received* 26 *May* 1992; *accepted* 18 *August* 1992)

Abstract—The reactions of aluminum alkyls, R_3Al (R = Me, Et, Pr^n, Bu^n and Bu^i), with $As(NMe_2)_3$ and $Sb(NMe_2)_3$ have been used to synthesize the respective tertiary arsines, R_3As, and tertiary stibines, R_3Sb, in good yields. $As(NMe_2)_3$ also reacts with Grignard reagents, RMgX (R = Et, Pr^n, Pr^i, Bu^n, Bu^i, Bu^t, $CH_2{=}CH{-}$, $CH_3CH{=}CH{-}$, $Me_3SiCH_2{-}$, Ph, *p*-tolyl and mesityl), to give R_3As. Complete ^{13}C and ^1H NMR spectral data on the synthesized R_3Sb and $[R_2AlNMe_2]_2$ are also reported.

Our recent studies on the reactivity of Me_3Al with $Me_{3-n}As(NMe_2)_n$ ($n = 1$–3) established the formation of a mono Al—N—As adduct with Me_2AsNMe_2, mono and bis Al—N—As adducts with $MeAs(NMe_2)_2$ and $As(NMe_2)_3$, and an Al—As adduct of $As(NMe_2)_3$ at −95°C.[1] Subsequent Al—N adduct decomposition with Me moiety transfer from the aluminum to the arsenic atom and As—N bond cleavage gave the next higher Me homologue in the $Me_{3-n}As(NMe_2)_n$ series and $[Me_2AlNMe_2]_2$. From this study, we designed novel and improved high-yield synthetic routes to Me_3As[1] and heteroleptic[2] tertiary arsines.

$$R_3Al + Me_2AsNMe_2 \longrightarrow Me_2AsR + 1/2[R_2AlNMe_2]_2$$

We have been interested for some time in the general reactivity of various alkylating agents with the aminoarsines as potential synthesis routes to organoarsines and have now extended these studies to the aminostibines.

The general synthetic routes to homoleptic tertiary arsines have been previously summarized and the primary literature cited.[3–6] These consist of the reactions of AsX_3 (X = halogen) with Grignard reagents, alkyl lithium, trialkylaluminum, dialkyl zinc and $LiAlR_4$. Yields of R_3As are variable and dependent upon the method used. Trialkylaluminum reagents alkylate As_2O_3 to give moderate yields of the tertiary arsines. They can also be prepared by treating As_2O_3, As_2S_3, arsenic thioacid esters and trialkylarsenites with Grignard reagents. A limited number of tertiary arsines have been synthesized via the reaction of elemental arsenic with SnR_4[7] and alkyl radicals.[8] Our recent studies on the reactions of $\overline{OCH_2CH_2OAs}Cl$ with organoaluminum, -magnesium, -lithium or -zinc reagents established a new general high-yield synthetic route[4] to the tertiary arsines, R_3As.

As in the tertiary arsine syntheses, SbX_3 (X = halogen) serves as a general reagent for the synthesis of R_3Sb. The reactions of SbX_3 with RMgX,[6] R_3Al,[9] $LiAlR_4$,[10] R_4Pb[11] and $(NH_4)_2(RSiF_5)$[12] produce R_3Sb in 45–85% yield. Reactions of Sb_2O_3 with R_3Al give 62–89% yields of R_3Sb, where R = Et, Bu^n, Bu^i and Hex^i.[13] Trimethyl and ethyl stibines have been prepared by the action of Me and Et radicals on elemental antimony.[8] Also, Me_3Sb has been synthesized by heating powdered antimony with Me_2Hg in the presence of $HgCl_2$.[14] The reactions of $(Me_2N)_3Sb$ with RMgX and RLi produce tertiary stibines in 66–78% yield.[15]

In this paper we report a study on the reactivity of $As(NMe_2)_3$ and $Sb(NMe_2)_3$ with R_3Al. From these studies, we obtain good yields of the respective R_3As and R_3Sb compounds (R = Me, Et, Pr^n, Bu^n, Bu^i). The other reaction product, $[R_2AlNMe_2]_2$, has also been isolated and characterized. This paper also gives the ^1H and ^{13}C NMR data on the synthesized tertiary stibines and aminoalanes. In addition, the reactivity of $As(NMe_2)_3$ with RMgX

* Author to whom correspondence should be addressed.

has been studied as an alternate route to R_3As. The merits and limitations of these synthetic routes are discussed. The relative reactivities of $As(NMe_2)_3$ and $Sb(NMe_2)_3$ towards R_3Al are compared.

EXPERIMENTAL

A Vacuum Atmospheres Model HE-43 Dri-lab equipped with a model HE-493 Dri-train was used for the storage and handling of all reagents and products. All reactions and work-ups were carried out under dry nitrogen using common Schlenk techniques. $As(NMe_2)_3$[16] was synthesized by the aminolysis of $AsCl_3$, while $Sb(NMe_2)_3$[17] was prepared by the amination of $SbCl_3$. These were purified by spinning band column distillation and their purities were checked by NMR spectroscopy prior to use. Aluminum alkyls were purchased from Ethyl Corporation and Texas Alkyls. The Grignard reagents, $LiNMe_2$, $AsCl_3$ and $SbCl_3$, were purchased from Aldrich Chemicals, Inc. and used as obtained. Dimethylamine (anhydrous) was purchased from Matheson and used as obtained. Solvents (pentane, Et_2O) were dried over sodium metal, distilled and stored over molecular sieves. Chloroform-d (MSD), benzene-d_6 (MSD) and Me_4Si (Aldrich) were stored over molecular sieves.

The IR spectra of the liquid compounds were recorded neat and of the solid as Kei—F and Nujol mulls on KBr plates using a Nicolet IR/42 FT spectrophotometer. Low-resolution EI-MS data were obtained on a HP 5986A GC/MS spectrometer at 70 eV with a 2400 V electron multiplier. Samples of tertiary arsines and tertiary stibines were introduced into the GC probe as C_6H_6 solutions, while aminoalanes were introduced by the direct insertion probe method.

The NMR spectral data were obtained on a GE(Nicolet) 300 MHz multinuclear FT-NMR spectrometer operating at 300.1 and 75.5 MHz for ^1H and ^{13}C, respectively. Spectra were collected at 24°C using 0.2 M chloroform-d (R_3As) and benzene-d_6 (R_3Sb and $[R_2AlNMe_2]_2$) solutions of the samples with TMS as the internal reference. ^{13}C coupled, $\{^1H\}$ decoupled and APT[18] spectra were obtained for each of the compounds. The ^1H NMR data of the tertiary stibines and aminoalanes are reported in Table 1, while the respective ^{13}C data are given in Table 2. References to earlier reported NMR data are noted in the tables. The NMR data on the tertiary arsines have been previously reported.[4]

All the compounds, except $[Bu^i_2AlNMe_2]_2$, have been mentioned in the literature. Satisfactory carbon, hydrogen and nitrogen analyses were obtained for $[Bu^i_2AlNMe_2]_2$ from E&R Microanalytical Laboratory, Inc., Corona, New York. Found: C, 64.7; H, 12.8; N, 7.7. Calc. for C, 64.9; H, 13.0; N, 7.6%. Melting points were determined in sealed capillaries and were not corrected. All the tertiary arsines that were obtained in this study were previously well-determined.[4] Our NMR, IR and MS data are in excellent agreement with the earlier data.[4] The IR[30,31] and mass spectral data[32,33] of the tertiary stibines are also in very good agreement with the earlier reported values.

IR data

Previously unreported IR data for the aminoalanes synthesized in this study are as follows:

$[Et_2AlNMe_2]_2$. 2984(vs), 2844(vs), 2797(vs), 2725(m), 2687(w), 1478(vs), 1459(vs), 1408(vs), 1375(m), 1234(vs), 1190(vs), 1164(vs), 1120(vs), 1066(s), 1045(vs), 981(vs), 953(vs), 897(vs), 672(vs,br), 588(vs,br), 550(vs), 522(vs), 493(vs) cm^{-1}.

Reactions of $As(NMe_2)_3$ *and* $Sb(NMe_2)_3$ *with* R_3Al

The respective trialkylaluminum, R_3Al (0.15 mol), was slowly added with stirring over a period of 2 h to a sample of $As(NMe_2)_3$ or $Sb(NMe_2)_3$ (0.05 mol) at 0°C. The reaction mixture was slowly warmed to room temperature, stirred for 4 h, and then heated for 12–24 h (see Tables 3 and 4). The optimum reaction conditions were determined by monitoring the reaction mixture with NMR spectroscopy. Fractional distillation gave R_3As or R_3Sb. The aminoalane $[R_2AlNMe_2]_2$ was isolated from the reaction residue by further distillation (R = Et, Pr^n, Bu^n) or sublimation (R = Me, Bu^i).

Table 3. Results obtained from the reactions of $Sb(NMe_2)_3$ with R_3Al

Aluminum alkyl	Reaction conditions	Compounds isolated	Yield (%)	B.p./m.p. (°C/mm Hg)

Reactions of $As(NMe_2)_3$ *with* RMgX

The respective Grignard reagent (0.15 mol) in Et_2O or pentane (100 cm^3) was added to a stirred 0°C solution of $As(NMe_2)_3$ (0.05 mol) in Et_2O or pentane (200 cm^3) over a period of 1 h. The reaction mixture was warmed to room temperature and refluxed for 12 h. Degassed, saturated, aqueous NH_4Cl solution (200 cm^3) was added to hydrolyse any unreacted Grignard reagent. The organic layer was separated and dried over anhydrous Na_2SO_4. After removal of most of the solvent by distillation, the arsine was purified by distillation on a spinning band column. The b.p. and yield data are given in Table 4.

NMR study on the reactions of $As(NMe_2)_3$ *and* $Sb(NMe_2)_3$ *with* R_3Al

R_3Al (1.5 mmol in 2 cm^3 of benzene-d_6) was added to a screw type 10 mm NMR tube (pyrex, Wilmad) containing 0.5 mmol of $As(NMe_2)_3$ or $Sb(NMe_2)_3$ in benzene-d_6 (1 cm^3). The room-temperature ^1H and ^{13}C NMR spectra of the reaction mixture were then recorded at regular time intervals.

RESULTS AND DISCUSSION

Tables 3 and 4 summarize the results obtained from the alkylation reactions of $Sb(NMe_2)_3$ and $As(NMe_2)_3$ with R_3Al, respectively. Both tertiary stibines, R_3Sb (63–87%), and arsines, R_3As (45–88%), are isolated in comparable yields. The NMR spectra of the reaction mixture at 25°C indicate the consumption of starting materials and the presence of R_3As or R_3Sb, $[R_2AlNMe_2]_2$ and Al—N—As or Al—N—Sb bonded species. Thus, heating was essential (see Tables 3 and 4) to achieve complete conversion to R_3As or R_3Sb and $[R_2AlNMe_2]_2$. In the aminostibine reactions the conversion to R_3Sb and $[R_2AlNMe_2]_2$ was more facile than with the aminoarsines. This observation is in agreement with the results of studies on the reactivity of $As(NMe_2)_3$ and $Sb(NMe_2)_3$ towards SO_2,[34] carbonyl compounds[35] and ethylacetate[36] and insertion reactions with amino–imino boranes[37] and ketenes.[38] By analogy to the synthesis of the Me_2AsR arsines,[2] only about a 50% yield of the arsine/stibine results when the distillation is carried out by heating the reaction mixture to *ca* 30°C above the reported boiling point of the product arsine/stibine. Higher yields are obtained by further raising the temperature and reducing the pressure. The yields of $Bu^i{}_3As$ and $Bu^i{}_3Sb$ are much lower than those of the n-butyl analogues. This is also the case in the reported syntheses of $Bu^i{}_3Sb$ (71%) and $Bu^n{}_3Sb$

Table 5. Comparison of yields from R_3Sb syntheses

R	$(Me_2N)_3Sb/R_3Al$	Yield of R_3Sb (%) $(Me_2N)_3Sb/RMgX$ or RLi	$SbCl_3AlR_3$	$SbCl_3/RMgX$
Me	82	—	—	60–70[6]
Et	83	63–66[15]	71[9]	80–85[6]
Pr^n	80	—	66[9]	60–70[6]
Bu^n	87	78[15]	—	70[6]
Bu^i	63	—	77[9]	32[6]

(87%) from the reaction of R_3Al with Sb_2O_3.[13] The yields of R_3Sb from the alkylation of $Sb(NMe_2)_3$ with R_3Al are better than those reported for Grignard (EtMgBr) and alkyl lithium (EtLi and Bu^nLi) alkylating reagents (see Table 5).[15]

The aminoalanes, $[R_2AlNMe]_2$ (R = Me, Et, Pr^n, Bu^n, Bu^i) which are the other products from these reactions, have been isolated in excellent yield. Both $[Me_2AlNMe_2]_2$[28,39–44] and $[Et_2AlNMe_2]_2$[26,29,45] are well-known and well-characterized. The Pr^n[46] and Bu^n[46,47] homologues have been briefly mentioned in the literature and characterized as dimers by cryoscopic molecular weight studies. Our mass spectral data were consistent with the dimeric nature of R_2AlNMe_2 and comparable to the previously reported data for $[Et_2AlNMe_2]_2$.[45] Their spectra show very weak molecular ion peaks. High intensity [M—R] peaks correspond to the loss of the alkyl group bound to the aluminum. The IR spectral data are consistent with those reported for $[Me_2AlNMe_2]_2$.[41] The ν(Al—N) peaks are observed in the region 520–525 cm^{-1}, which is similar to the ν(Al—N) value of 508 cm^{-1} reported for $[Me_2AlNMe_2]_2$.[41]

The results from the reactions of $As(NMe_2)_3$ with the Grignard reagents are summarized in Table 4. Seven of the 12 Grignard reagents gave tertiary arsines, R_3As (R = Et, Pr^n, Bu^n, $CH_2{=}CH{-}$, $CH_3{-}CH{=}CH{-}$, Ph and *p*-tolyl) in 60–80% yield. Although with R = Pr^i, Bu^i, $Me_3SiCH_2^-$ and mesityl there is NMR evidence that the reaction proceeds, we could not isolate the respective tertiary arsines. This is presumably due to incomplete alkylation on the arsenic and probably results from the steric bulk of the R groups. Thus, this method is useful for synthesizing tertiary arsines with less sterically hindered substituents. Possibly these results can be exploited as a potential route to heteroleptic tertiary arsines by first treating $As(NMe_2)_3$ with a sterically bulky Grignard reagent and then with an appropriate amount of a less bulky alkylating agent. For example, we have shown that the reactions of Me_2AsNMe_2 with a wide range of Grignard reagents produce very good yields of heteroleptic tertiary arsines, Me_2AsR.[2] Interestingly, in the reported reaction of $\overline{OCH_2CH_2OAsCl}$ with RMgX tertiary arsines, R_3As, are readily obtained[4] in excellent yield (60–95%) even with bulky R groups.

PROMOLECULES WITH A SUBSYMMETRY OF O_h. COMBINATORIAL ENUMERATION AND STEREOCHEMICAL PROPERTIES FOR CHARACTERIZING OCTAHEDRAL COMPLEXES

SHINSAKU FUJITA

Ashigara Research Laboratories, Fuji Photo Film Co. Ltd, Minami-Ashigara, Kanagawa 250-01, Japan

(*Received* 31 *July* 1992; *accepted* 12 *August* 1992)

Abstract—The concept of promolecules is presented for enumerating octahedral complexes, where achiral and chiral proligands are considered as substituents for an octahedral O_h skeleton. After the table of marks and its inverse are calculated, octahedral promolecules are enumerated using the USCI (unit-subduced-cycle-index) method. The numbers of isomers are obtained in an itemized manner with respect to their formulae and symmetries. The stereochemical relationships between the isomers are discussed in the light of the SCR (set-of-closet-representation) notation, which is also effective in clarifying stereochemical equivalency and non-equivalency of proligands and specifying the prochirality of octahedral promolecules and molecules.

Since the proposal of the coordination theory by Werner,[1,2] the stereochemistry of octahedral complexes has been widely investigated to verify the theory.[3] In particular, several studies have aimed at synthesizing all the possible geometrical isomers of a specific series.[4] For these purposes, it has been necessary to calculate the number of such isomers; this task has been done for several specific series. However, there have been few studies on systematic and combinatorial enumeration, except pioneering enumerations using Pólya's theorem[5,6] and using a computer.[7] Since these enumerations have been concerned with molecular formulae and have taken no account of symmetries, more systematic enumerations are desirable to comprehend the stereochemistry of octahedral complexes.

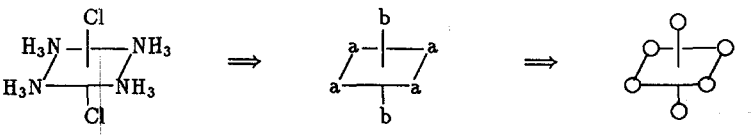
The present paper deals with a systematic approach to such enumerations and relevant problems, where we use a method based on unit-subduced-cycle-indices (USCIs).[8,9] Although the USCI method enables us to enumerate any objects in an itemized manner concerning formulae and symmetries, its application to octahedral complexes requires further derivation of several tables for the O_h point group. In this connection the inorganic complexes are examined in terms of the concept of promolecules, which was once proposed for discussing the stereochemical properties of organic compounds.[10] In addition, we discuss the stereochemical properties of the complexes in the light of the concept of chirality fittingness.[11]

RESULTS

Promolecules with a subsymmetry of the O_h *group*

To illustrate the concept of promolecules for octahedral complexes, let us examine the *trans*-tetraamminedichlorocobalt ion (**1**), i.e. *trans*-$[CoCl_2(NH_3)_4]^+$ (Fig. 1). First, we take into consideration the fixed conformer (**1a**) that has the highest attainable symmetry of D_{2d}. By substituting proligands *a* and *b* for the ammine ligands and the chloro ligands (atoms), respectively, the molecule is converted into the corresponding promolecule (**2**). Since proligands have been defined as hypothetical ligands that have chirality/achirality but are structureless,[10] promolecule **2** is concluded to belong to $\mathbf{D}_{4h}$ symmetry. The promolecule is in turn considered to be constructed by substituting a set of proligands (a_4b_2) for the six vertices of the octahedral skeleton of **3** with O_h symmetry.

If we start from another fixed conformer (**1b**) of C_{4v} symmetry, we are able to obtain the same



1a D_{2d} (D'_{2d}) 1b C_{4v} 2 D_{4h} 3 O_h

Fig. 1. Molecule, promolecule and skeleton.

promolecule and the same skeleton. This fact indicates that while the tetraamminedichlorocobalt ion has several conformers, the resulting promolecule (**2**) can be regarded as a rigid object.

Although such structures as **2** are frequently used in inorganic chemistry, they have not been well-defined enough to clarify these problems. This means that the conventional treatment has not taken into explicit consideration what happens conceptually when the conversion between **1** and **2** takes place. It follows that one of the main subjects of the present paper is to make clear which symmetrical properties of complexes such as **1** are maintained in the conversion into promolecules such as **2**. This discussion requires (1) combinatorial enumeration of promolecules derived from the octahedral skeleton (**3**), (2) stereochemical properties of the resulting promolecules and (3) a stereochemical relationship between promolecules and molecules.

Tables of marks and USCIs for the O_h *group*

To apply the USCI method to octahedral complexes we should prepare a table of marks, its inverse, and a table of USCIs with respect to the O_h group. The O_h group has an irredundant set of 33 subgroups (SSG):

$$\begin{aligned}\mathrm{SSG}_{O_h} = \{&C_1, C_2, C'_2, C_s, C'_s, C_i, C_3, C_4, S_4, D_2,\\ &D'_2, C_{2v}, C'_{2v}, C''_{2v}, C_{2h}, C'_{2h}, D_3, C_{3v}, C_{3i},\\ &D_4, C_{4v}, C_{4h}, D_{2d}, D'_{2d}, D_{2h}, D'_{2h}, T, D_{3d},\\ &D_{4h}, O, T_h, T_d, O_h\},\end{aligned}$$

where these subgroups are aligned in order of increasing orders. In accord with the SSG we can consider a complete set of coset representations (SCR):

$$\begin{aligned}\mathrm{SCR}_{O_h} = \{&O_h(/C_1), O_h(/C_2), O_h(/C'_2), O_h(/C_s),\\ &O_h(/C'_s), O_h(/C_i), O_h(/C_3), O_h(/C_4),\\ &O_h(/S_4), O_h(/D_2), O_h(/D'_2), O_h(/C_{2v}),\\ &O_h(/C'_{2v}), O_h(/C''_{2v}), O_h(/C_{2h}), O_h(/C'_{2h}),\\ &O_h(/D_3), O_h(/C_{3v}), O_h(/C_{3i}), O_h(/D_4),\\ &O_h(/C_{4v}), O_h(/C_{4h}), O_h(/D_{2d}), O_h(/D'_{2d}),\\ &O_h(/D_{2h}), O_h(/D'_{2h}), O_h(/T), O_h(/D_{3d}),\\ &O_h(/D_{4h}), O_h(/O), O_h(/T_h), O_h(/T_d),\\ &O_h(/O_h)\},\end{aligned}$$

which contains all of the transitive permutation representations concerning the O_h group.

Let G be a group of finite order and G_i and G_j be its subgroups. The mark of the subgroup G_j in a coset representation $G(/G_i)$ is defined as the number of fixed points of $G(/G_i)$ on the action of the subgroup G_j.[12] A table of marks (or a mark table) contains all of the marks concerning the G group. From a multiplication table and a group–subgroup relationship of the O_h group, we calculated a set of coset representations and counted fixed points (marks) for every subgroup. The resulting mark table and its inverse are found in Tables 1 and 2.

In order to construct the table of USCIs for the O_h group, we calculate the subduction of every coset representation (CR) by every subgroup. For example, let us examine the subduction of the $O_h(/C_{4v})$ CR by C_{2v}, which is denoted by the symbol $O_h(/C_{4v})\downarrow C_{2v}$. Since the SSG of the C_{2v} group is represented by

$$\mathrm{SSG}_{C_{2v}} = \{C_1, C_2, C_s, C'_s, C_{2v}\}, \qquad (1)$$

we collect the corresponding marks in the $O_h(/C_{4v})$ row of Table 1 to form a row vector, (62442). Note that C_s and C'_s of $\mathrm{SSG}_{C_{2v}}$ are conjugate within the O_h group. Hence, the value at the intersection between the $O_h(/C_{4v})$ row and the C_s column in Table 1 is doubly placed as the third and fourth elements of the row vector. The row vector is multiplied by the inverse of the mark table of the C_{2v} group[9] as follows:

$$(62442)\begin{bmatrix} 1/4 & 0 & 0 & 0 & 0\\ -1/4 & 1/2 & 0 & 0 & 0\\ -1/4 & 0 & 1/2 & 0 & 0\\ -1/4 & 0 & 0 & 1/2 & 0\\ 1/2 & -1/2 & -1/2 & -1/2 & 1 \end{bmatrix} = (00112). \qquad (2)$$

The resulting vector represents the multiplicities of the coset representations, which correspond to the equation:

$$O_h(/C_{4v})\downarrow C_{2v} = C_{2v}(/C_s) + C_{2v}(/C_s') + 2C_{2v}(/C_{2v}). \tag{3}$$

Each CR on the right-hand side of eq. (3) corresponds to a suborbit that emerges during the restriction of the original O_h symmetry to the subsymmetry C_{2v}. Since we have $|C_{2v}|/|C_s| = 2$, $|C_{2v}|/|C_s'| = 2$ and $|C_{2v}|/|C_{2v}| = 1$, we assign a dummy variable s_2 to the $C_{2v}(/C_s)$ CR and to the $C_{2v}(/C_s')$ CR, and s_1 to the $C_{2v}(/C_{2v})$ CR. Their product is the corresponding USCI, i.e. $s_1^2 s_2^2$, which is assigned to the subduction represented by eq. (3). This procedure is repeated for every subgroup to afford other USCIs, which are collected in Table 3.

On the other hand, we can construct the corresponding unit-subduced-cycle-index with chirality fittingness (USCI-CF) as follows. The three CRs on the right-hand side of eq. (3) are all homospheric, because all the subgroups involved are achiral. Hence, we assign dummy variables: a_2 to the $C_{2v}(/C_s)$ CR, a_2 to the $C_{2v}(/C_s')$ CR and a_1 to the $C_{2v}(/C_{2v})$ CR. We accordingly obtain the USCI-CF, $a_1^2 a_2^2$. The USCI-CFs concerning the $O_h(/C_{4v})$ orbit are obtained as shown in Table 3, where the variable a_d is ascribed to a d-membered homospheric orbit, variable b_d to a d-membered hemispheric orbit and variable c_d to a d-membered enantiospheric orbit. In a similar way, USCIs and USCI-CFs for other CRs have been obtained; however, they are abbreviated for simplicity's sake. The general procedure for constructing tables of USCIs and of USCI-CFs has been described in Chapter 9 of ref. 9.

Enumeration of octahedral promolecules with achiral proligands only

Supposing that the six vertices in the octahedral skeleton (**3**) of O_h symmetry are occupied with a set of achiral proligands selected from *a* to *f*. Then, the problem at issue is to obtain the number of isomers with a given formula and a given symmetry.

The first step is to assign a coset representation (CR) to the orbit of the six vertices. By counting fixed points on the action of every subgroup of SSR_{O_h}, we obtain a fixed-point vector (FPV) represented by (6 2 0 4 2 0 0 2 0 0 0 2 2 0 0 0 0 0 0 0 2 0 0 0 0 0 0 0 0 0 0 0 0 0). Since this vector is identical with the $O_h(/C_{4v})$ row of the mark table (Table 1), the orbit of the six vertices is concluded to be subject to the $O_h(/C_{4v})$ CR. As a result, the derivation of isomeric complexes from the skeleton can be discussed in the light of the subduction listed in Table 3.

The next step is to construct subduced-cycle-indices (SCIs).[8] Since we consider *a*–*f* as proligands, we have a ligand inventory:

$$s_d = a^d + b^d + c^d + d^d + e^d + f^d. \tag{4}$$

This inventory is introduced into the SCIs that are equal to the USCIs listed in Table 3. Thereby, we obtain the following equations:

For C_1:

$$s_1^6 = (a+b+c+d+e+f)^6; \tag{5a}$$

for C_2, C_s, C_{2v}:

$$s_1^2 s_2^2 = (a+b+c+d+e+f)^2 \, (a^2+b^2+c^2+d^2+e^2+f^2)^2; \tag{5b}$$

Table 3. USCIs and USCI-CFs for $O_h(/C_{4v})$

for C_2', C_i, D_2, C_{2v}'', C_{2h}, D_{2h}:

$$s_2^3=(a^2+b^2+c^2+d^2+e^2+f^2)^3; \quad (5c)$$

for C_s:

$$s_1^4s_2=(a+b+c+d+e+f)^4 (a^2+b^2+c^2+d^2+e^2+f^2); \quad (5d)$$

for C_3, C_{3v}:

$$s_3^2=(a^3+b^3+c^3+d^3+e^3+f^3)^2; \quad (5e)$$

for C_4, C_{2v}', C_{4v}:

$$s_1^2s_4=(a+b+c+d+e+f)^2 (a^4+b^4+c^4+d^4+e^4+f^4); \quad (5f)$$

for S_4, D_2', C_{2h}', D_4, C_{4h}, D_{2d}, D_{2d}', D_{2h}', D_{4h}:

$$s_2s_4=(a^2+b^2+c^2+d^2+e^2+f^2) (a^4+b^4+c^4+d^4+e^4+f^4); \quad (5g)$$

and for D_3, C_{3i}, T, D_{3d}, O, T_h, T_d, O_h:

$$s_6=a^6+b^6+c^6+d^6+e^6+f^6. \quad (5h)$$

After the expansion of each of these equations, we collect the coefficient of the term $a^{\theta_1}b^{\theta_2}c^{\theta_3}d^{\theta_4}e^{\theta_5}f^{\theta_6}$ to construct Table 4. For simplicity's sake, we designate the term by the partition $[\theta_1\theta_2\theta_3\theta_4\theta_5\theta_6]$, where we omit zero elements and presume $\theta_1 \geqq \theta_2 \geqq \theta_3 \geqq \theta_4 \geqq \theta_5 \geqq \theta_6$ without losing generality.

The data of Table 4 are regarded as a matrix, which is multiplied by the inverse (Table 2). The resulting matrix is found in Table 5, which contains

the number of isomers with $[\theta_1\theta_2\theta_3\theta_4\theta_5\theta_6]$ and a given symmetry at the corresponding intersection.

The total number of each row of Table 5 is calculated by means of a cycle index (CI), which is obtained using the USCIs and the coefficients listed in Table 3. The coefficients are calculated by adding the values in every row of Table 2;[13] each of them is non-zero only if the corresponding group is cyclic. By introducing the ligand inventory [eq. (4)], we have a generating function for calculating the number of isomers with a given partition:

$$
\begin{aligned}
&G(a,b,c,d,e,f)\\
&\quad=(1/48)(s_1^6+3s_1^2s_2^2+6s_2^3+3s_1^4s_2+6s_1^2s_2^2\\
&\qquad+s_2^3+8s_3^2+6s_1^2s_4+6s_2s_4+8s_6)\\
&\quad=(1/48)(s_1^6+9s_1^2s_2^2+7s_2^3+3s_1^4s_2+8s_3^2\\
&\qquad+6s_1^2s_4+6s_2s_4+8s_6)\\
&\quad=(a^6+\cdots)+(a^5b+\cdots)+2(a^4b^2+\cdots)\\
&\qquad+2(a^4bc+\cdots)+2(a^3b^3+\cdots)\\
&\qquad+3(a^3b^2c+\cdots)+4(a^3bcd+\cdots)\\
&\qquad+5(a^2b^2c^2+\cdots)+6(a^2bcd+\cdots)\\
&\qquad+9(a^2bcde+\cdots)+15(abcdef+\cdots). \qquad (6)
\end{aligned}
$$

Note that the cycle index is equivalent to that derived by Pólya's theorem;[14] this equivalency has been proved in general.[13] Each of the coefficients appearing in eq. (6) is identical to the corresponding value in the rightmost column of Table 5, which is obtained by summing up every row.

Figure 2 illustrates all the promolecules enumerated in Table 5. It should be noted that an arbitrary enantiomer is depicted as a representative of each pair of enantiomers, since the present method counts a pair of enantiomers once. The drawing of these promolecules is conducted without difficulty, since the values in Table 5 are itemized with respect to the partitions (molecular formulae) as well as to the symmetries.

Enumeration of octahedral promolecules with achiral and chiral proligands.

Let us next consider cases in which proligands are capable of being achiral or chiral. For simplicity's sake, we examine the case in which six proligands for **3** are selected from a set of three achiral proligands (a, b and c) and a pair of enantiomers (p and $\bar{p}$).

In order to obtain the numbers of isomers with a given formula and a given symmetry, we use the following three ligand inventories:

$$a_d = a^d+b^d+c^d, \qquad (7a)$$

$$b_d = a^d+b^d+c^d+p^d+\bar{p}^d, \qquad (7b)$$

$$c_d = a^d+b^d+c^d+2p^{d/2}\bar{p}^{d/2}; \qquad (7c)$$

where a_d is applied to a homospheric orbit, b_d to a hemispheric orbit and c_d to an enantiospheric orbit. These inventories are introduced into the SCI-CFs which are, in this case, identical with the USCI-CFs listed in Table 3. Thereby, we obtain the following

for C_{4h}:

$$c_2 c_4 = (a^2+b^2+c^2+2p\bar{p})(a^4+b^4+c^4+2p^2\bar{p}^2); \quad (8t)$$

for D_{2d}', D_{2h}', D_{4h}:

$$a_2 a_4 = (a^2+b^2+c^2)(a^4+b^4+c^4); \quad (8u)$$

and for D_{3d}, T_h, T_d, O_h:

$$a_6 = a^6+b^6+c^6. \quad (8v)$$

After the expansion of each of the equations, we collect the coefficient of each term, $a^{\theta_1}b^{\theta_2}c^{\theta_3}p^{\theta_4}\bar{p}^{\theta_5}$, to construct Table 6. We designate this term by the symbol $[\theta_1\theta_2\theta_3;\theta_4\theta_5]$, where we omit zero elements; and presume $\theta_1 \geqslant \theta_2 \geqslant \theta_3$ and $\theta_4 \geqslant \theta_5$ without losing generality. Terms containing achiral proligands only (i.e. $\theta_1+\theta_2+\theta_3 = 6$) are abbreviated, since they have already appeared in Table 4. If a promolecule has $[\theta_1\theta_2\theta_3;\theta_4\theta_5]$ in which $\theta_4 \geqslant 1$, $\theta_5 \geqslant 1$ and $\theta_4 \neq \theta_5$, it has an enantiomer that corresponds to $[\theta_1\theta_2\theta_3;\theta_5\theta_4]$. In accord with this fact, the values containing the factor 2* correspond to such cases to obtain the correct results.

The data of Table 6 are regarded as a matrix, which is then multiplied by the inverse (Table 2). The resulting matrix (Table 7) contains the number of isomers with $[\theta_1\theta_2\theta_3;\theta_4\theta_5]$ and a given symmetry at the corresponding intersection.

For verifying the values collected in Table 7, Fig. 3 illustrates all cases in which θ_4 and θ_5 are both equal to 1.

DISCUSSION

Inherent lack and accidental lack

Table 5 involves several columns in which all the values are equal to zero. Such a lack of derivatives of specific subsymmetries can be deduced by means of SCIs derived from USCIs. In general, a derivative of a given point group is inherently absent if the corresponding SCI is identical with the SCI of one of its supergroups. To discuss the octahedral promolecules we can use the USCIs collected in Table 3, since the corresponding skeleton **3** has one orbit. For example, the SCI of the C_2 group $(s_1^2 s_2^2)$ is the same as that of C_{2v}; hence, there inherently emerge no C_2 derivatives. In other words, even if we place ligands a_2b_2cd in agreement of the SCI

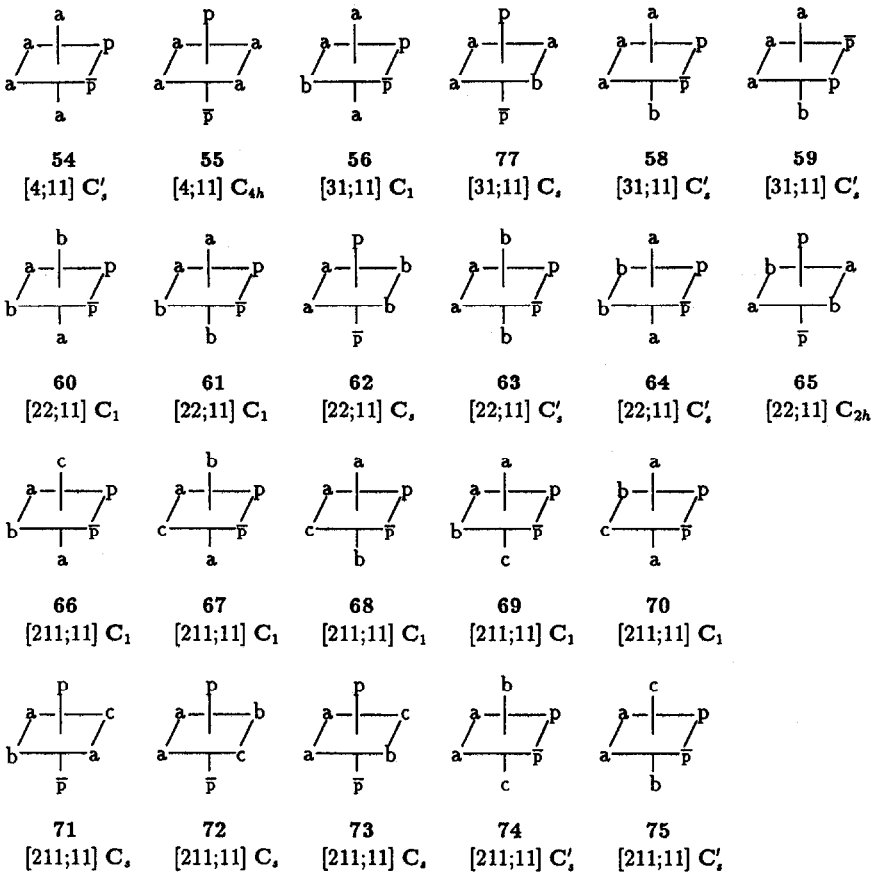

Fig. 3. Octahedral promolecules with achiral and chiral proligands.

$(s_1^2 s_2^2)$ on the vertices of the skeleton, the resulting molecule belongs not to C_2 but to C_{2v}.

By using the data collected in Table 3 and the group–subgroup relationship,[11] the inherent lack of derivatives for the octahedral complexes with achiral proligands is concluded to occur in the following cases:

$$C_2 \Rightarrow C_{2v}(s_1^2 s_2^2)$$

$$C'_2, C_i, D_2, C_{2h} \Rightarrow D_{2h}(s_2^3)$$

$$C_3 \Rightarrow C_{3v}(s_3^2)$$

$$C_4, C'_{2v} \Rightarrow C_{4v}(s_1^2 s_4)$$

$$S_4, D'_2, C'_{2h}, D_4, C_{4h}, D_{2d}, D'_{2d}, D'_{2h} \Rightarrow D_{4h}(s_2 s_4)$$

$$D_3, C_{3i}, T, D_{3d}, O, T_d, T_h \Rightarrow O_h(s_6);$$

where each group on the right-hand side represents a supergroup to be considered.

In the light of the SCI-CFs (derived from USCI-CFs in Table 3) we are able to determine the inherent lack of subsymmetries for cases in which achiral and chiral proligands are permitted:

$$D_3, T \Rightarrow O(b_6),$$

$$D'_{2d}, D'_{2h} \Rightarrow D_{4h}(a_2 a_4)$$

$$D_{3d}, T_d, T_h \Rightarrow O_h(a_6).$$

Table 7 involves the corresponding columns which all have zero values.

Enumeration collected in Table 7 involves another type of lack (C_i and D'_2), which is called *accidental lack*. This means that we can obtain derivatives of such symmetries if we increase the variety of the proligands. Thus, a C_i derivative can be obtained by placing three pairs of antipodal proligands, i.e. $p\bar{p}q\bar{q}r\bar{r}$, in the same line; substitution of $p_4 q_2$ gives a D'_2 derivative.

Algebraically speaking, such accidental lacks can be avoided by using the following ligand inventories in place of eqs (7a)–(7c).

$$a_d = a^d + \cdots + f^d, \tag{9a}$$

$$b_d = (a^d + \cdots + f^d) + (p^d + \bar{p} + \cdots u^d + \bar{u}^d), \tag{9b}$$

$$c_d = (a^d + \cdots + f^d) + 2(p^{d/2}\bar{p}^{d/2} + \cdots + u^{d/2}\bar{u}^{d/2}). \tag{9c}$$

However, the full calculation based on eqs (9a)–(9c) affords too large a list to be tabulated.

SCR notation of octahedral promolecules

We have already proposed the set-of-coset-representation (SCR) notation for characterizing organic compounds.[9,15] The SCR notation determines every coset representation and its members for specifying a compound. The notation is also useful for characterizing octahedral promolecules.

The [51], C_{4v} promolecule (**5**) is designated by the SCR notation, $C_{4v}[/C_s(a_4)\,;\,C_{4v}(a,b)]$. This notation stems from the fact that the four *a*s of **5** construct an orbit corresponding to the $C_{4v}(/C_s)$ CR; the remaining *a* is a member of one $C_{4v}(/C_{4v})$ orbit and *b* is a member of the other $C_{4v}(/C_{4v})$ orbit. The notation for **5** explicitly indicates that the four *a*s are not equivalent to the remaining *a*. Note that $|C_{4v}|/|C_s| = 8/2 = 4$ and $|C_{4v}|/|C_{4v}| = 8/8 = 1$; these values control the number of proligands to be accommodated by each of the orbits. In addition, it should be emphasized that a desymmetrization created by the a_5b (or [51]) substitution is exactly controlled by the subduction

$$O_h(/C_{4v})\downarrow C_{4v} = C_{4v}(/C_s)+2C_{4v}(/C_{4v}), \quad (10)$$

which is collected in the corresponding row of Table 3. Similarly, we obtain the SCR notations for the promolecules depicted in Figs 2 and 3, as found in Tables 8 and 9.

It should be noted that the point group C''_{2v} in $C''_{2v}[/C_s(a_2,b_2),\ /C'_s(a_2)]$ for **7** (also for **20**–**22**) is differentiated from the C_{2v} point group in $C_{2v}[/C_s(a_2),\ /C'_s(b_2),\ /C_{2v}(a,b)]$ *for* **11**, although they are equivalent as point groups after such subductions. Since they indicate different modes of deriving promolecules of the C_{2v} symmetry, such a differentiation between C_{2v} and C''_{2v} is useful when we emphasize the fact that we start from the O_h skeleton (**3**).

The symbols a_2 and $2a$ in the notation $C_s[/C_1(a_2),\ /C_s(2a,\ b,\ c)]$ for **9** (Table 8) indicate two distinct modes of substitution. The two *a*s in a_2 construct a two-membered orbit, while each *a* of $2a$ constructs a distinct one-membered orbit.

The promolecules **6** and **7** correspond to a *trans*--*cis* pair of [42] isomers; they are differentiated by

their SCR notations (Table 8). A *fac–mer* relationship for [33] isomers is exemplified by the pair **10** and **11**.

When an octahedral promolecule has a pair of enantiomorphic proligands several cases emerge to be carefully examined. For example, **58** and **59** are both achiral, whereas they contain chiral proligands. These cases correspond to organic compounds of the *meso*-type. Although **58** and **59** can be interchanged by the permutation of chiral proligands p and $\bar{p}$, they are by no means enantiomeric, but are diastereomeric.

Although several diastereomers have the same SCR notation, most promolecules are well characterized by the SCR notations. Thus, the SCR notations have several advantages over simple point-group notations: (1) Stereochemical equivalency and non-equivalency are easily determined; (2) the local symmetry for each ligand is explicitly designated by the symbol after a slash; (3) the coset representations in the square brackets are algebraically determined by the subduction of the original symmetry of the skeleton.

Stereochemical equivalency and non-equivalency

In general, proligands in the same orbit are determined to be stereochemically equivalent; on the other hand, proligands in different orbits are concluded to be stereochemically non-equivalent. The SCR notation described in the preceding subsection involves information for characterizing such equivalency/non-equivalency. Non-equivalent proligands can be differentiated by an appropriate method, such as NMR spectroscopy.

The present method provides us with unambiguous results for such complicated cases that even careful inspection is liable to mistakes. Let us examine the four *a*s in **54**. The two *a*s in the $C_s'(/C_1)$ orbit (on the left edge) are determined, without any confusion, to be equivalent to each other. Since the $C_s'(/C_1)$ orbit is enantiopheric, the relationship between the two *a*s is concluded to be enantiotopic.

On the other hand, the relationship between the remaining two *a*s (top and bottom) may be erroneously determined to be equivalent by a glimpse of the formula **54**. However, as the SCR notation indicates, one a in the $C_s'(/C_s)$ orbit is non-equivalent to the other a belonging to the other $C_s'(/C_s)$ orbit. In other words, they are diastereotopic.

This conclusion is affirmed by the facts that the bottom one of the two *a*s in **54** is replaced by b to produce **58**, that the replacement of the top a creates molecule **59**, and that the replacement of both by two *b*s affords **63**. These derivations are accompanied by no change in the C_s' symmetry, as found in their SCR notations.

In the same line, the two *a*s in **62** are stereochemically non-equivalent to each other; the *b*s in 62 are also non-equivalent. This fact is closely related to the relationship between **62** and **72** of the same C_s symmetry (or between **62** and **73**). The two *a*s in **63** are equivalent, while the two *b*s in **63** are non-equivalent. Compare **63** with **74** (or with **75**).

Prochiralities of octahedral promolecules and molecules

A promolecule that has at least one enantiospheric orbit is defined as being prochiral.[11] When a promolecule contains an enantiospheric orbit in which half the members are chiral proligands of the same kind and the remaining half are the same number of their antipodes, the two halves are equi-

valent and enantiotopic to each other. Even if all the members of an enantiospheric orbit are achiral as fragments, the half is antipodal to the other half when incorporated in the orbit. The equivalency concerning the two halves of the enantiospheric orbit is created only by improper rotations.

The definition of prochirality can be applied to the present cases of octahedral promolecules. The chirality/achirality/prochirality of each promolecule is found in the chirality columns of Tables 8 and 9. For example, **9** is prochiral because of the enantiospheric $C_s(/C_1)$ orbit; thus, the two *a*s in this orbit (at *trans* positions) can be differentiated by an attack of an appropriate chiral reagent. According to the conventional terminology, they are enantiotopic. If one of the *a*s is replaced by *d* during the attack, either **15** or its enantiomer is obtained in agreement with energetical requirements.

The prochirality of the promolecules in Fig. 3 should be carefully examined, since p and $\bar{p}$ can construct a single orbit. For example, **54** is prochiral because of its $C_s'(/C_1)$ orbits that are enantiospheric. Thus, the two-membered enantiospheric orbit is constructed by a pair, p and $\bar{p}$, and the other enantiospheric orbit is composed of a pair of two *a*s. Hence, a chiral synthesis can be realized by differentiating p from $\bar{p}$ (or one *a* from the other **a**) which are enantiotopic.

A molecule is considered to be a derivative of substituting appropriate ligands for the proligands of a promolecule. Let us re-examine **1a** and **1b**, which can be considered to be derived from **2**. The fixed conformer **1a** is represented by the SCR notation:

$$D'_{2d}[/C_1(H_8); /C_s(N_4, H_4); /C_{2v}(Cl_2); /D_{2d}(Co)].$$

The SCR notation of **1b** is

$$C'_{4v}[/C_1(H_8); /C_s(N_4, H_4); /C_{4v}(2Cl, Co)].$$

Since an enantiospheric orbit represents prochirality, these fixed conformers are prochiral.

If we consider rotations of four ammonia ligands we should use the EWP (extended-wreath-product) notation[16] for rotatable **1**,

$$D_{4h}(/C''_{2v})[4C_{3v}[/C_s(H_3); /C_{3v}(N)]] - D_{4h}(/C_{4v})[2C_{\infty v}[/C_{\infty v}(Cl)]],$$

where the symbol for the central cobalt is abbreviated. This EWP notation is obtained from the SCR notation for **6** (= **2**) and those for ammonia and chloro ligands. Since there emerge no enantiospheric orbits in the EWP notation, rotatable **1** is concluded not to be prochiral. The problem of which of these conclusions is predominant for complex **1** is open to further experimental investigation.

CONCLUSION

The USCI (unit-subduced-cycle-index) method has been applied to enumeration problems concerning octahedral complexes after the derivation of a mark table and relevant tables for the O_h point group. The concept of promolecules and the SCR (set-of-coset representation) notation have proved effective in discussing the stereochemical properties of the complexes, such as prochirality and equivalency/non-equivalency.

(*Received* 13 *July* 1992; *accepted* 10 *August* 1992)

Abstract—The complex $[Et_4N][(Ph_3P)_2\{CuS_2MoS_2Fe\}Cl_2]$ has been obtained by reaction of $[Et_4N]_2[S_2MoS_2FeCl_2]$ with $Cu(PPh_3)_3Cl$ in $MeCN/CH_2Cl_2$. In this new complex, the bond lengths of the Mo—Fe bond and the Mo—Cu bond are 2.769(2) and 2.786(2) Å, respectively.

The tetrathiometallate anions MoS_4^{2-} and WS_4^{2-} have been shown to be important in various biological processes.[1,2] Thiomolybdates were detected in the hydrolysis product of nitrogenase (Fe–Mo protein of *clostridium pasteurianium*)[1] and most probably are formed in the rumen of grazing animals.[2] Many types of compounds, which are interesting from the stand-point of structural chemistry, are formed with the aid of doubly, triply and quasi-quadruply bridging tetrathiomellate ligands. The complex anion $[S_2MoS_2FeCl_2]^{2-}$ [3] can serve as a precursor for the synthesis of Fe–Mo cofactors (FeMo-co).[4] The MoS_4^{2-} anion has been claimed to be the most effect antagonist[2b] of copper metabolism. Extensive research has been performed on MoS_4^{2-}-Cu[1,5–10] complexes which show a rich structural variety. Meanwhile a number of MoS_4^{2-}-Ag^I complexes[1,5b,10–13] have been obtained. Recently, some heterotrimetallic $[(PPh_3)_2AgS_2MS_2Cu(CN)]^-$ [14] (M = Mo, W) and $[(PPh_3)_2AgS_3MOCu(CN)]^-$ [15] (M = Mo, W) complexes were also synthesized in our laboratory.

The anionic fragment $[MoS_4FeCl_2]^{2-}$ may be expected to combine with another metal complex to form a heterobimetallic complex, for example a $[Cl_2FeS_2MoS_2FeCl_2]^{2-}$ [16] type cluster, but no heterotrimetallic complexes of this series have been reported as yet. In this paper, the designed synthesis of a novel heterotrimetallic complex is reported.

EXPERIMENTAL

All operations were carried out under dinitrogen. Solvents and reagents were degassed by repeated evacuation and flushing with pure dinitrogen before use. MeCN was distilled from CaH_2 and CH_2Cl_2 was of A.R. grade and used without further purification. $Cu(PPh_3)_3Cl$ was obtained from a CH_3OH solution of PPh_3 and CuCl (molar ratio 3:1). Elemental analyses were performed by the Elemental Analysis Laboratories in our Institute. The visible and UV electronic spectra were recorded on a Shimadzu UV-3000 spectrophotometer. IR spectra were obtained on a Perkin–Elmer 577 spectrometer.

Preparation of $[Et_4N][(Ph_3P)_2\{CuS_2MoS_2Fe\}Cl_2]$

A solution of $Cu(PPh_3)_3Cl$ (0.886 g, 1.0 mmol) in CH_2Cl_2 (30 cm^3) was slowly added to a solution of $[Et_4N]_2[MoS_4FeCl_2]$ [17] (0.612 g, 1.0 mmol) in MeCN (25 cm^3). After stirring for a while at 35°C, the colour changed from dark to red to black and a red precipitate appeared after 2 min. Pr^iOH (5 cm^3) was added and then filtered. The filtrate was kept in a refrigerator and black crystals of the title compound were obtained the next day. Yield 0.70 g (65.46%). Found: C, 49.5; H, 4.4; N, 1.8; P, 5.3; S, 12.3; Cl, 7.0; Cu, 5.8; Mo, 9.9; Fe, 5.4. Calc. for $C_{44}H_{50}NP_2Cl_2S_4CuMoFe$: C, 49.4; H, 4.7; N, 1.3; P, 5.8; S, 11.9; Cl, 6.6; Cu, 5.9; Mo, 8.9; Fe, 5.2%. IR spectra (KBr pellet, cm^{-1}); δ (C—H) in PPh_3: 750.2 (vs), 696 (vs); Cu—P: 519 (vs), 507.3 (vs);

Mo—μ_2-S: 478.4 (s), 468.5 (vs), 428.9 (w); Fe—Cl: 350.3 (s), 333.2 (vs).

Crystal structure determination

The crystal and refinement data for the structure of the compound are shown in Table 1, together with some experimental details. Data were collected on a Rikagu AFC5R diffractometer using Mo-K_α radiation ($\lambda = 0.71069$ Å) at 296 K. The ω scan speed was varied on the basis of the SEARCH intensity (maximum 16° min^{-1}). Three standard reflections were measured periodically in each case, and the absence of random deviations indicated crystal and electronic stability. The intensity error was defined as $\sigma(F^2) = c + \frac{1}{4}(t_c/t_b)^2(b_1+b_2)+(PI)^2$, where I is the intensity and P a factor which downweights strong reflections, taken to be 0.05. The data were corrected for Lorentz and polarization effects and for absorption using empirical ω scan data and DIFABS.[18] The structure was solved by the Patterson method and direct methods using MITHRIL.[19] The coordinates of the molybdenum atom were obtained from the Patterson function analysis, and the iron and copper atoms were located in the E-map. Most non-hydrogen atoms were successively located using the DIRDIF program;[20] some non-hydrogen atoms were located in the succeeding difference-Fourier syntheses. The structure was refined by a full-matrix least-squares calculation. Molybdenum, iron, copper, chlorine and sulphur in the anion and the two phosphorus atoms were refined with anisotropic temperature factors; all carbon atoms in the PPh_3 ligands and all the carbon atoms in the cations were refined with isotropic temperature factors. Structure details for the title complex anion are shown in Table 1. All calculations were performed on a VAX 785 computer using the TEXSAN program package.[21] Non-hydrogen scattering factors were taken from Cromer and Waber.[22]

Important bond lengths and bond angles for the title complex are given in Tables 2 and 3, respectively.

RESULTS AND DISCUSSION

Synthesis

The substitution reaction between metals or ligands may cause difficulties in obtaining the heterotrimetallic complex. In our procedure, two reac-

Fe—Cl(2)	2.216(4)	P(2)—C(221)	1.82(1)

tions can be presented as follows:

$$[MoS_4FeCl_2]^{2-} + Cu(PPh_3)_3^+ \longrightarrow [(Ph_3P)_2CuS_2MoS_2FeCl_2]^- \quad (1)$$

$$[(Ph_3P)_2CuS_2MoS_2FeCl_2]^- + Cu(PPh_3)_3^+ \rightleftharpoons [(Ph_3P)_2CuS_2MoS_2Cu(PPh_3)] + FeCl_2. \quad (2)$$

Due to eq. (2), the yield of the title compound was lower. If the concentration of $FeCl_2$ is increased, the yield of the title compound will be increased. Obviously, if the concentration of $Cu(Ph_3P)_3^+$ ions is increased, the yield of the title compound will be reduced. However, using $[MoS_4Fe(SPh)_2]^{2-}$ to replace $[MoS_4FeCl_2]^{2-}$, only $[(Ph_3P)_2CuS_2MoS_2Cu(PPh_3)]$ was produced, which may be because the Lewis acid strength of $FeCl_2$ is stronger than that of $Fe(SPh)_2$.

Structure

$[(Ph_3P)_2\{CuS_2MoS_2Fe\}Cl_2]^-$ is shown in Fig. 1. The arrangement of the three atoms Fe—Mo—Cu is approximately linear (Fe—Mo—Cu is 178.41°). C_{2v} is the idealized symmetry of the anion. In the structure of the anion the molybdenum atom retains its tetrahedral coordination by four sulphur atoms as in MoS_4^{2-}. The two metal atoms attached to the MoS_4 moiety all have approximately tetrahedral geometry.

The MoS_2Cu and MoS_2Fe cores are planar to within a maximum of 0.007 and 0.001 Å, respectively. Their dihedral angle is 90.10°, which means they are very closely perpendicular to each other. The Mo—Fe distance [2.769(2) Å] in the title compound is slightly shorter than the Mo—Fe distances [2.786(1) Å] in $[S_2MoS_2FeCl_2]^{2-}$ (**1**)[3] and [2.775(6) Å] $[Cl_2FeS_2MoS_2FeCl_2]^{2-}$ (**2**),[16] respectively. However, the Mo—Cu distance (2.786 Å) in the title compound is slightly longer than the Mo—Cu distance [2.775(2) Å] in $[(Ph_3P)_2CuS_2MoS_2Cu(PPh_3)]\cdot 0.8CH_2Cl_2$.[23] The mean value for the Mo—S (sulphur bonded to the iron atom) bond lengths [2.226(3) Å] in the title compound is slightly longer

$[Ph_4P]_2[Cl_2FeS_2MoS_2FeCl_2]$	472(5.8), 432(4.07), 314(12.3)	16
$[Et_4N][(Ph_3P)_2CuS_2MoS_2FeCl_2]$	475.6(4.9), 436.5(4.2), 312.5(15.9), 265.5(25.7)	This work

than the corresponding value of 2.204 Å in **2**; while the mean value for the Mo—S (sulphur is bonded to the copper atom) bond lengths [2.181 (3) Å] is slightly shorter than the corresponding value of 2.208 Å in $[(Ph_3P)_2CuS_2MoS_2Cu(PPh_3)]\cdot 0.8CH_2Cl_2$ (**3**).[24] The Fe—S bond length [2.276(4) Å] in the title compound is longer than the Fe—S bond length [2.263(2) Å] in **1** and shorter than the Fe—S bond length (2.295 Å) in **2**. The Cu—S distance [2.310(4)–2.330(4) Å] in the title compound is slightly longer than the Cu—S distance [2.212(5)–2.315(6) Å] in **3**.

The structure of the anion is quite similar to that of $[Cl_2FeS_2MoS_2FeCl_2]^{2-}$,[16] in which the MoS_4 unit bridges two terminal $FeCl_2$ moieties and the MoS_4^{2-} and $FeCl_2S_2$ fragments show distorted tetrahedral geometry around the metal.

The electronic spectra of the anions of the $[Et_4N]_2[MoS_4]$, $[Et_4N]_2[S_2MoS_2FeCl_2]$, $[Ph_4P]_2[Cl_2FeS_2FeCl_2]$ and $[Et_4N][(Ph_3P)_2CuS_2MoS_2FeCl_2]$ complexes are listed in Table 4. A simple molecular orbital (MO) scheme for MS_4^{2-} (T_d symmetry) may be devised[25] by assuming *nd*, $(n+1)s$ and $(n+1)p$ valence orbitals on M and 3*s* and 3*p* valence orbitals on S. The longest wavelength absorption at 477 nm can be unambiguously assigned[11,25] to the one-electron transition v_1: $t_1(n,\pi) \rightarrow 2e(d)$ on the basis of magnetic circular dichroism measurements. The absorption at 324 nm was plausibly assigned to v_2: $3t_2(\pi,\sigma) \rightarrow 2e(d)$, and the other absorption at 240–280 nm is assigned to v_3: $t_1(n,\pi) \rightarrow 4t_2(d)$. Our results are also consistent with the conclusion[10] that the bi- and trinuclear complexes absorb in the same energy regions as MoS_4^{2-}. It is demonstrated[10,25] that the spectra of the complex are dominated by the internal transitions of $[MoS_4]^{2-}$. The splitting of the v_1 absorption is plausibly due to raising the degeneracy of the $t_1(n,\pi)$ level in the lower symmetry of the complexes $[t_1(T_d) \leftrightarrow a_2+e(D_{2d}) \leftrightarrow a_2+b_1+b_2(C_{2v})]$. The MoS_4^{2-} S→Mo transition in the title compound is split, which is consistent with the Fe—MoS_4^{2-} complexes previously reported,[26] due to lowering in local symmetry about the central atom in the MS_4^{2-} unit from T_d to C_{2v} in the title compound. It is interesting that the longest wavelength band, v_1, in the title compound is somewhat red-shifted after the incorporation of a $Cu(PPh_3)_2^+$ group.

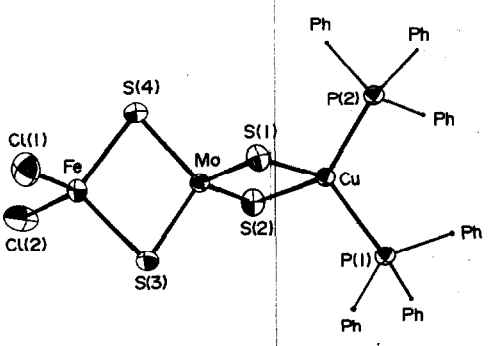

Fig. 1. The ORTEP drawing of the anion $[(PPh_3)_2\{CuS_2MoS_2Fe\}Cl_2]^-$.

Abstract—The EPR spectra of single-crystal samples of $^{63}Cu[(Pr^i_2O)_2PS_2]_2$ magnetically diluted in the corresponding palladium(II) and platinum(II) host lattices were studied at room temperature and eigen-values of the A and g tensors evaluated. The results obtained show that both the samples have approximately axial symmetry ($\Delta A = A_x - A_y \leqslant 3$ G; $\Delta g = g_x - g_y \leqslant 0.03$) with one molecule per unit cell in both host lattices. It is found that g_z coincides with A_z whereas the angle between g_x and A_x (g_y and A_y) is 27° and 11° for $^{63}Cu/Pt[(Pr^i_2O)_2PS_2]_2$ and $^{63}Cu/Pd[(Pr^i_2O)_2PS_2]_2$, respectively. The data about a quadrupole interaction obtained was considered with special attention, because their values are close to the experimental error. In view of this, the possibility for determiming Q values from simulated powdered EPR spectra was explored. The results show, however, inapplicability of this approach too. The crystal and molecular structure of bis(diisopropyldithiophosphato)palladium(II) was determined.

It is well known that the single-crystal EPR studies of paramagnetic species give comprehensive information about all spin-Hamiltonian parameters. In many cases, however, it is difficult or impossible to grow suitable single crystals. The spin-Hamiltonian parameters can then be determined from EPR spectra of powders and/or frozen solutions, but with less accuracy. However, in a typical case when anisotropy is present, only the principal values of various tensors can be obtained from powder-type EPR spectra and the mutual orientations of the principal directions of these tensors remain unknown. A possible solution of this problem would be the comparison between computer simulated spectra, by varying unknown parameters in reasonable limits, and experimentally obtained ones until satisfactory coincidence occurred. In this manner many authors have made conclusions not only about the strongest coupling constants but also about much weaker interactions such as quadrupole coupling.[1–3] The

* Author to whom correspondence should be addressed.

applicability of this approach can be verified when both single-crystal and powder-type EPR spectra of a given paramagnetic species are available. The constants of the quadrupole interaction evaluated in this way, for copper(II) chelate complexes in different host lattices, differ strongly from each other and do not coincide with the values obtained from the method of ENDOR spectroscopy.

In this paper the results obtained on single-crystal and powder-type experimentally recorded and simulated EPR spectra of bis(diisopropyldithiophosphato)copper(II), $Cu[(C^i_3H_7O)_2PS_2]_2$, magnetically diluted in the corresponding platinum and palladium host lattices, are presented. The molecular and crystal structure of $Pd[(C^i_3H_7O)_2PS_2]_2$ is also presented.

EXPERIMENTAL

Preparation of the samples

The preparation of magnetically diluted samples of $^{63}Cu/Pd[(C^i_3H_7O)_2PS_2]_2$ and $^{63}Cu/Pt[(C^i_3H_7O)_2PS_2]_2$ was performed by the following stages:

Synthesis of the ligand. The preparation of the potassium salt of the ligand $(C^i_3H_7O)_2PSSK$ was made according to the following equations:

$$4C^i_3H_7OH + P_2S_5 \longrightarrow 2(C_3H_7O)_2PS(S)H + H_2S \quad (1)$$

$$(C^i_3H_7O)_2PS(S)H + KOH \longrightarrow (C_3H_7O)_2PS(S)K + H_2O. \quad (2)$$

In a three-necked round-bottomed flask, equipped with a mechanical stirrer, condenser and nitrogen inlet, fine melted P_2S_5 was added in small portions to absolute $C^i_3H_7OH$. Nitrogen was bubbled through dry isopropanol and the mixture was stirred continuously and heated for 3 h at a temperature of 50°C. After that the mixture was cooled to room temperature, filtered and neutralized with KOH. The mixture was then cooled in an ice bath, the precipitate, $[(C^i_3H_7O)_2PS(S)K]$, formed was collected, washed with C_2H_5OH and dried at room temperature.

Preparation of the complexes. The complexes $Cu[(C^i_3H_7O)_2PS_2]_2$, $Pd[(C^i_3H_7O)_2PS_2]_2$ and $Pt[(C^i_3H_7O)_2PS_2]_2$ were obtained by mixing aqueous solutions of the corresponding $^{63}CuCl_2$ (obtained as CuO from AERE, Harwell and transformed in $CuCl_2$), K_2PdCl_4 (Fluka) and K_2PtCl_4 (Fluka) and the potassium salt of the ligand, $(C^i_3H_7O)_2PS(S)K$. The complexes precipitated were collected and recystallized from $CHCl_3$.

Single crystals of $Pd[(C^i_3H_7O)_2PS_2]_2$ suitable for X-ray study were obtained by slow evaporation of a chloroform/n-heptane (1 : 1 v/v) solution of $Pd[(C^i_3H_7O)_2PS_2]_2$ in an open beaker.

Preparation of magnetically diluted $^{63}Cu/Pd[(C^i_3H_7O)_2PS_2]_2$ and $^{63}Cu/Pt[(C^i_3H_7O)_2PS_2]_2$ powder and single-crystal samples. The powdered sample of $^{63}Cu/Pt[(C^i_3H_7O)_2PS_2]_2$ has been obtained by the exchange of approximately 2% platinum(II) with copper(II) from $CHCl_3$–water solutions. After intensive shaking for 30 min, or 12 h staying of the mixture, the organic phase was separated and evaporated.

The sample of $^{63}Cu/Pd[(C^i_3H_7O)_2PS_2]_2$ was prepared by dissolving the corresponding palladium(II) and copper(II) complexes (in a ratio of 98 : 2) in $CHCl_3$, followed by evaporation of the solvent. The magnetically diluted single-crystals of $^{63}Cu/Pt[(C^i_3H_7O)_2PS_2]_2$ and $^{63}Cu/Pd[(C^i_3H_7O)_2PS_2]_2$, suitable for EPR measurements, have been obtained by slow evaporation of their chloroform/n-heptane (1 : 1 v/v) solutions in an open beaker.

EPR measurement

All EPR spectra were recorded on a Bruker ER 200-D SRC X band spectrometer at room temperature using 100 kHz modulation of the magnetic field. The microwave frequency of each EPR spectrum was calculated from the line position of a point standard of powdered DPPH fixed on the bottom side of the cavity. A two-circle goniometer (Bruker G-2) was used for the orientation and rotation of the single-crystal samples in the magnetic field. The EPR spectra were taken every 10° in three mutually perpendicular planes. All spectra were acquired using the specialized module described in reference 4. The post-acquisition processing and manipulation of the spectra were performed on an IBM compatible PC using a special program prepared in this laboratory. A conventional spin-Hamiltonian parameter [eq. (1)] for this kind of paramagnetic species ($S = 1/2$, $I \neq 0$) was used to describe the experimentally obtained EPR spectra.

$$\mathcal{H} = \beta HgS + SAI + IQI - g_n\beta_n HI. \quad (1)$$

All the symbols in eq. (1) have their usual meaning. A perturbation approach with first- and second-order corrections to the energy levels with respect to the hyperfine, quadrupole and nuclear Zeeman coupling was used to get the relationship between the line positions for a given direction of the magnetic field and the components[5,6] of the tensors. Because this relationship is very complex a modified simplex procedure[7] was used to obtain the best estimation of the components of various tensors. A criterion for goodness of fit is the quantity

$$S = \left\{ \frac{1}{N(2I+1)} \sum_{i=1}^{N} \sum_{m_I=-I}^{I} [h\nu_i - f(i, m_I, P_\alpha)]^2 \right\}^{1/2}, \quad (2)$$

where N is the number of single-crystal spectra, ν_i the microwave frequency for the ith spectrum, I the spin of the central nucleus and P_α the components of the tensors. In all cases the minimum value of $S = 0.5 \times 10^{-4}$ cm^{-1}, which is comparable with the experimental error in measuring line positions (0.5 G), was chosen as a goodness-of-fit. After this fitting the g, A and Q tensors were diagonalized and their principal values, as well as their principal direction with respect to the laboratory reference frame, were obtained. Based on these data, powdered spectra of the samples were simulated and the best fit with the experimentally-recorded powdered spectra was found. The powdered EPR spectra were simulated using a computer program written on the basis of Pilbrow's algorithm[8,9] and assuming a Lorentz line shape in all cases.

X-ray study

A brown prismatically-shaped crystal of $Pd[(C^{i}_{3}H_7O)_2PS_2]_2$ with approximate dimensions $0.25 \times 0.28 \times 0.12$ mm was investigated at 290 K on an Enraf–Nonius CAD-4 diffractometer (graphite monochromator, Mo-K_α radiation, $\lambda = 0.70930$ Å). Crystal data: $C_{12}H_{28}PdO_4P_2S_4$, $Mr = 532.96$, triclinic system, space group $P\bar{1}$, $a = 6.379(1)$, $b = 8.449(1)$, $c = 10.977(3)$ Å, $\alpha = 99.89(1)$, $\beta = 97.04(1)$, $\gamma = 99.42(1)°$, $V = 568$ Å^3, $Z = 1$, $D_x = 1.558$ g cm^{-3}, $\mu = 13.1$ cm^{-1}, $F(000) = 272$.

The intensities were collected in an $\omega/2\theta$ scan mode with $\Delta\omega = [0.9 + 0.4 \tan\theta]°$. In total 5464 reflections were measured in the range $\sin\theta/\lambda < 0.660$ (h: -8 to 8, k: -11 to 11, l: -14 to 14). Three standard reflections were monitored every 2 h and exhibited intensity variation less than 0.4%. Lorentz, polarization and empirical absorption corrections (transmission factor 0.9424–0.9996) were applied. From 2732 unique reflections with $R(\text{int}) = 0.012$, 2413 with $I > 3\sigma(I)$ were used in further calculations. The structure was solved by the heavy-atom method by placing a palladium atom in the origin ($Z = 1$). Subsequent full-matrix least-squares refinement on Fs, followed by difference Fourier syntheses, revealed the remaining atoms. The positions of the hydrogen atoms were geometrically regularized and included in the final refinement as riding atoms, with fixed $U = 0.06$ Å^2. Final $R = 0.020$, $wR = 0.033$ and $S = 1.356$; $w = 4F_o^2/[s(F_o)^2]^2$. Max. $(\Delta/\rho) = 0.007$; max. and min. residual densities 0.31 and -0.57 e Å^{-3}. Atomic scattering factors and anomalous-dispersion coefficients were used as coded in the SDP/PDP V3.0 software (Enraf–Nonius, 1985).[10] Positional and thermal parameters have been deposited along with tables of F_o/F_c values.

RESULTS AND DISCUSSION

Single-crystal EPR study

Single crystal EPR spectra of $^{63}Cu/Pt[(C^{i}_{3}H_7O)_2PS_2]_2$ and $^{63}Cu/Pd[(C^{i}_{3}H_7O)_2PS_2]_2$ for two different arbitrarily chosen orientations with respect to the laboratory coordinate system are shown in Figs 1 and 2. Due to the hyperfine (hf) interaction with the ^{63}Cu nucleus ($I = 3/2$), both spectra consist of four hf lines. In addition, each hf line is further split into three lines with relative intensities 1:2:1, as a result of the superhyperfine (shf) interaction between $^{63}Cu^{II}$ unpaired electrons and two equivalent ^{31}P nuclei. Independently of the sample's orientation the shf splitting constant was evaluated to be 9.5 G. This result is in

agreement with the previous studies of other copper/nickel dialkyl-dithiophosphate[11] or -dithiophosphinate single-crystal samples.[12] The appearance of only one set of four hf lines suggests the presence of one molecule per unit cell of the platinum and palladium hosts. This finding is supported by both available crystallographic data for the platinum(II)[13] host and the results of our X-ray structural studies (*vide infra*). The principal values of A, g and Q tensors from single-crystal EPR measurements, as well as the angles between their principal directions, are collected in Table 1. The proximity of g_x and g_y, as well as the relation $g_x \approx g_y < g_z$, suggests nearly axial symmetry of the complexes studied and that the unpaired electron occupies predominantly the $d_{x^2-y^2}$ orbital. It is worthwhile to note, however, that the tensors are nearly axial ($g_x \approx g_y$, $A_x \approx A_y$), and hence the error (see Table 1) in the determination of the angles (g_{xx}, A_{xx}) and (g_{yy}, A_{yy}) is relatively high. Moreover, because the principal values of the quadrupole tensors obtained are much smaller than that of hf and shf interactions and are close to the limit of experimental error, the results were not considered reliable.

Crystallography

The centrosymmetric $Pd[(C^{i}_{3}H_7O)_2PS_2]_2$ molecule and the atom numbering scheme is depicted in Fig. 3. Selected interatomic distances and angles are given in Table 2.

The palladium atom disposed at the centre of symmetry is coordinated by four sulphur atoms at an average distance of 2.340(1) Å, the five-atom assembly being necessarily planar. The intramolecular Pd ··· P distance is 2.975(1) Å. The phosphorus atom deviates from the PdS_4 plane only by 0.077 Å, but the atom-to-plane distances of O(1) and O(2) are significantly different (−1.025 and 1.305 Å, respectively). The PS_2O_2 tetrahedron is highly distorted with angles varying from 95.89(8)° [O(1)—P—O(2)] to 114.64° [S(1)—P—O(2)].

sulphur and two carbon atoms, i.e. Pd···S(2) 4.5069(6) $(1+x, y, z)$, Pd···C(3) 4.261(3) $(x, y-1, z)$ and Pd···C(5) 4.304(3) Å $(x, y-1, z)$. The presumed orientation of the methyl hydrogen atoms at C(3) and C(5) is accompanied by the formation of short Pd···H(32) and Pd···H(52) linkages of 3.39 and 3.43 Å $(x, 1-y, z)$, respectively. The shortest Pd···Pd distance of 6.379(1) is realized along the *a*-axis. The palladium complex is isopointal to Pt $[(C^i_3H_7O)_2PS_2]_2$[13] and their molecular geometries are identical within the accuracy limits. It should be mentioned that the observed difference in the two Pd—S bond lengths of 0.01 Å takes place in the platinum complex as well. Hence, the two coordinative bonds are intrinsically different in both structures.

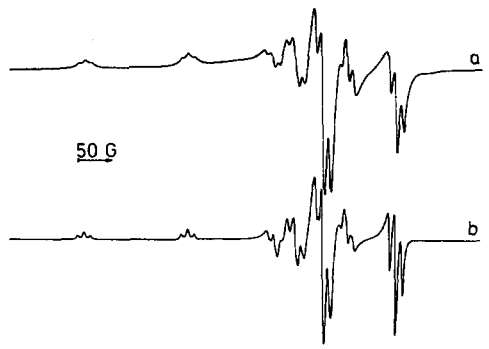

Fig. 5. EPR spectra of $^{63}Cu/Pt[(C^i_3H_7O)_2PS_2]_2$: (a) experimentally-recorded powdered spectrum; and (b) simulated spectrum with the parameters given in Table 5.

Powdered EPR measurements

The experimentally-recorded powdered EPR spectra of the samples $^{63}Cu/Pt[(C^i_3H_7O)_2PS_2]_2$ and $^{63}Cu/Pd[(C^i_3H_7O)_2PS_2]_2$ are shown in Figs 5(a) and 6(a) and their calculated EPR parameters are presented in Table 3. Comparing the principal values of g and A tensors obtained from single-crystal

measurements, collected in Table 1, with those received from powdered spectra (Table 3) shows a small difference between them. This difference may be considered as quite normal taking into account the fact that the line-widths in the powdered spectra are greater, and thus the uncertainty in the determination of g and A is relatively high.

An attempt to use computer-aided EPR spectroscopy to verify the quadrupole tensor components and the angles (g_x, A_x) *and* (g_y, A_y). The results of the studies summarized[1-3,12-18] in Table 4 on determining the quadrupole coupling constants from single-crystal EPR and ENDOR measurements of different copper(II) complexes show values which vary over a wide range. The great difference

[a] Abbreviations used: *Cu(dto)* = *bis(dithiooxalate)cuprate(II)*, *Cu(mnt')* = *bis(1,1-*dicyano-2,2-dithioethylene)cuprate(II), $Cu(mnt)_2$ = bis(1,2-dicyano-1,2-dithioethylene) cuprate(II), $Cu(dtc)_2$ = bis(dithiocarbamate)cuprate(II), $Cu(Et_2dtp)_2$ = bis(diethyldithiophosphate)copper(II), $Cu(SdbmO)_2$ = bis(*cis*-monodithiodibenzoilmethanate) copper(II) and $Cu(acac)_2$ = bis(acetylacetonate)copper(II).

between the results obtained from the EPR studies of the different authors and the deviations from the values resulting from ENDOR spectroscopy, which possess approximately 10^3 times higher resolution than the former one, typically occur. Having this in mind the conclusion was made that single-crystal EPR measurements are not precise enough to obtain values of quadrupole coupling in copper(II) complexes. On the other hand, however, some authors have used a computer-simulation procedure of powdered spectra of copper(II) chelate complexes in order to obtain this kind of data. In view of this we also tried to explore this approach to obtain more precise values on the quadrupole constants as well as about the angles (g_i, A_i).

The simulation of the powdered spectra of $^{63}Cu/Pt[(C^i_3H_7O)_2PS_2]_2$ and $^{63}Cu/Pd[(C^i_3H_7O)_2PS_2]_2$ with the exact values obtained from the single-crystal spectra (Table 1) do not agree well with the experimentally-recorded powdered EPR spectra. Therefore, it was necessary to search such EPR parameters which would lead to the best fit between experimentally obtained and theoretically simulated spectra. In order to find some information about the principal values of Q tensors as well as the angles (g_i, A_i), where $i = x$ or y, we have simulated the powdered EPR spectra using the principal values of g and A tensors shown in Table 1 as a precursor and varying Q_i and angles (g_i, A_i), respectively. The powdered EPR spectra thus simulated and showing best fit with the experimental ones are presented in Figs 5(b) and 6(b); the corresponding parameters are shown in Table 5. It is seen from Table 5 that for the $^{63}Cu/Pt[(C^i_3H_7O)_2PS_2]_2$ sample the principal values of A_x and A_y used for the simulation of the powdered spectra deviate slightly from the single-crystal data (within *ca* 2×10^{-4} cm^{-1}) and are close to higher in-plane values (A_y) obtained by single crystal measurements. For $^{63}Cu/Pd[(C^i_3H_7O)_2PS_2]_2$ the A values used for simulation are averaged between A_x and A_y from the single-crystal data, and the difference is greater (about 6×10^{-4} cm^{-1}). The principal values of the g tensor obtained from single-crystal data used for the simulation are in very good agreement with $^{63}Cu/Pt[(C^i_3H_7O)_2PS_2]_2$, whereas for $^{63}Cu/Pd[(C^i_3H_7O)_2PS_2]_2$ the values of g_x and g_y, in which the best-fit appears, are higher in comparison with single-crystal results. It was found that the angle (g_x, A_x) has no influence on the shape and EPR parameters of the simulated powdered spectra.

In the process of searching for the best fit between simulated and powdered spectra, a series of simulations were performed by varying the quadrupole coupling constants in the range 1×10^{-4}–10×10^{-4} cm^{-1} at fixed g and A values. The best fit was found for Q values shown in Table 5. As can be seen these values vary significantly from those obtained by single-crystal EPR measurements (Table 1). This is not surprising, because the literature data also show considerable differences between the Q values obtained by single-crystal EPR and ENDOR measurements, as well as the computer-simulated powdered spectra. Some of these data are collected in Table 4. All these results show that the determination of the quadrupole coupling constant obtained from single-crystal, powdered and simulated-powdered EPR spectra can give satisfactory information for the order of this interaction only, not for its exact value.

Abstract—The first indenyl complexes of germanium(II), $Ge(1,3\text{-}(Me_3Si)_2C_9H_5)_2$ (**1**) and $Ge(1,3\text{-}(Me_3Si)_2C_9H_5)(Me_5C_5)$ (**2**), have been prepared by treatment of $Li(1,3\text{-}(Me_3Si)_2C_9H_5)$ with $GeCl_2 \cdot$ dioxane and $[(\eta\text{-}Me_5C_5)Ge]BF_4$, respectively. The structure of **2** has been determined by X-ray crystallography.

The indenyl ligand has proved to be of importance in transition metal chemistry[1] due to the stabilization of the η^3-bonding mode in the cyclopentadienyl ring and the consequent enhanced rate of ligand substitution (the so-called "indenyl effect"[2]). Interestingly, this ligand system has been seldom used in the context of main group chemistry.[3] Here we report $Ge(1,3\text{-}(Me_3Si)_2C_9H_5)_2$ (**1**) and $Ge(1,3\text{-}(Me_3Si)_2C_9H_5)(Me_5C_5)$ (**2**), the first indenyl complexes of germanium. The X-ray crystal structure of **2** has been determined.

1,3-Bis(trimethylsilyl)indenyllithium was prepared from indene using the Bu^nLi/Me_3SiCl procedure described by Merola *et al.*[4] Tetrahydrofuran (80 cm^3) was added via a syringe to a cooled (−78°C) Schlenk flask, which had been loaded previously in a dry-box with $GeCl_2 \cdot$ dioxane (1.0 g, 4.32 mmol) and $Li(1,3\text{-}(Me_3Si)_2C_9H_5)$ (2.29 g, 8.64 mmol). The reaction mixture was allowed to assume ambient temperature and stirring was continued for 1 h thereafter. After removal of the solvent and volatiles by evacuation, the resulting orange residue was recrystallized from pentane to afford yellow crystalline **1** in 59% yield. Analytical

* Author to whom correspondence should be addressed.

data* are in accord with the formula $C_{30}H_{46}GeSi_4$. The ^1H and $^{13}C\{^1H\}$ NMR spectra for **1*** are indicative of a symmetrical sandwich-type structure with either an η^5- or η^3-attachment of germanium to the five-membered rings of the indenyl substituents. Kohler[5] has pointed out that for (unsubstituted) indenyl complexes, the hapticity can be assigned on the basis of the ^{13}C chemical shifts of the ring carbon atoms. For η^3-attachment, for example, the slip-fold distortion of the five-membered ring results in C(1)—C(3) being more shielded than C(8) and C(9).† This is not the case for **1**. Although the C(1)/C(3) resonance is more shielded than that of C(8)/C(9), the C(2) resonance appears at almost the same frequency as the latter. The ^{13}C NMR argument therefore leads to the conclusion that the germanium is attached in an η^5-fashion in **1**. Unfortunately, the crystals of this material proved to be unsatisfactory for X-ray analysis. It was, therefore, necessary to prepare another indenyl derivative of germanium(II).

(Pentamethylcyclopentadienyl)(2,6-bis(trimethylsilyl)indenyl)germanium(II) was prepared in a similar manner to that described for **1** using $[(\eta\text{-}Me_5C_5)Ge]BF_4$[6] (0.6 g, 4.48 mmol) and $Li[1,3\text{-}(Me_3Si)_2C_5H_9]$ (0.54 g, 2.03 mmol). After recrystallization from pentane (−30°C) the yield of orange crystalline **2** was 57% (0.54 g). Analytical data* are consistent with the composition $C_{25}H_{38}GeSi_2$ and the ^1H and $^{13}C\{^1H\}$ NMR data are similar to (a) those of η^5-bonded Me_5C_5-substituted germanium(II) compounds, and (b) those of **1**. An X-ray diffraction study‡ was undertaken to clarify the bonding arrangement in **2**. Individual molecules of **2**, which are well separated in the solid state, comprise a sandwich-type structure in which the germanium is bonded to an Me_5C_5 ring and the five-membered ring of the indenyl group (Fig. 1). Although there is a scatter in the ring-Ge distances due to "ring slippage", the Me_5C_5 group is best regarded as η^5-bonded. The five-membered ring of the indenyl substituent is planar, the maximum deviation from planarity being 0.01 Å. There is a very slight folding of this ring about the C(21)—C(28) vector (3.3°); however, the bonding to germanium is closest to η^5. Interestingly, there is a large difference (~0.4 Å) in the two ring centroid/germanium distances. The observation that this distance is shorter for the Me_5C_5 ring (2.066 Å) than the indenyl ring (2.438 Å) implies that the bonding of the latter to germanium is appreciably weaker. Finally, we note that the ring centroid/germanium/ring centroid angle (163.0°) is very close to that found in the sterically encumbered germanocene $[(C_6H_5CH_2)_5C_5]_2Ge$ (163.1°).[7]

(*Received* 4 *September* 1992; *accepted* 1 *October* 1992)

Abstract—The synthesis of iodoferrocenes using stannylferrocenes as key intermediates is described. The method is suitable for the bulk preparation of iodoferrocenes.

There has been a definite resurgence in the chemistry of metallocenes and in particular ferrocene chemistry in the past year or so. This comes with the recognition that ferrocene may be a useful synthon in the rapidly expanding areas of "new material science", for example in molecular ferromagnets,[1,2] molecular sensors[3,4] and self assembly.[5–7]

A significant proportion of ferrocene-based synthetic work relies on a few key reagents such as lithio-ferrocenes,[8,9] ferrocenylcarboxaldehydes,[10,11] ferrocenylcarboxylic acids[12] and haloferrocenes.[12–14] The conventional synthesis of haloferrocenes has been via either ferrocenylmercury reagents[15–17] or ferrocenyl boronic acids,[18] or the direct reaction of lithioferrocenes with hexachloroethane,[19] tetrabromodichloroethane or iodine[20] (Scheme 1). We have made use of these synthetic procedures for several years and have found them to be satisfactory; however, yields of iodoferrocenes tend to be low and variable. In one of our current research projects we require large quantities of iodoferrocene and, therefore, we decided to look for an alternative synthesis which would give more predictable and higher yields and at the same time be economically acceptable. A reasonable route seemed to be via organo-tin compounds since the halogen/organotin exchange reaction is well established. Wright has published the synthesis and use of 1,1′-bis-(tri-n-butylstannyl)ferrocene and its use as a precursor to monolithioferrocenes:[21] this reagent seemed well suited as a synthetic intermediate since the precursors required are inexpensive.

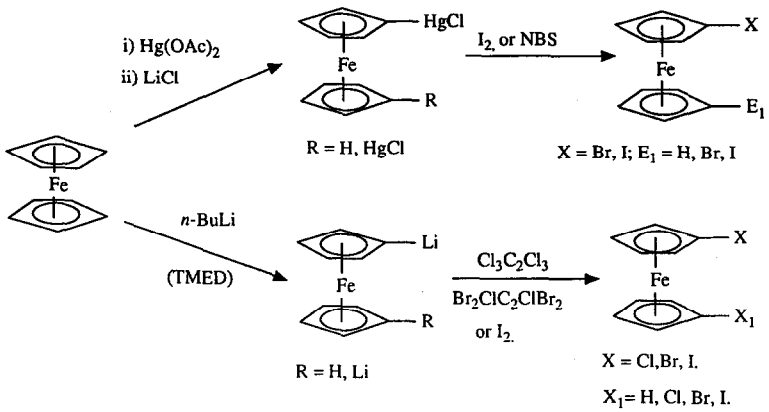
EXPERIMENTAL

Bis-tri-n-butylstannylferrocene (BSSF) or tri-n-butylstannylferrocene (BSF) were prepared by the literature procedure and purified by repeated chromatography on a neutral alumina support where pure samples were required. In some experiments crude BSSF and BSF were used, which had been purified by one chromatographic separation only. Bis-triphenylstannylferrocenes and triphenylstannylferrocene were prepared by reaction of dilithioferrocene or monolithioferrocene, respectively, with chlorotriphenyltin and were crystallized prior to use.

Reaction of crude BSF or BSSF with I_2

A cooled (approx -70°C) sample of either crude (isolated without column chromatography) BSF or BSSF (0.25 mol) in dichloromethane (1000 cm^3) was treated with I_2 (0.27 mol or 0.54 mol I_2, respectively) under a nitrogen atmosphere. The mixture was allowed to warm to room temperature and was stirred overnight. The mixture was then washed twice with 1 M solutions of sodium thiosulphate (200 cm^3), the organic layer separated and flashed through a small portion of neutral alumina. The

* Author to whom correspondence should be addressed.



Scheme 1.

solvent was then removed on a rotary evaporator to leave a viscous oil which was dissolved in MeOH (1000 cm^3). Excess KF (50 g) was then added to precipitate the stannyl by-products. The precipitated material ws removed by filtration and the MeOH was removed *in vacuo*. The solid/oil was then extracted with several portions of diethyl ether, again flashed through an alumina plug and the solvent removed to give an amber oil. ^1H NMR indicated the product iodo- or di-iodoferrocene was in each case contaminated with butyl-tin derivatives. Further separation and isolation of the iodo- or di-iodoferrocene were attempted but found to be extremely difficult except on small scale chromatographic purifications on neutral alumina.

Reaction of pure BSF or BSSF with I_2 *or* ICl

Identical reactions to the above method were carried out using pure bis-tri-n-butylstannylferrocene or tri-n-butylstannylferrocene on scales of up to 100 g of the starting compounds. These yielded pure 1,1′-di-iodo- or iodoferrocene, respectively, as amber oils without the need for chromatography. Yields are > 80% on average.

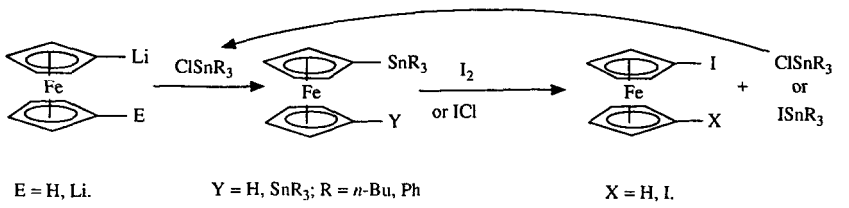
An identical reaction procedure using ICl in place of I_2 gave higher yields (> 90%) of the appropriate iodoferrocene.

Reaction of pure triphenylstannylferrocenes with ICl

The reaction of bis-triphenylstannylferrocene with ICl on a 0.2 mol scale gave bis 1,1′-diiodoferrocene as the sole ferrocene containing product. A similar methodology to the above was used except that it is not necessary to use KF since the by-products are not soluble in weakly polar solvents. For the work-up the solvent was removed from the crude reaction mixture and the product di-iodoferrocene was extracted into the diethyl ether and purified by passing the yellow product solution through an alumina plug. The yields using this procedure were > 85%. Similar treatment of triphenylstannylferrocene with ICl gave iodoferrocene again in high yield.

RESULTS AND DISCUSSION

The syntheses of tri-n-butylstannylferrocene (BSF) and 1,1′-bis-n-(tri-n-butylstannyl)ferrocene (BBSF) are straightforward.[21] The compounds are prepared from lithioferrocenes by reaction with tri-n-butylstannyl chloride and are obtained as golden brown oils. Purification of the product compounds is effected using column chromatography on a neutral alumina support, using hexane as an eluent. In the case of BBSF synthesis when the reactions were scaled up (> 50 g) the chromatographic purification became more difficult unless extremely large quantities of alumina were used. The ferrocene and BSF were easily removed from the BBSF; however, tetrabutyltin was more difficult to remove on a large scale. On treamtent of pure BBSF with I_2 or ICl the 1,1′-di-iodoferrocene cleanly forms in near quantitative yield and thus provides a viable alternative route for the synthesis of di-iodoferrocene. The product iodoferrocenes are isolated by removal of the co-produced stannyl chlorides or iodides. This was achieved by treatment of the crude reaction mixtures with KF in methanol, followed by filtration to remove the precipitated tri-n-butylstannylfluoride. Since it would be advantageous to use crude BSF or BBSF, attempts were made to use unchromatographed samples arising directly from the reaction of lithioferrocenes with tri-n-butylstannyl chloride. However, the actual isolation of the product posed problems, especially when carried out on a large scale (> 50 g). The problem



E = H, Li. Y = H, SnR_3; R = *n*-Bu, Ph X = H, I.

Scheme 2.

arises from residual impurities such as tetrabutyltin (formed by reaction of butyllithium with the tributylstannyl chloride) without several chromatographic steps.[22] Therefore, it is important to use pure 1,1′-bis-tri-n-butylstannylferrocene as the starting compound and not to proceed with an impure mixture—the best check of sample purity (BBSF or BSF) is to use the integration of the ^1H NMR cyclopentadienyl signals versus those of the butyl resonances as the basis for evaluation. Using pure 1,1′-bis-tri-n-butyl stannylferrocene we have been able to prepare > 100 g quantities of di-iodoferrocene in one batch. The drawback is that the alumina required for purification of the stannylferrocenes is now rather expensive. We therefore decided to examine the use of tri-phenylstannylferrocenes, which are solids and are easily purified by crystallization. Using the same methodology we have found that di-iodoferrocene is readily obtained in the same manner without the problems caused by impurities. The drawback here, however, is that chlorotriphenyltin is more commercially expensive than the butyl compound so that may limit large scale application.

In principle, the halo-stannyl by-products could be recycled (Scheme 2, step 1). We are currently attempting modifications to the isolation procedure which would allow this. Small scale experiments indicate that the procedure is applicable to the synthesis of bromoferrocenes; however, the yields are considerably diminished presumably caused by the direct side-reaction of bromine with ferrocene.

NUCLEAR MAGNETIC RESONANCE STUDIES OF MULTINUCLEAR CHROMIUM ASSEMBLIES

M. M. GLASS, K. BELMORE and J. B. VINCENT*

Department of Chemistry, University of Alabama, Tuscaloosa, AL 35487, U.S.A.

(*Received* 27 *July* 1992; *accepted* 5 *October* 1992)

Abstract—^{1}H NMR and ^{2}H NMR resonances of a series of oxo-centred trinuclear chromium complexes of the form $[Cr_3O(O_2CR)_6(L)_3]^+$ (R = —CH_3, —CH_2CH_3, —Ph, -4-MePh; L = H_2O, py, 2-Mepy, 3-Mepy, 4-Mepy) have been observed and assigned. The role of π- and σ-bonding frameworks in the delocalization of unpaired electron density onto the ligand protons is examined. The π-delocalization mechanism dominates where ligands contain aromatic substituents or carboxylate functionalities, consistent with the presence of a metal centre where unpaired electrons reside solely in t_{2g} orbitals. A comparison of the importance of these mechanisms with that in trinuclear manganese and iron complexes is reported. These results suggest that ^{1}H and ^{2}H NMR studies could be useful probes of proteins containing coupled multinuclear chromium assemblies.

Trinuclear oxo-centred metal carboxylate assemblies of the general composition $[M_3O(O_2CR)_6L_3]^{n+}$ have been of intense interest since the first structure determination by X-ray diffraction in 1965,[1] as emphasized by the appearance of a recent review article.[2] The importance of these compounds rests in their potential to serve as models to test theories of magnetic coupling between metal ions in multinuclear systems.[2–8] Hence, the properties of these systems, most specifically examples where M = Cr, Fe, or Cr and Fe, have been examined by a wide range of magnetic and spectroscopic techniques including variable-temperature magnetic susceptibility, inelastic neutron scattering, Mössbauer spectroscopy, etc.[2,9] However, nuclear magnetic resonance studies have only rarely been reported and are especially lacking on the M = chromium series. The trivalent oxidation level of chromium dominates the chemistry of the chromium-containing trinuclear assemblies. Each octahedrally-coordinated Cr^{III} thus supplies three unpaired electrons; however, antiferromagnetic coupling between the chromium centres reduces the effective magnetic moment of the complexes. As a consequence, observations of paramagnetically-shifted (and broadened) ^{1}H NMR resonances should be possible and provide information on the electronic environment.

In addition, the feasibility of ^{1}H NMR as a probe of chromium-containing proteins can be addressed using these trinuclear assemblies. Low molecular-weight chromium-binding substance is an oligopeptide that reportedly binds four Cr^{III} ions and serves as a chromium detoxifying agent and has a role in the potentiation of insulin action.[10,11] Charge considerations and the high ratio of chromium to amino acid residues (over half of which are aspartate or glutamate)[10,11] suggest that this protein contains an anion-bridged multinuclear chromium carboxylate assembly.

Herein are reported the successful observation and assignment of ^{1}H NMR resonances of $[Cr_3O(O_2CR)_6L_3]^+$ complexes and a discussion of the mode of spin delocalization in these systems.

EXPERIMENTAL

Syntheses

$[Cr_3O(O_2CMe)_6(H_2O)_3]Cl$,[12] $[Cr_3O(O_2CMe)_6(py)_3]ClO_4$,[13] $[Cr_3O(O_2CMe)_6(3\text{-Mepy})_3]ClO_4$,[12] $[Cr_3O(O_2CCH_2CH_3)_6(H_2O)_3]NO_3$,[3] $[Fe_3O(O_2CMe)_6(py)_3]ClO_4$[13] and $[Mn_3O(O_2CMe)_6(py)_3]ClO_4$[6] were prepared as described elsewhere. $[Cr_3O(O_2CMe)_6(X\text{-Mepy})_3]ClO_4$ (X = 2, 3, 4) were pre-

* Author to whom correspondence should be addressed.

pared in an analogous fashion to $[Cr_3O(O_2Me)_6(py)_3]ClO_4$ using the appropriate substituted-pyridine for pyridine. Compounds containing deuterium-labelled ligands were prepared in an analogous fashion to the protio analogues substituting DO_2CD_3, $DO_2CC_5D_5$, D_2O or NC_5D_5 as required. Reagents were obtained commercially and used as received.

$[Cr_3O(O_2CPh)_6(py)_3]ClO_4 \cdot 1.1CH_2Cl_2$. $Cr(ClO_4)_3 \cdot 6H_2O$ (18.70 g, 40.79 mmol) and benzoic acid (12.20 g, 99.90 mmol) were stirred in pyridine (100 cm^3). The mixture was refluxed for 4 h and allowed to cool to room temperature. The solution was filtered to reveal green microcrystals of the product. The microcrystals were washed copiously with diethylether and dried *in vacuo*. Yield: *ca* 65% based on chromium. Recrystallization may be accomplished from CH_2Cl_2/hexanes (or hot MeCN). Found: C, 52.2; H, 3.2; N, 3.2; Cl, 8.4; Cr, 11.4%. Calc. for $C_{58.1}H_{47.2}N_3O_{17}Cl_{3.2}Cr_3$: C, 52.5; H, 3.6; N, 3.2; Cl, 8.5; Cr, 11.7%.

NMR spectroscopy

^1H and ^2H spectra were obtained using a Bruker AM-360 spectrometer and a Bruker AM-500 spectrometer, respectively at *ca* 23°C. Chemical shifts are reported on the δ scale (shifts downfield are positive) using the solvent protio- or deutero-impurity signal(s) as a reference. Assignments were made on the basis of relative intensities and broadening and by substitution of appropriate ligands.

Other methods

Elemental analyses were performed at Galbraith Laboratories, Knoxville, TN, U.S.A. The purity of synthetic compounds was examined by IR (Nujol mull) spectroscopy, using a Perkin–Elmer 283 B spectrophotometer.

RESULTS AND DISCUSSION

Trinuclear oxo-centred metal carboxylate assemblies have the general structure shown in Fig. 1. The three metal centres and the μ_3-oxide are coplanar. Each pair of chromic ions are bridged by two carboxylate ligands; coordination about each octahedral Cr^{3+} ion is completed by a single terminal ligand, usually H_2O or pyridine. Each chromic ion, d^3, has each of its three unpaired electrons occupying a t_{2g} orbital, directed between the ligands. Chromium(III) complexes are thus magnetically isotropic or nearly so, and their dipolar shifts should be quite small or negligible.[14] Hence, isotropic shifts should be essentially solely contact

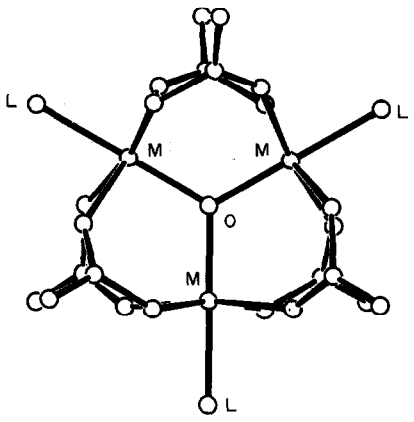

Fig. 1. General structure of oxo-centred trinuclear carboxylate assemblies.

in origin. This is counterbalanced by the long electronic spin-lattice relaxation time of isolated chromic ions, which renders ^1H NMR resonances of their coordination complexes difficult to observe. Reduction of the magnetic moment per Cr^{3+} ion as a result of antiferromagnetic coupling in the carboxylate assemblies (μCr for $[Cr_3O(O_2CMe)_6(py)_3]^+$ is 3.14 μ_B[13] vs *ca* 3.87 μ_B for mononuclear species) might yet allow the observation of such resonances.

The ^1H NMR spectrum of the simplest of these trinuclear compounds, $[Cr_3O(O_2CMe)_6(H_2O)_3]Cl$, displays only a single downfield-shifted, slightly broad ($\sim$ 2.4 ppm wide at half height) resonance in the range -100 to $+200$ ppm (Table 1 and Fig. 2). Comparison of this spectra with those of other acetate complexes where the terminal H_2O is substituted with another ligand (*vide infra*) reveals that this resonance is retained; thus, this signal is readily assigned to the methyl protons of the bridging acetate ligands. This compares favourably with ^2H NMR signals of O_2CCD_3-bridged chromium dimers ($+40$ to $+60$ ppm).[15] The protons of the water ligands because of their proximity to the chromium centres (separated by one oxygen in the σ-bonding framework) are broadened beyond detection. However, by using ^2H NMR signals in a given environment should be narrower than the corresponding ^1H NMR signal by up to $\gamma_H^2/\gamma_D^2 = 42.5$, where γ_H and γ_D are the gyromagnetic ratios of the proton and deuteron, respectively; a narrowing by a factor of 42 has been reported previously for $Cr(acac)_3$.[16] In contrast to the ^1H spectra, the aquo deuteron signal is readily observed by ^2H NMR for the D_2O analogue $[Cr_3O(O_2CMe)_6(D_2O)_3]^+$ (Table 2 and Fig. 3).

[d] Very broad.
[e] Superimposed on methyl resonance from *p*-toluate ligand.

$CH_2CH_3)_6(H_2O)_3]^+$ correspondingly shows two features. The ratio of the areas of the two signals is 1.5 : 1.0, with the least intense signal possessing the greater downfield shift (Table 1); this unambiguously identifies the strongly shifted feature with the methylene protons of the propionate ligand and is consistent with their closer proximity to the metal centres. It is of particular note that the methyl proton signal is shifted *upfield*, opposite the methylene protons. (The methyl proton signal of free propionic acid under similar conditions is at +1.04 ppm.) For bridging carboxylate ligands where the

metals and carboxylate moiety are co-planar, two mechanisms for spin delocalization are expected: σ and π, wth the π-pathway expected to predominate for protons more removed from the metal centre.[17] When substitution of a proton by a methyl group results in the methyl proton signal being shifted in the direction opposite the original proton, a π-spin delocalization is assumed to be in effect. As propionate can be considered to be a methyl-substituted acetate ligand, this provides clear evidence for a dominant π-pathway. In fact, the authors are unaware of any previous example of a bridging proprionate or similar carboxylate ligand where this methyl resonance is shifted upfield from the dimagnetic case, indicating the extreme dominance of this mechanism for chromium(III) complexes. (A shift of -6 ppm has been observed for a crotonate complex; crotonate has an extended π-system compared to propionate.[17])

To test the dominance of this π-delocalization mechanism, complexes with aromatic groups such as benzoate and pyridine (py) were examined. The ^{1}H NMR spectrum of $[Cr_3O(O_2CMe)_6(py)_3]^+$ contains two resonances in addition to that of the acetate methyl protons at +36.2 ppm (*vide supra*) (Table 1). This signal is unambiguously assigned as it is retained in the ^{1}H NMR spectrum of $[Cr_3O(O_2CMe)_6(NC_5D_5)_3]^+$ (Table 1). The upfield resonance from its position and width (0.6 ppm) is assigned to the 4-position proton; the broader (0.7 ppm) downfield resonance then corresponds to the 3-position proton, with the 2-position proton broadened beyond detection. (The signal assigned to the 4-position proton also integrates to appropriately half the area of the other.) Thus, the broadness [H(4) < H(3) < H(2)] and alternating sense of shift between the 3-position and 4-position protons is consistent with a strong π-delocalization pathway. In the ^{2}H NMR spectrum of the NC_5D_5 analogue, the 3-position and 4-position deuteron resonances are readily observable, as well as a third, broader signal, which is shifted strongly upfield and

assigned to the 2-position deuteron (Fig. 4 and Table 2). Substitution of the pyridine with 3-methyl-pyridine or 4-methylpyridine results in a decrease in intensity of or loss of the 3-position proton signal or 4-position proton signal, respectively, with the appearance of a new signal from the methyl group. In both cases, the sense of the isotropic shift of the methyl protons is opposite that of the replaced proton of the pyridine (Table 1), as expected for a π-delocalization pathway. For the 2-methyl-pyridine-

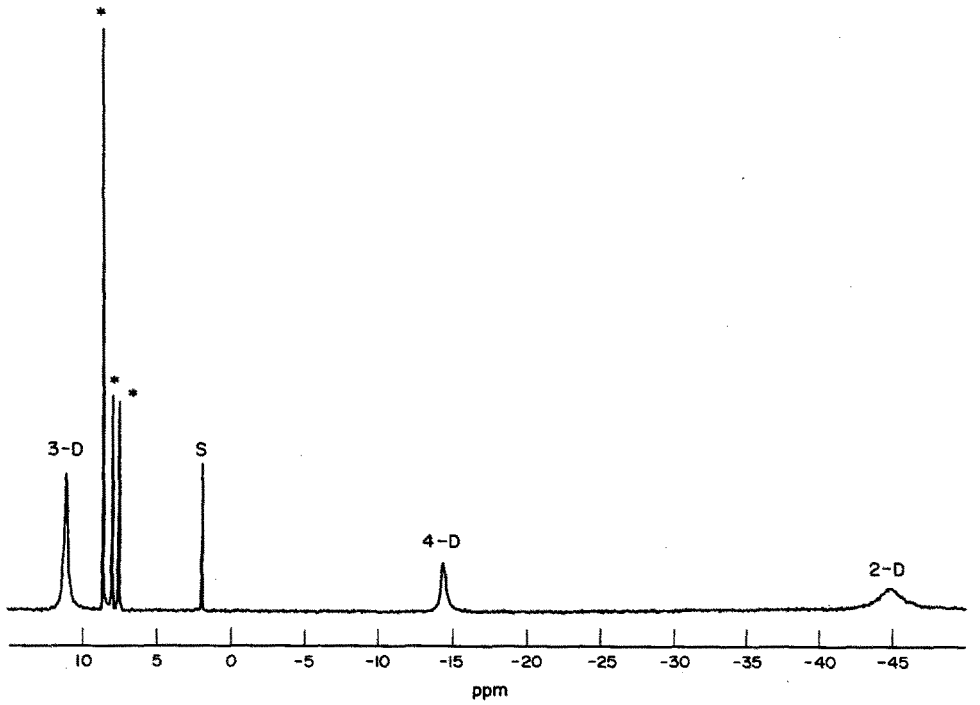

Fig. 4. ^2H NMR spectrum of $[Cr_3O(O_2CMe)_6(NC_5D_5)_3]^+$ in MeOH. * indicates a signal from added NC_5D_5 for comparison; S indicates the deutero-solvent impurity.

substituted complex, the methyl protons are shifted downfield (Table 1), opposed to the upfield shift of the deuterons in the 2-position of the NC_5D_5 complex.

As dipolar contributions to the isotropic shifts should be negligible, the ratio of the magnitude of the contact shifts of the pyridine protons/deuterons of the trinuclear complex and a previously reported mononuclear complex,[18] $[Cr(malonate)_2(d_5\text{-py})_2]^-$ ($\Delta H_{Cr_3}/\Delta H_{Cr}$), should approximate the ratio of the squares of the effective magnetic moments of the two species (μ_{eff}^2/μ_{eff}^2). The magnetic moment of the mononuclear complex has not been reported but can safely be assumed to be approximately the spin-only value for a d^3 system, 3.87 B.M. The ratio of the squares of the moments is then ~ 0.66. The ratio of the shifts (taken as the position of the proton/deuteron in the paramagnetic material compared to free pyridine under similar conditions) is 0.72 for the 3-position, 0.72 for the 4-position, and 0.68 for the 2-position. Thus, the magnitude of the shifts is controlled by the extent of coupling between chromic ions. The ability to detect ^1H NMR signals for the trinuclear compound and the need to use ^2H NMR for the mononuclear complex is a result of the relative broadness of the signals, which is also proportional to the effective magnetic moments and thus also linked to the extent of antiferromagnetic coupling.

This behaviour of alternating shifts about the pyridine ring is strongly in contrast to results previously reported for pyridine complexes of nickel(II) or cobalt(II), which suggest predominate σ-delocalization mechanisms,[19-22] but in agreement with the behaviour of a mononuclear chromium(III) NC_5D_5 complex.[18] This contrasting behaviour can be best understood by comparing the ^1H NMR spectrum of $[Cr_3O(O_2CMe)_6(py)_3]^+$ with those of its isostructural Mn^{III} and Fe^{III} analogues. For the Fe^{III} complex all three py resonances are downfield with the magnitude of the shifts of the order (2H > 3H > 4H) expected for a predominant σ-delocalization mechanism (Table 3 and Fig. 5). This reflects the different electron configuration of the ferric ions, d^5, which have two unpaired electrons in the e_g orbitals, directed along the metal–ligand σ-bonds. Octahedral nickel(II) and cobalt(II) ions also have two unpaired electrons in e_g orbitals. The acetate methyl signal for this complex is readily assigned by its intensity and displays a downfield shift of magnitude similar to the chromium compound.

Octahedral high-spin manganic ions are subject to a Jahn–Teller distortion, which removes the degeneracy of the e_g orbitals. If it is assumed the d_{z^2} orbital of each manganic ion is oriented along a Mn—oxide bond, the d_{z^2} orbital is destabilized and resides at a higher energy than the $d_{x^2-y^2}$ orbital. The $d_{x^2-y^2}$ orbital, which is oriented along the Mn—O (acetate) bonds, is then partially occupied. The d_{z^2} orbital is thus unoccupied. To a first approximation, the pyridine ring disposed *trans* to the oxide ligand would be expected to be influenced by only a π-spin delocalization pathway. Consequently, the pyridine protons experience alternating upfield and downfield shifts, consistent with a dominant π-delocalization mechanism (Table 3). The magnitude of the acetate methyl signal (assigned by its disappearance in the ^1H NMR spectrum of $[Mn_3O(O_2CCD_3)_6(py)_3]^+$) is greater than expected when compared to the magnitude of the pyridine proton signals. The NMR spectrum of the manganese complex is more complex than the chromium or iron compounds; manganese-ligated pyridine appears to be exchanging with free pyridine and perhaps solvent, resulting in a series of broad resonances between 5 and 15 ppm, which seem to obscure the 3-H pyridine resonance.

Table 3. Comparison of $[M_3O(O_2CMe)_6(py)_3]^+$ chemical shifts (ppm)

M	O_2CMe	py 2-H	py 3-H	py 4-H
Cr^{III} [a]	+36.2	n.o.[b]	+11.2	−14.4
Fe^{III} [c]	+30.4	+64.5	+29.0	+8.1
Mn^{III} [c]	+32.0	−63.0	[d]	−21.2

[a] d_4-MeOH.
[b] −45.1 ppm in ^2H NMR of NC_5D_5 analogue.
[c] d_3-MeCN.
[d] Probably obscured by resonances from solvent and free pyridine.

The ^1H NMR spectrum of $[Cr_3O(O_2CPh)_6(py)_3]^+$ displays four distinct resonances, while a very broad band seems barely definable above the baseline over the region *ca* 0–10 ppm. Two of these resonances occur in essentially identical positions as the 3-H and 4-H pyridine resonances of the analogous acetate compound and may be definitively assigned to these signals as they disappear in the spectrum of the NC_5D_5 analogue and are retained in the $O_2CC_5D_5$ analogue (Table 1). The ^2H NMR spectrum of the NC_5D_5 analogue (Table 2) discloses that the 2-D signal is also in a location similar to the acetate compound. These results indicate that the substitution of the bridging acetate ligands with benzoates does not substantially affect the coupling between the chromium ions.

The two remaining features, one with an upfield

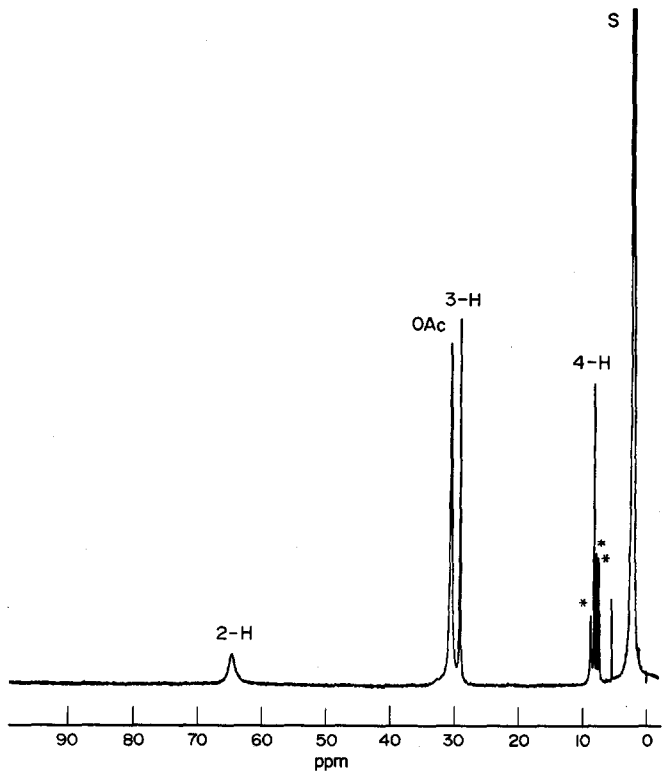

Fig. 5. ^{1}H NMR spectrum of $[Fe_3O(O_2CMe)_6(py)_3]^+$ in d_3-MeCN. S = protio-solvent impurity; * = pyridine solvate.

isotropic shift and the other with a tiny downfield shift, are assigned to the benzoate *para*-proton and *meta*-protons, respectively. This assignment is consistent with their intensities and width. Use of ^{2}D NMR is required to unambiguously observe the signal of the *ortho*-deuteron (proton), which is appreciably broader than the *meta*- or *para*-deuteron signals and upfield shifted, indicating a predominating π-delocalization is in operation (Table 2). This proton is probably responsible for the broad resonance in the ^{1}H NMR. To test which delocalization pathway is dominent, the *para*-toluate derivative was prepared. The *para*-methyl proton resonance is shifted downfield, in contrast to the *para*-proton resonance providing conclusive evidence for the existence of a dominant delocalization pathway (Table 1).

The alternating pattern of upfield and downfield resonances is consistent with the reported ^{1}H NMR of copper(II) benzoate,[23] and the position of the 2-D signal is similar to that reported for $[Cr_3O(2\text{-}d\text{-nicotinateH})_6(H_2O)_3]^{7+}$ in 1 M $HClO_4$.[24] (Listing of this 2-D chemical shift for this compound is the only reported NMR data on these trinuclear chromium complexes.)

CONCLUSIONS

Despite the long electronic spin-lattice relaxation time of Cr^{III} ions, the ^{1}H NMR spectra of oxo-centred trinuclear chromium carboxylate assemblies possess readily discernable signals (although signals due to protons in the closest proximity to the metal centres are broadened beyond detection). Using a combination of ^{1}H NMR and ^{2}H NMR all the proton/deuteron signals could be identified and unambiguously assigned. As the methyl and methylene protons of acetate and propionate are comparable to the α- and β-protons of the carboxylate side-chains of aspartate and glutamate, the results suggest that ^{1}H NMR studies could prove valuable to the study of proteins containing similar assemblies. This utility of ^{1}H NMR derives from the antiferromagnetic coupling between the chromium centres, which reduces the effective magnetic moment per chromium(III).

(*Received* 24 *July* 1992; *accepted* 1 *October* 1992)

Abstract—Combining $P(SiMe_3)_3$ or $As(SiMe_3)_3$ with Ph_2InCl in a 1 : 1 mole ratio results in the elimination of Me_3SiCl via a dehalosilylation reaction to yield $[Ph_2InP(SiMe_3)_2]_2$ (**I**) and $[Ph_2InAs(SiMe_3)_2]_2$ (**II**), respectively. X-ray structures were determined for **I** and **II**. The $(InP)_2$ core of dimer **I** is planar, whereas in dimer **II** the $(InAs)_2$ ring is slightly puckered.

The quest for suitable single-source precursors to ceramic and/or electronic III–V materials in previous years has resulted in a large number of fundamental reports concerning the structural aspects and reactivities of these compounds.[1,2] Elucidation of this basic chemistry is paramount to the understanding of the nature of the factors that influence the correct design and fabrication of such materials. Research in our laboratory has primarily centred on the use of silylarsines and, of late, silylphosphines in dehalosilylation reactions with a dialkyl group III halide or group III trihalide. These reactions eliminate a silyl halide thus forming a III–V bond.[1,3] This line of investigation has proven to be very fruitful in that a variety of compounds containing $\overline{MEME}$ (M = Ga, E = As;[4–7] M = In, E = P[8] or As[9]) and $\overline{MEMCl}$ (M = Ga, E = As[4,6,7] or P;[10] M = In, E = P[8] or As[9]) cores have been isolated. From the latter compounds, the possibility of replacing the chlorine atom with other functionalities exists.[11] Currently, for the case of compounds with cores consisting of $\overline{MEME}$ (M = In, E = P or As) rings, we have only employed this dehalosilylation methodology to $(Me_3SiCH_2)_2InCl$.[8,9] Herein we report our further explorations into this area with the synthesis and structural characterization of $[Ph_2InP(SiMe_3)_2]_2$ (**I**) and $[Ph_2InAs(SiMe_3)_2]_2$ (**II**).

EXPERIMENTAL

Synthesis

All manipulations were performed using general Schlenk, dry-box and/or high vacuum techniques. Solvents (including those for NMR spectra) were appropriately dried, distilled under argon and degassed prior to use. Literature methods were used to prepare Ph_3In,[12] $P(SiMe_3)_3$[13] and $As(SiMe_3)_3$.[14] Indium(III) chloride was purchased from Alfa Products, Ward Hill, MA, and purified by sublimation. Ph_2InCl was prepared via the equilibration of Ph_3In and indium(III) chloride in refluxing toluene in a 2 : 1 mole ratio and purified by recrystallization. ^1H, $^{13}C\{^1H\}$ and $^{31}P\{^1H\}$ NMR spectra were obtained on a Varian XL-300 at 300.0, 75.4 and 121.4 MHz, respectively. ^1H and ^{13}C spectra were referenced to TMS via the residual protons or carbons of C_6D_6. ^{31}P spectra were referenced to external 80% H_3PO_4 at δ 0.00 ppm. Melting points (uncorrected) were taken in sealed capillaries (Thomas–Hoover Uni-melt). Elemental analyses were performed by E+R Microanalytical Laboratory, Inc., Corona, NY. Single-crystal X-ray data were collected on an Enraf–Nonius CAD-4 diffractometer with graphite-monochromated Cu-K_α radiation.

$[Ph_2InP(SiMe_3)_2]_2$ (I)

Inside the dry-box a one-necked 250 cm^3 round-bottomed flask equipped with a Teflon valve was

charged with pentane (15 cm^3) and Ph_2InCl (0.250 g, 0.82 mmol), furnishing a white suspension to which was added dropwise $P(SiMe_3)_3$ (0.206 g, 0.82 mmol) in pentane (20 cm^3). The resulting milky mixture was placed in a sonicating water bath and allowed to react for 48 h after which it became pale yellow. The volatiles were removed *in vacuo* and the crude product was dissolved in warm pentane (15 cm^3). Upon cooling to −15°C for several days, colourless air-sensitive crystals of **I** formed; 0.224 g, 61.2% yield; m.p. 205–240°C (dec). Found: C, 48.4; H, 6.3%. Calc. for $C_{36}H_{56}In_2P_2Si_4$: C, 48.6; H, 6.3%. ^1H NMR: δ 0.34 (t, 36 H, SiMe_3 [J(P—H) = 2.7 Hz]), 7.17 (t, 4H, *para*-C_6H_5), 7.26 (t, 8H, *meta*-C_6H_5), 7.80 (d, 8H, *ortho*-C_6H_5). $^{13}C\{^1H\}$ NMR: δ 4.79 (t, SiMe_3 [J(P—C) = 4.7 Hz]), [127.63–129.17 (m, C_6H_5) partially obscured by solvent], 139.23 (s, C_6H_5). $^{31}P\{^1H\}$ NMR: δ −221.59 (s).

$[Ph_2InAs(SiMe_3)_2]_2$ (II)

In a manner similar to that employed for the preparation of **I**, Ph_2InCl (0.250 g, 0.82 mmol) in pentane (15 cm^3) and $As(SiMe_3)_3$ (0.243 g, 0.82 mmol) in pentane (20 cm^3) were combined. The resulting milky mixture was stirred for 48 h at room temperature giving a yellow solution. The volatiles were removed *in vacuo* and the crude product was dissolved in warm pentane (15 cm^3). Upon cooling to −15°C for several days, colourless air-sensitive crystals of **II** formed; 0.141 g, 35.0% yield; m.p. 185–190°C (dec. to orange liquid). Found: C, 44.5; H, 6.1%. Calc. for $C_{36}H_{56}As_2In_2Si_4$: C, 44.1; H, 5.8%. ^1H NMR: δ 0.35 (s, 36H, SiMe_3), 7.18 (t, 4 H, *para*-C_6H_5), 7.29 (t, 8H, *meta*-C_6H_5), 7.85 (d, 8H, *ortho*-C_6H_5). $^{13}C\{^1H\}$ NMR: δ 5.00 (s, SiMe_3), [127.80 (s, C_6H_5), 128.12 (s, C_6H_5) partially obscured by solvent], 139.00 (s, C_6H_5).

X-ray structural solution and refinement

Colourless crystals of **I** and **II** were mounted inside flame-sealed 0.6 mm thin-walled glass capillaries under an inert argon atmosphere. Oscillation and Weissenberg photographs provided preliminary unit cell parameters and space group information. The monoclinic space groups $P2_1/c$ for **I** and $P2_1/n$ (alternative setting of $P2_1/c$) for **II** were established unequivocally from the Laue symmetry and systematic absences. Crystallographic data are summarized in Table 1. Intensity data ($+h$, $+k$, $\pm l$; 4832 reflections, $\theta_{max} = 75°$ for **I**; 8025 reflections, $\theta_{max} = 65°$ for **II**), recorded on an Enraf–Nonius CAD-4 diffractometer (Cu-K_α radiation, $\lambda = 1.5418$ Å, graphite monochromator), were corrected for the usual Lorentz and polarization effects; empirical absorption corrections (derived from ψ-scans) were also applied. Equivalent reflections were averaged leaving 4598 (**I**) and 7734 (**II**) out of which 2765 and 3625, respectively, with $I > 3.0\sigma(I)$, were retained for the analyses. With two formula units per unit cell, dimer **I** must lie on a crystallographic centre of symmetry. For **II**, on the other hand, the unit cell contains four dimers that may either occupy general positions or two crystallographically independent dimers must lie on centres of symmetry. Initial indium atom coordinates for **I** were derived from a Patterson map. Approximate indium and arsenic coordinates for **II**, obtained from an E-map (MULTAN11/82), indicated that the molecules lay in general positions with no crystallographically-imposed symmetry. The remaining non-hydrogen atoms of **I** and **II** were located in a series of weighted F_o and difference Fourier syntheses phased successively by an increasing number of atoms. Several rounds of full-matrix least-squares adjustment of atomic positional and thermal parameters (at first isotropic, then anisotropic) followed. In the later iterations, hydrogen atoms were incorporated at their calculated positions (C—H = 1.05 Å) and an extinction correction was included as a variable. The parameter refinements converged at $R = 0.038$ ($R_w = 0.050$) for **I** and $R = 0.040$ ($R_w = 0.048$) for **II**. Final difference-Fourier syntheses revealed no unusual features [max. $\Delta\rho$ (e Å^{-3}): 0.54 (**I**) and 0.56 (**II**), both in the vicinity of the indium atom]. The solid-state structures of **I** and **II**, with their atom numbering schemes, are illustrated in Figs 1 and 2, respectively. Selected bond lengths and bond angles are listed in Tables 2 and 3. Crystallographic calculations were performed using the Enraf–Nonius structure determination package[15] on PDP11/44 and MicroVAX computers. For all structure–factor calculations, neutral atom scattering factors and their anomalous dispersion corrections were taken from ref. 16. In the least-squares iterations, $\Sigma w\Delta^2$ [$w = 1/\sigma^2(|F_o|)$, $\Delta = (|F_o| - |F_c|)$] was minimized. Supplementary material: atomic coordinates, thermal parameters, bond lengths and angles and crystal data have been deposited with the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

We have previously demonstrated the utility of dehalosilylation reactions between an organogroup III halide and a silylarsine[1] or silylphosphine[8,10] to form III–V bonds. Our initial efforts in pursuit of compounds possessing In—E bonds (E = As or P) involved only the reaction of organoindium species

bearing the Me_3SiCH_2 group,[8,9] an organic substituent that was chosen because of its steric bulk and relative stability. In an effort to ascertain the viability of our methodology for other systems, we have begun to explore the use of different organic substituents at the organoindium centre. We now report the synthesis, characterization and X-ray structures of two new compounds containing the In—E bond (E = P or As), $[Ph_2InP(SiMe_3)_2]_2$ (I) and $[Ph_2InAs(SiMe_3)_2]_2$ (II).

The 1 : 1 mole ratio reaction of Ph_2InCl with $E(SiMe_3)_3$ (E = P or As) at room temperature in pentane affords I and II, respectively, via a dehalosilylation reaction [eq. (1)].

$$2Ph_2InCl + 2E(SiMe_3)_3 \longrightarrow [Ph_2InE(SiMe_3)_2]_2 + 2Me_3SiCl \quad (1)$$

Compounds I and II are the second examples of dimeric In—P or In—As species to be prepared in our laboratory through the elimination of Me_3SiCl, with $[(Me_3SiCH_2)_2InP(SiMe_3)_2]_2$ (III)[8] and $[(Me_3SiCH_2)_2InAs(SiMe_3)_2]_2$ (IV)[9] constituting the first. Subsequent to III and IV being reported, Theopold and co-workers demonstrated that $[C_5Me_5(Cl)InP(SiMe_3)_2]_2$ (V)[17] results from a similar reaction. As with III, IV and V the core fragment of I consists of a planar four-membered $(InP)_2$ ring, whereas in II the $(InAs)_2$ ring is slightly puckered (*vide infra*). The ^1H, ^{13}C and for I, ^{31}P room-temperature NMR spectra for each compound are consistent with their solid-state structures. The dimeric nature of I is clearly demonstrated by the virtual coupling of the ring phosphorus atoms with the hydrogen and carbon atoms of the trimethylsilyl

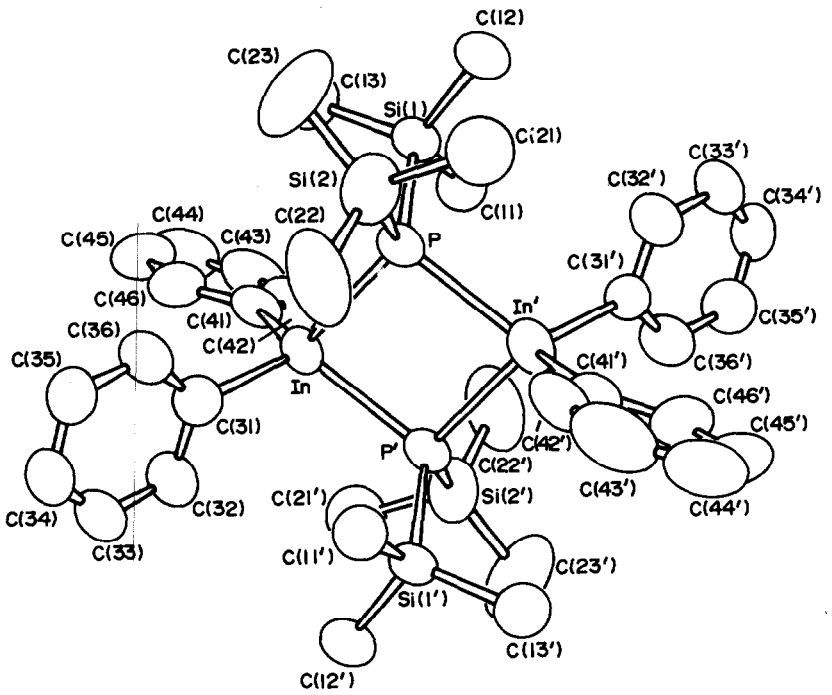

Fig. 1. ORTEP diagram (30% probability ellipsoids) of the solid-state structure of $[Ph_2InP(SiMe_3)_2]_2$ (**I**); primed atoms are related to the unprimed atoms by a crystallographic centre of symmetry. Hydrogen atoms have been omitted for clarity.

substituents at the phosphorus centre. This coupling gives rise to a triplet for these groups in the ^1H and ^{13}C NMR spectra. At room temperature no evidence of solution fluxionality has been observed for either **I** or **II**.

Compound **I** crystallizes in the monoclinic space group $P2_1/c$ with the two dimers in the unit cell lying on crystallographic centres of symmetry and accordingly the $(InP)_2$ ring is required to be strictly planar. The In—P bond lengths are both 2.612(1) Å, a distance which is distinctly shorter than the mean of 2.655 Å in **III**, reflecting the less sterically demanding nature of the phenyl substituents in **I** versus the much bulkier Me_3SiCH_2 moieties in **III**. The mean P—Si bond length of 2.262 Å in **I** is similar to the mean of 2.255 Å in **III**. Bond angles in the $(InP)_2$ core of **I** [In—P—In = 92.97(4)° > P—In—P = 87.03(4)°] are similar to and differ in the same sense as corresponding angles in **III** [93.6(1)°, 86.4° (mean)] and **V** [92.2(1)°, 87.8(1)°]. The C—In—C angle at 105.7(2)° in **I** is very much smaller that the mean of 123.2° in **III** where the considerable enlargement from an approximately tetrahedral value may be ascribed at least in part to the greater steric crowding by the geminal Me_3SiCH_2 substituents. It is relevant to note that the larger the exocyclic bond angle subtended at an opposite pair of ring atoms in four-membered rings, the greater the steric compression exerted on substituents at the other ring centres. It is, therefore, not surprising to find that the Si—P—Si angle of 108.3(1)° in **I** is slightly larger than that of 105.7(2)° in **III**. In contrast to the situations in [In(2,4,6-trimethylphenyl)$_2$I]$_2$,[18] $(Ph_2InOSiMe_3)_2$[19] and $[Ph_2GaAs(CH_2SiMe_3)_2]$,[5] where one of the phenyl ring planes approximately eclipses one of the four-membered ring bonds while the other is in a bisecting orientation, or in $Ph_2GaAs(SiMe_3)_2Ga(Ph)_2Cl$[6] where all are in approximately eclipsing orientations, both of the phenyl rings in **I** are rotated moderately away from either the eclipsing or the bisecting orientation [torsion angles: P—In—C(31)—C(36) = 36.4(6)°, P′—In—C(31)—C(32) = −49.5(5)°; P′—In—C(41)—C(42) = −22.5(6)°, P—In—C(41)—C(42) = 78.1(6)°] to minimize intramolecular non-bonded interactions with the proximal $SiMe_3$ substituents. The indium atom lies close to the C(41)—C(46) least-squares plane (Δ = 0.013 Å), but is displaced significantly (Δ = 0.108 Å) from that through the other phenyl ring atoms [C(31)—C(36)]. Substituent crowding is also indicated in the highly significant differences between the exocyclic bond angles at the *ipso* carbon atoms [In—C(31)—C(36) = 125.3(5)° > In—C(31)—C(32) = 118.2(5)°; In—C(41)—C(42) = 127.9(5)° > In—C(41)—C(46) = 114.5(5)°].

Crystals of dimer **II** also belong to the monoclinic system but they are not isomorphous with those of **I**. Compound **II** crystallizes in the space group $P2_1/n$ with four molecules occupying the general positions. In contrast to the planar $(InAs)_2$ ring in **I**, in **II** the ring is very slightly puckered [As(1)—In(1)—As(2)/As(1)—In(2)—As(2) dihedral angle = 6.0°]. The mean In—As bond length at 2.686 Å in **II** is significantly shorter than the value of 2.728 Å in the planar ring of **IV**; the difference between these distances (Δ = 0.042 Å), which is essentially the same as that between the corresponding bonds (Δ = 0.043 Å) in the phosphorus analogues **I** and **III**, again may be ascribed principally to the different steric demands of the geminal substituents, Ph ≪ Me_3SiCH_2. Endocyclic bond angles [In—As—In = 93.48°(mean) > As—In—As = 86.36°(mean)] in **II** lie close to the corresponding values for **IV** [94.57(5)°, 85.43°(mean)]. The mean As—Si bond length [2.355 Å] and the mean Si—As—Si bond angle [106.2°] in **II** do not differ significantly from those in **IV** [As—Si = 2.348 Å(mean), Si—As—Si = 105.4(2)°]. In addition, the mean In—C bond length at 2.18 Å in **II** is the same as that in **I** (2.182 Å). The mean of the C—In—C angles at 108.5° in **II** is slightly larger than that of 105.7(2)° in **I**, whereas it is much smaller than the mean of 125.4° in **IV** which has the bulky Me_3SiCH_2 substituents at indium. With the reduced symmetry of **II** versus **I**, the dispositions of the phenyl rings with respect to the As—In bonds show more variation [torsion angles: As(2)—In(1)—C(1)—C(2) = −27(1)°, As(1)—In(1)—C(1)—C(6) = 58(1)°; As(1)—In(1)—C(7)—C(12) = 41(1)°, As(2)—In(1)—C(7)—C(2) = −59(1)°; As(1)—In(2)—C(13)—C(14) = 15(1)°; As(2)—In(2)—C(13)—C(18) = −72(1)°; As(2)—In(2)—C(19)—C(24) = −25(1), As(1)—In(2)—C(19)—C(24) = 73(1)°]. The indium atom lies out of each of the phenyl ring planes [Δ = 0.070, 0.108, 0.151 and 0.156 Å, respectively, from the C(1)—C(6), C(7)—C(12), C(13)—C(18) and C(19)—C(24) least-squares planes]. In common with **I**, exocyclic bond angle deformation at the *ipso* carbon centres is also present in **II** [In(1)—C(1)—C(2) = 123(1)° > In(1)—C(1)—C(6) = 119(1)°; In(1)—C(7)—C(12) = 125(1)° > In(1)—C(7)—C(8) = 117(1)°; In(2)—C(13)—C(14) = 126(1)° > In(2)—C(13)—C(18) = 119(1)°; In(2)—C(19)—C(24) = 125(1)° > In(2)—C(19)—C(20) = 119(1)°] to aid in the minimization of intramolecular non-bonded interactions.

SYNTHESIS AND CARBONYLATION OF SOME α-ALKOXYALKYL COBALT COMPLEXES, $[RCH(OR')Co(CO)_3PPh_3]$ (R = H, CH_3; R′ = Me, Et)

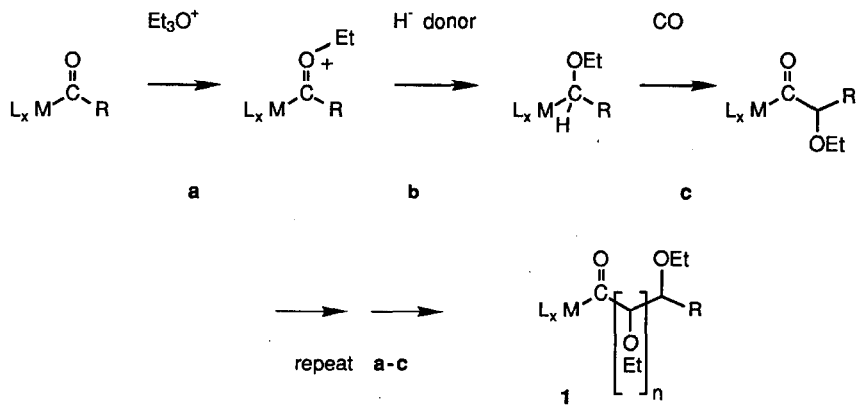
CHUNG C. TSO and ALAN R. CUTLER*

Department of Chemistry, Rensselaer Polytechnic Institute, Troy, NY 12180, U.S.A.

(*Received* 27 *January* 1992; *accepted* 1 *October* 1992)

Abstract—Cobalt α-alkoxyalkyl compounds $[ROCH_2Co(CO)_3PPh_3]$ (R = Me, Et) and $[CH_3(EtO)CHCo(CO)_3PPh_3]$ have been synthesized and transformed to their acyl derivatives, $[R'CH(OR)C(O)Co(CO)_3PPh_3]$ (R′ = H, CH_3), using 1 atm. of CO. The α-ethoxyethyl complex $[CH_3(EtO)CHCo(CO)_3PPh_3]$ was generated by treating the acetyl compound $[CH_3C(O)Co(CO)_3PPh_3]$ with triethyloxonium hexafluorophosphate in CH_2Cl_2 and then reducing with $LiHBEt_3$. The thermal instability of the resulting $[CH_3(EtO)CHCo(CO)_3PPh_3]$ compound precluded its full characterization, although it transformed into its acyl derivative in 82% isolated yield. The ethoxycarbene intermediate $[CH_3(EtO)C{=}Co(CO)_3PPh_3]^+PF_6^-$, the two alkoxymethyl complexes and the three acyl complexes have been characterized by elemental analysis and IR and NMR (^1H, ^{13}C, ^{31}P) spectroscopy. Attempts to convert the α-alkoxyacyl complexes $[ROCH_2C(O)Co(CO)_3PPh_3]$ and $[CH_3(EtO)CHC(O)Co(CO)_3PPh_3]$ into their alkoxycarbene compounds with a variety of alkylating agents instead afforded $[Co(CO)_3(PPh_3)_2]^+$.

The chain growth of a poly(alkoxymethylene)acyl ligand on an organotransition metal acyl complex (**1**) could incorporate CO [eq. (1)] by coupling acyl ligand reduction (**a** and **b**) and subsequent carbonylation (**c**) steps.[1,2] Although many examples of these ligand reactions are known individually,[3] sequentially iterating them requires careful choice of the organometallic systems ML_x due to their antithetical requirements. Steps **a**/**b** thus require the presence of a coordinatively saturated, non-labile metal centre on ML_x in order to restrict the chemistry to the acyl ligand,[3] whereas the alkyl-CO migratory-insertion step **c** needs a more labile metal centre.[4] Indeed, carbonylating α-alkoxyalkyl complexes is especially demanding.[3] Another consideration concerning the choice of ML_x is the potential use of metal–ligand stereoelectronic inter-

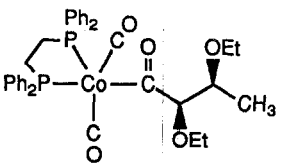


(1)

* Author to whom correspondence should be addressed.

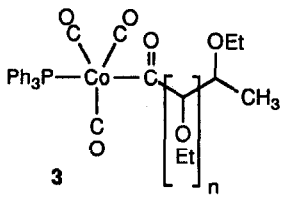
actions[5] to control the stereochemistry at each emerging chiral centre (step **b**).

Two organometallic templates ML_x thus far have proved useful in balancing the antithetical requirements of the acyl ligand reduction and carbonylation sequences. The (η^5-indenyl)iron system $Fe(CO)_2(\eta^5\text{-}C_9H_7)$ supports both steps **a**/**b** as well as the facile carbonylation of α-alkoxyalkyl ligands (step **c**).[2] Facility of this carbonylation step depends on reversible η^5/η^3-indenyl ring slippage on these iron complexes[6] to associate CO under conditions that their CpFe analogues are inert.[7] The other organometallic template is the extremely labile cobalt moiety $[Co(CO)_2(Ph_2PCH_2CH_2PPh_2)]$.[1] With these cobalt complexes, the presence of the η^2-dppe ligand retains the high lability at the cobalt centre that one associates with easy carbonylation of cobalt carbonyl alkyl complexes,[8] in addition to supporting the subsequent acyl ligand reduction sequence **a**,**b**. A gratifying outcome of this cobalt chemistry was our diastereoselective synthesis of the *threo*-diethoxybutanoyl **2**.[1] This diastereofacial selectivity (during iteration of step **b**), which could derive from the disposition of the axial phosphine phenyl rings of the dppe ligand, serves as the impetus for the present study.



2

The monophosphine-substituted cobalt system $Co(CO)_3(PPh_3)$ was used in the present study as the template for the reaction chemistry engendered in eq. (1), since the now remote phosphine phenyl rings should not contribute to the diastereoselectivity of acyl ligand reduction (steps **a**/**b**). This steric isolation of the phosphine ligand corresponds to the anticipated *trans* array of the phosphine and acyl (or ethoxycarbene) ligands that is depicted for the targeted cobalt acyl complexes **3**. The bis-axial, pseudo-C_{3v} geometry that is predicted for **3** has been established for a number of cobalt alkyl and acyl complexes, $[R'C(O)Co(CO)_3(PR_3)]$.[8,9] Moreover, these cobalt acyl complexes are readily available by carbonylating their alkyl precursors, as demonstrated for the related cobalt methyl $[CH_3Co(CO)_3(PPh_2Me)]$[10] and even methoxymethyl $[MeOCH_2CO(CO)_3(PPh_2Me]$[11] complexes. Our initial objective was to synthesize and to assess the stereochemistry of the cobalt diethoxybutanoyl complex **3** ($n = 1$): according to our previously advanced Felkin–Anh transition-state argument[1] it should form with *threo*-diastereoselectivity that is quite independent of the phosphine ligand.



3

EXPERIMENTAL

All synthetic manipulations were performed under a nitrogen atmosphere using standard Schlenk line and syringe/septum bench-top techniques for handling moderately air-sensitive organometallics.[12] Solvents for synthetic work and for recording spectral data were deoxygenated by purging with nitrogen for *ca* 15 min. Camag alumina (neutral, activity 3) was used for column chromatography.

IR spectra were recorded in CH_2Cl_2 solutions (0.10 mmol, 2.5 cm^3) in an NaCl solution cell with an amalgam spacer (0.10 mm) and were recorded on a Perkin–Elmer Model No. 297 spectrophotometer. The ν(CO) frequencies (2100–1600 cm^{-1}) were calibrated against the polystyrene 1601 cm^{-1} band; they are precise to ± 2 below and ± 5 above 2000 cm^{-1}. NMR spectral data were recorded in concentrated $CDCl_3$ solutions after trace amounts of insoluble residues were centrifuged. Varian Model XL-200 and IBM-WP100 instruments were used for recording the NMR spectra, which are reported as δ values downfield from internal $(CH_3)_4Si$ (^1H and $^{13}C\{^1H\}$ NMR spectra) or relative to external H_3PO_4 ($^{31}P\{^1H\}$). The PF_6^- absorption in ^{31}P NMR spectra, centred at -143.2 ppm [$J(PF) = 710$ Hz], also was used as an internal standard.

Organic and inorganic reagents were procured commercially and used as received. THF and diethyl ether were distilled under nitrogen from sodium benzophenone ketyl; methylene chloride likewise was obtained as needed from P_2O_5. Triethyloxonium hexafluorophosphate was recrystallized from nitrobenzene–ether to remove any residual acid.[13]

Preparation of $[Co(CO)_3PPh_3]_2$

Dimeric $[Co(CO)_3PPh_3]_2$ was prepared by a modification of the procedure reported by Manning.[14] A single-neck 300 cm^3 round-bottomed flask fitted with a magnetic stir bar was charged with $[Co(CO)_4]_2$ (10.00 g, 29.24 mmol) and PPh_3

(15.21 g, 58.00 mmol) before sealing with a rubber septum. The atmosphere was replaced by nitrogen and benzene (150 cm^3) was then injected via a syringe into the flask. Vigorous gas evolution ensued and a thick brick-red slurry consisting of $Co(CO)_3(PPh_3)_2{}^+Co(CO)_4{}^-$ formed.

CAUTION: Carbon monoxide (toxic) was vented in the hood through a mineral oil bubbler, which was attached to a syringe needle inserted through the septum of the reaction flask.

This slurry was stirred at 60°C for 10 h. The solvent was then evaporated at room temperature and the remaining red–brown solid was washed with ether (3×100 cm^3) and vacuum dried. $[Co(CO)_3PPh_3]_2$ (21.20 g, 89% yield), IR (Nujol): 1945 cm^{-1} (br). This solid, which is very slightly soluble to insoluble in benzene, ether, THF and CH_2Cl_2, was not further purified.

Synthesis of $CH_3C(O)Co(CO)_3(PPh_3)$ **(4)**

An oven-dried 500 cm^3 three-neck amalgam flask, which was fitted with an overhead ground-glass stirring shaft/teflon stirring paddle and a nitrogen inlet adapter, was cooled to room temperature in a stream of nitrogen. Enough 1.5% sodium amalgam was added to cover the teflon stirrer blade before adding THF (30 cm^3) and $[Co(CO)_3PPh_3]_2$ (5.00 g, 6.17 mmol). The brick red suspension converted slowly to a yellowish–green suspension upon stirring for 12 h; its light yellow–green supernatant liquid corresponded to $Co(CO)_3(PPh_3)^-Na^+$.[15] IR spectrum: ν(CO) 1934 (m), 1857 (s), 1810 (m) cm^{-1}. The anion slurry that remained after draining the amalgam was transferred via a stainless steel transfer needle into a 500 cm^3 one-neck round-bottomed flask, which was then cooled to −78°C. Methyl iodide (0.78 cm^3, 13.0 mmol) was added dropwise by syringe to the stirred suspension. Within 0.5 h, the yellowish green tint had turned dark yellow and its IR spectrum at room temperature (1.5 h) was consistent with conversion to $[CH_3Co(CO)_3(PPh_3)]$:[10,15a,16] ν(CO) 2037 (w), 1958 (s,br) cm^{-1}.

This suspension containing $[CH_3Co(CO)_3(PPh_3)]$ was stirred under 1 atm. of CO for 4 h (with no colour change), the solvent was evaporated on a Buchi rotovaporator and the residue was extracted with methylene chloride (4×10 cm^3). The combined extracts were filtered through celite; the filtrate was concentrated and chromatographed on alumina (2×3 cm column) with methylene chloride. This afforded a yellow band that upon evaporating left $[CH_3C(O)Co(CO)_3(PPh_3)]$ **(4)**[10,17] as a yellow solid (5.13 g, 93% yield). IR (THF): ν(CO) 2048 (w), 1978 (s), 1959 (s), 1677 (m) cm^{-1}.

Synthesis of $CH_3(CH_3CH_2O)C{=}Co(CO)_3(PPh_3)^+PF_6^-$ **(5)**

A solution of $CH_3C(O)Co(CO)_3(PPh_3)$ **(4)** (2.00 g, 4.46 mmol) in methylene chloride (100 cm^3) was treated with purified triethyloxonium hexafluorophosphate (1.66 g, 6.70 mmol) and the ensuing slow reaction was monitored by IR spectroscopy. The starting acetyl complex **(4)** was consumed in 24 h, although the original yellow colour remained. After the yellow solution was evaporated, the residue was extracted with methylene chloride (25 cm^3) and filtered through celite before adding a layer of ether (200 cm^3). White crystals of $Et_3O^+PF_6^-$ formed first (−5°C) at the solvent interface as a vitreous deposit or "ring" on the flask, then yellow crystals deposited on the lower wall of the flask over 12 h. The supernatant liquid was removed with a cannula and the two crystalline deposits were separated. Repeating this crystallization step afforded 2.25 g of a yellow crystalline solid that was characterized as $[CH_3(CH_3CH_2O)C{=}Co(CO)_3(PPh_3)]^+PF_6^-$ **(5)** (81% yield). Found: C, 48.3; H, 3.7. Calc. for $C_{25}H_{23}O_4P_2F_6Co$: C, 48.2; H, 3.7%.

The ethoxycarbene compound **5** is thermodynamically unstable as well as being extremely reactive towards nucleophiles. Either long-term storage of **5** as a solid at −10°C (> 2 days) or in CH_2Cl_2 solution at 22°C (> 12 h) degraded it to $[Co(CO)_3(PPh_3)_2]^+PF_6^-$ **(12)**[18] as the only identifiable cobalt complex. IR (CH_2Cl_2): 2008 cm^{-1} (CO); $^{31}P\{^1H\}$ NMR (CH_2Cl_2): δ 55.4. This degradation product was also found in the CH_2Cl_2–ether filtrates that were collected during the synthesis of **5**. Upon exposure either to traces of moisture (e.g. NaCl plates of an IR cell that had not been flushed with dry solvent) or to 1 equivalent of $Bu^n{}_4N^+I^-$ in methylene chloride, **5** immediately regenerated its acetyl precursor **4**.

Reduction of $[CH_3(CH_3CH_2O)C{=}Co(CO)_3(PPh_3)]^+PF_6^-$ **(5)**

The ethoxycarbene complex **5** (0.50 g, 0.80 mmol) was dissolved in methylene chloride (25 cm^3) at −78°C. To this dark yellow solution a lithium triethylborohydride–THF solution (80 cm^3, 1.0 M) was added dropwise with stirring. The solution immediately turned lighter and IR spectral monitoring was consistent with quantitative conversion to $[CH_3CH(OEt)Co(CO)_3(PPh_3)]$ **(6)**. None of the acetyl complex precursor **4** was detected by IR or ^{31}P NMR spectroscopy (−30°C). Passing the cold (−78°C) solution of **6** quickly through a 2×2 cm column of alumina–CH_2Cl_2 gave the unchanged

yellow–brown eluate, as ascertained by IR spectroscopy. This solution containing **6** slowly (2 h) turned reddish–brown and deposited $[Co(CO)_3(PPh_3)]_2$ as it warmed to room temperature. Rapid evaporation of the solvent from cold (−30°C) methylene chloride solutions of **6** on a vacuum line left a yellow–brown gum, which did not redissolve in CH_2Cl_2. Definitive ^1H NMR spectral data for **6** were not obtained due to paramagnetic broadening.

Synthesis of $[CH_3CH(OCH_2CH_3)C(O)Co(CO)_3(PPh_3)]$ **(7)**

A methylene chloride solution (20 cm^3) of $[CH_3(CH_3CH_2O)C{=}Co(CO)_3(PPh_3)]^+PF_6^-$ **(5)** (0.51 g, 0.82 mmol) was treated with an $LiHBEt_3$–THF solution (0.86 cm^3) (0.95 M, 0.82 mmol) at −78°C. The reaction was judged complete after 15 min (−78°C) by IR spectral monitoring, then the pale yellow solution was passed rapidly through 2 × 2 cm of alumina that had been precooled with CH_2Cl_2 (−78°C). The yellow band that eluted with cold methylene chloride immediately was exposed to 1 atm. of carbon monoxide with agitation for 2 h. The volume of the resulting yellow solution then was reduced and it was chromatographed on alumina (2 × 4 cm column) with CH_2Cl_2 or on silica gel with 1 : 5 THF–hexane. A yellow band eluted from both columns; slowly evaporating this eluate on a Buchi rotovaporator left a small amount of a clear vitreous deposit (borane residues) on the upper wall of the flask and a yellow–brown solid in the bottom of the flask. This yellow–brown material was collected and fractionally reprecipitated again from methylene chloride–hexane, before drying under reduced pressure. It was identified as $[CH_3CH(OCH_2CH_3)C(O)Co(CO)_3(PPh_3)]$ **(7)** (343 mg, 82% yield). Found: C, 61.4; H, 4.8. Calc. for $C_{26}H_{24}O_5PCo$: C, 61.6; H, 4.7%.

Synthesis of alkoxymethyl complexes $[ROCH_2Co(CO)_3(PPh_3)]$ **(8, R = CH_3; 9, R = CH_2CH_3)**

$[CH_3OCH_2Co(CO)_3(PPh_3)]$ **(8)**. A light yellow–green THF suspension (250 cm^3) containing $Co(CO)_3(PPh_3)^-Na^+$ (4.94 mmol) was generated by stirring a reddish-brown slurry of $[Co(CO)_3(PPh_3)]_2$ (2.00 g, 2.47 mmol) over excess 1% Na (Hg) for 8 h. This suspension was transferred via stainless-steel cannula, cooled to −78°C and treated with chloromethyl methyl ether (0.38 cm^3, 5.0 mmol).

CAUTION: Chloromethyl ethers are potentially carcinogenic and must be handled in a hood.

The greenish tint gradually left as the reaction mixture warmed to room temperature over 2 h. It then was evaporated and methylene chloride extracts (30 cm^3) were filtered through celite (all the yellow colour was washed through the celite pad with CH_2Cl_2). The combined filtrates were reduced in volume on a Buchi rotovaporator and chromatographed on alumina (2 × 3 cm) with methylene chloride. The yellow band that eluted cleanly afforded $[CH_3OCH_2Co(CO)_3(PPh_3)]$ **(8)**[19] as a stable yellow solid (1.98 g, 89% yield). Found: C, 61.0; H, 4.3. Calc. for $C_{23}H_{20}O_4PCo$: C, 61.3; H, 4.4%.

$[CH_3CH_2OCH_2Co(CO)_3(PPh_3)]$ **(9)**. The same procedure was repeated using chloromethyl–ethyl ether for alkylating $Co(CO)_3(PPh_3)^-Na^+$, thus affording $[CH_3CH_2OCH_2Co(CO)_3(PPh_3)]$ **(9)** in 83% yield after an identical workup. This stable yellow solid also can be stored for prolonged periods (over a month) in a refrigerator without noticeable decomposition. Found: C, 62.0; H, 4.7. Calc. for $C_{24}H_{22}O_4PCo$: C, 62.0; H, 4.7%.

Carbonylation of alkoxymethyl complexes $[ROCH_2Co(CO)_3(PPh_3)]$ **(8, R = CH_3; 9, R = CH_2CH_3)**

$[CH_3OCH_2C(O)Co(CO)_3(PPh_3)]$ **(10)**. A THF suspension (300 cm^3) containing $[CH_3OCH_2Co(CO)_3(PPh_3)]$ **(8)** (12.34 mmol) was generated from $[Co(CO)_3(PPh_3)]_2$ (5.0 g, 6.17 mmol) and was warmed to room temperature. An IR spectrum of the yellow supernatant solution was consistent with quantitatively forming **8**; ν(CO): 1955 (br) cm^{-1}. Carbon monoxide (1 atm.) was then bubbled into this solution for 3 h; although there was no change in physical appearance, quantitative conversion of **8** to $CH_3OCH_2C(O)Co(CO)_3(PPh_3)$ **(10)** was established by its IR spectrum: $\nu(C{\equiv}O)$ (THF) 2048 (w), 1978 (vs), 1958 (vs) cm^{-1}; $\nu(C{=}O)$ 1675 (br) cm^{-1}. Methylene chloride extracts (30 cm^3) of the evaporated reaction mixture were filtered through celite before they were concentrated and chromatographed on alumina (2 × 3 cm column) with methylene chloride. This cleanly eluted a yellow band that gave $[CH_3OCH_2C(O)Co(CO)_3(PPh_3)]$ **(10)**[17a,19] as a stable yellow solid (5.41 g, 91% yield). Found: C, 60.1; H, 4.2. Calc. for $C_{24}H_{20}O_5PCo$: C, 60.2; H, 4.2.

$[CH_3CH_2OCH_2C(O)Co(CO)_3(PPh_3)]$ **(11)**. Carbon monoxide was bubbled through a methylene chloride solution (75 cm^3) of $[CH_3CH_2OCH_2Co(CO)_3(PPh_3)]$ **(9)** (3.00 g, 6.47 mmol) for 3 h. The light yellow solution, unchanged in appearance, was filtered through 3 cm of alumina and the yellow band that washed through the column was evaporated to give analytically pure $[CH_3CH_2OCH_2C(O)Co(CO)_3(PPh_3)]$ **(11)** as a stable yellowish-tan solid (yield 3.01 g, 95%). Found: C,

60.9; H, 4.4. Calc. for $C_{25}H_{22}O_5PCo$: C, 60.9; H, 4.5%.

RESULTS AND DISCUSSION

In the present study, the ligand reactions corresponding to eq. (1) have been studied using $Co(CO)_3(PPh_3)$ as the ML_x template. The corresponding acyl-alkyl-alkoxy-carbene complexes for this template should offer increased thermodynamic stability with respect to the parent $Co(CO)_4$ compounds,[8,9] but the alkyl complexes should still undergo facile alkyl-CO migratory-insertion.[20] For example, Baird[10] and Cutler,[11] using the related $Co(CO)_3PPh_2Me$ template, carbonylated the methyl and methoxymethyl compounds, respectively, with 1 atm. of CO and isolated the corresponding acyl complexes $[CH_3C(O)Co(CO)_3(PPh_2Me)]$ and $[MeOCH_2C(O)Co(CO)_3(PPh_2Me)]$. Other cobalt acyl complexes, notably the $Co(CO)_3(PPh_3)$ acetyl,[10,17a] methoxyacetyl,[17a,19] hydroxyacetyl and siloxyacetyl[19] compounds, had been synthesized via the classic Heck and Breslow procedure of adding PPh_3 to $RCo(CO)_4/RCOCo(CO)_4$ mixtures.

We switched to using the $Co(CO)_3(PPh_3)$ vs the $Co(CO)_3(PPh_2Me)$[11] system because the alkyl and acyl complexes of the former moiety form as (sometimes crystalline) solids, whereas analogous complexes of the latter cobalt system invariably appear as gums or syrups. Once isolated as gums many of these cobalt alkyl and acyl complexes tend to decompose. The apparent gain in stability in working with $Co(CO)_3(PPh_3)$ alkyl-acyl complexes offsets the minor inconvenience encountered in using the now insoluble dimeric $[Co(CO)_3(PPh_3)]_2$ as our starting material.

Conversion of $[CH_3C(O)Co(CO)_3(PPh_3)]$ (**4**) *to* $[CH_3CH(OCH_2CH_3)C(O)Co(CO)_3(PPh_3)]$ (**7**)

A convenient two-step preparation of the cobalt acetyl complex $[CH_3C(O)Co(CO)_3(PPh_3)]$ (**4**) entails alkylating $Co(CO)_3(PPh_3)^-Na^+$[15] with methyl iodide and then carbonylating the resulting methyl compound, $[CH_3Co(CO)_3(PPh_3)]$, with 1 atm. of CO for 4 h. A 93% yield of **4** as a stable, yellow solid was realized after a work-up procedure involving chromatography on alumina. In addition to being prepared by the Heck and Breslow procedure,[17a] **4** previously had been generated by displacing iodide from $CH_3C(O)Co(CO)_3I^-$ with PPh_3.[17b] Its full ^1H, ^{13}C and ^{31}P NMR spectral properties are detailed in Table 1. (The unstable cobalt methyl precursor $[CH_3Co(CO)_3(PPh_3)]$[10,15a,16] was not characterized.)

We converted **4** to the ethoxypropionyl $[CH_3CH(OEt)C(O)Co(CO)_3(PPh_3)]$ (**7**) by the three-step set of coordinated ligand reactions outlined in eq. (2). In the first step reacting **4** with purified $Et_3O^+PF_6^-$ gave the ethoxycarbene salt **5**, which was isolated analytically pure in 80% yield as a thermally-sensitive yellow solid. The isolation procedure was complicated by the unavoidable presence of unreacted $Et_3O^+PF_6^-$. Because of the sluggishness of this alkylation reaction, excess triethyloxonium salt must be used to drive the reaction to completion before the product decomposes. Even in the presence of 1.5 equivalents of $Et_3O^+PF_6^-$, transforming **4** to **5** requires 18–24 h to consume the starting compound **4**. The thermal sensitivity of the purified ethoxycarbene salt **5** in CH_2Cl_2 solution is evident in its slow degradation at room temperature to the known[18] carbonyl salt $Co(CO)_3(PPh_3)_2^+PF_6^-$ (**12**). Interestingly, the more electron rich $[CH_3C(O)Co(CO)_2(dppe)]$ [acetyl $\nu(C{=}O) = 1630\ cm^{-1}$] transforms within 1 h to its stable ethoxycarbene derivative[1] with 1 equivalent of $Et_3O^+PF_6^-$.

[a] Spin–spin splittings (J values) in Hz.

[b] Phenyl assignments for **4**: δ 133.3 [d, J(PC) = 42 Hz, *ipso*-C], 133.0 [d, J(PC) = 12 Hz, *ortho*-C], 130.7 (s, *para*-C), 128.8 [d, J(PC) = 10 Hz, *meta*-C]. These assignments are representative for the alkyl/acyl $Co(CO)_3PPh_3$ complexes.

[c] NMR data correspond to CD_2Cl_2 solutions.

The trigonal bipyramidal structure depicted for the phosphinecobalt ethoxycarbene salt **5** is consistent with its spectral data. The IR spectrum of **5**, for example, exhibits one weak and two closely spaced strong intensity ν(CO) bands for the terminal carbonyls, a band pattern diagnostic for *trans*-axial RCo(CO)$_3$L structures of local C_{3v} symmetry.[8,9,21] The presence of a cationic cobalt centre on **5** is supported by the shifting of its IR terminal carbonyl ν(CO) bands to higher frequencies with respect to those of the starting acetyl complex **4**, and by downfield shifting of its ^{1}H NMR spectral C-methyl resonance at δ 3.32 with respect to that of **4** (2.78 ppm). A 78 ppm downfield shift for the carbenoid carbon in the ^{13}C{^{1}H} NMR spectrum of **5** (to δ 317 ppm) vs **4** further identifies **5** as a Fischer carbene complex.[22]

Complex **5** also has the reactivity of a typical Fischer carbene complex. Treatment of **5** in CH_2Cl_2 solution with 1 equivalent of $Bu^n_4N^+I^-$ immediately and quantitatively released its acetyl precursor **4**, thus satisfying a standard assay for cationic alkoxycarbene compounds.[3,13] In further agreement with its reactivity as a Fischer carbene complex, **5** instantaneously added hydride at the carbenoid centre[3] from $LiHBEt_3$ in THF at -78°C and transformed to its α-ethoxyethyl derivative [$CH_3CH(OEt)Co(CO)_3(PPh_3)$] (**6**). A surprising outcome of this second of the three-step set of coordinated ligand reactions in eq. (2) is that the cobalt α-ethoxyethyl product **6** promptly decomposed upon warming to room temperature. IR and ^{31}P{^{1}H} NMR spectral data for cold solutions of **6** nevertheless closely match that obtained for the stable alkoxymethyl compounds [$ROCH_2Co(CO)_3(PPh_3)$] (**8**, R = Me; **9**, R = Et) (*vide infra*).

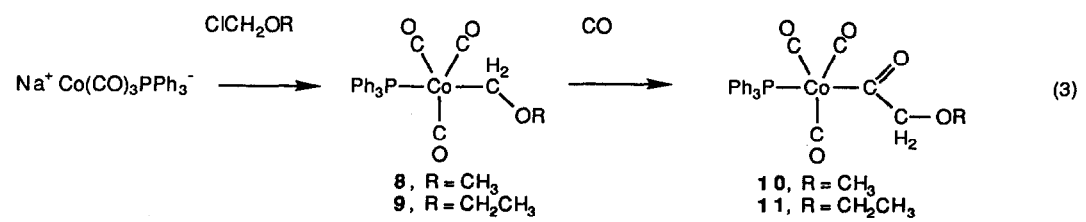
Carbonylating **6**, the third step set in eq. (2), between -78°C and room temperature with 1 atm. of CO provided the ethoxypropionyl complex [$CH_3CH(OEt)C(O)Co(CO)_3(PPh_3)$] (**7**). It was isolated as a stable, yellow solid in 82% yield. The IR spectrum of **7** in the terminal carbonyl stretching frequency region resembles those of [$CH_3C(O)Co(CO)_3(PPh_3)$] (**4**) and alkoxyacetyl compounds [$ROCH_2C(O)Co(CO)_3(PPh_3)$] (**10**, **11**), although the 25 cm^{-1} reduction in frequency of the acyl ν(C=O) band for **7** vs **10** and **11** exceeds the previously reported 12 cm^{-1} drop for the ethoxypropionyl vs alkoxyacetyl ligands coordinated to $Fe(CO)_2(\eta^5\text{-}C_9H_7)$.[2]

^{1}H and ^{13}C{^{1}H} NMR spectra of **7** (Table 1) further define the ethoxypropionyl ligand and closely resemble published data for [$CH_3CH(OEt)C(O)Fe(CO)_2(\eta^5\text{-}C_9H_7)]^-$[2] and [$CH_3CH(OEt)C(O)Co(CO)_2$(dppe)].[1] Noteworthy assignments for the ^{13}C{^{1}H} NMR spectrum of **7** (all carbons are assigned) include the doublets at δ 248 for the acyl carbonyl [J(PC) = 31 Hz] and δ 199 for the terminal carbonyls [J(PC) = 21 Hz]. The ^{31}P{^{1}H} spectrum for **7** shows a singlet at δ 50, in agreement with the other acyl complexes reported in this study, and demonstrates the absence of any other phosphorus-containing species.

The increased bench stability of the cobalt acyl complex **7** compared to its alkyl precursor **6** follows the trend that we noted for analogous pairs of acyl and alkyl complexes ligand to $Fe(CO)_2(\eta^5\text{-}C_9H_7)^2$ and $Co(CO)_2$(dppe).[1] Surprisingly, [$CH_3CH(OEt)Co(CO)_3(PPh_3)$] (**6**) readily decomposes at room temperature (cf. the cobalt alkoxymethyl complexes **8** and **9**) to give [$Co(CO)_3(PPh_3)]_2$ as the only organometallic product. Such reactivity is consonant with homolytic Co—C bond dissociation and the formation of a geminate radical pair, an established decomposition pathway of secondary alkyl cobalt(III) complexes.[23] If the unstable cobalt hydride $HCo(CO)_3(PPh_3)$[15a,24] had formed due to the operation of an alternative decomposition pathway, then we would have at least detected it, based on work by Martin and Baird[10] with $HCo(CO)_3(PPh_2Me)$.

Preparation of alkoxyacetyl complexes [$ROCH_2C(O)Co(CO)_3(PPh_3)$] (**10**, R = CH_3; **11**, R = CH_2CH_3)

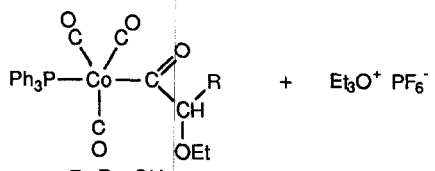
We prepared the methoxymethyl and ethoxymethyl complexes [$ROCH_2Co(CO)_3(PPh_3)$] (**8** and **9**, respectively) by metallating chloromethyl methyl and ethyl ethers with $Co(CO)_3(PPh_3)^-Na^+$ [eq. (3)]. Both **8** and **9**, stable yellow solids, were isolated analytically pure in 83–89% yields after column chromatography on alumina.



(3)

IR and NMR spectral data adequately characterize **8** and **9** as *trans*-diaxial alkoxymethyl

complexes, $[ROCH_2Co(CO)_3(PPh_3)]$, having local C_{3v} symmetry. Their IR spectra show two terminal carbonyl ν(CO) bands, a weak absorption near 2040 cm^{-1} and a broad, intense band at 2060 cm^{-1} (for the nearly degenerate E mode vibrations) which typify alkyl cobalt complexes, $RCo(CO)_3PR_3$.[8,9,21] NMR spectral absorptions for the $CoCH_2$ group



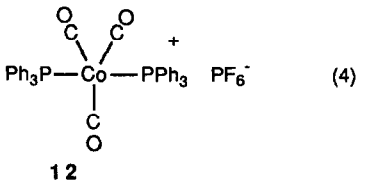
7, R = CH_3
11, R = H

are also diagnostic due to ^{31}P spin coupling: the $CoCH_2$ group absorbs as doublets in both the ^1H and $^{13}C\{^1H\}$ NMR spectra, δ 5.30, J(PH) = 2 Hz and δ 67–70, J(PC) = 27 Hz, respectively.

Carbonylating **8** and **9**, either *in situ* in THF or after purification in CH_2Cl_2, using 1 atm. of CO gives their alkoxyacetyl compounds **10** and **11** in over 90% isolated yields. These alkoxyacetyl compounds were isolated analytically pure as yellow solids that are stable at room temperature. Their IR spectra in relatively polar solvents such as CH_2Cl_2 or THF display one medium intensity acyl ν(C=O) band near 1670 cm^{-1} and three terminal carbonyl ν(C≡O) bands, including two closely spaced and intense E vibrational modes at 1982 and 1964 cm^{-1}. This pattern of carbonyl ν(CO) absorptions is typical for (acyl)$Co(CO)_3(PPh_3)$ compounds. The presence of two intense E vibrational modes for these acyl complexes vs one for the alkyl complexes (alkyl)$Co(CO)_3(PPh_3)$ has been noted previously for analogous pairs of such acyl/alkyl complexes.[21]

Both the methoxymethyl **8** and methoxyacetyl **10** compounds have been previously reported. The Heck–Breslow procedure had been used to generate **10**,[17a] which ejected CO upon warming to give **8**.[19] Although similar decarbonylation reactions have been noted recently under ambient conditions for analogous chloroacetyl[9b] and propargylacyl[25] compounds, we did not discern room-temperature decarbonylation of alkoxyacetyl compounds **10** and **11** to **8** and **9**, respectively, by ^1H or ^{31}P NMR spectroscopy. Our spectral data for **8** and **10** (Table 1) agrees with the previously reported IR and ^1H NMR spectral assignments.[17a,19]

The present high yield access to the alkoxyacetyl compounds **10** and **11** by direct carbonylation is not surprising given our previous report on converting a related ethoxymethyl, $[EtOCH_2Co(CO)_3(PMePh_2)]$ to its acyl derivative, $[EtOCH_2(CO)Co(CO)_3(PMePh_2)]$.[11] The ready availability of the more tractable triphenylphosphine-substituted alkoxyacetyl compounds **10** and **11**, as well as the ethoxypropionyl analogue $[CH_3CH(OEt)C(O)Co(CO)_3(PPh_3)]$ (**7**), make them attractive substrates for attempted chain growth reactions, as outlined in eq. (1) [R = H and Me; ML_x = $Co(CO)_3(PPh_3)$].



12

Reactions of $Et_3O^+PF_6^-$ *with α-alkoxyacyl complexes* $[CH_3CH(OEt)C(O)Co(CO)_3(PPh_3)]$ (**7**) *and* $[ROCH_2C(O)Co(CO)_3(PPh_3)]$ (**10**, R = Me; **11**, R = Et)

Treatment of either α-alkoxyacyl complex **7** or **11** with purified $Et_3O^+PF_6^-$ (1–1.5 equivalents) in CH_2Cl_2 [eq. (4)] provided identical results. The starting acyl complex was consumed in 8–20 h and the only organocobalt complex detected in significant concentration was the known[18] cobalt carbonyl salt $[Co(CO)_3(PPh_3)_2]^+PF_6^-$ (**12**). Its IR [ν(CO) 2008 cm^{-1}] and $^{31}P\{^1H\}$ NMR [δ 55.4] spectral data match that of independently prepared samples. Only trace amounts of $[Co(CO)_4(PPh_3)]^+PF_6^-$[26] were detected. IR: ν(CO) 2143 (s), 2100 (m), 2071 (vs, sh), 2058 (vs) cm^{-1}; $^{31}P\{^1H\}$ NMR: δ 57.3.

We substituted electrophilic methylating agents for triethyloxonium hexafluorophosphate in its reactions with cobalt acyl complexes. Thus, methyl triflate or $[HC(OMe)_2]^+PF_6^-$ (1.0–1.5 equivalents) upon adding to $[CH_3C(O)Co(CO)_3(PPh_3)]$ (**4**), $[EtOCH_2C(O)Co(CO)_3(PPh_3)]$ (**11**) and $[CH_3CH(OEt)C(O)Co(CO)_3(PPh_3)]$ (**7**) in CH_2Cl_2 at room temperature exclusively formed the same cobalt carbonyl degradation product, **12**. These results (particularly with the cobalt acetyl **4**) are surprising, since both methylating reagents had been used extensively in transforming iron acetyl complexes, $[CH_3C(O)Fe(CO)(L)Cp]$ (L = CO, PPh_3), to their cationic methoxycarbene compounds.[3] Not surprisingly, $HBF_4 \cdot OEt_2$ (1 equivalent) also rapidly converted **4** to **12**.

The ill-defined reactions of the α-ethoxyacyl cobalt compounds **7** and **11** with $Et_3O^+PF_6^-$ [eq. (4)] or other alkylation agents to give $Co(CO)_3(PPh_3)_2^+$ (**12**) do not preclude the desired alkoxycarbene compounds [cf. eqs (1) and (2)] from forming as kinetic products. Analogous $Co(CO)_2$(dppe) alkoxycarbene compounds have been character-

ized.[1] In the present study the anticipated alkoxycarbene intermediates [RCH(OEt)C(OEt)=Co(CO)$_3$(PPh$_3$)]$^+$ then apparently would degrade to **12**. In contrast, the fully characterized cobalt alkoxycarbene compound [CH$_3$C(OEt)=Co(CO)$_3$(PPh$_3$)]$^+$ (**5**) only slowly decomposes to **12**. The slow rates with which cobalt acyl complexes **4**, **7** and **11** reacted with even excess $Et_3O^+PF_6^-$ at room temperature precluded further study at lower temperatures.

CONCLUSIONS

Our inability to synthesize α-alkoxycarbene compounds, [RCH(OEt)C(OEt)=Co(CO)$_3$(PPh$_3$)]$^+$ (R = H, CH$_3$), prevented carrying out the first iteration of the acyl ligand activation–reduction–carbonylation sequence [eq. (1)]. The alkoxycarbene complex [CH$_3$(EtO)C=Co(CO)$_3$(PPh$_3$)]$^+PF_6^-$ (**5**) that was isolated is the first fully characterized, cationic cobalt Fisher carbene compound that we are aware of, although several neutral analogues,[22] e.g. [R(EtO)C=Co(CO)$_3$(MPh$_3$)] (M = Si, Sn, Ge),[27] have been reported. Another unexpected development was the instability of the secondary alkyl complex [CH$_3$CH(OEt)Co(CO)$_3$(PPh$_3$)] (**6**) vs the stable primary analogues [ROCH$_2$Co(CO)$_3$(PPh$_3$)] (**8** and **9**), an observation that merits further study.

(*Received* 18 *August* 1992; *accepted* 1 *October* 1992)

Abstract—The synthesis of dinitrosylmolybdenum(0) complexes of Schiff bases by a single-step ligand-exchange process has been reported for the first time by the reaction of $[Mo(NO)_2(acac)_2]$ with the Schiff bases (LH_2) obtained by the condensation of salicylaldehyde or *o*-vanillin and benzoylhydrazide, or isonicotinoylhydrazide, and are of the type $[Mo(NO)_2(LH)_2]$. The Schiff bases behave as monobasic bidentate ligands coordinating through the azomethine nitrogen and enolic oxygen after deprotonation. Two geometric isomers having nitrosyl groups *trans* to each other have been observed in solution. Another complex, $[MoO_2(sal\text{-}INH)\cdot MeOH]$, has also been synthesized for comparison.

In recent years there has been a great deal of interest in dinitrosylmolybdenum(0) complexes because of their use as homogeneous catalysts.[1,2] The widely applied routes to prepare these complexes are: (1) the reaction of $[\{Mo(NO)_2X_2\}_n]$ (X = halogens) with ligands[3] and (2) reaction of nitrosyl halides with molybdenum hexacarbonyl or its derivatives.[4] Bencze *et al.*[5] have generated dinitrosylmolybdenum(0) species by the reductive reaction of nitric oxide with molybdenum pentachloride. The generation of dinitrosylmolybdenum(0) species in aqueous-aerobic conditions and its stabilization using mono- and bidentate ligands have been reported recently.[6]

In spite of the considerable growth of literature on Schiff base complexes of dioxomolybdenum(VI),[7] no attempts have so far been reported of the synthesis of analogous dinitrosylmolybdenum(0) complexes.[8] In order to find a suitable starting material and to develop a more versatile synthetic route to dinitrosyl molybdenum(0) complexes, we have studied the reactivity of $[Mo(NO)_2(acac)_2]$ (acacH = acetylacetone) towards Schiff bases. Some dinitrosylmolybdenum(0) complexes of the following Schiff bases (**1** and **2**) have thus been isolated in a

single-step process and their spectral studies are reported here.

EXPERIMENTAL

Preparations

All reagents were of analytical grade and were used without further purification. The Schiff bases **1** and **2** were synthesized following the literature procedures.[9–11] $[Mo(NO)_2(acac)_2]$[6a] and $[MoO_2(acac)_2]$[12] were prepared by the methods described previously.

Preparation of $[Mo(NO)_2(Hsal\text{-}BZH)_2]$

A solution of $[Mo(NO)_2(acac)_2]$ (0.354 g, 0.001 mol) in methanol (10 cm^3) was added to a hot solution of **1a** (0.48 g, 0.002 mol) in methanol (25 cm^3) and the reaction mixture was refluxed on a water bath for 30 h. The separated yellow solid was filtered, washed with methanol and dried at 100°C. Yield: 0.39 g (60%). Found: C, 53.3; H, 3.3; N, 13.0; Mo, 15.5. Calc. for $C_{28}H_{22}N_6O_6Mo$: C, 53.0; H, 3.5; N, 13.2; Mo, 15.1%.

The following complexes were similarly prepared.

$[Mo(NO)_2(Hvan\text{-}BZH)_2]$. Yield: 0.35 g (50%). Found: C, 51.3; H, 3.7; N, 12.4; Mo, 13.6. Calc. for $C_{30}H_{26}N_6O_8Mo$: C, 51.9; H, 3.8; N, 12.1; Mo, 13.8%.

$[Mo(NO)_2(Hsal\text{-}INH)_2]$. Yield: 0.31 g (49%). Found: C, 49.2; H, 3.3; N, 17.3; Mo, 14.7. Calc. for $C_{26}H_{22}N_8O_6Mo$: C, 48.9; H, 3.5; N, 17.5; Mo, 15.0%.

$[Mo(NO)_2(Hvan\text{-}INH)_2]$. Yield: 0.39 g (56%). Found: C, 48.5; H, 3.8; N, 15.7; Mo, 13.4. Calc. for $C_{28}H_{26}N_8O_8Mo$: C, 48.1; H, 3.7; N, 16.0; Mo, 13.7%.

Preparation of $[MoO_2(sal\text{-}INH)\cdot MeOH]$

The Schiff base **2a** (0.482 g, 0.002 mol) was dissolved in methanol (25 cm^3) and to this $[MoO_2(acac)_2]$ (0.66 g, 0.002 mol) was added with vigorous stirring. The reaction mixture was boiled under reflux on a water bath for 3 h and the orange–yellow precipitate which separated was filtered, washed with methanol and dried *in vacuo* at room temperature. Yield: 0.27 g (68%). Found: C, 42.4; H, 3.2; N, 10.3; Mo, 23.9. Calc. for $C_{14}H_{13}N_3O_5Mo$: C, 42.1; H, 3.3; N, 10.5; Mo, 24.1%.

Measurements

Elemental analyses were performed by the microanalytical section of this laboratory. Molybdenum content was determined gravimetrically as bis(8-hydroxyquinolinato)dioxomolybdenum (VI) after decomposing the complexes with concentrated HNO_3. IR spectra were recorded as Nujol mulls and in KBr on a Perkin–Elmer Model 1620 FT-IR spectrophotometer. ^1H NMR spectra were obtained using a Bruker WH-90 spectrometer in DMSO-d_6 using tetramethylsilane as an internal standard. The electrical conductance measurements were performed in 1×10^{-3} M dimethylformamide solutions using a Toshniwal conductivity bridge (Type CL01-02A) and a dip-type cell calibrated with potassium chloride solutions. The molecular weight measurement was carried out by Rast's method[13] using diphenyl as the solvent.

RESULTS

$[MoO_2(acac)_2]$ has been used as a precursor to prepare dioxomolybdenum(VI) complexes by ligand exchange reactions involving protonated Schiff bases as well as other ligands.[7] $[MoO_2(sal\text{-}INH)\cdot MeOH]$ reported here has also been synthesized similarly using $[MoO_2(acac)_2]$ and **2a**. This complex has also been synthesized recently by Zhai *et al.*[14] using $[MoO_2(butanediolato)_2\cdot 2(butanediol)]$. The Schiff base behaves as a dibasic tridentate ligand and methanol occupies the sixth position.

The use of $[Mo(NO)_2(acac)_2]$ as a starting material for dinitrosylmolybdenum(0) complexes has not yet been reported in the literature. We have found this precursor very useful in preparing such complexes of the Schiff bases. Thus, $[Mo(NO)_2(acac)_2]$ undergoes ligand exchange reaction with the Schiff bases **1** and **2** in refluxing methanol to yield the corresponding dinitrosyl complexes of the type $[Mo(NO)_2(LH)_2]$ (LH_2 = Schiff bases **1** and **2**).

$$[Mo(NO)_2(acac)_2] + 2LH_2 \xrightarrow{MeOH} [Mo(NO)_2(LH)_2] + 2acacH$$

Under these reaction conditions complete removal of coordinated acetylacetone occurred and two molecules of the Schiff bases, which behave as monobasic bidentate ligands (*vide infra*), occupied four positions of the octahedron. Analytical data support the above formulation of the complexes. The decomposition temperature (> 250°C) indicates increased stability of the complexes. These diamagnetic complexes are insoluble in most of the

organic solvents but soluble in coordinating solvents like pyridine, DMF and DMSO. The nitrosyl complexes do not lose weight on heating at 150°C for 1 h but the dioxo complex does, corresponding to the loss of one molecule of methanol; information which confirms the coordination of methanol in $[MoO_2(sal\text{-}INH)\cdot MeOH]$. The coordinated monodentate ligands in dioxomolybdenum(VI) complexes of the type $MoO_2L\cdot X$ (X = monodentate ligand) are known to undergo cleavage on heating due to weak coordination and their labile nature.[15]

The low molar conductance values (3.0–8.0 Ω mol^{-1} cm^2) of the complexes in DMF indicate their non-electrolytic behaviour. Although molecular weight measurement on $[MoO_2(sal\text{-}INH)\cdot MeOH]$ indicated its monomeric nature (found: 382, calc.: 399), such measurements on nitrosyl complexes were not possible due to their poor solubility in suitable organic solvents. The monomeric nature of the dinitrosyl complex $[Mo(NO)_2(pic)_2]$ (pic = 2-picolinic acid) has, however, been confirmed by an X-ray study.[6c] Thus, we also suggest a monomeric nature with octahedral geometry for the nitrosyl complexes reported here.

IR spectra

A partial listing of the IR spectra of the ligands and their complexes is given in Table 1. The IR spectra of the complexes show distinct changes in their band positions relative to those of the starting material. For example, the IR spectrum of $[Mo(NO)_2(acac)_2]$ is reported to show two strong bands at 1763 and 1645 cm^{-1} due to ν(NO) stretches of the *cis*-$\{Mo(NO)_2\}^6$ moiety.[6a] In the dinitrosyl complexes reported here, the IR spectra show only one band centred at 1665–1678 cm^{-1} due to ν(NO), suggesting a *trans* disposition of the NO group.

The Schiff bases exhibit a broad band at 2800–3000 cm^{-1}, which is assigned to the intramolecularly hydrogen-bonded ν(OH) stretch. The absence of this band and appearance of a broad band at 3400 cm^{-1} suggests the existence of a free phenolic group in the nitrosyl complexes. In $[MoO_2(sal\text{-}INH)\cdot MeOH]$ this band may be due to the ν(OH) stretch of the coordinated methanol. This is further supported by the appearance of a new band at 1005 cm^{-1} due to the ν(C—O); the ν(C—O) stretch in methanol occurs at 1034 cm^{-1}.[16] Bands due to ν(C=O) and ν(NH) in the free Schiff bases appear in the regions 1650–1692 and 3200–3270 cm^{-1}, respectively. These bands disappear in the complexes indicating the destruction of the carbonyl moiety due to enolization and consequent proton replacement with the metal. A new band appearing in the region 1225–1256 cm^{-1} is assigned to the ν(C—O)(enolic) mode.[17] The ν(C=N) stretch of the ligands (1607–1626 cm^{-1}) shifts to a lower frequency by 6–24 cm^{-1}, indicating the coordination of the azomethine nitrogen.[18] A band at 900–1000 cm^{-1} due to the ν(N—N) stretch of the ligands shifts to a higher frequency by 11–48 cm^{-1} upon complexation. The magnitude of this shift indicates the monodentate coordination[19] of the >N—N< residue, as a shift of > 50 cm^{-1} is usually observed in bidentate coordination. A shift to a higher frequency in ν(N—N) is expected due to the reduction of the lone pair–lone pair repulsive forces of the adjacent nitrogen atoms.[20] Thus, the IR data suggest the monobasic bidentate nature of the Schiff bases in the nitrosyl complexes in which they coordinate through the azomethine nitrogen and deprotonated oxygen of the hydrazide moiety. Similar bidentate behaviour of the Schiff base H_2sal-BZH has been suggested in the complex $[UO_2(Hsal\text{-}BZH)_2]$.[9] In $[MoO_2(sal\text{-}INH)\cdot MeOH]$

the Schiff base behaves as a dibasic tridentate ONO donor ligand.

NMR spectra

Further evidence for the coordinating mode of the ligands is derived from the ^{1}H NMR spectra. The NMR spectra of the representative ligands and their complexes are given in Table 2. The sharp singlet due to the azomethine proton shifts downfield and splits into two signals. This downfield shift suggests the coordination of the azomethine nitrogen to molybdenum[21] while splitting of the signal may be due to the presence of two isomeric forms in solution as discussed later. The Schiff bases also exhibit signals at 11.15–11.23 and 12.0–12.28 ppm (singlet, 1H each) due to NH and phenolic protons, respectively. These signals are identified by the D_2O exchange experiments. The absence of NH proton resonance on complexation suggests the enolization of the keto group and subsequent coordination of the enolic oxygen. Further, two resonances are observed due to the phenolic OH which suggest the existence of the free phenolic group in the nitrosyl complexes. A slightly upfield shift of the resonances is expected due to the breaking of the hydrogen bond between the phenolic hydrogen and azomethine nitrogen atoms. The absence of both NH and phenolic proton resonances and the downfield shift of the azomethine proton resonance in $[MoO_2(sal\text{-}INH)\cdot MeOH]$ are in agreement with the dibasic tridentate behaviour of the ligand in the complex. The methyl protons of the methanol appear at 3.64 ppm.

DISCUSSION

The most common method used for the synthesis of dinitrosyl complexes is the reaction of $[\{Mo(NO)_2X_2\}_n]$ (X = halogen) with the free ligands. However, poor stability and high reactivity of this precursor towards air and moisture limit its use to an inert atmosphere. The synthetic route described here is a one-step ligand-exchange reaction between $[Mo(NO)_2(acac)_2]$ and the Schiff bases, which can be prepared in aerobic conditions using a simple set-up. It is interesting to note that during the exchange reaction the nitrosyl groups remain intact and do not oxidize to dioxo species as in the complex $[MoO_2(sal\text{-}INH)\cdot MeOH]$, which shows two bands at 938 and 911 cm^{-1} characteristic of ν_{sym}(O=Mo=O) and ν_{asym}(O=Mo=O) stretches, respectively. The nitrosyl complexes do not furnish any band in the O=Mo=O stretching region. Further, the presence of only one band at 1665–1680 cm^{-1} due to the ν(NO) stretch strongly suggests isomerization of the nitrosyl groups from *cis* in the precursor, $[Mo(NO)_2(acac)_2]$, to *trans* in the Schiff base complexes. The presence of the nitrosyl group was further confirmed qualitatively by using the Griess reagent.[22]

On the basis of *trans*-dinitrosyl geometry, the complexes are expected to show two geometrical isomers (**3** and **4**) and both the isomers are expected

[a] Letters given in parentheses indicate the type of signal. s = singlet, d = doublet, m = multiplet.

to show only one signal each for the azomethine and phenolic protons. However, chemical shifts may be different due to the different arrangement of the ligands around the molybdenum ion. The NMR spectra in fact show two sets of signals for each proton, indicating the presence of both isomers in solution. Based on the height of the signals and integration ratios, the percentage of these isomers in solution are approximated to be 60 : 40. However, it is not possible at present to distinguish between the set of the signals for each particular isomer. Unfortunately, the complexes reported here have not been suitable for X-ray diffraction.

CONCLUSIONS

The complexes prepared herein are the first examples of neutral dinitrosyl molybdenum(0) complexes of Schiff bases. Using $[Mo(NO)_2(acac)_2]$ as a precursor, it is now possible to prepare a variety of this kind of complex. Further investigation of the physical and chemical properties of these novel complexes and extension of this work is underway.

