RAPID SYNTHESIS OF TiN, HfN AND ZrN FROM SOLID-STATE PRECURSORS

J. C. FITZMAURICE, A. HECTOR and I. P. PARKIN*

Department of Chemistry, The Open University, Milton Keynes MK7 6AA, U.K.

(*Received* 10 *February* 1993; *accepted* 16 *February* 1993)

Abstract—Microwave or conventional oven initiation of the reaction between lithium nitride and anhydrous metal chloride (M = Ti, Zr, Hf) produces metal nitride MN, dinitrogen and lithium chloride via a metathesis reaction. The metal nitrides were characterized by X-ray powder diffraction, SEM, EDAX, IR, magnetic moment measurement and microanalysis.

Titanium nitride is a hard, durable refractory material with reflectance properties similar to that of gold.[1] It has been used as a hardness coating[2] for drill bits, as an abrasive and for microelectronic applications.[3] Conventionally titanium, zirconium and hafnium nitrides have been made by either high-temperature combination of the metal or metal hydride with ammonia/dinitrogen[4] or by reaction of metal tetrachloride with ammonia[5] at 800°C.

Current interest in finding low-energy "chemical molecular precursor routes" to ceramic nitrides has led to the study of facile unimolecular or ammonia-initiated bimolecular degradation of homoleptic metal amides.[6] This has been studied for thin film deposition[7] and for bulk solid synthesis.[8] Unfortunately, these routes ofen suffer from sample contamination either in the form of an oxide (from the reactor walls) or a carbide—the latter being formed from competitive decomposition pathways within the amide precursor.[9] Solid state routes to metal sulphides and phosphides have been developed by Kaner *et al.* by reaction of anhydrous metal halides with alkali metal pnictides[10] or chalcogenides.[11] Such reactions provide a facile method of producing low-impurity ceramic materials,[12] often with the reaction once initiated being highly exothermic.

We report here an alternative solid-state route to crystalline TiN, ZrN and HfN via a rapid, low-temperature initiated precursor approach.

EXPERIMENTAL

All reactions and preparations were carried out *in vacuo* or in a dinitrogen filled dry-box. Glass ampoules were made out of either pyrex, borosilicates or quartz glass and were either flame-dried under vacuum or heated to 400°C for 6 h prior to reaction. All solvents were degassed; THF was distilled from sodium/benzophenone and stored over 4 Å molecular sieves prior to use. Metal halides and lithium nitride were purchased from Aldrich Chemical Co. and Strem Chemicals and used as supplied. X-ray powder diffraction patterns were obtained using a Siemens D5000 diffractometer using Cu-K_α radiation, SEM and EDAX analysis on a Jeol JSM 820 equipped with Kevex program,[13] FT-IR as pressed KBr pellets on a Nicolet 205 (CsI), GC on a Pye–Unicam 204 with a 5 Å sieve column using a thermal conductivity detector and helium carrier gas, and magnetic moment measurements were determined by an Oxford Instruments resistive Faraday balance. Nitrogen microanalyses were measured by fierce condition combustion (powdered tin and maximum oxygen flow at 1800°C) by MEDAC Ltd, Brunel University. Thermal initiation of the reactions was performed in a 750 W industrial microwave oven with a ceramic brick support or a Lenton Thermal Designs Tube furnace.

Transition metal nitride preparation (M = Hf, Zr)

Lithium nitride (50–100 mg) and anhydrous metal chloride, MCl_4 (such quantities needed to

* Author to whom correspondence should be addressed.

achieve a 1 : 1 molar ratio of chlorine to lithium), were ground together using an agate pestle and mortar in a nitrogen filled dry-box. The powder was added to a thick-walled glass ampoule, sealed under vacuum and sonicated with an ultrasonic gun for 10 min. The ampoule was then wrapped in glass wool and placed in a conventional oven at 400°C for 5–10 min. After a variable induction time of a few seconds to 5 min (dependent on the sample) a red glow eminated from the ampoule for 2–3 s, during which time a white solid sublimed onto the reactor walls, whilst the main bulk of the product was contained in a grey–black solid-fused lump. The ampoule was removed from the oven, allowed to cool to room temperature and then broken open in a nitrogen filled glove-box. Trituration of the grey–black solid with THF ($3 \times 20\ cm^3$) for 10 h produced a fine black precipitate and a cloudy THF layer. Evaporation of the THF filtrate produces crystals of a white solid identified as LiCl by X-ray powder diffraction, lithium flame test and EDAX analysis (only chlorine present). The black powders were identified as transition metal nitrides by X-ray powder diffraction, EDAX analysis, magnetic moment measurements and nitrogen microanalysis. Ceramic yields, based on the metal after THF trituration, varied from 60% ZrN to 90% HfN. Microanalysis for HfN; Observed (%): $C < 0.2$, $H < 0.2$, $N = 6.41$, $Li < 0.25$, $Cl < 0.25$; required (%) $N = 7.25$. Magnetic moment measurements (0.4 T, 298 K), HfN: $\mu = 1.73$ B.M.

The same general procedure was followed for M = Ti; however, the product was not contained in a fused black lump but was uniformly distributed on the walls of the ampoule—typically the yield of crystalline TiN was less than 50%.

Alternative processes

(1) An identical procedure to that outlined above can be performed by initiating the reaction using a microwave oven with a variable induction period of 1–5 min depending on the sample. The work-up and properties of the materials obtained were identical to those initiated in a conventional oven.

(2) The metal nitrides produced can also be washed free of the lithium chloride by-product by triturating with degassed water for 10 min.

Mixed metal nitrides

Attempts at making mixed metal nitrides were investigated under the same conditions and work-up conditions as above, except equimolar quantities of the starting metal halide powders were ground together before adding lithium nitride.

Detection of evolved dinitrogen

These reactions were identical to those described above, except that evacuated glass ampoules sealable with Teflon taps and an adaptor suitable for use with a GC were used. After the reaction had been initiated (by the conventional oven technique) and allowed to cool to room temperature the ampoule was opened to an argon line for a few seconds to equalize the pressure and the gases in the ampoule run on a GC. This showed the presence of dinitrogen in excess of that of the initial argon and quantified as at least 20% of the nitrogen in the initial lithium nitride.

CAUTION! The reaction of hydrated metal halides with lithium nitride invariably leads to an uncontrollable exothermic reaction, which results in explosion of the ampoule. The reaction of anhydrous halides with lithium nitride is also extremely exothermic and approximately one in 20 of the ampoules explodes if poorly annealed. **The use of a safety screen around the oven and suitable tongs to handle the ampoule is advisable.** No reaction was observed between the anhydrous metal halides and lithium nitride on manually grinding the reagents together.

RESULTS AND DISCUSSION

Thermal initiation of the reaction of an anhydrous group IVA metal chloride ($TiCl_4$, $ZrCl_4$, $HfCl_4$) with lithium nitride (Li_3N) produces crystalline powders of the metal nitride, MN, in seconds via a metathesis reaction [eq. (1)]:

$$3MCl_4 + 4Li_3N \xrightarrow{\text{initiation}} 12LiCl + 3MN + \tfrac{1}{2}N_2. \quad (1)$$

The reactions were performed by placing preground Li_3N and the metal halide into a glass ampoule that was sealed under vacuum and initiated by either heating in a conventional (400°C) or a microwave oven. After a variable induction period ranging from a few seconds to a few minutes in either oven the ampoules glowed red for 2–3 s as the reaction proceeded. This glow was accompanied, in the reactions containing Zr and Hf, by sublimation of a white solid onto the walls of the ampoule and the formation of a black fused solid. In the reaction using $TiCl_{4(l)}$ as a starting material a black particulate solid was spread over the walls of the ampoule. This is probably due to the fact that $TiCl_4$ is a liquid/gas at the initiation temperature. The sublimed white solid was confirmed as LiCl by the lithium flame test, EDAX analysis (only chloride detected) and

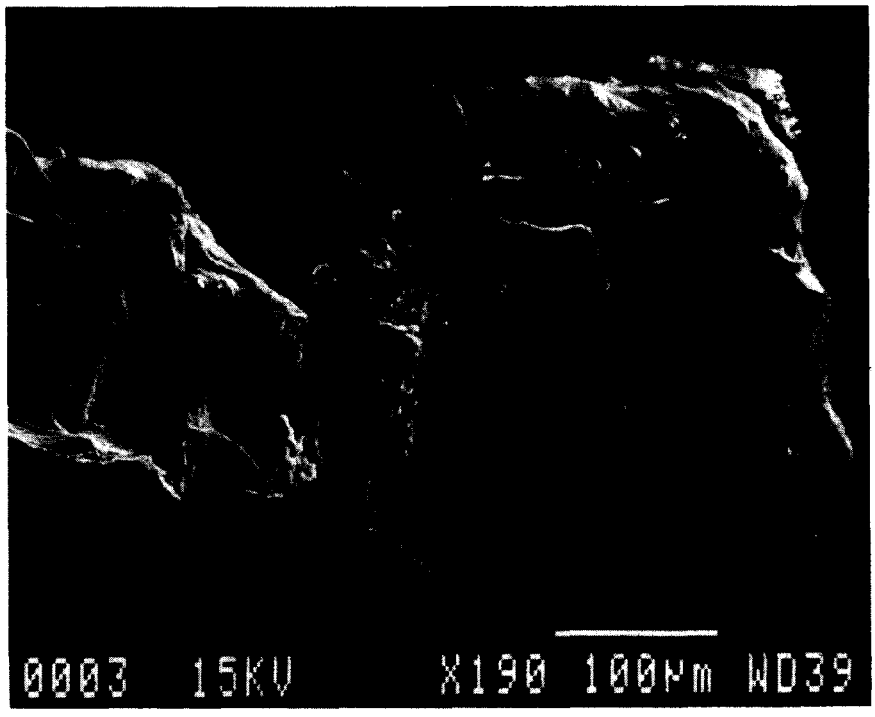

Fig. 1(a). SEM photograph of HfN, unwashed sample.

powder X-ray diffraction (XRD). The black solids were analysed by SEM, which indicated only smooth lines consistent with a lithium chloride coating [Fig. 1(a)]. Triturating the black solid with THF removed the lithium chloride coating and left (as assessed by SEM) small, uniform, micron-sized particles with sharp angles and faces [Fig. 1(b)]. The THF washings were allowed to evaporate in air and produced crystalline lithium chloride, in agreement with eq. (1). The formation of dinitrogen in the

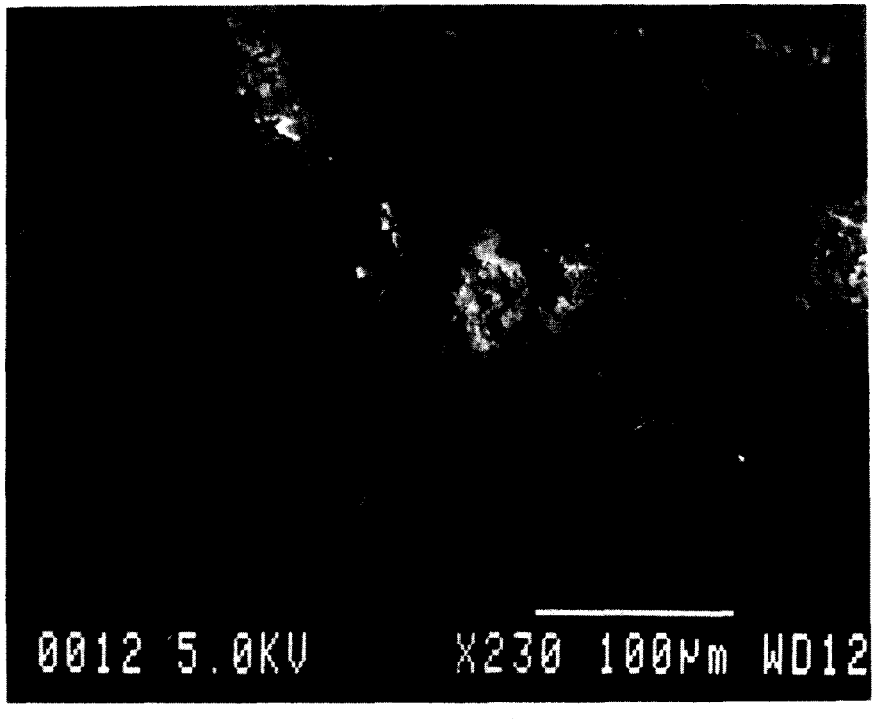

Fig. 1(b). SEM photograph of HfN, THF washed sample.

reaction of MCl_4 (M = Ti, Zr, Hf) and Li_3N was confirmed by performing the reaction in a glass ampoule sealed with a Young's Teflon tap, back filling the ampoule with argon and determining the concentration of dinitrogen by GC analysis. Quantification indicated that approximately 20% of the initial nitrogen in the lithium nitride forms dinitrogen in the ampoule [also in good agreement with eq. (1)].

The reactions are dependent on the quantities of Li_3N and the metal halide used. When performed on a small scale (50 mg of metal halide) some unreacted metal halide was observed by XRD; on a larger scale (500 mg of metal halide) no unreacted starting material was observed and the SEM and EDAX analysis of the fused lump indicated homogeneity across the surface. It is probable that larger scale reactions are better insulated against heat loss.

The THF-washed black powders were characterized as binary metal nitrides, MN, by X-ray powder diffraction, FT-IR, magnetic moment measurement, EDAX analysis and nitrogen microanalysis. Powder X-ray diffraction (XRD) shows that the materials are phase pure after THF washing and assume the NaCl-type structure (Fm3m) with lattice constants a (Å) = 4.23, 4.57 and 4.52 for TiN, ZrN and HfN, respectively, compared to literature values[14] of a (Å) = 4.24, 4.56 and 4.51. The X-ray powder diffraction patterns of HfN and TiN are shown in Figs 2(a) and (b). The Scherrer equation[15] based on the XRD line-widths indicates crystallite sizes of 200–250 Å for the TiN and HfN powders. Analysis of the black powders by FT-IR showed only a broad band at *ca* 450 cm^{-1}, probably due to M—N stretches. The observed room-temperature magnetic moment measurement of HfN ($\mu = 1.73$ B.M., 0.4 T) is consistent with one unpaired electron on the hafnium. The material displays an interesting field-dependent magnetism, which is currently being investigated.

The EDAX analysis of the THF triturated black powders showed only the metal and nitrogen are present. If the nitrides were exposed to air an oxygen peak was additionally detected, consistent with surface oxidation. This oxygen peak could be reduced by polishing the air-exposed sample and handling under an inert atmosphere. No peak due to chlorine was detected for the triturated powders by EDAX analysis. The microanalysis of the THF triturated powder from reaction of $HfCl_4$ and Li_3N showed no carbon or hydrogen and 6.41% nitrogen. This is approximately 90% of all the nitrogen expected for HfN (7.25%); the analysis was performed using a maximum oxygen flow and powdered tin to raise the temperature of the combustion. The refractory nature of the product HfN (m.p. = 3300°C) and its resistance to chemical attack, including oxidation even at high temperatures,[4] probably accounts for the incomplete nitrogen analysis; a residue was left after combustion analysis. Negligible values for lithium (< 0.25%) and chloride (< 0.25%) were observed for the HfN powder, indicating that THF

trituration removes the lithium chloride co-product.

The reaction of lithium nitride with a group IVA chloride is highly exothermic (as judged by the red glow and sublimation of LiCl) and once initiated is extremely rapid. The enthalpy of formation for the precursor reaction used to produce TiN is $\Delta H_f^{\ominus} = -900$ kJ mol^{-1}, from Hess law calculations.[16] The temperature reached could be as much as 1100°C, because metal nitrides often require annealing at 900°C for 12–24 h to induce sufficient crystallinity to be characterized by powder XRD.[4] Previous TGA studies of metal amide precursor routes to metal nitrides have generated metal nitrides with small crystallite size (80–150 Å) when rapidly heated to 1000°C in a platinum crucible and allowed to slowly cool to room temperature over an hour.[17] Optical pyrometry[10] studies of analogous solid state reactions to form GaP have indicated temperatures in excess of 850°C.

The sublimation of LiCl (b.p. = 1300°C) in the reaction of metal halides and Li_3N indicates that the high temperatures generated in the reactions are sufficient to overcome the solid-state diffusion barrier. Initiation, by heating in a conventional oven at temperatures up to 300°C, did not induce any reaction in the samples under observation, indicating that a critical temperature (assessed as 375–400°C) is required for sufficient localized reaction to proliferate throughout the whole material. The co-formation of LiCl and metal nitride may be advantageous in the formation of crystalline metal nitrides because the addition of both LiCl and $LiNH_2$ was found to decrease both the temperature and annealing time required to form lanthanide nitrides by a molecular precursor route.[18]

The initial process in the formation of hafnium and zirconium nitrides is likely to be the breakdown of the metal halide lattice, although notably no change in induction period or temperature was observed for the reaction involving $TiCl_{4(l)}$. The breakdown of the transition-metal halide lattice is accompanied by the formation of $LiCl_{(s)}$, which provides the driving force for the reaction and accounts for 80% of the energy produced in the reaction. However, initiation of these reactions was more difficult than for the formation of MoS_2 and GaAs[11] using a similar solid-state metathesis reaction, where grinding the reagents together was sufficient to stimulate reaction.

It is possible that intermixed Hf_xZr_yN compounds may be made by combination of suitable proportions of metal halide and lithium nitride. This is illustrated by the powder X-ray diffraction pattern for the reaction of equimolar quantities of $ZrCl_4$ and $HfCl_4$ with lithium nitride (Fig. 3). This shows diffraction lines which are slightly broader and intermediate in position between the individual diffraction lines for ZrN and HfN,[13] indicating that the same lattice (NaCl type Fm3m) is adopted for the mixed nitrides. The degree of actual intermixing is difficult to discern, however, because there is only a small difference in the pattern observed to that of overlapping two individual ZrN and HfN patterns. The EDAX step analysis of the mixed nitride

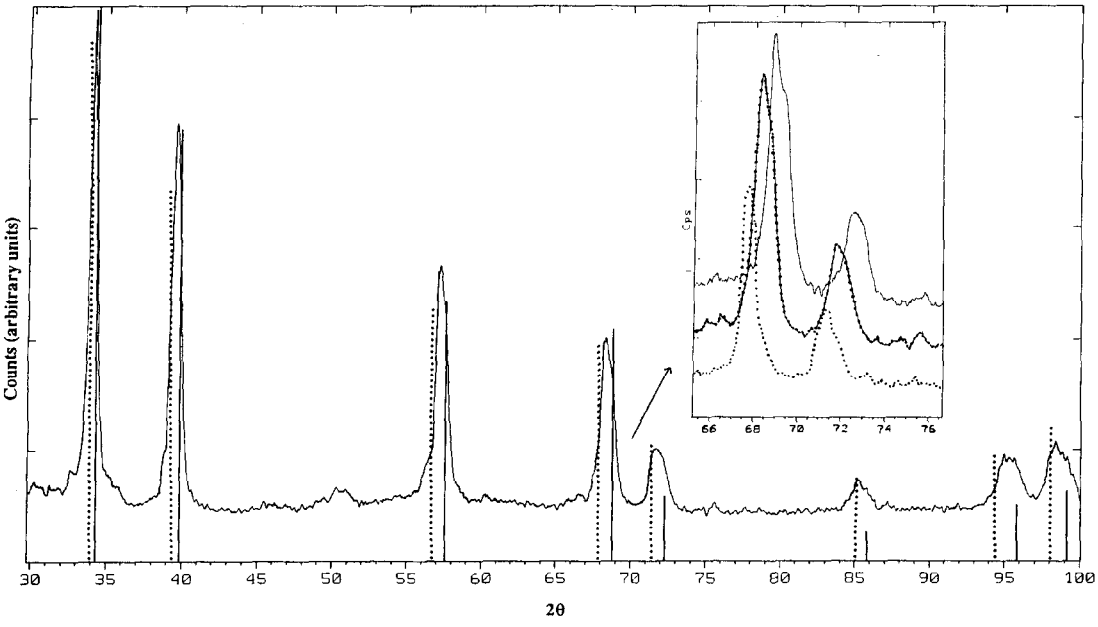

Fig. 3. X-ray powder diffraction pattern of the reaction of equimolar quantities of $HfCl_4$ and $ZrCl_4$ with Li_3N. Standard patterns for ZrN (· · ·) and HfN (——). Insert shows an expanded superposition of ZrN (· · ·) and HfN (——) made in this study and the mixed species obtained by reaction of equimolar quantities of $HfCl_4$, $ZrCl_4$ and Li_3N (–·–·–).

showed approximately equal concentrations for Zr and Hf, in agreement with the formation of an intermixed species.

Crystalline products are invariably produced by these metathesis reactions; however, by incorporation of a suitable inert heat sink (NaCl) it may be possible to control particle size and produce more amorphous materials.

(*Received* 27 *January* 1993; *accepted* 10 *February* 1993)

Abstract—The HeI photoelectron spectra of the 12-vertex *closo*-1-$SB_{11}H_{11}$, 11-vertex *nido*-7-$SB_{10}H_{12}$ and *nido*-7,8,10-$C_2SB_8H_{10}$, 10-vertex *arachno*-6,9-CSB_8H_{12} and nine-vertex *arachno*-4-CB_8H_{14} and *arachno*-4,6-$C_2B_7H_{13}$ species are reported. The highest symmetry 1-thia *closo* species has the simplest spectrum: The five well-resolved band systems are assigned to F(surface), D(surface + B—H), F(surface), P(B—H) and F(B—H) orbitals in the limit of spherical symmetry. The decrease of the symmetry in the open-face systems manifests itself in a greater complexity of photoelectron spectra and in the decrease of the first ionization energy by approximately 1 eV, due to the appearance of a new well-resolved band. The HOMO has a cluster surface bonding character in the open face systems. Going from *closo* to *arachno* clusters the contribution of hydrogen *s* functions in HOMO increases. For the *arachno* species a large H 1*s* contribution is found in low energy valence orbitals.

The bonding in deltahedral borane hydrides attracts considerable attention.[1,2] The interest of theoretical chemists is concentrated mainly on the high symmetry *closo* molecules where all vertices of the deltahedron are occupied.[3–11] These systems form an appealing paradigm for bonding in transition metal clusters through the isolobal principle.[12–14] The electronic structure of the *closo* species and the Wade–Williams–Rudolph electron counting rules[13,15–18] were rationalized in a straightforward way by the Stone's tensor surface harmonics (TSH) approach.[19–22] A reasonable agreement of the TSH method with the MNDO method was found.[8] The photoelectron (PE) spectral data on the cluster borane hydrides are rather scarce. Fehlner *et al.* published PE spectra of thiaboranes,[23] *closo*-1,2- and 1,4-dicarba-hexaboranes[24,25] and pentaborane.[26] The PE spectra of icosahedral carboranes were interpreted making use of MNDO orbital energies.[27–30] The electronic structures of *closo*-1-$SB_{11}H_{11}$ and especially *closo*-1-SB_9H_9 were described by Brint *et al.* in terms of the capping of the $B_{11}H_{11}$ and B_9H_9 fragments by the sulphur atom,[31] respectively. The recent *ab initio* results[32] for the *closo* species $C_2B_{10}H_{12}$ support the assignment of the lowest ionization energy (IE) band system to surface bonding orbitals. To our knowledge the only PE spectral data available for the low symmetry heteroboranes derived from an icosahedral skeleton are for the *nido*-6-SB_9H_{12} species.[23] The NMR chemical shifts in the nine-vertex *arachno* heteroboranes were correlated with the STO-3G and CNDO/2 density matrix properties, but the orbital energies were not published.[33] Understanding the bonding situation and the nature of the highest MOs of the low symmetry cluster boranes may contribute to the rationalization of the structural patterns of polyhedral metallaboranes.[34–36]

* Author to whom correspondence should be addressed.

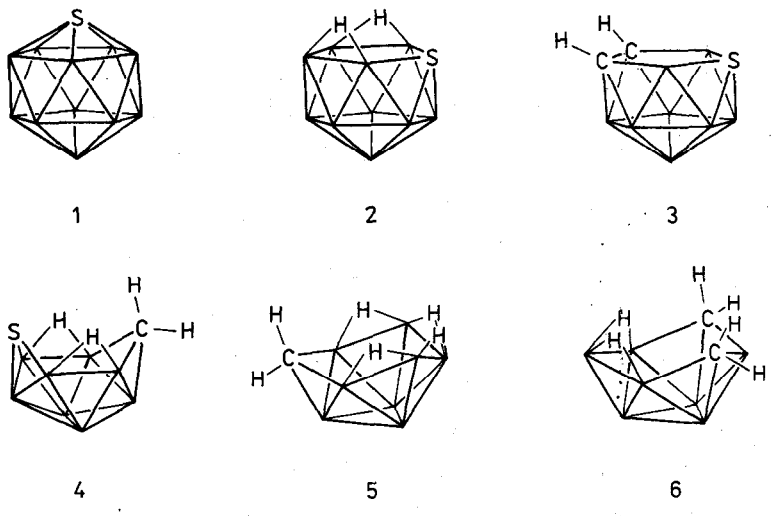

Fig. 1. Structures of studied boranes: *closo*-1-$SB_{11}H_{11}$ (**1**), *nido*-7-$SB_{10}H_{12}$ (**2**), *nido*-7,8,10-$C_2SB_8H_{10}$ (**3**), *arachno*-6,9-CSB_8H_{12} (**4**), *arachno*-4-CB_8H_{14} (**5**) and *arachno*-4,6-$C_2B_7H_{13}$ (**6**).

We report here the PE spectra of thia and carba cluster boranes derived from the icosahedron (12-vertex regular deltahedron) *closo*-1-$SB_{11}H_{11}$ (**1**), *nido* structures (one vacant vertex) 7-$SB_{10}H_{12}$ (**2**) and 7,8,10-$C_2SB_8H_{10}$ (**3**), *arachno* species (two vacant vertices) 6,9-CSB_8H_{12} (**4**), as well as nine-vertex *arachno* species 4-CB_8H_{14} (**5**) and 4,6-$C_2B_7H_{13}$ (**6**), derived from an 11-vertex *closo* precursor (two vacant vertices) (Fig. 1). The MNDO MO energies are used for the assignment of the PE spectra features.

EXPERIMENTAL

HeI photoelectron spectra were recorded using the VG Scientific UVG 3 instrument. The working resolution was 30–40 meV (full width at half maximum, FWHM). Spectra were calibrated by an Ar/Xe mixture. The temperature for the measurements was in the 120–140°C range.

The MNDO calculations were performed by the MOPAC 5.0 program. The standard parametrization for hydrogen and carbon was used.[37] The parameters for boron and sulphur were taken from refs 38 and 39, respectively. All internal coordinates were the subject of the optimization procedure.

The compounds were prepared by published methods: **1**,[40] **2**,[41], **3**,[42] **4**,[43] **5**[44] and **6**.[45,46]

RESULTS AND DISCUSSION

Closo-1-$SB_{11}H_{11}$ (1)

The PE spectrum of **1** is in general agreement with that already published by Fehlner *et al.*[23] The spectrum can be divided into three regions, analogous to the PE spectra of the isoelectronic $C_2B_{10}H_{12}$ species[28,29] (Fig. 2). Four overlapping ionizations between 10.67 and 11.56 eV (a–d) and a well-resolved band at 12.36 eV are found within the region A. Two maxima are resolved in the region B at 13.40 and 13.68 eV (f, g). In the deepest region C three bands lie below the HeI ionization edge.

Before discussing the assignment of the particular photoelectron bands it is feasible to introduce Stone's tensor surface harmonics formalism.[18] According to this theory the molecular orbitals

		$G_u\rightarrow E_1+E_2$

(MOs) of a *closo* system are classified in the spherical limit by the atomic orbital labels, and the $2n+1$ (n = number of vertices) occupied MOs can be separated into two groups. nMOs are B—H bonding and have a large outward pointing boron $2p$ composition (labelled S^x, P^x, D^x). The $n+1$ cluster bonding orbitals can be divided into two groups: (1) the MOs composed predominantly of the boron $2s$ orbitals have the properties of regular surface harmonic functions and are labelled S^σ, P^σ, D^σ; (2) the MOs composed of boron $2p$ orbitals oriented tangentially to the cluster surface. These orbitals have the properties of vector surface harmonic functions and are labelled P^π, D^π, F^π.

The inspection of the eigenvectors and the small average deviation of the p lobes from the tangent to the cluster surface shows that the highest occupied MO (HOMO) is the e_2 symmetry species, which is a component of the g_u level in the I_h symmetry (Table 1). The HOMO is composed mainly of the boron $2p$ orbitals, which are oriented nearly tangentially to the sphere encircling the icosahedron. Thus, the HOMO can be labelled F^π. The HOMO has no sulphur contribution. The s,p basis orbitals of the atoms located on the rotation axis cannot generate the e_2 representation. Thus, the calculated zero contribution of sulphur orbitals in the upper component of the F^π level may be a basis-dependent phenomenon due to the absence of the sulphur d-functions. The following three levels, namely $5e_1$, $7a_1$ and $3e_2$, correlate with the h_g representation of the I_h group. These orbitals have a 25–35% localization on the hydrogen atoms (Table 2). The p orbitals are more deviated from the tangential direction in comparison to HOMO. The weighted average (the p-localization is taken as the weight) is in the interval 22–54°. Brint and coworkers recently assigned the $2h_g$ orbitals to the B—H bonding D^x level, making use of the results of a localization procedure.[47] The $7a_1$ orbital has a 24% contribution from the sulphur p orbitals. It is equal to the hydrogen s participation in this orbital. The deviation of the p lobes from the cluster surface in these orbitals is lower than for the deeper lying levels of t_{1u} and t_{2u} symmetry, which can be un-

equivocally assigned to the B—H bonding interaction. The *p* orbital orientations (with the exception of the $7a_1$ orbital) tend to favour assignment to the D^{π} level, whereas the high hydrogen contribution clearly indicates the exo-bonding feature. The endo–exo mixing within the *D* level is symmetrically allowed as the 12 hydrogen *s* orbitals generate the a_g, t_{1u}, t_{2u} and h_g representations in the I_h group. The $2h_g$ orbitals cannot be assigned in a straightforward way to the endo or exo bonding.

The first four occupied orbitals are found in the 0.5 eV interval. Four overlapping bands are resolved within the first band system between 10.5 and 11.5 eV. Thus, bands a–d are assigned to the $4e_2$, $5e_1$, $7a_1$ and $3e_2$ orbitals ($1g_u$ and $2h_g$ species in the I_h symmetry). The next level is calculated approximately 1 eV deeper. It has the e_1 symmetry and has a 12% hydrogen 1*s* composition. The weighted average of the *p* orbitals' deviation from the cluster surface is lower in comparison to the $2h_g$ orbitals. Detailed inspection of the nodal properties indicate that the $4e_1$ level adheres to the $1g_u$ level in the I_h limit. Thus, this orbital can be labelled F^{π}. This level has its counterpart in the well-resolved band e, peaking at 12.36 eV. The appearance of band *e* forms a significant difference between the PE spectrum of **1** and that of the *closo*-$C_2B_{10}H_{12}$[29] species (Fig. 2). From the calculation it follows that the appearance of this band is due both to a higher splitting of the F^{π} level brought about by the perturbation of the I_h symmetry and by a decrease in the width of the group of *D* orbitals.

The B region of the PE spectrum, where two band maxima at 13.40 and 13.67 eV are found, can be assigned to the $6a_1$ and $3e_1$ orbitals which correlate with the $2t_{1u}$ level. The boron *p* orbitals point outward and the hydrogen 1*s* contributions are 29% and 40%, respectively, indicating unequivocally the B—H bonding character. Thus, these orbitals can be labelled as P^x.

In the deepest region C three maxima are resolved. They can be tentatively assigned to the $2e_2$, $5a_1$ and $4a_1$ orbitals. The $2e_2$ and $5a_1$ orbitals correlate with the $1t_{2u}$ level and the $4a_1$ orbital corresponds to the $2a_g$ species in the I_h group. These levels have hydrogen localizations of 30–42% and a prevailing outward pointing *p* orbital. The $1t_{2u}$ orbitals can be labelled as F^x and the $4a_1$ orbital corresponds to the S^x level.

The second set of occupied orbitals of *D* symmetry ($1h_g$) lies above the HeI ionization edge. The deviation of the *p* orbitals from the tangential direction and the hydrogen 1*s* contribution is lower than for the upper *D* level. The main contribution from the heavy atoms comes from the *s* orbitals. The $1h_g$ level has clearly a cluster bonding character, but it cannot be labelled as D^{π} due to the prevailing *s* composition. Brint *et al.* recently assigned the upper *D* level to B—H bonding and the lower *D* level to π-endo bonding.[46] It seems that a large exo/endo mixing and the *s*/*p* mixing occur in the *D* symmetry species, thus preventing the straightforward Stone's labelling.

Table 3. MNDO optimized internal coordinates for *closo*-1-$SB_{11}H_{11}$ (**1**)

[a] Electron diffraction results from ref. 48.
[b] Mean values.

The deepest three levels, $1e_2$, $2a_1$ and $1a_1$, correlate with the t_{1u} and a_g representations. They have a predominant heavy atoms *s* composition and clearly adhere to Stone's P^{σ} and S^{σ} levels.

The MNDO optimized geometry is in a good agreement with the electron diffraction results.[48] The sulphur atom is pulled slightly out of the deltahedron and the B—B distances in the pentagon neighbouring the sulphur are elongated in comparison with the more distant B—B bonds (Table 3).

Nido-7-$SB_{10}H_{12}$ (**2**) *and* nido-7,8,10-$C_2SB_8H_{10}$ (**3**)

The decrease in symmetry of the *nido* species results in higher complexity of their photoelectron spectra (Fig. 3). The low ionization energy (IE) region A of the PE spectra of the *nido* compounds differs significantly from the spectra of the *closo* species. A new isolated band appears before the onset of the broad band envelope. Due to the appearance of this band the first IE is 0.86 eV for **2** and 1.37 eV for **3**, which is lower in comparison to **1**. The calculations for both *nido* structures show that the HOMO is separated by nearly 1 eV from the second highest occupied orbital (HOMO-1). The HOMO has a negligible contribution from the hydrogen atoms and the direction of the *p* lobes is close to the cluster surface tangent (Tables 4 and 5). Thus, the first band (a) in the PE spectra of the

nido structures can be assigned to a surface bonding cluster MO.

In the PE spectrum of **2** four maxima are found within the broad band system in region A. In region B four observed ionization features (f–i) coalesce in an intense band system, peaking at 13.5 eV with an FWHM of 1.6 eV. In the high energy region C three bands (j–l) at 15.44, 16.62 and 17.5 eV are resolved. The calculation predicts a similar grouping of MOs. Five MOs below the HOMO lie within the 12.12–12.84 eV interval. The contribution from the hydrogen 1*s* orbitals is 20–40%. The sulphur *p* orbitals deviate more from the cluster surface in comparison to the HOMO. These orbitals can be described as cluster bonding MOs mixed with B—H orbitals. The band system between 10.7 and 12.01 eV can, therefore, be assigned to these orbitals. The following group of orbitals (18th MO to 13th MO in Table 4) can be assigned to the ionizations f–i in region B. The 18th MO has a 40% contribution from the sulphur atom. The sulphur *p* density is directed to the vacant vertex in the icosahedral skeleton. The deviation angle of the *p* lobes from the tangential direction indicates the *endo* bonding character of the 15th MO. The remaining levels within this band system have B—H bonding character. The *p* lobes of the skeletal atoms are pointed outwards and the contribution of hydrogen 1*s* orbitals exceeds 30%. In the high IE region the bands j and k can be tentatively assigned to three orbitals (12th MO to 10th MO) having the B—H character. The deepest ionization observed at 17.5 (**1**) may originate from the 9th MO, which has a considerable boron 2*s* contribution and can be labelled as σ-endo bonding.

In the spectrum of *nido*-7,8,10-$C_2SB_8H_{10}$ (**3**) band b at 10.45 eV is resolved on the onset of the broad band system in region A. According to the MNDO calculation the HOMO-1 has a low contribution from hydrogen 1*s* orbitals and the π-endo bonding character. In the following four MOs the hydrogen 1*s* composition varies from 17% to 31%. The inspection of the eigenvectors shows that these MOs have, analogous to **2**, endo bonding character with a B—H contribution. The band system between 10.98 and 11.73 eV (c–g) can be assigned to these orbitals. A new band system with two resolved maxima (g, h) appears between 12.6 and 13.0 eV. The shoulder at 12.63 can be assigned to the 18th MO, having predominantly π-endo character. Feature h can have its counterpart in the 17th and the 16th MO, which are calculated to be close in energy. These MOs have a cluster bonding character as follows from the 10–13% hydrogen 1*s* contribution. The 16th MO has the highest sulphur 2*p* composition. Contrary to **2** the sulphur *p* density is in the plane of the pentagonal face. The band system i–k, peaking at 14 eV, is attributed to the B—H bonding orbitals (15th and 13th MOs). The B—H bonding 12th and 11th MOs can be assigned to the bands l and m at 15.23 and 16.25 eV, respectively. The highest ionization energy feature observed at 17.64 eV (n) may come from the exo bonding MO and the uppermost σ-endo level.

Arachno-6,9-CSB_8H_{12} (**4**)

The absence of two atoms in the icosahedral cage makes the PE spectrum more complex (Fig. 4). In the low IE region three bands are observed before the steep onset of broad band envelopes. The calculation predicts the highest three occupied MOs to

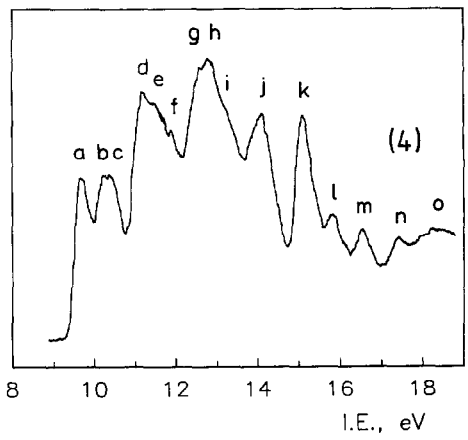

Fig. 4. HeI PE spectrum of *arachno*-6,9-CSB_8H_{12} (**4**).

[c] Weighted average of the deviation of the *p* direction from the tangent to the cluster surface. The weight is the *p* density at the atom.

be separated from the deeper lying levels (Table 6). The HOMO has a π-endo bonding character. The exo contribution to the HOMO is from the bridging hydrogen atoms and the C—H bonds. The following two MOs lie close in energy. This agrees with the presence of the two overlapping bands b and c. The HOMO-1 has unequivocally π-endo bonding character. The HOMO-2 has a large contribution from the sulphur atom. Inspection of the atomic orbital coefficients indicates that the sulphur *p* density is directed radially. As the hydrogen 1*s* composition is 10%, the HOMO-2 can be described as π-endo bonding.

In the deeper lying MOs a large endo–exo mixing occurs. The properties of the *p* orbitals of heavy atoms and the hydrogen 1*s* localization do not allow us to distinguish unequivocally the cluster bonding and the B—H bonding orbitals. The calculated grouping of MOs finds its counterpart in the observed IE band envelopes. The ionization features d–f can be assigned to the group of four MOs (20th to 17th MO). The band system within the 12.53 and 13.5 eV interval (g–i) can be assigned to MOs between 13.79 and 14.58 eV. The following bands can be tentatively assigned to single MOs. The highest IE band observed at 18.34 eV may correspond to the highest σ-endo level.

Arachno-4-CB_4H_{14} (**5**) *and* arachno-4,6-$C_2B_7H_{13}$ (**6**)

In the spectrum of **5** a resolved low IE band is found (Fig. 5). The corresponding HOMO has only a 13% hydrogen 1*s* composition (Table 7). The main hydrogen contribution comes from the bridge atoms more distant from the carbon atom. The average direction of the *p* lobes is very close to the surface tangent. The HOMO has unequivocally a π-endo bonding character. Band b at 10.71 eV can be assigned to the HOMO-1. The calculation provides a higher hydrogen 1*s* composition in comparison to HOMO. Thus, HOMO-1 can be classified as π-endo bonding with some contribution from B—H bonding. The successive bands observed in the PE spectrum are tentatively assigned to MOs, as depicted in Table 7. The MNDO calculation predicts a strong mixing of the hydrogen 1*s* orbitals with the cluster orbitals. It prevents any conclusion on the nature of the observed bands.

For the isoelectronic *arachno*-4,6-$C_2B_7H_{13}$ (**6**) a decrease in the first IE is observed (Table 8). Carbon atoms have a higher electronegativity than boron. The destabilization of the HOMO is obviously due to the decrease in the number of hydrogen atoms rather than due to the substitution of boron by

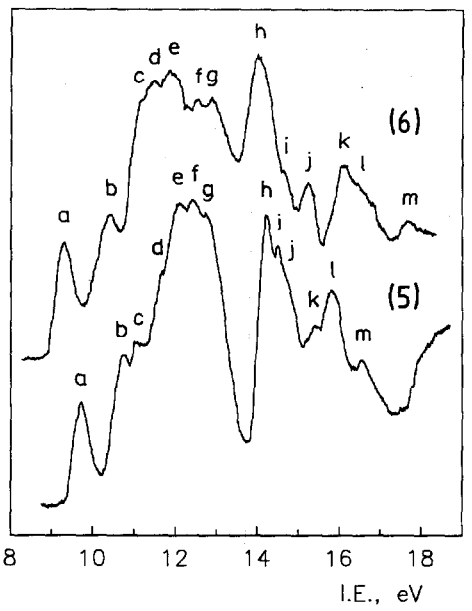

Fig. 5. HeI PE spectrum of *arachno*-4-CB_8H_{14} (**5**) and *arachno*-4,6-$C_2B_7H_{13}$ (**6**).

carbon. The same effect is observed for the *nido* species. The HOMO has a 10% contribution from the 1*s* orbitals of the bridging and carbon-bonded hydrogen atoms. This indicates the cluster bonding character. The directional properties of the *p* orbitals also corroborate the π-endo bonding character of the HOMO. Band b at 10.41 can be assigned to HOMO-1. The hydrogen 1*s* composition and nearly surface orientation of the *p* orbitals indicate the π-endo character of HOMO-1. The deeper MOs have large contributions from hydrogen 1*s* orbitals. It does not allow us to distinguish between the exo or endo bonding character of the observed spectral features. The MOs are tentatively assigned to the spectral bands, as shown in Table 8.

CONCLUSIONS

The PE spectra show a significant destabilization of the HOMO if one or more vertices are vacant in the icosahedral skeleton. The MNDO calculated orbital energies qualitatively agree with the observed PE band envelopes. In all species studied the HOMO has cluster bonding character. With the departure from icosahedral symmetry the endo bonding levels mix to a higher extent with B—H bonding orbitals. For the *arachno* species the endo/exo character of the particular levels cannot be distinguished. Thus, it seems that the endo/exo bonding separation cannot be applied if two or more vertices are vacant in the deltahedral cluster. In the *arachno* clusters derived from the 11-vertex *closo* species there is a significant contribution of the bridge hydrogen atoms to the cluster bonding

HOMO. This implies that the bridge hydrogen atoms in the open face of the deltahedron are involved in the cluster bonding. This is in an agreement with the earlier published idea by Rudolph[13] that the electrons of endo hydrogens contribute to the framework electron count.

(*Received* 10 *August* 1992; *accepted* 10 *February* 1993)

Abstract—The complex bis(N,N′-dimethyl-1,2-ethanediamine)copper(II) dinitrate, Cu(NN′-dmen)$_2$(NO$_3$)$_2$, undergoes a first-order thermochromic phase transition at *ca* 148°C, changing from blue–violet to blue. The low-temperature phase has been characterized by X-ray crystallography. The copper ion possesses distorted (4+2) octahedral geometry with two five-membered chelate rings, in the $\delta\lambda$ conformation, forming the CuN$_4$ plane [Cu—N = 2.000(6) and 2.033(7) Å] and oxygens from the two nitrate groups weakly coordinated in the two axial coordination sites [Cu—O = 2.506(8) Å]. The broad-line ^{1}H NMR indicates the onset of a dynamic disorder of diamine chelate rings at the phase transition temperature region. The electronic spectrum broadens on phase transition.

The thermochromic phenomena of copper(II) and nickel(II) salts with N,N-diethyl-1,2-ethanediamine (dieten) have been thoroughly investigated by several workers.[1–4] It is now well established that the discontinuous thermochromism exhibited by M(dieten)$_2$X$_2$ [where M = copper(II) or nickel(II) and X = ClO$_4$ or BF$_4$] is due to a weakening of the in-plane ligand field strength, resulting from the onset of dynamic disorder of the chelate rings, while the anions remain uncoordinated in both the low-

†Author to whom correspondence should be addressed.

Non-S.I. units employed: B.M. $\simeq 9.27 \times 10^{-24}$ Am^2; $S = 10^{-4}$ T.

and high-temperature phases.[5,6] Single-crystal X-ray analysis as well as temperature-variable ^{1}H NMR second-moment data have been found to be very useful to understand this type of thermochromic behaviour properly.

The same phenomena with other diamines are not well documented. The following factors are likely to play very important and crucial roles for this type of thermochromic phase transition: (1) steric effect of the alkyl group, (2) nature of the anions, (3) hydrogen-bonding network in the molecule, (4) decomposition temperature, etc. Amongst them, the role of the anion, especially that of nitrate, appears to be interesting in this connection. For example, in the complex $Cu(dicten)_2(NO_3)_2$[1,7] an increased axial interaction of the nitrate ions is taken into account to explain the drastic change in colour in addition to the dynamic disorder of the chelate rings. However, $Cu(dmpd)_2(NO_3)_2$[8] (dmpd = 2,2-dimethyl-1,3-propanediamine) and $Cu(daco)(NO_3)_2$[9] (daco = 1,5 diazocyclooctane) show similar but less drastic thermochromic transitions, which is explained to be due to the decrease in the axial interaction of the semi-coordinated nitrate ions. To generalize this it is necessary to search for similar systems.

We noticed for the first time that the complex $Cu(N,N'\text{-dmen})_2(NO_3)_2$ (where N,N'-dmen = N,N'-dimethyl-1,2-ethanediamine) is discontinuously thermochromic. Here we report the preparation, characterization and ^{1}H NMR second moment study of this complex. The crystal structure of the title complex was reported[10] to an R value of 0.072, without the hydrogen atom positions. However, to calculate the ^{1}H NMR second moment the positions of the hydrogen atoms are essential. Therefore, we have redetermined the crystal structure of the complex with hydrogen atom positions.

EXPERIMENTAL

Materials

N,N'-dimethyl-1,2-ethanediamine(NN'-dmen) was purchased from Fluka AG in high purity grade and used as received. All other chemicals used were of AR grade.

Synthesis of $Cu(NN'\text{-dmen})_2(NO_3)_2$

This was prepared by adding diamine (NN'-dmen) (2 mmol) dropwise to copper(II) nitrate (1 mmol) dissolved in methanol (10 cm^3). The resultant solution was stirred for 1 h. The desired blue–violet complex was separated and washed with methanol and dried in a desiccator. Found: C, 23.0; H, 6.7; N, 26.3; Cu, 17.6. Calc. for $C_8H_{24}N_6CuO_6$: C, 23.1; H, 6.6; N, 26.4; Cu, 17.4%. $\mu_{eff} = 1.83$ B.M.; $\lambda_{max} = 547, 742$ (sh) nm.

A crystal suitable for X-ray analysis was obtained from a methanolic solution kept at room temperature.

Physical measurements

The solid-state thermal measurements, elemental analyses, IR spectra (KBr discs, at ambient and above ambient), electronic spectra (mulls, at ambient and above ambient) and effective magnetic moments at room temperature were recorded using apparatus reported earlier.[11,12] The second moments of ^{1}H NMR absorptions were determined on a JEOL-MW-40S spectrometer at several temperatures, with an accuracy of ± 3 K, and X-ray powder patterns were recorded at 25°C and 155°C using a Rigaku Denki D-3F diffractometer equipped with a copper anticathode at Nagoya University, Japan. The visual colour change associated with phase transition was monitored by keeping the complex in the desired temperature range in an air oven.

Crystal data

$C_8H_{24}N_6CuO_6$, $M = 363.9$, monoclinic, $a = 7.425(2)$, $b = 8.533(2)$, $c = 13.072(3)$ Å, $\beta = 105.56(3)°$, $U = 797.86(4)$ Å^3 (by least-squares refinement on diffractometer angles for 20 automatically centred reflections, $\lambda = 0.71069$ Å), space group $P2_1/c$, $Z = 2$, $D_c = 1.51$ g cm^{-3}, $F(000) = 382$, blue–violet crystals, dimensions $0.35 \times 0.25 \times 0.15$ mm, $\mu(\text{Mo-}K_\alpha) = 14.04$ cm^{-1}, $T = 293$ K.

Data collection, structure solution and refinement

A Hilger–Watts diffractometer was used in the ω–2θ mode, with graphite-monochromated Mo-K_α radiation, and 1175 unique reflections measured ($1.5 \leqslant \theta \leqslant 25°$; $\pm h, k, l$) giving 726 with $I > 3\sigma(I)$. No significant decay of intensity controls occurred during data collection. Absorption corrections (max., min. transmission factors 0.941, 0.715) were performed following ref. 13.

The heavy-atom method was followed by a successive difference-Fourier analysis. The copper atom was located at a crystallographic inversion centre, so that only one chelated ligand (L) and one nitrate group are independent. A full-matrix least-squares refinement was performed, with all non-hydrogen atoms anisotropic and hydrogen atoms (methyl hydrogen atoms were kept fixed with $U_{iso} = 0.05$ Å^2) isotropic. The weighting scheme

$w = 1/[\sigma^2(F_o)+0.004F_o^2]$ with $\sigma(F_o)$ from counting statistics gave satisfactory analyses. Final R and R' values are 0.053 and 0.054. Programs, computers used and sources of scattering factor data are given in ref. 14.

Supplementary material. Tables of positional and thermal parameters, interatomic distances and angles, prominent lines in the X-ray powder patterns recorded below and above transition temperature and structure factors have been deposited with the Editor.

RESULTS AND DISCUSSION

Description of the structure

An ORTEP[15] view of the complex with the atom labelling scheme is shown in Fig. 1. Selected bond lengths and bond angles are listed in Table 1. The structure consists of $[CuL_2]^{2+}$ cations and two NO_3 anions. The copper atom at the inversion centre is co-planar with four ligand nitrogen atoms [N(1), N(2) and their centrosymmetrically related ones]. The geometry around copper is distorted square-planar, with an in-plane distortion introduced by the ligand bite angle N(1)—Cu—N(2) = 84.8(3)°. The two five-membered chelate rings are in the $\delta\lambda$ conformation. Weak coordinations, Cu—O(1) = 2.506(8) Å, of two symmetry-related oxygen atoms [O(1) at x, y, z and O(1)′ at $-x$, $-y$, $-z$] of the NO_3^- ion complete a distorted octahedron. O(2) of the nitrate ion is hydrogen bonded to one of the amino nitrogen atoms [N(1)] of the cation: O(2)···N(1) 3.02, O(2)···H(N1) 2.27 Å; N(1)—H(N1)—O(2) 148.5°. Similar weak hydrogen bonding between NO_3^- and nitrogen atoms in the ligand was reported for bis(1,5-diazacyclooctane)copper(II) nitrate.[9] The nitrate ion is essentially planar [displacement of N(3) from the weighted least-squares plane through O(1), O(2), O(3) being 0.007(7) Å] and inclined to the CuN_4 chelate plane by 66.4(3)°. The observed C(2)—C(3) bond, 1.441(16) Å (Table 1), is short but a similar

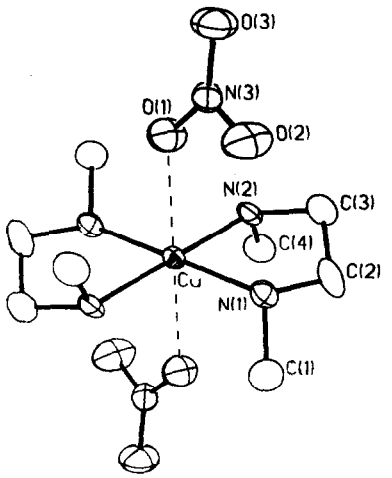

Fig. 1. ORTEP plot of $Cu(NN'\text{-dmen})_2(NO_3)_2$, showing the atom numbering scheme and the semi-coordination of the nitrate ions.

shortening of the C—C bond [1.41(1)–1.47(1) Å] in the 1,2-diaminoethane fragment is reported in the literature.[16] The Cu—N distances 2.000(6) and 2.033(7) Å are comparable to those observed in similar systems.[10,17,18] The small difference between the Cu—N(1) and Cu—N(2) distance is a consequence of an unsymmetrical interaction of the anion to the ligand.

Thermal analysis

The result of the simultaneous TG–DTA measurement of the title complex is shown in Fig. 2. The DTA curve shows a sharp endothermic peak associated with a colour change from blue–violet to blue in the temperature range 145–155°C, where the corresponding TG curve remains flat. The enthalpy change for this transformation was calculated from the DSC curve (ΔH = 12.1 kJ mol^{-1}). The transformation is reversible and on cooling the blue species reverts to its original form in the temperature range 90–120°C (ΔH = −12.4 kJ mol^{-1}).

Table 1. Selected bond lengths (Å) and angles (°)

Cu—N(1)	2.033(7)	Cu—N(2)	2.000(6)
Cu—O(1)	2.506(8)	N(1)—C(2)	1.455(12)
N(2)—C(3)	1.522(12)	N(3)—O(1)	1.243(11)
N(3)—O(2)	1.229(11)	N(3)—O(3)	1.204(12)
C(2)—C(3)	1.441(16)		
N(1)—Cu—N(2)	84.8(3)	N(1)—Cu—O(1)	94.2(3)
N(2)—Cu—O(1)	85.5(3)	O(1)—N(3)—O(2)	119.0(8)
O(1)—N(3)—O(3)	120.6(8)	O(2)—N(3)—O(3)	120.4(9)

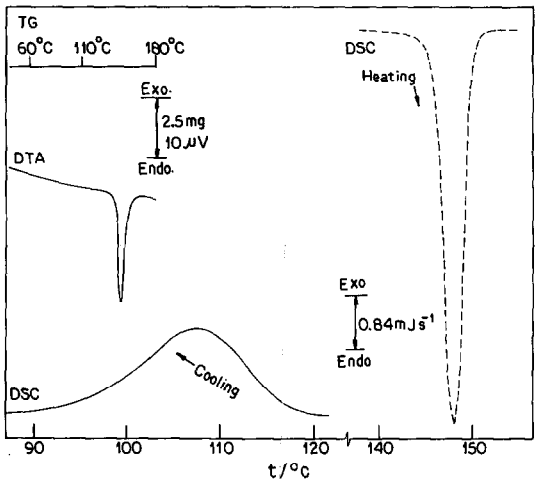

Fig. 2. Simultaneous TG–DTA (weight taken = 14.50 mg) and DSC (weight taken = 5.85 mg) (broken line for heating and solid line for cooling) curves for Cu(NN′-dmen)$_2$(NO$_3$)$_2$, showing the endothermic phase transformation.

Therefore, the transformation is associated with some amount of hysteresis.

IR and electronic spectra and X-ray powder diffraction

The IR spectra of the complex recorded at room temperature and at the temperature where phase transformation is assumed to be completed do not differ much. Only the combination band of the nitrate ion,[7,19] appearing at *ca* 1750 cm^{-1}, broadens on heating and a small change in the relative intensities of some of the bands is also observed in the fingerprint region,[12] although these changes are not so significant. Therefore, it is very difficult to draw any conclusion from the IR spectral change.

The colour change from blue–violet to blue, associated with reversible thermochromism, can be visually observed as mentioned earlier (*vide supra*). The visible absorption spectrum of the copper(II) complex recorded at room temperature (Fig. 3) shows a broad band at 547 nm with a shoulder at 742 nm. Gaussian resolution of the spectra has not been performed in this study but such a study has been published recently in a similar type of complex.[4] On phase transformations the absorption bands become broader and thereby none of the transitions can be assigned. However, the broadening of the spectrum was reported in a similar thermochromic complex.[8]

X-ray powder diffraction patterns of the complex were recorded below (at 25°C) and above (at 155°C) the transition temperature. The two powder patterns appear to be almost identical with respect to the positions of the lines, although some changes in the intensities of the corresponding diffraction maxima for the two phases are observed. This indicates that the unit cell dimensions of the two phases are almost the same, while the internal structures are different.

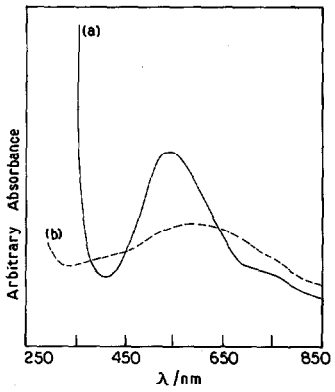

Fig. 3. Electronic spectra of Cu(NN′-dmen)$_2$(NO$_3$)$_2$: (a) at room temperature (25°C); (b) above the phase transition temperature (150°C).

Solid-state broad-line ^{1}H *NMR*

A broad-line ^{1}H NMR spectrum in the solid state of the complex Cu(NN′-dmen)$_2$(NO$_3$)$_2$ was taken from room temperature to its phase transformation temperature range. The second moment (M_2) of the resonance line was obtained by integration of the observed spectrum, as given in eq. (1),[20,21] where H_0 is the field at the centre of the peak and $I(H-H_0)$ is the intensity at a given field H. The results are shown in Fig. 4.

$$M_2 = \frac{\int [I(H-H_0)](H-H_0)^2 \, dH}{\int [I(H-H_0)] \, dH} \qquad (1)$$

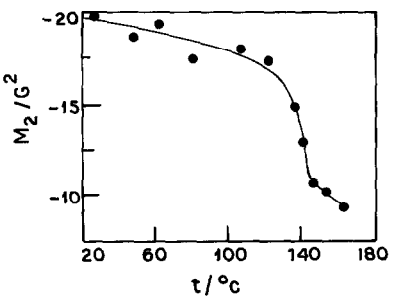

Fig. 4. Plot of ^{1}H NMR second moments vs temperature for Cu(NN′-dmen)$_2$(NO$_3$)$_2$.

Theoretical values of M_2 for possible motional states of the complex ion below and above the phase transition temperture are evaluated as follows: in the low-temperature phase, for example at room temperature, the reorientation of the two CH_3 groups about the C—N bonds in the complex ion is the only allowed motion and the rest of the complex ion is expected to be rigid. The M_2 calculation in a powder sample for this model was performed using Van Vleck's equation:[20]

$$M_2(\text{static})_{jk} = (9/10)g^2u_0^2N^{-1}\Sigma r_{jk}^{-6}, \qquad (2)$$

for the interacting protons j and k. Here g, N, u_0 and r_{jk} denote the proton g-factors, the number of interacting protons considered in the calculation, nuclear magneton and the distance between the protons, respectively. The contribution from the rotating CH_3 groups[21] was calculated assuming that the three protons are concentrated at the centre of gravity. The calculated values for this motional state, $M_2(\text{static})_{jk}$, are shown in Table 2 for the respective interproton interactions. The interproton distances used in this calculation were evaluated using the atomic coordinates from the X-ray structural analysis.

The total values of the theoretical M_2 can be given by the summation of the contributions from intramolecular interactions (20.4 G^2) and intermolecular origin (roughly estimated to be 2–3 G^2). The resultant value is close to the observed M_2 [19.5 G^2]. This small difference in these two values is attributable to the effects of thermal vibrations, which is also corroborated from the experimental observation that M_2 at low temperature is not constant but increases with lowering of the temperature.

We can also expect a contribution to line-width from the magnetic dipolar field due to the unpaired electrons in paramagnetic copper(II) atoms. In isolated paramagnetic systems like the present com-

[a] $CH_3(1)$ and CH_3(10) denote the average position of the three protons attached to the carbon atoms C(1) and C(4), respectively (Fig. 1), assuming that the protons are concentrated at the centre of gravity of the methyl group.

[b] Static molecule with rotating methyl groups.

[c] $\phi_0 = 25.7°$.

plex it is generally accepted[22] that the electron spin states are interconverting so rapidly that the time-average magnetic moments of electrons produce a constant local magnetic field at each proton. This results in a paramagnetic shift of the whole spectrum and/or an asymmetric line-shape caused by the superposition of various shifts at different proton sites in a molecule.[23] The latter contribution may change the line-width. In the present measurements, however, we could not observe either detectable shifts of spectra or any sign of anisotropic line-shapes in the whole temperature range studied. These results imply that effects from the paramagnetic electrons on the line-width are, if any, smaller than those from the interproton dipolar interactions.

Short relaxation times of unpaired electrons sometimes broaden the proton line-width and this effect can also be operative in the present system. To estimate this contribution we measured proton M_2 values in diamagnetic thermochromic nickel(II) complexes with N,N-diethyl-1,2-ethanediamine ligands[24] and compared the observed values with the reported data on paramagnetic copper(II) complexes[2] having the isomorphous crystal structure with the nickel(II) complexes. The M_2 values of these two kinds of complexes observed around the thermochromic phase transition temperatures appear to be quite similar to each other, suggesting that the broadening due to the paramagnetic electron spins in copper(II) atoms is much smaller than the interproton contribution. In the present complex the fact that the M_2 observed at room temperature is very close to the value calculated without paramagnetic contribution indicates the adequacy of this expectation. For these reasons we simplified the calculation and roughly evaluated the M_2 values without including contributions from the electron spins. An analogous treatment has been reported in the M_2 calculation for copper(II) complexes with N,N-diethyl-1,2-ethanediamine ligands.[2]

In the high-temperature phase the dynamic disorder of the chelate rings is the most probable motion for explaining the marked decrease of M_2 observed around 140°C, as is reported in the thermochromic $[Cu(dieten)_2]^{2+}$ complexes.[2] The theoretical M_2 value reduced by the puckering of the chelate rings was calculated by employing the same assumptions reported earlier[2] to simplify the calculation. The puckering motion was approximated by the jumps between the two equivalent orientations of the ligand molecules superimposed by rotating the molecules about the axis connecting the central metal and the mid-point of the CH_2—CH_2 bond by an angle of $51.5°(2\phi_0)$. This motion affords the reducing factor R_{jk} for the M_2 contribution from the dipolar interaction between protons j and k which is given by:

$$R_{jk} = [1+3(\sin^2\theta''_{jk}\cos 2\phi_0+\cos^2\theta''_{jk})^2]/4; \quad (3)$$

where θ''_{jk} is the angle between the rotation axis and the interproton vector r_{jk}. The values of M_2 which contributed by the interaction between protons j and k averaged by this motion can be given by:

$$M_d(\text{dynamic})_{jk} = M_2(\text{static})_{jk}\, R_{jk}. \quad (4)$$

The calculated values of $M_2(\text{dynamic})_{jk}$ are listed in Table 2 using the θ''_{jk} values evaluated from the X-ray data. Summation of these values gives M_2 (dynamic) of 12.74 G^2. This value is close to M_2 of 9.5 G^2 observed at 142°C. The difference between the calculated and observed values is attributable to the rough approximation of the puckering motion by two-fold rotation.

CONCLUSIONS

It is evident from the above discussion that a weakening of the in-plane ligand field strength due to the onset of dynamic disorder of the chelate rings (evident from the substantial drop of the second moment) is responsible for the thermochromic phase transition of the $Cu(NN'\text{-dmen})_2(NO_3)_2$ complex. Semi-coordination of the nitrate ion in the room-temperature phase and a slight change in colour upon phase transition lead to the conclusion that the thermochromic behaviour of the complex resembles that of bis(2,2-dimethyl-1,3-propanediamine)copper(II) dinitrate rather than that of bis(N,N-diethyl-1,2-ethanediamine)copper(II) dinitrate.

(*Received* 23 *November* 1992; *accepted* 8 *February* 1993)

Abstract—The formation of the iron(III) complex of 4-methyl-8-(carboxymethyl)aminomethyl umbelliferrone (**1**, H_2mug) and its N-methyl (**2**, H_2mugm) and N-carboxymethyl (**3**, H_3muia) derivatives has been investigated spectrophotometrically in an aqueous sodium nitrate solution (0.10 mol dm^{-3}) at 25°C. A 1 : 1 (metal : ligand) complex forms uniquely for all three ligands, indicating a steric interference between the coordinated and a coordinating ligand. The stability constant [log β_{11}/(mol^{-1} dm^3)] is 15.74 ± 0.20 for **4** [Fe(mug)$^+$], 15.69 ± 0.20 for **5** [Fe(mugm)$^+$] and18.67 ± 0.20 for **6** [Fe(muia)]. The complex formation reaction proceeds through two parallel pathways of Fe^{3+} and $Fe(OH)^{2+}$ with diprotonated ligand species of **1**, **2** and **3**; a slow coordination of the phenolato oxygen, followed by rapid donations of the amino nitrogen and carboxylato oxygen(s) to form a mono(terdentato- and tetradentato)iron(III) complex was deduced as the reaction mechanism. The possibility of changing the thermodynamic stability with no variation in the reaction mechanism by the introduction of substituent groups on the amino nitrogen of **1** is suggested.

The design and development of functional chelating agents for metal cations are some of our recent concerns. More specifically, we are now interested in the synthesis and the coordination characteristics of those multidentate ligands capable of forming fused chelate rings with metal ions, in which their aromatic groups are incorporated. As such a ligand, 4-methyl-8-(carboxymethyl)aminomethyl umbelliferrone (**1**, H_2mug) was designed and synthesized and its metal–chelate complex formation characteristics were studied with iron(III) from thermodynamic and kinetic aspects. Futhermore, they were compared with the related ligands 4-methyl-8-(N-carboxymethyl-N-methyl)aminomethyl umbelliferrone (**2**, H_2mugm) and 4-methyl-8-di(carboxymethyl)aminomethyl umbelliferrone (**3**, H_3muia) in order to elucidate the role of substituent groups on the amino nitrogen on these characteristics (cf. Scheme 1). Iron(III) was chosen here for the coordinated central metal atom because the iron(III) complex of aminocarboxylato ligating groups generally takes a high-spin d^5-state in octahedral coordination, being comparable with the aminocarboxylato metal(III) complexes of d^0- and d^{10}-electronic configurations of the same coordination structure, and because the former usually exhibits a characteristic charge-transfer (CT) band in the visible wavelength region, which is convenient for the spectrophotometric investigation of metal complex systems.

The present paper describes the thermodynamic stability and the formation reaction mechanism of the iron(III) complexes of **1**, **2** and **3**; attention was paid to the possibility of changing the thermodynamic stability with no variation in the formation reaction mechanism by introducing substituent groups on the amino nitrogen attached via a methylene group to the skeletal umbelliferrone.

EXPERIMENTAL

Materials

The ligand **1** was synthesized using a Mannich reaction with 4-methyl umbelliferrone, glycine and formaldehyde in acetic acid, according in principle to a procedure given in the literature.[1] The ligand was purified by recrystallization from water. Found: C, 58.8; H, 5.0; N, 5.3. Calc. for $C_{13}H_{13}NO_5 \cdot (1/5)H_2O$: C, 58.7; H, 5.1; N, 5.2%.

The ligands **2** and **3** were synthesized by the same procedure as **1**, but using sarcosine and iminodiacetic acid in place of glycine, respectively. **2**: Found: C, 57.9; H, 5.9; N, 4.6. Calc. for $C_{14}H_{15}NO_5 \cdot (2/3)H_2O$: C, 58.1; H, 5.6; N, 4.8%. **3**: Found: C, 54.4; H, 4.7; N, 4.3. Calc. for $C_{15}H_{15}NO_7 \cdot (1/2)H_2O$: C, 54.5; H, 4.9; N, 4.2%.

An aqueous iron(III) solution was prepared as described elsewhere.[2] All the other chemicals used were of an analytical or equivalent grade.

Measurements

Electronic absorption spectra were recorded on JASCO spectrophotometers, models UVIDEC-1M and -660. Absorbance change with time at a fixed wavelength was followed with a JASCO spectrophotometer, model SS-25, equipped with a stopped-flow attachment, model SFC-5, and a data processor, model DP-500.[3]

Other apparatus and the general procedures for the determination of protonation, stability and observed rate constants have been given in a previous paper,[3] except that the ionic strength was kept constant at 0.10 mol dm^{-3} $NaNO_3$. The formation of the iron(III) complex was monitored spectrophotometrically at 510 nm. Kinetic runs were performed under the pseudo-first-order conditions of an excess and constant ligand concentration. Temperature was maintained constant at 25.0 ± 0.2°C throughout the experiments.

RESULTS

Absorption spectral characteristics

The iron(III) complex of **1** shows an electronic absorption spectrum, which is given in Fig. 1. Figure 1 also depicts the absorption spectra of the iron(III) complexes of **2** and **3** and of the free ligands. Besides the maxima and shoulders due to intraligand charge-transfer transitions in the higher wave-number region, the iron(III) complex of **1** exhibits a characteristic spectral feature giving a maximum at 18.0×10^3 cm^{-1} with a molar absorption coefficient [log ε/(mol^{-1} dm^3 cm^{-1})] of 3.2 and a

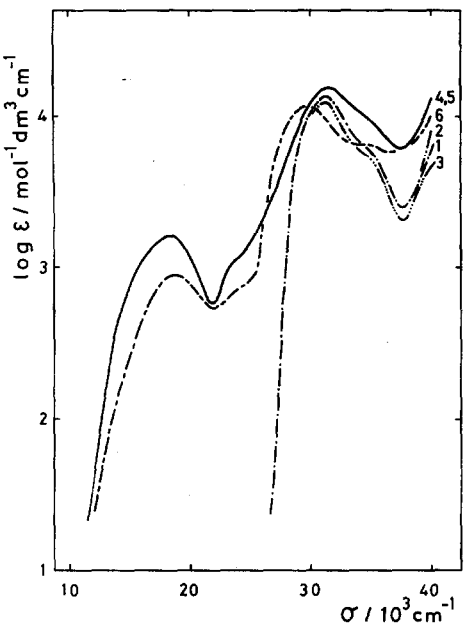

Fig. 1. Absorption spectra of the ligands and their iron (III) complexes. **1**: H_2mug (pH 2.50); **2**: H_2mugm (pH 2.50); **3**: H_2muia$^-$ (pH 2.50); **4**: Fe(mug)$^+$ (pH 2.50); **5**: Fe(mugm)$^+$ (pH 2.50); and **6**: Fe(muia) (pH 2.50).

shoulder around 24×10^3 cm^{-1}, with the coefficient slightly smaller in magnitude than the former; assignable to the $t_{2g}(O_h) \leftarrow \pi$ and $\pi^* \leftarrow e_g(O_h)$ charge-transfer transitions, respectively.[2] This spectral feature remains unchanged on going from the coordinated ligand of **1** to **2** and principally unchanged from **1** and **2** to **3**, although a slightly hypsochromic shift and a slight decrease in the molar absorption coefficient are noticed; this fact indicates that these iron(III) complexes equally have a metal-centred chromophore of the $[Fe^{III}(N)(O)_5]$-type.

The phenolate-oxygen protonated species of **1**, **2** and **3** gave characteristic fluorescence spectra of the same form with an excitation spectral maximum around 336 nm and an emission spectral maximum around 448 nm. However, this fluorescence disappeared completely in the iron(III) complexes of these ligands. Radiative $\pi^* \rightarrow \pi$ transition processes in the coumarin chromophore must have been replaced by an energy-transfer process, which accompanies an electron-transfer from the coordinated, excited coumarin chromophore to the central metal atom, followed by radiationless transitions via many intermediate *d*-electronic energy levels to the ground state in the metal-centred chromophore of the complex.

These results suggest that the ligand-to-metal charge-transfer band $[t_{2g}(O_h) \leftarrow \pi]$ is suitable for the thermodynamic and kinetic investigations of the iron(III) complexes of **1** and related ligands.

Thermodynamic stability

The protonation constants of **1** were determined spectrophotometrically, according in principle to a literature procedure.[3] The values of $K_{a(phOH)}$ and $K_{a(amNH)}$, corresponding to protonations at the phenolate oxygen and amino nitrogen atoms, were obtained from the experimental absorbance vs hydrogen-ion concentration plots by assignment based on comparison with related compounds (given in Table 1). Table 1 also summarizes $K_{a(phOH)}$ and $K_{a(amNH)}$ of **2** and $K_{a(phOH)}$, $K_{a(amNH)}$ and $K_{a(COOH)}$ of **3**, the latter corresponds to the protonation at the carboxylate oxygen atom.

Ligand **1** is potentially terdentate, capable of coordinating with two oxygen atoms and a nitrogen donor. The method of continuous variations[4] revealed the coordination of one ligand molecule to a central metal atom capable of taking an octahedral coordination, which indicates that a steric interference exists between the coordinated and a coordinating ligand in the iron(III) complex of **1** [**4**, Fe(mug)$^+$]. The same result was obtained for the iron(III) complex of **2** [**5**, Fe(mugm)$^+$]. The potentially tetradentate ligand **3** afforded a 1 : 1 (metal : ligand) complex of iron(III) [**6**, Fe(muia)].

Stability constants (β_{11}) were determined spectrophotometrically under the conditions $C_M \gg C_L$ and $C_L \gg C_M$ for complexes of **1** and **2** and $C_M \gg C_L$ for the complex of **3**, on the basis of a procedure given elsewhere:[2]

For complexes of **1** and **2**:

$$\beta_{11} = [\mathrm{Fe(mu)^+}]/[\mathrm{Fe^{3+}}] \times [\mathrm{mu^{2-}}] \quad (\mathrm{mu} = \mathrm{mug\ or\ mugm})$$

$$\log (A_{max} - A)/(A - A_{min}) = \log \{K_{a(amNH)}K_{a(phOH)}[H^+]^2 + K_{a(amNH)}[H^+] + 1\} + \log (1 + K^{11}_{OH}/[H^+]) - \log C_M - \log \beta_{11} \quad (C_M \gg C_L)$$

$$= \log \{K_{a(amNH)}K_{a(phOH)}[H^+]^2 + K_{a(amNH)}[H^+] + 1\} + \log (1 + K^{11}_{OH}/[H^+]) - \log C_L - \log \beta_{11} \quad (C_L \gg C_M); \qquad (1)$$

and for the complex of **3**:

$$\beta_{11} = [\mathrm{Fe(muia)}]/[\mathrm{Fe^{3+}}][\mathrm{muia^{3-}}]$$

$$\log (A_{max} - A)/(A - A_{min}) = \log \{K_{a(amNH)}K_{a(phOH)}K_{a(COOH)}[H^+]^3 + K_{a(amNH)}K_{a(phOH)}[H^+]^2 + K_{a(amNH)}[H^+] + 1\} + \log (1 + K^{11}_{OH}/[H^+]) - \log C_M - \log \beta_{11} \quad (C_M \gg C_L). \qquad (2)$$

[d] Hmu: 4-methyl umbelliferrone. $K_{a(phOH)}$ = [Hmu]/[H$^+$][mu$^-$] (at 355 nm); 0.10 mol dm^{-3} ($NaNO_3$), 25°C.

[e] H_3hbida: N-(2-hydroxybenzyl)iminodiacetic acid; 0.10 mol dm^{-3}, 25°C.

Here A_{max}, A_{min} and A represent the absorbance of the iron(III) complex, the free ligand and the complex and the free ligand co-existing at the hydrogen ion concentration of [H$^+$]; K_{OH}^{11} is the hydrolysis constant of iron(III) forming $Fe(OH)^{2+}$ [K_{OH}^{11} = [$Fe(OH)^{2+}$][H$^+$]/[Fe^{3+}], log K_{OH}^{11} (mol dm^{-3}) = −2.78 [0.10 mol dm^{-3} ($NaClO_4$), 25°C)];[5] and C_L and C_M are the total concentrations of iron(III) and the ligand, respectively. Linear relations were obtained for all the complexes between the absorbance and the hydrogen ion concentration terms in eqs (1) and (2) (cf. Fig. 2), with a slope of unity, which substantiates the formation of only the complex species of a 1 : 1 (metal : ligand) composition, i.e. **4**, **5** and **6**. The values of β_{11} for these complexes were calculated from the experimental data plots on the relation between these terms (summarized in Table 1).

Kinetics and mechanism

Stopped-flow spectrophotometric kinetic measurements at 510 nm of the iron(III)–**1** system allowed us to deduce that, under the conditions of $C_L \gg C_M$ and constant [H$^+$], a single exponential curve fits the experimental absorbance vs time plots well for more than 3.5 half-life periods. The same evidence was obtained for the iron(III)–**2** and –**3** systems. Hence, it is inferred that the formation reactions of the iron(III) complexes of these multidentate ligands proceed equally with a single rate-determining step.

The rate equation for the formation of the iron (III) complex of **1** was derived in an analogous way to that previously described,[2] with the consideration that the protonation/deprotonation processes are much faster than the coordination process[3] [cf. Scheme 2(a)].

$$k_{obsd}\{K_{a(amNH)}K_{a(phOH)}[H^+]^2 + K_{a(amNH)}[H^+] + 1\}(1 + K_{OH}^{11}/[H^+])/C_L = k_{32}K_{a(amNH)}K_{a(phOH)}[H^+]^2 + \{k_{31} + k_{22}K_{OH}^{11}K_{a(phOH)}\}K_{a(amNH)}[H^+] + k_{30} + k_{21}K_{OH}^{11}K_{a(amNH)} + k_{20}K_{OH}^{11}/[H^+] \quad (3)$$

Here k_{ij} (i = 2 and 3, and j = 0–2) is the rate constant for the formation reaction pathway of $Fe(OH)_{3-i}^{i+}$ and $H_jmug^{(2-j)-}$ species. Equation (3) also holds for the iron(III) complex of **2**, but eq. (4) should be applicable to the iron(III) complex of **3** [cf. Scheme 2(b)].

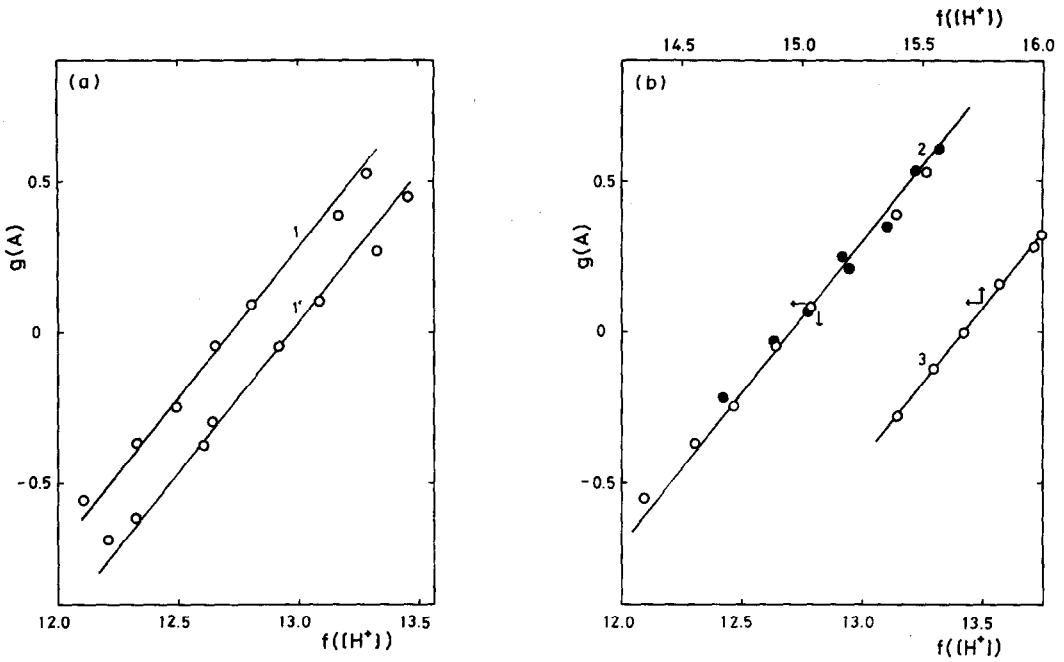

Fig. 2. Relation between the absorbance term, $g(A)$, and the hydrogen-ion concentration term, $f([H^+])$, of the iron(III)–ligand systems. $g(A) \equiv \log (A_{max}-A)/(A-A_{min})$; 0.10 mol dm^{-3} ($NaNO_3$), 25°C. Wavelength: 510 nm. $$

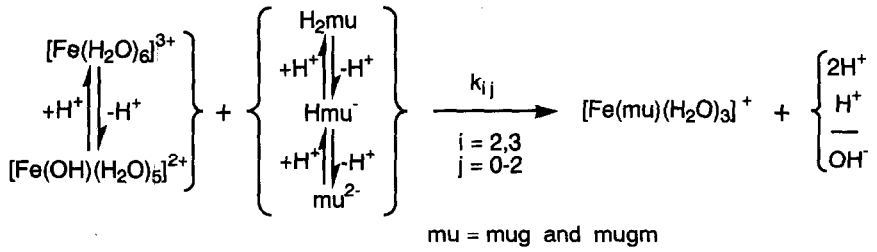
In eq. (4) k_{ij}(i = 2 and 3, and j = 0–3) is the rate constant for the formation reaction pathway of $Fe(OH)_{3-i}^{i+}$ and $H_jmuia^{(3-j)-}$.

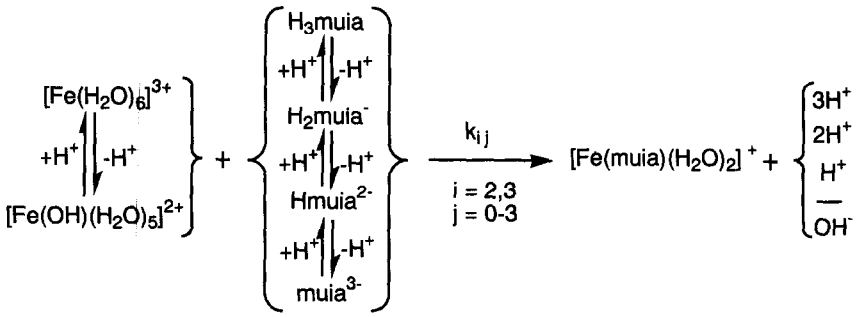
Kinetic experimental data are plotted in Fig. 3 in the form of a relation between the left-hand side of eqs (3) and (4) as a function of $[H^+]$. A quadratic curve of the form:

$$y = ax^2 + bx,$$

with y of an ordinate and x of an abscissa fit best the experimental data plots for the iron(III) complex of **1**, as well as the complexes of **2** and **3**. These results, together with a general kinetic characteristic of the iron(III) ion,[6a] indicate that the pathways of Fe^{3+} and $Fe(OH)^{2+}$ with diprotonated ligand species, which proceed in a parallel pathway, are universal among the complexes of **1**, **2** and **3**. A contribution of the pathways of Fe^{3+} with mono-protonated ligand species for **1**, **2** and **3** and the pathway of $Fe(OH)^{2+}$ with H_3muia species was ruled out because the estimated magnitude of each rate con-



Scheme 2(a).



Scheme 2(b).

stant was abnormally large in comparison with the reported rate constants of known reaction mechanisms[6a] (*vide infra*). The values of the single and composite rate constants determined experimentally are summarized in Table 2, together with those of the iron(III) complexes of concern.

DISCUSSION

Formation

The terdentate ligands **1** and **2** are anticipated, forming bis(ligand)- as well as mono(ligand)iron (III) complexes (cf. Scheme 1). However, no formation of the former was noticed. A molecular model consideraion indicated the possible configurations of *fac*(O,N,O) and *mer*(O,N,O) around the octahedral central metal atom, with the former more intraligand- and less interligand-crowded than the latter. The formation of the bis(ligand) iron(III) complex was due to a mutual repulsive interaction between the coordinated and a coordinating ligand because no thermodynamic reason could be found (cf. log $\beta_{11} = ca$ 12 mol^{-1} dm^3; Table 1).

Substitution of a methyl group for the hydrogen atom on the nitrogen donor atom in **1** causes a slight decrease in the stability constant, β_{11}, in contrast to the protonation constant, $K_{a(amNH)}$, related to the nitrogen atom [and the sum of $K_{a(amNH)}$ and $K_{a(phOH)}$], which increases as is expected from the electron-donating nature of the methyl group. This contrary change in the stability and protonation constants on substitution may be due to the steric restriction of a chelate ring conformation by the methyl group on the nitrogen rather than the thermodynamic consequence of changes in the basicity of the nitrogen by the substitution. A marked increase in the stability constant was confirmed when the coordinating carboxymethyl group was introduced on the nitrogen donor atom (cf. **4** and **6**).

Kinetics and mechanism

There have been many papers concerning the kinetics and mechanism of the formation of iron (III) complexes with ligands containing N and/or O donor atoms;[6] e.g. α-hydroxycarboxylic acids,[6b] substituted salicyclic acids,[6c] hydroxamic acid and derivatives,[6d–h] 4-isopropyltropolone,[6i] 2,4-pentanedione derivatives,[6j–l] 2-carboxy (and 2,6-dicarboxy)pyridines,[6m] etc.,[6a] excluding those ligands cited in Table 2 which are of direct concern to the present discussion.

A general kinetic feature of the formation of these iron(III) complexes lies in the fact that they form usually through more than one reaction pathway,[6] i.e. formation accompanies the proton ambiguity. This is also the case for the iron(III) complexes of **1**, **2** and **3**. Therefore, the composite rate constants are assigned to the constant of the individual pathway by taking its characteristic magnitude, existing

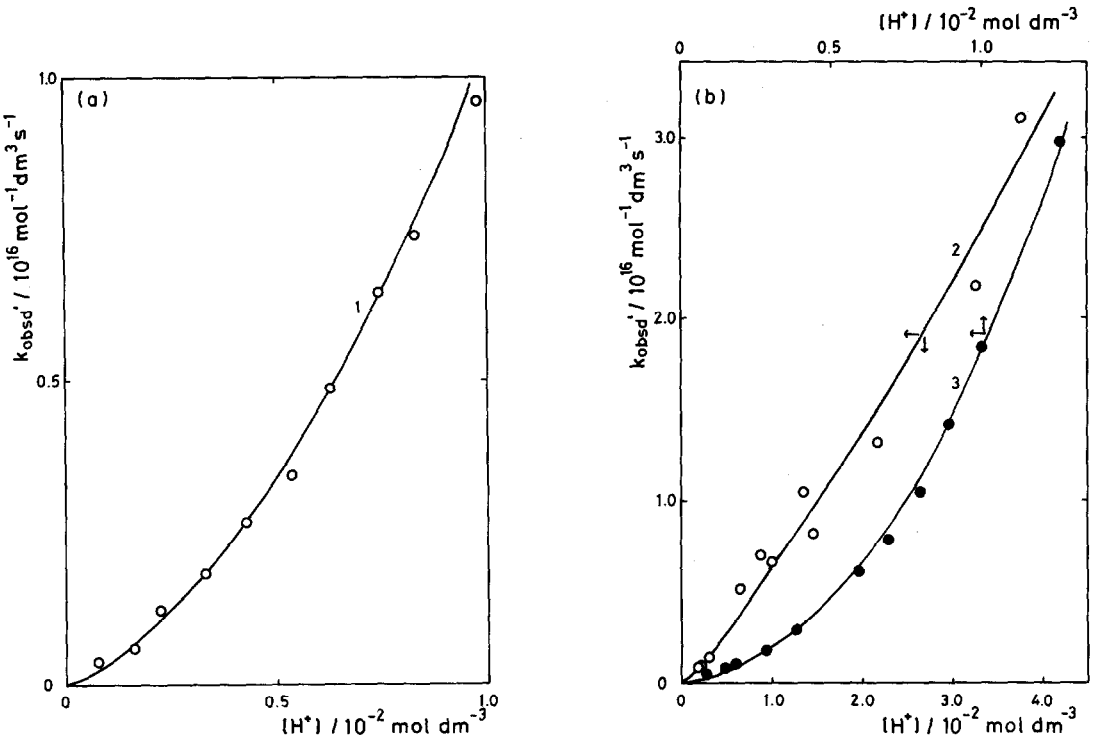


Fig. 3. Dependence of k_{obsd}' on [H$^+$] of the iron(III)–ligand systems. 0.10 mol dm^{-3} ($NaNO_3$), 25°C. Wavelength: 510 nm. $C_L \gg C_M$. (a) Iron(III)–**1** system. $k_{obsd}' \equiv k_{obsd}\{K_{a(amNH)}K_{a(phOH)}[H^+]^2+K_{a(amNH)}[H^+]+1\}(1+K_{OH}^{II}/[H^+])/C_L$. $C_L = 2.00\times10^{-3}$ mol dm^{-3}; $C_M = 1.00\times10^{-4}$ mol dm^{-3}. The bold line is theoretically drawn using the values of $K_{a(amNH)}$ and $K_{a(phOH)}$, of **1** given in Fig. 2, k_{32}/(mol^{-1} dm^3 s^{-1}) = 5.25×10^2, $k_{31}+k_{22}K_{OH}^{II}K_{a(phOH)}$/(mol^{-1} dm^3 s^{-1}) = 1.47×10^7. (b) Iron(III)–**2** and –**3** systems. Iron(III)–**2** system: $k_{obsd}' \equiv k_{obsd}\{K_{a(amNH)}K_{a(phOH)}[H^+]^2+K_{a(amNH)}[H^+]+1\}(1+K_{OH}^{II}/[H^+])/C_L$. $C_L = 2.00\times10^{-3}$ mol dm^{-3}; $C_M = 1.00\times10^{-4}$ mol dm^{-3}. The bold line is theoretically drawn using the values of $K_{a(amNH)}$ and $K_{a(phOH)}$ of **2** given in Fig. 2, k_{32}/(mol^{-1} dm^3 s^{-1}) = 6.17×10^2, $k_{31}+k_{22}K_{OH}^{II}K_{a(phOH)}$/(mol^{-1} dm^3 s^{-1}) = 1.03×10^6. Iron(III)–**3** system: $k_{obsd}' \equiv k_{obsd}\{K_{a(amNH)}K_{a(phOH)}K_{a(COOH)}[H^+]^3+K_{a(amNH)}K_{a(phOH)}[H^+]^2+K_{a(amNH)}[H^+]+1\}(1+K_{OH}^{II}/[H^+])/C_L$. $C_L = 0.50_0\times10^{-3}$ mol dm^{-3}; $C_M = 0.50_0\times10^{-4}$ mol dm^{-3}. The bold line is theoretically drawn using the values of $K_{a(amNH)}$, $K_{a(phOH)}$ and $K_{a(COOH)}$ of **3** given in Fig. 2, $k_{32}+k_{23}K_{OH}^{II}K_{a(COOH)}$/(mol^{-1} dm^3 s^{-1}) = 2.42, $k_{31}+k_{22}K_{OH}^{II}K_{a(phOH)}$/(mol^{-1} dm^3 s^{-1}) = 1.87×10^6.

metal and ligand species and the nature of the metal–donor atom bonds before discussing the reaction mechanism.

The rate constants for the formation of the iron(III) complex of **1** are $(5.25\pm0.20)\times10^2$ for k_{32} and $(1.47\pm0.20)\times10^7$ mol^{-1} dm^3 s^{-1} for $k_{31}+k_{22}K_{OH}^{II}K_{a(phOH)}$. The former may be of a reasonable magnitude for the iron(III) complex of a zwitter-ionic H_2mug ligand species. The latter, on the contrary, is too high for the iron(III) complex of singly protonated $Hmug^-$ ligand species. A tentative estimation of k_{22} from this composite rate constant value using K_{OH}^{II} and $K_{a(phOH)}$, by neglecting the pathway of k_{31} afforded k_{22} as $(1.14\pm0.30)\times10^3$ mol^{-1} dm^3 s^{-1}. This is quite a reasonable magnitude for the pathway of $Fe(OH)^{2+}$ with the H_2mug species. Accordingly, the iron(III) complex of **1** is expected to form via two parallel pathways of Fe^{3+} and $Fe(OH)^{2+}$ with H_2mug. The same consideration holds for the iron(III) complex of **2**: The estimated rate constant is $(1.92\pm0.30)\times10^2$ mol^{-1} dm^3 s^{-1}.

The tetradentate ligand **3** experimentally gave two composite rate constants of $k_{32}+k_{23}K_{OH}^{II}K_{a(COOH)} = 2.42\pm0.20$ and $k_{31}+k_{22}K_{OH}^{II}K_{a(phOH)} = (1.87\pm0.20)\times10^6$ mol^{-1} dm^3 s^{-1}. The same consideration afforded $k_{22} = (1.87\pm0.30)\times10^2$ mol^{-1} dm^3 s^{-1} from the latter. Likewise, an estimation of k_{23} from the former using K_{OH}^{II} and $K_{a(COOH)}$ gave k_{23} as $(1.84\pm0.30)\times10^{-1}$ dm^3 s^{-1}. This value is rather small compared with the rate constant of the $Fe(OH)^{2+}$ species.[6a] Hence, it may be safe to state that the pathway of k_{32} is with a rate constant 2.42 ± 0.20, and that of k_{23} may be of little contribution to the composite rate constants.

Table 2. Reaction rate constants

Ligand	Pathway	k_{ij} ($mol^{-1}\,dm^3\,s^{-1}$)	Ref.
1 (H_2mug)	$Fe^{3+}+H_2mug$ (k_{32})	k_{32}: $(5.25\pm0.20)\times10^2$	This work[a]

	$Fe^{3+}+salal^-$ (k_{30}) and $Fe(OH)^{2+}+Hsalal$ (k_{21})	$k_{30}+k_{21}K_{OH}^{II}K_{a(phOH)}$: 2.12×10^6	
Hphe[f]	$Fe^{3+}+Hphe$ (k_{31})	k_{31}: 2.5×10^1	13[f]
	$Fe^{3+}+phe^-$ (k_{30}) and $Fe(OH)^{2+}+Hphe$ (k_{21})	$k_{30}+k_{21}K_{OH}^{II}K_{a(phOH)}$: 7.2×10^2	

[a] 0.10 mol dm^{-3} ($NaNO_3$), 25°C.
[b] Hpdx-L-Htrp: N-pyridoxylidene-L-tryptophan; 0.50 mol dm^{-3} (NaCl), 25°C.
[c] HClac: chloroacetic acid; 1.0 mol dm^{-3} ($NaClO_4$), 25°C. $\log K_a(COOH)/(mol^{-1}\,dm^3) = 2.86$.
[d] Hac: acetic acid. 1.0 mol dm^{-3} ($NaClO_4$), 20°C. $\log K_{a(COOH)}/(mol^{-1}\,dm^3) = 4.53$.
[e] Hsalal: salicylaldehyde; 0.2 mol dm^{-3} ($LiClO_4$), 20°C. $\log K_{a(phOH)}/(mol^{-1}\,dm^3) = 8.13$.
[f] Hphe: phenol. 0.1 mol dm^{-3} (KNO_3), 25°C. $\log K_{a(phOH)}/(mol^{-1}\,dm^3) = 9.82$.

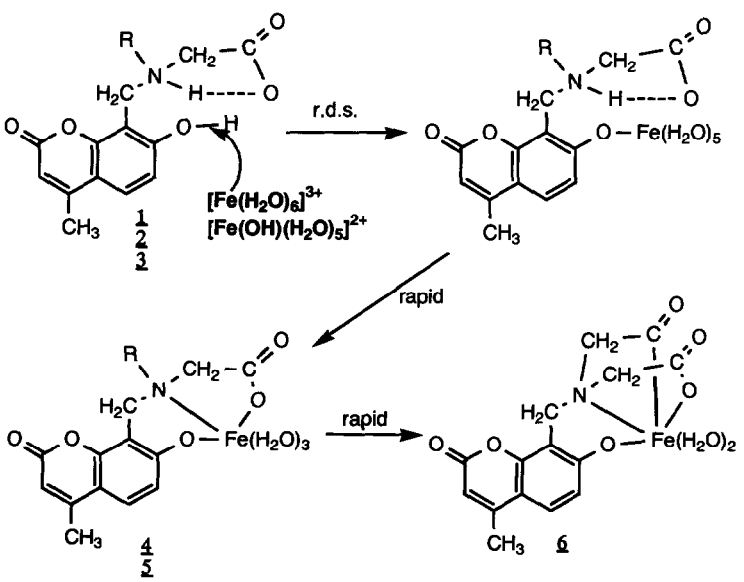
The fact that these three ligands take universal pathways for Fe^{3+} and $Fe(OH)^{2+}$ with the diprotonated ligand species suggests the formation reaction mechanism is based on the dependence of each rate constant on the basicity of the donor atoms and the molecular structure of the ligands.

The reaction mechanism of Fe^{3+} with H_2mug, H_2mugm and H_2muia$^-$, where Fe^{3+} has been accepted to have an associative or associative interchange characteristic,[7] can be explained in terms of a mechanistic rate-determining coordination of phenolato oxygen to iron(III). This is because the deprotonated carboxymethyl group on the nitrogen of **3**, which is expected to form an intramolecular hydrogen bond with the phenolic hydroxyl group, markedly decreases the formation rate constant k_{32}. In fact, the rate constant for the coordination of the (protonated) carboxylate group to Fe^{3+} is substantially smaller than that for the coordination of the (protonated) phenolate group (cf. Table 2); the latter being similar to k_{32} of H_2mug and H_2mugm. Contrary to the carboxymethyl group, the methyl group on the nitrogen donor atom of **2** influences very little the coordination reaction kinetics of Fe^{3+} species.

The mechanism of reaction of $Fe(OH)^{2+}$ with H_2mug, H_2mugm and H_2muia$^-$, where $Fe(OH)^{2+}$ has been accepted to have a dissociative interchange characteristic,[7] can also be explained by the mechanistic rate-determining interchange of a coordinated water molecule of $Fe(OH)^{2+}$ ($[Fe(OH)(H_2O)_5]^{2+}$) with a phenolato oxygen of the ligand species. The rather narrow range of k_{22} for the three ligand species of different molecular structure substantiates the dissociative interchange mechanism of $Fe(OH)^{2+}$. It is interesting to note that the substitution of the methyl or carboxymethyl group for hydrogen on the nitrogen causes a decrease in the magnitude of k_{22}.

An increase in the rate constant on going from Fe^{3+} to $Fe(OH)^{2+}$ was noticed for **1** and **3**, which is in line with those reported as a general feature of the iron(III) ion.[6a] Ligand **2** is an exception; no enhancement of the rate constant by the hydroxylation of iron(III) was noticed. This has already been reported for the iron(III) complex of salicylaldehyde [Hsalal; cf. Table 2: the rate constant for the pathway of $Fe(OH)^{2+}$ with Hsalal, k_{21}, estimated from the composite rate constant of 2.12×10^6 mol^{-1} dm^3 s^{-1}, K_{OH}^{11}, and the protonation constant (K_a) of the ligand ($\log K_a/(\text{mol}^{-1}\ \text{dm}^3) = 8.13$) is *ca* 8.5, which is smaller than the rate constant for the pathway of Fe^{3+} with Hsalal, $k_{31} = 2.46 \times 10$ mol^{-1} dm^3 s^{-1}]. The coordination reaction mechanism is shown in Scheme 3.

In conclusion, the formation of iron(III) complexes of **1** and the related terdentate (**2**) and tetradentate (**3**) ligands proceeds through pathways of Fe^{3+} and $Fe(OH)^{2+}$ with the diprotonated ligand species. They coordinate to iron(III) by the associative donation of and the dissociative interchange of a coordinated water molecule with phenolato oxygen as the mechanistic rate-determining step, which is followed by rapid donation of the amino nitrogen and carboxylato oxygen(s) to complete mono(terdentato- and tetradentato)iron(III) complexes. Steric repulsive interactions between the coordinated and coordinating ligand molecule may



Scheme 3.

be the reason why bis(terdentato)iron(III) complexes are not formed.

Abstract—Preparation of the title compound (**1**) is reported together with its detailed mass spectrometric investigations, which revealed the high stability of the molecular ion under electron impact and allow its fragmentation pathways to be rationalized. In dichloroethane solution the one-electron oxidation of **1** occurs at the highest potential value so far known for ferrocene molecules ($E^{\circ\prime} = +1.19$ V, vs S.C.E.).

Interest in metallocenes linked to cyclo(thia) phosphazenes arises from the fact that such small molecules can function as structural models for their open-chain high polymeric analogues, which should display physical properties quite different from those of conventional organic macromolecules.[2]

Chemical and electrochemical properties of metallocenes linked to some cyclophosphazene rings have been reported.[2,3] Here we present the chemical, mass spectrometric and electrochemical characterization of the ferrocene title compound **1**, in which each cyclopentadienyl ring bears one cyclophosphadithiazene unit. The crystal structure of such a species has been previously reported.[4]

are referred to the saturated calomel electrode (S.C.E.).

All synthetic experiments were performed in an atmosphere of dry, oxygen-free nitrogen, applying gas vacuum techniques in combination with Schlenk-type glassware. THF was distilled from a Na/K-melt prior to use. All other solvents were dried and distilled by conventional methods. *Cis*-$NPF_2(NSOPh)_2$ was synthesized using the method described in ref. 6. Ferrocene was sublimed prior to use. $Fe(C_5H_4Li)_2 \cdot TMEDA$ was prepared according to the method of Bishop *et al.*[7]

^1H NMR spectra ($CDCl_3$ solutions) were measured on a Bruker WH90 spectrometer (90 MHz), using TMS as an internal reference. ^{31}P and ^{19}F NMR spectra ($CDCl_3$ solutions) were recorded on a Nicolet NT200 spectrometer, operating at 81.0 and 188.2 Hz, respectively; $(NPCl_2)_3$ (19.9 ppm, $CDCl_3$ solution) and $CFCl_3$ (0.0 ppm, $CDCl_3$ solution) were used as external references. Chemical shifts are positive in the low-field direction.

Mass spectra were obtained by a double focusing VG 70-250S mass spectrometer operating in the electron ionization mode at 70 eV, emission current 0.2 mA, with a source temperature of 220°C and an accelerating voltage of 8 KV. The resolution was 2000 $M/\Delta M$ (10% of valley def.). The samples were introduced via the direct inlet system at room temperature. Metastable ions were measured by computer-controlled B/E and B^2/E linked scans performed in the first free region. Acquisition and analysis of the data were performed with a VG 11-250J data system equipped with a Digital PDP 11/83 minicomputer. High-resolution mass measurements were performed at resolution 10,000 $M/\Delta M$ against at perfluorokerosene standard (Fluka) under the control of the data system.

Preparation of $[(NSOPh)_2NPF]_2(C_5H_4)_2Fe$

To a mixture of $(\eta^5\text{-}C_5H_4Li)_2Fe \cdot TMEDA$ (0.52 g, 1.66 mmol) and $NPF_2(NSOPh)_2$ (1.20 g, 3.32 mmol) was added THF (10 cm^3) at −50°C. After stirring for 24 h the mixture was allowed to warm up to room temperature during 8 h. After filtration the residue was recrystallized from a $CHCl_3$–pentane mixture, yielding 0.570 g of orange crystals of $[(NSOPh)_2NPF]_2(C_5H_4)_2Fe$. The THF filtrate was subjected to column chromatography on silica gel-60 (Merck). Using successively pentane, CH_2Cl_2 and a mixture of CH_2Cl_2/THF as eluants, ferrocene, small amounts of a mono-substituted ferrocene derivative and an additional amount (0.200 g) of $[(NSOPh)_2NPF]_2(C_5H_4)_2Fe$ were obtained. The yield of $[(NSOPh)_2NPF]_2(C_5H_4)_2Fe$ was 0.770 g (0.89 mmol = 54%); m.p. ≈ 250°C. ^1H NMR: δ 5.2 (8H, m), 7.7 (10H, m). ^{19}F NMR: δ −49.4 [d, $^1J(PF) = 987$ Hz]. ^{31}P NMR: δ 35.8 [d, $^1J(PF) = 987$ Hz]. MS: Found: 867.9849. Calc. for $C_{34}H_{28}F_2FeN_6O_4P_2S_4$: m/z 867.9848.

RESULTS AND DISCUSSION

Synthesis of 1

Under the conditions illustrated in the Experimental the reaction of $(\eta^5\text{-}C_5H_4Li)_2Fe \cdot TMEDA$ with *cis*-$NPF_2(NSOPh)_2$ in a 1 : 2 ratio afforded the di-substituted ferrocenyl complex $[(NSOPh)_2NPF]_2(C_5H_4)_2Fe$ (**1**), which crystallized in two forms, one of which has been described previously.[4]

Mass spectrometric studies

In analogy with other ferrocene compounds[8] the mass spectrum of **1** (Table 1) is dominated by the molecular ion (m/z 868), which is responsible for 25% of the total ion current.

High-resolution mass data with the assignments of the elemental compositions of the molecular ion and main fragmentation ions are reported in Table 2. The main fragmentation pathways for the molecular ion obtained by B/E spectra are reported in Scheme 1.

A metal–ligand bond cleavage is observed and it produces the ion $[FeC_5H_4(NSOPh)_2NPF]^+$ at m/z 462. This ion is the more intense fragment ion in the spectra (23.8%), indicating that this fragmentation pathway is highly favoured.

In the crystal structure of **1** the average distance for Fe···N(—P) is 3.90 Å.[4] This structural arrangement also seems to be present in the gas

Table 1. Significant mass spectra data for **1**

m/z (relatve abundances, %)					
872(2.6)	871(8.5)	870(24.3)	869(41.2)	868(100)	
866(5.6)	464(2.7)	463(5.3)	462(23.8)	434(3.5)

phase and the direct interaction of the electron-deficient metal atom lacking one coordination site with one nitrogen atom of the $(NSOPh)_2NPF$ substituent can be responsible for the high stability of such an ion.

This type of fragmentation is also present in other ferrocenyl derivatives, in which an interaction of the metal ion with electronegatives groups, such as a double bond or an heteroatom possessing a lone pair, is allowed.[9]

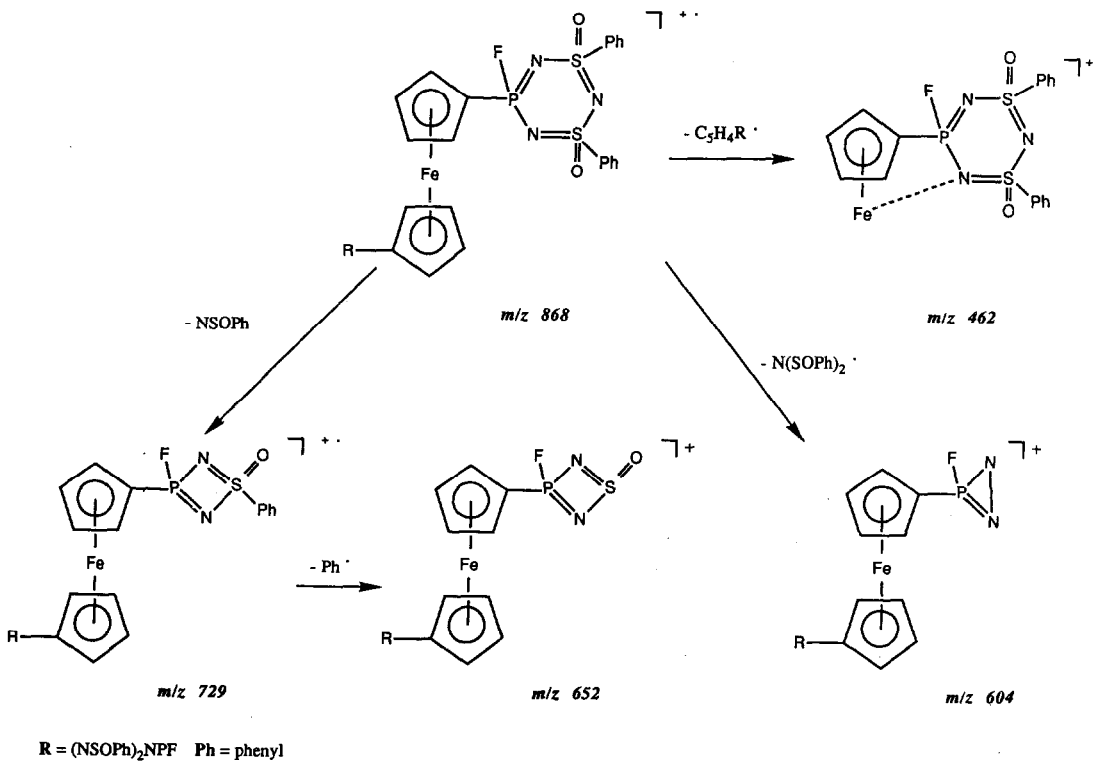
All other fragmentations of the molecular ion involve the NSOPh group yielding the ions at *m/z* 729 and 604 (Scheme 1).

An interesting feature in the behaviour of **1** under electron impact ionization is the presence of doubly charged ions. The molecular ion itself is present as M^{2+} at *m/z* 434, which in turn fragments to doubly-charged ions at *m/z* 302.0, 364.5 and 371.5, corresponding to the mono-charged species at *m/z* 604, 729 and 743. To the best of our knowledge this is the first case in which doubly-charged ions are described in the mass spectra of ferrocene molecules. It is likely that the stabilization of these ions comes from the aromatic character of the peripheral cyclophosphadithiazene rings.

Electrochemistry

As ferrocene molecules usually lose one electron to give the corresponding ferrocenium cations we decided to test the electrochemical behaviour of **1**. Unfortunately, the very low solubility of this complex in solvents useful for electrochemistry (insoluble in acetonitrile and dimethyl sulphoxide, very slightly soluble in dichloromethane, 1,2-dichloroethane and THF) prevented an accurate study.

Figure 1 shows the cyclic voltammogram exhibited by a saturated solution of **1** in 1,2-dichloroethane. As a result of the low concentrations caused by the poor solubility controlled potential coulometry ($Ew = +1.3$ V) showed no effective current. Therefore, it is not possible to calculate the number of electrons involved in the oxidation process. However, it is most likely that the observed redox change is attributable to the ferrocene/



Scheme 1.

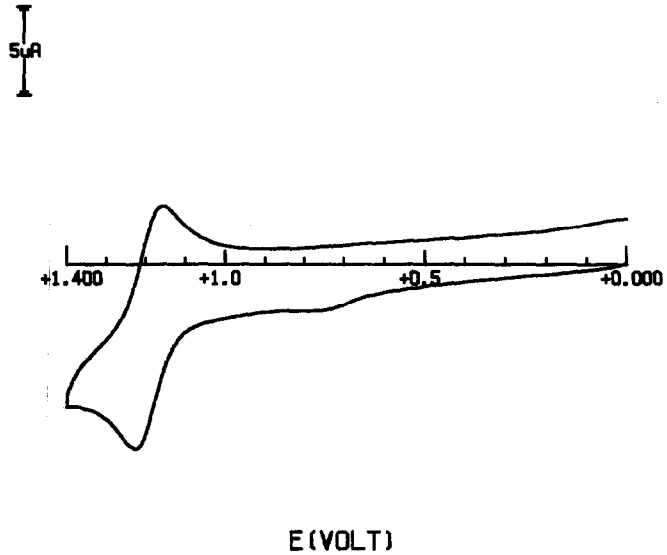


Fig. 1. Cyclic voltammogram recorded at a platinum electrode on a 1,2-$C_2H_4Cl_2$ solution containing $[NBu_4][ClO_4]$ (0.2 mol dm^{-3}) and saturated with **1** (4.5 mg in 25 cm^3). Scan rate = 0.5 V s^{-1}.

Table 3. Redox potentials (in V, vs S.C.E.) for the one-electron oxidation of some disubstituted ferrocene molecules, (X—C_5H_4)Fe(C_5H_4—X)

ferrocenium couple. Such an anodic step displays all the features of an uncomplicated electron transfer, substantially reversible in character; in fact, analysis[10] of the response with scan rate v varying from 0.02 to 10.24 V s^{-1} shows that the current ratio i_{pc}/i_{pa} is constantly equal to 1, the current function $i_{pa}\ v^{-1/2}$ remains constant and the peak-to-peak separation progressively increases from 68 to 130 mV (likely because of some uncompensated solution resistances).

Table 3 compares the redox potentials of the **1**/[**1**]$^+$ process with that of some related molecules. The strong electron-withdrawing effect of the two cyclophosphadithiazene rings is clearly evident when the formal electrode potential of **1**/[**1**]$^+$ is compared with that of unsubstituted ferrocene. Furthermore, the redox potential of the title compound is even higher than that of 1,1′-trifluoromethyl-substituted ferrocene.

REACTIONS OF $[WO_2Cl_2(dme)]$ WITH TERT.BUTYLTRIMETHYLSILYLAMINE— X-RAY STRUCTURE OF $[W(NBu^t)_2Cl_2(Bu^t\text{-dab})]$ (Bu^t-dab = N,N′-di-t-butyl-1,4-diaza-1,3-butadiene)

(*Received* 18 *December* 1992; *accepted* 1 *February* 1993)

Abstract—$[WO_2Cl_2(dme)]$ (dme = dimethoxyethane) reacts with 4 equivalents of $Me_3SiNH(Bu^t)$ to give different products depending on the solvent used. In n-hexane and dme as solvents the known complex $\{[W(NBu^t)_2Cl_2(NH_2Bu^t)]_2\}$ was obtained, a monomeric derivative of which, $[W(NBu^t)_2Cl_2(Bu^t\text{-dab})]$ (Bu^t-dab = N,N′-di-t-butyl-1,4-diaza-1,3-butadiene), has been characterized by X-ray structure determination. The molecule has a distorted octahedral geometry with *cis*-butylimido ligands [W—N distances: 1.756(8) and 1.758(8) Å; N—W—N angle: 105.9(4)°] and *trans*-dichloro ligands [W—Cl distances: 2.389(2) and 2.394(3) Å; Cl—W—Cl angle: 154.1(1)°]. The bidentate Bu^t-dab ligand is *trans* to the bisimido function; the W—N distances of Bu^t-dab are 2.507(7) and 2.533(7) Å and the N—W—N bite angle is 67.0(2)°. In dimethylformamide (dmf) as a solvent a binuclear tungsten(VI) compound is formed. A structure with a linear N═W—O—W═N arrangement and three terminal trimethylsilanolato ligands at each tungsten atom, $\{[W_2(NBu^t)_2(\mu\text{-}O)(OSiMe_3)_6]\cdot dmf\}$, is suggested for this complex. This suggestion is based on elemental analysis, molecular weight determination, FAB mass spectroscopy, ^1H, ^{13}C, ^{14}N, ^{17}O and ^{29}Si NMR, IR and Raman spectroscopy.

Much research activity is currently focused on high valent imido complexes of molybdenum and tungsten. Such compounds with M = NR functions can be used as catalysts or catalyst models of industrially important processes as ammoxidation[1–3] and olefin metathesis.[4–7] One of the preparative methods[8] by which an imido group, =N—R, can be introduced is the reaction of chloro, oxo or chloro-oxo metal complexes with monosilylated primary amines, as exemplified by different trimethylsilylamines Me_3SiNHR, R = 2,6 Pr^iPh[4–7] and R = Bu^t.[9–13] WCl_6[9–11] and $WOCl_4$[13] have been used as starting materials for the preparation of t-butylimido complexes of tungsten(VI), while WO_2Cl_2 has been found to be too unreactive to undergo reactions with $Me_3SiNH(Bu^t)$.[10,11]

The synthesis of monomeric $[WO_2Cl_2(dme)]$ (dme = dimethoxyethane) has recently been described.[14] This compound is highly soluble in organic solvents and more reactive than WO_2Cl_2. With this complex at hand we thought it worthwhile investigating its reactions with $Me_3SiNH(Bu^t)$. As the reactions of MoO_2Cl_2[10] and its 2,2′ bipyridyl adduct[15] with $Me_3SiNH(Bu^t)$ give different kinds of products depending partly on the solvents used it was considered necessary to perform the reactions of $[WO_2Cl_2(dme)]$ and $Me_3SiNH(Bu^t)$ in different solvents, viz. n-heptane, dme and dimethylformamide (dmf). The results of these experiments and the crystal structure of one of the compounds obtained, $[W(NBu^t)_2Cl_2(Bu^t\text{-dab})]$ (Bu^t-dab = N,N′-di-t-butyl-1,4-diaza-1,3-butadiene), are presented here.

RESULTS AND DISCUSSION

Reaction of $[WO_2Cl_2(dme)]$ *with* $Me_3SiNH(Bu^t)$ *in n-heptane and dme*

A yellow solution and a white precipitate were obtained from the reaction of $[WO_2Cl_2(dme)]$ with

* Author to whom correspondence should be addressed.

4 equivalents of $Me_3SiNH(Bu^t)$, either in dimethoxyethane homogeneously or in n-heptane heterogeneously. After 24 h reaction time at room temperature the reaction mixture was filtered to remove the white precipitate, identified by vibrational spectroscopy as pure $(Bu^tNH_3)Cl$. Approximately 0.25 mol equivalents of $(Bu^tNH_3)Cl$ relative to $[WO_2Cl_2(dme)]$ were formed at room temperature, but in reactions performed at 70°C for 6 h the relative amount of $(Bu^tNH_3)Cl$ increased substantially to approximately 0.5 mol equivalents. By cooling the filtrate at −30°C a yellow compound crystallized; IR and ^1H, $^{13}C\{^1H\}$ NMR data of this compound are in accordance with those of the well-known bisimido complex $\{[W(NBu^t)_2Cl_2(H_2NBu^t)]_2\}$[9] (**1**). Isolated yields of compound **1** were low, not exceeding 30% in the room-temperature reactions. The formation of **1** in the above reaction can be formulated as:

$$2[WO_2Cl_2(dme)] + 8Me_3SiNH(Bu^t) \longrightarrow [\mathbf{1}] + 4O(SiMe_3)_2 + 2H_2NBu^t + 2dme. \quad (1)$$

GLC analysis of the filtrate obtained after isolation of complex **1** revealed two of the reaction products, viz. dme and $O(SiMe_3)_2$. The third product of eq. (1), H_2NBu^t, has been consumed in aminolysis reactions of tungsten chlorine bonds, as indicated by the isolation of $(Bu^tNH_3)Cl$. The reaction of WO_2Cl_2 with primary amines, RNH_2, has been reported to give polymeric $[WO_2(NR)]_n$ and RNH_3Cl.[16] Brief experiments in the present study in which $[WO_2Cl_2(dme)]$ was reacted with 4 equivalents of H_2NBu^t in n-heptane gave 2 equivalents of $(Bu^tNH_3)Cl$ and a compound analysing to approximately $[WO_2(NBu^t)\cdot 0.5(H_2NBu^t)]$, which was highly soluble in common organic solvents. Found: C, 22.1; H; 4.7; N, 5.9; W, 55.9. Calc: C, 22.2; H, 4.5; N, 6.5; W, 56.8%.

The solution remaining after separation of $(Bu^tNH_3)Cl$ and the dimer **1** was evaporated at room temperature to give a yellow oil. The ^{13}C NMR spectrum of this oil showed the presence of traces of **1**, some $Me_3SiNH(Bu^t)$ and additional resonances between 60–70, 30–35 and 0.8–3.1 ppm, characteristic of the tertiary carbon atoms of t-butylimido groups and the methyl carbons of $NCMe_3$ and of $SiMe_3$, respectively. Aminolysis reactions leading to these imido species of unknown constitution and $(Bu^tNH_3)Cl$ are most likely the competitive reactions limiting the yield of complex **1**. Higher temperatures seem to accelerate aminolysis more than the complicated multistep reaction [eq. (1)] leading to the formation of complex **1**. Aminolysis of complex **1** by H_2NBu^t, which has been observed previously,[9] does not interfere under the reaction conditions used in the present study because no NMR signals of the reaction product, $[W(NBu^t)_2(HNBu^t)_2]$,[9,11] were observed in the filtrate. Due to easily accessible starting materials, WCl_6 and H_2NBu^t [or $Me_3SiNH(Bu^t)$], and higher yields it can be concluded that the original method of synthesizing the dimer **1**[9] is the superior one.

A derivative prepared by the reaction of complex **1** with 2 equivalents of Bu^t-dab in toluene provides further evidence of the nature of **1**. The crystal structure of this derivative, $[W(NBu^t)_2Cl_2(Bu^t\text{-dab})]$ (**2**), is discussed below. In analogy to the synthesis of $[Mo(NBu^t)_2Cl_2(bipy)]$ from $[MoO_2Cl_2(bipy)]$[15] it should be possible to prepare complex **2** by a different reaction path. $[WO_2Cl_2(Bu^t\text{-dab})]$[17] was, therefore, heated with 4 equivalents of $Me_3SiNH(Bu^t)$ in n-heptane; at room temperature the starting materials were left unchanged despite stirring the suspension for several weeks, while at 70°C a reaction occurred within 6 h. Unexpectedly, no $[W(NBu^t)_2Cl_2(Bu^t\text{-dab})]$ (**2**) was formed. By concentrating, filtering and cooling the reaction mixture yellow crystals and a white powder were isolated. The yellow crystals and the white substance were identified by vibrational spectroscopy as complex **1** and $(Bu^tNH_3)Cl$, respectively. The imido bridges of the dimer **1** are cleaved by reaction with Bu^t-dab or other nitrogen donors[9,18] to give monomeric bisimido complexes, such as complex **2**. The outcome of the reaction between $[WO_2Cl_2(Bu^t\text{-dab})]$ and $Me_3SiNH(Bu^t)$ is, therefore, unexpected and no straightfoward explanation can be given.

Finally, some further remarks on the reaction under discussion are noteworthy. Firstly, there is a clear reactivity difference between uncomplexed WO_2Cl_2 and $[WO_2Cl_2(dme)]$; the former does not react with $Me_3SiNH(Bu^t)$ in refluxing hexane,[10,11] while the latter reacts readily at room temperature. The reactivity difference is most likely related to the strong oxo-bridges in the polymeric structure of WO_2Cl_2,[19] which are not present in monomeric $[WO_2Cl_2(dme)]$ with the labile dme ligand.[14] Secondly, it has been observed that the reaction of MoO_2Cl_2 with $Me_3SiNH(Bu^t)$ in n-heptane leads to monomeric $[(Bu^tN)_2Mo(OSiMe_3)_2]$,[10,11] where chlorine has been removed and oxygen has been retained. Experiments in the present study using dme instead of n-heptane as the solvent confirm the same reaction product in that solvent. The opposite behaviour, i.e. retaining the chloro ligands and oxo/imido exchange, is observed in the case of $[WO_2Cl_2(dme)]$, where the dimeric complex **1** is formed. Thirdly, ethers cannot substitute the terminal amino ligand or break the imido bridges of complex **1**, because complex **1** is also formed in dme as the solvent.

Reaction of $[WO_2Cl_2(dme)]$ *with* $Me_3SiNH(Bu^t)$ *in dmf*

As can be observed by ^1H NMR and ^{13}C NMR dmf is immediately and quantitatively liberated upon dissolving $[WO_2Cl_2(dme)]$ in dmf. Due to a fast dme exchange at the tungsten centre which averages the NMR resonances no extra signals of the complex $[WO_2Cl_2(dmf)_2]$ can be observed. The addition of 2 equivalents of $Me_3SiNH(Bu^t)$ to $[WO_2Cl_2(dme)]$, dissolved in dmf, gave a solution which, according to its NMR spectrum, after stirring for 4 days at room temperature contained nothing but unreacted $Me_3SiNH(Bu^t)$, free dme and solvated WO_2Cl_2. The addition of 4 equivalents of $Me_3SiNH(Bu^t)$ to $[WO_2Cl_2(dme)]$ in dmf, however, gave a clear yellow solution from which a white solid began to precipitate after 2 h stirring. This substance could be sublimed easily at 70°C/0.01 torr to give a white diamagnetic and chlorine-free powder containing dmf and analysing as $C_{29}H_{79}N_3O_8Si_6W_2$ (**3**). A molecular weight determination (osmometry in dmf, 75°C) established that in solution compound **3** is a dimer and not a monomer (Mol. wt: found: 1030; (3-dmf) calc.: 1061). Further evidence of a dimeric species **3** was provided by its FAB mass spectrum. Although no molecular ion peak was detectable the fragment ions are larger than those expected from a monomer. Moreover, the solution and solid-state Raman spectra of compound **3** (see below) are similar, indicating that complex **3** is a dimer in the solid state. The compound is highly soluble in common organic solvents such as ethers, nitriles, aromatic, aliphatic and chlorinated hydrocarbons, while the solubility in dmf at room temperature is low. Dissolving the sublimed compound in heptane, precipitation by cooling and repeated sublimation did not remove dmf. GLC of the filtrate obtained after isolation of complex **3** showed the presence of dme, traces of $O(SiMe_3)_2$ and *ca* 10% of unreacted $Me_3SiNH(Bu^t)$; no Me_3SiCl was detected. Besides GLC no attempts were made to trace the fate of the reaction products not containing tungsten. The O/W ratio of ionic oxygen in the product is higher than that in the adducts (7:4). As the experiments were performed under rigorous exclusion of water/oxygen there are three sources for the additional oxygen atoms available, viz. those of dme, the oxo groups of the starting complex $[WO_2Cl_2(dme)]$ and the solvent dmf. Even if oxygen abstraction from complexed dme is known to occur in tungsten(VI) complexes,[20] dme is a weaker donor to tungsten(VI) than dmf. It is, therefore, unlikely that dme should re-enter the coordination sphere of tungsten during the reaction in dmf as the solvent. Furthermore, no deoxygenation products of dme such as methylchloride, 1,2-dichloroethane or 1-chloro-2-methoxyethane were detected by GLC. As complex **3** is formed in approximately 80% yield, the oxo groups of yet unreacted solvated WO_2Cl_2 cannot be the only source of the extra oxygen atoms. This leaves dmf as the most likely source of oxygen in the reaction.

No details of the reaction mechanism leading to complex **3** are known. One feature of the reaction, viz. the formation of the silanolato ligands in complex **3** (see below) by the migration of the trimethylsilyl group in complexed $Me_3SiNH(Bu^t)$ to some metal bound oxygen, is well known: the formation of silanolato ligands from metal oxo M=O bonds and $Me_3SiNH(Bu^t)$ has been ascribed to a rearrangement reaction from an intermediate oxo-amido complex $\{M(=O)[-N(Bu^t)(SiMe_3)]\}$ to an imido-silanolato complex $[M(=NBu^t)(-OSiMe_3)]$, M = V,[10,21,22] W.[13] Also, the reactions of $MOCl_3$ (M = Nb, Ta) with $Li[N(SiMe_3)_2]$ to form complexes $\{M(NSiMe_3)(OSiMe_3)[N(SiMe_3)_2]\}$[23] represent this reaction type. Attempts to obtain single crystals of **3** have until now been unsuccessful. Suggestions concerning the structure of **3** must, therefore, be based on the information from ^1H, ^{13}C, ^{14}N, ^{17}O, ^{29}Si NMR, IR and Raman spectra given in the Experimental.

Characterization of complex **3** *by spectroscopic methods*

The collected spectroscopic information prove the presence of a terminal monoimido function, W = NBu^t, in molecule **3**. The ^{14}N NMR spectrum shows, besides the ^{14}N resonance signal of free dmf, one resonance at 5.6 ppm. Only one ^{13}C NMR resonance, at 68.4 ppm, in the range of tertiary carbons is observed. The position of this resonance is characteristic of a tertiary carbon in a t-butylimido ligand.[24] Molecule **3** does not, therefore, contain amino or amido ligands, a conclusion strengthened by the absence of IR and Raman peaks at wave numbers higher than 3100 cm^{-1}, where N—H stretching vibrations occur.[25] Furthermore, a strong peak at 1298 cm^{-1} in the Raman spectrum, which is polarized in the CH_2Cl_2-solution Raman spectrum, can be assigned to ν_s(W=N—C) of a terminal imido function;[26] ν_{as}(W=N—C) appears with medium intensity at 958 and 954 cm^{-1} in the IR spectrum and the solution Raman spectrum (solvent: CH_2Cl_2), respectively; the Raman band at 954 cm^{-1} is not observed in the solid state spectrum. The deformation mode, δ(W=N—C), expected[26] between 600 and 700 cm^{-1}, is probably obscured by the vibrations of the trimethylsilyl group,[27]

$\nu_{as}(SiC_3)$ and $\nu_s(SiC_3)$, which are centred around 680 and 630 cm^{-1}, respectively.

The C—O stretching vibration of dmf in molecule **3** at 1662 (IR) and 1661 (Raman) cm^{-1} is not significantly shifted to lower wave numbers relative to neat dmf [measurements on dmf in the present study: 1668 (IR, Nujol, CsI), 1661 cm^{-1} (Raman)]; dmf is, therefore, not coordinated to tungsten in the solid state.

No spectroscopic evidence for terminally-bound oxo functions is found in the spectrum of molecule **3**. The W=O stretching vibrations of mono- and dioxo tungsten(VI) complexes[28] usually give rise to very intense Raman and IR bands between 850 and 1000 cm^{-1}; no intense Raman bands are found in this region. The intense IR bands at 921 and 898 cm^{-1} can be assigned to silicon–oxygen stretching vibrations,[29] which have low Raman and high IR intensities.[30]

The ^1H and ^{13}C NMR spectra of complex **3** reveal the presence of $OSiMe_3$ groups. By integration of the ^1H NMR signals the ratio 1:3:3 (dmf):18 (the two t-butyl signals):54 (all $OSiMe_3$ signals) is obtained. A formulation of complex **3** as $\{[W_2(NBu^t)_2(O)(OSiMe_3)_6]\cdot dmf\}$ is, therefore, reasonable.

For reasons of charge compensation one oxygen atom has been included in this formula to obtain tungsten(VI) and as no terminal oxo functions are present in complex **3**, this oxygen atom must be a bridging one. Based on the observation of a single ^{29}Si NMR resonance and provided no fast exchange between potentially bridging and terminal $OSiMe_3$ groups proceed at the ambient temperature at which the ^{29}Si NMR spectrum has been run, the six trimethylsilanolato ligands ought to be terminal ones; a conclusion supported by the ^{17}O NMR spectrum reported below. The tungsten–oxygen stretching vibrations ν(W—$OSiMe_3$) are assigned to the bands of highest intensity both in the IR and the solid-state Raman spectra between 400 and 620 cm^{-1}; they occur at 430 cm^{-1} and are very broad, with no fine structure discernable; this broad band is polarized in the CH_2Cl_2-solution Raman spectrum. Compared to the metal–oxygen stretching frequencies of terminal silanolato ligands in other metal complexes,[29,30] this band is shifted to the red and is in the region of bridging silanolato ligands (400–500 cm^{-1}).[31] However, it is very unlikely that all six silanolato ligands are bridging ones and it is not reasonable that a molecule with both terminal and bridging silanolato groups should have tungsten–oxygen stretchings ν(W—O_t) and ν(W—O_b) at similar wave numbers. Consequently, all $OSiMe_3$ ligands are of one kind, i.e. terminal ones. The ^{17}O NMR spectrum from −100 to 1100 ppm [$\delta(H_2{}^{17}O) = 0$ ppm] shows signals at 293 ppm, assignable to dmf (measurement on dmf in $CDCl_3$ in the present study: 307 pm), and at 199 ppm. As ^{17}O NMR signals of terminal $OSiMe_3$ ligands in a niobium and a tantalum complex[23] occur at 243 and 229 ppm the resonance at 199 ppm in the spectrum of **3** is due to terminally bound silanolate ligands. No signals of terminal or bridging oxo groups, which are expected at much lower fields[32] than those observed, are found. A low-field ^{17}O NMR signal of an isotope enriched compound **3** synthesized from $[W^{17}O_2Cl_2(dme)]$ in $HC(^{17}O)NMe_2$ as a solvent would, with no X-ray structure determination, confirm the presence of a bridging oxo ligand in complex **3**. The structure $\{[W_2(NBu^t)_2(\mu\text{-}O)(OSiMe_3)_6]\cdot dmf\}$ could also be indicated by the appearance of the symmetric and antisymmetric W—O—W stretching bands of a linear or bent W—O—W linkage. In a tungsten complex with a non-linear W—O—W bridge $\nu_{as}(W_2O)$ and $\nu_s(W_2O)$ have been assigned to bands at 700 (IR, Raman), 530 (IR) and 556 cm^{-1} (Raman), respectively;[33] intensities are high for $\nu_{as}(W_2O)$ in IR and $\nu_s(W_2O)$ in Raman. In the Raman spectrum of molecule **3** only two weak bands between 430 and 630 cm^{-1} appear, and thus no bent W—O—W group is present in molecule **3**.

In the complex $[W_2O_2(\mu\text{-}O)(CH_2CMe_3)_6]$,[34] with a linear O=W—O—W=O arrangement, $\nu_{as}(W_2O)$ and $\nu_s(W_2O)$ occur at 693 (IR) and 205 (Raman) cm^{-1}, respectively, while in other linear oxygen-bridged transition metal complexes $\nu_{as}(M_2O)$ and $\nu_s(M_2O)$ have been found between 840–890 (IR) and 200–250 cm^{-1} (Raman), respectively.[35] Vibrational spectroscopic studies in this laboratory on complexes of the type $W_2O_3Cl_4(L_2)_2$ (L_2 = dme and bidentate nitrogen donors)[36] showed $\nu_{as}(W_2O)$ with medium to low intensity in the range 815–850 cm^{-1} (IR); low-quality Raman spectra precluded the assignments of $\nu_s(W_2O)$ for these complexes. In the IR spectrum of molecule **3** three bands at 839, 748 and 681 cm^{-1} appear in the range 650–850 cm^{-1}. Due to the $SiMe_3$ groups present they are assigned to the rocking and stretching modes $\rho(CH_3Si)$ and $\nu_{as}(SiC_3)$,[27] respectively. If a linear W—O—W linkage exists in molecule **3** $\nu_{as}(W_2O)$ should appear in this spectral range or, if not observed separately from these three IR bands which is the case here, coincide with one of them. The Raman spectrum of the CH_2Cl_2 solution of complex **3** between 250 and 125 cm^{-1} shows (Fig. 1) that only one band in this region, at 186 cm^{-1}, is polarized. This observation is a strong indication that there is indeed a linear W—O—W linkage present in molecule **3** with $\nu_s(W_2O) = 186$ cm^{-1}. Molecule **3** could then, by analogy to $[W_2O_2(\mu\text{-}O)(CH_2CMe_3)_6]$,[34] consist of

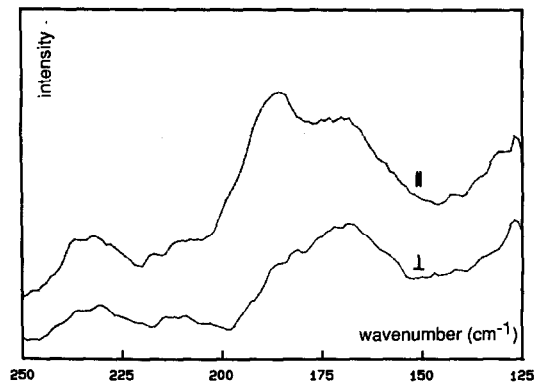

Fig. 1. Raman spectrum of compound **3** between 125 and 250 cm^{-1} in CH_2Cl_2 solution.

a linear N=W—O—W=N frame and three silanolato ligands about each tungsten atom, thus giving two apex-sharing trigonal bipyramids. In this context it is noteworthy that the size of the ^{14}N chemical shift of the imido nitrogen atom in complex **3** is consistent with data on tetra- and penta-coordinated terminal imido complexes with nitrogen and oxygen donors as co-ligands.[37]

The rhenium compound $[\{Re(NBu^t)_2(OSiMe_3)\}_2(\mu\text{-}O)(\mu\text{-}OReO_3)(\mu\text{-}OSiMe_3)]$[38] is another complex to which complex **3** could bear a structural resemblance. By analogy to the structure of this rhenium complex molecule **3** could be formulated as $\{[\{W(NBu^t)(OSiMe_3)_2\}_2(\mu\text{-}O)(\mu\text{-}OSiMe_3)_2] \cdot dmf\}$, but the spectroscopic data on the tungsten–oxygen stretchings of the silanolato groups are, as discussed above, not in accordance with such a structure.

Summarizing all the results molecule **3** has most probably a linear W—O—W arrangement and is best described as $\{[W_2(NBu^t)_2(\mu\text{-}O)(OSiMe_3)_6] \cdot dmf\}$.

One more complication concerning the ^1H and ^{13}C NMR spectra of complex **3**, not accounted for in the discussion above, cannot be left without comment. There are two resonances of the t-butyl methyl groups, one major at 1.33 and one minor at 1.23 ppm (integrals 9 : 1) in the ^1H NMR. This is matched by two methyl carbon resonances at 31.47 and 31.04 ppm in ^{13}C NMR. Furthermore, centred around the main resonances of the $OSiMe_3$ groups at 0.08 ppm in ^1H NMR and at 2.09 ppm in ^{13}C NMR small additional peaks appear at 0.15, 0.14, 0.09, 0.07, 0.06 and 0.03 ppm (^1H NMR) and at 1.69, 1.63 and 1.52 ppm (^{13}C NMR). The spectra obtained from different preparations are reproducible and these additional peaks are, therefore, not due to impurities of hydrolysis products. At present nothing but a proposal that these NMR peaks are due to some kind of isomerism can be given.

Structure of $[W(NBu^t)_2Cl_2(Bu^t\text{-}dab)]$ (**2**)

The structure of molecule **2** with atomic numbering is depicted in Fig. 2; selected bond distances and angles are given in Table 1. The tungsten atom in molecule **2** exhibits a distorted octahedral geometry, with *cis*-orientated t-butylimido and *trans*-dichloro ligands. The nitrogen atoms of Bu^t-dab are coordinated *trans* to the imido ligands. The tertiary carbon atoms of the two t-butylimido ligands are placed 0.12 Å above [C(11)] and 0.12 Å below [C(15)] and those of the Bu^t-dab ligand 0.29 Å below [C(7)] and 0.19 Å above [C(3)] the plane defined by the atoms N(3), W and N(4). The distance from the chlorine atoms to this plane is the same, 2.32 Å. Thus, the overall symmetry of molecule **2** is close to C_2 with the C_2 axis intersecting the N(3)—W—N(4) and Cl(1)—W—Cl(2) angles.

The tungsten–nitrogen bond lengths of the two imido ligands are very similar, 1.758(8) and 1.756(8) Å, respectively, and the corresponding W—N—C angles are far from linear, 161.8(7)° and 160.8(7)°. The two nitrogen atoms of these bent imido ligands have been described as six-electron donors, thus enabling an 18-electron count at the six-coordinate tungsten centre.[39] As can be seen from Table 2 the structural data of the $W(NBu^t)_2$ moiety of molecule **2** agree well with those of other known tungsten complexes with terminal bisimido ligands (see Table 2). The deviations from regular octahedral geometry comprise the wide N(3)—W—N(4) bond angle of 105.9(4)° and the small Cl(1)—W—Cl(2) bond angle of 154.1(1)°, whereby the chloro ligands are tilted away from the bisimido ligands. The tungsten chlorine bonds, 2.389(2) and 2.394(3) Å, indicate minimal or no participation of π-bonding in these bonds.[39]

The tungsten–nitrogen bond lengths of Bu^t-dab are 2.507(7) and 2.533(7) Å, respectively. They are

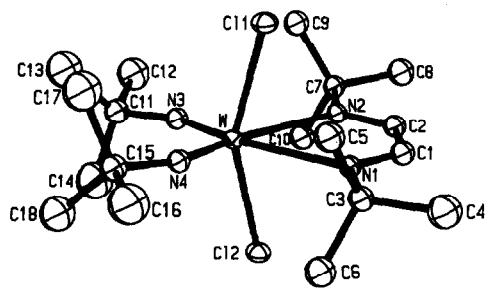

Fig. 2. A perspective view of the $[W(NBu^t)_2Cl_2(Bu^t\text{-}dab)]$ (**2**) molecule.

significantly longer than the bonds between tungsten and the nitrogen atoms of 2,2′-bipyridyl in $[W(NPh)_2Cl_2(bipy)]$,[39,40] 2.309(12) and 2.319(13) Å. Such large differences in metal–N(sp^2) bond lengths between Bu^t-dab complexes and their analogues containing aromatic dinitrogen ligands have been observed earlier, e.g. $[MoO_2Cl_2(Bu^t\text{-dab})]$[17] and $[MoO_2Cl_2(o\text{-phen})]$.[42] An interplay of electronic effects, viz. more electron donation from *o*-phen or bipy than from Bu^t-dab into empty metal *d*-orbitals and of steric effects, viz. the bulkiness of t-butyl in Bu^t-dab, can explain the shorter metal–nitrogen bonds in bipy and *o*-phen complexes.

In complexed Bu^t-dab the orientation of the three methyl groups of each t-butyl group is such that two carbon atoms are directed towards the other ligands with about the same distance to the tungsten atom, thus leading to four close carbon–nitrogen contacts with the two t-butyl imido nitrogen atoms in the range 3.41–3.49 Å (sum of the van der Waals radii of C and N: 3.39 Å[43]). Any rotation of the methyl groups around the N(1)—C(3) or N(2)—C(7) bond of Bu^t-dab should, therefore, lead to stronger methyl carbon/imido nitrogen repulsion. Similar conformations of Bu^t-dab methyl groups were earlier observed in $[MoO_2Cl_2(Bu^t\text{-dab})]$,[17] in which methyl carbon/oxo repulsions determine the t-butyl conformations.

In each t-butyl imido ligand only one methyl carbon is orientated towards the metal atom giving four short carbon–carbon contacts to the Bu^t-dab methyl carbons with an average C···C distance of 3.67 Å (van der Waals radius of C: 1.85 Å[43]). Any other orientations of the imido methyl groups will

introduce additional close contacts to the Bu^t-dab methyl groups and increase steric strain. The distances between the methyl carbon atoms of the two imido ligands are outside the double van der Waals radius of carbon.

EXPERIMENTAL

All manipulations were performed under argon as an inert gas using standard Schlenk techniques. n-Heptane and toluene were dried over activated molecular sieves, dimethylformamide was stirred with CaH_2 at 70°C for several hours and distilled under reduced pressure. $[WO_2Cl_2(dme)]$,[14] N,N'-di-t-butyl-1,4-diaza-1,3-butadiene (Bu^t-dab),[44] $[WO_2Cl_2(Bu^t\text{-dab})]$[17] and $Me_3SiNH(Bu^t)$[45] were prepared according to the literature. Elemental analyses and molecular weight determination were performed by Analytische Laboratorien Malissa und Reuter, Gummersbach, F.R.G. IR spectra (Nujol mulls between CsI plates) and Raman spectra were recorded with a Nicolet 20SXC and a Bruker FRA 106 spectrometer (excitation radiation 1064 nm, resolution 4 cm^{-1}, 1000–3000 scans), respectively. Polarization measurements were performed in CH_2Cl_2 solution with a Dilor Z 24 (excitation radiation 514.5 nm, resolution 4 cm^{-1}, laser power 400 mW). ^1H NMR, ^{13}C NMR ($SiMe_4$ as an internal standard with $\delta = 0$ ppm), ^{29}Si NMR [$SiMe_4$ as an external standard with $\delta(^{29}Si) = 0$ ppm] and ^{14}N NMR [CD_3NO_2 as an external standard with $\delta(^{14}N) = 0$ ppm] were recorded with a Varian XL 300 spectrometer. ^{17}O NMR [H_2O/D_2O (1/1) as an external standard with $\delta(^{17}O) = 0$ ppm] was recorded with a Varian–Unity 300 MHz spectrometer.

X-ray crystallography

Orange crystals of $[W(NBu^t)_2Cl_2(Bu^t\text{-dab})]$ (**2**) were obtained from toluene solution by cooling at −30°C for 2 weeks. A prismatic crystal of complex **2** was enclosed in a Lindemann capillary to protect it from air. Unit-cell parameters were derived from least-squares fitting of angular settings of 50 reflections. The data were corrected for a decrease of 10% during the data collection and for Lorentz, polarization and absorption effects, the latter by an empirical method.[46] Some crystal data are collected in Table 3.

The structure was solved by direct methods (MULTAN87), which gave the tungsten and chlorine positions, followed by subsequent difference-Fourier syntheses. In the final refinements the tungsten and chlorine atoms were refined with anisotropic and the other non-hydrogen atoms with isotropic temperature factors. The hydrogen atoms were included with fixed positional parameters at calculated positions with C—H = 0.95 Å.

Syntheses

$\{[W(NBu^t)_2Cl_2(NH_2Bu^t)]_2\}$ (**1**). To $[WO_2Cl_2(dme)]$ (1.90 g, 5.0 mmol), suspended in n-heptane (30 cm^3) was slowly added $Me_3SiNH(Bu^t)$ (2.92 g, 20.1 mmol) in n-heptane (10 cm^3) with stirring. The suspension immediately turned yellow. After 1 day stirring a white precipitate, $Bu^t(NH_3)Cl$ (0.13 g, 1.2 mmol), was separated by filtration and the yellow filtrate concentrated to approximately half the volume. The solution was kept at −30°C for 2 days and **1** collected on a filter and dried *in vacuo*. Yield: 0.67 g, 29%. The purity and identity of compound **1** was checked by comparison of its NMR and IR spectra with the spectra of a sample synthesized according to the published preparation of **1**.[9] Raman bands at: 3295w, 3175w, 3099w, 2979vs, 2920vs, 2794w, 2761w, 2731w, 2699vw, 2601vw, 2500vw, 1471m, 1448m, 1383vw, 1337vw, 1304m, 1283vs, 1237m, 1217m, 1151m, 1138m,

1105vw, 1075w, 1025w, 996w, 935w, 917w, 887w, 808m, 752w, 731m, 696vw, 635vw, 605w, 559w, 536w, 453m, 380vw, 350vw, 307w, 283m, 252m, 237m, 212m, 193m cm^{-1}.

$[W(NBu^t)_2Cl_2(Bu^t\text{-dab})]$ (**2**). Compound **1** (0.46 g, 0.5 mmol) was dissolved in toluene (10 cm^3) and solid Bu^t-dab (0.19 g, 1.1 mmol) was added with stirring. The solution was heated at 70°C for 5 h. The orange solution was then kept at −30°C for 2 weeks. Orange crystals of **2**, which contained single crystals suitable for an X ray structure determination, were collected, washed with a small amount of cooled ether and dried *in vacuo*. Yield: 0.32 g, 56.6%. Found: C, 37.3; H, 6.6; N, 9.5; Cl, 12.1. Calc. for $C_{18}H_{38}Cl_2N_4W$: C, 38.2; H, 6.8; N, 9.9; Cl, 12.5%. IR and *Raman* data (in cm^{-1}); 1630vw, 1609vw, *1631w*, *1613s* [*v*(C=N)]; 1260s, 1208s, *1262vs*, *1212m* [*v*(W=N—C)]; 318vs, 311s, 290sh, *317m*, *295m* [*v*(W—Cl)]. NMR data (CD_2Cl_2, $T = 293$ K); ^1H: 8.13 (s, 2H, —C*H*=N—), 1.58 [s, 18H, W=NC(CH_3)$_3$], 1.44 [s, 18H, CH=NC(CH_3)$_3$]. $^{13}C\{^1H\}$: 153.2 (—*C*H=N—), 69.2 [W=N*C*(CH_3)$_3$], 68.2 [CH=N*C*(CH_3)$_3$], 32.3 [W=NC(*C*H_3)$_3$], 29.4 [CH=NC(*C*H_3)$_3$].

$\{[W_2(NBu^t)_2(\mu\text{-O})(OSiMe_3)_6]\cdot dmf\}$ (**3**). $[WO_2Cl_2(dme)]$ (1.21 g, 3.2 mmol) was dissolved in dmf (13 cm^3); to the stirred solution was slowly added neat $Me_3SiNH(Bu^t)$ (1.86 g, 12.8 mmol). The colourless solution became yellow immediately and after approximately 2 h a white substance began to precipitate. After stirring for 24 h at room temperature and cooling at −30°C for 1 day the white precipitate was filtered and dried *in vacuo* for 5 h to give 1.55 g (84%) of raw product (**3**), which was sublimed at 70°C bath temperature and 10^{-2} torr. Yield of sublimed **3**: 1.24 g, 68.1%. Found: C, 31.3; H, 6.8; N, 3.4; W, 30.3. Calc. for $C_{29}H_{79}N_3O_8Si_6W_2$: C, 30.7; H, 7.0; N, 3.7; W, 32.4%. Mol. wt (osmometric, dmf, 75°C): calc. for $C_{26}H_{72}N_2O_7Si_6W_2$ (**3**-dmf): 1061; found: 1030. (*Received* 18 *December* 1992; *accepted* 1 *February* 1993)

Abstract—Microcrystalline powders of the complexes $(HC_6H_7N)_2[Ni(S_2C_2O_2)_2]$ (**1**), $(HC_6H_7N)_2[Pd(S_2C_2O_2)_2]$ (**2**) and $(HC_6H_7N)_2[Pt(S_2C_2O_2)_2]$ (**3**) were obtained by reaction of 2-methylpyridinium hydrochloride and the corresponding $K_2[M(S_2C_2O_2)_2]$ salts in aqueous solution. These compounds were characterized by elemental analysis, IR and UV–vis spectroscopies, thermal analysis (TG, DTG and DTA) and X-ray diffraction techniques. Single crystals of compound **1** were obtained by recrystallization in N,N-dimethylformamide and its crystal structure was determined from single-crystal X-ray diffraction. The crystal structure consists of mixed layers of quasi-planar complex $[Ni(S_2C_2O_2)_2]^{2-}$ anions and 2-methylpyridinium cations held together by electrostatic interactions, an extensive network of hydrogen bonds of the types N—H···O and C—H···O and anion–cation π–π interactions.

Interest in square-planar d^8 metal complexes involving sulphur donor ligands has received increased attention in recent years because of their crystal structures, based on columnar stacked structures of square co-planar metal complexes and their electronic properties.[1–11] The presence of four donor atoms in the dithiooxalate dianion and the possibilities of charge delocalization on its atoms result in a multifunctional ligand with unique coordination properties.[12] X-ray structure determinations demonstrate the ability of the dithiooxalate ligand to coordinate to the central metal ion by two sulphur or two oxygen donor atoms, respectively; furthermore, dithiooxalate may coordinate simultaneously to more than one metal ion in polynuclear complexes.[2,4]

Previous X-ray reports on the structures containing $[M(S_2C_2O_2)_2]^{2-}$ anions[7–11] have demonstrated that the nature and size of the counter-ions play an important role in the crystal packing of this kind of compound. The almost planarity of the most inorganic dithiooxalato anions leads to a more compact crystal packing in compounds containing organic planar cations than those observed for compounds of large and bulky cations.[8,11]

In this context we decided to study the reaction between aromatic organoammonium molecules and several square-planar inorganic metal(II) 1,2-dithiooxalato-S,S′ anions, in order to obtain a deeper insight into the cation and metal effects on the crystal packing and the strength of the intramolecular interactions in this type of compound. On the other hand, oxidative thermal decompositions of various nickel, palladium and platinum complexes are used for the production of metal and metal oxides, which are extensively applied as catalysts in a variety of important chemical processes.[13]

In the light of the recent interest in the bio-

† Author to whom correspondence should be addressed.

inorganic chemistry of nickel[14] the present paper reports the syntheses, the chemical characterization and the thermal behaviour of 2-methylpyridinium salts of 1,2-dithiooxalate-S,S′ metalate anions, $[M(S_2C_2O_2)_2]^{2-}$, where M is nickel(II), palladium (II) or platinum(II), as well as the crystal and molecular structure of the compound bis(2-methylpyridinium) bis(1,2-dithiooxalate-S,S′)nickelate(II) (**1**).

EXPERIMENTAL

General and instrumental

The dithiooxalate ligand was used as purchased from Eastman Kodak. Elemental analyses were performed on a Perkin–Elmer 240 C, H and N analyser. The metal was determined using atomic absorption. IR spectra were recorded in the 4000–350 cm^{-1} range on an IR Beckman 4240 spectrophotometer using KBr discs. A Bausch–Lomb Spectronic 2000 spectrophotometer was used to record the UV–vis spectra (650–220 nm) of ethanol solutions (2×10^{-5} M) in 1 cm silica cells. Density values were measured by flotation in a mixture of $CCl_4/CHBr_3$. The differential thermal analysis (DTA) and thermogravimetric analysis (TG and DTG) curves were obtained, simultaneously, in argon and argon–oxygen atmospheres on a SETARAM TAG 24 S16 thermobalance, with a heating rate of 5°C min^{-1}. X-ray powder diffraction patterns of **2**, **3** and the final products from thermal decompositions of compounds **1–3** were obtained on a Philips PW 1710 instrument with nickel-filtered Cu-K_α radiation. Diffraction patterns of thermal decomposition residues were compared with those obtained from the ASTM powder diffraction files of the Joint Committee on Powder Diffraction Standards.

Synthesis of complexes

The potassium salts of the complex anions $[M(S_2C_2O_2)_2]^{2-}$ were prepared following the procedure described by Cox[15] and the purity checked by elemental analysis.

Bis(2-*methylpyridinium*) *bis*(*dithiooxalato*)*nickelate* (II), $(HC_6H_7N)_2[Ni(S_2C_2O_2)_2]$ (**1**). A sample of 2-methylpyridinium hydrochloride (0.60 g, 4.63 mmol) was dissolved in water (25 cm^3) and an aqueous solution (25 cm^3) of $K_2[Ni(S_2C_2O_2)_2]$ (0.80 g, 2.12 mmol) was added with stirring at room temperature. Immediately an insoluble microcrystalline powder of **1** was obtained. Dark-purple single crystals suitable for X-ray investigations were obtained by recrystallization in an H_2O/DMF (3/1, v/v) mixture, after 3 weeks. Yield: 0.75 g, 1.53 mmol, 72% based on nickel. Found: C, 39.2; H, 3.4; N, 5.7; Ni, 12.2. Calc. for $C_{16}H_{16}N_2NiO_4S_4$: C, 39.4; H, 3.3; N, 5.8; Ni, 12.1%. Selected IR data (KBr, cm^{-1}): 1590vs, 1535vs, 1440s [ν(C=O)]; 1080vs [ν(C—C)+ν(C—S)]; 945s [δ(C—O)+ν_a(C—S)]; 580w, 520w, 435w [ν_s(C—S)]; 410m [ν_a(Ni—S)]; 360w [ν_s(Ni—S)]. UV–vis [EtOH, nm (ε, M^{-1} cm^{-1})]: 563.4 (2805), 511.3 (3471), 298.3 (22,089), 260.9 (23,843).

Bis(2-*methylpyridinium*) *bis*(*dithiooxalato*)*paladate*(II), $(HC_6H_7N)_2[Pd(S_2C_2O_2)_2]$ (**2**). This compound was synthesized from $K_2(Pd(S_2C_2O_2)_2]$ (0.25 g, 0.59 mmol) and 2-methylpyridinium hydrochloride (0.20 g, 1.54 mmol) in water (30 cm^3) following the general method described for **1**. The resultant yellow precipitate was isolated by vacuum filtration, washed with EtOH and Me_2O and recrystallized from DMF. Unfortunately, yellow dark crystals were twinned and were not suitable for single-crystal X-ray diffraction. Yield: 0.228 g, 0.54 mmol, 91% based on palladium. Found: C, 35.8; H, 3.2; N, 5.1; Pd, 19.8%. Calc. for $C_{16}H_{16}N_2O_4PdS_4$: C, 35.9; H, 3.0; N, 5.2; Pd, 19.9%. Selected IR data (KBr, cm^{-1}): 1585vs, 1440m [ν(C=O)]; 1080vs [ν(C—C)+ν(C—S)]; 940s [δ(C—O)+ν_a(C—S)]; 540w [ν_s(C—S)]; 410m [ν_a(Pd—S)]; 365m [ν_s(Pd—S)]. UV–vis [EtOH, nm (ε, M^{-1} cm^{-1})]: 388.7 (8498), 276.5 (39,504), 244.9 (22,996).

Bis(2-*methylpyridium*) *bis*(*dithiooxalato*)*platinate* (II), $(HC_6H_7N)_2[Pt(S_2C_2O_2)_2]$ (**3**). Red crystals of this compound were prepared from $K_2[Pd(S_2C_2O_2)_2]$ (0.10 g, 0.19 mmol) and 2-methylpyridinium hydrochloride (0.05 g, 0.42 mmol) in water (15 cm^3) by a similar procedure to above. Yield: 0.230 g, 0.37 mmol, 63% based on platinum. Found: C, 30.9; H, 2.6; N, 4.4; Pt, 31.1. Calc. for $C_{16}H_{16}N_2O_4PtS_4$: C, 30.8; H, 2.6; N, 4.5; Pt, 31.3%. Selected IR data (KBr, cm^{-1}): 1580vs, 1435m [ν(C=O)]; 1080vs [ν(C—C)+ν(C—S)]; 945s [δ(C—O)+ν_a(C—S)]; 575w, 520w, 435w [ν_s(C—S)]; 415m [ν_a(Pt—S)]; 390w [ν_s(Pt—S)]. UV–vis [EtOH, nm (ε, M^{-1} cm^{-1})]: 466.3 (4968), 433.3 (6062), 413.5 (5594), 332.7 (4156), 266.3 (9156), 260.5 (11,718), 239.9 (20,875).

Crystallographic data collection and structural refinement of **1**

A dark purple, prismatic, single crystal of **1** with the approximate dimensions $0.25 \times 0.30 \times 0.15$ mm was mounted on an Enraf–Nonius CAD4 four-circle diffractometer. X-ray data were collected with graphite-monochromated Mo-K_α radiation ($\lambda = 0.71069$ Å) at 295 K using the ω–2θ scan technique. Accurate unit-cell parameters and an orien-

tation matrix for data collection were obtained from least-squares refinement, using the setting angles of 25 reflections in the range $8 < \theta < 15°$. A total of 4389 independent reflections were measured in the range $2 \leqslant \theta \leqslant 35$ ($0 \leqslant h \leqslant 16$; $0 \leqslant k \leqslant 12$; $-22 \leqslant l \leqslant 22$), 1648 of which, with $I > 3\sigma(I)$, were used in the development and refinement of the structure. No significant decay of intensity of three standard reflections recorded after every 100 reflections was observed. The intensity data were corrected for Lorentz and polarization effects. An empirical absorption correction ($\mu = 13.954\ cm^{-1}$) following the procedure DIFABS[16] with minimum and maximum correction coefficients 0.551–1.263 was applied. The atomic scattering factors and anomalous dispersion corrections were taken from the International Tables for X-ray Crystallography (1974).[17] The structure was solved by a combination of Patterson and difference-Fourier methods and refined by full-matrix least-squares. Non-hydrogen atoms were refined anisotropically. A convenient weighting scheme[18] was used to obtain flat dependence in $\langle w\Delta^2F \rangle$ vs $\langle F_o \rangle$ and $\langle \sin\theta/\lambda \rangle$. All aromatic hydrogen atoms were clearly visible in a difference-Fourier synthesis and were refined isotropically. The hydrogens of the methyl groups were introduced in the final refinement in calculated positions as fixed isotropic contributors ($U = 0.07\ Å^2$). Last cycles of refinement led to the discrepancy indices $R = 0.038$ and $wR = 0.047$ for 144 parameters; goodness of fit = 1.23; maximum shift/error in the final cycle = 0.09 and the highest peak in the final difference-Fourier map was 0.21 e $Å^{-3}$. Most calculations were performed using the X-RAY76 system[19] running on a MicroVAX II computer. Final atomic positional and thermal parameters, together with anisotropic thermal parameters for non-hydrogen atoms, full list of bond distances and angles, dihedral angles, and a list of observed and calculated structure factors have been deposited as supplementary material with the Editor, from whom copies are available on request. Atomic coordinates have also been submitted to the Cambridge Crystallographic Data Centre.

Compounds **2** and **3** crystallize in insufficient quality to be studied as single crystals, but their cell parameters have been obtained by powder diffraction data. The powder diffraction pattern was recorded on a Philips PW 1710 diffractometer; 2θ values were corrected using the GUINIER program[20] with an α-SiO_2 standard pattern. Accurate cell parameters were obtained by least-squares refinement using the LSUCRE program.[21] Table 1 summarizes the crystal data for the three compounds and shows that all of them are isostructural.

RESULTS AND DISCUSSION

Spectroscopic characterization

The IR spectra certify the presence of the 2-methylpyridinium cations; giving evidence of this point are the corresponding bands at *ca* 3000 cm^{-1} for the C—H groups and 2700 cm^{-1} for N—H^+ groups. The characteristic and very strong bands of 2-methylpyridinium cations were obtained between 1650 and 600 cm^{-1}.[22] IR assignments of the bis(dithiooxalato)metallate(II) anions have been made in the 1600–350 cm^{-1} region and a comparison of the results with the observed spectra of the reported compounds[9–11] led to the assignments described in the Experimental.

The UV–vis spectra of the compounds exhibit two strong absorption bands in the UV range, at

ca 240 and 290 nm, which may be due to the $\pi^* \leftarrow n$ and $\pi^* \leftarrow \pi$ transitions of the aromatic cations and the dithiooxalate ligands. The less intensive bands in the visible region, which do not appear in the cation spectra, are attributable to metal–ligand charge transfer absorption and they are shifted as a function of the metal nature.[12,23–25]

Thermal analysis

Table 2 presents the thermoanalytical results of thermal decompositions of the three compounds in an argon–oxygen and argon atmospheres.

The TG–DTA curves for the compounds in the oxidative atmosphere are shown in Fig. 1. The compounds are anhydrous and stable up to approximately 185°C, beyond which a first abrupt weight loss takes place corresponding to an exothermic peak in the DTA curve. The thermal decompositions are quite similar and the first abrupt weight loss step is followed by a lower weight loss, which is accompanied by a stronger exothermic peak in the DTA curves. Final residues from the thermal decompositions at 600°C depend on the starting compound. For compound **1** the solid stable residue was identified as nickel(II) sulphide by its X-ray

powder diffractogram. The thermal decomposition of compound **2** yields a mixture of palladium(0) and palladium(II) oxide, whereas the final residue of **3** is platinum(0).

In an argon atmosphere (Fig. 2) most of the mass is lost in the first step with a high endothermic peak in the DTA curve around 240°C. For the nickel complex the solid residue at 265°C is stable and was identified as nickel(II) sulphide. No peaks belonging to nickel or other nickel compounds were found in the X-ray powder diffraction patterns. For **2** and **3** the first thermal decomposition step is followed by a progressive weight loss without clear peaks in the DTA curve and a constant mass was reached at 850°C. The final residues were identified as PdS and platinum for **2** and **3**, respectively.

X-ray structure determination

The asymmetric unit of **1** consists of one 2-methylpyridinium cation and one half of a complex anion, $[Ni(S_2C_2O_2)_2]^{2-}$, with the nickel atom lying on a centre of symmetry. Figure 3 shows the structure of the complex dianion and the cation with the atomic numbering scheme. Selected bond lengths, angles and the hydrogen contacts are listed in Table 3. The cation 2-methylpyridinium is almost planar and the bond lengths and angles are within the normal range reported in the bibliography.[22] The complex dianion is almost planar with a dihedral angle between the strictly planar NiS_4 group and the $S_2C_2O_2$ ligand mean plane of 1.83(5)°. This angle is in the lower end of the range previously

observed for similar bis(dithiooxalato)metallate(II) anions in compounds also containing aromatic cations[3,7] and is considerably lower than those observed in analogous complexes containing large and bulky cations.[8,11] The value of this angle is affected by a combination of factors, including the hydrogen contacts between the oxygen atoms and the hydrogen atoms of cations, as well as the π–π interactions between the aromatic cations and the dithiooxalate groups where a significant degree of electronic delocalization is present. Both of them may produce a displacement of the ligand atoms and a higher value of the dihedral angle between the MS_4 and the dithiooxalate groups. The short average C—S bond distance of 1.71 Å and the long average C=O bond distance of 1.22 Å are consistent with the existence of a significant degree of delocalization throughout the S—C—O units in the dianion, with a single C—C bond of 1.539(4) Å.

A stereoscopic view of the unit cell is shown in Fig. 4 (hydrogen contacts: dotted lines). The anions and cations are stacked in mixed sheets (at $z = 0$ and 1/2) along the [210] direction following the sequence ...accacc... (where a = anion and c = cation). Anion and cation best planes are almost parallel to each other, with a dihedral angle of 7.77(8)°. The crystal structure is stabilized by electrostatic attractions, an extensive network of hydrogen bonds of the type N—H···O and C—H···O is present (Table 3) and weak anion–cation π–π interactions. The ions situated in the same z-level are linked by a bifurcated hydrogen contact between the hydrogen atom of the pyridine ring nitrogen atom and two oxygen atoms of the same dithiooxalate ligand, and a monofurcated hydrogen contact between C(16) and O(2). The sheets placed in different z-levels are connected by hydrogen contacts among C(15) atoms of the cation and the anions. On the other hand, the stacking of cations and anions may suggest the existence of a significant interaction between the dithiooxalate groups and the π-systems of the aromatic cations, as found in other $[Ni(S_2C_2O_2)_2]^{2-}$ salts.[9,10] Each anion is placed between four 2-methylpyridinium

cations of two neighbour sheets, which are disposed above and below the dithiooxalate ligands. The interstack distances range from 3.30 to 3.70 Å and the shortest contacts between C(1) and C(13) and C(2) and C(13) are 3.39 Å. These values are comparable to interplanar distances found in aromatic π-systems (3.2–3.6 Å) with strong π–π interactions.[26] In these salts there is no evidence of π–π interactions between dithiooxalate groups belonging to neighbour anions or between aromatic cations, which have been observed previously.[9,10] Figure 5 shows the similar anion–cation overlapping in **1** and in the previously reported crystal structure of bis(3-aminopyridinium) bis(dithiooxalato)palladate(II).[9] Both arrangements are different to that found in the bis(4-aminopyridinium) bis(dithiooxalato)palladate(II) structure,[10] in which the anion is placed between two 4-aminopyridinium cations which lie up and down the PdS_4 plane. This arrangement suggests the existence of a significant interaction between the d_{z^2} orbital of the metal and the π-systems of the aromatic cations. Therefore, the nature and size of the cation play an important role in this type of interaction.

(*Received* 18 *December* 1992; *accepted* 1 *February* 1993)

Abstract—The crystal and molecular structure of a five-coordinate zinc tetrabenzoporphyrin, (tetrahydrofuran)(*meso*-tetraphenyltetrabenzoporphyrin)zinc(II), [(TPTBP)Zn(THF)], has been determined. The molecule is severely non-planar and assumes a saddle shape. The average absolute displacement of C_b from the mean plane is 0.7652 Å. The predominant feature of the crystal structure is layers of three saddle-shaped macrocycles stacked with infinite cylindrical channels along the crystallographic *c*-axes. The results of this study indicate that extension of the π-electron system of the porphyrinato core results in significant effects for both molecular and crystal structure.

Porphyrins continue to attract research interest, not only for well-established biological importance, but also for the good opportunities they offer to study structure–bonding–reactivity inter-relationships.[1] Within the whole spectrum of closely controlled variations of the basic porphyrin structure, tetrabenzoporphyrin (TBP) happens to be an exception. Tetrabenzoporphyrin has been claimed as a structural intermediate between porphyrin and phthalocyanine.[2] The extension of the π-electron system of porphyrin has the effect of a drastic decrease in the redox potential.[3] However, details of the coordination chemistry are limited by the poor solubility in most innocent organic solvents.[4] *Meso*-tetraphenyltetrabenzoporphyrin (TPTBP) is the *meso*-tetraphenylporphyrin (TPP) analogue of the tetrabenzoporphyrin system. Due to the enhanced solubility we have been able to make (TPTBP)Zn pure enough for some basic spectroscopic characterization.[5] In this paper we report the molecular and crystal structure of a five-coordinate *meso*-tetraphenyltetrabenzoporphyrin zinc complex, [(TPTBP)Zn(THF)], determined by single-crystal X-ray diffraction. To the best of our knowledge, other than the partially oxidized nickel complexes of octamethyltetrabenzoporphyrin (OMTBP) and tetrabenzoporphyrin,[6,7] this will be the first structural data for a TBP system.

EXPERIMENTAL

Synthesis

(TPTBP)Zn was prepared as previously reported by Remy.[8] The condensation of isoindole and two-fold benzaldehyde in the presence of zinc acetate as a template was fused at 375°C for 40 min. The product mixture was first purified through silica gel using CH_2Cl_2/hexane (2 : 1) as the eluant, then followed by repeated recrystallization from THF and hexane. Crystals suitable for diffraction studies were obtained by a combination of diffusion and evaporation of a layer of hexane floated on a THF

* Author to whom correspondence should be addressed.

solution of (TPTBP)Zn. The solution was left in the dark until half of the liquid had evaporated. All crystals collected were small thin cubes with the same crystalline phase under microscopic examination.

X-ray structure determination

Crystal data for [(TPTBP)Zn(THF)], together with details of the X-ray diffraction experiment, are reported in Table 1. A small blue crystal of approximate dimensions $0.025 \times 0.10 \times 0.20$ mm was mounted on a Nicolet R3m/V diffractometer equipped with a graphite monochromator (Mo-K_α radiation). Unit cell constants were determined from a least-squares fit to the automatically centred settings of 25 reflections with $14.73° < 2\theta < 24.74°$. The space group $R\bar{3}$ was determined from the systematic absences hkl, $-h+k+l = 3n$, and then confirmed by refinement. $\theta/2\theta$ scan data were collected at room temperature (23°C). The data were corrected for Lorentz and polarization effects.

The structure was solved by direct methods using SHELXTL PLUS.[9] Full-matrix least-squares refinement based on F with anomalous dispersion corrections for atoms with atomic numbers greater than 16 was used. Neutral-atom scattering factors were taken from the International Tables for X-ray Crystallography.[10] The weights had the form $w = [\Sigma^2(F)+gF^2]^{-1}$ with $g = 0.1196$. Carbon atoms which form phenyl substituents were confined to a rigid group (C—C = 1.395 Å, C—C—C = 120.0°) and refined isotropically. All of the hydrogen atoms included in the refinement were placed in idealized positions (C—H = 0.96 Å, H—C—H = 109.4°) and refined with a fixed U of

The average bond lengths and angles involving the tetrabenzoporphyrin core and the zinc atom may be found in Table 2. Tables of final fractional atomic coordinates and anisotropic thermal parameters for the non-hydrogen atoms, final positional parameters for the hydrogen atoms and complete bond distances and angles have been included as supplementary material.

RESULTS

Molecular structure

A projection of the structure and the atom-labelling scheme of [(TPTBP)Zn(THF)] is shown in Fig. 1. The extreme non-planar nature of the tetrabenzoporphyrin core is evident in the perspective view of an isolated molecule shown in Fig. 2. A formal diagram of the tetrabenzoporphyrin core is given in Fig. 3, in which we display the perpendicular displacement of each atom from the mean plane of the 40 atom core. As is readily observed in Figs 2 and 3 the isoindole rings are displaced, alternatively, above and below the mean plane of the tetrabenzoporphyrin core. The average absolute displacement of C_b from the mean plane is 0.7652 Å and that of C_d is 1.6647 Å. Although departures of the tetrabenzoporphyrin ring from planarity are large, individually the isoindole rings are planar to within 0.03 Å and the four *meso*-carbons are planar to within 0.071 Å. The dihedral angles between the mean tetrabenzoporphyrin

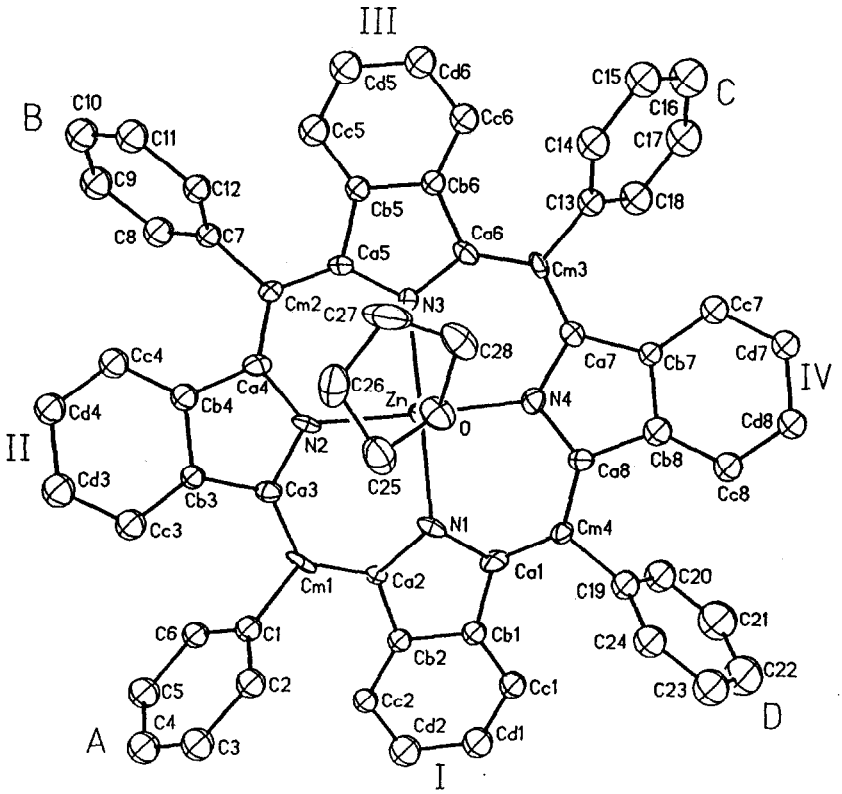

Fig. 1. Projection of the molecular structure in the porphyrin plane, including the atom-labelling scheme of [(TPTBP)Zn(THF)]. Hydrogens are omitted for clarity.

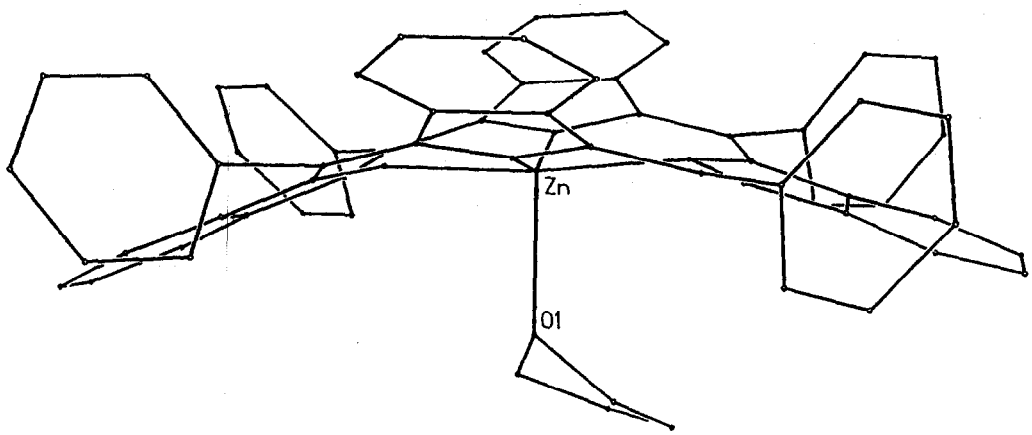

Fig. 2. Perspective view of [(TPTBP)Zn(HF)] that illustrates the saddle-deformation of the tetrabenzoporphyrin skeleton.

plane and isoindole rings I, II, III and IV are 24.1, 21.1, 21.2 and 22.2°, respectively.

The approximate D_{2d}-type ruffled geometry of this species, while differing from most of the corresponding *meso*-tetraphenylporphyrin analogues, can find similar trends for all π-cation-radical metalloporphyrin complexes[11] and sterically crowded zinc(II) octaethyltetraphenylporphyrinate (OETPPZn).[12] In agreement with previous studies of metalloporphyrins with a saddle core conformation the phenyl ring dihedral angles of 62.8, 66.1, 55.3 and 63.6° for rings A–D with the mean tetrabenzoporphyrin plane are toward the small end of other values of reported data. The orientations of the phenyl groups appear to depend upon interactions of the *ortho*-phenyl hydrogens with the adjacent isoindole hydrogens (the average contact distance between the hydrogens attached to benzo-

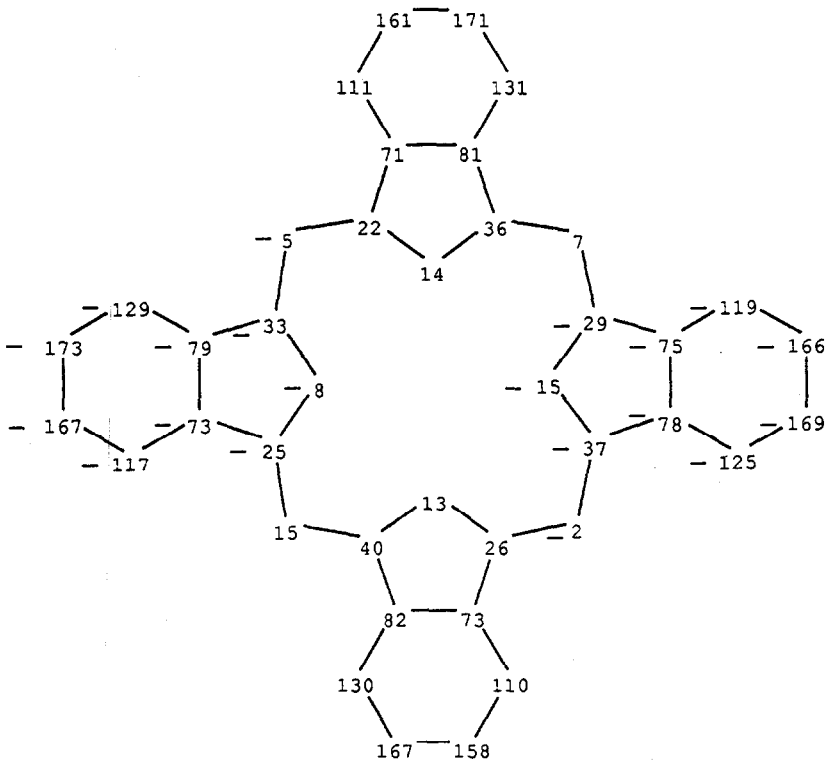

Fig. 3. Formal diagram of the tetrabenzoporphyrin core of [(TPTBP)Zn(THF)], showing displacements of the 40 atoms from the mean plane in units of 0.01 Å.

C_c and *ortho*-phenyl-carbon is 3.166 Å); they all tilt towards the troughs of the saddle. It is clear that the vertical tilt of the isoindole rings is important in maximizing phenyl and core atom contacts for phenyls with small dihedral angles.

The THF molecule is bound quite strongly to the zinc atom [Zn—O = 2.212(13) Å], as demonstrated by comparison with the much longer distance of 2.380(2) Å reported for the six-coordinate $[(TPP)Zn(THF)_2]$,[13] but compares well with that observed in the five-coordinate $[(TPP)Zn(H_2O)]$.[14] The coordinated THF molecule exhibits the commonly observed envelope conformation, with the pocket fold towards the porphyrin plane. It is also clear from Fig. 2 that the oxygen atom lies along the normal to the porphyrin plane instead of forming a tilt angle, as observed in the six-coordinate case.

The geometry about the zinc atom is close to square pyramid with zinc situated 0.240 Å above the base of the four-nitrogen plane, significantly smaller than the 0.347 and 0.33 Å out-of-plane displacements observed in $[(TPP)ZnClO_4]$ and [(TPyP)ZnPy].[15] Nevertheless, the average Zn—N distance (2.077 Å) is close to similar bonds in $[(TPP)ZnClO_4]$.

Other than the partially oxidized TBP system[6,7] there are no appropriate structural data available for comparison to reflect the major changes of the bond distances and angles caused by the macrocycle deformation. Comparison with average porphyrin values[12] illustrates that C_a—N—C_a, C_a—C_m—C_a and C_b—C_a—C_m angles increase with a concomitant decrease in N—C_a—C_b and Zn—N—C_a angles as a result of the saddle deformation. These bond angle changes do not parallel completely with those in (OETPP)Zn. The major difference in bond distances is the increase of C_b—C_b by 0.042 Å. However, this bond elongation should be ascribed mostly to the fused benzene ring in isoindole.

Crystal packing

Other than the unusual saddle-shaped molecular structure these molecules are also packed in a very special way in the crystals. The most pronounced feature is the extremely large unit cell with volume 23,674 $Å^3$ and $Z = 18$. Six of them form a "ball" around the inversion centre (Fig. 4) and a C_3 axis (Fig. 5). All the coordinated THF ligands point outwards with a cavity inside the ball. Along *c*-axes the cavities link into infinite channels (Fig. 6). This type of framework makes the density of the crystal (1.200 g cm^{-3}) lower than usual. Also there seems to be some extra electron densities inside the channels. These may be caused by the crystallographically disordered solvent molecules

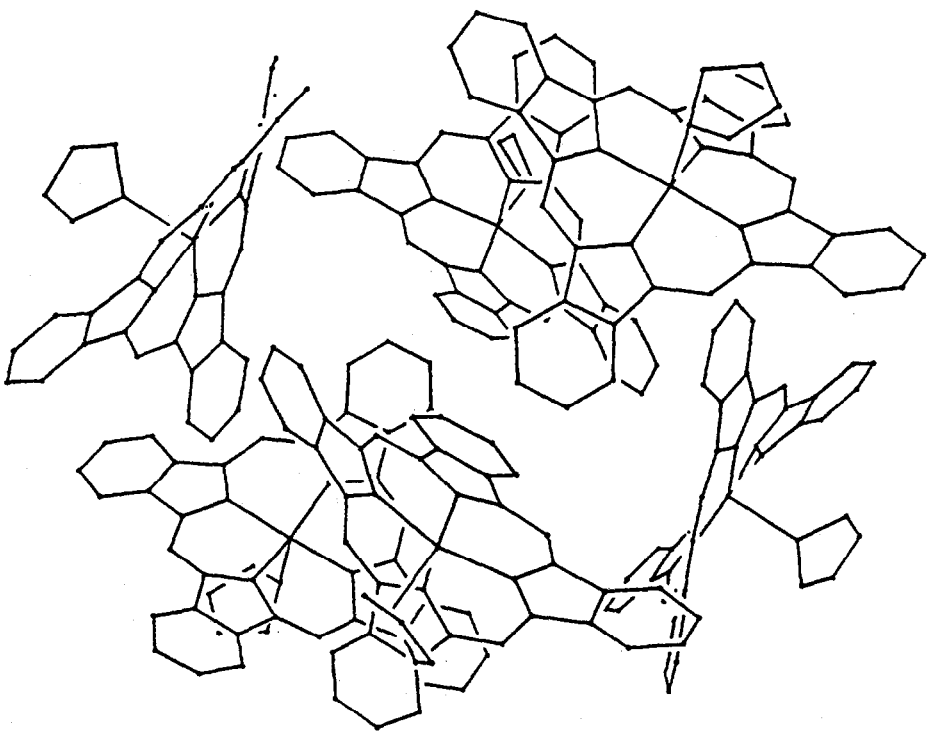

Fig. 4. Illustration of the packing of a six-molecules unit into a ball with an inversion centre and cavity inside. Phenyl substituents have been removed for clarity.

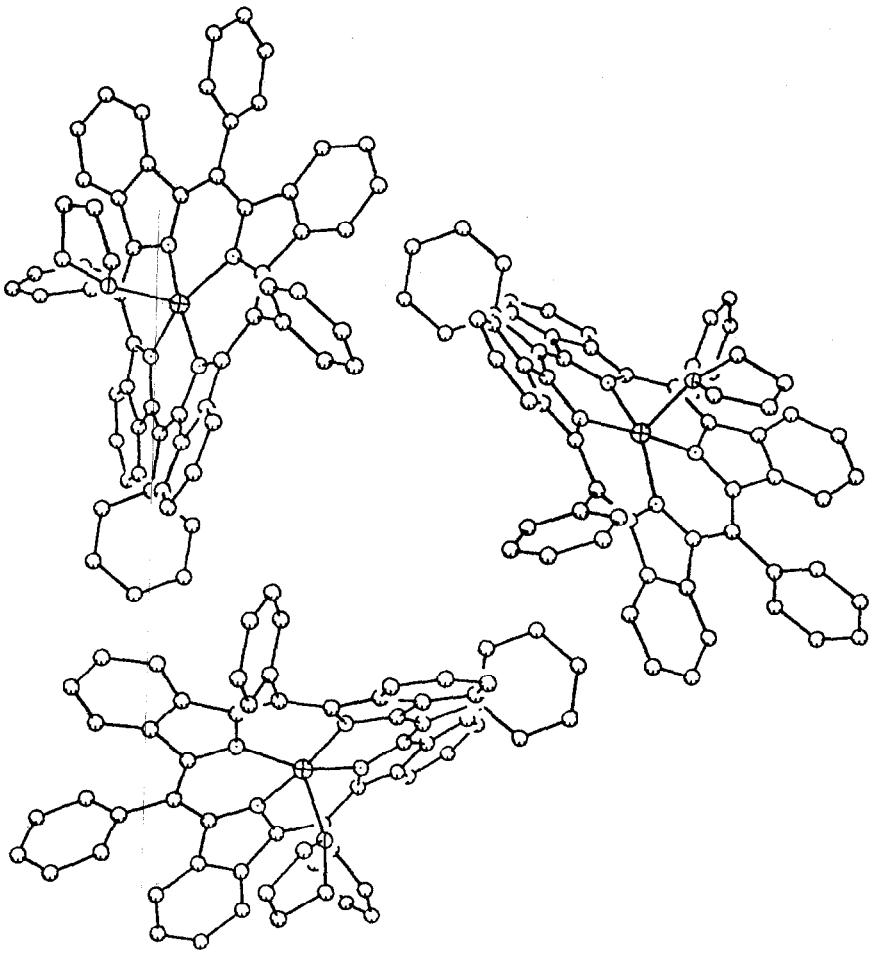

Fig. 5. Illustration of the arrangement of a three-molecules unit with C_3 axis.

residing in the channels. A similar phenomenon has recently been reported for a polynuclear copper complex, $[Cu_8(dmpz)_8(OH)_8]_2C_6H_5NO_2$ (Hdmpz = 3,5-dimethylpyrazole).[16] However, to the best of our knowledge this is the first example of this special crystal packing pattern reported for a porphyrin system. Most other saddle-shaped porphyrins tend to be dimerized with the porphinato core having similar orientation with respect to the unit cell axes.