STUDIES ON ACETYLFERROCENYLNAPHTHOYLHYDRAZONE (AND DIACYL HYDRAZONE) AND ITS COORDINATION COMPOUNDS WITH LEAD(II)

ZHANG HONGYUN,* LI FENG, CHEN PEIKUN, CHE DEJI, CHEN DONGLI and ZHANG HONGQUAN

Chemistry Department, Zhengzhou University, Zhengzhou 450052, China

(*Received* 10 *August* 1992; *accepted* 1 *October* 1992)

Abstract—Acetylferrocenylnaphthoylhydrazone, acetylferrocenyl-3-hydroxyl-2-naphthoylhydrazone, 1,1′-diacetylferrocenylnaphthoylhydrazone and 1,1′-diacetylferrocenyl-3-hydroxyl-2-naphthoylhydrazone have been synthesized by the condensation of acetylferrocene or 1,1′-diacetylferrocene with naphthoylhydrazine or 3-hydroxyl-2-naphthoylhydrazine, respectively. Their lead(II) coordination compounds have been prepared and characterized by elemental analyses, IR, ^{1}H NMR, UV, TG–DTA and molar conductivities. Results show that the ligands coordinate in the enolic form with lead(II) and the thermostabilities of the coordination compounds are higher than that of the corresponding ligand due to the formation of the chelate ring.

The special structure of ferrocene has attracted wide interest and a series of derivatives have been synthesized.[1–3] Due to the formation of stable coordination compounds with heavy metals ions the aroylhydrazone ligands are promising as specific reagents in analytical and extractive chemistry.[4] This type of compound possesses strong biological activity and can inhibit many vital enzymatic reactions catalysed by heavy metals.[5] It is reported that the replacement of aromatic groups by the ferrocenyl moiety in penicillin and cephalosporin molecules improves their antibiotic activity.[6] In recent years the research on ferrocenylaroylhydrazone and their coordination compounds has become more extensive.[7–9] In this paper, we report the syntheses of acetylferrocenylnaphthoylhydrazone, acetylferrocenyl-3-hydroxyl-2-naphthoylhydrazone, 1,1′-diacetylferrocenylnaphthoylhydrazone and 1,1′-diacetylferrocenyl-3-hydroxyl-2-naphthoylhydrazone and their coordination compounds with lead(II). The form in which the ligands coordinate lead(II), the composition and properties of the coordination compounds were elucidated by elemental analyses, IR, ^{1}H NMR, UV, TG–DTA and molar conductance measurements.

EXPERIMENTAL

Measurements

UV–vis spectra were recorded on a HITACHI 220A UV spectrophotometer in the 200–500 nm region using a solution in DMF. IR spectra were obtained using KBr discs with a SHIMADZU IR-435 spectrophotometer in the 4000–400 cm^{-1} region. ^{1}H NMR were measured with an AC-80 NMR spectrophotometer using DMSO as a solvent and TMS as an internal standard. TG–DTA data were measured with a RIGAKU thermal analyser in a nitrogen atmosphere from room temperature to 800°C. Molar conductance values were obtained with a DDS-11 conductometer from Shanghai Second Analytical Equipment Factory, using DMF as a solvent at 20°C. Carbon, hydrogen and nitrogen were measured with a CARLO-ERBA 1106 elemental analyser.

Materials

The ferrocene used was the industrial product from state operated 504 factory after purifying. Acetylferrocene and 1,1′-diacetylferrocene were prepared[10,11] and purified[12] by the method described in the literature. Naphthoylhydrazine and

3-hydroxyl-2-naphthoylhydrazine have been prepared, respectively, by the condensation of methyl naphthoate and methyl 3-hydroxyl-2-naphthoate with hydrazine hydrate. Acetates and other related reagents were of analytically pure grade.

Synthesis of ligand HL^1 (**1**)

Naphthoylhydrazine (3.72 g, 0.02 mol) and acetylferrocene (4.56 g, 0.02 mol) in anhydrous alcohol were heated under reflux with stirring at 85°C for 8 h, cooled and filtered. The crude product was recrystallized twice in anhydrous alcohol to obtain brown–red crystals and dried *in vacuo*. Yield 80%, m.p. 211–212°C.

Synthesis of ligand H_2L^2 (**2**)

H_2L^2 was synthesized with a molar ratio of 1 : 2 of 1,1′-diacetylferrocene and naphthoylhydrazine in anhydrous alcohol with the same operation as HL^1. The crude product was dissolved in DMF and filtered. Anhydrous alcohol was added to the filtrate with stirring and then the golden yellow powder was separated. Yield 65%, m.p. 209–210°C.

Synthesis of ligand HL^3 (**3**)

A mixture of acetylferrocene and 3-hydroxyl-2-naphthoylhydrazine in a molar ratio of 1 : 1 was reacted in anhydrous alcohol under reflux using the same operation as HL^1. The product was recrystallized with a mixed solvent of anhydrous alcohol and cyclohexane (1 : 1) and dried *in vacuo*, and reddish-orange crystals were obtained. Yield 85%, m.p. 187.5–188.5°C.

Synthesis of ligand H_2L^4 (**4**)

The reaction mixture of 1,1′-diacetylferrocene and 3-hydroxyl-2-naphthoylhydrazine in a molar ratio of 1 : 2 was heated under reflux with stirring until the precipitate appeared, and continuously refluxed for 5 h, following the operation used for H_2L^2. The orange–yellow precipitate was obtained. Yield 80%.

Syntheses of coordination compounds PbL_2^1 (**5**) *and* PbL_2^3 (**7**)

A solution of $Pb(O_2CMe)_2 \cdot 3H_2O$ (0.379 g, 1 mmol) in anhydrous alcohol (10 cm^3) was added dropwise to a solution of HL^1 (0.792 g, 2.02 mmol) or HL^3 (0.824 g, 2.02 mmol) in anhydrous alcohol (30 cm^3). The reaction mixture was heated under reflux with stirring at 85°C for 6 h. The crystals which separated out on cooling were filtered and washed successively three times with 0.5% HNO_3, water and anhydrous alcohol, and dried *in vacuo*. PbL_2^1 is a yellow coordination compound, yield 68%, and PbL_2^3 is a yellow coordination compound, yield 80%.

Synthesis of coordination compound PbL^2 (**6**)

A solution of $Pb(O_2CMe)_2 \cdot 3H_2O$ (0.379 g, 1 mmol) in anhydrous alcohol (10 cm^3) was added dropwise with stirring to a solution of H_2L^2 (0.606 g, 1 mmol) in anhydrous alcohol and DMF (1 : 3) (30 cm^3). Following the operation for PbL_2^1, a yellow coordination compound was obtained. Yield 65%.

Synthesis of coordination compound PbL^4 (**8**)

A solution of $Pb(O_2CMe)_2 \cdot 3H_2O$ (0.190 g, 0.5 mmol) in anhydrous alcohol (15 cm^3) and triethyl orthoformate (4 cm^3) was added dropwise to a solution of HL^4 (0.32 g, 0.5 mmol) in anhydrous alcohol (15 cm^3), and triethylamine (0.4 cm^3) was added. The reaction mixture was heated under reflux at 85°C for 8 h, then evaporated to remove unreacted triethylamine and a little ethanol, and cooled and filtered. The precipitate was washed three times with hot alcohol and dried *in vacuo*. An orange–red coordination compound was obtained. Yield 65%.

RESULTS AND DISCUSSION

Elemental analyses and some physical properties

The ligands **1** and **3** are soluble in hot ethyl alcohol, but **2** and **4** are insoluble. They dissolve in strong polar solvents such as DMF and DMSO. Four coordination compounds of lead do not dissolve in common organic solvents such as ethyl alcohol, but are soluble in DMF. The results of the elemental analyses of the ligands and coordination compounds are given in Table 1. The ligands **1** and **3** coordinate to lead(II) with a molar ratio of 2 : 1, but **2** and **4** coordinate as 1 : 1. As the solubility of these lead(II) coordination compounds is less, we attempted to prepare the single crystal, but did not succeed. The polymerization number *n* of the structural formula of **6** and **8** in Fig. 1 considers chiefly that the coordination between ferrocenyl diaroylhydrazone and metals decreases the steric effect.

IR spectra and ^1H *NMR spectra*

The important IR absorption frequencies of the ligands and lead(II) coordination compounds are

Abbreviations: vs = very strong, s = strong, m = medium, w = weak.

listed in Table 2, and ^{1}H NMR data in Table 3. It is shown in Table 2 that the characteristic absorption frequencies of ν(N—H), ν(C=O), ν(C=N) and ν(N—N) appeared in the 3140–3260, 1613–1642, 1500–1622 and 905–936 cm^{-1} regions, respectively. The results indicate that there is an acylhydrazonyl group in the molecule of all the ligands, which exists in the keto form in the solid state.[5]

The results in Table 3 show that the single peak (5H) of unsubstituted cyclopentadiene and multiple peak (4H) of substituted cyclopentadiene appear in the range 4.00–4.74 ppm in the ^{1}H NMR spectra of HL^1 and HL^3. A multiple peak (4H) of substituted cyclopentadiene was observed in the range 4.09–4.97 ppm in the ^{1}H NMR spectra of H_2L^2 and H_2L^4. A multiple peak (7H or 6H) of the naphthene ring appears at 7.52–8.01 ppm, and the single peaks (1H) of N—H were observed in the 10.70–13.88 ppm region in the ^{1}H NMR spectra of the four ligands. A single peak (1H) of O—H was observed in the region 8.22–8.61 ppm in the ^{1}H NMR spectra of HL^3 and H_2L^4.[13] The results of ^{1}H NMR further prove that the free ligands exist in the keto form.

The IR spectra of the coordination compounds show significant changes as compared with those of the corresponding ligands. The characteristic absorption bands due to ν(N—H) and ν(C=O) disappeared, but two new absorption bands were observed in the 1578–1650 and 999–1242 cm^{-1} regions, respectively, which can be attributed to the stretching vibration of conjugate  and C—O groups.[8] The ν(C=N) absorption band was shifted to a lower frequency by 25–62 cm^{-1}, while the band attributed to ν(N—N) was shifted to a higher frequency by 2–5 cm^{-1}. The changes in these frequencies show that the ligands coordinate to lead(II) to form neutral coordination compounds through the methylenimine group nitrogen atom and amide oxygen negative ion,[8] and the ligands are present in the enolic form in the corresponding coordination compounds. The coordination compounds $PbL^2 \cdot 2H_2O$ and PbL^4 are insoluble in deuterated DMSO. The proton peak due to the N—H group disappeared in the ^{1}H NMR spectra of PbL_2^1 and $PbL_2^3 \cdot H_2O$,

Table 3. ^{1}H NMR of ligands (ppm)

Formula	Methyl group	Ferrocenyl group	Naphthenyl group	N—H	O—H
HL^1	2.18 3H(s)	4.00–4.74 5H(s), 4H(m)	7.52–8.00 7H(m)	10.70 1H(s)	
H_2L^2	2.26 3H(s)	4.09–4.77 4H(m)	7.55–7.99 7H(m)	10.76 1H(s)	
HL^3	2.22 3H(s)	4.24–4.71 5H(s), 4H(m)	7.35–8.01 6H(m)	11.34 1H(s)	8.61 1H(s)
H_2^4	2.09 3H(s)	4.49–4.97 4H(m)	6.69–7.26 6H(m)	13.88 1H(s)	8.22 1H(s)

which supported the conclusion of the IR spectra above. The characteristic absorption bands of the naphthene ring were observed in the IR spectra of the ligands and coordination compounds at 1570–1595 and 733–742 cm^{-1}. The characteristic absorption bands observed at 3085, 1442, 1105, 830, 503 and 482 cm^{-1} were attributed to the ferrocenyl group as ν(C—H), ν(C—C), δ(C—H), π(C—H) and δ(Fe-ring), respectively.[5]

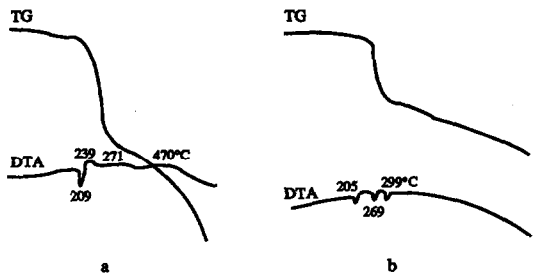

Fig. 2. The TG–DTA diagram of (a) the ligand H_2L^2 and (b) complex $PbL^2 \cdot 2H_2O$.

UV–vis spectra

UV–vis absorption bands of the ligands and lead(II) coordination compounds are shown in Table 4. It can be seen that there is a shoulder peak in the UV–vis spectra of the ligands and coordination compounds near 270 nm, which was attributed to the B band of cyclopentadiene. There is a weak and broad absorption band at *ca* 420–422 nm, arising from the transition of the 3*d* electrons on iron to either the non-bonding or antibonding orbitals of the cyclopentadienyl ring.[8] A strong K absorption band ($\pi \rightarrow \pi^*$ transition) appeared in the UV spectra of the ligands at 286–314 nm, while that of the coordination compounds is shifted to a longer wavelength by 2–20 nm. The results indicate that the ligands coordinate to lead(II) in the enol form, respectively, to form a greater conjugated system which decreased the energy of the whole system.

Thermal analysis

The results of TG–DTA for the ligand H_2L^2 and coordination compound $PbL^2 \cdot 2H_2O$ are shown in Fig. 2(a,b). It can be seen that the ligand H_2L^2 melted at 209°C, accompanied by the endothermal effect, then decomposed exothermally at 239°C. A weak endothermal peak appeared at 271°C. The whole weight loss is about 38.3% until 358°C, which suggests that two naphthalene rings break away from the molecule (calc. *ca* 42%). The weak and broad exothermal peak was observed at 470°C, and weight loss was 39% until 800°C, which was attributed to the decomposition of the ferrocenyl and acylhydrazonyl groups (the residue was iron). A weak endothermal peak and two endothermic decomposed peaks appear at 205, 269 and 299°C, respectively, in Fig. 2(b), $PbL^2 \cdot 2H_2O$. The three weight losses cannot be distinguished. It may be that it loses two molecules of water and two naphthalene groups, accompanied by the whole weight loss of *ca* 35.2% (calc. 34.2%). The two molecules of water lost at 205°C perhaps exist as coordination water. The chelate continues to decompose until 800°C to lose 26.4% of its weight. This suggests that whole coordination compounds decomposed completely and the remaining mixture perhaps is lead, iron and parts of the ferrocenyl group. The decomposition temperature of lead(II) coordination compounds is higher than that of the corresponding ligand, which suggests that the formation of the stable chelate ring in coordination compounds increased their thermal stable properties.

Molar conductance

The molar conductances of the ligands and coordination compounds in DMF are listed in Table

Table 4. UV–vis absorption bands of the ligands and coordination compounds (nm, λ_{max} DMF)

Formula	λ_{max} DMF I	II	III
HL^1	270sh	293	434
H_2L^2	270sh	286	438
HL^3	266	306	440
H_2L^4	270	314	440
PbL_2^1	270sh	295	431
$PbL^2 \cdot 2H_2O$	266sh	294	420
$PbL_2^3 \cdot H_2O$	266	326	440
PbL^4	270	326	442

Table 5. Molar conductance of the ligands and coordination compounds in DMF (Λ, $\Omega^{-1}\,cm^2\,mol^{-1}$), 20°C

Formula	Concentration (M)	Λ ($\Omega^{-1}\,cm^2\,mol^{-1}$)
HL^1	9.34×10^{-4}	6.76
H_2L^2	1.80×10^{-5}	38.40
HL^3	7.76×10^{-5}	45.10
H_2L^4	9.40×10^{-5}	46.00
PbL_2^1	1.91×10^{-4}	21.20
$PbL^2 \cdot 2H_2O$	1.30×10^{-5}	17.90
$PbL^3 \cdot H_2O$	1.00×10^{-5}	27.73
PbL^4	2.00×10^{-5}	47.00

5. The results from Table 5 show that the molar conductances are in the region 6.76–47.0 Ω^{-1} cm^2 mol^{-1} due to the ligands and coordination compounds being weak electrolytes (the reference values for 1 : 1 electrolytes have been taken as 65–90 Ω^{-1} cm^2 mol^{-1} in DMF).[14] Thus, it can be deduced that the ligand coordinates to lead(II) to form a stable neutral coordination compound, accompanied by the release of acetate.

(*Received* 17 *July* 1992; *accepted* 1 *October* 1992)

Abstract—Treatment of the Schiff bases 4-$MeC_6H_4C(H){=}NCy$ (**a**), 3-Me-4-$MeOC_6H_3$—$C(H){=}N$-2′,4′,6′-$Me_3C_6H_2$ (**b**) or 2,4-$Me_2C_6H_3C(H){=}N$-2′,4′,6′-$Me_3C_6H_2$ (**c**) with palladium(II) acetate gave the cyclometallated complexes **1a**, **1b** and **1c**. These reacted with NaX to give the halide-bridged complexes **2a**, **2b** and **2c** (X = Cl), **3a**, **3b** and **3c** (X = Br) and **4c** (X = I). Reaction of the halide-bridged dimers with $Ph_2PCH_2PPh_2$(dppm), *trans*-$Ph_2PCH{=}CHPPh_2$ (*trans*-dppe), *cis*-$Ph_2PCH{=}CHPPh_2$ (*cis*-dppe) or $Ph_2P(CH_2)_4PPh_2$ (dppb), as appropriate, in a dimer/diphosphine 1 : 1 or 1 : 2 molar ratio gave the dinuclear phosphine-bridged **4a**, **5a**, **4b**, **5b**, **5c–7c** and **8c–10c** and mononuclear **6a**, **6b**, **11c** and **12c** complexes, respectively. The structure of the bromo-bridged palladium(II) complex $[Pd\{4\text{-}Me\text{—}C_6H_3C(H){=}NCy\}(Br)]_2$ (**3a**) has been determined by X-ray crystallography. The structure has two asymmetrically bridging bromine atoms and a non-bonding Pd···Pd distance of 341.8(2) pm.

Cyclometallated complexes are an important part of organometallic chemistry and reviews covering them have appeared.[1–4] Many types of ligands may undergo cyclometallation reactions and we have studied those complexes derived from Schiff bases,[5] phenylimidazoles,[6] benzylidene hydrazones[7] and bis(N-benzylidene)-1,4-phenylenediamines.[8] The halide-bridged cyclometallated dimers are good starting materials for reactions with nucleophiles such as tertiary phosphines or diphosphines, pyridine, thallium acetylacetonate or thallium cyclopentadienyl. In particular, they react with tertiary diphosphines to give dinuclear or mononuclear species, depending on the dimer/diphosphine molar ratio.[9,10] The dinuclear compounds have bridging diphosphine and halide ligands. When the larger "bite" diphosphines are used the metal–metal distance is increased and complexes with a bridging disphosphine and terminal metal–halogen bonds are to be expected; such is the case of compounds with $Ph_2PCH_2CH_2PPh_2$.[11] In the present paper we report the synthesis and characterization of cyclometallated palladium(II) dinuclear and mononuclear complexes with the diphosphines $Ph_2PCH_2PPh_2$ (dppm), *trans*-$Ph_2PCH{=}CHPPh_2$ (*trans*-

* Author to whom correspondence should be addressed.

dppe), *cis*-$Ph_2PCH{=}CHPPh_2$ (*cis*-dppe) and $Ph_2P(CH_2)_4PPh_2$ (dppb). The "bite" of the diphosphine is also related to the symmetry of the compounds, as is described.

Another feature of the halide-bridged compounds is the question of whether they are dimeric or polymeric in nature. Spectroscopic results alone are not sufficient to resolve this problem; the most suitable method being X-ray diffraction. However, crystals of these complexes are often difficult to obtain, due to their low solubility, although some examples of chloro-bridged complexes are found in the literature.[12–16] For the bromo-bridged complexes only one cyclometallated bromine dimer has been reported[17] with monodentate Schiff base ligands (a novel tetranuclear bromine-bridged complex has also been described recently[8]). In the present paper we also report the X-ray crystal structure of one of the bromo-bridged complexes.

RESULTS AND DISCUSSION

Treatment of 4-$MeC_6H_4C(H){=}NCy$ (**a**), 3-Me-4-$MeOC_6H_3C(H){=}N$-2′,4′,6′-$Me_3C_6H_2$ (**b**) or 2,4-$Me_2C_6H_3C(H){=}N$-2′,4′,6′-$Me_3C_6H_2$ (**c**) with palladium(II) acetate in boiling glacial acetic acid under dinitrogen gave the cyclometallated acetato-bridged complexes **1a**, **1b** and **1c**, respectively, as air-stable solids. These were converted into the corresponding halide-bridged analogues by treatment in acetone with aqueous sodium chloride or sodium bromide to give the chloro-bridged **2a–2c**, bromo-bridged **3a–3c** and iodo-bridged **4c** complexes, respectively, as air-stable solids (see Experimental and Tables 1 and 2). Compounds **1b**, **2b** and **3b** have been prepared by us[18] earlier (corrected and more complete NMR data is given in this paper) and they have been used here as starting materials for the synthesis of the diphosphine complexes. The

[a] ν(C=N) values for **a** = 1642vs, **b** = 1635m and **c** = 1625s (cm^{-1}).

[b] ν(COO) values for **1a**: ν_{as}(COO) = 1578m, ν_s(COO) = 1415s; **2a**: ν_{as}(COO) = 1582s; ν_s(COO) = 1412m; ν_{as}(COO) = 1586, ν_s(COO) = 1408s (cm^{-1}).

acetato- and halide-bridged dimers show the typical features of similar complexes prepared by us.[5] Thus, the IR spectrum of complexes **1a–1c** shows the ν_{as}(COO) and ν_s(COO) stretching modes of the acetato ligands at 1578m, 1415s (**1a**), 1582s, 1412m (**1b**) and 1586s, 1408s cm^{-1} (**1c**); the separation between them is in agreement with bridging acetato groups.[19] The shift of the ν(C=N) vibration towards lower wavenumbers[20] and the shift of the *H*C=N resonance towards lower frequency[20] and the shift of the *H*C=N resonances towards lower frequency[21] in the ^{1}H NMR spectrum (*ca* 0.5–1.0 ppm) show that the palladium atom is bonded through the nitrogen atom of the C=N group (see Tables 1 and 2). Only one singlet (integrating for 6H) is observed in the ^{1}H NMR spectrum for the *Me*CO_2 resonances, indicating that the Schiff base ligands are in a *trans* disposition.[5a,10]

Treatment of the halide-bridged dimer complexes with $Ph_2PCH_2PPh_2$ (dppm), *trans*-Ph_2PCH=$CHPPh_2$ (*trans*-dppe) or $Ph_2P(CH_2)_4PPh_2$ (dppb) in a dimer/diphosphine 1 : 1 molar ratio gave the dinuclear complexes **4a**, **5a**, **4b** and **5b** as 1 : 1 electrolytes, and **5c–7c** and **8c–10c** as molecular compounds (see Scheme 1). They have been fully characterized by elemental analysis (carbon, hydrogen, nitrogen) and IR, $^{31}P\{^1H\}$ and ^{1}H NMR spectroscopy. The larger "bite" disphosphines *trans*-

[a] Spectra measured at 100.6 MHz (*ca* ±20°C); chemical shifts (δ) in ppm (±0.1) to a high frequency of 85% H_3PO_4.

[b] Spectra measured at 250 MHz (*ca* ±20°C); chemical shifts (δ) in ppm (±0.01) to a high frequency of $SiMe_4$.

[c] Coupling constants in Hz.

[d] s, singlet; d, doublet; dd, doublet of doublets; t, triplet.

[e] Proton resonances of the aniline ring.

[f] δ(Me) corresponds to the 2′-Me and 6′-Me groups; integration is for 6H.

[g] δ(Me) corresponds to the 4′-Me group; integration is for 3H.

[h] Corresponds to the C(4)-*Me* group in **a**, **1a–6a**; to the C(3)-*Me* group in **b**, **1b–6b**; and to the C(2)-*Me* and C(4)-*Me* groups in **c**, **1c–12c**. In **5c–12c** the lower value is for C(4)-*Me*.

[i] δ(H6) values: **1**, the H2, H3, H5 and H6 resonances appear as an apparent doublet of doublets (AA′XX′ spin system) centred at 7.40 ppm; **b**, 7.62dd, ^3J[H(5)H(6)] = 8.3, ^4J[H(5)H(6)] = 2.0; **c**, 8.0d, ^3J[H(5)H(6)] = 8.0.

[j] δ(O_2CMe) values: **1a**, 2.14s, 6H; **1b**, 1.70s, 6H; **1c**, 1.65s, 6H.

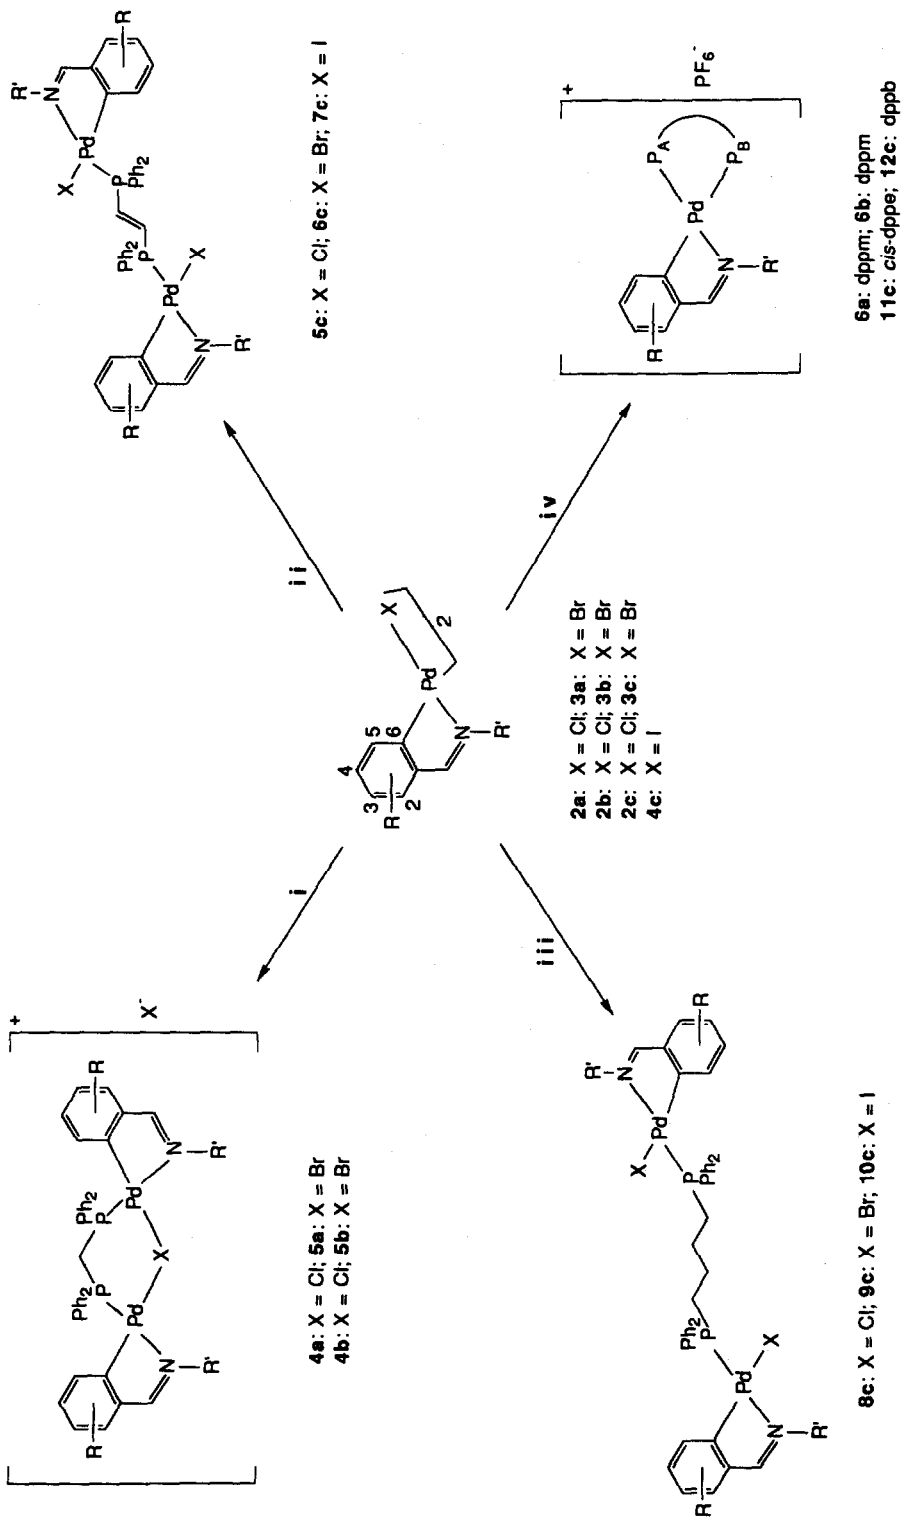
[k] Coupling constants: **6a**, ^2J(PP) = 63; **6b**, ^2J(PP) = 63; **11c**, ^3J(PP) = 11.6; **12b**, ^5J(pp) = 12.0 Hz.

[l] The higher value corresponds to P_A and the lower one to P_B.

[m] δ[PC(*H*)=C(*H*)P] values for: **5c**, δ6.97; **6c**, δ6.80; **7c**, δ6.68. N values *ca* 42Hz.

dppe and dppb, as opposed to the smaller "bite" diphosphines *trans*-dppe and dppb, as opposed to the smaller "bite" diphosphine dppm, preclude the possibility of a bridging halogen atom between the metal centres in **5c–7c** and **8c–10c**. Also noticeable is that for both cyclometallated moieties in each complex, only one set of signals is observed in the ^{1}H NMR spectrum and only one singlet in the $^{31}P\{^1H\}$ spectrum for both phosphorus atoms, showing the compounds to be symmetric, i.e. in complexes **4a**, **5a**, **4b** and **5b** the Schiff base ligands are in a parallel arrangement, whereas in complexes **5c–7c** and **8c–10c** they are in an antiparallel arrangement. As an example, the C(4)—*Me* and C(4)—*MeO* resonances (see Table 2) appear shifted to a lower frequency due to the shielding effect of the phosphine phenyl ring.[18] In antiparallel (**4a**, **5a**, **4b** and **5b**) and parallel (**5c–7c** and **8c–10c**) arrangements, one would observe two signals in each case, one shielded and one non-shielded by the phosphine ligand. This also evidences the geometry around the palladium atom with the phosphorus atom always *trans* to the nitrogen atom. Therefore, we may conclude that complexes **4a**, **5a**, **4b** and **5b** are symmetric across a two-fold axis and that complexes **5c–7c** and **8c–10c** are centrosymmetric. In complexes **5c–7c** the apparent triplet at *ca* 6.9–6.7 ppm was assigned to the PC*H*=C*H*P proton resonances (AA′XX′ spin system) with N *ca* 42 Hz.

Treatment of the halide-bridged dimer compounds with $Ph_2PCH_2PPh_2$ (dppm), *cis*-Ph_2PCH=$CHPPh_2$ (*cis*-dppe) or $Ph_2P(CH_2)_4PPh_2$ (dppb), and NH_4PF_6, in a dimer/diphosphine 1:2 molar ratio afforded the mononuclear species **6a**, **6b**, **11c** and **12c** as air-stable solids (see Experimental and Tables 1 and 2). The final products in each case are identical whether one uses the choro, bromo- or iodo-bridged dimer as the starting material, because the halogen is exchanged by the hexafluorophosphate ion (see Scheme 1). The $^{31}P\{^1H\}$ NMR spectrum showed two doublets for the two inequivalent phosphorus nuclei. The lower frequency doublet is assigned to the phosphorus nucleus *trans* to the phenyl carbon and the higher frequency one to the phosphorus nucleus *trans* to the nitrogen atom, assuming that a ligand of greater *trans* influ-



i: 1 equiv. of dppm; ii: 1 equiv. of *trans*-dppe ; iii: 1 equiv. of dppb; iv: 2 equiv. of dppm, *cis*-dppe or dppb, + NH_4PF_6
a: R = 4-Me, R' = Cy; **b**: R = 3-Me, 4-MeO; R' = 2',4',6'-$Me_3C_6H_2$; **c**: R = 2,4-Me_2; R' = 2',4',6'-$Me_3C_6H_2$

Scheme 1.

ence shifts the ^{31}P resonance of the phosphorus *trans* to it to a lower frequency.[22] The *H*C=N resonance is coupled to only one phosphorus nucleus, i.e. that *trans* to it [^4J(PH) = *ca* 7.0–8.0 Hz]. Selective decoupling experiments confirmed this. Selective irradiation of the P_A or P_B resonances reduces the *H*(5) resonance to a doublet [^4J(PH) = *ca* 6.0–10 Hz] and the *H*C=N resonance to a singlet (irradiating at P_A) or to a doublet (irradiating at P_B). In complexes **11c** and **12c** the PC*H*=C*H*P resonances are probably shielded by the phosphine phenyl rings and are shifted to a higher frequency, where they are occluded by the phenyl proton resonances and hence were not assigned.

Crystal structure of **3b**

Suitable crystals of compound **3b** were obtained by slowly evaporating a chloroform solution. The molecular structure and its numbering scheme are shown in Fig. 1 and the unit cell is shown in Fig. 2. Selected interatomic distances and angles are given in Table 3.

The molecule is dimeric, with two square-planar coordinated palladium atoms asymmetrically bridged by two bromine ligands [Pd(1)—Br(1) 259.7(2), Pd(1)—Br(2) 244.9(2), Pd(2)—Br(1) 245.0(2) and Pd(2)—Br(2) 257.8(2) pm]. The asymmetry results from the differing *trans* influence of the phenyl carbon and nitrogen atoms of the Schiff base ligand. The remaining coordination sites on each palladium are occupied by an aromatic carbon and an imino nitrogen atom of the bidentate ligand N-(4-methylbenzylidene)cyclohexylamine-C6,N [Pd(1)—C(1) 199.3(10), Pd(1)—N(1) 203.4(9), Pd(2)—C(16) 199.5(12) and Pd(2)—N(2) 204.9(7) pm]. The two cyclometallated ligands are in an overall antiparallel arrangement about the Pd_2Br_2 core, similar to that observed in other dimers.[17,23–26] The Pd—C bond lengths are shorter than the expected value of 208.1 pm based on the sum of the covalent radii for carbon and palladium, 77.1 and 131 pm, respectively;[27] this shortening observed in related complexes[8,17,25] is probably due to partial double bond character in the Pd—C linkage. The Pd—N bond distances are slightly longer than the value of

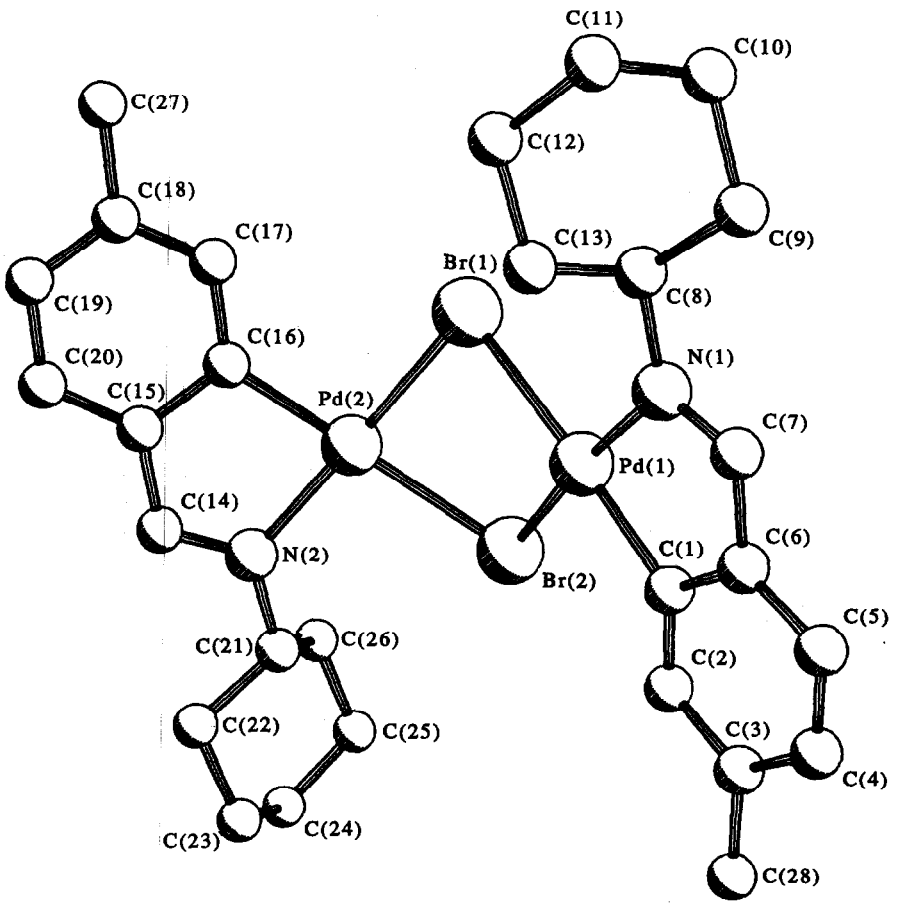


Fig. 1. Molecular and numbering scheme of compound **3a**.

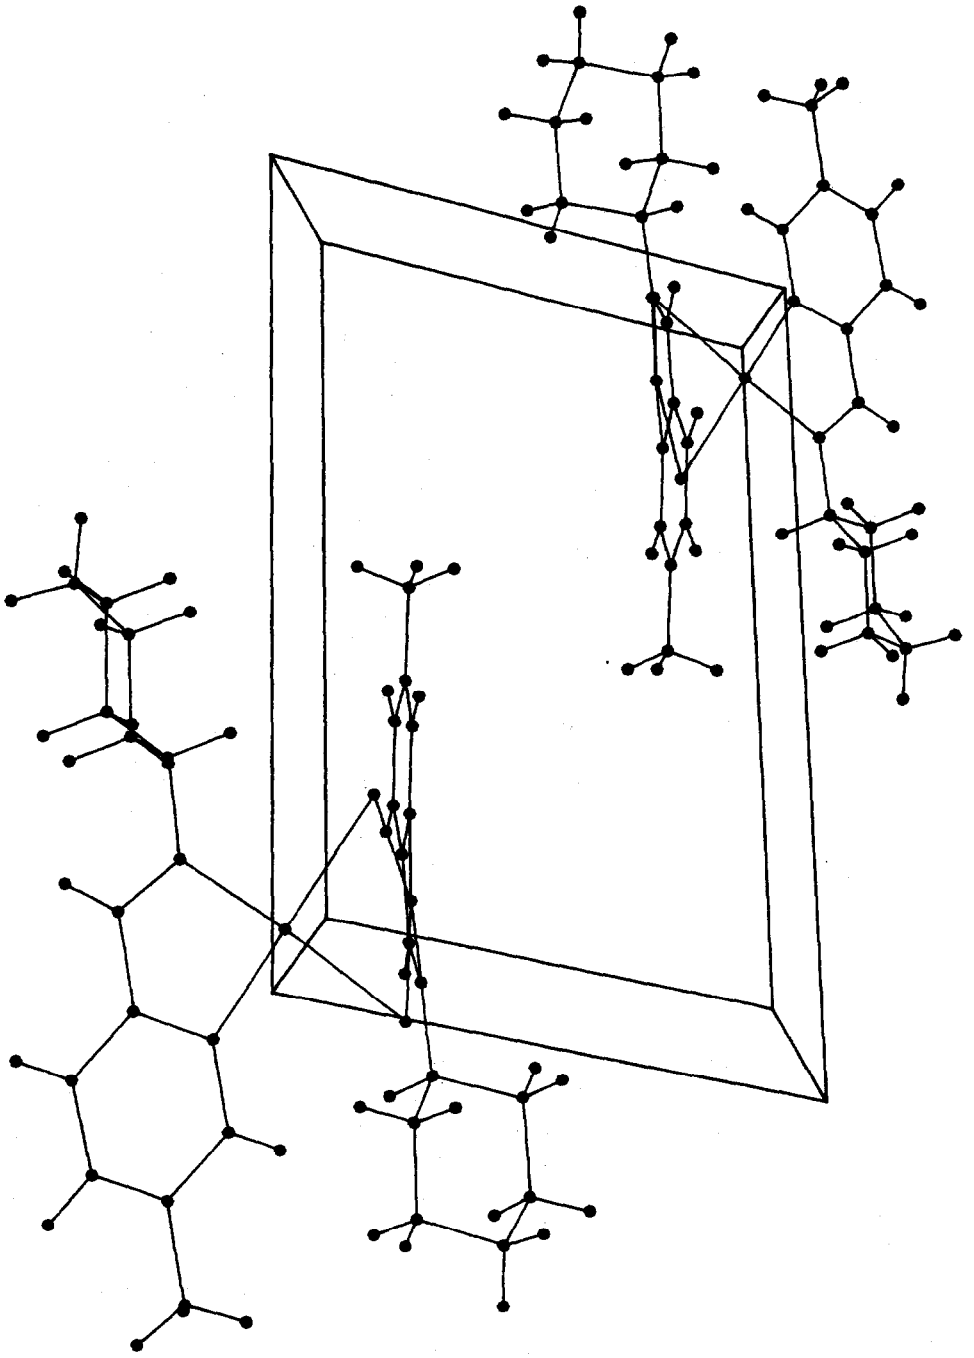

Fig. 2. Unit cell of compound **3a**.

201 pm obtained from the sum of the covalent radius for N(sp^2), 70 pm, and for palladium, 131 pm. The C=N distances [N(1)—C(7) 128.0(4) and N(2)—C(14) 129.0(6)] are somewhat longer than the value of 123.7(3) which is observed for a related free ligand;[28] this lengthening is typical of a coordinated Schiff base ligand[29] where the nitrogen atom is involved in a σ-bond to a metal atom and has been observed by us before.[8,17]

The bond angles at palladium do not deviate greatly from 90°, the most deviant being in the chelate rings [N(1)—Pd(1)—C(1) 81.2(4)° and N(2)—Pd(2)—C(16) 82.0(4)°]. The coordination of the palladium atoms is approximately planar, as expected for Pd^{2+} (r.m.s. deviations of coordinating atoms 4.4 and 6.0 pm), with the metals only 0.2 and 10.7 pm from the mean planes; the loss of five-atom co-planarity is represented by a symmetric

Pd(1)···Pd(2)	341.8(2)		

tetrahedral twist of 3.4° around Pd(1), and an asymmetric pyramidalization of 8.7° about Pd(2) (both bromines lie on the same side of the PdNC plane by 36.5 and 10.6 pm). The Pd_2Br_2 bridge is not planar, but is hinged about Br···Br by 46.4°; this contrasts with the situation observed in a similar complex[17] where the Pd_2Br_2 unit is planar and centrosymmetric. The chelate rings are planar (r.m.s. deviations 0.1 and 0.1 pm) with palladium deviations of 7.7 and 26.9 pm. The two aromatic rings are planar (r.m.s. deviations 0.9 and 1.4 pm, metal deviations 1.9 and 14.9 pm), and are twisted by 2.5° and 5.2° with respect to the adjacent chelate planes. The cyclohexyl fragments adopt chair conformations [plane of C(9) C(10), C(12), C(13) r.m.s. deviation 0.6 pm, displacements of C(8) and C(11) 69.5 and −61.3 pm; plane of C(22), C(23), C(25), C(26) r.m.s. deviation 1.8 pm, displacements of C(21) and C(24) 72.8 and −64.3 pm]. It is evident that the environment of Pd(2) is less regular than that of Pd(1).

The inter-palladium distance of 341.8(2) pm is shorter than the one observed for a related dibromo-bridged complex[17] of 354.9(9) pm reflecting the non-planarity of the Pd_2Br_2 unit in this case; nevertheless, this value excludes any metal–metal bonding.

There are no noteworthy intermolecular contacts.

EXPERIMENTAL

Solvents were purified by the standard methods.[30] Chemicals were reagent grade. Palladium(II) acetate, dppm and dppb were purchased from Aldrich Chemie and Strem Chemicals; *trans*- and *cis*-dppe were prepared as reported in ref. 31 but using *trans*- and *cis*-ClCH=CHCl, as appropriate. Elemental analyses were performed by Mr J. Ulloa in the Servicio de Analysis Elemental of the University of Santiago using a Carlo–Erba elemental analyser model 1108. IR spectra were recorded as Nujol mulls or polythene discs on a Perkin–Elmer 1330 spectrophotometer. $^{31}P\{^1H\}$ and ^1H NMR spectra were obtained as $CDCl_3$ solutions, referred to a high frequency of 85% H_3PO_4 or $SiMe_4$,

respectively, and recorded on a Bruker WM-250 spectrometer.

The Schiff base ligands and the acetato- and halide-bridged compounds were prepared as reported for similar compounds.[5,17]

Preparation of $[\{Pd[4\text{-}MeC_6H_3C(H)=NCy]\}_2(\mu\text{-}Ph_2PCH_2PPh_2)(\mu\text{-}Cl)]Cl$ (**4a**)

To a suspension of the chloro-bridged dimer **2a** (30.28 mg, 0.044 mmol) in acetone (*ca* 5 cm^3) was added dppm (16.98 mg, 0.044 mmol). The mixture was stirred at room temperature for 2 h, after which time it had become clear. After a further 2 h a yellow precipitate formed, which was filtered off and dried *in vacuo*. Recrystallization from dichloromethane–n-hexane gave the final product was a yellow solid. Complexes **5a**, **4b**, **5b**, **5c–7c** and **8c–10c** were made similarly.

Preparation of $[\{Pd[4\text{-}MeC_6H_3C(H)=NCy]\}(Ph_2PCH_2PPh_2\text{-}P,P)]PF_6$ (**6a**)

To a suspension of the chloro-bridged dimer (30.00 mg, 0.044 mmol) in acetone (*ca* 5 cm^3) was added dppm (33.65 mg, 0.088 mmol). The mixture was stirred at room temperature for 2 h, NH_4PF_6 (0.014 mg, 0.088 mmol) was added and the solution stirred for a further 2 h. Water was then added and the resulting solid filtered off and dried *in vacuo*. Recrystallization from dichloromethane–*n*-hexane gave the final compound as a white solid. Compounds **6b**, **11c** and **12c** were made similarly.

Single crystal X-ray diffraction analysis

Three-dimensional, room-temperature X-ray data were collected in the range $3.5 < 2\theta < 50°$ on a Nicolet R3 diffractometer by the ω-scan method. The 3580 independent reflections (of 5007 measured) for which $|F|/o(|F|) > 3.0$ were corrected for Lorentz and polarization effects, and for absorption by analysis of eight azimuthal scans (minimum and maximum transmission coefficients 0.262 and 0.522). The structure was solved by Patterson and Fourier techniques and refined by blocked-cascade least-squares methods. Hydrogen atoms were included in calculated positions with isotropic thermal parameters related to those of the supporting atom. Refinement converged at a final $R = 0.0596$ ($R_w = 0.0549$, 307 parameters, final mean and maximum Δ/σ 0.001 and 0.003, respectively), with allowance for the thermal anisotropy of all non-hydrogen atoms. A final difference electron density synthesis showed minimum and maximum values of -0.80 and $+1.35$ e $Å^{-3}$. Complex scattering factors were taken from ref. 32 and from the program package SHELXTL,[33] as implemented on the Data General Nova 3 computer. A weighting scheme $w^{-1} = [\sigma^2(F) + 0.00076(F)^2]$ was used in the latter stages of refinement.

Crystal data. $[Pd\{4\text{-}MeC_6H_3C(H)=NC_y\}Br]_2$, $C_{28}H_{36}Br_2N_2Pd_2$; $M = 773.22$. Crystallizes from solvent as yellow blocks; crystal dimensions $0.40 \times 0.20 \times 0.15$ mm. Triclinic, $a = 854.3(3)$, $b = 1309.7(3)$, $c = 1426.1(5)$ pm, $\alpha = 110.874(23)$, $\beta = 107.044(30)$, $\gamma = 97.003(27)°$, $U = 1.3793(9)$ nm^3; $D_c = 1.862$ g cm^{-3}, $Z = 2$. (*Received* 13 *July* 1992; *accepted* 1 *October* 1992)

Abstract—Polycrystalline layered $VOPO_4 \cdot 2H_2O$ reacts very readily with NaI solution in acetone producing green solids and releasing molecular iodine. This redox intercalation is joined with Na^+ ion insertion between layers of the host and with reduction of vanadium (V^V to V^{IV}). Three solid phases are created gradually with the compositions $Na_{0.3}V^{IV}_{0.3}V^V_{0.7}OPO_4 \cdot 2H_2O$, $Na_{0.5}V^{IV}_{0.5}V^V_{0.5}OPO_4 \cdot 2H_2O$ and $NaV^{IV}OPO_4 \cdot H_2O$. These phases are stages 3, 2 and 1 and agree with situations in which the host is intercalated from 33, 50 and 100%. Basal spacings of all three stages were measured. Changes in phase ratio in the solid reaction products were determined by X-ray phase analysis for the reaction time 0–500 h and temperature range 20–40°C. Magnetic susceptibility (−170–30°C), a.c. conductivity and thermal properties (20–600°C) of these phases were investigated.

The structure of $VOPO_4 \cdot 2H_2O$ was described by Ladwig,[1] Tietze[2] and Tachéz[3] as a layered tetragonal lattice, built up of neutral $(VOPO_4)_\infty$ networks and interlayer water molecules. Water can be easily replaced in this lattice by other molecules, for example aliphatic alcohols,[4,5] amines,[6] carboxylic acids,[7] pyridine,[8] *etc.* Some of these intercalation reactions have a redox character.

Also, the reaction of crystalline $VOPO_4 \cdot 2H_2O$ with an ethanolic solution of NaI, which is rapid and spontaneous at room temperature, is a redox process.[9–11]

$$V^VOPO_4 \cdot 2H_2O + x\text{NaI} \xrightarrow{C_2H_5OH} Na_xV^{IV}_xV^V_{1-x}OPO_4 \cdot 2H_2O + x/2I_2$$

The structure of the host layers is preserved during the reaction, but the distance between adjacent $(VOPO_4)_\omega$ layers decreases. The sodium ions which penetrate into the interlayer space among the water molecules modify the arrangement of the water layer and cause its contraction. It was shown that a good reducing agent (I^-, $S_2O_3^{2-}$, SO_2, N_2H_5Cl, etc.) present in the system enables other cations (Li^+, K^+, Rb^+, Cs^+, Mg^{2+}, Mn^{2+}, Co^{2+}, Ni^{2+} and Zn^{2+}) to intercalate into $VOPO_4 \cdot 2H_2O$.[12,13] An isostructural compound, $VOAsO_4 \cdot 2H_2O$, similarly undergoes this type of reaction.[11]

In this paper we present results of a study of intercalation in the modified system $VOPO_4 \cdot 2H_2O$–NaI–acetone. We replaced the ethanol in the system mentioned above by acetone because acetone is not able to form intercalates with $VOPO_4 \cdot 2H_2O$, in contrast to alcohols, and NaI is very soluble in it.

We attempted to identify the intermediate phases formed and to determine their ratio in the solid reaction product and their dependence on reaction time. Some properties of the products were studied.

EXPERIMENTAL

$VOPO_4 \cdot 2H_2O$ was prepared by prolonged boiling of a mixture of V_2O_5 and H_3PO_4 in water.[1]

* Author to whom correspondence should be addressed.

The removal of all the reducing materials from the chemicals used was necessary to eliminate the presence of V^{IV} in the resulting products.

Products of the intercalation reaction described by the formula $Na_xVOPO_4 \cdot yH_3O$ ($0 < x < 1$; $1 < y < 2$) were prepared in sealed glass tubes (*ca* 50 cm^3) by contact of a polycrystalline (size of particles: 0.1–0.2 mm) host (*ca* 0.4 g) with NaI (0.5 M) acetone solution (20 cm^3). Systems were shaken at constant temperature (20, 30 or 40 ± 0.1°C). Acetone was distilled before use and its water content was fixed at 2% (weight).

Dependence of the sodium content in the solid products on reaction time was studied on a series of simultaneous experiments which were interrupted after a definite period of time (from 5 min to 500 h). The solid phase was washed thoroughly with pure acetone immediately after interruption. The sodium content of the solids was determined by amperometric titration of released iodine with thiosulphate and by EDX microanalysis of sodium vanadium and phosphorus content.

The powder data of the solid reaction products were obtained with an X-ray diffractometer HZG-4 (Freiburg Prazision Mechanik, Germany); the methods of measurement and checking have been described in our previous work.[4]

All reaction products and their relative ratios were determined by X-ray phase analysis. Relative contents w_i of solid phases were calculated from the equation:

$$w_i = I_i(002) \Big/ \sum_n I_i(002), \qquad (1)$$

where $I_i(002)$ is the intensity of the diffraction line (002) of the ith phase and n is the number of present phases. The sodium content in phases x_i was calculated by multidimensional linear regression of the equation:

$$x = \sum_n x_i w_i, \qquad (2)$$

where x is the total sodium content in the samples (as a stoichiometric coefficient) determined by the titration and w_i is the relative content of the single phases in the sample.

Magnetic susceptibilities were measured in the range 90–300 K using a variable-temperature Gouy balance (Newport Instruments, England); the molar magnetic susceptibilities were corrected for diamagnetism. Magnetic moments were calculated from the Curie–Weiss equation.

DT and TG analyses were performed using a Derivatograph MOM (Hungary). The measurements were carried out under air between 20 and 900°C at a heating rate of 5°C min^{-1}. The weight of the samples was 100 mg.

An a.c. conductivity of solid products was investigated by means of an impedance meter, Tesla BM 507 (Czechoslovakia), working in the frequency region 100–500 kHz. The real and imaginary parts of impedance were determined for all the samples measured. Complex impedance plots of the samples in all cases showed arc-shaped curves, typical of solid ionic conductors.[14] The simplest equivalent electronic circuit describing curves of this type is a resistance connected in parallel with a constant phase element (CPE). An equation describing the dependence of impedance on frequency was derived for this circuit. Parameters of this equation were estimated from experimental values by the complex non-linear least-squares fittings,[15] and the conductivities of the samples were calculated. Rectangular pellets were prepared from microcrystalline intercalates before impedance measurements. A dry powder sample (0.150 ± 0.006 g) was pressed under pressure (95 kN cm^{-2}) in a rectangular matrix; platelets of intercalate under pressure are preferably orientated with layers of $(VOPO_4)_\infty$ perpendicular to the direction of the pressure. Samples of cuboid shape with the dimensions 7 × 3 × 2 mm were obtained in this way. This cuboid was placed between electrodes so that a.c. conductance was measured along the layers of $(VOPO_4)_\infty$. Better sample–electrode contacts are obtained using electrodes painted with graphite paste.

For the thermopower measurements a cuboid was mounted on the top of two stainless steel blocks with platinum contacts. One of the blocks was heated by a kanthal wire to create a temperature gradient across the sample. The temperature difference was monitored by a nickel/chromium–nickel thermocouple.

RESULTS AND DISCUSSION

X-ray diffraction analyses of all the solid products obtained in the $VOPO_4 \cdot 2H_2O$–NaI–acetone system showed that the samples are composed of three phases; their signature (column 1), lattice parameters (column 2) and line indicates (column 3) are given in Table 1.

It is obvious from phase diffractograms that the phases S3, S2 and S1 have typical layered structures. The periodicity of their structure along a layer is very similar to the periodicity of $VOPO_4 \cdot 2H_2O$, and their parameters, a, therefore, differ very slightly. Parameter c or its fraction decreases in the set $VOPO_4 \cdot 2H_2O$—S3—S2—S1 ($c = 0.7403$, $c/2 = 0.6685$, $c/2 = 0.6531$ and $c/2 = 0.5665$ nm).

Table 1. Composition and X-ray diffraction data of the reaction product

Phase signature	Calculated lattice constants[a] (nm)	Found diffraction lines	Stoichiometric coefficients x and y found for $Na_xVOPO_4 \cdot yH_2O$
S3	$a = 0.6240$ $c = 1.3370$	002, 102, 104 004, 200, 006 201, 202, 106 008	$x = 0.30 \pm 0.06$ $y = 2.0 \pm 0.1$
S2	$a = 0.6284$ $c = 1.3063$	002, 101, 102 004, 200, 201 202, 006, 106 310	$x = 0.50 \pm 0.01$ $y = 2.0 \pm 0.1$
S1	$a =$ — $c = 1.1330$	002, 004, 006	$x = 1.07 \pm 0.17$ $y = 1.00 \pm 0.05$

[a] Lattice constants of the host $VOPO_4 \cdot 2H_2O$: $a = 0.6202$, $2c = 1.4806$.

The need to use double values for parameters c to describe S3, S2 and S1 phase unit cells is probably caused by the tangential shift of $(VOPO_4)_\infty$ during intercalation. The time course of the S3 to the S1 phase formation is given in Fig. 1, where the relative phase ratio (% mol.) in the solid product is plotted against reaction time. The S3 phase is formed first at all temperatures (20, 30 and 40°C) and only this phase is present in the system in such a short period and so it is not possible to observe the kinetics of the S1 phase formation for the NaI concentration used. Therefore, only a decrease in the S3 phase is apparent, which is caused by S2 phase formation. The largest amount of the S2 phase is achieved after *ca* 20 h at 40°C. While at 20°C the first signs of the S1 phase appear after *ca* 270 h, at 40°C the S1 phase begins to form much sooner, even when the S3 phase has not totally disappeared. The reaction solid contains only 10% S1 phase at 20°C after 500 h, while at 40°C it contains 80% after the same amount of time.

Figure 2 shows the dependence of the total

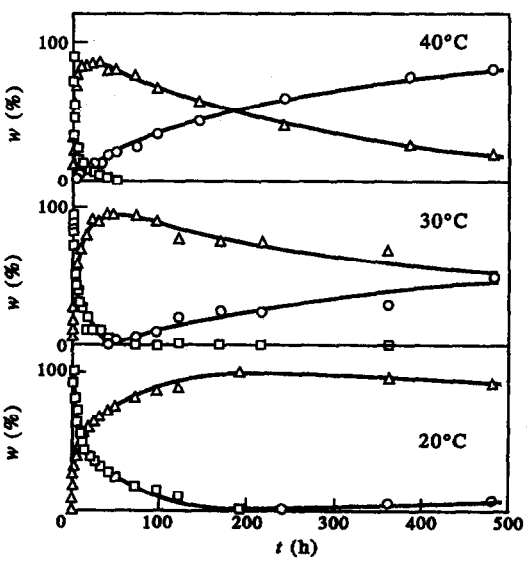

Fig. 1. Dependence of relative content w of the S3 (□), S2 (△) and S1 (○) phases in $Na_xVOPO_4 \cdot yH_2O$ on time t at 20, 30 and 40°C.

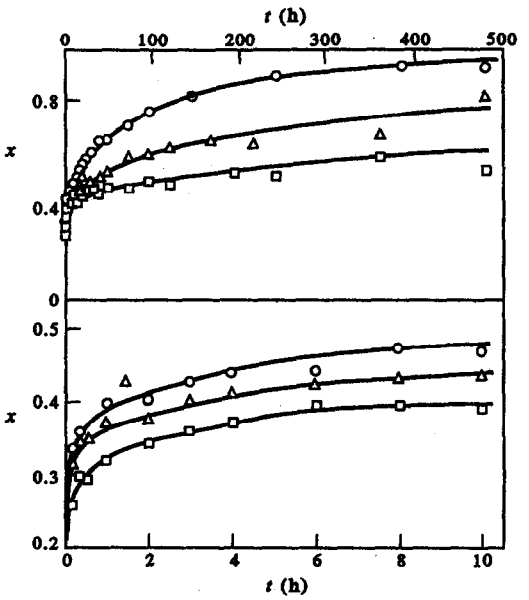

Fig. 2. Dependence of sodium content x in $Na_x VOPO_4 \cdot yH_2O$ on time t (□ 20°C, △ 30°C, ○ 40°C).

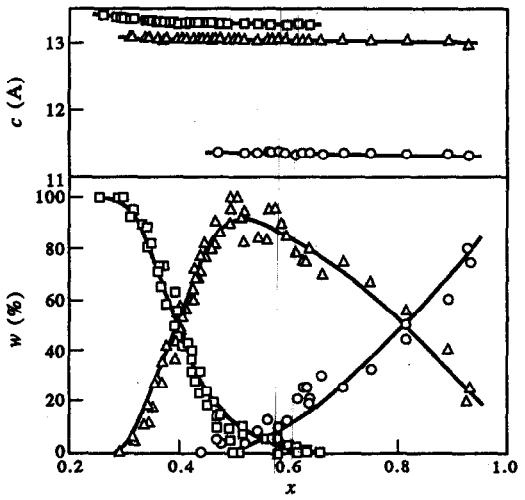

Fig. 3. Dependence of basal spacing c and relative content w of the stages 3 (□), 2 (△) and 1 (○) on sodium content x in $Na_xVOPO_4 \cdot yH_2O$.

sodium content, x, in $Na_xVOPO_4 \cdot yH_2O$ on the reaction time. This dependence is given in the lower part of this figure for three temperatures from 0 to 10 h; the upper part of the figure shows the same dependence from 0 to 500 h. We found no significant effect of light on the reaction rate.

Figure 3 shows the dependence of basal spacing c and relative content w for all three phases on the sodium content, x, in the solid reaction product. Values of x for all phases (Table 1, column 4) were determined by the multidimensional linear regression of the data. Coincident values of a phase composition found from experiments carried out at 20, 30 and 40°C show that temperature has no influence on the phase composition, but only on the rate of phase forming and transforming.

The upper part of Fig. 3 shows the parameters c obtained by X-ray diffraction analysis. A minimal scatter of basal spacings c calculated from 001 and *hkl* lines was found after treatment of X-ray diffractograms. There are no oscillations of diffraction lines connected with the formation of the statistic distribution of the intercalated and unintercalated layers (Hendricks–Teller effect[16]).

All the facts described suggest that the heterogeneous redox reaction of $VOPO_4 \cdot 2H_2O$ with NaI in acetone is an intercalation process. At first sodium ions enter into each third interlayer space among the water molecules. This process is associated with a contraction of the interlayer distance. This S3 phase (stage 3) has been described on the whole set of layered complexes, its basal spacing is in this case lower than in the parent host. The introduction of Na^+ is accompanied by reduction of vanadium in the host layers. Regarding the electroneutrality of the host crystal, the number of reduced vanadium atoms (V^V–V^{IV}) is equal to the number of intercalated sodium ions. When the reaction continues intercalated and non-intercalated water molecule layers are present in a 1 : 1 ratio in phase S2 (stage 2). The process is complete when only the S1 phase (stage 1) is present.

The solid reaction products with different sodium contents were studied by TG and DT analyses. The only process which occurs in the temperature region up to 600°C is the endothermic releasing of water. While $VOPO_4 \cdot 2H_2O$ releases water at 115°C ($VOPO_4 \cdot 2H_2O$ and $VOPO_4 \cdot 1H_2O$) and 150°C (formation of dehydrated $VOPO_4$), samples with the S3 phase predominance release water in two endothermic steps again but at 148 and 205°C. The S2 phase is dehydrated at 185 and 205°C, whilst the S1 phase loses water in one step at 265°C. Figure 4 shows the dependence of the sodium content x in solid products on y values calculated from a decrease of weight by dehydration. Two molecules of water pertain to one atom of phosphorus in the S3 and S2 phases, but in the S1 phase only one water molecule pertains to one atom of phosphorus. Probably the reduction of more than half of the vanadium atoms in the host layers leads to the breakdown of the water interlayer structure and the removal of half of the water molecules.

Results of magnetic susceptibility measurements confirm the presence of V^{IV} atoms in the reaction products. In contrast to diamagnetic $VOPO_4 \cdot 2H_2O$, the reaction products are markedly paramagnetic. Dependencies of reciprocal values of the corrected molar magnetic susceptibility on temperature are linear in the whole region of

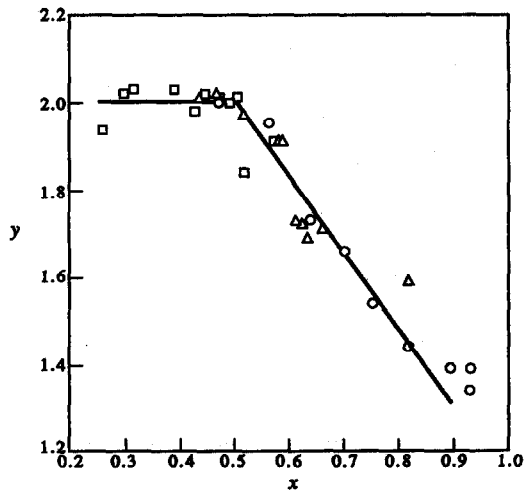

Fig. 4. Dependence of crystal water content y in $Na_xVOPO_4 \cdot yH_2O$ on sodium conent x (□ 20°C, △ 30°C, ○ 40°C).

measurements and there is no evidence of a Néel temperature. The samples with lower sodium content, formed by the S3 and S2 phases, have magnetic moments μ from 1.80 to 1.76 B.M. and Weiss constant θ values which range from -2 to -4 K. This magnetic moment value is in agreement with the pure spin contribution of the d^1 electron of the V^{IV} atom and therefore it is possible to assume the phases are magnetically dilute. The magnetic moments of the samples with high sodium content (high S1 phase content) range from $\mu = 1.7$ to 1.72 B.M. Weiss constant values of $\theta = -6$ to -8 K provide evidence about more significant coupling of paramagnetic V^{IV} centres. Apparently, there is an interaction in the V^{IV}—O—P—O—V^{IV} chain in the $(VOPO_4)_\infty$ layer or across the adjacent layers (V^{IV}—O—H···O—V^{IV}).

Pellets made by pressing the powdered $VOPO_4 \cdot 2H_2O$, with preferential orientation of platelet crystals, present relatively high conductivities ($\sigma_m = 3.10^{-5}$–$4.10^{-5}\ \Omega^{-1}\ cm^{-1}$) in a direction nearly parallel with the $(VOPO_4)_\infty$ layers, whilst pellets of dehydrated $VOPO_4$ show very low conductivity ($\sigma_m < 10^{-7}\ \Omega^{-1}\ cm^{-1}$). Conductivity across the layers in $VOPO_4 \cdot 2H_2O$ is about four-fold lower. Polarity measurements (Seebeck effect) on the same pellets demonstrate the positive charge of the charge carriers in $VOPO_4 \cdot 2H_2O$. Therefore, it is presumed that protons are charge carriers in the $VOPO_4 \cdot 2H_2O$ structure.

It was shown above that intercalation of $VOPO_4 \cdot 2H_2O$ by NaI acetone solution causes the reduction of vanadium, penetration of sodium ions into the water layer and elimination of water with S1 phase formation (as soon as the reaction passes 50%). Each of these changes by itself must cause a decrease in conductivity of the solid reaction product. The basicity of the water molecules coordinating vanadium atoms is increased by the reduction of vanadium, thus proton activity and mobility decrease. Penetration of the Na^+ ions into the host structure must also diminish the proton mobility in the water layers. The elimination of water from an interlayer space must have a similar effect.

These conclusions are in an agreement with the results of the conductivity measurements of the solid reaction products. The conductivity of the solid phase decreases linearly (Fig. 5) with the content of Na^+ ions ($x = 0.25$–0.5). When the S1 phase is formed ($x = 0.5$), conductivity σ_m becomes less dependent on the content of sodium x.

Our results could not explain the mechanism of this intercalation reaction. It is clear only that the electron transfer is not realized in the non-conducting $(VOPO_4)_\infty$ layer. Transport of voluminous iodide ions through the water layer into the solid phase to the vanadium atoms which are reduced also seems to be improbable.

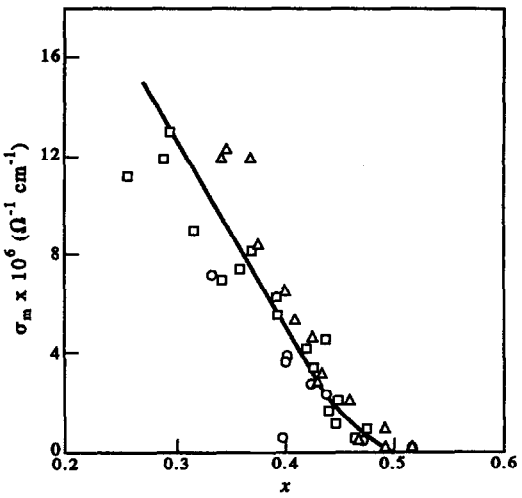

Fig. 5. Dependence of conductivity σ_m of Na_x-$VOPO_4 \cdot yH_2O$ pellets on sodium content x (□ 20°C, △ 30°C, ○ 40°C).

(*Received* 31 *July* 1992; *accepted* 29 *September* 1992)

Abstract—Neutral, bidentate thioethers such as 5,8-dithiadodecane, 3,6-dithiaoctane ("S_2") as well as the dithia-diole 1,8-dihydroxy-3,6-dithiaoctane ["$S_2(OH)_2$"] react with tetrachlorooxotechnetate ($TcOCl_4^-$) in acetone to give binuclear oxo species of the type [TcO("S_2")Cl_2]$_2$O with dithiaalkanes and [TcO("$S_2O(OH)$")Cl_2] with the dithia-diole, respectively. The complexes have been characterized by elemental analysis and spectroscopic methods. The crystal structures of [TcO(5,8-dithiadodecane)Cl_2]$_2$O (**1**) and [TcO(8-hydroxy-3,6-dithiaoctan-1-olato)Cl_2] (**3**) were determined from X-ray data: **1** consists of two independent [TcO("S_2")Cl_2] units bridged by an oxygen atom. Each technetium atom is centred in a distorted octahedron with the equatorial plane formed by the S_2Cl_2 donor set. The sulphur and chlorine atoms of the units are in the *anti* position with respect to the bridging oxygen. The structural analysis of **3** shows that the metal has distorted octahedral coordination, with the equatorial plane formed by the sulphur and chlorine atoms. Furthermore, one terminal oxygen is coordinated in the *trans* position to the $Tc{=}O^{3+}$ core, while the second hydroxy group is non-coordinated.

The well-known coordination chemistry of thioethers with transition metals such as ruthenium, platinum and palladium[1–3] implies that a variety of thioether complexes of technetium with the metal in various oxidation states may also be anticipated. The first fully characterized technetium complex in which thioether groups are involved in the coordination sphere, the cationic *trans*-dioxotechnetium(V) complex $[TcO_2(S_2N_2)]^+$ (S_2N_2: 1,4-dithia-8,11-diazacyclotetradecane), has been described by Ianoz *et al.* in 1989.[4,5] More recently we found that cationic technetium(III) complexes containing neutral tetradentate thioethers and monothioles as co-ligands are formed when an appro-

* Author to whom correspondence should be addressed.

priate technetium precursor is reduced by stannous chloride in the presence of both a tetrathiaalkane and a mono-thiole.[6]

As earlier observed,[7] the reaction of pertechnetate with two equivalents of stannous chloride in the presence of e.g. R—S—CH_2CH_2—S—R ("S_2", R = alkyl) in acetone or acetic acid delivers yellow–green coloured products. These species are reactive in ligand exchange reactions with e.g. 2,3-dimercaptosuccinic acid dimethylester, resulting in the formation of the known bis(dithiolato)oxotechnetate(V) complexes.[8] Therefore, we assume our new species to be in the oxidation state +V. This prompted us to attempt the isolation and characterization of definite technetium(V) complexes with dithiaalkanes and related compounds. Experiments for the preparation of technetium(V) complexes with the neutral dithiaalkanes 5,8-dithiadodecane and 3,6-dithiaoctane ("S_2") as well as with 1,8-dihydroxy-3,6-dithiaoctane ["$S_2(OH)_2$"], which will be described in this paper, were successful with tetrachlorooxotechnetate(V) as a precursor, but failed when the less reactive technetium(V) was used. The resulting compounds, μ-oxo-bis-[(5,8-dithia-dodecane)dichlorooxotechnetium(V)], [TcO("S_2")Cl_2]$_2$O, and [8-hydroxy-3,6-dithiaoctan-1-olato-(O,S,S)]dichlorooxotechnetium(V), [TcO("$S_2O(OH)$")Cl_2], were characterized by single-crystal X-ray structural analysis.

EXPERIMENTAL

UV–vis spectra were recorded on a Specord M 40 spectrometer from Carl–Zeiss Jena (solvent acetone). IR spectra were measured on KBr discs on a Specord M 80 spectrometer from Carl–Zeiss Jena. The content of technetium was determined by liquid-scintillation counting.

Abbreviations

"S_2" = 3,6-dithiaoctane and 5,8-dithiadodecane, "$S_2(OH)_2$" = 1,8-dihydroxy-3,6-dithiaoctane.

Synthesis of μ-oxo-bis[(5,8-dithiadodecane)dichlorooxotechnetium(V)] (1)

5,8-Dithiadodecane (42 mg, 200 μmol) dissolved in acetone (1 cm^3) was added to NBu_4TcOCl_4 (50 mg, 100 μmol) dissolved in acetone (1 cm^3). After addition of methanol (2 cm^3) the mixture was stirred for 1 h. Slow evaporation of the reaction mixture overnight to a volume of 1 cm^3 yielded yellow–green crystals suitable for X-ray analysis. Yield: 18 mg (45% relative to NBu_4TcOCl_4); m.p. 174–175°C. Found: C, 30.2; H, 5.4; S, 15.9; Cl, 17.5; Tc, 25.1. Calc. for $C_{20}H_{44}Cl_4O_3S_4Tc_2$: C, 30.0; H, 5.5; S, 16.0; Cl, 17.7; Tc, 24.8%. IR (KBr): 2880–3080 cm^{-1}, aliphatic CH; 920 cm^{-1}, Tc=O. UV–vis (acetone) [λ_{max} (log ε)]: 400 nm (3.9).

μ-Oxo-bis[(3,6-dithiaoctane)dichlorooxotechnetium(V)] (2)

This compound was prepared with 3,6-dithiaoctane (30 mg) following the procedure described above. Yield: 14 mg (40% relative to NBu_4TcOCl_4); m.p. 193–194°C. Found: C, 21.1; H, 4.3; S, 18.4; Cl, 20.2; Tc, 29.1. Calc. for $C_{12}H_{28}Cl_4O_3S_4Tc_2$: C, 20.9; H, 4.1; S, 18.6; Cl, 20.6; Tc, 28.8%. IR (KBr): 2880–3080 cm^{-1}, aliphatic CH; 920 cm^{-1}, Tc=O. UV–vis (acetone) [λ_{max} (log ε)]: 400 nm (3.8).

Synthesis of (8-hydroxy-3,6-dithiaoctan-1-olato-(O,S,S))dichlorooxotechnetium(V) (3)

1,8-Dihydroxy-3,6-dithiaoctane (36 mg, 200 μmol) dissolved in acetone (1 cm^3) was added to NBu_4TcOCl_4 (50 mg, 100 μmol) dissolved in acetone (1 cm^3). After the addition of methanol (2 cm^3) the colour changed to green and the mixture was stirred for 30 min. Standing of the reaction mixture in the refrigerator overnight yielded green crystals suitable for X-ray analysis. Yield: 22 mg (60% relative to NBu_4TcOCl_4); m.p. 148–149°C. Found: C, 19.5; H, 3.3; S, 17.6; Cl, 18.7; Tc, 27.2. Calc. for $C_6H_{13}Cl_2O_3S_2Tc$: C, 19.6; H, 3.5; S, 17.4; Cl, 19.3; Tc, 27.0%. IR (KBr): 2880–3080 cm^{-1}, aliphatic CH; 920 cm^{-1}, Tc=O. UV–vis (acetone) [λ_{max} (log ε)]: 405 nm (3.8).

Structure determination and crystal data

The X-ray data of both complexes were collected at room temperature (296 K) on an Enraf–Nonius CAD 4 diffractometer, using graphite monochromatized Mo-K_α radiation (λ = 0.71073 Å). A summary of the crystallographic data is given in Table 1. The positions of the non-hydrogen atoms were determined by the heavy-atom technique. After anisotropic refinement of the positions of these, the hydrogen positions were calculated according to ideal geometries. Empirical absorption corrections with the program DIFABS[9] were made at two stages during the structure refinement. Most of the calculations were carried out in the Enraf–Nonius SDP system with some local modifications. Relevant bond lengths and angles are contained in Tables 2 and 3. Difficulties in the structure refinement of both complexes arose from a partial

structural disorder caused by strong thermal motion of some substituents and by a flip-flop mechanism in the ring Tc(2), S(4), C(3), C(4), S(3) in [TcO("S_2")Cl$_2$]$_2$ and Tc, S(1), C(3), C(4), S(2) in [TcO("S_2O(OH)")Cl$_2$], respectively. This explains the very high temperature factors of some atoms and the relatively high R values. Atomic positional and thermal parameters, full lists of bond lengths and angles and F_o/F_c values have been deposited as supplementary material.

Health precautions

In view of the radioactivity of ^{99}Tc some health precautions were taken. All operations were carried out in a fume cupboard with gloves. ^{99}Tc is only a weak β^--emitter so that apart from some elementary precautions no further safety measures are required. Normal glassware gives adequate protection against the weak β^--emission. Bremsstrahlung becomes important if ^{99}Tc is handled on a larger scale.

RESULTS AND DISCUSSION

Preparation of new definite technetium(V) complexes were successful with tetrachlorooxotechnetate(V) as a precursor, but not with the less reactive technetium(V) gluconate. Dithialkanes as well as the potentially tetradentate 1,8-dihydroxydithiaoctane react with $TcOCl_4^-$ under the partial exchange of chloride ligands by sulphur atoms of dithia ligands. 3,6-Dithiaoctane (R = C_2H_5) and 5,8-dithiadodecane (R = C_4H_9) deliver in acetone/methanol analytically pure yellow–green oxo complexes of the type [TcO("S_2")Cl$_2$]$_2$O, which

precipitate from the reaction mixtures. In a similar manner 1,8-dihydroxy-3,6-dithiaoctane (R = CH_2CH_2—OH) reacts to give dark green crystals of [TcO("$S_2O(OH)$")Cl_2].

$$TcOCl_4^- \xrightarrow[\text{acetone/methanol}]{\text{"}S_2\text{"}} [TcO(\text{"}S_2\text{"})Cl_2]_2O$$

1: "S_2" = $C_4H_9SCH_2CH_2SC_4H_9$
2: "S_2" = $C_2H_5SCH_2CH_2SC_2H_5$

$$TcOCl_4^- \xrightarrow[\text{acetone/methanol}]{\text{"}S_2(OH)_2\text{"}} [TcO(\text{"}S_2O(OH)\text{"})Cl_2]$$

3: "$S_2(OH)_2$" =
HO—$CH_2CH_2SCH_2CH_2SCH_2CH_2$—OH

The neutral complexes are stable in air and, except for acetone and acetonitrile, insoluble in the common organic solvents. Elemental analyses are consistent with the proposed formulations.

In the IR spectra strong absorptions at 920 cm^{-1}, as well for **1**, **2** and **3**, indicate the Tc=O^{3+} core; ν(Tc—Cl) is not assigned owing to the absorption of other vibrations in the region 300–250 cm^{-1}.

In order to obtain an unambiguous structural assignment the structures of the complexes **1** and **3** were determined by X-ray structure analyses. Suitable crystals were obtained from acetone/methanol.

Drawings of **1** are shown in Figs 1 and 2 and of **3** in Fig. 3. Selected bond angles and distances are listed in Tables 2 and 3 and as supplementary material. In both complexes flip-flop mechanisms in the rings Tc(2), S(4), C(3), C(4), S(3) (complex **1**) and Tc, S(1), C(3), C(4), S(2) (complex **3**), respectively, are observed. This leads to a smearing of electron density of the C(4) atoms of both molecules.

The crystal structure of **1** consists of two independent TcO("S_2")Cl_2 units bridged by an oxygen atom. The characteristic feature is the presence of the O=Tc—O—Tc=O group. In this respect the structure of **1** is comparable to those of [TcO(salpd)]$_2$O [salpd = N,N′-propane-1,3-diylbis (salicylideneiminate)][10] and [TcO(N_2S_2)]$_2$O [N_2S_2 = N,N′-ethylene-bis(thioacetylacetoneiminate)].[11] The technetium atoms are centred in a flattened octahedron with the equatorial plane formed by the S_2Cl_2 donor set, in which the technetium atoms Tc(1) and Tc(2) are 0.12 Å out-of-plane towards O(1) and O(2), respectively. The S_2Cl_2 planes are almost parallel with a small deviation of 0.013 Å; the dihedral angle is 2.6°. The sulphur and chlorine donor atoms of the units are in the *anti* position with respect to the bridging oxygen.

The bond lengths of the Tc=O cores with 1.665 and 1.674 Å, respectively, are in the range generally found for those units (1.61–1.75 Å), but they are in between those in the octahedral O=Tc=O compounds and in square-pyramidal Tc=O complexes. This corresponds to the relatively low value of Tc=O absorption in the IR spectrum. The bridging Tc—O distances (Tc(1)—O(3) 1.898 and Tc(2)—O(3) 1.899 Å) are intermediate between the average Tc=O length and the average Tc—O bond

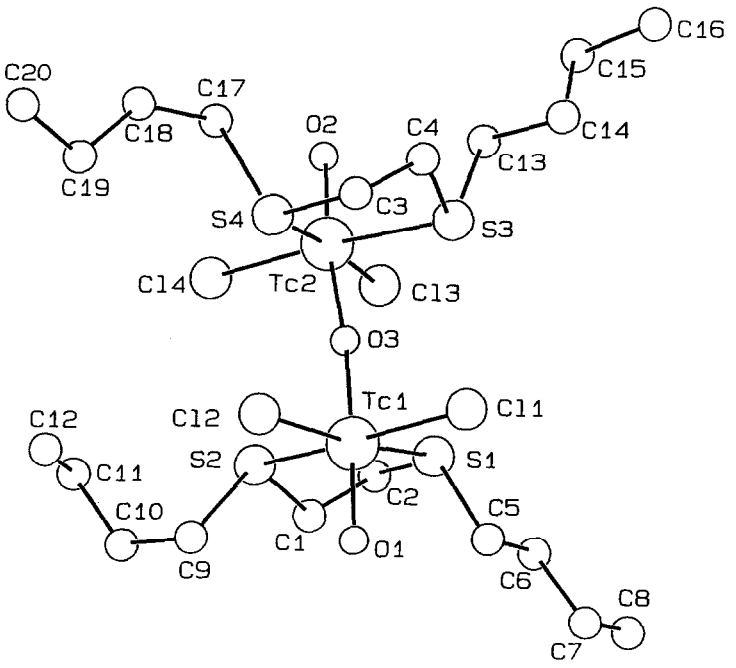

Fig. 1. CELLGRAF drawing of [TcO(5,8-dithiadodecane)$_2Cl_2$]$_2$O.

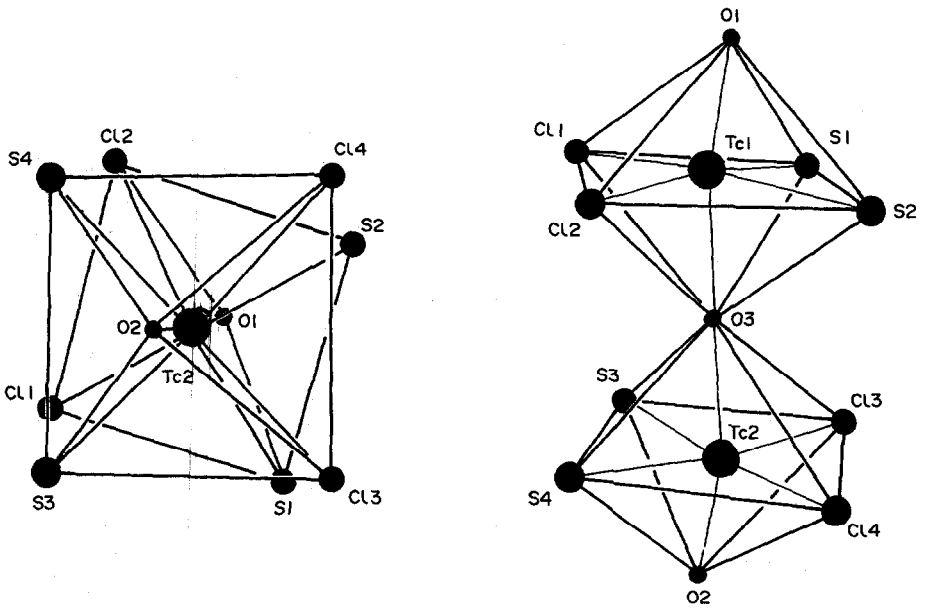

Fig. 2. Molecular geometry of $[TcO(5,8\text{-dithiadodecane})_2Cl_2]_2O$ viewed (a) perpendicular and (b) parallel to the O_1, Tc_1, O_3, Tc_2, O_2 axis.

distance, which are observed in the range 1.98–2.09 Å.[12–14]

As illustrated in Fig. 3, complex **3** consists of discrete monomolecular units containing the O= Tc—O— core. In general, the structure strongly resembles that of the complex derived from dithiaoctane. However, while in the dinuclear species the *trans* position is occupied by a bridging oxygen which may come from traces of water present in the reaction mixture, the *trans* position in complex **3** is occupied by an oxygen of one of the terminal hydroxy groups. The second hydroxy group remains "free". The CELLGRAF[15] drawing in Fig. 3 shows the two possible positions for the non-coordinated hydroxy group caused by a rotation disorder about the bond C(5), C(6). The sulphur atoms of the dithioether and the two chlorine atoms which remain at the metal due to the incomplete exchange at the tetrachlorooxotechnetium ion form a *cis* arrangement in the equatorial plane.

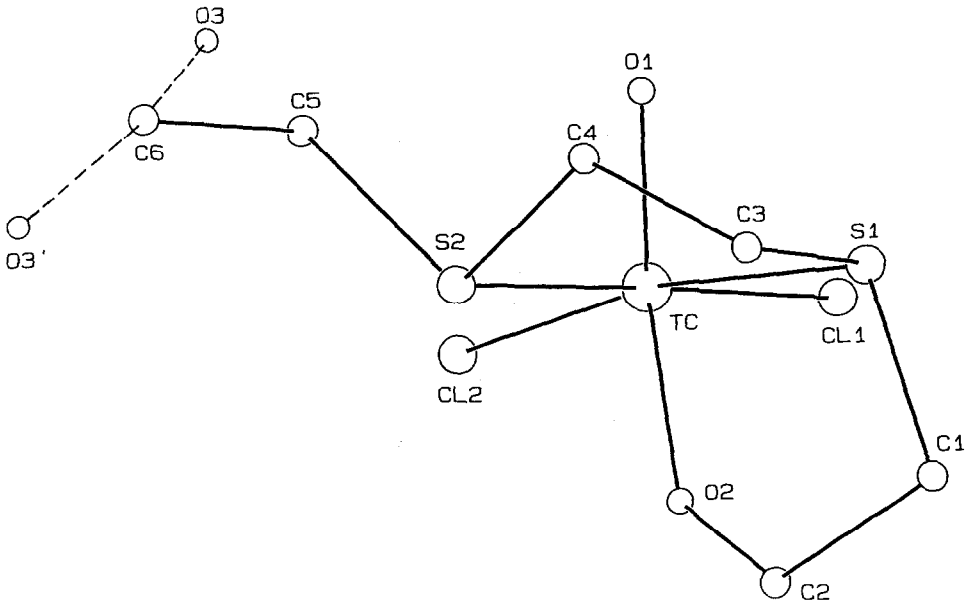

Fig. 3. CELLGRAF drawing of $[TcO\{8\text{-hydroxy-}3,6\text{-dithiaoctan-}1\text{-olato-}(O,S,S)\}Cl_2]$.

Compounds with single-bonded oxygen *trans* to the Tc=O core are scarcely described. The length of the Tc—O bond (1.912 Å) is comparable to that found in other *trans*-O=Tc—O^- groups.[15-18]

Special interest should be devoted to this new class of technetium complexes as many subsequent reactions may be anticipated to occur. In ligand exchange reactions diversity is given by various leaving groups in the coordination sphere. For complex **3** additional reactivity may be caused by the non-coordinated hydroxy group at the side chain. Therefore, new radiopharmacologically relevant compounds may be rendered accessible. Studies on the reactivity of the described complexes will follow.

Additional material concerning this paper can be ordered from Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-W-7514 Eggenstein-Leopoldshafen 2, Germany, quoting CSD No. 55698 ([TcO("S_2")Cl_2]$_2$O, [TcO("S_2O_2")Cl_2]), authors' names as well as the title of the paper.

Acknowledgements—This work was supported by a grant from the Fond der Chemischen Industrie. The authors thank Prof. E. Hoyer (Universität Leipzig) for the ligand 1,8-dihydroxy-3,6-dithiaoctane.

(*Received* 20 *August* 1992; *accepted* 11 *September* 1992)

Abstract—Some ruthenium(II) chiral Schiff base complexes of the composition $[RuL(PPh_3)(H_2O)_2]$ (**1–3**), where L = chiral Schiff bases derived from salicylaldehyde and L-amino acids, namely L-phenylalanine, L-tyrosine and L-methionine, have been synthesized. The interaction of the complexes with π-acceptor ligands such as 2,2′-bipyridyl and 1,10-phenanthroline gives substituted mixed-ligand complexes. The characterization of the complexes was accomplished by microanalysis, IR, UV–vis, ^1H, $^{13}C[^1H]$ and $^{31}P[^1H]$ NMR spectroscopy, conductance measurements, electrochemical studies, optical rotation and circular dichroism spectra. The conformational aspects regarding the asymmetric arrangement of substituents at the amino acid moiety of the Schiff bases, as well as the effect of the π-acceptor ligand around the ruthenium(II) metal ion, have been discussed. The complexes show irreversible behaviour and the redox potentials of the Ru^{II}/Ru^{I} couples are less negative in **4–9** than those of the parent chiral Schiff base complexes.

The use of classical transition metal complexes containing nitrogen and oxygen donor ligands as effective and sometimes stereospecific catalysts for oxidation,[1,2] reduction,[3] hydrolysis[4,5] and other transformations of organic compounds[6] is a challenging area of both organic and inorganic chemistry. One of many possible avenues of exploration in this field is the design and synthesis of transition metal complexes bearing additional functional side groups incapable of interaction with the central metal ion but capable of non-covalent interaction with an organic substrate.[6]

The structural studies of metal chelates of amino acids and aminopolycarboxylic acids show examples where the carboxyl function plays a variety of roles. In addition to free and metal bonded carboxylic groups (and metal chelates) free mono-, bi- and tridentate carboxylato groups are known in metal chelate compounds.[7–9] Amino acids themselves play an important role in the function performed by haeme proteins, either by controlling the size of the cavity available to the substrate molecule when it binds to the haeme or by modifying the local dielectric constant or polar character of this cavity.[10]

In continuation of our previous work[11,12] we describe here the synthesis of novel, neutral, chiral ruthenium(II) Schiff base complexes derived from salicylaldehyde, L-phenylalanine, L-tyrosine and L-methionine and substitution of these complexes with π-acceptor ligands such as 2,2′-bipyridyl and 1,10-phenanthroline. A variety of physicochemical methods including IR, ^1H, $^{13}C[^1H]$, $^{31}P[^1H]$, electronic and circular dichroism spectroscopy, optical rotation and electrochemistry have been used to study the extent of the π-back bonding from the ruthenium(II) metal ion to the unsaturated ligands. Here we are concerned that such an interaction may be partly responsible for the currently inexplicable differences in intensity between LMCT absorptions, CD patterns and electrochemical behaviour.

RESULTS AND DISCUSSION

The stoichiometric composition of all the mononuclear ruthenium(II) complexes **1–9** is consistent with the microanalysis of the complexes (Table 1). Millimolar solutions of the complexes in methanol

[a] Calculated numbers are in parentheses.

are non-electrolytic in nature. Some of the water is retained by the complexes in the solid state, as indicated by ν(OH) bands at 3300–3400 cm^{-1}, along with the deformation and rocking modes of water at 1620 and 620 cm^{-1} in the IR and far IR regions,[13] and also by elemental analysis. The imine structure of the chiral Schiff bases is also clearly indicated by intense bands near 1635–1610 cm^{-1}, which overlap with $\nu_{asym}(COO^-)$ stretching modes. This band undergoes a modest decrease on complexation to the metal ion, inferring coordination through the carboxylato oxygen and nitrogen of the azomethine group to the metal ion.[14] The symmetric (COO^-) stretching vibration absorbs at 1440 cm^{-1}. Other significant bands are listed in Table 2.

In the far-IR region the bands at 550 and 345 cm^{-1} are due to ν(Ru—P) and ν(Ru—N), respectively.

The electronic spectra of complexes **1–3** were recorded in dichloromethane and show high intensity bands in the UV region near 238 (ε = 1627) to 379 nm (ε = 2049), which are assigned to the $\pi \rightarrow \pi^*$ transition from the benzene ring and the double bond of the azomethene group. The absorption bands in the 449 nm region (ε = 458) are due to the $n \rightarrow \pi^*$ transition of the non-bonded electron present on the azomethine nitrogen of the Schiff bases. In the complexes this band undergoes a blue-shift due to coordination to the metal through the azomethine nitrogen atom. An allowed band in the range 612 (ε = 627) to 655 nm (ε = 468) is assigned to a $t_2(Ru) \rightarrow \pi^*(L)$ transition, i.e. an LMCT band. The position of the LMCT band depends on the R group attached to the azomethine group of the amino acid moiety.[15] The energy of the band decreases in the order Sal Meth > Sal Tyr > Salpheala, which is in agreement with those reported earlier.[11,12]

The circular dichroism data for all the complexes in CH_2Cl_2/MeOH are given in Table 3. Three representative circular dichroism spectra (Fig. 1) of

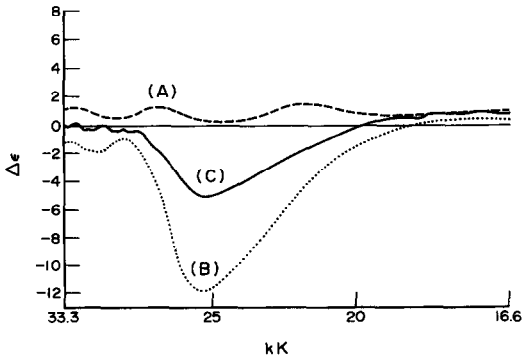

Fig. 1. Circular dichroism spectra of (A) Sal(L-methtriphenylphosphinodiaquoruthenate(II)), (B) Sal(L-tyrtriphenylphosphinodiaquoruthenate(II)), and (C) Sal(L-phealatriphenylphosphinodiaquoruthenate(II)).

chiral ruthenium(II) Schiff base complexes derived from L-Meth (**A**), L-Tyr (**B**) and L-Pheala (**C**) show that although all amino acids have the same absolute configuration, complexes **B** and **C** are stereospecifically coordinated to the ruthenium moiety so that the *gauche* chelate ring is located in the δ form with a very small preference for the λ isomer while complex **A** prefers only the λ conformation. For the amine, diamine and dipeptide[16] complexes with sulphur donor atoms the complex undergoes a non-bonded interaction between the (COO^-) group and the —S.CH_3 group of the methionine moiety, while the complexes derived from L-pheala and L-Tyro do not show such an interaction. This suggests that the strain for the conformation of the ligand affects the circular dichroism intensity without a pattern. Due to the steric interaction between the SCH_3 group and the —(COO^-) group, complex **A** acquires the *S*(*S*) configuration in dichloromethane solution, which is also evidenced by its optical rotation $[\alpha]_D^t = +[71.71]$. The two complexes **B** and **C** acquire the *R* configuration. Similar behaviour was also observed elsewhere.[12,15,17]

In the ligand field region, at 17.39–17.85 kK, circular dichroism bands of the positive Cotton effect are displayed which are assigned to both the *d–d* bands and spin-forbidden ligand bands. These bands undergo a blue shift with an increase in donor strength of the R group in the Schiff base complexes.[15] In the charge-transfer region the bands $d \rightarrow \pi^*$ lie in the range 24.69–25.31 kK and the ligand $\pi \rightarrow \pi^*$ (azomethine) transition bands are seen in the higher energy region at 27.39–32.25 kK. The shift in both the charge transfer and ligand transition with azomethine substituents is consistent with the inductive effect of the substituent R on the ligand π-levels.[18]

^{1}H NMR spectra of complexes **1–3** were recorded in $CDCl_3$ and show signals in the range 7.25–7.51 ppm, which are assigned to the phenyl protons of the triphenyl phosphino group, the salicylaldehyde moiety as well as the R group attached to the amino acid moiety (Table 4). The azomethine proton at 8.1 ppm in all chiral Schiff base ligands shows a downfield shift after complexation to the metal ion and lies at 8.30–8.47 ppm, inferring coordination

8.	Sal(L-phealatriphenylphosphino-2,2-dipyruthenate(II))	3.30	8.42(s)	7.56, 7.26, 9.5, 9.26, 9.18	58.40	206.06	132.5, 130.06, 129.5, 156.3, 124.4, 127.3
9.	Sal(L-phealatriphenylphosphino-1,10-phenruthenate(II))	3.29	8.7(s)	7.50, 7.29, 9.62, 9.24, 9.17	58.60	205.91	131.6, 134.4, 127.6, 151.9, 130.6, 127.8

through the azomethine nitrogen atom. In the case of complex **2** the signal at 5.95 ppm is due to the hydrogen-bonded phenolic group of the tyrosine moiety. After shaking the complex with D_2O this signal disappears due to proton exchange. Complexes **1–3** have a triplet in the region 2.93–4.22 ppm due to protons of the asymmetric —CH group, which are also reported by others.[19–21]

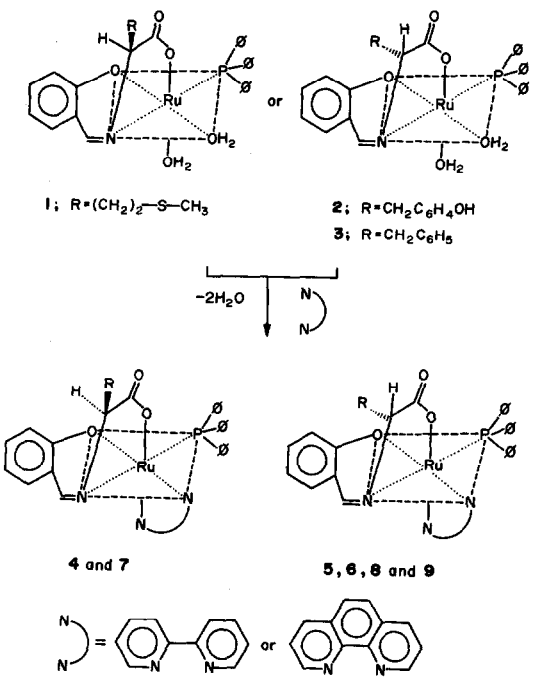
The $^{13}C[^1H]$ chemical shift data of all the complexes are given in Table 4. In the $^{13}C[^1H]$ NMR spectra of complexes **1–3** the signals due to the carbon of the carboxylato group and the azomethine carbon atom undergo a downfield shift from those of the free Schiff bases, which reflects that the complexes of ruthenium(II) functioned as terdentate O—N—O. However, the signals due to the ring carbon, asymmetric carbon and carbon of the $—CH_2$ group lie in the ranges 127–135, 56–62 and 27.9–30 ppm. In the case of complex **1** a signal at 16.21 ppm is due to a CH_3 group directly attached to the non-bonded sulphur atom, which is in agreement with data reported earlier.[16,22–24]

The $^{31}P[^1H]$ NMR spectra of all the complexes recorded in dichloromethane show only one signal in the range 29.5–32 ppm, which shows that only one phosphorus is in an axial position and is *trans* to the nitrogen of the azomethine group.[25,26]

The cyclic and differential pulse voltammograms of complexes **1–3**, in CH_2Cl_2 using tetrabutyl ammonium perchlorate as the supporting electrolyte with Ag/AgCl as the reference electrode, show irreversible behaviour. In the differential pulse voltammogram the $E_{1/2}$ value of the Ru^{II}/Ru^{I} reduction potential lies in the range -0.50 to -0.84 V. The more negative value of the redox potential in complex **1** is due to the presence of the methionine moiety, which increases the electron density at the metal centre and the $E_{1/2}$ value lies at the more cathodic side.[15,27]

The substitution reactions of complexes **1–3**, with π-acceptor ligands such as 2,2-bipyridyl and 1,10-phenanthroline, is summarized in Scheme 1.

Complexes **1–3** interact with 2,2-bipyridyl and 1,10-phenanthroline in refluxing CH_2Cl_2/MeOH with the replacement of two water molecules and show a colour change from green to brownish red, yielding the complexes **4–9**. All the complexes are non-electrolytes in methanol. The electronic spectra of the complexes in methanol show a high intensity charge-transfer band in the range 225 ($\varepsilon = 2442$) to 229 nm ($\varepsilon = 2089$), while the $n \rightarrow \pi^*$ bands lie at 419 ($\varepsilon = 759$) to 452 nm ($\varepsilon = 790$).[28] The appearance of shoulders in the region 521–585 nm and also 713 nm are due to ruthenium(II) $d \rightarrow \pi^*$ (2,2-bipy and 1,10-phenon), and a d–d transition which has also been reported by others.[29]



Scheme 1.

The IR spectra of the complexes **4–9** show bands at 1605, 1575, 1460, 1440, 1315, 1242, 1160 and 770 cm^{-1} and 1600, 1575, 1425, 1145, 845 and 725 cm^{-1} due to coordination of 2,2-bipyridyl and 1,10-phenanthroline, which are merged with the IR bands of the symmetric or asymmetric (COO^-) group and some of the ring bands.[30]

The circular dichroism spectra of the complexes **4–9** were recorded in methanol and show great differences in intensity compared to the parent complexes, which is comparable to the circular dichroism effect due to the presence of π-acceptor ligands. The strain for conformation affects the circular dichroism intensity without the pattern, see Fig. 2.

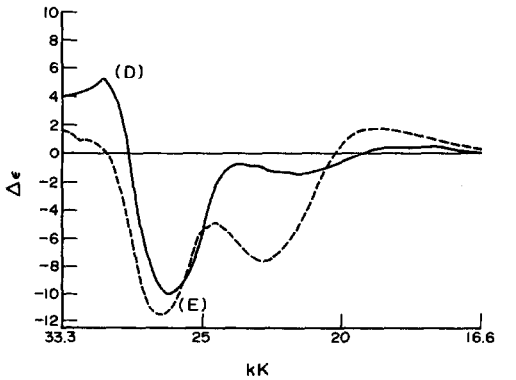


Fig. 2. Circular dichroism spectra of (D) Sal(L-tyrtriphenylphosphino(2,2-dipy)ruthenate(II)) and (E) Sal(L-tyrtriphenylphosphino(1,10-Phen)ruthenate(II)).

In the higher energy region the ligand $\pi \rightarrow \pi^*$ transition bands lie at 29.85–34.48 kK, while the charge-transfer band lies near 27.77 kK. The bands in the range 21.05–22.72 kK are due to the ruthenium(II) transition $d\pi \rightarrow \pi^*$ (2,2-bipy and 1,10-phenanthroline). In the ligand field region the circular dichroism bands with a positive Cotton effect lie in the region 17.24–19.23 kK and have been assigned to both *d–d* bands and spin-forbidden ligand bands which undergo a blue shift with an increase in donor strength of the R group attached to the amino acid moiety.[15]

The [^{1}H] NMR spectra of complexes **4–9** were recorded in a deuterated methanol and show signals in the range 7.89–9.60 ppm due to the ring protons of coordinated π-acceptor ligands such as 2,2-bipy and 1,10-phenanthroline. These assignments have also been reported elsewhere.[31]

The ^{13}C[^{1}H] NMR spectra of the complexes **4**, **6** and **8** in methanol show a signal at 151.01–156.77 ppm due to the carbon atom directly attached to the coordinated nitrogen atom of the 2,2′-bipyridyl ligand, while the rest of the carbon signals lie in the range 124.30–127.67 ppm and in complexes **5**, **7** and **9** the signal due to carbons attached to nitrogens lie in the range 152.50–152.67 ppm. The other carbon signals lie in the region 126.16–136.12 ppm which has also been reported earlier.[32]

The substituted complexes **4–9** are irreversible in nature in methanol using tetrabutylammonium perchlorate as the supporting electrolyte, Ag/AgCl as the reference electrodes. Their Ru^{II}/Ru^{I} reduction couple is less negative in the range -0.69 to -0.52 V compared to the parent complexes **1–3**. This is due to the π-accepting tendency of the substituents, such as 2,2-bipy and 1,10-phen, directly attached to the metal[33] and also to the inductive effect of the R group of the amino acid moiety. All these electronic effects are transmitted through the ligands to the ruthenium metal ion.[12,15]

EXPERIMENTAL

$RuCl_3 \cdot 3H_2O$ was obtained from Johnson Matthey. Triphenylphosphine (Sisco), salicylaldehyde, L-methionine, L-phenylalanine and L-tyrosine (Aldrich) were used as received. All the Schiff bases derived from salicylaldehyde and the L-amino acids were prepared by reported procedures.[11,12] The metal complex $RuCl_2(PPh_3)_3$ was synthesized by a known method.[34]

Preparation of the complexes **1**, **2** *and* **3**

$RuCl_2(PPh_3)_2$ (1.0 mmol) in acetone was refluxed with a methanolic solution of the chiral Schiff bases (1.0 mmol) under an inert atmosphere for 6–8 h. The completion of the reaction was ensured using TLC intermittently. After completion of the reaction the solution was filtered under argon. The filtrate was concentrated to *ca* 10 cm^3 and the complexes were precipitated by diethyl ether. The complexes were filtered and again washed with diethyl ether to remove excess PPh_3, recrystallized in methanol/dichloromethane and dried *in vacuo*. Yield: 70–75%.

Synthesis of the complexes [RuL(PPh$_3$)(2,2-bipy)] (**4**, **6** *and* **8**)

A hot solution of complexes **1**, **2** and **3** (0.01 mmol) in dichloromethane and methanol was refluxed with 2,2-bipyridyl (0.01 mmol) for 8–10 h with constant stirring. The resulting solution was filtered and concentrated to 10 cm^3 in a rotatory evaporator and the complexes were precipitated with diethyl ether, filtered, recrystallized and dried *in vacuo*. Yield: 60–65%.

Synthesis of the complexes [RuL(PPh)$_3$(1,10-phen)] (**5**, **7** *and* **9**)

Complexes **1**, **2** and **3** (0.01 mmol) were dissolved in dichloromethane/methanol and refluxed with 1,10-phenanthroline (0.01 mmol) dissolved in methanol for 10 h. The solution was filtered, concentrated and precipitated with diethyl ether. The complexes were then filtered, washed with the same solvent, recrystallized and dried *in vacuo*. Yield: 65–68%.

Physical measurements

Microanalyses of the complexes were performed on a Carlo–Erba analyser Model 1106. Molar conductance values were measured at room temperature on a Digisun Electronic Conductivity bridge DI-909. The IR spectra were recorded on Carl–Zeiss–Specord M-80 spectrophotometer in Nujol mulls/KBr. Electronic spectra were recorded on a Shimadzu UV–vis recording spectrophotometer model 160. [^{1}H], ^{13}C[^{1}H] and ^{31}P[^{1}H] NMR spectra were obtained on a Jeol FX-100 NMR spectrometer in $CDCl_3$ and chloroform using [$Si(CH_3)_4$] as an internal standard and operating at 99.55, 24.99 and 40.27 MHz. Cyclic voltammograms and differential pulse voltammogram polarograms were recorded with a Princeton Applied Research (PAR) instrument using tetrabutylammonium perchlorate as the supporting electrolyte in dichloromethane/MeOH. The optical rotation of the complexes in dichloromethane/

methanol was measured using a polarimeter Atago, Japan. The circular dichroism spectra were recorded in dichloromethane/methanol by JASCO Machine Model J-20, Japan.

(*Received* 10 *August* 1992; *accepted* 10 *September* 1992)

Abstract—The structures of four complexes involving divalent first-row transition metals and phenoxy substituted carboxylic acids have been determind by X-ray diffraction. These are tetraaquabis(2-phenoxybenzoato)nickel(II) dihydrate (**1**), diaquabis(4-fluorophenoxyacetato)zinc(II) (**2**), diaquabis(phenoxyacetato)cobalt(II) (**3**) and tetrakis-μ-(pentafluorophenoxyacetato)bis[aquacopper(II)] (**4**). Complex **1** is regular octahedral with *trans*-related unidentate carboxylates [Ni—O (carboxylate) 2.031(1) Å] and four waters [Ni—O 2.049, 2.104(2) Å]. Complex **2** has a skew trapezoidal bipyramidal stereochemistry, involving four oxygens from two asymmetric bidentate carboxylates [Zn—O 2.107, 2.332(3) Å] and two waters [Zn—O 1.989(4) Å]. The polymeric complex **3** is isomorphous and isostructural with the manganese(II) analogue, with centrosymmetric octahedral CoO_6 stereochemistry comprising four bonds to carboxylate oxygens (both bridging) [Co—O 2.076, 2.087(3) Å] and two to waters [Co—O 2.134(3) Å]. Complex **4** is a pseudo-centrosymmetric tetracarboxylate bridged dimer of the copper(II) acetate hydrate type with a Cu—Cu separation of 2.644(4) Å. Bond distances to copper are 1.96(1) (average, equatorial) and 2.15(1) Å (average, axial, to water).

The structural systematics of both phenoxyalkanoic acids and their complexes with metal ions have been an area of considerable research interest in our laboratories for a number of years. More than 60 metal complexes have been prepared and characterized, largely by single-crystal X-ray diffraction methods.[1,2] Complex **1**, tetraaquabis(2-phenoxybenzoato)nickel(II)dihydrate, represents the second known complex with 2-phenoxybenzoic acid (2-PBAH), the previous example being a tetracarboxylate-bridged dimer, $[Cu_2(2\text{-PBA})_4(2\text{-PBAH})_2]$.[3] Complex **2**, diaquabis(4-fluorophenoxyacetato)-

* Author to whom correspondence should be addressed.

zinc(II), has the same stoichiometric formula as the previously reported anhydrous zinc complexes of phenoxyacetic acid (PAH) and 4-chlorophenoxyacetic acid (4-CPAH), $[Zn(PA)_2(H_2O)_2]$ and $[Zn(4\text{-}CPA)_2(H_2O)_2]$, respectively.[4] Other complexes of 4-FPAH are $[Cu(4\text{-}FPA)_2(H_2O)_2]\cdot 2(4\text{-}FPAH)\cdot 2H_2O$,[5] $[Cu_2(4\text{-}FPA)_4(ampym)_2]$ (ampym = 2-aminopyrimidine),[5] $[Cu_{1.5}(4\text{-}FPA)_3(H_2O)_{5.5}]$[6] and $[Ag_2(4\text{-}FPA)_2(H_2O)_2]$.[7]

Complexes of phenoxyacetic acid (PAH) and 4-chlorophenoxyacetic acid (4-CPAH) give two different complex series with the metals zinc(II),[4] manganese(II), magnesium(II) and cobalt(II),[1] which are all isomorphous and isostructural. The structure of diaquabis(phenoxyacetato)cobalt(II) (**3**) confirms this isomorphism. No other structurally characterized complexes of cobalt(II) with phenoxyalkanoic acids are known. The structures of (pentafluorophenoxy)acetic acid (PFPAH) and its complexes with silver(I), $[Ag_2(PFPA)_2]$, and mercury(I), $[Hg(PFPA)]_n$, are also known.[8] The structure reported here, tetrakis[(pentafluorophenoxy)acetato(O,O′)]bis[aquacopper(II)], $[Cu_2(PFPA)_4(H_2O)_2]$ (**4**), represents the only example of a complex of PFPAH with a first-row transition series metal.

EXPERIMENTAL

Preparation of complexes

Complex **1** was prepared by digesting 2 : 1 molar quantities of $NiCO_3\cdot 2Ni(OH)_2\cdot 4H_2O$ and 2-phenoxybenzoic acid (2-PBAH) in 80% ethanol/water for 5 h at 90°C. Pale blue needle crystals were obtained from the filtrate after *ca* 2 months. The complexes **2**–**4** were prepared using a previously described procedure[1] by reacting 50% aqueous ethanolic solutions of the acids with the appropriate metal carbonate. Crystals were obtained after partial room temperature evaporation of the respective filtrates. The acids were synthesized using the general procedure of Synerholm and Zimmerman.[9] Elemental analyses, density measurement and preliminary single-crystal X-ray preliminary data suggested the formulae $Ni(2\text{-}PBA)_2(H_2O)_6$ (**1**), $Zn(4\text{-}FPA)_2(H_2O)_2$ (**2**), $Co(PA)_2(H_2O)_2$ (**3**) and $Cu(PFPA)_2(H_2O)$ (**4**). The dark green colour of **4** indicated that a tetracarboxylate-bridged dimer of the copper(II) acetate hydrate type was probable.

Crystal data, structure determination and refinement

Table 1 lists information about crystal data, data acquisition, structure solution and refinement for compounds **1**, **2**, **3** and **4**. Data were collected at room temperature (293 K) on Nicolet R3m (**1**–**3**) or Enraf–Nonius (**4**) four-circle diffractometers, using graphite crystal monochromatized Mo-K_α radiation ($\lambda = 0.71073$ Å). Structures were solved by heavy-atom methods using SHELX 76[10] and refined by full-matrix least-squares with anisotropic thermal parameters for all non-hydrogen atoms. Hydrogens were located by difference-Fourier methods and included in the respective refinements with both positional and isotropic thermal parameters refined (**1**, **2** and **4**) or with coordinates refined and isotropic U values set invariant at 0.05 Å^2 (**3**). No corrections were made for absorption or extinction. The high residual for **4** is the result of poor crystal quality because of twinning. Final atomic coordinates, anisotropic thermal parameters, intraligand bond distances and angles and observed and calculated structure factors have been deposited and are available from the Editor or the authors. Bond distances and angles about the respective coordination polyhedra are given in Table 2.

DISCUSSION

$[Ni(2\text{-}PBA)_2(H_2O)_4]\cdot 2H_2O$ (**1**)

The structure of complex **1** is typical of most nickel(II) carboxylates. The first complex of this type involving a phenoxyalkanoic acid was, $[Ni(PA)(H_2O)_4]$,[11] for which the structure was determined but only partially refined. The present complex also has regular octahedral NiO_6 coordination (Fig. 1), involving two centrosymmetrically related unidentate carboxylate ligands [Ni—O 2.031(1) Å] and four water molecules [Ni—O 2.049, 2.104(2) Å]. These values compare with other complexes of nickel(II) from the series with the general formula $[Ni(L)_2(H_2O)_4]$:

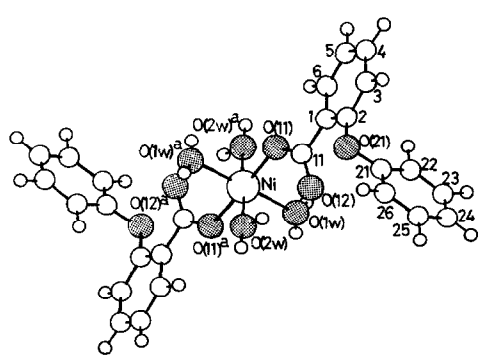

Fig. 1. Molecular configuration and atom naming scheme for $[Ni(2\text{-}PBA)_2(H_2O)_4]\cdot 2H_2O$ (**1**). Unless otherwise indicated, atoms are carbon.

Table 1. Crystal data for $[Ni(2\text{-PBA})_2(H_2O)_4]\cdot 2H_2O$ (**1**), $[Zn(4\text{-FPA})_2(H_2O)_2]\cdot 2H_2O$ (**2**), $[Co(PA)_2(H_2O)_2]$ (**3**) and $[Cu_2(PFPA)_4(H_2O)_2]$ (**4**)

L = (2-carbamoylphenoxy)acetate:[12] 2.072, 2.063, 2.076(2) Å; L = (4-carboxyphenoxy)acetate:[13] 2.058, 2.026, 2.084(4) Å; L = hydrogen benzene-1,2-dioxydiacetate:[14] 2.064(10), 2.092(7), 2.047(7) Å, respectively. This general stereochemistry is in contrast to the skew trapezoidal bipyramidal six-coordination of the isostructural yellow phenoxybutyrate complexes, $NiL_2(H_2O)_2$ [L = 4-phenoxybutyrate (a) and 4(4-chlorophenoxy)butyrate (b)].[15] With these, the carboxylate groups are only slightly asymmetrically bidentate chelate in their coordination mode [Ni—O(carboxyl), 2.181, 2.062(2) Å (a); 2.175, 2.068(2) Å (b). Ni—O (water), 2.020(2) Å (a); 2.016(2) Å (b)].

$[Zn(4\text{-FPA})_2(H_2O)_2]$ (2)

The zinc(II) complex of 4-fluorophenoxyacetic acid, $[Zn(4\text{-FPA})_2(H_2O)_2]$ (**2**), has distorted trapezoidal bipyramidal stereochemistry about zinc (Fig. 2), similar to that found for the isomorphous complexes $[Zn(PA)_2(H_2O)_2]$,[4] $[Zn(4\text{-CPA})_2(H_2O)_2]$[4] and $[Cd(PA)(H_2O)_2]$[16] (PA = phenoxyacetate; 4-CPA = 4-chlorophenoxyacetate). This is also found in the complex $[ZnL_2(H_2O)_2]$ [L = (2-formyl-6-methoxyphenoxy)acetate[17]]. Although it is surprising that isomorphism does not extend right through the series, $[Zn(PA)_2(H_2O)_2]$, $[Zn(4\text{-CPA})_2(H_2O)_2]$ to $[Zn(4\text{-FPA})_2(H_2O)_2]$ (**2**), all complexes possess the same crystallographically imposed two-fold rotational symmetry. Similar structural characteristics and stereochemistry are possessed by a number of other zinc(II) and cadmium(II) carboxylates. The six-

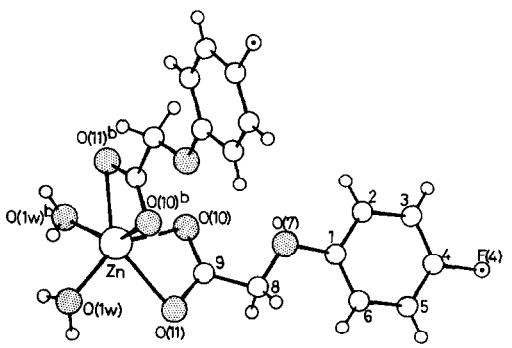

Fig. 2. Molecular configuration and atom naming scheme for $[Zn(4\text{-FPA})_2(H_2O)_2]$ (**2**).

[a] $\frac{1}{2}-x, \frac{1}{2}+y, z$.
[b] $-x, y, \frac{1}{2}-z$.

coordination comprises four oxygens from two bidentate chelate carboxylates [Zn—O, 2.107, 2.332(3) Å] and two water molecules [Zn—O, 1.989(4) Å]. The corresponding distances in [Zn $(PA)_2(H_2O)_2$] are 2.118, 2.337(1) and 1.994(1) Å, while with the formyl complex these are 2.073, 2.381(2) and 1.997(2) Å, respectively. Among the zinc structures, compound **2** is intermediate between the terahedral and octahedral structural types. Both types are found in the phenoxyalkanoate complex $[Zn(L)_2(H_2O)_2][Zn(L)_2(H_2O)_4]$ (L = 2,4-dichlorophenoxyacetate).[18] No other tetrahedral examples are known but the octahedral types with the general formula $[Zn(L)_2(H_2O)_4]$ are relatively common (L = 2-formylphenoxyacetate,[19] 2-fluorophenoxyacetate[20] or 2-chlorophenoxyacetate[17]). As for other similar examples of this series, no significant stabilizing intermolecular associations are involved in the packing of the complex monomers in the unit cell. The 4-fluorophenoxyacetate residues retain the planar conformation of the parent acid,[21] while the bond distances and angles are closely comparable.

$[Co(PA)_2(H_2O)_2]_n$ (**3**)

The structure determination of complex **3**, *catena*-[diaquabis(phenoxyacetato)cobalt(II)], confirms that it is isomorphous and isostructural with the manganese(II) complex $[Mn(PA)_2(H_2O)_2]_n$.[1] Single-crystal and powder X-ray diffraction studies previously indicated the isomorphism, which extends through to magnesium(II) and includes the 4-chlorophenoxyacetate analogues. The comparative cell for $[Mn(PA)(H_2O)_2]_n$ is $a = 7.007(4)$, $b = 7.699(4)$, $c = 33.22(2)$ Å, giving a volume which is 57 Å^3 larger than the present example. This is consistent with the increase in effective ionic radius going from cobalt (0.74 Å) to manganese (0.82 Å).[22] The coordination sphere about cobalt is centrosymmetric octahedral, comprising two bonds to *trans*-related waters and four to carboxylate oxygens of bidentate bridging phenoxyacetate ligands (Fig. 3). As for the manganese(II) analogue the Co—Ow (water) bonds are slightly elongated compared to the Co—O (carboxyl) oxygens. These bonds are also shorter and more regular than for the manganese analogue [Co 2.134, 2.076, 2.987(3) Å; Mn 2.216, 2.148, 2.155(2) Å]. As for the zinc(II) complexes (including compound 2) it is surprising that the series isomorphism does not extend to the 4-fluorophenoxyacetate complexes, although it

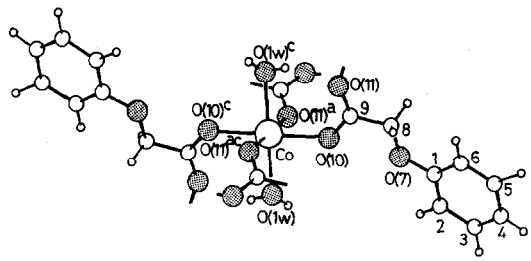

Fig. 3. Molecular configuration and atom naming scheme for $[Co(PA)_2(H_2O)_2]_n$ (**3**). An inversion symmetry operation is indicated by *c*.

does include those with phenoxyacetic acid and 4-chlorophenoxyacetic acid. For cobalt(II), preliminary single crystal data for the compound $[Co(4\text{-}FPA)_2(H_2O)_4]$[23] indicate that it is a regular centrosymmetric octahedral complex with one formula unit in the cell.*

$[Cu_2(PFPA)_4(H_2O)_2]$ (**4**)

The copper(II) complex of (pentafluorophenoxy)acetic acid, $[Cu(PFPA)_4(H_2O)_2]$, is a pseudo-centrosymmetric tetracarboxylato-(O,O′)-bridged dimer of the copper(II) acetate hydrate type[24] (Fig. 4). The dimer has a Cu—Cu separation of 2.644(4) Å with a mean Cu—O (equatorial) bond distance of 1.96(1) Å and a Cu—Ow (axial) bond distance of 2.15(1) Å. These distances are typical of the values found for five other known examples of dimeric copper(II) phenoxyalkanoates, all characteristically dark green in colour. However, the only completely analogous monomeric example in the series, having a general formula $[Cu_2(L)_4(H_2O)_2]\cdot nH_2O$, is copper(2,4-dichlorophenoxy)-acetate hydrate[25] (L = 2,4-D; $n = 2$), while ad-

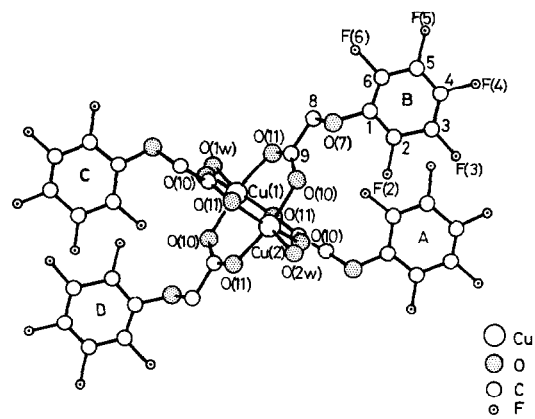

Fig. 4. Molecular configuration and atom naming scheme for $[Cu_2(PFPA)_4(H_2O)_2]$ (**4**).

*Cell data for $[Co(4\text{-}FPA)_2(H_2O)_4]$: $a = 5.051(2)$, $b = 6.814(5)$, $c = 14.75(2)$ Å, $\alpha = 84.87(9)$, $\beta = 85.03(8)$, $\gamma = 71.32(5)$ °; $Z = 1$, space group $P\bar{1}$.

ducts with nitrogen bases replacing the axial water in the dimer system are also known. These have the general formula $[Cu_2(L)_4(X)_2]$ [L = (2,4,5-trichlorophenoxy)acetate, X = pyridine;[25] L = (4-chlorophenoxy)isobutyrate, X = 2-aminopyrimidine[26]]. Polymeric modifications also exist, having the formula $[Cu_2(L)_4]_n$ [L = (2-chlorophenoxy)acetate[27]] or $[Cu_2(L)_4X]_n$ [L = 2-chlorophenoxy)acetate; X = 2-aminopyrimidine (providing a bifunctional bridging group)[27]].

Consistent with other analogous members of this dimeric series, the packing of the molecules in the unit cell shows no significant interdimer hydrogen bonding interactions. However, packing effects influence the conformation of the (pentafluorophenoxy)acetate residues, which results in the substituted ring systems all lying approximately parallel and forming stacks down the *b* cell direction, consistent with the perfect basal cleavage possessed by crystals of this compound. The result is that the side-chain conformation for the pair of residues which are *trans*-related (A and C) are similar but differ from the other pair (B and D). This is reflected in the side-chain torsion angles [C(2)—C(1)—O(7)—C(8), C(1)—O(7)—C(8)—C(9) and O(7)—C(8)—C(9)—O(10)], which are (−99.3, +133.9, −9.0)°, (−150.1, −99.1, −5.3)°, (+99.7, −133.7, +9.2)° and (+146.5, +103.9, +6.4)° for residues A, C, B and D, respectively. The corresponding angles in the parent (pentafluorophenoxy)acetic acid are +50.8°, −110.0° and −2.7°.[8]

SOLUBLE AND VOLATILE BARIUM ARYLOXIDE DERIVATIVES: SYNTHESIS AND MOLECULAR STRUCTURE OF $Ba_5(\mu_5\text{-}OH)(\mu_3\text{-}OAr)_4(\mu_2\text{-}OAr)_4(OAr)(THF)_5$, $[Ba(\mu_1,\mu_2\text{-}dpm)(dpm)(HOAr)_2(THF)]_2$ AND $[Ba(H_2NCH_2CH_2OH)(\mu_1,\mu_2\text{-}H_2NCH_2CH_2OH)(\mu_2\text{-}OH)(\mu_2\text{-}OAr)(HOAr)]_\infty$ (Ar = $C_6H_3Bu^t_2$-3,5; dpm = $Bu^tC(O)CHC(O)Bu^t$)

(*Received* 31 *July* 1992; *accepted* 10 *September* 1992)

Abstract—Various barium aryloxide derivatives have been investigated. $Ba_5(\mu_5\text{-}OH)(\mu_3\text{-}OAr)_4(\mu_2\text{-}OAr)_4(OAr)(THF)_5$ (**I**), obtained by the reaction of barium metal granules in THF with 3,5-di-tert-butylphenol using gaseous ammonia as a catalyst, has been characterized by X-ray diffraction. The high nuclearity of this square-pyramidal pentahydroxyaryloxide complex accounts for its poor volatility. Complex **I** reacts with dpmH or $H_2NCH_2CH_2OH$ (2 mol) to yield $[Ba(\mu_1,\mu_2\text{-}dpm)(dpm)(HOAr)_2(THF)]_2$ (**II**) and $[Ba(H_2NCH_2CH_2OH)(\mu_1,\mu_2\text{-}H_2NCH_2CH_2OH)(\mu_2\text{-}OH)(\mu_2\text{-}OAr)(HOAr)]_\infty$ (**III**), respectively. The molecular structure of **II** shows a dimeric nature with two bridging-chelating β-diketonate ligands. Each metal atom is eight-coordinated with dodecahedral geometry. This complex is volatile and dissociates upon heating into a barium containing compound for which the spectroscopic data are in accord with the formula $[Ba(dpm)_2(HOAr)]_n$, $n \geqslant 2$. Complex **III** consists of a chain structure based on the infinite repetition of $[Ba(H_2NCH_2CH_2OH)(\mu_1,\mu_2\text{-}H_2NCH_2CH_2OH)(\mu_2\text{-}OH)(\mu_2\text{-}OAr)(HOAr)]$ units. This polymeric compound which presents some intramolecular hydrogen bonding is soluble but not volatile.

Molecular compounds of barium such as barium amides,[1] alkoxides[2] and aryloxides[3] have drawn increasing attention as sources of oxide precursors for MOCVD applications. In fact, barium oxides are involved in various advanced materials such as high-Tc superconducting ceramics[4] and materials with valuable electronic properties.[5]

The main behaviour of the alkaline-earth metals is dominated by their ionic character and their high metal coordination number (5–9 for barium) in their molecular compounds. We have been interested in producing compounds containing sterically hindered ligands in order to have low degrees of molecular aggregation which can allow better volatility. The substituted phenols have proved to be a source of interesting metal aryloxides which in general are hydrocarbon-soluble and volatile;[6] they are often available with an unusual metal coordination number.[7]

Herein the synthesis, the characterization and the reactivity towards polydentate compounds of a barium hydroxyaryloxide complex derived from the substituted phenol 3,5-di-tert-butylphenol will be described. The molecular structures of $Ba_5(\mu_5\text{-}OH)(\mu_3\text{-}OAr)_4(\mu_2\text{-}OAr)_4(OAr)(THF)_5$, $[Ba(\mu_1,\mu_2\text{-}dpm)(dpm)(HOAr)_2(THF)]_2$ and $[Ba(H_2NCH_2CH_2OH)(\mu_1,\mu_2\text{-}H_2NCH_2CH_2OH)(\mu_2\text{-}OH)(\mu_2\text{-}OAr)(HOAr)]_\infty$ will be reported. Their thermal behaviour will also be discussed.

EXPERIMENTAL

All manipulations were routinely performed under argon using Schlenk tubes and vacuum-line techniques with solvents purified by standard methods. Dipyvaloylmethane [dpmH = Bu^tC

* Author to whom correspondence should be addressed.

$(O)CH_2C(O)Bu^t$] was purified and 3,5-di-tert-butylphenol was sublimed before use; barium granules were used as received. ^1H NMR and IR spectra were run on Bruker AC-250 and IR FT Nicolet ZDX spectrometers, respectively. IR spectra were obtained as Nujol mulls between KBr plates. Mass spectra were recorded on a 300 DX JEOL by Electronic Impact or Fast-Atom Bombardment positive-ion[8] with an NBA matrix (NBA = *meta*-nitrobenzylalcohol). Thermogravimetric analysis was made under an argon atmosphere and the heating rate was 5°C min^{-1}. Analytical data were obtained from the Centre de Microanalyses du CNRS et de l'ENSCM.

Synthesis of $Ba_5(\mu_5\text{-}OH)(\mu_3\text{-}OAr)_4(\mu_2\text{-}OAr)_4(OAr)(THF)_5$ **(I)**

Barium metal granules (1.37 g, 10 mmol), 3,5-di-tert-butylphenol (4.12 g, 20 mmol) and THF (40 cm^3) were stirred together. Ammonia gas was bubbled at intermittent intervals of 5 min until all the barium metal was consumed (4 h). The solvent and an excess of ammonia were removed *in vacuo*. The precipitate was redissolved in toluene/THF (40/20) and the mixture was filtered. The yellow–green filtrate was left to crystallize at 5°C for 12 h. A large crop of colourless crystals was formed. Yield: 98%, based on barium. Found: C, 61.2; H, 7.9; Ba, 21.0. Calc. for $C_{146}H_{230}O_{15}Ba_5$: C, 60.2; H, 7.9; Ba, 23.6%. IR (cm^{-1}): 3590 [ν(O—H)], 1581, 1362, 1320, 1243, 1230, 1204, 1114, 1043, 1027, 995, 964, 901, 851, 816, 727, 711; 584, 542, 442 [ν(Ba—O)]. ^1H NMR ($CDCl_3$, ppm): 6.62 s (CH, 1H); 6.49 s (CH, 2H); 3.45 t (CH_2, 2H); 1.72 t (CH_2, 2H); 1.10 s (CH_3, 18H). SM (*m/z*, FAB^+): Ar = $C_6H_3Bu^t$-3,5; Bz = $(C_6H_4CH_2)NO_2$-3: $Ba_2(OAr)_3$ (10%), $Ba(OAr)_2Ba(OBz)$ (8%), $Ba(C_{12}H_{15}O)_2$ (5%), Ba(OAr) (100%), Ba(OBz) (35%), Ba(OPh) (35%). Soluble in THF, $CHCl_3$ and CH_2Cl_2, partially soluble in pentane and toluene.

Alternative synthesis of **I**

Barium metal granules (0.28 g, 2 mmol) and 3,5-di-tert-butylphenol (0.84 g, 4 mmol) were stirred in THF (40 cm^3) at reflux temperature until all the metal was consumed (60 h). The solvent was evaporated to dryness to yield a white solid. It was crystallized in hexane at 5°C. The same spectroscopic data were obtained for this compound.

Synthesis of $[Ba(dpm)_2(HOAr)_2(THF)]_2$ **(II)**

DpmH (0.41 cm^3, 2 mmol) was added to a solution of $Ba_5(\mu_5\text{-}OH)(\mu_3\text{-}OAr)_4(\mu_2\text{-}OAr)_4(OAr)(THF)_5$ (0.58 g, 0.2 mmol) in toluene/THF (7 cm^3/1 cm^3). The mixture was stirred at room temperature for 2 h. After concentration, the crystallization at 5°C yielded a large crop of parallelopiped colourless crystals. Yield: 80%, based on barium. Found: C, 65.9; H, 9.3. Calc. for $C_{108}H_{180}O_{14}Ba_2$: C, 65.6; H, 9.1%. IR (cm^{-1}): 3070 [ν(O—H)], 1593, 1575, 1562, 1530, 1461, 1419, 1395, 1382, 1361, 1303, 1271, 1250, 1237, 1224, 1200, 1181, 1123, 1049, 1025, 999, 959, 951, 933, 898, 880, 864, 853, 795, 787, 774, 753, 737, 727, 713, 671, 647, 616, 592, 565, 537, 476, 386, 357. ^1H NMR ($CDCl_3$, ppm): 6.98 t (CH, 1H, ^3J = 1.2 Hz); 6.68 d (CH, 2H, ^3J = 1.2 Hz); 5.53 s (CH, 1H); 3.75 t (CH_2, 2H); 4.87 broad (OH); 1.86 t (CH_2, 2H); 1.29 s (CH_3, 18H); 0.99 s (CH_3, 18H). SM (m/z^+, IE): $Ba_2(dpm)(THF)(OAr)(Bu^tCO)$ (82%), $Ba_2(OAr)(THF)_2$ (5%), $Ba(OAr)(THF)(C(O)CH_2C(O)Bu^t)$ (7%), $Ba(OAr)(C(O)CH_2C(O)Bu^t)$ (15%), Ba(dpm) (100%), ArOH-Me (40%), $C(O)CH_2C(O)Bu^t$ (14%), Bu^t(95%). Soluble in THF, $CHCl_3$, CH_2Cl_2, heptane and toluene, partially soluble in pentane.

Synthesis of $[Ba(H_2NCH_2CH_2OH)(\mu_1,\mu_2\text{-}H_2NCH_2CH_2OH)(\mu_2\text{-}OH)(\mu_2\text{-}OAr)(HOAr)]_\infty$ **(III)**

$H_2NCH_2CH_2OH$ (0.12 cm^3, 2 mmol) was added to a solution of $Ba_5(\mu_5\text{-}OH)(\mu_3\text{-}OAr)_4(\mu_2\text{-}OAr)(THF)_5$ (0.58 g, 0.2 mmol) in toluene/THF (7 cm^3/1 cm^3). A reaction occurred and the colour of the medium changed from green to yellow. The mixture was stirred for 2 h. Colourless needles were obtained after concentration and crystallization at room temperature. Yield: 88%, based on barium. Found: C, 56.9; H, 8.3; N, 4.2. Calc. for $C_{32}H_{58}N_2O_5Ba$: C, 55.8; H, 8.4; N, 4.1%. IR (cm^{-1}): 3490, 3360 [ν(NH or/and OH)], 1581, 1323, 1244, 1261, 1242, 1204, 1170, 1157, 1107, 1027, 996, 964, 934, 898, 864, 843, 815, 774, 722, 585, 538. ^1H NMR (CD_2Cl_2, ppm): 6.58 s (CH, 1H); 6.48 s (CH, 2H); 3.29 broad (OCH_2, 2H); 2.34 broad (NCH_2, 2H); 1.23 s (CH_3, 18H). SM (m/z^+, IE): Ba(Ph)(OAr)$(HNC_2H_4O)(H_2NC_2H_4OH)$ (1%), Ba(HOAr)$(H_2NC_2H_4OH)_2$ (2%), Ba(OAr-Bu^t)$(H_2NC_2H_4OH)_2$ (3%), Ba(OAr-Bu^t)$(H_2NC_2H_4OH)(C_2H_4OH)$ (1%), Ba(OPh)$(H_2NC_2H_4OH)_2$ (4%), Ba(OAr-Bu^t)(CH_3OH) (2%), Ba(OH)(OPh)(CH_3OH) (20%), Ba(OPh)(CH_3OH) (5%), ArOH (23%), ArOH-CH_3 (90%), Bu^t (100%), NC_2H_4 (30%). Soluble in toluene, heptane, THF, $CHCl_3$ and CH_2Cl_2, partially soluble in pentane.

Crystallographic studies

The selected crystals of **I**, **II** and **III** were mounted onto a Siemens P3 automatic diffractometer. Accur-

ate unit cell dimensions and crystal orientation matrices, together with their estimated standard deviations, were obtained from least-squares refinement of the setting angles of 25 (compound **I**), 21 (compound **II**) and 22 (compound **III**) reflections. Crystallographic data and other pertinent information are summarized in Table 1. The data of **I** were corrected for linear decay by batch scaling from one set of checks to the next. Corrections were made for Lorentz and polarization effects. No correction for absorption was made. All calculations for these three investigations were performed on a VAX 3100. Complex neutral-atom scattering factors were employed. Anomalous dispersion terms were used. For the three investigated compounds the positions of the barium atom were found by analysis of a three-dimensional Patterson map using SHELXS 86[9] and was confirmed by direct methods using SIR.[10] All remaining non-hydrogen atoms were found by successive electron density map calculations using SHELX 76.[11] Anisotropic temperature factors were introduced for all non-hydrogen atoms in **II**. Due to a medium quality of the crystal of **I**, the data contained a large

proportion of weak reflections. Therefore, only barium atoms were allowed to move anisotropically in **I** in order to keep the ratio of observation-to-parameter higher than 10. For the same reason, in complex **III** the carbon atoms of the Bu^t groups as well as the solvent molecule were kept isotropic whereas the other atoms were refined anisotropically. For **II** and **III** hydrogen atoms were placed in calculated positions (C—H = 1.08 Å) and were not further refined but recalculated after each cycle. They were ignored in compound **I**. In complex **I**, in two THF groups, the distances between the carbon atoms refined to unreasonable values. The three carbon atoms involved were thus fixed in their found positions, leading to satisfactory bond lengths in these two THF groups. The solvent toluene molecule in the lattice was not refined (atoms were just included in found positions with a fixed isotropic temperature factor). The criteria for a satisfactory complete analysis were the ratios of the rms shift-to-standard deviation being less than 0.1 and no significant features in the final different map. Positional parameters and equivalent isotropic or isotropic parameters are given as supplementary material.

RESULTS AND DISCUSSION

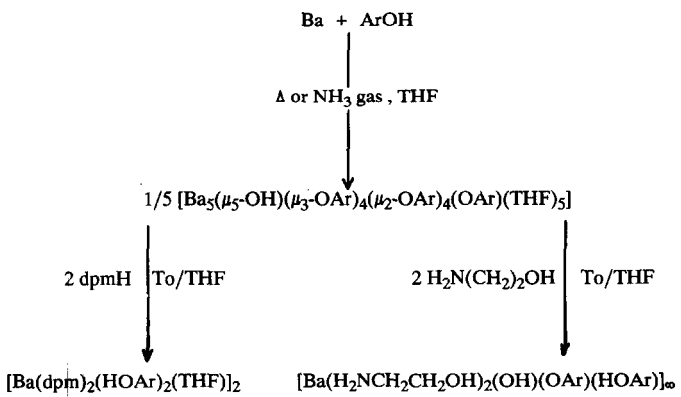
We have investigated the synthesis of 3,5-di-tert-butylphenoxide of barium and its reactivity towards dpmH and ethanolamine (Scheme 1). Each compound was characterized by elemental analysis and the usual spectroscopic methods: IR, NMR and mass spectroscopy. The complete structural characterization of $Ba_5(\mu_5\text{-}OH)(\mu_3\text{-}OAr)_4(\mu_2\text{-}OAr)_4(OAr)(THF)_5$, $[Ba(\mu_1,\mu_2\text{-}dpm)(dpm)(HOAr)_2(THF)]_2$ and $[Ba(H_2NCH_2CH_2OH)(\mu_1,\mu_2\text{-}H_2NCH_2CH_2OH)(\mu_2\text{-}OH)(\mu_2\text{-}OAr)(HOAr)]_\infty$ was achieved by X-ray diffraction. The thermal stability and volatility of each aryloxide derivative have been studied by heating the complexes *in vacuo* (10^{-2} mmHg) and by thermogravimetric analyses.

Synthesis and characterization of I

The pentahydroxyaryloxide aggregate of barium, $Ba_5(\mu_5\text{-}OH)(\mu_3\text{-}OAr)_4(\mu_2\text{-}OAr)_4(OAr)(THF)_5$ (**I**), was obtained by reaction between barium metal and 3,5-di-tert-butylphenol using ammonia gas as the catalyst in a 98% yield. This route has already been mentioned by Caulton;[12] it allows an easy and fast reaction of alkaline-earth metals by very sterically encumbered ligands in an oxygenated medium.[13] The direct reaction of the barium metal with 3,5-di-tert-butylphenol in THF has also been achieved by heating, but an alternate synthesis of **I** is very long (the reaction will be longer as the ArO ligand increases in size).

Despite the sterically hindered ligands, this compound presents a high nuclearity which accounts for its poor volatility. It decomposes by loss of ArOH at 100°C/10^{-1} mmHg. The thermogravimetric analysis of **I** shows a two-step process: a rapid weight loss in the range 100–120°C and a second one in the range 250–300°C. The percentage of weight loss corresponds to the THF and ArOH removal, respectively. The aggregate also displays good solubility.

The IR spectra display essentially the absorption bands of the ligands. The presence of the hydroxy group is obvious with a characteristic O—H stretching vibration at 3590 cm^{-1}. The ^{1}H NMR spectra show a single set of ArO and THF resonances. The solvent also acts as a Lewis base; it stabilizes the complex in which the coordination number of the barium is reached.



Scheme 1

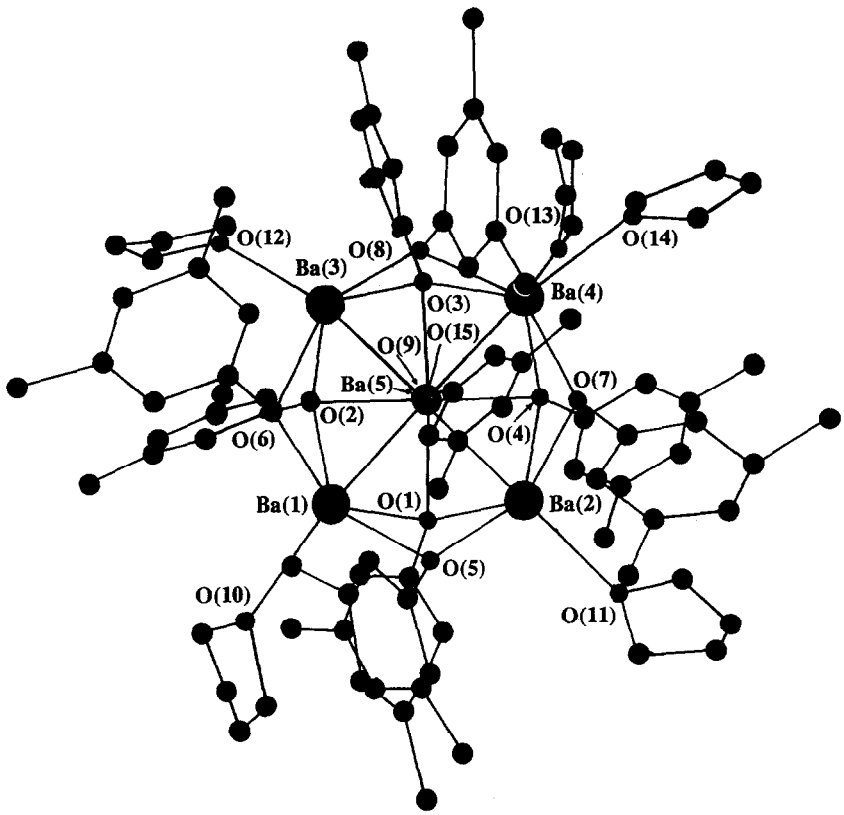


Fig. 1. Atomic numbering scheme for $Ba_5(\mu_5\text{-}OH)(\mu_3\text{-}OAr)_4(\mu_2\text{-}OAr)_4(OAr)(THF)_5$ (the terminal methyl groups of the Bu^t ligands are omitted for clarity).

Solid-state structure of $Ba_5(\mu_5\text{-}OH)(\mu_3\text{-}OAr)_4(\mu_2\text{-}OAr)_4(OAr)(THF)_5$

Since the spectroscopic data offer limited structural information, X-ray diffraction studies were carried out on $Ba_5(\mu_5\text{-}OH)(\mu_3\text{-}OAr)_4(\mu_2\text{-}OAr)_4(OAr)(THF)_5$. The molecular structure of **I** is a square-based pyramid of barium atoms with a single OH^- ligand lying 2.01(2) Å above the plane defined by the four basal barium centres (Fig. 1). The aryloxides are of three types: four triply bridging, four doubly bridging and one terminal. The μ_2- and μ_3-OAr groups are thus responsible for the stability of the structural arrangement. The μ_3-OAr groups occupy the four triangular faces of the square pyramid; the μ_2-OAr ligands bridge the four basal metal atoms and the single OAr terminal ligand bonds to the apical barium. Selected bond distances and angles are given in Table 2.

The same square pyramidal Ba_5 geometry found in $Ba_5(OH)(OAr)_9(THF)_5$ is also adopted in $HBa_5(O)(OPh)_9(THF)_8$.[3b] The distribution of the OAr ligands, four μ_3, four μ_2 and one terminal, duplicates that reported here. The lengths of analogous bonds in these two molecules are very similar. The structural differences are essentially due to the number and the coordination of the THF molecules. (1) In the aryloxide complex **I** three of the basal barium atoms are bonded to one THF molecule—they, and the apical barium, are hexa-coordinated—whereas the fourth basal barium bonded to two THF molecules is hepta-coordinated. (2) In the phenoxide complex each basal atom is bonded to two THF molecules—so they are ligated to seven oxygen atoms—whereas the apical barium is only six-coordinated.

Presumably the number of THF molecules is lower in **I** than in the phenoxide analogue because of the steric hindrance provided by the bulky Bu^t groups of the OAr ligand. The range of Ba—O(THF) distances is large (2.69–2.85 Å), indicating the different degree of steric hindrance imposed on each THF ligand.

The Ba—O(OAr) distances illustrate the different types of OAr groups: the more these groups are coordinated, the higher the bond length. This could be expected on the basis of electronic effects. These bond lengths are in good agreement with previous values reported in the literature.[3] In particular, the Ba—O(OAr terminal) bond length is typical of a

[a] Bond angles involving THF oxygen atoms cover a wide range of values, which does not permit any average. Minimum and maximum values for the different angles are reported below.

formal OAr^- group. Therefore, although the presence of the hydrogen atom in the neighbouring μ^5-O was not evident from the X-ray work, the μ^5-oxygen atom was definitively considered as a hydroxy group since it was the only possibility for the remaining hydrogen atom. Such an unambiguous assignment was not possible in the case of $HBa_5(O)(OPh)_9(THF)_8$. Furthermore, the hydroxy-ligand is observed in the IR spectra [ν(O—H) = 3590 cm^{-1}]; also, it allows the electroneutrality of the compound. Although the origin of the hydroxy ligand is not elucidated, its formation by "accidental" hydrolysis seems improbable since the isolation of the hydroxyaryloxide in high yield is reproducible.

The square-pyramidal configuration $M_5(\mu_5\text{-}O)(\mu_3\text{-}OR)_4(\mu_2\text{-}OR)_4$ has also been found for several alkoxide compounds, such as $M_5O(OPr^i)_{13}$ (Y,[14] In,[15] Yb[16]) and $(\eta^5Cp)_5Y_5O(OMe)_8$.[17] The molecular structures of alkaline-earth metal aryloxides remain relatively scarce; only mononuclear metal compounds with very sterically hindered ligands, such as $Ca(OCH_2Bu^t_2\text{-}2,6\text{-}Me\text{-}4)_2(THF)_3$[18] and $Ba(OC_6H_3Bu^t_2\text{-}3,5)_2(HOCH_2CH_2NMe_2)_4$,[3a] or metal clusters with phenoxide ligands, such as $HBa_5(O)(OPh)_9(THF)_8$[3b] and $Sr_4(OPh)_8(PhOH)_2(THF)_6$,[19] have been recently reported. By the metathetical reaction of an alkali metal aryloxide with a barium halide an oxoaryloxide cluster is obtained, $[Ba_4(\mu_4\text{-}O)\mu_2\text{-}OC_6H_2(CH_2NMe_2)_3\text{-}2,4,6)_6]\cdot 3(toluene)$,[3d] even with very encumbered ligands. None of them are volatile.

Reactivity of **I**

The reactions of **I** towards oxygenated compounds such as β-diketone (dpmH) and amino-alcohol ($H_2NCH_2CH_2OH$) have been studied. Such

polydentate compounds may be potentially useful in stabilizing the aryloxide complex **I** while reducing its polymerization. Complex **II**, $[Ba(dpm)_2(HOAr)_2(THF)]_2$, and complex **III**, $[Ba(H_2NCH_2CH_2OH)(\mu_1,\mu_2\text{-}H_2NCH_2CH_2OH)(\mu_2\text{-}OH)(\mu_2\text{-}OAr)(HOAr)]_\infty$, were obtained by reacting complex **I** with dpmH (2 mol) and $H_2NCH_2CH_2OH$ (2 mol), at room temperature in a mixture of toluene and THF.

Complex **II** displays a broad O—H stretching vibration in the IR spectrum at 3070 cm^{-1}. The ^1H NMR spectrum of this compound reveals a single average environment for the β-diketonate and the aryloxide groups. A broad resonance at 4.87 ppm is attributed to the alcohol proton. The ion with the highest molecular mass, $[Ba_2(dpm)(THF)(OAr)(Bu^tCO)]$ (82%), is present in the electron ionization mass spectrum, suggesting a dimeric nature for this complex. This is confirmed by X-ray crystal structure determination. It displays a good solubility and it dissociates upon heating between 200 and 220°C/10^{-2} mmHg into a barium-containing compound (EDX analyses), which shows the dpm and OAr ligands in ^1H NMR spectra. The elemental analysis of this sublimate compound agrees with the formula $[Ba(dpm)_2(HOAr)]_n$, $n \geqslant 2$. This sublimation with decomposition is obtained in a high yield (90% based on Ba). Thermogravimetric analyses have shown three weight losses of 7.3, 41.7 and 37.1% in the ranges 80–110°C, 160–310°C and 310–580°C, corresponding to THF, ArOH and dpmH removal, respectively. Thus, the volatility and the high solubility of complex **II** make it an attractive precursor for MOCVD and sol–gel processes. The ease with which complex **II** is obtained from **I** in very mild conditions proves the fragility of the polyhedron hydroxyaryloxide structure. The β-diketone dpmH causes the degree of molecular aggregation to decrease and enhances the volatility. Only very few volatile molecular barium compounds have been reported in the literature;[20,21] they often display a low degree of molecular aggregation (monomer or dimer) depending on whether or not the β-diketonate ligands are fluorinated.

The IR spectrum of complex **III** displays essentially the absorption bands of the ligands as well as broad stretching vibrations at 3490 and 3360 cm^{-1}, characteristic of ν(O—H) and/or μ(N—H) vibrations. The room-temperature ^1H NMR spectrum in CD_2Cl_2 reveals a single environment for the aryloxide groups and for the ethanolamine ligands. Integration establishes the presence of one ArO group for one ethanolamine. The alcohol and amine proton resonances are not observed. The polymeric nature of this compound has been determined by an X-ray crystal structure study. This and the presence of intramolecular hydrogen bondings in the building account for its non-volatility. A TG analysis presents a total weight loss of 78% in the range 100–700°C in various and badly defined steps. However, complex **III** is highly soluble.

Solid-state structure of $[Ba(\mu_1,\mu_2\text{-dpm})(dpm)(HOAr)_2(THF)]_2$ **(II)**

The structure of the $[Ba(dpm)_2(HOAr)_2(THF)]_2$ complex is shown in Fig. 2 and selected bond distances and angles are given in Table 3. The molecule is centrosymmetric and consists of a dimeric unit where barium atoms are bonded to eight oxygen atoms in a roughly dodecahedral environment. Both independant β-diketonate ligands are bidentate, but one occupies a terminal position whereas the other acts as a bridge between the two barium atoms of the dimeric complex. Such a pattern of dpm ligands is also encountered in related dimeric barium β-diketonate species, $[Ba(dpm)_2\cdot 2NH_3]_2$ and $[Ba(dpm)_2\cdot Et_2O]_2$.[21] However, in the latter compound each carbonyl oxygen of the two bridging dpm ligands is μ_2-coordinated, whereas in the studied complex **II** the dpm bridges are achieved by μ_1-O and μ_2-O carbonyl ligands. In addition, in the dpm ligands each metal centre is ligated to one THF and two ArOH molecules in terminal positions, yielding a coordination number of eight. Although the hydrogen atoms of the ArOH groups were not crystallographically located, an unambiguous assignment as coordinated alcohol was made on the basis of the long terminal Ba(1)—O(31) and Ba(1)—O(41) bond lengths of 3.003(3) and 2.815(5) Å, respectively. The alcohol group is confirmed by the spectroscopic data. This is also necessary in order to ensure the electroneutrality of the complex. The Ba—O distances are in good agreement with the expected ones. Ba—μ_1-O(dpm) bond lengths are shorter than Ba—μ_2-O(dpm) due to electronic effects. The Ba—O(THF) bond length is rather small compared to the Ba—O(THF) range observed in compound **I**. The present bond length indicates little steric hindrance from the other ligands to the THF ligand. The Ba—O(ArOH) distances are very long and thus ArOH groups should be considered as only interacting with the metal atom and not directly bonding to it.

Solid-state structure of $[Ba(H_2NCH_2CH_2OH)(\mu_1,\mu_2\text{-}H_2NCH_2CH_2OH)(\mu_2\text{-}OH)(\mu_2\text{-}OAr)(HOAr)]_\infty$

The structure of complex **III** is shown in Fig. 3. Relevant bond lengths and angles are collected in Table 4. The complex is shown to be polymeric and its chain structure is based on monomeric $[Ba(H_2N$

[a] Atoms marked with primes are related by the inversion centre.

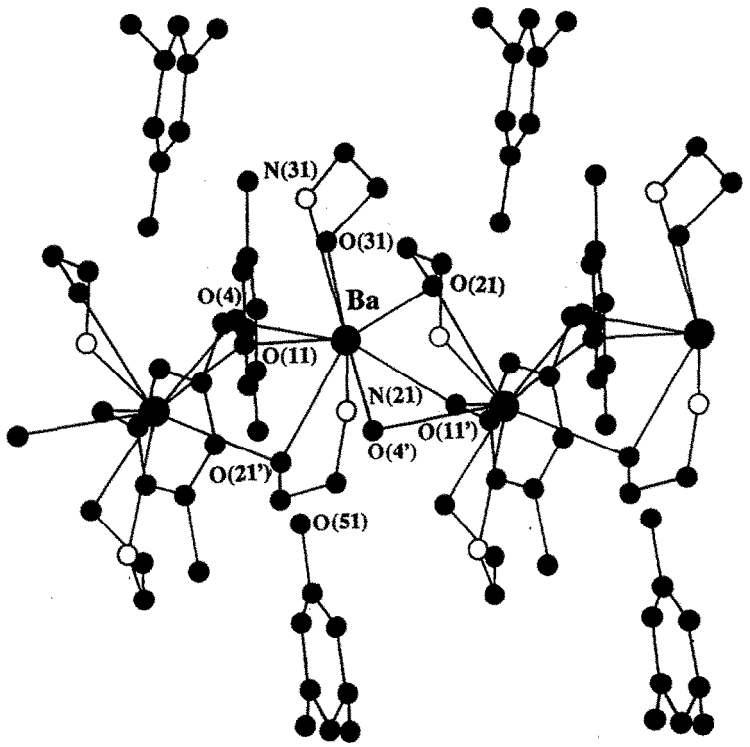

Fig. 3. Atomic numbering scheme for [Ba($H_2NCH_2CH_2OH$)(μ_1,μ_2-$H_2NCH_2CH_2OH$)(μ_2-OH)(μ_2-OAr)(HOAr)]$_\infty$ (the terminal methyl groups of the Bu^t ligands are omitted for clarity.

CH_2CH_2OH)(μ_1,μ_2-$H_2NCH_2CH_2OH$)(μ_2-OH)(μ_2-OAr)(HOAr)] units. The chains are growing along the *c*-axis through a 2_1 screw axis. The monomeric unit can be formulated in four different ways: (1) [Ba($H_2NCH_2CH_2OH$)(μ_1,μ_2-$H_2NCH_2CH_2OH$)(μ_2-OAr)(OAr)], (2) [Ba($H_2NCH_2CH_2OH$)(μ_1,μ_2-$H_2NCH_2CH_2O$)(μ_2-OH_2)(μ_2-OAr)(HOAr)], (3) [Ba($H_2NCH_2CH_2OH$)(μ_1,μ_2-$H_2NCH_2CH_2OH$)(μ_2-OH)(μ_2-OAr)(HOAr)] and (4) [Ba($H_2NCH_2CH_2O$)(μ_1,μ_2-$H_2NCH_2CH_2OH$)(μ_2-OH_2)(μ_2-OAr)(HOAr)].

Each of these four different possibilities allows for the electroneutrality of the molecule and arises from the non-location of the hydrogen atoms in the X-ray diffraction analysis. Nevertheless, the ethanolamine ligands are likely to be neutral according to the Ba—N (3 Å) and Ba—O (2.87 Å) bond distances, which fall in the range of the values previously reported in the literature.[22] Therefore, the formulation of the monomeric unit can only be 1 or 3. These two forms are tautomeric through the hydrogen bonding, according to the short oxygen–oxygen distances [O(4)—O(51) = 2.57, O(4)—O(31) = 2.59 and O(51)—O(21) = 2.58 Å], and it is impossible to differentiate one from the other in the present work. Nevertheless, we prefer to consider the isolated ArO(H) molecule as a solvent molecule rather than as a counter-ion, since generally isolated solvent molecules are more often encountered than isolated ions. Thus, in a further discussion complex **III** will be referred to as [Ba($H_2NCH_2CH_2OH$)(μ_1, μ_2-$H_2NCH_2CH_2OH$)(μ_2-OH)(μ_2-OAr)(HOAr)]$_\infty$, knowing that it could be otherwise.

The barium atoms are linked together by a chelating-bridging ethanolamine ligand, a doubly-bridging aryloxide ligand and a doubly-bridging hydroxy group. Their coordination is completed by a terminal ethanolamine ligand, resulting in a high degree of coordination of nine. The presence of relatively small ligands as ethanolamine or hydroxy groups reinforced by hydrogen bonding between them takes an important part in this high coordination of the metal centre. The Ba—O and the Ba—N bond lengths are usually observed for the different ligands.[22,23] It is noted that ethanolamine ligands play, in compound **III**, a similar role to the dpm ligands in compound **II**, as illustrated by the identical mode of coordination for these two ligands. In fact, since both complexes **II** and **III** originate from the reaction of dpmH and ethanolamine on the same complex (**I**), respectively, it appears to be a logical consequence to observe similar structural arrangements around the barium

Table 4. Selected bond lengths (Å) and angles (°) for $[Ba(H_2NCH_2CH_2OH)(\mu_1,\mu_2\text{-}H_2NCH_2CH_2OH)(\mu_2\text{-}OH)(\mu_2\text{-}OAr)(HOAr)]_\infty$ **(III)**[a] (standard deviations in parentheses)

[a] Atoms marked with primes are related by the 2_1 screw axis.

atom in complexes **II** and **III**. The infinite chains obtained in complex **III** are presumably a consequence of the relatively small size of the ethanolamine ligand compared to the dpm ligand, which precludes the polymerization due to the steric hindrance of the bulky Bu^t groups.

(*Received* 31 *July* 1992; *accepted* 10 *September* 1992)

Abstract—Reaction of $[Bu^n_4N][ReOCl_4]$ with two equivalents of the bidentate (1−) oxygen/sulphur donor ligand N,N-diethyl-N′-benzoylthiourea (DEBTH) or the sulphur/nitrogen donor ligand N,N-diethyl-N′-benzoyliminothiourea (DEBITH) in dry methanol leads to the formation of the neutral complexes $[ReOCl(DEBT)_2]$ (**1**) and $[ReOCl(DEBIT)_2]$ (**2**). The X-ray crystal structure of **1** shows the complex has a pseudo-octahedral geometry with the oxo and chloride ligands in *cis* positions. Complex **1** reacts with substituted anilines, $ArNH_2$, to give the imido complexes $[ReCl(NAr)(DEBT)_2]$ in good yield and with PPh_3 to form the rhenium(III) complex $[Re(DEBT)_2(PPh_3)_2]^+$. The spectroscopic and electrochemical properties of these complexes are discussed.

The coordination chemistry of bidentate sulphur–oxygen ligands has been widely investigated,[1] and the sulphur donor can be thiolate,[2–8] thioether[9–16] or other forms of neutral sulphur.[17–29] However, the coordination chemistry of N,N-diethylbenzoylthiourea (DEBTH, see Fig. 1) and N,N-diethyl-N′-benzoyliminothiourea (DEBITH, Fig. 1) have been comparatively little investigated apart from some complexes of first row transition metals,[30] although some technetium nitrido-complexes of DEBIT have recently been reported by Abram *et al.*[31] We have for some time been interested in the possibilities of using the thioamide group as a potential masked source of anionic sulphur by virtue of the thiol–thione tautomerism, and have reported the chemistry of thiohydrazide ($RCSNHNHR'$) ligands with a variety of metals. We are currently investigating the coordination chemistry of technetium with a wide range of such ligands and here we describe the chemistry of rhenium with DEBTH and DEBITH. Due to the strong analogies between technetium and rhenium, this can provide useful indications of how technetium may behave. Here we describe the preparation and structure of a rhenium(V) oxo complex with DEBT and its reaction with anilines to give arylimido complexes, together with some related chemistry of the DEBIT ligand system. The analogous technetium chemistry will be reported elsewhere.

EXPERIMENTAL

General

All manipulations were carried out under an inert atmosphere of dry dinitrogen gas. Standard Schlenk tube–vacuum line and syringe techniques were utilized where appropriate. Elemental analyses were performed by MEDAC Ltd, University of Brunel, using either a CEC 240XA or Carlo Erba 1106 instrument. Fast atom bombardment mass spectra were performed using 3-nitrobenzyl alcohol as a matrix material. IR spectra were recorded in the range 200–4000 cm^{-1} as Nujol mulls on KBr plates on a Perkin–Elmer 1330 spectrophotometer. ^1H and ^{13}C NMR were measured using a EX270 Jeol (270 MHz) NMR spectrophotometer in $CDCl_3$ solutions. UV–vis data were recorded on a Phillips PU8730 UV–vis spectrophotometer in the range 190–630 nm using dichloromethane solution in quartz cells. Cyclic voltammetry measurements were made at 200 K using an EG and G PAR model 362 scanning potentiostat linked to a PC with a Condecon 310 interface and software. A three-electrode cell configuration was used, with a platinum wire working electrode, platinum wire secondary electrode and a silver wire pseudo-reference electrode. The solvent was dichloromethane with 0.2 M tetrabutylammonium tetrafluoroborate as the support electrode. Potentials are quoted relative to the ferrocene/ferrocenium couple in the same system. $[Bu^n_4N][ReOCl_4]$ and DEBTH were made by the standard literature methods.[32,33]

Preparation of the complexes

Synthesis of $[ReOCl(DEBT)_2]$ (**1**). $[ReOCl_4][Bu^n_4N]$ (0.5 g, 0.85 mmol) was dissolved in degassed methanol (25 cm^3) and DEBTH (0.6 g, 2.56 mmol) was added. The solution was stirred at room temperature for 2 h producing a microcrystalline blue/green solid. The solid was washed with methanol and diethylether. The complex was recrystallized from dichloromethane/diethylether as dark green prisms. Found: C, 40.5; H, 4.2; N, 7.8. Calc. for $ReC_{24}H_{30}N_4O_3S_2Cl$: C, 40.7; H, 4.3; N, 8.0%.

Reaction of $[ReOCl(DEBT)_2]$ *with 4′-aminoacetophenone.* $[ReOCl(DEBT)_2]$ (0.2 g, 0.28 mmol) and $CH_3COC_6H_4NH_2$ (0.2 g, 1.41 mmol) were taken up in toluene (25 cm^3) and a few drops of triethylamine were added. The mixture was heated under reflux for 30 min until a dark green solution was formed. The toluene was removed under reduced pressure and methanol (20 cm^3) was then added. A dark green solid was formed. The complex recrystallized from CH_2Cl_2/Et_2O as a dark green complex (yield: 62%). Found: C, 46.8; H, 4.2; N, 8.3. Calc. for $ReC_{20}H_{22}N_5O_3S_2Cl$: C, 46.5; H, 4.5; N, 8.5%.

Reaction of $[ReOCl(DEBT)_2]$ *with 4-methoxyaniline.* The reaction was performed as above with $[ReOCl(DEBT)_2]$ (0.2 g, 0.28 mmol). The complex recrystallized from CH_2Cl_2/Et_2O as a dark green complex (yield: 64%). Found: C, 46.0; H, 4.2; N, 8.4. Calc. for $ReC_{19}H_{21}N_5O_3S_2Cl$: C, 45.8; H, 4.6; N, 8.6%.

Reaction of $[ReOCl(DEBT)_2]$ *with 2,6-diisopropylaniline.* The reaction was performed as above with $[ReOCl(DEBT)_2]$ (0.2 g, 0.28 mmol). The complex recrystallized from CH_2Cl_2/Et_2O as a dark green complex (yield: 59%). Found: C, 50.0; H, 5.2; N, 8.4. Calc. for $ReC_{21}H_{25}N_5O_2S_2Cl$: C, 45.8; H, 4.6; N, 8.6%.

Reaction of $[ReOCl(DEBT)_2]$ *with* PPh_3. $[ReOCl(DEBT)_2]$ (0.2 g, 0.28 mmol) and PPh_3 (0.22 g, 0.85 mmol) were heated under reflux in methanol (20 cm^3) to give a deep purple solution. Addition of $Na[BPh_4]$ gave the product as a red–brown solid, which was recrystallized from CH_2Cl_2–isopropanol (yield: 52%). Found: C, 61.9; H, 5.1; N, 4.4. Calc. for $ReBC_{79}H_{71}N_5O_2P_2S_5$: C, 61.8; H, 3.9; N, 4.8%. ^{31}P NMR: singlet, 14.0 ppm. ^{13}C NMR: 188.1 (*C*=O) and 173.7 ppm (*C*=S).

Preparation of $[ReOCl(DEBIT)_2]$ (**2**). $[Bu^n_4N][ReOCl_4]$ (0.25 g, 0.42 mmol) and DEBITH (0.3 g, 1.27 mmol) were stirred in methanol (20 cm^3) at room temperature to give the product as an emerald green solid. Found: C, 40.8; H, 4.2; N, 11.8. Calc. for $ReC_{19}H_{23}N_7OS_2$: C, 40.9; H, 4.3; N, 11.9%. ^{13}C NMR: 190.8 and 183.6 (*C*=O), 174.2 and 171.4 ppm (*C*=S). FAB mass spectrum: M^+ 707 with correct isotope splitting pattern.

X-ray crystal structure determination for $[ReOCl(DEBT)_2]$

A suitable single crystal was grown from dichloromethane–methanol and was mounted in air on a glass fibre.

Crystal data. $C_{24}H_{30}ClReN_4O_3S_2$, $M = 708.31$, orthorhombic space group *Pbca*, $a = 15.395(1)$, $b = 17.541(1)$, $c = 20.684(1)$ Å. $U = 5585.3$ Å, $Z = 8$, $D_c = 1.68\ g\ cm^{-3}$, $F(000) = 2800$, blue green prisms, crystal dimensions $= 0.30 \times 0.4 \times 0.30$ mm, $\mu(Mo\text{-}K_\alpha) = 46.8\ cm^{-1}$, $T = 18°C$.

Crystal collection and processing. Enraf–Nonius CAD4 diffractometer, graphite crystal monochromated Mo-K_α radiation ($\lambda = 0.71073$ Å), ω–2θ scan, ω scan speed 1–7.0° min^{-1}, scan width (°) $= 0.5 + 0.340 \tan\theta$, 5090 reflections measured ($1.5 < \theta < 25°$), 4906 unique.

Table 1. Some selected bond angles (°) and lengths (Å) for complex (1)

O(3)—Re—Cl	90.3(3)	S(2)—Re—O(2)	91.3(2)

Structure analysis and refinement. The structure analysis is based upon 3039 observed reflections with $F_o > 3.0\sigma$; the intensities were corrected for absorption using empirical scan data and for Lorentz and polarization factors. The structure was solved by Patterson and difference-Fourier methods and was refined by full-matrix least-squares techniques with anisotropic thermal parameters for all non-hydrogen atoms (316 variables). Final $R = 0.031$, $R_w = 0.038$, $S = 3.68$, $(\Delta/\sigma)_{max} = 0.10$. The final difference electron density synthesis showed maximum positive and negative features of 0.84 and -0.16 e $Å^{-3}$. All calculations were performed on a micro VAX using MolEN (Enraf–Nonius). The neutral atom scattering factors were taken from international tables. Selected bond lengths and angles are given in Table 1.

RESULTS AND DISCUSSION

Reaction of the rhenium(V) precursor $[ReOCl_4]^-$ with DEBTH or DEBITH in methanol at room temperature gives the neutral rhenium(V) oxo complexes $[ReOClL_2]$ rapidly in high yields. Attempts to prepare the same complexes from $[ReOCl_3(PPh_3)_2]$ were not successful, and intractable mixtures resulted. The emerald green complexes are air-stable in the solid state and in solution, and non-electrolytes in dichloromethane solution. The ^{13}C NMR spectra of both complexes show two distinct pairs of resonances for the carbonyl and thiocarbonyl carbons, indicating that the two ligands are not in equivalent environments. This is consistent with a *cis* arrangement of the bidentate ligands. The FAB mass spectra show the expected mass ions and isotope distribution patterns, and the UV spectra display a charge transfer band at *ca* 400 nm. The presence of the Re=O group is confirmed by the appearance of an intense IR band close to 1000 cm^{-1}.

The formation of the neutral pseudo-octahedral rhenium complexes is in contrast to the behaviour of technetium where cationic, square pyramidal complexes of the type $[TcO(DEBT)_2]^+$ are formed. This presumably reflects the greater lability of the chloride ligand *trans* to the oxo-group on technetium.

Cyclic voltammetry of $[ReOCl(DEBT)_2]$ (1) *and* $[ReOCl(DEBIT)_2]$ (2)

The cyclic voltammogram of complex 1 in dichloromethane at room temperature (Fig. 2) was mea-

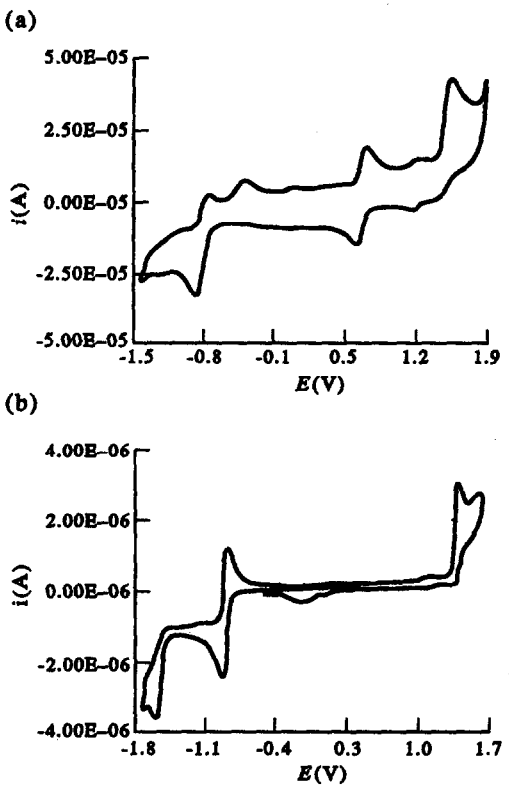

Fig. 2. The cyclic voltammogram of complex 1, in CH_2Cl_2 at room temperature and -80°C at a platinum electrode with 0.2 M $[Bu^n_4][BF_4]$ as the supporting electrolyte and a silver wire pseudo-reference electrode at a scan rate of 200 mV s^{-1}. The reversible couple at *ca*+0.7 V on the scale shown is due to ferrocene and is used as the internal standard of 0.0 V to quote potentials.

sured at a platinum electrode with 0.2 M $[Bu^n_4][BF_4]$ as the supporting electrolyte and a silver wire pseudo-reference electrode at a scan rate of 200 mV s^{-1}. There is a partially reversible reduction process at $E_{1/2} = -1.52$ V with an irreversible wave due to a product at -1.12 V (all potentials are quoted relative to an internal reference, the ferrocene–ferrocenium couple, taken as 0.0 V). In addition, an irreversible oxidation process occurs at $+0.88$ V. Convolution and deconvolution analyses of the primary processes indicate that both involve one electron. Addition of a large excess of chloride ion to the cell has no effect on the reduction at -1.52 V, strongly suggesting that the chemical process responsible for the irreversibility is not the expulsion of chloride. This reduction remained non-Nernstian, even at the fastest scan rates available, but became completely reversible at -80°C (Fig. 2). However, the oxidation process remained irreversible even at the low temperature. Convolution and deconvolution analyses confirmed that the -1.52 V process is entirely Nernstian at low temperature and involves one electron. A further completely irreversible reduction occurs at -2.27 V. The cyclic voltammogram of [ReOCl(DEBIT)$_2$] at room temperature is remarkably similar to that of **1**, with an irreversible reduction at -1.55 V and an irreversible oxidation at $+0.91$ V. The reduction process is noticeably less reversible at room temperature than the corresponding process for complex **1**. These results indicate a marginal stability for the rhenium(IV) anionic species at room temperature.

Reactions of [ReOCl(DEBT)$_2$]

The reaction of complex **1** with anilines in methanol under reflux gives the deep green imido complexes [Re(NAr)Cl(DEBT)$_2$] in good yield in the presence of triethylamine. The reaction does not proceed at all in the absence of additional base, which is in interesting contrast to the reaction of aromatic amines with $[ReOCl_3(PPh_3)_2]$ which does not require base catalysis. The imido complexes are formally 18-electron systems with the imide ligand functioning as a four-electron donor. The ^{13}C NMR spectra show an analogous four-peak pattern for the thiocarbonyl and carbonyl carbons, indicating a similar *cis* geometry to the oxo complexes. The FAB mass spectra all exhibit the expected mass ions and isotope distribution patterns.

Attempts to access rhenium(III) complexes by reaction of precursors such as $[ReCl_3(MeCN)(PPh_3)_2]$ with DEBTH or DEBITH were unsuccessful, complex mixtures of products being formed. However, reaction of **1** with excess triphenylphosphine in methanol under reflux gave the brown cationic rhenium(III) species $[Re(DEBT)_2(PPh_3)_2]^+$ in good yield. This showed a singlet in its ^{31}P NMR spectrum and only one carbonyl and one thiocarbonyl ^{13}C NMR peaks. These data are consistent with a *trans* disposition of the PPh_3 ligands, presumably as this geometry minimises steric repulsions with the bulky phosphine ligands.

The crystal structure of [ReOCl(DEBT)$_2$]

A perspective view of the molecule appears in Fig. 3, and selected bond lengths and angles are presented in Table 1. The geometry about the rhenium atom is essentially octahedral, with the chloride and oxo ligands *cis*. The Re—Cl and Re=O distances lie in the normal ranges found for rhenium(V) oxo complexes. The disposition of the two DEBT ligands is such that the sulphur and oxygen donor atoms are *cis*, and the phenyl groups are therefore located on the same side of the molecule. There is some steric interaction between them, and this causes a significant distortion in the Re—S(1)—C(10)—N(10)—C(11)—O(1) chelate ring. The rhenium atom lies 0.37 Å below and S(1) 0.49 Å above the least-squares plane through the six atoms of the chelate ring system. The other chelated ligand is comparatively close to being planar. The distortions within one chelate ring are reflected in the differing bite angles of 80.8(1)° and 91.3(2)°.

There is extensive delocalization throughout both chelate ring systems as evidenced by the remarkably uniform C—N distances of close to 1.33 Å, even for the exocyclic nitrogens N(11) and N(21). The geometry about N(11) and N(21) is essentially trigonal planar, and the N—CH_2 bonds are virtually coplanar with the chelate rings, which indicates that delocalization extends well into the chelate sub-

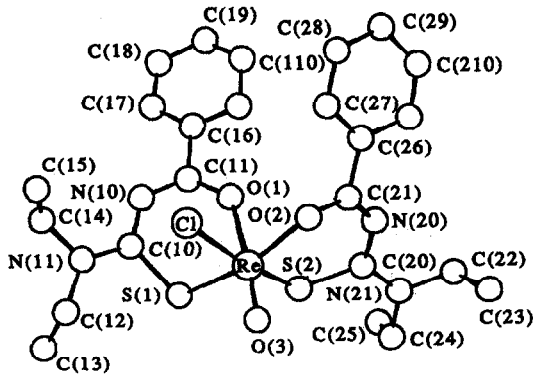

Fig. 3. A perspective view of the structure of [ReOCl(DEBT)$_2$] showing the atom labelling scheme.

stituents. The steric interaction between the two phenyl groups causes some deviations from coplanarity with the chelate rings, and the interplanar angles are 27.8° [S(1)—O(1) chelate] and 17.7°.

CONCLUSIONS

The ligands DEBT and DEBIT have been shown to behave similarly in forming neutral, six-coordinate rhenium(V) oxo complexes of the type $[ReOClL_2]$. The oxo group is relatively labile, and can be abstracted by PPh_3 to generate a rhenium(III) cation and can also be replaced by an arylimido ligand by reaction with aniline in a base catalysed reaction.

Acknowledgements—We thank Joanne Warmsley, University of Essex, for the NMR spectra, Edgar Potter, University of Essex, for the mass spectra and Neil Barnard, University of Essex, for the electrochemical results. We would also like to thank Hermann Stark GMBH, Berlin, for the generous gift of rhenium metal and Antony J. Hutson for the $[Bu^n_4N][ReOCl_4]$ preparation. One of us (JSL) thanks Hampshire LEA for the funding and ICI plc, U.K., for an additional grant payment.

Abstract—The synthesis of mixed-ligand fluoro complexes of UO_2^{2+} of the types $A_3[UO_2(GlyH)_2F_5]\cdot 3H_2O$ [A = K (**1**) or NH_4^+ (**2**)], $K_3[UO_2(AlanH)_2F_5]\cdot 2H_2O$ (**3**), $(NH_4)_5[UO_2(CysH)_2F_5]\cdot 2H_2O$ (**4**), $[UO_2(acac)F(H_2O)_2]\cdot 3H_2O$ (**6**), $K_2[UO_2(acac)F_3]$ (**8**) and $[UO_2(CH_3COO)F(H_2O)_2]$ (**9**) (GlyH = glycine, AlanH = alanine, $CysH^-$ = cysteinate and $acac^-$ = acetylacetonate) is described. The complexes have been characterized by a combination of chemical analyses, solution conductance measurements and spectroscopic studies. Vibrational spectroscopy has been used for their structural assessment. Laser Raman spectrum could be recorded only for $K_2[UO_2(acac)F_3]$ (**8**), while an extensive fluorescence foiled such attempts on the other complexes. Each of the three amino acid co-ligands acts in a unidentate manner, being coordinated to UO_2^{2+} through the caroxylate oxygen atom. While glycine and alanine occur in the zwitter-ionic form, cysteine seems to be present as a uninegative ligand. The reaction of $[UO_2(acac)F(H_2O)_2]\cdot 3H_2O$ (**6**) with aqueous HF produced $[UO_2F_2]\cdot 3H_2O$ (**7**). Treatment of $K_3[UO_2(GlyH)_2F_5]\cdot 3H_2O$ (**1**) with water afforded the hitherto unreported potassium heptafluorodioxouranate(VI) dihydrate, $K_5[UO_2F_7]\cdot 2H_2O$ (**5**), in a high yield with satisfactory analysis and electrical conductance measurement (590 Ω^{-1} cm^2 mol^{-1}). IR and laser Raman spectra provide clear evidence for the presence of *trans*-linked O=U=O and coordinated flouride. The solution Raman spectrum of **5** is similar to that of its solid indicating that the structure in aqueous solution is the same as the solid. Scanning electron microscopy has been used to ascertain its homogeneity and crystalline nature.

Uranium(VI) generally occurring as uranyl (UO_2^{2+}) has been known to form stable fluoro and mixed-ligand fluoro complexes.[1] Notable among the binary fluoro complexes[1,2] are $[UO_2F_3]^-$, $[UO_2F_4]^{2-}$, $[UO_2F_5]^{3-}$ and $[(UO_2)_3F_7]^-$. For the mixed-ligand fluoro complexes of UO_2^{2+} the co-ligands were drawn largely from sulphate,[3] carbonate,[3b] oxalate,[4] acetate,[1c] acetylacetonate,[5] propionate[6] and malonate.[6]

Interestingly, the fluoro complexes of the types $[UO_2F_6]^{4-}$ and $[UO_2F_7]^{5-}$ were not included in the earlier reports. We addressed ourselves to these complexes and the first synthesis of $(NH_4)_4[UO_2F_6]$ has been achieved very recently.[7] A fortuitous synthesis of heptafluorodioxouranate(VI), obtained as $K_5[UO_2F_7]\cdot 2H_2O$ (**5**), enables us now to make the first report on the complex. In addition, we have been interested in the complex chemistry of UO_2^{2+}[8–11] and some of our previous publications have dealt with mixed-ligand peroxo complexes, including fluoroperoxouranates(VI).[11]

* Author to whom correspondence should be addressed.

In this investigation we included the synthesis of a few selective mixed fluoro complexes with amino acids, such as glycine, L-alanine and L-cysteine, acetylacetonate and acetate as the co-ligands.

Incidentally, amino acids,[12–15] acetylacetonate[16] and acetate[1c,1d] have been known for a long time to form complexes with UO_2^{2+}, although their isolation in the solid state varied from case to case. In addition, the reaction solution pH conducive to the formation of such complexes, particularly with regard to amino acids and acetylacetonate ligands, seems to be an important parameter. One of our main concerns in this context was to ascertain appropriate experimental conditions leading to the synthesis of the desired complexes.

Herein are reported the synthesis of the mixed-fluoro complexes $A_3[UO_2(GlyH)_2F_5]\cdot 3H_2O$ [A = K (**1**) or NH_4^+ (**2**); GlyH = glycine], $K_3[UO_2(AlanH)_2F_5]\cdot 2H_2O$ (**3**) (AlanH = L-alanine), $(NH_4)_5[UO_2(CysH)_2F_5]\cdot 2H_2O$ (**4**) ($CysH^-$ = cysteinate), $[UO_2(acac)F(H_2O)_2]\cdot 3H_2O$ (**6**), $K_2[UO_2(acac)F_3]$ (**8**) ($acac^-$ = acetylacetonate) and $[UO_2(CH_3COO)F(H_2O)_2]$ (**9**), their spectroscopic characterization and the interaction of **1** with water, thus enabling us to make the first report on the heptafluorodioxouranate(VI) complex $K_5[UO_2F_7]\cdot 2H_2O$ (**5**).

EXPERIMENTAL

The chemicals used were of reagent grade quality and acetylacetone was distilled before use. IR spectra were recorded on a Perkin–Elmer Model 983 spectrophotometer and laser Raman (LR) on a SPEX Ramalog 1403 spectrophotometer using the 4880 Å laser line from a Spectra-Physics Model 165 argon laser. The pH values of the reaction solutions were measured using a Systronics type 335 digital pH meter and BDH indicator paper. Solution electrical conductances were measured using a Systronics type 304 digital direct reading conductivity meter. Bis(acetylacetonato)dioxouranium(VI) dihydrate, $UO_2(C_5H_7O_2)_2\cdot 2H_2O$, was prepared by a method developed in this laboratory.[16,17]

Preparation of $UO_3\cdot 4H_2O$

Uranyl nitrate hexahydrate, $UO_2(NO_3)_2\cdot 6H_2O$ (5.0 g, 9.96 mmol), was dissolved in water (100 cm^3), to which was added pyridine (10 cm^3) whereupon a yellow precipitate appeared. This was separated by decantation, washed three or four times with water, twice with acetone and finally dried on a steam bath to obtain yellow uranium trioxide, $UO_3\cdot 4H_2O$ (yield: 2.8 g; 78.4%).

Syntheses

$A_3[UO_2(GlyH)_2F_5]\cdot 3H_2O$ [A = K (**1**) *or* NH_4^+ (**2**)]. $UO_3\cdot 4H_2O$ (1.0 g, 2.79 mmol) was dissolved in an aqueous solution of a combination of aqueous HF (12 mmol) and AF (8.38 mmol) (A = K or NH_4^+). To the clear lemon yellow solution thus obtained was added an aqueous solution (5 cm^3) of glycine (0.42 g, 5.57 mmol) and the solution was stirred for *ca* 10 min. The solution after concentration by heating on a steam bath to nearly half of its volume afforded a lemon–yellow solid. The pH of the reaction solution was recorded to be *ca* 2.5. The compound was isolated by filtration and dried *in vacuo* over concentrated H_2SO_4. The yields of $K_3[UO_2(GlyH)_2F_5]\cdot 3H_2O$ (**1**) and $(NH_4)_3[UO_2(GlyH)_2F_5]\cdot 3H_2O$ (**2**) were 1.2 g (63%) and 1.1 g (65%), respectively.

$K_3[UO_2(AlanH)_2F_5]\cdot 2H_2O$ (**3**) *and* $(NH_4)_5[UO_2(CysH)_2F_5]\cdot 2H_2O$ (**4**). These complexes were prepared by a method similar to that employed for **1** and **2**, except that AHF_2 was used as the fluorinating agent instead of AF and HF. $UO_3\cdot 4H_2O$ (1.0 g, 2.79 mmol) was dissolved in an aqueous solution (5 cm^3) of AHF_2 (8.37 mmol). This was followed by the addition of L-alanine or L-cysteine (5.57 mmol). The pH of the resulting clear solution was *ca* 2.5. The solution upon concentration over a steam-bath produced **3** and **4**, respectively. The compounds were isolated in a manner similar to that of **1** and **2**. The yields of **3** and **4** were 1.3 g (66%) and 1.4 g (68%), respectively.

Treatment of **1** *with water and isolation of* $K_5[UO_2F_7]\cdot 2H_2O$ (**5**). A suspension of $K_3[UO_2(GlyH)_2F_5]\cdot 3H_2O$ (**1**) (1.0 g, 1.46 mmol) in water (10 cm^3) was stirred constantly for *ca* 5 min, whereupon the solid slowly dissolved. On further agitation, the solution deposited a bright lemon–yellow crystalline solid. The pH of the mother liquor was recorded to be *ca* 1.7. The solid thus obtained was collected by filtration and finally dried *in vacuo* over concentrated H_2SO_4 (yield: 0.7 g; 76%).

Synthesis of $[UO_2(acac)F(H_2O)_2]\cdot 3H_2O$ (**6**). (1) $UO_3\cdot 4H_2O$ (1.0 g, 2.79 mmol) in water (5 cm^3) was reacted with 48% HF (0.2 cm^3, 4.8 mmol) in the presence of acacH (1.0 cm^3, 10 mmol) and the resultant reaction mixture was stirred constantly on a steam bath for *ca* 15 min, whereupon a yellow solid precipitated out. The pH of the reaction solution was found to be *ca* 3.5. The yellow solid was collected by filtration and washed with ethanol (yield: 1.0 g; 77%).

(2) Alternatively, to an aqueous suspension (5 cm^3) of $UO_2(acac)_2\cdot 2H_2O$ (1.0 g, 1.98 mmol) was added 48% HF (0.2 cm^3, 4.8 mmol). The reaction solution upon stirring on a steam bath for *ca* 15

min afforded a yellow solid. The pH of the reaction solution measured at this stage was *ca* 3.5 (yield: 0.7 g; 74%).

Synthesis of $K_2[UO_2(acac)F_3]$ (**8**). Uranyl nitrate hexahydrate, $UO_2(NO_3)_2 \cdot 6H_2O$ (1.0 g, 1.99 mmol), was dissolved in water (15 cm^3) and 20% KOH solution was added until the yellow precipitate formation was complete. The precipitate was filtered off and washed free from alkali and nitrate. To a suspension of the yellow precipitate in an excess of acetylacetone (10 cm^3, 100 mmol) was added KF (0.7 g, 12 mmol), maintaining the atom ratio of U:F at 1:6. The reaction solution was stirred constantly over a steam bath for *ca* 2 h until the formation of a bright yellow compound was complete. The pH of the reaction solution at this stage was measured to be *ca* 3.5. The compound was separated by filtration and dried *in vacuo* over concentrated H_2SO_4 (yield, 0.7 g; 70%).

Synthesis of $[UO_2(CH_3COO)F(H_2O)_2]$ (**9**). $UO_3 \cdot 4H_2O$ (1.0 g, 2.79 mmol) was dissolved in a minimum amount of glacial acetic acid (2 cm^3, 35 mmol). To the resulting clear solution was added 48% HF (0.2 cm^3, 4.8 mmol) and the reaction solution was concentrated over a steam bath to afford a lemon–yellow solid. The pH of the reaction solution was *ca* 2.5. The solid was isolated by filtration, washed with ethanol and finally dried *in vacuo* over concentrated H_2SO_4 (yield: 0.8 g; 74%).

Elemental analyses

Uranium was estimated gravimetrically as uranyl oxinate.[18a] Fluoride was precipitated as PbClF and chloride estimated by Volhard's method, from which the fluoride content was also calculated.[18b] Carbon, nitrogen and hydrogen were determined by the Micro Analytical Laboratory of our university. Potassium was estimated using a Perkin–Elmer Model 2380 atomic absorption spectrophotometer. The uranium content was also checked using the Perkin–Elmer Model 2380 atomic absorption spectrophotometer.

RESULTS AND DISCUSSION

The synthesis of mixed-ligand fluorodioxouranates(VI) with the co-ligands drawn from amino acids, such as glycine, L-alanine and L-cysteine, and acetylacetonate and acetate required first the development of the appropriate experimental conditions. It is known[19] that amino acids do not coordinate with UO_2^{2+} below pH *ca* 1.8, while above pH 4–4.5 there is a strong tendency for hydrolysis of the complexes. Evidence for the formation of binary amino acid-uranyl complexes at pH *ca* 2 has been provided by pH titration and solvent extraction experiments.[14] Thus, it was anticipated that a pH range 2–4.5 might be conducive to the coordination of an amino acid to UO_2^{2+} in the presence of F^-. Incidentally, the reaction of $UO_3 \cdot 4H_2O$ with AHF_2 in the case of L-alanine and L-cysteine or a combination of AF and HF in the case of glycine gave rise to a natural pH of *ca* 2.5. The complexes were thus isolated as $A_3[UO_2(GlyH)_2F_5] \cdot 3H_2O$ [A = K (**1**) or NH_4^+ (**2**)], $K_3[UO_2(AlanH)_2F_5] \cdot 2H_2O$ (**3**) and $(NH_4)_5[UO_2(CysH)_2F_5] \cdot H_2O$ (**4**), respectively, in high yields.

The mixed-ligand amino acid fluoro complexes of UO_2^{2+} were unstable in aqueous solutions, undergoing decomposition to form intractable products, except for $K_3[UO_2(GlyH)_2F_5] \cdot 3H_2O$ (**1**). Significantly, **1** underwent hydrolysis affording a well-defined but hitherto unknown binary fluoro complex, $K_5[UO_2F_7] \cdot 2H_2O$ (**5**), enabling us to make the first report on the heptafluorodioxouranate(VI) species. Although it is difficult to say how exactly the formation of **5** from **1** occurred, presumably at least the hydrolysis of the complex $[UO_2(GlyH)_2F_5]^{3-}$ and a reorganization of the coordination sphere of the UO_2^{2+} ion must have occurred to afford the complex $[UO_2F_7]^{5-}$. The solution pH on the formation of the compound $K_5[UO_2F_7] \cdot 2H_2O$ (**5**) was recorded to be 1.7, which might have facilitated dissociation of the co-ligand GlyH.

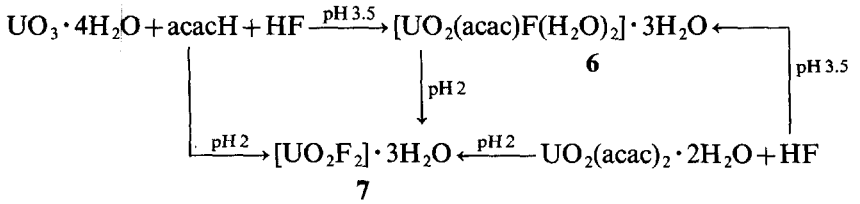
In some recent reports, direct syntheses of $UO_2(acac)_2 \cdot 2H_2O$ have been dealt with.[16,17] A pH of 5–5.5 was ascertained to be necessary for coordination of $acac^-$ to UO_2^{2+}. In order to design suitable experimental conditions for the synthesis of fluoro(acetylacetonato)dioxouranium(VI) complexes it was felt that the pH of the reaction medium might be important.

Our experience in dealing with uranyl systems[7–11] led us to believe that the reactions of $UO_2(acac)_2 \cdot 2H_2O$ with a controlled amount of F^- in acidic medium should be appropriate for accessing fluoro(acetylacetonato)dioxouranates(VI). It was important in this context to avoid a higher F^- ion concentration which would inhibit the formation of binary fluoro complexes. As shown here (see Experimental), the reaction of $UO_3 \cdot 4H_2O$ with aqueous HF and acacH at pH 3.5 (attained spontaneously) afforded the molecular complex $[UO_2(acac)F(H_2O)_2] \cdot 3H_2O$ (**6**). However, on lowering the pH to *ca* 2 by the addition of aqueous HF, a known fluoro compound, $[UO_2F_2] \cdot 3H_2O$[1a] (**7**), resulted. It should be mentioned that in two separate reactions $[UO_2(acac)_2] \cdot 2H_2O$ and $[UO_2(acac)F(H_2O)_2] \cdot 3H_2O$ (**6**) were reacted with excess aqueous HF to yield **6** and **7**, respectively.

An important implication of the observed sequential loss of coordinated acetylacetonate ligands from $[UO_2(acac)_2]\cdot 2H_2O$ at the pH values *ca* 3.5 and *ca* 2 is that an enhanced acidity appears to be detrimental to the formation of fluoro-(acetylacetonato) complexes of the metal. In other words, $[UO_2(acac)F(H_2O)_2]\cdot 3H_2O$ (**6**) may be regarded as an isolable intermediate in the process $[UO_2(acac)_2]\cdot 2H_2O$ to $[UO_2F_2]\cdot 3H_2O$.

5–9 are stable in water under the present experimental conditions. It may be important to mention that the reported solution electrical conductances for the salts of the complex ions $[UO_2F_3]^-$, $[UO_2F_4]^{2-}$ and $[UO_2F_6]^{4-}$ were *ca* 130,[22a] 216[22b] and 495[7] Ω^{-1} cm^2 mol^{-1}, respectively.

The common features of the IR spectra of complexes **1–9** are the bands at *ca* 900 and 375 cm^{-1},



The knowledge obtained from the preceeding results suggested that if a reaction of UO_2^{2+} with acacH and an excess of fluoride were conducted at pH *ca* 3.5, it would be possible to gain access to the anionic fluoro(acetylacetonato) complex of UO_2^{2+}. Indeed this is what has happened in one of the reactions where $K_2U_2O_7$ was reacted with KF and acetylacetone at pH 3.5 leading to $K_2[UO_2(acac)F_3]$ (**8**).

Our success in the synthesis of $[UO_2(acac)F(H_2O)_2]\cdot 3H_2O$ (**6**) caused us to anticipate that the adoption of a similar synthetic methodology might enable the preparation of analogous molecular mixed fluoro complexes with the co-ligand derived from a weak acid. To test this, the strategy was applied to a fluoro-acetato system and the compound $[UO_2(CH_3COO)F(H_2O)_2]$ (**9**) has been successfully synthesized.

The compounds are either yellow or lemon–yellow in colour and stable in the solid state. Their analytical data, molar conductance values and important IR and LR spectral bands along with their assignments are summarized in Tables 1 and 2, respectively. The results of the conductance experiments are of particular value in determining the mode of ionization of coordination compounds.[20,21] The conductances of dilute (10^{-3} M) solutions of 1 : 1, 1 : 2, 1 : 3, 1 : 4 and 1 : 5 types of electrolytic complexes are expected[20] to be *ca* 120, 240, 360, 480 and 600 Ω^{-1} cm^2 mol^{-1}, respectively, with the average value of ion conductance being *ca* 60 Ω^{-1} cm^2 mol^{-1}. For complexes **1–4** conductance measurements were not attempted due to their instability in aqueous solution; however, the solution (10^{-3} M) electrical conductances for compounds **5**, **6**, **7**, **8** and **9** were 590, 5, 7, 175 and 6 Ω^{-1} cm^2 mol^{-1}, respectively, which conforms to the formulations. This also implies that complexes assigned to ν(U=O)[23] (*trans* linked O=U=O) and ν(U—F)[23c] modes, respectively. The amino acids glycine and L-alanine form complexes with metals in either their zwitter-ionic or ionic forms,[24–26] and coordinate either through the N,O atoms in a bidentate manner or through the carboxylate oxygen atoms in a monodentate fashion. In addition to glycine and L-alanine, L-cysteine[27] was the other amino acid co-ligand included in the study which contained a sulphhydryl group as an additional coordination site.

Incidentally, the chosen amino acids are interesting probes useful in the IR spectroscopic determination of their modes of coordination.[26] There was a general pattern in the spectra of complexes **1–3**; for instance, the bands at *ca* 1600s [$\nu_{as}(COO^-)$], 1400s [$\nu_s(COO^-)$], 1120 m [$\rho_r(NH_3^+)$], 680m [$\rho_w(COO^-)$] and 580m [$\delta(COO^-)$] cm^{-1}. The observed pattern and band positions are clear reflections of the occurrence of glycine and alanine in their zwitter-ionic forms,[26,28a] thus being coordinated through their carboxylate oxygen atoms in the respective complexes. However, unlike complexes **1–3**, cysteine in **4** occurs in its cysteinate form ($CysH^-$). Important in this context have been the absorptions at 2565 cm^{-1} due to the S—H stretch[27] and at 1650s and 1385s owing to $\nu_{as}(COO^-)$ and $\nu_s(COO^-)$ modes, respectively. Notably, the observed shifts of $\nu_{as}(COO^-)$ to higher and $\nu_s(COO^-)$ to lower wave numbers than the corresponding values of free cysteine[27] provide evidence for the coordination of $CysH^-$ through its carboxylate oxygen atom. The complementary ν(U—O) mode was observed at 451m cm^{-1}. The fact that the nitrogen atom has not involved itself in coordination is clear from the unaltered NH_3^+ deformation band[27] observed at 1483 cm^{-1} for **4**. Thus, based upon the IR results described above, it

d = decomposed in water, GlyH = glycine ($C_2H_5NO_2$), AlanH = L-alanine ($C_3H_7NO_2$), $CysH^-$ = cysteinate ($C_3H_6NS^-$), $acac^-$ = acetylacetonate ($C_5H_7O_2^-$).

may be assumed that the amino acid in complexes **1–4** has acted as a monodentate ligand, coordinated with the metal centre through the carboxylate oxygen atom. In addition, the spectra exhibited the lattice water modes in their usual positions[28b] (Table 2). Unfortunately, no information could be extracted from laser Raman spectroscopic experiments on complexes **1–4** owing to extensive fluorescence.

The IR spectrum of potassium heptafluorodioxouranate(VI) dihydrate, $K_5[UO_2F_7]\cdot 2H_2O$ (**5**), is very straightforward. As expected, the spectrum exhibited only a few prominent bands; for instance, one at 866s [ν(U=O), *trans*-linked O=U=O] and another at 373 cm^{-1} [ν(U—F)], in addition to the ν(OH) and δ(HOH) modes of lattice water at 1640 and 3455 cm^{-1}, respectively. It may be mentioned that the ν(O—H) band at *ca* 3450 has been generally observed for complexes containing lattice water.[28a] Indeed, the ν(O—H) value of 3455 cm^{-1} has been argued to be rather typical of uncoordinated H_2O.[29] Incidentally, this is one of the few compounds, from among those reported herein, which exhibited a laser Raman spectrum with signals located at 920 cm^{-1} due to ν(U=O) (*trans*-linked O=U=O) and 314 cm^{-1} attributed to ν(U—F). These results not only complement the corresponding IR spectral observation but also augment our assumptions on the characteristic spectral features of the complex $[UO_2F_7]^{5-}$ species. The stability of the complex in water enabled recording its solution Raman spectrum. Significantly, the principal features of the spectrum include the appearance of the ν(U=O) and ν(U—F) signals at 915 and 325 cm^{-1}, respectively. The pattern resembles that of the corresponding solid, thus indicating that the structure of the complex $[UO_2F_7]^{5-}$ ion in aqueous solution is the same as the solid. It may be worth noting that the recently characterized[7] complex $[UO_2F_6]^{4-}$ displayed related bands at 951 and 340 cm^{-1}. The corresponding ν(U=O) and ν(U—F) modes for $[UO_2F_5]^{3-}$ were observed at *ca* 865s and 387m cm^{-1}, respectively, in the IR spectra[30,31] of the complex.

In order to gain an idea about the crystallinity and homogeneity of the product (**5**), it was subjected to Scanning Electron Microscopy (SEM). The SE micrograph (Fig. 1) attests to the homogeneity of the product as well as its crystalline character.

For compounds **6**, **8** and **9** the IR spectra provide, in addition to ν(U=O) and ν(U—F) bands, a pattern typical of chelated acetylacetonate[28c] for **6** and **8**, and bidentate acetate[28d] for **9**. Some of the charac-

teristic bands have been cited in Table 2. In agreement with their formulae the IR spectra of **6** and **9** showed a band at *ca* 725 cm^{-1}. We believe this originates from the rocking mode of coordinated water.[28b] The absence of a similar mode in the spectrum of **8** lends support to the aforementioned assignment. The only other compound which gave a good LR spectrum was **7**. In the region 1200–200 cm^{-1} there have been only two signals, one at 867 cm^{-1} assigned to ν(U═O) (*trans*-linked O═U═O) and another centred at 425 cm^{-1} due to ν(U—F), with the latter being broad.

8-QUINOLINOLATE COMPLEXES OF RUTHENIUM(II). SYNTHESIS, CHARACTERIZATION AND ELECTRON TRANSFER PROPERTIES

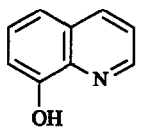
SAMARESH BHATTACHARYA

Department of Chemistry, Inorganic Chemistry Section, Jadavpur University, Calcutta 700032, India

(*Received* 23 *June* 1992; *accepted* 10 *September* 1992)

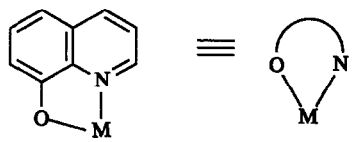
Abstract—Two stable 8-quinolinolate complexes of ruthenium(II), $[Ru(bpy)(Q)]ClO_4$ and $[Ru(tap)_2(Q)]ClO_4$ [bpy = 2,2′-bipyridine, Q = 8-quinolinolate anion, tap = 2-(*m*-tolylazo)pyridine] have been synthesized. The complexes are diamagnetic and show strong absorption near 1100 cm^{-1} in the IR spectra due to the presence of ClO_4^-. In acetonitrile solution they behave as 1 : 1 electrolytes. The complexes display intense absorption bands in the visible region (400–700 nm) which are assigned to MLCT transitions. The formal potential (E^0_{298}), determined cyclic voltammetrically for the ruthenium(II)–ruthenium(III) oxidation, is 0.48 V vs SCE for $[Ru(bpy)_2(Q)]^+$. The same oxidation takes place irreversibly at 1.00 V vs SCE (E_{pa} value) in the case of $[Ru(tap)_2(Q)]^+$. Reductions of the bound bpy and tap ligands are also observed.

The anion obtained from 8-quinolinol (HQ, 1; H is the dissociable phenolic proton) binds metal ions as a bidentate N,O coordinator forming five-membered chelate rings (**2**). The coordination chemistry of this ligand is rich and well studied.[1–12] However,



8-Quinolinol (HQ)

1



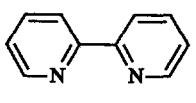
2

very few well-characterized 8-quinolinolate complexes of ruthenium exist in the literature.[6–12] The present work originated from the search for stable Ru^{II}-Q complexes. It is well documented in the literature that the 8-quinolinolate anion alone cannot afford stable complexes of ruthenium(II).[6] Therefore, 2,2′-bipyridine (bpy, **3**) and 2-(*m*-tolylazo)pyridine (tap, **4**) were used as co-ligands to stabilize the bivalent state of ruthenium. Synthesis, characterization and redox properties of two mixed ligand Ru^{II}-Q complexes are reported in this paper.

EXPERIMENTAL

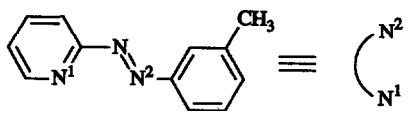
Materials

Commercial ruthenium trichloride (Arora Matthey, Calcutta, India) was converted to $RuCl_3 \cdot 3H_2O$ by repeated evaporation to dryness with concentrated hydrochloric acid. 2,2′-Bipyridine and 8-quinolinol were purchased from S.D. Fine-Chemicals, Bombay, India. 2-(*m*-Tolylazo)pyridine, *cis*-$Ru(bpy)_2Cl_2 \cdot 2H_2O$ and ctc-$Ru(tap)_2Cl_2$ were prepared following reported procedures.[13,14] BDH silica gel (60–120 mesh) was used for chromatography. Purification of acetonitrile and the preparation of tetraethylammonium perchlorate (TEAP) for electrochemical work were per-



2,2'- Bipyridine (bpy)

3



2- (*m* - Tolylazo) pyridine (tap)

4

formed as reported in the literature.[15,16] Dinitrogen gas was purified by successively bubbling it through alkaline dithionite and concentrated sulphuric acid. All other chemicals and solvents were reagent-grade commercial materials.

Preparation of complexes

(8-*Quinolinolato*)*bis*(2,2′-*bipyridine*)*ruthenium*(II) *perchlorate*, $[Ru(bpy)_2(Q)]ClO_4$. $Ru(bpy)_2Cl_2 \cdot 2H_2O$ (100 mg, 0.19 mmol) was taken in warm ethanol (30 cm^3). To this was added $AgClO_4$ (80 mg, 0.38 mmol) and the mixture was stirred for 15 min. The deposited AgCl was separated by filtration and to the filtrate was added 8-quinolinol (60 mg, 0.41 mmol) and sodium acetate (60 mg, 0.44 mmol). The resulting mixture was stirred for 18 h. Ethanol was then evaporated under reduced pressure to give a gummy solid, which was washed with water and dried *in vacuo* over P_4O_{10}. Recrystallization of the crude product from acetonitrile–benzene afforded $[Ru(bpy)_2(Q)]ClO_4$ as a crystalline solid; yield 88 mg, 70%.

(8-*Quinolinolato*)*bis*(2-(*m*-*tolylazo*)*pyridine*)*ruthenium*(II) *perchlorate*, $[Ru(tap)_2(Q)]ClO_4$. ctc-$Ru(tap)_2Cl_2$ (100 mg, 0.18 mmol) was taken in warm ethanol (30 cm^3) and $AgClO_4$ (75 mg, 0.36 mmol) was added to it. The mixture was stirred for 15 min. The deposited AgCl was then separated by filtration and to the filtrate was added 8-quinolinol (60 mg, 0.41 mmol) and sodium acetate (60 mg, 0.44 mmol). The resulting mixture was stirred for 20 h. Ethanol was then removed under reduced pressure and the resulting solid was dissolved in a minimum volume of acetonitrile. This solution was filtered to separate any insoluble material and the filtrate was chromatographed through a silica gel column. With chloroform as the eluant, a yellow band appeared first which was rejected. Using a 1 : 1 chloroform–acetonitrile solution as the eluant, a second deep blue-violet band separated. This fraction was collected and evaporation of the solvents gave crystalline $[Ru(tap)_2(Q)]ClO_4$; yield 85 mg, 65%.

Physical measurements

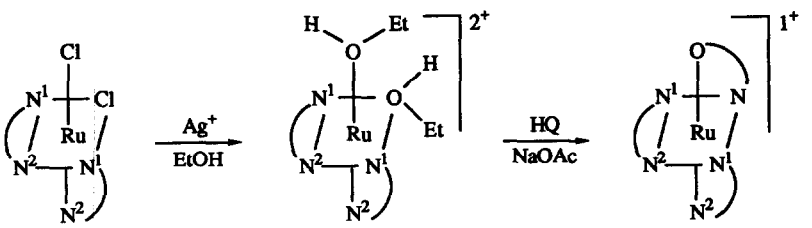
Electronic spectra were recorded on a Hitachi 330 spectrophotometer. IR spectra were obtained on a Perkin–Elmer 783 spectrometer with samples prepared as KBr pellets. ^1H NMR spectra were recorded on a Varian T-60A spectrometer. Solution electrical conductivity was measured using a Philips PR 9500 bridge with a solute concentration of 10^{-3} M. Magnetic susceptibilities were measured with the help of a PAR 155 vibrating sample magnetometer fitted with a Walker Scientific L75FBAL magnet. Electrochemical measurements were made using the PAR model 370-4 electrochemistry system incorporating the following components: 174A polarographic analyser, 175 universal programmer, RE0074 *X–Y* recorder, 173 potentiostat, 179 digital coulometer, 377 cell system. All electrochemical experiments were performed under a dinitrogen atmosphere. A planar Beckman 39273 platinum-inlay working electrode, a platinum-wire auxiliary electrode and an aqueous saturated calomel reference electrode (SCE) were used in a three electrode configuration. A platinum-wire gauge working electrode was used in the coulometric experiments. All electrochemical data were collected at 298 K and are uncorrected for junction potentials. Microanalyses (C, H, N) were performed using a Perkin–Elmer 240C elemental analyser.

RESULTS AND DISCUSSION

$[Ru(bpy)_2(Q)]^+$ has been synthesized from $Ru(bpy)_2Cl_2$ following the synthetic route shown in eq. (1).

$$Ru(bpy)_2Cl_2 \xrightarrow[EtOH]{Ag^+} [Ru(bpy)_2(EtOH)_2]^{2+} \xrightarrow[NaOAc]{HQ} [Ru(bpy)_2(Q)]^+ \quad (1)$$

The complex cation has been isolated in a good yield as the perchlorate salt in the solid state. $[Ru(tap)_2(Q)]ClO_4$ has similarly been prepared starting from ctc-$Ru(tap)_2Cl_2$ (**5**), as shown in eq. (2). The synthetic route used to obtain



ctc - Ru (tap)$_2$ Cl$_2$ — **5**

[Ru (tap)$_2$ (Q)]$^+$ — **6**

[e] Shoulder.
[f] E_{pa} value.

$[Ru(tap)_2(Q)]^+$ is known to be stereoretentive.[17] Therefore, structure **6** is assigned to the tap complex. As the 8-quinolinolate anion is an unsymmetrical bidentate ligand, the two tap ligands are non-equivalent in $[Ru(tap)_2(Q)]^+$. Two equally intense ^1H NMR methyl signals from the two tap ligands are observed at 2.16 and 2.23 ppm in $CDCl_3$ solution, as expected.

Microanalytical data (Table 1) confirm the formulations of the two complexes. The IR spectra of the complexes contain several sharp bands of different intensities. Individual band assignment has not been attempted. However, a very strong vibration near 1100 cm^{-1} is observed for both complexes due to the presence of ClO_4^-. The ν(OH) band observed in free HQ at ~ 3150 cm^{-1} is, of course, absent in these complexes. The complexes are diamagnetic as expected for low-spin d^6, $S = 0$ systems and in acetonitrile solution they behave as 1:1 electrolytes (Table 1). Both complexes display three intense absorption bands in the visible region (400–700 nm) in acetonitrile solution, which are assigned to MLCT transitions. Spectra are shown in Fig. 1 and data are given in Table 1.

The electron-transfer properties of the two complexes have been studied in acetonitrile solution by cyclic voltammetry. Voltammograms are shown in Fig. 2 and voltammetric data are given in Table 1. Both complexes show metal oxidation and ligand reductions. The ruthenium(II)–ruthenium(III) oxidation in $[Ru(bpy)_2(Q)]^+$ [eq. (3)] takes place reversibly at a formal potential (E^0_{298}) of 0.48 V vs SCE. The value of i_{pa}/i_{pc} (i_{pa} = anodic peak current; i_{pc} = cathodic peak current) for this couple is 1, as expected for a reversible couple. The one-electron stoichiometry of this ruthenium(II)–ruthenium(III) couple has been confirmed by constant potential coulometry. In RuQ_3 the same couple appears at −0.70 V vs SCE.[6] Therefore, the use of bpy as a co-ligand indeed stabilized the bivalent state of the metal to an appreciable extent.

$$[Ru^{II}(bpy)_2(Q)]^+ \rightleftharpoons [Ru^{III}(bpy)_2(Q)]^{2+} + e^- \quad (3)$$

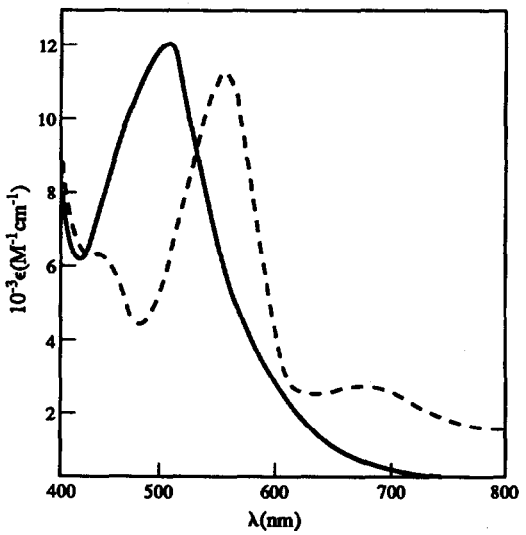

Fig. 1. Electronic spectra of $[Ru(bpy)_2(Q)]ClO_4$ (——) and $[Ru(tap)_2(Q)]ClO_4$ (– – –) in acetonitrile.

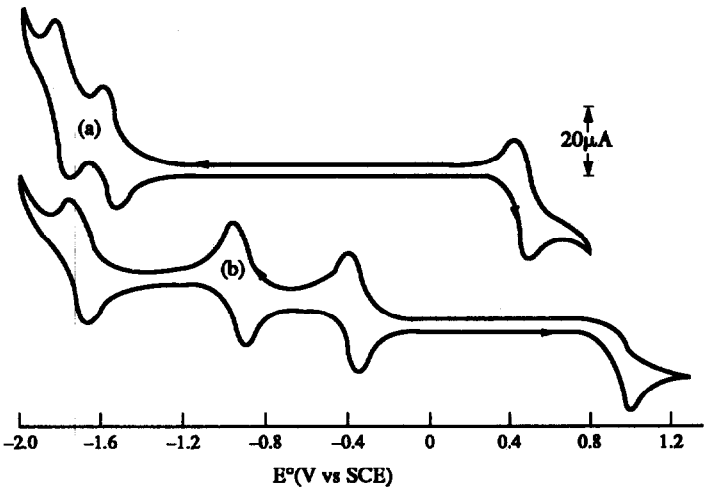

Fig. 2. Cyclic voltammograms of (a) $[Ru(bpy)_2(Q)]ClO_4$ and (b) $[Ru(tap)_2(Q)]ClO_4$ in acetonitrile (0.1 M TEAP) at a scan rate of 50 mV s^{-1}. The solute concentration in each case was *ca* 10^{-3} M.

In $[Ru(tap)_2(Q)]^+$ the ruthenium(II)–ruthenium(III) oxidation is irreversible [eq. (4)]. The anodic peak potential (E_{pa}) is 1.00 V vs SCE. The cathodic response corresponding to the reduction of $[Ru^{III}(tap)_2(Q)]^{2+}$, formed during the anodic scan, has not been observed, presumably due to the fast decomposition of $[Ru^{III}(tap)_2(Q)]^{2+}$. The one-electron nature of this oxidation is established from current height considerations. The tap ligand is found to be a better stabilizer of ruthenium(II), which is due to its better π-accepting ability as observed before.[17,18]

$$[Ru^{II}(tap)_2(Q)]^+ \longrightarrow [Ru^{III}(tap)_2(Q)]^{2+} + e^- \quad (4)$$

On the negative side of SCE $[Ru(bpy)_2(Q)]^+$ displays two successive reversible one-electron reductions at -1.55 and -1.77 V vs SCE, which are assgined to the reductions of the two bpy ligands as shown in eqs (5) and (6). The i_{pa}/i_{pc} values for these two couples are very close to 1, indicating their reversible nature. It is well documented[19,20] that bpy is a potential carrier of electron-transfer, each bpy successively accepting two electrons in one electrochemically accessible lowest unoccupied molecular orbital.

$$[Ru^{II}(bpy)_2(Q)]^+ + e^- \rightleftharpoons [Ru^{II}(bpy)(bp\dot{y})(Q)] \quad (5)$$

$$[Ru^{II}(bpy)(bp\dot{y})(Q)] + e^- \rightleftharpoons [Ru^{II}(bp\dot{y})_2(Q)]^- \quad (6)$$

Hence, in $[Ru(bpy)_2(Q)]^+$ four successive reductions are expected. Out of the expected four only two reductions have been experimentally observed. The remaining two reductions are not observed due to solvent cut-off. The formal potential of the first reduction of bpy in $[Ru(bpy)_2(Q)]^+$ [eq. (5)] is more positive than that of free bpy (-2.17 V)[20] due to the coordination of bpy to bivalent ruthenium. The two reduction potentials in the present complex compare well with those observed for $[Ru(bpy)_2(T)]^+$ (T = triazene-1-oxidato anion).[18]

The tap complex, $[Ru(tap)_2(Q)]^+$, displays three successive reversible one-electron reductions at -0.37, -0.93 and -1.70 V vs SCE, which are assigned to reductions of the bound tap ligands as shown in eqs (7)–(9).

$$[Ru^{II}(tap)_2(Q)]^+ + e^- \rightleftharpoons [Ru^{II}(tap)(t\dot{a}p)(Q)] \quad (7)$$

$$[Ru^{II}(tap)(t\dot{a}p)(Q)] + e^- \rightleftharpoons [Ru^{II}(t\dot{a}p)_2(Q)]^- \quad (8)$$

$$[Ru^{II}(t\dot{a}p)_2(Q)]^- + e^- \rightleftharpoons [Ru^{II}(t\dot{a}p)(t\dot{a}\dot{p})(Q)]^{2-} \quad (9)$$

As expected for reversible couples, the observed i_{pa}/i_{pc} values for these couples are all close to 1. Each tap ligand is known[17] to accept two electrons in its lowest unoccupied molecular orbital, which is largely azo in nature. Thus, four reductions are expected in $[Ru(tap)_2(Q)]^+$, three of which are observed but the fourth is not due to solvent cut-off. The free tap ligand shows[17] two reductions at -1.30 and -1.60 V. Due to coordination to ruthenium(II), the potentials of the first reduction

are shifted towards more positive values in $[Ru(tap)_2(Q)]^+$. The observed reduction potentials are comparable to those in $[Ru(tap)_2(T)]^+$.[17]

Concluding remarks

In combination with bpy and tap, the 8-quinolinolate anion can be bound to ruthenium(II) to form the stable species $[Ru^{II}(bpy)_2(Q)]^+$ and $[Ru^{II}(tap)_2(Q)]^+$. The ruthenium(II)–ruthenium(III) oxidation is observed on the positive side of SCE in these two complexes. The redox stability of the ruthenium(II) state is greater in the tap complex paralleling the π-acceptor order bpy < tap. Reductions of the bound tap and bpy ligands are also observed in these two complexes.

SYNTHESIS AND CHARACTERIZATION OF URANIUM(IV) COMPOUNDS WITH PIPERAZINES

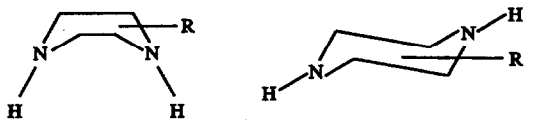
B. S. MANHAS*, S. PAL and A. K. TRIKHA

Department of Chemistry, Punjabi University, Patiala 147002, India

(*Received* 18 *March* 1992; *accepted* 10 *September* 1992)

Abstract—Compounds of the empirical formula $[UX_4 \cdot n(L) \cdot m\text{THF}]$ (where X = thiocyanate, perchlorate, bromide and iodide; n = 1–3; L = piperazine, 1-methyl-, 2-methyl-, 1-phenyl-, 1,4-dimethyl-, 2,5-dimethyl- and 2,6-dimethylpiperazine; m = 0 and 1) have been prepared and characterized by physical studies. IR spectra indicate the mode of coordination. Electronic spectral and variable-temperature magnetic data have been employed to ascertain the stereochemical environment of uranium. Except for the perchlorate compounds, which are 1 : 1 electrolytes, all other compounds are non-electrolytes.

Piperazines which exist in the chair conformation in their free state can form complexes in which they are either in (a) the boat form or (b) in the chair form, giving chelated and non-chelated polymeric complexes, respectively. Due to our interest in such



R=CH_3, C_6H_5

systems we report the complexes of uranium(IV) thiocyanate, perchlorate, bromide and iodide with piperazine (L_1), 1-methylpiperazine (L_2), 2-methylpiperazine (L_3), 1-phenylpiperazine (L_4), 1,4-dimethylpiperazine (L_5), 2,5-dimethylpiperazine (L_6) and 2,6-dimethylpiperazine (L_7) in this paper.

RESULTS AND DISCUSSION

Synthesis

The complexes were prepared by direct interaction of uranium(IV) salts with piperazines.[1] Complexes of various shades of green colour and of the formula $[UX_4 \cdot n(L) \cdot m\text{THF}]$ (where X = NCS, ClO_4, Br and I; n = 1–3; L = various piperazines; m = 0 and 1) were obtained by mixing solutions of piperazines in THF with the THF solutions of uranium(IV) salts, prepared *in situ* from UCl_4 according to reaction (1):

$$UCl_4 + 4MX \longrightarrow UX_4 + 4MCl \qquad (1)$$

X = Br, I and NCS for M = K and X = ClO_4 for M = Ag.

The products were filtered and dried under anhydrous conditions. The complexes of 1-phenylpiperazine, however, separated as dark green oils from which green solids were obtained after successive treatments with diethyl ether and THF.

All the complexes are stable at room temperature only in vacuum-sealed ampoules. They do not melt even when heated at 300°C, but decompose in the temperature range 51–182°. Some of the complexes are soluble in common organic solvents like ethanol, methanol, nitrobenzene, nitromethane, methyl cyanide, etc., but the solubility is too low to determine the molecular weights. Some relevant data are given in Table 1.

IR spectral studies (4000–250 cm^{-1}).

The NH stretch which appears at *ca* 3400 cm^{-1} for free piperazines is observed as a broad band in the region 3400–3150 cm^{-1} for the present complexes. This downward shift[2,3] is indicative of coordination of the NH nitrogen atom and is supported by the shift in the δ(NH) frequency, which

[a] Required values are given in parentheses.
[b] Slopes of plots $1/\chi_M$ vs T.
[c] Obtained by extrapolating the plots mentioned in b to $1/\chi_M = 0$.

appears at *ca* 1650 cm^{-1} for free piperazines and in the range 1625–1620 cm^{-1} for the complexes.[2] The broadness of the band due to ν(NH) may be caused by hydrogen bonding.[4] The CH stretches of NCH_3 which appear at 2750 and 2810 cm^{-1} in the IR spectra of 1-methyl- and 1,4-dimethylpiperazine are not observed in the IR spectra of the complexes. They presumably shift to higher frequencies and become mixed with the other CH bands occurring around 2900 cm^{-1}, on coordination of the NCH_3 nitrogen atom.[5]

The IR spectrum[6] of the 1,4-dimethylpiperazine complex of $PdCl_2$, in which piperazine has been shown to exist in the boat form by X-ray diffraction studies,[7] exhibits a large number of new bands of low and medium intensity in addition to changes in the bands characteristic of the free ligand. Except for the additional bands due to the metal–ligand and anions, the IR spectra of the present complexes are quite simple and no new bands of low and medium intensity assignable to the boat conformation[6] appear, thus showing that the piperazines retain their chair conformation in the complexes. The complexes are thus non-chelated polymers.

The COC frequency which appears at 1076 cm^{-1} in free THF[4] could not be identified in the complexes studied due to a strong ligand absorption at *ca* 1080 cm^{-1}. Therefore, IR studies do not say anything about the coordination of THF. However, TGA studies on the complex $[U(ClO_4)_4 \cdot (L_1) \cdot THF]$ indicate a weight loss at 132°C corresponding to one THF molecule, thus showing the presence of coordinated THF.

In the IR spectra of the thiocyanate complexes studied two prominent bands, one at *ca* 2050 cm^{-1} and the other at *ca* 2300 cm^{-1}, assignable to the CN stretch, are observed. This indicates that two types of thiocyanate groups, N-bonded and bridging, are present in the complexes.[8,9] In the perchlorate compounds with ligands L_1, L_2, L_3 and L_6, all the three known types of perchlorate are shown to be present since the broad band (ν_3) at *ca* 1110 cm^{-1}, due to ionic (T_d) perchlorate, a doublet at *ca* 1020 and 1135 cm^{-1} and a triplet at *ca* 1035, 1160 and 1270 cm^{-1} assignable to uni-(C_{3v}) and bidentate (C_{2v}) perchlorates, respectively, are observed.[8,10,11] The complexes with L_5 and L_7 contain unidentate and ionic perchlorates, while that with L_4 contains bidentate and ionic perchlorates only.

In the far-IR spectra of these complexes bands at *ca* 460 and 380 cm^{-1} (refs 3 and 4) have tentatively been assigned to the UO and UN stretches. The ligands exhibit two bands at 520 and 480 cm^{-1} assignable to rocking modes.

All of these compounds are genuine uranium(IV) complexes since all were green in colour and no bands assignable to the uranyl stretch were observed.

The molar conductance values in $\Omega^{-1}\,cm^2\,mol^{-1}$ of the millimolar solutions of the complexes of uranium(IV) bromide, thiocyanate and iodide determined in methanol, ethanol, dimethylsulphoxide and dimethylformamide range from 7.51 to 8.31, 2.14 to 3.87, 2.32 to 4.33 and 2.17 to 4.65. These complexes are thus considered to be non-ionic in nature.[12] The perchlorate complexes behave as 1 : 1 electrolytes since the values in methanol, dimethylsulphoxide and dimethylformamide lie in the ranges 59.77–76.65, 24.51–27.31 and 21.26–27.40.

Electronic reflectance spectra (200–2000 nm) *and magnetic susceptibility measurements*

The electronic reflectance spectra of the present complexes can be placed into three classes on the basis of intensity:[13] weak, strong and medium. The uranium atom may be present in a six-coordinate centrosymmetrical environment (compounds with Sr. No. 1, 3, 8, 10, 15, 17, 22 and 24),[13,14] eight-coordinate cubic environment without a centre of symmetry (compounds with Sr. No. 2, 4–7, 16, 18, 20, 21, 23, 25–28)[15] or an environment where eight-coordinate cubic or six-coordinate octahedral symmetry is destroyed by the presence of non-equivalent ligands (compounds with Sr. No. 9, 11–13).[13] This inference is based both on the nature of the spectrum and the positions of various bands. The band positions (Table 1) of the medium intensity spectra can be correlated more closely with those of the strong rather than the weak intensity type.

In the case of compounds indicated to be eight-coordinate by electronic reflectance spectra, the plot of $1/\chi_M$ (Fig. 1), corrected by least-squares, against temperature was linear and susceptibility varied according to the Curie–Weiss law, $1/\chi_M = S(T-\theta)$, over the temperature range 77–296 K. The susceptibility is, therefore, defined by the parameters S and θ (Table 1). The temperature dependence of the observed paramagnetic susceptibility and the room-temperature effective magnetic moment are both suggestive of the ligand field of a cube for these uranium(IV) compounds.[15–17] However, the small variation in magnetic susceptibility in the complexes where coordination geometry other than the cube (Fig. 1) is indicated by electronic spectra, may be due to a small distortion in the octahedral symmetry. A smaller magnitude of magnetic susceptibility at room temperature for these complexes is in close analogy with an earlier report.[18]

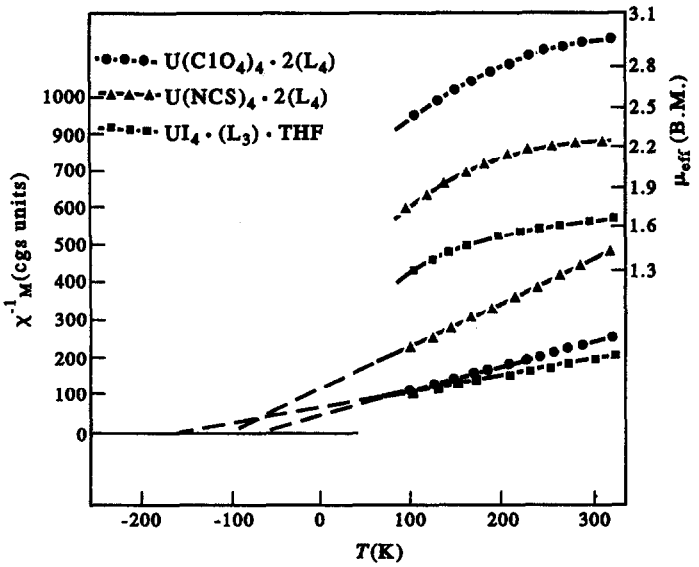

Fig. 1. Variation of molar magnetic susceptibility and effective Bohr magneton numbers with temperature of some representative compounds.

EXPERIMENTAL

The experimental manipulations were performed using Schlenk techniques. The solvents, piperazines and other starting materials were obtained and dried as described earlier.[1,19,20]

Preparation of the complexes

A three-fold excess of the ice-cooled ligand dissolved in THF (10 cm^3) was added to uranium(IV) bromide, iodide, thiocyanate and perchlorate (1.24–1.96 g, 2.63 mmol), prepared *in situ* in the same solvent as described below. The green complex which precipitated immediately was separated by addition of excess dry diethyl ether (*ca* 50 cm^3). The complex was then filtered in a G_4 filtration unit under anhydrous conditions, washed five to six times with ether and finally dried *in vacuo*. A continuous flow of purified nitrogen was maintained throughout the solution during this preparation.

The solutions of uranium(IV) salts employed in this study were obtained as follows:[1] To a solution of UCl_4 (1.00 g, 2.63 mmol) in THF (50 cm^3) were added solid KBr (1.25 g), KI (1.75 g), KNCS (1.02 g) and $AgClO_4$ (2.18 g) in a mole ratio of 1:4. In the preparation of the perchlorate, AgCl separated immediately on mixing. The mixtures for the preparation of the bromide, iodide and thiocyanate had to be stirred for 12 h to allow complete separation of the potassium salts. The green filtrate obtained after filtering out the precipitated salts was used for the preparation of the complexes.

Physical and analytical studies

IR[1,18] and electronic[1] spectra, magnetic[1] and molar conductance[19] measurements, and TGA[1,18] and elemental analysis[1] were performed as described earlier.

(*Received* 13 *July* 1992; *accepted* 3 *August* 1992)

Abstract—The X-ray photoelectron spectra of dicaesium hexachlororhodate(IV), tricaesium hexachlororhodate(III), a hydrated rhodium(III) oxide, and the barium salt of Claus' blue—previously formulated as a rhodate(VI)—suggest that the latter has rhodium(III) ions in an oxygen environment. ESR and Raman spectra of this blue solid confirm that the superoxide moiety is present. Prior work on higher oxidation states of rhodium in various environments is critically re-assessed. The compounds $Cs_2[MCl_6]$ (M = Rh, Pt and Ir) are isomorphous by X-ray powder diffraction.

Blue or violet aqueous solutions of rhodium species[2] can be made in two principal ways. First is the oxidation of rhodium(III) using various oxidants; many have been used, including peroxodisulphate, bismuthate, dichlorine or dibromine (or the equivalent hypochlorite or hypobromite) and inert anodes. The products have been variously formulated as containing rhodium(IV), (V) or (VI) and are often the bases of analyses for rhodium. One such blue solution[3] results from the action of dichlorine on an alkaline solution of rhodium(III) chloride. This solution is called "Claus' blue" and has been formulated as containing $[RhO_4]^{2-}$ ions; an anion precipitates with barium hydroxide. The second way is to oxidize complex compounds of rhodium—containing such nitrogenous ligands as pyridine, bipyridyl or 1,2-diamino-ethane—using a preformed source of the dioxygen link, such as peroxide, ozone or dioxygen. The products here are superoxides of rhodium(III).

All these blue and violet products, however made, in fact have very similar visible and ESR spectra, strongly suggesting[3] that they all contain the superoxide moiety.

There are a few oxidized inorganic complex compounds of rhodium where the electron deficiency is undoubtedly at the rhodium, rather than on ligands. $Cs_2[RhCl_6]$ is the simplest and best known[4] generated in an aqueous medium. We report here our results on the X-ray photoelectron spectra (XPS)

of this green compound, its pink rhodium(III) analogue, $Cs_3[RhCl_6]$, an oxide of rhodium(III) and Claus' blue, as its barium salt. The results, coupled with ESR and Raman measurements, support the formulation of Claus' blue as a bridged μ-superoxo-dirhodium(III,III) species.

It is clear from the quite extensive prior work[5] concerning the influence of the oxidation state of rhodium (in pure well-defined compounds) on its photoelectron binding energies that the higher the oxidation state, the higher the binding energy.

It must be strongly emphasized that comparisons of binding energies from distinct studies may *not* yield satisfactory agreement. The binding energy range for the commonly utilized $Rh(3d)_{5/2}$ level is[5,6] from 307 eV for rhodium(0) in rhodium metal to 310.6 eV for the very stable $K_3[Rh(CN)_6]$. The range would be rather larger if the value for "$K_3[Rh(NO_3)_6]$" (sic) was included, but that substance is of very doubtful provenance and character. Similarly, one study[5b] of the $Rh(3d)_{5/2}$ binding energy in various compounds containing di-, tri- and tetravalent rhodium reported absolute values that were appreciably higher than our own, although this may be in part due to the unusually high value (291.3 eV) used there for the reference C(1*s*) peak. Furthermore, reported binding energies for Rh_2O_3 vary widely; as discussed later, this may be because of different degrees of hydration of the oxide studied. Ultimately, caution must be exercised when comparing absolute XPS electron binding energies that derive from different laboratories.

EXPERIMENTAL

Tricaesium hexachlororhodate(III)

This pink compound was precipitated from an ice-cold solution of sodium hexachlororhodate(III) using caesium chloride. Sodium hexachlororhodate(III) was producted by vigorously boiling stoichiometric amounts of rhodium trichloride and sodium chloride in *ca* 6 M HCl, using the absorption spectrum (λ_{max} = 518, 412 nm) to follow the course of the reaction.

Dicaesium hexachlororhodate(IV)

The preparation, based on that of Dwyer *et al.*,[4a] oxidized dry, solid samples of $Cs_3[RhCl_6]$ with a 10-fold excess of 1 M $(NH_4)_2[Ce(NO_3)_6]$ solution. The green product was washed thoroughly with acetone. Samples were stored over P_2O_5 at atmospheric pressure.

Photoelectron spectra for this compound were measured on a sample which had been kept dry for about 1 month after its synthesis. Specimens of this compound were prepared for examination under nitrogen in a chamber attached to the spectrometer. Samples were inserted into the nitrogen-flushed spectrometer immediately after preparation, so that dry, inert conditions were maintained throughout. One specimen was examined at ambient temperature, another was cooled to -25°C before being subjected to X-ray irradiation. In the latter case, several Rh(3*d*) spectra were determined, each one contemporaneous with a C(1*s*) spectrum, i.e. scan 1 of the Rh(3*d*) spectrum, then scan 1 of the C(1*s*) spectrum, then scan 2 of the Rh(3*d*) spectrum, and so on. The initial Rh(3*d*) and C(1*s*) spectra were determined in the minimum time for an acceptable S/N ratio (about 35 min total, with the X-ray source separated at 10 kV, 10 mA).

Rhodium(III) *oxide hydrate*

NaOH (0.5 M) was added to a solution of rhodium trichloride forming a flocculent yellow precipitate. The solid was collected by filtration, washed with water (to remove chloride ions) and then dissolved in dilute perchloric acid. This scheme was then repeated twice.

Barium salt of Claus' blue

This was prepared[3] by passing dichlorine into the yellow solution from rhodium(III) trichloride and potassium hydroxide until a deep purple solution was produced (λ_{max} = 520 nm). The solid was formed on the addition of an excess of barium hydroxide. The dark blue precipitate was collected under nitrogen to prevent contamination by barium carbonate.

Dicaesium hexachloroplatinate(IV)

To a solution of chlorinated dihydrogen hexachloroplatinate(IV) (λ_{max} = 262, 202 nm) was added caesium chloride solution. The pale yellow solid was washed with a little water and dried over P_2O_5.

Dicaesium hexachloroiridate(IV)

$Na_3[IrCl_6]$ solution was chlorinated until the absorption spectrum showed that all iridium had been oxidized to the tetravalent state (λ_{max} = 488, 434, 410 nm). The deep red caesium salt was isolated by the addition of caesium chloride solution, washing with water and drying over P_2O_5.

Raman spectra were recorded in 1 M HCl solution on a Jeol JRS-S1 laser Raman spectrometer

equipped with rotating sample cells and 488 nm excitation. X-ray powder diffraction patterns were produced using a Debye–Scherrer camera (radius 57.3 mm) and Cu-K_α radiation.

Two distinct sets of XPS measurements were made upon different samples. All were mounted on double-sided adhesive tape and the oxides were also examined when pressed into indium foil. (a) refers to a Kratos XSAM 800 spectrometer using Mg-K_α radiation at 150 W with 80/40 eV pass energies and 7.5 mm slits. As in earlier work,[7] (b) relates to a Vacuum Generator ESCA3 spectrometer, unmonochromatized Mg radiation, 20 eV pass energy and 2 mm slits.

RESULTS

X-ray powder diffraction patterns (Table 1) confirmed close isomorphism between $Cs_2[MCl_6]$ (M = Rh, Pt and Ir), strongly supporting the presence of quadrivalent rhodium in the green compound. Our measured electron binding energies are given in Table 2.

A narrow and symmetrical Rh($3d$)$_{5/2}$ peak centred between 309.2 and 309.6 eV for $Cs_3[RhCl_6]$ is consistent with the trivalent oxidation state. Similarly, the Cl($2p$) and Cs($3d$) spectra are indicative of one major electronic environment for each element.

For $Cs_2[RhCl_6]$, all Rh($3d$) spectra remained essentially the same throughout the period of examination: the doublet peaks, however, were broader than for $Cs_3[RhCl_6]$, probably because of the presence of two components. The Rh($3d$)$_{5/2}$ peak maximum binding energy was situated at 309.9 eV; the shift of all peaks due to charging diminished by only 0.2 eV during 6 h of irradiation. This Rh($3d$)$_{5/2}$ binding energy is up to 0.6 eV greater than the corresponding value for $Cs_3[RhCl_6]$. The Cl($2p$) spectrum appeared to consist of two doublets, one at 197.9 eV (accounting for 75–80% of the intensity) and another shifted *ca* 1.2 eV to a higher binding energy. The Cs($3d$)$_{5/2}$ peak, at 723.6 eV, was significantly broader than for $Cs_3[RhCl_6]$ (*ca* 2.1 eV cf. *ca* 1.7 eV), suggesting the possibility of two caesium environments. The Cl($2p$) and Cs($3d$) spectra for the specimen cooled to −25°C were essentially identical to the corresponding spectra from the specimen examined at ambient temperature. Thus, the existence of more than one environment for the chlorine and caesium atoms was not an artefact of the cooling. Assuming that there should be only one distinguishable electronic environment for caesium, rhodium and chlorine atoms in $Cs_2[RhCl_6]$—and the elemental analyses of the compound confirm this stoichiometry—it appears that we have a mix-

[d] After several hours irradiation, the Rh(3*d*)$_{5/2}$ spectrum displayed a component shifted to 308.1 eV. This was not due to differential charging effects, since no similar asymmetry of the Cs(3*d*) peak was seen. This component may be rhodium(I) produced by photoreduction.
[e] Cl(2*p*) indicated two environments, as discussed in the text.
[f] This contamination is from NaOH in the preparative method.
[g] Carbonate C(1*s*) peak at 289.2 eV.

ture of trivalent and quadrivalent ions. The two environments observed for chlorine might imply ready decomposition of $Cs_2[RhCl_6]$ and we have certainly seen strong EPR signals from (Cl_2^-) in aged samples. This signifies the *instability* of rhodium(IV) compared to that of rhodium(III).

The barium salt of Claus' blue had a binding energy for rhodium virtually identical to that in rhodium(III) oxide; no change in the Rh(3d) spectrum was observed during the extended period of study. Line widths for our rhodium oxide pressed into indium foil were identical with those measured for the double-sided tape.

DISCUSSION

Werner's original bridged superoxo-dimetal complex ions contained not rhodium but its eutrope cobalt. The question of the formulation of the ion in salts like those of $[(en)_2Co(\mu\text{-}NH_2, \mu\text{-}O_2)Co(en)_2]^{4+}$ (with one unpaired electron) as containing either Co^{III}—$(O_2)^{2-}$—Co^{IV} or Co^{III}—$(O_2)^-$—Co^{III} was initially resolved[8] by Weil and his associates, who showed that the *g*-factor in the ESR spectrum was close to 2.02 (typical of superoxide) and that the signal was split into 15 lines from the equal input of the two ^{59}Co ions ($I = 7/2$). Further, an elegant experiment[8b] using ^{17}O in the bridge showed that the unpaired electron was shared by the cobalt ions via the dioxobridge. Unfortunately, in the case of rhodium, the gyromagnetic ratio of the ^{103}Rh nucleus (albeit 100% abundant) is so small as to render nugatory similar measurements of hyperfine structure. Nevertheless, the *g*-value offers a good means of establishing the presence of superoxide ligands, and such values have been tabulated.[1]

The X-ray photoelectron spectrum offers a better means of commenting on the complementary question of the *oxidation states* of rhodium. Our measured energies are collected in Table 2. These are corrected for the effects of charging using the C(1*s*) signal of adventitious carbon. Table 3 assembles some values for the rhodium levels ($3d_{5/2}$) from compounds with varying oxidation states. This includes values for rhodium with chloride ligands in several environments. One should note that $(NH_4)_3[Rh(S_5)_3] \cdot 2H_2O$ is without doubt a compound of rhodium(III) and the Rh(3*d*)$_{5/2}$ binding energy is discussed in ref. 7 as being at the low end of the range for rhodium(III). Table 4 collects values for rhodium in oxygen environments, including the few available for blue compounds.

The higher oxidation state, rhodium(IV), in $Cs_2[RhCl_6]$ gives a mean binding energy for Rh(3*d*)$_{5/2}$ of 309.9 eV against 309.4 eV for rhodium(III) in $Cs_3[RhCl_6]$. We would expect

at least as large a shift (if not far greater) in an oxygen ligand environment from rhodium(III) in the six-coordinated oxide lattice of Rh_2O_3 hydrate to rhodium(VI) in $Ba[RhO_4]$ if Claus' blue really did involve the $[RhO_4]^{2-}$ ion. In fact, the binding energies are 309.3 and 309.2 eV, respectively, which strongly supports a formulation of Claus' blue as containing rhodium(III) ions. "$Ba[RhO_4]$" might possibly react rapidly on exposure to air to produce a surface layer of a rhodium(III) oxide species. We think such a reaction unlikely because there was no evidence of carbonate in the C(1*s*) spectrum. The formation of carbonate usually accompanies such surface changes in air under ambient conditions. By contrast, a peak near 289.2 eV due to carbonate was evident in the C(1*s*) spectra of the rhodium oxide samples studied. The presence of a superoxide bridging two rhodium ions is indicated by the *g*-value ($g_{iso} = 2.044$)[1,3] and Raman spectrum (strong, broad absorption centred at 1088 cm^{-1}).

The barium salt of Claus' blue has been analysed several times by gravimetry and other classical bulk microanalytical methods leading to a Ba : Rh ratio of 1 : 1. The present observation on relative intensities of the signals for $Ba(3d)_{5/2}$ at 779.4 eV and $Rh(3d)_{5/2}$ of Rh at 309.2 eV confirms this stoi-

[c] This value may be high, since it is quoted without the binding energy of the standard and with no experimental detail.

chiometry; this ratio has been taken as consistent with the original formulation $Ba[RhO_4]$—it is, of course, equally consistent with $Ba_2\{[(H_2O)_4Rh]_2(\mu\text{-}O_2)(\mu\text{-}OH)\}$. Similar blue or violet paramagnetic species containing the $[Rh^{III}—(\mu\text{-}O_2)—Rh^{III}]^{5+}$ moiety, or more commonly the $[Rh^{III}—(\mu\text{-}O_2),(\mu\text{-}OH)—Rh^{III}]^{4+}$ fragment, with various ligands are known; crystallographic studies of compounds containing these moieties and their peroxo derivatives support the conclusion that the ESR signal derives from the superoxide bridge.[9]

This simple, elemental, microanalytical ratio is well founded. Otherwise, the analytical determination of properties helping to formulate such oxidized compounds of rhodium is complicated by three major factors. First, in titrations using reductants, there are catalytic effects (due to the very nature of rhodium) which may lead to irrelevant apparent stoichiometries. Secondly, elemental analyses rarely distinguish between compositions involving, say $(Rh^{IV}—OH)^{3+}$ or $(Rh^{III}—OH_2)^{3+}$, or between $Rh^{IV}—(O_2)^{2-}$ and $Rh^{III}—(O_2)^{-}$. Finally, the non-superoxo ligands on rhodium(III) are a combination of halide- and aquo-derived; for example, the solution of Claus' blue is a mixture of many different aquo, hydroxo, chloro, dimeric superoxo species (and possibly monomeric and peroxo species depending on the extent of chlorination). These problems with chemical analyses render spectroscopic studies particularly valuable.

The synthesis of Claus' blue *in the absence of oxygen* by passing dichlorine gas through an alkaline solution of rhodium(III) represents the unusual formation of an O—O link in the aqueous medium. We suspect that the O—O link comes from the dichlorine oxidation of hydroxide ions (which may be coordinated to rhodium in dimeric precursors) to form quantities of hydrogen peroxide (which, as its conjugate anion, may be coordinated). The peroxo-rhodium precursor may subsequently be involved in further dimerization and oxidation processes; problems arise in assigning[3] intermediates due to complicated spectroscopic signals observed in the course of the preparation.

We have used rhodium(III) oxide (precipitated from basic aqueous medium) here only as a reference. However, we should comment on some of the quite extensive prior work on the nature of rhodium centres in oxide matrices, since most of these substances were made in similar ways to our own. Most work was done in the context of heterogeneous catalysis and surface science, and has used, in general, either X-ray photoelectron spectra or ESR spectra as a means of commenting on the nature of the rhodium centres present, before and after modification.

There is a fair range of values for the $(3d)_{5/2}$ binding energies in samples described as $Rh_2O_3\cdot nH_2O$, of which ours (mean = 309.4 eV) could be regarded as typical. (Rhodium oxide is not a simple entity, and it is not always clear what form has been studied.) The parent oxide is, of course, diamagnetic, but there are several studies which have generated paramagnetic centres, variously described as rhodium(II) or rhodium(IV). The nature of such centres in isolated compounds is, of course, very much the nub of the present paper.

RhO_2 exists.[10a] It is $Rh^{IV}—(O^{2-})_2$ with the rutile structure and metallic conductance. It is not easy to make; very high pressures and temperatures are needed, even in the presence of such powerful oxidants as 7 M nitric or 2.7 M chloric acids. Similarly, Van Arkel[10b] and his colleagues made $Li_2[RhO_3]$ only by oxidizing rhodium sponge in lithium carbonate using O_2 at 600–1000°C for 20 h. It was isomorphous with $Li_2[TiO_3]$ and presumably contained rhodium(IV) ions.

Alternatively, various rather ill-defined dark solids have been made during the past century by relatively mild aqueous methods and classified as oxides of rhodium in higher oxidation states. This seems inconsistent, and our view is that they are probably all rhodium(III) superoxides and (perhaps) peroxides. They include $RhO_2\cdot xH_2O$, produced[11a] by electrochemical oxidation or by chlorination (cf. Claus' blue) of rhodium(III) in water. Likewise, Kalinina and Lyakushina[11b] precipitated "$RhO_2\cdot 2H_2O$" from dilute rhodium chloride by heating with hypobromite. This dissolved in dilute perchloric acid to give a dark red solution said to be of rhodium(IV) perchlorate. In bulk, it loses dioxygen at 800–900°C, forming Rh_2O_3.

In a sample of $RhO\cdot OH$ (with the orthorhombic InOOH structure) heated in air at 300°C, new EPR signals at $g_1 = 2.25$, $g_2 = 2.08$ and $g_3 = 1.94$ were attributed to rhodium(IV) centres. In rhodium on alumina exposed to dioxygen at 500°C, Yao and Shelef located an EPR signal at $g = 2.14$, which they likewise assigned[12] to rhodium(IV) centres. Consequently, the origin of other signals near this region in similar oxide systems comes into question. These included[13] the spectrum for rhodium on silica exposed to dioxygen at 200°C, with $g_1 = 2.092$, $g_2 = 2.031$ and $g_3 = 1.963$.

In much the same way, Goldfarb and Kevan exchanged[14] $[Rh(NH_3)_5Cl]Cl_2$ from its aqueous solution into the zeolite Linde-13X (NaX) at room temperature, exposed this to dioxygen at temperatures from 240°C upward and observed an ESR signal at $g = 2.06$. They assigned this to a paramagnetic rhodium ion whereas we consider it to arise from a superoxo-rhodium(III) species. This

may well be an amine-superoxide (rather than an oxide-superoxide) since the chloro-pentammine-rhodium(III) ion is quite thermally stable: not all the ammonia ligands would dissociate at 240°C unless there is a specific local destabilizing effect in the zeolite. Further, monomeric $[Rh—O_2]^{2+}$ and dimeric $[Rh—O_2—Rh]^{5+}$ units are well known[2] in solid amine and substituted amine compounds, such as the salts of $\{[Rh(en)_2Cl]_2(\mu\text{-}O_2)\}^{3+}$ (en = 1,2-diamino-ethane).

The factors which control the detailed nature of the products from the oxidation of platinum group element compounds are still unclear. However, Griffith[15a] and Holm[15b] have summarized the range of oxocomplexes of the transition elements and pointed out that all formations of terminal M—O bonds (formally double or triple) depend largely on the interaction of a filled $2p_\pi$ donor pair on oxygen with empty Lewis acceptor orbitals on M^{n+}. These orbitals are empty only for d^n configurations where $n \leqslant 4$ (cf. $n = 0$ for RuO_4 and $n = 2$ for $[RuO_4]^{2-}$); rhodates do not fulfil this criterion. Since many compounds of the iso-electronic ruthenium(IV) ($4d^4$) and (V) ($4d^3$) have been made, oxocompounds of rhodium in oxidation states higher than (III) may occur. There are as yet very few well-defined examples.

AN UNUSUAL LABILITY OF 2,2′-BIPYRIDYL CHELATED TO PLATINUM(II)[1]

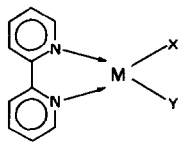
JUSTINE COLLINS, R. D. GILLARD* and MICHAEL B. HURSTHOUSE

School of Chemistry and Applied Chemistry, University of Wales College of Cardiff, P.O. Box 912, Cardiff CF1 3TB, U.K.

(*Received* 31 *July* 1992; *accepted* 18 *August* 1992)

Abstract—The pentakaidekasulphidoplatinate(IV) ion, $[Pt(S_5)_3]^{2-}$, is a product when dichloro-2,2′-bipyridyl-platinum(II) reacts with yellow ammonium sulphide. Pentasulphido-2,2′-bipyridylplatinum(II) has also been made.

The well-known chelated 1 : 1 derivatives (**I**) of the N-heterocyclic ligands 2,2′-bipyridyl and 1,10-phenanthroline with platinum(II) and (in some cases) palladium(II) have again attracted a great deal of interest recently. Wimmer *et al.* have recently extended our knowledge[2] of the systems based on **I** (M = Pt; X = OH; Y = OH_2; overall charges are omitted for simplicity; the chelating ligand is shown as bipyridyl, although several examples discussed here actually relate to 1,10-phenanthroline). The bis-aquo-bipyridylplatinum(II) cation (**I**, X = Y = H_2O) has been used as a bifunctional carrier for spin labels[3] and platinum has been bonded to polymers through the functionalized bipyridyl, to give[4] a hydrogenation catalyst.



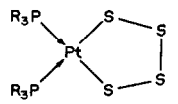
(I)

Many compounds (**I**) have been made, and their stabilities (both thermodynamic and against nucleophilic substitution) repeatedly described. Typically, for **I**, X = Y = ½en, the 2,2′-bipyridyl is inert[5a] (for weeks) to substitution by 1,2-diaminoethane. Similarly, the same compound was found[5b] by Watt and Upchurch to react with potassium in liquid ammonia, but only to deprotonate the NH_2 units of the 1,2-diaminoethane.

In 0.1 M potassium methylsulphonate, log K_{110} for **I** (M = Pt and Pd) are[6] 19.8 and 20.7, respectively. Some descriptions imply[7] that the stability of the 1 : 1 moiety is unusual, $[Pd(phen)]^{2+}_{aq}$ being described as "a new aromatic system".

We describe here a surprising displacement of 2,2′-bipyridyl from a 1 : 1 system with platinum.

The compound $[Pt(PR_3)_2(S_4)]$ (**II**) is made[8] from **III** by reaction (1).

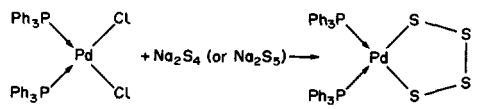


(II)

$$(NH_4)_2[Pt(S_5)_3] + 12PR_3 \longrightarrow [Pt(PR_3)_2(S_4)] + (NH_4)_2S + 10SPR_3 \quad (1)$$

(III) **(II)**

It is well characterized.[9] A similar palladium(II) compound (**IV**) exists, made[10] by the distinct route shown in eq. (2).



(2)

(IV)

We attempted to make the N-heterocyclic chelated (bipyridyl) analogue of the eutrope of **IV** by a related route, combining **I** (M = Pt; X = Y = Cl) with oligosulphide (S_n^{2-}; $4 \leqslant n \leqslant 6$) from aqueous yellow ammonium sulphide. We obtained both the desired product, with $n = 5$, and, in low yield, the unexpected product (**III**) as its ammonium salt

* Author to whom correspondence should be addressed.

$(NH_4)_2[Pt(S_5)_3]\cdot 2H_2O$. The form produced in the present work is a known[11] dimorph. Its formation represents a surprising contrast with the behaviour expected from eq. (1), where **III** is a factor rather than a product.

EXPERIMENTAL

K_2PtCl_4 (0.50 g) in hot water (300 cm^3) heated for 1 h with 2,2′-bipyridyl (1.95 g) in hydrochloric acid (2 M) gave 0.43 g (91%) of $[Pt(bipy)Cl_2]$. This compound (0.15 g) was treated with ammonium polysulphide (BDH yellow ammonium sulphide, 10 cm^3) and left for several hours until it had become olive green. The mixture was kept at 85°C, passing through yellow–orange to orange–red to dark brown. The brown product, pentasulphido-2,2′-bipyridylplatinum(II), $[Pt(bipy)(S_5)]$ (0.15 g), was removed by filtration and the filtrate kept at room temperature in a closed container.

$(NH_4)_2[Pt(S_5)_3]\cdot 2H_2O$

During 3–4 weeks, the filtrate gave crystals, initially of 2,2′-bipyridyl and finally of the bright red product. These were collected and dried over silica gel *in vacuo*. The bipyridyl dissolved in toluene and was extracted from it into ferrous sulphate in dilute HCl (2 M), giving the characteristic $[Fe(bipy)_3]^{2+}$.

Analyses are in Table 1 and properties in Table 2. IR spectra for $[Pt(bipy)X_2]$ (A, X = Cl; B, X = $\frac{1}{2}S_5$) were essentially similar from 3050 to 700 cm^{-1}, those absorptions arising from 2,2′-bipyridyl. A strong absorption at 355 cm^{-1} in A (arising from its $PtCl_2$ moiety) is very much weaker in B. Similarly, other new weak bands at 650 and 460 cm^{-1} in B may be assigned to S—S modes.

Table 2. Identity of $(NH_4)_2[Pt(S_5)_3]\cdot 2H_2O$ (unit cell sizes; Å)

	Present product	Dimorph A (*Cc*)[11]	Dimorph B (*C2/c*)[11]

β (°)	93.71	92.61	101.44

DISCUSSION

There are a number of possible mechanisms for this extraordinary reaction. It may not merely involve substitution at the d^8-centre. The driving force probably does relate to solution stability rather than displacement of an equilibrium toward an insoluble product. That is, the formation of solvated $[Pt(S_5)_3]^{2-}$ is indeed favoured because its ammonium salt, the product, is actually far more water soluble than the other platinum-containing compounds which could be formed as solids, such as $[Pt(bipy)(S_5)]$ or $[Pt(bipy)Cl_2]$. Nucleophilic attack on [Pt(bipy)XY] is slow,[12] although nucleophilic sulphur does react with $[Pt(bipy)_2]^{2+}$ via[13] a rather stable 1 : 1 adduct (possibly, however, involving a C—S bond rather than a Pt—S bond) as an intermediate. Indeed, some more polarizable nucleophiles, like cyanide, do slowly displace chelated bipyridyl, both from platinum(II) and the isoelectronic gold(III) in $[Au(phen)(Cl_2)]^+$, where the products include[14] $[Au(CN)_2Cl_2]^-$ and 1,10-phenanthroline.

In view of the ease of formation of the thioplatinate(IV) anion $[Pt(S_5)_3]^{2-}$ from platinum(II) chlorides [eq. (3)], or from bis-pentasulphidoplatinate(II) ions [eq. (4)], it may be that oligo-

Table 1. Analysis of products

Compound	Sample	Analysis C Calc.	C Found	H Calc.	H Found	N Calc.	N Found
$[Pt(bipy)Cl_2]$	1	28.4	28.8	1.9	1.9	6.6	6.7
	2	28.4	29.2	1.9	2.0	6.6	6.7
	2	28.4	28.8	1.9	1.9	6.6	6.6
$[Pt(bipy)(S_5)]$	1	23.5	23.2	1.6	1.7	5.5	5.8
	2	23.5	23.6	1.6	1.7	5.5	5.8
	2	23.5	23.8	1.6	1.8	5.5	5.7
$(NH_4)_2[Pt(S_5)_3]\cdot 2H_2O$	1	0	0	1.61	1.6	3.74	3.8
	2	0	0	1.61	1.5	3.74	3.8

sulphide oxidizes the factor or an intermediate.

$$[PtCl_4]^{2-} + 4S_5^{2-} \longrightarrow [Pt(S_5)_3]^{2-} + 4Cl^- + S_2^{2-} + S_3^{2-} \quad (3)$$

$$[Pt(S_5)_2]^{2-} + 2S_5^{2-} \longrightarrow [Pt(S_5)_3]^{2-} + S_2^{2-} + S_3^{2-} \quad (4)$$

The mere oxidation of N-heterocyclic chelates [Pt(bipy)XY] to platinum(IV) species does not of itself labilize the heterocyclic ligand. $[Pt(bipy)(en)]^{2+}$ may be oxidized[15] to $[Pt(bipy)(en)Cl_2]^{2+}$, and this will undergo reactions[16] within the ligands without metal–ligand bond breakage.

In studies[1] aimed at producing $[PtS_x]^{2-}$, with $12 \leqslant x \leqslant 21$ from platinum(IV) precursors, far and away the most common products were salts of the $[Pt(S_5)_3]^{2-}$ ion, and this has again formed here by an utterly distinct route.

The mixed compound is analogous to a number of other species (**I**), [M(NN)(X)(Y)], where M = Pd or Pt, NN = a chelating N-heterocycle bipy or phen, and X+Y = a doubly charged anion chelated through group 16 atoms. Examples include[17] [Pt(phen)(OCH_2CH_2O)] and [Pd(phen)(SCH_2CH_2S)], although there seems to be no other example of [Pt(bipy)(X)(Y)] where XY is bonded through two sulphur atoms.

Finally, we list the few displacements known to us of N-heterocyclic chelates from species **I**: these involve palladium(II) as the central metal ion, and non-aqueous conditions:

(a)[18] $[Pd(bipy)(C_6Cl_5)_2] + dppe \longrightarrow [Pd(dppe)(C_6Cl_5)_2]$

(dppe = 1,2-diphenylphosphinoethane)

(b)[19] $[Pd(NN)Cl_2]$ (in DMF) + en $\longrightarrow$ $[Pd(NN)(en)]^{2+} \longrightarrow [Pd(en)_2]^{2+}$,

the second step, in an excess of 1,2-diaminoethane, being very fast.

(*Received* 30 *September* 1992; *accepted* 22 *October* 1992)

Abstract—Through thermolysis of $[\eta^5\text{-EtO}_2\text{CC}_5\text{H}_4\text{W(CO)}_3]_2$ the title complex **1** has been prepared and characterized by elemental, spectroscopic and X-ray analyses. The X-ray analysis revealed that the $\text{Cp}^*_{\text{centre}}$—W—W′ axis of **1**, on the contrary to the linear configuration of the $\text{Cp}_{\text{centre}}$—Mo—Mo axis in its molybdenum analogue, is bent with a 20.1° departure from linearity.

Although the VIB metal–metal triply bonded complexes containing mixed cyclopentadienyl carbonyl ligands, such as $(\eta^5\text{-C}_5\text{R}_5)\text{M}_2(\text{CO})_4$ (M = Cr, Mo, W; R = H, Me), have been extensively studied,[1–6] the crystal molecular structure of any tungsten complex of this type has never been determined and the functionally substituted cyclopentadienyl-carbonyl W—W triply bonded derivatives have not been prepared even now. We now report the synthesis, characterization and X-ray structure analysis of the ethoxycarbonyl substituted cyclopentadienyl-carbonyl W—W triply bonded compound, **1**.

A solution of the corresponding W—W singly bonded complex[7] $[\eta^5\text{-EtO}_2\text{CC}_5\text{H}_4\text{W(CO)}_3]_2$ (0.648 g, 0.8 mmol) in diglyme (25 cm^3) was heated at 140°C for 9 h to give 0.137 g of $[\eta^5\text{-EtO}_2\text{CC}_5\text{H}_4\text{W(CO)}_2]_2$ (**1**) in 23% yield after column chromatography. It is an air-stable red–brown solid but quite air-sensitive in solution. The characterizing data‡ are in good agreement with the formulation of **1**. The IR data of 1909 and 1852 cm^{-1} are too low for normal terminal carbonyls and actually are characteristic of linear semi-bridging carbonyls (*vide infra*).

The structure of **1** is presented in Fig. 1,§ which includes some important bond lengths and angles.

As seen from Fig. 1, the molecule consists of

‡ Characterization data: Found: C, 31.8; H, 2.4. Calc. for $C_{20}H_{18}O_8W_2$: C, 31.9; H, 2.4%. IR (KBr disc): ν(C≡O), 1909 s, 1852 s, ν(C=O), 1713 s. ^{1}H NMR ($CDCl_3$): δ 1.33 (t, 6H, J = 7.0 Hz, $2CH_3$), 4.30 (q, 4H, J = 7.0 Hz, $2CH_2$), 5.50 (br. s, 4H, ring's H^3, H^4), 5.89 (br. s, 4H, ring's H^2, H^5). MS (EI): m/z 754 (M^+, 17%).

§ Crystal data for **1**: monoclinic, space group $P2_1/c$, a = 6.847(1), b = 11.644(2), c = 13.541(4) Å, β = 101.02(2)°, V = 1059.7 Å^3, Z = 2, Mr = 754.14, D_x = 2.40 g cm^{-3}, μ = 113 cm^{-1}, $F(000)$ = 700. A total of 1614 independent reflections were collected in the range $2° \leqslant \theta \leqslant 25°$ with Mo-K_α radiation by the ω–2θ scan mode, of which 1213 reflections were considered to be observed with $I \geqslant 3\sigma(I)$ and used in structure solution and refinement. The structure was solved by the Patterson method and refined to R = 0.025 and Rw = 0.029. Final atomic coordinates, thermal parameters and structure factor tables have been deposited with the Editor as supplementary material.

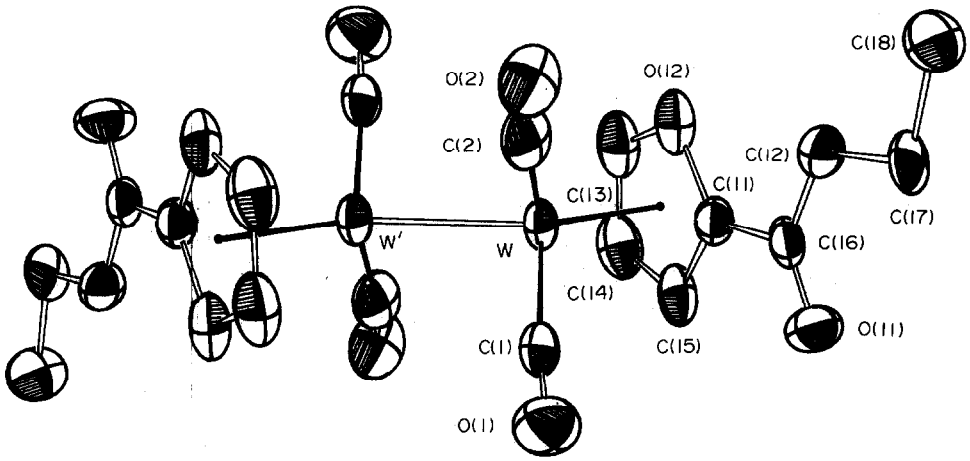

Fig. 1. The molecular structure of $[\eta^5\text{-}EtO_2CC_5H_4W_2(CO)_2]_2$ showing the numbering scheme. Selected bond lengths (Å) and angles (°): W—W′ 2.5064(6), W—C(1) 1.948(8), W—C(2) 1.946(9), W′—W—C(1) 81.9(2), W′—W—C(2) 71.3 (2), W—C(1)—O(1) 174.9(6), W—C(2)—O(2) 172.2(6). Symmetrical transformation: $' = (-x, 1-y, 1-z)$.

two $[\eta^5\text{-}EtO_2CC_5H_4W(CO)_2]$ moieties linked by a W—W bond. The W—W bond length of 2.5064 Å is about 0.72 Å shorter than that of $[\eta^5\text{-}C_5H_5W(CO)_3]_2$,[8] but almost the same as that (2.503 Å) of $L_2W_2(CO)_4$ ($L^- = [(C_5H_5)Co\{P(O)(OC_2H_5)_2\}_3]^-$).[9] On the basis of these facts and the 18-electron rule, a triple bond, W≡W, can be assigned for the bonding between the two tungsten atoms in **1**. As required from its space group, **1** is centrosymmetric and the two cyclopentadienyl rings are parallel to each other. The five non-hydrogen atoms of the functional substituent EtO_2C lie in a plane, which forms a dihedral angle of 6.8° with the cyclopentadienyl ring. So, the substituent ethoxycarbonyl is conjugated quite well with the cyclopentadienyl system. The average W—C—O angle for carbonyl is 173.5° which is close to 180°, and the average W′—W—C angle is 76.6°. Thus, the four carbonyls are bent back over the W—W bond, forming a semi-bridging structure. In this structural unit, the average "short" W—C distance is 1.947 Å and the average "long" W···C distance is 2.802 Å. The linear semi-bridging carbonyls are also observed in its chromium[3,4] and molybdenum[5,6,10] analogues, which donate their lone electron pairs of carbon atoms, as a two electron ligand, to the near metal and concurrently utilize their π^*-orbitals to accept π-electrons from M≡M.[6] The degree of bridge asymmetry, i.e. asymmetry parameter $a = (D_2 - D_1)/D_1$, equals 0.31, which is greater than those of $Cp_2Cr_2(CO)_4$ (0.29) and $Cp_2Mo_2(CO)_4$ (0.20).[4,5]

It is interesting to note that the angle of Cp^*_{centre}—W—W′ is 159.1° ($Cp^* = \eta^5\text{-}EtO_2CC_5H_4$); namely, the configuration of Cp^*_{centre}—W—W′ is bent, as those of Cp_{centre}—Cr—Cr in $Cp_2Cr_2(CO)_4$[4] and Cp''_{centre}—Cr—Cr in $Cp''_2Cr_2(CO)_4$[3] ($Cp'' = \eta^5\text{-}Me_5C_5$), but it is contrary to the linear Cp_{centre}—Mo—Mo in $Cp_2Mo_2(CO)_4$.[5] For the Cp'''_{centre}—M—M configurations in the $Cp'''_2M_2(CO)_4$ (M = Cr, Cp‴ = Cp, η^5-Me_5C_5; M = Mo, Cp‴ = Cp) complex Curtis[5] and Hall[6] proposed two explanations on the basis of electronic and steric factors, respectively. Obviously the bending configuration of Cp^*_{centre}—W—W′ in **1** cannot be explained according to the magnitude of the metal atom since tungsten is larger than molybdenum. In such a case the electronic and steric effects of the functionally substituted EtO_2C must play an important role in deciding the bent configuration of Cp^*_{centre}—W—W′ in **1**. However, further structural studies and the detailed preparative procedures of **1** and other functional substituted complexes of this type will be given in a full paper.

TETRAHEDRAL AND SQUARE-PYRAMIDAL SULPHUR-RICH COMPLEXES OF MANGANESE(II)

SHI-BAO YU and R. H. HOLM*

Department of Chemistry, Harvard University, Cambridge, MA 02138, U.S.A.

(*Received* 24 *July* 1992; *accepted* 22 *October* 1992)

Abstract—The reaction system $MnCl_2/2Na_2S_2/2.2CS_2/Et_4NSH/2Et_4NCl$ in acetonitrile affords $(Et_4N)_3[Mn(CS_4)_2Cl]$ in high yield. Upon prolonged standing, $(Et_4N)_2[Mn(S_6)_2]$ was isolated from the reaction mixture filtrate. The structures of these compounds were determined by X-ray crystallography. $[Mn(CS_4)_2Cl]^{3-}$ exhibits a distorted square pyramidal stereochemistry with chloride in the apical position and two five-membered chelate rings formed by the infrequently encountered perthiocarbonate ligand. Indistinguishable C—S bond distances to coordinated and free sulphur atoms at a common carbon atom indicate ligand delocalization. In $[Mn(S_6)_2]^{2-}$ the manganese atom occurs in an irregular tetrahedral coordination formed by two chelating hexasulphido ligands. This work adds to the small group of sulphur-rich manganese complexes of established structures.

The chemistry of metal complexes of sulphur-rich ligands has implications in both bioinorganic chemistry and catalysis. Although the majority of such complexes, with ligands such as polysulphide (S_x^{2-}) and the rare perthiocarbonate (CS_4^{2-}), have been prepared with molybdenum, tungsten and other second and third row transition elements,[1–3] several manganese species have also been characterized. Three structurally defined per- and polysulphide complexes of manganese are known. The first reported is $[Cp_2Mn_2(CO)_6S_2]$, in which two $CpMn(CO)_3$ units are bridged by persulphide.[4] Subsequently, tetrahedral $[MnS_{11}]^{2-}$, in which manganese(II) is coordinated by the polysulphide ligands S_5^{2-} and S_6^{2-},[5] and the related tetrahedral complex $[Mn(Se)_4]^{2-}$[6–8] have been described, as has octahedral $[L'Mn(S_4)(OH_2)]$[9] (L′ = N, N′,N″-trimethyl-1,4,7-triazacyclononane). Among perthiocarbonate complexes, $[Mn(CS_4)_2]^{2-}$ and $[Mn(CS_4)S_6)]^{2-}$ have been prepared[5] but not structurally characterized. Binuclear centrosymmetric $[Mn_2(CO)_6(CS_4)_2]^{2-}$ has been obtained by an unprecedented phase-transfer-catalysed reaction between $[Mn_2(CO)_9Br]^{1-}$ and sulphur; two $Mn(CO)_3$ units are linked by the perthiocarbonate ions, each acting as a bridging and terminal ligand to complete octahedral coordination.[10] We report here two additions to this small group of sulphur-rich manganese compounds, $(Et_4N)_3[Mn(CS_4)_2Cl]$ and a by-product of its preparation, $(Et_4N)_2[MnS_{12}]$.

EXPERIMENTAL

All operations were performed under a pure dinitrogen atmosphere using standard Schlenk techniques.

$(Et_4N)_3[Mn(CS_4)_2Cl]$ (1)

To a slurry of anhydrous $MnCl_2$ (0.50 g, 4.0 mmol), Na_2S_2 (0.88 g, 8.0 mmol), Et_4NCl (1.40 g, 8.4 mmol) and Et_4NSH (0.65 g, 4.0 mmol) in acetonitrile (100 cm^3), CS_2 (0.52 cm^3, 8.8 mmol) was added dropwise. The initial greenish colour quickly turned to red and a clear solution formed. The solution was stirred overnight, during which time an orange solid separated. This material was collected by filtration and recrystallized by adding ether to a concentrated acetonitrile solution. The product was obtained as 2.65 g (87%) of an orange

* Author to whom correspondence should be addressed.

microcrystalline solid. Absorption spectrum (acetonitrile): λ_{max} nm (ε_M M^{-1} cm^{-1}), 337 (23,300), 416 (11,400). IR spectrum (Nujol): 993 (s) cm^{-1}. Found: C, 40.5; H, 7.5; Cl, 4.7; Mn, 7.2; N, 5.4; S, 33.2. Calc. for $C_{26}H_{60}ClMnN_3S_8$: C, 41.0; H, 7.9; Cl, 4.6; Mn, 7.2; N, 5.5; S, 33.7%.

$(Et_4N)_2[Mn(S_6)_2]$ (**2**)

When the filtrate from the preceding preparation was stored at −20°C for 1 month, orange needle-like crystals developed. These were collected and identified by single-crystal X-ray diffraction.

Block-shaped orange crystals of **1** were grown in a 1:1 (v/v) acetonitrile/ether solution over several days at room temperature. Crystals of **2** were grown in the reaction filtrate. X-ray data collection and processing and structure solution and refinement were performed using the instrumentation and programs described elsewhere.[11] Three standard reflections monitored every 97 reflections exhibited no significant decay over the course of data collection. The asymmetric unit of **1** consists of one-half trianion with manganese and chlorine atoms residing on a two-fold axis, one full cation and one-half cation with its nitrogen atom on a two-fold axis. The asymmetric unit of **2** contains the dianion and two cations. In one of the cations each of the four methylene carbon atoms is disordered over two positions; these were modelled with equal site occupancies. Excluding disordered atoms, all non-hydrogen atoms for **1** and **2** were refined with anisotropic thermal parameters. In the final stages of the refinements hydrogen atoms were introduced on the non-disordered carbon atoms.

Crystallographic data using Mo-K_α ($\lambda = 0.71069$ Å) at $T = 297$ K: **1**, $C_{26}H_{60}ClMnN_3S_8$, $M = 761.7$, monoclinic, $C/2c$, $a = 21.991(7)$, $b = 13.302(3)$, $c = 13.275(2)$ Å, $\beta = 92.15(2)°$, $V = 3881(2)$ Å^3, $Z = 4$, $D_c = 1.30$ g cm^{-3}, $\mu = 8.31$ cm^{-1}, 2θ limits 3–45°, 3024 reflections collected, $R = 4.03$ ($R_w = 6.63$) for 2256 ($I > 3\sigma$) unique observed reflections. **2**, $C_{16}H_{40}MnN_2S_{12}$, $M = 700.2$, monoclinic, $P2_1/c$, $a = 12.747(3)$, $b = 17.725(3)$, $c = 14.501(2)$ Å, $\beta = 96.53(2)°$, $V = 3255(1)$ Å^3, $Z = 4$, $D_c = 1.43$ g cm^{-3}, $\mu = 11.4$ cm^{-1}, 2θ limits 3–48°, 6424 reflections collected, $R = 9.06$ ($R_w = 8.31$) for 2533 ($I > 4\sigma$) unique reflections.

RESULTS AND DISCUSSION

The apparent stoichiometry for the formation of $[Mn(CS_4)_2Cl]^{3-}$, which was isolated in 87% yield as its Et_4N^+ salt, is represented by reaction (1).

$$MnCl_2 + 2S_2^{2-} + 2CS_2 \longrightarrow [Mn(CS_4)_2Cl]^{3-} + Cl^- \quad (1)$$

While Et_4NSH does not appear in this reaction, its presence is required to obtain high yields. We conjecture that nucleophilic attack of HS^- on CS_2 generates CS_3^{2-}, which is stabilized by chelation. Insertion of sulphur from persulphide in the Mn—S bond affords coordinated perthiocarbonate and releases sulphide. In this picture hydrosulphide or sulphide is a catalyst in the formation of the product complex. Perthiocarbonate complexes are generally efficiently prepared by the reaction of CS_2 with species containing MS_4 chelate rings,[5,12] no doubt because nucleophilic and electrophilic sulphur atoms are present in the same structural fragment. Further, it has been demonstrated that the conversion $[Ni(CS_3)_2]^{2-} \rightarrow [Ni(CS_4)_2]^{2-}$ upon reaction of the trithiocarbonate complex with sulphur is nearly quantitative.[13] The means of formation of $[Mn(S_6)_2]^{2-}$ is obscure, but may result from adventitious oxidation of persulphide (despite anaerobic conditions) during prolonged storage of the reaction filtrate. We have not attempted to devise a synthesis of this species.

The structure of $[Mn(CS_4)_2Cl]^{3-}$ is presented in Fig. 1 and bond distances and angles are listed in Table 1. The complex is best described as distorted square pyramidal, with the nearly planar chelate rings in the *trans* orientation, required by the imposed C_2 axis along the Mn—Cl bond. The S_4 base of the pyramid is not planar; atoms S(1′,2′) deviate by 0.90 Å from the plane of the other three sulphur atoms. The overall structure is similar to that of $[MoS(CS_4)_2]^{2-}$.[12] The manganese atom is displaced toward the apical chloride ligand and the Mn—Cl distance of 2.400(2) Å is quite close to the corresponding distances (2.35–2.41 Å) in other square pyramidal manganese(II) complexes.[14–16] The Mn—S bond lengths (2.51–2.56 Å) are longer than those in tetrahedral Mn^{II}—S_4 complexes[5,17,18] (*vide infra*) and approach the value (2.57 Å) found in the octahedral tetrasulphide complex.[9] The C—S and S—S bond distances and angles approach those

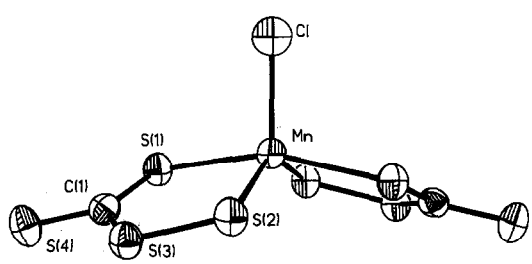

Fig. 1. The structure of $[Mn(CS_4)Cl]^{3-}$, showing the atom labelling scheme and 50% probability ellipsoids. An imposed C_2 axis passes through the manganese and chlorine atoms.

	average	109(1)		

exhibited by $[Ni(CS_4)_2]^{2-}$,[5] $[MoS(CS_4)_2]^{2-}$[12] and $[Mo_2S_4(CS_4)_2]^{2-}$,[12] the only other structurally characterized perthiocarbonate complexes, but there are certain significant differences.

The indistinguishability of the S(4)—C(1) and S(1)—C(1) bond lengths indicates delocalization of this portion of the ligand. This situation is very similar to that found with one of the two inequivalent anions in the structure of $K_2CS_4 \cdot MeOH$,[19] in which the corresponding bonds have the identical distance of 1.705 Å. In the other anion these distances differ by 0.086 Å, with one of these (1.745 Å) being appreciably longer than the S(4,1)—C(1) bonds in $[Mn(CS_4)_2Cl]^{3-}$. Ligand delocalization is also found in $[Ni(CS_4)_2]^{2-}$, where the two C—S distances differ by only 0.03 Å.[5] However, this feature is not an invariant property inasmuch as bond length differences in $[MoS(CS_4)_2]^{2-}$ (0.09 Å) and $[Mo_2S_2(CS_4)_2]^{2-}$ (0.17 Å)[12] are indicative of a far more localized ligand structure.

The structure of $[Mn(S_6)_2]^{2-}$ is set out in Fig. 2 and metric data are collected in Table 2. The complex contains manganese(II) in distorted tetrahedral coordination and is structurally very similar to $[Mn(S_5)(S_6)]^{2-}$.[5] The MnS_6 rings adopt a chair-type conformation very similar to those observed for some other complexes containing the S_6^{2-} ligand[2,20] and for cyclo-S_7.[21]

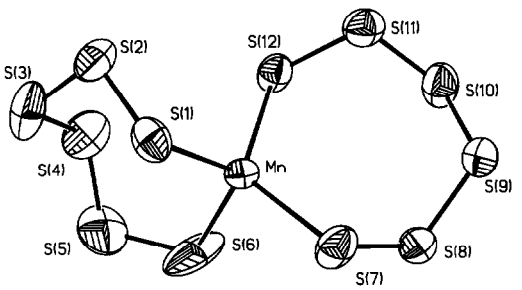

Fig. 2. The structure of $[Mn(S_6)_2]^{2-}$, showing the atom labelling scheme and 50% probability ellipsoids.

SYNTHESIS AND X-RAY CRYSTAL STRUCTURE OF A MONONUCLEAR ARYLOXIDE-CROWN ETHER OF BARIUM: [Ba(OAr)$_2$(18-crown-6)] · (2ArOH)(18-crown-6) (Ar = $C_6H_3Bu^t_2$-3,5)

Abstract—The reaction of elemental barium with 3,5-di-tert-butylphenol and 18-crown-6 in THF at reflux temperature and/or using gaseous ammonia as catalyst yields a monomeric barium compound. The complex has been characterized by IR, ^{1}H NMR, mass spectroscopy, elemental analysis and single-crystal X-ray studies and shown to be an alcohol and crown-ether solvate: [Ba(OAr)$_2$(18-crown-6)] · (2ArOH)(18-crown-6). The structure consists of two ArO ligands, one above and one below the planar barium-coordinating polyether resulting in an eight-coordination for the barium atom. The bulky aryloxide anions are hydrogen-bonded to the OH group of the 3,5-di-tert-butylphenol molecule and one free 18-crown-6 molecule fits between two [Ba(OAr)$_2$(18-crown-6)] · 2ArOH units. The poor thermal stability of this monomeric complex accounts for its non-volatility, whereas its high solubility is attractive for sol–gel processes.

The chemistry of alkaline-earth alkoxides has shown a growing interest over the last 5 years.[1,2] This is due to its new applications, including Chemical Vapour Deposition (CVD), for the preparation of high-temperature superconducting ceramics thin films.[3] Although there are satisfactory OMCVD sources for depositing copper and yttrium oxides,[4] only a very few compounds of barium having an adequate volatility are known.[1b,5] They often display fluorinated β-diketonate, macrocyclic polyether and alkoxide ligands.

Since the volatility of these species is consistent with a low degree of molecular aggregation, we approach the problem by attempting to prepare a mononuclear barium aryloxide-crown ether using two sterically hindered ligands: 3,5-di-tert-butyphenol and 18-crown-6 (1,4,7,10,13,16-hexaoxacyclooctadecane).

We describe here the synthesis and the characterization including X-ray diffraction crystal structure of [Ba(OAr)$_2$(18-crown-6)] · (2ArOH)(18-crown-6).

EXPERIMENTAL

All manipulations were routinely performed under argon using Schlenk tubes and vacuum-line techniques with solvents purified by standard methods. The 3,5-di-tert-butylphenol was sublimed before use; barium metal granules and 18-crown-6 were commercially available from Strem Chemicals and Aldrich-chemie, respectively. ^{1}H NMR and IR spectra were run on a Bruker AC-250 and an IR FT Nicolet ZDX spectrometer. IR spectra were obtained as Nujol mulls between KBr plates. Mass spectra were recorded on a 300 DX JEOL by Fast-Atom Bombardment, positive-ions[6] with an NBA matrix (NBA = *ortho*-nitrobenzylalcohol). Thermogravimetric analysis was made under argon atmosphere with an heating rate of 5°C min^{-1}. Analytical data were obtained from the Centre de Microanalyses du CNRS.

Synthesis of [Ba(OAr)$_2$(18-crown-6)] · (2ArOH)(18-crown-6) (**I**)

Barium metal granules (0.78 g, 5.7 mmol), 3,5-di-tert-butylphenol (2.35 g, 11.4 mmol) and 18-

* Author to whom correspondence should be addressed.

crown-6 (1.51 g, 5.7 mmol) were stirred together with THF (50 cm^3) at reflux temperature. Then ammonia gas was bubbled into the reaction medium in order to accelerate and complete the reaction. A beige precipitate appeared when all the barium metal was consumed. The mixture was concentrated to dryness. Extraction with 20 cm^3 of toluene and filtration yielded an orange–brown filtrate. Large crystals were easily obtained at −20°C, but then dissolved quickly at room temperature. The mixture was heated under reflux and after slow concentration, crystals suitable for X-ray were formed as air-sensitive colourless rods. Yield: 49% based on barium. Found: C, 64.2; H, 9.0. Calc. for $C_{80}H_{134}O_{16}Ba$: C, 64.5; H, 9.0%. IR (cm^{-1}): 3205 [ν(OH)], 1581, 1328, 1244, 1202, 1096, 1026, 998, 963, 899, 864, 836, 716, 583, 562. ^{1}H NMR ($CDCl_3$, 293 K, ppm): 6.57 t (CH, 1H); 6.54 d (CH, 2H); 3.69 s (CH_2, 12H); 1.21 s (CH_3, 18H). SM (*m/z*, FAB$^+$): Ar = $C_6H_3Bu^t_2$-3,5; Ar′ = $C_6H_4NO_2$-2, $Ba(OAr)_2$(18-crown-6) (3%), Ba(OAr)(18-crown-6) (100%), Ba(HOAr′)(18-crown-6) (25%), Ba(OPh)(18-crown-6) (8%), $Ba(OCH_2Ph)$(OAr) (25%), Ba(18-crown-6) (22%), Ba(OAr) (40%), Ba(OH) (45%). Several kinds of crystals may be obtained from the same synthesis, depending on the crystallization conditions. Despite their poor quality, which precluded an X-ray diffraction study, we have noted that their difference comes from the solvatation of the 18-crown-6 ether according to their spectroscopic data and elemental analysis.

Alternate synthesis of **I**

Barium metal granules (0.4 g, 2.9 mmol), 3,5-di-tert-butylphenol (2.4 g, 11.6 mmol) and 18-crown-6 (1.53 g, 5.8 mmol) were stirred together with THF (40 cm^3) under reflux for 1 week. When all the metal was consumed the mixture was filtered and concentrated. The filtrate was left to crystallize at 5°C, leading to crystals of **I**. Yield: 90% based on barium.

Crystallographic studies

A single-crystal of **I** was sealed in a Lindemann glass capillary and was mounted onto a Siemens P3 automatic diffractometer at room temperature. Accurate unit cell dimensions and crystal orientation matrix, together with their estimated standard deviations, were obtained from least-squares refinement of the setting angles of 22 reflections. Crystallographic data and other pertinent information are summarized in Table 1. Corrections were made for Lorentz and polarization effects. No correction for absorption was done. All calculations were performed on a VAX 3100. Complex neutral-atom scattering factors were employed. Anomalous dispersion terms were used. The position of the barium atoms was found by analysis of a three-dimensional Patterson map using SHELXS 86[7] and was confirmed by direct methods using SIR.[8] All remaining non-hydrogen atoms were found by successive electron density map calculations using SHELX 76.[9] In view of keeping the data/variables ratio higher than 10:1, only atoms from the chelated polyether and the phenyl ring were allowed to move anisotropically. This choice results in relatively high values for R of 0.0791 and for R_w of 0.0907. Refinement with anisotropic thermal parameters for all the non-hydrogen atoms leads to more reasonable values of 0.0484 and 0.0522 for both R and R_w, respectively, which does not reveal any problem of crystal quality. However, this latter refinement appears to be less accurate because of the small data/variables ratio of 6.7:1. For this reason, we decided to report here the results obtained from the first refinement type. Hydrogen atoms were placed in calculated positions (C—H = 1.08 Å) and were not further refined but recalculated after each cycle. Positional parameters and thermal parameters are given as supplementary material.

RESULTS AND DISCUSSION

[$Ba(OAr)_2$(18-crown-6)]·(2ArOH)(18-crown-6) was obtained by mixing metallic barium, 3,5-di-tert-butylphenol and 18-crown-6 (ratio 1:2:1, respectively) with THF in the presence of ammonia gas as a catalyst. Such a route has already been mentioned.[2e,10] It consists of a fast reaction of alkaline-earth metals with sterically hindered ligands in oxygenated medium using ammonia gas as a catalyst. However, the same compound can be selectively obtained in 90% yield with a molecular ratio of 1:4:2 for Ba:ArOH:18-crown-6, in THF under reflux.

The X-ray crystal structure of **I** is shown in Fig. 1. It comprises monomeric $Ba(OAr)_2$(18-crown-6) units solvated by alcohol and 18-crown-6 ether molecules. Selected bond lengths and angles are listed in Table 2. The barium atom is surrounded by the polyether ring forming an almost BaO_6 planar configuration (maximum deviation of 0.15 Å) and by two aryloxide ligands lying perpendicularly on both sides of this plane. Each oxygen atom of the aryloxide ligand has short contacts (2.48 Å), implying hydrogen bonding with the oxygen atom of the neighbouring 3,5-di-tert-butylphenol molecule. Finally, one free 18-crown-6 molecule fits between

two [Ba(OAr)$_2$(18-crown-6)]·2ArOH units. The barium atom is coordinated by eight oxygen atoms defining a hexagonal bipyramid. The Ba—O (polyether) distances are in good agreement with the ones previously reported for other barium derivatives with crown ether ligands,[5b,c] whereas the Ba—O(OAr) bond length is significantly longer than the usual Ba—O(aryloxide) distances.[2] This could be partly attributed to the already mentioned hydrogen bonding reinforced by the steric hin-

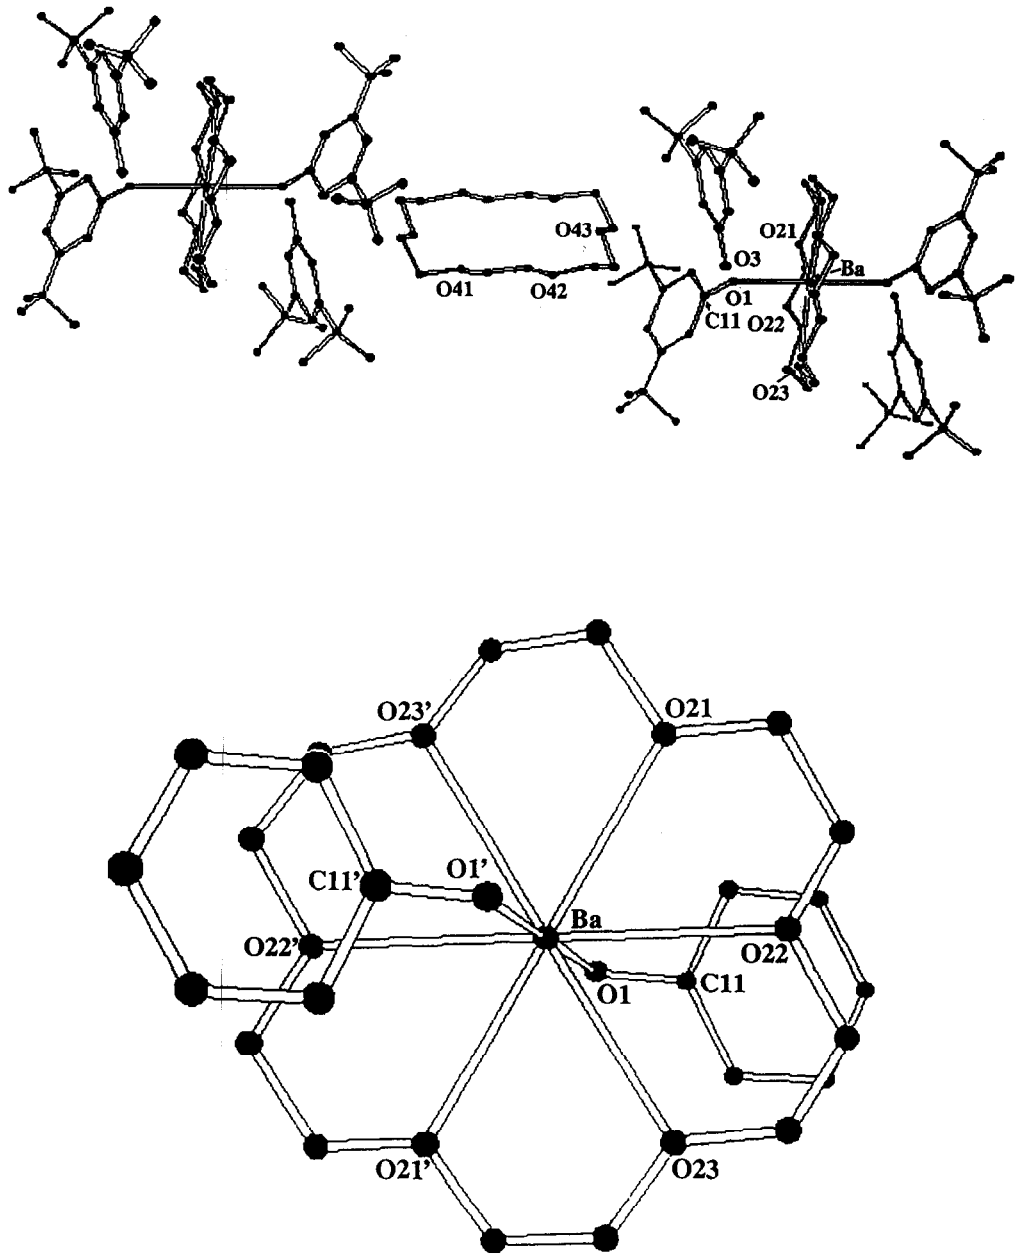

Fig. 1. Atomic numbering schemes of $[Ba(OAr)_2(18\text{-crown-}6)]\cdot(2ArOH)(18\text{-crown-}6)$ and of the monomeric moiety $[Ba(OAr)_2(18\text{-crown-}6)]$ (the Bu^t ligands are omitted for clarity).

drance from the bulky polyether ligand. Moreover, although the Ba—O(1)—C(11) bond angle of 136.1° is in favour of π-donation, the dihedral angle of 89.3° between the Ba—O(1)—C(11) plane and its adjacent phenyl ring allows no conjugation limiting the π-donation effect.

The coordination number of the barium–oxygen derivatives is generally high (5–10); multidentate Lewis base ligands as the cyclic polyether 18-crown-6 yield coordinatively saturated barium monomeric species. Some other molecular barium crown ether derivatives have been reported in the literature.[5b,c,d] They are generally associated with fluorinated β-diketonate ligands (such as 1,1,1,5,5,5-hexafluoro-2,4-pentanedionate) and their structure is similar to the $Ba(OAr)_2(18\text{-crown-}6)$ moiety. In fact, they consist of two β-diketonate ligands, one above and one below the planar barium-coordinating polyether. $[Ba(OAr)_2(18\text{-crown-}6)]\cdot(2ArOH)(18\text{-crown-}6)$ is the first example of an aryloxide crown ether complex of barium.

The monomeric nature of the compound is confirmed by Fast-Atom Bombardment positive-ion mass spectral data, which exhibit the parent molec-

ular ion without any ion of higher molecular mass. The IR spectrum displays essentially the absorption bands of the ligands as well as a broad ν(O—H) stretching vibration at 3205 cm^{-1}, characteristic of hydrogen-bonding. The room-temperature ^1H NMR spectrum in $CDCl_3$ reveals a single average environment for the aryloxide groups and for the cyclic polyether molecules. Integration establishes four ArO groups for two polyether molecules. A variable-temperature study shows that the aryloxo ligands remain unchanged; they are non-fluxional on the NMR time-scale. On cooling to 276 K two singlets of equal intensity appear at 3.69 and 3.66 ppm, assignable to the free and coordinated 18-crown-6, respectively. On decreasing the temperature in the range 276–255 K, only the signal of the coordinated crown ether moves to the high field. The alcohol proton resonance is not observed.

Since monomeric compounds are better candidates than oligomers for volatility properties, the monomeric studied complex could reasonably be expected to be volatile. Unfortunately, its poor thermal stability does not allow it to be volatile. In fact, compound **I** decomposes on heating *in vacuo* (10^{-1} mm of Hg) with sublimation of the 18-crown-6 and alcohol. Preliminary TGA results have shown two weight losses of 59 and 19% in the range 200–300°C and 380–450°C, respectively. It could be thought that the decomposition leads to coordinatively unsaturated barium species, which have a strong tendency to form non-volatile intermolecular aggregates. The compound is, thus, of no use for CVD applications; nevertheless, its hydrocarbon-solubility makes it interesting for sol–gel and pyro–sol methods.

SYNTHESIS, STRUCTURE AND REDOX PROPERTIES OF (μ-OXO)BIS(μ-CARBOXYLATO)DIRUTHENIUM(III) COMPLEXES CONTAINING THREE DIFFERENT TERMINAL LIGANDS

ARIYANCHIRA SYAMALA and AKHIL R. CHAKRAVARTY*

Department of Inorganic and Physical Chemistry, Indian Institute of Science, Bangalore 560 012, India

(*Received* 10 *September* 1992; *accepted* 1 *October* 1992)

Abstract—Blue coloured, unstable, essentially diamagnetic and non-electrolytic diruthenium(III) complexes of the formulation $[Ru_2O(O_2CR)_4(en)_2(PPh_3)_2]$ were prepared by reacting $[Ru_2O(O_2CR)_4(PPh_3)_2]$ with 1,2-diaminoethane (en) in CH_2Cl_2 (R = C_6H_4-*p*-X; X = H, Me and OMe). The molecular structure of the complexes is proposed as $[\{(\eta^1\text{-}O_2CR)(\eta^1\text{-en})(PPh_3)Ru\}_2(\mu\text{-}O)(\mu\text{-}O_2CR)_2]$ based on the ^1H NMR spectral data. The electronic spectra of the complexes display a band near 569 nm with a shoulder at 630 nm. In CH_2Cl_2–0.1 M $[Bu^n{}_4N]ClO_4$, the complexes exhibit redox couples $Ru_2^{III,III}/Ru_2^{III,IV}$ and $Ru_2^{III,IV}/Ru_2^{IV,IV}$ near 0.1 and 1.2 V (vs SCE), respectively. The potentials are the lowest among diruthenium(III) complexes with a similar core structure.

The present work stems from our interest in studying the role played by the terminal ligands in stabilizing and altering the electronic structure of (μ-oxo)bis(μ-carboxylato)diruthenium(III) complexes. It is recognized[1] that the chemistry at terminal positions is important in the biological activity of oxo-bridged diiron proteins. Although diiron complexes have been extensively studied[2] in recent years, the reaction chemistry at the terminal sites of analogous diruthenium complexes is virtually unknown. For such an investigation diruthenium(III) complexes having substitutionally inert heterocyclic bases[3] or capping tridentate ligands[4–6] are not suitable as precursors.

The higher stability of the $[Ru_2(\mu\text{-}O)(\mu\text{-}O_2CR)_2{}^{2+}]$ core and the ready availability of a synthon like $[Ru_2O(O_2CR)_4(PPh_3)_2]$ (**1a–1c**)[7–9] (R = C_6H_4-*p*-X; X = H, **a**; OMe, **b**; Me, **c**) have prompted us to explore the reaction chemistry of this precursor at the labile carboxylato terminal sites of the core. We have chosen the σ-only and potentially bidentate N,N-donor 1,2-diaminoethane (en) to initiate our programme. We have been able to isolate an unstable complex of the formulation $[Ru_2O(O_2CR)_4(en)_2(PPh_3)_2]$ (R = C_6H_4-*p*-X; X = H, **2a**; OMe, **2b**; Me, **2c**) from a reaction of the precursor with en in CH_2Cl_2. The molecular structures of **2a–2c**, deduced from spectral studies, show the presence of three different unidentate terminal ligands. Such an observation is of interest in the chemistry of (μ-oxo)bis(μ-carboxylato) dimetal(III) complexes.[2–9] The electrochemical behaviour of **2a–2c** is also found to be unusual. Herein, we report the synthesis, structure, spectral and redox properties of **2a–2c**.

RESULTS AND DISCUSSION

Synthesis and stability of 2a–2c

The complexes were prepared in high yield by reacting $[Ru_2O(O_2CR)_4(PPh_3)_2]$ with 1,2-diaminoethane (en) in CH_2Cl_2 at 0°C under a dinitrogen atmosphere [eq. (1)]. Conductivity measurements in nitromethane show the non-conducting nature of **2a–2c**.

$$[Ru_2O(O_2CR)_4(PPh_3)_2] + en \longrightarrow [Ru_2O(O_2CR)_4(en)_2(PPh_3)_2] \quad (1)$$

The complexes are highly soluble in acetone, CH_2Cl_2, $CHCl_3$ and aromatic hydrocarbons, less soluble in MeOH and MeCN, and essentially insoluble in aliphatic hydrocarbons and H_2O. The com-

* Author to whom correspondence should be addressed.

plexes, which are moderately stable in the solid state at low temperature, are unstable in solution.

Spectral nature and the molecular structure

The electronic spectra of the complexes **2a–2c** in CH_2Cl_2 show a strong visible absorption at 569 nm and a weak shoulder at 630 nm. The peak is diagnostic of the presence of a (μ-oxo)bis(μ-carboxylato)diruthenium(III) core in these complexes. The origin of the band is believed to be charge-transfer in nature, involving the Ru^{III}–$d\pi$ and μ-oxo-$p\pi$ orbitals.[3,5]

In **1a–1c** the band is observed[7,8] at 562 nm. It is interesting that the ligation of the σ-only donor ligand en has caused a shift of the band to a lower energy. In a structurally similar complex, $[Ru_2O(O_2CR)_2(PPh_3)_2\{NH_2CH_2CH_2NHC(Me)NH\}_2]^{2+}$, the visible band is seen[10] at 565 nm. The electronic spectral results suggest a *cis*-ligation of the η^1-O_2CR ligand, which is isoelectronic with the amidine moiety. The *trans* effect of the μ-oxo ligand is expected to facilitate removal of the *trans* ligand in the precursor.

The molecular structure of the complexes was deduced from the ^1H NMR spectral data (Table 1). A representative spectrum is shown in Fig. 1. The presence of two types of carboxylato ligands in a 1:1 ratio is observed from the peak integrations of the methyl resonances. Further, a 1:2:1 ratio of en : RCO_2^- : PPh_3 is evident in the spectrum. Considering the non-electrolytic behaviour of **2a–2c** and the electronic spectral feature showing the presence of an $[Ru_2(\mu\text{-}O)(\mu\text{-}O_2CR)_2^{2+}]$ core, the molecular structure of **2a–2c** is proposed as $[\{(\eta^1\text{-}O_2CR)(\eta^1\text{-en})(PPh_3)Ru\}_2(\mu\text{-}O)(\mu\text{-}O_2CR)_2]$. The structure is believed to be stabilized by hydrogen-bond formation involving the η^1-en and η^1-O_2CR ligands as shown below.

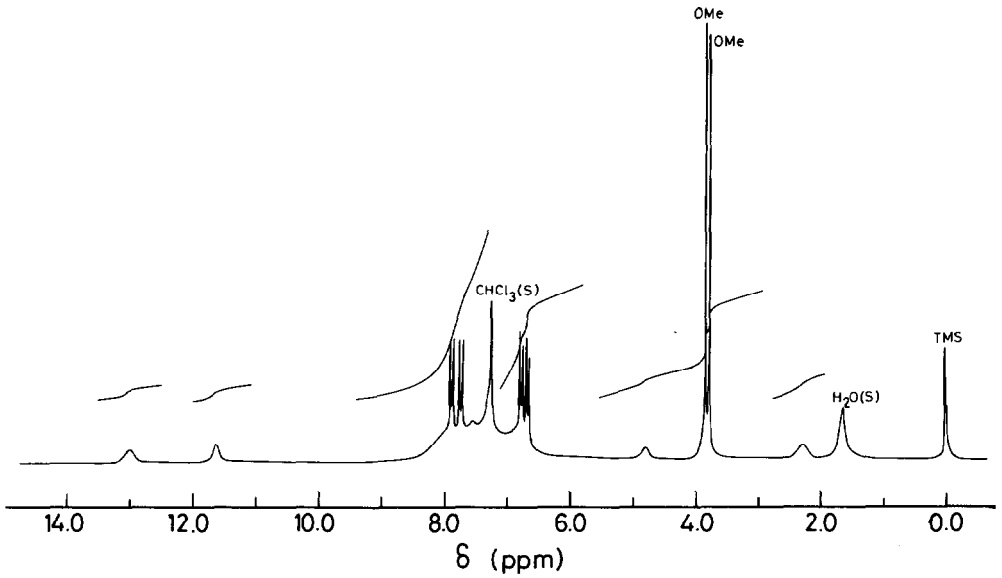

Fig. 1. ^1H NMR spectrum of $[Ru_2O(O_2CC_6H_4\text{-}p\text{-}OMe)_4(en)_2(PPh_3)_2]$ (**2b**) in $CDCl_3$ (S: solvent peak).

The complexes display two broad peaks in the ranges δ 11.6–12.6 and δ 13.0–13.5. Each signal corresponds to a single proton. On D_2O exchange, these two peaks disappear and a new peak is observed within δ 12.1–12.9. This peak, however, disappears completely after 10 h. The singlets are assignable to an amino group involved in the hydrogen bond formation. The amino protons *trans* to the μ-oxo ligand, appearing in the aromatic region at δ 7.6, also undergo exchange with D_2O.

The *trans* ligation of the η^1-en ligand in **2a–2c** could be rationalized from the X-ray structure of **1b**, which shows a longer Ru—O(*trans*) bond length than Ru—O(*cis*).[8] Sasaki *et al.*[3] have shown that in $[Ru_2O(O_2CMe)_2(py)_6]^{2+}$ a regioselective *trans*-pyridine exchange with py-d_5 in CD_3CN takes place exclusively without any exchange at the *cis* ligand. This suggests a selective chelate ring opening in **1a–1c** by η^1-en at the *trans* terminal position in preference to the *cis* site following a dissociative pathway.[3] However, the presence of two potentially bidentate O_2CR and en ligands in a unidentate fashion makes the complex unstable. In polar solvents the complex is unstable and converts to a purple diamagnetic complex, which is isolated as a perchlorate salt and characterized as $[Ru_2O(O_2CR)_2(en)_2(PPh_3)_2](ClO_4)_2$.[11] In non-polar solvents the formation of a mixture of products containing paramagnetic species is observed.

Redox properties

The electrochemical behaviour of **2a–2c** was studied to investigate the effect of terminal ligands on the stability and the electronic structure of the core. The cyclic voltammograms of **2c** are shown in Fig. 2. and the relevant data are presented in Table 1.

Diruthenium(III,III)–*diruthenium*(III,IV) *couple*

The complexes display a one-electron redox process occurring near 0.1 V (vs SCE) in CH_2Cl_2–0.1 M $[NBu^n_4]ClO_4$. A controlled potential electrolysis performed at a potential 200 mV higher than the anodic peak potential (E_{pa}) and 200 mV lower than the cathodic peak potential (E_{pc}) showed that the redox process occurring at 0.1 V is a one-electron oxidation [eq. (2)]. The peak-to-peak separation (ΔE_p) of > 58 mV and an i_{pa}/i_{pc} ratio of 1.0 at various scan rates (20–200 mV s^{-1}) indicate the quasi-reversible nature of the electron transfer (i_{pa} and i_{pc} are anodic and cathodic peak currents, respectively).

$$\{Ru_2^{III,IV}(\mu\text{-}O)(\mu\text{-}O_2CR)_2{}^{3+}\} \underset{-e^-}{\overset{+e^-}{\rightleftharpoons}} \{Ru_2^{III,III}(\mu\text{-}O)(\mu\text{-}O_2CR)_2{}^{2+}\} \quad (2)$$

The potentials of the $Ru_2^{III,III}/Ru_2^{III,IV}$ couple in **2a–2c** are the lowest among the known[3–10] diruthenium(III) complexes with an analogous core structure. Such a low potential accounts for the instability of the complexes in solution as well as in the solid phase. The unusual feature is that the facile oxidation takes place even in the presence of a π-acceptor ligand like PPh_3. The observed potential is significantly lower than that reported[4] in an anal-

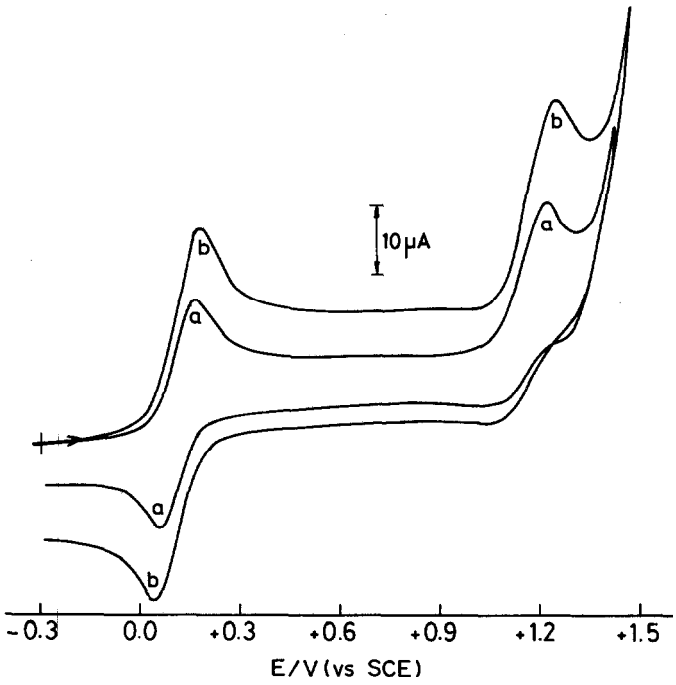

Fig. 2. Cyclic voltammograms of $[Ru_2O(O_2CC_6H_4\text{-}p\text{-}Me)_4(en)_2(PPh_3)_2]$ (**2c**) in CH_2Cl_2 containing 0.1 M $[NBu^n_4](ClO_4)$. Scan rates: (a) 20 and (b) 50 mV s^{-1}.

ogous complex containing a σ-only donor tridentate triazacyclononane capping ligand. A general trend, observed so far in the diruthenium(III) complexes, shows that a π-acceptor terminal ligand stabilizes the +2 and +3 oxidation states of ruthenium and the complex displays a low-energy visible band in the electronic spectrum. From the visible spectral and electrochemical data on several $[Ru_2(\mu\text{-}O)(\mu\text{-}O_2CR)_2]^{2+}$ complexes, given in Table 2, it is evident that complexes **2a**–**2c** stand as an exception to the general trend. The paucity of the experimental data, however, precludes us from drawing any definite conclusion on the unusual behaviour of **2a**–**2c**.

Diruthenium(III,IV)–*diruthenium*(IV,IV) *couple*

This couple is observed as an oxidation wave near 1.2 V with a broad and relatively ill-defined cathodic response showing diminished peak current. The one-electron stoichiometry of the redox process is

Table 2. A comparison of the redox data on the $Ru_2^{III,III}/Ru_2^{III,IV}$ couple and the low-energy visible band in (μ-oxo)bis(μ-carboxylato)diruthenium(III) complexes

Complex	$E_{1/2}$ (V)	λ_{max} (nm)	Ref.

[g] L″ = $NH_2CH_2CH_2NHC(Me)NH$.

determined from the i_{pa} values of this response with that of the $Ru_2^{III,III}/Ru_2^{III,IV}$ couple [eq. (3)].

$$[Ru_2^{IV,IV}(\mu\text{-O})(\mu\text{-}O_2CR)_2{}^{4+}] \underset{-e^-}{\overset{+e^-}{\rightleftharpoons}} [Ru_2^{IV,III}(\mu\text{-O})(\mu\text{-}O_2CR)_2{}^{3+}] \quad (3)$$

The i_{pc}/i_{pa} ratio of < 1.0 indicates a slow $Ru_2^{IV,IV} \rightarrow Ru_2^{IV,III}$ electron-transfer process. Prior to this work, there are only two reports[3,6] of observing this couple at a much higher potential in related diruthenium(III) complexes.

CONCLUSIONS

This work presents new diruthenium(III) complexes having three different terminal ligands of varied σ-donor and π-acceptor abilities. This gives us an opportunity to study the influence of the *trans*- and *cis*-oxo ligands on the spectral and redox properties of the $[Ru_2(\mu\text{-O})(\mu\text{-}O_2CR)_2{}^{2+}]$ core. The observation of a $Ru_2^{III,III}/Ru_2^{III,IV}$ couple at a near zero potential in **2a–2c** is of significance. Finally, the present study has shown that using suitable precursors having labile terminal sites, the chemistry of the $[Ru_2(\mu\text{-O})(\mu\text{-}O_2CR)_2{}^{2+}]$ complexes can be developed by selective incorporation of σ-donor as well as π-acceptor ligands at the terminal positions to tune the electronic structure of the core.

EXPERIMENTAL

Materials

Precursor complexes $[Ru_2Cl(O_2CMe)_4]$,[7] $[Ru_2Cl(O_2CR)_4]$[12] and $[Ru_2O(O_2CR)_4(PPh_3)_2]$[8] (**1**) (R = C_6H_4-*p*-X; H, **a**; OMe, **b**; Me, **c**) were prepared by published methods.

Preparation of $[Ru_2O(O_2CR)_4(en)_2(PPh_3)_2]$ (R = C_6H_4-*p*-X: X = H, **2a**; OMe, **2b**; Me, **2c**)

The complexes were prepared by following a general procedure. A representative one is given below.

A sample of **1b** (68 mg, 0.05 mmol) in CH_2Cl_2 (5 cm^3) was reacted with 0.3 M en solution (0.42 cm^3, 0.11 mmol) in CH_2Cl_2. The mixture was stirred for 1 h at 0°C under dinitrogen. Immediately after the addition of en, the colour of the purple reaction mixture changed to blue. A blue solid of **2b** was precipitated by adding petroleum ether (b.p. 60–80°C) to the reaction mixture. The product was filtered off, washed with a CH_2Cl_2–petroleum ether (1:20 v/v) mixture and dried over P_4O_{10} *in vacuo*. Yield: 45 mg (*ca* 65%). Found: C, 58.4; H, 5.2; N, 3.7. Calc. for $C_{72}H_{74}N_4O_{13}P_2Ru_2$: C, 58.9; H, 5.1; N, 3.8%. Λ_M (nitromethane, 25°C) = 15 Ω^{-1} cm^2 mol^{-1}. Electronic spectral data in CH_2Cl_2 at 25°C [λ_{max} (nm) (ε/M^{-1} cm^{-1})]: 630(sh), 569(12,200), 359(sh), 339(12,900), 289(sh). Complex **2a**: yield: *ca* 60%. Found: C, 60.2; H, 5.0; N, 4.3. Calc. for $C_{68}H_{66}N_4O_9P_2Ru_2$: C, 60.6; H, 4.9; N, 4.2%. Λ_M (nitromethane, 25°C) = 18 Ω^{-1} cm^2 mol^{-1}. Electronic spectral data [λ_{max} (nm) (ε/M^{-1} cm^{-1})] in CH_2Cl_2 at 25°C: 630(sh), 569(9700), 359(11,200), 333(sh), 296(sh). Complex **2c**: yield, *ca* 60%. Found: C, 61.2; H, 5.4; N, 3.9. Calc. for $C_{72}H_{74}N_4O_9P_2Ru_2$: C, 61.6; H, 5.3; N, 4.0%. Λ_M (nitromethane, 25°C) = 15 Ω^{-1} cm^2 mol^{-1}. Electronic spectral data [λ_{max} (nm) (ε/M^{-1} cm^{-1})] in CH_2Cl_2 at 25°C: 569(9400), 359(9600), 325(sh), 296(10,000). The complexes **2a–2c** are unstable in the solution phase and attempts to isolate single crystals suitable for X-ray diffraction studies were unsuccessful.

Physical measurements

The elemental analyses were made with a Heraeus CHN-O Rapid instrument. Electronic spectra were obtained from a Hitachi U-3400 spectrophotometer. The ^1H NMR spectra were recorded on Bruker WH-270 and AC(AF)200 MHz spectrometers. Conductivity measurements were performed on a Century CC603 digital conductivity meter. Cyclic voltammetric measurements were done using a three-electrode set-up on PAR model 174A polarographic analyser connected with a Houston Instruments Omnigraphic *X–Y* recorder. A platinum button, a platinum wire and a saturated calomel electrode (SCE) were used as working, auxiliary and reference electrodes, respectively. The measurements were performed at 25°C in CH_2Cl_2 containing 0.1 M $[NBu^n_4]ClO_4$ as a supporting electrolyte. The data reported are uncorrected for junction potentials. Ferrocene, $(\eta^5\text{-Cp})_2Fe$, was used as a standard to verify the potentials observed against the SCE and to obtain the electron-transfer stoichiometries of the redox couples by peak current measurements. The Fe^{II}/Fe^{III} couple of ferrocene was observed at 0.50 V (vs SCE) under similar experimental conditions in CH_2Cl_2–0.1 M $[Bu^n_4N]ClO_4$.

(*Received* 10 *September* 1992; *accepted* 1 *October* 1992)

Abstract—Parathiocyanogen or polythiocyanogen $(SCN)_x$ has been synthesized by the anodic oxidation of NaSCN solutions in methanol. The structure of parathiocyanogen $(SCN)_x$ has been studied by means of elemental analysis, IR, UV, ^{13}C NMR and ESR spectroscopy and also by comparison with a triazine-based model compound. All data collected clearly show that parathiocyanogen is structurally different from the triazine-based structure. On the basis of the data collected, the most probable structure should be a linear one, very similar to the one accepted for polysulphur nitride. Upon doping with iodine vapour the specific conductivity of parathiocyanogen increases by several orders of magnitude, as expected from a semi-conductive polymer.

A chemical route for the synthesis of parathiocyanogen $(SCN)_x$ was recently reported,[1] and its possible structure based on its IR and UV spectra was discussed. It was pointed out that $(SCN)_x$ should not have a 1,3,5-triazine structure as had been believed in the past, but it should have a linear structure very similar to that accepted for polysulphur nitride $(SN)_x$.[1]

In this work an electrochemical route in organic solvent is reported for the synthesis of parathiocyanogen, and it is shown that "electrochemical" $(SCN)_x$ has the same structure as "chemical" $(SCN)_x$. Moreover, we report a ^{13}C NMR and ESR study on parathiocyanogen versus a triazine-based model compound, as well as conductivity measurements on compressed pellets of undoped and iodine doped $(SCN)_x$.

EXPERIMENTAL

Physical and analytical measurements

^{13}C NMR spectra were measured in N,N-dimethylformamide solutions of each sample using a Bruker AC 200 spectrometer operating at 50.33 MHz, with $\langle^1H\rangle$ Waltz decoupling or without any decoupling. No differences have been noted between decoupled and undecoupled spectra. Spectral conditions are: size = 64 K, time domain 64 K; pulse width 60°, corresponding to 5 μs acquisition time, 2.75 s; sweep width 12,000 Hz and at least 12,000 scans. Chemical shifts are given in ppm from TMS, but were actually measured from the carbonyl of DMF.

The IR and UV spectra and elemental analyses were carried out as previously described.[1] ESR spectra were kindly obtained on solid samples at room temperature by Dr Luciano Montanari; the EPR spectrometer was a Varian E-3.

Electrochemical synthesis of parathiocyanogen

NaSCN (60.5 g) was dissolved in anhydrous methanol (270 cm^3) and the solution was electrolysed between two platinum electrodes under nitrogen, in a H-shaped cell at 45°C. The anodic compartment of the H-shaped cell was divided from the cathodic compartment by a G3 fritted glass septum. The syntheses were performed at 24 V with a current density at the platinum anode of *ca* 0.040 A cm^{-2}. During the electrolysis the cell was put into an ultrasonic cleaning bath and sonicated. The cavitation due to ultrasound stirred the solution and prevented the growth of a thick film on the anode surface, which could cause a drop in the passage of the current. After the first 10 min of electrolysis a brick-red–orange precipitate appeared. After 22,900 C (0.24 F) had passed through the cell the electrolysis was stopped. Parathiocyanogen was collected by filtration of the anodic solution. The polymer appeared as a very fine powder due to the mechanical effects of ultrasound; it was extracted in a Soxhlet apparatus with acetone for 20 h and then dried *in vacuo* for several days. The yield was 6.8 g (100% current yield). Found: C, 18.6; H, 0.73; N, 21.2; S, 53.3. Calc. for $(SCN)_x$: C, 20.7; N, 24.1; S, 55.2%. Similar results can be obtained by working in glacial acetic acid instead of methanol as the solvent. As a reference, chemically prepared parathiocyanogen was obtained, as described in part I of this work.[1]

Preparation of triazine-based model compound

This synthesis was accomplished by the nucleophilic substitution of chlorine with 2,4,6-trichloro-1,3,5-triazine and sodium disulphide as described previously.[1] Found: C, 12.0; H, 1.0; N, 15.3; S, 64.3. Calc. for $C_3N_3S_6H_2Na$ (model compound): C, 12.2; H, 0.68; N, 14.2; S, 65.1; Na, 7.8%. The IR spectrum has been reported previously.[1]

Doping of parathiocyanogen with iodine

A weighed sample of parathiocyanogen, prepared by electrochemical methods, was placed into a flask and left to absorb under reduced pressure, at 25°C, the iodine vapours escaping from the solid iodine present in the same flask from a separate vessel. After 4 days of treatment the polymer sample became black with the iodine absorbed, calculated from the total weight of the doped sample, being *ca* 30%; the conductivity of a compressed pellet of the sample was 2.0×10^{-6} S cm^{-1}. After 7 days in the same conditions the iodine content of the total weight of the doped sample was about 63%, and the conductivity of a compressed pellet was measured to be 1.2×10^{-4} S cm^{-1}. Undoped compressed pellets of parathiocyanogen showed a conductivity of 6.8×10^{-10} S cm^{-1}. A sample of parathiocyanogen doped with bromine vapours for 7 days in the same way as was used for iodine doping gave a conductivity of 1.3×10^{-7} S cm^{-1}. All the above-mentioned samples showed an ohmic response in the range 3.0–30 V. All conductivity measurements were performed using DC and the two-probe method, in air.

RESULTS AND DISCUSSION

The anodic oxidation of potassium thiocyanate in methanol at low temperatures has been described by early investigators[2] to yield a solution of thiocyanogen $(SCN)_2$. By heating the methanolic thiocyanogen solution at room temperature parathiocyanogen polymerizes into a brick-red amorphous material. We have optimized a procedure for the anodic oxidation of thiocyanates in methanol or glacial acetic acid at higher temperatures (45°C), to obtain parathiocyanogen directly without having to pass through thiocyanogen, assuming that the direct formation of parathiocyanogen by anodic oxidation occurs as shown in eqs (1) and (2).

$$x\mathrm{SCN}^- \rightarrow x\mathrm{SCN}^{\cdot} + xe \quad (1)$$

$$x\mathrm{SCN}^{\cdot} \rightarrow (\mathrm{SCN})_x \quad (2)$$

During electrolysis, in order to avoid direct film formation of the polymer on the electrode surface which could cause a drop in current and low yields, the cell was sonicated with ultrasound. Cavitation due to ultrasound detaches the polymer from the anode and allows current flow, even when large amounts of polymer had been obtained. There is also the possibility of obtaining thin films of the polymer on a platinum leaf used as the electrode (w/o ultrasound).

Elemental analyses performed on electrochemically prepared $(SCN)_x$ show the stoichiometric ratios C/N and C/S always close to 1.0. In order to obtain an acceptable elemental analysis it is necessary to use a H-shaped cell with a cathode compartment separated from the anode compartment by a fritted glass septum and also to stop electrolysis at relatively low conversions, as shown in the Experimental.

The IR spectra of parathiocyanogen obtained through the two different routes are presented in Fig. 1. They can be completely overlapped and clearly show the same structure. Moreover, these spectra are in agreement with the IR spectrum of

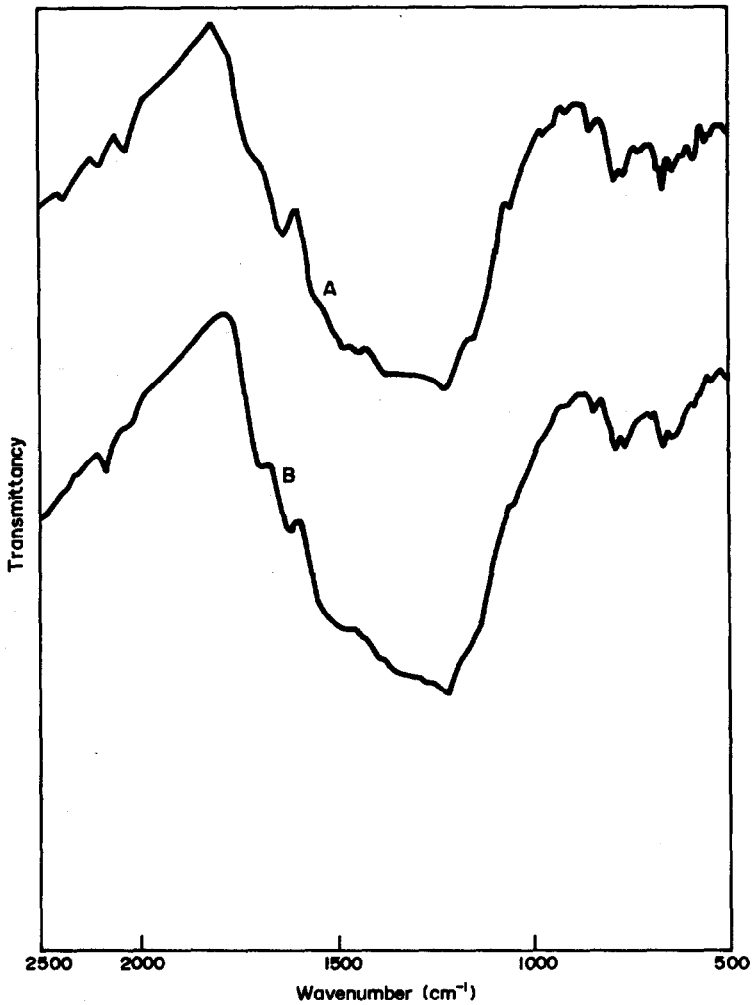

Fig. 1. IR spectra in KBr pellets of: (A) $(SCN)_x$ prepared electrochemically and (B) $(SCN)_x$ prepared chemically.

parathiocyanogen obtained from the anodic oxidation of molten thiocyanate salts, recorded by Pucciarelli *et al.*[3] A detailed discussion of the IR spectrum of $(SCN)_x$ in relation to its possible linear structure and in comparison to a triazine-based model compound can be found in the previous report.[1]

The ^{13}C NMR spectrum of a triazine-based model compound shows a neat narrow signal at 145.0 ppm, clearly due to sp^2 hybridized carbons of the triazine rings (Fig. 2). The ^{13}C NMR spectra of parathiocyanogen samples (Fig. 3) prepared through different routes (electrochemical or chemical) show only a very weak signal at 143.9 ppm. It is different both in chemical shift and mainly in intensity from the spectrum of the triazine-based model compound. No other signals were recorded from parathiocyanogen; these differences in its ^{13}C NMR spectrum compared with that of the triazine-based model compound are adduced as further proof to support the idea that parathiocyanogen has its own peculiar structure different from the triazine structure.

It should be noted that the ^{13}C NMR signal of carbon of an isothiocyanate —N=C=S group is expected in the range 120–140 ppm,[4] while potassium thiocyanate has a signal at 134.3 ppm. This means that in the parathiocyanogen ^{13}C NMR spectrum there is no trace of free thiocyanate ions. Also, the isothiocyanate groups, if present as the end groups of the linear structure proposed for parathiocyanogen, are practically not detectable.

Further evidence indicating that parathiocyanogen has a peculiar structure is shown in the UV spectra measured in N,N-dimethylformamide, shown in Fig. 4, in comparison with that of the triazine-based model compound and with a solution of NaSCN in the same solvent. Parathiocyanogen shows a maximum at 268 nm followed by a weak shoulder at *ca* 300 nm and

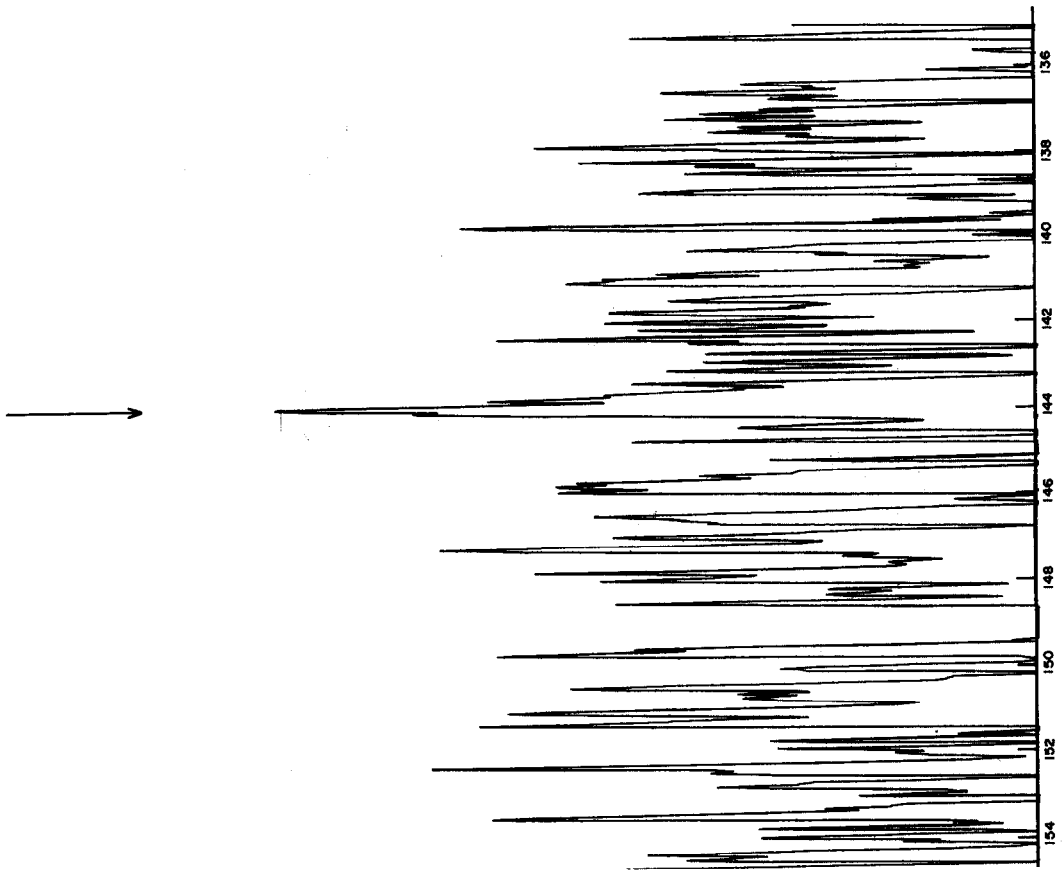

Fig. 3. C NMR spectra on $(SCN)_x$ prepared electrochemically.

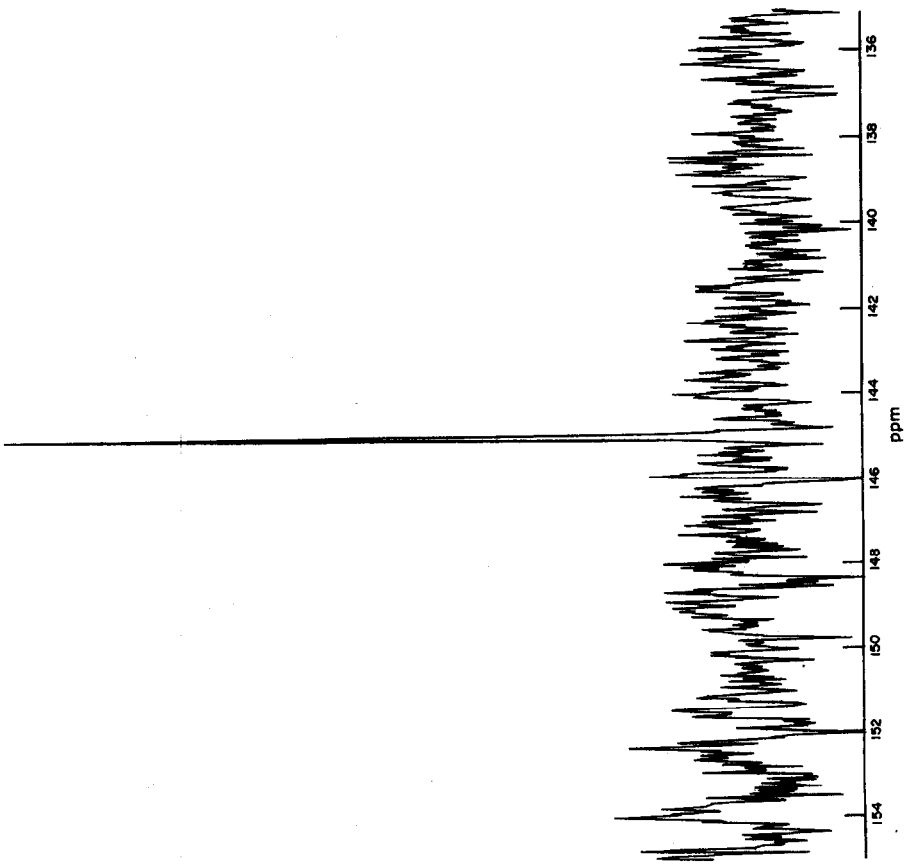

Fig. 2. C NMR spectra of the triazine-based model compound.

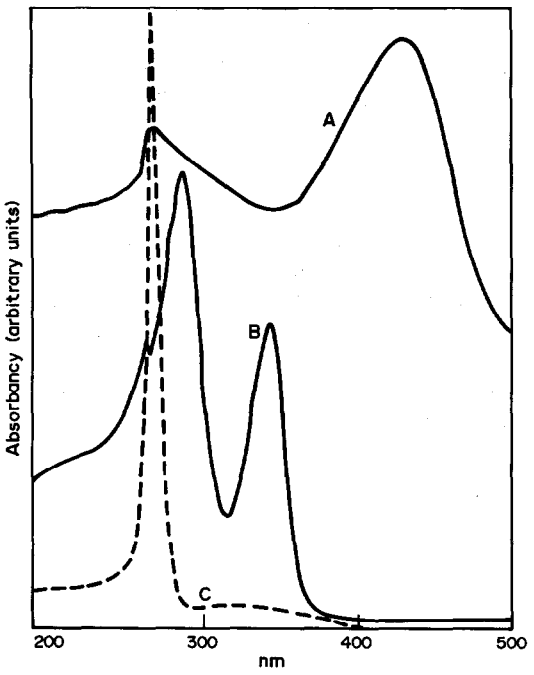

Fig. 4. Electronic spectra in N,N-dimethylformamide: (A) $(SCN)_x$ prepared electrochemically, (B) model compound containing a 1,3,5-triazine ring and (C) (dotted) NaSCN solution.

another maximum at 441 nm. However, the thiocyanate ion in the same solvent shows only a narrow absorption at 266 nm. Therefore, the new strong maximum shown by parathiocyanogen at 441 nm could account for conjugation along the polymeric chain, in agreement with the proposed linear structure.

The ESR spectrum was measured at room temperature, only for qualitative purposes, on the solid undoped sample of electrochemically-prepared parathiocyanogen for comparison with a solid sample of the triazine compound (Fig. 5). Parathiocyanogen showed a signal indicating the presence of a large number of unpaired spins. On the other hand, the ESR spectrum of the triazine model compound did not show any signal.

It is well known that conjugated polymers like polyacetylene or paracyanogen $(CN)_x$ have a very large number of unpaired spins due to the presence of defective structures along the polymeric chain.[5] Therefore, we should postulate the presence of unpaired electrons also in the case of parathiocyanogen, with the proposed linear structure. Unpaired electrons have not been detected in the compound having a triazine ring in its structure. We have measured a specific conductivity of 6.8×10^{-10} S cm^{-1} on compressed undoped pellets of electrochemically prepared parathiocyanogen.

Doping with iodine or bromine increases the specific conductivity of parathiocyanogen (see Experimental), as happens with other known conductive polymers. There should be an interaction between dopant and polymeric chain analogous to that between iodine or bromine and polysulphurnitride or polyacetylene chains, possibly with the formation of I^-, I_3^- and I_5^- or Br_3^-.[6] The maximum conductivity achieved with iodine doped samples of parathiocyanogen is somewhat lower

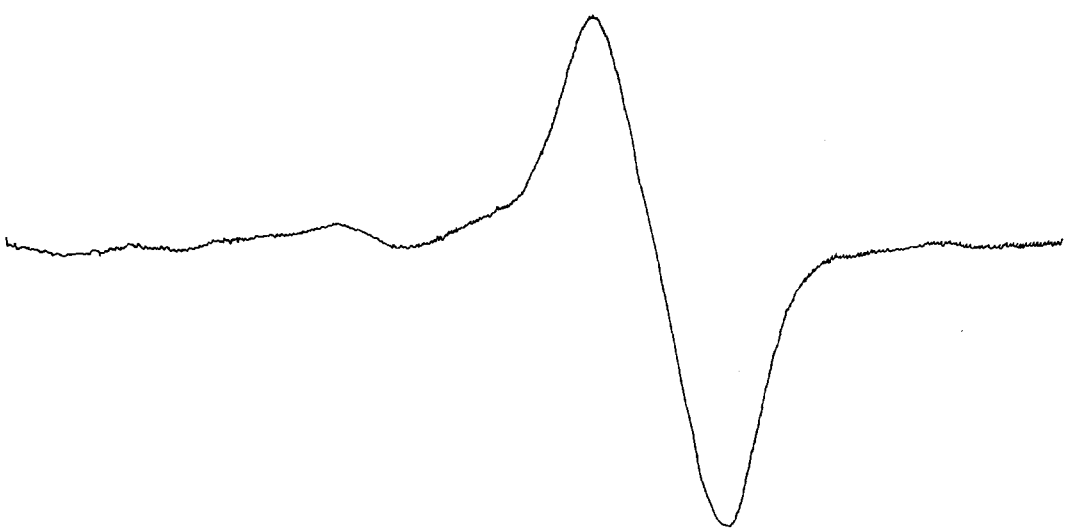

Fig. 5. Solid-state ESR spectrum of $(SCN)_x$ prepared electrochemically. The triazine model compound does not show a signal (practically).

than that reported for doped polysulphurnitride or polyacetylene samples.[6] It may be that the insertion of a carbon atom between sulphur and nitrogen lowers the delocalization of electrons along the polymeric chain. Hence, parathiocyanogen is only a high resistive semi-conductor while polysulphurnitride has quasi-metallic behaviour.

Acknowledgements—We thank Dr A. Segre of the "Istituto di Strutturistica Chimica L. Giacomello", Monterotondo (Rome), for ^{13}C NMR spectra and helpful discussion, Dr L. Montanari for ESR spectra and Prof. Nuti for the elemental analyses.

SYNTHESIS OF SOME NOVEL PENTA-COORDINATED COMPLEXES OF RUTHENIUM(II) CONTAINING AROMATIC ALDEHYDE AND OTHER MONODENTATE LIGANDS AND CATALYTIC OXIDATION OF TRIPHENYLPHOSPHINE USING SOME OF THEM

BIPUL C. PAUL, K. P. SARMA* and RAJ K. PODDAR†

Department of Chemistry, North-Eastern Hill University, Bijni Complex, Shillong 793003, India

(*Received* 31 *July* 1992; *accepted* 1 *October* 1992)

Abstract—The synthesis and characterization of some penta-coordinated ruthenium(II) complexes, viz. $[RuX_2(MPh_3)(C_4H_3OCHO)_2]$ (X = Cl or Br; M = P or As), $[RuBr_2(MPh_3)(C_6H_5CHO)_2]$ (M = P or As) and $[RuBr_2(CO)(PPh_3)_2]$, are described. The compounds were characterized using analytical data and various physical methods. $[RuBr_2(PPh_3)L_2]$ (L = C_4H_3OCHO or C_6H_5CHO) complexes catalysed the oxidation of PPh_3 by molecular oxygen.

Reports on the studies of ruthenium(II) and ruthenium(III) with weak donor ligands, such as dimethylsulphoxide, acetonitrile, benzaldehyde and other aldehydes, are more scarce compared to other donor ligands.[1–8] Complexes of ruthenium(II) containing weak donor ligands, or having both strong and weak donor ligands, have a strong potential to act as catalysts in various homogeneous reactions.[1]

Most of the complexes reported with weak donor ligands[1–8] have six coordination around the metal ion. Penta-coordinated complexes of ruthenium(II) and ruthenium(III) have a strong potential to act as catalysts in various homogeneous reactions.[9] Some of the complexes containing bromide and monodentate ligands, such as triphenylphosphine or dimethylsulphoxide, were found to be better catalysts than their corresponding chloro analogues.[10–12] Considering the above, we report here the synthesis and characterization of some of the penta-coordinated complexes of ruthenium(II) containing chloride or bromide, triphenylphosphine or triphenylarsine and benzaldehyde or furfural, and explore the catalytic activity of some of these complexes towards oxidation of triphenylphosphine to triphenylphosphine oxide by molecular oxygen.

EXPERIMENTAL

All the solvents were freshly distilled before use. $RuCl_3 \cdot 3H_2O$ was obtained from Arora–Matthey Ltd, Calcutta. The analyses for the chlorides and bromides were carried out by standard methods[13] after decomposition with a KOH and KNO_3 mixture. Carbon and hydrogen analyses were obtained from the Microanalytical section of the Department of Chemistry, NEHU, Shillong. The analytical data are presented in Table 1. IR spectra were recorded on a Perkin–Elmer 983 spectrometer in the 4000–200 cm^{-1} range. ^1H NMR spectra were recorded on a Varian EM-390, 90 MHz spectrometer, in $CDCl_3$. Electronic absorption spectra were recorded in solution on a Hitachi-330 spectrophotometer in the 1000–250 nm range. The results are given in Table 2. Magnetic susceptibilities were measured on an EG & G PARC Vibrating Sample Magnetometer at room temperature. Conductivity measurements were made on a Wayne Kerr, Automatic Precision Bridge B905 conductivity meter with millimolar solutions in acetonitrile.

Preparations

$[RuCl_2(MPh_3)(C_4H_3OCHO)_2]$ (M = P *or* As). To a solution of ruthenium trichloride trihydrate (0.1 g) in ethanol (10 cm^3) was added furfural (1

with methanol and dried *in vacuo*. The compounds were analysed for $[RuCl_2(MPh_3)(C_4H_3OCHO)_2]$ (M = P or As); yield: 70–75%.

$[RuBr_2(MPh_3)(C_4H_3OCHO)_2]$ (M = P *or* As). Hydrated ruthenium trichloride (0.1 g) was dissolved in ethanol (10 cm^3) and LiBr (0.4 g) was added to the solution and the mixture was refluxed for 1 h. To the clear solution furfural (1 cm^3) was added and the mixture was refluxed for a further 30 min. A solution of triphenylphosphine (0.5 g) or triphenylarsine (0.6 g) in ethanol (5 cm^3) was added to the hot reaction mixture and the mixture was refluxed for 45 min, when a compound separated out. It was isolated as in the preparation for $[RuCl_2(MPh_3)(C_4H_3OCHO)_2]$. The compounds were analysed for $[RuBr_2(MPh_3)(C_4H_3OCHO)_2]$ (M = P or As); yield: 65–70%.

$[RuBr_2(PPh_3)(C_6H_5CHO)_2]$. (a) To a solution of hydrated ruthenium trichloride (0.1 g) in n-butanol (10 cm^3) were added LiBr (0.4 g) and HBr (0.5 cm^3) and the mixture was refluxed for 30 min. Benzaldehyde (1 cm^3) was added to the mixture, refluxed for a further 15 min and a solution of triphenylphosphine (0.5 g) in n-butanol (5 cm^3) was added. The resulting solution was refluxed for a further period of 30 min, when a reddish-brown crystalline compound separated out. This compound was centrifuged, washed first with methanol and then with diethylether and dried *in vacuo*. It was analysed for $[RuBr_2(PPh_3)(C_6H_5CHO)_2]$; yield: 0.18 g, 64%.

(b) A reaction similar to that of $[RuBr_2(MPh_3)(C_4H_3OCHO)_2]$ was performed using benzaldehyde (1 cm^3) instead of furfural and the refluxing time for the final mixture was 3 h. A reddish-brown compound was isolated as in the preparation of $[RuCl_2(MPh_3)(C_4H_3OCHO)_2]$. It was analysed for $[RuBr_2(PPh_3)(C_6H_5CHO)_2]$; yield: 0.16 g, 57%.

$[RuBr_2(CO)(PPh_3)_2]$. A reaction similar to (a) was performed without using HBr and the product was isolated similarly. It was analysed for $[RuBr_2(CO)(PPh_3)_2]$; yield: 0.25 g, 80%.

$[RuBr_2(AsPh_3)(C_6H_5CHO)_2]$. A reaction similar to (a) was performed without using HBr and triphenylarsine (0.6 g) was added instead of triphenylphosphine and the mixture was refluxed for 1 h. The compound was isolated in a similar manner to (a). It was analysed for $[RuBr_2(AsPh_3)(C_6H_5CHO)_2]$; yield: 0.18 g, 60%.

Catalytic oxidation of triphenylphosphine

The catalytic oxidation of triphenylphosphine was performed using different molar ratios of catalyst: PPh_3 (1:5 to 1:20). The catalysts used were $[RuBr_2(PPh_3)L_2]$ (L = C_4H_3OCHO or C_6H_5CHO). The results are given in Table 3. A typical reaction using $[RuBr_2(PPh_3)(C_4H_3OCHO)_2]$ as the catalyst and PPh_3 (molar ratio 1:15) is described below.

A solution of $[RuBr_2(PPh_3)(C_4H_3OCHO)_2]$ (0.3 g) in n-butanol (10 cm^3) was added to a solution of triphenylphosphine (1.65 g) in n-butanol (15 cm^3) and the mixture was refluxed to boiling on an oil bath for 5 h, while oxygen was slowly bubbled through the solution. The solution was cooled to room temperature and a compound was separated by centrifugation. The solvent was removed from the mother liquor under reduced pressure and a white mass was obtained. It was washed several times with diethylether to free it from PPh_3 and dried *in vacuo*. It was analysed for $OPPh_3$; m.p. 155–157°C; yield: 1.48 g, 85%.

A reaction similar to that above was performed using $[RuCl_2(PPh_3)(C_4H_3OCHO)_2]$. The product isolated from the mother liquor after reaction for 5 h was found to be unoxidized PPh_3 only.

RESULTS AND DISCUSSION

$[RuX_2(MPh_3)(C_4H_3OCHO)_2]$ (X = Cl *or* Br; M = P *or* As]

New compounds containing halides, furfural and triphenylphosphine or triphenylarsine have the

Table 3. Oxidation of triphenylphosphine with ruthenium(II) compounds

Catalyst	Molar ratio catalyst: PPh_3	Quantity (g) Catalyst	PPh_3	$OPPh_3$	Yield (%)
$[RuBr_2(PPh_3)(C_4H_3OCHO)_2]$	1:5	0.3	0.55	0.52	89
$[RuBr_2(PPh_3)(C_4H_3OCHO)_2]$	1:10	0.3	1.10	1.00	86
$[RuBr_2(PPh_3)(C_4H_3OCHO)_2]$	1:15	0.3	1.65	1.48	85

No catalyst		0.0	1.00	0.00	

composition $[RuX_2(MPh_3)(C_4H_3OCHO)_2]$ (X = Cl or Br; M = P or As). The ^1H NMR spectra of $[RuCl_2(PPh_3)(C_4H_3OCHO)_2]$ and $[RuBr_2(PPh_3)(C_4H_3OCHO)_2]$ are superimposable (Table 2). The spectra showed one weak signal at δ 9.83 and four signals in the region δ 7.81–6.70. The ratio of the area under the signal at δ 9.83 and those in the region 7.81–6.7 δ is 2:21. The aldehydic proton is normally observed in the 10.1–9.5 δ range,[14] and thus, the signal at δ 9.83 could be assigned to the aldehydic proton of furfural. The proton signals in the aromatic region (δ 7.81–6.70) could be assigned to the phenyl and furan groups of triphenylphosphine and furfural, respectively. The ratio of the area for the aldehydic protons to the area under the signals in the aromatic region is as expected, 2:21. Similarly, the ^1H NMR spectra of the triphenylarsine analogues, viz. $[RuX_2(AsPh_3)(C_4H_3OCHO)_2]$ (X = Cl or Br), showed one signal at δ 9.9 and three signals in the region δ 7.80–7.24. The ratio of the area under the signals at δ 9.9 to those in the aromatic proton region is again 2:21, as expected for two aldehydic protons and 21 protons of phenyl and furan groups for the aforementioned compositions.

The IR spectra of the complexes $[RuX_2(MPh_3)(C_4H_3OCHO)_2]$ (X = Cl or Br; M = P or As) showed all the characteristic bands due to triphenylphosphine or triphenylarsine and furfural. A strong sharp band around 1605 cm^{-1} in the complexes may be due to ν(CO) of the furfural coordinated to the ruthenium [ν(CO) for free furfural is observed at 1700 cm^{-1}, which upon coordination is shifted to a lower frequency[15]]. A medium band at 326 cm^{-1} was observed for $[RuCl_2(PPh_3)(C_4H_3OCHO)_2]$, which was absent (no absorption in the region 400–250 cm^{-1}) in the case of $[RuBr_2(PPh_3)(C_4H_3OCHO)_2]$. This could be assigned to ν(Ru—Cl) of the complex. A strong band at 321 cm^{-1} was observed for $[RuCl_2(AsPh_3)(C_4H_3OCHO)_2]$, whereas a medium band at 318 cm^{-1} was observed for $[RuBr_2(AsPh_3)(C_4H_3OCHO)_2]$. The band in the case of the chloro compound could be assigned to a coupled vibration of ν(Ru—Cl) and characteristic vibrations due to triphenylarsine, whereas in the case of the bromo compound this band must be due to the vibration of the triphenylarsine molecule.[16]

$[RuBr_2(MPh_3)(C_6H_5CHO)_2]$ (M = P *or* As) *and* $[RuBr_2(CO)(PPh_3)_2]$

$[RuCl_2(MPh_3)(C_6H_5CHO)_2]$ (M = P or As) were reported earlier from our research group. Presently $[RuBr_2(MPh_3)(C_6H_5CHO)_2]$ (M = P or As) have been synthesized by the metathesis of chloride in $RuCl_3$ with LiBr, following a similar method as described earlier.[8] For the synthesis of $[RuBr_2(PPh_3)(C_6H_5CHO)_2]$ HBr was used in addition to $RuCl_3$, LiBr, PPh_3 and C_6H_5CHO, and n-butanol was used as a solvent. HBr was not required when ethanol was used as a solvent, similar to the preparation of its furfural analogue. In n-butanol the reaction took place at a higher temperature than in ethanol, which favoured the decarbonylation of benzaldehyde in the presence of PPh_3 leading to the formation of $[RuBr_2(CO)(PPh_3)_2]$. The addition of HBr (n-butanol as solvent) prevented decarbonylation, which may be due to the protonation of benzaldehyde. The ^1H NMR spectrum of $[RuBr_2(AsPh_3)(C_6H_5CHO)_2]$ in $CDCl_3$ showed one signal around δ 10.1 and two signals in the region δ 7.96–7.39. The proton signal around δ 10.1 is assigned to the aldehyde proton and the rest is due to the presence of the phenyl groups of benzaldehyde and triphenylphosphine or triphenylarsine. The ratio of the area under the signal around δ 10.1 and in the aromatic proton region is 2:25, thereby confirming the presence of two benzaldehyde and one PPh_3 or $AsPh_3$ molecules in the complex. The IR spectra of $[RuBr_2(MPh_3)(C_6H_5CHO)_2]$ (M = P or As) showed all the bands due to benzaldehyde and triphenylphosphine or triphenylarsine. Three bands of medium intensity at 1613, 1595 and 1575 cm^{-1} were observed, one of which could be due to ν(CO) of coordinated benzaldehyde.[8] The absence of any coordinated benzaldehyde group in $[RuBr_2(CO)(PPh_3)_2]$ is confirmed by IR and ^1H NMR spectra. The IR spectra show a strong and sharp band at 1935 cm^{-1} assignable to ν(CO) (terminal). A compound of the same molecular formula was reported by James *et al.*[17]

All the complexes discussed above show diamagnetic behaviour at room temperature, confirming a low-spin d^6 configuration of ruthenium(II). These complexes are non-electrolytic ($\Lambda_M \simeq 2$–$5\ \Omega^{-1}\ cm^2\ mol^{-1}$ in MeCN), thereby confirming covalent coordination of the halides with the metal ions.

Electronic spectra

The electronic absorption spectra of the complexes $[RuX_2(MPh_3)L_2]$ (L = C_4H_3OCHO, X = Cl or Br, M = P or As; L = C_6H_5CHO, X = Br, M = P or As) in chloroform show a general pattern of the three absorption bands; the first between 900 and 500 nm, the second between 500 and 400 nm and the third between 315 and 270 nm. Since the complexes are five-coordinate assuming an axial distortion from the octahedral geometry, the first and second absorption bands could be assigned to

$^1A_1 \rightarrow {}^1E$ and $^1A_1 \rightarrow {}^1A_2$ transitions, respectively.[18] The molar extinction coefficient for the second absorption band is of the order 10^3, which is higher than the *d–d* transition in second row transition metals. Hence, the band between 500 and 400 nm may have a contribution from the charge-transfer transition [ruthenium(II) → ligand], besides being due to $^1A_1 \rightarrow {}^1A_2$. In the case of $[RuCl_2(MPh_3)(C_4H_3OCHO)_2]$ (M = P or As), the band between 900 and 800 nm is characteristic of a penta-coordinated square pyramidal ruthenium(II) complex.[8,16] The third absorption band in the region 315–270 nm has a molar extinction coefficient of the order 10^4, which suggests it to be either a charge-transfer band or an allowed transition as observed in the ligand. The absorption at 270 nm in the case of $[RuBr_2(MPh_3)(C_4H_3OCHO)_2]$ (M = P or As) may be assigned to the $\pi \rightarrow \pi^*$ transition of the carbonyl group of the furfural molecules[19] and the absorption between 295 and 305 nm in the cases of $[RuCl_2(MPh_3)(C_4H_3OCHO)_2]$ (M = P or As) could be assigned to a combination of $\pi \rightarrow \pi^*$ of the furfural and ruthenium(II) → Cl charge-transfer transitions.

Catalytic activity of $[RuBr_2(PPh_3)L_2]$ (L = C_4H_3OCHO *or* C_6H_5CHO)

A reaction of PPh_3 with molecular oxygen took place in refluxing n-butanol in the presence of $[RuBr_2(PPh_3)L_2]$ (L = C_4H_3OCHO or C_6H_5CHO) to yield $OPPh_3$. Reactions were carried out by taking different molar ratios of catalyst : PPh_3 (1 : 5 to 1 : 20) (Table 3) and in all cases *ca* 80–90% of $OPPh_3$ was obtained. When a blank reaction without a catalyst was performed, no $OPPh_3$ could be isolated. $OPPh_3$ was characterized by carbon and hydrogen analyses, melting point determination and IR spectroscopy [a strong sharp band at 1190 cm^{-1} characteristic of $\nu(P{=}O)$ was observed[5]]. The complex isolated after the reaction using $[RuBr_2(PPh_3)(C_4H_3OCHO)_2]$ as a catalyst was analysed for $[RuBr_2(CO)(PPh_3)_2]$. The compound is the same as reported in the preceding part of the work. The mechanism of oxidation of PPh_3 by molecular oxygen using $[RuBr_2(PPh_3)L_2]$ (L = C_4H_3OCHO or C_6H_5CHO) may involve the loss of one aldehyde molecule in the first step, followed by the addition of one PPh_3 molecule. In the next step the addition of O_2 *cis to* the two PPh_3 molecules occurs, which is similar to that described by Graham *et al.*[20] An attempt to oxidize PPh_3 by molecular oxygen using $[RuCl_2(PPh_3)(C_4H_3OCHO)_2]$ as a catalyst was unsuccessful.

THIOETHER-LIGATED NICKEL. SYNTHESIS, X-RAY CRYSTAL STRUCTURE AND REDOX BEHAVIOUR OF COMPLEXES OF HEXADENTATE LIGANDS INCORPORATING THIOETHER AND TRIAZENE-1-OXIDE FUNCTIONS

SOMA KARMAKAR, SURANJAN BHANJA CHOUDHURY, DEBASHIS RAY and ANIMESH CHAKRAVORTY*

Department of Inorganic Chemistry, Indian Association for the Cultivation of Science, Calcutta 700 032, India

(*Received* 20 *August* 1992; *accepted* 29 *September* 1992)

Abstract—The hexadentate ligands $RN(O)NNHC_6H_4S(CH_2)_3SC_6H_4NHN(O)NR$ (H_2L^1: R = Me; H_2L^2: R = Pr^n; general abbreviation H_2L) and their nickel(II) complexes, [NiL^1] and [NiL^2], have been synthesized. The X-ray structure of [NiL^1] has revealed the presence of a severely distorted $NiN_2O_2S_2$ coordination sphere with longer than normal Ni—S distances: 2.494(4) and 2.526(3) Å. The low symmetry of the ligand field is reflected in large splittings of octahedral ν_1 and ν_2 bands. In dichloromethane solution the nickel(III)–nickel(II) redox couple is observable cyclic voltammetrically and the $E_{1/2}$ values are: [NiL^1] = 0.74 and [NiL^2] = 0.75 V (vs SCE). Frozen (77 K) solutions of the electrogenerated nickel(III) species display rhombic EPR spectra: $g_1 = 2.195$, $g_2 = 2.145$, $g_3 = 2.038$ for [NiL^1]$^+$; $g_1 = 2.199$, $g_2 = 2.138$, $g_3 = 2.035$ for [NiL^2]$^+$. The g_1 and g_2 parameters for each complex can be considered as split components of $g_\perp$ of the idealized geometry affording the inequality $g_\perp > g_\parallel$, which corresponds to an effective axial elongation and $(d_{z^2})^1$ ground state.

An isolated thioether function is a poor coordinating agent[1] for bivalent nickel. However, macrocyclic ligation can stabilize the nickel(II)-thioether binding and a number of complexes of this type have been characterized.[2,3] Such stabilization should in principle be achievable also in the case of polydentate acyclic ligands which can achieve multiple chelation. This work forms part of our programme[4–6] on the use of this strategy for synthesizing stable complexes of nickel(II) derived from acyclic chelators incorporating the thioether function. A pair of new hexadentate ligands having thioether and triazene-1-oxide functions have been synthesized and these have afforded stable nickel(II) complexes of the coordination type $NiN_2O_2S_2$. The X-ray structure of one of these is reported. There is a large distortion of the coordination sphere from idealized octahedron and this is also reflected in large splittings of ligand field bands. The complexes are electroactive due to metal redox and the EPR spectra of nickel(III) congeners generated in solution are reported. The binding of redox-active nickel-to-sulphur ligands is of bioinorganic interest.[7,8]

EXPERIMENTAL

Materials

Commercially available reagents were used for the synthesis of ligands and complexes. 1,3-Bis(2-aminophenylthio)propane was prepared following a reported method.[9] The N-methyl- and N-*n*-propylhydroxylamines were prepared by the reduction of the corresponding nitro compounds with zinc dust and ammonium chloride in neutral aqueous medium.[10] The preparation of tetraethylammonium perchlorate (TEAP) and purification of dichloromethane for electrochemical/spectroscopic work were performed as before.[11]

Physical measurements

Microanalytical data (carbon, hydrogen, nitrogen) were obtained with a Perkin–Elmer model 240C elemental analyser. Electronic and IR spectra were recorded with Hitachi model 330 and Perkin–Elmer model 783 IR spectrophotometers, respectively. Electrochemical measurements were performed using the PAR model 370-4 electrochemistry system as before[12] and all potentials are referenced to SCE. Magnetic susceptibilities were measured on a PAR-155 vibrating-sample magnetometer fitted with a Walker Scientific magnet. The EPR spectra were recorded in the *X*-band with a Varian E-109C spectrometer fitted with a quartz Dewar flask for measurements at 77 K (liquid nitrogen) and diphenylpicrylhydrazyl (dpph) ($g = 2.0037$) was used for their calibration.

Synthesis of the ligands

The ligands H_2L^1 and H_2L^2 are synthesized as pale yellow solids by the reaction of diazotized amines with the hydroxylamines. Details are given for the representative case of H_2L^1, 1,3-bis[*o*-(1-methyltriazene-1-oxido)phenylthio]propane. 1,3-Bis(2-aminophenylthio)propane (3.50 g) taken in concentrated HCl (8 cm^3) and water (8 cm^3) was diazotized at 0°C with $NaNO_2$ (1.7 g) dissolved in water (10 cm^3). The diazotized solution was added with stirring to N-methylhydroxylaminehydrochloride (2.05 g) in water (40 cm^3) cooled to 0°C. The pH of the reaction mixture was kept in the range 3–5 by gradual addition of an aqueous solution (50 cm^3) of sodium acetate (12 g). The solution was stirred for 20 min. After the addition of diazonium salt solution was completed, the solid ligand separated out. This was filtered and recrystallized from alcohol to yield pale yellow needles. Yield: 70%. Found: C, 50.2; H, 5.4; N, 20.6. Calc. for $C_{17}H_{22}N_6O_2S_2$: C, 50.3; H, 5.4; N, 20.7%. The ligand H_2L^2 was synthesized similarly in 65% yield. Found: C, 54.5; H, 6.4; N, 18.2. Calc. for $C_{21}H_{30}N_6O_2S_2$: C, 54.6; H, 6.5; N, 18.2%.

Synthesis of the complexes

The same general procedure was followed for both the complexes. Details are given for $[NiL^1]$. An aqueous solution of nickel(II) acetate tetrahydrate (250 mg, 1.0 mmol) was added to a hot ethanol solution of H_2L^1 (400 mg, 1.0 mmol). The mass was then refluxed for 30 min and on concentration, a pale brown crystalline compound separated out. The complex was washed with cold alcohol and water and dried *in vacuo* over P_4O_{10}. Yield: 70%. Found: C, 44.1; H, 4.3; N, 18.1. Calc. for $C_{17}H_{20}N_6O_2S_2Ni$: C, 44.1; H, 4.3; N, 18.1%.

The complex $[NiL^2]$ was synthesized similarly in a 73% yield. Found: C, 48.5; H, 5.4; N, 16.1. Calc. for $C_{21}H_{28}N_6O_2S_2Ni$: C, 48.6; H, 5.4; N, 16.2%.

X-ray structure determination

Single crystals of $[NiL^1]$ were grown by slow diffusion of hexane into a dichloromethane solution. Cell dimensions were obtained by the least-squares refinement of diffractometer angles of 30 automatically centred reflections. Data were collected at 296 K on a Nicolet R3m/V diffractometer with graphite monochromated Mo-K_α ($\lambda = 0.71073$ Å) radiation in the ω–2θ scan mode. Two check reflections measured after every 98 reflections showed no significant variations. Lorentz and polarization corrections were followed by semi-empirical absorption correction on the basis of azimuthal scans.[13] The structure was solved by direct methods

and was refined by full-matrix least-squares procedures. All the non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included at the calculated positions in the final refinement cycle with isotropic thermal parameters (0.08 Å^2). Crystal data and other details are collected in Table 1. Computations were carried out on a MicroVAX II computer using the SHELXTL-PLUS program system.[14]

Tables of atomic coordinates, anisotropic thermal parameters, full listing of bond lengths and angles, and observed and calculated structure factors are available as supplementary material from the Editor.

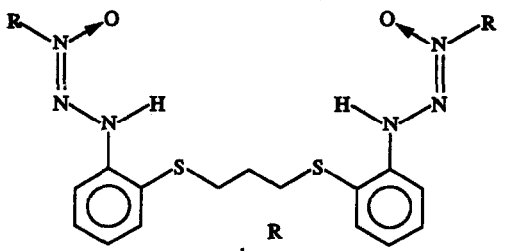
RESULTS AND DISCUSSION

Synthesis and characterization

Triazene-1-oxides can be generated[15] by coupling a diazotized aromatic amine with a substituted hydroxylamine, eq. (1).

$$ArN_2^+ + RNHOH \longrightarrow RN(O){=}NNHAr + H^+ \quad (1)$$

The hexadentate ligands (**1**) utilized in the present work are H_2L^1 and H_2L^2 (general abbreviation



(1)

H_2L). These were prepared as pale yellow solids in good yields by reacting N-methyl- or N-*n*-propylhydroxylamine (2 mol) with a fully diazotized solution of the diamine 1,3-bis(2-aminophenylthio)propane. The H_2L ligands react with nickel(II) acetate in aqueous ethanol affording brown crystalline complexes of the type [NiL]. Selected characterization data are given in Table 2.

The complexes behave as two-electron paramagnets. In dichloromethane solution four relatively weak bands/shoulders are observed in the region 500–1500 nm. The two bands at ~ 1400 nm and ~ 1000 nm are assigned to the octahedral ν_1 transition split by low symmetry ligand field components. Similarly, the absorptions at *ca* 650 and 500 nm are attributed to split components of the ν_2 transition. The relatively large magnitudes of these splittings (3000–5000 cm^{-1}) are indicative of a severe distortion of the coordination sphere and this is in agreement with the X-ray structure of [NiL^1] reported below. The expected ν_3 transition is not observable due to the presence of other intense bands in the UV region. Two characteristic vibrations[16] of the triazene-1-oxide chelate ring corresponding to the N_3 and NO moieties are observed in the present complexes (Table 2).

X-ray structure of [NiL^1]

The lattice consists of discrete hexa-coordinated molecules. A perspective view is shown in Fig. 1 and a selected list of bond parameters is collected in Table 3. The thioether sulphur atoms are ligated to the metal, affording the coordination sphere $NiN_2O_2S_2$. Angular distortions from formal octahedral symmetry are large. For example, the angles S(1)—Ni—O(1), 156.9(2)°, and S(2)—Ni—O(2), 156.7(2)°, fall far short of 180°. The angles at the metal between atoms coordinated in *cis* positions span a wide range, 76.7(3)–106.6(3)°.

In conformity with the triazene-1-oxide formulation (—N(O)=N—N—) of the coordinated ligand N(1)—N(2) and N(5)—N(6) distances—

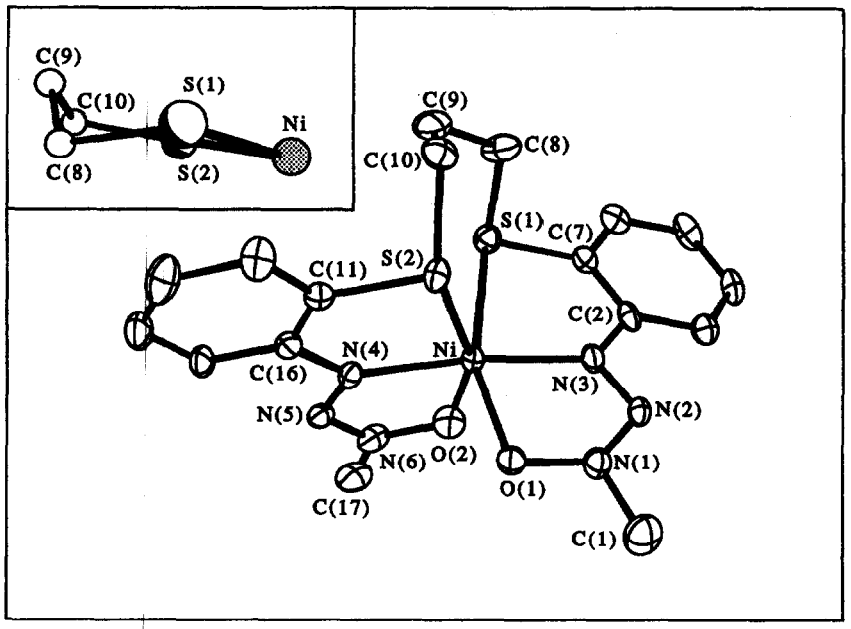

Fig. 1. Perspective view and atom labelling scheme of [NiL^1]. Atoms are shown as 50% thermal probability ellipsoids. The inset shows the half-chair conformation of the Ni—S(1)—C(8)—C(9)—C(10)—S(2) ring.

1.264(13) and 1.268(13) Å—are shorter than the N(2)—N(3) and N(4)—N(5) distances—1.307(12) and 1.332(12) Å. The ligand anionic charge primarily resides on N(3) and N(4). This is reflected in the Ni—N distances [1.984(8) and 1.993(8) Å] being significantly shorter than the Ni—O distances [2.075(8) and 2.060(7) Å].

In known nickel(II)-thioether complexes the Ni—S distances span the range 2.39–2.44 Å.[4,5,17] The sum of ionic radii has been estimated to be 2.44 Å.[1] An unusual feature of the present complex is that the Ni—S distances lie outside the above range, 2.494(4) and 2.526(4) Å. The nickel(II)–thioether bonds in [NiL^1] appear to be weaker than normal.

All the five-membered chelate rings are nearly perfectly planar (mean deviations 0.002–0.02 Å), except the ring incorporating S(1) which is moderately planar (mean deviation 0.09 Å). The six-membered NiS_2C_3 ring can be considered as a half-chair (inset in Fig. 1).

Table 3. Selected bond distances (Å) and angles (°)[a] for NiL^1

(a) Cyclic voltammogram (scan rate 50 mV s^{-1}) of 10^{-3} mol dm^{-3} solutions of [NiL^1] (——) and electro-generated (298 K) [NiL^1]$^+$ (– – –) in dichloromethane (0.1 mol dm^{-3} NEt_4ClO_4) at a platinum electrode at 298 K. (b) *X*-band (9.11 GHz) EPR spectrum of [NiL^1]$^+$ in frozen (77 K) dichloromethane.

Electrochemistry

In dichloromethane solution [NiL] displays a quasi-reversible cyclic voltammetric response near 0.7 V (vs SCE), see Fig. 2. The voltammogram is assigned to the metal redox couple of eq. (2).

$$[Ni^{III}L]^+ + e \rightleftharpoons [Ni^{II}L] \qquad (2)$$

The one-electron nature of the couple is revealed by constant potential (1.04 V) coulometry. The $E_{1/2}$ values and coulometric data are collected in Table 4. Among currently known nickel complexes incorporating thioether sulphur bonding, the nickel (III)–nickel(II) reduction potentials span the range 0.3–0.8 V[4–6,18] and the $E_{1/2}$ values of the present complexes lie at the higher end of this range.

We have not succeeded in isolating [NiL]$^+$ as pure salts, but coulometrically generated (258–298 K) brown solutions of [NiL]$^+$ have the same voltammogram (initial scan cathodic) as the cor-

[f] In frozen (77 K) dichloromethane solution.

responding nickel(II) parent (initial scan anodic), see Fig. 2. Upon coulometric reduction (0.4 V) of the oxidized solutions, the original [NiL] complex is regenerated. It is, therefore, logical to assume that there is no gross structural change upon metal redox and the $NiN_2O_2S_2$ coordination is retained in the oxidized complex $[NiL]^+$.

EPR spectra of $[NiL]^+$

That the oxidized complexes indeed contain trivalent nickel has been confirmed by EPR spectra of frozen (77 K) electro-oxidized solutions. The spectrum of $[NiL^1]^+$ is shown in Fig. 2 and g values are listed in Table 4. The spectra (all gs > 2) are compatible with low-spin trivalent nickel (d^7, $S = 1/2$).[4,19–21]

Due to the low symmetry of the $NiN_2O_2S_2$ coordination sphere the spectra are as expected rhombic. If g_1 and g_2 are considered to be split components of $g_\perp$, the axial limit of the spctrum is defined by $g_\perp = 1/2(g_1+g_2)$ and $g_\parallel = g_3$. In this formalism the $[NiL]^+$ complexes belong to the type $g_\perp > g_\parallel$, which corresponds to an effective axial elongation, $(d_{z^2})^1$ ground state.[19,20]

CONCLUSIONS

The hexadentate ligand system H_2L, incorporating triazene-1-oxide and thioether functions, binds nickel(II) affording [NiL], in which the $NiN_2O_2S_2$ coordination sphere is severely distorted. The Ni—S(thioether) bond is longer than normal and the ligand field bands display large splittings. Oxidation to the nickel(III) congener $[NiL]^+$ is electrochemically achievable. The frozen solution EPR spectrum of $[NiL]^+$ is rhombic with the ground state (d_{z^2}).[1]

Abstract—The monomeric compound bis[(carbonyl)(quinoline-2-thiolate-N,S)]iron(II) was synthesized and studied by IR and Mössbauer spectroscopy, cyclic voltammetry and X-ray diffraction. The molecule has two terminal carbonyl groups and two quinoline-2-thiolate anions coordinated as N,S-donor chelates, and the iron atom shows an octahedral coordination geometry.

The first reaction of a metal carbonyl with an amine N-oxide was described[1] in 1959. Since then, notably in the last few years, there has been an increase in the use of trimethylamine N-oxide (TMNO) as a reagent to induce decarbonylation.[2–5] Such promoted decarbonylation reactions constitute an interesting alternative synthetic route to novel or known molecules, and in this paper we report the one-pot synthesis of the mononuclear compound $[Fe(qnS)_2(CO)_2]$ (qnS = quinoline-2-thiolate), which was subjected to a full IR, Mössbauer, cyclic voltammetry and X-ray crystallographic characterization. There are two main reasons for carrying out this work. First, considerable interest has been demonstrated during the past few years in compounds containing heterocyclic thiols as ligands, stemming from the similarity of these ligands with thiolated nucleosides. Secondly, several coordination possibilities[6] have been observed for the heterocyclic ligand employed in this study. Indeed, depending upon reactions conditions, such as pH, it can coordinate to the metallic centre as the free ligand (qnSH) or as the conjugated base (qnS^-) and in this last case it can act as a monodentate N- or S-bonded ion, or as an N,S-donor chelate or bridging anion.