DISCUSSION

The quality of the structure determination is not very good, however, this is presumably because residual electron density due to solvent molecules residing in the channels was not accounted for. Nevertheless, the severe distortion of the tetrabenzoporphyrin ring and the unique crystal packing pattern are noteworthy. Prior to the structural determination of this complex it was expected that the aromaticity of the extended π-electron system is the most crucial factor that should dictate the structure of the macrocycle. Based on the available structural data a large number of tetraarylporphyrin complexes can be described as planar, while some of them have been reported to be "ruffled" or "saddle-shaped".[11] The origin of the unusual distorted conformation can be traced to either internal strain within a contracted or an expanded core, or the steric requirements of face-to-face dimer formation. Solid-dimer formation has been proved to lead to antiferromagnetic coupling between the ring radicals of the π-cation–radical metalloporphyrin complexes. It is obvious that in our case of [(TPTBP)Zn(THF)] the saddle deformation is not due to either the size of the metal or dimerization. Actually, other than the extended π-system, (TPTBP)Zn and (OETPP)Zn have similar carbon skeletons and should suffer similar steric hindrances which would prevent them from forming planar macrocycles. Based on the red-shifted

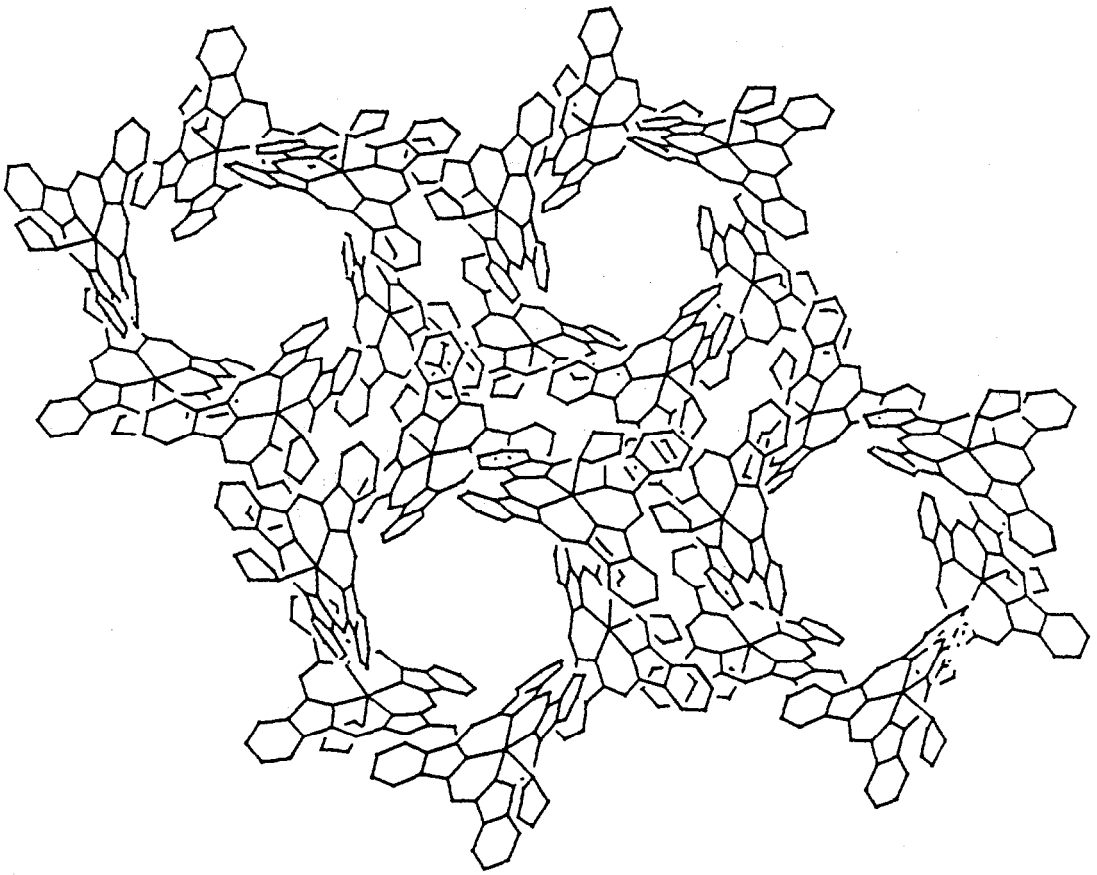

Fig. 6. Illustration of the packing in [(TPTBP)Zn(THF)] along c-axes; the cavities link into infinite hallow channels. Phenyl substituents have been removed for clarity.

electronic absorption spectra and molecular mechanics calculations another two TPP derivatives with peripheral steric strain were also claimed to adopt non-planar conformations.[17] While partially oxidized TBPNi maintains a planar structure partially oxidized (OMTBP)Ni assumes a ruffled conformation, presumably for the same steric reasoning. More structural data for the TBP system are expected to appear in the near future for detailed comparison.

The consequences of saddle deformation on the properties of the non-planar tetrabenzoporphyrin are significant. As reported previously the cumulative effects of conformational changes and substituent addition are reflected in the red-shifted optical spectrum, diminished fluorescence, increased basicity[5] and ease of oxidation of the neutral compound, and in a shift of unpaired spin density from a_{1u} (TBPZn) to a_{2u} (TPTBPZn) character in the cation radical.[18] The increased basicity also results in decreased axial coordination ability, i.e. five-coordinate [(TPTBP)Zn(THF)] instead of six-coordinate [(TPTBP)Zn(THF)$_2$]. Similar effects on optical, redox, basicity and excited-state properties have also been noticed in (OETPP)Zn and related systems.[12]

The results of this study indicate that, compared with TPP and TBP, extension of the π-electron system of the porphyrinato core or introduction of the *meso*-phenyl substituents results in tremendous effects for both molecular and crystal structure, and the properties following them. Therefore, TPTBP may not be a more soluble model for TBP, but it offers a good chance to study the conformational effect. Further studies of this conformational effect on the bonding of transition metal complexes of TPTBP are underway in our laboratory.

Abstract—The reactions of $ZnCl_2$, $CdCl_2$ and $Hg(NO_3)_2 \cdot H_2O$ with deprotonated diclofenac (L) were studied in aqueous solutions. Complexes of the formulae $[Zn(L)_2(H_2O)]$, $[Cd(L)_2(H_2O)]$, $[HgL_2]$ and $[Cd_2(H_2O)(C_2H_5OH)_2(L)_4]_n$ were isolated and characterized as solid products by elemental analyses and spectral (IR, ^1H NMR) and thermal studies. The crystal structure of the complex $[Cd_2(H_2O)(C_2H_5OH)_2L_4]_n$ was also solved. The central feature of the macromolecule is a dinuclear moiety. Distorted octahedral coordination at Cd(1) is completed by oxygen atoms from one molecule of water, two molecules of C_2H_5OH, two oxygen atoms from one chelating ligand with a monoatomic bridging oxygen that bridges the atoms Cd(2)—Cd(I) = 4.490(1) Å and one oxygen from a bidentate bridging carboxylato group that bridges the atoms Cd(1)—Cd(2) = 4.300(1) Å. The geometry at Cd(2) is that of a distorted square pyramid with oxygen atoms from one chelating and one monodentate carboxylato group and the monoatomic bridging oxygen atom occupying equatorial positions. The apical site of the square pyramid is occupied by the oxygen atom of the bidentate bridging carboxylato group. The crystal structure of the diclofenac acid is also reported.

Diclofenac sodium [2-[(2,6-dichlorophenyl)amino]-phenyl]acetate is a potent non-steroidal anti-inflammatory drug (NSAID), therapeutically used in inflammatory and painful diseases of rheumatic and non-rheumatic origin. The anti-inflammatory activity of diclofenac and most of its other pharmacological effects are thought to be related to the inhibition of the conversion of arachidonic acid to prostaglandins, which are the mediators of the inflammatory process.[1,2] Diclofenac is a potent inhibitor of cyclo-oxygenase *in vitro* and *in vivo*, thereby decreasing the synthesis of prostaglandins, prostacyclin and thromboxane products. Also diclofenac is a potent reversible inhibitor of the secondary phase of induced platelet aggregation. Like other NSAIDs, diclofenac is highly (> 95%) protein bound.[1]

The importance of zinc to biochemistry, biology, pathology and clinical and veterinary medicine is now generally recognized. In the cells it is incorporated into more than 200 metalloenzymes involved in nucleic acid, protein, carbohydrate and lipid metabolism. Although zinc belongs to the "essential" metal ions, it becomes hazardous when present in excess. As a result there are metabolic disorders connected with both deficiencies and excess amounts of the metal ion. Cadmium and mercury have been found to be environmental pollutants. The toxicity of metals such as cadmium and

* Author to whom correspondence should be addressed.

mercury on a biological system may result from blocking the essential functional group of the biomolecules and inhibiting or enhancing their enzymatic activities or from displacing the essential metal ion in biomolecules. Cadmium appears to compete with zinc at the active sites of enzymes; isolation in the kidney and liver of a cadmium-containing metalloprotein, metallothionein, suggest that the protein is involved in detoxification processes.[3]

The interaction of these metal ions with drugs administered for therapeutic reasons is a subject of considerable interest. It is known that the drugs act via chelation or by inhibiting the activity of metalloenzymes, but for most of the drugs such as diclofenac little is known about how metal binding influences their activity.

As part of our research on understanding drug–metal interactions[4] we have been studying the complexing ability of diclofenac with d^{10} metal ions and transition metal ions.[4c]

RESULTS AND DISCUSSION

The complexes $[Zn(L)_2(H_2O)]$ (**1**), $[Cd(L)_2(H_2O)]$ (**2**) and $[Hg(L)_2]$ (**3**) were formed according to eqs (1)–(3) in aqueous solution in the pH range 5.0–7.0. Diclofenac has a dissociation constant near 4; at a physiological pH of 7.4 the molecules dissociate to more than 99% and thus are essentially confined to plasma in intra- and extracellular water.[2]

$$ZnCl_2 + 2LNa + H_2O \longrightarrow [ZnL_2H_2O] + 2NaCl \quad (1)$$

$$CdCl_2 + 2LNa + H_2O \longrightarrow [CdL_2H_2O] + 2NaCl \quad (2)$$

$$Hg(NO_3)_2 \cdot H_2O + 2LNa + H_2O \longrightarrow [HgL_2] + 2NaNO_3 + 2H_2O \quad (3)$$

Crystals of the complex $[Cd_2L_4Et_2H_2O]_n$ (**4**) suitable for X-ray analysis were formed by slow evaporation of an ethanolic solution of complex **2**. The

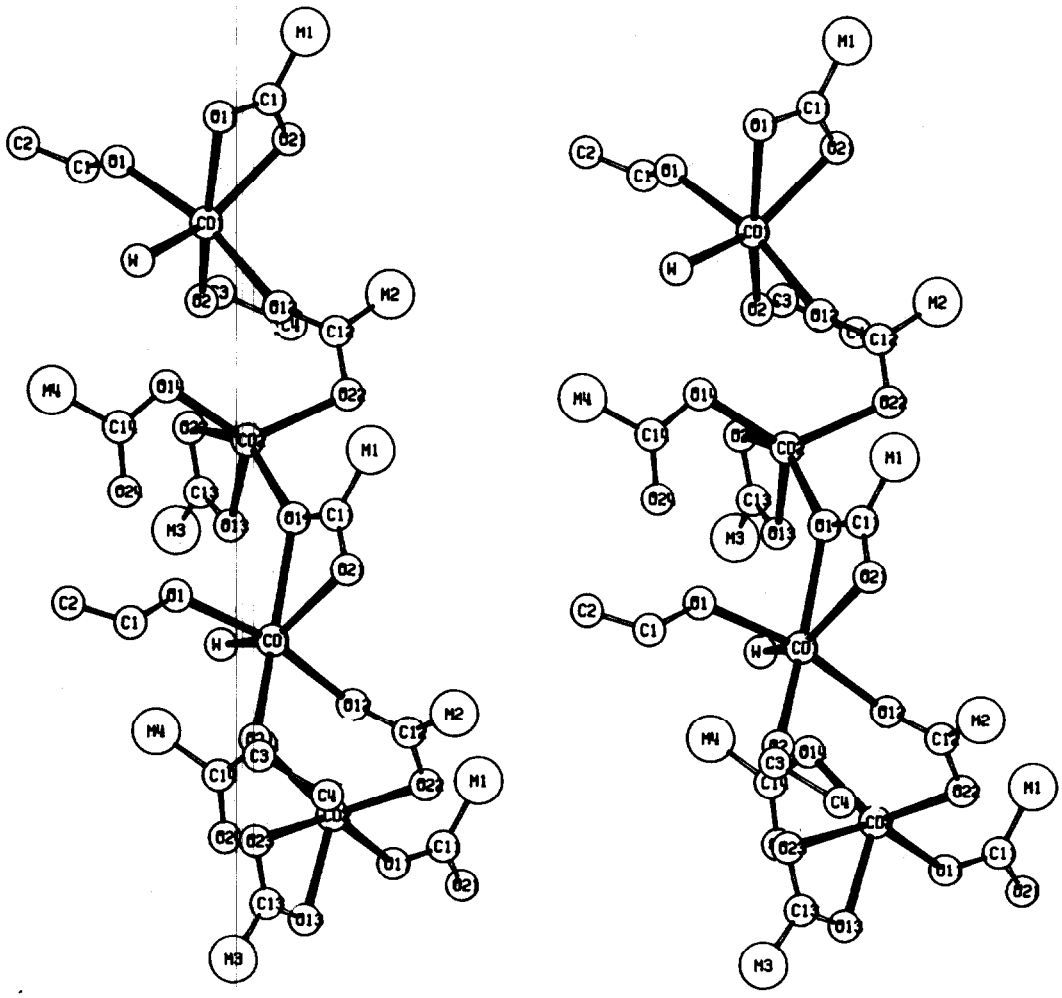

Fig. 1. Structure of compound **4**.

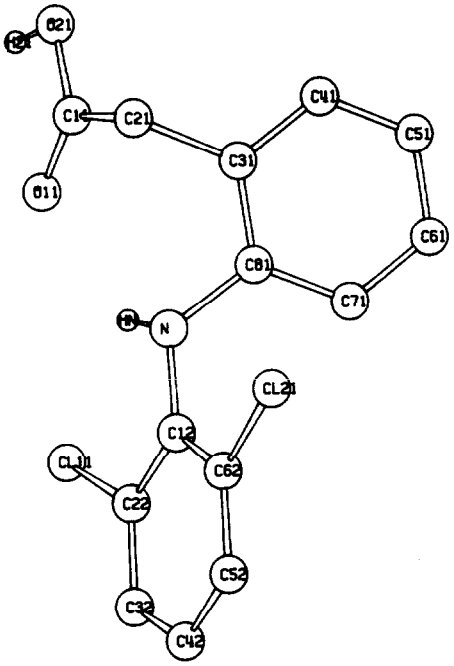

Fig. 2. Structure of diclofenac acid.

compounds are white, microcrystalline, diamagnetic solids that appear to be air- and moisture-stable. They are soluble in CH_3OH, C_2H_5OH, C_6H_{12} and are insoluble in water.

Description of the structures

An ORTEP plot of the inner coordination sphere about the Cd(1) and Cd(2) core for complex **4** is depicted in Fig. 1. The structure of diclofenac acid is shown in Fig. 2. A crystal packing diagram for the same complex (**4**) is shown in Fig. 3. Complete crystal data and parameters for data collection for diclofenac acid and complex **4** are reported in Table 1. Selected bond distances and angles are given in Table 2.

The formation of the compound only took place in ethanolic solution; during crystallization two molecules of EtOH are incorporated into the coordination sphere of Cd(1). The coordination geometry around each metal ion is severely distorted by the bulky ligand L. The compound is polymeric, consisting of hexa-coordinated Cd(1) atoms connected by oxygens O(12) and O(22) of a bridging carboxylato group to the Cd(2) atom, which is penta-coordinated and connected by the monoatomic bridging oxygen O(11) to Cd(1). The Cd(2) atom is, however, subjected to a sixth weaker interaction in the form of a carboxylato oxygen atom, O(12), approaching the Cd(2) atom. The distance Cd(2)—O(12) is 2.76(8) Å, long enough to be considered as a bond distance. When only the bonding interactions are considered Cd(2) is penta-coordinated. The Cd(1)—O(12)—O(22)—Cd(2) bridge is nearly symmetrical with bond distances Cd(1)—O(12) = 2.249(9) and Cd(2)—O(22) = 2.216(1) Å, $\Delta\delta$ = 0.031 Å, while the Cd(2)—O(11)—Cd(1) bridge is asymmetrical with the two Cd—O distances, Cd(2)—O(11) = 2.278(8) and Cd(1)—O(11) = 2.407(7) Å, being significantly different. This bonding mode is probably responsible for the distortion of the coordination polyhedron.

In the complex molecule the ligands surround the Cd(1) atom in a propeller-like arrangement. The resulting coordination about the Cd(1) atom assumes distorted octahedral geometry with the

Cd(1)—O distances showing rather wide ranges of values. Cd(1) is surrounded by one water molecule, two EtOH molecules and three oxygen atoms from two carboxylato groups of the ligands M_1 and M_2. The penta-coordinate Cd(2) atom assumes square pyramidal geometry, with one apical bond, Cd(2)—O(22), from the bidentate bridging carboxylato group of the ligand M_2 and four equatorial bonds, two from the chelating carboxylate group O(13), O(23) of the ligand M_3, one from the monodentate carboxylate group O(14) of the ligand M_4 and one from the monoatomic bridging oxygen O(11) of the chelated carboxylato monoinion M_1. The cadmium-to-EtOH oxygen distances are Cd(1)—O(1) = 2.27(1) and Cd(1)—O(2) = 2.253(8) Å. The cadmium-to-H_2O oxygen distance is Cd(1)—O = 2.213(8) Å. One Cd—$O_{(carb.)}$ bond length, Cd(2)—O(23) = 2.5051(8) Å, is longer than the others. The Cd(2)—$O(14)_{(carb.monod.)}$ bond distance is 2.173(8) Å. The Cd—$O_{(carb.chel.)}$ bonds range from 2.282(8) to 2.505(8) Å. Although bidentate chelating carboxylates are known,[5–10] the formation of a four-membered M—O—C—O ring with the high angular strain involved is not expected to be energetically favourable. The distortion as well as the significant difference between Cd(2)—O(14) and Cd(2)—O(23) distances, 2.173 and 2.505 Å, respectively, could be due to intraligand steric interactions and a different coordination mode.

A comparison of the cadmium–oxygen bond distances in the present compound with those in other

cadmium–carboxylate and cadmium–oxygen species are presented in Table 3.

The C—O bond lengths range from 1.22 to 1.30 Å and the C—C bonds of the C_6H_5 ring from 1.36 to 1.42 Å, while the $C_6H_3Cl_2$ ring ranges from 1.32 to 1.42 Å. The shorter C—O bond of each carboxylato group is held to the cadmium atom, indicating that the doubly-bonded oxygen is coordinated.

The relative orientation of the two phenyl rings depends upon the torsional angles. The observed values of the ligands M_1, M_2, M_3 and M_4 in the present crystal structure, compared with those of diclofenac acid are given in Table 4. The two torsion angles C(7j)—C(8j)—N(j)—C(1i) and C(8j)—N(j)—C(1i)—C(2i), between the two phenyl rings and the nitrogen, and the angle of twist C(8j)—N(j)—C(1i)—C(6i), between the planes of the phenyl rings, show that diclofenac acid and the ligands of complex **4**, M_1, M_3 and M_4, show very similar preferred conformations.

Moser *et al.*[2] studied for 36 congeners of diclofenac the inhibition of cyclooxygenase at the enzyme level and the *in vivo* inhibition of rat adjuvant arthritis and found that both activities can be explained by the lipophilicity and the twisting of the two aromatic rings (angle of twist = 58–69°). These findings allowed the rationalization of the high activity of diclofenac.

Spectral and thermal studies

Table 5 presents some diagnostic IR bands. In the $\nu(OH)_{water}$ region the spectra of complexes **1**, **2** and **4** show a broad absorption at 3500 cm^{-1}, attributed to the presence of coordinated water. As the carboxylic hydrogen is more acidic than the amino hydrogen the deprotonation occurs in the carboxylic group. This is confirmed by the IR spectra of the complexes, showing the characteristic bands for the secondary amino groups and for the coordinated carboxylate group.[11–13] The strong band at 3388 cm^{-1}, which appears in diclofenac, is assigned to the NH stretching motion and the broad band at 3260 cm^{-1} is taken to represent the ν(NH---O) mode, due to intramolecular hydrogen bonding.[2] The absence of large systematic shifts of the ν(NH) and δ(NH) bands in the spectra of the complexes compared with those of the ligand indicates that there is no interaction between the NH group and the metal ions, which is also confirmed by X-ray analysis. Assignment of the type of carboxylate group coordination was based on both the position of the ν_s and ν_{as} bands and the values of Δ_ν.[11–13] The separations between ν_{as} and ν_s, Δ_ν, in a bidentate (chelate) complex will be significantly smaller than in the free ion; in the bridging complex the Δ_ν value is closer to the free ion, while in the monodentate complex it will be

higher.[11,12] The $\nu_{as}(COO^-)$ and $\nu_s(COO^-)$ bands of complex **2** are observed at 1545 and 1410 cm^{-1}, respectively; the difference, $\Delta_\nu = 135\ cm^{-1}$, is less than that of the free ion (sodium salt diclofenac), $\Delta_\nu = 1572–1402 = 170\ cm^{-1}$, as expected for bidentate coordination. Two $\nu_{as}(COO^-)$ bands at 1630 and 1545 cm^{-1} and two $\nu_s(COO^-)$ bands at 1436 and 1395 cm^{-1} are observed for complex **1**. The bands at 1630 and 1395 cm^{-1}, $\Delta_\nu = 235\ cm^{-1}$, are assigned to the stretching mode for monodentate carboxylate ligation, while the bands at 1545 and 1436 cm^{-1}, $\Delta_\nu = 109\ cm^{-1}$, are assigned to the stretching mode for bidentate chelate carboxylate ligation. The $\nu_{as}(COO^-)$ and $\nu_s(COO^-)$ bands are observed at 1577 and 1350 cm^{-1} for complex **3**; the difference, $\Delta_\nu = 227\ cm^{-1}$, is consistent with monodentate coordination. The new bands in the region 400–200 cm^{-1} are assigned to $\nu(M—O)(H_2O)$ and $\nu(M—O)(COO^-)$ modes.[11–14] The metal–ligand vibrations are important in determining the structures of the complexes and are included in Table 5.

Table 6 gives the ^1H NMR chemical shifts of diclofenac and its complexes in DMSO-d_6. The study was based on comparisons with a number of related ligands and complexes.[2,15,16]

Coordination of a metal centre to NH or a carboxylato group causes a downfield shift in the proton resonances. These metal ions deshield the CH_2 protons attracting electron density; the CH_2 protons are affected more, while the phenyl ring protons, away from the coordination site, are less affected. The above data show that all the δ values move to lower fields on complex formation. The $\Delta\delta$ values ($\delta_{complex}$-$\delta_{free\ ligand}$) depend on the proximity of the proton in question to the metal centres. The H—C(7j) signal of diclofenac appears at the rather high field 6.26 ppm, due to the shielding effect of the aryl ring (2,6-dichlorophenyl).[2] The proton on the nitrogen atom undergoes rapid exchange and is decoupled from the nitrogen atom and from protons on adjacent carbon atoms. The NH peak is, therefore, a sharp singlet. A deshielding effect is exerted on this NH proton via intramolecular or intermolecular hydrogen bonding, with the resonance occurring at low fields[15,16] from 7.66 to 10.24 ppm.

Complexes **1** and **2** show that a similar decomposition occurs in two steps. The complex CdL_2H_2O was decomposed at 194°C. This reaction appears to be completed at 265°C. Two endothermic and one exothermic effect are observed at 199, 229 and 240°C, respectively. The first inflection in the mass loss curve corresponds to a loss of $H_2O \cdot 1\frac{1}{2}L$ molecules. The thermal decomposition of the complex is completed in the 465–605°C temperature range. The final residue of pyrolysis was the corresponding carbonate salt and metallic oxide.

From the overall study presented above it is concluded that in all the new complexes prepared diclofenac behaves as a monodentate or bidentate ligand, bonding through the carboxylate oxygen atoms. Several stereochemistries are assigned for the diclofenac complexes in the solid state. Synthetic and spectroscopic data suggests that **1** consists of the pseudo-tetrahedral ZnO_4 entity, formed by one bidentate chelate ligand, one monodentate ligand and one coordinated water molecule. For complex **2** two ligands are coordinated to one cadmium(II) atom in a bidentate chelate mode, with both the oxygens of the carobylato group bound to the metal centre. Complex **2** consists of the $CdO_{2(carb.chel.)}O_{2(carb.chel.)}O_{(H_2O)}$ coordination sphere. In complex **3** the coordination environment around the Hg^{2+} atom is linear and the ligands are bound in a monodentate fashion. Complex **4** has a polymeric structure with both the monodentate and bidentate ligands chelating and bridging. One M_2 ligand is in the familiar bidentate bridging mode and another M_1 ligand is in the rare monoatomic bridging mode.

EXPERIMENTAL

All the solvents and chemicals used were of high purity and purchased from Fluka. Diclofenac was a gift from "HELP EPE". Physicochemical measurements and spectroscopic techniques were performed using published methods.[4,17,18] Proton NMR spectra were obtained on a Bruker AC 250 MH FT-NMR spectrophotometer with Me_4Si as an internal standard. Chemical shifts are reported in parts per million (ppm).

Preparation of the complexes

The complexes were prepared by mixing aqueous solutions of the ligand diclofenac (sodium salt) and aqueous solutions of the metal salts (4 : 2 ligand-to-metal molar ratio). The pH of the reaction mixture was adjusted to 5.5–7.5 by the addition of small quantities of 0.1 N KOH. The reaction mixture was stirred for 4–6 h at room temperature. The resulting powders were filtered, washed with water and dried *in vacuo* over silica gel. They were further dried at 90°C *in vacuo* over P_4O_{10}. The yields of the products were 82% for complex **3** and *ca* 100% for complexes **1** and **2**. The elemental analyses agreed very well with the assigned formulae.

X-ray analysis

The crystal system and space group (Table 1) were determined from preliminary oscillation and

Weissenberg photographs. Unit cell dimensions were derived from least-squares refinement of the setting angles of 15 automatically centred reflections in the range $50° < 2\theta < 52°$ on a Syntex $P2_1$ diffractometer using nickel filtered Cu-K_α radiation. The crystal was of very low quality. The intensities of three standard reflections monitored after every 67 reflections showed $<3\%$ intensity fluctuation. Lorentz, polarization and ψ-scan absorption corrections were applied.

The structure was solved by direct methods using the SHELX86 program.[19] Refinement was performed by blocked full-matrix least-squares, in which $\Sigma w\Delta^2$ was minimized with SHELX76.[20] All hydrogen atoms were calculated as riding on carbon atoms at 0.96 Å. All non-hydrogen atoms were refined using anisotropic and hydrogen atoms using isotropic temperature factors. Atomic scattering factors were taken from the International Tables of X-ray Crystallography.[21]

Supplementary material. Tables of positional parameters and anisotropic temperatures factors, observed and calculated structure factors and a list of bond distances and angles of the ligand have been deposited.

(*Received* 7 *January* 1993; *accepted* 27 *January* 1993)

Abstract—The syntheses of the neutral bis-dimethylglyoximato [$(DH)_2$] dimethylsulphide (DMS) cobalt(III) complexes, [$Co(DH)_2(DMS)X$] (X = Cl, Br, I, SeCN), are described. Substitution of the DMS ligand in these complexes by aziridine (Az) produces the neutral complexes [$Co(DH)_2(Az)X$] (X = Cl, Br, I, SeCN), containing one aziridine ligand. The syntheses of the cationic bis-aziridine complex [$Co(DH)_2(Az)_2$]Cl and its bis-diphenylglyoximato (DpgH) analogue [$Co(DpgH)_2(Az)_2$]Cl are also described.

As part of our interest in the preparation of cobalt (III) complexes containing cytotoxic ligands[1,2] we made a series of cobalt(III) aziridine complexes containing ammine and amine ancilliary ligands.[3] We have now extended this chemistry to the synthesis of a new series of cobalt(III) aziridine complexes containing the bis-dimethylglyoximato pseudo-macrocycle, [$(DH)_2$].

We wished to prepare a series of bis-dimethylglyoximato complexes containing only one aziridine ligand and one other ligand which could be varied in order to tailor the properties of the complexes. The choice of a synthetic route for the preparation of such aziridine complexes required careful consideration. Aziridine is a volatile and highly reactive molecule that readily undergoes ring-opening reactions, particularly under acid conditions. In addition the preparation of neutral cobalt(III) complexes of the form [$Co(DH)_2LX$] is often impeded by symmetrization reactions, leading to complex salts of the formula [$Co(DH)_2L_2$]$^+$ [$Co(DH)_2X_2$]$^-$. Substitution of aziridine for the labile neutral ligand dimethylsulphide (DMS) in suitable precursor complexes proved to be successful for the preparation of neutral complexes containing one aziridine ligand. A cationic complex containing two aziridine ligands, [$Co(DH)_2(Az)_2$]Cl, has been reported in the literature, but was characterized only by elemental analysis. We have reinvestigated this chemistry and fully characterized both this complex and its bis-diphenylglyoximato [$(DpgH)_2$] analogue. The synthesis, characterization and spectroscopic data for the cationic bis-aziridine complexes, neutral DMS precursor complexes and neutral mono-aziridine complexes all containing cobalt(III) are detailed below.

EXPERIMENTAL

IR spectra were recorded on a Perkin–Elmer Model 597 spectrometer using Nujol mulls between KBr discs. ^1H and $^{13}C\{^1H\}$ NMR spectra were recorded on a Bruker AM400 spectrometer operating at 400 and 100 MHz, respectively. Microanalyses were performed by Dr R. Cunninghame and associates at the Department of Chemistry, University of Otago. Aziridine, prepared by published procedures,[4,5] was purified by repeated distillation from NaOH and was stored under nitrogen over NaOH at 5°C. **CAUTION:** Aziridine is a highly toxic and volatile substance. All reactions involving aziridine were performed under nitrogen using Schlenk techniques in a well-ventilated fumehood. All aziridine residues were decomposed by treatment with aqueous HCl. [$Co(DH)_2(DMS)Br$] (**1b**),[6] [$Co(DH)_2(Az)_2$]Cl (**3**)[7] and [$Co(DH)(DH_2)Cl_2$][8] were prepared by modifications of literature methods.

Synthesis of [Co(DH)$_2$(DMS)Cl] (**1a**)

(a) A solution of DH$_2$ (3.02 g, 0.026 mol) in hot 95% ethanol (75 cm^3) was added to a solution of Co(NO$_3$)$_2$·6H$_2$O (3.79 g, 0.013 mol) in hot 95% ethanol (75 cm^3). After heating the resulting red–brown suspension for 5 min a solution of NaCl (1.18 g, 0.020 mol) in water (4 cm^3) was added. The mixture was cooled to 35°C, dimethylsulphide (1.5 cm^3, 1.27 g, 0.020 mol) was added and air oxidation was achieved by stirring the mixture vigorously in air for 8 h. A fine gelatinous precipitate formed during this time, which was isolated by filtration, washed with water, ethanol and diethyl ether and dried in air to give a brown solid. This was extracted into CH_2Cl_2, filtered and CH_2Cl_2 removed under reduced pressure to produce a brown powder. Yield 0.48 g, 9.5%.

(b) A green suspension of [Co(DH)(DH$_2$)Cl$_2$] (1.65 g, 0.005 mol) in $CHCl_3$ (45 cm^3) was shaken with dimethylsulphide (0.84 cm^3, 0.71 g, 0.011 mol) and left to stand for 5 min. Water (15 cm^3) was added and the mixture was shaken vigorously to give a two-phase system, an upper aqueous layer containing flocculant green material and a lower $CHCl_3$ layer as an orange–brown suspension. After stirring the two-phase system for several hours the $CHCl_3$ layer was collected and washed with water several times until the washings were colourless. The aqueous layer was extracted with $CHCl_3$ (45 cm^3) and the two $CHCl_3$ portions were combined and concentrated by removal of the solvent under reduced pressure. The product was precipitated by the addition of ethanol and dried in air. Yield 0.30 g, 18%.

Synthesis of [Co(DH)$_2$(DMS)I] (**1c**)

This complex was prepared as described for **1a**, method (a), using DH$_2$ (3.02 g, 0.026 mol), Co(NO$_3$)$_2$·6H$_2$O (3.79 g, 0.013 mol), NaI (3.00 g, 0.020 mol) and dimethylsulphide (1.5 cm^3, 1.27 g, 0.020 mol). The product was recrystallized from $CHCl_2$/hexane. Yield 0.97 g, 16%.

Synthesis of [Co(DH)$_2$(DMS)(SeCN)] (**1d**)

To a hot solution of DH$_2$ (6.40 g, 0.055 mol) in methanol (150 cm^3) was added solid Co(OAc)$_2$·4H$_2$O (6.23 g, 0.025 mol) with stirring to form a dark brown solution. The solution was cooled to room temperature and dimethylsulphide (1.90 cm^3, 1.60 g, 0.026 mol) was added to the reaction mixture with stirring, followed by an aqueous solution of KSeCN (3.60 g, 0.025 mol) in water (20 cm^3). After passing a stream of air through the solution for 90 min the light brown solid which had precipitated out was filtered and washed with water, methanol, hexane and diethyl ether. The tan powder was dried over P_2O_5 and dissolved in CH_2Cl_2, filtered and crystallized by the addition of hexane. Yield 4.75 g, 40%.

Synthesis of [Co(DH)$_2$(Az)Cl] (**2a**)

The DMS complex **1a** (1.80 g, 4.65 mmol) was dissolved in CH_2Cl_2 (20 cm^3) and aziridine (0.23 cm^3, 0.19 g, 4.44 mmol) was slowly added to the solution with stirring. The solution was stirred for 20 min, during which time a light brown solid precipitated, which was isolated by filtration and washed with diethyl ether. The solid was suspended in water and stirred for 10 min, filtered, dried in air and recrystallized from CH_2Cl_2/hexane. Yield 0.431 g, 25%. Found: C, 32.0; H, 4.9; N, 18.1. Calc. for $C_{10}H_{19}ClCoN_5O_4$·0.5H$_2$O: C, 31.9; H, 5.2; N, 18.6%.

Synthesis of [Co(DH)$_2$(Az)Br] (**2b**)

This complex was prepared as described for **2a** using complex **1b** (1.20 g, 2.78 mmol) and aziridine (0.14 cm^3, 0.12 g, 2.70 mmol). Yield 0.69 g, 60%. Found: C, 29.1; H, 4.5; N, 17.1. Calc. for $C_{10}H_{19}BrCoN_5O_4$: C, 29.1; H, 4.7; N, 17.0%.

Synthesis of [Co(DH)$_2$(Az)I] (**2c**)

This complex was prepared as described for **2a** using complex **1c** (1.50 g, 3.14 mmol) and aziridine (0.17 cm^3, 0.14 g, 3.28 mmol). Yield 1.07 g, 74%. Found: C, 25.9; H, 4.1; N, 15.4. Calc. for $C_{10}H_{19}CoIN_5O_4$: C, 26.2; H, 4.2; N, 15.3%.

Synthesis of [Co(DH)$_2$(Az)(SeCN)] (**2d**)

This complex was prepared as described for **2a** using complex **1d** (1.50 g, 3.29 mmol) and aziridine (0.18 cm^3, 0.15 g, 3.48 mmol). Yield 1.17 g, 81%. Found: C, 30.6; H, 4.0; N, 19.7. Calc. for $C_{11}H_{19}CoN_6O_4Se$: C, 30.2; H, 4.4; N, 19.2%.

Synthesis of [Co(DH)$_2$(Az)$_2$]Cl (**3**)

CoCl$_2$·6H$_2$O (0.50 g, 2.10 mmol) and DH$_2$ (0.50 g, 4.31 mmol) were dissolved in 95% ethanol (12 cm^3), resulting in a dark red–brown solution to which aziridine (1.0 cm^3, 0.83 g, 19.3 mmol) in 95% ethanol (3 cm^3) was added. A stream of air was passed through the solution for 1 h, during which time the colour lightened. The solution was cooled on ice and orange–brown crystals of the product

deposited. These were filtered, washed with ethanol and diethyl ether and dried. Yield 0.42 g, 49%. Found: C, 32.9; H, 6.3; N, 19.2. Calc. for $C_{12}H_{24}ClCoN_6O_4 \cdot 1.5H_2O$: C, 32.9; H, 6.2; N, 19.2%.

Synthesis of $[Co(DpgH)_2(Az)_2]Cl$ (**4**)

$CoCl_2 \cdot 6H_2O$ (0.48 g, 2.02 mmol) and $DpgH_2$ (0.96 g, 4.01 mmol) were dissolved in hot 95% ethanol (100 cm^3). The initially green solution changed to brown as it was cooled to room temperature and aziridine (1.0 cm^3, 0.83 g, 19.3 mmol) was added. The solution was bubbled with a stream of air for 30 min and was then allowed to stand for a further 90 min, resulting in the precipitation of a mustard–brown solid. This was filtered, washed with ethanol and diethyl ether and dried. Yield 0.67 g, 50%. Found: C, 56.1; H, 5.3; N, 11.5. Calc. for $C_{32}H_{32}ClCoN_6O_4 \cdot C_2H_6O \cdot H_2O$: C, 56.5; H, 5.6; N, 11.6%.

RESULTS AND DISCUSSION

The complex $[Co(DH)_2(DMS)Br]$ is readily prepared from a cobalt(II) salt in the presence of DH_2, Br^- and DMS by air oxidation in ethanol.[6] This complex was chosen as a potential precursor to a neutral monoaziridine complex because the labile DMS ligand is known to be readily substituted by amines.[6] We have prepared this complex using the published method and we have extended this chemistry by preparing new complexes containing Cl^-, I^- and $SeCN^-$ in place of Br^-, by substituting the appropriate sodium salt for NaBr in the reaction to give the series of complexes $[Co(DH)_2(DMS)X]$ (X = Cl, **1a**; Br, **1b**; I, **1c**; SeCN, **1d**). The use of $Co(OAc)_2 \cdot 4H_2O$ rather than $Co(NO_3)_2 \cdot 6H_2O$ as the source of Co^{2+} ions for the preparation of the $SeCN^-$ complex **1d** resulted in an improvement in the yield. Attempts to prepare complexes containing F^-, NO_2^-, CN^-, OCN^- and SCN^- were unsuccessful. Reactions for the preparation of neutral complexes $[Co(DH)_2LX]$ (L = neutral ligand) often give, in addition to the desired product, significant yields of the complex salt $[Co(DH)_2L_2]^+$ $[Co(DH)_2X_2]^-$.[9,10] The low yields reported for the preparations of **1a** and **1c** were presumed to be a consequence of the formation of such salts (L = DMS), based on the formation of significant amounts of water-soluble material which could not be extracted into CH_2Cl_2. An alternative synthesis of the chloro complex **1a** in better yield was by substitution of DMS on the preformed complex $[Co(DH)(DH_2)Cl_2]$ with concomitant elimination of HCl.

[a] Data recorded in $CDCl_3$ or DMSO-d_6 (except where specified) and referenced to internal TMS (tetramethylsilane). ^{1}H data recorded at 400 MHz, $^{13}C\{^{1}H\}$ data at 100 MHz.

[b] Referenced to internal DSS (3-(trimethylsilyl)-1-propanesulphonic acid, sodium salt).

[c] Referenced using internal dioxane (66.6 ppm downfield from TMS).

[d] Phenyl protons at 7.40 ppm.

[e] Phenyl resonances at 127.90 (*ortho*), 129.48 (*para*), 129.66 (*meta*) and 132.75 (*ipso*) ppm.

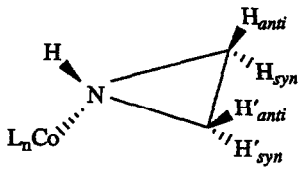
The series of complexes $[Co(DH)_2(DMS)X]$ (X = Cl, **1a**; Br, **1b**; I, **1c**; SeCN, **1d**) was characterized by ^1H NMR and IR spectroscopy, ^{13}C NMR spectroscopy for **1b** and by comparison of the spectroscopic data with that published for **1b**.[6] The presence of one DMS ligand and two dimethylglyoximato ligands was confirmed by the 1 : 2 ratio of the corresponding methyl resonances in the ^1H NMR spectra of **1a–d**. The chemical shift of the DMS methyl resonance (1.48 ppm for **1c**) shifts progressively downfield in the order X = I, Br, Cl, SeCN. The $(DH)_2$ methyl group resonances are almost invariant across the series. IR and NMR spectroscopic data are collected in Tables 1 and 2, respectively.

The reactions of **1a–d** with 1 equivalent of aziridine in chloroform at room temperature served both to complete the characterization of **1a–d** by substitution of the DMS ligand by aziridine and to prepare the new aziridine complexes $[Co(DH)_2(Az)X]$ (X = Cl, **2a**; Br, **2b**; I, **2c**; SeCN, **2d**). These complexes precipitated from solution as brown solids, which were recrystallized from dichloromethane/hexane. Although the preparation of the precursor complexes **1a–d** gave low yields in some cases, the substitution of aziridine for coordinated DMS proceeded in good yield, an important consideration since it is desirable to minimize the preparation and handling of the toxic and reactive aziridine.

The cationic bis-aziridine complexes $[Co(DH)_2(Az)_2]Cl$ (**3**) and $[Co(DpgH)_2(Az)_2]Cl$ (**4**) were prepared by air oxidation of $CoCl_2$ in ethanol in the presence of the glyoxime and excess aziridine, and were isolated as red–brown crystalline species. The use of excess aziridine is required because, in addition to coordinating to cobalt, the aziridine acts as a base towards the two protons released upon coordination of the two glyoximato ligands. Complexes **2–4** were characterized by IR, ^1H NMR and ^{13}C NMR spectroscopy (Tables 1 and 2) and by elemental analysis.

The presence of the intact aziridine ligand in **2–4** was confirmed by a characteristic medium strong band near 890 cm^{-1} in the IR spectra, which is assigned to a deformation of the coordinated aziridine ring.[11] The $SeCN^-$ ligand in **2d** gives rise to a ν(CN) stretch at 2120 cm^{-1}, consistent with the expected coordination of selenocyanate through the nitrogen atom to the hard cobalt(III) centre.[12]

The two pairs of chemically equivalent protons on the aziridine ring are defined as H_{syn} and H_{anti} (where H_{syn} is on the same side of the aziridine ring as the cobalt atom). Inversion at nitrogen is suppressed on coordination of aziridine to cobalt.[3] The H_{syn} and H_{anti} protons exhibit non-first-order coupling and appear as two multiplets with different splitting patterns, primarily due to the different NH—H_{syn} and NH—H_{anti} coupling constants in the AA′MM′X spin system. Exchange of the NH proton of **3** or **4** in D_2O results in simplification of the H_{syn} and H_{anti} multiplets, which become identical in form. The aziridine CH resonances are assigned by comparison with those in the cobalt(III) aziridine complexes containing amine ligands, with the H_{syn} resonance appearing upfield of the H_{anti} resonance.[3] In the $(DH)_2$ series of complexes the chemical shift difference between the H_{syn} and H_{anti} resonances is generally greater than that observed in the amine series, with the H_{syn} resonances shifted markedly upfield (0.59–0.77 ppm for **2a–d**) as a result of shielding of these protons due to their proximity to the π-electron clouds on the dimethylglyoximato ligands.



The two aziridine carbon atoms give rise to only one resonance in the ^{13}C NMR spectrum as a result of the symmetric nature of the complexes and free rotation about the Co—N_{Az} bond. This resonance moves downfield in the order I < Br < SeCN ~ Cl, consistent with increasing inductive electron withdrawal by the *trans* ligand. A similar progression is observed for the imine carbon resonance of the $(DH)_2$ ligand. Both the ^1H and ^{13}C NMR spectra of the cationic bis-aziridine complexes **3** and **4** show downfield shifts of the aziridine resonances relative to the neutral mononaziridine complexes. For example, the mid-point position of the H_{anti} and H_{syn} aziridine proton resonance in **3** (1.33 ppm) is closer to the free ligand value of 1.48 ppm than in the neutral complex **2a** (0.95 ppm). This may be ascribed to the greater deshielding of the aziridine hydrogen atoms in the cationic relative to the neutral complexes.

A further series of cationic cobalt(III) bis-aziridine complexes containing Schiff base ligands is the subject of a separate report.[13]

AN ^{15}N NMR SPECTROSCOPIC STUDY OF SOME RHODIUM COMPLEXES OF 3,5-DICARBOMETHOXY-4-PHENYLPYRIDINE-^{15}N

LAURENCE CARLTON* and GINA DE SOUSA

Centre for Molecular Design, Department of Chemistry, University of the Witwatersrand, Johannesburg, Republic of South Africa

(*Received* 21 *December* 1992; *accepted* 27 *January* 1993)

Abstract—^{15}N NMR data are reported for the complexes [*cis*-$RhX(PPh_3)_2$(dcpp-^{15}N)], [$Rh(H)_2X(PPh_3)_2$(dcpp-^{15}N)] (X = Cl, SC_6F_5; dcpp-^{15}N = 3,5-dicarbomethoxy-4-phenylpyridine-^{15}N), [$RhCl(PPh_3)(L)$(dcpp-^{15}N)] (L = C_2H_4, CO) and [$Rh(H)(C_2Ph)(X)(PPh_3)_2$(dcpp-^{15}N)] (X = Cl, OCN, N_3, C_2Ph), prepared *in situ* from [$RhX(PPh_3)_3$], [$Rh_2Cl_2(C_2H_4)_4$] and [$Rh_2(SC_6F_5)_2(PPh_3)_4$].

Pyridines and related compounds serve as ligands in a wide range of metal complexes. Where the metal in these complexes exists to a significant extent as an isotope of spin 1/2 and/or where other ligands that bind via a spin 1/2 nucleus are present ^{15}N NMR spectroscopy can provide valuable structural information. In an earlier study[1] natural-abundance ^{15}N NMR data (obtained using the INEPT[2] method) were reported for a series of complexes [$Rh(H)_2(PPh_3)_2(O_2CArN)$][3] ($O_2CArN$ = e.g. pyridine-2-carboxylate): here the value of the ^{15}N—^1H *trans* coupling constant, required to optimize delay times in the INEPT pulse sequence, was measured from a partially ^1H-decoupled ^{15}N spectrum to an accuracy no greater than 10%. The use of an ^{15}N-enriched ligand, in addition to greatly increasing the ^{15}N sensitivity, allows the relevant ^{15}N—^1H coupling constants to be measured directly from the ^1H spectrum. In the present study the ^{15}N-enriched (~ 99%) compound 3,5-dicarbomethoxy-4-phenylpyridine-^{15}N (dcpp-^{15}N) (Fig. 1) was prepared by a method described by Chennat and Eisner[4] for the synthesis of substituted pyridines and incorporated into a number of complexes of rhodium.

EXPERIMENTAL

The ligand dcpp-^{15}N was prepared by the method of Chennat and Eisner.[4] A mixture of ammonium-^{15}N acetate, methyl propiolate, benzaldehyde and acetic acid (in a 0.4 : 1 : 1 : 1 molar ratio) was first heated (100°C, 2 h) and then cooled to −20°C for 3 days to give crystals of 3,5-dicarbomethoxy-5-phenyl-1,4-dihydropyridine-^{15}N, which was subsequently oxidized with 20% nitric acid to give dcpp-^{15}N. Ammonium-^{15}N acetate was obtained from ammonium-^{15}N chloride by exchange with silver acetate. The overall yield (based on ^{15}N) was 20%; in our hands the step by which the dihydropyridine was formed gave yields no better than 25% (the authors quote 79%). [$Rh(OCN)(PPh_3)_3$][5] and [$Rh(N_3)(PPh_3)_3$][5] were prepared from [$RhCl(PPh_3)_3$];[6] [$Rh_2(SC_6F_5)_2(PPh_3)_4$][7] was prepared from [$RhH(PPh_3)_4$]; [$Rh_2Cl_2(C_2H_4)_4$], ammonium-^{15}N chloride, methyl propiolate and phenylacetylene were purchased from Aldrich. Benzaldehyde was distilled before use.

Spectra were recorded on a Bruker AC200 FT spectrometer operating at 200.13 (^1H), 20.29 (^{15}N) and 81.01 (^{31}P) MHz. Solutions in toluene-d_8 or toluene/toluene-d_8 in tubes of diameter 5 mm (*ca* 0.06 M complex, *ca* 0.2 M dcpp-^{15}N, 0.5 cm^3) or 10 mm (*ca* 0.015 M complex, *ca* 0.03 M dcpp-^{15}N,

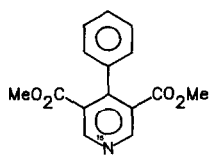

Fig. 1. dcpp-^{15}N.

3.0 cm^3) were prepared under nitrogen. Reagents {$[Rh_2Cl_2(C_2H_4)_4]$, 0.25–1.0 equivalents; PhC_2H *ca* 5 equivalents with respect to Rh; H_2, CO, bubbled through the solution for 1–2 min at room temperature} were then added as required. Spectra (1000–25,000 scans) were obtained using a spectral width of 7000 Hz and an acquisition time of 1.16 s; after zero-filling this gave a digital resolution of 0.2 Hz/pt. INEPT delay times were based on ^{15}N—^1H coupling constants measured from the ^1H spectrum of free dcpp-^{15}N or, where appropriate, from the ^1H spectrum of the complex. Chemical shifts were measured relative to CH_3NO_2 (external standard).

RESULTS AND DISCUSSION

In the ^1H spectrum of the ^{15}N-enriched ligand dcpp-^{15}N the two equivalent hydrogens in the 2 and 6 positions appear as a doublet (δ 9.09 ppm, J = 10.6 Hz, solution in $CDCl_3$) as a result of spin-coupling to ^{15}N. INEPT delay times derived from this coupling constant were used in a number of the experiments described below. However, it is generally found that where more than one spin-coupling interaction (^{15}N—^1H) exists, as in the case where the nitrogen dcpp and a hydride are positioned *trans* to each other in a complex, the results obtained using polarization transfer from the hydrogen exhibiting the larger coupling are the more satisfactory. The value of $J(^{15}N$—^1H-*trans*) in the rhodium hydride complexes of dcpp-^{15}N, measured directly from the ^1H spectrum (Fig. 2), has a value of *ca* 22 Hz (Table 1): accordingly, in acquiring ^{15}N spectra from these compounds polarization was transferred from the hydride rather than from the dcpp ring protons.

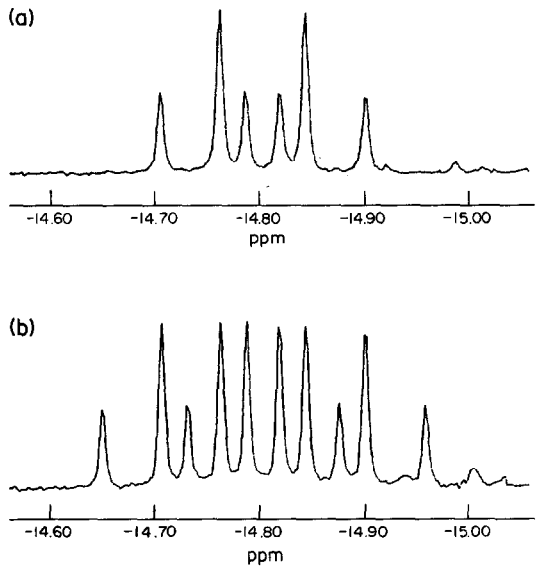

Fig. 2. Highfield signal in the ^1H spectrum of $[Rh(H)(N_3)(C_2Ph)(PPh_3)_2(dcpp)]$ (a) dcpp unenriched and (b) dcpp-^{15}N (99% ^{15}N-enriched).

^1H, ^{15}N and ^{31}P spectral data for the dcpp-^{15}N complexes are shown in Tables 1–3, respectively.

The complexes described in this study are analogues of known compounds containing pyridine[5,7,8] or 2,6-dimethylpyridine.[9] [*cis*-$RhX(PPh_3)_2(py)$] (X = Cl, SC_6F_5; py = pyridine) [Fig. 3(a)] is readily prepared *in situ* from $[RhCl(PPh_3)_3]$ or $[Rh_2(SC_6F_5)_2(PPh_3)_4]$ in the presence of excess pyridine. Where the pyridine carries substituent groups (as with dcpp) the formation of the pyridine-substituted compound is less favoured and a higher concentration of ligand

is required to achieve full (> 95%) conversion.

$$[RhCl(PPh_3)_3] \underset{-dcpp+PPh_3}{\overset{-PPh_3+dcpp}{\rightleftharpoons}} [cis\text{-}RhCl(PPh_3)_2(dcpp)] \quad (1)$$

$$[Rh_2(SC_6F_5)_2(PPh_3)_4] \underset{-dcpp}{\overset{+dcpp}{\rightleftharpoons}} [cis\text{-}Rh(SC_6F_5)(PPh_3)_2(dcpp)] \quad (2)$$

In the case where X = SC_6F_5 [eq. (2)] a 0.2 M concentration of dcpp is sufficient to convert a 0.05 M solution of [Rh$_2$(SC$_6$F$_5$)$_2$(PPh$_3$)$_4$] almost quantitatively to [*cis*-Rh(SC$_6$F$_5$)(PPh$_3$)$_2$(dcpp)], but with X = Cl [eq. (1)] the conversion is *ca* 25% and with [RhX(PPh$_3$)$_3$] (X = OCN, N$_3$) ⩽ 5%. Clearly the position of the equilibrium in eq. (1) can be forced to the right if a means can be found to remove free PPh$_3$ from solution without causing other major changes. A reagent which performs this task admirably is [Rh$_2$Cl$_2$(C$_2$H$_4$)$_4$]. In solution in the presence of PPh$_3$ it releases ethylene and forms [*trans*-RhCl(PPh$_3$)$_2$(C$_2$H$_4$)][6,10] and [RhCl(PPh$_3$)$_3$]. When treated with 0.25 equivalents of [Rh$_2$Cl$_2$(C$_2$H$_4$)$_4$] a

mixture of $[RhCl(PPh_3)_3]$ (0.05 M) and dcpp (0.15 M) in toluene at 22°C is converted almost entirely to [*cis*-$RhCl(PPh_3)_2$(dcpp)] and some $[RhCl(PPh_3)(C_2H_4)$dcpp)]. By increasing the amount of $[Rh_2Cl_2(C_2H_4)_4]$ used in the reaction $[RhCl(PPh_3)(C_2H_4)$(dcpp)] can be obtained as the major product: of three possible isomers only one [Fig. 3(b)] is formed. On bubbling carbon monoxide through the solution the ethylene is readily replaced by CO to give the carbonyl derivative [Fig. 3(c)].

The complexes $[Rh(H)(C_2Ph)(X)(PPh_3)_2$(dcpp)] (X = Cl, OCN, N_3) (Fig. 4) are formed from $[RhX(PPh_3)_3]$ and PhC_2H in the presence of dcpp as the major products, even where the concentration of [*cis*-$RhX(PPh_3)_2$(dcpp)] is very low, thus removing the need for a phosphine scavenger. It would appear that one or both $[RhX(PPh_3)_3]$ and [*cis*-$RhX(PPh_3)_2$(dcpp)] combine with phenylacetylene to give a product which readily binds dcpp, but is reluctant to bind a third phosphine. The complex $[Rh(H)(C_2Ph)(X)(PPh_3)_2$(dcpp)] (X = N_3) undergoes further reaction with PhC_2H to give $[Rh(H)(C_2Ph)_2(PPh_3)_2$(dcpp)]; with X = Cl or OCN this tendency is greatly reduced.

Figure 2 shows the hydride signal in the ^1H spectrum of $[Rh(H)(C_2Ph)(N_3)(PPh_3)_2$(dcpp)] in both unenriched and 99% ^{15}N-enriched forms (with decoupling of the pyridine 2- and 6-hydrogens in order to improve the line shape). In Fig. 2(a) (unenriched) it is a doublet of triplets (coupling to rhodium—100% ^{103}Rh, nuclear spin 1/2—and two equivalent phosphines), while in Fig. 2(b) it is a doublet of doublets of triplets [the multiplet in Fig. 2(a) is further split by coupling to ^{15}N]. In Fig. 5 the $^{15}N\{^1H\}$ spectra of three complexes are shown: Figs 5(a) and (b) were obtained using INEPT delay times corresponding to $J(^{15}N—^1H) = 10.6$ Hz (polarization transfer from the pyridine 2- and 6-

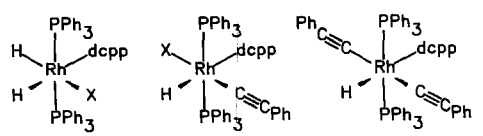

Fig. 4. Coordination geometries of the rhodium(III)-dcpp complexes. (a): X = Cl, SC_6F_5; (b): X = Cl, OCN, N_3.

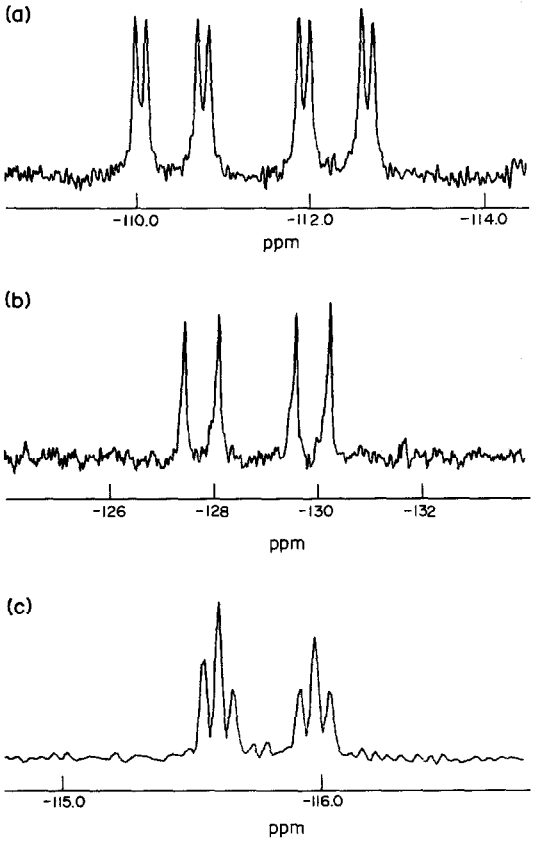

Fig. 5. $^{15}N\{^1H\}$ spectra of: (a) [*cis*-$Rh(SC_6F_5)(PPh_3)_2$(dcpp-^{15}N)] (0.07 M, 0.5 cm^3, 22°C, 25,000 scans); (b) $[RhCl(PPh_3)(CO)$(dcpp-^{15}N)] (0.015 M, 3.0 cm^3, −25°C, 1000 scans); (c) $[Rh(H)(C_2Ph)(OCN)(PPh_3)_2$(dcpp-$^{15}N$)] (0.05 M, 0.5 cm^3, 22°C, 14,000 scans). Solutions in toluene, $\delta^{15}N$ relative to CH_3NO_2 (ext. standard).

hydrogens), while Fig. 5(c) was obtained using a delay time corresponding to 22.8 Hz (polarization transfer from the hydride positioned *trans* to nitrogen).

In [*cis*-$Rh(SC_6F_5)(PPh_3)_2$(dcpp-^{15}N)] the nitrogen resonates as a doublet of doublets of doublets [Fig. 5(a)], coupling to rhodium and to phosphorus (two non-equivalent nuclei); the magnitude of the $^{31}P—^{15}N$ *trans* coupling (38.2 Hz) being approximately 15 times larger than that of $^{31}P—^{15}N$ *cis* (Table 2). The $^{15}N\{^1H\}$ signal from $[RhCl(PPh_3)(CO)$(dcpp-^{15}N)] [Fig. 5(b)] is a doublet of doublets with $J(^{31}P—^{15}N) = 43.5$ Hz, indicating a *trans*-phosphorus–nitrogen geometry [Fig. 2(c)]. The geometry of the complex $[Rh(H)(C_2Ph)(OCN)(PPh_3)_2$(dcpp-$^{15}N$)] [Figs 4(b) and 5(c)] is established unambiguously by a combination of ^1H (the magnitude of the $^{15}N—^1H$ coupling in the hydride signal indicates a *trans* configuration), ^{15}N

(the nitrogen resonates as a doublet of triplets, with coupling to rhodium and two equivalent phosphines) and ^{31}P (the phosphines give a single doublet confirming that they are equivalent, i.e. positioned mutually *trans*) NMR data.

Ligand exchange effects in the complexes [*cis*-$RhX(PPh_3)_2L$] (X = Cl, SC_6F_5; L = py, dcpp) are observed only at higher concentrations of N-donor ligand than were used in the present study, and become evident in the $^{31}P\{^1H\}$ spectrum as a broadening of the signals. Such effects are likely to be responsible for the broadening of the lines in the $^{15}N\{^1H\}$ spectra of $[Rh(H)_2X(PPh_3)_2(dcpp\text{-}^{15}N)]$ {X = Cl, SC_6F_5; formed from [*cis*-$RhX(PPh_3)_2$ (dcpp-^{15}N)] by treatment with hydrogen under ambient conditions} to the point where ^{31}P—^{15}N *cis* coupling cannot be observed. The spectrum of [*cis*-$RhCl(PPh_3)_2$(dcpp-^{15}N)] was recorded at −25°C in order to reduce the rate of conversion of the complex to $[Rh_2Cl_2(PPh_3)_4]$, a process that is accelerated by the removal from solution of free PPh_3. The complexes $[RhCl(PPh_3)(L)$(dcpp-^{15}N)] are also unstable in solution under the conditions required to generate them, their lifetime being prolonged at reduced temperature.

^{15}N NMR studies of complexes of rhodium have been reported for the ligands N_2,[11–13] NO,[14] ArN_2,[15,16] ArNSO,[17] NH_3,[18] 5-hydro-3,8-*R*,*R*-1,6-dioxa-4,9-diaza-5-phosphaspiro[4,4]nonane[19] (all with ^{15}N enrichment), pyridine, ethylenediamine, 1,2- and 1,3-diaminopropane, bipyridyl, 1,10-phenanthrolinc[20] and pyridine-2-carboxylate and related compounds[1] (natural abundance). ^{15}N studies of complexes of other metals have been comprehensively reviewed.[21–24] The change in chemical shift of nitrogen on complexation to a metal is considered to arise principally from three factors:[22] circulation of non-bonding and π-electrons (deshielding), asymmetry of the valence electrons (deshielding) and the energy separation (ΔE) between the ground and lowest excited states (the smaller the separation the greater the deshielding). The upfield shift (or, more correctly in the case of pulsed FT NMR, the shift to low frequency) of the ^{15}N resonance of pyridine on protonation is attributed largely to a change in ΔE when the lone pair electrons form a bond to hydrogen. Similar shifts have been observed on bonding of pyridine and derivatives to rhodium[1,20] and in the present study upfield shifts of *ca* 50 ppm were found in the dcpp-^{15}N signal. The values of δ^{15}N for the dcpp-^{15}N complexes show no obvious correlation with the properties of the other ligands: this may be a result of the fact that the ligand positioned *trans* to nitrogen is in all cases either PPh_3 or hydride and an investigation of the effects of a wide range of *trans* ligands is required before further comment can be made. Work in this direction is in progress.

Although the value of $J(^{103}Rh—^{15}N)$ (Table 2) appears to be related to the oxidation state of the metal these differences cannot be generalized and disappear when a wider range of complexes is considered: $[Rh(H)_2(O_2CArN)(PPh_3)_2]$ (O_2CArN = isoquinoline-1-carboxylate),[1] $J(^{103}Rh—^{15}N)$ = 10.1 Hz; $[RhCl(N_2Ph)(PMePh_2)_3][PF_6]$,[16] $J(^{103}Rh—^{15}N)$ = 15.9 Hz; [*trans*-$Rh(py)_4Cl_2$]Cl,[20] $J(^{103}Rh—^{15}N)$ = 17.1 Hz.

TRIPHOSPHA-FERROCENES AS LIGANDS: CRYSTAL AND MOLECULAR STRUCTURES OF $[Fe(\eta^5\text{-}C_5Me_5)(\eta^5\text{-}C_2Bu^t{}_2P_3)Cr(CO)_5]$ AND OF THE NOVEL NICKEL COMPLEX $[Fe(\eta^5\text{-}C_5Me_5)(\eta^5\text{-}C_2Bu^t{}_2P_3)Ni(CO)_2]_2$ CONTAINING TWO INTERLINKED $[Fe(\eta^5\text{-}C_5Me_5)(\eta^5\text{-}C_2Bu^t{}_2P_3)]$ SYSTEMS

(*Received* 18 *December* 1992; *accepted* 27 *January* 1993)

Abstract—The lone pair electrons of the two adjacent phosphorus atoms of the $C_2Bu^t{}_2P_3$ ring in the triphospha-ferrocene complex $[Fe(\eta^5\text{-}C_5Me_5)(\eta^5\text{-}C_2Bu^t{}_2P_3)]$ can ligate to other metal centres to afford novel bi- and tetrametallic complexes, whose structures have been elucidated by NMR and single-crystal X-ray studies. In the reaction of $[Fe(\eta^5\text{-}C_5Me_5)(\eta^5\text{-}C_2Bu^t{}_2P_3)]$ with $Ni(CO)_4$ the tetrametallic complex $[Fe(\eta^5\text{-}C_5Me_5)(C_2Bu^t{}_2P_3)Ni(CO)_2]_2$ is formed. This complex is of particular interest because it represents the first example of the intermolecular interlinkage of two phospha-ferrocene units by two metal centres. A six-membered ring consisting of four phosphorus and two nickel atoms forms the core of the molecule and exhibits a boat configuration. The starting material $[Fe(\eta^5\text{-}C_5Me_5)(\eta^5\text{-}C_2Bu^t{}_2P_3)]$ reacts with $Cr(CO)_5(thf)$, $W(CO)_5(thf)$ and $Fe_2(CO)_9$ to yield the η^1-complexes $[Fe(\eta^5\text{-}C_5Me_5)(\eta^5\text{-}C_2Bu^t{}_2P_3)M(CO)_n]$ (M = Cr, W, $n = 5$; M = Fe, $n = 4$). Variable-temperature $^{31}P\{^1H\}$ NMR studies reveal that these complexes are fluxional in solution.

Syntheses and structures of di-, tri-, penta- and hexaphosphorus analogues of ferrocenes, hexaphosphorus analogues of chromocene and η^3-transition metal complexes of the $C_2Bu^t{}_2P_3$ ring system have been described.[1–7] Unlike their simple metallocene analogues, however, these complexes have further ligating potential towards other transition metal centres by virtue of the availability of the ring phosphorus lone-pair electrons not already utilized in their η^3- or η^5-metal ligation. In a previous paper[8] we have described the synthesis and structural characterization of four such compounds: $[Fe(\eta^5\text{-}C_2Bu^t{}_2P_3)_2Fe(CO)_4]$, $[Fe(\eta^5\text{-}C_2Bu^t{}_2P_3)_2W(CO)_5]$, $[Fe(\eta^5\text{-}C_3Bu^t{}_3P_2)(\eta^5\text{-}C_2Bu^t{}_2P_3)W(CO)_5]$ and $[Fe(\eta^5\text{-}C_2Bu^t{}_2P_3)_2Ru_3(CO)_{10}]$ (**1**). The latter is of special interest since it represents the first example of (1) attachment of a transition metal carbonyl cluster to another $(\eta^5\text{-}C_2Bu^t{}_2P_3)$ metal complex and (2) interlinkage of both $(\eta^5\text{-}C_2Bu^t{}_2P_3)$ ligated ring systems in hexaphospha-ferrocene complexes.

Very recently[9] we described the synthesis and structural characterization of the ruthenium compound $[Fe(\eta^5\text{-}C_5Me_5)(\eta^5\text{-}C_2Bu^t{}_2P_3)Ru_3(CO)_9]$ (**2**) as a first example of a triphospha-ferrocene in which adjacent phosphorus atoms act as η^1-donors (see Fig. 1).

In this paper we report the synthesis of the tetrametallic complex $[Fe(\eta^5\text{-}C_5Me_5)(\eta^5\text{-}C_2Bu^t{}_2P_3)Ni(CO)_2]_2$ (**4**), by treatment of $[Fe(\eta^5\text{-}C_5Me_5)(\eta^5\text{-}C_2Bu^t{}_2P_3)]$ (**3**) with $Ni(CO)_4$. The nickel complex **4** represents the first example of intermolecular interlinkage of two phospha-ferrocene systems by two metal centres. Furthermore, we describe the syntheses of the complexes $[Fe(\eta^5\text{-}C_5Me_5)(\eta^5\text{-}C_2Bu^t{}_2P_3)Cr(CO)_5]$ (**5**). $[Fe(\eta^5\text{-}C_5Me_5)(\eta^5\text{-}C_2Bu^t{}_2P_3)W(CO)_5]$ (**6**) and $[Fe(\eta^5\text{-}C_5Me_5)(\eta^5\text{-}C_2Bu^t{}_2P_3)Fe(CO)_4]$ (**7**) by treatment of **3** with $Cr(CO)_5(thf)$, $W(CO)_5(thf)$ and $Fe_2(CO)_9$, respectively. X-ray crystal structures of the complexes **4** and **5** have been determined in order to elucidate

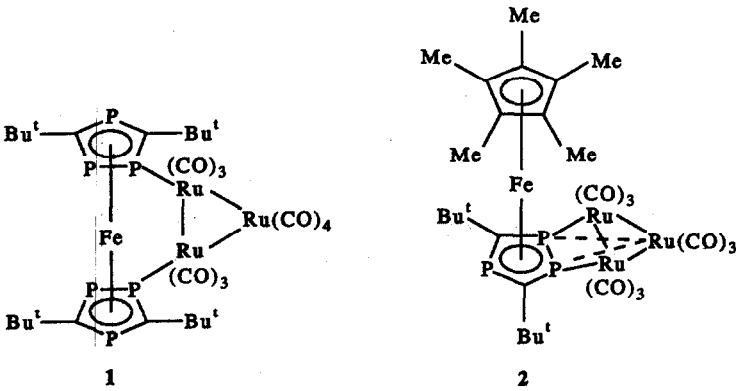

Fig. 1.

structural relationships within a series of related phospha-ferrocenes (see Table 1).

EXPERIMENTAL

All experiments were performed under oxygen-free nitrogen using conventional Schlenk techniques. Solvents were dried over sodium wire and distilled prior to use. The complexes $Cr(CO)_5(thf)$,[10] $W(CO)_5(thf)$[10] and $[Fe(\eta^5\text{-}C_5Me_5)(\eta^5\text{-}C_2Bu^t{}_2P_3)]$ (**3**)[9] were prepared according to literature procedures; all other starting materials were commercially available. IR spectra were obtained using a Nicolet 320 FT-IR spectrometer. NMR

$[Fe(\eta^5\text{-}C_5Me_5)(\eta^5\text{-}C_2Bu^t{}_2P_3)Ni(CO)_2]_2$ (**4**)

A solution of nickel tetracarbonyl (2.64 g, 15.46 mmol) in DME (3 cm^3) was added to a solution containing $[Fe(\eta^5\text{-}C_5Me_5)(\eta^5\text{-}C_2Bu^t{}_2P_3)]$ (**3**) in DME (10 cm^3) with stirring at 0°C. Carbon monoxide was released immediately and stirring was continued for 16 h at room temperature. After removal of the volatile material *in vacuo* the orange residue was extracted with n-hexane and fractionated by column chromatography (kieselgel/n-hexane). Some starting material and impurities were eluted with n-hexane, then the nickel complex **4** was isolated by elution with toluene. Some orange coloured crystals of **4** suitable for X-ray analysis were obtained by recrystallization from n-hexane. However, the compound could not be isolated without traces of impurities and, therefore, the yield was not determined and a microanalysis was not performed. FAB-MS: $C_{44}H_{66}Fe_2Ni_2O_4P_6$ (1074), *m/z* (%): 1018 (0.7) $[M-2\ CO]^+$, 959 (1.6) $[M-Ni(CO)_2]^+$, 422 (100) $[\mathbf{3}]^+$, 284 (18) $[\mathbf{3}-C_2Bu^t{}_2]^+$, 253 (7) $[\mathbf{3}-C_2Bu^t{}_2-P]^+$. IR (n-hexane): ν(CO) = 2013 (vs), 1969 (s) cm^{-1}.

$[Fe(\eta^5\text{-}C_5Me_5)(\eta^5\text{-}C_2Bu^t{}_2P_3)Cr(CO)_5]$ (**5**)

A THF solution of $Cr(CO)_5$(thf) prepared from $Cr(CO)_6$ (280 mg, 1.27 mmol) in THF[10] was added to a solution of **3** (385 mg, 0.91 mmol) in THF (3 cm^3) and the reaction mixture was stirred for 4 h at room temperature. The volatile material was removed *in vacuo* and the orange–brown residue was extracted with n-hexane and fractionated by column chromatography (kieselgel/n-hexane). After the removal of the solvent and recrystallization from n-hexane deep brown crystals of **5** were obtained, which were suitable for X-ray analysis. Yield: 510 mg (91%); m.p. 162°C (dec.). Found: C, 48.8; H, 5.6; P, 15.1. Calc. for $C_{25}H_{33}CrFeO_5P_3$ (614.30): C, 48.9; H, 5.4; P, 15.1%. IR (n-hexane): ν (CO) = 2063 (vs), 1987 (s), 1944 (vs) cm^{-1}.

$[Fe(\eta^5\text{-}C_5Me_5)(\eta^5\text{-}C_2Bu^t{}_2P_3)W(CO)_5]$ (**6**)

Complex **6** was prepared using $W(CO)_5$(thf), prepared from $W(CO)_6$ (380 mg, 1.08 mmol)[10] and **3** (325 mg, 0.77 mmol) as starting materials. Deep brown crystals of **6** were obtained from n-hexane. Yield: 521 mg (91%); m.p. 159°C (dec.). Found: C, 40.4; H, 4.5; P, 12.5. Calc. for $C_{25}H_{33}FeO_5P_3W$ (746.15): C, 40.2; H, 4.5; P, 12.4%. IR (n-hexane): ν (CO) = 2071 (vs), 1984 (s), 1944 (vs) cm^{-1}.

$[Fe(\eta^5\text{-}C_5Me_5)(\eta^5\text{-}C_2Bu^t{}_2P_3)Fe(CO)_4]$ (**7**)

Compound **7** was prepared from **3** (423 mg, 1.00 mmol) and $Fe_2(CO)_9$ (510 mg, 1.40 mmol). Brown crystals of **7** were obtained from n-hexane. Yield: 515 mg (87%); m.p. 134°C (dec.). Found: C, 49.0; H, 5.6; P, 19.0. Calc. for $C_{24}H_{33}Fe_2O_4P_3$ (590.14): C, 48.8; H, 5.6; P, 18.9%. IR (n-hexane): ν (CO) = 2058 (vs), 2048 (vs), 1976 (vs), 1949 (vs) cm^{-1}.

Crystal structure determination for complexes **4** *and* **5**

Crystals were mounted in inert oil on glass fibres and transferred to the cold gas stream of the diffractometer (**4**: Siemens R3, $T = -95$°C; **5**: Stoe STADI-4, $T = -115$°C). Data were collected using monochromated Mo-K_α radiation. Absorption corrections based on ψ-scans were applied. Cell constants were refined from setting angles (**4**) or $\pm\omega$ angles (**5**) of *ca* 50 reflections in the 2θ range 20–23°. The structures were solved by direct methods and refined anisotropically. Hydrogen atoms were included using a riding model: weighting schemes of the form $w^{-1} = \sigma^2(F)+gF^2$ were employed. The program system was "Siemens SHELXTL PLUS". Full details of the structure determinations have been deposited at the Fachinformationszentrum Karlsruhe, Gesellschaft für Wissenschaftlich-technische Information mbH, D-7514 Eggenstein-Leopoldshafen 2, Germany. Any request for this material should quote a full literature citation and the reference number CSD 56974.

RESULTS AND DISCUSSION

Synthesis and spectroscopy

We recently[9] described the preparation of $[Fe(\eta^5\text{-}C_5Me_5)(\eta^5\text{-}C_2Bu^t{}_2P_3)]$ (**3**). Treatment of this complex with nickel carbonyl results in the formation of the tetrametallic complex **4**, in which two phosphaferrocenes (**3**) are linked by two $Ni(CO)_2$ centres. The ^{31}P NMR spectrum of **4** represents an AB_2 spin system with $\delta(P^A)$ 36.14 and $\delta(P^B)$ 35.00 ppm (Table 2). No molecular ion could be detected in the EI mass spectrum of **4**. Only the mass peak of complex **3** and its fragments could be established. Complex **4** cannot be transferred into the gas phase without decomposition because of its high mass. The molecular ion of **4** could also not be detected in the FAB

mass spectrum, but fragments of lower intensity could be observed that resulted from the loss of carbonyl groups and a $Ni(CO)_2$ fragment. Again, the molecular ion of **3** represents the strongest peak, corresponding to the typical fragmentation pattern[9] (see Experimental). Treatment of **3** with $Cr(CO)_5$(thf), $W(CO)_5$(thf) and $Fe_2(CO)_9$ afforded the η^1-complexes **5**, **6** and **7** as deep brown crystals. The new complexes were characterized by microanalysis, IR spectroscopy (see Experimental) and ^1H, ^{31}P and ^{13}C NMR spectroscopy (see Scheme 1, Tables 2 and 3). The molecular structure of **5** was confirmed by a single-crystal X-ray diffraction study, indicating that the $C_2Bu^t_2P_3$ ring is bonded in an η^5-η^1-fashion to the iron and chromium atom, respectively, with the iron atom sandwiched between the two five-membered rings (Fig. 2). The $^{31}P\{^1H\}$NMR spectra of **5**, **6** and **7** represent ABX spin systems with values of chemical shifts and coupling constants lying in the same region as described for $[Fe(\eta^5\text{-}C_5H_5)(\eta^5\text{-}C_2Bu^t_2P_3)W(CO)_5]$[7] (see Table 2). For all complexes $^2J(P^AP^B)$ is smaller than $^2J(P^AP^X)$. In contrast to the corresponding cyclopentadienyl compound,[7] no ^{183}W satellites could be observed for the pentamethylcyclopentadienyl compound **6**. Variable-temperature $^{31}P\{^1H\}$ NMR studies reveal that complexes **5**, **6** and **7** are fluxional in solution. At −35°C the spectra of **5** and **6** exhibit the characteristic ABX pattern expected for the rigid structure. As the temperature is raised resonances P^B and P^X broaden and become featureless at room temperature (see Fig. 3 for the

chromium complex **5**). This fluxional process is best visualized as an intramolecular 1,2-shift of chromium, tungsten or iron between P^B and P^X, as shown in Scheme 2 for chromium. In contrast to the chromium and tungsten compounds **5** and **6** the intramolecular 1,2-shift is slow for the $Fe(CO)_4$ adduct **7**. Although the signals in the $^{31}P\{^1H\}$ NMR spectrum of **7** are broadened at room temperature, the coupling constants $^2J(P^AP^B)$ and $^2J(P^AP^X)$ can still be observed.

This type of mechanism has been postulated for the complex *trans*-[$MCl(C_2R_2P_3)(PEt_3)_2$] (R = Bu^t, 1-adamantyl; M = Pd, Pt),[4] in which the 1,2,4-triphosphacyclopentadienyl system is η^1-ligated, and for related systems involving nitrogen, sulphur and selenium heterocycles.[11,12] The ^1H NMR spectra of the complexes **5**, **6** and **7** show only one resonance for the protons of the Bu^t groups. The intramolecular 1,2-shift of the metal fragment $M(CO)_x$ is obviously so fast, relative to the ^1H NMR time-scale, that even at −35°C no splitting of the signal could be observed. The ^{13}C NMR spectrum of **5** exhibits two signals for the carbonyl groups in *cis*/*trans* positions, whereas **6** shows only one resonance for the carbonyl groups in a *cis* position. Furthermore, only one resonance appears in the ^{13}C NMR spectrum of **7** for the carbonyl groups in equatorial positions. The value of the phosphorus–carbon coupling in **7** is 12.3 Hz (slow 1,2-shift), whereas no phosphorus–carbon couplings could be observed in the ^{13}C NMR spectra of **5** and **6** at room temperature because of the intramolecular 1,2-shift of the metal fragment $M(CO)_x$, which is fast relative to the ^{13}C NMR time-scale.

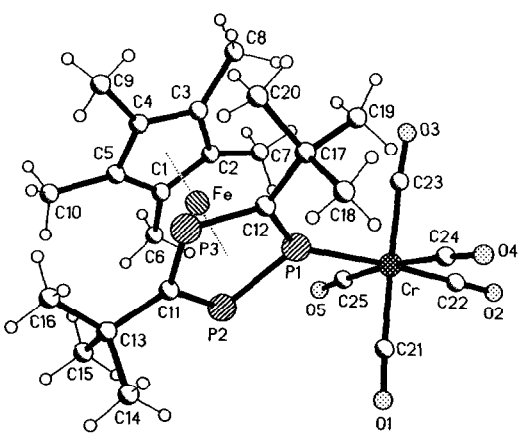

Fig. 2. Molecular structure of **5**.

X-ray investigations

The molecular structures of compounds **4** and **5** with analogous atomic numbering schemes are shown in Figs 2 and 4. Selected bond lengths and angles are given in Table 4. The molecule of **4** consists of two triphospha-ferrocene groups (**3**), doubly bridged by two $Ni(CO)_2$ fragments via the two adjacent phosphorus atoms of the $C_2Bu^t{}_2P_3$ ring

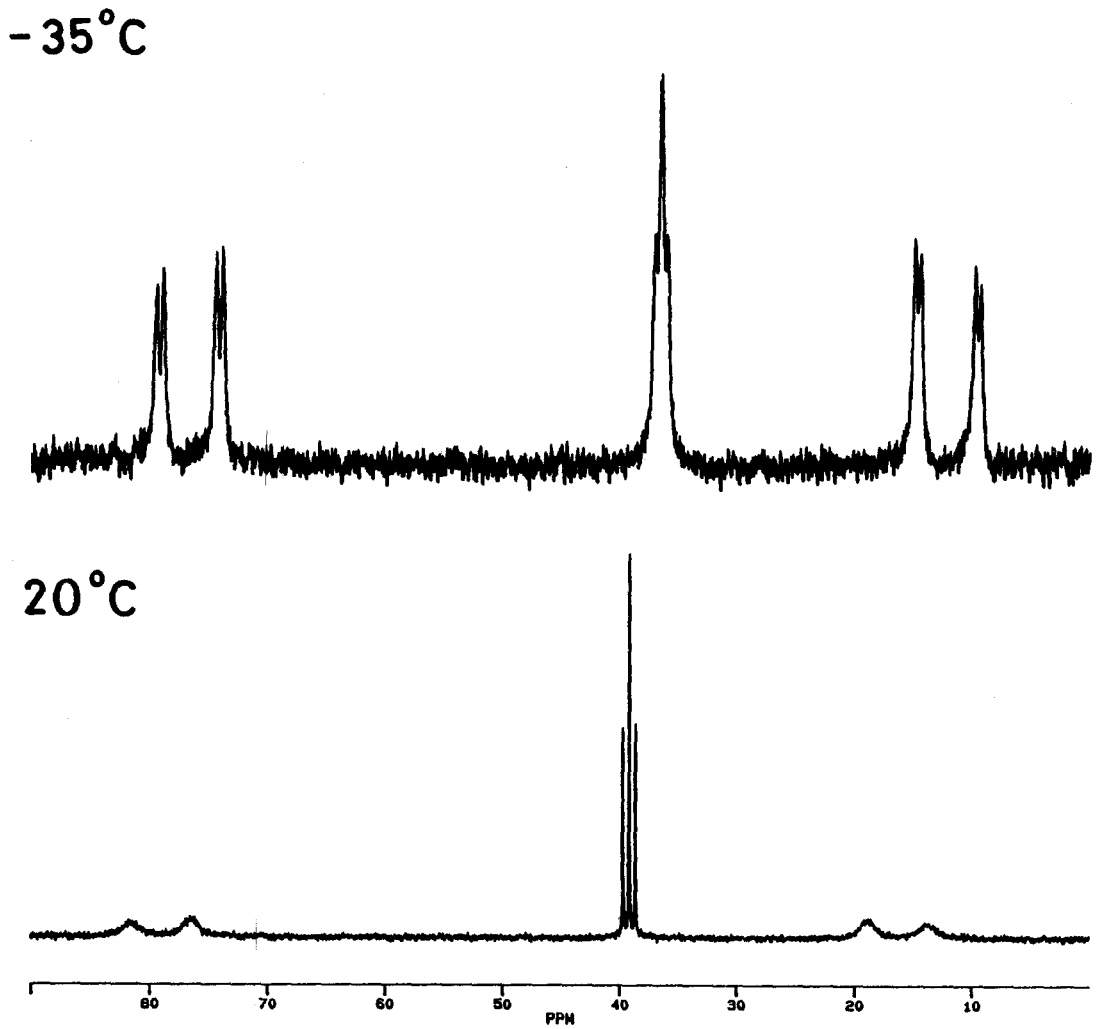

Fig. 3. Temperature-dependent $^{31}P\{^{1}H\}$ NMR spectra of the chromium complex **5**.

systems. Bond lengths and angles in the [Fe(η^5-C_5Me_5)(η^5-$C_2Bu^t{}_2P_3$)] moieties agree well with those of closely related sandwich compounds.[1-9] The triphosphacyclopentadienyl systems reveal only negligible deviation from planarity (av. 0.003 Å). The C_5Me_5 and $C_2Bu^t{}_2P_3$ ring systems are essentially parallel (dihedral angle 3.1°) and almost eclipsed. The observed iron-cyclopentadienyl ring centre distance of 1.711 Å and the iron-triphosphacyclopentadienyl ring distance of 1.656 Å are very similar to those of the ruthenium complex **2**.[9] The nickel atoms in the phosphorus–nickel six-membered ring in **4** occupy the centres of distorted tetrahedrons, in which the P—Ni—P,

P—Ni—C and C—Ni—C bond angles deviate by up to 5° from ideal angles. The six-membered ring that forms the core of the molecule exhibits a boat configuration. The values of the Ni—P bond lengths in **4** lie in the range 2.213–2.221 Å and agree well with those of known $Ni(CO)_2$-bridged structures.[13,14] The Ni—C—O angles show only minor deviations from linearity (Fig. 4).

The molecular structure of the chromium complex **5** illustrated in Fig. 2 agrees well with that of the closely related tungsten complex $[Fe(\eta^5\text{-}C_5H_5)(\eta^5\text{-}C_2Bu^t{}_2P_3)W(CO)_5]$.[7] The observed P—P and P—C distances in the $C_2Bu^t{}_2P_3$ ring system are very similar in both complexes. The triphosphacyclopentadienyl ring in **5** shows a slight deviation of 0.015 Å (av.) from planarity. The distances between the iron atom and the centres of the cyclopentadienyl and triphosphacyclopentadienyl ring systems (1.716 and 1.663 Å) resemble those in the nickel complex (**4**). The ring systems are almost parallel (dihedral angle 1.8°) and show an eclipsed configuration. The chromium pentacarbonyl fragment possesses the structure of a slightly distorted tetrahedron. Due to the steric demand of the tert-butyl groups, the neighbouring carbonyl groups display wider bond angles. The Cr—P(1) bond distance of 2.402 Å in **5** is in good agreement with the corresponding distance in $(Ph_3P)Cr(CO)_5$ (2.422 Å).[15,16] The Cr—C—O bond angles show only minor deviations from linearity. Bond lengths and angles of the chromium pentacarbonyl fragment in **5** are very similar to those in chromium pentacarbonyl adducts of comparable phosphaferrocenes.[17,18]

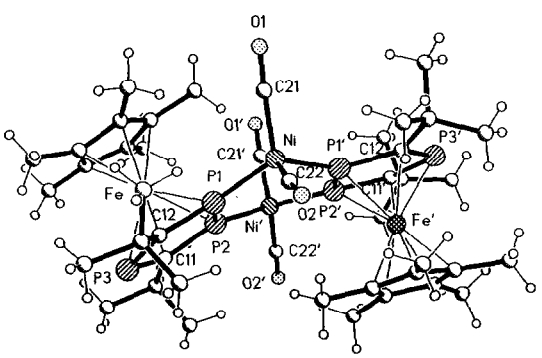

Fig. 4. Molecular structure of **4**.

We conclude that the geometry of the 2,5-di-

t-butyl-1,3,4-triphosphacyclopentadienyl ring in **4** and **5** is hardly changed on complexation from that in the parent complex $[Fe(\eta^5\text{-}C_2Bu^t{}_2P_3)_2]$.[1]

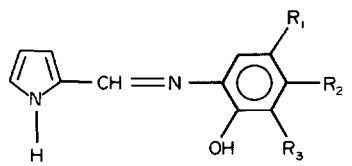
(*Received* 23 *November* 1992; *accepted* 27 *January* 1993)

Abstract—The electrochemical oxidation of anodic metals (Co, Ni, Cu, Zn and Cd) in acetonitrile solution containing a Schiff base (H_2L) derived from H-pyrrole-2-carbaldehyde and a substituted *o*-aminophenol yielded the complexes $M(HL)_2$ and acetonitrile-bis{2-[(2-pyrrole)methylimino]-4,6-dimethylphenolato}zinc(II). X-ray data show the latter to have a distorted bipyramidal coordination polyhedron that does not include the pyrrole nitrogen atoms.

In previous papers we have reported the electrochemical synthesis of complexes of various metals with Schiff bases derived from H-pyrrole-2-carbaldehyde and anilines,[1,2] cysteamine or (2-aminophenyl)disulphide.[3] The electrochemical oxidation of a metal in a cell containing a solution of a ligand is simple, affords high yields and allows the one-step preparation of mixed complexes by inclusion of a second ligand in the cell solution [recently published examples include mixed complexes containing 2-pyrrole-N-(*o*-hydroxyphenyl)-aldimines and either 1,10-phenanthroline or 2,2′-bipyridine].[4] In continuation of our work in this field we have now synthesized complexes of metals with 2-[(2-pyrrole-)-methylimino]phenols (H_2L):



where $R_1 = R_2 = R_3 = H$ (HL^a); $R_1 = Cl$, $R_2 = R_3 = H$ (HL^b); $R_1 = CH_3$, $R_2 = R_3 = H$ (HL^c); $R_2 = CH_3$, $R_1 = R_3 = H$ (HL^d); $R_1 = R_3 = CH_3$, $R_2 = H$ (HL^e).

The crystal structure of acetonitrile-bis{2-[(2-pyrrole)methylimino]-4,6-dimethylphenolato}zinc(II) is also reported.

EXPERIMENTAL

Cobalt, nickel, copper, zinc and cadmium (Ega Chemie) were used as plates (*ca* 2 × 2 cm). All other reagents, including acetonitrile, H-pyrrole-2-carbaldehyde and amines were commercial products and were used without further purification.

Schiff base formation

Equimolecular amounts of the H-pyrrole-2-carbaldehyde and amine in chloroform solution were refluxed until the theoretical amount of water had been collected in a Dean–Stark trap. The solids isolated were crystallized from n-hexane and their purity was confirmed by elemental microanalysis and their IR and ^1H NMR spectra.

* Author to whom correspondence should be addressed.

Preparation of complexes

These compounds were obtained using an electrochemical procedure similar to that described by Tuck *et al.*[5] The cell consisted of a 100 cm^3 tall-form beaker containing an acetonitrile solution of the Schiff base (with a small amount of tetraethylammonium perchlorate as a current carrier), a platinum wire cathode and a sacrifical metal anode. Direct current was obtained from a purpose-built d.c. power supply. Applied voltages of 15–30 V allowed sufficient current flow for smooth dissolution of the metal. The cells can be summarized as $Pt_{(-)}/CH_3CN + H_2L/M_{(+)}$.

The solution compositions and experimental conditions are given in Table 1. In some cases the product formed during electrolysis was recrystallized from hot acetonitrile. The analytical data of the compounds are given in Table 2.

X-ray crystal structure analysis

$[Zn(C_{13}H_{13}N_2O)_2 \cdot CH_3CN]$, *Crystal data.* $C_{28}H_{29}N_5O_2Zn$, $M = 532.95$, orthorhombic, space group *Pbcn*, $a = 14.398(4)$, $b = 8.190(2)$, $c = 22.298(4)$ Å, $V = 2629(2)$ Å^3, $Z = 4$, $D_c = 1.346$ g cm^{-3}, $F(000) = 1112$, $\lambda(\text{Cu-}K_\alpha) = 1.5418$ Å, $\mu = 15.79$ cm^{-1}.

Data collection and processing. Structure determination was performed at room temperature with an Enraf–Nonius CAD4 diffractometer using a crystal of approximate dimensions $0.3 \times 0.2 \times 0.1$ mm. Lattice constants were obtained from the setting angles of 25 reflections. In the $+h+k+l$ quadrant of the reflection sphere 4509 reflections in the range $5 < \theta < 65°$ were recorded with Cu-K_α radiation (graphite monochromator) by the ω/θ scan technique. After averaging 2322 unique reflections remained ($R_{int} = 0.023$). Lorentz, polarization and

$Cd(HL^e)_2 \cdot 3H_2O$	9.0(9.5)	52.8(52.8)	5.0(5.4)

empirical absorption corrections[6] were applied (max. and min. transmission factors 100 and 97%, respectively). Three standard reflections showed no significant variation in intensity during the course of data collection. The structure was solved by Patterson and difference-Fourier methods. Refinement was performed using 1627 independent observations with $I > 1.0\ \sigma(I)$ by minimizing the function $\Sigma w(|F_o| - |F_c|)^2$ with $w^{-1} = \sigma^2(F_o)$. Hydrogen atom positions were calculated (C—H = 0.98 Å; $B_{iso} = 1.3 \times B_{eq}$ of the atom bonded to it) and were not refined, but included isotropically in structure-factor calculations. In the final least-squares cycles all non-hydrogen atoms were refined with anisotropic displacement parameters and a correction for secondary extinction was applied. Refinement converged at $R = 0.039$, $R_w = 0.048$ for a total of 174 variables. A final difference-Fourier map showed a local electron density maximum of 0.54 e $Å^{-3}$ close to the metal atom. Calculations were performed on a VAXstation 3100 computer with the SDP system[7] and the program ORTEP.[8] Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissen-schaftlich-technischs Information mbH, D-7514 Eggenstein-Leopoldshafen 2, on quoting the depository number CSD-56729. Atomic coordinates have also been deposited at the Cambridge Crystallographic Data Centre.

Physical measurements

Carbon, hydrogen and nitrogen microanalyses were performed using a Carlo–Erba EA 1108 elemental analyser. IR spectra were recorded in KBr mulls on a Perkin–Elmer 180 spectrophotometer. Solid spectra were recorded on a Perkin–Elmer Lambda 9 spectrophotometer. Magnetic moment data were obtained with a SQUID susceptometer. Proton NMR spectra were recorded in $CDCl_3$ or DMSO solutions using a Bruker WM250 MHz spectrometer; chemical shifts were determined with respect to TMS as an internal standard.

RESULTS AND DISCUSSION

The elemental analyses (Table 2) indicate that the above electrochemical method can be satisfactorily used for the synthesis of compounds of the general formula $M(HL)_2$, where HL is the monoanionic form of the Schiff base ligands and M is cobalt(II), nickel(II), copper(II), zinc(II) or cadmium(II).

The electrochemical efficiency, E_F, defined as the amount of metal dissolved per Faraday of charge, was found to be close to 1.0 mol F^{-1} for the copper complexes. This and the release of hydrogen at the cathode are compatible with the formation of copper(I) at the anode in accordance with the process:

$$\text{Cathode:}\quad H_2L + e^- \longrightarrow 1/2H_{2(g)} + HL^-$$

$$\text{Anode:}\quad Cu + HL^- \longrightarrow [Cu(HL)] + e^-$$

followed by oxidation to copper(II) in the solution

$$[Cu(HL)] + H_2L \longrightarrow [Cu(HL)_2] + 1/2H_{2(g)}.$$

For the other complexes the E_F values are close to 0.5 mol F^{-1} and the reaction mechanism may accordingly be written:

$$\text{Cathode:}\quad H_2L + e^- \longrightarrow 1/2H_{2(g)} + HL^-$$

$$\text{Anode:}\quad M + 2HL^- \longrightarrow [M(HL)_2] + 2e^-.$$

Structure of $[Zn(C_{13}H_{13}N_2O)_2 \cdot CH_3CN]$

As illustrated in Fig. 1 the structure consists of monomeric $[Zn(C_{13}H_{13}N_2O)_2 \cdot CH_3CN]$ units situated on a two-fold crystallographic axis with the central zinc atom penta-coordinated to the imino nitrogen and phenolato oxygen atoms of two bidentate HL^- ligands and an acetonitrile nitrogen atom. The solvent molecule is disordered around the two-fold axis and shows large displacement parameters perpendicular to the axis. The pyrrole nitrogen atoms of each Schiff base ligand are not coordinated to the zinc. The environment of the zinc atom must be described as a distorted trigonal bipyramid, with the oxygen atoms of the Schiff bases and the acetonitrile nitrogen atom occupying equatorial sites and the imino nitrogen atoms axial sites. The zinc and the equatorial donors are co-planar to within the limits of experimental error.

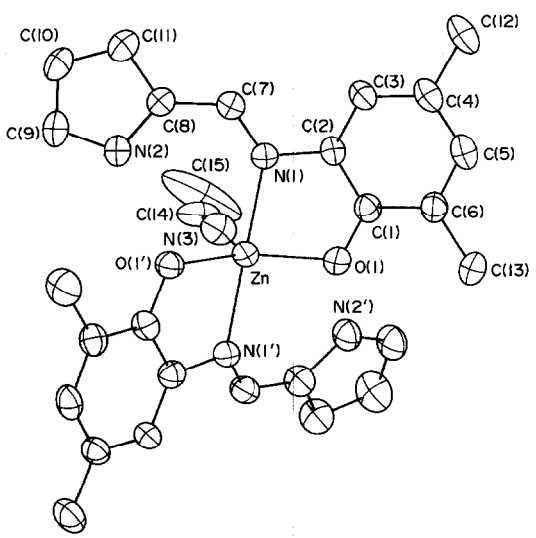

Fig. 1. Molecular structure of acetonitrile-bis{2-[(2-pyrrole)methylimino]-4,6-dimethylphenolato}zinc(II).

Angular distortions are observed both in the equatorial plane (Table 3), with the two O(1)—Zn—N(3) angles close to 112.99(6)° and an O(1)—Zn—O(1) angle of 134.0(1)°, and along the axial direction of the trigonal bipyramid, with an N(1)—Zn—N(1) angle of 176.2(1)°.

The deviation from strictly trigonal bipyramidal geometry also emerges in the difference between the Zn—O and Zn—N bond lengths. The average Zn—O(1) (phenolato) bond length, 1.938(2) Å, is in good agreement with those found in the perchlorate of {1,5,9-triazacyclododecane[2-(2-phenolate)aquo]}zinc(II)[9] [1.930(4) Å], [N,N'-ethylene-bis(salicylideneiminato)aquo zinc(II)][10] (1.94 Å) and other salicylaldiminates complexes of zinc(II), in which the metal is, as here, five-coordinated (1.944–1.965 Å).[11] The average Zn—N(1) (imino) bond length, 2.169(2) Å, is longer than those found in five-coordinated salicylaldiminates of zinc (II) (2.051–2.097 Å),[10,11] but is similar to those reported for several five-coordinated complexes of zinc(II) with non-salicylaldimine Schiff bases [e.g. 2.175(5) Å in {2,6-bis[1-(2-imidazol-4-ylethylimino)ethyl]pyridine}zinc(II) perchlorate[12] and 2.191(7) Å in bis[(2-thiobenzaldimino)-2,6-diacetylpyridine]zinc(II)].[13]

The distance between zinc and the acetonitrile nitrogen atom, 2.114(4) Å, is significantly longer than that reported in the tetrahedrally coordinated $[ZnCl_2 \cdot (CH_3CN)_2]$, 2.046(3) Å,[14] and even a little longer than those found in the six-coordinated zinc (II) complex $[Zn(15\text{-crown-}5) \cdot CH_3CN]$, 2.093(13) and 2.069(12) Å.[14]

The mean N—C and C—C distances in the pyrrole ring [1.355(4) and 1.378(5) Å respectively], the mean C—C distance in the phenyl ring [1.392(4) Å] and the mean C(sp^2)—C(methyl) distance [1.504(4) Å] are essentially identical to those found in other complexes and are unremarkable. The C(7)—N(1) distance [1.288(3) Å] is as expected for azomethine C=N bonds.[15] C(1)—O(1) [1.339(3) Å] is shorter than for a C—O single bond, but not as long as for C=O double bonds.[16] In the acetonitrile molecule

the C(14)—N(3) distance [1.075(6) Å] does not differ from the normal C≡N triple bond length.[17]

The phenyl and pyrrole rings are essentially planar, the maximum deviation of any atom being 0.01 Å. However, the ligand as a whole deviates considerably from planarity (the largest deviation of any atom from the best least-squares plane is 0.4 Å), since the phenyl and pyrrole rings are twisted with respect to each other so that the phenolato oxygen atom of each Schiff base is involved in a strong hydrogen bond with the pyrrole N—H ring group of the other Schiff base (O···N = 2.74 Å).[18]

Vibrational spectra

The IR spectrum of the free Schiff base shows bands attributable to ν(N—H) and ν(O—H) at 3340–3440 cm^{-1} and 3290–3300 cm^{-1}, respectively. One of these bands is absent from the complexes, suggesting that one of the two hydrogen atoms is lost during synthesis. The other is replaced by bands over 2700–2900 cm^{-1}, characteristic of NH groups involved in hydrogen bonds. The hypothesis that it is the phenolic group which is deprotonated and that the ligand is, therefore, coordinated in monoanionic form via the phenolate oxygen is corroborated by the observed shift to higher frequencies of the band attributable to ν(C—O). At the same time coordination via the azomethine nitrogen is indicated by the shift to lower frequencies of bands assignable to azomethine ν(C=N). These conclusions are in accordance with the structure found for $[Zn(C_{13}H_{13}N_2O)_2 \cdot CH_3CN]$ by X-ray diffraction. On this basis we proposed that the ligands are bidentate in the $[M(HL)_2]$ complexes, in which the coordination number of the metal is, therefore, four. In the spectrum of $[Zn(C_{13}H_{13}N_2O)_2 \cdot CH_3CN]$ the coordination of the acetonitrile nitrogen to the zinc is reflected by the two ν(C≡N) bands at 2305 and 2280 cm^{-1} being located at higher frequencies than those observed for free CH_3CN.

NMR spectra

For the zinc and cadmium complexes the ^{1}H NMR data (Table 4) are in keeping with the above conclusions. The single signal between 13 and 14.5 ppm in the spectra of the complexes is attributable to a hydrogen of the N—H group involved in a hydrogen bond.[4] This signal lies at 11.8 ppm in the free ligand and in pyrrole complexes, in which the N—H group is not involved in hydrogen bonds.[2] The azomethine signal shifts downfield, and the peak attributable to the phenolic hydrogen is absent from the spectra of the complexes.

Electronic studies

The solid state electronic spectra of the cobalt(II) complexes in the near-IR–vis region show two *d–d* transition bands in the 8300–9200 and 12,500–15,000 cm^{-1} ranges, both of the type expected for distorted tetrahedral cobalt(II) compounds.[19] The band in the visible region has been assigned to a $^4A_2 \rightarrow {}^4T_1(P)(\nu_3)$ transition and the multicomponent band in the near IR region to a $^4A_2 \rightarrow {}^4T_1(F)(\nu_2)$ transition. No $^4A_2 \rightarrow {}^4T_2(\nu_1)$ transition was observed and the band at *ca* 20,000 cm^{-1} may be attributed to a charge-transfer transition.

The magnetic moments of the nickel complexes lie in the 3.01–3.60 B.M. range at room temperature. These values are as expected for octahedral and tetrahedral complexes. The diffuse reflectance spectra of these complexes show bands in the 7300–8000 and 14,900–15,600 cm^{-1} regions, which can be assigned to $^3T_1(F) \rightarrow {}^3A_2(\nu_2)$ and $^3T_1(F) \rightarrow {}^3T_1(P)(\nu_3)$ transitions and are consistent with tetrahedral coordination geometry. The weak band observed in some complexes at *ca* 11,000 cm^{-1} is attributed to a spin-forbidden transition.

The magnetic moments of the copper complexes at room temperature lie in the 1.8–1.9 B.M. range, corresponding to one unpaired electron. The solid state electronic spectra show a very broad band at 15,000–18,000 cm^{-1}, compatible with square-planar geometry. The high intensity band observed at 20,500–23,000 cm^{-1} may be attributed to a charge-transfer transition.

SYNTHESIS AND CHARACTERIZATION OF NOVEL HOMO- AND HETEROLEPTIC NONAISOPROPOXODIZIRCONATOSAMARIUM(III) COMPLEXES

G. GARG, A. SINGH* and R. C. MEHROTRA†

Department of Chemistry, University of Rajasthan, Jaipur 302 004, India

(*Received* 13 *July* 1992; *accepted* 26 *January* 1993)

Abstract—Heterobimetallic isopropoxide derivatives of samarium(III) of the types $[Cl_{3-n}Sm\{Zr_2(OPr^i)_9\}_n]$ ($n = 1$, 2 or 3) have been prepared by the interaction of $SmCl_3 \cdot 3Pr^iOH$ with $K\{Zr_2(OPr^i)_9\}$ in the desired molar (1:1, 1:2 or 1:3) ratios in benzene. Chloride-isopropoxo (or tetraisopropoxoaluminato) exchange reactions have led to the formation of interesting hetero-(bi- or tri-) metal isopropoxides of samarium(III), $L_{3-n}Sm\{Zr_2(OPr^i)_9\}_n$ [$L = OPr^i$, $n = 1$ or 2; $L = Al(OPr^i)_4$, $n = 1$]. All these products have been characterized by elemental analyses and spectroscopic (IR, NMR) studies.

During the last few years there has been an unprecedented spurt of interest in the alkoxide chemistry of yttrium and lanthanum, due to various reasons such as (1) the formation of alkoxide derivatives of unusual compositions and structural patterns,[1–7] (2) the presence of yttrium and lanthanum in high temperature oxide superconductors,[8] (3) heterometal alkoxide derivatives proving to be useful precursors for ceramic materials via the sol–gel process,[9–12] (4) the possibility of utilization of volatile heterometal alkoxides as convenient precursors for oxide films by MOCVD techniques,[13,14] and (5) the high technological applications of samarium based magnets such as Sm_5Co.

Although samarium diiodide has recently proved to be a versatile stoichiometric reagent in various organic transformations,[15,16] the chemistry of metal-organic derivatives of samarium is mainly restricted to organometallics[15,16] except for derivatives like $[Sm\{N(SiMe_3)_2\}_3]$,[17] $[Sm\{Al(OPr^i)_4\}_3]$,[18] and $Li_5Sm(OBu^t)_8$[19] and $Sm[TeC_6Me_3\text{-}2,3,6]_2(THF)_2$.[20]

Further, although organometallic[15,16] derivatives of samarium are now well known in both tri- and bivalent states, the alkoxide and amide chemistry of samarium is so far limited to the trivalent state.[17,21,22]

In view of the above we report herein the synthesis and characterization of homo- and heteroleptic alkoxo-zirconates of samarium(III), with the intuition that derivatives of the types $[ClSm\{Zr_2(OPr^i)_9\}_2]$ and $[Cl_2Sm\{Zr_2(OPr^i)_9\}]$ may prove useful as precursors for the synthesis of heterometallic alkoxide systems, and that these chloro-precursors would make accessible the hetero-bimetallic alkoxides of samarium(II).

EXPERIMENTAL

In view of the highly moisture-sensitive nature of the heterometal isopropoxide systems, stringent precautions were taken to exclude moisture during all of the experimentation.

All solvents were dried by refluxing and distilling over the appropriate agent (in parentheses): benzene, toluene and n-hexane (Na/benzophenone), isopropanol [Na; $Al(OPr^i)_3$] prior to use. Finally, traces of moisture from benzene and isopropanol were removed by azeotropic distillation after adding 1–2 cm^3 of dry isopropanol or benzene, respectively.

Anhydrous samarium trichloride was prepared by heating a mixture of hydrated samarium trichloride and ammonium chloride (in excess) in a current of dry chlorine and hydrogen chloride

gases; the heating temperature was carefully regulated to avoid the formation of fusible oxychloride [SmOCl]. The anhydrous chloride was finaly converted into $SmCl_3 \cdot 3Pr^iOH$, by dissolving and crystallizing using isopropyl alcohol as a solvent. Zirconium isopropoxide isopropanolate was prepared by the literature procedure.[23]

Zirconium was estimated as ZrO_2 after precipitation as mandelate and ignition to the oxide. After removal of zirconium as mandelate the samarium content in the filtrate was precipitated as oxalate and estimated as Sm_2O_3.

Isopropoxy contents in the new derivatives were estimated by the oxidimetric method[24] using N—$K_2Cr_2O_7$ solution in 12.5% H_2SO_4. Chlorine was estimated by Volhard's method.[25]

IR spectra [4000–200 cm^{-1}] were recorded on Nujol mulls on Perkin–Elmer 557 and Carl–Zeiss M80 spectrophotometers using CsI optics. ^1H (89.55 MHz) and ^{13}C (22.49 MHz) NMR were recorded on a JEOL FX 90Q FT NMR spectrometer in $CDCl_3$ or C_6H_6, respectively. Chemical shifts were referenced internally to protio solvent impurities (δ 7.25/$CDCl_3$) and solvent ^{13}C references (δ 128.5, C_6H_6) and have been reported in ppm downfield of tetramethylsilane (TMS).

Synthesis of $Cl_2Sm\{Zr_2(OPr^i)_9\}$

A benzene (*ca* 25 cm^3) solution of $K\{Zr_2(OPr^i)_9\}$ [freshly prepared by the interaction of potassium (0.114 g, 2.91 mmol) in isopropyl alcohol (*ca* 5 cm^3) and refluxing with $Zr(OPr^i)_4 \cdot Pr^iOH$ (2.25 g, 5.80 mmol) in (*ca* 20 cm^3) benzene, followed by removal of volatiles under reduced pressure] was added dropwise to a benzene suspension (*ca* 20 cm^3) of $SmCl_3 \cdot 3Pr^iOH$. The reaction mixture was stirred for *ca* 12 h, during which time the colour of the reaction mixture was changed from light yellow to dirty white. Precipitated KCl (0.21 g, 2.82 mmol) was separated by filtration and the excess solvent from the filtrate was removed under reduced pressure to afford a crystalline solid product of the composition $Cl_2Sm\{Zr_2(OPr^i)_9\}$ (2.71 g, 99%), which was recrystallized from n-hexane in 60% yield. Found: Sm, 15.9; Zr, 20.5; Cl, 7.5; OPr^i, 56.7. Calc. for $Cl_2Sm\{Zr_2(OPr^i)_9\}$: Sm, 16.1; Zr, 19.5; Cl, 7.5; OPr^i, 56.9%.

Preparation of $[ClSm\{Zr_2(OPr^i)_9\}_2]$

A benzene (*ca* 20 cm^3) solution of $K\{Zr_2(OPr^i)_9\}$ [freshly prepared by dissolving potassium (0.4 g, 6.13 mmol) in isopropyl alcohol (*ca* 5 cm^3) and benzene (*ca* 10 cm^3) and then interacting under refluxing conditions with $Zr(OPr^i)_4 \cdot Pr^iOH$ (4.85 g, 12.50 mmol), followed by stripping off the volatiles under reduced pressure] was slowly added to a continuously stirred suspension of $SmCl_3 \cdot 3Pr^iOH$ (1.36 g, 3.11 mmol) in benzene (*ca* 20 cm^3). After stirring the reaction mixture at room temperature for 12 h the precipitated KCl (0.53 g, 7.11 mmol) was separated by filtration. Volatiles were removed from the filtrate under reduced pressure to afford a dirty white solid product of the composition $[ClSm\{Zr_2(OPr^i)_9\}_2]$ (4.69 g, 93%). The compound was purified by distillation at (145°C/0.5 mm) in 60% yield. Found: Sm, 9.1; Zr, 22.8; Cl, 2.2; OPr^i, 65.3. Calc. for $[ClSm\{Zr_2(OPr^i)_9\}_2]$: Sm, 9.3; Zr, 22.6; Cl, 2.2; OPr^i, 65.9%.

Preparation of $[Sm\{Zr_2(OPr^i)_9\}_3]$

A solution of $K\{Zr_2(OPr^i)_9\}$ [freshly prepared by dissolving potassium (0.31 g, 7.92 mmol) in the presence of dry isopropyl alcohol (*ca* 5 cm^3) and benzene (*ca* 20 cm^3) followed by refluxing and removal of volatiles under reduced pressure] in benzene (*ca* 20 cm^3) was added slowly to a suspension of $SmCl_3 \cdot 3Pr^iOH$ (1.15 g, 2.63 mmol) in benzene (*ca* 15 cm^3). The reaction mixture was refluxed for 3 h. The precipitated KCl (0.59 g, 7.92 mmol) was filtered off. After the removal of volatiles from the filtrate under reduced pressure an off-white sticky solid product of the composition $[Sm\{Zr_2(OPr^i)_9\}_3]$ (5.72, 95%) was obtained. The compound was purified by sublimation at 182°/0.5 mm in 80% yield. Found: Sm, 6.4; Zr, 24.2; OPr^i, 69.3. Calc. for $[Sm\{Zr_2(OPr^i)_9\}_3]$: Sm, 6.5; Zr, 23.8; OPr^i, 69.5%.

Reaction of $[ClSm\{Zr_2(OPr^i)_9\}_2]$ *with* $K(OPr^i)$

A benzene (*ca* 20 cm^3) suspension of $KOPr^i$ [prepared by the interaction of potassium with isopropyl alcohol (*ca* 20 cm^3), followed by the removal of volatiles] was added dropwise to a solution of $[ClSm\{Zr_2(OPr^i)_9\}_2]$ (3.05 g, 1.88 mol) in benzene (*ca* 15 cm^3). The reaction mixture was stirred at room temperature for *ca* 8 h. The precipitated KCl (0.18 g, 2.14 mmol) was removed by filtration. After removal of the volatiles from the filtrate under reduced pressure a dirty white sticky solid of the composition $[(OPr^i)Sm\{Zr_2(OPr^i)_9\}_2]$ (3.03 g, 97%) was obtained, which was distilled at 174°C/0.5 mm in 50% yield. Found: Sm, 9.4; Zr, 22.5; OPr^i, 68.5. Calc. for $[(OPr^i)Sm\{Zr_2(OPr^i)_9\}_2]$: Sm, 9.2; Zr, 22.3; OPr^i, 68.5%.

A similar procedure was adopted to prepare the off-white solid product of the composition $[(OPr^i)_2Sm\{Zr_2(OPr^i)_9\}]$ (1.29 g, 99%) by the interaction of $KOPr^i$ and $Cl_2Sm\{Zr_2(OPr^i)_9\}$ in a 2:1 molar ratio. The compound was recrystallized from

an n-hexane and toluene mixture. Found: Sm, 15.2; Zr, 19.6; OPr^i, 66.0. Calc. for $[(OPr^i)_2Sm\{Zr_2(OPr^i)_9\}]$: Sm, 15.2; Zr, 18.5; OPr^i, 66.1%.

Reaction of $[Cl_2Sm\{Zr_2(OPr^i)_9]$ *with* $K\{Al(OPr^i)_4\}$ *in a* 1:2 *molar ratio*

A benzene (*ca* 20 cm^3) suspension of $K\{Al(OPr^i)_4\}$ [freshly prepared from potassium (0.24 g, 6.13 mmol) and $Al(OPr^i)_3$ (1.25 g, 6.11 mmol) in isopropyl alcohol (*ca* 15 cm^3) and benzene (*ca* 15 cm^3) followed by the removal of the volatiles] was slowly added to a benzene solution (*ca* 20 cm^3) of $[Cl_2Sm\{Zr_2(OPr^i)_9\}]$ (2.87 g, 3.06 mmol). The reaction mixture was stirred at room temperature for 12 h and the precipitated KCl (0.50 g, 6.71 mmol) was separated by filtration. Removal of volatiles from the filtrate under reduced pressure afforded a pale white sticky mass of the composition $\{Al(OPr^i)_4\}_2Sm\{Zr_2(OPr^i)_9\}$ (3.54 g, 83%), which was distilled at 235°C/0.05 mm in 50% yield. Found: Sm, 10.2; Zr, 14.4; OPr^i, 72.0. Calc. for $\{Al(OPr^i)_4\}_2Sm\{Zr_2(OPr^i)_9\}$: Sm, 10.8; Zr, 13.1; OPr^i, 72.2%.

RESULTS AND DISCUSSION

Interaction of $SmCl_3 \cdot 3Pr^iOH$ and $K\{Zr_2(OPr^i)_9\}$ in different molar ratios (1:1, 1:2 and 1:3) in benzene results in the formation of hetero- and homoleptic nonaisopropoxodizirconatosamarium(III) complexes, according to the following reactions:

$$SmCl_3 \cdot 3Pr^iOH + nK\{Zr_2(OPr^i)_9\} \longrightarrow [Cl_{3-n}Sm\{Zr_2(OPr^i)_9\}_n] + nKCl\downarrow + 3Pr^iOH$$

Ia: $n = 1$; **Ib**: $n = 2$; **Ic**: $n = 3$.

Replacement of chloride in the derivatives **Ia** and **Ib** with alkoxo and/or alkoxometallato groups produced derivatives according to the reaction shown below:

$$[Cl_{3-n}Sm\{Zr_2(OPr^i)_9\}_n] + (3-n)KL \xrightarrow{(3-n)KCl} [(L)_{3-n}Sm\{Zr_2(OPr^i)_9\}_n]$$

IIa: $L = OPr^i, n = 1$;
IIb: $L = OPr^i, n = 2$;
IIc: $L = Al(OPr^i)_4, n = 2$.

All of these new hetero-(bi- or tri-)metallic isopropoxo derivatives are off-white coloured solids (in some cases sticky in nature), highly moisture-sensitive, soluble in common organic solvents and generally volatile.

IR spectral studies

The IR spectra of hetero-(bi- or tri-)metallic isopropoxides[26–29] of samarium(III) exhibit characteristic absorptions in the region (cm^{-1}): 1160–1190 (Me_2C skeleton vibrations), 950–1070, ν(C—O terminal), 920–950, ν(C—O bridging); 670–699, ν(Al—O); 540–570, ν(Zr—O); and 400–470, ν(Sm—O). Samarium–chlorine stretching absorptions[30,31] have been observed in **Ia** and **Ib** in the range 210–380 cm^{-1}.

NMR (^1H *and* ^{13}C) *spectral studies*

The ^1H NMR spectra of the new derivatives (in $CDCl_3$ at room temperature) exhibit doublets ($J = 6$ Hz) for gem-dimethyl protons at δ 1.24 (**IB**), 1.36 (**IIa**), 1.21 (**IIb**) and 1.26 (**IIc**), while methine protons of these complexes are observed as averaged septets ($J = 6$ Hz) at δ 4.39, 4.48, 4.04 and 4.31 ppm, respectively. However, the derivative **Ic** exhibits two doublets ($J = 6$ Hz) of gem-dimethyl protons at δ 1.24 and 1.35, but the methine protons appear as a broad peak centred at δ 4.28 ppm. Similarly, ^{13}C NMR spectra of the two typical derivatives **Ib** and **IIc** display only two types of resonances (**Ib**, 69.67, 26.49; **IIc**, 66.30, 26.50 ppm), characteristic of α- and β-carbons of the isopropoxy groups, respectively. The ^1H NMR signals of the above derivatives could not be resolved further, even at −65°C, to throw any light on their structural features.

Interestingly, the spectrum of **Ia** exhibits the following chemical shifts for gem-dimethyl protons, which could be grouped in the intensity ratio 5:2:2, respectively: (a) two overlapping doublets ($J = 6$ Hz) at δ 1.55 and 1.63 (terminal OPr^i); (b) a doublet ($J = 6$ Hz) at δ 2.35 (μ_2-OPr^i); and (c) a doublet ($J = 6$ Hz) at δ 9.22 (μ_3-OPr^i) ppm. A broad peak centred at δ 4.89 ppm may be ascribed to the methine protons of the terminal and μ_2-OPr^i groups, whereas the methine proton resonances of μ_3-OPr^i could not be distinguished in the range −50 to +55 ppm. Although any conjectures may be rather speculative in the absence of a single-crystal X-ray structure so far, these data appear to conform essentially to three types of isopropoxy groups, as observed in the ^1H NMR spectrum of $[\{Cd\{Zr_2(OPr^i)_9\}(\mu\text{-}Cl)\}_2]$,[32] the X-ray structure[33] of which showed a tetradentate ligation mode of $\{Zr_2(OPr^i)_9\}^-$ units.

The above results, coupled with (1) the tendency of samarium(III) (ionic radii = 1.10 Å) to achieve higher coordination states,[34,35] (2) the ability of $\{Zr_2(OPr^i)_9\}^-$ to function in a bi-,[36] tri-[36] or tetradentate[32,37] fashion, and (3) the observed

molecular complexities in benzene tend to favour tetradentate ligation of $\{Zr_2(OPr^i)_9\}^-$ in **Ia** and **IIa**, tridentate bonding in **Ib** and **IIb** and bidentate ligation in **Ic** and **IIc**. Furthermore, in derivatives **Ib**, **IIb**, **Ic** and **IIc** the possibility of ligation of a more suitably situated isopropoxy group(s) to increase the coordination state of the samarium(III) ion cannot be ruled out.

IONIZATION OF THE Fe—X BOND IN POLAR SOLVENTS: A SPECTROSCOPIC STUDY OF CpFe(dppe)X COMPLEXES

C. DÍAZ,† N. YUTRONIC and B. WEISS

Departamento de Química, Facultad de Ciencias, Universidad de Chile, Las Palmeras 3425, Santiago, Chile

(*Received* 23 *November* 1992; *accepted* 26 *January* 1993)

Abstract—Electronic absorption spectra for complexes CpFe(dppe)X [with X = Cl, I and CN; dppe = $(Ph)_2PCH_2CH_2P(Ph)_2$; Cp = η^5-C_5H_5] and the cationic derivative $[CpFe(dppe)NCCH_3]PF_6$ in different solvents have been measured. The lower energy bands were assigned to iron *d–d* orbital transitions on the basis of intensities, solvent effects and extended Hückel MO calculations. The complexes CpFe(dppe)X (with X = Cl and I) undergo ionization in polar solvents to give the cationic solvated species [CpFe(dppe)(solvent)]$^+$. This behaviour can be explained on the basis of the theoretical calculations.

Compounds containing CpMLL′ moieties (with M = Fe, Ru; L, L′ = CO, phosphines and phosphites) are among the most versatile systems in organo-transition metal chemistry.[1–5] Although the carbonyl derivatives have been extensively studied, the phosphine and phosphite counterparts have not been so well investigated.[4,5]

Interest in compounds containing the fragment CpMLL′ (with L, L′ = phosphine and diphosphine) arises mainly because they show interesting catalytic properties in some C—C bond deformation[6] and C—H bond activation reactions.[7] The CpM(diphosphine) moiety activates coordinated π-bonds towards nucleophilic attack[8] and stabilizes alkylidene[9] and vinylidene groups.[10] Therefore, these structures are of considerable interest in organic synthesis.

A theoretical study on Cp-iron diphosphine derivatives has been recently made,[11] but only a few spectroscopic studies have been reported.[7] In this paper we present a UV–vis absorption study of the complexes CpFe(dppe)X (with X = Cl, I and CN) and $[CpFe(dppe)NCCH_3]PF_6$. Recently it has been shown that these cyclopentadienylphosphinoethane iron(II) halide compounds are also useful precursors of both mononuclear[12] and binuclear complexes[13] containing the above-mentioned moiety. To support the experimental results an extended Hückel calculation was performed on CpFe(dppe)Cl and some properties discussed.

RESULTS AND DISCUSSION

Figure 1 shows the absorption spectrum of CpFe(dppe)I and CpFe(dppe)CN in $CHCl_3$. The

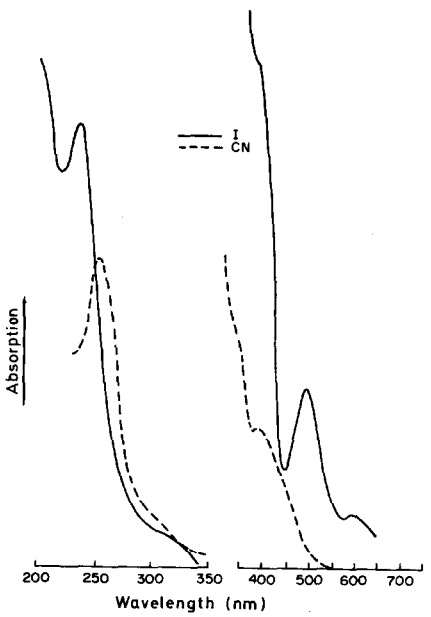

Fig. 1. UV–vis absorption spectra of the complexes CpFedppeX [X = I(– – – –), CN(· · · ·)] in $CHCl_3$ solution at room temperature.

iodide complex (solid line) shows absorptions at 600, 490 and 390 nm with low intensities. The spectrum of the chloride is very similar to that of the iodide, as can be seen from Table 1, but is not shown in Fig. 1. The band at 600 nm is responsible for the red colour of the halide complexes. This band, as well as the more intense one located at 490 nm and the shoulder at *ca* 390 nm, is only slightly influenced by the polarity of the solvent, as shown in Table 2. This behaviour is typical of *d–d* bands and has been reported before in other complexes.[14] The low intensities of these bands also support the *d–d* character of these transitions. These assignments are in agreement with those reported for the Cp^*ML_2X complexes.[7] Additional information on the nature of these transitions has been obtained from an extended Hückel MO calculation, performed on CpFe(dppe)Cl. The geometry of the heavy atom skeleton was obtained from an X-ray diffraction study on the iodide derivative[15] and the hydrogen atoms were located at standard positions. Some results of this calculation are shown in Table 3. The HOMO and the next three internal orbitals are mainly localized on the metal and their composition is largely accountable to the contribution of the iron *d*-orbitals. The next inner orbitals contain important contributions from the π-orbitals of the cyclopentadienyl ligand. These results are in agreement with previously reported MO calculations in similar systems.[16] The LUMO is also predominantly iron *d*-orbitals, with a small contribution from Cp π-orbitals. The character of the next unfilled orbitals, as well as the LUMO, contains some iron *d*-orbital contribution, but the participation of phosphorus and Cp π-orbitals is also important. The higher energy orbitals are mainly localized around the chlorine and phosphorus atoms. It is interesting to note that because of the low contribution of phosphorus and chlorine orbitals to the nature of the MO near the frontier orbital zone, they have similar character to those obtained for the related complexes $CpM(CO_2)X$[16] and $CpM(PH_3)_2X$.[11] Participation from the phenyl groups to the calculated molecular orbitals is observed at higher and lower energies than the orbitals discussed before. The X substituents with π-donor–acceptor capabilities have a strong influence on the character of the frontier orbitals. For instance, the π- and π^*-orbitals of acetylide and vinylidene ligands are known to make a significant contribution to the character of the frontier orbitals.[11]

The calculated atomic charges on the chloride complex are shown in Fig. 2. The high negative charge on the chlorine atom is strong evidence in support of the ionic character of the iron–chlorine bond. On the other hand, the Cp ligand shows a total charge of -0.45, possibly due to a charge-transfer of $(Fe)d \rightarrow Cp\pi^*$, and is consistent with the anionic formulation commonly used for this group in transition metal chemistry.[17]

As expected the coordination of dppe to iron induces a positive charge on the phosphorus atoms, also in agreement with the calculation. Atomic overlap population values indicate that the order of degree covalency is Fe—Cp $\approx$ Fe—P $\gg$ Fe—Cl and this trend correlates with the corresponding bond distances.[15,18]

According to this MO scheme the first three predicted electronic transitions involve *d*-orbitals from the iron atom, in agreement with the characteristics of the observed spectra. Besides, the band centred at 250 nm, present in the CpFe(dppe)X complexes, can be assigned mainly to an internal charge-transfer in the Cp ligand, in agreement with previously reported assignments in similar compounds.[19] Consistent with this interpretation, the MOs with significant contribution from the Cp π-orbitals appear above and below the frontier orbitals. The shoulder at *ca* 295 nm could be ascribed to transitions that belong to the phenyl groups in dppe.

The spectrum of the halide complexes could not be measured in polar solvents because the formation of the cationic species $[CpFe(dppe)(solvent)]^+$ occurs. This is due to the high ionic character of the Fe—X bond, in agreement with the calculation. The formation of these cationic complexes (in propane-1,2-diolcarbonate as the solvent)

is slow (minutes) for the iodide derivative and very slow (hours) for the chloride derivative. After this time absorptions at 465 and 450 nm, characteristic of the cationic complexes, are observed. The iodide complex undergoes ionization in solvents with $\varepsilon > 35$, whereas the chloride complex requires higher dielectric constants, $\varepsilon > 38$. This observation is consistent with an easy halide abstraction from CpFe(dppe)X complexes by $TlPF_6$ and NH_4PF_6 salts in the synthesis of cationic mononuclear[12] and binuclear complexes.[13]

The spectrum of the CpFe(dppe)CN complex (see Fig. 1) shows an absorption band at *ca* 400 nm, which is not sensitive to the nature of the solvent (see Tables 1 and 2). Similar to the halide derivatives, these absorptions can be assigned principally to *d–d* iron orbital transitions. The low energy band of the halide derivatives suffers a shift to higher energy in the cyanide complex. This observation can be rationalized in terms of the extra stabilization of the HOMO due to the participation of π^*-unfilled orbitals from the CN group. The stabilization of the HOMO by ligand π-acceptors has been reported in related systems.[20] This observation can also be explained in terms of the ligand field strength of the CN moiety.[21] The high frequency region of the spectrum shows similar characteristics to those observed for the halide complexes.

The spectrum of the cationic methylcyanide complex exhibits a broad and asymmetric band around 450 nm, as shown in Fig. 3. This may suggest the existence of more than one absorption near 450 nm. Similar to the complexes mentioned before, intensities and solvent effects were used as criteria for the assignment, showing that this transition has strong *d–d* iron orbital character. Finally, the shift to high energy of the maxima of the absorptions on going from neutral to cationic species can be explained by the increase of the HOMO–LUMO gap, as found in calculations of $CpFe(PH_3)_2X$ and $[CpFe(PH_3)_2NCH]^+$.[11]

EXPERIMENTAL

The complexes CpFe(dppe)X, with X = Cl, I, CN, and $[CpFe(dppe)NCCH_3]PF_6$ were prepared using previously reported synthetic routes.[12,13] UV–vis absorption spectra were recorded using Cary-17 and Varian DMS-90 spectrophotometers, with 1 cm optical path cuvettes. The concentration of the complex was 10^{-3}–10^{-4} M. The solvents were all previously purified by standard methods.

The extended Hückel calculation[22] was performed using the program FORTICON8 (QCPE catalogue 344). The parametrizations employed were those reported in previous work.[23]

CHROMIUM(V) SPECIES CAN BE GENERATED DURING THE REACTION OF SOLID WELDING FUME WITH SOLUTIONS OF GLUTATHIONE

PAUL O'BRIEN* and GUOFANG WANG

Department of Chemistry, Queen Mary and Westfield College, University of London, Mile End Road, London E1 4NS, U.K.

(*Received* 5 *January* 1993; *accepted* 5 *March* 1993)

Abstract—Welding fume, when suspended in neutral solutions of glutathione (40 mM), leads to the generation of chromium(V) species, as detected by ESR spectroscopy ($g = 1.986$ and 1.996). Such complexes have been implicated in the formation of DNA lesions in *in vitro* assays.

Chromium, in oxidation state six, in many different compounds is a well-established carcinogen,[1–5] although the exact effect appears to depend to some extent on the nature of the chromium(VI) containing material.[6] One major potential source of occupational exposure to high oxidation state chromium species is from "welding fume" (the complex particulate material generated during welding, especially of high chrome steels such as stainless steel).[1] The reduction of chromate is essential for the formation of DNA lesions *in vitro* and the peptide glutathione (γ-glutamyl cysteinyl glycine, GSH) is a likely intracellular reductant.[3–5] Consequently, we were interested to see if a sample of welding fume, in combination with GSH, could generate the kind of reactive intermediates known to be of significance in the generation of DNA lesions, such as strand breaks.[7–16] In the present communication we report on the interaction of solid welding fume with neutral solutions of GSH and show that similar chromium(V) species are formed to those well established during the reduction of chromate by GSH.[14–17]

Samples of welding fume were obtained from fume extractor dust from a system carrying two types of electrodes: (a) 20% chromium, 32% nickel and 1.3% niobium and (b) 25% chromium and 9% nickel. The brown material was fairly insoluble in water and the supernatant gave little or no ESR signal [Fig. 1(a)]. However, when a sample was shaken with a 40 mM solution of GSH (5 mg welding fume, 1 cm^3 solution, pH 7) strong ESR signals were generated at $g = 1.986$ and 1.996 [Fig. 1(b)], typical of the chromium(V) species known to be generated in the reaction of chromate with glutathione.[13–16] Furthermore, in the presence of the spin trap 5,5-dimethyl-1-pyrroline-N-oxide (DMPO), the species characteristic[4,9,12] of $RS^{\bullet}$ is generated [Fig. 1(c)]. The behaviour of the system is further confirmed to be similar to that of chromate, in that when the above experiment is performed in the presence of H_2O_2 (10 mM) and EtOH (10% solution) the ethanolate radical is trapped, typical of the generation of $OH^{\bullet}$.

Chromium(V) species and the combination of chromate and GSH are known to be able to cause the generation of single strand breaks in DNA *in vitro* assays.[7,8,10,13] Furthermore, intermediates of the kind detected in the present paper are believed to be important in mediating such lesions. One possible mechanism by which welding fume could cause lung/nasal toxicity could involve particles of welding fume being taken up by pinocytosis. The subsequently slow-release hypervalent chromium species could, after activation by reductive processes, lead to DNA lesions.

SYNTHESIS AND X-RAY CRYSTAL STRUCTURE OF $TaBr_2(PPhMe_2)_4$

LILIANE G. HUBERT-PFALZGRAF* and ABDENASSER ZAKI

Laboratoire de Chimie Moléculaire, URA-CNRS, Université de Nice-Sophia Antipolis, 06108 Nice Cedex 2, France

(*Received* 22 *February* 1993; *accepted* 4 *March* 1993)

Abstract—The reduction of $TaBr_5$ by $LiBEt_3H$ in toluene in the presence of dimethylphenylphosphine offers a tantalum(II) complex, $TaBr_2(PhPMe_2)_4$, which has been characterized by X-ray crystallography. The coordination polyhedron, in which the bromide ligands are in *cis* positions [∠ BrTaBr 84.23(4)°], is severely distorted towards a bicapped tetrahedron.

Low-valent early transition metal halide adducts have generally been obtained by the reduction of halide derivatives using various metals or sodium amalgam. In the case of niobium and tantalum[1] the issue of the system metal halide–tertiary phosphine, MX_n–PR_3 (M = Nb or Ta), has been found to be highly dependent on the nature of the reductant, of the phosphine and of the solvent. Mononuclear,[2] dinuclear[3] or trinuclear[4] units have been reported for the trivalent halide adducts, while the divalent ones are limited to the monomeric chloride complexes *t*-$MCl_2(PMe_3)_4$ and *t*-$TaCl_2(dmpe)_2$ (dmpe = dimethylphosphinoethane).[5] The use of bromide derivatives as precursors to group 15 low-valent derivatives has been less explored. $NbBr_n(PPhMe_2)_3$ complexes ($n = 4$ and 3) have been obtained by reduction of $NbBr_5$ by the phosphine and sodium amalgam (1 equivalent), respectively.[6] The reduction of $TaBr_5$ by Na/Hg over 1 h and in the presence of dimethylphenylphosphine leads to the *cis*-$TaBr_4(PhPMe_2)_2$ polymorphs, independently of the stoichiometry—one or two—of the reductant used.[7] When the latter reaction (1 : 2 stoichiometry) was achieved with longer reaction times (24 h) or when greater amounts of reductant were used, no compound suitable for X-ray structural determination could be isolated. We were thus interested in finding alternative reductive routes. Hydrides have been less investigated as reductants for access to non-cyclopentadienyl low-valent niobium and tantalum derivatives, although R_3SnH has, for instance, been used for the large scale preparation of $NbCl_3(DME)$ (DME = dimethoxyethane), which might be used in organic synthesis.[8] The use of vitride offered one of the few tantalum(I) derivatives as a mixed-metal $TaH_2Al(OC_2H_4OMe)(dmpe)_2$ species.[1]

Superhydride $LiBEt_3H$ is a versatile reactant, acting as a reductant[9] and a source of either hydride or alkyl ligands.[10] Its use offered access to a monomeric tantalum(II) adduct, $TaBr_2(PhPMe_2)_4$, whose synthesis and molecular structure are reported here.

Reaction between $TaBr_5$ in toluene in the presence of $PhPMe_2$ (3.5 equivalents) with an excess of $LiBEt_3H$ (3.5 equivalents) in THF led to an immediate gaseous evolution (probably hydrogen), while

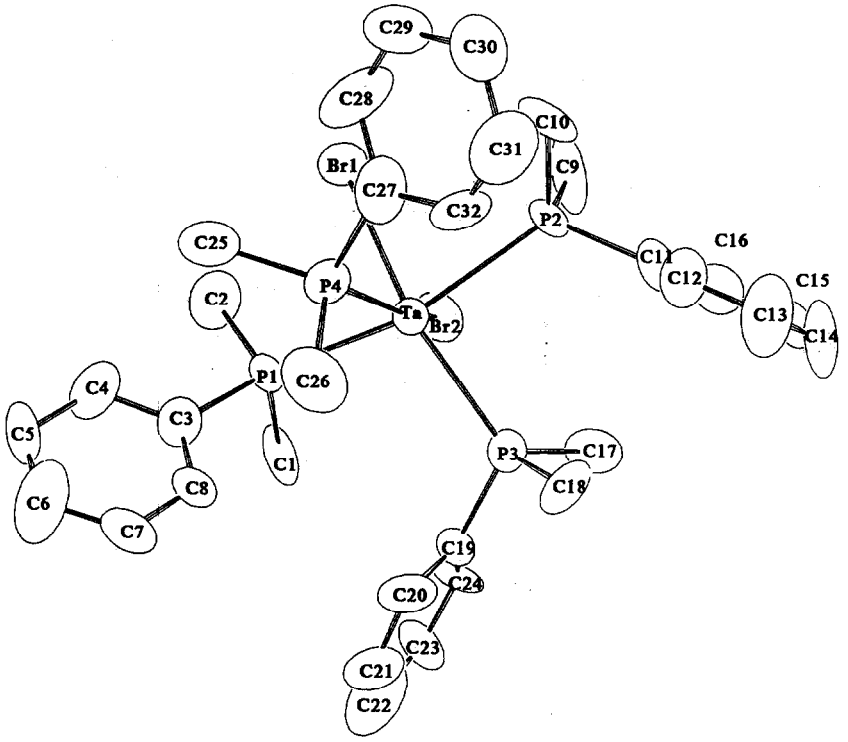

Fig. 1. Molecular structure of $TaBr_2(PPhMe_2)_4$ showing the atom labelling scheme. Selected bond lengths (Å): Ta—Br(1) 2.680(1), Ta—Br(2) 2.702(1), Ta—P(1) 2.675(4), Ta—P(2) 2.650(5), Ta—P(3) 2.587(4), Ta—P(4) 2.574(2); selected angles (°): Br(1)—Ta—Br(2) 84.23(4), Br(1)—Ta—P(1) 76.77(6), Br(1)—Ta—P(2) 83.11(7), Br(1)—Ta—P(3) 80.34(7), Br(1)—Ta—P(4) 158.34(7), Br(2)—Ta—P(1) 85.01(9), Br(2)—Ta—P(2) 77.41(9), Br(2)—Ta—P(3) 161.95(8), Br(2)—Ta—P(4) 77.62(8), P(1)—Ta—P(2) 154.46(9), P(1)—Ta—P(3) 100.4(1), P(1)—Ta—P(4) 89.8(1), P(2)—Ta—P(3) 91.4(1), P(2)—Ta—P(4) 104.1(1), P(3)—Ta—P(4) 119.3(1).

the colour of the reaction medium turned from yellow to brown–green and finally red. After elimination of the colloidal metal particles by filtration, a paramagnetic, extremely air-sensitive compound (**1**) was isolated as red crystals* by concentration and cooling of the filtrate.

Since this red compound is only slightly soluble in toluene and displays a poor stability in polar solvents, its identity was established by X-ray diffraction.† It corresponds to a tantalum(II) monomer, $TaBr_2(PhPMe_2)_4$, whose molecular structure is shown in Fig. 1. The bromide ligands occupy *cis* positions [∠ BrTaBr 84.23(4)°] in a distorted six-coordinated tantalum surrounding. Compound **1** is thus not isostructural with $TaCl_2(PMe_3)_4$[5] or with other MX_2L_4 species (M = Nb, X = OAr, L = 1/2 dmpe;[11] M = Mo, L = PMe_3, X = Cl, Br, M = W, X = I[12]). In fact, the geometry around the metal centre is severely distorted with respect to an octahedron and the various angles of the coordination polyhedron range from 76.77(6) to 161.95(8)° and the stereochemistry around tantalum tends towards a bicapped tetrahedron.[13] Since trimethylphosphine and dimethylphenylphosphine have almost the same cone angles, the change in the metal geometry with respect to $TaCl_2(PMe_3)_4$ is probably induced by the relative orientation of the phenyl rings. X-ray data on tantalum bromide adducts remain scarce and limited to the *cis*-$TaBr_4(PMe_2Ph)_2$ poly-

* Spectroscopic data: IR (cm^{-1}): 1576 [ν(C=C)]; 1180, 1097, 1020, 939, 918, 744, 729sh, 703, 580, 492, 401. ESR (toluene, room temperature): ⟨g⟩: 1.96, ⟨A⟩ = 133 G. Found: C, 42.5; H, 4.7; Br, 19.6. Calc. for $C_{32}H_{44}Br_2P_4Ta$: C, 43.0; H, 5.0; Br, 17.9%.

† Crystal data: $C_{32}H_{44}Br_2P_4Ta$, M = 893.4, a = 9.737(3), b = 9.950(9), c = 19.384(8) Å, α = 86.52(3), β = 75.73(6), γ = 77.14(4)°, V = 1774 Å^3, Z = 2, triclinic P-1, μ = 54.92. The structure was solved using conventional heavy-atom methods, R = 0.046, Rw = 0.052 from 1812 unique observed reflections with $2\theta < 50°$, measured with Mo-K_α radiation (λ = 0.71073 Å) and corrected for absorption. Atomic coordinates, bond lengths and angles and thermal parameters have been deposited as supplementary data with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

morphs[7] and to $(\eta^5\text{-}C_5Me_4Et)_2Ta_2(\mu\text{-}Br)_2Br_4$[14] and for niobium to the $NbBr_n(PPhMe_2)_3$ adducts, $n = 3$, 4.[6] The tantalum(II)–bromide distances observed for $TaBr_2(PhPMe_2)_4$ are significantly longer (2.691 Å av.) than those previously reported for the tantalum(IV) adducts [Ta—Br (*trans*-P) 2.53 Å];[7] this may originate from decreases in the metal's oxidation state, as well as from a *trans* effect due to the phosphine ligands. Indeed, the Ta—P bond distances vary from 2.580 Å av. for those *trans* to the bromides to 2.667 Å av. when another phosphine is in the *trans* position. The Ta···Me distances are slightly shorter than the Ta···Ph ones (3.76 vs 3.83 Å), but their values exclude agostic CH interactions.[15]

The novel 15-electron tantalum(II) complex isolated in a 43% yield[16] is highly reactive. It is unstable in the polar solvents required for its solubilization. In acetonitrile, for instance, its evolution leads to ionic derivatives, as evidenced by the appearance in the ^{31}P NMR spectrum of a doublet ($J = 520$ Hz) at -2 ppm characteristic of the $HPPhMe_2^+$ cation. Another salient feature is the presence of a broad signal at *ca* 3.7 ppm in the proton NMR spectrum, which has been tentatively attributed to a Ta—Me resonance.[17] Ionic low-valent complexes stabilized by phosphonium cations have been identified for niobium and tantalum[18] as well as for the molybdenum[19] derivatives, but no indication has been given regarding the source of the proton. The formation of ionic, diamagnetic species, the presence of resonances due to Ta—C bonds and thus of P—C bond cleavage reactions suggest complex modification of the metal coordination sphere and the behaviour has not been further investigated.

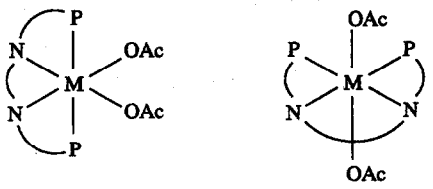
Abstract—The interaction of $Ru(OAc)_2(Ph_3P)_2$ with 1 equivalent of N,N′-bis[*o*-(diphenylphosphino)benzylidene]ethylenediamine (P_2N_2) in refluxing dichloromethane gives *trans*-$Ru(OAc)_2(P_2N_2)$ (**I**) in moderate yield (63%); in refluxing toluene the reaction gives a red product, which upon recrystallization in $CHCl_3$/hexane gives *trans*-$Ru(OAc)_2Cl_2 \cdot 2H_2O$ (**III**) in good yield (92%). Compounds **I** and **III** have been fully characterized by analytical and spectroscopic methods. The structure of **III** has been determined by an X-ray diffraction study.

$Ru(OAc)_2(Ph_3P)_2$ is a very versatile reagent. It provides a very good entry to ruthenium(II) complexes. Since its preparation a large number of ruthenium carboxylate complexes have been synthesized, and most of the known mononuclear acetates are Ph_3P complexes. Recently, ruthenium diphosphine and triphosphine complexes have been synthesized.[1,2] Ruthenium acetate complexes have been shown to display various catalytic properties,[3] particularly those with chiral chelating diphosphine ligands.[4] Chelating multidentate phosphine ligands offer several advantages over monodentate phosphines containing similar phosphino groups. They can provide better control over the coordination number and stereochemistry of the resulting complexes, increase basicity at the metal centres and slow down intra- and intermolecular exchange processes.[5] N,N′ - bis[*o* - (diphenylphosphino)benzylidene]ethylenediamine (P_2N_2), a polydentate ligand, can serve as a bi-, tri- and tetradentate ligand depending on the reaction conditions.[6–8] It is likely that a ruthenium acetate complex containing the P_2N_2 ligand may display some interesting structural, chemical and catalytic properties that are not observed in other chelating phosphine complexes. In this communication the interaction of $Ru(OAc)_2(Ph_3P)_2$ with the polydentate diiminodiphosphine ligand P_2N_2 is reported.

When $Ru(OAc)_2(Ph_3P)_2$ was treated with 1 equi-

* Authors to whom correspondence should be addressed.

valent of P_2N_2 in refluxing dichloromethane for 16 h, work-up gave red crystals of the stoichiometry $[Ru(P_2N_2)(CH_3COO)_2]\cdot 2H_2O$ (**I**)* in moderate yield (63%) after recrystallization from an acetone/Et_2O mixture. Compound **I** exhibits absorptions at 1562vs and 1380s cm^{-1} in the IR spectrum and a singlet at δ 1.06 ppm in the ^1H NMR spectrum for the acetate groups. The $^{31}P\{^1H\}$ NMR spectrum of **I** exhibits a singlet at δ 48.6 ppm, indicating that the two phosphino groups of the P_2N_2 ligand are coordinated and equivalent. The IR and ^1H NMR data indicate that the two acetate groups are monodentate and equivalent. This rules out the salt formulation $[Ru(O_2CCH_3)(P_2N_2)][CH_3CO_2]$. There are two possible isomers for **I**. These are the *cis*- and *trans*-isomers, as shown below.



Cis *Trans*

The available spectroscopic data cannot distinguish between the two isomers. However, since the corresponding chloro complex, $Ru(P_2N_2)Cl_2$, adopts a *trans*-configuration (*via infra*), a *trans*-configuration is assigned to **I**.

When the above reaction was performed in refluxing toluene for 16 h, work-up gave a red solid (**II**), whose IR and ^1H NMR spectra showed the absence of the acetate groups. Compound **II** has a very complex ^1H NMR spectrum; however, its $^{31}P\{^1H\}$ NMR spectrum exhibits only a singlet at δ 3.8 ppm. Attempts to obtain an analytically pure sample of **II** for analysis were unsuccessful. When **II** was recrystallized from a $CHCl_3$/hexane mixture, dark red crystals of stoichiometry $Ru(P_2N_2)Cl_2\cdot 2H_2O$ (**III**)† were obtained in high yield (92%). This showed that **II** reacted with chloroform to give **III** and the chloro ligands of **III** originated from chloroform. The IR and ^1H NMR spectra of **III** do not exhibit any absorption due to acetate groups. The ^1H NMR spectrum of **III** exhibits resonances due to the P_2N_2 alone, whereas a resonance due to the methyl protons of acetate is not observed. $^{31}P\{^1H\}$ NMR of **III** exhibits a singlet at δ 46.1 ppm, indicating that the two phosphino groups of the P_2N_2 ligand are coordinated and equivalent. Since the available spectroscopic data again cannot be used to distinguish between the cis- and *trans*-isomers of **III**, an X-ray diffraction study‡ was performed to establish the structure unequivocally. A perspective drawing and selected bond lengths and angles of **III** are shown in Fig. 1 and its caption. All bond lengths and angles are normal.

The solid state structure of **III** reveals a *trans*-configuration for the complex. The structure shows that the two chloro ligands are mutually *trans* to each other and the P_2N_2 ligand acts as a tetradentate ligand with the two phosphino groups *cis* to each other.

COMMUNICATION

OXIDATION REACTIONS BY THE COORDINATED NITROSYL GROUP

ALOK K. DEB and SREEBRATA GOSWAMI*

Department of Chemistry, North-Eastern Hill University, Shillong 793 003, India

(*Received* 17 *November* 1992; *accepted* 4 *March* 1993)

Abstract—The oxidation reaction by the coordinated nitrosyl group in $[Ru(NO)(NO_2)(m\text{-tap})_2](ClO_4)_2$ (**1**) (*m*-tap = *m*-tolylazopyridine) is described. Complex **1** brings about the oxidative coupling of N,N-dimethylaniline (DMA) to tetramethylbenzidine (TMB) and the oxidation of $RuCl_2(bpy)_2$ (bpy = 2,2′-bipyridine) to $[RuCl_2(bpy)_2]^+$. These redox reactions have been studied voltametrically and the results have been analysed in terms of the electrophilicity of the coordinated NO^+ in **1**.

Examples of the electrophilic coordinated nitrosonium ion (NO^+) acting as an oxidant in a net chemical reaction are uncommon.[1–5] In the present communication we report two examples illustrating (1) oxidative coupling of N,N dimethylaniline (DMA) and (2) oxidation of $RuCl_2(bpy)_2$ by a highly electrophilic mononitrosyl complex, $[Ru(NO)(NO_2)(m\text{-tap})_2](ClO_4)_2$ (**1**) (*m*-tap = *m*-tolylazopyridine, L). Recently, the electrochemical properties of **1** have been described.[6] It undergoes electrochemically reversible one-electron reduction in acetonitrile at 0.76 V and a second irreversible one-electron reduction at 0.17 V vs S.C.E. at a platinum working electrode. Complex **1** is an example where electron transfer occurs to and from a coordinated ligand and it is a moderately strong oxidant.

Oxidative coupling

The cationic nitrosyl complex **1** is converted to the corresponding cationic $[Ru(CH_3CN)(NO_2)(m\text{-tap})_2]^+$ (**2**) complex by DMA in acetonitrile. In an electrochemical experiment a solution of **1** (1 mmol) in acetonitrile was mixed with DMA (1 mmol) and the resultant solution was examined cyclic voltametrically. It shows the characteristic reversible response[7] at $E^0_{298} = 0.4$ V ($\Delta E_p = 60$ mV) of N,N,N′,N′-tetramethylbenzidine (TMB), evidently formed by the oxidative coupling reaction shown in eq. (1). The voltamograms are displayed in Fig. 1.

$$2DMA + 2\,\mathbf{1} \xrightarrow{CH_3CN} TMB + 2\,\mathbf{2} + 2NO + 2H^+ \quad (1)$$

The cyclic voltametric current height of the TMB response corresponds to 35–40% utilization of the

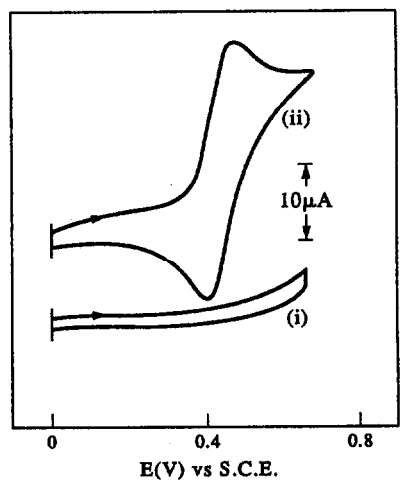

Fig. 1. Segmented cyclic voltamograms of: (i) free DMA and (ii) DMA mixed with an equimolar quantity of **1** in CH_3CN.

* Author to whom correspondence should be addressed.

oxidation equivalent for the coupling reaction. The rest of the amine is evidently lost in the side reactions.[8] In the preparative scale reaction (1) was performed in acetonitrile and on column chromatographic purification TMB and **2** were isolated. Complex **2** was crystallized as the perchlorate salt and was characterized[9] by molar conductance and spectral data. The electrochemical behaviour of compound **2**, thus isolated, was examined cyclic voltametrically at a platinum working electrode using tetraethylammoniumperchlorate (TEAP) as a supporting electrolyte. This showed[10] the reversible oxidative response at $E^0_{298} = 1.64$ V ($\Delta E_p = 120$ mV). It may be noted here that in the case of primary amines the present nitrosyl complex has been successfully used[9] as a nitrosating agent, whereas in the case of tertiary amines the same nitrosyl complex behaves as an oxidant. The difference in the oxidation potentials[11] of primary and tertiary amines is no doubt the controlling factor in driving the two reactions. The first reduction potential of **1** [E^0(**1**)] is just enough for the oxidation of DMA, whereas it is a weaker oxidant with respect to the primary amines.

Formation of trivalent ruthenium

Cis-dichlorobis(2,2′-bipyridyl)ruthenium(II), *cis*-$RuCl_2(bpy)_2$, is quantitatively oxidized to the corresponding ruthenium(III) chelate, $[RuCl_2(bpy)_2]^+$, by **1** [eq. (2)].

$$\mathbf{1} + RuCl_2(bpy)_2 \xrightarrow{CH_3CN} \mathbf{2} + [RuCl_2(bpy)_2]^+ \qquad (2)$$

This reaction was followed cyclic voltametrically. The cyclic voltamogram of a mixture of **1** and $RuCl_2(bpy)_2$ is shown in Fig. 2. A solution prepared by mixing $RuCl_2(bpy)_2$ (*ca* 10^{-3} mol) with **1** (*ca* 10^{-3} mol) shows the characteristic cyclic voltamogram[12] of $[RuCl_2(bpy)_2]^+$ and an additional reversible response at $E^0_{298} = 1.63$ V ($\Delta E_p = 120$ mV) was also observable due to the formation[10] of **2** (Fig. 2).

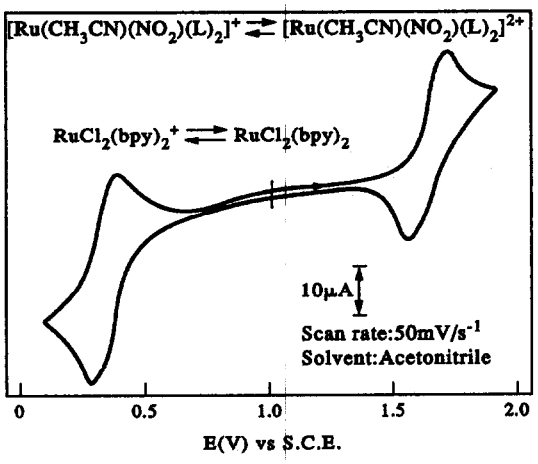

Fig. 2. Cyclic voltamogram of a mixture of **1** and $RuCl_2(bpy)_2$ in CH_3CN.

The origin of the solvento complex **2** from reactions (1) and (2) is perhaps one-electron reduction of Ru^{II}–NO^+ to give Ru^{II}–NO^0, followed by a rapid solvolysis reaction to form **2**. The mechanism and more general applicability of the oxidation reactions are under study.

EXPERIMENTAL

Complex **1** was prepared as described previously.[6]

Electrochemical reactions

(1) *Oxidative coupling.* A sample of **1** (0.006 g, 0.008 mmol) and TEAP (0.200 g, 0.87 mmol) was dissolved in deaerated acetonitrile (8 cm^3) in an electrochemical cell. To it a solution of DMA (0.001 g, 0.008 mmol) in acetonitrile (2 cm^3) was added. The resulting solution was then studied cyclic voltametrically at a platinum working electrode. A reversible oxidative couple at $E^0_{298} = 0.4$ V ($\Delta E_p = 60$ mV), indicating the formation of TMB, was observable. A similar experiment, without the addition of **1**, showed no response in the range 0.0–0.60 V. The yield of TMB formed in the experiment as stated above was assessed from the current height data of the reversible couple at 0.4 V.

(2) *Formation of trivalent ruthenium.* A sample of **1** (0.011 g, 0.014 mmol) and TEAP (0.200 g, 0.87 mmol) was dissolved in deaerated acetonitrile (10 cm^3) in an electrochemical cell. To it was added *cis*-$RuCl_2(bpy)_2$ (0.007 g, 0.014 mmol) and the mixture was stirred under nitrogen for 5 min. The resulting solution showed a reversible reductive response at $E^0_{298} = 0.33$ V ($\Delta E_p = 80$ mV), indicating the formation of $[RuCl_2(bpy)_2]^+$. Another oxidative response due to the oxidation of **2** was also recorded at $E^0_{298} = 1.63$ V ($\Delta E_p = 120$ mV). In the absence of **1** $RuCl_2(bpy)_2$ showed an oxidative response at 0.32 V.

Chemical reactions

Reaction of **1** *with* DMA. The salt of **1** (0.125 g, 0.16 mmol) was dissolved in acetonitrile (10 cm^3) and DMA (0.02 g, 0.16 mmol) was added. The mixture was stirred for 30 min at room temperature (298 K) and then evaporated to dryness. The crude

product was then dissolved in dichloromethane (10 cm^3) and subjected to column chromatography on a silica gel column. The first yellow fraction was eluted with benzene. The second brownish-red fraction was eluted with a 1:9 acetonitrile–dichloromethane mixture.

The yellow solution was concentrated in benzene and a yellow crystalline compound was obtained. This was filtered and dried *in vacuo* over P_4O_{10}; yield 40%; m.p. 139°C. Found: C, 80.1; H, 8.4; N, 11.7. Calc. for $C_{16}H_{20}N_2$: C, 80.0; H, 8.3; N, 11.7%.

The second brownish-red fraction was evaporated to dryness and recrystallized from a 1:1 dichloromethane–hexane mixture. A dark crystalline compound was obtained, yield 50%. Found: C, 44.7; H, 3.9; N, 16.1. Calc. for $C_{26}H_{27}N_8O_7ClRu$: C, 44.6; H, 3.9; N, 16.0%. Λ_M (298 K, CH_3CN): 145 Ω^{-1} cm^2 mol^{-1}. ν_{max} (KBr): 1370(NO_2), 2300(C≡N) and 1365 cm^{-1} (N=N). λ_{max} (CH_3CN): 518, 350 and 305 (sh)nm (ε, 6600, 12,200 and 12,000 dm^3 mol^{-1} cm^{-1}).

COMMUNICATION

THE PREPARATION AND X-RAY CRYSTAL STRUCTURE OF THE FIRST HOMOBIMETALLIC $\mu(\eta^2\text{-O,O}':\eta^1\text{-C})$ CARBON DIOXIDE COMPLEX: (dppp)$(CO)_2ReO_2CRe(CO)_3$(dppp)

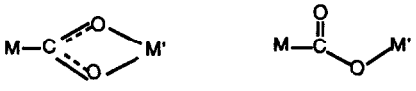
SANTOSH K. MANDAL, JEANETTE A. KRAUSE and MILTON ORCHIN†

Department of Chemistry, University of Cincinnati, OH 45221 0172, U.S.A.

(*Received* 8 *December* 1992; *accepted* 4 *March* 1993)

Abstract—The molecular structure of the title compound involves a carboxylate group acting as a bidentate ligand to one rhenium atom, while acting as a monodentate ligand to the other rhenium atom. It was prepared in a one-step reaction by treating a THF solution of *fac*-(dppp)$(CO)_3ReCO_2H$ with solid KOH.

Bimetallic bridging carboxylates or μ-CO_2 complexes may have either structure **1** or **2**:



1 **2**

As is evident, the two structures differ with respect to whether or not there is symmetrical bonding between M′ and the two oxygen atoms. Both structures may be regarded as metal salts of carboxylic acids and both, perhaps responding to current interest in carbon dioxide fixation,[1] have been called μ-CO_2 bridging complexes. There are no reports on the interconversion of the two structures.

Complexes having structure **1**, where M and M′ are both transition metals, have been prepared by several groups of workers.[2] Also such complexes where M is a transition metal and M′ is a group IV element (Si, Ge, Sn, Pb) have been prepared.[3] Examples of complexes having structure **2**, where both transition metals are the same[4] or different,[5a] have been reported as well as an example where M′ is a group IV element.[5b] Also μ_3-CO_2 bridging complexes involving three or more metal centres are known.[6] We wish to report here the first example of a fully characterized complex having structure **1**, where M = M′, namely the complex (dppp)$(CO)_2$ $ReO_2CRe(CO)_3$(dppp), where dppp is 1,3-bis(diphenylphosphino)propane. The synthesis of this complex was achieved by treating a THF solution of *fac*-(dppp)$(CO)_3ReCO_2H$ with solid KOH. Although we have not investigated all the details of this reaction we believe the use of solid KOH is critical.

EXPERIMENTAL

Preparation of (dppp)$(CO)_2ReO_2CRe(CO)_3$(dppp)

To *fac*-(dppp)$(CO)_3ReCO_2H$[7] (1 g, 1.3 mmol) in THF (200 cm^3) was added solid KOH (5 g). After stirring for 24 h the mixture, which became red during this time, was filtered through a bed of celite and the THF was removed from the filtrate on a rotary evaporator. The residue was triturated with benzene (100 cm^3) and the benzene then evaporated. The residue was recrystallized from CH_2Cl_2/benzene/hexane to give 0.54 g (0.39 mmol) of the desired product; light brown crystals, m.p. 183–185°C. Data: IR (cm^{-1}, C_6H_6): ν(C≡O) 2022vs, 1946s, 1921vs, 1908s, 1835s. ^{1}H NMR (δ, CD_2Cl_2): 7.32 (m, 40H, C_6H_5), 2.78 (m, CH_2 12H). ^{13}C NMR (δ, CD_2Cl_2): 229.5 (t, J = 11 Hz, CO_2), 203.9 (t, J = 8 Hz, C≡O), 200.6 (dd, J = 71 Hz, 8 Hz, 2C≡O), 196.7 (t, J = 8 Hz, C≡O), 191.7 (t, J = 45 Hz, C≡O), 142.5–128.1 (m, C_6H_5), 31.9–19.5 (m, CH_2). ^{31}P NMR (δ, CD_2Cl_2, reference: 85%

† Author to whom correspondence should be addressed.

H_3PO_4): 11.85 (d, $J = 18$ Hz), 0.39 (d, $J = 18$ Hz), −9.55 (d, $J = 31$ Hz), −10.26 (d, $J = 31$ Hz). Found: C, 52.0; H, 3.7. Calc. for $C_{60}H_{52}O_7P_4Re_2$: C, 52.1; H, 3.8%.

X-ray structure determination

$(dppp)(CO)_2ReO_2CRe(CO)_3(dppp)\cdot C_6H_6$, mol. wt 1459.4, triclinic, space group $P\bar{1}$, $a = 10.902(2)$, $b = 13.657(3)$, $c = 21.591(4)$ Å, $\alpha = 98.90(2)$, $\beta = 99.900(10)$, $\gamma = 93.639(10)°$, $V = 3115.4(10)$ Å^3, $Z = 2$, $D_{calc} = 1.556$ g cm^{-3}, $F(000) = 1440$, Mo-K_α radiation ($\lambda = 0.71073$ Å), $\mu = 4.085$ mm^{-1}.

Diffraction intensities (crystal size $0.25 \times 0.40 \times 0.30$ mm, $2\theta = 3.5$–$45°$, 8201 unique data) were collected at 20°C on a Siemens R3m/V diffractometer using the 2θ–θ scan mode (1.5–14.65° min^{-1} in ω) in the range $3.5 \leqslant 2\theta \leqslant 45°$. Data processing, absorption corrections, structure solution and full-matrix least-squares refinement were performed with the SHELXTL-PLUS program package.[8] The non-hydrogen atoms were refined anisotropically. All the hydrogen atoms were generated geometrically (C—H = 1.00 Å), assigned isotropic temperature factors and included in the structure-factor calculations. The final residuals were $R = 4.60\%$ and $wR = 6.47\%$ for 6017 observed data with $F > 4.0\sigma(F)$.

RESULTS AND DISCUSSION

The IR spectrum of the complex exhibits five ν(C≡O)s. The ^{13}C NMR spectrum shows a resonance at δ 229.5 (t) for the CO_2 group and four resonances due to five terminal C≡Os. The ^{31}P NMR spectrum shows four doublets for the four non-equivalent phosphorus atoms.

The molecular structure of the complex was confirmed by X-ray determination. A distorted octahedral environment is observed for each rhenium atom (Fig. 1). The bridging carboxylate occupies two *cis* positions on Re(1) acting as a bidentate ligand, whereas the same ligand is monodentate on Re(2). This homobimetallic compound represents the first example reported of a carboxylate group acting as a bidentate ligand to one transition metal atom, while acting as a monodentate ligand to another identical atom. Other structural features involve one terminal CO and one phosphorus atom *trans* to the carboxylate ligand on Re(1) and the remaining terminal CO group and the phosphorus atom *cis* to the carboxylate. One terminal CO is *trans* to the carboxylate ligand on Re(2). The remaining two phosphorus atoms and COs occupy positions *cis* to the carboxylate.

The two oxygen atoms of the carboxylate group

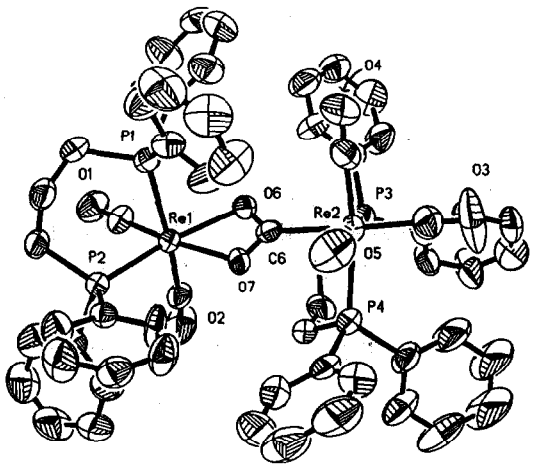


Fig. 1. Perspective drawing of the molecule $(dppp)(CO_2)ReO_2CRe(CO)_3(dppp)$. Selected bond distances (Å) and angles (°): Re(1)—P(1) = 2.474(3), Re(1)—P(2) = 2.343(3), Re(1)—O(6) = 2.208(8), Re(1)—O(7) = 2.198(8), Re(1)—C(1) = 1.867(13), Re(1)—C(2) = 1.916(11), Re(1)—C(6) = 2.633(13), Re(2)—P(3) = 2.483(3), Re(2)—P(4) = 2.467(4), Re(2)—C(3) = 1.937(17), Re(2)—C(4) = 1.919(15), Re(2)—C(5) = 1.939(14), Re(2)—C(6) = 2.191(13); P(1)—Re(1)—P(2) = 89.5(1), P(2)—Re(1)—O(6) = 163.0(2), P(2)—Re(1)—O(7) = 106.0(2), P(1)—Re(1)—C(7) = 85.9(4), P(1)—Re(1)—C(2) = 171.5(4), O(6)—Re(1)—C(2) = 94.6(4), C(1)—Re(1)—C(2) = 85.7(5), P(3)—Re(2)—C(3) = 97.6(4), P(3)—Re(2)—C(4) = 94.9(4), C(3)—Re(2)—C(4) = 89.0(7), P(4)—Re(2)—C(5) = 90.2(4), C(4)—Re(2)—C(5) = 88.5(6), P(4)—Re(2)—C(6) = 83.3(3), C(4)—Re(2)—C(6) = 87.7(6), P(3)—Re(2)—C(5) = 174.8(4), P(4)—Re(2)—C(4) = 171.0(5), C(3)—Re(2)—C(6) = 173.0(5), O(6)—C(6)—O(7) = 112.9(11).

are bonded to Re(1) in a symmetrical fashion with the Re—O distances being essentially equal [Re(1)—O(6) = 2.208(6) and Re(1)—O(7) = 2.198(8) Å]. The Re(2)—C(6) distance of 2.191(13) Å is slightly longer than the corresponding distance of 2.058(9) Å in $Cp^*(PPh_3)(NO)ReCO_2SnPh_3$[3a] and 2.04(4) Å in $[Cp^*(CO)(NO)ReCO_2WCp_2][BF_4]$.[2c] The C(6)—O(6) distance of 1.260(15) Å is slightly shorter than the C(6)—O(7) distance of 1.289(14) Å. The O(6)—C(6)—O(7) angle of 112.9(11)° is almost equal to the corresponding angle of 112.2(8)° in $Cp^*(PPh_3)(NO)ReCO_2SnPh_3$.[3a] However, this angle is significantly smaller than the corresponding angle of 115.8° in $(PMe_3)_2(CO)_2Mn(O_2CCH_3)$[9] and 118(1)° in $(PPh_3)_2(CO)_2Re(O_2CCH_3)$[10] and larger than the angle of 106(3)° in $[Cp^*(CO)(NO)ReCO_2WCp_2][BF_4]$.[2c]

Supplementary materials. Tables of positional and isotropic thermal parameters, anisotropic thermal parameters and bond distances and angles (7

pages); tables of structure factors (30 pages). Directions for ordering are given on any current masthead page.

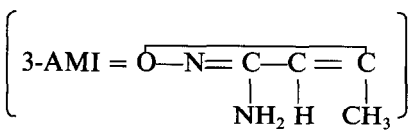
(*Received* 27 *November* 1992; *accepted* 25 *February* 1993)

Abstract—From EPR studies on copper(II)-doped $Cd(3\text{-AMI})_2(SCN)_2$, $Zn(3\text{-AMI})_2(SCN)_2$, $Cd(3\text{-AMI})Cl_2$ and $Ca(3\text{-AMI})_2Cl_2\cdot H_2O$ (3-AMI = 3-amino,5-methylisoxazole) it was found that 3-AMI bonds via the N_{ring} and the coordination polyhedra of the former three complexes are distorted more towards compressed tetrahedral symmetry than the latter one, which is at variance with earlier conclusions.

The IR and electronic spectral studies on metal complexes of 3-amino, 5-methylisoxazole



tentatively indicated that this ligand acts either as a monodentate (N_{ring} or O_{ring} bonded), bidentate or bridging bidentate (N_{ring} and O_{ring} bonded) ligand in metal complexes.[1,2] From the above studies it was also tentatively concluded that $Cd(3\text{-AMI})_2(SCN)_2$, $Zn(3\text{-AMI})_2(SCN)_2$[1] and $Ca(3\text{-AMI})_2Cl_2\cdot H_2O$[2] complexes are monomeric and tetrahedrally distorted complexes having CdN_2O_2, ZnN_2O_2 and CaN_2Cl_2 atomic sets in coordination polyhedra, respectively, unlike the polymeric bridging chloride octahedral complex $Cd(3\text{-AMI})Cl_2$,[1] which was tentatively interpreted as having the $CdCl_4NO$ moiety. Since the metal–ligand stretching frequencies of Cu—O and Cu—N fall in the same range, it will be difficult to conclude from IR spectra the actual coordinating atom among the above two if the ligands like 3-AMI contain both these donor atoms. Hence, the authors felt that EPR spectroscopy, with copper(II) as the paramagnetic probe, is the right method to unambiguously determine the type of coordinating atoms and the type of distortion in the coordination geometry of the above four complexes. EPR results obtained from polycrystalline samples are presented here.

EXPERIMENTAL

The complexes under investigation were synthesized as described earlier.[1,2] Small single crystals of 1% copper-doped complexes under consideration were grown following the usual procedure from solutions. The EPR spectra of these complexes after crushing to a fine powder form were recorded as described earlier.[3] TCNE (tetracyanoethylene), which gives a very sharp EPR signal, is used as a g (= 2.00277) marker. The errors in g and A are *ca* ± 0.001 and ± 2 G, respectively.

* Author to whom correspondence should be addressed.

RESULTS AND DISCUSSION

The EPR spectra of these complexes are shown in Fig. 1. The spin-Hamiltonian constants, metal–ligand σ-bond parameter α_σ^2 and the value of R (cm) ($|g_\parallel/A_\parallel|$) for these complexes are given in Table 1. The values of α_σ^2 in the case of $Cd(Cu)(3\text{-AMI})_2(SCN)_2$, where the ligand hyperfine structure on the parallel features is obtained, can be calculated using the procedure of Maki and McGarvey.[4] For the remaining complexes this is calculated using the expression[5] given below.

$$\alpha_\sigma^2 = \frac{|A_\parallel|}{P} + [g_\parallel - 2.0023] + 3/7[g_\perp - 2.0023] + 0.04 \quad (1)$$

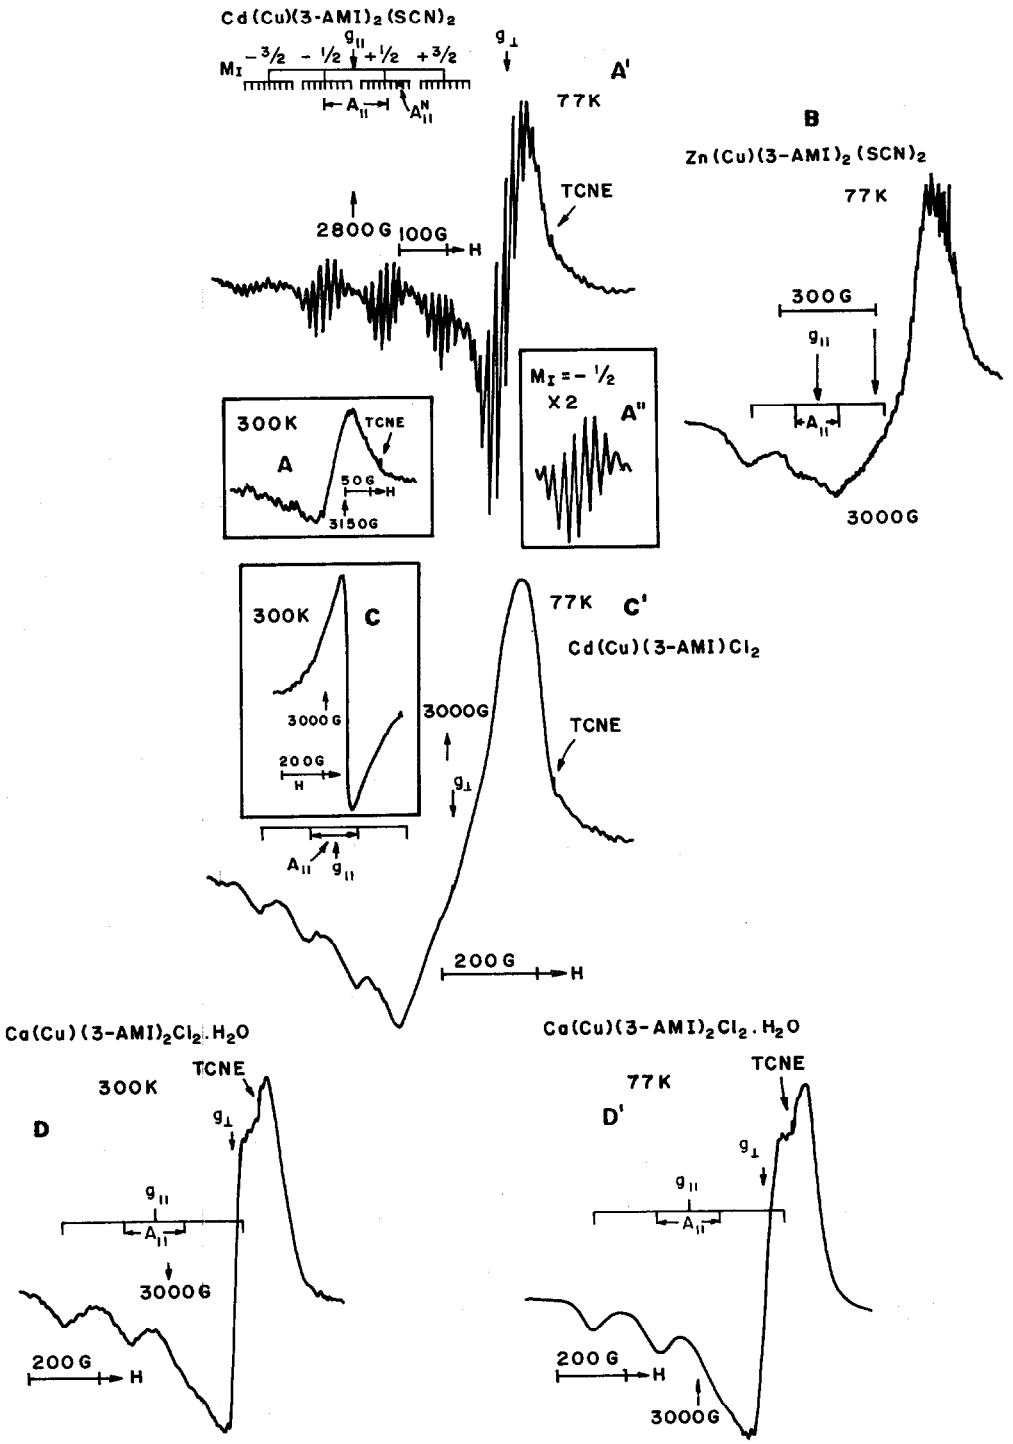


Fig. 1. ESR spectra of copper(II) in diamagnetic metal complexes of 3-AMI in polycrystalline form.

Table 1. Spin-Hamiltonian constants, α_σ^2 and R (cm) values of copper(II) in diamagnetic complexes

Sample	Temperature (K)	$g_\parallel$	$g_\perp$	$A_\parallel$ ($\times 10^4$ cm^{-1})	$A_\parallel^N$	R (cm)	α_σ^2
Cd(Cu)(3-AMI)$_2$(SCN)$_2$	77	2.305	2.069	117.9	13.75	196	0.68
Cd(Cu)(3-AMI)Cl$_2$	77	2.348	2.059	109.2	—	215	0.73
Zn(Cu)(3-AMI)$_2$(SCN)$_2$	77 and 300	2.208	2.104	143.7	—	153	0.69
Ca(Cu)(3-AMI)$_2$Cl$_2$·H$_2$O	300	2.200	2.049	179.0	—	123	0.76
	77	2.198	2.058	184.1	—	119	0.77

The following structural information for these complexes has been extracted from the above data.

(1) The greater resolution of the EPR spectra observed at low temperatures in the case of copper (II)-doped cadmium complexes (Fig. 1A, A′, A″, C and C′) indicates the presence of strong spin-lattice interactions. In addition larger $g_\parallel$ and smaller $A_\parallel$ values (Table 1) are obtained in these complexes. These two facts strongly support the presence of tetrahedral distortion in the coordination geometries of the above two complexes. The R (cm) values in both complexes indicate a dihedral angle[6] of *ca* 70°. Even though IR studies indicated this tetrahedral distortion in Cd(3-AMI)$_2$(SCN)$_2$, it failed to identify the above distortion in Cd(3-AMI)Cl$_2$.[1]

(2) The nine ligand hyperfine lines (LHL) on each copper(II) hyperfine line of the parallel features of the EPR spectrum of Cd(Cu)(3-AMI)$_2$(SCN)$_2$ (Fig. 1A′ and A″) clearly indicate a CuN_4 moiety, which differs from the conclusions drawn on the basis of IR studies. Even though LHL are not observed on the parallel features, LHL on the perpendicular features (Fig. 1B) and the $g_\parallel$ and $A_\parallel$ values of Zn(Cu)(3-AMI)$_2$(SCN)$_2$ are similar to those of Cu(TC-55) (TC = tropocoronand),[7] where the dihedral angle of CuN_4 coordination tetrahedral geometry is 61°. In this case also the IR spectral predictions about the coordinating atoms failed. In both the above two complexes the metal–ligand σ-bond is stronger than in the other two complexes.

(3) High $A_\parallel$ and low $g_\parallel$ and R (cm)(119) values observed in Ca(Cu)(3-AMI)$_2$Cl$_2$·H$_2$O rule out the possibility of considerable tetrahedral distortion, as predicted by IR studies, since the dihedral angle from the value of R (cm) is only 40°.[6]

(4) From the above observation it is evident that 3-AMI acts as a monodentate N_{ring}-bonded ligand in all the complexes.

ANNUAL POLYHEDRON PUBLICATION AWARD

Pergamon Press Ltd is pleased to announce the award annually of a cash prize of US$1000 for the best paper published in *Polyhedron*.

The award will be made to the authors of the original research paper (not including *Polyhedron* Reports) judged to be the best on the basis of scientific originality, significance, clarity and style of presentation. Members of the Editorial Board will each be invited to nominate two papers for the award and the final selection will be made by an anonymous committee appointed by the Editors who themselves will not be eligible for the award.

The award for 1992 will be announced this year.

The recipients of the yearly award:

1987 A. J. SCIOLY, M. L. LUETKENS JR. R. B. WILSON JR, J. C. HUFFMAN and A. P. SATTELBERGER, "Synthesis and characterization of binuclear tantalum hydride complexes", *Polyhedron* Vol. 6. No. 4, pp. 741–757 (1987).

1988 G. PARKIN and J. E. BERCAW, "Halide, hydride, alkyl, oxo and related derivatives of bis(pentamethylcyclopentadienyl)tungsten(IV)", *Polyhedron* Vol. 7, No. 19/20, pp. 2053–2082 (1988)

PREPARATION AND CRYSTAL STRUCTURE OF $MoO_2Cl_2(H_2O)_2 \cdot H_2O \cdot Et_4NCl$ IN RELATION TO THE NATURE OF THE MOLYBDENUM(VI) SPECIES IN HYDROCHLORIC ACID SOLUTIONS

MICHAEL J. TAYLOR,* WANG JIRONG and CLIFTON E. F. RICKARD

Department of Chemistry, University of Auckland, Auckland, New Zealand

(*Received* 5 *January* 1993; *accepted* 5 *March* 1993)

Abstract—Crystallization of a solution of Mo^{VI} in HCl containing Et_4NCl yields the molecular complex dioxodichlorodiaquamolybdenum(VI) in association with Et_4N^+ and Cl^- ions. Structure determination of the title compound by X-ray crystallography reveals $MoO_2Cl_2(H_2O)_2$ units with *cis,trans,cis* arrangement of ligands, which are linked by forming hydrogen bonds to the H_2O molecule of crystallization. Vibrational spectroscopic data confirm this complex as the predominant Mo^{VI} species in hydrochloric acid solutions.

The coordination chemistry of molybdenum (VI) oxo complexes holds continuing interest.[1,2] Recently, the molecular structures of MoO_2Cl_2 and MoO_2Br_2 have been redetermined by electron diffraction in the gas phase and shown to have C_{2v} symmetry, the bond angle O=Mo=O measuring 106.3° (Cl) or 107.8° (Br).[3] Derivatives of the type $MoO_2Cl_2L_2$ (L = neutral donor) are numerous;[4] the general structure is one in which the oxo-atoms are *cis*, the anionic ligands are *trans* and the neutral ligands are *trans* to oxo and thus *cis* to each other. Exceptions may arise if the neutral donors are in the form of a bidentate ligand such as tetramethylethylenediamine; an example is MoO_2Cl_2 (tmen), which is thought to have one N-donor *trans* to oxygen but the other *trans* to chlorine.[5]

In previous work we have gained structural evidence relating to the species $MoO_2X_2(H_2O)_2$ (X = Cl or Br) in solution using ^{95}Mo NMR and vibrational spectroscopy[6] and have also identified $[MoO_2Cl_4]^{2-}$ as the Cs^+ salt which can be prepared from a solution of Mo^{VI} in hydrochloric acid. Seeking to obtain oxohalogenomolybdenum(VI) species in crystalline form suitable for X-ray investigation, we have prepared the compound $(Et_4N)MoO_2Cl_3 \cdot 3H_2O$. This could possibly have contained an Mo^{VI} anion such as $[MoO_2Cl_3]^-$, $[Mo_2O_4Cl_6]^{2-}$ or $[MoO_2Cl_3(H_2O)]^-$, but instead reveals the molecular complex $[MoO_2Cl_2(H_2O)_2]$ whose structure and dimensions we have determined by means of crystallography.

EXPERIMENTAL

Preparation of $[(C_2H_5)_4N]MoO_2Cl_3 \cdot 3H_2O$

Tetraethylammonium chloride (1.00 g, 6.0 mmol) dissolved in concentrated hydrochloric acid (4 cm^3) was added slowly with stirring to a solution of $Na_2MoO_4 \cdot 2H_2O$ (0.97 g, 4.0 mmol) in a warm mixture of concentrated HCl (3 cm^3) and water (1 cm^3). The white precipitate (NaCl) was removed by filtration. The filtrate was allowed to stand; crystallization began after 1 h and was completed overnight. The colourless crystals were collected and dried on filter paper. The product is air-stable although the crystals become cloudy on long exposure, probably through partial loss of water of crystallization. A freshly prepared sample was analysed after drying over silica gel at room temperature. Found: C, 23.4; H, 6.2; N, 3.3; Cl, 26.7. Calc. for $C_8H_{26}Cl_3MoO_5N$: C, 23.0; H, 6.2; N, 3.3; Cl, 25.4%.

Attempted preparation of other complexes

Attempts to prepare analogous compounds using Pr^n_4NCl, Bu^n_2NCl or Et_4NBr and $Na_2MoO_4 \cdot 2H_2O$

* Author to whom correspondence should be addressed.

using similar methods did not give well-defined products.

Crystallography

A colourless crystal of the title compound was mounted on a silica fibre on an Enraf–Nonius CAD-4 diffractometer. Unit cell parameters were obtained from a least-squares fit to the four circle coordinates of 25 reflections using monochromatic Mo-K_α radiation ($\lambda = 0.71069$ Å). Intensity data were collected using ω–2θ scans with scan width $0.8 + 0.35 \tan\theta$, giving 3804 unique reflections in the range $2° < 2\theta < 55°$. The data were corrected for Lorentz and polarization effects and an absorption correction applied using empirical phi scans.

Crystal data. $C_8H_{26}Cl_3MoO_5N$, $M = 418.29$, triclinic, space group $P\bar{1}$, $a = 11.141(4)$, $b = 7.242(1)$, $c = 11.810(4)$ Å, $\alpha = 96.46(2)$, $\beta = 114.45(3)$, $\gamma = 77.87(2)°$, $U = 847.7$ Å^3, $Z = 2$, $D_o = 1.65$, $D_c = 1.638$ g cm^{-3}, $F(000) = 428$, μ(Mo-K_α) = 11.7 cm^{-1}.

The structure was solved by conventional Patterson and difference-Fourier techniques and refined by full-matrix least-squares. Non-hydrogen atoms were assigned anisotropic thermal parameters. Hydrogen atoms of the tetraethylammonium group were included in calculated positions and allowed to ride on the atom to which they were attached. Hydrogen atoms of the water molecule were located from difference Fourier maps and allowed to refine with restrained O—H distances and a common thermal parameter. The final R and R' values were 0.041 and 0.042, respectively, for the 3626 observed data ($I > 3\sigma\{I\}$) and weights $1.0/[\sigma(F^2) + 0.016F^2]$. Final atomic coordinates, thermal parameters and tables of observed and calculated structure factors have been deposited with the Editor.

Spectroscopy

IR spectra were measured using a Digilab FTS-60 spectrometer and Raman spectra using a Jobin–Yvon U1000 system with the green line of a Spectra Physics argon-ion lazer as the excitation source.

RESULTS AND DISCUSSION

The X-ray structure determination shows that the solid which forms from a solution of Mo^{VI} in hydrochloric acid, containing tetraethylammonium chloride, consists of Et_4N^+ and Cl^- ions co-crystallized with $MoO_2Cl_2(H_2O)_2$ molecules. The arrangement of these species in the unit cell is displayed in Fig. 1. The third H_2O molecule [oxygen O(5)] exists in the solid as water of crystallization; its position shows it to be involved in hydrogen bonding between the ligand H_2O groups of different molecules of the molybdenum complex, such that these are linked throughout the structure. The distances, O(1)—O(5) of 2.75 and O(5)—O(2′) of 2.75 Å, are normal for hydrogen bonds between oxygen atoms. The Et_4N^+ cation has the expected values of bond lengths and angles; these dimensions are not cited here but form part of the supplementary material.

A view of the $MoO_2Cl_2(H_2O)_2$ molecule is given in Fig. 2 and the bond distances and angles are listed in Table 1. The structure is distorted octahedral with *cis*-oxo groups, *cis*-H_2O ligands and *trans*-chlorine atoms, which is the expected pattern for a complex of this type.[4] The Mo=O distances of 1.685(2) and 1.690(2) Å are slightly less than the average value of 1.704 Å derived from a large number of dioxomolybdenum structures,[7] whilst the O=Mo=O angle of 103.5° is at the low end of the established range (102–114°).[1] The Cl—Mo—Cl angle of 157.9° is far removed from the nominal

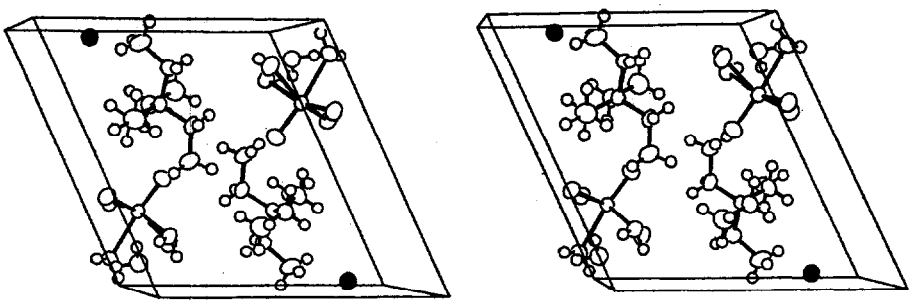

Fig. 1. The contents of the unit cell of $MoO_2Cl_2(H_2O)_2 \cdot H_2O \cdot Et_4NCl$. The chloride ions are shown in black.

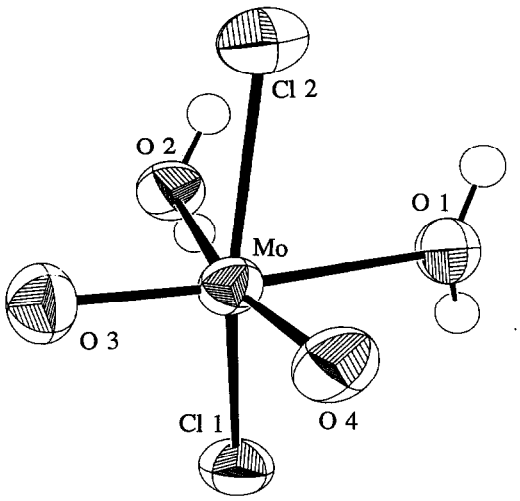

Fig. 2. A perspective view of the $MoO_2Cl_2(H_2O)_2$ molecule.

180° owing to repulsion between the Mo=O and Mo—Cl groups. The Mo—Cl bond lengths are practically equal at 2.346(1) Å. However, the distances to the H_2O ligands differ significantly, being 2.261(2) and 2.283(2) Å, perhaps in consequence of their involvement in hydrogen bonding to the third water molecule. The structure is akin to that of $MoO_2Cl_2(H_2O)_2 \cdot 2C_5H_5NHCl$, which is built up from the neutral molybdenum complex, pyridinium and chloride ions,[8] but lacks the water of crystallization which occurs in the present compound.

It is worthwhile to compare the structure of $MoO_2Cl_2(H_2O)_2$ with that of the uncomplexed MoO_2Cl_2 molecule in which r(Mo=O) = 1.686(4) and r(Mo—Cl) = 2.258(3) Å, ∠O=Mo=O = 106.3 and ∠Cl—Mo—Cl = 113.9°.[3] The introduction of the water molecules as ligands *trans* to the oxo groups appears to cause no change in the Mo=O bond lengths, whereas the Mo—Cl bonds are increased in length by almost 0.1 Å. The unsaturation of the MoO_2Cl_2 molecule is evident from the fact that anhydrous MoO_2Cl_2 has a layer structure in the solid state, in which both oxygen atoms participate in an Mo—O—Mo bridging system.[9] In the monohydrate, $MoO_2Cl_2 \cdot H_2O$, the entry of a water molecule into the coordination sphere of molybdenum atoms breaks down the layers into chains of octahedra, in which one oxo oxygen atom is bridging and one is terminal.[10]

The IR and Raman spectra of the solid $MoO_2Cl_2(H_2O)_2 \cdot H_2O \cdot Et_4NCl$ were investigated in the range 100–1200 cm^{-1}. After making allowances for bands due to the Et_4N^+ ion the remaining features are in good agreement with the spectra assigned to $MoO_2Cl_2(H_2O)_2$ in our earlier work.[6] Assignments for the solid (with the solution-state values in parentheses) are ν_{sym}(Mo—Cl) 318 (310), ν_{asym}(Mo—Cl) 353 (346), ν_{asym}(Mo=O) 910 (922) and ν_{sym}(Mo=O) 950 (960) cm^{-1}. Our previous study of molybdenum(VI) complexes[6] gave evidence that $MoO_2Cl_2(H_2O)_2$ is the predominant species in aqueous solution at high HCl concentration, and is the form in which molybdenum(VI) enters the organic phase during solvent extraction by ether or a ketone. The co-crystallization of $MoO_2Cl_2(H_2O)_2$ with Et_4NCl supports its presence in HCl solutions (notwithstanding the fact that the addition of CsCl leads to the separation of $Cs_2MoO_2Cl_4$ crystals). Ease of replacement of ligands *trans* to the oxo groups is a characteristic property of oxomolybdates, which has been widely used in the synthesis of such complexes.[4] The observation that either $MoO_2Cl_2(H_2O)_2$ or $MoO_2Cl_4^{2-}$ can be obtained from the Mo^{VI}/HCl solution simply by choice of the added halide salt is in harmony with this fact.

Table 1. Selected bond distances (Å) and angles (°) for $MoO_2Cl_2(H_2O)_2$

Mo—O(1)	2.283(2)	Mo—Cl(1)	2.347(1)
Mo—O(2)	2.261(2)	Mo—Cl(2)	2.346(1)
Mo—O(3)	1.685(2)		
Mo—O(4)	1.690(2)		
O(1)—Mo—O(2)	78.5(1)		
O(3)—Mo—O(4)	103.5(1)		
Cl(1)—Mo—Cl(2)	157.9(0)

(*Received* 31 *July* 1992; *accepted* 5 *March* 1993)

Abstract—A stable diamagnetic complex of the type $[(Ru^{III}edta)_2\text{-}\mu\text{-}(amino\text{-}acidato)_2\text{-}\mu\text{-}oxo]^{6-}$ is reported. The amino acid bridge in the presence of oxygen undergoes oxidative deamination, as shown by the formation of an α-keto acid and the liberation of NH_3. The reaction is catalytic.

μ-Oxo-μ-diacetato diiron(II) cores in non-haeme proteins are known to be active centres.[1,2] Depending on the nature of the bridging groups these proteins act as oxygen carriers,[1,2] oxygen activating systems[3,4] and in the hydrolysis of phosphoric acid esters.[5,6] This led to extensive research in the chemistry of μ-oxo-μ-diacetato diiron(III) complexes with reference to their optical and magnetic properties and structures.[7] There has been a growing interest in developing the parallel chemistry of μ-oxo-ruthenium(III) complexes.[8,9] The iron and ruthenium complexes studied so far incorporate simple carboxylates as bridges[10] rather than amino acids, as in the natural systems.[1–6] In this paper we report diruthenium(III)-μ-oxo complexes with bridged amino acids, viz. alanine, phenylalanine and valine complexes, which have been characterized in solution as well as in the solid state. The complexes are stable under inert atmosphere and undergo oxidative deaminations under oxygen. The reactions were found to be catalytic.

EXPERIMENTAL

Materials

$RuCl_3$ was purchased from Johnson Matthey. All other chemicals used were of A.R. grade. All organic solvents were purified using known procedures.[11,12]

$K[Ru(edtaH)Cl]\cdot 2H_2O$ (**1**) was prepared by a known procedure.[13]

Syntheses of $Na_6[(edtaRu)_2\text{-}\mu_2\text{-amino acid-}\mu\text{-oxo}]$

Compound **1** *(0.2 mmol) and the appropriate* amino acid were dissolved in H_2O (10 cm^3) and the solution degassed with nitrogen. The pH was raised to 10.5 and the solution left overnight when it turned maroon. The solution was transferred to a flask containing degassed acetone (100 cm^3) and left under nitrogen for a week at 0°C. A dark purple solid separated, which was washed with ethanol, acetone and dried *in vacuo*. All operations were performed using the Schlenk technique. The yields ranged from 22 to 25%. Physicochemical data for the complexes are presented in Table 1.

Physical measurements

Absorption spectra were recorded on a Shimadzu UV–vis 160 spectrophotometer equippd with a TCC-240A temperature controller. Electrochemical studies were performed on PAR (model 174A) electrochemical equipment. The cyclic voltammogram (CV) at pH 10.5 was recorded using a mercury electrode as the working electrode and S.C.E. as the reference electrode. Raman spectra were recorded on a Spex Ramalog spectrometer

[b] In degassed H_2O.

using 514.5 nm line of an Ar ion laser (Spectra-physics) for excitation.

Kinetics

The complex was dissolved in degassed NaOH (0.001 M) and the pH was adjusted to 10.5 with HCl and oxygen was then bubbled through. The kinetics of the deamination of amino acid bridged complexes were followed spectrophotometrically by monitoring the disappearance of the characteristic peak λ_{max} of the bridged dimer complexes. The concentration of dissolved oxygen was varied by passing through an oxygen and nitrogen mixture of varying composition. The rate constant data are reproducible to within $\pm 4\%$.

Detection of NH_3 *and α-keto acids*

The complex was dissolved in degassed NaOH, the pH adjusted to 10.5 and then oxygen was slowly bubbled through. The outlet of the reaction vessel was connected to another vessel containing HCl (0.1 M). Bubbling was continued for 24 h, after which time the HCl was back-titrated with standard NaOH. Meanwhile, bubbling of oxygen was continued and NH_3 collected as described above. This procedure was continued for 72 h until there was no appreciable change in the titre value of NaOH. From the difference in titre values before and after back-titration the amount of NH_3 was determined. From another experiment the presence of NH_3 was confirmed using Nesslers reagent.

After completion of the reaction with oxygen (72 h) the solution was acidified and the complex precipitated with ethanol and filtered. The filtrate was reduced to 4 cm^3, again acidified and the volume reduced *in vacuo*. A white solid separated, which gave a positive test for the keto group with 2,4-dinitrophenylhydrazine, and the presence of the —COOH group was confirmed by the effervescence of CO_2 on addition of $NaHCO_3$.

RESULTS AND DISCUSSION

Characterization of complexes **2–4**

Complexes **2–4** are formulated as $Na_6[Ru_2(edta)_2$-μ-(amino acid)$_2$-μ-O] on the basis of elemental analysis, UV–vis and proton NMR spectra. The absorption spectra of the complexes exhibit a strong band around 550 nm, which is assigned to M ← O charge-transfer in the Ru^{III}—O—Ru^{III} group. The assignment is based on comparison of the absorption spectra of the μ-oxo-diacetato diruthenium(III) complexes reported so far.[8–11] A similar complex of ethylenediamine exhibits a band at 565 nm. The shift in the reported complexes may be due to stronger binding of edta. These complexes, as also reported, are essentially diamagnetic (Evan's method). For the sake of clarity the details for complex **2** will be given. Similar results were obtained with complexes **3** and **4**. λ_{max} and $E_{1/2}$ were of course different.

The proton NMR spectrum exhibits peaks at 2.328 (CH_2 of ethylenediamine), 2.775 (CH_2 of —CH_2COO in edta), 3.050 (CH of amino acid), 3.375 (CH_2 of amino acid) and 7.550 ppm (phenyl protons of amino acid).

The laser Raman spectrum exhibits bands due to symmetric and asymmetric stretching of Ru^{III}—O—Ru^{III} at 636 and 729 cm^{-1} (Fig. 4), respectively. These values are *ca* 80 cm^{-1} towards a higher frequency compared with Fe^{III} complexes[14] and may be due to more diffused 4*d* orbitals in ruthenium(III).

The DPP and CV of the complex exhibit peaks at −0.28 and −0.44 V, due to stepwise reduction of Ru^{3+} to Ru^{2+}.

Complex **2** was dissolved in degassed NaOH (0.001 M) solution and the pH was adjusted to 10.5 by adding HCl (0.1 M). The absorption spectrum of complex **2** at pH 10.5 exhibited a band at 539 nm [Fig. 1(b)], whose intensity was low compared with those of μ-oxo-μ-carboxylato complexes pre-

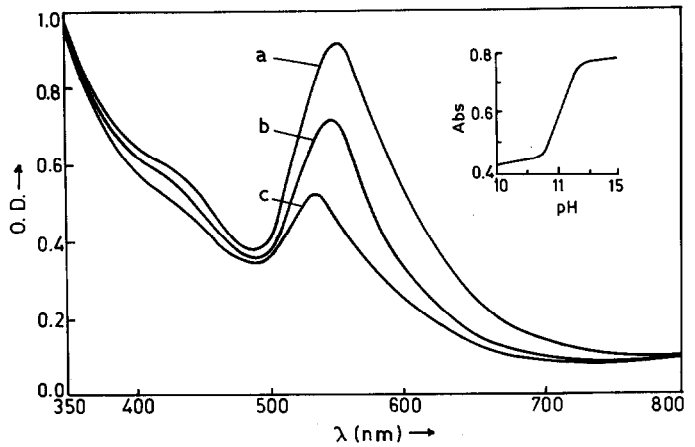

Fig. 1. Absorption spectra of complex **2**: (a) under nitrogen at pH 11.2, (b) under nitrogen at pH 10.5 and (c) after passing oxygen through (15 min) at pH 10.5. (Inset shows plot of absorbance at 548 nm as a function of pH under nitrogen.)

viously reported.[8-11] One of the reasons could be the dissociation of the complex to a monomeric species.

$$\mathrm{LMOML} \underset{-H_2O}{\overset{+H_2O}{\rightleftharpoons}} 2\mathrm{LMOH} \underset{-H^+}{\overset{+H^+}{\rightleftharpoons}} 2\mathrm{ML(H_2O)}$$

If this is so then an increase in pH would favour the formation of the dimer and the spectrum at higher pH would have shown an increase in absorbance. However, the spectrum of **2** at pH 11 showed a shift in λ_{max} to 548 nm with ε_{max} comparable to those of reported complexes.[8-11] Such behaviour is reminiscent of the protonation/deprotonation of the μ-oxo group.[11]

$$\mathrm{LMOML} \overset{+H^+}{\rightleftharpoons} \mathrm{L\overset{H}{M}OML} \qquad (1)$$

Decreasing the pH of the solution from 11.0 to 10.5 resulted in the reappearance of the peak at 539 nm. When the pH of the complex solution was again adjusted to 11.0 (addition of NaOH) the peak at 548 nm reappeared. Thus, increases and decreases of pH back and forth reproduced the spectrum at the corresponding pH value, demonstrating the existence of an equilibrium [eq. (1)]. From the plot of absorbance vs pH (Fig. 1 inset) the dissociation constant (pK_a) for reaction (1) was found to be 10.9 ± 0.1 ($T = 35°C$, $\mu = 0.1$). Thus, the species at pH 10.5 under nitrogen is a μ-hydroxo rather than a μ-oxo species.

On passing oxygen through the above solution the peak shifts further to 533 nm [Fig. 1(c)]. This may be due to the coordination and concomitant reduction of oxygen by transfer of electrons from Ru^{3+}. DPP (Fig. 2) and CV of this solution exhibit a peak at +0.04 V, assigned to an Ru^{4+}/Ru^{3+} couple. Due to oxidation of Ru^{3+} to Ru^{4+} the acidity of μ-OH increases and, therefore, it becomes deprotonated to form a μ-oxo species. Thus, the

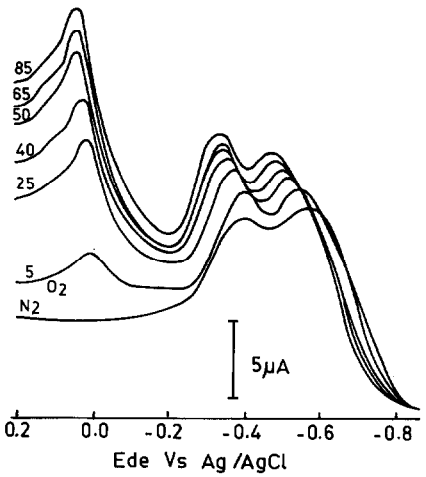

Fig. 2. DPP of **2** under nitrogen and under oxygen at different time intervals (indicated on DPP in minutes); $T = 35°C$, $\mu = 0.10$ M (KCl).

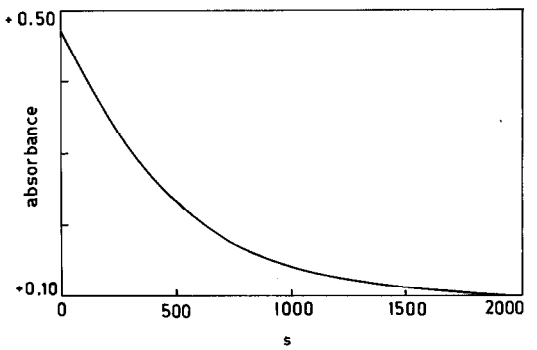

Fig. 3. Trace showing the decrease in intensity of the peak at 533 nm after passing oxygen through a solution of complex **2**; $T = 35°C$, $\mu = 0.10$ M (KCl).

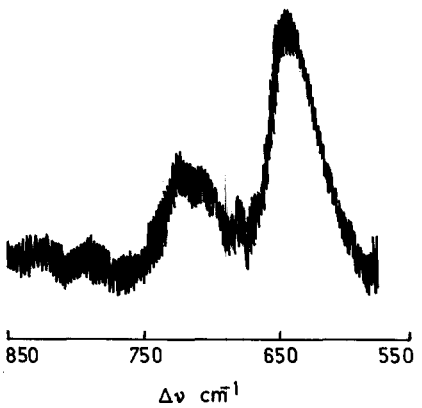

Fig. 4. Raman spectrum of complex **2**, excitation line: 514.5 nm, Ar ion 50 mW. Average of two scans.

species at pH 10.5 under oxygen is a μ-oxo peroxo diruthenium(IV) complex (**2a**).

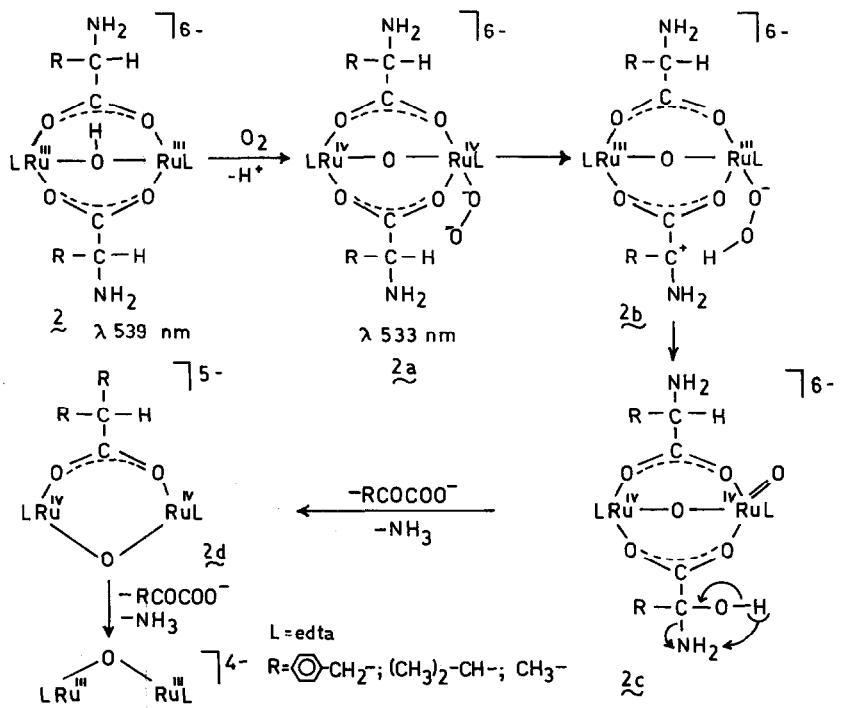
$$\overset{H}{LMOML} \xrightarrow{O_2} LMOML(O_2)+H^+ \qquad (2)$$

Complex **2a** could not be isolated due to its instability under oxygen.

Oxidation of amino acid

On passing oxygen through a solution of the complex the peak at 533 nm starts decreasing (Fig. 3) until the spectrum resembles that of **1** in the absence of the amino acid. The reaction mixture gives a positive test for the α-keto acid and NH_3 as produced. The amount of NH_3 varied between 70–75% of the theoretical value. To account for these observations a possible mechanism is given below in Scheme 1.

In Scheme 1 hydride is abstracted from the α-carbon atom of the coordinated amino acid, which ultimately transfers its $2e^-$ to two ruthenium(IV) centres resulting in an Ru^{III}–Ru^{III} hydroperoxo species (**2d**). The cleavage of the C—H bond is facilitated by the presence of the R groups on C(2) atoms. An OH^- is then transferred to the α-carbonium ion thus produced to give **2c**.[15] The prototropic changes result in the formation of the keto acid and elimination of NH_3 to give complex **2d**. Species **2d** once again undergoes the same sequence of reactions and a second molecule of coordinated amino acid is oxidized (reaction requires **2c** and **2d** in Scheme 1). If at this stage the solution is degassed with argon and fresh amino acid added then the 539 nm peak again builds up. On passing oxygen through once again it disappears, repeating the cycle. Several such cycles could be run, indicating the catalytic nature of the reaction. If hydride abstraction takes place as proposed above then k_{obs} should follow the order valine > α-alanine > phenylalanine, since the R group with better electron donating properties will facilitate the hydride abstraction. The k_{obs} calculated are 1.31×10^{-3}, 0.85×10^{-3} and 0.68×10^{-3}



Scheme 1.

s^{-1} for valine, alanine and phenylalanine, respectively, thus supporting the assumption.

(*Received* 30 *September* 1992; *accepted* 10 *February* 1993)

Abstract—The catalytic oxidation of tertiary phosphines, PR_3 (R = *p*-fluorophenyl, phenyl and cyclohexyl), by molecular oxygen to the corresponding phosphine oxide, (PR_3O), catalysed by $Ru^{III}(EDTA\text{-}H)(H_2O)$ is reported as a function of catalyst, substrate (PR_3) and molecular oxygen concentration at a constant pH 3.0 in water–dioxan (50% v/v) medium. The reactivity of PR_3 towards catalytic oxidation by molecular oxygen decreases in the order tris(*p*-fluorophenyl)phosphine > triphenylphosphine > tris-(cyclohexyl)-phosphine. A reverse reactivity order was observed in the case of stoichiometric oxidation of PR_3 by $[O{=}Ru^{V}(EDTA)]^-$. The proposed mixed-ligand complex Ru^{III}-EDTA-PR_3 intermediate in the catalytic oxidation of PR_3 with molecular oxygen has been isolated and its structure solved by single-crystal X-ray diffraction. The experimental results are discussed in terms of the σ-basic and π-acidic character of the phosphine substrates in the homolytic bond cleavage of O—O bonds of the μ-peroxo intermediate and oxygen atom transfer to the substrate. The bond dissociation energy for O—O bond cleavage is computed by the kinetic data obtained for oxygen atom transfer from the oxo complex $[O{=}Ru^{V}(EDTA)]^-$.

The oxidation of phosphines by transition-metal oxo complexes has been the subject of much current interest.[1–5] In our laboratory we have been engaged in developing non-porphyrinic ruthenium(III) complex catalysts for the oxidation of a variety of organic substrates.[6–10] These non-porphyrinic ligands involve aminopolycarboxylic acids such as ethylenediaminetetraacetic acid (EDTA), propylenediaminetetraacetic acid (PDTA), N-hydroxyethylethylenediaminetriacetic acid (HEDTA), Schiff bases and dimethylglyoxime, which do not undergo self-oxidation during the catalytic processes. In our earlier contribution[11] we reported the oxidation of PPh_3 to PPh_3O with molecular oxygen catalysed by the Ru^{III}-EDTA complex where we proposed the formation of a mixed-ligand Ru-EDTA-PPh_3 intermediate in the catalytic cycle. We have now successfully isolated the complex $Ru^{III}(EDTA\text{-}H)PPh_3$ and determined its structure.

In order to gain an insight into the mechanistic details of the reaction, such as coordination of the phosphine ligand to the metal ion and the nature of the oxygen atom transfer, we have studied the oxidation of various phosphines (PR_3; R = *p*-fluorophenyl, phenyl and cyclohexyl) by molecular oxygen catalysed by complex **1**. We have also studied the stoichiometric oxygen atom transfer reaction in the oxidation of PR_3 by the $Ru^{V}(EDTA)(O)^-$ complex. The experimental results are discussed in terms of σ-basicity and π-acidity of PR_3 substrates, which governs the reactivity of Ru^{III} and Ru^{V} complexes.

EXPERIMENTAL

The complex $K[Ru^{III}(EDTA\text{-}H)Cl]$ (**1**) was prepared following the published procedure.[12] Dis-

† Author to whom correspondence should be addressed.
‡ Present address: 17-3-479 Yakutpura, Hyderabad 500023, A.P., India.

tilled dioxane (HPLC grade) and doubly distilled water were used to prepare all solutions. All other chemicals used were of A.R. grade.

Synthesis of $K[Ru^{V}{=}O(EDTA)]\cdot 2H_2O$

The complex $K[Ru^{V}{=}O(EDTA)]$ was prepared by interacting $K[Ru^{III}(EDTA\text{-}H)Cl]$ with iodosylbenzene.[13] To a stirred solution of K[Ru(EDTA-H)Cl] [1 mmol in 10 cm^3 water–dioxane (1 : 1)] was added iodosylbenzene (1.1 mmol) and the solution was stirred for 1 h in the dark. The greenish-brown product, $[Ru^{V}{=}O(EDTA)]^-$, thus formed was precipitated by adding acetone, immediately filtered and washed with a cold acetone–water mixture (9 : 1) and dried. Found: C, 24.9; H, 3.3; N, 5.8. Calc.: C, 25.0; H, 3.3; N, 5.8%. UV–vis spectra, λ_{max} (nm) [ε_{max} (mol^{-1} dm^3 cm^{-1})] = 390(1860). IR spectra: ν(Ru=O), 870 cm^{-1}. $E_{1/2}$ (determined by cyclic voltammetric studies) for Ru^{5+}/Ru^{4+}, Ru^{4+}/Ru^{3+} and Ru^{3+}/Ru^{2+} redox couples are 0.91, 0.14 and −0.21 V (vs S.C.E.), respectively.

Synthesis of [Ru(EDTA-H)(PR_3)] *complexes*

[Ru(EDTA-H)(PPh_3)] (**2**). To a refluxing solution of $K[Ru^{III}(EDTA\text{-}H)Cl]$ (500 mg, 1 mmol) was slowly added triphenylphosphine (260 mg, 1 mmol) dissolved in a minimum volume of dioxane. The mixture was refluxed (under nitrogen) for a period of 2 h until the colour of the solution changed from yellow to orange–yellow. The solution was then allowed to cool down and an orange–yellow product precipitated. The product was filtered, washed with cold water several times and finally with ether and dried *in vacuo* (yield: 89%). Found: C, 51.0; H, 4.8. Calc.: C, 51.5; H, 4.3%. UV–vis in H_2O, λ_{max} (nm) [ε_{max} (mol^{-1} dm^3cm^{-1})]: 485 (3.8×10^2), 375 (1.6×10^3), 260 (6.7×10^3). IR: ν(Ru—P) = 532 cm^{-1}, μ_{eff} (Evans' method): 1.78 B.M. at 300 K.

Complexes $[Ru^{III}(EDTA\text{-}H)(P(C_6H_4{-}F)_3)]$ (**3**) and $[Ru^{III}(EDTA\text{-}H)(C_6H_{11})_3]$ (**4**) were prepared following a similar procedure as described for the preparation of **2**. Found: C, 49.4; H, 5.8; N, 3.9. Calc. for $[Ru^{III}(EDTA\text{-}H)P(C_6H_4{-}F)_3]$: C, 50.1; H, 6.9; N, 4.3%. UV–vis, λ_{max} (nm) [ε_{max} (mol^{-1} dm^3 cm^{-1})] = 481 (3.67×10^2).

$[Ru^{III}(EDTA\text{-}H)P(C_6H_{11})_3]$. Found: C, 47.5; H, 3.4; N, 3.9. Calc.: C, 47.6; H, 3.5; N, 4.0%. UV–vis, λ_{max} (nm) [ε_{max} (mol^{-1} dm^3 cm^{-1})] = 487 (4.1×10^2).

The redox potentials for the Ru^{3+}/Ru^{2+} couple of complexes **2**, **3** and **4** determined by cyclic voltammetric studies (vs S.C.E.) are −0.11, −0.14 and −0.27 V, respectively. The ^{31}P NMR spectra of complexes **2**, **3** and **4** give a singlet at δ (ppm) = 25.79, 23.51 and 52.3, respectively. The shifts are in accordance with the decreasing shielding on the phosphorus atom in the phosphines in the order **4**, **2**, **3**.

Instrumentation and techniques

Microanalyses were performed using a Carlo–Erba elemental analyser. The electronic spectra of the complexes were recorded with a Shimadzu-160 UV–vis spectrophotometer. The IR and far-IR spectra were recorded on Beckman Aculab-10 (4000–600 cm^{-1}) and Perkin–Elmer-621 (600–200 cm^{-1}) spectrometers, respectively. pH measurements were performed using a Digisun pH meter with an accuracy of ±0.01 unit. Electrochemical studies were performed with PAR 174A electrochemical apparatus. Cyclic voltammetric studies were performed in 0.1 M $HClO_4$ medium using a glassy carbon working electrode.

Kinetic studies

Kinetics of the catalytic oxidations of PR_3 with molecular oxygen were followed by measuring the absorption of oxygen with time as described earlier.[11] Stoichiometric oxygen atom transfer from $Ru^{V}(EDTA)O^-$ to PR_3 was studied spectrophotometrically by following the decrease in the peak at 393 nm of the complex$Ru^{V}(EDTA)O^-$ with time. For this purpose equal volumes (1 cm^3) of solutions (pre-equilibrated at the desired temperature) of the oxo complex (5×10^{-4} M) and PR_3 (2.5×10^{-3}–2.5×10^{-2} M) were mixed in a spectrophotometric cell and the corresponding pseudo-first-order rate constant (k_{obs}) values were obtained from the absorbance vs time trace by the usual procedure. The rate constant data are reproducible to within ±4%.

Product analysis

The oxidation products PR_3O were analysed by ^{31}P and ^{19}F [(*p*-fluorophenyl)$_3$P] NMR spectra recorded on a JEOL FX-100 NMR spectrometer using phosphoric acid and trifluoroacetic acid, respectively, as standards. The formation of tertiary phosphine oxide with time is shown in Fig. 1.

X-ray crystallographic studies

Large yellowish-orange crystals of the complex could be obtained by recrystallization from an aqueous solution. A crystal of the dimensions $0.19\times0.28\times0.31$ mm was used for data collection. Crystal data are summarized in Table 1. Density

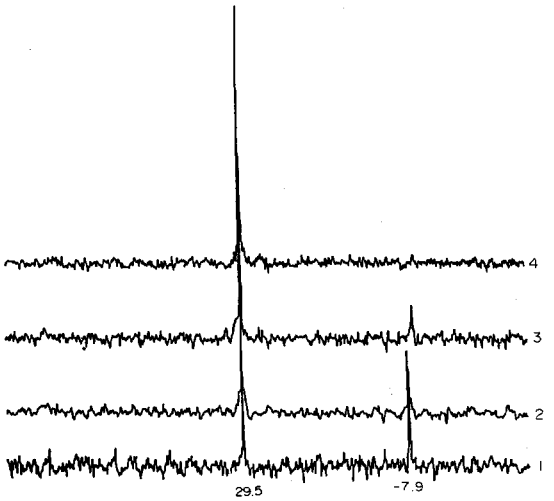

Fig. 1. ^{31}P NMR spectra for the formation of $(C_6H_4—F)_3PO$ with time at 35°C: (a) $t = 30$, (b) 60, (c) 90 and (d) 120 min.

considerations (Table 1) indicated the presence of two independent [Ru(EDTA-H)PPh_3] moieties with some solvent of crystallization. Two sets of reflection controls were used to monitor orientation and decay. Absorption corrections were applied using three intense reflections near Chi = 90°, employing the empirical absorption correction method.[14]

The structure was solved by the heavy atom method and was developed by alternating cycles of isotropic least-squares followed by difference-Fourier syntheses. Three water molecules in addition to two [Ru(EDTA-H)PPh_3] moieties could be located. Hydrogens could be either generated using stereochemical constraints or obtained from difference maps. A mixed mode refinement was adopted in which ruthenium, phosphorus and oxygen were refined anisotropically and carbon and nitrogen isotropically. The hydrogens were fixed employing a weighting scheme with a Dunitz–Seiler factor.[15] This resulted in convergence at an R of 0.031 ($Rw = 0.039$). Because of the large number of atoms refinement was performed in blocks. At the end of the refinement the largest shift-to-error ratio of refined parameters was 0.03; the difference map had ripples of 0.9 e Å^{-1} around the ruthenium atoms. The scattering factors for ruthenium, phosphorus, carbon, nitrogen and oxygen were from Vol. IV of the International Tables for Crystallography,[16] while those of hydrogens were from Stewart *et al.*[17] All the crystallographic computations were obtained using the SDP set of programs available on the PDP-11/73 system.[18]

RESULTS AND DISCUSSION

Figure 2 shows a PLUTO view of molecule **1**; the structure of molecule **2** is similar. The selected bond lengths and angles along with e.s.d.s are shown in Table 2. The PPh_3 moiety is *trans* with respect to one of the nitrogens of the bound EDTA ligand in both the molecules and the resulting ruthenium(III) octahedra are distorted; the dis-

tortion being reflected in the *cis* angles which span from 78.8(2)° to 102.2(2)° in molecule **1** and from 79.4(2)° to 101.4(2)° in molecule **2**. The range from *trans* angles in molecule **1** is 160.6(2)–175.0(20)° and for **2** 162.5(2)–173.2(2)°. The EDTA-aquo complex has a span of 17° in *cis* angles. Part of the increase in the span of *cis* angles in our complex is due to the steric effects produced by the bulky PPh_3 group and part of it comes from the elongated Ru(1)—N(1) distance produced by the *trans* influence of the PPh_3 ligand. The distances involving oxygen atoms coordinating as a pair are smaller [1.998(6), 1.981(5), av. 1.990(6) Å in molecule **1**; 1.999(5), 1.984(6), av. 1.992(6) Å in molecule **2**] than those which coordinate singly [2.060(8) and 2.041(6) Å in molecules **1** and **2**]; a phenomenon found in other metal–EDTA structures[6,19,20] and may have resulted due to the greater coordinating ability of the carboxylate group when both the oxygens are pulled into the coordination sphere of the metal ion. The difference in Ru—O and Ru—N distances involving the coordinated acetato groups and the connecting amino moiety are 0.071(6) and 0.056(6) Å for molecule **1** and 0.087(6) Å for molecule **2**. While part of the difference arises from the difference in the ionic radii of oxygen and nitrogen, the remainder can be attributed to steric factors. Other metal–aminopolycarboxylate derivatives also exhibit the same trend.

The Ru^{III}—O and Ru^{III}—N distances in the structure are within the range reported for [Ru(EDTA-H)(H_2O)],[19] as well as in K[Ru(EDTA-H)Cl]·$2H_2O$.[20] The Ru^{III}—P distances of 2.351(2) Å in the structure compare well with those found for $Ru_2O[O_2(Ph)_2MeCN(PPh_3)_2](ClO_4)\cdot H_2O$,[21] $Ru_2O(O_2C—C_6H_4—P—OMe_4(PPh_3)_2$[22] and $Ru_2Cl_6(DPPM)_2$.[23]

The coordinated C—O lengths (Table 2) in molecule **1** [av. 1.305(1) Å] and molecule **2** [av. 1.287(15) Å] are longer than the uncoordinated C—O bonds (Table 2) [av. 1.21(2) Å] in molecules **1** [av. 1.23(2) Å] and **2**; a situation encountered in other metal complexes of aminopolycarboxylic acids. A difference of 0.07–0.09 Å exists between the C—O lengths, of which the larger value is associated with the oxygen involved in coordination resulting in a stronger metal–oxygen binding. By this complexation the single bond is shortened by 0.03 Å, while the double bond becomes elongated by 0.04 Å.

The O—C—O angle is widened from the value of 120° by 3.3° in **1** and 4° in **2**, which is compensated for by a contraction in the —CCO angles in the coordinated carboxylate groups. In the protonated non-coordinating carboxyl group the difference in C—O lengths is more pronounced; 0.12(1) Å in **1** and 0.14(1) Å in **2**. One of the —CCO angles is widened and the other compressed in molecule **1**, whereas in molecule **2** both the —CCO angles are compressed. The compression of the —CCO angles is due to its involvement in hydrogen bond formation.

The bond lengths and angles in the EDTA moiety lie in the range reported for other structures.[19,20] The torsion angles [N(1)—C(1)—C(2)—N(2)] in **1** and **2** have values of $-56.6(8)°$ and lie in the range (53–63°) reported for similar structures. The ethylenediamine ring adopts an unusual envelope conformation, with the atom C(1) displaced by 0.668(6) Å from the plane of Ru(1)N(1)N(2)C(2) [maximum deviation 0.086(6) Å]. This conformation has been found in other mono-substituted pentadentate EDTA complexes of ruthenium.[19,20] Rings R_1 in **1** and **2** are planar within 0.015(6) and 0.035(6) Å, while rings R_2 and G are more strained and exist as envelopes with N(2) out of the Ru(1)C(7) C(8)O(6) plane by 0.413(6) Å. In ring G N(1) is displaced by $-0.508(6)$ Å from Ru(1)C(3) C(4)O(6) in **1**. The acetate groups are planar within experimental error.

Equilibrium studies for the formation of mixed-ligand $[Ru^{III}(EDTA)(PR_3)]^-$ *complexes*

The formation constants (K_1) of Ru^{III}-EDTA-PR_3 mixed-ligand complexes determined spectrophotometrically[11] at $\lambda_{max} = 481$ nm under nitrogen are summarized in Table 3. The values of the formation constants decrease with a decrease in π-acidity of the PR_3 ligands (Table 3). The stability of the mixed-ligand complex $[Ru^{III}(EDTA)(PR_3)]^-$ decreases in the following order:

$$[Ru^{III}(EDTA)P(C_6H_4—F)_3]^- > [Ru^{III}(EDTA)P(C_6H_5)_3]^- > [Ru^{III}(EDTA)P(C_6H_{11})_3]^-.$$

Catalytic oxidation of PR_3 *with oxygen*

Catalytic oxidations of PR_3 to PR_3O with molecular oxygen were studied in 50% water–dioxane medium. The rate of reaction was found to be first-order with respect to catalyst concentration for each substrate studied. The rate of reaction increases with an increase in PR_3 concentration. At high PR_3 concentration ($[PR_3]/[Cat] > 10^2$) a limit in rate[11] was observed for all the phosphine substrates studied. At constant catalyst (5×10^{-4} M) and PR_3 (5×10^{-3} M) concentrations the rate of reaction was found to be half-order with respect to dissolved oxygen concentration. The kinetic details are similar to those published earlier[11] at 35°C. Based on the above kinetic results a mechanism is proposed, as outlined in Scheme 1, which is similar to that reported earlier.[11]

The catalyst $K[Ru^{III}(EDTA\text{-}H)Cl]$ (**1**) is rapidly aquated when dissolved in water to the corresponding aquo complex (**1a**) at low pH ($\simeq 3$).[23] Complex **1a** reacts with PR_3 to give a mixed-ligand complex (**2**) in a pre-equilibrium step (1) (Scheme 1). The formation of this complex is supported by the successful isolation of (Ru^{III}-EDTA-PR_3) complexes in the present studies. Complex **2** subsequently reacts with dissolved molecular oxygen to form a transient μ-peroxo intermediate (**3**), which undergoes a homolytic cleavage of the O—O bond with one oxygen atom transfer to the substrate in a concerted rate-determining step to give the catalyst (Ru^{III}-EDTA complex) along with the oxidation product (PR_3O). The equilibrium constant (K_2) (determined kinetically)[11] and the rate constant (k) values are summarized in Tables 3 and 4, respec-

tively. The reactivity of the phosphines towards oxidation by molecular oxygen decreases in the order $P(C_6H_4F—P)_3 > P(C_6H_5)_3 > P(C_6H_{11})_3$, which can be explained in terms of the stability of the Ru^{III}-EDTA phosphine and Ru—μ-peroxo bond strengths in the intermediate **3** (Table 3). The fluoro-substituted substrate $P(C_6H_4—F)_3$ has maximum reactivity since it is more π-acidic in nature than $P(C_6H_5)_3$. The electron density at the ruthenium centre is depleted by increasing π-acidity of the PR_3 ligands in the $[Ru^{III}(EDTA)(PR_3)]^-$ mixed-ligand complexes. This is further supported by the positive shift of the redox potentials for Ru^{3+}/Ru^{2+} couples, increasing in the order **3** > **2** > **4**. The stability (K_2) of the μ-peroxo ternary $[Ru^{IV}(EDTA)PR_3]_2O_2$ complexes also increases in the same order.

It is of interest to note that Taqueshi has synthesized Ru^{IV}=O complexes with phosphine coordinated *cis* to the oxo ligand in the complex $[O=Ru^{IV}(bipy)(PPh_3)]$.[24] The coordinated phosphine in this complex is not oxidized to $OPPh_3$. The complex nevertheless oxidizes PPh_3 in solution by an outer sphere mechanism, without the "spectator" phosphine coordinating to the metal ion. In our case, however, the presence of the σ-basic EDTA ligand makes the oxo oxygen of the Ru=O intermediate (after cleavage of the O—O bond in **3**) sufficiently labile for oxygen atom transfer to coordinated phosphine. Thus, the oxygen atom transfer in our case occurs through a coordinated phosphine, as supported by the kinetic evidence (first-order dependence on phosphine concentration). The reaction is slowest in the case of the most basic $P(C_6H_{11})_3$, in which the σ-donation of electrons from phosphine to the metal centre strengthens the O—O bond towards homolytic cleavage. Triphenylphosphine falls between the fluoro and the tricyclohexylphosphine in terms of σ-basicity and π-acidity and thus has a reactivity intermediate of the two extremes.

The catalytic oxidation of PR_3 with molecular

Table 4. Rate and activation parameters for the catalytic oxidations of different aryl-phosphines (PR_3) with molecular oxygen; [Cat] = 5×10^{-4} M, O_2 pressure = 1 atm., pH = 3.0

System	Temperature (°C)	k_1 (s^{-1})	$\Delta H^{\ddagger}$ (kcal mol^{-1})	$\Delta S^{\ddagger}$ (cal ° mol^{-1})	$\Delta G^{\ddagger}$ (kcal mol^{-1})
$Ru^{III}(EDTA)(H_2O)^-/P(C_6H_4F)_3/O_2$	25	1.8×10^{-4}			
	35	3.0×10^{-4}	8±1	−48±2	22.5
	45	4.6×10^{-4}			
$Ru^{III}(EDTA)(H_2O)^-/P(C_6H_5)_3/O_2$	25	1.4×10^{-4}			
	35	2.2×10^{-4}	9±1	−46±2	22.6
		3.9×10^{-4}			
$Ru^{III}(EDTA)(H_2O)^-/P(C_6H_{11})_3/O_2$	25	0.5×10^{-4}			
	35	1.0×10^{-4}	13±2	−36±3	23.3
	45	1.9×10^{-4}			

oxygen was studied at three different temperatures and the activation parameters calculated from the temperature dependence of the rate constant are summarized in Table 4. The low value of $\Delta H^{\ddagger}$ and negative value of $\Delta S^{\ddagger}$ are consistent with the concerted oxygen atom transfer process, as shown in Scheme 1.

Stoichiometric oxygen atom transfer from $Ru^{V}(EDTA)(O)^{-}$ *to* PR_3

In order to probe into the nature of the oxygen atom transfer step in the catalytic oxidation of PR_3 with oxygen we have studied the stoichiometric oxygen atom transfer reaction from the oxo complex $Ru^{V}(EDTA)(O)^{-}$ to the phosphine PR_3 under the pseudo-first-order condition of excess phosphine, where the rate of reaction was found to be first-order with respect to the oxo complex concentration. The rate of reaction increases with an increase in PR_3 concentration (Fig. 3). The above kinetic data suggest the following mechanism [eq. (4)] for the oxo transfer reaction:

$$[Ru^{V}(EDTA)(O)]^{-} + PR_3 \xrightarrow[\mathbf{4}]{k_2} [Ru^{III}(EDTA)(OPR_3)]^{-} \xrightarrow[H_2O]{\text{Fast}} \underset{\mathbf{5}}{} [Ru^{III}(EDTA)(H_2O)]^{-} + OPR_3. \quad (4)$$

In the above mechanism the substrate PR_3 attacks the oxo oxygen in a rate determining redox step to give an $[Ru^{III}(EDTA)(OPR_3)]^{-}$ intermediate, which undergoes rapid hydrolysis to give the $Ru^{III}(EDTA)(H_2O)^{-}$ complex and PR_3O as an oxidation product.

The reactivity order for the oxygen atom transfer reaction in the oxidation of PR_3 by $Ru^{V}(EDTA)(O)^{-}$ decreases in the order $P(C_6H_{11})_3 > P(C_6H_5)_3 > P(C_6H_4—F)_3$, in accordance with the decrease in nucleophilicity of the phosphines. The rate and the activation parameters are reported in Table 5. The small positive value of $\Delta H^{\ddagger}$ and negative $\Delta S^{\ddagger}$ values are in good agreement to the proposed mechanism [eq. (4)].

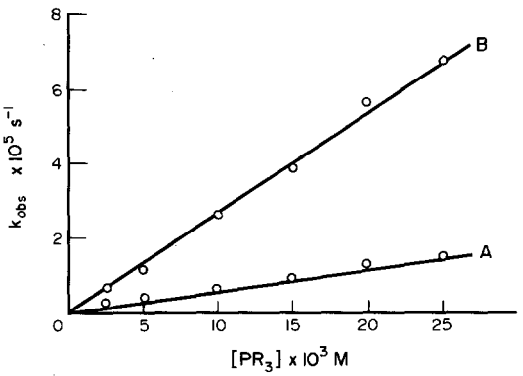

Fig. 3. Effect of $[PR_3]$ on rate constant (k_{obs}) at 30°C: (a) $P(C_6H_5)_3$, (b) $P(C_6H_4—F)_3$; $[Ru^{V}]_T = 5 \times 10^{-4}$ M, pH = 3.0 and μ = 0.2 M (KCl).

It is of interest to compare the free energy of activation, $\Delta G^{\ddagger}$, for the catalytic oxidation of phosphine by molecular oxygen to those observed for the stoichiometric reaction with the oxo complex **4**. $\Delta G^{\ddagger}$ is more positive (2–3 kcal mol^{-1}) for the molecular oxygen reaction compared with $\Delta G^{\ddagger}_2$ for the stoichiometric reaction with complex **4**. The small difference ($\Delta G^{\ddagger} - \Delta G^{\ddagger}_2$), which is significant, reflects on the lowering of the O—O bond dissociation energy in the intermediate μ-peroxo complex **3**.

The interaction of one π^* orbital of the oxygen

Table 5. Rate and activation parameters for the reaction $(EDTA)Ru^{V}{=}O^{-} + PR_3 \rightarrow (EDTA)Ru^{III}(H_2O)^{-} + PR_3O$; $[Ru^{V}] = 5 \times 10^{-4}$ M, pH = 3.0

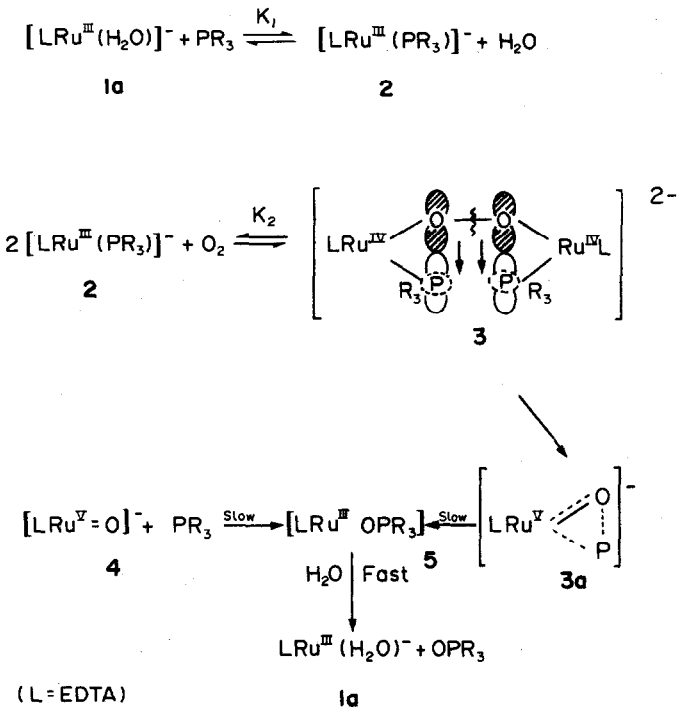
	50	12.1×10^{-2}			



Scheme 2.

atom of the μ-peroxo group with the substrate has been suggested by Solomon *et al.*[25] as the crucial step in the oxygen atom transfer reaction in tyrosinases. The oxygen atom transfer to phosphine in the molecular oxygen oxidation occurs through a concentrated homolytic cleavage of the μ-peroxo bond, assisted by electron withdrawal by the substrate and transfer of oxo oxygen to phosphine to form Ru^{III}-OPR_3 (**5**) species. This interaction may be triangular **3a** with the association of phosphine either with the metal ion or/and the oxo oxygen. The rate-determination step in this case is the transfer of oxo oxygen to the phosphine to form Ru^{III}-OPR_3 species (Scheme 2).

(*Received* 16 *December* 1992; *accepted* 4 *March* 1993)

Abstract—The compound $Pb(O_2CCH_3)_2$(18-crown-6)·$3H_2O$ was synthesized via the reaction of either an aqueous solution of lead(II) acetate with 18-crown-6 or by reaction of lead(II) carbonate with acetic acid and 18-crown-6 in water. The product was shown to be monomeric in the solid state, as determined by single-crystal X-ray diffraction. The molecule is markedly asymmetric with both acetate ligands chelating to the same side of the 10-coordinate lead(II) centre. Solid-state FTIR of a crystalline sample revealed a difference, Δ, in ν_{asym}(C—O) and ν_{sym}(C—O) of 612 cm^{-1}. Solution ^{207}Pb NMR spectroscopy was consistent with coordination of the 18-crown-6 ligand to the lead centre in aqueous solution. Thermogravimetric analysis studies showed that $Pb(O_2CCH_3)_2$(18-crown-6)·$3H_2O$ thermally decomposed in air to form crystalline PbO at 380°C.

There has been considerable interest in the formation of perovskite phase mixed-metal oxide materials because they exhibit a variety of interesting physical and chemical properties including dielectric, pyroelectric, ferroelectric and piezoelectric phenomena,[1–3] superconductivity,[4] catalytic activity[5] and oxygen transport.[6] For many applications it is desirable that crystalline thin films of these materials be formed at low temperatures. The deposition of thin, crystalline films of these materials is being attempted by gas phase routes such as chemical vapour deposition (CVD) and liquid phase routes[7] commonly involving sol–gel reaction chemistry.[8] Both these routes suffer from the common problem that metal–organic complexes of a number of the necessary components, most notably the metal-organic complexes of the divalent metals Pb, Ca, Sr and Ba, have a strong tendency to oligomerize. These cations are large,[9–11] exhibit high coordination numbers and their oligomerization reduces both the volatility and solubility of their complexes.[12–15] However, these problems are being circumvented by either reducing the cation coordination number through introduction of sterically demanding ligands, or introducing polydentate ligands into the coordination sphere of the metal. For example, the monomeric barium(II) compound $Ba[N(SiMe_3)_2]_2(THF)_2$[16] with sterically demanding amido ligands, and the monomeric polyether complexes M(18-crown-6)$(hfac)_2$ (18-crown-6 = 1,4,7,10,13,16-hexaoxacyclooctadecane), where M = Sr, Ca and Ba,[17] Ba(2,5,8,11,14-pentaoxapentadecane)$(hfac)_2$[18,19] and $Ba[O(CH_2CH_2O)_nCH_3]_2$ (n = 2, 3)[20] were recently prepared. However, much less work has been devoted to developing soluble or volatile lead compounds suitable for the synthesis of lead-based metal oxide ceramics.

Here we report the synthesis, characterization and solid-state single-crystal X-ray diffraction study of a monomeric lead(II) carboxylate compound, $Pb(O_2CCH_3)_2$(18-crown-6)·$3H_2O$. This species was prepared to investigate the ester elimination reaction between lead(II) carboxylates and titanium alkoxides that has been proposed to result in the formation of crystalline $PbTiO_3$.[21–26]

EXPERIMENTAL

General procedures

All reactions were performed under ambient conditions with no attempt to exclude atmospheric oxygen or moisture. All hydrocarbon and ethereal solvents were dried and distilled from sodium benzophenone ketyl and stored over 4 Å molecular sieves. Acetic acid, lead(II) carbonate, lead(II) acetate and 18-crown-6 starting materials were purchased from Aldrich Chemical Co. and used without further purification. Elemental analyses were performed by Ms R. Ju at the University of New Mexico, Department of Chemistry. NMR data were recorded on a Bruker AC-250P NMR spectrometer using the protio impurities of the deuterated solvents as references for the ^{1}H NMR and the ^{13}C resonance of the solvents as a reference for ^{13}C NMR spectroscopy. Temperatures were calibrated with either ethylene glycol or methanol. ^{207}Pb NMR data were recorded on a Bruker AC-250P NMR spectrometer at 52.3 MHz using the $Pb(NO_3)_2$ resonance (−2900 ppm) as an external reference. IR data were recorded on a Perkin–Elmer model 7000 series instrument under an air atmosphere.

Syntheses

Preparation of $Pb(O_2CCH_3)_2(18\text{-crown-6})\cdot 3H_2O$. $PbCO_3$ (0.58 g, 2.17 mmol) and 18-crown-6 (1.25 g, 4.72 mmol) were suspended in water (20 cm^3) and acetic acid (0.28 g, 4.67 mmol) was added. Alternatively, $Pb(O_2CCH_3)_2$ (1.75 g, 4.61 mmol) and 18-crown-6 (2.58 g, 9.76 mmol) can be dissolved in water (30 cm^3). The resulting clear solutions were stirred for at least 3 h and the volatile portion of the mixture was removed to leave a sticky white solid. Excess 18-crown-6 was removed by washing with dried pentane and the resulting white powder was air-dried; yield 93%. Characterization data: $Pb(O_2CCH_3)_2(18\text{-crown-6})\cdot H_2O$: ^{1}H NMR ($D_2O$, 300 K, 250 MHz): 3.43 (s, O_2CCH_3), 1.98 ppm [s, $(CH_2CH_2O)_6$]. IR (KBr pellets): 3456 (s), 2889 (s), 1567(vs), 1406 (s), 1100 (vs). Found: C, 30.9; H, 5.9. Calc. for $C_{16}H_{36}O_{13}Pb$: C, 29.9; H, 5.6%. Calc. for $Pb(O_2CCH_3)_2(18\text{-crown-6})\cdot 2H_2O$, $C_{16}H_{34}O_{12}Pb$: C, 30.7; H, 5.9% TGA (air, 1 atm.): 96.4% at 120°C [$Pb(O_2CCH_3)_2(18\text{-crown-6})\cdot 2H_2O$, calc. 97.2%], 46.5% at 270°C [$Pb(CH_3COO)_2$, calc. 50.5%], 33% at 380°C (PbO, calc. 34.9%). The final decomposition product was confirmed to be a mixture of α-PbO and Massicot phases by powder X-ray diffraction.

X-ray crystallographic studies

Crystals suitable for single-crystal X-ray diffraction study of $Pb(O_2CCH_3)_2(18\text{-crown-6})\cdot 3H_2O$ were grown by slow evaporation of water and were sealed in a glass capillary. The crystal data collection and refinement parameters are collected in Table 1. The determination of the space group $P2_1$ in the monoclinic crystal system was unambiguous. A semi-empirical correction for absorption was applied to the data. Of the 4580 data collected (max. $2\theta = 50°$), 3664 were both observed ($3\sigma F_o$) and independent. All non-hydrogen atoms were refined with anisotropic thermal parameters and hydrogen atoms were treated as idealized contributions. At convergence, $R(F) = 3.45\%$, $R(wF) = 2.81\%$, GOF = 1.07, highest unassigned peak in the final difference map = 1.50 Å^3. All computations used SHELXTL-PLUS software systems (G. Sheldrick, Siemens Corp., Madison, WI, U.S.A.). Selected bond lengths and angles are given in Tables 2 and 3. The atom numbering scheme of the molecule is shown in Figs 1 and 2 and a ball-and-stick drawing showing the positions of the water molecules is given in Fig. 3. Figure 4 is a schematic representation of the coordination environment about lead(II). Supplementary material is available from the Cambridge Crystallographic Database.

RESULTS AND DISCUSSION

The compound $Pb(O_2CCH_3)_2(18\text{-crown-6})\cdot 3H_2O$ was synthesized either by reacting $PbCO_3$, 18-crown-6 and acetic acid in a 1:2:2 molar ratio or the direct reaction of $[Pb(O_2CCH_3)_2]$ and 18-

crown-6 in a 1:2 molar ratio in aqueous solution. The reaction mixtures were stirred for 3 h after they became clear. A sticky white solid was collected upon removal of the volatile components *in vacuo*, which was washed with hexane until all free 18-crown-6 was removed. The resulting white solid *completely* dissolved in water and the ^1H NMR spectrum in D_2O showed two resonances at 3.43 (CH_2) and 1.98 ppm (CH_3) in the integrated ratio 24:6, respectively, corresponding to the empirical formula $Pb(O_2CCH_3)_2$(18-crown-6). The presence of water in the crystalline material could not be distinguished unambiguously from these NMR data obtained in D_2O. Elemental analysis was consistent with the empirical formula $Pb(O_2CCH_3)_2$(18-crown-6)·$2H_2O$ and the presence of the hydroxyl functionality was confirmed by IR spectroscopy through observation of a band at 3456

cm^{-1}. This solid did not completely dissolve in benzene-d_6, the integration ratio of the soluble material changed to 48 (3.46 ppm): 6 (1.98 ppm) with the precipitation of $Pb(O_2CCH_3)_2$. Attempts to sublime this material at *ca* 10^{-2} torr and 120°C resulted in the sublimation of 18-crown-6 only. This observation indicated that the strength of interaction between the lead centre and the polyether ligand was weak.

For further investigation of the nature of the interaction between the lead centre and the 18-crown-6 ligand a saturated aqueous solution of $Pb(O_2CCH_3)_2$ was titrated with aliquots of 18-crown-6 and monitored by ^{207}Pb NMR spectroscopy.[27-29] The ^{207}Pb resonance of saturated $Pb(O_2CCH_3)_2$ aqueous solution was observed at −1338.2 ppm, consistent with the literature data.[28] The addition of the 0.5 equivalent amount of 18-

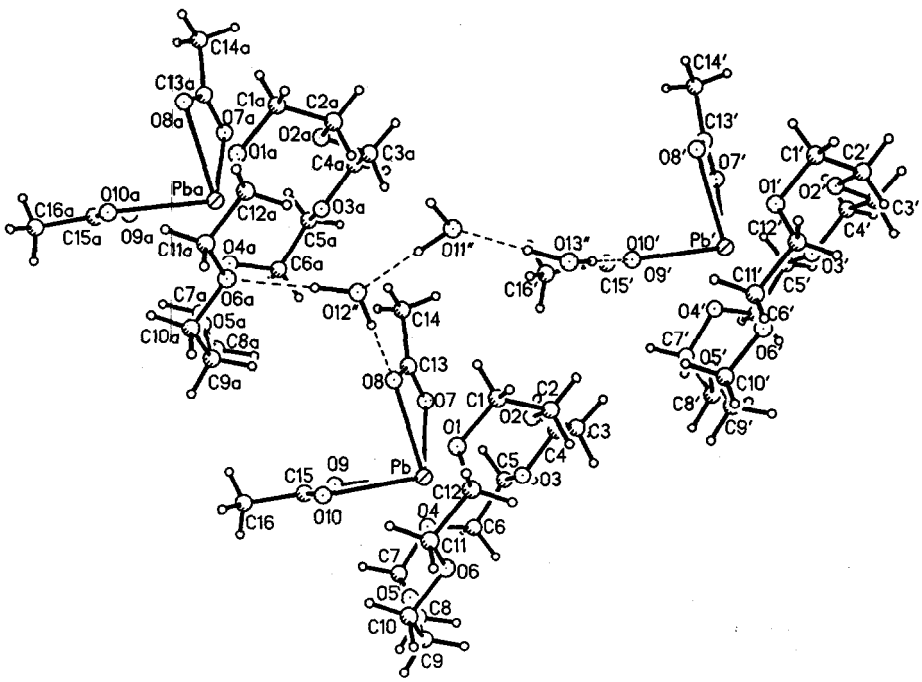

Fig. 3. Ball-and-stick drawing of the crystal structure of $Pb(O_2CCH_3)_2(18\text{-crown-6})\cdot 3H_2O$, emphasizing the intermolecular hydrogen bonding interactions.

crown-6 lead to complete disappearance of the intense ^{207}Pb resonance, probably as the result of an exchange process on the NMR time-scale. The ^{207}Pb resonance reappeared at −2492.5 ppm, and was sharp only after 2 equivalents of 18-crown-6 were added. Further addition of 18-crown-6 did not affect either the peak position or intensity. These data show that the presence of the 18-crown-6 ligand has a marked effect on the chemical environment of the lead.

To provide further information on the interaction between $Pb(O_2CCH_3)_2$ and 18-crown-6 a solid-state single-crystal X-ray diffraction study was performed. This revealed the presence of three water molecules of crystallization with the empirical formula $Pb(O_2CCH_3)_2$(18-crown-6)·$3H_2O$. ORTEP plots of two views of the molecular structure are shown in Figs 1 and 2 and relevant bonds lengths and angles are given in Tables 2 and 3, respectively. The lead atom is bonded to two chelating acetate groups at distances consistent with the sums of the covalent radii for lead oxygen (2.52 Å), with Pb—O(10) slightly longer (2.745 Å).[11] The 18-crown-6 ligand is asymmetrically coordinated to the lead with Pb—O distances that range from 2.867 to 3.184 Å. These distances are significantly longer than Pb—O bonding interactions and are consistent with the observed lability of this ligand. Some of the asymmetry in the coordination of the 18-crown-6 and acetate ligands maybe due to hydrogen bonding between the water molecules and these ligands. The water molecules are hydrogen bonded between O(6) of the 18-crown-6 ligand of one molecule and either O(8) or O(10) of an acetato ligand of an adjacent molecule, as shown in Fig. 3. It is interesting that the Pb—O(8) distance is normal, while Pb—O(10) is significantly lengthened.

Other lead(II) carboxylate compounds that have been characterized to date exhibit oligomeric or polymeric structures in the solid state and typically possess bridging carboxylate ligands as a general structural feature.[30–34] The complete abstinence of the acetate ligands in bridging interactions in the case of $Pb(O_2CCH_3)_2$(18-crown-6)·$3H_2O$ is highly unusual and is probably a result of the steric protection and coordinative saturation afforded by the 18-crown-6 ligand. The lead(II) centre is approximately 10-coordinate with no obvious free coordination site apparent for a stereochemically active lone pair. The coordination geometry is shown in Fig. 4. This geometry is quite different to that recently observed for $Pb(NO_3)_2$(18-crown-6),[35] which exhibits a more symmetrical structure where the lead ion lies in the centre of the 18-crown-6 ring and the bidentate nitrate ligands are coordinated above and below this plane.

The monomeric nature of this complex, which results in the presence of *chelating* acetate ligands that do not participate in bridging to another metal centre, provides a point of comparison with the literature correlation between the carbonyl stretching frequencies and carboxylate ligand coordination mode. It has been proposed that unidentate, chelating and bridging carboxylate ligands can be distinguished by the difference (Δ) between the asymmetric and symmetric carbonyl stretching frequencies.[36,37] Complexes that contain unidentate carboxylate ligands exhibit Δ values that are greater than that of the free carboxylate ion (164 cm^{-1} for acetate), while those that are chelating exhibit values that are significantly lower. Bridging carboxylate ligands exhibit Δ values that are similar to those of the free ion. In this case crystalline $Pb(O_2CCH_3)_2$(18-crown-6)·$3H_2O$ exhibited ν_{asym}(C—O) of 1567 cm^{-1} and ν_{sym}(C—O) of 1406 cm^{-1}, giving a Δ value of 161 cm^{-1}. Thus, based on this correlation, it might have been predicted that the acetate ligand was bidentate and bridging. However, these predictions are somewhat complicated by the presence of water which is hydrogen bonded to the acetate ligands in this compound.

Thermogravimetric analysis of this compound showed three distinct transformations as a function of increasing temperature. On heating to 120°C a weight loss corresponding to the loss of one water molecule was observed, consistent with the formation of $Pb(O_2CCH_3)_2$(18-crown-6)·$2H_2O$. This observation is also consistent with the elemental analysis data. Further heating to 270°C resulted in a weight loss consistent with the loss of the remaining water molecules and 18-crown-6 to form lead acetate. This species then lost weight, consistent with the formation of PbO at 380°C. X-ray powder diffraction analysis showed that crystalline PbO had been formed, which existed as a mixture of two phases, α-PbO and Massicot.

CONCLUSIONS

The synthesis and characterization of a monomeric lead(II) carboxylate compound have been achieved through steric and electronic saturation of the lead coordination environment with the polyether 18-crown-6 ligand. The resultant molecule is surprisingly asymmetric in the solid state and the 18-crown-6 ligand appears to be weakly coordinated to the lead centre. IR spectra reveal ν(C—O) stretching mode differences which are inconsistent with literature trends, although this may be complicated by the water molecules of crystallization present. Thermal decomposition of the title compound resulted in the formation of

crystalline lead(II) oxide at 380°C. Further studies are in progress to examine the reactivity of this species towards metal alkoxide compounds and to utilize this lead compound for the formation of perovskite phase mixed-metal oxide materials.

(*Received* 27 *January* 1993; *accepted* 3 *March* 1993)

Abstract—The ^{197}Au Mössbauer spectra of some chloro-gold(III) and -gold(I) compounds with N-alkylimidazole- or -benzoaxole-type ligands are reported and discussed. Two sites of types $AuNCl_3$ and $[AuCl_4^-][HNR^+]$, or AuNCl and $[AuCl_2^-][HNR^+]$ (where N indicates the 3-nitrogen atom of the imidazole- or benzoxazole-type ligands, R), are evidenced. Their ratio depends on a delicate balance between electronic and steric effects.

Gold compounds are interesting, *inter alia*, for their biological and medical applications: some gold(III) complexes seem to have antitumoral activity[1,2] and the presence of N-donor ligands has been considered suitable for modern chrysotherapy.[3,4] Understanding the mechanism of the biological activity of such compounds requires an understanding of their chemistry, i.e. knowledge of their structure and bonding. X-ray crystal data are not always available because of the lack of suitable crystals and such an occurrence is not rare in the field of gold chemistry.

In spite of the disadvantages of ^{197}Au Mössbauer spectroscopy,[5,6] in comparison with that of ^{57}Fe or ^{119m}Sn, such as the short half-life of the ^{197}Pt parent isotope and the low recoil-free fraction which requires the use of low temperatures, the technique provides a useful method for elucidating the structure and bonding of gold compounds in the solid state.[7–9] Progress in the interpretation of the ^{197}Au spectra has resulted, in particular, from the availability of the increasingly reliable correlations of isomeric shift and quadrupole splitting with chemical properties such as the oxidation state and the gold coordination number, as well as with the electronic influence of the ligands.[6]

Since the presence of azoles, purines and pyrimidines as constitutive parts of nucleic acids, vitamins, coenzymes and antibiotics is well known, it seemed useful to investigate the coordinating behaviour of azole-type ligands toward gold(III) and gold(I) to detect the influence of different substituents on the electronic structure and hence on their possible biological activity.[10] For this purpose Mössbauer spectroscopy has been employed in the study of some chloro-gold(III) and -gold(I) compound with N-alkylimidazole- or -benzoaxole-type ligands, in order to extract structural and electronic information.

* Author to whom correspondence should be addressed.

RESULTS AND DISCUSSION

The spectra exhibit two superimposed Mössbauer quadrupole doublets, except for those of samples **4** and **6** (Fig. 1). The parameters such as isomer shift, IS, quadrupole splitting, QS, and linewidth, LW, are listed in Table 1. As shown in Fig. 2, where the observed IS and QS parameters are reported, together with the literature linear relationships for gold(III) and gold(I) complexes[11] samples **1–6** are considered containing gold(III) and samples **7** and **8** gold(I) sites. The unsplit line, with shift of *ca* -1.25 mm s^{-1}, in the spectrum of **3** or **4** (Fig. 1) indicates the presence of metallic gold[5] formed because of partial decomposition of the sample.

The spectrum of **6** (Fig. 1) exhibits, within the limits of detection of the ^{197}Au resonance,[5] one electric quadrupole interaction. Its spectral parameters compare well with those reported[12] for $C_5H_5NAuCl_3$ (IS 1.45 mm s^{-1}) and $(C_5H_5)_2N_2AuCl_3$ (QS 2.22 mm s^{-1}) suggesting a similar stereochemistry, i.e. a more-or-less distorted square-planar site $AuNCl_3$. The larger doublet exhibited from samples **1–3** and **5**, with QS and IS in the range 1.87–2.20 and 1.34–1.40 mm s^{-1}, respectively, is analogously indicative of the site $AuNCl_3$, in agreement with their IR, UV and ^1H NMR data.[10]

The spectrum of **4** (Fig. 1) consists of a quadrupole-split doublet together with a more intense unsplit line, assigned to metallic gold. The doublet with larger splitting, before attributed to the site $AuNCl_3$, is not evidenced in the fit indicating the complete reduction of its site to metallic gold. The parameters of the quadrupole interaction detected in sample **4** (and for the similar interaction exhibited from the second site in **1–3** and **5**), requiring a donor more electronegative than the heterocyclic nitrogen, are more consistent with a site of type $AuCl_4$ than $AuNCl_3$.

Such a spectral component is not attributable to the starting material $HAuCl_4 \cdot 4H_2O$ (IS 0.71 and QS 0.98 mm s^{-1}),[13] since its presence is not consistent with conductivity data[10] or the fitting procedure. The alternative possibility of an increase in the gold coordination number in the site $AuNCl_3$ is ruled out since the expected splitting should be too small in comparison with the observed ones. The last possiblity demands the attribution of such a spectral component to the $AuCl_4$ hydrogen bonded

to the heterocyclic nitrogen in the site of type $[AuCl_4^-][HNR^+]$ (where N indicates the 3-nitrogen atom of the imidazole- or benzoxazole-type ligands, R).

Compared with $HAuCl_4 \cdot 4H_2O$ the larger splitting for the sites $[AuCl_4^-][HNR^+]$ in **1**–**5** implies a larger anisotropy among the σ-bonding orbitals and then a larger principal component of the electric field gradient tensor along the symmetry axis. The imbalance in electron charge would arise from differences in the gold *p*- and *d*-electron involvement in the Au—Cl bonds. As a consequence a large difference in the Au—Cl bond lengths is predicted for the sites of type $[AuCl_4^-][HNR^+]$ in comparison with those reported for $HAuCl_4 \cdot 4H_2O$: Au—Cl 2.283 (×2) and 2.286 Å (×2).[14]

As shown in Fig. 2 the two quadrupole-split doublets of samples **7** or **8** have parameters typical of linearly coordinated gold(I), in agreement with their IR and ^{1}H NMR measurements.[10] Additional evidence for linearly coordinated gold(I) is provided, in the framework of the point-charge model, by the agreement between the experimental splitting and that predicted using the partial quadrupole splitting values of −1.57 for Cl[6] and −2.09 mm s^{-1} (the value for 2-isopropylimidazole[8] as a working approximation) for N-EtIm or N-PrIm. Since the predicted splittings for the sites AuNCl and $AuCl_2^-$ are −7.32 and −6.28 mm s^{-1}, respectively, the observed larger splittings in **7** and **8** can be attributed to AuNCl and the smaller ones tentatively to the site of type $AuCl_2$.

In comparison with $AuCl_2^-$ (IS 0.59 and QS 6.28 mm s^{-1}),[12] the second site of samples **7** or **8** presents less *s*-electron density, not delocalized in the *sp* hybridization, and less population in the p_z-orbital. These effects cannot be explained with the possible presence of distortions in the $AuCl_2$ site since the plot of Fig. 3 shows that the quadrupole splitting calculated by the point-charge[15] does not reproduce the observed splittings of **7** and **8** within a realistic Cl—Au—Cl angular distortion. Instead a possible cause is the involvement of one chloride in hydrogen bonding of type $[AuCl_2^-][HNR^+]$ (N is the 3-nitro-

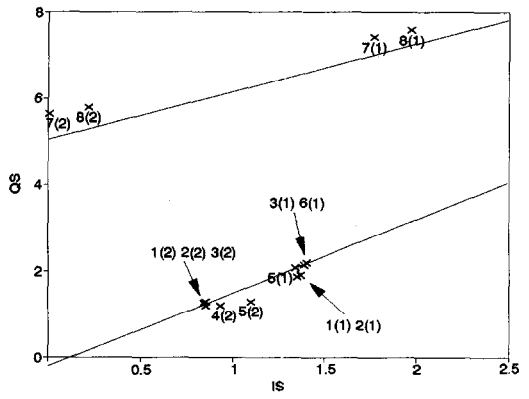

Fig. 2. Plot of QS vs IS values. The first number is that of Table 1. The second number indicates the gold site: 1 for $AuNCl_3$ or AuNCl, 2 for $[AuCl_4^-][HNR^+]$ or $[AuCl_2^-][HNR^+]$. The linear relationships for gold(III) and gold(I) compounds are QS = $-0.22+1.74$ IS and QS = $5.05+1.06$ IS, respectively.

gen atom of N-EtIm or N-PrIm) in cases connected to an increase in the gold coordination number.

On going from the sample **1** to **6** is generally observed an increase in the *s*-electron density, not involved in the dsp^2 hybridization, together with an increase in *p*-asymmetry or *d*-symmetry around the gold centre. Both effects are due to the small increase of the σ-donor strength produced by alkyl substitution at the N-atom in the imidazole-type ligands or by methyl insertion in benzoxazole. Therefore, the ligands may be roughly ordered following their increasing donor ability: Cl < N-MeIm < N-EtIm < N-PrIm and 2-MeBO < 2,5-diMeBO. The trend is also confirmed by the spectral parameters of the two gold(I) samples **7** and **8**.

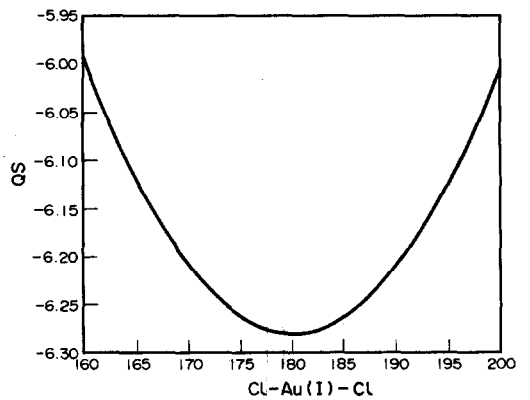

Fig. 3. Plot of the quadrupole splitting (in mm s^{-1}) calculated by the point-charge model[15] vs the angular distortion Cl—Au—Cl in (°).

The presence in the samples of two gold sites, one without hydrogen bonding and the other hydrogen bonded, in a variable ratio seems to be the result of steric and electronic effects. In fact the growing steric hindrance of the alkyl in the imidazole-type ligands (samples **1–3**, **7** and **8**), or that of one or two methyls in benzoxazole (**4–6**), may hamper the formation of the weaker hydrogen-bonded gold site among close molecular units. The accommodation of ligands with growing steric hindrance may introduce substantial deviations in the gold coordination geometry up to steric inhibition in the formation of weaker bonding. This effect is generally observed in Table 1, where the per cent of the hydrogen bonded site is larger in the presence of the less hindered ligand (sample **1**), decreases for more hindered ligands (samples **2**, **3**, **7** and **8**) and is negligible in the presence of the ligand 2,5-diMeBO (sample **6**).

The introduction of an additional hydrogen-bonded gold site might improve the comprehension of the Mössbauer spectra reported, *inter alia*, for some chlorogold nucleosides. In particular it might give a better comprehension of the Mössbauer spectra of $Au(trino)Cl_3$ and $Au(trguo)Cl_3$ (trino, triacetylinosine; trguo, triacetylguanosine) interpreted in the past on the basis of the presence of the sole gold site $AuNCl_3$.[16] Since the observed quadrupole doublet for such nucleosides (as reported in Fig. 2 and Table 1 or ref. 14) is asymmetric, the fit has been performed using a couple of different lines. On the contrary the introduction of an additional gold site might improve the fit by using couples of lines with equal width and equal intensity. In conclusion two sites of the types $AuNCl_3$ and $[AuCl_4^-][HNR^+]$ or AuNCl and $[AuCl_2^-][HNR^+]$ (where N indicates the 3-nitrogen atom of the imidazole- or benzoxazole-type ligands, R) are generally present in the reported chlorogold derivatives. Their ratio depends on the delicate balance between electronic and steric effects.

EXPERIMENTAL

The compounds have been prepared using solvents with gold and monodentate ligands in the required stoichiometric ratio. The compounds are microcrystalline, generally soluble in DMSO, DMF and $CHCl_3$ and non-conductors in DMSO. The compounds have been characterized by elemental analysis, conductivity measurements, UV, IR and ^1H NMR data.[10] The IR spectra were recorded again after the Mössbauer measurements and no change was observed.

The ^{197} Pt activity feeding the 77.3 keV Mössbauer transition was produced by neutron irradiation of enriched ^{196}Pt metal. Both source and

absorber were kept at 4.2 K. A sinusoidal velocity wave-form and an intrinsic Ge detector were used. The spectra have been fitted by the program MOS 90 with sets of equal Lorentzian lines. The calculated errors were *ca* 0.02 mm s^{-1} or 1 for per cent data.

For high-energy Mössbauer transitions the approximation of equal Lamb–Mössbauer factors is not correct[7] and in particular when metallic gold and gold(III) are present, as in samples **3** or **4**, the contributions to the resonance area are not proportional to their masses. In order to estimate the ratio of the Lamb–Mössbauer *f*-factors for gold (III) and metallic gold sample **6** was selected as a probe, since it contains merely one gold(III) site. The Mössbauer spectrum of the specimen containing sample **6** (74.92 mg Au cm^{-2}) together with the reference metallic gold (8.84 mg Au cm^{-2}) was collected at 4.2 K and the ratio $fAu^{III} : fAu = 3:10$ used to calculate the per cent data for samples **3** and **4** in Table 1.

STRUCTURE AND MAGNETIC EXCHANGE OF AN IMIDAZOLATE-BRIDGED COPPER DIMER: [(dtma)Cu(im)Cu(dtma)]$ClO_4 \cdot 2.5H_2O$

MAO ZONGWAN, FU DEGANG, HANG QINWEI and TANG WENXIA*

(*Received* 27 *November* 1992; *accepted* 3 *March* 1993)

Abstract—The compound of the formula [(dtma)Cu(im)Cu(dtma)]$ClO_4 \cdot 2.5H_2O$ (where dtmaH is 4-diethylenetriamineacetic acid and im is the imidazolate anion) was synthesized and its crystal structure determined by X-ray diffraction methods. The structure consists of a dimeric complex bridged by the deprotonated imidazole. The geometries of the coordination polyhedron around the copper(II) ions are very near to tetragonal pyramid. The *X*-band ESR powder spectrum shows broad $\Delta M = 1$ and weak $\Delta M = 2$ absorptions. Variable-temperature (4.2–300 K) magnetic susceptibility data gave the antiferromagnetic interaction parameters $J = -37$ cm^{-1}. This behaviour is best accounted for by a superexchange mechanism involving σ- and π-exchange pathways.

Binding of imidazole-type molecules to metal complexes is a subject of considerable interest because of the frequency occurrence of imidazole derivatives in biologically important metal complexes. One of the most extensively studied members of this group is the Cu—Zn superoxide dismutase,[1] which has been shown by X-ray crystallography to have an imidazole bridge between the two metals. Temperature-dependent ESR measurements on the modified enzyme, in which zinc(II) has been substituted by copper(II), show that the two copper(II) ions are antiferromagnetically coupled with a singlet–triplet separation ($2J$) of -52 cm^{-1}.[2]

Consequently a number of imidazolate bridged polynuclear copper(II) units have been prepared.[3–7] In most of them the non-bridging ligands are polydentate amine ligands. These studies have shown that the magnitude of the antiferromagnetic exchange is strongly dependent upon the geometry and energy of the singly occupied metal orbitals and the highest occupied orbitals of the bridging group.

Most recently, an interesting new compound, [(dtma)Cu(im)Zn(dtma)]$ClO_4 \cdot 2.5H_2O$, containing an imidazolate-bridged copper(II)–zinc(II) binuclear unit, was reported as a possible model for the Cu, Zn-SOD,[8] in which the non-bridging ligand contains a carboxylate. In this paper the synthesis and structure of the compound [(dtma)Cu(im)Cu(dtma)]$ClO_4 \cdot 2.5H_2O$ is reported and the magnetic susceptibility data are discussed in detail.

EXPERIMENTAL

Preparation of [(dtma)Cu(im)Cu(dtma)]$ClO_4 \cdot 2.5H_2O$

The ligand dtmaH (4-diethylenetriamineacetic acid, $C_6H_{15}N_3O_2$) and the complex [Cu(dtma)]ClO_4 were prepared as described in the literature.[8,9] The title complex was prepared as follows:

[Cu(dtma)]ClO_4 (0.646 g, 2 mmol) and imH

* Author to whom correspondence should be addressed.

(0.068 g, 1 mmol) were mixed in water (15 cm^3) and then NaOH solution (1.0 cm^3, 1.0 N) was added with stirring. By slow evaporation of the solution, blue prismatic crystals were obtained. After being filtered, washed with water and ethanol and dried the title compound was obtained, 0.433 g (yield 65.6%). Found: C, 27.3; H, 5.2; N, 16.7; Cu, 19.1. Calc. for $C_{15}H_{36}ClN_8O_{10.5}Cu_2$: C, 27.3; H, 5.5; N, 17.0; Cu, 19.2%.

Crystal structure determination of [(dtma)Cu(im)Cu(dtma)]$ClO_4 \cdot 2.5H_2O$

Crystal data. $C_{15}H_{36}ClN_8O_{10.5}Cu_2$, $M = 659.02$, monoclinic, space group $P2_1/a$, $a = 13.133(2)$, $b = 14.224(3)$, $c = 15.788(3)$ Å, $\beta = 114.22(2)°$, $V = 2690(1)$, $Z = 4$, $D_c = 1.63$ g cm^{-3}, (Mo-K_α) = 0.71073 Å, (Mo-K_α) = 17.46 cm^{-1}, $F(000) = 1364$.

Data collection. A blue single crystal ($0.20 \times 0.40 \times 0.40$) was mounted on an R3M/E four-circle X-ray diffractometer. Data were collected at room temperature, in the ω–2θ scan mode with 8° min^{-1} scan speed and graphite-monochromated Mo-K_α radiation. Of the 4498 reflections measured (h: 0–15, k: 0–16, l: −18–18, $2° \leqslant 2\theta \leqslant 47°$), 4408 were unique and 3088, having $I > 3\sigma(I)$, were used for the fine refinement. The intensities of three standard reflections measured revealed no significant variation (<3%). Data for intensities were corrected for Lorentz–polarization effects and no absorption corrections have been made.

Structure solution and refinement. The structure was solved by heavy-atom techniques. The atomic coordinates of metal atoms were first obtained by analysing Patterson functions. The other non-hydrogen atom coordinates were gradually obtained by Fourier synthesis. After all the coordinates and isotropic and anisotropic thermal parameters of the non-hydrogen atoms were refined the hydrogen atom coordinates were obtained from difference-Fourier synthesis and analysis of geometry. Finally, the coordinates, the anisotropic thermal parameters of non-hydrogen atoms and the isotropic thermal parameters of hydrogen atoms were refined by block diagonal-matrix least-squares. All calculations were performed on an Eclipse/S140 computer with the SHELXTL program system (SHELXTL, 1985). The final R was 0.0669, $R_w = 0.0581$, where $w = [1 - \exp(-5 \sin\theta/\lambda)^2]/[\sigma^2(F) + 0.0001(F)^2]$, for all observed reflections. Further details are presented as supplementary data, together with thermal parameters, bond lengths and angles, mean average planes and structure factors.

Physical measurements

The ESR spectra at X-band frequency were recorded with a Bruker ER 200D-SRC spectrometer at 110 K. Magnetic susceptibility measurements in the temperature range 4.2–300 K were obtained on a model CF-1 vibrating-sample magnetometer using the Faraday method.

RESULTS AND DISCUSSION

Description of structure

Selected bond lengths and angles are given in Table 1. The structure of the title compound is shown in Fig. 1, together with the atomic numbering system.

The structure consists of one complex cation, $[(dtma)Cu(im)Cu(dtma)]^+$, one ClO_4^- anion and two and a half water molecules. In the cation two copper atoms are bridged by a deprotonated imidazole to form a binuclear complex. The coordination polyhedron around the copper(II) ions is better described as a distorted tetragonal pyramid. Each copper atom is penta-coordinate, surrounded by an approximate basal plane of four nitrogen atoms from the dtma and imidazolate ligands and by one oxygen atom of the dtma ligand situated on the axis of a distorted tetragonal pyramid. The best planes are calculated through N(1), N(2), N(3) and N(4) and N(5), N(6), N(7) and N(8) atoms, the dihedral angle of which is 46.3° and the separations of Cu(1) and Cu(2) from which are 0.235 and 0.236 Å, respectively. The average values of the angles $\angle O_{axial}—Cu—O_{basal}$ are 96° for both Cu(1) and Cu(2), while those of the angles $\angle N—Cu—N$ (neighbouring) in the basal plane are 89°. Likewise, the distortion (Δ) of the coordination polyhedron, from trigonal bipyramid ($\Delta = 0$) towards a regular tetragonal pyramid ($\Delta = 1$), has been calculated according to Mutterties and Galy.[10,11] The values obtained, $\Delta = 0.82$ and $\Delta = 0.64$ for Cu(1) and Cu(2), respectively, indicate that the geometry of coordination around the copper atoms is close to TP in a different degree.[13,14]

The average bond lengths of Cu—N (at the apex of the dtma ligand) and Cu—O are 2.076 and 2.184 Å, respectively. The distance between two copper atoms in the Cu—im—Cu moiety is 5.984 Å. The bond distances of N—C and C—C in the imidazolate anion group range from 1.330 to 1.371 Å and the bond angles from 103.9 to 113.5°, which are very close to the corresponding values in other imidazolate-bridged compounds.[8,12] While the constituent atoms of the imidazolate anion all lie within ±0.004 Å of the best mean plane through the ring

N(4)—C(9)—N(5)	113.5(5)		

Cu(1) and Cu(2) are 0.016 and 0.041 Å, respectively, out of the plane. The two ions are attached on the same side of this plane.

Magnetic properties

The X-band ESR spectra of the title complex measured in undiluted polycrystalline powder and DMSO frozen solution at 110 K are shown in Fig. 2. In both cases a $\Delta M = 1$ signal appears as a single broad absorption at $g = 2.075$ or $g = 2.079$. A much weaker signal is observed at $g = 4.611$ and is recognized as a $\Delta M = 2$ transition. The broadening of the $\Delta M = 1$ transition and the absence of hyperfine structure suggest that the interaction would be mainly dipolar in character. The appearance of the $\Delta M = 2$ signal indicates a magnetic interaction between the copper(II) ions of the binuclear complex bridged by imidazolate.

Variable-temperature (4.2–300 K) magnetic susceptibility data for the title compound show antiferromagnetic interactions with a maximum in their susceptibility against temperature curve at *ca* 47 K. The magnetism of this compound is analysed on the basis of the revised Bleaney–Bowers equation[15]:

$$\chi_M = \frac{2Ng^2\beta^2}{kT}[3+\exp(-2J/kT)]^{-1}(1-\rho) + \rho\frac{2Ng^2\beta^2S(S+1)}{3kT} + N_\alpha. \quad (1)$$

Here ρ is the mole fraction of paramagnetic impurity.[16]

The temperature-independent paramagnetism N_α was taken as 60×10^{-6} e.m.u. mol^{-1} for copper.[17] The other symbols have their usual meaning. The best-fit parameters are $g = 2.177$, $J = -37.3$ cm^{-1} and $\rho = 0.00025$. The generalized R factor, $R = [\Sigma\chi_M(\text{obs.}) - \chi_M(\text{calc.})]^2/\Sigma\chi_M(\text{obs.})^2$, a convenient statistical indicator of the quality of fit, was

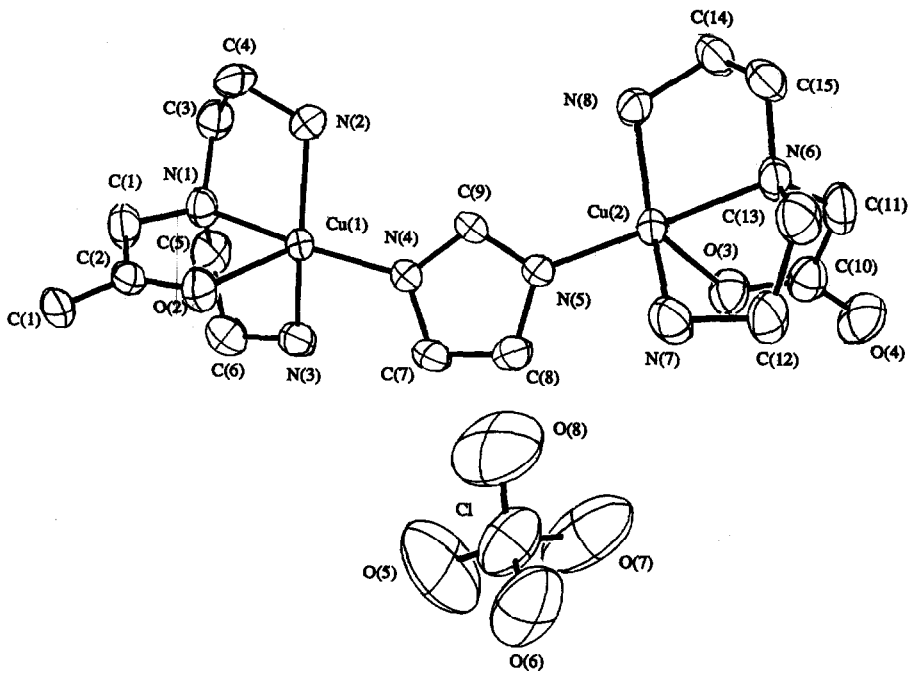

Fig. 1. Molecular structure of $[(dtma)Cu(im)Cu(dtma)]ClO_4$.

0.0008. The susceptibility against temperature data obtained are given in Fig. 3, together with a theoretical curve calculated from eq. (1), which is represented by a solid line, and obviously the fit to the experimental data is good for the whole range of temperatures.

Exchange mechanism

All the imidazolate-bridged copper(II) complexes having been reported exhibit antiferromagnetic exchange interactions with J varying from 0 to -88 cm^{-1}. The value of J of the title complex is just in this range and is almost equal to that of the compound $[(tren)Cu(im)Cu(tren)](ClO_4)_3$ [$J = -38$ cm^{-1}, trend = tri(2-ethylamine)amine], which has the same bridging ligand and a similar terminal ligand. The structural study of the title complex shows that the copper–copper distance in the Cu—im—Cu moiety is 5.984 Å. The observed coupling is too large to result from direct, through-space copper–copper interactions; the exchange is, there-

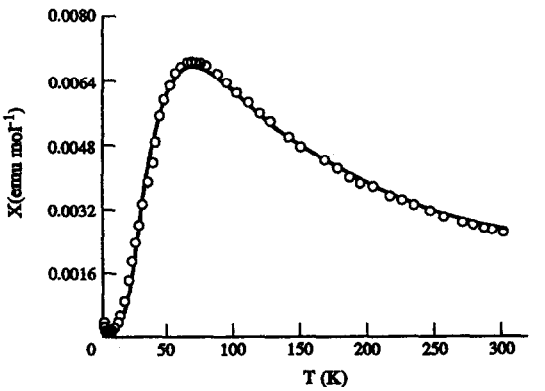

Fig. 3. The temperature dependence of the magnetic susceptibility (χ_M/e.m.u. mol^{-1}) of $[(dtma)Cu(im)Cu(dtma)]ClO_4 \cdot 2.5H_2O$. The experimental data are represented as circles and the line results from a least-squares fit to eq. (1).

fore, mediated by the bridging imidazolate ligand.

For square-planar or square-pyramidal copper(II) complexes the unpaired electron is in the $d_{x^2-y^2}$ orbital. In terms of Hoffmann's model[18] linear combinations of the two $d_{x^2-y^2}$ orbitals are given by eqs (2) and (3), where a and b refer to the two copper atoms.

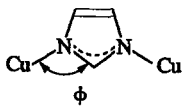
$$\varphi_S \simeq d^a_{x^2-y^2} + d^b_{x^2-y^2} \quad (2)$$

$$\varphi_A \simeq d^a_{x^2-y^2} - d^b_{x^2-y^2} \quad (3)$$

In the absence of a bridging ligand φ_A and φ_S are degenerate in energy. On combining with bridging ligand orbitals of appropriate symmetry the antibonding orbitals of the resulting species are separated by an energy difference of $E_1 - E_2$. $-2J$ is related to $E_1 - E_2$ by eq. (4), where K_1 and K_2 are nearly constant quantities for small perturbations of the system. Equation (4) indicates that the larger the energy difference $E_1 - E_2$ the stronger the antiferromagnetic exchange interaction.

$$-2J = E_T - E_S = -2K_1 + (E_1 - E_2)^2/K_2 \quad (4)$$

It has been suggested that both the σ- and π-orbitals of the imidazole ligand are capable of acting as the superexchange pathways between copper atoms.[3,19] In a σ-pathway two linear combinations of the nitrogen lone pair orbitals interact with the metal linear combination φ_S and φ_A, respectively. The magnitude of J perhaps correlates the ϕ angle of $\angle$Cu—N—$C(2)_{im}$.[3] The ϕ angles are generally



in the range 120–130° and the J values vary from -17 to -38 cm^{-1}. In a π-pathway the $d_{x^2-y^2}$ orbitals of copper atoms may interact with the π-orbitals of the imidazolate ion. The π-exchange pathway should be appreciable only when θ, which is defined as the dihedral angle between the imidazolate ring and copper coordination square plane, differs considerably from 0 to 90°. Spatial overlap of the copper $d_{x^2-y^2}$ and imidazolate π-orbitals is expected to be quite poor compared with the overlap with imazolate σ-orbitals (nitrogen lone pair) due to the long ($\geqslant 3$ Å) copper–carbon distance.[19]

The values of ϕ_1, ϕ_2, θ_1 and θ_2 of the title complex have been calculated and are 129.5, 129.0, 27.9 and 22.6°, respectively. The φ angles are in range 120–130° and θ angles are considerably different from 0°. These facts indicate that the exchange interactions involve two pathways. However, the average copper–carbon distance of imidazolate is 2.991 Å, approximately 3 Å, which indicates that the π-exchange interaction is very weak. The above results show that the σ-orbitals of the bridging imidazolate group provide the main, not the only, superexchange pathway in the compound reported here.

SYNTHESIS AND CHARACTERIZATION OF A SERIES OF $[Mo_3O_4(CN)_{9-x}(H_2O)_x]^{(5-x)-}$ ($x = 0$–3) IONS

J. SZKLARZEWICZ and A. SAMOTUS*

Faculty of Chemistry, Jagiellonian University, Ingardena 3, 30-060 Kraków, Poland

(*Received* 27 *January* 1993; *accepted* 26 *February* 1993)

Abstract—Thermal or photochemical decomposition of $(bpyH)_3(H_3O)[Mo(CN)_8]\cdot H_2O$ in aqueous solutions gives amorphous salts with anions formulated as $[Mo_3O_4(CN)_{9-x}(H_2O)_x]^{(5-x)-}$ ($x = 0$–3). The series of mixed-ligand complexes was characterized by chemical analyses, UV–vis, IR and ESR spectrometry, as well as cyclic voltammetry, thermogravimetry and electrophoresis measurements. Chemical reactions, typical of molybdenum(IV) trimers, support the formulation of salts as containing the (Mo_3O_4) core.

The composition and structure of molybdenum(IV) complexes in acidic aqueous solutions has been the subject of several investigations.[1–15] X-ray crystallographic studies of $Cs_2[Mo_3O_4(C_2O_4)_3(H_2O)_3]\cdot 4H_2O\cdot 0.5H_2C_2O_4$,[2] $Cs_2[Mo_3O_4(C_2O_4)_3(H_2O)_3]\cdot CF_3SO_3\cdot 3H_2O$,[8] $Na_2[Mo_3O_4((O_2CCH_2)_2NCH_3)_3]\cdot 7H_2O$,[6] $Na_4[(Mo_3O_4)_2(edta)_3]\cdot 14H_2O$,[3] $[(CH_3)_4N]_4[Mo_3O_4(NCS)_8(H_2O)]\cdot 3H_2O$,[5] $[Pt(en)_2][Mo_3O_4(C_2O_4)_3(H_2O)_3]\cdot 3H_2O$[9] and $[Mo_3O_4(H_2O)_9](CH_3C_6H_4SO_3)_4\cdot 13H_2O$[13] have demonstrated that all possess the incomplete cuboidal (metal depleted) trinuclear core $Mo_3O_4^{4+}$ (Fig. 1), with near C_{3v} symmetry, Mo—Mo distance of *ca* 2.5 Å, Mo—μ_3-O, 2.0–2.1 Å, Mo—μ_2-O, 1.90–1.95 Å and Mo—O_3—Mo angle of *ca* 76°. It was established that in this type of cluster the oxygen atoms of the core are extremely inert,[4,9,10,13] whereas other ligands (e.g. H_2O, SCN^- and $C_2O_4^{2-}$) are much more labile and susceptible to substitution.[1,4,9,12,13]

Considerable effort has been devoted to the synthesis of the trimeric Mo^{IV}_{aq} and related complexes. These are obtained in acidic solutions (HCl, CH_3SO_3H, Hpts = *p*-toluenesulphonic acid) by the comproportionation reaction of molybdenum(II) or molybdenum(III) and molybdenum(V) or molybdenum(VI).[4,7,13] To obtain pure solutions of Mo^{IV}_3 cation-exchange chromatography is generally used, but this lowers the yield of the reaction.

In recent years we have studied the chemistry and photochemistry of the reaction of $[M(CN)_8]^{4-}$ with bpy (M = Mo, W; bpy = 2,2′-bipyridine).[16–20] In this work we have found that $(bpyH)_3(H_3O)[Mo(CN)_8]\cdot H_2O$ can be converted with relatively good yield into a compound whose properties are analogous to those of the molybdenum(IV) trimers. To date there have been no such studies on trimeric molybdenum(IV) ions with cyano ligands. The latter cannot be prepared by standard methods due to the evolution of HCN in acidic solution required for synthesis.

EXPERIMENTAL

Reagents and physical measurements

The synthesis of initial $(bpyH)_3(H_3O)[Mo(CN)_8]\cdot H_2O$, analytical methods and physical measurements (IR, UV–vis, ESR and thermogravimetry) were as described earlier.[16,17] Reflectance spectra (in $BaSO_4$) were recorded on a VSU 2P (Carl Zeiss, Jena) spectrophotometer.

Electrophoresis was performed using an OE210 apparatus (Hungary) with silica gel plates and aqueous 0.5 M $NaClO_4$ as an electrolyte. Cyclic

voltammetry measurements* were obtained as described earlier[21] (the potentials are reported vs NHE). Ion exchange measurements were performed using a Dovex IR120 ion exchange resin (in H^+ form).

Steady-state photolysis was performed using a medium-pressure mercury quartz lamp with open output in a glass flask under argon. Irradiation of an aqueous solution of 0.1 M $(bpyH)_3(H_3O)[Mo(CN)_8]$ was performed for periods of up to 6 h.

Syntheses

The trimeric complexes were prepared from $(bpyH)_3(H_3O)[Mo(CN)_8]\cdot H_2O$ using two simple methods and only one example of each procedure is given.

Tris-2,2′-bipyridinium diaquaheptacyanotetraoxotrimolybdate(IV), $(bpyH)_3[Mo_3O_4(CN)_7(H_2O)_2]$. Method (a): A solution (2.5×10^{-2} M) of $(bpyH)_3(H_3O)[Mo(CN)_8]\cdot H_2O$ (natural pH = 2.8) was heated at 80°C for 2 h. The resulting reddish-brown amorphous product was filtered, washed with water and ethanol and then dried in air.

Method (b): The same solution (2.5×10^{-2} M) of $(bpyH)_3(H_3O)[Mo(CN)_8]\cdot H_2O$ was irradiated with a medium-pressure mercury quartz lamp (main line 365 nm) under argon for 6 h to obtain a solid product, which was treated as above.

Details of the synthesis, yields and analytical data for the complexes are given in Table 1.

*The measurements were performed at the Department of Chemistry of the University of Ferrara, Ferrara, Italy.

The conversion of **1–4** *into* $Mo_3O_4^{4+}{}_{aq}$ *and* $[Mo_3O_4(NCS)_{9-x}(H_2O)_x]^{(5-x)-}$

The following methods were used to convert the $[Mo_3O_4(CN)_{9-x}(H_2O)_x]^{(5-x)-}$ complexes into trimers described in the literature:

(a) The solid complex was treated with $AgNO_3$ (0.5 M) in HNO_3 (0.2 M) and the mixture was heated up to 40°C and allowed to stand for 4 h. After filtration excess Ag^+ ions in the supernatant were removed by the addition of KCl and the resulting AgCl was filtered to yield a red solution of $Mo_3O_4^{4+}{}_{aq}$ ions. The identity of these ions was confirmed by electrophoresis, ion exchange experiments and UV–vis spectrophotometry.

(b) A similar procedure was used to obtain a solution of $Mo_3O_4^{4+}{}_{aq}$, except $HgCl_2$ was used as the precipitating agent for cyano ligands.

(c) The solid complex was treated with an aqueous solution (1.3 M) of NH_4SCN in Hpts (0.2 M). After 3 days standing the mixture was filtered to leave a red solution. Ion exchange experiments and electrophoresis show the negative charge of the ion (as expected for $x \leqslant 4$). Electronic absorption spectra match those previously reported for this type of complex.

RESULTS AND DISCUSSION

Syntheses

Thermal decomposition of $(bpyH)_3(H_3O)[Mo(CN)_8]\cdot H_2O$ in aqueous solutions of natural pH (pH $\leqslant$ 3) yields a brown amorphous salt. The same result can be obtained upon irradiation of an aqueous solution of this salt with polychromatic light. The composition of the product

depends on the concentration of $(bpyH)_3(H_3O)[Mo(CN)_8]\cdot H_2O$ (Mo:CN ratio changes from 1:2 in diluted solutions to 1:3 in saturated ones), but the analytical data always fit the trimeric compound (Table 1). In the conditions described repeated syntheses and analyses always produced the same results; the analytical data at concentrations between those reported in Table 1 indicate a mixture of compounds. It is noteworthy that the maximum number of cyano ligands per $Mo_3O_4^{4+}$ core was nine and no more ligands could be incorporated into the coordination sphere of the trimer. Thus, compound **4** should be the last complex of the series and not a mixture of higher and lower cyano analogues. In more dilute solutions ($c < 10^{-3}$ M) no precipitation of salt was observed. The change in colour suggests, however, the presence of lower cyano trimers, which are probably more soluble. Ion exchange experiments and electrophoresis of such solutions indicate the positive charge of the red ions.

The characteristic feature is that the complex with nine cyano ligands is formed only in more concentrated ($c > 0.3$ M) solutions where a large concentration of CN^- is present. The other compounds are formed by reversible aquation of the cyano complex in more dilute solutions. Similarly, a single-crystal X-ray study[5] showed that the typical complex formed with SCN^- as the ligand is $[Mo_3O_4(NCS)_8(H_2O)]^{4-}$, while the nine thiocyanato analogue requires very rigorous concentration conditions.

The reaction of **1–4** with $AgNO_3$ or $HgCl_2$:

$$[Mo_3O_4(CN)_{9-x}(H_2O)_x]^{(5-x)-} + (9-x)Ag^+ \longrightarrow [Mo_3O_4(H_2O)_9]^{4+} + (9-x)AgCN + xH_2O \quad (1)$$

resulted in the formation of $Mo_3O_4^{4+}{}_{aq}$, with $\lambda_{max} = 505$ nm and $\varepsilon = ca\ 60\ M^{-1}\ dm^3\ cm^{-1}$ per molybdenum (lit. data: $\lambda_{max} = 505$ nm, $\varepsilon = 63\ M^{-1}\ dm^3\ cm^{-1}$[7,12]). The red salt thus obtained is positively charged (as discovered by electrophoresis and ion exchange chromatography) and its electrochemical behaviour is identical to that described for $Mo_3O_4^{4+}{}_{aq}$ (quasi-reversible reduction at -0.154 V in 0.5 M $HClO_4$; the potential increases with increasing acid concentration).[22–25]

The reaction with a concentrated solution of thiocyanate:

$$[Mo_3O_4(CN)_{9-x}(H_2O)_x]^{(5-x)-} + 9SCN^- \longrightarrow [Mo_3O_4(NCS)_9]^{5-} + (9-x)CN^- + xH_2O \quad (2)$$

is expected to give the $[Mo_3O_4(NCS)_9]^{5-}$ ion,[9,26]

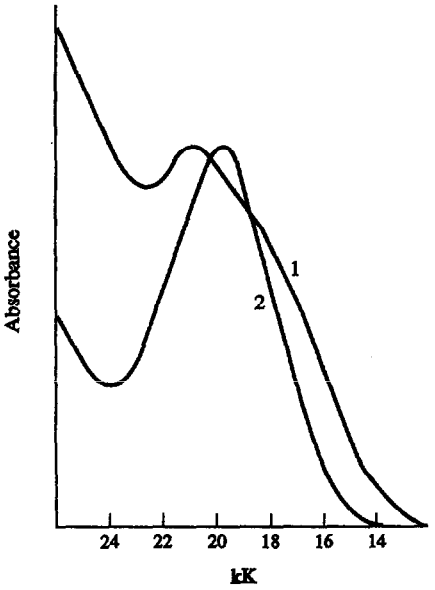

Fig. 2. Visible electronic spectra of **1** after treatment with concentrated KSCN solution in Hpts (curve 1) and after dilution with 1 M Hpts (curve 2).

which shows the appropriate ion-exchange and electrophoresis properties (negative charge) and electronic spectra (Fig. 2). The spectrum of the solution diluted by 1 M Hpts correlates very well to the spectrum of $[Mo_3O_4(H_2O)_9]^{4+}$. All these data suggest that the parent compounds also contain the Mo_3O_4 entity.

Characterization of the complexes

The products are stable towards air oxidation. They are insoluble in polar and non-polar solvents, but they dissolve in alkaline aqueous solution or basic solvents (such as pyridine) with decomposition and oxidation to molybdates.

The ESR spectra indicate that complexes **1–4** are diamagnetic, whereas the redox titration with $KMnO_4$ (under argon) indicates the two-electron oxidation per molybdenum, showing the presence of molybdenum(IV) but the absence of $Mo(CN)_8^{4-}$ ions which are oxidized to molybdenum(V). In the reflectance spectra the band at *ca* 520 nm is attributed to the transition within the quasi-aromatic cluster $Mo_3O_4^{4+}$ [27] and bands typical of the $bpyH^+$ cation and Mo^{IV}-CN anions (at 240 and 310 nm) also appear. No peaks can be seen for the complexes in the near-IR region (mixed-valence band).

As expected the complexes show strong IR bands at 2105–2115 cm^{-1}, typical for C≡N stretching vibrations (Table 2). When the charge of the anion decreases from -2 to -5 (from **1** to **4**), the strength

Table 2. Selected IR frequencies (in cm^{-1}) for salts **1–4**

Complex	Band (intensity) ν(M—O)		ν(CN)	ν(OH)	Intensity ratio[a] ν(OH)/ν(CN)	Molar ratio H_2O/CN^-
1	743(10)	960(10)	2115(10)	3400(5.4)	0.39	0.50
2	747(5.8)	956(7)	2115(10)	3400(4.2)	0.27	0.29
3	747(8.0)	955(10)	2110(10)	3400(2.7)	0.12	0.13
4	748(10)	961(10)	2105(10)	3400(1.5)	—	—

[a] The intensity of OH stretching vibrations was corrected assuming as a background the intensity of the band for salt **4**, which contains only the lattice water.

of the C≡N bonds also decreases. The lack of any shift compared with monomeric cyano complexes of molybdenum(IV) indicates that no CN^- bridging of the two molybdenum centres occurs. In the region typical of OH stretching vibrations (3100–3400 cm^{-1}) we observed a band at 3400 cm^{-1}, assigned to coordinated water molecules. The relative intensity of this band can be roughly correlated (after subtraction of the background) with the molar ratio of H_2O to CN^- in the complex anions (Table 2). All four complexes show bands at 956 and 747 cm^{-1}, assigned to the molybdenum–oxygen–molybdenum bridging system.

CONCLUSIONS

It is now well established that the reddish coloured $[Mo_3O_4(H_2O)_9]^{4+}$ ion is present in acidic solution containing only weakly complexing acids such as HCl, CH_3SO_3H or Hpts. In the presence of complexing agents the substituted ions are formed. We have found simple synthetic procedures based on the thermal or photochemical decomposition of $(bpyH)_3(H_3O)[Mo(CN)_8]\cdot H_2O$ leading to cyano-substituted compounds, $[Mo_3O_4(CN)_{9-x}(H_2O)_x]^{(5-x)-}$ ($x = 0$–3). It was established that the $Mo_3O_4^{4+}$ core can be transferred from one to the other compound, whereas CN^- ligands are labile and susceptible to substitution.

HIGHEST Co^{III}–Co^{II} REDOX POTENTIAL IN $Co^{II}N_6$ ($S = 3/2$) COMPLEXES OF TRIDENTATE LIGANDS. PREDOMINANCE OF STERIC OVER ELECTRONIC EFFECT

S. MAHAPATRA, T. K. LAL and R. N. MUKHERJEE*

Department of Chemistry, Indian Institute of Technology, Kanpur 208 016, India

(*Received* 7 *January* 1993; *accepted* 26 *February* 1993)

Abstract—Using the tridentate ligand 2,6-bis(pyrazol-1-ylmethyl)pyridine and its methyl-substituted derivatives a new group of high-spin grossly octahedral cobalt(II) complexes has been synthesized and characterized. The field strength of these ligands with high-spin cobalt(II) progressively decreases with an increase in the number of methyl substituents near the donor site, as revealed from their crystal-field spectral analysis. The trends in the anodic peak potentials (Co^{III}–Co^{II} couple with $E_{1/2}/E_{pa}$ values of 0.78–1.06 V vs S.C.E.) are rationalized on the basis of predominance of the steric effect over the electronic effect of the methyl groups present near the donor site.

We have recently reported the synthesis of a group of three tridentate pyridylpyrazole ligands (L^1—L^3) and demonstrated the novel redox behaviour of their high-spin manganese(II), high-spin iron(II) and low-spin ruthenium(II) bis chelates.[1–3] It has been found that a systematic fine tuning of the M^{III}/M^{II} redox potentials from steric[1,2] over electronic to effectively an electronic[3] effect can be achieved. Additionally, we have discovered that the ligand L^1 induces temperature-dependent spin-transitions toward Fe^{2+}.[4]

The present work originates from our search for unusually stable cobalt(II) states toward oxidation in $Co^{II}N_6$ ($S = 3/2$) coordination, exploiting the steric effects of L^1–L^3 ligands. Here we report the outcome of this endeavour.

EXPERIMENTAL

Materials

Solvents were purified as before.[5] Tetrabutylammonium perchlorate was prepared/purified as reported previously.[6]

Synthesis of complexes

$[Co(L^1)_2](ClO_4)_2 \cdot 2H_2O$. To an ethanolic solution (5 cm^3) of L^1 (100 mg, 0.42 mmol) was added an aqueous solution (5 cm^3) of $CoCl_2 \cdot 6H_2O$ (50 mg, 0.21 mmol). The mixture was stirred at room temperature for 30 min, after which time a saturated aqueous solution (1 cm^3) of sodium perchlorate was added. The pale yellow microcrystalline solid was collected, washed with C_2H_5OH–H_2O (1:1 v/v) and dried *in vacuo* (yield *ca* 68%). Found: C, 40.4; H, 3.7; N, 18.2. Calc. for $C_{26}H_{30}N_{10}O_{10}Cl_2Co$: C, 40.4; H, 3.9; N, 18.1%. Λ_M (298 K, MeCN) = 270 Ω^{-1} cm^2 mol^{-1}. ^1H NMR (CD_3CN, δ downfield of $SiMe_4$): −10.2 (H^4), −8.0 (CH_2), −6.6 ($H^{3'}$). 17.2 ($H^{4'}$), 55.2 ($H^{5'}$), 60.4 (CH_2), 62.2 ($H^{3,5}$).

$[Co(L^2)_2](ClO_4)_2 \cdot 2H_2O$. To a stirred solution of L^2 (150 mg, 0.56 mmol) in ethanol (10 cm^3) was added an aqueous solution (5 cm^3) of $Co(ClO_4)_2 \cdot 6H_2O$ (100 mg, 0.27 mmol). The mixture was stirred for 1 h and kept at room temperature for slow evaporation. Orange crystals were

collected after 48 h, washed with C_2H_5OH/H_2O (1 : 1 v/v) and dried *in vacuo* (yield *ca* 62%). Found: C, 43.3; H, 4.6; N, 16.7. Calc. for $C_{30}H_{38}N_{10}O_{10}Cl_2Co$: C, 43.5; H, 4.6; N, 16.9%. Λ_M (298 K, MeCN) = 260 Ω^{-1} cm^2 mol^{-1}.

$[Co(L^3)_2](ClO_4)_2 \cdot 2H_2O$. This complex was synthesized following a similar method as described above for the ligand L^2 (yield *ca* 75%). Found: C, 46.0; H, 5.3; N, 15.9. Calc. for $C_{34}H_{46}N_{10}O_{10}Cl_2Co$: C, 46.2; H, 5.2; N, 15.8%. Λ_M (298 K, MeCN) = 263 Ω^{-1} cm^2 mol^{-1}. ^{1}H NMR (CD_3CN, δ downfield of $SiMe_4$): −28.8 ($Me^{3'}$), −9.6 (H^4), −3.2 (CH_2), 16.8 ($H^{4'}$), 22.8 ($Me^{5'}$), 63.8 ($H^{3,5}$), 82.0 (CH_2).

CAUTION! Although no problem was experienced in handling these complexes, perchlorate salts of complexes with organic groups should be regarded as potentially explosive.

Measurements

Conductivity and spectroscopic data were obtained as described previously.[5,6] Solution-state magnetic susceptibility was obtained by the NMR technique of Evans[7] in MeCN with a PMX-60 Jeol (60 MHz) NMR spectrometer.

The magnetic susceptibility of a powdered sample of $[Co(L^1)_2](ClO_4)_2 \cdot 2H_2O$ was measured by using the Faraday method between 8 and 300 K. Diamagnetic contributions (-306×10^{-6} cm^3 mol^{-1}) were applied with the use of Pascal's constants.[8] The details of the measurements are as described previously.[9] The system was calibrated using $Hg[Co(SCN)_4]$ and $[Fe(acac)_3]$ (acac = acetylacetonate anion). Variable-temperature magnetic moment data for $[Co(L^1)_2](ClO_4)_2 \cdot 2H_2O$ (T/K, μ_{eff}/μ_B): 300, 5.12; 280, 5.18; 260, 5.24; 240, 5.30; 220, 5.32; 200, 5.39; 180, 5.38; 160, 5.44; 140, 5.51; 120, 5.53; 100, 5.53; 80, 5.51; 60, 5.47; 40, 5.35; 20, 5.12; 11.8, 5.07; 8.8, 5.07.

All electrochemical experiments were performed under a dinitrogen atmosphere using a Princeton Applied Research (PAR) Model 370-4 electrochemistry system, as described previously.[5,6] The data were collected at 298 K, referenced to an aqueous S.C.E. and are uncorrected for junction potentials. The cyclic voltammetric measurements utilized a planar Beckman Model 39273 platinum inlay as a working electrode. The solutions were *ca* 1.0 mM in the complex and 0.2 M in the supporting electrolyte. The $E_{1/2}$ values were calculated as the average of the cathodic (E_{pc}) and anodic (E_{pa}) peak potentials.

RESULTS AND DISCUSSION

Synthesis, magnetism and ligand field spectra

The synthetic method reported herein for the preparation of cobalt(II) bis-chelates is relatively straightforward. The reaction of $CoCl_2 \cdot 4H_2O$ or $Co(ClO_4)_2 \cdot 6H_2O$ with the appropriate tridentate ligand in aqueous methanol affords complexes with a 1 : 2 metal-to-ligand ratio, having the general formula $[CoL_2](ClO_4)_2 \cdot 2H_2O$ (when $CoCl_2 \cdot 4H_2O$ was used a saturated aqueous solution of $NaClO_4 \cdot H_2O$ was added to isolate the desired product). The orange to pale yellow complexes are indefinitely stable in air. The complexes are 1 : 2 electrolytes[10] in MeCN solution.

Solution-state magnetic susceptibility measurements reveal that these cobalt(II) complexes are high-spin octahedral with a ground term of $^4T_{1g}$ origin.[11–13] The temperature-dependent solid-state magnetic behaviour of $[Co(L^1)_2](ClO_4)_2 \cdot 2H_2O$ has been examined (see Experimental) and is prototypical of the magnetically dilute high-spin cobalt(II) ion in a grossly octahedral field.[13]

The absorption spectral properties of these complexes were examined (Table 1) in MeCN solutions and the behaviour of a representative complex is displayed in Fig. 1. The spectra of these complexes are similar to those observed for grossly octahedral high-spin cobalt(II) complexes.[11] In the present complexes the number of *d–d* transitions are more due to low symmetry (*vide infra*) in the ligand field component. Following Figgis,[14] Dq and B were calculated (as it was not possible to obtain an unambiguous choice of parameters[13] to fit the solid-state magnetic data we have ignored the spin-orbit coupling term) as 1200 and 750 cm^{-1}, respectively. Similarly, for $[Co(L^2)_2]^{2+}$ and $[Co(L^3)_2]^{2+}$ the Dq values were calculated as 1120 and 1080 cm^{-1}, respectively, and the corresponding B values are 770 and 830 cm^{-1}, respectively. From the above three com-

plexes B_{av} was calculated as 786 cm^{-1}, which is approximately 70% of the free-ion value (1120 cm^{-1}).[14] This indicates *ca* 30% covalent character in the metal–ligand bonds. A most interesting result that is emerging is the gradual reduction in $10Dq$ values toward cobalt(II) in going from L^1 to L^2 to L^3. It is the increased steric crowding near the donor sites (3-methyl substituents) that progressively decreases the value of $10Dq$ due to interligand steric interactions. Similar effects were also observed in the iron(II)[1] and nickel(II)[15] complexes of these ligands.

^{1}H *NMR spectra*

To extract structural information in these six-coordinate cobalt(II) ($S = 3/2$) complexes in CD_3CN we have investigated the ^{1}H NMR spectral

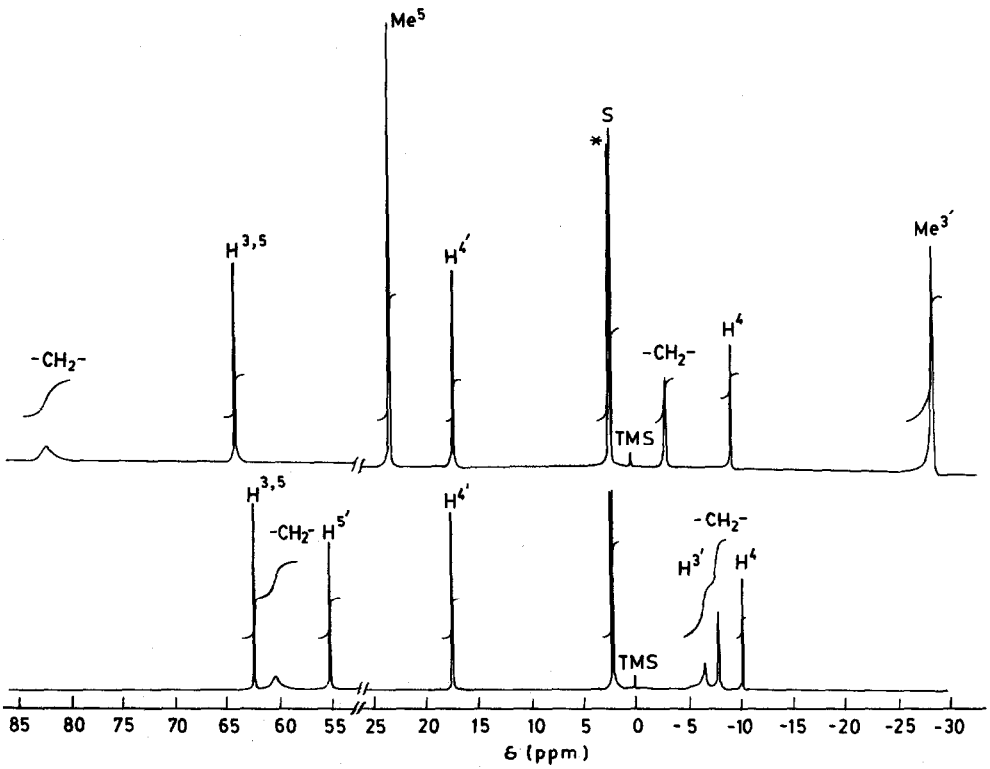

Fig. 2. 400 MHz ^{1}H NMR spectra of $[Co(L^1)_2](ClO_4)_2 \cdot 2H_2O$ and $[Co(L^3)_2](ClO_4)_2 \cdot 2H_2O$ in CD_3CN (solvent and water peaks marked by S and *, respectively).

properties of two representative complexes, $[Co(L^1)_2]^{2+}$ and $[Co(L^3)_2]^{2+}$ (Fig. 2). These two complexes are sufficient to establish the assignments given (see Experimental). The ligand proton assignments have been made on the basis of intensity, the effects of substitution of the methyl group for hydrogen, relative line widths and comparison with the spectra of related iron(II)[1] and nickel(II)[15] complexes. The singlet nature of all the pyridine and pyrazole ring proton resonances is consistent with two equivalent chelate rings, reflecting the grossly octahedral symmetry of these high-spin cobalt(II) complexes in CD_3CN solution. However, the occurrence of two methylene proton resonances is indicative of a non-planar chelate ring conformation, as observed in the solid-state structures of $[Fe(L^2)_2](ClO_4)_2$[16] and $[Ni(L^1)_2](ClO_4)_2$.[17] The ^1H NMR spectra, as shown in Fig. 2, have been reported very recently[18] utilizing cobalt(II) complexes of pyrazole-rich tridentate ligands.

Redox properties

(a) *The* Co^{III}/Co^{II} *couple.* Cyclic voltammetric studies using a platinum electrode gave an oxidative response with $i_{pc}/i_{pa} \approx 1.0$. The one-electron nature of this redox response has been identified by comparison of current height with the redox response[1] of a sample of $[Fe(L^1)_2]^{2+}$ under the same experimental conditions. The peak differences were 80 ($[Co(L^1)_2]^{2+}$), 100 ($[Co(L^2)_2]^{2+}$) and 180 mV ($[Co(L^3)_2]^{2+}$) at a scan rate of 50 mV s^{-1}. Thus, the Co^{III}–Co^{II} couple is electrochemically reversible[5,19] for the unsubstituted complex; however, the reversibility progressively decreases for $[Co(L^2)_2]^{2+}$ and $[Co(L^3)_2]^{2+}$. This is understandable, given an incremental steric crowding at the $Co^{II}N_6$ coordination unit on passing from $[Co(L^1)_2]^{2+}$ to $[Co(L^3)_2]^{2+}$, which in turn causes a substantial structural change between the redox states Co^{II} and Co^{III} and hence a decrease in the reversibility. The $E_{1/2}$ values of the Co^{III}–Co^{II} couple are 0.74 and 0.83 V vs S.C.E. for $[Co(L^1)_2]^{2+}$ and $[Co(L^2)_2]^{2+}$, respectively. For $[Co(L^3)_2]^{2+}$ the E_{pa} value is 1.06 V vs S.C.E. To the best of our knowledge the $E_{1/2}$ (E_{pa}) values[2] observed for the present complexes are the highest[20] (the $[Co(bpym)_3]^{3+}/[Co(bpym)_3]^{2+}$ couple[20f] is 0.80 V vs S.C.E.; bpym = 2,2′-bipyrimidine) known so far for high-spin cobalt(II) bis- or tris-chelates having CoN_6 coordination.

(b) *Effect of methyl substituents.* Since the observed oxidative responses are not reversible for all the three complexes, for the purpose of comparison the emphasis is given to the anodic peak potentials[2] which are the potentials measured when the anodic peak current is at its maximum. The

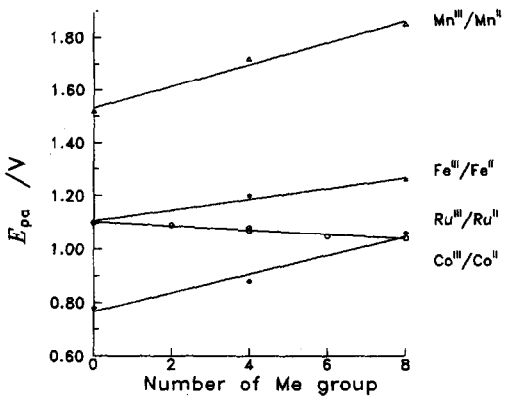

Fig. 3. Plot of anodic peak potentials (E_{pa} V vs S.C.E.) for the M^{III}–M^{II} couple against the total number of methyl groups in the complex with ligands L^1, L^2 and L^3.

observed unusual trend in the E_{pa} values (Table 1) can be rationalized[1,2] by considering the predominance of steric factors caused by substitution at the 3-position(s) over the electronic contribution prevailing at the 5-position(s) in the ligands L^2 and L^3. In the bis complexes of ruthenium(II)[3] we observed the predominance of electronic over steric effects. Figure 3 neatly summarizes our experimental findings for the M^{III}/M^{II} couple (M = Mn, Fe, Co and Ru; a positive slope signifies steric predominance and a negative slope indicates electronic predominance) in the bis complexes of the present ligands.

(*Received* 27 *October* 1992; *accepted* 26 *February* 1993)

Abstract—The structure of $(Et_4N)_3H_6[AsV_{12}O_{40}(VO)_2]\cdot 20H_2O$ has been determined by single-crystal X-ray diffraction analysis. In the anion the central AsO_4 tetrahedron and $12VO_6$ octahedra form the usual Keggin structure (α-isomer) and the remaining two VO^{3+} groups occupy the cavities in the Keggin structure, where a two-fold axis passes to form *trans*-located tetragonal pyramidal caps.

A number of heterotungstates and -molybdates adopt either the Keggin structure or a structure derived from fragments of it.[1] In these polyanions some of the molybdenum or tungsten atoms are replaced by vanadium atoms.[2,3] However, our knowledge on heteropolyvanadates containing a tetrahedrally-coordinated heteroatom is still limited. The mineral structure $[AlV_{14}O_{40}]^{9-}$ [4] and its isostructural anion $[AsV_{14}O_{40}]^{7-}$ [5] contain octahedrally coordinated heteroatoms. A series based on capping by VO or As_2O the sets of O_4-square faces of the rhombicuboctahedron of the Keggin anions has been synthesized and reported.[6,7] For a normal Keggin anion of vanadium, $XV_{12}O_{40}$, a high negative charge might prevent its formation, but it could be stabilized by capping two VO^{3+} or AsO^{3+} groups to form a bicapped Keggin structure.[8,9] We report here a bicapped Keggin structure in which arsenic is the tetrahedrally coordinated heteroatom.

EXPERIMENTAL

Synthesis and elemental analysis

The title compound was prepared by mixing NH_4VO_3 (0.83 g), Na_2HAsO_4 (0.49 g) and NH_2OH HCl (0.88 g) in water (50 cm^3) and 1 N HCl solution (2 cm^3). The mixture was heated at reflux temperature for *ca* $1\frac{1}{2}$ h followed by adding Et_4NBr (0.35 g) after the reaction solution had cooled to room temperature. Dark blue crystals were obtained from the above solution and dark red crystals were recrystallized from water at room temperature.

Found: C, 13.7; N, 1.9; V, 32.3; As, 3.6. Calc. for $C_{24}N_3H_{106}O_{82}V_{14}As$: C, 13.0; N, 1.9; V, 32.2; As, 3.40%.

Crystal structure determination

A single crystal of the dimensions $0.3\times0.4\times0.5$ mm^3 was used for the data collection on a Siemens R3m/V diffractometer equipped with graphite monochromatized Mo-K_α radiation ($\lambda = 0.7073$ Å). $\omega/2\theta$ scans with variable speeds, 4.88–29.3° min^{-1}, were used. The cell parameters were refined by a least-squares method on the basis of 25 reflections with $17 \leqslant 2\theta \leqslant 25$; two standard reflections were monitored every 100 reflections and showed no significant change; 2901 reflections were collected ($2\theta_{max} = 45°$, $0 \leqslant h \leqslant 16$, $0 \leqslant k \leqslant 26$, $0 \leqslant l \leqslant 45$) and merged to give 2603 independent reflections, of which 2034 reflections with $F > 5\sigma(F)$ were used in the calculations.

Crystal data. $C_{24}N_3H_{106}O_{62}V_{14}As$, orthorhombic, space group *Fddd*, $M = 2217$, $a = 14.938(4)$, $b = 24.712(7)$, $c = 42.619(12)$ Å, $V = 15.732(7)$ Å^3, $Z = 8$, $D_m = 1.867$ g cm^{-1}, $D_x = 1.87$ g cm^{-1}, $F(000) = 8976$, μ(Mo-K_α) = 2.049 mm^{-1}.

The positions of the arsenic and vanadium atoms were obtained by direct methods, subsequent Fourier syntheses yielded the coordinates of the remaining oxygen, nitrogen and carbon atoms by standard least-squares techniques (SHELXTL PLUS program system). No hydrogen atoms were included. The final R value was 0.0595.

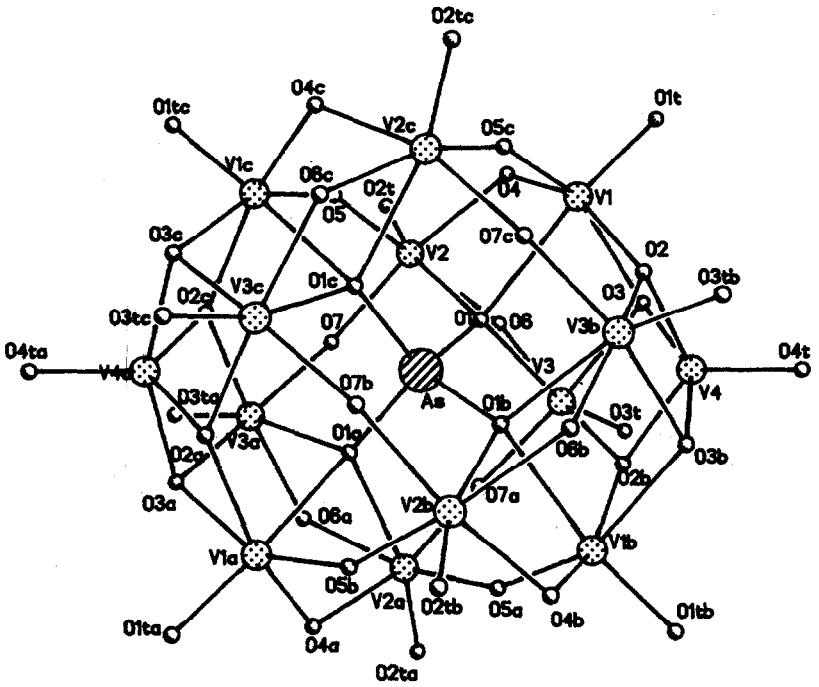

Fig. 1. A view of the $[AsV_{12}O_{40}(VO)_2]^{9-}$ anion.

Atomic positional coordinates, displacement factor coefficients, full lists of bond lengths and angles and a list of F_o/F_c values have been deposited as supplementary data with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

The anion structures are shown in Figs 1 and 2. Selected bond distances and bond angles are listed in Tables 1 and 2, respectively.

In the anion the central tetrahedral AsO_4 shares its oxygen atoms with four V_3O_{13} groups, each of which is made up of $V(1)O_6$, $V(2)O_6$ and $V(3)O_6$ edge-sharing octahedra. These four V_3O_{13} groups are connected to each other by a shared corner. This part is the well-known α-Keggin structure. The AsO_4 tetrahedron is almost perfectly regular. The As—O distances are all 1.686 Å and the O—As—O angles are 108.9–110.1°, the average being 109.5°. The AsO_4 tetrahedron thus has *Td* symmetry and the four V_3O_{13} units are linked in *Td* symmetry with a central AsO_4 group. Two other VO units, through which a crystallographic two-fold axis passes,

occupy *trans*-located sites forming two tetragonal pyramidal caps.

All of the oxygen atoms in the polyanion are classified into four groups—Oa, Ob, Oc and Od. Oa is the oxygen atom bound to one central arsenic atom and to three vanadium atoms of the same V_3O_{13} unit, and Ob is shared by two vanadium atoms. Oc is a three-coordinate oxygen atom, which is bound to one capping and two other vanadium atoms of V_3O_{13} units; Od is a terminal oxygen atom combined with only one vanadium atom.

The metal–oxygen bonds in VO_6 and VO_5 are not equivalent. V—Od bond lengths are the shortest; range 1.586–1.620 Å with an average of 1.597 Å; the distances for the V—Oa bond, which is opposite to the V—Od bond, are the longest; range 2.298–2.326 Å with an average of 2.314 Å, and an average Od—V—Oa angle of 165.1°. The V—Ob distances are between 1.724 and 1.977 Å with an average of 1.863 Å, while the values for V—Oc are between 1.819 and 2.129 Å with an average of 1.982 Å. For VO_5 tetragonal pyramidal caps the V—Od bond length is 1.585 Å, three-coordinated V—Oc distances are 1.819 and 1.938 Å, respectively, and the average is 1.879 Å.

There are five kinds of crystallographically different water molecules in the crystals, each one having significant hydrogen bonds to the anion and other water molecules. A total of 20 water molecules, together with three Et_4N^+ cations, play an important role in stabilizing the crystals.

IRON–MOLYBDENUM–SULPHUR AND IRON–TUNGSTEN–SULPHUR COMPLEXES OF DIIMINES

VASANTHI LAKSHMANAN, K. S. NAGARAJA* and M. R. UDUPA†

Department of Chemistry, Indian Institute of Technology, Madras 600 036, India

(*Received* 23 *November* 1992; *accepted* 25 *February* 1993)

Abstract—The complexes $FeLMS_4$ (L = bipy or phen; M = Mo or W) were prepared and characterized. The linearity of the χ_M^{-1} vs T plot and Mössbauer spectral parameters (δ: 0.28 mm s^{-1}; E_Q: 0.37 mm s^{-1}) of $[Fe(bipy)_2MoS_4]$ suggested that iron(II) assumes a distorted octahedral geometry with an intermediate spin state. The thiometallate acts as a bidentate chelating ligand towards iron(III), as evidenced by IR spectral results. An irreversible anodic wave observed at +1.04 V vs S.C.E. in the cyclic voltammogram of $[Fe(bipy)_2MoS_4]$ in DMSO suggested the oxidation of iron(II) to iron(III) and the reduction of the bipyridyl ligand occurs at −1.40 V.

Although several iron–molybdenum–sulphur complexes have been reported,[1,2] the mechanism of redox reaction and the coordination environment around molybdenum in the nitrogenase enzyme have not been understood in detail. Thus, more studies on iron–molybdenum–sulphur complexes are demanded. We reported in this paper the preparation and characterization of iron–molybdenum–sulphur and iron–tungsten–sulphur complexes of 2,2′-bipyridine (bipy) and 1,10-phenanthroline (phen).

EXPERIMENTAL

Ammonium tetrathiometallates, $(NH_4)_2MoS_4$ and $(NH_4)_2WS_4$, and $[Fe(bipy)_2MoO_4]$ were prepared by the reported procedures.[3]

Preparation of $[Fe(bipy)_2MoS_4]$

Ammonium tetrathiomolybdate (0.26 g, 0.001 mol) solution was added to the deep red solution resulting from mixing an aqueous solution of iron(II) sulphate heptahydrate (0.28 g, 0.001 mol) and 2,2′-bipyridine (0.45 g, 0.003 mol). The mixture was stirred for 1 h. The red complex formed was filtered, washed with water, ethanol and acetone and dried over anhydrous calcium chloride. Yield: 55%. Complexes $[Fe(phen)_2MoS_4]$, $[Fe(bipy)WS_4]$ and $[Fe(phen)_2WS_4]$ were prepared by a similar procedure. Yield: 50–55%.

Carbon, hydrogen and nitrogen analyses were performed on a Hewlett–Packard CHN 185 analyser. The magnetic susceptibility studies were measured on a VSM sample magnetometer. UV–vis, IR and FIR spectra were recorded on Perkin–Elmer Cary 2300, Perkin–Elmer 983 and Polytech IR 12 spectrophotometers, respectively. Mössbauer spectra were recorded using an ECI MBS 35 spectrometer, operating at constant acceleration mode with a ^{57}Co source diffused in a rhodium matrix mounted on a transducer. The chemical isomer shifts (δ) were measured relative to the mid-point of the spectrum of an absorber of natural iron. The cyclic voltammetric measurements were performed in DMSO using tetraethylammonium perchlorate as the supporting electrolyte. The thermal decomposition studies were performed on a Stanton–Redcroft STA-780 thermobalance with a heating rate of 10°C min^{-1}.

RESULTS AND DISCUSSION

The analytical data of the complexes are given in Table 1. The complexes are insoluble in water and common organic solvents and undergo thermal decomposition (Table 2) in two stages. The chemical analysis and X-ray diffraction patterns of the products obtained on heating the complexes confirmed the intermediate phases to be a mixture of FeS and

MoS_3, from thiomolybdates, and FeS and WS_3, from thiotungstates. The sulphides undergo further decomposition to the oxides as shown by IR[4] from the X-ray powder patterns of the end residues. The magnetic susceptibility measurements of $[Fe(bipy)_2MoS_4]$ indicated that the plot of χ_M^{-1} vs T (Fig. 1) is linear. The absence of Neel's temperature ruled out the presence of antiferromagnetic exchange interactions. The octahedral iron(II) complexes exhibited unusual magnetic behaviour[5] due to a spin cross-over mechanism ($^5T_2 - {}^1A_1$). However, complexes $[Fe(bipy)(CH_2CO_2CO_2)]$ and $[Fe(bipy)_2C_2O_4]$, with μ_{eff} at room temperature around 3.1 B.M., exhibited[6] linearity in the χ_M^{-1} vs T plot, which is attributed to the presence of an inherent half-quenched spin-state ($^3T_1$) of iron(II). The intermediate spin-state arises when the ligand field strength lies between strong and weak fields and thus the linear behaviour of the χ_M^{-1} vs T plot is attributed to the presence of an intermediate spin-state of iron(II) in $[Fe(bipy)MoS_4]$ and not due to antiferromagnetic coupling. The Mössbauer spectra of $Fe(bipy)MoS_4$ is given in Fig. 2 and the room-

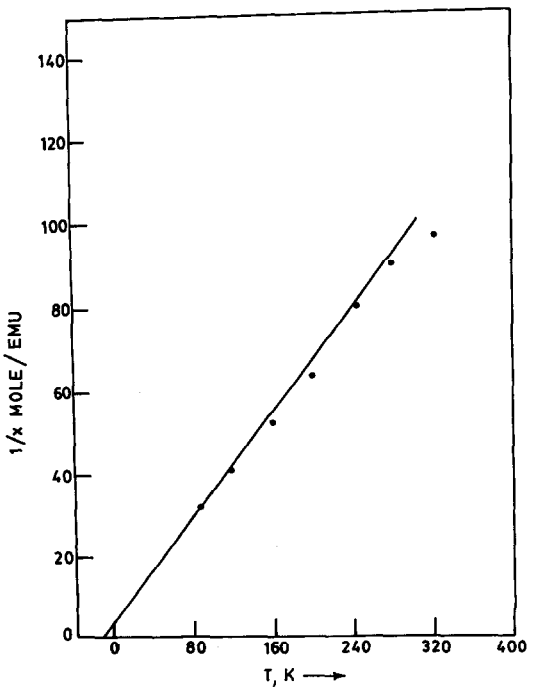

Fig. 1. $1/x$ vs T plot for $[Fe(bipy)_2MoS_4]$.

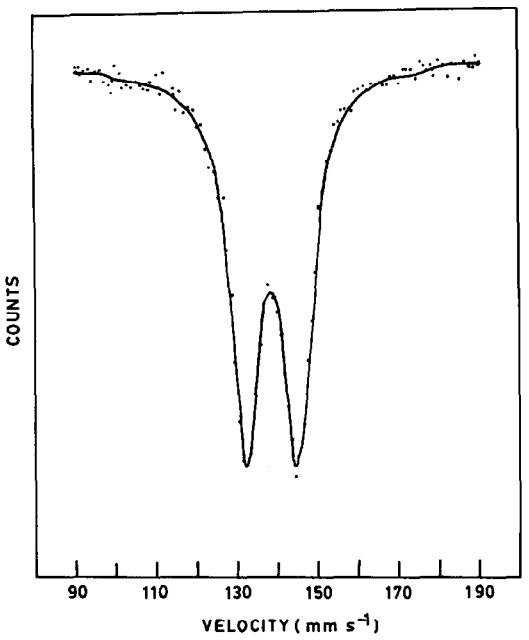

Fig. 2. Mössbauer spectrum of the complex $[Fe(bipy)_2MoS_4]$ at room temperature.

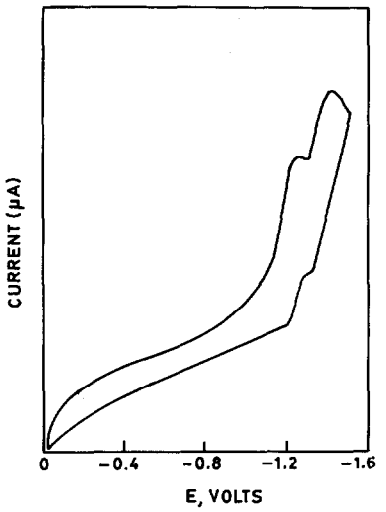

Fig. 3. CVM of $[Fe(bipy)_2MoS_4]$ in DMSO at a sweep rate of 100 mV s^{-1}.

temperature spectral parameters δ and ΔE_Q are 0.28 and 0.37 mm s^{-1}, respectively. These values are found[6] to be of the same order as observed for the intermediate spin-state complex $[Fe(bipy)C_2O_4]$. If iron(II) was in a high-spin state the reported[6] δ value would be in the range 1.65–1.45 mm s^{-1}. The low value of ΔE_Q may be due to a small electric field gradient[7] arising from the almost spherical electron distribution around the iron nucleus. Thus, magnetic data with a room-temperature effective magnetic moment of 2.7 B.M. and the Mössbauer data confirm that iron(II) in $[Fe(bipy)_2MoS_4]$ is in a distorted octahedral geometry with intermediate spin-state.

The electronic spectral transitions observed for the complexes at 520, 500 and 390 nm are attributed[8,9] to d (Fe) $\rightarrow \pi_1$ (diimine) and d (Fe) $\rightarrow \pi_2$ (diimine) charge-transfer transitions of the $[Fe(diimine)_2]^{2+}$ moiety. Additional bands due to π(S) $\rightarrow$ d(W) charge-transfer transitions occur around 410 and 330 nm. The charge transfer bands π(S) $\rightarrow$ dM^{VI} of $(MS_4)^{2+}$ suffer bathochromic shifts in the complexes.[10,11] The transition observed around 310 nm in all the complexes is characteristic[12] of the $\pi_1 \rightarrow \pi_2$ transition of the diimine ligand.

The IR frequencies ν(CN) and ν(CC) of bipyridine and phenanthroline undergo positive shifts of 10–30 cm^{-1} in the complexes, suggesting coordination through the diimine nitrogen atoms. The IR bands observed around 240 cm^{-1} for $[Fe(bipy)_2MS_4]$ complexes and 290 cm^{-1} for $[Fe(phen)_2MS_4]$ complexes are assigned[13] to M—S stretching frequencies. The splitting of these frequencies suggested that the MS_4 group probably acts as a bridging ligand towards iron(II). Thus, iron(II) is bonded through 4s atoms of the thiometallate and the coordination is completed by the bidentate diimine ligands.

The cyclic voltammogram of $[Fe(bipy)_2MoS_4]$ is given in Fig. 3. The CVM displays an irreversible anodic wave at +1.04 V and two quasi-reversible cathodic waves at −1.40 and −1.25 V. The anodic wave at +1.04 V is attributed[14] to the oxidation of iron(II) to iron(III). The quasi-reversible cathodic waves observed at −1.40 and −1.25 V in the cyclic voltammogram of $[Fe(bipy)_2MoS_4]$ are due to the reduction[15,16] of the bipyridyl ligand bonded to iron(II). In order to compare the electrochemical behaviour with that of $[Fe(bipy)_2MoO_4]$ the cyclic voltammogram of the latter was taken. It exhibited two quasi-reversible cathodic waves at −1.40 and −1.25 V, which are attributed[15,16] to the reduction of the bipyridine ligand bonded to iron(II). However, no anodic wave was observed to indicate the oxidation of iron(II) to iron(III). An irreversible wave did however appear at −0.20 V, which disappeared when the scan was reversed prior to the reduction of $[Fe(bipy)_2]^{2+}$. Thus suggests that the oxidation of iron(II) to iron(III) is difficult when the oxo ligand is coordinated to iron(II).

The geometries of Fe^{II} and M^{VI} are tetrahedral in $FeLMO_4$. However, in FeL_2MS_4 complexes Fe^{II} is six-coordinate and M^{VI} is four-coordinate. Oxo coordination probably saturates the hard acid character of iron(II) and thus only one diimine ligand can be accommodated, giving rise to a tetrahedral geometry around iron(II). In the case of oxometallates, both oxygen and nitrogen of the

diimine ligand compete for similar molecular orbitals, σ and p_π, and, therefore, only one diimine ligand coordinates to iron(II). In sulphido complexes the sulphur atoms compete for *d*-orbitals, whereas the nitrogen of diimine competes for σ- and p_π-orbitals. Thus, two diimine ligands could be accommodated around iron(II). This may be the reason for obtaining a tetrahedral iron(II) complex when oxo metallate is used and an octahedral iron(II) complex when thiometallate is used.

(*Received* 29 *October* 1992; *accepted* 25 *February* 1993)

Abstract—Potassium antimony(III) citrate, $\{[K_2Sb_4(citrate)_8(H_2O)_2]\}$ (**1**), and lithium antimony(III) citrate, $\{[LiSb(citrate)_2(H_2O)]\cdot 2H_2O\}$ (**2**), have been prepared and their structures determined by X-ray diffraction. With **1** each of the two independent centrosymmetric tetramers in the repeating unit of the complex comprises four independent antimony ions and eight citrate residues interlinked by two potassium centres [K—O range 2.62–3.06(1) Å]. The difference between the two tetramers is that potassium is seven-coordinate in one and eight-coordinate in the other. The water molecules are coordinated to the potassium ions. Each antimony forms the usual distorted pseudo-trigonal bipyramidal four-coordinate complex through the α-hydroxy carboxylate oxygens of two citrate residues. A feature of the structure is the presence of three differently charged citrate species (1-, 2-, 3-), giving the formula $\{K_2[Sb(C_6H_6O_7)_2]_2[Sb(C_6H_7O_7)(C_6H_5O_7)]_2(H_2O)_2\}$. The coordination about antimony in **2** is similar, but the lithium links the two citrate residues together via a carboxyl and a hydroxyl oxygen from one ligand and a carboxyl oxygen from the second. A water completes the tetrahedral coordination sphere [mean Li—O, 1.942(5) Å]. Except for the four-coordination about lithium, the complex is similar to the analogous sodium complex $\{[NaSb(citrate)_2(H_2O)_2]\cdot H_2O\}$.

Antimony(III) complexes with citrate have shown only one coordination type, irrespective of the charge carried by the ligand species. This involves the α-hydroxycarboxyl moieties of two citrate residues in a bis-chelate mode, giving a very distorted pseudo-trigonal bipyramidal four-coordination about antimony. Known example types are $\{[NaSb(citrate)_2]_2(H_2O)_2]\cdot H_2O\}$,[2] $\{[AgSb(citrate)_2]_2$[2] [both (2−)]}, $\{[Co(NH_3)_6][Sb(citrate)_2]\cdot 5H_2O\}$[3] and $\{K_3[Sb(citrate)_2]\cdot 2H_2O\}$[3] [both (3−)]. The only previously described example in which mixed-valence citrate species are found is $[CuSb(citrate^{2-})(citrate^{3-})(H_2O)_2]\cdot 2.5H_2O$,[4] in which a terminal carboxyl proton is lost from one citrate residue, providing a cross-link between chains formed through five-coordinate copper(II) centres.

In all structures the observation is that deprotonation of the α-hydroxy group occurs at quite low pH (*ca* 1.5), due to lowering of its effective pK_a after initial coordination of the adjacent carboxyl group. As part of a program of investigation in our laboratories into the phenomenon of univalent and divalent metal ion stabilization of group 15 complexes with hydroxy acids the title compounds were prepared using similar pH conditions to those for

Copper antimony citrate

the silver, sodium and copper analogues.[2,4] For the potassium analogue (**1**) reported here the stoichiometry determined from elemental analysis, preliminary X-ray examination and density determination, $[KSb_2(citrate)_4(H_2O)]$, suggested probable mixed-valence citrate species. This has been confirmed by the X-ray structure determination. For the lithium complex (**2**) the stoichiometry, $[LiSb(citrate)_2(H_2O)_3]$, was the same as that of the sodium analogue,[2] although the structure determination has shown that the two are not isostructural.

EXPERIMENTAL

Preparation

Compounds were prepared using a previously described procedure[2] by the digestion of antimony(III) oxide in aqueous citric acid solution with subsequent addition of potassium or lithium nitrate to the syrupy concentrate. Large, hard colourless prismatic crystals grew from the digests after several weeks at room temperature.

Crystal data

1: $C_{48}H_{54}K_2O_{38}Sb_4$, $Mr = 1803.6$, $a = 12.239(9)$, $b = 16.085(10)$, $c = 18.458(9)$ Å, $\alpha = 79.12(5)$, $\beta = 76.84(5)$, $\gamma = 79.83(5)°$, $V = 3440(4)$ Å^3, space group $P\bar{1}$, $Z = 2$, $D_c = 1.748$, $D_m = 1.77$ g cm^{-3}, $\mu = 17.9$ cm^{-1}, Mo-K_α radiation ($\lambda = 0.71073$ Å), $F(000) = 1776$, $T = 297$ K.

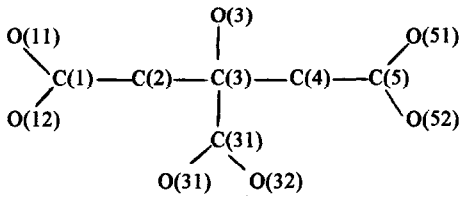
2: $C_{12}H_{18}LiO_{17}Sb$, $Mr = 562.9$, $a = 7.712(6)$, $b = 10.763(7)$, $c = 12.756(9)$ Å, $\alpha = 75.600(9)$, $\beta = 77.29(6)$, $\gamma = 74.85(6)°$, $V = 976(1)$ Å^3, space group $P\bar{1}$, $Z = 2$, $D_c = 1.914$, $D_m = 1.93$ g cm^{-3}, $\mu = 15.0$ cm^{-1}, Mo-K_α radiation ($\lambda = 0.71073$ Å), $F(000) = 560$, $T = 297$ K.

Data collection, structure solution and refinement

X-ray diffraction data were collected from crystals of dimensions $0.25 \times 0.20 \times 0.20$ mm (**1**) and $0.20 \times 0.20 \times 0.15$ mm (**2**), mounted on an Enraf–Nonius CAD-4 diffractometer using graphite crystal monochromatized Mo-K_α X-radiation. Although the unit cell volume for **1** suggested the possibility of a non-reduced cell, standard cell reduction procedures failed to show any higher symmetry involving a smaller molecular asymmetric unit. Of 9972 (**1**) and 3715 (**2**) reflections collected up to $2\theta_{max} = 50°$, 8593 ($R_{int} = 0.021$) and 3433 ($R_{int} = 0.009$), respectively, were unique, while 6105 and 3232 with $I > 2.5\sigma(I)$ were considered observed and used in structure refinement. Collection ranges were h, -14 to 14; k, -19 to 19, l, 0 to 21 (**1**) and h, 0 to 9, k, -12 to 12 and l, -15 to 15 (**2**). The data were corrected for Lorentz and polarization effects and for absorption [empirical corrections: maximum and minimum transmission factors: 0.98, 0.85 (**1**) and 0.99, 0.96 (**2**)]. The structures were solved using the automatic Patterson procedure of SHELXS 86[5] and refined to residuals $R = 0.041$ and $R_w = 0.045$ ($S = 0.97$) (**1**) and 0.017 and 0.019 ($S = 1.5$) (**2**) using blocked-matrix least-squares (SHELX 76[6]), with anisotropic thermal parameters for all non-hydrogen atoms. Weighting schemes with $w = [\sigma^2(F_o) + 1.9 \times 10^{-3}(F_o)^2]^{-1}$ (**1**) and $[\sigma^2(F_o) + 1.8 \times 10^{-4}(F_o)^2]^{-1}$ (**2**) were used. Hydrogens were located by difference methods and were included in the respective refinements with coordinates and temperature factors refined (**2**), but with isotropic U values set invariant at 0.05 Å^2 for **1**. For **1** two atoms [O(111) and O(121)] gave non-positive definite temperature factor conditions and so were restored to isotropic refinement.

Atomic coordinates, anisotropic thermal parameters, observed and calculated structure factors

and intraligand bond distances and angles have been deposited with the Editor as supplementary material; copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre. Bond distances and angles about the metal coordination polyhedra are given in Table 1. The atom numbering scheme follows the convention adopted for previous structures of this series.[1,2,4]



DISCUSSION

$[K_2Sb_4(citrate)_8(H_2O)_2]$

The two centrosymmetric tetramers in the repeating unit of compound **1** comprise four independent antimony(III) centres and eight citrate residues bound together by two potassium ions (Fig. 1). However, in one tetramer the potassiums are eight-coordinate, the other seven. The two waters in each are also bonded to the potassium ions. The units are related by a pseudo-A-face centring in a triclinic cell, although this symmetry could not be invoked crystallographically. The reason for this lies in asymmetry due to the conformational variations in the citrate residues, particularly at the terminal carboxylate groups, and in the difference in the coordination polyhedra about the two potassium centres. Figure 2 shows the stereochemistry about one of the antimony centres [Sb(1)], which is typical of all centres and involves four oxygens from two bidentate chelate α-hydroxycarboxyl groups of two citrate residues. The four-coordination is similar to that found for all known antimony(III) citrates,[1-4] with very distorted pseudo-trigonal bipyramidal stereochemistry, although this is less easily recognized due to some bond elongation and angle distortion. However, the axial sites are occupied typically by the carboxylate oxygens [O(31)], while in the equatorial sites are found the shorter bonds to hydroxyl oxygens [O(3)]. With the silver(I),[2] sodium[2] and copper(II)[4] antimony citrates the Sb—O(carboxyl) distances are 2.096 and 2.218(2), 2.153 and 2.164(1) and 2.177 and 2.230(6) Å, respectively, compared with Sb—O(hydroxyl): 2.007 and 2.008(2), 1.988 and 1.998(1) and 1.974 and 2.009(5) Å, respectively. In the present complex the comparative Sb—O bond distances are used to identify the protonated functional groups on the citrate residues, to enable the justification of the unusual stoichiometry in the overall complex, arising from a requirement to balance the net (14+) charge of the two potassium and four antimony(III) ions. It would normally be expected that a basic (2−) charge would arise on each citrate residue from deprotonation of both functional groups of the subterminal α-hydroxycarboxy moiety. This occurs even at the pH levels which are employed using the

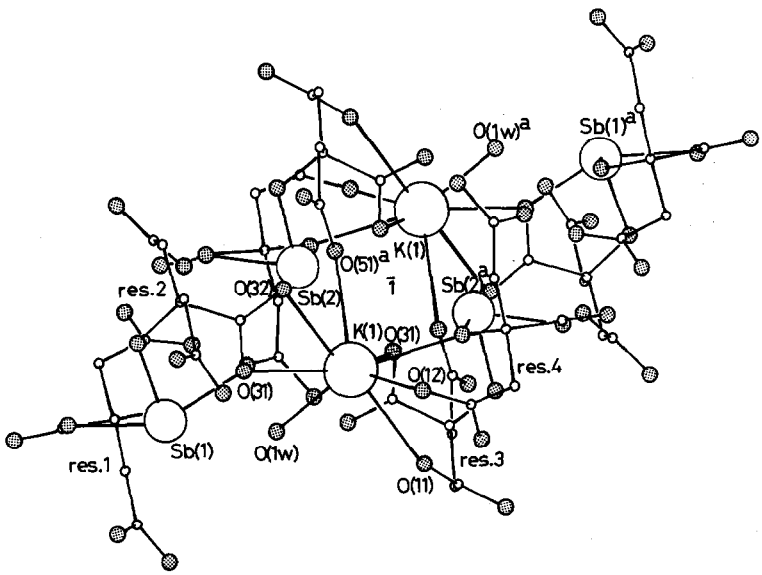


Fig. 1. A view of the centrosymmetric molecular repeating unit in the complex tetramer. Only one unit [involving K(1), Sb(1)–Sb(4) and citrate residues 1–4] is shown. The second unit [involving K(2), Sb(5)–Sb(8) and citrate residues 5–8] is configurationally similar.

usual method of preparation. However, in the case of **1** variable negative charges arise on the citrate residues, (1−) from loss of the hydroxyl proton (all residues), (2−) from loss of both α-hydroxyl and carboxyl protons and (3−) from loss of an additional terminal carboxyl proton. The Sb—O(31) and Sb—O(3) distances involving residue 1 [to Sb(1)], residue 4 [to Sb(2)], residue 6 [to Sb(3)] and residue 8 [to Sb(4)] are 2.34(1) and 2.00(1), 2.30(1) and 2.00(1), 2.26(1) and 2.01(1) and 2.30(1) and 2.00(1) Å, respectively, indicating that the carboxyl groups remain protonated with a (1−) charge carried by each residue. The corresponding distances in residue 2 [to Sb(1)], residue 3 [to Sb(2)], residue 5 [to Sb(3)] and residue 7 [to Sb(4)] are 2.11(1) and 1.98(1), 2.07(1) and 2.01(1), 2.11(1) and 2.00(1) and 2.11(1) and 2.02(1) Å, indicating that both hydroxyl and carboxyl groups are deprotonated. The additional two charges arise from deprotonation of terminal carboxyl groups on residues 2 and 3. The total formula is, therefore, made up as follows:

[Sb(1)(residue 1)$^-$(residue 2)$^{3-}$]

[Sb(2)(residue 4)$^-$(residue 3)$^{3-}$] (tetramer **1**)

and

[Sb(3)(residue 6)$^-$(residue 5)$^{2-}$]

[Sb(4)(residue 8)$^-$(residue 7)$^{2-}$] (tetramer **2**),

with their inversion-related halves. Identification of the terminal carboxyl group which carries the (1−) charge is on the basis of located hydrogen atoms and on C—O bond distances, which become more equidimensional with deprotonation compared with their free acid values [typically, C=O 1.20 Å, C—OH 1.32 Å[7]].

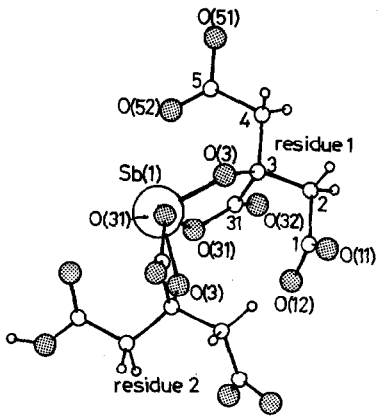

Fig. 2. Molecular configuration and atom naming scheme for the Sb(citrate)$_2$ complex centres. Only that for Sb(1) is shown. The centres about Sb(2), Sb(3) and Sb(4) are similar. Unless otherwise indicated, atoms are carbon.

The irregular coordination centres about each potassium ion [K(1) and K(2)] are similar (Fig. 3), involving oxygens from a single water molecule and from both carboxyl and hydroxyl groups of the α-hydroxycarboxyl moieties. However, K(1) is seven-coordinate while K(2) is eight-coordinate, with the K—O distances significantly longer about K(1) [2.72–3.06(1) cf. 2.62–3.01(1) Å for K(2)]. Bonds to K(1) are from a water [O(1w)], from carboxyl oxygens [O(11) (terminal) and O(31) (central) of citrate 3; O(12) (terminal carboxyl) and O(3) (hydroxyl) from citrate 4], a carboxylate link to O(31) (central carboxyl) from citrate 2 and one bridging link to an inversion-related carboxyl oxygen [O(513) $(-x, -y, 1-z)$]. The mean K—O distance is 2.87(1) Å. An almost identical stereochemistry is found about K(2), with bonds to O(2w), O(115) and O(315), O(116) and O(36), O(317) and O(327) [symmetric bidentate] and O(515) (also across an inversion centre). The eighth

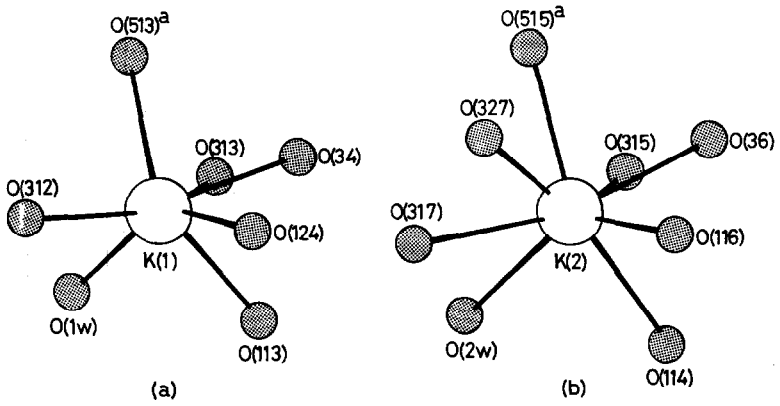

Fig. 3. The coordination polyhedra about the two potassium centres.

bond to K(2) corresponds to the second in the symmetric bidentate carboxylate association [K—O 3.01, 3.03(1) Å]. With K(1) this group becomes asymmetric, with significant elongation of the second bond [K(1)—O(312), 2.85(1); K(1)—O(322), 3.20(1) Å]. The mean K—O distance about K(2) is 2.86(1) Å. The stability of this basic tetramer unit in **1** is reflected in the isomorphous and isostructural rubidium complex $[Rb_4Sb_4(citrate)_8(H_2O)_2]$, which has now been prepared and its structure determined.[8]

$[LiSb(citrate)_2(H_2O)]\cdot 2H_2O$

The lithium antimony citrate complex (**2**) is monomeric (Fig. 4) and structurally similar to the sodium analogue $[NaSb(citrate)_2(H_2O)_2]\cdot H_2O$,[2] both of which involve only citrate(2−) species. However, lithium adopts its most usual tetrahedral coordination, with two oxygens from one citrate residue {one carboxyl [O(512)], one hydroxyl [O(32)], the latter also bridging to antimony}, one carboxyl oxygen from the second citrate residue [O(121)] and a single water. The mean Li—O distance is 1.942(5) Å. Also, in contrast to the sodium analogue, the third carboxyl oxygen (from the second citrate residue) is from the terminal rather than the central acid group. Furthermore, the five-coordinate sodium complex has an additional water in the distorted trigonal bipyramidal coordination sphere. With complex **2**, having the same stoichiometry, the additional water moves into the lattice as a molecule of solvation. Despite these variations in the peripheral coordination the stereochemistry about antimony is comparable to both the sodium analogue[2] and to other antimony citrates.[3,4] This involves hydroxyl oxygens in the axial sites of a very distorted pseudo-trigonal bipyramid [Sb—O 1.998 and 2.009(2) Å, cf. 1.988 and 1.998(1) Å for the sodium analogue] and oxygens of the central carboxyl groups in the equatorial sites [Sb—O 2.117 and 2.195(2) Å, cf. 2.153 and 2.164(1) Å].

STRUCTURE AND BONDING IN CHAIN-LIKE POLYHALONIUM CATIONS AND POLYHALIDE ANIONS

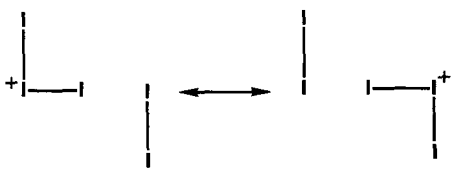
ZHENYANG LIN and MICHAEL B. HALL*

Department of Chemistry, Texas A&M University, College Station, TX 77843, U.S.A.

(*Received* 7 *December* 1992; *accepted* 25 *February* 1993)

Abstract—*Ab initio* calculations with both all-electron basis sets and effective core potentials (ECP) were employed to study the bonding in chain-like polyhalogen cations and anions. An electron density analysis based on Bader's theory of atoms in molecules shows that these polyhalogen cations and anions can be described in terms of the VSEPR model. On the basis of this analysis one can also distinguish covalent and dative bonds in these polyhalogen cations and anions. Covalent bonds exist only between atoms where both are four-coordinate (including the number of lone pairs), because higher coordinate halogens must form a three-centre four-electron bond with its adjacent atoms. The arrangement of iodine–fluorine contacts in the crystal structure of $(I_5^+)(AsF_6^-)$ can be explained by the distributions of lone pairs associated with the relevant iodines.

Heavy halogens (X) exhibit a strong tendency to form chain-like polyhalonium cations and polyhalide anions.[1] For example, I_3^+, $I_5^+(Br_5^+)$, $I_3^+(Br_3^-)$ and I_5^- molecules have been well characterized.[2–7] It is striking that the X_3^+ cation has a V-shaped structure while its corresponding X_3 anion adopts a linear one, and that X_5^+ has a Z-shaped structure but X_5^- is V-shaped. The geometrical features of these polyhalogen cations and anions can be rationalized in terms of the VSEPR model.[8] Based on the available structural parameters of these polyhalogen cations and anions we deduced the valence structures shown in Fig. 1. Based on the X—X bond lengths we make a distinction between dative and covalent bonds, which is also shown in Fig. 1. For the X_5^+ molecule the valence structure predicts that the central halogen carries the most positive charge. The fact that the crystal structure of I_5^+ in its AsF_6^- salt[2] shows the presence of iodine–fluorine contacts for the four non-central iodines, however, seems to imply little positive charge in the central halogen atom. This contradiction led to a bonding description that involves the resonance structures **I** and **II**.[2] Recent density functional calculations also gave support for these resonance structures.[9] In this paper *ab initio* calculations were used to reinvestigate the electronic structures of these polyhalogen ions. These results provide the connection between the VSEPR model and accurate measures of the electron density and resolve several controversies.



(I) (II)

Theoretical details

Both all-electron basis sets and effective core potentials (ECP)[10] were employed in these calculations. Geometries were optimized with the restricted Hartree–Fock calculations; HF/all electron and HF/ECP calculations, and with the second-order Moller–Plesset method (MP2/ECP).

In the all-electron calculations the 3-21G split-valence basis sets, augmented with polarization functions [$\zeta_d(I) = 0.266$, $\zeta_d(Br) = 0.389$, $\zeta_d(Cl) = 0.514$], were used.[11] In the ECP calculations double-ζ basis sets and the same polarization functions were used. All calculations were performed with the GAMESS package[12] at the Super-

computer Center of Texas A&M University on a Cray Y-MP2/116 and on our Silicon Graphic Iris Indigo workstation. The net atomic charges were based on Bader's theory of atoms in molecules and calculated with the OMEGA program.[13] The Laplacian of valence electron density was plotted with the use of the program MOPLOT.[14]

RESULTS AND DISCUSSION

Geometry optimizations have been completed on tri-atomic and penta-atomic halogen cations and anions. The calculated structural parameters together with experimental results are shown in Figs 2 and 3. Overall, the theoretical predictions at both HF and MP2 levels agree quite well with the experimental results (see Figs 2 and 3). The predictions of bond angles are not as good as those of bond lengths. The results of all-electron calculations (HF/all electron) show a slightly better agreement than those of HF/ECP calculations. The MP2/ECP results show that the electron correlation is not very important in predicting the structural parameters for these polyhalogen systems, particularly in predicting the geometrical trends.

The density functional calculations[9] showed that the lowest energy geometry for the free Br_5^+ is a skew structure with the three central bromine atoms forming an angle of 168.6° and the two terminal bromine atoms exhibiting a dihedral angle of 82°, a result which is in contrast to the planar *trans* geometry found in the solid state.[4] Our all-electron calculations yield a slightly different skew structure with a linear unit for the three central atoms and a dihedral angle of 90° between the two terminal atoms. For the all-electron calculations the energy of this skew structure is only 0.16 kcal mol^{-1} lower in energy than that of the planar *trans* structure. Therefore, we expect an essentially free rotation of the two terminal Br_2 (or I_2) units about the central atom for the Br_5^+ (or I_5^+) molecule.

To investigate the charge distribution in these polyhalogen cations and anions we calculated the net atomic charges from the all-electron HF results using Bader's theory of atoms in molecules.[15] The results are listed in Table 1. As can be seen in Table 1 the central atom for I_3^+, I_3^- and I_5^+ carries the most positive charge, while the central atom for I_5^- carries the most negative charge. These results support the valence structures in Fig. 1, although these structures oversimplify the true electronic structures. The charge analyses can also explain the site preference for mixed polyhalogen cations and

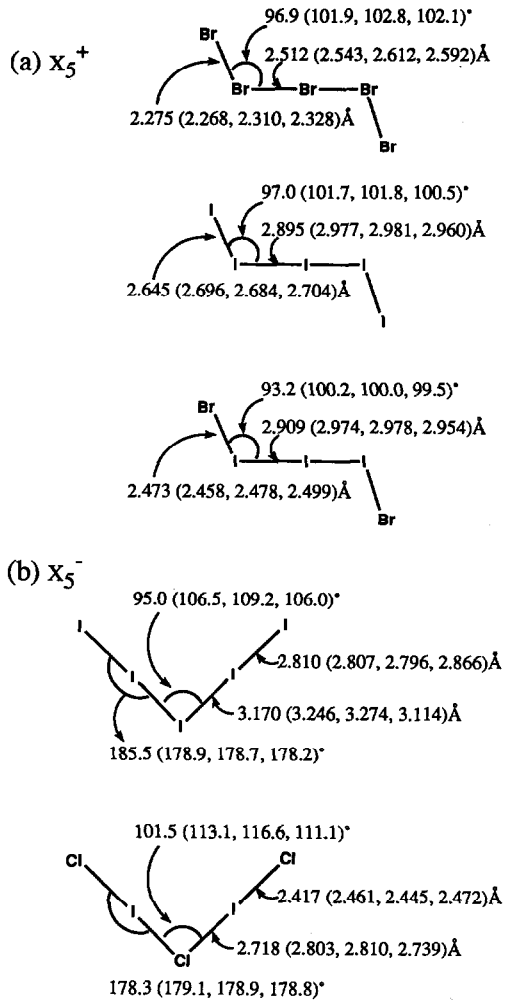

Fig. 3. Optimized geometries for some selected pentaatomic halogen molecules.

anions, in which the less electronegative atom prefers to occupy the site with the most positive charge (see examples of mixed molecules in Figs 2 and 3).

To further examine the bonding in these polyhalogen cations and anions we calculated the Laplacian of the valence electron density, $-\nabla^2\rho$,[15] from the HF/ECP wavefunctions. Plots in the molecular plane for the I_3^+, I_3^-, I_5^+ and I_5^- molecules are shown in Figs 4 and 5. In the contour plot solid lines denote $-\nabla^2\rho > 0$, where the electron density

is locally concentrated, and dashed lines denote $-\nabla^2\rho < 0$, where the electron density is locally depleted.

Figure 4 shows significant electron density accumulations between iodine atoms in I_3^+, but much less in I_3^-. This is expected from the valence model (see Fig. 1), because in I_3^+ the bonds are covalent but in I_3^- they are dative. For I_5^+ Fig. 5(a) indicates covalent bonds between the terminal and adjoining atoms (an adjoining atom is an atom which connects both terminal and central atoms), but dative bonds from the adjoining atom to the central atom. In Fig. 5(b) the central atom of I_5^- exhibits a spherical-like electron density with slightly larger charge concentrations in the directions of I—I bonds. This result implies weak dative bonds, with electron pairs donated from the central atom, whose formal charge is -1, to the adjoining atoms. In the second valence structure for X_5^- molecules (see Fig. 1) covalent bonds were drawn between the adjoining and terminal atoms. However, the dative bonds from the central atom to the adjoining atoms significantly destabilize the bonds between the adjoining and terminal atoms. This destabilizing effect is consistent with the observed very long I—I bond length (2.810 Å, compared to the covalent bond length, 2.645 Å, in the I_5^+ molecule) and with the electron density map of Fig. 5(b), in which, unlike Fig. 5(a), there is no significant electron accumulation in the centre of the corresponding I—I bond. Thus, bonds between the adjoining and terminal atoms in the I_5^- molecule are almost dative in nature, i.e. more contributions from the first of the two X_5^- valence structures in Fig. 1.

In summary, all analyses above strongly support the valence structures in Fig. 1. The question now is how can we explain the experimentally observed iodine–fluorine contacts in the structure of $(I_5^+)(AsF_6^-)$. The crystal structure of this salt indicates that each adjoining atom has two iodine–fluorine contacts (less than the sum of van der Waals radii), while each terminal atom has only one such contact.[2] The central atom has no iodine–fluorine contact, although it carries the most positive charge according to our calculations.

The valence structure for the I_5^+ molecule (see Fig. 1) indicates that the central atom has three lone pairs plus two dative bonds, each adjoining atom has two lone pairs plus one dative and one covalent bond, and each terminal atom has three lone pairs plus one covalent bond. The $-\nabla^2\rho$ plots suggest that the adjoining atom has the most capacity to attract electron pairs from fluorine atoms of the AsF_6^- anion. Since it has the fewest lone pairs (large charge concentrations), it has larger holes in the valence shell. Two fluorines can weakly cap the holes around each of these adjoining atoms. Thus, the two capping fluorines are co-planar with the molecular plane, which is indeed observed in the solid state.[2a] For each terminal atom in I_5^+ a hole is seen in the *trans* direction of the I—I bond, which can be capped by a fluorine to make the third observed close contact. The iodine–fluorine contacts are also found in the AsF_6^- salt of I_3^+.[2b] The contact pattern in I_3^+, where the central atom has two contacts and each terminal atom has one, is analogous to that found in I_5^+. For solid $[ICl_2^+][SbF_6^-]$[16] the central iodine atom has two iodine–fluorine contacts and the terminal chlorine atoms have none. Since the more electronegative chlorine atom has lower polarizability and smaller holes, it has less tendency to form large chain-like polyhalogen molecules of any type.

For polyhalogen anions, the negative charge on the molecule decreases the ability of each halogen atom to attract electron pairs from its cationic counterpart in the solid state. In addition, the cationic counterpart usually does not contain electronegative fluorine ligands. Therefore, few reports on the corresponding cation–anion contacts have been found.

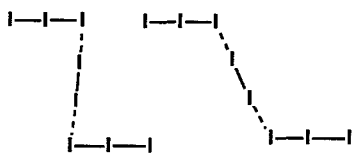
At this stage we have satisfactorily explained the relationship between structure and bonding in these polyhalogen cations and anions. One may raise questions on the distinction between dative and covalent bonds in Fig. 1. For example, the V-shape X_3^+ molecule has two covalent bonds around the central atom, while the X_5^- molecular has two dative bonds around the central atom. Examining the number of lone pairs in the relevant molecules we see that each atom in the X_3^+ molecule is four-coordinate (including the lone pairs). In X_5^- both adjoining atoms are five-coordinate (three lone pairs and two bonds). Each adjoining atom forms a three-centre four-electron bond with the central and terminal atoms by using a *p*-orbital with maximum amplitudes along the bonding axis. The three-centre four-electron bond around a five-coordinate halogen is, therefore, responsible for long X—X bonds. The first four valence structures in Fig. 1 summarize our conclusion that covalent bonds only exist between atoms having a coordination number of four (taking into account the number of lone pairs).

Other chain-like polyhalogen cations and anions

Other chain-like polyhalogen cations and anions have been reported.[17] They can be taken as aggregations of the triatomic and pentaatomic units discussed in this paper. For example, the largest poly-

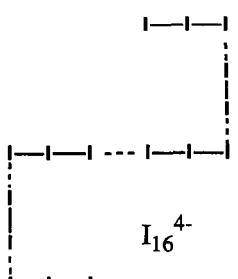
iodine cation,[2c] I_{15}^{3+}, consists of three I_5^+ units linked by weak iodine–iodine interactions. In these weak interactions a lone pair of a terminal atom in one I_5^+ aligns itself with the hole of a terminal atom in another I_5^+ unit (see Fig. 1).