EXPERIMENTAL

Synthesis of $[Fe(qnS)_2(CO)_2]$

All operations involved in the synthesis, except the weighings, were performed in an atmosphere of purified nitrogen in a Schlenk apparatus. A solution containing 2-quinolinethiol (0.8 g, 5 mmol) and trimethylamine N-oxide (0.6 g, 5.5 mmol) dissolved in ethanol (15.0 cm^3) was added dropwise to a solution of $[Fe(CO)_5]$ (0.6 cm^3, 4.56 mmol) in ethanol (3 cm^3). The mixture was stirred for 2 h and the brown solid obtained was filtered off, washed with ethanol and ether and dried *in vacuo*. Recry-

* Author to whom correspondence should be addressed.

stallization from ethanol gave brown crystals suitable for X-ray analysis. The elemental analysis results were in agreement with the proposed formula.

IR spectrum

The IR spectrum of the title compound was measured as a Nujol mull between CsI plates on a Nicolet 730-FT spectrophotometer.

Mössbauer spectrum

The Mössbauer spectrum was obtained at room temperature and 85 K in the standard transmission geometry with a Wiss-El transducer. The source employed was ^{57}Co in rhodium. The sample was kept *in vacuo* in order to avoid oxidation during the measurements. The lines were fitted with Lorentzians without constraining any parameter and the isomer shift was made relative to metallic iron.

Electrochemical measurements

The electrochemical measurements were carried out under nitrogen at 25°C. The cyclic voltammograms and the coulometric investigation were performed with a PAR model 273 Potentiostat–Galvanostat in conjunction with a Hewlett–Packard 7090A *X–Y* recorder. All experiments were performed using a conventional three-electrode cell. A platinum disc was used as the working electrode in cyclic voltammetry and a platinum gauze was used as the working electrode in the controlled potential electrolysis. The reference electrode was Ag/Ag^+ (10^{-2} M), 0.5 M $NaClO_4$ (supporting electrolyte) in acetonitrile, which was purified by standard methods used in electrochemical studies. The auxiliary electrode was a platinum wire.

Crystal structure determination of $[Fe(qnS)_2(CO)_2]$

A crystal of the title compound was mounted on an Enraf–Nonius CAD4 diffractometer. Using graphite monochromated Mo-K_α radiation, unit cell parameters (by automatic centring of 25 reflections) and intensity data were obtained. Table 1 gives the data collection and refinement conditions. The data were corrected for Lorentz and polarization effects and for absorption [μ(Mo-K_α) = 9.94 cm^{-1}]. The structure was solved by the Patterson method.[7] The refinement was by full-matrix least-squares.[8] The hydrogen atoms were placed at their calculated positions (C—H 1.08 Å) and allowed to ride on their respective carbon atoms. Scattering factors for the non-hydrogen atoms were taken from Cromer and Mann[9] with an anomalous dispersion correction from Cromer and Liberman[10] and for hydrogen atoms from Stewart *et al.*[11] Lists of atomic parameters, tables of bond lengths and angles, observed and calculated structure factors and anisotropic thermal parameters have been deposited with the Editor as supplementary material.

RESULTS AND DISCUSSION

Among the cyclic molecules showing the tautomeric forms —NH—C(X)— $\rightleftharpoons$ —N=C(XH)— (X = O or S) are relevant biological compounds and sulphur ligands as thiols.[12] Taking into account both the important aspects of the coordination chemistry of the thiols as well as the synthetic potentialities of decarbonylation reactions induced by trimethylamine N-oxide, we performed the reaction of $[Fe(CO)_5]$ with quinoline-2-thiol (qnSH), which afforded the microcrystalline compound $[Fe(qnS)_2(CO)_2]$. The new compound was found to be quite stable in the atmosphere. Some important points emerged from the analysis of the IR spectrum[13] of this complex. First, only two ν(CO) stretching bands were observed at 2030s and 1969vs cm^{-1}. Secondly, when a comparison was made with the IR spectrum of the free ligand, no bands assignable to ν(NH) (3500–3200 cm^{-1}) or ν(SH) (2500–2400 cm^{-1}) modes were detected. These facts allowed us to conclude that only CO terminal groups are present and furthermore that the heterocyclic ligand is coordinated to the iron atom in a deprotonated form.

In order to better elucidate these aspects related to the geometry around the iron atom and the metal oxidation state, we made use of Mössbauer spectroscopy. The Mössbauer spectrum of the title compound consisted of a single quadrupole splitting. The small quadrupole splitting observed, $QS = 0.51$ mm s^{-1}, is typical of iron complexes with an octahedral structure. In addition the isomer shift value, $IS = 0.07$ mm s^{-1}, is similar[14] to those of other low-spin iron(II) compounds

It is instructive at this point to relate the preceding results with those of the electrochemical investigation. The electrochemical oxidation of $[Fe(qnS)_2(CO)_2]$ was studied by cyclic voltammetry and controlled potential electrolysis in 0.5 M $NaClO_4$ (acetonitrile). Figure 1 shows the cyclic voltammogram for the compound, obtained on a platinum electrode at a potential scan rate $v = 50$ mV s^{-1} and 25°C. In the range from −0.20 to +1.0 V (vs Ag/Ag^+) only one anodic current peak is observed at +0.83 V, independent of the scan rate. This result suggests that at this potential the iron(II) → iron(III) oxidation probably occurs, pro-

ducing a non-electrochemically active species.[15] The number of electrons obtained from the controlled potential electrolysis was one, supporting the proposal of an iron(II) → iron(III) oxidation. The cyclic voltammogram after exhaustive electrolysis at the anodic potential peak showed the disappearance of this peak. The electrochemical behaviour of $[Fe(qnS)_2(CO)_2]$ was described as one-electron oxidation, with an irreversible electrochemical reaction on the platinum electrode.

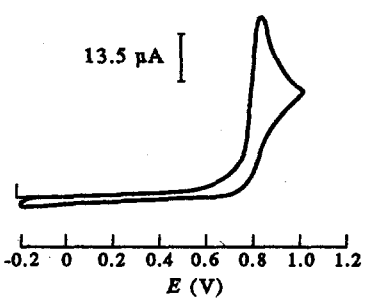

Fig. 1. Cyclic voltammogram for $NaClO_4$ (0.5 M) in acetonitrile solution with $[Fe(qnS)_2(CO)_2]$ (1.0×10^{-3} M) at a platinum electrode, 25°C and $v = 50$ mV s^{-1}.

The monomeric nature of the compound and the important structural features suggested by IR and Mössbauer spectroscopies and supported by its electrochemical behaviour were definitely proved by the crystal and molecular structural X-ray analysis. The structure of the compound with the labelling scheme is presented in Fig. 2. Selected bond lengths and angles are given in Table 2. Two carbonyl groups and two quinoline-2-thiolate anions coordinated as N,S-donor chelates achieve a slightly distorted octahedral environment about the iron atom. The average Fe—C and C—O distances, 1.778(6) and 1.122(8) Å, respectively, and the average Fe—C—O angle, 177.5(6)°, are in agreement with the average values[16,17] observed in other iron carbonyl compounds.

In addition, inspection of the polyhedra around the iron atom showed that the carbonyl groups are disposed in a *cis* arrangement with the angle C(A)—Fe—C(B) being 92.3(3)°. Moreover, the influence of the atom in a *trans* position to the carbon atoms on Fe—C distances can be clearly verified since the bond length *trans* to nitrogen [Fe—C(A) = 1.768(6) Å] is shorter than the one *trans* to sulphur [Fe—C(B) = 1.788(6) Å]. Fur-

thermore, the angles C(1)—N(1)—C(9) and C(11)—N(11)—C(91) of 119.8(4)° and 119.7(4)°, respectively, are within the range expected for deprotonated N-heterocycles[18] and demonstrate that the chelates (qnS) are effectively deprotonated.

Finally, it is important to note the advantages of the synthetic strategy adopted in this work, due to the fact that the reactions of iron pentacarbonyl with nitrogen-based ligands usually lead to iron disproportionation to ferrous complexes and groups of ferrate ions, depending on the base and the reactions conditions.[19] Accordingly, the present procedure relies on the formation of NMe_3 from the decarbonilating TMNO. This strong base is effective for *in situ* deprotonation reactions such as those involved in the formation of $[Fe(qnS)_2(CO)_2]$. Other syntheses are being carried out in order to extend this preparative route to a wide class of nitrogen and phosphorus based ligands.

(*Received* 31 *July* 1992; *accepted* 10 *September* 1992)

Abstract—The complexes [MoO_2Cl_2(Bu^t-dab)], [WO_2Cl_2(Bu^t-dab)] (Bu^t-dab = N,N′-di-t-butyl-1,4-diaza-1,3-butadiene), [MoO_2Cl_2(dmp)] and [WO_2Cl(dmp)] (dmp = N,N′-dimethylpiperazine) have been prepared and characterized by IR, Raman, ^{1}H and ^{13}C NMR spectroscopy. [MO_2Cl_2(dmp)] (M = Mo, W) has *cis*-dichloroligands and [MoO_2Cl_2(dmp)] shows fluxional behaviour of the coordinated ligand in CH_2Cl_2 solution, as monitored by ^{1}H NMR spectroscopy. The structures of [MoO_2Cl_2(tmen)] (tmen= N,N,N′,N′-tetramethylethylenediamine) and [MoO_2Cl_2(Bu^t-dab)] are reported. Both compounds are built up of discrete molecules with distorted octahedral geometry and *cis*-dioxoligands, the former having the unusual *cis*-dichloro and the latter the common *trans*-dichloro arrangement. MoO_2Cl_2(tmen) has Mo=O distances of 1.681(4) and 1.697(4) Å with an O—Mo—O angle of 103.1(2)°. The *trans* influence of the oxo-ligands is shown by two different Mo—Cl distances [2.449(2) Å *trans* to O and 2.338(2) Å *trans* to N] and two different Mo—N distances [2.464(4) Å *trans* to O and 2.278(4) Å *trans* to Cl]. MoO_2Cl_2(Bu^t-dab) has an Mo=O distance of 1.688(3) and an O—Mo—O angle of 104.5(2)°. The *trans*-dichloro ligands have equal distances to molybdenum, *d*(Mo—Cl) = 2.356(1) Å. The Mo—N distances of the nitrogen atoms *trans* to the oxo groups are 2.399(2) and 2.388(2) Å.

The syntheses of catalytically active alkylidene and alkylidyne complexes,[1,2] of importance in industrial processes such as the olefin metathesis reaction and ring opening polymerization, have recently initiated large interest in the chemistry of high valent molybdenum and tungsten complexes. Moreover, molybdenum complexes containing the *cis*-dioxomolybdenum(VI) cation, $[MoO_2]^{2+}$, coordinated to ligands containing nitrogen, oxygen and/or sulphur donors, are intensely investigated because such complexes are proposed as model compounds for the active site in a number of oxo-transfer molybdato enzymes.[3,4] We are currently studying high valent molybdenum and tungsten complexes in relation to the olefin metathesis reaction and we have recently described the synthesis and structure of [WO_2Cl_2(tmen)] (tmen = N,N,N′,N′-tetramethylethylenediamine).[5] This complex was found to be structurally unique among known octahedral [$WO_2X_2L_2$] complexes (X = anionic ligand and L = neutral ligand) in that the configuration of the ligating atoms O, X = Cl, L = N around the tungsten atom is all-*cis* and not the commonly en-

* Author to whom correspondence should be addressed.

countered *cis,trans,cis* of O, X, L. $[MoO_2Cl_2(tmen)]$ was also prepared in that study and found to be isostructural to its tungsten analogue, but a lack of suitable crystals precluded an X-ray structure determination. Despite the very large number of structurally known octahedral molybdenum complexes derived from $[MoO_2]^{2+}$ with different kinds of mono- to tetradentate ligands there seems to be only one additional example[6] with an all *cis* configuration, the ligand in that case being a dianionic tetradentate ligand of the Schiff base type, X = O, L = N.

A less repulsive interligand interaction, i.e. chlorine–N-methyl interaction, in an all *cis* configuration as compared to a hypothetical *cis,trans,cis* configuration was the suggested reason for the unusual all *cis* arrangement of the ligands in both $[MoO_2Cl_2(tmen)]$ and $[WO_2Cl_2(tmen)]$. To test this hypothesis of interligand repulsion as a factor governing the coordination geometry of MO_2Cl_2 complexes (M = Mo and W) we have performed further studies using bidentate N-donor ligands by varying the steric demands of the ligands along two lines. Firstly, using N,N′-dimethylethylenediamine (dmed) with two methyl groups less than tmen or N,N′-dimethylpiperazine (dmp), where the two methyls are replaced by two methylene groups, might lead to a reduced steric bulk, which could cause a structural change to a *trans*-dichloro arrangement. However, our attempts to prepare complexes with dmed as the ligand have been unsuccessful, giving analytically impure products most probably because of aminolysis as a side-reaction. Secondly, 2,2′-bipyridyl (bipy) and *o*-phenanthroline (*o*-phen) are the bidentate N-donor ligands often used. These are known to form *cis,trans,cis* configurated complexes $[MO_2X_2(L_2)]$ (M = Mo, W; L_2 = bipy or *o*-phen) in which these ligands are close to planar.[7–14]

The question raised in relation to ligands such as e.g. bipy was if the introduction of sterically bulky groups in the 3,3′ position of bipy would lead to all *cis* configurated complexes. N,N′-disubstituted 1,4-diaza-1,3-butadienes, R—N=CH—CH=N—R (R-dab), are easily accessible ligands related to 3,3′-disubstituted bipy. Such ligands have been widely applied to the stabilization of low-valent metal complexes,[15] but rarely used for high-valent ones.[16,17] In fact, no molybdenum(VI) or tungsten(VI) complex containing R-dab is reported in the literature. Due to their bulkiness R-dab ligands are known to alter stabilities and the structures of R-dab metal complexes relative to their bipy- and *o*-phen analogues.[18] Bu^t-dab was considered as an obvious choice for a sterically demanding R-dab ligand since the tert-butyl groups introduce bulkiness perpendicular to the plane of the N=C—C=N skeleton. In this report we present the X-ray structures of $[MoO_2Cl_2(tmen)]$ (**1**) and $[MoO_2Cl_2(Bu^t\text{-dab})]$ (**2**) and the spectroscopic characterization of **2**, $[WO_2Cl_2(Bu^t\text{-dab})]$ (**3**), $[MoO_2Cl_2(dmp)]$ (**4**) and $[WO_2Cl_2(dmp)]$ (**5**).

RESULTS AND DISCUSSION

Synthesis and general characteristics of the complexes

The synthesis and characterization of complex **1** have been described earlier[5] and the same general preparative principles have been used here. Thus, the new compounds **2–5** were synthesized in a straightforward way from the corresponding dme complexes and a slight excess (5%) of the ligand, by dme/ligand exchange. For complexes **2** and **3** the reactions were performed in CH_2Cl_2 at room temperature, but for complexes **4** and **5** the temperature must not exceed 0°C otherwise extensive decomposition to insoluble and untractable products occurs. The molybdenum complexes **2** and **4** were also prepared by direct reaction between molybdenum dioxodichloride and the corresponding ligand. The tungsten complex **3** was additionally synthesized from $WOCl_4$, $O(SiMe_3)_2$ and Bu^t-dab, as described for the preparation of $[WO_2Cl_2(dme)]$[20] and $[WO_2Cl_2(bipy)]$.[8]

All the complexes (**1–5**) are susceptible to hydrolysis. For a given metal the hydrolytic stability decreases in the following order: Bu^t-dab > tmen ≫ dmp. The bipy complexes, $[MO_2Cl_2(bipy)]$ (M = Mo, W), are indefinitely air-stable;[8] **2** is at least 3 days stable as the present X-ray structure determination performed in air proves, but the dmp complexes **4** and especially **5** are rather sensitive and should be kept under inert gas in the freezer (−30°C). Furthermore, complexes **4** and **5** are light-sensitive showing a grey–blue colour after some days exposure to daylight, therefore, no acceptable Raman spectrum of **5** could be obtained.

Description and discussion of the structures of $[MoO_2Cl_2(tmen)]$ (**1**) *and* $[MoO_2Cl_2(Bu^t\text{-dab})]$ (**2**)

Views of the molecules **1** and **2** with atomic numbering are shown in Figs 1 and 2, respectively. Selected bond distances and angles are given in Table 1.

The bond distances and angles of **1** are close to those of the isostructural tungsten complex $[WO_2Cl_2(tmen)]$, as is also the case in the isostructural complexes $[MO_2Cl_2(dme)]$ (M = Mo,[19]

W[20]). This is not surprising in view of the very small difference between molybdenum and tungsten in their atomic and covalent radii.[21]

Both **1** and **2** have a distorted octahedral arrangement of the six ligand atoms around the molybdenum centre with *cis*-dioxo ligands, as is commonly found in other d^0 six-coordinated dioxo-complexes.[22] There is no significant difference in molybdenum–oxygen distances between complexes **1** and **2** and their O=Mo=O angles differ by only 1.4°, which emphasizes the structural rigidity of the MO_2^{2+} moiety when no competing π-donors are present *trans* to the oxo ligands. The mean Mo=O distances of **1** (1.689 Å) and **2** (1.688 Å) are close to the average value of 1.704 Å reported for a wide range of molybdenum dioxo-complexes.[22]

With respect to the overall geometry the two compounds differ in that MoO_2Cl_2(tmen) (**1**) has *cis*-dichloro ligands as its tungsten analogue,[5] but MoO_2Cl_2(Bu^t-dab) (**2**) has *trans*-dichloro ligands. Consequently, each of the two nitrogen atoms and each of the two chlorine atoms in complex **1** have different *trans* ligands, while in complex **2** both nitrogen and both chlorine atoms have one kind of *trans* ligand, oxo and chloro respectively. The *trans* influence of the multiply bonded oxo ligands in **1** is demonstrated by longer molybdenum–nitrogen and molybdenum–chlorine distances *trans* to oxo; Mo—N(1), 2.464(4) Å, as compared to Mo—N(2), 2.278(4) Å, and Mo—Cl(1), 2.449(2) Å, as compared to Mo—Cl(2), 2.338(2) Å. Thus, the *trans*-lengthening effect of O(1) relative to Cl(2) on the molybdenum nitrogen distances is 0.186 Å and of O(2) relative to N(2) on the molybdenum chlorine distances is 0.111 Å, which compares well with the *trans*-lengthening observed in the tungsten analogue.[5] The molybdenum–chlorine distance in **2**, 2.356(1) Å, is similar to that in other dioxo-dichloromolybdenum complexes with *trans*-chloro ligands,[7,19,23–27] while the Mo—Cl(2) distance in **1** *trans* to N(2), 2.278(4) Å, is shorter. Thus, the relative *trans* influence of the donors on the molybdenum–chlorine bond follows the order: $O^{2-} > Cl^- > N$.

A comparison of the molybdenum–nitrogen distances *trans* to oxo in complex **2** [2.399(2) and 2.388(2) Å] and in complex **1** [2.464(4) Å] reveals that they are significantly shorter in the former than in the latter. The higher degree of alkyl substitution and the sp^3 hybridization of the nitrogen atoms in tmen imply a higher basicity and donor ability of tmen relative to Bu^t-dab; taking only donor strength arguments into consideration shorter molybdenum–nitrogen distances could, therefore, be expected in the tmen complex **1**. The alkyl substituents of tmen increase its steric bulk leading to repulsive interligand interactions in the complex, which may hamper the aforementioned bond strengthening inductive effect. The full donor capacity of the tmen ligand might therefore not be reflected in the Mo—N(1) bond distance.

Our motive for preparing **2** was to see if the use of the Bu^t-dab ligand with the two bulky t-butyl groups would result in the formation of an all *cis* configurated $MO_2Cl_2L_2$ complex. Despite the bulkiness of the ligand the configuration around the molybdenum atom in **2** is, however, the commonly encountered *cis,trans,cis*. The nitrogen atoms N(1) and N(2), the carbon atoms C(1) and C(2) of the five-membered metallacycle, the tertiary carbon atoms C(3) and C(6) and one of the methyl carbon atoms in each tertiary butyl group, C(4) and C(7), all lie in the plane of the molybdenum atom and the oxo ligands (Fig. 2). C(4) and C(7) are directed away from the MoO_2 moiety. This particular conformation of Bu^t-dab is adopted because here the distances between the methyl and the oxo groups are maximal: 3.250(4) and 3.272(5) Å for O(1)···C(5) and O(2)···C(8), respectively. Considering the sum of the van der Waals' radii of oxygen and carbon which is approximately 3.25 Å,[21] any rotation of the methyl groups around C(6)—N(2) or C(3)—N(1) would lead to methyl–oxygen repulsion. Molecule **2** has C_s symmetry very close to C_{2v}. The chlorine atoms in **2** are bent towards the Bu^t-dab ligand resulting in a Cl—Mo—Cl angle of 156.6°, a deviation from linearity commonly encountered in MoO_2^{2+} complexes and caused by the high π-electron density in the two Mo=O bonds.[13]

Since the *o*-phen ligand can formally be regarded as a bis-imine ligand, [MoO_2Cl_2(*o*-phen)] is a complex of MoO_2Cl_2 closely related to complex **2**. Comparing the $MoO_2Cl_2N_2$ cores of these two molecules shows that in complex **2** the mean Mo—N distance, 2.393 Å, is much larger than that in [MoO_2Cl_2(*o*-phen)], 2.308 Å.[7] The mean M=O distance is slightly longer in the *o*-phen complex, 1.695(3) Å, than in complex **2**, 1.688 Å. These differences may arise from the π-donor/π-acceptor properties of the two ligands *o*-phen and Bu^t-dab: 1,4 diaza-1,3-butadienes like Bu^t-dab are known to be exceptionally good π-acceptors and consequently weaker π-donors compared to *o*-phen,[18,28] and π-donation from *o*-phen into empty *d*-orbitals of molybdenum(VI) reduces the electrophilicity of the metal centre. This in turn reduces to some extent the π-donation from the oxo ligands to molybdenum. Thus, the Mo=O bond is weakened and the Mo—N bond strengthened relative to the case of the Bu^t-dab ligand, as reflected in the metal–ligand bond lengths in the two complexes. The Mo=O

stretching vibrations of $[MoO_2Cl_2(o\text{-phen})]$[29] at 935 and 902 cm^{-1} (IR) and those of complex **2** at 948 and 915 cm^{-1} (IR) support this interpretation.

Another difference between complex **2** and $[MoO_2Cl_2(o\text{-phen})]$ concerns the inner ligand distances and is a consequence of the aromaticity of the *o*-phen ligand. The central C(1)—C(2) bond between the two imino-carbon atoms in **2** is a pure sigma bond [1.476(4) Å] and relatively unaffected by complexation [free Bu^t-dab :[30] 1.496(20) Å], while in the *o*-phen ligand it has double bond character [1.423(6) Å].

Spectroscopic characterization of the complexes

Crystals of the dmp complexes **4** and **5** could not be obtained; conclusions concerning their configuration must therefore rely on vibrational and NMR spectroscopy.

As shown in the Experimental complexes **2**–**5** show two intense IR and Raman peaks between 890 and 960 cm^{-1}. These peaks belong to the symmetric and antisymmetric M=O stretching vibrations of MO_2^{2+} complexes with a *cis*-dioxo arrangement.[4,31] For the Bu^t-dab complexes **2** and **3** two peaks appear between 200 and 260 cm^{-1}. Based on assignments made on some diazabutadienemetaltetracarbonyl complexes, $M(CO)_4$(R-dab)],[32] these bands can be tentatively assigned to antisymmetric and symmetric metal–nitrogen stretching vibrations. Preliminary force-field calculations[33] on the molybdenum complex **2**, the structure of which has been presented above, are also in agreement with these assignments. On the other hand, in the vibrational spectra of complexes $MoO_2Cl_2X_2$ with X = an oxygen donor[34] IR absorptions of medium intensity between 250 and 260 cm^{-1} are always present and are considered to be molybdenum–oxygen rocking vibrations of the *cis*-O=Mo=O moiety; ^{15}N labelling experiments might therefore help to reach a definite conclusion concerning the metal–nitrogen vibrations.

Neither the metal–oxo nor the metal–nitrogen vibrations are of value in distinguishing between an all *cis* or a *cis,trans,cis* configuration of $MO_2Cl_2N_2$ complexes, but the vibrational spectra in the metal–chlorine stretching region may hold some information on this matter. The metal–chlorine stretching vibrations in complexes **2** and **3** follow the intensity patterns usually found in other *trans*-dichloro complexes,[34] the band at a higher wave number [ν_{as}(M—Cl)] has medium to high intensity in IR and low intensity in Raman, whilst the band at a lower wave number [ν_s(M—Cl)] shows appreciable intensity in Raman while the IR absorption is weak. In the two hitherto characterized octahedral complexes with *cis*-dichloro configuration, $[WO_2Cl_2$(t-men)][5] and $[MoO_2Cl_2$(tmen)] (**1**), the IR spectra show two metal–chlorine stretching vibrations at 345(m), 307(vw) and 350(m), 303(vw) cm^{-1}, respectively, thus exhibiting the same intensity patterns as *trans*-dichloro complexes. The assignments of the symmetric stretching vibrations made here are reassignments to those suggested earlier.[5] Contrary to the IR intensities there is a difference in the Raman spectra between *cis,trans,cis* configurated complexes, such as $[MoO_2Cl_2$(Bu^t-dab)] and $[MoO_2Cl_2$(bipy)], and the all *cis* configurated complex $[MoO_2Cl_2$(tmen)] (**1**). In the latter case the Raman intensities of the symmetric and asymmetric stretching vibrations at 303 and 343 cm^{-1} are of about equal intensity, while in the former complexes the Raman intensity of the asymmetric stretching vibrations is weak (see Fig. 3). Thus, two Raman peaks of about equal intensity in the Mo—Cl stretching region might be a useful criterion for distinguishing between *cis*- and *trans*-dichloro configurated complexes, $MoO_2Cl_2L_2$. When applied to the molybdenum complex **4** this criterion implies that it has a *cis*-dichloro configuration like its monocyclic counterpart **1**. Due to the lack of a Raman spectrum no conclusion can be drawn for $[WO_2Cl_2$(dmp)] (**5**). However, the NMR spectra of **5** and **4** discussed below indicate a *cis*-dichloro arrangement for both complexes. The NMR spectra of complexes **2** and **3** consist of two singlets in the ^1H NMR spectra and three resonances in the $^{13}C\{^1H\}$ spectra (see Experimental), i.e. there is only a single set of signals for the two ligand halves of Bu^t-dab. In accord with the solid-state structure of **2** this shows that Bu^t-dab is symmetrically bound to MoO_2Cl_2 with the nitrogen atoms *trans* to the oxo ligands. The NMR spectra of **3** exhibit the same patterns as those of **2**, implying that **3** in solution

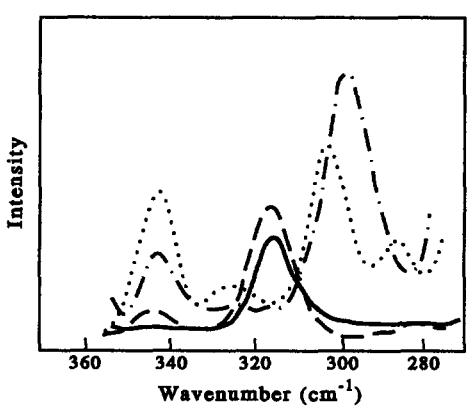

Fig. 3. Raman spectra of: —— MoO_2Cl_2(bipy); ---- MoO_2Cl_2(Bu^t-dab) (**2**); ····· MoO_2Cl_2(tmen) (**1**); and –·–·– MoO_2Cl_2(dmp) (**4**).

also has the chelating ligand symmetrically bound. X-ray powder photograms reveal that the two complexes are not isostructural in the solid state, but this does not imply that the molecular structure of the two complexes are different. The ^1H and ^{13}C NMR resonances of the azomethine groups in complexes **3** and **4** are typical for Bu^t-dab in the σ,σ'-bidentate coordination mode.[35] To avoid decomposition during acquisition the NMR spectra of $[MoO_2Cl_2(dmp)]$ (**4**) and $[WO_2Cl_2(dmp)]$ (**5**) were obtained at $-34°C$ in CD_2Cl_2. At this temperature five resonances at 3.84, 3.54, 2.88, 2.77 and 2.56 ppm (**4**) and 3.87, 3.70, 3.06, 2.97 and 2.83 ppm (**5**) appeared in ^1H NMR with the relative intensities 2:2:6:2:2. The four resonances each representing two protons are broad, having approximately 17 Hz half-width, while the single peak of the two methyl groups has only 2.5 Hz half-width. The $^{13}C\{^1H\}$ NMR spectra show two methylene resonances at 59.5 and 56.4 ppm (**4**), 60.8 and 57.3 ppm (**5**) and a methyl resonance at 47.3 and 47.5 ppm for **4** and **5**, respectively. Compared to the free ligand all proton and carbon resonances in complexes **4** and **5** are shifted to lower field, as is also observed for complexes **2** and **3**. Two possible configurations of **4** are shown in Figs 4(a) and (b). The NMR data presented above make the symmetrical configuration of **4** [Fig. 4(b)] unlikely. It has C_{2v} symmetry, thus only two sets of proton resonances (for protons *e* and *f*), a singlet for the methyl groups and two carbon resonances, one for the four methylenes and one for the methyls, should appear. On the other hand, if the configuration seen in Fig. 4(a) is adopted the observed NMR spectra can be rationalized. The spatial proximity of the protons *a* to Cl(2) and *b* to O(1) makes *a* chemically inequivalent to *b* and consequently *d* inequivalent to *c*. The carbon nuclei to which the hydrogen atoms *a*, *d* and *b*, *c*, respectively, are attached are magnetically equivalent. There are two isolated AA′BB′ spin systems present in the ^1H NMR spectrum, one consisting of protons *a* and *d* and the other consisting of protons *b* and *c*. The AA′BB′ splitting patterns as a result of geminal and vicinal couplings are not resolved and this may explain part of the broadening of the resonances assigned to these protons. Furthermore, it is reasonable that in the diazamolybdena[2.2.1]bicycloheptane frame the *exo* protons *a* and *b*, which are directed towards Cl(2) and O(1), respectively, are more deshielded than the *endo* protons *d* and *c* which are directed away from these ligands. Somewhat unexpectedly both N-methyl groups have the same chemical shift implying that they are affected by O(2) and Cl(1) to the same extent. This observation is, however, in contrast to the NMR spectra observed for MoO_2Cl_2(tmen) (**1**) and its tungsten analogue[5] where the four N-methyl groups appear as four singlets in ^1H and $^{13}C\{^1H\}$ NMR.

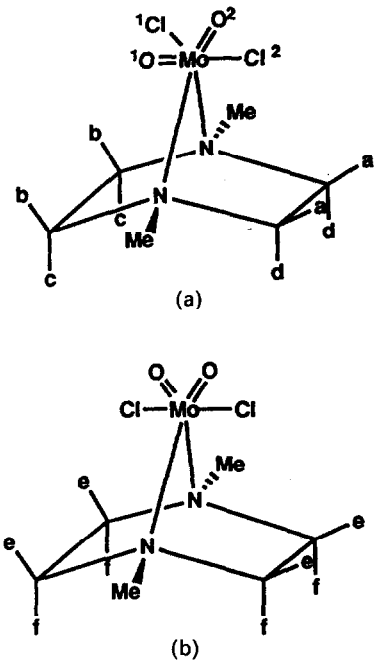

Fig. 4. Two possible configurations of $MoO_2Cl_2(dmp)$ (**4**). Hydrogen atoms a–f are omitted for clarity. (a) All *cis* and (b) *cis,trans,cis*.

Interestingly, in the ^1H NMR spectrum of complex **4** at 0°C the resonances of the protons *a*, *b* and *d*, *c* coalesce, while the methyl resonance at 2.88 ppm is not affected in position or in half-width. This effect has not been possible to confirm in the tungsten complex **5** because it is more unstable than the molybdenum complex **4** at this higher temperature.

An explanation for the observed fluxional behaviour cannot be given to date, but it can be proposed that fast scrambling on the NMR time-scale of the oxygen and chlorine atoms *cis* to the bridge-head nitrogen atoms by some not yet identified process make the protons *a* and *b* and consequently *d* and *c* equivalent.

CONCLUSIONS

In the complex $[MoO_2Cl_2(tmen)]$ (**1**), which adopts the unusual all *cis* configuration, there are two methyl groups directed above and two below a plane defined as that containing the metal atom and the nitrogen atoms. Thus, there are similarities between $[MoO_2Cl_2(Bu^t\text{-dab})]$ (**2**) and the tmen complex (**1**) with regard to the orientation of the four methyl substituents on sp^3 hybridized atoms to the MoO_2Cl_2 core. One important difference between **1** and **2** is at hand, however. In the tmen complex

(1) the sp^3-hybridized atoms are nitrogen atoms directly linked to the metal atom, thereby placing the methyl groups close to the apical ligands; in the case of the Bu^t-dab complex (2) the methyl groups are attached to the carbon atoms of the tertiary butyl groups which are not directly linked to the metal centre, thereby placing these methyl groups further away from the MoO_2Cl_2 core. Since the tmen complex (1) and the Bu^t-dab complex (2) adopt different configurations of the MoO_2Cl_2 core we find it reasonable to conclude that indeed interligand repulsions between the methyl groups of the bidentate dinitrogen ligands and the chloro and oxo ligands are of importance in determining the overall structures of the complexes **1** and **2**.

EXPERIMENTAL

All manipulations were performed on a vacuum line using standard Schlenk techniques and argon as an inert gas. Diethylether and dimethoxyethane (dme) were distilled over $LiAlH_4$ and hexamethyldisiloxane (Janssen) and solvents were dried over activated molecular sieves. N,N′-Dimethylpiperazine (dmp) (Janssen) was distilled over CaH_2; N,N′-di-t-butyl-1,4-diaza-1,3-butadiene (Bu^t-dab),[36] $WOCl_4$,[37] MoO_2Cl_2,[37] $[MoO_2Cl_2(dme)]$,[19] $[MoO_2Cl_2(tmen)]$ (**1**)[5] and $[WO_2Cl_2(dme)]$[20] were prepared according to published methods. Elemental analyses were performed by Analytische laboratorien Malissa und Reuter, Gummersbach, F.R.G. The tungsten analysis was done gravimetrically as WO_3. IR spectra (Nujol mulls between CsI plates) were recorded using a Nicolet 20SXC spectrometer. Raman spectra were recorded with a Bruker FRA 106 instrument [excitation radiation 1064 nm, resolution 4 cm^{-1}, 1000 scans, laser power 10 (**4**) to 50 mW (**2**, **3**)]. ^1H and ^{13}C spectra in $CDCl_3/CH_2Cl_2$ (**2**, **3**) or CD_2Cl_2 (**4**, **5**) solution were recorded with a Varian XL 300 spectrometer (300 MHz, $T = 298$ K (**2**, **3**), $T = 239$ K (**4**, **5**); $SiMe_4$ was the internal standard with $\delta = 0$ ppm).

X-ray crystallography

Crystals of $[MoO_2Cl_2(tmen)]$ (**1**) and $[MoO_2Cl_2(Bu^t\text{-dab})]$ (**2**) were obtained from CH_2Cl_2/heptane and CH_2Cl_2/ether, respectively. For the data collections, only the single crystals of $[MoO_2Cl_2(tmen)]$ (**1**) had to be enclosed in a capillary to keep it from air. The two data sets were corrected by Lorentz, polarization and absorption effects, the latter by an empirical method.[38] Some crystal data for complexes **1** and **2** are collected in Table 2.

The structure of $[MoO_2Cl_2(tmen)]$ (**1**) was refined with starting parameters from the isostructural tungsten compound and the structure of $[MoO_2Cl_2(Bu^t\text{-dab})]$ (**2**) was solved by direct methods (MULTAN 87), which gave the positions of the atoms in the MoO_2Cl_2 core. The remaining atoms were located from subsequent difference Fourier syntheses. In the final refinements all non-hydrogen atoms were refined with anisotropic parameters and the hydrogen atoms with isotropic temperature factors.

Preparations

$[MoO_2Cl_2(Bu^t\text{-dab})]$ (**2**). Bu^t-dab (0.97 g, 5.7 mmol) was added to a solution of $[MoO_2Cl_2(dme)]$ (1.61 g, 5.6 mmol) in CH_2Cl_2 (90 cm^3). Alternatively, MoO_2Cl_2 (1.11 g, 5.6 mmol) suspended in CH_2Cl_2 (90 cm^3) was applied. After stirring overnight and filtering the filtrate was concentrated to approximately 30 cm^3. The white crystals which precipitated after the addition of diethylether (40 cm^3) and cooling at −30°C were collected, repeatedly washed with ether and dried *in vacuo*. Yield: 1.57 g, 77.2%. Found: C, 32.9; H, 5.3; N, 7.7; Cl, 19.2. Calc. for $C_6H_{20}Cl_2MoN_2O_2$: C, 32.7; H, 5.4; N, 7.6; Cl, 19.3%. IR and *Raman* data (in cm^{-1}): 1587w, *1588s* [ν(C=N)]; 948vs, 912vs; *948vs*, *915m* [ν(Mo=O)]; 349s, 314vw, *344w*, *316m* [ν(Mo—Cl)]; 248s, *250m*, *215s* [ν(Mo—N)]. NMR data: ^1H: 8.24 (s, 2H, —C*H*=N—) and 1.70 [s, 18H, =N—C(CH_3)$_3$]; $^{13}C\{^1H\}$: 153.8 (—*C*H=N—), 66.1 [=N—*C*(CH_3)$_3$], 28.9 [=N—C(*C*H_3)$_3$].

$[WO_2Cl_2(Bu^t\text{-dab})]$ (**3**). (a) Bu^t-dab (1.29 g, 7.7 mmol) was added to $[WO_2Cl_2(dme)]$ (2.76 g, 7.3 mmol) in CH_2Cl_2 (130 cm^3). Bu^t-dab dissolved immediately to give a clear colourless solution. After stirring for 4 h the reaction mixture was filtered and the filtrate concentrated to approximately 90 cm^3. The addition of ether (50 cm^3) and cooling at −30°C gave **3** as a white powder, which was isolated by filtration, washed thoroughly with ether (4 × 10 cm^3) and dried *in vacuo*. Yield 2.19 g, 65.7%. If the product is grey it can be recrystallized from hot acetonitrile.

(b) Hexamethyldisiloxane (1.67 g, 10.3 mmol) was added to a suspension of $WOCl_4$ (3.35 g, 9.8 mmol) in CH_2Cl_2 (150 cm^3). After vigorously stirring for 75 min solid Bu^t-dab (1.65 g, 9.8 mmol) was added to the yellow suspension. Stirring was continued for 2 h, meanwhile most of the yellow solid dissolved. The reaction mixture was filtered and the pink filtrate stored at −30°C overnight to give 1.8 g of the white product, which was isolated by filtration. Further concentration of the filtrate and cooling at −78°C gave another fraction of 1.34 g of $WO_2Cl_2(Bu^t\text{-dab})$. The solids were combined and repeatedly washed with ether and dried *in vacuo*. Yield: 3.14 g, 70.4%. Found: C, 26.7; H, 4.5; N, 6.2; Cl, 15.8; W, 40.5. Calc. for $C_6H_{20}Cl_2O_2W$: C, 26.3; H, 4.4; N, 6.1; Cl, 15.5; W, 40.4%. IR and *Raman* data (in cm^{-1}): 1606w, *1608m* [ν(C=N)]; 960vs, 925vs, *960vs*, *928m* [ν(W=O)]; 339s, 303vw, *337m*, *303vw* [ν(W—Cl)]; 247vs, *245vs*, *224m* [ν(W—N)]. NMR data: ^1H: 8.43 (s, 2H, —C*H*=N—) and 1.66 [s, 18H, =N—C(CH_3)$_3$]; $^{13}C\{^1H\}$: 155.7 (—*C*H=N—), 67.1 [=N—*C*(CH_3)$_3$], 28.8 [=N—C(*C*H_3)$_3$].

$[MoO_2Cl_2(dmp)]$ (**4**). Dmp (0.19 g, 1.7 mmol) dissolved in CH_2Cl_2 (20 cm^3) was added dropwise either to a solution of $[MoO_2Cl_2(dme)]$ (0.47 g, 1.6 mmol) in CH_2Cl_2 (15 cm^3) at −78°C or a suspension of MoO_2Cl_2 (0.32 g, 1.6 mmol) in CH_2Cl_2 (15 cm^3) at −78°C. After the addition of dmp (10 min) the cooling was removed and the clear orange–brown solution was stirred at approximately −10°C for 90 min. The brown–green precipitate which formed was filtered and the filtrate quickly evaporated to dryness. The remaining light brown powder was dried *in vacuo*. Yield: 0.33 g, 66%. Found: C, 23.2; H, 4.6; N, 8.8; Cl, 22.6. Calc. for $C_8H_{14}Cl_2MoN_2O_2$: C, 23.0; H, 4.5; N, 8.9; Cl, 22.6%. IR and *Raman* data (in cm^{-1}): 933vs, *933vs* [ν_s(Mo=O)]; 896vs, *902vs* [ν_{as}(Mo=O)]; 340s,b, 296w, *342w*, *297m* [ν(Mo—Cl)]. NMR data: ^1H: 3.84 (m, 2H, CH_2), 3.54 (m, 2H, CH_2), 2.88 (s, 6H, CH_3), 2.77 (m, 2H, CH_2), 2.56 (m, 2H, CH_2); $^{13}C\{^1H\}$: 59.5 (*C*H_2), 56.4 (*C*H_2), 47.3 (*C*H_3).

$WO_2Cl_2(dmp)]$ (**5**). This compound was obtained under the same reaction conditions as $[MoO_2Cl_2(dmp)]$: $[WO_2Cl_2(dme)]$ (1.43 g, 3.79 mmol) and dmp (0.45 g, 3.98 mmol) in CH_2Cl_2 (70 cm^3) gave **5** as a grey, light-sensitive powder. Yield: 0.67 g, 42.0%. Found: C, 17.8; H, 3.7; N, 6.8; Cl, 17.8; W, 45.4. Calc. for $C_8H_{14}Cl_2N_2O_2W$: C, 17.9; H, 3.5; N, 6.9; Cl, 17.6; W, 45.8%. SYNTHESIS AND SPECTROSCOPIC STUDIES OF OXOVANADIUM(IV) COMPLEXES WITH 16- AND 18-MEMBERED MACROCYCLIC LIGANDS

H. S. YADAV

Chemistry Division, North Eastern Regional Institute of Science and Technology, Nirjuli 791 109, Itanagar, Arunachal Pradesh, India

(*Received* 23 *June* 1992; *accepted* 10 *September* 1992)

Abstract—Oxovanadium(IV) complexes of the type $[VO(L)](SO_4)$ (where L = ligands derived by reaction between 2,6-pyridinedicarboxylic acid and ethylenediamine or propanediamine in a 1 : 2 molar ratio) have been prepared by *in situ* synthesis. These complexes react with different β-diketones to yield macrocyclic products of the type $[VO(mac)](SO_4)$ (where mac = macrocyclic ligands). Tentative structures of the complexes have been proposed on the basis of elemental analyses, magnetic moments and spectral (IR, electronic and ESR) data. The *X*-band ESR spectra of all the complexes were recorded at room temperature and at liquid nitrogen temperature (177 K). The values of $|g|$, $g_\parallel$, $g_\perp$, $|A|$, $A_\parallel$ and $A_\perp$ were obtained. The room temperature ESR spectra do not show anisotropy because of rapid tumbling of the molecules in solution, but it is clearly visible at 177 K. The spectral studies support square pyramidal geometry for the five-coordinate oxovanadium(IV) complexes.

Vanadium is widely distributed in the biosphere[1] and its essential role has been recognized in both plants and animals.[2–8] The oxovanadium(IV) cation has been found to inhibit the plasma membrane ATPase of *Neurospora crassa*[9] and *Saccharomyces cerevisiae*,[10] the proton translocating ATPase of *Mycobacterium phlei*[11] and Ca^{2+}-ATPase of red cell membranes.[12] It has been observed that the free vanadyl ion is oxidized to vanadate within a few minutes in aqueous solution exposed to air at neutral pH. However, the tetravalent state appears to be stable when complexed with intracellular proteins or smaller molecules.[13] Thus, the complex formation of the oxovanadium(IV) cation with macrocyclic ligands appears to be interesting, particularly in order to explore the biochemical importance of the oxovanadium(IV) cation *in vitro* at neutral pH. In this communication, the synthesis and characterization of oxovanadium(IV) complexes with ligands derived from 2,6-pyridinedicarboxylic acid and ethylenediamine or propanediamine (type I) are reported. The reactions of these complexes with β-diketones such as acetylacetone, benzoylacetone and dibenzoylmethane, leading to the formation of macrocyclic products (type II), are also reported.

EXPERIMENTAL

The oxovanadium(IV) complexes of type I were prepared by mild heating and stirring the solutions of vanadyl sulphate, 2,6-pyridinedicarboxylic acid and ethylenediamine or propanediamine in 1 : 1 : 2 molar ratios in ethanol for 1 h. The resulting green precipitate was filtered, thoroughly washed with ethanol and dried at 110°C. A suspension of complex **I** in ethanol was mixed with an appropriate β-diketone solution in ethanol in a 1 : 1 molar ratio and the reaction mixture was stirred with mild heating for 1 h. The resulting deep-green coloured complexes were filtered, thoroughly washed with ethanol and dried at 110°C.

Microanalyses for carbon, hydrogen and nitrogen were performed by the CDRI, Lucknow. Sulphur was estimated as barium sulphate.[14] The vanadium was estimated gravimetrically as its vanadate after decomposing the complex with concentrated nitric acid.[15] The magnetic susceptibility measurements and electronic spectra of complexes were performed at the Faculty of Science, University of Gorakhpur. IR spectra were recorded in KBr medium on a Perkin–Elmer Model 983 spec-

trometer at RSIC, NEHU, Shillong. The ESR spectra were recorded on a Varian-E-4 spectrometer (*X*-band) in DMSO at RSIC, IIT, Madras.

RESULTS AND DISCUSSION

The oxovanadium(IV) complexes of type I were synthesized *in situ* by stirring with mild heating of the reaction mixture containing vanadyl sulphate, 2,6-pyridinedicarboxylic acid, ethylenediamine or propanediamine in 1 : 1 : 2 molar ratios in aqueous ethanol medium. The reactions appear to proceed as follows:

$$VOSO_4 \cdot H_2O + \text{2,6-pyridinedicarboxylic acid} \xrightarrow[\text{ethanol}]{+\text{ethylenediamine or propanediamine}} \underset{\textbf{(I)}}{[VO(L)]SO_4} + 3H_2O;$$

where L = ligand derived by reaction of 2,6-pyridinedicarboxylic acid with ethylenediamine or propanediamine.

The reaction of complex **I** with different β-diketones in 1 : 1 molar ratios results in the condensation of the terminal amino group of complex **I** with ketonic groups of the β-diketones yielding macrocyclic complexes of type **II**, [VO(mac)](SO$_4$). The elemental analyses (Table 1) of complexes show 1 : 1 metal-to-ligand stoichiometry.

IR spectra

The important IR bands for the complexes are listed in Table 2. The oxovanadium(IV) complexes of type I show bands at 1690, 1510, 1230 and 470 cm^{-1}, assignable[16] to amide-I [ν(C=O)], amide-II [ν(CN) + δNH], amide-III (δNH) and amide-IV (ϕCO) vibrations, respectively. It is evident that in the complexes the amide-II and amide-III bands are lowered ($\sim$ 30 cm^{-1}), whereas the amide-I and amide-IV bands are unperturbed in comparison to the free ligands. This indicates the coordination of amide nitrogen atoms and the non-coordination of amide oxygen atoms.[17] The bands appearing at 3350 and 3180 cm^{-1} may be assigned to asymmetrical and symmetrical N—H stretching modes of the coordinated terminal amino group.[18] The coordination of nitrogen atoms to vanadium is further supported by the appearance of a band at *ca* 310 cm^{-1}, which may be assigned to the ν(V—N) vibrations.[19] The unchanged pyridine ring

s = strong; m = medium; w = weak.

vibrations[20,21] occuring at 1580 (8a, pyridine ring deformation), 610 (6a, in-plane ring deformation) and 400 cm^{-1} (16b, out-of-plane ring deformation) in the complexes indicate non-coordination of the pyridine nitrogen to vanadium. The oxovanadium(IV) complexes show a band at 980 cm^{-1}, which is assigned to the ν(V=O) vibration.[22] The presence of an ionic sulphate group in the complexes is confirmed by the appearance of three bands at *ca* 1130–1135 (ν_3), 955–960 (ν_1) and 600–610 cm^{-1} (ν_4). The absence of a ν_2 band and non-splitting of the ν_3 band indicate that *Td* symmetry is retained.[16] The IR spectra of macrocyclic complexes show the same pattern of bands, except a new band at 1610–1615 cm^{-1} which is assigned to the coordinated ν(>C=N) group.[23] The two bands due to asymmetric and symmetric N—H stretching modes also disappear in the macrocyclic complexes and only one band is observed in the ν(NH) region at 3210 cm^{-1} which may be due to a secondary amino group, establishing the condensation of a primary amino group of type I complexes with the carbonyl group of diketones.

Magnetic moments and electronic spectra

Oxovanadium(IV) complexes show magnetic moment values in the range 1.70–1.76 B.M. at room temperature. These values are in the range reported for oxovanadium(IV) complexes with one unpaired electron.[24] The electronic spectra show bands in the regions 11,040–11,980, 15,040–15,920 and 21,090–22,380 cm^{-1}. These spectra are similar to other five coordinate oxovanadium(IV) complexes involving nitrogen donor atoms. Such a spectrum has been predicted for five-coordinate complexes possessing the effective C_v symmetry of a square pyramid. Wasson *et al.*[25] have reported an energy level scheme ($d_{xy} < d_{yz} < d_{xz} < d_{x^2-y^2} < d_{z^2}$) to interpret the electronic spectra of distorted, five-coordinate square-pyramidal oxovanadium(IV) complexes. Accordingly, the observed bands can be assigned to $^2B_2 \rightarrow {}^2E$, $^2B_2 \rightarrow {}^2B_1$ and $^2B_2 \rightarrow {}^2A_1$ transitions, respectively. One more band is observed in the region 35,280–35,780 cm^{-1}, which may be due to transitions of the azomethine linkages.[26]

ESR spectra

The *X*-band ESR spectra of an oxovanadium(IV) complex recorded in DMSO at room temperature and at liquid nitrogen temperature (177 K) is shown in Figs 1(a) and 1(b), respectively. The ESR spectra of the complexes were analysed by the method of Kneubuhl,[27] Sands[28] and Garman *et al.*[29] The room-temperature ESR spectra show eight lines, which are due to hyperfine splitting arising from the interaction of the unpaired electron with a ^{51}V nucleus having the nuclear spin number $I = 7/2$. This confirms the presence of a single oxovanadium(IV) cation as the metallic centre in the complex. The anisotropy is not observed due to rapid tumbling of molecules in solution at room temperature and only *g*-average values are obtained. The anisotropy is clearly visible in the spectra at liquid nitrogen temperature and eight bands each due to $g_\parallel$ and $g_\perp$ are observed separately. The $g_\parallel$, $g_\perp$, $A_\parallel$ and $A_\perp$ values (Table 3) are measured from the spectra, which are in good agreement for a square-pyramidal structure.[30–32] The g_{iso} value from mobile solution at room temperature and g_{av} from frozen solution at liquid nitrogen temperature do not agree very closely since the *g* and *A* tensors are corrected for second-order. Furthermore, the *g*

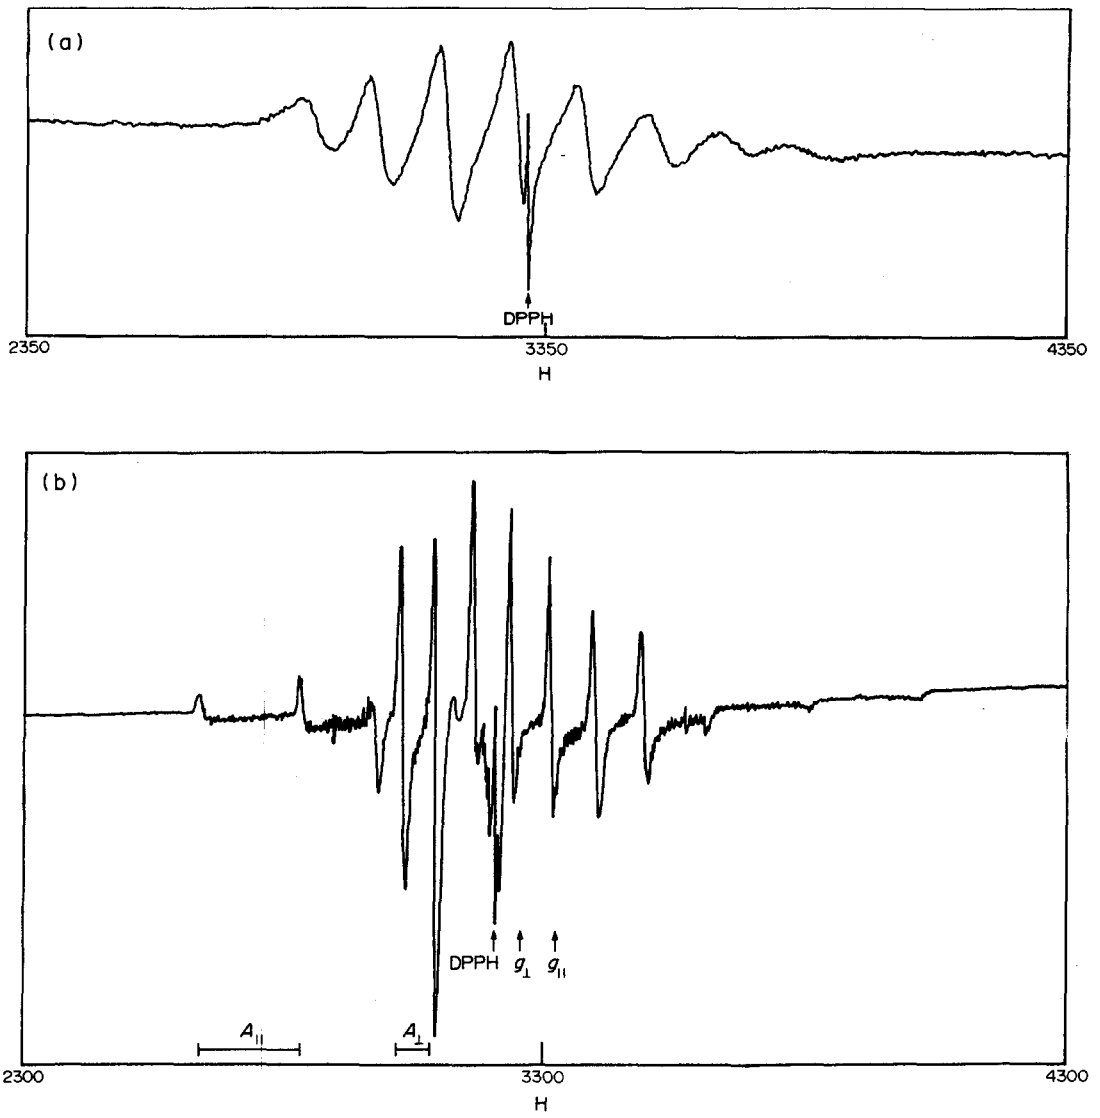

Fig. 1. EPR spectra of $[VO(L^1)](SO_4)$ in DMSO at (a) room temperature and (b) liquid nitrogen temperature.

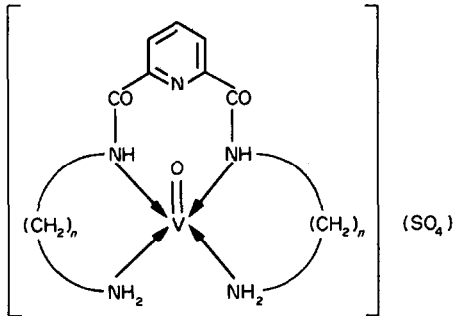
Table 3. Room temperature g values and liquid nitrogen temperature g and A values of oxovanadium(IV) complexes

Complex	Room temperature	Liquid nitrogen temperature					
	$\|g\|$	$g_\parallel$	$g_\perp$	$\|g\|$	$A_\parallel$	$A_\perp$	$\|A\|$
$[VO(L^1)](SO_4)$	1.973	1.931	1.971	1.957	190.70	66.40	107.83
$[VO(L^2)](SO_4)$	1.982	1.934	1.978	1.963	191.65	65.81	107.75
$[VO(mac^1)](SO_4)$	1.988	1.935	1.979	1.977	188.54	64.82	106.06
$[VO(mac^2)](SO_4)$	1.978	1.932	1.976	1.961	185.46	65.50	105.55
$[VO(mac^3)](SO_4)$	1.980	1.938	1.984	1.968	186.45	66.74	106.64
$[VO(mac^4)](SO_4)$	1.979	1.933	1.976	1.961	184.38	64.50	104.46
$[VO(mac^5)](SO_4)$	1.976	1.938	1.983	1.968	188.25	66.79	107.27
$[VO(mac^6)](SO_4)$	1.978	1.935	1.978	1.963	187.46	66.59	106.88

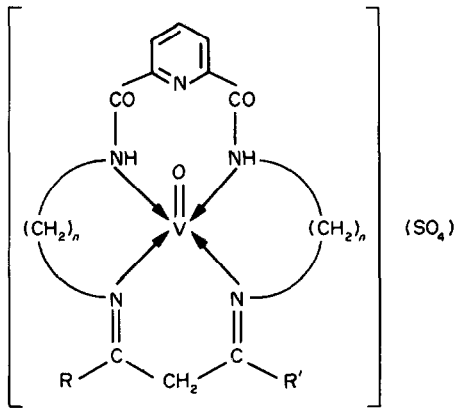
values are all very close to the spin-only value (free electron value) of 2.0023, suggesting little spin-orbit coupling.

On the basis of the above studies, the following tentative structures may be proposed for these oxovanadium(IV) complexes.



I

where $n = 2$ for ethylenediamine,
$n = 3$ for propanediamine.



II

where $n = 2$ for ethylenediamine,
$n = 3$ for propanediamine

and

R	R′	β-Diketone
CH_3	CH_3	Acetylacetone
C_6H_5	CH_3	Benzoylacetone
C_6H_5	C_6H_5	Dibenzoylmethane

Acknowledgements—The author thanks the C.S.I.R., New Delhi, for financial help and Dr Harish Chand, Department of Chemistry, NEHU, Shillong, for his valuable discussions on the ESR spectra.

Abstract—Treatment of $[NEt_4][Rh(cod)(\eta^5\text{-}7,8\text{-}C_2B_9H_9Me_2)]$ (cod = cyclo-octa-1,5-diene) in THF with $[CPh_3][BF_4]$ affords the complex $[Rh(1\text{-}3:5,6\text{-}\eta^5\text{-}C_8H_{11})(\eta^5\text{-}7,8\text{-}C_2B_9H_9Me_2)]$, the structure of which has been established by X-ray diffraction. The *nido*-$7,8\text{-}C_2B_9H_9Me_2$ ligand is attached to the rhodium in the usual pentahapto manner, while the cyclo-octadienyl C_8H_{11} group ligates the metal centre in a $1\text{-}3:5,6\text{-}\eta^5$ bonding mode. The complex $[Rh(\eta^3\text{-}C_8H_{13})(\eta^5\text{-}7,8\text{-}C_2B_9H_9Me_2)]$ in CH_2Cl_2 adds a molecule of CO to afford $[Rh(CO)(\eta^3\text{-}C_8H_{13})(\eta^5\text{-}7,8\text{-}C_2B_9H_9Me_2)]$, and reacts with excess PMe_3 and PEt_3 to give $[RhCl(PMe_3)_2(\eta^5\text{-}7,8\text{-}C_2B_9H_9Me_2)]$ (whose structure was determined by X-ray crystallography) and $[RhH(PEt_3)_2(\eta^5\text{-}7,8\text{-}C_2B_9H_9Me_2)]$, respectively.

We have reported elsewhere the syntheses of complexes in which rhodium is bonded to rhenium, cobalt, iridium, platinum or gold using as reagents the salts $[NEt_4][Rh(CO)(L)(\eta^5\text{-}7,8\text{-}C_2B_9H_9R_2)]$ (L = PPh_3 or CO, R = H or Me).[1] In a recent extension of this study we have employed the salt $[NEt_4][Rh(cod)(\eta^5\text{-}7,8\text{-}C_2B_9H_9Me_2)]$ (**1**) to obtain dimetal species with bonds between rhodium and copper and manganese.[2] The anionic complex $[Rh(cod)(\eta^5\text{-}7,8\text{-}C_2B_9H_9Me_2)]^-$ was first prepared by Hawthorne and co-workers,[3] who isolated it as the $[N(PPh_3)_2]$ salt. It was found that protonation with CF_3CO_2H afforded initially an unstable intermediate with a C—H→Rh interaction, which rearranged to give an unusually stable 16-electron allylic complex, $[Rh(\eta^3\text{-}C_8H_{13})(\eta^5\text{-}7,8\text{-}C_2B_9H_9Me_2)]$ (**2**). In this paper we report the results of treating **1** with the hydride abstracting reagent $[CPh_3][BF_4]$, and reactions of compound **2** with CO, PMe_3 and PEt_3.

RESULTS AND DISCUSSION

The reaction between **1** and $[CPh_3][BF_4]$ in THF gave the complex $[Rh(1\text{-}3:5,6\text{-}\eta^5\text{-}C_8H_{11})(\eta^5\text{-}7,8\text{-}C_2B_9H_9Me_2)]$ (**3**) (Scheme 1), characterized by microanalysis and NMR spectroscopy (Tables 1 and 2). The molecular structure of **3** was fully established by a single-crystal X-ray diffraction study, data from which are listed in Table 3. The molecular structure is shown in Fig. 1.

The rhodium atom is penta-coordinated by the open face of the *nido*-icosahedral $7,8\text{-}C_2B_9H_9Me_2$ fragment in the usual manner,† with Rh—C_2B_3 ring distances in the range 2.181(3)–2.272(3) Å. In compound **2** the corresponding connectivities are 2.12–2.20 Å.[3] The cyclo-octadienyl ligand in **3** ligates the metal via carbon atoms C(21), C(22), C(24), C(25) and C(26) [Rh—C(21) 2.251(3), Rh—C(22) 2.258(3), Rh—C(24) 2.331(4), Rh—C(25) 2.166(4), Rh—C(26) 2.202(3) Å]. The allyl function is not symmetrically bound to the rhodium, with Rh—C(24) being the longest separation and Rh—C(25) the shortest, and Rh—C(26) being intermediate between the two. This may be partly due to the conformation adopted by the C_8H_{11} moiety and partly to give sufficient clearance for the

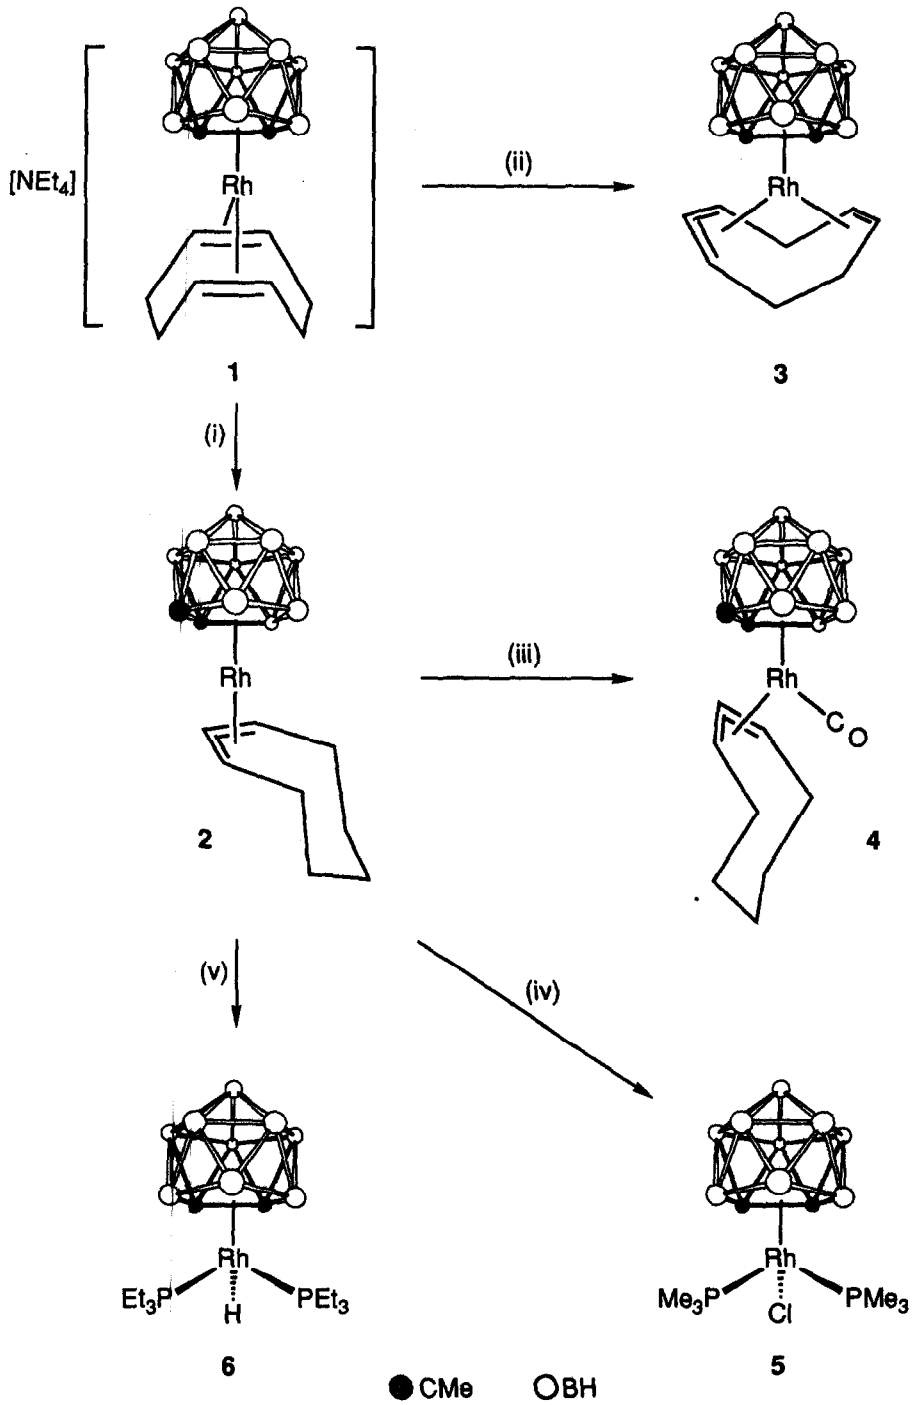
† In this paper, and in related articles,[1] we designate the four-electron donor carbaborane cage as $\eta^5\text{-}7,8\text{-}C_2B_9H_9Me_2$ in order to emphasize its relationship with the five-electron donor $\eta^5\text{-}C_5H_5$ group. However, in **3** the rhodium atom and the carbaborane framework form a *closo*-$1,2\text{-}Me_2\text{-}3,1,2\text{-}RhC_2B_9H_9$ structure.



Scheme 1. (i) CF_3CO_2H/CH_2Cl_2, (ii) $[CPh_3][BF_4]/CH_2Cl_2$, (iii) CO, (iv) PMe_3/CH_2Cl_2 and (v) PEt_3/CH_2Cl_2.

$C(23)H_2$ group, the single methylene fragment separating the η^3-allyl and η^2-alkene functions. In contrast with the asymmetric allylic-rhodium bonding in **3**, that in complex **2** is essentially symmetric (Rh—η^3-C_3 2.136, 2.167 and 2.130 Å).[3]

The 1-3 : 5,6-η^5-C_8H_{11} bonding in **3** is similar to that established by X-ray crystallography in the compound $[Ru(1\text{-}3 : 5,6\text{-}\eta^5\text{-}C_8H_{11})(\eta^6\text{-}C_8H_{10})][PF_6]$ (η^6-C_8H_{10} = 1,3,5-cyclo-octatriene).[4] In this complex also the allyl function is not symmetrically bound to the metal [Ru—η^3-C_3 2.20(2), 2.21(2) and 2.46(3) Å]. As in **3** the longer connectivity is associated with the CH group separated by only one CH_2 fragment from the η^2-CH=CH moiety.

[a] Calculated values are given in parentheses.

[b] In their IR spectra all the compounds showed a broad band at *ca* 2550 cm^{-1} due to B—H. In addition, complex **4** displayed a very strong ν_{max}(CO) absorption at 2047 cm^{-1}.

[c] Complex crystallizes with a molecule of CH_2Cl_2.

The ^1H and $^{13}C\{^1H\}$ NMR data for **3** (Table 2) are in agreement with the molecular structure established by X-ray crystallography. The ^1H assignments were determined from a 2D-COSY spectrum and are further supported by similar data obtained for the 1-3 : 5,6-η^5-C_8H_{11} ligand in [Ru(1-3 : 5,6-η^5-C_8H_{11})(η^6-C_8H_{10})][PF_6] and related molecules.[4] The $^{13}C\{^1H\}$ NMR spectrum of **3** shows eight resonances for the non-equivalent carbons of the C_8H_{11} ring. The assignments in Table 2 are made on the basis of the very detailed measurements made in the ruthenium species containing the 1-3 : 5,6-η^5-C_8H_{11} moiety.[4]

The rhodium atom in **3** can be regarded as being

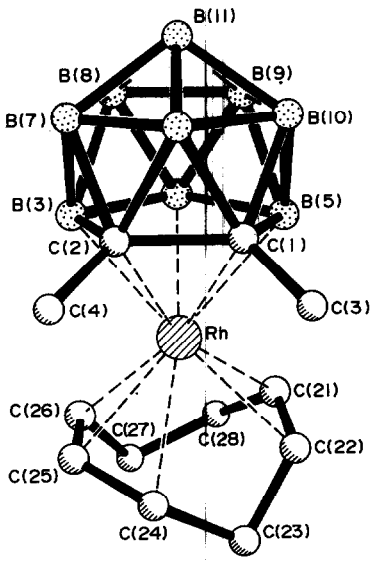

Fig. 1. Molecular structure of [Rh(1-3 : 5,6-η^5-C_8H_{11})(η^5-7,8-$C_2B_9H_9Me_2$)] (**3**) showing the crystallographic numbering scheme.

essentially octahedrally coordinated, assuming that the carbaborane group is a tridentate ligand, the allyl function occupies two sites and the alkene function occupies one. The molecule is also electronically saturated with the rhodium atom having an 18-electron closed shell. This is in contrast with the coordinatively- and electronically-unsaturated 16-electron rhodium species **2**, features which encouraged us to investigate reactions between **2** and some donor molecules.

If CH_2Cl_2 solutions of **2** are treated at ambient temperatures and pressures with CO the electronically and coordinatively saturated complex [Rh(CO)(η^3-C_8H_{13})(η^5-7,8-$C_2B_9H_9Me_2$)] (**4**) is formed (Scheme 1). Data characterizing this species are given in Tables 1 and 2. The ^{1}H NMR spectrum revealed characteristic allylic resonances; a quartet at δ 5.81 corresponding to two hydrogens [J(HH) 8] and a triplet at δ 4.65 with an intensity for one hydrogen [J(HH) 8]. The methyl groups of the carbaborane cage display a single signal at δ

2.16. The equivalence of these CMe fragments indicates a degree of symmetry, discussed further below.

The $^{13}C\{^1H\}$ NMR spectrum did not show a CO peak and we attribute this to the signal-to-noise ratio in the spectrum being inadequate. Nevertheless, the IR spectrum of the molecule displayed a strong CO stretch at 2047 cm^{-1}. The number of resonances seen in the $^{13}C\{^1H\}$ spectrum indicate that there is a plane of symmetry through the C—C connectivity of the C_2B_9 cage, the metal atom and two of the carbons of the C_8H_{13} ring, namely, the central carbon of the η^3-allyl moiety and the carbon of the CH_2 group separated from the allyl fragment by two other methylene groups. The presence of such a plane renders the carbaborane cage CMe groups equivalent, leading to the observation of two resonances (δ 68.2, *C*Me and 30.0, C*Me*). It also results in the occurrence of five rather than eight resonances for the carbons of the C_8H_{13} ligand since two CH and four CH_2 groups are symmetrically related in pairs on either side of the plane of symmetry.

The reaction between PMe_3 and **2** was anticipated to yield a complex structurally analogous to **4**, with a phosphine ligand present instead of a CO molecule. However, in CH_2Cl_2 solution the product was [RhCl(PMe_3)$_2$(η^5-7,8-$C_2B_9H_9Me_2$)] (**5**), characterized by an X-ray diffraction study (Table 4 and Fig. 2).

The rhodium atom carries the carbaborane cage in the usual manner and is also ligated by the two PMe_3 molecules [Rh—P_{av} 2.332 Å] and the chloride

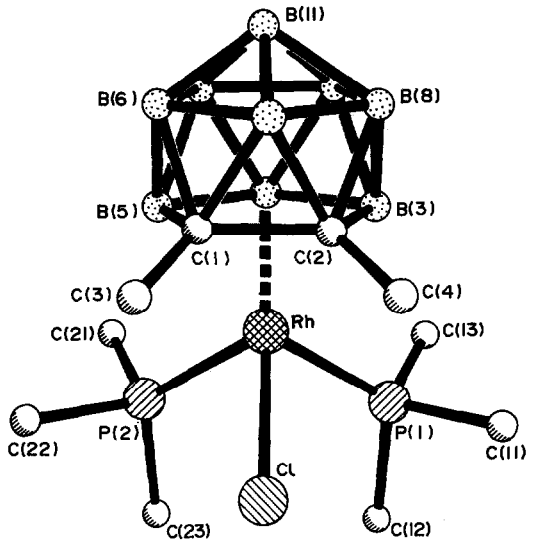

Fig. 2. Molecular structure of [RhCl(PMe_3)$_2$(η^5-7,8-$C_2B_9H_9Me_2$)] (**5**) showing the crystallographic numbering scheme.

[Rh—Cl 2.435(2) Å]. The molecule **5** is closely related to [RhCl(PPh_3)$_2$(η^5-7,8-$C_2B_9H_{11}$)].[5,6] Although the structure of the latter has not been determined by X-ray crystallography, that of the monophosphine complex [RhCl(PPh_3)(η^5-7,9-$C_2B_9H_{11}$)] has. The Rh—Cl [2.215(4) Å] and Rh—P [2.329(1) Å] separations in this species are significantly shorter than those in **5**, in accord with the former having an electron deficient metal centre.[5] Evidently

the chlorine ligand is derived from the CH_2Cl_2 solvent used in the reaction, and this feature is discussed further below. The ^1H and $^{13}C\{^1H\}$ NMR spectra of **5** showed no peaks due to the η^3-C_8H_{13} group, as expected, and the $^{31}P\{^1H\}$ NMR spectrum displayed a doublet signal at δ 3.17 [J(RhP) 125].

The reaction between **2** and PEt_3 also results in displacement of the 1-3-η^3-C_8H_{13} ligand, the product being the hydrido-rhodium complex [RhH$(PEt_3)_2(\eta^5$-7,8-$C_2B_9H_9Me_2)$] (**6**). The ^1H NMR spectrum revealed a high-field resonance at δ −9.87 as a triplet [J(PH) 31], and the $^{31}P\{^1H\}$ NMR spectrum displayed a doublet at δ 32.6 [J(RhP) 135]. These data may be compared with those for [RhH$(PEt_3)_2(\eta^5$-7,8-$C_2B_9H_{11})$] [^1H δ −14.1, J(PH) 29, J(RhH) 16; $^{31}P\{^1H\}$, δ 30.6, J(RhP) 120], reported by Hawthorne and coworkers.[5]

We suggest that compound **6** forms via the following steps. Addition of a PEt_3 molecule to **2** affords an intermediate [Rh$(PEt_3)(\eta^3$-$C_8H_{13})(\eta^5$-7,8-$C_2B_9H_9Me_2)$], which is structurally akin to **4**. Although such an intermediate is ostensibly electronically saturated at the rhodium, slippage of the metal atom to an exopolyhedral site on the carbaborane cage, a process well documented,[5] could lead to an unsaturated rhodium centre, thereby facilitating transfer of hydride to the metal from the hydrocarbon group. The latter, having lost a hydrogen atom, would be released as cyclo-octa-1,3- or -1,5-diene. The resulting metal-containing species, [RhH$(PEt_3)(\eta^5$-7,8-$C_2B_9H_9Me_2)$], would readily add a further molecule of PEt_3 to yield **6**. We assume that the synthesis of **5** proceeds via a complex [RhH$(PMe_3)_n(\eta^5$-7,8-$C_2B_9H_9Me_2)$] (n = 1 or 2), the hydrido ligand of which is replaced by Cl from CH_2Cl_2. Evidence supporting this proposal comes from the observation that [RhCl$(PMe_2Ph)_2$ $(\eta^5$-7,8-$C_2B_9H_{11})$] was obtained in quantitative yield by crystallizing [RhH$(PMe_2Ph)_2(\eta^5$-7,8-$C_2B_9H_{11})$] from CH_2Cl_2.[5]

EXPERIMENTAL

Light petroleum refers to the fraction of b.p. 40–60°C, and all solvents were freshly distilled over appropriate drying agents prior to use. Alumina used in chromatography columns (*ca* 20 cm in length and 3.0 cm in diameter) was BDH aluminium oxide (Brockmann Activity II). Experiments were carried out using Schlenk-tube techniques under nitrogen. IR spectra were measured with a Perkin–Elmer FT1600 spectrometer and NMR spectra recorded with JEOL JNM FX 90Q and GX 270 spectrometers. The $^{31}P\{^1H\}$ NMR chemical shifts are in ppm to high frequency of 85% H_3PO_4 (external). The reagent, [NEt_4][Rh(cod)$(\eta^5$-7,8-$C_2B_9H_9Me_2)$], was prepared by treating [$Rh_2(\mu$-Cl$)_2$(cod$)_2$] with two molar equivalents of Tl[$TlC_2B_9H_9Me_2$][7] in THF, followed by the addition of [NEt_4]Cl.

Synthesis of the complex [Rh(1-3 : 5,6-η^5-$C_8H_{11})(\eta^5$-7,8-$C_2B_9H_9Me_2)$]

The salt **1** (0.20 g, 0.39 mmol) was dissolved in THF (10 cm^3) and treated with [CPh_3][BF_4] (0.13 g, 0.39 mmol), and the mixture stirred for 2 h. Solvent was removed *in vacuo*, the residue dissolved in CH_2Cl_2 (*ca* 3 cm^3) and the solution chromatographed. Elution of the column with CH_2Cl_2–light petroleum (1 : 1) removed a yellow band, which afforded yellow microcrystals of [Rh(1-3 : 5,6-η^5-$C_8H_{11})(\eta^5$-7,8-$C_2B_9H_9Me_2)$] (**3**) (0.09 g), on removal of the solvent *in vacuo*.

Reactions of the complex [Rh(1-3-η^3-$C_8H_{13})(\eta^5$-7,8-$C_2B_9H_9Me_2)$]

(1) Compound **2** (0.20 g, 0.52 mmol) was dissolved in CH_2Cl_2 (10 cm^3) and CO was bubbled through the solution for 10 min, producing a colour change from orange to yellow. The solvent was removed *in vacuo* and the residue was recrystallized twice from CH_2Cl_2–light petroleum (10 cm^3, 1 : 4) to give yellow microcrystals of [Rh(CO)(1-3-η^3-$C_8H_{13})(\eta^5$-7,8-$C_2B_9H_9Me_2)$] (**4**) (0.18 g).

(2) Similarly, **2** (0.20 g, 0.52 mmol) was treated with excess PMe_3 (*ca* 2 mmol) in CH_2Cl_2 (15 cm^3) and the mixture stirred for *ca* 3 h. Solvent was removed *in vacuo*, the residue dissolved in CH_2Cl_2 (*ca* 5 cm^3) and chromatographed. Elution of the column with CH_2Cl_2–light petroleum (1 : 2) removed a yellow fraction, which afforded, after the removal of the solvent *in vacuo*, yellow microcrystals of [RhCl$(PMe_3)_2(\eta^5$-7,8-$C_2B_9H_9Me_2)$] (**5**) (0.17 g). Use of less than an excess of PMe_3 in the reaction afforded only complex mixtures.

(3) In a similar experiment, employing an excess of PEt_3 in CH_2Cl_2, compound **2** (0.20 g, 0.52 mmol) gave orange microcrystals of [RhH$(PEt_3)_2(\eta^5$-7,8-$C_2B_9H_9Me_2)$] (**6**) (0.13 g).

Crystal structure determinations and refinement

Data were collected using a Siemens R3m/V four-circle diffractometer (293 K, Mo-K_α X-radiation, graphite monochromator, $\bar{\lambda}$ = 0.71073 Å). The data were corrected for Lorentz, polarization and X-ray absorption effects, the latter by an empirical method based upon azimuthal scan data.[8] The

structures were solved by conventional heavy-atom or direct methods and successive difference-Fourier syntheses were used to locate all non-hydrogen atoms. All calculations were performed on a DEC micro-Vax II computer with the SHELXTL PLUS system of programs.[8] Scattering factors with corrections for anomalous dispersion were taken from ref. 9. Additional material available from the Cambridge Crystallographic Data Centre comprises the atom coordinates, thermal parameters and remaining bond lengths and angles.

Crystals of **3** were grown from CH_2Cl_2–light petroleum as yellow prisms and that used had the dimensions *ca* $0.65 \times 0.50 \times 0.20$ mm. Of the 4358 data collected (Wyckoff ω-scan, $2\theta \leqslant 55°$), 3253 unique data had $F \geqslant 5\sigma(F)$, and only these were used for structure solution and refinement.

Crystal data for $C_{12}H_{26}B_9Rh$. $M = 370.5$, monoclinic, space group $C2/c$, $a = 17.972(3)$, $b = 8.131(2)$, $c = 23.757(4)$ Å, $\beta = 99.63(2)°$, $U = 3423(1)$ Å^3, $Z = 8$, $D_c = 1.44$ g cm^{-3}, $F(000) = 1504$, μ(Mo-K_α) = 9.7 cm^{-1}.

All non-hydrogen atoms were refined with anisotropic thermal parameters. Methyl hydrogen atoms were included in calculated positions (C—H 0.96 Å) with fixed isotropic thermal parameters ($U_{iso} = 0.08$ Å^2). The positions of the remaining hydrogen atoms were refined with fixed isotropic thermal parameters ($U_{iso} = 0.05$ Å^2). Final $R = 0.027$ ($R' = 0.028$) with a weighting scheme of the form $w^{-1} = [\sigma^2(F) + 0.0002F^2]$. The final electron-density difference synthesis showed no peaks > 0.46 or < -0.32 e Å^{-3}.

Crystals of **5** were grown as for **3**, and that used had the dimensions *ca* $0.60 \times 0.51 \times 0.40$ mm. Of the 3289 data collected (Wyckoff ω-scan, $2\theta \leqslant 55°$), 2566 unique data had $F \geqslant 5\sigma(F)$ and only these were used for structure solution and refinement.

Crystal data for $C_{10}H_{33}B_9ClP_2Rh \cdot CH_2Cl_2$. $M = 535.9$, orthorhombic, space group $P2_12_12_1$, $a = 10.443(3)$, $b = 12.606(4)$, $c = 19.033(4)$ Å, $U = 2506(1)$ Å^3, $Z = 4$, $D_c = 1.42$ g cm^{-3}, $F(000) = 1088$, μ(Mo-K_α) = 11.2 cm^{-1}.

All non-hydrogen atoms were refined with anisotropic thermal parameters. Methyl hydrogen atoms and the methylene hydrogen atoms of the CH_2Cl_2 solvent of crystallization were included in calculated positions (C—H 0.96 Å) with fixed isotropic thermal parameters [$U_{iso} = 0.08$ (Me) and 0.10 (CH_2) Å^2]. The positions of the remaining hydrogen atoms were refined with fixed isotropic thermal parameters ($U_{iso} = 0.08$ Å^2). Final $R = 0.040$ ($R' = 0.041$), with a weighting scheme of the form $w^{-1} = [\sigma^2(F) + 0.001F^2]$. The final electron-density difference synthesis showed no peaks > 0.57 or < -0.48 e Å^{-3}.

REDOX ACTIVITY OF BIMETALLIC MOLYBDENUM AND TUNGSTEN NITROSYLS CONTAINING LIGANDS BASED ON 4-HYDROXYPHENYLALKANOLS

AMITAVA DAS,† CHRISTOPHER J. JONES and JON A. McCLEVERTY†‡

School of Chemistry, University of Birmingham, Edgbaston, Birmingham B15 2TT, U.K.

(*Received* 10 *August* 1992; *accepted* 18 *August* 1992)

Abstract—The redox-active bimetallic complexes, $[\{M(NO)L^*X\}_2Q]$ [L* = tris(3,5-dimethylpyrazolyl)borate, $HB(3,5\text{-}Me_2pyz)_3$; M = Mo, X = Cl or I; M = W, X = Cl; Q = $OC_6H_4(CH_2)_nO$ (n = 1–3) or $NHC_6H_4(CH_2)_nO$ (n = 2, 3)], have been prepared and characterized spectroscopically and electrochemically (cyclic voltammetry, coulometry). The electrochemical data indicate that there can be weak interactions between the two metal-based redox centres.

Cyclic voltammetric (CV) studies of the bimetallic tris(3,5-dimethylpyrazolyl)borato molybdenum and tungsten complexes, $[\{M(NO)L^*X\}_2Q]$ (where M = Mo or W, X = halide and Q = O, OC_6H_4O, $NHC_6H_4OC_6H_4NH$, etc.)[1,2] reveal that they undergo two one-electron addition processes. In many cases there was evidence for significant interactions between the two metal redox centres, and in that situation, the E_f values of the first and second reductions are more anodic and more cathodic, respectively, than the E_f value for the reduction of the corresponding *monometallic* species. These CV results further revealed that the extent of the interaction between the two metal centres, as measured by ΔE_f, the separation in mV between the two reduction potentials, was strongly dependent on the nature of Q, being greatest when Q = O or EC_6H_4E (E = O or NH).[1–3]

However, in our studies of the electrochemistry of these bimetallic species we noticed that the inclusion of saturated groups within the bridging system caused a significant reduction in the interaction between the metal centres. This effect was especially noticeable in $[\{Mo(NO)L^*I\}_2(OCH_2C_6H_4CH_2O)]$, where ΔE_f is $\geqslant$100 mV, whereas in $[\{Mo(NO)L^*Cl\}_2OC_6H_4O\text{-}p]$ ΔE_f is 460 mV, and it is reasonable to suppose that the attenuation of ΔE_f is due in part to the "insulating" effect of the aliphatic linkages.[1,2] In this paper, we report further studies of the effect inserted methylene groups have on the electrochemistry of the complexes $[\{M(NO)L^*X\}_2\{OC_6H_4(CH_2)_nO\}]$ (n = 1–3) and in related anilido species $[\{M(NO)L^*X\}_2\{NHC_6H_4(CH_2)_nO\}]$.

EXPERIMENTAL

All reactions were carried out under oxygen-free dry nitrogen. Dry freshly distilled dichloromethane and toluene were used for all reactions. All other commercial reagents were used as received. The starting materials $[ML(NO)X_2]$ (M = Mo/W, X = Cl, I) were prepared following known procedures.[4] New compounds were purified by column chromatography using silica gel 60 (70–230 mesh) and CH_2Cl_2 and CH_2Cl_2/n-hexane mixtures as the eluant; the bimetallic species were stable in solution and in the presence of air for short periods. IR spectra were recorded using either PE357 or PE1600 FTIR spectrophotometers and ^1H NMR spectra were recorded using a JEOL JN Max 270 spectrometer. Cyclic voltammetric and differential pulse polarographic data were obtained using a PAR174 instrument using dry CH_2Cl_2 as a solvent and $[NBu^n_4][PF_6]$ (0.2 mol dm^{-3}) as a supporting electrolyte. The data obtained were reproducible, the experimental error being $\pm$10 mV. Some of the experiments were repeated in THF, but a variation of only up to +20 mV, with respect to CH_2Cl_2, was detected. Thus, it seems reasonable to compare the

results obtained in CH_2Cl_2 with those obtained in CH_3CN.

[Mo(NO)L*Cl($OC_6H_4CH_2OH$)]

A solution of [Mo(NO)L*Cl_2] (0.207 g, 0.4 mM) and 4-hydroxybenzyl alcohol (0.099 g, 0.8 mM) was refluxed in CH_2Cl_2 (30 cm^3) for 4 h. The solution was then evaporated to a small volume and thin-layer chromatography (tlc) showed the residue to be a mixture of two compounds. Using column chromatography the second major brown fraction was collected and identified as [Mo(NO)L*Cl ($OC_6H_4CH_2OH$)], which was recrystallized from dichloromethane/n-hexane mixtures giving the complex as a dark brown powder (yield: 0.13 g, 53%).

[{Mo(NO)L*Cl}$_2$($OC_6H_4CH_2O$)]

Method 1. A mixture of [MoL*(NO)Cl(OC_6H_4 CH_2OH)] (0.10 g, 0.17 mM), [Mo(NO)L*Cl_2] (0.84 g, 0.17 mM) and triethylamine (0.17 g, 0.17 mM) was refluxed in toluene (50 cm^3) for 90 min. The reaction mixture was then evaporated *in vacuo*, the residue redissolved in CH_2Cl_2 and filtered. The filtrate was evaporated to low volume and chromatographed using CH_2Cl_2/n-hexane (20% v/v) as an eluant. The first major fraction was collected, the solvent evaporated *in vacuo* and the residue recrystallized from dichloromethane/n-hexane affording the complex as a brown powder (yield: 0.04 g, 25%).

Method 2. [Mo(NO)L*Cl_2] (0.207 g, 0.4 mM) was stirred in CH_2Cl_2 (30 cm^3) containing $AgBF_4$ (0.078 g, 0.4 mM) at room temperature for 1 h under nitrogen. The resulting mixture was then filtered under nitrogen and to the filtrate was added 4-hydroxybenzyl alcohol (0.0245 g, 0.2 mM), the mixture then being refluxed for 18 h. The solution was then evaporated to low volume and purified by column chromatography, the complex being isolated as brown microcrystals (yield: 0.04 g, 20%).

[Mo(NO)L*I($OC_6H_4CH_2OH$)]

This compound was prepared in the same way as [Mo(NO)L*Cl($OC_6H_4CH_2OH$)] using [Mo (NO)L*I_2] instead of [Mo(NO)L*Cl_2] as the starting material, the reaction mixture then being refluxed for 2 h. The complex was obtained as a red–brown powder after recrystallization from dichloromethane/n-hexane (yield: 0.14 g, 52%).

[{Mo(NO)L*I}$_2$($OC_6H_4CH_2O$)]

This compound was prepared following the same method described in Method 1 above for [{Mo(NO)L*Cl}$_2$($OC_6H_4CH_2O$)], but using [Mo(NO)L*I_2] and hexamine. After work-up and recrystallization from CH_2Cl_2/n-hexane, the compound was isolated as a dark red–brown powder (yield: 0.04 g, 30%).

[{MoL*(NO)Cl}$_2$($OC_6H_4CH_2CH_2O$)]

A mixture of [Mo(NO)L*Cl_2] (0.207 g, 0.4 mM) and 2-(4-hydroxyphenyl)ethanol (0.027 g, 0.2 mM) was refluxed in toluene (50 cm^3) in the presence of triethylamine for 8 h. The reaction mixture was then evaporated *in vacuo*, the residue redissolved in CH_2Cl_2 and chromatographed using n-hexane/ dichloromethane (30% v/v) as an eluant. The first major fraction was collected, evaporated to low volume and the red–brown product was precipitated by adding n-hexane (yield: 0.072 g, 35%).

[{MoL*(NO)I}$_2$($OC_6H_4CH_2CH_2O$)]

A mixture of [Mo(NO)L*I_2] (0.27 g, 0.4 mM), 2-(4-hydroxyphenyl)ethanol (0.027 g, 0.2 mM) and hexamine (0.34 g, 0.4 mM) was refluxed in toluene (50 cm^3) for 8 h. The mixture was evaporated *in vacuo*, the residue redissolved in CH_2Cl_2 and the resulting solution filtered. The filtrate was then evaporated to low volume and chromatographed using n-hexane/dichloromethane (25% v/v) as an eluant. The complex was isolated as a brown powder after work-up and recrystallization from CH_2Cl_2/n-hexane (yield: 0.10 g, 37%).

[{Mo(NO)L*Cl}$_2$($OC_6H_4CH_2CH_2CH_2O$)]

This compound was synthesized in the same way as [{MoL*(NO)Cl}$_2$($OC_6H_4CH_2CH_2O$)] using 3-(4-hydroxyphenyl)propanol in place of 2-(4-hydroxyphenyl)ethanol and was obtained as a brown microcrystalline solid (yield: 0.07 g, 34%).

[{Mo(NO)L*I}$_2$($OC_6H_4CH_2CH_2CH_2O$)]

This compound was prepared in the same way as [{Mo(NO)L*I}$_2$($OC_6H_4CH_2CH_2O$)]. 3-(4-Hydroxyphenyl)propanol was used instead of 2-(4-hydroxyphenyl)ethanol, and the compound was isolated as a dark brown microcrystalline solid (yield: 0.81 g, 30%).

[{Mo(NO)L*Cl}$_2$($NHC_6H_4CH_2CH_2O$)]

This compound was prepared in a way similar to [{Mo(NO)L*Cl}$_2$($OC_6H_4CH_2CH_2O$)] described above, using 2-(4-aminophenyl)ethanol (0.03 g, 0.02 mM) in refluxing toluene (50 cm^3) over 6 h.

Table 1. Elemental analyses for [ML*(NO)XY]

W	Cl	$NHC_6H_4CH_2CH_2OWL^*(NO)Cl$	0	36.6(36.57)	4.2(4.15)	16.1(16.14)

^{a} Number of moles of C_6H_{14} or CH_2Cl_2; this factor also confirmed by independent ^{1}H NMR spectral analysis.

The complex was obtained as a red–brown powder (yield: 0.06 g, 28%).

[{Mo(NO)L*I}$_2$(NHC$_6$H$_4$CH$_2$CH$_2$O)]

This compound was prepared in the same way as [{Mo(NO)L*I}$_2$(OC$_6$H$_4$CH$_2$CH$_2$O)} using 2-(4-aminophenyl)ethanol (0.03 g, 0.2 mM) and was refluxed for 5 h. The complex was isolated as black microcrystals (yield: 0.09 g, 33%).

[{W(NO)L*Cl}$_2$Q] (Q = OC$_6$H$_4$CH$_2$O, OC$_6$H$_4$CH$_2$CH$_2$O, OC$_6$H$_4$CH$_2$CH$_2$CH$_2$O *and* HNC$_6$H$_4$CH$_2$CH$_2$O)

These complexes were prepared following the same method as for [{Mo(NO)L*Cl}$_2$(OC$_6$H$_4$CH$_2$CH$_2$O)], but were refluxed for 12 h. Yields of the respective tungsten complexes were generally 35%.

RESULTS AND DISCUSSION

Synthetic studies

The monometallic species [Mo(NO)L*X(OC$_6$H$_4$CH$_2$OH)] (X = Cl or I) were obtained by direct reaction between [Mo(NO)L*X$_2$] and HOC$_6$H$_4$CH$_2$OH in dichloromethane. The bimetallic complexes [{M(NO)L*X}$_2$EC$_6$H$_4$(CH$_2$)$_n$O] (M = Mo, X = Cl or I; M = W, X = Cl; E = O or NH), however, could be prepared by two methods: either by refluxing 2 mole equivalents of [M(NO)L*X$_2$] with 1 mole equivalent of the desired bridging ligand in toluene, or by preforming [M(NO)L*X{EC$_6$H$_4$(CH$_2$)$_n$OH}] and treating that with 1 mole equivalent of [M(NO)L*X$_2$] in the presence of amine (triethylamine or hexamine). It was also possible to produce the bimetallic species by reaction of [Mo(NO)L*X$_2$] with Ag$^+$ in dichloromethane, followed by addition of the desired bridging ligand but, in general, reactions in toluene were more rapid, presumably because of the higher reaction temperature.

In these reactions with bifunctional ligands, [M(NO)L*X$_2$] preferentially selected the alkoxy group and earlier work has shown that arylamines react in preference to phenoxy ligands.[5] The yields of bimetallic complexes were relatively low, those of the molybdenum complexes being significantly lower than those of their tungsten analogues.

The new compounds were obtained as microcrystalline powders, whose formulations are based on elemental analyses (Table 1), spectroscopic (Table 2) and electrochemical studies (Table 3).

Spectroscopic studies

The IR spectra of the new complexes exhibited bands characteristic of the tris(3,5-dimethylpyrazolyl)borato ligand and the bridging ligand, with ν(BH) at *ca* 2550 cm^{-1} and ν(NH) at *ca* 3228 cm^{-1}. The monometallic species [Mo(NO)L*X(OC$_6$H$_4$CH$_2$OH)] exhibited ν(NO) at *ca* 1680 cm^{-1} [X = Cl and 1670 cm^{-1} (X = I)], typical of this class of phenolato compounds, as

[a] Studied in CH_2Cl_2 vs SCE using a platinum bead electrode, unless otherwise stated: bimetallic species exhibited two reduction processes.

[b] Separation between cathodic and anodic CV peak for one-electron process values is 90 ± 10 mV for $[FeCp_2/[FeCp_2]^+$ couple.

[c] R = reversible process; EC = reversible process accompanied by a chemical reaction.

[d] Measured in CH_3CN.

observed earlier.[5] The bimetallic complexes exhibited two NO stretching frequencies, one for each metal–donor atom arrangement. Thus, for complexes of the type [Mo(NO)L*Cl{$OC_6H_4(CH_2)_nO$}Mo(NO)*X] these NO stretching frequencies are in the range 1680–1685 cm^{-1} and at 1670 cm^{-1}, and from comparisons with spectral data taken from related mono- and bimetallic species, the former absorptions are associated with the *phenoxide* {Mo(NO)L*Cl(OAr)} fragment and the latter with the *alkoxide* {Mo(NO)L*Cl[$O(CH_2)_nAr$]} fragment. In the related iodo complexes, these two sets of absorptions occur at 1655–1660 and 1665–1670 cm^{-1}, respectively. In the spectra of the related tungsten complexes, ν(NO) occurred at 1640, 1630 and 1625 cm^{-1}, associated with phenolato, arylamide and alkoxy fragments, respectively.

The ^1H NMR spectra of the new complexes (Table 2) were generally unexceptional and are consistent with the formulation of the complexes. Thus, in all complexes, the 4-H protons of the pyrazole rings occurred in the range δ 5.7–6.1 ppm, appearing either as two signals of relative intensity 2:1 or three of relative intensity 1:1:1. The latter is expected because of the asymmetric ML*(NO)X centre and it can be presumed that a 2:1 pattern arises because the non-equivalence of two of the protons is not resovled. The absence of a plane of

symmetry is confirmed by the methyl signals of the pyrazolyl rings which appeared as a set of six lines in the region δ 2.04–2.68 ppm. In a few cases, the pyrazolyl ring signals were more complex probably because of the presence of diastereoisomers of $[\{ML^*(NO)X\}_2Q]$, which we were unable to separate (each metal centre is chiral). In the spectra of the bimetallic species, the ratio of integrated intensities for the protons of the methyl groups in the pyrazole ring relative to the 4-H protons was close to 36:6, while that relative to the aromatic ring protons was 36:4. These observations are consistent with the bimetallic nature of the complexes. Solvent of crystallization could be detected in the spectra of those complexes, whose elemental analytical data indicated that it was present.

In the ^1H NMR spectra of $[\{Mo(NO)L^*X\}_2\{OC_6H_4(CH_2)_nCH_2O\}]$ ($n = 1, 2$) signals due to L* appeared at very similar δ values, irrespective of n. The aromatic protons resonated at δ 7.3–7.4 ppm, a slightly lower field than in the monometallic $[Mo(NO)L^*X(OC_6H_4CH_2OH)]$. The methylene protons on the carbon atoms α to the oxygen atom of the alkoxy group occurred at *ca* δ 6.2 ppm, whereas those associated with the other methylenic groups appeared in more normal positions. In the spectrum of $[\{WL^*(NO)Cl\}_2\{OC_6H_4(CH_2)_nCH_2O\}]$ ($n = 1, 2$), the aromatic signals also occurred at δ 7.2, the α-C protons also appeared near 6.2 ppm due to the strong electronegativity of $\{M(NO)L^*X\}$.[5] The resonances of the α-methylene protons in $[\{M(NO)L^*X\}_2OC_6H_4CH_2O]$ [δ 6.4–6.5 (M = Mo); δ 6.5 (M = W)] were slightly more deshielded than those found in $[\{Mo(NO)L^*I\}_2OCH_2C_6H_4CH_2O]$ (δ = 6.5–6.9 ppm),[2] suggesting that the electron-withdrawing ability of the $\{Mo(NO)L^*(X)OC_6H_4\}$ group is somewhat stronger than that of the $\{Mo(NO)L^*XOCH_2C_6H_4\}$ group.

As the metal in $[Mo(NO)L^*Cl(OR)]$ is chiral, the methylene protons within the alkoxide group are inequivalent, and differential couplings to the aromatic protons should occur. This appears to be generally the case in the spectra examined, but we were unable to obtain reliable assignments due to the difficulty of separating the diastereomeric mixtures. In most complexes the aromatic proton signals appeared as AA'BB' multiplets which revealed additional fine structure, almost certainly due to coupling with the inequivalent α-C methylene protons in the alkoxide group.

In the spectra of the molybdenum arylamido iodo complexes $[\{M(NO)L^*X\}_2NHC_6H_4CH_2CH_2O]$ δ(NH) occurred at low field, the value depending on M and X, as expected. In general the spectra were similar to those of $[\{M(NO)L^*X\}_2OC_6H_4CH_2CH_2O]$, the methylene protons on the carbon atom α to the alkoxide oxygen atom also being significantly deshielded, as expected, because of the electronegativity of the $[M(NO)L^*X]$ centre.[5]

Electrochemical studies

The electrochemical behaviour of the new complexes was investigated by cyclic voltammetry (Table 3) and by differential pulse polarographic techniques, using a platinum bead electrode in dichloromethane, unless otherwise stated. The electrochemical behaviour of a few complexes was also determined in CH_3CN, but the data were almost identical to those obtained in dichloromethane. In accord with earlier findings, the complexes exhibited a poorly defined irreversible oxidation process at potentials more anodic than +0.5 V for the molybdenum complexes and +0.8 V for the tungsten complexes. A number of the reductive electrode processes were reversible or nearly so, this being established by comparison of wave shape with that of the electrode behaviour of ferrocene under the same conditions. The separation of peaks in the reversible system (i.e. ΔE_p) varied from 80 to 120 mV depending on the solvent and the cells used for the measurements.

The nature of the reduction processes was established by plotting the cyclic voltammogram scan rate (v) vs $i_p v^{1/2}$, for reversible processes a straight line was obtained; further tests relied on the constancy of the dependency of E_f values on $v^{1/2}$. The reduction processes of iodo complexes $[\{MoL^*(NO)I\}_2Q]$ were presumed to be electrochemically reversible, but were coupled to a subsequent chemical reaction, as observed earlier.[6] In a few selected cases the number of electrons in each transfer was checked by coulometry. The data obtained are presented in Table 3 along with some previously reported data from $[\{M(NO)L^*X\}_nY]$ (Y = OPh, $n = 1$, and $OCH_2C_6H_4CH_2O$, $n = 2$).[2,7] It is assumed that the new complexes undergo discrete one-electron transfer processes, the wave shapes being analysed by comparison with known one-electron transfer species (e.g. $[Mo(NO)L^*Cl_2]$ and $[Mo(NO)L^*Cl(OPh)]$).

$[Mo(NO)L^*Cl_2]$ and $[W(NO)L^*Cl_2]$ undergo a one-electron reversible reduction, whereas $[Mo(NO)L^*I_2]$ exhibits a one-electron quasi-reversible reduction process, the E_f values being −0.09, −0.46 and +0.22 V vs SCE, respectively, in CH_3CN.[8] $[Mo(NO)L^*Cl(OPh)]$ was reduced in CH_2Cl_2 at *ca* −0.4 V, while its iodo analogue was reduced at −0.25 to −0.28 V.[7] The reduction potentials for $[Mo(NO)L^*I(OEt)]$ have been reported at *ca* −0.61 V[6] and those for $[Mo(NO)L^*I(OCH_2C_6H_4CH_2OH)]$ at −0.53 V,[2] while the

E_f values for the arylamido [Mo(NO)LX(NHPh)] derivatives occurred at *ca* −0.85 (X = Cl) and −0.83 (X = I) V, respectively.[9] The reduction potentials for phenoxy, benzyloxy and arylamido derivative of [W(NO)L*Cl_2] were −0.86, −1.10 and −1.30 V, respectively, the values being slightly solvent dependent.[2,9]

On the basis of the above data, it may be concluded that for [{Mo(NO)L*X}$_2$ $OC_6H_4(CH_2)_nCH_2O$] (X = Cl or I, n = 1 or 2), the molybdenum centre linked to the phenoxy end of the bridging ligand is reduced in the potential range −0.32 to −0.37 V, while that attached to the alkoxy function is reduced in the range −0.67 to −0.58 V. In [{W(NO)L*Cl}$_2$$OC_6H_4(CH_2)_nCH_2O$] ($n$ = 1 or 2), these values are −0.88 and −1.22 V, respectively.

For [{Mo(NO)L*X}$_2$$NHC_6H_4CH_2CH_2O$] the alkoxy- and arylamido-linked metal centres are reduced in the regions −0.5 to −0.6 V and −0.82 to −0.9 V, respectively. The alkoxy- and arylamido-linked metal centres are presumed to be reduced reversibly as E_f is independent of the CV scan rate, but in both cases electrochemical reduction is followed by a chemical reaction as proposed earlier.[6] Metal phenoxide centres are either reduced reversibly or the rate of chemical decomposition of the reduced species is low, and comparing the cathodic reduction peak shape for alkoxy and arylamido derivatives with that for phenoxy derivatives and ferrocene we suggest that electron transfer rates for the aryl amido and alkoxy derivative are relatively slow. If we compare the E_f values for the reduction processes for these bimetallic and the corresponding monometallic complexes, it is evident that there is not much variation (±30 mV), i.e. ΔE_f is almost 0, which clearly indicates that there is little interaction between the two metal centres in the bimetallic complexes.

However, the situation is slightly different in [{Mo(NO)L*X}$_2$($OC_6H_4CH_2O$). Metal centres linked to the phenoxy end of the ligand are reduced at values 70 mV more *anodic* than the corresponding monometallic complexes, while alkoxy linked metal centres are reduced at values approximately 20 mV more *cathodic* than the expected potentials. This suggests that there *is* an interaction between the two metal centres, although its extent is much lower than that occurring in [{Mo(NO)L*Cl}$_2$$OC_6H_4O$-*p*] ($\Delta E_f$ = 460 mV). Thus, it can be concluded that insertion of CH_2 groups into the bridging ligand significantly reduces the extent of interaction between two metal centres, partly because of the attenuation of conjugation. These findings may be contrasted with the situation in the ruthenium complexes [{$(NH_3)_5Ru$}$_2$ {NC_5H_4—X—C_5H_4N-4,4′}]$^{4+}$ (X = nothing, S-S), where the incorporation of the S_2 bridge leads to the four-fold increase in the intermetallic interaction, measured electrochemically by ΔE_f.[10]

SYNTHESIS AND X-RAY STUDIES OF THE SEVEN-COORDINATE Ti^{IV}(THPED) DIMER

(*Received* 1 *October* 1992; *accepted* 13 *November* 1992)

Abstract—The synthesis and X-ray structure of the seven-coordinate Ti^{IV}(THPED) dimer, where H_4THPED = N,N,N′,N′-tetrakis-(2-hydroxypropyl)ethylenediamine, is described. The structure is dimeric with each titanium atom chelating to an N_2O_5 donor set. One oxygen atom in each ligand is binucleating, thus forming a central Ti_2O_2 ring.

Recently we have reported the synthesis of zirconium(IV) and hafnium(IV) complexes with the encapsulating octadentate ligand ethylene glycol-O,O′-bis-(2-aminoethyl)-N,N,N′,N′-tetraacetic acid, which possesses an N_2O_6 donor set.[1] Titanium(IV) has a much reduced ionic radius compared to zirconium(IV) and hafnium(IV) and its complexes also have a tendency to hydrolyse to compounds containing Ti—O linkages and/or oxo-bridges. X-ray studies have been carried out on $Ti^{IV}(EDTA)\cdot H_2O$,[2] $[NEt_3H][Ti^{IV}(Htripace)]\cdot 1.5\,CH_3CN$[3] and Ti^{IV}-crown-ether[4] derivatives and to our knowledge these represent the only titanium complexes reported which utilize ligands with denticity greater than or equal to six.

The titanium tartrate complexes developed by Sharpless and co-workers[5,6] which are responsible for a number of highly successful asymmetric epoxidation reactions remain the principal route to many enantiospecific products. The data available support a dimeric species, $[Ti_2(tartrate)_2(OR)_4]$, as the catalyst, but the structure has been assigned on the basis of the related dibenzyltartramide analogue.[7] This complex utilizes hydroxylate oxygen donors, which bridge to form a Ti_2O_2 ring.

Here, we describe the synthesis and X-ray characterization of the air stable complex $[Ti^{IV}(THPED)]_2\cdot C_7H_8$, where H_4THPED = N,N,N′,N′-tetrakis-(2-hydroxypropyl)ethylenediamine (Quadrol, Fig. 1), formed by the reaction shown in eq. (1).†

$$2Ti(OPr^i)_4 + 2H_4THPED \longrightarrow [Ti(THPED)]_2 + 8HOPr^i \quad (1)$$

† Preparation of $[Ti^{IV}(THPED)]_2\cdot C_7H_8$. Titanium(IV) isopropoxide (4.07 cm^3, 13.7 mmol) was added to a solution of H_4THPED (4.0 g, 13.7 mmol) in dichloromethane. The mixture was refluxed for 24 h, evaporated to dryness and recrystallized from hot toluene. Yield: 4.36 g, 42%. Found: C, 53.5; H, 8.5; N, 7.5. Calc. for $[Ti^{IV}(THPED)]_2\cdot C_7H_8$: C, 55.0; H, 8.4; N, 7.3%. Mass spectrum (FAB$^+$, glycerol + thioglycerol + trifluoroacetic acid matrix): $m/z = 337$ and 673, which corresponds to $[Ti^{IV}(THPED)H]^+$ and $\{[Ti^{IV}(THPED)]_2H\}^+$, respectively.

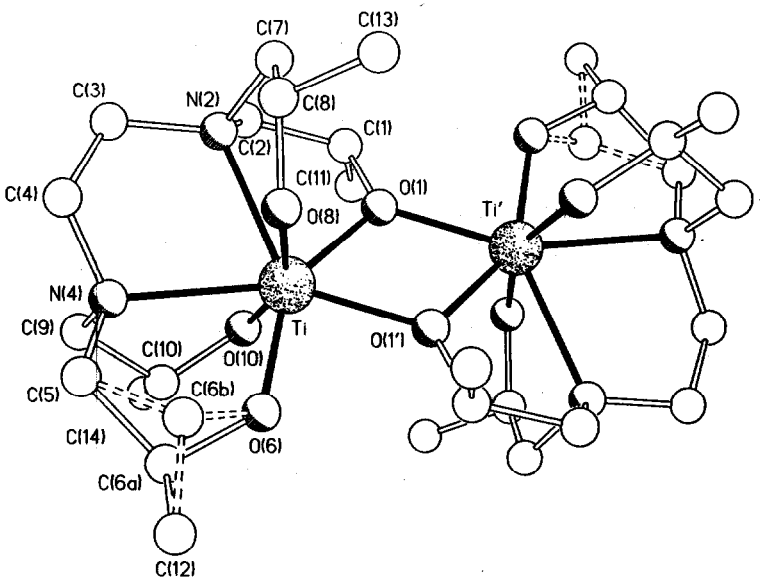

Fig. 2. The X-ray structure of $[Ti(THPED)]_2$ in $[Ti(THPED)]_2 \cdot C_7H_8$. The dotted bonds to C(6b) show the two disordered configurations that exist for this portion of the ligand in the crystal.

* Crystals of $[Ti^{IV}(THPED)]_2 \cdot C_7H_8$ suitable for X-ray diffraction measurements were recrystallized from toluene.

Crystal data. $[Ti^{IV}(THPED)]_2 \cdot C_7H_8$: $C_{35}H_{64}N_4O_8Ti_2$, $M = 764.7$, monoclinic, $a = 22.476(9)$, $b = 10.176(9)$, $c = 18.403(9)$ Å, $\beta = 112.43(4)°$, $U = 3891$ Å^3, space group $C2/c$, $Z = 4$. The complex has crystallographic C_i symmetry. $D_c = 1.305$ Mg m^{-3}. Clear block, dimensions $0.33 \times 0.40 \times 0.43$ mm, μ(Mo-K_α) = 0.463 mm^{-1}, $\lambda = 0.71073$ Å, $F(000) = 1640$.

Data collection and processing. Siemens P4/PC diffractometer, room temperature, ω scan method (2θ range 3.0–50.0°), graphite monochromated Mo-K_α radiation; 3427 independent measured reflections, 2325 observed [$|F_o| > 4.0\sigma(|F_o|)$], corrected for Lorentz and polarization factors.

Structure analysis and refinement. The structure was solved by direct methods and all the non-hydrogen atoms refined anisotropically. A ΔF map revealed the presence of disorder for one of the CH groups [C(6)]. This disorder corresponds to an inversion of this centre and two positions [C(6a) and C(6b) each of occupancy 50%] were refined anisotropically. The positions of hydrogen atoms were idealized (C—H = 0.96 Å), assigned isotropic thermal parameters $U(H) = 1.2U_{eq}(C)$ and allowed to ride on their parent carbons. The methyl groups were refined as rigid bodies. Refinement was by full-matrix least-squares to $R = 0.054$ ($R = \Sigma[|F_o| - |F_c|]/\Sigma|F_o|$), $R_w = 0.054$ [$w^{-1} = \sigma^2(F) + 0.0007F^2$]. The mean and maximum shifts/errors in the final refinement cycle were 0.014 and 0.743, respectively. The maximum and minimum residual electron densities were 0.50 and -0.36 e Å^{-3}, respectively. Computations were carried out on an IBM 386/70 using SHELXTL PC.[8]

The X-ray crystal structure* shows the molecule to be dimeric (Fig. 2) with each titanium atom being seven-coordinate, binding to all six of the potential donor atoms of the ligand. One oxygen atom [O(1)] of the ligand is binucleating, serving to bridge between adjacent titanium centres. The binuclear molecule is centrosymmetric with a crystallographic centre of symmetry at the centre of the planar Ti_2O_2 ring. The transannular Ti···Ti′ and O(1)···O(1′) distances are 3.41 and 2.29 Å and the O(1)—Ti—O(1′) and Ti—O(1)—Ti′ angles are 67.8(1)° and 112.2(1)°, respectively. Although the ligand is capable of binding the metal with a high degree of symmetry the potential molecular C_2 symmetry is broken both by C(10) and by one of the two disordered C(6) configurations (see below). The coordination polyhedron can be considered as either a distorted monocapped trigonal prism [Fig. 3(a)] with O(1)···N(2)···O(10) and O(1′)···O(6)···O(8) forming the prism and with N(4) as the capping atom or as a distorted pentagonal biprism [Fig. 3(b)] with O(8)···O(10) forming the principal axis. The lengths of the edges for the monocapped prism are in the range 2.29 [O(1)···O(1′)] to 2.99 Å [N(2)···O(10)] and those for the pentagonal biprism are in the range 2.29 [O(1)···O(1′)] to 3.20 Å [O(1′)···O(10)]. The Ti—O coordination distances (Table 1) are in the range 1.880(3) [Ti—O(6)] to 2.078(3) Å [Ti—O(1)]. These distances, with the exception of those involving the bridging oxygen atoms [O(1) and O(1′)], are noticeably shorter than those in $Ti(EDTA) \cdot H_2O$

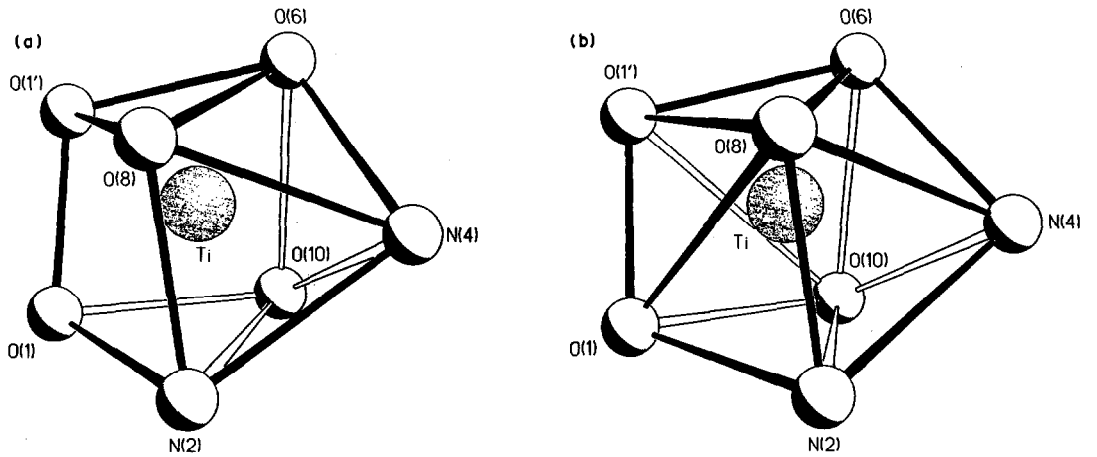

Fig. 3. (a) Distorted monocapped trigonal prismatic and (b) distorted pentagonal biprismatic representations of the coordination sphere about each titanium atom. In the binuclear structure the polyhedra are linked edge to edge about O(1)···O(1').

[range 1.922(2)–1.985(2) Å]. In contrast, both Ti—N distances [2.349(4), N(2); 2.386(5) Å, N(4)] are significantly longer than those in Ti(EDTA)·H_2O [mean 2.302(3) Å].[2] The similar structure of the seven-coordinate binuclear oxygen-bridged titanium cation $[\{TiCl(\mu\text{-}O)(12\text{-crown-}4)\}_2]^{2+}$ contains μ-oxo groups where, as expected, the bridging Ti—O distances are significantly shorter at 1.811(3) and 1.823(4) Å than those observed here [2.078(3), Ti—O(1); 2.025(4), Ti—O(1')].[4] In contrast, the Ti—O distances of the six-coordinate binuclear hydroxylate bridged $Ti_2(DBTA)_2(OPr^i)_4$ complex, where H_2DBTA = (*R*,*R*)-N,N'-dibenzyltartramide, are comparable [2.160(9) and 1.973(9) Å].[7]

As each ligand contains four chiral centres, there is the potential to form, in a binuclear structure, i.e. 2562,[8] configurational isomers. However, many of these must be sterically unfavourable when the ligand is complexed to a metal centre, although the disorder that is observed at C(6) (which corresponds to an inversion at this centre) clearly indicates that more than one configuration for the complexed ligand can exist in the solid state. As the binuclear complex is centrosymmetric the relative configurations about the two titanium centres are enantiomeric.

Attempts to characterize the complex in solution by NMR spectroscopy confirmed the presence of numerous isomers. The ^1H NMR spectrum of the complex showed that racemization was slow on the

NMR time-scale with different isomers separated in the spectrum (Fig. 4). There is a certain degree of overlap due to the inability of NMR to distinguish between diastereomers, however, this leads to only a small reduction in the complexity of the system, thus individual assignments cannot be made.

The complex described is an example of a titanium dimer which utilizes a bridging hydroxylate moiety from the ligand to form a Ti_2O_2 ring analogous to titanium catalysts used in asymmetric organic syntheses. However, the success of the titanium catalysts depends on the orientation of the ligands and the mechanism of the reaction is believed to involve six-coordinate titanium intermediates.[5] In contrast, the $[Ti(THPED)]_2$ complex described here is a stable dimer with seven-coordinate titanium atoms. The observations reported here may stimulate investigations to evaluate the possibility of seven-coordinated titanium intermediates in catalysis.

Acknowledgements—We are grateful to the SERC for an equipment grant. We also thank Mr R. N. Sheppard for the 500 MHz NMR spectra and Mr M. Domin for the mass spectrum. One of us (C.Y.W.) thanks the SERC for a grant.

TWO NEW STRUCTURAL TYPES FOR d^3–d^3 DIMERS OF MOLYBDENUM AND TUNGSTEN: $[K(18\text{-crown-6})]^+[Mo_2(OCH_2Bu^t)_7]^-$ AND $[W_2\{P(c\text{-hexyl})_2\}_3(OCH_2Bu^t)_3\{HP(c\text{-hexyl})_2\}]$

THEODORE A. BUDZICHOWSKI, MALCOLM H. CHISHOLM,* JAMES D. MARTIN, JOHN C. HUFFMAN, K. G. MOODLEY and WILLIAM E. STREIB

Department of Chemistry and Molecular Structure Center, Indiana University, Bloomington, IN 47405, U.S.A.

(*Received* 1 *October* 1992; *accepted* 13 *November* 1992)

Abstract—The syntheses and structures (determined by single-crystal X-ray diffraction techniques) are reported for $[K(18\text{-crown-6})]^+[Mo_2(OCH_2Bu^t)_7]^-$ and $[W_2\{P(c\text{-hexyl})_3\}_3(OCH_2Bu^t)_3\{HP(c\text{-hexyl})_2\}]$. The former contains a single bridging (μ-OCH_2Bu^t) ligand, six terminal alkoxide ligands and an M≡M triple bond. The latter contains three bridging (μ-PR_2) ligands and an M—M bond distance that is most consistent with the presence of a single bond. These two compounds are the first examples of M_2L_7 complexes with bridging ligands. They highlight the delicate balance of metal–metal vs metal–ligand bonding in the coordination chemistry of d^3–d^3 dimers of molybdenum and tungsten.

The coordination chemistry of M_2^{6+} containing compounds, where M = molybdenum and tungsten, is extremely rich because of the subtle interplay between metal–ligand and metal–metal bonding.[1] Compounds of the form M_2L_6 generally adopt an ethane-like geometry, $L_3M{\equiv}ML_3$, for L = alkyl, alkoxide, thiolate and amide. This type of geometry is also found for numerous mixed-ligand sets, as in $M_2(NMe_2)_4X_2$ compounds, where X = halide or alkyl. The compounds $M_2(OR)_6$ react reversibly with donor ligands L such as pyridine and PMe_3 to give adducts $M_2(OR)_6L_2$, which contain two roughly square-planar four-coordinate metal atoms united by an unbridged M≡M bond.[2] The monoligated adducts $M_2(CH_2Ph)_2(OPr^i)_4(PMe_3)$[3] and $W_2(p\text{-tolyl})_2(OPr^i)_4(HNMe_2)$[4] provide the only known examples of d^3–d^3 dimers having seven ligands and in each case there is an unbridged M≡M bond between three- and four-coordinated metal atoms, as might have been anticipated by the removal of one of the neutral ligands from an $M_2(OR)_6L_2$ compound. Nevertheless, it seemed reasonable to suppose that for compounds with seven ligands bridged structures should be accessible. Indeed bridged structures were implicated by two earlier observations. (1) The reversible addition of PMe_3 to $(Pr^iO)_2(PhCH_2)Mo{\equiv}Mo(CH_2Ph)(OPr^i)_2$ yielded $(PMe_3)(Pr^iO)(PhCH_2)_2Mo{\equiv}Mo(OPr^i)_3$ by way of facile benzyl/alkoxide ligand migrations.[3] (2) In the amide for halide substitution involving $(Me_3SiCH_2)_2BrMo{\equiv}MoBr(CH_2SiMe_3)_2$ and $LiNMe_2$ (2 equivalents) the compound $(Me_3SiCH_2)(Me_2N)_2Mo{\equiv}Mo(CH_2SiMe_3)_3$ was formed, whereas by an alternate synthesis the 1,2-isomer $(Me_3SiCH_2)_2(Me_2N)Mo{\equiv}Mo(NMe_2)(CH_2SiMe_3)_2$ was formed.[5] Furthermore, although 1,1- and 1,2-isomers of the formula $M_2X_4Y_2$ do not interconvert readily in solution, when $X = NMe_2$ and $Y = PR_2$, we have observed an equilibrium involving the 1,2-ethane-like dimers and bridged isomers $W_2(\mu\text{-}PR_2)_2(NMe_2)_4$. In the latter metal–phosphorus bonding is maximized at the expense of metal–metal bonding.[6]

The addition of 1 equivalent of an alkoxide anion Q^+OR^- (1 equivalent) to hydrocarbon solutions of $M_2(OR)_6$ compounds [M = Mo, R = Pr^i and CH_2Bu^t, and M = W, R = Bu^t; $Q^+ = K^+$ (18-

* Author to whom correspondence should be addressed.

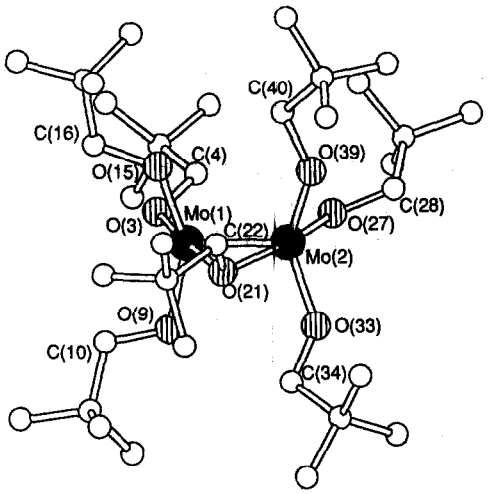

Fig. 1. A ball-and-stick drawing of one of the $Mo_2(OCH_2Bu^t)_7^-$ anions found in the structure of $[K(18\text{-crown-6})]^+[Mo_2(OCH_2Bu^t)_7]^- \cdot 2.5C_6H_6$. Selected averaged distances (Å) and angles (°) are Mo—Mo = 2.218(3), Mo—μ-O = 2.15(2), Mo—O terminal 1.92–1.97, *trans*-O(bridge)—Mo—O = 175 and 170, equatorial O terminal—Mo—O terminal = 146, 132, 147 and 131, and Mo—O(bridge)—Mo = 62.

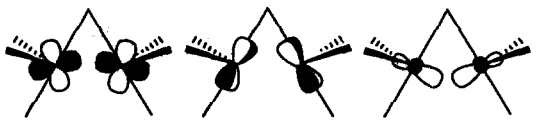
crown-6)] yields a colour change from yellow–orange to purple. By ^1H NMR spectroscopy only one type of OR ligand is observed at room temperature in benzene-d_6 and at −40°C in pyridine-d_5. Adduct formation was confirmed in the solid state by a single-crystal X-ray structural determination of the $[K(18\text{-crown-6})]^+[Mo_2(OCH_2Bu^t)_7]^-$ salt.* A drawing of the anion is shown in Fig. 1.

The $Mo_2(OCH_2Bu^t)_7^-$ anion contains two four-coordinate molybdenum atoms that share a single bridging OR ligand. The Mo—Mo distance, 2.22 Å, is essentially the same as that in the ethane-like unbridged parent compound $Mo_2(OCH_2Bu^t)_6$, Mo—Mo = 2.222(2) Å.[7] The formation of an Mo—Mo triple bond in the $Mo_2(OR)_7^-$ anion can be anticipated based on a consideration of the Mo_2O_7 skeleton, which contains an acute Mo—O—Mo angle (62°). The coordination geometry about each molybdenum atom can be considered to be derived from a trigonal bipyramid, wherein one equatorial site is vacant. The bridging OR ligand occupies a common apical site and the frontier orbitals of the two d^3-ML_4 fragments interact to form an M—M triplebond having one σ- and two π-components, as shown below.



In the unit cell there are two independent $Mo_2(OCH_2Bu^t)_7^-$ anions and in both the oxygen atom of the bridging OR ligand is distinctly pyramidal: Σ angles at μ-O = 318.6 and 322.2. This is unusual for μ-OR ligands, but can be understood in terms of the formation of an Mo—Mo triple bond having one σ- and two π-components. A trigonal-planar bridging oxygen would introduce a filled oxygen p_π-orbital of the correct symmetry to interact with a filled M—M π-orbital. This filled–filled orbital interaction is avoided by the pyramidal rather than trigonal hybridization at the bridging oxygen.

In the reaction between $W_2(p\text{-tolyl})_2(OCH_2Bu^t)_4$ and HP(c-hexyl)$_2$ (4 equivalents) in benzene at room temperature a red crystalline compound is formed in *ca* 60% yield, based on tungsten and was shown to be $[W_2(OCH_2Bu^t)_3\{P(c\text{-hexyl})_2\}_3\{HP(hexyl)_2\}]$ by single-crystal X-ray crystallography.[7] A ball-and-stick drawing of the molecule is given in Fig. 2. The two tungsten atoms are united by three μ-PR_2 ligands. One tungsten atom,

*Crystal data (i) for $[K(18\text{-crown-6-})]^+[Mo_2(OCH_2Bu^t)_7]^- \cdot 2.5C_6H_6$ at −165°C: a = 19.653(4), b = 22.244(4), c = 19.228(3) Å, α = 110.99(1)°, β = 107.51(1)°, γ = 98.19(1)°, Z = 4, d_{calc} = 1.22 g cm^{-3}, and space group $P\bar{1}$; (ii) for $[W_2\{P(c\text{-hexyl})_2\}_3(OCH_2Bu^t)_3\{HP(c\text{-hexyl})_2\}] \cdot 1.5C_6H_6$ at −156°C: a = 14.824(5), b = 19.262(7), c = 13.845(5) Å, α = 93.84(2)°, β = 108.10(2)°, γ = 95.62(2)°, Z = 2, d_{calc} = 1.37 g cm^{-3} and space group $P\bar{1}$.

W(2), has two terminal OR ligands and its WP_3O_2 geometry may be described as square pyramidal with the bridging phosphido ligand P(3) occupying the apical site. The other tungsten atom W(1) is in a pseudo-trigonal bipyramidal geometry, wherein the bridging phosphido ligand P(3) and the terminal phosphine ligand occupy axial sites.[8] There is only one terminal RO ligand bound to W(1). In solution the molecule is stereochemically labile so that on the ^{31}P NMR time-scale at room temperature all three bridges are equivalent, $\delta = 235$, but show coupling to two inequivalent tungsten nuclei, $^1J(^{183}W—^{31}P) = 247$ and 303 Hz. The phosphine ligand appears as a singlet at $\delta = 27.5$. Evidently, proton transfer between the phosphine and the phosphido ligands is slow. At $-80°C$ in toluene-d_8 there is evidence for the freezing-out of two types of μ-PR_2 ligands, δ 241 and 202, as expected based on the observed solid-state structure.

Although we are not sure how the phosphido bridged compound is formed in the reaction between $W_2(p\text{-tolyl})_2(OCH_2Bu^t)_4$ and dicyclohexylphosphine, we report it here because its structure represents a situation where metal–ligand bonding in the form of three bridging phosphido ligands is favoured at the expense of metal–metal bonding. Note the W—W distance of 2.62 Å. This contrasts with the structure of the $Mo_2(OCH_2Bu^t)_7^-$ anion, where the essential elements of the triple bond are preserved.

In conclusion, we note that the present structural characterizations provide the first examples of bridged M_2^{6+}-containing compounds supported by seven ligands and add to the wealth of structural diversity in the chemistry of d^3–d^3 dimers of molybdenum and tungsten. In one case we see the preference for M—M bonding, while in the other M—M bonding is sacrificed in favour of metal–ligand bonding. The structure and fluxional behaviour of the $Mo_2(OR)_7^-$ anion provide insight into the likely mechanism of facile ligand transfer between the metal atoms that occurs when seven ligands are present at the dinuclear centre. Ligand transfer does not occur rapidly when only six ligands are present.*

Further studies are in progress.

Supplementary material available. Listing of atomic coordinates and isotropic thermal parameters have been deposited with the Cambridge Crystallographic Data Center.

COMMUNICATION

INCORPORATION OF CHELATING 2,2′-BIPYRIDINE (bipy) LIGANDS AT THE EQUATORIAL SITES OF $Cu_2(\mu\text{-}O_2CMe)_4(H_2O)_2$: AN X-RAY STRUCTURE OF $[Cu_2(\mu\text{-}O_2CMe)_2(H_2O)(bipy)_2](PF_6)_2$

SHANMUGAM MEENAKUMARI and AKHIL R. CHAKRAVARTY*

Department of Inorganic and Physical Chemistry, Indian Institute of Science, Bangalore 560 012, India

(*Received* 13 *August* 1992; *accepted* 1 *October* 1992)

Abstract—The asymmetric dicopper(II) title complex with a $[Cu_2(\mu\text{-}O_2CMe)_2]^{2+}$ core was isolated from the reaction between $Cu_2(\mu\text{-}O_2CMe)_4(H_2O)_2$ and bipy in EtOH in the presence of NH_4PF_6 and has been characterized by X-ray diffraction analysis.

Perlepes *et al.* have recently reported[1] the isolation of a dicopper(II) complex, $[Cu_2(\mu\text{-}O_2CMe)_2(H_2O)_2(bipy)_2](ClO_4)_2 \cdot H_2O$, from the reaction between $[Cu_2(OH)_2(bipy)_2](ClO_4)_2$ and $MeCO_2H$. In this communication we report an unusual and hitherto unknown $Cu_2(\mu\text{-}O_2CMe)_4 \rightarrow Cu_2(\mu\text{-}O_2CMe)_2^{2+}$ core conversion, resulting in the formation of $[Cu_2(\mu\text{-}O_2CMe)_2(H_2O)(bipy)_2](PF_6)_2$ (**1**). The reactivity of the tetra-μ-acetatodicopper(II) precursor towards bipy has been extensively studied.[1–4] However, previous attempts to isolate a complex with a $[Cu_2(\mu\text{-}O_2CMe)_2]^{2+}$ core using this precursor remained unsuccessful. Complex **1**, having bipy ligands at the equatorial sites, is unique in showing different coordination geometries at two copper(II) centres.

The reaction between $Cu_2(\mu\text{-}O_2CMe)_4(H_2O)_2$ and bipy in EtOH, followed by the addition of NH_4PF_6, led to the formation of a mixture of dicopper(II)[1–3] and tricopper(II)[4] complexes. Complex **1** was isolated as a minor product from this mixture by fractional crystallization. The molecular structure of **1** has been determined by X-ray diffraction.[5]†

An ORTEP view[6] of the cationic complex is shown in Fig. 1. Selected bond distances and angles are given in Table 1. The structure consists of a dicopper(II) unit held by two acetato bridges. The chelating bipy ligands occupy the equatorial sites and are in *syn* positions stabilized by stacking interactions. The coordination geometries of two copper(II) centres are square-planar and square-pyramidal. The removal of two bridging acetato ligands from the precursor has resulted in an increased Cu—Cu separation from 2.616(1) to 2.965(3) Å in **1**. The Cu—Cu distance in **1** is, however, the shortest among the reported[1,7] di-

† Analytical and crystal data for $[Cu_2(\mu\text{-}O_2CMe)_2(H_2O)(bipy)_2](PF_6)_2$ (**1**): Found: C, 33.1; H, 3.3; N, 6.4. Calc. for $C_{24}H_{24}N_4O_5F_{12}P_2Cu_2$: C, 33.3; H, 2.8; N, 6.5%. Mol. wt = 865.5, monoclinic, $a = 16.120(2)$, $b = 12.482(4)$, $c = 17.467(2)$ Å, $\beta = 113.98(1)°$, $U = 3211(1)$ Å^3, $Z = 4$, space group $P2_1/n$, $D_c = 1.79$ g cm^{-3}, $T = 290$ K, $\mu = 15.34$ cm^{-1}, $F(000) = 1728$, $R(R_w) = 0.0808$ (0.0904) for 3176 reflections with $I > 3\sigma(I)$, weighting scheme $w = 1.0000/(\sigma^2 |F_o| + 0.000115 |F_o|^2)$. The higher values of the R indices could be due to the presence of highly disordered PF_6 anions in the crystal lattice. Intensity data, collected on an Enraf–Nonius CAD4 diffractometer (Mo-K_α radiation, $\lambda = 0.7107$ Å), were corrected for Lorentz, polarization and absorption effects (transmission coefficients 0.92–1.00). The structure was solved and refined using the SHELX 76 program[5a] with Fourier syntheses and full-matrix least-squares. Atomic coordinates, full lists of bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre.

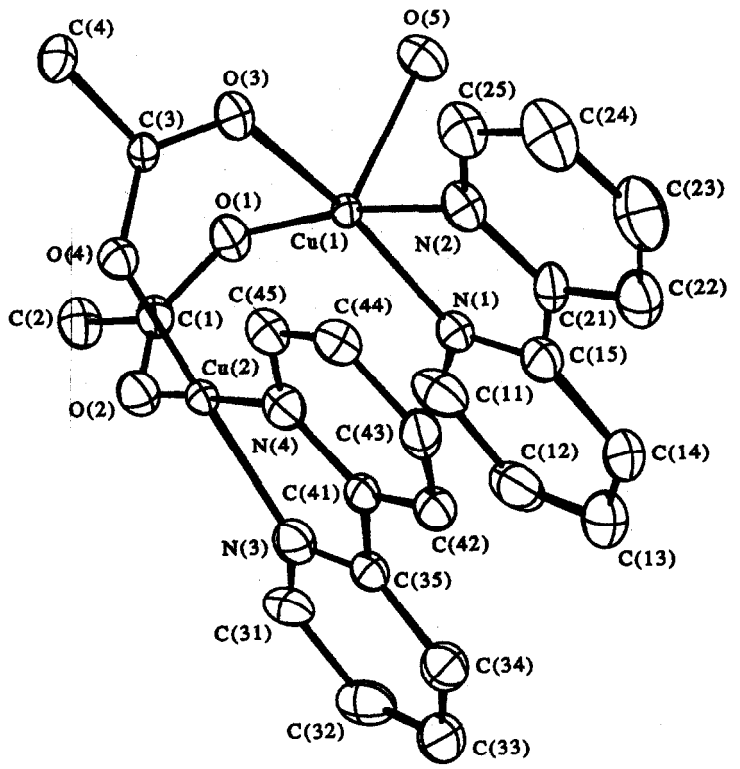

Fig. 1. An ORTEP view of the complex cation $[Cu_2(\mu\text{-}O_2CMe)_2(H_2O)(bipy)_2]^{2+}$ along with the atom numbering scheme.

copper(II) complexes containing a $[Cu_2(\mu\text{-}O_2CR)_2]^{2+}$ core (R = alkyl group) and two axial ligands. Complex **1** exemplifies the first dicopper(II) complex containing one axial ligand bonded to the di-μ-acetatodicopper(II) core.

The ESR spectrum of **1**, recorded at *X*-band in frozen methanol and shown in Fig. 2, exhibits well-resolved resonances which correspond to $\Delta M_s = \pm 1$, giving $g_\parallel$ and $g_\perp$ values of 2.28 and 2.06 ($A_\parallel = 165$ G, $A_\perp = 14$ G; $1\text{G} = 10^{-4}$ T), respectively. The fact that $g_\parallel > g_\perp$ is consistent with the X-ray structure. The ESR results indicate a weak antiferromagnetic interaction between the copper (II) centres as is observed[1] in analogous complexes. Further synthetic and magneto-chemical work on **1** is in progress.

CAUTIONARY NOTE

The compound $[Co(NH_3)_5(H_2O)](ClO_4)_3$ (solid) decomposed in an explosive way when the researcher who had prepared the sample placed it on a porcelain capsule, producing serious injuries to his eyes and hands.

The substance has been used in our laboratory for 25 years as a precursor of other compounds, e.g. **Synthesis and characterization of *trans*-$[Co(NH_3)_4(NH_2CH_3)L]^{3+}$ [L = $(CH_3)_2SO$ or $(CH_3)_2NCHO$] complexes,** B. Sienra and A. Massaferro, *Polyhedron* 1991, **10**, 2075. On this occasion the usual steps for its preparation and recrystallization had been followed. The only plausible hypothesis to explain the accident is that deprotonation could have been caused by localized heating produced by friction in the solid.

TEMPLATE SYNTHESIS OF A NEW DINUCLEAR NICKEL(II) COMPLEX OF A BIS(MACROBICYCLIC) LIGAND

SHIN-GEOL KANG,* SOO-KYUNG JUNG, JAE KEUN KWEON and MI-SEON KIM

Department of Chemistry, Taegu University, Kyungsan 713-714, Korea

(*Received* 10 *September* 1992; *accepted* 28 *October* 1992)

Abstract—A one-pot condensation reaction of 1,4,8-triazaoctane, ethylenediamine and formaldehyde in the presence of nickel(II) produced a new dinuclear nickel(II) complex of a bis(macrobicyclic) ligand, $[Ni_2(\mathbf{D})](ClO_4)_4$, in which two fully saturated hexaazamacrobicycles are linked together by an ethylene chain. Each macrobicyclic subunit of the complex contains one 1,3-diazacyclohexane ring and has a square-planar geometry with a 5–6–5–6 chelate ring sequence. The electronic spectra and electrochemical properties show that metal–metal interactions of the dinuclear complex are negligible.

Dinuclear complexes of polyazamacrocycles are important in the study of intramolecular metal–metal interactions and multielectron catalysts.[1–3] Although various types of such compounds have been prepared and investigated, those of fully saturated bis(macrocyclic) ligands are relatively rare[4–6] and in most cases the synthetic routes require several steps.

A one-pot metal template condensation reaction of amines and formaldehyde has been employed in the preparation of mononuclear complexes of fully saturated macrocyclic ligands.[7–13] The nickel(II) complexes of **A** and **B** have been synthesized by the reactions of eqs (1)[7] and (2),[9] respectively. Recently, this type of reaction was extended to the synthesis of dinuclear complexes of bis(macrocyclic) ligands.[14,15] For example, the dinuclear nickel(II) complex of **C** was prepared in our group by the reaction [eq. (3)] of the nickel(II) ion with ethylenediamine, methylamine and formaldehyde.[14] Utilizing the characteristics of the reactions, we have designed and prepared a new dinuclear nickel(II) complex of the bis(macrobicyclic) ligand **D** that contains two fully saturated hexaazamacrocyclic subunits with one 1,3-diazacyclohexane ring, by the one-pot reaction [eq. (4)] of 1,4,8-triazaoctane, ethylenediamine and formaldehyde in the presence of the metal ion. The synthesis and characterization of the dinuclear complex $[Ni_2(\mathbf{D})]^{4+}$ are reported. Comparisons of the properties of the dinuclear complex with those of $[Ni(\mathbf{B})]^{2+}$ and $[Ni_2(\mathbf{C})]^{4+}$ are also presented.

EXPERIMENTAL

Materials and measurements

All chemicals used in the syntheses were of reagent grade. Solvents for spectral and electrochemical measurements were of spectroscopic and electroanalytical reagent grade, respectively.

IR spectra were obtained using a Shimadzu IR-440 spectrophotometer. Visible spectra were recorded with a Kontron Uvikon 860 UV–vis spectrophotometer. Conductance measurements were made using a Metrohm Herisau Conductometer E518. NMR spectra were recorded on a Bruker WP 300 FT NMR spectrometer. Elemental analyses were performed at the Koloin R&D center, Kumi, Korea. The cyclic voltammograms were recorded using a Yanaco Voltammetric Analyser p-1000 equipped with an FG-121B function generator and a Watanabe *X–Y* recorder. The cyclic voltammetric data were obtained by published methods.[7]

Synthesis

$[Ni_2(\mathbf{D})](ClO_4)_4$. To a methanol solution (25 cm^3) of $NiCl_2 \cdot 6H_2O$ (3.0 g) were added 97% 1,4,8-triazaoctane (1.3 cm^3), 99% ethylenediamine (1.7 cm^3) and *para*-formaldehyde (2.1 g). The mixture

was heated at reflux for 24 h until a dark orange–red solution resulted and then cooled to room temperature. Excess perchloric acid was added dropwise to the solution with stirring and then yellow solids were precipitated. The solids collected by filtration contain the dinuclear complex and a small amount (<5%) of orange [Ni(**B**)]$(ClO_4)_2$ as a by-product. The crude product was dissolved in the minimum volume of hot water and then cooled to room temperature. The first crop of the precipitates contained mainly [Ni_2(**D**)]$(ClO_4)_4$. The pure product was obtained by fractional recrystallizations of the crude product from hot water. Yield: *ca* 20%. Found: C, 28.4; H, 5.4; N, 16.1 Calc. for $Ni_2C_{24}H_{54}N_{12}Cl_4O_{16}$: C, 28.1; H, 5.3; N, 16.4%. IR: 3200 [ν(N—H)], 1100 cm^{-1} [$\nu(ClO_4^-)$].

[Ni_2(**D**)]$(PF_6)_4$. To a hot saturated solution of the above complex was added excess NH_4PF_6 dissolved in water. The yellow solids formed were filtered, washed with a cold water–methanol (1:1) mixture and dried in air. Found: C, 24.0; H, 4.7; N, 13.7. Calc. for $Ni_2C_{24}H_{54}N_{12}P_4F_{24}$: C, 23.8; H, 4.5; N, 13.9%. ^{13}C NMR (CD_3NO_2): δ 23.5, 44.1, 47.0, 47.5, 48.5, 49.1, 55.8, 58.2, 68.2, 68.3, 70.5, 74.1 ppm.

RESULTS AND DISCUSSION

The reaction of excess formaldehyde with a 2:2:3 molar mixture of nickel(II) ions, 1,4,8-triazaoctane and ethylenediamine, followed by the addition of excess perchloric acid, yields a mixture of the bis(macrobicyclic) complex [Ni_2(**D**)]$(ClO_4)_4$ and a small amount of the mononuclear complex [Ni(**B**)]$(ClO_4)_2$ as a by-product. However, the major product is the dinuclear complex, which can be easily isolated by fractional recrystallizations of the mixture from hot water. The proportion of the by-product in the crude product can be reduced to less than 5% by employing a 2:1:6:4 molar mixture of the reactants (see Experimental). The routes to give the dinuclear complex of **D** may be similar to

those reported for the complexes of **A**–**C**.[7,9,14] The bis(macrobicyclic) complex is extremely stable in the solid state and is decomposed very slowly even at low pH. The visible spectra of the complex (2.0×10^{-3} M) in HNO_3 solution (0.3 M) show that only about 10% of the complex is decomposed in 10 h at 20°C. The slow decomposition in acidic solutions was also observed for the complexes of **A**–**C**.[7,9,14]

The ^{13}C NMR spectrum of $[Ni_2(D)](PF_6)_4$ measured in CD_3NO_2 shows 12 resonances, indicating that the complex contains 12 pairs of non-equivalent carbon atoms and this is consistent with the ligand structure. Four carbon peaks of N—C—N linkages are observed at 74.1, 70.5, 68.3 and 68.2 ppm. A peak of the N—C—C—N chain, that links two macrobicyclic subunits, is observed at 44.1 ppm and peaks of the chains on the macrobicyclic rings at 47.0, 47.5, 48.5 and 49.1 ppm. Other peaks at 23.5, 55.8 and 58.2 ppm are assigned to the carbons of the N—C—C—C—N linkages. The IR spectrum of $[Ni_2(D)](ClO_4)_4$ shows a single strong absorption at 3200 cm^{-1}, which is attributed to N—H stretching vibrations of the coordinated secondary amino groups. No peak near 1600 cm^{-1} assignable to primary amines was observed, indicating that the cyclization reaction took place. The values of molar conductance measured in aqueous and acetonitrile solutions of the dinuclear complex (2.0×10^{-4} M) are 498 and 506 Ω^{-1} mol^{-1} cm^2, respectively, showing that the complex is a 1 : 4 electrolyte.

The visible spectra of $[Ni_2(D)](ClO_4)_4$ in nitromethane and aqueous solutions show the *d–d* transition band at 455 ($\varepsilon = 150$ M^{-1} cm^{-1}) and 452 nm ($\varepsilon = 107$ M^{-1} cm^{-1}), respectively, indicating that each metal ion of the complex is in a square planar Ni—N_4 environment.[7–15] In each solvent the wavelength of the band is intermediate between those of the dinuclear complex of **C** (~444 nm)[14] and the mononuclear complex of **B** (~465 nm).[9] The molar extinction coefficient for the complex of **D** in nitromethane solution also falls between that for **C** (135 M^{-1} cm^{-1})[14] and twice that for **B** (95 M^{-1} cm^{-1}).[9] It is likely that the two chromophores of the dinuclear complex of **D** behave independently, likewise the complexes of **C** and other bis(macrocyclic) ligands in which two macrocyclic subunits are linked together by a $-(CH_2)_n-$ chain.[14,15] Therefore, the weaker ligand field strength of **D**, compared to that of **C**, can be attributed to the increased Ni—N bond length caused by the formation of the 1,3-diazacyclohexane ring.[9,12] The visible spectra also show that the molar extinction coefficient of the bis(macrobicyclic) complex is much lower in water than in nitromethane. This indicates that the complex dissolves in water to give an equilibrium mixture of the square planar $[Ni_2(D)]^{4+}$ and octahedral $[Ni_2(D)(H_2O)_4]^{4+}$ species, as shown in eq. (5).[7,10–14]

$$[Ni_2(D)]^{4+} + 4H_2O \overset{K}{\rightleftharpoons} [Ni_2(D)(H_2O)_4]^{4+} \quad (5)$$

The equilibrium constant (K) for the reaction determined by published methods[7,12,14] at 25°C is 0.40, which is larger than that for **C** (0.26).[14] This trend is quite similar to the reported result that the K value (0.77) of the mononuclear nickel(II) complex of **B**[12] containing two 1,3-diazacyclohexane rings is much larger than that for **A** (0.44).[7]

The cyclic voltammograms of $[Ni_2(D)](ClO_4)_4$ obtained in 0.1 M $(Bu^n)_4NClO_4$ acetonitrile solution showed only one anodic and cathodic peak corresponding to a Ni^{II}/Ni^{III} process. This implies that the interactions between the two metal ions are negligible and each metal ion is able to release one electron nearly at the same potentials.[6,14,15] The oxidation potential (+1.08 V vs S.C.E. at 20°C) of the complex also falls between those for the nickel (II) complexes of **C** (+0.97 V)[14] and **B** (+1.34 V).[12] It has been widely observed that the stepwise alkylation on the coordinated secondary nitrogens of the macrocyclic ligands makes the oxidation of the nickel(II) complexes a more unfavourable process.[16]

Summary

The results show that the new compound prepared in this work is the dinuclear nickel(II) complex of **D**, in which four nitrogen atoms of each macrobicyclic subunit are coordinated to the metal ion with a square-planar geometry. The present synthetic method is interesting because formation and linking of the two macrobicycles with small ring moieties are performed by the simple one-pot reaction. Furthermore, relatively simple reagents are required for the reaction. This work also supports the idea that the intramolecular metal–metal interactions of dinuclear complexes, in which two uncoordinated nitrogen atoms of fully saturated macrocyclic subunits are linked together by an ethylene chain, are negligible. Comparisons of the spectral and chemical properties of the dinuclear complex with those of **B** and **C** show that these properties are largely affected by the number of 1,3-diazacyclohexane ring moieties fused to the ligands.

THE PREPARATION AND REACTIONS WITH DONOR LIGANDS OF $[MoBrI(CO)_3(NCMe)_2]$

PAUL K. BAKER,* KEVIN R. FLOWER, H. MARGARET NAYLOR and KATHERINA VOIGT

Department of Chemistry, University of Wales, Bangor, Gwynedd LL57 2UW, U.K.

(*Received* 8 *October* 1992; *accepted* 15 *October* 1992)

Abstract—Equimolar quantities of *fac*-$[Mo(CO)_3(NCMe)_3]$ {prepared *in situ* by reacting $[Mo(CO)_6]$ in refluxing acetonitrile for 24 h} and BrI react at 0°C to give the seven-coordinate complex $[MoBrI(CO)_3(NCMe)_2]$ (**1**). Complex **1** reacts with 1 equivalent of L (L = PPh_3, $AsPh_3$ or $SbPh_3$) to initially give the mono(acetonitrile) complexes $[MoBrI(CO)_3(NCMe)L]$, which subsequently dimerize to afford $[Mo(\mu\text{-}I)Br(CO)_3L]_2$. Reaction of **1** with 2 equivalents of L (L = PPh_3, $AsPh_3$ or $SbPh_3$) gives the bis(ligand) compounds $[MoBrI(CO)_3L_2]$. The preparation and characterization of a series of new mixed-ligand complexes $[MoBrI(CO)_3LL']$ [L = PPh_3, L′ = $AsPh_3$; L = PPh_3, L′ = $SbPh_3$; L = $AsPh_3$, L′ = $SbPh_3$; L = PPh_3, $AsPh_3$ and $SbPh_3$; L′ = $SPPh_3$, $SC(NH_2)_2$ and $SC(NMe_2)_2$] are also described. Equimolar quantities of $\widehat{LL}$ [$\widehat{LL}$ = $Ph_2P(CH_2)_nPPh_2$ (n = 1–3); 1,10-phen] and $[MoBrI(CO)_3(NCMe)_2]$ react to afford the acetonitrile displaced products $[MoBrI(CO)_3(\widehat{LL})]$ in high yield. The synthesis of the novel, dicarbonyl five different ligand compound $[MoBrI(CO)_2(NCMe)(SbPh_3)_2]$ is also reported.

In 1986[1] we reported the preparation of the highly versatile seven-coordinate diiodo complexes $[MI_2(CO)_3(NCMe)_2]$ (M = Mo or W). These compounds react with both donor ligands[2–5] and alkynes[6,7] to give a range of new organometallic complexes. In order to increase the number of different ligands attached to a transition-metal centre we herein describe the preparation of the new mixed-halide seven-coordinate complex $[MoBrI(CO)_3(NCMe)_2]$ and discuss some of its reaction chemistry.

EXPERIMENTAL

All the reactions described in this paper were performed under an atmosphere of dry nitrogen using standard Schlenk-line techniques. The solvents CH_2Cl_2 and NCMe were dried over P_4O_{10}, acetone was dried over molecular sieves (4 Å) and diethyl ether was dried over sodium. All solvents were distilled before use and were free from dioxygen. The complex *fac*-$[Mo(CO)_3(NCMe)_3]$ was prepared *in situ* by the published method.[8] All chemicals were purchased from commercial sources except BrI, which was also synthesized by a literature method.[9]

Elemental analyses (carbon, hydrogen and nitrogen) were determined using a Carlo–Erba Elemental Analyser MOD 1106 (using helium as a carrier gas). IR spectra were recorded as $CHCl_3$ films between NaCl plates on a Perkin–Elmer 197 IR spectrophotometer. ^1H NMR spectra were recorded on a Bruker AC 250 CP/MAS NMR spectrometer. All spectra were referenced to tetramethylsilane.

$[MoBrI(CO)_3(NCMe)_2]$ (1)

A suspension of $[Mo(CO)_6]$ (3.96 g, 0.015 mmol) in degassed acetonitrile (150 cm^3) was heated under reflux in a nitrogen atmosphere for 24 h. The solution was cooled to 0°C and BrI (3.18 g, 0.015 mmol) was added to the solution. The mixture immediately

* Author to whom correspondence should be addressed.

became brown. The solvent was removed *in vacuo* to give a light-brown crystalline complex, $[MoBrI(CO)_3(NCMe)_2]$ (**1**), which was recrystallized from $MeCN/Et_2O$. Yield = 6.54 g, 92%.

Reactions of $[MoBrI(CO)_3(NCMe)_2]$ (**1**) *with* 1 *equivalent of L to give* $[MoBrI(CO)_3(NCMe)L]$

In a typical reaction: To $[MoBrI(CO)_3(NCMe)_2]$ (0.496 g, 1.05 mmol) dissolved in CH_2Cl_2 (15 cm^3) with continuous stirring under a stream of dry nitrogen was added PPh_3 (0.278 g, 1.1 mmol). After stirring the solution for 30 min the mixture was filtered. Removal of the solvent *in vacuo* gave mid-brown crystals of $[MoBrI(CO)_3(NCMe)(PPh_3)]\cdot\frac{1}{2}CH_2Cl_2$ (**2**), which were recrystallized from CH_2Cl_2/Et_2O. Yield = 0.492 g, 64%.

Similar reactions of $[MoBrI(CO)_3(NCMe)_2]$ with an equimolar amount of L (L = $AsPh_3$ or $SbPh_3$) in CH_2Cl_2 at room temperature gave after 30 min the new complexes $[MoBrI(CO)_3(NCMe)L]$ (**3** and **4**). For physical and analytical data see Table 1.

Reactions of $[MoBrI(CO)_3(NCMe)_2]$ *with* 1 *equivalent of L to give* $[Mo(\mu\text{-}I)Br(CO)_3L]_2$

In a typical reaction: To $[MoBrI(CO)_3(NCMe)_2]$ (0.5 g, 1.066 mmol) dissolved in CH_2Cl_2 (15 cm^3) with continuous stirring under a stream of dry nitrogen was added PPh_3 (0.28 g, 1.066 mmol). After stirring the solution for 4 h, the mixture was filtered. Removal of the solvent *in vacuo* gave mid-brown crystals of $[Mo(\mu\text{-}I)Br(CO)_3(PPh_3)]_2$ (**5**), which were recrystallized from CH_2Cl_2/Et_2O. Yield = 0.35 g, 50%.

Similar reactions of $[MoBrI(CO)_3(NCMe)_2]$ with an equimolar amount of L (L = $AsPh_3$ or $SbPh_3$) in CH_2Cl_2 at room temperature gave after 4 h the new compounds $[Mo(\mu\text{-}I)Br(CO)_3L]_2$ (**6** and **7**). For physical and analytical data see Table 1.

Reactions of $[MoBrI(CO)_3(NCMe)_2]$ *with* 2 *equivalents of L to give* $[MoBrI(CO)_3L_2]$

In a typical reaction: To $[MoBrI(CO)_3(NCMe)_2]$ (0.460 g, 0.98 mmol) dissolved in CH_2Cl_2 (15 cm^3) with continuous stirring under a stream of dry nitrogen at room temperature was added $AsPh_3$ (0.600 g, 1.96 mmol). After stirring the solution for 150 min the mixture was filtered. Removal of the solvent *in vacuo* gave brown crystals of $[MoBrI(CO)_3(AsPh_3)_2]$ (**9**), which were recrystallized from CH_2Cl_2/Et_2O. Yield = 0.578 g, 59%.

Similar reactions of $[MoBrI(CO)_3(NCMe)_2]$ with 2 equivalents of L (L = PPh_3 or $SbPh_3$) gave the new complexes $[MoBrI(CO)_3L_2]$ (**8** and **10**). For physical and analytical data see Table 1.

Reactions of $[MoBrI(CO)_3(NCMe)_2]$ *with L, followed by L′ to give* $[MoBrI(CO)_3LL']$

In a typical reaction: To $[MoBrI(CO)_3(NCMe)_2]$ (0.271 g, 0.58 mmol) dissolved in CH_2Cl_2 (15 cm^3) with continuous stirring under a stream of dry nitrogen at room temperature was added $SbPh_3$ (0.204 g, 0.58 mmol). After stirring the solution for 5 min $SPPh_3$ (0.170 g, 0.58 mmol) was added and the mixture was stirred for a further 30 min. Filtration, followed by removal of the solvent *in vacuo*, gave the dark orange solid $[MoBrI(CO)_3(SbPh_3)(SPPh_3)]$ (**16**), which was recrystallized from CH_2Cl_2. Yield = 0.354 g, 59%.

Similar reactions of $[MoBrI(CO)_3(NCMe)_2]$ with 1 equivalent of L [L = PPh_3 (1 min), $AsPh_3$ (3 min) or $SbPh_3$ (5 min)], followed by an equimolar amount of L′ {L′ = PPh_3, $AsPh_3$, $SbPh_3$, $SPPh_3$, $SC(NH_2)_2$ [reactions carried out in acetone with $SC(NH_2)_2$], $SC(NMe_2)_2$} (all 30 min), gave the new mixed-ligand complexes $[MoBrI(CO)_3LL']$ (**11–15**, **17–22**). For physical and analytical data see Table 1.

Reactions of $[MoBrI(CO)_3(NCMe)_2]$ *with an equimolar quantity of* $\widehat{LL}$ *to give* $[MoBrI(CO)_3(\widehat{LL})]$

In a typical reaction: To $[MoBrI(CO)_3(NCMe)_2]$ (0.5 g, 1.066 mmol) dissolved in CH_2Cl_2 (15 cm^3) with continuous stirring under a stream of dry nitrogen at room temperature was added $Ph_2P(CH_2)PPh_2$ (0.41 g, 1.066 mmol). After stirring the solution for 2 h the mixture was filtered. Removal of the solvent *in vacuo* gave mid-brown crystals of $[MoBrI(CO)_3\{Ph_2P(CH_2)PPh_2\}]\cdot\frac{1}{2}CH_2Cl_2$ (**23**), which were recrystallized from CH_2Cl_2/Et_2O. Yield = 0.53 g, 61%.

Similar reactions of $[MoBrI(CO)_3(NCMe)_2]$ with an equimolar quantity of $\widehat{LL}$ [$\widehat{LL}$ = $Ph_2P(CH_2)_n PPh_2$ (n = 2 and 3), 1,10-phen] in CH_2Cl_2 at room temperature gave $[MoBrI(CO)_3(\widehat{LL})]$ (**24–26**). For physical and analytical data see Table 1.

Bubbling a stream of nitrogen through a solution of $[MoBrI(CO)_3(SbPh_3)_2]$ *in acetonitrile to give* $[MoBrI(CO)_2(NCMe)(SbPh_3)_2]$ (**27**)

A stream of nitrogen gas was bubbled into a stirred suspension of $[MoBrI(CO)_3(SbPh_3)_2]$ (0.543 g, 0.5 mmol) in acetonitrile (15 cm^3) at room temperature. After 3 h the three bands of the tricarbonyl complex had been replaced by two new carbonyl bands of equal intensity. At this stage, the

solvent was removed *in vacuo* to give pale yellow crystals of $[MoBrI(CO)_2(NCMe)(SbPh_3)_2]$ (**27**), which were recrystallized from CH_2Cl_2/Et_2O (yield = 0.548 g, 99%).

RESULTS AND DISCUSSION

It is interesting to note that in their original paper in 1962 describing the preparation of the tris (acetonitrile) complexes *fac*-$[M(CO)_3(NCMe)_3]$ (M = Cr, Mo, W),[8] Tate, Knipple and Augl reported that "reaction of $[W(CO)_3(NCMe)_3]$ with an equimolar quantity of iodine in methanol gave a non-carbonyl containing product". From our previous work we have found that reaction of *fac*-$[M(CO)_3(NCMe)_3]$ *in situ*, i.e. in acetonitrile with equimolar quantities of I_2 (M = Mo or W),[1] $SnCl_4$ (M = Mo)[10] and $GeCl_4$ (M = Mo),[11] gave the seven-coordinate bis(acetonitrile) compounds $[MI_2(CO)_3(NCMe)_2]$, $[MoCl(SnCl_3)(CO)_3(NCMe)_2]$ and $[MoCl(GeCl_3)(CO)_3(NCMe)_2]$, respectively.

Equimolar quantities of *fac*-$[Mo(CO)_3(NCMe)_3]$ {prepared *in situ* by reacting $[Mo(CO)_6]$ in refluxing acetonitrile[8]} and BrI react to give high yields of the light brown crystalline complex $[MoBrI(CO)_3(NCMe)_2]$ (**1**). Complex **1** is very air-sensitive in solution and also air-sensitive in the solid state. It is considerably more sensitive and less stable compared to the diiodo-analogue $[MoI_2(CO)_3(NCMe)_2]$.[1] Compound **1** has been characterized by elemental analysis (carbon, hydrogen and nitrogen) (it was very difficult to obtain good analytical results for this complex due to its air-sensitivity), IR and ^1H NMR spectroscopy (Tables 1–3). Since the IR and ^1H NMR spectral properties of **1** closely resemble those of the diiodo-complex (which has been structurally characterized by X-ray crystallography),[12] the most likely struc-

[a] Spectra recorded as thin films in $CHCl_3$ between NaCl plates. s, strong; m, medium; w, weak.

ture for **1** is capped octahedral with a carbonyl ligand in the capping position with the more bulky iodide ligand *trans* to the more crowded capped face (Fig. 1.).

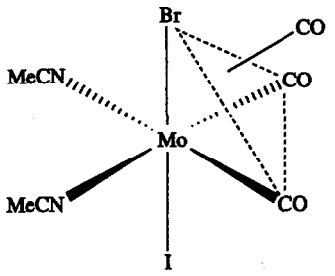

Fig. 1. Most likely structure for $[MoBrI(CO)_3(NCMe)_2]$ (**1**).

The reaction of **1** with an equimolar amount of L (L = PPh_3, $AsPh_3$ or $SbPh_3$) in CH_2Cl_2 at room temperature initially gave the monomers $[MoBrI(CO)_3(NCMe)L]$ (**2–4**), which were isolated and characterized (Tables 1–3). However, the complexes $[MoBrI(CO)_3(NCMe)L]\cdot\frac{1}{2}CH_2Cl_2$ (**2**) (L = PPh_3) and **4** (L = $SbPh_3$) were confirmed as $\frac{1}{2}CH_2Cl_2$ solvates by repeated elemental analyses and ^1H NMR spectroscopy. Stirring CH_2Cl_2 solutions of the monomers (**2–4**) at room temperature for 4 h gave the fully characterized (Tables 1–3) dimers $[Mo(\mu\text{-}I)Br(CO)_3L]_2$ (**5–7**) in good yield. These results are very similar to the reactions of $[MI_2(CO)_3(NCMe)_2]$ (M = Mo or W) with L (L = PPh_3, $AsPh_3$ and $SbPh_3$) in CH_2Cl_2 at room temperature, which gave $[MI_2(CO)_3(NCMe)L]$ and subsequently upon further stirring in CH_2Cl_2 gave the dimers $[M(\mu\text{-}I)I(CO)_3L]_2$.[4]

[a] Spectra recorded in $CDCl_3$ at +25°C.
[b] Spectra recorded in $(CD_3)_2CO$ at +25°C.

Two equivalents of the ligands L (L = PPh_3, $AsPh_3$ and $SbPh_3$) reacted with **1** in CH_2Cl_2 at room temperature to afford the bis(ligand) compounds $[MoBrI(CO)_3L_2]$ (**8–10**) in high yields. Compounds **8–10** have been characterized by elemental analysis (carbon, hydrogen and nitrogen), IR and ^1H NMR spectroscopy (Tables 1–3). Since a number of seven-coordinate complexes of the type $[MX_2(CO)_3L_2]$ have been structurally characterized, and have been shown to have capped octahedral geometry,[13–18] the geometry of **8–10** and other mononuclear complexes described in this paper are likely to be capped octahedral. Unfortunately, many attempts to grow suitable single crystals for X-ray crystallography of several complexes were unsuccessful.

Reactions of $[MoBrI(CO)_3(NCMe)_2]$ with an equimolar quantity of L (L = PPh_3, $AsPh_3$ or $SbPh_3$) initially gave $[MoBrI(CO)_3(NCMe)L]$, which when reacted *in situ* with an equimolar amount of L′ [L′ = PPh_3, $AsPh_3$, $SbPh_3$, $SPPh_3$, $SC(NH_2)_2$ or $SC(NMe_2)_2$] in CH_2Cl_2 at room temperature or acetone [for L′ = $SC(NH_2)_2$] afforded the mixed-ligand compounds $[MoBrI(CO)_3LL']$ (**11–22**) in good yield. These new complexes were characterized by elemental analysis (carbon, hydrogen and nitrogen) (Table 1), IR (Table 2) and ^1H NMR spectroscopy (Table 3). The complexes are soluble in chlorinated solvents such as CH_2Cl_2, $CHCl_3$ and acetone [for $SC(NH_2)_2$ and $SC(NMe_2)_2$] complexes, however, they are insoluble in hydrocarbon solvents and diethyl ether.

Equimolar quantities of **1** and $\widehat{LL}$ [$\widehat{LL}$ = $Ph_2P(CH_2)_nPPh_2$ (n = 1–3) and 1,10-phen] react in CH_2Cl_2 at room temperature to give the acetonitrile displaced products $[MoBrI(CO)_3(\widehat{LL})]$ (**23–26**) in high yield. Characterization of (**23–26**) was obtained by elemental analysis (carbon, hydrogen and nitrogen), IR and ^1H NMR spectroscopy (Tables 1–3). Complexes **23–25** were shown to be $\frac{1}{2}CH_2Cl_2$ solvates by repeated elemental analyses and ^1H NMR spectroscopy.

It is interesting to note that bubbling a stream of dry nitrogen through an acetonitrile solution of $[MoBrI(CO)_3(SbPh_3)_2]$ gave the seven-coordinate dicarbonyl compound $[MoBrI(CO)_2(NCMe)(SbPh_3)_2]$ with five different ligands attached to the molybdenum. It should be noted that Brisdon and Hodson[19] have reported the preparation and characterization of the related dihalo-complexes $[MX_2(CO)_2(NCMe)L_2]$ (for M = Mo, X = Br, L = $PEtPh_2$, PMe_2Ph or PEt_2Ph, X = Cl, Br or I, L = $PMePh_2$; for M = W, X = Br, L = PMe_2Ph, $PMePh_2$).

In summary, the mixed-halide complex $[MoBrI(CO)_3(NCMe)_2]$ is much less stable compared to its diiodide analogue; however, the reaction chemistry of **1** is very similar to $[MoI_2(CO)_3(NCMe)_2]$. The reaction products derived from **1** are very similar to $[MoI_2(CO)_3(NCMe)_2]$ and the reaction products derived from **1** were considerably more stable than **1**. Hence, full characterization of **2–27** was achieved.

(*Received* 1 *October* 1992; *accepted* 15 *October* 1992)

Abstract—The interaction of transition metal dichlorides with the chelating diphosphine (diphos) ligands 1,2-bis(phosphino) benzene, 1,2-bis(2-propylphosphino) benzene and 1,2-bis(dimethylphosphino) benzene leads to the octahedral complexes *trans*-$MCl_2(diphos)_2$, (M = V, Cr, Fe or Co). Interaction of $FeCl_2[1,2\text{-}(Me_2P)C_6H_4]_2$ with $NaBPh_4$ in refluxing MeCN gives the nitrile complex *trans*-$[Fe(NCMe)_2(diphos)_2](BPh_4)_2$, whereas $VCl_2[1,2\text{-}(C_3H_7PH)_2C_4H_4]_2$ gives only the complex $[V(CNMe)_6](BPh_4)_2$. This difference is attributed to the weaker basicity (exemplified by the longer M—P bond lengths) of the secondary phosphine ligand. X-ray crystal structures of the following compounds have been determined: $MCl_2[1,2\text{-}(C_3H_7PH)_2C_6H_4]_2$ (M = V, Cr or Fe) and $[Fe(NCMe)_2\{1,2\text{-}(Me_2P)C_6H_4\}_2](BPh_4)_2$. In all cases the octahedral complexes have *trans*-Cl or MeCN groups.

We have previously described the synthesis and X-ray crystal structures of 1,2-bis(dimethylphosphino)ethane (dmpe) complexes of divalent first row transition metals, *trans*-$MX_2(dmpe)_2$ (M = Ti, V, Cr, Mn or Fe; X = Me or halide).[1] While dmpe,[1,2a–c] dppe,[2d] dippe, [1,2-bis(diisopropylphosphino)ethane],[2e] 1,2-bis(diphenylphosphino)-ethane[3a] complexes and the salts of the cations *trans*-$[M(NCR)_2(dmpe)_2]^{2+}$ (M = V,[2a] Cr[2b] and Fe;[2c] R = Me or Et) and dmpp, 1,3-bis(dimethylphosphino)propane,[3b] have been thoroughly investigated, similar ditertiary aryl phosphines of the type $1,2\text{-}C_6H_4(PR_2)_2$ have been less studied. The bis-dimethyl[3c] group has been shown to stabilize high oxidation state complexes of first row elements as readily as the more commonly studied diarsine $1,2\text{-}(Me_2As)_2C_6H_4$.[3d]

By contrast, few studies on bis(primary/secondary) phosphinobenzene have been reported.[4] Analogues of dmpe types[1,2] have not been described; these are now reported for $1,2\text{-}(H_2P)_2C_6H_4$ and $1,2\text{-}(R^1R^2P)_2C_6H_4$ (R^1 = H, R^2 = $C^i{}_3H_7$; R^1 = R^2 = Me.

Analytical data for new compounds are given in Table 1.

RESULTS AND DISCUSSION

phosphino benzenes (diphos) in toluene at ambient temperature readily gives the adducts *trans*-MCl_2(diphos)$_2$. However, all attempts to prepare *trans*-$MnCl_2$(diphos)$_2$, where diphos = primary or secondary phosphino benzene, were unsuccessful. The tertiary phosphino benzene complex $MnCl_2(1,2\text{-}(Me_2P)_2C_6H_4]_2$ has previously been reported.[3c].

All the present MCl_2(diphos)$_2$ complexes have IR spectra showing strong bands typical of P—H groups (*ca* 2340 cm^{-1}) as well as a single M—Cl band except for $CrCl[1,2\text{-}(Me_2P)_2C_6H_4]_2$ (**6**) and $CoCl_2[1,2\text{-}(C_3H_7PH)_2C_6H_4]_2$ (**9**) that have split bands and hence may have *cis* and *trans* isomers—see below), consistent with the monomeric *trans* geometry confirmed by X-ray diffraction studies as quoted for the manganese compound.[3c]

The low solubility of the primary phosphine complexes in non-coordinating organic solvents, even at elevated temperatures, precludes crystallization and further characterization. In the case of $VCl_2[C_6H_4(PH_2)_2]_2$ (**1**), analytical data (see Table 1) suggests small contamination of the product with zinc salts, as is well known.[5] However, use of the secondary phosphine $[1,2\text{-}(C_3H_7PH)_2C_6H_4]$ results in more soluble species, and crystals suitable for X-ray diffraction were obtained for M = V, Cr and Fe. The vanadium and chromium compounds are air sensitive, especially in solution, but the iron and cobalt complexes may be handled as solids in air.

The *X*-band EPR spectrum for $VCl_2[1,2\text{-}(C_3H_7PH)_2C_6H_4]_2$ (**2**) as a frozen toluene solution at −196°C comprises broad low-field features at *ca* $g = 4.2$ and 2.8, and several weaker transitions to higher field, similar to those previously reported for $VCl_2(dmpe)_2$.[1] By contrast, $VCl_2[1,2\text{-}(Me_2P)_2C_6H_4]_2$ (**3**) possesses an isotropic spectrum ($g = 1.995$) at room temperature with poorly defined splitting; as a frozen MeCN solution (−196°C) the splitting is only slightly more resolved. The ^1H NMR spectra are broad and uninformative, except for the iron(II) low-spin d^6 complex (see Experimental), which gives a red–brown solution at room temperature. The ^{31}P NMR spectrum of $FeCl_2[1,2\text{-}(C_3H_7PH)_2C_6H_4]_2$ is consistent with extensive isomerization in solution. A singlet at $\delta = 82$ ppm can be assigned to the *trans* isomer **7**, whilst two triplets ($\delta = 70.4$ and 96.2 ppm, A_2B_2 coupling) are consistent with the two sets of equivalent P present in the *cis*-isomer. Similar isomerism is anticipated for $CoCl_2[1,2\text{-}(C_3H_7PH)_2C_6H_4]_2$ (**9**); the split band at *ca* 290 cm^{-1} in the IR spectrum is consistent with *cis* and *trans* isomers. Interestingly, a recent report[6] concerning two diphosphines of comparable steric bulk to $1,2\text{-}(C_3H_7PH)_2C_6H_4$, namely DEPE [1,2-bis(diethylphosphino)ethane] and DPrPE [1,2-bis(di-n-propylphosphino)ethane], describes solution paramagnetism for iron(II) complexes and associates this with partial reversible dissociation of phosphine.

In addition, we have also synthesized by the same method other complexes, $MCl_2[(Me_2P)_2C_6H_4]_2$.

Three complexes have been studied by X-ray

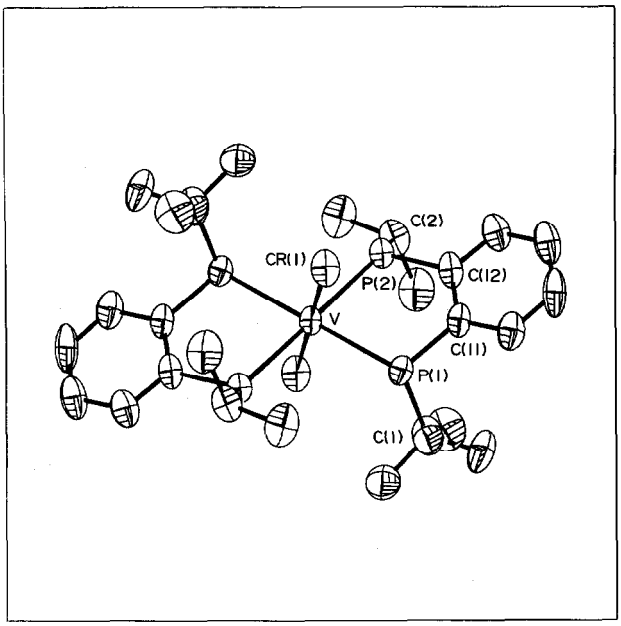

Fig. 1. The structure of *trans*-$VCl_2[(Pr^iHP)_2C_6H_4]_2$.

crystallography (M = V, Cr, Fe); surprisingly, the crystal structures are all different (the vanadium complex is solvated) but the molecular structures are analogous. In each case the metal atoms lie on centres of symmetry and in each diphos ligand the isopropyl groups are *syn*. The crystal structures of the chromium and iron complexes each contain two independent centrosymmetric molecules. A diagram of the vanadium complex is shown in Fig. 1; bond lengths and angles for all three complexes are given in Table 2.

The structures are analogous to those previously determined[1] for the related dmpe complexes[1] of titanium, vanadium and chromium, and it is interesting to compare geometry parameters for the two groups. Relevant data are plotted in Fig. 2, from which it can be seen that the M—Cl bond lengths here are slightly shorter than in the comparable bonds in the dmpe complexes, while only the V—P bond lengths are slightly longer (*ca* 0.02 Å). Clearly, similar variations exist within each series. Whereas in the dmpe complexes the M—P bond is longer

Table 2. Selected bond lengths (Å) and angles (°) for the complexes $MCl_2(diphos)_2$, M = V, Cr and Fe. The atomic numbering relates to that in Fig. 1

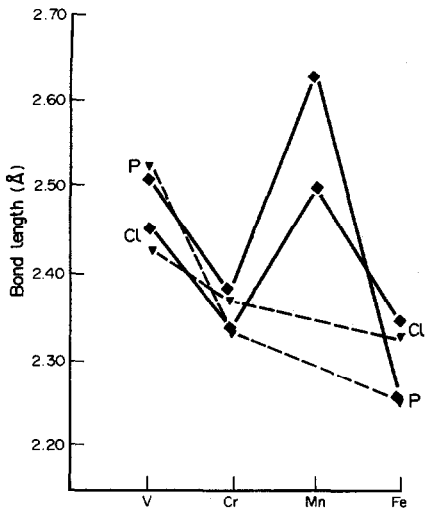

Fig. 2. Variations in M—Cl and M—P distances: ◆ $MCl_2(dmpe)_2$ from ref. 1; ▼ $MCl_2[(Pr^iHP)_2C_6H_4]_2$.

than the M—Cl bond for vanadium, chromium and manganese but shorter for iron, in the bis-isopropyl phosphine complexes the M—P bond is longer than the M—Cl bond only for vanadium; for chromium and iron it is shorter.

The cross-over for the $FeCl_2(dmpe)_2$ case was explained[1] in terms of greater $p\pi$–$d\pi$ back-bonding for d^6-Fe^{II}; in the present complexes it seems to have occurred already for d^4-Cr.

The diphos ligand bonds symmetrically with essentially equal M—P—C angles, which differ from complex to complex in correlation with M—P bond lengths and P—M—P angles (see Table 2); the angles at C in P—C—C—P are fairly constant at 115–117°. This contrasts strongly with the geometry of the diphosphido bonding in the complexes $[L_nM\{P(Ph)C_6H_4PPh\}]$, where M = Zr and Sn[4b] and where the M—P—C(benz), M—P—C (phenyl) and P—M—P angles, and, in the case of the zirconium complex, Zr—P distances, vary considerably. This may well arise from steric factors, since the other ligands in these two complexes are very bulky. Comparison between these structures and our phosphines cannot be taken too far, however, in view of the formal chemical differences between the phosphorus atoms and their associated stereochemistries.

One final point of note in the present complexes is the small tilts of the M—Cl bonds relative to the MP_4 planes, as a result of steric interactions, and between the chlorine atoms and the *syn*-isopropyl substituents.

Attempts to alkylate $MCl_2[(C_3H_7PH)_2C_6H_4]_2$ with MeLi were generally unsuccessful. This could be in part due to the increased strength of the M—Cl bonds (cf. dmpe complexes[1]) or simply due to the greater steric constraints of the isopropyl groups.

Nitrile complexes

Interaction of $FeCl_2[1,2\text{-}(Me_2P)_2C_6H_4]_2$ with excess $NaBPh_4$ in refluxing acetonitrile yields bright yellow, diamagnetic crystals of *trans*-$[Fe(diphos)_2(MeCN)_2](BPh_4)_2 \cdot MeCN$. The complex has two weak C≡N stretches in the IR spectrum (2285 and 2246 cm^{-1}), consistent with a lowering of $\nu(C{\equiv}N)$ upon coordination, and is a 1:2 electrolyte in MeCN. Unlike the analogous chromium dmpe complex, this iron complex, like its iron dmpe analogue, does not react with oxygen or with methanol.[2b,c]

The structure, as the MeCN solvate, has been confirmed by X-ray crystallography. A diagram of the cation is shown in Fig. 3; selected bond lengths and angles are given in Table 3. The structure is analogous to the closely related cationic M^{II}

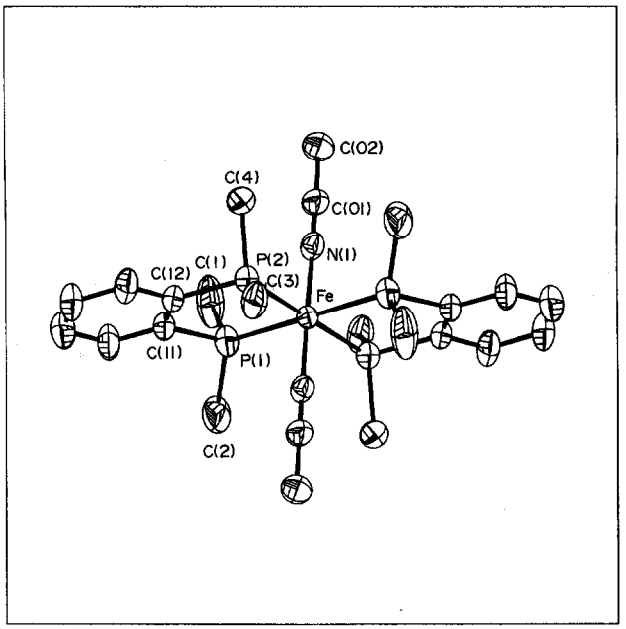

Fig. 3. The structure of *trans*-$\{Fe[(Me_2P)_2C_6H_4]_2(NCMe)_2\}^{2+}$ in the tetraphenylborate, MeCN solvate.

species $[M(NCMe)_2(dmpe)_2]^{2+}$ (M = V, Cr or Fe)[2]. Indeed, the Fe—P distances are essentially comparable (2.268–2.278 Å) to those of the dmpe complex (2.264–2.270 Å), whilst the Fe—N(nitrile) distances (1.92 Å) are slightly larger compared to 1.905 Å in the dmpe complexes. This is to be expected for complexes containing chelating bis-phosphines with similar basicity and series constraints at P.

A similar reaction using $VCl_2[(C_3H_7PH)_2C_6H_4]_2$ gives only the hexakis(acetonitrile)vanadium(II) salt $[V(NCMe)_6](BPh_4)_2$, characterized by analysis and spectra.[2a]

Failure to give $\{V(MeCN)_2[(C_3H_7PH)_2C_6H_4]_2\}(BPh_4)_2$ is presumably due to the weaker M—P bonding associated with the secondary phosphine with lesser involvement of $Md\pi \rightarrow Pd\pi$ back-bonding in the M—P bond. The influence of $d\pi$–$d\pi$ back-bonding will of course be greater for iron (increasing *d*-electron count).

Further work is in progress in an effort to obtain crystal structures of metal organoimido/diphos complexes for comparison with the previously reported *trans*-$[Cr^{IV}Cl(NEt)(dmpe)_2]CF_3SO_3$ and *trans*-$[Cr^{IV}(N{=}CHMe_2)(dmpe)_2](BPh_4)_2$.[2b]

EXPERIMENTAL

General procedures and instrumentation have been described.[7] Microanalyses were by Pascher, Remagen and MEDAC Ltd, Brunel University. The precursors $[V_2(\mu\text{-}Cl)_3(THF)_6]_2[Zn_2Cl_6]$[8] and $CrCl_2 \cdot THF$[9] were prepared as previouly described. 1,2-Bis(phosphino)benzene and related alkylated ligands were prepared by the method of Kyba *et al.*[10] All operations were carried out under oxygen-free nitrogen or argon. NMR spectra: Bruker WM 250 MHz (^1H, ^{31}P) δ in ppm referred to Me_4Si and 85% H_3PO_4 (external), respectively. IR spectra: (cm^{-1}) in Nujol mulls. Mass spectra: *m/z*% in fast atom bombardment (matrix, *m*-nitrobenzyl alcohol) unless otherwise stated. Commercial chemicals are from Aldrich.

Trans-*bis*[1,2-*bis*(*phosphino*)*benzene*]*dichlorovanadium*(II) (1)

To a suspension of $[V_2(\mu\text{-}Cl)_3(THF)_6]_2(Zn_2Cl_6)$ (0.6 g, 2.26 mmol) in toluene (*ca* 40 cm^3) was added 1,2-bis(phosphino)benzene (0.64 cm^3, 4.51 mmol). After 24 h the apple-green precipitate was collected, washed with toluene (2×20 cm^3) and hexane (*ca* 30 cm^3) and dried *in vacuo*. Yield 80–90%. IR: 3332w, 2727w, 2672w, 2329w, [*v*(P—H)], 1716w, 1296w, 1261m, 1170m, 1149m, 1067m, 1026s, 915m, 880s, 820s, 749m, 722m, 683w, 454w, 329m, 302s.

Trans-*bis*[1,2-*bis*(2-*propylphosphino*)*benzene*]-*dichlorovanadium*(II) (2)

To a suspension of $[V_2(\mu\text{-}Cl)_3(THF)_6][Zn_2Cl_6]$ (0.33 g, 1.24 mmol) in toluene (*ca* 40 cm^3) was added 1,2-bis(2-propylphosphino)benzene (0.57 cm^3, 2.52 mmol). The suspension slowly developed a yellow–

brown colour and was stirred for 24 h. The suspension was concentrated to *ca* 25 cm^3, warmed to dissolve all solid and cooled to −20°C. The large golden brown prisms were collected: further crops could be obtained by concentration and cooling of the supernatant. Yield *ca* 70%. IR: 2729w, 2307s [*ν*(PH)], 1722w, 1603w, 1575w, 1558w, 1495m, 1300w, 1275w, 1256w, 1239s, 1163m, 1134s, 1081w, 1061s, 1048m, 1029w, 966w, 931m, 887s, 877s, 865s, 808s, 766s, 728s, 695m, 641s, 628m, 498s, 467s, 467w, 436m, 405w, 324s [*ν*(VCl)]. EPR: see text.