Two forms of I_8^{2-} have been reported (see **III**).[17a] The difference in I—I···I angles between the two forms indicates weak I···I bonding. Qualitatively, both forms can be viewed as two linear I_3^- units being weakly connected by an I_2 molecule. For the I_2 molecule theory predicts a single covalent bond between iodine atoms and three lone pairs on each iodine arranged as the lone pairs of terminal atoms in Fig. 1. Therefore, each iodine atom in the I_2 molecule has a hole *trans* to the covalent bond. This hole can weakly attract electron pairs from other polyhalogen units. The two holes in both iodine atoms of the I_2 molecule attract the lone pairs of the terminal atom of I_3^- to form the I_8^{2-} unit. The largest polyiodine anion,[17b] I_{16}^{4-}, can be viewed as an aggregation of two I_8^{2-} units (see **IV**), although we do not have an explanation of how the two are linked together. Each I_8^{2-} unit in I_{16}^{4-} is in an eclipsed form, while those shown in **III** are in the staggered form.



I_8^{2-}

(III)



I_{16}^{4-}

(IV)

Linear I_4^{2-} deserves comment here. Two structural forms have been identified.[17a] One has three almost equal I—I bond distances (*ca* 3.14–3.18 Å), while the other one has two long terminal bonds (3.34 Å) and one short central bond (2.80 Å). The MP2/ECP geometry optimization only gave the latter structure. One can view this structural form as two terminal I^- units bonded to an I_2 molecule (see **V**).

I_4^{2-}

(V)

CONCLUSIONS

The electron density analyses from *ab initio* calculations indicate that the structure in the chain-like polyhalogen cations and anions can be satisfactorily rationalized in terms of the VSEPR model. A covalent bond exists only between atoms with a coordination number, including the number of lone pairs, of four. Since they are less electronegative and more polarizable, heavy atoms in the polyatomic cations can attract additional electron pairs from atoms such as fluorine in the anion. This attraction depends only on the number of lone pairs and on the size of holes associated with the relevant atom and not on its formal charge.

In the discussion of heteroconjugated organic molecules[18] it was argued that those atoms which are more electronegative prefer to occupy sites which bear a larger negative charge in the parent polyenes. Based on the formal charge assignment in Fig. 1 one can predict the site preference for other heterohalogen chain-like clusters. For example, fluorine atoms in ClF_2^+ and BrF_2^+ occupy terminal sites in a V-shaped structure. In the linear $[Y—X—Y]^-$ molecules the central X atom is always the least electronegative, e.g. ClF_2^-, BrF_2^-, $BrCl_2^-$, IF_2^- and ICl_2^-.[2] Again, the site preference in $I_3Cl_2^+$, $I_3Br_2^+$, $I_2Cl_3^-$ and $I_2Br_3^-$[3,7] can be understood through the formal charge assignment in Fig. 1.

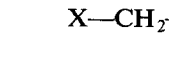
Abstract—Pyruvic acid semicarbazonato manganese(II) hydrate, $Mn(C_4H_6N_3O_3)_2 \cdot H_2O$, has been prepared and its IR spectra and thermal decomposition (TG) have been investigated. The crystal structure was determined by X-ray diffraction analysis. The crystal is triclinic, space group $P\bar{1}$ with unit cell dimension $a = 8.916(2)$, $b = 9.362(2)$, $c = 10.067(2)$ Å, $\alpha = 101.92(3)$, $\beta = 91.25(2)$, $\gamma = 117.08(3)^\circ$ and $V = 725.6(7)$ Å^3, $Z = 2$, $D_c = 1.644$ g cm^{-3}. The structure was solved by the heavy-atom technique from 3586 observed, independent reflections recorded at 293 K and refined to a final $R = 0.053$. The manganese atom has a distorted octahedral coordination with ONO donor sets from hydrazone ligands. The crystal structure contains one water molecule of crystallization. The tight hydrogen-bonding network in the crystal packing gives rise to high thermal stability of the complex.

Hydrazone ligands derived from pyruvic acid (a significant metabolism intermediate) and hydrazides are generally superior in medicinal activity to the unique hydrazides.[1,2] Besides, the metal complexes with particular configuration and reactivity can probably provide us with some information about the pharmaceutical metabolism catalysed by metal enzymes.[3] Therefore, we have studied the synthesis, structure, property and biological activity of a series of complexes with pyruvic acid hydrazones as ligands.[4] Here we report the metal complex of another hydrazone ligand—pyruvic acid semicarbazone. Owing to their remarkable antitumor, antiviral and antimalarial activities semicarbazones and their thio-analogues have received considerable attention and intensive investigation in coordination chemistry.[5] As for the pyruvic acid hydrazones their complexes were first studied by Ablov *et al.*[6–8] in 1970. To date, the ligands reported can be summarized with the general formula (**I**):



(**I**)

where R = H, CH_3, CH_3CH_2; X = H, C_6H_5, 4-$CH_3C_6H_4$; H_2Y = $H_2NNHCONH_2$,[6,9,10] $H_2NNHCSNH_2$,[6–13] $H_2NN{=}C(SCH_3)NH_2$,[14] $H_2NNHCOC_6H_5$,[15] H_2NNHCO—  .[4]

However, only a few crystal structures of complexes are known, including $[Cr(Hthpu)(thpu)] \cdot H_2O$,[11] $\{[Cu(Hpt)Cl] \cdot 2H_2O\}_n$, $[Cu(ept)Cl]_2$[13] and $[Mn(H_2PAPH)(OH_2)_2] \cdot 2.5H_2O$.[4] Perhaps because of

* Author to whom correspondence should be addressed.

tautomerism the structure of the complexes varies with the synthetic conditions.

EXPERIMENTAL

Preparations

The hydrazone ligand, pyruvic acid semicarbazone, was obtained by a previous method.[3]

Freshly prepared solid $Mn_2(OH)_2CO_3$ (over 1 mmol) was added in portions to a stirred solution of the ligand (2 mmol) in distilled water (20 cm^3) at 80°C. At pH = 7 the solution was filtered and yellow crystals suitable for X-ray structural analysis were obtained after the filtrate was allowed to stand for *ca* 2 weeks at room temperature.

Measurements

IR spectra were measured with an American 5 DX-FTIR spectrometer and the TG spectra with a Du Pont 1090B-951 thermogravimeter.

Structure determination. A yellow crystal ($0.2 \times 0.2 \times 0.3$ mm) was mounted on an Enraf–Nonius CAD-4 diffractometer. The unit cell was measured by centring 25 reflections ($10 \leqslant \theta \leqslant 15°$) and refined by least-squares. Mo-K_α radiation was used. Intensities were measured with an ω–2θ scan technique, scan width : $0.52 \pm 0.34 \tan\theta$ ($h = -11$–11; $k = -12$–12; $l = 0$–13). 3686 independent reflections were collected, of which 3192 were considered observed [$I \geqslant 3\sigma(I)$]. Lorentz and polarization but no absorption corrections were made.

The manganese atom was located from a Patterson synthesis and the remaining non-hydrogen atoms from Fourier syntheses. The structure was refined isotropically and anisotropically by least-squares refinement. The function minimized was $\Sigma w(|F_o| - |F|)^2$, where w = 1. All hydrogen atoms were located from a difference synthesis and refined with an overall isotropic thermal parameter. Final $R = 0.048$ ($wR = 0.053$); $(\Delta/\sigma)_{max} = 0.59$ and the final difference-Fourier map showed peaks at 0.39 e $Å^{-3}$. Atomic scattering factors were taken from ref. 16. All calculations were performed on a PDP 11/44 computer using the SDP package.[17]

RESULTS AND DISCUSSION

Crystal structure of $Mn(C_4H_6N_3O_3)_2 \cdot H_2O$

Selected interatomic distances and bond angles are given in Table 1. Chemical analysis of the complex suggested the formula $Mn(C_4H_6N_3O_3)_2 \cdot H_2O$. Structural analysis indicates one complex unit $Mn(C_4H_6N_3O_3)_2$ and one lattice water molecule in the unit. The structure of the complex is shown in Fig. 1 and a diagram showing the unit cell contents is given in Fig. 2.

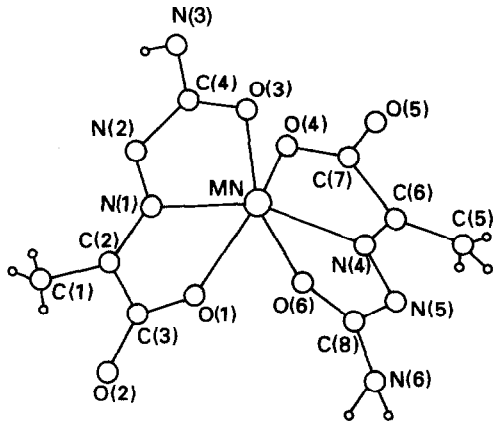


Fig. 1. Structure of the title compound showing the atomic numbering scheme.

It is notable that the unit cell consists of two $Mn(C_4H_6N_3O_3)_2 \cdot H_2O$ molecules bound with a tight hydrogen bond network, which is similar to that of $[Cr(Hthpu)(thpu)] \cdot H_2O$.[11] This network leads to a high thermal stability, which was confirmed by TG analysis. The crystal water is situated just in the hydrogen bond network.

As seen in Fig. 1 each ligand is a tridentate chelate with its ONO atoms bonded to the metal. The coordination sphere about manganese is a slightly distorted octahedron, the coordination atoms of the same ligand and the manganese atom are nearly co-planar.

From the torsion angles (Table 2) the relative spatial arrangement of the complex can be examined. Taking the first ligand (left part in Fig. 1) as an example, the torsion angles of Mn—N(1)—N(2)—C(4), 5.30°, and Mn—O(3)—C(4)—N(2), 3.01°, indicate that Mn metal is situated in the chelate plane of Mn—N(1)—N(2)—C(4)—O(3)—Mn. Similarly, the second chelate

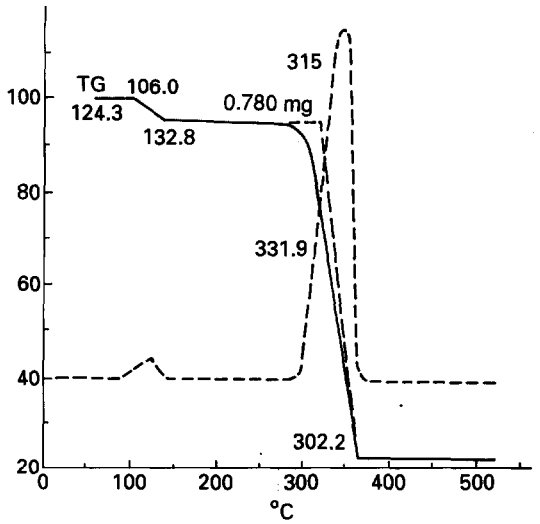

Fig. 3. TG of the complex.

ring of the same ligand, composed of Mn, N(1), N(2), C(4) and O(3), is also almost co-planar. Also from the torsion angles the two least-squares planes are staggered to each other at an angle somewhere between 60 and 100°, but not the ideal perpendicular.

In a normal octahedron all the angles between adjacent planes should be 90°. However, in this complex only the angles between the coordination atoms of different ligands and the metal are approximately 90°: O(3)—Mn—O(4) = 93.98(5) and O(1)—Mn—O(6) = 89.25(6). The angles between atoms of the same ligand and Mn are averaged to 71°. As for the bond lengths, among the four Mn—O bonds Mn—O(6) is the longest, which is due to hydrogen bond formation with non-coordinated NH_2. This fact also reveals that the effect of hydrogen bonds between molecules cannot be ignored in this crystal.

TG analysis and IR spectra

The TG curve of the complex is given in Fig. 3 and it can be seen that the temperature at which water is lost is rather high (106.0–132.8°C); this is probably due to the existence of a tight hydrogen bond network between different complex molecules, as stated above.

The IR spectra of the complex gives ν(Mn—O) = 540 cm^{-1} and the absorption bands which appear at 1750 [ν(C=O)(COOH)], 1679 [ν(C=O)(semicarbazide)] and 1620 cm^{-1} [ν(C=N)] in the ligand are shifted relatively far to the low wave number region at 1681, 1626 and 1607 cm^{-1}, respectively. This fact also indicates that the coordination between the ligand and Mn^{2+} is rather strong. The IR spectra also reflect the coordination characteristics that the ligand is coordinated to Mn^{2+} by its O—N—O atoms.

REACTIONS OF 1,3-BUTANEDIOL WITH HEXACHLOROCYCLOTRIPHOSPHAZENE: UNUSUAL NON-EQUIVALENCE OF PHOSPHORUS NUCLEI IN THE SPIROCYCLIC PRODUCT $N_3P_3Cl_4[OCH(CH_3)CH_2CH_2O]$

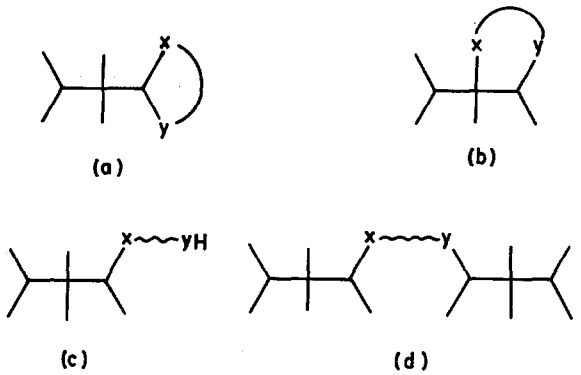
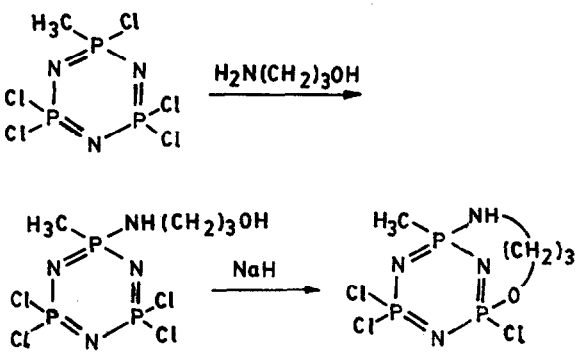
(*Received* 21 *October* 1992; *accepted* 19 *February* 1993)

Abstract—The reaction of hexachlorocyclotriphosphazene, $N_3P_3Cl_6$ (**1**), with 1,3-butanediol affords the tetrachloro derivative $N_3P_3Cl_4[OCH(CH_3)(CH_2)_2O]$ (**2**). This product (**2**) and its derivative $N_3P_3(NMe_2)_4[OCH(CH_3)(CH_2)_2O]$ (**3**) possess spirocyclic structures. The phosphorus NMR spectrum of **2** is of the AMX type instead of the expected AB_2 or AX_2 types observed for other spirocyclic products. The synthesis of **2** and **3** and their characterization by proton and phosphorus NMR are discussed.

There are four main products possible in a reaction between hexachlorocyclotriphosphazene, $N_3P_3Cl_6$ (**1**), and any difunctional reagent such as a diamine or a diol. These are (a) spirocyclic, (b) ansa, (c) open-chain and (d) inter-molecular bridging.[1]



The type of product formed depends on the nature of the difunctional reagent. Thus, with a number of aliphatic difunctional reagents, $HY(CH_2)_nXH$ (X = Y = NH, n = 2, 3, 4, 5; X = Y = NCH_3, n = 2, 3; X = H, Y = NCH_3, n = 2; X = NH, Y = O, n = 2, 3; X = Y = O, n = 2, 3, 4), the reaction proceeds to afford predominantly the spirocyclic product.[2] Similarly reactions with aromatic difunctional reagents also give products containing five-, six- or seven-membered spirocyclic rings.[3] The first example where an "*ansa*" product is obtained in high yields consists of an indirect route:[4]



A French group has reported that the reaction of bis-2-amino ethyl ether with $N_3P_3Cl_6$ leads predominantly to the formation of an *ansa* product, $N_3P_3Cl_4[NH(CH_2)_2O(CH_2)_2NH]$.[5] More recently there have been reports that in reactions between aliphatic diols and $N_3P_3Cl_6$ small amounts of the *ansa* product could also be isolated, in addition to the major spirocyclic product.[6] In order to explore this possibility further we have studied the reactions of $N_3P_3Cl_6$ with an unsymmetrical difunctional reagent, 1,3-butanediol. It was reasoned that with such a reagent product characterization would be unambiguous. Thus, a spirocyclic product would show an AB_2 or AX_2 spin pattern, while an *ansa* product would be of the ABX, AMX or ABC spin type in the phosphorus NMR. The other two possibilities can be distinguished by analytical data

alone. Surprisingly in our investigations of the above reaction we find that the spectroscopic behaviour of the product belies such simplistic reasoning. Thus, the product obtained in the above reaction, $N_3P_3Cl_4[OCH(CH_3)CH_2CH_2O]$ (**2**), shows a three-spin system (AMX) in the phosphorus NMR. However, more careful analysis of the NMR data reveals that the structure is spirocyclic as a result of the diastereotropic nature of the two $\equiv PCl_2$ groups. These results are discussed below.

EXPERIMENTAL

$N_3P_3Cl_6$ (Aldrich) was recrystallized from light petroleum ether (60–80°C); 1,3-butanediol (Fluka) was used as received. Anhydrous dimethyl amine was liberated from an aqueous solution (40% w/v) by treatment with KOH. The liberated amine was further dried by passing over KOH towers before collecting in a trap cooled at −78°C. The other solvents and reagents were purified by standard procedures.[7]

The proton and phosphorus NMR spectra were recorded on a Bruker 400 MHz instrument and chemical shifts are reported in ppm relative to Me_4Si in $CDCl_3$ and 85% H_3PO_4(ext.), respectively. Mass spectra were measured on a Kratos MS 80 RFA instrument (E.I./70 eV).

Preparation of $N_3P_3Cl_4[OCH(CH_3)(CH_2)_2O]$ (**2**)

$N_3P_3Cl_6$ (3.50 g, 10.1 mmol) was dissolved in dry benzene (150 cm^3). 1,3-Butanediol (0.91 g, 10.1 mmol) and triethyl amine (3.10 g, 30.6 mmol) were also dissolved in dry benzene (50 cm^3) and added over a period of 30 min to the solution of the trimeric chloride, with constant stirring. A calcium chloride guard tube was used to prevent moisture. After the addition was complete the reaction mixture was heated under reflux for 5 h. The reaction was monitored by TLC by the disappearance of $N_3P_3Cl_6$ (eluant: petroleum ether 60–80°C). The reaction mixture was allowed to cool and was then filtered to remove triethylamine hydrochloride. The filtrate was then washed with water (2×30 cm^3) and dried (Na_2SO_4). Benzene was stripped off *in vacuo*, affording a "semi" solid. This was pumped overnight and purified by crystallization from methylene chloride and petroleum ether (60–80°C) (1 : 1). The product isolated was identified as $N_3P_3Cl_4[OCH(CH_3)CH_2CH_2O]$ (**2**); m.p. 153–154°C. Yield 2.04 g, 55.60%. Mass spectra: parent ion at m/z 363 (^{35}Cl) showing the four chlorine isotope pattern. ^1H NMR: C(4)H_3: 1.44 (d of d), ^3J(H—H), 6.3 Hz, ^4J(P—H) 2.6 Hz; C(2)H_2: 1.80(m), 2.05(m); O—C(3)H_2: 4.39(m), 4.56(m); OC(1)H: 4.82(m).

A similar product was obtained in lesser yield when 2 equivalents of triethyl amine was used as a hydrogen chloride acceptor.

Preparation of $N_3P_3(NMe_2)_4[OCH(CH_3)(CH_2)_2O]$ (**3**)

Compound (**2**) (3.659 g, 10 mmol) was reacted with an excess of anhydrous dimethyl amine (25 g, 0.56 mol) in boiling chloroform (200 cm^3) for 4 h. The reaction mixture was allowed to reach room temperature and then washed with water (4×50 cm^3) to remove dimethyl amine hydrochloride and excess dimethyl amine. The organic layer was dried ($CaCl_2$) and the removal of solvent afforded an oil, which was identified as compound **3**. Mass spectra: parent ion at m/z 409. ^{31}P NMR: complex pattern, multiplets centred at 27.92 and 16.02 ppm. Spectrum recorded under proton coupled conditions affects both multiplets. ^1H NMR: CH—C(4)H_3: 1.32 (d of d), ^3J(H—H), 6.3 Hz; ^4J(P—H), 2.2 Hz. C(2)H_2: 1.56(m), 1.91(m); N—CH_3 2.61, ^3J(P—H) 11.2 Hz; 2.60, ^3J(P—H) 11.3 Hz; O—C(3)H_2: 4.16(m), 4.5(m), O—C(1)H, 4.73(m).

RESULTS AND DISCUSSION

The reaction of $N_3P_3Cl_6$ (**1**) with 1,3-butanediol proceeds smoothly with the replacement of two chlorines, in the presence of triethylamine:

$$N_3P_3Cl_6 + HO—CH(CH_3)(CH_2)_2OH \xrightarrow{2Et_3N}$$

$$N_3P_3Cl_4[OCH(CH_3)(CH_2)_2O]\,(\mathbf{2}) + 2Et_3N \cdot HCl.$$

The remaining four chlorines in **2** are easily replaced by $HNMe_2$ giving $N_3P_3(NMe_2)_4[OCH(CH_3)(CH_2)_2O]$ (**3**). The proton and phosphorus NMR of **2** are shown in Figs 1 and 2, respectively.

The proton NMR spectrum of **2**, even at 400 MHz, is quite complex. Homonuclear decoupling experiments have enabled the assignment of the peaks. The CH_3 group attached to C(1) appears as a doublet of doublets as a result of a three-bond coupling to OCH and a four-bond coupling to phosphorus. Such four-bond couplings are quite rare in phosphazenes. The OC(1)H is the most deshielded (4.82 δ). This is easily assigned since decoupling of the CH_3 resonance at 1.44 δ affects only the peak at 4.82 δ. The methylene protons of O—C(3)H_2 and C—C(2)H_2 are non-equivalent. The protons of C—C(2)H_2 appear as two multiplets centred at 1.80 and 2.05 δ. The complex multiplicity is as a result of coupling to the two non-equivalent protons of O—C(3)H_2 and O—C(1)H. Similarly, the O—C(3)H_2 protons appear as two sets of complex multiplets.

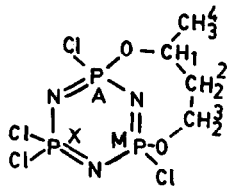
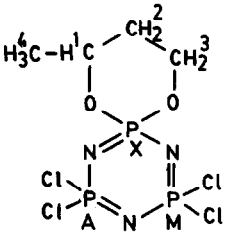
[a] $\delta P_A = P(CH_3)(NHR)$; $\delta P_B = P(Cl)(O)$; $\delta P_X = P(Cl_2)$.
[b] J(A—B) = 4.0; J(A—X) = 9.8; J(B—X) = 48.8 Hz.
[c] δPCl_2.
[d] $\delta PCl(OR)$
[e] δP(spiro).
[f] J(A—B) = 57.9; J(A—X) = 61.7; J(B—X) = 78.6 Hz.

The proton NMR spectrum of the dimethyl amino derivative $N_3P_3(NMe_2)_4[OCH(CH_3)(CH_2)_2O]$ (3) shows similar features to that of 2; in addition, two N—CH_3 signals are seen, both without virtual coupling.

The phosphorus NMR spectrum of 2 is of the AMX type (Fig. 2). The results are presented in Table 1. Spirocyclic products obtained with other unsymmetrical difunctional reagents, $N_3P_3Cl_4[N(CH_3)CH_2CH_2O]$,[2i] $N_3P_3Cl_4[HNCH_2CH_2O]$[2b] and $N_3P_3Cl_4[HN(CH_2)_3O]$,[2k] exhibit an AB_2 type of phosphorus NMR spectrum. The *ansa* product $N_3P_3Cl_3CH_3[HN(CH_2)_3O]$[4] shows an ABX spectrum. Therefore, an AMX type of pattern in the phosphorus NMR for 2 suggests an *ansa* structure. If this were so the phosphorus atom containing the chlorines would be of the X type and the phosphorus atoms having one chlorine and one oxygen each would belong to the AM type.



Ansa



Spirocyclic

However, this would mean assigning the peak at 2.7 ppm to $\equiv PCl_2$. All known $\equiv PCl_2$ resonances in six-membered cyclophosphazenes are much more downfield than this value (+15.0 to +25.0 ppm).[1] Further, when the phosphorus NMR spectrum is recorded under proton coupled conditions, if the structure were *ansa* the A and M portions of the spectrum (downfield region) should be affected. However, as can be seen from Fig. 2 it is the X portion *alone* which is affected, leaving the A and M regions untouched. This is possible only if the structure is spirocyclic. Also, in a spirocyclic structure the A and M portions are assignable to $\equiv PCl_2$ (25.59 and 22.10 ppm), whose chemical shifts are now completely in agreement with the literature observations.

The non-equivalence of the methylene protons [C—C(2)H_2 and O—C(3)H_2], as well as the two phosphorus nuclei bearing chlorines, is presumably due to the influence of the —CH_3 substituent on C(1) of the spirocyclic ring. This would render the two $\equiv PCl_2$ groups diastereotropic. Such an influence of an asymmetric carbon substituent on the phosphorus chemical shifts has recently been demonstrated in *gem* alkyl (hydroxy alkyl) tetrachlorocyclotriphosphazenes, $N_3P_3Cl_4(CH_3)(CR^1R^2OH)$, where R^1 and R^2 are different.[8] Another reason for the observed non-equivalence of $\equiv PCl_2$ in 2 could be that the CH_3 substituent on C(1) would prefer an equatorial position of the energetically favourable chair conformation of the six-membered phosphate ring. This preference would substantially freeze the conformation leading to the observed pattern. In the absence of such effects the phosphorus NMR of spirocyclic products would be of the AB_2 type. We are investigating more examples of this nature to substantiate this point.

Acknowledgements—We are thankful to DST (India) for financial support. Thanks are due to Dr R. Yamadagni,

University of Calgary, Alberta, Canada, for help in recording some of the spectra.

(*Received* 2 *February* 1993; *accepted* 18 *February* 1993)

Abstract—Δ,Λ-[Cd(phen)$_2$(*S*-aa)]$^+$NO$_3^-$ diastereomeric systems (where phen = 1,10-phenanthroline and *S*-aa = *S*-alaninate, *S*-serinate, *S*-threoninate, *S*-prolinate, *S*-valinate, *S*-leucinate and *S*-phenylalaninate) have been prepared in the form of methanolic solutions and characterized by spectral (UV, CD, ORD) and conductance measurements. The CD spectra of these systems in the β' band region of the diimine ligand exhibit residuary exciton splittings, whose intensities and sign patterns suggest the following decreasing order of [Λ]/[Δ] diastereoisomeric equilibrium constants: *S*-prol > *S*-phenala > *S*-val > 1 > *S*-ala > *S*-leu > *S*-ser > *S*-threo. The same order is inferred from the ORD data over the range 400–600 nm. Comparison with the selectivities observed for some zinc analogues and the analysis of molecular models suggest that in the cadmium systems the chiral discriminations are governed mainly by a balancing between intramolecular steric repulsion, differential solvation and discriminating ion association. Solvent effects on the optical activity of some cadmium and zinc systems in methanol/n-propanol and methanol/benzene mixtures have also been studied. The corresponding results are discussed in terms of the contributions of the above discriminating forces.

The circular dichroism (CD) spectra in the aromatic region of Δ,Λ-[M(diimine)$_2$(aa)]$^{(z-q)+}$ systems, where M^{z+} is a transition or an $(n-1)d^{10}$ metal ion, diimine is 1,10-phenanthroline or 2,2′-bipyridine and aa^{q-} is an optically active α-aminoacidate, in aqueous or methanolic solution, exhibit residuary exciton bands whose intensities and sign patterns can be mainly connected with the particular positions of the respective diastereoisomeric equilibria:[1–4]

$$\Delta\text{-[M(diimine)}_2\text{(aa)]}^{(z-q)+} \rightleftharpoons \Lambda\text{-[M(diimine)}_2\text{(aa)]}^{(z-q)+}.$$

The equilibrium constants for the preceding reactions show, in turn, a clear dependence upon the nature of the side-chain of the chiral ligand. Usually, the chelation of an *S*-aminoacidate having an apolar side-chain induces an equilibrium shift towards an increase in concentration of the Λ-isomer. Here, the origin of chiral discrimination has been ascribed to a prevalence of intramolecular ligand–ligand steric repulsive interactions in the less preferred Δ-isomer.[2–6] On the other hand, the chelation of an *S*-aminoacidate having a polar side-chain may lead to the predominance of either the Δ- or the Λ-diastereoisomer, depending on the particular metal ion and diimine ligand involved. Thus, concerning the trend to Δ-isomer predominance, for systems containing *S*-serinate the order Ru^{II} > Co^{III} can be established from the data reported at present.[1,7] The order 2,2′-bipy > 1,10-phen is also observed for the above tendency in systems of ruthenium(II) with *S*-serinate, *S*-aspartate or *S*-glutamate.[1,8,9] This sequence has been ascribed to the greater flexibility of the bipyridine ligand,[8] which should cause a decrease in the intramolecular ligand–ligand steric repulsion, thus enhancing other types of non-covalent interactions that are referred to below. Indeed, for 1,10-phen systems in aqueous solution chiral induction involving Δ/Λ > 1 occurs only in Δ,Λ-[Ru(phen)$_2$(*S*-glu)]^0 and Δ,Λ-

$[Ru(phen)_2(S\text{-threo})]^+$, whereas Δ,Λ-$[Ru(phen)_2(S\text{-asp})]^0$ and Δ,Λ-$[Ru(phen)_2(S\text{-ser})]^+$ show no stereoselectivity.[1,8–10] In general, chiral discrimination favouring the stability of one diastereoisomer would arise partly from a balancing between steric repulsive interactions and other intramolecular forces, such as hydrogen bonding and possible hydrophobic bonding interactions.[8,9] Further, some intermolecular factors have also been suggested as sources of stereoselectivity, namely differential solvation[11] and hydrogen bonding interactions with the surrounding chiral solvent sheaths,[12] which are concomitant with the dissymmetry of the complex ions. A structural feature of rather obvious interest for the study of the different kinds of interactions previously mentioned would be the metal ion size. An increase in the metal ion radius should diminish the intramolecular steric repulsion effects, which are usually predominant, thus allowing other discriminating forces to become apparent with relatively higher intensities. This report is concerned with the stereoselective effects of non-resolvable *S*-aminoacidatobis(1,10-phenanthroline)cadmium(II) complexes in methanolic solution. In these complexes the metal–ligand bond lengths should be nearly 0.2 Å larger than those of the corresponding complexes of zinc or ruthenium(II). Hence, a somewhat different balancing of intramolecular interactions should be expected here regarding the analogues of those metal ions. Similarly to zinc systems, cadmium systems exhibit very rapid diastereoisomeric equilibration rates. This prevents both the use of ordinary resolution procedures and the experimental estimation of the respective Δ/Λ equilibrium constants from optical activity measurements. Notwithstanding the above restraints, these complexes provide in return the certainty of dealing with truly equilibrated diastereoisomeric systems.

EXPERIMENTAL

Nitrate salts of the heterochelated ions Δ,Λ-$[Cd(phen)_2(S\text{-aa})]^+$ were prepared as 0.007 or 0.018 M solutions in methanol, by means of the following general reaction:

$$Cd(NO_3)_2\cdot 4H_2O + 2phen\cdot H_2O + S\text{-aaH} + (1/2)Ba(OH)_2\cdot 8H_2O \longrightarrow \Delta,\Lambda\text{-}[Cd(phen)_2(S\text{-aa})]NO_3 + (1/2)Ba(NO_3)_2 + 11H_2O;$$

where *S*-aaH = *S*-alanine, *S*-serine, *S*-threonine, *S*-valine, *S*-leucine, *S*-phenylalanine or *S*-proline. Stoichiometric amounts of the analytical reagent or CP-grade chemicals were mixed in methanol *pro analysi* as a solvent, and heated at 60°C in stoppered flasks until complete reaction of the amino acid. Once cooled the resulting mixtures were ultrasonically stirred and allowed to stand at room temperature for 2 days. Barium nitrate was discarded by filtration under suction. The resulting solutions were concentrated by boiling and standardized to 0.007 or 0.018 M at 25°C. For the sake of comparison chloride and sulphate salts of similar zinc complexes were also prepared as methanolic solutions (0.007 or 0.018 M in complex ions) by methods previously reported.[4] Electronic spectral measurements in the UV region were performed at room temperature on a Carl–Zeiss DMR-21 spectrophotometer using 5.6×10^{-5} M solutions in 0.1 cm cells. CD spectra were recorded on a Cary 60 spectropolarimeter, at room temperature, using 2.1×10^{-4} or 4.2×10^{-4} M solutions in closed 0.1 cm cells. Optical rotatory dispersion (ORD) spectra were measured at 25°C on a modified Perkin–Elmer 141 polarimeter, using 0.007 M solutions in thermostated closed 2 or 10 cm cells. Conductivity measurements were performed at 25°C with a YSI model 32 conductance bridge and an immersion cell ($1.022\ cm^{-1}$), using 0.007 M solutions. Molar ratio studies of optical rotation at 450 nm of the systems Cd^{II} : phen : *S*-aa = $1:x:1$ were performed at 25°C over the range $1 \leqslant x \leqslant 3$ for *S*-aa = *S*-threo and *S*-val. Moreover, solvent effects of increasing concentrations of n-propanol and benzene on the optical activity of some 0.0018 M cadmium systems were tested over the ranges 0–12 M and 0–10 M, respectively. Some zinc systems were also considered in these experiments. The effects of the relatively small water contents of the complex salt solutions on diastereoisomeric and formation equilibria were assumed to be neglible for comparative purposes.

RESULTS AND DISCUSSION

Spectral properties and diastereoisomeric equilibria

Results of the molar ratio studies on the systems Cd^{II} : phen : *S*-aa^- : NO_3^- = $1:x:1:1$ of *S*-valinate and *S*-threoninate are compared in Fig. 1, where the molecular rotations at 450 nm are plotted against $x = [phen]_{total} : [Cd^{II}]_{total}$. From these data it becomes apparent that the species responsible for the optical activity in the above system are $[Cd(phen)_2(S\text{-aa})]^+$ diastereoisomeric complexes. This inference agrees with the conductance data listed in Table 1. Although these values are not accurate, they strongly suggest that the cadmium systems prepared consist predominantly of uniu-

nivalent electrolytes.[13,14] Moreover, the UV absorption spectra in the region of the long-axis-polarized π–π^* transitions of the diimine ligand, which are virtually identical for the different cadmium systems, show bathochromic shifts of the *β*′- and *p*-bands that are similar to those of Δ,Λ-[Ni(phen)$_2$(*S*-aa)]$^+$ and Δ,Λ-[Zn(phen)$_2$(*S*-aa)]$^+$ complexes[4] (Figs 2 and 3). Some features of the CD spectra in the *β*′-band region of the studied cadmium systems are given in Table 1 and CD spectra in the *β*′- and *p*-band region of some selected systems are shown in Figs 2, 3 and 4. According to these data residuary exciton bands are always present in the CD spectra, their intensities and sign patterns being clearly dependent upon the structure of the side-chain of the chiral ligand. In fact, the typical sign pattern indicating the predominance of the Λ-diastereoisomer is observed only in the systems of *S*-phenylalaninate, *S*-prolinate and *S*-valinate, i.e. in systems of *S*-aminoacidates having

bulky, exceedingly rigid or *β*-substituted side-chains, respectively. Chiral discrimination arising from intramolecular steric repulsive interations must be preponderant in the above systems.[2,5] On the other hand, the exciton CD spectra of the remaining cadmium systems exhibit sign patterns characteristic of Δ-diastereoisomer predominance. Here, discriminating forces other than steric effects would be determinant. Interestingly, two systems containing aminoacidate ligands with apolar side groups are found amongst those exhibiting chiral induction with a preference for the Δ-isomer, viz. the *S*-ala and *S*-leu systems. The exciton CD spectrum of the latter is compared with its zinc analogue in Fig. 4. From a general point of view the above dependences of the CD spectra upon the nature of the side groups of the aminoacidates indicate at least that these ligands are acting as chelating agents.

Molecular rotation values for the cadmium systems are listed in Table 2. As can be seen, these data are in good agreement with the respective CD spectra. This fact is reflected by the plot of the molecular rotation at 450 nm against the maximum of circular dichroism of the low-energy long-axis-polarized π–π^* transition, which gives a fairly good linear correlation ($r = 0.994$). Taking into account the relative intensities of the low-energy exciton CD bands (Table 1) and the molecular rotation values at 450 nm (Table 2), the following sequence of diastereoisomeric equilibrium constants can be proposed for the cadmium systems: K(*S*-prol) > K(*S*-phenala) > K(*S*-val) > 1 > K(*S*-ala) > K(*S*-leu) > K(*S*-ser) > K(*S*-threo), where K(*S*-aa) = [Λ]/[Δ]. The preceding sequence differs noticeably from that obtained for analogues of zinc,[3] where steric effects are always predominant and no cases are observed of chiral discrimination enhancing the equilibrium concentration of the Δ-isomer: K(*S*-val) > K(*S*-prol) > K(*S*-threo) > K(*S*-ser) > K(*S*-leu) > K(*S*-ala) > 1 (Table 2).

Exciton splitting and hydrophobic interactions

For the sake of comparison the ORD spectra of the cadmium and zinc systems under study were

described over the range 400–600 nm through many-term Drude equations of the form:[4]

$$[\Phi]_\lambda = \frac{10^4}{1.4}\left[\frac{C_1\lambda_1^2}{\lambda^2-\lambda_1^2}+\frac{C_2\lambda_2^2}{\lambda^2-\lambda_2^2}+C_3\right];$$

where subscripts 1 and 2 are the β'-exciton bands, $\lambda_1 > \lambda_2$, and C_3 is a term comprising the weaker contributions. If the same excitation resonance splitting is assumed for both Δ and Λ isomers, the wavelengths of the absorption maxima of the exciton bands become $\lambda_1 = 10^7\lambda_0/(10^7-|\Sigma|\lambda_0)$ and $\lambda_2 = 10^7\lambda_0/(10^7+|\Sigma|\lambda_0)$, where λ_0 is the wavelength in nm of the baricenter of the β'-band and $|\Sigma|$ is the mean absolute value of the excitation resonance energy in cm^{-1}. The parameters C_1, C_2 and C_3 were calculated from the molecular rotation data at 400, 450 and 550 nm by iterating $|\Sigma|$ values until $C_1 \approx 0.1091\ [\Phi]_{450\,nm}$ was obtained. This condition arises from an assumed proportionality between C_1 and $[\Phi]_{450\,nm}$. The above proportionality constant was obtained from the previously studied system Δ,Λ-[Zn(phen)$_2$(*S*-ala)]Cl, for which $|\Sigma| = 100$ cm^{-1} was arbitrarily taken.[4] In other words this approximation implies that in these systems the intensity of the ORD spectrum depends much more upon the position of the Λ/Δ diastereoisomeric equilibrium than on the extent of the excitation resonance splitting. The $|\Sigma|$, C_1, C_2 and C_3 parameters thus obtained are shown in Table 2. The ORD curves calculated with these figures are in excellent agreement with the experimental ones. This fact becomes apparent on plotting the experimental against the calculated molecular rotation values over the range 400–600 nm. Straight lines almost passing through the origin are thus obtained, whose slopes are very close to unity, the corresponding correlation coefficients always being greater than 0.9996. Although the pairs of C_1 and C_2 values listed in Table 2 show the right sign patterns, they do not reflect the relative intensities of the residuary exciton bands (Table 1). However, some uncertainty could also be expected in the magnitudes of the residuary exciton bands since the diimine ligand exerts strong absorption in the aromatic spectral region, rendering the CD measurements difficult in most cases. On the other hand, for both cadmium and zinc systems the variation of $|\Sigma|$ through the aminoacidate series shows no correlation with the remaining Drude equation parameters. Nevertheless, for systems with *S*-aminoacidates having apolar side-chains amazingly good correlations are observed with a rather rough topological index consisting of the total number of atoms of the side-chain. Such correlations are shown in Fig. 5, where the systems of *S*-serinate and *S*-threoninate are also included, although they are not considered in the regression analysis. As can be seen these diagrams result in similar arrangements for the systems of both metal ions, even concerning the positions of the systems that contain *S*-aminoacidates with polar side-chains. Intramolecular non-covalent interactions could also be responsible for this behaviour. These forces should induce small geometrical changes that modify the effective distance between the transition dipoles located at the molecular centres of the adjacent diimine ligands. This assumption agrees with the fact that for each aminoacidate ligand the $|\Sigma|$ value of the zinc system is always greater than that of the cadmium system (Table 2), consistent with the dipole–dipole approximation.[15] Moreover, the $|\Sigma|$ values of systems containing *S*-aminoacidates with apolar side-chains follow the order *S*-phenala > *S*-leu > *S*-val > *S*-prol > *S*-ala, which parallels the hydrophobicity scale for side-chains of aminoacids.[16] Hence, the above defined topological index would also be reflecting the variation in this property through the aminoacidate series. Further, since the variation of the [Λ]/[Δ] equilibrium position of the cadmium and zinc systems through the aminoacidate series does not parallel the aforementioned hydrophobicity scale, it can be concluded that the contributions of intramolecular hydrophobic interactions are not determinant for the observed stereoselective effects. Indeed, intramolecular hydrophobic interactions would rather

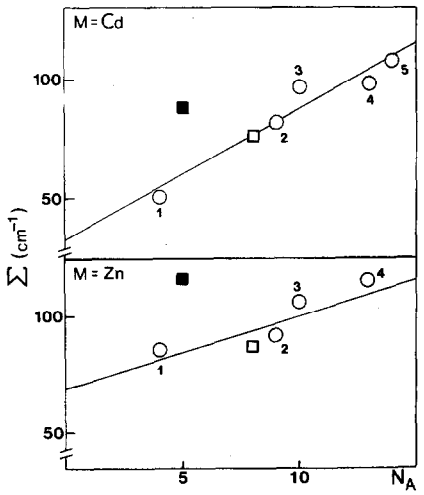

Fig. 5. Correlation of mean excitation resonance energies of Δ,Λ-[M(phen)$_2$(*S*-aa)]$^+$ systems vs side-chain sizes. enhance the stability of the Λ-isomer, as can be shown from the structure proposed by Sigel *et al.*[17] for the folded form of the species [Zn(phen)(*S*-leu)]$^+$.

Solvent effects

It seems reasonable to assume that both polar solvation and ion-pairing interactions of the diastereoisomeric species occur mainly through the amino group, because its hydrogen atoms would carry a substantial fraction of the positive charge of the metal chelates.[18] Thus, both differential polar solvation and discriminating ion association would take place on account of the different intramolecular environments that surround the coordinating amino group in each diastereoisomer. Analysis of molecular models suggests that although the Δ-diastereoisomer must be sterically less favoured than the Λ-form, it should be subjected in turn to better polar solvation on the amino group and stronger ion-pairing interactions, which would obviously contribute to increasing its thermodynamic stability. The above observations are illustrated in Fig. 6, where a comparison is attempted of the intramolecular environment of the assumed main polar solvation sites in the Δ- and Λ-isomers of the *S*-leucinate system. In these schematic representations the diastereoisomeric chelates are viewed along the $H_2N—Cd^{2+}$ bonds; consequently, the metal ions are eclipsed by the amino nitrogen donors. Moreover, both species are shown in folded form. As can be seen, in the Δ-isomer one of the hydrogen atoms of the NH_2 group remains freely exposed towards the bulk of the solvent, whatever the conformation adopted by the side-chain. Further, such a hydrogen atom would lie nearly 2.6 Å over the molecular plane of the phenanthroline ligand having both nitrogen donors in *cis* positions to the amino group. On the contrary, in the folded form of the Λ-isomer polar solvation should be somewhat hindered by the hydrophobic groups of the side-chain. As previously mentioned, in the case of the Λ-isomer the folded conformer would correspond to the "closed" form proposed by Sigel to account for the intramolecular hydrophobic interactions in the [Zn(phen)(*S*-leu)]$^+$ system.[17] Such interactions would be responsible for the slightly higher stability of the above 1 : 1 : 1 system in comparison with the *S*-alaninate analogue.[17] From the above considerations it could be proposed that, at least for the cadmium systems containing aminoacidates with apolar side-chains, the position of the [Λ]/[Δ] equilibrium is mainly determined by balancing between polar differential solvation, discriminating ion association and steric repulsive interactions. These factors in combination with hydrophobic solvation could also account for the observed effects that the increasing concentration of n-propanol has on chiral discrimination of cadmium and zinc systems in methanol/n-propanol mixtures (Figs 7 and 8). As can be seen, in systems containing aminoacidates with apolar side-chains the increasing concentration of n-propanol usually induces an equilibrium shift towards an increase in concentration of the Δ-isomer. This fact would be ascribed to the solvating properties of n-propanol. Apart from the ability to solvate the amino group, which is common for both solvents, n-propanol must be more

capable than methanol of interacting hydrophobically through its apolar end with the phenanthroline ligand lying almost perpendicular to the H_2N—Cd^{2+} bond (Fig. 6). The simultaneous occurrence of both types of interactions would be more favourable for the Δ-isomer, contributing to its stabilization. Moreover an increase in the discriminating ion-pair effects, favouring the Δ-form, would be expected from the decrease in dielectric constant of the solvent mixture. On the other hand, in the case of the system [Cd(phen)$_2$(*S*-prol)]NO$_3$ the optical rotation varies slightly, exhibiting a tendency to increase with increasing concentration of n-propanol (Fig. 8). This behaviour could be ascribed to the predominance of the unstabilizing effects of intramolecular steric repulsive forces in the Δ-isomer, owing to the extreme rigidity of the side-chain of the *S*-prolinate ligand. The small ascent in molecular rotation can be attributed to a shift of the formation equilibrium:

$$\Delta,\Lambda\text{-}[Cd(phen)_2(solv)_2]^{2+} + S\text{-prol}^- \rightleftharpoons \Delta,\Lambda\text{-}[Cd(phen)_2(S\text{-prol})]^+ + 2solv$$

towards the diastereoisomeric species, because of the decrease in dielectric constant of the solvent mixture. This assumption is supported by the fact that on counteracting the effects of such an equilibrium shift, i.e. in the system [Cd(phen)$_2$(*S*-prol)]*S*-prol (Fig. 8), the behaviour of molecular rotation as a function of n-propanol concentration is similar to those of the cadmium systems of *S*-leucinate or *S*-valinate (Fig. 7). The cadmium system containing *S*-threoninate, where the effects of polar differential solvation and discriminating ion association are predominant (Fig. 7), also exhibits a slight variation in optical rotation as a function of n-propanol concentration. Moreover, such a variation tends to be opposite to those observed for the remaining systems. This behaviour can be explained by assuming that the decrease in the dielectric constant of the solvent mixture causes the polar group of the side-chain to draw near the carboxylate or amine groups; thus, CO---HO or NH---OH hydrogen bonding would be promoted. The conformational changes involved here would be sterically more favourable in the Λ-isomer, as can be recognized from the analysis of molecular models. Hence, an increase in concentration of the Λ-isomer would be responsible for the slight rise in optical rotation observed on increasing the concentration of n-propanol above 6 M. The results obtained for the cadmium system with *S*-threoninate in methanol/benzene mixtures seem to be in support of the validity of the above assumptions (Fig. 9). In this case a conspicuous rise in optical rotation is observed with an increase in benzene concentration above 3.5 M; the greater intensity of this effect being in agreement with the more drastic decrease in dielectric constant involved here.

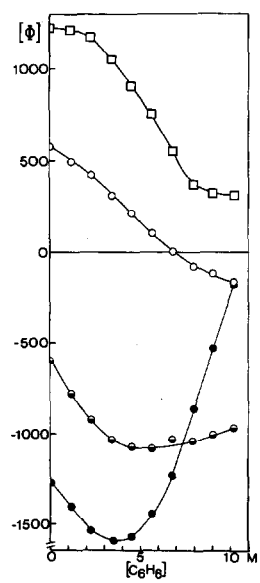

Fig. 9. Variation of molecular rotation at 450 nm of systems Δ,Λ-[M(phen)$_2$(*S*-aa)]X in methanol/benzene mixtures with varying benzene concentration, at room temperature. From a general point of view, for the systems in methanol/benzene mixtures (Figs 9 and 10) the observed effects of the increasing concentration of benzene could be ascribed in part to the fact that the polar groups of the chiral ligand, mainly the amino group, tend to keep the polar ends of the methanol molecules clustered at the solvation sites of the metal chelates, making polar differential solvation prevail as the discriminating factor. Moreover, discrimination arising from differential ion pairing should become more operative on decreasing the dielectric constant. Thus, for the cadmium system containing *S*-threoninate the above effects would predominate at least up to 3.5 M benzene. However, in all of the systems under study, both in methanol/benzene and methanol/n-propanol mixtures, chiral discriminating effects are obviously superposed with the effects arising from equilibrium shifts towards the formation of 1 : 2 : 1 diastereoisomeric species. Such equilibrium shifts would account for the more negative slopes of variation in optical rotation observed in the concentration range 0–3.5 M of benzene for the cadmium systems of *S*-leucinate or *S*-threoninate, as compared with the cadmium system containing *S*-valinate or the zinc system containing *S*-leucinate (Fig. 9). Instead, for the systems of cadmium and zinc containing *S*-prolinate and *S*-valinate, respectively, the effects of the formation equilibrium shifts clearly predominate in the range 0–4 M (Fig. 10). For the systems containing *S*-aminoacidates with apolar side-chains, except that of cadmium with *S*-leucinate, the effects of the polar differential solvation and discriminating ion association on the [Λ]/[Δ] ratios seem to predominate in almost all the concentration range considered, or at least above 3.5 M. The different behaviour of the cadmium system containing *S*-leucinate (Fig. 9) would be ascribed to a predominance above 5 M of the effects of an apolar differential solvation, which would arise from a more favourable hydrophobic solvation of the folded form of the Λ-isomer.[19] These effects would also be responsible for the changes in curvature or slight rises in optical rotation observed above 8 M benzene for the remaining systems containing *S*-aminoacidates with apolar side-chains (Figs 9 and 10).

(*Received* 27 *January* 1993; *accepted* 18 *February* 1993)

Abstract—Four binuclear complexes have been synthesized, namely $[Cu(oxae)Ni(L)_2](ClO_4)_2 \cdot H_2O$, where oxae denotes the N,N′-bis(2-aminoethyl)oxamido dianion and L denotes 2,2′-bipyridyl (bpy), 4,4′-dimethyl-2,2′-bipyridyl (Me_2bpy), 1,10-phenanthroline (phen) or 5-nitro-1,10-phenanthroline ($NO_2 \cdot$phen). Based on IR, elemental analyses, conductivity measurements and electronic spectra these complexes are proposed to have extended oxamido-bridged structures and to consist of the copper(II) ion in a square environment and the nickel(II) ion in an octahedral environment. The temperature dependences of the magnetic susceptibilities of $[Cu(oxae)Ni(bpy)_2](ClO_4)_2 \cdot H_2O$ and $[Cu(oxae)Ni(Me_2bpy)_2](ClO_4)_2$ have been studied in the 4.2–300 K range, giving the exchange integral $J = -112.7$ cm^{-1} for bpy and $J = -123.8$ cm^{-1} for Me_2bpy. These results are commensurate with antiferromagnetic interactions between the adjacent metal ions.

Binuclear metal complexes with extended bridged structures are of current interest due to spin-exchange and charge-transfer between metal ions and homogeneous catalysis.[1] In view of the effective bridged ability of the oxamido group Ojima and Nonoyama[2] first utilized N,N′-bis(2-aminopropyl)oxamidocopper(II), [Cu(oxap)], and N,N′-bis(3-aminopropyl)oxamidocopper(II), [Cu(oxpn)], as a bidentate mononuclear fragment to prepare the binuclear complex, but its detailed physicochemical properties have not been reported. Recently, complexes of this kind with various terminal ligands and other metal ions, such as $[Cu(oxap)M(L)_2](ClO_4)_2$ (M = Zn, Ni, Co, Mn, L = bpy, phen and $NO_2 \cdot$phen)[3–6] and $[Cu(oxpn)M(L)_2](ClO_4)_2$ (M = Zn, Ni, Co, Mn, L = bpy, phen and $NO_2 \cdot$phen)[7–10] were synthesized in our laboratory and their magnetic properties and some crystal structures were studied. As an extension of that investigation in this paper we report the synthesis, characterization and magnetism of four new complexes, $[Cu(oxae)Ni(L)_2](ClO_4)_2$ [where L = 2,2′-bipyridyl (bpy), 4,4′-dimethyl-2,2′-bipyridyl (Me_2bpy), 1,10-phenanthroline (phen) and 5-nitro-1,10-phenanthroline ($NO_2 \cdot$phen)].

EXPERIMENTAL

Preparation of Cu(oxae)

The procedure for the synthesis of Cu(oxae) has been reported previously by Ojima *et al.*[11] We have used a modification of this procedure in our study.

To an absolute ethanol solution (75 cm^3) of ethylenediamine (24.6 g, 0.4 mol) was added dropwise an absolute ethanol solution (200 cm^3) of diethyl oxalate (29.2 g, 0.2 mol). The mixture was refluxed for 4 h and then cooled. A suspension of copper(II) hydroxide (15.6 g, 0.16 mol) in water (100 cm^3) was added, which led to a blue solution and a violet–red solid residue. By adding $Cu(OH)_2$ in less than a stoichiometric amount, the formation of the green binuclear complex is avoided. The mixture was filtered and the solid residue was washed with water in order to extract all the expected compound. Violet–red microcrystals of Cu(oxae) were obtained by the addition of ethanol; Cu(oxae) is very soluble in water and insoluble in methanol or ethanol.

Preparation of $[Cu(oxae)Ni(bpy)_2](ClO_4)_2 \cdot H_2O$

To Cu(oxae) (94.2 mg, 0.4 mmol) stirred in methanol (5 cm^3) were successively added a solution of $Ni(ClO_4)_2 \cdot 6\,H_2O$ (146.3 mg, 0.4 mmol) in methanol (10 cm^3) and bpy (125.0 mg, 0.8 mmol) in methanol (10 cm^3). After stirring for 5 h the solution was filtered. Violet–red microcrystals were obtained, washed several times with absolute methanol and diethyl ether and dried *in vacuo*. Found: C, 37.5; H, 3.4; N, 13.6; Cu, 7.7; Ni, 7.0. Calc. for $C_{26}H_{28}N_8O_{10}Cl_2CuNi \cdot H_2O$: C, 37.9; H, 3.7; N, 13.6; Cu, 7.7; Ni, 7.1%.

Preparation of $[Cu(oxae)Ni(Me_2bpy)_2](ClO_4)_2$

This complex was obtained as violet–red microcrystals by the same procedure but using Me_2bpy instead of bpy. Found: C, 41.4; H, 4.2; N, 12.9; Cu, 7.1; Ni, 6.6. Calc. for $C_{30}H_{36}N_8O_{10}Cl_2CuNi$: C, 41.8; H, 4.2; N, 13.0; Cu, 7.4; Ni, 6.8%.

Preparation of $[Cu(oxae)Ni(phen)_2](ClO_4)_2 \cdot 0.5H_2O$

This complex was prepared in the same way but using phen instead of bpy. Light red microcrystals were obtained. Found: C, 41.7; H, 3.3; N, 12.7; Cu, 7.4; Ni, 6.7. Calc. for $C_{30}H_{28}N_8O_{10}Cl_2CuNi \cdot 0.5H_2O$: C, 41.8; H, 3.4; N, 13.0; Cu, 7.4; Ni, 6.8%.

Preparation of $[Cu(oxae)Ni(NO_2 \cdot phen)_2](ClO_4)_2$

This complex was obtained in the same way but replacing bpy with $NO_2 \cdot$phen. Apricot–red microcrystals were obtained. Found: C, 38.0; H, 2.6; N, 14.4; Cu, 6.6; Ni, 6.1. Calc. for $C_{30}H_{26}N_{10}O_{14}Cl_2CuNi$: C, 38.2; H, 2.8; N, 14.8; Cu, 6.7; Ni, 6.2%.

Measurements

Elemental analyses of carbon, hydrogen and nitrogen were performed using a Perkin–Elmer elemental analyser, Model 240. Metal contents were determined by EDTA titration, IR spectra were measured on a Shimadzu IR spectrophotometer, Model 408, using KBr pellets, and the electronic spectra (methanol solution) were measured on a Hitachi-240 spectrophotometer. The molar conductance was measured with a DDS-11A conductometer. Variable temperature magnetic susceptibilities were measured on a vibrating sample magnetometer, Model CF-1. Diamagnetic corrections were made with Pascal's constants for all the constituent atoms, and the magnetic moments were calculated using the equation $\mu = 2.828(\chi T)^{1/2}$. ESR spectra were measured with a JES-FEIXG ESR apparatus using the *X*-band.

RESULTS AND DISCUSSION

General characterization

Elemental analyses indicated that the reaction of Cu(oxae) with $Ni(ClO_4)_2 \cdot 6H_2O$ and bpy, Me_2bpy, phen or $NO_2 \cdot$phen yielded the binuclear complexes. For the four $[Cu(oxae)Ni(L)_2](ClO_4)_2$ complexes, the molar conductance values (see Table 1) fall in the expected range for 1:2 electrolytes,[12] indicating that the two perchlorate anions are situated outside the metal coordination sphere. The significant bands in the IR spectra of the complexes are given in Table 1. The $\rangle C{=}O$ (carbonyl) stretching vibration at 1615 cm^{-1} for Cu(oxae) and the $\rangle C{=}N-$ stretching vibration at 1450–1500 cm^{-1} for the terminal ligands (bpy, Me_2bpy, phen and $NO_2 \cdot$phen) were shifted to higher frequencies in their binuclear complexes. It is likely that the bond order of C=O in the binuclear complexes is higher than that in the mononuclear complexes. These shifts have often been used as definite proof for the existence of the oxamido bridge.[2] In addition, the $-NH_2$ vibration at 3250 cm^{-1} for Cu(oxae) was present for all complexes and a broad, intense band is observed at 1085 cm^{-1},

1 = $[Cu(oxae)Ni(bpy)_2](ClO_4)_2 \cdot H_2O$; **2** = $[Cu(oxae)Ni(Me_2bpy)_2](ClO_4)_2$; **3** = $[Cu(oxae)Ni(phen)_2](ClO_4)_2 \cdot 0.5H_2O$; **4** = $[Cu(oxae)Ni(NO_2 \cdot phen)_2](ClO_4)_2$.

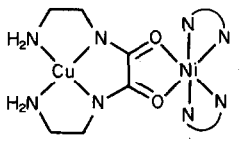

Fig. 1. Proposed chemical structure of $[Cu(oxae)Ni(L)_2]^{2+}$ (L = bpy, Me_2bpy, phen and $NO_2 \cdot$ phen).

which is typical for a non-coordination perchlorate ion.[13] Two strong absorptions in the UV range and only a weak absorption in the visible range can be observed. The former may be attributed to the charge-transfer absorption bands and the latter to the *d–d* transition.[8] Based on the discussion above these complexes are proposed to have an extended oxamido-bridged structure and to contain copper(II) in a planar environment and nickel(II) in an octahedral environment, as shown in Fig. 1.

Magnetic properties

The observed magnetic moment for the binuclear complexes at room temperature (2.74 B.M. for bpy and Me_2bpy) is considerably less than the spin-only value (3.32 B.M.). This suggests the operation of an antiferromagnetic spin-exchange interaction in these complexes. Variable-temperature susceptibility data were collected for bpy and Me_2bpy (Figs 2 and 3) and the magnetic analysis was performed using the susceptibility equation based on the Heisenberg spin operator ($\hat{H} = -2J\hat{S}_1\hat{S}_2$, $S_1 = 1/2$, $S_2 = 1$).[14]

$$\chi_M = \frac{N\beta^2}{4KT}\frac{g_{1/2} + 10g_{3/2}\exp(3J/KT)}{1 + 2\exp(3J/KT)}, \qquad (1)$$

where χ_M denotes the susceptibility per binuclear complex and $g_{1/2}$ and $g_{3/2}$ are g factors associated with the doublet and the quartet states, respectively. They are related to the local g factors g_{Ni} and g_{Cu}, assumed to be isotropic through $g_{1/2} = (4g_{Ni} - g_{Cu})/3$, $g_{3/2} = (2g_{Ni} + g_{Cu})/3$. The remaining symbols have their usual meanings. As shown in Figs 2 and 3 and good fits to the experimental data were obtained for $J = -112.7$ cm^{-1}, $g_{Ni} = 2.29$, $g_{Cu} = 2.10$, $\bar{g} = 2.20$ (bpy) and $J = -123.8$ cm^{-1}, $g_{Ni} = 2.29$, $g_{Cu} = 2.00$, $\bar{g} = 2.15$ (Me_2bpy). The agreement factor F defined here as $F = \Sigma[(\chi_M)_{obs} - (\chi_M)_{calc}]^2/\Sigma(\chi_M)_{obs}$ is then equal to 1×10^{-4}.

To describe the mechanism of exchange interaction several models have been proposed.[15–17]

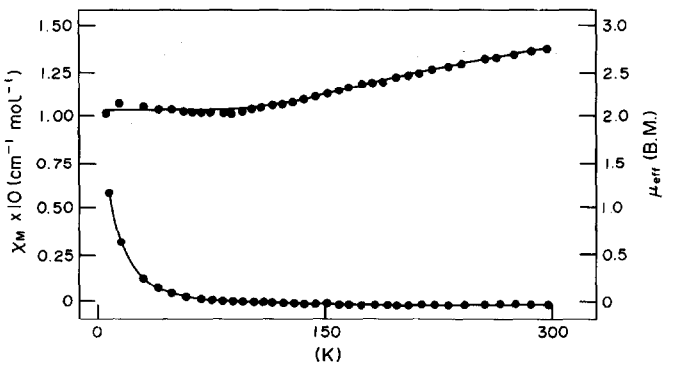

Fig. 2. Temperature variation of the magnetic susceptibility and magnetic moment for $[Cu(oxae)Ni(bpy)_2](ClO_4)_2 \cdot H_2O$. The curve is drawn based on eq. (1) using the magnetic parameters given in the text.

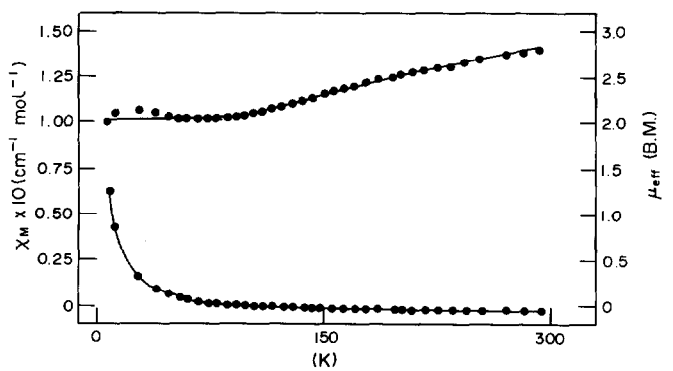

Fig. 3. Temperature variation of the magnetic susceptibility and magnetic moment of $[Cu(oxae)Ni(Me_2bpy)_2](ClO_4)_2$.

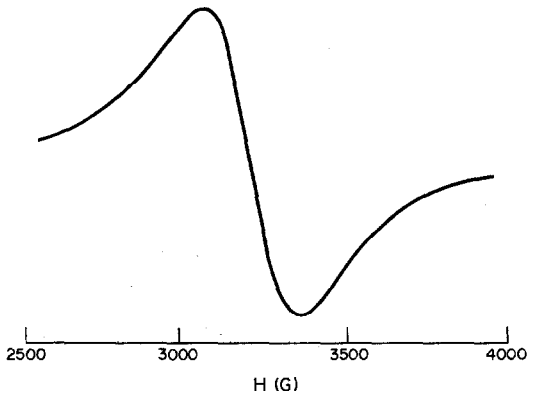

Fig. 4. *X*-band powder ESR spectra of [Cu(oxae)Ni $(Me_2bpy)_2](ClO_4)_2$ at room temperature.

According to these models strict orbital orthogonality results in ferromagnetism. For the present complexes if the overall molecular symmetry is considered to be C_{2v}, the 3*d* orbitals of the copper(II) and nickel(II) ions transform as a_1 (d_{z^2} and $d_{x^2-y^2}$), a_2 (d_{yz}), b_1 (d_{xy}) and b_2 (d_{xz}).[14] Since there is no orthogonality between the *b* magnetic orbitals centred on the copper(II) and nickel(II) ions, an antiferromagnetic interaction should be observed.

ESR spectra

As shown in Fig. 4 the *X*-band powder ESR spectrum at room temperature for complex **2** only exhibits a large, broad and intense band centred at $g = 2.20$, which corresponds to the allowed $|1/2, -1/2\rangle \rightarrow |1/2, 1/2\rangle$ transition in the $S = 1/2$ ground state.

(*Received* 21 *December* 1992; *accepted* 18 *February* 1993)

Abstract—The reaction of $Co_2(CO)_8$ with the heterocyclic thioamide $S\overline{COCH_2CH_2NH}$ provided the synthesis of the chiral cluster $[Co_3(CO)_6(\mu_3\text{-}S)(\overline{COCH_2CH_2NH})(\mu\text{-}\eta^2\text{-}S\overline{COCH_2CH_2N})]$ (**1**), where $S\overline{COCH_2CH_2N}$ is a three-electron bridging bidentate ligand linked by nitrogen and sulphur to two cobalt atoms and $\overline{COCH_2CH_2NH}$ is a two-electron terminal carbene ligand linked by carbon to the third cobalt atom, as shown by X-ray structure analysis. The molecule has an almost perfect regular triangular-pyramidal Co_3S skeleton.

Heterocyclic thioamides, $S{=}\overline{CX(CH_2)_2NH}$ (where X = S, O, NH, etc.), have been shown to be the versatile reactants in the reactions of transition metal carbonyls giving the metal carbonyl cluster derivatives with a variety of new structures and bonding modes. This is due to the different fragments cleaved from heterocyclic thioamides (SAH) which can be linked to the metal cores by different coordination atoms and various shapes.

The interaction of SAH with triosmium clusters provided the syntheses of three new clusters containing the μ_2-η^1-SA, μ_3-1,3-η^2(S,N)-SA and μ_2-1,2-η^2(C,N)-A ligands, respectively (types 1, 2 and 3),[1] but the interaction of SAH with triruthenium yielded only the cluster product containing the μ_3-1,3-η^2(S,N)-SA ligand (type 2).[2] The reaction of SAH with triiron dodecarbonyl provided the synthesis of the cluster with a terminal carbene AH ligand (type 4).[3] The reaction of a linear thioamide with dicobalt octacarbonyl yielded a chiral cluster, $[Co_3(CO)_7(S)(\mu\text{-}SC(CH_3)NH)]$ (**2**), containing the bridging μ_2-1,3-η^2(S,N)SA ligand belonging to type 5.[4] In this paper we report that the reaction of SAH with dicobalt octacarbonyl provided syntheses of the cluster containing the μ_2-1,3-η^2(S,N)-SA ligand (type 5) and the cluster containing both AH and μ_2-1,3-η^2(S,N)-SA ligands (type 6).

All the structures of the new clusters are shown in Fig. 1.

The crystal and molecular structural determinations showed that the new chiral tricobalt sulphur carbonyl cluster $[Co_3(CO)_6(\mu_3\text{-}S)(\overline{COCH_2CH_2NH})(\mu\text{-}1,3\text{-}\eta^2\text{-}S\overline{COCH_2CH_2N})]$ (**1**) (type 6) contains a three-electron bridging bidentate $S\overline{COCH_2CH_2N}$(SA) ligand linked to the Co(1) and Co(3) atoms of the cluster by a cobalt–nitrogen and a cobalt–sulphur bond, respectively, and a two-electron terminal carbene $\overline{COCH_2CH_2NH}$ (AH) ligand linked to the Co(2) atom of the cluster by a

cobalt–carbon bond. We believe this is the first time that a trinuclear cobalt carbonyl cluster containing a terminal carbene ligand has been reported.

Herein we report the synthesis and structure of **1** and discuss the influence of the introduction of the bridging bidentate ligand and the terminal carbene ligand on the configuration change of the Co_3S cluster framework.

EXPERIMENTAL

Material and methods

Petroleum ether, THF and methylene chloride were dried by distillation with sodium-benzophenone and P_4O_{10}, respectively; $S\overline{COCH_2CH_2NH}$ was prepared by the literature method.[5] Dicobalt octacarbonyl was purchased and recrystallized from toluene as the solvent.

The synthetic reaction procedure was performed under a nitrogen atmosphere, using the Schlenk technique and degassed solvents. The IR spectrum was recorded on a Mattson Alpha–Centauri FTIR spectrophotometer in the range 1600–2200 cm^{-1} using CH_2Cl_2 as the solvent. ^1H NMR spectra were measured on a Varian FX-100 instrument using $CDCl_3$ as the solvent and TMS as the internal standard. Mass spectra were recorded on a Finigan MAT 711 instrument using the field dissociation method. Elemental analyses for carbon, hydrogen and nitrogen were conducted on an elemental analyser—Perkin–Elmer 240 C.

Synthesis of $[Co_3(CO)_6(\mu_3\text{-}S)(\overline{COCH_2CH_2N})(\mu\text{-}S\overline{COCH_2CH_2N})]$ (**1**)

$Co_2(CO)_8$ (0.34 g, 1 mmol) and $S\overline{COCH_2CH_2NH}$ (0.20 g, 2 mmol) were dissolved in THF (10 cm^3). The solution was stirred for 24 h at 25°C and then evacuated to dryness. The resulting black residue was dissolved in CH_2Cl_2 and chromatographed on a silica gel column. The separation and crystallization yielded 0.04 g (yield 12%) of $[Co_3(CO)_7(\mu_3\text{-}S)(\mu\text{-}S\overline{COCH_2CH_2N})]$ from the first part of the eluant (petroleum ether: CH_2Cl_2 = 1 : 1) and 0.03 g (yield 8%) of $[Co_3(CO)_6(\mu_3\text{-}S)(\overline{COCH_2CH_2NH})(\mu\text{-}S\overline{COCH_2CH_2N})]$ (**1**) from the second part of the eluant (CH_2Cl_2). A dry sample of **1** was analysed. Found: C, 26.4; H, 1.9; N, 4.7. Calc. for $[C_{12}H_9N_2O_8S_2Co_3]$: C, 26.2; H, 1.6; N, 4.4%. Mass spectral data: m/z 550; calc. 550.31.

X-ray crystallography

The deep brownish block-shaped crystal (0.30 × 0.30 × 0.10 mm) was measured on a Rigaku AFC 5R diffractometer through graphite monochromated Mo-K_α radiation and diffraction data to $3° \leqslant 2\theta \leqslant 50°$ were collected in the θ–2θ scan mode. The 1392 unique reflections $[I \geqslant 3\sigma(I)]$ observed were obtained after correction of 3724 reflections for Lorentz, polarization and empirical absorption. The crystallographic data are given in Table 1.

Structure determination and refinement

All calculations were performed on a Micro VAX-II computer with the TEXSAN programs. At first the positions of a number of non-hydrogen atoms were obtained by direct methods from the electron density map. Then difference-Fourier syntheses were used to reveal the positions of all remaining non-hydrogen atoms. Final refinement was conducted through a full-matrix least-squares procedure with non-hydrogen atoms anisotropic and hydrogen atoms isotropic. Resulting R values were R = 0.057 and R_w = 0.066. The structure of **1** is shown in Fig. 2. The selected bond lengths and angles are listed in Table 2.

RESULTS AND DISCUSSION

Molecule **1** is formally derived from $Co_3(\mu_3\text{-}S)(CO)_9$ by replacing three terminal CO ligands with a three-electron donating bridging bidentate $S\overline{COCH_2CH_2N}$ ligand (nitrogen atom as a two-electron donor and sulphur as a one-electron

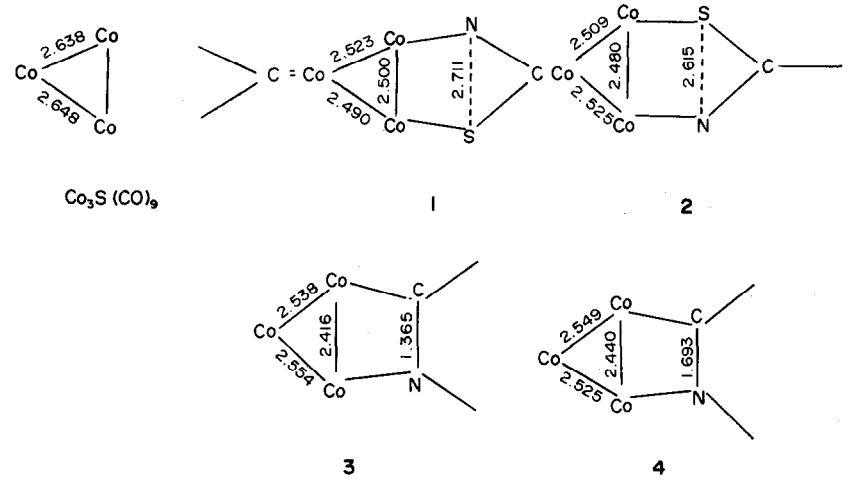
donor) and a two-electron donating carbene $\overline{COCH_2CH_2NH}$ ligand.

The three cobalt atoms form an almost equilateral triangle with Co—Co bond lengths = 2.499(3)–2.523(3) Å and average Co—Co—Co bond angles = 60°. The bond distances of diamagnetic species **1** are shorter than the paramagnetic parent cluster $Co_3S(CO)_9$ [mean value of the Co—Co bond length 2.637(3) Å],[6] which possesses an extra unpaired electron in delocalized anti-

Chart I Distance unit (Å)



bonding orbitals. Benoit *et al.*[4] have discussed the compression effect in the bridging bidetate ligand-containing tricobalt sulphur carbonyl clusters and have shown that the bridged Co—Co edge is shorter than the other two Co—Co edges of the Co_3 triangle. Moreover, as shown below, modification of the geometrical constraint imposed by the bridge results in the progressive lengthening of the Co—Co bond as the "elongation effect" in $[Co_3(CO)_7(S)(\mu\text{-}CH_3C{=}NC_6H_{11})]$ (**3**) → $[Co_3(CO)_7(S)(\mu\text{-}CSNMe_2)]$ (**4**) → **2**. Comparison with the symmetrical cluster $Co_3S(CO)_9$ showed that significant modifications of the Co_3 core and Co_3S framework did appear in **3**, **4** and **2**.

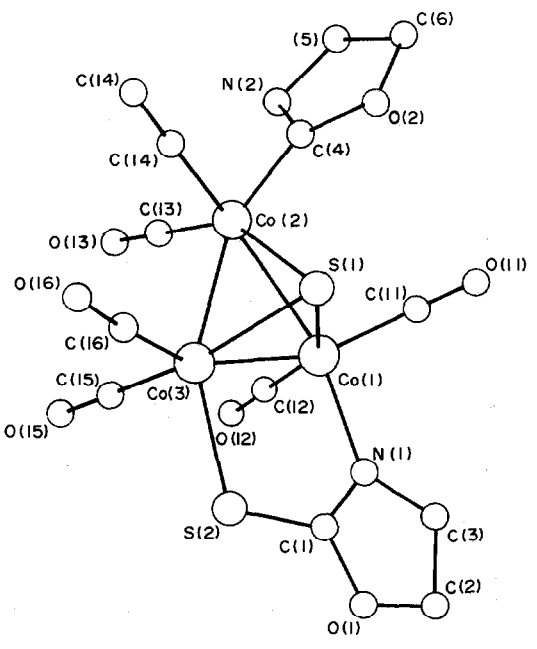


Fig. 2. Molecular structure of $[Co_3(CO)_6(\mu_3\text{-}S)(\overline{COCH_2CH_2NH})(\mu,\eta^2\text{-}S\overline{COCH_2CH_2N})]$.

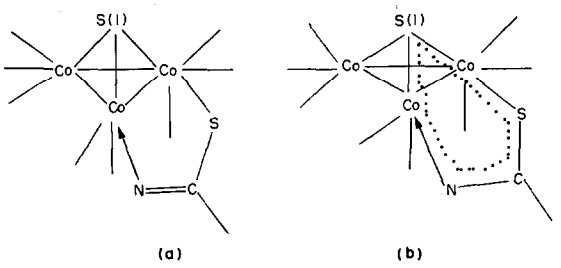
The result on our tricobalt sulphur carbonyl cluster (**1**) is different. The compression effect of the bridged edge of the Co_3 triangle vanishes in **1** and the Co_3S framework of **1** is a regular triangular pyramid with the Co—S bond lengths = 2.166(4)–2.173(5) Å. This shows that the four electrons of the μ_3-S donor bond are almost equal to each of the Co_3 atoms. The big heterocyclic carbene ligand located in the vertex of the cobalt atom may play a counterpart role to the bridging bidentate ligand located in the opposite edge of two cobalt atoms to keep the Co_3 core remaining an equilateral triangle as a whole. The dihedral angle between the metallic triangle and the μ-$S\overline{COCH_2CH_2N}$ plane is 10.01°, C(1)—N(1) bond distance = 1.30(2) Å (in the range of carbon–nitrogen double bonds and the sp^2 hybridized C—N single bond length of 1.46 Å).[7] Bond angles around the C(1) and N(1) atoms (114–112°) and the total of the surrounding three bond angles (359°) clearly show the sp^2 character of the C(1) and N(1) atoms. The C(1)—S(2) bond length [1.71(2) Å] is closer to the value of a carbon–sulphur single bond than that of a carbon–sulphur double bond [1.741(2) vs 1.634(3) Å, respectively[8]]. All these characteristics of the ligand seem to favour the canonical formula **a** as a better representation of the electronic state of molecule **1** rather than the

alternative valence bond formulation such as **b**, suggested by Benoit *et al.*,[4] in which there is electron delocalization over the six atoms concerned because the S(1)—Co bond lengths (with the dashed lines) are significantly shorter than the S(1)—Co bond length (without the dashed line) of cluster **2**.



There is one two-electron donating heterocyclic carbene terminal $\overline{COCH_2CH_2NH}$ ligand in cluster **1**. The dihedral angle of the heterocyclic ring with the Co_3 plane is 76.16° and the heterocyclic ring acts as a carbene ligand to replace the axial carbonyl (according to the Co_3 plane) of the parent cluster $Co_3S(CO)_9$. The surrounding bond angles about C(4) [carbene] are 111(1)°, 123(1)° and 126(1)° and the total is 360°, which clearly shows the sp^2 character of the carbene. The Co(2)—C(4) distance [1.94(2) Å] corresponds to other cobalt stabilized bridging carbenes such as 1.953(3) Å in **3** and 1.958(5) Å in **4** are shorter than the Fe—C single bond average length of 2.151 Å[9] (the estimated single bond covalent radii of 1.165 and 1.162 Å for iron and cobalt, respectively, are virtually identical). Therefore, it has double bond character and stabilizes cluster **1**. However, we note that the Co(2)—C(4) distance observed must imply less double bond character than is present in the Co—CO bonds (average bond length 1.80 Å). The π-acceptor/σ-donor ratio is also significantly low for a carbene ligand where the neighbouring atoms are nitrogen and oxygen compared with CO. The shortest Co—CO bond of 1.76(2) Å, which is located in the *trans* position of the heterocyclic carbene ligand, once more clearly shows that the π-accepting ability is weak for this carbene ligand. The C(4)—N(2) and C(4)—O(2) bonds here have considerable double bond character, as indicated by their lengths of 1.28(2) and 1.32(2) Å, respectively (normal single bond lengths of sp^2 hybridized C—N and C—O are 1.46[7] and 1.43 Å,[10] respectively). The π-interaction between the carbene carbon and neighbouring nitrogen and oxygen atoms is another important factor in stabilizing cluster **1**.

The formulation and structure of **1** are consistent with experimental data obtained from elemental analysis, mass spectrometry, IR and ^1H NMR experiments. The IR spectrum in the carbonyl region has four bands with wave numbers of 1972–2064 cm^{-1}, which indicates the presence of only terminal COs. The wave numbers of ν(CO) of **1** were 25–61 cm^{-1} less than the values of $Co_3(S)(CO)_9$,[11] which provides further evidence that the π-accepting ability of the bridged $S\overline{COCH_2CH_2N}$ ligand and carbene $\overline{COCH_2CH_2NH}$ ligand of **1** is much weaker than the CO ligand.

Cluster **1** contains a Co_3 core and four kinds of ligands, namely μ_3-S, μ-$S\overline{COCH_2CH_2N}$, $\overline{COCH_2CH_2NH}$ and CO. The former three are fragments of the same reactant, heterocyclic thioamide SAH. This ligand precursor was cleaved to afford three kinds of fragments, namely S, SA and AH, during the reaction with $Co_2(CO)_8$ and all these fragments are linked to the same Co_3 core by the atoms carbon, nitrogen and sulphur (belonging to groups IVA, VA and VIA of the periodic table, respectively) and each coordinated atom locates in each Co of the Co_3 core. This is an interesting method of preparing a new type of metal carbonyl cluster derivative, by the cleavage of the reactant (ligand precursor) to obtain a variety of fragmental ligands in order to build the new cluster.

Supplementary material. The atomic coordinates and thermal parameters and a table of interatomic distances and angles have been deposited with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited at the Cambridge Crystallographic Data Centre.

THE SYNTHESIS AND CHARACTERIZATION OF CADMIUM AND ZINC COMPLEXES WITH DITHIOCARBAMATE DERIVATIVES OF DIAMINES

M. AZAD MALIK, TAHIR SAEED and PAUL O'BRIEN*

Department of Chemistry, Queen Mary and Westfield College, Mile End Road, London E1 4NS, U.K.

(*Received* 11 *December* 1992; *accepted* 8 *February* 1993)

Abstract—The synthesis and characterization of four new compounds, zinc or cadmium complexes with dithiocarbamates derived from N,N,N-trimethylethylenediamine or N,N,N-trimethylpropylinediamine as ligands are reported. Preliminary growth studies show that the cadmium complexes with N,N,N-trimethylpropylinediamine may be useful precursors for the deposition of the CdS, at temperatures as low as 350°C.

Thin films of cadmium sulphide have been used in solar cells,[1–6] light emitting diodes[7] and ultrasonic transducers.[8] A number of single-molecular precursors for the deposition of II/VI materials have been developed, including thiophosphinates,[9,10] thiocarbamates,[11,12] selenocarbamates,[13] thiolates,[14–16] bulky thiolates such as 2,4,6-tritertiarybutylphenylchalcogenides[15,16] and silicon-based systems [e.g. $M(ESi(SiCH_3)_3)_2$, M = Zn, Cd, Hg and E = Se, Te],[17] and alkyl-metal-thio/selenocarbamates.[18,19] We have recently reported the use of some mixed alkyl-dialkyldithiocarbamates of cadmium or zinc and the deposition of thin films of CdS or ZnS by metal organic chemical vapour deposition (MOCVD).[18] These compounds and the parent dithiocarbamates are in general dimers involving bridging sulphur atoms.[13,18]

In an attempt to improve the volatility of simple thiocarbamates we have developed thiocarbamates based on various diamines. These ligands have the potential to form additional coordinate linkages to the metal, via the nitrogen groups, which may influence both the degree and type of any aggregation and the strength of association between individual molecular units. In the present paper we report the synthesis and characterization of bistrimethylethylenediaminedithiocarbamatozinc(II) (**1**), bistrimethylethylenediaminedithiocarbamatocadmium(II) (**2**), bistrimethylpropylenediaminedithiocarbamatozinc(II) (**3**) and bistrimethylpropylenediaminedithiocarbamatocadmium(II) (**4**). Chalcogenide films have been deposited from **4** at temperatures as low as 350°C.

EXPERIMENTAL

All reagents were purchased from Aldrich Chemicals Ltd.

Physical measurements

IR spectra were recorded with a Mattson Polaris FT-IR spectrometer as Nujol mulls; ^{13}C and ^{1}H solution NMR were recorded with a Bruker AM 250 pulsed Fourier-transform NMR instruments; solid-state ^{13}C and ^{113}Cd NMR were recorded on a Bruker MSL-300 multinuclear instrument and mass spectra were recorded with a Kratos MS50 TC instrument. σ_1, σ_2 and σ_3 for ^{113}Cd NMR spectra were calculated using Herzselt and Berger's method.[20] Microanalyses were performed by the University College, London service, and EDAX was recorded with a JEOL 1200 EX II TEMSCAN electron microscope.

Synthesis of compounds **1** *and* **2**

A mixture of carbon disulphide (10 mmol) and N,N,N-trimethylethylenediamine (10 mmol) in water (20 cm^3) was stirred for 0.5 h at 5°C and then allowed to warm to room temperature. On addition of zinc nitrate (2.5 mmol) in water (10 cm^3) a white

* Author to whom correspondence should be addressed.

solid product was obtained. The product analysed as bistrimethylethylenediaminedithiocarbamatozinc (II) (**1**); yield 41%, m.p. 140°C. Found: C, 33.9; H, 6.1; N, 12.9; S, 33.0. Calc. for $C_{12}H_{26}N_4S_4Zn$: C, 34.4; H, 6.2; N, 13.4; S, 30.5%.

The cadmium complex (**2**) was prepared by the same method using cadmium nitrate; yield 46%, m.p. 143°C. Found: C, 29.6; H, 5.7; N, 11.2; S, 26.2. Calc. for $C_{12}H_{26}N_4S_4Cd$: C, 30.9; H, 5.6; N, 12.0; S, 27.5%.

Synthesis of compounds **3** *and* **4**

Carbon disulphide (10 mmol) was added to a stirred solution of N,N,N-trimethylpropylenediamine (TMPDA) (10 mmol) in water (20 cm^3) at 5°C for 30 min. The mixture was warmed to room temperature and a solution of zinc nitrate (2.5 mmol) in water (10 cm^3) was added. A white solid product analysed as bistrimethylpropylenediaminedithiocarbamatozinc(II) (**3**) was obtained; yield 60%, m.p. 102°C. Found: C, 36.4; H, 6.9; N, 11.8; S, 27.3. Calc. for $C_{14}H_{30}N_4S_4Zn$: C, 37.6; H, 6.7; N, 12.6; S, 28.2%.

The cadmium complex (**4**) was prepared by the same method using cadmium nitrate; yield 60%, m.p. 131°C. Found: C, 33.7; H, 5.9; N, 10.9; S, 25.7. Calc. for $C_{14}H_{30}N_4S_4Cd$: C, 34.0; H, 6.07; N, 11.3; S, 25.2%.

All four compounds have been characterized by NMR and IR spectroscopies. Compounds **3** and **4** were additionally characterized by mass spectrometry.

$Zn[S_2CNCH_3(CH_2)_3N(CH_3)_2]_2$ (**1**). ^{13}C NMR (solid state), δ (ppm): 205.97 (CS_2), 44.42 (NCH_3), 45.11 (NCH_3), 49.199 (NCH_3), 55.263 (CH_2N), 58.413 (NCH_2). IR (cm^{-1}), major bands and assignments are: 455 (M—S), 993 (C—S), 1462 (C=N).

$Cd[S_2CNCH_3(CH_2)_2N(CH_3)_2]_2$ (**2**). ^{13}C NMR (solid state), δ (ppm): 205.82 (CS_2), 45.21 (NCH_3), 45.82 (NCH_3), 49.35 (NCH_3), 54.15 (CH_2N), 58.53 (NCH_2). IR (cm^{-1}), major bands and assignments are: 433 (M—S), 1008 (C—S), 1465 (C=N).

$Zn[S_2CNCH_3(CH_2)_3N(CH_3)_2]_2$ (**3**). ^1H NMR solution ($[^2H_6]$ $CHCl_3$, 250 MHz), δ (ppm): 1.97 [(4H, t, ^3J(H—H) = 7.5 Hz), (CH_2—CH_2—CH_2)], 2.35 [12H, s, $N(CH_3)_2$], 2.41 [(4H, t, ^3J (H—H) = 7.5 Hz), (CH_2—CH_2N)], 3.44 (6H, s, NCH_3), 3.91 [(4H, t, ^3J(H—H) = 7.5 Hz), (NCH_2—CH_2)]. ^{13}C NMR ($[^2H_6]C_6H_6$, 250 MHz), δ (ppm): 204.38 (CS_2), 24.98 (—NCH_3), 42.83 (CH_2—CH_2—CH_2), 45.94 $N(CH_3)_2$, 55.50 (CH_2—CH_2N), 57.09 (NCH_2—CH_2). IR (cm^{-1}), major bands and assignments are: 424 (M—S), 989 (C—S), 1461 (C=N). Mass spectrum (m/z): base peak 58.1 (100%) $[CH_2N(CH_3)_2]$; other peaks at 44.1 (20.7%) $[N(CH_3)_2]$, 88 (28.8%) $[CH_2N(CH_3)_2]$, 111.1 (10.8%) $[CH_3(CH_2)_3N(CH_3)_2]$, 159.1 (30.1%) (CH_3ZnCS_2).

$Cd[S_2CNCH_3(CH_2)_3N(CH_3)_2]_2$ (**4**). ^1H NMR solution ($[^2H_6]$ $CHCl_3$, 250 MHz), δ (ppm): 2.10 [(4H, t, ^3J(H—H) = 7.3 Hz), (CH_2—CH_2—CH_2)], 2.41 [12H, s, $N(CH_3)_2$], 2.52 [(4H, t, ^3J (H—H) = 7.4 Hz), (CH_2—CH_2N)], 3.46 (6H, s, NCH_3), 3.95 [(4H, t, ^3J(H—H) = 7.5 Hz), (NCH_2—CH_2)]. ^{13}C NMR ($[^2H_6]C_6H_6$, 250 MHz), δ (ppm): 205.71 (CS_2), 25.22 (—NCH_3), 44.29 (CH_2—CH_2—CH_2), 46.24 $N(CH_3)_2$, 56.96 (CH_2—CH_2N), 57.47 (NCH_2—CH_2). ^{113}Cd NMR (solution state): singlet at δ 298 ppm. IR (cm^{-1}), major bands and assignments are: 420 (M—S), 917 (C—S), 1461 (C=N). Mass spectrum (m/z): base peak 58.1 (100%) $[CH_2N(CH_3)_2]$; other peaks at 44.1 (45.4%) $[N(CH_3)_2]$, 88 (45.1%) $[CH_2N(CH_3)_2]$, 111.1 (7.9%) $[CH_3(CH_2)_3N(CH_3)_2]$, 159 (54.8%) $[CS_2CH_3N(CH_2)_3N]$.

Deposition of thin films

Cadmium sulphide or zinc sulphide thin films were deposited onto glass microscope slides or GaAs by chemical vapour deposition using compounds **3** or **4**, respectively. Samples (50 mg) were placed at one end of a Schlenk tube placed in a horizontal tube furnace. Glass slides were placed at the centre of the furnace. The tube was continuously pumped and a pressure of *ca* 10^{-2} Torr was maintained in the reactor. Cadmium sulphide thin film depositions were performed in the furnace at 350°C, whereas for zinc sulphide thin films the furnace temperature was 450°C. The precursor itself was located slightly outside the furnace and, therefore, was at a somewhat lower temperature than that of the furnace; thin specular films were obtained relatively rapidly, in *ca* 20 min. The films were characterized by elemental detection by analytical X-rays (EDAX) using electron microscopy and reflection high energy electron diffraction (RHEED) for CdS on GaAs.

DISCUSSION

Compounds **1** and **2** are insoluble, presumably polymeric materials, and **3** and **4** are microcrystalline solids soluble in toluene and benzene. Repeated attempts to obtain suitable samples of any of these compounds for single crystal X-ray diffraction studies were unsuccessful. Compounds **1** and **2** are intractable solids; however, the IR spectra of these compounds contain bands at 455, 993 and 1462 cm^{-1}, typical of coordinated thiocarbamate functions.[21] Vibrations due to M—N

bonding probably occur at too low an energy to be measured other than with specialized equipment ($<200\ cm^{-1}$).[22] The solid-state ^{13}C NMR spectra of both **1** and **2** have clear six-line spectra (Fig. 1). The CS_2 carbon appears at the lowest field, while the other five signals appear close to each other at higher field. The $N(CH_3)_2$ carbons give two overlapping signals, probably indicating a non-equivalance in the solid state. The ^{113}Cd solid-state NMR spectrum of **2** indicates the presence of two discrete cadmium centres (δ 289 and δ 278 trace impurities); this may be a similar phenomenon to the two cadmium sites observed for the powder form of bis(2-mercaptobenzothiazolato)cadmium(II).[23] The chemical shift δ 289 ppm probably indicates that cadmium is in a similar environment to that in bis(5-mercapto-1-methyltetrazolato)cadmium(II), δ 274 ppm, or bis(pyrolidinedithiocarbamato)cadmium(II), δ 280 ppm.[23] All three different σ-values suggest low symmetry and analysis of the spinning side band for the principal cadmium resonance leads to an anisotropy parameter of 0.40 and may suggest S_4CdN coordination with distorted trigonal bipyramidal coordination (see Table 1 for data).

Compounds **3** and **4** show similar bands in the IR spectra, confirming coordination of the thiocarbamate functionality.[21] Unlike **1** and **2** these compounds could be further purified by recrystallization to give good elemental analyses. These compounds have been characterized by ^1H and ^{13}C NMR spectroscopies in solution (see the Experimental). Both compounds **3** and **4** give similar ^1H NMR spectra. The α- and γ-methylene protons give triplets due to coupling with β-methylene protons with similar coupling constants. The β-methylene protons appear as a quintet at higher field through coupling with four equivalent neighbouring methylene protons. The $N(CH_3)_2$ and $N(CH_3)$ protons give singlets for both **3** and **4**, with the expected 2 : 1 intensity ratio. The chemical shifts for the cadmium compound are at lower field, for all protons, as compared to the corresponding zinc compound. The ^{13}C NMR of both compounds show the expected six-line spectra. The ^{113}Cd solid-state NMR spectrum of **4** shows a single line at δ 291 ppm, with no evidence for quadrupolar coupling to nitrogen (Fig. 2). The greater purity of **4** is not surprising as it was relatively easy to recrystallize the compound. The chemical shift δ 291 ppm is similar to that for **2** and indicates a similar cadmium environment; an analysis of the spinning side bands leads to anisotropy parameters similar to **2** and suggests a similar coordination sphere. The ^{113}Cd solution state NMR spectrum gives a singlet at δ 298 ppm, which shows that the cadmium maintains

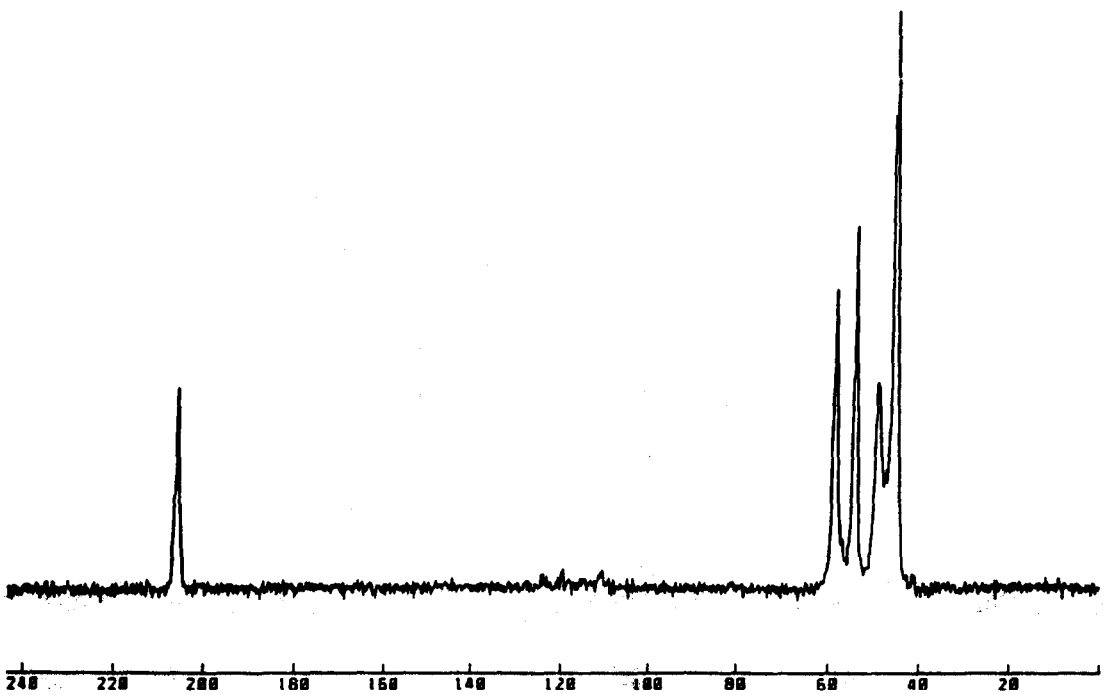

Fig. 1. ^{13}C NMR spectrum (solid state) of bis(trimethylethylenediaminedithiocarbamato)-cadmium(II) (**2**).

Table 1. Summary of solid-state ^{113}Cd NMR results

Compound coordination	δ(ppm)	σ_1	σ_2	σ_3
Bistrimethylethylene–CdS_4N (distorted diaminedithiocarbamato–trigonalbipyramid)-cadmium (**2**)	289	53	188	626
(impurity *ca* 5%)	276			
Bistrimethylpropylene–CdS_4N (distorted diaminedithiocarbamato–trigonalbipyramid)-cadmium (**4**)	291	40	203	631

a similar coordination environment in solution to that in the solid state.

The X-ray crystal structure of a related compound, $MeCdS_2CN(Me)(CH_2)_3N(Me)_2$, has been determined recently,[24] which may provide some idea of the bonding of the thiocarbamate group in **3** and **4**. In $MeCdS_2CN(Me)(CH_2)_3N(Me)_2$ the ligand bridges between adjacent cadmiums, giving a polymeric structure with CS_2N coordination at each cadmium centre. Given the similarity between the dimeric structures of metal bisthiocarbamates and mixed-alkyl complexes, such as $[MeMSCNEt_2]_2$ (MS_5 and MCS_3, respectively), it seems likely that compounds **3** and **4** have weakly bonded polymeric structures based on CdS_4N coordination.

Growth work

Compounds **3** and **4** have been successfully used to deposit thin films of metal sulphide on glass slides and GaAs by low-pressure metal organic chemical vapour deposition (MOCVD); some of the conditions and observations are summarized in Table 2. The 1 : 1 composition of CdS in the films have been confirmed by analytical X-ray (EDAX) measurements in the electron microscope. CdS films are polycrystalline with *ca* 10 micron crystallites.

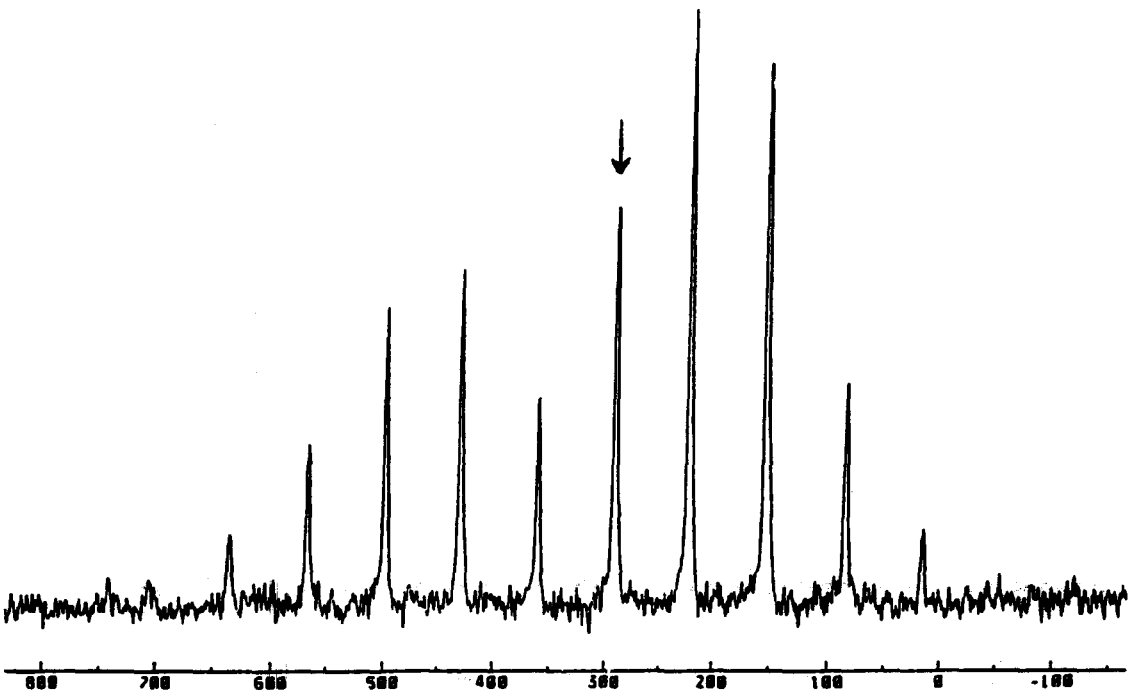

Fig. 2. ^{113}Cd NMR spectrum (solid state) of bis(trimethylpropylenediaminedithiocarbamato)-cadmium(II) (**4**).

Table 2. Summary of growth results using a hot wall LP-MOCVD apparatus

Compound	Film	Time (min)	Temperature (°C)	Substrate	Comments
3	ZnS	20	450	Glass	Poor morphology and uneven film thickness
	ZnS	20	425	Glass	Cloudy films
	ZnS	20	400	Glass GaAs	Very thin layers on GaAs substrate
4	CdS	20	400	Glass GaAs	Thick and even growth on both substrates
	CdS	20	375	Glass GaAs	Good even growth on glass and GaAs
	CdS	20	350	Glass GaAs	Thin even layers on both substrates
	CdS	20	325	Glass GaAs	Good specular layer on GaAs substrate

In the apparatus used in the present study deposition from the parent diethyldithiocarbamates was not observed at temperatures <400°C (20 min).

Both CdS and ZnS films were specular and adherent; their band gaps were 2.43 (lit. 2.425 eV)[25] and 3.57 eV (lit. 3.65 eV),[25] respectively. Compound **4** gave good even films on glass and GaAs substrates at temperatures as low as 325°C in 20 min. Using the present apparatus no deposition was observed from the parent diethydithiocarbamate in 20 min at temperatures less than 400°C,[12] indicating substantial advantages for the present compounds as a precursor. The film thickness appeared to decrease with temperatures (400–325°C) for a constant 20 min growth period.

The quality, as judged by reflectivity, of ZnS films grown from **3** (>400°C) was not better than that of equivalent films grown from zinc-diethyldithiocarbamate.[12] The films appeared cloudy with uneven thickness and lower growth rates.

CONCLUSIONS

Preliminary growth studies with these complexes indicate that better quality films of CdS can be obtained at a higher rate using bistrimethylpropylenediaminedithiocarbamatocadmium(II) as a precursor than those obtained with the parent diethyldithiocarbamate. The corresponding zinc derivative gave poorer quality films and only at higher temperatures; the overall performance of the zinc complex as a precursor is not substantially better than the parent bisdiethyldithiocarbamatozinc(II).

Acknowledgements—We thank the SERC for a grant to Paul O'Brien, Dr P Barrie of the ULIRS solid-state NMR service at University College, London, for recording the solid-state NMR spectra and assistance in their interpretation.

Abstract—EPR and optical absorption studies have been made on lead acetate glasses containing 1–10 mol% $MnSO_4 \cdot H_2O$. The EPR spectra of Mn^{2+} ion-doped lead acetate glasses exhibit a sextet centred at $g = 2.02$. Remarkable changes have been observed in the EPR spectrum with changes in temperature, particularly at the glass transition temperature ($T_g = 317$ K). The optical absorption spectrum at room temperature shows five bands characteristic of Mn^{2+} ions in an octahedral symmetry. The crystal field parameter (Dq) and the Racah interelectronic repulsion parameters (B and C) have been evaluated. EPR and optical absorption studies reveal that the site symmetry around the transition metal ion is octahedral.

Interest in the research in common glasses and other less-common non-crystalline solids containing transition metal ions has grown in recent years, because of their potential use as optical fibres and efficient laser hosts. EPR and optical absorption spectra of transition metal ions in glasses have made it possible not only to interpret the energy levels involved in the observed transitions, but also to comment on the chemical and structural environment about the metal ion centre.

Glass-forming molten acetates have been studied extensively as these provide a bridge between essentially polymeric and ionic systems.[1] These glasses can be prepared over a wide range of glass compositions and these embrace cations of widely different chemistries.[2] This range includes (1) single component systems, e.g. LiOAc or $Pb(OAc)_2$; and (2) various mixtures, e.g. KOAc–$Ca(OAc)_2$ and KOAc–$Pb(OAc)_2$. Of particular interest to us is the lead acetate glass, because its glass transition temperature (T_g) lies within the range of the EPR measurements at different temperatures (123–423 K).

In the present investigation we describe the results of EPR and optical absorption spectra of Mn^{2+} ions in lead acetate glasses through the glass transition temperature (T_g).

EXPERIMENTAL

Glasses were prepared by melting appropriate amounts of Analar grade lead acetate with $MnSO_4 \cdot H_2O$ in an electric furnace at a temperature 50 K higher than that of the liquid. The melt was then quenched between two porcelain plates.

EPR spectra were recorded at 300 K at 9.205 GHz on a JEOL FE1X EPR spectrometer with a magnetic field modulation of 100 KHz. The magnetic field was scanned between 2250 and 4250 G. The EPR spectra were also recorded at different temperatures (123–423 K). The temperature was varied using a JES-VT-1A variable-temperature controller capable of regulating the temperature

* Author to whom correspondence should be addressed.

from 523 to 103 K. A temperature stability of ± 1 K was easily obtained by waiting for half an hour at the set temperature before recording the spectrum.

Optical absorption spectra were recorded using a Perkin–Elmer 551 spectrophotometer in the wavelength region 250–650 nm at 300 K. The wave number accuracy for sharp bands is ± 5 cm^{-1}.

RESULTS AND DISCUSSION

In undoped glasses no EPR signal is detected. When Mn^{2+} ions are introduced into the lead acetate glasses, all investigated samples exhibit absorption lines. Figure 1 shows the EPR spectrum of Mn^{2+} ions in lead actate glasses at 300 K. The spectrum shows the characteristic six-line hyperfine splitting spectrum centred at $g = 2.02 \pm 0.02$. There is also a relatively weak absorption centred at $g = 4.3 \pm 0.2$.

EPR spectra at different temperatures (123–423 K) were also recorded to study the temperature dependence of the intensity of the resonance line at $g = 2.02$. The intensity of the resonance line at $g = 2.02$ decreased gradually with increases in the temperature from 123 K, in proportion to the Boltzmann factor. A marked difference in the intensity of the resonance line at $g = 2.02$ was observed as the glass transition temperature was approached. The decrease in the intensity of the transition became more rapid at $T \sim T_g$ and the sextet almost disappeared leaving behind a single broad line. EPR spectra at different temperatures are shown in Fig. 2. From Fig. 2 it is clear that the intensity of the resonance line at $g = 2.02$ decreased with increases in temperature. The observed intensity of the resonance line at $g = 2.02$ at different temperatures is compared to the Boltzmann factor, i.e. $1/T$, and is shown in Fig. 3. For a derivative spectrum the measurement associated with the area under the absorption curve (i.e. intensity) is the peak-to-peak height $\times$ width^2.

The optical absorption spectrum measured at room temperature (300 K) for Mn^{2+} ions (10 mol %) in lead acetate glass is shown in Fig. 4. From the position and the number of observed bands the authors assumed Mn^{2+} ions in an octahedral symmetry. The optical absorption spectrum at 300 K consists of five bands centred at 17,235, 19,450, 24,445, 26,660 and 27,624 cm^{-1} and they are denoted as A, B, C, D and E, respectively. The bands C and E are sharp, whereas bands A and B are broad and band D is moderately sharp. Among the sharp bands band C is very sharp. When the number of t_{2g} electrons is the same in both the ground and excited states the energy expressions for the transitions are independent of Dq and the ligand field bands appear to be sharp.[3] The sharp band C is, therefore, assigned to the transition $^6A_{1g}(S) \rightarrow {}^4A_{1g}(G)$; $^4E_g(G)$ as the energy expression is independent of Dq. The broad bands A and B are assigned to the transitions $^6A_{1g}(S) \rightarrow {}^4T_{1g}(G)$ and $^6A_{1g}(S) \rightarrow {}^4T_{2g}(G)$, respectively. The bands at D and E are assigned to the transitions $^6A_{1g}(S) \rightarrow {}^4T_{2g}(D)$ and $^6A_{1g}(S) \rightarrow {}^4E_g(D)$, respectively.

The EPR spectrum of Mn^{2+} ions in glasses are characterized by an intense resonance at $g = 2.0$ with a hyperfine structure, an absorption at $g = 4.3$ and a distinct shoulder at $g = 3.3$[4].

The EPR spectra of manganese obtained for lead

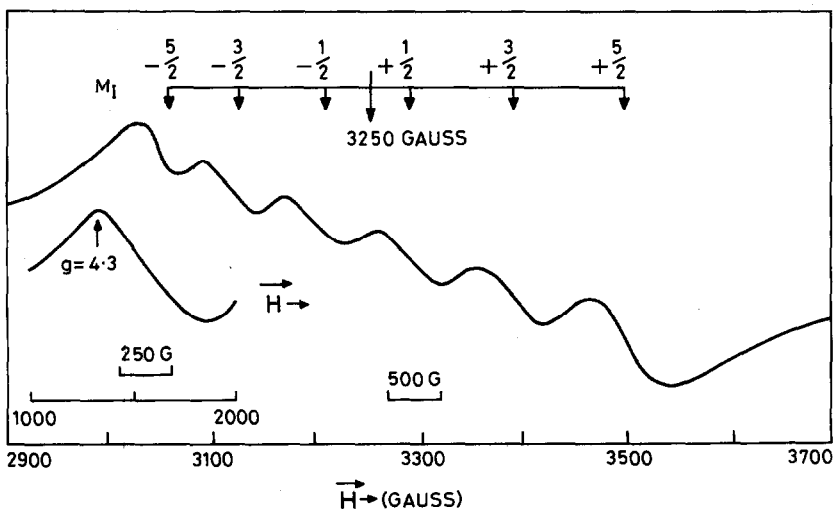

Fig. 1. EPR spectrum of Mn^{2+} ions in lead acetate glass at 300 K.

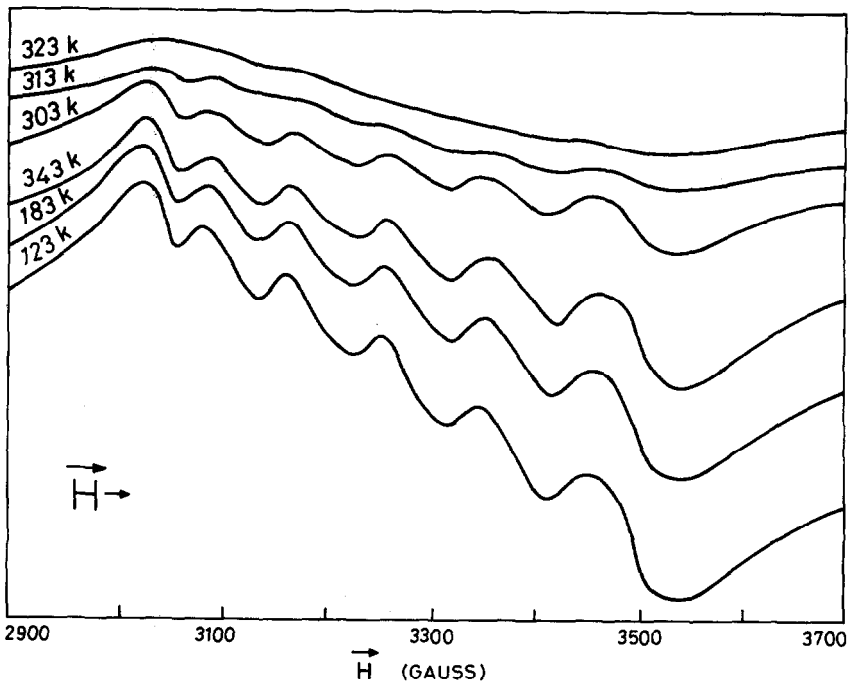

Fig. 2. EPR spectrum of Mn^{2+} ions in lead acetate glass at different temperatures.

acetate glasses are qualitatively very similar to those reported for Mn^{2+} ions in various glasses.[4-11] Due to this similarity one may conclude that Mn^{2+} ions are responsible for the EPR spectra.

The EPR spectrum comprising a sextet is analysed using the following expression for resonant fields:

$$H_m = H_0 - A_0 m - A_0^2(35-4m^2)/8H_0$$

where $H_0 = h\nu/g_0\beta$ and $m = -5/2, -3/2, \ldots +5/2$; g_0 is the isotropic g factor and A is the isotropic interaction parameter. The isotropic sig-

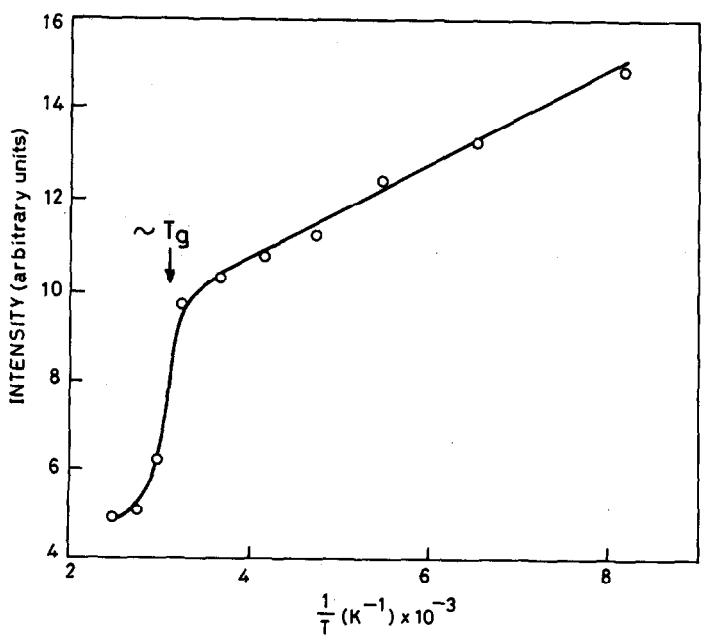

Fig. 3. Temperature dependence of the intensity of the resonance line at $g = 2.02$ at different temperatures is compared to the Boltzmann factor, i.e. $1/T$.

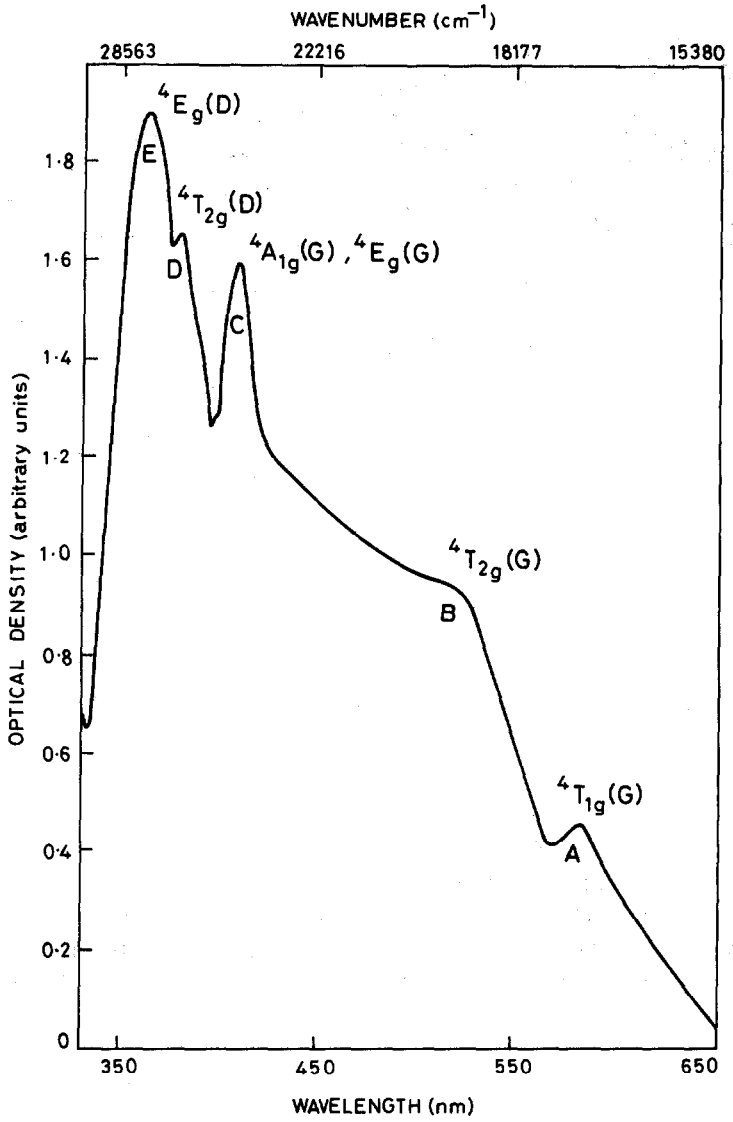

Fig. 4. Optical absorption spectrum of 10 mol % Mn^{2+} ions in lead acetate glass at room temperature (300 K).

nal at $g = 2.02$ is due to Mn^{2+} ions in an environment close to octahedral symmetry. The value of $A = 90$ G is consistent with Mn^{2+} ions in an octahedral coordination.[10,12–15]

The magnitude of the hyperfine splitting constant A provides a measure of covalency between the Mn^{2+} ion and its ligands. Van Wieringer[16] empirically determined a positive correlation between A and the ionicity of the manganese–ligand bond. On this basis it was found that Mn^{2+} ions in lead acetate glasses are quite ionic ($A = 90$ G), consistent with Mn^{2+} ions in alkali borate[5] and K_2SO_4–$ZnSO_4$[17] glasses ($A = 92$ G).

The decrease in the signal intensity of the resonance line at $g = 2.02$ with an increase in temperature from 123 K could be due to an efficient spin-lattice relaxation. A closer inspection reveals that the decrease in the intensity of the transitions becomes more rapid as the glass transition temperature, $T_g = 317$ K,[1] is approached. Similar observations were found for Mn^{2+} ions in the EPR studies of non-silicate inorganic glasses by Parthasarathy *et al.*[8] as the glass transition temperature (T_g) of sulphate (460 K), phosphate (469 K) and PbO—$PbCl_2$ (480 K) is approached. The glass transition temperature (T_g) for lead acetate glasses is 317 K,[1] at which temperature the authors observed a sudden decrease in the intensity of the resonance line at $g = 2.02$, as is shown in Fig. 3.

By diagonalizing the energy matrices[18] for the d^5 configuration the crystal-field parameter (Dq) and the Racah interelectronic repulsion parameters (B

Table 1. Experimental data and analysis of the absorption spectrum of Mn^{2+} ions in lead acetate glass at room temperature: $B = 600$, $C = 3395$, $Dq = 1000$, $\alpha = 76\ cm^{-1}$

Absorption peak	Transition $^6A_{1g}(S) \rightarrow$	Observed wavelength (nm)	Observed wave number (cm^{-1})	Calculated wave number (cm^{-1})
A	$^4T_{1g}(G)$	580	17,235	17,232

E	$^4E_g(D)$	362	27,624	27,420

and C) have been evaluated. In the analysis of the optical absorption spectrum Tree's correction[19] parameter, α, has been incorporated, which is equal to 76 cm^{-1} in order to obtain a good fit to the observed and calculated values. The observed and calculated energies along with the assignments are given in Table 1.

In the present work the value of the inter-electronic repulsion parameter, $B = 600\ cm^{-1}$ (free ion value is 960 cm^{-1}),[20] was obtained, which indicates that the bonding is moderately ionic. This is also confirmed from the EPR spectra.

CONCLUSIONS

The EPR and optical absorption spectra of Mn^{2+} ions in lead acetate glasses have been investigated. EPR spectra at different temperatures reveal that there is a rapid fall in the intensity near the glass transition temperature T_g. The EPR and optical absorption studies of Mn^{2+} ions in lead acetate glasses show that the site symmetry around the transition metal ion is octahedral.

SYNTHESIS, STRUCTURE AND ELECTROCHEMICAL PROPERTIES OF COMPLEXES WITH A (μ-OXO)BIS-(μ-CARBOXYLATO)DIRUTHENIUM(III) CORE

ARIYANCHIRA SYAMALA and AKHIL R. CHAKRAVARTY*

Department of Inorganic and Physical Chemistry, Indian Institute of Science, Bangalore 560 012, India

(*Received* 11 *December* 1992; *accepted* 1 *February* 1993)

Abstract—Reaction of $[Ru_2O(O_2CR)_2(MeCN)_4(PPh_3)_2](ClO_4)_2$ (**1**) with 1,2-diaminoethane (en) in MeOH–H_2O yielded a mixture of products, from which a purple diamagnetic and 1:2 electrolytic diruthenium(III) complex, $[Ru_2O(O_2CR)_2(en)_2(PPh_3)_2](ClO_4)_2$ (**2**), was isolated along with a trace by-product of $[Ru_2O(O_2CR)_2(en)_2(PPh_3)_2](ClO_4)(MeCONH)$ (**3**) (R = C_6H_4-*p*-X: X = H, **a**; OMe, **b**; Me, **c**). Complex **3b** has been characterized by X-ray diffraction analysis. The structure shows the presence of a $\{Ru_2(\mu\text{-}O)(\mu\text{-}O_2CR)_2^{2+}\}$ core, with the metal centre bonded to an unidentate PPh_3 and a bidentate chelating en terminal ligand. The Ru—Ru distance and the Ru—O—Ru angle in the core are 3.255(3) Å and 119.1(4)°. The amidate anion, formed presumably by nucleophilic attack of OH^- on the MeCN ligand in complex **1**, remains uncoordinated to the metal. In MeCN/0.1 M $[NBu^n_4]ClO_4$ complex **2** exhibits a nearly reversible $Ru_2^{III,III}$–$Ru_2^{III,IV}$ couple near 0.9 V and an irreversible $Ru_2^{III,III}$–$Ru_2^{III,II}$ process at −0.6 V (vs S.C.E.). The mechanistic aspects of the substitution and nucleophilic reactions in the formation of complexes **2** and **3** are discussed.

The chemistry of (μ-oxo)bis(μ-carboxylato)di-metal(III) complexes has gained considerable current interest[1] following the discovery of such a core in several non-haeme metalloproteins. Based on the chemical relevance of the low molecular weight transition-metal complexes as model systems, the major thrust was on the synthesis of di-iron complexes. However, in recent years several 3*d*- and 4*d*-metal complexes have also been reported.[2–8] Although the importance of the terminal sites of the core has earlier been recognized[9] in the biological activity of several μ-oxodi-iron proteins, the reaction chemistry at the facial positions in model systems is virtually unexplored[10] due to the presence of substitutionally inert terdentate or polydentate ligands in the majority of complexes. The easy accessibility of various oxidation states, the inert behaviour of ruthenium complexes and the ready availability of a precursor complex, $[Ru_2O(O_2CR)_2(MeCN)_4(PPh_3)_2](ClO_4)_2$ (**1**),[8] containing labile terminal ligands, have prompted us to investigate the effect of terminal ligands on the redox and spectral properties of the diruthenium(III) core.

In a previous report[8] we have shown that under mild reaction conditions the nitrile ligands in complex **1** undergo nucleophilic attack with 1,2-diaminoethane (en) to form amino-amidine moieties. In this paper we describe other reaction pathways leading to the formation of $[Ru_2O(O_2CR)_2(en)_2(PPh_3)_2](ClO_4)_2$ (**2**) and $[Ru_2O(O_2CR)_2(en)_2(PPh_3)_2](ClO_4)(MeCONH)$ (**3**) (R = C_6H_4-*p*-X: X = H, **a**; OMe, **b**; Me, **c**). Complex **3b** is structurally characterized by X-ray methods.

EXPERIMENTAL

The solvents and reagents were purchased from commercial sources. $Ru_2Cl(O_2CMe)_4$, $Ru_2Cl(O_2CR)_4$ and $[Ru_2O(O_2CR)_2(MeCN)_4(PPh_3)_2](ClO_4)_2$ (**1**) (R = C_6H_4-*p*-X: X = H, **a**; OMe, **b**; Me, **c**) were prepared by literature methods.[4a,6,11]

Preparation of the complexes

The complexes of formulations $[Ru_2O(O_2CR)_2(en)_2(PPh_3)_2](ClO_4)_2$ (**2a–2c**) and $[Ru_2O(O_2CR)_2$

* Author to whom correspondence should be addressed.

$(en)_2(PPh_3)_2](ClO_4)(MeCONH)$ (**3a**–**3c**) were prepared as a mixture, containing complex **2** as a major product along with a trace quantity of complex **3** (*ca* 5%), using a general procedure. A representative procedure is given below.

Complex **1b** (50 mg, 0.04 mmol) in a mixture of MeOH–H_2O (10 cm^3; 4:1 v/v) was reacted with 0.3 M en (0.3 cm^3, 0.09 mmol) in MeOH. The solution was heated under reflux for 2 h, followed by cooling to an ambient temperature. The resulting bluish-purple solution was added to an aqueous solution of $NaClO_4$ (10 cm^3). The purple precipitate thus formed was removed by filtration and washed with water. The crude product (yield: *ca* 60%), after drying *in vacuo* over P_4O_{10}, was subjected to chromatography on a silica gel column in petroleum ether (b.p. 60–80°C). A blue fraction was eluted first, followed by a purple band which was collected using a $CHCl_3$–MeOH mixture (9:1 v/v) as the eluant. A purple solid was obtained after removal of the solvent and crystallization from methanol by slow evaporation at 25°C. The product was found to be essentially complex **2b** with *ca* 5% complex **3b**, as observed from ^1H NMR studies. The yield after chromatographic separation was 10 mg (*ca* 20%). Found: C, 49.9; H, 5.1; N, 4.7. Calc. for $C_{56}H_{60}N_4O_{15}P_2Cl_2Ru_2$: C, 49.3; H, 4.4; N, 4.1%. Complex **2a**: Yield *ca* 20%. Found: C, 50.2; H, 4.5; N, 4.8. Calc. for $C_{54}H_{56}N_4O_{13}P_2Cl_2Ru_2$: C, 49.7; H, 4.3; N, 4.3%. Complex **2c**: yield *ca* 18%. Found: C, 50.9; H, 4.9; N, 4.7. Calc. for $C_{56}H_{60}N_4O_{13}P_2Cl_2Ru_2$: C, 50.5; H, 4.5; N, 4.2%.

Physical measurements

The elemental analyses were performed using a Heraeus CHN-O Rapid instrument. Electronic spectra were recorded on a Hitachi U-3400 spectrophotometer. The ^1H NMR spectra were obtained using Bruker WH-270 and AC(AF) 200-MHz spectrometers. Conductivity measurements were performed on a Century CC 603 digital conductivity meter. Cyclic voltammetric measurements were obtained using a three-electrode set-up on a PAR Model 174A polarographic analyser connected to a Houston Instruments Omnigraphic *X*–*Y* recorder. A platinum button, a platinum wire and a saturated calomel electrode (S.C.E.) were used as working, auxiliary and reference electrodes, respectively. The measurements were performed at 25°C in MeCN containing $[NBu^n_4]ClO_4$ (0.1 M). The data reported are uncorrected for junction potentials. Ferrocene, $(\eta^5\text{-Cp})_2Fe$, was used as a standard to verify the potentials observed against the S.C.E. and to obtain the electron-transfer stoichiometries of the redox couples by peak current measurements. The $Fe^{II/III}$ couple of ferrocene was observed at +0.42 V (vs S.C.E.) under similar experimental conditions.

Crystal structure determination of $[Ru_2O(O_2CC_6H_4\text{-}p\text{-}OMe)_2(en)_2(PPh_3)_2](ClO_4)(MeCONH)\cdot H_2O$ (**3b**)

The purple coloured rectangular crystals, obtained from slow evaporation of a methanolic solution of the purple mixture containing complex **2b** ≫ complex **3b**, were found to be unstable outside the mother liquor. A suitable crystal was sealed in a Lindemann capillary along with the mother liquor.

Crystal data. $C_{58}H_{66}N_5O_{13}P_2ClRu_2$, $M = 1340.7$, triclinic, $P\bar{1}$, $a = 13.066(6)$, $b = 13.531(3)$, $c = 19.132(2)$ Å, $\alpha = 95.53(1)$, $\beta = 94.62(2)$, $\gamma = 112.06(2)°$, $V = 3095(2)$ $Å^3$, $Z = 2$, $d_c = 1.44$ g cm^{-3}, $F(000) = 1376.0$, $\lambda = 0.7107$ Å, $\mu(\text{Mo-}K_\alpha) = 6.34$ cm^{-1}, $T = 293$ K.

Data collection, structure solution and refinement. CAD4 diffractometer, ω scan mode with scan width $= 0.90+0.35 \tan\theta$, prescan speed = 5.5° min^{-1} [the final scan with a speed calculated to satisfy the condition $\sigma(I)/I \leqslant 0.03$], graphite-monochromated Mo-K_α radiation; 9400 reflections measured ($4° \leqslant 2\theta \leqslant 46°$, h, $\pm k$, $\pm l$), 8589 unique giving 4829 with $I > 3\sigma(I)$. No decay was observed during data collection. Data were corrected for Lorentz and polarization effects. The data, collected in four stages using different orientation matrices due to the movement of the weakly diffracting crystal in the capillary, were not subjected to absorption correction (transmissions: 85–95%).

Direct methods (ruthenium and chlorine atoms) followed by normal heavy-atom procedures were used. Full-matrix least-squares refinement was performed (in three blocks for final, anisotropic cycles) with all non-hydrogen atoms anisotropic, except the positionally disordered perchlorate oxygens, the methoxy group atoms and the solvent water molecules with site-occupancy factors other than 1.0. The aryl group atoms of a bridging carboxylate, comprising atoms C(11)–C(16), were refined as a rigid group. Residuals: $R = 0.0767$ ($R_w = 0.0816$ for $w = 1/[\sigma^2(F_o) + 0.002853\ F_o^2]$), max. peak in final difference Fourier = 0.68 e $Å^{-3}$. The positional and thermal disorder of several atoms has contributed to the high values of the residuals. The ClO_4 anion is refined with two sets of four oxygens with site occupancy factors (s.o.f.) of 0.8 and 0.2. The disordered methoxy group is refined with a s.o.f. of 0.5. The probable source of water as the solvent of crystallization could be the methanol. All calculations were performed using a VAX88 computer and the SHELX system of programs[12]

at the Computer Centre of the Indian Institute of Science. Atomic scattering factors were taken from ref. 13. Positional and isotropic thermal parameters and bond lengths and angles have been forwarded to the Director, Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

Synthesis and spectral properties

The reaction of complex **1** with en under refluxing conditions in MeOH–H_2O leads to the formation of a mixture of products containing a blue, purple and yellow species. When the crude product is subjected to column chromatography a blue coloured minor product elutes first, followed by a purple band containing a (μ-oxo)diruthenium(III) complex, which is formulated as $[Ru_2O(O_2CR)_2(en)_2(PPh_3)_2](ClO_4)_2$ (**2**) from the analytical and conductivity data (Table 1). Preliminary studies[14] show that the yellow product is a monomeric ruthenium(III) complex. Earlier we have reported[8] the blue complex, which was isolated in a higher yield by conducting the reaction under mild thermal conditions. Complex **2** is stable in the solid state and in solution. It is soluble in polar organic solvents and exhibits a 1:2 electrolytic behaviour in MeCN. Subsequent studies on this purple species show the presence of a trace quantity (*ca* 5%) of $[Ru_2O(O_2CR)_2(en)_2(PPh_3)_2](ClO_4)(MeCONH)$ (**3**). The characterization of **3** has been unambiguously achieved by single-crystal X-ray diffraction studies.

Complex **2** is essentially diamagnetic. Relevant ^1H NMR data are presented in Table 1. Complexes **2b** and **2c** display a singlet for the methyl protons of two carboxylato bridging ligands, which are chemically equivalent in the solution phase. The chelating en ligands in complex **2** display four multiplets for the CH_2 protons in a static configuration. The amino protons appear in the aromatic region. While one is visible at δ 7.2, the other resonance is obscured by the phenyl proton signals of the PPh_3 ligands. The spectrum of the purple complex also shows the presence of a trace quantity (*ca* 5% from peak integrals) of the amidate anion of complex **3** (Fig. 1). A relatively weak signal, visible at δ 2.0, is tentatively assigned to the methyl protons of the amidate anion. The spectral features of the cationic species of complex **3** are identical with those of complex **2**.

Complex **2** displays a strong visible band at 559 nm (Table 1), which is assigned[4–8] to a charge-transfer transition involving the Ru^{III}-$d\pi$ and O(μ)-

$p\pi$ orbitals. In complex **1** this band is observed[6] at 581 nm. The substitution of the π-acceptor MeCN ligands by σ-only donor en ligands caused a shift in the charge-transfer band to a higher energy.

Electrochemistry

The redox behaviour of **2** has been studied by cyclic voltammetry using a platinum button working electrode in MeCN containing 0.1 M $[NBu^n_4](ClO_4)$. Complex **2** undergoes a nearly reversible oxidation at *ca* 0.9 V and an irreversible reduction near *ca* −0.6 V *vs* S.C.E. (Fig. 2, Table 1). The one-electron stoichiometry of the redox processes is obtained from the peak current measurements using ferrocene as a standard. The ratio of cathodic and anodic peak currents for the oxidation couple is found to be *ca* 1.0 for scan rates 20–200 mV s^{-1}. The couples involved are given in eq. (1).

$$\{Ru_2^{III,IV}(\mu\text{-}O)(\mu\text{-}O_2CR)_2{}^{3+}\} \underset{-e}{\overset{+e}{\rightleftharpoons}} \{Ru_2^{III,III}(\mu\text{-}O)(\mu\text{-}O_2CR)_2{}^{2+}\} \xrightarrow{+e^-} \{Ru_2^{II,III}(\mu\text{-}O)(\mu\text{-}O_2CR)_2{}^{+}\} \quad (1)$$

Crystal structure

An ORTEP[15] view of the cationic complex of complex **3b** is shown in Fig. 3. It consists of a

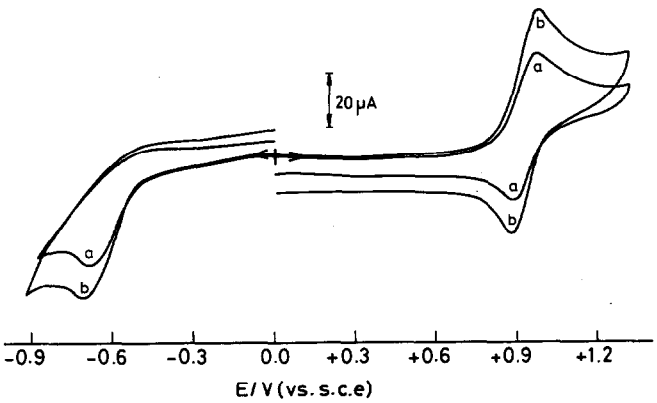

Fig. 2. Cyclic voltammograms of $[Ru_2O(O_2CC_6H_4\text{-}p\text{-}OMe)_2(en)_2(PPh_3)_2](ClO_4)_2$ (**2b**) in MeCN/0.1 M $[NBu^n_4]ClO_4$ at scan rates of (a) 20 and (b) 50 mV s^{-1}.

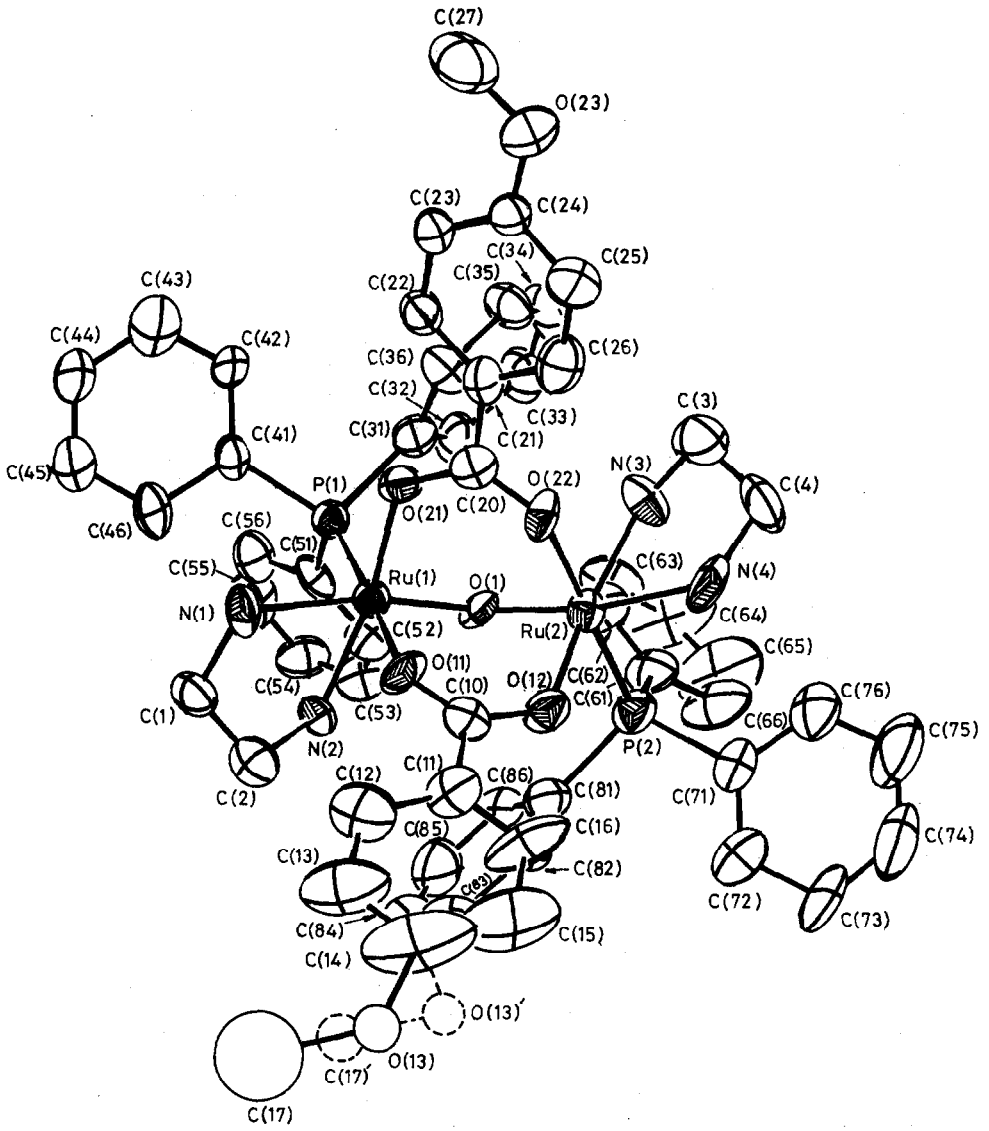

Fig. 3. An ORTEP view of $[Ru_2O(O_2CC_6H_4\text{-}p\text{-}OMe)_2(en)_2(PPh_3)_2]^{2+}$ in **3b**, showing 50% probability thermal ellipsoids, the atom numbering scheme and the positionally disordered methoxy group.

diruthenium(III) unit held by an oxo and two carboxylato bridges in a *cis* position to form a $\{Ru_2(\mu\text{-}O)(\mu\text{-}O_2CR)_2^{2+}\}$ core. The geometry around each metal centre is essentially octahedral, while the molecule has a staggered conformation. The facial sites of the core are occupied by chelating en and unidentate PPh_3 ligands. Selected bond distances and angles are listed in Table 2. The Ru(1)—Ru(2), av. Ru—O(1) distances and Ru(1)—O(1)—Ru(2) angle in the core are 3.255(3), and 1.888(9) Å and 119.1(4)°. In the chelate rings the Ru(1)—N(1) and Ru(2)—N(4) distances [av. 2.168(12) Å] are longer than the Ru(1)—N(2) and Ru(2)—N(3) bond lengths [av. 2.112(10) Å]. This is indicative of a significant *trans* influence of the μ-oxo ligand similar to that observed[4-8] in analogous μ-oxo complexes. A packing diagram showing the disposition of the complex cation and the anions in the unit cell is displayed in Fig. 4. The isolation of a single crystal of **3b** from the bulk of **2b** leads to the serendipitous discovery of nucleophilic attack by hydroxide in a triply-bridged dimeric system.

Mechanistic aspects

As shown in Scheme 1 the reactions pertaining to this work and in the formation of an amino-amidine complex[8] are believed to proceed through a common reactive intermediate (**I**), which involves a substitution of *trans*-MeCN to the μ-oxo ligand of complex **1** by η^1-en. In a recent study Sasaki *et al.* have shown[5] that $Ru_2O(O_2CMe)_2(py)_6^{2+}$ under-

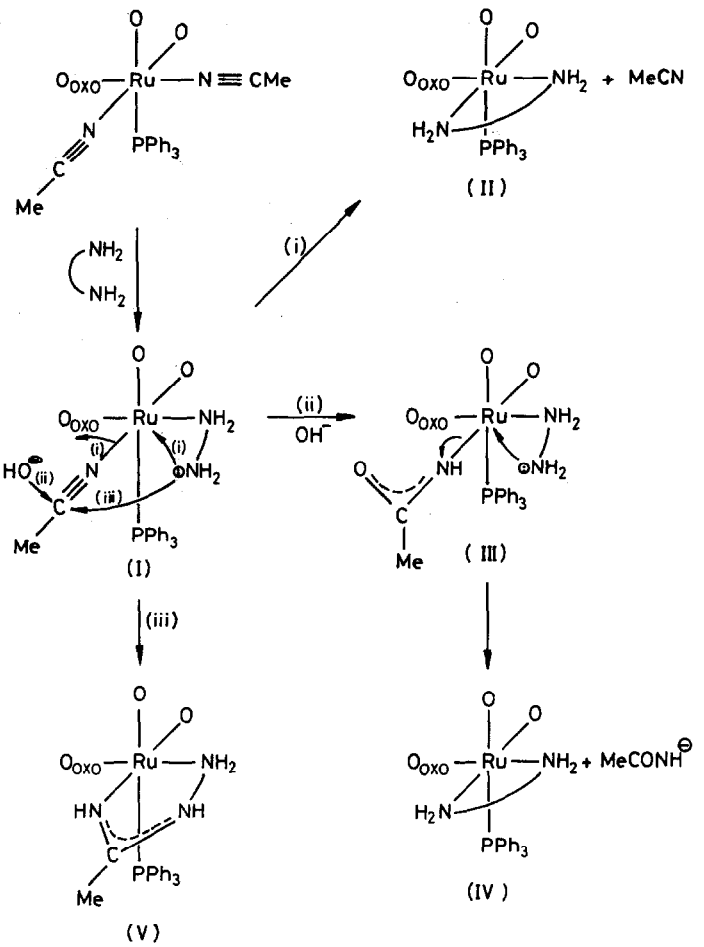
goes an exclusive exchange of the *trans*-pyridine to the μ-oxo ligand with py-d_5 in CD_3CN. A similar regioselective process in complex **1** is expected to result in an exclusive *trans*-MeCN substitution as the first step. The X-ray structural data[6] for complex **1**, showing a longer *trans*-Ru—N bond compared with *cis*, also support this view.

The formation of complexes **2**, **3** and the reported[8] amino-amidine complex from the intermediate (**I**) can be rationalized by proposing three reaction pathways. (1) The intramolecular pathway, leading to the formation of a chelate ring by elimination of the *cis*-MeCN ligand, is expected to be a facile process. (2) The intramolecular pathway,



Scheme 1. A tentative mechanism for the nucleophilic reactions at the terminal nitrile ligands in $[Ru_2O(O_2CR)_2(MeCN)_4(PPh_3)_2]^{2+}$.

which involves nucleophilic attack of the free amino group of η^1-en on the carbon atom of the *cis*-nitrile ligand, forming a seven-membered amino-amidine chelate ring (**V**).[8] While the latter pathway is found to be more favourable under mild reaction conditions, the chelation process predominates at elevated reaction temperatures. The formation of **3** can be rationalized[16] by an intermolecular nucleophilic attack of hydroxide on the *cis*-nitrile carbon atom to form an η^1-bonded amidato intermediate (**III**), followed by an en-chelation (**IV**) by eliminating the amidato anion in a high dielectric medium such as an MeOH–H_2O mixture. The isolation of a trace quantity of complex **3** from the reaction indicates that the intramolecular processes are, as expected, more favourable than intermolecular.

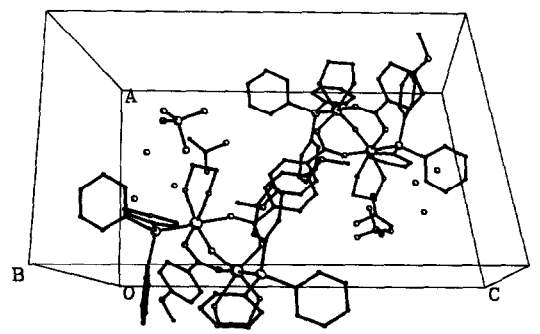


Fig. 4. A unit cell packing diagram of **3b**. The disorders in the ClO_4^- anion and the methoxy group are not shown for clarity.

(*Received* 8 *October* 1992; *accepted* 26 *January* 1993)

Abstract—A new potentially heptadentate tripodal ligand has been synthesized by the condensation reaction between tris(2-aminoethyl)amine and acetylsalicyclic acid in a 1:3 molar ratio. The *o*-acetyl linkage is cleaved by treating with KOH to form the desired ligand with the donors that include three amide nitrogens, three phenolate oxygens and one bridgehead nitrogen. $Fe(acac)_3$ readily forms a dark red 1:1 complex with the ligand. The complex behaves as a non-electrolyte in acetonitrile. The electronic absorption spectrum in the visible region is dominated by a strong absorption with λ_{max} at 425 nm, assignable to an LMCT transition from phenolate oxygen to iron(III) in an octahedral coordination geometry. The magnetic moment value at room temperature (5.5 μ_{eff}/μ_B) and the EPR spectra in the solid state and in solution ($g = 4.06$) are consistent with high-spin rhombically distorted octahedral iron(III). Room-temperature Mössbauer data provide the following values: isomer shift 0.37 mm s^{-1} and quadrupole splitting 0.82 mm s^{-1}. These data are consistent with a discrete, high-spin octahedral iron(III) complex.

Our interest in tripodal ligands stems from the fact that these ligands are capable of forming complexes with metal ions that can exhibit unusual coordination, high thermodynamic stability and kinetic inertness.[1,2] Besides, the tripodal ligands can serve as precursors to the synthesis of macrobicycles.[3–5] The present paper describes the synthesis of a new, potentially heptadentate tripodal ligand having an N_4O_3 donor set and its complexing ability towards iron(III). There has been continued interest in iron(III) chemistry with N,O-donor ligands. A large number of iron tyrosinate proteins are known where iron is bound mostly by nitrogen and oxygen atoms of the amino acid residues like histidine, tyrosine, aspartic acid, etc.[6–10] These proteins all contain high-spin iron(III), characterized by a $g = 4.3$ signal and an intense absorption in the visible region (400–600 nm) with an ε_{max} value in the range 2000–4000 M^{-1} cm^{-1}, due to a phenolate oxygen-to-iron(III) LMCT transition. Modelling these sites has been an active area of research.[11–15] The present work was undertaken for the dual purposes of modelling the iron tyrosinate active sites and probing the binding characteristics of the ligand towards a transition metal ion for the possible use of the complex as a precursor in the synthesis of various macrobicyclic compounds.[5]

EXPERIMENTAL

Materials

Reagent grade tris(2-aminoethyl)amine, ethylchloroformate and acetylacetone (Merck), salicyclic acid, glacial acetic acid, acetic anhydride and ferric chloride (Glaxo, India) were used as received. All the solvents (Glaxo) were purified[16] prior to use.

Physical measurements were made as reported earlier.[17] The Mössbauer spectra were recorded with the help of a Wissel Mössbauer spectrometer (Wissel Electronik GmbH, Germany) operating in constant acceleration mode. The spectra were recorded at room temperature (300 K). Elemental analyses were performed at the Central Drug Research Institute, Lucknow, India.

Synthesis of the ligand L

The ligand was synthesized by the mixed anhydride method (Fig. 1).[18] Acetylsalicylic acid[19] (2 g, 11 mmol) was dissolved in THF (20 cm^3) under argon and cooled in an ice–salt bath. Freshly distilled triethylamine (1.12 g, 11 mmol) diluted with THF (20 cm^3) was added to the cold solution dropwise with constant stirring. After the addition was complete the solution was stirred for a further period of 20 min. Ethylchloroformate (1.2 g, 11 mmol) mixed with THF (20 cm^3) was then slowly added to the cold solution in 15 min. Finally, tris(2-aminoethyl)amine (0.54 g, 3.7 mmol) mixed with THF (20 cm^3) was added to the well-stirred solution over a period of 45 min. After all the additions were complete the reaction mixture was stirred at 0°C for 2 h and then left at room temperature overnight.

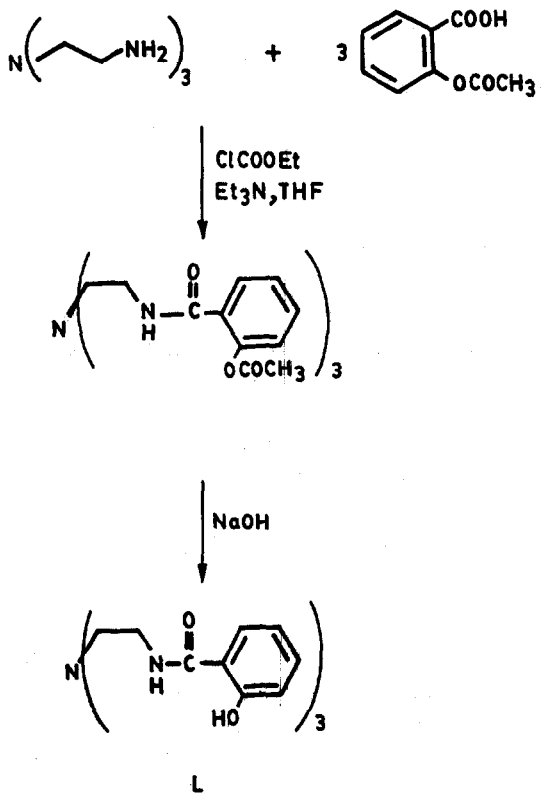

Fig. 1. Synthetic scheme for the tripodal ligand.

Solid triethylamine hydrochloride was removed by filtration and the almost colourless filtrate evaporated to dryness to obtain a pale yellow, thick, oily liquid. This was taken in $CHCl_3$ (25 cm^3) and washed four times with water. After drying the $CHCl_3$ layer the product was stripped of solvent to obtain the pure ligand (L) in 80% yield. ^1H NMR (80 MHz, $CDCl_3$, δ_{TMS} ppm): 7.5 (m, 12H), aromatic; 4.1 (m, 9H), $OCOCH_3$; 3.0 (t, 12H), CH_2.

Synthesis of the iron(III) *complex* (**1**)

A solution of $[Fe(acac)_3]$[20] (1 g, 2.8 mmol) in DMF (10 cm^3) was added dropwise with constant stirring at room temperature to a solution of the ligand, L (1.42 g, 2.8 mmol), in DMF (10 cm^3). The colour of the solution changed slowly to dark red. The dark red solution was allowed to reflux for 1/2 h and filtered after cooling to room temperature. All of the DMF was removed from the filtrate under low pressure and the residue was dissolved in methanol (25 cm^3). The red solution thus obtained was filtered and the filtrate was allowed to evaporate slowly at room temperature, affording a dark-red crystalline solid overnight; yield 47%. A small amount of the second crop of the product could be isolated on further evaporation. Found: C, 58.6; H, 4.8; N, 10.1; O, 17.5. Calc. for $C_{27}H_{27}N_4O_6Fe$: C, 58.0; H, 4.9; N, 10.0; O, 17.2%.

RESULTS AND DISCUSSION

The compound is stable at room temperature in the solid state or in solution in acetonitrile, alcohols, DMF, etc. The complex behaves as a non-electrolyte in these solvents. The IR spectrum in KBr shows a strong band at 1650 cm^{-1}, which is red-shifted by *ca* 35 cm^{-1} with respect to the free ligand, indicating that the three amide nitrogens are bonded to the metal ion.

The complex shows an intense band at 425 nm (λ_{max}), for which it has a dark red colour. The electronic spectra of a number of model iron(III) phenolate complexes have been studied.[12–15,21] Hexa-coordinated (distorted octahedral) iron(III) phenolates show an intense LMCT transition in the 420–470 nm region. This transition is assigned as due to the transition from a *p*-orbital on the phenolate oxygen to the half-filled *d*-orbital on iron(III).[22] In the present case the peak at 425 nm is similarly assigned. For di-iron(III) lactoferrin (Fe_2lf) this band appears at 465 nm (λ_{max}). The high molar absorptivity of the transition is due to a good Fe—O overlap. The IR and conductivity data show that the amides are not deprotonated in **1**. A protonated amide is a poor donor. In complex **1** the

poor donating abilities of the amide nitrogens are compensated by stronger bonds between iron(III) and phenolate oxygens—a fact corroborated by room-temperature Mössbauer data. This is reflected in the higher molar absorptivity for the LMCT band involving phenolate oxygens. The ligand field transitions are obscured due to the strong 42.5 nm band.

The room-temperature magnetic moment value after diamagnetic corrections is 5.5 μ_{eff}/μ_B, which is within the normal range found[15,21,23] for octahedral high-spin iron(III) complexes, corresponding to $S = 5/2$. The X-band EPR spectra of the complex in the solid state as well as in acetonitrile solution (*ca* 1×10^{-3} M) were examined at room temperature (300 K) and at liquid nitrogen temperature (77 K). In the solution phase the complex does not exhibit a well resolved spectrum either at room temperature or at 77 K. However, in the solid state it shows a well resolved signal at $g = 4.06$. The signal at $g = 4.06$ is due to a transition between the middle Kramers doublet. Iron tyrosinate proteins[6-8] and model iron(III) complexes[11-15] exhibit similar EPR spectra, which are typical of high-spin iron(III) complexes with rhombically distorted octahedral geometry.

Cyclic voltammograms for the complex were recorded at room temperature in acetonitrile (*ca* 1×10^{-3} M) at a glassy carbon electrode. When scanned in the positive direction first no well-defined peak could be observed either in the positive or in the negative side. However, when scanned in the negative direction first a broad cathodic peak appears at -1.02 V (vs S.C.E.) and on scan reversal the corresponding anodic peak appears at -0.5 V (vs S.C.E.). If the scan continues to *ca* $+0.6$ V then no peak appears anywhere. This signifies the breakdown of the ligand–metal ensemble on oxidation. The couple with $E_{1/2}$ at -0.76 V is attributable to the following redox process:

$$[FeL] + e^- = [FeL]^- \qquad (1)$$

The ligand-based nature of the couple is ruled out because nickel(II) and manganese(III) complexes of L do not show any couple at this $E_{1/2}$ value.[24] The large separation of the peaks can be attributed to extensive rearrangement of the product accompanying the redox process.

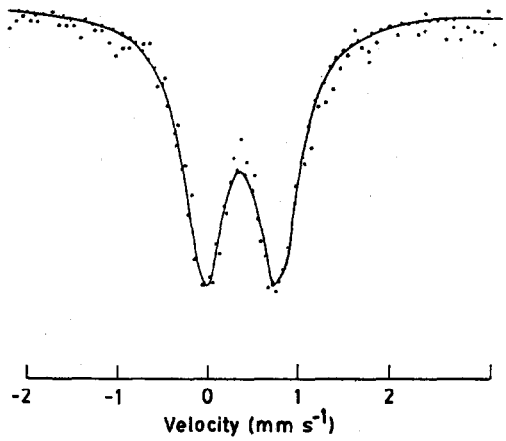

Fig. 2. Room-temperature Mössbauer spectrum for **1**.

The Mössbauer data for **1** and related systems are collected in Table 1. The complex shows (Fig. 2) an isomer shift of 0.37 mm s^{-1} with respect to iron metal, suggesting more covalency in the bonding between iron(III) and the ligands. This value lies close to that of lactoferrin[25] (0.39 mm s^{-1}) and transferrin[26] (0.38 mm s^{-1}), besides other octahedral high-spin iron(III) complexes. For octahedral complexes where the iron(III)–ligand bonding is more ionic an isomer shift of *ca* 0.5 mm s^{-1} with respect to the iron metal is observed.[12] Complex **1** shows quite a large value for the quadrupole splitting reflecting an unsymmetrical field around the ferric ion. Similar values are obtained in the case of structurally characterized, rhombically-distorted octahedral iron(III) complexes, as well as in cases of some iron tyrosinate proteins (Table 2).

CONCLUSION

A new tripodal ligand has been synthesized, which forms a rhombically-distorted octahedral complex with iron(III). The Mössbauer data for this complex closely resembles those of the iron tyrosinate proteins, lactoferrin and transferrin. The EPR and electronic spectral results are also very

Abstract—Three technetium(II) complexes of the type $[Tc(dtc)(DEPE)_2]^+$ have been newly prepared and isolated, where DEPE denotes 1,2-bis(diethylphosphino)ethane and dtc represents dimethyldithiocarbamate (dmdc), diethyldithiocarbamate (dedc) or pentamethylenedithiocarbamate (pmdc). The complexes have been characterized by elemental analysis, UV–vis spectroscopy, FAB mass spectroscopy, electrochemistry and high performance liquid chromatography. Bidentate coordination of the dithiocarbamate ligand is confirmed by a single-crystal structural analysis of the prototypical complex $[Tc(dmdc)(DEPE)_2](PF_6)$. Bond lengths around the approximately octahedral technetium(II) centre are Tc—S = 2.449(6), Tc—P (*trans* to P) = 2.43(2) and Tc—P (*trans* to S) = 2.38(2) Å. The Tc—P length *trans* to the sulphur atom is significantly shorter than that which is *trans* to a phosphorus atom. Electrochemical measurements for the $[Tc(dtc)(DEPE)_2]^+$ complexes show a reversible technetium(II/I) couple between −0.517 and −0.544 V (vs Ag/AgCl) and another reversible technetium(III/II) couple ranging from +0.298 to +0.312 V (vs Ag/AgCl) in 0.5 M TEAP/DMF. The relevance of this chemistry to the design and development of new technetium radiopharmaceuticals is briefly discussed.

The interest in technetium complexes was initially, and still continues to be, derived largely from their utility in diagnostic medicine when prepared with the nuclide ^{99m}Tc.[1] Radiopharmaceutical design demands a careful control of many chemical factors, including reactivity, charge, lipophilicity and redox potential. Systematic studies through graduated classes of complexes, such as the technetium–diphosphine–thiolato series developed in our laboratory,[2–9] are necessary to understand and manipulate the complex factors responsible for *in vivo* metabolism.

As candidates for inclusion in our systematic investigations, dithiocarbamates provide an interesting group of sulphur donor ligands. These ligands possess a mixture of resonance forms and can bond in a variety of modes: unidentate, biden-

tate symmetric, bidentate asymmetric, S,S-bridging and μ-bridging. Unusual metal oxidation states are often stabilized by dithiocarbamate (dtc) ligands and their small chelate bite angle can accommodate high coordination numbers.[10]

In our continuing studies of low-valent, cationic technetium-bis(diphosphine) complexes[2-9] containing sulphur-donating ligands we were eager to incorporate the unusual properties of dithiocarbamate ligands and thus sought to synthesize $[Tc^{II}(dtc)(D)_2]^+$ (D = diphosphine ligand) complexes. When dtc functions as a chelating ligand the sulphur atoms are constrained to lie mutually *cis*, so the *cis*/*trans* interconversion reactions of $[Tc^{III/II}(SR)_2(D)_2]^{+/0}$ thiolato complexes are avoided. The charge on the dtc ligand is formally -1, as compared to a -2 contribution from two thiolato ligands, so that the overall charge of a dtc complex is relatively more positive than that of bis(thiolato) complexes. We were further interested in how the presence of the dtc ligand would affect the coordination geometry and redox potential of technetium-diphosphine complexes and especially what oxidation state of technetium would be favoured. This report contains the results of these investigations, highlighted by the syntheses and characterizations of three $[Tc(dtc)(DEPE)_2]^+$ complexes.

Acronyms and abbreviations

The following acronyms and abbreviations are used in this article: dedc = diethyldithiocarbamate; DEPE = 1,2-bis(diethylphosphino)ethane; dmdc = dimethyldithiocarbamate; DMF = N,N-dimethylformamide; DMPE = 1,2-bis(dimethylphosphino)ethane; DPPE = 1,2-bis(diphenylphosphino)ethane; dtc = dithiocarbamate; FAB = fast atom bombardment; HPLC = high performance liquid chromatography; LTMCT = ligand-to-metal charge transfer; Me = methyl; OTTLE = optically transparent thin-layer electrode; PDE = platinum disk electrode; Ph = phenyl; pmdc = pentamethylenedithiocarbamate; STE = structural *trans* effect; tdt = 3,4-toluenedithiolate; TEAP = tetraethylammonium perchlorate; TMT = tetramethylthiourea.

EXPERIMENTAL

CAUTION! Technetium-99 emits a low energy (0.292 MeV) β particle with a half-life of 2.12×10^5 years. When handled in milligram amounts ^{99}Tc does not present a serious health hazard since common laboratory materials provide adequate shielding. Bremsstrahlung is not a significant problem due to the low energy of the β particle emission, but normal radiation safety procedures must be used at all times, especially when dealing with solid samples, to prevent contamination and inadvertant inhalation. In this paper the symbol Tc refers only to technetium-99; the metastable isotope ^{99m}Tc was not used in these studies.

Reagents

Unless otherwise noted, all chemicals were of reagent grade. Technetium-99, in the form of solid ammonium pertechnetate, was obtained from Oak Ridge National Laboratory and purified.[11] The DEPE ligand was purchased from Strem Chemical Co. and used without further purification. The pmdc was prepared by a procedure similar to that published.[12] DMF was obtained from Burdick and Jackson Lab. Polarographic grade TEAP from G. F. Smith Chemicals was used in the electrochemical measurements. Prior to use the TEAP was dried at 60°C *in vacuo* over P_2O_5. No significant electroactive impurities were detected in either the solvent or supporting electrolyte. Na(dedc)·$3H_2O$ was purchased from Fisher Scientific and Na(dmdc)·$2H_2O$ from Aldrich Chemical.

Synthesis of $[Tc(dedc)(DEPE)_2](PF_6)$

The starting complex, *trans*-$[Tc(OH)(O)(DEPE)_2](PF_6)_2$, was prepared by the method similar to that described in a previous paper,[2] using NH_4TcO_4 (200 mg, 1.1×10^{-3} mol) and DEPE (1.5 cm^3, 4.8×10^{-3} mol). To a solution containing *trans*-$[Tc(OH)(O)(DEPE)_2](PF_6)_2$ (200 mg) in degassed 50/50 (v/v) ethanol–water (12 cm^3) was added a solution containing Na(dedc)·$3H_2O$ (350 mg) in degassed water (6 cm^3). The resultant mixture was stirred at *ca* 50°C for 5 min under argon. To this solution was gradually added a solution made up of formamidine sulphinic acid (110 mg) and NaOH (50 mg) in degassed water (12 cm^3). The mixture was continuously stirred at *ca* 50°C for 30 min under an argon atmosphere, during which time the colour of the precipitate gradually changed from yellow to red–brown. The precipitate was collected by filtration, washed with ethanol/water and water and dried in air; yield: 143 mg.

The complex was then recrystallized as follows. The crude product (above) (90 mg) was dissolved in ethanol (6 cm^3) in air. After 15 min an aqueous solution (7 cm^3) of NH_4PF_6 (700 mg) was added. After 1 h the red–brown precipitate was collected by filtration, washed with ethanol/water and water and dried in air; yield: 71 mg. Found: C, 37.3; H, 7.5; N, 1.7; P, 18.1; F, 13.4. Calc. for $[Tc(dedc)(DEPE)_2](PF_6)\cdot H_2O$, $C_{25}H_{60}NOS_2P_5F_6Tc$: C, 36.5; H, 7.4; N, 1.7; P, 18.8; F, 13.9%.

Synthesis of $[Tc(dmdc)(DEPE)_2](PF_6)$

This complex was prepared by a procedure similar to that above for $[Tc(dedc)(DEPE)_2](PF_6)$, using *trans*-$[Tc(OH)(O)(DEPE)_2](PF_6)_2$ (200 mg) and $Na(dmdc)\cdot 2H_2O$ (260 mg). A yellow impurity was insoluble in ethanol and acetonitrile, so the desired complex was extracted by ethanol. In the recrystallization procedure the resultant dmdc complex was dissolved in ethanol (5 cm^3) and acetonitrile (2 cm^3) and filtered. To the filtrate was added an aqueous solution (8 cm^3) containing NH_4PF_6 (800 mg). The precipitate was collected by filtration, washed with ethanol/water and water and dried in air; yield: 152 mg. Found: C, 35.6; H, 7.1; N, 1.8; P, 19.4; F, 14.3. Calc. for $[Tc(dmdc)(DEPE)_2](PF_6)$, $C_{23}H_{54}NS_2P_5F_6Tc$: C, 35.6; H, 7.0; N, 1.8; P, 19.9; F, 14.7%.

Single crystals suitable for X-ray analysis were obtained by dissolving the red–brown product in methanol at *ca* 50°C. The solution was filtered to remove insoluble materials. The filtrate was held at room temperature for 4 h under argon. The crystals which appeared were collected by filtration, washed with water and dried in air. These crystals were air stable throughout the duration of the X-ray diffraction experiment.

Synthesis of $[Tc(pmdc)(DEPE)_2](PF_6)$

This complex was prepared by a procedure similar to that above for $[Tc(dedc)(DEPE)_2](PF_6)$, using *trans*-$[Tc(OH)(O)(DEPE)_2](PF_6)_2$ (200 mg) and Na(pmdc) (315 mg). To recrystallize the pmdc complex the crude product was dissolved in ethanol (5 cm^3) and then filtered. (The colour of the undissolved material was yellow. This yellow complex was washed with ethanol/water and water and dried in air; yield: 55 mg.) To the filtrate was added an aqueous solution (8 cm^3) containing NH_4PF_6 (800 mg). The precipitate was collected by filtration, washed with ethanol/water and water and dried in air; yield: 126 mg. $[Tc(pmdc)(DEPE)_2](PF_6)$ is less soluble in both polar and non-polar solvents than the other dtc complexes reported here. Found: C, 37.0; H, 7.1; N, 1.7; P, 18.8; F, 13.3. Calc. for $[Tc(pmdc)(DEPE)_2](PF_6)\cdot 1/2H_2O$, $C_{26}H_{59}NO_{0.5}S_2P_5F_6Tc$: C, 37.8; H, 7.2; N, 1.7; P, 18.8; F, 13.8%.

HPLC analyses

HPLC experiments were conducted on an ISCO model 2350 liquid chromatograph with a gradient programmer model 2360, equipped with a guard column containing pellicular C-8 packing material and a reversed-phase C-8 analytical column (4.8 × 150 mm). The mobile phase was 97/3 ethanol/0.1 mol dm^{-3} NH_4CH_3COO (aqueous) and the flow rate 1 cm^3 min^{-1}. Spectrophotometric detection was performed with a Hewlett–Packard 1040A HPLC diode array detection system, which recorded the spectrum between 200 and 600 nm for selected points in each peak on the chromatogram.

Measurements

Elemental analyses were performed by Galbraith Laboratories, Knoxville, Tennessee. UV–vis spectra were recorded in acetonitrile on a Cary 210 spectrophotometer (Varian) at ambient temperature. FAB mass spectra were recorded using *m*-nitrobenzylalcohol as the matrix on a VG 30-250 spectrometer (VG Instruments). Xenon was used as the primary beam gas and the ion gun was operated at 8 KeV and 100 μA. The mass data were generally collected over the mass range 200–1000 Da at 0.7 s per scan.

Electrochemical measurements were obtained with a Bioanalytical Systems, Inc. (BAS) CV-1B voltammograph. Potentials were monitored with a Keithley 178 digital multimeter and voltammograms were recorded on a Hewlett–Packard 7015B *X–Y* recorder. Cyclic voltammograms were obtained in 0.5 M TEAP/DMF solutions under argon *vs* an Ag/AgCl (3 M NaCl) reference electrode,[13] using a platinum disk working electrode (BAS MF 2013) and a platinum wire auxiliary electrode. The reference electrode was isolated from the solution by a porous Vycor plug.

Crystallography

Single-crystal X-ray diffraction experiments were performed on a Nicolet R3m automated diffractometer with a graphite monochromator. Data are summarized in Table 1. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were allowed to ride on their respective carbon atoms with C—H = 0.96 Å and with isotropic thermal parameters fixed at 0.08 $Å^2$. The methyl groups of the dmdc ligand were treated as rigid groups with rotational freedom and all P—F bonds in the hexafluorophosphate anion were constrained to 1.56 Å. The inverse (enantiomeric) model was tested and found to converge at slightly higher residuals ($R = 0.041$ and $wR = 0.052$) and thus was rejected. Absorption corrections were empirically derived from psi scans. Structure solutions by Patterson methods and refinements used the programs of SHELXTL-PLUS,[14] including its stored values for neutral atom-scattering factors and corrections for anomalous dispersion.

RESULTS AND DISCUSSION

Synthesis and characterization

Three $[Tc^{II}(dtc)(DEPE)_2]^+$ complexes (dtc = dmdc, dedc and pmdc) were prepared by the reaction of *trans*-$[Tc(OH)(O)(DEPE)_2](PF_6)_2$ with dtc in the presence of the reducing agent formamidine sulphinic acid in alkaline solution. HPLC analysis shows that the crude initial product consists of two compounds. Recrystallization of the crude product from ethanol and aqueous NH_4PF_6 yields a solid product, the HPLC retention time of which corresponds to the latter eluted species in the HPLC of the crude product. This recrystallized solid is pure since the HPLC indicates only one band and identical 200–600 nm spectra were exhibited at multiple points within the HPLC band (thus confirming the homogeneity of the product). The absorption spectrum of the recrystallized precipitate in acetonitrile is identical to the corresponding spectra obtained from the HPLC measurements. The composition of one of the recrystallized products was determined by X-ray structural analysis to be $[Tc(dmdc)(DEPE)_2](PF_6)$. Therefore, we conclude that the latter eluted species in the crude product and the recrystallized materials are all members of the class of technetium(II) complexes $[Tc(dtc)(DEPE)_2]^+$.

The earlier eluted species observed in the dmdc and dedc preparations could not be obtained as a solid because they are unstable in solution. The colour of this species (for the dmdc preparation) is pale yellow; absorption maxima are observed at *ca* 364 and 290 nm using the HPLC detection system. Further, the positive ion-mode FAB mass spectrum for the earlier eluting, yellow component of the pmdc preparation suggests the same composite formulation as that of the latter eluting $[Tc^{II}(pmdc)(DEPE)_2]^+$ species: both exhibit a parent peak at $m/z = 671$. Therefore, since the two species of the crude product have the same atomic composition but different HPLC retention times, a difference in complex charge is implied. The assignment of a neutral technetium(I) species, i.e. $[Tc^{I}(pmdc)(DEPE)_2]^0$, is consistent with the more rapid HPLC elution under the given conditions. Therefore, the crude product of the pmdc synthetic reaction contains both $[Tc^{I}(pmdc)(DEPE)_2]^0$ and $[Tc^{II}(pmdc)(DEPE)_2]^+$. This assignment is supported by the facile technetium(II/I) redox chemistry discussed below.

Elemental analyses of the red–brown recrystallized materials are in acceptable agreement with the proposed formulations: $[Tc(dtc)(DEPE)_2](PF_6)\cdot nH_2O$ ($n = 0$ for dtc = dmdc; $n = 1$ for dtc = dedc; $n = 1/2$ for dtc = pmdc). These analyses are consistent with a +1 charged complex cation. Compositional assignments are also reliably made by positive ion-mode FAB mass spectrometry. A typical FAB mass spectrum is shown in Fig. 1; the interpretation of high molecular weight, positively charged, fragments is straightforward. Parent peaks occur at $m/z = 631$ for $[Tc(dmdc)(DEPE)_2]^+$, $m/z = 659$ for $[Tc(dedc)(DEPE)_2]^+$ and $m/z = 671$ for $[Tc(pmdc)(DEPE)_2]^+$, which are consistent with the calculated masses for those cations (631.17, 659.20 and 671.20 Da, respectively). Several fragment ions corresponding to the loss of C_2H_5 ($m/z = 29$), $CH_2CH_2P(C_2H_5)_2$ ($m/z = 117$) and/or DEPE ($m/z = 206$) are also observed as summarized in Table 2. Fragment ions resulting from loss of the dtc ligand and its components were not observed for the three complexes investigated.

Our previous attempt to prepare $[Tc(dtc)(DEPE)_2]^+$ complexes was conducted in acidic solution; this led to cleavage of the dtc moiety at the C—N bond and the formation of an unusual condensation product of the dtc fragment

Table 2. FAB mass spectral data for $[Tc(dtc)(DEPE)_2]PF_6$

dtc	Complex ion (M^+)	Fragment ion [M − ( )] C_2H_5	$CH_2CH_2P(C_2H_5)_2$	DEPE
dmdc	631[a]	602	—	—
dedc	659[a]	630	542	453
pmdc	671[a]	642	554	465

[a] Intense peak.

and excess DMPE.[7] However, under alkaline conditions the dtc moiety remains intact and ligates to technetium. The reductant, formamidine sulphinic acid, used in these syntheses has been employed in other technetium-dtc preparations,[15] in which pertechnetate is the starting material. The present work demonstrates the utility of formamidine sulphinic acid as a reductant for the technetium(V) complex *trans*-$[Tc(OH)(O)(DEPE)_2]^{2+}$.

Although dtc ligands are capable of a large number of bonding modes, with technetium only the bidentate form of dtc bonding has been observed. A handful of technetium-dtc complexes have been structurally examined and include two five-coordinate technetium(V) complexes,[16,17] $[TcN(dedc)_2]$ and $[TcO(dmdc)(TMT)_2]$, a six-coordinate technetium(I) complex,[18] $[Tc(CO)_2(PPh_3)_2(dtc)]$, four seven-coordinate technetium(III) complexes,[15,19–21] $[Tc(dedc)_3(CO)]$, $[Tc(dedc)(PMe_2Ph)]$, $[Tc(dedc)_2Cl_2(NS)]$ and $[Tc(dedc)_2Br_2(NS)]$, and one other six-coordinate technetium(II) complex,[17] $[Tc(dmdc)(DPPE)_2]^+$. The latter complex was an accidental result of a synthesis intended to produce a mixed ligand complex containing a thiourea derivative. The presently reported $[Tc(dtc)(DEPE)_2]^+$ complexes are the first technetium(II)-dtc examples to be generated by a deliberate, rational synthesis and are more fully characterized than the others mentioned above. It is worth noting that those technetium complexes containing multiple dtc ligands are stable in higher oxidation states [technetium(III) and technetium(V)], which seems to attest to the effective σ-donor ability of dtc, while those dtc complexes in which technetium is in a lower formal oxidation state [technetium(I) and technetium(II)] contain π-accepting carbonyl and/or phosphine ligands.

All three $[Tc^{II}(dtc)(DEPE)_2]^+$ complexes exhibit

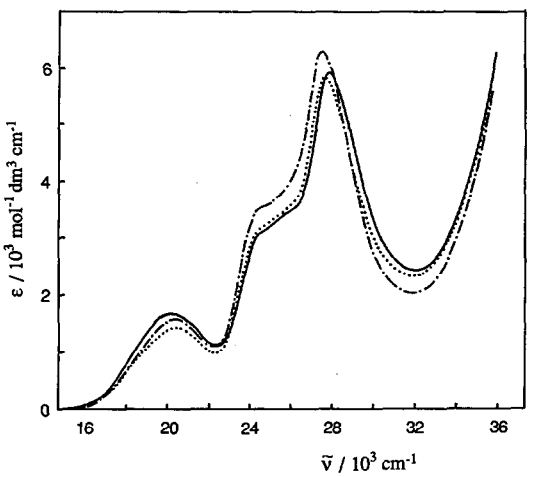

Fig. 2. The absorption spectra of $[Tc(dtc)(DEPE)_2]^+$ recorded in acetonitrile: dtc = dmdc (——), dedc (· · · ·) and pmdc (–·–·–).

similar UV–vis absorption spectral patterns, as shown in Fig. 2. The bands in this region consist of one peak at *ca* 20×10^3 cm^{-1}, an indistinct intermediate shoulder region and an intense absorption around 28×10^3 cm^{-1}. Extinction coefficients for these transitions are greater than 10^3 M^{-1} cm^{-1}. Absorption data are presented in Table 3. The X-ray analysis has definitively identified the $[Tc^{II}$

Table 3. UV–vis spectral data for $[Tc(dtc)(DEPE)_2]^+$ [a]

dtc	λ_{max} (10^3 cm^{-1}) ($\varepsilon/10^3$ M^{-1} cm^{-1})		
dmdc	20.20 (1.68)	25.00sh (3.22)	27.86 (5.93)
dedc	20.40 (1.43)	25.00sh (3.27)	27.66 (5.85)
pmdc	20.33 (1.58)	24.69sh (3.55)	27.55 (6.29)

[a] sh denotes a shoulder.

$(dmdc)(DEPE)_2]^+$ complex and the similarities in spectral characteristics of all three dtc complexes strongly suggest that they all contain technetium in the +2 oxidation state with similarly bound ligands.

LTMCT bands in the near UV–vis region typically occur at *ca* 540 and 440 nm for *trans*-$[Tc^{II}(S\text{-alkyl})(DMPE)_2]^0$ complexes (determined by OTTLE)[3] and around 520, 450 and 390 nm for *cis*-$[Tc^{II}(S\text{-aryl})_2(DMPE)_2]^0$ complexes (determined by OTTLE).[5] These bands are assigned to arise from $S(\pi) \rightarrow Tc(\pi^*)$ transitions; they mask the lower intensity *d–d* transitions observed in this region in the absorption spectra of $[Tc^{II}(DMPE)_3]^{2+}$ and $[Tc^{II}(DEPE)_3]^{2+}$.[22] In the three $[Tc^{II}(dtc)(DEPE)_2]^+$ complexes reported here, the intense LTMCT absorptions at 490 and 400 (sh) nm appear to be analogous to the 452 and 338 (sh) nm absorptions observed in $[Tc^{II}(tdt)(DMPE)_2]^0$ (determined by OTTLE)[7] with a similar pattern of intensities.

Crystallography, $[Tc(dmdc)(DEPE)_2](PF_6)$

A perspective view of the complex cation $[Tc(dmdc)(DEPE)_2]^+$ is illustrated in Fig. 3 along with the atomic labelling scheme. The independent portion of the structure consists of one discrete complex cation and one hexafluorophosphate anion. All atoms occupy general positions in the unit cell. The technetium ion is at the centre of a tris-chelate ligand arrangement, where the six donor atoms are as close to octahedral as possible within the constraints of the chelate bite angles. An evaluation of the *fac* twist angle[23] indicates that no trigonal distortion is exhibited by the ligands in $[Tc(dmdc)(DEPE)_2]^+$. Assigning the dmdc ligand a formal −1 charge leads to the conclusion that the technetium centre is in a formal +2 oxidation state.

Selected bond lengths and angles are reported in Table 4. The dmdc molecule acts as a symmetric bidentate (S,S) ligand. The two Tc—S bond distances are equivalent, implying a delocalization of the −1 charge in the dithiocarbamate. The entire dmdc ligand is planar (rmsd = 0.022 Å) and technetium is located 0.20 Å out of this plane. The dmdc bite angle is 71.5(1)°. The Tc—P distances average 2.43(2) Å when the *trans* ligand is a phosphine and 2.38(2) Å when the *trans* ligand is the dithiocarbamate. Therefore, in this complex the dmdc sulphur donor induces a *trans* shortening of 0.05 Å on the Tc—P bond distance. DEPE bite angles are normal at 81.8(1)° and 81.9(1)°.

The set of technetium–thiolato–diphosphine complexes characterized to date[2,4–8] show Tc—S(thiol) lengths to be dependent on technetium oxidation state; Tc^{III}—S averages 2.30(1) and Tc^{II}—S averages 2.42(1) Å. The Tc^{II}—S(dtc) lengths of 2.45(1) in $[Tc(dmdc)(DEPE)_2]^+$ and 2.44(1) Å in $[Tc(dmdc)(DPPE)_2]^+$[17] are close to the technetium(II)–thiolato length. Table 5 summarizes the structural parameters for technetium-dtc compounds. The first technetium(III) complexes of Table 5 all have expanded coordination numbers ($n = 7$) and this tends to lengthen bond distances.

Table 5. Structural comparison of technetium-dtc complexes[a]

[a] n is the coordination number, Oxidation is the oxidation state of technetium. E.s.d.s on lengths are of the order 0.01–0.03 Å. E.s.d.s on angles are of the order 1–2°. The bond lengths and angles quoted in the table are only those involved in the dtc ligands.

[b] One Tc—S length is 2.52 *trans* to CO and not included in this average.

[c] This work.

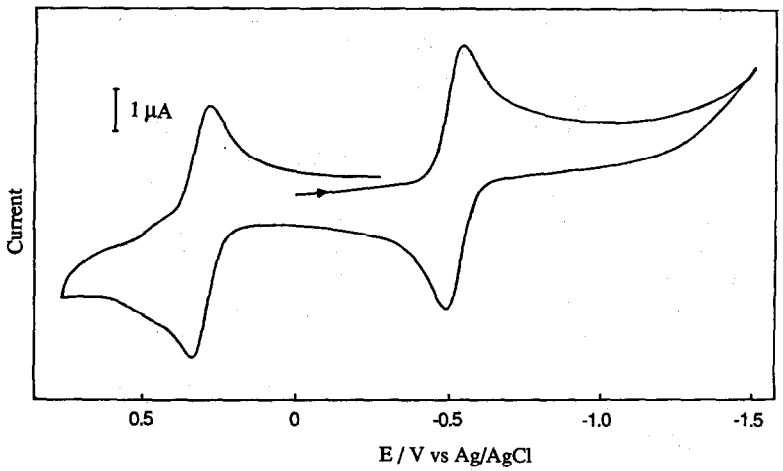

Fig. 4. A cyclic voltammogram of $[Tc(dmdc)(DEPE)_2]^+$ (6.2×10^{-4} g cm^{-3}) in 0.5 M TEAP/DMF at a PDE. Scan rate is 100 mV s^{-1}.

Taking this into account, Tc—S(dtc) lengths increase with decreasing technetium oxidation state, as we have observed with Tc—S(thiolato) lengths in the absence of other factors. The geometry of the dmdc ligand in $[Tc^{II}(dmdc)(DEPE)_2]^+$ is entirely in agreement with the other entries of Table 5.

The Tc^{II}—P length in $[Tc(dmdc)(DEPE)_2]^+$ averages 2.43(2) Å when *trans* to another phosphorus atom. The Tc^{II}—P(DMPE) length is *ca* 2.39 Å in similar complexes[4] and Tc—P(DMPE) lengths are slightly shorter than equivalent Tc—P(DEPE) lengths.[2] The Tc—P(DPPE) lengths (*trans* to phosphorus) in $[Tc^{II}(dmdc)(DPPE)_2]^+$ [17] are longer at 2.46(2) Å, due to the increasing bulk of the DPPE substituents; however, a *trans* shortening of the Tc—P length opposite the sulphur ligand is similarly observed. In contrast, technetium(III) and technetium(II) complexes containing thiols and DMPE exhibit Tc—P lengths which are longer when located *trans* to a thiolato ligand relative to those *trans* to another phosphine.[4,5] This indicates some fundamental bonding differences between thiolato and dtc ligands.

Electrochemistry

Cyclic voltammograms were obtained for solutions of the $[Tc(dtc)(DEPE)_2]^+$ (dtc = dmdc, dedc and pmdc) complexes in 0.5 M TEAP/DMF at a PDE. The voltammogram shown in Fig. 4 is that of $[Tc(dmdc)(DEPE)_2]^+$, but is typical of the other dtc complexes as well. For $[Tc(dmdc)(DEPE)_2]^+$ a negative potential scan initiated at 0.0 V exhibits a single reduction wave at −0.488 V. Upon reversing that scan at −1.5 V the corresponding reoxidation wave appears at −0.546 V. A positive potential scan to +0.75 V shows one other major redox couple centred at +0.312 V. These redox couples are assigned as diffusion-controlled, reversible, one-electron transfers on the basis of fulfilment of the accepted criteria for reversibility.[24] The formal reduction potentials, $E^{0\prime}$, are summarized in Table 6. With reference to the previously reported electrochemistry of technetium-diphosphine complexes,[2,3,5,7,11,22,25,26] these two redox processes are assigned as technetium(II/I) and technetium(III/II) reversible redox couples:

$$[Tc^{II}(dtc)(DEPE)_2]^+ + e^- \rightleftharpoons [Tc^{I}(dtc)(DEPE)_2]^0$$

$$E^{0\prime} = -0.52 \text{ to } -0.54 \text{ V}$$

$$[Tc^{III}(dtc)(DEPE)_2]^{2+} + e^- \rightleftharpoons [Tc^{II}(dtc)(DEPE)_2]^+$$

$$E^{0\prime} = +0.30 \text{ to } +0.31 \text{ V}.$$

Table 6 compares technetium(III/II) and technetium(II/I) redox potentials for similar complexes and shows that the reduction potentials characterizing $[Tc(dtc)(DEPE)_2]^+$ are unusual for technetium–sulphur/phosphine ligand complexes. In the dtc complexes the lower oxidation states are markedly stabilized relative to the dithiolato analogues. In general, the technetium(III) dithiocarbamate complexes are *ca* 500–900 mV easier to reduce to technetium(II) and the technetium(II) complexes are *ca* 600–1400 mV easier to reduce to technetium(I) than are the dithiolato analogues. From our studies of $[Re(SR)_2(DMPE)_2]^+$ complexes[27] it has been noted that rhenium(III/II) redox potentials vary only *ca* 50 mV between *cis* and *trans* geometries, the *cis*-$[Re(SR)_2(DMPE)_2]^+$ complexes being slightly easier to reduce than the *trans*. Therefore, the marked difference between the

reducibility of $[Tc^{III}(dtc)(DEPE)_2]^{2+}$ and the *cis*- and *trans*-$[Tc^{III}(SR)_2(D)_2]^+$ complexes of Table 6 signifies a profound effect on the energy levels of the complex engendered by the dtc ligand, not by the coordination geometry. The lowest unfilled orbital in $[Tc^{III}(dmdc)(DEPE)_2]^{2+}$ is at least 500 mV lower in energy than that of any other $[Tc^{III}(SR)_2(D)_2]^+$ complex examined. In fact, comparable redox potentials within this series occur only in *trans*-$[Tc^{III}(NCS)_2(DPPE)_2]^+$, where the NCS ligand binds to technetium through nitrogen and both NCS^- and DPPE are effective π-acceptors.[25] Both $[Tc^{II}(dtc)(DEPE)_2]^+$ and $[Tc^{II}(NCS)_2(DPPE)_2]$ are isolated as stable technetium(II) species. The comparable technetium(III/II) reduction potentials of $[Tc(dtc)(DEPE)_2]^{2+/+}$ and $[Tc(NCS)_2(DPPE)_2]^{+/0}$ are even more remarkable in light of the fact that DPPE ligands are better π-acceptors than DEPE ligands: otherwise equivalent $[Tc^{III}X_2(DPPE)_2]^+$ complexes are ~250 mV easier to reduce than $[Tc^{III}X_2(DEPE)_2]^+$ complexes (see Table 6). Therefore, the dtc ligand is very potent at lowering the technetium(III/II) reduction potential and this certainly implicates dtc as a significant π-acceptor ligand in technetium-diphosphine complexes. The effect of substituent exchanges within the ligands dmdc, dedc and pmdc leads to very little effect on the $E^{0\prime}$ values.

Animal experiments have shown that the technetium(III/II) couple of the prototypical bis(phosphine) complex $[TcCl_2(DMPE)_2]^{+/0}$ is biologically accessible and that the injected technetium(III) complex undergoes *in vivo* reduction to the technetium(II) form.[28] Replacement of the two chloride ligands by two thiolato ligands stabilizes the technetium(III) state, while replacement of the two chloride ligands by a dtc ligand stabilizes the technetium(II) state. Thus, careful control of the sulphur-donating ligands in bis(phosphine) technetium(III/II) complexes allows one to design and synthesize ^{99m}Tc radiopharmaceuticals with the properties (lipophilicity, charge, redox potential, etc.) required for specific imaging applications. For instance, it should be possible to design a neutral bis(phosphine) technetium(II) complex which can cross the blood–brain barrier and then undergo electron transfer within relatively oxidizing brain tissue[29] to a cationic technetium(III) species which will be trapped in the brain for a time long enough to allow imaging.[30] Some neutral bis(phosphine) technetium(II) complexes are already known to cross the blood–brain barrier.[30]

In addition to their readily tuneable redox properties, the $[Tc^{II}(dtc)(DIP)_2]^+$ complexes described in this work possess characteristics which are fundamental to the design of new ^{99m}Tc radiopharmaceuticals. These complexes are kinetically robust, do not undergo *cis*/*trans* isomerization reactions and have well-defined chemistry. It should

be noted that other classes of ^{99m}Tc-dtc complexes are also under active development as radiopharmaceuticals; Duatti and co-workers[31,32] are investigating [$^{99m}Tc^{V}N(dtc)_2$] as a myocardial perfusion imaging agent.

LOW TEMPERATURE ROUTES TO EUROPIUM AND YTTERBIUM CHALCOGENIDES

I. P. PARKIN* and J. C. FITZMAURICE

Department of Chemistry, The Open University, Walton Hall, Milton Keynes MK7 6AA, U.K.

(*Received* 18 *December* 1992; *accepted* 5 *April* 1993)

Abstract—Reaction of europium or ytterbium metal in liquid ammonia with sulphur, selenium or tellurium (at room temperature in a pressure tube) affords a convenient route to crystalline binary metal chalcogenides.

The solubility of alkali metals and alkaline metal earths in ammonia to generate blue or bronze solutions containing solvated electrons and metal cations is well known.[1] These solutions have been used to perform a range of reductions both in organic chemistry in, for instance, the Birch reduction[2] and in inorganic chemistry to afford metal polychalcogenide species, M_xE_y (M = group Ia, IIa; E = chalcogenide, $y \geqslant x$).[3] Europium and to a lesser extent ytterbium metal also dissolve in liquid ammonia to form deep blue or bronze solutions;[4] however, the synthetic utility of these solutions (to our knowledge) has not been reported.

Lanthanide sulphides, selenides and tellurides of varying stoichiometry LnE to Ln_3E_7 (E = S, Se, Te; Ln = lanthanide) have been synthesized by high temperature (> 1000°C) techniques, either by reduction of the metal oxide with H_2S and H_2Se or by direct combination of the elements.[5] Here we report the room temperature synthesis of crystalline europium and ytterbium chalcogenides.

RESULTS AND DISCUSSION

Reaction of europium metal in liquid ammonia at room temperature in a pressure tube with sulphur, selenium or tellurium affords the binary compounds EuE (E = S, Se, Te) (Table 1). The europium and chalcogenide were added under nitrogen to ammonia at −77°C to generate a deep blue or bronze solution, which was magnetically stirred and allowed to warm to room temperature (under pressure). The ammonia was maintained in the system by closing a Young's tap; after a couple of hours the blue or bronze colour was discharged and a green, yellow or purple homogeneous precipitate formed dependent on the ratio of europium to chalcogenide. After 12 h the solution was cooled and the ammonia allowed to evaporate under nitrogen. Removal of the final traces of ammonia *in vacuo* generally darkened the precipitate to black in the case of tellurium and dark red–brown for the selenium or sulphur derivatives. The reaction of excess europium with the chalcogenides leads to the formation of a pyrophoric material comprising of finely divided metal and metal chalcogenide. Reaction of excess chalcogenide with europium leads to the formation of the same metal species (Table 1) and unreacted chalcogenide, as detected both by X-ray powder diffraction and by extraction of the chalcogenide with CS_2.

The precipitates were characterized by microanalysis, S.E.M./EDAX, X-ray powder diffraction, magnetic moment measurement and IR spectroscopy. The IR spectra† showed only a broad band at 400 cm^{-1} for EuS with no evidence of any S—H or N—H stretches. The microanalysis of EuE showed no carbon, hydrogen or nitrogen present and chalcogenide analyses were satisfactory.

	Chalcogenide			
Metal	O	S	Se	Te
Europium	Eu_2O_3[a]	EuS/Eu_3S_4	EuSe	EuTe
Ytterbium	Yb_2O_3[a]	YbS/Yb_3S_4	YbSe[b]	YbTe[b]

[a] Oxide formed by exposing the finely divided metal to air. **Caution:** extremely exothermic reaction.

[b] Material heated in the pressure tube to 250°C for 2 h after NH_3 evaporated.

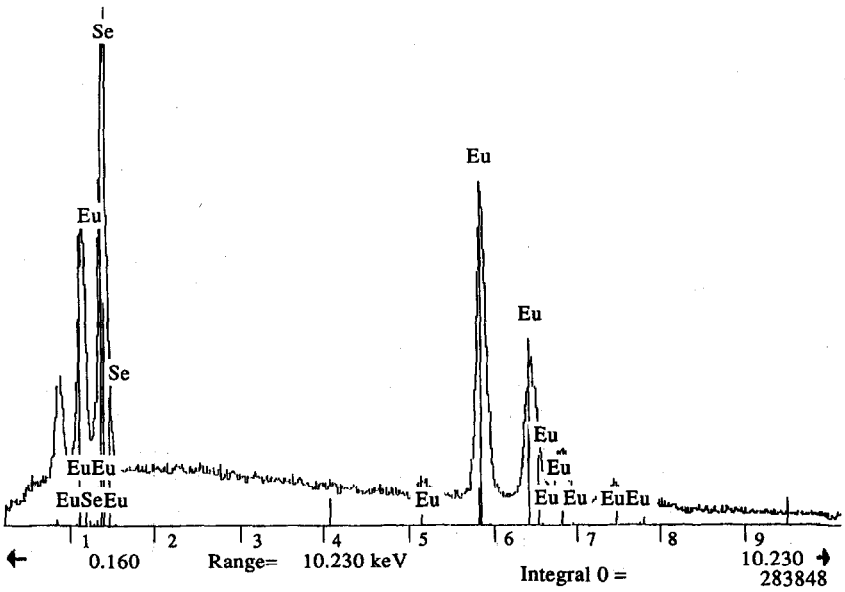

Fig. 1. S.E.M./EDAX elemental profile of europium selenide, EuSe.

The S.E.M./EDAX analysis* showed both a homogenous morphology and elemental profile standardized as EuE (Fig. 1). Samples of EuE decompose slowly in air, liberating H_2E and the formation of Eu_2O_3. Incorporation of oxygen was shown by a small peak in the EDAX analysis which increased in size with sample age.

The magnetic moments† and colours of the EuE compounds were identical to the literature.[5]

The X-ray powder diffraction data‡ showed that the product from the room temperature reaction was crystalline, with the predominant phase being EuE (Fig. 2). In the case of excess sulphur to europium a small amount of Eu_3S_4 and sulphur was also detected. When the reaction of selenium and tellurium with europium was performed with up to an eight-fold excess of the chalcogenide only EuSe and selenium metal or EuTe and tellurium metal were detected.

The analogous reactions with ytterbium were investigated. These showed that with selenium and tellurium even in excess only a small amount of YbSe and YbTe was formed after evaporation of the ammonia. The majority of material present was in the form of unreacted and finely divided metal. On exposure to air this powder ignited and pro-

†Magnetic moments were determined via the Evans method on a Johnson–Matthey balance.

‡X-ray powder diffraction data were obtained on a Siemens diffractometer D5000.

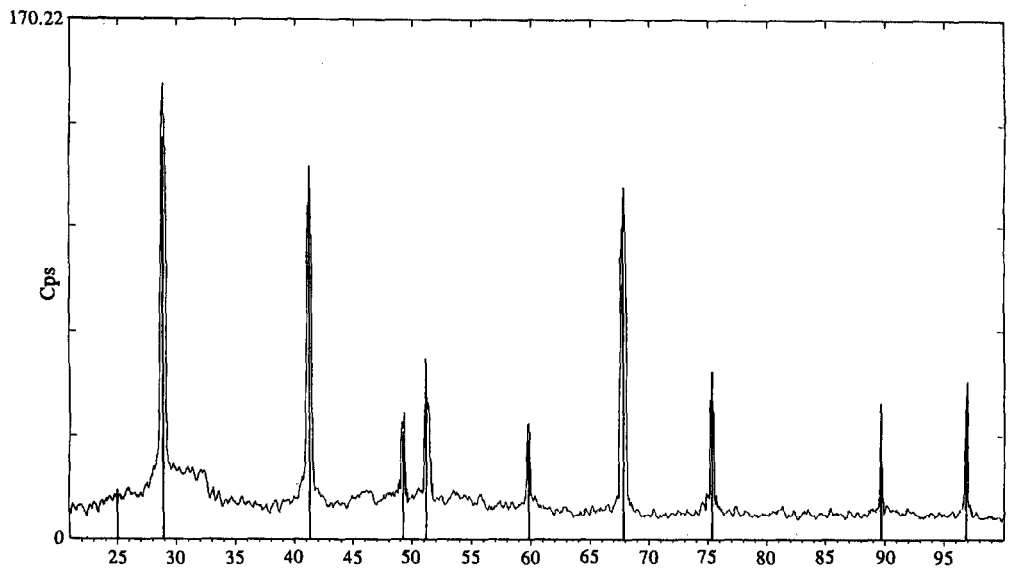

Fig. 2. X-ray powder diffraction pattern from reaction of europium with selenium in liquid ammonia at room temperature.

duced the metal oxide Yb_2O_3. However, YbSe and YbTe can be formed by gentle thermolysis of the ammonia precipitate (fully intermixed ytterbium and selenium or tellurium) at 250°C for 2 h under vacuum. Ytterbium sulphide formed at room temperature under the same conditions as the europium analogue.

Convenient preparation of both Eu_2O_3 and Yb_2O_3 can be achieved by generating finely divided metal by adding europium or ytterbium metal to liquid ammonia and allowing the ammonia to evaporate with vigorous stirring; careful pouring of the metal powder onto a ceramic dish (in air) causes spontaneous ignition and formation of the metal oxide.

The formation of europium and ytterbium chalcogenide by the ammonia route is significantly lower in energy than that of previous studies, where elevated temperatures were required.[5] However, it does seem limited to europium and ytterbium, as the other lanthanides are not soluble in ammonia. Indeed reaction of samarium and gadolinium under the same conditions failed to generate metal chalcogenides.

The chalcogenides are soluble in ammonia, forming a variety of different ions dependent on the concentration of the chalcogenide.[6] The reactions described here seem to proceed analogously to group IA and IIa chemistry where M_2E and ME compounds are known,[7] however, with excess chalcogenide no lanthanide polychalcogenide species are produced.

THE SYNTHESIS AND X-RAY CRYSTAL STRUCTURE OF MOLYBDENUM OXOMETHOXIDE $[MoO(OMe)_4]_2$

VADIM G. KESSLER,*† ANDREJ V. MIRONOV and NATALIYA YA. TUROVA

The Department of Chemistry, Lomonosov Moscow State University, Moscow, Leninskije Gory, 117234 Moscow, Russia

and

ALEXANDR I. YANOVSKY and YURI T. STRUCHKOV

The A.N.Nesmeyanov Institute of Organoelement Compounds, 28 Vavilov Street, 117813 Moscow, Russia

(*Received* 10 *September* 1992; *accepted* 27 *November* 1992)

Abstract—$MoO(OMe)_4$ has been prepared by anodic oxidation of molybdenum metal in anhydrous methanol containing LiCl as an electrolyte. The X-ray single crystal study showed the complex to consist of pseudo-centrosymmetric dimeric molecules, $[MoO(OMe)_3(\mu\text{-}OMe)]_2$. The general effect of the $M(\mu\text{-}OR)_2M$ ring upon the arrangement of bonds with increased multiplicity is discussed in this and related molecules.

The molybdenum(VI) oxoalkoxides, $MoO(OR)_4$, in spite of increasing interest as possible molecular precursors for MoO_3-based complex oxide materials, are scarcely studied. This seems to be a result of the low stability of these products, due to their significant tendency to ether elimination leading to the formation of $MoO_2(OR)_2$ species and high sensitivity to hydrolysis which is followed by the formation of "molybdenum blues".[1–3] $MoO(OMe)_4$—the only solid representative of the $MoO(OR)_4$ series—has been described in the literature as a brownish-yellow amorphous powder.‡ It was prepared by the alcohol interchange reaction of $MoO(OEt)_4$ with excess methanol. In the present work the synthesis and X-ray single-crystal investigation of $MoO(OMe)_4$ crystalline species (**I**) are described.

The anodic oxidation of metallic molybdenum in anhydrous MeOH was carried out in a cell without subdivision of the cathodic and anodic space, with water cooling. LiCl (0.025 M) was used as the electrolyte and the temperature in the cell did not exceed 50°C. Platelets of molybdenum with an area of *ca* 12–15 cm^2 were taken as anodes and cathodes (the average current density being 0.1 Å cm^{-2} as used earlier[4] for the anodic oxidation of tungsten). The duration of the synthesis in all the experiments was *ca* 36 h. Slow cooling of the solutions (the molybdenum concentrations reached *ca* 0.16–0.20 M) deposited $MoO(OMe)_4$ in the form of big, light yellow prismatic crystals.‡ The crystals of **I** are highly soluble in methanol, especially on heating, but poorly soluble in hexane. Their thermal decomposition, as well as for amorphous species, occurs at 110–140°C.

‡ The formation of **I** only as amorphous powder in the course of $MoO(OEt)_4$ alcohol interchange reactions is connected apparently with its insufficient purity. The easy formation of $MoO_2(OEt)_2$ due to ether elimination from the corresponding oxoethoxide gives rise to $MoO_2(OMe)_2$ which hinders the crystallization.

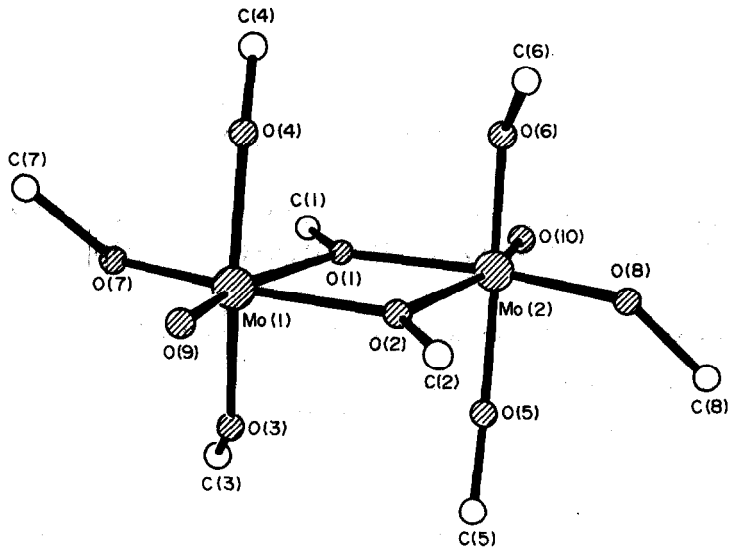

Fig. 1. The molecular structure of $MoO(OMe)_4$. Selected bond distances (Å) and angles (°): Mo(1a)—O(1a) 2.226(5), Mo(1a)—O(2a) 2.050(5), Mo(1a)—O(3a) 1.881(5), Mo(1a)—O(4a) 1.873(5), Mo(1a)—O(7a) 1.886(6), Mo(1a)—O(9a) 1.672(5); O(1a)—Mo(1a)—O(2a) 69.1(2), O(1a)—Mo(1a)—O(7a) 92.6(2), O(7a)—Mo(1a)—O(9a) 105.3(3), O(3a)—Mo(1a)—O(4a) 164.9(2).

The structure of **I** was determined by single-crystal X-ray investigation.*

The crystals of **I** are built up of $[MoO(OMe)_3(\mu\text{-}OMe)]_2$ pseudo-centrosymmetric dimeric molecules (Fig. 1) (two symmetrically independent molecules with practically identical geometric parameters in the unit cell). The molybdenum atoms possess distorted octahedral coordination: two longer Mo—O bonds are formed in the equatorial plane by the oxygen atoms of the bridging methoxo groups [Mo(1a)—O(1a) 2.226(5) and Mo(1a)—O(2a) 2.050(5) Å], the double-bonded oxo group being situated in the *trans* position to the longest of them, while other sites in the coordination sphere of the metal atom are occupied by terminal alkoxo groups. The latter are characterized by rather close values of bond lengths [1.886(6), 1.881(5) and 1.873(5) Å for one equatorial and two apical lengths, respectively]. It should be mentioned that in this case the coordination polyhedra of molybdenum atoms turn out to be seriously distorted in comparison with those usually determined for the various coordination compounds of molybdenum(VI).[6] While for the majority of molybdenum(VI) derivatives studied the sums of interatomic distances for atoms situated in *trans* positions to each other and to the molybdenum atom are nearly equal along all three dimensions of the octahedron. In the structure of **I** the distances are rather less for the apical substituents (3.754 Å) compared with the equatorial ones (3.898 and 3.936 Å). This fact, taking into consideration the considerably higher valent angles at the oxygen atoms of the apical alkoxo groups [Mo(1a)—O(3a)—C(3a) 134.5(5)°, Mo(1a)—O(4a)—C(4a) 137.2(6)°] compared with that of the equatorial angle [Mo(1a)—O(7a)—C(7a) 130.7(6)°], proves the absence of any significant "*trans* effect" in this structure. Such an unusual relationship between bond lengths and bond angles has already been mentioned in earlier descriptions of the molecular structures of $[Nb(OMe)_5]_2$,[7] $[W(NPh)(OMe)_3(\mu\text{-}OMe)]_2$[8] and the quite recently studied $[WO(OMe)_4]_2$,[9] which is apparently very similar to **I**. This can be

*Crystal data for $C_8H_{24}Mo_2O_{10}$ (**I**): $M = 472.2$, orthorhombic, space group $P2_12_12_1$, $a = 11.790(2)$, $b = 10.410(2)$, $c = 27.180(5)$ Å, $V = 3335.9(2)$ Å^3, $D_c = 1.880$ g cm^{-3} for $Z = 8$, $\lambda(\text{Mo-}K_\alpha) = 0.71073$ Å, 3946 reflections with $F^2 > 3\sigma(F^2)$ were collected at 20°C up to $2\theta_{max} = 45°$ with a CAD4 Enraf–Nonius diffractometer. The structure was solved by standard direct methods; the molybdenum atom coordinates were taken from the initial solution and the other non-hydrogen atoms were located in subsequent Fourier syntheses. The structure was refined by full-matrix least-squares in an isotropic and then in an anisotropic approximation. The positions of all the hydrogen atoms were calculated geometrically and included in the final cycles of refinement in an isotropic approximation. Final discrepancy factors are $R = 0.0397$ and $R_w = 0.0460$ (the absolute structure was determined by the Hamilton test, $R_{inv} = 0.0400$). All calculations were performed with an IBM PC using SHELXTL PC programs.[5] Atomic coordinates for this compound have been deposited at the Cambridge Crystallographic Data Center.

completely explained by the influence of the $M(\mu\text{-}OR)_2M$ cycle rigid geometry upon the ability of the M atom to π-bond. The formation of bridging σ-bonds (a significant input in which is made by the $d_{x^2-y^2}$ metal atom orbital) leads to a large deviation in the angle between the σ-bonding orbitals in the equatorial plane from 90°—in order to allow both metal and oxygen atoms of the bridging cycle to remain in the same plane [the endocyclic angle O(1a)—Mo(1a)—O(2a), 69.1(2)°; the exocyclic angle O(7a)—Mo(1a)—O(9a) 105.3(3)°]. However, this has practically no influence on the orbitals responsible for π-bonding—d_{xz}, d_{xy} and d_{yz}. Due to this distortion of the metal atom geometry, the effectiveness of π-bonding decreases for the oxygen atoms situated in the equatorial plane (Fig. 2), remaining unchanged for the apical oxygen atoms. This results apparently in the observed *trans* configuration of the M—OR bonds possessing increased multiplicity. The absence of this effect in the molecular structures of Ce, Zr and Hf solvated isopropoxides, $[M(OPr^i)_4Pr^iOH)]_2$,[10] which are also based on the $M(\mu\text{-}OR)_2M$ four-membered ring, can be explained by the fact that one of the apical positions of the metal-oxygen octahedron should be occupied by the solvating molecule of the alcohol, the active hydrogen atom, which is incorporated in the intramolecular hydrogen bonds. The arrangement of the latter is in this case responsible for the geometry of the molecule as a whole.

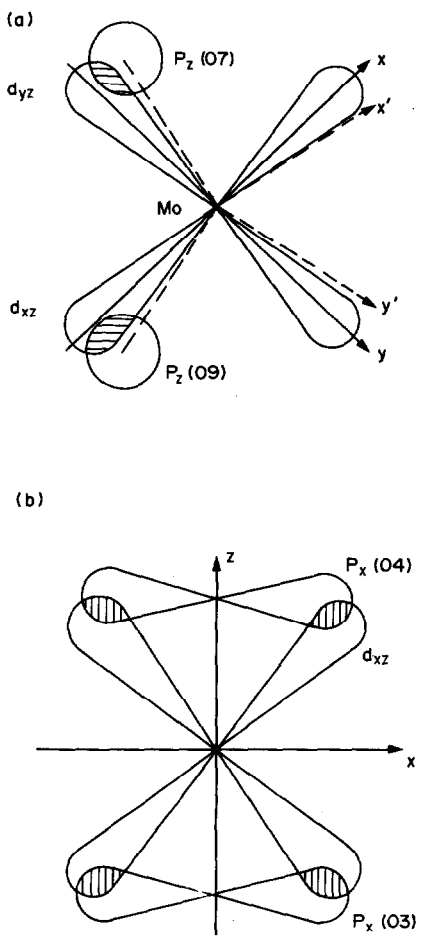

Fig. 2. Scheme of overlapping π-orbitals: (a) in the equatorial plane and (b) in the *xz* or *yz* plane.

The IR spectrum of the $MoO(OMe)_4$ crystalline species was found to be in accordance with the molecular structure described above: two bands at 950 and 920 cm^{-1}, respectively, correspond to the vibration of Mo=O terminal bonds (the appearance of the doublet in the spectrum is probably caused by superposition of stretching modes for two equivalent bonds in the structure), while the bands at 570 and 520 cm^{-1} correspond to the vibrations of terminal and bridging alkoxo groups, respectively. From the spectrum of the amorphous $MoO(OMe)_4$ species, that of **I** differs only by the higher intensity of the band at 520 cm^{-1} and better resolution of the Mo=O vibration bands. Such a difference might be caused by the presence of significant amounts of impurities [probably $MoO_2(OMe)_2$ or monomeric $MoO(OMe)_4$ in the species prepared by the alcohol interchange reaction of $MoO(OEt)_4$, which possesses a vigorous tendency to ether elimination and of which the molecular complexity is less than 2[1]].

Consequently, it is noteworthy that the investigated preparation, properties and structure of $MoO(OMe)_4$ provide one more illustration for the fundamental difference in the chemical nature of the analogous molybdenum(VI) and tungsten(VI) compounds. Thus, while the anodic oxidation of the molybdenum metal is a facile route to the oxotetraalkoxide, $WO(OMe)_4$ cannot be obtained in a pure form by this method; the samples prepared always contain a significant admixture of $W(OMe)_6$.[4] The reason for this fact probably lies in the rather higher stability of the initially formed *ortho* derivative $M(OMe)_6$ to both ether elimination and reduction–reoxidation processes for tungsten rather than for the molybdenum compound. It should also be mentioned that the dimeric alkoxo-bridged structure seems to be not only adaptable for $WO(OR)_4$, R = Me, Et. The IR and X-ray powder investigation of the latter compounds, prepared by exchange reaction of $WOCl_4$ with NaOR, showed them to be oxo-bridged polymeric species—analogues of $WOCl_4$.[11] The formation of a structure different from $MoO(OMe)_4$ for the tungsten compound is probably caused by the presence of traces of NaOR, irremovable by recrystallization which

is used for the purification of the products. It is interesting that for $MoO(OEt)_4$ and $MoO(OPr^i)_4$ [but not $MoO(OMe)_4$] polymerization in the presence of traces of NaOR also occurs, but only by the formation of alkoxo-bridges.[12] In the background of this difference in chemical and structural characteristics apparently lies the higher multiplicity and lower donor ability of Mo=O in comparison with W=O bonds.

Acknowledgements—The authors would like to express their gratitude to Dr A. A. Buchachenko for a fruitful discussion of electronic structure of the entitled and allied compounds.

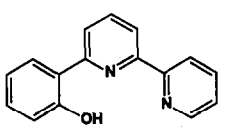
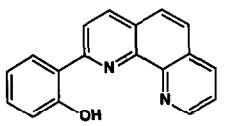
(*Received* 22 *February* 1993; *accepted* 30 *March* 1993)

Abstract—Reaction of the N,N,O-terdentate ligands 6-(2-hydroxyphenyl)-2,2′-bipyridine (HL^1) and 2-(2-hydroxyphenyl)-1,10-phenanthroline (HL^2) with $Na_2PdCl_4\cdot 3H_2O$ afforded the complexes $[PdL^1Cl]$ and $[PdL^2Cl]$; the crystal structure of $[PdL^1Cl]\cdot(CH_2Cl_2)$ shows it to be a square-planar monomer with extensive intramolecular π-stacking interactions involving the aromatic ligands.

We have recently been studying the structural properties of transition metal complexes containing polydentate aromatic ligands such as 6-(2-hydroxyphenyl)-2,2′-bipyridine (HL^1) and 2-(2-hydroxyphenyl)-1,10-phenanthroline (HL^2) and the competition between the various factors which influence their structures.[1–6] Complexes with metals which



HL^1



HL^2

have a strong electronic preference for octahedral geometries such as ruthenium(II), ruthenium(III), cobalt(III) and chromium(III) adopt the expected structures in which the metal adopts its most favoured geometry.[1,4,6] In complexes with copper(II) and nickel(II), however, which have weaker stereoelectronic preferences, some unexpected structures have arisen, in which other factors can be seen to be involved in contributing to the structures, in particular π-stacking between parallel fragments of aromatic rings.[1–3] Such π-stacking interactions occur frequently in coordination complexes containing aromatic ligands[7] and in purely organic systems[8] and as such have been the subject of extensive theoretical studies.[9] Although they are relatively weak and could not be said exclusively to control the structures of complexes in which they occur, we have shown that they may be sufficient to tip the balance between two different structural types; thus, the nickel(II) complexes of the two related ligands HL^1 and HL^2 have very different structures, because in the latter case the additional aromatic ring of HL^2 becomes involved in some very close inter-ring π-stacking interactions.[3]

To examine the π-stacking effects with these ligands systematically, we decided to prepare and structurally characterize their complexes of palladium(II) and platinum(II). These complexes would be expected to have planar structures in which any inter-ring stacking will be free to occur without any steric impedance from axial ligands. We report here the preparations of palladium(II) complexes with HL^1 and HL^2 and the crystal structure of $[PdL^1Cl]\cdot(CH_2Cl_2)$.

EXPERIMENTAL

^1H NMR spectra were recorded on a Jeol GX270 spectrometer. Fast-atom bombardment (FAB) mass spectra were recorded on a VG-Autospec at the SERC Mass Spectrometry Service Centre, Swansea, with 3-nitrobenzylalcohol as a matrix. All starting materials were purchased from Aldrich and used as received. HL^1 and HL^2 were prepared as

described earlier.[1,3] The equipment used for the electrochemical measurements has been described previously.[1]

Preparation of [PdL^{1}Cl] *and* [PdL^{2}Cl]

A mixture of the appropriate ligand and 1 equivalent of $Na_2PdCl_4 \cdot 3H_2O$ in methanol was stirred for 4 h at room temperature. After this time the mixture was filtered and the yellow–orange solid washed with methanol and dried. Yields were typically 60%. Crystals of [PdL^{1}Cl]$\cdot(CH_2Cl_2)$ suitable for X-ray diffraction were grown by layering hexane on a concentrated solution of the complex in CH_2Cl_2 and allowing the layers to mix.

[PdL^{1}Cl]: FABMS, $m/z = 388$ (M^+), 353 ($M^+ - Cl$). ^{1}H NMR (270 MHz, CD_3SOCD_3): $\delta = 9.13$ (1H, d, $J = 5.3$), 8.57–8.65 (2H, m), 8.51 (1H, d, $J = 6.6$), 8.30–8.40 (2H, m), 8.04 (1H, dd, $J = 8.5, 1.5$), 7.78 (1H, td, $J = 6.7, 1.1$), 7.26 (1H, td, $J = 7.6, 7.1$), 6.99 (1H, dd, $J = 8.6, 1.3$), 6.74 (1H, td, $J = 7.5, 1.5$ Hz). Found: C, 48.7; H, 2.9; N, 7.0. Calc. for $C_{16}H_{11}N_2ClOPd$: C, 49.4; H, 2.8; N, 7.2%.

[PdL^{2}Cl]: FABMS, $m/z = 437$ ($M^+ + Na$), 412 (M^+), 377 ($M^+ - Cl$). ^{1}H NMR (270 MHz, CD_3SOCD_3): δ 9.40 (1H, dd, $J = 4.4, 1.5$), 8.99 (1H, d, $J = 8.2$), 8.93 (2H, s), 8.22–8.35 (3H, m), 8.13 (1H, dd, $J = 8.8, 5.2$), 7.34 (1H, t, $J = 8.0$), 7.08 (1H, d, $J = 8.8$), 6.81 (1H, td, $J = 8.4, 1.0$ Hz). Found: C, 51.5; H, 2.4; N, 6.5. Calc. for $C_{18}H_{11}N_2ClOPd$: C, 52.3; H, 2.7; N, 6.8%.

Crystal structure determination

Crystals of [PdL^{1}Cl]$\cdot(CH_2Cl_2)$ were grown from a CH_2Cl_2/hexane mixture as amber needles. The crystal used for data collection was sealed in a tube under an atmosphere of nitrogen saturated with CH_2Cl_2. Despite this precaution it is probable that some solvent loss occurred during data collection. Moreover, the intensity of three standard check reflections diminished by *ca* 18% during the course of the data collection. The latter observation together with the comparatively poor resolution of intensities along the *a*-axis mean that the overall accuracy of the structural determination should be treated with due caution. Data were collected using a Siemens R3m/V four-circle diffractometer (293 K, Mo-K_α *X*-radiation, graphite monochromator, $\bar{\lambda} = 0.71073$ Å). The data were corrected for Lorentz, polarization and X-ray absorption effects and an empirical absorption correction was applied using a method based upon azimuthal scan data.[10] Details of the crystal data and intensity collection are given in Table 1.

Table 1. Summary of crystal data and intensity collection for [PdL^{1}Cl]$\cdot(CH_2Cl_2)$

	[PdL^{1}Cl]$\cdot(CH_2Cl_2)$
Formula	$C_{17}H_{13}Cl_3N_2OPd$
M_r	474.0

Largest and mean Δ/σ	0.005, 0.001
Largest difference peak and hole (e Å^{-3})	0.77, −0.64

The structure was solved by conventional heavy-atom methods and successive difference-Fourier syntheses were used to locate all non-hydrogen atoms. All non-hydrogen atoms were refined with anisotropic thermal parameters and hydrogen atoms were included in calculated positions (C—H 0.96 Å) with fixed isotropic thermal parameters ($U_{iso} = 0.08$). Final refinements by full-matrix least-squares procedures were performed on a μ-Vax computer with the SHELXTL system of programs.[10] Scattering factors with corrections for anomalous dispersion were taken from ref. 11.

RESULTS AND DISCUSSION

The complexes [PdL^{1}Cl] and [PdL^{2}Cl] were simply prepared by reaction of equimolar amounts of the appropriate ligand and $Na_2PdCl_4 \cdot 3H_2O$ in methanol at room temperature. The formulations of both were confirmed by elemental analysis and FAB mass spectrometry. In addition, proton NMR spectra in d^6-dimethylsulphoxide showed the

expected number of resonances in the aromatic region in each case, although these have not been assigned. Electrochemical investigations showed only totally irreversible processes at high positive and negative potentials.

We were able to obtain X-ray quality crystals of [PdL^{1}Cl]·(CH_2Cl_2) by recrystallization from CH_2Cl_2/hexane; views of the structure are shown in Figs 1 and 2. Relevant bond lengths and angles are in Table 2. The basic square-planar structure of the complex is shown in Fig. 1; the distortions from idealized square geometry are small and arise principally because the 2,2′-bipyridyl fragment is not sufficiently flexible to attain a 90° bite angle in the five-membered chelate ring.[12] The ligand is very nearly flat, with dihedral twists of *ca* 1° between the pyridyl rings and *ca* 5° between the central pyridyl and terminal phenolate rings. This is in marked contrast to all other structures with this ligand, where inter-ring dihedral angles of up to 40° are observed, particularly between the central pyridyl and terminal phenolate rings. It also contrasts with the structure of [Pd(2-pp)$_2$][2-ppH = 2-(2-hydroxyphenyl)pyridine], where there is a 26° twist between the pyridyl and phenolate rings of each of the two ligands.[13] The stacking of the planar complex units is shown in Fig. 2(a). They are not all aligned in the same way, but alternate such that the two components of each pair are related by an inversion centre [Fig. 2(b)]; this is no doubt partly to avoid unfavourable steric and electronic interactions between chloride groups in adjacent complexes. The

presence of π-stacking interactions between the complex units is evident. The separations of atoms in one ligand from the mean plane of the next vary from 3.30 [C(12)] to 3.59 Å [C(15)], with the average separation being 3.44 Å. Stacking appears to be maximized by overlap of all three aromatic rings of one complex unit with its neighbour. This precludes any axial interactions between the palladium atom of one complex and donor atoms from its neighbours, since the resulting substantial offset between the complexes would remove most of the stacking interaction.

Abstract—New mixed oxides of composition $Fe_{1-x}Cr_xSbO_4$ and $Fe_{1-x}Ga_xSbO_4$ have been prepared. New X-ray powder diffraction data for the compound $GaSbO_4$ are presented and the decrease in lattice parameters of $FeSbO_4$ when Fe^{3+} is substituted by smaller Cr^{3+} or Ga^{3+} ions is discussed. The temperature dependence of the inverse magnetic susceptibility of $Fe_{1-x}Cr_xSbO_4$ at temperatures exceeding *ca* 200 K follows a Curie–Weiss law. The Curie temperatures and effective magnetic moments decrease with decreasing iron content and are consistent with the substitution of Fe^{3+} by Cr^{3+} and a reduction in magnetic interaction between cations in the solid. Deviations from the Curie–Weiss law occur at lower temperatures with increasing chromium content and reflect the effect of chromium on the formation of clusters with short-range magnetic order amongst the Fe^{3+} species. A second Curie–Weiss law at even lower temperatures and a maximum in the magnetic susceptibility data recorded from $Fe_{0.85}Cr_{0.15}SbO_4$ and $Fe_{0.63}Cr_{0.37}SbO_4$ between 30 and 10 K is indicative of a spin glass-type transition in these materials. The trends in magnetic properties of materials of the type $Fe_{1-x}Ga_xSbO_4$ are similar, but more marked as a result of the substitution of paramagnetic Fe^{3+} by diamagnetic Ga^{3+}. The ^{57}Fe Mössbauer spectra recorded from $Fe_{1-x}Cr_xSbO_4$ and $Fe_{1-x}Ga_xSbO_4$ show an absence of magnetic splitting at 77 K, indicative of faster relaxation times than occur in $FeSbO_4$. The ^{121}Sb Mössbauer spectra recorded at low temperature show evidence for a super-transferred hyperfine magnetic field on the Sb^{5+} ion from iron via oxygen in the iron-rich mixed oxides.

In previous studies of rutile-related iron antimonate of composition $FeSbO_4$ we identified evidence for spin glass-type magnetic behaviour at low temperatures.[1,2] We report here on our subsequent studies of compounds of composition $Fe_{1-x}Cr_xSbO_4$ and $Fe_{1-x}Ga_xSbO_4$, where substitution of iron by chromium and diamagnetic gallium ions might induce weaker metal–metal magnetic interactions and thereby change the magnetic properties according to the degree of substitution.

EXPERIMENTAL

Materials of composition $Fe_{1-x}Cr_xSbO_4$ ($0 < x < 1$) and $Fe_{1-x}Ga_xSbO_4$ ($x = 0$–1) were prepared by co-precipitation techniques. Concentrated ammonia solution (Sp.Gr. 0.88) was added to stirred concentrated nitric acid (Sp.Gr. 1.42) solutions of the metal-nitrate hydrates or -chloride hydrates [$Fe(NO_3)_3 \cdot 9H_2O$, $Ga(NO_3)_3 \cdot xH_2O$, $CrCl_3 \cdot 6H_2O$] and antimony(V) chloride which had been prepared with molar ratios of total metal: antimony of 1 : 1. The resulting precipitates were removed by filtration, washed with water until the washings attained a pH between 6 and 7, dried at

110°C (18 h) in air, ground and calcined at 500°C (8 h) in air and subsequently at 1000°C (96 h) in air. The compound of composition $CrSbO_4$ was prepared by a similar method using concentrated hydrochloric acid (Sp.Gr. 1.18) solutions of chromium-chloride hydrate. The compound $GaSbO_4$ was also prepared by calcination of a ground mixture of gallium(III) oxide and antimony(V) oxide at 1200 °C in air.

X-ray powder diffraction data were recorded with a Philips PW 1050/70 diffractometer using Cu-K_α radiation. Energy dispersive X-ray microanalysis (e.d.x.) were performed with a Philips EM400T electron microscope interfaced with an EDAX energy dispersive X-ray analysis system. ^{57}Fe and ^{121}Sb Mössbauer spectra were recorded with a microprocessor-controlled Mössbauer spectrometer using $^{57}Co/Rh$ and $Ca^{121m}SnO_3$ sources. The drive velocities were calibrated with a $^{57}Co/Rh$ source and natural iron foil. All the spectra were computer fitted. The ^{57}Fe Mössbauer chemical isomer shifts were calculated relative to metallic iron and the ^{121}Sb Mössbauer chemical isomer shifts were calculated relative to indium antimonide. Magnetization measurements were performed with a Quantum Design SQUID magnetometer.

RESULTS AND DISCUSSION

Iron chromium antimonates

The X-ray powder diffraction patterns recorded from the materials of composition $Fe_{1-x}Cr_xSbO_4$ were all similar to those recorded from iron- and chromium-antimonate, which showed good agreement with data reported in the literature.[3] The variation of the lattice parameters with increasing chromium content, as determined by energy dispersive X-ray microanalysis, is contained in Table 1. The decrease in the *a* and *b* lattice parameters may be associated with the substitution of Fe^{3+} (0.645 Å in octahedral coordination)[4] by the smaller Cr^{3+} (0.615 Å in octahedral coordination),[4] which leads to a contraction of the unit cell.

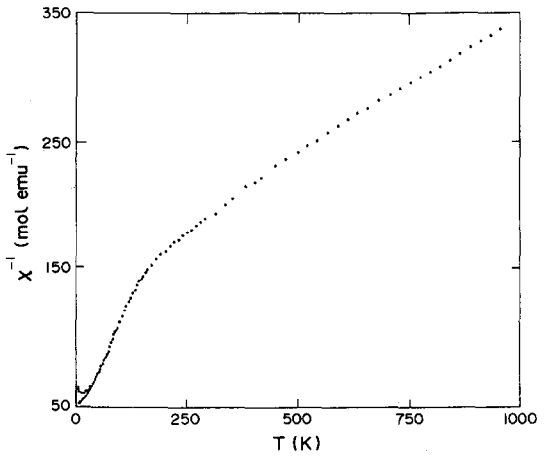

Fig. 1. The temperature dependence of the inverse zero field-cooled and field-cooled magnetic susceptibility recorded from iron antimonate in a magnetic field of 500 G.

The temperature dependence of the inverse zero field-cooled and the field-cooled magnetic susceptibility of iron antimonate recorded between 4 and 1000 K in a magnetic field of 500 G is shown in Fig. 1. The result shows that the susceptibility of the sample increases with decreasing temperature until the onset of irreversibility, which is attained at *ca* 70 K. At lower temperatures (*ca* 20 K) the zero field-cooled susceptibility begins to decrease, whereas the field-cooled susceptibility continues to increase. This low temperature behaviour is similar to that which characterizes a spin glass[5] and has been discussed in detail elsewhere.[1,2] However, in the high temperature region where the temperature exceeds *ca* 600 K a Curie–Weiss law is obeyed with the computer calculated effective magnetic moment of 6.0(1) B.M./ion, corresponding to high-spin paramagnetic Fe^{3+}, and the Curie temperature θ of +580 K being indicative of strong antiferromagnetic interactions.

The computer-calculated effective magnetic moments and Curie temperatures of compounds of composition $Fe_{1-x}Cr_xSbO_x$ were derived from magnetic susceptibility measurements and are collected in Table 2. The temperature dependence of the inverse magnetic susceptibility was influenced by the chromium content and was essentially of two types. The behaviour is illustrated by the data recorded from $Fe_{0.85}Cr_{0.15}SbO_4$ and $Fe_{0.26}Cr_{0.74}SbO_4$, which are shown in Figs 2 and 3. The magnetic susceptibility of the materials in the high temperature regions, i.e. > *ca* 200 K, obeyed the Curie–Weiss law. The temperature range over which the Curie–Weiss law is obeyed became

greater as the iron content of the materials was reduced. The data contained in Table 2 show that the Curie temperatures and effective magnetic moments of compounds of composition $Fe_{1-x}Cr_xSbO_4$ decrease with decreasing iron content, indicating a reduction in the number of magnetic interactions between the cations in the solid. The results are consistent with the replacement of Fe^{3+} ions with five unpaired electrons by Cr^{3+} ions with three unpaired electrons and with the iron–chromium and chromium–chromium interactions in the iron chromium antimonates being much weaker than those between the iron species in iron antimonate. A deviation from the Curie–Weiss law was found to occur at temperatures which depended on the chromium content of the materials. The deviation for compounds of composition $Fe_{0.85}Cr_{0.15}SbO_4$, $Fe_{0.63}Cr_{0.37}SbO_4$, $Fe_{0.40}Cr_{0.60}SbO_4$ and $Fe_{0.26}Cr_{0.74}SbO_4$ occurred at *ca* 190, 160, 140, and 110 K, respectively. The deviations are similar to that recorded[1] in iron antimonate, which was associated with the development of clusters with short range magnetic order between the moments on the Fe^{3+} species. The progressively lower temperatures at which the deviation from the Curie–Weiss law begins is a reflection of the effect of smaller Fe^{3+} concentrations on the formation of clusters. Given that iron–chromium and chromium–chromium magnetic interactions are weaker than iron–iron interactions a decrease in Fe^{3+} concentration correlates with a decrease in magnetic interactions. The results reported here show that the antiferromagnetic ordering of the Fe^{3+} ions in a cluster in a sample dilute in iron can only be achieved at lower temperatures.

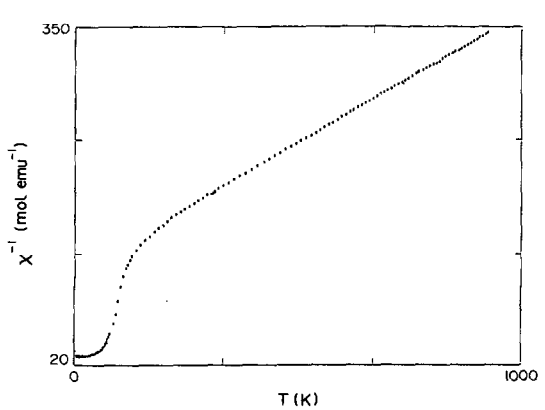

Fig. 2. The temperature dependence of the inverse zero field-cooled magnetic susceptibility recorded from the compound $Fe_{0.85}Cr_{0.15}SbO_4$.

An increase in magnetic susceptibility with further decreases in temperature was observed in $Fe_{0.85}Cr_{0.15}SbO_4$ and $Fe_{0.63}Cr_{0.37}SbO_4$ (as illustrated in Fig. 2), which indicated that a second Curie–Weiss law is obeyed at lower temperatures, which is analogous to that observed[1] in iron antimonate between 130 and 70 K. This new Curie–Weiss law may, as in the case of iron antimonate, be associated with the paramagnetic-like behaviour of small magnetically ordered clusters. At temperatures between 30 and 10 K a maximum was observed in the magnetic susceptibility data recorded from these two iron chromium antimonates (Fig. 2) which is similar to that associated with spin glass behaviour in iron antimonate. The absence of this low temperature behaviour in materials dilute in iron implies that the magnetic phenomena are inhibited by the reduction in the magnetic interactions or by the interference of substituted chromium with the cation order.

The ^{57}Fe Mössbauer spectra recorded at 298 K from materials of composition $Fe_{1-x}Cr_xSbO_4$ contained quadrupole split absorptions with ^{57}Fe Mössbauer parameters, δ *ca* 0.37 mm s^{-1}, Δ *ca* 0.71 mm s^{-1}, Γ *ca* 0.42 mm s^{-1}, characteristic of high-spin Fe^{3+}. Given that the magnetic susceptibility measurements indicate the existence of some short range magnetic order at this temperature the absence of magnetic splitting in the Mössbauer

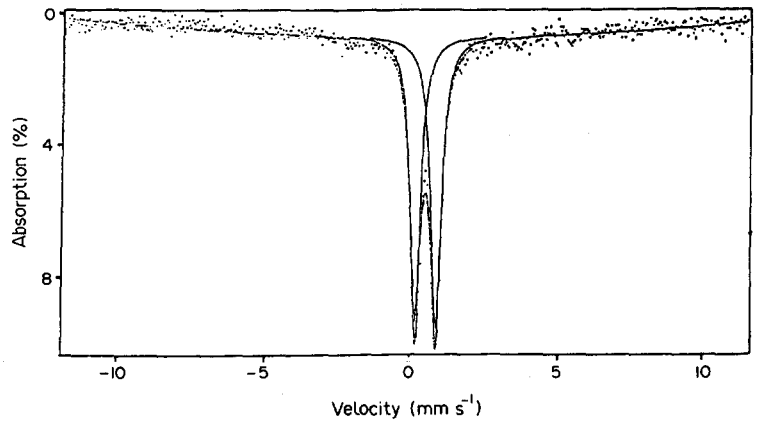

Fig. 4. ^{57}Fe Mössbauer spectrum recorded at 77 K from $Fe_{0.85}Cr_{0.15}SbO_4$.

spectrum indicates that the magnetic relaxation processes occurring in the clusters in the iron chromium antimonates have faster time scales than the Mössbauer time scale of 10^{-8} s. The ^{57}Fe Mössbauer spectra recorded at 77 K were similar (Fig. 4), δ *ca* 0.44 mm s^{-1}, Δ *ca* 0.71 mm s^{-1}, Γ *ca* 0.43 mm s^{-1}, and in contrast with the spectrum recorded[1] from iron antimonate at 77 K showed no evidence of magnetic splitting. The result is indicative of faster relaxation times between the magnetic interactions in iron chromium antimonates as a result of the smaller concentration of the Fe^{3+} species. The ^{121}Sb Mössbauer spectra recorded from the iron chromium antimonates at 298 and 77 K all gave single absorptions characteristic of Sb^{5+} (Fig. 5). The Mössbauer parameters are collected in Table 3. The samples with a high iron content, $x < 0.4$, showed a larger line width at 77 K than at 298 K. In the absence of a structural transformation the results are consistent with the presence of a super-transferred hyperfine magnetic field at antimony from iron via oxygen, as previously observed in iron antimonate at low temperature.[1] Presumably, the effect would be seen in the ^{57}Fe Mössbauer spectra recorded from iron-rich samples at very low temperature. It appears that the super-transferred hyperfine magnetic field is less significant as the iron content is decreased and, as shown by the magnetic susceptibility measurements, the magnetic interactions weaken.

Iron gallium antimonates

The X-ray powder diffraction data recorded from gallium antimonate prepared by both co-precipitation and solid state techniques were somewhat different from those reported in the literature.[6] The new data recorded here are contained in Table 4. The X-ray powder diffraction patterns recorded from materials of composition $Fe_{1-x}Ga_xSbO_4$ were all similar to each other and to those recorded from iron and gallium antimonate. The lattice parameters are collected in Table 5 and show a decrease as Fe^{3+} ions (ionic radii in six-fold coordination

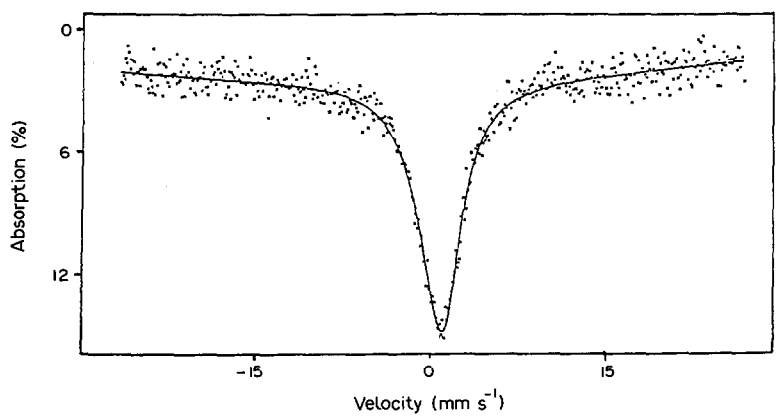

Fig. 5. ^{121}Sb Mössbauer spectrum recorded at 77 K from $Fe_{0.85}Cr_{0.15}SbO_4$.

x	θ (K)	μ (B.M./ion)
0.00	580	6.0
0.10	447.3	5.62
0.32	346.8	4.96
0.52	209.8	4.09
0.70	98.7	3.05

6. At temperatures exceeding *ca* 200 K the magnetic susceptibility data recorded from all the iron gallium antimonates followed the Curie–Weiss law. The trends of decreasing Curie temperatures and effective magnetic moments with decreasing Fe^{3+} content are more marked than those observed in the iron chromium antimonates because of the diamagnetic nature of Ga^{3+} which, by substitution for paramagnetic Fe^{3+} ions, dilutes the magnetic interactions between the Fe^{3+} species.

At temperatures below *ca* 200 K a deviation from the high temperature Curie–Weiss law was observed in the magnetic susceptibility data recorded from

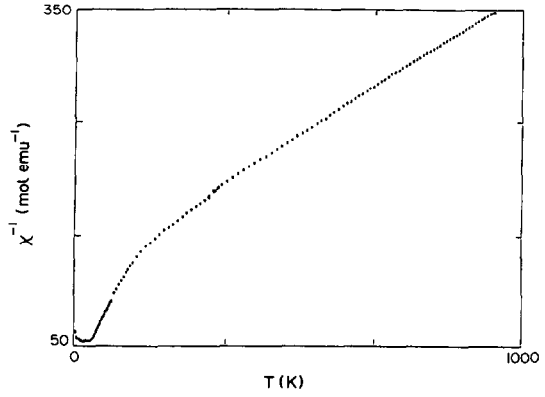

Fig. 6. The temperature dependence of the inverse zero field-cooled magnetic susceptibility recorded from the compound $Fe_{0.90}Ga_{0.10}SbO_4$.

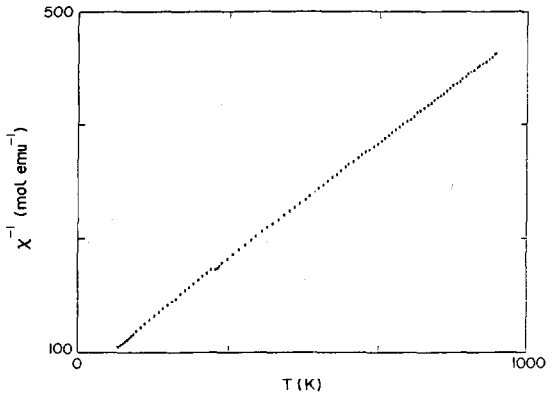

Fig. 7. The temperature dependence of the inverse zero field-cooled magnetic susceptibility recorded from the compound $Fe_{0.30}Ga_{0.70}SbO_4$.

the materials of composition $Fe_{1-x}Ga_xSbO_4$, ranging from 190 K when $x = 0.10$ to 100 K when $x = 0.70$. This deviation from the Curie–Weiss law may be associated with the formation of short-range magnetically ordered clusters, as observed in iron antimonate and the iron chromium antimonates, and the progressively lower temperatures at which these deviations begin may reflect the effect of larger Cr^{3+} concentrations on the formation of the clusters.

A second Curie–Weiss law was observed in the materials of composition $Fe_{0.90}Ga_{0.10}SbO_4$ and $Fe_{0.68}Ga_{0.32}SbO_4$ (see Fig. 6) at lower temperatures, which may be associated with the paramagnetic-like behaviour of the small magnetically ordered clusters as previously observed for iron antimonate and the iron chromium antimonates with high Fe^{3+} ion contents. At even lower temperatures between 10 and 30 K the magnetic susceptibility recorded from $Fe_{0.90}Ga_{0.10}SbO_4$ (Fig. 6) showed a maximum similar to that observed in the data obtained in high magnetic fields from iron antimonate, $Fe_{0.85}Cr_{0.15}SbO_4$ and $Fe_{0.63}Cr_{0.37}SbO_4$. The absence of a cusp in the magnetic susceptibility data recorded from iron gallium antimonates with lower iron concentrations may imply that the spin glass magnetic phenomena may be inhibited by the reduction in the magnitude and number of magnetic interactions or by interference of substituted gallium with the cationic anti-site ordered.

The ^{57}Fe and ^{121}Sb Mössbauer spectra recorded from the iron gallium antimonates at 298 K were similar to those recorded from the iron chromium antimonates (*vide supra*). The ^{57}Fe Mössbauer spectra recorded at 77 K from $Fe_{1-x}Ga_xSbO_4$ were also similar to those recorded from $Fe_{1-x}Cr_xSbO_4$ and failed to show any evidence for the magnetic interaction previously observed at 77 K in the spectrum recorded from iron antimonate.[1] The ^{121}Sb Mössbauer spectrum recorded at 77 K from $Fe_{0.90}Ga_{0.10}SbO_4$ showed a broader line as compared with that recorded at 298 K and may be associated with the onset of a super-transferred hyperfine magnetic interaction from iron to antimony via oxygen.

EXTRACTION BEHAVIOUR OF SILVER(I) WITH SOME CYCLIC TETRATHIOETHERS

KEIITSU SAITO,* SATOMI MURAKAMI and AKIHIKO MUROMATSU

Division of Natural Environment and Chemistry, Faculty of Human Development, Kobe University, Tsurukabuto, Nada, Kobe 657, Japan

and

EIICHI SEKIDO

Department of Chemistry, Faculty of Science, Kobe University, Rokkodai, Nada, Kobe 657, Japan

(*Received* 22 *February* 1993; *accepted* 23 *March* 1993)

Abstract—The extraction behaviour of silver(I) with 12-, 13-, 15- and 16-membered cyclic tetrathioethers (*n*-ane-S_4, where *n* represents the total number of carbon and sulphur atoms in the cyclic ligand ring) was examined stoichiometrically using the picrate ion (Pic^-) for the formation of the ion pair and chloroform and 1,2-dichloroethane as solvents. The composition of the extracted species and the extraction constant were determined. Silver(I) was extracted with these four ligands (L) into chloroform and 1,2-dichloroethane as the ion-pair compound $[AgL]^+Pic^-$. The extracted species with these four ligands is different from that previously reported for 14-ane-S_4, $[AgL_2]^+Pic^-$.

The complexing properties of macrocyclic polythioethers have been studied and metal complexes with macrocyclic polythioethers have been isolated and characterized.[1–8] Macrocyclic polythioethers have also been studied as an extraction reagent which is selective for soft metal ions.[9–15] Silver(I) belonging to soft Lewis acids[16] is extracted completely with macrocyclic polythioethers and an appropriate counter-anion under a large excess of the ligand and counter-anion. The extraction system has been applied to the spectrophotometric determination of silver using an appropriately coloured anion, such as picrate or Bromocresol Green.[10] Recently, the molecular structure of the dimeric silver(I)-13,14-benzo-1,4,8,11 - tetrathiocyclopentadec - 13 - ene picrate complex has been reported.[17] The structure of the dimeric silver(I) complex of 1,4,8,11-tetrathiacyclotetradecane has also been reported,[18] while studies concerning the extraction equilibria have shown that the extracted species is $[AgL_2]^+Pic^-$.[11] Therefore, it is of interest to determine whether the dimeric complex with a macrocyclic polythioether other than 1,4,8,11-tetrathiacyclotetradecane is formed or not in the organic solution in the presence of a large excess of the ligand. Moreover, it is of interest to study the composition of the extracted species of silver(I) with a continuous series of homologous macrocyclic polythioethers which have the same number of sulphur atoms. Thus, the extraction behaviour of silver(I) with 12-, 13-, 15- and 16-membered cyclic tetrathioethers (*n*-ane-S_4, where *n* represents the total number of carbon and sulphur atoms in the cyclic ligand ring) was examined using the picrate ion as the counter-anion. Chloroform and 1,2-dichloroethane were used as solvents. The results were compared with those previously reported for 14-ane-S_4.[11] The cyclic tetrathioethers considered in this work are shown in Fig. 1.

EXPERIMENTAL

Reagents

All cyclic tetrathioethers were synthesized according to the method of Ochrymowycz *et al.*[19]

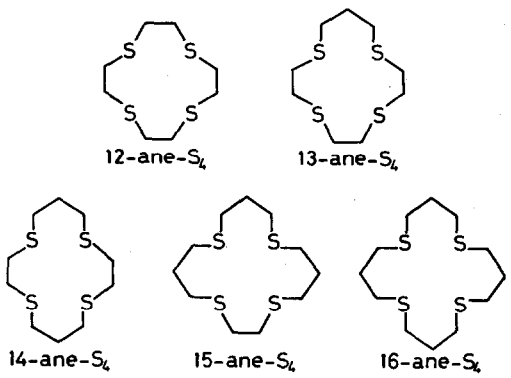

Fig. 1. Cyclic tetrathioethers investigated.

The products were purified by the method described previously.[15] Chloroform was shaken three times each with sulphuric acid (1 M), sodium hydroxide solution (2 M) and distilled water, dried over anhydrous sodium sulphate and distilled. 1,2-Dichloroethane was purified as described before.[15] Silver sulphate (analytical-reagent grade) was used to prepare a 2×10^{-2} M silver(I) stock solution. Other reagents were of analytical grade.

Apparatus

Extraction was performed in a Taiyo M-100 incubator at 25 ± 0.1°C. Seiko SAS-725 and Hitachi Z-8000 atomic absorption spectrometers were used to determine the concentration of the silver ion. The UV–vis absorption spectra were measured with a Hitachi U-3200 spectrophotometer. The pH of the aqueous phase was measured with a Toa HM-7E pH meter.

Liquid–liquid extraction of silver(I)

An aqueous solution (10 cm^3) containing silver(I), picrate ions and a buffer solution was taken in a 50 cm^3 glass cylindrical tube fitted with a glass stopper. The buffer solution was prepared with sulphuric acid (pH < 3) or acetic acid and sodium acetate (pH 3–6). The ionic strength was kept at 0.1 with sodium sulphate. After the addition of a cyclic tetrathioether solution (10 cm^3) of chloroform or 1,2-dichloroethane the mixture was shaken for 30 min at 200 inversions min^{-1} at 25 ± 0.1°C and then centrifuged for 5 min at 2000 rounds min^{-1}. After the two phases had separated the pH of the aqueous phase was measured and the concentration of the picrate ion in the aqueous phase was determined spectrophotometrically at 354 nm. The concentrations of silver ions in the aqueous and organic phases were determined by atomic absorption spectrometry. The silver ion concentration of the organic phase was determined as follows: a suitable volume of the organic phase was allowed to evaporate, the residue was treated with concentrated nitric acid (1 cm^3) and diluted with water (to 10 cm^3) and the concentration of silver ions was determined by atomic absorption spectrometry.

RESULTS AND DISCUSSION

Dependence on pH

The extraction of silver(I) with 12-ane-S_4 from an aqueous solution containing picrate ions (1×10^{-3} M) into 1,2-dichloroethane was examined in the pH range 2.5–5.5. A plot of the logarithmic distribution of silver(I), $\log D$, against the pH of the aqueous phase is shown in Fig. 2. The extractability of silver(I) is constant at > 99% ($\log D > 2$) in the pH range 2.5–5.5 under the present conditions.

Extraction of silver(I) *with cyclic tetrathioethers*

As crystallographic studies of silver(I) complexes with 14-ane-S_4[18] and 13,14-benzo-1,4,8,11-tetrathiacyclopentadec-13-ene[17] have shown that the 2:2 dimeric complex cation, $[Ag_2L_2]^{2+}$, is formed in the solid state, the formation of polynuclear complexes should be taken into account. If the species extracted into an organic phase is represented by $Ag_jL_m(Pic)_n$ the extraction equilibrium and the extraction constant, K_{ex}, are given by eqs (1) and (2), respectively:

$$jAg^+ + mL(o) + nPic^- \overset{K_{ex}}{\rightleftharpoons} Ag_jL_m(Pic)_n(o) \quad (1)$$

$$K_{ex} = [Ag_jL_m(Pic)_n]/[Ag^+]^j[L]_o^m[Pic^-]^n, \quad (2)$$

where (o) and subscript o indicate the species in the organic phase. When the complexation of silver(I) in the aqueous phase is neglected and the species present in the organic phase is only the ion-pair

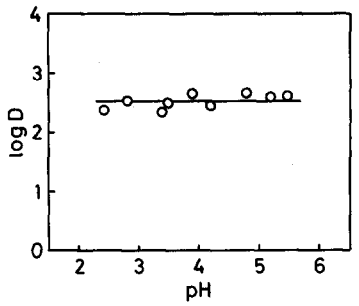

Fig. 2. Plot of $\log D$ vs pH. Initial concentrations: silver(I), 5×10^{-5} M; 12-ane-S_4, 5×10^{-3}M; picrate ion, 1×10^{-3} M.

$Ag_jL_m(Pic)_n$ the total concentration of silver(I) in the organic phase is presented by:

$$\log C_{Ag,o} = j\log[Ag^+] + m\log[L]_o + n\log[Pic^-] + \log j + \log K_{ex}. \quad (3)$$

Determination of the degree of polymerization of the extracted species

According to eq. (3) the plot of $\log C_{Ag,o}$ against $\log[Ag^+]$ at constant concentrations of the ligand and picrate ion should yield a straight line with a slope of j, the degree of polymerization. In order to determine the degree of polymerization of the extracted species the extraction of silver(I) at pH 4.8 was examined at various concentrations of silver(I) under constant concentrations of the ligand and picrate ion. Chloroform was used as the solvent because of the high extractibility of silver(I) into 1,2-dichloroethane in the presence of a large excess of the ligand and picrate ion. The results are shown in Fig. 3. Four straight lines with the slope of 1.0 were obtained, indicating that $j = 1$. This suggests that the monomer can be presented as the extracted species under these conditions.

Determination of the number of picrate ions involved in the extracted species

When the monomeric silver(I) species is extracted eqs (1) and (2) become:

$$Ag^+ + mL(o) + nPic^- \overset{K_{ex}}{\rightleftharpoons} AgL_m(Pic)_n(o) \quad (1')$$

$$K_{ex} = [AgL_m(Pic)_n]_o/[Ag^+][L]_o^m[Pic^-]^n. \quad (2')$$

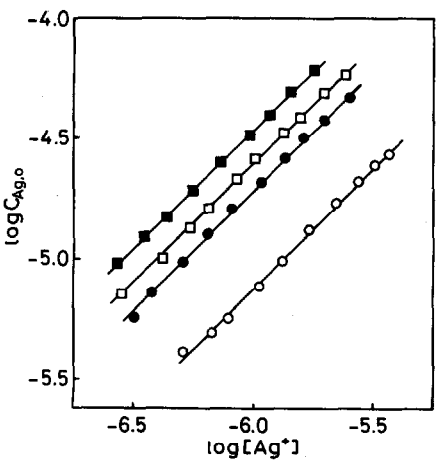

Fig. 3. Plots of $\log C_{Ag,o}$ vs $\log[Ag^+]$ at pH 4.8. Initial concentrations: n-ane-S_4, 1×10^{-3} M; picrate ion, 1×10^{-3} M. Ligands: (○) 12-ane-S_4; (●) 13-ane-S_4; (□) 15-ane-S_4; (■) 16-ane-S_4. Solid lines are straight with a slope of 1.0.

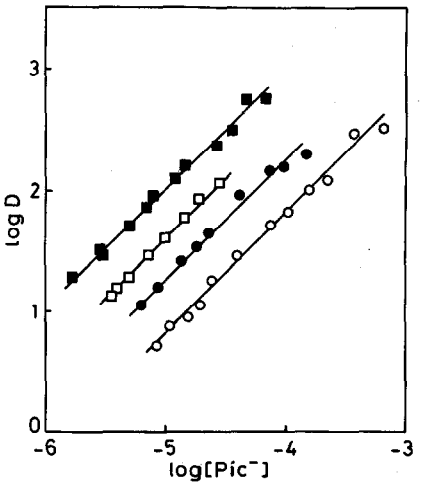

Fig. 4. Plots of $\log D$ vs $\log[Pic^-]$ at pH 4.9. Initial concentrations: silver(I), 5×10^{-5} M; n-ane-S_4, 5×10^{-3} M. Ligands: (○) 12-ane-S_4; (●) 13-ane-S_4; (□) 15-ane-S_4; (■) 16-ane-S_4. Solid lines are straight with a slope of 1.0.

The logarithmic distribution of silver(I) is presented by:

$$\log D = \log K_{ex} + m\log[L]_o + n\log[Pic^-]. \quad (4)$$

The extraction of silver(I) into 1,2-dichloroethane at pH 4.9 was examined at various concentrations of the picrate ion under constant concentration of the ligand. The results are shown in Fig. 4. Four straight lines with a slope of 1.0 were obtained, i.e. $n = 1$. This indicates that the molar ratio of the

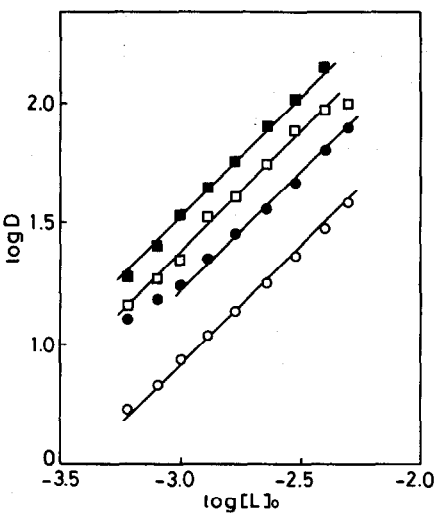

Fig. 5. Plots of $\log D$ vs $\log[L]_o$ at pH 4.8. Solvent: chloroform. Initial concentrations: silver(I), 5×10^{-5} M; picrate ion, 1×10^{-3} M. Ligands: (○) 12-ane-S_4; (●) 13-ane-S_4; (□) 15-ane-S_4; (■) 16-ane-S_4. Solid lines are straight with a slope of 1.0.

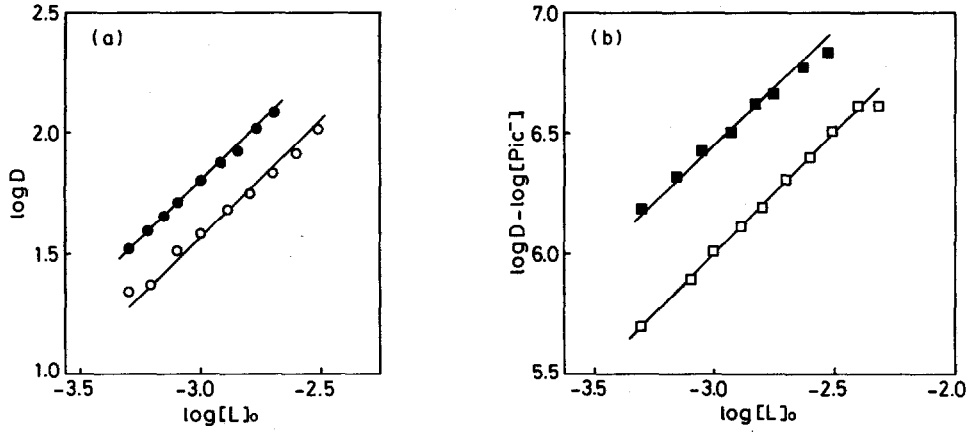

Fig. 6. Plots of (a) $\log D$ vs $\log[L]_o$ for (○) 12-ane-S_4 and (●) 13-ane-S_4 and (b) $\log D - \log[Pic^-]$ vs $\log[L]_o$ for (□) 15-ane-S_4 and (■) 16-ane-S_4; pH 4.8. Solvent: 1,2-dichloroethane. Initial concentrations: silver(I), 5×10^{-5} M for (a) and (b); picrate ion, 5×10^{-4} M for (a). Solid lines are straight with a slope of 1.0.

silver(I) and picrate ions is 1 : 1, as expected from the charges of the silver(I) and picrate ions.

Determination of the number of ligand molecules involved in the extracted species

The extraction of silver(I) into chloroform at pH 4.8 was examined at various concentrations of the ligand under constant concentration of the picrate ion. The relationships between $\log D$ and the logarithm of the ligand concentration in the organic phase are shown in Fig. 5. Four straight lines with the slope close to 1.0 were obtained, i.e. $m = 1$. This indicates that silver(I) is extracted with four cyclic tetrathioethers into chloroform as the complex $[AgL]^+$. The extraction of silver(I) into 1,2-dichloroethane was also examined at pH 4.8. The results obtained for 12-ane-S_4 and 13-ane-S_4 are shown in Fig. 6(a). Two straight lines with the slope close to 1.0 were obtained. The value of m for 15-ane-S_4 and 16-ane-S_4 could not be determined by the same method because of the high extractability of silver(I) into 1,2-dichloroethane in the presence of a large excess of the ligand and picrate ions to silver(I). Therefore, the extraction of silver(I) was performed at the total concentration of picrate ion, $[Pic^-]_t = 6.5 \times 10^{-5}$ and 6.0×10^{-5} M for 15-ane-S_4 and 16-ane-S_4, respectively, and $\log D - \log[Pic^-]$ was plotted against $\log[L]_o$. The results are shown in Fig. 6(b). Two straight lines with the slope close to 1.0 were obtained, i.e. $m = 1$. The molar ratio method for these two ligands has also shown that the extracted species is $[AgL]^+$. These results indicate that silver(I) is extracted with four ligands into 1,2-dichloroethane as the 1 : 1 complex $[AgL]^+$, as with chloroform.

Consequently, in the present extraction system the extraction equilibrium is expressed as follows:

$$Ag^+ + L(o) + Pic^- \rightleftharpoons AgL(Pic)(o).$$

Table 1. Compositions and extraction constants for silver(I)-cyclic tetrathioether complexes extracted into organic solvents

Ligand	$Ag^I : L : Pic^-$	Log K_{ex}[a] Chloroform	1,2-DCE[b]
12-ane-S_4	1 : 1 : 1	6.89 ± 0.03(4)	7.99 ± 0.12(2)
13-ane-S_4	1 : 1 : 1	7.23 ± 0.04(4)	8.33 ± 0.23(2)
14-ane-S_4[11]	1 : 2 : 1	10.9 ± 0.1	11.7 ± 0.2
15-ane-S_4	1 : 1 : 1	7.41 ± 0.04(3)	8.96 ± 0.05(2)
16-ane-S_4	1 : 1 : 1	7.56 ± 0.08(4)	9.37 ± 0.06(2)

[a] Mean value. The figures in parentheses are the number of measurements.

[b] 1,2-Dichloroethane.

Equation (4) becomes:

$$\log D = \log K_{ex} + \log [L]_o + \log [Pic^-]. \quad (4')$$

The logarithmic extraction constant was calculated according to eq. (4'). The results are shown in Table 1. As the studies concerning the extraction equilibria for the extraction of silver(I) picrate with 14-ane-S_4 have shown that the extracted species is $[AgL_2]^+Pic^-$,[11] the 1:2 molar ratio of silver(I)-to-ligand was expected for two smaller ligands, 12-ane-S_4 and 13-ane-S_4. However, the extracted species with 12-ane-S_4 and 13-ane-S_4 is $[AgL]^+Pic^-$.

(*Received* 4 *January* 1993; *accepted* 23 *March* 1993)

Abstract—The crystal structure of *cis*-[Co(atac)Cl_2]$ClO_4 \cdot \frac{1}{2}H_2O$ [atac = 6-methyl-6-(4-amino-2-azabutyl)-1-thia-4-azacycloheptane] has been determined by X-ray diffraction methods. The tetradentate ligand atac contains the N_3S donor set and is coordinated to cobalt(III) through a secondary amine and a thioether in the cycloheptane ring, and through a pendant primary amine. The chloro ligands coordinated in a *cis* arrangement make up the octahedral environment of the metal ion.

Extensive use has been made of the reaction between 1,2-diaminoethane and suitably substituted neopentyl or pentaerythritol derivatives in order to prepare multidentate ligands containing the —$NHCH_2CH_2NH_2$ fragment.[1–8] The reaction permits large scale preparation of the desired ligands;[1] the propensity for the formation of a range of by-products, however, necessitates extensive purification procedures.[1,3] In a number of instances these by-products themselves represent interesting ligands and studies of their metal complexes have been pursued.[2,5] We have previously reported the characterization of the cobalt(III) complexes of two such by-products isolated from reactions in which sulphur-containing neopentyl moieties were reacted with 1,2-diaminoethane.[5] One of these complexes contained the seven-membered ring ligand 6-methyl-6-(4-amino-2-azabutyl)-1-thia-4-azacycloheptane (atac).[5] This paper now reports the isolation and characterization of the complex *cis*-[Co(atac)Cl_2]$ClO_4 \cdot \frac{1}{2}H_2O$.

RESULTS AND DISCUSSION

Reaction between 1,1,1-tris[{(benzenesulphonyl)oxy}methyl]ethane and the sodium salt of 2-aminoethanethiol, and subsequent reaction of the product with 1,2-diaminoethane, has been shown to result in a mixture of products. Depending on the reaction conditions and stoichiometry, the reaction has resulted in the isolation of the hexadentate ligands 5-methyl-5-(4-amino-2-azabutyl)-3,7-dithianonane-1,9-diamine[9] and 5-methyl-(4-amino-2-thiabutyl)-3,7-diazanonane-1,9-diamine.[10] The ligand 6-methyl-6-(4-amino-2-azabutyl)-1-thia-4-azacycloheptane (atac) has been shown to also be a major product from this type of reaction.[5] The formation of this product, which presumably arises from an intramolecular cyclization reaction,[2] is not unexpected and this type of product has been observed in similar systems. Indeed, for the reactions of 1,2-diaminoethane with pentaerythrityltetrabromide or 1,1,1-tris[{(toluenesulphonyl)oxy}methyl]ethane the products arising from the intramolecular pathway, 6,6-bis(4-amino-2-azabutyl)-1,4-diazacycloheptane[3] and 6-methyl-6-(4-amino-2-azabutyl)-1,4-diazacycloheptane,[2]

* Author to whom correspondence should be addressed.

respectively, were reported to constitute 30–50% of the products obtained.

The complex *cis*-$[Co(atac)Cl_2]^+$ was isolated as a major purple band from Dowex 50WX2 cation exchange chromatography and was isolated as the perchlorate salt from aqueous solution. The structure consists of two independent complex cations, two perchlorate anions, one of which is disordered, and a water molecule. The complex cations are not significantly different; each has a tetradentate ligand coordinated through three (N)amine and one (S)thioether donor groups to a cobalt(III) ion and two chloro ligands coordinated in a *cis* arrangement. The geometry about the cobalt is approximately octahedral although ligand constraints reduce some of the angles to *ca* 80°. The C(2)—C(4)—N(1) angle in the dichloro complex is 115.6(3)°, compared with 120.9(8)° in [Co(atac)en]$^{3+}$,[5] and is in fact comparable to the angle observed in the all-nitrogen complex $[Co(L)en]^{3+}$, where L = 6-methyl-6-(4-amino-2-azabutyl)-1,4-diazacycloheptane.[2] It appears then that the increased strain in this angle is not only a result of incorporation of the thioether into the cycloheptane ring, but may in addition be the result of strain induced by the coordination of the remainder of the ligand, e.g. some Co—N—C angles are opened to 122°. The Cl(1)—Co—Cl(2) bond angle 89.0(1)° is larger than the corresponding angle in [Co(atac)en]$^{3+}$ [83.8(3)°][5] and $[Co(L)en]^{3+}$ [84.3(1)°][2] and suggests the source of increased strain within the complex. The N(1)—C(7)—C(6)—S(1) torsion angle (~ 0.0°) indicates that this part of the chelate ring is essentially flat, with the hydrogen atoms eclipsed. The Co—N and Co—S bond lengths are longer than average, but not greatly so.[11,12] The Co—N(1) bond length in the dichloro complex is shorter than that observed in [Co(atac)en]$^{3+}$, 1.984(3) Å compared with 2.056(6) Å, respectively.[5] In contrast to the coordination observed in the [Co(atac)en]$^{3+}$ cation, where the primary amine of the ligand was *trans* to the thioether in the cycloheptane ring, in the present complex the primary amine of atac is *trans* to the secondary nitrogen in the cycloheptane ring. The Co—Cl bond lengths are slightly shorter (av. 2.268 Å) than those in $[Co(NH_3)_5Cl]Cl_2$ [2.286(2) Å][13] and those *trans* to sulphur are not significantly different to those *trans* to nitrogen.

EXPERIMENTAL

Fourier-transform $^{13}C[^1H]$ NMR spectra were recorded with a Bruker AC200F spectrometer. Chemical shifts for the spectra recorded in D_2O are reported in parts per million (δ) as positive downfield and negative upfield from the internal reference dioxane. Visible spectra were recorded with a Beckman DU7500 UV–vis spectrophotometer. Microanalyses were determined by the University of Queensland Microanalytical Service.

Ligand synthesis

1,1,1-Tris[{(benzenesulphonyl)oxy}methyl]ethane[14] (150 g, 0.28 mol) was reacted with the sodium salt of 2-aminoethanethiol (9.17 g, 0.092 mol) under reflux in ethanol (250 cm^3) and the yellow oil isolated upon removal of the solvent was refluxed with 1,2-diaminoethane, essentially as described previously.[1–5,9] The heavy oil obtained after removal of the solvent was employed without further purification in the preparation of the metal complex.

Synthesis of cis-$[Co(atac)Cl_2]ClO_4 \cdot \frac{1}{2}H_2O$

The oil obtained from the ligand synthesis was dissolved in methanol (250 cm^3) and whilst a slow stream of air was drawn through the solution a methanol solution (100 cm^3) of cobaltous chloride (22 g, 0.09 mol) was added dropwise over a period of 0.5 h. Air was continued to be drawn through the solution for 2 h after the completion of the addition, after which time the solution was filtered, diluted to a large volume with water and loaded on a column of Dowex 50WX2 cation exchange resin (H^+ form, 200–400 mesh). After washing with water and HCl (1 M) to remove minor bands, the intense purple band which eluted with HCl (2 M) was collected. Solvent was removed under reduced pressure and the purple residue obtained was dissolved in a large volume of water and loaded on a column of Sephadex C25 cation exchange resin (Na^+) form. After washing the column with water and NaCl (0.1 M) the purple band which eluted with NaCl (0.2 M) was collected on Dowex cation exchange resin, washed with water and HCl (0.5 M) and eluted with HCl (2 M). Removal of the solvent under reduced pressure and crystallization of the residue from an aqueous solution of $NaClO_4$ resulted in purple crystals. Found: C, 23.9; H, 4.8; N, 8.9. Calc. for $C_9H_{22}CoN_3SCl_3O_{4.5}$: C, 24.5; H, 5.0; N, 9.5%. ^{13}C NMR (D_2O): δ −5.37, −6.95, −9.36, −11.14, −24.00, −35.73, −27.75 (—CH_2); −26.21 (C_q); −44.04 (CH_3). Visible spectrum (0.1 HCl) [λ_{max} nm, ε (M^{-1} cm^{-1})]: 561 (218), 395 (175).

space group $C2/c$, $a = 30.291(3)$, $b = 9.282(1)$, $c = 24.883(3)$ Å, $\beta = 100.82(1)°$; $V = 6871.9$ Å^3 $Z = 16$, $D_c = 1.707$ g cm^{-3}, μ(Mo-K_α) 15.73 cm^{-1}. λ(Mo-K_α) 0.7107 Å, F(000) 3632 electrons.

Data collection and processing. For diffractometry a crystal of dimensions $0.25 \times 0.11 \times 0.10$ mm was mounted on a glass fibre with cyanoacrylate resin. Lattice parameters at 21°C were determined by least-squares fit to the setting parameters of 25 independent reflections, measured and refined on an Enraf–Nonius CAD4F four-circle diffractometer employing graphite monochromated Mo-K_α radiation.

Structure analysis and refinement. Intensity data were collected in the range $1 < \theta < 25°$ using an ω–1.33θ scan. The scan width and horizontal counter aperture employed were $(0.80 + 0.34 \tan\theta)°$ and $(2.70 + 1.05 \tan\theta)$ mm, respectively. Data reduction and application of Lorentz, polarization and absorption (max. trans. 0.865, min. trans. 0.714) corrections were performed using the Enraf–Nonius structure determination package.[15] Of the 5410 independent non-zero reflections collected 4407 with $I > 2.5\sigma(I)$ were considered observed and used in the calculations. The structure was solved by direct methods using SHELXS-86[16] and the solution was extended by difference-Fourier methods. Hydrogen atoms were included at calculated sites with group isotropic thermal parameters and all other atoms, with the exception of minor contributors to disordered species (one perchlorate anion), were refined anisotropically. Blocked-matrix least-squares refinement of an overall scale factor was performed and positional and thermal parameters converged (all shifts $< 0.10\sigma$) with $R = 0.039$, $R_w = 0.045$ and $w = 1.93/(\sigma^2(F_o) + 0.00026F_o^2)$ ($R = (||F_o| - |F_c||)/F_o$, $R_w = (w(|F_o| - |F_c|)^2/wF_o^2)^{1/2}$). Maximum excursions in a final difference map were +0.7 and −0.7 e Å^{-3}. Scattering factors and anomalous dispersion terms used for cobalt were taken from the International tables[17] and all others used were those supplied by SHELX-76.[18] All calculations were performed using SHELX-76[18] and plots were drawn using ORTEP.[19] The atom numbering scheme is given in Fig. 1. Bond lengths and angles are listed in Table 1. Positional parameters, listing of observed and calculated structure factors, hydrogen atom coordinates and thermal parameters (Tables S1–S4) are available from the Cambridge Crystallographic Data Centre.

ARENE RUTHENIUM COMPLEXES WITH PICOLINIC ACID, 1-AMINOETHYLPHOSPHONOUS ACID AND α-HYDROXYKETONES. X-RAY STRUCTURE OF [(η-1,3,5-$C_6Me_3H_3$)RuCl($NC_5H_4CO_2$)]

LEE CARTER, DAVID L. DAVIES,* JOHN FAWCETT and DAVID R. RUSSELL

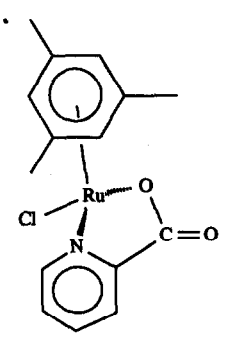
(*Received* 18 *December* 1992; *accepted* 23 *March* 1993)

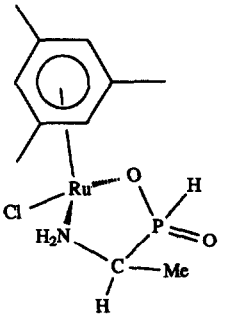
Abstract—The ligands LH (LH = picolinic acid, 1-aminoethylphosphonous acid, ethyl maltol and N-methyl-3-hydroxy-2-ethyl-4-pyridinone) react with [(η-1,3,5-$C_6Me_3H_3$)$RuCl_2]_2$ and sodium methoxide to give the complexes [(η-1,3,5-$C_6Me_3H_3$)RuClL] (**1–3**), which are all soluble in water. The structure of [(η-1,3,5-$C_6Me_3H_3$)RuCl($NC_5H_4CO_2$)] (**1**) has been determined by X-ray diffraction.

It has been shown previously that [(arene)$RuCl_2]_2$ will react with biologically important ligands such as amino acids,[1–4] peptides[5] and also with substituted nucleobases such as 9-ethylguanine.[4] In addition their reactions with hydroxy pyridines have been studied.[6] We now report our results on the reactions of [(η-1,3,5-$C_6Me_3H_3$)$RuCl_2]_2$ with picolinic acid, 1-aminoethylphosphonous acid, the α-hydroxyketone ethyl maltol and a 3-hydroxy-4-pyridinone. Picolinic acid and aminoethylphosphonous acids are naturally occurring ligands related to α-amino acids, while hydroxypyrones and -pyridinones have found applications in medicinal chemistry.[7]

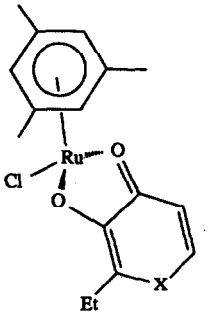
Refluxing the ligands LH and 1 equivalent of sodium methoxide with [(η-1,3,5-$C_6Me_3H_3$)$RuCl_2]_2$ gives moderate to good yields of the complexes [(η-1,3,5-$C_6Me_3H_3$)RuClL] (**1–3**), in which the ligands are bonded in a bidentate fashion. The sodium chloride by-product can be separated by dissolving the complexes in dichloromethane; however, in the case of **2** this does not work and the samples are always contaminated with some sodium chloride. Complexes **1** and **2** contain N, O chelates, while **3a** and **3b** have O, O donor atoms. The complexes are all soluble in water and also in dichloromethane. Water-soluble organometallic complexes are of interest because of the potential industrial benefits from aqueous soluble catalysts in terms of reduced costs of recovery and recycling of precious metal-based catalysts.[8]



1



2



3a X=O
3b X=NMe

The complexes have all been characterized by microanalysis, ^1H NMR and mass spectroscopy, and $^{31}P\{^1H\}$ NMR spectroscopy for **2**. All the ^1H NMR spectra show signals due to coordinated mes-

* Author to whom correspondence should be addressed.

itylene and the relevant ligand. For complex **1** the ^1H NMR spectrum in D_2O shows the presence of two species. This is due to the substitution of the chloride ligand by D_2O, which has been observed previously for the amino acid complexes.[1] Addition of excess LiCl displaces the equilibrium in favour of chloride coordination. Complex **2** has three chiral centres, ruthenium, phosphorus and carbon, and exists as a mixture of diastereomers; as a result the ^1H NMR spectrum is very complicated. This is more clearly seen in the $^{31}P\{^1H\}$ NMR spectrum, where three signals are observed in CD_3OD. There are four possible diastereomeric pairs, of which only three are observed. In D_2O there are six signals which reduce to three in the presence of excess LiCl. Complexes **3a** and **3b** only show one species in the ^1H NMR spectrum in D_2O, which is believed to be that with D_2O coordinated in place of chloride. In this case the addition of LiCl does not cause an immediate coordination of chloride. The reason for this difference is not clear, but it could be that for **3a** and **3b** there is more hydrogen bonding with the coordinated water. Also, particularly for **3b**, it is possible to draw resonance structures in which the overall positive charge of $[(\eta\text{-}1,3,5\text{-}C_6Me_3H_3)RuL(D_2O)]^+$ can be delocalized onto the ligand. The extent of hydrogen bonding in these complexes can be important; it has previously been suggested that it plays a key role in determining the diastereomeric ratio in amino acid complexes.[4]

We have determined the structure of complex **1** as shown in Fig. 1 and selected bond lengths and angles are listed in Table 1. The Ru—N bond length of 2.102(4) Å is intermediate between that found for a related N,O-bound hydroxypyridine [2.084(7) Å][6] and that of a monodentate pyridine [2.127(7) Å].[9] However, the Ru—O bond length of 2.101(4) Å and the bite angle N—Ru—O of 77.9(2)° are comparable with those [2.085(8) and 2.093(9) Å and 76.4(4)° and 78.1(4)°] found for the five-membered chelate rings in the diastereomers of $[(\eta\text{-}1,3,5\text{-}C_6Me_3H_3)RuCl\{H_2NCH(Me)CO_2\}]$.[10] The complex crystallizes as the trihydrate. The hydrogen atoms of the water molecules were not located, but the O—O separations (2.78–2.85 Å) suggest hydrogen bonding between the water molecules. In addition, there are close contacts between a water molecule and the chlorine and also between the two carboxylate oxygens and the remaining two water molecules.

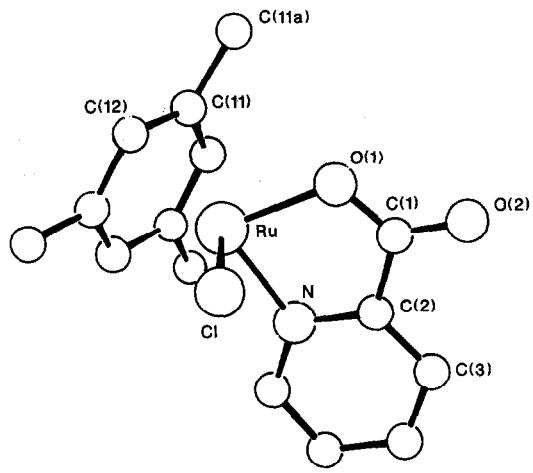


Fig. 1. Molecular structure of $[(\eta\text{-}1,3,5\text{-}Me_3C_6H_3)RuCl(NC_5H_4CO_2)]\cdot 3H_2O$ (**1**).

We are currently exploring the coordination of other biologically important molecules with organometallic complexes and also the use of some of these species as water-soluble catalysts.

EXPERIMENTAL

Petroleum ether and diethyl ether were dried by refluxing over purple sodium/benzophenone under

nitrogen, while dichloromethane was purified by refluxing over calcium hydride. The complex $[(1,3,5\text{-}Me_3C_6H_3)RuCl_2]_2$[11] and ligands 1-aminoethylphosphonous acid[12] were prepared using literature procedures, while N-methyl-3-hydroxy-2-ethyl-4-pyridinone was made by the same method as that used for the corresponding 2-methyl derivative.[13] The reactions described were performed in deoxygenated solvents under nitrogen; however, once isolated as pure solids the compounds are relatively air-stable and precautions for their storage are unnecessary.

^1H NMR spectra were recorded on Bruker AM300 or Varian EM390 spectrometers. Microanalyses were performed by Butterworth Laboratories Ltd, Middlesex. FAB mass spectra were performed at the SERC Mass Spectroscopy service centre at University College Swansea.

Preparation of $[(1,3,5\text{-}Me_3C_6H_3)RuCl(NC_5H_4CO_2)]$ (**1**)

Sodium methoxide (44 mg, 0.86 mmol) and picolinic acid (106 mg, 0.86 mmol) were added to a suspension of $[(1,3,5\text{-}Me_3C_6H_3)RuCl_2]_2$ (251 mg, 0.43 mmol) in methanol/water (1 : 1) (70 cm^3) and the mixture was refluxed for 3 h. The solvent was removed and the residue was dissolved in dichloromethane (100 cm^3) and filtered. Evaporation of the solvent gave $[(1,3,5\text{-}Me_3C_6H_3)RuCl(NC_5H_4CO_2)]$ (**1**) (267 mg, 82%) as a yellow solid. Found: C, 44.9; H, 4.5; N, 3.4. Calc. for $C_{15}H_{16}ClNO_2Ru \cdot H_2O$: C, 45.3; H, 4.6; N, 3.7%. ^1H NMR (D_2O+LiCl): δ 2.18 (s, 9H, Me), 5.37 (s, 3H, C_6H_3) [7.84 (t, 1H, $J = 6$), 7.92 (d, 1H, $J = 7$), 8.14 (t, 1H, $J = 7$), 9.20 (d, 1H, $J = 5$), all picolinic acid]. FAB-MS: m/z 379 $[M]^+$, 344 $[M-Cl]^+$.

Preparation of $[(1,3,5\text{-}Me_3C_6H_3)RuCl\{H_2NCH(Me)P(H)O_2\}]$ (**2**)

Sodium methoxide (34 mg, 0.74 mmol) and 1-aminoethylphosphonous acid (81 mg, 0.74 mmol) were added to a suspension of $[(1,3,5\text{-}Me_3C_6H_3)RuCl_2]_2$ (217 mg, 0.37 mmol) in methanol/water (1 : 1) (70 cm^3) and the mixture was refluxed for 3 h. The solvent was removed and the residue was dissolved in dichloromethane/methanol (15 cm^3 : 2 cm^3) and diethylether (3 cm^3) was added. A pale orange solid was removed by filtration and the remaining solution was evaporated to dryness to give $[(1,3,5\text{-}Me_3C_6H_3)RuCl\{H_2NCH(Me)P(H)O_2\}]$ (**2**) (100 mg, 37%) as a solid. Found: C, 30.9; H, 4.4; N, 3.1. Calc. for $C_{11}H_{19}ClNO_2PRu \cdot NaCl$: C, 31.2; H, 4.5; N, 3.3%. $^{31}P\{^1H\}$ NMR (CD_3OD): δ 40.52, 48.56, 48.72. FAB-MS: m/z 366 $[M]^+$.

Preparation of $[(1,3,5\text{-}Me_3C_6H_3)RuCl(EtMal)]$ (**3a**)

Sodium methoxide (68 mg, 1.32 mmol) and ethylmaltol (186 mg, 1.32 mmol) were added to a suspension of $[(1,3,5\text{-}Me_3C_6H_3)RuCl_2]_2$ (387 mg, 0.66 mmol) in methanol/water (1 : 1) (60 cm^3) and the mixture was refluxed for 2 h. The solvent was removed and the residue was dissolved in dichloromethane (80 cm^3) and filtered. The solvent was evaporated and the orange solid was recrystallized from dichloromethane/diethylether to give $[(1,3,5\text{-}Me_3C_6H_3)RuCl(EtMal)]$ (**3a**) (421 mg, 80%), as orange crystals. Found: C, 47.9; H, 4.8. Calc. for $C_{16}H_{19}ClO_3Ru$: C, 48.5; H, 4.8%. ^1H NMR ($CDCl_3$): δ 1.21 (t, 3H, CH_3, $J = 7.5$), 2.25 (s, 9H, Me_3), 2.80 (dq, 1H, CHH^1, $J = 15, 7.5$), 2.91 (dq, 1H, CHH^1, $J = 15, 7.5$), 4.91 (s, 3H, C_6H_3), 6.49 (d, 1H, CH, $J = 5$), 7.57 (d, 1H, CH, $J = 5$). FAB-MS: m/z 396 $[M]^+$, 361 $[M-Cl]^+$.

Preparation of $[(1,3,5\text{-}Me_3C_6H_3)RuCl(Pyr)]$ (**3b**)

Sodium methoxide (60 mg, 1.16 mmol) and N-methyl-3-hydroxy-2-ethyl-4-pyridinone (177 mg, 1.16 mmol) were added to a suspension of $[(1,3,5\text{-}Me_3C_6H_3)RuCl_2]_2$ (338 mg, 0.58 mmol) in methanol/water (1 : 1) (60 cm^3) and the mixture was refluxed for 2.5 h. The solvent was removed and the residue was dissolved in dichloromethane (80 cm^3) and filtered. The solvent was evaporated and the brown solid was recrystallized from methanol/diethylether to give $[(1,3,5\text{-}Me_3C_6H_3)RuCl(Pyr)]$ (**3b**) (320 mg, 68%) as a brown solid. Found: C, 50.1; H, 5.5; N, 3.5. Calc. for $C_{17}H_{22}ClNO_2Ru$: C, 49.9; H, 5.4; N, 3.4%. ^1H NMR (CD_3OD): δ 1.23 (t, 3H, CH_3, $J = 7.5$), 2.20 (s, 9H, Me_3), 2.95 (q, 2H, CH_2, $J = 7.5$), 3.77 (s, 3H, NMe), 5.05 (s, 3H, C_6H_3), 6.41 (d, 1H, CH, $J = 7.5$), 7.29 (d, 1H, CH, $J = 7.4$). FAB-MS: m/z 409 $[M]^+$, 374 $[M-Cl]^+$.

X-ray structure determination

Crystal data for $[(\eta\text{-}1,3,5\text{-}C_6Me_3H_3)RuCl(NC_5H_4CO_2)] \cdot 3H_2O$ (**1**). $M = 432.87$, monoclinic, space group $P2_1/a$, $a = 13.416(13)$, $b = 16.212(16)$, $c = 8.234(2)$ Å, $\beta = 99.63(1)°$, $U = 1766$ Å^3, $z = 4$, $\mu = 9.37$ cm^{-1}, $\lambda(Mo\text{-}K_\alpha) = 0.7107$ Å, $F(000) = 784$, $D_c = 1.47$ g cm^{-3}. Crystal dimensions $0.08 \times 0.36 \times 0.28$ mm.

The crystal used for data collection was mounted in air and the unit cell parameters were determined by least-squares refinement of ω measurements of

different layers.[14] Data were collected on a Stöe STADI-2 diffractometer with an ω scan technique in the range $7 < 2\theta < 54°$. Scattering factors were taken from ref. 15. The intensities of 3998 reflections were measured and these data were corrected for Lorentz and polarization effects to give 3600 unique reflections, of which 2660 had $I > 3\sigma(I)$. The structure was solved by conventional Patterson techniques and all subsequent calculations were performed with the computer programme SHELX-76.[16] All hydrogen atoms were included in calculated positions (C—H = 0.95 Å) with isotropic thermal parameters refined as groups. All non-hydrogen atoms were refined anisotropically. Final cycles of refinement employed a weighting factor w calculated from $w = (\sigma^2 F + 0.00027F^2)$ and gave final values of $R = 0.0462$ and $R_w = 0.0497$.

Acknowledgements—We thank the S.E.R.C. for a studentship (L.C.), the Hickinbotham Trust for financial support and Leicester University Computer Centre who provided support and facilities for X-ray single-crystal calculations. The FAB mass spectra were provided by the SERC mass spectrometry service at Swansea and by Dr G. Eaton at Leicester University.

SINGLET⇌QUINTET TRANSITION IN A SIX-COORDINATE IRON(II) COMPLEX OF A TRIDENTATE BIS(PYRAZOLYL)PYRIDINE LIGAND

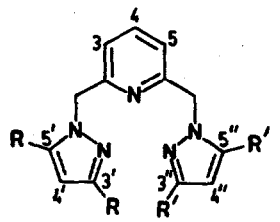
S. MAHAPATRA and R. N. MUKHERJEE*

Department of Chemistry, Indian Institute of Technology, Kanpur 208 016, India

(*Received* 27 *January* 1993; *accepted* 5 *March* 1993)

Abstract—The bis(ligand)iron(II) complex $[Fe(L^1)_2](ClO_4)_2 \cdot H_2O$ (**1**) [L^1 = 2,6-bis-(pyrazol-1-ylmethyl)pyridine] displays in the solid-state anomalous magnetic properties which are associated with a temperature-induced singlet ($^1A_1$)⇌quintet ($^5T_2$) transition. Mössbauer spectral data confirm this and reveal separate contributions from the singlet and quintet species with a strong temperature dependence of their relative intensities. Variable-temperature magnetic and Mössbauer studies establish that $[Fe(L^2)_2](ClO_4)_2 \cdot 2H_2O$ (**2**) [L^2 = 2-(3,5-dimethylpyrazol-1-ylmethyl)-6-(pyrazol-1-ylmethyl)pyridine] and $[Fe(L^3)_2](ClO_4)_2 \cdot 2H_2O$ (**3**) [L^3 = 2,6-bis(3,5-dimethylpyrazol-1-ylmethyl)pyridine] are purely high-spin species. For **1** three *d–d* transitions originating from the quintet and singlet state have been identified.

Recently we have been interested[1–5] in the identification of the steric effect of methyl substituent(s) adjacent to donor atoms in a group of bis-chelates, $M^{II}L_2^{2+}$ (M = Mn, Fe, Co, Ni or Ru), using a new family of tridentate heterocyclic ligands, L^1–L^3. We discovered that the ligand L^1 provides a field about iron(II) close to the critical value at the singlet/quintet cross-over from the absorption spectral data for the complex $[Fe(L^1)_2]^{2+}$ as well as from the data on the related nickel(II) complex.[1,4] To underscore a systematic spin-state behaviour of iron(II) bis-chelates we have undertaken the present study.



H_4bpp : R = R′ = H (L¹)

H_2Me_2bpp : R = H; R′ = Me (L²)

Me_4bpp : R = R′ = Me (L³)

We report here the characterization of a novel iron(II) system, $[Fe(L^1)_2]^{2+}$, exhibiting a spin transition in the solid-state from variable-temperature (8–300 K) magnetic susceptibility and ^{57}Fe Mössbauer spectral measurements. For the sake of completeness we also provide here the results on $[Fe(L^2)_2]^{2+}$ and $[Fe(L^3)_2]^{2+}$.

EXPERIMENTAL

Syntheses

$[Fe(L^1)_2](ClO_4)_2 \cdot H_2O$ (**1**), $[Fe(L^2)_2](ClO_4)_2 \cdot 2H_2O$ (**2**) and $[Fe(L^3)_2](ClO_4)_2 \cdot 2H_2O$ (**3**) were synthesized using literature methods.[1]

Measurements

Variable-temperature magnetic susceptibility measurements were obtained on powdered samples over the temperature range 8.0–300 K by the Faraday method using a locally built susceptometer at the Chemical Physics Group, Tata Institute of Fundamental Research (TIFR), Bombay, India. The details of the measurements are already described in the literature.[6] Effective magnetic moments were calculated from $\mu_{eff} = 2.828\,[\chi_M \cdot T]^{1/2}$, where χ_M is

* Author to whom correspondence should be addressed.

the corrected molar susceptibility. The diamagnetic contributions were calculated using values[7] of -239×10^{-6} cm^3 mol^{-1} for **1** and -400×10^{-6} cm^3 mol^{-1} for **3**. Mössbauer spectral measurements were performed at the Low-Temperature Physics Group, TIFR, India, using a standard, constant-acceleration spectrometer calibrated with metallic iron at room temperature. The observed spectra were computer-fitted to Lorentzian lines as described earlier.[6]

RESULTS AND DISCUSSION

Magnetism

First-row transition-metal complexes with electronic configurations d^4–d^7 have been found to exhibit thermally driven spin-state transitions between the high-spin state (HS) and the low-spin state (LS). This is because in these systems two electronic states of differing multiplicity become nearly equienergetic and a thermal population of the excited state is possible. Six-coordinate iron(II) complexes with heterocyclic nitrogen donor atoms and α-diimine ligands have been found to exhibit such a transition.[8]

From this background the variable-temperature (8–300 K) magnetic susceptibility studies on **1** were performed. Among the two other complexes we decided to study the fully methyl-substituted complex (**3**) to gain a better understanding. The magnetic properties are shown in Fig. 1 in the form of μ_{eff} vs T.

The magnetic properties of **1** are indicative of the occurrence of a temperature-induced singlet⇌quintet transition in the cation. The moments at high temperature are normal for iron(II) in the quintet $^5T_2$ state. At low temperatures **1** has very low magnetic moments, which are typical for the metal ion in the singlet $^1A_1$ state. As the temperature is increased the moment gradually increases and this is indicative of an increased population of quintet state species.

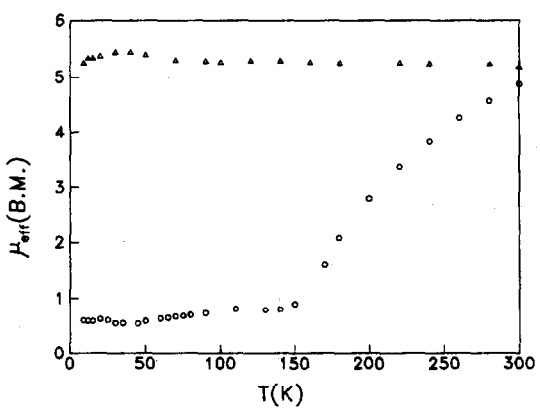


Fig. 1. Effective magnetic moment of **1** (○) and **3** (△) as a function of temperature.

Complex **3** follows the Curie–Weiss behaviour from room temprature down to 8 K. The Curie constant is in good agreement with that for an $S = 2$ ground state ($C = 3$ when $g = 2$) with a Curie–Weiss temperature of -1.45 K. Thus, no spin pairing was observed in **3** even at the lowest limit of the experimental temperature range. The methyl groups adjacent to the pyrazole nitrogen atoms apparently interfere with the close approach to the metal atom necessary for spin pairing.

An attempt to evaluate enthalpy and entropy changes for the spin transition of **1** [eq. (1)] was made using the standard equations.[9,10]

$$[Fe(L^1)_2]^{2+}(^1A_1, ls) \rightleftharpoons [Fe(L^1)_2]^{2+}(^5T_2, hs) \quad (1)$$

The pure high-spin data were evaluated from the data for **3** at the corresponding temperatures and the pure low-spin data were determined for **1** from the low-temperature data. Despite the limited range (170–300 K) over which a linear plot of ln K against $1/T$ was obtained it was possible to extract some information on the thermodynamic parameters. It is admitted that the data obtained from the present analysis (see below) are not that *accurate* compared with the more involved method of Zimmermann and König.[11] The derived ΔH and ΔS values are 13 kJ mol^{-1} and 56 J K^{-1} mol^{-1}, respectively. These thermodynamic parameters are similar to those found for other spin equilibria systems of iron(II).[9–13] The source of ΔH is the Fe—N bond length increase,[8] which accompanies the transition from low- to high-spin, i.e. reorganization of the inner coordination sphere. The entropy term for a simple spin equilibrium between singlet and quintet levels would be only 13.4 J K^{-1} mol^{-1}, due to the spin multiplicity change (R ln 5 = 13.4 J K^{-1} mol^{-1}).[12–14] The value of ΔS in excess of that predicted for a change in spin only is a feature of most of the examples of spin equilibria in six-coordinate iron(II) systems described so far. This could be accounted for in terms of a temperature dependence of the effective crystal field and on the different vibrational frequencies in the high-spin and low-spin states.

Mössbauer spectra

The origin of the temperature dependence of the magnetism of **1** is clearly revealed by Mössbauer spectral data. The Mössbauer spectral data (Table 1), like the magnetic data, show the temperature-induced change in the ground state for **1**. Figure 2

Table 1. Mössbauer data for iron(II) systems

Complex	Temperature (K)	Spin-state	δ (mm s^{-1})	ΔE_Q (mm s^{-1})
$[Fe(L^1)_2](ClO_4)_2 \cdot H_2O$	300	$^5T_2$	0.98	1.92
	200	$^5T_2$	0.71	2.42
		$^1A_1$	0.50	0.37
	80	$^1A_1$	0.53	0.39
$[Fe(L^2)_2](ClO_4)_2 \cdot 2H_2O$	300	$^5T_2$	1.06	2.45
	80	$^5T_2$	1.13	2.88
$[Fe(L^3)_2](ClO_4)_2 \cdot 2H_2O$	300	$^5T_2$	1.07	2.85

shows three typical spectra at 80, 200 and 300 K. With increasing temperature the $^5T_2$ state gains intensity, while the intensity of the $^1A_1$ state simultaneously decreases. At 300 K the contribution of the $^5T_2$ state is clearly predominant. At 80 K the contribution of the quintet state species has disappeared and the spectrum shows a doublet with small quadrupole splitting, characteristic of the $^1A_1$ state. The spectrum at 200 K reveals a superposition of separate spectra due to singlet and quintet state species.

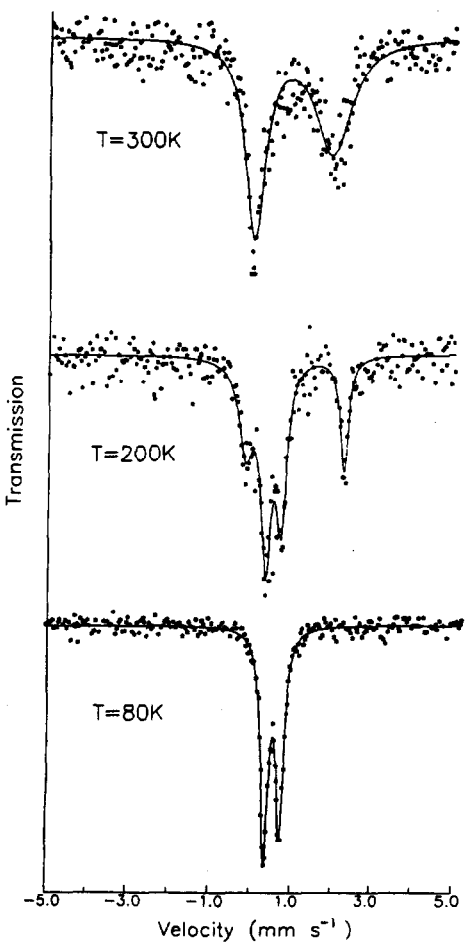

Fig. 2. ^{57}Fe Mössbauer spectra of **1** at 80, 200 and 300 K.

Complexes **2** and **3** display Mössbauer spectra (300 K) characteristic of purely high-spin states. The temperature dependence of **2** was also investigated. Interestingly, it remains high-spin even at 80 K (Table 1). The isomer shift and quadrupole splitting observed for the singlet and quintet state species in the spectra of **1**–**3** are comparable with those of the high-spin and low-spin complexes of related systems.[8]

d–d *transitions*

Even though the field strengths of L^1, L^2 and L^3 towards six-coordinate iron(II) were determined from their $^5T_2 \rightarrow {}^5E$ transitions, the present work adds to the previous assignments[1] of the bands for **1**. Among the three high-spin (at room temperature) iron(II) complexes, **1**–**3**, in acetonitrile solution **1** exhibits additional spectral features (an absorption at 543 nm of low intensity and a band at 415 nm with a shoulder at 368 nm);[1] the source of which was not appreciated earlier. Due to the high energy and the intensity of the band at 543 nm, we tentatively assign this band to the spin-allowed $^1A_1 \rightarrow {}^1T_1$ transition.[8] The band at 415 nm is probably due to[8] the transition $^1A_1 \rightarrow {}^1T_2$. The observed high intensity of this band could arise due to intensity stealing from the MLCT band at 368 nm. The feature observed at *ca* 400 nm is closely similar to a related spin equilibrium system.[13]

CONCLUSIONS

It follows from the temperature dependence of the magnetic susceptibility for **1** that the ligand field

arising from the two tridentate ligands (L^1) is such that the difference between the two spin states of the iron(II) ion is of the order kT and that the population of the states in question can be altered by changes in temperature. This has been substantiated by the Mössbauer results. The present investigation provides a clear indication of the existence of a spin-state transition for complex **1**. In contrast, methyl group substituents in the 3-position(s) of the pyrazole rings in L^2 and L^3 give rise to much weaker ligand fields to exhibit a high-spin configuration over the accessible temperature range. This arises from the steric crowding of the methyl group substituents near the donor site.

Acknowledgements—Financial assistance received from the Department of Science and Technology, Government of India and Council of Scientific and Industrial Research, New Delhi, India, is gratefully acknowledged. Our sincere thanks are due to Professor S. Mitra, TIFR, Bombay, for his hospitality in the use of his laboratory during the stay of one of us (RNM) as a visiting scientist. We thank Dr A. K. Nigam of TIFR for allowing us to use his Mössbauer set-up. We thank Mr B. T. Kansara, Mr R. S. Sannabhadti and Dr S. Veeturi for recording the solid-state magnetic data and Mössbauer data, respectively.

XPS STUDY OF METAL COMPLEXES WITH AN UNSYMMETRICAL TRIDENTATE SCHIFF BASE

ZHOU LIXIN

Department of Chemistry, Gansu Education College, Lanzhou 730000, P.R.C.

and

WANG BO, YANG SHIYAN* and JIN DAOSEN

Lanzhou Institute of Chemical Physics, Academia Sinica, Lanzhou 730000, P.R.C.

(*Received* 8 *January* 1993; *accepted* 5 *March* 1993)

Abstract—Complexes of 14 lanthanide metals with the new tridentate Schiff base derived from salicylaldehyde and furfuraldehyde with *o*-phenyldiamine (HL) have been prepared and studied using X-ray photoelectron spectroscopy (XPS). The nitrogen 1*s* peak for all the complexes is symmetrical relative to the two asymmetric peaks of the ligand. This behaviour suggests that a coordination conjugation of four equatorial nitrogens occurs, the complexes are in an octahedral structure and the nitrogen 1*s* electron BE increases from La to Lu in accordance with the "Four Subgroup Effect".

A large number of Schiff bases and their complexes have been studied for their interesting and important properties, e.g. their ability to reversibly bind oxygen,[1] catalytic activity in hydrogenations of olefins[2] and transfer of an amino group,[3] photochromic properties,[4] complexing ability towards some toxic metals,[5] and so on.

However, only a few compounds of this type have been studied by XPS, namely the symmetric tetradentate Schiff bases, such as H_2salen, H_2salphen and related metal complexes.[6] The main results have been obtained by comparing the spectra of different ligands of this type amongst themselves and with spectra of complexes containing the same cation. The variation of the nitrogen and nitrogen 1*s* electron BEs can be rationalized considering the reduction in electron density on the donor atoms after complexation. Protonation is accompanied by an even greater decrease in their electron density, therefore, the BEs increase follow the order: uncomplexed atom < complexed atom < protonated atom.

Most studies were restricted to a few metals, such as cobalt, nickel and copper, so that information on the role of the central atom is very limited. Our studies are aimed at bridging this gap. The present paper describes the XPS spectra of a set of complexes, $[LnL_2]ClO_4$, where HL denotes an asymmetrical Schiff base, but after complexing the four coordinated nitrogen atoms appear chemically identical.

EXPERIMENTAL

Methods and materials

All chemicals and solvents were analytical grade and were used without further purification. The preparation of the ligand has been described previously.[7] Lanthanide perchlorates were made from oxide and perchloric acid.

Preparation of the complexes

The same method of synthesis was adopted for all complexes. In a typical reaction an MeOH solution of $Ln(ClO_4)_3$ (1 mol) and the Schiff base (2 mol) was stirred and refluxed for 4 h, whereupon an ammonia solution was added dropwise. The solid product was filtered off, washed successively with MeOH and Et_2O and dried *in vacuo* (80 mm Hg) at 80° for 1 h. The complexes were thus prepared and their yields are given in Table 1.

[a] S cm^2 mol^{-1} and *ca* 10^{-3} M DMSO.

Physical measurements

Molar conductances of the complexes in DMSO at 0.001 M concentration were measured with a DDS-IIA molar conductometer at 25°C. The IR spectra (CsI pellets) were obtained on a NIC-5DX spectrophotometer in the 200–4000 cm^{-1} region.

The X-ray photoelectron spectra were measured on a PHI-550 spectrometer. Non-monochromatic Mg-K_α (1253.6 eV) radiation was used from an X-ray gun operated at 15 kV and 20 mA. The base pressure was better than 7×10^{-11} mbra in the analyser. The samples were finely pulverized and spread on a gold holder as thin films. For all the samples the intense carbon 1*s* photopeak observed on the lowest energy side, whose FWHM was nearly 1.1 eV, was used as a standard for the binding energy. The peak mostly arises from carbon atoms of aromatic hydrocarbon character in the compounds to be studied, but not from possible impurities or surface contaminations, and the binding energy at the peak was assumed constant for all the compounds. The binding energy at the standard peak was determined to be 284.8 eV, such that it could reproduce the binding energies of N 1*s*, O 1*s* and Cl 1*s*. The observed spectra, subtracted from the background contribution, were reproduced by a superposition of Gaussians with an FWHM of *ca* 1.1 eV. The parameters to be determined were the line position and height for each composite peak. An optimum set of parameters was obtained in such a way that the root mean square deviations of the trial spectra were minimized by changing the parameters according to the simple method for function minimization.[6]

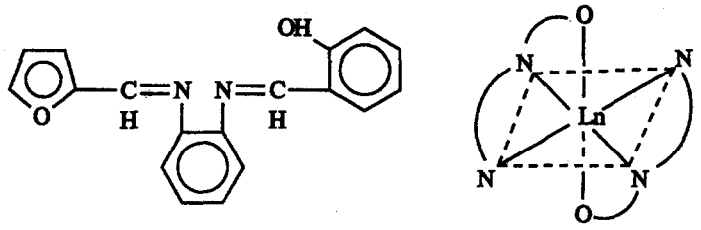
Room-temperature (298 K) magnetic susceptibility measurements were obtained by Gouy's method using solid samples with $Hg[Co(CNS)_4]$ as the calibrant. TG and DTA measurements were obtained in a nitrogen atmosphere between room temperature and 800°C using a Thermoflex TG–DTA meter.

RESULTS AND DISCUSSION

The complexes of HL are in a mononuclear form in which one metal ion is bonded to two ligands. This result has been confirmed by molecular weight determination (by Rast's method), which suggests that the complexes have the general formula $[LnL_2]ClO_4$. In the presence of metal ions HL is deprotonated, thus satisfying the charge on the metal. The complexes exhibit fairly high thermal stability and are moderately soluble in DMF and DMSO. The conductance values suggest that they are 1 : 1 electrolytes[7] (Table 1).

IR spectra

The IR spectra of the ligand and the complexes are complicated (see Table 2). However, attempts have been made to identify some important bands which furnish information regarding the mode of bonding. The absence of ν(OH) in the spectra of the complexes indicates deprotonation of the —OH group (structure **1**). The ν(C—O) frequency



1

decreases by *ca* 10 cm^{-1} to 1555 cm^{-1} in the complexes, indicative of phenolic oxygen coordination. Similarly, ν(C=N) in the spectra of the complexes is at *ca* 1605 cm^{-1}, a lower frequency by *ca* 15–20 cm^{-1}, compared with two bands at 1624 and 1615 cm^{-1} which can be assigned to azomethine I and II, respectively. The absence of a ν(N—H) absorption in the spectra of the ligand and the complexes rules out the possibility of the C=N group in a protonated form. All complexes exhibit a ν(C—O—C) furfural ring frequency which is almost unshifted relative to the free ligand (1406 cm^{-1}), suggesting that the furfural ring oxygen[9] is not coordinated. Bands assignable to ν(Ln—O) and ν(Ln—N) are observed at *ca* 390 and 250 cm^{-1}, respectively.[10] The vibrational spectra indicate that perchlorate ions are not coordinated in the complexes studied.

XPS studies

The results of the XPS semi-quantitative analyses of the surface layers are in agreement with the sample compositions.

The 3*d* or 4*d* electron BEs of the metals and the values for the nitrogen 1*s* electron BEs are given in Table 3. Although the Ln 3*d* or 4*d* electron BE is closely related to the central atom charge and therefore to its valency, it is difficult to determine the valency only on the basis of this criterion since the intervals for various oxidation states may overlap. Nevertheless, we can obtain the same result as that reported previously.[11]

From the spectra we find only one symmetric nitrogen 1*s* peak for all the complexes relative to two 1*s* peaks of equal intensity for the ligand, as shown in Table 3. This behaviour suggests that the four nitrogen atoms in the complexes, $[LnL_2]ClO_4$, become chemically identical and a coordination conjugation of four equatorial nitrogens occurs, and as can be seen in structure **1**; the nitrogen 1*s* electron BEs in the complexes increase in the sequence: La > Ce < Pr < Nd < (Pm) > Sm < Eu < Gd > Tb < Dy < Ho < Er > Tm < Yb < Lu, which is exactly the same order as in the "Four Subgroup Effect" series of stability constants.[12] These energies reflect the amount of electron density transferred from the nitrogen

Table 2. Significant IR bands of HL and its complexes (cm^{-1})

atoms to a metal ion via coordination bonds and, as expected, correlate with the sum of the metal ionization potentials.[12]

Oxygen occurs in three different chemical environments in the complexes, i.e. in the perchlorate groups and in the furfural ring and the deprotonated phenolic oxygen. These three oxygen environments result in a broad O1*s* peak, which consists of two shoulder peaks and one sharp peak with relative intensities in the ratio 1 : 1 : 2. This is indicated by the FWHM values (full width at half height) of just above 5 eV for the complexes. Deconvolution indicates that the O 1*s* peaks are derived from the ClO_4^- group and the furfural ring remained almost unchanged for all the complexes compared with the values of the ligand and $La(ClO_4)_3$. However, the BE values of the O 1*s* peak from phenolic oxygen are slightly higher than that of the ligand.

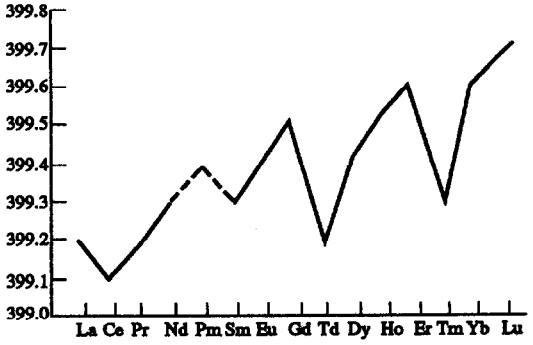

Fig. 1. The nitrogen 1*s* electron binding energies in $[LnL_2]ClO_4$ complexes.

Magnetic moments

The paramagnetic behaviour of the lanthanide(III) ions is consistent with the presence of unpaired electrons. The room-temperature magnetic moments of all the complexes show very little deviation from the Van Vleck values,[13] indicating little participation of the 4*f* electrons in bond formation.

TG and DTA

The thermolysis of all the compounds has similar patterns. In the first step the ClO_4^- group is split, with a strong exothermic effect. On increasing the temperature intermediate compounds decompose continuously and finally oxides formed.

On the basis of the above discussion a six-coordinated octahedral structure is suggested for the complexes and the "Four Subgroup Effects" can be confirmed by the XPS method.

PYRIDINE FUNCTIONALIZED ALKYLS OF TRANSITION METALS, SYNTHESIS OF BIS[C,N-2-PYRIDYLBIS(TRIMETHYLSILYL)METHYL]NICKEL

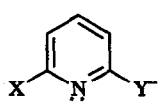
KEITH J. IZOD and PETER THORNTON*

Department of Chemistry, Queen Mary and Westfield College, Mile End Road, London E1 4NS, U.K.

(*Received* 26 *February* 1993; *accepted* 5 *March* 1993)

Abstract—Alternate lithiation and reaction with $ClSiMe_3$ of 2,6-dimethylpyridine gave the lithium derivatives of pyridine substituted at the 2- and 6-positions by mono- or bis(trimethylsilyl)methyl groups. The relative ease of formation of these compounds is discussed and compared to their reactivity with transition metal halides. The reaction of $NiCl_2$ with the lithium derivative of bis(trimethylsilyl)methylpyridine gives the remarkably air-stable nickel(II) alkyl bis[C,N-2-pyridylbis(trimethylsilyl)methyl]nickel(II).

Ligands of type **I**, the 2-functionalized pyridines, are of particular interest since they are often found to exhibit a wide variety of coordination patterns. A wide range of substituents X and Y have been employed to vary the properties of these ligands, usually combinations of X as H, alkyl or halogen and Y as O, S, NR, PR or CRR′.



I

There are comparatively few studies of 2-pyridylalkyl compounds, Y = CRR′; of these over half are of the sterically hindered ligands with R = R′ = $SiMe_3$ or R = H, R′ = $SiMe_3$, here abbreviated as btsmp and tsmp, respectively. Both chelating and bridging modes of coordination have been established, but there is an intriguing variety of structures to be found among their homoleptic compounds. The isostructural cadmium, magnesium and zinc derivatives of btsmp have very distorted tetrahedral geometry, which in the cadmium compound leads to a C—Cd—C angle of 174.3°.[1] For these compounds the bite angle of 67° is comparable to those in pyridonate and pyridinethionates. In $[M(btsmp)_2]^+[MCl_4]^-$ (M = Al, Ga) the tetrahedral environment of the cation is more regular, but clashing of the two close $C(SiMe_3)_2$ groups is relieved by lengthening the M—N and M—C bonds to one of the ligands.[2] For tin(II) the stereochemically active lone pair appears to be responsible for compressing the bite angle to 59°.[3] In $Hg(btsmp)_2$] the characteristic two coordination of mercury is shown by the ligands bonding only through carbon, although there may be weaker links to nitrogen at a much longer distance.[1]

This varied coordination pattern of btsmp prompted us to study the coordination of btsmp and tsmp to first row transition metals. This paper describes the synthesis and properties of $[Ni(btsmp)_2]$ and points of interest on the ligand synthesis and reactivity.

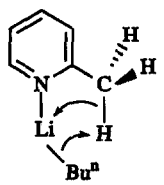
Additional motivation for our work comes from the opportunity to study further the behaviour of lithiated alkylpyridines, which, despite having widespread use as intermediates in organic chemistry, for forty years,[4] were not used for transmetallations until much later.[5]

Alkylpyridines are much more acidic than toluene or xylene, which only undergo metallation by organolithium reagents when complexed by tertiary amines, as in Bu^nLi(tmeda), whereas alkylpyridines are deprotonated by uncomplexed organolithiums or by sodium amides in liquid ammonia. This may be attributed to the ring nitrogen's ability to accommodate much of the negative charge which is delocalized into the aromatic π-system away from the carbanion centre, as has been shown by ^1H and ^{13}C NMR spectroscopy correlated with electron

* Author to whom correspondence should be addressed.

densities calculated by the CNDO/2 method.[6] It has been known for a number of years that silyl groups adjacent to a carbon bearing a negative charge act to stabilize the carbanion, but this extra stabilization is thought to be lost on going from the free anion to a metallated derivative, although an intermediate situation may occur in solution.

The lithiation of 2-alkylpyridines is also facilitated by a complex-induced proximity effect.[7] In the first step of the deprotonation the ring nitrogen of the ligand coordinates the lithium atom of the metallating alkyllithium, e.g. Bu^nLi. This gives an increase in the nucleophilicity of the Bu^n group and a decrease in the molecular association of the organolithium. In such a pre-equilibrium complex the organolithium is held in a position where the alkyl group may be directed towards the active hydrogen of the free ligand. This allows the deprotonation step to proceed through a favoured six-membered ring intermediate, **II**.



II

RESULTS AND DISCUSSION

Ligand formation

Despite the predicted order of carbanion stabilization $C(SiMe_3)_2 > CHSiMe_3 > CH_2$, discussed above, our initial metallation experiments suggested that the order of acidity of the 2-alkylpyridines was Htsmp > Hbtsmp > Hmp (Hmp = 2-methylpyridine). To study this anomaly further 2,6-dimethylpyridine was repeatedly lithiated and reacted with $ClSiMe_3$, with the results outlined in Scheme 1. The position of lithiation or silylation was identified by ^1H and ^{13}C NMR spectroscopy, allowing the relative acidities of unsubstituted mono- and bis-silylated alkyl groups in the ligand to be compared directly.

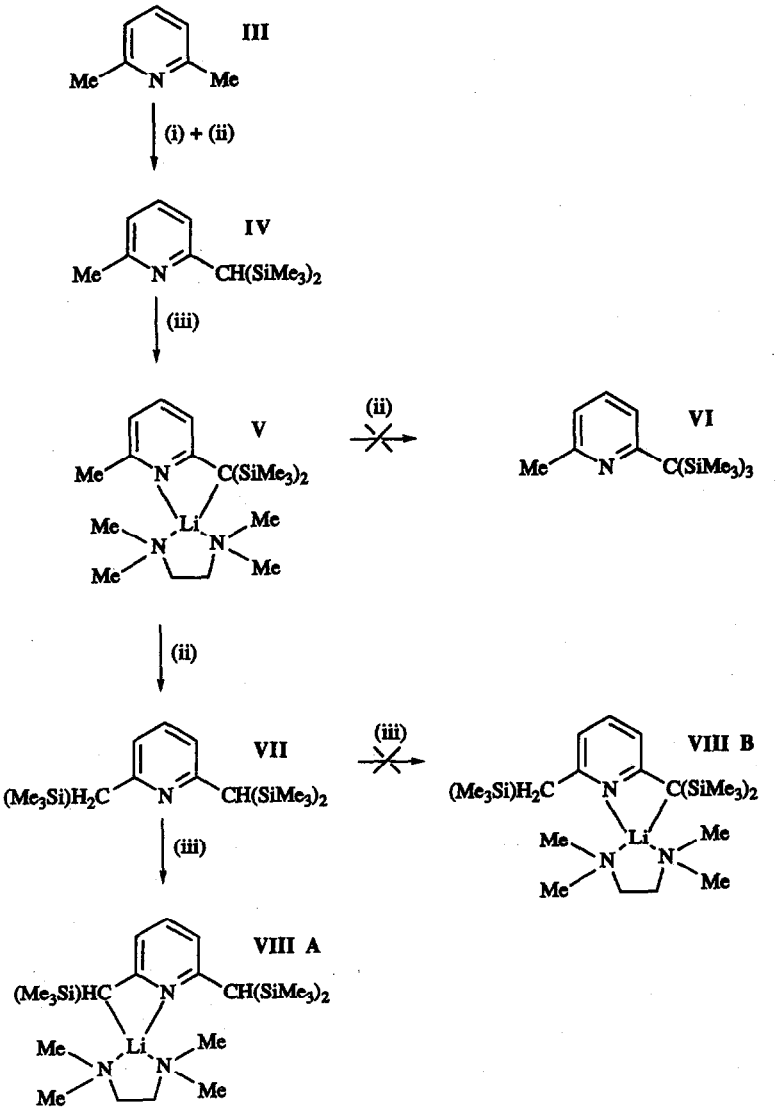
Reaction of 2,6-dimethylpyridine (**III**) with 2 equivalents of Bu^nLi in ether, followed by 2 equivalents of $ClSiMe_3$, leads to the disubstituted product **IV**, substitution occurring at one carbon only. Such a substitution pattern is expected since initial reaction of **III** would give a mono-subsituted product which was not isolated but which then reacts preferentially at the substituted carbon through a silyl-stabilized carbanion.

Further reaction of **IV** with Bu^nLi(tmeda) yielded a crystalline product whose ^1H NMR spectrum corresponded to **V**. Deprotonation occurs to give a carbanion stabilized by two Me_3Si groups rather than at the less sterically hindered methyl, clearly demonstrating the greater acidity of CH_2SiMe_3 and $CH(SiMe_3)_2$ substituents relative to CH_3.

Addition of $ClSiMe_3$ to a freshly prepared ether solution of **V** does not give the trisubstituted product **VI**, but yields **VII** through a tautomerization of the carbanion. This tautomerization may be compared to that observed in lithiated 2,4-dialkylpyridines and 2,4-dialkylquinolines. Reaction of Bu^nLi with 2,4-dimethylpyridine leads to the 2-lithiated product through a complex-induced proximity effect. However, this is seen to isomerize slowly to the thermodynamically more stable 4-lithio derivative in such coordinating solvents as THF.[8] The rate of isomerization is increased by the presence of tertiary amines such as tmeda and is dramatically increased by the presence of an extra equivalent of the parent heterocycle.[9,10] This has been interpreted as implying that the isomerization occurs through equilibration of small amounts of unreacted heterocycle with the carbanion. A marked dependence on solvent is also observed; in THF 2,4-dimethylquinoline undergoes lithiation at the 2-position with Bu^nLi. After 144 h this is found to have isomerized completely to the 4-lithio compound. In ether, however, the 2-lithio derivative does not isomerize even after prolonged periods in solution; indeed it is found that the 4-lithio derivatives isomerize to the 2-lithio derivatives in this solvent.

The isomerization observed in the present carbanion differs from those outlined above in three respects. First, for 2,4-dimethylpyridine isomerization favours the formation of a thermodynamically more stable product after initial kinetically controlled formation of the 2-lithio product, but in our compound the carbanion formed initially is both kinetically and thermodynamically favoured since it is stabilized by two $SiMe_3$ groups. The reaction occurs through an intermediate in which the negative charge is localized on the naked alkyl group, a situation relatively disfavoured thermodynamically. Second, the lithium derivative **V** is indefinitely stable in hexane, ether and THF solutions despite the presence of the tertiary amine tmeda. Third, isomerization is only observed when $ClSiMe_3$ is added.

From this it may be concluded that the tautomerization of **V** is neither a tautomerization from a carbanion formed under kinetic control to a more thermodynamically stable one, nor is it induced by solvent, the presence of tertiary amines or the unreacted parent heterocycle. The formation of **VII**

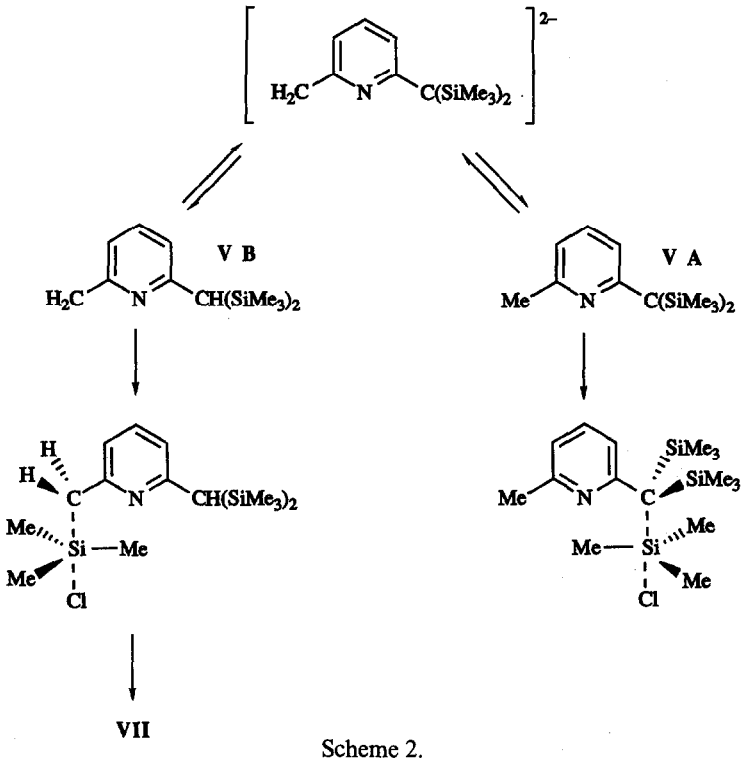


Scheme 1. (i) Bu^nLi in ether, 0°C; (ii) $ClSiMe_3$ in ether, 0°C; (iii) Bu^nLi(tmeda) in ether or pentane, 0°C.

may be rationalized as follows: In ether solution an equilibrium may exist between two carbanion tautomers **Va** and **Vb** (Scheme 2), with tautomerization occurring through a dianionic intermediate $[2\text{-}CH_2\text{-}6\text{-}C(SiMe_3)_2C_5H_3N]^{2-}$. Such a dianion has a precedent in the ready metallation of 2,6-bis(trimethylsilylmethyl)pyridine at both alkyl carbons with Bu^nLi(tmeda).[11]

The high polarizability of silicon suggests that nucleophilic attack of the carbanion on $ClSiMe_3$ would tend to favour an S_N2 mechanism, requiring the formation of a transition state in which the silicon atom is five-coordinate. It can be clearly seen that reaction through **Va** involves a transition state in which steric interactions between the silyl substitutents and the incoming group would be large, but in the transition state derived from **Vb** steric interactions between the alkyl protons and the silyl group would be minimal and so this route is favoured.

Metallation of **VII** provides a direct comparison of the acidities of mono- and disubstituted 2-alkyl groups. Reaction of **VII** with Bu^nLi(tmeda) in ether may give either **VIIIa** or **VIIIb**, but ^1H and ^{13}C NMR studies clearly indicate that deprotonation occurs at the mono-substituted alkyl, leading exclusively to the product **VIIIa**. Appreciable signal broadening in the ^1H resonance assigned to the $C(SiMe_3)_2$ protons suggests magnetic inequivalence of the methyl protons caused by restricted rotation about the C_{alkyl}—C_{ipso} bond in this very sterically crowded complex. The order of acidity of the alkyl groups of 2-alkylpyridines may now be confirmed as: $CH_2SiMe_3 > CH(SiMe_3)_3 > CH_3$, in agree-



Scheme 2.

ment with competitive lithiation experiments[12] on a mixture of Hbtsmp and Htsmp.

Transmetallation reactions and ligand coupling

A convenient and frequently employed route to organometallic compounds is transmetallation:

$$n\mathrm{MR} + \mathrm{M'X}_n \longrightarrow n\mathrm{MX} + \mathrm{M'R}_n$$

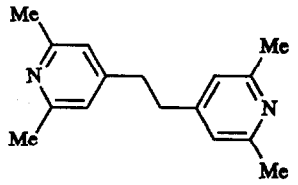
where M is an electropositive metal such as lithium or sodium and X is a halogen. Since 2-alkylpyridines may readily be lithiated and many anhydrous transition metal halides are available, we adopted this route, which others have used to prepare $[M(btsmp)_2]$ (M = Zn, Cd, Hg)[1] and $[M_2(btsmp)_2]$ (M = Cu, Ag, Au).[13] However, our reactions turned out to be much more complex.

Reaction of lithiated alkylpyridines with transition metal halides in appropriate stoichiometric ratios rarely gave clean products and in several cases only intractable mixtures, particularly for the early heavy transition metals Nb, Mo and W, which have many easily accessible oxidation states. The unsubstituted 2-pyridylmethyl ligand, mp, was particularly intractable, giving a sticky brown oil with $ZrCl_4$ from which an ESR active zirconium(III) species was isolated.[14] It has previously been noticed that no tractable products are formed[15] on attempting to fully substitute $HfCl_4$ or $ThCl_4$ with Li(dmp) (Hdmp = 2,6-dimethylpyridine) and that reaction of $[Li_2(tsmp)_2(OEt_3)_2]$ with $AgBF_4$ or Au(CO)Cl gave a silver mirror and colloidal gold, respectively.[13] Only brief mention was made of these complications and in neither case was an explanation put forward. The complications seem to be caused by a redox process and we suggest that reduction of metals occurs through a ligand coupling reaction.

The reduction process was most effectively studied when $[Li_2(btsmp)_2]$ was used as a transmetallating agent. When an ether solution of this was added to a suspension of $NiCl_2$ in ether a large amount of grey solid, probably a mixture of LiCl and metallic nickel, was precipitated and a deep red solution was given. Attempts to isolate more than trace amounts of a pure product from the solution were unsuccessful.

When the reaction was repeated under the same conditions but with the additional presence of more than 4 mol of PEt_3 per mole of $NiCl_2$, much less grey solid was formed. Removal of this solid and crystallization of the red oil obtained from the filtrate from pentane gave crystals of $[Ni(PEt_3)_4]$.[16] The purely organic product could be isolated by removing solvent from the red filtrate, subliming away the excess PEt_3 *in vacuo* at 60°C and subliming the pale red residue at 150°C/10^{-2} Torr repeatedly. The sublimate could thus be divided into a little $[Ni(btsmp)_2]$ and some colourless crystals, although

these could not be completely separated. The ^1H NMR spectrum of this product (see Experimental) is consistent with the formation of 2-bis(trimethylsilyl)methyl-5-{2-pyridylbis(trimethylsilyl)-methyl}pyridine (**IX**), recently reported,[17] with crystal structure, from the reaction of $BiCl_3$ with $[Li_2(btsmp)_2]$.

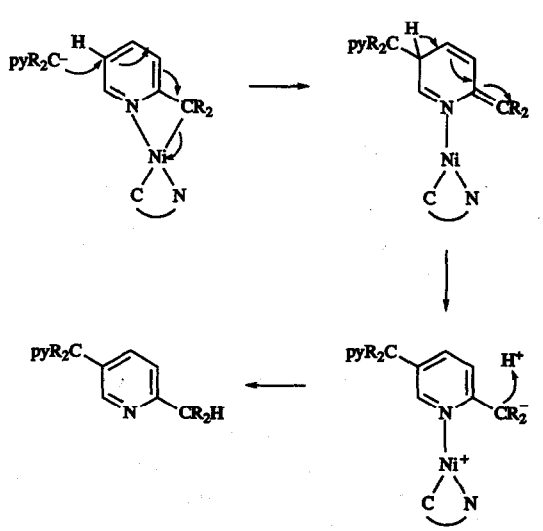


IX

The overall reaction consists of the formation of $[Ni(btsmp)_2]$ and a consequent competition between $NiCl_2$ and preformed $[Ni(btsmp)_2]$ for $[Li_2(btsmp)_2]$ with the subsequent formation of zero-valent nickel by a ligand coupling reaction:

$$NiCl_2 + [Li_2(btsmp)_2] \longrightarrow x[Ni(btsmp)_2] + yNi + z''(btsmp)_2''$$

A possible mechanism for the reduction process is shown in Scheme 3. The initial product is $[Ni(btsmp)_2]$. Addition of more lithium reagent results in nucleophilic attack of a btsmp carbanion at the 5-position of one of the pyridine rings of the preformed $[Ni(btsmp)_2]$ and transfer of electrons to nickel. Recovery of aromaticity by the loss of the 5-proton and its transfer to the remaining carbanion centre completes the reaction. Support for this mechanism is as follows: (1) Solutions of lithiated alkylpyridines are indefinitely stable, so the presence of a more readily reducible metal centre is essential to ligand coupling to take place. (2) $[Ni(btsmp)_2]$ is very stable to light, heat and hydrolysis, but is almost completely destroyed by addition to its solution in ether of $[Li_2(btsmp)_2]$. (3) Significantly lower yields are observed on reaction of $NiCl_2$ with the more nucleophilic carbanion formed upon lithiation of Htsmp.[16] This would be difficult to explain if the ligand coupling reaction proceeded by a reductive elimination mechanism. Isolation of the 5-coupled species only also argues against a radical based mechanism where a wider variety of products might be expected. (4) Electron transfer to a transition metal has been observed in nucleophilic additions to coordinated cyclopentadienyls, as in the reaction of $NaBH_4$ with $[Fe(C_5H_5)(CO)_2(PPh_3)]$ to give $[Fe(C_5H_6)(CO)_2(PPh_3)]$.[18]



Scheme 3.

It has been suggested that lithiation of 2-alkylpyridines increases electron density at the 3- and 5-positions over the 2-, 4- and 6-positions[6,19] and consequently that nucleophilic attack at the former is disfavoured. Studies of uncharged pyridines coordinated to transition metals also suggest deactivation of the 3- and 5-positions towards nucleophilic attach may occur.[20] However, in the present case it appears that the presence of empty low-lying *d*-orbitals on the metal creates a situation whereby the 3- and 5-positions of the pyridine ring may readily undergo a form of reductive nucleophilic attack, whereas no such mechanism of electron transfer is available for the 2-, 4- or 6-positions.

The observed preference for substitution at the 5- over the 3-position may be attributed to efficient steric blocking of the latter by the two adjacent $SiMe_3$ groups, especially in conjunction with the large size of the incoming nucleophile.

$[Ni(btsmp)_2]$

Unlike the great majority of nickel alkyls $[Ni(btsmp)_2]$ is stable to air and dilute aqueous acids. The methyl groups of the $SiMe_3$ moieties probably lie above and below the nickel atoms and prevent attack by nucleophiles at the metal centre. The compound can be sublimed and its mass spectrum gives the molecular ion as a strong peak. It was not possible to obtain X-ray quality single crystals, but its diamagnetism and well-resolved ^1H and ^{13}C spectra indicate a square planar structure. The ^1H NMR spectrum shows significant upfield shifts of the ring protons compared with the free ligand, consistent with Ni—N $d\pi$–$p\pi$ back donation; the ^{13}C NMR spectrum is most remarkable for the small shift in the alkyl carbon resonance (3 ppm) when compared with the free ligand Hbtsmp, suggesting covalency in the Ni—C bond and in line with the spectra of $[M_2(btsmp)_2]$ (M = Au, Cu).[13]

EXPERIMENTAL

Materials

All compounds were assumed to be extremely air-sensitive until proven otherwise and were handled in a nitrogen atmosphere or under vacuum with standard Schlenk techniques. Solid materials were handled in a nitrogen-filled dry glove-box. Solvents were dried by standing over sodium wire, refluxing for 4 h over the sodium ketal of benzophenone, followed by distillation under dry nitrogen, and were stored in grease-free reservoirs over activated 3 Å molecular sieves. Deuterated solvents were dried over activated 3 Å molecular sieves and degassed by three freeze–pump–thaw cycles. Xylene, 2-methylpyridine, 2,6-dimethylpyridine and tmeda were dried and degassed by refluxing over CaH_2 and distillation under dry nitrogen. $ClSiMe_3$ (Aldrich) was distilled at reduced pressure onto 3 Å molecular sieves. Bu^nLi was used as a 2.5 M solution in hexanes (Aldrich) immediately after standardization.[21]

Instrumentation

^1H and ^{13}C NMR spectra were obtained on Bruker WP80 and WP250 spectrometers and mass spectra on AEI MS902 or Kratos M550 TC spectrometers.

2-*Trimethylsilylmethylpyridine*

The procedure is similar to that in the literature.[22] 2-Methylpyridine (10 cm^3, 0.102 mol) was added to an ice-cold solution of Bu^nLi (40 cm^3, 0.102 mol) in ether (100 cm^3). After stirring for 1 h the resulting orange solution was added dropwise to a solution of $ClSiMe_3$ (13 cm^3, 0.102 mol) in ether (100 cm^3). After stirring for 30 min the precipitated LiCl was removed by filtration, the solvent was removed by vacuum at 0°C and the product was distilled under reduced pressure (20°C/10^{-2} Torr). Yield: 12 g (71%). ^1H NMR (C_6D_6): δ 0.05 (s, 9H, Si*Me*$_3$), 2.20 (s, 2H, C*H*$_2$SiMe$_3$), 6.7 (m, 2H, 3,5-Ar*H*), 7.15 (m, 1H, 4-Ar*H*), 8.45 (m, 1H, 6Ar*H*).

Bis(trimethylsilyl)methylpyridine[22]

A solution of Bu^nLi (80 cm^3, 0.204 mol) and tmeda (30 cm^3, 0.2 mol) in ether (30 cm^3) was added to an ice-cold solution of 2-methylpyridine (10 cm^3, 0.102 mol) in ether (100 cm^3). After stirring for 1 h a solution of $ClSiMe_3$ (26 cm^3, 0.2 mol) in ether (60 cm^3) was added to the resulting orange solution. This mixture was stirred for 2 h, the precipitated LiCl removed by filtration, the solvent removed by vacuum at room temperature and the residue distilled under reduced pressure (65–70°C/10^{-2} Torr). Yield: 15 g (63%). ^1H NMR (C_6D_6): δ 0.15 [s, 18H, (Si*Me*$_3$)$_2$], 1.72 [s, 1H, C*H*(SiMe$_3$)$_2$], 6.60 (m, 2H, 3,5-Ar*H*), 7.10 (m, 1H, 4-Ar*H*), 8.45 (m, 1H, 6-Ar*H*).

2-*Methyl-6-bis(trimethylsilyl)methylpyridine* (IV)

$ClSiMe_3$ (22 cm^3, 0.17 mol) was added to the orange solution formed by the addition of Bu^nLi (63 cm^3, 0.17 mol) to an ice-cold solution of 2,6-dimethylpyridine (10 cm^3, 0.086 mol) and tmeda (26 cm^3, 0.17 mol) in ether (100 cm^3). The precipitated LiCl was removed by filtration and solvent removed by vacuum from the filtrate. The resulting colourless liquid was distilled under reduced pressure (85–90°C/10^{-2} Torr). ^1H NMR (C_6D_6): δ 0.12 [s, 18H, (Si*Me*$_3$)$_2$], 1.58 [s, 1H, C*H*(SiMe$_3$)$_2$], 2.32 (s, 3H, C*H*$_3$), 6.50 (m, 2H, 3,5-Ar*H*), 7.10 (m, 1H, 6-Ar*H*).

2-*Bis(trimethylsilyl)methyl-6-trimethylsilylmethylpyridine*(VII)

A solution of Bu^nLi (5.7 cm^3, 0.015 mol) and tmeda (1.8 cm^3, 0.015 mol) in ether (50 cm^3) was added to a solution of 2-methyl-6-bis(trimethysilyl)methylpyridine (5 cm^3, 0.015 mol) in ether (100 cm^3). $ClSiMe_3$ (1.9 cm^3, 0.015 mol) was added to the resulting solution, the precipitated LiCl removed by filtration, the solvent removed by vacuum and the product distilled under reduced pressure (100°C/10^{-2} Torr) as a colourless liquid. ^1H NMR (C_6D_6): δ 0.15 [s, 18H, (Si*Me*$_3$)$_2$], 0.30 (s, 9H, Si*Me*$_3$), 1.70 [s, 1H, C*H*(SiMe$_3$)$_2$], 2.27 (s, 2H, C*H*$_2$SiMe$_3$), 6.5 (m, 2H, 3,5-Ar*H*), 7.00 (m, 1H, 4-Ar*H*).

$Li(mp)(OEt_2)_n$, $Li_2(btsmp)_2$ *and* $Li_2(tsmp)_2(OEt_2)_2$

All these were prepared by the literature method[22] by the reaction of Bu^nLi with the respective ligands in ether. These lithium derivatives can be used in other reactions without further purification or isolation and appeared to form quantitatively.

[2-Me-6-C(SiMe$_3$)$_2$C$_5$H$_3$N]Li(tmeda) (V)

Bu^nLi (7 cm^3, 0.019 mol) was added to an ice-cold solution of 2-methyl-6-bis(trimethylsilyl)methylpyridine (8 cm^3, 0.019 mol) and tmeda (3 cm^3, 0.02 mol). After being stirred for 1 h the solvent was removed from the orange solution

by vacuum and the orange oil was recrystallized from pentane at −70°C to give the product as orange prisms. Yield: 4.4 g (61%). ^{1}H NMR (C_6D_6): δ 0.49 [s, 18H, (SiMe_3)$_2$], 1.70 (s, 4H, NCH_2), 1.85 (s, 12H, NMe_2), 2.15 (s, 3H, ArCH_3), 6.20 (m, 1H, 4-ArH), 6.90 (m, 2H, 3,5-ArH).

[2-CHSiMe$_3$-6-CH(SiMe$_3$)$_2$C$_5$H$_3$N]Li(tmeda) (**VIIIa**)

Bu^{n}Li (7.8 cm^3, 0.021 mol) was added to a solution of 2-bis(trimethylsilyl)methyl-6-trimethylsilylmethylpyridine (8 cm^3, 0.021 mol) and tmeda (3.2 cm^3, 0.02 mol) in pentane (30 cm^3). After being stirred for 1 h the solvent was removed by vacuum and the resulting orange oil was recrystallized from pentane at −70°C as orange prisms. ^{1}H NMR (C_6D_6): δ 0.37 (s, 9H, SiMe_3), 0.52 [s, br, 18H, (SiMe_3)$_2$], 1.85 [s, *ca* 8H, NCH_2+CH(SiMe$_3$)$_2$+CHSiMe$_3$], 2.05 (s, 12H, NMe_2), 5.85 (m, 2H, 3,5-ArH), 6.85 (m, 1H, 4-ArH). ^{13}C NMR (C_7D_8): δ 3.39 (q, SiMe_3), 7.64 [q, (SiMe_3)$_2$], 47.02 (q, NMe_2), 49.73 [d, CH(SiMe$_3$)$_2$], 57.99 (t, NCH$_2$), 100.89 (d, Ar), 105.69 (d, *Ar*), 136.09 (d, *Ar*), 169.5 (s, *Ar*).

Bis[*C,N*-2-*pyridylbis*(*trimethylsilyl*)*methyl*]*nickel*(II), [Ni(btsmp)$_2$]

Triethylphosphine (5 cm^3, 0.034 mol, > 4 equivalents) was added to a suspension of NiCl$_2$ (1.0 g, 7.71 mmol) in ether (50 cm^3) and stirred for 2 h. A solution of [Li$_2$(btsmp)$_2$] (7.75 mmol) in ether (40 cm^3) was then added over 2 h and stirring continued for 15 min. The dark precipitate produced was removed by filtration and the solvent removed from the filtrate by vacuum pumping to give a sticky red solid. This was redissolved in toluene (5 cm^3). This solution can now be handled in air. The solution in toluene was washed twice with water (10 cm^3) and chromatographed on Spence alumina, eluting with pentane. All the red fractions were combined, the solvent removed and the red solid recrystallized from pentane at −25°C to give twinned crystals of the product. Yield: 0.17 g (5%); m.p. 154–157°C. Found: C, 53.4; H, 8.7; N, 4.9. Calc. for $C_{24}H_{20}N_2NiSi_4$: C, 54.2; H, 8.4; N, 5.3%. IR: 2926s, 2855s, 1586s, 1558w, 1458s, 1425s, 1248s, 1212s, 1148m, 1103w, 1027w, 962w, 923s, 895s, 870m, 829s, 752m, 681w, 656s. MS: 530.1992 [20.6%, Ni(btsmp)$_2$ {calc. 530.1937}]; 294.1 [20%, Ni(btsmp)]; 222.1 (21.8%, btsmp—CH$_3$]; 73.04 [100%, SiMe$_3$]. ^{1}H NMR (C_6D_6): δ 0.52 (s, 18H, SiMe_3), 6.08 (m, 1H, 5-ArH), 6.62 (m, 1H, 3-ArH), 6.81 (m, 1H, 4-ArH), 7.62 (m, 1H, 6-ArH). ^{13}C NMR (C_7D_8): δ 4.096 (SiMe_3), 30.88 [C(SiMe$_3$)$_2$], 117.68, 125.57, 136.46, 149.10 (3,4,5,6-aromatics), 179.64 (2-Ar).

2-*Bis*(*trimethylsilyl*)*methyl*-5-[2-*pyridylbis*(*trimethylsilyl*)*methyl*]*pyridine* (**IX**)

The procedure of the synthesis of [Ni(btsmp)$_2$] was followed for the reaction of PEt$_3$, NiCl$_2$ and [Li$_2$(btsmp)$_2$]. After this mixture had been stirred for 15 h at room temperature the dark precipitate was removed by filtration and the solvent removed by vacuum. The sticky red solid was heated in vacuum to 60°C to remove excess PEt$_3$. The remaining solid was carefully sublimed (150°C/10^{-2} Torr), giving a colourless crystalline product which could be purified from the red impurity by repeated sublimation, but giving only small yields. ^{1}H NMR (C_6D_6): δ 0.21 [s, 18H, (SiMe_3)$_2$], 0.26 [s, 18H, (SiMe_3)$_2$], 1.78 [s, 1H, CH(SiMe$_3$)$_2$], 6.52 (m, 1H, ArH), 6.65 (m, 1H, ArH), 6.88–6.97 (m, 2H, ArH), 7.25 (m, 1H, ArH), 8.35 (m, 1H, ArH), 8.65 (m, 1H, ArH).

Acknowledgement—We thank Mr G. Coumbarides for NMR spectra and the Science and Engineering Research Council (U.K.) for a research studentship to K.J.I.

(*Received* 10 *February* 1993; *accepted* 5 *March* 1993)

Abstract—The reaction of the ethanol solvated strontium ethoxide [Sr(OEt)$_2$(EtOH)$_4$]$_\infty$ with the β-diketonate thd-H in the presence of tetraglyme in hexane at ambient temperature yields [Sr(thd)$_2$(tetraglyme)] (**1**); while the analogous reaction of the *in situ* prepared [Sr(tfa)$_2$]$_\infty$ and triglyme produces [Sr(tfa)$_2$(triglyme)] (**2**). Reaction of [Sr(Ph$_2$acac)$_2$]$_\infty$ with tetraglyme yields [Sr(Ph$_2$acac)$_2$(tetraglyme)] (**3**). The corresponding barium complex [Ba(OEt)$_2$(EtOH)$_4$]$_\infty$ also reacts rapidly with thd-H and tetraglyme in hexane to yield the glyme-chelated monomeric complex [Ba(thd)$_2$(tetraglyme)] (**4**). These complexes are all monomeric and have been characterized by IR, ^{1}H and ^{13}C NMR spectroscopy, microanalysis, mass spectrometry, and in selected cases TGA and DSC. The X-ray structures of [Sr(Ph$_2$acac)$_2$(tetraglyme)] (**3**) and [Ba(thd)$_2$(tetraglyme)] (**4**) reveal that they are monomeric with similar nine-coordinate metal centres. The tetraglyme coordinates via all its available oxygen atoms which wrap in a meridional plane and the two β-diketonates are positioned on either side of this plane.

In the course of our research on alkaline earth metal chemistry directed towards volatile single source CVD precursors we have encountered a wide range of problems using the bulk metals as starting materials to a range of metal alkoxides or aryloxides.[1] Notable difficulties encountered include contamination of the metal surfaces by either hydroxide or oxide groups, which has frequently resulted in the incorporation of hydroxo or oxo groups into the end products. A further limitation has been passivation of the metal surface, which has often resulted in poor reproducibility of reactions. These problems have hindered the growth of the chemistry of the heavier metals of Group IIA, although seminal contributions have been made previously by Grignard, Beckman, Gilman, Bradley and Coates.[2] We have previously noted that cleavage of a range of organic ligands by alkaline non-aqueous solutions of these metals may occur, i.e. P—N cleavage of HMPA, C—O cleavage of THF and C—O scission of Bu^{t}OH.[1,3]

Given the above difficulties, a range of approaches has been used to overcome the inherent limitations of the bulk metal metallation route. Several strategies have recently been used; notable amongst these has been the use of metathesis, especially in the area of metal cyclopentadienyl complexes, which has only one drawback, i.e. the formation of "ate" complexes.[4] Other researchers active in

* Authors to whom correspondence should be addressed.

this area have used high-temperature metal vaporization techniques, pioneered by Green and Timms in the 1970s.[5] Less esoteric techniques have involved the use of metal trialkylsilylamido compounds [e.g. $Ba(N\{SiMe_3\}_2)_2(THF)_2$] prepared via transmetallation, using either mercury[6] or tin organometallic reagents.[7] This is an excellent route and the only small drawback is the additional cost/time in preparing the mercury or tin amide starting materials.

An alternative approach uses a mixed ammoniacal-organic solvent route, which has achieved a considerable degree of success. This is a remarkably low cost route, having one disadvantage, which is the tendency of bond cleavage reactions to occur as outlined above.[8]

Given the above state of the art we have sought to define the basic criteria that are essential for group IIA organometallic reagents.[9] Firstly, the materials should preferably be crystalline solids of known stoichiometry, which are hydrocarbon soluble (and not amorphous/insoluble polymeric solids). Secondly, they should have good thermal stability and be stable over extended periods (i.e. 3–6 months shelf-life) in a controlled atmosphere (e.g. a nitrogen or argon filled glove-box); and finally these reagents should be reactive enough that most reactions occur at or near ambient temperature. This last point effectively implies that they are low molecular weight species.

We have recently observed that the group IIA tetra-solvated metal ethoxides are suitable materials, which fulfil the fundamental criteria outlined above. These heavier alkaline earth (A.E.) ethoxides, $[M(OEt)_2(HOEt)_4]_\infty$ (M = Ca, Sr or Ba), are hydrocarbon-soluble crystalline sources of these metals.[10] These materials are proving to have an enormous versatility as organometallic A.E. precursors. Previously we have observed a facile reaction between these metal ethoxides and a range of β-diketonates in hexane at room temperature,[11] analogous to the work of Bradley *et al.*[12] on transition metal complexes.

The use of metal alkoxides or alternatively β-diketonates as organometallic chemical vapour deposition (OMCVD) precursors for metal oxides is a field of immense interest, due to their potential applications in the area of electroceramics. Prior researchers have extensively used either tetramethyl-heptane-2,4-dionato or hexafluoro-pentane-2,4-dionato-alkaline earth salts, but *such materials have been found to be not only highly dependent on their synthesis but also on their "later history".* Specific examples include $[Ba(thd)_2]_\infty$, which when prepared by an aqueous solvent route was found to actually be $[Ba_5(OH)(thd)_9(H_2O)_3]$,[13] while the more volatile hexafluoro-pentane 2,4-dionato salts available commercially have also been shown to be hydrated species, e.g. $[Ba(hfa)_2(H_2O)]_\infty$.[14]

A notable feature of complexes of the group IIA metals is their strong Lewis acidity, which ensures that in the absence of Lewis base solvents they *generally form polymeric insoluble materials.* However, on the addition of Lewis base solvents to group IIA organometallics the polymeric ensembles are cleaved to yield simpler molecular species.[1] A wide variety of molecular geometries are available, provided that judicious choice of hydrocarbyl ligands (or other organic substrates) and/or Lewis bases are used to achieve coordinative saturation of the large M^{2+} cations, to reduce potential polymerization processes. For such a strategy a precedent is available, with the prior use of macrocyclic ligands, e.g. crown ethers and cryptands.[15]

We now demonstrate that the oligomeric group IIA metal β-diketonate complexes prepared *in situ*[12] react readily at room temperature in hexane with multidentate Lewis bases (e.g. glymes) to yield monomeric air- and moisture-stable products.

EXPERIMENTAL

General procedures

All manipulations were carried out under dry (molecular sieves) nitrogen using standard dry-box and Schlenk techniques. All hydrocarbon solvents were rigorously pre-dried and then distilled first over calcium oxide and then over sodium metal by standard techniques. Elemental analyses were performed by the microanalytical department of the Department of Chemistry, Imperial College. The melting points were measured under argon in sealed capillaries and are uncorrected values.

Instrumentation

IR spectra were recorded on a Perkin–Elmer FTIR 1720 spectrometer as either Nujol or hexachlorobutadiene mulls between 25 × 4 mm KBr plates. The samples were protected from the atmosphere by an O-ring-sealed Presslok holder.

Mass spectra were run on a Kratos MS30 spectrometer using the instrument in electron impact positive mode at the Royal School of Pharmacy Mass Spec. Service, University of London.

NMR spectra were recorded on a Jeol GS 270 MHz NMR spectrometer, using the protio impurities of the deuterated solvent as a reference for ^1H spectra and the ^{13}C resonance of the solvent as a reference for ^{13}C spectra. Chemical shifts were also independently referenced to tetramethylsilane (*ca*

1%) added by volume. All chemical shifts are reported positive to high frequency of the standard.

Controlled thermal analysis of the complexes was investigated using a Polymer Laboratories 1500H simultaneous thermal analyser, controlled by an Omni Pro 486DX-33 PC connected to a Rioch 1200 Laser printer. The weight of the samples investigated was between 10 and 25 mg. The measurements were performed in alumina crucibles under an atmosphere of flowing dry nitrogen gas (25 cm^3 min^{-1}), using heating rates of 5°C min^{-1}.

Starting materials

Strontium and barium metal (as either granules or chunks) were purchased from Alfa–Ventron Chemicals and stored in an inert atmosphere glove-box. 2,2,6,6-Tetramethyl-3,5-heptanedione, trifluoroacetylacetone and tetraglyme were both obtained from Inorgtech of Mildenhall, Suffolk, U.K. Nujol and hexachlorobutadiene were obtained from Aldrich and dried over 4 A molecular sieves prior to use. The complexes $[Sr(OEt)_2(EtOH)_4]_\infty$ and $[Ba(OEt)_2(EtOH)_4]_\infty$ were prepared by literature routes.[11]

All of the complexes described here are air- and moisture-stable, but were routinely prepared under dry argon using thoroughly degassed and dry solvents.

CAUTION: Both strontium and barium metals and their respective solutions are toxic, with low LDA values, and must be handled with considerable care. For safest handling, fume cupboards with adequate ventilation rates are recommended.

Synthesis of $[Sr(thd)_2(tetraglyme)]$ (**1**)

$[Sr(OEt)_2(EtOH)_4]$ (2.72 g, 8.13 mmol) was weighed into a Schlenk tube and n-hexane (25 cm^3) added. To the resulting clear solution was added thd-H (3.46 cm^3, 16.25 mmol) and the reaction mixture left to stir for 5 min; tetraglyme (1.96 cm^3, 8.13 mmol) was then added and the reaction left for a further 10 min. The solvent and liberated ethanol were then removed *in vacuo* to yield a waxy solid, which was redissolved in hot n-hexane (20 cm^3) and stored at −25°C. Crystals were obtained over a period of 3 days. Yield 4.1 g, 66% based on strontium ethoxide; m.p. 56–60°C. Found: C, 56.6; H, 9.1. Calc. for $SrO_9C_{32}H_{60}$: C, 56.8; H, 9.2%. IR (Nujol, ν cm^{-1}): 1591(s), 1532(s), 1502(s) 1222(s), 1179(m), 1081(m), 1025(m), 952(s), 874(s), 855(m), 840(m), 788(m), 745(s), 729(s), 592(w), 469(w). IR (hexachlorobutadiene, ν cm^{-1}): 2969(s), 1505(s), 1452(s), 1425(s), 1356(s), 1272(m), 1224(s), 1104(s), 1068(m), 1012(m), 748(m), 731(m), 591(w). ^1H NMR (270 MHz, C_6D_6, 20°C): δ 1.24 (36H, s, Me), 3.10 (6H, s, OCH_3), 3.21 (4H, m, OCH_2 b), 3.24 (4H, m, OCH_2 a), 3.36 (4H, s, OCH_2 c), 3.39 (4H, s, OCH_2 d), 5.70 (2H, s, CH). $^{13}C\{^1H\}$ NMR (67.94 MHz, C_6D_6, 20°C): δ 28.81 (s, Me), 40.67 (s, CMe_3), 58.82 (s, OMe), 69.92 (s, OCH_2 b), 69.97 (s, OCH_2 a), 70.13 (s, OCH_2 c), 71.64 (s, OCH_2 d), 86.90 (s, H), 196.53 (s, CO). Mass spectrometry (electron impact positive ion): 725 $[Sr_2(thd)_3]$, 677 [Sr(thd)(tetraglyme)], 454 $[Sr(thd)_2]$, 397 [Sr(thd)(Bu^{t}COCHCOH)], 271 [Sr(thd)].

Synthesis of $[Sr(tfa)_2(triglyme)]$ (**2**)

Reacting $[Sr(OEt)_2(EtOH)_4]$ (2.15 g, 6.40 mmol) in n-hexane (20 cm^3) with tfa-H (1.55 cm^3, 12.78 mmol) and triglyme (1.21 cm^3, 6.40 mmol), in the same way as for **1**, yielded a pale orange solid, which was redissolved in hot toluene (20 cm^3) and left to crystallize at −20°C. Yield 2.2 g, 63.9% based on strontium ethoxide; m.p. 73–75°C. Found: C, 37.9; H, 4.7. Calc. for $SrO_8C_{18}F_6H_{26}$: C, 37.8; H, 4.5%. IR (Nujol, ν cm^{-1}): 1638(m), 1512(s), 1268(s), 1208(m), 1130(s), 948(s), 873(s), 852(m), 841(m), 764(m), 722(s). IR (hexachlorobutadiene, ν cm^{-1}): 2925(s), 1508(s), 1467(s), 1356(s), 1282(m), 1021(m), 765(m), 722(m), 549(w). ^1H NMR (270 MHz, C_6D_6, 20°C): δ 1.82 (36H, s, Me), 3.05 (6H, s, OCH_3), 2.96 (4H, m, OCH_2 b), 3.12 (4H, m, OCH_2 a), 3.21 (4H, s, OCH_2 c), 5.76 (2H, s, CH). $^{13}C\{^1H\}$ NMR (67.94 MHz, C_6D_6 20°C): δ 28.89 (s, Me), 58.83 (s, OMe), 68.98 (s, OCH_2 b), 69.31 (s, OCH_2 a), 70.73 (s, OCH_2 c), 93.26 (s, CH), 122.17 (q, CF_3, $^1J = 297$ Hz), 169.15 (q, CO, $^2J = 29$ Hz), 195.06 (s, CO). Mass spectrometry (electron impact positive ion): 572 $[Sr(tfa)_2(triglyme)]$, 397 [Sr(tfa)(triglyme)], 241 [Sr(tfa)].

Synthesis of $[Sr(Ph_2acac)_2(tetraglyme)]\cdot 0.5C_7H_8$ (**3**)

The complex was prepared by reacting [Sr(OEt)$_2$(EtOH)$_4$] (2.51 g, 6745 mmol) in $CHCl_3$ (20 cm^3) with Ph_2acac-H (3.34 cm^3, 14.92 mmol) and tetraglyme (1.64 cm^3, 7.46 mmol), in the same manner as for **1**. The yield is quantitative and the crystals were isolated in the atmosphere. M.p. 96–98°C. Found: C, 63.8; H, 6.1. Calc. for $SrO_9C_{43.5}H_{48}$: C, 63.5; H, 5.8%. IR (Nujol, ν cm^{-1}): 1620(s), 1582(s), 1512(s), 1324(s), 1222(s), 1108(m), 935(s), 870(s), 733(s), 580(w), 513(w). X-ray determinations of **3** *and* **4**

As the precise nature of the complexes could not be fully elucidated by spectroscopic investigations, X-ray single-crystal structural studies were undertaken for complexes **3** and **4** to unambiguously characterize these species and also to determine the disposition and coordination modes of the ligands.

The unit cell and intensity data were obtained at 150 K using a Delft-Instruments FAST TV area detector diffractometer and graphite monochromated Mo-K_α radiation at $\lambda = 0.71069$ Å, following previously described procedures.[16] The data were corrected for Lorentz and polarization effects and also for absorption.[17] The crystal data and details of data collection and structure refinement are presented in Table 1. The structures were solved via direct (compound **3**) and Patterson methods (compound **4**) and refined by full-matrix least-squares using the SHELX program system.[18] The non-hydrogen atoms were refined anisotropically.

For **3** the methyl hydrogens on the tetraglyme were located from the difference map and included in the calculation of F_c; the methylene hydrogens on the tetraglyme and those on the Ph_2acac groups were allowed to ride on their parents in calculated positions (C—H = 0.96 Å); a common U_{iso} was refined for all hydrogens; the hydrogens on the disordered toluene were ignored.

For **4** the CH and CH_2 hydrogens were included in the idealized positions with a common U_{iso} value, but the methyl hydrogens were ignored. The methyl carbon atoms of one tert-butyl group were refined in two orientationally disordered tetrahedra with occupancies of 0.6 and 0.4.

Selected bond lengths, angles and other geometry parameters for **3** and **4** are given in Tables 1, 2, 3 and 4, respectively. Atomic coordinates, displacement factor coefficients, full lists of bond lengths and angles and F_o/F_c values have been deposited as supplementary data with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data centre.

RESULTS

Synthesis

The reaction of the pre-formed metal ethoxides[10] $[M(OEt)_2(EtOH)_4]_\infty$ of the heavier alkaline earth metals, Sr and Ba, with tetramethylheptane-2,4-dione in hexane has been previously shown by us to yield the homoleptic aggregates, $[M(thd)_2]_\infty$, as shown in eq. (1).[11]

$$[M(OEt)_2(EtOH)_4]_\infty + 2\beta\text{-diket-H} \longrightarrow [M(\beta\text{-diket})_2]_\infty + 6EtOH \quad (1)$$

(M = Ca, Sr or Ba; β-diket = acac, Ph_2acac, tfa, hfa and thd).

These materials are highly sensitive to moisture, heat and the presence of external Lewis bases (e.g. H_2O or NH_3); given these shortcomings, we have sought to eliminate these handling problems.[19] We have investigated the reaction of the homoleptic group IIA β-diketonates with chelating O-donor Lewis base ligands, relying on the chelate effect to achieve our objective.

The *in situ* reaction of the "pre-formed" A.E. metal β-diketonates with O-donor glyme ligands (defined as L-L) has been found to yield monomeric air-stable products in *ca* 10 min at ambient temperature, as shown in eq. (2). These ligands are

exceptionally versatile, being non-toxic, cheap and easy to handle.

$$[M(\beta\text{-diketonate})_2]_\infty + \text{L-L} \longrightarrow [M(\beta\text{-diketonate})_2)\text{L-L})] \quad (2)$$

A wide variety of complexes may be made by this route and we have selected several examples to illustrate this strategy. The reaction of $[Sr(OEt)_2(EtOH)_4]_\infty$ with a range of β-diketonates in the presence of a glyme ligand yields $[Sr(thd)_2$(tetraglyme)] (**1**); with $[Sr(tfa)_2]_\infty$ this yields $[Sr(tfa)_2$(triglyme)] (**2**) and also $[Sr(Ph_2acac)_2$(tetraglyme)] (**3**). The related complex $[Ba(OEt)_2(EtOH)_4]_\infty$ reacts with thd-H and tetraglyme to yield the species $[Ba(thd)_2$(tetraglyme)] (**4**). All of the complexes are obtained as crystalline solids in greater than 65% yield on crystallization as air- and moisture-stable materials.

This synthetic strategy may be contrasted with other routes to alkaline earth metal β-diketonates. Purdy *et al.* have used the bulk metal as the starting source of the A.E. metal β-diketonates with the ligand suspended in thf and the reaction mixture refluxed for a period of several days, which results in poor to low yields of products being obtained.[20] Other researchers have recently used the well-known metal hydroxide route, e.g. $[Ba(OH)_2 \cdot 8(H_2O)]$ and thd-H, to yield the pentameric hydrated cluster $Ba_5(OH)(thd)_9(H_2O)_3$[13] and also separately with hfa-H the oligomeric complex $[Ba(hfa)_2(H_2O)]_\infty$ is obtained.[12] Since both of these barium complexes contain coordinated water, they consequently have poor mass transport properties and volatility. Finally, recent reports have mentioned the use of $BaCO_3$ as a barium source and its reaction with the highly acidic ligand hfa-H in EtOH to yield hydrated metal β-diketonates stabilized by crown ethers.[21] Commercial sources of these materials (e.g. Strem Chemicals) have

also been shown to be hydrated materials, e.g. $[Ca(hfa)_2(H_2O)_2]_2$.[14]

When more stringent precautions are used the Lewis base solvated complexes $[Ba_2(thd)_4(L)_2]$ ($L = Et_2O$,[22] NH_3[23]) may be prepared. The materials reported here have an important advantage over the majority of the previous routes, that they yield *reproducible anhydrous products*, provided of course that anaerobic techniques are used. Most importantly reaction stoichiometry may be precisely controlled, which is not possible with the use of the commercial Group IIA metal hydrides, which are notoriously unreliable, since their metallation reactivity varies considerably from batch to batch.

If 2 equivalents or more of a glyme (e.g. triglyme or tetraglyme) are used in the preparations of complexes **1–4**, then generally an oily product results. This possibly implies that the complexes are highly soluble in an excess of the Lewis base, presumably forming more highly solvated species.

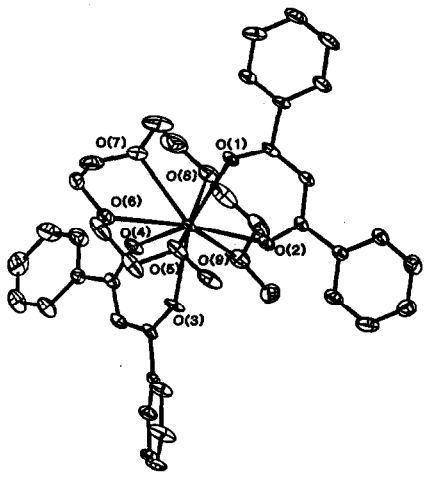

Fig. 1. Molecular structure of $[Sr(Ph_2acac)_2(tetraglyme)]$ (**3**) showing the atom numbering scheme. Hydrogen atoms have been omitted for clarity.

X-ray structures

The X-ray crystal structures of $[Sr(Ph_2acac)_2(tetraglyme)]\cdot 0.5(C_7H_8)$ (**3**) and $[Ba(thd)_2(tetraglyme)]$ (**4**) are shown in Figs 1 and 3, respectively. In both complexes the metal centres have a high coordination number, i.e. nine, although this is not excessive when compared with barium thiocyanate or β-diketonate complexes coordinated by crown or glyme ligands, e.g. $[Ba(hfa)_2(tetraglyme)]$.[24] In all of the above complexes the metals have very similar glyme ligand dispositions, with the O-donor ligand wrapped around the metal centre in a meridional plane and the two β-diketonates being positioned on either side of this plane.

The coordination geometry around the metal centres in complexes **3** and **4**, illustrated in Figs 2 and 4, is highly irregular and cannot be described in terms of any of the normal nine-coordinate polyhedra. However, it may be described as a distorted dodecahedron (eight-coordinate geometry)

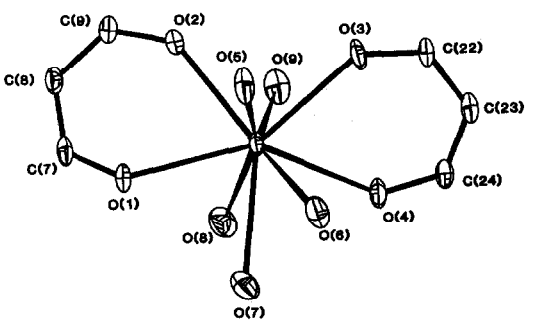

Fig. 2. The coordination polyhedron in $[Sr(Ph_2acac)_2(tetraglyme)]$ (**3**).

with an additional atom [O(7)] intruding on the O(6)···O(8) edge.

The metal–oxygen bonds in both structures fall into two discrete categories. In **3** the Sr—$O_{(thd)}$ bonds range from 2.500(6) to 2.540(6) Å, average 2.540(6) Å, and the Sr—$O_{(glyme)}$ distances vary from 2.708(6) to 2.791(7) Å, average 2.748(5) Å. Similarly, in **4** the Ba—$O_{(thd)}$ values range from 2.656(7) to 2.713(7) Å, with an average of 2.678(7) Å, and the Ba—$O_{(glyme)}$ distances range from 2.863(8) to 2.959(9) Å, with an average of 2.901(9) Å. The fact that the M—O bonds in **4** are *ca* 0.20 Å longer than the corresponding values in **3** is consistent with the atomic radius difference of barium and strontium. The Ba—O distances in **4** are also comparable with the corresponding values in $[Ba(hfa)_2(tetraglyme)]$,[24] $[Ba(hfa)_2(18\text{-crown-6})]$[25] and the dimeric complexes $[Ba(thd)_2(L)_2]_2$ (where L = Et_2O[22] and NH_3[23]). It may be noted in this context that variations in the M—O distances involving the β-diketonate and tetraglyme ligands appear to be a common phenomenon in alkaline earth metal complexes.

An interesting observation may be made about the influence of the β-diketonate substituents (e.g. CMe_3 or CF_3) on the relative strengths of the Ba—O bonds. For example, in $[Ba(hfa)_2(tetraglyme)]$[24] the Ba—O(β-diketonate) and Ba—O(tetraglyme) distances are 2.683(2)–2.713(2) Å, average

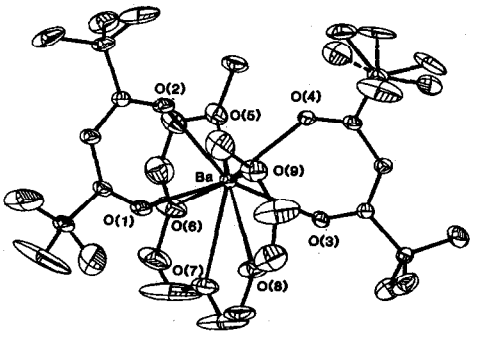

Fig. 3. Molecular structure of $[Ba(thd)_2(tetraglyme)]$ (**4**) showing the atom numbering scheme. Hydrogen atoms have been omitted for clarity. The t-butyl group [C(10)] is orientationally disordered between two tetrahedra, one indicated by solid lines (occupancy 0.6) and the other by dashed lines (occupancy 0.4).

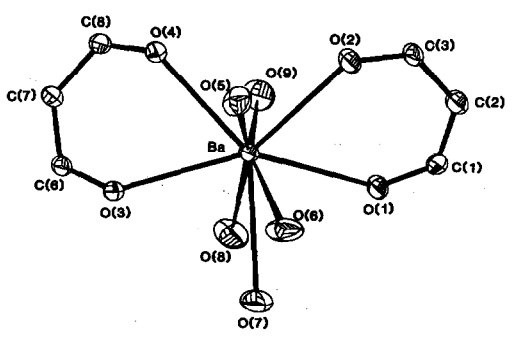

Fig. 4. The coordination polyhedron in $[Ba(thd)_2(tetraglyme)]$ (**4**).

2.703(2), and 2.809(2)–2.893(1), with an average of 2.857(2) Å, respectively. These values are respectively longer and shorter than the corresponding values in **4**. Although the differences are small (0.02–0.04 Å), the values seem to be real and may be correlated with the relative weakening of the Ba—$O_{(\beta\text{-diketonate})}$ bonds in the hfa derivatives due to the strong electron-withdrawing nature of the CF_3 substituents vs the strong electron-releasing nature of CMe_3 groups in **4** and the consequent relative strengthening of the Ba—$O_{(tetraglyme)}$ bonds in this compound.