Trans-*bis*[1,2-*bis*(*dimethylphosphino*)*benzene*]-*dichlorovanadium*(II) (**3**)

To a suspension of $[V_2(\mu\text{-}Cl)_3(THF)_6](Zn_2Cl_6)$ (0.3 g, 1.13 mmol) in toluene (*ca* 30 cm^3) was added 1,2-bis(dimethylphosphino)benzene (0.45 cm^3, 2.27 mmol). After 24 h the yellow–brown precipitate was collected, washed with toluene (2 × 25 cm^3) and hexane (30 cm^3) and dried *in vacuo*. Yield: *ca* 80%. IR: 1717w, 1494w, 1422s, 1299s, 1262m, 1149s, 1115s, 1057m, 1040m, 955s, 910s, 874m, 802w, 764s, 737s, 696m, 465s, 379w, 357w, 326w, 280s. EPR: see text.

Trans-*bis*[1,2-*bis*(*phosphino*)*benzene*]*dichlorochromium*(II) (**4**)

To a suspension of $CrCl_2 \cdot THF$ (0.27 g, 1.39 mmol) in toluene (*ca* 40 cm^3) was added [1,2-bis(phosphino)benzene (0.4 g, 2.81 mmol). The suspension rapidly developed a deep orange colour and was stirred for 24 h. The pale orange–tan precipitate was collected, washed with toluene (2 × 25 cm^3) and hexane (30 cm^3) and dried *in vacuo*. Yield *ca* 80%. IR: 2324 [*ν*(P—H)], 1720w, 1552w, 1303w, 1258m, 1156w, 1107m, 1053m, 1043m, 1027m, 894w, 834s, 757s, 723s, 448s, 337s [*ν*(CrCl)]. MS (E.I.): M^+ 407.

Trans-*bis*[1,2-*bis*(2-*propylphosphino*)*benzene*]-*dichlorochromium*(II) (**5**)

To a suspension of $CrCl_2 \cdot THF$ (0.24 g, 1.23 mmol) in toluene (*ca* 30 cm^3) was added 1,2-bis(2-propylphosphino)benzene (0.55 g, 2.43 mmol). The solution rapidly developed a deep red colour. After 4 h the solution was filtered, concentrated to *ca* 20 cm^3 and cooled to −20°C. The large red prisms were collected: further crops may be obtained by concentration and cooling of the supernatant. Yield: *ca* 80%. IR: 2290m, 2271m, [*ν*(PH)], 1717w, 1558w, 1280w, 1261m, 1241m, 1164m, 1132w, 1112s, 1058s, 1033s, 929w, 895s, 878s, 821s, 809s, 764s, 755s, 723m, 67w, 629s, 501s, 461m, 443w, 348s, [*ν*(CrCl)]. MS: 574 (M^+), 539 $(M-Cl)^+$, 348 $(M-L)^+$, 313 $(M-L-Cl)^+$.

Trans-*bis*[1,2-*bis*(*dimethylphosphino*)*benzene*]-*dichlorochromium*(II) (**6**)

To a suspension of $CrCl_2 \cdot THF$ (0.2 g, 1.03 mmol) in toluene (*ca* 30 cm^3) was added 1,2-bis(dimethylphosphino)benzene (0.4 g, 2.02 mmol). The solution rapidly developed a blood-red colour. After 24 h the solution was concentrated and the product precipitated hexane (*ca* 30 cm^3) and dried *in vacuo*. Yield *ca* 80%. IR: 1723w, 1420s, 1292s, 1278s, 1246m, 1156w, 1134w, 1104m, 1047w, 1037m, 1019m, 942s, 902s, 866s, 837m, 802w, 769s, 728s, 688s, 655w, 458sm, 431s, 341s, 306s.

Trans-*bis*[1,2-*bis*(2-*propylphosphino*)*benzene*]-*dichloroiron*(II) (**7**)

To a suspension of $FeCl_2$ (0.62 g, 4.88 mmol) in toluene (*ca* 325 cm^3) was added 1,2-bis(2-propylphosphino)benzene (2.19 g, 9.68 mmol). The solution slowly developed a red–brown colour and was stirred for 12 h. The solution was filtered, a hexane layer (*ca* 30 cm^3) added and cooled to 0°C. Emerald green crystals of the complex were obtained. Yield: *ca* 30%. IR: 2720w, 2322s [*ν*(PH)], 1713w, 1560w, 1361m, 1283m, 1246m, 1167w, 1135w, 1118s, 1091w, 1059s, 929m, 893s, 880s, 853s, 834s, 759s, 731s, 673m, 638s, 512m, 504s, 484s, 461m, 449w, 376w, 349m [*ν*(FeCl)], 317w, 263w. MS: 578 (M^+), 543 ($M^+ - Cl$), 448 ($2L - 2H_2$), 317 ($M - L - Cl$). $^{31}P\{^1H\}$ ($CDCl_3$, 250 mHz): δ = 81.8 (s, *trans* isomer), 77.4 [t, J(P—P) = 47.6 Hz, *cis* isomer], 96.2 [t, J(P—P) = 47.7 Hz, *cis* isomer].

Trans-*bis*(*acetonitrile*)*bis*[1,2-*bis*(*dimethylphosphino*)*benzene*]*iron*(II)*bis*(*tetraphenylborate*) (**8**)

To *trans*-$[FeCl_2\text{-}1,2\text{-}(Me_2P)_2C_6H_4]$[3c] (1.0 g, 1.19 mmol) in MeCN (*ca* 40 cm^3) was added $NaBPh_4$ (1.31 g, 3.83 mmol). The solution was refluxed vigorously for 12 h, cooled and then filtered. Concentrating and cooling (−20°C) the orange solution gave golden yellow prisms. Yield: *ca* 90%. IR: 2285w ("free" MeCN), 2246m [coordinated nitrile *ν*(C≡N)], 1714w, 1579m, 1562w, 1426s, 1367s, 1308m, 1301m, 1287m, 1267w, 1253w, 1182w, 1143m, 1118m, 1066w, 1032m, 941s, 905s, 862w, 841m, 759m, 731s, 704s, 691m, 614m, 481s, 461m, 417w, 374w. MS: 534.3 (M^{2+}), 492 (M^{2+} − MeCN). Conductivity (MeCN): Λ_M = 183 Ω cm^2 mol^{-1}.

Trans-*bis*[1,2-*bis*(2-*propylphosphino*)*benzene*]-*dichlorocobalt*(II) (**9**)

To a suspension of $CoCl_2 \cdot THF$ (0.25 g, 1.26 mmol) in toluene (*ca* 35 cm^3) was added 1,2-bis(2-propylphosphino)benzene (0.56 g, 2.48 mmol). After 12 h the solvent was removed and the residue extracted with CH_2Cl_2 (*ca* 30 cm^3). Concentration and cooling (−20°C) gave a bright green microcrystalline solid. Yield: *ca* 30%. IR: 2328w (νPH), 1567w, 1424w, 1365w, 1288w, 1257m, 1245m, 1158w, 1136w, 1121m, 1089w, 1064m, 1038s, 967w, 928m, 885s, 859s, 842s, 769s, 746s, 735s, 708s, 675m, 637s, 518s, 504s, 470s, 460s, 441m, 390w, 372w, 297s, 285s.

X-ray crystal structures

Crystals of all four complexes were sealed under argon in thin walled glass capillaries. Cell dimensions and intensity data were recorded using a FAST TV area detector diffractometer, as previously described.[11] The structures were solved and developed via the heavy atom method and refined via full-matrix least-squares. An absorption correction was applied using the DIFABS method.[12] Non-hydrogen atoms were refined anisotropically and organic hydrogens were included in idealized positions and assigned group U_{iso} values. The phosphine hydrogens were not located or included. In the vanadium complex one of the isopropyl groups shows 70/30 disorder over two orientations. Crystal data and experimental details are given in Table 4. Tables of coordinates and other data have been deposited as supplementary material with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited at the Cambridge Crystallographic Data Centre.

Acknowledgements—We thank the SERC for support and for provision of X-ray facilities.

(*Received* 1 *September* 1992; *accepted* 12 *October* 1992)

Abstract—The ESR spectra of the ion *trans*-$[Cl(py)_4Rh(\mu\text{-}O_2)Rh(py)_4Cl]^{3+}$, pure and magnetically dilute in diamagnetic *trans*-$[Rh(py)_4Cl_2]Cl \cdot 5H_2O$, are given to confirm the presence of the superoxide bridge; structural studies support this assignment.

The blue superoxo-dirhodium(III,III) moiety $[Rh_2(\mu\text{-}O_2)]^{5+}$ was discovered[2] in a search for the cause of the green colourations common during the preparation of *trans*-dichlorotetrakispyridine-rhodium(III) chloride, itself yellow, from aqueous rhodium trichloride and pyridine, catalysed by ethanol. The greening is observed particularly for aqueous ethanolic solutions left in air. The blue species responsible is[2] the μ-superoxo-bis(*trans*-chlorotetrakispyridine)dirhodium(III,III) cation (**A**). Such blue compounds with a range of ligands are now quite common.[3,4]

The most convenient demonstration of the presence of the μ-superoxo-dirhodium(III,III) unit is its ESR spectrum, since many of these complexes contain ClO_4^- anions; perchlorate can obscure the vibrational spectra of dioxygen compounds. A few compounds containing the superoxide moiety are listed in Table 1; all show the average g-value (g_{av}) at *ca* 2.03 ± 0.01. One crystallographic study[4] of $[\{(CH_3CN)(py)_3Rh\}_2(\mu\text{-}O_2)(\mu\text{-}OH)](ClO_4)_4 \cdot H_2O$ established that the species giving the characteristic ESR signals ($g_{av} = 2.035$) was indeed the superoxide; the oxygen–oxygen bond length is 133.6 pm, typical of O_2^-.[3c] The measured[4] Rh—O distances for the $Rh^{(III)}$—$(\mu\text{-}O_2)$—$Rh^{(III)}$ moiety were 198.6 and 194.9 pm.

† Author to whom correspondence should be addressed.

For the prototype cation **A**, as its perchlorate, a rhodium–rhodium vector of 487 pm was measured.[5] Oddly, Zehnder attributed this to the structural unit **B**, but acknowledged[5] that this led to the extraordinary Rh—O bond length of 243.7 pm.

$$[Rh^{(IV)}\text{—}O\text{—}Rh^{(III)}]^{5+}$$
B

In the tetrafluoroborate of **A** (isostructural with the perchlorate) this laboratory found that the Rh—Rh vector was similarly 486.2 pm, but[6] there was disorder in exactly the region of the rhodium–oxygen components.

Metal–oxygen interatomic distances decrease as the oxidation state of the metal increases. This is reflected in the Rh—O bond lengths of coordinated *terminal* water ligands; the longest M—O distances for aqueous generated rhodium(II) and rhodium(III) species are 233.2[7] and 216.2 pm.[8] Indeed, the only genuine linear, oxo-bridged dirhodium species[9] contains rhodium(IV) ions, $[Rh^{(IV)}\text{—}O\text{—}Rh^{(IV)}]^{6+}$, with an Rh—O distance of *ca* 190 pm. Contrary to this trend, reduction of unit **B** was said to result in a *shortening* of the Rh—O bond by 32.5 pm.[5]

We now show that for the original system,[2] the ESR spectrum is indeed that of a superoxide: the g-value, shape and intensity of the ESR spectrum

Table 1. ESR spectra for superoxide and its complexes

[b] Crystalline sample.

would be very different[10] if the complex did contain rhodium(IV), i.e. the fragment **B**.

The powder ESR spectrum of $\{[Rh(py)_4Cl]_2(\mu\text{-}O_2)\}^{3+}$ in $[Rh(py)_4Cl_2]Cl$, shown in Fig. 1, is typical of a species having an orthorhombic g-tensor with no hyperfine interactions with either the rhodium or nitrogen nuclei; the spectrum of pure solid $\{[Rh(py)_4Cl]_2(\mu\text{-}O_2)\}(ClO_4)_3 \cdot 8H_2O$ is given in Fig. 2 for comparison.

The magnetically dilute sample of paramagnetic $\{[Rh(py)_4Cl]_2(\mu\text{-}O_2)\}^{3+}$ illustrated in Fig. 1 appears to contain a second minor superoxide species, as shown by the shoulders positioned at $g_{xx} = 2.001$ and $g_{zz} = 2.092$. However, the absorptions due to the minor species can be regarded as non-reproducible, since the shoulders are variable, sometimes negligible, in intensity. The principal g-values (determined from the turning points of the derivative spectrum), the value of g_{av} and the ESR parameters for other paramagnetic superoxo species are listed in Table 1. The g_{av} value of 2.041 is larger than that of organic superoxides (*ca* $g_{iso} = 2.015$),[11] smaller than that of O_2^- in alkali metal matrices, but similar to the values for O_2^- in dipolar matrices. These features strongly indicate that the unpaired electron resides mainly in one of the $1\pi_g^*$ antibonding orbitals of the bridging dioxygen with minimal spin density at the rhodium centres, i.e. the description $[Rh^{(III)}—(\mu\text{-}O_2)—Rh^{(III)}]^{5+}$ is accurate.

The principal values of the g-tensor in the x, y and z directions for the magnetically dilute sample correspond very closely to that of superoxide-bridged dirhodium(III,III) complexes with other nitrogenous ligands. g_{zz} shows the largest deviation from free spin ($g_e = 2.0023$) and must correspond to the case where the field is along the O—O bond axis. The value of g_{xx} is close to g_e, thus identifying the x-axis as that of the orbital containing the unpaired electron, i.e. π_x^*. The deviation of g_{yy} from g_e is larger in these rhodium complexes than in other superoxides and the small but significant difference between g_{yy} and g_{xx} requires non-axial symmetry around the O—O bond, suggesting that the Rh—O—O—Rh bond is not co-linear or co-planar in the dinuclear complexes. The larger shift in g_{yy} is associated with a lowering of the energy gap between the $2p\sigma_g$ and the $2p\pi_g^*$ orbitals, presumably through a repulsive interaction between d_{zy} and σ_g electrons. Comparison of the g-tensors for the rhodium species with those of the similar $\{[Co(NH_3)_5]_2(\mu\text{-}O_2)\}^{5+}$ suggests[12] that the greater shift away from the free electron value in the rhodium complexes is also due, in part, to the larger spin orbit coupling constant for rhodium.

EXPERIMENTAL

The ESR spectra of magnetically dilute $\{[Rh(py)_4Cl]_2(\mu\text{-}O_2)\}^{3+}$ in *trans*-$[Rh(py)_4Cl_2]Cl \cdot 5H_2O$ and NaO_2 in Na_2O_2 were recorded on a Bruker 300E ESR spectrometer at 77K; calibration of the magnetic field was achieved using α,α′-diphenyl-β-picrylhydrazyl. The ESR spectrum of μ-superoxo-bis(*trans*-chlorotetrakispyridine)dirhodium(III,III) triperchlorate octahydrate crystals was obtained using a JES RE2X spectrometer with

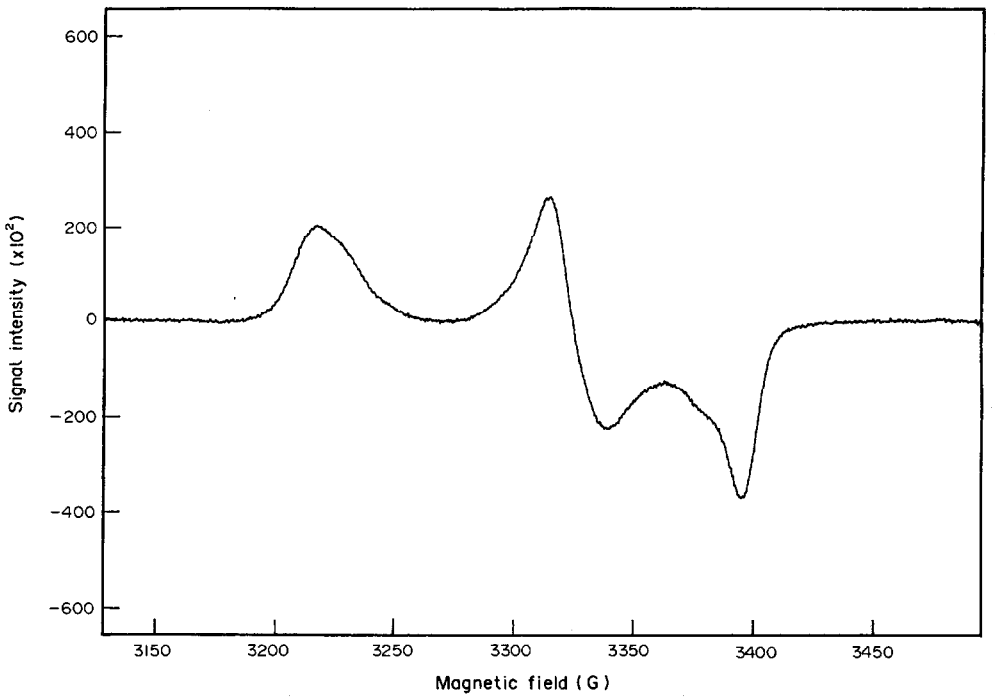

Fig. 1. The ESR spectrum of $[\{Rh(py)_4Cl\}_2(\mu\text{-}O_2)]^{3+}$ in diamagnetic *trans*-$[Rh(py)_4Cl_2]Cl \cdot 5H_2O$ at 77 K.

manganese markers. Crystallographic studies were carried out using a single-crystal diffractometer.

Sodium peroxide beads, containing sodium superoxide as an impurity, were used without further treatment.

Trans-dichlorotetrakispyridinerhodium(III) chloride was prepared by the method of Gillard and Wilkinson[13] using a catalyst of ethanol rather than sodium hypophosphite. This preparation[13] states that the yield may be increased by allowing the filtrate to stand for a few days; during this time the ethanolic solution slowly becomes green, indicating the formation of the paramagnetic species. Evaporation gives the green crystals of the diluted superoxide complex.

Preparations of $\{[Rh(py)_4Cl]_2(\mu\text{-}O_2)\}(X)_3 \cdot nH_2O$,

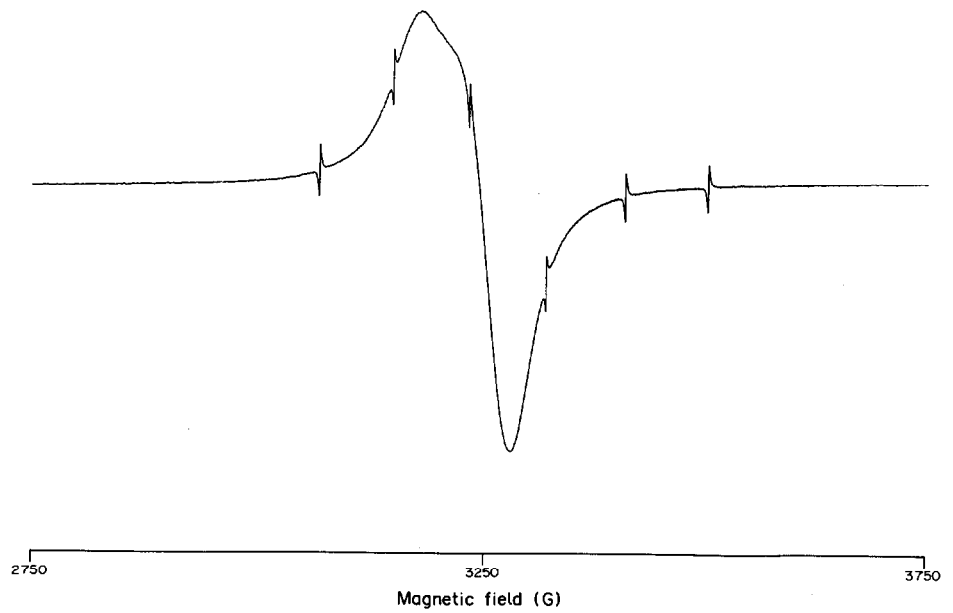

Fig. 2. The ESR spectrum of crystalline $\{[Rh(py)_4Cl]_2(\mu\text{-}O_2)\}(ClO_4)_3 \cdot 8H_2O$ with manganese markers.

where X is the perchlorate anion ($n = 8$) or the tetrafluoroborate anion ($n = 0$), were based on the method reported elsewhere.[2] However, crystals from the blue solution ($\lambda = 646$ nm), resulting[2] from ozonolysis of an alkaline ethanolic solution of $[Rh(py)_4Cl_2]Cl$, were isolated in a different fashion.

The addition of excess solid $NaClO_4$ to a freshly prepared sample of the blue solution gave a silver/blue precipitate. After filtering and washing with a small volume of water, the solid was redissolved in the minimum quantity of boiling $HClO_4$ (0.5 M); alternatively, to generate the tetrafluoroborate salt, excess boiling $NaBF_4$ solution was added to this perchlorate acid solution. The hot solution was immediately placed in a sealed dewar and allowed to crystallize (refrigerator) for 48 h. Once collected, the crystals were washed with a little acetone.

It should be noted that although some degree of twinning of crystals took place using the conditions described above, recrystallization of the salts in any medium other than an aqueous acidic solution of anion (e.g. pyridine, acetone, etc.) resulted in the decay of the compound or the twinning of all crystals.

Acknowledgements—I.J.E., R.D.G. and J.M. wish to thank SERC and the Universities of Bristol and Bath for the purchase of the Bruker 300E ESR spectrometer. Further, I.J.E. and R.D.G. wish to express their gratitude to M. B. Hursthouse, C. W. Lehmann and A. B. Lehmann (SERC crystallographic group, Cardiff) for structural studies.

THE NATURE OF THE OXIDATION PRODUCTS OF DICYANORUTHENIUM PHTHALOCYANINE IN AQUEOUS AND NON-AQUEOUS SOLVENTS

TEBELLO NYOKONG

Chemistry Department, Rhodes University, Grahamstown 6140, Republic of South Africa

(*Received* 13 *July* 1992; *accepted* 12 *October* 1992)

Abstract—The cyclic voltammetry of $[(CN)_2Ru^{II}Pc]^{2-}$ in acetonitrile or dichloromethane shows two oxidation couples at $E_{1/2} = 0.31$ and 0.85 V (vs S.C.E.) in CH_2Cl_2 and $E_{1/2} = 0.45$ and 1.15 V (vs S.C.E.) in acetonitrile. The spectroelectrochemistry of $[(CN)_2Ru^{II}Pc]^{2-}$ in these solvents showed that oxidations occur at the phthalocyanine ligand. $K_2[(CN)_2Ru^{II}Pc]$ dissolves in water at pHs greater than 5. The cyclic voltammetry of this complex showed oxidation couples at 0.32 and 0.29 V (vs S.C.E.) for aqueous solutions containing sodium sulphate (0.1 M) and for buffered solutions (pH = 9), respectively. Both cyclic voltammetry and controlled potential coulometry gave evidence of electrocrystallization of the oxidation product. Chemical oxidations of $[(CN)_2Ru^{II}Pc]^{2-}$ in water also showed phthalocyanine ligand oxidation.

Phthalocyanine complexes have established themselves industrially as green or blue dyes. Potential applications of metal phthalocyanine (MPc; Pc = phthalocyanine dianion) complexes include uses in catalysis, pollution control, electronic devices, photovoltaic devices and many others. Most of these applications involve the exchange of one or two electrons per reaction and hence, an understanding of the redox properties of the phthalocyanine complexes is very important. There is also an interest in metal-based drugs that can act against the rapid toxic effects of cyanide, and for this metalloporphyrin complexes have been suggested.[1–5] Phthalocyanines are structurally similar to the porphyrins and hence, studies of the cyano complexes of MPc complexes are of interest; a number of $(CN)_2MPc$ complexes have been reported.[6–8]

Cyclic voltammetry (CV) studies of a series of dicyanometallo phthalocyanines have been reported.[6] In these studies the first oxidation potential in $[(CN)_2Ru^{II}Pc]$ was assigned to the oxidation of the ruthenium metal to ruthenium(III), based on the comparison with the CV results of ruthenium porphyrin complexes. In this work, we take a closer look at the electrochemical properties of the $[(CN)_2Ru^{II}Pc]$ complex. The CV studies will be coupled with controlled potential coulometry and the site of the first and second oxidations will be determined.

Phthalocyanine complexes are normally insoluble in water. Attaching sulphonic acid groups to the outer periphery of the phthalocyanine ring renders these complexes soluble in water.[9–12] Sulphonated phthalocyanine complexes, however, aggregate in aqueous solution and are photoinactive. $[(CN)_2Ru^{II}Pc]$ shows solubility in water; the redox properties of this complex in water are reported in this work.

EXPERIMENTAL

Materials

Crude RuPc was synthesized from $RuCl_3 \cdot 3H_2O$ and *o*-cyanobenzamide and extracted with glacial acetic acid following the method of Dolphin *et al.*[13]

$K_2[(CN)_2RuPc]$ was prepared according to synthetic procedures for other $[(CN)_2MPc]^{2-}$ complexes.[7,8] Crude RuPc (0.05 g, 0.08 mmol) and KCN (0.05 g, 0.77 mmol) were suspended in absolute ethanol or DMF (10 cm^3) and refluxed for 3 h, giving a blue solution. The solution of $K_2[(CN)_2$ RuPc] was filtered to remove the insoluble RuPc and the filtrate evaporated to dryness, giving a purple solid which was washed in hexanes and recrystallized from acetone, giving 40 mg (66%) of $K_2[(CN)_2RuPc] \cdot 3H_2O$.

$K_2[(CN)_2RuPc]$ could also be prepared by reacting $[(DMSO)_2RuPc \cdot 2DMSO]$ (0.02 g, 0.02 mmol) with KCN (0.03 g, 0.46 mmol) in DMF (10 cm^3), following the procedure outlined above, giving 0.013 g (80%) of $K_2[(CN)_2RuPc] \cdot 3H_2O$. $(DMSO)_2RuPc \cdot 2DMSO$ was prepared following procedures outlined previously.[14] Found: C, 50.9; H, 3.3; N, 17.1. Calc. for $K_2C_{34}H_{22}N_{10}O_3Ru$: C, 51.2; H, 2.8; N, 17.6%. IR spectra (KBr discs): ν(Ru—CN), 2075; ν(O—H), 3440 cm^{-1}. UV–vis (CH_3CN) λ_{max} (nm): 620 (ε = 46,000), 565, 345.

CH_2Cl_2 and CH_3CN were dried over calcium hydride and phosphorus pentoxide, respectively, and then distilled. DMF and DMSO were stirred with alumina, distilled under reduced pressure and stored over molecular sieves. Distilled deionized water was used for studies in aqueous solutions. Tetrabutylammonium perchlorate (TBAP), tetraethylammonium perchlorate (TEAP) and Na_2SO_4 were recrystallized and used as electrolytes for electrochemical studies. Ferrocene was recrystallized from ethanol before use as an internal standard. All other materials were reagent grade and used without further purification.

Methods

Electrochemical data were collected with the BAS CV 27 voltammograph connected to an HP 7047A *X–Y* recorder. All electrochemical measurements were carried out under an atmosphere of nitrogen. For cyclic voltammetry a platinum disc (1.6 mm diameter) was used as the working electrode and a platinum wire as the auxiliary electrode. A silver wire coated with silver chloride was used as a quasi-reference electrode. Potentials were referenced internally to the ferrocenium/ferrocene (Fc^+/Fc) couple.[15,16] The Fc^+/Fc couple was measured as 0.47 V vs S.C.E. in CH_2Cl_2 containing TBAP and 0.44 vs S.C.E. in CH_3CN containing TBAP or TEAP. Platinum sheet working and auxiliary electrodes and an Ag/AgCl reference were employed for bulk electrolysis, the auxiliary electrode being separated from the compartment housing the reference and working electrodes by a fine glass frit. TBAP or TEAP (0.03–0.1 M) in CH_3CN or CH_2Cl_2 were used as supporting electrolytes for electrochemical studies in non-aqueous solutions. Sodium sulphate (0.1 M) and phthalate and phosphate buffers were employed as electrolytes for electrochemical experiments in aqueous solutions. HCl and NaOH were used to adjust pH in unbuffered aqueous solutions.

A Quanta Ray Neodynium Yag pumped dye laser with a DCM dye for irradiation at 640 nm was used as a source of the ns pulses. EPR measurements were carried out at room temperature or in liquid nitrogen with the Bruker ESR spectrometer. IR spectra (KBr discs) were collected with a Perkin–Elmer Model 180 IR spectrometer. Electronic absorption spectra were recorded with a Varian Techtron UV–vis spectrophotometer, model 635.

RESULTS AND DISCUSSION

Studies in non-aqueous solvents

Both ruthenium(II) and ruthenium(III) porphyrin complexes are known to form cyano complexes.[2] As has been observed before[6] the oxidation state of ruthenium in $(CN)_2RuPc$ is +2. The $(CN)_2RuPc$ complex prepared in this work is EPR inactive, consistent with an oxidation state of +2 for ruthenium and the formulation of the complex as $[(CN)_2Ru^{II}Pc]^{2-}$. The Ru—CN vibration is observed at 2075 cm^{-1}.

Cyclic voltammetry. Two successive ring oxidations from the non-degenerate $a_{1u}(\pi)$ orbital of the phthalocyanine ligand and four successive ring reductions into the doubly degenerate $e_g(\pi^*)$ orbital are theoretically possible in metal phthalocyanine complexes. Some MPc complexes show redox activity at the central metal.[17–19] CV and controlled potential coulometry studies of $[(L)_2Ru^{II}Pc]$ complexes show that oxidations occur at the phthalocyanine ligand in these complexes.[13,19]

Figure 1 shows the CV of $[(CN)_2Ru^{II}Pc]^{2-}$ in CH_2Cl_2 containing TBAP. Two oxidation couples

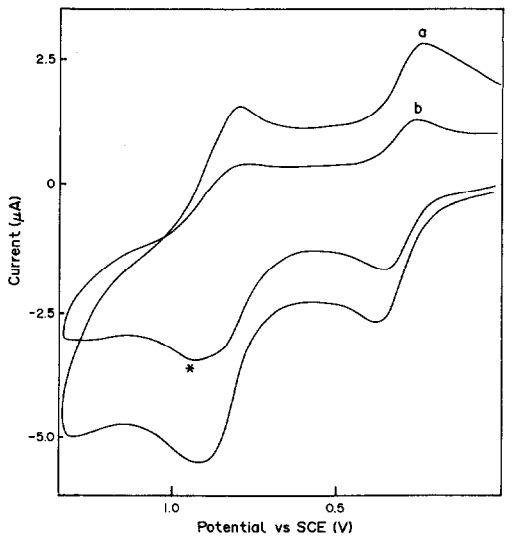

Fig. 1. Cyclic voltammogram of $[(CN)_2Ru^{II}Pc]^{2-}$ in dichloromethane containing TBAP (0.05 M). Scan rate (a) 50 and (b) 200 mV s^{-1}. * refers to the irreversible peak following the second oxidation couple.

Table 1. Half-wave[a] potentials of the $[(CN)_2RuPc]$ complex in various solvents and electrolytes

Solvent/electrolyte	Pc^-/Pc^{2-} (V)	Pc^0/Pc^- (V)
CH_3CN/TEAP	0.45 (0.01)	1.15 (0.71)
CH_2Cl_2/TBAP	0.31 (−0.16)	0.85 (0.38)
H_2O/Na_2SO_4	0.34	
H_2O/pH 9 buffer	0.29	

[a] Note: Numbers in brackets are half-wave potentials ($E_{1/2}$) vs the ferrocenium/ferrocene (Fc^+/Fc) couple. $E_{1/2}$ values vs S.C.E. were obtained by adding $E_{1/2}$ (Fc^+/Fc) = 0.47 V vs S.C.E. (for dichloromethane solutions) or 0.44 V vs S.C.E. (for acetonitrile solutions) to $E_{1/2}$ vs Fc^+/Fc values in brackets.

were observed: the first at a half-wave potential ($E_{1/2}$) of 0.31 V and the second at 0.85 V, Table 1. The first oxidation couple is quasi-reversible with an anodic-to-cathodic peak separation of approximately 100 mV. The second oxidation couple is reversible with a peak separation of 59 mV. The second couple is immediately followed by an irreversible peak at a potential of 0.97 V. This peak is more prominent at low scan rates, Fig. 1(a).

The oxidation potential of 0.31 V observed for $[(CN)_2Ru^{II}Pc]^{2-}$ is lower than potentials generally observed for the first ligand oxidation of MPc complexes.[19] However, all $[(L)_2Ru^{II}Pc]$ complex studies so far[13,19,20] show oxidation at the phthalocyanine ligand and not at the ruthenium metal. Thus, it is suggested here that the first oxidation in $[(CN)_2Ru^{II}Pc]^{2-}$ occurs at the phthalocyanine ligand giving an $[Ru^{II}Pc]^-$ π-cation radical species. The quasi-reversible nature of the first oxidation couple could be due to axial ligand exchange or the formation of five-coordinate intermediates. Five-coordinate ruthenium(II) porphyrins are known.[2] The second oxidation couple at 0.85 V vs S.C.E. is assigned to the removal of the second electron from the phthalocyanine ligand. Spectroelectrochemistry is used to confirm these CV assignments.

CV results similar to those reported in CH_2Cl_2 were also obtained when acetonitrile was employed as a solvent. The oxidation potentials were observed at 0.45 and 1.15 V for the first and second oxidation potentials, respectively (Table 1).

Spectroelectrochemistry. Oxidation at the phthalocyanine ligand in MPc complexes occurs by the removal of electrons from the $1a_{1u}$ highest occupied molecular orbital, resulting in a drastic change in transitions that arise from this orbital. Data presently available for the MPc^- π-cation radical species show that the formation of this species is accompanied by the loss of intensity of the Q band, which arises from the $1a_{1u}$ orbital, and the formation of a broad band centred at approximately 500 nm.[13,16,19-21] Metal centred oxidation would result in a shift in the Q band without much change in intensity.[19,22]

Figure 2, shows the absorption spectral changes observed when solutions of $[(CN)_2Ru^{II}Pc]^{2-}$ in acetonitrile containing TBAP (0.05 M) were exhaustively electrolysed at potentials 50 mV positive of the first oxidation potential, viz. 0.5 V. As electrolysis proceeds the Q band decreases in intensity,

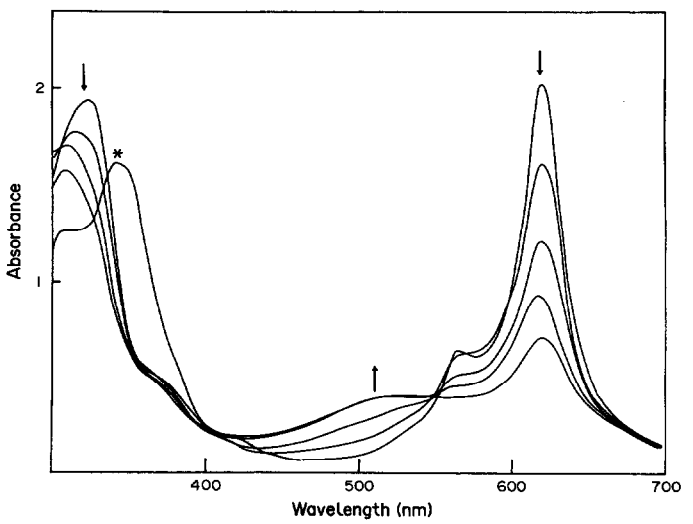

Fig. 2. Absorption spectral changes observed when solutions of $[(CN)_2Ru^{II}Pc]^{2-}$ in acetonitrile containing TBAP (0.05 M) were exhaustively electrolysed at 0.5 V vs S.C.E. * refers to the Soret band of the original complex.

Table 2. Electronic absorption spectral data for $[(CN)_2RuPc]$ in various solvents, showing only the main band centres

Complex[a]	Solvent	Data	
$RuPc^{2-}$	CH_3CN	345	620
	CH_2Cl_2/TBAP	345	623
	H_2O	313	
$RuPc^-$	CH_3CN	358	520[b]
	CH_3CN	308	520[c]
	CH_2Cl_2	300	520[c]
	H_2O	308	550[d]
$RuPc^0$	CH_2Cl_2	~400[c]	

[a] Axial ligands have been excluded.
[b] Ferric chloride oxidized.
[c] Electrochemically oxidized.
[d] Bromine oxidized.

the Soret band shifts from 345 to 325 nm and finally to 308 nm at the end of the electrolysis (Table 2). The spectra of the final oxidation product with a broad band at 520 nm is typical of the spectra of the MPc^- π-cation radical species. Thus, the first oxidation in $[(CN)_2Ru^{II}Pc]$ occurs at the phthalocyanine macrocycle and not at the metal, contrary to that suggested before.[6] Values of $n = 1 \pm 10\%$ (where n is the number of electrons involved in the electron transfer step) were obtained for oxidation at the first oxidation potentials of the $[(CN)_2Ru^{II}Pc]$ complex. The EPR spectra, at 77 K, of the oxidized complex show a signal centred at $g = 2.00$. Reduction of the oxidized species at 0 V vs S.C.E. does not regenerate the original species with the Soret band at 345 nm, but regenerates the intermediate species, the Soret band centred at 325 nm. The original species is only observed on addition of CN^- to the reduced species, implying that the oxidation of $[(CN)_2Ru^{II}Pc]$ to the π-cation radical species is accompanied by loss of cyanide. Loss of both cyanide ligands is unlikely as unligated RuPc is highly insoluble. It is likely that the lost CN^- is replaced by the electrolyte ClO_4, to give $[(CN)(ClO_4)RuPc]^-$.

Similar results were observed when solutions of $[(CN)_2Ru^{II}Pc]$ in dichloromethane containing TBAP (0.05 M) were exhaustively electrolysed at 0.4 V. The spectral changes are again typical of the formation of a π-cation radical species, accompanied by the exchange of axial ligands.

Exhaustive electrolysis at the potentials of the second oxidation gave the spectral changes shown in Fig. 3. The first step is the formation of the $RuPc^-$ complex with a typical broad peak at 520 nm. As the electrolysis proceeds the 520 nm peak is reduced in intensity and a new broad peak is observed at *ca* 400 nm; we tentatively assign the final oxidation product of this electrolysis to the formation of the $RuPc^0$ dication radical. There is considerable decomposition accompanying the formation of these species. The oxidation of the cyanide ligand is known to occur at approximately

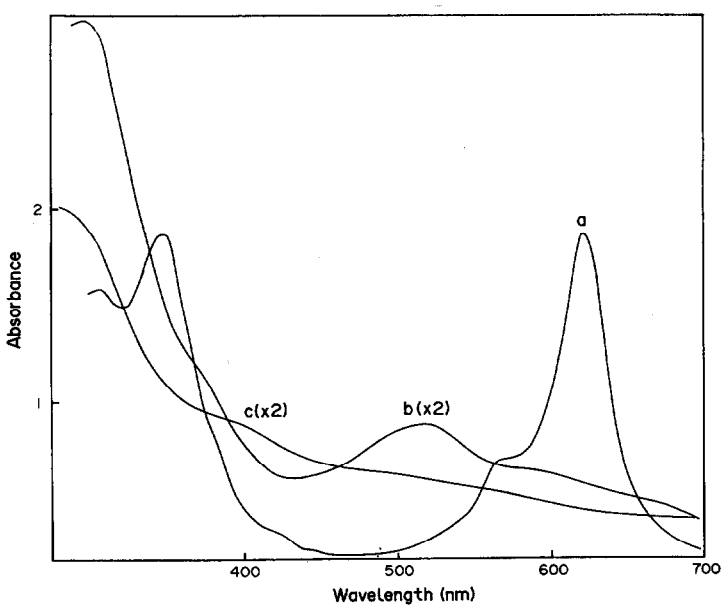

Fig. 3. Absorption spectral changes observed when solutions of $[(CN)_2Ru^{II}Pc]^{2-}$ in dichloromethane containing TBAP (0.05 M) were exhaustively electrolysed at 0.9 V vs S.C.E. (a) Unoxidized complex: (b) π-cation radical species; and (c) final species obtained on oxidation.

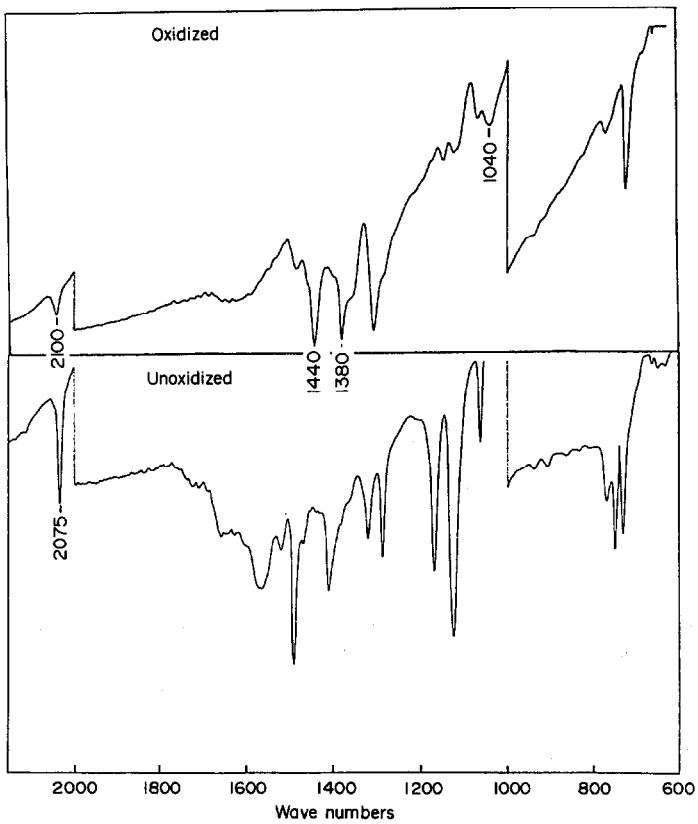

Fig. 4. The IR spectra (KBr discs) of the bromine-oxidized and unoxidized $K_2[(CN)_2Ru^{II}Pc]$.

1.0 V,[23] hence, the shoulder observed at 0.97 V is associated with the oxidation of the CN^- ligand.

Chemical oxidation. Bromine oxidation of $[(CN)_2Ru^{II}Pc]$ in acetonitrile forms the π-cation radical species with clear isosbestic points, with no evidence for axial ligand exchange. Reduction of the oxidized species with $Na_2S_2O_4$ completely regenerates the spectra due to the neutral species.

The IR spectra of the bromine-oxidized $[(CN)_2Ru^{II}Pc]^-$ complex is not complicated by vibrations of the electrolyte and in Fig. 4 we compare the IR spectra of $[(CN)_2Ru^{II}Pc]^{2-}$ and of the oxidized species. The oxidized species for IR were obtained by evaporating off the solvent from acetonitrile solutions of the bromine-oxidized $[(CN)_2Ru^{II}Pc]^-$ complex. The oxidized complex shows the Ru—CN vibration at 2100 cm^{-1}, an increase of 25 cm^{-1} from the frequency of the original species at 2075 cm^{-1} (Fig. 4). The increase in energy of the M—CN^- frequency when MPc^- are formed has been observed before.[6] The IR spectra of the MPc^- species are of lower intensity than those of the neutral species.[6,24] Bands typical of the MPc^- complexes[6,24] are observed at 1040, 1380 and 1440 cm^{-1}.

The reaction between ferric chloride and $[(CN)_2Ru^{II}Pc]$ proceeds through several stages. Initially, the Q band broadens and shifts to slightly lower energies [Fig. 5(b)]. The spectra are still typical of $[(L)_2Ru^{II}Pc]$ complexes, hence maybe assigned to the exchange of axial ligands, probably the formation of the $[(Cl)(CN)Ru^{II}Pc]$ complex. Similar spectral changes were observed during the oxidation of cobalt tetraneopentoxyphthalocyanine by $SOCl_2$[25] and were assigned to axial ligation effects. Further addition of ferric chloride results in the formation of the π-cation radical species [Fig. 5(b)] with an Ru—CN vibration at 2090 cm^{-1}, thus, confirming that at least one cyanide ligand remains coordinated to the $RuPc^-$ complex.

Studies in water

Phthalocyanine complexes that are not substituted peripherally by sulphonic acid groups are insoluble in water. $K_2[(CN)_2RuPc]\cdot 3H_2O$, however, dissolves in water with an extinction coefficient (at $\lambda = 630$ nm) of 3×10^4 $dm^3\,mol^{-1}\,cm^{-1}$. This value is of the same order of magnitude as the value reported for other $(L)_2RuPc$ complexes.[13]

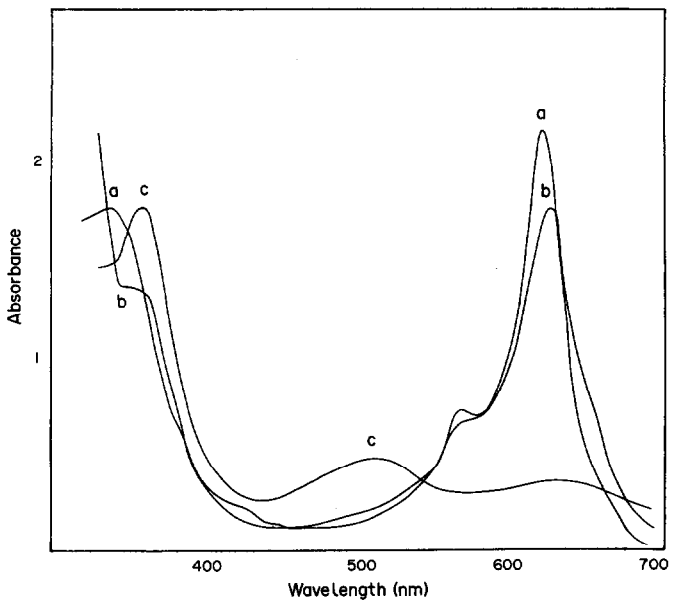

Fig. 5. Absorption spectral changes observed on addition of ferric chloride to acetonitrile solutions of $[(CN)_2Ru^{II}Pc]$. (a) No $FeCl_3$ added; (b) complex formed on addition of small amounts of $FeCl_3$; and (c) oxidized complex, excess $FeCl_3$ added.

$K_2[(CN)_2RuPc]\cdot 3H_2O$ dissolves in aqueous solutions above pH = 5, forming blue–green solutions. Beer's law is obeyed in the concentration range 10^{-6}–10^{-3} M. Below pH = 5, the solubility of $[(CN)_2Ru^{II}Pc]$ is considerably decreased. In this pH range a green solution is obtained with an uncharacteristically broad Q band centred at *ca* 670 nm, Fig. 6. Addition of hydroxide or cyanide to the green solution results in the regeneration of the blue–green solution and the narrowing of the Q band as it shifts back to 630 nm. Addition of SO_2 or $Na_2S_2O_4$ to basic solutions of $[(CN)_2Ru^{II}Pc]$ also resulted in the broadening of the Q band shown in Fig. 6(c). The dependence of the spectra on pH has been observed before in ruthenium(II) porphyrin complexes and has been attributed to the loss of the cyanide ligands at low pH.[2] We similarly assign the species at low pH to an $Ru^{II}Pc$ complex which has lost the cyanide ligands.

Cyclic voltammetry of the $[(CN)_2Ru^{II}Pc]$ com-

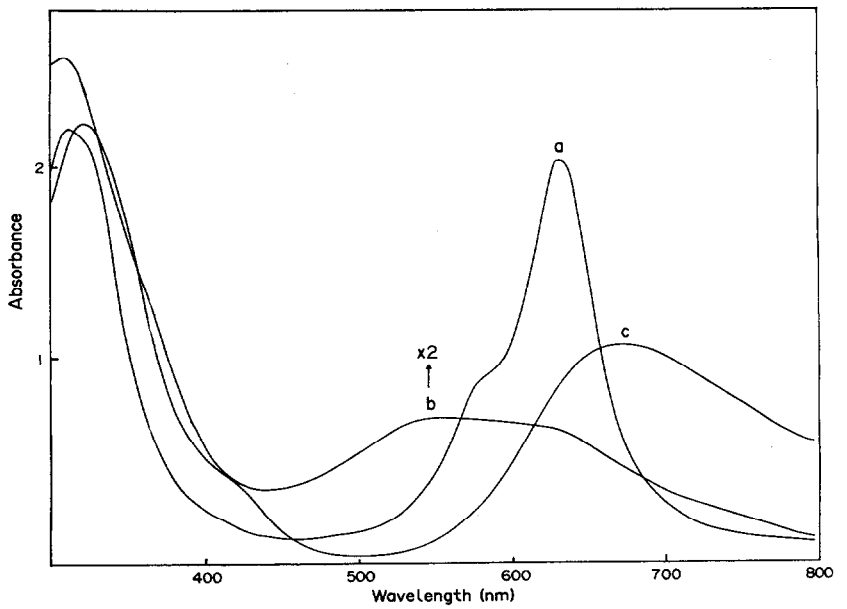

Fig. 6. Absorption spectra of (a) unoxidized $[(CN)_2Ru^{II}Pc]^{2-}$ dissolved in pH = 9 buffer; (b) bromine oxidized $[(CN)_2Ru^{II}Pc]^-$, pH = 9; and (c) $[(CN)_2Ru^{II}Pc]$ in water at pH < 5.

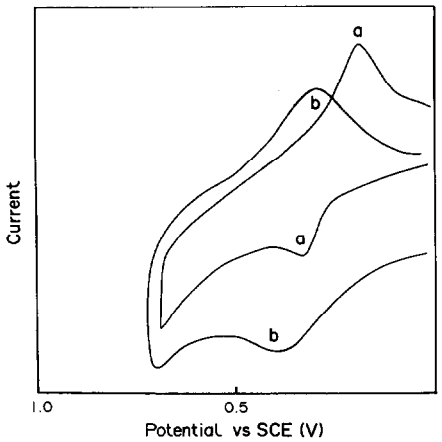

Fig. 7. Cyclic voltammogram of solutions of $[(CN)_2Ru^{II}Pc]$ in (a) pH 9 buffer; scan rate 200 mV s^{-1}; and (b) water containing sodium sulphate (0.1 M); scan rate = 1 V s^{-1}.

plex in buffered solutions (pH = 9) or in water containing sodium sulphate (0.1 M) shows a quasi-reversible oxidation couple at 0.29 and 0.34 V, respectively (Fig. 7). These potentials are in the range reported above for the first oxidation of the phthalocyanine macrocycle, showing that oxidation of the $[(CN)_2Ru^{II}Pc]$ complex in water also occurs at the phthalocyanine ligand. The cathodic currents for these oxidation couples (Fig. 7) are greatly enhanced when compared to the anodic currents. This behaviour is typical of a weakly adsorbed product.[26] Indeed exhaustive electrolysis at 0.4 V resulted in considerable electrocrystallization and adsorption of the product to the electrodes. However, bromine oxidation of $[(CN)_2Ru^{II}Pc]$ in basic aqueous solutions gave spectral changes which are characteristic of the formation of the MPc^- π-cation radical species with a broad band at 550 nm [Table 2 and Fig. 6(b)]. Reduction of the oxidized species with sodium borohydride regenerates more than 95% of the original species.

Laser irradiations of basic solutions of $[(CN)_2Ru^{II}Pc]$ at wavelengths of the Q band produced a short-lived ligand-centred $^3\pi\pi^*$ state at a wavelength of 520 nm and with a half-life of 75 ns. Such short-lived species have been observed in other RuPc complexes.[27]

SYNTHESIS AND CHARACTERIZATION OF COMPLEXES OF COBALT(II), NICKEL(II), ZINC(II), CADMIUM(II) AND MERCURY(II) WITH *p*-ACETAMIDOBENZALDEHYDE THIOSEMICARBAZONE

G. KANAGARAJ and G. N. RAO*

Chemistry Department, Indian Institute of Technology, New Delhi 110016, India

(*Received* 1 *September* 1992; *accepted* 9 *October* 1992)

Abstract—Some complexes of *p*-acetamidobenzaldehyde thiosemicarbazone (thiacetazone) with cobalt(II), nickel(II), zinc(II), cadmium(II) and mercury(II) have been prepared and their magnetic, spectral and thermal data suggest that the thiacetazone acts as a neutral bidentate ligand binding the metal ion through the hydrazine nirogen and the carbothioamide sulphur. A brown-coloured nickel(II) complex, $Ni(TA)_2$, was isolated and found to be diamagnetic and it contains a monoanionic bidentate ligand (thiol form). All the metal complexes of the type $M(TAH)_2X_2$ (where X is Cl, Br, NO_3 and SCN) are octahedral, while $Ni(TA)_2$ is square planar in structure.

p-Acetamidobenzaldehyde thiosemicarbazone (thiacetazone) is used to treat mycobacterial infections that are resistant to isoniazid, a well-known antituberculosis drug. Leibermeister showed that copper ions enhanced the anti-tubercular activity of thiacetazone.[1] The copper complex of thiacetazone was reported by Kuhn and Zilliken in 1954 and its use in chemotherapy of tuberculosis has been discussed briefly.[2] Copper(II) and nickel(II) complexes of the type $[ML_2]SO_4$ and ML_2 were reported with magnetic susceptibility, electronic and IR spectral data.[3]

This paper presents detailed information on the preparation and properties of the complexes formed by thiacetazone with cobalt(II), nickel(II), zinc(II) and mercury(II).

EXPERIMENTAL

Thiacetazone was procured from Sigma Chemical Co. (USA) and was used without further purification. All the metal salts used were of Analar reagent grade.

The metal halide (2.5 mmol) dissolved in acetone or methanol (10 cm^3) was added slowly to a refluxing acetone solution (100 cm^3) of the ligand thiacetazone (2.5 mmol). The solid which separates out on concentration of the solution was filtered, washed with a small amount of acetone and then dried in a vacuum desiccator.

Cobalt(II) nitrate hexahydrate was used to prepare the cobalt(II) complex containing nitrate as the anion. An alcoholic ammonia solution (1 : 1) was added to the reaction mixture of nickel(II) chloride and thiacetazone until a brownish product appeared and the reaction mixture was refluxed for 1 h to isolate the brown colour complex of nickel (II), $Ni(TA)_2$. For the preparation of the nickel (II) complex with isothiocyanate anion a stoichiometric amount of ammonium thiocyanate (in a small amount of water) was added to the reaction mixture of nickel(II) chloride and thiacetazone. The yield of all the metal complexes was found to be in the range 60–80%.

Physical measurements

Elemental analyses for carbon, hydrogen and nitrogen were carried out on a Perkin–Elmer 240°C microanalyser. The amount of metal present in the complexes was determined using a Pye–Unicam SP191 atomic absorption spectrophotometer. Conductivities of the metal complexes were measured in dimethylformamide at room temperature using a Metrohm 660 conductometer. Magnetic susceptibilities of the metal complexes were measured

* Author to whom correspondence should be addressed.

using a Cahn 2000 Faraday magnetic balance calibrated with $Hg[Co(NCS)_4]$ at room temperature.

Diffuse reflectance spectra were recorded on a Hitachi 300 UV–vis spectrophotometer, fitted with a standard reflectance attachment. IR spectra were recorded on a Nicolet DX FTIR instrument and a Perkin–Elmer 1700X FT far-IR spectrophotometer. Proton magnetic resonance spectra were recorded on a JEOL JNM FX-100 FT NMR spectrometer, using tetramethylsilane as a reference in d^6-DMSO at room temperature. Thermograms were recorded on a Stanton Redcroft STA 780 thermal analyser.

RESULTS AND DISCUSSION

The analytical data for the metal-thiacetazone complexes (see Table 1) were found to be in agreement with the proposed molecular formulae.

Conductivity

Thiacetazone and its metal complexes were found to be non-conducting in acetone. In dimethylformamide, however, thiacetazone complexes of cobalt(II) chloride(110), zinc(II) chloride (104) and cadmium(II) chloride (119) were found to have molar conductivities (Ω^{-1} cm^2 mol^{-1}) in the range expected for 1 : 1 electrolytes. The mercury(II) complex (17) and $Ni(TA)_2$ (10) behaved as non-electrolytes at room temperature. Other metal complexes including that of cobalt(II) bromide (356), cobalt(II) nitrate (707) and nickel(II) isothiocyanate (443) were found to have high molar conductivities, possibly due to solvolysis in dimethylformamide.[4]

Magnetic susceptibility

The effective magnetic moment values (in B.M.) for thiacetazone complexes of cobalt(II) bromide (4.58), cobalt(II) nitrate (4.98) and nickel(II) isothiocyanate (2.99) were obtained from susceptibility measurements at room temperature and suggest that the ligand field environment around cobalt(II) and nickel(II) ions is octahedral with three and two unpaired electrons, respectively.[5] The brown coloured $Ni(TA)_2$ was found to be diamagnetic, thereby suggesting a spin paired square-planar stereochemistry for the d^8 Ni^{2+} complex.

IR spectral study[6]

Thiacetazone exhibits four prominent IR bands in the regions 3310, 3250, 3220 and 3145 cm^{-1}. Although it is very difficult to assign each band to any symmetric or asymmetric stretchings of the three different NH groups present, namely acetamide NH, hydrazine NH and carbothioamide NH_2, the overall positive shifts of these bands in the IR spectra of metal complexes indicate the non-involvement of the NH group in metal binding (Table 2).[7] Other IR bands due to NH_2 bending (1610 and 1590 cm^{-1}), amide **III** (1325 and 1285 cm^{-1}), ρ (NH_2) (1270 and 1180 cm^{-1}), ω (NH_2) (1015 cm^{-1}) and δ (NCS) (460 and 440 cm^{-1}) showed no shift on coordination of the ligand to the metal ion.

A strong band at 1680 cm^{-1} (due to carbonyl stretching) in the case of both thiacetazone and its metal complexes indicates the presence of the acetamide carbonyl group free from metal binding. Two vibrational bands at 1115 and 815 cm^{-1} in the spectrum of thiacetazone might be due to C=S

stretching, perhaps coupled with N—C—N stretching. These bands showed a negative shift of 35–50 cm^{-1} (1060–1080 cm^{-1}) and of relatively less magnitude, 5–10 cm^{-1} (800–810 cm^{-1}), in the case of all metal complexes.[8] These observations indicate the involvement of the C=S group in bonding to the metal ion. In the spectrum of $Ni(TA)_2$ only the band at 820 cm^{-1} was observed. The disappearance of the other band in the range 1115–1060 cm^{-1} indicates the loss of C=S double bond character on coodination.[7] Thiacetazone, in this case, probably acts as an anion (deprotonated thiol form), binding the nickel(II) ion through sulphur.

Additional IR bands at 2060 [ν(C=N)], 820 [ν(C=S)], 445 and 500 cm^{-1} [δ(NCS)] in the spectrum of the nickel(II) isothiocyanate complex of thiacetazone suggest that the coordination of the isothiocyanate anion to the nickel(II) ion is through nitrogen.[9] In the far -IR spectra of the metal complexes absorptions due to metal–ligand stretching vibrations are identified, which can be assigned to various M—L (M—N and M—S) and M—X (M—Cl, M—Br and M—NO_3) bondings (Table 2).

Electronic spectral study

Diffuse reflectance spectra recorded for the cobalt(II) complexes of thiacetazone showed two principal regions of absorptions, one in the range 8000–10,000 cm^{-1} due to the $^4T_{2g} \leftarrow {}^4T_{1g}$ electronic transition (ν_1) and the other in the range 18,000–21,000 cm^{-1} due to the $^4T_{1g}$(P) electronic transition (ν_3) (Table 3). In the case of $[Co(TAH)_2(NO_3)_2]$ a weak absorption observed at 15,870 cm^{-1} could be due to the $^4A_{2g} \leftarrow {}^4T_{1g}$ transition (ν_3). These observations suggest an octahedral ligand field environment around the d^7 cobalt(II) ion in the complexes prepared.[10]

The three electronic bands observed at 11,430 16,390 and 26,320 cm^{-1} (shoulder) in the spectrum of $[Ni(TAH)_2(NCS)_2]\cdot 2H_2O$ indicate octahedral stereochemistry for the d^8 nickel(II) ion with $^3A_{2g}$ as a ground electronic state in the complex (Table 3). In the case of the diamagnetic $Ni(TA)_2$ complex only one absorption band at 19,610 cm^{-1} was observed. This could be attributed to the $^1B_{2g}$ (XY) $\leftarrow {}^1A_{1g}$ transition in a square-planar ligand field environment around the nickel(II) ion.

^{1}H NMR spectral study

The number of protons related to all the chemical shifts observed in the spectrum of thiacetazone remained unchanged in the spectra of the diamagnetic metal complexes (Table 4). This shows the non-deprotonated nature of the ligand in the complexes of zinc(II), cadmium(II) and mercury (II). The chemical shifts,[11] in δ ppm, due to acetamide NH (10.09) and hydrazine NH (11.37) protons remained unchanged in the spectra of zinc(II) and cadmium(II) complexes. This indicates neither acetamide NH nitrogen nor hydrazine NH nitrogen are involved in metal coordination of the ligand.

The split in the proton signal due to carbothioamide-NH_2 groups (7.97 and 7.90 δ ppm) observed in the spectrum of the ligand disappeared and only one stronger signal corresponding to two protons was found in the case of zinc(II) and cadmium(II) complexes (Table 4). This split in the proton signal due to the NH_2 group can be explained on the basis that because of the partial double-bond character of the C—N bond (due to resonance in the

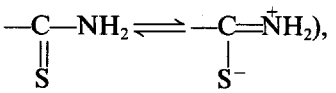
carbothioamide moiety



the two NH_2 protons have a different environment (*cis* and *trans*).[12] The presence of only one signal due to the NH_2 protons in these complexes indicates a substantial reduction in the double-bond character of the C—N bond, which allows free single-bond rotation at room temperature, thereby making the two NH_2 protons equivalent.

In the spectrum of $Hg(TAH)_2Cl_2$, however, the doublet nature of the proton signal due to the carbothioamide NH_2 group (8.82 and 8.74 δ ppm) was observed. The downfield shift of this proton signal when compared to that of thiacetazone, $Zn(TAH)_2Cl_2$ and $Cd_2(TAH)Cl_4$ could be attributed to the change in the structure of the ligand from thione to thiol forms. The presence of the thiol form of the ligand in the mercury(II) complex is further supported by the broad signal observed at 12.15 δ ppm, which could be due to the SH proton. The absence of the proton signal (11.37 δ ppm) cor-

responding to the hydrazine NH proton in the spectrum of $Hg(TAH)_2Cl_2$ indicates the involvement of this proton in thione–thiol tautomerism.[13]

Thermal decomposition study[14]

Thiacetazone was found to be stable up to 280°C, above which the ligand decomposed, continuously exhibiting a broad exotherm centred at 585°C. On heating thiacetazone complexes of cobalt(II) with chloride, bromide and nitrate as anions decomposed exothermically, resulting in the formation of cobalt(II) oxides, probably a mixture of CoO and Co_3O_4.

The thermogram of the nickel(II) isothiocyanate complex of thiacetazone showed an initial weight loss of 5.0% around 120°C. This indicates the presence of at least two water molecules of hydration in the complex. The anhydrous compound [Ni $(TAH)_2(NCS)_2$] was found to be decomposing further exothermically, resulting in the formation of nickel(II) oxide, NiO (above 750°C). The brown coloured $Ni(TA)_2$ complex was found to be stable up to 300°C. On further heating of the sample a constant weight residue, probably a mixture of NiS and NiO, was obtained around 660°C.

$Zn(TAH)_2Cl_2$ and $Cd_2(TAH)Cl_4$ complexes gave exothermic decompositions, yielding their respective metal oxides. $Hg(TAH)_2Cl_2$, which was found to be stable up to 320°C, gave a complete loss of the sample due to continuous exothermic decomposition at higher temperature.

Abstract—The reactions of $(Me_3Al)_2$ with 11 aminoarsines, Me_2AsR (R = Et_2N, $Pr^n{}_2N$, $Pr^i{}_2N$, $Bu^n{}_2N$, $Bu^i{}_2N$, C_4H_8N, $C_5H_{10}N$, $C_6H_{12}N$, $CH_3NC_4H_8N$, Ph_2N and Bzl_2N, where Bzl = $PhCH_2$—), have been studied by multinuclear NMR spectroscopy. The results are compared with those of our previous studies on the Me_3Al/Me_2AsNMe_2 system. In each case, except Me_2AsNPh_2, the final reaction products are $[Me_2AlR]_2$ and Me_3As. The reaction intermediates have been identified and, in most cases, the As—N—Al adducts and $Me_2AlR \cdot AlMe_3$ are observed. With Me_2AsNPh_2 the product is $Me_3As \cdot Me_2AlNPh_2$. The influence of steric and electronic effects on arsenic vs nitrogen bonding site preference, adduct stability, complexity of overall reaction and ease of forming Me_3As and $[Me_2AlR]_2$ are discussed. $[Me_2AlR]_2$, $Me_2AlR \cdot AlMe_3$ and $Me_3Al \cdot HR$ have been independently synthesized and characterized. A comparison of the ^{13}C NMR chemical shift values for Me_2AsR and $Me_2AsR \cdot AlMe_3$ provides information on steric interactions that influence adduct stability.

Numerous reactions of trialkylaluminum species with compounds containing group 15 elements have been reported.[1–7] $(Me_3Al)_2$ reacts readily with secondary amines to form adducts of the type $Me_3Al \cdot HNR_2$, which upon heating undergo alkane elimination to yield Al—N cyclic dimers.[8–11] For example, thermolysis of $Me_3Al \cdot HNMe_2$ at 120°C yields CH_4 and $[Me_2AlNMe_2]_2$.[8] The reactions of $(Me_3Al)_2$ with multidentate nitrogen compounds such as diamines,[3,4] triamines[12] and open-chain[13–16] and cyclic[17–20] amines have also been investigated. In certain cases, the resulting Al—N bonded species may contain penta-[13,15] and hexa-coordinate[16,20] aluminum.

Aluminum alkyls have also been reacted with compounds that contain adjacent, competing, group 15 Lewis base sites, i.e. N—N,[21,22] P—N,[23] As—N,[6,24–26] Sb—N,[26] P—N—N[27] and P—N—P[23,28,29] bonds. Typically when the Lewis base molecule contains an N—H bond, alkane elimination occurs with the formation of a condensed Al—N bonded species. For example, in the reaction of $(Ph_2P)_2NH$ with $(R_3Al)_2$ (R = Me, Et), the aluminum-containing product is $[R_2AlNPPh_2]_2$, which in the Me case contains a six-membered AlNPAlNP ring.[29] With P—N bond containing species having no NH bonds the reaction is not as straightforward, but appears to depend upon the bulkiness of the substituents on phosphorus and nitrogen. For example, in the reaction of $(Et_3Al)_2$ with Me_2PNMe_2 an Al—P adduct, $Et_3Al \cdot Me_2PNMe_2$,[23] is formed; with Ph_2PNEt_2 no adduct formation has been observed,[23] and with $(Ph_2P)_2NR$ (R = Me, Et, Pr^n, Bu^n) only Al—P bonded 1:1 adducts[23,28] are obtained.

Reports on the reactivity of trialkylaluminum with As—N bonded compounds are limited.[6,24–26] Unlike in the P—N systems, the As—N bond is cleaved by $(Me_3Al)_2$. For example, with Me_2AsNMe_2 there is initial formation of the Al—N bonded adduct, $Me_2AsNMe_2 \cdot AlMe_3$,[6] which decomposes in solution at room temperature to Me_3As and $[Me_2AlNMe_2]_2$.[6] Although analogous products are obtained with $MeAs(NMe_2)_2$ and $As(NMe_2)_3$,[6] the As—N bond is more labile than with Me_2AsNMe_2. These reactions have been exploited as synthetic pathways to Me_3As,[6] R_3As[26] and Me_2AsR[25] (R = Et, Pr^n, Bu^n, and Bu^i) by reacting $As(NMe_3)_3$ and Me_2AsNMe_2 with the appropriate R_3Al. As the bulkiness of the R group increases, higher temperatues are needed to achieve

adduct decomposition to the respective Me_2AsR and $[R_2AlNMe_2]_2$ species.

We were also interested in investigating the generality of the $(Me_3Al)_2/Me_2AsNMe_2$ reaction when the amino substituent is varied in order to study the influence of substituent steric and electronic effects on arsenic vs nitrogen binding site preference, adduct stability, complexity of decomposition pathways and ease of forming Me_3As and the respective aminoalane. In this paper, we report an NMR (^1H and ^{13}C) investigation of the reactions of trimethylaluminum with 11 aminoarsines, Me_2AsR (R = Et_2N, $Pr^n{}_2N$, $Pr^i{}_2N$, $Bu^n{}_2N$, $Bu^i{}_2N$, C_4H_8N, $C_5H_{10}N$, $C_6H_{12}N$, $CH_3NC_4H_8N$, Ph_2N and Bzl_2N, where Bzl = $PhCH_2$—). The results obtained from these reactions are then compared with those from the Me_2AsNMe_2 system. Because the $(Me_3Al)_2/Me_2AsR$ systems yield $[Me_2AlR]_2$, we independently synthesized 12 aminoalanes by the reaction of $(Me_3Al)_2$ with the respective secondary amine.[8] These reactions initially gave the $Me_3Al\cdot$amine adducts, which were then isolated and subsequently pyrolysed to the aminoalanes. The $Me_3Al\cdot$amine adducts and the aminoalanes were characterized by IR, MS, ^1H, ^{13}C and ^{27}Al NMR and elemental analysis. These data are reported for 11 adducts (eight previously unreported) and 12 aminoalane dimers (five previously unreported).

EXPERIMENTAL

Standard high vacuum-line techniques in conjunction with a Vacuum Atmospheres HE-43 Dri-Lab equipped with Model HE-493 Dri-Train was used for the synthesis and subsequent manipulations of all compounds. All the amines employed in this study, except Me_2NH (Matheson Gas Products) and $Bu^i{}_2NH$ (Fluka), were purchased from Aldrich Chemicals, Inc. Ph_2NH was recrystallized from a mixture of C_6H_6 and hexane, while the other amines were dried over sodium and distilled before use. Me_2AsNMe_2 (b.p. 108°C) was synthesized by the aminolysis[30] of Me_2AsCl, which was obtained by the reduction of $Me_2As(O)OH$.[31] Me_2AsNPh_2 was synthesized by the amination[32] of Me_2AsCl with Ph_2NK. The other aminoarsines were obtained by a modified transamination[32] reaction involving Me_2AsNMe_2 and the respective amine. The aminoarsines were distilled on a spinning band column and their purities were checked by ^1H and ^{13}C NMR spectroscopy. Diethylether, benzene and hexane were dried over sodium metal and distilled before use. Benzene-d_6 and Me_4Si were purchased from Aldrich Chemicals, Inc. and stored over molecular sieves.

A Nicolet 300 MHz multinuclear FT NMR spectrometer operating at 300.1, 75.4 and 78.2 MHz was used to record the ^1H, ^{13}C and ^{27}Al NMR spectra, respectively. The ^1H and ^{13}C chemical shift values of $Me_3Al\cdot HR$ and $[Me_2AlR]_2$ were measured as 0.2 M solutions of the compounds in C_6D_6 with TMS as the internal standard. For ^{27}Al data were obtained on C_6D_6 (0.1 M) solutions with $[Al(H_2O)_6{}^{3+}](NO_3)_3$ as the external reference. Both ^{13}C coupled and $\{^1H\}$ decoupled, and APT[33] spectra, were obtained for each compound. The NMR data of the Al—N adducts and dimers are reported in Tables 1–4. Previously reported NMR data are referenced. The following numbering system is used for the NMR data. Position 1 is assigned to the carbon bound to the nitrogen in the alkyl derivatives and to the nitrogen bound to aluminum in the cyclic amine derivatives. Position 7 is assigned to the exocyclic carbon. Normal aromatic ring numbering is used.

IR spectra were obtained as KeI-F/Nujol mulls or as neat liquids on KBr plates using a Nicolet IR/42 FT spectrophotometer. Low resolution EI-MS data were recorded on a HP5986A GC/MS spectrometer operated at 70 eV with a 2400 V electron multiplier. Samples were introduced directly into the probe in the vapour phase. Carbon, hydrogen and nitrogen analyses of the previously uncharacterized solid adducts and aminoalanes were obtained from E&R Microanalytical laboratory, Inc., Corona, NY (see Table 5). Melting points were determined in sealed capillaries and are uncorrected.

IR data

Previously unreported IR data for the $Me_3Al\cdot HR$ adducts and $[Me_2AlR]_2$ synthesized in this study are as follows:

$Me_3Al\cdot HNEt_2$. 3250(vs), 2984(vs), 2922(vs), 2891(vs), 2814(s), 1478(m), 1470(m), 1459(m), 1440(w), 1422(w), 1388(m), 1366(w), 1122(m), 1075(sh; m), 1057(s), 1012(sh; s), 1001(s), 904(m), 900(m), 846(s), 794(s), 783(s), 695(br; vs), 625(vs), 577(s), 521(s).

$Me_3Al\cdot HNPr^n{}_2$. 3250(vs), 2969(vs), 2921(vs), 2875(vs), 2810(vs), 1472(vs), 1459(vs), 1432(m), 1421(s), 1387(s), 1314(w), 1266(w), 1181(vs), 1125(m), 1069(s), 1060(s), 1035(vs), 1017(s), 1008(m), 953(vs), 943(vs), 887(m), 859(m), 850(m), 784(m), 746(sh; s), 700(br; vs), 625(vs), 578(s), 522(vs).

tube (10 mm, pyrex, with a PTFE insert) containing Me_2AsR (1 mmol) in C_6D_6 (1 cm^3) at room temperature. The reaction mixture composition was monitored by ^1H and ^{13}C NMR spectroscopy as a function of time. During storage, the tubes were wrapped in aluminum foil to minimize exposure of the reaction mixtures to light. The products formed and the time required for the completion of each reaction are listed in Table 6. Products were identified by comparing their chemical shifts with those of the authentic samples. Variable-temperature NMR studies were also carried out on $(Me_3Al)_2$ reactions with Me_2AsR (R = Me_2N, Ph_2N and Bzl_2N) using the previously described procedure.[6]

General synthesis of Me_3Al·HR

The secondary amine (10 mmol) was added to a 50 cm^3 reaction flask containing trimethylaluminum (10 mmol) at −76°C. The reaction mixture was slowly warmed to room temperature with stirring. At room temperature white solid adducts formed when R = Me_2N, C_4H_8N, $C_5H_{10}N$, $C_6H_{12}N$, $CH_3NC_4H_8N$ and Bzl_2N. The solid adducts were purified by sublimation at *ca* 50°C/10^{-5} torr Hg to give nearly quantitative yields of Me_3Al·HR, except in the case of R = $NC_4H_8NCH_3$ (70%). In the case of the liquid adducts (R = Et_2N, $Pr^n{}_2N$, $Pr^i{}_2N$, $Bu^n{}_2N$ and $Bu^i{}_2N$), further purification was not necessary. The physical, NMR spectral and analytical data for the adducts are given in Tables 1–5.

General procedure for the synthesis of $[Me_2AlR]_2$

The adduct Me_3Al·HR (5 mmol) was heated slowly (100–140°C) in a 50 cm^3 flask equipped with a reflux condensor and a nitrogen by-pass until gas evolution was observed. Heating was continued at that temperature until gas evolution ceased. After cooling to room temperature the resulting product was sublimed at 100–130°C/10^{-5} torr Hg to give white crystalline materials, $[Me_2AlR]_2$, in greater than 90% yield. However, $[Me_2AlN(Bzl)_2]_2$ could not be sublimed, because it decomposed when heated above 150°C. The unsublimed sample of $[Me_2AlN(Bzl)_2]_2$ was found to be analytically pure.

The physical, NMR spectral and analytical data of the aminoalane dimers are listed in Tables 1–5. Since pure $[Me_2AlNPh_2]_2$ could not be obtained by this procedure, it was synthesized by the following alternate route.

Synthesis of $[Me_2AlNPh_2]_2$

To a solution of Ph_2NH (169 mg, 1 mmol) in C_6D_6 (2 cm^3) was added slowly Me_6Al_2 (72 mg, 0.5 mmol) in C_6D_6 (1 cm^3) at room temperature. Upon mixing, gas evolution occurred. The reaction mixture composition was monitored by ^1H and ^{13}C NMR spectroscopy as a function of time. Within 3 days, the NMR spectrum indicated the complete disappearance of the parent peaks. The solvent was removed under reduced pressure and the white, light-sensitive solid $[Me_2AlNPh_2]_2$ was obtained in quantitative yield. Physical, spectroscopic and analytical data are given in Tables 1–5.

RESULTS AND DISCUSSION

Reactions of $(Me_3Al)_2$ *with aminoarsines*

The results obtained from the NMR study of the reactivity of trimethylaluminum with the various aminoarsines are summarized in Table 6. In the room temperature studies the Al—N bonded adducts, $Me_2AsR \cdot AlMe_3$, are initially observed, except for Me_2AsNPh_2 and $Me_2AsNBzl_2$. $Me_2AsNC_4H_8NMe$, the spectra imply the prese of additional, uncharacterized Al—N bon species. With time, the Al—N adducts decom to yield ultimately Me_3As and the respective am alane dimer $[Me_2AlR]_2$.

The reaction of $(Me_3Al)_2$ with Me_2AsN yields initially $Me_2AsNMe_2 \cdot AlMe_3$, which converts to Me_3As and $[Me_2AlNMe_2]_2$, wit

week. Initially $(Me_3Al)_2$ reacts with Me_2AsNEt_2 to form $Me_2AsNEt_2 \cdot AlMe_3$. However, within 1 day we note the formation of a small amount of $Me_2AlNEt_2 \cdot AlMe_3$, with an accompanying shift in the NMR spectrum of the As—N—Al adduct peaks toward those of the parent aminoarsine. The analogous $Me_2AlNR'_2 \cdot AlMe_3$ species have been reported, where R′ = Me,[42], Ph[43] or Me_3Si.[44] In the Me case the adduct is not isolable at room temperature.[42] As discussed below, we have independently synthesized and determined the NMR chemical shift values of the $Me_2AlR \cdot AlMe_3$ adducts, where R = Et_2N, $Pr^n{}_2N$, $Pr^i{}_2N$, $Bu^n{}_2N$, $Bu^i{}_2N$, C_4H_8N, $C_5H_{10}N$, $C_6H_{12}N$ and Bzl_2N. $Me_2AlNEt_2 \cdot AlMe_2$ possibly results from the competition of Me_2AlNEt_2 for the $AlMe_3$ bound in $Me_2AsNEt_2 \cdot AlMe_3$. The resulting parent Me_2AsNEt_2 is then exchanged with $Me_2AsNEt_2 \cdot AlMe_3$. With $Me_2AsNPr^n{}_2$ and $Me_2AsNBu^n{}_2$ there is incomplete initial As—N—Al adduct formation. Line-width broadening of adduct peaks in the ^1H spectrum suggests adduct/parent aminoarsine exchange. As $Me_2AlR \cdot AlMe_3$ forms the line width narrows and the resonances shift towards those of the parent aminoarsine. Aminoalane dimer forms as peaks associated with $Me_2AlR \cdot AlMe_3$ and $Me_2AsR \cdot AlMe_3$ decrease in intensity. Complete conversion to products and consumption of reactants takes *ca* 2 weeks. When $Me_2AsNPr^i{}_2$ and $Me_2AsNBu^i{}_2$ are mixed with $(Me_3Al)_2$, not only are the $AlMe_3$ adducts of the parent aminoarsines and the aminoalanes formed and observed to be in exchange, but an exchange averaged adduct, $Me_3As \cdot AlMe_3$, is also observed. Thus, with the more sterically demanding Bu^i and Pr^i moieties, Me_3As is effective in competing for $AlMe_3$. Now the conversion to final products takes approximately 1 and 3 months, respectively.

In the case of the cyclic amine substituents As—N—Al adducts are formed, except with $Me_2AsNC_4H_8NMe$. The nature of the cyclic amine substituent influences adduct stability. With $Me_2AsNC_4H_8$ the As—N—Al adduct slowly converts, over 6 months, to Me_3As and the aminoalane dimer. This is accompanied by the formation of a small amount of $Me_2AlNC_4H_8 \cdot AlMe_3$. For $Me_2AsNC_6H_{12}$, a slow conversion (4 months) to Me_3As and the respective aminoalane dimer also occurs. In this case the NMR spectra indicate that a slightly greater amount of $Me_2AlNC_6H_{12} \cdot AlMe_3$ forms, which is in exchange with $Me_2AsNC_6H_{12} \cdot AlMe_3$. In the case of $Me_2AsNC_5H_{10}$, the As—N—Al adduct converts to Me_3As and the aminoalane dimer over a 2 month period. A significant amount of $Me_2AlNC_5H_{10} \cdot AlMe_3$ is observed prior to dimer formation.

The reaction of $(Me_3Al)_2$ with $Me_2AsNBzl_2$ at room temperature gives a mixture of $Me_3Al \cdot Me_2AlNBzl_2$, $Me_3Al \cdot AsMe_3$, Me_3As and unreacted $Me_2AsNBzl_2$. Chemical shift data and line-width broadening indicate exchange involving $Me_3Al \cdot AsMe_3$ and Me_3As and an $Me_3Al \cdot Me_2AsNBzl_2$ adduct and $Me_2AsNBzl_2$. Upon standing for 1 day, the reaction is almost complete with the final products being $[Me_2AlNBzl_2]_2$ and Me_3As.

In order to further investigate the reaction of $(Me_3Al)_2$ with the aminoarsines, a variable-temperature, multinuclear NMR study was carried out on the 1 : 1 $Me_3Al/Me_2AsNBzl_2$ system. At −80°C, NMR resonances are observed that can be assigned to both $Me_2AsNBzl_2$ and $Me_3Al \cdot Me_2AsNBzl_2$ in slow exchange. With increasing temperature rapid exchange averaging occurs up to 0°C without any observed decomposition reaction. The sample was recooled to −80°C and the reversibility of the exchange process was established. Upon standing at 0°C, decomposition occurred to yield peaks assignable to $Me_3Al \cdot AsMe_3$ and $Me_3Al \cdot Me_2AlNBzl_2$. With increasing temperature further reaction occurs; chemical shift data and line-width broadening indicate subsequent exchange involving $Me_3Al \cdot AsMe_3$ and Me_3As, and there is additional formation of $Me_3Al \cdot Me_2AlNBzl_2$. With time at room temperature decomposition proceeds, $[Me_2AlNBzl_2]_2$ forms and the amount of free Me_3As increases.

These results suggest that the nature of the amino substituent impacts the relative importance of various exchange reactions that involve the As—N—Al bonded adduct, aminoalane monomer, aminoalane · $AlMe_3$ adduct, $Me_3As \cdot AlMe_3$ and Me_3As. These influence the time required for complete conversion to Me_3As and $[Me_2AlNR]_2$.

Thus, the following reactions can occur in these Me_3Al/Me_2AsR reaction systems:

$$Me_2AsR + 1/2(Me_3Al)_2 \rightleftharpoons Me_2AsR \cdot AlMe_3 \quad (1)$$

$$Me_2AsR + 1/2(Me_3Al)_2 \rightleftharpoons Me_2AsR \cdot AlMe_3 \longrightarrow Me_3As + Me_2AlR \quad (2)$$

$$Me_2AlR + 1/2(Me_3Al)_2 \rightleftharpoons Me_2AlR \cdot AlMe_3 \quad (3)$$

$$Me_2AlR + Me_2AsR \cdot AlMe_3 \rightleftharpoons Me_2AlR \cdot AlMe_3 + Me_2AsR \quad (4)$$

$$Me_3As + 1/2(Me_3Al)_2 \rightleftharpoons Me_3As \cdot AlMe_3 \quad (5)$$

$$Me_3As \cdot AlMe_3 + Me_2AsR \longrightarrow Me_3As + Me_2AsR \cdot AlMe_3 \quad (6)$$

$$Me_3As \cdot AlMe_3 + Me_2AlR \longrightarrow Me_3As + Me_2AlR \cdot AlMe_3 \quad (7)$$

$$Me_2AlR \longrightarrow 1/2[Me_2AlR]_2. \quad (8)$$

The nature of the substituent on the N of the amino moiety influences the relative importance of certain reactions in solution. Increasing bulkiness favours incomplete formation of $Me_2AsR \cdot AlMe_3$ and its involvement in exchange in solution [eqs (1) and (4)], decreased stability of $Me_2AsR \cdot AlMe_3$ [eq. (2)], stabilization of Me_2AlR through adduct formation and exchange [eqs (3), (4) and (7)], formation of $Me_3As \cdot AlMe_3$ and its involvement in exchange in solution [eqs (5), (6) and (7)] and slower formation of final reaction products, Me_3As and $[Me_2AlR]_2$ [eqs (2) and (8)]. On the basis of our study, we cannot distinguish whether conversion of $Me_2AsR \cdot AlMe_3$ to Me_3As and $[Me_2AlR]_2$ arises by decomposition of $Me_2AsR \cdot AlMe_3$ or through dissociation to the original reactants and then subsequent effective recombination that proceeds to a concerted formation of products.[45,46]

In contrast, $(Me_3Al)_2$ reacts with Me_2AsNPh_2 at room temperature to give a mixture of Me_3As, $Me_3As \cdot Me_2AlNPh_2$, $Me_3As \cdot [Me_2AlNPh_2]_2$ and $[Me_2AlNPh_2]_2$. There is no evidence for the formation of an Al—N bonded adduct of Me_2AsNPh_2. Upon standing, the reaction proceeds to give predominantly $Me_3As \cdot Me_2AlNPh_2$. Because these results suggested that Me_3As reacts with $[Me_2AlNPh_2]_2$ to yield $Me_3As \cdot Me_2AlNPh_2$, the independent reactions of Me_3As with $[Me_2AlNPh_2]_2$ in 1:1 and 2:1 stoichiometries were performed. In the 1:1 case reaction occurred upon mixing to give a mixture of $Me_3As \cdot Me_2AlNPh_2$, $Me_3As \cdot [Me_2AlNPh_2]_2$ and $[Me_2AlNPh_2]_2$. With a 2:1 stoichiometry, all the $[Me_2AlNPh_2]_2$ was consumed.

Because the $(Me_3Al)_2/Me_2AsNPh_2$ reaction system gave unique results in comparison with the other aminoarsine systems, a variable-temperature (−90–25°C) NMR study was conducted on the reaction of $(Me_3Al)_2$ with Me_2AsNPh_2 in a 1:1 Al:N mole ratio. At low temperature the NMR data indicate the formation of an Al—As adduct, $Me_3Al \cdot Me_2AsNPh_2$, which is in exchange with $(Me_3Al)_2$ and Me_2AsNPh_2. At −80°C a decomposition reaction leads to the formation of $Me_3As \cdot AlMe_3$ and $Me_2AlNPh_2 \cdot AlMe_3$. With increasing temperature the Al—As adduct dissociates and further reaction occurs (−50°C) to yield $Me_3As \cdot AlMe_3$ and $[Me_2AlNPh_2]_2$. By −40°C all the original adduct has disappeared. With increasing temperature more $Me_3As \cdot AlMe_3$ and $[Me_2AlNPh_2]_2$ are formed and the presence of $Me_3As \cdot Me_2AlNPh_2$ and $Me_3As \cdot [Me_2AlNPh_2]_2$ are noted as the original reactants are consumed. At 25°C the results are analogous to those obtained from the room temperature study.

A comparison of the ^{13}C NMR chemical shift values for the parent aminoarsine, Me_2AsR, and its Me_3Al adduct (Table 7) gives insight into the steric interactions that influence adduct stability. The underscored entries in Table 7 highlight the greatest changes in chemical shifts that occur upon adduct formation. ^{13}C NMR chemical shifts are known to be very sensitive to steric effects and have been used to study conformational equilibria in the coordination of borane with nitrogen heterocycles.[47] When Me_3Al adducts to the C_4H_8N derivative there is a large change in the C(2)/C(5) ^{13}C chemical shift, which indicates that the five-membered ring is

Table 7. Differences in ^{13}C NMR chemical shifts—$\delta(Me_2AsR \cdot AlMe_3) - \delta(Me_2AsR)$[30]

R	Me_2As	C(1)	C(2)	C(3)	C(4)	C(5)	C(6)	C(7)
Me_2N	0.50	−1.02	—	—	—	—	—	—

$C_5H_{10}N$	1.82	—	−0.99	−4.87	−1.90	−4.87	−0.99	—
$C_6H_{12}N$	1.04	—	−0.21	−3.19	−1.33	−1.33	−3.19	−0.21
$NC_5H_{11}N$	0.07	—	−6.02	−3.18	—	−3.18	−6.02	−6.37

sufficiently flexible to minimize steric repulsions and this enhances adduct stability. In contrast with the $C_5H_{10}N$ and $C_6H_{12}N$ derivatives large ^{13}C chemical shift changes occur at the C(3) position. This is indicative of strong 1,3-diaxial interactions[47] between the Me_3Al group upon binding to the nitrogen and the proton at C(3), which adversely affect adduct stability. This is consistent with the classic studies of Brown *et al.* on the binding of Me_3B with C_4H_8NH and $C_5H_{10}NH$[48] and our results on the times required for the conversion of the Me_3Al adducts of Me_2AsR (R = C_4H_8N, $C_5H_{10}N$ and $C_6H_{12}N$) to Me_3As and the respective aminoalane.

Steric effects, as evidenced by the ^{13}C chemical shift data, are also observed in the alkyl amino derivatives. Significant changes in the C(2) ^{13}C chemical shifts are noted for the Et, Pr^n and Bu^n derivatives upon adduct formation, but are not observed for the Pr^i and Bu^i derivatives. With the latter, the adduct formation is incomplete and the Me_3As that is produced effectively competes for the unbound Me_3Al in the reaction mixture.

Reaction of $(Me_3Al)_2$ *with secondary amines*

The reactions of $(Me_3Al)_2$ with the secondary amines in a 1 : 1 Al : N mole ratio give quantitative yields of the respective Al—N adducts, $Me_3Al \cdot HR$, which were isolated and characterized except in the $HNPh_2$ case. The Et_2N—, $Pr^n{}_2N$—, $Pr^i{}_2N$—, $Bu^n{}_2N$— and $Bu^i{}_2N$— derivatives were isolated as liquids and the others as white crystalline solids. Since $Me_3Al \cdot HNPh_2$ readily decomposes at room temperature, only the dimer $[Me_2AlNPh_2]_2$ was isolated from the reaction. Although **XIII**,[8,34] **XIV**[34] and **XX**[10] have been previously synthesized, their characterization is reported in this paper.

Thermolysis of the $Me_3Al \cdot$ amine adducts gives excellent yields of the white crystalline aminoalane dimers, $[Me_2AlR]_2$, which were purified by sublimation. Although the previously reported[9,38] preparation of $[Me_2AlNPh_2]_2$ involved heating a mixture of $(Me_3Al)_2$ and $HNPh_2$, we observed that this also gives side products. On the other hand, the simple room-temperature decomposition of $Me_3Al \cdot HNPh_2$ affords the pure dimer. All the $Me_3Al \cdot$ amine adducts and the aminoalane dimers were characterized by IR, MS and NMR (^1H, ^{13}C and ^{27}Al) spectroscopy.

The IR spectra of the adducts, $Me_3Al \cdot HR$, show an intense band in the NH region, 3080–3290 cm^{-1} (see Table 1), which is *ca* 30–180 cm^{-1} less than the values observed in the free amines. This band is absent from the spectra of the product aminoalanes. The mass spectra of the adducts usually exhibit a high intensity peak at $[M-15]^+$, with molecular ion peaks also being observed for **XIV** and **XVI**. The mass spectra of the aminoalanes typically give low intensity $[M]^+$ and fairly intense $[M-15]^+$ peaks. This is consistent with the known dimeric nature of **I**,[8,11] **II**,[11,35] **IV**,[36] **VII**,[37] **VIII**,[10] **XI**[8,11,38] and **XII**[11] and previously reported mass spectral data.[10,26,37,49] The ^{27}Al NMR data are consistent for a tetra-coordinate aluminum bound to a nitrogen[50] in both the adducts and the aminoalanes. The $\delta(^{27}Al)$ values for the aminoalanes are generally 3–9 ppm upfield of those for the parent adducts. The benzyl derivatives are an exception to this trend, where the parent adduct $\delta(^{27}Al)$ value is 7 ppm upfield of that for the aminoalane. Although **XV**, **XVI**, **XVII** and **XVIII** could not be distilled, the IR, MS and NMR data support the conclusion that these are molecular adducts and not 1 : 1 stoichiometric mixtures of Me_3Al and the amine. Compounds **XIII** and **XIV** are known to be molecular adducts from thermodynamic studies.[34]

The reactions of $(Me_3Al)_2$ with the secondary amines in a 3 : 1 Al : N mole ratio were carried out for the purpose of synthesizing the $Me_2AlR \cdot AlMe_3$ adducts, which were observed as reaction intermediates in the Me_3Al/Me_2AsR systems. The NMR data (Table 4) of these adducts were identical with those observed in the various reaction systems. Attempts to isolate and purify the adducts were unsuccessful because removal of excess Me_3Al causes concomitant Al—N dimer formation. These results are consistent with those previously reported for $Me_2AlNPh_2 \cdot AlMe_3$.[40]

THEORETICAL STUDY OF THE INFLUENCE OF THE HALIDE LIGANDS ON THE METAL–METAL QUADRUPLE BOND IN THE $M_2X_4(PH_3)_4$ (M = Mo, W; X = Br, Cl, I) SERIES OF COMPLEXES

MARIA C. MILLETTI

Department of Chemistry, Eastern Michigan University, Ypsilanti, MI 48197, U.S.A.

(*Received* 23 *March* 1992; *accepted* 5 *October* 1992)

Abstract—The relationship between the metal–metal bond length and the nature of the halide ligands in complexes of the type $M_2X_4(PH_3)_4$ (M = Mo, W; X = Br, Cl, I) is investigated using the Fenske–Hall semi-empirical molecular orbital method. The relative positions of the molecular orbitals follow the pattern predicted by electronic spectral data, with the ^{1}(delta → delta*), HOMO–LUMO transition and the higher-energy LMCT transition both red-shifting as the halide ligand changes from chlorine to bromine to iodine. This pattern is present for both the molybdenum and the tungsten complexes. Although halide ligand contributions to the metal–metal valence molecular orbitals are significant and are a strong function of ligand identity, this does not seem to influence the metal–metal bond length. This would suggest that changes in the bond order brought about by changes in the identity of the halide ligands are not large enough to cause a significant variation in the metal–metal bond length.

The largest known group of compounds containing quadruple bonds are those formed by molybdenum. Among these are a category of molybdenum neutral complexes of the type $M_2X_4L_4$, containing both halide and uncharged sigma-donor ligands.[1] As for other transition-metal complexes containing M—M quadruple bonds, the delta overlap between metal centres is the focus of widespread experimental efforts to elucidate the electronic characteristics of the interaction between the two metals. Although bond order cannot always be used to faithfully predict M—M bond lengths, partially because bond orders are not objectively measurable, in general an increase in the amount of delta overlap between metal centres is expected to result in a shortening of the M—M bond length. Even though the actual extent of orbital overlap is also not directly measurable, often the energy of the ^{1}(delta → delta*) transition is taken as an indicator of the strength of the delta bond. In fact, several works have shown a nearly linear relationship between the metal–metal bond distance and the energy of the ^{1}(delta → delta*) band in several limited series of complexes.[2]

At this time, compounds of the type $M_2X_4(PMe_3)_4$ (M = Mo, W; X = Cl, Br, I) have been investigated through electronic, vibrational and photoelectron spectroscopy, in conjunction with X-ray crystallography, in order to enhance the understanding of the molecular and electronic structure of quadruply bonded complexes.[3] The results for the $Mo_2X_4(PMe_3)_4$ series indicate that although the metal–metal distances of these species appear to be independent of the nature of the X ligand, the electronic absorption spectra show that the ^{1}(delta → delta*) transition does have a marked sensitivity to the nature of the X ligand.[3a] In fact, previous SCF-Xalpha-SW calculations confirm that the metal-localized delta- and pi-bonding levels possess non-negligible halogen orbital character.[4] The question arises, therefore, of why the close similarity of the metal–metal bonding suggested by the crystal structures of the complexes is not reflected in the energies and intensities of their ^{1}(delta → delta*) transitions. This work analyses the bonding in the series of compounds $Mo_2X_4(PH_3)_4$ and $W_2X_4(PH_3)_4$ via molecular orbital calculations and suggests an answer to the above question.

COMPUTATIONAL PROCEDURE

Calculations have been carried out using the Fenske–Hall semi-empirical method[5] on a VAX

mainframe computer. Atomic basis functions were employed; for phosphorus, chlorine, bromine and iodine Clementi's double-zeta functions were used,[6] except for 1*s* and 2*s* functions, which were curve-fit to single-zeta using the maximum overlap criterion.[7] For bromine and iodine, *d*-basis set functions were employed. The hydrogen exponent was set to 1.16. The molybdenum functions were developed by the method of Bursten *et al.*,[8] in which Slater functions are fitted to the numeric functions generated by Xalpha methods for atomic orbitals. The tungsten functions were taken from the results of Richardson *et al.*[9] The 5*s* and 5*p* exponents for molybdenum were set to 1.85 and the 6*s* and 6*p* exponents for tungsten were set to 1.852 to avoid working with metal outer functions that are too diffuse, which often leads to meaningless results.

The geometry used for $Mo_2Cl_4(PH_3)_4$ and $W_2Cl_4(PH_3)_4$ was taken from the X-ray structures determined by Cotton *et al.*;[2b] the X-ray structures for $Mo_2Br_4(PMe_3)_4$ and $Mo_2I_4(PMe_3)_4$ were determined by Gray *et al.*[3a] The geometry of the remaining tungsten compounds was extrapolated from that of the corresponding molybdenum complexes. For simplicity of interpretation and greater ease in the calculations, the trimethylphosphine groups present in each of the complexes have been substituted with phosphine groups. The P—H distance was set to 1.350 Å.[4]

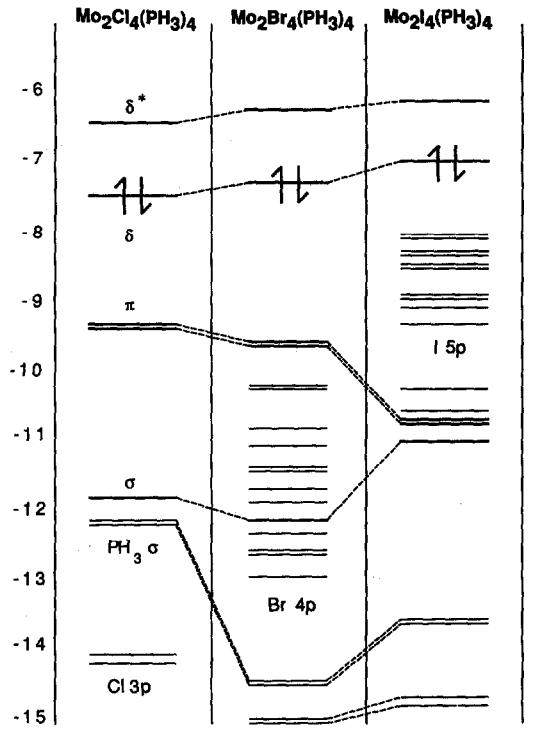

Fig. 1. Comparison molecular orbital diagram for $Mo_2Cl_4(PH_3)_4$, $Mo_2Br_4(PH_3)_4$ and $Mo_2I_4(PH_3)_4$.

RESULTS AND DISCUSSION

The analysis of the bonding in the series of $M_2X_4(PH_3)_4$ compounds will start from an examination of each species' molecular orbital diagram and its relationship with the electronic spectrum. Subsequently, trends in energy and composition of each complex's molecular orbitals will be used to explain the influence of the identity of the halide ligand on metal–metal distance.

Figure 1 shows a comparison molecular orbital diagram of the molecules $Mo_2Cl_4(PH_3)_4$, $Mo_2Br_4(PH_3)_4$ and $Mo_2I_4(PH_3)_4$. In all cases, the HOMO–LUMO transition, which corresponds to the lowest energy band of the electronic spectrum, is clearly a delta → delta* transition. Also, the energetic pattern of orbitals representing M—M bonds remains the same for all three molecules, namely sigma, pi and delta in order of increasing energy. On the other hand, as the halide ligands change from chlorine (more electronegative) to iodine (less electronegative), the halogen *p*-orbitals rise in energy and contribute heavily first to the band of orbitals between the sigma and pi M—M orbitals (for bromine) and eventually to the band above the pi M—M orbitals (in the case of iodine). Consequently, while in the case of $Mo_2Cl_4(PMe_3)_4$ and $Mo_2Br_4(PMe_3)_4$ the second electronic transition is primarily a ^{1}(pi → delta*) transition, for $Mo_2I_4(PH_3)_4$ it acquires a large LMCT character.

In the past there has been some disagreement as to whether the phosphine sigma orbitals fall between the pi and delta M—M orbitals[4] or whether they are lower in energy than any of the metal orbitals.[10] The present Fenske–Hall calculations show that the sigma orbitals of the phosphine ligands lie at a lower energy than either the M—M bonding orbitals or the halide *p*-orbitals in all of the systems under consideration, and therefore do not participate in the first several electronic transitions. This is confirmed by photoelectron data on $W_2Cl_4(PMe_3)_4$.[11]

Figure 2 shows a comparison molecular orbital diagram, similar to that of Fig. 1, for molecules $W_2Cl_4(PH_3)_4$, $W_2Br_4(PH_3)_4$ and $W_2I_4(PH_3)_4$. The observed pattern is the same as that shown in Fig. 1, with the delta and delta* M—M orbitals being the HOMO and the LUMO, respectively, followed by the two degenerate pi orbitals and the sigma orbital at lower energies. Again, as the halide ligand changes from chlorine to bromine to iodine the halogen *p*-orbitals rise in energy as the electro-

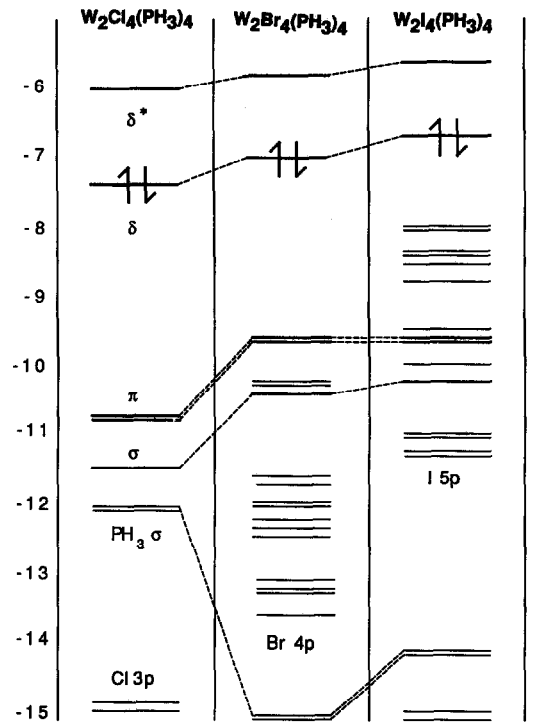

Fig. 2. Comparison molecular orbital diagram for $W_2Cl_4(PH_3)_4$, $W_2Br_4(PH_3)_4$ and $W_2I_4(PH_3)_4$.

negativity of the atom decreases. This causes some bromine 4*p*-symmetry-combination orbitals to appear between the sigma and pi M—M orbitals and most of the iodine 5*p*-orbitals to become the levels below the HOMO in $Mo_2I_4(PH_3)_4$. It should also be noted that for $Mo_2Br_4(PH_3)_4$ and $Mo_2I_4(PH_3)_4$, the rise of the outer *p*-halide orbitals causes a certain degree of scattering of the metal sigma and pi character among sets of two or three molecular orbitals. The orbitals indicated in Fig. 2 as sigma and pi for $Mo_2Br_4(PH_3)_4$ and $Mo_2I_4(PH_3)_4$ are in fact those carrying the larger metal contribution. Minor metal–metal sigma and pi contributions also appear in a few other molecular orbitals.

By comparing the energy patterns observed in Figs 1 and 2 it can be concluded that as the halide ligand changes from chlorine to bromine to iodine, there is a gradual decrease both in the HOMO–LUMO gap and in the separation between the set of molecular orbitals below the HOMO (either the M—M pi set or the halide *p*-band, depending on the complex) and the LUMO. This pattern is consistent with experimental observations that show the low-energy band of the electronic spectra for these compounds red-shifting as the halide ligands change from chlorine to iodine.[3a] On the other hand, in going from molybdenum to tungsten, the energy separation between these levels in the MO diagram is observed to increase. This trend can most clearly be seen in Fig. 3, where complexes with identical ligands but different metal centres are compared. However, electronic spectra show that while a blue shift in band I (the HOMO to LUMO transition)

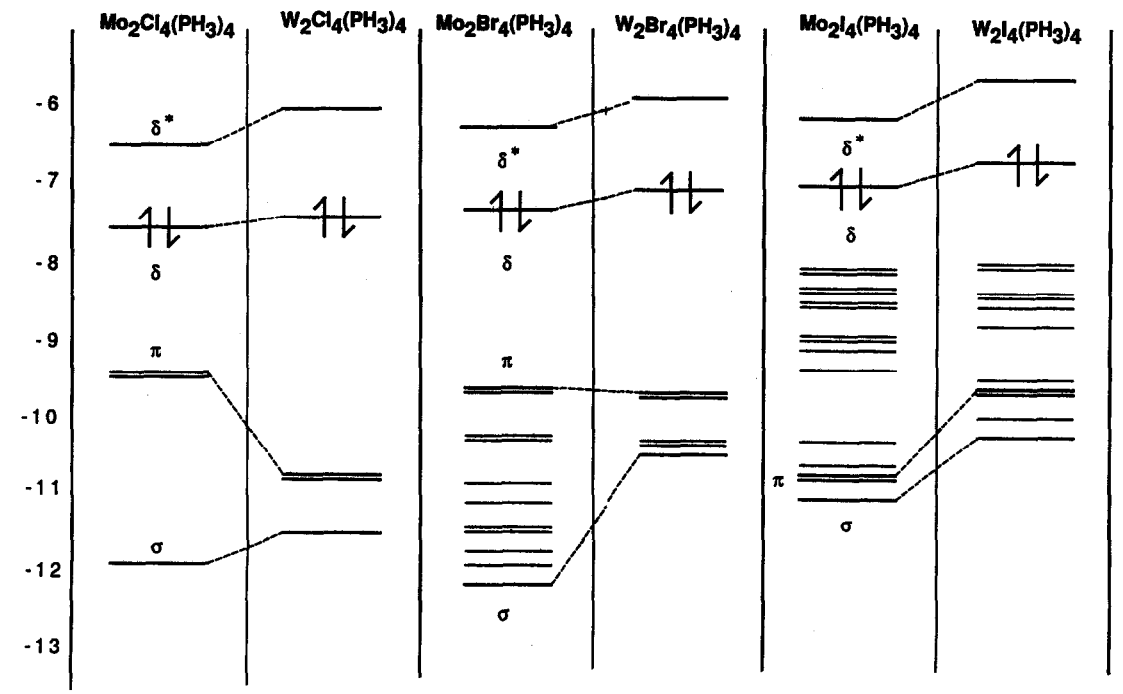

Fig. 3. Comparison of valence molecular orbitals for molecules with the same set of ligands but different metal centres.

is observed on replacing tungsten by molybdenum complexes, the same comparison reveals a red shift for band II.[3a]

Now that the general energy and composition patterns for the molecular orbitals of interest have been examined, we turn to the question of the influence of the halide ligands on the metal–metal bond. Previous theoretical calculations on $M_2L_4X_4$ compounds suggest that the halide *p*-orbitals contribute significantly to the M—M bonding orbitals in the molecule.[4] This would imply that changing the identity of the halide ligand should have an impact on the strength and length of the quadruple bond between the metal centres for the molecules under consideration. Indeed, the calculations performed in this work also confirm that the valence M—M orbitals contain a significant percentage of X ligand character (see Table 1). More specifically, the amount of contribution to the metal–metal bonds from the halogen *p*-orbitals seems to increase as X = Cl → Br → I. The current calculations show that the nature of the halide ligands also influences the amount of overlap between metal centres. More specifically, the metal–metal overlap decreases as the halide ligand changes and the contribution from the ligand to the M—M orbitals increases. This is true for both molybdenum and tungsten complexes. Table 2 shows that the total amount of overlap between metal centres decreases in going from chlorine to bromine to iodine, by an amount between 2% and 5% each time. This would suggest that the metal–metal quadruple bond is weakened by halide ligands with low electronegativity (such as I), the *p*-orbitals of which heavily mix in with the metal orbitals.

However, these observations are not consistent with the fact that the metal–metal bond distance does not change significantly throughout the halide series, at least for the molybdenum metal.[3a] On closer scrutiny of Table 2 one notices that the amount of change in the sigma overlap is very small, except for the $W_2I_4(PH_3)_4$ molecule, in which it increases significantly. This would suggest that the length of the metal–metal bond is mainly a function of the sigma overlap in the molecule. In fact, both molecular orbital calculations[10] and experimental results[3,4] indicate that the sigma portion of the overlap between the two metal centres is of little importance to the strength of the bond. Alternatively, the lack of change in the metal–metal bond lengths might suggest that the changes in the bond order brought about by changes in the halide ligands are not large enough to cause a significant variation in the bond length. This is supported by the fact that bond lengths for several cation complexes show that quadruple bonds are not substantially shorter than triple bonds.[10a]

Table 2. Mulliken overlap populations between metal centres

	Sigma	Pi	Delta	Total
$Mo_2Cl_4(PH_3)_4$	0.162	0.480	0.088	0.730
$Mo_2Br_4(PH_3)_4$	0.161	0.474	0.082	0.717
$Mo_2I_4(PH_3)_4$	0.163	0.454	0.071	0.688
$W_2Cl_4(PH_3)_4$	0.143	0.472	0.097	0.712
$W_2Br_4(PH_3)_4$	0.142	0.468	0.088	0.698
$W_2I_4(PH_3)_4$	0.204	0.408	0.076	0.688

CONCLUSIONS

The results of the calculations confirm the accepted description of metal–metal bonding in

quadruply bonded tungsten and molybdenum complexes[1] and follow the electronic spectral band assignments.[3a] The metal–metal bonding molecular orbitals appear to have significant halide contributions, which also affect the amount of pi and delta metal–metal overlap. Crystal structure data, however, indicate that these changes in electron distribution have essentially no influence on the M—M bond length.

Abstract—A new procedure for the deoxygenation of VO^{2+} complexes utilizing carboxylic acid halides in toluene or methylene chloride has been successfully applied to several vanadyl complexes with different ligand types. Facile conversion of vanadyl β-diketonates, dialkyldithiocarbamates, β-ketiiminates, 8-quinolinolate and porphyrin complexes to the corresponding dihalide complexes has been achieved, demonstrating the general application of the synthetic method. The β-diketonate complexes were studied in the greatest detail. $VX_2(Y)_2$ (X = Cl, Br; Y = $CH_3COCHCOCH_3$, $CH_3COCHCOC_6H_5$) were synthesized in high yield, and the single-crystal X-ray structure of $VCl_2(CH_3COCHCOCH_3)_2$ was obtained. The structure contains a mononuclear unit with *trans*-chloride ligands and distorted octahedral symmetry. The complexes were examined by IR; the spectra exhibited the characteristic loss of the V=O band at approximately 1000 cm^{-1}. For $VX_2(CH_3COCHCOCH_3)_2$ the ligand bands indicate more delocalization of charge onto the ligands compared with the vanadyl starting material, which is consistent with the *trans* octahedral geometry of $VCl_2(CH_3COCHCOCH_3)_2$ and its co-planar chelate ligands. The UV–vis spectra show a weak maximum around 600–700 nm with ε_m of approximately 2000 dm^3 mol cm^{-1}, typical of dihalogenated complexes.

Recently we reported a new, more convenient method of synthesizing V^{IV} dihalide complexes involving the reactions of vanadyl starting materials with acetyl halides.[1] Vanadyl dialkyldithiocarbamates were shown to readily convert to the corresponding dihalide compounds in high yield. For example, vanadyl diethyldithiocarbamate reacts with 3.0 equivalents of acetyl chloride or acetyl bromide to produce dichloro-bis(diethyldithiocarbamate)vanadium(IV) (**1**) or dibromo-bis(diethyldithiocarbamate)vanadium(IV) (**2**), respectively. Single X-ray examination of these complexes shows the halides to be *cis*, consistent with spectroscopic properties that indicate less ligand–metal interactions due to distortions out of the ligand bonding plane. Although the synthetic method works well with dithiocarbamates, we have felt it important to explore application of the procedure to $VO(acac)_2$ ($acac^- = CH_3COCHCOCH_3^-$) and related species for two reasons: (1) $VO(acac)_2$ is an excellent starting material (cheap and air stable); and (2) even though $VCl_2(acac)_2$ has been known for many years, controversy surrounds the precise arrangement of the chlorine atoms because no single-crystal X-ray

2

examination has been reported; spectroscopic studies on dihalide β-diketonates have suggested both *trans* and *cis* arrangements.[2-5]

In this report, we describe the extension of the deoyxgenation reaction of acetyl halides to a broader group of vanadyl complexes, generalizing the utility of the method. In addition we report the single-crystal X-ray analysis of $VCl_2(acac)_2$, the only structurally characterized dichloro V^{IV} β-diketonate complex. The structure is very similar to that of VCl_2(salen-N-Bu^t)$_2$ in possessing *trans*-chlorine atoms.[6,7]

EXPERIMENTAL

All syntheses were carried out in a dry/inert atmosphere of purified dinitrogen employing standard Schlenk glassware. Air-sensitive samples for spectroscopic study were prepared in a dinitrogen glove-bag or Vacuum Atmospheres glove-box. IR spectra were recorded as KBr pellets with the Mattson Polaris Model 10410 spectrophotometer. Far-IR spectra were recorded on a Perkin–Elmer Model 283 spectrophotometer. Electronic spectra were recorded in CH_2Cl_2 solutions using a Varian Model 503 spectrophotometer and Spectrochem quartz anaerobic cells. Because the dihalide complexes readily convert back to the corresponding vanadyl complexes upon exposure to even trace quantities of water, excess acetyl chloride (AcCl) or acetyl bromide (AcBr) was added to the solutions. Elemental analyses were performed by Galbraith Laboratories, Inc., Knoxville, TN.

Reagents

Spectroanalytical grade methylene chloride (0.006% water), toluene and hexanes were obtained from Burdick and Jackson Laboratories. Methylene chloride and toluene were dried using CaH_2 (Aldrich Chemical Co.) and the hexanes were dried using $LiAlH_4$ (Aldrich Chemical Co.). All solvents were dried under dinitrogen and degassed before use. AcCl, AcBr and benzoyl chloride (BzCl) were purchased from Aldrich Chemical Co. The AcBr was distilled before use and the AcCl and BzCl were used as purchased.

Synthesis of the complexes

The vanadyl complexes $VO(acac)_2$ [acac = acetylacetonate] and VO(TPP) (TPP = 5,10,15,20-tetraphenyl-porphine) were obtained from Aldrich Chemical Co.; VO(PTC) (PTC = phthalocyanine) and $VOOH(8HQ)_2$ (8HQ = 8-hydroxyquinolinate) were obtained from Pfaltz & Bauer Chemicals, Inc.; $VO(bzac)_2$ (bzac = 1-phenyl-1,3-butanedionate) was obtained from Eastman Kodak Co.; $VO(S_2CNMe_2)_2$ (S_2CNMe_2 = dimethyldithiocarbamate), $VO(S_2CNEt_2)_2$ (S_2CNEt_2 = diethyldithiocarbamate) and $VO(S_2CNPy)_2$ (S_2CNPy = pyrrolidinedithiocarbamate) were prepared by the method of McCormick[8] and recrystallized from methylene chloride; $VO(edt)_2(PPh_4)_2$ (edt = ethanedithiolate) was prepared by the method of Wiggins *et al.*;[9] VO(bzen) (bzen = bisbenzoylacetoneethylenediiminate) and VO(acen) (acen = bisacetylacetoneethylenediiminate) were prepared by the method of Boucher *et al.*;[10] $VO(quin)_2$ (quin = 2-methyl-8-quinolinolate) was prepared by the method of Stoklosa *et al.*[11]

Dichlorobis(acetylacetonato)vanadium(IV), $VCl_2(acac)_2$. $VO(acac)_2$ (6.00 g, 0.0226 mol) was dissolved in toluene (200 cm^3) to give a dark green solution. The solution was degassed and AcCl (4.8 cm^3, 0.068 mol) was added while stirring. The green solution slowly turned dark blue. The reaction mixture was stirred at room temperature overnight, then layered with hexanes (125 cm^3) and placed in a freezer. Storage at -10°C for 3 days led to the formation of purple–black crystals. The crystals were filtered and dried *in vacuo*. The yield of crude product was 85% based on vanadium. Recrystallization from a CH_2Cl_2/hexanes mixture (layered) led to a

pure material as determined by IR, UV–vis and elemental analysis. The preparation was also performed by heating the reaction mixture for 3 h at approximately 100°C, followed by the above crystallizing procedure. Found: C, 37.4; H, 4.6; V, 15.9%. Calc. for $C_{10}H_{14}O_4Cl_2V$: C, 37.5; H, 4.4; V, 15.9%. Mol. wt = 320.07. Electronic absorption maxima, λ(nm) (ε_m, dm^{-3} mol^{-1} cm^{-1}): 628.9 (1849), 396.0sh (2179), 348.0sh (3942).

$VCl_2(acac)_2$ was also prepared by reacting $VO(acac)_2$ (6.00 g, 0.0226 mol) with BzCl (7.9 cm^3, 0.068 mol) in a manner similar to the above procedure. The crude product yield was 60% with respect to vanadium.

The other V^{IV} dihalogen complexes were prepared by the method above described for $VCl_2(acac)_2$, utilizing either AcCl or AcBr with the corresponding vanadyl starting material. The products were identified by comparisons with spectroscopic data found in the literature. For $VBr_2(acac)_2$ [λ (nm), (ε_m, dm^{-3} mol^{-1} cm^{-1})]: 715.8 (1799), 468.0sh (1689); $VCl_2(bzac)_2$: 638.3 (2183), 384.4sh (6541); $VBr_2(bzac)_2$: 706.4 (2243), 627.0sh (1990), 395.0sh (5626). The products were isolated and recrystallized using the same solvents and procedures as above. Crude yields, with respect to vanadium, were 75, 81 and 65%, respectively.

X-ray crystallography and structure solution

Data were collected on a Picker four-circle diffractometer using standard low-temperature facilities. Details of the diffractometry, low-temperature facilities and computational procedures employed by the Molecular Structure Center are available elsewhere.[12] Data collection parameters are summarized in Table 1 for $VCl_2(acac)_2$. The structures were solved by a combination of MULTAN and Fourier techniques, and refined by full-matrix least-squares.

For $VCl_2(acac)_2$ a systematic search of a limited hemisphere of reciprocal space located a set of diffraction maxima with symmetry and systematic absences indicating the unique space group $P2_1/c$. Subsequent solution and refinement of the structure confirmed this choice. A total of 1870 reflections were collected. Following the usual data processing, 1739 unique reflections remained. Of the 1739 reflections, 884 were considered observed [$F > 2.33\sigma(F)$]. All non-hydrogen atoms were readily located and refined with anisotropic thermal parameters. A difference Fourier synthesis revealed the location of some, but not all, hydrogen atoms. All hydrogen atom positions were therefore calculated using ideal geometries and d(C—H) = 0.95 Å, and the hydrogen atoms were included as fixed contributors in the final refinement cycles. The final difference map was essentially featureless, with the largest peak being 1.24 e $Å^{-3}$ at the vanadium site.

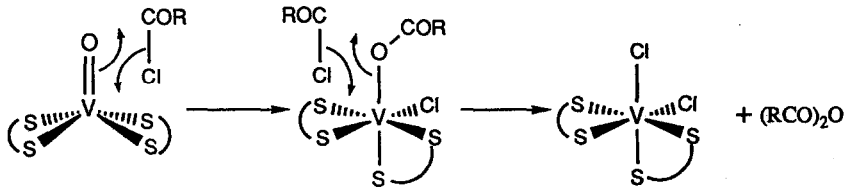
RESULTS AND DISCUSSION

Synthesis

Vanadyl complexes can be deoxygenated by a variety of reagents ($SOCl_2$, $SOBr_2$, PCl_5, $SeOCl_2$ and $COCl_2$)[3,7,13,14] to yield the corresponding dihalide derivatives. These reagents, however, are caustic and often react with the ligands. In addition, some dihalide complexes can be made by the direct reaction of VCl_4 (which is difficult to handle) with the ligand,[5] and by less direct methods including via thiuram disulphide intermediates.[15] We have now discovered carboxylic acid halides can also be used to synthesize V^{IV} dihalide complexes. The cheap and relatively easy-to-handle RX reagents (X = Cl, Br; R = CH_3CO, $C_6H_5CH_2CO$) directly afford the dihalide complexes, overcoming potential side-reactions of the other reagents. As a result we have recently reported the synthesis of, directly from the corresponding vanadyl complexes, $VCl_2(S_2CNMe_2)_2$, $VCl_2(S_2CNEt_2)_2$, $VBr_2(S_2CNEt_2)_2$ and $VCl_2(S_2CNPy)_2$ by eq. (1). Previous attempts in the literature to synthesize such compounds using the other halogenating agents mentioned above often led to poorly characterized, impure products, probably due to the halogenating agent reacting with the ligand.

Although we have reported the characterization of the dihalodithiocarbamates, our original development of carboxylic acid halides as vanadyl deoxy-



Scheme 1.

genation reagents was with the vanadyl β-diketonates. $VCl_2(acac)_2$, $VBr_2(acac)_2$, $VCl_2(bzac)_2$ and $VBr_2(bzac)_2$ can all be successfully prepared by eq. (1). The procedure yields very clean products, which has made single-crystal growth facile. All the complexes are relatively easily isolated and may be purified by recrystallization from CH_2Cl_2/hexanes (layered). As a result, a single-crystal X-ray analysis of $VCl_2(acac)_2$ has been performed to unequivocally establish the geometry around the metal.

$$VO(L)_2 + 2RX \longrightarrow VX_2(L)_2 + R_2O \qquad (1)$$

(X = Cl, Br; R = CH_3CO, $C_6H_5CH_2CO$)

An excess (50%) of RX has been routinely employed after observation of incomplete conversion with stoichiometric amounts of reagents (probably due to hydrolysis by adventitious water) in preliminary experiments.

Although we have not experimentally verified the mechanism of the reaction, it probably involves electrophilic attack by the carboxylic acid halide at the VO^{2+} oxygen atom to lead to a bound acetate group that can then undergo attack by a second acid halide molecule (Scheme 1). This sequence would suggest a *cis* isomer might result, as found in the dithio carbamate complexes, but it is likely that *cis*/*trans* isomerization will be rapid, allowing for the formation of the observed *trans* isomer for the β-diketonate complexes. The extreme rapidity of the reaction and the paramagnetic nature of the V^{IV} species have precluded attempts to probe this point further by normal spectroscopic methods.

To explore the scope of the deoxygenation reaction further, several other representative vanadium(IV) complexes and one vanadium(V) species were mixed with AcCl, AcBr or BzCl in CH_2Cl_2. (We assume the reactivity displayed when only AcCl was used will extend to other carboxylic acid halides.) Table 2 summarizes the results. The identification of products was either by full analysis, including X-ray crystallography, or in some cases,

Table 2. Summary of products from the reaction of vanadyl complexes with carboxylic acid halides in CH_2Cl_2

by diagnostic spectroscopic changes. As can be seen in Table 2, the reaction by eq. (1) is able to efficiently convert several different types of vanadyl compounds to the corresponding dihalide complexes. The vanadyl β-diketonate, dialkyldithiocarbamate, β-ketiiminate, 8-quinolinate and tetrapyrrole complexes demonstrate the utility of the reaction. However, VO(PTC) did not exhibit any reactivity, probably due to its low solubility (higher temperatures were not used); $VOOH(8HQ)_2$ appeared to only partially react as evidenced by IR; $VO(edt)_2^{2-}$ was extremely reactive, producing $VOCl_4^-$. In the sequence of the latter reaction a dark blue intermediate was formed, which could possibly be the dihalide product.[16] This intermediate was so short-lived that it could not be isolated by standard techniques. Further attempts to isolate this material are in progress.

Description of structure

Figure 1 shows the structure of *trans*-$VCl_2(acac)_2$ with the atom numbering scheme. Selected structural parameters are collected in Table 3. The crystal is composed of discrete molecules of $VCl_2(acac)_2$ with the expected octahedral coordination around the vanadium. The molecule has virtual C_{2v} symmetry with the chlorine atoms *trans* to the equatorial plane formed by the oxygen atoms of the acetylacetonate groups. A very similar coordination and geometry is observed in VCl_2(salen-N-Bu^t)$_2$, the only other reported[6] example of a structurally characterized V^{IV} dihalide with *trans* chlorine atoms. In that case the equatorial plane is formed by

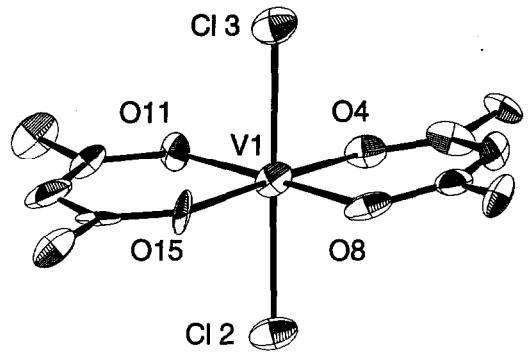

Fig. 1. ORTEP drawing of *trans*-$VCl_2(acac)_2$ showing the appropriate atom numbering scheme.

two nitrogen and two oxygen atoms. Several studies (EPR and IR) have suggested the existence of both *trans* and *cis* isomers is possible and the geometrical preference seems to be based on the polarity of the solvent medium.[2-5] Whereas the *cis* configuration is predicted in polar solvents, we have isolated the *trans* isomer from CH_2Cl_2.

Table 3 shows the V—Cl bond lengths to be essentially the same. Comparing to other reported dichloride structures, the average V—Cl bond length is longer than those reported for *cis*-$VCl_2(S_2CNEt_2)_2$ (2.25 and 2.26 Å) and is consistent with the argument of a more efficient delocalization of charge onto the chelate ligands in *trans*-type structures.[3] The V—Cl bond lengths of $VCl_2(acac)_2$, however, are slightly shorter than those reported for VCl_2(salen-N-Bu^t)$_2$ (2.35 Å),[6] probably an effect of the different ligand types. The ligand type[17-19] and substituents on the ligand[20] have been shown

to affect the V=O bond distance in vanadyl complexes. Little structural comparison among V^{IV} dihalide complexes to establish this point can be made due to the paucity of comparable structures. However, $VCl_2(acac)_2$ has an O_4Cl_2 first coordination sphere, while VCl_2(salen-N-Bu^t)$_2$ has an $O_2N_2Cl_2$ coordination sphere. The average V—Cl bond length of *trans*-$VCl_2(acac)_2$ is also similar to the average V—Cl bond length in $VOCl_2(C_5H_{12}N_2O)_2$ (2.34 Å)[21] and $VOCl_2(C_4H_8O)_2H_2O$ (2.39 Å),[22] but is longer than that of $VOCl_2(NMe_3)_2$ (2.25 Å).[23] These former two vanadyl dichlorides have square-pyramidal geometry with chlorine atoms on opposite sides of the basal plane (roughly *trans* configuration). The latter vanadyl dichloride has a trigonal bipyramidal structure with the chlorine atoms adjacent to each other similar to the chlorine atoms in *cis*-$VCl_2(S_2CNEt_2)_2$.

The four V—O bonds of $VCl_2(acac)_2$ are essentially equivalent as well as the four C—O bonds, as expected. Since the single-crystal X-ray structure has also been performed on the vanadyl starting material,[17] an interesting comparison can be made to see what effects the chlorine atom substitution for the oxygen atom have on the $[V(acac)_2]^{2+}$ subunit structure. Table 4 lists the comparison for selected bond distances and angles. Also included are some structural features of $[V(acac)_3][SbCl_6]$, another non-vanadyl V^{IV} β-diketonate.[24] The dihalo complex is shown to be more planar as a result of substitution of the chlorine atoms. This is evident in the average V—O bond lengths of the dichloro complex as compared to the average V—O of the vanadyl starting material. The dichloro derivative also exhibits V—O bond lengths similar to $V(acac)_3^+$. However, this difference does not appear to extend past the first coordination sphere, because the average C—O bond lengths are the same for the three complexes.

IR spectra

Table 5 lists the most important and characteristic bands of the IR spectra of $VCl_2(acac)_2$, $VBr_2(acac)_2$, $VCl_2(bzac)_2$ and $VBr_2(bzac)_2$. Included are the same characteristic bands for the corresponding vanadyl starting material. For all the dihalide derivatives, as expected, the strong V=O band is absent, indicating the conversion to the dihalide. We used this method as our best indicator of completeness of reaction.

For $VCl_2(acac)_2$ and $VBr_2(acac)_2$ the principal ligand bands in the 1500–1550 cm^{-1} range combine to form one unresolved peak. This does not agree with the assignments of Behzadi and Thompson[14] for the same compounds. [X-ray powder pattern diffraction data of our preparation of $VCl_2(acac)_2$ were consistent with their reported values.] However, $[V(acac)_3][SbCl_6]$ exhibits only one unresolved peak for these ligand bands.[24] The position of this combined band for both $VCl_2(acac)_2$ and $VBr_2(acac)_2$ is lower in energy than either of those assigned in the vanadyl precursor. This is consistent with the ligand band position of other vanadium(IV) dihalide complexes that have or are considered to have *trans* geometry when compared to the corresponding vanadyl starting materials. In these cases on going from the vanadyl structure (where the metal is somewhat out of the basal plane) to the *trans* structure (where the metal is in the equatorial plane), the σ-bonding d_{xy} orbital is slightly destabilized and the π-bonding $d_{x^2-y^2}$ orbital is greatly destabilized due to increased orbital overlap. This overlap increases delocalization, effectively reducing the charge on the ligand and therefore shifts the position of the diagnostic ligand bands to lower energy.

For $VCl_2(bzac)_2$ and $VBr_2(bzac)_2$ the principal bands are resolved and are shifted to higher energy than the corresponding bands for the vanadyl starting materials. This is not consistent with the observation of Behzadi and Thompson[14] for $VCl_2(bzac)_2$, who reported much lower energies for the C—O and C—C bands. However, our assignments are consistent with their assignment of these bands for $VBr_2(bzac)_2$ and are very similar to assignments of these bands for other vanadium(IV)

complexes with bzac as a ligand [for example, V(cat)(bzac)$_2$,[25] [V(bzac)$_3$][SbCl$_6$][24] and V(dtbc)(bzac)$_2$[25]].

The shift of the ligand bands for the bzac cases when going from VO(bzac)$_2$ to the dihalide complexes is opposite to the shift of the corresponding bands in the acac cases discussed above and for the salen-N-Bu^t case. One expectation is that VCl$_2$(bzac)$_2$ and VBr$_2$(bzac)$_2$ might have *cis* geometry, based on the behaviour of the analogous dithiocarbamate complexes.[1] [The principal ligand bands of VCl$_2$(S$_2$CNEt$_2$)$_2$ and VBr$_2$(S$_2$CNEt$_2$)$_2$ are shifted to a higher frequency than the corresponding bands for VO(S$_2$CNEt$_2$)$_2$ and this has been accounted for by the *cis* geometry reducing delocalization from the ligand plane.] However, Von Dreele and Fay[5] determined the geometry of VCl$_2$(*t*-C$_4$H$_9$COCHCO-*t*-C$_4$H$_9$)$_2$ by examining the V—Cl bands in the far-IR. Their assignment of 362 cm^{-1} for the *trans* geometry matches ours of 359 cm^{-1} for VCl$_2$(bzac)$_2$ and 365 cm^{-1} for VCl$_2$(acac)$_2$. The expected position for the *cis* geometry would be around 385 cm^{-1}. This evidence indicates VCl$_2$(bzac)$_2$ and VBr$_2$(bzac)$_2$ also have *trans* geometry and that the shift to higher wave-numbers is probably due to electronic effects of the aromatic ring of the ligand.

CONCLUSIONS

The new and convenient synthetic method of converting vanadyl dialkyldithiocarbamate complexes to the corresponding vanadium(IV) dihalide complexes using carboxylic acid halides has been successfully applied to a wide variety of vanadyl systems. In general, as verified by spectroscopic methods, the reaction was found to work well with β-diketonates, β-ketiiminates, 8-quinolinolate and some tetrapyrroles, as well as dithiocarbamates. In specific, the reaction using VO(acac)$_2$ and AcCl produced a highly crystalline product which, when characterized by single-crystal X-ray analysis, showed the chlorides to be *trans* with respect to the bonding plane formed by the acac ligands. This geometry is similar to that of VCl$_2$(salen-N-Bu^t)$_2$, but contrary to the *cis* structures of VX$_2$(S$_2$CNEt$_2$)$_2$ (X = Cl, Br). Regardless of the structural differences of these products, the reaction using carboxylic acid halides appears to be a general method to produce dihalide derivatives from vanadyl complexes without the deleterious side-reactions seen for syntheses using some other, more well-known halogenating reagents.

Supplementary material. Complete listings of atomic coordinates, isotropic and anisotropic thermal parameters, bond distances and angles (20 pages); listings of observed and calculated structure factors for VCl$_2$(acac)$_2$ are available on request. Ordering information is given on any current masthead page. The complete MSC structure report (No. 89164) is available on request from the Indiana Chemistry Library.

(*Received* 1 *September* 1992; *accepted* 1 *October* 1992)

Abstract—The reaction between $Mo_2(O_2CBu^t)_4$ and $[Bu^n_4N]^+[Bu^tCO_2]^-$ in toluene yields the yellow toluene-soluble salt $[Bu^n_4N]^+[Mo_2(O_2CBu^t)_5]^-$ as large yellow plates upon crystallization. The molecular structure of the anion contains the now common paddle-wheel or lantern $M_2(O_2C)_4$ core, Mo–Mo = 2.1035(7) and Mo—O = 2.12(2) Å (av), with a monodentate pivalate ligand coordinated to one metal atom, Mo—O = 2.298(5) Å in the axial position and Mo—Mo—O (η^1-pivalate) = 176.6(1)°. In CD_2Cl_2 and toluene-d_8 solutions the anion shows fluxional behaviour such that exchange between all pivalates is rapid on the NMR time-scale at room temperature. At −80°C this fluxional process becomes sufficiently slow to lead to the expected 4:1 ratio for the Bu^t protons. In pyridine-d_5 the exchange of pivalates is slower but still sufficiently fast to lead to coalescence at elevated temperatures. In pyridine solution the predominant species are $Mo_2(O_2CBu^t)_4(py)_2$ and $[Bu^n_4N]^+[Bu^tCO_2]^-$. These findings complement earlier work wherein $[Et_4N]^+[Mo_2(O_2CCF_3)_5]^-$ was prepared (Garner and Senior, *J. Chem. Soc., Dalton Trans.* 1975, 1171) and the exchange of $CF_3CO_2^-$ groups in the reaction between $Mo_2(O_2CCF_3)_4$ and NaO_2CCF_3 in CH_3CN was studied (Sasaki *et al.*, *Bull. Chem. Soc. Japan* 1979, **52**, 446). The facile intramolecular exchange of pivalate ligands in the $Mo_2(O_2CBu^t)_5^-$ anion emphasizes that Mo_2^{4+} containing compounds are kinetically labile to associative nucleophilic substitution reactions. Possible reaction pathways leading to exchange of $Bu^tCO_2^-$ are discussed.

The mechanisms and rates of ligand exchange reactions involving mononuclear transition metal ions are strongly influenced by the electronic configuration of the metal ion.[1] For example, octahedral complexes with the t_{2g}^6 configurations are generally substitutionally inert and react via dissociative or interchange dissociative mechanisms, while the pseudo-octahedral complexes with the electronic configuration $t_{2g}^3e_g^1$ or $t_{2g}^6e_g^3$ are generally super-labile. Compare the rates of $k_{exch}(H_2O)$ for the $M(H_2O)_6^{n+}$ ions which span the range 10^{-8}–10^9 s^{-1} in water at 25°C.[2] In organometallic chemistry the electronic configuration of the complex is also important. Typically, 18-electron complexes undergo nucleophilic substitution by dissociative mechanisms and are relatively inert. When associative behaviour is observed there is most often a special explanation such as a rearrangement of the binding of a coordinated ligand (e.g. a ring slippage η^5 to η^3 or a bending of linear nitrosyl) or there is a reversible attack on a coordinated ligand, which in turn facilitates ligand loss.[3] By contrast, 17- and 19-electron organometallic species are generally kinetically labile to associative and dissociative processes, respectively.[4]

For some time we have been interested in the reactivity of dinuclear compounds containing M—M multiple bonds and we recently noted[5] that the structurally related compounds of the formula $M_2(O_2CMe)_2(NCCH_3)_4^{2+}(BF_4^-)_2$, where M = molybdenum[6,7] and rhodium,[6] showed very different

† Author to whom correspondence should be addressed.

substitution chemistry. Specifically, the acetonitrile ligands were extremely labile to exchange in CD_3CN solvent at $-40°C$ for M = molybdenum, whereas the CH_3CN ligands bound to the Rh_2 complex were inert at room temperature. Indeed the $t_{1/2}$ for MeCN bound to $Rh_2(O_2CMe)_2(NCCH_3)_4^{2+}$ dissolved in CD_3CN as a solvent was of the order 4 h at $+100°C$. Studies of the kinetics of CH_3CN for CD_3CN exchange as a function of temperature led to the activation parameters $\Delta H^{\ddagger} = 33(1)$ kcal mol^{-1} and $\Delta S^{\ddagger} = +11(3)$ eu for M = rhodium, suggestive of bond breaking being most important in the transition state. Since there is no reason to believe that molybdenum–nitrogen or –oxygen bonds are weaker than their rhodium analogues, we speculated that the difference in lability was due to a difference in mechanism and that this in turn was influenced by the M—M bonding electronic configuration Mo—Mo $\sigma^2\pi^4\delta^2$ vs Rh—Rh $\sigma^2\pi^4\delta^2\delta^{*2}\pi^{*}$.[4]

In this paper we describe our preparation and characterization of the $Mo_2(O_2CBu^t)_5^-$ anion, which allows us to probe the exchange mechanism between free and Mo_2^{4+}-coordinated carboxylate ligands.

RESULTS AND DISCUSSION

Synthesis

The reaction between $Mo_2(O_2CBu^t)_4$ and $[Bu^n_4N]^+[Bu^tCO_2]^-$ in toluene yields the yellow crystalline compound $[Bu^n_4N]^+[Mo_2(O_2CBu^t_5]^-$.

This synthetic procedure has precedence in the work of Garner and Senior,[8] who studied the reactions of the trifluoroacetate complex $Mo_2(O_2CCF_3)_4$ with $[Et_4N]^+X^-$ which yielded 1 : 1 salts, $[Et_4N]^+[Mo_2(O_2CCF_3)_4X]^-$, where X = Cl, Br, I, CF_3CO_2 and $SnCl_3$, as well as 2 : 1 salts, $[Et_4N]_2[Mo_2(O_2CCF_3)_4X_2]$, where X = Br and I.

Molecular structure of $[Bu^n_4N]^+[Mo_2(O_2CBu^t)_5]^-$

A summary of crystal data is given in Table 1 and selected bond distances and bond angles are given in Tables 2 and 3, respectively. A molecular drawing of the anion showing the atom number scheme is given in Fig. 1.

The molecular structure of the $Mo_2(O_2CBu^t)_5^-$ anion contains the typical $Mo_2(O_2C)_4$ lantern or paddle-wheel structure seen now in so many structures of $Mo_2(O_2CR)_4$ compounds.[9] The Mo—Mo distance of 2.1035(7) Å is typical of those for Mo$\overset{4}{-}$Mo bonds.[9] The Mo—O(μ-O_2CBu^t) distances, 2.12(2) Å (av.), are slightly longer than those in the parent compound $Mo_2(O_2CBu^t)_4$, 2.105(10) Å (av.).[10] Also on average the Mo(1)—O distances are slightly longer, 2.132 Å, than those for Mo(2)—O, 2.109 Å. Although only a small difference, this is not surprising in view of the fact that Mo(1) is ligated by five oxygen atoms while Mo(2) has only four. The axially aligned η^1-O_2CBu^t ligand, Mo(2)—Mo(1)—O(31) = 176.6(1)°, has an Mo(1)—O(31) distance, 2.298(5) Å, somewhat longer than the other Mo—O distances. This is consistent with the general observation of rather long axial Mo—L bonds in $Mo_2(O_2CR)_4L_2$ complexes[9] and most certainly reflects the strong *trans* influence[11] of the Mo$\overset{4}{-}$Mo bond.

It should be noted that the structure of $Mo_2(O_2CBu^t)_5^-$ reported here is analogous to that predicted on the basis of spectroscopic studies by Garner and Senior[8] for the $Mo_2(O_2CCF_3)_5^-$ anion.

^{1}H *NMR studies*

The solution behaviour of $[Bu^n_4N]^+[Mo_2(O_2CBu^t)_5]^-$ with and without added $[Bu^n_4N]^+[Bu^tCO_2]^-$ has been investigated in the solvents toluene-d_8, CD_2Cl_2 and pyridine-d_5.

In pyridine-d_5 the ^{1}H spectrum of $[Bu^n_4N]^+[Mo_2(O_2CBu^t)_5]^-$ at 22°C shows two signals in the ratio 4:1 assignable to $Mo_2(O_2CBu^t)_4(py)_2$ and the free carboxylate anion $Bu^tCO_2^-$. The chemical shift position of the signal assignable to $Mo_2(O_2CBu^t)_4$ is the same as that arising when pure $Mo_2(O_2CBu^t)_4$ is dissolved in pyridine-d_5. Addition of an excess of $[Bu^n_4N]^+[Bu^tCO_2]^-$ to $[Bu^n_4N]^+[Mo_2(O_2CBu^t_5)]^-$ in pyridine-d_5 causes an increase in the signal assigned to $[Bu^n_4N]^+[Bu^tCO_2]^-$, but does not influence that assigned to $Mo_2(O_2CBu^t)_4$. Upon raising the temperature the signals assigned to free and coordinated Bu^tCO_2 ligands initially broaden and coalesce at +70°C.

These findings parallel the behaviour of the ex-

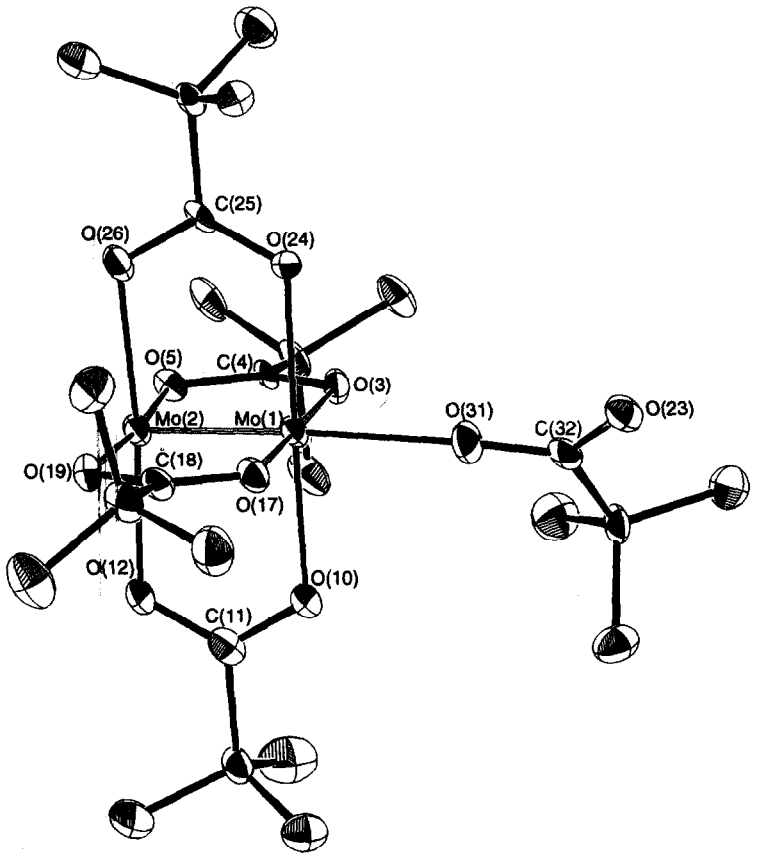

Fig. 1. A ball-and-stick drawing of the $Mo_2(O_2CBu^t)_5^-$ anion found in the crystal structure of $[Bu^n_4N][Mo_2(O_2CBu^t)_5]$. The hydrogen atoms have been omitted for clarity.

change of free $CF_3CO_2^-$ with the coordinated ligands in $Mo_2(O_2CCF_3)_4$ previously studied by chemists in Japan.[12]

In the solvents CD_2Cl_2 and toluene-d_8 at 22°C there is only one broad ^1H signal for the $Mo_2(O_2CBu^t)_5^-$ anion, implying rapid exchange of all $Bu^tCO_2^-$ ligands on the ^1H NMR time-scale. Upon lowering the temperature the signal broadens further and then splits into two signals in the ratio 1 : 4 at −80°C. Neither ^1H signal has the chemical shift assignable to free $Bu^tCO_2^-$ (as its $Bu^n_4N^+$ salt) or $Mo_2(O_2CBu^t)_4$. Thus, at low temperature the ^1H spectrum is consistent with expectations based on the solid-state structure.

If more than 1 equivalent of $[Bu^n_4N]^+[Bu^tCO_2]^-$ is added to a solution of $Mo_2(O_2CBu^t)_4$ in CD_2Cl_2, the NMR spectra at −80°C reveal the presence of the free pivalate anion and the signals associated with $Mo_2(O_2CBu^t)_5^-$ noted above. Thus, if $Mo_2(O_2CBu^t)_6^{2-}$ is formed in solution, it is formed reversibly and by an equilibrium that, at relatively low concentrations of $Bu^tCO_2^-$, favours $Mo_2(O_2CBu^t)_5^-$ and free $Bu^tCO_2^-$.

Discussion of the mechanism of carboxylate exchange

Sasaki, Saito and their co-workers[12] proposed the reaction scheme shown in eq. (1) for the exchange of $CF_3CO_2^-$ groups in the reaction between $Mo_2(O_2CCF_3)_4$ and NaO_2CCF_3 in CH_3CN. (They showed that NaO_2CCF_3 was effectively ionized in CH_3CN solutions.)

(i) $Mo_2(O_2CCF_3)_4(\underline{NCCH_3})_2 + {}^*CF_3CO_2^- \rightleftharpoons$

$Mo_2(O_2CCF_3)_4(\underline{NCCH_3})(\underline{O^2C}{}^*\underline{CF_3})^-$

$+ CH_3CN$ (1)

(ii) $Mo_2(O_2CCF_3)_4(\underline{NCCH_3})(\underline{O_2C}{}^*\underline{CF_3})^- \rightleftharpoons$

$Mo_2(O_2CCF_3)_3(O_2C{}^*CF_3)(\underline{NCCH_3})(\underline{O_2CCF_3})^-$

The ligands underlined in eq. (1) represent axial ligands, i.e. those aligned along the axis. From their studies they were able to rule out the importance of the dianionic species $Mo_2(O_2CCF_3)_4(\underline{O_2CCF_3})_2^{2-}$. Furthermore, they determined that the equilibrium eq. 1(i) in CH_3CN lies well to the left. By ^{19}F NMR spectroscopy at −40°C only the signals associated

with $Mo_2(O_2CCF_3)_4(\underline{NCCH_3})_2$ and free $CF_3CO_2^-$ were seen. This directly parallels the carboxylate exchange of $[Bu^n_4N]^+[Mo_2(O_2CBu^t)_5]^-$ dissolved in pyridine. Pyridine is a relatively good ligand to the Mo_2^{4+} centre and when present as the solvent readily displaces the axially coordinated $Bu^tCO_2^-$ ligand of the $Mo_2(O_2CBu^t)_5^-$ anion. The rate of carboxylate exchange in pyridine-d_5 is slower than that in CD_2Cl_2 or toluene-d_8 (as evidenced by the higher temperature of coalescence in the ^1H NMR spectrum) because the free carboxylate ligand must compete with pyridine for axial ligation prior to ligand scrambling.

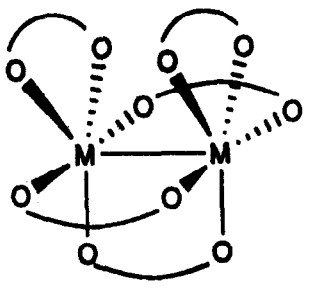
In the solvents CD_2Cl_2 and toluene-d_8, the ^1H NMR spectra are indicative of the exchange process shown in eq. (2) which parallels that proposed for $CF_3CO_2^-$ exchange in eq. 1(ii).

$$[Mo_2(O_2CBu^t)_4(O_2\underline{C}^*\underline{Bu^t})(\underline{solvent})]^- \rightleftharpoons$$
$$[Mo_2(O_2CBu^t)_3(O_2C^*Bu^t)(\underline{solvent})(\underline{O_2CBu^t}]^- \quad (2)$$

From the coalescence temperature we can estimate the energy of activation for axial $\eta^1 \rightleftarrows \mu\text{-}O_2CR$ exchange to be *ca* 11 kcal mol^{-1}.[13] The exchange between free carboxylate and $\mu\text{-}O_2CR$ ligands is not much higher in energy because the axial sites of ligation, those along the M—M axis, are easily and reversibly accessed.

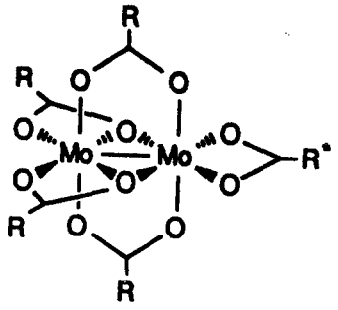
How is axial $\eta^1\text{-}O_2CR$ and $\mu\text{-}O_2CR$ site exchange so easily achieved? What is the reaction coordinate? Bond breaking cannot be very important when $\Delta G^\dagger = 11$ kcal mol^{-1}. Only weak bonds can be broken or as bonds break new bonds must be formed.

There are known structurally characterized d^3–d^3 compounds of the formulae $W_2(O_2CNMe_2)_6$,[14] $W_2(O_2CBu^t)_6$[15] and $W_2(O_2CNEt_2)_4(Me)_2$.[14] These contain tungsten atoms that form five W—L bonds in a pentagonal plane roughly perpendicular to the W—W bond axis. Based on this structural motif one might speculate about a symmetrical transition state or reactive intermediate of the type shown in **A**. Defining the *Z*-axis to be coincident with the M—M axis, then the d_{xy} and $d_{x^2-y^2}$ orbitals must be involved in metal–ligand bonding. It is easy to formulate an M—M triple bond of configuration $\sigma^2\pi^4$ for a d^3–d^3 dimer by the use of metal atomic orbitals d_{z^2} and d_{xy}, d_{yz}. However, for a d^4–d^4 dimer we would have to populate a relatively high energy metal-based orbital, formally derived from metal p_z–p_z interactions. Because of the mixing of *s*, d_{z^2} and p_z in M—M σ-interactions, this orbital could be either weakly bonding or weakly antibonding. Perhaps it is best to describe it as σ non-bonding. In order to proceed from the ground state structure of $Mo_2(O_2CBu^t)_4(\eta^1\text{-}O_2CBu^t)^-$ to **A**, two Mo—O bonds are formed in the *xy* plane and one relatively weak axial Mo—O bond is lost, along with some loss of M—M bonding being equivalent to at least the δ-component.



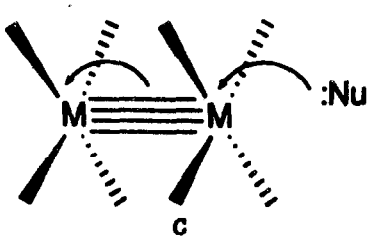
A

The other alternative that we present is shown in Scheme 1. This reaction involves a sort of merry-go-round of ligands or a slippage of carboxylates.[16] The intermediate shown in **B** is a distorted bi-octahedron sharing an edge. The formation of **B** represents a formal increase in metal–oxygen bonding, 10 Mo—O bonds vs nine Mo—O bonds in the ground-state structure $Mo_2(O_2CBu^t)_4(\eta^1\text{-}O_2CBu^t)^-$ and a loss of M—M bonding. The ordering of the δ and δ^* orbitals in edge-shared bioctahedra is often inverted as a result of oxygen p_π–metal *d* interactions[17] and so we might represent the M—M bonding in **B** as $\sigma^2\pi^2(\delta/\delta^*)$,[4] which emphasizes that both δ and δ^* would be occupied. The formation of **B** thus sacrifices M—M bonding in going from Mo–$\overset{4}{}$M to Mo–$\overset{2}{}$Mo.

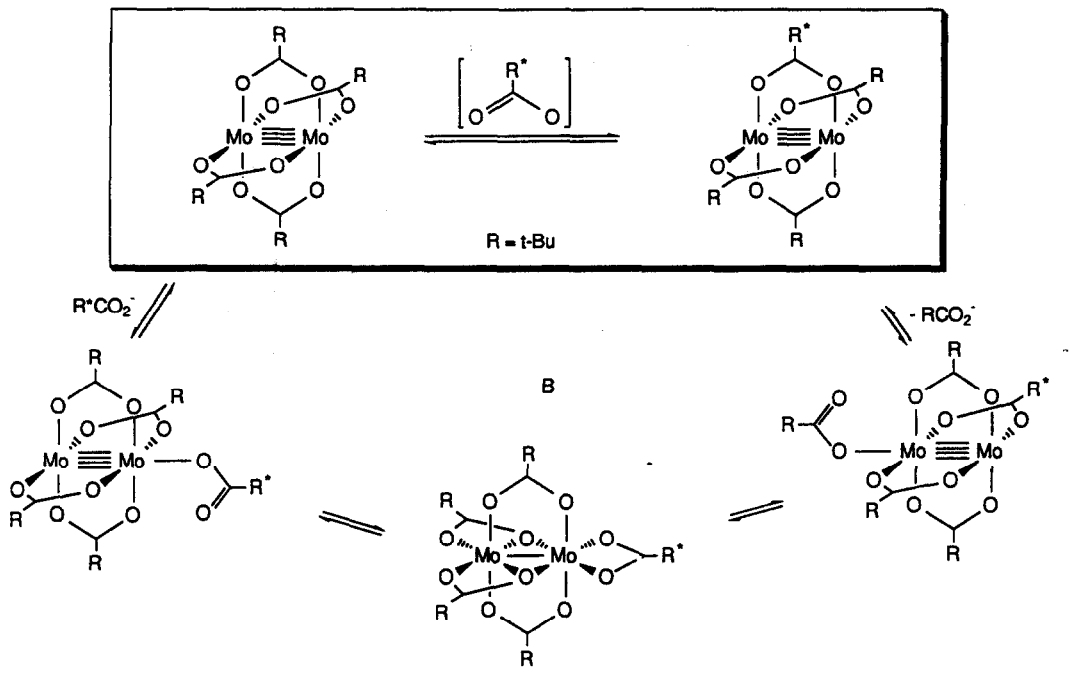


B

Further speculation is pointless, suffice to say that the presence of the low energy empty metal-based δ^* orbitals makes the $Mo_2(O_2CR)_4$ compounds labile to associative nucleophilic substitution reactions. In a simple picture we can envisage nucleophilic attack as shown below in **C**.



C



Scheme 1. A possible mechanism for carboxylate group scrambling in the reaction between $Mo_2(O_2CR)_4$ and RCO_2^-. The activated complex or reactive intermediate shown in **B** is an edge-shared bioctahedron, which is an alternative to **A** discussed in the text.

The formation of a fifth bond in a pentagonal plane at one molybdenum atom destroys the Mo—Mo δ-bond and places a pair of electrons at the other metal centre in the metal based d_{xy} orbital. The new metal–ligand bond may then assist in the displacement of either the axial ligand (or solvent molecule) or one of the other ligands in the equatorial pentagonal plane. Once the fifth ligand is lost from the pentagonal plane by either dissociation or migration to the axial site as the original axial ligand or solvent leaves, the δ-bond is restored.

An estimate of the δ-bond strength based on a rotational barrier in a Mo_2(porphyrin)$_2$ complex is *ca* 11 kcal mol^{-1}.[18] Since our proposed mechanism for substitution involves the loss of the Mo—Mo δ-bond but with the accompanying formation of a new metal–ligand bond, it is not unreasonable to suppose that the enthalpy of activation for substitution at dinuclear centres containing the M^4–M bonds of electronic configuration $\sigma^2\pi^4\delta^2$ will be limited by (1) the loss of M—M bonding upon the formation of a new metal–ligand bond and (2) steric factors. Consequently, we predict that compounds with M^4–M bonds will in general be substitutionally labile and will react via associative or interchange associative mechanisms with Lewis bases.

Finally, it is worth noting that Espenson and Webb[19] studied the bromide-for-chloride exchange reaction shown in eq. (3). The halide ligands adopt the axial sites. They noted that the reaction in CH_3CN was catalysed by the presence of various nucleophiles [H_2O, py, THF, $(Me_2N)_2C{=}O$]. We suggest that the dissociation of Cl^- is facilitated in this reaction by the associative interchange mechanism involving the nucleophiles as described in this paper.

$$Cl{-}Re(\mu\text{-}O_2CEt)_4Re{-}Cl + Br^- \longrightarrow Cl{-}Re(\mu\text{-}O_2CEt)_4Re{-}Br + Cl^- \quad (3)$$

In aqueous trifluorosulphonic acid, the Mo_2^{4+} aquo ion shows substitutional lability comparable to the MO^{2+} aquo ions (M = Ti, V) toward NCS^- and the analogy between metal–metal and metal–ligand multiply-bonded systems was noted by Sykes and co-workers some 10 years ago.[20]

EXPERIMENTAL

^{1}H NMR spectra were recorded on a Varian XL300 spectrometer at 300 MHz in dry and oxygen-free pyridine-d_5, toluene-d_8 and methylene chloride-d_2. All ^{1}H NMR chemical shifts are reported in ppm relative to the protio impurity resonance at 7.19 ppm for pyridine-d_5, 2.09 ppm for toluene-d_8 and 5.32 ppm for methylene chloride-d_2.

All reactions were carried out under an atmosphere of dry and oxygen-free nitrogen using standard Schlenk and glove-box techniques. All solvents were dried and degassed by standard methods and distilled prior to use. Pivalic acid and tetra-n-butyl ammonium hydroxide were purchased from Aldrich and used as received. Dimolybdenum tetrapivalate was prepared by a published procedure.[21]

$[Bu^n_4N]^+[Bu^tCO_2]^-$

To a flask containing pivalic acid (0.5107 g, 5.0 mmol) dissolved in benzene (15 cm^3) was added a solution of tetra-n-butyl ammonium hydroxide (5 cm^3, 1.0 M) in methanol. The volatile components were removed *in vacuo* and dried for 1 h to yield a white solid. The material was slurried in pentane, the volatile components were again removed under vacuum and the resulting white powder was dried *in vacuo* at 70°C for 12 h. The powder was washed with 5 × 10 cm^3 of pentane, filtered and dried under vacuum for 3 h to yield 1.380 g (80%).

$[Bu^n_4N]^+[Mo_2(O_2CBu^t)_5]^-$

To a flask containing $Mo_2(O_2CBu^t)_4$ (0.090 g, 0.15 mmol) and $[Bu^n_4N]^+[Bu^tCO_2]^-$ (0.075 g, 0.22 mmol) was added toluene (10 cm^3). The mixture was heated until all the material dissolved giving a clear yellow solution. Slow cooling of this solution to room temperature afforded 0.120 g (85%) of large yellow plates. ^1H NMR (−80°C), methylene chloride-d_2: δ 0.85 (s, 9H), 0.91 (t, 12H), 1.27 (m, 8H), 1.35 (s, 36H), 1.48 (m, 8H), 3.05 (m, 8H). Coalescence temperatures: T_c = +30°C in toluene-d_8 and +70°C in pyridine-d_5.

Crystallographic study

General operating procedures and listings of programs have been described.[22]

A suitable crystal was selected by using inert atmosphere handling techniques and transferred to the goniostat, where it was cooled to −181°C for characterization and data collection. A systematic search of a limited hemisphere of reciprocal space yielded a set of reflections which exhibited monoclinic ($2_1/m$) symmetry. The systematic extinction of $0k0$ for $k = 2n+1$ and of $h01$ for $h+1 = 2n+1$ uniquely identified the space group as $P2_1/n$. The structure was solved by a combination of direct methods and Fourier techniques. Following the initial refinement almost all of the hydrogen atoms were located; this included at least two on each of the methyl groups. The hydrogen atom positions were idealized and introduced in the least-squares refinement. The full-matrix least-squares refinement was completed using anisotropic thermal parameters on all non-hydrogen atoms. The hydrogen atoms were refined using isotropic thermal parameters.

The closest approach between Mo(2) and the cation is 3.8 Å. The distance between Mo(2) and the n-butylammonium cation nitrogen atom is 4.645(6) Å. The closest distance from O(33) to atoms in the cation is 3.133(8) Å.

The final difference map was essentially featureless, the largest peak being 0.66 e $Å^{-3}$ in the vicinity of Mo(1).

(*Received* 20 *August* 1992; *accepted* 1 *October* 1992)

Abstract—Some new complexes of chromium(III), cobalt(III) and rhodium(III) containing 1,4,8,12-tetra-azacyclopentadecane and imido ligands have been prepared and characterized by elemental analyses, conductometric, magnetic, IR and electronic spectral studies. The complexes have the general formula *trans*-$[ML(im)_2]ClO_4$ [where M = chromium(III), cobalt(III) or rhodium(III); L = 1,4,8,12-tetra-azacyclopentadecane; im = anion of succinimide (sim^-) or phthalimide (pim^-)]. A proposed *trans* configuration for the complexes is supported by spectral data.

Imides and their metal complexes have wide applications in pharmacological,[1,2] industrial[3,4] and analytical[5,6] fields. The role of synthetic macrocyclic complexes as models for their natural counterparts is now well recognized.[7,8] The coordination chemistry of chromium(III),[9–11] cobalt(III)[12–14] and rhodium(III)[15,16] with 14-membered, saturated cyclic tetraamines has been studied in some detail, but only limited information is available on the complexes of these metal ions with 1,4,8,12-tetra-azacyclopentadecane (L).[17–20] The ligand L normally gives complexes of the type *trans*-$[MLA_2]$ (M = chromium(III), cobalt(III) or rhodium(III); A = monodentate ligand],[18–20] and only in the presence of chelating ligands have complexes with a *cis* geometry been reported.[18,19] Keeping these facts in view, we herein report the preparation and characterization of some complexes of chromium(III), cobalt(III) and rhodium(III) ions containing 1,4,8,12-tetra-azacyclopentadecane (L) and imido anions.

EXPERIMENTAL

Physical measurements

IR spectra (as KBr discs) were recorded on a Pye–Unicam SP3-300 IR spectrophotometer. Electronic spectra in acetonitrile were recorded on a Ultrospec K-4053 spectrophotometer. Magnetic measurements were made on a Johnson–Matthey magnetic susceptibility balance. Conductivities of 1.0×10^{-3} mol dm^{-3} solutions of the complexes in acetonitrile were measured at 28°C using a WPA CM35 conductivity meter and a dip-type cell with platinized electrodes.

Reagents

All the chemicals used were of reagent grade and were used as such. The potassium salts of the imides (succinimide and phthalimide) were prepared by mixing saturated ethanolic solutions of an imide and potassium hydroxide. The macrocyclic ligand 1,4,8,12-tetra-azacyclopentadecane was synthesized according to a literature method.[21]

Analyses

Carbon, hydrogen and nitrogen analyses were carried out by the Regional Sophisticated Instrumentation Centre, Central Drug Research Institute, Lucknow, India.

Preparation of the complexes

Trans - *dichloro*(1,4,8,12 - *tetra* - *azacyclopentadecane*)*chromium*(III) *perchlorate*, trans-$[CrLCl_2]ClO_4$. A solution of chromium(III) chloride hexahydrate (1.6 g, 0.006 mol) in dimethylformamide (30 cm^3) was boiled for 0.5 h and then cooled to *ca* 90°C. A solution of L (1.29 g, 0.006 mol) in dimethylformamide (20 cm^3) was added to the chromium(III) solution. Water (100 cm^3) was then added to the above mixture followed by the addition of concentrated hydrochloric acid (10 cm^3) and $NaClO_4 \cdot H_2O$ (1.5 g). The volume of the solution was reduced to *ca* 50 cm^3 by heating the mixture on a steam-bath and then leaving to cool. The green crystalline product which deposited was filtered off, recrystallized from hot hydrochloric acid (6 mol dm^{-3}), washed with 2-propanol and then dried in a vacuum desiccator over anhydrous silica gel. Found: C, 30.0; H, 6.1; N, 12.7. Calc. for $C_{11}H_{26}Cl_3CrN_4O_4$: C, 30.2; H, 6.0; N, 12.8%.

Trans - *dichloro*(1,4,8,12 - *tetra* - *azacyclopentadecane*)*cobalt*(III) *perchlorate*, trans-$[CoLCl_2]ClO_4$. Cobalt(II) chloride hexahydrate (1.42 g, 0.006 mol) and the ligand L (1.30 g, 0.006 mol) were dissolved in methanol (100 cm^3) to give a deep brown solution. Air was bubbled through this solution for 2 h. Concentrated hydrochloric acid was then added dropwise until the brown solution turned green (3 cm^3). Aeration was continued until the volume of the solution was reduced to *ca* 50 cm^3. Water (25 cm^3) was then added followed by $NaClO_4 \cdot H_2O$ (1.5 g). The volume of the solution was reduced to *ca* 25 cm^3 by heating on a steam-bath and then cooled. The bright green crystals formed were filtered off, recrystallized from hot hydrochloric acid (6 mol dm^{-3}), washed with 2-propanol and then dried *in vacuo* over silica gel. Found: C, 29.4; H, 5.8; N, 12.4. Calc. for $C_{11}H_{26}Cl_3CoN_4O_4$: C, 29.8; H, 5.9; N, 12.6%.

Trans - *dichloro*(1,4,8,12 - *tetra* - *azacyclopentadecane*)*rhodium*(III) *perchlorate*, trans-$[RhLCl_2]ClO_4$. Rhodium(III) chloride trihydrate (1.58 g, 0.006 mol) and the ligand L (1.30 g, 0.006 mol) were dissolved in methanol (100 cm^3) and heated under reflux for 48 h. The resulting solution was evaporated to dryness and the residue dissolved in water (25 cm^3). NaCl (1.0 g) was then added to this solution followed by the addition of $NaClO_4 \cdot H_2O$ (1.5 g). The solution was then warmed and stirred. The orange–yellow precipitate which formed was filtered off, recrystallized from hot water and dried *in vacuo* over silica gel. Found: C, 26.9; H, 5.4; N, 11.4. Calc. for $C_{11}H_{26}Cl_3RhN_4O_4$: C, 27.1; H, 5.4; N, 11.5%.

General method for the preparation of complexes **1–6**: trans-$[ML(im)_2]ClO_4$ (M = Cr^{III}, Co^{III} *or* Rh^{III}; L = 1,4,8,12-*tetra-azacyclopentadecane*; *im* = *anion of succinimide or phthalimide*). A methanolic solution of the sodium salt of an imide [prepared by adding a saturated methanolic solution of the potassium salt of an imide (0.002 mol) to a saturated methanolic solution of $NaClO_4 \cdot H_2O$ (0.5 g) and filtering off the insoluble $KClO_4$] was added to a solution of *trans*-$[MLCl_2]ClO_4$ (0.001 mol) in methanol (30 cm^3). The mixture was refluxed on a steam-bath for *ca* 4 h and filtered while hot. The filtrate was cooled in an ice–salt bath. The crystals formed were filtered off and recrystallized from hot methanol. The crystals collected were washed with ice-cooled methanol and diethyl ether and then dried *in vacuo* over silica gel.

RESULTS AND DISCUSSION

The complexes of the type *trans*-$[MLCl_2]ClO_4$ were prepared by some variations of the published methods.[18–20] Using the dichloro complexes as precursors, the desired diimido complexes were prepared. Treatment of *trans*-$[MLCl_2]ClO_4$ with a stoichiometric amount of the sodium salt of an imide resulted in the replacement of two chlorine atoms from the coordination sphere, leading to the formation of *trans*-$[ML(im)_2]ClO_4$.

The analytical and physical data of the complexes (**1–6**) are collected in Table 1. The complexes are soluble in water, acetonitrile and dimethylsulphoxide. The molar conductance values (Table 1) indicate that all the complexes are 1 : 1 electrolytes in acetonitrile.[22] The analytical and physical data are consistent with six-fold coordination of the metal atoms.

IR spectral data of the complexes are summarized in Table 2. An imide anion may be coordinated through its carbonyl oxygen or imido nitrogen (N^-). On the basis of the Lewis acid–base concept, it may be established that the negatively charged imido nitrogen is more likely to be coordinated to the metal ion and coordination through the carbonyl oxygen is expected to be inhibited by steric hindrance.[23] Again, any change (due to coordination) in the imido nitrogen which is directly linked to the carbonyl group will alter the molecular environment and, hence, the absorption frequency of the latter even if it is not coordinated.[24] In the present complexes the ν(C=O) mode is found at $\sim$ 1685 cm^{-1} compared to $\sim$ 1720 cm^{-1} in free succinimide or phthalimide.[25] This decrease in frequency may be due to the mass effect.[26] The observed ν(C—N) mode of free succinimide or phthalimide at $\sim$ 1310 cm^{-1} is shifted to 1340–

[a] Relative band intensities are denoted by vs, s, m and w meaning very strong, strong, medium and weak, respectively.

Table 3. Electronic spectral data of the complexes (extinction cofficients in dm^3 mol^{-1} cm^{-1} are given in parentheses)

Compound	Spectral band maxima (cm^{-1})
1	17,730 (34), 23,923 (40)
2	17,182 (25), 23,041 (47)
3	16,420 (62)
4	16,835 (38)
5	23,640 (59)
6	22,988 (83)

1365 cm^{-1} in the spectra of the complexes, thereby suggesting N^- formation and coordination.[25,27]

All the complexes show characteristic absorption for the secondary NH stretching mode in the region 3140–3185 cm^{-1}, indicating coordination of the macrocycle through the nitrogen atoms. The presence of M—N bonds is evident from the appearance of ν(M—N) vibrations at 430–470 cm^{-1} in the spectra of the complexes.[18] The complexes show strong bands at ~ 1095 and ~ 625 cm^{-1}, characteristic of ionic perchlorate.

The observed values of effective magnetic moments at room temperature are given in Table 1. The chromium(III) complexes yield effective magnetic moments (3.92 and 4.12 B.M.) corresponding to three unpaired electrons, consistent with essentially octahedral stereochemistry. The effective magnetic moments of cobalt(III) and rhodium(III) complexes (0.14–0.48 B.M.) indicate that the complexes are low-spin diamagnetic species and this revealed that there was no change in the oxidation state of the metal ions upon complex formation.

The electronic spectral data of the complexes are given in Table 3. The chromium(III) complexes gave two bands in the regions 17,182–17,730 and 23,041–23,923 cm^{-1} corresponding to the transitions $^4A_{2g} \rightarrow {}^4T_{2g}$ and $^4A_{2g} \rightarrow {}^4T_{1g}$(F), respectively.[11,18] The cobalt(III) and rhodium(III) complexes produced a single band at 16,420–16,835 and 22,988–23,640 cm^{-1}, respectively, corresponding to the transition $^1A_{1g} \rightarrow {}^1T_{1g}$.[19,20] A *trans* structure is suggested for these complexes from the low energy of the *d–d* bands present and their low extinction coefficients (Table 3).

OLIGOPHOSPHINE LIGANDS—XXXVII.* STEREOCHEMICAL FEATURES OF COMPLEXES CONTAINING THE *cis*-L_4Ru FRAGMENT: MOLECULAR STRUCTURES OF $(Me_3P)_4RuH_2$ AND $\{P[(CH_2)_3PMe_2]_3\}RuH_2$

LUTZ DAHLENBURG† and KAY-MICHAEL FROSIN

Institut für Anorganische Chemie der Universität Hamburg, Martin-Luther-King-Platz 6, D-2000 Hamburg 13, Germany

(*Received* 20 *August* 1992; *accepted* 29 *September* 1992)

Abstract—The title compounds have been studied by single-crystal X-ray diffraction. Both structures can be described as distorted octahedra. P—Ru—P angles between phosphorus atoms at mutually *cis* positions are considerably larger than 90°, with the sum of the *cis* angles amounting to 495.6° for $(Me_3P)_4RuH_2$ (**1**) and to 486.2° for $\{P[(CH_2)_3PMe_2]_3\}RuH_2$ (**2**). These structural parameters and the observed bending over of the two axial donor sets toward the hydrido ligands, which results in *trans* P—Ru—P angles of 151.5° for complex **1** and of 153° for structure **2** averaged over four crystallographically independent molecules, suggest a considerably higher degree of steric encumbrance in *cis*-$(Me_3P)_4Ru$ than in $\{P[(CH_2)_3PMe_2]_3\}Ru$ systems. They thus correspond to both the well-known ability of the $\{P[(CH_2)_3PMe_2]_3\}Ru(0)$ fragment to insert across C—H bonds of non-coordinated hydrocarbons and the propensity of *cis*-$(Me_3P)_4Ru(0)$ to undergo spontaneous cyclometallation. Selected bond lengths of compound **1** are: Ru—P (*trans* ligand H), 2.306(1) and 2.306(2) Å; Ru—P (*trans* to each other), 2.276(1) and 2.289(2) Å. For the averaged structure **2**, the mean distances between the central metal and the donor atoms are 2.270(5) Å for the bridging phosphorus atom, 2.292(6) Å for the PMe_2 group *trans* to hydrogen, and 2.281(7) and 2.284(10) Å for the PMe_2 substituents situated at mutually *trans* positions.

Within the scope of our studies with the $(pp_3)Ru$ metal/ligand system ($pp_3 = P[(CH_2)_3PMe_2]_3$)[4–11] we also came across several complexes derived from the closely related *cis*-$(Me_3P)_4Ru$ fragment, which have been synthesized in great variety, first by Wilkinson,[12–17] then by Schmidbaur,[18] Werner[19] and Green,[20] and recently by Andersen and Bergman[21–27] as well as Osakada and Yamamoto.[28] The structurally characterized ruthenium complexes *cis*-$L_4Ru(X)(Y)$, with trimethylphosphine as the common ligand L, include the alkyl $L_4Ru(H)(Et)$,[17] the aryl $L_4Ru(OH)(Ph)$,[23b] the arylamide and -oxide $L_4Ru(H)(NHPh)$[26] and $L_4Ru(H)(OC_6H_4$ Me-4),[26,28] the mercury-bridged heterotrimetallic $[L_4Ru(Me)]_2Hg$,[16] as well as a series of further derivatives where the *cis*-L_4Ru moiety is part of a three- to five-membered metallaheterocycle, including $L_4Ru(CH_2CH_2)$,[17] $L_4Ru(C_6H_4)$,[23] $L_4Ru[CH_2C(O)CH_2]$,[27b,d] $L_4Ru[CH_2C(=CHCMe_3)O]$[27d] and several *ortho*-metallated systems, such as $L_4Ru(o\text{-}C_6H_4CH_2)$,[29] $L_4Ru(o\text{-}C_6H_4OCH_2)$,[30] $L_4Ru[o\text{-}C_6H_4C(=CH_2)O]$[27c] and $L_4Ru(o\text{-}C_6H_4C(Ph)=N)$.[23b]

Here we report the results of two X-ray structure determinations performed on the parent dihydride of the above derivatives, *cis*-$(Me_3P)_4RuH_2$ (**1**), and its closely related analogue, $(pp_3)RuH_2$ (**2**). Dihydride **1** represents a key-compound in ruthenium trimethylphosphine chemistry. The complex has

thus been shown to undergo H/D exchange with C_6D_6 solvent,[24] to assist proton-transfer processes with OH acids[26,28] and even with the weaker NH acids,[26] presumably on a pathway that involves the reversible formation of a non-classical cation $[(Me_3P)_4RuH_3]^+$ containing both a hydride and a dihydrogen ligand.[26,28] $(Me_3P)_4RuH_2$ furthermore serves as an efficient catalyst for the homo-dimerization of terminal alkynes, RC≡CH, to yield 1,4-disubstituted but-1-en-3-ynes, RCH=CHC≡CR,[31] as well as for the co-dimerization of 1-alkynes with buta-1,3-diene to afford substituted hex-3-en-5-ynes, $CH_3CH_2CH{=}CHC{\equiv}CR$.[32] Upon photolytic conversion with Me_3SiH to $(Me_3P)_3RuH_3(SiMe_3)$, dihydride **1** finally mediates the dehydrogenative coupling of trialkylsilanes to generate carbosilanes as a net result of silane Si—H and C—H activation and organosilicon Si—C bond formation.[33]

The two structural analyses were performed on the principal expectation that their results would help to improve our understanding of factors that govern the competition between *intra-* and *inter*molecular C—H oxidative addition reactions occurring on coordinatively unsaturated phosphine complexes of ruthenium: A common problem with reactive poly(trimethylphosphine) systems such as $(Me_3P)_4Ru$ is their propensity for undergoing ligand cyclometallation rather than hydrocarbon C—H bond activation.[19,24] Metal/ligand fragments with chelating phosphines, e.g. $(Me_2PCH_2CH_2PMe_2)_2Ru$[34,35] or $\{P[(CH_2)_3PMe_2]_3\}Ru$,[3,6,9–11] on the other hand, are in general capable of intermolecular reactivity. The control of balance between *intra-* and *inter*molecular C—H cleavage on transition metal complexes has been attributed to arise from two opposing effects; (1) conformational strain within the ligand sphere, retarding the metallation of ligand C—H bonds due to an extra amount of activation energy required to bend the ligand over in the proper orientation; and (2) steric congestion about the metal centre, which prevents additional molecules from entering into the coordination sphere but may bring coordinated ligands a bit closer to the central metal atom and may therefore be thought to drive the sterically more encumbered systems toward *intra*molecular reactivity.[36] Both **1** and **2** appear to be particularly suited for evaluating the degree of steric encumbrance and/or conformational strain in chelated and non-chelated L_4Ru systems, as it can be anticipated that the additional two hydrido ligands required to stabilize the otherwise highly reactive 16e fragments will distort the phosphine coordination less than sterically more demanding substituents such as halides or alkyl groups.

EXPERIMENTAL

$(Me_3P)_4RuH_2$[15,16,19,24] (**1**) was prepared from $(Me_3P)_3Ru(H)(CH_2PMe_2)$ by reaction with methanol as described by Werner and Werner[19a,c] and was isolated in 71% yield by repeated high-vacuum sublimation at 50–80°C. Dihydride **2** was obtained from $(pp_3)RuCl_2$ and $LiAlH_4$, as reported previously,[5] and was also purified by sublimation at *ca* 70°C in the dynamic vacuum of a mercury diffusion pump. Single crystals of **1** grew when hexane solutions were allowed to evaporate slowly at ambient conditions; crystals of **2** suitable for X-ray analysis were collected from re-sublimed samples of the compound.

X-ray measurements were carried out at 20 ± 2°C on a Syntex $P2_1$ diffractometer using Mo-K_α radiation, as described elsewhere.[37] Data were corrected for Lorentz and polarization effects, but not for absorption or extinction.

In each structure the ruthenium, as well as several of the phosphorus atoms, were readily located by comparison of the Patterson map with the results of the TREF direct-methods attempts of SHELXS-86.[38] Subsequent alternate cycles of difference-Fourier synthesis and least-squares refinement (full-matrix for **1**, block-diagonal for **2**), employing the SHELX-76 program package[39] with scattering factors from the sources given therein, revealed the positions of the remaining non-hydrogen atoms. The structure models resulting for the two complexes were refined with allowance for anisotropic thermal motion of all non-hydrogen atoms. In both structures, many of the hydrogen atoms present were also located experimentally, although most of those belonging to the phosphine methyl and methylene groups did not refine well. Hence, only the ruthenium-bound hydrogens (as far as detected) were freely refined with isotropic thermal parameters, whilst those on the phosphine ligands were included into the molecular models in geometrically idealized positions with C—H distances constrained to 0.96 Å. No attempts were made to resolve the disorder of the methyl groups attached to the phosphorus atom P(4) in structure **1**, which became obvious from high values of the displacement factor coefficients characterizing the anisotropic thermal motion of the respective carbon atoms.

A summary of relevant crystallographic information and results is collected in Table 1. Atomic positional coordinates, thermal parameters, full lists of bond lengths and angles and lists of observed and calculated structure factors have been deposited as supplementary material with the Editor, from whom copies are available upon request.

RESULTS

Complex **1** crystallized in the space group $P2_12_12_1$ (No. 19). Selected bond lengths and angles are collected in Table 2. A SCHAKAL drawing[40] of the molecule is shown in Fig. 1. Dihydride **2** was found to crystallize in space group $Pn2_1a$ (unconventional setting of $Pna2_1$, No. 33) with four crystallographically independent molecules that had structures similar to each other. A perspective view of one of these molecules is given in Fig. 2. Table 3

summarizes relevant interatomic distances and bond angles. For simplicity, only averaged values of the latter, such as also presented in Table 3, will be used throughout further discussion.

DISCUSSION

In both structures, the four phoshorus atoms and the two hydrogens bonded to the ruthenium atom are situated at the coordination sites of distorted octahedra.

For molecule **1** the distances between the central metal and the phosphorus atoms P(1) and P(2) *trans* to the hydride ligands are equally long, 2.306(2) Å, and are significantly elongated relative to those between the ruthenium centre and the phosphorus atoms P(3) and P(4), situated at mutually *trans* positions [2.276(1) and 2.289(2) Å]. Although this is expected from the usual *trans* influencing properties of metal-bound hydride and phosphine, respectively, all these distances remain remarkably short as compared to the Ru—P bond lengths for PMe_3 ligands located *trans* to Ru—H or *trans* to a second phosphine in other hydrido(trimethylphosphine)-ruthenium complexes of the composition *cis*-$(Me_3P)_4Ru(H)(X)$; X = Et,[17] NHPh,[26] OC_6H_4Me-4.[26,28] In these latter systems, the Ru—P separations for the phospine *trans* to the hydride substituent range from 2.326(3) Å in the ethyl compound[17] to 2.359(5) Å (averaged for two independent molecules) in the anilido complex[26] to 2.371(5) Å (mean value from two independent structure determinations) in the *p*-cresolato derivative,[26,28] with the metal–phosphorus bond lengths for the phosphines *trans* to each other varying between 2.313(3) Å in $(Me_3P)_4Ru(H)(Et)$[17] and 2.329(6) Å (average of 10 values) in $(Me_3P)_4Ru(H)(NHPh)$[26] and $(Me_3P)_4Ru(H)(OC_6H_4Me$-4),[26,28] respectively. The *trans* P—Ru—P distances measured for **1** are approximately as short as those reported for the Ru—P bonds opposite to the poor *trans* influence ligand $PhNH^{(-)}$ in the crystallographically independent molecules of *cis*-$(Me_3P)_4Ru(H)(NHPh)$, 2.268(2) and 2.271(2) Å,

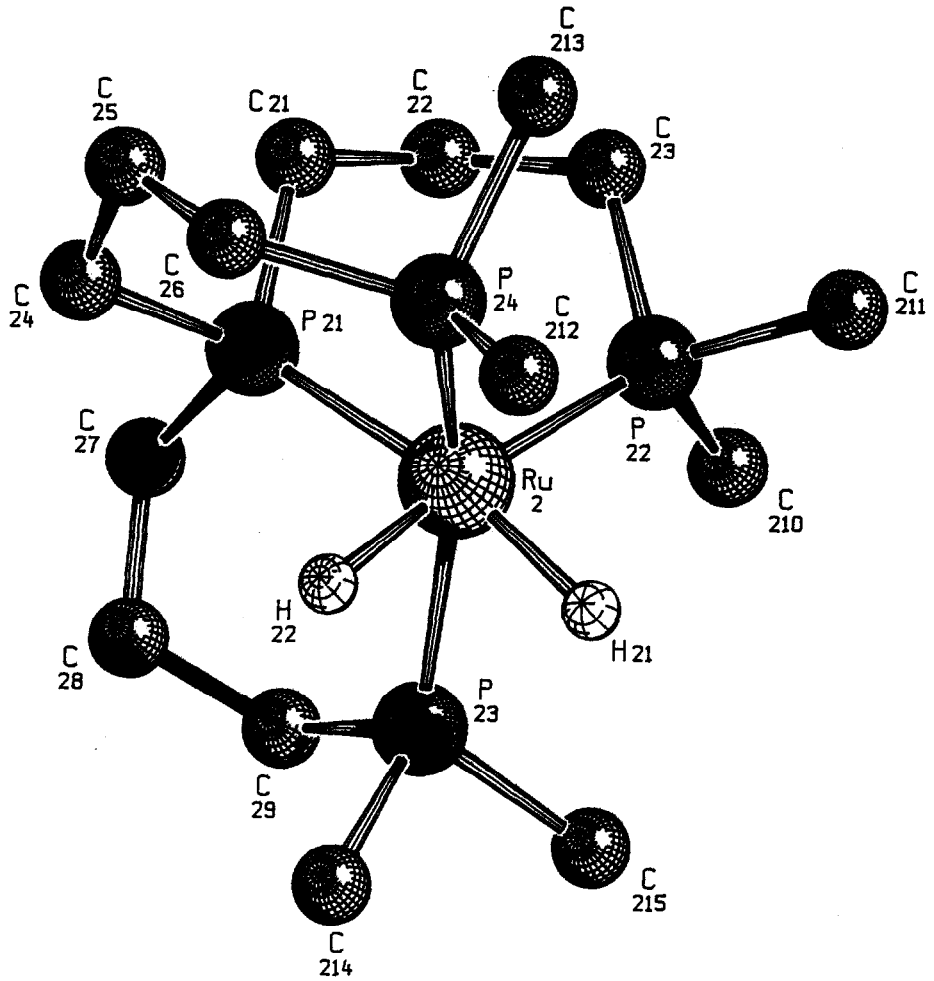

Fig. 2. Perspective view of one of the four independent molecules of $\{P[(CH_2)_3PMe_2]_3\}RuH_2$ (2) defining the atomic numbering scheme (phosphine hydrogen atoms removed for clarity).

respectively.[26] The contraction of the metal–phosphine separations in **1** is attributed to the stereochemically undemanding nature of hydride substituents relative to that of other anionic groups linked to ruthenium, since the wealth of structural data available for trimethylphosphine derivatives, *cis*-$(Me_3P)_4Ru(X)(Y)$, suggest that the separations *d*(Ru—P) for the mutually *trans*-arranged phosphines are particularly sensitive to the steric demand of the two additional ligands X and Y, increasing in the order X, Y = H, H [2.283(7) Å] < H, Et [2.313(3) Å][17] < $—CH_2CH_2—$ [2.326(3) Å][17] ≈ H, NHPh [2.329(9) Å][26] ≈ H, OC_6H_4Me-4 [2.330(3) Å][26,28] < $—CH_2C(=CHR)O—$* [2.343(2) Å][27d] < $—CH_2C(O)CH_2—$† [2.355(3) Å][27d] ≈ —*o*-$C_6H_4C(=CH_2)O—$‡ [2.357(1) Å],[27c] as shown by the distances given parenthetically as mean values for the two *trans* bonds.

For the four independent molecules of structure **2**, the average separation between the central atom and the terminal Me_2P group *trans* to one of the hydride ligands, 2.292(6) Å, is longer than that of 2.270(5) Å between the metal and the bridging phosphorus atom of the tripodal-tetradentate pp_3 system, but is barely elongated when set against the average length of the Ru—P bonds in the *trans* P—Ru—P moieties of the four molecules, 2.282(9) Å. These parameters can be compared directly with those of several aryl(hydrido)ruthenium(II) derivatives of the pp_3 ligand, as there exist only marginal differences in *trans* influencing properties between the hydride and aryl groups. For a series of $(pp_3)Ru(H)(Ar)$ compounds with Ar = C_6H_5, C_6H_4Me-3, $C_6H_3Me_2$-3,4, $C_6H_3Me_2$-3,5 and $C_6H_4CF_3$-3, the length of the bond between the

2.281(7)	P(4)					

ruthenium atom and the Me_2P substituent opposite to Ru—H has previously been determined as 2.342(5) Å, on average.[9–11] Thus, the distance of the Me_2P group *trans* to hydrogen from the central metal is considerably shorter in $(pp_3)RuH_2$ than in $(pp_3)Ru(H)(Ar)$, and the same applies to the average values obtained for $d(Ru—PMe_2)$ in the *trans* P—Ru—P portions of the different molecules, 2.282(9) Å for **2** but 2.310(6) Å for the aryl hydrides,[9–11] as well as to the separations between the ruthenium centre and the bridging phosphorus atom *trans* to hydride or aryl, 2.270(5) Å for dihydride **2** vs 2.289(3) Å for the various aryl hydrido complexes.[9–11] $Ru—PMe_2$ bonds *trans* to hydrogen or phosphorus that are significantly longer than in structure **2** have also been observed for $(pp_3)Ru(H)(Cl)$, where the mutually *trans*-coordinated Me_2P substituents and the Me_2P group *trans* to the Ru—H linkage are at distances from the ruthenium atom of 2.310(2) and 2.343(2) Å, respectively.[7] Thus, the two families of complexes *cis*-$(Me_3P)_4Ru(H)(X)$ and $(pp_3)Ru(H)(X)$ (X = alkyl, aryl, arylamide, aryloxide, halide) are structurally similar in that in both series of compounds it is the dihydride that is characterized by the shortest Ru—P distances, as long as bonds opposite to the very weak *trans* influence ligands containing highly electronegative donor atoms are not considered.

In structures **1** and **2** all P—Ru—P angles between phosphorus atoms at mutually *cis* positions are considerably larger than 90°, while the axial Ru—P bonds *trans* to each other are bent towards the hydride ligands with P—Ru—P angles much smaller than 180°. Both deformations result from steric repulsions that are larger between the methyl substituents on the phosphorus atoms *cis* to each other than those between the metal-bound hydrogens and the *cis*-located PMe_3 ligands and Me_2P substituents, respectively. In agreement with the stereochemically undemanding nature of the hydride, as compared to other anionic ligands, these distortions are much more pronounced in dihydrides **1** and **2** than in *cis*-$(Me_3P)_4Ru(H)(X)$ or $(pp_3)Ru(H)(X)$, where X = alkyl, aryl, amide, alkoxide or halide. Thus, the sum of *cis* angles, $\Sigma(PRuP)_{cis}$, which would be 450° for an ideal octahedron, adds up to 495.6° for compound **1** and 486.2° for the averaged structure **2**. Values of $\Sigma(PRuP)_{cis}$ found for other *cis*-L_4Ru complexes with trimethylphosphine ligands are $\approx$ 479° for $L_4Ru(CH_2CH_2)$,[17] 482–483° for $L_4Ru(H)(Et)$[17] and $L_4Ru(H)(NHPh)$,[26] and *ca* 484° for $L_4Ru(H)(OC_6H_4Me\text{-}4)$.[26,28] In the structures of $(pp_3)Ru(H)(Cl)$[7] and $(pp_3)Ru(H)(Ar)$[9–11] (for aryl ligands Ar, see above), *cis* P—Ru—P angles, resulting in approximately constant sums of 476–477°, have been observed in previous work.

The finding that the angle sum $\Sigma(PRuP)_{cis}$ obtained for dihydride **1** exceeds that of its chelated analogue **2** by nearly 10°, and the observation that the angle *trans* P—Ru—P determined as 151.5° for *cis*-$(Me_3P)_4RuH_2$ tends to be some two to three degrees smaller than that of 153.5–154.0° measured for three of the four independent molecules of structure **2***, are in agreement with the view that there is a higher degree of steric crowding about the central metal in *cis*-$(Me_3P)_4Ru$ than in $(pp_3)Ru$ systems.[6] Hence, a 16e fragment, *cis*-$L_4Ru(0)$, coordinated by the tripodal-tetradentate $P[(CH_2)_3PMe_2]_3$ ligand can indeed be thought of as being more open and more accessible at the central metal than a formally related fragment with four monodentate PMe_3 ligands bonded to the ruthenium atom. This in turn corresponds to the observed propensity of *cis*-$(Me_3P)_4Ru(0)$ to stabilize by metal atom insertion across C—H bonds of its own ligands,[19,24] as contrasted with the ability of $(pp_3)Ru(0)$ to form stable products by oxidative addition of solvent C—H bonds.[3,6,9–11]

In view of the limited accuracy obtained for the positions of the hydrido ligands of both **1** and **2**, it is difficult to discuss and compare Ru—H bond lengths and angles.

C-SPIROPHOSPHORANE-SUBSTITUTED PHOSPHORUS YLIDES*

IGOR V. SHEVCHENKO, AXEL FISCHER, PETER G. JONES and REINHARD SCHMUTZLER†

Institut für Anorganische und Analytische Chemie der Technischen Universität, Hagenring 30, 3300 Braunschweig, Germany

(*Received* 10 *August* 1992; *accepted* 29 *September* 1992)

Abstract—The methylenephosphinophosphorane **2** was methylated by MeI forming the phosphonium salt **4**, which is stable in crystalline form but rearranges into isomer **10** when heated in chloroform solution at 80°C in a sealed tube for 16 h. The isomerization occurs by elimination of N,N′-dimethylcarbodiimide and formation of the methylenephosphonium phosphonate **5**. Compound **5** reacts with the carbodiimide via its ylide form **5a** to give the ylide **9**, which is transformed reversibly into **10**. Compound **2** shows unusual properties, such as its reaction with hexafluoroacetone via its ylide form **2a** forming the addition product **12**. The ylide structure of **12** was confirmed by X-ray analysis. The coordination geometry at P(2) is distorted trigonal bipyramidal, with axial substituents O (of the chelate ring) and N (of the four-membered ring). The bond lengths and angles at the ylidic carbon confirm the partial multiple bond character of the P—C bonds. There is evidence for a C—H···O hydrogen bond from the carbon atom bearing the CF_3 groups. The ylide **13** was obtained by the elimination of HI from **4** with triethylamine. Compound **2** reacted with CCl_4 to give the P-chloroylide **15**, as well as a small amount of **16**, which contains two phosphorus atoms of opposite formal charge and different coordination number (λ^4P^+, λ^6P^-). Compound **16** is isomeric to **3**, which we obtained earlier and investigated by X-ray analysis.

In previous work[1,2] we described a new rearrangement in phosphorus chemistry; the spirophosphorane **1** was transformed gradually into the isomeric compound **2**. The methylenephosphinophosphorane **2**, containing one phosphine and one spirophosphorane phosphorus atom bridged via a methylene group, is a new type of compound and shows unusual chemical properties. For example, its oxidation with tetrachloroorthobenzoquinone (TOB) leads to the formation of the unusual zwitterionic compound **3**, containing two phosphorus atoms of opposite formal charge and different coordination number (λ^4P^+, λ^6P^-) [eq. (1)]. The formation of **3** is probably the result of the addition of TOB to the two phosphorus atoms of compound **2**.[2]

* Dedicated to Professor Robert W. Parry on the occasion of his 75th birthday.

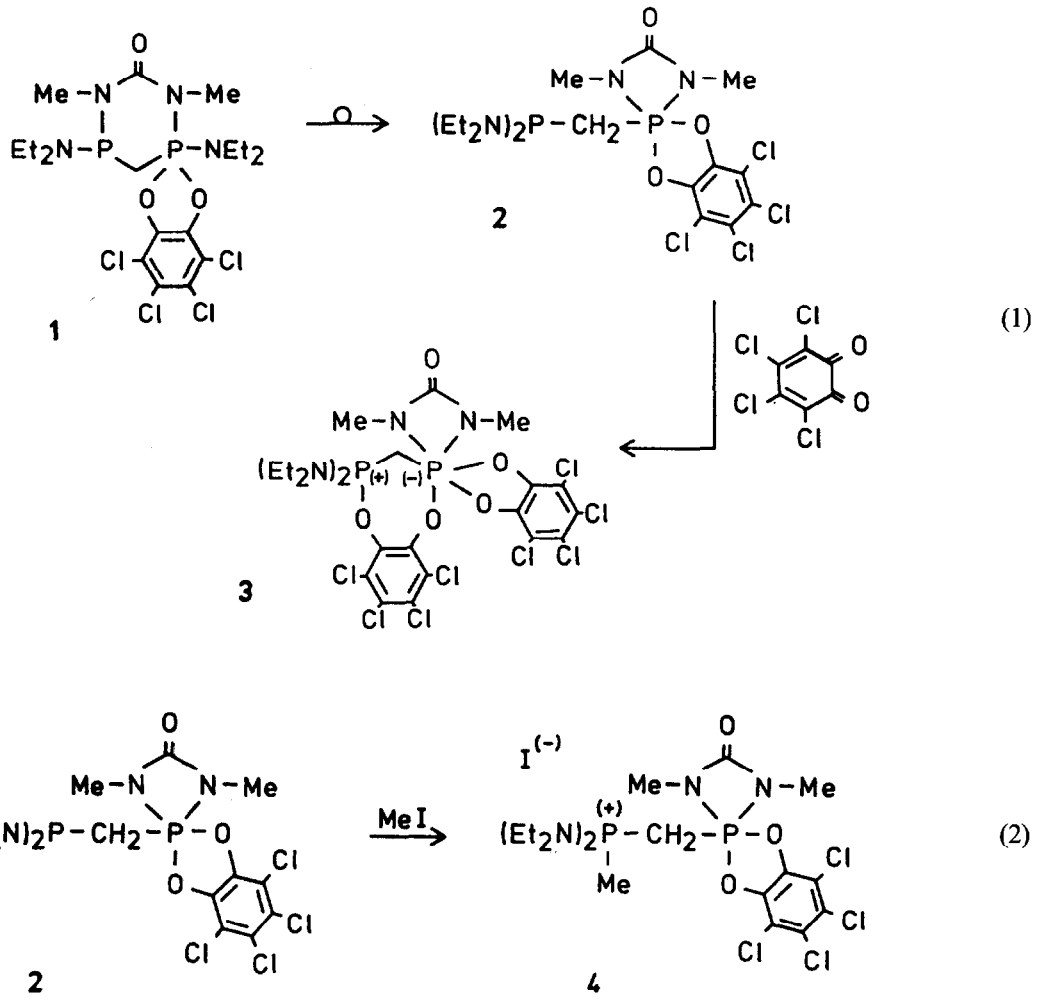
RESULTS AND DISCUSSION

The chemical properties exhibited by the methylenephosphinophosphorane **2** are closely connected to the presence of the methylene group between two electronegative phosphorus groups. The hydrogen atoms possess high acidity, which, together with the presence of bulky substituents at the phosphorus atoms, should promote the formation of stable ylides. This article is devoted to the investigation of this feature.

The methylenephosphinophosphorane **2** reacts with methyl iodide to give the phosphonium salt **4**. The nucleophilic properties of the trivalent phosphorus atom of **2** are substantially reduced and its methylation occurs slowly; it is completed in 10–16 h when a large excess of alkylation agent is used [eq. (2)]. The phosphonium salt **4** is a colourless crystalline product, insoluble in non-polar organic solvents. The structure of **4** is confirmed by its analytical and NMR spectroscopic data. The ^1H NMR spectrum shows a characteristic double doublet for



the methylene group P—CH_2—P at 3.99 ppm, which testifies to the high acidity of the methylene protons. In the ^{31}P NMR spectrum there are two doublets at 53.39 and −34.14 ppm. The coupling constant $^2J(PP)$ is small, amounting to only 5.1 Hz, although its value in the starting product **2** is 96 Hz.

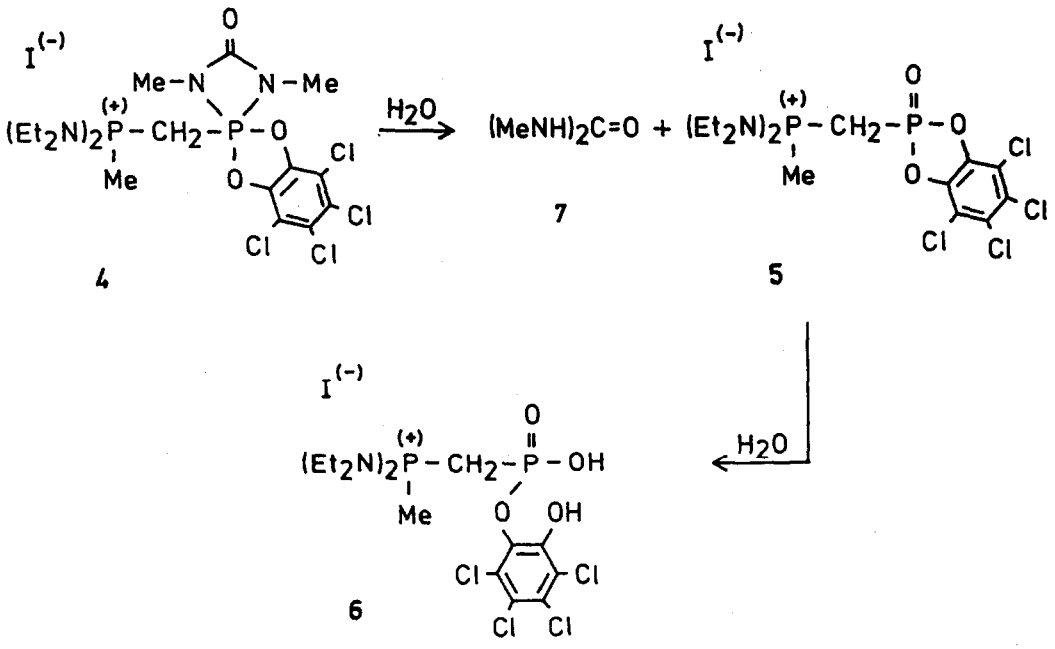
The phosphonium salt **4** is very sensitive to moisture. Its hydrolysis proceeds according to eq. (3). The addition of the first molecule of water leads to the elimination of N,N′-dimethylurea (**7**) and to the formation of the methylenephosphonium phosphonate (**5**).

Compound **5** was isolated as a colourless crystalline product. The phosphonium and the tetrachlorophenoxyphosphonate groups—two powerful electron-withdrawing groups, attached to the bridging methylene group—make this compound a strong C—H acid. The CH_2 group manifests itself in the ^1H NMR spectrum as a characteristic double doublet with a large $\delta(H)$ value, 5.12 ppm.

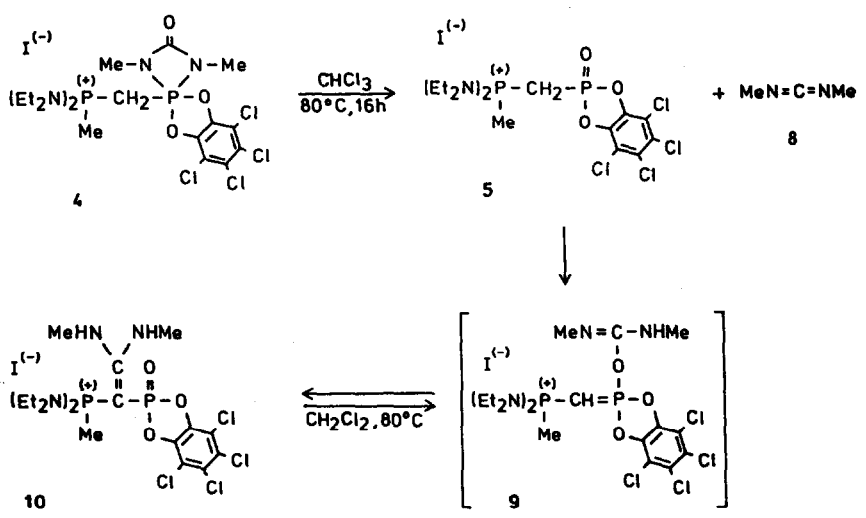
Like the starting phosphonium salt **4**, compound **5** is very sensitive to moisture. Careful hydrolysis of **5** leads to the cleavage of the dioxaphosphole ring with the formation of compound **6**. This process gives no by-products and **6** is, therefore, obtained in the reaction solution in NMR spectrally pure form. The cleavage of one of the P—O bonds of the phosphole heterocycle is confirmed by the ^1H NMR spectrum, where the CH_2 group gives rise to a double doublet at only 3.93 ppm. For the two OH groups of **6** one broad signal at 10.35 ppm can be seen, probably because of exchange processes. The ^{13}C NMR spectrum of **6** shows six signals for the carbon atoms of the benzene ring, one of them being a doublet with $^1J(PC) = 9.85$ Hz.

Further hydrolysis of **6** takes place considerably more slowly and leads to the elimination of the *o*-dioxytetrachlorophenyl group.

The phosphonium salt **4** is stable in its crystalline form. Upon heating the crystals to 100°C no changes are seen in the ^{31}P and ^1H NMR spectra. However, heating **4** in chloroform solution in a sealed tube at 80°C for 16 h brings about the elimination of N,N′-dimethylcarbodiimide (**8**) with the formation of **5** [eq. (4)].



(3)



(4)

Under the reaction conditions some of compound **5** reacts with the carbodiimide to give the addition product **9**, which has an ylide structure. The ^{31}P NMR spectrum of the reaction mixture shows the presence of **5** and **9**. Compound **5** can be quantitatively isolated from the mixture as a crystalline product. Samples of **5** obtained by two independent methods (see above) gave the same NMR spectroscopic parameters. After the separation of **5** the reaction solution contains, judging by the ^{31}P NMR spectrum, only compound **9**, exhibiting two doublets at 53.82 and 58.43 ppm with $^2J(PP) = 65.3$ Hz. Compound **9** is stable only in solution and cannot be isolated in a pure state. Careful removal of the solvent *in vacuo* (0.05 mm) gives rise to its isomerization into compound **10**.

The crystalline compound **10** remaining after removing the solvent yields the addition product of the protons of the active methylene group to the carbodiimide. We were unable to recrystallize **10** to investigate its structure by X-ray analysis. However, the structure of **10** was confirmed by ^1H and ^{31}P NMR spectra and is in agreement with the results of the elemental analysis.

The formation of **10** is also suggested by literature data. For example, it is known that strong CH acids add to carbodiimides with the formation of a C=C double bond.[3–5] For phosphorus-containing CH acids the analogous addition reaction has been carried out by Fild *et al.*[6]

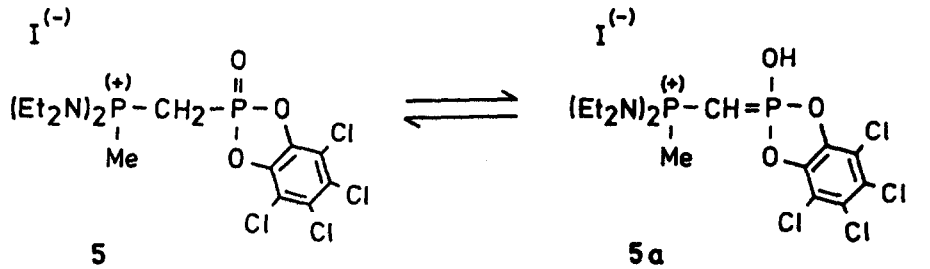
Compounds **4** and **10** are isomers, but the reverse transformation **10** → **4** cannot be realized. How-

ever, **10** can again be partly transformed into the ylide form **9**. After dissolving **10** in methylene chloride and heating the solution for 10 h at 80°C in a sealed tube, the formation of the intermediate ylide form **9** is observed by ^{31}P NMR spectroscopy.

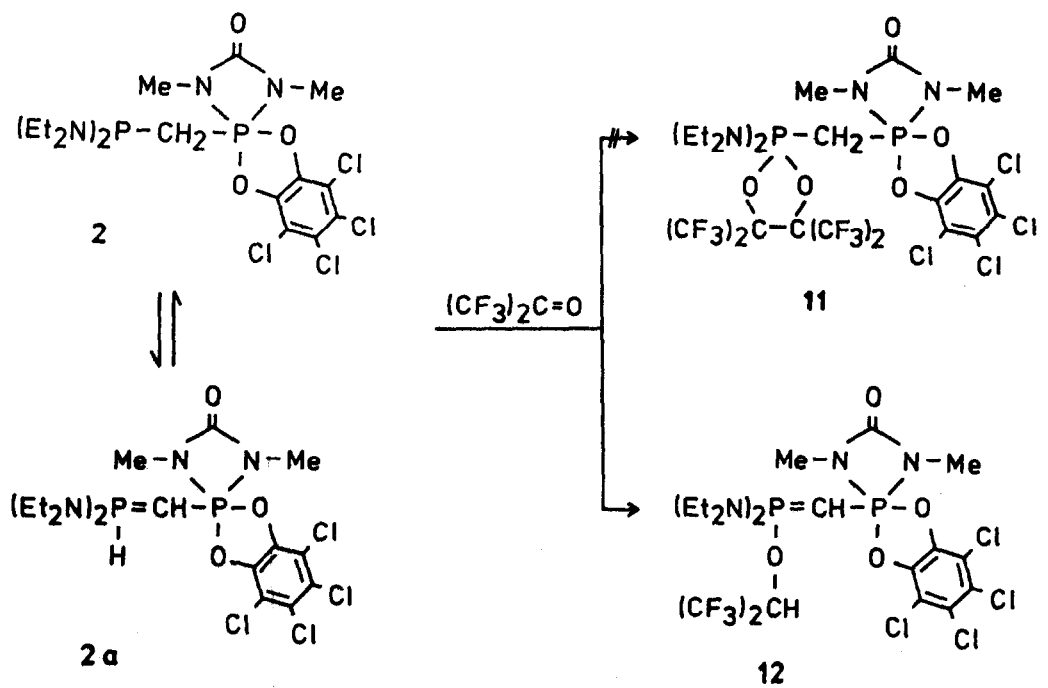
The suggested structure of **9** is confirmed by its readiness to undergo the Wittig reaction with benzaldehyde. It is interesting that this process is accompanied by the patial isomerization of **9** into **10**. Isomer **10** does not possess an ylide structure and does not react with benzaldehyde.

The structure of **9** is also confirmed by independent synthesis. Compound **5** reacted under the same conditions (heating in chloroform or methylene chloride at 80°C in a sealed tube) with dicyclohexylcarbodiimide with the formation of a product with the same signals in the ^{31}P NMR spectrum. Compound **5** added to carbodiimide not as a CH acid, but as the ylide form **5a** [eq. (5)]. The ability of the phosphoryl group to undergo enolization has been known since 1976.[7] This process requires the presence of sufficiently strong acidifying substituents (for example, the phosphonium group) at the central carbon atom of the $P—CH_2—P$ group.[8,9]

The suggested mode of formation of **9** was indirectly confirmed by the reaction of the methylenephosphinophosphorane **2** with hexafluoroacetone. In spite of an excess of hexafluoroacetone, the reaction did not lead to the oxidation product **11**, but to the ylide **12** which is an addition product of **2** to the carbonyl group of hexafluoroacetone. The reaction presumably proceeds through the ylide form **2a**, which, as in the case of compound **5**, cannot be detected by NMR spectral methods [eq. (6)].



(5)



(6)

Ylide **12** is a colourless stable crystalline product, the structure of which is in accordance with the NMR spectral and analytical data. The ^{31}P NMR spectrum contains two characteristic doublets

(64.35 and −29.65 ppm) with a similar value of the ^2J(PP) coupling constant (49.7 Hz) as in **9**. The ^{1}H NMR spectrum has a low-field signal for the $(CF_3)_2CH$ proton (5.43 ppm) as a well-resolved double quartet. The detailed structure of **12** was established by X-ray analysis (Fig. 1 and Table 1).

The coordination geometry at P(1) is tetrahedral, although O(3)—P(1)—N(4) (98.7°) is narrower and O(3)—P(1)—C(7) and N(4)—P(1)—C(7) (114.4, 120.2°) wider than the ideal angles. There is no obvious reason for these irregularities.

The atom P(2) displays trigonal bipyramidal coordination geometry; the axial substituents are O(1) and N(1) [O(1)—P(2)—N(1) 165.0°], with N(2), O(2) and C(7) equatorial. The four-membered ring (which is planar, r.m.s. deviation 0.5 pm) is necessarily a major cause of distortion from ideal angles [e.g. N(1)—P(2)—N(2) 74.0°]. The axial bonds are *ca* 10 pm longer than equatorial bonds to the same element.

The bonding at the ylidic carbon C(7) is described by the parameters P(1)—C(7), 169.4, P(2)—C(7), 168.8 pm (indicating appreciable multiple bond character), P(1)—C(7)—P(2), 130.9°.

The hydrogen atom at C(10), the central carbon atom derived from the hexafluoracetone molecule, should possess some acidic character; consistent with this, a short contact C(10)···O(4) $(1-x, 1-y, -z)$, 315 pm, is observed, which may be a C—H···O hydrogen bond.

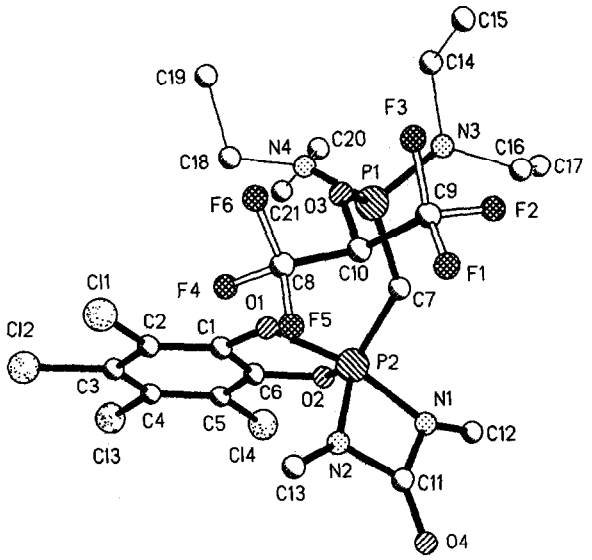


Fig. 1. A molecule of compound **12** in the crystal. Radii are arbitrary; hydrogen atoms are omitted.

The synthesis of ylides on the basis of the methylenephosphinophosphorane **2** can be carried

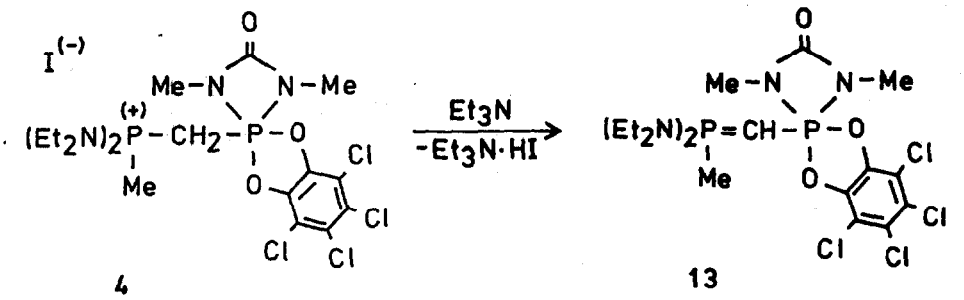
out in another way. The methylation of **2** by MeI led to the phosphonium salt **4** containing an iodide anion and a mobile α-CH hydrogen atom as a potential leaving group. The elimination of HI occurs very rapidly under the action of triethylamine with the formation of the P—Me substituted ylide **13** [eq. (7)].



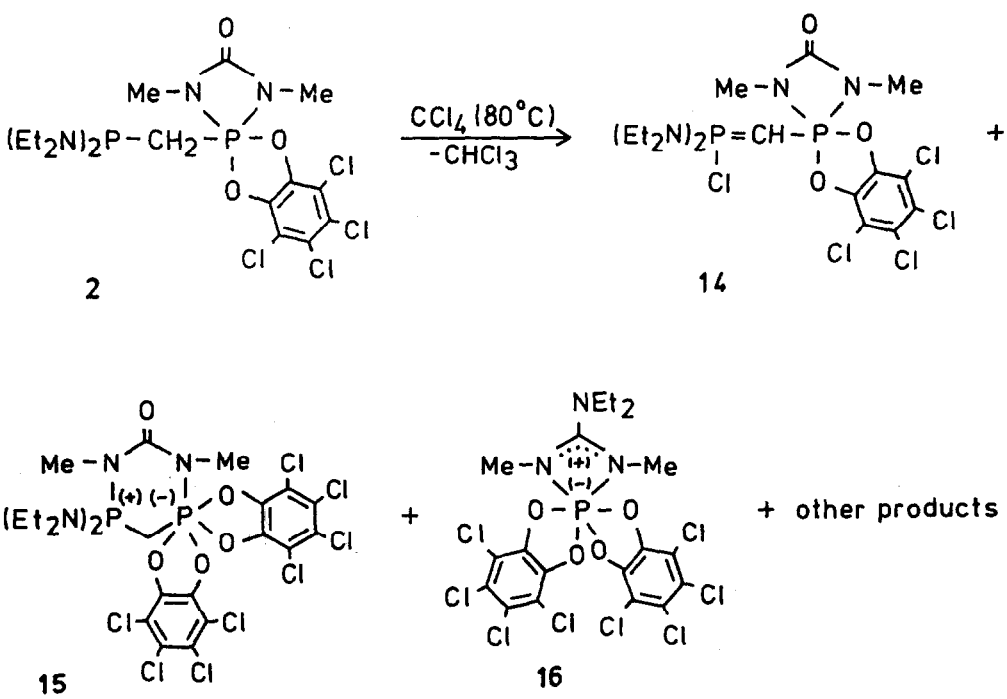
4 13 (7)

The ylide **13** was isolated as a colourless crystalline product, the structure of which was confirmed by analytical and NMR spectral methods.

It is known that phosphines containing a mobile C—H bond in the α-position to a trivalent phosphorus atom react very readily (even at −78°C) with carbon tetrahalides with the formation of P-halogenoylides.[10] In this respect the methylenephosphinophosphorane **2** represents an interesting starting material. It was found that the nucleophilic properties of **2** are substantially reduced; reaction with CCl_4 takes place only when it is used as a solvent, and upon heating [eq. (8)].

After 10 min at 80°C the ^{31}P NMR spectrum of the reaction mixture shows only the signals of the ylide **14** as two doublets at 74.10 and −32.75 ppm. The coupling constant $^2J(PP)$ is 46.2 Hz. Compound **14** can be obtained in good yield, but it is stable only in solution. All our attempts to isolate this compound in pure crystalline form failed and only a slow decomposition with the formation of a complicated mixture of products was observed.

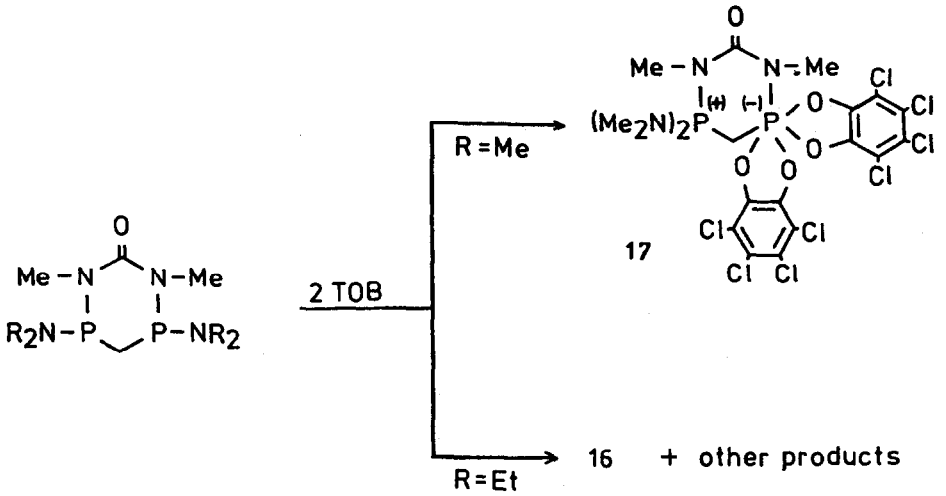
Further heating of the mixture of **2** with CCl_4 at 80°C led to the appearance of small amounts of **15** and **16**, containing six-coordinate phosphorus atoms, as well as small quantities of other unidentified products. The phosphorate **16** was observed ^{31}P NMR spectroscopically in a yield of *ca* 1–2% ($\delta_P = -103$ ppm). Earlier we obtained this compound in another way and confirmed its structure



by single-crystal X-ray structure analysis.[1] The content of **15** in the reaction mixture is not more than 6–8% and does not increase on heating for a longer time.

The formation of **15** and **16** in reaction (8) is not yet understood. It is possible that this process is connected with the presence of small amounts of by-products, together with the starting material **2**,

Compound **15** is an isomer of compound **3**, the structure of which we have also confirmed by X-ray analysis.[1] The isomers **3** and **15** exist independently of each other and do not undergo mutual isomerization [eq. (10)]. Unlike **15**, isomer **3** is thermally unstable and decomposes in boiling toluene with the formation of a complicated mixture of products that does not contain **15**.



(9)

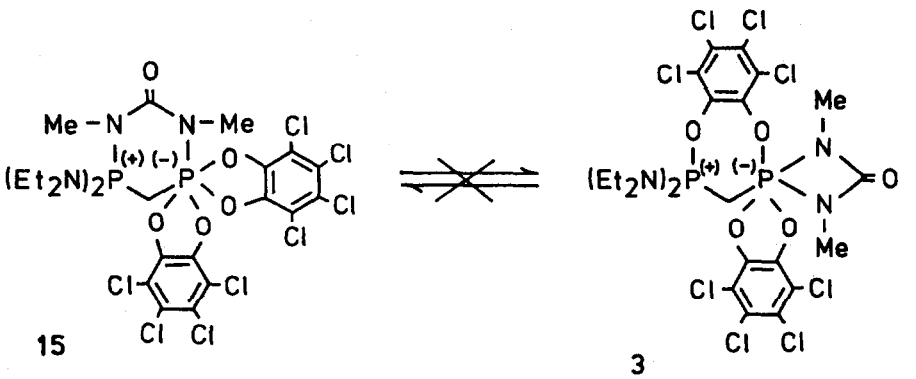
which was obtained according to our procedure[2] and was used without further purification.

Compound **15**, containing two phosphorus atoms of opposite charge and different coordination number, was isolated as a colourless, high-melting crystalline product, which, owing to its zwitter-ionic structure, is insoluble in non-polar and poorly soluble in polar organic solvents. The ^{31}P NMR spectrum shows two characteristic doublets at 55 and -115 ppm with a coupling constant $^{2}J(PP)$ of only 3.5 Hz.

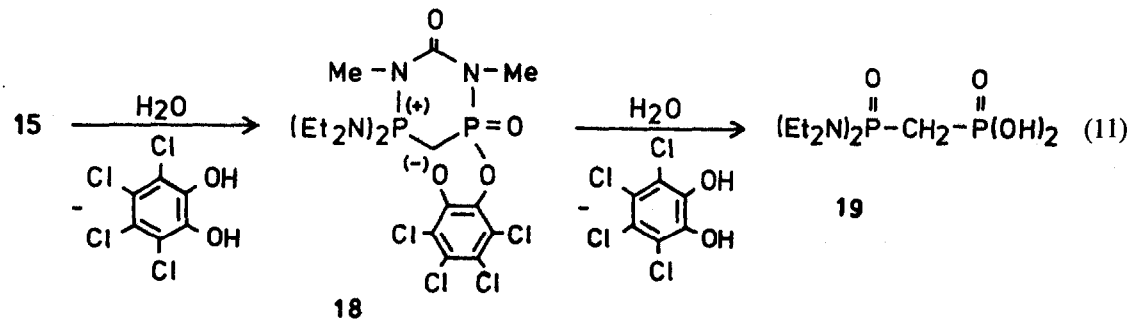
Compound **15** is a homologue of **17**, which we had obtained earlier [eq. (9)][11] and subjected to X-ray analysis. Compound **15** shows spectral characteristics similar to **17** and thus presumably has an analogous structure. Compound **15** cannot be obtained in the same way; cleavage of the original heterocycle is observed with the formation of **16** and other products.[1]

The hydrolysis of isomer **15** confirmed its structure. The process proceeds in two stages [eq. (11)]. At first, cleavage of the two P—O bonds at the six-coordinate phosphorus atom takes place to give the zwitter-ionic product **18**. The second stage of the hydrolysis is substantially slower, thus allowing **18** to be obtained in solution in spectroscopically pure form. The ^{31}P NMR spectrum shows two doublets at 10.39 and 52.52 ppm [$^{2}J(PP) = 6.6$ Hz] and the ^{1}H NMR spectrum two doublets due to the non-equivalent N—Me groups of the urea unit. After removal of the solvent there remains a crystalline product, for which elemental analysis confirms the presence of only one *o*-dioxytetrachlorophenyl group in the molecule.

Further hydrolysis proceeds slowly with the cleavage of the 1,5-diaza-2,4-diphosphorinane-6-one heterocycle and formation of **19**. This process



(10)



(11)

is illustrated by the disappearance of the signals of **18** and the appearance of two new doublets at 16.5 and 30.5 [^2J(PP) = 10.1 Hz] in the ^{31}P NMR spectrum. Unfortunately, the isolation of **19** and a more detailed investigation of **18** are complicated by the very low yield of the starting material **15**.

EXPERIMENTAL

Materials and spectroscopy

All experiments were conducted with the exclusion of moisture in sealed systems in an atmosphere of dried nitrogen (BASF BTS catalyst). Solvents were purified and dried according to the usual methods.[12,13] NMR spectra: Bruker AC 200 (^{1}H at 200.1 MHz; ^{13}C at 50.3 MHz; ^{31}P at 81.3 MHz). Reference substances were $SiMe_4$ (TMS) ext. (^{1}H, ^{13}C) and 85% H_3PO_4 ext. (^{31}P). High-field shifts were given negative, low-field shifts positive signs. Materials: the methylenephosphinophosphorane **2** was synthesized according to ref. 2 and was used without further purification.

Synthesis of **4**

To **2** (1.0 g, 1.81 mmol) was added MeI (1.28 g, 9.05 mmol) and the mixture was stirred for 5 h at 20°C. Excess MeI was removed *in vacuo* (0.5 mm); the residue was washed with ether (3 × 10 cm^3) and dried *in vacuo* (0.05 mm). The colourless crystalline product (1.12 g, 89%; m.p. 138–142°C) was dissolved in CH_2Cl_2 (3 cm^3) and ether was added dropwise while stirring until the solution just remained clear. The solution was allowed to stand at 20°C for 2 days and for 1 day at −20°C. The crystals formed were separated and dried *in vacuo* (0.05 mm). Yield after crystallization: 0.64 g (51%); m.p. 149–151°C. ^{1}H NMR ($CDCl_3$): 1.12 [t, ^3J(HH) = 6.9 Hz, CH_3—CH_2—N]; 1.15 [t, ^3J(HH) = 6.9 Hz, CH_3—CH_2—N]; 2.33 [d, ^2J(PH) = 13.3 Hz, CH_3P]; 2.93 [d, ^3J(PH) = 13.2 Hz, CH_3N]; 3.15 (m, CH_3—CH_2—N); 3.99 [dd, ^2J(PH) = 18.03 Hz, ^2J(PH) = 20.51 Hz, P—CH_2—P]. ^{31}P NMR ($CDCl_3$): 53.39 [d, ^2J(PP) = 5.1 Hz]; −34.14 [d, ^2J(PP) = 5.1 Hz]. Found: C, 32.7; H, 4.7; N, 7.9. Calc. for $C_{19}H_{31}Cl_4IN_4O_3P_2$ (694.15): C, 32.9; H, 4.5; N, 8.1%.

Formation of **5**

A solution of **4** (1 g, 1.44 mmol) in $CHCl_3$ (10 cm^3) was heated at 80°C for 16 h in a sealed tube. The solvent was removed *in vacuo* (0.5 mm). The residue was immediately dissolved in CH_2Cl_2 (2.5 cm^3) and ether was slowly added dropwise while stirring at room temperature until the solution just remained clear. The crystals of **5** formed after 48 h at 20°C were separated from the mother liquor and dried *in vacuo* (0.05 mm). Colourless product m.p. 206–208°C; yield 0.38 g (39.6%). ^{1}H NMR ($CDCl_3$) δ: 1.28 [t, ^3J(HH) = 7.1 Hz, N—CH_2—CH_3]; 2.52 [d, ^2J(PH) = 14.3 Hz, P—CH_3]; 3.2–3.5 (m, N—CH_2—CH_3); 5.12 [dd, ^2J(PH) = 16.2 Hz; ^2J(PH) = 23.3 Hz; P—CH_2—P]; 5.24 (s, CH_2Cl_2). ^{31}P NMR ($CDCl_3$): 52.61; 39.38 ppm. ^2J(PP) could not be determined. Found: C, 30.0; H, 4.3; Cl, 27.1; I, 19.9; N, 4.9; P, 8.4. Calc. for $C_{16}H_{25}Cl_4IN_2O_3P_2 \cdot 1/2CH_2Cl_2$ (666.52): C, 29.7; H, 3.9; Cl, 26.6; I, 19.0; N, 4.2; P, 9.3%.

Hydrolysis of compound **5**

A stream of moist nitrogen was slowly bubbled through a stirred solution of **5** (0.15 g, 0.23 mmol) in $CDCl_3$ (2 cm^3) until the signals of **5** completely disappeared (^{31}P NMR control). The solution of **6** thus formed shows the following NMR spectroscopic parameters: ^{1}H NMR ($CDCl_3$) δ: 1.19 [t, ^3J(HH) = 7.1 Hz, CH_3—CH_2—N]; 2.35 [d, ^2J(PH) = 13.5 Hz, CH_3—P]; 3.01–3.35 (m, CH_3—CH_2—N); 3.93 [dd, ^2J(PH) = 16.5 Hz; ^2J(PH) = 22.2 Hz, P—CH_2—P]; 10.35 (P—OH, Ar—OH). ^{13}C NMR ($CDCl_3$): 12.85 [d, ^1J(PC) = 84.5 Hz, CH_3—P]; 14.20, 14.23 (CH_3—CH_2—N); 25.76 [dd, ^1J(PC) = 75.9 Hz, ^1J(PC) = 133.8 Hz, P—CH_2—P]; 40.59, 40.68 (CH_3—CH_2—N); 122.22 (Ar); 123.80 (Ar); 125.85

(Ar); 129.45 (Ar); 136.14 [d, ^2J(PC) = 9.9 Hz, Ar]; 145.50 (Ar). ^{31}P NMR ($CDCl_3$): 14.38; 54.79 [^2J(PP) coupling was not resolved].

Formation of compounds **9** *and* **10**

The mother liquor left after the separation of compound **5** (see above) contained mainly compound **9**, which was stable only in solution. ^{31}P NMR of **9** (C_6D_6 solvent): 53.82 [d, ^2J(PP) = 65.32 Hz]; 58.43 [d, ^2J(PP) = 65.32 Hz].

After removing the solvent and drying the residue *in vacuo* (0.05 mm) for 2 h, **10** remained as a crystalline product which was washed with ether (2 × 10 cm^3) and dried *in vacuo* (0.05 mm). Colourless crystals; yield 0.49 g. ^{1}H NMR ($CDCl_3$): 1.18 [t, ^3J(HH) = 7.1 Hz, N—CH_2—CH_3]; 2.23 [d, ^2J(PH) = 13.5 Hz, P—CH_3]; 2.97 (NH—CH_3); 2.99 (NH—CH_3); 3.0–3.3 (m, N—CH_2—CH_3); 3.49 (s, NH). ^{31}P NMR ($CDCl_3$): 9.58; 58.46 [^2J(PP) coupling was not resolved]. Found: C, 33.6; H, 4.7; N, 8.7. Calc. for $C_{19}H_{31}Cl_4IN_4O_3P_2$ (694.15): C, 32.9; H, 4.5; N, 8.1%.

Synthesis of compound **12**

To a flask containing a solution of **2** (0.85 g, 1.54 mmol) in ether (15 cm^3) cooled to −20°C was added hexafluoroacetone (150 cm^3, 1.11 g, 6.70 mmol) with a syringe while stirring. After 10 min the reaction mixture was allowed to warm to 20°C; after 1 h the mixture was cooled to −20°C and the crystals formed after 24 h were separated from the mother liquor and dried *in vacuo* (0.05 mm). Colourless product; m.p. 166–168°C; yield 0.43 g (40%). ^{1}H NMR ($CDCl_3$) δ: 1.03 [t, ^3J(HH) = 7.1 Hz, CH_3—CH_2—N]; 2.72 [dd, ^2J(PH) = 12.1 Hz, the second ^2J(PH) was not resolved, P—CH_2—P]; 2.72 [d, ^3J(PH) = 12.1 Hz, CH_3—N]; 2.7–3.3 (m, CH_3—CH_2—N); 5.43 [dq, ^3J(PH) = 19.3 Hz, ^3J(FH) = 6.3 Hz, CF_3—CH—CF_3]. ^{13}C NMR ($CDCl_3$) δ: 13.84, 13.87 (CH_3—CH_2—N); 17.89 [dd, J(PC) = 59.5 Hz, J(PC) = 185.7 Hz, P—CH—P]; 26.21, 26.25 (CH_3—CH_2—N); 40.69, 40.79 (CH_3—N); 114.48 [d, ^2J(PC) = 12.6 Hz, Ar]; 124.07 (Ar); 142.42 (Ar), 157.23 [d, ^2J(PC) = 14.5 Hz, C=O]. ^{19}F NMR ($CDCl_3$) δ: −72.78. ^{31}P NMR: 64.35 d, ^2J(PP) = 49.7 Hz; −29.65 d, ^2J(PP) = 49.7 Hz. Found: C, 35.4; H, 4.1; N, 7.7. Calc. for $C_{21}H_{28}Cl_4F_6N_4O_4P_2$ (718.23): C, 35.1; H, 3.9; N, 7.8%.

Synthesis of compound **13**

A solution of **4** (0.5 g, 0.72 mmol, recrystallized) in CH_2Cl_2 (6 cm^3) was cooled to −20°C and triethylamine (0.73 g, 7.2 mmol) was added. After 20 min the solvent was removed *in vacuo* and the residue was dried *in vacuo* (0.05 mm) for 1 h. The remaining colourless crystalline product was extracted with boiling petroleum ether (60–70°C; 2 × 20 cm^3). The colourless crystals formed after the extract were allowed to stand at −20°C for 24 h, were separated and dried *in vacuo* (0.05 mm); m.p. 128–129°C; yield 0.26 g (63%). ^{1}H NMR ($CDCl_3$) δ: 1.05 [t, ^3J(HH) = 7.06 Hz, CH_3—CH_2N]; 1.62 [d, ^2J(PH) = 13.49 Hz, CH_3—P]; 2.15 [dd, ^2J(PH) = 13.92 Hz, ^2J(PH) = 22.31 Hz, P—CH_2—P]; 2.73 [d, ^3J(PH) = 11.83 Hz, CH_3—N]; 2.9–3.2 (m, CH_3—CH_2—N). ^{13}C NMR ($CDCl_3$) δ: 13.76, 13.81 (CH_3—CH_2—N); 16.23 [d, J(PC) = 98.1 Hz, CH_3—P]; 19.49 [dd, J(PC) = 147.0 Hz, J(PC) = 233.5 Hz, P—CH—P]; 26.31, 26.36 (CH_3—CH_2—N); 38.95, 39.05 (CH_3—N); 113.93 [d, ^2J(PC) = 12.29 Hz, Ar]; 123.04 (2C, Ar); 142.71 (2C, Ar); 157.96 [d, ^2J(PC) = 11.5 Hz, C=O]. ^{31}P NMR ($CDCl_3$): 62.8 [d, ^2J(PP) = 44.3 Hz]; −29.7 [d, ^2J(PP) = 44.3 Hz]. Mass spectrum: M_{calc} = 566.24. M_{exp}(EI) = 566. Found: C, 39.9; H, 5.3; N, 9.5. Calc. for $C_{19}H_{30}Cl_4N_4O_3P_2$ (566.24): C, 40.3; H, 5.3; N, 9.9%.

Interaction of **2** *with* CCl_4

A solution of **2** (1.0 g, 1.81 mmol) in CCl_4 (4 cm^3) was heated at 80°C for 10 min in a sealed tube. The reaction mixture after this time contained only the P-chloroylide **14** with the following ^{31}P NMR data: 74.10 [d, ^2J(PP) = 46.2 Hz]; −32.75 [d, ^2J(PP) = 46.2 Hz].

The reaction mixture was heated further at 80°C for 24 h. The colourless crystalline product **15** was separated and washed with ether (4 cm^3) and CH_2Cl_2 (1.5 cm^3), and was recrystallized from acetonitrile (yield 80 mg); mp. 250–252°C. ^{1}H NMR ($CDCl_3$) δ: 1.20 [t, ^3J(HH) = 7.1 Hz, CH_3—CH_2—N]; 2.65 [dd, ^2J(PH) = 15.1 Hz; ^2J(PH) = 16.8 Hz, P—CH_2—P]; 3.00 [d, ^3J(PH) = 6.46 Hz; CH_3—N]; 3.02 [d, ^3J(PH) = 8.8 Hz, CH_3—N]; 3.12–3.40 (m, CH_3—CH_2—N). ^{31}P NMR ($CDCl_3$) δ: 55.12 [d, ^2J(PP) = 3.5 Hz]; −114.39 [d, ^2J(PP) = 3.5 Hz]. Mass spectrum: M_{calc} = 798.09; M_{exp}(FAB) = 799 [M+H$^+$]. Found: C, 35.8; H, 3.7; N, 6.8. Calc. for $C_{24}H_{28}Cl_8N_4O_5P_2$ (798.09): C, 36.1; H, 3.5; N, 7.0%.

Hydrolysis of compound **15**

A mixture of **15** (50 mg), $CDCl_3$ (2 cm^3) and water (0.1 cm^3) was stirred at 20°C until **15** had

dissolved and its ^{31}P NMR signals disappeared. The resulting solution of **18** showed the following NMR parameters: ^1H NMR ($CDCl_3$) δ: 1.17 [t, $^3J(HH) = 7.0$ Hz, CH_3—CH_2—N]; 2.74 [d, $^3J(PH) = 4.8$ Hz, CH_3—N]; 3.00 [d, $^3J(PH) = 10.2$ Hz, CH_3—N]; 3.05–3.3 (m, CH_3—CH_2—N, P—CH_2—P). ^{31}P NMR ($CDCl_3$): 10.39 [d, $^2J(PP) = 6.6$ Hz]; 52.52 [d, $^2J(PP) = 6.6$ Hz].

After removing the solvent **18** remained as a white crystalline product with the following analytical data: Found: C, 36.9; H, 4.9; Cl, 26.5. Calc. for $C_{18}H_{28}Cl_4N_4O_4P_2$ (568.21): C, 38.0; H, 5.0; Cl, 25.0%.

Crystal structure analysis of compound **12**

Crystal data. $C_{21}H_{28}Cl_4F_6N_4O_4P_2$, $M = 718.2$, triclinic, space group $P\bar{1}$, $a = 1090.1(3)$, $b = 1134.9(3)$, $c = 1250.9(3)$ pm, $\alpha = 82.05(2)$, $\beta = 85.41(2)$, $\gamma = 79.85(2)°$, $U = 1.5063$ nm^3, $Z = 2$, $D_x = 1.584$ Mg m^{-3}, λ(Mo-K_α) = 71.069 pm, $\mu = 0.57$ nm^{-1}, $F(000) = 732$, $T = -95°C$.

Data collection and reduction. Data were collected from two colourless prisms, *ca* $0.3 \times 0.3 \times 0.3$/$0.5 \times 0.45 \times 0.2$ mm, which were mounted on glass fibres with inert oil and transferred to the cold gas stream of the diffractometer (Siemens R3 with LT-2 low temperature attachment). 3162/5028 intensities were registered to $2\theta_{max}$ 50°, of which (after appropriate scaling, $R_{int} = 0.022$) 5314 were independent and 3969 considered significant ($> 4\sigma(F)$). Cell constants were refined from diffractometer angles of 50 reflections in the 2θ range 20–23°.

Structure solution and refinement. The program system "Siemens SHELXTL PLUS" was used. The structure was solved by direct methods and refined anisotropically. Hydrogen atoms were included using a riding model. The weighting scheme was $w^{-1} = \sigma^2(F) + 0.0003F^2$. The final R value was 0.043, with $wR = 0.040$. 376 parameters; $S = 1.8$; max. Δ/σ 0.001; max. $\Delta\rho$ 1.1×10^{-6} e pm^{-3} near C(17), which probably indicates some disorder of the associated ethyl group.

Full details of the structure determination (including structure factors) have been deposited at the Fachinformationszentrum Karlsruhe, Gesellschaft für Wissenschaftlich-technische Information mbH, W-7514 Eggenstein-Leopoldshafen 2, Germany. Any request for this material should quote a full literature citation and the reference number CSD 56910.

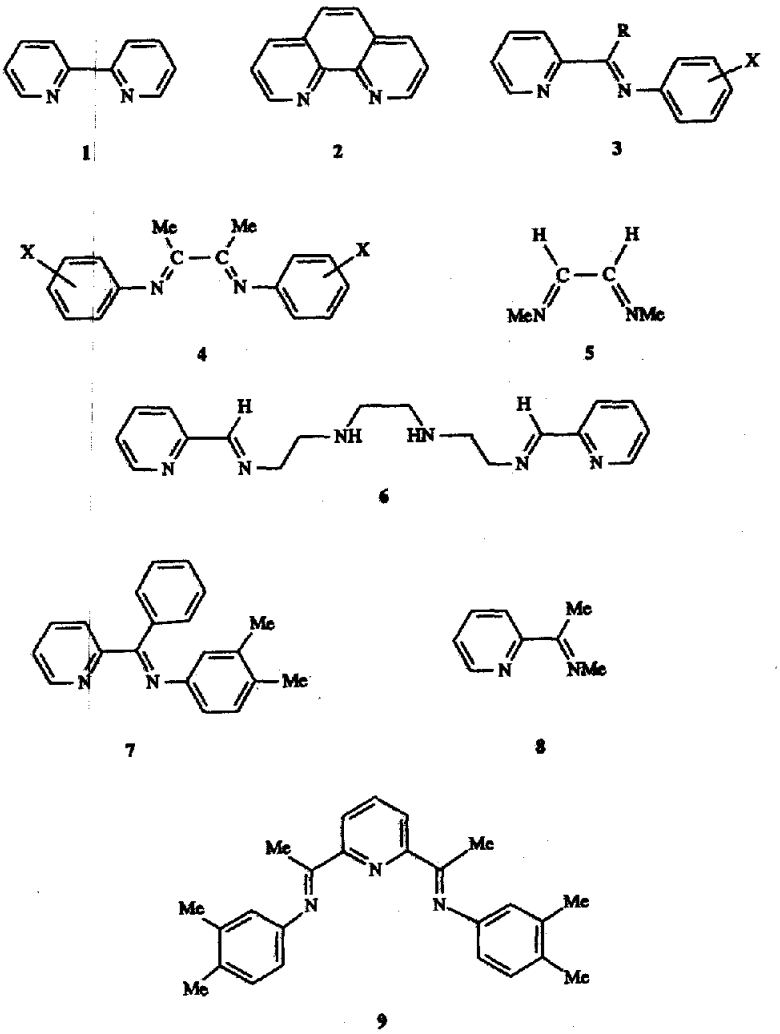
(*Received* 28 *September* 1992; *accepted* 20 *November* 1992)

Abstract—The reactivity and solvation of the iron(II) tris complex made from the bidentate ligand obtained by condensing phenyl 2-pyridyl ketone and 3,4-dimethylaniline have been examined in aqueous solution and in aqueous solvent mixtures. Base hydrolysis kinetics measurements upon the complex ion, $[Fe(Me_2bsb)_3]^{2+}$, show an increasing rate of dissociation with increasing co-solvent concentration, due largely to the destabilization of the hydroxide ion. The predicted preference the lipophilic complex would exhibit toward solvents less polar than water is an expectation that is realized when transfer (from water to aqueous solvent mixtures) chemical potential trends are analysed. The latter parameters were obtained from solubility measurements. When corresponding transfer chemical potentials for the transition state are also considered, the factors controlling reactivity patterns are shown; this is described by an initial state—transition state analysis. Base hydrolysis kinetics carried out at high pressures (up to 1 kbar) yield the volumes of activation, ΔV^*, which provide a complementary view of solvation. Some measurements with a similar complex, $[Fe(Me_2tsb)_2]^{2+}$, are reported for comparison.

Kinetics of the reaction of iron(II) complexes of ligands of the 2,2′-bipyridyl (bipy, **1**) and 1,10-phenanthroline (phen, **2**) type have been extensively studied for many years.[1] A reasonable range of substituents can be introduced into these ligands by appropriate synthetic approaches, but at times the organic chemistry is difficult, involving multistage syntheses including two Skraup reactions.[2] An alternative approach to the introduction of substituents into diimine ligands is to prepare them from pyridine 2-carboxaldehyde, 2-acetyl pyridine, 2-benzoyl pyridine[3,4] or from 2,3-butanedione[3,5] and substituted anilines, which are available in great profusion, to give ligands of the type **3** or **4**. We have studied the kinetics of a selection of substitution and redox reactions of such complexes, particularly those of type **3**.[4,6] In recent years we have been particularly interested in solvation and reactivity of iron(II)-diimine complexes in binary aqueous solvent mixtures.[7,8] Several years ago we showed that ligand variation has a dramatic effect on the

† Author to whom correspondence should be addressed.

hydrophilic/hydrophobic properties of such complexes,[9,10] with complexes of such ligands as gmi (**5**) or the hexadentate Schiff base **6** (hxsbH) showing only a very slight preference for alcohols over water; however, much more hydrophobic ligands, such as **7** (= **3** with R = Ph, X = 3,4-Me_2), are strongly preferentially solvated by organic co-solvents. Thus, the cation derived from **7** is stabilized by *ca* 50 kJ mol^{-1} on transfer from water into methanol. We have studied solvation and base hydrolysis kinetics of the almost hydrophilic complexes $[Fe(gmi)_3]^{2+}$ and $[Fe(hxsbH)]^{2+}$ extensively establishing reactivity trends and activation volumes in several series of binary aqueous solvent mixtures.[10–12] A parallel study of the extremely hydrophobic complex containing ligand **7**, $[Fe(Me_2bsb)_3]^{2+}$, has been fraught with difficulties, both of preparation of pure materials and of reproducibility of kinetic and solubility measurements. It has become clear that most of the problems arise from the production of varying amounts of *mer* and *fac* isomers when preparing salts of this complex under various conditions. This matter has been fully investigated and documented recently for the analogous tris complex of the ligand **8**, derived from 2-acetyl pyridine and methylamine (**8** = **3** with R = Me and N—C_6H_5 replaced by N—CH_3),[13] whose kinetic and spectroscopic properties (^{1}H NMR and visible absorption spectra) are particularly favourable for the resolution of this isomer problem. We are now in a position to resolve most of the problems with the $[Fe(Me_2bsb)_3]^{2+}$ cation, so now present the results of our kinetic studies on base hydrolysis of this most hydrophobic complex, particularly in relation to co-solvent effects on reactivity trends and on activation volumes. In the latter connection we report activation volumes for some related complexes which also have very bulky and



hydrophobic leaving ligands. These ligands include the 3-methyl and 4-methoxy analogues of **7** and the terdentate analogue **9** (Me_2tsb).

EXPERIMENTAL

Materials

Samples of $[Fe(Me_2bsb)_3](ClO_4)_2$ were either those obtained earlier[11] or were prepared during this study according to established methods.[14,15] The perchlorate salt of $[Fe(Me_2tsb)_2]^{2+}$ was prepared as reported in earlier work.[7] Reagents used in dissociation studies, sodium hydroxide and sodium chloride were Analar grade. Co-solvents used in solubility and kinetics measurements were high-grade commercial products and employed without further purification.

Methods

Solubility measurements were made according to the method described earlier,[7] but a longer period of absorbance sampling was carried out for the bidentate containing complex (references to and discussion of complex ion isomerism, the reason for modification of the method, are found in earlier and in later parts of this paper). The wavelengths of maximum absorbance of $[Fe(Me_2bsb)_3]^{2+}$ and $[Fe(Me_2tsb)_2]^{2+}$ are 585 and 592 nm, respectively. Absorbance measurements were made on a Pye–Unicam SP 8-100 spectrophotometer or on a Cary 219 spectrophotometer. Dissociation kinetics at atmospheric pressure were carried out on a Pye–Unicam SP 8-100, Unicam SP 1800 or a Cary 219 spectrophotometer, with temperature controlled to 298.2 ± 0.1 K, at the appropriate wavelength to monitor the loss of the complex ion. Data were either processed manually or with data treatment software indicated elsewhere.[7,16]

The reactions were carried out under first-order conditions with the hydroxide ion in a large excess over the metal complex concentration. In many solvent mixtures the first-order rate constant, k_{obs}, was obtained at several different hydroxide concentrations. A linear dependence of k_{obs} on hydroxide ion concentration was observed when $[OH^-] < 0.15$ mol dm^{-3}. The slopes of these plots, when available, were used to calculate k_2, the second-order rate constant. Otherwise, for comparison of dissociation in different solvent mixtures k_{obs} at a given hydroxide ion concentration was used. For both methods the hydroxide concentrations were sufficiently low to avoid any higher order terms than first in the rate equation. With increasing co-solvent concentration the non-linear dependence portion of the k_{obs} versus hydroxide plot occurs at lower hydroxide ion concentrations. All solvent mixtures have compositions given, which refer to the composition before mixing.

Kinetics at high pressure were carried out in the range 1 bar to 1.3 kbar, as described earlier.[11,17] The rate constants obtained (k_p) were used in plots of $\ln(k_p/k_0)$ vs pressure, where k_0 is the rate constant at 1 atmos. for an aliquot of the same solution employed in the high pressure experiment. The slopes of such plots (there was no detectable curvature indicating a negligible compressibility of activation) yield ΔV^*, the volume of activation. Values quoted in this paper refer to the volume of activation at 1 bar. In the high pressure measurements hydroxide ion concentrations were always below those where complications of higher order terms can arise.[18]

RESULTS AND DISCUSSION

Solvation

We deal first with the hydrophobicity of the complex $[Fe(Me_2bsb)_3]^{2+}$, as reflected in solvation in binary aqueous solvent mixtures. Here the isomer problem presents considerable difficulties in regard to obtaining precise solubilities and transfer chemical potentials, but does not prevent us from presenting an informative semi-quantitative picture. It is clear that the transfer chemical potentials for the *mer* and *fac* isomers do not differ by more than 10% and that solubility measurements carried out under constant conditions (equilibration for 24 h) can give results which are reliable, reproducible and consistent to this order of uncertainty. In view of the large changes in transfer chemical potential with solvent composition, the solvation pattern shown in Fig. 1 can be deemed reliable, even if individual

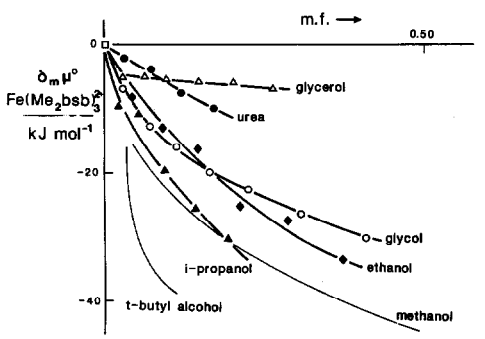


Fig. 1. Transfer chemical potentials (kJ mol^{-1}) from water into aqueous solvent mixtures for the $[Fe(Me_2bsb)_3]^{2+}$ species vs solvent composition (mole fraction) at 298.2 K.

values have larger uncertainties than usual. The results in this figure are derived from published data[9,19,20] and from previously unpublished solubilities. Details are given in Table 1. The pattern is similar to that of other iron(II)-diimine complexes, but transfer chemical potentials are generally larger than for most other such complexes. This is illustrated for the typical case of methanol–water in Fig. 2[7,21] (exceptionally, in urea–water mixtures differences between trends for various complexes are very

much less marked[19]). As discussed below such marked stabilization by most organic co-solvents has a dominant effect when reactivity trends are analysed into their initial state and transition state contributions.

Kinetics

Base hydrolysis kinetic runs were carried out on solutions of the complex which had been aged (allowed to stand for at least 24 h) and, therefore, contained predominantly the more stable (presumably *mer*) isomer. These runs showed no significant deviation from first-order behaviour (hydroxide always present in a large excess) over at least three half-lives. First-order rate constants calculated, as is our normal custom,[7] from absorbance changes monitored over the first 2.5 half-lives are reported in Table 2. The general rate law for hydroxide attack at iron(II)-diimine complexes is:

$$-\mathrm{d[complex]}/\mathrm{d}t = \{k_1 + k_2[\mathrm{OH^-}] + k_3[\mathrm{OH^-}]^2 \ldots\}[\mathrm{complex}].$$

For hydroxide concentrations up to *ca* 0.15 mol dm^{-3} contributions from $[OH^-]^2$ and higher terms

are negligible for this complex, although the square term begins to be significant at higher hydroxide concentrations.[11] The k_1 term is also vanishingly small here. Values of k_2 are included in Table 2. They, together with published data on this reaction,[11] are plotted in Fig. 3 to give an overall picture of reactivity. This again shows a similarity to such patterns for the other iron(II)-diimine complexes. One common and important feature is the steadily increasing effect of mono-hydroxylic alcohols as their carbon content increases, to which the transfer chemical potential trends and consequent nucleophilicity of the hydroxide contribute. The effect of added dimethyl sulphoxide is somewhat less than perhaps intuitively expected, but is in fact exactly similar to that in base hydrolysis of the $[Fe(phen)_3]^{2+}$ cation.[22]

Initial state–transition state analysis

Solvation effects on reactivity can be probed informatively through dissection into initial state and transition state components.[23,24] This is illustrated for methanol–water solvent media in Figs 4 and 5 (see also Table 3), and for ethane-1,2-diol in Fig. 6. We have chosen these two mixed solvent series firstly because kinetic measurements cover a wide range of compositions and secondly because hydroxide is destabilized on transfer to aqueous methanol[7] but stabilized on transfer to aqueous ethane-1,2-diol.[20] The complex is of course greatly stabilized in both cases. Two representations have been provided for the methanol–water system, since one emphasizes the relation between the magnitude of the solvation changes and that of the activation barrier (ΔG^*), the other emphasizes how solvation of the periphery of the complex dominates initial and transition state trends. This is, of course, also the case for other co-solvents. The picture is

markedly different from those for the much less hydrophobic complexes $[Fe(gmi)_3]^{2+}$ [7,8] and $[Fe(hxsbH)]^{2+}$.[12] Even for $[Fe(bipy)_3]^{2+}$, which is moderately hydrophibic, it is hydroxide solvation variation rather than complex solvation which dominates the base hydrolysis reactivity trend in dimethyl sulphoxide–water media.[22]

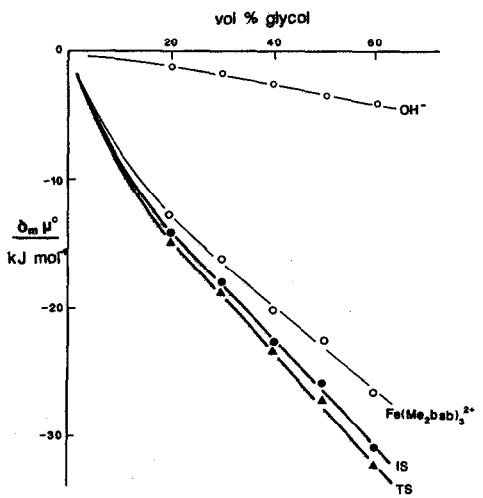

Fig. 6. Initial state–transition state analysis for base hydrolysis of $[Fe(Me_2bsb)_3]^{2+}$ in aqueous 1,2-ethanediol mixtures at 298.2 K.

Activation volumes

Values of ΔV^* for the reaction of hydroxide with $[Fe(Me_2bsb)_3]^{2+}$ in water have been interpreted as arising from a dominant contribution from the solvation component.[11] Specifically, desolvation of the incoming hydroxide ion gives rise to a contribution of just over 20 cm^3 mol^{-1}, as the expected ΔV^* value from an intrinsic contribution alone would be −10 cm^3 mol^{-1} for an associative mechanism.[25] The relative insensitivity of the observed ΔV^* to the nature of the iron(II) diimine cation has been recorded previously,[26] and is here reinforced for bsb type ligands by recalling that the ΔV^* values for the iron(II) tris complexes of the 3Me- and 4MeO-bsb ligands (3) are 13 and 12 cm^3 mol^{-1}, respectively.

At first examination the changes in ΔV^* with co-solvent addition (see Table 4) are paradoxical in that a large increase in the values indicates a loss of restricted solvent, the alcohol co-solvent, from the very lipophilic cation upon forming the transition state, with the hydroxide ion being similarly desolvated as it is in purely aqueous solution. Yet since the charge upon the reactant cation is reduced by one as the transition state is formed, it could be argued that this would permit increased solvation by the co-solvent to occur. There is no doubt that

Table 4. Ratios of rate constants for base hydrolysis of $[Fe(Me_2bsb)_3]^{2+}$ at high pressures (k_p) to those at atmospheric pressure (k_0), in methanol–water media at 298.2 K [I = 0.33 mol dm^{-3} (NaCl)] and derived activation volumes, ΔV^*

[a] $\Delta V^* = +11$ cm^3 mol^{-1} in water.[11]
[b] [NaOH] = 0.073 mol dm^{-3}.
[c] Also −1.310 at 1.34 kbar.
[d] KOH/KCl.
[e] Also −1.204 at 1.17 kbar.
[f] $\Delta V^* = +14$ cm^3 mol^{-1} in water.[26]
[g] $\Delta V^* = +12$ cm^3 mol^{-1} in water.[26]

the initial state iron complex cation is strongly solvated by the co-solvent as the transfer chemical potentials, for example from water into aqueous methanol at 41 kJ mol^{-1} to mole fraction of methanol 0.64,[9] indicate. Therefore, it must be surmised that the consequence of charge reduction is very small for such a huge cation, and that the hydroxide ion upon penetrating the periphery of the heavily solvated cation, en route to the central iron and effectively breaking the first iron–nitrogen bond, perturbs a considerable array (in the case of methanol) of solvent molecules. To reinforce the point of a small charge–change/size ratio it is recalled that $\delta_m\mu^\circ$ ($[Fe(Me_2bsb)_3]^{2+}$) > $\delta_m\mu^\circ$ (Ph_4As^+) or $\delta_m\mu^\circ$ (Ph_4B^-).[7] In Fig. 7 it can be seen that, as reported earlier,[9] ΔV^* increases in an approximately proportional manner with increasing per cent of methanol after an initial jump from 11 to almost 20 cm^3 mol^{-1} at 33% co-solvent, with a value of 27 cm^3 mol^{-1} being reached at 93% methanol. There is nothing unique about methanol as the results for ethanol and isopropanol-aqueous mixtures mostly mirror this trend, although less markedly so. This could reflect fewer of the larger mono-ols initially solvating the complex cation and thus fewer are released upon reaction, but this is quite speculative. There is a dramatic effect obtained using t-butyl alcohol as the co-solvent. The increase to 24 cm^3

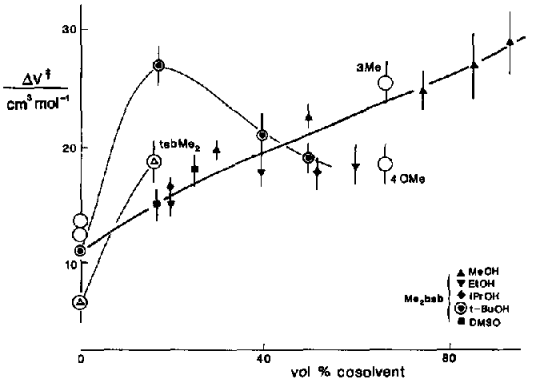

Fig. 7. Volumes of activation vs aqueous solvent mixture compositions for base hydrolysis of $[Fe(Me_2bsb)_3]^{2+}$ and $[Fe(Me_2tsb)_2]^{2+}$ at 298.2 K, ionic strength 0.33 mol dm^{-3}.

mol^{-1} at 17% co-solvent has been noted earlier. Due to the magnitude of this effect and the error range obtained earlier[9] this point has been redetermined and is now established as 26 ± 2 cm^3 mol^{-1}, with a subsequent decrease to *ca* 20 cm^3 mol^{-1} at 40 and 50% t-butyl alcohol. Given the extreme bulkiness of this alcohol relative to the lower homologues these changes are probably a consequence of a big volume change per released co-solvent molecule. Actually the maximum value of ΔV^* is the same in both methanol and t-butyl alcohol, but with the maximum occurring at a much lower mole fraction for the bigger mono-ol. This is not unexpected given the structural changes to water proposed by the two mono-ols in question and the co-solvent concentrations where these effects are manifested.[27] Modelling studies in progress[28] should help to address these hypotheses and enable a semi-quantitative explanation to emerge. The occupancy by solvent molecules of the spaces between ligand entities, within the complex cation, clearly a feature of the system addressed here, has been discussed earlier for the $[Fe(phen)_3]^{2+}$ complex cation.[21] While exactly the same values of ΔV^* are not obtained in water or in 67% methanol, for base hydrolysis of the tris complexes of the 4-methoxy and 3-methyl analogues of Me_2bsb (see Table 4), the closeness of the values and the general trends are the same, indicating parallel solvation changes. Collectively for the three complex cations this is in contrast to the pattern of ΔV^* values and associated solvation changes for the complex ions $[Fe(hxsbH)]^{2+}$ [9] and $[Fe(gmi)_3]^{2+}$.[10] We note here that a trend of activation volumes increasing with increasing mole fraction of organic co-solvent has recently been reported for homolysis of cobaloxime derivatives in n-propanol–water mixtures and interpreted in terms of a cage effect controlled by solvent structural effects.[29]

The large effect of t-butyl alcohol is not restricted to the bsb-type complexes. The terdentate ligand Me_2tsb forms a bidentate complex with iron(II); the kinetics of base hydrolysis of this complex over a range of pressures yield ΔV^* values of $+6$ and $+18$ cm^3 mol^{-1}, respectively, in water and in 17% t-butyl alcohol. The difference in ΔV^* values, considering the quantities for 17% t-butyl alcohol and water solution, are very similar for the complexes of Me_2bsb and Me_2tsb. In each case $\Delta(\Delta V^*)$ is *ca* 13 cm^3 mol^{-1}, which is a reflection of the similar lipophilic exteriors of the complex ions.

What is now really needed for a fuller understanding of the trends discussed in the preceding paragraphs is a full set of partial molar volumes for the complexes in question in the mixed solvents studied. Unfortunately, this is a major research exercise in itself, for it would be necessary to establish partial molar volumes for a number of salts in each solvent mixture before it would be possible to deduce single ion values for such reference ions as $AsPh_4^+$ and BPh_4^- and thence values for our charged iron(II) complexes.

X-RAY CRYSTAL STRUCTURE OF $InCl_3 \cdot 2THF$, A NEUTRAL FIVE-COORDINATE BIS-ADDUCT OF AN INDIUM(III) TRIHALIDE

MARK F. SELF, ANDREW T. McPHAIL and RICHARD L. WELLS*

Department of Chemistry, Paul M. Gross Chemical Laboratory, Duke University, Durham, NC 27708, U.S.A.

(*Received* 14 *September* 1992; *accepted* 20 *November* 1992)

Abstract—The 2 : 1 mole ratio reaction of $InCl_3$ and $P(SiMe_3)_3$ in a toluene/THF mixture was investigated. The reaction appears to occur in a 1 : 1 mole fashion, since the products obtained are unreacted $InCl_3$ (48.5% recovered) as $InCl_3 \cdot 2THF$ and a fine powder which appears to be $[Cl_2In_3P_3(SiMe_3)_2]_n$. The latter was characterized by melting point and partial elemental analysis. The X-ray crystal structure of $InCl_3 \cdot 2THF$ shows it to be a neutral penta-coordinated bis-adduct of an indium(III) trihalide. The crystal structure consists of discrete monomeric units with no abnormally short intermolecular separations. The geometry about the indium atom approximates to trigonal bipyramidal with oxygen atoms of each of the THF molecules occupying axial positions [In—O = 2.257(9) Å, O—In—O = 178.5(3)°], while the three chlorine atoms (mean In—Cl = 2.321 Å) lie in the equatorial plane.

For some time our laboratory has been investigating convenient and facile routes to the formation of novel compounds containing Ga—As bonds.[1] In fact, one such compound with the empirical formula $(AsCl_3Ga_2)_n$ (**I**) can be easily converted into nanocrystalline GaAs itself.[2] Compound **I** results from the 2 : 1 mole ratio reaction of $GaCl_3$ and $As(SiMe_3)_3$. In related work, Barron and co-workers recently reported that the 1 : 1 mole ratio reaction of $InCl_3$ and $P(SiMe_3)_3$ at low temperature yields $[Cl_2InP(SiMe_3)_2]_x$ (**II**).[3] In that we have now begun to direct considerable attention to the production of compounds containing In—P bonds,[4–7] it was decided that the In/P analogue of the reaction leading to the formation of **I** should be investigated [i.e. the 2 : 1 reaction of $InCl_3$ and $P(SiMe_3)_3$], the goal being the possible isolation of the new precursor $(PCl_3In_2)_n$. We report that although the 2 : 1 reaction of $GaCl_3$ and $As(SiMe_3)_3$ to produce **I** occurs cleanly and readily, the corresponding reaction of $InCl_3$ and $P(SiMe_3)_3$ affords $[Cl_2In_3P_3(SiMe_3)_2]_n$ (**III**) and unreacted $InCl_3$ (48.5% of the starting $InCl_3$) in a solvated form [$InCl_3 \cdot 2THF$ (**IV**)]. Compound **III** (characterized by melting point and partial elemental analysis) was isolated as a relatively unreactive fine orange powder. It is insoluble in hydrocarbon solvents, THF and Et_2O and air-stable for several hours at room temperature. Complex **IV** has been previously synthesized and quite extensively characterized by Fairbrother *et al.*,[8] but no solid-state structure was ever obtained. Herein, we report the crystal structure of **IV** as it represents a novel example of a neutral penta-coordinated bis-adduct of an indium (III) trihalide.

EXPERIMENTAL

Synthesis

All manipulations were performed using general Schlenk techniques. Colourless crystals of **IV** were obtained by the 2 : 1 mole reaction of $P(SiMe_3)_3$[9] and $InCl_3$ (purchased from Strem chemicals). In the dry-box (Vacuum/Atmospheres HE-493 Dri-Lab containing an argon atmosphere) $P(SiMe_3)_3$ (0.250 g, 0.998 mmol) was dissolved in anhydrous, degassed toluene (25 cm^3; distilled from sodium/benzophenone ketyl) in a 100 cm^3 one-necked round-bottomed flask equipped with a Teflon valve and a microstir-bar. A suspension of $InCl_3$ (0.441

* Author to whom correspondence should be addressed.

g, 1.99 mmol) in toluene (15 cm^3) and anhydrous, degassed THF (15 cm^3) (distilled from sodium/benzophenone ketyl) was slowly added dropwise. Immediately upon addition the reaction mixture became yellow–orange and quite turbid. The reaction mixture was stirred at room temperature for 2 days and then allowed to settle undisturbed for 1 day. Decantation of the colourless mother liquor from the bright orange powder gave $[Cl_2In_3P_3(SiMe_3)_2]_n$ (**III**), 0.204 g, 47% yield based on In; m.p. = 200–260°C (dec. to black). Found: C, 11.4, 11.6; H, 2.6, 2.5; Cl, 10.7, 10.9. Calc. for $C_6H_{18}Cl_2In_3P_3Si_2$: C, 11.0; H, 2.7; Cl, 10.8%. Subsequent cooling at −15°C for 3 days afforded crystals of **IV** (0.352 g, 48.5% yield based on In), suitable for X-ray analysis.

X-ray structural solution and refinement

Crystallographic data are summarized in Table 1. The crystal used was a colourless block mounted inside a flame-sealed 0.6 mm thin-walled glass capillary under an inert argon atmosphere. Oscillation and Weissenberg photographs yielded preliminary unit cell parameters and space group information. X-ray intensity data were recorded on an Enraf–Nonius CAD-4 diffractometer at 25°C using graphite-monochromated Cu-K_α radiation (λ = 1.5418 Å). Lorentz and polarization corrections were applied, as was an empirical absorption correction. The crystal structure was solved by direct methods. Initial coordinates for the indium and chlorine atoms were derived from an *E*-map. Carbon and oxygen atoms were located in a difference-Fourier synthesis phased by these atoms. Several rounds of full-matrix least-squares adjustment of non-hydrogen atom positional and thermal parameters (at first isotropic, then anisotropic) followed. Hydrogen atoms were incorporated at their calculated positions (C—H = 1.05 Å) in the later iterations which converged (max. shift: e.s.d. = 0.02) at R = 0.042 (R_w = 0.058). A final difference-Fourier synthesis revealed no unusual features (max. 0.56, min. −0.41 e $Å^{-3}$, both in the vicinity of the indium atom). Crystallographic calculations were performed using the Enraf–Nonius Structure Deter-

[a] Primed atoms are related to unprimed atoms by the following transformation: $-x, y, 1/2-z$.

mination Package (SDP).[10] For all structure-factor calculations, neutral atom scattering factors and their anomalous dispersion corrections were taken from ref. 11. Selected distances and angles are provided in Table 2. An ORTEP diagram showing the atom labelling scheme and solid-state conformation of **IV** is presented in Fig. 1; the packing arrangement of molecules of **IV** in the crystal is illustrated in Fig. 2. Full information concerning conditions for crystallographic data collection and structure refinement, atomic coordinates, positional parameters, anisotropic thermal parameters and observed and calculated structure factors have been deposited with the Cambridge Crystallographic Data Centre.

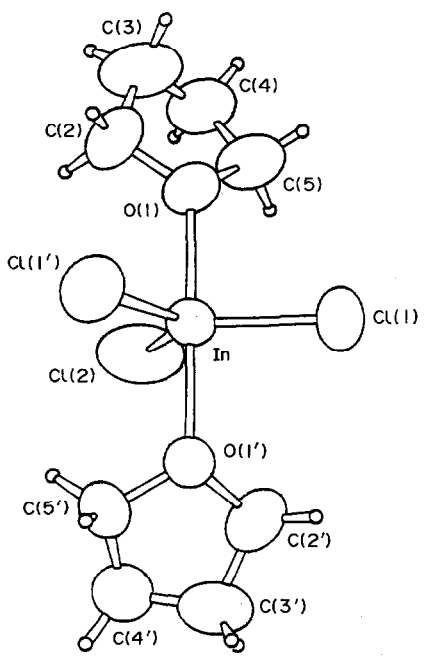

Fig. 1. ORTEP diagram (50% probability ellipsoids) showing the atom numbering scheme and solid-state conformation of $InCl_3 \cdot 2THF$ (**IV**); primed atoms are related to the unprimed atoms by a crystallographic C_2 symmetry axis passing through In and Cl(2). Small circles represent hydrogen atoms.

RESULTS AND DISCUSSION

Although the structural chemistry of five-coordinate aluminum and gallium compounds has been well examined, corresponding investigations of such indium compounds have remained more sparse.[12] Currently, there are seven penta-coordinate indium(III) trihalide bis-adducts which have been crystallographically characterized [viz. $InX_3 \cdot L_2$: X = Cl; L = PPh_3 (**V**),[13] HMPA ($OP\{N(Me)_2\}_3$) (**VI**),[14] NMe_3 (**VII**),[15] $SPMe_3$ (**VIII**),[16] $SAsMe_3$ (**IX**)[16]; X = Br; L = $SPMe_3$ (**X**),[16] $SAsMe_3$ (**XI**)[16]]. Of these, it is interesting to note that five (**VII–XI**) were only reported within the last 6 years and **IV** is only the second such compound containing In—O bonds to be structurally characterized, the first being **VI**.

The crystal structure of **IV** consists of discrete monomeric units which have one of their In—Cl bonds lying on a crystallographic C_2 symmetry axis (see Fig. 1). In common with the other $InX_3 \cdot L_2$ adducts, the coordination geometry about the indium atoms is trigonal-bipyramidal with three chlorine atoms defining the equatorial plane and the oxygen atoms of the THF molecules occupying the axial sites. The O—In—O angle at 178.5(3)° in **IV** deviates only slightly from an exactly linear value

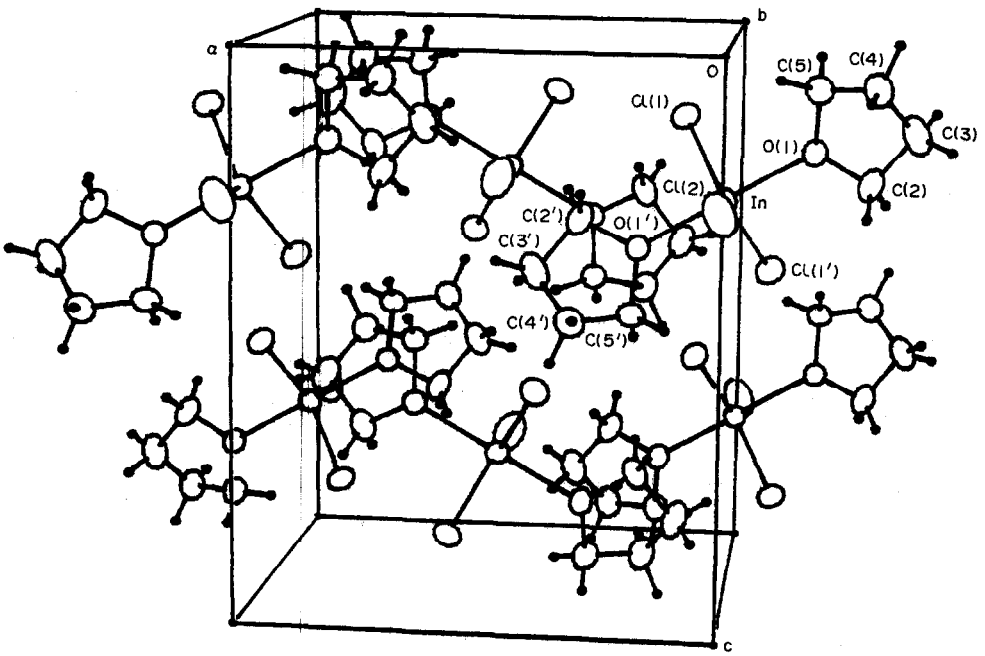

Fig. 2. Packing arrangement of molecules of $InCl_3 \cdot 2THF$ (**IV**) in the crystal.

and lies close to that of 178.0(2)° in **VI**. The In—O bond length of 2.257(9) Å in **IV** is significantly longer and thus weaker than the corresponding bonds in **VI**, where they average 2.180 Å; this difference may be ascribed to the increased electron-donating ability of the oxygen atom in the HMPA ligand. The mean In—Cl bond length at 2.321 Å in **IV** is shorter than that of 2.359 Å in **VI**, as well as the corresponding lengths of 2.360–2.412 Å in **V** and **VII–IX**. The observed decrease in the equatorial bond lengths in **IV** vs **VI** is correlated with the aforementioned lengthened axial bond distance in the former. Endocyclic torsion angles characterizing the conformation of the THF molecule are related by an approximate C_2 symmetry axis which passes through the oxygen atom and the mid-point of the C(3)—C(4) bond, and, accordingly, this ring is in a half-chair conformation. The mean bond angle subtended at the oxygen atom is 118° and thus the geometry about this atom lies closer to trigonal planar than to tetrahedral. X-ray crystallographic studies[16] on the series $InX_3 \cdot L_2$ (X = Cl, Br; L = $SPMe_3$, $SAsMe_3$) have shown that in the solid state the angle subtended at the axial sulphur atom is dependent on intermolecular as well as intramolecular non-bonded interactions. The orientation of the In—O bond with respect to the THF ring in crystals of **IV** produces no unusually short intramolecular Cl···H non-bonded distances (min. Cl···H = 3.29 Å). Crystal packing requirements involving two equidistant intermolecular interactions between Cl(2) in the reference molecule and one of the hydrogen atoms at C(2) in neighbouring molecules [Cl(2)···H(2) = 2.87 Å] apparently dictate the geometry at the oxygen atom in the solid state.

SINDO STUDIES OF $[M(CN)_5CO]^{n-}$ COMPLEX IONS FOR M = IRON, MANGANESE AND CHROMIUM

EWA WASIELEWSKA† and ELWIRA ILKOWSKA

Faculty of Chemistry, Jagiellonian University, ul. Ingardena 3, 30 060 Kraków, Poland

(*Received* 10 *November* 1992; *accepted* 16 *November* 1992)

Abstract—SINDO type calculations were performed for $[M(CN)_5CO]^{n-}$ complexes (where M = Fe, Mn or Cr) in different oxidation states. The results seem to predict that $[Mn^{II}(CN)_5CO]^{3-}$ and $[Cr^{II}(CN)_5CO]^{3-}$ could be synthesized as thermally stable complex ions, besides $[Fe^{II}(CN)_5CO]^{3-}$ which is already known. On the basis of the results of the calculations the changes in properties of the CO molecule upon coordination are discussed.

The hexacyano complexes of iron, manganese and chromium form an interesting group of compounds which have been studied extensively, both experimentally and theoretically.[1–3] Also several complexes of the $[M(CN)_5NO]^{n-}$ type, in which the CN^- ligand is replaced by the isoelectronic NO^+ molecule, are known and well characterized.[4] On the contrary only one example of carbonylpentacyanometallates has been reported as a stable complex, namely $[Fe^{II}(CN)_5CO]^{3-}$ [5,6] (also $[Fe(CN)_5CO]^{2-}$ could be observed but only within minutes[7]). The existence of more compounds of the type $[M(CN)_5CO]^{n-}$ should be expected on the basis of the properties of the CO group, which has intermediate acceptor properties between isoelectronic molecules CN^- and NO^+.[8] The intermediate character of the CO ligand should result in the $[M(CN)_5CO]^{1-n}$ properties being intermediate between those of $[M(CN)_6]^{n-}$ and $[M(CN)_5NO]^{2-n}$.

In order to confirm these expectations we decided to undertake a theoretical study of the properties of carbonylpentacyano complexes of iron, manganese and chromium in different oxidation states. There have been no such calculations reported in the literature until now. The calculations were performed by means of the SINDO method which has proven to give reasonable results for different cyano and mixed cyano complexes. On the basis of the SINDO method the influence of the central atom and its oxidation state on physical properties as well as the thermal reactivity of $[M(CN)_5NO]^{n-}$ complexes has been explained.[4–9] The characteristics of the excited states obtained by the SINDO method has enabled the photochemical behaviour of $[Fe(CN)_5NO]^{2-}$, $[Fe(CN)_6]^{4-}$ and $[Cr(CN)_6]^{3-}$ complexes to be interpreted.[10–12]

METHOD AND DETAILS OF CALCULATIONS

SINDO[13] is a scaled version of the INDO method with integrals depending on the actual charge and configuration of the constituent atoms. Two centre electron repulsion integrals are approximated using Ohno's formula. As far as the electronic structure is concerned there are no parameters of molecular origin in this treatment. Core–core repulsion terms on the other hand, which are estimated by a method taken from the MINDO/2 procedure, require such parameters. For pairs of ligand atoms they have been estimated from experimental bond energies and bond lengths of simple diatomic molecules.[9] Due to the lack of appropriate experimental data the estimation of parameters for metal–ligand core–core repulsion terms was not unequivocal.

The bond lengths for which actual calculations have been performed have been chosen on the basis of the trends in the changes of the strength of metal–ligand bonds accompanying the substitution of the CN^- ligand by a CO molecule with fixed geometry. Two centre contributions to the total energy with one centre referring to the metal atom and the other to the atoms of the ligand, together with the bond order, have been selected here as the indices characterizing the bond strength. The results

Table 1. Comparison of M—CO and M—CN bonds in $[M(CN)_5CO]^{n-}$ complexes; p^{π} denotes π-electronic bond order and E^{cov}_{A-B} is the covalent diatomic contribution to the total energy (in eV)

	$[Fe(CN)_5CO]^{3-}$	$[Mn(CN)_5CO]^{4-}$	$[Cr(CN)_5CO]^{5-}$
p^{π}_{M-CO}	1.492	1.626	1.636
E^{cov}_{M-CO}	−45.34	−43.71	−41.16
$p^{\pi}_{M-CN_{eq}}$	0.905	1.009	1.060
$E^{cov}_{M-CN_{eq}}$	−41.99	−39.49	−37.04
$p^{\pi}_{M-CN_{ax}}$	0.864	0.924	0.926
$E^{cov}_{M-CN_{ax}}$	−41.84	−38.94	−36.10

of the calculations for the isoelectronic series $[Fe(CN)_5CO]^{3-}$, $[Mn(CN)_5CO]^{4-}$ and $[Cr(CN)_5CO]^{5-}$ are presented in Table 1. In this table p^{π} contribution to the bond order and the sum of the covalent diatomic contribution to the total energy for the metal —CO ligand, equatorial CN^- and axial CN^- ligand are listed. It is clear from Table 1 that both these indicies for M—CO are always significantly different from those characteristic for M—CN bonds, whereas the differences between axial and equatorial M—CN fragments are small. On the other hand it can be shown that the influence of iron oxidation states as well as ligand substitution on the Fe—CN bond strength is insignificant (compare, for example, the values of p^{π}_{Fe-CN} equal to 0.998 and 0.924 eV and E^{cov}_{Fe-CN} equal to −42.44 and −42.12 eV, respectively, for $[Fe^{II}(CN)_6]^{4-}$ and $[Fe^{III}(CN)_6]^{3-}$). This behaviour of the CN^- ligand is consistent with the experimental data. According to the X-ray measurements the Fe—CN bond length is equal to 1.93 for $[Fe^{II}(CN)_6]^{4-}$ and 1.95 Å for $[Fe^{III}(CN)_6]^{3-}$. The experimental data for $[Fe^{II}(CN)_5CO]^{3-}$ are not known, but the length of Fe—CN bonds in $[Fe^{II}(CN)_5NO]^{2-}$ is only 0.03 Å shorter than in $[Fe(CN)_6]^{4-}$. As NO^+ is an even stronger acceptor than the CO molecule one can expect that also in the $[Fe(CN)_5CO]^{3-}$ complex the Fe—CN bond length should not change very much. Consequently, we fixed the M—CN bond lengths equal to the experimentally known value for appropriate hexacyanometallates in all calculations.

The same procedure could not be applied to the M—CO bond length. In each case we performed a series of calculations in which the M—CO distance was varied from the smallest value, equal to the M—NO distance in $[M(CN)_5NO]^{2-n}$, to the largest value, equal to the experimentally observed M—CN bond length in $[M(CN)_6]^{n-}$. In Table 2 the properties of the CO ligand in the case of $[Fe(CN)_5CO]^{3-}$ are listed and compared with those obtained for the free CO molecule. Here the results are given for two selected values of Fe—CO bond lengths, where 1.93 Å is the Fe—CN distance in $[Fe(CN)_6]^{4-}$ and 1.63 Å is the Fe—NO distance in $[Fe(CN)_5NO]^{2-}$. These results were obtained for R(C—O) kept constant at 1.13 Å, characteristic for the free molecule. We have also made calculations for the intermediate values of the distance and we

Table 2. Characteristics of free CO against coordinated to the $[Fe^{II}(CN)_5]^{3-}$ moiety; q_x denotes here net charge on X, p = appropriate bond orders, E^{cov}_{C-O} = covalent diatomic contribution and E^{tot}_{C-O} = full diatomic contribution to the total energy (in eV)

	CO	$[Fe(CN)_5CO]^{3-}$	$[Fe(CN)_5CO]^{3-}$
R (Fe—C) (Å)		1.93	1.63
q_C	0.448	0.795	0.712
q_O	−0.448	−0.803	−0.903
q_{CO}	0.0	−0.008	−0.191
p^{σ}_{C-O}	1.791	1.890	1.900
p^{π}_{C-O}	1.565	1.040	0.830
E^{cov}_{C-O}	−70.62	−64.28	−61.70
E^{tot}_{C-O}	−71.14	−68.23	−66.29

have found that the properties changed only gradually in this range. From the analysis of the results given in Table 2 the following conclusions may be drawn. The bond strength within CO decreases upon coordination, which is illustrated by bond order and energetical parameters. This decrease comes mainly from the π-contribution, which can be seen from the large changes in p^{π}_{CO} values in contrast to the values of p^{σ}_{CO}. This result is consistent with the experiment which gives the frequencies ν_{CO} in the $[Fe(CN)_5CO]^{3-}$ ion *ca* 160 cm^{-1} smaller than in the free molecule.[6] The polarization in the CO bond increases upon coordination and on decreasing the distance between the CO ligand and the metal atom. The charge transfer from the central atom to the CO ligand is larger for the smaller distances. These properties suggest that for the complexes studied here the Fe—CO distance should be smaller than for Fe—CN, whereas the carbon–oxygen distance should be greater than that in the free molecule.

Finally, we assume the Fe—CO bond to be shorter by 0.1 Å than the Fe—CN bond and the CO distance equal to 1.16 Å for all $[Fe(CN)_5CO]^{n-}$ complexes. The same geometrical parameters for the M—CO fragment in other complexes under consideration were selected by analogy. Nevertheless, the additional calculations for slightly different geometries were performed in order to check the validity of this assumption. The results have shown that the small variation of the M—C—O geometry does not influence the general conclusions.

DISCUSSION

Carbonylpentacyano complexes of iron

$[Fe^{II}(CN)_5CO]^{3-}$. Electronic features of the carbonylpentacyanoferrates studied are listed in Table 3. The ground state configuration for $[Fe(CN)_5CO]^{3-}$ is $2b_2^2 8e^4$, the same as for the isoelectronic $[Fe(CN)_5NO]^{2-}$ complex. The two highest occupied molecular orbitals lie very close in energy, −5.74 and −5.32 eV, respectively. The LUMO orbital is that of 9*e* symmetry, again in full accordance with the electronic structure of the $[Fe(CN)_5NO]^{3-}$ ion. Ligand π^* orbitals contribute significantly to all discussed frontier orbitals. Orbital $2b_2$ is a mixture of metal *d* (58%) and π^*CN (42%) orbitals. In both orbitals of *e* symmetry π^*CO also plays an important role. Its contribution (bonding) to the 8*e* orbital is equal to 13%, whereas in the 9*e* orbital the contribution is as high as 72% and it is antibonding. The energies of the HOMO and LUMO orbitals decrease in the isoelectronic series: $[Fe^{II}(CN)_6]^{4-} > [Fe^{II}(CN)_5CO]^{3-} > [Fe^{II}(CN)_5NO]^{2-}$. This tendency explains the experimentally observed redox properties in this series. $[Fe(CN)_6]^{4-}$, with the highest HOMO energies (close to 0.0 eV), is indeed known as a reducer. On the other hand the oxidative properties of the $[Fe(CN)_5NO]^{2-}$ complex may be explained on the basis of the value of the LUMO energy (−10.86 eV), which is the lowest in the series. The intermediate complex $[Fe(CN)_5CO]^{3-}$ should not easily undergo redox reactions since its HOMO energy is

too low and LUMO energy too high to facilitate appropriate electron loss or gain.

$[Fe^{III}(CN)_5CO]^{2-}$. The highest occupied orbitals in the case of $[Fe(CN)_5CO]^{3-}$ are closely distributed and it was not clear from which of them one electron should be removed in the oxidation process, thus a series of calculations was performed. The configuration $8e^4 2b_2^1$ appears to be the most favourable (see Table 3), independently of the assumed bond distances. The oxidation of $[Fe(CN)_5CO]^{3-}$ results in a decrease of electron density, mainly of the iron atom ($\Delta q = +0.287$) and CO ligand ($\Delta q = +0.289$), leading even to a positive charge in the latter. This is accompanied by the strengthening of CO and weakening of Fe—CO bonds. Iron–cyano bonds both in axial and equatorial positions are influenced only slightly. The low orbital energy (−4.66 eV) of the semi-occupied $2b_2$ orbital should facilitate reduction of the complex. Moreover, the positive charge on the CO group, together with a small positive value of LUMO energy and a large contribution of π^*CO (85%), should lead to great susceptibility towards nucleophilic attack. The expected high reactivity of the $[Fe(CN)_5NO]^{2-}$ ion is confirmed by experiment and this species is observed only as a short lived moiety.[7]

$[Fe^{I}(CN)_5CO)]^{4-}$. The ground state configuration of this complex has been established as $2b_2^2 8e^4 9e^1$ (Table 3). The ground state energy term is the double degenerate ^{2}E one. We can expect that the geometrical structure of $[Fe(CN)_5CO]^{4-}$ would be unstable. The reduction of $[Fe(CN)_5CO]^{3-}$ results in a great increase in electron density on the CO ligand, and simultaneously the Fe—CO bond undergoes considerable weakening. The complex should behave as a stronger reducer than $[Fe(CN)_6]^{4-}$ due to the considerable negative charge on the CO group ($q = -0.561$), high positive energy of the $9e$ orbital with one unpaired electron (+9.47 eV) and significant decrease in the total energy of the complex caused by one-electron oxidation ($\Delta E = -13.28$ eV). All these factors lead to the conclusion that the probability of the existence of $[Fe^{I}(CN)_5CO]^{4-}$ is very low.

Carbonylpentacyano complexes of manganese and chromium

The results of calculations for $[Mn(CN)_5CO]^{n-}$ and $[Cr(CN)_5CO]^{n-}$ complexes are gathered in Tables 4 and 5. The complexes which are isoelectronic with $[Fe^{II}(CN)_5CO]^{3-}$ are $[Mn^{I}(CN)_5CO]^{4-}$ and $[Cr^{0}(CN)_5CO]^{5-}$, respectively. The ground state of both these complexes is again $2b_2^2 8e^4$. The negative net charge on the CO group increases in the series Fe < Mn < Cr. The same trend is observed for the HOMO orbital energies. This ability to change electronic properties leads to the conclusion that the $[Mn(CN)_5CO]^{4-}$ complex should be more active in oxidation reactions than the $[Fe(CN)_5CO]^{3-}$ ion. The $[Cr(CN)_5CO]^{5-}$ complex is expected to be an extremely strong reducer (note the values of $q_{CO} = -0.619$ and $\varepsilon_{HOMO} = +14.73$ eV). Significant lowering of the total energy which follows one-electron oxidation fully supports this conclusion ($\Delta E = -15$ eV).

In the case of the manganese complex we have studied its oxidized and reduced form. Similarly, as in the case of iron complexes, their ground state configurations are $8e^4 2b_2^1$ and $2b_2^2 8e^4 9e^1$, respec-

ΔE	−15.00	−10.00	−5.18

tively. The trends in the changes of electronic structure factors caused by oxidation/reduction are the same as for iron complexes. Nevertheless, for $[Mn^{II}(CN)_5CO]^{3-}$ no oxidative properties can be expected. It remains a weak reducer ($q_{CO} = -0.155$). However, the reduced form $[Mn(CN)_5CO]^{5-}$ should be very active in redox reactions with even stronger reducing properties than $[Fe(CN)_5CO]^{4-}$ ($q_{CO} = -0.795$, $\varepsilon_{HOMO} = +13.88$ eV, $\Delta E = -18.77$ eV).

The isoelectronic species to the iron(II) complex is the $[Cr^0(CN)_5CO]^{5-}$ ion so only its oxidized forms have been taken into account. $[Cr^I(CN)_5CO]^{4-}$ can be expected to exhibit fairly strong reducing properties, which together with an unstable ground state configuration seem to indicate that this complex should not be observed experimentally. The ground state configuration of the $[Cr^{II}(CN)_5CO]^{3-}$ complex is $8e^4$. The net charge on the CO ligand ($q = -0.266$) and the HOMO orbital energy ($\varepsilon = -3.88$ eV) enable this complex to show at least mild reducing behaviour.

On the basis of the results discussed some general conclusions regarding the relative thermal stabilities of carbonylpentacyano complexes of iron, manganese and chromium can be drawn. Obviously the most stable complex should be $[Fe^{II}(CN)_5CO]^{3-}$, which is indeed observed experimentally. Its oxidized form, $[Fe^{III}(CN)_5CO]^{2-}$, may be expected to be the only oxidant within the studied compounds. The weak reducing properties and stable electronic configurations of $[Mn^{II}(CN)_5CO]^{3-}$ and $[Cr^{II}(CN)_5CO]^{3-}$ suggest that these complexes could be the next candidates for a successful synthesis.

REACTIONS OF LANTHANIDE NITRATES WITH DIMETHYLBENZOYLPHOSPHONATE

ANDREW W. G. PLATT

Chemistry Division, Staffordshire University, College Road, Stoke-on-Trent ST4 2DE, U.K.

(*Received* 30 *September* 1992; *accepted* 6 *November* 1992)

Abstract—The reactions between lanthanide nitrates and $(MeO)_2P(:O)C(:O)Ph$ in methanol have been studied. The products of the reaction are $(MeO)_2P(:O)H$, $[(MeO)_2P(:O)]_2C(OH)Ph$ and $PhC(:O)OMe$. At high concentrations of reactants the complexes $Ln(NO_3)_3\{[(MeO)_2P(:O)]_2C(OH)Ph\}_2$ are formed (Ln = La, Ce) whilst loss of nitrate occurs for the heavier metals giving $Ln(PO_4)\{(MeO)_2P(:O)H\}_2 \cdot H_2O$ (Ln = Yb). The kinetics of the reaction in dilute solution have been studied and a mechanism proposed. Derivation of a rate equation from the full mechanism is not possible but the kinetics data have been fitted to an approximate expression and the results compared with first order analysis. Supporting evidence for the proposed mechanism (mainly ^{31}P NMR spectroscopy) is also presented.

Alpha ketophosphonates readily undergo acid or base catalysed cleavage of the P—C bond[1–3] and calculations suggest that protonation of the phosphoryl oxygen is followed by P—C bond breaking with zero activation energy.[4] Complex formation with metals might be considered to be analogous to protonation, and indeed catalytic decomposition of α-ketophosphonates by Lewis acids has been mentioned but no details were reported.[4] Despite this there are several reports of stable complexes being formed between α-ketophosphonates and metals in both aprotic[5] and protic systems.[6,7] We report here studies on the reactions between lanthanide nitrates and dimethylbenzoylphosphonate, $(MeO)_2P(:O)C(:O)Ph$, in methanol.

RESULTS AND DISCUSSION

Attempts to prepare lanthanide nitrate complexes with dimethylbenzoyl phosphonate (**1**) were not successful. On reaction with lanthanide nitrates, $Ln(NO_3)_3$ (Ln = La, Ce, Pr, Dy, Er and Yb), in warm methanol the yellow colour of **1** was rapidly discharged. On cooling the new complexes **2** crystallized, where Ln = La or Ce.

$$Ln(NO_3)_3[\{(MeO)_2P(:O)\}_2C(OH)Ph]_2$$

2

2a Ln = La

2b Ln = Ce

The complexes were characterized by elemental analysis and IR spectroscopy, which showed strong bands consistent with the presence of bidentate nitrate groups at 1450 and1385 cm^{-1},[8–10] and a strong absorption at 1210 cm^{-1} due to the coordinated PO group. There were no bands attributable to the CO group of the original phosphonate. The complexes were insoluble in all common organic solvents, but did dissolve in water with decomposition to give the free ligand in solution.

Cerium(III) nitrate reacted in an identical manner. Both dysprosium and ytterbium nitrates caused rapid decolourization of the solutions giving the same phosphorus containing products (^{31}P NMR evidence). However, no dysprosium or ytterbium complexes analogous to **2** could be crystallized from solution. In the case of dysprosium no solid material could be obtained, whilst reduction of the solvent by slow evaporation of the ytterbium nitrate solution produced an amorphous solid whose IR spectrum indicated the presence of coordinated phosphite [ν(PH) 2415 cm^{-1} compared with 2440 cm^{-1} for dimethylphosphite] and phosphate groups, with no bands attributable to nitrate. This was supported by elemental analysis, which gave an approximate composition of $Yb(PO_4) \cdot [(MeO)_2P(:O)H]_2 \cdot H_2O$.

The reaction can be conveniently monitored in dilute solution by ^{31}P NMR spectroscopy, as shown in the case of lanthanum nitrate in Fig. 1. In lanthanum nitrate solution (10 mmol dm^{-3}) spectra

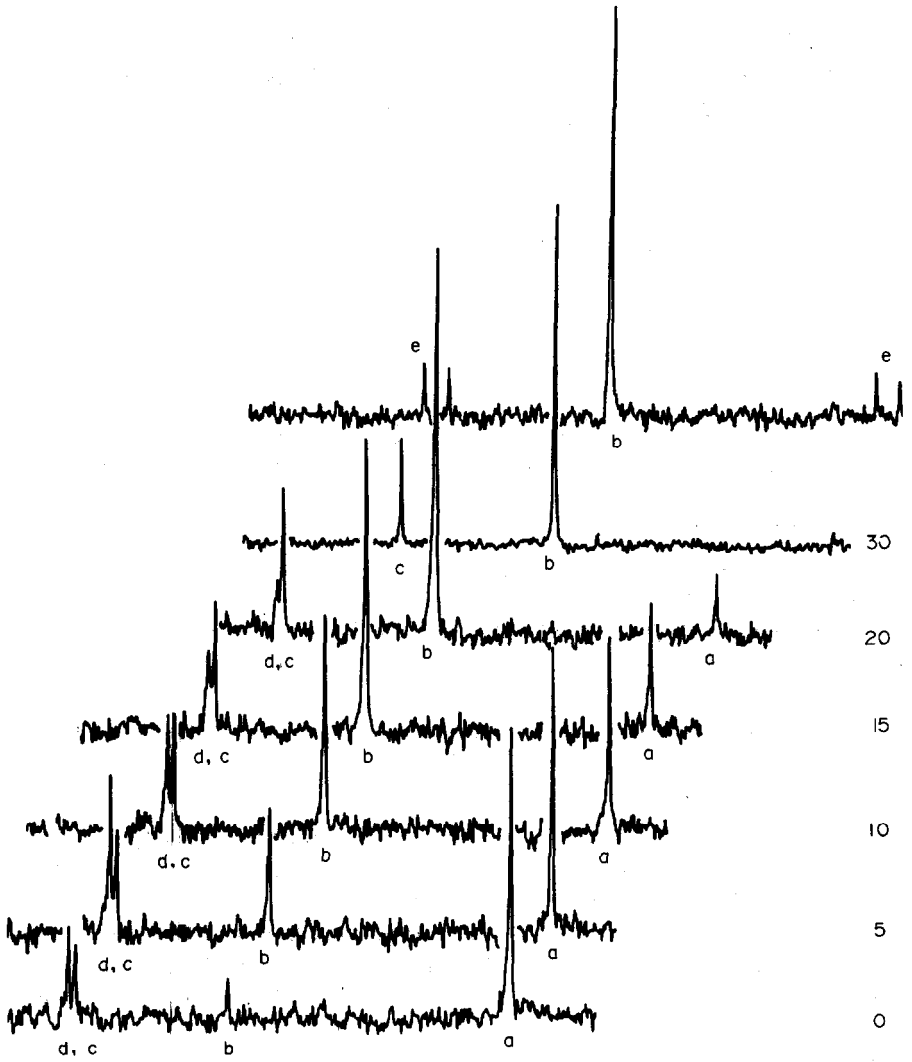

Fig. 1. ^{31}P NMR spectra taken from the reaction between $La(NO_3)_3$ (10 mmol dm^{-3}) and $(MeO)_2P(:O)C(:O)Ph$ in methanol as a function of time (min). The top trace is for the reaction mixture after the addition of a trace of triethylamine. Key: a = $(MeO)_2P(:O)C(:O)Ph$, b = $(MeO)_2P(:O)H$, c = $[(MeO)_2P(:O)]_2C(OH)Ph$, d = $(MeO)_2P(:O)C(OH)(OMe)Ph$, e = $(MeO)_2P(:O)OCH(Ph)P(:O)(OMe)_2$.

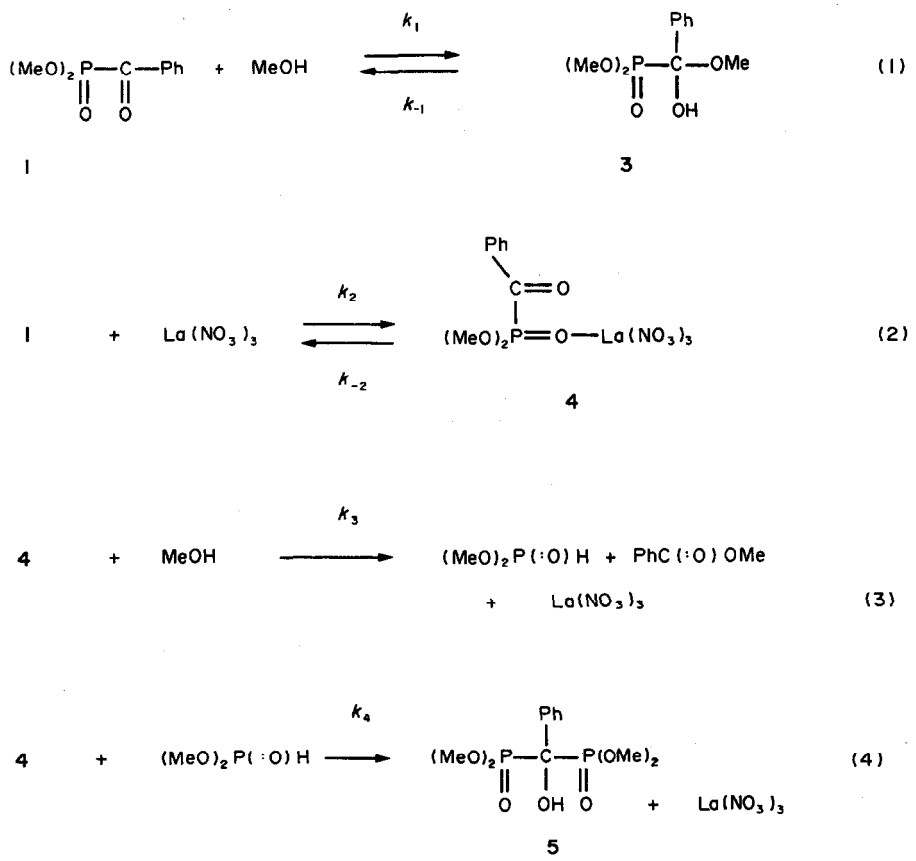
show that in the initial stages of the reaction the products are dimethylphosphite, the methanol adduct of the original phosphonate, $(MeO)_2P(:O)C(OH)(OMe)Ph$, and $[(MeO)_2P(:O)]_2C(OH)Ph$, formed by reaction between dimethylphosphite and the dimethylbenzoyl phosphonate. At the end of the reaction dimethylphosphite and the diphosphonate are the only phosphorus containing species. The identity of $[(MeO)_2P(:O)]_2C(OH)Ph$ was confirmed by its isomerization by either heating or by adding traces of triethylamine to the mixed phosphate–phosphonate $(MeO)_2P(O)OCH(Ph)P(O)(OMe)_2$,[11] which exhibits two characteristic doublets at δ 19.8 and 0.7 ppm, $^3J(PP)$ 33 Hz (see Fig. 1, signals "e"). A possible mechanism for the solvolysis of the phosphonate **1** in dilute solution is shown in Scheme 1.

The following observations support this mechanism.

(1) Reaction (1) can be observed independently by electronic spectroscopy and ^{31}P NMR spectroscopy, which shows the gradual appearance of a resonance at 18.0 ppm assigned to **3**, in addition to that of **1** at 0.3 ppm. The assignment to **3** is in good agreement with the value of 17.9 quoted for the corresponding hydrate.[1] First order kinetics were observed for this reaction with the rate coefficient corresponding to k_1+k_{-1}.

(2) Complex **4** could not be observed in solutions containing lanthanum nitrate and **1** by either NMR



Scheme 1.

or UV–vis spectroscopy, which implies that it is only present in low concentration. The fact that coordination of $(MeO)_2P(:O)C(:O)Ph$ to the metal [eq. (2)] is important in the decomposition was demonstrated by the reduced rate of solvolysis in the presence of O-dimethyl-methylphosphonate, $(MeO)_2MeP(:O)$, and when the complex $Lu(NO_3)_3\{(EtO)_2P(:O)CH_2C(:O)OEt)_2$[12] was used instead of lanthanum nitrate. In both these instances there would be increased competition for the coordination sphere of the metal.

(3) In step (3) the cleavage of the P—C bond could be brought about by reaction with methanol or possibly water coordinated to the lanthanide (hydrated salts were used throughout). The reaction carried out in CH_3OD shows unambiguously that $(MeO)_2P(:O)D$ [δ 11.2 ppm, $^1J(PD) = 108$ Hz; lit. δ 11.2 ppm, $^1J(PD) = 107$ Hz[13]] is the major product. Methylbenzoate was detected by gas chromatography of the reaction mixture.

(4) The phosphonate **1** does not react with dimethylphosphite in methanol in the absence of lanthanum nitrate. Thus, it seems reasonable to suppose that reaction (4) in the scheme is the likely route to the formation of the diphosphonate **5**.

Kinetic studies were carried out by monitoring the n–π^* transition at 365 nm. This band was chosen rather than the more sensitive π–π^* band due to the fact that nitrate and the aromatic containing products absorb in this region in addition to **1**.

Analysis of the data as a pseudo-first-order process gave reasonable fits with experimental data, as indicated in Table 1. However, the experimental data points appear to oscillate about the best-fit line rather than give a random scatter. An example is shown in Fig. 2, which shows the residuals (calculated minus observed absorbances) as a function of time. This is compared with the residuals from fitting the same data to eq. (1) (see below).

Full analysis of the scheme, assuming a steady-state approximation for complex **4**, leads to a set of differential equations which cannot be solved analytically to give an expression for C_1. However, if it is assumed that, as a first approximation, reaction (4) is of minor importance [the ratio of diphosphonate (**5**) to dimethylphosphite in the reaction mixture at completion was approximately 1 : 5, as measured by ^{31}P NMR spectroscopy in the presence of chromium trisacetylacetonate as a relaxation reagent] then the analysis gives the simultaneous differential equations:

$$DC_1 = -aC_1 + bC_3$$

$$DC_3 = dC_1 - bC_3,$$

Table 1. Results of the analysis of kinetic data for the hydrolysis of **1** catalysed by lanthanum nitrate in methanol

$[La(NO_3)_3]$ (mmol dm^{-3})	k_{obs} (min^{-1})[a]	Sum of squares[b]	$x(1)$[c]	Sum of squares[b]
10.8	0.165	6.0	0.250	18.0

1.3	0.061	5.4	0.058	3.8
0.0	0.015[d]	0.1		

[a] Values obtained from first-order analysis.
[b] $\Sigma(A_{calc}-A_{obs})^2 \times 10^3$ for 30 data points.
[c] Values obtained by fitting to eq. (5).
[d] k_1+k_{-1} derived from first-order analysis.

The equilibrium constant was estimated as 0.94, giving values of $k_1 = 0.0073$ and $k_{-1} = 0.0078$ min^{-1}.

where $D = d/dt$, $a = k_1+k_2k_3C_{La}/(k_{-2}+k_3)$, $b = k_{-1}$, $d = k_1$ and C_1 and C_3 are the concentrations of **1** and **3**, and C_{La} is the concentration of lanthanum nitrate. Eliminating C_3 gives

$$[D^2+(a+b)D+(ab-bd)]C_1 = 0,$$

which can be solved to give

$$C_1 = \exp\left(-\frac{t}{2}[x(1)+2b]\right) \times \left\{x(2)\exp\left(\frac{t}{2}\sqrt{x(1)^2+4bd}\right) + x(3)\exp\left(-\frac{t}{2}\sqrt{x(1)^2+4bd}\right)\right\}+x(4), \quad (5)$$

where $x(1)$ to $x(4)$ are constants whose values are found by fitting the experimental data to eq. (5).

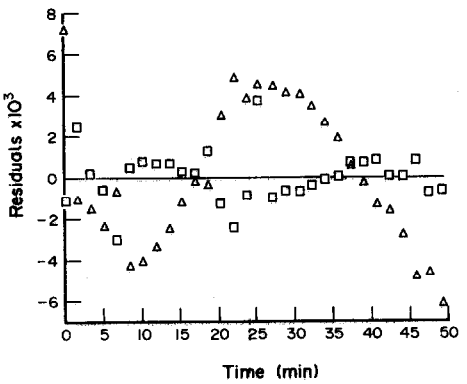

Fig. 2. Plot of the residuals, $(A_{calc}-A_{obs}) \times 10^3$, for kinetic data from the solvolysis of **1** in lanthanum nitrate (2.5 mmol dm^{-3}) fitted to a first-order equation (△) and to eq. (5) (□).

The parameter $x(1)$ corresponds to $(a-b)$. From the initial conditions the sum $x(2)+x(3)$ equals the initial concentration of phosphonate whilst $x(4)$ represents a baseline correction. In practice it was found that the sum $x(2)+x(3)+x(4)$ invariably equalled the initial absorbance value, giving some confidence that the fit to eq. (5) is chemically sensible. The results analysed by fitting to eq. (5) generally give better results than a simple first-order analysis, as indicated by a lower sum of squares, although the values of coefficients obtained are virtually the same. The fit to eq. (5) becomes progressively better as the concentration of lanthanum nitrate is decreased. Figure 2 shows that whilst the residuals are smaller than obtained from the first-order plot, there is still a periodic pattern evident.

If eqs (5) accurately represent the reaction then a plot of $x(1)$ vs C_{La} should give a straight line. A reasonable straight line ($R^2 = 0.97$) is obtained for C_{La} in the region 1–10 mmol dm^{-3}, as shown in Fig. 3. The intercept of 0.021(15) agrees fairly well with the expected value of around zero (corresponding to k_1-k_{-1}). The probable reason for the small discrepancy is the exclusion of reaction (4) in the scheme from the rate equation. The fact that the fit to eq. (5) becomes progressively worse with increasing concentration of lanthanum nitrate may be due to other reactions becoming significant at higher concentrations. One possibility is complex formation between **3** and the metal leading to P—C bond breaking. Although it is not possible to take this into account in the rate equation, some experimental evidence for the reaction can be obtained from ^{31}P NMR measurements on an equilibrated mixture of **1** and **3** in methanol. Thus, addition of small amounts of gadolinium nitrate caused pref-

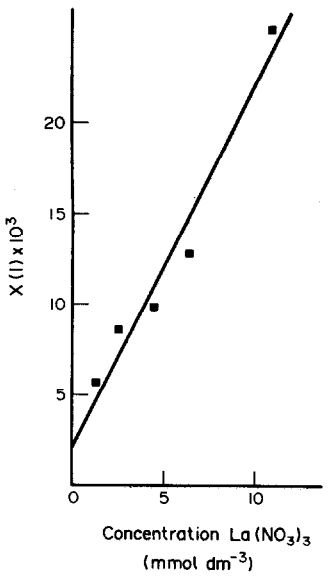

Fig. 3. Plot of $x(1)$ vs concentration of $La(NO_3)_3$.

erential broadening of the signal due to **3**, whilst that due to **1** remained relatively sharp. Also, addition of praseodynium nitrate caused a rapid decrease in the concentration of **3**, whereas the signal due to **1** decreased at a slower rate. Both these observations support the fact that **3** forms complexes with the lanthanide nitrates more readily than **1**, and that this process also leads to P—C bond breaking.

Thus, although the kinetic data cannot be used to support the proposed mechanism directly, the first three reactions in the scheme do give a reasonable approximation. The overall rate of solvolysis would indicate that steps (3) and (4) in the scheme are rate determining. The rate of complex formation is known to be of the order $10^9\ s^{-1}$ for lanthanide ions with simple monodentate ligands.[14] If this process was followed by bond breaking with zero activation energy, as proposed for the analogous protonated systems,[4] then the overall catalysis would be much more rapid. The observation that **1** does not undergo rapid solvolysis in 0.01 M $HClO_4$ in methanol and the fact that previous work has shown that the rate of hydrolysis in aqueous solution decreases with decreasing pH[1,3] indicate that the results of such calculations are not directly applicable to the chemistry in the protic solvents studied.

EXPERIMENTAL

Dimethylbenzoyl phosphonate was prepared by the reaction of trimethylphosphite with freshly distilled benzoyl chloride[11] in 89% yield.

Preparation of $Ln(NO_3)_3\{[(MeO)_2P(:O)]_2C(OH)Ph\}_2$ (**2a** *and* **2b**)

Ln = La. $La(NO_3)_3 \cdot 6H_2O$ (1 g, 2.3 mmol) was dissolved in methanol (10 cm^3) and the phosphonate (2 g, 9.3 mmol) was added. The solution was warmed to 50°C for 2 min, during which time the yellow colour of the phosphonate was discharged. The mixture was allowed to cool to room temperature and on standing crystals of the colourless complex were formed. Filtration followed by washing with ethanol and diethyl ether gave 0.51 g (22%) of **2a**. Found: C, 27.2; H, 3.8; N, 4.1. Calc.: C, 27.1; H, 3.7; N, 4.3%.

Ln = Ce. $Ce(NO_3)_3 \cdot 6H_2O$ (1 g, 2.3 mmol) was reacted as above to give the corresponding cerium complex as colourless crystals. Yield 0.5 g (22%) of **2b**. Found: C, 27.4; H, 4.0; N, 4.2. Calc.: C, 27.1; H, 3.7; N, 4.3%.

Reaction of ytterbium nitrate with **1**

$Yb(NO_3)_3 \cdot 6H_2O$ (1 g, 2.14 mmol) was allowed to react with **1** (2 g) in methanol as above. On standing for 1 week a white amorphous solid was deposited from the decolourized solution (0.5 g). Found: C, 8.8; H, 3.0. Calc.: for $Yb(PO_4)[(MeO)_2P(:O)H]_2 \cdot H_2O$: C, 9.5; H, 3.2%.

Kinetic measurements were performed using a Varian DMS 100 in cells thermostated to 25°C. Optical density data were collected over *ca* three half-lives using 30 points. For first-order kinetics the data were fitted by a non-linear least-squares program with the rate coefficient, initial and infinity absorbancies as the adjustable parameters. Data were fitted to eq. (5) using an iterative procedure by a NAG subroutine.[15] The values are averages of at least three independent runs and were reproducible to within 5%. ^{31}P NMR spectra were run on a JEOL FX90Q.

Acknowledgements—Thanks are due to Dr C. D. Adam for his invaluable assistance with the program for fitting the data to eq. (5) and to Dr J. T. Thompson for the use of the non-linear least-squares program and for valuable discussions.

FORMATION OF ISOPOLYOXOMETALLATE(VI) ANIONS IN THE REACTION BETWEEN $M(CO)_6$ (M = W, Mo) AND ACETIC ACID: X-RAY CRYSTAL STRUCTURE OF $[W_3(\mu_3\text{-}O)_2(\mu_2\eta^2\text{-}O_2CCH_3)_6(H_2O)_3]_2[W_{10}O_{32}]\cdot$SOLVENT

(*Received* 30 *September* 1992; *accepted* 4 *November* 1992)

Abstract—$W(CO)_6$ reacts with a mixture of acetic acid/acetic anhydride to give $[W_3(\mu_3\text{-}O)_2(\mu_2\eta^2\text{-}O_2CCH_3)_6(H_2O)_3](CH_3CO_2)_2$ (**1**), which was converted by $HClO_4$ to $[W_3(\mu_3\text{-}O)_2(\mu_2\eta^2\text{-}O_2CCH_3)_6(H_2O)_3](ClO_4)_2$ (**2**). Addition of CH_3CO_2Na to the above reaction mixture, and prolonged exposure of the solution to air, results in the formation of the W^{IV}/W^{VI} complex salt $[W_3(\mu_3\text{-}O)_2(\mu_2\eta^2\text{-}O_2CCH_3)_6(H_2O)_3]_2[W_{10}O_{32}]\cdot$solvent (**3**). Complex **3** was also prepared by reacting **1** with $Na_2WO_4\cdot 2H_2O$ in acetic acid, and it has been characterized by X-ray crystallography. Addition of $[CH_3(CH_2)_3]_4N(ClO_4)$ to the reaction filtrate remaining after the preparation of $[Mo_2(\mu\text{-}O_2CCH_3)_4]$ [from $Mo(CO)_6$, CH_3CO_2H and $(CH_3CO)_2O$], followed by exposure to air, gives $([CH_3(CH_2)_3]_4N)_2[Mo_6O_{19}]$ (**4**).

One of the most commonly encountered structural units in tungsten(IV) carboxylate chemistry is the bioxo-capped trinuclear cluster $[W_3(\mu_3\text{-}O)_2(\mu_2\eta^2\text{-}O_2CR)_6(H_2O)_3]^{2+}$.[1–4] The acetate dication $[W_3(\mu_3\text{-}O)_2(\mu_2\eta^2\text{-}O_2CCH_3)_6(H_2O)_3]^{2+}$ can be prepared either by the oxidation of W^0 [as $W(CO)_6$] in acetic acid/acetic anhydride[4] or by the reduction of W^{VI} (as WO_4^{2-}) with zinc in acetic anhydride.[1] These routes have led to the structurally characterized salts $[W_3(\mu_3\text{-}O)_2(\mu_2\eta^2\text{-}O_2CCH_3)_6(H_2O)_3](CF_3SO_3)_2$ and $[W_3(\mu_3\text{-}O)_2(\mu_2\eta^2\text{-}O_2CCH_3)_6(H_2O)_3][ZnBr_4]\cdot 8H_2O$, respectively.

In this paper we outline the preparation of the trinuclear tungsten(IV) acetate and perchlorate salts $[W_3(\mu_3\text{-}O)_2(\mu_2\eta^2\text{-}O_2CCH_3)_6(H_2O)_3](CH_3CO_2)_2$ (**1**) and $[W_3(\mu_3\text{-}O)_2(\mu_2\eta^2\text{-}O_2CCH_3)_6(H_2O)_3](ClO_4)_2$ (**2**), together with the synthesis and structure of the W^{IV}/W^{VI} complex salt $[W_3(\mu_3\text{-}O)_2(\mu_2\eta^2\text{-}O_2CCH_3)_6(H_2O)_3]_2[W_{10}O_{32}]\cdot$solvent (**3**). In addition, the isolation of the isopolyoxomolybdate(VI) ion $[Mo_6O_{19}]^{2-}$ from a reaction involving $Mo(CO)_6$ and acetic acid/acetic anhydride is also discussed.

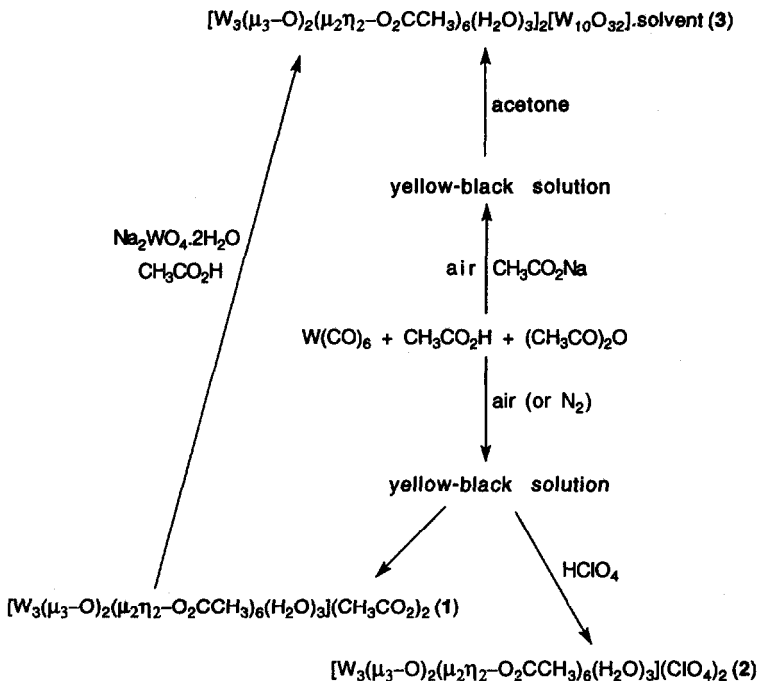
RESULTS AND DISCUSSION

Tungsten

Routes to the tungsten complexes are summarized in Scheme 1. During the reaction of $W(CO)_6$ with acetic acid/acetic anhydride the reaction mixture undergoes a number of subtle colour changes, finally giving a yellow–black solution. Furthermore, the pattern of these colour changes appears to be essentially the same when the reaction is conducted in air or under nitrogen. When the yellow–black solution is exposed to air for a short time during concentration the diacetate salt **1** is recovered. The perchlorate salt **2** is recovered in a similar manner following addition of perchloric acid to the yellow–black solution prior to concentration. However, if the initial yellow–black



Scheme 1.

solution (containing some added sodium acetate) is allowed to stand in air for a long time (*ca* 3 months), then crystals of **3** are formed. Having discovered from X-ray crystallography (see later) that **3** contained trinuclear tungsten(IV) cations and a decanuclear tungsten(VI) anion, it was decided to try and make **3** by reacting **1** with a source of tungsten(VI), namely $Na_2WO_4 \cdot 2H_2O$. This method did indeed yield **3**.

The IR spectra of **1**, **2** and **3** all showed bands for the bridging bidentate acetate ligands in the region 1450–1550 cm^{-1}. Complex **1** exhibited $\nu_{asym}(CO_2)$ and $\nu_{sym}(CO_2)$ bands for the two non-coordinated acetate groups at 1635 and 1270 cm^{-1}, respectively,[5] whilst strong bands were present at 1085–1145 and 625 cm^{-1} for the perchlorate ions in **2**.[6] The spectrum of **3** contained prominent bands at 805, 895 and 960 cm^{-1}, arising from W—O—W and W=O vibrations of the $[W_{10}O_{32}]^{4-}$ ion.[7,8] None of these latter bands were present in the spectra of **1** and **2**.

In the first paper to be published on the reaction of $W(CO)_6$ with acetic acid/acetic anhydride (under nitrogen) Stephenson and Whittaker[9] tentatively formulated their yellow–brown microcrystalline product as $W_3O(CH_3CO_2)_8(OH)L$ ($L = H_2O$ or CH_3OH, depending on the reaction work-up procedure). On the basis of the present and previous work,[4] it seems likely that their compound was $[W_3(\mu_3\text{-}O)_2(\mu_2\eta^2\text{-}O_2CCH_3)_6(H_2O)_3](CH_3CO_2)_2$ (**1**). Furthermore, they reported that when an acetic acid solution of $W_3O(CH_3CO_2)_8(OH)CH_3OH$ was exposed to oxygen a deep yellow solid precipitated. Although the authors did not report any microanalytical data for this solid they did, however, mention that its IR spectrum was identical to that of $W_3O(CH_3CO_2)_8(OH)CH_3OH$, except for the growth of bands at 820 and 890 cm^{-1}, which they attributed to W—O—W and W=O vibrations, respectively. We believe that this deep yellow solid is a close relative of our present complex, $[W_3(\mu_3\text{-}O)_2(\mu_2\eta^2\text{-}O_2CCH_3)_6(H_2O)_3]_2[W_{10}O_{32}] \cdot$ solvent (**3**).

The crystal structure of **3** consists of two separate trinuclear tungsten(IV) dications, $[W_3(\mu_3\text{-}O)_2(\mu_2\eta^2\text{-}O_2CCH_3)_6(H_2O)_3]^{2+}$ (Fig. 1), and one decanuclear isopolyoxotungstate(VI) tetraanion, $[W_{10}O_{32}]^{4-}$ (Fig. 2). Although separate X-ray crystal structures of the cation[1,4] $[W_3(\mu_3\text{-}O)_2(\mu_2\eta^2\text{-}O_2CCH_3)_6(H_2O)_3]^{2+}$ and the anion[8] $[W_{10}O_{32}]^{4-}$ have previously been reported, complex **3** represents the first example of a structurally characterized tungsten salt in which the cation contains the metal in one oxidation state [tungsten(IV)] and the anion having the metal in a different oxidation state [tungsten(VI)]. The average values of the W—W and W—O bond lengths in **3** were found to be very similar to those listed in the literature for the independent ions (Table 1).

Molybdenum

When $Mo(CO)_6$ is refluxed under nitrogen with an acetic acid/acetic anhydride mixture yellow crys-

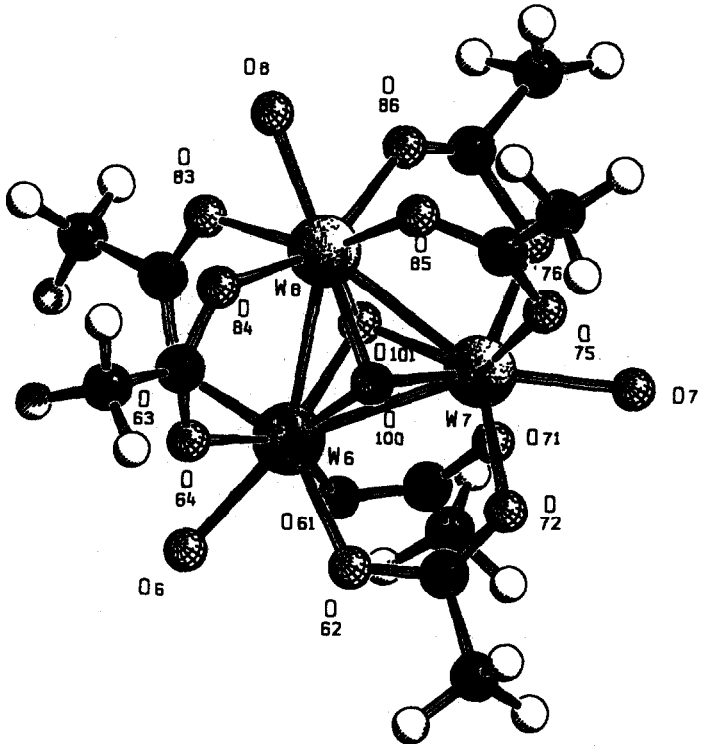


Fig. 1. One of the two trinuclear tungsten(IV) dications, $[W_3(\mu_3\text{-}O)_2(\mu_2\eta^2\text{-}O_2CCH_3)_6(H_2O)_3]^{2+}$, present in **3**·decanuclear isopolyoxotungstate(VI) tetraanion $[W_{10}O_{32}]^{4-}$.

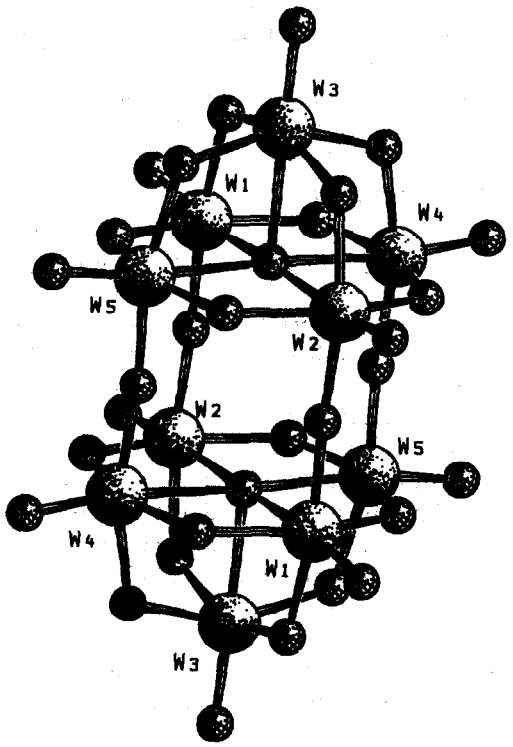

Fig. 2. The decanuclear isopolyoxotungstate(VI) tetraanion $[W_{10}O_{32}]^{4-}$ present in **3**.

tals of $[Mo_2(\mu\text{-}O_2CCH_3)_4]$ are deposited in a low[10] to moderate[11] yield at the bottom of a dark brown supernatant. If the above reaction is conducted in air,[12,13] or if the dark brown filtrate is subsequently exposed to air,[14] then a series of trinuclear cluster

Table 1. Comparison between tungsten ions and their previously determined structures. All bond lengths quoted are averages for similar bonds in the structures, therefore, no errors are listed

$[W_3(\mu_3\text{-}O)_2(\mu_2\eta^2\text{-}O_2CCH_3)_6(H_2O)_3]^{2+}$	This work (Å)	Ref. 1 (Å)
W—W	2.741	2.735
W—capping O	1.99	1.98
W—O	2.09	2.09
$[W_{10}O_{32}]^{4-}$	This work (Å)	Ref. 8 (Å)
W—central O	2.30	2.31

complexes of the type $[Mo_3(\mu_3\text{-}X)_2(\mu_3\text{-}Y)_2(\mu_2\eta^2\text{-}O_2CCH_3)_6(H_2O)_3](anion)_x \cdot yH_2O$ are formed. We have found that if the above-mentioned dark brown filtrate is treated with $[CH_3(CH_2)_3]_4N(ClO_4)$, and then exposure to air for a few days, yellow crystals of the known[15-17] isopolyoxomolybdate(VI) salt $([CH_3(CH_2)_3]_4N)_2[Mo_6O_{19}]$ (**4**) slowly form.

In conclusion, this work has established that in reactions between $M(CO)_6$ (M = W, Mo) and acetic acid/acetic anhydride (under aerobic conditions) the fate of some of the metal lies in the formation of isopolyoxometallate(VI) anions of the type $[M_xO_y]^{n-}$. Work is currently in progress on tyring to improve the yield of complex **3** in order that its reaction chemistry can be investigated further.

EXPERIMENTAL

Chemicals were purchased from commercial sources and, unless specified, were used without further purification. Diglyme was dried by distilling from sodium. IR spectra (KBr discs) were recorded in the region 4000–200 cm^{-1} on a Perkin–Elmer 783 grating spectrometer. Elemental analyses were carried out by the Microanalytical Laboratory, University College Cork, Ireland.

Crystallography

Crystal data for $[W_3(\mu_3\text{-}O)_2(\mu_2\eta^2\text{-}O_2CCH_3)_6(H_2O)_3]_2[W_{10}O_{32}]\cdot$solvent (**3**). Formula: $C_{12}H_{24}O_{33}W_8$ (in asymmetric unit), solvent: $C_{14.5}$. Mr = 2341.25, monoclinic, $P2_1/n$, a = 14.104(2), b = 14.097(1), c = 26.217(4) Å, β = 89.996(8)°, U = 5212(1) $Å^3$, D_c = 2.983 g cm^{-3}, Z = 4, $F(000)$ = 4156, μ(Mo-K_α) = 180.85 cm^{-1}.

A yellow–brown needle shaped crystal was mounted on an Enraf–Nonius CAD4 diffractometer and intensities of 6799 reflections were measured in the range $1° < \theta < 22°$ using graphite monochromated Mo-K_α radiation. The final cell coordinates were obtained by least-squares refinement of the setting angles for 25 automatically centred reflections, in the range $15° < \theta < 18°$. The crystal class was checked by examining a series of equivalent reflections. The data were not corrected for decay, but an empirical absorption correction was carried out using psi-scan data from three reflections. The data was reduced to give 5632 unique reflections (merging R of 0.0175), of these 4837 had $|I| > 4\sigma|I|$ and were used in the structure solution and refinement.

The structure was solved by the Patterson method of SHELXS. A $[W_3O_2(O_2CCH_3)_6(H_2O)_3]^{2+}$ cation and half of the $[W_{10}O_{32}]^{4-}$ anion, along with a number of solvent molecules, were found to be in the asymmetric unit. The structure was refined by blocked full-matrix least-squares of 507 parameters to give a final R value of 0.0323; the tungsten and oxygen atoms were all refined with anisotropic temperature factors. There were no significant correlations in the refinement. Difficulty was experienced in resolving the solvent molecules in the structure. A disordered acetic acid dimer was identified. The other positions of high electron density were assumed to be partially occupied acetones, and all atoms were refined with carbon structure factors. The weighting scheme was refined to give a flat analysis of variance, R_w = 0.0324. The final difference-Fourier had a goodness of fit of 1.77 and a highest peak in the difference map of 1.26 e $Å^{-1}$, adjacent to a tungsten atom.

SHELXS-86 and SHELX-76 were used by kind permission of G. M. Sheldrick, University of Göttingen.

$[W_3(\mu_3\text{-}O)_2(\mu_2\eta^2\text{-}O_2CCH_3)_6(H_2O)_3](CH_3CO_2)_2$ (1)

$W(CO)_6$ (0.5 g, 1.42 mmol), glacial acetic acid (10 cm^3) and acetic anhydride (4 cm^3) were refluxed together for 48 h under nitrogen. The initial pale yellow colour of the mixture gradually changed to orange–brown and finally to yellow–black. The solution was concentrated to low volume and the green product precipitated. The solid was filtered off, washed with acetone and then dried *in vacuo*. Yield 0.26 g (49%). The complex was very soluble in water and was slightly soluble in ethanol and methanol. Found: C, 17.7; H, 2.3. Calc.: C, 17.3; H, 2.7%. IR: 3400, 1635, 1510, 1460, 1270, 1020, 690, 642, 600, 350 cm^{-1}.

$[W_3(\mu_3\text{-}O)_2(\mu_2\eta^2\text{-}O_2CCH_3)_6(H_2O)_3](ClO_4)_2$ (2)

$W(CO)_6$ (0.4 g, 1.14 mmol), glacial acetic acid (10 cm^3) and acetic anhydride (10 cm^3) were refluxed together in air for 36 h. The initial pale yellow colour of the mixture gradually changed to orange–brown and finally to yellow–black. To the hot solution was slowly added $HClO_4$ (60%, 5 cm^3). The solution immediately changed to a light-brown colour and the green product precipitated. After cooling to room temperature the solid was filtered off, washed with acetone and then dried *in vacuo*. The complex was very soluble in water, ethanol and methanol and was slightly soluble in acetone, ether and chloroform. Found: C, 12.2; H, 2.2; Cl, 6.1. Calc.: C, 12.1; H, 2.0; Cl, 6.0%. IR: 3300, 1535, 1460, 1145, 1115, 1085, 690, 650, 625, 360, 340 cm^{-1}.

$[W_3(\mu_3\text{-}O)_2(\mu_2\eta^2\text{-}O_2CCH_3)_6(H_2O)_3]_2[W_{10}O_{32}]$ · solvent (**3**)

Method (*a*). $W(CO)_6$ (0.6 g, 1.70 mmol), glacial acetic acid (20 cm^3), acetic anhydride (10 cm^3) and sodium acetate (0.1 g, 1.2 mmol) were refluxed together in air for 36 h. The resulting yellow–black solution was allowed to cool to room temperature and then filtered to remove any undissolved solid. Acetone was then added to the filtrate, and on standing in air for *ca* 3 months a small amount of the product formed as yellow–brown crystals. One of these crystals was selected for the structure determination.

Method (*b*). Complex **1** (0.08 g, 0.07 mmol) and $Na_2WO_4 \cdot 2H_2O$ (0.12 g, 0.36 mmol) were refluxed in glacial acetic acid for 6 days in air. The mustard suspension was filtered whilst hot to give a yellow solid (0.1 g) and a yellow filtrate. The solid was washed with a little acetone and these acetone washings were added to the initial filtrate. Upon standing in air for *ca* 10 days crystals of **3** formed in the filtrate. Found: C, 7.3; H, 1.5%. IR: 3440, 2930, 1540, 1460, 1382, 960, 895, 805, 690, 645, 430, 400, 350 cm^{-1}.

$([CH_3(CH_2)_3]_4N)_2[Mo_6O_{19}]$ (**4**)

$Mo(CO)_6$ (3.0 g, 11.36 mmol), glacial acetic acid (40 cm^3), acetic anhydride (8 cm^3) and dry diglyme (45 cm^3) were refluxed together under nitrogen for 5 h, during which time yellow crystals of $[Mo_2(\mu\text{-}O_2CCH_3)_4]$ slowly precipitated from the dark brown solution. When $[Mo_2(\mu\text{-}O_2CCH_3)_4]$ (1.55 g) was filtered off $[CH_3(CH_2)_3]_4N(ClO_4)$ (0.5 g, 1.46 mmol) was added to the remaining dark brown filtrate. Upon standing in air for *ca* 4 days the solution deposited large yellow crystals of **4** (0.2 g). The solid was filtered off, washed with a little dry methanol and then dried *in vacuo*. Found: C, 28.5; H, 5.5; N, 2.2. Calc.: C, 28.2; H, 5.3; N, 2.1%. IR: 2970, 2880, 1470, 1382, 955, 800, 595, 430 cm^{-1}.

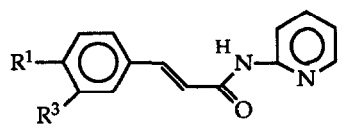
Abstract—The reaction of the title ligand N-(2-pyridyl)-3-phenyl-2-propene amide (O-N) with MX_2 salts yields compounds of the type $M(O\text{-}N)_2X_2$ and $[M(O\text{-}N)_2(H_2O)_2]X_2$, which were characterized by elemental analysis, magnetic moments and IR and EPR spectroscopies. From the IR spectra the ligand is found to be bidentate via the pyridyl nitrogen and the amide oxygen, except in $[Pd(O\text{-}N)_2Cl_2]$ where only the pyridyl ring is coordinated. The magnetic moments, IR spectra and thermograms of the $M(O\text{-}N)_2(NO_3)_2 \cdot 3H_2O$ compounds [M = nickel(II), cobalt(II)] are consistent with the presence of *trans*-$[M(O\text{-}N)_2(H_2O)_2]^{2+}$ ions, similar to the *trans*-$[Zn(O\text{-}N)_2(CH_3OH)_2]^{2+}$ species observed earlier. The EPR spectra of the *trans*-$Cu(O\text{-}N)_2X_2$ compounds ($X = NO_3^-$, $CF_3SO_3^-$) indicate an elongated octahedral coordination with equatorial bidentate (O-N) ligands and solvent molecules or anions in axial sites. The solid-state spectra reveal the presence of more than one type of copper(II) centre. The crystal structure of *trans*-$Cu(O\text{-}N)_2(CF_3SO_3)_2$ was determined by X-ray diffraction. The unit cell contains two types of discrete *trans*-$Cu(O\text{-}N)_2(CF_3SO_3)_2$ molecules, in which bidentate (O-N) ligands are strongly bonded to the equatorial sites of a tetragonally distorted octahedron. The axial positions are filled by

* Authors to whom correspondence should be addressed.

more weakly bonded unidentate triflate anions completing an all-*trans* stereochemistry. In the molecules sitting on crystallographic inversion centres, departure from D_{4h} symmetry in the copper coordination sphere is small and the roughly planar (O-N) ligands lie close to the equatorial plane. Molecules of the second type have no crystallographic symmetry and they are severely distorted: one of the axial copper–triflate bonds is very long, the equatorial CuN_2O_2 plane exhibits a significant tetrahedral distortion and the (O-N) ligands make angles of *ca* 17° with this plane.

The biosynthesis of lignin in plants is catalysed by the enzyme CAD, in which the active site contains a Zn^{2+} centre.[1-3] Efforts have recently been devoted to the synthesis of tailor-made molecules, which would be better ligands for zinc than the enzyme and thus might prevent or reduce lignin biosynthesis. Encouraging results have been obtained *in vitro* using the following type of molecule:[4,5]



$R^1 = H$; $R^3 = H$ (O-N)
$R^1 = OH$; $R^3 = OMe$

These compounds contain both an amido oxygen and a pyridyl nitrogen as donor atoms, properly oriented to close a chelate ring around the metal ion. Their chelating ability, however, is still poorly documented, except for a few publications dealing with the related ligand 2-pyridylacetamide (aapH).[6-9]

We describe here the complexes of Cu^{2+}, Ni^{2+} and Co^{2+} obtained by reacting the (O-N) molecule with the corresponding metal salts. A Pd^{2+} complex has also been prepared to evaluate the influence of this second row metal on the mode of coordination. To our knowledge, the effect of these metal ions on the enzymatic reaction *in vitro* is still unknown. The X-ray structure of the molecular copper complex $Cu(O\text{-}N)_2(CF_3SO_3)_2$ has been determined. It illustrates how a complicated interplay of electronic and steric effects triggered by inter- and intramolecular steric hindrance contributes to stabilize drastically different structures without disrupting the tetragonally distorted octahedron geometry about copper. Comparisons with the cationic zinc analogue[10] show that the differences are essentially steric in nature and may be due to the smaller Cu^{2+} radius (0.62 Å) compared to Zn^{2+} (0.72 Å).

EXPERIMENTAL

The ligand N-(2-pyridyl)-3-phenyl-2-propene amide (O-N)[4] was synthesized according to published procedures. $Cu(CF_3SO_3)_2$ was obtained from Aldrich.

$Cu(O\text{-}N)_2(CF_3SO_3)_2$ (1)

To an acetonitrile solution (10 cm^3) of $Cu(CF_3SO_3)_2$ (0.34 g, 0.9 mmol) was added a THF solution (10 cm^3) of (O-N) (0.4 g, 1.8 mmol) at room temperature with constant stirring. The green precipitate immediately formed was filtered, washed with THF and dried *in vacuo*. Recrystallization from an acetonitrile: THF 1:1 mixture gave green crystals of **1**. Yield: 75%. Found: C, 44.4; H, 3.0; N, 7.0; F, 14.5; S, 7.7; Cu, 7.7. Calc. for $C_{30}H_{24}F_6N_4O_8S_2Cu$: C, 44.5; H, 3.0; N, 6.9; F, 14.1; S, 7.9; Cu, 7.8%.

$Cu(O\text{-}N)_2(NO_3)_2 \cdot H_2O$ (2), $Ni(O\text{-}N)_2(NO_3)_2 \cdot 3H_2O$ (3), $Co(O\text{-}N)_2(NO_3)_2 \cdot 3H_2O$ (4)

To $Cu(NO_3)_2 \cdot 3H_2O$ (0.3 g, 1.24 mmol) dissolved in methanol (10 cm^3) was added (O-N) (0.55 g, 2.45 mmol) in the same solvent. The green precipitate was filtered, washed several times with methanol and ether, and dried *in vacuo*. Recrystallization from hot methanol gave a green microcrystalline powder. Yield: 65%. Found: C, 51.6; H, 3.7; N, 12.8. Calc. for $C_{28}H_{26}N_6O_9Cu$: C, 51.4; H, 3.8; N, 12.8%.

Similar synthetic procedures were used for the nickel and cobalt compounds.

$Ni(O\text{-}N)_2(NO_3)_2 \cdot 3H_2O$ was precipitated from THF. Light blue crystals were obtained by recrystallization in hot methanol. Yield: 72%. Found: C, 49.3; H, 4.3; N, 11.9. Calc. for $C_{28}H_{30}N_6O_{11}Ni$: C, 49.1; H, 4.4; N, 12.3%. $Co(O\text{-}N)_2(NO_3)_2 \cdot 3H_2O$ was precipitated as a powder from methanol. Orange crystals were grown by recrystallization from hot methanol. Yield: 69%. Found: C, 49.6; H, 4.4; N, 11.7. Calc. for $C_{28}H_{30}N_6O_{11}Co$: C, 49.1; H, 4.4; N, 12.3%.

$Pd(O\text{-}N)_2Cl_2$ (5)

Water was added to K_2PdCl_4 (0.33 g, 1.02 mmol) suspended in THF (10 cm^3) until the salt completely

dissolved (70 cm^3). Upon addition of (O-N) (0.46 g, 2.04 mmol) dissolved in ethanol, the colour of the solution changed from red to yellow. A light yellow powder precipitated, which was filtered, washed several times with ethanol and ether. Yield: 45%. Found: C, 53.0; H, 3.7; N, 8.8. Calc. for $C_{28}H_{24}Cl_2N_4O_2Pd$: C, 53.7; H, 3.8; N, 8.9%.

Measurements

The analytical data were obtained from the Laboratoire de Microanalyse du CNRS (Lyon, France) and the Centre de Microanalyse de l'INP (Toulouse, France).

The magnetic moments were determined in the solid state by the Faraday method, using a Cahn microbalance coupled with a Drusch electromagnet. Measurements were performed at room temperature and $HgCo(NCS)_4$ was used as standard ($Xg = 16.44 \times 10^{-6}$ cgs emu). The experimental values were corrected for the diamagnetism of the ligands.[11] The ESR spectra were measured on a Bruker ER 200 TT spectrometer operating at an *X*-band frequency between 90 and 300 K. The IR spectra were recorded on a Perkin–Elmer 1600 FTIR spectrophotometer in Nujol or KBr. TGA curves were recorded with a Mettler B85 system.

Crystal data

$[Cu(C_{14}H_{12}N_2O)_2](CF_3SO_3)_2$ (**1**). Formula: $CuC_{30}H_{24}F_6N_4O_8S_2$, $fw = 810.20$, triclinic, *P*-1; $a = 10.648(9)$, $b = 14.080(7)$, $c = 18.294(10)$ Å, $\alpha = 81.86(4)°$, $\beta = 77.06(6)°$, $\gamma = 71.21(5)°$, $V = 2523.4$ Å^3, $D_c = 1.599$ g cm^{-3}, $Z = 3$, μ(Mo-K_α) = 8.54 cm^{-1}, λ(Mo-K_α) = 0.71069 Å, $T = 190$ K.

Crystallographic measurement and structure determination

Crystals suitable for X-ray work were obtained by recrystallization of the crude product from an MeCN–THF mixture. The specimen used was a parallelepiped with the following dimensions (mm) between the indicated pairs of faces: 0.48 (100–100) × 0.11 (012–012) × 0.17 (011–011). The crystallographic work was performed on an Enraf–Nonius CAD-4 diffractometer. The unit cell was determined from 25 reflections ($10 \leqslant \theta \leqslant 11°$) found by the automatic search routine and centred in the counter aperture. This cell was checked with axial photographs taken along each of the three axes. The Niggli parameters ruled out all lattices of higher symmetry. The intensity data were collected over one half of the Laue sphere *hkl*, *hk̄l*, *hkl̄*, *hk̄l̄* ($2\theta_{max} = 50°$) by the ω-scan technique. The $\Delta\omega$ range was $(1.00 + 0.35 \tan\theta)°$ and a constant scan rate of 4° min^{-1} was used. Intensity was checked every hour on seven standard reflections, which showed fluctuations within ±1.9% during data collection. The same standard reflections were used to check orientations every 200 measurements. A total of 8891 independent reflections were measured, of which 3468 reflections [$I > 3\sigma(I)$] were retained for structure resolution and refinement.

The structure was solved by the heavy-atom method. The copper atoms were located from a Patterson map and the remaining non-hydrogen atoms were found from difference Fourier (ΔF) maps calculated with the SHELX program.[12] Refinement was based on $|F|$ (initially by full-matrix least-squares, last cycles with the block-diagonal approximation). All non-hydrogen atoms were refined anisotropically. The hydrogens were visible in the ΔF map. They were introduced at idealized positions [C(N)—H = 0.95 Å, $B_{iso} = 4.0$ Å^2]. Their coordinates were recalculated after each least-squares cycle. The final agreement factors were $R = \Sigma||F_o|-|F_c||/\Sigma|F_o| = 0.049$ and $R_w = (\Sigma w||F_o|-|F_c||^2/\Sigma|F_o|^2)^{1/2} = 0.038$ (weights based on counting statistics). The goodness-of-fit ratio was 1.39 for 692 parameters refined. Electron density fluctuations in the final ΔF map were within ±0.42 e Å^{-3}.

The scattering curves were from standard sources. The anomalous dispersion contributions of copper and sulphur were taken into account.[13,14]

RESULTS AND DISCUSSION

The complexes are all obtained in good yields. They are air stable, but poorly soluble in usual solvents. Decomposition temperatures determined from thermograms indicate that **3** and **4** lose three water molecules between 20 and 200°C. Then, decomposition starts at 250°C for nickel and 220°C for cobalt.

The palladium complex is diamagnetic (Table 1), whereas the nickel and cobalt complexes have magnetic susceptibilities typical of high-spin octahedral species.[15,16]

The most significant IR frequencies are reported in Table 1. The strong band corresponding to the amide ν(C=O) vibration at 1694 cm^{-1} in the free ligand is shifted by ~ 30 cm^{-1} to lower wave numbers for complexes **1**–**4**, showing that the carbonyl oxygen is coordinated to the metal.[6] The characteristic deformation band of the pyridine ring, at 621 cm^{-1} in the free ligand, undergoes shifts to higher wave numbers for the copper, nickel and cobalt compounds, as expected for coordination

Table 1. Spectroscopic and magnetic data for the ligand and its complexes

Compound	IR ν(CO) (cm^{-1})	IR δ(pyridine) (cm^{-1})	Magnetic moment (B.M.)	ESR (G)
O-N	1694	621		
$Co(O\text{-}N)_2(CF_3SO_3)_2$ (**1**)	1657	651	1.88	$g_\parallel = 2.296$, $g_\perp = 2.060$, $A_\parallel = 141$; solid, room temperature $\langle g \rangle = 2.082$; solid, 90 K $g_\parallel = 2.280$, $g_\perp = 2.061$, $A_\parallel = 146$; MeOH, 90 K
$Cu(O\text{-}N)_2(NO_3)_2 \cdot H_2O$ (**2**)	1668	650	1.89	$\langle g \rangle = 2.050$; solid, room temperature $\langle g \rangle = 2.067$; solid, 90 K $g_\parallel = 2.288$, $g_\perp = 2.070$, $A_\parallel = 145$; MeOH, 90 K
$Ni(O\text{-}N)_2(NO_3)_2 \cdot 3H_2O$ (**3**)	1667	646	3.18	
$Co(O\text{-}N)_2(NO_3)_2 \cdot 3H_2O$ (**4**)	1666	645	4.96	
$Pd(O\text{-}N)_2Cl_2$ (**5**)	1694	658	diamagnetic	

through the ring nitrogen atom.[17a] Interestingly, the palladium complex **5** shows appreciable shift only for the pyridine band, indicating that ligand coordination to this second-row metal occurs only through the ring nitrogen and leaves the amide group unbonded.[6]

No evidence for the coordination of $CF_3SO_3^-$ to Cu^{2+} can be deduced from the IR spectrum. This complex presents a single strong $\nu(SO_3)$ stretch at 1031 cm^{-1}, the other vibrations being masked by ligand bands. The presence of uncoordinated NO_3^- anions in **3** and **4** is very likely, since both compounds exhibit only one strong and broad ν_3 vibration at 1375 cm^{-1}, in the range for free NO_3^-. On the other hand, two stretching bands at 1378 and 1340 cm^{-1} in **2** suggest that the two NO_3^- groups are not equivalent and that one of them might be coordinated to Cu^{2+}.[17b,18a,19,20]

These data are all consistent with the O-N ligand acting as a chelating agent. The coordination geometries suggested by the analytical and magnetic data are square planar for palladium and octahedral for nickel and cobalt. Therefore, assuming *trans*-stereochemistry the two axial sites in **3** and **4** should be occupied by water molecules, as observed in $[Ni(aapH)_2(H_2O)_2](NO_3)_2$.[8]

Complexes **1** and **2** have room-temperature magnetic moments (1.88 and 1.89 B.M., respectively) characteristic of copper(II) compounds.[21] The ESR spectrum of **1**, recorded at room temperature in the solid state, consists of an intense absorption at high field and a set of three broad and weaker signals at lower field ($g_\parallel = 2.296$, $g_\perp = 2.06$, $A_\parallel = 141$ G). Spectrum broadening by exchange narrowing is observed when the temperature is decreased ($\langle g \rangle = 2.082$), in agreement with the presence of copper atoms with different environments (*vide infra*). When dissolved in methanol **1** gives an anisotropic axial spectrum with $g_\parallel = 2.280$, $g_\perp = 2.061$ and $A_\parallel = 146$ G at 90 K. These spectra with $g_\parallel > g_\perp > 2$ are typical of copper(II) compounds with a $d_{x^2-y^2}$ ground state and an elongated octahedral geometry resulting from Jahn–Teller effects. The ESR spectra of **2**, recorded at room temperature and 90 K on the polycrystalline powder, reveal in both cases a quasi-isotropic signal at $\langle g \rangle = 2.050$ (room temperature) and 2.067 (90 K). Moreover, a weak absorption corresponding to the $\Delta M = 2$ transition is apparent in the half-field region (at $\sim$ 1650 G). This line is held to be indicative of the presence of Cu—Cu exchange interaction in the solid.[22] Such an absorption is commonly seen for powdered samples of copper(II) dimers, but it has also been reported for the polymeric chains in a pyrazine copper(II) nitrate complex[23] and in potassium dioxalatocuprate.[24] The five-line pattern expected for an elongated octahedral geometry is again observed for **2** when dissolved in methanol at 90 K, with $g_\parallel = 2.288$, $g_\perp = 2.070$ and $A_\parallel = 145$ G.

Due to the plasticity of the coordination sphere, such differences between the solid and solution structures are common in copper chemistry. To see if these ESR data can be used to establish a reliable spectra–structure relationship, attempts were made to grow single crystals of **1** and **2**. To our knowledge no complete structural work has been carried out yet on copper(II) complexes with N-phenolamide model ligands. Only **1** gave a suitable crystalline material. Its X-ray crystal structure was determined.

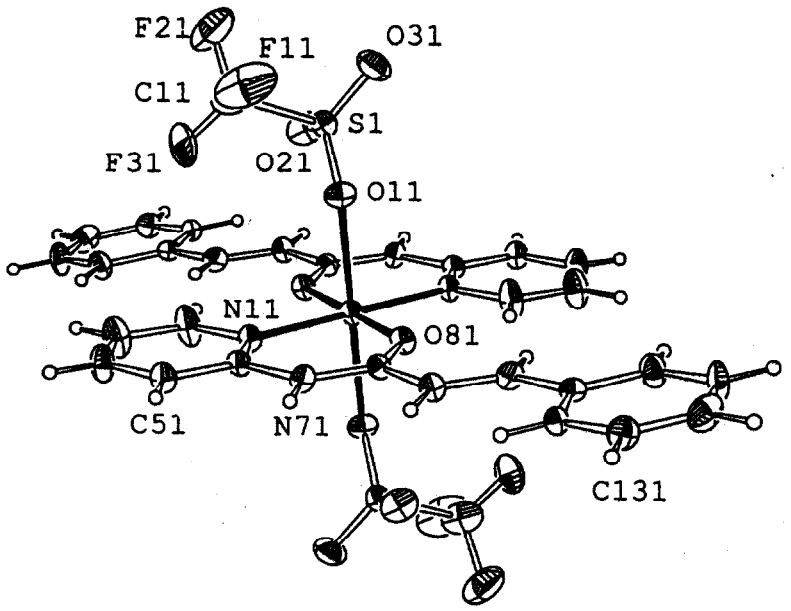


Fig. 1. ORTEP drawing of the *trans*-$[Cu(O\text{-}N)_2(CF_3SO_3)_2]$ complex, molecule **A**. The central Cu(1) atom occupies a crystallographic inversion centre. Atom numbering is explained in Fig. 3. Ellipsoids correspond to 35%, except for hydrogens, which are shown as spheres of arbitrary size.

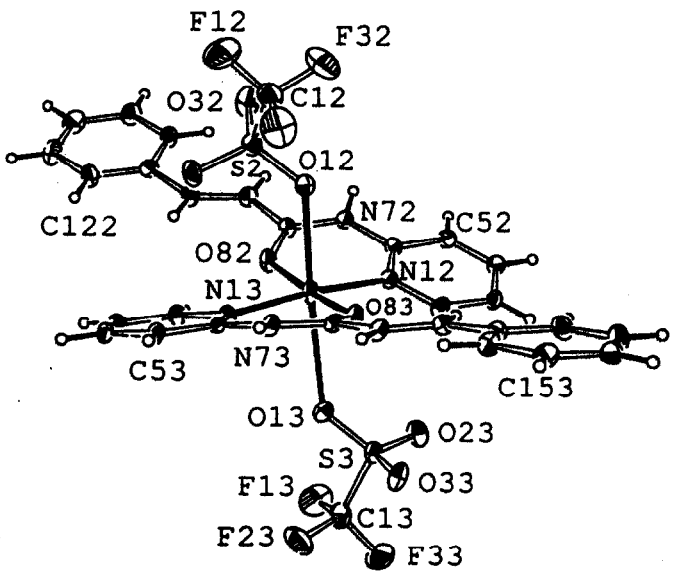

Fig. 2. ORTEP drawing of the *trans*-$[Cu(O\text{-}N)_2(CF_3SO_3)_2]$ complex, molecule **B**. The central atom is Cu(2). Other conditions as in Fig. 1.

The structure consists of well-separated $Cu(O\text{-}N)_2(CF_3SO_3)_2$ entities. The unit cell contains two symmetry independent kinds of molecules shown in Fig. 1 (molecule **A**) and Fig. 2 (molecule **B**). The atoms are labelled following the numbering scheme of Fig. 3, with an extra (right-most) digit added to identify the ligands individually.† Interatomic distances and bond angles are listed in Table 2.

The environment of both types of copper atoms can be described as an octahedral arrangement of four strongly bonded, roughly co-planar, equatorial donors and two semi-coordinated axial ligands. The equatorial positions are occupied by pyridine nitrogens N(1) and amide oxygens O(8) of two chelating

† When the ligands are discussed collectively, the atoms are represented by the unparenthesized symbols of Fig. 3. To designate one particular ligand, individual parenthesized symbols are used.

[a] $-x, -y, -z$.

(O-N) molecules. The two axial sites are filled by unidentate $CF_3SO_3^-$ ligands, completing an all-*trans* coordination about the metal. This type of tetragonally distorted (4+2) coordination is widespread in the chemistry of copper(II), a d^9 metal centre with a non-spherical *d*-shell particularly sensitive to the Jahn–Teller effects.[25] A similar all-*trans* arrangement has been observed for a related cationic zinc complex,[10] in which methanol molecules occupy the axial positions filled here by triflate oxygens.

In molecule **A** the metal sits on a crystallographic inversion centre. Therefore, all *trans* bond angles are exactly equal to 180° and the four copper–donor bonds in each of the three principal planes are rigorously co-planar. Departure from ideal D_{4h} sym-

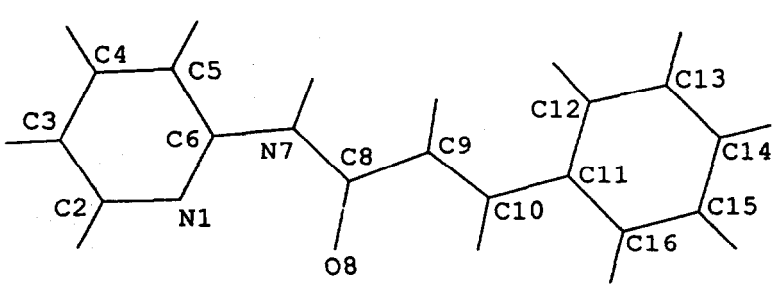

Fig. 3. Numbering scheme used for the ligand atoms. An extra digit representing the ligand number is added at the right-most position.

metry in the $CuN_2O_2(trif)_2$ framework is small, as can be appreciated from the dihedral angles between the principal planes being all close to 90°: $CuN_2O_2/CuN_2(trif)_2 = 85.6°$, $CuN_2O_2/CuO_2(trif)_2 = 87.3°$ and $CuN_2(trif)_2/CuO_2(trif)_2 = 89.3°$. The "bite" of the (O-N) ligand allows the *cis* bond angles in the equatorial plane [89.2(2)° and 90.8(2)°] to be close to ideal values. As usual, the angles involving the axial groups [85.6(2)°, 87.2(2)°] show greater deviation from 90°. Binding of oxo-anions off the axial direction is commonly encountered in such systems and large distortions sometimes lead to coordination numbers > 6 by allowing more than one oxygen to lie within bonding distance from the metal.[18b] However, in the present case the anions remain monodentate and the copper–triflate bonds deviate by only 5.2° from the axial direction.

In the chelate ring, the N(11), N(71), C(81) and O(81) atoms are co-planar, whereas C(61) is displaced from this plane by 0.044(7) Å, defining a significant, but small "envelope" conformation. Also, the angle between the plane of these four atoms and the CuN_2O_2 plane is only 1.2° (Table 3). Thus, molecule **A** shows only minor distortions.

Molecule **B** (Fig. 2) has no crystallographically-imposed symmetry and it is severely distorted, although the immediate environment of copper is affected only to a limited extent. The *cis* angles in the equatorial plane remain in the 89.9(2)–90.3(2)° range. The deviation from 180° for the *trans* angles [174.2(2)°, 173.6(2)°] is due to a tetrahedral distortion in the CuO_2N_2 "plane". The distances to the least-squares plane are: O(82), 0.090(5); O(83), 0.087(5); N(12), −0.122(5); N(13), −0.119(5); Cu(2), −0.008(1). The tetrahedral deformation can be envisioned as resulting from the N(12)—Cu(2)—O(82) and N(13)—Cu(2)—O(83) planes being twisted by 6.5° in opposite directions about their common bisector. Displacement of the triflate oxygens from the axial direction is more important, the angles with the equatorial donors ranging from 84.7(2) to 100.9(2)°. Although somewhat greater than in molecule **A**, the distortions *in the coordination sphere* of **B** remain relatively small.

The peripheral part of molecule **B**, however, is found to be severely distorted. A larger "envelope" effect is noted in the chelate rings: C(62) and C(63) are displaced by 0.142(7) and 0.078(6) Å, respectively, from the plane of the other four atoms. Furthermore, folding about the N(1)—O(8) line displaces considerably both ligands on the O(12) side. The angle between the ring and the Cu—N(1)—O(8) plane, which is 1.2° for molecule **A**, is now 17.6° for ligand 2 and 16.1° for ligand 3 (Table 3).

The Cu—N bond distances are significantly different in **A** and **B** but remain in the range of the values reported for [(pyridine-2-acetamide)$_2$ Cu]$(ClO_4)_2$,[26] pyridine-2-carboxamide compound,[27] pyrazine-2,3-dicarboxamide complex[28] and a series of N-donor compounds.[29–33]

$CuL_4(triflate)_2$ compounds are known with L = isoquinoline[32] and pyridine.[33] They have roughly D_{4h} symmetry and contain similar axially coordinated triflate anions with Cu—O(triflate) distances from 2.425(4) to 2.472(9) Å. Thus, the value of 2.356(5) Å can be regarded as relatively short in molecule **A**, where Cu(1)—N(11) is longer [2.069(6) Å]. In molecule **B**, where shorter Cu—N bonds [mean 2.017(6) Å] are found, one of the Cu—O(triflate) bonds is normal at 2.466(5) Å, whereas the other is much longer [2.800(5) Å], but still within the limit (~ 3 Å) normally accepted for semi-coordination of an oxo-anion.[34] Although the long Cu—O(13) bond could suggest that the octahedron is *on its way* to a square pyramid, the expected displacement of the metal from the CuO_2N_2 plane towards the *short* O(12) bond is not observed here, the Cu(2) atom lying only 0.008(1) Å from the plane and on the *opposite* side. It is noteworthy that bending along the N(1)—O(8) lines brings both chelate rings to the O(12) side, thereby ruling out the possibility that the long Cu—O(13) bond could result from *intramolecular* steric hindrance.

The dihedral angles between the four individually planar units (pyridine, chelate, olefin region and phenyl) are listed in Table 3 (details in supplementary material). As found in the zinc analogue they are all significantly different from 0, but they remain relatively small and the ligand can still be regarded as an uninterrupted system of π-electrons.

The triflate ligands show the usual ethane-like staggered conformation with mean values for bond lengths and angles similar to those found in other complexes.[32,33,35–37] Even though the S—O(1) distances involving the coordinated oxygens O(1) tend to be slightly greater than the two others, the dis-

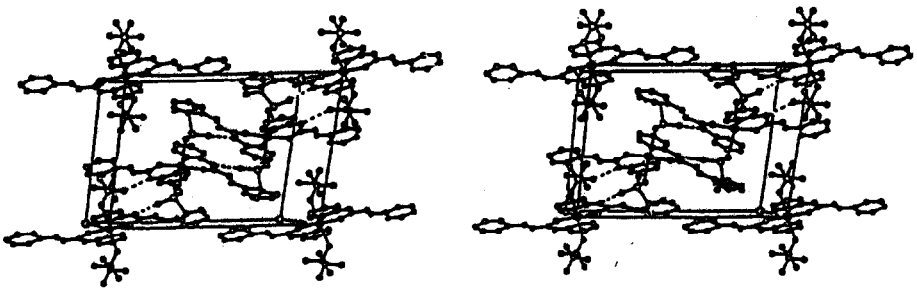

Fig. 4. View of the unit cell of *trans*-$[Cu(O\text{-}N)_2(CF_3SO_3)_2]$ down the a^*-axis. The b- and c-axes are roughly vertical and horizontal, respectively, in the plane of the figure. The copper atoms are shown as black spheres and the remaining non-hydrogen atoms can be identified by comparison with Figs 1 and 2. Hydrogens are omitted for simplicity. The unit cell origin is occupied by molecules of type **A**, whereas molecules of type **B** are inside the unit cell. Dashed lines represent hydrogen bonds.

tinction between coordinated and non-coordinated S—O bond lengths is not very clear because of the presence of hydrogen bonds involving one oxygen on each triflate ligand.

A view of the unit cell is given in Fig. 4, which illustrates the presence of intermolecular interactions. The amide N—H groups, which are the only hydrogen-bond donors present in the structure, each form a moderately strong N—H···O bond with one of the triflate oxygens [N···O = 2.778(8)–2.819(8) Å, N—H—O = 170–173°]. Besides these localized bonds, intermolecular interactions consist mainly of van der Waals forces, namely in the copper environment. The long axial Cu—O(triflate) bond and the puckered arrangement in molecule **B** undoubtedly contribute to optimizing molecular packing without being themselves too energy costly.

The large distortions found in **B** were not predictable and they should not be retained in the free molecule, so that molecule **A** probably better represents the normal geometry of the complex. Nevertheless, the equatorial plane remains a constricted region. It has been noted previously[10] that co-planar arrangement in the *trans*-$Zn(O\text{-}N)_2$ unit introduces short contacts between H(2) of one ligand and the H(10)—O(8) region of the other. Steric strain is likely to be still more important here than in the Zn^{2+} analogue,[10] since the metal–ligand bonds are *ca* 0.1 Å shorter, as expected from the difference between the radii of Cu^{2+} (0.62 Å) and Zn^{2+} (0.72 Å).[38] In molecule **A** the inter-ligand distances are 2.34 [H(2)···H(10)] and 2.19 Å [H(2)···O(8)], definitely shorter than the normal van der Waals separations of 2.4 and 2.7 Å, respectively. Although these values are derived from calculated hydrogen coordinates and displacement from these idealized positions could increase the separations, very close inter-ligand contacts are certainly present, especially between H(2) and O(8). In molecule **B**, folding along the N(1)—O(8) line allows the ligands to become non-co-planar, resulting in greater non-bonded distances of 2.62 (H···H) and 2.26 Å (H···O).

The differences observed between the Cu—N bond lengths are probably correlated with these steric features. In molecule **B** normal Cu—N distances of *ca* 2.017 Å are observed, whereas in molecule **A** the Cu(1)—N(11) bonds are stretched by *ca* 0.05 Å in order to counteract the greater inter-ligand repulsions. In turn, the extent of Cu—N binding in the equatorial plane seems to affect the binding to the axial sites. Thus, the long Cu—N bonds in **A** apparently reduce electron donation to copper in the equatorial plane, thereby improving the acceptor character of the axial sites, where the copper-triflate bond is found to be relatively short (2.35 Å). In molecule **B**, where the Cu—N bonds are of normal lengths and donation in the equatorial plane is better, no such short Cu(2)–triflate bonds are observed.

Thus, a complicated interplay of electronic and geometric effects triggered by inter- and intramolecular steric hindrance contributes to make the overall structures of the two $Cu(O\text{-}N)_2(CF_3SO_3)_2$ units drastically different, without disrupting the tetragonally distorted octahedron about copper.

Supplementary material available. Anisotropic temperature factors, idealized hydrogen coordinates, geometry of the hydrogen bonds, weighted least-squares planes and structure factor amplitudes (41 pages). Copies may be obtained upon request from A.L.B.

A ^{31}P AND ^{95}Mo NMR STUDY OF SOME MOLYBDENUM AND TUNGSTEN CARBONYL COMPLEXES OF A SMALL AIR-STABLE ALIPHATIC PHOSPHINE, 1,3,5-TRIAZA-7-PHOSPHAADAMANTANE (PTA)

ELMER C. ALYEA,* KEITH J. FISHER,† SENG FOO and BRUNO PHILIP

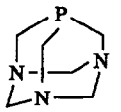
Guelph–Waterloo Centre for Graduate Work in Chemistry, Guelph Campus, Department of Chemistry and Biochemistry, University of Guelph, Guelph, Ontario, Canada N1G 2W1

(*Received* 15 *September* 1992; *accepted* 4 *November* 1992)

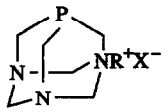
Abstract—Complexes of molybdenum and tungsten of the type $M(CO)_5L$, $M(CO)_4L_2$ and $M(CO)_3L_3$ have been prepared, where L = 1,3,5-triaza-7-phosphaadamantane (PTA), a small air-stable aliphatic phosphine. The ^{31}P coordination chemical shifts indicate a strong σ-interaction between the metals and PTA. The ^{95}Mo chemical shifts also indicate a large nephelauxetic effect and/or a significant π-interaction of the ligand with molybdenum. Some PTA methyl iodide derivatives of these metal carbonyls have also been prepared and these also have a strong interaction with molybdenum and tungsten through the phosphorus atom of the novel ligand.

1,3,5-Triaza-7-phosphaadamantane (PTA) is a small air-stable aliphatic phosphine first prepared by Daigle and co-workers in 1974.[1] Fluck *et al.*[2] determined the crystal structure of PTA and prepared halogen and benzyl chloride derivatives. The study of a few metal carbonyl complexes of PTA and the determination of the crystal structure of $Mo(CO)_5PTA$ by Darensbourg and co-workers[3,4] seem to be the only complexation studies of this potentially important ligand. That work showed the similarity of the force constants of the carbonyl stretching frequencies and also of the ^{31}P coordination chemical shifts in the complexes $Mo(CO)_5L$ (L = Me_3P, PTA). The crystal structure of $Mo(CO)_5PTA$ indicated that PTA has a smaller cone angle (102°) than Me_3P (118°) and that the Mo—P bond length is 2.48 Å.[4] This bond length is short compared with 2.56 Å in $Mo(CO)_5PPh_3$ and 2.51 Å in $Mo(CO)_5P(CH_2CH_2CN)_3$.[5] The possibility that PTA may be a suitable alternative to PMe_3 as a ligand for transition metals due to its attractive properties (such as water solubility) attracted our attention; in addition, the specific nature of its interaction with molybdenum and other transition metals needs exploration.

Our current investigations of the coordinating ability of PTA include the syntheses and NMR characterization of some water soluble derivatives,[6] a solid-state ^{31}P CP-MAS NMR study of mercury(II) complexes[7] and an exploration of PTA complexation with various other metal salts (e.g. Co, Ni, Cu, Ph, Rd, Pt, Au).[8] In the present study we sought to extend the range of molybdenum and tungsten complexes of PTA and to utilize ^{31}P and ^{95}Mo NMR parameters to characterize the Mo—P bonding interaction. Various ^{95}Mo NMR studies in our laboratory,[9] as well as others,[10] have demonstrated the sensitivity of $\delta(^{95}Mo)$ values to the nature of phosphorus ligands.



PTA



PTAR$^+$X$^-$

EXPERIMENTAL

General procedures

All operations were carried out under oxygen-free dry dinitrogen and all solvents were degassed.

† Present address: School of Chemistry, The University of New South Wales, P.O. Box 1, Kensington, N.S.W. 2033, Australia.

^{31}P NMR spectra were recorded at ambient temperature on Bruker WH-400 or Bruker AM-250 spectrometers in the FT mode using 85% H_3PO_4 as an external standard. ^{95}Mo spectra were recorded at ambient temperature on a Bruker WH-400 spectrometer tuned to 26.08 MHz at a field strength of 9.3956 T. 2 M K_2MoO_4 in an aqueous solution of pH 11 was used as a standard.

Synthesis of $Mo(CO)_5PTA$

$Me_3NO \cdot 2H_2O$ (0.21 g 1.89 mmol) was added to a solution of $Mo(CO)_6$ (0.50 g 1.89 mmol) in acetonitrile (20 cm^3). After 30 min stirring at room temperature a solution of PTA (0.30 g 1.90 mmol) in methanol (20 cm^3) was added to the yellow acetonitrile solution. The resulting solution was refluxed for 30 min. The solvent was removed *in vacuo* and the solid washed in cold hexane (10 cm^3) and water (10 cm^3) and recrystallized from hexane. Yield 0.46 g (62% theory). Found: C, 33.1; H, 3.0; N, 10.6. Calc. for $Mo(CO)_5[PN_3(CH_2)_6]$: C, 33.6; H, 3.1; N, 10.7%.

Synthesis of $W(CO)_5PTA$

$W(CO)_5PTA$ was prepared in a similar manner to that described above for the molybdenum analogue, except that the reaction of $Me_3NO \cdot 2H_2O$ with $W(CO)_6$ took about 2 h at room temperature. Found: C, 27.5; H, 2.5; N, 9.0. Calc. for $W(CO)_5[PN_3(CH_2)_6]$: C, 27.4; H, 2.5; N, 8.7%.

Synthesis of cis-$Mo(CO)_4(PTA)_2$

A solution of PTA (0.83 g 5.3 mmol) in methanol (15 cm^3) was added to a solution of $Mo(CO)_4(NHC_5H_{10})_2$ (1.00 g 2.6 mmol) in dichloromethane (15 cm^3). The solution was stirred for 30 min and the yellow colour faded. The solvent was removed *in vacuo* and the resulting solid recrystallized from acetonitrile. Yield 1.10 g (80% theory). Found: C, 36.5; H, 4.7; N, 16.0. Calc. for $Mo(CO)_4[P_2N_6(CH_2)_{12}]$: C, 36.8; H, 4.6; N, 16.1%. IR CO: 2012, 1932, 1910 cm^{-1} (trichloroethylene). FTICR *m/z*: 524 (^{98}Mo).

Synthesis of cis-$W(CO)_4(PTA)_2$

$W(CO)_4(PTA)_2$ was prepared in a similar manner to the analogous molybdenum compound. Found: C, 31.2; H, 4.0; N, 13.7. Calc. for $W(CO)_4[P_2N_6(CH_2)_{12}]$: C, 31.5; H, 3.9; N, 13.8%. IR CO: 2016, 1928, 1904, 1848 cm^{-1}. FTICR *m/z*: 610 (^{184}W).

Attempts to prepare the *trans*-$M(CO)_4(PTA)_2$ derivatives by isomerization in boiling toluene were unsuccessful.

Syntheses of $M(CO)_3(PTA)_3$ *compounds*

Reactions of PTA with $Mo(CO)_6$ or $W(CO)_6$ in boiling acetonitrile for several days produced solutions containing mainly the $M(CO)_4(PTA)_2$ derivatives with some insoluble polymeric material. Reaction of PTA with $M(CO)_3(CH_3CN)_3$ solutions gave mixed products of mainly $M(CO)_4(PTA)_2$ and some $M(CO)_3(PTA)_3$. Pure compounds could not be isolated so they were studied in acetonitrile reaction solutions.

Syntheses of methyl iodide derivatives

The methyl iodide derivatives were prepared by the reaction of methyl iodide with the PTA metal carbonyl complexes in acetonitrile or by the reaction of PTAMeI with $M(CO)_5NMe_3$[11] or $M(CO)_4(NHC_5H_{10})_2$.[12] Similar spectra were obtained using either method.

RESULTS AND DISCUSSION

$Mo(CO)_5PTA$ and $W(CO)_5PTA$ were prepared by the reaction of PTA with the trimethylamine derivatives $M(CO)_5NMe_3$.[11] These compounds were previously synthesized by Darensbourg[3,4] using refluxing diglyme or a photochemical synthesis of $Mo(CO)_5THF$.

Cis-$Mo(CO)_4(PTA)_2$ and *cis*-$W(CO)_4(PTA)_2$ were prepared using the piperidine derivatives.[12] The IR spectrum of *cis*-$Mo(CO)_4(PTA)_2$ was similar to a *cis*-$Mo(CO)_4L_2$ spectrum reported by Darensbourg.[12] Isomerization to the *trans* isomer is expected to be very slow, as indicated by Darensbourg;[12] we found no evidence of isomerism in these complexes, possibly due to the small cone angle of PTA causing ligand dissociation to be negligible.