The O—M—O chelate angles for the thd ligands of **4** are both 64.3(2) and those in the tetraglyme ligand fall within the narrow range 56.3(3)–58.3(3)°. These values are comparable with the corresponding values 63.9(2)°, 64.1(2)° and 56.8(2)–59.8(2)° in $[Ba(hfa)_2(tetraglyme)]$,[24] and seem to be mostly determined by the ligand geometry. The respective angles in the strontium complex (**3**) are similar and have values 76.6(2)°, 69.4(2)° and 57.9(2)–62.3(2)°.

The polyether ligands in these complexes bind to the metals via the chelate effect, to give a five pronged coordination mode. In both complexes the β-diketonates bind symmetrically to the metals; the metal centres lie very close to one OCCCO plane, while the other β-diketonate shows considerable fold about the O···O axis [12.0(2)° in **3** and 22.9(2)° in **4**]. These are probably caused by the steric requirements of the ligands around the metal centres. In **3** the phenyl rings are twisted relative to the OCCCO planes by 14.7(2)° and 31.2(2)° in one ligand and 14.1(2)° and 35.0(2)° in the other ligand. The polyether ligand adopts a conventional geometry with *gauche* and *anti* relationships around the C—C and C—O bonds, respectively.

Spectroscopic results

The formulation of these complexes as monomeric species is entirely consistent with the data acquired from IR, ^1H and ^{13}C NMR spectrocopy, mass spectrometer and microanalysis.

IR spectroscopic data

The IR spectra of complexes **1**–**4** show characteristic bands for the β-diketonates, with strong absorption bands in the region 1570–1635 cm^{-1} for C=O [in the parent thd-H ligand 1605 cm^{-1} C=O and 1500–1540 C=C]. These results may be contrasted with the IR spectra of the base-free complexes $[M(\beta\text{-diket})_2]_\infty$, where several bands are observed in the IR spectra, which is due to the differing coordination modes in their structures. Precise assignments of the different C=C and C=O modes is at present not possible since the bands are coupled.

The bands assigned as ν(C—O—C) in complexes **1**–**4** for the glyme ligands occur at slightly lower frequencies than the same peaks for the free ligands (either triglyme or tetraglyme), 1350–1360, 1270, 1220 and also at 1110±20 cm^{-1}. The shifts from the free ligand are *ca* 20 cm^{-1}, which is indicative of coordinated glyme ligands with relatively weak M—O ineractions.

NMR spectroscopic data

The most important features of both the ^1H and ^{13}C NMR spectra for complexes **1**–**4** are recorded in the Experimental. These spectroscopic data are in excellent accord with the reactions and structures described herein. There is no evidence of ethanol present in any of these complexes, from the starting complexes $[M(OEt)_2(EtOH)_4]_\infty$. The ^1H NMR spectra of all four complexes in d_6-benzene (see Experimental) show only a characteristic signal for one type of β-diketonate and glyme ligand environment at room temperature, which is also in accord with the solid state structures of complexes **3** and **4**. The integration ratio of β-diketonate to glyme ligand was observed to be 2 : 1. A shift downfield of the methylene signals in the glyme ligands is observed on coordination to the alkaline earth metal cations Ca, Sr and Ba. This effect has also been previously noted by other researchers using multidentate ligands.[15]

The ^{13}C NMR spectra have been assigned by direct comparison with both free ligands and the parent homoleptic complexes, $[M(\beta\text{-diketonate})_2]_\infty$. Signals due to the thd ligands in complexes **1** and **4** are observed at δ 28.8 (Me group), δ 40.6 (CMe_3 group) and a further singlet at δ 87.2±0.1 for the CH group. While the signals for the methyl and quarternary carbon have been shifted to lower field, those for the CH and CO are shifted to higher field with respect to the parent ligand thd-H. This effect has been observed previously and was ascribed to the formation of an electron-rich 1,3-diketonato chelating ring system. The electron density accumulates on the carbon atoms of the ring system (i.e. CH and CO), and this therefore results in electron withdrawal from the Bu^t groups and a resulting deshielding occurs.

The fluorinated β-diketonate complex $[Sr(tfa)_2$ (triglyme)] (**2**) shows additional features due to the CF_3 group, with both ^1J and ^2J coupling constants observed in the ^{13}C NMR spectrum of this

complex. The diphenylacac complex [Sr(Ph$_2$acac)$_2$(tetraglyme)] (**3**) has ^{1}H and ^{13}C NMR spectra in accord with its solid state structures.

Mass spectrometry

Mass spectroscopic data for complex **1** show not only the expected monomeric species. e.g. [Sr(thd)(tetraglyme)]$^+$ with *m/z* 677, but also *more intense peaks* due to [Sr$_2$(thd)$_3$] at 725. For this complex other intense peaks are observed at *m/z* 397 for [Sr(thd)(Bu^{t}COCHCO)]$^+$ and at *m/z* 271 for [Sr(thd)]$^+$. The related barium complex (**4**) also has a weak molecular ion, at *m/z* 629 for [Ba(thd)(Bu^{t}COCHCOH)(triglyme)]$^+$, and in a similar fashion to that of **1** shows more intense peaks due to oligomeric complexes, e.g. [Ba(thd)$_2$]$^+$ and [Ba(thd)]$^+$ with *m/z* 505 and 321, respectively. Cleavage of the thd ligand is also observed, with a peak at *m/z* of 127 corresponding to the fragment [Bu^{t}COCHCOH]$^+$.

Complex **2** reveals rather different behaviour to that of **1** and **2**, with a clear molecular ion being observed at 572 a.m.u. for [Sr(tfa)$_2$(triglyme)]$^+$, and then sequential loss of a tfa ligand to yield [Sr(tfa)(triglyme)]$^+$ at 397 a.m.u. and the lower clearly discernable molecular ion observed at 241 a.m.u. for [Sr(tfa)]$^+$. In contrast, complex **3** was not sufficiently volatile for a mass spectrum to be obtained.

The isotope patterns of the metal containing complexes are consistent with those which may be obtained from natural abundance patterns or by computer simulation. The *m/z* ratios which are given relate to the isotopes of greatest natural abundance, e.g. ^{88}Sr and ^{138}Ba.

These data imply that in the vapour state the two thd complexes readily dissociate to form the oligomeric donor-Lewis base free complexes, [M(thd)$_2$]$_\infty$. Such behaviour is important because as O-donor adducts we can now deliver these materials into the gas phase at *ca* 100°C lower than has previously been observed. While the corresponding strontium trifluoroacetylacetonate is far more stable in the vapour phase, the monomeric Lewis base-adducted complex evidently persists.

Physical properties

All of these complexes have extensive solubility in both aliphatic (except for **2** and **3**) and aromatic solvents and show appreciable solubility in coordinating solvents such as ethers (i.e. diethyl ether and thf) and DMSO. This pronounced solubility is undoubtedly due to the presence of both glyme and β-diketonate ligands chelating to the metal centre. These materials are all air- or moisture-stable and water coordination to these materials seems unlikely to occur.

The glyme stabilized complexes all have relatively low melting points (see Experimental) in the range 56–98°C at atmospheric pressure. This is a significant reduction in melting point when compared with their parent materials (e.g. [Sr(thd)$_2$]$_\infty$ 172–175, [Sr(tfa)$_2$]$_\infty$ dec. > 150 and [Ba(thd)$_2$]$_\infty$ 194–197°C). Sublimation studies are in accord with these results and also with our mass spectroscopic data; thus, complexes **1** and **3** decompose at *ca* 100°C and 10^{-3} torr to yield the unadducted thd complexes, while the strontium tfa complex (**2**) is stable and sublimes at 140–160°C and 10^{-3} torr. This difference in stability between thd and tfa complexes may possibly be ascribed to both steric and electronic effects due to the R-groups (i.e. Bu^t vs Me vs F$_3$C); thus, in the gas phase the binding of tetraglyme to the metal centre is considerably weakened when a thd ligand chelates. This is an important observation since we may thus use the adducted thd complexes of strontium and barium as low temperature sources of the parent thd complexes.

DSC/TGA data

Thermal gravimetric analysis has found extensive usage in both molecular and non-molecular chemistry, materials science and electronic engineering. This technique gives valuable information where a study of weight loss vs temperature may yield valuable information on thermal behaviour of materials over a wide temperature range. Differential scanning calorimetry allows the study of the entropy changes occurring during a controlled thermolysis and most importantly, whether a reaction is occurring (i.e. a phase change or melting point) or a chemical change (e.g. an irreversible decomposition). In our apparatus these two techniques are performed simultaneously.

Two complexes were selected as potentially suitable materials, these were [Sr(thd)$_2$(tetraglyme)] (**1**) and [Ba(thd)$_2$(tetraglyme)] (**4**).

The differential scanning calorimetry curve for complex **1** reveals a sharp reversible melting point endotherm at 75.38°C (−8.08 mcal mg^{-1}) and two other isotherms, the first at 215.48°C (−17.55 mcal mg^{-1}) and the second at 370.89°C (−6.85 mcal mg^{-1}). The first of these two isotherms is presumably due to loss of the glyme (see TGA discussion following) and the second is attributed to the end point of sublimation of the homoleptic [Sr(thd)$_2$]$_n$ material. The thermal gravimetric analysis curve of complex **1** has two steps (see Fig. 5), the

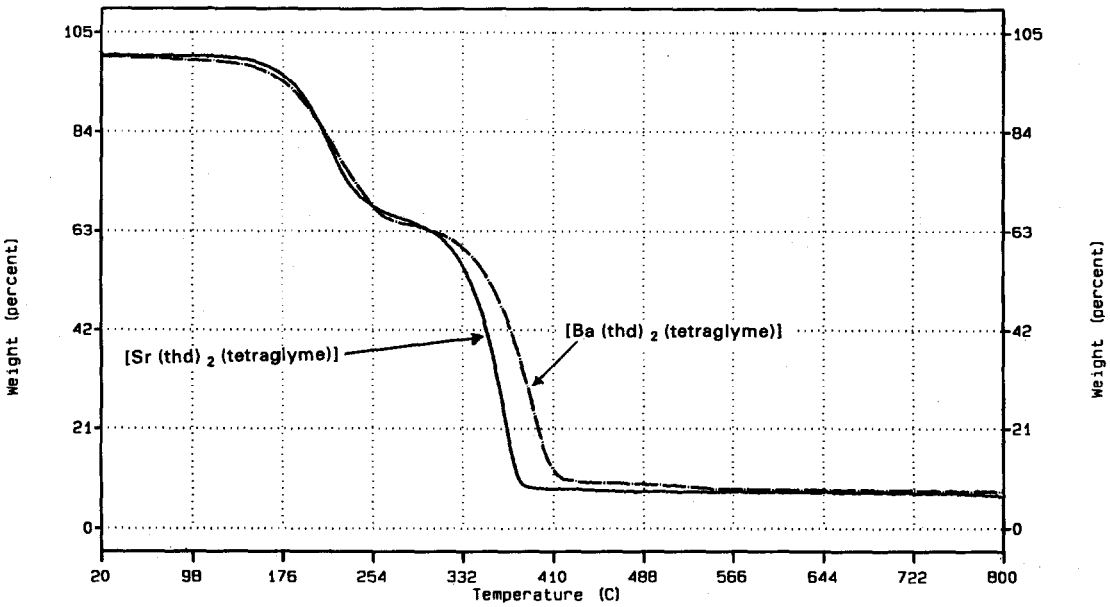

Fig. 5. Thermal gravimetric analysis of complexes **1** and **4**.

first starts at *ca* 150°C and is essentially complete by 260°C and represents the loss of the tetraglyme ligand (found 32.72%, expected 32.84%). This leaves the $[Sr(thd)_2]_n$ complex intact which sublimes intact between 250 and 382°C. A small amount of carbanceous solid remains (5.58%), which is probably due to some thermal decomposition of the thd ligand.

The barium complex (**4**) shows related behaviour in its DSC, with a sharp melting point at 103.8°C (-10.43 mcal mg^{-1}) and two further isotherms. The first of these is at 223.0°C (-20.12 mcal mg^{-1}) with the second at 396.6°C (-10.02 mcal mg^{-1}). The first of these two isotherms is attributed to the loss of the glyme and consequent structural change (see TGA discussion following), and the second at the end point of sublimation to the homoleptic $[Ba(thd)_2]_n$ compound. The TGA of complex **4** (see Fig. 5) is similar to that of **1** having two clearly defined steps (see Fig. 5), the first starts at *ca* 170°C and is essentially complete by 255°C and represents the loss of the tetraglyme ligand and also sublimation of the homoleptic compound $[Ba(thd)_2]_n$] (found 35.33%, expected 30.61%). This leaves $[Ba(thd)_2]_n$ remaining, which sublimes intact over the temperature range, *ca.* 250 to 410.7°C. A small amount of carbanaceous solid also remains (*ca* 6%).

The TGA data for these two complexes clearly reveal that these compounds do not sublime intact, which is in accord with our sublimation data. Yet they are important materials, since they are air- and moisture-stable precursors which will deliver the homoleptic thd complexes into the gas phase easily. Such materials are of importance if they can be obtained as liquids at or just above room temperature, and may then find application in bubblers for CVD work.

DISCUSSION

There have been considerable difficulties with the preparation of group IIA metal alkoxides and β-diketonates due to the continued unexpected appearance of either water, oxo or hydroxo ligands incorporated into the final products. Using a general synthetic strategy for complex **1**, we can switch not only β-diketonates, i.e. tfa to thd, but also donor chelating ligands, from triglyme to tetraglyme. We have thus explored the potential of using either strontium or barium β-diketonates as *in situ* prepared starting materials.[14] Such complexes have several pertinent properties; namely that they are readily obtainable as crystalline solids of known stoichiometry, soluble in hydrocarbons (both aliphatic or aromatic), stable in an inert atmosphere and are sufficiently reactive that most reactions occur at or slightly above room temperature.

The X-ray structural characterization of metal β-diketonates stabilized by a tetraglyme ligand has demonstrated that tailored synthetic strategies can and do work for the heavier metals of group IIA. It is our belief that this strategy has wide scope in developing the chemistry of the metallorganic complexes of this group, which have until recently

focused principally on the cyclopentadienyls and pentamethylcyclopentadienyls.[4]

There are several synthetic features that are important here: (i) this synthetic strategy of using a metal β-diketonate prepared *in situ* from a crystalline metal ethoxide is the first example for group IIA complexes and this leads to *anhydrous* complexes. (ii) The coordinative saturation of the hard acid metal centre by the multidentate Lewis base chelate and β-diketonate leads to *air- and moisture-stable* precursors of known stoichiometry and is thus highly flexible, since L-L may be varied. (iii) The designed synthesis of volatile discrete molecular alkaline earth metal organics is now possible without having to use large sterically hindered ligands, e.g. Ph_3CO^-, $OC_6H_2Bu^t_3$.

The use of such ligands will reduce the conventional problems of oligomerization and subsequent low volatility. We consider that an important requirement when designing A.E. molecule precursors is that sufficient coordinative saturation be incorporated into both ligand and Lewis base chelate, such that a low molecular mass volatile monomer will result. This approach of using a tailored synthetic rational for group IIA molecular precursors is currently being used for control of thin films by CVD, due to their high stability.

CONCLUSIONS

We postulate that for heavier alkaline earth complexes supported by O-chelates a coordination number of 7 appears to be the minimum required for such coordination complexes to be air- and moisture-stable. Data are rapidly accumulating to support this conjecture and a wide range of glyme/amine complexes of metal β-diketonates have been prepared, e.g. with L-L = diglyme, triglyme, tetraglyme, pentamethyldiethylenetriamine, hexamethyltriethylenetetramine, etc.

Careful design of such precursors should reap great benefit to not only the metal oxygen based chemistry, but one can envisage the use of these complexes as a template for further reactivity with either lithium organometallics, to yield stabilized alkaline earth organometallics, or other rare earth β-diketonates, to yield the as yet unexplored area of mixed metal β-diketonates.

Abstract—Interactions of $[PPh_4]_2[OsO_2Cl_4]$ and $[Bu^n{}_4N][OsNCl_4]$ with Li_2L [H_2L = 1,2-bis(*p*-toluenesulphonylamido)benzene] gave binuclear osmium(VI) compounds $(PPh_4)_2[Os_2O_4L_2(\mu\text{-}OH)_2]$ (**1**) and $Os_2N_2L_2(\mu\text{-}OH)_2$ (**2**), respectively. The structures of both compounds have been determined by X-ray crystallography. The crystal structure of the $[Os_2O_4L_2(\mu\text{-}OH)_2]^{2-}$ anion contains two *trans*-$OsO_2(L)$ units bridged by two OH groups; the Os—O(oxo) bond length is *ca* 1.74 Å. The crystal structure of **2** contains two OsN(L) units bridged by two OH groups; the Os—N(nitrido) bond length is *ca* 1.56 Å.

Multianionic chelating ligands are of current interest because they can stabilize metal ions in high oxidation states. High-valent metal complexes with deprotonated amido ligands, e.g. those of manganese(V),[1] iron(IV),[2] cobalt(IV),[3] nickel(III)[4] and copper(III),[5] are well documented. However, there are relatively few studies on complexes of sulphonyl amido groups. As the sulphonyl group is more electron-withdrawing than the carbonyl group one might expect that sulphonyl amido ligands can be deprotonated more readily and hence could display interesting coordination chemistry. To this end we set out to investigate the chemistry of complexes containing chelating sulphonyl amido ligands, e.g. bis-(toluenesulphonylamido)benzene (H_2L), as shown in Fig. 1. The unique features of the ligand H_2L are: (a) it is bidentate and dianionic; (b) it can stabilize highly oxidizing metal centres due to the strong σ-donating deprotonated sulphonyl amido groups; and (c) it is sterically bulky. Recently, the crystal structures of some copper complexes of H_2L have been described.[6] We herein report the synthesis and crystal structures of two osmium(VI) compounds of the ligand.

EXPERIMENTAL

The ligand H_2L,[6a] $[PPh_4]_2[OsO_2Cl_4]$[7] and $[Bu^n{}_4N][OsNCl_4]$[8] were prepared according to the literature procedures. Organic solvents were purified by standard methods and distilled before use. ^1H NMR spectra were recorded on a JEOL EX 400 spectrometer. Chemical shifts (δ) were reported referenced to $Si(CH_3)_4$. IR spectra (Nujol) were

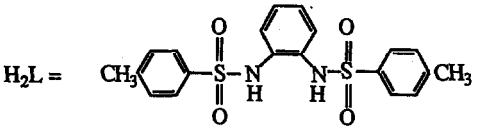

Fig. 1.

† Author to whom inquiries concerning X-ray crystallography should be addressed.

obtained on a Perkin–Elmer 1600 FT-IR spectrophotometer. Elemental analyses were performed by MEDAC Ltd (Middlesex, U.K.).

Preparation of $[PPh_4]_2[Os_2O_4L_2(\mu\text{-}OH)_2]$ (**1**)

To a suspension of H_2L (0.4 g, 0.96 mmol) in THF (20 cm^3) at −40°C was added 2 equivalents of Bu^nLi (*ca* 1.25 cm^3 of a 1.6 M solution in hexanes). The resulting mixture was warmed to room temperature and stirred for 1 h. To this solution was added $[PPh_4]_2[OsO_2Cl_4]$ (0.51 g, 0.5 mmol) under nitrogen and the reaction mixture was stirred at room temperature overnight. After the removal of volatiles the dark red residue was extracted with acetonitrile/ether. Slow evaporation of the extract at room temperature afforded red crystals, which were collected and washed with ether (yield 0.25 g). ^1H NMR (CD_3CN): 2.34 (s, 12H, *p*-CH_3), 5.96 (br, s, 2H, OH) and aromatic protons. IR (Nujol)/cm^{-1}: ν(O—H) 3437; ν(S=O) 1152, 1108; $\nu(OsO_2)$ 859. Found: C, 53.2; H, 4.0; N, 3.3%. Calc. for $[Os_2C_{88}H_{78}N_4O_{14}P_2S_4]$: C, 53.2; H, 4.0; N, 2.8%.

Preparation of $Os_2N_2L_2(\mu\text{-}OH)_2$ (**2**)

The lithium salt of H_2L was prepared as for $[Os_2O_4(\mu\text{-}OH)_2]^{2-}$. To a THF solution of Li_2L (prepared from 0.41 g H_2L and 1.25 cm^3 Bu^nLi) was added $[Bu^n_4N][OsNCl_4]$ (0.29 g, 0.5 mmol). The reaction mixture was stirred overnight and evaporated to dryness. The dark yellow residue was extracted with THF. Careful addition of hexane to the extract afforded the crude product, which was recrystallized from THF/ether/hexane to give yellow crystals (yield 0.2 g). ^1H NMR (CD_3CN): 2.29 (s, 6H, *p*-CH_3); 6.28, 6.83, 7.06, 7.81 (all broad singlets, 12H, aroamtic protons). IR (cm^{-1}): ν(O—H) 3450; ν(S=O) 1150, 1126; ν(OsN) 986. Found: C, 61.5; H, 5.5; N, 11.0. Calc. for $[Os_2C_{40}H_{38}N_6O_{10}S_4]$: C, 62.3; H, 4.9; N, 10.9%.

X-ray crystallography

Diffraction measurements were performed on an Enraf–Nonius CAD-4 diffractometer. Lattice parameters of **1** were obtained from 25 reflections with 2θ angles in the range 17.00–21.00°, whereas cell dimensions of complex **2** were determined from 25 reflections with 2θ angles in the range 11.06–20.40°. All reflections were collected for Lorentz, polarization and adsorption effects. All data reduction and refinement were performed using the NRCC-SPD-VAX packages. The structures were solved by direct methods and refined by full-matrix least-squares; all non-hydrogen atoms were refined with anisotropic thermal parameters. Both complexes **1** and **2** crystallize in the triclinic system with the space group $P\bar{1}$. Hydrogen atoms on the organic ligands were calculated in idealized positions and were included in the structure factor calculation. The combined data collection and refinements are given in Table 1. Selected bond lengths and angles for complexes **1** and **2** are given in Tables 2 and 3, respectively.

RESULTS AND DISCUSSION

Interaction of $[PPh_4]_2[OsO_2Cl_4]$ with 2 equivalents of the lithium salt of H_2L [H_2L = 1,2-bis(*p*-toluenesulphonylamido)benzene] in THF gave the air-stable binuclear hydroxo-bridged osmium(VI)-dioxo compound (**1**), isolated as its $[PPh_4]^+$ salt. A monomeric compound could not be obtained even when excess ligand was used, presumably because the ligand is too bulky for formation of a planar bischelate complex. The IR spectrum of **1** does not show any sharp N—H band, indicating that the sulphonyl amido group is in the deprotonated form. The broad band near 3470 cm^{-1} can be assigned to the ν(O—H) stretch. The Os=O stretch at 845 cm^{-1} is within the range expected for *trans*-OsO_2 compounds.

The binuclear structure of **1** was confirmed by an X-ray diffraction study. A diagram of the $[Os_2O_4L_2(\mu\text{-}OH)_2]^{2-}$ anion is shown in Fig. 2; selected bond lengths and angles are given in Table 2. The geometry around each osmium is best described as octahedral with the two oxo groups as axial ligands and L and two hydroxo groups as equatorial ligands. The two *trans*-OsO_2L units are bridged by the two hydroxo ligands with the Os—O(H)—Os′ bond angle of *ca* 108.7°. A similar structure has been observed for the binuclear oxo-bridged $Os_2O_6py_4$.[9] The Os—O(oxo) bond lengths (*ca* 1.74 Å) are normal by comparison with *trans*-osmium(VI)-dioxo compounds. The Os—N(sulphonyl amido) bond length of *ca* 2.03 Å is similar to that for Os—N(amido) found in a related osmium(VI)-nitrido compound of a tetradentate amido ligand.[10] Of note, the four toluenesulphonyl groups of the ligands adopt a "two-up–two-down" geometry.

Treatment of $[Bu^n_4N][OsNCl_4]$ with 2 equivalents of Li_2L gave the neutral dimeric osmium(VI)-nitrido compound **2**. Again, the steric bulk of the ligand L precludes the formation of the monomeric bischelate complex. The presence of the bridging hydroxo group is indicated by the broad IR band at 3450 cm^{-1}. The Os—N stretch at 986 cm^{-1} is

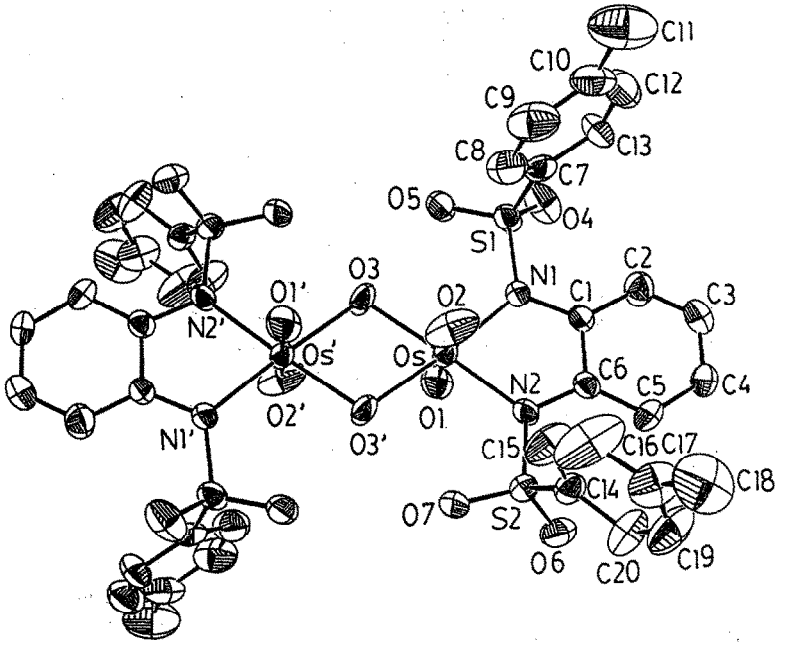

Fig. 2. A perspective view of the $[Os_2O_4L_2(\mu\text{-}OH)_2]^{2-}$ anion.

normal for nitrido compounds. The ^1H NMR spectrum of **2** is consistent with the solid-state structure.

The structure of **2** has been determined by X-ray crystallography. An ORTEP drawing of **2** is shown in Fig. 3 and selected bond lengths and angles are given in Table 3. The geometry around each osmium is square pyramidal with the nitrido group as an axial ligand. The two Os(N)L units are bridged by the two hydroxo ligands with the two nitrido ligands on the same side. The Os(1)—O(H)—Os(2) bond angle of 104.2° and Os—N(amido) bond length of 1.973 Å are similar to those for **1**. The Os—N(nitrido) bond length is normal for osmium(VI)-nitrido compounds.[11] It might be noted that this is the first structure of a binuclear osmium-nitrido compound.

The reactivity of these two osmium complexes is being studied.

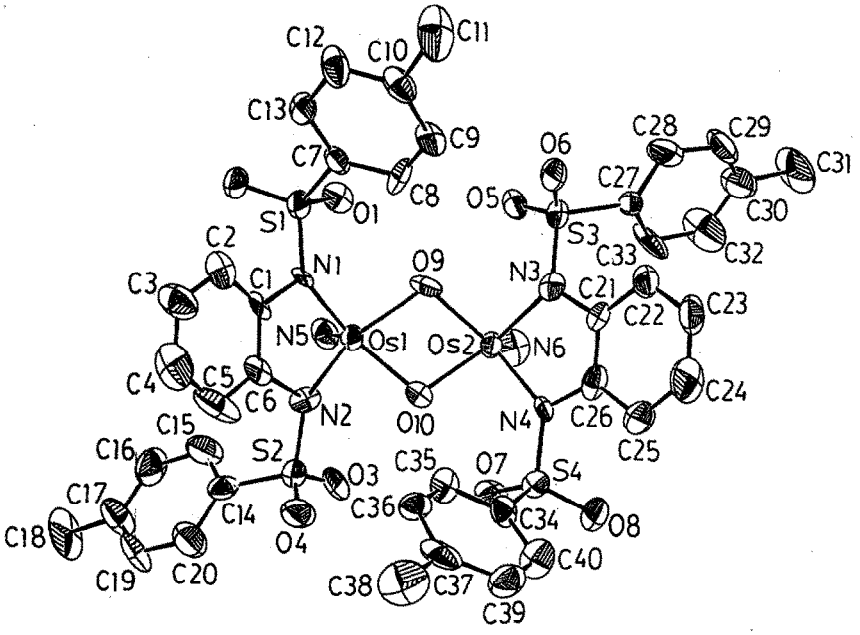

Fig. 3. A perspective view of **2**.

(*Received* 8 *February* 1993; *accepted* 5 *March* 1993)

Abstract—The heavier lanthanide nitrate complexes with dibenzo-24-crown-8 (DB24C8) have been prepared in acetonitrile. These new complexes with the general formula $[Ln(NO_3)_3(OH_2)_3]\cdot(DB24C8)$ (Ln = Gd–Lu) have been characterized by means of elemental analysis, IR spectra, ^1H NMR spectra and conductivity measurements. The crystal and molecular structure of $[Gd(NO_3)_3(OH_2)_3]\cdot(DB24C8)$ has been determined by single-crystal X-ray diffraction. The gadolinium(III) ion is coordinated to the six oxygen atoms of three bidentate nitrate groups and three water molecules. The crown ether molecule is hydrogen bonded to these three water molecules. The average Gd—O(nitrate) and Gd—O(water) distances are 2.464(4) and 2.388(3) Å, respectively. The average O(water)···O(crown ether) separation is 2.787 Å. The coordination polyhedron is a distorted tricapped trigonal prism.

A large number of lanthanide-crown ether complexes have been investigated and some have been studied by single-crystal X-ray diffraction methods.[1,2] Among these studies the lanthanide complexes with large cavity crown ethers were little reported.[3,4] In order to investigate the coordination power of large cavity crown ethers with these ions we synthesized a series of lanthanide complexes with large cavity crown ethers.[5–8] We found that the lanthanide isothiocyanates reacted with DB24C8, dicyclohexyl-24-crown-8 (DCH24C8) and dibenzo-30-crown-10 (DB30C10) to yield $RE(NCS)_3\cdot DB24C8\cdot 2H_2O\cdot CH_3CN$ (RE = La–Lu, Y),[5,6] $RE(NCS)_3\cdot(DCH24C8)\cdot nH_2O$ (RE = La–Er, Yb, Lu, Y, n = 1–3)[7] and $Ln(NCS)_3\cdot(DB30C10)\cdot nH_2O$ (Ln = La–Lu, n = 1–3),[8] in which the ligands are all directly coordinated to the metal ions. In order to investigate the influence of different inorganic anions on the coordination properties of crown ethers in complexes we recently synthesized the complexes of lanthanide nitrates with DB24C8 and studied their composition, properties and structures.

EXPERIMENTAL

Reagents

Hydrated lanthanide nitrates were prepared by dissolving Ln_2O_3 (AnalaR) in 1 : 1 nitric acid. The

* Author to whom correspondence should be addressed.

ligand was obtained from Shanghai Reagent Company and purified by recrystallization from ethanol before use; m.p. = 101.5–102.0°C. All other chemicals were AnalaR grade.

Chemical and physical measurements

The metal ion contents were determined by EDTA titration using xylenol orange as an indicator. Carbon, nitrogen and hydrogen contents were determined using a Carlo–Erba 1106 elemental analyser. The IR spectra were recorded in the 4000–200 cm^{-1} region using KBr pellets and a 170 SX FTIR spectrometer. The ^1H NMR spectra were recorded on a FT-80A spectrophotometer using acetone-d_6 as a solvent and TMS as an internal standard. Conductivity measurements were carried out with a DDS-11A type conductivity bridge for freshly prepared solutions in acetone at 25°C. The crystal data were collected on a R3M/E diffractometer by the $\theta/2\theta$ scan technique.

Preparation of the complexes

A solution of $Ln(NO_3)_3 \cdot nH_2O$ (Ln = Gd–Lu) (0.63 mmol) in acetonitrile (2 cm^3) was added dropwise to a solution of DB24C8 (0.3 mmol) in acetonitrile (2 cm^3). The mixture was stirred at room temperature for 36 h. The precipitated solid complexes was filtered, washed with ethyl acetate and dried in a desiccator (0.1 mm Hg) over P_4O_{10} for 2 days. All the complexes were powdered solids with the characteristic colour of the corresponding lanthanide nitrates.

Single crystals of the gadolinium complex were obtained by dissolving the powdered solid complex in nitromethane and leaving the solution in a desiccator over $CaCl_2$ at room temperature. After *ca* 1 month colourless crystals suitable for X-ray analysis formed from the solution.

Under the same preparation conditions we could not obtain the solid complexes when DB24C8 was reacted with the lighter lanthanide nitrates (La–Eu).

X-ray structure determination

The structure was solved by the Patterson method and subsequent difference-Fourier techniques and refined by full-matrix least-squares methods with anisotropic thermal factors for all non-hydrogen atoms. The crown ether hydrogen atoms were placed in calculated positions. All calculations were performed using the SHELXTL system of computer programs. The final values $R = 0.053$ and $Rw = 0.044$ were obtained. The crystal data are listed in Table 1.

RESULTS AND DISCUSSION

The composition of the complexes

The analytical data for these new complexes, listed in Table 2, indicate that they all conform to 1 : 1 stoichiometry of the metal ion to the crown ether.

IR spectra

The most important IR peaks of the ligand and the complexes are reported in Table 3.

Compared with those of the free ligand, the absorptions of ν(Ar—O—R) and ν(R—O—R) of the complexes showed small shifts towards lower wave numbers. This suggests that the ligand does not coordinate directly to the lanthanide(III) ion.[9]

In the IR spectra of the complexes the absorptions appearing in the 3239–3270, 1656–1664 and 569–578 cm^{-1} regions are clearly due to ν(OH), δ(HOH) and ρ_r(HOH), respectively, indicating that coordinated water molecules exist in the complexes.[10] Compared with normal ν(OH) (*ca* 3400 cm^{-1}) bands for water molecules the absorptions of ν(OH) of these complexes show a red-shift, which

suggests that hydrogen bonding exists in the title complexes.[11,12]

The characteristic frequencies of coordinating nitrate groups appear in the IR spectra of the complexes (see Table 3), the difference between the two strongest absorptions (ν_1 and ν_4) of the nitrate groups being *ca* 200 cm^{-1}, indicating that the nitrate groups in the complexes coordinate to the metal ions as bidentate ligands.[10] The absence of absorptions around 1360 cm^{-1} indicates that all the nitrate groups in the complexes coordinate to the lanthanide ions.[10] This result is consistent with

those of the molar conductance values (Table 2) and the crystal structure determination.

^{1}H *NMR spectra*

Comparing the proton chemical shifts of the free ligand [δ(Ar—H) = 6.92, δ(—CH_2—) = 3.75–4.19 ppm] with those of the lutetium complex [δ(Ar—H) = 6.91, δ(—CH_2—) = 3.75–4.19 ppm] it can be found that these values are almost the same, indicating that the ligand does not directly coordinate to the lutetium(III) ion. This conclusion is consistent with the IR spectrum and the crystal structure determination.

Solubility and molar conductance

All the complexes are sparingly soluble in benzene and tetrachloromethane, slightly soluble in ethyl acetate, ethyl ether and chloroform and soluble in acetonitrile, nitromethane and acetone. The molar conductances measured in acetone at 25°C lie in the range 1.2–4.7 Ω^{-1} cm^2 mol^{-1} (Table 2), indicating that all the complexes are non-electrolytes.[13] This indicates that all the nitrate groups in the complexes are coordinated to the metal ions.

Crystal and molecular structure of the gadolinium complex

Selected bond lengths and angles are given in Tables 4 and 5, respectively. Figure 1 shows the molecular structure of the gadolinium(III) complex whilst Fig. 2 illustrates the molecular packing arrangement in the unit cell.

The gadolinium(III) ion is nine-coordinated with three bidentate nitrates and three water molecules, forming a distorted tricapped trigonal prism (Fig. 3). Three oxygen atoms of three water molecules form one bottom plane of the trigonal prism and another bottom plane is formed by three oxygen atoms from three nitrate groups; the other three nitrate oxygen atoms cap each quadrilateral face of the trigonal prism. The average Gd—O(nitrate) and Gd—O(water) bond lengths are 2.464(4) and 2.388(3) Å, respectively.

Although the positions of the hydrogen atoms of the coordinated water molecules were not located, the presence of hydrogen bonding can be inferred from the close O···O non-bonded contacts.[14] It can be seen that five hydrogen atoms of three coordinated water molecules are bonded to five oxygen atoms in the crown ether (Table 6). The hydrogen bonding contacts range from 2.707 to 2.843 Å and average 2.787 Å. This value is close to those observed in $[Y(OH_2)_8]Cl_3 \cdot (15C5)$ [average 2.76(7) Å][14] and $[UO_2(NO_3)_2(OH_2)_2] \cdot (DB18C6)_2$ (average 2.860 Å).[15] The O(1)···O(19)···O(7) and

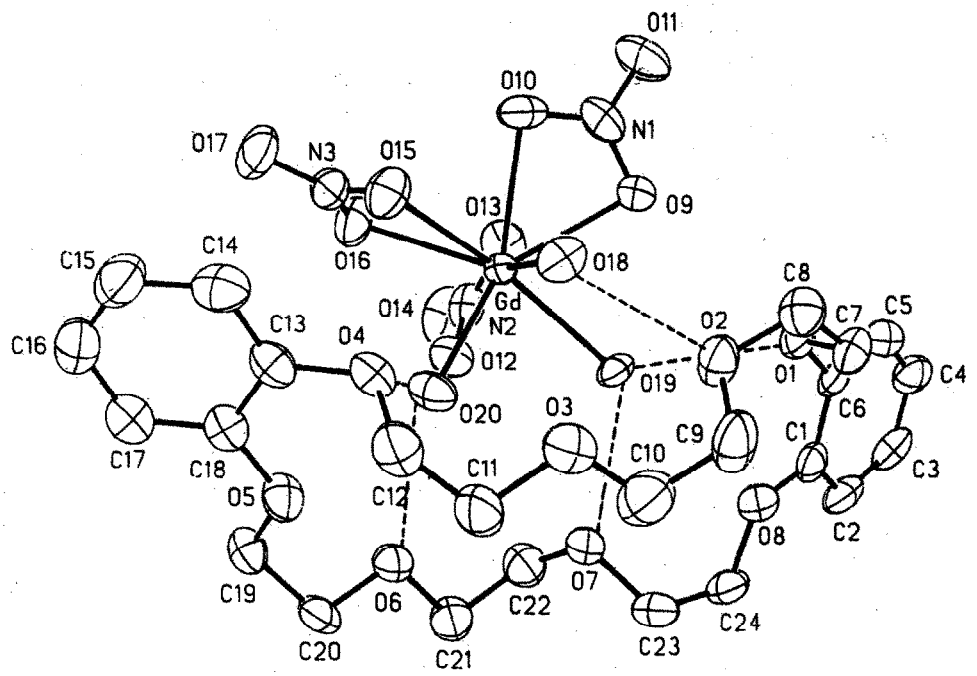

Fig. 1. The molecular structure of $[Gd(NO_3)_3(OH_2)_3]\cdot$(DB24C8).

O(4)···O(20)···O(6) angles are 109.1° and 107.4°, respectively, close to the H—O—H bond angle.

Owing to the unsuitable HO—H···O(crown) angle, a hydrogen atom in O(18) cannot form hydrogen bonds with the crown ether oxygen atom and this allows the other hydrogen atom in O(18) to form more efficient hydrogen bonds with O(2). This can be proved by the existence of the shortest O(18)···O(2) hydrogen bonding contact (see Table 6).

CONCLUSIONS

The Ln^{3+} ions can react with large cavity crown ethers to form two kinds of complexes with two different modes of coordination:

(1) In the presence of isothiocyanate groups the number of coordination atoms from the anions is only three, so the large cavity crown ethers (DB24C8, DCH24C8 and DB30C10) can directly coordinate to the Ln^{3+} ions to meet the need of the higher coordination numbers of the Ln^{3+} ions.[5–8]

(2) In the presence of the strong bidentate nitrates DB24C8 cannot directly coordinate to the Ln^{3+} ions due to its too large cavity and limited flexibility. The neutral $[Ln(NO_3)_3(OH_2)_3]$ unit and DB24C8 are linked together by hydrogen bonding through the intermediary water molecules.

(*Received* 11 *November* 1992; *accepted* 3 *March* 1993)

Abstract—The title compounds have been obtained by the reaction of $[NH_4]_2[WS_4]$, CuBr, $[NEt_4]_4Br$ and $[Bu^n_4N]Br$ in the solid state (**1**), or by the reaction of $[NH_4]_2[WS_4]$, CuI and $[Bu^n_4N]I$ in the solid state and the pyridine substitution of the solid-state product in acetonitrile (**2**). X-ray diffraction analysis confirms that in the structure of **1** five of the six edges of the $[WS_4]^{2-}$ tetrahedron are coordinated by CuBr units forming an open, double cubane-like structure, which possesses crystallographically imposed C_2 symmetry. The structure of **2**, which possesses a crystallographic $\bar{4}$ symmetry axis situated at the tungsten atom, consists of a tetrahedral WS_4 core enveloped by an octahedral array of six copper atoms, forming a WS_4Cu_6 aggregate. Linked by $—Cu_{eq}—I—Cu_{eq}—$ bridges, this aggregate connects with its nearest neighbours and develops a two-dimensional network. The substitution reactions of the solid-state product with pyridine are discussed.

The tetrathiometallate anions MS_4^{z-} (M = Mo, W, V, Re) have been shown to act as multidentate ligands to a wide variety of metal ions[1] and particularly with copper. The reaction of Cu^+ with MS_4^{z-} has led to a large number of heteronuclear compounds.[2–12] So far, almost all of these M—Cu—S cluster compounds reported in the literature have been prepared in solution. Recently, we have undertaken investigations on cluster compounds formed by reaction of $[NH_4]_2[MS_4]$ (M = Mo, W) with CuX (X = Cl, Br, I, CN, NCS) in the solid state and have prepared and structurally characterized a number of mixed-metal cluster compounds.[13–15] As a novel extension of this research, we herein report the synthesis and structural characterization of two new heteronuclear cluster compounds, $[NEt_4][WS_4Cu_5Br_7]$ (**1**) and $+WS_4Cu_6I_4(Py)_4+_n$ (**2**).

EXPERIMENTAL

All solid-state reactions were performed in an atmosphere of pure argon. IR spectra (KBr pellets) were recorded with a Fourier–Nicolet FT-170 SX spectrophotometer and electronic spectra on a

* Author to whom correspondence should be addressed.

Shimada UV-240 spectrophotometer (CH_3CN solution, 10^{-3} dm^3 mol^{-1} cm^{-1}). Cyclic voltammetry measurements of **1** were performed on a PAR Model 370 electrochemical apparatus equipped with an *X–Y* recorder at room temperature, under anaerobic conditions, using a three-electrode system with a platinum working electrode, a platinum wire auxiliary electrode and an S.C.E. references electrode. Potentials were also referenced to the ferrocene/ferrocinium system. The supporting electrolyte was Bu_4NBF_4 (0.1 M) and the sample was dissolved in DMF solution (5×10^{-3} M). The scan rate was 100 mV s^{-1}. $[NH_4]_2[WS_4]$ was prepared by the literature method.[16] Other reactants and solvents were used as purchased.

Synthesis of $[NEt_4]_4[WS_4Cu_5Br_7]$ **(1)**

A well-ground mixture of $[NH_4]_2[WS_4]$ (0.35 g, 1.0 mmol), CuBr (0.29 g, 2.0 mmol), $[NEt_4]Br$ (0.42 g, 2.0 mmol) and $[Bu^n_4N]Br$ (0.65 g, 2.0 mmol) was put into a reaction tube. A reddish-orange solid was obtained by heating the mixture in the solid state at 115°C for 14 h. After extracting the product with CH_2Cl_2 (40 cm^3) and filtering the reddish-orange coloured extract, the filtrate, on slow evaporation by standing in air, deposited 0.14 g (20.5%) of the reddish-orange crystals of the title compound. Found: C, 21.0; H, 4.6; N, 3.5; W, 9.9; Cu, 18.5. Calc. for $C_{32}H_{80}Br_7Cu_5N_4S_4W$: C, 21.1; H, 4.7; N, 3.3; W, 10.7; Cu, 18.6%.

Synthesis of $-[WS_4Cu_6I_4(Py)_4]-_n$ **(2)**

A well-ground mixture of $[NH_4]_2[WS_4]$ (0.35 g, 1.0 mmol), CuI (0.38 g, 2.0 mmol) and $[Bu^n_4N]I$ (1.48 g, 4.0 mmol) was placed in a reaction tube. A red solid was obtained by heating the mixture in the solid state at 120°C for 15 h. After extracting the product with CH_2Cl_2 (40 cm^3) and filtering the red coloured extract the filtrate, on slow evaporation by standing in air, deposited 0.16 g of the red crystals (as an intermediate). The product thus obtained was dissolved in CH_3CN (20 cm^3) in a tube, which was then placed in a closed beaker containing a small amount of pyridine. Slow diffusion of pyridine vapour into the tube at room temperature formed red octahedral crystals of the title compound a month later. Yield: 0.10 g (19.8%). Found: C, 15.6; H, 1.2; N, 3.9; W, 11.7; Cu, 24.8. Calc. for $C_{20}H_{20}Cu_6I_4N_4S_4W$: C, 15.8; H, 1.3; N, 3.7; W, 12.1; Cu, 25.1%.

Crystal data and structure determination

The crystals obtained directly from the preparations were suitable for single-crystal X-ray works. A single crystal was mounted in a random orientation of a glass fibre. Data were collected using a Nicolet R3m/E (**1**) or MSC/Rigaku (**2**) four-circle diffractometer with graphite-monochromated Mo-K_α [$\lambda = 0.71073$ (**1**) or 0.71069 Å (**2**)] radiation at room temperature. Cell constants were obtained by least-squares analysis on 23 (**1**) or 20 (**2**) diffraction maxima [the search limits of 2θ: 7.08–24.28° (**1**) or 10–25° (**2**)]. Details of the data collection together with structure refinement are summarized in Table 1.

Intensity data were corrected for Lorentz–polarization factors and for absorption empirically. For **1** there was no evidence of crystal decay from standard reflections monitored every 1.5 h of exposure. For **2**, as a check on crystal and electronic stability, three representative reflections were measured every 300 reflections and there was also no evidence of crystal and electronic decay.

The structure of **1** was solved by the heavy-atom method. Three-dimensional Patterson maps revealed the position of the tungsten atom. Successive least-squares refinements and difference-Fourier calculations revealed the positions of the remaining non-hydrogen atoms. Anisotropic temperature factors were introduced for all atoms of the anion and the cations. Hydrogen atoms were not included in the refinements. Neutral atom scattering factors with anomalous dispersion corrections were taken from ref. 17. Atomic parameters were refined by the full-matrix least-squares method using the SHELXTL program package (Nicolet corporation, 1986) on an Eclipse S/140 computer.

The structure of **2** was solved by direct methods. Six atoms were located from an E map; successive least-squares refinements and difference-Fourier calculations revealed the positions of the remaining atoms. The structure was refined by full-matrix least-squares with anisotropic thermal parameters for all non-hydrogen atoms and isotropic thermal parameters for all hydrogen atoms. Neutral atom scattering factors with anomalous dispersion corrections were taken from ref. 17. All calculations were performed on a VAX computer using the SDP/VAX program package.[18]

Important bond lengths and angles for **1** and **2** are given in Tables 2 and 3, respectively.

RESULTS AND DISCUSSION

The structure determination confirms that compound **1**, in which the anion has crystallographically imposed C_2 symmetry, is isostructural to $[NMe_4]_4[MS_4Cu_5Cl_7]$ (M = Mo,[5] W[4]) and $[PPh_4][NEt_4][ReS_4Cu_5X_7]$ (X = Cl, Br).[12] A perspective view of the cluster anion is shown in Fig.

[a] $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$.

[b] $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2}$. For **1**, $w = 1/[\sigma^2(|F_o| + 0.00015|F_o|^2)]$. For **2**, $w = F_o/114.0$ if $F_o < 114.0$; $w = 114.0/F_o$ if $F_o > 114.0$.

1. The geometry about the tungsten atom is nearly tetrahedral, see Table 2. Five CuBr units are bound to the WS_4 core [Cu—S 2.287(3)–2.371(4) Å] through double-bridged copper atoms, the sixth edge of the WS_4 tetrahedron remaining uncoordinated. The overall geometry can be viewed as a distorted double cube with two long Cu—Br distances [Cu(2)—Br(4) 2.685(2) and Cu(3a)—Br(4) 2.713(2) Å], as reported in other similar dicubane structures. The W—Cu distances [2.682(2)–2.705(2) Å] are comparable to the W—Cu distances observed in $[NEt_4]_4[WS_4Cu_5Cl_7]$ [2.656(2)–2.689(1) Å][4] or $\{Cu_3WS_3Br\}(PPh_3)_3S$ [2.715(2)–2.733(2) Å].[15]

A perspective view of the molecular structure and the cell packing of compound **2** are shown in Figs 2 and 3, respectively. The structure consists of an essentially tetrahedral WS_4 moiety encapsulated by a slightly distorted octahedron of six copper atoms, forming a WS_4Cu_6 aggregate with a crystallographic $\bar{4}$ symmetry axis situated at the tungsten atom. Linked by $—Cu_{eq}—I—Cu_{eq}—$ bridges, this aggregate connects with its nearest neighbours and develops a two-dimensional network. It is worth noting that the structure of the $[WCu_6]$ core in this cluster is very different from that of the $[MoCu_6]$ core in similar heptanuclear clusters, $[NMe_4]_5[MoS_4Cu_6Cl_9]$[6], or the $[VCu_6]$ core in $[VS_4Cu_6(PPh_3)_5Cl_3]\cdot CH_2Cl_2$.[10] The symmetry of the $[WCu_6]$ core in compound **2** is D_{4h}, while the symmetry of $[MoCu_6]$ in $[NMe_4]_5[MoS_4Cu_6Cl_9]$[6] is C_{3v} and the $[VCu_6]$ core in $[VS_4Cu_6(PPh_3)_5Cl_3]\cdot CH_2Cl_2$[10] possesses practically no symmetry element. The WS_4 core has retained the ideal geometry of free thiotungstate with the same W—S length [2.260(2) Å] and similar S—W—S angles [108.8(1)–109.8(3)°]. Each copper atom is bound across an edge of the WS_4 tetrahedron, giving each

sulphur atom a μ_4-S coordination. There are two types of copper atoms in the Cu_6 octahedron: two axial Cu(1) atoms and four equatorial Cu(2) atoms. Each axial Cu(1) atom has one terminal iodine atom and two μ_4-S atoms, forming a trigonal geometry. Each equatorial Cu(2) atom is four-coordinated by a pair of μ_4-S atoms, one μ_2-I atom and one nitrogen atom of a pyridine molecule with a distorted tetrahedral $ICu(\mu_4\text{-}S)_2N$ unit. It is of interest to note that the Cu_{eq}—I length [2.764(3) Å], which is comparable to the values observed in compounds containing tetrahedrally-coordinated copper (e.g. 2.700 Å in $[PEt_3CuI]_4$[19] or 2.629(1)–2.639(1) Å in $[MoS_4Cu_4I_2(Py)_6]$[20]), is 0.322 Å longer than that of

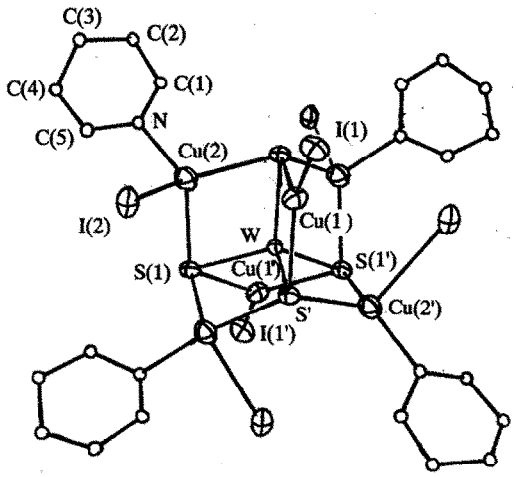

Fig. 2. Structure of the cluster compound $-[WS_4Cu_6I_4(Py)_4]-_n$.

the Cu_{ax}—I length [2.442(4) Å]. The Cu—S lengths also reflect the mode of coordination of the copper atoms: 2.282(2) Å for trigonal geometry, 2.325(4) Å for a tetragonal environment. These Cu—S lengths are very similar to those reported for $[NMe_4]_5[MoS_4Cu_6Cl_9]$[6] or $[VS_4Cu_6(PPh_3)_5Cl_3]\cdot CH_2Cl_2$.[10] Owing to the slight distortion of the Cu_6 octahedron, the W—Cu lengths are slightly different: 2.668(2) Å for the W—Cu_{ax} length and 2.694(3) Å for the W—Cu_{eq} length, respectively. These values are typical of corresponding lengths observed in other W—Cu—S clusters (e.g. 2.656(2)–2.689)(1) Å in $[NMe_4]_4[WS_4Cu_5Cl_7]$[4] or 2.6885(7)–2.6932(8) Å in $[NEt_4]_2[WS_4(CuNCS)_4]$[9]).

Since the W—Cu(1)—I(1) and Cu(1)—W—Cu(1′) angles are 180° and the tungsten atom remains situated on the 4-axis, the W, Cu(1), Cu(1′), I(1) and I(1′) atoms are co-linear. The Cu(1)—W—Cu(2) angle is 95.93(6)°, indicating that the tungsten atom is slightly above or below the mean plane composed of the four Cu_{eq} atoms.

In the IR spectrum of compound **1** bands at 447s and 421s cm^{-1} are assigned to the bridged WS_4 group. In the 350–250 cm^{-1} region bands at 310m, 290m, 260m and 253m are considered as the

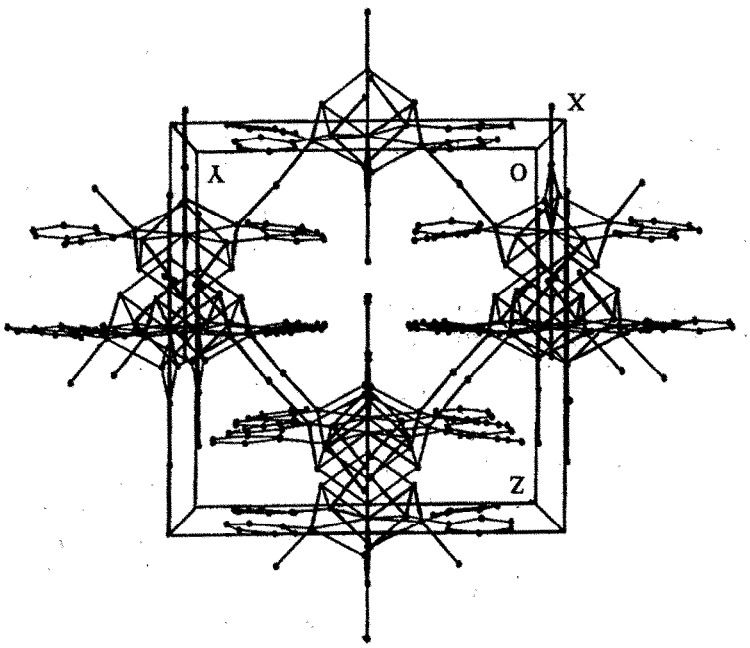

Fig. 3. Cell packing of $-[WS_4Cu_6I_4(Py)_4]-_n$.

ν(Cu—Br) vibrations. The electronic spectrum shows the expected $s \rightarrow w$ charge transfer at 438(3.7), 330(sh) and 310(12.2) nm.

In the IR spectrum of compound **2** the band at 430s cm^{-1} is assigned to the symmetric bridged WS_4 group. The electronic spectrum shows the expected $s \rightarrow w$ charge transfer at 443(5.3), 335(sh) and 263(26.2) nm.

Cyclic voltammetric measurements for $[WS_4Cu_5Br_7]^{4-}$ in DMF in the range -2.0 to -0.0 V display one pair of quasi-reversible oxidation–reduction waves ($E_{pa} = -0.275$, $E_{pc} = -0.55$, $\Delta E = 0.275$ V) and one irreversible reduction wave at -1.25 V.

The $[Bu^n_4N]Br$ compound is used to decrease the melting point of the solid mixture in the solid-state synthesis of compound **1**. It is noted that the title compound contains no $[Bu^n_4N]^+$ cation, only four $[NEt_4]^+$ cations are present. We cannot explain this priority at present.

In the synthesis of compound **2** the possible formula of the red solid-state intermediate product was concluded to be $[Bu^n_4N]_4[WS_4Cu_6I_8]$ using IR spectroscopy [ν(W—μ_4—S): 436.12s, 417.58 cm^{-1}] and elemental analysis. Found: C, 28.2; H, 5.2; N, 2.4; Cu, 14.0; W, 6.5. Calc. for $C_{64}H_{144}Cu_6I_8N_4W$: C, 28.7; H, 5.4; N, 2.1; Cu, 14.2; W, 6.9%. Attempts to obtain a single crystal of good quality failed. Interestingly, when the pyridine vapour slowly diffused into the acetonitrile solution of the intermediate product and partly substituted four of the eight iodine groups a beautiful octahedral crystal of the title compound formed. A possible substitution reaction is given as follows:

$$[Bu^n_4N]_4[WS_4Cu_6I_8] \xrightarrow[1\text{ month}]{\text{Pyridine vapour}} +[WS_4Cu_6I_4(Py)_4]+_n.$$

When the intermediate product was dissolved in excess pyridine one red brick-like crystal was formed in a couple of days and a reddish-orange needle crystal was deposited on standing in air a month later. Based on the elemental analysis and IR spectra of these two products the red brick-like crystal and the reddish-orange needle crystal were concluded to be the known compounds $[WS_4Cu_4I_2(Py)_6]$[21] and $[WS_4Cu_2(Py)_4]$,[22] respectively. The formation of these two cluster compounds was attributed to the collapse of the framework of the cluster core WS_4Cu_6. The two reactions are given as follows:

$$[Bu^n_4N]_4[WS_4Cu_6I_8] \xrightarrow[1\text{–}2\text{ days}]{\text{Pyridine}} [WS_4Cu_4I_2(Py)_6]$$

$$[Bu^n_4N]_4[WS_4Cu_6I_8] \xrightarrow[1\text{ month}]{\text{Pyridine}} [WS_4Cu_2(Py)_4].$$

It is expected that a series of new cluster compounds can be prepared from substitution of iodine groups in this intermediate product with other strong ligands, such as PPh_3, dppm and $S_2CNMe_2^-$[1]. Research on this aspect of the work is currently under way.

(*Received* 28 *January* 1993; *accepted* 5 *March* 1993)

Abstract—We describe the synthesis and characterization by elemental analysis, conductance measurements and ^1H NMR and IR spectrometry of compounds with the general formula $[M(BBDH)X_2]$ [M = Zn, Cd or Hg; X = Cl, Br or I; BBDH = 1,6-bis(benzimidazol-2-yl)-2,5-dithiahexane], which were prepared by reaction of zinc, cadmium or mercury dihalides with BBDH in ethyl alcohol. In addition, the structure of $Hg(BBDH)Cl_2 \cdot EtOH$ (**VI**) was determined by single-crystal structure analysis. The mercury atom is coordinated with slightly distorted tetrahedral geometry to the unprotonated nitrogen atoms of the BBDH benzimidazolyl groups [Hg—N = 225.8(5) and 223.6(6) pm] and to two chlorine atoms [Hg—Cl = 251.3(3) and 249.9(2) pm].

Acquisition of the fairly comprehensive knowledge we now have of the coordination chemistry of transition metals (especially cobalt, nickel and copper) with linear NSSN tetradentate ligands, in which the sulphur atoms belong to a thioether and the nitrogen atoms to heterocycles such as imidazole, benzimidazole, pydidine or quinoline,[1–5] has been prompted in part by the fact that the resulting complexes seem to be acceptable models of the active centres of metallobiomolecules;[6,7] all four donors of the *facultative* ligands being theoretically able to coordinate simultaneously to the metal atom. The versatility of these ligands as regards the number of donor atoms actually involved in coordination, and the relative ease with which they can adapt to a variety of coordination geometries, has been repeatedly demonstrated in complexes with the above-mentioned transition metals.[8–12]

By contrast, NSSN ligands have rarely been complexed with post-transition metals such as zinc, cadmium and mercury, in spite of zinc being a metal of considerable importance in many biological systems.[13]

In continuation of our studies on the coordination chemistry of the halides of divalent group 12 metals[14–19] in this work we report the synthesis and structures of the products of reaction between zinc, cadmium or mercury dihalides and 1,6-bis(benzimidazol-2-yl)-2,5-dithiahexane (BBDH), a linear NSSN tetradentate ligand whose capacity to coordinate with transition metals is well documented.[5,8,20–25]

EXPERIMENTAL

Materials

BBDH was prepared using a published method.[26] Metal(II) halides and solvents were reagent-grade commercial products.

Metal complexes

All the complexes were prepared by the following general procedure. A solution of BBDH (1 mmol) in hot ethanol (15 cm^3) was added to a solution of metal(II) halide (1 mmol) in ethyl alcohol (25 cm^3) and the mixture kept stirring for several days. The solid products were filtered off, washed thoroughly with cold ethanol and dried over $CaCl_2$ (yield 70–95%). Crystals of **VI** were grown by dissolving the crude product in EtOH and slow evaporation of the solvent.

Physical measurements

Carbon, hydrogen and nitrogen analyses were performed on a Perkin–Elmer 240B microanalyser. Conductance measurements in methylcyanide at *ca* 10^{-3} M were obtained at 293 K on a WTW Type LF-3 conductivity bridge. ^1H NMR spectra were recorded in DMSO-d_6 on a Bruker WM250 spectrometer using TMS as an internal standard. IR spectra were recorded over the range 4000–400 cm^{-1} on a Perkin–Elmer 1330 spectrophotometer using KBr pellets and in the range 500–100 cm^{-1} on a Perkin–Elmer 180 spectrophotometer using Nujol mulls between polyethylene windows. Analytical data are listed in Table 1.

X-ray analysis

A colourless crystal of **VI** with the dimensions $0.20 \times 0.30 \times 0.10$ mm was mounted on an Enraf–Nonius CAD4 diffractometer and intensities were measured at room temperature using graphite-monochromated Mo-K_α radiation ($\lambda = 0.71073$ Å). The cell constants were determined from the setting angles of 25 reflections. Crystal data are summarized in Table 2. 4516 reflections were collected in the range $3 < \theta < 25°$ in the ω–θ scan mode. Of 3884 unique data measured ($R_{int} = 0.025$) 3221 with $I > 3\sigma(I)$ were used in the structure determination and refinement. Lp corrections and an empirical absorption correction[27] were applied to the data.

The structure was solved by direct methods[28] and refined on F by full-matrix least-squares procedures.[29] In the last refinement all non-hydrogen atoms were assigned anisotropic temperature parameters. the hydrogen atoms were located on a difference map and included in structure–factor calculations with B_{iso} fixed at 4.0 $Å^2$, but not refined. A secondary extinction correction was made[30] and the final coefficient refined in the least-squares cycle was 1.248×10^{-7}. The final R value was 0.035 with $Rw = 0.039$ [weighting scheme $w = 1/\sigma^2(F)$; 272 parameters; $S = 1.967$; maximum Δ/σ in final cycle < 0.001; maximum $\Delta\rho = 0.799$ e $Å^{-3}$]. Scattering factors were taken from the International Tables.[31]

RESULTS AND DISCUSSION

The metal complexes are quite stable at room temperature, having shown no signs of decomposition since their synthesis. The conductivities of *ca* 10^{-3} M solutions in methylcyanide at 20°C (5.0–30.0 S m^2 mol^{-1}; Table 1) class them as non-electrolytes[32] and hence show that their halogen atoms are coordinated to the metal.

Structure of VI

Compound **VI** is a 1:1 $HgCl_2$-BBDH complex with an ethyl alcohol molecule included in the crystal structure. The conformation of the complex is shown with the atom labelling used in Fig. 1. The bond lengths and angles involving the mercury atom are listed in Table 3.

The mercury atom has a slightly distorted tetrahedral coordination sphere involving two chlorine atoms and two unprotonated nitrogen atoms of the benzimidazolyl groups of the ligand. The Hg—Cl distances are within the range of divalent Hg—Cl bond lengths reported in other studies.[33,34]

In a comprehensive statistical analysis of interatomic distances in accurately determined structures of inorganic and organometallic complexes Allen *et al.*[34] observed that Hg—N distances fall into two fairly well-defined groups, with means of 214.0 and 240.0 pm, although no chemical distinction between long and short bonds was apparent. The Hg—N distances in **VI**, 225.8(5) and 223.6(6) pm, are intermediate. In this structure the Hg—N bond may involve weak back-donation from mercury due to the electron-withdrawing effect of the chlorine ligands.[18,19]

The extent of the tetrahedral distortion is shown by the angles about the mercury atom varying from 101.0(2)° in Cl(1)—Hg—N(3) to 117.0(2)° in Cl(2)—Hg—N(3).

IR spectra

The assignments of some of the IR bands of free BBDH and its complexes are listed in Table 4.

4000–500 cm^{-1} *Range.* The IR spectra of the compounds are very similar to one another and to that of BBDH itself. The most significant differences are in the NH stretching region, the frequency of ν(NH) increasing by 350–500 cm^{-1} on coordination, and in the 1450–1400 cm^{-1} region,

Table 3. Coordination distances (pm) and angles (°) in **VI**

Hg—Cl(1)	251.3(3)	Hg—N(1)	225.8(5)
Hg—Cl(2)	249.9(2)	Hg—N(3)	223.6(6)
Cl(1)—H—Cl(2)	111.44(9)	Cl(2)—Hg—N(1)	108.9(2)
Cl(1)—Hg—N(1)	109.1(2)	Cl(2)—Hg—N(3)	117.0(2)
Cl(1)—Hg—N(3)	101.0(2)	N(1)—Hg—N(3)	109.1(1)

	263 m	191 m	233 m	187 w	147 m	216 m	166 w	142 w	

where δ(NH) shifts from 1438 cm^{-1} in the free ligand to around 1400 cm^{-1} in the complexes. These changes indicate direct bonding between the unprotonated nitrogen atoms of the benzimidazolyl groups and the metal atom. A weak band observed at 700 cm^{-1} and assigned mainly to the ν(CS) stretching vibration[35] is unshifted upon coordination, suggesting that these complexes are not sulphur-bonded.

BBDH exhibits absorptions at 1630 and 1597 cm^{-1}, which are assumed to be due mainly to C—N stretching in the imidazole ring. The complexes all exhibit the same two bands, the lower energy band maintaining the same position while the higher energy band shifting to 1598–1602 cm^{-1}. These shifts in ν(CN) to lower frequencies indicate delocalization of the imidazole ring, in keeping with the C—N distances found in compound **VI**.

500–100 cm^{-1} *Range*. The IR spectra of all the complexes have two strong bands in the region 280–140 cm^{-1} and two weak-to-medium absorptions around 350–330 and 310–280 cm^{-1}. The strong bands are assigned to ν(MX), their observed frequencies being consistent with reported values for non-bridging halogen–metal bonds in a distorted tetrahedral MN_2X_2 skeleton with ideal C_{2v} symmetry.[19,36,37] For a given metal ν(MX) decreases in the order M—Cl > M—Br > M—I. In addition, the frequency ratios ν(MBr)/ν(MCl) = 0.73–0.80 and ν(MI)/ν(MCl) = 0.62–0.66 are consistent with those of tetrahedral structures which have appeared in the literature.[38,39] The bands in the 350–330 and 310–280 cm^{-1} regions may be attributed to the symmetric and assymmetric ν(MN) modes.[37,40]

^1H *NMR spectra*

The NMR spectral data obtained in this work are presented in Table 5, together with those of the free ligand.[9] The methylene and ethylene proton resonances occur as singlets, indicating equivalent protons. The methylene protons are shifted downfield and the ethylene protons upfield, but the magnitude of these shifts is insufficient to suggest

Table 5. ^1H NMR spectral data of BBDH and the complexes (δ ppm) relative to TMS[a]

Compound	HC(3), HC(4) HC(15), HC(16)	HC(2), HC(5) HC(14), HC(17)	$H_2C(8)$ $H_2C(11)$	$H_2C(9)$ $H_2C(10)$	HN(2) HN(4)
BBDH	7.50 m	7.14 m	3.97 s	2.79 s	12.55
I	7.65 m	7.22 m	4.10 s	2.68 s	13.07
II	7.63 m	7.20 m	4.08 s	2.71 s	nd
III	7.58 m	7.20 m	4.06 s	2.76 s	nd
IV	7.55 m	7.18 m	4.02 s	2.77 s	nd
V[b]	7.53 m	7.17 m	4.00 s	2.77 s	nd
VI[b]	7.72 m	7.23 m	4.20 s	2.70 s	nd
VII	7.76 m	7.29 m	4.23 s	2.69 s	nd
VIII	7.68 m	7.25 m	4.18 s	2.74 s	nd

[a] For proton nomenclature see the description of the structure of **VI**. The abbreviation nd indicates not detected.

[b] The ethanol resonances are found at 1.04 (t), 3.42 (q) and 1.05 (t) , 3.45 (q), respectively.

coordination via the thioether sulphur atoms. BBDH thus acts as a bidentate ligand, as was shown for **VI** by X-ray studies.

BBDH exhibits two groups of aromatic proton resonances approximately 0.36 ppm apart. These two groups also appear in the spectrum of all the complexes, but the high-field group is shifted downfield by up to 0.15 ppm and the low-field group by up to 0.26 ppm. It is assumed that the low-field group comprizes the benzene ring protons nearest to the imidazole ring and that coordination via an imidazole nitrogen atom deshields one of these protons much more than the other ring protons. Since only one set of benzimidazolyl proton resonances appears in the spectrum, it is further assumed that both benzimidazolyl groups coordinate to the same metal atom.

The presence of well-resolved, deshielded, imidazole-ring proton resonances in the NMR spectrum complex **I** also indicates M—N binding.

Regardless of which halogen was present, the aromatic proton signals are shifted most in mercury complexes and least in cadmium complexes. This difference may reflect the strength of the metal–ligand bond.*

CRYSTAL STRUCTURE AND SPECTROSCOPIC PROPERTIES OF $(NH_4)[UBr_2(CH_3CN)_2(H_2O)_5]Br_2$

E. ZYCH, P. STARYNOWICZ, T. LIS and J. DROŻDŻYŃSKI*

Institute of Chemistry, University of Wrocław, 50-383 Wrocław, Poland

(*Received* 27 *January* 1993; *accepted* 5 *March* 1993)

Abstract—The synthesis, crystal structure and spectroscopic properties of a uranium(III) compound of the formula $(NH_4)[UBr_2(CH_3CN)_2(H_2O)_5]Br_2$ is reported. The IR, Raman and electronic spectra of the compound have been recorded in the 30–4000 and 4000–26,000 cm^{-1} spectral ranges, respectively, and are discussed. The assignments of the IR and Raman frequencies are given.

In a previous paper[1] the synthesis and characterization of a compound with an incorrectly assumed formula, $NH_4UBr_4 \cdot 1.5CH_3CN \cdot 6H_2O$, was reported. The crystal structure determination presented in this paper reveals that the correct formula of the compound is $(NH_4)[UBr_2(CH_3CN)_2(H_2O)_5]Br_2$. For the first time uranium(III)–nitrogen bond lengths have been determined from single crystal data. The paper also reports an analysis of the IR and electronic spectra of the compound.

EXPERIMENTAL

Synthesis

In order to obtain single crystals of the compound uranium tetrabromide (5–6 g) together with an excess of ammonium bromide were added to acetonitrile (*ca* 100 cm^3). The mixture was shaken from time to time and left standing for 10–15 h. Subsequently, propionic acid (0.7 cm^3) and freshly distilled ethyl ether (15 cm^3) were added. After filtering, the solution, together with *ca* 1 cm^3 of liquid zinc amalgam, was transferred to a glass tube *ca* 15 cm long and 1.5 cm in diameter. The solution was added until its level reached a narrowing of 0.5 cm in the middle of the tube. Next, the tube was transferred to a flask and the solution was degassed by connecting the flask to a vacuum pump, reduced by gentle shaking and finally kept under nitrogen. A 100 : 15 : 0.7 : 0.9 solution of acetonitrile, ethyl ether, propionic acid and water, respectively, had been prepared separately. Approximately the same volume of solution as before was degassed and carefully transferred into the upper part of the tube. Afterwards the glass tube was sealed off and left standing for a couple of days. Several single crystals which grew around the constriction were separated in an inert gas glove-box and placed in Lindemann capillaries under paraffin oil.

Crystal structure determination

Crystal data for $(NH_4)[UBr_2(CH_3CN)_2(H_2O)_5]Br_2$: $C_4H_{20}Br_4N_3O_5U$, $M = 747.9$, orthorhombic, space group *Pnma* (D_{2h}^{16}), $a = 8.98(2)$, $b = 9.99(2)$, $c = 20.24(4)$ Å, $Z = 4$, $V = 1816(7)$ Å^3, $D_c = 2.74(1)$ g cm^{-3}, $D_m = 2.81$ g cm^{-3}, $F(000) = 1348$, $\lambda(\text{Mo-}K_\alpha) = 0.71069$ Å, $\mu = 96.5$ mm^{-1}.

A brown parallelepiped crystal of approximate dimensions $1.0 \times 0.6 \times 0.08$ mm^3 was sealed in a deoxygenated capillary and mounted on a KM4 Kuma diffractometer with κ geometry. The cell parameters were determined from angular settings of 25 reflections with 2θ between 16 and 25°. 3978 reflections were measured in the $4 \leqslant 2\theta \leqslant 42°$ range. Out of these 1359 had $I \geqslant 3\sigma(I)$. The data collection was performed at 298 K using Mo-K_α radiation and the $\omega/2\theta$ scan mode with variable scan speed. Three control reflections were monitored after 50 measured intensities. The mean relative variation was 3.1%. The data were corrected for the Lorentz and polarization factors, as well as for absorption calculated from the crystal shape. For the latter correction a grid composed of 4096

* Author to whom correspondence should be addressed.

points imposed on the crystal volume was used. Thus, calculated transmission factors were between 0.014 and 0.252. The position of the uranium atom was determined by the Patterson method and the other atoms were found from a difference-Fourier map. No attempt was made to locate the hydrogen atoms. Then, 245 weak reflections with the largest e.s.d.s were removed from the reflection file. The structure was refined using the full-matrix least-squares method. For the final refinement 932 unique reflections, yielded from merging 1114 data ($R_{int} = 0.076$), were used. The minimized function was $S = \Sigma w(|F_o| - |F_c|)^2$, with the weights $w = 1/\sigma^2(F)$. The scattering factors of neutral carbon, nitrogen and oxygen atoms, as well as those of U^{3+} and Br^-, were included[2] in the refinement. The C—N distances were constrained, with the common distance refined as an additional variable. The restraint of 1.45 Å was imposed on the C—C distances. As an additional variable the scaling length for absorption was applied. The uranium and bromine atoms had anisotropic thermal parameters, all other atoms were isotropic. The refinement of 59 parameters converged at $R = 0.0461$ and $R_w = 0.0391$; the maximum Δ/σ was less than 0.01 and the residual electron density was between -0.86 and 1.73. The highest peaks were around the uranium cation. The SHELXS86[3] program was used for solution and the locally modified SHELX76[4] for the refinement. The atomic parameters as well as the full list of bond lengths and angles have been deposited as supplementary material.

IR and Raman spectra

The IR transmission measurements were performed at room temperature on a Bruker JFS 88 FT-IR spectrometer in the 30–4000 cm^{-1} spectral range. The KBr disc and Nujol mull suspension techniques were applied.

The Raman spectra were observed in back-scattering geometry at 300 K. The 5145 Å line of an Ar^+ ion laser and the line of a solid Nd : YAG laser were the excitation sources. For measurements of the Raman spectra DFS 24 and Yvon Jobin monochromators were used. They were supplied with photon detection systems from Product for Research INC (Massachusetts, U.S.A.).

Electronic spectrum

The solid-state electronic spectrum of the compound was recorded on a Cary–Varian 2300 spectrophotometer in the 4000–26,000 cm^{-1} absorption range. In order to obtain the spectrum a well-ground mixture of the compound with a few drops of chlorinated naphthalene (index of refraction = 1.635) was placed between two quartz windows, approximately 1 cm in diameter, pressed to obtain a transparent layer and placed into the cell compartment of the spectrophotometer.

RESULTS AND DISCUSSION

Crystal structure

The crystal is composed of complex monomeric pentaaquabis(methyl cyanide)dibromouranium cations, ammonium cations and bromide anions. The uranium atom is placed on the *m* (C_s) plane and is surrounded by two bromide anions, two methyl cyanide nitrogen atoms and five oxygen atoms of the water molecules. The shortest U—U distance is 7.05(2) Å. Other selected bond lengths are presented in Table 1. The coordination figure of uranium is intermediate between a tricapped trigonal prism and a capped square antiprism. In the former case the best fitted figure had the upper and lower bases defined by Br(1), O(1), O(2′) and Br(1′), O(1′), O(2), respectively, and the caps by N(2), N(1), O(3). The parameter Δ, defined as $\Sigma d_i^2/9$ is equal to 0.066 $Å^2$, where d_i is the distance between the *i*th atom and the relevant vertex of the idealized least-squares fitted polyhedron.[5] In the latter case the non-capped base was spanned by O(3), O(2′), N(1), O(2), the capped base by Br(1), O(1), O(1′), Br(1′) with N(2) being the cap, $\Delta = 0.066$ $Å^2$. The structure is held together by N—H · · · Br and O—H · · · Br hydrogen bonds, the former probably disordered. An ORTEP[6] view of the complex cation is presented in Fig. 1. and that of the crystal cell in Fig. 2.

Symmetry-based vibrational data

The IR transmission spectra for $(NH_4)[UBr_2(CH_3CN)_2(H_2O)_5]Br_2$ are presented in Fig. 3 and those of the Raman spectra are shown in Fig. 4. The unit cell of the compound consists of four

Table 1. Lengths of bonds formed by the uranium cation

U—Br(1),Br(1′)[a]	3.074(4)
U—O(1),O(1′)	2.538(12)

U—N(1)	2.517(30)
U—N(2)	2.688(26)
U—O(3)	2.652(20)

[a] Primed atoms are related to those unprimed through the mirror plane at *x*, 1/2 − *y*, *z*.

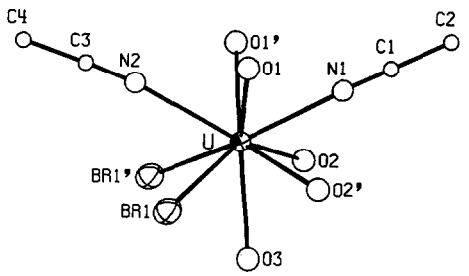

Fig. 1. View of the complex cation. Symmetry generated atoms are marked with primes, see Table 1.

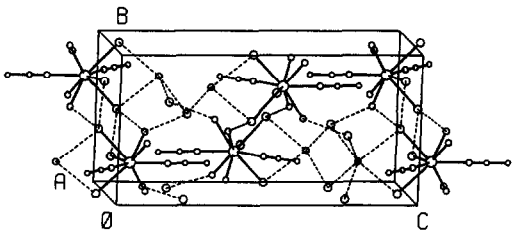

Fig. 2. View of the unit cell. The possible hydrogen bonds are marked with dashed lines.

formula units comprising 148 atoms. As mentioned before, the uranium ion lies inside the polyhedron with nine vertices. Since the uranium ion occupies the *c*-position of the unit cell, the structure of the coordination polyhedron is described by C_s symmetry. Hence, the 444 vibrational modes of the unit cell decompose according to the following representation:

$$T = 61A_g + 50B_{1g} + 61B_{2g} + 50B_{3g} + 50A_u + 61B_{1u} + 50B_{2u} + 61B_{3u},$$

where $B_{1u}+B_{2u}+B_{3u}$ are acoustic modes. Thus, there are 441 optical zone-centre modes, 45 of which are translational lattice modes, 24 librational lattice modes and 372 internal modes connected with the $[UBr_2(CH_3CN)_2(H_2O)_5]$ core. Table 2 lists these phonons with their symmetries and the polarizations necessary for their observations.

Since the $UBr_2N_2O_5$ coordination polyhedron has C_s symmetry, all the internal vibrations have IR and Raman components. 24 normal vibrations of this skeleton are described by the $13A'+11A''$ representation, which consists, amongst others, of two $A'+A''$ stretching $\nu(UBr_2)$, two $A'+A''$ stretching $\nu(UN_2)$ and five $3A'+2A''$ stretching $\nu(UO_5)$ modes. The interaction between the four molecules in the unit cell leads to the splitting of these modes as shown below.

Site symmetry C_s	Factor group symmetry D_{2h}
A'	A_g
	B_{2g}
	B_{1u}
	B_{3u}
A''	B_{1g}
	B_{3g}
	A_u
	B_{2u}

The remaining 19 fundamentals correspond to the bending vibrations of the $UBr_2N_2O_5$ skeleton. Based on the theoretical considerations, Table 3 lists the frequencies of the IR and RS bands along with the line assignments.

The IR and Raman studies reveal all characteristic lines expected for coordinated CH_3CN and H_2O ligands. Coordination through nitrogen is indicated by the bands at 202 (IR) and 282 (R) cm^{-1}, which correspond to the $\nu(UN_2)$ modes. The $\nu(CH_3)$, $\delta(CH_3)$, ν(C—C) and $\nu(C\equiv N)$ frequencies appear in energy ranges characteristic for the free ligand,[7,8] as well as for the cerium and uranium trichloride monoacetonitrile complexes.[9] The peaks near 2307 cm^{-1} have been assigned to a $\nu_3+\nu_4$ combination band of the symmetric $\delta_s(CH_3)$ and ν_s(C—C) modes. The pattern of lines typical for coordinated water molecules are observed both in the IR and RS spectra. This multiplet appears in the 400–770 cm^{-1} range with components at *ca* 600–670 and 700–770 cm^{-1} and is related to the wagging and rocking modes.

Very broad and poorly resolved bands observed in the 300–550 cm^{-1} region correspond to the $\nu(U—OH_2)$ and δ(OUO) vibrations of the UO_5 skeleton. The uranium–bromine vibrations appear in two regions: 110–190 cm^{-1} for the $\nu(UBr_2)$ stretching modes and 50–100 cm^{-1} for the δ(BrUBr) modes.

For a more detailed mode identification of some data on polarization properties of the modes observed in single crystals are required. One can note from Table 2 that all Raman modes have an IR counterpart and that the number of IR and R modes is less than expected from the theoretical FGA prediction. This is due to the use of polycrystalline samples in the measurements. Besides, due to the limited resolution and poor signal-to-noise the weaker oscillators can be dominated by the stronger ones, as well as by emission bands. The strong contour observed in the Raman spectra at *ca* 18,550 cm^{-1} has been assigned to emission connected with the Laporte allowed $5f^2 \rightarrow 5f^26d^1$ transitions.

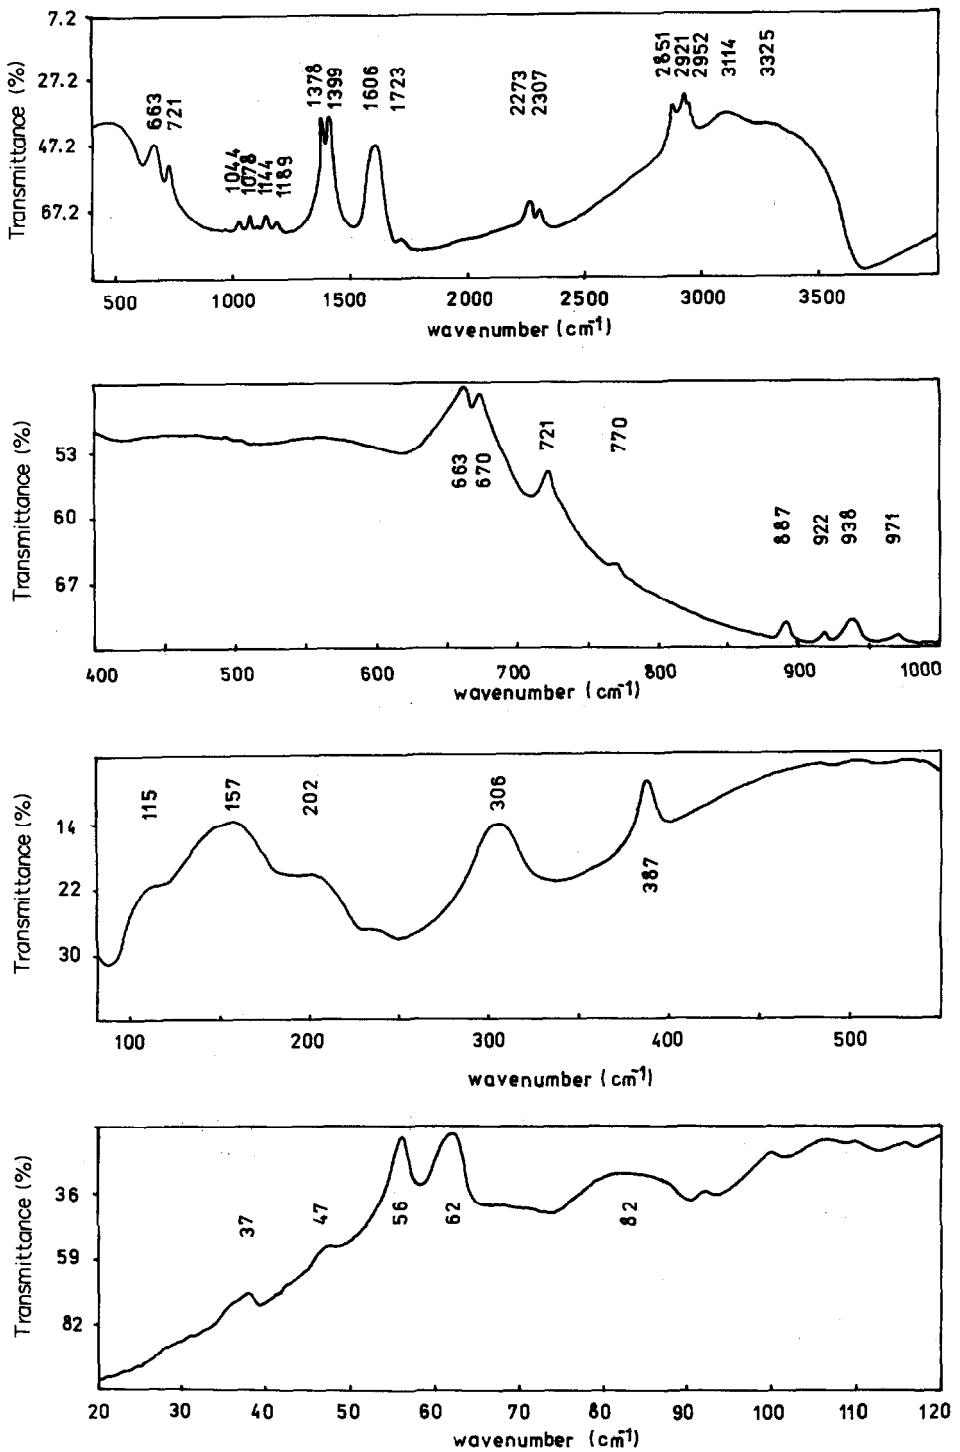

Fig. 3. IR transmission spectra.

Electronic spectrum

The solid-state electronic absorption spectrum of the compound is typical for all those uranium(III) compounds which possess some of the uranium–ligand bonds of more covalent character.[10]

In the 4000–15,000 cm^{-1} absorption range one observes the characteristic $5f^3 \rightarrow 5f^3$ transitions of

the U^{3+} ion with energies (in cm^{-1}) of the band maxima at 4325, 4490, 4595 ($^4I_{11/2}$),* 6920 ($^4F_{3/2}$),* 7999, 8200, 8457, 8650 ($^4I_{13/2}$),* 9092, 9302, 9393 ($^2H_{9/2}$),* 9633, 9850, 9940, 10,202 ($^4F_{5/2}$),* 11,112, 11,506, 11,795 ($^4S_{3/2}$, $^4G_{5/2}$, $^4I_{15/2}$, $^4F_{7/2}$),* 13,159, 13,690 ($^4G_{7/2}$)* and 14,797 ($^4F_{9/2}$).* One may note, however, that the bands are not well resolved and do not exhibit all crystal-field components.

Above this region the $5f^3 \rightarrow 5f^3$ transitions are obscured by strong and broad $5f^3 \rightarrow 5f^2 6d^1$ bands with centres at 16,705, 17,462, 18,870, 19,510, 21,650 and 25,000 cm^{-1}. A red shift of the first *f–d* bands from wavelengths higher than 20,000 cm^{-1} to the visible range has been attributed[10,11] to the formation of inner-sphere complexes, with some of the uranium–ligand bonds of a markedly more covalent character compared with those of the U^{3+} aquo ion.[10] The results of the hitherto investigated bromo complexes confirm the above:

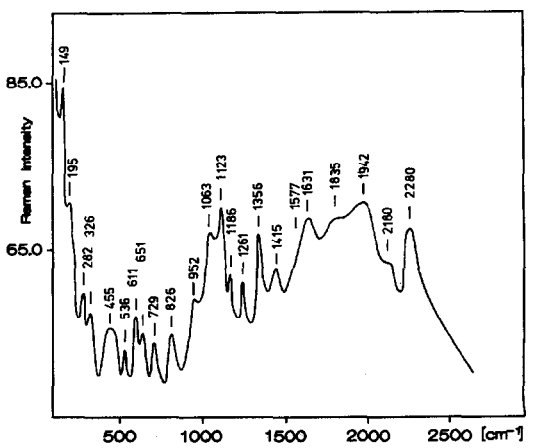

Fig. 4. Raman spectrum.

(*Received* 27 *January* 1993; *accepted* 5 *March* 1993)

Abstract—The crystal structures of four platinum(II) complex cations containing the organic ligand 2,6-bis(methylthiomethyl)pyridine (SNS), $[Pt(SNS)Cl]^+$ (**1**), $[Pt(SNS)(SCN)]^+$ (**2**), $[Pt(SNS)Br]^+$ (**3**) and $[Pt(SNS)(Py)]^{2+}$ (**4**) have been determined by X-ray diffraction. In all complexes SNS behaves as a tridentate neutral ligand with the two sulphur atoms in *trans* positions to each other. The fourth coordination position, *trans* to the nitrogen atom of SNS, is occupied either by a monodentate chloride, sulphur-bonded thiocyanate, bromide or nitrogen of a pyridine molecule, respectively, in a square planar arrangement. No Pt—Pt interactions in the linear chain are present. Pt—N(pyridine) bond distances are related to the charge of the complexes.

As part of our interest in the synthesis, structure and reactivity of coordination compounds of d^8 metal ions with chelating ligands containing the pyridine moiety,[1–9] we have recently studied the binding ability of the tridentate ligand 2,6-bis-(methylthiomethyl)pyridine (SNS) with protons, palladium(II) and copper(II) and determined the formation constants of the palladium(II) and copper(II) cationic complexes $[Pd(SNS)Tu]^{2+}$ (Tu = thiourea) and $[Cu(SNS)(H_2O)]^{2+}$ in aqueous solutions.[10] Due to the much higher formation constant of the palladium complex (log $K = 28.92 \pm 0.09$) with respect to its copper counterpart ($\log K = 4.6 \pm 0.1$), which certainly stresses the fact that the ligands being exchanged are different (Tu vs H_2O), it was thought the polymers functionalized with SNS groups would be selective for the extraction of palladium(II) from mixtures of palladium(II) and copper(II) in aqueous solutions. A chelating resin was thus prepared by reacting the derived ligand 2,6-bis(methylthiomethyl)-3-hydroxypyridine with a chloromethylated macroporous cross-linked polystyrene, which has been shown to be able to separate quantitatively and rapidly ($t_{1/2} = 11$ min) palladium(II) from copper(II), even when present in 150-fold excess, from acidic chloride (pH = 1) aqueous solutions.[11]

Successively, the complex cation of platinum(II), $[Pt(SNS)Cl]^+$, has been prepared and the kinetics of the associatively activated replacement of chloride by a wide variety of anionic and neutral nucleophiles has been studied in water.[12] Here we report the X-ray crystal structure of the chloro complex cation $[Pt(SNS)Cl]^+$ (**1**), as well as those of the substitution cationic products $[Pt(SNS)(SCN)]^+$ (**2**), $[Pt(SNS)Br]^+$ (**3**) and $[Pt(SNS)(Py)]^{2+}$ (**4**).

EXPERIMENTAL

Preparation of the complexes

The complexes were prepared and crystallized as previously reported.[12]

Determination of the structures

Intensity data were collected on an Enraf–Nonius CAD4 diffractometer with monochromated Mo-K_α radiation using the $\omega/2\theta$ scan technique. Cell parameters were obtained from least squares refinement of 25 centred reflections in the range $7 < \theta < 14°$. Crystal data are reported in Table 1. Intensities were corrected for Lorentz, polarization and absorption (minimum transmission factors: 0.86, 0.43, 0.35 and 0.78 for compounds **1**, **2**, **3** and **4**, respectively). Scattering factors and anomalous dispersion parameters were taken from ref. 13; solution was by Patterson and Fourier methods. The structure of compound **2** was refined by full-matrix least-squares using anisotropic thermal parameters for all non-hydrogen atoms and isotropic ones for hydrogens. All the other structures were refined by full-matrix least-squares using anisotropic thermal parameters for all non-hydrogen atoms and hydrogen atoms in calculated fixed positions. Weights for the last cycle were applied according to the scheme given in Table 1. All calculations were performed by the MolEN[14] and PARST[15] programs. Final positional and thermal parameters, as well as supplementary material, have been deposited with the Editor.

RESULTS AND DISCUSSION

ORTEP[16] drawings of the four square-planar tetra-coordinate cation complexes of platinum (II) bis-2,6-(methylthiomethyl)pyridine derivatives, showing the atom number scheme, are given in Fig. 1. Bond distances and angles are reported in Tables 2 and 3, respectively. In all complexes the organic ligand behaves as a tridentate neutral ligand with

the two sulphur atoms *trans* to each other. The cations of compounds **1**, **3** and **4** have a C_2 symmetry, but only the cation of compound **4** lies on a two-fold crystallographic axis passing through the Pt, N(1), N(2), C(3) and C(12) atoms. In general the tridentate ligands containing the pyridine moiety, as 2,2′,2″-terpyridine, 6-phenyl-2,2′-bipyridine and 2,6-pyridine dicarboxylate, usually give rise to strained square-planar platinum(II) complexes with exceptionally short Pt—N(pyridine) bond distances, observed in the range 1.88–1.97 Å, and N—Pt—X(*cis*) angles far from the ideal value of 90°, the average value being 81.0(8)° as calculated from a sample of 14 angles.[17–20]

In the compounds under examination, owing to the C(6) and C(7) sp^3 hybridized atoms and the Pt—S long distances, which are in the range 2.27–2.29 Å, the straining is less pronounced, with the N—Pt—S angles in the range 85.6–87.6° and Pt—N(pyridine) distances of 2.004(9), 2.014(13) and 2.004(7) Å in compounds **1**, **2** and **3**, respectively. In compound **4**, however, the Pt—N(1) distance remains very short, that is 1.937(9) Å, but it can be stressed in this case the *trans* position to N(1)

is occupied by the N(2) nitrogen of a pyridine with a Pt—N(2) distance of 2.069(7) Å. This complex, unlike the other three, contains a neutral molecule *trans* to the N(1) atom and consequently the cation has two positive charges; the two different values of Pt—N(1) and Pt—N(2) could be related to a different positive charge redistribution on the cation. To support this hypothesis it can be noted that the average value of the two Pt—N bond lengths, 2.003 Å, corresponds very well to the Pt—N distances found in the other three complexes and to the Pt—N(pyridine) distances observed in other chelated platinum(II) square-planar derivatives, where the chelated ions or molecules are mono- or bidentate.[20–27] All the other distances are normal; the Pt—S distances can be compared with the Pt—S distances between platinum(II) and neutral sulphur in other square-planar complexes.[27–30] All the crystals contain ions with no short interatomic distances. No Pt—Pt distance less than 4.50 Å has been observed and consequently no metal–metal interactions in the linear chains are present, as in similar square-planar complexes where molecules or ions are stacked in columns with Pt—Pt distances in the range 3.24–3.73 Å.[17,18,20,23,24,28,31,32]

SPECTROELECTROCHEMISTRY OF IRON COMPLEXES OF THE C_2-CAPPED PORPHYRIN LIGAND

JAMES H. CAMERON* and STEVEN C. TURNER

Department of Chemistry, Heriot-Watt University, Riccarton, Edinburgh EH14 4AS, U.K.

(*Received* 27 *January* 1993; *accepted* 5 *March* 1993)

Abstract—The coordination chemistry of iron complexes of C_2-capped porphyrin ligand has been examined by spectroelectrochemistry. In solution, in dimethylsulphoxide (DMSO), the chloride ion of [$Fe^{III}(C_2cap)Cl$] remained bound to iron(III). In the presence of 1-methylimidazole (1-MeIm) the Cl^- ion is substituted by OH^-, generated by reaction of 1-MeIm with trace amounts of water in the system. Controlled potential reduction of [$Fe^{III}(C_2cap)(OH)$] in DMSO solution produced the six-coordinate iron(II) complex [$Fe^{II}(C_2cap)$(1-MeIm)(DMSO)], with the DMSO ligand bound within the capping group. Reduction of [$Fe^{III}(C_2cap)Cl$], in solution in CH_2Cl_2 containing 1-MeIm, produced the five coordinate iron(II) species, $Fe^{II}(C_2cap)$(1-MeIm).

The coordination chemistry of iron porphyrin complexes has been a topic of great interest, largely because of the widespread use of the haem group in bioinorganic chemistry and the desire to model the physical characteristics of the natural systems.[1] Early attempts to model the chemistry of the oxygen carrying proteins, haemoglobin and myoglobin, led to the conclusion that unhindered porphyrin complexes were not suitable because of the strong driving force for the iron(II) to achieve a six-coordinate, low spin state. This resulted in the formation of a number of families of substituted porphyrins with some form of steric protection for one, or more, of the axial binding sites of the iron(II) ion.[2] One of the earliest examples of this strategy, and one of the most successful, was the "capped porphyrin" molecule of Baldwin and co-workers, first reported in 1975.[3] [$Fe^{II}(C_2cap)$] (**1**) has a benzenoid "cap", attached to the porphyrin ring by four side-arm groups, forming a protected cavity, from which all but the smallest molecules are excluded. Thus, even in the presence of large quantities of ligands such as pyridine, the metal centre remains five-coordinate.[4] These systems may thus be regarded as exercizing a form of molecular recognition, where the physical dimensions of the cavity act to select or exclude potential binding groups for the metal centre.

A number of reports have appeared concerning the binding of dioxygen and carbon monoxide to both this complex and its analogues, producing six-coordinate complexes.[5] Relatively little work has been reported on the interaction of [$Fe^{II}(C_2cap)$] with other ligands. Basolo and co-workers reported the binding of ammonia to [$Fe^{II}(C_2cap)$(1-MeIm)] [1-MeIm = 1-methyl-imidazole], producing six-coordinate species with ammonia bonded inside the cap.[6] In an interesting paper Collman *et al.* used magnetic circular dichroism (MCD) spectra to characterize the coordination number and spin state of, amongst others, [$Fe^{II}(C_2cap)$] in the presence of ligands of varying steric bulk.[7] With the larger

ligands, such as 1-MeIm or pyridine, the five-coordinate, high spin ($S = 2$) nature of the resultant complex was confirmed, but a somewhat different situation was encountered using the smaller n-propylamine. In the presence of a dilute solution of Pr^nNH_2 (0.1 mol dm^{-3}) the complex was still predominantly five-coordinate, but there was evidence in the spectrum for some six-coordinate, low spin ($S = 0$) material. Increasing the concentration of Pr^nNH_2 (to 1.0 mol dm^{-3}) increased the relative concentration of six-coordinate material, but some five-coordinate complex was still evident. Related behaviour with i-butylamine was also reported, although formation of the six-coordinate species was very slow.

Recently Brewer and Brewer reported on the formation of binuclear complexes involving $[Fe^{III}(C_2cap)]^+$ species, formed by ligation of an imidazolate group of a copper(II) complex to the iron(III) centre, giving a five-coordinate iron(III) ion.[8]

Although the spectroelectrochemistry of $[Co^{III}(C_2cap)]$ has been reported,[9] the electrochemistry of the corresponding iron complex has not been discussed in the open literature. Some work concerning the electrochemistry of $[Fe^{II}(C_2cap)]$ and its oxygen adduct has appeared in the patent literature,[10] but the electrochemical behaviour of the complexes was not reported in detail. Saveant and co-workers have reported on the electrochemistry of some strapped and bridged iron(III) porphyrin complexes, which display unusual properties derived from the restricted solvation of the bulky porphyrin species.[11] In this work we report on the spectroelectrochemistry of $[Fe^{II}(C_2cap)]$ in different solvents and also report upon the formation of an unusual six-coordinate iron(II) complex in solution in DMSO.

RESULTS AND DISCUSSION

The cyclic voltammogram of $[Fe^{III}(C_2cap)Cl]$ dissolved in a DMSO solution, containing 10% by volume of 1-MeIm (1.25 mol dm^{-3}) is shown in Fig. 1. In the range 0 to -2 V (vs an S.C.E.) four reduction waves were observed, each having an associated oxidation wave on the reverse sweep (Table 1). This behaviour is similar to that observed for other iron(III) porphyrin complexes and, by analogy, the four one-electron reduction steps are assigned as two reductions of the metal ion, followed by two reductions of the porphyrin ring.[12]

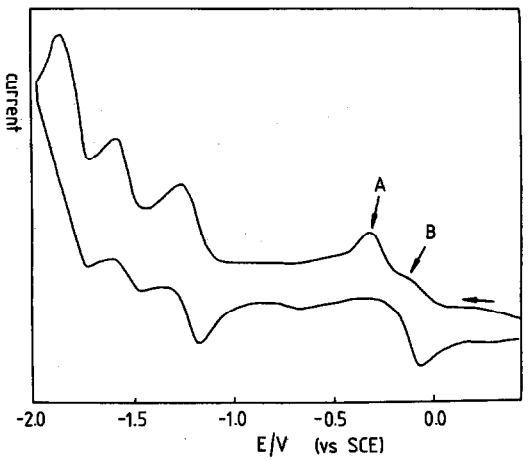

Fig. 1. Cyclic voltammogram of $Fe^{III}(C_2cap)Cl$ (5×10^{-3} mol dm^{-3}) dissolved in DMSO containing 10% by volume of 1-MeIm, with Bu_4NBF_4 (0.1 mol dm^{-3}) as an electrolyte.

Table 1. Electrochemical data for reduction of $Fe^{III}(C_2cap)Cl$

Couple	$E_{1/2}$ (V)	ΔE_p (mV)
$Fe^{III}(P)/Fe^{II}(P)$[a]	−0.20 (−0.10)	300 (100)
$Fe^{II}(P)/Fe^{I}(P)$	−1.22	110
$Fe^{I}(P)/Fe^{I}(P^{\cdot-})$	−1.52	130
$Fe^{I}(P^{\cdot-})/Fe^{I}(P^{2-})$	−1.80	140

[a] Two overlapping processes.

$$[Fe^{III}(Por)]^+ \xrightarrow{+e^-} [Fe^{II}(Por)] \xrightarrow{+e^-} [Fe^{I}(Por)]^- \xrightarrow{+e^-} [Fe^{I}(Por)^-]^{2-} \xrightarrow{+e^-} [Fe^{I}(Por)^{2-}]^{3-}$$

where Por represents a generalized porphyrin ligand. The ratio of current peak heights for each cathodic/anodic couple was approximately unity, indicating that the electron-transfer reactions were largely unaffected by any subsequent chemical reactions. The peak separation, ΔE_p, was in each case in excess of the theoretical value for a one-electron process of 59 mV and so each couple is best described as being quasi-reversible. This is in good agreement with the literature data for related systems.[12]

No oxidation reactions involving $[Fe^{III}(C_2cap)]^+$ were observed up to the anodic potential limit of the solvent (*ca* 0.8 V). This is in keeping with the results of a study of the oxidation reactions of $[Co^{II}(C_2cap)]$, in dichloromethane solution,[9] in which two oxidations of the porphyrin ring were observed, at 1.02 and 1.20 V vs S.C.E., and hence the corresponding oxidations of the iron(III) complex are beyond the solvent limit of the present system.

Closer examination of the wave assigned to the iron(III)/iron(II) couple suggests that two over-

lapping reduction steps are observed (A and B), indicating the presence of two distinct reducible species in solution. This behaviour is ascribed to the occurrence of an equilibrium between different species of the general formula $[Fe^{III}(C_2cap)X]$, where X is Cl^- or OH^- (*vide infra*).

$$[Fe^{III}(C_2cap)Cl]_{(solv)} + OH^-_{(solv)} \underset{}{\overset{DMSO}{\rightleftharpoons}} [Fe^{III}(C_2cap)(OH)]_{(solv)} + Cl^-_{(solv)}$$

Similar behaviour has been noted by Saveant and co-workers in the oxidation of the iron(II) complex of a strapped porphyrin ligand, where Cl^- competes successfully with dimethyl formamide as a ligand to iron(II), producing two oxidizable species.[11] In this work the electronic spectrum of the iron(III) species is sensitive to the nature of the axial ligand.[13] Since the electronic spectrum of $[Fe^{III}(C_2cap)Cl]$ in the non-coordinating solvent $CHCl_3$ (λ_{max} 514 nm) is identical to that in DMSO, then it is believed that DMSO does not displace chloride ions from the complex, nor does DMSO bind within the capping group in the sixth coordination site. DMSO is normally regarded as a good solvent for charged species, having a relatively high dielectric constant, but in this case dissociation of the neutral complex does not occur, instead strong ion pairing is favoured. Similar behaviour has been reported in the literature for other iron(III) porphyrin complexes, albeit in solvents of lower polarity than DMSO.[14] Thus, a species of the form $[Fe^{III}(C_2cap)(DMSO)]^+$ can be eliminated from discussion. This behaviour is in marked contrast to the situation found for the corresponding complex of the tetraphenylporphyrin ligand (TPP) $[Fe^{III}TPPCl]$. In DMSO solution the chloride ion is displaced by DMSO and a six-coordinate complex, $[Fe^{III}TPP(DMSO)_2]^+$, is formed.[15] This difference may arise because the bound Cl^- requires to be labilized by a *trans*-ligated DMSO molecule before substitution is favoured. This can occur readily with the TPP complex, but is disfavoured with the capped species. By analogy with other sulphoxide-ligated iron(III) porphyrin complexes, the DMSO would have to bind via the oxygen atom and it would appear that the capping group is unable to accommodate the DMSO in this coordination mode.[16]

In contrast the spectrum of $[Fe^{III}(C_2cap)Cl]$ in solution, in DMSO containing 10% by volume of 1-MeIm, has λ_{max} at 575 nm, indicating that the Cl^- ion is displaced, but not apparently by 1-MeIm since the spectrum is markedly different from a literature report of an imidazole ligand bonded to $[Fe^{III}(C_2cap)]^+$.[8] Brewer and Brewer have also observed the species with λ_{max} at 575 nm and have assigned it as the OH^- ligated complex $[Fe^{III}(C_2cap)OH]$.[8] In this work the spectrum retains a shoulder at *ca* 510 nm, ascribed to the presence of a small amount of the chloro complex. In solution in neat 1-MeIm this should be absent and only the peak assigned to $[Fe^{III}(C_2cap)OH]$, λ_{max} = 575 nm, is observed. The appearance of this OH^- ligated species presumably arises from the presence of trace amounts of water in the system. Deprotonation of this water by 1-MeIm produces the OH^- ion which is able to compete successfully for the iron(III) coordination site, even in neat 1-MeIm. The involvement of H_2O was confirmed by treating a $CHCl_3$ solution of $[Fe^{III}(C_2cap)Cl]$ with 1-MeIm, to which some water had been deliberately added. Whereas no reaction was observed in the absence of water, in the presence of water the characteristic spectrum of $[Fe^{III}(C_2cap)OH]$ was generated. Treating a DMSO solution of $[Fe^{III}(C_2cap)Cl]$ with aqueous NaOH also produced the spectrum of the hydroxo complex.

In the cyclic voltammogram the more negative, and larger, iron(III) reduction wave (A) is assigned, therefore, to reduction of the major species in solution, $[Fe^{III}(C_2cap)OH]$. The observed potential shift between waves A and B is ascribed to the stronger Lewis basicity of OH^-, relative to the chloride ion, making the iron(III) ion in $[Fe^{III}(C_2cap)OH]$ more difficult to reduce than that in $[Fe^{III}(C_2cap)Cl]$.

The corresponding oxidation reaction involves only a single peak and hence it is believed that the anionic ligand of $[Fe^{II}(C_2cap)X]^-$ (X = Cl^- or OH^-) is replaced by 1-MeIm, generating a single iron(II) species. The coordination environment of this iron(II) complex is discussed below.

Spectroelectrochemistry results

The above discussion has highlighted the utility of both electrochemistry and electronic spectroscopy in the characterization of the various iron-capped porphyrin species. An obvious extension is to combine the two techniques for simultaneous examination of the behaviour of the complexes and to this end the spectroelectrochemistry of $[Fe^{III}(C_2cap)X]$ (X = Cl^- or OH^-) was performed using an optically transparent thin layer electrode (OTTLE) cell. The spectroscopic changes accompanying the reduction of $[Fe^{III}(C_2cap)X]$ in DMSO/10% 1-MeIm solution are shown in Fig. 2. The initial spectrum, as described above, is assigned as belonging to a mixture of predominantly $[Fe^{III}(C_2cap)OH]$ with a small amount of $[Fe^{III}(C_2cap)Cl]$. During reduction of the system at −0.4 V a new spectrum, with λ_{max} 535 and 570 nm, grew in over a period of *ca* 5 min. This spectrum strongly

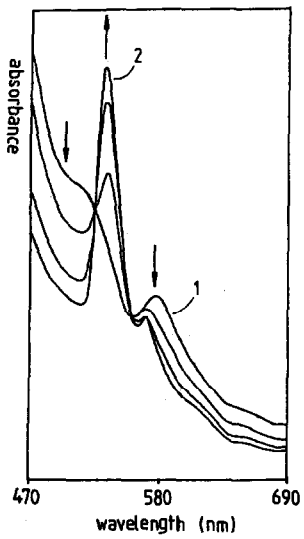

Fig. 2. Time resolved thin-layer electronic spectra during reduction of [$Fe^{III}(C_2cap)OH$] in solution in DMSO/10% 1-MeIm. Applied potential −0.4 V; 1, $t = 0$, 2, $t = 5$ min.

resembles literature results for six-coordinate, low spin iron(II) porphyrin complexes.[17]

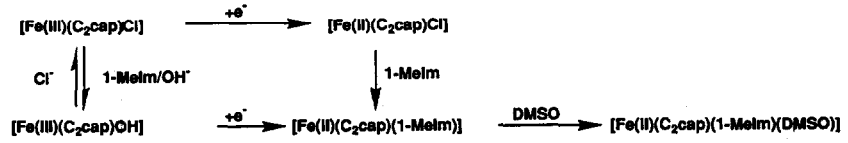
The aim in designing the capped porphyrin was to produce a sterically protected binding site which only small molecules, such as O_2 or CO, could access. The crystal structure of [$Fe^{III}(C_2cap)Cl$] demonstrated that this had been achieved, with the capping group lying only 403 pm from the N_4 plane of the porphyrin.[18] This meant that the cavity must expand to accommodate even diatomic ligands. As described above Baldwin and co-workers showed that 1-MeIm was too large to enter the cavity of [$Fe^{II}(C_2cap)$],[4] but Basolo and co-workers[6] and Collman *et al.*[7] showed that smaller ligands, such as ammonia or n-propylamine or i-butylamine, respectively, could bind to the protected axial coordination site. In this work the only ligand present which is small enough to enter the cavity and bind to the iron(II) is DMSO, and so the six-coordinate iron(II) species generated in the electrolysis reaction is assigned as being [$Fe^{II}(C_2cap)$(1-MeIm)(DMSO)]. It is presumed that the DMSO ligand binds to iron(II) via its sulphur atom, although this remains to be confirmed. There is precedent for DMSO binding within the cavity of capped porphyrins. In an NMR study of zinc(II) species Williams and co-workers found evidence from NMR spectroscopy for DMSO entering the cavity of C_3-capped porphyrin and binding to the metal centre.[19]

The spectroscopic changes observed in the electrochemical experiment were reproduced when the [$Fe^{III}(C_2cap)Cl$] species was chemically reduced to [$Fe^{II}(C_2cap)$], isolated and then dissolved in DMSO/10% 1-MeIm solution. Moreover, the initial spectrum in Fig. 2 can be regenerated fully by applying an oxidizing potential of +0.2 V. This confirms that the redox reaction

$$Fe^{III} + e^- \rightleftharpoons Fe^{II}$$

is fully reversible under anaerobic conditions. The electron pathway that accounts for all of the observed results is shown in Scheme 1.

To confirm the involvement of DMSO in the coordination chemistry of the system, the spectroelectrochemistry of [$Fe^{III}(C_2cap)Cl$] in solution in dichloromethane containing 10% by volume of 1-MeIm was examined and the results are illustrated in Fig. 3. The initial spectrum (λ_{max} = 514, 588 and 650 nm) is typical of [Fe^{III}(tetraphenylporphyrin)Cl] species,[20] indicating that in CH_2Cl_2 solution the Cl^- ion is not replaced by 1-MeIm. This again represents a dramatic difference in behaviour



Scheme 1.

relative to that of [Fe^{III}TPPCl], which readily forms a bis(base) adduct in solvents of low polarity.[21] Since CH_2Cl_2 is more readily kept dry than DMSO, there is no involvement of OH^- in the coordination chemistry of [$Fe^{III}(C_2cap)]^+$ in this solvent. If water is deliberately added to the system, however, the hydroxo complex is again observed, underlining the necessity of working in anhydrous conditions with the capped complex. The inability of 1-MeIm to replace Cl^- ions in anhydrous conditions is in keeping with the strong binding of Cl^- to iron(III), reported by Walker *et al.* for [Fe^{III}TPPCl].[13] Although this species does undergo substitution, K_{diss} for Cl^- in $CHCl_3$ solution is very small ($< 10^{-6}$ mol dm^{-3}).

The electronic spectrum of the fully reduced material in CH_2Cl_2/10% 1-MeIm is very different from that of the fully reduced material in DMSO/10% 1-MeIm solution. It has λ_{max} at 540 nm with a shoulder at *ca* 564 nm, strongly resembling the spectrum of the five-coordinate $Fe^{II}(C_2cap)$(pyridine) species reported in the literature.[4] Therefore, the product of electrochemical reduction is assigned as the five-coordinate complex [$Fe^{II}(C_2cap)$(1-MeIm)]. The reaction pathway for reduction of $Fe^{III}(C_2cap)Cl$ in CH_2Cl_2/100% 1-MeIm is described by Scheme 2.

$$[Fe^{III}(C_2cap)Cl] \xrightarrow{+e^-} [Fe^{II}(C_2cap)Cl]^- \xrightarrow{-Cl^-}$$

$$[Fe^{II}(C_2cap)] \xrightarrow{1\text{-MeIm}} [Fe^{II}(C_2cap)(1\text{-MeIm})$$

Scheme 2.

The spectroelectrochemical results indicate that electron transfer is accompanied by isosbestic points in the electronic spectra. This implies that the intermediate species in the scheme are but transient, and Cl^- dissociation from [$Fe^{II}(C_1cap)Cl]^-$ and 1-MeIm binding to [$Fe^{II}(C_2cap)$] are both rapid processes. Notably the spectroscopic changes of Fig. 3 are completely reversible upon controlled potential oxidation of the system. This indicates that $Fe^{III}(C_2cap)Cl$ is reformed during the oxidation step and we ascribe this behaviour to the poor ability of CH_2Cl_2 to stabilize ions, which leads to rapid association of [$Fe^{III}(C_2cap)]^+$ and Cl^- to reform the starting material.

The electrochemical behaviour of the iron C_2-capped porphyrin complex in the presence of dioxygen will form the basis of a separate report.

CONCLUSIONS

The chloride ion of [$Fe^{III}(C_2cap)Cl$] is not displaced by DMSO when the complex is dissolved in that solvent. In contrast, when 1-MeIm is added to the solvent system the Cl^- ion is replaced by OH^-, formed from trace amounts of water, to produce a five-coordinate complex, [$Fe^{III}(C_2cap)OH$]. This species undergoes four quasi-reversible one-electron reduction steps in the region 0 to -2 V (vs S.C.E.). Controlled potential reduction at -0.4 V produces a six-coordinate iron(II) complex, [$Fe^{II}(C_2cap)$(1-MeIm)(DMSO)], where the DMSO ligand binds within the capping group. This redox reaction was shown to be reversible by spectroelectrochemistry.

Spectroelectrochemistry of [$Fe^{III}(C_2cap)Cl$] in CH_2Cl_2 containing 1-MeIm indicates that the Cl^- ion is not replaced by 1-MeIm until reduction has occurred. The iron(II) product of controlled potential reduction is the five-coordinate species $Fe^{II}(C_2cap)$(1-MeIm). Re-oxidation generates [$Fe^{III}(C_2cap)Cl$].

EXPERIMENTAL

All solvents and 1-MeIm were carefully dried using standard literature procedures. Tetrabutylammonium tetrafluoroborate was recrystallized from ethanol and dried *in vacuo* at 80°C. The C_2-capped porphyrin ligand was prepared by the method of Baldwin and co-workers.[3]

Preparation of [$Fe^{III}(C_2cap)Cl$]

This was prepared by a modification of the literature procedure.[22] A solution of the free-base ligand (0.100 g, 9.65×10^{-5} mol) and $Fe^{II}Cl_2 \cdot 4MeCN$ (0.360 g, 1.24 mmol) in THF was heated at reflux, under nitrogen, for 5 days. The flask was protected from light during this process. The THF was removed, the residue was dissolved in $CHCl_3$ and the organic layer was extracted with three portions of 1 M HCl (15 cm^3). The organic layer was dried, reduced in volume to *ca* 1 cm^3 and then chromatographed on neutral alumina using $CHCl_3$ as an eluant. The fast-moving coloured band was collected and HCl gas was bubbled through the solution, to react with the μ-oxo dimer by product. Removal of the solvent gave the product as a lustrous, dark blue solid (yield 0.080 g, 76%).

The electrochemical apparatus was that described in detail in a previous report.[23] The internal resistance of the solvent was compensated for by the PAR 273 potentiostat. Potentials were referenced externally to a sample of ferrocene, run immediately prior to each experiment. In addition an OTTLE cell based upon the design of Scherson *et al.*[24] was also used. This allowed incorporation of an S.C.E. reference electrode rather than the platinum wire pseudo-reference of the other system.

Qualitatively the results were identical in either cell. All potentials quoted in this work are with respect to the S.C.E. reference. Typically the electrochemical experiments were run on solutions *ca* 3.3×10^{-3} mol dm^{-3} in the porphyrin complex and 0.1 mol dm^{-3} in the supporting electrolyte $[Bu_4NBF_4]$. The electronic spectra were recorded using Shimadzu UV-240 or Philips Analytical SP1800 spectrophotometers.

Abstract—The reaction of $NiCl_2 \cdot 6H_2O$ with tetrahydrofuran-2,3,4,5-tetracarboxylic acid, $THF(COOH)_4$, partially deprotonated by Na_2CO_3 (1 : 1 metal/ligand molar ratio), yielded $Ni[THF(COOH)_2(COO)_2](H_2O)_3$ (**1**). The molecular structure of **1** was determined by X-ray diffraction on the monocrystal. The structure consists of a mononuclear neutral unit with the nickel atom coordinated by a $[THF(COOH)_2(COO)_2]^{2-}$ ligand, which acts as a tridentate ligand, and three water molecules. Direct interaction of $NiCl_2 \cdot 6H_2O$ and $CoCl_2 \cdot 6H_2O$ (1 : 1 molar ratio) with $THF(COOH)_4$ previously deprotonated by Na_2CO_3 (1 : 1 metal/ligand molar ratio) gave, by slow evaporation of the solution obtained, green crystals of the non-stoichiometric complex $Ni_{0.7}Co_{0.3}[THF(COOH)_2(COO)_2](H_2O)_3 \cdot H_2O$ (**2**). Its crystal structure was solved by single-crystal X-ray diffraction methods. The structure is similar to that determined for compound **1**, but with 30% of the sites for the metal atom occupied by cobalt and including a water molecule of crystallization. The thermal decomposition of both compounds showed three effects: An endothermic effect, corresponding to the loss of water which occurred at about 150°C and second and third exothermic processes, which overlapped each other at *ca* 310 and 330°C, corresponding to the decomposition of the complex and subsequent formation of oxides at very low temperatures.

Ligands containing more than one functional group can be used efficiently to bond two or more metal centres, depending on the number of functional groups contained in the ligand. Dicarboxylic acids like oxalic acid have been used extensively in the synthesis of dinuclear homonuclear and heteronuclear complexes.[1,2] However, polycarboxylic

* Authors to whom correspondence should be addressed.

acids have not been used to the same extent. Tetrahydrofurantetracarboxylic acid, $THF(COOH)_4$, is commercially available as a mixture of diastereoisomers. It has been described that this ligand acts as a metal trapping agent in detergents,[3,4] although a small number of studies concerning the formation of complexes with this ligand have been performed. Thus, as far as we know, only three structures containing the $THF(COOH)_4$ ligand have been published: that of $[Co(en)_3][THF(COO)(COOH)_3][THF(COO)_2(COOH)_2] \cdot 2.5H_2O$,[5] where the dihydrogen and trihydrogen tetrahydrofurantetracarboxylates are present as anionic species, balancing the charge of the $[Co(en)_3]^{3+}$ cation, but are not acting as proper ligands; and those of polymeric $[Cs(THF(COO)(COOH)_3)]$ and $[Ca_2(THF(COO)_4(H_2O)_6)] \cdot 2H_2O$,[6] in which, in contrast, the ligand coordinates several metal atoms to give complicated three-dimensional structures.

The presence of four carboxylate groups in the ligand creates the possibility of acting with different coordination modes, for example, coordinating a unique atom as bidentate or tridentate, coordinating two metal atoms as bis-bidentate or acting as polydentate. In this sense we are interested in the coordination behaviour of this ligand with transition metal cations. We report here preliminary studies with nickel and cobalt.

EXPERIMENTAL

Preparation of the compounds

Preparation of $Ni[THF(COOH)_2(COO)_2](H_2O)_3$. Na_2CO_3 (106 mg, 1.0 mmol) was added to an aqueous solution (10 cm^3) of tetrahydrofuran-2,3,4,5-tetracarboxylic acid (248 mg, 1.0 mmol) and carbon dioxide evolved. The mixture was stirred for 5 min and an aqueous solution (10 cm^3) of $NiCl_2 \cdot 6H_2O$ (237 mg, 1.0 mmol) was added. Slow evaporation of the resulting green solution gave after several days suitable crystals for X-ray diffraction studies (yield 60%).

The IR spectrum of the compound obtained gave the following bands: 3480(m), 3380(m), 3220(m), 1730(s), 1670(m), 1590(s), 1410(s), 1335(w), 1295(w), 1235(w), 1220(w), 1190(m), 1100(w), 1055(m), 1020(w), 970(w), 955(w), 930(m), 870(w), 805(m), 760(m), 690(w) cm^{-1}.

Preparation of $Ni_{0.7}Co_{0.3}[THF(COOH)_2(COO)_2](H_2O)_3 \cdot H_2O$. Na_2CO_3 (106 mg, 1.0 mmol) was slowly added to an aqueous solution (10 cm^3) of tetrahydrofuran-2,3,4,5-tetracarboxylic acid (248 mg, 1.0 mmol) and the mixture was stirred for 5 min. A mixture of $NiCl_2 \cdot 6H_2O$ and $CoCl_2 \cdot 6H_2O$ (1 : 1 molar ratio) was then added in a metal/ligand molar ratio of 1 : 1. Slow evaporation of the solution thus obtained yielded after several days green crystals suitable for X-ray diffraction studies (yield 54%).

The IR spectrum of the compound obtained gave the following bands: 3420(m), 3376(m), 3243(m), 1739(s), 1670(m), 1599(s), 1415(s), 1343(w), 1305(w), 1251(w), 1232(w), 1189(m), 1108(w), 1067(m), 1020(w), 981(w), 965(w), 940(m), 876(w), 815(m), 766(m), 697(w) cm^{-1}.

The Ni/Co molar ratio was determined by flame atomic absorption and confirmed by microanalysis using scanning electron microscopy (SEM).

Materials and measurements

Tetrahydrofuran-2,3,4,5-tetracarboxylic acid $[THF(COOH)_4]$ was used as commercially available (Aldrich). Anhydrous sodium carbonate and hexahydrate nickel(II) and cobalt(II) chlorides were from Panreac.

IR spectra were recorded on KBr discs with a Perkin–Elmer 781 IR spectrophotometer between 600 and 4000 cm^{-1}. The two complexes were also studied in the solid state by UV–vis spectroscopy by the diffuse reflectance technique, with a UV–vis–NIR double beam spectrometer in the frequency range 4000–50,000 cm^{-1}. The thermal behaviour of both complexes was studied by TGA, DTG and DTA with Perkin–Elmer DTA1700 and TGA7 apparatus, between 20 and 600°C at a heating rate of 5 K min^{-1}, in a platinum crucible in air with a flow rate of 45.00 cm^3 min^{-1} and using alumina as a reference.

Analysis for metals was performed by flame atomic absorption spectroscopy using a Perkin–Elmer flame atomic absorption spectrometer. Microanalyses by scanning electron microscopy (SEM) (Hitachi S-2500) and energy dispersive X-ray analyses (EDX) (KEVEX, Delta IV quantum 8000) were performed on single crystals with 20 kV accelerating voltage; crystals being mounted on brass stubs with colloidal silver.

X-ray crystallographic procedures

Well-formed crystals of $Ni[THF(COOH)_2(COO)_2](H_2O)_3$ (**1**) and $Ni_{0.7}Co_{0.3}[THF(COOH)_2(COO)_2](H_2O)_3 \cdot H_2O$ (**2**) were grown by slow evaporation of aqueous solutions of the corresponding metal/ligand system and used for the structure determination. Crystallographic constants and experimental details for both structures are summarized in Table 1. X-ray diffraction data were collected on an Enraf–Nonius CAD4 single-crystal diffractometer using graphite-monochromated

[a] $R_{int} = \Sigma(|I| - \langle I \rangle)/\Sigma I$.
[b] $\Sigma w(F_o - F_c)^2$, $w = 1/[\sigma^2(F_o) + g(F_o)^2]$.

Mo-K_α radiation. Unit cell parameters were determined from the angular settings of 25 reflections with $11° < \theta < 18°$. A triclinic cell was obtained and the space group *P*-1 was confirmed from structure determination in both complexes. Reflections were measured in each case using the ω–2θ scan technique and a variable scan rate with a maximum scan time of 60 s per reflection. The intensity was checked throughout data collection by monitoring three standard reflections every 60 min. A profile analysis was performed on all reflections.[7,8] An empirical absorption correction was applied using ψ-scans.[9] Some Friedel pairs were averaged, $R_{int} = \Sigma(|I| - \langle I \rangle)/\Sigma I$. Lorentz and polarization corrections were applied and data reduced to $|F_o|$ values.

The structures were solved by the Patterson interpretation using the program SHELX86[10] and completed by DIRDIF.[11] Isotropic least-squares refinement was performed using SHELX76.[12] An additional empirical absorption correction was applied.[13] Further anisotropic refinements followed by difference-Fourier syntheses allowed the location of most of the hydrogen atoms. Positional parameters and anisotropic thermal parameters of non-hydrogen atoms were refined in complex **1**, except O(41) and O(42) which were found strongly disordered with two alternative positions, named O(41′) and O(42′), with a refined occupation factor of 0.63(3) for O(41) and 0.61(2) for O(42), and they were isotropically refined. In complex **2** occupation factors for the heavy atom were fixed from the atomic absorption analysis data, i.e. 0.7 for nickel and 0.3 for cobalt, and they were isotropically refined. All hydrogen atoms were refined isotropically, riding on their parent atoms with a com-

mon thermal parameter. The final difference-Fourier map showed no peaks higher than 1.30 e $Å^{-3}$ and deeper than -2.00 e $Å^{-3}$ for complex **1**; most of the highest peaks were found near the disordered carboxylic group and some of the weakest around the central nickel atom. Atomic scattering factors were taken from the International Tables for X-ray Crystallography.[14] Geometrical calculations were performed with PARST[15] and the molecular illustration was drawn with PLUTO.[16] All calculations were made on a MicroVax-3400 at the Scientific Computer Center, University of Oviedo.*

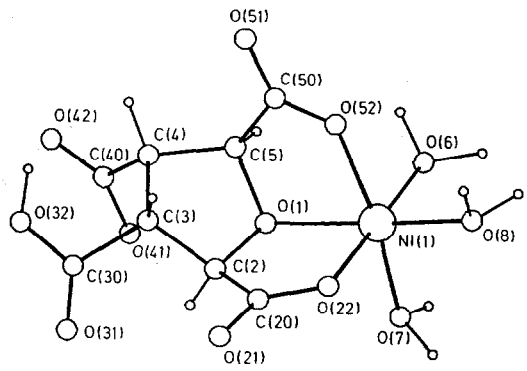

Fig. 1. Molecular structure of $Ni[THF(COOH)_2(COO)_2](H_2O)_3$.

RESULTS AND DISCUSSION

The reaction in aqueous medium of $THF(COOH)_4$ with $NiCl_2 \cdot 6H_2O$ in the presence of Na_2CO_3 (1 : 1 : 1 molar ratio) gave the compound $Ni[THF(COOH)_2(COO)_2](H_2O)_3$ (**1**) in good yield. Although the reaction was performed using the $THF(COOH)_4$ ligand as a commercially available mixture of diasteroisomers, complex **1** contains the coordinated ligand (partially deprotonated) in a *trans–cis–trans* conformation. The same behaviour is observed for other examples reported in the literature.[5,6] Inter- and intramolecular forces or packing forces may be related to the presence of only the *trans–cis–trans* isomer in the solid state, starting from a mixture of diastereoisomers in solution. This observation is supported by the fact that when crystals are separated the remaining solution refuses to crystallize, indicating that under these experimental conditions only the *trans–cis–trans* isomer is able to produce crystals.

Figure 1 shows a perspective view of the molecule for compound **1** with the atomic numbering scheme. Table 1 summarizes crystallographic data for compounds **1** and **2**. Selected bond distances and angles for compounds **1** and **2** are given in Tables 2 and 3, respectively.

The structure of compound **1** consists of a mononuclear neutral unit with the nickel atom coordinated by a $[THF(COOH)_2(COO)_2]^{2-}$ ligand acting as tridentate by coordinating two oxygen atoms from the carboxylate groups and one furanic oxygen from the ring. Three water molecules complete the coordination sphere. The crystallographic packing includes an extensive three-dimensional hydrogen-bond network involving carboxylic groups and water molecules. For compound **2** the crystal structure is very similar to that found for compound **1**, already shown in Fig. 1. However, for complex **2** nickel is substituted by cobalt in 30% of the sites of the heavy atom. We have confirmed the presence of cobalt in complex **2** quantitatively by flame atomic absorption spectroscopy and also semi-quantitatively by scanning electron microscopy, as well as by UV–vis spectroscopy, on the same crystals used for X-ray diffraction.

For both complexes the metal atom shows quite a regular octahedral environment with *cis* angles from 78.2(3) to 97.8(4)° for complex **1** and from 77.7(1) to 98.5(2)° for complex **2** and *trans* angles from 166.8(4) to 176.2(4)° (complex **1**) and from 166.1(2) to 175.8(2)° (complex **2**). The metal–oxygen bond distances fall in the ranges 2.103(8)–2.013(9) Å (compound **1**) and 2.143(4)–2.030(4) Å (compound **2**), averaging 2.050 and 2.086 Å, respectively. In the ligand the average C—C distance is 1.53 Å. The C(5)—O(1) and C(2)—O(1) bond distances are 1.45(1) and 1.46(1) Å for compound **1** and 1.457(6) and 1.453(6) Å for compound **2**; the average value given for the same distance in related structures being 1.43 Å. In the carboxylate groups the mean values for the bond length between carbon and oxygen atoms are C—OH 1.32 (complex **1**) and 1.27 Å (complex **2**), C—O 1.27 Å for both complexes and C=O 1.20 and 1.17 Å, respectively; average values reported for the same distances in the coordinated ligand are 1.31, 1.26 and 1.19 Å, respectively.

It has been suggested that the carboxylate groups on C(20) and C(50)[6] are more acidic than the remainder. Accordingly in compounds **1** and **2** these two carboxylate groups are deprotonated, which allows the ligand to act as a tridentate ligand (see

* Fractional positional and thermal parameters, full list of bond lengths and bond angles, anisotropic temperature factors for non-hydrogen atoms, fractional positional parameters for hydrogen atoms, bond lengths and bond angles involving hydrogen atoms, angles between least-squares planes, hydrogen contacts, principal torsion angles and observed and calculated structure factors have been deposited.

pound **2**) must be associated with disorder problems in the oxygen atoms of the non-coordinated carboxylate groups for complex **1**.

The UV–vis spectrum of complex **1** (Fig. 2) shows three absorption bands in agreement with the octahedral coordination of nickel(II): (a) a medium band at 9000 cm^{-1} corresponding to the $^3T_{2g}(F) \leftarrow {}^3A_{2g}(F)$ transition; (b) a strong band with a maximum at 15,300 cm^{-1} attributed to the $^3T_{1g}(F) \leftarrow {}^3A_{2g}(F)$ transition, and (c) a strong band at 25,700 cm^{-1} due to $^3T_{1g}(P) \leftarrow {}^3A_{2g}(F)$. The spectrum for complex **2** (Fig. 2) shows these bands of octahedral nickel(II) with a little lower intensity than for complex **1** and the first band displaced to 8800 cm^{-1}, and, in addition, two strong bands at 19,600 and 20,750 cm^{-1}. These two bands correspond, respectively, to $^4A_{2g}(F) \leftarrow {}^4T_{1g}(F)$ and $^4T_{1g}(P) \leftarrow {}^4T_{1g}(F)$ transitions for octahedral cobalt(II), while the displacement of the lower frequency band towards 8800 cm^{-1} can be explained as due to two overlapping transitions: the $^4T_{2g}(F) \leftarrow {}^4T_{1g}(F)$ transition of cobalt(II) and the $^3T_{2g}(F) \leftarrow {}^3A_{2g}(F)$ transition of nickel(II). Therefore, it is clear from these spectra that in compound **2** nickel(II) has been substituted to some extent by cobalt(II).

Complexes with metal atoms coordinated to ligands containing only carbon, oxygen and hydrogen are useful as precursors for producing the corresponding oxides at low temperatures. In this way we performed the thermal decomposition of the title compounds by TGA, DTG and DTA. The thermogravimetric study confirms the stoichiometry of complexes **1** and **2** found in the structural study. Figure 3 shows the thermal behaviour of compound **1**. Three thermal effects are clearly detected on the DTA curve. The first appears as a small endothermic peak between 110 and 185°C, with a maximum at 157°C. The other two appear as asymmetric overlapped exothermic peaks, one between 225 and 318°C with a maximum at 310°C and the other, much larger than the former, between 318 and 350°C with a maximum at 340°C. The endothermic effect corresponds to a weight loss which is observed in TGA and DTG curves between 125 and 175°C with a maximum at 154°C for compound **1** and 115 and 210°C with a maximum at 151°C for compound **2**, due to water evolution (three and four water molecules, respectively). The exothermic effects are accompanied by two overlapping larger weight losses corresponding to the decomposition of the complexes to the metal oxides, the second occurring at a much higher rate and developing a large amount of heat. The first loss takes place at 175–323°C with a maximum at 310°C for complex **1** and at 210–321°C with a maximum at 313°C for complex **2**, and the second loss occurs at 323–338°C with a maximum at 330°C and at

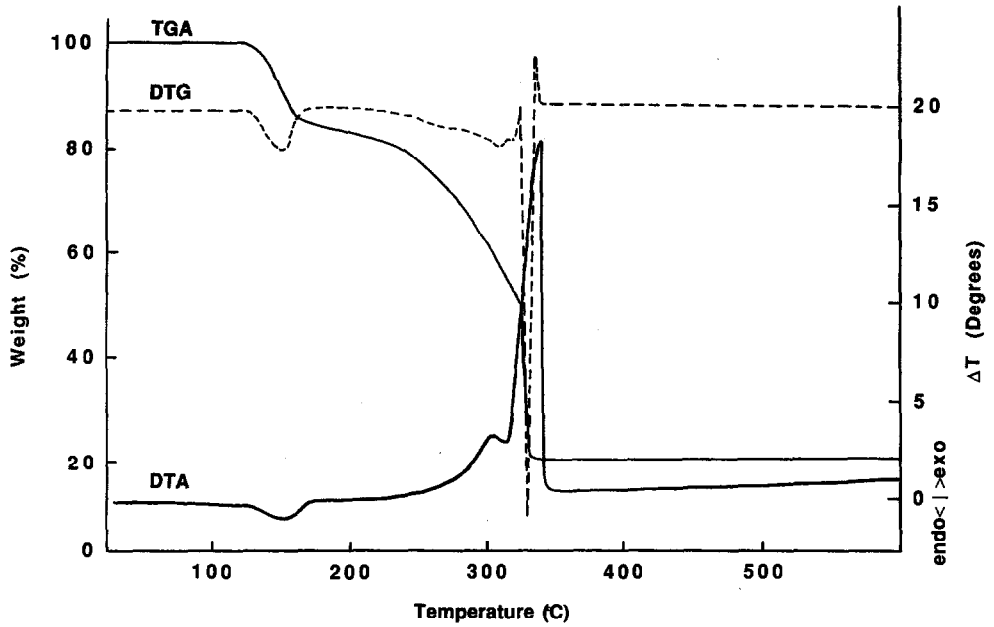

Fig. 3. TGA, DTG and DTA curves of $Ni[THF(COOH)_2(COO)_2](H_2O)_3$.

321–334°C with a maximum at 327°C, respectively.

As a conclusion this study reveals the ability of the $THF(COOH)_4$ ligand to give non-stoichiometric complexes; in fact, complex **2** should be considered as a non-stoichiometric compound. Studies oriented to the preparation of complexes with variable compositions of nickel and cobalt and the influence of the composition on structural parameters are now in progress. Furthermore, from this study the possibility of using this ligand to prepare precursors for the production of mixed oxides is opened.

Abstract—Treatment of CH_2Cl_2 solutions of $[N(PPh_3)_2][closo\text{-}1,2\text{-}Me_2\text{-}3\text{-}(\eta^3\text{-}C_3H_5)\text{-}3,3\text{-}(CO)_2\text{-}3,1,2\text{-}WC_2B_9H_9]$ with aqueous HI in the presence of CO affords $[N(PPh_3)_2][closo\text{-}1,8\text{-}Me_2\text{-}2\text{-}I\text{-}2,2,2\text{-}(CO)_3\text{-}2,1,8\text{-}WC_2B_9H_9]$ in virtually quantitative yield. In contrast, the reaction between $[N(PPh_3)_2][closo\text{-}1,2\text{-}Me_2\text{-}3\text{-}(\eta^3\text{-}C_3H_5)\text{-}3,3\text{-}(CO)_2\text{-}3,1,2\text{-}MoC_2B_9H_9]$ and aqueous HI gives initially $[N(PPh_3)_2][closo\text{-}1,2\text{-}Me_2\text{-}3\text{-}I\text{-}3,3,3\text{-}(CO)_3\text{-}3,1,2\text{-}MoC_2B_9H_9]$, but the latter undergoes a cage framework rearrangement to afford $[N(PPh_3)_2][closo\text{-}1,8\text{-}Me_2\text{-}2\text{-}I\text{-}2,2,2\text{-}(CO)_3\text{-}2,1,8\text{-}MoC_2B_9H_9]$, which is slow at room temperature. Protonation of $[NEt_4][closo\text{-}1,2\text{-}Me_2\text{-}3\text{-}(\equiv CC_6H_4Me\text{-}4)\text{-}3,3\text{-}(CO)_2\text{-}3,1,2\text{-}MoC_2B_9H_9]$ with aqueous HI yields initially $[NEt_4][closo\text{-}1,2\text{-}Me_2\text{-}8\text{-}(CH_2C_6H_4Me\text{-}4)\text{-}3\text{-}I\text{-}3,3,3\text{-}(CO)_3\text{-}3,1,2\text{-}MoC_2B_9H_8]$, which isomerizes at room temperature to give $[NEt_4][closo\text{-}1,8\text{-}Me_2\text{-}11\text{-}(CH_2C_6H_4Me\text{-}4)\text{-}2\text{-}I\text{-}2,2,2\text{-}(CO)_3\text{-}2,1,8\text{-}MoC_2B_9H_8]$. The reaction between $[N(PPh_3)_2][closo\text{-}1,8\text{-}Me_2\text{-}2\text{-}I\text{-}2,2,2\text{-}(CO)_3\text{-}2,1,8\text{-}MoC_2B_9H_9]$ and $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$ in CH_2Cl_2 in the presence of $TlPF_6$ affords mainly $[MoW(\mu\text{-}CC_6H_4Me\text{-}4)(CO)_3(\eta^5\text{-}nido\text{-}2,8\text{-}Me_2\text{-}2,8\text{-}C_2B_9H_9)(\eta\text{-}C_5H_5)]$ together with some of its polytopal isomer $[MoW(\mu\text{-}CC_6H_4Me\text{-}4)(CO)_3(\eta^5\text{-}nido\text{-}7,8\text{-}Me_2\text{-}7,8\text{-}C_2B_9H_9)(\eta\text{-}C_5H_5)]$.

We have recently reported the synthesis of the allyl(carborane)-molybdenum and -tungsten complexes $[N(PPh_3)_2][closo\text{-}1,2\text{-}Me_2\text{-}3\text{-}(\eta^3\text{-}C_3H_5)\text{-}3,3\text{-}(CO)_2\text{-}3,1,2\text{-}MC_2B_9H_9]$ (**1**, M = W or Mo) and have described some protonation ($HBF_4\cdot Et_2O$) reactions of these species in the presence of donor molecules.[1] The products isolated are of the formulation expected if it is assumed that the acid releases the allyl ligand as $MeCH{=}CH_2$ and the resultant coordinatively unsaturated carborane–metal fragment captures donor substrate molecules. The compounds $[closo\text{-}1,2\text{-}Me_2\text{-}3,3\text{-}(CO)_2\text{-}3,3\text{-}(L)_2\text{-}3,1,2\text{-}MC_2B_9H_9]$ (**2**, L = CO or PPh_3) and $[closo\text{-}1,2\text{-}Me_2\text{-}3\text{-}(CO)\text{-}3,3\text{-}(RC_2R)_2\text{-}3,1,2\text{-}MC_2B_9H_9]$ (**3**, M = W, R = Ph; M = Mo, R = Me) are examples of species obtained by this procedure.

Earlier we described reactions of salts of the anionic alkylidyne complexes $[closo\text{-}1,2\text{-}Me_2\text{-}3\text{-}(\equiv CR)\text{-}3,3\text{-}(CO)_2\text{-}3,1,2\text{-}MC_2B_9H_9]^-$ (M = W or Mo, R = alkyl or aryl) with $HBF_4\cdot Et_2O$ in the presence of donor molecules.[2] The compounds $[closo\text{-}1,2\text{-}Me_2\text{-}8\text{-}(CH_2C_6H_4Me\text{-}4)\text{-}3,3\text{-}(CO)_2\text{-}3,3\text{-}(L)_2\text{-}3,1,2\text{-}MC_2B_9H_8]$ (**4**, L = CO or PPh_3)[2a,b] and $[closo\text{-}1,2\text{-}Me_2\text{-}8\text{-}(CH_2C_6H_4Me\text{-}4)\text{-}3\text{-}(CO)\text{-}3,3\text{-}(PhC_2Ph)_2\text{-}3,1,2\text{-}WC_2B_9H_8]$ (**5**)[2a] are simple examples of the species obtained and are clearly structurally related to compounds **2** and **3**. However, the presence of the cage $CH_2C_6H_4Me$-4 substituents in **4** and **5** suggests that their formation proceeds via an intermediate alkylidene–metal complex, the alkylidene group subsequently inserting into a cage B—H vertex. This process is accompanied at some stage by ligation of CO, PPh_3 or PhC_2Ph molecules to the coordinatively and electronically unsaturated metal centres, as discussed elsewhere.[2a,3]

In a parallel study[2d,e] treatment of the complexes $[NEt_4][closo\text{-}1,2\text{-}Me_2\text{-}3\text{-}(\equiv CR)\text{-}3,3\text{-}(CO)_2\text{-}3,1,2\text{-}WC_2B_9H_9]$ [R = Me (**6a**), C_6H_4Me-4 (**6b**) or C_6H_4OMe-2 (**6c**)] with aqueous HI yielded the salts $[NEt_4][closo\text{-}1,8\text{-}Me_2\text{-}11\text{-}(CH_2R)\text{-}2\text{-}I\text{-}2,2,2\text{-}(CO)_3\text{-}2,1,8\text{-}WC_2B_9H_8]$ (**7a–c**). The reactions were rapid and occurred below ambient temperatures and it

was not possible to determine if the cage rearrangement took place prior or subsequent to insertion of the initially formed alkylidene group into the B—H vertex.

In this paper we describe further protonation studies, using aqueous HI as the proton source and the compounds **1** and $[NEt_4][closo\text{-}1,2\text{-}Me_2\text{-}3\text{-}(\equiv CC_6H_4Me\text{-}4)\text{-}3,3\text{-}(CO)_2\text{-}3,1,2\text{-}MoC_2B_9H_9]$ (**6d**) as the reagents. It was hoped that the results obtained would provide further information about the cage framework rearrangement process.

RESULTS AND DISCUSSION

Treatment of a CO saturated CH_2Cl_2 solution of **1a** at room temperature with aqueous HI, followed by column chromatography of the reaction mixture on silica at −20°C gave the complex $[N(PPh_3)_2][closo\text{-}1,8\text{-}Me_2\text{-}2\text{-}I\text{-}2,2,2\text{-}(CO)_3\text{-}2,1,8\text{-}WC_2B_9H_9]$ (**8a**) in essentially quantitative yield. The compound was fully characterized by the data given in Tables 1 and 2.

The ^1H and $^{13}C\{^1H\}$ NMR data (Table 2) are crucial in establishing that **8a** has the unsymmetrical 2,1,8-WC_2B_9 icosahedral core structure with no connectivity between the carbon vertices. This is reflected in the $^{13}C\{^1H\}$ NMR spectrum with the appearance of three CO resonances at δ 231.8, 221.6 and 221.2, and four signals for the cage CMe groups at δ 63.3 and 63.0 (*C*Me) and at δ 32.8 and 29.3 (C*Me*). The peak at δ 63.3 is appreciably broader than that at 63.0. This is diagnostic for a 2,1,8-WC_2B_9 cage framework in which the two non-adjacent CMe groups occupy vertices in different pentagonal rings of the cage.[2d,3] In such an arrangement one cage carbon nucleus (δ 63.3) is more strongly influenced by the quadrupolar effect of adjacent ^{11}B nuclei than the other (δ 63.0). This was initially observed for the compound $[NEt_4][closo\text{-}1,8\text{-}Me_2\text{-}11\text{-}(CH_2C_6H_4Me\text{-}4)\text{-}2\text{-}Cl\text{-}2,2,2\text{-}(CO)_3\text{-}2,1,8\text{-}WC_2B_9H_8]$, an analogue of **7**, for which an X-ray structure determination confirmed the cage topology.[2d] In contrast with **8a** the $^{13}C\{^1H\}$ spectrum of its precursor **1a** displays a single *C*Me resonance (δ 57.2),[1] as does that of **4a** (δ 70.3),[2a] where both cage carbon vertices lie in the pentagonal C_2B_3 ring ligating the tungsten atom. Consistently, the ^1H NMR spectrum of **8a** shows two C*Me* resonances at δ 1.62 and 1.94, whereas the spectra of **1a** and **4a** each display one signal at δ 2.29 and 2.44, respectively.

In contrast to the results obtained with **1a**, the reaction between CO-saturated CH_2Cl_2 solutions of **1b** and aqueous HI gave the compound $[N(PPh_3)_2][closo\text{-}1,2\text{-}Me_2\text{-}3\text{-}I\text{-}3,3,3\text{-}(CO)_3\text{-}3,1,2\text{-}MoC_2B_9H_9]$ (**9**), in which the 3,1,2-MoC_2B_9 core

Table 1. Analytical[a] and other data for the new compounds

[a] Chemical shifts (δ) in ppm, coupling constants (J) in Hz. Measurements at ambient temperatures in CD_2Cl_2.
[b] Proton resonances for terminal B—H groups occur as broad unresolved peaks in the range δ *ca* −2 to +3.
[c] Hydrogen-1 decoupled, chemical shifts are positive to the high frequency of $SiMe_4$.
[d] Chemical shifts are positive to the high frequency of $BF_3 \cdot Et_2O$ (external). Signals ascribed to more than one boron nucleus may result from overlapping peaks and do not necessarily indicate symmetry equivalence.
[e] Resonances due to cage carbon atoms were too broad to be identified.
[f] Formed as a mixture with **11a**, therefore, some resonances are obscured by those of **11a**, see text.

structure of the precursor is retained. This is evident from the ^1H and $^{13}C\{^1H\}$ NMR data (Table 2). Thus, in the ^1H NMR spectrum there is only one resonance at δ 2.40 for the cage CMe groups. Correspondingly, in the $^{13}C\{^1H\}$ NMR spectrum the equivalent CMe vertices give rise to two signals at δ 71.0 (*C*Me) and 33.4 (C*Me*). As expected there are two peaks for the CO ligands and these occur at δ 243.9 and 230.8, with the latter resonance having twice the intensity of the former. This is the pattern expected for a symmetrical structure with a plane of symmetry through the molybdenum and iodine atoms, the mid-point of the cage C—C connectivity and the CO group transoid to the iodide ligand.

Interestingly, some changes were observed in the $^{13}C\{^1H\}$ NMR spectrum of **9** during the time of data acquisition. After recording the spectrum, fresh ^1H NMR measurements on the sample suggested that the complex had undergone a partial polytopal rearrangement in solution. Accordingly, a CH_2Cl_2 solution of **9** was heated under reflux for 8 h, after which time column chromatography afforded $[N(PPh_3)_2][closo\text{-}1,8\text{-}Me_2\text{-}2\text{-}I\text{-}2,2,2\text{-}(CO)_3\text{-}2,1,8\text{-}MoC_2B_9H_9]$ (**8b**), but in relatively low yield (*ca* 35%). The formation of another product was observed, but it could not be identified. It was also found that if CD_2Cl_2 solutions of **9** are left at ambient temperatures, ^1H NMR measurements revealed that after 10 days approximately 90% of the sample decomposed, with a small amount of **8b** being formed. Possibly the low yield of **8b** and the formation of the unidentified species is due to the instability of some intermediate along the slow pathway for isomerization of **9** into **8b**, since **8a** was prepared in high yield.

The spectroscopic data for **8b** are very similar to those of **8a**, as expected. In particular, the 2,1,8-MoC_2B_9 cage framework leads to the appearance in the $^{13}C\{^1H\}$ NMR spectrum of four resonances for the CMe groups [δ 68.2 and 64.4 (*C*Me), and 32.4 and 29.0 (C*Me*)]. Moreover, the more deshielded *C*Me signal was very broad. The three carbonyl ligands give rise to three peaks at δ 243.3, 229.9 and 229.3. These are more deshielded than those observed for **8a** as is usual for CO groups ligating molybdenum rather than tungsten. In accordance with the lack of symmetry the ^1H NMR spectrum revealed two signals for the CMe groups at δ 1.61 and 1.74. The $^{11}B\{^1H\}$ NMR spectrum displayed nine resonances for the non-equivalent boron nuclei.

As mentioned earlier treatment of the tungsten species **6a–c** with aqueous HI yielded the salts **7a–c**, respectively, in reactions that involved framework rearrangements of the cages from 3,1,2-WC_2B_9 to 2,1,8-WC_2B_9 core structures. These reactions also resulted in migration and hydroboration of the alkylidyne groups in the precursors and it was not apparent whether the migratory process preceded or followed the polytopal rearrangement of the cages. Since this work was restricted to tungsten complexes, it was hoped that a similar study with the molybdenum compound $[NEt_4][closo\text{-}1,2\text{-}Me_2\text{-}3\text{-}(\equiv CC_6H_4Me\text{-}4)\text{-}3,3\text{-}(CO)_2\text{-}3,1,2\text{-}MoC_2B_9H_9]$ (**6d**) might allow a resolution of this matter.

Addition of aqueous HI to a CH_2Cl_2 solution of **6d**, followed by column chromatography of the reaction mixture on silica at $-20°C$ gave a red–brown oil. The ^1H, $^{13}C\{^1H\}$ and $^{11}B\{^1H\}$ NMR measurements on this material revealed that it was a mixture of the two isomers $[NEt_4][closo\text{-}1,8\text{-}Me_2\text{-}11\text{-}(CH_2C_6H_4Me\text{-}4)\text{-}2\text{-}I\text{-}2,2,2\text{-}(CO)_3\text{-}2,1,8\text{-}MoC_2B_9H_8]$ (**7d**) and $[NEt_4][closo\text{-}1,2\text{-}Me_2\text{-}8\text{-}(CH_2C_6H_4Me\text{-}4)\text{-}3\text{-}I\text{-}3,3,3\text{-}(CO)_3\text{-}3,1,2\text{-}MoC_2B_9H_8]$ (**10**). Repeated experiments showed that depending on the time taken to work up the mixture, the isomer ratio varied because **10** slowly converts to **7d**, together with the formation of some unidentified carborane cage-containing material. Complete conversion of **10** into **7d** in solution requires about 10 h at ambient temperatures and is thus faster than the isomerization of **9** into **8b**. This must be due to the presence of the $CH_2C_6H_4Me$-4 substituent on the boron atom β to the two carbon atoms in the pentagonal CCB*B*B face of the cage ligating the molybdenum atom of **10**.

Assignment of resonances in the ^1H NMR spectrum of a mixture of **7d** and **10** was readily accomplished because the signals due to the latter species become weaker as the conversion to **7d** progressed. Indeed, in the $^{13}C\{^1H\}$ NMR spectrum only signals due to **7d** were observed. The ^1H NMR spectrum displayed two sets of $(AB)_2$ patterns due to the C_6H_4 groups of the two isomers. The signals at δ 6.81 and δ 6.89 [J(AB) 8 Hz] are assigned to **10** and the other peaks at δ 6.84 and 6.91 [J(AB) 8 Hz] to compound **7d**. Two resonances at δ 2.23 and 2.22 may be attributed to the Me-4 groups of **7d** and **10**, respectively. As expected the spectrum of **10** displays one peak at δ 2.39 for the two equivalent cage CMe groups, whereas **7d** has two signals for these groups at δ 1.58 and 1.71. A broad peak at δ 2.34 may be attributed to a BCH_2 group, very probably that of **7d**. The corresponding signal in the ^1H NMR spectrum of **7b** ($[N(PPh_3)_2]$ salt) is at δ 2.40.[2d] In the $^{11}B\{^1H\}$ NMR spectrum of the isomeric mixture there are diagnostic signals for the $BCH_2C_6H_4Me$-4 groups of the two isomers at δ 8.0 (**7d**) and 14.7 (**10**).[3] As mentioned above the $^{13}C\{^1H\}$ NMR spectrum of the mixture reveals resonances due only to **7d**. The non-equivalent CO ligands of the latter species display peaks at δ 242.2,

230.0 and 228.5. The signals due to the cage *C*Me nuclei were not observed, probably because broadening resulted in their being lost in the base-line. However, peaks due to the non-equivalent C*Me* groups were seen at δ 32.4 and 29.3, and there is a typical broad signal at δ 21.1 attributable to the $BCH_2C_6H_4Me$-4 nucleus.[3]

The dimetal complex $[MoW(\mu\text{-}CC_6H_4Me\text{-}4)(CO)_3(\eta^5\text{-}nido\text{-}7,8\text{-}Me_2\text{-}7,8\text{-}C_2B_9H_9)(\mu\text{-}C_5H_5)]$ (**11a**)* has been previously prepared by treating THF solutions of $Tl_2[closo\text{-}1,2\text{-}Me_2\text{-}3,3,3\text{-}(CO)_3\text{-}3,1,2\text{-}MoC_2B_9H_9]$ with 2 equivalents of $AgBF_4$ in the presence of $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$.[1] In the present study an attempt to obtain **11a** by treating **1b** with $HBF_4 \cdot Et_2O$ in the presence of $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$ was unsuccessful. However, compound **11a** was obtained when complex **9** in CH_2Cl_2 solution was treated with $TlPF_6$ in the presence of $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$. The compound $[MoW(\mu\text{-}CC_6H_4Me\text{-}4)(CO)_3(\eta^5\text{-}nido\text{-}2,8\text{-}Me_2\text{-}2,8\text{-}C_2B_9H_9)(\eta\text{-}C_5H_5)]$ (**11b**), the isomer of **11a**, having the 2,1,8-MoC_2B_9 topology for the cage framework, was not formed in this reaction. However, treatment of a mixture of the compounds **8b** and $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$ in CH_2Cl_2, with the addition of $TlPF_6$ to remove iodide as insoluble TlI, gave a mixture of the two isomeric dimetal compounds **11a** and **11b** in a *ca* 1:3 ratio, based on relative peak intensities in the NMR spectra. No interconversion between **11a** and **11b** was observed at room temperature and refluxing mixtures in CH_2Cl_2 or THF led only to decomposition.

In the $^{13}C\{^1H\}$ NMR spectrum of **11b** the resonance for the μ-C nucleus of the alkylidyne ligand occurs at δ 384.2, to be compared with that for **11a** at δ 380.1.[1] Both isomers are electronically unsaturated, with 32 cluster valence electrons, and the relatively deshielded chemical shifts observed for the μ-^{13}C nuclei in the two species are in accordance with this feature.[4] Isomer **11b** shows three CO peaks at δ 232.5, 217.9 and 214.6 in the $^{13}C\{^1H\}$ NMR spectrum, while those for **11a** occur at δ 226.1, 217.8 and 213.3.[1] The signals for the carbon vertices of the cage for **11b** were not observed probably due to the broadening discussed above. However, signals for the non-equivalent C*Me* groups were observed at δ 32.7 and 28.1, to be compared with those in the spectrum of **11a** at δ 31.6 and 31.3.[1] Generally, cages with the 3,1,2-MC_2B_9 topology, and with non-equivalent CMe groups, have ^{13}C NMR signals for these fragments which are less disparate than those for cages with 2,1,8-MC_2B_9 frameworks where the CMe groups are always non-equivalent.

The ^1H NMR spectrum of **11b** showed a diagnostic resonance for the B—H→W group at δ −8.25 [J(BH) 55 Hz].[3] The corresponding quartet signal in the ^1H NMR spectrum of **11a** is at δ −8.10.[1] The peaks in the spectrum of **11b** for the Me groups are seen at δ 1.39 and 1.76 for the cage CMe fragments and at δ 2.55 for the Me-4 substituent on the aryl ring.

The new reactions described in this paper give further information about the proton-induced icosahedral cage framework rearrangements from the 3,1,2- to the 2,1,8-MC_2B_9 topology. Thus, treatment of **1b** with aqueous HI yields initially compound **9**, which subsequently isomerizes to **8b**. This contrasts with the reaction of **1a** with the acid, in which no tungsten analogue of **9** was detected prior to the formation of **8a**. Correspondingly, whereas treatment of the tungsten compound **6b** with aqueous HI yields **7b** directly, the reaction of the molybdenum analogue **6d** with the acid proceeds in such a manner that complex **10** can be identified along the reaction profile before the final product **7d** is obtained. This observation is particularly important because it establishes that the polytopal rearrangement from a 3,1,2- to a 2,1,8-icosahedral framework occurs after protonation of the alkylidyne and insertion of the resulting alkylidene moiety into the cage B—H vertex. In the earlier studies with the tungsten species, because **7a–c** were formed so rapidly, it was not established that the two processes were independent with the framework rearrangement as the final step. However, some indication of the stepwise process came from an earlier observation[2d] that **4a** reacts slowly with NEt_4Cl in THF to give $[NEt_4][closo\text{-}1,8\text{-}Me_2\text{-}11\text{-}(CH_2C_6H_4Me\text{-}4)\text{-}2\text{-}Cl\text{-}2,2,2\text{-}(CO)_3\text{-}2,1,8\text{-}WC_2B_9H_8]$, the chloro-analogue of the iodo complex **7b**.

It is perhaps surprising that the skeletal rearrangements proceed more slowly with the molybdenum complexes than with their tungsten analogues. The mechanism of these cage isomerizations remains to be established, but as a consequence of proposals made elsewhere[5] we favour attack of I^- at the metal in species like **9** or **10** to yield a *nido*-12-vertex metallacarborane, with a formally 14-electron count for the polyhedral skeleton. This skeletal framework would be free to undergo rearrangement through diamond–square–diamond

* This compound has a 1,2-dicarba-3-tungsta-dodecacarborane structure. However, use of this numbering system for dimetal complexes leads to an impossibly complex nomenclature. For this reason we treat the cages in dimetal species as *nido*-11 vertex ligands with numbering as for an icosahedron from which the 12th vertex has been removed.

processes with rotation of a triangular face having a carbon and two boron atoms. Closure of the *nido*-intermediate would yield a 2,1,8-MC_2B_9 core structure as the final step.

EXPERIMENTAL

All solvents were freshly distilled over appropriate drying agents prior to use. Light petroleum refers to the fraction with b.p. 40–60°C. Chromatography columns were *ca* 15 cm long and 3 cm in diameter and unless otherwise stated were packed with silica (Aldrich, 70–230 mesh). All experiments were performed under nitrogen using Schlenk-tube techniques. The NMR measurements were obtained using a Bruker AMX 360 MHz spectrometer and IR spectra were recorded with a Bruker IFS 25 instrument. The reagents **1**,[1] **6d**[4c] and [W(≡CC_6H_4Me-4)$(CO)_2(\eta$-$C_5H_5)$][6] were obtained by methods described previously.

Protonation of the allyl(carborane)metal complexes [$N(PPh_3)_2$][closo-1,2-Me_2-3-(η^3-C_3H_5)-3,3-$(CO)_2$-3,1,2-$MC_2B_9H_9$] (M = W *or* Mo)

(i) A CH_2Cl_2 (50 cm^3) solution of **1a** (0.10 g, 0.10 mmol) was saturated with CO at room temperature and treated with HI (0.10 cm^3, 57% aqueous solution, 0.70 mmol). The mixture was stirred for 0.5 h, while maintaining the CO atmosphere. The solvent was removed *in vacuo* and the residue was extracted with CH_2Cl_2 (10 cm^3) and chromatographed at −20°C. Elution with CH_2Cl_2 removed an orange–yellow band. The solvent was removed *in vacuo* and the product was dried *in vacuo* giving orange–red microcrystals of [$N(PPh_3)_2$][*closo*-1,8-Me_2-2-I-2,2,2-$(CO)_3$-2,1,8-$WC_2B_9H_9$] (**8a**) (0.11 g).

(ii) In a similar experiment a CO-saturated CH_2Cl_2 (40 cm^3) solution of **1b** (0.10 g, 0.11 mmol) was treated with HI (0.10 cm^3, 57% aqueous solution, 0.70 mmol). After removal of the solvent the residue was extracted with CH_2Cl_2–light petroleum (10 cm^3, 1:1) and chromatographed at −20°C using neat CH_2Cl_2 as the eluant. The solvent was removed *in vacuo* from the red eluate to give red microcrystals of [$N(PPh_3)_2$][*closo*-1,2-Me_2-3-I-3,3,3-$(CO)_3$-3,1,2-$MoC_2B_9H_9$] (**9**) (0.11 g).

Framework rearrangement of the icosahedral cage

(i) A CH_2Cl_2 (20 cm^3) solution of **9** (0.10 g, 0.10 mmol) was refluxed for 8 h. The solvent was reduced in volume *in vacuo* to *ca* 10 cm^3 and the mixture chromatographed (2 × 5 cm column) at −20°C. Elution with CH_2Cl_2 gave a red–brown solution. The solvent was removed *in vacuo* to yield brown microcrystals of [$N(PPh_3)_2$][*closo*-1,8-Me_2-2-I-2,2,2-$(CO)_3$-2,1,8-$MoC_2B_9H_9$] (**8b**) (0.035 g).

(ii) The NMR spectra (^1H and $^{11}B\{^1H\}$) of a sample of **9** (0.30 g, 0.03 mmol) were recorded and the NMR tube kept for 10 days at room temperature. Remeasurement of the spectra revealed a more than 90% conversion to complex **8b**, together with some unidentified species.

Protonation of the complex [NEt_4][closo-1,2-Me_2-3-(≡CC_6H_4Me-4)-3,3-$(CO)_2$-3,1,2-$MoC_2B_9H_9$]

A CH_2Cl_2 (20 cm^3) solution of **6d** (0.10 g, 0.18 mmol) was treated with HI (0.20 cm^3, 57% aqueous solution, 1.40 mmol) at room temperature and the mixture was stirred for 0.5 h. The solvent was removed *in vacuo*, the residue extracted with CH_2Cl_2 (10 cm^3) and the extracts chromatographed at −20°C (2 × 5 cm column). Elution with CH_2Cl_2 removed a red–brown band, which after removal of solvent *in vacuo* afforded an oily mixture of [NEt_4][*closo*-1,8-Me_2-11-($CH_2C_6H_4$Me-4)-2-I-2,2,2-$(CO)_3$-2,1,8-$MoC_2B_9H_8$] (**7d**) and [NEt_4][*closo*-1,2-Me_2-8-($CH_2C_6H_4$Me-4)-3-I-3,3,3-$(CO)_3$-3,1,2-$MoC_2B_9H_8$] (**10**) (0.08 g).

Synthesis of the isomers [MoW(μ-CC_6H_4Me-4)$(CO)_3(\eta^5$-nido-$Me_2C_2B_9H_9)(\eta$-$C_5H_5)$] (**11**)

A CH_2Cl_2 (20 cm^3) solution of a mixture of **8b** (0.10 g, 0.11 mmol) and [W(≡CC_6H_4Me-4)$(CO)_2(\eta$-$C_5H_5)$] (0.04 g, 0.11 mmol) was treated with $TlPF_6$ (0.07 g, 0.20 mmol) and stirred at room temperature for 2 h. The solvent was removed *in vacuo*, the residue extracted with CH_2Cl_2–light petroleum (10 cm^3, 1:1) and chromatographed on alumina (Brockmann activity II). Elution with the same solvent mixture gave a green fraction. The solvent was removed *in vacuo* and the residue washed with light petroleum (2 × 2 cm^3) and dried *in vacuop* to give green microcrystals (0.05 g) of [MoW(μ-CC_6H_4Me-4)$(CO)_3(\eta^5$-7,8-*nido*-Me_2-7,8-$C_2B_9H_9)(\eta$-$C_5H_5)$] (**11a**) and [MoW(μ-CC_6H_4Me-4)$(CO)_3(\eta^5$-*nido*-2,8-Me_2-2,8-$C_2B_9H_9)(\eta$-$C_5H_5)$] (**11b**).

CYANO-BRIDGED COPPER(I)–RUTHENIUM(II) COMPLEXES: SYNTHESES, CHARACTERIZATION AND SPECTROSCOPIC STUDIES

RAMSHARAN SINGH and S. K. DIKSHIT†

Department of Chemistry, Indian Institute of Technology Kanpur, Kanpur (U.P.) 208016, India

(*Received* 28 *January* 1993; *accepted* 26 *February* 1993)

Abstract—New complexes of the formulae [(N-N)Cu(PPh_3)CN] (N-N = 2,2′-bipyridine, 1,10-phenanthroline) have been isolated and used to synthesize the novel cyano-bridged copper(I)–ruthenium(II) complexes [(N-N)Cu(PPh_3)(μ-CN)Ru(bpy)$_2$Cl]PF_6 (bpy = 2,2′-bipyridine) and [(N-N)Cu(PPh_3)(μ-CN)Ru(η^5-Cp)(PPh_3)$_2$]PF_6 (Cp = cyclopentadienyl anion). In addition, the complexes [(PPh_3)$_2$Cu(μ-CN)Ru(bpy)$_2$Cl]PF_6 and [(PPh_3)$_2$Cu(μ-CN)Ru(η^5-Cp)(PPh_3)$_2$]PF_6 or BF_4 have been synthesized using [(PPh_3)$_2$CuCN]. All the complexes have been characterized on the basis of elemental analyses, spectroscopic data (IR, UV–vis, ^{1}H, ^{13}C and ^{31}P NMR), and magnetic and conductivity measurements. Spectroscopic data clearly indicate that in these complexes copper(I) and ruthenium(II) are bonded via a cyanide bridge.

The design of suitable chromophores to be used as sensitizers in the photochemical conversion of solar energy is one of the goals of coordination chemists.[1] In this context ruthenium(II)-polypyridine complexes have attracted the attention of many workers because of their excellent properties involving the role of light absorption and a light emission sensitizer.[2] In recent years much work has been performed on cyano-bridged homo- and heteropolynuclear complexes[3–7] to explore the various photophysical properties, including sensitization. The copper(I) centre, a d^{10} system, is very electron rich in nature and can be stabilized by ligands having π-acidic character, viz PPh_3, bpy, phen, CO, CN^-, etc. Extensive studies of copper(I) cyanide,[8] cyanide phosphine mixed-ligand complexes[9] and the phosphine polypyridine complexes[10,11] are reported in the literature. There are some reports[4,12,13] on heteronuclear bimetallic cyanide-bridged complexes containing ruthenium(II) and other metal centres, but, to the best of our knowledge, these are the first cyano-bridged heteronuclear bimetallic complexes containing copper(I) and ruthenium(II) metal centres. Since copper(I) complexes also show the photophysical and photochemical properties,[14] it stimulated us to study the various aspects of copper(I)–ruthenium(II) dinuclear complexes. Our interests are four-fold: (a) to study the nature of the stretching frequency of the cyano group when it is bonded to two electron-rich metal centres, copper(I)–ruthenium(II); (b) how this cyanide bridging affects the electronic and photophysical properties of the spectator ligands and the sub units; (c) to study the photo-induced intramolecular energy and electron transfer in the partially oxidized state; and (d) to study the electrochemical properties. In this paper we would like to report the syntheses, characterization and the study of IR stretching frequencies of the cyano group and the electronic (UV–vis) spectral properties of these complexes.

EXPERIMENTAL

The ^{1}H NMR spectra were recorded on a Jeol PMX-60 MHz spectrometer in the range 0–20 ppm(δ) using TMS as an internal calibrant. The ^{13}C and ^{31}P NMR spectra were recorded on a Bruker WM-400 NMR spectrometer. For ^{31}P NMR spectra 85% H_3PO_4 was used as an external calibrant, whereas ^{13}C NMR peaks were relative to TMS (0 ppm). IR spectra were recorded on Shimadzu IR-

† Author to whom correspondence should be addressed.

420 and Perkin–Elmer IR-841 double-beam spectrophotometers as KBr pellets in the ranges 4000–400 and 2500–2000 cm^{-1}, respectively. The electronic (UV–vis) spectra were recorded on a Shimadzu double-beam UV-160 spectrophotometer in acetonitrile solution. Conductivity measurements were performed on an Elico conductivity bridge type CM 82T in nitrobenzene or acetonitrile solutions. Magnetic measurements were performed using a parallel-field vibrating sample magnetometer (VSM), model-150A (Princeton Applied Research Corporation, Princeton, New Jersey). Melting points of the complexes were recorded on a Fisher–John melting point apparatus and are uncorrected. Microanalyses were performed at the RSIC, CDRI Lucknow, India.

All the chemicals used were either of Analar or chemically pure grade. Invariably manipulations were performed under dry oxygen-free nitrogen using standard Schlenk line and other techniques.[15] The solvents were dried by standard procedures[16] before use.

The complexes $[(\eta^5\text{-Cp})Ru(PPh_3)_2Cl]$[17] and $[(bpy)_2RuCl_2]\cdot 2H_2O$[18] were prepared according to the literature procedures. Cuprous cyanide[19] and the complex $[Cu(PPh_3)_2CN]$[20] were prepared by modifying the literature methods.

Syntheses

Cuprous cyanide. In a warm (60°C) water solution of $CuSO_4\cdot 5H_2O$ (2.5 g, 0.01 mol, 50 cm^3) with a constant bubbling of sulphur dioxide gas a solution of an equivalent amount of sodium cyanide (0.49 g, 0.01 mol, 25 cm^3) in water was added with vigorous stirring. A precipitate immediately appeared, which was filtered and washed thoroughly with water, ethanol and finally with ether and dried *in vacuo* over P_4O_{10} for several hours. The yield was almost quantitative.

Cyanobis(triphenylphosphine)copper(I) (**1**). To a suspension of CuCN (0.01 mol) in benzene (50 cm^3) was added a solution of triphenylphosphine (0.04 mol) in benzene (70 cm^3) and the mixture was refluxed for 2 h. The clear solution thus obtained was cooled and filtered to remove any insoluble materials and the solvent was removed under reduced pressure. The residue was washed many times with ether to ensure the complete removal of excess triphenylphosphine. It was recrystallized from benzene/petroleum ether and dried *in vacuo*.

Cyanobipyridinetriphenylphosphinecopper(I) (**2**). To a solution of $[Cu(PPh_3)_2CN]$ (1 mmol) in benzene (30 cm^3) was added a solution of bipyridine (1 mmol) in benzene (30 cm^3) with constant stirring. The resulting yellow solution was refluxed for 1 h. The clear solution thus obtained was cooled, the volume was reduced to half and excess petroleum ether (60–80°C) (100 cm^3) was added, which resulted in the precipitation of a pale yellow compound. It was washed several times with petroleum ether and dried *in vacuo*.

Cyano-1,10-phenanthrolinetriphenylphosphinecopper(I) (**3**). To solution of $[Cu(PPh_3)_2CN]$ (1 mmol) in benzene (30 cm^3) was added a solution of 1,10-phenanthroline (1 mmol) in benzene (30 cm^3) with constant stirring. Immediately an orange–red precipitate appeared. This mixture was refluxed for half an hour. After cooling excess petroleum ether (60–80°C) (100 cm^3) was added to ensure the complete precipitation of the complex. The complex was centrifuged and washed several times with petroleum ether and dried *in vacuo*.

Bis(triphenylphosphine)copper(I)(*μ-cyano*)*chlorobis*(2,2′-*bipyridine*)*ruthenium*(II)*hexafluorophosphate* (**4**). A mixture of $[Cu(PPh_3)_2CN]$ (1 mmol) and $[Ru(bpy)_2Cl_2]\cdot 2H_2O$ (1 mmol) was suspended in ethanol (30 cm^3) and the suspension was refluxed for 1 h. An equal volume of water was then added and the solution was further refluxed for 1 h. The solution was cooled and filtered to remove any insoluble material present. To the filtrate was added a highly concentrated solution of NH_4PF_6 in water (1 cm^3), which effected the immediate precipitation of the complex. The precipitate was centrifuged and washed thoroughly with water and finally with ether and dried *in vacuo*.

Bis(triphenylphosphine)copper(I)(*μ-cyano*)*cyclopentadienylbis(triphenylphosphine)ruthenium*(II)*hexafluorophosphate* (**5**). A mixture of $[Cu(PPh_3)_2CN]$ (1 mmol), $[(\eta^5\text{-Cp})Ru(PPh_3)_2Cl]$ (1 mmol) and NH_4PF_6 (1.2 mmol) was suspended in methanol (60 cm^3) and refluxed for 1 h. During reflux all the $[(\eta^5\text{-Cp})Ru(PPh_3)_2Cl]$ was dissolved and a pale yellow precipitate appeared. The solvent was evaporated to dryness *in vacuo* and the residue was extracted with a small amount of dichloromethane and filtered. To the filtrate was added excess petroleum ether (100 cm^3) and the complex was precipitated, which was centrifuged and washed several times with petroleum ether and dried *in vacuo*.

Bis(triphenylphosphine)copper(I)(*μ-cyano*)*cyclopentadienylbis(triphenylphosphine)ruthenium*(II)*tetrafluoroborate* (**6**). The procedure of the hexafluorophosphate was followed except $NaBF_4$ was used in place of NH_4PF_6.

2,2′-*Bipyridinetriphenylphosphinecopper*(I)(*μ-cyano*)(*chlorobis*(2,2′-*bipyridine*)*ruthenium*(II)*hexafluorophosphate* (**7**). A mixture of $[Cu(bpy)(PPh_3)CN]$ (0.2 mmol) and $[Ru(bpy)_2Cl_2]\cdot 2H_2O$ (0.2 mmol) in a 1:1 mixture of water and ethanol (50 cm^3) was suspended and refluxed for 3 h.

The resulting solution was cooled and filtered to remove any insoluble material. To the filtrate was added a concentrated aqueous solution of NH_4PF_6 (1 cm^3). A precipitate immediately appeared, which was centrifuged, washed several times with water and ether and dried over P_4O_{10} for several hours *in vacuo*.

1,10-*Phenanthrolinetriphenylphosphinecopper*(I)-(*μ-cyano*)*chlorobis*(2,2′-*bipyridine*)*ruthenium*(II)-*hexafluorophosphate* (**8**). The above procedure for the 2,2′-bipyridine analogue was followed, but in place of [Cu(bpy)(PPh_3)CN] its 1,10-phenanthroline analogue was used.

2,2′-*Bipyridinetriphenylphosphinecopper*(I)(*μ-cyano*)*cyclopentadienylbis*(*triphenylphosphine*)*ruthenium*(II)*hexafluorophosphate* (**9**). To a solution of [(η^5-Cp)Ru(PPh_3)$_2$Cl] (0.1 mmol) in methanol (30 cm^3) was added solid [(phen)Cu(PPh_3)CN] (0.1 mmol) and the mixture was refluxed for 2.5 h, whereby a clear solution was obtained. After cooling the reaction mixture was filtered to remove any insoluble material. To the filtrate was added a concentrated aqueous solution of NH_4PF_6 (2 cm^3) to precipitate the complex. The complex obtained was centrifuged and washed several times with water and ether and dried *in vacuo* over P_4O_{10} for several hours.

1,10-*Phenanthrolinetriphenylphosphinecopper*(I)-(*μ-cyano*)*cyclopentadienylbis*(*triphenylphosphine*)*ruthenium*(II)*hexafluorophosphate* (**10**). The above procedure for the 2,2′-bypiridine analogue was followed using the 1,10-phenanthroline analogue in place of [(bpy)Cu(PPh_3)CN].

RESULTS AND DISCUSSION

The analytical data for the complexes are given in Table 1, which are consistent with the stoichiometries proposed. Conductivity measurements were performed in nitrobenzene or acetonitrile solutions. The conductivity data of complexes **1**, **2** and **3** show their non-electrolytic nature, whereas the other cation complexes are 1:1 electrolytes.[21] All the complexes are diamagnetic at room temperature.

IR spectra

The ν(CN) stretching frequency data of the complexes are given in Table 2. The ν(CN) band of [Cu(PPh_3)$_2$CN] occurs at 2121 cm^{-1} (lit.,[22] 2105 cm^{-1}). In solid cuprous cyanide ν(CN) occurs[23–26] at 2172 cm^{-1}. A red shift of *ca* 51 cm^{-1} indicates that the CN group is terminal. In addition copper(I)

[d] The ^{13}C NMR signal of the bridging cyano group was not observed.

is an electron-rich centre, which is also bonded to triphenylphosphine, a stronger σ-donor than π-acceptor, therefore, a strong back-donation from copper(I) to the cyanide group is expected, which may also be contributing to the red shift of ν(CN) in $[Cu(PPh_3)_2CN]$. There is a small red shift of ν(CN) in $[Cu(bpy)(PPh_3)CN]$ (*ca* $\Delta = 13\ cm^{-1}$) and $[Cu(phen)(PPh_3)CN]$ (*ca* $\Delta = 15\ cm^{-1}$) compared with ν(CN) of $[Cu(PPh_3)_2CN]$, which is in accordance with the analogy that as the coordination number increases the net positive charge on the metal centre decreases and in turn the σ-bonding from the cyanide group decreases, resulting in a decrease in ν(CN).[27]

In general the bridging cyano group gives the stretching band at a higher wave number[27] than the terminal cyano group. The shifting of the ν(CN) group to the higher region on bridging has been explained on the basis of force field arguments.[23] However, this is not always the case and the band position of the cyano group depends upon many other factors. The ^{13}C and ^{15}N NMR and IR studies[28] of cyano (ligand) cobaloximes have furnished evidence for cobalt(I)-to-cyanide π-bonding. The ν(CN) band tends to decrease with increasing basicity of the ligand *trans* to CN^-. Strong bases make cobalt(I) richer in electron density, resulting in increased back-bonding to π^* of CN^- which causes a decrease in ν(CN). The complexes reported here also show a red shift of ν(CN) on bridging. Both copper(I) and ruthenium(II) centres are electron rich and are also bonded to strong σ-donor and poor π-acid ligand triphenylphosphine and/or electron rich ligands. Lowering of the ν(CN) stretching frequency on bridging may be because of enhanced π-back donation from ruthenium and copper to the π^*-orbitals of the cyano group. All the characteristic bands due to the other ligands, namely triphenylphosphine, 2,2′-bipyridine and 1,10-phenanthroline, are found in their spectral region. The characteristic vibrational frequency due to Cp was completely masked by the strong, broad, characteristic peak of PF_6^- in the complexes having this group, but the presence

of the Cp group in the respective complexes is evident by the NMR signal of the Cp group.

^{1}H *NMR chemical shifts*

The ^{1}H NMR data are collected in Table 2. Complexes having the Cp group show a sharp singlet signal in the range 4.1–4.4 ppm(δ), which is diagnostic. The Cp peak of the complexes shifts slightly to higher δ (low field) in comparison to the parent complex [(η^5-Cp)Ru(PPh_3)$_2$Cl]. The shifting of the Cp proton signal to the higher δ (low field) on coordination through the nitrogen atom of the CN group is consistent with the literature reported observation.[5,29,30] The high δ value of the Cp protons in these complexes also suggest that the complexes must be cationic in nature.[5,6] The proton signals of the phenyl groups and the bpy and phen ligands appear in the region 7.0–8.0 ppm as broad multiplets.

^{13}C *and* ^{31}P *NMR chemical shifts*

The ^{13}C and ^{31}P NMR data of compounds **1** and **6** are collected in Table 2. All the peaks in the ^{13}C NMR spectra are found in the expected region of the phenyl group[31,32] for compound **1**. However, the ^{13}C NMR peaks due to the phenyl groups associated with copper and ruthenium metal centres for compound **6** become too complicated to be assigned properly (Fig. 1). The distinct ^{13}C NMR peak at 85.6 ppm(δ) is due to the cyclopentadienyl group, which is in the expected region.[33–36] Compound **1** shows only one ^{31}P NMR signal at -2.6 ppm, which is at a lower field relative to the free triphenylphosphine ^{31}P NMR signal[31] at -6.00 ppm(δ). This is expected as the formation of complex **1** causes deshielding of the phosphorus nuclei, because of the shifting of electron density from the phosphorus atom to the copper metal centre, which is in accordance with the greater σ-donating than the π-accepting properties of the triphenylphosphine ligand. The dinuclear complex **6** as expected shows two ^{31}P NMR signals at 48.9 and -3.4 ppm, which are assigned for the phosphorus atoms of the triphenylphosphine ligands associated with ruthenium[37] and copper metal centres, respectively. The ^{31}P NMR signal in compound **6**, at -3.4 ppm due to the copper sub-unit, is at higher field [less ppm(δ)] in comparison with compound **1** and at lower field (higher ppm) than the free triphenylphosphine. This shows that the back π-bonding from ruthenium to the cyanide group is predominant over the σ-donation of the cyano group to ruthenium. The electron density increases on the cyano group, which in turn affects the σ-donating and π-accepting behaviour of the cyano group, which results in the shielding of the phosphorus nuclei of triphenylphosphine of the copper sub-unit and, therefore, shifting of the ^{31}P NMR signal to high field [less ppm(δ)]. These types of trends indicate that shifting of electron density from a ruthenium centre to a cyano group may cause the deshielding of the phosphorus nuclei associated with the ruthenium sub-unit and hence shifting of the ^{31}P NMR signal to lower field [high ppm(δ)]. In fact the ^{31}P signal of the ruthenium sub-unit is observed at 48.9 ppm, which is much higher in comparison to the parent compound, [(η^5-Cp)Ru(PPh_3)$_2$Cl] (lit.,[29] 38.6 ppm), which supports the discussed trend of the shifting of ^{31}P NMR signals and ruthenium to the cyano group π-back-bonding.

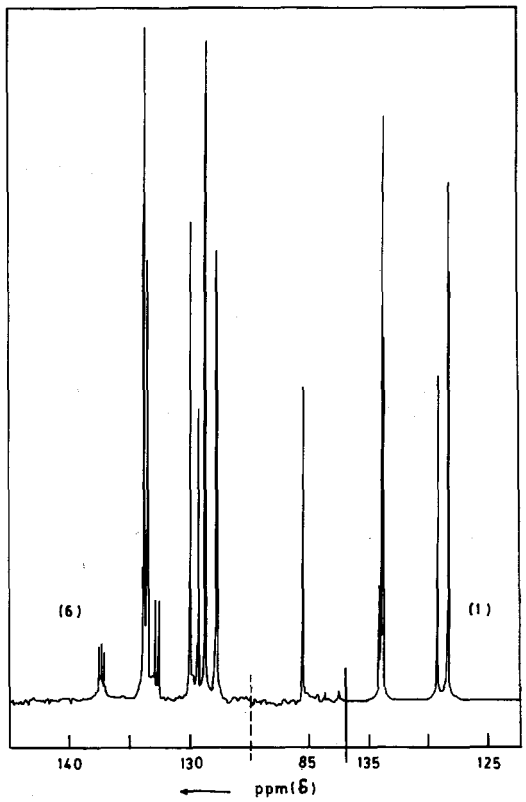

Fig. 1. The ^{13}C NMR spectra of complexes **1** and **6**.

Electronic (UV–vis) properties

Data for the electronic spectra are given in Table 2. In the electronic absorption spectra of complexes **4** and **9** four peaks and a shoulder at 244 nm are observed. These bands are denoted as I–V in order of increasing energy (Fig. 2). These are characteristic bands of the Ru(bpy)$_2^{2+}$ chromophore.[18,38,39] Assignments of these bands are given in Table 2. In all the complex having this chromophoric

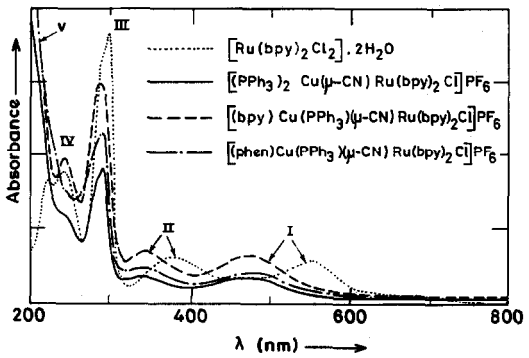

Fig. 2. The electronic (UV–vis) spectra of complexes **4**, **7**, **9** and $[Ru(bpy)_2Cl_2]\cdot 2H_2O$.

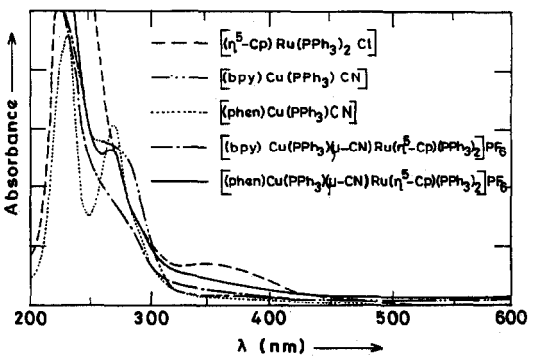

Fig. 3. The electronic (UV–vis) spectra of complexes **2**, **3**, **8**, **10** and $[(\eta^5\text{-Cp})Ru(PPh_3)_2Cl]$.

group, band III, which is assigned as the $\pi^* \leftarrow \pi$(bpy) intraligand transition, has very slightly shifted to the higher energy in comparison to the parent complex $[Ru(bpy)_2Cl_2]\cdot 2H_2O$. Assignments of bands I $[\pi^*_{bpy} \leftarrow d\pi(Ru)]$ and II $[\pi^*_{bpy} \leftarrow d\pi(Ru)]$ as charge-transfer transitions is based on literature reports.[18,38,39] In these complexes, due to the strong back bonding from ruthenium(II) to the cyano group, both bands I and II move to higher energies. This behaviour is expected if the *d*-orbitals are increasingly stabilized, because of increased back bonding from ruthenium(II) to the cyano group. In this context the π^*(bpy) $\leftarrow d\pi$(Ru) transitions act as spectator transitions for the CN–Ru interactions. This indicates the strong back bonding from ruthenium to the cyano group, which is also evident from the shifting of the ν(CN) stretching frequency to the lower energy region. Band IV appears as a shoulder on band V and can be assigned to the intraligand $\pi^* \leftarrow \pi$(bpy) transition[18,39] or, where aromatic phosphines are present, to a mixture of π(bpy)-π^*(bpy) and π(phenyl)-π^*(phenyl) transitions.[18] It is clearly seen in the absorption spectrum of complex **7**, as this complex has relatively less PPh_3 and more bpy groups, it shows a well-resolved peak of band IV at 244 nm (Fig. 2). Complexes **1**, **2** and **3** give absorption bands at 259.5, 268 and 261 nm (shoulder), respectively, which are assigned as MLCT transitions and the other bands in the higher energy region are assigned as $\pi^* \leftarrow \pi$ intraligand (IL) transitions. The band at 259.5 nm of complex **1** appears as a shoulder on band III of compound **4** at 280 nm. Similarly the band at 268 nm of complex **3** appears as a shoulder on band III of complex **9** at 270 nm. On the other hand in the case of complex **7**, because its band III occurs reasonably well in the higher energy (287 nm) region there is mixing of the band at 261 nm of compound **2** and no shoulder is observed. The higher energy IL bands of complexes **1**, **2** and **3** are mixed with $\pi^* \leftarrow \pi$(IL) bands at 222 nm of the bpy ligand and appear as band V in complexes **4**, **7** and **9**. The absorption spectra of compounds **2**, **3**, **8** and **10** are given in Fig. 3. The MLCT transition at 349 nm of the complex $[(\eta^5\text{-Cp})Ru(PPh_3)_2Cl]$ is shifted to the higher energy region on the formation of the bridged complexes **8** and **10** and becomes a very broad shoulder. This higher shifting of the band indicates the increasing stabilization of the ruthenium *d*-orbitals by back bonding from ruthenium to the cyanide group. Such shifting is also observed in the complexes having the $Ru(bpy)_2Cl^+$ sub-unit, as discussed earlier, and is in very good agreement with the shifting of ν(CN) to lower energy in the IR spectra. The shoulder at 261 nm in complex **2** and an absorption peak at 268 nm in complex **3**, which are assigned as the MLCT transitions for the copper sub-units, are almost unaffected in their corresponding complexes **8** and **10**, respectively, on bridge formation. The IL bands, in the higher energy regions, which are mainly localized on the phenyl group, in complexes **2** and **3** are mixed with the strong IL bands at 240 nm due to the complex $[(\eta^5\text{-Cp})Ru(PPh_3)_2Cl]$, in the bridged complexes (Fig. 3). On bridge formation the MLCT transition at 260 nm in complex **1** becomes broad and appears as a shoulder, whereas the MLCT transition band of the complex $[(\eta^5\text{-Cp})Ru(PPh_3)_2Cl]$ shifts towards the higher energy region and becomes broad due to the reasons discussed earlier.

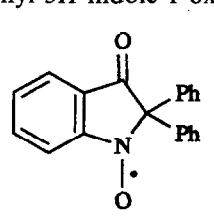
Abstract—Copper hexafluoroacetylacetonate reacts with an indole nitroxide (1,2-dihydro-3-oxo-2,2-diphenyl-3*H*-indole-1-oxyl) in hexane to yield a trinuclear complex with two bridging nitroxides, bis-[μ-(1,2-dihydro-3-oxo-2,2-diphenyl-3*H*-indole-1-oxyl)-O; O′]hexakis(hexafluoroacetylacetonato)tricopper(II), which has been structurally characterized by X-ray crystallography. The nitroxide functions of the paramagnetic ligands are coordinated to the terminal copper atoms. Magnetic measurements revealed strong antiferromagnetic coupling between the spins of the nitroxides and of the terminal copper atoms.

At present a good deal of information concerning the chemical, structural and magnetochemical properties of the complexes of the hexafluoroacetylacetonates of first row transition metals, [M(hfac)$_2$], with stable nitroxide radicals have been amassed, the results of these studies being summarized in a number of reviews.[1–3] Major efforts were devoted to the complexes of 3-imidazoline-1-oxyl and 2-imidazoline-1-oxyl 3-oxide derivatives, while the other types of nitroxides have been considerably less studied. For this reason we attempted to extend the range of nitroxides involved by studying the adducts formed by M(hfac)$_2$ with indole nitroxide derivatives. To the best of our knowledge nitroxides of this type have never been used as ligands. The choice of a strong acceptor—M(hfac)$_2$—as the metal salt was dictated by the well-known weakness of the nitroxide group as a donor. In this paper we report the results of the investigation of the Cu(hfac)$_2$ complex with 1,2-dihydro-3-oxo-2,2-diphenyl-3*H*-indole-1-oxyl (L^1).



L^1

EXPERIMENTAL

The nitroxides 1,2-dihydro-3-oxo-2,2-diphenyl-3*H*-indole-1-oxyl, 2,2,6,6-tetramethyl-4-oxo-piperidine-1-oxyl, 2,2,5,5-tetramethyl-3-oxo-pyrrolidine-1-oxyl and $Cu(hfac)_2$ were synthesized by literature methods.[4-6] Reagent-grade hexane was used as purchased.

Preparation of $[Cu(hfac)_2]_3L^1_2$

A mixture of L^1 (100 mg, 0.33 mmol) and anhydrous $Cu(hfac)_2$ (160 mg, 0.34 mmol) was dissolved in boiling hexane (approximately 40 cm^3) to form a brown coloured solution. After filtration the solution was kept at ambient temperature for 12 h. During this time greenish-brown table-shaped crystals deposited, which were filtered off and washed with cold hexane. Yield 100 mg (30%). The crystals appeared to be suitable for X-ray diffraction study; m.p. 138–140°C. Found: Cu, 9.4; C, 40.4; H, 1.5; N, 1.7. Calc. for $Cu_3C_{70}H_{34}F_{36}N_2O_{16}$: Cu, 9.4; C, 41.3; H, 1.7; N, 1.4%.

Crystal structure solution and refinement

The intensity data were obtained on a Syntex $P2_1$ diffractometer with Cu-K_α (graphite monochromator) radiation and corrected for Lorentz and polarization effects. The absorption correction was performed with the DIFABS package.[7] The structure was solved by the heavy atom method. Anisotropical full-matrix least-squares refinement was performed using the YANX package,[8] atomic scattering factors being taken from ref. 9. Hydrogen atoms were included in the last refinement cycle in idealized positions.

Crystal data for the compound are summarized in Table 1 and selected bond lengths and angles are reported in Table 2.

Magnetic measurements

The magnetic susceptibility of the complex was measured by Faraday's method over a 77–300 K temperature range. The data were corrected for diamagnetic contributions, estimated from Pascal's constants, and for copper(II) temperature-independent paramagnetism.

ESR spectra

The ESR spectrum of a finely ground solid $[Cu(hfac)_2]_3L^1_2$ was recorded on a P-1306 spectrometer (*X*-band) at 77 K (800 G scan, 200 G min^{-1} scan rate, −20 Db microwave power, 2.8 G modulation amplitude).

RESULTS AND DISCUSSION

Copper hexafluoroacetylacetonate reacts with indole nitroxide L^1 in hexane forming the complex of composition $[Cu(hfac)_2]_3L^1_2$. No other adducts were obtained upon variation of the starting $Cu(hfac)_2 : L^1$ ratio from 1 : 1 to 3 : 2 or cooling of the reaction mixture to −15°C. The anhydrous $Cu(hfac)_2$ may be substituted by its hydrated forms, the same product being obtained. This indicates, taking into account the rather low solubility of $Cu(hfac)_2$ in hexane, that L^1 molecules effectively replace coordinated water.

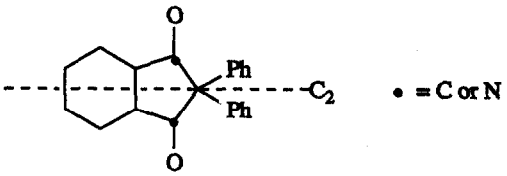
The investigation of the $[Cu(hfac)_2]_3L^1_2$ structure has shown that this complex has a trinuclear structure (Fig. 1). In $[Cu(hfac)_3]_3L^1_2$ three $Cu(hfac)_2$ fragments are bridged by two O,O′-coordinated nitroxides. The central copper atom lies on the inversion centre (0,0,0) and has a tetragonally distorted octahedral coordination environment with four $hfac^-$ oxygen atoms in the equatorial plane (mean Cu—O = 1.93 Å) and two oxygen atoms of the paramagnetic ligands in the axial positions [Cu(1)—O(3) = 2.41(1) Å]. The terminal copper atoms have a distorted trigonal-bipyramidal coordination geometry similar to that found in the other trinuclear $Cu(hfac)_2$-nitroxide complexes reported so far.[10-12] The paramagnetic ligand is coordinated in the equatorial plane of the bipyramid, the Cu(2)—O(4) bond being equal to 2.00(1) Å. It is noteworthy that the equatorial Cu(2)—O(6) bond is elongated to 2.19(1) Å, while the other Cu—O_{hfac} bonds have the usual lengths of approximately 2.0 Å. Similar elongation of Cu—O bonds was observed in different $Cu(hfac)_2$-nitroxide complexes

Table 2. Selected bond lengths (Å) and angles (°) for $[Cu(hfac)_2]_3L^1_2$

Cu(1)—O(1)	1.91(1)	Cu(1)—O(2)	1.95(1)
Cu(1)—O(3)	2.41(1)	Cu(2)—O(4)	2.00(1)
Cu(2)—O(5)	1.88(1)	Cu(2)—O(6)	2.19(1)
Cu(2)—O(7)	1.97(1)	Cu(2)—O(8)	1.89(1)
C(6)—O(3)	1.24(1)	O(4)—N(1)	1.28(1)
O(1)—Cu(1)—O(2)	87.8(4)	O(5)—Cu(2)—O(6)	89.1(4)
O(1)—Cu(1)—O(3)	87.3(3)	O(5)—Cu(2)—O(7)	89.5(4)
O(2)—Cu(1)—O(3)	88.8(3)	O(5)—Cu(2)—O(8)	170.8(6)
O(4)—Cu(2)—O(5)	89.0(4)	O(6)—Cu(2)—O(7)	99.3(4)
O(4)—Cu(2)—O(6)	94.8(3)	O(6)—Cu(2)—O(8)	99.5(4)
O(4)—Cu(2)—O(7)	165.9(5)	O(7)—Cu(2)—O(8)	92.0(4)
O(4)—Cu(2)—O(8)	87.3(4)		

with the trigonal-bipyramidal environment of the copper atom.[10,11,13,14]

From the structural point of view the nitroxide L^1 manifests one interesting property: it contains chemically inequivalent but structurally similar nitroxide and carbonyl groups; therefore, the whole molecule has a C_2-pseudosymmetry axis.

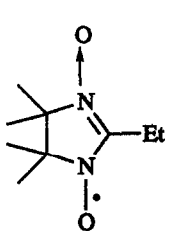


For this reason, on the examination of the $[Cu(hfac)_2]_3L^1_2$ structure the question arises whether L^1 is coordinated to the central copper atom by the nitroxide or the carbonyl group. Both variants were attempted in the course of the refinement. They appeared to be indistinguishable according to Hamilton's test[15] at the 99% level of probability. However, the variant of the terminal copper–nitroxide coordination was chosen for further refinement because the opposite one yielded a "non-positive" nitrogen atom and somewhat worse thermal parameters for adjacent atoms. The final values of the bond lengths for the carbonyl and nitroxide groups are in good accord with the refinement model. The bond length of 1.28(1) Å, found for the group coordinated to the terminal copper atom, is close to the value of 1.27 Å suggested as a "standard" for a nitroxide group.[16] The group coordinated to the central copper atom has the bond length equal to 1.24(1) Å, this value falling between the average bond lengths reported for free and coordinated carbonyl groups.[17,18] Thus, it is reasonable to suppose that the N→O group is coordinated to the terminal copper atom and the C=O group to the central copper atom.

Magnetic susceptibility measurements for $[Cu(hfac)_2]_3L^1_2$ showed that the room-temperature magnetic moment of the compound was equal to 1.82 B.M. and remained constant down to 77 K. This indicates the presence of strong antiferromagnetic coupling between the copper and nitroxide spins, resulting in the $S = 1/2$ ground state. According to the results of the ESR study of solid $[Cu(hfac)_2]_3L^1_2$ the odd electron is localized on a copper(II) ion: a typical spectrum of a copper(II) ion ($g_\parallel = 2.32$, $g_\perp = 2.06$, $A_\parallel = 147$ G) was observed (Fig. 2). The presence of well-resolved hyperfine splitting in parallel orientation shows that the magnetic sites are well-shielded, the exchange energy between copper(II) ions being negligible in comparison with the hyperfine splitting energy.

These results are easily understood if the N→O group is coordinated to the terminal copper atom. Such a coordination mode is known to result in effective pairing of the copper and nitroxide electron spins.[1,2] In the present case the remaining unpaired electron resides on the central copper atom, which is fully consistent with the observed magnetic moment and ESR spectrum of $[Cu(hfac)_2]_3L^1_2$.

It should be noted that very similar magnetic properties were reported for another trinuclear complex with nitroxide to terminal copper coordination—$[Cu(hfac)_2]_3(NITEt)_2$ (NITEt = 4,4,5,5-tetramethyl-2-ethyl-2-imidazolinyl-1-oxyl 3-oxide).[13]



NITEt

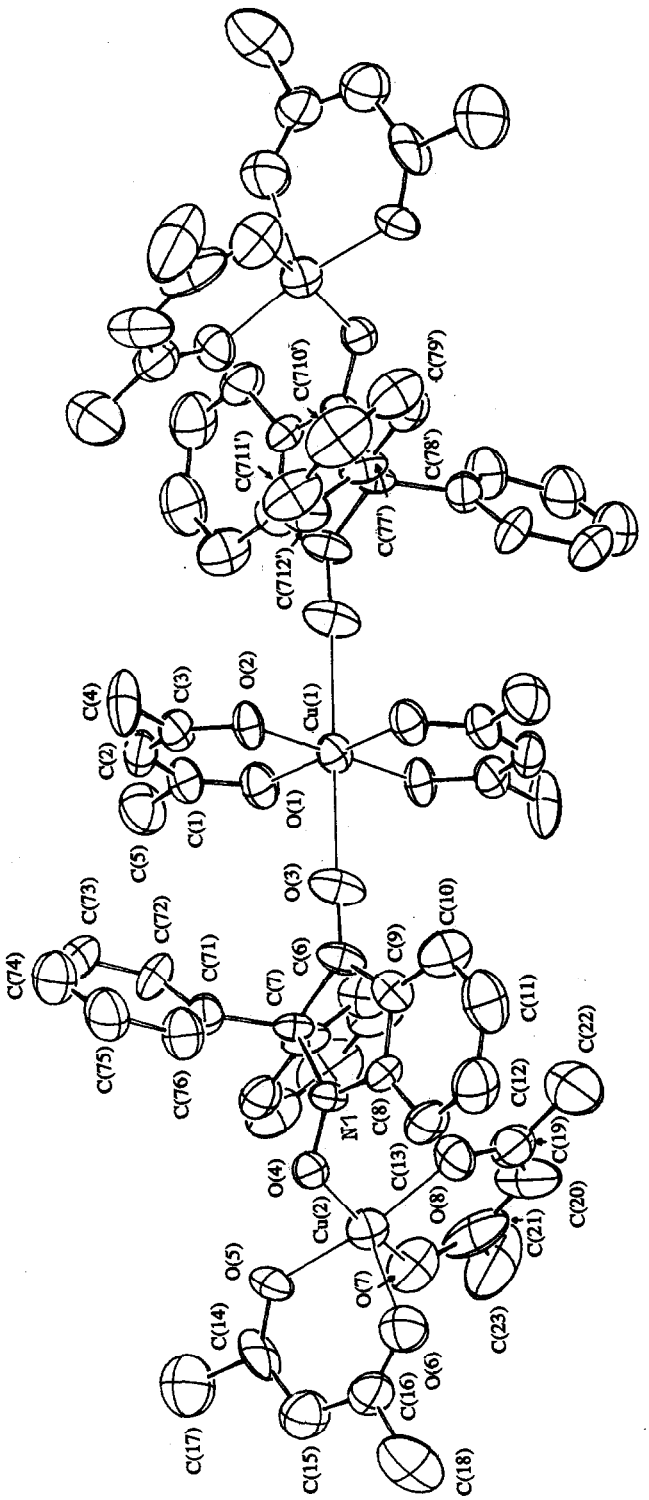


Fig. 1. ORTEP drawing of the $[Cu(hfac)_2]_3L^1_2$ molecule (ellipsoids are contoured at the 50% probability level, fluorine atoms are omitted for clarity). The labels with primes are given to the atoms related by the inversion centre.

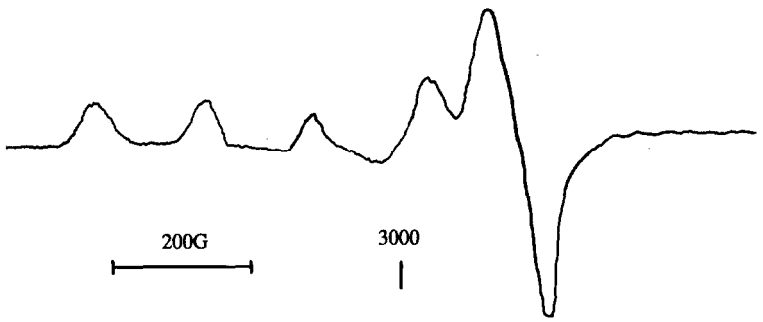

Fig. 2. *X*-band ESR spectrum of solid $[Cu(hfac)_2]_3L^1_2$ at 77 K.

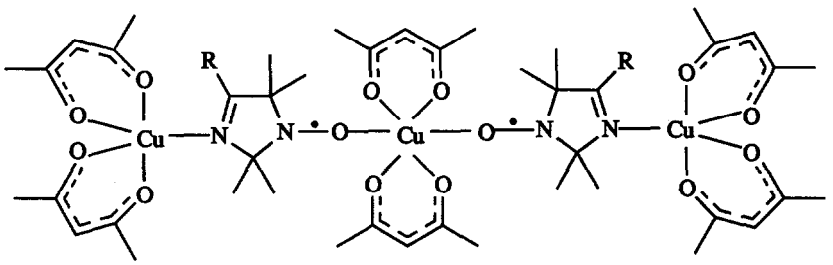
Therefore, the results of the structural and magnetochemical investigation of the complex create a sound basis for the existence of N→O groups of L^1 molecules coordinated to the terminal copper ions.

The $[Cu(hfac)_2]_3L^1_2$ molecule manifests one specific feature when compared with other known complexes of the same stoichiometry: the N→O groups of both bridging paramagnetic ligands are always coordinated to the central copper atom, but not to the terminal one; the complex of symmetric NITEt being the only known exception.[13] It should be noted that the "terminal" bonds (approximately 2.0 Å) are always shorter than the "central" bonds (2.4–2.5 Å) and in the case of imidazoline derivatives, the shorter "terminal" bonds are formed by the stronger (imine) donor functions.[10,11]

account that both TEMPO and acetone are aliphatic bases and in L^1 both groups are conjugated with the aromatic π-system. However, the difference in ΔH seems to be large enough to assume that in the L^1 molecule the N→O group still remains the stronger donor. It is quite probable that this fact accounts for the "inversion" of the nitroxide radical.

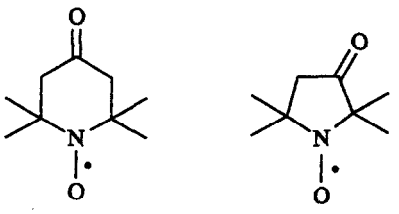
These considerations have encouraged us to attempt to synthesize more trinuclear $Cu(hfac)_2$ complexes with "inverted" paramagnetic ligands, using nitroxides having structurally distinct N→O and C=O donor sites. For this purpose we engaged 2,2,6,6-tetramethyl-4-oxo-piperidine-1-oxyl (L^2) and 2,2,5,5-tetramethyl-3-oxo-pyrrolidine-1-oxyl (L^3). However, these nitroxides appeared to form



R = Et, Pr^i, Ph

Therefore, it is reasonable to suppose that in the case of L^1 the N→O group has stronger, or at least the same donor properties as the carbonyl group of the ligand. These considerations gain some support from the estimate of the donor ability of the N→O and C=O groups towards $Cu(hfac)_2$, on the basis of Drago's equation.[19] The calculations of the adduct formation enthalpy yield approximately -12 kcal mol^{-1} for the N→O group [2,2,6,6-tetramethylpiperidinyl-1-oxyl (TEMPO) as the base] and -7 kcal mol^{-1} for the C=O group (acetone as the base). Apparently, these figures should be considered as very rough estimates, taking into

only adducts of 1 : 1 stoichiometry under conditions that yielded $[Cu(hfac)_2]_3L^1_2$ in the case of the indole nitroxide. Therefore, the presence of peculiar donor groups is insufficient to result in the formation of a trinuclear complex.



L^2 L^3

To conclude it is worth pointing out that the synthesized complex of the indole nitroxide is the first example of a trinuclear $Cu(hfac)_2$ nitroxide adduct with an "inverted" nitroxide. Further investigations of the complexes of indole nitroxide derivatives are in progress.

Abstract—The complex $[Mo(NO)\{HB(OPr^i)(3\text{-}Pr^i\text{-}5\text{-}MeC_3HN_2)_2\}(CO)_2]$ has been isolated from one attempt to prepare $[Mo(NO)\{HB(3\text{-}Pr^i\text{-}5\text{-}MeC_3HN_2)_3\}(CO)_2]$; a crystal structure shows the presence of an isopropoxide group with the alkoxy oxygen bound to the boron and molybdenum atoms [Mo—O = 2.225(5) Å].

Following their initial development by Trofimenko[1] the trispyrazolylborate ligand and its derivatives have assumed an important role in modern coordination chemistry.[2] These ligands have found applications in a wide variety of contexts, including organometallic systems which exhibit photochemical reactivity,[3,4] models for bio-inorganic systems[5–8] and complexes used to study intramolecular electron transfer processes.[9,10] Although it is generally assumed that the trispyrazolylborate ligand system represents an inert group capable of occupying three facial coordination sites on a metal, several examples are known in which the ligand itself undergoes reactions. These reactions may

† Authors to whom correspondence should be addressed.

involve varying degrees of ligand degradation. At one extreme asymmetrically substituted trispyrazolylborates carrying bulky substituents may undergo boratropic rearrangements which involve ligand reorganization without the loss of any pyrazolyl groups.[1,12] Presumably these rearrangements are driven by the energy benefit of achieving the most sterically efficient disposition of the bulky substituents within the complex when this substitution pattern differs from that initially present in the ligand. At the other extreme, complete degradation of the trispyrazolylborate ligand has been observed in the reaction[13] of K[HB(3,5-$Me_2C_3HN_2)_3$] with [{Ru(η^6-C_6H_6)Cl_2}$_2$] to give [Ru(η^6-C_6H_6){NH=CMe(Me_2pz)}Me_2Hpz)]$^{2+}$ and in deboronation of [Mo(NO){HB(3,5-$Me_2C_3HN_2)_3$}I_2] by catechol to give [Mo(NO)($O_2C_6H_4$)(Me_2pzH)$_2$(Me_2pz)].[14] Between these extremes there are examples in which one pyrazolyl group is displaced from a trispyrazolylborate ligand by another group. Evidence has been obtained that the reactions between [Mo(NO){HB(3,5-$Me_2C_3HN_2)_3$}I_2] and 2-aminobenzenethiol or 1,2-diaminobenzene result in the replacement of one of the dimethylpyrazolyl groups by the aminoaryl moiety, although the structures of the products could not be definitively assigned.[15] In this communication we report a further example of the partial degradation of a trispyrazolylborate ligand associated with the {Mo(NO)} moiety and describe the crystal structure of the product.

The synthesis of [Mo(NO){HB(MePr^i$C_3$$HN_2)_3$}(CO)$_2$] according to the previously reported method[12] has been successfully repeated on a number of occasions in our laboratory. However, on one occasion the product obtained was not the expected compound but a derivative having a different NMR spectrum. This contained doublets [J(HH) = 7 Hz] of relative areas 6:6:6 at 1.30, 1.18 and 1.03 ppm, attributable to three pairs of isopropyl methyl groups, a singlet of relative area 6 at 2.31 ppm, attributable to two equivalent pyrazolyl methyl substituents, two multiplets of relative areas 2:1 at 3.15 and 4.09 ppm, attributable to the isopropyl Me_2CH- groups, and a singlet of relative area 2 at 5.80 ppm, attributable to two equivalent pyrazolyl 4-CH protons. The spectrum was lacking in signals attributable to the methyl and 4-CH protons of a third pyrazolyl group. The IR spectrum contained bands at 2480, 2010, 1915 and 1660 cm^{-1} attributable to the BH, NO and CO groups. These spectroscopic data are in accord with the formulation [Mo(NO){HB(OPr^i)(3-Pr^i-5-$MeC_3HN_2)_2$}(CO)$_2$], in which one pyrazolyl group in the tripodal ligand has been replaced by an isopropoxide group. This formulation is also in accord with the structure established by X-ray methods and described below. The source of the isopropoxide remains unclear. Except for the sample of butyl nitrite, the reagents used in the preparation were taken from the same samples used in previous reactions and which afforded the expected product. It is possible that the butyl nitrite was impure but none of this sample remained for further investigation. We have found that heating [Mo(NO){HB(MePr^i$C_3HN_2)_3$}(CO)$_2$] under reflux in either Pr^{i}OH or Me_2CO, for longer than the reaction time used in its preparation, does not lead to the formation of [Mo(NO){HB(OPr^i)(3-Pr^i-5-$MeC_3HN_2)_2$}(CO)$_2$]. Thus, it appears that the degradation reaction must have occurred prior to, or during, the formation of [Mo(NO){HB(OPr^i)(3-Pr^i-5-$MeC_3HN_2)_2$}(CO)$_2$].

The crystal structure* of [Mo(NO){HB(OPr^i)(3-Pr^i-5-$MeC_3HN_2)_2$}(CO)$_2$] reveals a *fac* arrangement of the {(NO)(CO)$_2$} ligand set within a dis-

* *Crystal data.* Crystals of $MoBN_5O_4C_{19}H_{30}$ are orthorhombic, space group $P2_12_12_1$, a = 8.146(3), b = 16.886(3), c = 17.812(2) Å, U = 2450(1) Å^3, $F(000)$ = 1032, μ = 5.52 cm^{-1}, Z = 4, D_c = 1.35 g cm^{-3}. A crystal of dimensions 0.3 × 0.3 × 0.2 mm^3 was coated with epoxy resin and mounted in a kappa diffractometer. The cell dimensions were refined by least-squares fitting of the values of 25 reflections. The intensities of 4010 unique reflections within $2 < \theta < 30$ and indices from (0,0,0) to (11,23,25) were measured at 295 K with monochromatic Mo-K_α radiation (λ = 0.71069 Å) and an $\omega/2\theta$ scan technique. There was no appreciable drop in the intensity of standard reflections monitored every hour. The intensities were corrected for Lorentz and polarization effects and 2475 with $\{I < 2\sigma(I)\}$ were considered observed and used in the analysis. Scattering factors for neutral atoms and anomalous dispersion corrections for molybdenum were taken from ref. 16. The structure was solved by Patterson and Fourier methods. An empirical absorption correction[17] was applied at the end of the isotropic refinement. Final refinement with fixed isotropic thermal parameters and coordinates for hydrogen atoms and unit weights led to R = 0.44 and R_w = 0.051. No trend in F vs F_0 or $(\sin\theta)/\lambda$ was observed. Average shift-to-error ratios were < 0.03. A final difference synthesis showed no significant electron density.

The nitrogen atom of the nitrosyl ligand and the carbon atoms of the carbonyl ligands became indistinguishable. The positions of these three atoms were considered occupied by carbon and nitrogen atoms with population factors 0.66 and 0.34, respectively. The atom labelled as O(1) has been assigned as an oxygen atom on the basis of the spectroscopic data. Calculations were performed using the X-ray 80 system.[18] Additional material available from the Cambridge Crystallographic Data Centre comprises atom coordinates and thermal parameters.

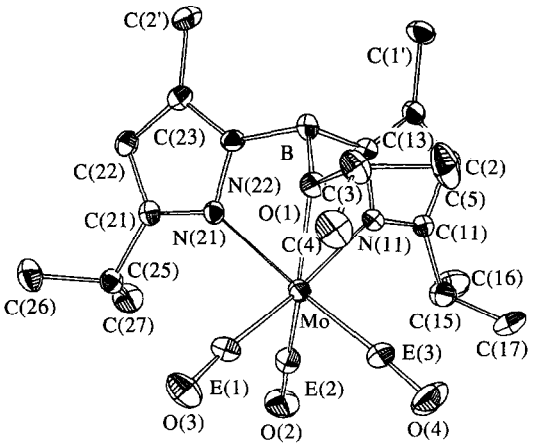

Fig. 1. A view of $[Mo(NO)\{HB(OPr^i)(3\text{-}Pr^i\text{-}5\text{-}MeC_3HN_2)_2\}(CO)_2]$ showing the atom numbering with 20% probability ellipsoids. Hydrogen atoms have been omitted for clarity. Selected bond lengths (Å) and angles (°): Mo—O(1), 2.225(5); Mo—N(11), 2.227(7); Mo—N(21), 2.204(7); Mo—E(1), 1.987(9); Mo—E(2), 1.955(10); Mo—E(3), 1.809(7); B—O(1), 1.501(11) Å; E(1)—Mo—E(2), 87.5(4); E(1)—Mo—E(3), 86.5(4); E(2)—Mo—E(3), 85.2(4); E(1)—Mo—O(1), 99.8(4); E(2)—Mo—O(1), 100.9(3); E(3)—Mo—O(1), 171.3(3); Mo—O(1)—B, 102.8(5); Mo—E(1)—O(3), 174.3(9); Mo—E(3)—O(4), 177.0(9); Mo—E(2)—O(2), 178.9(8); B—O(1)—C(3), 119.3(7)°.

torted octahedral coordination geometry around the formally 18-electron molybdenum centre (Fig. 1). The remaining three coordination sites are occupied by two pyrazolyl nitrogens and an oxygen atom derived from an isopropoxide moiety, which has replaced one of the pyrazolyl groups in the tripodal ligand. Within the first coordination sphere of the molybdenum atom the Mo—O(Pr^i) distance [2.225(5) Å] is comparable with the two Mo—N(pyrazolyl) distances [av. 2.216(7) Å], which in turn are similar to those found[19] in $[Mo(NO)\{HB(pz)_3\}(CO)_2]$ [av. 2.213(4) Å] but smaller than in $[Mo(NO)\{HB(C_3H_2N_2C_6H_4OMe\text{-}4)_3\}(CO)_2]$ [av. 2.253; range 2.23(1)–2.27(1) Å].[20] In contrast the E—Mo—E′ (E, E′ = N, C) angles in $[Mo(NO)\{HB(OPr^i)(3\text{-}Pr^i\text{-}5\text{-}MeC_3HN_2)_2\}(CO)_2]$ (av. 86.4°) are smaller than in $[Mo(NO)\{HB(pz)_3\}(CO)_2]$ [av. 90.45(30)°] and more comparable with the average value of 85.0° found in the more sterically constrained complex $[Mo(NO)\{HB(C_3H_2N_2C_6H_4OMe\text{-}4)_3\}(CO)_2]$. These findings indicate that, compared with $HB(pz)_3$, the $HB(OPr^i)(3\text{-}Pr^i\text{-}5\text{-}MeC_3HN_2)_2$ ligand produces some steric compression of the $\{Mo(NO)(CO)_2\}$ moiety, but that this is not reflected in the Mo—N pyrazolyl distances, unlike the situation in $[Mo(NO)\{HB(C_3H_2N_2C_6H_4OMe\text{-}4)_3\}(CO)_2]$. The average Mo—E(O) distance of 1.917 Å in $[Mo(NO)\{HB(OPr^i)(3\text{-}Pr^i\text{-}5\text{-}MeC_3HN_2)_2\}(CO)_2]$ lies between the average values of 1.907 and 1.930 Å found respectively in $[Mo(NO)\{HB(C_3H_2N_2C_6H_4OMe\text{-}4)_3\}(CO)_2]$ and $[Mo(NO)\{HB(pz)_3\}(CO)_2]$.

The findings described here provide a further example of the friability of the trispyrazolylborate ligand system and emphasize the need for those working with these ligands to be alert to the possibility of ligand degradation reactions.

ORTHOMETALLATION REACTION IN DIRHODIUM(II) COMPOUNDS. SELECTIVE FORMATION OF DOUBLY-METALLATED COMPOUNDS WITH HEAD-TO-HEAD STRUCTURE

M. V. BORRACHERO, F. ESTEVAN, P. LAHUERTA,* J. PAYÁ and E. PERIS

Departamento de Química Inorgánica, Universitat de Valencia, C/Dr. Moliner 50, E-46100 Burjassot-Valencia, Spain

(*Received* 10 *November* 1992; *accepted* 20 *April* 1993)

Abstract—The reaction of the mono-metallated compound $Rh_2(O_2CCH_3)_3[(C_6H_4)P(CH_3)(C_6H_5)]\cdot 2(HO_2CCH_3)$ with PPh_3 (1:1 molar ratio) has been studied by ^{31}P NMR spectroscopy. The reaction yields the doubly-metallated compound $Rh_2(O_2CCH_3)_2[(C_6H_4)P(CH_3)(C_6H_5)][(C_6H_4)P(C_6H_5)_2]\cdot 2(HO_2CCH_3)$ with a head-to-head (H-H) configuration. An intermediate reaction compound, not previously observed, has been spectroscopically detected in solution. Analogous intermediate compounds have been detected using $P(p\text{-}CH_3C_6H_4)_3$ and $P(p\text{-}ClC_6H_4)_3$ instead of triphenylphosphine.

It is known[1,2] that rhodium acetate reacts with triarylphosphines (PR_3) or alkylarylphosphines $\{P(CH_3)(C_6H_5)_2$ or $P(CH_3)_2(C_6H_5)\}$ to give mono- and doubly-metallated dirhodium(II) compounds. In the course of our investigation on the reactivity of dirhodium(II) tetracarboxylate and arylphosphines we have observed[1d,e] two general reaction pathways yielding doubly-metallated compounds with head-to-head (H-H) and head-to-tail (H-T) configurations. As a rule compounds with H-H configuration were only formed when excess phosphine was present in solution.

It has been reported that $Rh_2(O_2CCH_3)_4$ and $P(CH_3)(C_6H_5)_2$ (in a 1:2 molar ratio) react in refluxing acetic acid to yield the doubly-metallated compound $Rh_2(O_2CCH_3)_2[(C_6H_4)P(CH_3)(C_6H_5)]_2\cdot 2(HO_2CCH_3)$, which has been structurally characterized.[2a] We have found that the same reaction performed using an Rh_2:P molar ratio of 1:1 yields a mixture of the mono-metallated compound $Rh_2(O_2CCH_3)_3[(C_6H_4)P(CH_3)(C_6H_5)]\cdot 2(HO_2CCH_3)$ (**1**)† and the already reported doubly-metallated compound.[2a] When **1** reacts with $P(CH_3)(C_6H_5)_2$ (1:1 molar ratio) in chloroform at room temperature for 4 days only the titled compound with H-T configuration, $Rh_2(O_2CCH_3)_2[(C_6H_4)P(CH_3)(C_6H_5)]_2\cdot 2(HO_2CCH_3)$,[2a] is isolated (yield 70%). When **1** is reacted with triphenylphosphine in the same reaction conditions the doubly-metallated compound with H-H configuration, $Rh_2(O_2CCH_3)_2[(C_6H_4)P(CH_3)(C_6H_5)][(C_6H_4)P(C_6H_5)_2]\cdot$

* Author to whom correspondence should be addressed.

† Preparation of compound **1**: $Rh_2(O_2CCH_3)_4\cdot 2(CH_3OH)$ (300 mg, 0.59 mmol) was added to a solution of $PMePh_2$ (0.114 cm^3, 0.6 mmol) in CH_2Cl_2 (30 cm^3). The resulting brown suspension was stirred at room temperature for 10 min. The solvent was removed and a mixture of toluene: acetic acid (60 cm^3, 3:1) was added. The solution was refluxed for 45 min and the solvent was evaporated to dryness. The crude solid was dissolved in CH_2Cl_2 (5 cm^3) and transferred into a chromatography column. By elution with CH_2Cl_2: hexane: acetic acid (10:10:5) a purple band containing $Rh_2(O_2CCH_3)_2[(C_6H_4)P(CH_3)(C_6H_5)]_2\cdot 2(HO_2CCH_3)$ was separated. Further elution with CH_2Cl_2: hexane: acetic acid (10:10:10) separated a violet band of **1**, which was precipitated in a mixture (5 cm^3) of hexane: CH_2Cl_2 (yield 52%).

Characterization of **1**: Spectroscopic data: $^{31}P\{^1H\}$NMR: δ_P = 13.7 ppm, ^1J(Rh—P) = 147.7 Hz, ^2J(RhP) = 6.2 Hz. ^1H NMR (in ppm): 1.15 (3H, CH_3, s), 1.69 (3H, CH_3, s), 1.85 [3H, CH_3, d, ^1J(H—P) = 12 Hz], 2.28 (6H, CH_3, s), 2.32 (3H, CH_3, s), 6.9–7.7 (8H, aromatics, m), 8.43 (1H, aromatic, q). $^{13}C\{^1H\}$NMR (in ppm): 11.4 [CH_3, d, ^1J(P—C) = 32 Hz), 21.6 (CH_3, s), 23.4 (CH_3, s), 23.9 (CH_3, s), 122–145 (aromatics, m), 162.7 (metallated C, m), 179.2 (OCO, s), 182.3 (OCO, s) 189.5 (OCO, s), 189.9 (OCO, s). Found: C, 38.6; H, 4.2. Calc. for $Rh_2PO_{10}C_{23}H_{29}$: C, 39.3; H, 4.2%.

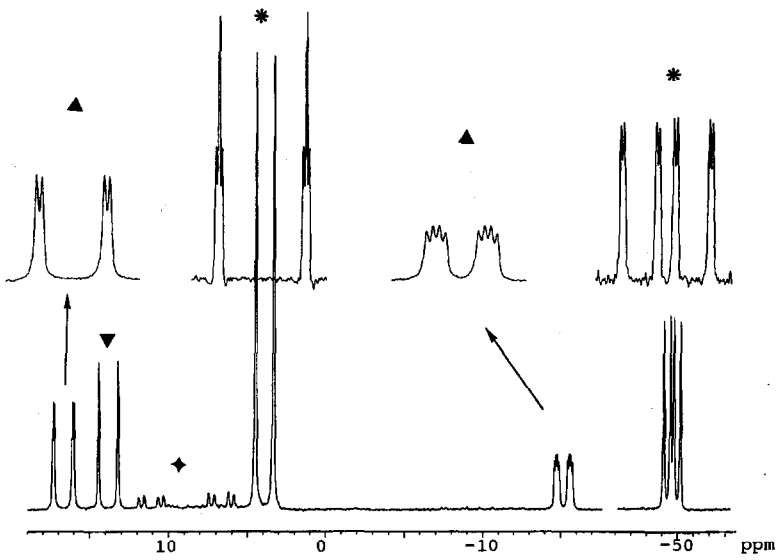

Fig. 1. ^{31}P NMR spectrum of a mixture of **1** and PPh_3 (molar ratio $P/Rh_2 = 0.8$) in $CDCl_3$ at $-50°C$: ▼ signals due to unreacted **1**, ▲ signals due to **1**·PPh_3, * signals due to **2** and ◆ signals due to impurities.

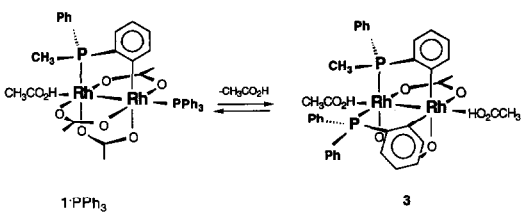
$2(HO_2CCH_3)$ (**3**),* is obtained in 6 h (yield 62%). The observation of a $^2J(P—P')$ coupling constant value of 42 Hz in the ^{31}P NMR spectrum of **3** is diagnostic of an H-H configuration of the two metallated ligands.[1e] Up until now we had only observed the formation of compounds with H-H structure when excess phosphine was present in solution. This is the first time that we observe the formation at room temperature of a compound with H-H structure under stoichiometric amounts of ligand (see Scheme I).

We have monitored the reaction **1** → **3** by ^{31}P NMR spectroscopy. The spectrum of the solution resulting from adding triphenylphosphine to a chloroform solution of **1** (molar ratio $P:Rh_2 = 1$) at $-40°C$ shows the presence of two main species: the phosphine mono-adduct $Rh_2(O_2CCH_3)_3[(C_6H_4)P(CH_3)(C_6H_5)]\cdot(PPh_3)(HO_2CCH_3)$ (**1**·PPh_3)[1e,3] and a new species **2**, which has two resonances



Scheme I.

at -49.23 and 3.90 ppm (Fig. 1). Different spectra recorded in the temperature range -40 to $+20°C$ show that the species **1**·PPh_3 and **2** are in equilibrium. The amount of species **2** in solution increases as the temperature decreases. Some line broadening is observed in the spectra recorded at 20°C.

At 30°C there is already a slow chemical evolution and signals due to the doubly-metallated compound **3** appear in the spectrum while those corresponding to **1**·PPh_3 and **2** disappear. The reaction is completed after 12 h and compound **3** can be isolated from the reaction mixture in moderate yield. Compound **3** could be obtained as a mixture of two isomers (with the methyl group attached to the phosphine in an *endo* or *exo* configuration relative to the dihedral angle formed by the two metallated ligands). The observation of very sharp resonances in the ^{31}P NMR spectra suggests that the reaction is regio-selective and only one of the two possible isomers, we propose the less sterically crowded, is formed.

In the two reported[1d,e] reaction pathways the observed intermediate species (**I** and **II**, Scheme II)

* Characterization of **3**: Spectroscopic data: $^{31}P\{^1H\}$NMR: $\delta_{P1} = 24.4$ ppm, $^1J(Rh(1)—P(1)) = 150$ Hz, $^2J(Rh(2)—P(1)) = 6.0$ Hz; $\delta_{P2} = 5.8$, $^1J(Rh(1)—P(2)) = 145$ Hz, $^2J(Rh(2)—P(2)) = 6.4$ Hz, $^2J(P(1)—P(2)) = 42$ Hz. ^1H NMR (in ppm): 0.85 (3H, CH_3, s), 1.27 [3H, CH_3, d, $^1J(H—P) = 15$ Hz], 1.63 (3H, CH_3, s), 2.11 (6H, CH_3, s), 6.2–8.1 (23H, aromatics, m). $^{13}C\{^1H\}$NMR (in ppm): 14.2 (CH_3, s), 22.8 (CH_3, s), 23.4 [CH_3, d, $^1J(P—C) = 32$ Hz], 29.9 (CH_3, s), 127–145 (aromatics, m), 161.8 (metallated C, m), 163.6 (metallated C, m), 181.7 (OCO, s), 182.6 (OCO, s) 182.8 (OCO, s). Found: C, 51.1; H, 4.7. Calc. for $Rh_2P_2O_8C_{39}H_{40}$: C, 51.8; H, 4.4%.

Scheme II.

contained one equatorial phosphine in a previous situation to the transfer of one proton to a partially displaced acetate group. The spectroscopic data observed for **2** indicate that this intermediate compound is structurally different to species **I** and **II**. The high-field resonance at −49.23 ppm cannot be assigned to one triphenylphosphine in the equatorial coordination position, which usually has chemical shift values in the range 30–50 ppm.[4] The ^{1}H NMR spectrum of the reaction mixture does not show any resonance indicative of agostic interactions or Rh—H bond formation.

Based on the spectroscopic data we are not able to make a definitive structural assignment for compound **2**. Even though the resonance at 3.90 ppm [^1J(Rh—P) = 140.1 Hz, ^2J(Rh—P) = 4.8 Hz and J(P(1)—P(2)) = 4.7 Hz] can be assigned to a metallated dimethylphenylphosphine the assignment of the signal at −49.23 ppm [^1J(Rh—P) = 76.5 Hz, ^2J(Rh—P) = 51.2 Hz and ^3J(P(1)—P(2)) = 4.7 Hz] is not completely clear to us. The ^{13}C NMR spectrum of this sample at −40°C did not give any additional information.

In a separate experiment we performed the same reaction using $P(C_6D_5)_3$.* The same equilibrium between species **1** and **2** was obtained. After adding CH_3CO_2H (0.1 cm^3) to the NMR tube the sample was warmed at 20°C for several minutes and was immediately cooled to −40°C. The process was repeated several times, after which only the two species **1** and **2** were still observed in solution. The ^{1}H NMR spectrum did not show any signal in the aromatic region indicative of the occurrence of exchange in the $P(C_6D_5)_3$ ligand. This experiment rules out the equilibrium **1**·$PPh_3 \leftrightarrow$ **2**, involving metallation and demetallation of the triphenylphosphine ligand. The same reaction performed with **1** and $P(p\text{-}CH_3C_6H_4)_3$ or $P(p\text{-}ClC_6H_4)_3$ behaved in a very similar way, yielding doubly-metallated compounds with H-H structure through reaction intermediates that show analogous ^{31}P NMR spectra.

The only possible structure for the intermediate **2** is the one involving axial coordination of the entering phosphine at the same rhodium atom that is bonded to the phosphorus of the metallated phosphine.

The spectroscopic data do not reject this assignment, which is fully consistent with the structure of the reaction product obtained. This particular adduct at room temperature might selectively undergo axial to equatorial rearrangement of the phosphine so explaining the H-H configuration of the reaction product.

Further experiments, aimed at a better elucidation of the mechanistic aspects of this particular metallation reaction, are in progress.

(*Received* 24 *July* 1992; *accepted* 1 *April* 1993)

Abstract—The kinetics of oxidation of indoles (**1a–d**) to the corresponding oxindole by the title oxidant in alkaline medium catalysed by osmium(VIII) at 30°C has been studied. The reaction shows first-order each in [chloramine-T] (**2**), [Os^{VIII}] (**3**) and [indole] (**1a**). Effects of added anions and *p*-toluenesulphonamide (**5**) as well as varying ionic strength and dielectric constant of the medium have been investigated. Activation parameters have been computed. An isokinetic relationship was observed with $\beta = 325$, indicating enthalpy as the rate-controlling factor. With the available data, including the substituent effects ($\rho^+ = -1.0$) which were obtained from a Hammett plot, the proposed mechanism and the derived rate laws are in agreement with the observed kinetics.

Enzymatic oxidation of indole (**1a**) has attracted the attention of chemists for the past several decades. The metabolic oxidation of study of **1a** to indoxyl was attempted by Laroche and Desbordes.[1] Although the indole (**1a**) has been oxidized by sodium performate in the presence of acetone and methyl paraoxane as a promoter,[2] very few kinetic investigations of indole oxidations have been reported. The studies presented in this paper were undertaken to investigate the oxidation of various indoles by N-halogenated compounds. Specifically of interest is chloramine-T, a versatile oxidant.[3] Mechanistic studies of the oxidation of various organic substrates by organic haloamines have been earlier reported from this laboratory;[4–6] however, there seems to have been no report on the oxidation of indoles (**1a–d**) by chloramine-T (**2**). In this paper the kinetics and mechanism of base and osmium tetroxide (**3**) catalysed 5-substituted indole (**1a–d**) oxidations (30°C, 10% aqueous methanol) are reported.

EXPERIMENTAL

Chloramine-T, CAT (**2**, LobaChemie), was purified by the method of Morris *et al.*[7] An aqueous solution was prepared iodometrically standardized and stored in brown bottles to prevent photochemical deterioration. Indoles (**1a–d**, Aldrich Co.) were of accepted grades of purity and were used as such. Solutions of the compounds were prepared in 10% methanol (v/v). Osmium tetroxide (Johnson and Mathey, London) was prepared in 0.2 M NaOH. All other reagents used were analytical grades of purity. Doubly distilled water was employed in solution preparations. The ionic strength of the system was maintained at a constant

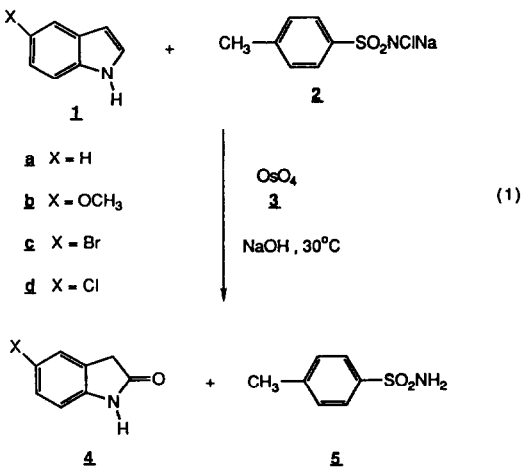
high value ($\mu = 0.5$ M) using a concentrated solution of sodium perchlorate.

Kinetics

The reaction was performed in stoppered Pyrex glass tubes with outer surfaces coated black to eliminate the possible photochemical effects. For each run, requisite amounts of solutions of NaOH, $NaClO_4$, OsO_4, water and methanol (to maintain the total volume constant and 10% methanol medium throughout) were added into a glass tube. Indoles (**1a–d**) and CAT solution pre-equilibrated separately at 30°C were added successively to the reaction mixture to initiate the reaction. The course of the reaction was followed by iodometric determination of unreacted CAT present in the measured aliquots of the reaction mixture withdrawn at different intervals of time. The reaction was studied for two half-lives. The pseudo-first-order rate constants calculated were reproducible within ±3%.

Product studies

Reaction products of the oxidation of indole with **2** in the presence of NaOH and OsO_4 (**3**) in 10% MeOH were isolated from varying amounts of known excess of CAT over indole at 30°C for 24 h. Determination of unreacted CAT in the reaction mixture showed that every mole of indole consumed 1 mol of CAT [eq. (1)].



The residual brown solid obtained by the product studies was subjected to column chromatography on silica gel (60–200 mesh) using gradient elution (dichloromethane to acetone). After initial separation, reaction products were further purified by recrystallization. Reaction products were characterized by ^{1}H NMR, IR and GC/MS. Materials were identified by comparison to commercially available samples.

Oxindole (**4**). Recrystallized from dichloromethane/petroleum ether (m.p. = 118–120°C), known m.p. = 125–127°C (Beil. **21**, 282). The *Rf* value (0.13) was determined from TLC (CH_2Cl_2). IR (KBr): 3217 (N—H stretch), 3070 and 3032 (aromatic C—H stretch), 2925 (aliphatic C—H stretch), 1701 (C=O stretch), 1619 (C=C stretch), 1473, 1333, 1234, 749, 674 and 552 cm^{-1}. ^{1}H NMR ($CDCl_3$): δ = 7.22–6.83 (m, 4H, aromatic C—H), 3.54 (S, 2H, aliphatic C—H), and 1.71 (s, 1H, N—H). GC/MS, *m/z*: 133 (m^+), 104 ($m^+ - NH_2$), 78 ($m^+ - C_2HNO$), 77, 51 and 36 (15% yield).

p-*Toluenesulphonamide* (*PTS*) (**5**). Recrystallized from dichloromethane/petroleum ether (m.p. = 134–135.5°C), known m.p. = 137–140°C (Beil **11**, 104). The *Rf* value (0.84) was determined from TLC (CH_2Cl_2). IR (KBr): 3332 and 3244 (N—H stretch), 3125 (aromatic C—H stretch), 2925 (aliphatic C—H stretch), 1576 (C=C stretch), 1326 and 1172 (SO_2 stretch), 1094, 808, 665, 558 and 532 cm^{-1}. ^{1}H NMR ($CDCl_3$): δ = 7.87–7.26 (m, 4H aromatic C—H), 4.68 (s, 2H, N—H) and 2.43 (s, 3H, aliphatic C—H). GC/MS, *m/z*: 171 (m^+), 155 ($m^+ - NH_2$), 91 ($m^+ - SO_2NH_2$), 65 and 39 (65% yield).

RESULTS

The oxidation of **1a–d** with **2** in the presence of NaOH and OsO_4 in 10% MeOH proceeds in a pseudo-first-order fashion for at least two half-lives. At constant [OH^-] and [**3**] with substrate **1a** in excess plots of log [CAT] vs time were linear, indicating a first-order dependence of rate on [**2**]. Values of pseudo-first-order rate constants (k') are given in Table 1. The rate increases initially with increase in [**1a**], which levels off at higher [**1a**]. Plot of log k' vs

Table 1. Pseudo-first-order rate constants for the variation of [**2**] and [**1a**] at 30°C

—	—	6.0	15.78
—	—	8.0	15.84

[**3**] = 15.7×10^{-6} M; [OH^-] = 0.002 M

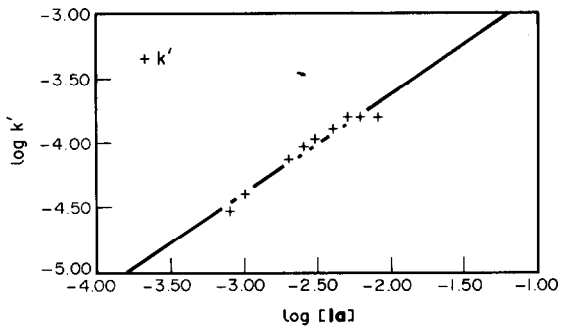

Fig. 1. Plot of log k' vs log [**1a**] at 30°C (k' are pseudo-first-order rate constants). [**2**] = 8.0×10^{-5} M; [OH^-] = 0.002 M; [**3**] = 15.7×10^{-6} M.

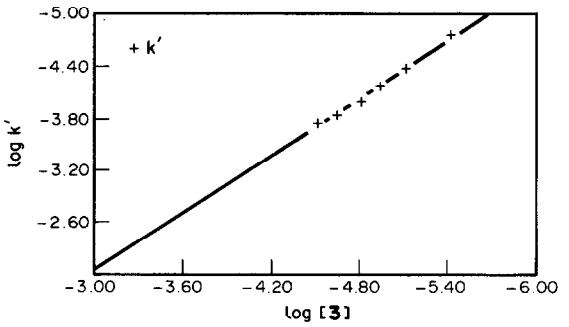

Fig. 2. Plot of log k' vs log [**3**] at 30°C. [**2**] = 8.0×10^{-5} M; [OH^-] = 0.002 M; [**1a**] = 2.5×10^{-3} M.

log [**1a**] was linear ($\gamma = 0.992$, Fig. 1) with unit slope (Table 1). At constant [**2**], [**1a**] and [**3**] the rate is independent of [OH^-] (Table 2). Dependence of rate on [**3**] was studied and found that the rate is accelerated by increasing [**3**] (Table 2). A plot of log k' vs log [**3**] was linear ($r = 0.997$, Fig. 2) with unit slope. Rate studies were made in water–methanol mixtures of varying composition. The rate decreases with an increase in methanol content of the reaction mixture. A plot of log k' vs $1/D$ (D is the dielectric constant of the medium) gave a straight line with negative slope supporting a rate limiting step with partial ionization.[8] Blank experiments with methanol, however, showed that there is slight decomposition of solvent under experimental conditions. This was allowed for in the calculation of the net reaction rate constant for the oxidation of indole. The effect of varying the ionic strength of the medium by adding a concentrated solution of $NaClO_4$ did not alter the rate of the reaction. Addition of the reduced product (**5**) had no effect on the rate. No effect of anions, such as Cl^- or Br^-, on the rate were observed.

From the Arrhenius plots of log k' vs $1/T$ kinetic and thermodynamic parameters were calculated (Table 3). A plot of log k'_2 (Table 3, second-order rate constants k'_2) vs the σp (σ^+) parameter for the ring substituents of **1a–d** is shown in Fig. 4. The Hammett correlations[9,10] were fitted with the $\sigma p = \sigma_I + \sigma_{R^-}$ scale.

DISCUSSION

N-Chloro-N-sodio-*p*-toluenesulphonamide (**2**) acts as an oxidizing agent in both acidic and alkaline

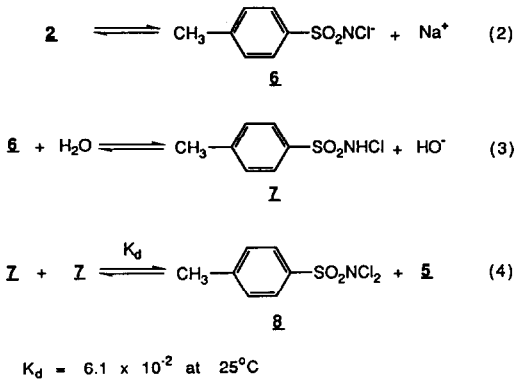
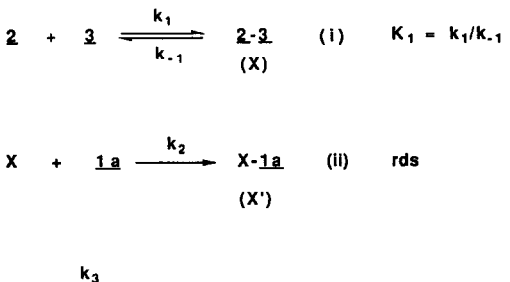
media. In general **2** undergoes a two-electron change in its reactions, the products being **5** and sodium chloride. The reduction potential of **2**/**5** is pH dependent and decreases with an increase in the pH of the medium, having values of 1.14 V at pH 0.65 and 0.5 V at pH 12. Depending on the pH of the medium, **2** furnishes different types of reactive species in solution, such as **7**, **8** [eqs (3) and (4)], HOCl and possibly H_2OCl^+ in acid solutions.[4,6,10]



In alkaline solutions **8** does not exist and the predominant species are **6**, **7**, HOCl and the OCl^- ion. Hardy and Johnston[11] have calculated the concentrations of species present in alkaline **2** solutions. At pH *ca* 11 the concentration of the OCl^- ion is small and it does not make a significant contribution to the oxidation of **1a–d**. This potent oxidant (**2**) is of special interest for studying reaction mechanisms as it behaves both as a chlorinating and as an oxidizing agent. Compound **2** behaves as a strong electrolyte in aqueous solutions and dissociates as shown in eq. (2). It has been suggested[4,6] that the reactivity of **2** in weakly alkaline solutions is due to the formation of conjugate acid **7** from **6** in a base retarding step [eq. (3)]. Therefore, the possible oxidant species of **2** in alkaline solution is **6**.

The observed first-order dependence of rate on [**2**] and nearly first-order in [**1a**], which becomes gradual saturation at higher [**1a**], and the rate independence of [OH^-] can be explained by Scheme 1.



Scheme 1.

According to Scheme 1,

$$\text{rate} = k_2[\text{X}]\,[\mathbf{1a}]. \tag{5}$$

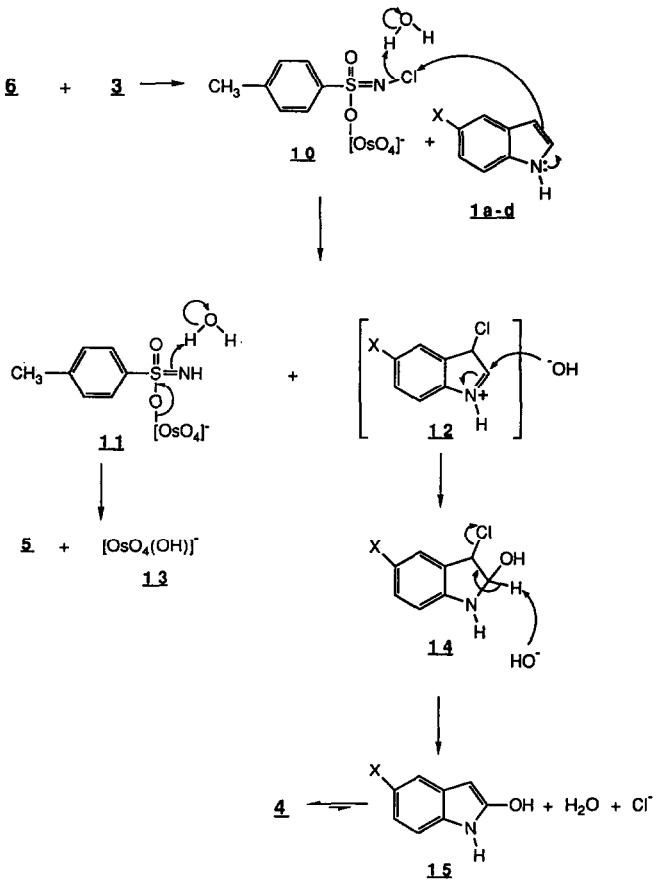
Assuming steady state for [X],

$$\text{rate} = \frac{k_1 k_2 [\mathbf{2}]\,[\mathbf{3}]_0\,[\mathbf{1a}]}{k_{-1} + k_1[\mathbf{2}] + k_2[\mathbf{1a}]} \tag{6}$$

because

$$[\mathbf{3}] = [\mathbf{3}]_0 - [\text{x}] = \frac{k_{-1} + k_2[\mathbf{1a}]}{k_{-1} + k_1[\mathbf{2}] + k_2[\mathbf{1a}]}\,[\mathbf{3}]_0. \tag{7}$$

The most probable structure of X is **10** and X^1 are **11** and **12** from Scheme 2. A proposed mechanism of the oxidation of **1a–d** by **2** catalysed by **3** in alkaline medium is shown in Scheme 2. Osmium(VIII) (**3**) exists[12] in alkaline medium as $[OsO_4(OH)]^-$ (**13**), which on further coordination with OH^- gives $[OsO_4(OH)_2]^{2-}$. Since the reactions were performed under comparable conditions of alkalinity and there is independence of [OH^-] in the oxidation of **1a–d**, it is unlikely that $[OsO_4(OH)_2]^{2-}$ reacts with the substrate. Compound **2** first coordinates with **3**, activating chloramine-T via stabilization of the nitrogen's anionic charge and polarizing the nitrogen–chlorine bond. Since **3** is known to bind with one or even two hydroxide anions, the hydroxide anion(s) can then be replaced by **2**. Then, the base-catalysed indole chlorination via activated chloramine-T (**10**) affords the 3-



Scheme 2.

chloroindoleninium ion (**12**), a short-lived cationic intermediate and a *p*-toluenesulphonamide-osmium tetroxide complex (**11**). Hydration of complex **11** results in **5** and a hydroxide anion/osmium tetroxide complex (**13**). The formation of the 3-bromoindoleninium cation as an intermediate has been reported during the oxidation of indole to oxindole by NBS.[13] Hydroxylation of **12** to 2-hydroxy-3-chloroindoline (**14**) followed by base-catalysed removal of hydrogen chloride affords 2-hydroxyindole (**15**); **15** being in equilibrium with its more stable keto form (**4**). The low sensitivity of k'_2 to ring substituents ($\rho^+ = -1.0$, Fig. 4) indicates significant bond formation between the substrate and the oxidant in the rate limiting step.

The calculated activation enthalpies and entropies of oxidation of **1a–d** were linearly related by plotting $\Delta H^\ddagger$ vs $\Delta S^\ddagger$ (Fig. 3). From the slope the computed value of isokinetic temperature (β) is 325 K. Further verification of the isokinetic relation was completed by the Exner criterion[14] from which β is determined to be 325 K. The values of β from both the plots calculated are higher than the experimental temperature (303 K), indicating enthalpy as a controlling factor. The linear correlation and the consistency of $\Delta G^\ddagger$ values (Table 3) indicate that **1a–d** undergo oxidation via the same mechanism. Corbett *et al.*[15] have studied the enzymatic oxidation of **1a** to **4** by peroxide employing chloroperoxidase enzyme. They observed a first-order reaction with respect to [**1a**] up to 8 mM, which was the highest concentration of **1a** that could be investigated. On the other hand, 2-methylindole was not effected by peroxide and chloroperoxidase, but its presence largely inhibited **1a** oxidation. The isomer 2-methylindole was a poor substrate for chloroperoxidase oxidation and a weak inhibitor of **1a** oxidation. Their results suggest the possibility that chloroperoxidase oxidation of the carbon atom adjacent to nitrogen atom in part results from hydrogen bonding of the substrate N—H to the enzyme active site. Our studies show that the reaction rate becomes independent of [**1a**] from 5 mM to 15 mM at constant [OH^-] (5 mM). Hence, it is probable that the change in mechanism may be attributed to the fact that the oxidation of [**1a**] does not occur with either **3** or **2** alone. It can be assumed that a complex of these two serves as an oxidant.[16] The possible oxidizing species in this case would be **7**. Based on the oxidizing capacity observed, a cyclic

structure (**9**) can be proposed for the complex. The structure shows that the electron density around the nitrogen atom is lowered, resulting in a weakening of the N—Cl bond. The subsequent oxidizing capacity of N-chlorotoluene-*p*-sulphonamide is increased after complexation, which results in a fast interaction of complex **9** with the appropriate form of the substrate. The detailed study of this aspect as well as with strong electron withdrawing ($-NO_2$) and electron donating ($-CH_3$) groups as 5-position substituents on indole to critically examine substituent effects (ρ^+) is currently under investigation.

Abstract—Phenylphosphinic acid ($HPhPO_2H$) and phenylphosphonic acid ($PhPO_3H_2$) react with a methanolic solution of $[Ru_2(\mu\text{-}O_2CCH_3)_4(O_2CCH_3)_2]H \cdot 0.7H_2O$ at room temperature to give $[Ru_2(\mu\text{-}O_2CCH_3)_4(HPhPO_2)_2]H$ (**1**) and $[Ru_2(\mu\text{-}O_2CCH_3)_4(PhPO_3H)_2]H \cdot H_2O$ (**2**), respectively. The X-ray crystal structures of **1** and **2** each show the Ru—Ru core to be ligated by four bridging bidentate acetate ligands [Ru—Ru distances: **1** = 2.272(1) Å; **2** = 2.267(2) Å] and two axial phenylphosphinate and phenylphosphonate ligands, respectively. In each complex the individual bimetallic molecules are linked together by a hydrogen ion which bridges the oxygen atoms of neighbouring axial ligands. In **2** the water molecule is also hydrogen-bonded to one of the axial phenylphosphonate groups. Spectroscopic, magnetic and cyclic voltammetric data for the complexes are given.

Phenylphosphinic acid ($HPhPO_2H$) and phenylphosphonic acid ($PhPO_3H_2$) are each renowned for their ability to form polymeric layered complexes with the *d*-block metals.[1–3] Recently,[4] we have shown that by employing pyridine as the reaction solvent monomeric copper(II) phenylphosphonate complexes can be prepared and the complexes $[Cu(PhPO_3H)_2(C_5H_5N)_4] \cdot 2CH_3OH$ and $[Cu(PhPO_3H)_2(C_5H_5N)_4]$ were structurally characterized. Herein, we present details of the synthesis, structure and physical properties of the monomeric[5] tetra-μ-acetatodiruthenium(II,III) phenylphosphinate and phenylphosphonate complexes $[Ru_2(\mu\text{-}O_2CCH_3)_4(HPhPO_2)_2]H$ (**1**) and $[Ru_2(\mu\text{-}O_2CCH_3)_4(PhPO_3H)_2]H \cdot H_2O$ (**2**), respectively.

Excess phenylphosphinic acid and phenylphosphonic acid each react at room temperature with a methanolic solution of the diruthenium (II,III) complex $[Ru_2(\mu\text{-}O_2CCH_3)_4(O_2CCH_3)_2]H \cdot 0.7H_2O$[6–8] to give **1** and **2**, respectively. During both of these reactions the $[Ru_2(\mu\text{-}O_2CCH_3)_4]^+$ moiety remains intact and the axial $CH_3CO_2^-$ ligands are replaced by $HPhPO_2^-$ and $PhPO_3H^-$.[9] The reaction of phenylphosphinic acid with $[Ru_2(\mu\text{-}O_2CCH_3)_4(O_2CCH_3)_2]H \cdot 0.7H_2O$ contrasts with that found for the dicopper(II,II) complex $[Cu_2(\mu\text{-}O_2CCH_3)_4(H_2O)_2]$.[4] In the latter reaction the phenylphosphinic acid is oxidized to phenylphosphonic acid and is recovered as the monomeric copper(II) complex $[Cu(PhPO_3H)_2(C_5H_5N)_4] \cdot H_2O$. This conversion of phenylphosphinic acid to the copper(II) phenylphosphonate complex was accompanied by the loss of the ν(P—H) IR stretching band. In the IR spectrum of **2** this medium intensity ν(P—H) band was present at 2370 cm^{-1}.

The X-ray crystal structure of the phenylphos-

phinate complex $[Ru_2(\mu\text{-}O_2CCH_3)_4(HPhPO_2)_2]H$ (**1**) (Fig. 1) shows that the Ru—Ru core is ligated by four equatorial bridging bidentate acetate groups and two axial monodentate phenylphosphinate ligands. Individual $[Ru_2(\mu\text{-}O_2CCH_3)_4(HPhPO_2)_2]^-$ units in **1** are linked together at neighbouring O(6) atoms by a proton to give an infinite hydrogen-bonded chain. Thus, the complex is best formulated as $[Ru_2(\mu\text{-}O_2CCH_3)_4(HPhPO_2)_2]H$. This formulation is similar to that proposed[7] for the structurally characterized[8] starting complex $[Ru_2(\mu\text{-}O_2CCH_3)_4(O_2CCH_3)_2]H \cdot 0.7H_2O$.

The structure of the phenylphosphonate complex $[Ru_2(\mu\text{-}O_2CCH_3)_4(PhPO_3H)_2]H \cdot H_2O$ (**2**) (Fig. 2) is similar to that of the phenylphosphinate complex **1**. Although the hydrogen-bonding hydrogen was not located directly in **2** the intermolecular distances between the oxygen atoms on neighbouring axial phenylphosphonate ligands [O(52)—O(62) = 2.431 Å] suggested that there was a proton bridging these two ligands. Hydrogen bonding was also present between the water molecule and one of the phenylphosphonate ligands. Thus, complex **2** is best formulated as $[Ru_2(\mu\text{-}O_2CCH_3)_4(PhPO_3H)_2]H \cdot H_2O$. It is interesting to note that in the structure of the phenylphosphinate complex **1** the phenyl groups are in the expected *trans* configuration with respect to each other, whereas in the phenylphosphonate complex **2** they are in the more sterically congested *cis* arrangement. It is thought that the latter stereochemistry may have been imposed, in part, by the more extensive hydrogen-bonding network that pervades **2**.

The more important bond distances and angles for structures **1** and **2** are listed in Tables 1 and 2, respectively. The Ru—Ru and Ru—O(carboxylate) distances in each complex are similar to those reported for other Ru_2^{5+} complexes.[7,8,10–12] In addition, the Ru—O(phenylphosphinate or phenyl-

phosphonate) distances in **1** and **2** are also similar to those found in other Ru_2^{5+} carboxylates containing axial oxygen donor ligands.[7,8,12] The mean Ru—O(phenylphosphonate) distance in **2** (2.23 Å) is only slightly shorter than the mean Cu—O(phenylphosphonate) distances in $[Cu(PhPO_3H)_2(C_5H_5N)_4]\cdot 2CH_3OH$ (2.42 Å) and $[Cu(PhPO_3H)_2(C_5H_5N)_4]$ (2.32 Å).[4]

Complexes **1** and **2** behaved as 1 : 1 electrolytes in methanol and their electronic absorption spectra and magnetic moments were very similar to those normally found for Ru_2^{5+} carboxylates.[13–15]

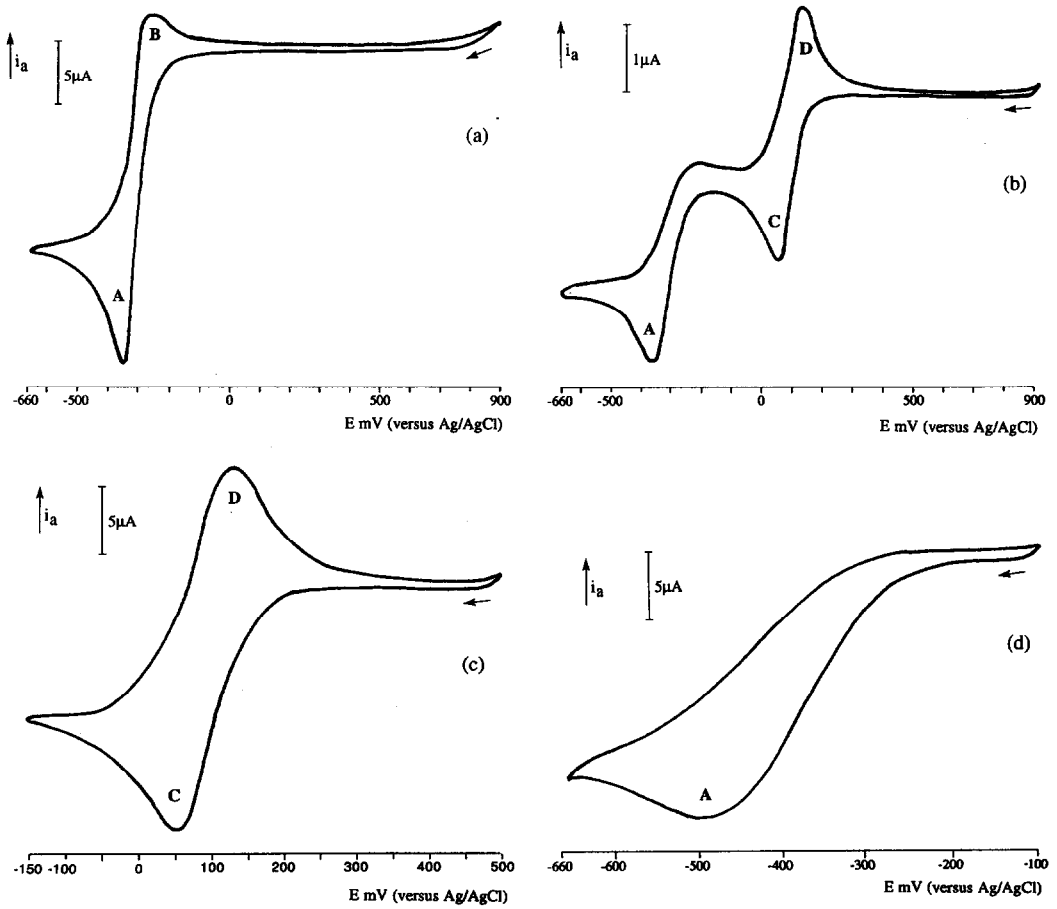

Fig. 3. Cyclic voltammograms of: (a) free phenylphosphinic acid; (b)–(d) $[Ru_2(\mu\text{-}O_2CCH_3)_4(HPhPO_2)_2]H$ (**1**) between different switching potentials. Potentials are quoted with respect to the Ag/AgCl reference electrode. Scan rate = 20 mV s^{-1}.

Cyclic voltammograms of free phenylphosphinic acid and $[Ru_2(\mu\text{-}O_2CCH_3)_4(HPhPO_2)_2]H$ (**1**) are displayed in Fig. 3. In the potential range +0.90 to −0.66 V (vs Ag/AgCl) the free acid [Fig. 3(a)] showed a single quasi-reversible wave AB with $E_{1/2} = -298$ mV. Within the same potential limits complex **1** [Fig. 3(b)] showed a reversible wave (CD; $E_{1/2} = +100$ mV) for the Ru_2^{5+}/Ru_2^{4+} couple[7,13] and an irreversible reduction wave (A; $E_c = -337$ mV), which is thought to be associated with the phenylphosphinate moieties. Figures 3(c) and 3(d) show the voltammograms of **1** recorded between the narrow potential ranges +0.50 to −0.15 V and −0.10 to −0.66 V, respectively, and these clearly demonstrate the reversibility of the Ru_2^{5+}/Ru_2^{4+} couple and the irreversibility of the phenylphosphinate reduction.

Voltammograms of free phenylphosphonic acid and $[Ru_2(\mu\text{-}O_2CCH_3)_4(PhPO_3H)_2]H \cdot H_2O$ (**2**) are shown in Fig. 4. In the range +0.90 to −0.66 V (vs Ag/AgCl) the phenylphosphonic acid [Fig. 4(a)] showed an essentially reversible redox couple (EF; $E_{1/2} = -369$ mV).[16] Across the same potential range complex **2** [Fig. 4(b)] exhibited an irreversible Ru_2^{5+}/Ru_2^{4+} reduction (G; $E_c = +21$ mV) as well as a pair of broad ill-defined peaks (EF), which are thought to arise from the redox activity of the liberated phenylphosphonic acid. Figure 4(c) shows the voltammogram of **2** between the constricted potential limits of +0.30 to −0.05 V and this clearly illustrates the somewhat unusual irreversibility of the Ru_2^{5+}/Ru_2^{4+} couple.

It is envisaged that **1** and **2** may be useful starting materials for the synthesis of polymeric phenylphosphinate and phenylphosphonate complexes containing strongly metal-to-metal bonded diruthenium centres.[9]

EXPERIMENTAL

$[Ru_2(\mu\text{-}O_2CCH_3)_4(O_2CCH_3)_2]H \cdot 0.7H_2O$ was prepared by the literature method.[8] IR spectra (KBr

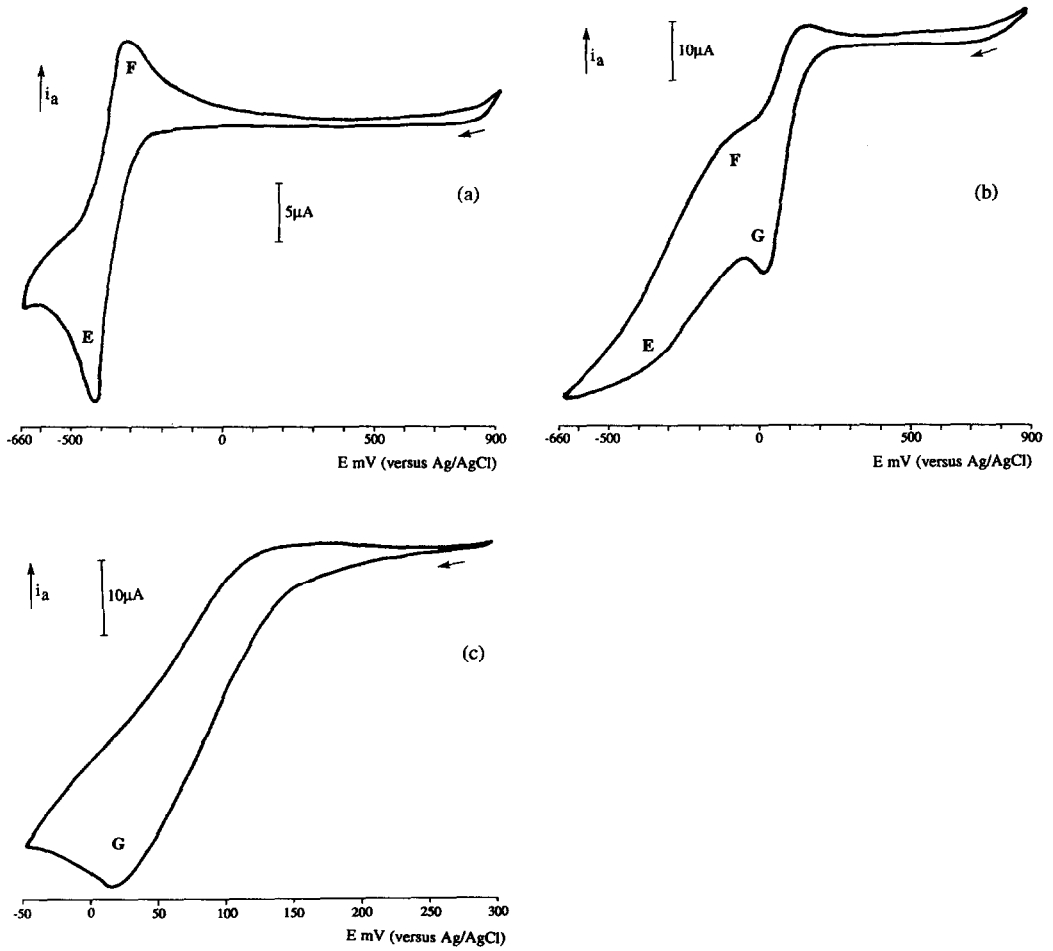

Fig. 4. Cyclic voltammograms of: (a) free phenylphosphonic acid; (b), (c) $[Ru_2(\mu\text{-}O_2CCH_3)_4(PhPO_3H)_2]H \cdot H_2O$ (**2**) between different switching potentials. Potentials are quoted with respect to the Ag/AgCl reference electrode. Scan rate = 20 mV s^{-1}.

discs) were recorded in the region 4000–200 cm^{-1} on a Perkin–Elmer 783 grating spectrometer and UV–vis spectra were obtained using a Milton Roy Spectronic 3000 Array. Room-temperature magnetic susceptibility measurements were made on a Johnson–Matthey Magnetic Susceptibility balance. An AGB Scientific Model 10 Conductivity meter was used for conductivity measurements. Cyclic voltammograms were recorded (*ca* 20°C and under nitrogen) using an EG&G Model 264A polarographic analyser and the data were analysed using the EG&G Condecon software package. A platinum bead and a platinum wire were used as the working and counter-electrodes, respectively. Tetra-n-butylammonium perchlorate in methanol (0.1 M) was used as the supporting electrolyte/solvent system. Sample concentration was 4.0×10^{-3} M and the scan rate was 20 mV s^{-1}. Potentials were recorded with respect to a silver–silver chloride reference electrode (3.5 M aqueous KCl), against which the ferrocene/ferrocenium(1+) couple had $E_{1/2} = +514$ mV. Elemental analyses were performed by the Microanalytical Laboratory, University College Cork, Ireland.

Crystallography

Complex **1**. A brown needle-shaped cystal was mounted on an Enraf–Nonius CAD4 diffractometer and the intensities of 2683 reflections were measured in the range $1° < \theta < 26°$ using graphite monochromated Mo-K_α radiation. The accurate cell dimensions were obtained by refining the setting angles of 25 reflections ($16° < \theta < 18°$). The data were reduced to give 2465 unique reflections, $R_{merg} = 0.0174$. Of these 2373 had $|F_{obs}| > 4\sigma|F_{obs}|$ and were used in the structure solution and refinement.

Crystal data for $C_{20}H_{25}O_{12}P_2Ru_2$ (**1**), $M_r = 721.496$. Triclinic, $P\bar{1}$ (No. 2), $a = 7.585(2)$, $b = 8.002(2)$, $c = 12.413(3)$ Å, $\alpha = 99.76(1)$, $\beta = 93.69(1)$, $\gamma = 117.29(1)°$, $U = 652.7(3)$ $Å^3$, $D_c = 1.835$ g cm^{-3}, $Z = 1$, $F(000) = 358$, $\lambda = 0.71069$ Å, μ(Mo-K_α) = 12.00 cm^{-1}.

The structure was solved using the Patterson method of SHELXS-86 with some operator intervention and was found to have half a molecule in the asymmetric unit. The rutheniums were found to have bridging acetate groups and the phenylphosphinate ligands in the axial positions. The structure was refined by full-matrix least-squares with all the non-hydrogen atoms anisotropic. The hydrogen atoms were located from difference-Fourier and allowed to refine with the exception of the bridging hydrogen, which is disordered and the hydrogen attached to the phosphorus. These hydrogens were located but were not allowed to refine. The refinement was weighted to give a flat analysis of variance and a final R of 0.0344 and R_w of 0.0373. The difference-Fourier had a highest peak of 1.2 e $Å^{-1}$ in the vicinity of the ruthenium atom.

Complex **2**. A small brown crystal was mounted on the above-mentioned diffractometer. The cell parameters were determined by refining the setting angles of 25 reflections with $14° < \theta < 16°$. The intensities of 3797 reflections ($\pm h$, $\pm k$, $+l$) in the range $1° < \theta < 22°$ were measured using graphite monochromated Mo-K_α radiation. The Laue symmetry of the diffraction pattern was not clear (although the lattice geometry was very close to orthorhombic) so the data were collected in triclinic symmetry. The structure was solved satisfactorily in the space group $P2_1$. The data were merged to give the unique non-centrosymmetric quadrant of data—1908 unique reflections (merging $R = 0.1144$), of which 1695 had $F_{obs} > 4\sigma F_{obs}$ and were used for structure solution and refinement.

Crystal data for $C_{20}H_{27}O_{15}P_2Ru_2$ (**2**), $M_r = 771.509$. Monoclinic, $P2_1$ (No. 4), $a = 11.361(4)$, $b = 11.040(5)$, $c = 11.679(6)$ Å, $\beta = 90.92(3)°$, $U = 1464(1)$ $Å^3$. $D_c = 1.750$ g cm^{-3}, $Z = 2$, $F(000) = 770$, $\lambda = 0.71069$ Å, μ(Mo-K_α) = 10.76 cm^{-1}.

The structure was solved by both the Patterson and direct methods of SHELXS-86 in space group $P2_1$. The structure was refined to a final R factor of 0.0564 using full-matrix least-squares analysis. The ruthenium, phosphorus and oxygen atoms of the "lantern" ligands were refined with anisotropic temperature factors. The phenyl rings were refined with fixed geometries. The hydrogen atoms on the phenyl ring were placed geometrically and their common temperature factor refined to 0.03(1) $Å^2$. The methyl hydrogens were placed using SHELX76, but not refined, and their common temperature factor refined to 0.18(6) $Å^2$. The hydrogen-bonding hydrogens could not be located from difference-Fourier, but hydrogen-bond distances were observed between the two molecules and between the molecule and the solvent. The weighting scheme was refined to give a flat analysis of variance and an R_w value of 0.0619. The final difference-Fourier had a highest peak of 1.06 e $Å^{-1}$.

The programs SHELXS and SHELX 76 were used with kind permission of Prof. G. M. Sheldrick (Universität Göttingen).

$[Ru_2(\mu\text{-}O_2CCH_3)_4(HPhPO_2)_2]H$ (**1**)

To a solution of $[Ru_2(\mu\text{-}O_2CCH_3)_4(O_2CCH_3)_2]H \cdot 0.7H_2O$ (0.30 g, 0.52 mmol) in methanol (60 cm^3) under nitrogen was added phenylphosphinic acid

(0.77 g, 5.42 mmol). The resulting red–brown solution was stirred at room temperature for 48 h. The solution was then concentrated under high vacuum (without heating) until the mustard–brown product precipitated. The solid was filtered off, washed with small amounts of methanol and with water and it was then dried *in vacuo*. Crystals suitable for X-ray diffraction studies were obtained by allowing the reaction filtrate to evaporate slowly in air. Yield: 0.26 g (69%). Found: C, 33.5; H, 3.3. Calc.: C, 33.3; H, 3.5%. IR: 3440, 3050, 2940, 2370, 1590, 1440, 1400, 1360, 1140, 1050, 1000, 970, 750, 690, 530, 400, 340 cm^{-1}; $\mu = 3.97$ B.M. per Ru_2 unit; λ_{max} (CH_3OH) = 429 nm ($\varepsilon = 712$ mol^{-1} dm^3 cm^{-1}); Λ_M (CH_3OH) = 49 S cm^2 mol^{-1} [for free phenylphosphinic acid Λ_M (CH_3OH) = 15 S cm^2 mol^{-1}].

$[Ru_2(\mu\text{-}O_2CCH_3)_4(PhPO_3H)_2]H \cdot H_2O$ (**2**)

To a solution of $[Ru_2(\mu\text{-}O_2CCH_3)_4(O_2CCH_3)_2]H \cdot 0.7H_2O$ (0.30 g, 0.52 mmol) in methanol (60 cm^3) under nitrogen was added phenylphosphonic acid (0.85 g, 5.38 mmol). The resulting red–orange solution was stirred at room temperature for 48 h. The solution was then concentrated under high vacuum (without heating) to *ca* 5 cm^3. Water (2 cm^3) was slowly added and on stirring in air the mustard–brown product precipitated. The solid was filtered off, washed with small amounts of methanol and with water and it was then dried *in vacuo*. Crystals suitable for X-ray diffraction studies were obtained by allowing the reaction filtrate to evaporate slowly in air. Yield: 0.24 g (60%). Found: C, 30.9; H, 4.3. Calc.: C, 31.1; H, 3.5%. IR: 3460, 3060, 2950, 1450, 1405, 1150, 1050, 960, 700, 570, 515, 405, 345 cm^{-1}; $\mu = 3.97$ B.M. per Ru_2 unit; λ_{max} (CH_3OH) = 428 nm ($\varepsilon = 765$ mol^{-1} dm^3 cm^{-1}); Λ_M (CH_3OH) = 53 S cm^2 mol^{-1} [for free phenylphosphonic acid Λ_M (CH_3OH) = 5 S cm^2 mol^{-1}].

Acknowledgement—We thank Johnson–Matthey plc for the loan of ruthenium trichloride.

16. We have found (see ref. 4) that in the potential region +0.80 to −1.70 V (vs Ag/AgCl) free phenylphosphonic acid was electroinactive in a 1:4 pyridine:methanol solution. It is likely that in this solvent mixture the pyridinium salt $[C_5H_5NH]^+[PhPO_3H]^-$ is formed and that the $[PhPO_3H]^-$ ion is electroinactive. This suggests that in the voltammogram of **2** it is the free phenylphosphonic acid (and not the phenylphosphonate anion) that is liberated upon dissolving the complex in methanol that is giving rise to the broad waves EF in Fig. 4(b). In the same pyridine:methanol solvent mixture free phenylphosphinic acid has also been found to be electroinactive between +0.80 to −1.00 V. However, beyond −1.10 V a large irreversible reduction wave was observed for this acid.

REDOX CHEMISTRY AND SPECTROSCOPY OF THE MANGANESE-QUINIZARINE-THIOSALICYLIC ACID MIXED-LIGAND COMPLEX IN APROTIC MEDIUM

MARIO E. BODINI,* M. ANGÉLICA DEL VALLE and VERÓNICA ARANCIBIA

Departamento de Química Analítica y Electroquímica Facultad de Química, Pontificia Universidad Católica de Chile, Casilla 306, Santiago de Chile, Chile

(*Received* 27 *January* 1993; *accepted* 30 *March* 1993)

Abstract—The addition of the monoanion of thiosalicylic acid to the insoluble compound formed between manganese(II) and the dianion of quinizarine forms a very intense blue soluble new complex. The stoichiometry of this complex is Mn : Qz : 2-MBA = 1 : 1 : 2, in the presence of 4 equivalents of base in order to neutralize the two hydroxylic protons of quinizarine and the carboxylic proton of each equivalent of 2-MBA. This mixed-ligand complex is oxidized in several steps and a total of 4 equivalents of charge per metal ion are transferred in this process. The complete oxidation at +0.90 V vs S.C.E. produces the destruction of this mixed-ligand complex. However, it is possible to oxidize sequentially at +0.35 and +0.65 V vs S.C.E. and the association between the metal ion and the ligands prevails. These two oxidations involve 1 equivalent of charge each and lead to the formation of a dark red complex. The stoichiometry of this complex is maintained with respect to the original blue compound and it is proposed that the metal ion is in the +3 oxidation state, the quinizarine has been oxidized to its semi-quinonic form and the monoanion of thiosalicylic acid has not changed. The final process at +0.90 V vs S.C.E. corresponds to the oxidation of the monoanion of the latter which leads to the decomposition of the complex. It is concluded that the mixed-ligand complex formed after the two-electron oxidation process can be considered as a very good model for biological systems in which it is known that manganese plays an important role as a catalyst for redox processes and ligands such as those studied here are present.

Interest in the chemistry of manganese catecholate and semi-quinonate complexes has greatly increased in recent years.[1–6] An important reason has been the recognition of the fundamental role of quinone and catechol-containing groups in biology.

Our group has studied for some time the complexes of manganese with this type of ligand.[7–9] On the other hand, it is known that higher oxidation states of manganese are involved in some biological systems[10,11] and that a mixed-ligand association is most likely to occur in these systems.[12–15] Therefore, based on our previous results concerning the stabilization of manganese(III) in the presence of thiosalicylic acid[16] and quinizarine,[17] which can be oxidized to the corresponding semi-quinone, we have now undertaken the study of mixed-ligand complexes of manganese with these two ligands in order to obtain an analogue of an amino acid (cysteine in the case of thiosalicylic acid) which tends to stabilize a higher oxidation state of the metal ion, and a second ligand such as quinizarine in the coordination sphere so that its dihydroxylic system can be oxidized to the corresponding semi-quinone at a potential positive enough to allow the stabilization of manganese(III) in this system. The characteristics of these compounds should be very important in understanding the role of manganese in different biological systems.

The monoanion of thiosalicylic acid forms a 1 : 2 complex with manganese(II), which can be oxidized reversibly to manganese(III) at −0.45 V vs S.C.E., yielding another 1 : 2 complex. The corresponding reduction to manganese(II) is observed at −0.50 V vs S.C.E.[16]

* Author to whom correspondence should be addressed.

In the case of quinizarine it is an important fact that manganese(II) forms a slightly soluble 1 : 1 compound with the semi-quinone produced by the oxidation of the dianion of this ligand. This compound presents two low intensity oxidation peaks at +0.50 and +0.75 V vs S.C.E. Therefore, these oxidation potentials are favourable to our purpose.

It is important to remark that the voltammetric and spectroscopic results obtained with the latter species are the same as those presented by a solution of manganese(III) and the dianion of quinizarine. Consequently, an internal charge-transfer is produced from the metal to the ligand (MLCT).[17]

EXPERIMENTAL

Equipment

A three-electrode potentiostat (Tacussel Model PRT 20-2X potentiostat–galvanostat with a Model GSTP wave generator) was used for the cyclic voltammetric and controlled-potential electrolysis experiments. A current integrator based on operational amplifiers was used as a coulometer in the controlled-potential electrolyses. Cyclic voltammograms were recorded on a Hewlett–Packard Model 7004 A *X–Y* recorder. The electrochemical cell was equipped with a Beckman platinum-inlay working electrode (area 0.23 cm^2), a platinum coil auxiliary electrode and an Ag/AgCl reference electrode filled with an aqueous tetramethylammonium chloride solution and adjusted to 0.00 V vs S.C.E. The latter was contained in a Pyrex tube with a soft-glass cracked tip; this electrode was placed inside a Luggin capillary. For controlled potential electrolysis a platinum-mesh working electrode was employed. A Beckman Model ACTA CV spectrophotometer was used for UV–vis spectrophotometric measurements. Air-sensitive compounds were handled in a glove-bag (Aldrich) under a nitrogen atmosphere and the oxygen content was monitored with a Beckman Model Monitor II Oxygen Analyser.

Reagents

The reagents for the investigation and syntheses included $Mn(ClO_4)_2 \cdot 6H_2O$ (G. Frederick Smith), tetraethylammonium hydroxide (TEAOH) (1.0 M in methanol, Eastman), tetramethylammonium chloride (Aldrich) and tetraethylammonium perchlorate (TEAP) (G. Frederick Smith). The ligands thiosalicylic acid and quinizarine were obtained from Aldrich and were purified by reduced pressure sublimation and recrystallization in acetic acid, respectively.

Aldrich "Gold Label" solvents were used without further purification for all the experiments. High purity argon was used to deaerate solutions.

Since the solvation water of $Mn(ClO_4)_2 \cdot 6H_2O$ interfered with the stoichiometric formation of the complexes under study, $[Mn^{II}(DMU)_6][ClO_4]_2$ (DMU = dimethylurea)[18] was used in all the experiments in which the manganese complexes were formed *in situ*. As a source of manganese(III) $[Mn^{III}(urea)_6][ClO_4]_3$[19] was used in all the experiments.

RESULTS AND DISCUSSION

Solutions of different combinations of manganese(II), quinizarine (Qz) and thiosalicylic acid (2-MBA) in dimethylsulphoxide were analysed electrochemically and spectroscopically in order to verify the possible formation of a mixed-ligand complex and to establish its redox chemistry. The amount of base present in these solutions was varied in order to generate the unprotonated species of the ligands. In most cases the electrochemical and spectroscopic behaviour of the solutions corresponds either to the free ligands or to the manganese complexes already reported, plus the excess of the second ligand. If the amount of base is enough to neutralize all the protons from Qz and 2-MBA the solution presents a behaviour indicating that a simple complex between manganese and 2-MBA has formed in the presence of excess Qz. Therefore, in this case there is no mixed-ligand complex formation and the more stable species $Mn(2\text{-}MBA)_2$ prevails in the presence of excess quinizarine.

A different behaviour was observed only when the mole ratio Mn^{II} : Qz : 2-MBA : base was 1 : 1 : 2 : 4. In this case the dark blue solution and the solid formed when manganese(II) and Qz are combined in a 1 : 1 mole ratio shows a dramatic change upon addition of the dianion of 2-MBA. The solid dissolves and the solution turns deep blue. The UV–vis spectrum of this solution is shown in Fig. 1(C). The absorption maxima in the visible region are different from those of either the simple complexes with the ligands under study or the combination of these ligands in the absence of the metal ion, as shown in Figs 1(A) and (B). Therefore, we conclude that a new species is being formed under these conditions.

The cyclic voltammograms of the solution with a Mn^{II} : Qz : 2-MBA : base = 1 : 1 : 2 : 4 mole ratio [Figs 2(A)–(D)] show that no reduction peak is observed for free manganese(II), indicating that this ion is present as a complex. On the other hand, the voltammetric peaks that have been assigned to the ligands are not observed in this case, which indicates that under these conditions the mole ratio in the

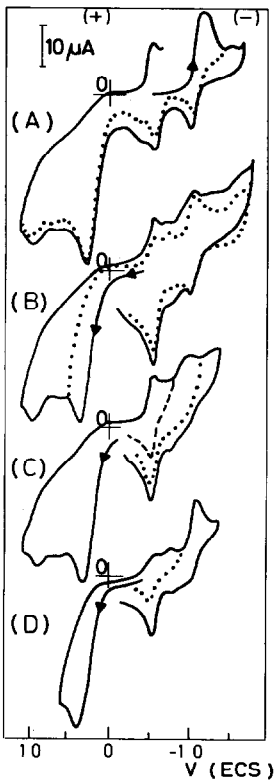

Fig. 2. Cyclic voltammograms of a solution of 1.0 mM Qz, 2.0 mM 2-MBA, 4.0 mM TEAOH and 1.0 mM manganese(II) in which: (A) illustrates the initial negative scan direction and (B), (C) and (D) illustrate initial positive scan directions with different reversal potentials. The solution is 0.1 M TEAP and the scan rate is 100 mV s^{-1}.

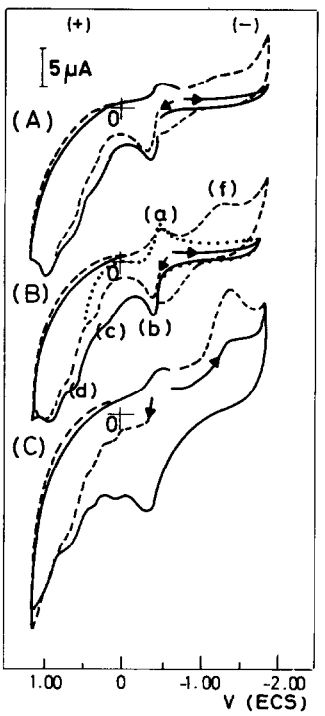

Fig. 3. Cyclic voltammograms of 1.0 mM 2-MBA, 2.0 mM TEAOH solutions and: (A) 0.33 mM manganese(II) (metal: ligand = 1:3), (B) 0.66 mM manganese(II) (metal: ligand = 1:2) and (C) 1.0 mM manganese(II) (metal: ligand = 1:1). The solutions are 0.1 M TEAP and the scan rate is 100 mV s^{-1}.

solution corresponds exactly to the stoichiometric relation and, therefore, we do not observe an excess either of the metal ion or of any of the ligands. The reduction peaks observed are different from those shown by the simple complexes with Qz or 2-MBA (Figs 3 and 4), therefore, we conclude that a new mixed-ligand species has formed.

Figures 2(B)–(D) indicate that when the mixed-ligand complex is oxidized this process occurs in steps which take place at +0.35, +0.65 and +0.90 V vs S.C.E. Controlled-potential electrolysis at +0.60 V vs S.C.E. indicates that 2 equivalents of charge are transferred per mole of manganese. It is impossible in this case to separate the two oxidation processes which might involve one electron each. The cyclic voltammogram of the final solution obtained shows no reduction peak corresponding to free manganese(II) [Fig. 5(B)], so that we can conclude that the metal ion is present as a complex in solution. This solution is dark red and the UV–vis spectra are illustrated in Fig. 6(C). The absorption maxima presented by the solution before the oxidation process [Fig. 6(B)] now show a bathochromic shift and can be observed at 675, 540 and a shoulder at 510 nm.

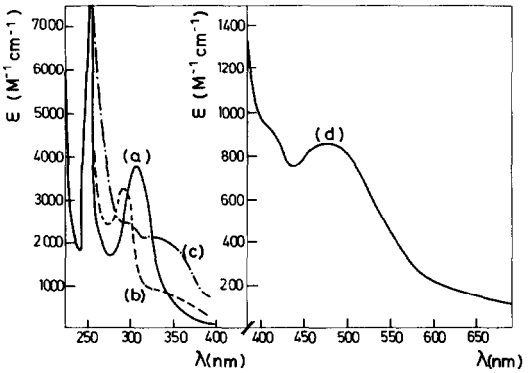

Fig. 4. UV spectra of solutions that are: (a) 1.0 mM 2-MBA and 2.0 mM TEAOH, (b) same as (a) plus 0.5 mM manganese(II), (c) same as (b) after controlled-potential oxidation at −0.25 V vs S.C.E. and (d) visible spectrum of solution (c).

The last 2 equivalents of charge transferred per mole of metal ion correspond to the oxidation of 1 of the 2 mol of 2-MBA present (the Mn^{II} : 2-MBA mole ratio is 1 : 2 in this solution). The oxidation of the —SH group would explain the destruction of the complex by formation of the corresponding dimer and the reprotonation of the dianion of quinizarine to regenerate the original ligand, as indicated by its UV–vis spectrum in Fig. 7.

Further oxidation of the dark red solution at +0.90 V vs S.C.E. again indicates that 2 equivalents of charge have been transferred per mole of metal ion before a residual current is obtained [Fig. 5(D)]. The solution becomes light orange, which is characc-

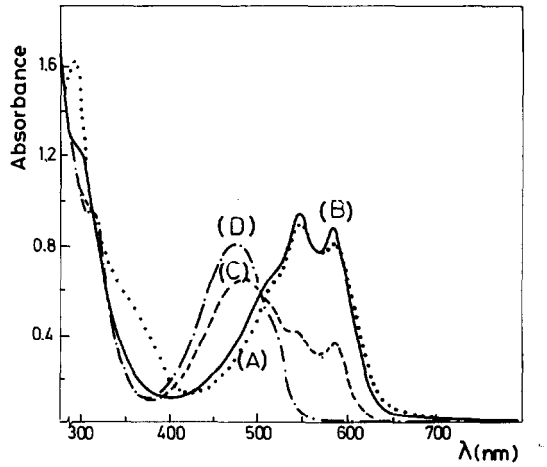

Fig. 7. UV–vis spectra of a solution of 1.0 mM Qz, 2.0 mM 2-MBA, 4.0 mM TEAOH and 1.0 mM manganese(II) after controlled-potential oxidation at: (A) 0.35 (1 equivalent of charge transferred), (B) 0.65 (2 equivalents of charge transferred), (C) 0.9 (3 equivalents of charge transferred) and (D) 0.9 V vs S.C.E. (4 equivalents of charge transferred).

teristic of quinizarine. The cyclic voltammograms, Figs 5(C) and (D), and the spectra shown in Fig. 7 indicate that in this case we have a mixture of the metal ion and the anions of the ligands with no complex formation, as the spectrum in Fig. 7(D) is identical to that in Fig. 1(A) which corresponds to a mixture of the ligands in the absence of manganese.

If we consider that the 4 equivalents of base added with respect to the metal ion correspond to the neutralization of the carboxylic protons of each mole of 2-MBA and of both hydroxylic protons of quinizarine the result is a species in which the 2-MBA residues would maintain their —SH groups. Therefore, it is conceivable to explain the behaviour of the system as follows: in the first oxidation process the 2 equivalents of charge that are transferred per mole of metal ion (at the end of which manganese appears to be forming a complex species) can be attributed either to the bound quinizarine or to the oxidation of the metal ion. In the first case the diquinone (DQ) species would be formed, which, as has been previously reported, does not form a complex species with manganese.[17] On the other hand, if the metal ion is oxidized its final oxidation state would be 4+ and the resulting complex would be neutral. Consequently, this species would be either insoluble or difficult to oxidize by electrolysis, which was not observed in our case.

Therefore, the following alternatives can explain the first oxidation process observed and both lead to the same oxidized species in solution. The only way to establish the correct alternative would be to isolate the intermediate species, which unfortunately was not possible. The first alternative would be to oxidize the dianion of quinizarine to the corresponding semiquinone and manganese(II) to manganese(III):

$$[Mn^{II}(Qz^{2-})(2\text{-MBA})_2]^{4-} \rightarrow [Mn^{III}(SQ^{-})(2\text{-MBA})_2]^{2-} + 2e^{-}. \quad (1)$$

The second alternative would be the oxidation of bound quinizarine to the corresponding semiquinone and then an internal charge transfer to produce manganese(III) and regenerate quinizarine. A second charge transfer process would oxidize quinizarine again and the final product would be the same as that illustrated in eq. (1).

Notice that upon the generation of the semi-quinone of quinizarine it is conceivable to consider its reprotonation, as described in the study of its simple manganese complex,[17] which would eliminate the possibility of forming a neutral species. If this reprotonation process occurs after the first oxidation step the oxidation of bound 2-MBA to the corresponding dimer with the consequent destruction of the complex would involve the $-S^{-}$ group instead of —SH. Therefore, the last oxidation step can be represented by:

$$[Mn^{III}(SQ)(2\text{-MBA})_2]^{0} \rightarrow Mn^{II} + DQ + (2\text{-MBA})_2 + 2e^{-}. \quad (2)$$

The reprotonation of the quinizarine semiquinone through an internal proton transfer from 2-MBA would give more stability to the manganese(III) complex as compared with manganese(II). Consequently, the oxidation of the mixed-ligand complex is totally irreversible as the manganese(III) species cannot be reduced. Furthermore, this oxidation process also involves the modification of the ligands which cannot be regenerated electrochemically.

In this work the manganese(II) and manganese(III) species have been stabilized with a coordination sphere that can be very relevant for some biological systems. It is important to notice that the oxidized species presents a sort of shoulder at 510 nm, which is coincident with the wavelength of absorption of the enzyme acid purple phosphatase[20] (the only protein that for certain has a sulphur atom in its first coordination sphere). Although the values of the wavelength for the absorption maxima can be affected by the solvent, the really interesting feature of the spectra is the shift of the maxima for one species or other, which would be indicative that, according to Christou,[21] the different nature of the atoms that are part of the coordination sphere of the metal ion determines its properties in every metalloprotein.

For these reasons we think it is convenient to study the mixed-ligand complexes in which we have a semi-quinone or catechol as one of the ligands and a second species in the coordination sphere that favours the Mn—N bond. That way the resulting complex would have an analogous structure to that proposed by O'Hara *et al.*[22] for the enzyme acid purple phosphatase. A species such as this would have a better redox reversibility and would be more useful to mimic its biological activity.

On the basis of Sekido *et al.*'s results[23] we can mention that the presence of 2-MBA (analogue of cysteine) is fundamental, because this amino acid is found at the active site of this enzyme. It is also feasible to find an Mn—O bond given by the presence of a quinonic or semi-quinonic ligand. This fact is inferred because the 8-mercaptoquinolinate complexes of both manganese(II) and manganese(III) (—N,S donor ligand) do not present either the spectroscopic or redox characteristics of the purple acid phosphatase or any other biological system.

Finally, it must be mentioned that we have been able to generate the semi-quinone of quinizarine in the presence of manganese at a very positive potential as compared with the oxidation observed in the absence of the metal ion.[17] Therefore, we have undertaken the study of analogous dihydroxy ligands such as 2,5-dihydroxybenzoic acid (2,5-DHBA), which presents a carboxylic group that deactivates the benzene ring leading to more positive oxidation potentials and which has been reported by the authors.[24] The metal ion presents in this complex a coordination sphere that is very common in biological systems, so that the system studied in this work is an important contribution to the basic knowledge in our field of interest.

VOLTAMMETRIC AND SPECTROSCOPIC STUDIES OF THE BEHAVIOUR OF MANGANESE(II) AND MANGANESE(III) COMPLEXES WITH ISOQUINOLINECARBOXYLIC ACID IN APROTIC MEDIUM

MARIO E. BODINI,* ROBERTO LEIVA, MARÍA A. DEL VALLE and VERÓNICA ARANCIBIA

Departamento de Química, Analítica y Electroquímica, Facultad de Química, Pontificia Universidad Católica de Chile, Casilla 306, Santiago, Chile

(*Received* 8 *February* 1993; *accepted* 23 *March* 1993)

Abstract—The redox chemistry of the manganese(II) and manganese(III) complexes with 1-isoquinolinecarboxylate (1-IQC) in dimethylsulphoxide has been studied. Cyclic voltammetry, polarography, controlled-potential electrolysis, UV–vis spectroscopy and magnetic susceptibility measurements have been performed on the solutions. In the presence of the anion 1-isoquinolinecarboxylate the manganese(II) ion forms an $Mn^{II}(1\text{-IQC})_2$ complex, whose conditional formation constant has been evaluated polarographically and turns out to be $5 \times 10^7\ M^{-2}$ at 25°C. The polarograms of the solution of this complex show a cathodic wave with $E_{1/2} = -1.60$ V vs S.C.E., corresponding to the reduction of the metal ion with its subsequent destruction. On the other hand the voltammograms on a platinum electrode show the reduction of the bound ligand at −1.66 V vs S.C.E., probably to a bound radical species, and two oxidation processes at −1.37 and −1.49 V vs S.C.E. The manganese(II) complex does not decompose after this reduction, but the species produced was not obtained quantitatively as the reduction potential was too close to the solvent discharge. The manganese(II) complex is oxidized to the $Mn^{III}(1\text{-IQC})_3$ mononuclear complex, whose conditional formation constant was evaluated polarographically and turns out to be $4 \times 10^{14}\ M^{-3}$ at 25°C.

The coordination chemistry of manganese has been a rather neglected field until fairly recently, perhaps because high-spin manganese(II) has historically been the dominant oxidation state in well-characterized compounds. Not only does the high-spin d^5 manganese(II) ion have a zero crystal field stabilization energy (CFSE), but it gives no useful UV–vis spectral information from *d–d* bands. The majority of manganoproteins utilize only manganese(II). In these redox-inactive proteins other divalent metal ions frequently can functionally substitute for manganese and in many cases it is unclear whether manganese is even the physiologically relevant cation.[1–4]

The higher valence states of manganese have been increasingly studied and it has led to the discovery of a whole series of stable coordination complexes, mainly of d^4 manganese(III) and d^3 manganese(IV). A further difficulty is that in the absence of suitable ligands manganese(III) tends to disproportionate to manganese(II) and manganese(IV). The manganese(III) state can be stabilized by anionic strongly donating ligands. The *d–d* transitions have substantial intensity in manganese(III) complexes and most are green, red or brown; charge-transfer bands are probably also of importance in certain cases. Interest in binuclear and polynuclear complexes of manganese in relatively high oxidation states stems largely from the involvement of such species in a wide variety of biological oxidative processes; the most relevant example to the present work is the water oxidizing enzyme in photosystem II, disproportionation of hydrogen peroxide (catalase activity) in microorganisms and their potential use as redox catalysts.[5–9]

* Author to whom correspondence should be addressed.

Carboxylate groups show a tendency to bind to manganese in either a monodentate or bidentate manner; in the latter case with the formation of a symmetrical μ-carboxylato bridge.[10-14] Our group has studied the mononuclear complexes with manganese(II) and binuclear complexes with manganese(III) formed with the ligand 4-methoxy-2-quinolinecarboxylate[15] and we now report the study of complexes of this metal ion with 1-isoquinoline-carboxylate in order to compare their behaviour, considering that in this case the carboxylic group is in a different position and that this ligand has no substitution groups in their structure. Therefore, the redox chemistry and the stabilities of the complexes formed should be different from those reported in the past.

EXPERIMENTAL

Equipment

A three-electrode potentiostat (Bioanalytical Systems) Model CV-1A 230 and a Linear Model 8036 *X–Y* recorder were used for the cyclic voltammetric experiments. Controlled-potential coulometric electrolysis was accomplished with a Bioanalytical Systems Model SP-2 potentiostat and PUC coulometer.

The electrochemical cell was equipped with a Beckman platinum-inlay electrode for the voltammetric experiments. The auxiliary electrode was a platinum-coil electrode, which was isolated from the bulk solution by a glass tube with a fine-porosity glass frit at the end; it contained a concentrated solution of supporting electrolyte. The reference electrode was an Ag/AgCl (aqueous tetramethylammonium chloride) cracked glass-bead electrode, which was adjusted to 0.00 V vs S.C.E.[16] The reference electrode was located inside a Luggin capillary in the cell assembly. A platinum-mesh working electrode was used for the controlled-potential electrolysis experiments.

The UV–vis spectra were obtained with a Hewlett–Packard Model 8452 A spectrophotometer.

The magnetic susceptibility measurements were made by the Evans[17] method as modified by Rettig[18] using an NMR spectrometer Varian Model XL-100.

Reagents

The reagents for the investigation and syntheses included $Mn(ClO_4)_2 \cdot 6H_2O$ (G. Frederick Smith), tetrabutylammonium hydroxide (TBAOH) (1.0 M in methanol, Aldrich), tetramethylammonium chloride (Aldrich) and tetraethylammonium perchlorate (TEAP) (G. Frederick Smith). The ligand 1-isoquinolinecarboxylic acid was obtained from Aldrich.

Aldrich "Gold Label" solvents were used without further purification for all of the experiments. High purity argon was used to deaerate the solutions.

Since the solvation water of $Mn(ClO_4)_2 \cdot 6H_2O$ interfered with the stoichiometric formation of the complexes under study, $[Mn^{II}(DMU)_6][ClO_4]_2$ (DMU = dimethylurea)[19] was used in all the experiments in which the manganese complexes were formed *in situ*. As a source of manganese (III) $[Mn^{III}(urea)_6][ClO_4]_3$[20] was used in all the experiments.

RESULTS AND DISCUSSION

The cyclic voltammogram of a solution of 1-isoquinolinecarboxylic acid (1 mM) in dimethylsulphoxide (DMSO) is illustrated in Fig. 1. Two reduction processes are observed at -1.23 and -1.33 V vs S.C.E. (peaks a and b) and the corresponding anodic processes occur at -0.50 and $+0.08$ V vs S.C.E. (peaks c and d), which are due to the oxidation of the species generated on the surface of the electrode. A very reversible post-peak is also observed in Fig. 1, with $E_{p,c} = -1.66$ and $E_{p,a} = -1.64$ V vs S.C.E. The electrochemical behaviour of this ligand has been previously studied by our group.[21]

If 1 equivalent of base (TBAOH) is added to this solution the proton of the carboxylic group is neutralized and its cyclic voltammogram is shown in Fig. 1(B). Notice that the only electrochemical process shown by this compound is the irreversible oxidation of the carboxylate group[22] at $+0.95$ V vs S.C.E.

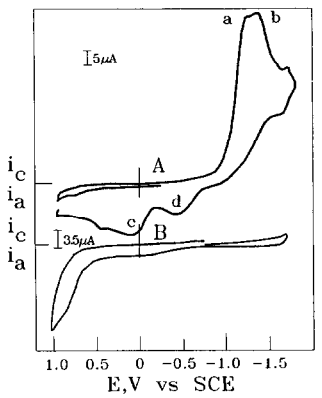

Fig. 1. Cyclic voltammograms in DMSO (TEAP 0.1 M, $V = 0.10$ V s^{-1}) of solutions that are: (A) 3.0 mM in 1-isoquinolinecarboxylic acid and (B) 3.0 mM in 1-isoquinolinecarboxylic acid + 3.0 mM in TBAOH.

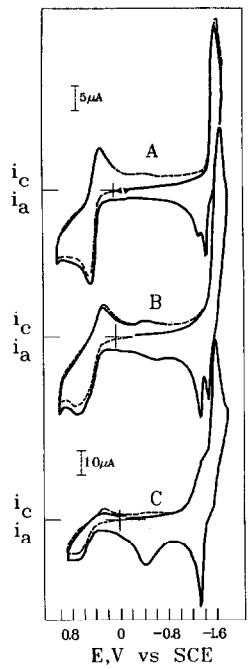

Fig. 2. Cyclic voltammograms in DMSO (TEAP 0.1 M, $V = 0.10$, V s^{-1}) of solutions 9.0 mM in 1-isoquinolinecarboxylic acid and 9.0 mM in TBAOH in the presence of: (A) $Mn(DMU)_6(ClO_4)_2$ (3.0 mM), (B) $Mn(DMU)_6(ClO_4)_2$ (4.5 mM) and (C) $Mn(DMU)_6(ClO_4)_2$ (9.0 mM).

Figure 2 illustrates the cyclic voltammograms of solutions of the anion of the ligand in the presence of increasing amounts of $Mn^{II}(DMU)_6(ClO_4)_2$ so that 1 : 3, 1 : 2 and 1 : 1 metal-to-ligand mole ratios are obtained [Figs 2(A), (B) and (C), respectively]. In this medium the manganese(II) ion reduces at -1.35 V vs S.C.E. and the oxidation of manganese metal depends on the negative potential limit at which the scan is reversed. In this case the corresponding anodic peak occurs at -0.40 V vs S.C.E. At the 1 : 3 and 1 : 2 metal-to-ligand mole ratios [Figs 2(A) and (B)] stable complexes are formed, which can be concluded from the fact that the reduction of free manganese(II) to manganese(0) is not observed. Only when the metal-to-ligand mole ratio is 1 : 1 does this process become evident.

Figure 3 shows the UV–vis spectra of these solutions, in which the monoanion of the ligand presents absorption maxima at 278 ($\varepsilon = 5451$ M^{-1} cm^{-1}), 314 ($\varepsilon = 4006$ M^{-1} cm^{-1}) and 326 nm ($\varepsilon = 4280$ M^{-1} cm^{-1}) [Fig. 3(A)]. In the presence of manganese(II) the absorption maximum is shifted from 278 to 282 nm and a lower absorbance is observed if the metal-to-ligand mole ratio is 1 : 3. The maximum at 314 nm disappears and a wide absorption band becomes evident between 322 and 338 nm, whose absorption is maximum for a metal-to-

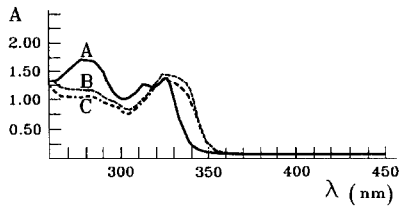

Fig. 3. UV absorption spectra in DMSO of: (A) 9.0 mM in 1-isoquinolinecarboxylic acid + 9.0 mM in TBAOH, (B) solution A in the presence of $Mn(DMU)_6(ClO_4)_2$ (3.0 mM) and (C) solution A in the presence of $Mn(DMU)_6(ClO_4)_2$ (4.5 mM).

ligand mole ratio of 1 : 2 [Fig. 3(C)]. For a 1 : 1 ratio the absorption spectrum does not change because the excess free manganese(II) is spectroscopically inactive in this wavelength region.

Therefore, according to voltammetric and spectroscopic results we can conclude that the 1-isoquinolinecarboxylate ligand forms a mononuclear complex with manganese(II) with a 1 : 2 metal-to-ligand stoichiometry.

If the potential is scanned initially in the negative direction (Fig. 2) a reduction process is observed at -1.66 V vs S.C.E. and two oxidations associated to this process appear at -1.37 and -1.49 V vs S.C.E. The electrochemical reduction must correspond to electron transfer to the bound ligand because the presence of free manganese(II) is not observed after this process. If free manganese(II) is released after the decomposition of the complex its reduction to manganese metal and the oxidation of the metallic deposit should become evident in the manganese(II) complex solution cyclic voltammograms.

When controlled-potential electrolysis at -1.80 V vs S.C.E. is performed on a solution of 1-isoquinolinecarboxylate and manganese(II) with a metal-to-ligand mole ratio of 1 : 2, in order to obtain quantitatively the reduced complex, the solution becomes a little darker, but unfortunately the applied potential was too close to the solvent discharge and the complete electrolytic process was not possible.

Based on our previous experience on the reduction of an analogous ligand[15] we can propose in this case that the bound ligand is reduced to a radical species, which is stabilized by the presence of the metal ion.

$$Mn^{II}(1\text{-IQC})_2 + e^- \longrightarrow Mn^{II}(1\text{-IQC})(1\text{-IQC}^{\cdot})^- \quad (1)$$

The presence of two oxidation peaks can be explained in terms of two different radicals, produced when this type of ligand is reduced.[15]

If a dropping mercury electrode (D.M.E.) is used the reduction of the manganese(II) complex to the corresponding amalgam is observed before the reduction of the ligand and it shifts to more negative potentials as the concentration of the ligand is increased in the solutions. This polarographic behaviour of our system was used to confirm the stoichiometry of the complex and to evaluate its conditional formation constant. The difference, $E_{3/4}-E_{1/4}$, of the polarographic wave was 78 mV, which was used to determine the value of the charge-transfer coefficient (α), which was 0.378. From the slope of the straight line obtained for the dependence of the half-wave potential with the concentration of the ligand in the solutions[23] (-0.168) it was confirmed that the manganese(II) complex had a 1 : 2 stoichiometry and from its intercept with the ordinate axis (-0.603) its conditional formation constant was estimated to be 5×10^7 M^{-2}.

Reference to Fig. 2 indicates that if the potential is scanned initially in the positive direction an oxidation process is observed at +0.46, +0.68 or +0.72 V vs S.C.E., depending on the manganese(II) concentration in the solutions. These potentials correspond to 1 : 3, 1 : 2 and 1 : 1 metal-to-ligand mole ratios, respectively. The corresponding reduction occurs at −0.22 V vs S.C.E. and it does not shift as the concentration of the metal ion is varied, indicating that the electrochemical process becomes more irreversible.

In order to quantitatively oxidize the species of manganese(II) in solution controlled-potential electrolysis was performed at +0.70 V vs S.C.E. of a solution with a metal-to-ligand mole ratio of 1 : 3 (oxidation peak potential = +0.46 V vs S.C.E.). The original pale yellow solution turned red–brown and a residual current was obtained after the transfer of 1 equivalent of charge. The magnetic susceptibility of the resulting solution was 4.91 B.M., which indicates that a manganese(III) species has been generated in solution. When solutions with 1 : 2 or 1 : 1 metal-to-ligand mole ratios were electrolysed at +0.75 V vs S.C.E. the same mononuclear manganese(III) complex was obtained, presenting a 1 : 3 stoichiometry. The cyclic voltammograms of these solutions are shown in Fig. 4.

In order to generate directly the oxidized species solutions of 1-isoquinolinecarboxylate and $[Mn^{III}(Urea)_6](ClO_4)_3$ with 1 : 3, 1 : 2 and 1 : 1 metal-to-ligand mole ratios were prepared. The cyclic voltammograms of these solutions are shown in Fig. 5 and the corresponding visible spectra are illustrated in Fig. 6. Figure 5(A) shows the cyclic voltammograms of a solution of $[Mn^{III}(Urea)_6](ClO_4)_3$ (5 mM). Although the crystal structure of this com-

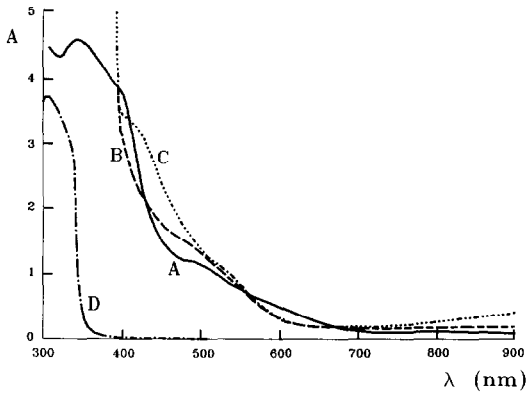

Fig. 6. UV–vis spectra in DMSO of solutions that are: (A) 5.0 mM in $Mn(Urea)_6(ClO_4)_3$, (B) 5.0 mM in $Mn(Urea)_6(ClO_4)_3$ and 10 mM in 1-isoquinolinecarboxylate, (C) 5.0 mM in $Mn(Urea)_6(ClO_4)_3$ and 15 mM in 1-isoquinolinecarboxylate and (D) 15 mM in 1-isoquinolinecarboxylic acid and 15 mM in TBAOH.

pound has been obtained[20] and it corresponds to a mononuclear complex, it is observed that in solution a polynuclear species is formed which presents reduction peaks at +0.87, +0.62 and −0.48 V vs S.C.E. Controlled-potential electrolysis after the third reduction process indicates that 1 equivalent of charge is being transferred, generating the manganese(II) complex. Upon addition of 1-isoquinolinecarboxylate to the solution of manganese(III) ions (5 mM) the intensity of these cathodic peaks decrease and a new reduction process is observed at +0.26 V vs S.C.E. This reduction peak presents its maximum intensity after the addition of three equivalents of the monoanionic ligand [Fig. 5(D)]. On the other hand the manganese(III)-urea complex is very unstable if it is electrochemically reduced [Fig. 5(A)] and the corresponding oxidation of the manganese(II) species is not observed. Only in the presence of 1-isoquinolinecarboxylate and in a 1:3 metal-to-ligand mole ratio is it possible to stabilize a mononuclear species. This solution presents the same cyclic voltammogram and spectrum as the solution obtained by electrolytic oxidation of the manganese(II) complex with this stoichiometric ratio. If the metal-to-ligand mole ratio is 1:1 or 1:2 the presence of free manganese(III) is observed and its reduction takes place at a higher potential due to the instability of this metal ion.

The UV–vis spectra of solutions of $[Mn^{III}(Urea)_6](ClO_4)_3$ are shown in Fig. 6. This compound has absorption maxima at 350 ($\varepsilon = 920\ M^{-1}\ cm^{-1}$), 400 ($\varepsilon = 760\ M^{-1}\ cm^{-1}$), 490 ($\varepsilon = 240\ M^{-1}\ cm^{-1}$) and a little shoulder at 600 nm ($\varepsilon = 100\ M^{-1}\ cm^{-1}$) [Fig. 6(A)]. The monoanionic ligand presents an absorption maximum at 309 nm ($\varepsilon = 253\ M^{-1}\ cm^{-1}$) and it contributes to the overall absorption spectrum up to approximately 380 nm [Fig. 6(D)]. The mononuclear tris complex $[Mn(IQC)_3]$ presents an absorption maximum at 410 ($\varepsilon = 650\ M^{-1}\ cm^{-1}$) and a little shoulder at 520 nm ($\varepsilon = 240\ M^{-1}\ cm^{-1}$) [Fig. 6(C)].

A polarographic analysis of solutions of the mononuclear species of manganese(III) indicates a wave with $E_{1/2} = 0.26$ V vs S.C.E., corresponding to the reduction of $Mn^{III}(IQC)_3$ to $Mn^{II}(IQC)_2$. From the shift in the half-wave potential with the concentration of the ligand we can obtain the ratio of the formation constants of the two complexes involved. As we had previously determined the constant for the manganese(II) complex the corresponding manganese(III) complex conditional formation constant is $4 \times 10^{14}\ M^{-3}$ at 25°C.

Therefore, we can conclude from this work that the 1-isoquinolinecarboxylate ligand forms mononuclear complexes both with manganese(II) and manganese(III). This is different from the behaviour presented by the previously reported ligand 4-methoxy-2-quinolinecarboxylate,[15] where a binuclear complex of manganese(III) formed in solution. This indicates that the position of the carboxylate group is very important in determining the structure of the oxidized species. Probably a steric effect precludes the formation of a bridge between the two metal centres in the case of the 1-isoquinolinecarboxylate ligand.

ZINC(II) COMPLEXES WITH THE REDUCTION PRODUCTS OF 2,3-DIMETHOXY-1,4-NAPHTHOQUINONE IN DIMETHYL SULPHOXIDE REDOX CHEMISTRY AND SPECTROSCOPY

VERÓNICA ARANCIBIA and MARIO BODINI*

Departamento de Química Analítica Electroquímica, Facultad de Química, Pontificia Universidad Católica de Chile, Casilla 306, Santiago, Chile

(*Received* 23 *November* 1992; *accepted* 23 *March* 1993)

Abstract—In dimethylsulphoxide the 2,3-dimethoxy-1,4-naphthoquinone (Q) is reduced in two successive one-electron steps, which are electrochemically reversible at low scan rates. At −0.72 V vs S.C.E. the semiquinone anion radical is formed and at −1.42 V vs S.C.E. a second reduction to the corresponding dianion is observed. A mixture of zinc(II) and the dianion of 2,3-dimethoxy-1,4-naphthoquinone at a mole ratio of 1 : 1 in Me_2SO yields a stable complex. The zinc(II)-semiquinone complex is formed only on the surface of the electrode because under these conditions this radical ligand disproportionates producing the corresponding quinone and the dianion. The different forms of the ligand and the zinc(II)-dianion complex have been characterized by cyclic voltammetry, UV–vis spectroscopy and magnetic susceptibility measurements. The stability constants for the 1 : 1 zinc(II)-dianion and zinc(II)-semiquinone complexes are large, but it was not possible to determine their exact value as their voltammetric behaviour was irreversible. However the high stability of the dianion complex causes the disproportionation of the ligand in the semiquinone complex.

There is considerable interest in metal complexes containing quinone and quinone-derived ligands. These ligands can potentially bind to metal ions in three different forms, namely quinone, semiquinone or dianion. Quinones are present in a number of biological systems, and their role appears to be as electron transfer agents in redox reactions.[1–7] The interaction of quinones and their reduced species with metal ions such as manganese(II), manganese(III), iron(II), iron(III) and copper(II) has been used as a model for some biological systems, for example Photosystem II of green plant photosynthesis.[8–10]

Most of the work in this area has been performed with three ligands in their various electronic forms: 3,5-di-t-butylbenzoquinone, 9,10-phenanthrenequinone and tetrachloro-1,2-benzoquinone.[11–13]

The zinc(II) ion, which is redox inactive under the conditions where the bound dianion (DA^{2-}) and the semiquinone ($SQ^{\cdot -}$) are electroactive, is a hard acid and forms strong coordinate bonds with oxo ligands.[14] This characteristic should favour strong complexation of zinc(II) by DA^{2-}-$ySQ^{\cdot -}$ and the degree of interaction should be equal to or greater than that of these ligands with manganese(II) or iron(II).

The present paper summarizes the results of an electrochemical, spectroscopic and magnetic characterization of the complexes of zinc(II) with different forms of the ligand 2,3-dimethoxy-1,4-naphthoquinone in dimethyl sulphoxide (Me_2SO).

EXPERIMENTAL

Equipment

A three-electrode potentiostat (Bioanalytical Systems) Model CV-1A 230 and a Linear Model 8036 *X–Y* recorder were used for the cyclic voltammetric experiments. Controlled-potential electrolysis was accomplished with a Bioanalytical Systems Model SP-2 potentiostat and PUC coulometer.

* Author to whom correspondence should be addressed.

The electrochemical cell was equipped with a Beckman platinum-inlay electrode (area 0.23 cm^2) for the voltammetric experiments. The auxiliary electrode was a platinum-coil electrode, which was isolated from the bulk solution by a glass tube with a fine-porosity glass frit at the end; it contained a concentrated solution of supporting electrolyte. An Ag/AgCl reference electrode filled with an aqueous tetramethylammonium chloride solution and adjusted to 0.00 V vs S.C.E. was used in all the experiments.[15] This electrode was contained in a Pyrex tube with a soft-glass cracked tip and was located inside a Luggin capillary in the cell assembly. A platinum-mesh working electrode was used for the controlled-potential electrolysis experiments.

The UV–vis spectra were obtained with a Hewlett–Packard Model 8452 A diode-array spectrophotometer.

The magnetic susceptibility measurements were made by the Evans[16] method as modified by Rettig,[17] using an NMR Varian Model XL-100 spectrometer. Diamagnetic corrections were made.[18]

Air-sensitive compounds were handled in a glove-bag (Aldrich) under a nitrogen atmosphere and the oxygen content was monitored with a Beckman Model Monitor II Oxygen Analyser.

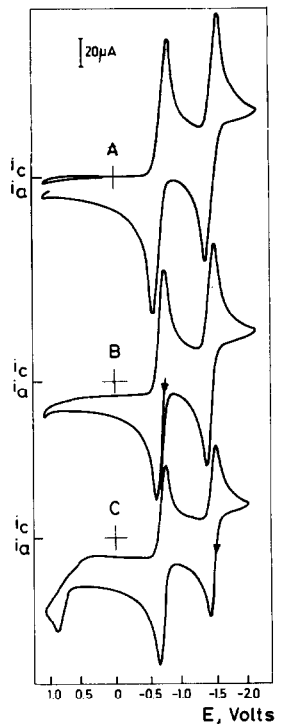

Fig. 1. Cyclic voltammograms in Me_2SO (0.1 M TEAP; $v = 0.1$ V s^{-1}) of solutions that are 3.0 mM in (A) 2,3-dimethoxy-1,4-naphthoquinone (Q), (B) 2,3-dimethoxy-1,4-naphthoquinone after electrolysis at −0.92 V vs S.C.E: ($n = 1$, $SQ^{\cdot -}$) and (C) 2,3-dimethoxy-1,4-naphthoquinone after electrolysis at −1.62 V vs S.C.E. ($n = 2$, DA^{2-}).

Reagents

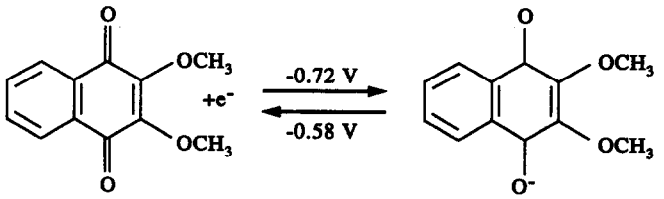
2,3-Dimethoxy-1,4-naphthoquinone (Q) was obtained from Aldrich Chemical Co., $[Zn^{II}(DMU)_6](ClO_4)_2$[19] (DMU = dimethylurea) was used as the source of zinc(II) ions; tetramethylammonium chloride was obtained from INC Pharmaceuticals Inc.; tetraethylammonium perchlorate (TEAP) was obtained from reaction of a 25% aqueous solution of tetraethylammonium hydroxide (Aldrich) and concentrated perchloric acid (Merck) and recrystallized from anhydrous ethyl alcohol; dimethyl sulphoxide (Me_2SO) was obtained from Aldrich (water < 0.005%) and was used without further purification. High-purity argon was used to deaerate the solutions.

RESULTS AND DISCUSSION

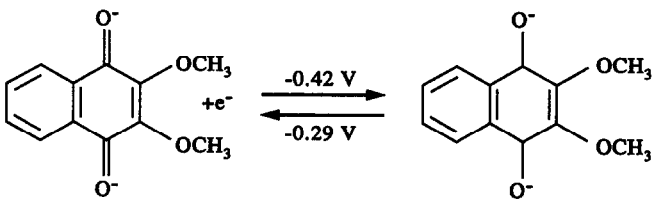
Figure 1 shows the cyclic voltammograms of the ligand 2,3-dimethoxy-1,4-naphthoquinone (Q) in dimethylsulphoxide (Me_2SO). The quinone presents two reduction processes at −0.72 V vs S.C.E. and −1.42 V vs S.C.E. with the corresponding oxidations at −0.58 V vs S.C.E. and −1.29 V vs S.C.E. A 3 mM solution of this ligand is yellow and controlled-potential electrolysis at −0.92 V vs S.C.E. indicates that 1 equivalent of charge is being transferred in the process. A dark brown solution is obtained, which is extremely sensitive to the presence of oxygen. The magnetic susceptibility of this solution is 1.75 B.M., which indicates that a radical species is being formed in this electrolysis [Fig. 1(B)]. Controlled-potential electrolysis on this solution at −1.62 V vs S.C.E. yields a red–brown solution and again 1 equivalent of charge is transferred. The compound produced in this process is very sensitive to oxidation by oxygen as well. Its cyclic voltammogram is shown in Fig. 1(C), where it can be observed that a new oxidation peak occurs at +0.86 V vs S.C.E.

On the other hand, controlled-potential electrolyses at −1.09 V vs S.C.E. and −0.38 V vs S.C.E. to produce oxidations of the compound generated in the former elecrolytic processes indicated that 1 equivalent of charge is transferred in each case and the initial compound is regenerated.

We suggest that the following reactions are taking place in our system:



Quinone (Q) Semiquinone ($SQ^{\cdot-}$)



Semiquinone ($SQ^{\cdot-}$) Dianion (DA^{2-})

The semiquinone does not dimerize on the timescale of the electrolysis experiment and in the presence of oxygen it is oxidized to the original quinone. In the case of the dianion it is very reactive and gets oxidized on the surface of the electrode first to the semiquinone and then to the quinone. The latter presents a new oxidation peak at +0.86 V vs S.C.E.

The UV–vis spectra of the quinone, the semiquinone ($SQ^{\cdot-}$) and the dianion (DA^{2-}) are shown in Figs 2(A), (B) and (C). It can be observed that the quinone presents an absorption maximum at 330 nm ($\varepsilon = 3331\ M^{-1}\ cm^{-1}$), whereas the semiquinone shows its maxima at 300 ($\varepsilon = 8014\ M^{-1}\ cm^{-1}$), 406 ($\varepsilon = 6600\ M^{-1}\ cm^{-1}$) and 460 nm ($\varepsilon = 6491\ M^{-1}\ cm^{-1}$). On the other hand, the dianion presents its absorption maxima at 300 ($\varepsilon = 5899\ M^{-1}\ cm^{-1}$) and 410 nm ($\varepsilon = 6686\ M^{-1}\ cm^{-1}$).

Figure 3 shows the cyclic voltammograms of a solution of 2,3-dimethoxy-1,4-naphthoquinone in the presence of increasing amounts of zinc(II), so that 1:1, 1:2 and 1:3 metal-to-ligand stoichiometric ratios are obtained in solution. It can be observed that as the concentration of metal ion increases the peak current at −0.72 V vs S.C.E.

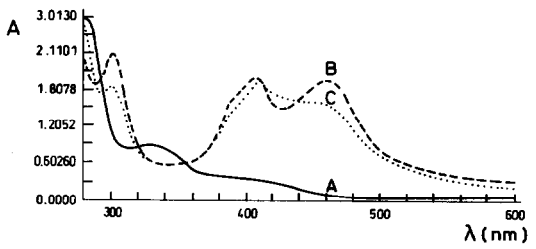


Fig. 2. Absorption spectra of solutions in Me_2SO containing: (A) 2,3-dimethoxy-1,4-naphthoquinone (3 mM) (Q), (B) 2,3-dimethoxy-1,4-naphthoquinone (3 mM) after electrolysis at −0.92 V vs S.C.E. ($n = 1$, $SQ^{\cdot-}$) and (C) 2,3-dimethoxy-1,4-naphthoquinone (3 mM) after electrolysis at −1.62 V vs S.C.E. ($n = 2$, DA^{2-}).

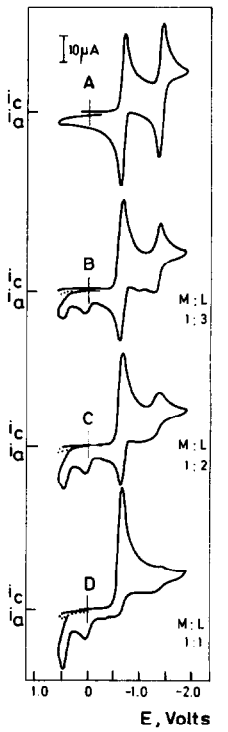

Fig. 3. Cyclic voltammograms in Me_2SO (0.1 M TEAP; $v = 0.1\ V\ s^{-1}$) of: (A) a solution (3 mM) of 2,3-dimethoxy-1,4-naphthoquinone, (B), (C) and (D) after the addition of 1, 1.5 and 3 mM $[Zn(DMU)_6](ClO_4)_2$, respectively.

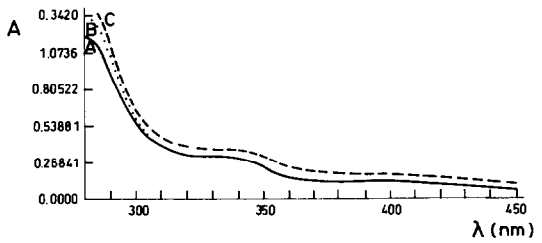

Fig. 4. Absorption spectra of solutions in Me_2SO containing: (A) 2,3-dimethoxy-1,4-naphthoquinone (3 mM); (B) and (C): solution (A) after the addition of 1.5 and 3 mM $[Zn(DMU)_6](ClO_4)_2$, respectively.

increases as well, whereas the current intensities associated with the processes at −1.42, −1.29 and −0.58 V vs S.C.E. decrease. On the other hand, new oxidations are observed at +0.05 and −0.50 V vs S.C.E. The most important effect is observed when the metal-to-ligand stoichiometric ratio is 1 : 1.

In order to prepare this compound a solution (3 mM) of both the quinone and zinc(II) was prepared and controlled-potential electrolysis at −0.92 V vs S.C.E. was attempted (peak potential = −0.72 V vs S.C.E.). As the electrolysis starts the current drops almost immediately to the residual value and the desired compound is not formed. Apparently, this compound precipitates and passivates the electrode.

The cyclic voltammograms of Fig. 3 show that the reduction of free quinone does not shift to more negative potentials in the presence of the metal ion, as would be the case if some interaction exists between these two species. Furthermore, the UV–vis spectra of the quinone ligand do not change in the presence of zinc(II), as is illustrated in Figs 4(B) and (C). Therefore, we can conclude that there is no interaction between the metal ion and the quinone.

As the peak current for the reduction of quinone to semiquinone almost doubles and the reduction of the free semiquinone to the corresponding dianion almost disappears, this would be indicative that a very stable complex forms between the metal ion and the dianion produced as a consequence of the reduction of the ligand.

The dianion was produced by controlled-potential electrolysis at −1.62 V vs S.C.E. of a solution (3.0 mM) of the quinone and then zinc(II) ions were added to the solution to produce 1 : 1 and 1 : 2 metal-to-ligand mole ratios. The cyclic voltammograms of the resulting solutions are shown in Fig. 5, whereas the corresponding UV–vis spectra are illustrated in Fig. 6. Notice that the cyclic voltammograms and the spectra indicate that when the metal-to-dianion stoichiometric mole ratio is 1 : 2

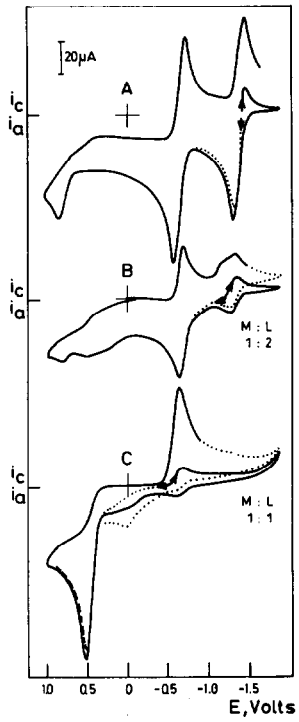

Fig. 5. Cyclic voltammograms (0.1 M TEAP; $v = 0.1$ V s^{-1}) of solutions in Me_2SO containing: (A) 2,3-dimethoxy-1,4-naphthoquinone (3 mM) after electrolysis at −1.62 V vs S.C.E. (DA^{2-}); (B) and (C): solution (A) after the addition of 1.5 and 3 mM $[Zn(DMU)_6](ClO_4)_2$, respectively.

the free dianion is absent, because its oxidation peak at −1.29 V vs S.C.E. is not observed and its characteristic absorption maxima at 300 and 410 nm do not occur. Therefore, we can conclude that a very stable 1 : 2 zinc(II)-dianion complex is formed, which is oxidized very easily at −0.66 and +0.50 V vs S.C.E.

$$Zn^{2+} + 2DA^{2-} \longrightarrow Zn(DA)_2^{2-}$$

$$Zn(DA)_2^{2-} \xrightarrow{-0.66\,V} ZnDA + Q + 2e^-$$

$$ZnDA \xrightarrow{+0.50\,V} Zn^{2+} + Q + 2e^-$$

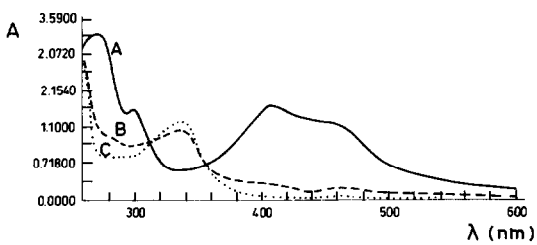

Fig. 6. Absorption spectra of solutions in Me_2SO containing: (A) 2,3-dimethoxy-1,4-naphthoquinone (3 mM) after electrolysis at −1.62 V vs S.C.E. (DA^{2-}); (B) and (C): solution (A) after the addition of 1.5 and 3 mM $[Zn(DMU)_6](ClO_4)_2$, respectively.

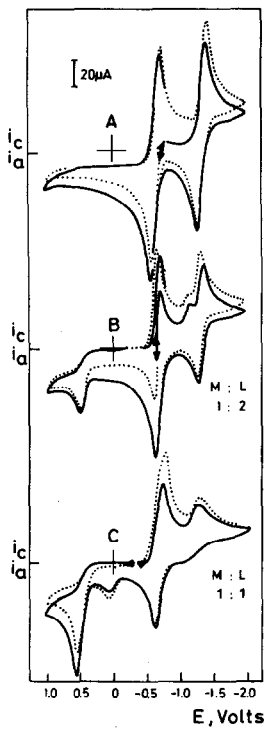

Fig. 7. Cyclic voltammograms (0.1 M TEAP; $v = 0.1$ V s^{-1}) of solutions in Me_2SO containing: (A) 2,3-dimethoxy-1,4-naphthoquinone (3 mM) after electrolysis at −0.92 V vs S.C.E. ($SQ^{\cdot -}$); (B) and (C): solution (A) after the addition of 1.5 and 3 mM $[Zn(DMU)_6](ClO_4)_2$, respectively.

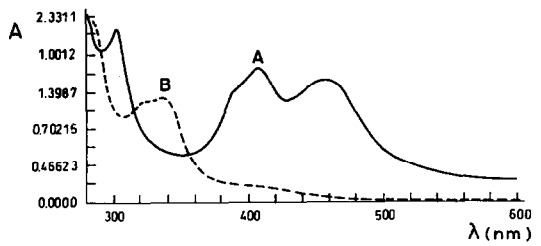

Fig. 8. Absorption spectra of solutions in Me_2SO containing: (A) 2,3-dimethoxy-1,4-naphthoquinone (3 mM) after electrolysis at −0.92 V vs S.C.E. ($SQ^{\cdot -}$); (B) solution (A) after the addition of 3 mM $[Zn(DMU)_6](ClO_4)_2$.

In the presence of excess zinc(II) the solution becomes colourless and another very stable complex with a 1 : 1 stoichiometric mole ratio is formed, which is oxidized in a single step at +0.50 V vs S.C.E. to the corresponding quinone and the free metal ion.

$$Zn^{2+} + DA^{2-} \longrightarrow ZnDA$$

$$ZnDA \underset{-0.65\,V}{\overset{+0.50\,V}{\rightleftharpoons}} Zn^{2+} + Q + 2e^-$$

This complex has an absorption maximum at 338 nm ($\varepsilon = 5113\ M^{-1}\ cm^{-1}$), which is very close to the absorption maximum of the quinone (330 nm, $\varepsilon = 3301\ M^{-1}\ cm^{-1}$) but with a larger extinction coefficient.

Upon the addition of zinc(II) the semiquinone completely disproportionates and as a consequence both the concentration of free quinone and the zinc-dianion complex increase.

$$Zn^{2+} + SQ^{\cdot -} \longrightarrow 1/2ZnDA + 1/2Q + 1/2Zn^{2+}$$

The UV–vis spectrum of this solution [Fig. 8(B)] shows an absorption band that ranges from 300 to 338 nm with an extinction coefficient of 4380 M^{-1} cm^{-1}, which confirms that half of the ligand is present as the quinone (330 nm; $\varepsilon = 3301\ M^{-1}\ cm^{-1}$) and half as the zinc-dianion complex (338 nm; $\varepsilon = 5113\ M^{-1}\ cm^{-1}$). Therefore, if we consider a contribution of 50% of the concentration as the quinone and 50% as the zinc-dianion complex the result is an absorbance such as that shown in Fig. 8(B).

Notice that if the complex is produced by direct combination of the metal ion and the dianion of the ligand it is oxidized in one step (+0.50 V) to the corresponding quinone and the free metal ion, whereas when the quinone is reduced in the presence of Zn^{2+} [Figs 3(B), 3(C), 3(D), 5(C) and 7(C)] the species being formed on the surface of the electrode is oxidized in two steps, which is probably due to the formation of a lower stability complex with the semiquinone. It was not possible to study the latter complex because in the presence of the metal ion the semiquinone disproportionates and the formation of the dianion complex is favoured.

Based on the behaviour of the zinc(II) complexes with 3,5-di-tert-butyl-catechol[11] we assume that the semiquinone complex formed on the surface of the electrode has 1 : 1 stoichiometry and from the shift in the oxidation potentials we could estimate their conditional formation constants.[11] Unfortunately, the voltammetric behaviour of these species is not reversible and it was not possible to determine their exact value. However, the oxidation of bound semiquinone to free quinone occurs 1.08 V more positive than the oxidation of free semiquinone, whereas the oxidation of bound dianion to bound semiquinone occurs 1.34 V more positive than the oxidation of the free dianion. This indicates that the corresponding conditional formation constants are large.

From our observations we can conclude that in this case the stability of the *para*-semiquinone complex is not enough to preclude the disproportionation of the ligand, considering that the dianion complex is much more stable. The complex

with the dianion is further stabilized due to the presence of methoxy groups in the *ortho* position with respect to the hydroxylic oxygens. This observation may be pertinent to the redox chemistry of related systems in biology.

(*Received* 10 *February* 1993; *accepted* 30 *March* 1993)

Abstract—The title compound of manganese(II) with picolinic acid was synthesized and characterized by spectroscopic and X-ray crystallographic methods. In the structure of the complex $[Mn(C_5H_4NCO_2H)(C_5H_4NCO_2)Cl]_2$ each manganese(II) atom is coordinated by two nitrogen atoms at Mn—N distances of 2.268(6) Å and two carboxylic oxygen atoms O(1) at Mn—O bond lengths of 2.191(4) Å, belonging to two picolinato groups. The Cl^- anions act as bridging ligands to build edge-sharing dimeric Mn_2Cl_2 units [Mn—Cl = 2.500(2) Å] with the Mn···Mn separation of 3.608(2) Å and Cl···Cl separation of 3.462(1) Å. The four-membered dimeric Mn_2Cl_2 rings are planar and oriented along the *c*-axis of the unit cell. The O(2)···O(2) separation between non-coordinated carboxylate oxygen atoms of adjacent dimeric coordination polyhedra is 2.423(7) Å. The IR and Raman spectral results confirm the existence of neutral picolinic acid as well as the picolinate anion. The vibrational bands of diagnostic value are compared with the values of the carboxylic acid and the free anion.

There is continuing interest in the synthesis and characterization of manganese(II)-picolinic acid complexes.[1–4] This, on one hand, is due to the identification of several manganese biomolecules that appear to contain di- and tetranuclear manganese units, including the water oxidation/oxygen evolution centre within the photosynthesis apparatus of green plants and cyanobacteria,[5] the manganese catalases[6] and even the recently identified manganese ribonucleotide reductases.[7] A further reason comes from the fact that picolinic acid and its derivatives have a broad spectrum of physiological effects on the activity functions of both animal and plant organisms, which have been attributed to their ability to form complexes with transition metals.[8] In this regard many complexes of picolinic acid and its derivatives together with their crystal structures have been reported.[9–12]

Recently we described the preparation and characterization of gold(III) halide complexes of picolinic acid (hereafter abbreviated as: H-pic), together with the crystal structure of $[AuBr_4][K(H\text{-}pic)_2(H_2O)_2]\cdot(H\text{-}pic)_2$[13] as well as the structure of $Mn(pic)(N_3)(H_2O)$.[14] In the present work we employed picolinic acid in preparing the title manganese(II) chloride complex and determined its structure by spectroscopic and X-ray crystallographic methods, in order to elucidate the molecular and coordination geometry.

EXPERIMENTAL

Preparation of the $[Mn(C_5H_4NCO_2H)(C_5H_4NCO_2)Cl]_2$ *complex*

The complex compound was prepared by dissolving $MnCl_2\cdot 4H_2O$ (1.44 g, 10 mmol) in ethanol (20 cm^3) with stirring at 298 K. Picolinic acid (2.46 g, 20 mmol) was then dissolved in warmed ethanol (15 cm^3) and added dropwise. The turbidity was filtered off and the clear solution mixture allowed to stand in a dark, cold place for several days. Transparent yellow crystals of the complex were obtained, filtered, washed with a little amount of ethanol, air dried and kept in a desiccator. The complex is insoluble in many polar solvents, e.g. water, alcohols, acetone, $CHCl_3$, etc., as well as benzene and CCl_4. Found: C, 42.6; H, 2.1; N, 8.0; Cl, 10.8. Calc.: C, 42.9; H, 2.7; N, 8.3; Cl, 10.6%.

The experimental procedures and instruments used for spectral measurements have been given previously.[14]

X-ray analysis

The density of the crystals was determined by flotation in CCl_4/CH_2Br_2. A prism-shaped crystal was measured at 300(2) K on a modified STOE four-circle diffractometer. The cell dimensions were determined from setting angles of 50 reflections. Intensity data were collected with graphite monochromatized Mo-K_α radiation ($\lambda = 0.71069$ Å) and processed in the usual way (corrections: LP factor, but no absorption or extinction).

The structure was solved via the heavy-atom procedure and Fourier syntheses (following full-matrix least-squares, with scattering factors calculated using the data from ref. 15). All non-hydrogen atoms were refined with anisotropic displacement factors. Four hydrogen atoms were identified in difference maps and included in the refinements with isotropic U values, but with constraints applied to the positional parameters. The programs SHELX-76,[16] SHELXS-86,[17] PLATON[18] and THE XRAY SYSTEM[19] were used for computations. Crystallographic data and processing parameters are given in Table 1 and selected bond distances and bond angles in Table 2. Positional parameters, anisotropic thermal parameters, a full list of bond lengths and angles and observed and

calculated structure factors have been deposited with the Editor as supplementary material.

RESULTS AND DISCUSSION

The reaction between picolinic acid and manganese(II) chloride afforded a complex of the formula $[Mn(H\text{-pic})(pic)Cl]_2$, which differs from the frequently produced complexes of the type $M(pic)_2 \cdot nH_2O$, $n = 0$, 2 or 4, which have been described previously.[3,9–12] The manganese complex is similar to those obtained for cobalt(II), nickel(II) and copper(II) of the type M(H-pic)(pic)X, reported earlier.[20–22]

The room-temperature magnetic moment value of 5.8 B.M. found for the manganese(II) complex falls very well within the range reported for octahedral manganese(II) complexes.[23] This result is consistent with the X-ray structure analysis of the complex given in Fig. 1, which illustrates its essential structural features. $[Mn(H\text{-pic})(pic)Cl]_2$ crystallizes in the tetragonal I-centred lattice with 16 formulae per unit cell. Both heavy atoms occupy special positions with site symmetry 2; the manganese(II) centre, the special position 16d (0, 1/4, z), the Cl^- anion, the special position 16f (x, $x+1/4$, 1/8). The 16 neutral H-pic and 16 picolinato anions are located on the general position 32g of space group $I4_1/acd$. Thus, in this crystal structure it is not possible by X-ray crystallography to distinguish between the H-pic and (pic^-) molecules.

As seen from Fig. 1, each manganese(II) atom is six-coordinated via the N and O(1) atoms of H-pic

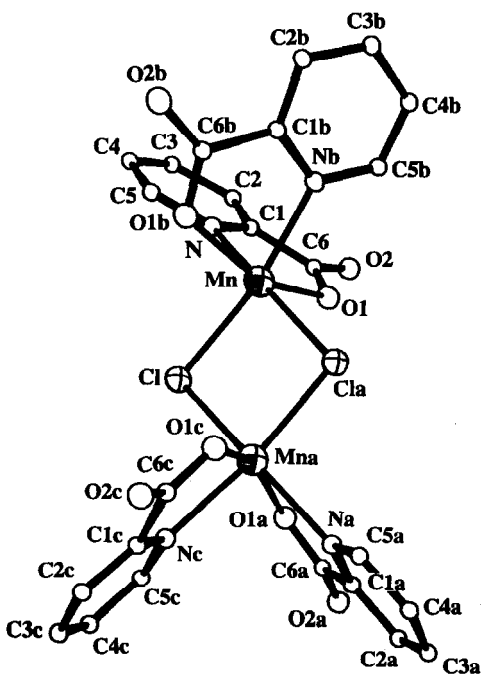

Fig. 1. The molecular structure of $[Mn(H\text{-pic})(pic)Cl]_2$ and the atom numbering scheme. Hydrogen atoms are omitted.

and (pic^-) molecules with Mn—N and Mn—O(1) bond lengths of 2.268(6) and 2.191(4) Å, respectively, and two Cl^- anions. The Cl^- anions act as bridging ligands to build edge-sharing dimeric units. The dimeric units are oriented along the *c*-axis of the unit cell. There is evidence that a hydrogen bond of the type O(2)—H(5)···O(2d) exists. The O(2)···O(2d) separation between adjacent coordination polyhedra is 2.423(7) Å. Attempts to locate the H(5) atom on the calculated position (with site occupation of 1/2; due to space group symmetry the vice versa hydrogen bond O(2d)—H(5d)···O(2) is also generated) failed. The O(2)···O(2d) separation is very close to that found in the structure of the silver(I) picolinate complex, $Ag(C_5H_4NCO_2H_{1/2})_2 \cdot H_2O$;[11] the hydrogen atoms are, therefore, equally shared by the $—COO^-$ groups and there is no distinct molecule of silver(I) picolinate. Within the dimeric units the Mn···Mn(b) separation is 3.608(2) Å and the Cl···Cl(a) separation equals 3.462(1) Å. The four-membered Mn_2Cl_2 ring is planar (restriction of the two two-fold rotation axes normal to each other). The Mn—Cl distances are equal [2.500(2) Å] and the Mn—Cl—Mn(b) angle is 92.38(4)°, whereas the Cl—Mn—Cl(a) angle equals 87.63(5)°. These manganese–chloride bonds and angles are comparable with those reported for other manganese(II) complexes, e.g. $[(CH_3)_3NH]_3Mn_2Cl_7$ [Mn—Cl from 2.369(3) to 2.559(3) Å, Mn···Mn = 3.208(3) Å, Mn—Cl—Mn = 77.46(8)° and Cl—Mn—Cl = 85.20(9) and 95.00(9)°].[24]

The coordination mode of the picolinato group in the title complex differs from that found in the $Mn(pic)(N_3)(H_2O)$ complex.[14] In the latter complex the picolinato anion chelates a metal atom via its ring nitrogen and a carboxylate oxygen to form a five-membered ring. The chelating carboxylate oxygen is further bridging another manganese(II) centre, giving rise to dimeric Mn_2O_2 units.[14] The type of bonding of the picolinate anion in the title complex, however, is similar to that observed in the structure of $[Mg(pic)_2(H_2O)_2]$.[9]

The room-temperature IR and Raman spectra of the crystalline picolinic acid, the sodium salt of the picolinic acid and the $[Mn(H\text{-}pic)(pic)Cl]_2$ complex are given together with tentative assignments of the bands in Table 3. The (N—Mn—N) bending, (Mn-pic) torsion and (Mn-pic) rocking vibrational modes are expected to be of lower energy and probably responsible for the complex group of bands between 30 and 180 cm^{-1}. Coupling of these modes with lattice vibrations and Mn_2Cl_2 deformations may also produce spectral features in this region.

In the high energy region hydrogen bonding involving the carboxylic acid group is considerable and causes very broad bands of the type (O—H···O) centred around 3400 cm^{-1}, which is observed in both the free acid as well as the solid complex, indicating the presence of the picolinic acid form (—COOH) in the complex. Hydrogen bonding of the type (O—H···N) is indicated in the free acid by the presence of broad, medium strong bands near 2565, 2150 and 2070 cm^{-1}.[25] These bands are completely absent in the spectra of the solid complex, as well as the corresponding salt, indicating that all nitrogen atoms are involved in the coordination with the central metal ion.[26]

The ν_{as}(—COOH) vibration frequencies of the free picolinic acid at 1719 s,br, 1655 m (IR)[27,28] and 1691 ms, 1655 vw (Raman) are shifted to lower frequencies at 1655 s, 1625 s (IR) for the sodium salt of picolinic acid. The solid complex shows a broad medium to strong band at 1713 cm^{-1}, a very strong band at 1636 cm^{-1} (IR) and a medium to strong band at 1638 cm^{-1} (Raman). This result suggests that the complex contains both coordinated picolinic acid and picolinate anion, since complexes containing only picolinate anions, and as shown in the sodium salt, do not show any absorption in the vicinity of 1700 cm^{-1}.[3,4] Compared with the sodium salt, the complex shows a slight increase of $\nu_{as}(—COO^-)$, 1636 vs (IR) and 1638 wm (Raman), and a decrease of $\nu_s(—COO^-)$, to 1355 s (IR) and 1388 m (Raman), which is indicative of bidentate coordination as was found for acetato complexes.[29,30]

It is noticeable that some bands of the free picolinic acid are broad, similar to those of the pyridine moiety, and not shifted. However, the bands related to the pyridine ring in the solid complex are shifted to higher frequencies, e.g. the ring breathing mode *ca* 1014 vs, 1018 vs (IR) and 1010 vs, 1020 vs (Raman), indicating also the presence of two different pyridine moieties. N,O-bidentate neutral picolinic acid exhibits the ν_{as}(—COOH) mode at a little higher wave number in the spectrum of the $[AuBr_4][K(H\text{-}pic)_2(H_2O)_2] \cdot (H\text{-}pic)_2$ complex[13] when compared with that of the free acid. Thus, while the above IR and Raman spectral results indicate the N,O-bidentate picolinato anion, it is not clear from ν_{as}(—COOH) that the H-pic molecule is linked via its carbonyl oxygen atom. However, as no bands in the range 1340–1310 cm^{-1} attributable to ν_s(—COOH) could be detected in the spectrum of the complex, one may suggest N,O-bidentate coordination for the neutral picolinic acid molecule in the title complex as well (cf. structural data).

In the far-IR region we tentatively assigned the medium strong bands at 376 (IR) and 335 cm^{-1} (Raman) as ν(Mn—O(pic)) and 230 vs (IR) and 240 w (Raman) to ν(Mn—N(pic)). According to the

Abstract—The structures of two triphenylphosphine rhodium(I) complexes with anthranilic and N-phenylanthranilic acid, which are active in hydrogenation of some alkenes, dienes, aromatic and heteroaromatic compounds, are described, together with some of their catalytic properties. A monomeric aminocarboxylate analogue of Wilkinson's catalyst is postulated for the anthranilate complex (**1**) and a dimeric structure with carboxylate bridges and two *cis*-triphenylphosphine molecules coordinated to each rhodium atom is proposed for N-phenylanthranilate (**2**). On treatment with hydrogen both complexes give *cis*-dihydrides, but variable temperature ^1H and ^{31}P NMR studies of the product derived from **1** reveal that a temperature-dependent equilibrium involving dissociation of PPh_3 occurs. Complexes **1** and **2** are stable under hydrogenation conditions and enable slow hydrogenation of 1-alkenes and cyclohexadienes. For cyclohexadienes some selectivity to cyclohexene formation is observed, especially in DMF. Although the activities of **1** and **2** towards the hydrogenation of arenes and heteroaromatics are generally very low, pyridine can be hydrogenated to piperidine to a substantial degree.

A rhodium complex of N-phenylanthranilic acid formulated as $[H\{Rh_2(PAA)_2Cl\}]$ (HPAA = N-phenylanthranilic acid) has been reported as one of a few homogeneous catalysts capable of arene hydrogenation.[1,2] Its structure as well as the structure of the other amino carboxylic acid complexes have not been fully elucidated. Khidekel[1] and co-workers suggest the existence of a rhodium to phenyl π-bond, apart from the bidentate O—C—O bond in the N-phenylanthranilato complex.[1,3]

Our previous studies revealed[4–6] that N-phenylanthranilate tends to form a bridging rather than a chelate linkage through the carboxylate anion, while the anthranilate (HAA = anthranilic acid) is liable to form monomeric structures with N—Rh—O bonds.[7–11]

The rhodium complexes with these two amino carboxylic acids and 1,5-COD (1,5-cyclooctadiene) described previously[7] turned out to be unstable under hydrogenation conditions. In this paper we report our structural and catalytic studies of the two anthranilato and N-phenylanthranilato complexes containing triphenylphosphines, i.e. ligands which are better than 1,5-COD at stabilizing the low oxidation state of the metal under a hydrogen atmosphere.

RESULTS AND DISCUSSION

Reaction of the green dirhodium cation Rh_2^{4+}, in a methanolic solution of triphenylphosphine,[12] with lithium or sodium anthranilate (NaAA) and

the reaction of sodium N-phenylanthranilate (NaPAA) with $[\{RhCl(PPh_3)_2\}_2]$,[13] respectively, give products of stoichiometry $[Rh(AA)(PPh_3)_3]$ and $[Rh(PAA)(PPh_3)_2]$, which have been characterized by spectral methods.

IR spectra

Table 1 shows the characteristic vibrational frequencies of the two complexes, as well as of sodium salts of the amino carboxylic acids.

The N—H stretching vibrations of the anthranilic acid complex (**1**) appear almost at the same frequencies as those of sodium anthralinate, suggesting that the amine nitrogen remains uncoordinated in the complex.[7] Instead of ν_{as} and $\nu_{s}(COO^{-})$ bands present in the spectrum of sodium anthranilate there are two new bands in the spectrum of the complex at 1635 and 1360 cm^{-1}. The increase observed for ν_{as}(COO) is characteristic of carboxylic acids coordinated through only one of the oxygen atoms.[7,14]

The N—H stretching vibrations in **2** (Table 1) are only slightly shifted when compared with those of the sodium N-phenylanthranilate, suggesting that the nitrogen is uncoordinated in the complex. The positions of $\nu_{as}(COO^{-})$ and $\nu_{s}(COO^{-})$, differing marginally as compared with those found for sodium N-phenylanthranilate, and $\Delta\nu$ = 235 cm^{-1} favour a bridging O—C—O coordination[7,15] between two rhodium atoms.

Vibrational spectra of the solutions of the complexes under a hydrogen atmosphere reveal solvent independent bands in the region associated with ν(Rh—H) at *ca* 2000 cm^{-1} (Table 2). After solvent evaporation in a stream of hydrogen a bright yellow or a white precipitate for **1** and **2**, respectively, has been obtained. The solids darken when exposed to air, but are stable enough for their IR spectra to be taken. The IR spectrum of **2** shows two absorptions in the solid state and a single, broad signal in solution, whereas generally two bands are present for **1** both in the solid state and in solution. An additional absorption at 825 cm^{-1}, assignable to δ(Rh—H), has been observed for **2**. No further new bands could be found in the 800–600 cm^{-1} region for complex **1** in the solid state and for **1** and **2** in solution after treatment with hydrogen.

Solution studies followed via ^1H *and* ^{31}P *NMR spectroscopies*

Room-temperature ^1H NMR spectra of both complexes in CD_2Cl_2 show broad multiplet resonances from the phenyl protons of the amino carboxylic acids and PPh_3 with shifts of around δ 7 ppm (Table 3). There is no evidence for π-bonding of the phenyl ring in **2**. The amine proton resonances are broadened and appear centred at δ *ca* 5 (**1**) and δ *ca* 9 (**2**). The relative intensities of the amine to aromatic protons suggest the composition of one anthranilate per three PPh_3 in **1** and one N-phenylanthranilate group per two triphenylphosphine groups in complex **2**.

At room temperature in benzene only broad resonances are observed in the ^{31}P NMR spectrum of **1**. The low-temperature (223 K) spectrum in CH_2Cl_2 shows a doublet of doublets at δ −33.1 [$J(RhP_A)$ = 152 Hz], assignable to two equivalent ^{31}P nuclei and a doublet of triplets at δ 50.6 [$J(RhP_B)$ = 176.7, $J(P_AP_B)$ = 4 Hz] due to the unique phosphorus nucleus *trans* to oxygen, consistent with the structure shown in Scheme 1. Such a structure has been reported for many similar complexes containing other carboxylate anions.[16,17] However, some irreversible decomposition appears to occur after warming the solution to room temperature, as evidenced by a signal from free PPh_3 at δ *ca* −4 ppm and by the appearance of some weak sharp lines in the ^{31}P NMR spectrum.

On reaction of **1** with hydrogen (1 mol per 1 mol of rhodium is absorbed) at room temperature at least two hydrido compounds are formed. In the ^{31}P NMR (at 223 K where the resolution is better) one compound shows (Table 4) a doublet of doublets (δ 39.8) that has been assigned to two *trans* phosphorus atoms and a doublet of triplets (δ 24) originating from the unique phosphorus atom coupled to the mutually *trans* triphenylphosphines. Such a spectrum along with the hydride region of the ^1H NMR spectrum [δH_A −6.61, δH_B −17.1, $J(P_BH_A)$ = 165 Hz] allows unambiguous assignment of the compound as configuration **B** (Scheme 1).

The other resonance (a doublet at *ca* 43 ppm) arises from a different compound (**C**), since its relative intensity varies for different solvents and at different temperatures. The stereochemistry for **C** (Scheme 1) is assigned on the basis of the ^{31}P chemical shift of the phosphorus atoms, which is similar to that of the mutually *trans* phosphorus atoms in **1**. The important finding is that the two compounds (**B** and **C**) are interconvertible. At low temperatures (223 K, d_8-toluene) only **B** is observed, whilst at high temperatures (323 K) there are only signals attributable to **C**. At intermediate temperatures **B**

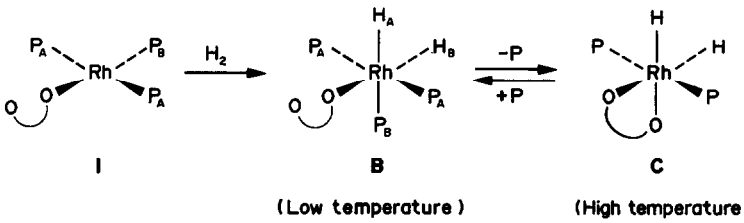

Scheme 1. Structure of **1** and the products of its reaction with hydrogen. P = PPh_3, O—O = anthranilato.

and **C** are observed in varying amounts (e.g. **B**/**C** ratio is *ca* 3.5 at 273 K in d_8-toluene), although some decomposition is observed after high temperature measurements.

The ^1H NMR spectrum of **C** consists of a doublet of triplets [δ −19.0 ppm, J(PH) = *ca* 17 Hz, J(RhH) = *ca* 22 Hz] and is changed into a doublet [J(RhH) = 21.8 Hz] on decoupling phosphorus.

These NMR spectral data indicate that under hydrogen at 243 K and above the new complex (**C**) is formed at the expense of **B**. Additionally, the existence of a coupling of rhodium to both dihydrides as well as to the two phosphorus atoms implies that a temperature dependent equilibrium between **B** and **C** occurs (Scheme 1).

Free triphenylphosphine is observed as a broad signal at δ −4 ppm at room temperature, but the breadth of the signal indicates that it is exchanging with compound **B** for which the signals are also broadened. Such an exchange is well established for the complex $[RhH_2Cl(PPh_3)_3]$, which has analogous stereochemistry.

It is very difficult to rationalize why no signal from free PPh_3 is observed at high temperature where compound **C** predominates, particularly as there does not appear to be exchange of the bound phosphines [J(RhP) is preserved], however, the stoichiometry of compounds **B** and **C** is certain since all the couplings have been confirmed by heteronuclear double resonance experiments. At 223 K the complex exists only in form **B**, hence no free phosphine is present in solution.

The ^{31}P NMR spectrum of **2** shows a doublet at δ 58.1 [J(RhP) = 200 Hz]. On the basis of this chemical shift, which is similar to that of the unique phosphorus atom in **1**, we assign this as arising from P *trans* to carboxylate and hence the compound must have two mutually *cis* phosphorus atoms.

We assumed the complex as a dimer (Scheme 2) on the basis of the known preference of N-phenylanthranilato anions for bridging rather than chelate binding to rhodium[4–6] and because monomeric *cis*-bis-triphenylphosphine complexes of rhodium(I) are unknown. On hydrogenation the phosphorus atoms remain equivalent (a doublet), but the resonance moves to higher fields (δ 42.1 ppm). The coupling constant also changes to a smaller value [J(RhP) = 119 Hz] that is consistent with a change of oxidation state from rhodium(I) to rhodium(III).[18,19] The proton NMR spectrum in C_6D_6 at 183 K shows a doublet of triplets [δ −20.4 ppm, J(PH) = 17.1 Hz, J(RhH) = 24.5 Hz].

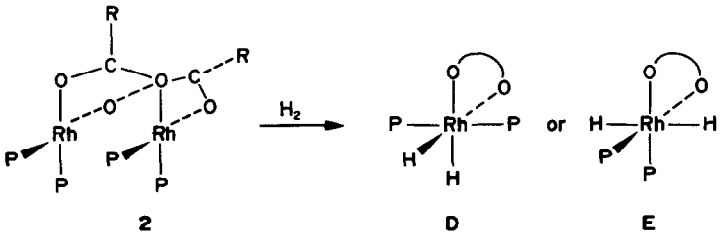
[e] In C_6D_6, 297 K.



Scheme 2. Structure of **2** and the possible products of its reaction with hydrogen. P = PPh_3, O—O = N-phenylanthranilato.

Based on the findings suggesting that both phosphorus atoms as well as both hydrides are equivalent one can put forward two possible structures for the hydrido species formed (Scheme 2).

Structure **D** seems to be more likely since it can be formed directly from **2** by hydrogen activation, while **E** requires a rearrangement. Moreover, the upfield shift of the phosphorus resonance would be much smaller for **E** than that observed (Table 4) since in the starting complex (**2**) and in **E** the phosphorus atoms are *trans* to oxygen atoms. Additional support for structure **D** is provided by the IR studies of **2** under hydrogen, which show two ν(Rh—H) in the isolated solid. The dihydrido complex is formulated as a monomer since a dimeric formation with mutually *trans*-PPh_3 groups on the rhodium atoms would place two PPh_3 groups on different rhodium atoms unacceptably close together.

Catalytic studies

The catalytic activities of both complexes were evaluated for hydrogenation reactions of unsaturated compounds under ambient conditions or under pressure (Table 5). Reaction rates, expressed as the number of catalytic cycles per rhodium h^{-1}, are low and do not exceed *ca* 12 for 1-alkenes up to C_{10}.

The two isomers of cyclohexadiene are hydrogenated with slower rates than 1-alkenes and the hydrogen consumption remains constant throughout the course of the reaction. The hydrogenation of cyclohexa-1,3-diene in toluene catalysed by **2** produces 2 : 1 cyclohexene : cyclohexane after 10 h, suggesting that a two-stage hydrogenation process is in operation. The reaction stops after *ca* 10% total conversion as an uncharacterized yellow solid precipitates.

Generally, complexes **1** and **2** show similar activities in hydrogenation reactions of cycloalkadienes after comparable reaction times, but the 1,3-isomer is reduced a little faster than the 1,4-isomer. A similar phenomenon has been observed in the hydrogenation of cyclohexadiene isomers in the presence of cationic complexes of rhodium(I).[20] That process was, however, accompanied by a large degree of isomerization of 1,4-cyclohexadiene to the 1,3-isomer. Such an isomerization has not been observed in our studies.

By carrying out the hydrogenation of cyclohexadienes in DMF the catalyst lifetime can be enhanced and the conversion increased. The reaction still occurs in two stages and selectivities up to 7 : 1 in favour of cyclohexene can be obtained at low conversion. Since the substrate is not completely soluble in DMF, the reason for such a product composition may not be purely kinetic. It may depend on diffusion processes between DMF soluble and DMF insoluble layers.

Hydrogenation of mono- and bicyclic arenes and nitrogen containing heteroaromatics is generally ineffective with conversions below 3% being observed both at ambient conditions and under elevated pressure. However, pyridine, which normally inhibits hydrogenation by Wilkinson's catalyst, can be hydrogenated to piperidine in reasonable yield. This is a most unusual specificity and suggests that decomposition to rhodium metal is not responsible for the hydrogenation. In experiments performed under elevated pressure using neat benzene a pale yellow precipitate soluble in polar solvents was found when **1** was used. No such effects were observed for pyridine. Both bicyclic substrates naphthalene and quinoline are not susceptible to hydrogenation at ambient conditions, but naphthalene shows low conversion, at elevated pressure in acetone, to decalins in the presence of **1** or to a mixture of tetralin and decalins when **2** is used.

EXPERIMENTAL

Apparatus

Elemental analyses were performed by the Research Centre of Molecular and Macromolecular Studies, Polish Academy of Sciences, Lodz. Melting points were evaluated on an Electrothermal melting point apparatus in capilliary tubes sealed under

vacuum and are uncorrected. IR absorption spectra in Nujol and Voltalef 3S oil were recorded on a Specord 71 IR spectrophotometer. ^1H and ^{31}P NMR spectra were acquired on a Bruker WM 250 spectrometer (University of Liverpool) operating in the Fourier-transform mode with proton noise decoupling (^{31}P). GC analyses of napthalene and the products of its hydrogenation were performed on a Chrom-4 apparatus using a steel column (3 m × 3 mm) packed with EGA (10%) on Chromosorb W (80–100 mesh). The other GC analyses were performed as described previously.[6]

Materials

Analytical grade reagents and solvents were used throughout. $RhCl_3 \cdot 3H_2O$ (40% rhodium) was purchased from Fluka AG, N-phenylanthranilic acid from Loba and anthranilic acid from POCH. DMF was freshly distilled and dried over molecular sieves. Toluene and benzene were dried over sodium and distilled under argon. Triphenylphosphine and naphthalene were recrystallized from ethyl alcohol. Solvents and reagents were degassed prior to use and reactions as well as other operations were performed under oxygen-free (BTS catalyst) argon or hydrogen using standard Schlenk-line and catheter-tubing techniques.

Preparation of the complexes

Preparation of the anthranilato complex was based on the techniques described by Mitchell *et al.*[21] for a range of carboxylate analogues of Wilkinson's catalyst.

Anthranilato-O-tris(triphenylphosphine)rhodium(I), $[Rh\{O_2C(C_6H_4)NH_2\}(PPh_3)_3]$ (**1**). To a solution of PPh_3 (0.5 g, 1.9 mmol) in methanol (50 cm^3) was added a green methanol solution of Rh_2^{4+}[12] (10 cm^3, *ca* 0.2 mmol of rhodium), followed by an excess of a methanolic solution (20 cm^3) of lithium anthranilate (0.86 g, 6 mmol). The resulting orange–red solution was boiled for *ca* 20 min and filtered hot. On cooling the orange–yellow crystals were collected, washed with methanol and vacuum dried (yield 0.16 g, 80%). Found: C, 70.8; H, 5.2; N, 1.3; P, 8.6; Rh, 10.1. Calc. for $RhC_{61}H_{51}NO_2P_3$: C, 71.3; H, 5.0; N, 1.4; P, 9.1; Rh, 10.0%. This compound always crystallizes in two forms; the major one gives orange needles, m.p. 135–138°C (decomposition), whilst the minor one forms yellow rhombs, m.p. 192–196°C (decomposition).