Although pure compounds were not obtained for the tri-substituted complexes by the acetonitrile method,[13] the ^{95}Mo NMR spectrum (a quartet) indicated the presence of a species with three equivalent phosphorus atoms, indicating the formation of the *fac*-isomer of $Mo(CO)_3(PTA)_3$.

The ^{31}P and ^{95}Mo data are given in Table 1 for the molybdenum carbonyl complexes and included in Table 1 are ^{31}P data for the tungsten carbonyl complexes.

The molybdenum complexes all give substantial ^{31}P coordination chemical shifts, relative to the complexes of PMe_3 and PEt_3 (Table 2), confirming a strong σ-interaction. The $J(^{31}P—^{95}Mo)$ obtained

Table 1. ^{31}P and ^{95}Mo NMR data of some PTA complexes in acetonitrile

Complex	$\delta^{31}P$	Δ^a	J (Hz)	$\delta^{95}Mo$
$Mo(CO)_5PTA$	−55.9	44.9	126	−1877
$Mo(CO)_4(PTA)_2$	−54.9	45.9	126	−1837
$Mo(CO)_3(PTA)_3$	−54.7	46.1	126	−1759
$Mo(CO)_5PTAMeI^b$	−30.2	54.1	127	−1860
$Mo(CO)_4(PTAMeI)_2^b$	−32.2	52.2	127	−1819
$W(CO)_5(PTA)$	−78.4	25.4	224	—
$W(CO)_4(PTA)_2$	−75.0	25.8	210	—
$W(CO)_3(PTA)_3$	−74.5	26.3	204	—
$W(CO)_5PTAMeI^b$	−53.7	30.6	236	—

[b] PTAMeI = 1-methyl-1-azonia-3,5-diaza-7-phosphaadamantane.

from the ^{95}Mo spectrum are all similar and are in the range generally observed for triaryl- and trialkylphosphines.[9,10]

The $\delta(^{95}Mo)$ value for the complex $Mo(CO)_5$PTA (−1877 ppm) indicates that the molybdenum shielding is even greater than that found for $Mo(CO)_6$ (−1855 ppm in acetonitrile) or the related complex $Mo(CO)_5PEt_3$ (−1854 ppm). This surprising result implies that either a large nephelauxetic effect and/or a significant π-interaction is operative, as well as the strong σ-interaction.[9,10] The short Mo—P bond of 2.48 Å found in $Mo(CO)_5$PTA[4] strongly suggests the presence of considerable π-bonding as the major factor, especially since PTA is less basic than PEt_3 (pK_a = 6.0 vs 8.69 for PEt_3; protonation actually occurs at one nitrogen atom, not at the phosphorus atom).[6] The three $\delta(^{95}Mo)$ values for the $Mo(CO)_{6-n}PTA_n$ (n = 1–3) complexes are very similar to those known for $Mo(CO)_{6-n}[P(OMe)_3]_n$ (n = 1–3; −1864, −1827 and −1756 ppm, respectively),[9,10] where $P(OMe)_3$ is acknowledged to be a strong π-acceptor ligand. By comparison, the $\delta(^{95}Mo)$ values for the three $Mo(CO)_{6-n}(PMe_3)_n$ (n = 1–3) complexes, which are −1819, −1723 and −1583 ppm,[9,10] respectively, signify that π-bonding is not a significant factor in the complexes of this basic aliphatic phosphine ligand. The ^{95}Mo chemical shift data thus shows that PTA has bonding properties which are much closer to those of $P(OMe)_3$ than PMe_3. This behaviour is obviously a consequence of the restricted C—P—C angles in the adamantane structure of PTA.

Previous workers[14–16] have shown that there is a good correlation between $\Delta\delta^{31}P$ of metal complexes and the free ligand chemical shift δ using the equation:

$$\Delta = A\delta + B.$$

We have used recent values of the parameters A and B, determined by Nelson,[16] but find our values give a poor fit to this equation (Table 2). We also note that data for Me_3P and Et_3P[17] also give a poor fit to this equation, as shown in Table 2. It may be that data used by Nelson was only applicable for arylphosphines of similar cone angle and the correlations may break down when small cone angle phosphines with quite different electronic properties such as Me_3P or PTA are used. It is interesting that our data for the *fac* isomers gives a better fit, although Nelson's data gave the poorest correlation with the least number of compounds.

Earlier work[3,6] showed that coordinated PTA might be alkylated by adding MeI and that the alkylated derivatives might also be prepared by the reaction of the hexacarbonyl with the alkylated derivative of PTA. We were able to prepare two such molybdenum derivatives and their ^{31}P data

Table 2. Observed and calculated values of the ^{31}P coordination chemical shift

Compound	Δ_{obs}	Δ_{calc}[a]	Diff.
$Mo(CO)_5$PTA	44.9	54.3	9.4
$Mo(CO)_5PMe_3$	43.7	48.9	5.2
$Mo(CO)_5PEt_3$	39.0	42.9	3.9
cis-$Mo(CO)_4$(PTA)	45.9	57.6	11.7
cis-$Mo(CO)_4(PMe_3)_2$	46.5	52.2	5.7
cis-$Mo(CO)_4(PEt_3)_2$	32.0	46.5	14.5
fac-$Mo(CO)_3(PTA)_3$	46.1	47.1	1.0
fac-$Mo(CO)_3(PMe_3)_3$	42.3	42.9	0.6
fac-$Mo(CO)_3(PEt_3)_3$	27.0	38.5	11.5

[a] Calculated using values given by Nelson.[16]
$LMo(CO)_5$; A = −0.142, B = 40.19.
cis-$L_2Mo(CO)_4$; A = −0.136, B = 43.90.
fac-$L_3Mo(CO)_3$; A = −0.105, B = 36.49.

indicate an even stronger σ-interaction with molybdenum. The ^{95}Mo data indicates a smaller σ- or nephelauxetic effect and/or a lower π-acceptor ability of PTAMeI. Previous $\delta(^{95}Mo)$ data[9,10] for phosphine and phosphite-substituted molybdenum carbonyl complexes showed that the better π-acceptor ligands caused molybdenum to be most shielded, presumably due mainly to their effect on the HUMO–LUMO separation, and hence the paramagnetic shift term for this quadrupolar nuclei ($I = 5/2$, 15.7% natural abudance).

The tungsten carbonyl complexes give much lower ^{31}P coordination chemical shifts than for the analogous molybdenum complexes, as observed for other phosphines.[10] These data also give a poor fit to the coordination chemical shift correlation equation.[16] The value for *fac*-$(PTA)_3W(CO)_3$ is close (observed $\Delta = 26.3$ ppm, calculated 27.2 ppm), but as the original data is only based on three determinations the agreement may be fortuitous.

The $J(^{31}P—^{183}W)$ coupling constants observed for the complexes are low. The value of 224 Hz for $W(CO)_5PTA$ would make PTA a poorer donor than PBu_3^n (227 Hz) and a much poorer donor than PPh_3 (245 Hz). The $J(^{31}P—^{183}W)$ values show significant and intriguing differences in the complexes studied. Other metal complexes are being investigated to provide a better assessment of $J(^{31}P—^{n}M)$ values and the nature of M—PTA bonds.

AN *IN SITU* STOPPED-EXCHANGE SOLUTION ^{31}P NMR COMPARISON STUDY OF 1-PHENYLDIBENZOPHOSPHOLE AND TRIPHENYLPHOSPHINE LIGANDS IN $[Hg(DMF)_{4-n}L_n][ClO_4]_2$ ($n = 1$–4)

ELMER C. ALYEA* and JOHN MALITO

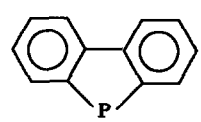
Guelph–Waterloo Centre for Graduate Work in Chemistry, Guelph Campus, Department of Chemistry and Biochemistry, University of Guelph, Guelph, Ontario, Canada N1G 2W1

(*Received* 9 *September* 1992; *accepted* 22 *October* 1992)

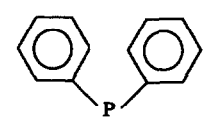
Abstract—Upon dissolution in DMF $Hg(ClO_4)_2$ is solvated to give $[Hg(DMF)_4][ClO_4]_2$, which reacts with 1-phenyldibenzophosphole (DBP) or triphenylphosphine (PPh_3) to give $[Hg(DMF)_{4-n}L_n][ClO_4]_2$ (n = 1–3 for DBP and 1–2 for PPh_3). One-bond Hg—P coupling constants, which reach 11,014 Hz in the $[Hg(DMF)_3(DBP)]^{2+}$ cation, and coordination chemical shifts are higher and lower, respectively, for the DBP species. The former and latter observations are ascribed to electronic and steric effects, respectively. The ultimate $n = 4$ species are not observed in DMF solution but form readily in the non-coordinating solvent CH_2Cl_2. Overall, the PPh_3 species show higher kinetic lability, which contrasts with the opposite behaviour observed earlier for group 11 complexes.

Mercuric complexes of the type HgX_2L_2 (X = halide, pseudohalide; L = tertiary phosphine) have been well studied;[1] our earlier contributions focussed on ligand steric and electronic effects active within these and related complexes.[2] These reports established that for a given X and variable L relative Hg—P bond strengths are indicated by the magnitudes for $^1J(^{199}Hg—^{31}P)$[3], which in turn are sensitive to the steric and electronic properties of L. For weakly or non-coordinating X cationic species of variable stoichiometry are possible, dependent upon the natures of both X and L[4].

In this paper we apply the above knowledge in undertaking an *in situ* solution ^{31}P NMR study to compare the relative ligating properties of 1-phenyldibenzophosphole (DBP) and triphenyl phosphine (PPh_3) in reactions with $Hg(ClO_4)_2$. We have already reported complexation studies of DBP, which is both less sterically demanding[5a] and less basic than its nearest tertiary phosphine analogue PPh_3, with group 6 and 11 metals.[5]



DBP



Ph_3P

EXPERIMENTAL

1-Phenyldibenzophosphole was supplied by Professor John H. Nelson (University of Nevada, Reno) while triphenylphosphine was purchased from a commercial source; each of these ligands was used as received. All syntheses were carried out under dinitrogen in 10 mm OD NMR tubes for stoichiometric additions of ligand solutions to $Hg(ClO_4)_2$ solutions (1 equivalent = 0.1 mmol). DMF and CH_2Cl_2 solvents were deoxygenated and of spectroscopic grades.

^{31}P NMR spectra were recorded at 223 K on a Bruker WH-400 spectrometer operating at 161.98 MHz and chemical shifts are reported relative to an external standard of aqueous 85% H_3PO_4. Chemical shifts for ^{199}Hg are reported relative to a 0.50 M solution of $HgCl_2$ in EtOH, set to −1497.0 ppm

* Author to whom correspondence should be addressed.

relative to neat $HgMe_2$ at 0.00 ppm.[6] The magnet was shimmed for sample ^1H FID spectra (^{31}P NMR) or deuterium in pure D_2O (^{199}Hg NMR). In all cases chemical shifts to higher frequency (i.e. downfield) are considered positive.

RESULTS AND DISCUSSION

The magnitude of the one-bond coupling constant $^1J(^{199}Hg—^{31}P)$, for species of the type HgX_2L_2, is sensitive to both experimental conditions of measurement[7] and the ligand properties of X and L. For strongly coordinating X the coupling constant magnitudes increase linearly with increasing tertiary phosphine basicities.[2,3,7] A similar trend has been reported for the analogous system CdX_2L_2.[8] If, however, X is weakly bonded or non-coordinating, then the trend is reversed and coupling constant magnitudes increase with decreasing basicities.[9] These trends, consistent with a Hg—P bond dominated by σ-character, are summarized, for a collection of literature data for three different anions,[2,3,7,9] in Fig. 1.

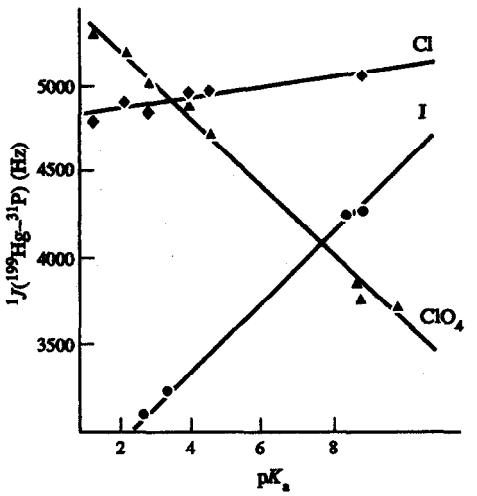


Fig. 1. Plots for $^1J(^{199}Hg—^{31}P)$ (Hz) vs ligand pK_a for HgX_2L_2 (X = Cl, I, ClO_4; L = tertiary phosphine).

For a given L, the coupling constant magnitude increases as (X=) CN < I < SCN < Br < Cl < OAc < NO_3 < ClO_4,[3,7-10] or as the Hg—X bond becomes more ionic. This is consistent with Bent's rule[11] and implies that as X becomes more electronegative, the bonding orbitals on mercury directed toward X and P gain in *p*- and *s*-character, respectively. Thus, $^1J(^{199}Hg—^{31}P)$ values, which reflect the amount of *s*-character in the Hg—P bond, should and do reflect Hg—P bond strengths.[3,10,12]

Our comparison studies for DBP and PPh_3 confirm the trends discussed above. In an earlier short paper[5b] we reported that for HgX_2L_2 (X = I, SCN; L = DBP, PPh_3) $J(^{199}Hg—^{31}P)$ values increase in magnitude as I < SCN and DBP < PPh_3. For $[Hg(DMF)_{4-n}L_n][ClO_4]_2$ (n = 1–3) (see Table 1), however, coupling constants are larger for L = DBP. For the n = 4 species, the coupling constants should be,[5b] but are not, equal in magnitude. Thus, which of DBP or PPh_3 forms the stronger bond with mercury(II) will depend on what other ligands are also bound to the same mercury(II) centre.

The maximum coordination species, $[HgL_4][ClO_4]_2$, are not observed in DMF solution even for a 10 times molar excess of added L. These species are observed, however, in the much less interactive solvent CH_2Cl_2. Thus, the assignments made in Table 1 assume complete solvation of $Hg(ClO_4)_2$ in DMF to give $[Hg(DMF)_4][ClO_4]_2$. Similar solvent interactions with mercury(II) have been previously suggested for DMF,[10a] as well as MeOH[4a], py[4a] and DMSO.[13] As part of this study we have observed that for saturated solutions of $Hg(ClO_4)_2$, the ^{199}Hg chemical shift moves upfield as acetone (−1504

Table 1. ^{31}P NMR data for $[Hg(DMF)_{4-n}L_n][ClO_4]_2$

Species	L = DBP $\Delta\delta^{31}P^{a,b}$ (ppm)	L = DBP $^1J(^{199}Hg—^{31}P)$ (Hz)	L = PPh_3 $\Delta\delta^{31}P^{a,c}$ (ppm)	L = PPh_3 $^1J(^{199}Hg—^{31}P)$ (Hz)	Solvent
$[Hg(DMF)_3L]^{2+}$	34.1	11,014	39.6	10,547	DMF
$[Hg(DMF)_2L_2]^{2+}$	44.0	6868	48.6	6413	DMF
$[Hg(DMF)L_3]^{2+}$	40.7	3888	[d]	[d]	DMF
$[HgL_4]^{2+}$	25.2	2051	32.4	2076	CH_2CH_2

[a] $\Delta\delta = \delta^{31}P$ (P coordinated) − $\delta^{31}P$ (P free).
[b] $\delta^{31}P$ (DBP free) = −11.0 ppm in DMF; −11.9 ppm in CH_2CH_2.
[c] $\delta^{31}P$ (PPh_3 free) = −6.8 ppm in DMF; −5.6 ppm in CH_2Cl_2.
[d] Not observed.

ppm) < H_2O (−2264 ppm) < DMSO (−2320 ppm) < DMF (−2346 ppm), i.e. as the solvent nucleophilicity increases.[14] In support of this, Sens *et al.*[15] have reported that shielding of mercury(II) in $HgMe_2$ increases with solvent Lewis basicity for 20 different solvents. Therefore, reaction of DBP or PPh_3 with $[Hg(DMF)_4][ClO_4]_2$ must involve displacement of a coordinated DMF molecule.

The ligands were added sequentially in stoichiometric quantities to DMF solutions of $Hg(ClO_4)_2$. Ensuing reactions were monitored *in situ* by ^{31}P NMR spectrometry at 223 K. This low temperature is required to resolve the ^{199}Hg satellites to measure $^1J(^{199}Hg—^{31}P)$. At this temperature, except for those cases where exchange occurs (*vide infra*), the line widths are typically 10 Hz or less and assignments are unambiguous.

Cationic species of the type $[HgL]^{2+}$ have been previously reported for phosphite ligands,[16] but comparable species for L = tertiary phosphine also contain either coordinated anions[17] or solvent molecules.[4a,10a,13] In DMF there is a very smooth stepwise formation observed for $[Hg(DMF)_{4-n}(DBP)_n]^{2+}$ (to $n = 3$) as DBP is added. Once three equivalents of DBP are added, a resonance assignable to free (or uncoordinated) DBP is observed and all resonances begin to broaden, indicating exchange of free ligand with $[Hg(DMF)(DBP)_3]^{2+}$. The case for PPh_3 is very different. The maximum coordination species observed is $[Hg(DMF)_2(PPh_3)_2]^{2+}$ and a resonance assignable to free PPh_3 does not appear until at least six equivalents of PPh_3 are added. The $n = 1$ and $n = 2$ species appear to be in equilibrium with each other and with free PPh_3.

It is clear that DBP competes more effectively than PPh_3 with DMF for coordination sites on mercury(II). This is most likely due to the smaller size of DBP, relative to PPh_3, in spite of the lower basicity for DBP. It is also clear that the PPh_3 species are much more kinetically labile than their DBP counterparts, contrary to our earlier observations for the group 11 metals,[5b] but consistent with results from our more recent study for L_nAuCl.[18]

Assignments for the PPh_3 species in Table 1 are consistent with data for similar species reported in the current literature.[4,9,19] The higher $^1J(^{199}Hg—^{31}P)$ values measured for the DBP species are also consistent with expectations based on relevant literature data.[9] These larger coupling constants, however, correspond with smaller complex coordination chemical shifts [$\Delta\delta = \delta$(coordinated P) − δ(free P)], opposite to what is usually observed for tertiary phosphine ligands.[2d,7b,10a] This suggests that the $\Delta\delta$ parameter, in this case, merely reflects larger C—P—C bond angle changes upon coordination for PPh_3 than for the more rigid DBP molecule.[5a] Also, $\Delta\delta$ appears to be maximized for the $n = 2$ species, indicating that steric crowding is a factor that is active for $[Hg(DMF)_{4-n}L_n]^{2+}$, as has been observed for other related species.[5b,9b]

Our comparison studies, including multinuclear NMR techniques, of the ligating properties of phosphole and dibenzophosphole ligands with their tertiary phosphine analogues continue. Nevertheless, it can be said at this point that whether DBP or PPh_3 is the "better" ligand depends upon several factors, including the nature of the metal centre and whatever ancillary ligands are also present.

PREPARATION OF $Mn(C_6F_5)_2$ COMPOUNDS BY TREATMENT OF $Hg(C_6F_5)_2$ WITH MANGANESE METAL—A NOVEL SYNTHESIS OF *d*-BLOCK ORGANOMETALLICS

GLEN B. DEACON,* RON S. DICKSON, JOZEF L. LATTEN and BRUCE O. WEST

Chemistry Department, Monash University, Clayton, Victoria 3168, Australia

(*Received* 27 *October* 1992; *accepted* 2 *November* 1992)

Abstract—Prolonged reaction of manganese metal with bis(pentafluorophenyl)mercury in thf or 1,2-dimethoxyethane (dme) yields $Mn(C_6F_5)_2(thf)_2$ or $Mn(C_6F_5)_2(dme)$. The latter reacts with N,N,N′,N′-tetramethylethane-1,2-diamine (tmen) in toluene to give $Mn(C_6F_5)_2$(tmen). Mass spectra indicate the complexes have associated structures. Impure $Mn(p\text{-}HC_6F_4)_2(dme)$ was obtained from manganese metal and $Hg(p\text{-}HC_6F_4)_2$.

Redox transmetallation between organomercurials and main group elements (e.g. Li, Mg, Al and Sn) is a well-established route to their organic derivatives [eq. (1)].[1,2]

$$E + n/2HgR_2 \longrightarrow ER_n + n/2Hg \downarrow \qquad (1)$$

The method is applicable to a number of main group polyfluorophenyl derivatives,[2,3] but has only limited use for perfluoroalkyls.[2] These syntheses are generally carried out in the absence of a solvent or in hydrocarbon media, at elevated temperatures, hence thermally stable target molecules are required. A free radical mechanism is likely for most reactions, although alternatives have been proposed for some of the few cases where mild conditions are used.[1] The main advantage of reaction (1) is that it provides a "halide-free" synthesis. In addition, where no solvent or a hydrocarbon solvent is used solvent coordination is avoided. There is no clear example of the use of reaction (1) in the synthesis of a *d*-block organometallic. In a related preparation ferrocene has been obtained in modest yield (24–30%) from treatment of iron powder with the crude product [stated to be a mixture of $Hg(C_5H_5)_2$ and $Hg(C_5H_5)Cl$] of the reaction of sodium acetate, cyclopentadiene and mercuric chloride.[4] However, the synthesis is not "halide-free" and the initial stoichiometry (C_5H_6:$HgCl_2$ = 1:1) favours $Hg(C_5H_5)Cl$ rather than $Hg(C_5H_5)_2$ as the main reactant. Widespread application of reaction (1) to the synthesis of *d*-block organometallics appears unlikely, because there are a number of low energy decomposition paths for these compounds. However, it has been shown that some *f*-block organometallics, including the thermally-unstable $Ln(C_6F_5)_2$ (Ln = Eu or Yb) derivatives,[5,6] can be prepared by redox transmetallation in ether solvents.[7,8] These may be envisaged as involving carbanion transfer to the highly electropositive lanthanide metal rather than a free radical mechanism.[5] The possibility of extension to *d*-block organometallics can be viewed as speculative, since the metals, apart from the neolanthanides Sc and Y, are much less electropositive than the lanthanide elements. Nevertheless, we now report the synthesis of bis(pentafluorophenyl)manganese by redox transmetallation.

RESULTS AND DISCUSSION

Prolonged reaction of bis(pentafluorophenyl)-mercury with manganese metal flake in thf at room temperature gave $Mn(C_6F_5)_2(thf)_2$ in reasonable yield after a difficult purification [eq. (1), E = Mn, R = C_6F_5, n = 2]. Reaction between the mercurial and manganese metal powder in refluxing 1,2-dimethoxyethane (dme) for a much shorter time gave $Mn(C_6F_5)_2(dme)$. Although microanalytical data deviated somewhat from calculated values, the variations were not excessive for highly air- and moisture-sensitive compounds. Moreover, acidolysis of $Mn(C_6F_5)_2(dme)$ [eq. (2)], which had the less satisfactory analyses, and determination of the C_6F_5H : dme ratio confirmed the composition.

* Author to whom correspondence should be addressed.

$$Mn(C_6F_5)_2(dme) + 2H^+ \longrightarrow Mn^{2+} + 2C_6F_5H + dme \quad (2)$$

In addition, the complex was converted by ligand exchange with N,N,N′,N′-tetramethylethane-1,2-diamine (tmen) into $Mn(C_6F_5)_2(tmen)$ [eq. (3)], which gave good microanalysis data.

$$Mn(C_6F_5)_2(dme) + tmen \longrightarrow Mn(C_6F_5)_2(tmen) + dme \quad (3)$$

Impure $Mn(p\text{-}HC_6F_4)_2(dme)$ was also obtained by redox transmetallation [eq. (1), R = p-HC_6F_4, n = 2, E = Mn).

The pentafluorophenylmanganese complexes showed IR absorptions characteristic[3,9] of pentafluorophenylorganometallics at *ca* 1630 and 1500 cm^{-1} [ν(CC)] and 1045 and 945 cm^{-1} [ν(CF)]. In addition, the thf complex showed intense features at 1019 and 862 cm^{-1} attributable to ring C—O stretching of coordinated thf, shifted characteristically from free ligand values.[10] Main group element[9] and some *d*-block pentafluorophenyls[11] show an "X-sensitive" mode involving metal–carbon stretching at 850–760 cm^{-1}. No corresponding absorption could be observed for $Mn(C_6F_5)_2L$ [L = $(thf)_2$, dme or tmen]. Bands for the thf and dme complexes at *ca* 860 cm^{-1} cannot be assigned to this mode, as there is no analogous absorption for $Mn(C_6F_5)_2(tmen)$. The absence of such a feature is consistent with the predominantly ionic character for the Mn—C bonds. Likewise, no clear assignment of this mode could be made for highly ionic $Yb(C_6F_5)_2(thf)_4$.[5] The IR spectrum of $Mn(p\text{-}HC_6F_4)_2(dme)$ showed the distinctively different ν(CF) bands (1200–1100; 879 cm^{-1}) exhibited by 2,3,5,6-tetrafluorophenylorganometallics.[5]

Magnetic moments consistent with high-spin manganese(II) were observed for the complexes. No parent ions or $Mn(C_6F_5)_2^+$ ions were observed in the mass spectra. However, several Mn_2^+-containing ions appeared with $Mn_2F(C_6F_5)_3^+$, $Mn_2H(C_6F_5)_3^+$, $Mn_2F_2(C_6F_5)_2^+$ and $Mn_2HF(C_6F_5)_2^+$ common to the spectra of the three $Mn(C_6F_5)_2L$ complexes and $Mn_2(C_6F_5)_2C_6F_4^+$, $Mn_2(C_6F_5)_2^+$ and $Mn_2F(C_6F_5)^+$ present in two (see Experimental). Only one ion containing a single manganese was evident, viz. $Mn(C_6F_5)dme^+$. These features indicate an associated, possibly dimeric, structure for the complexes. Although all ligands, even thf,[12] potentially can be bridging, the observation of dimers as dominant species under gas phase, mass spectrometric conditions at 200°C implies bridging pentafluorophenyl groups. Possible structures include a six-coordinate polymer with four bridging C_6F_5 groups per manganese or a five-coordinate dimer with two bridging and one terminal C_6F_5 group per manganese. Dimeric structures with bridging organic groups are known for organomanganese(II) Lewis base complexes.[13,14] Crystals suitable for X-ray crystallography could not be obtained.

Formation of $Mn_2F(C_6F_5)_3^+$ as the highest observed ion can be envisaged as resulting from loss of tetrafluorobenzyne from the desolvated dimer $Mn_2(C_6F_5)_4$. An ion with the composition $Mn_2(C_6F_5)_2C_6F_4^+$ has been observed for two compounds. This may plausibly be a 2-nonafluorobiphenylyl species, $Mn_2(C_6F_5)(2\text{-}C_{12}F_9)^+$, formed by insertion of tetrafluorobenzyne into an Mn—C_6F_5 bond. Analogous insertions are a well-established decomposition path for highly ionic C_6F_5Li[3] and C_6F_5-lanthanide[6] compounds. The ion $(C_6F_5)_2^+$ may be indicative of thermal decomposition into decafluorobiphenyl via pentafluorophenyl radicals.

The use of redox transmetallation between mercurials and manganese metal has provided a route to the first pentafluorophenylmanganese(II) complexes. It is the first authentic use of this synthetic method in *d*-block organometallic chemistry, and it indicates that use of polar solvents and mild reaction conditions for prolonged times can enable redox transmetallation to be used for the preparation of compounds with facile thermal decomposition paths. The discovery that a commercial form of manganese metal is sufficiently reactive to undergo redox transmetallation with mercurials offers the possibility that others of the more electropositive *d*-block metals may undergo convenient analogous reactions.

EXPERIMENTAL

All work was carried out under argon using standard Schlenk and dry-box techniques, as the products are very air-sensitive. Thf and 1,2-dimethoxyethane were distilled from sodium and benzophenone, whilst toluene and N,N,N′,N′-tetramethylethane-1,2-diamine were distilled from sodium and hexane from sodium–potassium alloy. Manganese flake was obtained from Aldrich; manganese powder was obtained by grinding the flake with a mortar and pestle in a recirculating atmosphere dry-box. Bis(pentafluorophenyl) mercury(II)[15] and bis(2,3,5,6-tetrafluorophenyl) mercury(II)[16] were prepared according to literature methods. Elemental analyses were carried out by National Analytical Laboratories, on preweighted encapsulated samples. IR spectra were recorded as Nujol mulls with a Perkin–Elmer 1600 Series FTIR spectrometer. Mass spectra were recorded on a VG

Micromass 7070F mass spectrometer, using a sample holder which could be loaded in the dry-box. Magnetic moments were determined using a Johnson–Matthey magnetic susceptibility balance calibrated with $Ni(en)_3S_2O_3$.

$Mn(C_6F_5)_2(thf)_2$ (1)

Manganese flake (0.28 g, 5.1 mmol) and bis(pentafluorophenyl)mercury (2.51 g, 4.7 mmol) were stirred in thf (20 cm^3) at room temperature for 2.5 months, giving a brown solution which was evaporated to dryness under a vacuum. The residue was extracted with boiling toluene and filtered. On cooling the extract to room temperature, fine needles were deposited, which were isolated by decanting the mother liquor, washed with hexane and dried *in vacuo*. A second crop was isolated by concentration of the mother liquor to saturation at its boiling point. Fine pale brown needles (1.17 g, 2.2 mmol, 47%) were obtained after a second recrystallization from boiling toluene. Found: C, 46.0; H, 3.2. Calc. for $C_{20}H_{16}F_{10}MnO_2$: C, 45.0; H, 3.0%. IR: 1670w, 1631m, 1606w, 1583w, 1498s, 1321m, 1279w, 1070w, sh, 1046vs, 1019s, 945vs, 862s, 750m, 722m, 713w, 676w, 593w, 480w cm^{-1}. $\mu_{eff} = 5.8$ B.M. MS (*m/z*): 630 ($[Mn_2F(C_6F_5)_3]^+$), 612 ($[Mn_2H(C_6F_5)_3]^+$), 482 ($[Mn_2F_2(C_6F_5)_2]^+$), 464 ($[Mn_2HF(C_6F_5)_2]^+$), 334 ($[C_6F_5C_6F_5]^+$), 316 ($[C_6F_5C_6F_4H]^+$), 168 (100%, $[C_6F_5H]^+$), 99 ($[C_5F_2H]^+$), 72 (thf^+).

$Mn(C_6F_5)_2(dme)$ (2)

Manganese powder (0.27 g, 4.9 mmol) and bis(pentafluorophenyl)mercury (2.31 g, 4.3 mmol) were stirred in refluxing 1,2-dimethoxyethane (10 cm^3) for 1 week. The resulting brown suspension was cooled and evaporated to dryness under reduced pressure. Extraction of the residue with boiling toluene, filtration and cooling to room temperature gave pale brown crystals, which were isolated by decanting the mother liquor, washed with hexane and dried *in vacuo*. A second crop was isolated by concentration of the mother liquor to saturation at its boiling point. Fine pale brown needles (0.83 g, 1.7 mmol, 40%) were obtained after a second recrystallization from boiling toluene. Found: C, 41.6; H, 2.6. Calc. for $C_{16}H_{10}F_{10}MnO_2$: C, 40.1; H, 2.1%. IR: 1633m, 1500m, 1324m, 1278w, 1254m, 1194w, 1093w, 1071m, 1049vs, 1003m, 944vs, 865s, 823w, 759w, 722m, br, 592m, 483m cm^{-1}. $\mu_{eff} = 5.8$ B.M. MS (*m/z*): 630 ($[Mn_2F(C_6F_5)_3]^+$), 612 ($[Mn_2H(C_6F_5)_3]^+$), 592 ($[Mn_2(C_6F_5)_2(C_6F_4)]^+$), 482 ($[Mn_2F_2(C_6F_5)_2]^+$), 464 ($[Mn_2HF(C_6F_5)_2]^+$), 444 ($[Mn_2(C_6F_5)_2]^+$), 334 ($[C_6F_5C_6F_5]^+$), 316 ($[C_6F_5C_6F_4H]^+$), 312 ($[Mn(C_6F_5)(dme)]^+$), 296 ($[Mn_2F(C_6F_5)]^+$), 168 ($[C_6F_5H]^+$), 99 ($[C_5F_2H]^+$), 98 ($[C_5F_2]^+$), 90 ($dme^+$), 60 (100%, $[OCH_2CH_2O]^+$).

$Mn(C_6F_5)_2(tmen)$ (3)

$Mn(C_6F_5)_2(dme)$ (0.74 g, 1.6 mmol), N,N,N'N'-tetramethylethane-1,2-diamine (0.5 cm^3, 3.3 mmol) and toluene (10 cm^3) were heated under reflux for 10 min. The brown solution was cooled and evaporated to dryness under reduced pressure. The residue was extracted with boiling toluene and filtered. Cooling the extract to room temperature gave brown needles, which were isolated by decanting the mother liquor, washed with hexane and dried *in vacuo*. Fine pale brown needles (0.43 g, 0.85 mmol, 55%) were obtained after a second recrystallization from boiling toluene. Found: C, 42.9; H, 3.1; N, 5.8. Calc. for $C_{18}H_{16}F_{10}MnN_2$: C, 42.8; H, 3.2; N, 5.5%. IR: 1628m, 1533w, 1496m, 1319w, 1282w, 1246m, 1168w, 1120w, 1073m, 1060m, 1041s, 1019w, 1006m, 951s, 944s, 798m, 769w, 750w, 722s, 592w, 587w, 479w cm^{-1}. $\mu_{eff} = 5.8$ B.M. MS (*m/z*): 630 ($[Mn_2F(C_6F_5)_3]^+$), 612 ($[Mn_2H(C_6F_5)_3]^+$), 592 ($[Mn_2(C_6F_5)_2(C_6F_4)]^+$), 482 ($[Mn_2F_2(C_6F_5)_2]^+$), 464 ($[Mn_2HF(C_6F_5)_2]^+$), 444 ($[Mn_2(C_6F_5)_2]^+$), 334 ($[C_6F_5C_6F_5]^+$), 316 ($[C_6F_5C_6F_4H]^+$), 298 ($[Mn_2(tmen)(C_4H_{10}N)]^+$), 296 ($[Mn_2F(C_6F_5)]^+$), 168 ($[C_6F_5H]^+$), 116 ($tmen^+$), 99 ($[C_5F_2H]^+$), 58 (100%, $[Me_2NCH_2]^+$).

$Mn(p\text{-}HC_6F_4)_2(dme)$ (4)

Manganese powder (0.39 g, 7.1 mmol) and Hg $(p\text{-}HC_6F_4)_2$ (1.52 g, 3.1 mmol) were heated under reflux in 1,2-dimethoxyethane (10 cm^3) for 11 days. The clear solution slowly turned cloudy and a fine grey precipitate formed. The suspension was evaporated to dryness under reduced pressure. The residue was recrystallized from boiling toluene, filtered and slowly cooled to room temperature giving colourless crystals. These were isolated by decanting the mother liquor, washed with hexane and dried *in vacuo*. A second crop was obtained by concentration of the mother liquor. Yield: 0.44 g, 0.99 mmol, 32%. Found: C, 40.3; H, 3.1. Calc. for $C_{16}H_{12}F_8MnO_2$: C, 43.4; H, 2.7%. IR: 3090w, 1771w, 1663w, 1599s, 1571w, 1533w, 1318w, 1308s, 1278m, 1239m, 1200s, 1172vs, 1089s, 1044vs, 1018m, 998m, 974w, 935w, 879vs, 858vs, 832s, 820m, 798w, 793w, 722s, 697s, 658m, 502w, 491m cm^{-1}. $\mu_{eff} = 6.0$ B.M.

Acidolysis of **2**

Compound **2** (20 mg, 42 μmol) was dissolved in pyridine-d_5 (0.7 cm^3) and frozen in a liquid nitrogen bath. Trifluoroacetic acid (0.1 cm^3, 1.3 mmol) was added to the frozen mixture, which was then allowed to thaw. On reaching room temperature a pale orange solution formed. The volatile components of the orange solution were vacuum distilled in a closed system and collected in a flask cooled in a liquid nitrogen bath. The solid residue was gently warmed to ensure that all volatiles had evaporated. An ^1H NMR spectrum of the condensed volatiles showed peaks at δ 7.39 (C_6F_5H), 3.49 ($MeOCH_2)_2$ and 3.27 ppm ($MeOCH_2)_2$ in a peak area ratio of 1 : 2 : 3, as required for hydrolysis of **2** [eq. (2)].

COMPLEXES OF MOLYBDENUM(V) WITH DITHIOCARBAMATE DERIVED FROM α-AMINO ACIDS

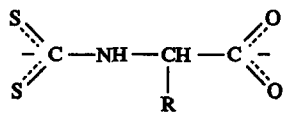
B. MACIAS,* J. J. CRIADO, M. V. VILLA, M. R. IGLESIAS and M. CASTILLO

Departamento de Química Inorgánica, Facultad de Farmacia, Universidad de Salamanca, Avda. Campo Charro s.n., 37007 Salamanca, Spain

(*Received* 15 *October* 1992; *accepted* 26 *October* 1992)

Abstract—Complexes formed through reaction of dithiocarbamate derived from α-amino acids with molybdenum(V) chloride in an inert atmosphere have been synthesized. These same complexes have also been prepared by the reduction of sodium molybdate with dithionite in an acidic medium. Chemical analyses for the complexes indicate the general formula $[Mo_2O_4(dtc\ a.a.)_2]\cdot 2H_2O$, where a.a. is the corresponding amino acid. No absorption band for the $Mo_2O_4^{2+}$ moiety was recorded in the visible range. IR spectra indicate that the carboxyl group is in the acid form, without binding to the metal cation. X-ray photoelectron spectra confirm the oxidation state of the molybdenum ions (Mo^{5+}), and that both sulphur atoms of the dithiocarbamate unit are equivalent.

The coordination chemistry of molybdenum has received much attention in the last decades, especially studies on the high oxidation states of this metal, as found in molybdoenzymes.[1–3] The complexes synthesized so far have provided information about the chemical behaviour of this element, and as it has been reported that molybdenum–sulphur bonds exist in these molybdoenzymes much effort has focussed on preparing and characterizing complexes with donor sulphur atoms.[4–6] Within this group of compounds, dialkyldithiocarbamate complexes have been studied, as they can undergo redox reactions as in molybdoenzymes.[4,7,8] These dialkyldithiocarbamate are easily synthesized through the reaction of the amine with carbon sulphide in a basic medium. However, if an α-amino acid is used instead of an amine, dithiocarbamate derivatives of α-amino acids are obtained[9,10] with the general formula:



The simultaneous presence of the dithiocarbamate and the carboxylic groups makes these ligands very interesting, as both can coordinate the metallic cation and will modify the solubility of the complexes because of their polar properties. On the other hand, the nature of the side chain (R) is characteristic of the starting α-amino acid and may also affect the donor properties of the dithiocarbamate moiety.

In order to analyse the effect of this side-chain on the properties of the complexes thus formed, we have selected a series of α-amino acids with branched or linear side-chains of different lengths: R = H, glycine (gly); $-CH_3$, alanine (ala); $-CH_2-CH_3$, α-aminobutyric acid (α-ambut); $-CH_2-CH_2-CH_3$, norvaline (norval); $-CH-(CH_3)_2$, valine (val); $-CH_2-CH_2-CH_2-CH_3$, norleucine (norleu); $-CH_2-CH-(CH_3)_2$, leucine (leu); $-CH-(CH_2-CH_3)(CH_3)$, isoleucine (isoleu). The complexes formed upon reaction of these dithiocarbamate derivatives with molybdenum(V) chloride have been characterized.

EXPERIMENTAL

Materials and methods

All amino acids (in the DL form), $Na_2MoO_4\cdot 2H_2O$, $Na_2S_2O_4$ and CS_2 were from Fluka (p.a.). $MoCl_5$ was from Aldrich and the organic solvents, acetone and dimethylformamide (DMF),

* Author to whom correspondence should be addressed.

were from Carlo–Erba (RPE). All reactions were performed under a nitrogen atmosphere using standard Schlenk techniques.

Chemical analyses for carbon, hydrogen and nitrogen were performed using a Perkin–Elmer model 2400 analyser; sulphur contents were determined in the Instituto Bio-Organica de Barcelona (CSIC); the molybdenum content was determined using a Perkin–Elmer model 2380 Plasma-2 ICP spectrometer. Magnetic susceptibilities were determined by the Gouy method using a Stanton MC-5 microbalance, with $Hg[Co(SCN)_4]$ as the reference. FT-IR spectra were recorded using a Perkin–Elmer FT-IR 1730 spectrometer, with KBr pellets. Electronic spectra were recorded in a Shidmazu model UV-240 double beam spectrophotometer, using a diffuse reflectance accessory for solid samples and MgO as a reference. X-ray photoelectron spectra were recorded in the Departamento de Química Inorgánica (University of Sevilla), using a Leybold Heraeus LHS-10 apparatus, with Al-K_α radiation, an intensity of 20 mA, the samples being outgassed *in situ* at a residual pressure of 10^{-9} Torr, and using the C(1s) signal at 284.6 eV as a reference.

Preparation of the complexes

$MoCl_5$ (0.004 mol) was dissolved in doubly distilled water (15 cm^3), previously degassed, and the freshly prepared dithiocarbamate derivative (0.006 mol) of the α-amino acid (dissolved in 10 cm^3 of doubly distilled water) was slowly added with continuous stirring. After the addition of the first drops a brown–purple precipitate was observed, which increased in amount as the process continued. The precipitate was filtered using Schlenk flasks and washed three times with doubly distilled, degassed water (20 cm^3). The brown–ochre solid was dried *in vacuo* in the same flask. The yield ranges from 60% (for long-chain derivatives) to 40% (for short-chain derivatives).

These same complexes can also be prepared through reaction of the dithiocarbamate derivatives with sodium molybdate, using $Na_2S_2O_4$ as the reducing agent. The reaction takes place also under nitrogen. A solution was prepared by dissolving $Na_2MoO_4 \cdot 2H_2O$ (0.015 mol) in doubly distilled water (10 cm^3) and the sodium salt (0.025 mol) of the dithiocarbamate derivative in doubly distilled water (25 cm^3); to this solution, another containing sodium dithionite (0.045 mol) in NaOH (15 cm^3, 0.2 M) was added. Then, HCl (15 cm^3, 6 M) was slowly added dropwise to the former solution and a brown precipitate was formed, while the colour of the solution changed to orange. The precipitate was filtered and washed several times with doubly distilled water in order to remove excess dithionate, and was finally dried *in vacuo*. The yield was only 15–20% as more washing cycles were needed, due to the larger number of chemicals and reaction products.

RESULTS AND DISCUSSION

Data for chemical analyses for the complexes obtained following the two methods outlined above are included in Table 1. The general formula calculated from these data corresponds to $[Mo_2O_4(dtc\ a.a.)_2] \cdot 2H_2O$. Complexes containing the $Mo_2O_4^{2+}$ moiety have been previously described in the literature,[4,8,11] and they usually contain a two-oxygen atom bridge and two terminal oxygen atoms in *cis* positions; the oxidation state of molybdenum is Mo^{5+}. Solubility in water is low for all complexes prepared and so the low yields attained for the short-chain compounds can be associated with their higher solubility due to their lower organic character. Solubility is also low in methanol and acetone,

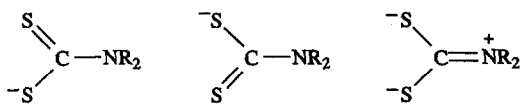
n.m. = not measured.

where they decompose slowly at room temperature; on the contrary, solubility is higher in DMF, forming brown coloured solutions. In any case, due to the low stability in solution crystals could not be obtained and the molecular structure could not be determined.

All compounds are diamagnetic, with pairing between the odd electrons in both molybdenum atoms of the $Mo_2O_4^{2+}$ moiety occurring through the bridging oxygen atoms. No absorption band was recorded in the visible range. Only a band at 330 nm was recorded when acetone was used as a solvent, with a molar extinction coefficient of 6500 $dm^3\ mol^{-1}\ cm^{-1}$. This band can be associated with a S → Mo charge-transfer process. A band recorded at 280 nm in DMF with a very large extinction coefficient (21,000 $dm^3\ mol^{-1}\ cm^{-1}$) can be due to intraligand electron transfer. A broad band recorded in the solid state may contain both of the absorptions detected separately in solution. This sort of finding has already been reported in the literature for dinuclear molybdenum complexes with a two-oxygen bridge and containing the $Mo_2O_4^{2+}$ moiety; for complexes with a one-oxygen bridge ($Mo_2O_3^{4+}$), the band is recorded at 500 nm.[4,8,12–14]

The positions of the most significant FT-IR bands are included in Table 2. The band due to the C—N stretching mode is recorded at *ca* 1530 cm^{-1} in all cases, thus indicating a fairly large bond order. According to the valence bond theory, the structure of these dithiocarbamate units can be depicted as:



(a) (b) (c)

and so structure **c** would contribute to a larger extent than the others to the real structure, as confirmed by X-ray diffraction studies for some dithiocarbamate complexes, showing that the C—N distance is between those corresponding to a single and a double bond.[15–18] It has been reported[16,19–21] that this band shifts towards lower wave numbers as the length of the side-chain increases, because of the increasing molecular mass, but this effect is hardly observed in our case, probably due to the presence of the relatively heavy carboxylic group which make the relative differences between the point masses less important. The C—N stretching mode between the carbon atom and the nitrogen atom from the amino acid fragment is also recorded (see Table 2) and corresponds to a single C—N bond.[22,23]

vs = very strong, s = strong, m = medium, w = weak.

As in both synthetic routes outlined above the complexes are prepared in an acidic medium. The carboxylic group of the amino acid remains as such (i.e. it is not ionized to the carboxylate form) and thus does not participate in bonding to the molybdenum cation. This fact was confirmed by the presence of a single strong band for all complexes at 1724 cm^{-1}, due to the C=O stretching mode, together with the band due to the C—O stretching and OH in-plane deformation modes at 1410 and 1240 cm^{-1}, and the O—H stretching band at 3435 cm^{-1}.

With regard to bands due to vibrations involving the molybdenum atom, a strong band at 970 cm^{-1} can be assigned to the ν(Mo=O) mode; a well-defined medium intensity band at 725 cm^{-1} is also recorded, and it has been previously reported[24,25] for two-oxygen bridged molybdenum(V) units. Finally, the band due to the ν(S—Mo) mode is recorded in the expected[26–28] range.

Ionization energies for the most representative energy levels of the atoms forming these complexes, as measured by XPS, do not show significant differences from one complex to another. The peak due to O(1*s*) levels is recorded as a complex feature, due to the existence of oxygen atoms in different chemical environments, but the maximum is centred at 531.4 eV. For N(1*s*) the peak is recorded at 400.0 eV in all cases, a value slightly higher than that reported[29] for dithiocarbamate complexes of copper(II), nickel(II) and cobalt(II), thus confirming that resonance form **c** mainly contributes to the structure of the complexes, in agreement with the FT-IR results. A peak at 396.7 eV, i.e. close to that for N(1*s*), should be ascribed to the Mo(2*p*) level.

However, the most interesting signals to analyse the donor ability of dithiocarbamate are those due to the sulphur atoms. The value recorded for S(2*p*) is at 162.7–162.8 eV, slightly larger than that reported by Walton[30] for dithiocarbamate complexes, thus suggesting a larger donor capacity of these atoms in our case. Only the expected $2p_{1/2}$–$2p_{3/2}$ splitting is observed, indicating that both sulphur atoms are chemically equivalent; the ligand thus acting as bidentate, as in most of the dithiocarbamate complexes reported in the literature.[31,32] The Mo($3d_{3/2}$) and Mo($3d_{5/2}$) signals are recorded at 230.8 and 234.0 eV (the difference reported in the literature is 3.1 eV). The value for the Mo($3d_{5/2}$) level, usually taken to compare the ionization energy of molybdenum species, coincides with that reported for complexes of molybdenum(V) with polysulphides,[33] where it is coordinated solely by sulphur atoms, and is very close to that for complexes of molybdenum(V) with cystein (231.1 eV) and penicylamine (231.0 eV).[34,35] For $Mo_2S_4(dtc)_2$ (dtc = diethyldithiocarbamate) the value is 229.6 eV,[36] as in this case only sulphur atoms are bonded to Mo^{5+} and the more electronegative oxygen atoms (present as bridging and terminal atoms in our case) are absent.

SYNTHESIS AND STRUCTURAL STUDIES ON Z-2-BENZYLTHIO-4-HYDROXIMINOMETHYL-1-*p*-METHOXYPHENYL IMIDAZOLE METAL COMPLEXES

R. LOPEZ-GARZON, M. N. MORENO-CARRETERO,* M. A. SALAS-PEREGRIN and J. M. SALAS-PEREGRIN

Departamento de Química Inorgánica, Facultad de Ciencias Experimentales, Universidad de Granada, 23071 Jaén, Spain

(*Received* 30 *September* 1992; *accepted* 22 *October* 1992)

Abstract—Complexes of Z-2-benzylthio-4-hydroximinomethyl-1-*p*-methoxyphenyl imidazole (Z-OXLME) with Co^{II}, Ni^{II}, Cu^{II}, Zn^{II}, Cd^{II} and Hg^{II} were prepared and characterized by IR, UV–vis–NIR diffuse reflectance, ^{1}H and ^{13}C NMR spectroscopies and magnetic and thermal measurements. In all the complexes the organic compound acts as a chelator through $N(3)_{imid}$ and N_{oxime} atoms.

Organic compounds containing the oxime group are of great biological interest. In 1950, Wilson found that the hydroxylamine acts as a regenerator of the phosphorylated acetylcholinesterase.[1] Since then, many other oximic derivatives have been obtained with the aim of improving their toxicity; among these derivatives several N-methyl derivatives of pyridinaldoximes,[2] the compound 1-dodecyl-2-hydroximinomethyl pyridinium[3–5] and the quaternary salts derived from the 2-hydroximinomethyl imidazole may be highlighted. Other oximic derivatives, e.g. the α-cetoglutamic oxime acid and the dimethylglyoxime exhibit *in vitro* antitumor activity.[6–8] In some cases this activity is enhanced in the presence of certain metal ions; so, Takamiya proved that the *in vitro* antitumor activity of the α-cetoglutamic oxime acid is minor compared with that of their Fe^{II} and Cu^{II} metal chelates. Likewise, in the case of the dimethylglyoxime the *in vitro* antitumor activity is enhanced when the compound is supplied together with Cu^{II} ions, but not with other metal ions like Ni^{II}, Co^{II}, Zn^{II}, Fe^{II}, Mn^{II}, Hg^{I} or Hg^{II}.[6] This suggests that the antitumoral activity of a metal chelate depends not only on its permeability through the cellular membrane, but of the structural characteristics of both metal ion and chelating agent. Thus, dimethylglyoxime-copper and bis-(acetylmonoxime)-copper(II) are both of them permeable to Erhlich carcinoma and 180 Crocker sarcoma cellules; nevertheless, only the former inhibited tumor development.

Other oxime complexes, *trans*-bis[salicylaldoximate]copper(II) and *trans*-bis[resorcylaldoximato]copper(II), also show strong *in vitro* and *in vivo* anticancer activities against Leukaemia L1210 and Erhlich *ascites carcinome*.[9]

As a continuation of a previous work,[10] in which the coordination ability of the compound E-1-*p*-ethoxyphenyl-4-hydroximinomethyl imidazole (EALDH) against several metal ions was studied, the present paper is focussed on the synthesis and characterization of metal complexes from the monoximic derivative Z-2-benzylthio-4-hydroximinomethyl-1-*p*-methoxyphenyl imidazole (Z-OXLME) with Co^{II}, Ni^{II}, Cu^{II}, Zn^{II}, Cd^{II} and Hg^{II}. The compound Z-OXLME differs structurally from the former in the presence of a benzylthio group substituted on C(2) of the imidazolic ring. These compounds are analogous to some others which are regenerators of the phosphorylated acetylcholinesterase.[11]

EXPERIMENTAL

Preparation of the ligands and complexes

The compound used as the ligand, Z-OXLME, was prepared according to a reported procedure.[11]

The complexes were obtained by adding with stirring the corresponding metallic chloride (1 mmol) to an ethanolic solution (75 cm^3) of Z-

* Author to whom correspondence should be addressed.

OXLME (0.339 g, 1 mmol). The resulting solutions were evaporated in air until precipitation of the complexes occurred (about 3 days later), except in the case of the copper(II) complex, which precipitated almost immediately.

Apparatus and methods

Microanalyses of carbon, hydrogen and nitrogen were performed in the Technical Services of University of Granada (STUGRA). IR spectra were obtained on a Perkin–Elmer 983G spectrophotometer, from KBr pellets in the 4000–250 cm^{-1} range and polyethylene pellets in the 600–180 cm^{-1} range. ^1H and ^{13}C NMR spectra were recorded on a Bruker AM-300 machine, using DMSO-d_6 as a solvent and TMS as the internal standard. UV–vis–NIR reflectance spectra of the complexes in the 240–1400 nm range were obtained from pellets of the corresponding samples, using a Shimadzu MPC-3100 spectrophotometer and $BaSO_4$ as a reference. Magnetic susceptibilities of the ligand and complexes at room temperature were measured using Faraday–Bruker Magnet Mod. B-E15 equipment. Dependence of susceptibility values on the temperature was measured on a Mannics DSM-8 susceptometer. The temperature range investigated was 80–280 K. The ESR spectrum of $CuCl_2$(Z-OXLME)·$2H_2O$ was obtained in the *X*-band using a Bruker E.S.P.-300 spectrometer. Finally, the thermal study of the ligand and complexes was performed using a Mettler TA-3000 system, provided with a Mettler TG-50 thermobalance and a DSC-20 differential scanning calorimeter. TG curves were obtained on heating samples of the corresponding solids in a dynamic pure air atmosphere (100 cm^3 min^{-1}) in the 35–850°C temperature range, whereas DSC plots were recorded under a static air atmosphere in the temperature range between 35 and 450°C. In both cases a heating rate of 10°C min^{-1} and samples varying in weight from 1 to 10 mg were utilized.

RESULTS AND DISCUSSION

The assignments of the bands of the IR spectra of Z-OXLME were performed in accordance with the literature.[12–17] These assignments (Table 1) point out that the tautomeric form of Z-OXLME in the solid state is the hydroxioximic one instead of the nitronic one. The assignments of the broad band at 2844 cm^{-1} at ν(OH) of the oxime group and that of 1681 cm^{-1} at δ(OH) in plane deformation due to hydrogen bridged OH groups were proved by the shifting from 2720 to 2200 cm^{-1} of the former and the disappearance of the second upon deuteration of Z-OXLME.

The low wave number value and widening of the ν(OH) band (2844 cm^{-1}), together with the appearance of the δ(OH) band in the IR spectrum of Z-OXLME, prove the existence of an intramolecular hydrogen bridge[12] between the OH group and probably the N(3) atom of the imidazole ring (as shown in Fig. 1), which is favoured by the *Z* conformation of the compound.

NMR data are summarized in Table 2. It is noticeable that the value of the chemical shift of the hydroxylic hydrogen atoms in the ^1H NMR spectrum of Z-OXLME is high (11.60 ppm) compared to the one corresponding for EALDH (10.80 ppm),[10] in which an intramolecular hydrogen bridge of the above type is prevented; this fact is also in accordance with the structure depicted in Fig. 1. Moreover, the higher melting enthalpy of the compound EALDH (51 kJ mol^{-1}) than Z-OXLME (22 kJ mol^{-1}), measured from their corresponding DSC plots, is also in accordance with the existence of stronger intramolecular interactions in the former compound than in the latter.

the carbon atoms of the imidazolic moiety together with that of C_α oxime, which are of special interest in order to supply information about the coordination pattern of Z-OXLME to the metal ions, are given in Table 2. The assignments were carried out on the basis of those ones for analogous compounds,[11,12] together with the information provided by the DEPT technique.

The colour, analytical data and proposed formulae for the metal complexes are given in Table 3. All of them contain the organic ligand in the neutral form and the metal/organic ligand stoichiometries are either 1/1 (Cu^{II}, Zn^{II}, Cd^{II} and Hg^{II} complexes) or 1/2 (Co^{II}, Ni^{II} and Cd^{II} complexes). The complexes are fairly soluble in water, except copper(II), and ethanol. The hydrated character of $M^{II}Cl_2$(Z-OXLME)·H_2O complexes (M^{II} = Cu, Hg and Cd) was determined from their TG and DSC curves; nevertheless, the accurate determination of dehydration energies has not been possible because the corresponding endothermic effects overlap with the exothermic effects, due to the pyrolysis of the organic ligand in the three hydrated complexes.

The pyrolytic decomposition of Z-OXLME starts at 220°C via an intramolecular dehydration according to the following process:

$$R—HC{=}N—OH \longrightarrow H_2O + R—C{\equiv}N.$$

The complexes show similar thermal behaviour. They start pyrolytic decomposition at the above temperature (except Hg^{II} which starts the pyrolysis at 190°C by the sublimation of $HgCl_2$, as proved by the disappearance of the ν(Cl—Hg) band in the IR spectrum of a sample heated up to the temperature 195°C). The above dehydration process gave rise to the disappearance of the ν(OH) and δ(OH) characteristic bands of the oxime group in the IR spectra of the ligand and their metal complexes. The decompositions of the compounds proceed steadily up to the formation of Co_3O_4, CuO, ZnO and CdO residues. In the case of the mercury(II) complex no residue was found at the end of the pyrolysis, due to the whole sublimation of $HgCl_2$.

Z-OXLME ligand binding mode

IR spectral data of the seven complexes in Table 1 show the shifting at higher wave number values

of the ν(NO) oxime characteristic band, which suggests, in accordance with the literature data,[12,18] that the coordination takes place through the N_{oxime} atom instead of the O_{oxime} atom. This hypothesis is also supported by the increase in wave number of $\nu(C{=}N)_{oxime}$ bands;[12] when the ligand acts as a chelator upon coordination, the possibility of retrodonating metal → ligand bonds gave rise to an increase in the π-electronic delocalization, which is opposed to the above cited expected increase in $\nu(C{=}N)_{oxime}$. This fact would explain the variable increments in the frequency of the above cited band observed in the spectra of the complexes.

From low-frequency IR data no evidence of ν(M—N) bands were obtained, due to the high absorbance of the ligand. Nevertheless, in all cases a new and strong band was observed, which is assignable to the ν(M—Cl) mode which suggests that the chloride ions are directly linked to the metal ions in all the complexes. The presence of only one band for this vibration mode indicates that chloride ligands are probably in *trans* positions.[19]

The IR spectra of those complexes having ligand: metal stoichiometries of 2:1 show in-plane deformation δ(OH) bands characteristic of O···H···O grouping, which suggests probable planar structures in which the interactions between the oxime groups of the two Z-OXLME molecules give rise to the above arrangement.

The NMR spectra of the $CdCl_2$(Z-OXLME) complex could not be obtained with enough resolution because of its poor solubility; that of $HgCl_2$(Z-OXLME)·H_2O, despite its good resolution, is equal to that of free Z-OXLME, due probably to its total dissociation in solution. Thus, only the NMR spectra of $ZnCl_2$(Z-OXLME) and $CdCl_2$(Z-OXLME)·H_2O were available. The assignment of the corresponding signals are summarized in Table 2, together with those of Z-OXLME. The downfield shift of the $C_\alpha H$ signal is due to the deshielding of a hydrogen atom on coordinating N_{oxime} atoms to metal ions, whereas the strong shift to higher field in NOH signals of both complexes can be explained on the basis of a change from the *Z* to the *E* isomer upon coordination to metal ions. This change becomes the breaking of the intramolecular hydrogen bridge interaction characteristic of the *Z* isomers, which produces a strong shielding in the OH hydrogen atom.[20] Finally, the shifting to lower field values in the $C(5)H_{imid}$ signal could be caused by a change in the electronic density of the imidazole moiety, this fact being consistent with the coordination of the $N(3)_{imid}$ atom to the metal ions.

^{13}C NMR data also corroborate this hypothesis; namely, the deshielding of C_α and $C(5)_{imid}$ signals is in accordance with a chelation of the ligand in the *E* isomeric form, through the N(3) atom of the imidazolic ring and the N atom of the oxime group.[10] It is interesting to point out that the deshielding in $C(5)_{imid}$ in Z-OXLME has also been observed upon the protonation of $N(3)_{imid}$.[11]

Thus, the similarity in the IR spectra of all complexes, together with their formulae, suggests that the organic ligand Z-OXLME acts as a chelator, which is linked to the metal ions through the nitrogen atom of the oxime group and the N(3) atom of the imidazolic ring.

Coordination environment of metal ions

The magnetic moment value at room temperature for $CoCl_2$(Z-OXLME)$_2$ complex, 4.80 B.M., is considerably higher than that corresponding to the expected spin-only value for a d^7-system with three unpaired electrons.[12] The existence of an orbital contribution suggests an octahedral arrangement of the two halogen atoms and the two bidentate Z-OXLME molecules, in which the two chlorine atoms, according to far-IR data, are in *trans* positions.

In accordance with this fact, the NIR–vis reflectance spectrum of this complex shows three bands assignable to the three expected transitions in octahedral complexes of cobalt(II) ions;[21] thus, the band at 7.9 kK is assigned to the $^4T_{2g}(F) \leftarrow {}^4T_{1g}$ transition and the two remaining at 13.8 and 18.6 kK (the first one being the weakest) are assigned to $^4A_{2g}(F) \leftarrow {}^4T_{1g}$ and $^4T_{1g}(P) \leftarrow {}^4T_{1g}$ transitions, respectively.

The above IR spectral data of the $NiCl_2$(Z-OXLME)$_2$ complex suggest that the two Cl^- ions are coordinated to nickel(II) in *trans* positions. On the other hand, the magnetic moment at room temperature for this complex is 2.90 B.M., which is in agreement with the expected one for the spin-only moment in a d^8-system with two unpaired electrons.[12] In accordance with this the two bidentate Z-OXLME molecules and the two Cl^- ions could be in a distorted $NiCl_2N_4$ octahedral arrangement. The three expected bands for octahedral complexes of nickel(II), corresponding to $^3T_{1g}(P) \leftarrow {}^3A_{2g}$, $^3T_{1g}(F) \leftarrow {}^3A_{2g}$ and $^3T_{2g}(F) \leftarrow 3A_{2g}$ transitions,[21] appear in the NIR–vis reflectance spectrum of the complex at 27.0, 15.6 and 10.0 kK, respectively. The most probable structure for these cobalt(II) and nickel(II) complexes is shown in Fig. 2.

Spectral data for the $CuCl_2$(Z-OXLME)·$2H_2O$ complex suggest that the two water molecules are not coordinated to the metal ion, whereas the two Cl^- ions are directly bound to copper ions.

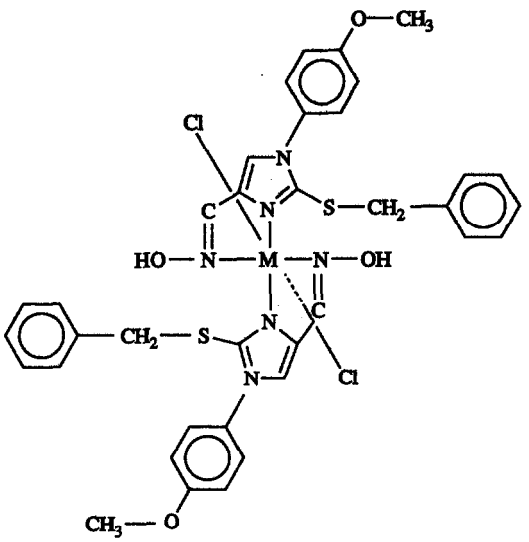

Fig. 2. Structure of $CoCl_2$(Z-OXLME)$_2$, $NiCl_2$(Z-OXLME)$_2$ and $CdCl_2$(Z-OXLME)$_2$ complexes.

All these data suggest a four-coordinated $CuCl_2N_2$ sphere for the metal ion in this complex. The magnetic moment at room temperature, 1.42 B.M., is considerably lower than that expected for the spin-only contribution in a d^9-system;[12,22] this fact suggests a probable antiferromagnetic interaction between copper(II) ions and consequently a planar or distorted tetrahedral arrangement of the four donor atoms around each copper(II) ion. In order to explain this fact magnetic susceptibility values of the complex were measured in the 80–280 K temperature range; the results are presented in Fig. 3, which shows the variation of χ_M and $1/\chi_M$ versus T values.

These data indicate that the complex follows

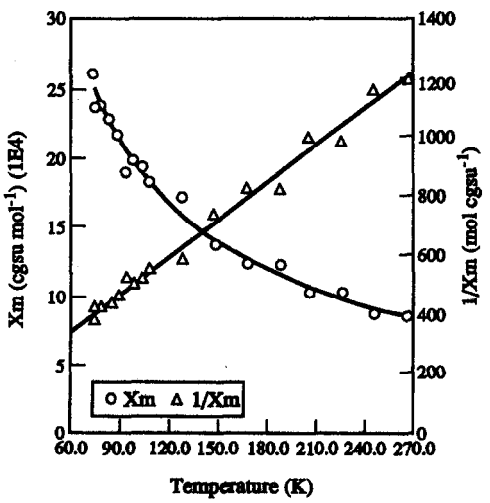

Fig. 3. Variation of χ_M and $1/\chi_M$ vs T for the $CuCl_2$(Z-OXLME)$\cdot 2H_2O$ complex.

Curie–Weiss behaviour in the studied temperature range:

$$1/\chi_M = (T+\theta)/C;$$

$C = 0.242$ cm^3 K mol^{-1}; $\theta = 23.29$ K; $\mu = 1.40 \pm 0.03$ B.M. (r value of $1/\chi_M$ vs T plot = 0.9932).

In order to elucidate if this deviation from Curie's law is due to the existence of temperature-independent paramagnetism (TIP), χ_M observed values have been plotted versus T. The resulting curve has been adjusted, using the ENZFITTER non-linear regression data analysis program (R. J. Leatherbarrow, Elsevier-Biosoft, 1987), to the general equation:

$$\chi_M = \chi_T + \chi_{TIP} = \frac{C}{T+\theta} + \chi_{TIP},$$

in which both temperature-dependent and -independent contributions to the total value of paramagnetism have been taken into account. From this plot (Fig. 3) the following values have been obtained: $\chi_{TIP} = 1.237 \times 10^{-4}$ cm^3 mol^{-1}, $\theta = 9.9$ K and $C = 0.202$ cm^3 K mol^{-1}. The agreement factor of this plot, defined as $\Sigma(\chi_{obs} - \chi_{calc})^2/\Sigma\chi_{obs}^2$, was 1.5×10^{-3}. The θ value indicates this compound displays a Curie behaviour in its temperature-dependent component. Knowing the χ_{TIP} value, the magnetic moment of the Cu^{2+} ion in this complex has been calculated using the molar susceptibility of the compound corrected by both diamagnetic and TIP contributions. The value obtained for the magnetic moment is 1.26 ± 0.03 B.M. This gives a μ_{TIP} value of 0.14 B.M., which is in accordance with the values found in the literature for this magnitude.[22]

The ESR spectrum of $CuCl_2$(Z-OXLME)$\cdot 2H_2O$ shows an isotropic signal at a g value of 2.11. This would suggest the presence of a copper(II) ion in a complex containing grossly misaligned tetragonal axes; this situation being, according to Hathaway and Billing,[23] the most common reason for the observation of an isotropic ESR spectrum. The reflectance spectrum of the complex presents an asymmetric band centred at 12.5 kK which may involve several $d \rightarrow d$ transitions in square-planar or slightly distorted tetrahedral copper(II) complexes.[21]

From exposed experimental data for the complexes $ZnCl_2$(Z-OXLME), $CdCl_2$(Z-OXLME) and $HgCl_2$(Z-OXLME)$\cdot H_2O$, tetrahedral structures, as shown in Fig. 4, can be proposed.

In the $CdCl_2$(Z-OXLME)$_2$ complex, a CdN_4Cl_2 octahedral arrangement of the six donor atoms with the two Cl^- ions in *trans* positions would be expected (see Fig. 2).

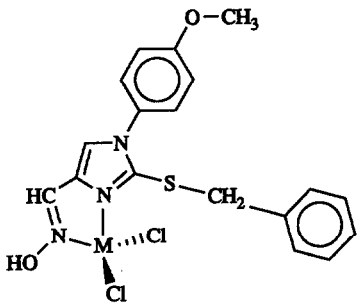

Fig. 4. Structure of $ZnCl_2$(Z-OXLME), $CdCl_2$(Z-OXLME)·H_2O and $HgCl_2$(Z-OXLME)·H_2O complexes.

(*Received* 18 *August* 1992; *accepted* 22 *October* 1992)

Abstract—Reaction of the N,O-chelated complexes $[ReCl_2(N_2COC_6H_4\text{-}4\text{-}R)(PPh_3)_2]$ (R = H, Me, NO_2) with N,N- and certain N-substituted hydrazines gave the ammine complexes $[ReCl_2(NH_3)(NNCOC_6H_4\text{-}4\text{-}R)(PPh_3)_2]$ [R = H (**1**), R = Me (**2**), R = NO_2 (**3**)]. The mechanism is believed to involve intermolecular homolytic cleavage of the N—N bond. The X-ray structure of **1** revealed a pseudo-octahedral geometry with *trans*-phosphines. The ammine ligand is *cis* to the benzoyldiazenido group and the ammine hydrogens are hydrogen-bonded to the carbonyl oxygen.

Reaction of $[ReOCl_3(PPh_3)_2]$ with excess $Ph_2NNH_2 \cdot HCl$ in ethanol gave both $[ReCl_3(NNPh_2)(PPh_3)_2]$ (**6**) and $[ReCl_2(N)(NNPh_2)(PPh_3)]$ (**7**). In the presence of base the rhenium(VII) cation $[ReCl_2(NNPh_2)_2(PPh_3)]^+$ was formed. The geometry of **7** was shown by X-ray structural determination to be a distorted square-based pyramid, with the nitride in the apical position. Attempted derivatization of **7** led to N—N bond cleavage and the generation of nitrido complexes.

The nitrido complex $[ReCl(N)(Me_2CNNCOPh)(PPh_3)_2]$ (**8**) was unexpectedly formed in the reaction of $[ReOCl_3(PPh_3)_2]$ with $Me_2C{=}NNHCOPh$ in ethanol in the presence of HCl. The X-ray crystal structure of **8** showed a pseudo-octahedral geometry with the nitride ligand *trans* to the oxygen of the N,O-chelated hydrazonato(1-) ligand. The possible mechanisms of N—N bond cleavage are discussed.

Despite intensive investigations, the exact details of the N—N bond cleavage step in the protonation of coordinated dinitrogen remain obscure.[1] The cleavage of the N—N bond of hydrazines on reaction with metals can be viewed as a possible model for this step and many examples have been reported. One of the most intensively investigated systems has involved the reactions of hydrazine or phenylhydrazine hydrochlorides with $[ReOCl_3(PPh_3)_2]$ to give $[ReCl_2N(PPh_3)_2]$ and $[NH_4]Cl$ or $PhNH_2 \cdot HCl$, respectively. Ethanol was shown to be essential and $[ReO(OEt)Cl_2(PPh_3)_2]$ is a key intermediate.[2] Superficially, the reaction is a condensation-type process and might be expected to involve intermediates such as $Re{=}NNH_2$.

† Benzoyldiazenidodichloro(ammine)dichlorobis(triphenylphosphine)rhenium(III); dichlorodiphenylhydrazido(2-)nitridotriphenylphosphinerhenium(VII); chloronitridoacetonebenzoylhydrazonato(1-)bistriphenylphosphinerhenium(V).

However, additional PPh_3 is required and triphenylphosphine oxide can be identified in the reaction mixture.[3] It therefore appears possible that the reaction proceeds via oxygen abstraction with PPh_3 and halide metathesis to give species such as $[ReCl_2(NHNH_2)(PPh_3)_2]$. Here we report three further examples of N—N bond cleavage on rhenium under a variety of circumstances and discuss the mechanisms involved.

RESULTS AND DISCUSSION

The formation of $[ReCl_2(NH_3)(NNCOC_6H_4\text{-}4R)(PPh_3)_2]$ [R = H (**1**), Me (**2**), NO_2 (**3**)]

It has previously been reported that the reaction of the chelated derivative $[ReCl_2(N_2COPh)(PPh_3)_2]$[3] with benzoylhydrazine under relatively dilute conditions gives $[ReCl_2(NNHCOPh)(NHNHCOPh)(PPh_3)_2]$. The identity of the product as a hydrazido(2-) hydrazido(1-) complex was confirmed by an X-ray structure determination.[12] We have had some difficulty in repeating this reaction, and now report the surprizing observation that when this reaction is carried out at higher concentrations, the ammonia complex $[ReCl_2(NH_3)(NNCOPh)(PPh_3)_2]$ is formed rapidly in quantitative yield. This occurs both on reaction with benzoylhydrazine and certain other N- and N,N-substituted hydrazines of the types $RNHNH_2$ (R = Me, Ph) and R_2NNH_2 (R_2 = MePh, Me_2, Ph_2). The NH_3 complex is directly analogous to $[ReCl_2(NH_3)(NNPh)(PMe_2Ph)_2]$, formed by reaction of $[ReCl_3(PMe_2Ph)_3]$ with $PhNHNH_2$.[4]

The reaction of $[ReCl_2(NNCOPh)(PPh_3)_2]$ with hydrazines proceeds rapidly in dichloromethane or toluene in air or under dinitrogen, and yields of the ammonia complex are consistently $\geq 90\%$.[5] Monitoring of the reaction in benzene by ^{31}P NMR revealed a relatively short-lived intermediate and the reaction is essentially complete in less than 2 min at room temperature. It appears very likely that this intermediate is of the type $[ReCl_2(H_2NNR_2)(NNCOPh)(PPh_3)_2]$, since the chelated complex $[ReCl_2(NNCOPh)(PPh_3)_2]$[3] is known to undergo facile ring opening reactions with Lewis bases such as MeCN to give benzoyldiazenido complexes of the type $[ReCl_2(NCMe)(NNCOPh)(PPh_3)_2]$.[3]

The formation of ammonia from the proposed hydrazide intermediate requires two electrons and two protons. There is, however, no obvious source of electrons as the reaction proceeds in a high overall yield. If the metal or the hydrazine were providing the electrons the yields would have to be much lower at the 1:1 stoichiometry. We accordingly suggest that the N—N bond cleavage reaction occurs *homolytically* with the formation of rhenium(IV), $[ReCl_2(NH_2)(NNCOPh)(PPh_3)_2]$, and an N-based radical such as HNCOPh. Analysis of the organic by-products, from the reaction with $MePhNNH_2$, revealed the presence of $MeC_6H_4NH_2$. The formation of the aniline we propose is from the radical scavenging of a hydrogen radical by the aniline radical. We also note the formation of other organonitrogen species by GLC, which is consistent with the radical mechanism. Further support for the concept of homolytic N—N bond cleavage comes from the greater ease of N—N bond cleavage found for Ph_2NNH_2, where the Ph_2N radical has higher stability.

We have also observed that the cleavage of the N—N bond of the 1-arylhydrazines $4\text{-}RC_6H_4NHNH_2$ on reaction with $[ReCl_2(NNCOPh)(PPh_3)_2]$ is markedly dependent on the nature of R. With R = H, or an electron-withdrawing substituent such as $4\text{-}NO_2$, then N—N bond cleavage occurs rapidly to give the ammonia complex **7**. However, when the substituent is electron donating (Me, MeO), then the N—N bond is retained and the hydrazidodiazenido complexes $[ReCl_2(NNH_nCOPh)(NNH_mAr)(PPh_3)_2]$ ($n, m = 0$ or 1) appear. NMR and IR spectroscopy do not distinguish between the proton being located on the PhCONN or PhNN fragments. In view of the relatively greater basicity of the ArN nitrogen, this seems to be the most probable location for the hydrogen. These reactions serve to emphasize further the relatively subtle factors that determine whether N—N bond cleavage occurs, and an understanding of these is particularly important in the context of the design of radiopharmaceuticals incorporating hydrazide and diazenide fragments. Further details of the benzoyldiazenidoarylhydrazide complexes will be published elsewhere.

Spectroscopy alone was unable to distinguish whether complexes **1**, **2** and **3** were $[ReCl_2(NH)(NNCOC_6H_4\text{-}4\text{-}R)(PPh_3)_2]$ or the ammonia complexes. The IR spectra all showed a band at 1575 cm^{-1} characteristic of the benzoyldiazenide ligand, and a sharp band at *ca* 3200 cm^{-1}, due to ν(N—H). The N—H protons appeared as a very broad singlet at 3.20 ppm in the ^1H NMR spectrum, and the peak width made accurate integration difficult. Accordingly, a single-crystal X-ray structure determination of complex **1** was undertaken.

Structure of $[ReCl_2(NH_3)(NNCOPh)(PPh_3)_2]\cdot Et_2O$ (**1**)

A perspective view of the structure of complex **1** appears in Fig. 1, and some selected bond lengths

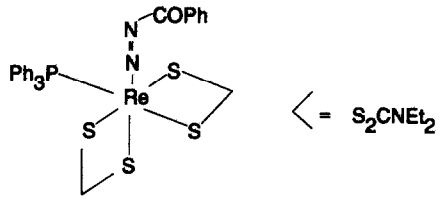

Fig. 1. Proposed structures of the complexes of the type $[Re(NNCOAr)(S_2CNEt_2)_2(PPh_3)]$ (Ar = phenyl or 4-substituted phenyl group).

and angles are given in Table 1. The overall geometry about the rhenium is best described as pseudo-octahedral, with the bulky PPh_3 ligands occupying *trans* sites. The chloride ligands are *trans* to the nitrogen ligands and the Re—Cl distances are unexceptional. The Re—N—N angle is 178(1)°, which, when coupled with the Re—N(1) distance of 1.77(1) Å, indicates that the diazenide ligand is functioning as a three-electron donor. The Re—N(3) bond length of 2.16(1) Å is typical for a metal ammonia complex, and the N(3)—O(1) distance of 2.89(2) Å is indicative of a strong hydrogen-bonding interaction between the ammonia hydrogens and the carbonyl oxygen.

Substitution reactions of **1**, **2** *and* **3**

Sodium diethyldithiocarbamate reacts readily with **1**, **2** or **3** to give the brown crystalline complexes $[Re(NNCOC_6H_4\text{-}4\text{-}R)(S_2CNEt_2)_2(PPh_3)]$ in high yield. The ^1H NMR spectrum of each complex shows four triplets for the dithiocarbamate CH_3 protons, suggesting that the complexes have a structure with *cis*-dithiocarbamato-ligands (Fig. 2). The observation of two different environments for the

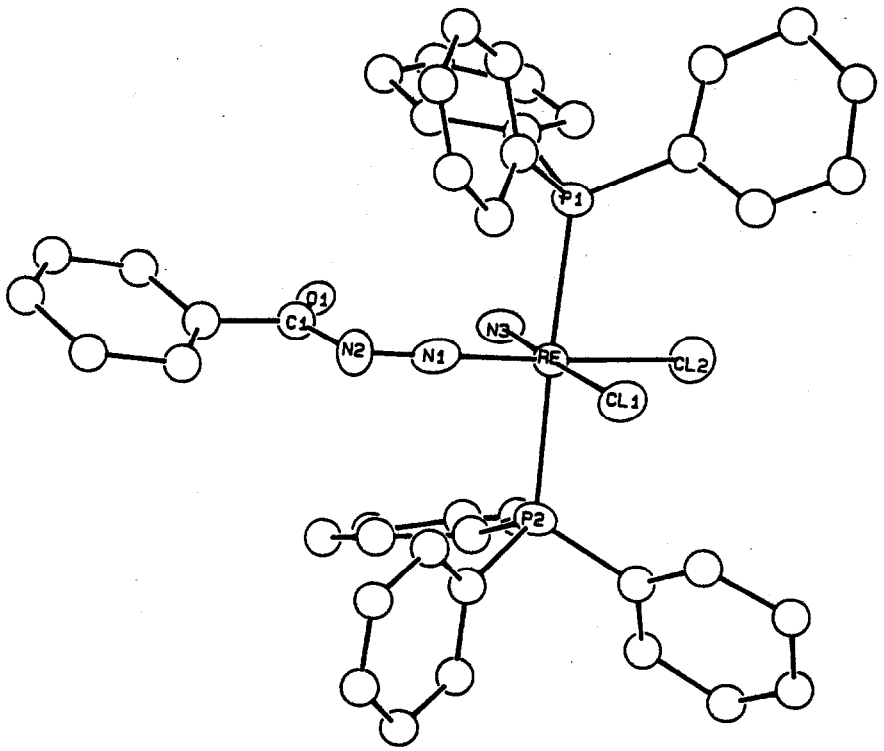

Fig. 2. A perspective view of the structure of $[ReCl_2(NH_3)(NNCOPh)(PPh_3)_2]$, showing the atom labelling scheme.

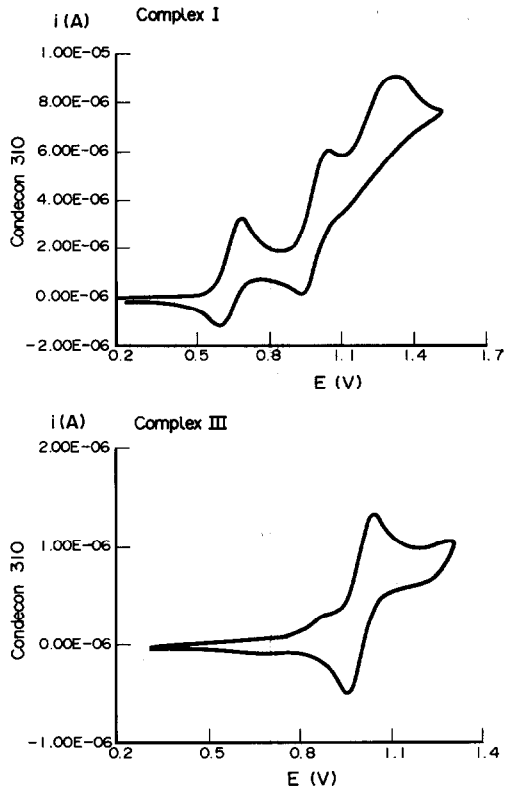

Fig. 3. Cyclic voltammograms for $[ReCl_2(NH_3)(NNCOPh)(PPh_3)_2]$ and $[ReCl_2(NNCOC_6H_4\text{-}4\text{-}NO_2)(PPh_3)_2]$. Recorded at room temperature in CH_2Cl_2 at a platinum wire auxiliary electrode and silver wire pseudo-reference electrode.

dithiocarbamate ligands confirms that the complexes are not fluxional at room temperature.

Electrochemistry of complexes **1** *and* **3**

The cyclic voltammogram of complex **1** (Fig. 3) was recorded at room temperature in dichloromethane solution at a platinum wire working electrode with 0.2 M $[Bu^n_4N][BF_4]$ as the supporting electrolyte. Potentials are quoted relative to the ferrocene–ferrocenium couple, taken as 0.0 V, and details are quoted in Table 2. The complex shows three one electron oxidation processes, the first two appearing reversible and the last irreversible. The oxidations correspond to the formation of a rhenium(IV) monocation, a rhenium(V) dication and a rhenium(VI) trication.

The introduction of the 4-NO_2 group in complex **3** causes a profound shift in potentials and a single reversible one-electron oxidation at $E_{1/2} = +0.56$ V occurs. This corresponds to the formation of a monocationic rhenium(IV) species. The electron-withdrawing 4-NO_2 group raises the potential for the second and third oxidation beyond the observable range. There are a number of reduction processes associated with the NO_2 group which were not analysed further. Attempts to monitor the reaction by cyclic voltammetry were not successful as the reaction was too fast in the accessible temperature range.

Reaction of $[ReOCl_3(PPh_3)_2]$ *with* 1,1-*diphenylhydrazine*

Two products were obtained on reaction of $[ReOCl_3(PPh_3)_2]$ with an excess of diphenylhydrazine hydrochloride in methanol under reflux. The first is a rather insoluble orange precipitate of the rhenium(V) complex $[ReCl_3(NNPh_2)(PPh_3)_2]$ (**6**) in 42% yield. The yellow filtrate gave yellow crystalline rhenium(VII), $[ReCl_2(N)(NNPh_2)(PPh_3)]$ (**7**), in 30% yield on reduction in volume and addition of diethyl ether. By contrast, we showed earlier[6] that reaction of $[ReOCl_3(PPh_3)_2]$ with $PhMeNNH_2$ gave $[ReCl_2(NNMePh)_2(PPh_3)]^+$, and here the analogous complex $[ReCl_2(NNPh_2)_2(PPh_3)]^+$ (**8**) is formed only when $Ph_2NNH_2 \cdot HCl$ is used in the presence of Et_3N. This confirms that the N—N bond cleavage reaction is highly pH sensitive. The fact that it

[a] All potentials are quoted relative to the ferrocenium/ferrocene couple taken as 0.0 V. Ferrocene was added to the cell for each measurement. Scan rate: 0.2 V s^{-1}.

does not occur in the presence of base strongly suggests that in this instance the cleavage occurs by electron transfer from the metal and protonation. A rhenium(V) intermediate such as $[ReCl_2(NNPh_2)(NHNPh_2)(PPh_3)_2]$ seems likely. All these complexes showed the expected mass ion in their FAB mass spectra.

We have also observed that the N—N bond of complex **6** is cleaved readily on attempted metathesis reactions. Thus, reaction of **6** with sodium diethyl dithiocarbamate results in a near quantitative yield of the known $[ReN(S_2CNEt_2)_2]$. The source of electrons for the cleavage of the N—N bond are not clear, but it could be the dithiocarbamate anion. However, we cannot entirely rule out that this system involves a similar homolytic bond cleavage reaction to that discussed in the last section.

Structure of $[ReCl_2(N)(NNPh_2)(PPh_3)]$ **(7)**

There are very few examples of the nitride ligand occurring in combination with other multiply-bonded ligands and those that are known generally involve oxo-ligands (e.g. $[OsO_3N]^{3-}$).[6] Accordingly, a single-crystal X-ray structural determination of complex **7** was undertaken and a perspective view of the structure appears in Fig. 4, together with a partial atom labelling scheme. Selected bond lengths and angles appear in Table 3. The structure can be compared to the recently reported $[Tc_2N_2(N_2Ph_2)(2,4,6\text{-}Pr^i_3C_6H_2S)_4]\cdot 0.5(C_2H_5)_2O$.[7]

The structure, as for the technetium complex, is best described as distorted square-based pyramid with the nitride ligand at the apex. The metal–nitride distance of 1.653(5) Å [technetium complex 1.64(1) Å] lies within the range normally found for terminal metal nitrido complexes.[8] The diphenylhydrazido(2-) ligand occupies a basal site and is

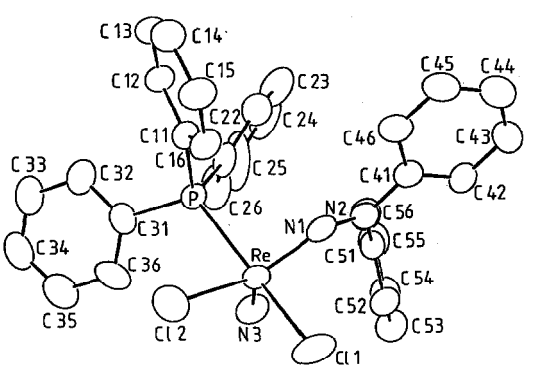

Fig. 4. A perspective view of the structure of $[ReCl_2N(NNPh_2)(PPh_3)_2]$, together with an atom labelling scheme.

Table 3. Table of selected bond distances (Å) and angles (°) of **7**

Re—Cl(1)	2.396(2)
Re—Cl(2)	2.388(2)
Re—P	2.445(1)
Re—N(1)	1.837(5)
Re—N(3)	1.653(5)
N(1)—N(2)	1.280(6)
N(2)—C(41)	1.437(7)
N(2)—C(51)	1.455(7)
Cl(1)—Re—Cl(2)	84.46(6)
Cl(1)—Re—P	161.78(5)
Cl(1)—Re—N(1)	89.2(1)
Cl(1)—Re—N(3)	104.2(2)
Cl(2)—Re—P	84.21(5)
Cl(2)—Re—N(1)	140.0(2)
Cl(2)—Re—N(3)	112.4(2)
P—Re—N(1)	90.4(1)

N(1)—Re—N(3)	107.5(2)
Re—N(1)—N(2)	142.9(4)

significantly bent at N(1) [Re—N(1)—N(4) angle = 142.9(4)°, average Tc—N—N angle 140.4(4)°]. This suggests the hydrazide ligand is functioning as a two-electron donor and this is supported by the Re—N(1) distance of 1.837(5) and N(1)—N(2) distance of 1.280(6) Å. This compares with Tc—N 1.87(1) and 1.89(1) Å and N—N 1.25(1) and 1.24(2) Å for $[Tc_2N_2(N_2Ph_2)(2,4,6\text{-}Pr^i_3C_6H_2S)_4]$. For $[Re(NNMePh)_2(S_2CNMe_2)_2]^+$[5] the Re—N and N—N distances are 1.78 and 1.30 Å, where each hydrazido(2-) ligand is virtually linear and formally donating four electrons. The 18-electron rule is not invariably useful for predicting the bonding of hydrazide ligands, and in this case an 18-electron configuration would require the hydrazide to be a four-electron donor. The strongly π-donating nitride ligand competes for the empty metal orbitals and prevents donation of the lone pair on N(1).

The preparation of $[ReCl(N)(Me_2CNNCOPh)(PPh_3)_2]$ **(8)**

We have previously shown that reaction of $[ReOCl_3(PPh_3)_2]$ with $PhCONHNH_2$ in acetone gives the complex $[ReOCl_2(Me_2CNNCOPh)(PPh_3)]$ with a chelated benzoyl hydrazonato(1-) ligand.[3] If, however, $[ReOCl_3(PPh_3)_2]$ is reacted with $Me_2C{=}NNHCOPh$ in ethanol in the presence of dilute HCl, the orange nitrido complex $[ReCl(N)(Me_2NNCOPh)(PPh_3)_2]$ is formed in high yield. The reaction presumably involves partial hydrolysis of the hydrazone to the free hydrazine and subsequent N—N bond cleavage to give the nitride. This reaction of the hydrazone is in interesting con-

trast to the reaction of PhNHNHCOPh, which under related conditions undergoes N—N bond cleavage to form the imide $[ReCl_3(NPh)(PPh_3)_2]$ in high yield.[9]

Structure of $[ReClN(Me_2CNNCOPh)(PPh_3)_2]$ (**8**)

A perspective view of the structure of complex **8** appears in Fig. 5, together with a partial atom labelling scheme and some selected bond lengths and angles are given in Table 4. The geometry about the rhenium is pseudo-octahedral with *trans*-phosphine ligands. The metal–nitride distance of 1.662(6) Å is typical for rhenium(V) nitrido-complexes, and the metal–chlorine and metal–phosphorus distances are unremarkable. The bond distances within the hydrazonato ligand confirm the loss of the proton on N(3). The C(1)—N(3) distance of 1.30(1) Å is typical for a C=N bond.

EXPERIMENTAL

All manipulations were carried out under an inert atmosphere of dry dinitrogen gas unless stated

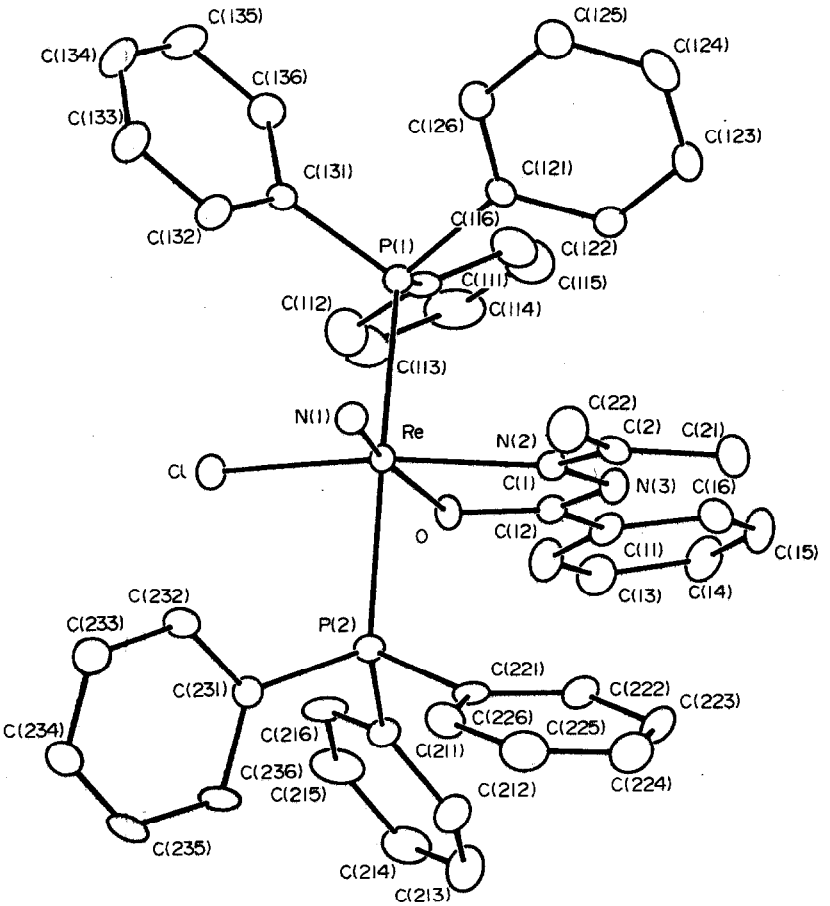

Fig. 5. A perspective view of the structure of $[ReCl(N)(Me_2C{=}NNCOPh)(PPh_3)_2]$, together with an atom labelling scheme.

otherwise. Standard Schlenk-tube, vacuum-line and syringe techniques were employed throughout where appropriate. Elemental analyses were performed by Medac Ltd, University of Brunel. IR spectra were measured in the range 200–4000 cm^{-1} as Nujol mulls (KBr plates) on a Perkin–Elmer 1330 IR spectrometer. ^1H NMR and $^{31}P\{^1H\}$ NMR spectra were measured using a JEOL EX270 spectrometer. Fast-atom bombardment mass spectra were obtained from the SERC service at University College of Swansea, using either thioglycerol or 3-nitrobenzyl alcohol (3-NOBA) as matrix materials. All isotope distributions were compared to a computer generated distribution pattern written by one of us (J.R.M.). HPLC measurements were taken using a Gilson model 702 isocratic HPLC system fitted with a poly(styrene-divinylbenzene) copolymer column and UV detection module HM Holochrome (set at 250 nm). UV studies were performed on a Phillips PU8730 spectrophotometer in dried dichloromethane using quartz cells. Methanol and dichloromethane were dried by standard methods.[10] All other materials and reagents were obtained commercially (Aldrich, Fisons) and used without further purification. $[ReOCl_3(PPh_3)_2]$[11] and $[ReCl_2(N_2COPh)(PPh_3)_2]$[12] were prepared from rhenium metal using the published procedures.

Cyclic voltammetry measurements were made at 200 K using an EG and G PAR model 362 scanning potentiostat linked to a PC with a Condecon 310 interface and software. A three-electrode cell configuration was used, with a platinum wire working electrode, platinum wire secondary electrode and a silver wire pseudo-reference electrode. The solvent was dichloromethane with 0.2 M tetrabutylammonium tetrafluoroborate as the supporting electrolyte. Potentials are quoted relative to the ferrocene/ferrocenium couple in the same system.

Preparation of $[ReCl_2(NH_3)(N_2COPh)(PPh_3)_2]$ **(1)**

$[ReCl_2(N_2COPh)(PPh_3)_2]$ (0.3 g, 0.4 mmol) and $MePhNNH_2$ (0.2 cm^3, 1.7 mmol) were heated under reflux in ethanol (20 cm^3) for 30 min. The emerald green suspension changed to a dark brown solution with the presence of an olive green solid, which was filtered off and washed with diethylether and dried *in vacuo*. The olive green product was recrystallized from CH_2Cl_2/Et_2O; yield 0.24 g, 80%. The reaction proceeds equally well at room temperature. IR (KBr): 1510, 1610 cm^{-1} (NNCOPh ligand). ^1H NMR ($CDCl_3$): 3.7 ppm [3H, s, br, NH_3], 7.2–7.9 ppm [35H, multiplet, phenyl H]. $^{31}P\{^1H\}$ NMR ($CDCl_3$): 0.46 ppm (singlet). Found: C, 55.6; H, 4.1; N, 4.4. Calc. for $ReC_{43}H_{35}N_3Cl_2P_2O_2$: C, 55.4; H, 4.1; N, 4.5%. FAB mass spectrum *m/z* (%): (932, 8), $[ReCl_2(NH_3)(N_2COPh)(PPh_3)_2]^+$ (915, 10), $[ReCl_2(N_2COPh)(PPh_3)_2]^+$.

Preparation of $[ReBr_2(NH_3)(N_2COPh)(PPh_3)_2]$

$[ReBr_2(N_2COPh)(PPh_3)_2]$ (0.3 g, 0.3 mmol) and $MePhNNH_2$ (0.2 cm^3, 1.6 mmol) were heated under reflux in ethanol (20 cm^3) for 30 min. The emerald green suspension changed to a dark brown solution with the presence of an olive green solid, which was filtered off, washed with diethylether and dried *in vacuo*. The olive green product was recrystallized from CH_2Cl_2/Et_2O; yield 0.18 g, 55%. IR, ^1H and ^{31}P NMR as for complex **1**. Found: C, 50.6; H, 3.9; N, 4.2. Calc. for $ReC_{43}H_{35}N_3Br_2P_2O_2$: C, 50.6; H, 3.8; N, 4.1%.

Preparation of $[ReCl_2(NH_3)(N_2COC_6H_4\text{-}OMe)(PPh_3)_2]$ **(2)**

Reaction of $[ReCl_2(NH_3)(N_2COC_6H_4\text{-}OMe)(PPh_3)_2]$ (0.2 g, 0.2 mmol) with $MePhNNH_2$ (0.1 cm^3, 1.2 mmol) as above yielded the ammine/4-OMe-benzoyldiazenido complex; yield 0.16 g, 70%. IR: 1510, 1610 cm^{-1} (NNCOPh ligand). ^1H NMR ($CDCl_3$): 3.7 [3H, s, br, NH_3], 7.2–7.9 [35H, multiplet, phenyl H], 3.8 ppm [3H, s, OCH_3]. $^{31}P\{^1H\}$ NMR ($CDCl_3$): 0.46 ppm (singlet). ^{13}C NMR ($CDCl_3$): 170.4 [*C*—O] and 55.2 ppm [O*C*H_3]. Found: C, 54.8; H, 4.7; N, 4.1. Calc. for $ReC_{44}H_{36}N_3Cl_2P_2O_2$: C, 54.9; H, 4.2; N, 4.4%. FAB mass spectrum, *m/z* (%): (963, 10), $[ReCl_2(NH_3)(N_2COC_6H_4\text{-}OMe)(PPh_3)_2]^+$; (781, 27), $[ReCl_2(PPh_3)_2]^+$; (519, 24), $[ReCl_2(PPh_3)^+$; (263, 100), $[PPh_3]^+$.

Preparation of $[ReCl_2(NH_3)(N_2COC_6H_4\text{-}4\text{-}NO_2)(PPh_3)_2]\cdot H_2O$ **(3)**

Reaction of $[ReCl_2(N_2COC_6H_4\text{-}4\text{-}NO_2)(PPh_3)_2]$ (0.2 g, 0.3 mmol) with $MePhNNH_2$ (0.2 g, 2.6 mmol) as above yielded the ammine/4-NO_2 benzoyldiazenide complex, yield 0.14 g, 58%. IR: 1510, 1610 (NNCOPh ligand), 1160 and 850 cm^{-1} (NO_2). ^1H NMR ($CDCl_3$): 4.0 [3H, br, s, NH_3], 7.2–8.4 ppm [35H, multiplet, phenyl H]. $^{31}P\{^1H\}$ NMR ($CDCl_3$): −0.55 ppm (singlet). Found: C, 51.4; H, 3.8; N, 5.7. Calc. for $ReC_{43}H_{36}N_4Cl_2P_2O_4$: C, 51.9; H, 3.9; N, 5.6%. FAB mass spectrum, *m/z* (%): (976, 40), $[ReCl_2(NH_3)(N_2COC_6H_4\text{-}NO_2)(PPh_3)_2]$; (924, 15), $[ReCl_2(N_2COC_6H_4\text{-}NO_2)(PPh_3)_2]^+$; (781, 100), $[ReCl_2(PPh_3)_2]^+$.

Preparation of $[Re(S_2CNEt_2)_2(N_2COPh)(PPh_3)]$ **(4)**

$[ReCl_2(NH_3)(N_2COPh)(PPh_3)_2]$ (0.3 g, 0.3 mmol) and NaS_2CNEt_2 (0.3 g, 1.6 mmol) were heated under reflux in ethanol (20 cm^3) for 1 h. The green suspension gave way to a dark brown solution and a brown solid, which was filtered off and washed with diethylether. IR: 1620 (dithiocarbamate C—N) and 1580, 1490 cm^{-1} (NNCOPh). ^1H NMR ($CDCl_3$): 0.8–1.4 [CH_3, 3t, 12H], 3.0–4.0 ppm [CH_2, m, 8H]. $^{31}P\{^1H\}$ NMR ($CDCl_3$): 16.6 ppm (singlet). $^{13}C\{^1H\}$ NMR ($CDCl_3$): 12 [CH_3, 4], 43–44 [CH_2, 4 singlets], 127–135 [phenyl], 171.7 [CS_2] and 203.8 ppm [CO]. Found: C, 47.6; H, 4.6; N,

(*Received* 23 *June* 1992; *accepted* 22 *October* 1992)

Abstract—The five-coordinate copper(II) complex [(3,3′-trimethylenedinitrilo)bis(2-butanone oximato)]copper(II) bromide (CuHLBr) has been prepared and its crystal structure has been determined. The complex has a square-pyramidal structure with the copper displaced 0.43 Å out of the basal nitrogen plane. The Cu—Br distance is 2.955 Å. The differences in the structures of the copper(II) and copper(I) complexes is discussed. Covalency of the coordinate bond for the title complex is also discussed based on ESR spectra.

There has been recent interest in the study of macrocyclic complexes containing copper atoms as possible models for biochemically important proteins and enzymes.[1–3] In this paper the structural features of the complex of copper(II) with 3,3′-(trimethylenedinitrilo)bis(2-butanone dioxime) (H_2L) are reported.

EXPERIMENTAL

The ligand H_2L was prepared by the literature method.[3]

Synthesis of the complex

Copper(II) bromide and H_2L (mole ratio 1:1) were dissolved in warm acetone. The solutions were mixed and set aside for 2 days to give dark green crystals of the complex. Found: C, 34.6; H, 5.0; N, 14.7. Calc. for $C_{11}H_{19}N_4O_2CuBr$: C, 34.5; H, 5.0; N, 14.6%.

Instruments

PE-240 elemental analysis meter; Shimadzu IR-408 spectrometer; Perkin–Elmer Hitachi-240 spectrophotometer; Enraf–Nonius CAD4 automated diffractometer, JES-FEIXG ESR spectrometer.

X-ray structure determination

A single crystal of the complex having the approximate dimensions $0.2 \times 0.3 \times 0.3$ mm^3 was mounted on a glass fibre. Determination of the unit cell and data collection were performed with Mo-K_α radiation ($\lambda = 0.71073$ Å) on a CAD4 diffractometer equipped with a graphite monochromator. A total of 2845 independent reflections were collected by the ω–2θ scan technique in the range $2 \leqslant \theta \leqslant 25°$, from which 1154 reflections [$I \geqslant 3\sigma(I)$] were considered to be observed. Intensity data were corrected for Lorentz and polarization factors.

The structure was solved by direct methods (MULTAN82). The copper atom was located from an E-map. The other non-hydrogen atoms were

determined with successive difference-Fourier syntheses. The final refinement by the full-matrix least-squares method with anisotropic thermal parameters for the non-hydrogen atoms converged with the unweighted and weighted agreement factors 0.065 and 0.083, respectively (unit weights for all observed reflections). The highest peak in the final difference Fourier map had a height of 0.79 e $Å^{-3}$. All calculations were performed on a PDP 11/44 computer using the SDP-PLUS program system. The related bond lengths and angles for the complex are given in Table 1.

RESULTS AND DISCUSSION

Elemental analyses, IR and electronic spectra have indicated that the reaction of the ligand H_2L with $CuBr_2$ yielded the title complex. In the electronic absorption spectra of an aqueous solution of the complex a broad absorption at 510 nm ($\varepsilon = 5 \times 10^2\ M^{-1}\ cm^{-1}$) and a strong absorption at 228 nm ($\varepsilon = 2 \times 10^5\ M^{-1}\ cm^{-1}$) were observed. The former may be attributed to the *d–d* transition and the latter to the charge-transfer absorption bands. Features of the optical spectra are consistent with the expected five-coordinate copper(II) complex.[4]

The crystal structure of the complex

The complex crystallizes in the monoclinic space group $P2_1/c$ with $a = 13.329(4)$, $b = 7.535(2)$, $c = 14.773(6)$ Å and $\beta = 103.68(3)°$, $V = 1441.55$ $Å^3$, $Mr = 382.7$, $Z = 4$, $D_x = 1.759$ g cm^{-3}, $F(000) = 772$.

Figure 1 shows the structure and labelling scheme of the five-coordinated copper(II) complex. The copper atom sits in an asymmetrical square-pyramidal environment and is displaced 0.43 Å from the basal plane of the four nitrogen atoms. The bromine atom coordinates at the apex of the square-pyramid with a Cu—Br distance of 2.534(1) Å. Both copper and bromine atoms sit at the same side of the basal plane. Cu—N bond lengths ranging from 1.961(7) to 1.993(7) Å (mean 1.967 Å) characterize the equatorial asymmetry. The *trans*-N—Cu—N angles are 154.1(4) and 155.6(3)° and the *cis*-N—Cu—N angles range from 80.2(3) to 94.4(3)°.

There is an intramolecular hydrogen bond between the oxime oxygens.[3] A structural determination of copper(I) coordinated to H_2L has been reported.[1] Due to the smaller size of the copper(II) ion, it is not surprising that the geometry of the coordination is different. The Cu—N bond lengths in the copper(II) complex reported here average 0.165 Å shorter than those in the copper(I) complex of H_2L. The copper(I) ion is displaced 0.96 Å out of the plane of the equatorial nitrogen atoms,[3] but there is a smaller displacement of the metal atom from the plane of the four nitrogen atoms in Cu(HL)Br. The planarity of the basal plane of the four nitrogens in the copper(II) complex Cu(HL)Br is better than the one in the copper(I) complex. The basal plane deviates from planarity as evidenced by a dihedral angle of 31.9° between the N(1)—C(12)—N(4) and N(2)—C(23)—C(22)—N(3)

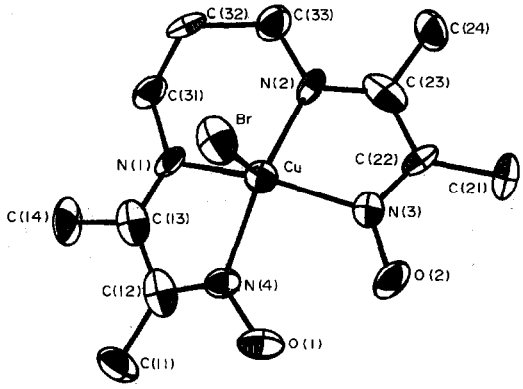

Fig. 1. The structure of the copper(II) complex.

planes. This angle is 60.0° for the copper(I) complex.

ESR spectra

The *X*-band powder ESR spectrum of the complex at room temperature is shown in Fig. 2. $g_{\parallel} = 2.155$ and $g_{\perp} = 2.053$ are obtained; $g_{\parallel} > g_{\perp} > g_e$ and this fact implies that the $3d$ unpaired electron of the copper(II) ion should occupy the $d_{x^2-y^2}$ orbital and the coordination compound would have elongated tetragonal octahedral, square planar or square pyramidal stereochemistry. The latter is in agreement with the result of the X-ray structure determination.

The ESR spectra of the complex in both glass and solution states are shown in Fig. 3. An approximate estimation of $g_{\parallel}$, $g_{\perp}$, $A_{\parallel}$ and $A_{\perp}$ was first performed following the suggestions of Kivelsen and Neiman.[5] These were then used in a computer simulation program[6] and varied on a trial and error basis until a reasonable fit was obtained. The final computer simulation spectrum of Fig. 3(b) is shown in Fig. 3(c). The ESR and bonding parameters of the complex are as follows: $g_{av} = 2.090$, $a_{av} = 84.6$ G for room temperature solution; $g_{\parallel} = 2.155$, $g_{\perp} = 2.056$, $A_{\parallel} = 0.0199$, $A_{\perp} = 0.0026$ cm^{-1}, $g_{av} = 2.089$ $((g_{\parallel}+2g_{\perp})/3)$, $a_{av} = 84.3$ G, $\alpha^2 = 0.72$, $K = 0.0115$ cm^{-1} for the glass.

The g values in powder and frozen solution states are the same, which indicates that the complex is very stable in solution and the molecular configuration in both states is not changed. The ESR parameters have been used to obtain the bonding parameter α^2 and Fermi contact interaction term K.[7] If $\alpha^2 = 1$, the bond would be completely ionic. If $\alpha^2 = 0.5$, the bond would be completely covalent. The smaller value of α^2 ($\alpha^2 = 0.72$) of this complex indicates that the σ-bonding is quite covalent in nature. This is in agreement with the result of the crystal structure determination in which the Cu^{II}—N bond lengths are short. The K value of the complex shows that the polarization is responsible for the isotropic hyperfine interaction between the copper nucleus and the unpaired electron.

(*Received* 11 *August* 1992; *accepted* 22 *October* 1992)

Abstract—Reaction of rhenaenolates $[(\eta^5\text{-}C_5Me_5)(NO)(PPh_3)Re(COCH_2Li)]$ (**2**) and $[Re(CO)_4(PPh_3)(OSO_2CF_3)]$ in THF at −78°C gave the μ-ketene complex $[(\eta^5\text{-}C_5Me_5)(NO)(PPh_3)Re[\mu\text{-}(COCH_2)\text{-}C^1\text{:}C^2]Re(CO)_4(PPh_3)]$ (**5**). The structure of (**5**) was determined by single-crystal X-ray analysis.

The reaction of metallaenolates and metal carbonyl electrophiles represents a potentially useful and straightforward route towards μ-(C,C)-ketene complexes.[1] However, the only well-characterized example of this synthetic approach involves reaction of $[(\eta^5\text{-}C_5H_5)Fe(CO)(PPh_3)(COCH_2)]^-Li^+$ and the non-carbonyl containing metal halide $(PPh_3)AuCl$ to give a μ-(C,C)-ketene complex, $(\eta^5\text{-}C_5H_5)Fe(CO)(PPh_3)(COCH_2)Au(PPh_3)$ (**1**, Scheme 1).[2] Akita and Kondoh found that the related enolate $[(\eta^5\text{-}C_5H_5)Fe(CO)_2(COCH_2)]^-Li^+$ gave bimetallic complexes with no ketene ligand upon reaction with either $(\eta^5\text{-}C_5H_5)Fe(CO)_2Cl$ or $(\eta^5\text{-}C_5H_5)Mo(CO)_3I$[3]. In this case it is not clear if the μ-ketene complexes were initially formed. Geoffroy reported spectroscopic observation of an unisolable μ-ketene complex from $[(\eta^5\text{-}C_5H_5)Fe(CO)(PPh_3)(COCH_2)]^-Li^+$ and $M(CO)_5Br$ (M = Re, Mn).[1a] We recently reported that the rhenium enolate $(\eta^5\text{-}C_5Me_5)(NO)(PPh_3)Re(COCH_2Li)$ (**2**)[4] reacts with a carbon monoxide ligand of $(CO)_5ReBr$ to generate the lithium chelating malonyl complex $\{(\eta^5\text{-}C_5Me_5)(NO)(PPh_3)Re[\mu\text{-}(COCH_2CO)\text{-}C^1\text{:}C^3]Re(CO)_4(Br)\}^-Li^+$ (**3**, Scheme 2).[3e] Abstraction of the lithium cation in **3** with 12-crown-4 led to the loss of LiBr and formation of a chelating malonyl complex, $(\eta^5\text{-}C_5Me_5)(NO)(PPh_3)Re[\mu\text{-}(COCH_2CO)\text{-}C^1\text{:}C^3, O^1]Re(CO)_4$ (**4**). We have now discovered that modification of the metal electrophile utilized in reaction with **2** results in the formation of an isolable bimetallic ketene complex, $(\eta^5\text{-}C_5Me_5)(NO)(PP_3)Re[(COCH_2)\text{-}C^1\text{:}C^2]Re(CO)_4(PPh_3)$ (**5**, Scheme 3).

EXPERIMENTAL

General

All manipulations, unless otherwise stated, were performed under purified nitrogen using Schlenk techniques or a Vacuum Atmospheres nitrogen box equipped with Dri-Train MO 40-1 purifier. IR spectra were recorded on a Perkin–Elmer 1330 IR spectrometer. Melting points were determined in sealed capillaries using an electrothermal melting point apparatus equipped with a calibrated thermometer. Mass spectra were performed at the University of California, Riverside Mass Spectroscopy (UCRMS) facility. Elemental analyses were performed by Galbraith Laboratories. ^1H, ^{13}C and ^{31}P NMR spectra were recorded at ambient probe temperature unless otherwise stated on either a GE QE NMR or a Varian UNITY 500 NMR spectrometer. ^1H NMR chemical shifts are reported relative to the residual protio-solvent resonance: $CHCl_3$, δ 7.24; THF-d_7, 3.58. ^{13}C NMR chemical shifts are reported relative to the solvent resonance: $CDCl_3$, δ 77.0; THF-d_8, 67.4. ^{31}P NMR chemical shifts are reported

relative to external H_3PO_4 (85%). Thoroughly dried and degassed solvents were used throughout. (η^5-C_5Me_5)(NO)(PPh_3)Re($COCH_3$) was prepared according to published procedures.[4]

Preparation of cis-$(CO)_4(PPh_3)Re(OSO_2CF_3)$.

A procedure similar to that for $(CO)_5Re(OSO_2CF_3)$ was employed.[6] A round-bottomed flask equipped with a magnetic stir bar was charged with $(CO)_4(PPh_3)ReBr$ (1.00 g, 1.56 mmol, 31 mM), $Ag(OSO_2CF_3)$ (0.44 g, 1.71 mmol) and CH_2Cl_2 (50 cm^3) and stirred in the dark for 2 h. The solution was concentrated under vacuum to *ca* 5 cm^3 and filtered. Hexanes (20 cm^3) were slowly added and large clear plates of *cis*-$(CO)_4(PPh_3)Re(OSO_2CF_3)$ were isolated by filtration, along with small patches of a black solid. The crude *cis*-$(CO)_4(PPh_3)Re(OSO_2CF_3)$ was dissolved in CH_2Cl_2 (10 cm^3) and filtered. Hexanes were added to the filtrate and *cis*-$(CO)_4(PPh_3)Re(OSO_2CF_3)$ was isolated as a white solid by filtration (0.75 g, 1.06 mmol, 68%); m.p. 113–117°C. IR (CH_2Cl_2): 2120 (s), 2015 (vs), 1964 (s), 1335 (m), 1233 (m), 1200 (s), 1095 (m), 1008 (m) cm^{-1}. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ 186.3 (d, $J = 9.4$ Hz, *cis*-Re*C*O), 184.9 (d, $J = 5.8$ Hz, *cis*-Re*C*O), 182.6 (d, $J = 54.9$ Hz, *trans*-Re*C*O), 133.2 (d, $J = 10.8$ Hz, C_6H_5), 131.6 (d, $J = 2.6$ Hz, C_6H_5), 130.4 (d, $J = 49.9$ Hz, C_6H_5), 129.2 (d, $J = 10.3$ Hz, C_6H_5). FAB MS: 561 (M^+-OTf), 1271 *m/z* ($2M^+$-OTf). Found: C, 38.7; H, 2.1. Calc for $C_{23}H_{15}F_3O_7PReS$: C, 38.9; H, 2.1.

Preparation of (η^5-C_5Me_5)(NO)(PPr_3)Re[(CO CH_2)C^1:C^2]Re($CO)_4$(PPh_3) (**5**)

A round-bottomed flask equipped with a magnetic stir bar was charged with the acyl complex (η^5-C_5Me_5)Re(NO)(PPh_3)($COCH_3$) (525 mg, 0.800 mol, 27 mM), THF (30 cm^3) and cooled to −78°C. A 1.6 M solution of n-BuLi in hexanes (0.5 cm^3, 0.802 mmol) was added and the deep red solution stirred for 0.5 h at −78°C. This solution was then added to a stirred −78°C THF (45 cm^3) solution of $(CO)_4(PPh_3)Re(OSO_2CF_3)$ (569 mg, 0.802 mmol, 18 mM) and warmed to room temperature. The solvent was removed *in vacuo* and the residue was chromatographed under an atmosphere of nitrogen on activated silica. An orange band was eluted with 4:3 hexanes/THF (v/v). After removal of the solvent under vacuum the residue was recrystallized twice with $CHCl_3$/hexanes to give **5** as an orange crystalline solid (212 mg, 0.174 mmol, 22%); m.p. 147–151°C (dec). FAB HRMS: 1214. 2051 *m/z* (MH^+), calc. 1214.2016. IR (CH_2Cl_2): 2075 (m), 1975 (vs), 1920 (s), 1625 (m), 1481 (w), 1431 (w) cm^{-1}. ^1H NMR ($CDCl_3$): δ 7.25–7.39 (m, 30H), 2.32 (dd, $J = 11.7$, 5.8 Hz, 1H), 1.86 (dd, $J = 11.7$, 8.2 Hz, 1H), 1.68 (s, 15 H). $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ 263.9 (dd, $J = 8.2$, 3.1

Hz, $ReCOCH_2$), 193.1 (d, $J = 10.1$ Hz, *cis*-ReCO), 192.8 (d, $J = 9.8$ Hz, *cis*-ReCO), 190.1 (d, $J = 53.4$ Hz, *trans*-ReCO), 188.5 (d, $J = 7.0$ Hz, *cis*-ReCO), 135.6 (d, $J = 53$ Hz, C_6H_5), 134.1 (d, $J = 11.1$ Hz, C_6H_5), 133.6 (d, $J = 45.3$ Hz, C_6H_5), 133.6 (d, $J = 10.1$ Hz, C_6H_5), 130.1 (d, $J = 2.0$ Hz, C_6H_5), 129.5 (C_6H_5), 128.4 (d, $J = 10.1$ Hz, C_6H_5), 127.7 (d, $J = 10.1$ Hz, C_6H_5), 101.8 (d, $J = 2.0$ Hz, C_5Me_5), 39.8 (ps, t, $J = 3.0$, 2.6 Hz, CH_2), 9.8 (C_5Me_5). $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ 23.2, 8.5. Found: C, 47.4; H, 3.6; N, 1.04. Calc. for $C_{52}H_{47}NO_6P_2Re_2 \cdot CHCl_3$: C, 47.7; H, 3.6; N, 1.0. A sample was also recrystallized from CH_2Cl_2/pentane. Found: C, 48.53; H, 3.74; N, 1.29. Calc. for $C_{52}H_{47}NO_6P_2Re_2 \cdot 0.7CH_2Cl_2$ [CH_2Cl_2 observed by ^1H NMR ($CDCl_3$) spectroscopy]: C, 48.80; H, 3.76; N, 1.08.

X-ray structure determination for $(\eta^5\text{-}C_5Me_5)(NO)(PPh_3)Re[\mu\text{-}(COCH_2)\text{-}C^1{:}C^2]Re(CO)_4(PPh_3)$ (**5**)

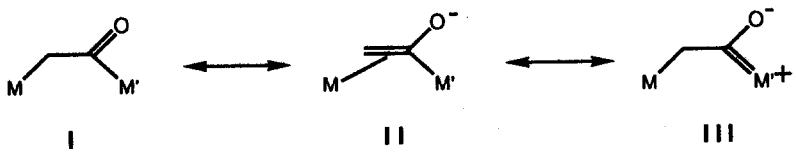
An orange crystal of **5** containing a CH_2Cl_2 molecule of crystallization was obtained from layering of a CH_2Cl_2 solution with pentane and mounted on a glass fibre along the longest dimension. Data collection parameters are summarized in Table 1. The unit cell dimensions were obtained from 20 reflections in the range $15 < 2\theta < 30°$. Intensities of monitor reflections (three measured every 200 reflections) decreased by ~8% during 48 h of X-ray exposure. All non-hydrogen atoms were refined anisotropically using Patterson methods and a full-matrix least-squares refinement method. Hydrogen atoms were included in ideal positions with U fixed at 0.08 Å^2. A residual peak (1.46 e Å^{-3}) near the chlorine atoms of the solvent molecule suggested disorder in CH_2Cl_2. No evidence of secondary extinction was observed, therefore, no correction was applied. No systematic absences suggested the space group $P\bar{1}$, which was confirmed by successful solution of the structure.

RESULTS AND DISCUSSION

Treatment of a THF solution of the known acyl complex $[(\eta^5\text{-}C_5Me_5)Re(NO)(PPh_3)(COCH_3)]$ with n-BuLi generated the rhenolate anion **2**, to which was added a cold THF solution of $[(CO)_4(PPh_3)Re(OSO_2CF_3)]$. Evaporation of the volatiles, chromatography of the residue and recrystallization of the resultant orange solid led to isolation of an orange crystalline product, identified as the μ-ketene complex **5** (34% yield; Scheme 3).

In the IR spectrum of **5** a band at 1625 cm^{-1} is attributed to coincidental overlap of ν(C≡O) and ν(N≡O) bands. In the ^1H NMR spectrum ($CDCl_3$) the diastereotopic methylene hydrogens of the ketene ligand are observed at δ 2.32 [dd, J(HH) = 11.7 Hz, J(PH) = 5.8 Hz, 1H] and 1.85 [dd, J(HH) = 11.7 Hz, J(PH) = 8.2 Hz, 1H]. In the $^{13}C\{^1H\}$ NMR spectrum ($CDCl_3$) of **5** the COs *cis* to the PPh_3 ligand appear at 192.8 (d, $J = 9.8$ Hz), 193.1 (d, $J = 10.1$ Hz) and 188.5 (d, $J = 7.0$ Hz). This observation that CO ligands *trans* to one another are diastereotopic is an unusual one. The carbonyl carbon of the ketene ligand is observed at 264 ppm [dd, ^2J(PC) = 8.2 Hz, ^3J(PC) = 3.1 Hz]. For comparison, $(\eta^5\text{-}C_5Me_5)Re(NO)(PPh_3)(CO CH_2Ph)$ (**6**) exhibits ν(CO) and ν(NO) bands in the IR spectrum ($CHCl_3$) at 1574 and 1636 cm^{-1}, respectively, whereas the methylene hydrogens appear in the ^1H NMR spectrum ($CDCl_3$) at δ 3.66 (d, $J = 11.3$ Hz) and 2.83 (d, $J = 11.3$ Hz), and the carbonyl carbon appears at 261.2 ppm (d, $J = 10.3$ Hz) in the $^{13}C\{^1H\}$ NMR spectrum ($CDCl_3$).[4] The analogous spectroscopic data for the malonyl **3** are as follows: IR (CH_2Cl_2): 1648 ν(N≡O) and 1482 ν(C≡O), 1560 ν(C≡O). ^1H NMR (CD_2Cl_2): δ 1.93 (d, $J = 15.2$ Hz) and 5.82 (d, $J = 15.1$ Hz). $^{13}C\{^1H\}$ NMR spectrum (CD_2Cl_2): 270.8 (d, $J = 9.5$ Hz) and 270.7 (s) ppm.[5e] The 67 cm^{-1} shift to a higher frequency for ν(C≡O) on going from acyl **6** to ketene **5** is in the reverse direction to that observed (−35 cm^{-1}) on going from $(\eta^5\text{-}C_5H_5)Fe(CO)_2(COCH_3)$ to the μ-(C,C)-ketene complex $(\eta^5\text{-}C_5H_5)Fe(CO)_2(COCH_2)Fe(CO)_2(\eta^5\text{-}C_5H_5)$ (**7**). In the case of **7** the shift to lower frequency has been attributed to a contribution of the π-complex **II**, in addition to the expected oxycarbene structure **III** (Scheme 4).[1d]

The solid state structure of **5** was determined by



Scheme 4.

X-ray crystallography and is illustrated in Fig. 1. Crystal data, data collection and refinement parameters are summarized in Table 1. Selected bond distances and angles are given in Table 2. As was observed for the structures of related malonyl complexes, the ON—Re(1)—C(12)—O(11) torsion angle θ, as defined by Gladysz,[4] is 179.9°. Table 3 lists the structural parameters for the ketene ligand in **5** along with those for other (C,C)-ketene and acyl complexes.[1d] It is clear from a comparison of these parameters that **5** exhibits the least degree of π-complex character (**II**) in the bimetallic ketenes structurally characterized to date. Complex **5** adopts a conformation with an Re(2)—C(11)—C(12)—O(11) torsion angle φ of 54.7°, which places Re(2) opposite the ketene ligand plane from P(1) and bent away from the C_5Me_5 ligand. As previously discussed by Akita, the angle φ is one of the structural parameters pertinant to the question of a π-complex contribution (**II**) in **5** and other μ-(C,C)-ketene complexes.[1d] A dihedral angle of 90° would maximize overlap between the Re(2)—C(11) bond and the carbonyl *p*-orbital on C(12). Comparison of the *b*, *c* and *d* structural parameters in **5** to those for the rhenium acyl (η^5-C_5Me_5)

$Re(NO)(PPh_3)(COCHMeCH_2Ph)$ (**8**)[7] also indicates negligible structural differences; once again mitigating against a significant π-contribution (**II**) to the structure of **5**. The C(11)—C(12) bond length in **5** is the longest reported to date for a μ-(C,C)-ketene complex.

When $(CO)_4(PPh_3)ReBr$ was utilized in reaction with metallaenolate **2** and the product recrystallized from CH_2Cl_2/ether, a mixture of two new products (**9**) was isolated in a ~90:10 ratio (45% yield), with no evidence for the formation of ketene **5**. The ^1H and ^{13}C NMR spectra of these two compounds were very similar. In the ^1H NMR spectrum ($CDCl_3$), methylene hydrogen resonances are observed at δ 4.87 (d, J = 20.4 Hz) and 3.61 (dd, J = 20.6, 1.1. Hz) for the major isomer and 3.68 (d, J = 19.5 Hz) and 4.48 (d, J = 19.4 Hz) for the minor isomer. The observed geminal coupling constant of ~20 Hz is consistent with a five-membered chelate ring as observed for the malonyl complex **4** (δ 2.84, d, J = 20.7 Hz; 3.13, d, J = 20.7 Hz).[5e] In the $^{13}C\{^1H\}$ NMR spectrum ($CDCl_3$) acyl carbon resonances were observed as doublets at 300.0 (J = 10.3 Hz) and 270.2 ppm (J = 8.8 Hz) for the major isomer, and at 300.4 (J = 9.4 Hz) and 270.1 ppm (J = 9.4 Hz) for the minor isomer. These low-field shifts are again consistent with a malonyl structure similar to that of **4**. When the malonyl complexes (**9**) were dissolved in THF-d_8 and allowed to stand for 2 days, complete decomposition occured to give the μ-ketene complex **5** in 21% yield, along with uncharacterized other products. It thus appears that the formation of **5** occurs by initial attack of the enolate on the carbonyl ligand of

(*Received* 17 *July* 1992; *accepted* 6 *October* 1992)

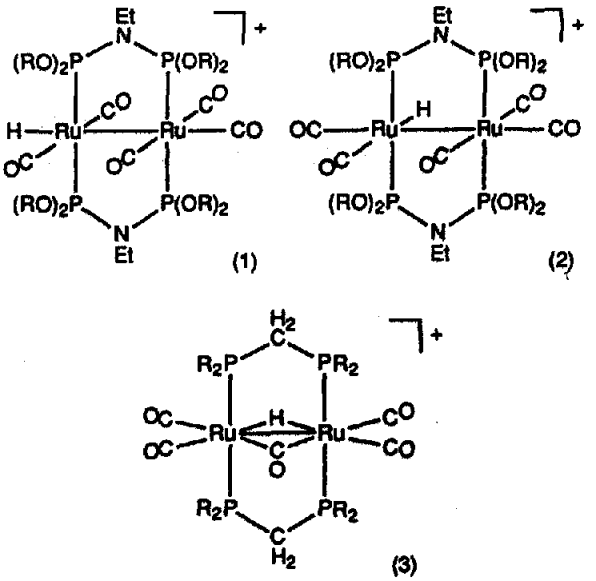
Abstract—Reaction of the di-iron heptacarbonyl compounds $[Fe_2(\mu\text{-CO})(CO)_6(\mu\text{-}R_2PCH_2PR_2)_2]$ (R = Me or Ph) with a range of diphosphorus or diarsenic ligands under photochemical conditions affords the ligand-bridged pentacarbonyl derivatives $[Fe_2(\mu\text{-CO})(CO)_4(\mu\text{-}Me_2PCH_2PMe_2)(\mu\text{-L-L})]$ [L-L = $(MeO)_2PN(Et)P(OMe)_2$ or $(EtO)_2PN(Me)P(OEt)_2$] and $[Fe_2(\mu\text{-CO})(CO)_4(\mu\text{-}Ph_2PCH_2PPh_2)(\mu\text{-L-L})]$ [L-L = $Me_2PCH_2PMe_2$, $Ph_2PN(Et)PPh_2$, $Ph_2AsCH_2AsPh_2$, $(MeO)_2PN(Et)P(OMe)_2$ and $(EtO)_2PN(Me)P(OEt)_2$] in good yield. Treatment of these mixed ligand-bridged complexes with the protic acids $HBF_4 \cdot Et_2O$ or CF_3COOH leads exclusively to the formation of the hydride-bridged species $[Fe_2(\mu\text{-H})(\mu\text{-CO})(CO)_4(\mu\text{-}R_2PCH_2PR_2)(\mu\text{-L-L})]^+$ isolated as the tetrafluoroborate salts. Hydride-bridged products are also obtained by protonation of $[Fe_2(\mu\text{-CO})(CO)_4\{\mu\text{-}(R'O)_2PN(R'')P(OR')_2\}_2]$ (R'' = Me, R' = Et; R'' = Et, R' = Me, Pr^i or Ph) and $[Fe_2(\mu\text{-CO})(CO)_4(\mu\text{-}R_2PCH_2PR_2)_2]$ (R = Me or Ph), but whereas the diphosphazane-bridged species $[Fe_2(\mu\text{-H})(\mu\text{-CO})(CO)_4\{\mu\text{-}(R'O)_2PN(R'')P(OR')_2\}_2]^+$ are only stable to deprotonation in the presence of excess acid, the ditertiary phosphine-bridged species $[Fe_2(\mu\text{-H})(\mu\text{-CO})(CO)_4(\mu\text{-}R_2PCH_2PR_2)_2]^+$ can only be deprotonated by strong bases such as $NaBH_4$. The structure of $[Fe_2(\mu\text{-CO})(CO)_4(\mu\text{-}Ph_2PCH_2PPh_2)_2]$ has been established X-ray crystallographically. The two iron atoms, which are bridged by a carbonyl group as well as by the two ditertiary phosphine ligands, are separated by a distance of 2.742(4) Å, corresponding to a formal iron–iron bond.

Although it is widely accepted that the reactivity and structures of homo-dinuclear compounds bridged by two bidentate diphosphorus ligands are governed by the electronic and stereochemical properties of the bridging ligands, the number of systematic studies aimed at probing these factors has been somewhat limited.[1] Nevertheless, Puddephatt *et al.* have shown, in their studies of di-

* Author to whom correspondence should be addressed.

platinum compounds bridged by ditertiary phosphines, that the nature of the product formed in the reaction of $[Pt_2(\mu\text{-}H)H_2(\mu\text{-}R_2PCH_2PR_2)_2]^+$ with $R_2PCH_2PR_2$ (R = Et or Ph) is dependent on the identity of the ditertiary phosphine,[2,3] while we have established that the structures of the diphosphazane-bridged dirhodium compounds of stoichiometry $[Rh_2Cl_2(CO)_2\{\mu\text{-}(RO)_2PN(Et)P(OR)_2\}_2]$ and $[Rh_2Cl_2(CO)\{\mu\text{-}(RO)_2PN(Et)P(OR)_2\}_2]$ (R = Me, Et, Pr^i or Ph) vary with the alkoxy or aryloxy groups attached to the phosphorus atoms.[4,5] Furthermore, studies by Eisenberg *et al.*, Kubiak *et al.* and Cowie *et al.* on the reactivity of the dirhodium and diiridium derivatives $[Rh_2(CO)_3(\mu\text{-dppm})_2]$,[6,7] $[Rh_2(CO)_3(\mu\text{-dmpm})_2]$,[8] $[Ir_2(CO)_3(\mu\text{-dppm})_2]$[9,10] and $[Ir_2(CO)_3(\mu\text{-dmpm})_2]$[11,12] (dppm = $Ph_2PCH_2PPh_2$, dmpm = $Me_2PCH_2PMe_2$), as well as of related isocyanide derivatives,[12-14] towards various substrates have revealed that the reactivity patterns for the dmpm-bridged species are often quite different to those for the corresponding dppm-bridged derivatives.

We have also established that while the reactions of the tetra-alkoxydiphosphazane-bridged diruthenium compounds $[Ru_2(\mu\text{-}CO)(CO)_4\{\mu\text{-}(RO)_2PN(Et)P(OR)_2\}_2]$ (R = Me or Pr^i) with acids of non-coordinating conjugate bases, e.g. HBF_4 and HPF_6, give protonated products of the type $[Ru_2H(CO)_5\{\mu\text{-}(RO)_2PN(Et)P(OR)_2\}_2]^+$, which from spectroscopic evidence occur as mixtures of the two isomers **1** and **2** in solution, in which the hydride ligand is coordinated terminally at either an axial or an equatorial site,[15] the protonation of the corresponding dppm- and dmpm-bridged derivatives, $[Ru_2(\mu\text{-}CO)(CO)_4(\mu\text{-dppm})_2]$ and $[Ru_2(\mu\text{-}CO)(CO)_4(\mu\text{-dmpm})_2]$, by these acids affords products resulting from the formal addition of a proton across the two ruthenium atoms, viz. $[Ru_2(\mu\text{-}H)(\mu\text{-}CO)_4(\mu\text{-dppm})_2]^+$ (**3**, R = Ph) and $[Ru_2(\mu\text{-}H)(\mu\text{-}CO(CO)_4(\mu\text{-dmpm})_2]^+$ (**3**, R = Me), respectively.[15a,16] With the object of establishing whether a similar reactivity pattern is observed for the corresponding di-iron complexes, the protonation behaviour of a range of these compounds using tetrafluoroboric acid diethyletherate as the source of protons was investigated. Also, in order to probe further the effect of the nature of the bridging ligand on the reactivity of the iron centres in these compounds, a range of mixed ligand complexes of the type $[Fe_2(\mu\text{-}CO)(CO)_4(\mu\text{-dppm})(\mu\text{-L-L})]$ and $[Fe_2(\mu\text{-}CO)(CO)_4(\mu\text{-dmpm})(\mu\text{-L-L})]$, where L-L represents various diphosphine (R_2PYPR_2) or diphosphite $\{(RO)_2PYP(OR)_2\}$ type ligands, were synthesized and their protonation behaviour also studied. The results of these investigations are reported here.



RESULTS AND DISCUSSION

Synthesis of the mixed-ligand derivatives, $[Fe_2(\mu\text{-}CO)(CO)_4(\mu\text{-L-L})(\mu\text{-L'-L'})]$

Cotton and Troup were the first to report the synthesis of a simple substituted derivative of $[Fe_2(CO)_9]$ and, in particular, they showed that the reaction of this binary carbonyl with a half molar amount of bis(diphenylphosphino)methane (dppm) under thermal conditions affords a product mixture containing primarily the heptacarbonyl derivative $[Fe_2(\mu\text{-}CO)(CO)_6(\mu\text{-dppm})]$ (**4**).[17] We subsequently established that this compound as well as a range of related diphosphazane- and pyrophosphite-bridged complexes can be synthesized in high yield[18] photochemically. Furthermore, we also established that treatment of these substituted heptacarbonyl derivatives with an excess of the corresponding ligand under photochemical conditions leads to the formation of pentacarbonyl products of the type $[Fe_2(\mu\text{-}CO)(CO)_4(\mu\text{-L-L})_2]$ [L-L = $Ph_2PCH_2PPh_2$, $(EtO)_2POP(OEt)_2$, $(MeO)_2PN(Et)P(OMe)_2$, etc.] in good yield.[18]

We have now found that this procedure is excellent for the synthesis of the mixed-ligand derivatives $[Fe_2(\mu\text{-}CO)(CO)_4(\mu\text{-L-L})(\mu\text{-L'-L'})]$ [L-L = $Ph_2PCH_2PPh_2$ or $Me_2PCH_2PMe_2$, L'-L' = $(MeO)_2PN(Et)P(OMe)_2$, etc.]. In particular, photolysis of a solution of $[Fe_2(\mu\text{-}CO)(CO)_6(\mu\text{-dppm})]$ and an excess of bis(dimethylphosphino)methane (dmpm) or the diphosphazane ligands $R_2PN(R')PR_2$ (R' = Et, R = Ph or OMe; R' = Me, R = OEt) or bis(diphenylarsino)methane (dpam) was found to yield crystalline or microcrystalline products characterized by means of IR and ^1H and ^{31}P NMR spectroscopy, as well as from elemental analysis as

the mixed-ligand derivatives $[Fe_2(\mu\text{-CO})(CO)_4(\mu\text{-dppm})(\mu\text{-dmpm})]$, $[Fe_2(\mu\text{-CO})(CO)_4(\mu\text{-dppm})\{\mu\text{-R}_2PN(R')PR_2\}]$ or $[Fe_2(\mu\text{-CO})(CO)_4(\mu\text{-dppm})(\mu\text{-dpam})]$, respectively.

Both the solid-state and the solution IR spectra of these compounds exhibited band patterns in the C—O stretching region similar to those for $[Fe_2(\mu\text{-CO})(CO)_4(\mu\text{-dppm})_2]$ and $[Fe_2(\mu\text{-CO})(CO)_4(\mu\text{-dmpm})_2]$,[18] the structures of which have been established X-ray crystallographically (*vide infra* and ref. 19), while the $^{31}P\{^1H\}$ NMR spectra of $[Fe_2(\mu\text{-CO})(CO)_4(\mu\text{-dppm})(\mu\text{-dmpm})]$ and $[Fe_2(\mu\text{-CO})(CO)_4(\mu\text{-dppm})\{\mu\text{-R}_2PN(R')PR_2\}]$ contained sets of resonances of AA'BB' patterns. These results are interpreted in terms of the structures illustrated in **5** and **6** respectively; the singlet observed in the $^{31}P\{^1H\}$ NMR spectrum of $[Fe_2(\mu\text{-CO})(CO)_4(\mu\text{-dppm})(\mu\text{-dpam})]$ is consistent with **7**. Significantly, in contrast to $[Fe_2(\mu\text{-CO})(CO)_4(\mu\text{-dppm})_2]$, which degrades on alumina or silica gel columns or even on standing in solution in aromatic solvents, the above mixed-ligand complexes could be purified by column chromatography; any degradation is readily monitored by means of $^{31}P\{^1H\}$ NMR spectroscopy. A compound of the type $[Fe_2(\mu\text{-CO})(CO)_4(\mu\text{-dppm})\{\mu\text{-R}_2PN(R')PR_2\}]$, for instance, would afford two singlets instead of an AA'BB' pattern of peaks if it underwent ligand scrambling to give $[Fe_2(\mu\text{-CO})(CO)_4(\mu\text{-dppm})_2]$ and $[Fe_2(\mu\text{-CO})(CO)_4\{\mu\text{-R}_2PN(R')PR_2\}_2]$. Furthermore, the solubility of $[Fe_2(\mu\text{-CO})(CO)_4(\mu\text{-dppm})_2]$ is limited even in solvents such as dichloromethane, whereas the mixed dppm/tetraalkoxydiphosphazane-bridged derivatives are relatively soluble and as a consequence are far more amenable for further study.

Mixed-ligand pentacarbonyl derivatives derived from $[Fe_2(\mu\text{-CO})(CO)_6(\mu\text{-dmpm})]$ have also been synthesized. Thus, treatment of a solution of the latter, readily synthesized from $[Fe_2(CO)_9]$ and dmpm, with an excess of $(MeO)_2PN(Et)P(OMe)_2$ or $(EtO)_2PN(Me)P(OEt)_2$ and irradiation of the resultant solution with UV light was shown to produce the mixed-ligand complexes $[Fe_2(\mu\text{-CO})(CO)_4(\mu\text{-dmpm})\{\mu\text{-(RO)}_2PN(R')P(OR)_2\}]$ (R' = Et, R = Me; R' = Me, R = Et) (**8**), characterized by elemental analysis as well as by spectroscopic (IR and $^{31}P\{^1H\}$ NMR) methods.

Attempts were made to synthesize $[Fe_2(\mu\text{-CO})(CO)_4(\mu\text{-dpam})_2]$ and $[Fe_2(\mu\text{-CO})(CO)_4(\mu\text{-dppea})_2]$ [dppea = $Ph_2PN(Et)PPh_2$], but in contrast to the relative ease of synthesis of $[Fe_2(\mu\text{-CO})(CO)_4(\mu\text{-dppm})_2]$ and $[Fe_2(\mu\text{-CO})(CO)_4(\mu\text{-dmpm})_2]$ all efforts proved unsuccessful. Furthermore, the dppea-bridged heptacarbonyl species $[Fe_2(\mu\text{-CO})(CO)_6(\mu\text{-dppea})]$ (**9**), which could be isolated as a brown microcrystalline solid from light petroleum, was found to readily degrade in toluene solution to the mononuclear derivative $[Fe(CO)_3(dppea)]$, characterized X-ray crystallographically.[20]

Crystal structure of $[Fe_2(\mu\text{-CO})CO)_4(\mu\text{-dppm})_2]\cdot 2Me_2CO$

In attempts to obtain single crystals of the mixed-ligand complex $[Fe_2(\mu\text{-CO})(CO)_4(\mu\text{-dppm})(\mu\text{-dppea})]$ it was found that the first batch of crystals which separated on crystallizing this species from acetone at −10°C were in fact of $[Fe_2(\mu\text{-CO})(CO)_4(\mu\text{-ddpm})_2]$. Second and subsequent crops afforded single crystals of $[Fe_2(\mu\text{-CO})(CO)_4(\mu\text{-dppm})(\mu\text{-dppea})]$, but these were found to be disordered. The structure of $[Fe_2(\mu\text{-CO(CO)}_4(\mu\text{-}$

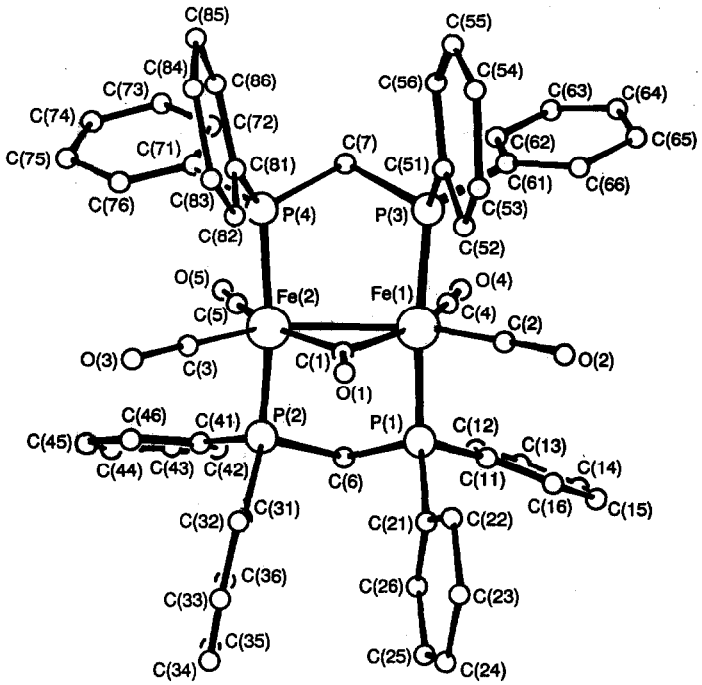


Fig. 1. Molecular stereochemistry of $[Fe_2(\mu\text{-CO})(CO)_4(\mu\text{-dppm})_2]$, showing the atom labelling scheme.

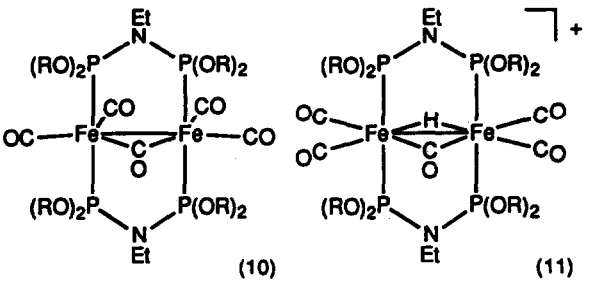
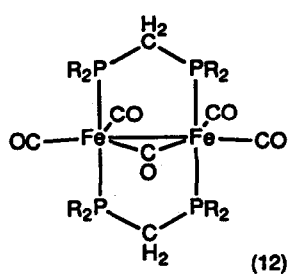
dppm)$_2$] was established X-ray crystallographically and the stereochemistry of the compound is illustrated in Fig. 1. The two iron atoms, which are separated by a distance of 2.742(4) Å corresponding to a formal iron–iron bond, are bridged by the two dppm ligands, *trans* disposed with respect to each other, as well as by a carbonyl group, symmetrically positioned with respect to the iron–iron vector. The remaining four carbonyls are terminal and essentially co-planar with the bridging carbonyl and the two iron atoms, with the plane defined by these groups being essentially orthogonal to the one defined by the four phosphorus and the two iron atoms. The two equatorial carbonyls subtend angles of 111.1(7)° and 113.6(7)° with the iron–iron vector, while the two axial carbonyls subtend angles of 140.8(7)° and 146.7(8)° with it. The structure is thus analogous to those established previously for $[Fe_2(\mu\text{-CO})(CO)_4\{\mu\text{-(EtO)}_2\text{POP(OEt)}_2\}_2]$,[21] $[Fe_2(\mu\text{-CO})(CO)_4\{\mu\text{-F}_2\text{PN(Me)PF}_2\}_2]$,[22] $[Fe_2(\mu\text{-CO})(CO)_4\{\mu\text{-Me}_2\text{PCH}_2\text{PMe}_2\}_2]$[19] and $[Ru_2(\mu\text{-CO})(CO)_4\{\mu\text{-(MeO)}_2\text{PN(Et)P(OMe)}_2\}_2]$.[18]

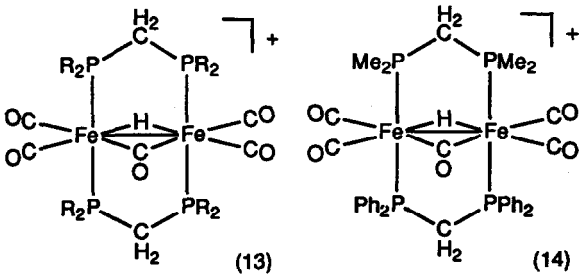
Protonation studies

As communicated previously[15a] reaction of the diphosphazane-bridged derivatives $[Fe_2(\mu\text{-CO})(CO)_4\{\mu\text{-(RO)}_2\text{PN(R')P(OR)}_2\}_2]$ (R' = Et, R = Me, Pr^i or Ph; R' = Me, R = Et) (**10**) with tetrafluoroboric acid diethyletherate in either ether or benzene was found to afford products identified as $[Fe_2(\mu\text{-H})(CO)_4\{\mu\text{-(RO)}_2\text{PN(Et)P(OR)}_2\}_2]BF_4$ (**11**, BF_4), which, according to IR and NMR spectroscopic evidence, contain a bridging hydride as well as bridging diphosphazane ligands. These protonations are reversible, however, with the cationic hydrides being readily deprotonated in the absence of excess acid by the solvent utilized and with the ease of deprotonation increasing along the series R = Et < Pr^i < Me < Ph.



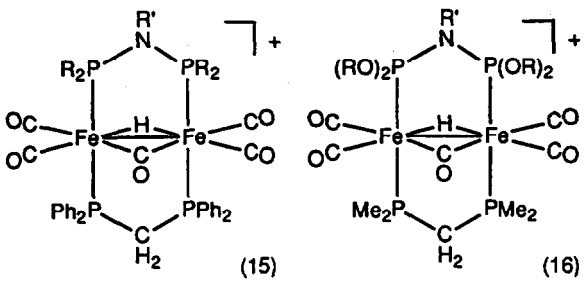


Protonation of the dppm- and dmpm-bridged derivatives $[Fe_2(\mu\text{-}CO)(CO)_4(\mu\text{-}dppm)_2]$ (**12**, R = Ph) and $[Fe_2(\mu\text{-}CO)(CO)_4(\mu\text{-}dmpm)_2]$ (**12**, R = Me) by both tetrafluoroboric acid diethyletherate and trifluoroacetic acid was also shown to lead to the formation of hydride-bridged products, viz. $[Fe_2(\mu\text{-}H)(\mu\text{-}CO)(CO)_4(\mu\text{-}dppm)_2]$Anion (Anion = BF_4 or CF_3COO) (**13**, Anion; R = Ph) and $[Fe_2(\mu\text{-}H)(\mu\text{-}CO)(CO)_4(\mu\text{-}dmpm)_2]$Anion (**13**, Anion; R = Me). However, in contrast to the corresponding diphosphazane-bridged derivatives, these compounds are relatively stable to deprotonation, with strong bases such as $NaBH_4$ being required to remove the proton.



(13)

(14)



(15)

(16)

Not surprisingly hydride-bridged products, viz. $[Fe_2(\mu\text{-}H)(\mu\text{-}CO)(CO)_4(\mu\text{-}dppm)(\mu\text{-}dmpm)]BF_4$ (**14**, BF_4), $[Fe_2(\mu\text{-}H)(\mu\text{-}CO)(CO)_4(\mu\text{-}dppm)\{\mu\text{-}(RO)_2PN(R')P(OR)_2\}]BF_4$ (**15**, BF_4) and $[Fe_2(\mu\text{-}H)(\mu\text{-}CO)(CO)_4(\mu\text{-}dmpm)\{\mu\text{-}(RO)_2PN(R')P(OR)_2\}]BF_4$ (**16**, BF_4), were isolated from the reactions of the mixed-ligand complexes $[Fe_2(\mu\text{-}CO)(CO)_4(\mu\text{-}dppm(\mu\text{-}dmpm)]$ (**5**), $[Fe_2(\mu\text{-}CO)(CO)_4(\mu\text{-}dppm)\{\mu\text{-}R_2PN(R')PR_2\}]$ (R' = Et, R = Ph or OMe; R' = Me, R = OEt) (**6**) and $[Fe_2(\mu\text{-}CO)(CO)_4(\mu\text{-}dmpm)\{\mu\text{-}(RO)_2PN(R')P(OR)_2\}]$ (R' = Et, R = OMe; R' = Me, R = OEt) (**8**), respectively, with HBF_4 etherate. Selected examples of these compounds were characterized fully, while the others were identified spectroscopically; the relevant spectral features of these compounds were the presence of a set of four peaks of a particular pattern in the terminal carbonyl stretching region and a single peak in the bridging carbonyl region of their IR spectra, a quintet readily assigned to a bridging hydride in their ^1H NMR spectra and either an AA'BB' or an AA'XX' pattern of peaks in their $^{31}P\{^1H\}$ NMR spectra (*vide* Figs 2 and 3, respectively). Significantly, these complexes are considerably more stable to deprotonation than the diphosphazane-bridged species $[Fe_2(\mu\text{-}H)(\mu\text{-}CO)(CO)_4\{\mu\text{-}(RO)_2PN(Et)P(OR)_2\}_2]BF_4$ (**11**, BF_4), and at the same time considerably more soluble in the more common polar organic solvents than $[Fe_2(\mu\text{-}H)(\mu\text{-}CO)(CO)_4(\mu\text{-}dppm)_2]BF_4$ (**13**, BF_4, R = Ph) and as such, similar to their parent compounds, are ideal precursors for further study.

EXPERIMENTAL

All reactions were carried out using Schlenk line techniques under nitrogen. Chromatographic separations (on silica gel columns) and photochemical experiments were performed under nitrogen and argon atmospheres, respectively. All solvents (best grade available) were pre-dried using recommended agents and were freshly distilled prior to use. The IR spectra were recorded with Philips Pye–Unicam SP3-200 spectrophotometer using cells with KBr windows, while NMR spectra were measured on a Varian FT80A instrument using TMS (internal) and H_3PO_4 (external) as references for the ^1H NMR and $^{31}P\{^1H\}$ NMR spectral measurements, respectively. The ligands $Ph_2PCH_2PPh_2$, $Ph_2AsCH_2AsPh_2$ and $Me_2PCH_2PMe_2$ were purchased from Strem Chemicals and used without further purification. The diphosphazane ligands $Ph_2PN(Et)PPh_2$ and $(RO)_2PN(R')P(OR)_2$ (R' = Et, R = Me, Pr^i or Ph; R' = Me, R = Et) were synthesized according to known methods,[23,24] which were modified to improve yields. $[Fe_2(\mu\text{-}CO)(CO)_4(\mu\text{-}dppm)_2]$, $[Fe_2(\mu\text{-}CO)(CO)_4(\mu\text{-}dmpm)_2]$, $[Fe_2(\mu\text{-}CO)(CO)_4\{\mu\text{-}(RO)_2PN(Et)P(OR)_2\}_2]$ (R = Me, Pr^i or Ph), $[Fe_2(\mu\text{-}CO)(CO)_6(\mu\text{-}dppm)]$ and $[Fe_2(\mu\text{-}CO)(CO)_6(\mu\text{-}dpmpm)]$ were also synthesized according to literature procedures.[17,18] Elemental analyses (carbon, hydrogen and nitrogen) were performed by the Microanalytical Section of the Department of Chemistry, University of Natal, Pietermaritzburg.

Synthesis of mixed-ligand complexes

All mixed-ligand complexes were synthesized by very similar methods. Typically, the red–brown oil of $[Fe_2(\mu\text{-}CO)(CO)_6(\mu\text{-}dppm)]$ or $[Fe_2(\mu\text{-}CO)(CO)_6(\mu\text{-}dmpm)]$, obtained from the reaction of $[Fe_2(CO)_9]$ with $Ph_2PCH_2PPh_2$ and $Me_2PCH_2PMe_2$, respectively, was transferred to the photochemical reactor, together with light petroleum (*ca* 120 cm^3; 60–80°C), and a stoichiometric amount of the second ligand dissolved in a suitable solvent (3–5 cm^3) was added. The stirred reaction mixture

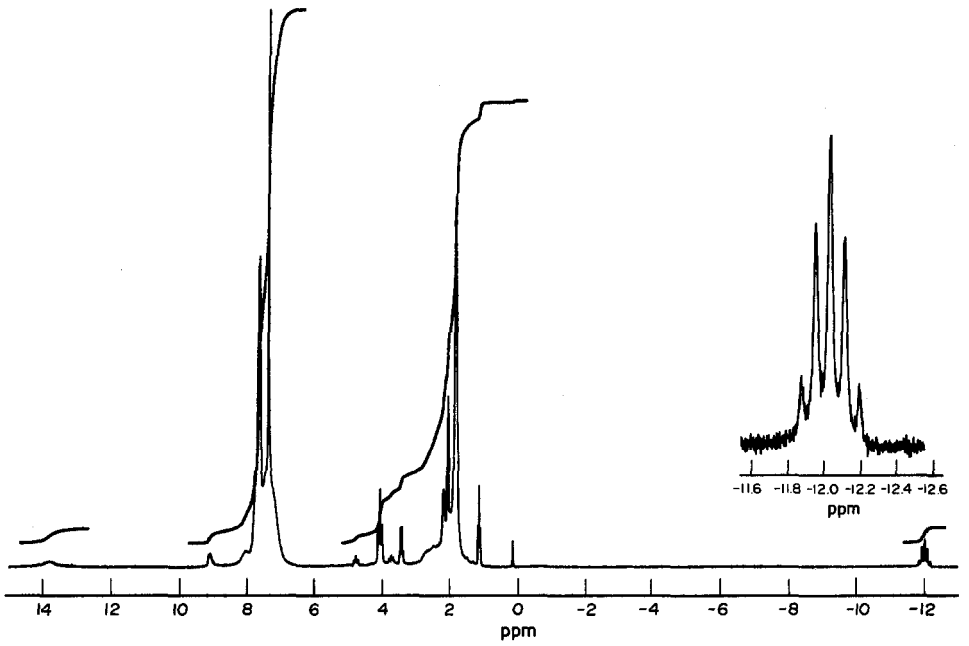


Fig. 2. ^1H NMR spectrum of $[Fe_2(\mu\text{-}H)(\mu\text{-}CO(CO)_4(\mu\text{-}dppm)(\mu\text{-}dmpm)]BF_4$ measured in acetone-d_6.

(under an atmosphere of argon) was irradiated by means of a 125 W or a 250 W medium-pressure mercury vapour lamp for a period of 6–30 h. The yield of the product, isolated as a light to dark brown microcrystalline material from this reaction mixture, ranged from 50 to 85%. The analyses and the spectral data for the compounds synthesized are summarized in Tables 1 and 2, respectively.

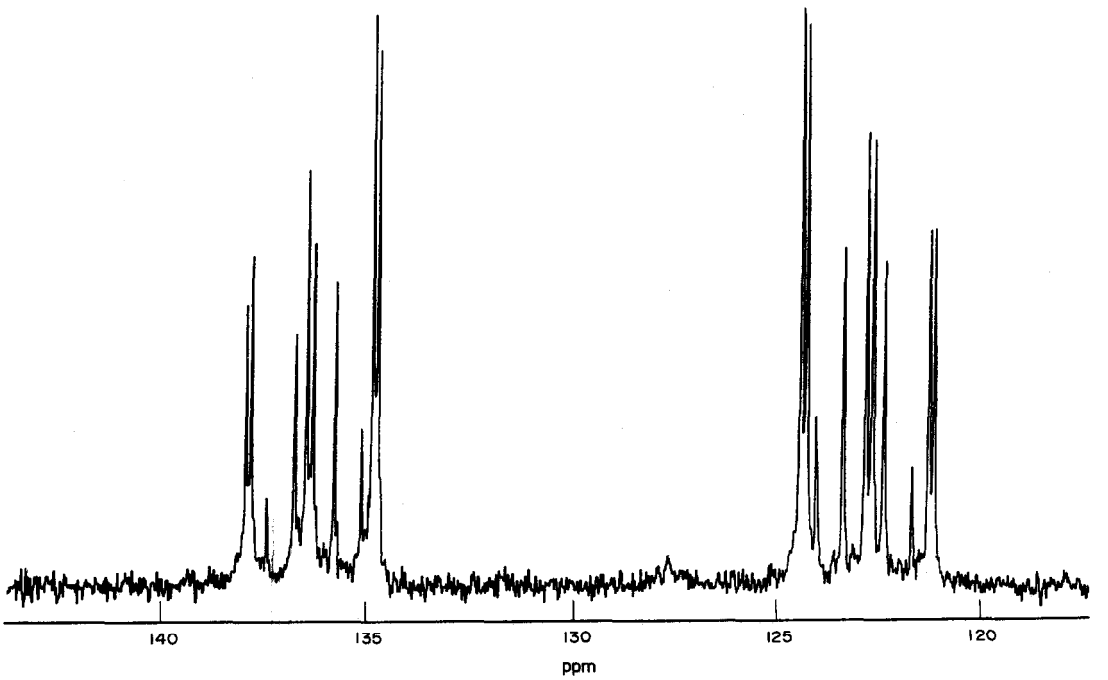

Fig. 3. $^{31}P\{^1H\}$ NMR spectrum of $[Fe_2(\mu\text{-}H)(\mu\text{-}CO)(CO)_4(\mu\text{-}dppm)(\mu\text{-}dmpm)]BF_4$ measured in acetone-d_6.

Protonation reactions

All protonation reactions were carried out using the same general procedure. A slight excess of tetrafluoroboric acid diethyletherate in ether or trifluoroacetic acid in benzene (*ca* 30 cm^3) was added dropwise to a stirred solution of $[Fe_2(\mu\text{-CO})(CO)_4(\mu\text{-dppm})_2]$, $[Fe_2(\mu\text{-CO})(CO)_4(\mu\text{-dmpm})_2]$ or the mixed-ligand complex (0.1–0.2 mmol) in benzene (*ca* 30 cm^3) at room temperature and stirring continued until the reaction was complete, as determined by monitoring by means of IR spectroscopy. The red–orange solid that separated from solution was isolated, washed with dry pentane and crystallized from acetone/pentane at −20°C. Yields of the crystalline protonated products varied from 40 to 60%.

The protonated products of the diphosphazane derivatives $[Fe_2(\mu\text{-CO})(CO)_4\{\mu\text{-(RO)}_2PN(Et)P(OR)_2\}_2]$ could not be isolated as a solid material and were identified by spectroscopic means only.

Crystal structure determination

Crystal data. $C_{61}H_{56}Fe_2O_7P_4$, $M = 1136.7$, triclinic, space group $P\bar{1}$, $a = 13.549(8)$, $b = 14.455(9)$, $c = 16.065(9)$ Å, $\alpha = 89.99(4)$, $\beta = 68.75(6)$, $\gamma = 68.63(5)°$, $V = 2698.98$ $Å^3$, $D_c = 1.399$ g cm^{-3}, $Z = 2$, Mo-K_α radiation, $\lambda = 0.71069$ Å, $\mu = 7.053$ cm^{-1}, $F(000) = 1108$.

Intensity data were collected on a Nonius CAD-4 diffractometer using graphite monochromated Mo-K_α radiation. A least-squares fit of 25 high angle reflections ($\theta > 12°$) was used to obtain accurate cell constants. Diffraction intensities were measured in the range $3 < 2\theta < 46°$ using the ω–2θ scan technique, with background counts made for half the total scan time on each side of the peak. Three

standard reflections measured every hour showed no decrease in intensity during data collection. Lorentz and polarization as well as empirical absorption corrections were made. Of the 6716 unique reflections measured 2892 were classed as observed $[I > 3\sigma(I)]$ and these were used for the solution and refinement of the structure.

The structure was solved by conventional Patterson and Fourier techniques. Hydrogen atoms were not located and, because of disorder problems, both of the acetone solvent molecules were refined as rigid groups. All of the non-hydrogen atoms were assigned anisotropic temperature factors, except the phenyl carbon atoms which were assigned isotropic thermal parameters. The phenyl rings were also refined as rigid groups. A weighted full-matrix least-squares refinement (319 variables) converged at $R = 0.099$, $R_w = 0.106$. A final difference Fourier was featureless. Complex neutral scattering factors were taken from tables[25] and the program SHELX-76 was used for the calculations.[26] Selected interatomic distances and angles are given in Tables 3 and 4, respectively.*

(*Received* 13 *May* 1992; *accepted* 6 *October* 1992)

Abstract—A new acyclic ligand has been synthesized by Schiff base condensation of 2-dimethylaminoethyl amine with diisobutyraldehyde disulphide, which can coordinate to a metal ion through four nitrogens. Introduction of a large bite angle for two nitrogens forces the coordination geometry around a metal ion to distort from planarity towards tetrahedral. The presence of a disulphide linkage along with two imine linkages make the ligand somewhat neoplastic so that the four nitrogens can impose a pseudo-tetrahedral geometry upon a metal ion overcoming its own preference for a particular geometry. The electronic spectral results when compared with the square planar complex $Cu(L)_2(ClO_4)_2$ (L = 2-dimethylaminoethyl amine) are consistent with a pseudo-tetrahedral coordination geometry for copper(II). We have tested the rigidity of the donor atoms' topology through synthesis and characterization of neat copper(II) and copper(II)-doped zinc(II) complexes. ESR spectral results show that the neat copper(II) as well as the copper(II)-doped zinc(II) complexes give axial spectra and almost identical $g_\parallel$ and $A_\parallel$ values, which are attributable to similar pseudo-tetrahedral coordination. Thus, the ligand-field driven tendencies of zinc(II) to form tetrahedral complexes of copper(II) to form square planar complexes with four nitrogen donors are overcome through ligand design. The neat copper(II) complex shows a quasi-reversible copper(II)/copper(I) couple at $E_{1/2} = +0.18$ V (vs SCE), which is shifted by more than +450 mV compared to the square-planar analogue $Cu(L)_2(ClO_4)_2$.

Simple monodentate or bidentate N-donor ligands favourably form square-planar complexes with copper(II) and tetrahedral complexes with zinc(II) ions. Thus, it is possible, in principle, to test the rigidity of the donor atoms' topology of any ligand by complexing it with copper(II), as well as zinc(II), and observing whether imposition of a particular coordination geometry can be effected onto the aforesaid metal ions. Studies of this kind have bioinorganic relevance. Metalloproteins having intrinsic active sites[1] are often characterized by low symmetry of coordination geometry. In these proteins the amino acid side-chains of the protein backbone provide the donor atoms imposing a low symmetry of coordination onto the metal ions. The low symmetry arises due to conformationally imposed constraints upon amino acid side-chains that comprise the donors. This imposition of an irregular geometry is designed by nature[2] to achieve a condition energetically favourable to carry out its assigned biological role(s). Recently, the synthesis of a geometrically constrained bidentate imidazole derivative has been reported,[3] which forms pseudo-tetrahedral (D_{2d}) complexes with copper(II), nickel (II), cobalt(II) and zinc(II). Our interest in the imposition of a desired coordination geometry onto metal ions[4] has led us to synthesize the ligand L_1. Examination of molecular models revealed that the ligand with a constrained donor set and a large bite angle should be able to impose a coordination which would be substantially distorted from planarity. To test the rigidity of the donor set a zinc(II) complex with copper(II) as the dopant has been synthesized, in addition to a neat copper(II) complex, and subjected to EPR studies as both g and A values

are quite sensitive to the symmetry of coordination.[5] The ligand L is known[6] to form a square-planar complex with copper(II) perchlorate hexahydrate. This complex is included in the present study to compare the spectroscopic and electrochemical characteristics of the copper(II) complexes formed with L and L_1.

EXPERIMENTAL

Materials

Sulphur monochloride and 2-dimethylaminoethyl amine (Merck) were used as received without further purification. Perchlorate salts of copper(II) and zinc(II) were synthesized by treating the corresponding carbonate with aqueous perchloric acid. Isobutyraldehyde (Merck) was distilled prior to use. All the solvents were purified following standard procedures.[7]

Physical measurements were made as reported earlier.[8] Elemental analyses were performed at the Central Drug Research Institute, Lucknow, India.

Synthesis of the ligand and complexes

Synthesis of the ligand was achieved in several steps, as shown schematically in Fig. 1.

Diisobutyraldehyde disulphide. The dialdehyde was prepared by homolytic cleavage of the S—Cl bond by isobutyraldehyde, following a published procedure.[9] Sulphur monochloride (20 g, 0.15 mol) in dry CCl_4 (25 cm^3) was added dropwise to a solution of freshly distilled isobutyraldehyde (21.4 g, 0.30 mol) mixed with dry CCl_4 (40 cm^3), maintaining the temperature at 40–45°C throughout. At the beginning the temperature of the reaction mixture increased rapidly and cooling was necessary. As soon as sulphur monochloride came into contact with isobutyraldehyde copius evolution of HCl gas occurred, which was driven out of the reaction vessel by occasional passage of nitrogen gas. The total addition time was 3 h, after which time the reaction mixture was maintained at 40°C for 48 h for completion of the reaction. To collect the product CCl_4 was evaporated off and the resulting pale yellow, thick liquid was washed several times with distilled water to remove dissolved HCl and finally allowed to distil under reduced pressure. The dialdehyde was obtained as a pale yellow oily liquid (15 mm; 90–100°C; lit.[9] 1 mm; 110–115°C) in 81% yield. ^1H NMR (80 MHz; $CDCl_3$; TMS, ppm): 1.1 (s, 12H), $4CH_3$; 9.0 (s, 2H), 2CHO. The NMR spectral data were in agreement with the reported data.[9] The dialdehyde can easily form Schiff bases with different amines. The X-ray structure of one such compound is available.[10]

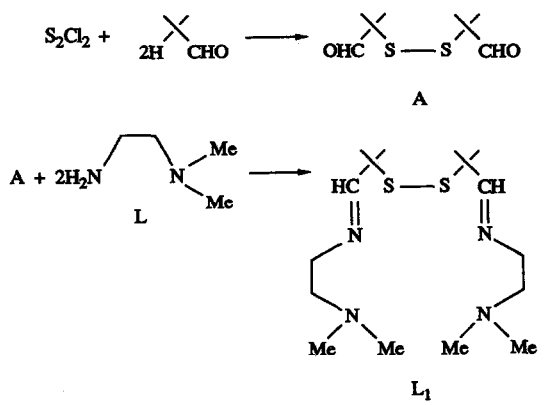

Fig. 1. Schematic diagram for the synthesis of the ligands.

Synthesis of L_1. Diisobutyraldehyde disulphide (2 g, 0.01 mol) was allowed to reflux in the dark and in an atmosphere of purified nitrogen with 2-dimethylaminoethyl amine (1.7 g, 0.02 mol) in dry ethanol (20 cm^3) for 2 h to give an orange solution of the Schiff base. Ethanol was removed completely under reduced pressure and the thick orange liquid was used for complexation without further purification.

Synthesis of $Cu(L_1)\cdot 2ClO_4$ (**1**). When $Cu(H_2O)_6(ClO_4)_2$ (1 g, 0.003 mol) was allowed to react with the ligand L_1 (0.93 g, 0.003 mol) in ethyl acetate a green crystalline solid separated immediately. The solid was collected by filtration and dried *in vacuo*. Yield 42%.

Synthesis of copper(II)*-doped* $Zn(L_1)\cdot 2ClO_4$ (**2**). This was synthesized as above using acetone instead of ethyl acetate as the medium, with nominal 2% doping of copper(II). In a typical experiment a mixture of $Zn(H_2O)_6(ClO)_2$ (1.2 g, 0.003 mol) and $Cu(H_2O)_6(ClO_4)_2$ (0.001 g, 0.003 mmol) was heated with the ligand L_1 (0.95 g, 0.003 mol) in acetone for 30 min. The colour of the solution turned pale green, which on evaporation afforded the product as a pale yellow solid in 53% yield.

Synthesis of $Cu(L)(ClO_4)_2$ (**3**). $Cu(H_2O)_6(ClO_4)_2$ was allowed to stir at room temperature with 2-dimethylaminoethyl amine (L) in a 1 : 2 molar ratio in ethanol to obtain a dark blue solution, which on slow evaporation yielded dark blue plates of **3** in 80% yield.

Analytical data for the complexes are given in Table 1.

RESULTS AND DISCUSSION

Conductivity data (Table 1) ethanol and acetonitrile are consistent[11] with the 1 : 2 electrolytic

Table 1. Conductivity and analytical data[a] for the complexes

Complex	Conductance in CH_3CN (Ω^{-1} cm^2 mol^{-1})	Conductance in Ethanol (Ω^{-1} cm^2 mol^{-1})	Analysis (%) C	H	N
1	263	82	31.9(31.5)	6.1(5.6)	9.0(9.2)
3	266	83	21.5(21.9)	5.3(5.5)	12.6(12.8)

[a] Calculated values are given in parentheses.

nature of the complexes. IR spectra of the complexes **1–3** show a strong peak around 1610 cm^{-1}. The downward shift in imine stretching frequency is consistent with the fact that the imine nitrogens are coordinated to the metal ion.

Magnetic moment values (Table 2) for the neat copper(II) complexes after diamagnetic corrections are indicative of discrete mononuclear species.[12] EPR data for **1–3** and related complexes are collected in Table 2. In the solid state **1** shows a broad EPR spectrum with $g_{av} = 2.10$, while in acetonitrile solution at room temperature a four-line EPR spectrum ($A_{av} = 79 \times 10^{-4}$ cm^{-1}) is obtained. In acetonitrile glass (liquid nitrogen temperature) **1** shows an axial spectrum which is very similar to that of **2**. The axial nature of the EPR spectra exhibited by each complex is characteristic of copper(II) with the $d_{x^2-y^2}$ ground state. However, the $g_\parallel$ and $A_\parallel$ values (Table 2) are consistent with a geometry that is substantially distorted from planarity[13] for a CuN_4 chromophore. For tetragonal geometry the expressions for $g_\parallel$ and $g_\perp$ are:[1]

$$g_\parallel = g_e + \frac{-8\xi}{\Delta E_{xy}}$$

and

$$g_\perp = g_e + \frac{-2\xi}{\Delta E_{xz,yz}}. \quad (1)$$

E_{xy} is the energy difference between d_{xy} and $d_{x^2-y^2}$ (ground state); similar for $E_{xz,yz}$; ξ is the one electron spin-orbit coupling parameter. The hyperfine couplings are expressed as:

$$A_\parallel = P_d[-\chi - 4/7\alpha^2 + (g_\parallel - 2) + 3/7(g_\perp - 2)]$$

and

$$A_\perp = P_d[-\chi + 2/7\alpha^2 + 11/14(g_\perp - 2)]; \quad (2)$$

where χ is the contribution from the indirect Fermi contact, and the second term is the anisotropic dipolar contribution; P_d is a constant which is *ca* 350×10^{-4} cm^{-1} for the free copper ion. As these equations indicate, $g_\parallel$ and $A_\parallel$ values are dependent on the ligand field strength, specifically in the equatorial plane. Increasing the strength of the ligand field, keeping the geometry unaltered, will lead to a lower value for $g_\parallel$ and a higher value for $A_\parallel$. As the geometry distorts from planar (D_{4h}) towards flattened tetrahedral (D_{2d}), the ligand field strength

Fig. 2. Ligand L' from ref. 3.

decreases and consequently the $g_{\parallel}$ value increases while $A_{\parallel}$ decreases.[1] Hence, for **1** compared with **3** the increase in $g_{\parallel}(\Delta g_{\parallel} = 0.10)$ and decrease in $A_{\parallel}(\Delta A_{\parallel} = 35 \times 10^{-4}\ cm^{-1})$ are attributable to the distortion of the coordination geometry towards pseudo-tetrahedral. For **2** the $g_{\parallel}$ as well as the $A_{\parallel}$ values do not differ to any significant extent with respect to those found in **1**. This result is consistent with grossly the same coordination geometry in both cases. Schugar *et al.*[3] found that comparing the EPR spectral data for neat copper(II) and copper(II)-doped zinc(II) complexes of the ligand 2,2'-bis(imidazolyl)biphenyl (Fig. 2), the $g_{\parallel}$ as well as the $A_{\parallel}$ values (Table 3) change significantly for a slight change in the dihedral angle describing the tetrahedral geometry.

Electronic spectral data for the complexes are collected in Table 3. Complex **1** in the solid state has features similar to those in acetonitrile solution. This suggests that the chromophore is preserved in acetonitrile solution. Ligand field bands are quite sensitive to the coordination geometry. As the coordination geometry distorts from planarity towards tetrahedral, the overall splitting of the *d*-orbital energy levels will decrease resulting in a red shift for the *d–d* bands.[14] Attempts have been made to relate the band maxima with the value of the dihedral angle.[15] Any conclusion based on such correlations, however, should be made only for closely related ligands. The X-ray crystallographically-characterized pseudo-tetrahedral CuN_4 chromophore shows[3] more than one ligand field band. However, for both **1** and **3** only one broad asymmetric band appears in the ligand field region; a situation not so uncommon for copper(II) complexes.[16] This band is considerably red-shifted (135 nm) in **1** compared to that in **3**, signifying appreciable distortion of the geometry from planarity as envisaged. Electronic spectra of the bis-copper(II) complexes with the ligand $H_2NCH_2CH_2NH_2$ (en) and its alkyl derivatives have been studied in detail.[6,17] The parent square planar complex $[Cu(en)_2]2ClO_4$ absorbs at 240 nm, which is attributable to the (N) → Cu^{II} LMCT transition. Alkylation of the nitrogen atoms lowers the ionization potential of the amine[18] and results in a systematic red-shift of this band. The observed correlation between the position of this band and the estimated first ionization potential of the free diamines[6] suggests this transition to occur at 285 nm for $[Cu(L_1)_2]2ClO_4$. Thus, for **1** the peak that appears at 280 nm is attributable to the (N) → Cu^{II} LMCT transition. The ligand moiety absorbs significantly at higher energies, but we did not probe further.

A DMF solution of **3** (*ca* 1×10^{-3} M) gives a quasi-reversible response (Fig. 3) at $E_{1/2} = -0.28$ V vs SCE with $\Delta E_p = 130$ mV (room temperature, 100 mV s^{-1}). The i_{pa}/i_{pc} ratio is found to be 1.05, which is independent of sweep rate. The quasi-reversible response is attributable to the Cu^{II}/Cu^{I} couple, as shown below:

$$3 + e \longrightarrow 3^{-}. \qquad (3)$$

When scanned further on the negative side a small peak appears at −0.9 V, which disappears in the reverse scan. However, a very sharp rise in anodic current occurs which peaks at 0.15 V. This is attributable to the oxidation of metallic copper

Table 3. Cyclic voltammetric[a] and electronic spectral data for the complexes

Complex	$E_{1/2}$ (V)	ΔE_p (mV)	λ_{max} (nm) (ε/dm^3 mol^{-1} cm^{-1})	Assignment	Ref.
1	+0.28	80	730(25)	LF	This work
			280(1750)	σN → Cu^{II} LMCT	
3	−0.18	110	595(30)	LF	This work
			280(1600)	σN → Cu^{II} LMCT	
$Cu(L')_2(ClO_4)_2$	+0.11	90	650(260)	LF	3
			800(120)	LF	

[a] Results for **1** and **3** were obtained at 298 K at a scan rate of 100 mV s^{-1} and referenced to SCE; $E_{1/2} = 0.5\ (E_{pc} + E_{pa})$; E_{pc} and E_{pa} are cathodic and anodic peak potentials, respectively.

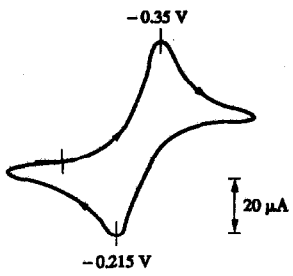

Fig. 3. Cyclic voltammogram (100 mV s^{-1}) of **3** in DMF at a glassy carbon electrode.

deposited at the electrode surface. Examples of this behaviour of copper complexes are known.[19] The peak at −0.9 V is then due to the reduction of copper(I) to copper(O), which partly gets deposited at the electrode surface. Under these circumstances, the anodic peak, which appears at the same position, dramatically increases in current height. Complex **1** in DMF (*ca* 1×10^{-3} M) gives a cyclic response (Fig. 4) at $E_{1/2} = +0.18$ V vs SCE with $\Delta E_p = 80$ mV (room temperature, 100 mV s^{-1}). ΔE_p increases with increasing scan rate. The response is due to the following electrochemical reaction:

$$\mathbf{1} + e \longrightarrow \mathbf{1}^-. \quad (4)$$

The i_{pa}/i_{pc} ratio here is 1.3, which does not alter with the scan rate. The slightly higher magnitude of the anodic current is due to the oxidation of the ligand moiety in addition to the metal ion. No other well-defined peak appears on scanning further on either side, except one attributable to the desorption of metallic copper from the electrode surface when scanned further on the negative side (as found for **3**). These results indicate that as coordination geometry around copper(II) distorts from planar in **3** to distorted tetrahedral in **1**, $E_{1/2}$ shifts positively by 0.46 V. Copper(I) favours tetrahedral geometry; as the geometry distorts towards tetrahedral it becomes easier to reduce copper(II) to copper(I).

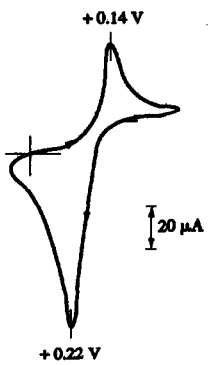

Fig. 4. Cyclic voltammogram (100 mV s^{-1}) of **1** in DMF at a glassy carbon electrode.

CONCLUSION

We have studied the ligating behaviour of a tetradentate nitrogen donor ligand towards copper(II) and zinc(II). Electronic spectral, ESR and electrochemical data are consistent with a pseudo-tetrahedral geometry in both **1** and **2**. The ligand design has made the four nitrogen donors somewhat neoplastic, so that they are capable of imposing a desired coordination geometry onto the above metal ions. In an intrinsic active site of a metalloprotein the geometry around the metal is often much distorted as a result of conformationally imposed constraints upon amino acid side-chains that comprise the donors. In mimicking such sites multidonor ligands with rigid topology are likely to provide the best results.

Abstract—The interaction of the paramagnetic complex $[Eu(CH_3COO)_2L]Cl \cdot 4H_2O$, where L is the six N-donor macrocyclic ligand $C_{22}H_{26}N_6$, with a series of organic substrates having potential O-donor atoms has been investigated. The ^1H NMR resonances of anionic or acidic substrates were greatly shifted in the presence of the europium complex, whereas those of uncharged substrates remained essentially unchanged. The $^5D_0 \rightarrow {}^7F_2$ emission of the europium complex was considerably enhanced in the presence of certain heteroaromatic carboxylates; new complexes of the formula $[Eu(RCOO)_2L]Cl \cdot nH_2O$, where R is $-C_6H_5$, $-C_4H_3O$, $-C_4H_3S$, $-C_4H_3NH$ or $-C_5H_4N$ and $n = 2$–4, were isolated in the solid state. The crystal and molecular structure of the triacetate, $[Eu(CH_3COO)_2L](CH_3COO) \cdot 9H_2O$, was established by single-crystal X-ray crystallography. The structure is ionic, with a 10-coordinate europium(III) linked to the six N-donor atoms of the macrocyclic ligand and to two bidentate chelating acetates situated on opposite sides of the macrocycle. An ionic acetate and a network of hydrogen-bonded H_2O molecules (nine per complex unit) completed the crystal lattice.

The compounds of europium(III) have recently attracted considerable interest in two unrelated areas: certain europium(III) salts and substituted tris-β-diketonates have found useful applications as NMR shift reagents in organic analysis,[1] while a number of luminescent complexes of chelating

* Author to whom correspondence should be addressed.

ligands have been suggested as markers in cytology and immunology.[2] As NMR shift reagents, the complexes of europium(III)—an f^6 system—offer the advantage of producing relatively large paramagnetic shifts in the spectra of organic substrates, without excessive broadening of the resonances. As luminescent markers, they offer the advantage of long-lived, narrow emissions in the visible region of the spectrum, thus avoiding interference with any intrinsic fluorescence of the bio-substrate. The usefulness of europium(III) compounds in these two areas, however, is often severely limited either by lack of solubility in the desired solvent, especially water, or by the ease with which most lanthanide (III) complexes are decomposed by acids and competing ligands, including strong donor solvents.

In view of these limitations, the $[Eu(CH_3COO)_2L]Cl \cdot 4H_2O$ complex, where L is the six N-donor macrocyclic ligand $C_{22}H_{26}N_6$ illustrated in Fig. 1,[3,4] offers interesting new possibilities. This complex is very soluble in water as well as in organic solvents, and the {EuL} entity is substitution-inert and retains its identity in solution even at acidic pH and in the presence of strongly competing ligands; in contrast, the exocyclic acetate ligands are labile and easily exchanged. This complex, therefore, may provide a useful alternative to existing NMR shift reagents[5] and may serve as a prototype for a new class of luminescent bio-markers.[6]

The present paper reports a study of the interaction between the $[Eu(CH_3COO)_2L]Cl \cdot 4H_2O$ complex and a representative series of oxygen-containing organic substrates—alcohols, phenols, ketones, carboxylic acids and their anions—with the dual purpose of evaluating its performance as an NMR shift reagent and to identify exocyclic ligands that might enhance its luminescence intensity to practically useful levels. Preliminary results of these studies have been reported.[7,8] In order to establish the maximum number of exocyclic carboxylates which can actually coordinate to the metal centre of the {EuL} macrocyclic moiety, a triacetate complex, $EuL(CH_3COO)_3 \cdot 9H_2O$, was synthesized and its structure determined by X-ray crystallography.

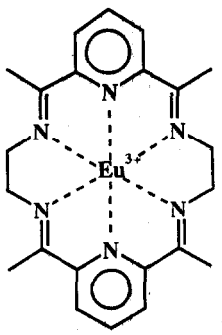

Fig. 1. Schematic formula of the {EuL} moiety, $L = C_{22}H_{26}N_6$.

EXPERIMENTAL

Starting materials

Hydrated europium(III) acetate, 2,6-diacetylpyridine, 1,2-diaminoethane, the organic compounds investigated as substrates (acetone, methanol, 1-butanol, 2-butanol, 2-methyl-2-butanol, phenol, catechol; sodium carboxylates: formate, acetate, propanoate, butanoate, succinate, benzoate) and the carboxylic acids used in luminescence studies (benzoic, 2-furancarboxylic, 2-thiophenecarboxylic, 2-pyrrolecarboxylic, 2-pyridinecarboxylic) were commercially available products; they were checked for purity by NMR and/or IR spectroscopy and recrystallized or distilled whenever necessary. The complex $[Eu(CH_3COO)_2L]Cl \cdot 4H_2O$ was prepared and characterized as previously described.[4] Deuterated solvents for NMR studies (deuterochloroform, deuterium oxide and methanol-d_4, all from Aldrich) and spectrograde solvents for luminescence measurements were used as received.

$[Eu(CH_3COO)_2L](CH_3COO) \cdot 9H_2O$

This complex was prepared similarly to $[Eu(CH_3COO)_2L]Cl \cdot 4H_2O$, except that freshly distilled 1,2-diaminoethane was used as the starting material instead of a mixture of the diamine dihydrochloride and KOH. The product was recrystallized several times from methanol–diethyl ether and obtained as off-white shiny crystals; yields *ca* 80%. The complex is very soluble in water, alcohols, chloroform and other polar organic solvents; it is insoluble in ethers, alkanes and carbon tetrachloride. The IR spectrum is nearly identical to that of $EuL(CH_3COO)_2Cl \cdot 4H_2O$[4] and $YL(CH_3COO)_2Cl \cdot 4H_2O$,[9] except for an additional strong absorption at 1571 cm^{-1} (antisymmetric stretching mode of ionic acetate). Crystallographic analysis data are given in a following section.

$[Eu(RCOO)_2L]Cl \cdot nH_2O$ (R = —C_6H_5, —C_4H_3O, —C_4H_3S, —C_4H_3NH *and* —C_5H_4N; n = 2–4)

These complexes were prepared by the following general procedure, employing a 2:1 mole ratio of carboxylic acid to europium complex. The solid carboxylic acid was added to a solution of

$[Eu(CH_3COO)_2L]Cl \cdot 4H_2O$ (0.10 mmol in 5 cm^3 $CHCl_3$) and the mixture was stirred at 40–50°C for 10 min, or until the acid had dissolved. The resulting slightly cloudy solution was filtered; the clear filtrate was diluted with 10–15 cm^3 of diethyl ether and chilled for several hours in a freezer. The colourless crystalline solid that formed was filtered with suction, washed on the filter with a 1:3 mixture of chloroform–diethyl ether and dried at 60°C. Yields were nearly quantitative. The products thus obtained were analytically pure; however, samples used for luminescence measurements were recrystallized from methanol–diethyl ether. Microanalyses (Atlantic Microlab, Atlanta, GA): $[Eu(C_6H_5COO)_2L]Cl \cdot 3H_2O$: Found: C, 50.4; H, 4.9; N, 9.2. Calc.: C, 50.2; H, 4.9; N, 9.3%. $[Eu(C_4H_3OCOO)_2L]Cl \cdot 4H_2O$: Found: C, 44.9; H, 4.9; N, 9.9. Calc.: C, 44.8; H, 4.7; N, 9.8%. $[Eu(C_4H_3SCOO)_2L]Cl \cdot 2H_2O$: Found: C, 45.3; H, 4.2; N, 9.5. Calc.: C, 45.0; H, 4.2; N, 9.8%. $[Eu(C_5H_4NCOO)_2L]Cl \cdot 4H_2O$: Found: C, 46.4; H, 4.8; N, 12.6. Calc.: C, 46.4; H, 4.8; N, 12.7%. $[Eu(C_4H_4NCOO)_2L]Cl \cdot 3H_2O \cdot 0.5CH_3OH$: Found: C, 45.8; H, 4.8; N, 13.0. Calc.: C, 45.8; H, 5.0; N, 13.1%. The IR spectra of the solid complexes showed in each case the absorptions of the macrocyclic ligand,[9] together with those of the respective anionic ligand: benzoate,[9] 2-furancarboxylate,[10] 2-pyrrolecarboxylate[11] and 2-pyridinecarboxylate.[12] For 2-thiophenecarboxylate the absorptions (not available in the literature) were: 3474 w, br, 3089 w, 3075 w, 1619 sh, 1593 sh, 1555 vs, br, 1522 m (only partly resolved), 1428 vs, 1396 vs, 1381 sh, 1343 s, 1225 w, 1111 m, 1073 vw, 1040 m, 999 sh, 921 vvw, 858 s, 803 s, 776 vs, 691 vs, 653 m, 563 vvw and 479 w cm^{-1}.

Identical products (yields *ca* 35% based on the starting europium diacetate chloride complex) were obtained when the reaction was carried out with a 1:1 mole ratio of RCOOH to europium. Reactions with ratios higher than 2:1 resulted again in the same products, but these were contaminated by variable amounts of unreacted acids.

NMR spectra

Experiments were carried out with a GE QE-300 spectrometer at ambient temperature, using high-precision Pyrex 5 mm o.d. NMR tubes (Wilmad). Spectra in $CDCl_3$ and CD_3OD were referenced either to TMS or to the residual protonated solvent resonance. Spectra in D_2O were referenced to the HOD resonance, which was not shifted in the presence of the europium(III) complex. (The DSS resonance usually employed in aqueous solution was unsuitable because it is shifted in the presence of $[Eu(CH_3COO)_2L]Cl \cdot 4H_2O$.)

The following general procedure was used in the study of the {EuL}–substrate interaction. The proton spectrum of a 3.0×10^{-2} M solution of substrate in the chosen solvent was recorded. An equivalent molar amount of solid europium reagent was added to the substrate solution, and the spectrum was recorded again. When multiple substrate:europium ratios were studied, further equivalent molar aliquots of (solid or liquid) substrate were added stepwise, and the spectrum was recorded after each addition.

Absorption, emission and excitation spectra; excited state lifetimes

Absorption spectra of the $[Eu(RCOO)_2L]Cl \cdot nH_2O$ complexes (R = $—C_6H_5$, $—C_4H_3O$, $—C_4H_3S$, $—C_4H_3NH$, $—C_5H_4N$) in methanol or ethanol (1.0×10^{-4} M) were obtained with Shimadzu 265 UV–vis and Perkin–Elmer 6 spectrophotometers. The spectra were nearly identical to one another and consisted of two broad absorptions centred at *ca* 250 ($\varepsilon = 3.9–4.0 \times 10^4$) and 300 nm ($\varepsilon = 1.6–1.8 \times 10^4$), the latter with a shoulder at 310–320 nm. An SLM 8000 and a Perkin–Elmer L 50 spectrofluorimeter were used for excitation and emission spectra of the complexes in ethanol or methanol at various concentrations (10^{-4}–10^{-5} M). The excitation spectra, for $\lambda_{em} = 614$ nm, were very similar for all complexes and matched the absorption spectra, except for a lower relative intensity of the high energy band. The emission spectra were all identical in regard to pattern and energies, but differed greatly in intensity; under identical experimental conditions, the relative intensities varied with R approximately as follows: $—CH_3$, 1; $—C_4H_3NH$, 1; $—C_6H_5$, 1; $—C_4H_3O$, 7; $—C_5H_4N$, 8; $—C_4H_3S$, 12.

Luminescence "titrations" of $[Eu(CH_3COO)_2L]Cl \cdot 4H_2O$ with the RCOOH acids (R = $—C_6H_5$, $—C_4H_3O$, $—C_4H_3S$, $—C_4H_3NH$, $—C_5H_4N$) consisted of measuring the emission intensities of methanol or ethanol solutions containing the same concentration (2.0×10^{-4} M) of $[Eu(CH_3COO)_2L]Cl \cdot 4H_2O$ and increasing RCOOH:Eu mole ratios (0.5, 1.0, 1.5, 2.0, 2.5 and 10). For R = $—C_4H_3S$, $—C_4H_3O$ and $—C_5H_4N$, the emission intensity gradually increased with the RCOOH:{EuL} ratio and reached a maximum for ratios slightly exceeding 2:1. No enhancement was observed for R = $—C_4H_3NH$ or $—C_6H_5$. Excited-state lifetimes, obtained with a Perkin–Elmer L 50 spectrofluorimeter for freshly prepared ethanol solutions (1.0×10^{-4} M) of the $[Eu(RCOO)_2L]Cl \cdot nH_2O$

complexes, were single exponentials in the 1–2 ms range ($\tau = 1.7$ and 1.4 ms for R = —C_4H_3S and —CH_3, respectively).

IR spectra

Spectra of the solid complexes were obtained on a Perkin–Elmer Model 1600 Fourier-transform instrument. Samples were examined both as KBr pellets and as mulls in hexachlorobutadiene (4000–1800 and 1500–1300 cm^{-1}, supported on NaCl disks) and Nujol (1800–1500 and 1300–400 cm^{-1}, supported on KBr disks). No difference was observed between the spectra obtained in KBr pellets and those in mulls.

X-ray measurements and structure determination

The crystal and refinement data of $[Eu(CH_3COO)_2L](CH_3COO)\cdot 9H_2O$ (pale yellow, almost spherical irregular prisms) are summarized in Table 1. A crystal of dimensions $0.50 \times 0.54 \times 0.42$ mm was lodged in a Lindemann glass capillary and centred on a four-circle Phillips PW 1100 diffractometer with graphite-monochromated Mo-K_α radiation. The orientation matrix and preliminary unit cell dimensions were determined from 25 reflections obtained by mounting the crystal at random and varying each of the orientation angles χ and ϕ over the range 120°, with $5° \leqslant \theta \leqslant 7°$. For the determination of the precise lattice parameters, 25 strong reflections with $10° \leqslant \theta \leqslant 13°$ were considered. Integrated intensities for *hkl* reflections with $h = \pm 14$, $k = \pm 20$ and $l = 16$ were measured, and three standard reflections, 2,1,2, −4,3,1 and −7,−1,3 were monitored every 180 min. There were no significant fluctuations of intensities other than those expected from Poisson statistics.

The intensity data were corrected for Lorentz–polarization effects and for absorption, following the method of North *et al.*;[13] no correction was made for extinction. The structure was solved by three-dimensional Patterson and Fourier techniques and was refined with anisotropic thermal parameters assigned to all non-hydrogen atoms. The hydrogen atoms of the methyl groups (macrocycle and acetates) were introduced at calculated

positions and allowed to ride on associated carbon atoms during the least-squares refinement [d(C—H) = 0.98 Å and U = 0.08 Å^2]. Other carbon-attached hydrogen atoms were introduced at the positions observed in the final difference-Fourier map. The hydrogen atoms of the water molecules were disordered and were not introduced. The function minimized was $\Sigma w\Delta^2$ with $\Delta = (|F_o| - |F_c|)$. The anomalous dispersion terms[14] for europium were taken into account in the refinement which reached convergency at $R = 0.026$. Atomic scattering factors were taken from ref. 15. Data processing and computation were carried out with the SHELX 76 program package;[15] PLUTO[16] and ORTEP[17] were used for drawing. Atomic fractional coordinates and thermal parameters, fractional hydrogen coordinates and observed as well as calculated structure factors (× 10) are available as supplementary material (Tables A–C).

RESULTS AND DISCUSSION

Effect of $[Eu(CH_3COO)_2L]Cl \cdot 4H_2O$ *on the proton NMR spectra of potential* O-*donor compounds*

The interaction between the $[Eu(CH_3COO)_2L]Cl \cdot 4H_2O$ complex and a representative series of potential O-donor substrates, including both uncharged and negatively charged species, was investigated in solution by proton NMR spectroscopy. In each case spectra were recorded for the organic substrate alone as well as for mixtures of the substrate and the {EuL} diacetate chloride complex.

(a) *Alcohols, phenols and ketones.* A first group of substrates included acetone, methanol, 1-butanol, 2-butanol and 2-methyl-2-butanol; the three butanols provided examples of increasing steric hindrance near the potential europium-binding site of the substrate. The ^1H NMR spectra, recorded both in D_2O and $CDCl_3$, did not reveal significant shifts or loss of resolution for any of the substrate resonances at a 1 : 1 mole ratio of substrate to {EuL} complex, indicating no interaction of these uncharged substrates with the paramagnetic europium centre. Results are available as supplementary material (Table D). A similar conclusion had been previously reached for uncharged N-donor substrates.[18] Since even in chloroform solution the acetate ligands of $[Eu(CH_3COO)_2L]Cl \cdot 4H_2O$ are partly ionized,[19] leaving the europium centre accessible to other ligands, the failure of uncharged organic substrates to bind to europium must result chiefly from the preferred coordination of the H_2O molecules present in the original complex.

Slightly different results were obtained with phenol and catechol. Although the changes in the chemical shifts observed for 1 : 1 mixtures of the substrate and the {EuL} complex were minor, significant broadening of the resonances did occur even in D_2O solution. Figure 2 illustrates the situation for catechol: the resonance of the protons at the 2 and 5 positions, which are closer to the O-donor atoms, is considerably more broadened than that of the protons at positions 3 and 4. These results show that phenols, which are somewhat more acidic than alcohols, interact to a small extent with the paramagnetic europium(III) centre even in a strongly coordinating solvent.

(b) *Carboxylates.* The interaction of $[Eu(CH_3COO)_2L]Cl \cdot 4H_2O$ with a series of sodium carboxylates (formate, acetate, propanoate, butanoate, benzoate and succinate) was investigated in D_2O. In each case significant downfield shifts of the substrate resonances were observed, and the proton(s) closest to the carboxylate group underwent the greatest shift. The magnitude of the shifts increased with increasing europium content of the mixture; additionally, loss of multiplicity invariably occurred. Spectral data are reported in Table 2. These results show that a substitution equilibrium is established between the carboxylate substrate and the acetate ligands of the original complex; this equilibrium must be rapid on the NMR time-scale since separate sets of resonances for bound and unbound species were never observed for either the substrates or the acetates.

The resonance of the formate proton, unlike those of all other carboxylates examined in this work, was shifted upfield in the presence of $[Eu(CH_3COO)_2L]Cl \cdot 4H_2O$. This anomalous behaviour suggests that the formate proton, being only three bonds away from the metal centre, may experience a predominantly contact shift; an upfield shift of the formate proton resonance would indeed be expected if the contact shift for formate were to approximate the value calculated for the acetate protons of $[Eu(CH_3COO)_2L]Cl \cdot 4H_2O$.[20]

Comparison of $Eu(NO_3)_3$ *and* $[Eu(CH_3COO)_2L]Cl \cdot 4H_2O$ *as aqueous shift reagents*

Simple salts of europium(III), such as $Eu(NO_3)_3$, $EuBr_3$ and $EuCl_3$, are known to act as upfield NMR shift reagents in aqueous solution.[1] The results reported in the preceding sections are therefore somewhat unexpected in that all anionic substrates studied, except formate, shifted downfield in the presence of $[Eu(CH_3COO)_2L]Cl \cdot 4H_2O$. To provide a direct comparison, the proton NMR spectra of sodium butanoate and sodium succinate were recorded in D_2O in the presence of equimolar

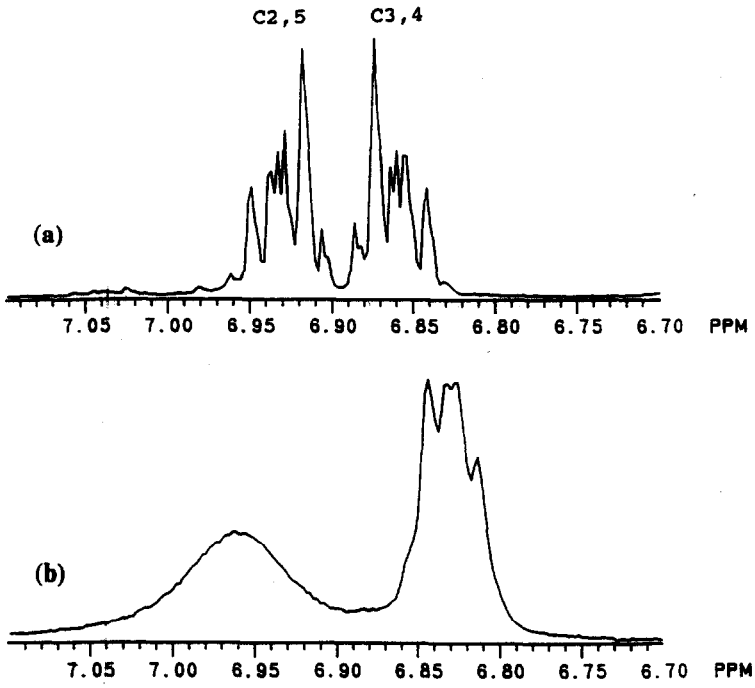

Fig. 2. Proton NMR spectra of: (a) catechol alone and (b) a 1:1 mixture of catechol and $[Eu(CH_3COO)_2L]Cl \cdot 4H_2O$.

amounts of $Eu(NO_3)_3$. As expected, all shifts were in an upfield direction; also, their magnitude was much smaller than for $[Eu(CH_3COO)_2L]Cl \cdot 4H_2O$: for succinate, the shift was −0.93 ppm (upfield) for $Eu(NO_3)_3$, and +7.42 ppm (downfield) for $[Eu(CH_3COO)_2L]Cl \cdot 4H_2O$. The data are presented in Table 3.

The downfield direction of the shifts induced by $[Eu(CH_3COO)_2L]Cl \cdot 4H_2O$ may in itself be a distinct advantage, since the upfield shifts caused by simple europium(III) salts tend to move normally low-field resonances closer to the aliphatic resonances, which are more likely to remain unshifted by a paramagnetic reagent.

An intrinsic limitation in the use of $[Eu(CH_3COO)_2L]Cl \cdot 4H_2O$ as an NMR shift reagent is that at least three of its four resonances occur between 0 and 10 ppm, where they may overlap with resonances of the substrate. This limitation, however, is not serious; the resonances of the europium complex are easily identified because their positions remain very nearly constant in any

given solvent and because the characteristic multiplicities of the pyridine resonances generally are retained. Synthesis of a predeuterated version of the macrocyclic species would of course eliminate this problem.

Effect of aromatic and heteroaromatic carboxylic acids on the luminescence of $[Eu(CH_3COO)_2L]Cl \cdot 4H_2O$

The absorption and luminescence spectra of $[Eu(CH_3COO)_2L]Cl \cdot 4H_2O$ have been previously investigated in detail.[20] Low-lying metal–ligand charge-transfer states were shown to be absent and the broad, intense absorptions in the near-UV region were ascribed to electronic transitions of the macrocyclic ligand. Excitation into the $^5D_6$ level of europium(III) at 394 nm resulted in efficient emission for the $^5D_0 \rightarrow {}^7F_2$ europium(III) line ($\Phi_{em} = ca\ 10^{-1}$), but excitation into the intra-ligand absorptions caused only faint luminescence ($\Phi_{em} = ca\ 10^{-3}$ for λ_{ex} = 300 nm).[21] It could be expected that the luminescence of the {EuL} moiety might be enhanced by axial coordination of organic ligands that are better chromophores than acetates in a region suitable for energy transfer to europium(III), and a variety of uncharged as well as anionic O-donor ligands were screened as potential enhancers.[8] Several heteroaromatic monocarboxylic acids showed promise.[21–24] Their effect on the luminescence of the {EuL} moiety was further investigated in the present work, both by performing luminescence "titrations" of the diacetate chloride with the free heteroaromatic acid, RCOOH, and by obtaining the emission/excitation spectra of the $[Eu(RCOO)_2L]Cl \cdot nH_2O$ complexes synthesized for this purpose (see the following section). Coincident results were obtained in the two sets of experiments.

No enhancement relative to the corresponding diacetate chloride occurs for the $[Eu(RCOO)_2L]Cl \cdot nH_2O$ complexes containing benzoate or 2-pyrrolecarboxylate, whereas complexes containing 2-thiophenecarboxylate, 2-pyridinecarboxylate or 2-furancarboxylate show an appreciable (7–12 fold) increase in emission intensity. This luminescence enhancement is not accompanied by any change in either the shape or the position of the emission bands (Fig. 3), indicating that the coordination sphere of the europium(III) emitter still has essentially the same symmetry as in the diacetate chloride complex. Furthermore, the absorption spectra are virtually identical for all the $[Eu(RCOO)_2L]Cl \cdot nH_2O$ complexes, regardless of their emission intensity, and closely resemble the corresponding spectra of the diacetate chloride analogue. The luminescence enhancement observed for R = —C_4H_3S, —C_4H_3O and —C_5H_4N may, therefore, be attributed chiefly to more effective protection of the excited europium(III) centre from vibrational deactivation by solvent molecules or other high-frequency oscillators. This conclusion is in agreement with the somewhat longer luminescence decay time of $[Eu(C_4H_3S—COO)_2L]Cl \cdot 2H_2O$ compared to the diacetate chloride analogue.

Synthesis and IR spectra of $[Eu(RCOO)_2L]Cl \cdot nH_2O$ *complexes*

To provide a better understanding of the luminescence enhancement of the {EuL} moiety in the presence of certain heteroaromatic carboxylates, new complexes were prepared by metathesis between $[Eu(CH_3COO)_2L]Cl \cdot 4H_2O$ and a series of aromatic and heteroaromatic monocarboxylic acids. Independent of the complex-to-carboxylic acids ratio employed, the products had the general formula $EuL(RCOO)_2Cl \cdot nH_2O$, where R is —$C_6H_5$, —$C_4H_3O$, —$C_4H_3S$, —$C_4H_3NH$ or —C_5H_4N. These complexes are colourless crystalline solids, soluble in water and polar organic solvents; their IR spectra show absorptions characteristics of the macrocyclic ligand[9] as well as those arising from the respective carboxylates. Single crystals suitable for X-ray analysis were not obtained for any of these compounds; however, the values of the symmetric and antisymmetric stretching frequencies of the —COO^- groups and their frequency separation, Δ (Table 4), provide a reliable

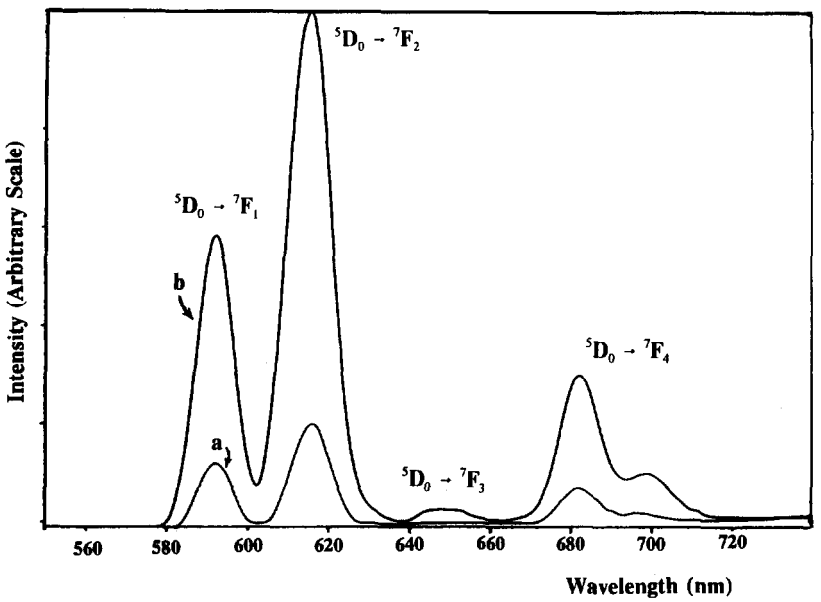

Fig. 3. Emission spectra of 1.0×10^{-4} M methanol solutions of: (a) $[Eu(CH_3COO)_2L]Cl \cdot 4H_2O$ and (b) $[Eu(C_4H_3SCOO)_2L]Cl \cdot 2H_2O$ (both for $\lambda_{ex} = 320$ nm).

basis for structural assignments. A Δ value smaller than that of the sodium salt is indicative of bidentate chelating coordination, whereas a greater Δ value is considered diagnostic of monodentate coordination; bidentate bridging carboxylates exhibit a Δ value close to that of the free ion.[25]

The —COO^- absorptions summarized in Table 4 show that in the solid complexes both $RCOO^-$ groups are coordinated to the europium(III) centre; the coordination formula is almost certainly $[Eu(RCOO)_2L]Cl \cdot nH_2O$, as in the corresponding diacetate chloride[4] and in the triacetate, the X-ray analysis of which is discussed in a following section. The Δ values (cm^{-1}) further suggest that in the complexes containing benzoate, 2-furancarboxylate, 2-pyrrolecarboxylate or 2-thiophenecarboxylate the —COO^- groups act as bidentate chelating ligands. However, the decrease in Δ relative to the sodium salt (−15 for benzoate, −10 for 2-thiophenecarboxylate, −10 for 2-pyrrolecarboxylate and −49 for 2-furancarboxylate) is in each case much smaller than for the diacetate and triacetate complexes (−79 and −73, respectively) and suggests a higher ionic character of the metal–carboxylate bond. The presence of bridging carboxylates, sometimes observed in complexes of these anions,[26,27] may be ruled out for the $EuL(RCOO)_2Cl \cdot nH_2O$ species in view of their solubility in organic solvents and by analogy with the corresponding diacetate chloride and triacetate complexes. The bidentate chelation of the carboxylate group further leads to the conclusion that in these complexes the ring heteroatom cannot be coordinated to the europium (III) centre, since the "bite" of the ligands is not

sufficient to permit tridentate chelation. Non-coordination of the ring heteroatom has also been observed in other complexes of these five-membered heteroaromatic carboxylates for which crystal structures are known.[24,28–30]

The spectrum of the 2-pyridinecarboxylate complex indicates instead monodentate coordination of the —COO group, since its Δ value is somewhat greater than in the sodium salt. Again, the difference is quite small (+10), showing that the metal–carboxylate bond has a highly ionic character. It is reasonable to conclude that the ligand nitrogen heteroatom must also be coordinated, forming a relatively unstrained five-membered chelate ring with europium(III). This mode of binding is common for mononuclear 2-pyridinecarboxylate complexes.[13,31–34]

Proton NMR spectra of $[Eu(RCOO)_2L]Cl \cdot nH_2O$ *complexes*

The spectra of the $[Eu(RCOO)_2L]Cl \cdot nH_2O$ complexes in CD_3OD are reported in Table 5. All resonances are broadened and considerably shifted downfield relative to those of the free acids, showing that in this solvent coordination of the carboxylates to europium(III) is largely maintained. To further investigate these systems, spectra were also determined for mixtures of $[Eu(CH_3COO)_2L]Cl \cdot 4H_2O$ and the free acids, at 1 : 1, 1 : 2 and 1 : 3 mole ratios. The solvent used was again CD_3OD, both for solubility reasons and to allow direct comparison with the luminescence studies. All resonances of the carboxylic acids were broadened and shifted downfield by addition of the {EuL} diacetate chloride complex. The magnitude of shifts for 1 : 2 and 1 : 3 mixtures (Table 5) were generally comparable to those of the $[Eu(RCOO)_2L]Cl \cdot nH_2O$ complexes themselves, indicating that under these conditions the $RCOO^-$ anions largely replace the acetates within the coordination sphere of the complex. The shifts observed for these carboxylic acid–$[Eu(CH_3COO)_2L]Cl \cdot 4H_2O$ mixtures are, however, smaller than those observed for the sodium carboxylate mixtures discussed in a preceding section. For example, the resonance of the C(2) proton of benzoic acid (in CD_3OD) moved only by 1.86 ppm, whereas that of sodium benzoate (in D_2O) moved by 3.36 ppm. This difference must reflect the combination of ligand substitution and acid–base equilibria present in solution; although benzoic acid ($pK_a = 4.2$)[35] is slightly stronger than acetic acid

($pK_a = 4.7$), the benzoic acid–acetate equilibrium does not result in a concentration of benzoate ion equivalent to that present in sodium benzoate at the same molarity.

Crystal structure of $[Eu(CH_3COO)_2L](CH_3COO) \cdot 9H_2O$

The complex was prepared to provide information concerning the maximum number of carboxylates that can coordinate to the {EuL} moiety. The compound is ionic; the complex cation consists of 10-coordinate europium(III) linked to the six N-donor atoms of the macrocyclic ligand and to two bidentate chelating acetates situated on opposite sides of the macrocycle. A non-coordinated acetate balances the ionic charge of the complex cation. Clathrated water molecules (nine per complex unit) form an extensive network of hydrogen bonds that runs in channels through the crystal and includes the oxygen atoms of the coordinated and ionic acetates. An ORTEP view of the cation and anion is shown in Fig. 4. The crystal packing, including water molecules, is illustrated in Fig. 5. Selected bond lengths and angles are listed in Table 6; torsion angles are listed in Table 7.

A comparison between the complex cation present in this triacetate complex and the formally identical cation present in the diacetate chloride species $[Eu(CH_3COO)_2L]Cl \cdot 4H_2O$[4] reveals qualitative similarities as well as quantitative differences. In both compounds the macrocycle has the "folded butterfly" conformation common to other complexes of this ligand and consists of two approximately planar sections that include the pyridine rings and are hinged at the $—CH_2—CH_2—$ side-chains. The folding of the macrocycle, however, is considerably more pronounced in the triacetate complex; the angle between the two planar sections being 122.50(7)° vs 132.37(6)° in the diacetate chloride. Also, the torsion angles of the two $—CH_2—CH_2—$ side-chains of the triacetate, although fairly close to one another [N(5)—C(19)—C(20)—N(6) = 51.7(5)° and N(2)—C(8)—C(9)—N(3) = 50.9(5)°], differ significantly from the corresponding angles [55.4(4)° and 56.6(5)°] of the diacetate chloride. In both compounds the two acetates are staggered; the angle between the two O—C—O planes is 79.2(2)° in the triacetate and 94.8(2)° in the diacetate chloride.

In both compounds the acetate on the concave side of the macrocycle is oriented approximately along the fold line of the macrocycle and leans toward one of the two planar sections; in the triacetate the angle formed by the O—C—O plane with the plane of the N(2)N(1)N(6) macrocyclic section is 69.5(1)° and that formed with the plane of the N(5)N(3)N(4) section is 125.5(2)°; in the diacetate chloride the corresponding angles are 55.1(2)° and 102.6(2)°, respectively. The two $Eu—O_{acetate}$ bond lengths on the concave side of the macrocycle [Eu—O(3) = 2.491(3) and Eu—O(4) = 2.519(3) Å] are more symmetrical, as well as

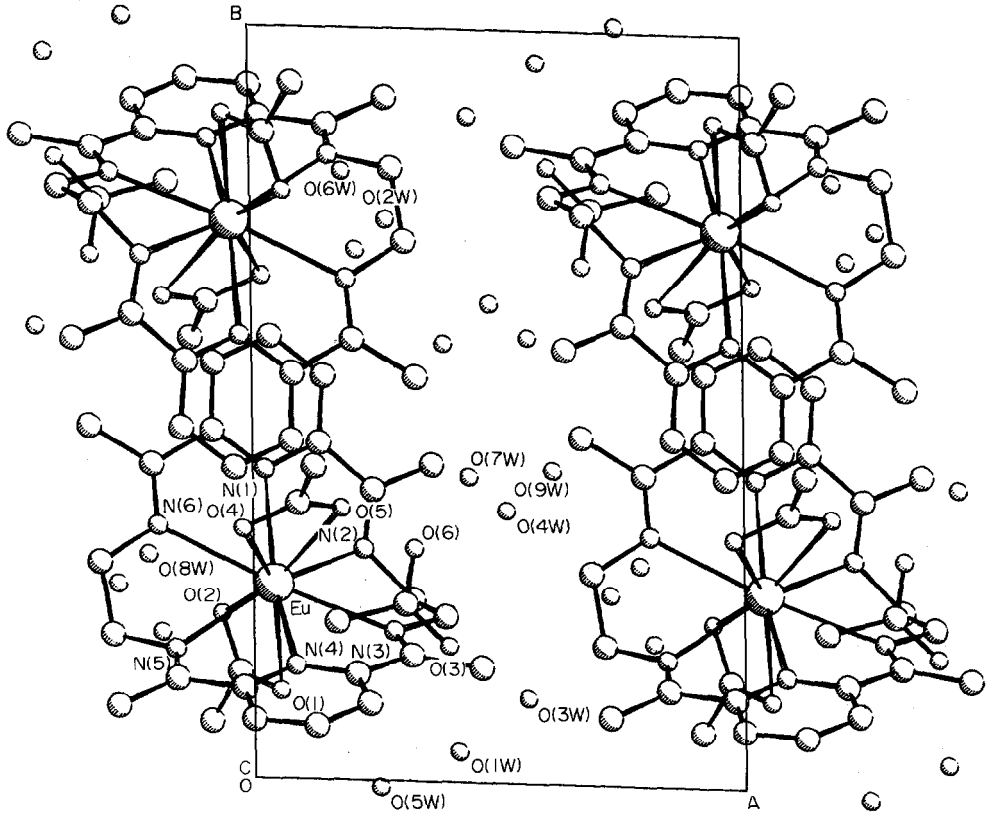

Fig. 5. Crystal packing of $[Eu(CH_3COO)_2L]CH_3COO \cdot 9H_2O$, including water molecules.

slightly longer than those on the convex side [Eu—O(1) = 2.495(3) Å and Eu—O(2) = 2.459(3) Å]. Conversely, the two shortest acetate–nitrogen separations on the concave side [O(3)—N(1) = 3.111(4) and O(4)—N(4) = 2.990(4) Å] are both appreciably shorter than the two shortest acetate–nitrogen separations on the convex side [O(2)—N(1) = 3.209(4) and O(6)—N(4) = 3.222(4) Å].

In the triacetate complex, the Eu—N bond lengths fall into three equal pairs, with values increasing in the order Eu—$N_{imine\text{-}2,5}$ = 2.570(2), Eu—$N_{pyridine}$ = 2.604(3) and Eu—$N_{imine\text{-}3,6}$ = 2.642(3) Å. The same order is found in the diacetate chloride, where, however, all distances are slightly longer: Eu—$N_{imine\text{-}2,5}$ = 2.607(3), Eu—$N_{pyridine}$ = 2.638(3) and Eu—$N_{imine\text{-}3,6}$ = 2.658(3) Å.

A ring-puckering analysis[36] for the six nitrogen system of the triacetate complex shows a slightly twisted conformation with puckering constants Q = 1.035(3), Θ = 90.6(1)° and Φ = 38.7(2)°, whereas the diacetate chloride has a twist-boat conformation with Q = 0.957(3), Θ = 91.6(2)° and Φ = 71.1(2)°. The conformational differences observed among various complexes of the L macrocycle have previously been attributed to changes in the metal size and in the number as well as steric requirements of the exocyclic ligands (anions and solvent molecules). The present work offers the opportunity to compare formally identical metal-macrocycle species in compounds that differ only in the (uncoordinated) counter-ion and in the extent of hydration. Any variations in bond lengths, angles and geometries observed for $[Eu(CH_3COO)_2L](CH_3COO) \cdot 9H_2O$ and $[Eu(CH_3COO)_2L]Cl \cdot 4H_2O$ must necessarily arise from factors outside the coordination sphere. In particular, the numerous water molecules of the triacetate appear to play an important role, for they are involved in hydrogen bonding not only among themselves but also with the oxygens of the coordinated and ionic acetates. These considerations show that the L macrocycle is extremely susceptible to conformational changes that may be induced—for the same metal centre—not only by the exocyclic ligands but also by interaction with species external to the coordination sphere.

CONCLUSIONS

The results of this work lead to several general conclusions. First, the interaction between the $[Eu(CH_3COO)_2L]Cl \cdot 4H_2O$ complex and the O-donor organic substrates—ketones, alcohols, phenols and carboxylic acids—is clearly charge-dependent. Among the substrates investigated, only those which are either anionic or sufficiently acidic to

produce an appreciable concentration of anions experience NMR shifts in the presence of the paramagnetic europium(III) complex; similarly, ligands that enhance the intrinsic luminescence of the {EuL} moiety are invariably anionic or acidic in character. This conclusion agrees with the results of a parallel study involving N-donor substrates;[19] of the uncharged substrates studied in that work, including some that are good chelating ligands for the free europium(III) ion (e.g. 1,10-phenanthroline and 2,2′-bipyridyl), none showed any sign of interaction with the europium(III) centre of $Eu(CH_3COO)_2L]Cl \cdot 4H_2O$. With anionic or potentially anionic substrates, the interaction undoubtedly involves an equilibrium substitution of the acetate ligands; aromatic and heteroaromatic

monocarboxylates actually yield fully substituted products of the formula $[Eu(RCOO)_2L]Cl \cdot nH_2O$. Crystallographic evidence for the triacetate complex $[Eu(CH_3COO)_2L](CH_3COO) \cdot 9H_2O$ suggests that in macrocyclic species of this type the europium(III) will bind at most four exocyclic donor atoms, even when additional suitable ligands are available.

A second general conclusion is that $[Eu(CH_3COO)_2L]Cl \cdot 4H_2O$ can function as an effective NMR shift reagent, both in water and in organic solvents, toward those O-donor substrates that are or can become anionic. The complex is especially promising as an aqueous shift reagent because it retains its identity and solubility over a wide pH range; in addition, it produces downfield shifts that are considerably larger than the upfield shifts induced by simple europium(III) salts.

Finally, this work has shown that replacement of the acetates of $[Eu(CH_3COO)_2L]Cl \cdot 4H_2O$ with certain other carboxylates can substantially enhance the luminescence of the {EuL} moiety. These counter-ions allow more efficient absorption of light via an "antenna effect" and also serve to reduce quenching by protic solvents. A search for even more effective enhancers is in progress.

Abstract—The synthesis and X-ray crystal structures of the acetamidinato complexes $[M\{PhN{\cdots}C(Me){\cdots}NPh\}_3]$ (M = Ru, Rh) and the triazenido complexes $[Rh(PhN{\cdots}N{\cdots}NPh)_3]$ and $[Rh_2(PhN{\cdots}N{\cdots}NPh)_4]$ are reported.

The "small bite" 1,3-diaryltriazenide anions $ArN{\cdots}N{\cdots}NAr^-$ and their 1,3-diarylamidinate analogues $ArN{\cdots}C(R){\cdots}NAr^-$ have recently attracted much attention as bridging ligands in binuclear "lantern" structures of the general form $[M_2(ArN{\cdots}X{\cdots}NAr)_4]$ (X = N or CR; R = H, alkyl or aryl).[1,2] Their ability to act as chelate ligands and thereby generate highly strained, four-membered chelate rings is also of considerable interest.[1] However, whereas homoleptic tris(1,3-diaryltriazenido) chelates $[M(ArN{\cdots}N{\cdots}NAr)_3]$ have been reported for a wide range of trivalent transition metal ions, notably chromium,[3] iron,[4] ruthenium,[5] osmium,[5] cobalt,[6,7] rhodium[5] and iridium,[5] the only examples of *d*-block tris (amidinato) complexes are provided by the rather air- and moisture-sensitive iron(III) species $[Fe\{PhN{\cdots}C(R){\cdots}NPh\}_3]$ (R = H, Me, Ph) of indeterminate structure.[8] We have now prepared the ruthenium(III) and rhodium(III) tris(acetamidinato) chelates $[M\{PhN{\cdots}C(Me){\cdots}NPh\}_3]$ and have determined the crystal structures of both compounds. For the purpose of comparison we have also determined the X-ray crystal structure of the analogous rhodium(III) tris(1,3-diphenyltriazenido) complex $[Rh(PhN{\cdots}N{\cdots}NPh)_3]$. Finally, we have established the crystal structure of the hitherto unknown rhodium(II) triazenido complex $[Rh_2(PhN{\cdots}N{\cdots}NPh)_4]$ using a single crystal isolated as a by-product during the synthesis of the corresponding rhodium(III) derivative.

1,3-Diphenylacetamidine, PhN=C(Me)—NHPh, reacts with $RuCl_3 \cdot 3H_2O$ and $RhCl_3 \cdot 3H_2O$ in boiling ethanol in the presence of base (NEt_3) to generate green (M = Ru) or red–brown (M = Rh) air-stable isostructural crystalline com-

plexes, $[M\{PhN\cdots C(Me)\cdots NPh\}_3]$, in *ca* 30% yield. The molecular and crystal structure of $[Ru\{PhN\cdots C(Me)\cdots NPh\}_3]$ (**1**) and $[Rh\{PhN\cdots C(Me)\cdots NPh\}_3]$ (**2**) are essentially identical* and are shown in Fig. 1 together with selected bond lengths and angles. In both structures small but apparently significant differences in Rh—N and, to a lesser degree, N—C bond lengths within each chelate ring suggest the presence of some asymmetry in the metal amidinate bonding.

The corresponding rhodium(III) triazenido complex $[Rh(PhN\cdots N\cdots NPh)_3]$ was prepared by adding 1,3-diphenyltriazene to a boiling ethanolic solution of $RhCl_3 \cdot 3H_2O$ in the presence of base (NEt_3) and was isolated as maroon crystals. The molecular structure of $[Rh(PhN\cdots N\cdots NPh)_3]$ (**3**) is shown in Fig. 2, together with selected bond length and angle data. The molecule has a crystallographic diad axis. The molecular dimensions [Rh—N_{av} 2.030(6) Å, <N—Rh—N_{av} 60.9(3)°] are very similar to those observed for the rhodium tris(acetamidinato) complex [Rh—N_{av} 2.046(7) Å <N—Rh—N_{av} 62.8(3)°]. The slightly smaller angles subtended at the rhodium by the triazenide ligands relative to the acetamidinate ligands may be an indirect consequence of the greater steric requirements of the lone pair on the central nitrogen atoms of the former.

An atypical dark red crystal selected from a sample of $[Rh(PhN\cdots N\cdots NPh)_3]$ was also subjected to X-ray structure determination and found to be $[Rh_2(PhN\cdots N\cdots NPh)_4]$, the first example of the long anticipated[9] but hitherto unknown class of rhodium(II) triazenido derivatives of the general form $[Rh_2(ArN\cdots N\cdots NAr)_4]$. The molecular structure of $[Rh_2(PhN\cdots N\cdots NPh)_4]$ (**4**) is shown in Fig. 3, together with selected bond lengths and angles. The Rh—Rh bond length [2.377(3) Å] is very similar to those found for the closely related rhodium(II) formamidinato, $[Rh_2\{ArN\cdots C(H)\cdots NAr\}_4]$ (Ar = *p*-tolyl),[10] and benzamidinato, $[Rh_2\{PhN\cdots C(Ph)\cdots NPh\}_4]$,[11] derivatives, where the Rh—Rh distances are 2.4336

and 2.389 Å, respectively. Rhodium–nitrogen bond lengths at 2.050 Å (average) are essentially the same in all three complexes.

Data collection

Unit cell dimensions and intensity data for compounds **1**, **2**, **3** and **4** were obtained at 295 K using an Enraf–Nonius area detector diffractometer and graphite monochromated Mo-K_α radiation, following previously described procedures ($D = 40$ mm, $2\theta = 18$).[12] The structures were solved by Patterson and Fourier techniques and refined by blocked full-matrix least-squares methods.[13] Hydrogen atoms were included in calculated positions with isotropic thermal parameters related to those of the parent atoms and refined in riding mode. All four sets of data were corrected for absorption using the DIFABS procedure,[14] adapted for FAST geometry by A. Karaulov, University of Cardiff (1991). Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Data Centre.

All calculations were made on a T800 transputer hosted by an IBM/AT personal computer.

(*Received* 13 *October* 1992; *accepted* 10 *November* 1992)

Abstract—The rate constants for the hydrolysis reactions of cyclic and linear condensed phosphate oligomers were determined as a function of pressure at 40°C in a 0.1 M HCl solution. The hydrolysis rates increased with the increase in pressure. The volumes of activation were determined from the linear relations between $\ln k$ vs P. The volumes of activation, which were negative and ranged from -3.8 to -5.7 cm^3 mol^{-1}, were obtained. The mechanism of these hydrolysis reactions is discussed.

Condensed phosphates have been known as important polyvalent inorganic electrolytes and have been used for various purposes.[1] They have been prepared by dehydrating monophosphates, and two of them, one with an open chain and the other with cyclic structure, are well known. When treating these condensed phosphates in the aqueous state, much attention should be given to the hydrolysis reaction. The hydrolysis reactions of condensed phosphate oligomers have been investigated from different points of view and reaction mechanisms have been extensively discussed.[2–8]

In this study the pressure dependence of the hydrolysis rate constants of the cyclic hexamer and octamer and the corresponding linear hexamer and octamer were determined, and the volumes of activation for the hydrolysis reactions were estimated. The hydrolysis rates for the above four phosphates increased with the increase in pressure of the reaction cell. All the volumes of activation determined were negative and thus the molecular volumes of the activated complexes decreased.

Sodium cyclo-hexa- and cyclo-octaphosphate were prepared following the methods described in the literature.[9,10] Other chemicals used were reagent grade and commercially available.

The initial concentration of the phosphate to be degraded was 2.5×10^{-3} M in 0.1 M HCl. The temperature of the reacting solution was maintained at 40°C in a high pressure cell. The sample cell used was part of an injector and the dimensions were 10 mm in diameter and 70 mm in length, as shown in Fig. 1. The high-pressure vessel shown in

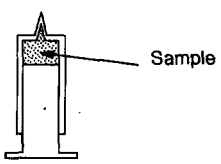

Fig. 1. Sample cell.

* Author to whom correspondence should be addressed.

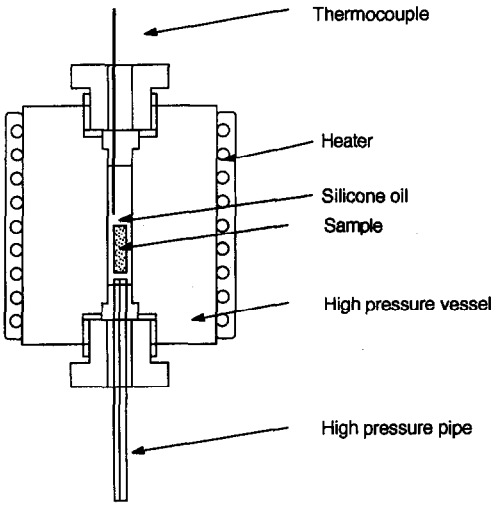

Fig. 2. High pressure vessel.

Fig. 2 was connected to a high-pressure generating pump. Silicone oil was used as a pressure-transmitting medium and the pressure was measured with a Heise gauge attached to a calibrated manganin wire: the accuracy of the pressure measured was ± 0.5 MPa. The temperature of the reaction cell was measured with an alumel–chromel thermocouple inserted in the silicone oil near the cell.

The hydrolysis samples were analysed using the chromatographic system described in our previous paper.[6]

The hydrolytic degradations of cyclic and linear condensed phosphates (abbreviated as P_{nm} and P_n, respectively; in both cases, n indicates the polymerization degree) are characterized by the following equation:

$$P_{nm} \xrightarrow{k_m} P_n \xrightarrow{k_n} P_{n-1}, P_{n-2}, \ldots, P_1, P_{3m},$$

where k_m and k_n are the first-order rate constant of cyclic and linear phosphates, respectively. At first, the cyclic oligomers are hydrolysed to linear oligomers with the same polymerization degree, and then to lower linear phosphates. The hydrolysis rate has been known to be first-order and, therefore, the rate equations can be written as:

$$-\frac{dx}{dt} = k_m x \quad (1)$$

$$-\frac{dy}{dt} = k_n y - k_m x \quad (2)$$

where x and y are the concentrations of cyclic and linear phosphates at time t. These differential equations are solved by assuming that the initial values of x and y are x_0 and y_0, respectively.

$$x = x_0 \exp(-k_m t) \quad (3)$$

$$y = \frac{k_m x_0}{(k_n - k_m)} \exp(-k_m t) + \left\{ y_0 - \frac{k_m x_0}{(k_n - k_m)} \right\} \exp(-k_n t) \quad (4)$$

Equation (3) can be rewritten as:

$$\log \frac{x}{x_0} = -\frac{k_m t}{2.303}. \quad (5)$$

Hydrolysis samples were analysed by the liquid chromatographic system devised by us, and thus, from the chromatograms obtained, x and y were determined as a function of time t. For the hydrolysis of cyclo-hexa- and cyclo-octaphosphate in a 0.1 M HCl solution at 40°C and at various pressures, $\log(x/x_0)$ vs t plots are shown in Figs 3 and 4. Good linear relations were obtained and the first-order rate constants were calculated from the slopes of the straight lines for each pressure. The hydrolysis rates of both cyclic phosphates increased with an increase in pressure. From the chromatograms of the hydrolysis samples of cyclic phosphates, the concentration of linear phosphates with the same polymerization degree as the cyclic phosphates, y, was also determined. Finally, using equation (4), the first-order rate constant k_n was estimated by the least-squares procedure. As an example, for the hydrolysis of hexaphosphate in a 0.1 M HCl solution at 40°C and at 400 MPa, the value of y was

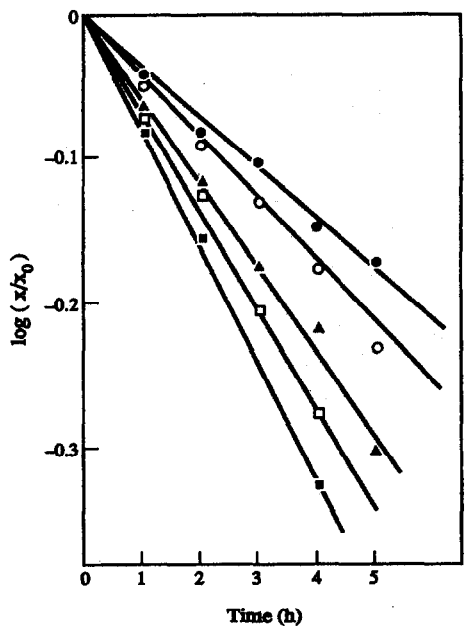

Fig. 3. First-order rate data for cyclo-hexaphosphate hydrolysis in 0.1 M HCl at 40°C and at various pressures: ●, 100 MPa; ○, 200 MPa; ▲, 300 MPa; □, 400 MPa; ■, 500 MPa.

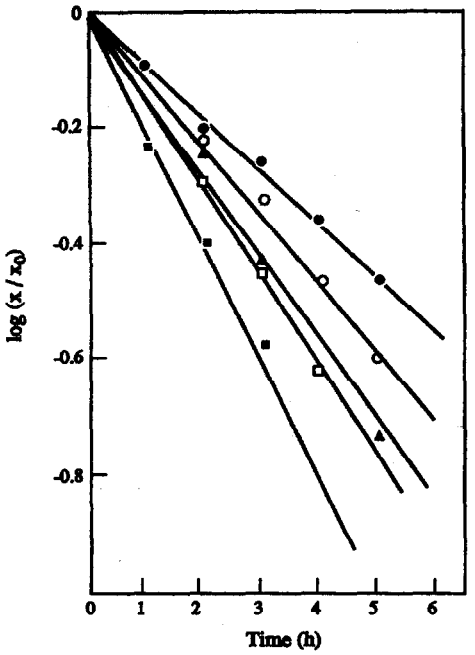

Fig. 4. First-order rate data for cyclo-octaphosphate hydrolysis in 0.1 M HCl at 40°C and at various pressures: ●, 100 MPa; ○, 200 MPa; ▲, 300 MPa; □, 400 MPa; ■, 500 MPa.

plotted as a function of time. The solid line in this figure indicates the value of y calculated by substituting k_m and k_n in equation (4), and the black circles are experimental points. Table 1 presents the rate constants of each phosphate thus obtained.

Table 1. Rate constants (h^{-1}) at various pressures and volumes of activation in 0.1 M HCl at 40°C

Pressure (MPa)	P_{6m}	P_6	P_{8m}	P_8
0.1	0.061	0.348	0.150	0.624
100	0.081	0.574	0.210	1.30
200	0.098	0.639	0.266	1.74
300	0.134	0.750	0.316	1.60
400	0.156	0.878	0.351	1.50
500	0.184	0.970	0.457	1.68
$\Delta V^{\ddagger}$ ($cm^3\ mol^{-1}$)	−5.67	−3.81	−5.35	−3.87

As mentioned above, the rate constants of each phosphate increased with an increase in pressure. According to the transition-state theory, if the volume of activation is defined as $\Delta V^{\ddagger}$, the rate constant can be related to pressure by the following equation:

$$\frac{d(\ln k)}{dP} = -\frac{\Delta V^{\ddagger}}{RT}. \quad (6)$$

If $\Delta V^{\ddagger}$ does not depend on pressure, equation (6) can be integrated to give:

$$\ln k = \ln k_0 - \frac{\Delta V^{\ddagger}}{RT} P, \quad (7)$$

where k_0 is the rate constant at pressure 0 and can be regarded as the value at atmospheric pressure (0.1 MPa). In Fig. 6, for cyclo-hexaphosphate hydrolysis, the pressure dependence of $\log k$ is shown and a linear model is adequate to describe the data. From the slopes of the straight lines the

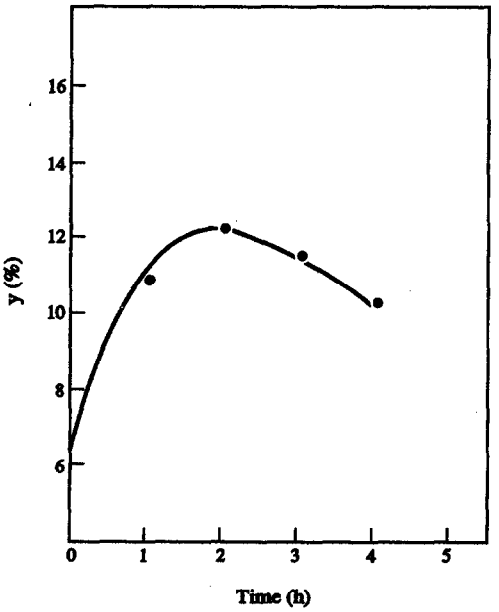

Fig. 5. First-order rate data for linear hexaphosphate hydrolysis in 0.1 M HCl at 40°C and 400 MPa.

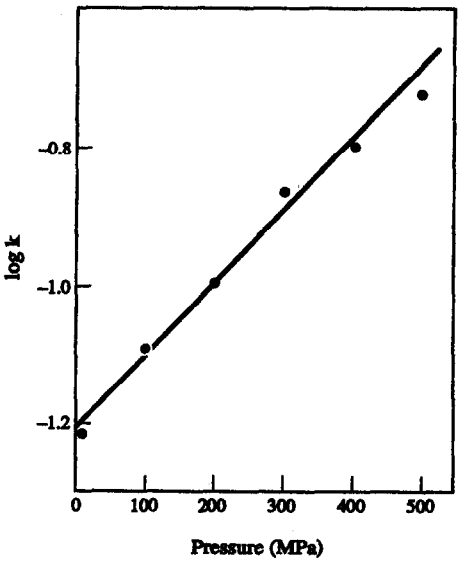

Fig. 6. Pressure dependence of the rate constant of cyclo-hexaphosphate in 0.1 M HCl at 40°C.

volumes of activation, the various $\Delta V^{\ddagger}$, were determined and are shown in Table 1. For all phosphates $\Delta V^{\ddagger}$, represented by the difference in molar volume between the transition state and the reactants of the condensed phosphates in acidic solutions, are regarded to proceed via nucleophilic attack on phosphorus atoms by H_2O molecules. Although the H_2O molecule bonds to the phosphate in the transition state, the molar volume of the activated complex is decreased. One of the hydrating water molecules which are loosely bound to the phosphate becomes more tightly bonded to the phosphorus atom in the activated complex and this association processes the rate determining step, thus causing the decrease in the molar volume. In our previous papers,[2,3] we pointed out that hydrogen ions strongly accelerate the hydrolysis rates of condensed phosphates. Although a pressure dependence for the degree of bonding of H^+ with the phosphate anions cannot be estimated, it has generally been known that many acids dissociate with an increase in pressure.[11] If this were so, the pressure increase should cause a decrease in the protonation of phosphate anions and thus a decrease in the hydrolysis rate. However, the changes in activation volumes are more effective and the rates actually increased. Negative volumes of activation have been observed for the hydrolysis reactions of various esters, which may be bimolecular reactions similar to the scission of P—O—P bonds in the phosphates, caused by the reaction between water molecules and phosphates.

1. INTRODUCTION

In our previous analysis of metal-centred oxygen atom (oxo) transfer reactions[1] the three most common reaction types, eqs (1)–(3), were identified, in which X/XO is a generalized oxygen atom acceptor/donor. In the *primary* oxo transfer reaction, eq. (1), the metal oxidation state is altered by two units. In the *incomplete* intermetal oxo transfer reaction, eq. (2), a binuclear μ-oxo species is formed and the oxidation state of the metal is increased by one unit. In the *complete* intermetal oxo transfer reaction, eq. (3a), metal centres act as the oxo donor and acceptor, an intermediate μ-oxo species is formed and the oxidation state changes are the same as in reaction (1). Much less frequently encountered is the complete intermetal oxo transfer reaction, eq. (3b), in which metal oxidation states are altered by one unit and products have the same number of oxo atoms. Reactions (2)–(3b) are obviously specific cases of reaction (1), in which metal complexes function as X/XO. For this set of reactions, ligand numbers n are not necessarily the same in reactant and product, $a = 0$–3, and products X and XO may be coordinated in the forward and reverse, respectively, of reaction (1). These processes are readily extended to two different metals in reactions (2)–(3b) and to higher

nuclearities in all reactions. This report deals with *thermodynamic* aspects of oxo transfer; reaction kinetics, some data for which have been summarized,[1] are not considered.

$$M^zO_aL_n + XO \rightleftharpoons M^{z+2}O_{a+1}L_n + X \quad (1)$$

$$M^zO_aL_n + M^{z+2}O_{a+1}L_n \rightleftharpoons [L_nM^{z+1}O_a]_2O \quad (2)$$

$$M^zO_aL_n + M^{z+2}O_{a+1}L'_n \rightleftharpoons M^{z+2}O_{a+1}L_n + M^zO_aL'_n \quad (3a)$$

$$M^zO_aL_n + M^{z+2}O_{a+2}L'_n \rightleftharpoons M^{z+1}O_{a+1}L_n + M^{z+1}O_{a+1}L'_n \quad (3b)$$

In order to provide a predictive basis for the outcome of primary oxo transfer reactions, we have introduced a simple reactivity scale that reduces substrate reactions to a common thermodynamic basis.[1-3] Consider generalized reactions (4) and (5), whose enthalpy changes are the differences in the standard molar heats of formation ($\Delta_fH^0_m$) of product and reactant. If $|T\Delta S| \ll |\Delta H|$ and $\Delta H_{X/XO} > \Delta H_{Y/YO}$, reaction (6) is spontaneous. With the use of reaction (7) the bond dissociation energies, D, in reaction (8) can be calculated for an oxidized molecule such as $XO_{(g)}$.

$$X + \tfrac{1}{2}O_{2(g)} \longrightarrow XO \qquad \Delta H_{X/XO} \quad (4)$$

$$Y + \tfrac{1}{2}O_{2(g)} \longrightarrow YO \qquad \Delta H_{Y/YO} \quad (5)$$

$$XO + Y \rightleftharpoons X + YO \qquad \Delta H = \Delta H_{Y/YO} - \Delta H_{X/XO} \quad (6)$$

$$\tfrac{1}{2}O_{2(g)} \longrightarrow O_{(g)} \qquad \Delta_fH^0_m = 59.55 \text{ kcal mol}^{-1}\ ^{15} \quad (7)$$

$$XO_{(g)} \longrightarrow X_{(g)} + O_{(g)} \qquad D = -\Delta H_{X/XO} + \Delta_fH^0_m(O_{(g)}) \quad (8)$$

A series of reactions, or *couples*, such as eqs (4) and (5), when compiled in a descending order of decreasing ΔH, has a utility analogous to that of a table of standard reduction potentials: the reduced member Y of a couple Y/YO with a smaller (more negative) ΔH is thermodynamically competent to reduce the oxidized member XO of a couple X/XO with a larger ΔH. With a sufficient body of data such a compilation would allow prediction of the directions of a large number of oxo transfer reactions and, in a number of gas phase cases, the differences in X—O and Y—O bond energies. Provided the structural differences between X and fragment X in XO and Y and fragment Y in YO are small, ΔH of reaction (6) is a measure of $D_{X-O} - D_{Y-O}$.

Our initial compilation, which was relatively short, was limited to enthalpies of oxidation couples that consisted mainly of the more common oxo donors and acceptors in the solution and gas phases.[1] Since that time new $\Delta_fH^0_m$ and $\Delta_fG^0_m$ data have become available, uncertainties in several previously quoted data have been clarified and examples of the utilization of the reactivity scale in our own work[2-7] and that of others[8-10] have appeared. Indeed, Tolman and co-workers[8,9] have independently obtained a scale of heats of oxidation which they have employed in considerations of alkane oxidation. In view of the importance of and current interest in atom transfer reactions we have sought to formulate a more extensive reactivity scale. Towards that end we have examined the extensive $\Delta_fH^0_m$ and $\Delta_fG^0_m$ data bases.[11-19] Additionally, recent measurements of standard molar heats of combustion and sublimation have permitted calculation of new or more accurate gas phase $\Delta_fH^0_m$ values and X—O bond dissociation energies. Useful examples include a series of N-oxides[20-25] and Ph_3AsO.[26]

2. THERMODYNAMIC REACTION COUPLES

Enthalpies and free energies (where available) for an extensive series of reaction couples are presented in Tables 1–4. Several aspects of these compilations are briefly noted. In order that they contain a considerable quantity of useful information but be limited in size compounds X and XO are restricted to the same pure phase in each of Tables 1–3; aqueous solution data are given in Table 4. The large majority of data refer to standard states of the various compounds. However, because this is not entirely the case the enthalpy and free energy symbols do not indicate standard state. In the few instances in which data from two or more sources were not in agreement results were taken from the 1982 NBS tables[15] when available. Estimated errors are not included, but can be obtained from the original sources in most cases. A general guideline is $\pm$(2-3) kcal mol^{-1} in ΔG and ΔH values. For those oxo donor and acceptors in reasonably common use, the tabulations

contain all available data. Also presented are values for infrequently employed or potential oxo transfer reaction couples, some of which, because of their familiar constituents (e.g. $NO_{(g)}/NO_{2(g)}$), may serve as "calibration" points for the scale. In this regard ΔH values for the gas-phase couples CH_4/CH_3OH (−30.2 kcal mol^{-1}) and H_2/H_2O (−57.8 kcal mol^{-1}) attend the same purpose. Lastly, with practically no exceptions, ΔG and ΔH data parallel each other in Tables 1–3 and thus lead to the same predictions of relative reactivity. The much more extensive body of enthalpy data is utilized in the considerations that follow.

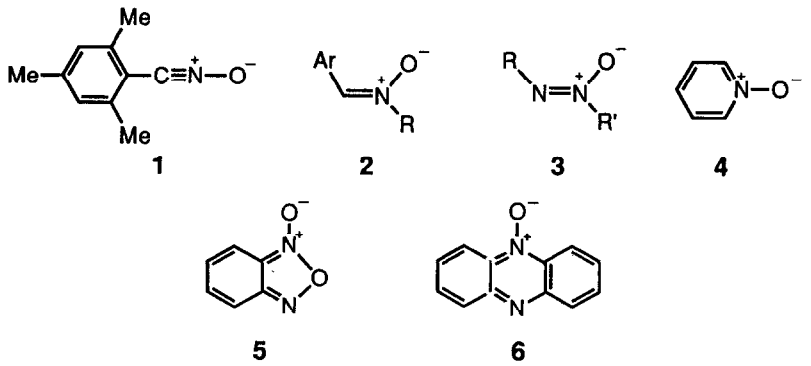
2.1. *Gas phase*

The thermodynamics of gas-phase couples provide the best measure of *intrinsic* oxo donor and acceptor reactivity. Data for some 53 couples, which are of two types, are included in Table 1. The large majority involve species in which a bond to a single atom is made or broken in the course of oxo transfer, as in reaction (6). Bond energies of oxo donors are readily calculated from reaction (8); selected examples are given in Table 5. In several couples, exemplified by Si_2Cl_6/Si_2OCl_6, the oxygen atom is inserted between two acceptor atoms, permitting the estimation of a mean X—O bond energy. Examples of the applications of various oxo donors and acceptors noted below in atom transfer reactions through 1986 are given elsewhere.[1] Certain more recent applications are summarized below.

It is immediately evident that the strongest oxo donor is ozone, followed by hydrogen peroxide and nitrous oxide. Being a highly reactive gas, ozone is an inconvenient and often indiscriminant reagent. The use of hydrogen peroxide is largely confined to aqueous or mixed-aqueous solvent systems. Nitrous oxide is a relatively unreactive gas with a high activation energy for dissociation (*ca* 60 kcal mol^{-1}).[28] Its utility as an oxo donor has been largely limited to low valent compounds of titanium, zirconium, vanadium and chromium. Dichlorine monoxide,[29] a gas under ordinary conditions, has found restricted use as an oxo source. Solutions of Cl_2O can be prepared in certain anhydrous organic solvents such as CCl_4.[30] In the presence of water the compound hydrolyses to HOCl; hypochlorite is an effective oxo transfer agent in both aqueous and non-aqueous solvents. The most practical strong donor is t-butylhydroperoxide, which is conventionally employed as a solution in an organic solvent; other compounds of the types ROOH and ROOR[31] are presumably of comparable strength.



1 2 3 4

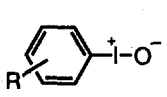
5 6

The next portion of the scale is primarily composed of various N-oxides, beginning with the nitrile oxide **1** and including azomethine (**2**), diazine (**3**) and pyridine (**4**) oxides. The available data, due to Acree, Pilcher and co-workers,[20–25] define a graded class of compounds with $6 \geqslant \Delta H \geqslant -20$ kcal mol^{-1}, corresponding to the bond energies $83 \geqslant D \geqslant 53$ kcal mol^{-1} (Table 5). Also part of this set are benzofuroxan (**5**, $\Delta H = -0.4$ kcal mol^{-1}) and phenazine N-oxide (**6**, $\Delta H = -12.7$ kcal mol^{-1}).[24] Azomethine and diazine N-oxides are usually found in the solid state as the *trans* forms **2** and **3**, respectively, but there are exceptions.[32,33] The *cis* and *trans* isomers can be interconverted thermally or photochemically in solution.[32–34] While the *cis* isomer is the less sterically hindered, the formation of an O-bonded complex of **2**, $Cp(CO)_2Fe—O—N(Ph)=CH(p\text{-}C_6H_4OMe)$,[35] indicates that a *trans* isomer with substituents as large as phenyl can approach a simulated metal oxo acceptor site that is relatively unhindered. Organic N-oxides and S-oxides are the only sets of compounds for which there are extensive, comparative thermodynamic data for the common fragment, element O. Aside from pyridine N-oxides, the oxo transfer propensities of N—O compounds are essentially uninvestigated. Given the range of ΔH values, they may find use as selective oxidants.

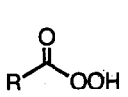
The remainder of the reactivity series in Table 1, from -20 to -99 kcal mol^{-1}, contain a variety of organic and inorganic donors and acceptors. Of acceptors and donors of moderate strength, sulphides and sulphoxides, respectively, are frequently useful. There is a considerable body of $\Delta_f H^0_m$

data, summarized by Herron,[36] for sulphides, sulphoxides and sulphones, and also for sulphite and sulphate esters. The limited data presented in Table 1 suffice to place sulphide/sulphoxide and sulphoxide/sulphone couples at meaningful positions in the reactivity scale. Dissociation energies of S—O bonds vary very little within the two classes of compounds. For common aliphatic sulphoxides and Ph_2SO the range is only 87–90 kcal mol^{-1}, and for aliphatic sulphones and Ph_2SO_2 it is 111–114 kcal mol^{-1}. Note that the positions of $SeCl_2/SeOCl_2$ and $SCl_2/SOCl_2$ follow the expected periodic trend, with the S—O bond energy exceeding that of the Se—O bond by 46 kcal mol^{-1} (Table 5). Related behaviour is found for the couples $MoCl_4/MoOCl_4$ and $WCl_4/WOCl_4$, for which $D_{W=O} - D_{Mo=O} = 26$ kcal mol^{-1}. The most familiar generally useful oxo acceptors are the tertiary phosphines and phosphites. Of all the compounds for which data are available hexamethyldisilane is the strongest acceptor. While we are incognizant of significant uses of this compound as an atom transfer reductant, Si_2Cl_6 is a most effective reductant of tertiary phosphine oxides.[37] Consequently, ΔH for the Si_2Cl_6/Si_2OCl_6 couple must be less than *ca* -80 kcal mol^{-1}, provided, as the evidence suggests, that Si_2OCl_6 is a primary product of oxo transfer itself and does not arise from another reaction event. The reductions of chiral phosphine oxides by this method proceed with a high degree of stereospecificity and with inversion of configuration.[37]

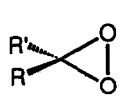
Table 1 is extensive and, *inter alia*, includes ΔH values for strong oxo donors and acceptors. However, the thermodynamic data required to calculate values for couples involving certain other strong oxo donors have not been reported. Among such donors are the iodosylarenes (**7**),[38–40] percarboxylic acids (**8**),[41] dioxiranes (**9**),[42,43] carbonyl oxides (**10**)[44] and tertiary amine N-oxides such as Me_3NO. While **7**–**10** would appear to be comparable in strength with at least t-butylhydro-



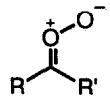
7



8



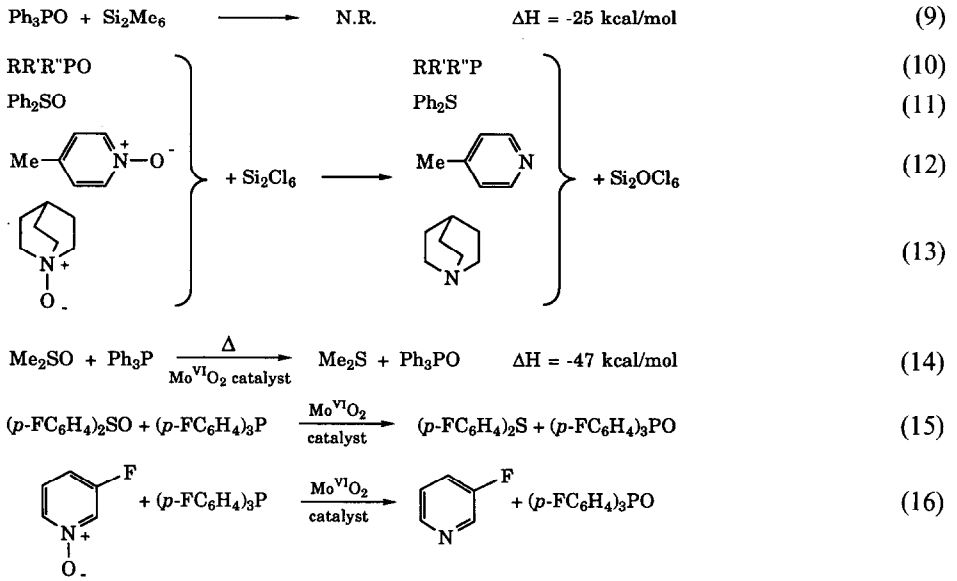
9



10

peroxide, at this point they cannot be precisely fixed in the reactivity scale. Iodosylarenes, in particular, have been widely employed as strong oxidants, including the formation of highly reactive oxometallates capable of hydrocarbon activation.[1,45,46]

The reactivity scale of Table 1 can be applied only when the system in question has the overall stoichiometry of reaction (6). In such cases a given couple X/XO, lacking the thermodynamic data required for the evaluation of ΔH, can be approximately placed in the scale on the basis of the occurrence of one or two reactions with components of other couples. For example, if compound X reduces PrN=N(O)Pr to PrN=NPr and compound XO oxidizes Ph_3As to Ph_3AsO, then for X/XO $-20 \geqslant \Delta H \geqslant -43$ kcal mol^{-1}. If only one reaction is examined, it is possible to assign an upper or lower limit to ΔH. This procedure has been used to estimate upper limits for several $Mo^{IV}O/Mo^{VI}O_2$ couples.[2] It is most effective if reactions are complete or equilibria are decisively shifted, but even limiting or widely bracketed ΔH values are preferable to none at all. Throughout, it must be borne in mind that the reactivity scale is based on gas phase data. However, we are aware of only several reactions with appreciable enthalpic driving forces ($\Delta H < -20$ kcal mol^{-1}) from gas phase data that do not follow the predictions of the scale when conducted in solution. One case is reaction (9), which is reported not to proceed in refluxing benzene over a 3 day period,[37] despite the apparent driving force of -25 kcal mol^{-1}. Reactions (10)–(13), arranged in probable order of increasing driving force, proceed in good yields under mild conditions.[37] Despite a highly favourable enthalpy change, reaction (14) does not occur when the reactants are maintained at 189° for at least 1 h.[47] Reduction of Me_2SO can be accomplished with a variety of tertiary phosphines, but elevated temperatures and longer reaction times are required for appreciable yields.[48] In contrast, reactions (14)–(16) in DMF solution proceed readily at room temperature in the presence of an $Mo^{VI}O_2$ catalyst.[4,49] In the absence of the catalyst, neither system (15) or (16) showed any detectable reaction (from ^{19}F NMR spectra) for at least 120 h at 25°C. These examples of very slow kinetics of uncatalysed reactions emphasize that any placement in the scale of a couple with an unknown ΔH value should be made on the basis of an observed reaction rather than the lack of reaction.



2.2. *Solid and liquid phases and aqueous solution*

Values of ΔH based on thermodynamic data for solids and liquids are set out in Tables 2 and 3, respectively. These values differ from those in Table 1 by the differences in the heats of sublimation or vaporization of X and XO. In the case of solids this relationship tends to alter the order of certain couples in the listings compared to that of Table 1. For liquids the order is the same as in the gas phase, owing to an effective cancellation of the heats of vaporization of members of a given couple. Table 2 serves to suggest oxo donors and acceptors that may find use in heterogeneous reaction systems.

A reactivity scale for aqueous solutions is presented in Table 4. The ΔH values were derived from thermodynamic data. Earlier, we had provided a scale in terms of $\Delta G^0{}_{298}$ values[1] that were calculated from standard potentials.[14] There are some minor numerical discrepancies between those data (not tabulated here) and the $\Delta G_{X/XO}$ values, presumably in part because potentials and thermodynamic data were not measured under identical solution conditions. However, the order of reaction couples is the same and each reactivity series can be utilized in an internally consistent manner. In Table 4 the strongest common oxo donors are hydrogen peroxide and the hypochlorite ion, and the strongest acceptor is the cyanide ion. However, because dioxiranes oxidize chloride to hypochlorite[42] their ΔH values in aqueous solution are considerably above +14 kcal mol^{-1}. As indicated by this and other reactivity aspects, dioxiranes are decidedly strong oxo transfer agents and thus should be placed near the tops of Tables 1 and 4.

We next consider selected recent applications of oxo donors and acceptors which have been reported since our previous treatment of the subject.[1]

3. APPLICATIONS

Applications of donors and acceptors in metal-centred oxo transfer reactions are summarized in order to illustrate recent uses of these reagents, where possible in relation to their positions on the thermodynamic reactivity scale. The principal applications of oxo transfer have been in metal-centred oxidation, involving reagents at the top of Table 1 and also **7** and **8** and, to a very limited extent, **9** and **10**. In addition we note the use of other, less powerful oxidants and of certain reductants.

3.1. *Strong oxo donors*

The very strong donors PhIO, H_2O_2, ROOH, RCO_3H and OCl^- continue to find extensive use in the generation of high-valent oxochromium,[50,51] oxomanganese[52-57] and oxoiron[51,58-66] porphyrin species in reactions (17)–(19). Reactions (17) and (18) are examples of primary oxo transfer, reaction (1). Reaction (19) results in oxidation of the metal and porphyrinate ligand,

the latter to a π-radical. Reaction (17), with M = Fe and Mn, has also been accomplished with dimethyldioxirane in acetone at low temperatures.[67] The oxidation of Mn(TMP)Cl with dioxygen under phase transfer conditions (aqueous NaOH, chloroform) is thought to occur via the carbonyl oxide Cl_2COO formed from dichlorocarbene and dioxygen.[52] While Fe(TPP) can be oxidized in reaction (17) with N-methylmorpholine N-oxide or Me_3NO,[68] the available evidence indicates that stronger donors are required in reactions (18) and (19). The minimal donor strength on the reactivity scale of Table 1 has not been established. There does not appear to be a common mechanism for all oxidants, XO. With peroxidic reagents, YOOH, the simplest pathway involves heterolytic O—O bond cleavage, oxidative addition of the nascent oxygen atom to the metal centre and departure of YOH. A summary of the leading mechanistic aspects of these reactions has been provided by Bruice.[69]

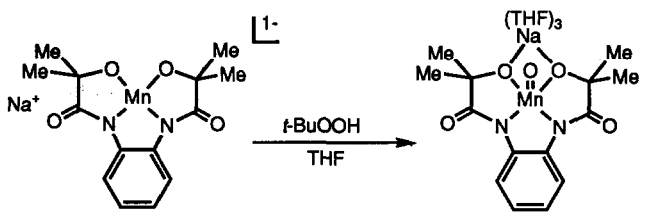
$$M^{II}(P)+XO \longrightarrow M^{IV}O(P)+X \qquad (M = Cr, Mn, Fe) \tag{17}$$

$$Mn^{III}(P)L+XO \longrightarrow Mn^{V}O(P)L+X \tag{18}$$

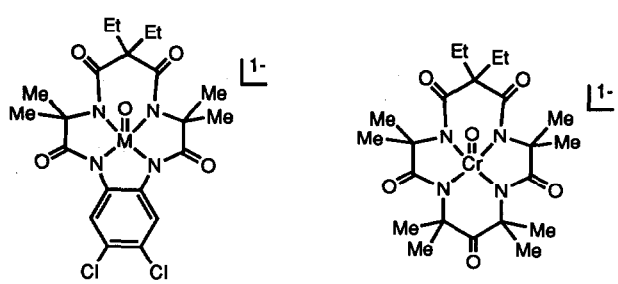
$$Fe^{III}(P)L+XO \longrightarrow Fe^{IV}O(P^{\cdot})L+X \tag{19}$$

Catalytic systems for the epoxidation of olefins and the hydroxylation of saturated hydrocarbons are based on reactions (18) and (19) for the generation of the oxometal catalyst. The epoxidation of olefins is frequently regarded as indicative of the formation of (highly reactive) oxometal species, at least with iron and earlier transition metals. The chemistry of these metals otherwise includes such species whose existence has been demonstrated spectroscopically, as with iron, or by X-ray structure determinations for compounds of groups 4–7. Meunier[70] has presented a comprehensive account of the formation and catalytic reactions of oxometalloporphyrins. The formation of active Fe=O species by atom transfer from strong oxo donors is not restricted to porphyrins, as inferred from hydrocarbon oxidation in non-haeme systems (PhIO, H_2O_2, Bu^{t}OOH)[71,72] and by the antitumor antibiotic bleomycin (PhIO, H_2O_2) and its synthetic analogues.[73]

The active oxidants in the foregoing hydrocarbon activation systems have proven difficult to isolate and characterize because of their reactive nature. However, with suitably stable ligand systems and strong oxo donors Collins and co-workers[74–77] have shown that it is possible to prepare, isolate and structurally characterize high-valent oxochromium and oxomanganese complexes. Thus, the primary oxo transfer reaction (20) of the Mn^{III} complex **11** affords the $Mn^{V}O$ product **12**.[76] Complexes **13**–**15** were obtained in good yields by the reaction of metal(II) precursors with excess Bu^{t}OOH,[74,75] in reactions that must involve both electron and atom transfer. Oxo transfer with strong donors has also been effective in building up polynuclear clusters from smaller precursors. As one example, treatment of mixed-valence $Mn_3O(O_2CPh)_6(py)_2(OH_2)$ with 1.33 equivalents of PhIO in acetonitrile results in full incorporation of oxygen in the manganese(III) product cluster $Mn_9O_7(O_2CPh)_{13}(py)_2$.[78]



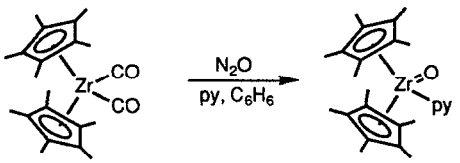
11 **12** (20)



13: M = Cr
14: M = Mn

15

Two of the more powerful oxidants in Table 1, Cl_2O and N_2O, both with $\Delta H \approx +19$ kcal mol^{-1}, have found limited applications. Dichlorine monoxide as a solution in CCl_4 oxidizes manganese(III) porphyrins to higher-valent compounds, probably including $Mn^{IV}O(P)$, but none of these oxidized species have been definitely identified.[30] Solutions of this reagent are described as containing chlorine, which complicates the oxidation chemistry. Reactions of N_2O with Cp^*_2Ti and Cp_2V in toluene produce polynuclear products with no terminal oxo ligands.[1,79,80] In a recent significant development, it has been found that the presence of pyridine shunts related reaction system (21) to the mononuclear oxo product **17**,[81] formed by a primary oxo transfer to the dicarbonyl **16**. Compound **17** is a stabilized derivative of Cp^*_2ZrO, which has been generated by the thermolysis of $Cp^*_2Zr(Ph)(OH)$ and trapped as oxametallocycles by reactions with unsaturated organic compounds.[82] These developments open the chemistry of the heretofore elusive Zr=O group. The Hf=O group is presently unknown, although the potential precursor $Cp^*_2Hf(Ph)(OH)$ has been prepared by treatment of $Cp^*_2HfH(Ph)$ with N_2O in a reaction that demonstrates oxo insertion in a metal–ligand bond when metal-centred oxidation is not possible.[83]

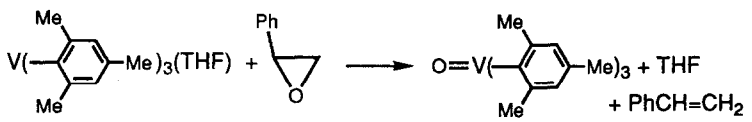


(21)

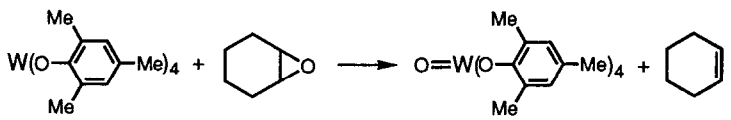
16 **17**

3.2. *Other oxo donors*

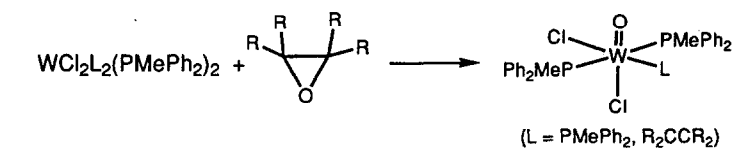
Epoxides have been found to effect a number of primary oxo transfer reactions, among them reactions (22)–(24).[84–87] For these M^n/M^{n+2} couples ΔH is evidently less than *ca* -25 kcal mol^{-1}, indicating that these vanadium(III) and tungsten(II,IV) compounds are oxo acceptors of at least moderate strength. Pyridine N-oxide, Me_3NO and Me_2SO have been found to effect the $Tc^{III} \rightarrow Tc^{V}O$ transformation of tris(2,4,6-trimethylbenzenethiolate) complexes.[88] Lastly, the $W^{IV}O_5(OH_2)$ unit in a heteropolytungstate "brown" anion has been shown to undergo primary oxo transfer, leading to a $W^{VI}O(O)_5$ product.[89] Oxidation is effected by Me_2SO, Ph_2SO or Ph_3AsO at elevated temperatures in toluene or acetonitrile solutions and by PhNO at 25°C in these solvents. However, $(MeO)_2SO_2$, Me_2SO_2, PhNCO and Ph_3PO were not reduced, even after prolonged reaction times. Consequently, for the $W^{IV}/W^{VI}O$ couple $\Delta H < -43$ kcal mol^{-1} as an upper limit, but the lower limit cannot be securely set on the basis of lack of reaction.



(22)[84]



(23)[85]

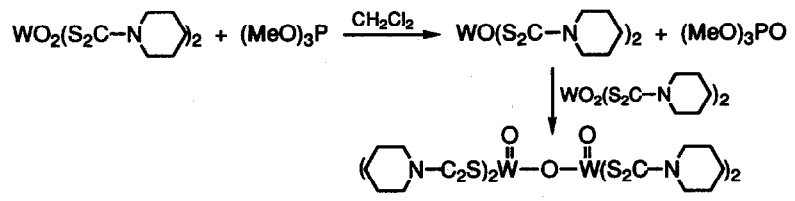


(24)[86,87]

3.3. *Oxo acceptors*

Tertiary phosphines and phosphites are the most commonly employed oxo acceptors. With the exception of Si_2Cl_6 and possibly Si_2Me_6, no soluble non-metal compounds of known ΔH values are

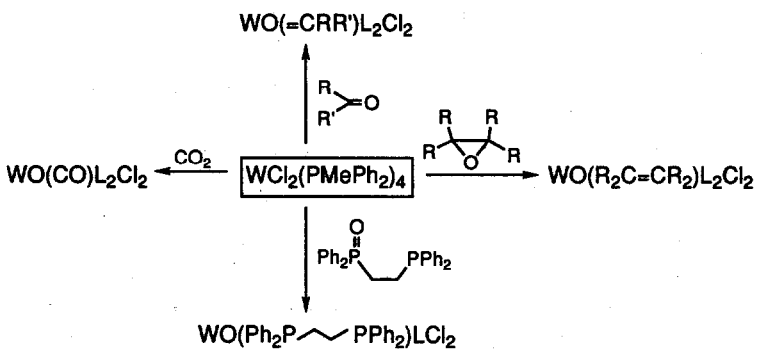
more powerful acceptors. There are numerous recent applications of these compounds as oxo acceptors. Here we note two instances of the infrequent reductive transformation $W^{VI}O_2 \rightarrow W^{IV}O$ by atom transfer. Reaction (25) proceeds readily at room temperature to afford the μ-oxo $W^{V}{}_2O_3$ product in 86% yield.[6] By analogy to well-studied molybdenum systems,[1] the product is consistent with the initial formation of the $W^{IV}O$ compound followed by an inner sphere electron transfer reaction with the $W^{VI}O_2$ reactant. In reaction (26), conducted at 67°C for 7 h, the $W^{IV}O$ product was isolated in 55% yield as the triethylphosphine adduct.[90] Excess phosphine suppressed the formation of the μ-oxo compound. The $W^{IV}O$ group is of general interest because, at parity of the ligand, it should be a more powerful oxo acceptor than the $Mo^{IV}O$ group, a matter that, however, has not been adequately tested.



(25)

(26)

Mayer and co-workers[91–96] have demonstrated that W^{II} compounds of the type $WCl_2(PR_3)_4$ are among the most powerful oxo acceptors known. Thus, the prototypical complex $WCl_2(PMePh_2)_4$ oxidatively adds carbon dioxide and deoxygenates ketones,[92,93] alcohols,[94] epoxides[91,95] and $Ph_2PCH_2CH_2P(O)Ph_2$.[96] Leading transformations are summarized in eq. (27). Reactions are not necessarily general for a given substrate type and minority products are sometimes observed. Reactions with ketones afford tungsten(VI) oxo alkylidenes. Other products contain tungsten(IV) and occur in primary oxo transfer reactions, resulting in the reduction of XO and coordination of reduced product X. Reduction of the phosphine oxide is the only known metal-mediated reaction of this type. When taken together with the finding that PPh_3 does not react under the same conditions, it has been proposed[96] that the reduction of tertiary phosphine oxides $OPRPh_2$ is thermodynamically favourable but kinetically unfavourable owing to weak binding of the phosphine oxide to the metal centre. If correct, the couple $WCl_2(PMePh_2)_4/WOCl_2(PMePh_2)_3 + PMePh_2$ is placed at $\Delta H < -74$ kcal mol^{-1} on the reactivity scale. $WCl_2(PMePh_2)_4$ should find further applications as a powerful oxo acceptor.



(27)

4. THE OXO TRANSFER CHEMISTRY OF RHENIUM

Of all metals, the oxo chemistry of rhenium has been expanded to the largest extent relative to the situation in 1987.[1] At that time, the great majority of reactions resulted in oxo transfer from rhenium to the substrate. Significant new information has been gained in the last half a dozen years on the synthesis and structures of oxorhenium groups and on oxo transfer reactions resulting in oxidative and reductive transformations of these groups. Consequently, the current use of oxo

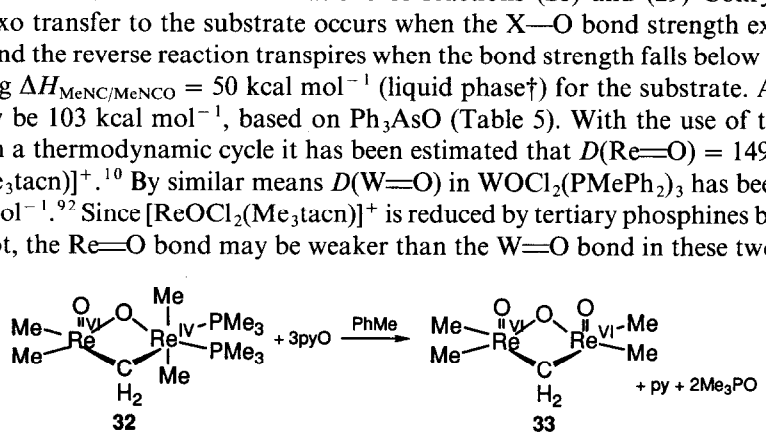
transfer reagents and, where possible, of the thermodynamic reactivity scale are well illustrated by leading developments in the oxo transfer chemistry of rhenium, taken together with the foregoing applications. Contemporary advancement of oxorhenium chemistry is due nearly exclusively to the investigations of Herrmann, Hoffman, Mayer and their co-workers, and has been largely motivated by interest in high-valent organometallic oxides, alkyls and unsaturated organic derivatives. Certain parts of the early work of the Herrmann group have been summarized.[1,97-99] In the sections that follow, examples of structures and reactions are confined to those reported in the last 6 years. The coverage is comprehensive in that all significant structural and reaction types are included, but it is not exhaustive.

4.1. *Oxorhenium functional groups*

We begin our considerations by noting the three types of oxorhenium functional groups, ReO, ReO_2 and ReO_3. Due to the possibilities of different oxidation states and structures, there are seven known groups in this set. These are depicted as **18**–**24** in Table 6, which lists structurally proven examples of each.[100-122] *Cis* (**19**) and *trans* (**20**) versions of the $Re^{V}O_2$ group are known. Efficient syntheses of compounds containing these groups have been reported,[123-125] including *cis* and *trans* forms of pyridyl/bipyridyl complexes.[125] The $Re^{VI/VII}O_2$ groups are known only in the *cis* forms **21**/**22**, while the $Re^{VII}O_3$ group is pyramidal (**23**) in nominally six-coordinate complexes and $MeReO_3$ but is planar (**24**) in five-coordinate, 16-electron species. These groups may then be implicated in the binuclear bridged units **25**–**31**, some of which may be formalized in terms of combinations of mononuclear groups with and without electron transfer. For example, **26** is a combination of **18** and **22** and **30** is a combination of **18** and **23**, both with electron transfer, while **31** is an adduct of **22** and **23**/**24** and **29** is a dimer of **19**/**20**. The extent of metal–metal bonding in certain complexes containing units **28** and **29** has been discussed elsewhere.[126] While other elements exhibit MO_{1-3} functional groups,[1,127] no other element forms groups with as many oxidation states and stereochemistries and displays the diversity of binuclear units as does rhenium. As will be seen the majority of groups and binuclear units in Table 6 are formed by or are reactive in oxo transfer processes. Not included in this table are certain low-valent oxorhenium groups in complexes derived from alkynes,[128-130] where the metal oxidation state may be regarded as less clearly defined than in **18**–**24**.

4.2. *Oxo transfer reactions*

Examples of the leading types of metal-centred oxo transfer reactions, eqs (28)–(42), of rhenium are provided in Table 7. Reaction products X/XO are obvious and are not specified. Several other reactions involving alkyne complexes with less well-defined oxidation states have been reported,[131] but are not tabulated. Reactions (28)–(31) are of the primary oxo transfer type (1); as indicated, reaction (31) involves the oxidation of only one rhenium atom in the binuclear precursor complex. In examining the $Re^{III} \rightleftarrows Re^{V}O$ transformations of reactions (28) and (29) Conry and Mayer[10] observed that oxo transfer to the substrate occurs when the X—O bond strength exceeds 133 kcal mol^{-1} (Ph_3P), and the reverse reaction transpires when the bond strength falls below 110 kcal mol^{-1} (Bu^tNCO), using $\Delta H_{MeNC/MeNCO}$ = 50 kcal mol^{-1} (liquid phase†) for the substrate. A more reliable upper limit may be 103 kcal mol^{-1}, based on Ph_3AsO (Table 5). With the use of these and other bond energies in a thermodynamic cycle it has been estimated that D(Re=O) = 149(9) kcal mol^{-1} for $[ReOCl_2(Me_3tacn)]^+$.[10] By similar means D(W=O) in $WOCl_2(PMePh_2)_3$ has been estimated to be > 138 kcal mol^{-1}.[92] Since $[ReOCl_2(Me_3tacn)]^+$ is reduced by tertiary phosphines but the tungsten compound is not, the Re=O bond may be weaker than the W=O bond in these two compounds.



32 **33** (31)

† This value was incorrectly ascribed to the gas phase.[1]

[e] Terminal-bridge angle.
[f] Bridge angle.
[g] Re—O—Re = 166°.
[h] Terminal oxygen angle.
[i] Re—O—Re = 180°.

Reactions (32)–(35) are examples of the incomplete intermetal oxo transfer process (2). The conversion reaction (32) does not proceed by oxo removal from the initial binuclear complex. Instead, this species is subject to a ligand-assisted dissociation to form $Re^{V}O$ and $Re^{VII}O_2$ complexes; the latter is reduced to the former by $X = Me_3P$ in a primary oxo transfer process. The same pathway is likely for reaction (33). In reaction (34) $XO = pyO$ oxidizes the dissociated $Re^{V}O$ complex to the $Re^{VII}O_2$ product, while in reaction (35) Ph_3P affects the reverse conversion. Underlying these four reactions is the inner sphere electron transfer, eq. (43), analogous to the numerous examples of the formation and dissociation of the μ-oxo $Mo^{V}_2O_3$ unit.[1]

$$Re^{V}_2O_3(CH_2SiMe_3)_6 + Me_3P \rightleftharpoons Re^{V}O(PMe_3)(CH_2SiMe_3)_3 + Re^{VII}O_2(CH_2SiMe_3)_3 \quad (32)$$

$$Re^{V}O(PMe_3)(CH_2SiMe_3)_3 + XO \rightleftharpoons Re^{VII}O_2(CH_2SiMe_3)_3 + X \quad (34,35)$$

Reactions (36)–(38) appear to involve a primary oxo step followed by non-redox ligand substitution. In reaction (36) the second oxygen ligand is derived from the water solvent. In reaction (37) Ph_3P acts as the oxo acceptor and Me_3SiCl functions to remove oxide while concomitantly supplying chloride ligands. This reaction type can be extended to the formation of the non-oxo rhenium(V) product Cp^*ReCl_4 from Cp^*ReO_3.[117] Similar comments apply to reaction (38), in which $GeCl_2$ has the effective dual function of oxo and oxide acceptor and chloride donor. Reactions (39) and (40) are easily interpreted in terms of the non-redox group dimerization reaction, eq. (44). The course of reaction (41) is less clear but may involve process (43) with the mononuclear components subject to ligation by chloride and Ph_3PO. Reaction (42) results in the formation of that bridge unit with the most terminal oxo ligands, as might be expected for rhenium(VII), rather than retaining a bis(μ-oxo) structure.

$$[ReO_3(tacn)]^{1+} + Ph_3P + 2Me_3SiCl \longrightarrow [ReOCl_2(tacn)]^{1+} + Ph_3PO + (Me_3Si)_2O \quad (37)$$

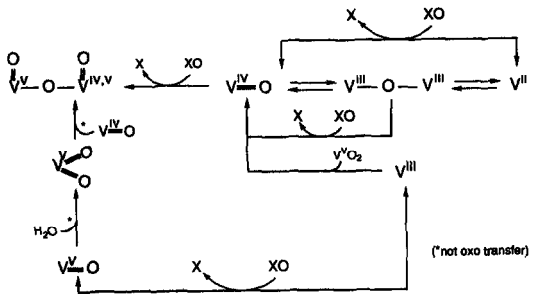
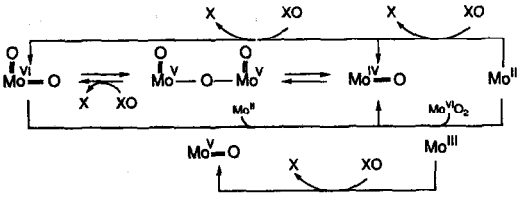
5. OXO TRANSFER REACTION DIAGRAMS

The elements vanadium, chromium, molybdenum, tungsten, manganese, rhenium and ruthenium each sustain a metal-centred oxo transfer reaction chemistry that is substantial in terms of numbers of reported reactions, varieties of oxometal functional groups and oxo-bridged units, and the range of oxidation states. As on previous occasions[7,132] we suggest that reaction patterns can be effectively summarized in the form of oxo transfer reaction diagrams. Those for vanadium[7] and molybdenum[132] are set out in Schemes 1 and 2, respectively. The diagram for rhenium is presented in Scheme 3 and is based on the reaction types in Table 7 and other examples presented previously.[1] These diagrams, which are restricted to mono- and binuclear oxometal species, recapitulate all known primary oxo transfer reactions of these elements in terms of transformations between functional groups and bridged units.

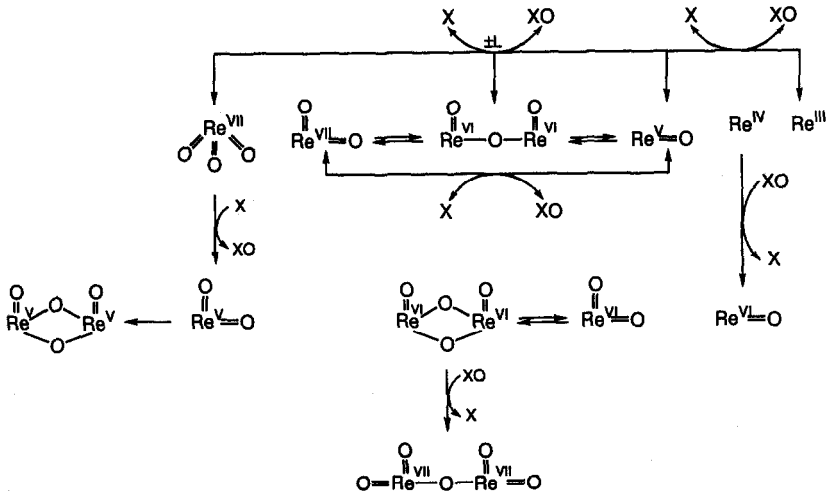
Oxometal groups joined by straight line segments are accessible in uni- or bidirectional reactions, signified by single- and double-headed curved arrows. The schemes are generalized; not all transformations are spontaneous with a given functional group in different molecules nor with a given oxo donor/acceptor. Scheme 2 does not include peroxide species which may be formed in part by oxo transfer. Several important transformations between groups and bridging units that do not



Scheme 1. Oxo transfer reactions of vanadium.



Scheme 2. Oxo transfer reactions of molybdenum.



Scheme 3. Oxo transfer reactions of rhenium.

proceed solely by atom transfer are included in this scheme because these species and reactions are encountered with some frequency. This is also the case in Scheme 3 where ancillary ligands are involved in the $Re^{V}O \rightleftarrows Re^{VII}O_3$ transformations. These diagrams suggest what reactions might be possible with new complexes of these elements and what transformations might be accomplished that have not been reported. The thermodynamic reactivity scale can be of significant assistance in planning reactions within the chemistry of a given element once a small body of empirical reactivity information has been gathered. Reactions of X/XO in the middle of the scale (Table 1) are particularly useful in providing rough limits on ΔH values for oxometal species. In this respect, we find the Ph_3As/Ph_3AsO couple, at -41 kcal mol^{-1}, a useful indicator of the thermodynamic oxo transfer

Table 7. Oxo transfer reactions of rhenium

Reactant	X/XO	Product		Ref.

[a] cf. ref. 131 for an apparent $Re^{IV}{}_2O_3 \rightarrow Re^{V}O_2$ transformation.

propensity of metal species. Regrettably, there is virtually no thermodynamic information on oxometal complexes that permits their placement in the scale.

Watt *et al.*, in a pioneering study,[133] performed direct calorimetric measurements of reactions of $Mo^{IV,V,VI}$ dithiocarbamate complexes in 1,2-dichloroethane solutions. Among these reactions was the oxidation of $MoO(S_2CNEt_2)_2$ by dioxygen to $MoO_2(S_2CNEt_2)_2$, for which $\Delta H = -35(3)$ kcal mol^{-1}. This value predicts that the $Mo^{IV}O$ complex will reduce Me_2SO (-8 kcal mol^{-1}), azoxybenzene (-18 kcal mol^{-1}) and pyO (-22 kcal mol^{-1}) because of the favourable apparent enthalpic driving forces indicated. These reactions have been observed.[134] However, this complex is not expected to reduce Ph_3AsO because of an apparently unfavourable enthalpy change ($+8$ kcal mol^{-1}). Yet from the reaction system $MoO(S_2CNEt_2)_2/Ph_3AsO$ in benzene (20 h, 40°C), Ph_3As has been isolated in 84–98% yield.[134] This result suggests that users of the gas phase reactivity scale of Table 1 for solution reactions should exercise discretion when enthalpy differences are relatively small, with perhaps 10 kcal mol^{-1} being a cautionary value.

OXIDE-BASE ADDUCTS OF ALUMINUM: X-RAY CRYSTAL STRUCTURES OF $Me_3Al(OPPh_3)$, $Me_3Al(ONMe_3)$ AND $[(CH_3)_3SiO]_3Al(OPPh_3)$

FRANK J. FEHER,† THEODORE A. BUDZICHOWSKI and KEITH J. WELLER

Department of Chemistry, University of California, Irvine, CA 92717, U.S.A.

(*Received* 15 *September* 1992; *accepted* 23 *November* 1992)

Abstract—The crystalline molecular structures of three Lewis adducts of aluminum are reported. The structures of the 1:1 adducts between trimethylaluminum and triphenylphosphine oxide, **1**: $Me_3Al(OPPh_3)$, trimethylaluminum and trimethylamine-N-oxide; **2**: $Me_3Al(ONMe_3)$; and **3**: $[(CH_3)_3SiO]_3Al(OPPh_3)$ are discussed, and a comparison is made to the previously characterized aluminosilsesquioxane complex $(c\text{-}C_6H_{11})_7Si_7O_{12}Al(OPPh_3)$ (**5**).

As part of our efforts to develop useful chemical models for silica and aluminosilicate surfaces,[1] we recently synthesized the first well-characterized examples of polyhedral aluminosilsesquioxanes.[2] Complexes **5**, **6** and **7**, which are readily available from the reactions of **4** with Ph_3PO, Me_3NO and $Me_4SbOSbMe_4$, respectively, exhibit a number of structural similarities to aluminosilicate frameworks, suggesting that aluminosilsesquioxanes will be excellent models for the aluminoferrous sites in zeolites.

In an earlier paper we compared the structural data for **5** with metrical data available from the numerous structural studies on aluminosilicates and zeolites.[2a] At that time **5** was the only crystallographically characterized phosphine oxide complex of aluminum and it was not possible to compare metrical data for the Al—O—P moiety with other chemically similar complexes.[3] Since the appearance of our original paper, Burford *et al.* have reported the structural and spectroscopic characterization of several aluminum/phosphine oxide

adducts, including the single-crystal X-ray diffraction studies of $Cl_3AlOPPh_3$ (**8**) and $Br_3AlOPPh_3$ (**9**).[4] In this paper we report the results from X-ray crystallographic studies of **1**, $Me_3Al(OPPh_3)$, **2**, $Me_3Al(ONMe_3)$ and **3**, $[(CH_3)_3SiO]_3Al(OPPh_3)$, and compare these results to the other structurally characterized phosphine oxide adducts of aluminum.

RESULTS AND DISCUSSION

1, $Me_3Al(OPPh_3)$

The molecular structure of **1** is shown in Figs 1(a) and 1(b), a summary of crystallographic data appears in Table 1, and selected bond distances and angles are collected in Table 2. The complex crystallizes from benzene/hexane as colourless rhombohedra in the space group $R\bar{3}$, with the Al—O—P linkage aligned along the crystallographic three-fold rotational axis. Thus, the Al—O—P bond angle is crystallographically imposed at 180°. This interesting structural feature has also been observed in the solid state and in solution for the triphenylphosphine oxide adducts of $AlCl_3$ (**8**) and $AlBr_3$ (**9**) and is indicative of π-delocalization over the Al—O—P linkage (*vide infra*).[4] As expected, the aromatic rings on phosphorus adopt a propeller-like orientation and are staggered from the methyl groups on aluminum. The C(1)—Al—P—C(2b) dihedral angle is 45. [Fig. 1(b)]. There are no significant non-bondi interactions between adjacent molecules in the u cell.

Comparisons of metrical data for **1** with fr Me_3Al[5] and Ph_3PO[6] indicate that the largest stru tural changes occur at the aluminum centre (Tab 3). The trigonal Me_3Al molecule undergoes pyr midalization upon the coordination of Ph_3P [C—Al—C = 113.3(1)°] and the Al—C bond di tances increase slightly from 1.957 to 1.965(3) as pyramidalization increases the percentage of character in the Al—C bonds. Changes in tl molecular structure of Ph_3PO upon coordinatic of Me_3Al are more difficult to quantify becau the molecular structures of Ph_3PO occur in low symmetry space groups with a relatively wide ran of metrical data.[6] The P—O bond distance increas slightly from 1.484(1) to 1.500(2) Å, while the P— bond distances become somewhat (0.01 Å) shorte The C—P—C bond angles also appear to becom more obtuse, but all of these changes are not fa outside their limits of statistical significance.

2, $Me_3Al(ONMe_3)$

The molecular structure of **2** is shown in Fig 2(a) and 2(b), a summary of crystallographic dat appears in Table 1, and selected bond distance and angles are collected in Table 4. The comple

crystallizes from benzene/hexane as colourless plates in the space group $P2_1/n$. The molecule is situated at a general position with no exceptional intermolecular contacts between the four molecules which comprise the unit cell.

In stark contrast to the crystallographically C_{3v} symmetric phosphine oxide adduct **1**, the trimethylamine oxide adduct **2** is bent, with an Al—O—N bond angle of 128.2(1)° (Table 4). Although this angle differs by more than 50° from that in **1**, the Al—O bond distance [1.857(2) Å] is lengthened by only 0.02 Å. The Me_3Al moiety is pyramidalized with average Al—C distances of 1.981 Å and average C—Al—C bond angles of 112.6°. As observed in **1** coordination of $AlMe_3$ to Me_3NO leads to a slight lengthening of the N— bond and appears to flatten the C_3N moiety. Mo of these changes are, however, only minor and the significance is questionable. One of the more inte esting features of the structure is the O—Al—C(bond angle of 99.3(1)°, which is approximately 1(more acute than the other two O—Al—C angl [109.2 and 109.8(1)°] in the adduct. Normal tetr hedral angles are observed for the free amine oxide

collected in Table 5. The complex crystallizes from benzene/hexane in the triclinic space group $P\bar{1}$. The molecule resides at a general position within the unit cell and displays no significant non-bonded interactions.

The Al—O—P linkage is bent [146.7(2)°] with Al—O(P) and P—O bond lengths of 1.807(4) and 1.517(4) Å, respectively. In this complex the Si—O—Al linkages are also quite obtuse [149.8(2)° av.] and may reflect the cumulative effects of steric interactions and weak Al(Si)—O π-bonding. Again, the phenyl rings adopt a propellar-like arrangement and are staggered from the ligands bound to the aluminum centre. Both the aluminum and phosphorus centres are very nearly tetrahedral: the only statistically significant structural change which

occurs in the phosphine oxide is the increase in P—O bond length. As in complexes **1** and **2** (Tables 2 and 4), the substituents about the aluminum centre in **3** are skewed slightly towards the Lewis base [O—Al—O = 113.8° av., O—Al—O(P) = 104.6° av.].

Nature of π-bonding in Lewis oxide-adducts

The presence of linear Al—O—P linkages in phosphine-oxide adducts of aluminum suggests that extensive π-delocalization occurs in these systems.[4] A number of such complexes have been structurally characterized, and it is now possible to postulate about the origins of such interactions. In particular we have determined the structures of three closely related complexes (**1**, **3** and **5**) by single-crystal X-ray diffraction on the same diffractometer system and at the same temperature (−90°C). For convenience, the pertinent bond distances and angles for the complexes described here, as well as several other related species, are collected in Table 6.

The following observations have been made. For adducts of the type E—O—D, where E is an electrophilic group 13 element and its ligands and D is a nucleophilic oxide of a group 15 element and its ligands, a 180° bond angle is observed only for those cases where E and D are from the third row (or greater) of the periodic table. Thus, **2** and F_3B—O—PPh_3[8] are bent, with bond angles of 146.7(2)° and 134.5(2)°, respectively. Also linear Al—O—P linkages are observed only in those cases where the ligands about the aluminum and phosphorus centres are not significant π-donors. Interestingly, Burford and Rogers have recently shown that chemically analogous phosphine-selenide and phosphine-sulphide complexes do not show the same tendency towards linearity, presumably because of weaker π-bonding.[9]

Although it would be tempting to suggest that *d*-orbitals are responsible for the observed behaviour, the role of $d\pi$–$p\pi$ bonding in main group syster in general has been refuted based on numero theoretical[10] and experimental studies.[11] Fu thermore, the significance of π-bonding for alun num complexes has recently come into question. An alternative possibility recently advanced by Ba ron,[13] which is also consistent with the above obse vations, is the interaction of π-symmetry-fill orbitals on oxygen with empty π-symmetry σ orbitals on both the group 13 and group 15 elemen involved in the linkage (Fig. 4). This type of inte action is very weak, but can have significant stru tural impact on bonds with soft flexing potentia such as the Al—O—P linkages described here.

As a result of π–$\sigma^*\pi$ interaction concomita lengthening of the σ-bonds may be observed.[1] Although statistically significant changes are n observed in the systems discussed thus far [perha due to only weak interaction spread over three di tinct M—L bonds, Figs 4(a) and 4(b)], this result not inconsistent with recent theoretical calculatio for this type of interaction.[10c] For **2** and **3** whe cylindrical symmetry at oxygen is not observed the solid state, interesting variations in the Al— and P—C bond distances occur. The lower syn metry causes differing effects and bonds with c orbitals directed at the presumed location of t lone pair orbitals on oxygen are somewhat long [Al—A and P—A in Fig. 4(c)]. In **2** Al—C(1) ar Al—C(2) are approximately 0.01 Å longer tha Al—C(3) [Fig. 2(b)]. Nitrogen, a first row elemen forms strong covalent bonds to carbon and do not display significant N—C bond alterations. I **3** Al—O(2) is 0.01 Å longer than Al—O(1) ar Al—O(3), while P—C(10) and P—C(22) are 0.0 Å longer than P—C(16) (Fig. 3). It should b pointed out that, while consistent with a π–σ^* interaction, these changes are not outside of the statistical limits of significance and may be the resu of other factors such as crystal packing and ster forces.

Effects of the ligands on Lewis acidity

After a brief inspection of Table 6 it is immediately obvious that there is little correlation between Al—O bond distance and Al—O—P bond angle. This result is not surprising and has been previously noted for alkoxide complexes of the early transition metals[14] and main group elements.[15] Equally obvious, however, is the large range for Al—O(P) bond distances. While this range may or may not be due to the influence of π-bonding, it is no doubt a reflection of the electrophilicity of the aluminum centres in these complexes. Aluminosilsesquioxane **5** has one of the shortest Al—O bond distances and the aluminum centre is presumably much more electrophilic than the corresponding simple alkoxide and siloxide complexes such as **3**.

Burford *et al.* recently noted that the ^{31}P chemical shifts for phosphine oxide complexes are dramatically shifted downfield upon ligation by Lewis acids and suggested that this was the result of significant P—O bond disruption.[9] While there does not appear to be a good correlation between the ^{31}P chemical shift and the P—O bond distance (Table 6), there is an excellent correlation between the latter and the observed Al—O(P) distances (Fig. 5). The lack of correlation between δ ^{31}P and *d* P—O is readily explained by the small range of values observed for P—O separations (0.019 Å compared to 0.067 Å for *d* Al—O), considering the accuracy with which bond distances are determined by X-ray diffraction. The spectroscopic data also suggest that the aluminum centre in **5** is significantly more electrophilic than in the corresponding simple siloxide **3**.

EXPERIMENTAL

All manipulations were performed in a Vacuum Atmospheres Corporation Dri-lab. Benzene and hexanes were distilled from dark purple solutions of potassium benzophenone ketyl containing tetraglyme under nitrogen. Trimethylaluminum (Aldrich) was vacuum distilled and stored under nitrogen prior to use. Triphenylphosphine oxide (Aldrich) was filtered through silica gel

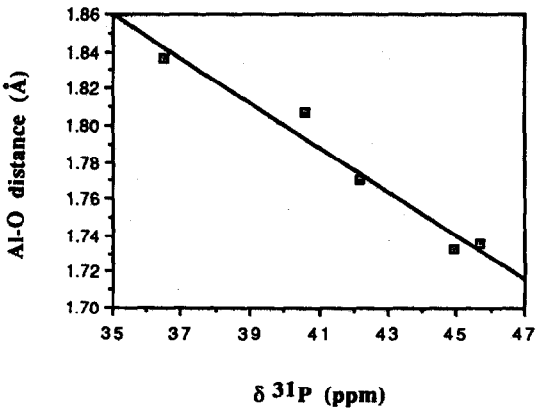

Fig. 5. Plot of Al—O distance (Å) versus δ ^{31}P (ppm) for complexes **1**, **3**, **5**, **8** and **9**. Data from Table 6.

($EtOH/CHCl_3$) and recrystallized from ether. Anhydrous trimethylamine-N-oxide (Aldrich) was obtained by azeotropic dehydration of $Me_3NO \cdot 2H_2O$ (toluene, 110°C) and vacuum sublimation. Paratone-N (viscous lubricant) was degassed under a dynamic vacuum (0.01 torr) overnight. NMR spectra were recorded on a General Electric GN-500 spectrometer ($^{31}P\{^1H\}C_6D_6$, 25°C) and were referenced to H_3PO_4 (0.00 ppm). The spectrum for **5** was originally misreferenced[2a] and was re-recorded under identical conditions to **1** and **2**.

Preparation of **1** *and* **2**

The Lewis adducts were prepared by the addition of an equimolar amount of neat trimethylaluminum to a benzene solution of either triphenylphosphine oxide or trimethylamine-N-oxide.[3e,f] After stirring for 15 min the volatiles were removed *in vacuo* (10^{-3} Torr, 25°C) to afford quantitative yields (NMR) of the respective compounds. Suitable single crystals for X-ray diffraction studies were obtained by the slow diffusion of hexane into benzene solutions of the adducts. The crystals used for X-ray diffraction studies were manipulated under a protective layer of Paratone-N.

Preparation of **3**

This adduct was prepared according to the literature procedure.[16] Suitable crystals for X-ray diffraction were obtained by slow diffusion of hexanes into a saturated benzene solution of **3**.

Collection of X-ray diffraction data

Crystals suitable for X-ray diffraction were cut from larger crystalline masses and mounted using standard procedures under a stream of nitrogen at −90°C on a Syntex P3 automated four-circle diffractometer equipped with a locally modified Syntex LT-1 low-temperature device.[12] Unit cell parameters and intensity data were obtained using standard procedures which have been described previously.[2,17] Low-temperature intensity data were collected using the θ–2θ scan technique with graphite-monochromated Mo-K_α radiation (λ = 0.71069 Å) under the conditions listed in Table 5. All crystallographic calculations were performed using the SHELXTL PLUS program set. The structures were solved by direct methods, which yielded one set of phase relationships with high internal consistency for each adduct. In each case a series of difference-Fourier syntheses revealed the positions of all atoms, including hydrogen atoms for **1** and **2**. For **3** hydrogen atoms were placed in calculated positions with δ C—H = 0.96 Å. Complete details of the refinements are listed in Table 5. In all cases, final difference-Fourier syntheses showed no significant features.

Acknowledgements—We express our thanks to Dr Joseph W. Ziller for assistance with the X-ray structural studies. These studies were supported by the National Science Foundation (CHE-8703016). Funds for the purchase of the X-ray diffraction equipment were made available from NSF Grant CHE-85-14495. Financial support from the UCI Academic Senate Committee on Research is also gratefully acknowledged. One of us (TAB) gratefully acknowledges financial support from the Fannie and John Hertz Foundation as a pre-doctoral fellowship.

SYNTHESIS AND CHARACTERIZATION OF THE MOLYBDENUM(IV) OXO-SELENOLATE COMPLEX [MoO($Ph_2P(O)CH_2CH_2P(Ph)CH_2CH_2PPh_2$)(Se-2,4,6-$(CH_3)_3C_6H_2)_2$]

P. MICHAEL BOORMAN,* HEINZ-BERNHARD KRAATZ and MASOOD PARVEZ

Department of Chemistry, University of Calgary, Calgary, Alberta, Canada T2N 1N4

(*Received* 5 *October* 1992; *accepted* 20 *November* 1992)

Abstract—The presence of adventitious oxygen in the reaction of [(Triphos)$MoCl_3$] (Triphos = $Ph_2PCH_2CH_2P(Ph)CH_2CH_2PPh_2$) with $NaSeC_6H_2Me_3$-2,4,6 in THF leads to the formation of [*fac*-MoO($Ph_2P(O)CH_2CH_2P(Ph)CH_2CH_2PPh_2$)($SeC_6H_2Me_3$-2,4,6)$_2$]. This is the first example of a structurally characterized molybdenum(IV)oxo-selenolato complex. It contains a chelating triphosphine mono-oxide ligand. The formation can be understood in terms of an oxidative addition of dioxygen to the metal centre followed by oxygen atom transfer to the triphos ligand and reduction of molybdenum to molybdenum(IV).

In recent years oxo transfer processes have been receiving an increasing amount of attention, stimulated by the involvement of metal-oxo species in biological systems,[1] as well as in industrially relevant processes.[2] In particular molybdenum-oxo systems have been the focus of intense research into the mechanism of the oxygen transfer from the metal to a substrate due to their biorelevance.[3] Since EXAFS results suggest the presence of MoO or MoO_2 units and of thiolate ligands in these enzymes,[4] it is not surprising that modelling studies have mainly focussed on systems combining these features. Furthermore, it has been noted that systems with chelating and monodentate sulphur-based ligands are particularly suitable to study oxygen transfer reactions. Phosphines have been widely used in such studies to abstract an oxygen from the metal centre to form a very stable phosphine oxide[5] (see e.g. ref. 3), according to eq. (1).

$$L_mMo^{(n)}{=}O + R_3P \longrightarrow L_mMo^{(n-2)} + R_3P{=}O \quad (1)$$

To our knowledge, there are no reports of oxygen atom transfer processes involving complexes with selenolate spectator ligands. This is understandable considering the small number of well-characterized selenolate complexes.[6] As part of our ongoing study of the reactivity of early transition metal selenolates we have inadvertently prepared a molybdenum(IV) oxo-selenolate-triphosphine mono-oxide complex and we now report its synthesis and crystal structure and a possible pathway for its formation involving molecular oxygen.

EXPERIMENTAL

All operations were carried out under argon using standard double-manifold techniques. Analytical grade THF was dried with sodium and distilled from Na/benzophenone. $MoCl_3(MeCN)_3$[7] and NaSeMes[8] were prepared according to the literature procedures. Bis(2-diphenylphosphinoethyl)phenylphosphine (Triphos) was purchased from Aldrich and was used as received. Elemental analyses were performed by the University of Calgary, Department of Chemistry, Analytical Service Laboratory. IR spectra (2000–200 cm^{-1}) were recorded as Nujol mulls between CsI plates using a Mattson 4030 Galaxy Series FT-IR spectrometer. Routine ^1H NMR spectra were recorded on a Bruker ACE-200 spectrometer (referenced to external $SiMe_4$). ^{31}P NMR spectra were recorded on a Varian XL-200 spectrometer (referenced to external H_3PO_4).

Synthesis of $MoCl_3$(Triphos) (**1**)

$MoCl_3(MeCN)_3$ (0.2 g, 0.615 mmol) and bis-(2-diphenylphosphinoethyl)phenylphosphine (Triphos) (0.33 g, 0.615 mmol) were charged into a Schlenk flask and acetonitrile (20 cm^3) was added. The reaction mixture was stirred for 30 min at room temperature, giving a yellow–brown solution. The volatiles were then removed and the resulting yellow–brown solid redissolved in a minimum amount of CH_2Cl_2 (15 cm^3) and cooled to −25°C to give **1** as a microcrystalline yellow powder. Yield: 0.44 g; 87%. Found: C, 51.8; H, 3.9. Calc. for $C_{34}H_{33}P_3Cl_3Mo \cdot CH_2Cl_2$: C, 51.1; H, 4.2%. ^{1}H NMR ($CDCl_3$, 200 MHz), δ (in ppm): 8.1–6.8 (br, aromatics), 1.6 br s, aliphatics). IR (cm^{-1}): 322 (br) ν(Mo—Cl).

Preparation of [MoO($Ph_2P(O)CH_2CH_2P(Ph)CH_2CH_2PPh_2$)(Se-2,4,6-$(CH_3)C_6H_2)_2$] (**2**)

A mixture of **1** (0.39 g, 0.48 mmol) and NaSeMes (0.41 g, 1.95 mmol) was cooled to −196°C and degassed THF (20 cm^3) was added. The reaction mixture was then degassed three times (freeze–thaw cycles) and allowed to warm up to room temperature. The solution turned dark green over a period of 40 min. The solvent was removed *in vacuo* and all organics were removed by Et_2O extraction leaving a green solid. This solid was redissolved in THF (10 cm^3) and the same amount of hexanes was added. Dark green X-ray quality crystals deposited over a period of 2 weeks. Compound **2** crystallizes as a THF solvate. Yield: 0.177 g; 25%. Found: C, 58.1; H, 4.6. Calc. for $C_{52}H_{55}MoO_2P_3Se_2$: C, 59.0; H, 5.2%. (The poor analysis is probably due to some solvent loss.) ^{31}P NMR, δ: 107.9, 84.8, 69.7 ppm. IR (cm^{-1}): 1152 (vs), 1132 (vs) (P=O), 1082 (s), 1024 (m), 970 (m), 936 (vs) (Mo=O), 844 (w), 694(s), 570 (w), 542 (w), 518 (mw), 341 (mw), 250 (w).

X-ray crystallography study

Crystal data for [MoO($Ph_2P(O)CH_2CH_2P(Ph)CH_2CH_2PPh_2$)(Se-2,4,6-$(CH_3)_3C_6H_2)_2$] · THF. $C_{56}H_{63}P_3Se_2MoO_3$, M = 1130.89, triclinic, space group $P\bar{1}$ (No. 2), a = 12.244(6), b = 19.303(1), c = 11.872(4) Å, α = 91.17(5)°, β = 104.34(3)°, γ = 103.12(5)°, V = 2638(2) Å^3 (−121.0°C), Z = 2, λ(Mo-K_α) = 0.710 Å (graphite monochromated), D_c = 1.423 g cm^{-3}, F(000) = 1156.0, μ(Mo-K_α) = 17.38 cm^{-1}, R = 0.059, R_w = 0.058.

Data collection and refinement. A dark diamond-shaped crystal of dimensions 0.20 × 0.15 × 0.25 mm was mounted onto a glass fibre and coated with epoxy resin. Accurate cell dimensions and the crystal orientation matrix were determined on a Rigaku AFC6S diffractometer by a least-squares refinement of 25 reflections (ω scan average peak width 0.38°) (28.7 < θ < 36.5°). The choice of space group was $P\bar{1}$ (No. 2). Intensity data were collected using the ω–2θ scan method, using a scan speed of 4.0° per minute in ω and monochromatized Mo-K_α radiation (λ = 0.71069 Å) in the range 2° < θ < 25°. The intensities of 9357 reflections were measured, of which 5526 had $I > 3.00\sigma(I)$. The data were corrected for Lorentz and polarization effects. An empirical absorption correction was applied (transmission factors: 0.9101–0.9994). The data were also corrected to account for crystal decay (average drop in intensity of 3.24% for three standard reflections).

The structure was solved using direct methods using the TEXSAN[9] program package. Refinement of the structure was by full-matrix least-squares calculations, minimizing the function $\Sigma(F_o - F_c)^2$, initially with isotropic temperature factors for the non-hydrogen atoms. At an intermediate stage in the refinement a difference map revealed most of the hydrogen atoms. These were included in the subsequent cycles at geometrically idealized positions (C—H 0.95 Å) and fixed isotropic temperature factors. The refinement converged with R = 0.059 and R_w = 0.058. In the refinement cycles, weights were derived from the counting statistics. Scattering factors were those of Cromer and Mann[10] and Stewart *et al.*[11] Allowance was made for anomalous dispersion.[12] A difference map at the end of the refinement had no chemically significant features ($\Delta\rho$ of −0.92–1.33 e Å^{-3}). Figure 1 was plotted using ORTEP II.[13]

RESULTS AND DISCUSSION

Structure of **2**

Selected interatomic distances and interbond angles are given in Table 1. The crystal structure of **2** contains well-separated molecules with the molybdenum being in a distorted octahedral environment (Fig. 1). The molybdenum is bound to two selenolates *cis* to a terminal oxo group and a chelating Triphos-mono-oxide. The two bulky selenolates are bent away from the terminal oxo group [O(2)—Mo(1)—Se(1) 105.8(3); O(2)—Mo(1)—Se(2) 98.5(3)] in order to minimize their steric interaction. The Mo=O distance compares well to that of other molybdenum(IV)-oxo complexes[14] [Mo(1)—O(2) = 1.682(8) Å]. The complex adopts a facial geometry with respect to the chelating tripodal ligand. The phosphine groups are acting as a tether bringing the phosphine oxide group close to the metal centre and allowing its coordination

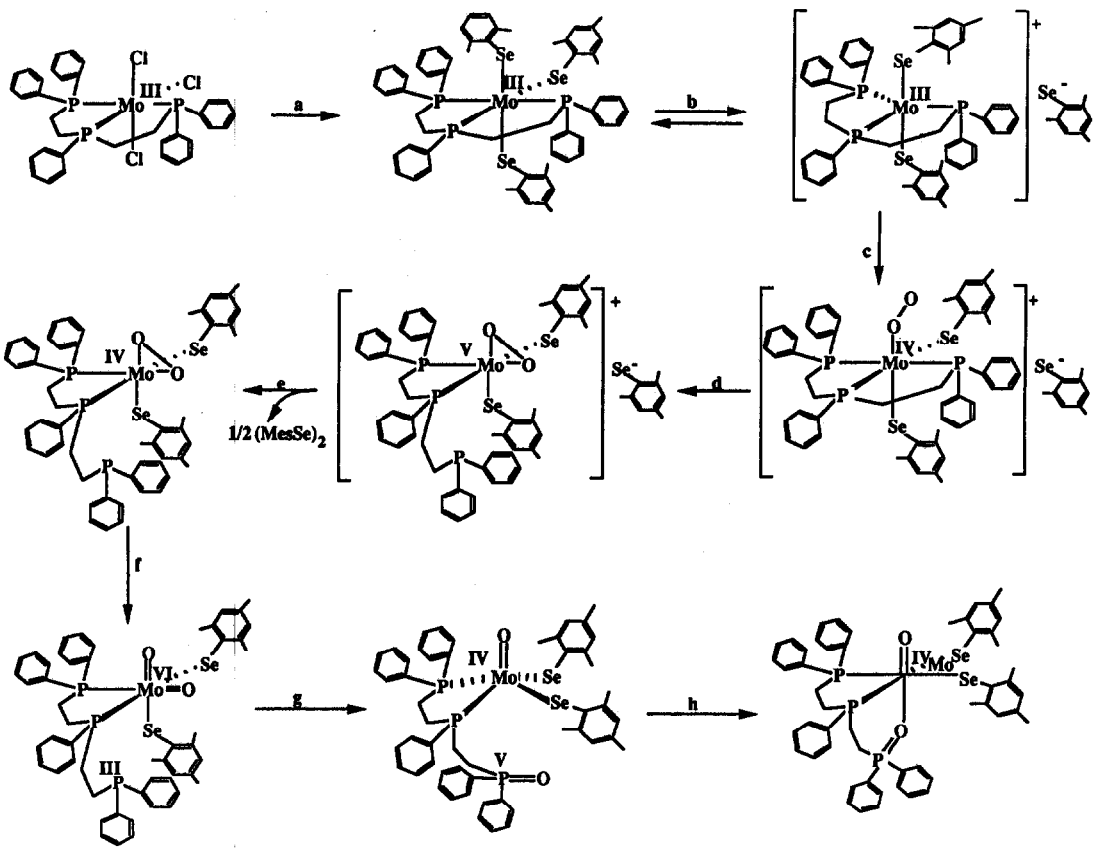
trans to the oxo group [O(1)—Mo(1)—O(2) = 160.4(3)°] and *cis* to the phosphine groups [O(1)—Mo(1)—P(2) = 74.3(2)°; O(1)—Mo(1)—P(3) = 81.2(2)°]. This geometry is understandable in terms of the arguments brought forward by Mayer and co-workers.[15] According to this the position *trans* to an oxo group is favourable for hard donors in d^2 complexes. The positions *cis* to an oxo group will be preferred by soft π-donors and acids.

The phosphine oxide group does not show any unusual features and has the dimensions P(1)—O(1) = 1.51(1), P—C = 1.79 Å (mean) and the angles O(1)—P(1)—C in the range 110.0–111.5°. It has been noted that the M—O—P linkage is very flexible and can accommodate a wide range of angles.[16a] However, the Mo(1)—O(1)—P(1) angle observed for **2** is notably smaller [135.6(5)°] compared to those found in complexes containing monodentate phosphine oxide ligands.[16] This rather small angle is probably a consequence of the steric interactions of the ligands and the requirements of the six-membered chelate ring and compares well with those observed in chelating diphosphine mono-oxide complexes. The steric requirements of the chelate ring in the molybdenum(V) complex $[MoCl_3O\{Et_2PCH_2CH_2P(O)Et_2\}]$[17] are seen as the cause for the small Mo—O—P angle of 142.3(1)°. The even more rigid aromatic backbone of the chelating ligand in $[RuCl_2\{o\text{-}C_6H_4(PMePh)_2\}\{o\text{-}C_6H_4(PMePh)(P(O)MePh)\}]$[18] leads to an even smaller M—O—P angle of 134.9(3)°.

Origin of **2**

In an attempt to prepare the triselenolato complex [(Triphos)Mo(SeMes)$_3$] (**3**) [$MoCl_3$(Triphos)] (**1**) and a stoichiometric amount of NaSeMes was stirred in THF to give a dark green solution. No resonances were observable in the ^{31}P NMR, indicating the presence of a paramagnetic intermediate (*vide infra*). After the removal of the solvent *in vacuo* and repeated washing of the remaining solid with ether it was crystallized from THF, giving X-ray quality crystals of **2**.

The presence of the MoO and OPR_3 moieties can be seen as indicators for the presence of small amounts of oxygen in the reaction mixture, as has been seen previously.[17] Only minute amounts of



Scheme 1.

adventitious oxygen are needed to yield oxo-molybdenum species, which usually crystallize well from solution.

The likely pathway for the reaction is outlined in Scheme 1. The triphosphine-molybdenum trichloride (**1**) is most likely the *mer* isomer, analogous to similar polydentate phosphine molybdenum(III) complexes.[19] After the initial metathetical reaction of **1** with NaSeMes (a) the target complex (Triphos)Mo(SeMes)$_3$ is formed. Due to steric pressure this complex is in equilibrium (b) with the ionic complex [(Triphos)Mo(SeMes)$_2$][SeMes]. Similar cationic complexes with polydentate ligands have been observed before.[20] Molybdenum(III), which is a molybdenum-based radical species, can react with dioxygen, initially forming a superoxo complex (c). Such interactions are thought of being of importance in the reversible coordination of O_2 in oxyhaemoglobin and related model complexes.[21] Conversion of the η^1-superoxo group to an η^2-peroxo group will oxidize the molybdenum(IV) to molybdenum(V), which can be reduced with selenolate (e) to give back a molybdenum(IV) complex. The selenyl radical will dimerize to give the corresponding diselenide. In the ^{77}Se NMR spectrum a signal at δ 368 indicates the presence of mesityl diselenide. The high stability of the Mo=O linkage[22] will drive the reaction towards the conversion into an $Mo^{VI}O_2$ complex with a dangling phosphine (f). These complexes are known to be easily reduced by phosphines, leading to molybdenum(IV) complexes and phosphine oxides.[3] Hence, the dangling phosphine will reduce the $Mo^{VI}O_2$ complex to a molybdenum(IV) mono-oxo complex (g). Since the phosphine oxide is attached to the coordinated phosphines, it will stay in close proximity to the molybdenum(IV) centre, allowing it to coordinate to the metal centre (h) to yield the observed complex **2**.

Supplementary material available. Tables of distances and angles, atomic coordinates of all atoms, anisotropic and isotropic thermal parameters of all non-hydrogen atoms, listings of calculated and observed ($10F_o/10F_c$) structure factors and a stereoscopic view of the packing diagram for **2** have been deposited with the Editor.

MOLECULAR STRUCTURE AND MAGNETIC PROPERTIES OF A LINEAR CHAIN COMPOUND, $Ru_2(O_2CCMePh_2)_4Cl$

F. ALBERT COTTON,* YOUNGMEE KIM and TONG REN

Department of Chemistry and Laboratory for Molecular Structure and Bonding, Texas A & M University, College Station, TX 77843, U.S.A.

(*Received* 16 *September* 1992; *accepted* 20 *November* 1992)

Abstract—The linear-chain compound $Ru_2(O_2CCMePh_2)_4Cl$ was prepared by reaction of $Ru_2(O_2CCH_3)_4Cl$ with 2,2-diphenylpropionic acid. The compound has been characterized by X-ray crystallography and magnetic susceptibility measurements from *ca* 2 to 300 K. The chloride ligands bridge the dinuclear units into linear chains. The Ru—Ru′, Ru—O (carboxylate) and Ru—Cl distances are 2.2893(9), 2.030(5) and 2.5016(6) Å, respectively. There is an antiferromagnetic electronic interaction between dinuclear units with J (coupling constant) $= -10.9\ cm^{-1}$. The magnetic moment of $Ru_2(O_2CCMePh_2)_4Cl$ at 300 K is 4.4 μ_B, which indicates three unpaired electrons in each dinuclear unit.

The first carboxylato-bridged diruthenium compound to be structurally characterized,[1] $Ru_2(O_2CC_3H_7)_4Cl$, was found to have the $Ru_2(O_2CC_3H_7)_4^+$ units linked into infinite chains by bridging chloride ions, with equal Ru—Cl distances and an Ru—Cl—Ru angle of 125.4°. Subsequently, another compound with zigzag chains has been reported.[2] In two similar compounds, however, there are chains in which the Ru—Cl—Ru bridges are perfectly linear and symmetrical.[3,4] All available data for such chain structures are summarized in Table 1. Since the $Ru_2(O_2CR)_4^+$ unit has a ground state with $S = 3/2$, the question arises as to whether there is measurable coupling between the $Ru_2(O_2CR)_4^+$ units across the Cl^- bridges. This question has already been addressed in the case of the butyrate,[5] where it was concluded that no detectable coupling exists. Since the manner in which bridging Cl^- ions might effectuate magnetic coupling between $Ru_2(O_2CR)_4^+$ units is not understood in detail, we wondered whether linear bridges might be effective even though the bent ones in the butyrate system are not.

We have chosen to carry out a magnetic study on a new linear system instead of employing one of the two previously known compounds. The reason for this was that the R group, $CMePh_2$, in the new compound is very large and thus keeps the chains well separated. It is, therefore, more likely that any magnetic coupling that might be observed would be correctly attributed to interactions along the chains through the bridging Cl^- ions. Naturally, it was necessary to determine the crystal structure of the new compound in order to be sure it fulfils the requirements of linearity and substantial separation of the chains.

EXPERIMENTAL

$Ru_2(O_2CCH_3)_4Cl$ was prepared using a literature procedure.[6] 2,2-Diphenylpropionic acid was purchased from Aldrich Chemical Company and used as received.

Synthesis

A sample (235 mg, 0.5 mmol) of $Ru_2(O_2CCH_3)_4Cl$ was dissolved in a 1:1 methanol–water (v/v) mixture (50 cm^3). 2,2-Diphenylpropionic acid (570 mg, 2.5 mmol) was added to this solution. The reaction mixture was refluxed for 5 h and the brown precipitate was collected after cooling down. It was washed with methanol and diethylether and dried *in vacuo*: yield 390 mg (68%). The product was recrystallized from CH_2Cl_2 several times. The single crystal for X-ray data collection was prepared by slow diffusion of hexane into a dichloromethane

Structure determination

A dark-brown needle crystal of $Ru_2(O_2CCMePh_2)_4Cl$ was wedged in a Lindemann capillary with a mixture of its mother liquor and mineral oil. The diffraction data were collected on a Nicolet P3/F diffractometer equipped with graphite-monochromated Mo-K_α ($\lambda = 0.71073$ Å). The determination of the crystal system, data collection procedures, structure solution and refinements were all carried out by procedures that have been described before.[7,8]

The unit cell parameters and orientation matrix were refined by a least-squares fit to the positions of 25 reflections in the range $21 < 2\theta < 30°$. The data were collected using the 2θ–ω scan technique in the range $4 < 2\theta < 50°$. The overall decay of intensity during the period of data collection was 0.3%. A correction was applied.[9] The space group was determined as $P\bar{4}2_1c$ (No. 114) based on the systematic absences. The crystallographic data are summarized in Table 2 and the final positional parameters are available as supplementary material.*

The Patterson map revealed the position of a ruthenium atom; the positions of the other non-hydrogen atoms were obtained by an alternating sequence of difference Fourier maps and least-squares refinements. All atoms were refined with anisotropic thermal parameters.

Measurements

The IR spectrum was recorded from 4000 to 400 cm^{-1} on a Perkin–Elmer 783 spectrophotometer. The electronic spectrum was recorded as a solution on a Cary 17D UV–vis spectrophotometer. Magnetic susceptibility measurements were carried out on polycrystalline samples in the 2.0–300 K temperature range with a SQUID (superconducting quantum interference device) at Northwestern University. The sample was quenched in a field of 5 kG.

RESULTS AND DISCUSSION

Structure

The tetragonal unit cell contains two formula units. The ruthenium atom and the chlorine atom reside on a $\bar{4}$ axis at 0,0,z and 0,0, 1/2, respectively. The chlorine atoms connect the Ru_2 units into linear chains. Figure 1 shows one $Ru_2(O_2CCMePh_2)_4Cl$ unit and Fig. 2 shows the stereoview of the linear chains through one unit cell and its neighbours. The chains are exactly linear (Ru—Cl—Ru′ = 180°). The Ru—Ru′ distance is 2.2893(9) Å and the Ru—Cl distance is 2.5016(6) Å (Table 3).

Magnetic properties

The magnetic susceptibilities of $Ru_2(O_2CCMePh_2)_4Cl$ were measured from *ca* 2 to 300 K. The molar magnetic susceptibilities χ_M were calculated from the measured magnetic susceptibilities (χ_g) and molar diamagnetic corrections (χ_D) were calculated from a table of Pascal constants.[10] The measured susceptibilities and the simulated curve of $Ru_2(O_2CCMePh_2)_4Cl$ are plotted in Fig. 3. The measured susceptibility plot shows a typical

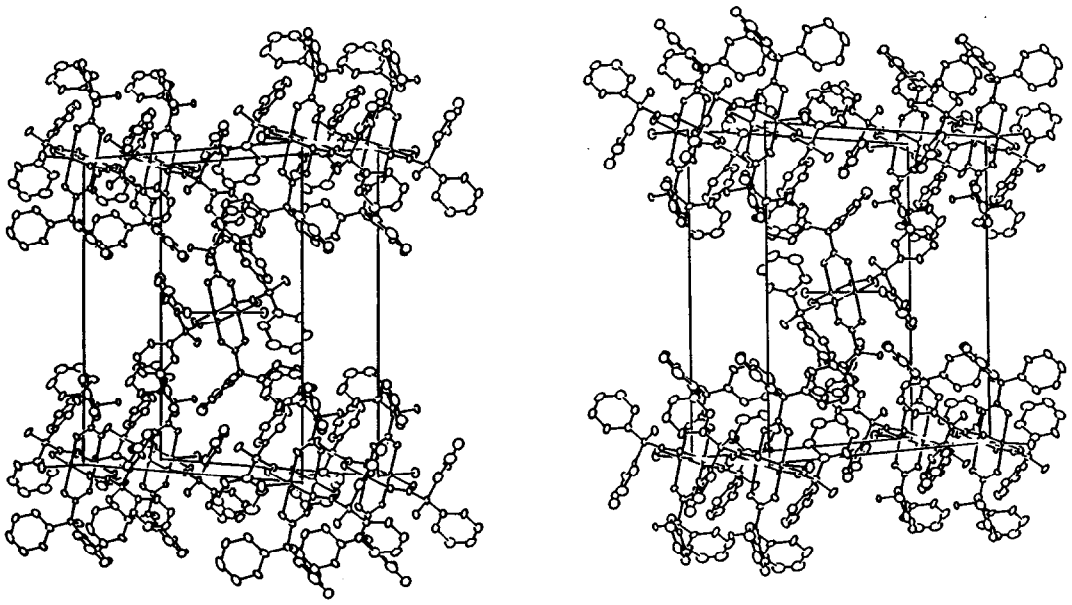

Fig. 2. Stereo ORTEP drawing of the unit cell of $Ru_2(O_2CCMePh_2)_4Cl$, showing the alignment of the linear chains.

paramagnetic impurity tail at low temperature and a turning point at *ca* 70 K. This turning point indicates that there is an antiferromagnetic exchange coupling between the $Ru_2(O_2CCMePh_2)_4^+$ units, which we believe must be through the bridging chloride ligands. These data were fitted to the one-dimensional Ising model developed by Suzuki and co-workers[11] for an infinite linear chain of antiferromagnetic exchange-coupled $S = 3/2$ units. The equation is quite long and will not be written here. The measured susceptibility of $Ru_2(O_2CCMePh_2)_4Cl$ shows the presence of a paramagnetic impurity in the low temperature region. The measured susceptibility for $Ru_2(O_2CC_3H_7)_4Cl$[5] was used to make a correction for the impurity. The measured molar susceptibility of $Ru_2(O_2CCMePh_2)_4Cl$ can be expressed as

$$\chi_M = (1-\alpha)\chi_o + \alpha\chi_{imp} + \text{tip},$$

where χ_o comes from the equation for the one-dimensional Ising model. As mentioned above χ_{imp} is the measured susceptibility for $Ru_2(O_2CC_3H_7)_4Cl$

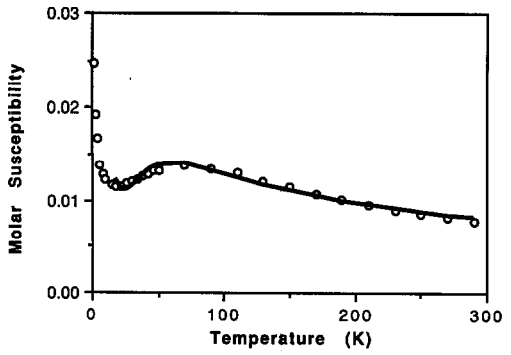

Fig. 3. Molar susceptibility per $Ru_2(O_2CCMePh_2)_4Cl$ molecule as a function of temperature. The solid line results from a least-squares fit to the theoretical equation for an infinite linear chain of antiferromagnetic exchange-coupled $S = 3/2$ units.

and α is the molar fraction of the impurity. The tip is the temperature independent paramagnetism. A g value fixed at 2.0 was used during fitting. The coupling constant J that gave the best fit is -10.9 cm^{-1}. This J is defined by expressing the coupling energy as $-2JS_1 \cdot S_2$.

Concluding remarks

The results of this study suggest that antiferromagnetic coupling between $Ru_2(O_2CR)_4^+$ units linked by Cl^- ions into infinite chains is possible, but only when the chains are linear or at least not bent at Cl^- to angles as small as 125°. It must be noted that there is one respect, other than the linearity at Cl^-, in which the present compound differs from the compounds having zigzag chains, namely, in the shorter Ru—Cl distances, 2.502 Å vs an average of 2.57 Å in the zigzag structures. It is uncertain whether this is a critical difference or not. Interestingly, the three previously known linear compounds also have Ru—Cl distances of *ca* 2.57 Å. In any event, the one-dimensional Ising model[11] for an infinite chain of coupled $S = 3/2$ units can account satisfactorily for the magnetic susceptibility of $Ru_2(O_2CCMePh_2)_4Cl$ as a function of temperature, with a significant coupling constant of -10.9 cm^{-1}. In only one other case[12] has evidence been presented for a similar situation, but the coupling was evidently much weaker and no attempt was made to fit the data to a theoretical expression.

Acknowledgements—We thank the National Science Foundation for support. We are also grateful to Professor T. J. Marks and Mr Douglas Schulz for the SQUID measurements.

(*Received* 1 *October* 1992; *accepted* 13 *November* 1992)

Abstract—The X-ray analysis showed that the title compound is isomorphous with the iron analogue reported previously. It exists as the centrosymmetric tetramer with two different types of cobalt(II) centres corresponding to octahedral $CoCl_4O_2$ and trigonal bipyramidal $CoCl_4O$ chromophores. The four cobalt atoms, bridged by two μ_3- and four μ_2-chlorine atoms, constitute a rhombus of dimensions: 3.686(3), 3.646(3) (edges) and 3.630(3), 6.37(1) Å (diagonals). The magnetic susceptibility measured over the range 4.2–293 K suggests overall ferromagnetic interactions in the tetrameric molecule. Attempts have been made to simulate the magnetism of the tetramer with the isotropic Heisenberg model. The magnetic properties of the title compound are compared to those of its iron analogue.

The formation of the first-row transition metal chloride complexes with THF such as *cis*- and *trans*-$[TiCl_4(THF)_2]$,[1] [*mer*-$MCl_3(THF)_3$], M = Sc, Ti, V, Cr,[2–4] and $[FeCl_3(THF)]$,[5] $[FeCl_3(THF)_2]$[6] is well documented. However, at the lower oxidation state only the remarkable tetrameric compound $[Fe_4(\mu_3\text{-}Cl)_2(\mu\text{-}Cl)_4Cl_2(THF)_6]$ is known.[7,8] The composition of the cobalt $CoCl_2 \cdot 1.5(THF)$ adduct[9] is similar to that of the iron tetramer $[FeCl_2 \cdot 1.5(THF)]_4$, thus the iron and the cobalt complexes could be isostructural.

In this paper the crystal structure and magnetic properties of the title compound are described.

EXPERIMENTAL

All manipulations were carried out under an inert atmosphere using a standard Schlenk system and a vacuum line. Cobalt dichloride was the commercial material. Solvents were dried and purified by standard techniques. Magnetic susceptibilities were measured by the Faraday method within the temperature range 4.2–293 K. Corrections for diamagnetism were made with Pascal's constants.[10] The following spectrophotometers were used: Specord Perkin–Elmer 180 for IR and Beckman UV 5240 for UV–vis spectroscopy.

Syntheses

A suspension of $CoCl_2$ (1.6 g, 1.25 mmol) in THF (50 cm^3) was refluxed for 10 h and the dark blue solution was filtered off and left in a refrigerator for crystallization. After 1 week the blue needles were filtered off, washed with n-hexane (3×5 cm^3) and dried *in vacuo*. Yield: 0.8 g (the yield is low because only part of $CoCl_2$ undergoes dissolution in THF). Found: Cl, 29.6; Co, 24.6. Calc. for $C_{24}H_{48}Cl_8Co_4O_6$: Cl, 29.8; Co, 24.8%. IR (Nujol): ν(Co—Cl) 310vs, 258s, 204vs cm^{-1}; other 676m, 720m, 876vs, br, 908s, 1032vs, 1172m, 1246m, 1296m cm^{-1}. UV–vis in THF: 7692, 15,530, 16,260 and 17,240 cm^{-1}. Reflectance spectrum: 14,300, 15,400, 17,200sh, 19,300sh and 23,400 cm^{-1}.

X-ray crystallography

A sample of dimensions $0.8 \times 0.8 \times 0.6$ mm was cut from a large crystal and sealed in a capillary. A Syntex $P2_1$ diffractometer (Mo-K_α radiation, graphite monochromator, $\theta/2\theta$ scanning, $2\theta_{max} < 42°$) was used. 2023 reflections were measured, from which 1852 with $I > 3\sigma(I)$ were used for calculations. Crystals were triclinic: $a = 9.931(7)$, $b = 10.573(9)$, $c = 10.919(9)$ Å, $\alpha = 62.63(7)$, $\beta = 67.88(7)$, $\gamma = 81.64(7)°$, $Z = 1$, space group $P\bar{1}$, $V = 942.7(16)$ Å^3, $d_{calc} = 1.677(4)$ g cm^{-3}, $d_{meas} = 1.69$ g cm^{-3}, $\mu = 23.3$ cm^{-1}. The structure was solved by direct methods and refined by

* Bis-μ_3-Cl-tetrakis-μ_2-Cl-dichlorohexakis(tetrahydrofuran-O)tetracobalt(II).

† Author to whom correspondence should be addressed.

full-matrix least-squares using the SHELX76 program.[11] The hydrogen atoms were placed in geometrically calculated positions. Absorption corrections following the DIFABS procedure[12] were applied; minimum and maximum absorption corrections were 0.953 and 1.091. Neutral-atom scattering factors were taken from ref. 13 and the real and imaginary components of anomalous dispersion were included for all non-hydrogen atoms. The final R was 0.0348 and $R_w = 0.0464$. For the last cycle of the refinement the maximal Δ/σ ratio was 0.04. The maximal peaks on the final difference map were 0.32 e $Å^{-3}$.

RESULTS AND DISCUSSION

Properties and structure of $[Co_4(\mu_3\text{-}Cl)_2(\mu_2\text{-}Cl)_4Cl_2(THF)_6]$

The direct reaction of anhydrous $CoCl_2$ with THF yields the blue $CoCl_2 \cdot 1.5(THF)$ compound, which can be stored under dinitrogen.

The IR spectrum shows bands at 204vs, 258s and 310vs cm^{-1}, assigned to Co—Cl vibrations. The electronic spectrum of the compound in THF solution shows bands at 7763 cm^{-1} [$^4A_2 \rightarrow {}^4T_1$(F)] and three transitions at 14,700, 15,800 and 17,200 cm^{-1} being the result of splitting of $^4T_{1g} \rightarrow {}^4T_1$(P), as in those observed for tetrahedral high-spin d^7 compounds, cf. $[Bu_4N][CoCl_4]$.[14] The complex as a solid shows bands at 14,300, 15,400, 17,200sh, 19,300sh and 23,400 cm^{-1} in its diffuse reflectance spectrum. The electronic spectra suggest that the structure of the $CoCl_2$ THF adduct possesses different solution and solid-state structures.

Crystals of the title compound are isomorphous with those of $[Fe_4(\mu_3\text{-}Cl)_2(\mu_2\text{-}Cl)_4Cl_2(THF)_6]$. The reduced cell parameters of the iron compound for the data reported in other papers[7,8] are similar to those of the cobalt compound. The structure presented here consists of centrosymmetric tetranuclear molecules. Its overall view and the numbering scheme are shown in Fig. 1. Selected bond lengths and angles are listed in Table 1. In the tetramer a nearly regular Co_4 rhombus is bridged by two μ_3-chlorine atoms Cl(1) and Cl(1′), one above and one below the Co_4 plane and in addition μ_2-chlorine atoms bridge Co—Co edges. The $[Co_4(\mu_3\text{-}Cl)_2(\mu_2\text{-}Cl)_4Cl_2(THF)_6]$ molecule contains two types of cobalt centres: the six-coordinate Co(1) atoms and the five-coordinate Co(2) atoms. The coordination sphere around Co(1) is a slightly distorted octahedron formed by two μ_3-Cl atoms, two μ_2-Cl atoms and two oxygen atoms from THF ligands (in *cis* positions). The Co(1)—Cl bond distances [2.435(2)–2.465(2) Å] are of the order of

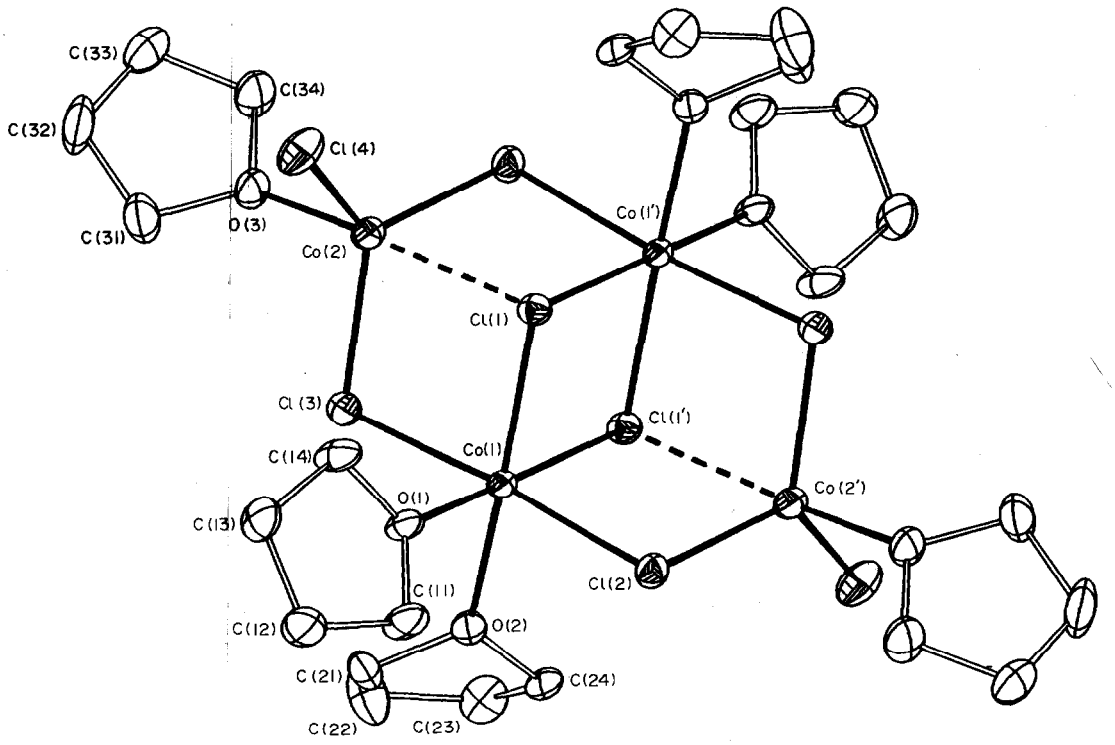

Fig. 1. Molecular structure of $[Co_4(\mu_3\text{-}Cl)_2(\mu_2\text{-}Cl)_4Cl_2(THF)_6]$. Primed and unprimed atoms are related by the inversion centre.

[a] Primed atoms are related to unprimed atoms by $1-x$, $1-y$, $1-z$.

other Co—Cl distances that have been observed in the octahedral structures of the cobalt(II) compounds.[15,16] However, the average Co(1)—(μ_2-Cl) distance of 2.46(1) Å is slightly longer than the average Co(1)—(μ_3-Cl) distance of 2.44(2) Å; in contrast to the order of corresponding Fe—Cl distances, Fe—(μ_3-Cl) is larger than Fe—(μ_2-Cl), found in the iron analogue. The Co(2) atoms have trigonal bipyramidal geometry with Cl(1)—Co(2)—O(3) [174.0(2)°] representing the nearly linear group. The equatorial plane of each bipyramid is formed by three chlorine atoms (one terminal and two μ_2-Cl type). The bridging Co(2)—(μ_2-Cl) bonds of 2.285(2) Å are slightly elongated compared to the terminal Co(2)—Cl bond of 2.216(2) Å, but all equatorial Co(2)—Cl distances are within the range observed for the tetrahedrally coordinated cobalt(II) compounds.[15] Since the Co(2) distance to the μ_3-Cl(1) atom at one apex of the bipyramid is long [2.844(3) Å] and the Co(2) atom is displaced from the equatorial plane by 0.2 Å towards the O(3) atom, the coordination of this cobalt atom can also be described as a distorted tetrahedron. It is noteworthy that in the iron tetramer the corresponding Fe—(μ_3-Cl) bond of 2.736(3) Å is shorter and the iron atom almost lies in its equatorial plane.

The THF molecules containing O(1) and O(2) atoms have the envelope conformations with oxygen atoms at the apex and the THF molecule with the O(3) atom has the twist conformation.

Magnetic properties

The temperature dependence of the magnetic moment per cobalt(II) ion, observed for the title compound, is shown in Fig. 2. The high temperature limit of μ_{eff} (4.91 B.M.) is the typical value of the magnetically isolated high-spin cobalt(II) complexes.[17] The increase of the magnetic moment on lowering the temperature (up to 7.1 B.M. at 4.2 K) suggests the overall ferromagnetic interactions in the tetrameric molecule.

The simplest isotropic Heisenberg approximation was used to interpret these magnetic properties, although in the case of orbitally degenerated cobalt(II) ions it could give only the rough estimate

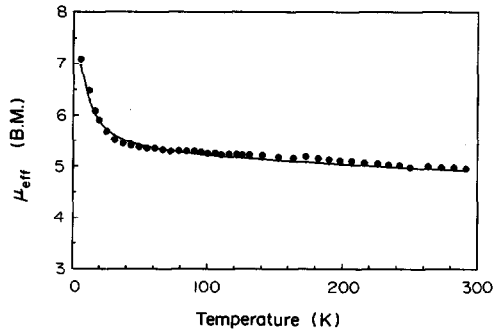

Fig. 2. Effective magnetic moment per cobalt(II) ion vs temperature curve for $[Co_4(\mu_3\text{-}Cl)_2(\mu_2\text{-}Cl)_4Cl_2(THF)_6]$. The solid line represents a fit to the theoretical expression (see text).

of the exchange interactions. The magnetic analysis was carried out with the susceptibility equation based on the Hamiltonian (1), where $S_i = 3/2$ and the numbering scheme for S_iS_j terms is that used in Fig. 1. The J_a parameter refers to the coupling of each of the six-coordinated cobalt ions with each of its five-coordinated neighbours, while the J_b parameter describes the interaction of the two six-coordinate cobalt ions.

$$H = -J_a(S_1S_2 + S_2S'_1 + S'_1S'_2 + S'_2S_1) - J_b(S_1S'_1) \quad (1)$$

A relative error minimization procedure was carried out for various fixed values of the g factor. The best-fit obtained for $g = 2.3$, $J_a = 1.8 \pm 0.5$ cm^{-1} and $J_b = 91 \pm 22$ cm^{-1} is shown by the solid line in Fig. 2. As expected the fit is not quantitative, but the agreement is remarkably good ($r = 2\%$). The low accuracy of the J_b parameter indicates that the interaction represented by this parameter has little effect on the magnetic properties, which are principally determined by four interactions represented by the J_a parameter. The insensitivity of fitting the data to the value of J_b has already been observed for other tetramers,[18] the magnetism of which has been interpreted on the basis of the same Hamiltonian as used here.

The magnetic parameters for the $[Fe_4(\mu_3\text{-}Cl)_2(\mu_2\text{-}Cl)_4Cl_2(THF)_6]$ compound have been reported.[7] The J_b value for our compound corresponds well to the ferromagnetic constant (*ca* 50 cm^{-1}) stated for the interaction between the two six-coordinated iron(II) ions in the iron tetramer. It is noteworthy that the geometries of the central dimers in both tetramers are very similar, e.g. the chlorine bridging angles are 96.0(1)° and 96.6(1)° for the cobalt and iron compound, respectively. Instead, there is the difference in the interactions (J_a) between the six- and five-coordinated metal ions, which are negative for the iron tetramer (*ca* -3 cm^{-1}) and positive for cobalt. This difference cannot be rationalized in terms of angular dependence of superexchange,[19] because the Co(1)—(μ_2-Cl)—Co(2) angles of 101.1° on averaging are larger than corresponding Fe—Cl—Fe angles of 98.7°. The theory predicts a change from ferro- to antiferromagnetic interactions upon increasing the bridging metal–ligand–metal angle.

Abstract—Tris(bis-chelate)metallic complexes formed with non-equivalent ligands having the general formula $[ML_1L_2L_3](B\emptyset_4)_2$ [where M = Cu, Zn, Cd; L_1 = 1,2-diaminoethane (en), tetramethyl en ($enMe_4$); L_2 = 1,2-diaminopropane (1,2-Pn); L_3 = 1,3-diaminopropane (1,3-Pn); $B\emptyset_4$ = tetraphenylborate] have been synthesized and characterized using IR, electronic and EPR techniques in the solid state in order to understand the nature of the coordination geometries of these complexes using copper(II) as a paramagnetic probe. The small variations observed in magnetic and metal–ligand bond parameters of these complexes are interpreted in terms of the changes in their structure and coordination geometries, depending on the type of metal ion and the value of the sample temperature.

Even though tris(bis-chelate)copper(II) complexes with equivalent ligands were studied in diluted and undiluted forms to study genuine Jahn–Teller distortion,[1–3] none of the workers so far have studied the nature of the coordination geometries of complexes with non-equivalent bidentate ligands. In the case of non-equivalent ligands one inevitably expects small differences in bond lengths and angles, hence the existence of three equivalent potential wells of the adiabatic potential energy surface does not arise, leading to the elimination of dynamic Jahn–Teller distortion. Still, one can expect either only one or two lowest potential wells to give rise to pseudo-Jahn–Teller distortions. Due to this we have taken up the synthesis and spectroscopic studies of a series of nine metallic complexes formed with non-equivalent ligands having the general formula $[ML_1L_2L_3](B\emptyset_4)_2$, where M, L_1, L_2, L_3 and $B\emptyset_4$ are copper(II), zinc(II) and cadmium(II), 1,2-diaminoethane (en), tetramethyl en ($enMe_4$) and diethyl en ($enEt_2$), 1,2-diaminopropane (1,2-Pn) and 1,3-diaminopropane (1,3-Pn) and tetraphenylborate, respectively, to study the difference between the coordination geometries of equivalent and non-equivalent nitrogens in the coordination sphere of CuN_6 complexes and the fluxional nature using IR, electronic and EPR spectral techniques.

EXPERIMENTAL

En, $enMe_4$, $enEt_2$, 1,2-Pn, 1,3-Pn, $NaB\emptyset_4$ and metal chlorides of copper, zinc and cadmium were commercially available. The present complexes were obtained by adding L_1 (11 mmol), L_2 (11 mmol) and L_3 (11 mmol) (dissolved in water) to a hot aqueous solution of the corresponding metal chloride (10 mmol). A hot aqueous solution of $NaB\emptyset_4$ (20 mmol) was then added dropwise to the above mixture. The complexes were filtered and washed in water and dried for several days over P_4O_{10}. Copper(II) doped zinc and cadmium complexes were obtained by the usual procedure of

* Author to whom correspondence should be addressed.

evaporation of the aqueous solution containing copper(II) and zinc(II) or cadmium(II) complexes (Cu : Zn/Cd = 1 : 100). The IR, electronic and EPR measurements were collected as previously described.[4]

RESULTS AND DISCUSSION

Table 1 gives the analytical data of these complexes, along with their vibrational modes in the far-IR region and the reflectance electronic spectral values. In undiluted copper(II) complexes copper(II) hyperfine lines are obtained, perhaps due to the presence of the bulky anion. The values of g, A, $\Delta A_{\parallel}$% and the metal–ligand σ-bond parameter, α_{σ}^{2}, obtained from the expression[5] given below, are given in Table 2, along with the corresponding values in complexes having equivalent ligands.

$$\alpha_{\sigma}^{2} = \frac{|A_{\parallel}|}{P} + (g_{\parallel} - 2.0023) + \frac{3}{7}(g_{\perp} - 2.0023) + 0.04 \quad (1)$$

A negative shift of *ca* 35 cm^{-1} from free ligand values in the IR bands of $\nu_s(NH_2)$ (3260–3330 cm^{-1}), $\nu_{as}(NH_2)$ (3230–3270 cm^{-1}), ν(NH) (3120–3160 cm^{-1}) and $\delta(NH_2)$ (1570–1612 cm^{-1}),[8] the absence of any band in the frequency range 2820–2760 cm^{-1} of alkylated complexes[9] and the bands in the range 460–480 cm^{-1}, which correspond to ν(M—N), ensure that all the six nitrogens in these complexes are bonded to the metal ions. The ligand reflectance spectra of copper(II) complexes are asymmetric with a prominent peak in the range 17,800–18,500 cm^{-1}, which indicates tetragonally distorted octahedral coordination geometry.[10] The asymmetric nature of these spectra is also indicative of a second peak at lower energies (7–9000 cm^{-1}), similar to that of other $[Cu(chelate)_3]^{2-}$ cations.[3,6,11] The correct value of this low energy peak can only be obtained when a Gaussian analysis of the reflectance spectra is made.[12]

From Table 2, it is evident that the values of g, A and α_{σ}^{2} for equivalent and non-equivalent ligands are different, indicating differences both in the structure and the metal–ligand σ-bond strengths of these complexes. No sudden change in the EPR spectra was found at low temperatures in the present complexes, unlike the case of equivalent ligand complexes. The small differences noticed in $g_{\parallel}$ and $A_{\parallel}$ values of all the present complexes, except in $[Cu/Zn(enEt_2)(1,2\text{-Pn})(1,3\text{-Pn})](B\text{Ø}_4)_2$ where no change is observed in $g_{\parallel}$ and $A_{\parallel}$ values, with temperature can be attributed both to the temperature dependent structural changes and to the fluxional nature of the coordination geometries. The metal–ligand σ-bonds of the present complexes are found to have almost the same strength with moderate covalency.

(*Received* 18 *August* 1992; *accepted* 11 *November* 1992)

Abstract—The complex $[Y(NO_3)_3(OH_2)_3]\cdot$(dibenzo-24-crown-8) (DB24C8) has been prepared and characterized by elemental analyses, IR spectra and molar conductance. The structure of the complex has been determined by single-crystal X-ray diffraction. The yttrium(III) ion is nine-coordinate, bonded to three bidentate nitrate groups and three water molecules. The crown ether molecule is hydrogen bonded to these three water molecules. The average Y—O(nitrate) and Y—O(water) distances are 2.426(4) Å and 2.344(4) Å, respectively. The average O(water)···O(crown) hydrogen bonded separation is 2.787 Å. The coordination geometry of the yttrium(III) ion is a distorted, tricapped trigonal prism.

Recently, Rogers *et al.*[1–7] reported a series of hydrogen bonded complexes of rare earth ions with crown ethers. In their studies, it was found that hydrated yttrium nitrate reacted with 12-crown-4 in CH_3CN or in a 3/1 CH_3CN:HOMe mixture to form the anhydrous product $Y(NO_3)_3$(12-crown-4).[8] However, under the same conditions hydrated yttrium nitrate reacted with 15-crown-5 to yield $[Y(NO_3)_2(OH_2)_5](NO_3)\cdot 2$(15-crown-5).[2]

In order to investigate the possibility that one crown ether is bonded directly to two yttrium ions in one molecule, we recently prepared the complexes of hydrated yttrium nitrate with DB24C8 and dibenzo-30-crown-10 (DB30C10) in acetonitrile. Under the same conditions of preparation, we obtained two different kinds of complex: $[Y(NO_3)_2(DB30C10)(OH_2)_2]_2\cdot[Y(NO_3)_5]$ and $[Y(NO_3)_3(OH_2)_3]\cdot$(DB24C8). In the former complex, the Y^{3+} ions are directly bonded to three of the crown ether oxygen atoms[9] and in the latter complex the Y^{3+} ion is not directly bonded to the crown ether oxygen atoms. In this paper, we report the synthesis, characterization and crystal structure of a hydrogen-bonded DB24C8 complex with yttrium nitrate.

EXPERIMENTAL

Reagents

Hydrated yttrium nitrate was prepared by dissolving the Y_2O_3 (Anala R) in 1:1 nitrate acid. The ligand was obtained from Shanghai Reagent Company and purified by recrystallization from ethanol before using, m.p. = 101.5–102.0°C.

Chemical and physical measurements

The yttrium ion content was determined by EDTA titration using Xylenol-orange as an indicator. Carbon, nitrogen and hydrogen were determined using a Carlo–Erba 1106 elemental analyser. The IR spectra were recorded in the 4000–200 cm^{-1} region using KBr pellets and a 170 SX FTIR spectrometer. Conductivity measurements were obtained with a DDS-11A type conductivity bridge for a freshly prepared solution in acetone at 25°C.

* Author to whom correspondence should be addressed.

X-ray diffraction intensities were collected at room temperature on an R3M/E diffractometer with graphite-monochromated Mo-K_α radiation.

Preparation

A solution of $Y(NO_3)_3 \cdot 6H_2O$ (0.42 mmol) in acetonitrile (3 cm^3) was added dropwise to a solution of DB24C8 (0.2 mmol) in acetonitrile (3 cm^3). The mixture was stirred at room temperature over 24 h. The precipitated solid complex was filtered, washed with acetonitrile and then dissolved in nitromethane. The solution was placed in a desiccator over $CaCl_2$ at room temperature. After *ca* 2 weeks the colourless crystal of the title complex formed from the solution. Found: C, 37.2; H, 4.9; N, 5.7; Y, 11.4. Calc. for $C_{24}H_{38}N_3O_{20}Y$: C, 37.1; H, 4.9; N, 5.4; Y, 11.4%.

X-ray structure determination

The structure was solved by the Patterson method and subsequent difference Fourier techniques and refined by full-matrix least-squares methods with anisotropic thermal factors for all non-hydrogen atoms. The crown ether hydrogen atoms were placed in calculated positions. All calculations were performed using the SHELXTL system of computer programs. The final values $R = 0.0531$ and $Rw = 0.0435$ were obtained. The crystal data are listed in Table 1.

RESULTS AND DISCUSSION

Solubility and molar conductance

The complex is sparingly soluble in benzene and tetrachloromethane, slightly soluble in ethyl acetate, diethyl ether and chloroform, and partly soluble in acetonitrile, nitromethane and acetone. The molar conductance measured in acetone at 25°C is 4.2 Ω^{-1} cm^2 mol^{-1}, indicating that the complex is a non-electrolyte.[10] This indicates that all the nitrate groups in the complex are coordinated to the yttrium ion, consistent with the results of the IR spectra and the crystal structure determination.

IR spectra

After the formation of the complex the characteristic frequencies of the free ligand, ν(Ar—O—R) at 1256 and 1224 cm^{-1} and ν(R—O—R) at 1126 and 1102 cm^{-1}, showed small shifts of 5 and 33 cm^{-1} and 13 and 22 cm^{-1}, respectively, towards lower wave numbers. Moreover, no bands assignable to the ν(Y—O_{crown}) stretching frequency in the 380–400 cm^{-1} region[11] were found in the IR spectrum of the complex, suggesting that the ligand does not directly coordinate to the yttrium ion.

In the IR spectrum of the complex the absorptions appearing at 3258, 1664 and 571 cm^{-1} due to ν(OH), δ(HOH) and ρ_γ(HOH) indicate that coordinated water molecules exist in the complex.[12] Compared with the normal ν(OH) band (*ca* 3400 cm^{-1}) of the water molecule, the absorptions of ν(OH) of this complex show a red shift, which suggests that hydrogen bonds exist in this complex.[13,14] This inference was verified by the result of the structure determination.

The characteristic frequencies of the coordinating nitrate groups appear at 1777($\nu_2+\nu_5$), 1734($\nu_2+\nu_6$), 1503(ν_1), 1295(ν_4), 1031(ν_2) and 815(ν_3) cm^{-1}, and the difference between two strongest absorptions (ν_1 and ν_4) of the nitrate groups is over 200 cm^{-1}, indicating that the nitrate groups in the complex coordinate to the yttrium ion as bidentate ligands.[12]

Structural studies

The selected bond lengths and bond angles are given in Tables 2 and 3. Figure 1 shows the molecular structure of the complex and Fig. 2 illustrates the molecular packing arrangement in the unit cell.

Yttrium(III) *coordination*

The Y^{3+} ion is nine-coordinated with three bidentate nitrate groups and three water molecules, forming a distorted tricapped trigonal prism (Fig. 3) with nitrate oxygen atoms capping each quadrilateral face: O(9), O(12) and O(15). This same geometry was observed for $[Y(NO_3)_2(DB30C10)(OH_2)_2]^+$,[9] $[Y(NO_3)_3(OH_2)_2(NCMe)][Y(NO_3)_3(OH_2)_2(HOMe)]\cdot 2(B15C5)\cdot HOMe$[6] and $[MCl(OH_2)_2(18C6)]^{2+}$ (M = Y, Dy).[3]

The average Y—O(nitrate) and Y—O(water) bond lengths are 2.426(4) and 2.344(4) Å, respectively. These are in good agreement with other Y^{3+} complexes of similar geometry; $[Y(NO_3)_2(OH_2)_2(DB30C10)]^+$:[9] Y—O(nitrate) = 2.427, Y—O(water) = 2.353 Å; $[Y(NO_3)_3(OH_2)_2(NCMe)][Y(NO_3)_3(OH_2)_2(HOMe)]\cdot(B15C5)\cdot OHMe$:[6] Y—O(nitrate) = 2.42(3), Y—O(water) = 2.33(3) Å; $Y(NO_3)_3(OH_2)_3\cdot 2(C_{10}H_8N_2)$:[15] Y—O(nitrate) = 2.45(3), Y—O(water) = 2.32(1) Å.

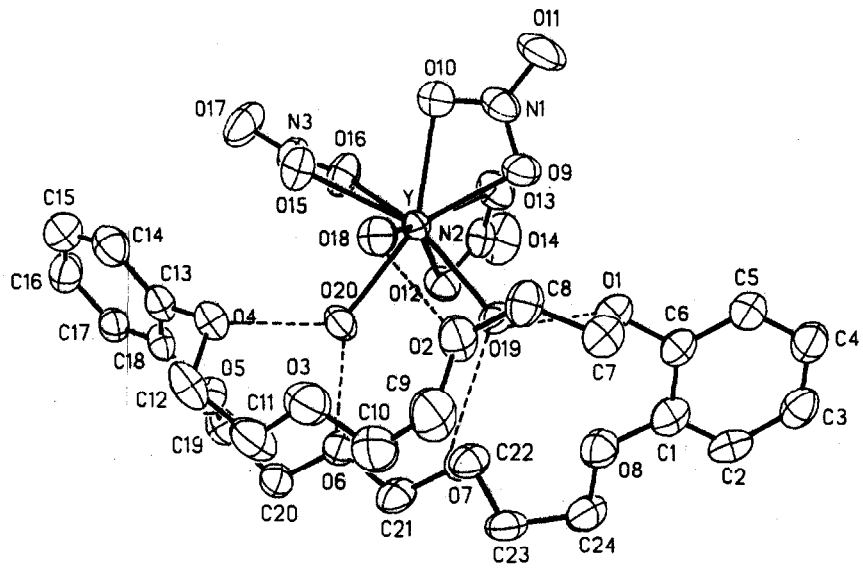

Fig. 1. The molecular structure of the complex.

Hydrogen bonding

Since it was not possible to locate the coordinated water hydrogen atoms, the presence of hydrogen bonding must be inferred from close O···O non-bonded contacts.[1] It can be seen that the five hydrogen atoms in three coordinated water molecules are bonded to five oxygen atoms in the crown ether. The HO—H···O contacts range from 2.705 to 2.839 Å and average 2.787 Å (see Table 4); this value is close to those observed in $[Y(OH_2)_8]Cl_3 \cdot$(15-crown-5) [average 2.76(7) Å],[1] $[UO_2(NO_3)_2(OH_2)_2] \cdot$(dibenzo-18-crown-6)$_2$ [range from 2.800 to 2.840 Å][16] and $[Y(NO_3)_3(OH_2)_2(NCMe)][Y(NO_3)_3(OH_2)_2(OHMe)] \cdot 2(B15C5) \cdot HOMe$ [average 2.77(7) Å].[6]

Crown ether conformation

Even the relatively weak forces involved in hydrogen bonding to crown ether oxygen atoms are known to influence the crown ether conformation.[17,18] The hydrogen bonding in the title complex makes the symmetry of the crown ether lower, from C_i in the free crown ether[19] to C_1 in the title complex. From the torsion angles given in Table 5 it can be seen that in order to form the

hydrogen bonding more efficiently the alkyl O—C—C—O angles (range: 61.0–72.8°) become smaller compared with those of the free crown ether (range: 78.0–84.1°). This change can also be found in $[(KNCS)_2(DB24C8)]$,[20] in which the mean C—O(alkyl) distance is 1.44(1) Å and the alkyl O—C—C—O angles range from 61° to 68°. The average distances and angles are: C—O(alkyl) = 1.428(9), C—O(aryl) = 1.380(8), C—C(alkyl) = 1.480(10), C—C(aryl, crown only) = 1.397(9) Å; O—C—C(alkyl) = 110.0(6)°, O—C—C(aryl) = 120.3(6)°, C(alkyl)—O—C(alkyl) = 113.1(5)°, C(alkyl)—O—C(aryl) = 115.3(5)°.

CONCLUSIONS

The ionic diameter of yttrium(III) is small and the cavity diameter of DB24C8 is too large; furthermore, compared with DB30C10, the flexibility of DB24C8 is less and so DB24C8 cannot adopt the folded conformation necessary to achieve the correct Y—O distance. In the presence of nitrate groups, Y^{3+} ion cannot directly coordinate to DB24C8 and it exists in the lattice by hydrogen bonding through the coordinated water molecules.

OPTICAL AND ESR STUDIES ON DIMERIZATION OF METALLOTETRA-CROWNED PHTHALOCYANINES

DAMODAR REDDY and T. K. CHANDRASHEKAR*

Department of Chemistry, Indian Institute of Technology, Kanpur 208016, India

(*Received* 31 *July* 1992; *accepted* 10 *November* 1992)

Abstract—The cation and solvent induced dimerization of free base tetra-crowned phthalocyanine (H_2tCRPc) and its metal derivatives (Ag^{2+} and VO^{2+}) have been studied by optical and ESR methods. Dimerization induces a blue shift of Q and Soret bands in the optical spectrum with a reduction in intensity. The exciton formalism accounts for the spectral blue shift upon dimerization. ESR studies reveal the formation of a cofacial dimer with axial symmetry upon the addition of cations. The measured zero-field splitting values in parallel and perpendicular regions suggest that the two paramagnetic centres are separated by 4.9 Å in VOtCRPc and 4.8 Å in AgtCRPc. In the micellar medium, the dimerization effects are observed only in 0.1 M SDS, while the tetra-crowned phthalocyanines remain aggregated in 0.1 M CTAB and in 5% TX-100.

Alkali cations are known to induce dimerization in porphyrins and phthalocyanines appended with crown ether cavities.[1,2] Many recent studies on these systems have been directed towards an understanding of the dynamics of the dimerization process.[3–5] Kobayashi and Lever have recently studied the dimerization of various metallocrowned phthalocyanines and have presented evidence for the formation of both non-cofacial and cofacial dimers in solution upon the addition of cations.[6] We have been interested in the dimerization of porphyrin systems and our previous studies have shown that the dimerization in porphyrins can be promoted by addition of crown ethers and cations.[7–9] In continuation of our efforts towards an understanding of the dimerization process we have investigated cation- and solvent-induced dimerization of Ag^{2+} and VO^{2+} derivatives of tetra-crowned phthalocyanines (Fig. 1). Being good paramagnetic probes, Ag^{2+} and VO^{2+} ions offer an opportunity to study dimerization by the ESR technique. Furthermore, the dimerization is also followed in micellar medium. It is shown that the dimerization effects are observed only in anionic sodium dodecyl sulphate (SDS), while in cationic cetyl trimethyl ammonium bromide (CTAB) and neutral triton-X-100 (TX-100) the crowned phthalocyanines remain aggregated even in dilute solution.

RESULTS AND DISCUSSION

$CHCl_3$ exhibit well-defined Q and Soret bands in the visible region. The addition of increasing amounts of K^+ ions to a $CHCl_3$ solution results in the following changes: (a) the Q bands are shifted to blue (46 nm for VO^{2+} and 37 nm Ag^{2+}) with broadening and reduced absorbance; and (b) Soret bands also experience a small blue shift (8–10 nm) with reduced absorbance (Table 1). Figure 2 shows the absorption spectra of VOtCRPc before and after the addition of K^+ ions. These results suggest the existence of an equilibrium involving two species.[6] Based on our earlier findings[7–9] and literature reports,[1–3] it is concluded that the two species involved are monomers and dimers of MtCRPc. In the absence of K^+, under our experimental conditions, both VO^{2+} and Ag^{2+} derivatives exist as monomers and the addition of K^+ ions strongly drives the equilibrium to the dimer side. The driving force for the formation of the dimer is the affinity of appended crown ethers for alkali cations[10] to form a cation crown ether complex, thereby bringing the two phthalocyanine rings in close proximity and promoting interaction between the two π-systems.

The inset in Fig. 2 gives a plot of the intensity changes of the Q bands of AgtCRPc due to monomeric and dimeric species upon the addition of increasing amounts of K^+ ions. The shape of the curve reveals that the process of dimer formation involves more than one step. A non-sandwich type dimer of the type MtCRPC-K^+-MtCRPc, involving only one K^+ ion per dimer, and a sandwich type dimer involving two or more cations can be visualized from the fact that crown ethers are known to form both sandwich and non-sandwich type complexes with alkali cations.[10] The intensity decrease (monomer peak) and increase (dimer peak) is sharp at lower concentrations of K^+ ions, probably suggesting the formation of a non-sandwich type dimer. At higher concentrations of K^+ the non-sandwich type dimer encapsulates more K^+ ions to change over to a sandwich type dimer, bringing two phthalocyanine rings in a cofacial geometry.[6] ESR studies (*vide infra*) further confirm the presence of two phthalocyanine rings in a face-to-face geometry.

In order to see whether different cations have different effects on dimer formation optical spectra of solutions containing the same concentration of MtCRPc (7.96×10^{-6} M) and KCl (1.6×10^{-5} M), $NH_4(CH_3COO)_2$, NaCl, LiCl and CsCl were recorded. It was found that complete dimerization was observed in the presence of K^+ and NH^+_4 ions, about 70% dimerization with Cs^+ ions, while no detectable cofacial dimer was observed with Li^+ and Na^+ ions. However, the addition of high concentrations of Na^+ ions did decrease the absorb-

ance of the monomer peak, probably suggesting a non-sandwich type complex formation. Similar effects were observed for several crown-ether linked porphyrins and phthalocyanines upon complexation with alkali metal cations.[2,3,6] The nature of the complex (sandwich type or non-sandwich type) depends on the size of the crown ether cavity and the ionic radii of the cation. Benzo-15-crown-5 (the crown ether linked to the phthalocyanine ring in the present study) is known to form stable sandwich-type complexes with K^+ and NH^+_4 ions, while the stability of the sandwich type complex formed by Cs^+ ions is much less relative to K^+. On the other hand, Na^+ ions form a non-sandwich type complex where the Na^+ ions are encapsulated in the cavity of the crown ether, whilst no detectable complex formation is observed with Li^+ ions.[10,11] Thus, the observed effects in the electronic spectra are in line with these results.

Effect of solvents

The intensity and position of the Q bands of VO^{2+} and Ag^{2+} derivatives are highly dependent upon the solvent used. Figure 3(a) shows the effect of various solvents on the absorption spectrum of AgtCRPc. The Q bands at 674 and 642 nm (shoulder) in $CHCl_3$ correspond to the monomeric AgtCRPc. In polar solvents like ethanol and butan-1-ol the monomeric band at 674 nm loses considerable intensity and a new band at *ca* 630 nm gains intensity, indicating the presence of dimeric and higher aggregates in solution. However, in methanol the band structure is completely lost and a featureless, broad absorption in the Q band region clearly suggests the formation of oligomeric AgtCRPc in solution. The addition of a small amount of methanol to a $CHCl_3$ solution of AgtCRPc generates the dimeric species and the amount of dimeric species formed was found to be dependent on the concentration of methanol. Figure 3(b) shows the effect of increasing methanol concentration on the absorbance of the peak at 633 nm, due to the dimeric species. It is apparent from the plot that at *ca* 10% methanol concentration (v/v) in $CHCl_3$ solution maximum dimeric species are formed and any further increase leads to the formation of the high aggregates. Thus, at lower concentrations of methanol ($\leqslant$ 10%) the change in the absorption spectrum exactly parallels that observed upon the addition of K^+ or NH^+_4 ions, implying that the dimerization can also be induced by the solvents. VOtCRPc also shows a similar behaviour. These data are consistent with earlier reports on the metallo-crowned phthalocyanines.[6]

(2) *Micellar medium.* The optical absorption spectrum of a *ca* 10^{-6} M solution of H_2tCRPc in SDS (0.1 M) shows well-defined Q and Soret bands, while in CTAB (0.1 M) and 5% TX-100 the absorption bands are broad and featureless, suggesting that H_2tCRPc remains monomeric in SDS while the same is aggregated in CTAB and TX-100. The metal derivatives also show a similar behaviour.

The effect of the addition of increasing concentrations of NH^+_4 ions to a 2.5×10^{-5} M solution of H_2tCRPc in SDS (0.1 M) is displayed in Fig. 4.

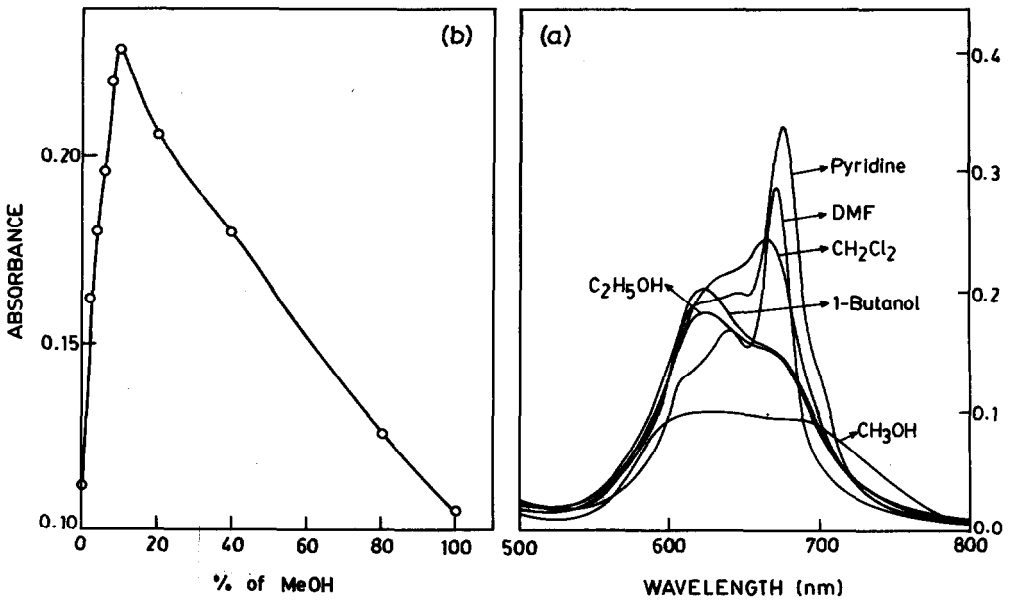

Fig. 3. (a) Absorption spectra of AgtCRPc (1.52×10^{-5} M) in different solvents. (b) Absorption changes of AgtCRPc at 633 nm (dimer peak) with increasing concentrations of CH_3OH in $CHCl_3$ solution.

The inset shows the plot of intensity changes of prominent Q-band(s) for H_2tCRPc and CutCRPc vs the concentration of NH^+_4 ions. The observed changes are similar to those seen in non-aqueous medium for the dimerization process. The progressive decrease in absorbance on the addition of cations are analysed by a method described previously[9] to evaluate the formation constants for the

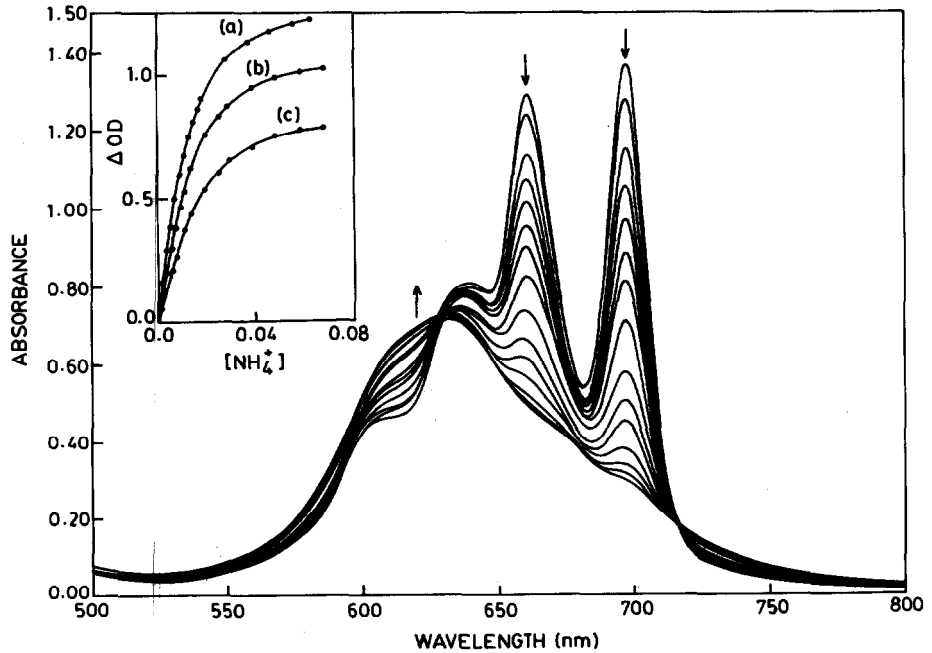

Fig. 4. Effect of the addition of increasing amounts of NH_4^+ ions (1.94×10^{-3}–6.80×10^{-2} M) on the absorption spectrum of H_2tCRPc (2.5×10^{-5} M) in SDS (0.1 M). Inset: intensity changes of prominent Q band(s) of (a) CutCRPc (674 nm), (b) H_2tCRPc (700 nm), and (c) H_2tCRPc (660 nm) on the addition of increasing amounts of NH_4^+ ions in SDS (0.1 M).

dimerization process, which can be represented as

$$2P + nC^+ \rightleftharpoons^{K} (P_2C_n)^{n+},$$

where P stands for phthalocyanine containing crown ether rings, C^+ represents the alkali cation added to induce the dimerization process and n is the number of cations. The value of n was varied from 1 to 4. A computer program was devised to carry out the calculations using the Newton–Raphson iterative method. Calculations were performed varying the value of n from 1 to 4 and in all the cases the best fit was observed when $n = 4$, suggesting that four cations are involved per dimer unit. The magnitudes of the formation constants are comparable to those observed for the cation–crown ether induced dimerization of water soluble porphyrins.[3,9]

Origin of dimerization induced shifts