Di-μ-N-phenylanthranilato-O,O′-tetrakis(triphenylphosphine)dirhodium(I), $[Rh_2\{O_2C(C_6H_4)NH(C_6H_5)\}_2(PPh_3)_4]$ (**2**). A mixture of $[\{RhCl(PPh_3)_2\}_2]$[13] (0.33 g, 0.25 mmol) and sodium N-phenylanthranilate (0.18 g, 0.75 mmol) was heated under reflux in THF (20 cm^3) for 4 h. After cooling a red solution was decanted and the solvent evaporated under vacuum. The resulting red precipitate was washed thoroughly with water, vacuum dried at *ca* 40°C and dissolved in acetone (12 cm^3). The red solution was filtered promptly and left overnight at room temperature. The reddish-brown (terracotta) crystals were collected and washed with cold (0°C) acetone before drying *in vacuo* (yield 0.19 g, 45%); m.p. 180°C (darkens), 192–197°C (melts). Found: C, 69.5; H, 4.9; N, 1.7; P, 7.1; Rh, 11.9 ± 0.6. Calc. for $Rh_2C_{98}H_{80}N_2O_4P_4$: C, 70.0; H, 4.8; N, 1.7; P, 7.4; Rh, 12.2%.

Hydrogenation apparatus and procedure

Apparatus. Hydrogenations under atmospheric pressure were performed in a glass reactor (500 cm^3) fitted with a reflux condenser, a set of stopcocks to allow inlet and outlet of gases and introduction of reagents and a mercury burette for pressure equilibration. Intensive agitation was ensured by means of a magnetic stirrer. A catalyst was placed in a teflon bucket and suspended inside the reactor over the surface of a solvent and could be brought into contact with the solvent on turning the arm on which it was hanging.

Reactions under elevated pressure were performed in an apparatus consisting of a stainless reactor (250 cm^3) equipped with a glass vessel (*ca* 70 cm^3) closed with a stopper containing a capilliary orifice for pressure equilibration, a set of stopcocks to allow inlet and outlet of gases and a magnetic stirrer ensuring effective agitation.

Procedure. Hydrogenations under ambient conditions. To a reactor containing the solvent, degassed prior to its saturation with hydrogen, a catalyst was introduced and agitation ensured. After *ca* 15 min of exposure to hydrogen the degassed substrate was added. The amount of hydrogen consumed during the course of the reaction was estimated from the pressure drop in the closed reactor–burette system.

Hydrogenations under elevated pressure. To a glass vessel filled with hydrogen and containing a catalyst, a solvent saturated with hydrogen was introduced. After the catalyst was dissolved a degassed substrate was added. The vessel was closed with the stopper containing a capillary orifice and installed inside the reactor filled with hydrogen. The reactor was then flushed with hydrogen and after setting up a required pressure magnetic stirring was ensured. Conversions were measured using GC analysis of the product solution.

(*Received* 3 *March* 1993; *accepted* 30 *March* 1993)

Abstract—The reactions of some dicyanophosphines, $RP(CN)_2$ (R = Me, Et or Ph), with phosphites have been investigated in solution by means of ^{31}P NMR spectroscopy. In each instance a new P—P coupled compound was obtained, with no indication of organocyanophosphide ion, $RP(CN)^-$, formation, even when $NaPO(OEt)_2$ was used.

Although dicyanophosphines, $RP(CN)_2$, are well-established compounds, their reactions with phosphites have not been investigated. Schmidpeter and Zwaschka have shown that phosphorus tricyanide, $P(CN)_3$, reacts with $NaPO(OR)_2$ (R = Me or Et) and with $HPO(OR)_2$ in the presence of Et_3N to form salts of the dicyanophosphide ion,[1,2] eqs (1) and (2).

$$P(CN)_3 + NaPO(OR)_2 \longrightarrow Na^+P(CN)_2^- + NCPO(OR)_2 \quad (1)$$

$$P(CN)_3 + HPO(OR)_2 + Et_3N \longrightarrow Et_3NH^+P(CN)_2^- + NCPO(OR)_2 \quad (2)$$

(R = Me or Et)

The products were unstable in solution, but the anion could be stabilized as its [18]-crown-6 sodium derivative,[1] the crystal structure of which was subsequently determined.[2] In the absence of triethylamine, however, $P(CN)_3$ reacted with $HPO(OEt)_2$ to give a compound with a P—P bond, δ ^{31}P P_A-14, P_B-121 ppm, $^1J(PP)$ = 88 Hz [eq. (3)].

$$P(CN)_3 + HPO(OEt)_2 \longrightarrow HCN + (NC)_2P_BP_AO(OEt)_2 \quad (3)$$

The dicyanophosphide ion can also be prepared by reaction of $P(CN)_3$ with cyanide ions, when the initially formed phosphoranide $P(CN)_4^-$ loses cyanogen, eq. (4).[3,4]

$$P(CN)_3 + CN^- \longrightarrow [P(CN)_4]^- \longrightarrow P(CN)_2^- + (CN)_2 \quad (4)$$

We have shown that cyanide ions react with dicyanophosphides, $RP(CN)_2$ (R = Me, Et or Ph), leading to the formation of organocyanophosphide(I) ions by a similar pathway.[5] It was, therefore, of considerable interest to study the reactions of some dicyanophosphines with phosphites.

RESULTS AND DISCUSSION

In contrast with the behaviour of $P(CN)_3$ mentioned above, $MeP(CN)_2$ reacted in acetonitrile solution with $NaPO(OEt)_2$ yielding a P—P bonded compound **I**, to which the structure $Me(NC)P_BP_AO(OEt)_2$ may be attributed, eq. (5). (The ^{31}P NMR parameters for the new phosphorus compounds prepared in this work are given in Table 1.)

$$MeP(CN)_2 + NaPO(OEt)_2 \longrightarrow NaCN + Me(NC)P_BP_AO(OEt)_2 \quad (5)$$

I

Table 1. δ ^{31}P (ppm) for the new P—P bonded compounds I–IV

Compound	δ ^{31}P (P_A)	δ ^{31}P (P_B)	^1J(PP) (Hz)	Solvent
I	26.6	−90.3	119	MeCN
II	30.9(±0.7)	−91.7(±0.6)	126(±10)	CH_2Cl_2
III	27.5	−77.5	158	CCl_4
IV	25.1	−76.6	117	CCl_4

All ^{31}P resonances are doublets.

This reaction parallels that reported for $P(CN)_3$ with $HPO(OEt)_2$ in the absence of base.[1]

A similar result was obtained for $MeP(CN)_2$ and $HPO(OMe)_2$ in CH_2Cl_2 solution. When a solution of the phosphite in this solvent was treated with $MeP(CN)_2$ two new doublets were seen in the ^{31}P spectrum (Table 1), as well as a doublet at 11.3 ppm, $^1J(PH) = 707$ Hz, from unreacted phosphite.[6] The phosphite doublet disappeared after the addition of more $MeP(CN)_2$, but the two new doublets were still present, together with a resonance at −81.5 ppm from excess $MeP(CN)_2$.[7] The reaction thus follows eq. (6), with the product **II** apparently stable in the presence of either excess phosphite or excess $MeP(CN)_2$.

$$MeP(CN)_2 + HPO(OMe)_2 \longrightarrow HCN + Me(NC)P_BP_AO(OMe)_2 \quad (6)$$

II

There was no evidence for formation of a cyanophosphide ion in either case.

Interestingly, $EtP(CN)_2$ did not react with $HPO(OMe)_2$ in CH_2Cl_2 solution, but yielded the analogous P—P bonded compound **III** in CCl_4 as the solvent.

$$EtP(CN)_2 + HPO(OMe)_2 \longrightarrow HCN + Et(NC)P_BP_AO(OMe)_2 \quad (7)$$

III

Similar behaviour was observed for $PhP(CN)_2$. No reaction was apparent with $HPO(OMe)_2$ in CH_2Cl_2, but the coupled compound **IV** was detected in CCl_4.

$$PhP(CN)_2 + HPO(OMe)_2 \longrightarrow HCN + Ph(NC)P_BP_AO(OMe)_2 \quad (8)$$

IV

We thus conclude that the dicyanophosphines react with either $NaPO(OEt)_2$ or $HPO(OMe)_2$ with the elimination of NaCN or HCN, respectively, and the formation of P—P coupled species, as clearly shown by ^{31}P NMR evidence. The main difference from the previously reported[1] reactions of $P(CN)_3$ with phosphites arises in the interaction of $MeP(CN)_2$ with $NaPO(OEt)_2$, where there was no indication of the presence of the $MeP(CN)^-$ ion[5] and the P—P derivative appeared to be stable in solution. The choice of solvent also seems to be critical for larger R groups in $RP(CN)_2$, with CCl_4 superior to CH_2Cl_2 in promoting reaction, although the reason for this behaviour was not readily apparent. The $P(CN)_2^-$ ion is likely to be appreciably more stable than $RP(CN)^-$, so the non-observation of the latter in these reactions is not surprising.

EXPERIMENTAL

All manipulations, including NMR sample preparation, were performed either *in vacuo* or under dry nitrogen. The dicyanophosphines were prepared as reported in a previous publication.[7] Sodium diethylphosphite, $NaPO(OEt)_2$, was synthesized by the method of Pudovik and Arbuzov.[8]

^{31}P NMR spectra were recorded at 307.2 K relative to external 85% H_3PO_4, as described previously,[7,9] with the higher frequency (lower field) direction taken as positive.

SYNTHESIS AND REACTIVITY OF TECHNETIUM(VII) IMIDO COMPLEXES

JEFFREY C. BRYAN,* ANTHONY K. BURRELL, MARY M. MILLER, WAYNE H. SMITH, CAROL J. BURNS and ALFRED P. SATTELBERGER

Los Alamos National Laboratory, Los Alamos, New Mexico 87545, U.S.A.

(*Received* 2 *January* 1993; *accepted* 30 *March* 1993)

Abstract—The synthesis, characterization and electrochemistry of a series of new technetium complexes, $Tc(NAr)_3X$ and $Tc(NAr')_3X$ ($X = OSiMe_3$, alkyl, I)†, is reported. These complexes are shown to be resistant to reduction and moderately air-sensitive. The siloxy complex $Tc(NAr)_3(OSiMe_3)$ (**1a**) reacts with fluoride ion to give the tris(imido)oxo anion $[TcO(NAr)_3]^-$. Less sterically hindered $M(NAr')_3(OSiMe_3)$ complexes react with Ar'NCO in a net [2+2] fashion to give the urylene complexes $M(NAr')_2(NAr'C(O)NAr')(OSiMe_3)$ (**2a**, M = Tc; **2b**, M = Re). The X-ray crystal structures of **1a**, **2b** and $Tc(NAr)_3I$ (**4a**) suggest that the imido ligands moderate their level of electron donation to reflect the electronic requirements of the metal and the ancillary ligands.

The coordination of multiple π-donors to a metal centre (π-loading) can result in increased stabilization of high-valent metal centres and/or in increased nucleophilicity of relatively inert ligands such as oxo (O^{2-}) or imido (RN^{2-}).[1,2] Technetium(VII) complexes are relatively rare, usually requiring stabilization by highly electronegative oxo, fluoride or chloride ligands, and are typically very sensitive to moist air and unstable towards reduction.[3] We set out to prepare new, stable technetium(VII) complexes using imido ligands. Rhenium complexes containing the imido (NR^{2-}) ligand are known for a variety of oxidation states and coordination numbers,[1,4–6] while technetium imido complexes have only recently been reported.[7] This paper describes the preparation of a series of new technetium(VII) imido complexes that are only slightly air-sensitive and remarkably stable towards reduction. Some of these complexes have been previously communicated.[8]

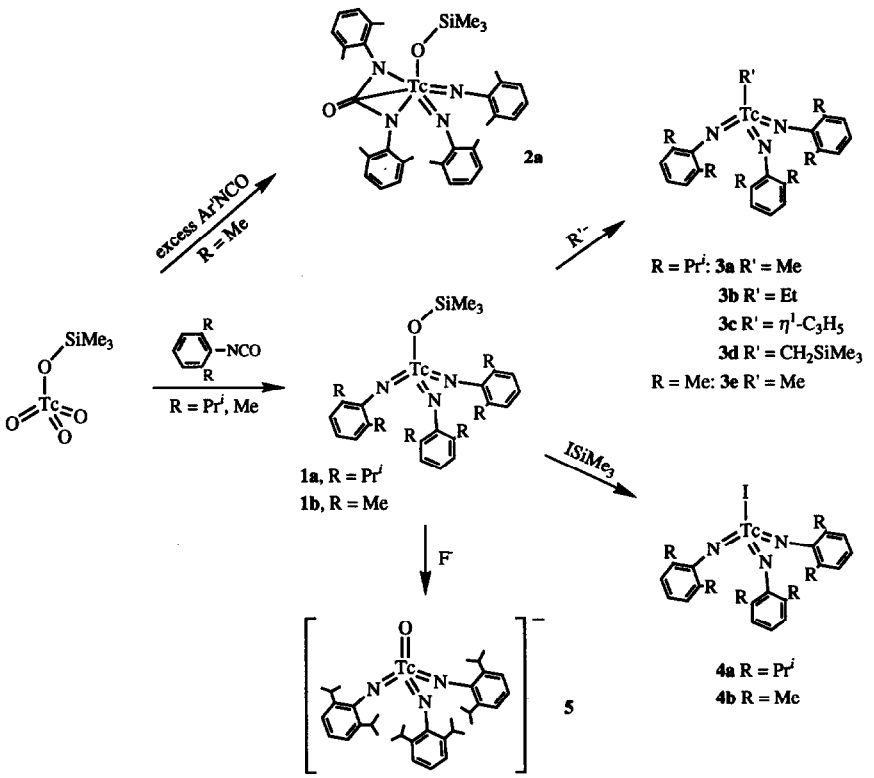
† Abbreviations: Ar = 2,6-diisopropylphenyl; Ar' = 2,6-dimethylphenyl; PPN^+ = bis(triphenylphosphine) *iminium*.

RESULTS

Synthesis

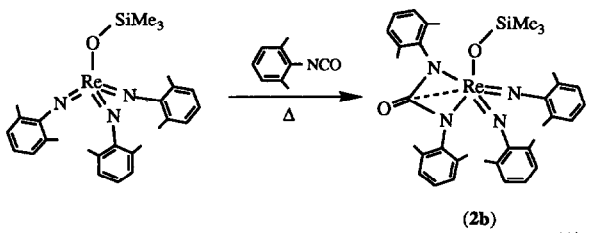
When a hexamethyldisiloxane solution of $TcO_3(OSiMe_3)$[9] is treated with 3 equivalents of 2,6-diisopropylphenylisocyanate at 100°C for 18 h deep green $Tc(NAr)_3(OSiMe_3)$ (**1a**, Ar = 2,6-diisopropylphenyl) is formed (Scheme 1). Similar reactivity is observed for 2,6-dimethylphenylisocyanate and $TcO_3(OSiMe_3)$, forming $Tc(NAr')_3(OSiMe_3)$ (**1b**, Ar' = 2,6-dimethylphenyl),[10] although the reaction temperature must be lowered to 60°C and the reaction time shortened to 6 h. This prevents formation and subsequent thermal decomposition of the urylene complex $Tc(NAr')_2(NAr'C(O)NAr')(OSiMe_3)$ (**2a**, described below). Complex reactivity, involving the loss of $SiMe_3$, is observed when the less sterically hindered *p*-tolylisocyanate reacts with $TcO_3(OSiMe_3)$ under similar conditions. The latter result suggests that steric bulk about nitrogen is critical to the success of this reaction.

Preparations of **1b** can be complicated by the formation of the urylene complex $Tc(NAr')_2(NAr'C(O)NAr')(OSiMe_3)$ (**2a**). This complex most likely arises from the net [2+2] addition of the C=N bond of Ar'NCO with a Tc=N bond of **1b**. Similar [2+2] additions between imido ligands



Scheme 1.

and isocyanates have recently been reported.[6,11] Formation of the urylene complex **2a** can be minimized by careful control of the relative amounts of reactants, temperature and time of reaction. Complex **2a** can be prepared in reasonable yield by heating an excess of Ar'NCO with $TcO_3(OSiMe_3)$ to 80°C in hexamethyldisiloxane solvent overnight. The rhenium analogue of **2a**, $Re(NAr')_2(NAr'C(O)NAr')(OSiMe_3)$ (**2b**), can be prepared by heating $Re(NAr')_3(OSiMe_3)$[5] and an excess of Ar'NCO in hexamethyldisiloxane solvent to 120°C for 15 h [eq. (1)].



(1)

The bulkier tris(2,6-diisopropylphenylimido) complexes **1a** and $Re(NAr)_3(OSiMe_3)$[5] are not observed to react with excess ArNCO to form urylene complexes analogous to **2a** and **2b**.

The trimethylsiloxy ($^-OSiMe_3$) ligand in **1a, b** is readily substituted (Scheme 1). THF solutions of $Tc(NAr)_3(OSiMe_3)$ (**1a**) react quickly at room temperature with Grignard reagents to form deep blue–green $Tc(NAr)_3R$ (**3a–c**, R = Me, Et, η^1-allyl) and with $LiCH_2SiMe_3$ to form $Tc(NAr)_3(CH_2SiMe_3)$ (**3d**). Similarly, $Tc(NAr')_3(OSiMe_3)$ (**1b**) reacts with methyl Grignard in THF to form $Tc(NAr')_3Me$ (**3e**). Complexes **1a** and **1b** also react with trimethylsilyliodide in toluene forming $Tc(NAr)_3I$ (**4a**)[8c] and $Tc(NAr')_3I$ (**4b**), respectively. When this reaction is performed in a sealed NMR tube 1 equivalent of hexamethyldisiloxane is the only other observed product.

The trimethylsilyl group can be selectively removed from the trimethylsiloxy ligand in **1a** by fluoride ions (Scheme 1). A methylene chloride solution of **1a** reacts with [PPN]F [$PPN^+ = (Ph_3P)_2N^+$] to form the tris(imido)oxo anion $[TcO(NAr)_3]^-$ (**5**).[12] Complex **5** is a tris(imido) analogue of pertechnetate and is also formed, albeit in lower yields, when **1a** is treated with $^-OSiMe_3$.

Characterization

Complexes **1–5** have been characterized by NMR and combustion analysis. Additionally, complexes **1, 2b** and **3a–c** have been characterized by UV–vis and complexes **1b, 2** and **5** by IR. Generally, NMR spectra show a single set of resonances for the terminal imido ligands at room temperature, indi-

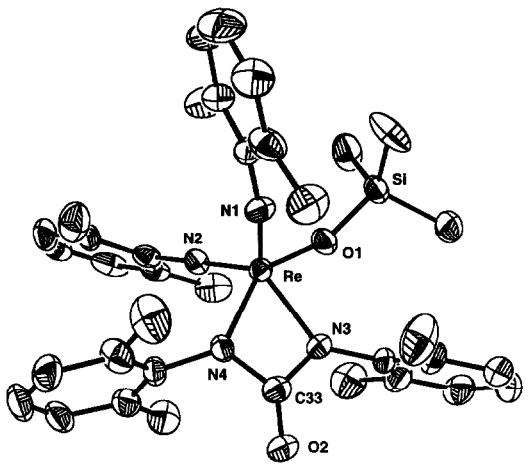

Fig. 2. ORTEP representation of $Re(NAr')_2(NAr'C(O)NAr')(OSiMe_3)$ (**2b**, Ar′ = 2,6-dimethylphenyl) with hydrogen atoms omitted. Selected bond distances (Å) and angles (°) not already presented in Table 1: Re—N(3) 2.035(7), Re—N(4) 2.052(7), Re···C(33), 2.627(9), O(1)—Re—N(1) 100.8(3), O(1)—Re—N(2) 100.2(3), O(1)—Re—N(3) 84.0(3), O(1)—Re—N(4) 146.0(3), N(1)—Re—N(2) 110.3(3), N(1)—Re—N(3) 119.6(3), N(1)—Re—N(4) 102.4(3), N(2)—Re—N(3) 128.1(3), N(2)—Re—N(4) 94.6(3), N(3)—Re—N(4) 63.0(3).

cating free rotation about the N—C bonds. The urylene complexes **2** exhibit three resonances in a 2:2:4 ratio attributable to CH_3 on the 2,6-dimethylphenyl groups. The largest of these three resonances can be assigned to the terminal imido ligands and the smaller two to the methyls on each of the Ar′ groups of the urylene ligand. This assumes free rotation about all N—C bonds, symmetry-related terminal imido groups and inequivalent environments for the 2,6-dimethylphenyl groups on the urylene ligand. This is consistent with the solid state structure (described below, see Fig. 2) determined for **2b**, where a mirror plane relates the two imido ligands and one urylene Ar′ is *cis* to the siloxy ligand and the other *trans*. The urylene carbonyl functionality is observed in the IR at 1676 and 1696 cm^{-1} and in the $^{13}C\{^1H\}$ NMR at δ 165.8 and 161.6 ppm for **2a** and **2b**, respectively. These values are comparable to known urylene complexes.[6,11] NMR spectra of $Tc(NAr)_3(C_3H_5)$ (**3c**) indicate that the allyl ligand is σ-bound to technetium in an η^1 fashion, as observed for a related rhenium complex, $Re(NBu^t)_3(C_3H_5)$,[6] and for the cyclopentadienyl ligand in $CpTc(NAr)_3$.[8b]

Complexes **1a**, **2b** and **4a** have been characterized by X-ray crystallography. The structures are shown in Figs 1–3, as are selected bond distances and angles specific to an individual structure. Additional bond distances and angles are presented in Table 1. The coordination geometry about the metal is approximately tetrahedral in all three complexes, assuming the urylene ligand in **2b** occupies one coordination site. Alternatively, the urylene complex **2b** could be described as a distorted square-based pyramid, where N(1) occupies the apex. All three structures exhibit short M—N bond lengths and large M—N—C angles for the terminal imido ligands, indicating considerable multiple bond character.[1] Similarly the M—O bond lengths and the M—O—Si angles in **1a** and **2b** suggest that there may be multiple bond character to the trimethylsiloxy ligand. In general, the bond distances and angles in **1a** and **4a** are similar to those observed for related $M(NR)_3X$ (X = monoanionic ligand) complexes.[2a,8b,13]

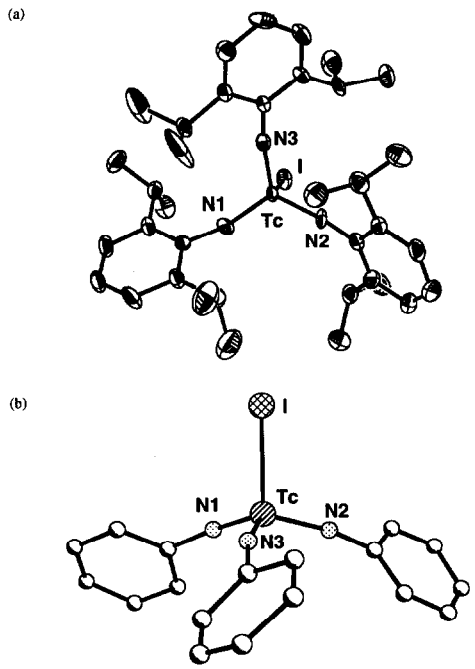

Fig. 3. Representations of $Tc(N\text{-}2,6\text{-}Pr^i_2C_6H_3)_3I$ (**4a**). (a) 40% thermal ellipsoids with hydrogen atoms omitted. (b) Ball and stick diagram with hydrogen atoms and isopropyl groups omitted. Selected bond distance (Å) and angles (°) not already presented in Table 1: Tc—I 2.654(1), I—Tc—N(1) 107.5(2), I—Tc—N(2) 105.7(2), I—Tc—N(3) 105.0(2), N(1)—Tc—N(2) 114.3(3), N(1)—Tc—N(3) 111.4(3), N(2)—Tc—N(3) 112.2(3).

The UV–vis spectra of these complexes exhibit very intense absorptions. Since these are d^0 complexes it is assumed that ligand-to-metal charge transfer is responsible for the observed transitions. The lowest energy absorption in the spectrum (200–800 nm) for $Tc(NAr)_3(OSiMe_3)$ (**1a**) is red shifted by 120 cm^{-1} relative to the same feature observed in the spectrum for $Re(NAr)_3(OSiMe_3)$. Such a shift

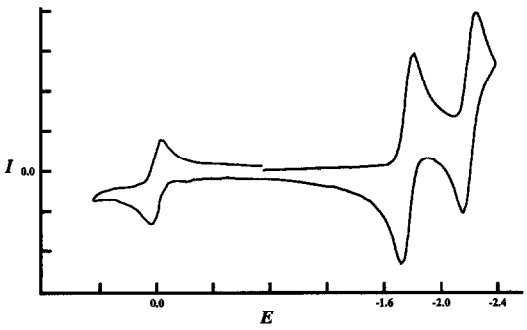

Fig. 4. Cyclic voltammogram showing reversible reductions of $Tc(NAr)_3(OSiMe_3)$ (**1a**, −1.77 V) and $Re(NAr)_3(OSiMe_3)$ (−2.21 V) and the Cp_2Fe/Cp_2Fe^+ couple as a reference (0.0 V).

is expected since the empty technetium-based 4*d* orbitals should be lower in energy, and therefore closer in energy to the filled ligand-based orbitals, than the analogous rhenium-based 5*d* orbitals.

Electrochemistry

Reductions of the d^0 complexes **1**, **3a**, **4a** and **5** were explored by cyclic voltammetry. Results are presented in Table 2. The tris(imido) complexes **1** and **3a** exhibit only a single reversible reduction up to −2.5 V. When scanned beyond this value additional features (irreversible reductions and oxidations) are observed in the voltammogram and the reversibility of the original reduction becomes questionable. As expected,[3a] the rhenium complex $Re(NAr)_3(OSiMe_3)$ is more difficult (440 mV) to reduce than its technetium analogue **1a** (Fig. 4). The tris(imido)iodide complex **4a** exhibits an irreversible reduction wave at −1.62 V when scanned at 0.20 V s^{-1}, which becomes reversible at higher scan rates (see Table 3). The chemical reduction of **4a** has been previously communicated.[8c] Additional details of

the chemical and electrochemical reductions of **4a** will be the subject of a future publication. The tris (imido)oxo anion **5** is the most difficult to reduce of all the complexes reported here, exhibiting an irreversible reduction wave at −2.51 V. Since complexes **1a**, **3a**, **4a** and **5** all contain the $[Tc(NAr)_3]^+$ fragment and differ only in the identity of the final ligand, an arrangement of these complexes by ease of reduction should reflect the relative donor ability of the unique ligand:

$$I^-, \mathbf{4a} > {}^-OSiMe_3, \mathbf{1a} > Me^-, \mathbf{3a} > O^{2-}, \mathbf{5}$$

$$\longleftarrow \text{ease of reduction}$$

Finally, it is more difficult to reduce **1a** than **1b**, which may indicate that 2,6-diisopropylphenylimido is a better donor than 2,6-dimethylphenylimido.

DISCUSSION

The complexes reported here contain several strong π-donor ligands, as such they are heavily "π-loaded". As a result of the competition between the strong π-donor ligands the imido ligands in these complexes are best represented by resonance structure **I**:

I II

where the metal–nitrogen bond order is lowered, bending at nitrogen *may* be observed and electron density is displaced from the metal–nitrogen bond to the nitrogen atom making the imido ligand more nucleophilic at nitrogen.[1,2]

The effects of π-loading can be observed in the structures of **1a** and **4a**. Terminal imido ligands can generally be expected to be linear at nitrogen when they are able to donate both pairs of p-π electrons. All the Tc—N—C angles in complexes **1a** ($\angle$Tc—N—C_{av} = 155.8°) and **4a** ($\angle$Tc—N—C_{av} = 166.6°) are bent significantly from 180°, falling within the range often observed for complexes with multiple π-donors.[1,2a,8b,13] The iodo complex (**4a**) is closer to being linear at nitrogen than the siloxy complex (**1a**), and while **1a** is very close to tetrahedral about technetium **4a** is distorted towards a trigonal-based pyramid where the iodide occupies the apex. These differences are probably due to the greater electronic dominance of the imido ligands in **4a**, where there is less competition from the more weakly donating I^-. Similar comparison of the structures for **1a** and **2b** ($\angle$Tc—N—C_{av} = 170.6°) suggests that replacement of an imido with a urylene ligand allows the remaining imido ligands to donate more strongly. These three structures suggest that the imido ligands moderate their donor ability depending on donor strength of the other ligands.

π-loading can also be used to rationalize some of the reactivity reported here. Extra electron density at the imido nitrogen is observed in the formation of the urylene complexes **2**, if the reaction is viewed as nucleophilic attack by an imido nitrogen on the isocyanate carbon.[11a,14] Subsequent reaction of the remaining imido ligands in **2** with isocyanate, forming additional urylene ligands, is probably inhibited because the imido ligands in **2** have less competition for π-electron density, are able to donate to technetium more strongly and are, therefore, less nucleophilic at nitrogen.[11a] Since the trimethylsiloxy ligand in complexes **1** is a good π-donor on a π-loaded complex, it may also exhibit nucleophilic character at oxygen. This is observed in the reactions of Me_3SiI with complexes **1**, which can be thought of as electrophilic attack of Me_3Si^+ at the siloxy oxygen.

The tris(imido) fragment "$[Tc(NAr)_3]^+$" imparts a high degree of stability to the normally oxidizing Tc^{VII} centre. For instance, electrochemical studies on the tris(imido) complexes demonstrate that they are difficult to reduce. Additionally, the tris(imido)siloxy (**1**) and tris(imido)alkyl (**3**) complexes are stable to air as solids for extended periods. Complex **1a** decomposes in solutions exposed to air over 2–3 days. $Tc(NAr)_3(CH_2SiMe_3)$ (**3d**) is stable to 1 equivalent of water in Et_2O solution at room temperature for 18 h! The tris(imido)technetium fragment is even capable of stabilizing iodide, a ligand that is quite susceptible to oxidation.[15] In fact, complexes **4** are the first examples of technetium(VII) iodide complexes.[16] $Tc(NAr)_3I$ (**4a**) is also stable to moist air in solution for short periods. All of this contrasts strongly with known oxotechnetium(VII) complexes, which are generally more sensitive to moist air and unstable towards reduction.[3]

EXPERIMENTAL

General considerations

CAUTION! ^{99}Tc is a weak β^--emitter (E = 0.3 MeV, $t_{1/2} = 2.12 \times 10^5$ years). All experiments are performed in designated laboratories approved for low-level radioactive materials following procedures and techniques described below and elsewhere.[17] All manipulations were performed in a helium atmosphere dry-box equipped with a freezer (−40°C) or in a well-ventilated fume hood with the appropriate secondary containment. Personnel are trained in the safe handling of radioactive materials, use beta–gamma counters to detect areas of contamination and wear protective lab. coats, approved safety glasses and disposable gloves at all times. Every reasonable effort was made to recover ^{99}Tc from reaction residues. Radioactive wastes were disposed of in appropriate containers.

Toluene, hexane, THF, diethyl ether, hexamethyldisiloxane and dimethoxyethane were distilled under nitrogen from sodium or sodium/potassium alloy and methylene chloride from phosphorous pentoxide. Ammonium pertechnetate was obtained from Oak Ridge National Laboratory and was purified as described previously.[18] $[(Ph_3P)_2N]F$,[19] $Tc(O)_3(OSiMe_3)$,[9] $Re(NAr')_3(OSiMe_3)$[5] and **4a**[8c] were prepared following published procedures. Arylisocyanates and $ISiMe_3$ (Aldrich) were distilled and stored in a dry-box prior to use. Alkylating reagents were used as supplied from Aldrich.

NMR spectra were recorded in C_6D_6 on an IBM AF-250 or a Bruker WM-300 spectrometer, referenced to solvent unless otherwise noted and reported below as chemical shift in δ (multiplicity, integral, coupling constant in Hz, assignment). IR spectra were obtained as Nujol mulls using a Per-

kin–Elmer 1500 or a Bio–Rad FTS-40 spectrometer and are reported in cm^{-1}. Elemental analyses were obtained on a Perkin–Elmer 2400 analyser. UV–vis spectra were recorded on a Hewlett–Packard 8450A spectrophotometer and are reported as λ_{max} (ε) unless otherwise noted. Cyclic voltammograms were measured with a Princeton Applied Research Model 273 electrochemistry system using a platinum disk working electrode (BAS Model MF2013), a platinum wire counter electrode and a silver wire quasi-reference electrode separated from the bulk solution via a fine porosity glass frit. Test solutions were approximately 2 mM of the measured compound with approximately 0.1 M of $[Bu^n_4N]BF_4$ (anhydrous and recrystallized) as the supporting electrolyte in THF. The scan rate was 0.2 V s^{-1} unless otherwise noted. Potentials are quoted relative to the ferrocene/ferrocenium redox couple used as an internal reference standard.

$Tc(NAr)_3(OSiMe_3)$ (**1a**)

A solution of $TcO_3(OSiMe_3)$ (0.50 g, 2.1 mmol) and ArNCO (1.28 g, 6.3 mmol) in hexamethyldisiloxane (12 cm^3) was stirred at 110°C under argon for 21 h. The reaction mixture was concentrated to 5 cm^3 and cooled to −40°C. The resulting solids were filtered, washed with cold hexamethyldisiloxane (3 × 2 cm^3) and dried *in vacuo*, yielding 0.88 g (60%) of deep green **1a**. ^1H NMR: 7.00 (m, 9, Ar), 3.50 (sept, 6, $J = 6.8$, $CHMe_2$), 1.10 (d, 36, $J = 6.8$, $CHCH_3$), 0.45 (s, 9, $SiCH_3$). $^{13}C\{^1H\}$ NMR: 139.5 (Ar), 126.9 (Ar), 122.7 (Ar), 29.1 ($CHMe_2$), 23.7 ($CHCH_3$), 2.6 ($SiCH_3$). Found: C, 65.8; H, 8.3; N, 5.9. Calc. for $C_{39}H_{60}N_3OSiTc$: C, 65.6; H, 8.4; N, 5.9%. UV–vis (nm): 277 (30,000), 319 (35,000), 588 (4500).

$Tc(NAr')_3(OSiMe_3)$ (**1b**)

A solution of $TcO_3(OSiMe_3)$ (0.24 g, 1.0 mmol) and Ar'NCO (0.45 g, 3.1 mmol) in hexamethyldisiloxane (15 cm^3) was stirred at 62°C under argon for 5 h. The reaction mixture was cooled to −40°C. The resulting solids were filtered, washed with hexamethyldisiloxane (2 × 5 cm^3) and dried *in vacuo*, yielding 0.33 g (61%) of **1b**. Preparations of **1b** often contain **2a**, which can be selectively crystallized from hexane or hexamethyldisiloxane. ^1H NMR: 6.75 (m, 9, Ar), 2.24 (s, 18, $ArCH_3$), 0.37 (s, 9, $SiCH_3$). $^{13}C\{^1H\}$ NMR (CD_2Cl_2): 130.2 (Ar), 127.9 (Ar), 126.5 (Ar), 18.9 ($ArCH_3$), 2.1 ($SiCH_3$). IR: 1274 vs, 1246 s, 1158 m, 1094 m, 951 vs br, 834 s, 772 vs, 762 m, 744 m, 726 m. Found: C, 59.5; H, 6.2; N, 8.1. Calc. for $C_{27}H_{36}N_3OSiTc$: C, 59.4; H, 6.6; N, 7.7%. UV–vis (nm): 237 (40,000), 310 (30,000), 584 (4500).

$\overline{Tc(NAr')_2(NAr'C(O)NAr')}(OSiMe_3)$ (**2a**)

A solution of $TcO_3(OSiMe_3)$ (0.22 g, 0.92 mmol) and Ar'NCO (1.02 g, 6.9 mmol) in hexamethyldisiloxane (40 cm^3) was stirred at 80°C under argon for 11 h. The reaction mixture was cooled to −40°C. The resulting solids were filtered, washed with cold hexamethyldisiloxane (3 × 4 cm^3) and dried *in vacuo*, yielding 0.32 g (50%) of red–brown **2a**. ^1H NMR: 6.69 (m br, 5, Ar), 6.57 (m, 7, Ar), 2.80 (s, 6, $ArCH_3$), 2.33 (s, 6, $ArCH_3$), 2.23 (s, 12, $ArCH_3$), −0.15 (s, 9, $SiCH_3$). $^{13}C\{^1H\}$ NMR (CD_2Cl_2): 165.8 (*C*O), 137.3 (Ar), 136.9 (Ar), 131.6 (Ar), 128.7 (Ar), 128.5 (Ar), 128.0 (Ar), 126.7 (Ar), 126.4 (Ar), 19.3 ($ArCH_3$), 18.8 ($ArCH_3$), 1.6 ($SiCH_3$). IR: 1676 vs [ν(CO)], 1312 w sh, 1284 m, 1247 m, 899 s, 890 m sh, 840 m, 774 m, 764 m. Found: C, 62.7; H, 6.5; N, 8.3. Calc. for $C_{36}H_{45}N_4O_2SiTc$: C, 62.5; H, 6.6; N, 8.1%.

$\overline{Re(NAr')_2(NAr'C(O)NAr')}(OSiMe_3)$ (**2b**)

A solution of $Re(NAr')_3(OSiMe_3)$ (0.10 g, 0.2 mmol) and Ar'NCO (0.26 g, 1.8 mmol) in hexamethyldisiloxane (5 cm^3) was stirred at 120°C for 15 h. Volatiles were pumped away and hexane (3 cm^3) was added. The suspension was cooled to −40°C and the resulting solids were filtered, washed with hexane (3 × 2 cm^3) and dried *in vacuo*, yielding 0.84 g (68%) of red **2b**. ^1H NMR: 7.02 (m, 2, Ar), 6.73 (m, 8, Ar), 6.56 (m, 2, Ar), 2.78 (s, 6, $ArCH_3$), 2.39 (s, 6, $ArCH_3$), 2.29 (s, 12, $ArCH_3$), −0.22 (s, 9, $SiCH_3$). $^{13}C\{^1H\}$ NMR (THF-d_8): 161.6 (*C*O), 153.6 (Ar), 147.5 (Ar), 145.7 (Ar), 141.0 (Ar), 140.6 (Ar), 139.8 (Ar), 133.3 (Ar), 131.7 (Ar), 131.2 (Ar), 130.1 (Ar), 129.7 (Ar), 19.9 ($ArCH_3$), 19.2 ($ArCH_3$), 18.4 ($ArCH_3$), 1.4 ($SiCH_3$). IR: 1696 vs [ν(CO)], 1315 w sh, 1294 s, 1249 m, 907 vs, 841 m, 772 m, 763 m. Found: C, 55.6; H, 5.7; N, 7.0. Calc. for $C_{36}H_{45}N_4O_2ReSi$: C, 55.4; H, 5.8; N, 7.2%. UV–vis (all λ_{sh}) (nm): 236 (40,000), 275 (25,000), 396 (9000), 486 (4500).

$Tc(NAr)_3Me$ (**3a**)

A solution (3 M) of MeMgCl (0.04 cm^3, 0.1 mmol) in THF was added dropwise to a THF (20 cm^3) solution of $Tc(NAr)_3(OSiMe_3)$ (0.082 g, 0.1 mmol). The reaction mixture was stirred for 90 min. Volatiles were pumped away and hexane (3 cm^3) was then added. The resulting suspension was filtered through Celite®, which was then washed with hexane (2 × 5 cm^3). The filtrates were pumped to

dryness, yielding 0.055 g (75%) of deep blue–green **3a**. ^{1}H NMR: 7.01 (m, 9, Ar), 3.72 (sept, 6, $J = 7.0$, C*H*Me$_2$), 2.61 (s, 3, TcC*H*$_3$), 1.13 (d, 36, $J = 7.0$, CHC*H*$_3$). ^{13}C{^{1}H} NMR (CD_2Cl_2): 140.2 (Ar), 132.2 (Ar), 126.4 (Ar), 122.6 (Ar), 30.1 (Tc*C*H$_3$), 29.0 (*C*HMe$_2$), 23.2 (CH*C*H$_3$). Found: C, 69.5; H, 8.1; N, 6.1. Calc. for $C_{37}H_{54}N_3Tc$: C, 69.6; H, 8.5; N, 6.6%. UV–vis (nm): 257 (30,000), 336 (30,000), 598 (5500).

Tc(NAr)$_3$Et (**3b**)

This was prepared from EtMgCl in 86% yield as a deep blue–green solid following the procedure for **3a**. ^{1}H NMR: 7.02 (m, 9, Ar), 3.75 (sept, 6, $J = 6.8$, C*H*Me$_2$), 3.74 (q, 2, $J = 7.3$, C*H*$_2$CH$_3$), 2.21 (t, 3, $J = 7.3$, CH$_2$C*H*$_3$), 1.14 (d, 36, $J = 6.8$, CHC*H*$_3$). ^{13}C{^{1}H} NMR (CD_2Cl_2): 155.4 (Ar), 140.5 (Ar), 126.3 (Ar), 122.6 (Ar), 34.7 (*C*H$_2$CH$_3$), 28.8 (*C*H), 23.4 (CH*C*H$_3$), 22.0 (CH$_2$*C*H$_3$). Found: C, 69.9; H, 8.6; N, 6.4. Calc. for $C_{38}H_{56}N_3Tc$: C, 69.8; H, 8.6; N, 6.4%. UV–vis (nm): 258 (35,000), 339 (30,000), 604 (6000).

Tc(NAr)$_3$(C$_3$H$_5$) (**3c**)

This was prepared from (C$_3$H$_5$)MgCl in 70% yield as a deep blue–green solid following the procedure for **3a**. ^{1}H NMR: 7.01 (m, 9, Ar), 6.66 (m, 1, C*H*=CH$_2$), 5.25 (d, 1, $J = 17$, *trans*-CH=C*H*H′), 4.99 (d, 1, $J = 10$, *cis*-CH=CH*H*′), 4.33 (d, 2, $J = 8$, TcC*H*$_2$), 3.71 (sept, 6, $J = 6.8$, C*H*Me$_2$), 1.12 (d, 36, $J = 6.8$, CHC*H*$_3$). ^{13}C{^{1}H} NMR (CD_2Cl_2): 143.3 (Ar), 140.9 (Ar), 126.7 (Ar), 122.7 (Ar), 113.4 (*C*H=CH$_2$), 66.2 (CH=*C*H$_2$), 34.8 (Tc*C*H$_2$), 28.8 (*C*HMe$_2$), 23.5 (CH*C*H$_3$). Found: C, 70.8; H, 9.1; N, 5.9. Calc. for $C_{39}H_{56}N_3Tc$: C, 70.3; H, 8.5; N, 6.3%. UV–vis (nm): 255 (45,000), 339 (30,000), 606 (6500).

Tc(NAr)$_3$(CH$_2$SiMe$_3$) (**3d**)

This was prepared from Li(CH$_2$SiMe$_3$) in 70% yield as a deep blue–green solid following the procedure for **3a**. ^{1}H NMR: 7.00 (m, 9, Ar), 3.84 (sept, 6, $J = 6.9$, C*H*Me$_2$), 2.69 (s, 2, TcC*H*$_2$), 1.18 (d, 36, $J = 6.9$, CHC*H*$_3$), 0.25 (s, 9, SiC*H*$_3$). ^{13}C{^{1}H} NMR (CD_2Cl_2): 155.3 (Ar), 141.7 (Ar), 126.9 (Ar), 122.9 (Ar), 34.3 (*C*H$_2$Si), 28.6 (*C*HMe$_2$), 23.7 (CH*C*H$_3$), 1.4 (Si*C*H$_3$). Found: C, 67.3; H, 8.9; N, 6.0. Calc. for $C_{40}H_{62}N_3SiTc$: C, 67.6; H, 8.8; N, 5.9%.

Tc(NAr′)$_3$Me (**3e**)

This was prepared from Tc(NAr′)$_3$(OSiMe$_3$) in 74% yield [together with < 10% yield of red Tc$_2$(NAr′)$_4$(μ-NAr′)$_2$[20]] as a deep green oil following the procedure for **3a**. ^{1}H NMR: 6.75 (m, 9, Ar), 2.48 (s, 3, TcC*H*$_3$), 2.27 (s, 18, ArC*H*$_3$). Found: C, 64.0; H, 6.6; N, 9.1. Calc. for $C_{25}H_{30}N_3Tc$: C, 63.8; H, 6.4; N, 8.9%.

Tc(NAr′)$_3$I (**4b**)

A solution of Tc(NAr′)$_3$(OSiMe$_3$) (0.10 g, 0.19 mmol) and Me$_3$SiI (0.027 cm^3, 0.19 mmol) in toluene (10 cm^3) was stirred at room temperature for 40 min. Volatiles were pumped away yielding 0.085 g (76%) of **4b** as a deep green solid. ^{1}H NMR: 6.70 (m, 9, Ar), 2.21 (s, 3, ArC*H*$_3$). Found: C, 49.5; H, 4.8; N, 7.0. Calc. for $C_{24}H_{27}N_3ITc$: C, 49.5; H, 4.7; N, 7.2%.

[(Ph$_3$P)$_2$N][TcO(NAr)$_3$] (**5**)

A solution of Tc(NAr)$_3$(OSiMe$_3$) (0.10 g, 0.14 mmol) and [(Ph$_3$P)$_2$N]F (0.10 g, 0.16 mmol) in CH_2Cl_2 (10 cm^3) was stirred at room temperature for 5 min. Volatiles were pumped away and dimethoxyethane/Et$_2$O (5:1, 12 cm^3) was then added. The resulting suspension was cooled to −40°C and filtered through Celite®, which was then washed with Et$_2$O (2 × 3 cm^3). The filtrates were pumped to dryness, yielding 0.12 g (73%) of red **5**. ^{1}H NMR: 7.45 (m, 30, P*Ph*$_3$), 6.97 (m, 9, Ar), 4.06 (sept, 6, $J = 6.8$, C*H*Me$_2$), 1.29 [d, 36, $J = 6.8$, CH(C*H*$_3$)$_2$]. IR: 1411 s, 1324 vs, 1264 vs br, 1183 w, 1111 s, 997 w, 960 m, br, 932 w sh, 834 m, 808 m, 744 s, 720 vs, 691 s, 545 s, 533 vs, 497 m. Found: C, 72.8; H, 6.5; N, 4.7. Calc. for $C_{72}H_{81}N_4OP_2Tc$: C, 73.3; H, 6.9; N, 4.7%.

X-ray structure determinations for Tc(NAr)$_3$(OSiMe$_3$) (**1a**), Re(NAr′)$_2$(NAr′C(O)NAr′)(OSiMe$_3$) (**2b**) *and* Tc(NAr)$_3$I (**4a**)

Data were collected on crystals mounted on glass fibres. Preliminary photographic examination and data collection were performed on a Siemans R3m/V diffractometer with graphite monochromated Mo-K_α radiation. Cell constants and an orientation matrix were obtained by least-squares refinement, using the setting angles of at least 25 reflections. Good crystal quality was also suggested by measuring omega scans of several intense reflections and by examining axial photographs. Intensity data were obtained using θ–2θ (**1a** and **2b**) or ω scans (**4a**). The data were scaled for linear decay and a semi-empirical absorption correction based on the average relative intensity curve of azimuthal scan data was applied. The structures were solved using standard heavy atom methods and refined

with full-matrix least-squares. All non-hydrogen atoms were refined anisotropically, hydrogen atom positions were calculated (C—H = 0.96 Å) and were added to the structure–factor calculations without refinement. All calculations were performed using SHELXTL PLUS programs provided by Siemans Analytical. Crystallographic data are given in Table 3. Positional and thermal parameters and complete tabulations of bond lengths and angles are available as supplementary material from the Cambridge Crystallographic Data Center.

(*Received* 14 *December* 1992; *accepted* 29 *March* 1993)

Abstract—Reaction of the dichloride [$TaCl_2(CH_2$—C_6H_4-4Me)$_3$] (**1**) (CH_2—C_6H_4-4Me = 4-methylbenzyl) with the dialkylmagnesium compound [$Mg(CH_2$—C_6H_4-4-Me)$_2$] leads to the homoleptic 4-methylbenzyl compound [$Ta(CH_2$—C_6H_4-4Me)$_5$] (**2**). The solid state structure of **2** shows a distorted square-pyramidal geometry for the central TaC_5 core. Four of the 4-methylbenzyl ligands are σ-bound to the tantalum with Ta—CH_2—C angles of 108.4(5)–125.7(5)°, while the remaining ligand has an acute Ta—CH_2—C angle of 90.4(5)°. In solution all alkyl groups are equivalent by ^{1}H and ^{13}C NMR even at −60°C, indicating facile exchange of non-equivalent alkyl groups on the NMR time-scale.

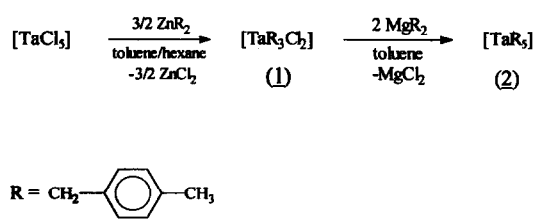
The study of the simple alkyl derivatives of the group 5 metals niobium and tantalum has played an important role in organometallic chemistry. This importance stems from the discovery by Schrock of the α-hydrogen abstraction process that can lead to stable alkylidene and alkylidyne derivatives of these metals.[1] This early work has now resulted in the development of a whole new field of organometallic chemistry, much of which is focussed on the stoichiometric and catalytic reactivity of these functional groups.[2]

During our studies of the catalytic hydrogenation of arene rings by group 5 metal compounds[3] we required a mononuclear, homoleptic alkyl derivative of tantalum as a molecular precursor to oxide surface bound organometallic species of tantalum.[4] Our attention focussed upon the penta-benzyl compound [$Ta(CH_2C_6H_5)_5$] reported by Schrock to be an isolable,[5] although thermally unstable,[5,6] red crystalline material. We wish to report here our synthesis of the analogous 4-methylbenzyl derivative as well as upon the solid state and solution structure of the compound.

RESULTS AND DISCUSSION

The 4-methylbenzyl compound [$Ta(CH_2C_6H_4$-4-Me)$_5$] (**2**) was obtained via the intermediate [$TaCl_2(CH_2$—C_6H_4-4-Me)$_3$] (**1**) by using a procedure essentially identical to that reported by Schrock[5] (Scheme 1). The red–orange dichloride **1**, generated by treating $TaCl_5$ with [$Zn(CH_2$—C_6H_4-4-Me)$_2$] in hexane/toluene, was a crude, low melting solid that was used without further purification. The penta(4-methylbenzyl) compound (**2**) was obtained as deep red crystals from hexane solution after allowing **1** and [$Mg(CH_2$—C_6H_4-Me)$_2$] to react in toluene at room temperature. The rapid isolation of **2** from the reaction mixture is necessary due to its thermal instability (*vide infra*).

The homoleptic alkyl **2** was subjected to a single-crystal X-ray diffraction analysis. The data set was collected at −98°C due to the thermal instability of the compound. The diffraction study (Figs 1 and 2 and Table 1) confirmed the stoichiometry of the compound and shows some interesting features. The solid state structure of **2** can best be described as



Scheme 1.

distorted square-pyramidal for the central TaC_5 core. The axial benzyl group Ta—C(10) makes an angle of 104.7(3)–118.2(3)° to the four basal benzyl ligands. The angles between each of these four basal groups lies in the narrow range 80.6(3)–84.6(3)°. The electronic aspects involved in determining which geometry is adopted in five-coordinate transition metal compounds have been thoroughly evaluated by Hoffman and Lauer.[7] There are now a significant number of five-coordinate compounds of the group 5 metals that have been structurally characterized.[8] The observed structures are normally rationalized using a combination of electronic arguments along with the steric influence of ligands containing non-trivial bulk. Of particular importance for high valent metal derivatives (typically d^0-metal configuration) has been the influence of π-donor ligation that tends in large part to dictate the structure that is observed.[9] In compound **2** the central coordination sphere contains donor atoms only capable of σ-bonding. On the basis of simple VSEPR rules one would, therefore, predict a trigonal bipyramidal structure, cf. heavier group 15 metal derivatives, $[MX_5]$ (M = P, As, Sb). However, the importance of crystal packing forces in determining observed solid state structures should not be overlooked. This is clearly demonstrated in the structures of the isoelectronic pentaalkyl compounds $[Sb(C_6H_5)_5]$[10] and $[Sb(C_6H_4\text{-}4\text{-}Me)_5]$,[11] where the former adopts an unexpected square-pyramidal geometry in contrast to a regular trigonal bipyramid for the latter. The influence of crystal packing forces was argued to influence which of the two structures were adopted in solution.[11] Another factor that may also influence the structure of **2** is the acute Ta—CH_2—C angle observed for one of the basal benzyl ligands (*vide infra*).

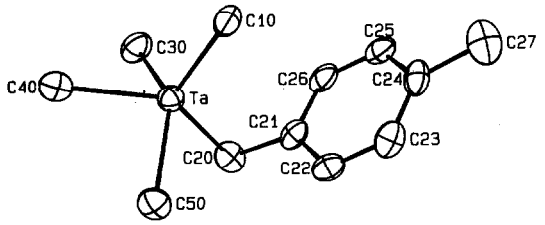

Fig. 2. ORTEP view of the central coordination sphere in **2** showing the orientation of the benzyl ligand bound through C(20).

The five Ta—CH_2 distances span the narrow range 2.151(8)–2.216(8) Å and are essentially identical to values found in the tantalum aryloxide compounds of the formula $[Ta(OAr)_2(CH_2Ph)_3]$ (Table 2). An important characteristic of benzyl ligands is their ability to interact in an η^n ($n > 1$) fashion to electron deficient metal centres. This type of bonding is typified by the η^3-benzyl compound $[CpMo(\eta^3\text{-}CH_2\text{—}C_6H_4\text{-}4Me)(CO)_2]$,[12] where the metal makes close contacts with the α, *ipso*- and

ortho-carbon atoms with distances of 2.269(7), 2.364(5) and 2.480(6) Å, respectively. In the case of high valent, early *d*-block metals multisite bonding of benzyl ligands to the electron deficient metal centre has been established in a number of cases. However, a broad spectrum of interactions appears to exist. This is exemplified by the homoleptic benzyl derivatives of the group 4 metals, [M(CH$_2$Ph)$_4$] (M = Ti, Zr, Hf).[13] In these compounds the M—CH$_2$—Ph angles at the α-carbon atom vary from 85° to 115°. The close contact of the aryl rings is often quoted as justification for the thermal stability of these compounds compared to simple alkyl derivatives. The stepwise substitution of benzyl ligands by aryloxide groups leads to an increase in the average M—CH$_2$—Ph angles, reflecting either decreasing electron deficiency of the metal centre or, more likely, steric congestion precluding close approach of the arene ring.[14]

In compound **2** one of the benzyl ligands has a small angle at the α-carbon, Ta—C(20)—C(21) = 90.4(5)°. The four remaining benzyl ligands have corresponding angles of 108.4(5)–125.7(5)°. A search of the Cambridge Crystallographic Database uncovered a limited number of benzyl compounds of tantalum that had been subjected to single-crystal X-ray diffraction analysis.[15–21] In Table 2 are listed the values of M—CH$_2$ and M—CH$_2$—Ar reported for the most relevant of these compounds. It can be seen that the M—C

distances lie in a narrow range. The longest distances are found in benzyl compounds containing two cyclopentadienyl ancillary ligands. It is also apparent that the majority of benzyl ligands have "normal" M—C—Ph angles between 100° and 120°. However, the acute benzyl ligand in **2** and one of the ligands in the aryloxide compound $[Ta(OC_6H_3Me_2\text{-}2,6)_2(CH_2Ph)_3]$ have angles below 100°.

Despite the square-pyramidal geometry observed in the solid state structure of **2** only one set of resonances for the benzyl ligands are detected in the ^1H and ^{13}C NMR spectra. Cooling à toluene-d_8 solution of **2** to −60°C showed only one Ta—C*H*$_2$ and 4-*Me* resonance in the ^1H NMR, indicating that exchange of non-equivalent benzyl ligands is facile on the NMR time-scale at this temperature. In the ^{13}C NMR spectrum of **2** the benzylic carbon was found to resonate at δ 105.2 ppm and appears as a triplet of triplets. The observed $^1J(^{13}C—^1H)$ coupling of 123.3 Hz is identical to the value of 123 Hz reported by Schrock *et al.* for $[Ta(CH_2Ph)_5]$. The value of this coupling constant is very close to that expected for an undistorted sp^3-CH bond and correlates well with the average Ta—CH$_2$—C angle of 111.5° found in the solid state structure of **2**.

A fresh, deep-red benzene-d_6 solution of crystalline **2** was found to undergo decomposition at room temperature to produce a dark brown solution along with a dark precipitate. Analysis of this reaction by ^1H NMR showed that 2–3 equivalents of *p*-xylene per tantalum metal centre were generated in solution. This reactivity is identical to that reported for $[Ta(CH_2Ph)_5]$.[5,6]

EXPERIMENTAL

All operations were performed under a dry nitrogen atmosphere either in a Vacuum Atmospheres dri-lab or by standard Schlenk techniques. Hydrocarbon solvents were dried by distillation from sodium benzophenone under a nitrogen atmosphere. ^1H and ^{13}C NMR spectra were performed on a Gemini 200 MHz spectrometer.

Preparation of $[Zn(CH_2C_6H_4\text{-}4Me)_2]$

A sample of magnesium turnings (26.73 g, 1.09 mol, 50% excess) was dried in an oven overnight and placed in a 5 dm^3 flask. The metal was further dried with a heat gun under vacuum for 10 min. Diethylether (750 cm^3) was added to the flask followed by α-chloro-*p*-xylene (70 cm^3, 734 mmol) in diethylether (50 cm^3) dropwise over a period of 1 h. The resulting mixture was allowed to stir for an additional 3 h. Dry $ZnCl_2$ (50 g, 3.66 mol) was added over an hour and the reaction mixture was left to stir overnight. The solvent was removed under vacuum to leave a white–brown mixture and excess magnesium turnings. The mixture was extracted with toluene. The solvent was removed *in vacuo* from the yellow filtrate and the resulting residue washed with hexane yielding 68.62 g (68%) of white $[Zn(CH_2C_6H_4\text{-}4Me)_2]$.

Preparation of $[TaCl_2(CH_2C_6H_4\text{-}4Me)_3]$ **(1)**

Solid $TaCl_5$ (21.99 g, 61 mmol) was placed in a 500 cm^3 flask and a 1:1 mixture of toluene and hexane (200 cm^3) was added to the solid. $[Zn(CH_2C_6H_4\text{-}4Me)_2]$ (25.4 g, 0.092 mol) was added over 15 min. The reaction was allowed to stir for an additional 45 min. The solvent was removed *in vacuo* and the dried residue was extracted with hexane and filtered. The resulting deep red–orange filtrate was evaporated to a liquid containing the crude product.

Preparation of $[Ta(CH_2C_6H_4\text{-}4Me)_5]$ **(2)**

$[TaCl_2(CH_2C_6H_4\text{-}4Me)_3]$ (1.00 g, 1.763 mmol) was dissolved in toluene (10 cm^3) in a 50 cm^3 flask. A sample of $[Mg(CH_2C_6H_4\text{-}4Me)_2(EtO_2)_2]$ (0.675 g, 1.763 mmol) was dissolved in toluene (10 cm^3) and added dropwise to the flask over 30 min. The reaction was then allowed to stir for an additional 20 min. The mixture was filtered and the filtrate evaporated to dryness. Toluene (3 cm^3) was added and the red solution was layered with hexane. Cooling at −20°C yielded crystals of $[Ta(CH_2C_6H_4\text{-}4Me)_5]$. Yield = 0.20 g (18%).

^1H NMR (δ, C_6D_6, 25°C): 7.00 (d), 6.78 (d), 2.71 (s, C*H*$_2$), 2.25 (s, C*H*$_3$). Selected ^{13}C NMR data (δ, C_6D_6): 105.2 [t–t, *C*H$_2$, $^1J(^{13}C—^1H)$ = 123.3 Hz, $^3J(^{13}C—^1H)$ = 4.36 Hz]; 21.0 [q–t, *C*H$_3$, $^1J(^{13}C—^1H)$ = 126.0 Hz, $^3J(^{13}C—^1H)$ = 4.38 Hz].

(*Received* 20 *November* 1992; *accepted* 29 *March* 1993)

Abstract—The compound (hfac)Ag(1,5-cod) was synthesized by the reaction of 1,1,1,5,5,5-hexafluoroacetylacetone (hfacH) with Ag_2O and 1,5-cyclooctadiene (1,5-cod) and characterized in the solid state by single-crystal X-ray diffraction. In contrast to the corresponding copper(I) compound (hfac)Ag(1,5-cod) exhibited lower volatility and was found to be dimeric in the solid state, containing the two unusual β-diketonate coordination modes, namely, μ^4-η^2-hfac and μ^2-hfac. The deterioration of the crystal and extensive disorder precluded a detailed comparison of the metrical parameters of this compound with other literature data. However, the solid-state FTIR data showed substantial differences in the ν(C—O) and ν(C—C) stretching regions compared with the chelated hfac ligand in (hfac)Cu(1,5-cod). These data will be useful in assigning the coordination mode of β-diketonate ligands in metal-organic β-diketonate complexes by FTIR.

The rational design of metal-organic compounds as precursors for the chemical vapour deposition (CVD) of metals is a topic of intense research interest.[1] These precursors need to meet certain design criteria if they are to be used to deposit high-quality metal films that are likely to be integrated into semiconductor device technology as, for example, vertical interconnects. The design criteria for such compounds are that they exhibit high volatility (vapour pressure preferably greater than 100 mtorr at the evaporation temperature), are thermally stable at room temperature, deposit pure metal films at high rates and relatively low temperatures (< 400°C) and can deposit selectively on one material in the presence of another. Some of these criteria have been attained for the CVD of copper from a number of Lewis base adducts of copper(I) β-diketonate compounds, (β-diketonate)CuL.[2–13] It has been shown that these species undergo a thermally-induced disproportionation reaction on a variety of surfaces to deposit pure copper metal with near bulk resistivity, according to the reaction in eq. (1) below.

$$2(\beta\text{-diketonate})\text{CuL} \longrightarrow \text{Cu} + \text{Cu}(\beta\text{-diketonate})_2 + 2\text{L} \quad (1)$$

In this system the 1,1,1,5,5,5-hexafluoroacetylacetonato (hfac) derivatives are most useful because they exhibit higher volatility compared to the other β-diketonate derivatives investigated. The Lewis base ligands, L, have been chosen from triorganophosphines, olefins and alkynes.

In this work we set out to examine the possibility of extending this work to investigate the chemistry of analogous (β-diketonate)ML compounds of group 11 and to compare their propensity for the formation of metal via disproportionation from volatile silver(I) precursors. While disproportionation reactions of copper(I) [eq. (1)] and gold(I) [eq. (2)] are well known the disproportionation of silver(I) [eq. (3)] is poorly characterized.[14] However, complexes of both silver(II) and silver(III) are known with oxygen ligands.

$$3\text{Au}^{\text{I}} \longrightarrow 2\text{Au} + \text{Au}^{\text{III}} \quad (2)$$

‡Author to whom correspondence should be addressed.

$$2Ag^{I} \longrightarrow Ag + Ag^{II} \quad (3)$$

Here we describe the synthesis and characterization of the silver(I) compound (hfac)Ag(1,5-cod), where 1,5-cod = 1,5-cyclooctadiene, which exhibits an unexpected structure in the solid state.

EXPERIMENTAL

General procedures

All manipulations were performed under a dinitrogen atmosphere using standard Schlenk techniques or in a nitrogen atmosphere dry-box.[15] Hydrocarbon and ethereal solvents were predried over sodium wire, distilled from sodium benzophenone ketyl and stored over 4 Å molecular sieves under nitrogen. Combustion element analyses were performed by Ms R. Ju in the Department of Chemistry at the University of New Mexico. NMR data were recorded on a Bruker AC-250P NMR spectrometer using the protio impurities of the deuterated solvents as references for the ^{1}H NMR and the ^{13}C resonance of the solvents as reference for ^{13}C NMR specroscopy. Temperatures were calibrated with either ethylene glycol or methanol. IR data were recorded on a Perkin–Elmer Model 1620 FTIR spectrophotometer.

Synthesis of [(hfac)Ag(1,5-cod)]$_2$

A suspension of Ag_2O (2.122 g, 9.16 mmol) in THF (69 cm^3) was stirred in a 250 cm^3 Schlenk flask for 10 min under nitrogen. A slight excess of 1,5-cyclooctadiene (2.4 cm^3, 19.6 mmol, *ca* 2.1 equivalents) was added dropwise over a 5 min period and the entire solution was stirred under nitrogen for 10 min. A small excess of hexafluoroacetylacetone (2.7 cm^3, 19.3 mmol, *ca* 2.1 equivalents) was added dropwise over a 5 min period. The black Ag_2O solution gradually dissolved forming a cloudy solution. This solution was stirred under nitrogen for 3 h. Removal of the volatile components under vacuum gave a dirty brown/tan solid which was dissolved in toluene (100 cm^3) and filtered to remove any unreacted Ag_2O. The filtered solution was brown/yellow and translucent. Removal of toluene *in vacuo* gave colourless, crystalline (hfac)Ag(1,5-cod) (4.9946 g, 11.8 mmol, 65.5% yield). Crystals of (hfac)Ag(1,5-cod) were obtained by dissolving *ca* 50 mg of the product in toluene and room temperature and cooling to −10°C. Found: C, 36.7; H, 3.3. Calc. for $C_{13}H_{13}O_2F_6Ag$: C, 36.9; H, 3.1%. Spectroscopic data: NMR data: ^{1}H (C_6D_6, 20°C) (ppm): 1.70 (s, br, 8H, CH_2 in 1,5-COD), 5.30 (s, br, 4H, CH in 1,5-COD), 6.26 (s, 1H, CH in hfac). $^{13}C\{^{1}H\}$ (ppm): 27.65 (s, CH_2 in 1,5-COD), 87.18 (s, CH in hfac), 124.62 (s, CH in 1,5-COD), 177.5 ($CF_3C{=}O$ in hfac). ^{19}F (ppm): 132.08 (s, CF_3 in hfac).

Crystallographic data

Single crystals were isolated from a saturated solution in toluene, cooled to −10°C. The crystal data collection and refinement parameters are summarized in Table 1. The crystal showed signs of deterioration during the data collection. The crystal was originally clear and colourless, but was dark grey and translucent at the end of data collection. The peak profiles also broadened by *ca* 20% during the data collection. The space group assignment of $P2(1)/n$ is consistent with the observed extinctions. A semi-empirical absorption correction was applied to the data set. Direct methods were used to find initial silver coordinates and the rest of the non-hydrogen atoms were located by full-matrix refinements on the trial positions and subsequent interpretation of the difference-Fourier maps. The R factor converged to 18% for all non-hydrogen atoms isotropic. At this point large isotropic Us for the Fs and some of the 1,5-cod carbon atoms were evident. Also, there were large deviations from the expected bond lengths: C—F ranged from 1.22(5) to 1.43(4); C—C bond lengths ranged from 1.34(6) to 1.71(6). In spite of the large deviations these are still within 3.4 standard deviations of the expected values. Difference-Fourier primary F sites (occupation factors > 50%) and secondary F sites were based on residual difference Fourier peaks. The positions of the primary sites were allowed to vary and

T (°C)	20
λ (Å)	0.71073
ρ_{calc} (g cm^{-3})	1.817
μ (cm^{-1})	12.93
$R(F_o)^a$ (%)	10.10
$R_w(F_o)^b$ (%)	10.33

$^a R(F_o) = \Sigma(|F_o|-|F_c|)/\Sigma|F_o|$.

$^b R_w(F_o) = \Sigma(w^{1/2}(|F_o|-|F_c|))/(w^{1/2}|F_o|)$; $w^{-1} = \sigma^2(F_o)+0.0027F_o^2$.

the positions of the secondary sites were fixed. Each of these sets had common isotropic *U*s, which were also varied. The CF_3 group on C(5) did not have any difference-Fourier peaks which could be associated to a second set of Fs. These F positions were constrained to have the average C—F bond length of 1.310 Å in a tetrahedral arrangement about C(5). These Fs also shared a common variable isotropic *U*. Hydrogen atoms in idealized positions (riding model) with isotropic *U*s set to 1.25*U*(equiv.) of their parent atoms were included in the final refinements. The final *R* factor is 10.10%. All software and the source of scattering factors are contained in the SHELXTL program library (G. Sheldrick, Nicolet Corp., Madison, WI). Selected bond distances and angles are given in Tables 2 and 3, respectively.

There is one independent molecule in the asymmetric unit. The two hfac units are bonded differently to the silver atoms, but the two 1,5-cod units are similarly bonded, one to each silver atom. The bond lengths and angles show large standard deviations, a result of the marginal data set. However, this data is sufficient to show the general structure and dimeric nature of the molecule.

RESULTS AND DISCUSSION

The species (hfac)Ag(1,5-cod) was prepared according to the literature method,[16,17] where silver(I) oxide was first mixed with 1,5-cod and then reacted with hfacH according to the stoichiometry of eq. (4).

$$Ag_2O + 2hfacH + 2\,1,5\text{-cod} \xrightarrow{(thf)} [(hfac)Ag(1,5\text{-cod})]_2 + H_2O \quad (4)$$

After removal of the volatile components *in vacuo* the product was recrystallized from toluene to give satisfactory analytical data. As in the case of (hfac)Cu(1,5-cod) ^1H and ^{13}C NMR data for (hfac)Ag(1,5-cod) revealed a solution structure in which all the aliphatic proton resonances were equivalent and where all four olefinic carbon and all four aliphatic carbon environments were identical. These data are consistent with the corresponding data for the copper(I) analogue, (hfac)Cu(1,5-cod), which has been structurally characterized in the solid state and shown to exhibit an unusual "3+1" coordination mode for the olefin ligand, as shown in Fig. 1, where one copper–olefin distance is considerably longer than the other.[18] For the copper analogue the NMR data have been interpreted in terms of the degenerate rearrangement according to eq. (5), although a dissociative mechanism could not be ruled out.

sistencies were noted between the spectroscopic data and physical properties of the copper(I) and silver(I) analogues. The FTIR spectra of the two compounds exhibited some substantial differences. For chelating, bidentate β-diketonate monoanionic ligands a number of characteristic bands are typically observed in the region between 1700 and 1400 cm^{-1}. For monomeric (hfac)Cu(L) complexes[19–23] in the solid state, for example, (hfac)Cu(1,5-cod),[18] there are two strong bands at 1636 and 1482 cm^{-1}, two medium intensity bands at 1554 and 1527 cm^{-1}, a medium intensity shoulder at 1668 cm^{-1} and a weak band at 1593 cm^{-1}. For (hfac)Ag(1,5-cod) a quite different envelope was observed in this region. Five bands were observed at different positions, namely, 1672, 1643, 1542, 1527 and 1492 cm^{-1}. A comparison of these two IR spectra is shown in Fig. 2. These differences can be interpreted in terms of the different coordination modes of the β-diketonate ligand in these two complexes, where it was shown by a single-crystal X-ray diffraction study (see later) that for (hfac)Cu(1,5-cod) the β-diketonate ligand only chelates, whereas for [(hfac)Ag(1,5-cod)] the β-diketonate ligands bridge two metal centres in addition to chelating. An alternative explanation is that these differences could be attributed to solid-state effects, such as the different point group symmetries of the copper(I) and silver(I) imposed by the solid state. However, we and others[24–26] have shown that in copper(I) and copper(II) β-diketonate compounds the solid-state and gas-phase IR data are similar where no intermolecular interactions exist in the solid state and that the differences generally involve changes in intensity rather than the position of the IR bands. No intermolecular interactions were observed in the solid-state structure of [(hfac)Ag(1,5-cod)]. Therefore, we believe that the difference in the hfac coordination mode is likely to be the predominant effect.

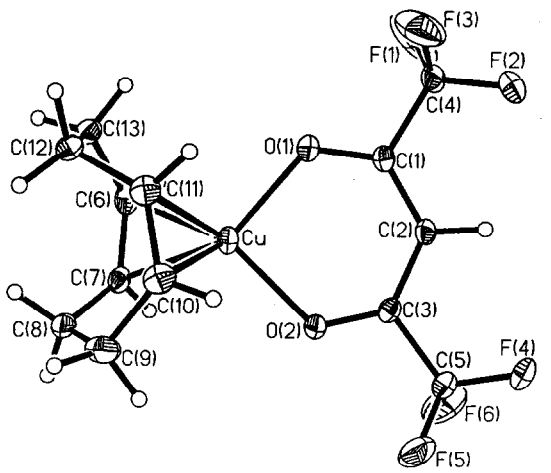

Fig. 1. ORTEP plot showing the solid-state structure of (hfac)Cu(1,5-cod).

In addition to these differences between the copper(I) and silver(I) compounds observed in the IR spectra a substantial difference was observed, qualitatively, in volatility. The silver compound was noticeably less volatile than the copper analogue, which was consistent with a higher degree of oligomerization for the silver(I) species. To investigate the nature of (hfac)Ag(1,5-cod) further a single-crystal X-ray diffraction study was performed which revealed the origin of the differences observed in the spectroscopic data and physical properties.

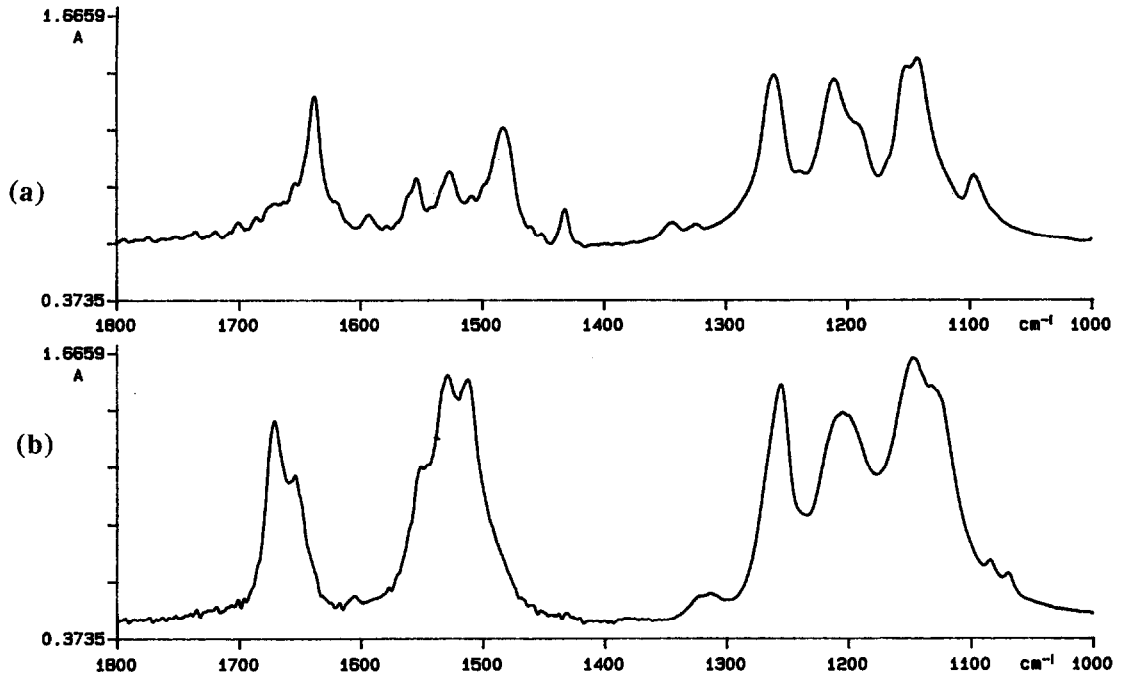

Fig. 2. Comparison of the FTIR data for (hfac)M(1,5-cod), M = (a) Cu and (b) Ag in the region 1800–1000 cm^{-1}.

An ORTEP plot is shown in Fig. 3, together with the atom labelling scheme. This species is dimeric in the solid state with one β-diketonate ligand, which both chelates and bridges two silver atoms in a μ^4,η^2-fashion, and a β-diketonate ligand, which bridges the two metal centres in an μ^2-fashion. The μ^4,η^2-β-diketonate binding mode is not common and has been observed only in three previous structures, namely, $[Ba_4(2,2,6,6,tetramethylheptandionato)_2]_4$,[27,28] Ca(1,3-diphenyl-1,3-propanedionate)$_2$ hemiethanolate[29] and Sr(1,3-diphenyl-1,3-propanedionate)$_2$ hemiethanolate.[30] The structure can be described as exhibiting an octahedral core with four β-diketonate oxygen atoms in an approximate square plane with silver atoms on opposite apices. Unfortunately, this compound is photosensitive and deteriorated significantly during the data collection. There is also significant disorder in the CF_3 groups. As a result it is unwise to interpret these data in great detail. However, it seems that the μ^4,η^2-hfac ligand bridges the silver(I) centres with similar Ag—O bond lengths (2.56 Å av.), while the other hfac ligand is markedly asymmetric with one short Ag—O bond length (2.46 Å av.) and one long distance (2.72 Å av.) that is longer than the sum of the covalent radii of silver and oxygen. Each silver atom is also coordinated to one 1,5-cod ligand through both double bonds. The marked asymmetry that was observed in the coordination of the copper(I) centre to the two double bonds of 1,5-cod in (hfac)Cu(1,5-cod) is not observed in the case of silver. The C=C distance in the 1,5-cod ligand of (hfac)Ag(1,5-cod) is close to the value of the double bond. These bonds lengths are similar to those observed for silver(I) complexes of 1,5-cod[31,32] and other olefins.[33–50]

CONCLUSIONS

The compound (hfac)Ag(1,5-cod) was synthesized by the literature method and characterized

in the solid state by single-crystal X-ray diffraction. In contrast to the corresponding copper(I) compound it was found to be dimeric in the solid state and contained two unusual β-diketonate coordination modes, μ^4,η^2-hfac and μ^2-hfac. The deterioration of the crystal and extensive disorder precluded a detailed comparison of the metrical parameters of this compound with other literature data. However, the solid-state FTIR data showed substantial differences in the ν(C—O) and ν(C—C) stretching regions compared with the chelated hfac ligand in (hfac)Cu(1,5-cod). The data presented here will be useful in assigning the coordination mode of β-diketonate ligands in metal-organic complexes and on metal and metal oxide surfaces by FTIR.[24–26]

The dimeric nature of $[(hfac)Ag(1,5\text{-cod})]_2$ compared with the copper(I) analogue is probably the result of the larger size of silver(I) compared with copper(I), with the resulting desire for a higher coordination number for silver(I). It is interesting to note that analogous rhodium(I) complexes are monomeric even though rhodium(I) and silver(I) have a similar size and are from the same period.[51] However, for silver(I) there is no *d*-orbital-imposed geometrical preference as there is in the case of rhodium(I), which is probably a major influence in determining the coordination number and geometry of the rhodium(I) analogues.

(*Received* 27 *January* 1993; *accepted* 23 *March* 1993)

Abstract—Two new complexes, $NiL \cdot 3H_2O$ and $CuL \cdot H_2O$ (L = N-hydroxylethyl-N-benzimidazolylmethylethylenediaminediacetic actate), have been synthesized and characterized by elemental analysis, IR and ESR spectra. The crystal structure of $NiL \cdot 3H_2O$ has been determined by single-crystal X-ray diffraction. The nickel centre is six-coordinate with distorted octahedral symmetry. IR and ESR spectra show that the structure of the copper compound is different from that of the nickel compound. The former may be a dimer and with a $d_{x^2-y^2}$ ground state. The hyperfine structure splitting parameter in copper is $A_2^N = 37.2$ G.

The aminopolycarboxyl complexes have attracted great interest in recent years for their use as the contrast-enhancing agents in magnetic resonance imaging, as probes in biochemistry and medical science.[1–3] Metal complexes of polydentate ligands containing imidazole are of current interest due to their being potential models for metalloenzymes and metalloproteins.[4,5] When preparing the ligand N-hydroxylethyl-N,N′,N′-tribenzimidazolylmethylethylenediamine we obtained the title ligand, a new benzimidazole aminopolycarboxyl acid. This paper reports the complexes of copper and nickel with the title ligand L.

EXPERIMENTAL

Synthesis of $CuL \cdot 2H_2O$ **(1)**

A water solution containing $CuAc_2$ (2 mmol) was added to an L–water solution (1 mmol). The mixture was heated for 2 h and then kept at room temperature for 1 week. A blue precipitate was formed slowly. The product was collected and dried in air. Found: C, 42.4; H, 5.0; N, 12.6. Calc. for $C_{16}H_{24}N_4O_7Cu$: C, 42.8; H, 5.4; N, 12.6%.

Synthesis of $NiL \cdot 3H_2O$ **(2)**

The compound was obtained in a similar manner to **1**, except $Ni(ClO_4)_2$ was used instead of $CuAc_2$ and the reaction solution was left in air for 1 month. Found: C, 40.8; H, 4.9; N, 12.5. Calc. for $C_{16}H_{26}N_4O_8Ni$: C, 41.7; H, 5.6; N, 12.2%.

Compound **2** was dissolved in hot water and slowly evaporated at room temperature for several weeks until a single crystal suitable for X-ray structure analysis was obtained.

X-ray data collection, structure determination and refinement for **2**

A transparent blue crystal of complex **2** having approximate dimensions $0.05 \times 0.2 \times 0.3$ mm was

* Author to whom correspondence should be addressed.

mounted on a glass fibre in a random orientation. The determination of the unit cell and the data collection were performed with Mo-K_α radiation ($\lambda = 0.71073$ Å) on an Enraf-Nonius CAD4 diffractometer equipped with a graphite crystal monochromator. A total of 3458 independent reflections were collected in the range $2° \leqslant \theta \leqslant 24°$ by the ω–2θ scan technique at room temperature, in which 1136 reflections with $[I \geqslant 3\sigma(I)]$ were considered to be observed and used in the succeeding refinement. A correction for Lp effects was applied to the data.

Crystals are rhombic, space group *Pbca*, $a = 10.863(2)$, $b = 13.874(2)$, $c = 25.727(7)$ Å, $V = 3877(3)$ Å^3, $Mr = 461.12$, $Z = 8$, $D_x = 1.58$ g cm^{-3}, $\mu = 10.54$ cm^{-1}, $F(000) = 1936$.

The structure was solved by direct methods (MULTAN 82). The nickel was located on an *E*-map. All the other non-hydrogen atoms were determined from successive difference-Fourier syntheses. The final refinement by full-matrix least-squares with anisotropic thermal parameters for non-hydrogen atoms converged with agreement factors of $R = \Sigma|\Delta F|/\Sigma|F_o| = 0.049$ and $Rw = [\Sigma_w|F|^2/\Sigma_w|F_o|^2]^{1/2} = 0.055$ (unit weights for all observed reflections). The highest peak on the final difference-Fourier map had a height of 0.48 e Å^{-3}.

All calculations were performed on a PDP11/44 computer using the SDP-PLUS program system.

Tables of final atomic positional and thermal parameters, full lists of bond lengths and angles and equations of least-squares planes have been deposited as supplementary material with the Editor.

Numbers in parentheses are estimated standard deviations in the least significant digits.

In the molecule NiL·3H$_2$O, L is a pentadentate ligand. The five-coordinate atoms are N(2) (imidazole), N(3) (amine), N(4) (amine) and O(2), O(4) (two different acetic acids). The hydroxyl group is not coordinated to nickel in the molecule. The coordination number of nickel is six. The sixth coordinated atom is oxygen, which is from one water molecule. The six atoms around nickel make up a distorted coordination octahedron. The other two non-coordinated waters in the molecule are linked to L by hydrogen bonds.

The Ni—N distances in the molecule range from 2.051 to 2.203 Å (mean 2.109 Å) and Ni—O from 2.063 to 2.107 Å (mean 2.079 Å). The Ni—N(3) distance is longer than the others.

The O(2), O(5), N(2) and N(3) atoms lie approximately in a plane (plane 1). The maximum deviation from the plane is 0.1765 Å (nickel). The dihedral angle between plane 1 and the benzimidazole plane is 11.97°.

IR spectra

The IR spectra of these two complexes have the features of the spectrum L. No absorptions can be attributed to ClO_4^- and Ac^-. This result is in accordance with the constituents. In complex **1** the C=O stretching vibrations appear at 1625, 1575 and 1534 cm^{-1} [ν_{as}(CO)] and 1380 and 1400 cm^{-1} [ν_s(CO)], indicating different CO_2^- environments. From the values of $\Delta\nu = \nu_{as}(CO) - \nu_s(CO)$ we can deduce that both monodentate CO_2^- ($\Delta\nu > 220$ cm^{-1}) and bridging CO_2^- ($\Delta\nu$ 130–190 cm^{-1}) may be present in the complex.[6]

In the nickel complex the CO_2^- stretching vibrations appear at 1675, 1640, 1400 and 1365 cm^{-1}. Only monodentate CO_2^- is present. The result is also confirmed by the crystal structure. Two sets of CO_2^- absorptions imply two different CO_2^- types in the structure. For the free ligand H_2L the CO_2^- vibrations are at 1640, 1380 and 1365 cm^{-1} (sh).

The IR spectra indicate that the structure of the copper compound is different from that of nickel. The former may exist as a dimer.

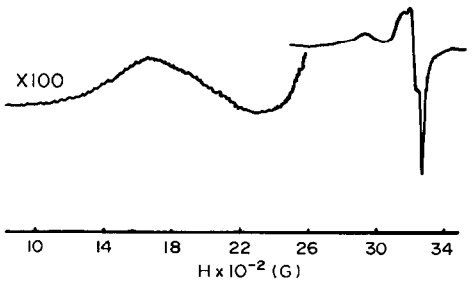

Fig. 2. *X*-band ESR powder spectrum of CuL·H$_2$O at 120 K.

ESR spectra

The powder ESR spectrum of the copper complex at −120 K is shown in Fig. 2. Three g values have been observed: $g_1 = 2.023$, $g_2 = 2.070$ and $g_3 = 2.247$. $R = (g_2 - g_1)/(g_3 - g_2) < 1$, which indicates that a predominant $d_{x^2-y^2}$ ground state is present. The coordinate structure of copper may be square pyramidal (coordinate number 5) or elongated tetragonal octahedron (coordinate number 6).[7]

The hyperfine structure was also found at g_2 for nuclear nitrogen (N, $I = 2$) at low temperature. The splitting parameter is *ca* $A_2^N = 37.2$ G.

The half-field line was also observed with a g-value centred at *ca* 4.0. The peak is weaker due to the forbidden transition $\Delta Ms = 2$. The appearance of the half-field line reveals that the complex is binuclear.

The intensity of the signals for $\Delta Ms = 1$ decreases upon cooling down towards 120 K. This confirms that the resonance occurs within the triplet excited state and a spin exchange interaction exists between copper ions.[8] Thus, the structure of the copper complex may be dimeric with the carboxyl acting as a bridging group.

The effective magnetic moments of the copper complex (**1**) are 1.3 B.M. at 4 K and 1.6 B.M. at 100 K. These values are lower than the spin-only magnetic moment 1.73 B.M. The effective magnetic moment decreases with decreasing temperature which implies the existence of an antiferromagnetic spin exchange interaction between the two copper ions in the dimer.

Abstract—The binuclear double-bridged acetylide complexes $[Pt(\mu\text{-}C{\equiv}CR)(C_6F_5)(PPh_3)]_2$ [R = Ph (**1**), Bu^t (**2**), $SiMe_3$ (**3**)] have been synthesized from [*trans*-$Pt(C{\equiv}CR)_2(PPh_3)_2$] and [*cis*-$Pt(C_6F_5)_2(THF)_2$] (THF = tetrahydrofuran). The crystal structure of $[Pt(\mu\text{-}C{\equiv}CPh)(C_6F_5)(PPh_3)]_2$ (**1**) has been established by X-ray diffraction methods. The structure shows that two identical $[(PPh_3)(C_6F_5)PtC{\equiv}CPh]$ units are joined together through η^2-bonding of M—C≡CPh units. This indicates that the complex is formed via a rearrangement of groups between the two metal centres. Treatment of $[Pt(\mu\text{-}C{\equiv}CR)(C_6F_5)(PPh_3)]_2$ with L (L = PPh_3, py = pyridine) produces simple bridge-cleavage reactions giving the mononuclear complexes [*trans*-$Pt(C_6F_5)(C{\equiv}CR)(PPh_3)L$] (**4–9**).

Over the past decade intense research activity has been expended on homo- and heterobinuclear complexes stabilized through bridging acetylide ligands.[1–3] This is due both to their structural interest and to the possibility of observing new useful transformations by means of the activation of the acetylenic fragment (—C≡CR) coordinated to two reactive metal centres.[4–6]

Following our recent studies on the chemical reactivity of platinum acetylide complexes we have shown that [*cis*-$M(C_6F_5)_2(THF)_2$] (M = Pt, Pd) are excellent precursors for the synthesis of complexes containing the moiety "$M(C_6F_5)_2$". Thus, the neutral bis-acetylide complexes [*cis*-$L_2Pt(C{\equiv}CR)_2$] react with [*cis*-$M(C_6F_5)_2(THF)_2$] to yield the neutral asymmetric binuclear complexes $[\{L_2Pt(C{\equiv}CR)_2\}M(C_6F_5)_2]$, in which the unit "*cis*-$L_2Pt(C{\equiv}CR)_2$" is acting as a chelating metallo ligand towards the "$M(C_6F_5)_2$" fragment. By contrast, treatment of [*cis*-$M(C_6F_5)_2(THF)_2$] with the anionic derivatives Q_2[*cis*-$Pt(C_6F_5)_2(C{\equiv}CR)_2$] gives, probably through intramolecular σ-alkynyl migration reactions, doubly acetylide-bridged complexes of the type $Q_2[(C_6F_5)_2Pt(\mu\text{-}C{\equiv}CR)_2M(C_6F_5)_2]$.[7] In this paper we describe the reactions between [*trans*-$Pt(C{\equiv}CR)_2(PPh_3)_2$] (R = Ph, Bu^t, $SiMe_3$) and [*cis*-$Pt(C_6F_5)_2(THF)_2$], which

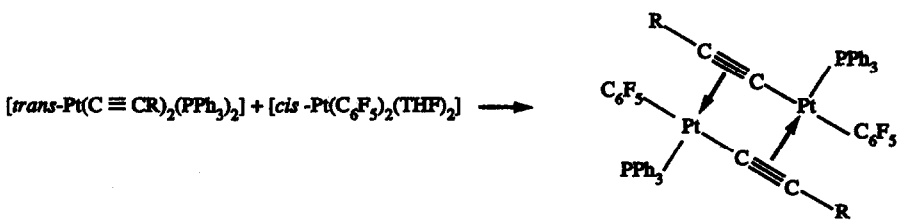
take place with redistribution of the ligands. The neutral binuclear doubly acetylide bridged complexes $[Pt(\mu\text{-}C{\equiv}CR)(C_6F_5)(PPh_3)]_2$ are obtained and the reactions of such binuclear complexes with neutral ligands are studied.

RESULTS AND DISCUSSION

The reactions between [*trans*-$Pt(C{\equiv}CR)_2(PPh_3)_2$] and [*cis*-$Pt(C_6F_5)_2(THF)_2$] in CH_2Cl_2, at room temperature and under nitrogen, render neutral double-bridged binuclear acetylide complexes **1–3** in good yield [eq. (1)]. These complexes have been characterized by elemental analysis and spectroscopic methods [mass spectrometry, IR, ^1H (Experimental), ^{31}P and ^{19}F NMR (Table 1)], together with the X-ray structure of complex **1**. Compound **2** crystallizes with CH_2Cl_2, which is supported by elemental analysis and ^1H NMR spectroscopy.



(1)

R = Ph (1)
R = Bu^t (2)
R = $SiMe_3$ (3)

As is well known acetylide bridging ligands can display a range of different bonding situations[1] and in order to ascertain the structural characteristics of the acetylide groups in these neutral complexes, an X-ray diffraction study of complex **1** has been performed. Suitable crystals for X-ray study have been obtained by slow diffusion of n-hexane into a dichloromethane solution of the compound at room temperature.

A drawing of the molecular structure of **1** is shown in Fig. 1. Selected bond distances and angles are listed in Table 2. Compound **1** is a centrosymmetric alkynyl-bridged dimer formed by the mutual interaction of two identical $(PPh_3)(C_6F_5)Pt(C{\equiv}CPh)$ units. In each unit the platinum atom is in an approximately square-planar environment formed by the phosphorus atom of the PPh_3 ligand, two carbon atoms mutually *trans* (the C-*ipso* atom of the C_6F_5 group and the C_α atom of the C≡CPh ligand) and the midpoint of the C≡C triple bond of the phenylacetylide ligand of the other unit. The central C_4Pt_2 core atoms are co-planar, although both planar[3,8] and non-planar[4,7] C_4M_2 cores have been found in double-bridged binuclear acetylide complexes. The Pt(1)—P(1) [2.250(2) Å], Pt(1)—C(1) [2.026(6) Å] and Pt(1)—C(9) [2.049(6) Å] distances are similar to those found in other platinum complexes with these types of ligands.[7,9–11]

The most significant feature is that the platinum

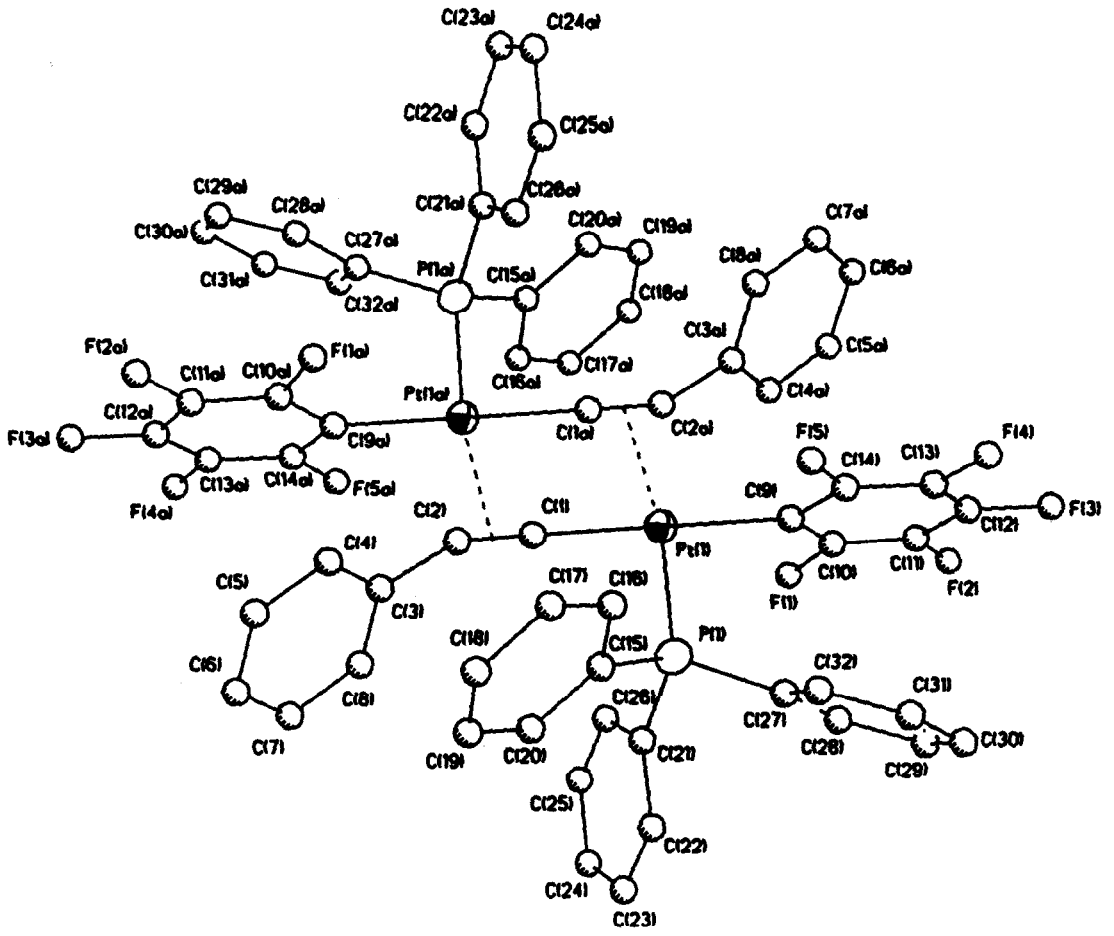


Fig. 1. View of the structure of the complex $[Pt(\mu\text{-}C{\equiv}CPh)(C_6F_5)(PPh_3)]_2$ (**1**) with the atomic numbering scheme.

acetylide π-linkages are asymmetric, as is reflected by the bond lengths from Pt(1A) to the two carbon atoms C(1) and C(2); the Pt(1A)—C(2) distance [2.261(6) Å] being substantially shorter than Pt(1A)—C(1) [2.362(6) Å]. Although this very characteristic structural feature contrasts with the symmetrical π-linkages found in the binuclear anion $[(C_6F_5)_2Pt(\mu\text{-}C{\equiv}CPh)_2Pt(C_6F_5)_2]^{2-}$ (**A**),[7] it has been previously observed in other σ–π acetylide-bridging binuclear complexes[4,8a,12,13] and is partly explained by the resonance structures shown in Scheme 1.

Table 2. Selected bond lengths (Å) and angles (°) for complex **1**

B C B'

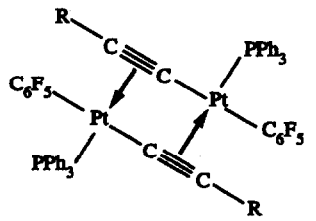
On coordination the Pt(1)—C(1)—C(2) unit remains almost linear [175.1(5)°], but the phenyl group is slightly bent away [∠C(1)—C(2)—C(3) = 151.2(6)°] from the side-on coordinated metal centre Pt(1A). The acetylide groups adopt a *cis*-bent arrangement. The C(1)—C(2) distance [1.199(8) Å] is identical (within experimental error) to the corresponding distances found in the binuclear anion **A**.[7] In contrast, the distance between the platinum atoms is much longer in complex **1** [3.653(1) Å] than in the binuclear anion **A** (3.43 Å).[7]

The IR spectra of compounds **1–3** all show a medium intensity absorption in the 1915–1986 cm^{-1} region due to $\nu(C{\equiv}C)$. As expected these absorptions appear at lower frequencies than those in the starting materials [*trans*-$Pt(C{\equiv}CR)_2(PPh_3)_2$] [R = Ph,[14] Bu^t,[9] $SiMe_3$ (see Experimental)] (2110–2041 cm^{-1}). Complexes **2** and **3** show an absorption due to the *X*-sensitive mode of the C_6F_5[15] groups (B_u), in good agreement with that expected for a compound of C_{2h} symmetry. The assignment of this *X*-sensitive band in **1** is precluded because of the presence, in this region, of an internal absorption of —C≡CPh.

The ^{31}P NMR spectra of **1–3** exhibit the expected singlet flanked by two platinum satellites (Table 1). The magnitude of $^1J(^{195}Pt—^{31}P)$ (3976–4006 Hz) is larger than that of the corresponding asymmetric isomers [$\{(PPh_3)_2Pt(C{\equiv}CR)_2\}Pt(C_6F_5)_2$] (*ca* 2600 Hz) reported previously.[7] These values are also considerably larger than those reported for mononuclear acetylide complexes having a tertiary phosphine *trans* to a terminal acetylide group (*ca* 2100 Hz).[16] This suggests that acetylide groups bound in a π-fashion exert a lower *trans* influence than corresponding groups which are σ-bonded. In complexes **2** and **3** both acetylide ligands are equivalent, giving rise in their ^1H NMR spectra to the expected singlet for the Bu^t and $SiMe_3$ groups, respectively (see Experimental). The ^{19}F NMR spectra of complexes **1** and **3** exhibit the typical pattern of three signals in a 2:1:2 ratio (Table 1) due to two equivalent C_6F_5 groups, for which the plane of coordination is a plane of symmetry. By contrast the corresponding ^{19}F NMR spectrum of the t-butyl derivative **2** at room temperature shows five signals: one sharp resonance at −163.7 ppm (Fp), two broad *ortho*-fluorine resonances centred on −111.7 and −117.1 ppm, respectively, and two broad *meta*-fluorine signals (−164.2 and −165.9 ppm). By lowering the temperature (see Fig. 2 and Table 1 for data at −85°C) the five signals are clearly resolved. This spectral pattern indicates the lack of a symmetry plane in this molecule and can be explained by assuming a non-planar structure for complex **2** at low temperature. Similar non-planar structures have been previously found in doubly acetylide-bridged binuclear complexes.[4,7] At higher temperatures (40°C, 55°C) the two *ortho*-fluorine signals (as well as the two *meta*-fluorine signals) collapse to give broad unresolved signals (δF_{ortho} = −112.8; δF_{meta} = −164.9 ppm) at 55°C, suggesting the beginning of dynamic behaviour.

Finally, it is interesting to emphasize the different behaviour of both [*cis*-$M(C{\equiv}CR)_2L_2$] and [*trans*-$M(C{\equiv}CR)_2L_2$] towards [*cis*-$M(C_6F_5)_2(THF)_2$]. With the *cis*-derivatives binuclear asymmetric complexes [$\{L_2Pt(C{\equiv}CR)_2\}M(C_6F_5)_2$], with the bis-acetylide complex acting as a chelate ligand, are formed,[7] while the reactions with the *trans*-derivatives result in a redistribution of ligands and formation of the symmetric binuclear complexes **1–3**.

In order to explore the reactivity of these doubly acetylide-bridged diplatinum complexes (**1–3**) a few reactions with neutral donor ligands have been performed. Treatment of the bridged complexes **1–3** with PPh_3 or py brings about bridge splitting to give mononuclear complexes [*trans*-$Pt(C_6F_5)(C{\equiv}CR)(PPh_3)_2$] [R = Ph (**4**), R = Bu^t (**5**), R = $SiMe_3$ (**6**)] and [$Pt(C_6F_5)(C{\equiv}CR)(PPh_3)py$] [R = Ph (**7**), R = Bu^t (**8**), R = $SiMe_3$ (**9**)], respectively [eq. (2)].



$$+2L \longrightarrow 2\ [Pt(C_6F_5)(C{\equiv}CR)(PPh_3)L] \quad (2)$$

R = Ph;	L = PPh_3(4)	R = Ph;	L = py(7)
R = Bu^t;	L = PPh_3(5)	R = Bu^t;	L = py(8)
R = $SiMe_3$;	L = PPh_3(6)	R = $SiMe_3$;	L = py(9)

We have observed that the fastest and easiest reactions occur with complex **1**. Thus, whereas **1** reacts readily with a stoichiometric amount of PPh_3 or py, the reaction between **2** and PPh_3 requires 6 h for completion and a large excess of py must be used to bring about complete reaction (see Experimental). On the other hand, although the acetylide bridges in complex **3** are easily cleaved by using a stoichiometric amount of PPh_3, the reaction with pyridine is more complex. Thus, treatment of **3** with a slight excess of pyridine (4 h under reflux and 12 h at room temperature) renders a colourless solution, from which a first fraction containing **9** and unreacted **3** (IR spectroscopy) and a second fraction of **9** (25% yield) can be isolated. However, with a shorter reaction time (3 h at room temperature) **3** did not react appreciably with py and longer reaction times or a large excess of py only produce mixtures which contain [*cis*-$Pt(C_6F_5)_2py_2$] (IR spectroscopy), **6**, **9** (^{31}P NMR spectroscopy) and an unidentified material with $\delta(P) = 14.8$ and $^1J(^{195}Pt—^{31}P) = 3674$ Hz. The formation of **6** indicates that the reaction occurs with ligand rearrangement. On the other hand, **1**, the most reactive, does not react in CH_2Cl_2 with CO at room temperature, and from the reactions between **1** or **3** with 2,2′-bipy (molar ratio 1 : 1) in CH_2Cl_2 (at room temperature or at reflux), only the starting materials are recovered.

Analysis, yields, relevant IR data and ^1H NMR data for complexes **4**–**9** are given in the Experimental. ^{19}F and ^{31}P NMR data are listed in Table

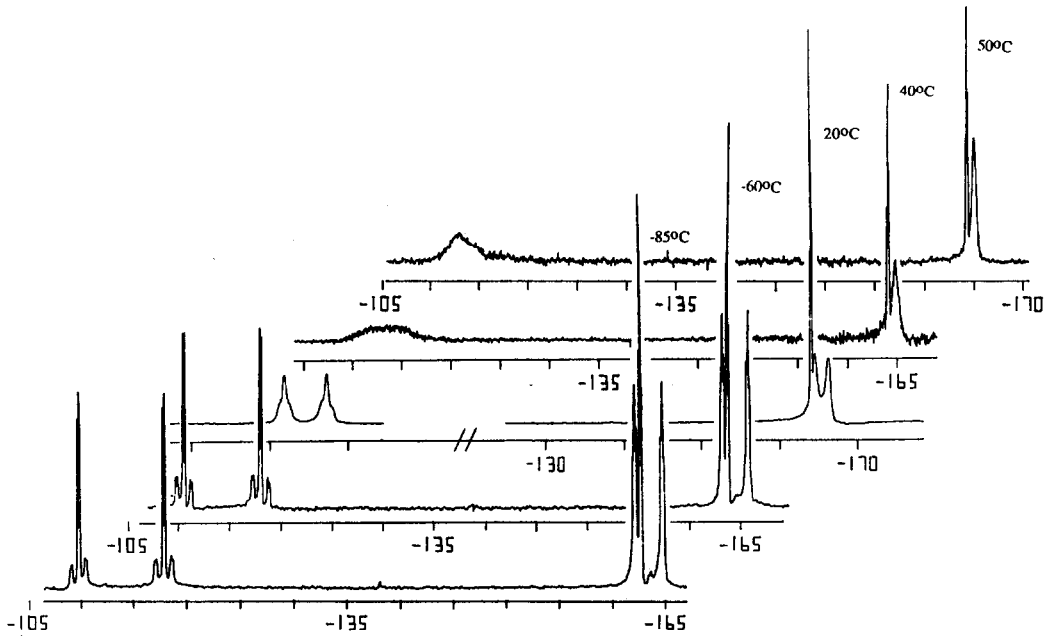


Fig. 2. ^{19}F NMR spectra of the complex [Pt(μ-C≡CBu^t)(C_6F_5)(PPh_3)]$_2$ (**2**) in CD_3COCD_3 at different temperatures.

1. The IR spectra of all the complexes show an absorption in the 2047–2119 cm^{-1} range, due to $\nu(C{\equiv}C)$, which indicates terminal coordination of the acetylide ligand.[17] The ^{31}P NMR spectra of complexes **4–6** show (Table 1) that both phosphorus nuclei are equivalent, indicating a *trans* structure for these complexes. Moreover, the absence of an absorption due to PPh_3 in the 540–560 cm^{-1} region (IR spectra) agrees with this assertion.[18] For the complexes $[Pt(C_6F_5)(C{\equiv}CR)(PPh_3)py]$ [R = Ph (**7**), R = Bu^t (**8**), R = $SiMe_3$ (**9**)] the structure with pyridine and PPh_3 ligands *trans* to one another is tentatively assigned on the basis of $^1J(^{195}Pt—^{31}P)$. Thus, the three compounds show one phosphorus resonance with this platinum–phosphorus coupling constant in the range (3768–3829 Hz), characteristic of $[trans\text{-}PtX_2(PR_3)py]$[19] and $[PtXY(PR_3)py]$[20] (phosphine *trans* to py) compounds.

EXPERIMENTAL

General considerations

Carbon, hydrogen and nitrogen analyses were performed on a Perkin–Elmer 240-B microanalyser. IR spectra were recorded (in the range 4000–200 cm^{-1}) on a Perkin–Elmer 883 spectrometer using Nujol mulls between polyethylene sheets. Proton, ^{19}F and ^{31}P NMR spectra were recorded on a Varian XL-200 or Unity-300 spectrometer. Chemical shifts are reported in ppm relative to external standards ($SiMe_4$, $CFCl_3$ and 85% H_3PO_4). Mass spectra were recorded on a VG Autospec. Literature methods were used to prepare: $[PtCl_2(tht)_2]$,[21] $[cis\text{-}PtCl_2(PPh_3)_2]$,[22] $[cis\text{-}Pt(C_6F_5)_2(THF)_2]$[23] and $[trans\text{-}Pt(C{\equiv}CPh)_2(PPh_3)_2]$.[14] $[Trans\text{-}Pt(C{\equiv}CR)_2(PPh_3)_2]$ (R = Bu^t, $SiMe_3$) were prepared as described below.

$[Trans\text{-}Pt(C{\equiv}CBu^t)_2(PPh_3)_2]$[24]

$[PtCl_2(tht)_2]$ (0.7 g, 1.583 mmol) was added, under nitrogen, to an ethereal solution of $LiC{\equiv}CBu^t$ at −10°C (8.706 mmol)[10] and the stirred mixture was allowed to warm to room temperature over 30 min. Moist ether (10 cm^3) was added to destroy the excess $LiC{\equiv}CBu^t$ and the solution was evaporated to dryness. The residue was treated with EtOH (40 cm^3) and acetone (20 cm^3), giving a colourless solution which was stirred with PPh_3 (1.24 g, 4.746 mmol) for 12 h. The resulting white solid, $[trans\text{-}Pt(C{\equiv}CBu^t)_2(PPh_3)_2]$, was filtered off, washed with acetone and air dried, yield 84%.

$[Trans\text{-}Pt(C{\equiv}CSiMe_3)_2(PPh_3)_2]$

A solution of $LiBu^n$ in hexane (1.8 mol dm^{-3}, 1.67 cm^3, 3.036 mmol) was added dropwise, under nitrogen, to an ethereal (20 cm^3) solution of $Me_3SiC{\equiv}CH$ (0.29 g, 2.0357 mmol) at −10°C. After 30 min stirring $[cis\text{-}PtCl_2(PPh_3)_2]$ (0.8 g, 1.0119 mmol) was added and the mixture stirred overnight at room temperature. The resulting white suspension was evaporated to dryness and the residue extracted with CH_2Cl_2 (50 cm^3) and filtered. The resulting solution was evaporated to dryness and the residue was treated with acetone (20 cm^3), giving $[trans\text{-}Pt(C{\equiv}CSiMe_3)_2(PPh_3)_2]$ as a white solid; yield 65%. Found: C, 60.4; H, 5.3. Calc.: C, 59.7; H, 5.6%. IR data (cm^{-1}): $\nu(C{\equiv}C)$ 2041 (s). ^1H NMR ($CDCl_3$, 200 MHz): δ −0.49 (s, $SiMe_3$), δ 7.35, 7.74 (m, Ph). $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ 18.46 [$^1J(^{195}Pt—^{31}P)$ = 2690 Hz].

Preparation of the complexes

$[Pt(\mu\text{-}C{\equiv}CPh)(C_6F_5)(PPh_3)]_2$ (**1**). $[Cis\text{-}Pt(C_6F_5)_2(THF)_2]$ (0.0704 g, 0.1085 mmol) was added, under N_2, to a CH_2Cl_2 solution of $[trans\text{-}Pt(C{\equiv}CR)_2(PPh_3)_2]$ (0.1 g, 0.1085 mmol) and the mixture was stirred at room temperature for 4 days. The yellow solution was filtered, reduced in volume (*ca* 1 cm^3) and mixed with hexane (*ca* 10 cm^3). The resulting solid was recrystallized from dichloromethane–hexane giving white crystals of **1**. Yield 73%. Found: C, 52.8; H, 2.9. Calc.: C, 53.0; H, 2.8%. IR data (cm^{-1}): $\nu(C{\equiv}C)$ 1963 (m). EI–MS: m/z = 1450 [M^+].

$[Pt(\mu\text{-}C{\equiv}CR)(C_6F_5)(PPh_3)]_2$ [R = Bu^t (**2**), R = $SiMe_3$ (**3**)]. A mixture of $[cis\text{-}Pt(C_6F_5)_2(THF)_2]$ (0.07635 g, 0.1134 mmol) and $[trans\text{-}Pt(C{\equiv}CR)_2(PPh_3)_2]$ (0.1 g for R = Bu^t or 0.1037 g for R = $SiMe_3$; 0.1134 mmol) in CH_2Cl_2 (20 cm^3) was stirred at room temperature for 4 days under nitrogen. Concentration of the resulting yellow solution and addition of EtOH (*ca* 30 cm^3) afforded **2** or **3** as white crystals, which were washed with EtOH; yields: **2**, 60%; **3**, 63%.

$[Pt(\mu\text{-}C{\equiv}CBu^t)(C_6F_5)(PPh_3)]_2 \cdot CH_2Cl_2$ (**2**). Found: C, 48.9; H, 3.2. Calc.: C, 48.9; H, 3.4%. IR data (cm^{-1}): $\nu(C{\equiv}C)$ 1986 (m), νX-sens(C_6F_5) 786 (vs). ^1H NMR ($CDCl_3$, 300 MHz): δ 0.4 (s, Bu^t); δ 5.30 (CH_2Cl_2); δ 7.36, 7.66 (m, Ph). E.I.–MS: m/z = 1410 [M^+].

$[Pt(\mu\text{-}C{\equiv}CSiMe_3)(C_6F_5)(PPh_3)]_2$ (**3**). Found: C, 48.1; H, 3.2. Calc.: C, 48.3; H, 3.3%. IR data (cm^{-1}): $\nu(C{\equiv}C)$ 1915 (s); νX-sens(C_6F_5) 790. ^1H NMR ($CDCl_3$, 200 MHz): δ −0.7 (s, $SiMe_3$); δ 7.4, 7.66 (m, Ph). E.I.–MS: molecular peak not observed.

[*Trans*-Pt(C≡CR)(C_6F_5)(PPh_3)$_2$] [R = Ph (**4**), R = Bu^t (**5**), R = $SiMe_3$ (**6**)]. Compound **4**: Triphenylphosphine (0.036 g, 0.1314 mmol) was added to a CH_2Cl_2 (15 cm^3) solution of **1** (0.1 g, 0.0662 mmol) and the mixture stirred at room temperature for 30 min. The solvent was removed and EtOH (5 cm^3) was added to the residue affording a white solid (**4**) which was washed with EtOH; yield 85%. Complexes **5** (yield 60%) and **6** (yield 63%) were prepared similarly. For **5** the initial yellow mixture of **2** and PPh_3 in CH_2Cl_2 was stirred until a colourless solution was obtained (*ca* 6 h). **4**. Found: C, 61.3; H, 3.6. Calc.: C, 60.8; H, 3.6%. IR data (cm^{-1}): ν(C≡C) 2119 (s); νX-sens(C_6F_5) 800 (s). E.I.–MS: m/z = 987 [M$^+$]. **5**: Found: C, 59.5; H, 3.9. Calc.: C, 59.6; H, 4.3%. IR data (cm^{-1}): ν(C≡C) 2129 (w); νX-sens(C_6F_5) 787 (s). ^{1}H NMR ($CDCl_3$, 200 MHz): δ 0.4 (s, Bu^t); δ 7.7, 7.4 (m, Ph). E.I.–MS: m/z = 967 [M$^+$]. **6**: Found: C, 57.1; H, 4.0. Calc.: C, 57.4; H, 4.0%. IR data (cm^{-1}): ν(C≡C) 2052 (m); νX-sens(C_6F_5) 789 (m). ^{1}H NMR ($CDCl_3$, 200 MHz): δ −0.6 (s, $SiMe_3$); δ 7.6, 7.3 (m, Ph). E.I.–MS: molecular peak not observed, m/z = 886 [M−C≡C$SiMe_3$].

[Pt(C_6F_5)(C≡CPh)(PPh_3)py] (**7**). To a solution of **1** (0.1 g, 0.0689 mmol) in CH_2Cl_2 (10 cm^3) was added pyridine (0.11 cm^{-3}, 0.1378 mmol). Immediately the solution turned deep yellow. The mixture was stirred for 2 h and then evaporated to dryness. Addition of n-hexane (10 cm^3) to the residue rendered **7** as a yellow solid, which was washed with n-hexane and air dried; yield 78%. Found: N, 1.6; C, 55.0; H, 3.1. Calc.: N, 1.7; C, 55.2; H, 3.1%. IR data (cm^{-1}): ν(C≡C) 2118 (s); νX-sens(C_6F_5) 781 (m). ^{1}H NMR ($CDCl_3$, 200 MHz): δ 6.98, 7.24, 7.30, 7.72 (m, overlapping, aromatic, PPh_3, py); δ 8.95 (m,. py). E.I.–MS: m/z = 804 [M$^+$].

[Pt(C_6F_5)(C≡CBu^t)(PPh_3)py] (**8**). Excess pyridine (0.2 cm^{-3}, 2.5054 mmol) was added to a yellow solution of **2** (0.124 g, 0.0878 mmol) in CH_2Cl_2 and the mixture was stirred at room temperature for 12 h. The resulting colourless solution was evaporated to dryness and n-hexane (20 cm^3) was added to give **8** as a white solid; yield 90%. Found: N, 1.9; C, 53.6; H, 3.6. Calc.: N, 1.8; C, 53.6; H, 3.7%. IR data (cm^{-1}): ν(C≡C) 2110 (w); νX-sens(C_6F_5) 787 (s). ^{1}H NMR ($CDCl_3$, 200 MHz): δ 0.8 (s, Bu^t); δ 7.3 (m, aromatic, PPh_3); δ 7.7 (m, overlapping, aromatic PPh_3, py); δ 8.97 (m, py). E.I.–MS: m/z = 784 [M$^+$].

[Pt(C_6F_5)(C≡C$SiMe_3$)(PPh_3)py] (**9**). Py (0.021 cm^3, 0.258 mmol) was added to a dichloromethane solution of **3** (0.125 g, 0.086 mmol) and the mixture stirred under reflux for 4 h and finally at room temperature for 12 h. Evaporation of the resulting solution and addition of isopropanol (2 cm^3) and n-hexane (5 cm^3) caused the precipitation of a white solid, which was identified by IR spectroscopy as a mixture of **3** [ν(C≡C) 1915 cm^{-1}] and **9** [ν(C≡C) 2047 cm^{-1}]. The resulting filtrate was concentrated and cooled to −30°C, yielding white crystals of **9** (25% yield). Found: N, 1.6; C, 51.0; H, 3.6. Calc.: N, 1.7; C, 51.0; H, 3.6%. IR data (cm^{-1}): ν(C≡C) 2047 (w): νX-sens(C_6F_5) 788 (s). ^{1}H NMR ($CDCl_3$, 200 MHz): δ −0.3 (s, $SiMe_3$); δ 7.32 (m, aromatic, PPh_3); δ 7.7 (m, overlapping, aromatic Ph_3, py); δ 8.93 (m, py). E.I.–MS: m/z = 800 [M$^+$].

Crystal structure determination

The crystal data for compound **1** are summarized in Table 3, together with some experimental details. Data were collected on an Enraf–Nonius CAD4 diffractometer using Mo-K_α radiation (λ = 0.71069 Å) at room temperature. The lattice dimensions and Laue group of the crystal were based on 25 reflections ($12° < \theta < 13°$). The structure was solved by Patterson synthesis (SHELXTL PLUS).[25] Most non-hydrogen atoms were located in the succeeding difference Fourier synthesis. The structure was refined by full-matrix least-squares with anisotropic thermal parameters for all atoms.

Table 3. Crystallographic data for complex **1**

Empirical formula	$C_{64}H_{40}F_{10}P_2Pt_2$
Crystal system	Monoclinic
Space group	$P2_1/n$
Unit cell dimensions	
a (Å)	8.384(2)
b (Å)	14.120(3)
c (Å)	22.664(5)
β (°)	99.90(3)
Volume (Å^3)	2643.1(10)
Z	2
Formula weight	1451.1
Density (calc.) (Mg m^{-3})	1.82
Absorption coefficient (mm^{-1})	5.423
2θ range (°)	4.0–50.0
Index ranges	$0 \leqslant h \leqslant 9$, $0 \leqslant k \leqslant 16$, $-27 \leqslant l \leqslant 27$
Reflections collected	4971
Observed reflections	3945 [$F > 5.0\sigma(F)$]
Abs.min.,Max.	1.141, 1.523
Weighting scheme	$w^{-1} = \sigma^2(F)+0.0004F^2$
Final R indices (obs. data)	R = 0.0277, wR = 0.0457
Largest shift/e.s.d.	< 0.001
Largest difference peak (e Å^{-3})	0.71

An empirical absorption correction was applied[26] after isotropic convergence. Hydrogen atoms were not included and C_6H_5 rings were treated as rigid, planar hexagons (C—C = 1.395 Å). The computer programs SHELXTL PLUS,[25] CADABS[27] and DIFABS[26] were used. Geometrical calculations were performed with the program PARST.[28] In the final converging refinement 304 parameters were fitted using 3945 data for a data-to-parameter ratio of 12.97.

Supplementary materials. Tables of interatomic distances, bond angles, positional and anisotropic thermal parameters, and observed and calculated structure factors have been deposited at the Cambridge Crystallographic Data Centre.

(*Received* 8 *January* 1993; *accepted* 23 *March* 1993)

Abstract—Fourteen lanthanide complexes of 1-phenyl-3-(2-hydroxylphenyl)-2-propenone with thiosemicarbazone (HL) of the composition $[LnL_2]ClO_4$ have been prepared and characterized on the basis of their chemical analyses, magnetic measurements, conductance, visible and IR spectra, TG–DTA and XPS data. It was found that HL acts as an SNO tridentate ligand; the electronic spectra of Pr^{3+}, Nd^{3+} and Sm^{3+} show characteristic *f–f* transitions and the nephelauxetic parameter ($\bar{\beta}$), the bonding parameter ($b^{1/2}$) and covalency parameter (δ) have been evaluated.

Studies relating the nature of metal complexes to an aspect of their biological activity are increasingly important. The reported antifungal properties of 2-acetyl-pyridine thiosemicarbazone[1] prompted a series of reports on the metal complexes of thiosemicarbazides and their thiosemicarbazones containing 3*d*, 4*d* and 5*d* electrons.[2–4] But lanthanide complexes of thiosemicarbazone with 1-phenyl-3-(2-hydroxyphenyl)-2-propenone have not been reported. It was therefore thought of interest to investigate the lanthanide complexes of thiosemicarbazones. The work described here is an attempt in this direction and deals with the synthesis of lanthanide metal complexes of ligand (HL) and the bonding model by the XPS method.

EXPERIMENTAL

Methods and materials

All chemicals and solvents were analytical grade and used without further purification. 1-Phenyl-3-(2-hydroxylphenyl)-2-propenone was prepared by a literature procedure.[5] Lanthanide metal perchlorates were made from their oxides and perchloric acid.

Physical measurements

Molar conductance of the complexes in DMSO at 0.001 mol l^{-1} concentration was measured with a DDS-IIA molar conductometer at 25°C. Electronic spectra of the solutions of the complexes in the 190–700 nm region were recorded on a Shimayu 240 spectrophotometer from Japan. The IR spectra (CsI pellets) were obtained on a NIC-5DX spectrophotometer in the 200–4000 cm^{-1} region. The magnetic measurement was made by the Guoy method using $Hg[Co(CNS)_4]$ as a calibrant. XPS were taken on a PHI-550 X-ray photoelectron spectrophotometer. Non-monochromatic Mg-K_α radiation was used from an X-ray gun operated at 15 kV and 20 mA. The base pressure was better than 7×10^{-9} mbar in the analyser. TG and DTA measurements were made in a nitrogen atmosphere between room temperature and 800°C using a thermoflex TG-DTA meter. The C, H, N, S and Cl contents were microanalysed on a Perkin–Elmer 240C Elemental Analyser. Metals were determined volumetrically by EDTA titrations[6] using xylenol orange as the indicator.

*Author to whom correspondence should be addressed.

Preparation of the ligand

1-Phenyl-3-(2-hydroxylphenyl)-2-propenone (1 mol), dissolved in the minimum quantity of MeOH (40 cm^3), and a solution of thiosemicarbazone (1 mol) in MeOH (20 cm^3) were mixed and refluxed for 2 h on a water-bath. The resulting solution was cooled and a crystalline product separated. The solid was filtered, washed with cold EtOH and Et_2O, dried *in vacuo*.

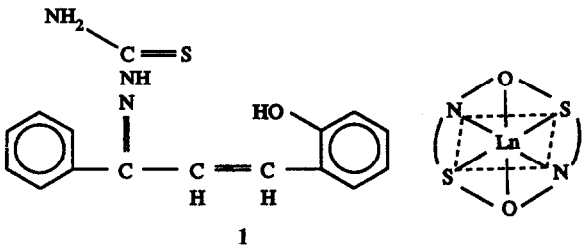
Preparation of the complexes

The same method of synthesis for the complexes was adopted as with the ligand. In a typical reaction, a dioxane solution of lanthanide (III) perchlorate and the ligand in a 1 : 2 molar ratio was refluxed for 3 h, then the product precipitated. It was filtered off, washed with dioxane followed by Et_2O and dried *in vacuo*.

RESULTS AND DISCUSSION

Elemental analyses, functional group tests, IR and XPS spectral data indicate the structure shown (structure **1**) for the ligand. The geometry of the ligand ruled out tetradentate coordination to a single metal ion and binuclear or multinuclear complex forms can also be excluded by molecular weight determinations (by Rast's method).

The complexes have the general formula $[LnL_2]ClO_4$, where Ln = lanthanide (excluding Pm). They are air-stable yellow solids, soluble in



1

dimethylformamide, dimethylsulphoxide and methanol, but insoluble in benzene and ethylacetate. The molar conductances of the complexes fall in the range expected for 1 : 1 electrolytes[7] and show little solvolytic tendency in DMSO.

IR spectra

The important bands observed in the IR spectra of the ligand as well as in its metal complexes are given in Table 2 along with their assignments. These assignments are based on the corresponding assignments of thiosemicarbazone[8] and the metal complexes derived from it.

The strong band observed at 3540 cm^{-1} in the IR spectra of the ligand has been assigned to the —OH stretching vibration. The disappearance of this band in the IR spectra of all the complexes indicates that the OH group of the ligand is involved in bond formation.

The absorption bands in the region 3340–3045 cm^{-1} in the free ligand and its metal complexes are assigned to NH stretching frequencies.[3] The ν(C=N) band of the ligand at 1625 cm^{-1} was

shifted down to *ca* 1600 cm^{-1} in the complexes, indicating participation of the azomethine nitrogen.[9] The decrease in ν(CS) from 865 cm^{-1} to *ca* 800 cm^{-1} shows the coordination of the thiol sulphur.[10] The characteristic bands around 1140 and 625 cm^{-1} arise from the ionic perchlorate which is uncoordinated. Of the several bands observed in the far-IR spectra, some may be tentatively assigned to ν(Ln—N), ν(Ln—S) and ν(Ln—O) vibrations. On the basis of the discussion referred to above, it is possible to conclude that the ligand is attached to the metal ion at three coordination sites involving one phenolic oxygen, one thioketosulphur and one nitrogen of the unsaturated CN group.

Magnetic moments and electronic spectra

The magnetic moments of the lanthanide complexed in Table 1 show little deviation from the Van Vleck values,[11] thereby indicating that 4*f*-electrons do not participate in bond formation in these complexes. Thus, the magnetic moments of these complexes are within the range predicted and observed in the compounds of the lanthanide ions.

The *f–f* transitions normally show weak perturbations on complexation. Increase in the intensity, shift of the centre and splitting of certain bands due to crystal field with respect to those of aquo ions are effects that can be observed on complex formation. The electronic spectra of Pr^{III} and Sm^{III} complexes were recorded in 2×10^{-3} M DMSO solutions. The spectra of the complexes show a shift of the spectral bands towards lower energy as compared with those of the aquo ions[12] due to the nephelauxetic effect (which is regarded as a measure of covalency). The bonding parameter ($b^{1/2}$), the covalency parameter (δ) and nephelauxetic ratio ($\bar{\beta}$) have been calculated[13] and compiled in Table 3. The lower nephelauxetic parameter ($\bar{\beta}$), positive bonding parameter ($b^{1/2}$) and Sinhas' parameter (δ) indicate some covalent character of the bond between the metal and ligand.

XPS spectra

The results of the XPS semi-quantitative analyses of the surface layers are in agreement with sample compositions. The only exception is the Cl:Ln ratio which decreases during irradiation of the sample. A new peak simultaneously appears with a Cl 2*p*-electron BE about 10 eV smaller, indicating decomposition of perchlorate anions. No other change either in positions or intensities of the other peaks was observed during the measurements.

The 3*d*- or 4*d*-electron BEs of the metals and the values for the N(C=N) 1*s* and the S 1*s* electron BEs are given in Table 4. The Ln 3*d*- or 4*d*-electron BE is closely related to the central atom charge and therefore to its valency.[14] The N 1*s*-electron spectra of the complexes are asymmetric and their deconvolution yields three binding energy components with an intensity ratio 1:1:1. The component with the highest BE value, belonging to the azomethine nitrogen, relative to that in the ligand indicates that the two coordinated nitrogens are in a symmetric form (structure).

The sulphur 1*s* peak of both the complexes and ligand is symmetric but with an intensity ratio 2:1.

The higher BE value relative to the ligand suggests thiol sulphur participation in coordination with the lanthanide metal. The measured 1*s* peak of O and deconvolution also revealed the symmetric character of the complexes. Carbon occurs in different chemical environments in the studied complexes, i.e. in phenyl groups (C is at 284.60 eV), in keto carbon (C is at 286.4 eV), and in N=C—C=C— groups (C is at 285.2 eV).

TG and DTA

Thermogravimetric analyses show all the complexes in a similar decomposition and in an anhydrous state. It can be seen from the diagrams that the complexes, $[LnL_2]ClO_4$, begin decomposing at *ca* 310°C exothermically. Decomposition is completed at *ca* 690°C with the formation of the lanthanide oxide.

From the above discussion a possible octahedral structure of these complexes is proposed.

THE STRUCTURES OF CROWN-ETHER/OXONIUM/AsF_6^- SPECIES

H. FEINBERG, I. COLUMBUS, S. COHEN, M. RABINOVITZ, H. SELIG* and G. SHOHAM

Institute of Chemistry, The Hebrew University of Jerusalem, Jerusalem 91904, Israel

(*Received* 7 *January* 1993; *accepted* 23 *March* 1993)

Abstract—The reaction of $XeF^+AsF_6^-$ with a series of crown ethers (containing *ca* 0.1 weight % H_2O) resulted in three new oxonium complexes of crown ethers, two of whose structures have been determined in detail by X-ray crystallography. Complex **I**, 18-C-6/H_3O^+/AsF_6^-, m.p. 180°C, is orthorhombic. In this structure the oxonium occupies the centre of the crown cavity, coordinated to its six ether oxygens with hydrogen bonds of average distance 2.75 Å. The AsF_6^- counter-ion is perfectly octahedral at a distance of 7.1 Å from the oxonium oxygen, forming no direct contacts with the crown ether. 18-C-6 adopts the most common "D_{3d}-like" conformation. Complex **II**, 2(15-C-5)/H_3O^+/AsF_6^-, m.p. 285°C, is tetragonal. The crystal structure shows a sandwich complex where the oxonium is located between the crown ethers. The counter-anion, AsF_6^-, is 8.0 Å from the oxygen atom of the oxonium and has no direct contacts with the crown ethers. The crown ether molecules are disordered. Complex **III**, 2(12-C-4)/H_3O^+/AsF_6^-, m.p. 150°C, is monoclinic. This structure is also a sandwich complex, where the oxonium is located between two crown ethers. Only five of the eight crown ether oxygens are involved in hydrogen bonds to the oxonium ion. The distances O_C—O_W range from 2.53 to 2.84 Å. The other three oxygens are at distances exceeding 3 Å from the oxonium ion.

Although $H_3O^+AsF_6^-$ is one of the most stable oxonium salts its crystallographic structure has not yet been determined. The lack of structural analysis of this species results probably from the fact that it exists at room temperature in a plastic phase, where the ions, centred on the atomic positions of an NaCl structure, are in large oscillatory motions.[1] Crown ethers are known for their abilities of complexation and stabilization of various ions and some of their complexes with oxonium salts have been characterized. Most of the complexes reported, such as 18-C-6/H_3O^+/Cl_2H^-,[2] DCH-18-C-6/H_3O^+/ClO_4^-,[3] 18-C-6$(COOH)_4/H_3O^+/Cl^-$[4] and 18-C-6/H_3O^+/BF_4^-,[5] are those with the common 18-C-6 crown ether, probably because of its cavity diameter, 2.6–3.2 Å, which is commensurate with the size of the oxonium ion. This is not the case with the smaller crown ethers, 15-C-5 and 12-C-4, which have cavities of 2.0 and 1.2 Å, respectively.[6] Oxonium ions cannot enter these cavities without severe distortions and until now no crystal structures of oxonium complexes involving these crown ethers have been reported.

We present here a series of oxonium complexes with the crown ethers 18-C-6, 15-C-5 and 12-C-4 and we follow the mode of complexation of the oxonium ion from encapsulation in the first instance to sandwich formation in the others.

EXPERIMENTAL

Materials

The crown ethers were obtained from Aldrich Co. and were used as supplied. They contained *ca* 0.1 wt % of water, as obtained by a Karl Fischer titration. $XeF^+AsF_6^-$ was prepared by the reported photochemical synthesis.[7] This species was identified by its Raman spectrum.[8]

* Author to whom correspondence should be addressed.

Preparation

Our original intention had been to encapsulate the XeF^+ cation in crown ethers by reacting $XeF^+AsF_6^-$ with a solution of the crown ether in CH_2Cl_2 solution, for **I** and **II**, or in CH_3CN, in the case of 15-C-5. However, during the experimental analysis it was realized that the water impurity in the crown ethers hydrolyses XeF^+ according to the equation:

$$XeF^+AsF_6^- + 2H_2O \longrightarrow Xe + 1/2O_2 + H_3O^+AsF_6^- + HF$$

and the resulting oxonium ion is encapsulated instead. Attempts to remove the water by refluxing with thionyl chloride or by azeotropic distillation with benzene were only partially successful, but were not sufficient to remove the H_2O completely. The reactants were loaded into a three-necked flask in a glove-bag under dry nitrogen. One of the side-arms was fitted with a $CaCl_2$ drying tube. $XeF^+AsF_6^-$ was added to the solution under a dry nitrogen flow with constant magnetic stirring. This was done by inverting an L-shaped side-arm connected via a ground glass joint, which was fitted with a Teflon sleeve. Crystals were obtained from the resulting solution by slow evaporation of the solvent. Similar results were obtained by pre-synthesizing $H_3O^+AsF_6^-$ [9] and reacting it with the crown ether in solution. However, this salt is less soluble in CH_2Cl_2. Complete crystallographic analyses were obtained on complexes **I** and **III**. An incomplete crystallographic analysis was obtained for complex **II**, but its stoichiometry was ascertained by chemical analysis. 2(15-C-5)/H_3O^+/AsF_6^-. Found: As, 11.9; C, 37.8; H, 6.8. Calc.: As, 11.5; C, 37.0; H, 6.7%.

Crystal structure analyses

Crystal structure determination of **I**. Crystal data: 18-crown-6/H_3O^+/AsF_6^-, $C_{12}O_7H_{27}F_6As$, $Mr = 472.25$, orthorhombic, *Pbam* (No. 55), $a = 10.097(2)$, $b = 8.877(1)$, $c = 10.958(2)$ Å, $V = 982.2(5)$ Å^3, $Z = 2$, $D_c = 1.60$ g cm^{-3}, Cu-K_α radiation, $\lambda = 1.54178$ Å, $\mu = 31.6$ cm^{-1}, $F(000) = 484$, T = room temperature.

Data collection and processing: Crystallographic measurements for compound **I** were performed on an Enraf–Nonius CAD-4 automatic four-circle diffractometer with graphite monochromated Cu-K_α radiation. Cell constants and an orientation matrix for data collection were obtained from a least-squares refinement based on the setting angles of 25 carefully centred high-order reflections. The data were collected using an $\omega/2\theta$ scan procedure to a maximum 2θ angle of 140°. A total of 1030 unique reflections were collected. The intensity of three reflections measured every 60 min remained constant throughout data collection and hence no decay correction was applied. An azimuthal scan of several reflections indicated no need for absorption corrections.

Structure analysis and refinement: The structure of **I** was solved by direct methods.[10] All non-hydrogen atoms were found in the initial *E*-map. For convenience all hydrogen atoms of the crown ether were initially calculated at idealized positions relative to the corresponding carbon atoms and were refined as "riding" atoms on their carbon atoms, with ideal C—H bond lengths and ideal H—C—H bond angles. The final cycle of full-matrix least-squares refinement was based on 783 observed reflections [with $I > 3\sigma(I)$] and 68 variable parameters and converged smoothly (with maximum shift/e.s.d. of 0.01) to crystallographic agreement parameters of $R = 5.4\%$ and $R_W = 8.2\%$. The maximum and minimum peaks in the final difference electron density map corresponded to 0.60 and -0.38 e Å^{-3}, respectively. All calculations were performed using the TEXSAN crystallographic software package.[10]

Crystal structure determination of **II**. Crystal data: 2(15-crown-5)/H_3O^+/AsF_6^-, $C_{20}O_{11}H_{43}F_6As$, $Mr = 648.47$, tetragonal, $P4_2$ (No. 77), $a = b = 9.187(2)$, $c = 17.884(3)$ Å, $V = 1509.4(9)$ Å^3, $Z = 2$, $D_c = 1.43$ g cm^{-3}, Mo-K_α radiation, $\lambda = 0.71069$ Å, $\mu = 11.99$ cm^{-1}, $F(000) = 676$, T = room temperature.

Data collection and processing: Crystallographic measurements for compound **II** were performed on a Phillips 1100/20 automatic four-circle diffractometer with graphite monochromated Mo-K_α radiation. Cell constants and an orientation matrix for data collection were obtained from a least-squares refinement using the setting angles of 22 carefully centred high-order reflections. Intensity data were collected in the $\omega/2\theta$ scan mode in the range $4° < 2\theta < 46°$, using a constant scan speed. Due to the small absorption coefficient and insignificant radiation damage, it was unnecessary to make corrections for radiation decay or absorption. The integrated intensities of 1254 reflections were measured, of which 1102 are unique.

Structure analysis and refinement: The structure of **II** was partially solved by direct methods. Most of the non-hydrogen atoms could be located in the initial *E*-map, which indicated that the crown ether molecules in the crystal are disordered. Most of the electron density observed in the map could be interpreted with a set of molecules of partial statistical occupancy of *ca* 0.6–0.7. The positional par-

ameters of these molecules were partially refined, using only the non-hydrogen atoms and isotropic temperature factors. Refinement was performed with considerable difficulties because of the unaccounted residual electron density, probably due to the alternative positions of the crown ethers at lower occupancy. The model at this stage clearly indicated a "sandwich" complex with two 15-C-5 macrocycles encapsulating each oxonium ion and a separate, non-interacting, AsF_6^- counter-anion. Refinement was stopped, however, because of the poor electron density map and insufficient observed data for a full atomic refinement. At this point the crystallographic R factor was 13.8%. Due to the relatively low level of confidence in the resulting structure it was decided not to continue with the crystal structure analysis, and hence the final model is not presented here in detail. The general features of the structure, the complex stoichiometry (which is supported by chemical analysis) and the oxonium–macrocycle interaction scheme are used here, therefore, only for comparison purposes.

Crystal structure determination of **III**. Crystal data: 2(12-crown-4)/H_3O^+/AsF_6^-, $C_{16}O_9H_{35}F_6As$, $Mr = 560.36$, monoclinic, $P2_1/c$ (No. 14), $a = 9.524(2)$, $b = 11.901(3)$, $c = 21.214(5)$ Å, $\beta = 98.8(2)°$, $V = 2376.2(9)$ Å^3, $Z = 4$, $D_c = 1.57$ g cm^{-3}, Mo-K_α radiation, $\lambda = 0.71069$ Å, $\mu = 15.1$ cm^{-1}, $F(000) = 1160$, $T =$ room temperature.

Data collection and processing: All measurements were made on a Phillips 1100/20 automatic four-circle diffractometer, with graphite monochromated Mo-K_α radiation. The cell constants and orientation matrix for data collection were obtained from least-squares refinement of 25 carefully centred high-order reflections. Intensity data were collected in the $\omega/2\theta$ scan mode in the range $4° < 2\theta < 50°$, using a constant scan speed. Out of the 3820 measured reflections, only 3708 unique reflections ($R_{int} = 0.016$) were used for refinement. No corrections for radiation damage or absorption effects were needed.

Structure analysis and refinement: The structure of **III** was solved by direct methods.[10] As for the case of compound **I** all the non-hydrogen atoms were found in the initial electron density map and all hydrogens were subsequently placed at calculated ideal positions. Cycles of full-matrix least-squares refinement were based on 2910 observed reflections [for which $I > 3\sigma(I)$] and 289 variable atomic parameters. The refinement converged in the last cycle (max. shift/e.s.d. of 0.02) to crystallographic agreement factors of $R = 4.3\%$ and $R_W = 5.3\%$. The maximum and minimum peaks in the final electron density difference map were 0.51 and -0.54 e Å^{-3}, respectively. All the steps of refinement and density maps were calculated with the TEXSAN crystallographic software package.[10]

RESULTS AND DISCUSSION

Final intramolecular bond lengths in complexes **I** and **III** are listed in Tables 1(a) and 1(b), respectively. Final intramolecular bond angles in complexes **I** and **III** are listed in Tables 2(a) and 2(b), respectively. The final crystal structure and the numbering scheme of **I** are shown in Fig. 1, while a stereoview of the crystal packing is shown in Fig. 2. Similarly, the numbering scheme and the structure of complex **III** is shown in Fig. 3, while the crystal packing is shown in Fig. 4.

In complex **I** (Fig. 1) the crown adopts the common round configuration of symmetry, "D_{3d}-like", where the oxonium ion occupies the centre of the macrocycle.[11] The oxonium ion is located practically equidistant (2.71–2.79 Å) from the six ether oxygens. Of these, three alternating oxygens are pointing "down" and three are pointing "up". The

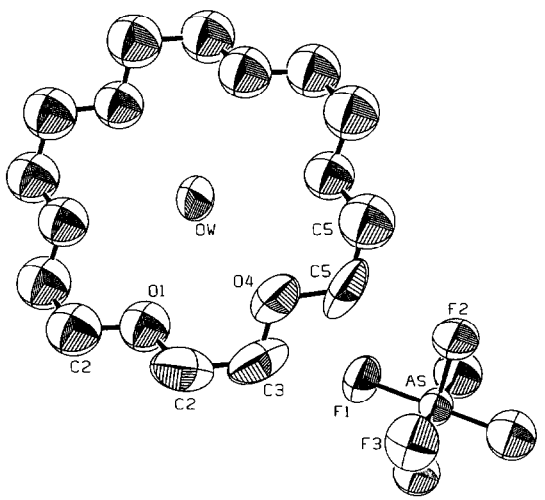

Fig. 1. The final crystal structure of the complex 18-crown-6/$H_3O^+AsF_6^-$ (compound **I**). Note the almost symmetrical interactions of the oxonium ion (Ow, centre) and the six macrocyclic etheral oxygens.

planes defined by these two sets of oxygens are nearly parallel to each other (interplanar angle of 173° and interplanar distance of 0.34 Å) and the oxonium ion is positioned midway between these

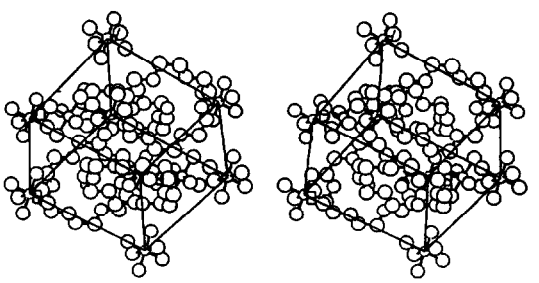

Fig. 2. A stereo view of the crystallographic unit cell packing of compound **I**. The packing scheme demonstrates that there are no intermolecular contacts between the counter-ion and either the oxonium ion or the crown ether.

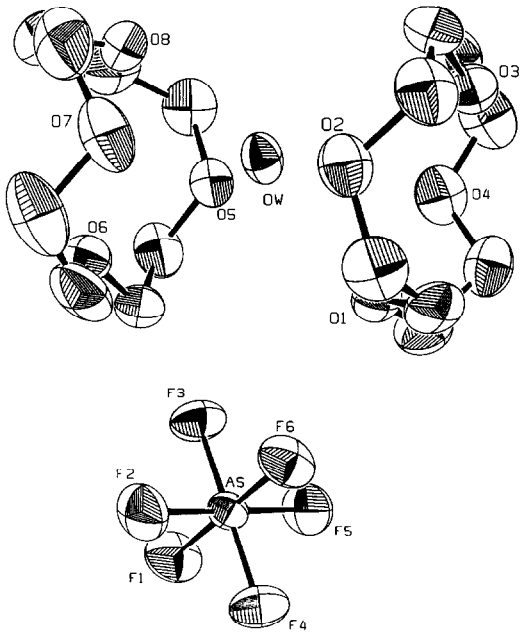

Fig. 3. The final crystal structure of the complex 2(12-crown-4)/$H_3O^+AsF_6^-$ (compound **III**). The oxonium ion (Ow, upper centre) is trapped nearly symmetrically between two 12-C-4 macrocycles, while the counter-ion (bottom) is outside of the interaction range.

planes. Since we are unable to locate the hydrogens of the oxonium ions in the electron density maps, we assume that the oxonium ion adopts two alternative orientations (each at 50% statistical occupancy) around the oxygen, such that two alternative sets of hydrogen positions are formed. One set involves the crown oxygens pointing "down" and the other set involves those pointing "up". The AsF_6^- anion, which is perfectly octahedral, is positioned 7.05 Å from the oxonium ion and is located 3.96 Å above the average plane of the six ether oxygens. The anion is not involved in any direct intermolecular contacts (Fig. 2). Complex **I** can also be considered a "sandwich structure" where the oxonium ion is sandwiched between the two alternative oxygen planes of the crown ether.

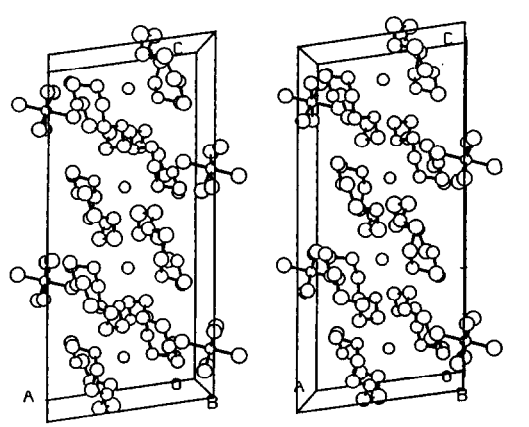

Fig. 4. A stereo view of the crystallographic unit cell packing of compound **III**, demonstrating no significant intermolecular interactions by the AsF_6^- counter-ion.

In complex **III**, 2(12-C-4)/H_3O^+/AsF_6^- (Fig. 3), the oxonium is sandwiched between two crown molecules, probably because of the size of the cavity, which is only 1.2 Å, not permitting encapsulation. In this complex the 12-C-4 molecules have practically no internal symmetry. In each molecule three of the ether oxygens [O(1), O(2) and O(4)] of one crown ether and three [O(5), O(7) and O(8)] of the other crown ether are pointing towards the oxonium, while one oxygen [O(3) and O(6)] of each crown ether is directed "outside". Since we are unable to locate the oxonium hydrogens in the electron density maps, we have to assume that they are located between the three macrocycle ether oxygens located at hydrogen bond distances from the oxonium ion. The "outside" pointing oxygens [O(3) and O(6)] are located at distances of 3.16 and 3.04 Å, respectively, from the oxonium oxygen and thus are not involved in hydrogen bonding. The other six oxygens are pointing "inside" towards the oxonium ion. Of these only five, O(1) and O(2) from one crown ether and O(5), O(7) and O(8) from the other crown ether, are at hydrogen bond distances of 2.64, 2.84 Å, and 2.53, 2.60 and 2.82 Å, respectively. The O(4) oxygen, despite its orientation, is located at a distance of 3.24 Å from the oxonium oxygen and hence cannot be involved in the hydrogen bonding scheme. This deviation is probably explained by crystal limitations or coordination sphere problems. It should also be pointed out that in one of the crown ethers four oxygens, O(1)–O(4), are in one plane (plane 1) within 0.22 Å, while in the other crown ether the four oxygens, O(5)–O(8), are in the plane (plane 2) within only 0.47 Å. The distance of plane 1 to O_W is 2.15 Å and that of plane 2 is 1.99 Å. The averages of the two planes are not exactly parallel, but at a dihedral angle of 16.4°. The counter-anion, AsF_6^-, is not involved in any direct intermolecular contacts (Fig. 4). The distance As—O_W is 6.80 Å and it is situated nearer plane 1 than plane 2.

As explained above no complete structure was obtained for complex **II** and only the oxygen of the oxonium ion and the atoms of AsF_6^- were located with certainty. The crown molecules were disordered. However, chemical analyses supported the 2 : 1 sandwich stoichiometry.

To our knowledge this is the first crystallographic report on a series of simple oxonium complexes with crown ethers and AsF_6^- counter-anions. The parameter of significance in this series appears to be the size of the "cavity", which determines whether

the oxonium ion is encapsulated or forms a sandwich with two crown ether molecules. In the case of 18-C-6 the size of the oxonium is exactly commensurate with the size of the "cavity", while with 15-C-5 and 12-C-4 the cavity is too small and hence sandwich compounds are formed. In all cases the AsF_6^- counter-anion is used to neutralize the overall charge of the system, but it is not in direct contact with the oxonium cation or the crown ether. The lack of such interactions could be explained, as least in part, by the softness and relative stability of the AsF_6^- species.

Supplementary material. Lists of the fractional coordinates of all atoms of 18-crown-6/H_3O^+/AsF_6^- (compound **I**) and 2(12-crown-4)/H_3O^+/AsF_6^- (compound **III**) [Tables S1(a), S1 (b)], anisotropic temperature factors for non-hydrogen atoms of **I** and **III** [Tables S2(a), S2(b)], all intramolecular distances in **I** and **III** (Tables S3(a), S3(b)], all intramolecular bond angles in **I** and **III** [Tables S4(a), S4(b)], all torsion angles for non-hydrogen atoms in **I** and **III** [Tables S5(a), S5(b)] and lists of observed and calculated structure factors for **I** and **III** [Tables S6(a), S6(b)] are provided as supplementary material (39 pages).

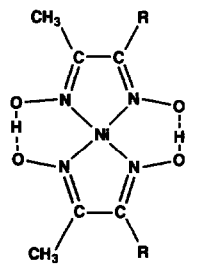
(*Received* 11 *November* 1992; *accepted* 23 *March* 1993)

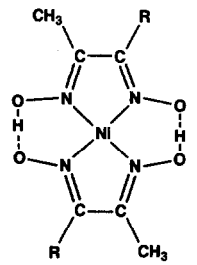
Abstract—The existence of geometrical isomers of several bis(*vic*-dioximato)nickel complexes with non-symmetrical ligands has been clarified by ^{1}H NMR. The general formula of the ligands is $CH_3C(=NOH)C(=NOH)R$, here R = Et, Pr^n, Bu^n, Ph, *p*-MeC_6H_4, *p*-$MeOC_6H_4$ and *p*-ClC_6H_4. The *trans* isomer of each complex is predominant in pyridine-d_5 solution. The *cis–trans* equilibrium constants of these complex in pyridine-d_5 have been estimated.

The structures of $Ni(Hdioxm)_2$ complexes (H_2dioxm = *vic*-dioxime) have been investigated and it has been established that, in the solid state or in chloroform solution, they take the square planar configuration.[1] On the other hand, they tend to be coordinated by one or two solvent molecules at the apical positions in pyridine or in other nucleophilic solvents, leading to square pyramidal or tetragonally distorted geometry.[2] Therefore, the existence of the *cis* and *trans* isomers of $Ni(Hdioxim)_2$ with non-symmetrical ligands was considered to be reasonable and several chemists have attempted to distinguish and separate the isomers.

In 1932 Sugden reported the separation of α- and β-forms of bis(1-phenyl-2,3-butanedione dioximato)nickel(II) by taking advantage of the difference in their solubilities in benzene. He assigned them to the *cis* and *trans* isomers, respectively.[3] Cavell and Sugden further reported that they also succeeded in separating geometrical isomers of bis(2,3-hexanedione dioximato)nickel(II).[4] However, Jensen *et al.* reinvestigated Sugden's



cis



trans

*Author to whom correspondence should be addressed.

experiment on bis(1-phenyl-2,3-butanedione dioximato)nickel(II) and concluded that the separated compounds are not geometrical isomers but isomers with different crystal forms.[5] Later, Pedersen and Larsen also investigated the isomerism of bis(1-phenyl-1,2-propanedione dioximato)nickel(II) by ^{1}H NMR. They concluded that only the *trans* isomer is present in a chloroform-d solution of the complex.[6]

We now report the presence of *cis* and *trans* isomers of Ni(Hdioxm)$_2$ complexes in equilibrium in solutions of chloroform and pyridine.

EXPERIMENTAL

Preparation of the oximes

1-*Phenyl*-1,2-*propane dionedioxime* (H_2phg). This compound was prepared by an ordinary synthetic method used in organic chemistry.[7] 1-Phenyl-1,2-propanedione was heated with approximately twice the molar amount of hydroxylamine hydrochloride in a 1 : 1 ethanol–water mixture under reflux for *ca* 1 h. The white precipitate which formed was recrystallized from ethanol.

2,3-*Pentanedione dioxime* (H_2ethg), 2,3-*hexanedione dioxime* (H_2prg) *and* 2,3-*heptanedione dioxime* (H_2butg). These compounds were prepared from commercially obtained 2,3-pentanedione, 2,3-hexanedione and 2,3-heptanedione, respectively, in a similar manner to the synthesis of H_2phg.

1-(p-*Methylphenyl*)-1,2-*propanedione dioxime* (H_2mephg). The preparation of this compound was performed according to the method of Hartung.[8] As a first step 1-(*p*-methylphenyl)-1,2-propanedione 2-oxime was synthesized by introducing freshly prepared gaseous nitromethane to an ethereal solution of equimolar *p*-methylpropiophenone for 15 min. After standing overnight the product was extracted with aqueous 10% NaOH solution and the extract was neutralized with cold hydrochloric acid. The white crystals which separated were recrystallized from toluene. The 1-(*p*-methylphenyl)-1,2-propanedione 2-oxime thus obtained was dissolved in aqueous 20% NaOH solution and an equimolar amount of hydroxylamine hydrochloride was added to the solution. The mixture was heated for 1 h and on adding sodium acetate a white precipitate was formed, which was recrystallized from 80% aqueous acetic acid.

1-(p-*Methoxyphenyl*)-1,2-*propanedione dioxime* (H_2mophg) *and* 1-(p-*chlorophenyl*)-1,2-*propanedione dioxime* (H_2clphg). These compounds were prepared in a similar manner to that used in the synthesis of H_2mephg described above, the starting materials being *p*-methoxypropiophenone and *p*-chloropropiophenone, respectively.

Preparation of the nickel complexes

The preparation of the nickel complexes with dioximes, i.e. Ni(Hethg)$_2$,[9] Ni(Hprg)$_2$,[9] Ni(Hbutg)$_2$,[3] Ni(Hphg)$_2$,[10] Ni(Hmophg)$_2$,[11] Ni(Hmephg)$_2$[11] and Ni(Hclphg)$_2$[11], has been reported. Each complex was prepared by mixing an oxime (2 mmol) in ethanol (30 cm^3) with nickel acetate 4-hydrate (1 mmol) in water (10 cm^3). After the mixture was heated on a water bath for 30 min an orange to orange–red precipitate was formed, which was recrystallized from chloroform and dried *in vacuo*. The elemental analyses of the nickel complexes are summarized in Table 1.

NMR measurement

^{1}H NMR spectra of the complexes were measured by a JNM GSX 400 spectrometer equipped with a temperature control apparatus.

The deuterated solvents were purchased from Aldrich Chemical Co. The concentrations of the samples were in the range 2×10^{-2}–5×10^{-2} mol dm^{-3} for pyridine-d$_5$ solutions and 5×10^{-3}–1×10^{-2} mol dm^{-3} for chloroform-d solutions.

The molar ratio of the isomers of each complex was estimated from the ratio of the areas of the two methyl peaks derived from each isomer in the spectrum. As the two peaks were slightly overlapped in most cases the area of each peak was calculated graphically on a computer by assuming them to be Lorentz curves. A cutting and weighing method was used in cases where overlapping regions of the peaks were negligible.

RESULTS AND DISCUSSION

The ^{1}H chemical shifts of the CH_3 groups of the complexes in chloroform-d and pyridine-d$_5$ at room temperature are summarized in Table 1. As shown in Table 1, each complex gives a single methyl peak or two largely overlapped methyl peaks in chloroform-d solution. For example, the separation between the two peaks is 0.003 ppm for Ni(Hmephg)$_2$. However, at -30°C, as shown in Table 1, all the single methyl peaks split into two peaks except Ni(Hprg)$_2$. The intensity ratio of the two peaks is approximately unity in every case. It is suggested that the two peaks derive from each of the geometrical isomers and that rapid interchange between them may occur at room temperature.

A broad peak at *ca* 18 ppm was observed for every complex in chloroform-d, which was assigned

Table 1. Elemental analyses and ^1H chemical shifts for CH_3 groups of $Ni(Hdioxm)_2$ complexes

Complex	Analysis: Found (Calc.) (%) C	H	N	Solvent	Chemical shift (ppm) CH_3—C=N[a]	Other CH_3 group

				C_5D_5N	2.029[b] 2.059			

[a] Chemical shifts (in $CDCl_3$) at $-30°C$ are given in parentheses.
[b] More intense signal.

to the hydrogen-bonded O—H···O proton in bis(dioximato)nickel complexes coordinated by nitrogen atoms.[6] Marov *et al.* reported, however, three peaks in this region for $Ni(Hdioxm)_2$ with non-symmetrical ligands for some solvents at room temperature. They suggested that this proved the existence of the *cis* and *trans* isomers.[12] The absence of split peaks in the region of our experiment may be due to rapid exchange reactions of hydrogen-bonded hydrogen atoms or fast isomeric exchange reactions of these complexes in chloroform-d.

The ^1H NMR spectrum of each complex in pyridine-d_5 showed a single CH_3C=N methyl peak immediately after dissolution, followed by the gradual appearance of a second peak in the lower field. The second peak grew with time, while the intensity of the first peak decreased, until a finite intensity ratio of the two peaks was attained. It can be concluded from the above observation that in the solid state only one of the isomers exists and on dissolution in pyridine it slowly isomerizes to the other, until the equilibrium

$$\textit{trans}\text{-Ni(Hdioxm)}_2 \rightleftharpoons \textit{cis}\text{-Ni(Hdioxm)}_2$$

$$K = [\textit{cis}\text{-Ni(Hdioxm)}_2]/[\textit{trans}\text{-Ni(Hdioxm)}_2]$$

is reached. As the table shows CH_3 groups other than from the CH_3—C=N group also split in the ^1H spectra. X-ray analysis of $Ni(Hethg)_2$ has already revealed that it has *trans* geometry in the solid state.[13] It follows that in the case of $Ni(Hethg)_2$ the primary signal arises from the *trans* isomer and the second from the *cis* isomer. For other complexes similarly only *trans* isomers may probably be prepared in an ordinary recrystallization process. Therefore, the primary peak can be assigned to the *trans* isomer in each case. The isomerization reaction of these complexes reaches its equilibrium in several hours at room temperature.

It can, therefore, be concluded that these complexes isomerize much faster in chloroform than in pyridine. These square planar complexes in chloroform probably isomerize by rapid intramolecular ligand rotation through a tetrahedral intermediate. The evidence in support of this mechanism is the absence of ligand exchange reactions between two different kinds of $Ni(Hdioxm)_2$ complexes in chloroform-d solution.[6]

The substituent effects of the complexes on the equilibrium constants of the isomerization reactions were estimated for these complexes at several

temperatures ranging from 303 to 343 K in pyridine-d_5. For the series $Ni(Hethg)_2$, $Ni(Hprg)_2$ and $Ni(Hbutg)_2$ $K = 1$ was given.

In the series $Ni(Hmophg)_2$, $Ni(Hmephg)_2$, $Ni(Hphg)_2$ and $Ni(Hclphg)_2$ the K values at room temperature are 0.95, 0.80, 0.74 and 0.71, respectively. In this series the electronic effects of the substituents on the phenyl groups appear to contribute to the K values as it is shown that the order of increase in K values coincides with that of the decrease in σ-values of Hammett's constants of the substituent on the phenyl group.

SYNTHESIS, THERMAL AND SPECTRAL INVESTIGATION OF A NEW BERYLLIUM PERIODATE HYDRATE

M. MANEVA* and M. GEORGIEV

Department of Inorganic Chemistry, Sofia Technology University, 1156 Sofia, Bulgaria

(*Received* 17 *June* 1992; *accepted* 23 *March* 1993

Abstract—A new beryllium periodate hydrate has been synthesized whose composition is $Be_2HIO_6 \cdot 6.5H_2O$. It has been identified by DTA, TG, DSC, IR spectra and X-ray powder diffraction. The compound is thermally stable up to 60°C, followed by three-step dehydration and decomposition to form BeO. The IR spectra prove the presence of the following structural groups: HIO_6^{4-}, BeO_4 and H_2O.

Published data about beryllium periodates are rather scanty. The first communications have been made by Atterberg[1–3] and are related to a meso-periodate of composition $Be_3(IO_5)_2 \cdot nH_2O$, where $n = 5, 11, 13$. Data have also been quoted in prominent literature about the formation of $Be_3(IO_5)_2 \cdot nH_2O$, where $n = 8, 12$.[4,5] More extensive studies have been reported for $Be(IO_4)_2 \cdot 8H_2O$[6–8] and, accordingly, $Be(H_4IO_6)_2 \cdot 4H_2O$. There is also information about the preparation and identification of $Be(H_4IO_6)_2 \cdot 2H_2O$.[7]

Interest in compounds of this group accounts for further studies in this direction. They resulted in the elaboration of a method of synthesizing a new beryllium periodate hydrate of composition $Be_2HIO_6 \cdot 6.5H_2O$, identified by DTA, TG, IR spectra and X-ray diffraction. This is the subject of the present publication.

EXPERIMENTAL

$Be_2HIO_6 \cdot 6.5H_2O$ was obtained using H_5IO_6 and $Be(NO_3)_2 \cdot 4H_2O$—p.a. Merck.

A solution of $Be(NO_3)_2 \cdot 4H_2O$ (20 g) in H_2O (20 cm^3) was added with continuous stirring using a magnetic agitator to a solution of H_5IO_6 (6 g) in H_2O (20 cm^3), the temperature being maintained at 60 ± 1°C. The homogeneous solution obtained was concentrated to a jelly-like mass, which was cooled and then treated several times with absolute C_2H_5OH under continuous trituration of the precipitate on the walls of the beaker. A white, fine crystalline substance was finally obtained and, after filtration, left in the air until a constant mass was obtained.

The compound was analysed by quantitative analysis: Be^{2+} was determined by weight as BeO upon heating to 950°C, while iodine was determined iodometrically.[9]

The thermal investigations of $Be_2HIO_6 \cdot 6.5H_2O$ were performed using a derivatograph MOM OD-102 Paulic–Paulic–Erdey system in the temperature range 25–1000°C, at a heating rate of 10° min^{-1} and 200 mg sensitivity. The DSC curves were obtained using an apparatus of the Mettler company—System TA 3000—at a heating rate of 10° min^{-1} in the 30–500°C temperature interval and 5 mg mass of the sample.

The IR spectra were taken in the 4000–2800 cm^{-1} range in Hostaflon and over 2800–400 cm^{-1} in KBr tablets on an IR "Shimatsu" spectrophotometer and on a UR-10 Zeiss spectrometer.

The diffractograms of the newly obtained compound and products of its decomposition were obtained using the apparatus HZG 4C-Zeiss with Cu-K_α radiation, $\lambda = 1.54178$ Å, and a nickel filter in the interval 4.03–78.18°.

RESULTS AND DISCUSSION

The data from the quantitative analysis, averaged from three different syntheses, are: Be = 5.07% and I = 35.33%. Those theoretically calculated for a compound with the formula $Be_2HIO_6 \cdot 6.5H_2O$ are, accordingly, Be = 5.02% and I = 35.36%.

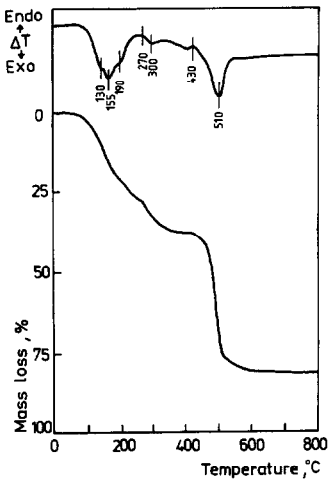

Fig. 1. DTA and TG curves of $Be_2HIO_6 \cdot 6.5H_2O$.

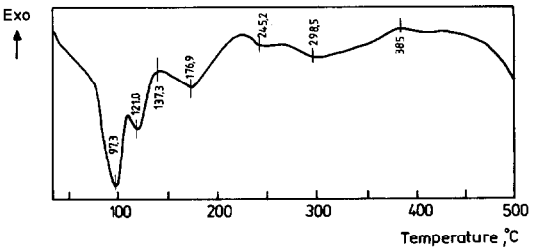

Fig. 2. DSC curve of $Be_2HIO_6 \cdot 6.5H_2O$.

The DTA and TG curves of $Be_2HIO_6 \cdot 6.5H_2O$ are shown in Fig. 1, while the DSC curve is shown in Fig. 2.

Table 1 shows the diagrams of thermal dehydration and decomposition, together with the values of the change in enthalpies of some phase transitions determined by the DSC curve. Figure 3 shows the IR spectrum of $Be_2HIO_6 \cdot 6.5H_2O$.

The curves shown in Figs 1 and 2 and the data from Table 1 indicate that the compound is stable up to 60°C. The process of dehydration takes place at three stages, the last also being associated with a process of decomposition of the compound.

The first endothermal effect observed in the DTA curve has a particularly marked width and makes it possible to record three temperatures—130°C, 155°C and 190°C. At the first two temperatures it is possible to record along the TG a change in the character of the curve, corresponding to $\Delta m_{exp} = 20.1\%$ theoretically and according to the proposed diagram of dehydration [Table 1, eq. (1)], $\Delta m_{calc} = 20.15\%$.

Corresponding to the examined effects in DSC there are two distinct and separate peaks with $T_{max} = 97.3°C$ and $T_{max} = 121.0°C$, with a total ΔH^0 of 60.3 kJ mol^{-1}. This ΔH^0 value is, however, relatively small for the release and evaporation of 4 mol H_2O under the conditions of DSC and leads to the formation of a three-phase systems: solid, liquid and vapours. This is corroborated by the small exothermal effect observed with $T_{max} =$ 137.3°C in DSC, which may be due to crystallization or dissolution of the newly obtained intermediate phase. The same exothermal effect is not seen in the DTA curve. The second dehydration stage, associated with the expansion of the endo effect observed in DTA, corresponds to $T_{max} = 190°C$. Corresponding to this in TG is $\Delta m_{exp} = 30.4\%$, as opposed to $\Delta m_{calc} = 30.08\%$ according to Table 1, eq. (2). This change in mass is recorded well due to the existence of distinct retention in TG. The examined degree of dehydration is registered along DSC by a separate endothermal effect with $T_{max} = 176.9°C$, characterized by $\Delta H^0 = 30.2$ kJ mol^{-1}.

The further course of the curves in DTA and DSC is analogous, with identical effects. There follows a

Table 1. DTA, TG and DSC data for $Be_2HIO_6 \cdot 6.5H_2O$

No.	Scheme of thermal decomposition	DTA and TG data			DSC data	
		T_{max} (°C)	Calc.	Exp.	T_{max} (°C)	ΔH^0 (kJ mol^{-1})

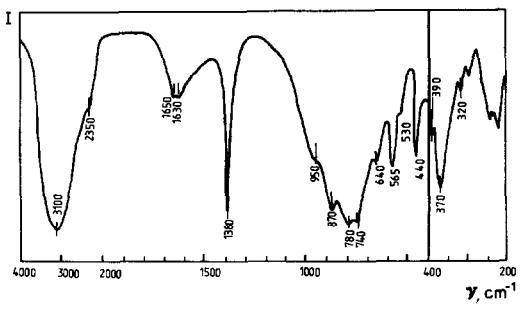

Fig. 3. IR spectra of $Be_2HIO_6 \cdot 6.5H_2O$.

small exo effect (T_{max} = 270°C at DTA and 245.2°C at DSC), which is probably due to crystallization of the compound obtained. The compound is unstable and a large endo effect (300°C DTA and 298.5° at DSC) corresponds to its decomposition. The products of the decomposition are BeO and $Be(IO_3)_2$, which are proved by X-ray phase analysis.

The amount of released oxygen and water leads to a decrease in the mass of 40.2% along the TG curve, with theoretically calculated Δm_{calc} = 39.55%. The change in enthalpy at the decomposition of the compound, recorded along DSC, is 20.3 kJ mol^{-1}. The horizontal section in the TG curve is proof of the stability of the intermediate mixture of BeO and $Be(IO_3)_2$. Corresponding to the decomposition of $Be(IO_3)_2$ is the exo effect at T_{max} = 430°C along DTA, which passes abruptly into an endo effect, in line with the decomposition of I_2O_5—fully analogous to those observed by us at the thermal investigations of other beryllium iodates and periodates.[7,18] The final product of the decomposition is BeO, which is identified using IR spectra and X-ray phase analysis. The thermal decomposition of $Be_2HIO_6 \cdot 6.5H_2O$ may be referred to one of the four diagrams for the decomposition of periodates, namely periodate–iodate–oxide, which is typical for the decomposition of the other beryllium periodates we examined.

The interpretation of the IR spectra of $Be_2HIO_6 \cdot 6.5H_2O$ is of particular interest, because it is possible that a compound with the formula $Be_4I_2O_{11} \cdot 14H_2O$ may correspond to the same chemical composition. This is why it was of interest to firstly identify the character of the anion. The anion of the type HIO_6^{4-} is best proved by the presence of the two bending vibrations of the I—O—H group, namely δ(I—OH) and γ(I—OH), whose absorption bands are observed in the spectrum of the compound (Fig. 3) at 1380 and 780 cm^{-1}. Reference of these absorptions to the bending vibrations is on the basis of published data.[10,11] The presence of the IO_6^{5-} ion is also identified with the appearance in the spectrum of the absorption band at 640 cm^{-1}, which is attributed to the asymmetric stretching vibration (ν_3)[11,12] of I—O for this periodate ion. The analogous vibration for IO_4^- lies at 850 cm^{-1}.[11,12] The $\nu_3(F_2)$ vibration examined appears in immediate proximity to the strong and relatively broad absorption bands with maxima at 870, 780 and 740 cm^{-1}, on account of which it appears with reduced intensity. It is possible that some of the components of the triply degenerated ν_3 vibration, upon disturbed symmetry, could also lie in this region.

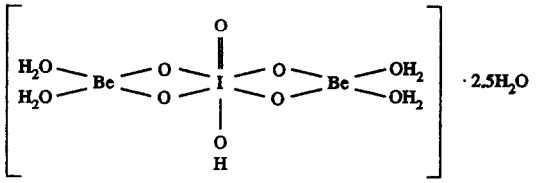
The absorptions (780, 740 cm^{-1}) may be differentiated by attributing the librational vibration (R) of the coordinated water molecules to the band at 740 cm^{-1} due to the weak absorption observed at 2630 cm^{-1}, which is in turn due to the composite vibration $\delta(H_2O)+R$.

According to data published in the prominent literature the absorption band observed at 440 cm^{-1} may be attributed to the bending vibration of the O—I—O group.[13]

The spectrum (Fig. 3) also shows an absorption band at 565 cm^{-1}, which we refer to as the $\nu_1(A_1)$ vibration of the BeO_4 group participating in the structure of the investigated compound,[14–17] while that at 370 cm^{-1} may be attributed to the stretching vibration ν(Be—O). The weak absorption band at 320 cm^{-1} (ν_4) is also due to the same group.

The data on hydrated water [$\nu(H_2O)$ and ν(OH)] show the presence of two crystallographically different water molecules [$\nu(H_2O)$ is split—1650 and 1630 cm^{-1}]. In this case four water molecules are coordinated around beryllium, while the remaining ones are involved in hydrogen bonds.

The information on $Be_2HIO_6 \cdot 6.5H_2O$ obtained from the IR spectra makes it possible to propose the following molecular formula:



The newly synthesized compound has been characterized by X-ray powder diffraction and the data for *d*-spacings and intensity ratios are given in Table 2.

COVALENT ATTACHMENT OF TWO IMPORTANT DICOPPER(II) SYSTEMS IN A ONE-DIMENSIONAL POLYMERIC CHAIN: AN X-RAY STRUCTURE OF $[\{Cu_2(en)_2(OH)_2 \cdot Cu_2(O_2CMe)_4\}(PF_6)_2 \cdot 0.5EtOH]_\alpha$ SHOWING THE SHORTEST Cu···Cu DISTANCE IN THE TETRAACETATO CORE

SHANMUGAM MEENAKUMARI and AKHIL R. CHAKRAVARTY*

Department of Inorganic and Physical Chemistry, Indian Institute of Science, Bangalore 560 012, India

(*Received* 26 *February* 1993; *accepted* 2 *April* 1993)

Abstract—Reaction of $Cu_2(O_2CMe)_4(H_2O)_2$ with 1,2-diaminoethane(en) in ethanol, followed by the addition of NH_4PF_6, led to the formation of a covalently linked 1D polymeric copper(II) title complex showing alternating $\{Cu_2(en)_2(OH)_2^{2+}\}$ and $\{Cu_2(O_2CMe)_4\}$ units in the chain and the shortest Cu···Cu separation of 2.558(2) Å in the tetraacetato core.

Current interests in the chemistry of spin-coupled dimeric and polymeric copper(II) complexes lie towards understanding the magneto-structural relationships of such systems.[1–3] The discrete dimeric species that are subjected to extensive studies belong primarily to two important classes of copper(II) complexes, viz. $[Cu_2(O_2CMe)_4L_2]$ and $[Cu_2(OH)_2L'_2]^{2+}$, where L and L′ are neutral unidentate and bidentate ligands, respectively. While the copper(II) centres in the tetraacetato core are known[2] to be antiferromagnetically coupled, the magnetic interaction phenomena in the other core are dependant on the Cu—OH—Cu angle.[3a–c] In this communication we report a unique copper(II) complex, $[\{Cu_2(en)_2(OH)_2 \cdot Cu_2(O_2CMe)_4\}(PF_6)_2]_\alpha$ (**1**), in which two different dimeric units belonging to the above mentioned classes of complexes are covalently linked in a one-dimensional polymeric chain.

Complex **1** was prepared by reacting $Cu_2(O_2CMe)_4(H_2O)_2$ (1 mmol) with 1,2-diaminoethane (1 mmol) in ethanol (10 cm^3) with stirring at 50°C for 10 min. The solution after cooling to an ambient temperature was filtered and NH_4PF_6 (1 mmol) was added to the filtrate. The blue coloured precipitate thus obtained was isolated, washed with an ice-cold 1:1 (v/v) ethanol–water mixture and dried *in vacuo* over P_4O_{10} (yield 70%). Complex **1** has been structurally characterized†[4,5] by X-ray diffraction.

*Author to whom correspondence should be addressed.

† Analytical data for **1**: Found: C, 15.5; H, 3.5; N, 5.7. Calc. for $C_{12}H_{30}N_4O_{10}F_{12}P_2Cu_4$: C, 15.4; H, 3.2; N, 6.0%. Single crystals, suitable for X-ray studies, were obtained by slow evaporation of an ethanolic solution of **1**. Crystal data: $[C_{12}H_{30}N_4O_{10}F_{12}P_2Cu_4 \cdot 0.5EtOH]_\alpha$, mol. wt (polymer unit) = 957.54, monoclinic, a = 11.945(1), b = 21.044(3), c = 8.073(1) Å, β = 123.79(1)°, U = 1686.5(4) Å^3, Z = 2, space group $C2/m$, D_c = 1.89 g cm^{-3}, T = 290 K, μ = 27.02 cm^{-1}, $F(000)$ = 954, $R(R_w)$ = 0.0570 (0.0662) for 1148 reflections with $I > 2.5\sigma(I)$, weighting scheme $w = [\sigma^2|F_o| + 0.003767|F_o|^2]^{-1}$. Intensity data, collected on an Enraf-Nonius CAD4 diffractometer (Mo-K_α radiation, λ = 0.7107 Å) using a dark blue needle-shaped crystal of dimensions 0.3 × 0.1 × 0.1 mm, were corrected for Lorentz, polarization and absorption[4] effects (transmission coefficients: 0.89–1.00). The structure was solved and refined by Fourier syntheses and full-matrix least-squares using the SHELX 76 program.[5a] Atomic coordinates, full lists of bond lengths and angles and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre. Magnetic susceptibility data at 288 K using a Faraday balance: $\chi_g = 3.185 \times 10^{-6}$ cm^3 g^{-1}, χ_M^{corr}/Cu = 0.85×10^{-3} cm^3 mol^{-1}, μ_{eff}/Cu = 1.40 B.M. at 2100 G and $\chi_g = 3.805 \times 10^{-6}$ cm^3 g^{-1}, χ_M^{corr}/Cu = 1.0×10^{-3} cm^3 mol^{-1}, μ_{eff}/Cu = 1.52 B.M. at 850 G (diamagnetic correction: $\chi^{dia} = -442 \times 10^{-6}$ cm^3 mol^{-1}; molecular weight of **1** = 934.5).

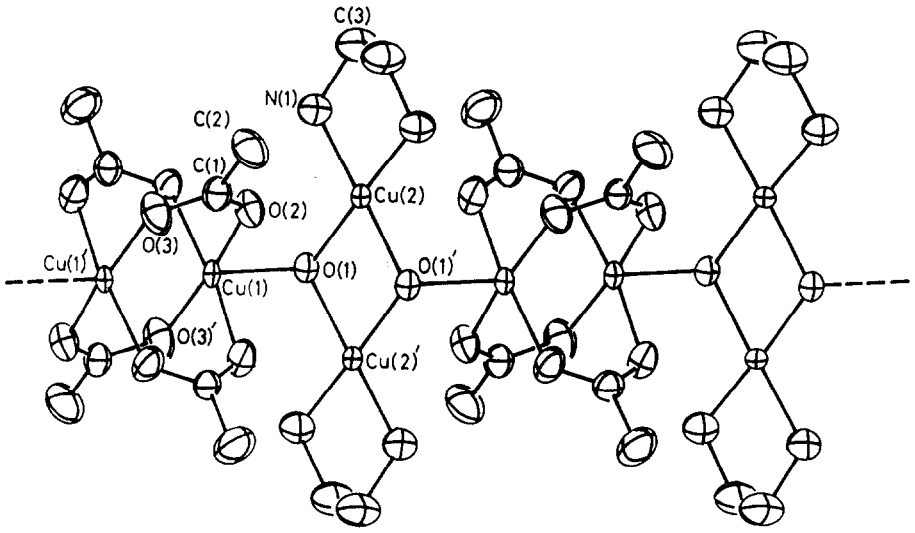

Fig. 1. An ORTEP view of the one-dimensional chain structure in **1** with atom numbering scheme.

The crystal structure of **1** consists of one-dimensional chains of the cationic polymers with PF_6 anions and the lattice ethanol molecules lying in between the isolated chains. An ORTEP[6] view of a portion of the polymeric chain is shown in Fig. 1. The chains are formed by covalent attachment of the $\{Cu_2(O_2CMe)_4\}$ and $\{Cu_2(en)_2(OH)_2^{2+}\}$ units by the μ_3-OH ligand. The geometries around the Cu(1) and Cu(2) atoms are essentially square-pyramidal and square-planar, respectively. The Cu(1)···Cu(1)′, Cu(2)···Cu(2)′ and Cu(1)···Cu(2) distances in **1** are 2.558(2), 3.005(3) and 3.231(1) Å, respectively. The Cu(1)···Cu(1)′ length is the shortest among known[2,7,8] tetra-μ-carboxylatodicopper(II) complexes. The Cu···Cu distance in $Cu_2(O_2Me)_4(H_2O)_2$[7] is 2.614(2) Å. The shortening of the Cu(1)···Cu(1)′ separation may be attributed to the Cu(1)′···Cu(1)—O(2), O(3) angles which are much lower than 90° (Table 1). The Cu(1)—O(1) distance is, however, similar to that observed[7] for the diaqua adduct. The inter-unit intrachain Cu(1)···Cu(2) distance in **1** is also found to be the shortest among related complexes having a covalent and/or hydrogen-bond linkage between discrete mono-, bi- or polynuclear units.[9-11] In the 1D chain the Cu(1)···Cu(1)′ and Cu(2)···Cu(2)′ axes are orthogonal to each other.

The *X*-band ESR spectrum of an aqueous solution of **1** at 77 K exhibits an isotropic signal with a g_{av} value of 2.12. Preliminary susceptibility measurements on **1** at 288 K show a field depen-

1. INTRODUCTION

Lewis base adducts of alane, AlH_3, have a wide range of applications in organic synthesis as selective reducing agents,[1] the preparation of transition metal aluminohydrides[2] and in materials science, with the latter evolving in recent years mainly in relation to the application of volatile Lewis base adducts in chemical vapour deposition (CVD) technology.[3–8] Adducts of gallane are starting to gain attention for application in CVD technology[9] and in synthesis.[10]

Advantages of the use of adducts of alane and gallane in CVD over conventional group 13 alkyl precursors include (i) facile M—H bond cleavage relative to M—C cleavage[8] and (ii) a reduction in the amount of carbonaceous contaminant in the deposited metal, in consequence of the lack of direct metal–carbon bonds in the precursors. The primary process in the decomposition of adducts of alane is thought to be ligand loss,[7,11,12] which is followed by aluminium catalysed hydrogen loss, forming AlH then metal.[6] Thus, varying the nature of the ligands, in particular base strength, is likely to effect the thermal stability of the adducts, as for gallane adducts. Other applications of adducts of alane include (i) the use of solutions of triethylamine-alane, H_3AlNEt_3, and $LiAlH_4$ to

* Author to whom correspondence should be addressed.

electroplate aluminium onto copper surfaces[13] and (ii) the generation of silane from SiF_4 and $AlH_3(NEt_3)$.[14]

The recent resurgence in the chemistry of the adducts of alane and gallane follows on the pioneering work of the 60s and 70s.[11,15–17] The characterization of uncoordinated gallane was detailed as recently as 1990.[18,19] It is a symmetrical dimer in the gas phase, $[H_2Ga(\mu\text{-}H)_2GaH_2]$, although it tends to associate into oligomers of *ca* four units in the condensed phase. In contrast, alane yields polymeric and involatile solids. One fully characterized phase shows octahedral aluminium with each hydride bridging two metal centres.[20] On structural considerations alone gallane is more like the ubiquitous diborane, $[H_2B(\mu\text{-}H)_2BH_2]$, which reflects the trend in group 13 electronegativities: boron, 2.0; aluminium, 1.5; gallium, 1.8 (Allred and Rochow). Thus, the more polarized Al—H bonds result in a greater tendency for MH_3 to associate and greater reactivity relative to Ga—H bonds.[21,22] Indane (InH_3) and thallane (TlH_3) are apparently too unstable to exist in the uncoordinated state, but may have a transitory existence in ethereal solutions at reduced temperatures.[23] For these heavier elements the only structurally authenticated compounds with M—H bonds are mixed potassium salts of bulkyalkylindane species.[24,25]

Prior to 1991 the structural elucidation of alane adducts was confined to a few poorly refined cases[26–29] and to a single, poorly defined structure of a gallane, H_3GaNMe_3.[30] Much conjecture has surrounded the solid state structure of tertiary amine adducts of the type H_3AlNR_3, with uncertainty as to whether they are monomeric or dimeric through hydride bridges. For $H_3AlN(Bu^n)_3$ the X-ray structural determination shows the compound to be monomeric,[26] but when the amine substituents are less sterically demanding dimerization may occur.[12] The structure of amine adducts in solution has also been a controversial issue with the degree of association being put at anywhere from 1 to 2, depending on the nature of the substituent, the solvent or the concentration of the adduct.[12,31,32] Lewis base adducts of gallane are seemingly simplified by almost exclusively forming four-coordinate species, exemplified by H_3GaNMe_3 being monomeric in both the vapour and solid phases.[22,30,33,34]

Our recent endeavours in this field include further elaborating the chemistry of Lewis base adducts of alane and gallane. Structure elucidation via X-ray crystallography, coupled with theoretical studies and the investigation of surface adsorption characteristics, has provided a firm base for the continuing study into applications of these adducts. Closely related work has led to the preparation of alane and gallane amido complexes. These are of interest for application in CVD technology, e.g. $(H_2GaNH_2)_3$ yields semi-conducting GaN.[35] Some of our publications on alane chemistry have been recently reviewed in Chemtracts (Inorganic Chemistry).[36]

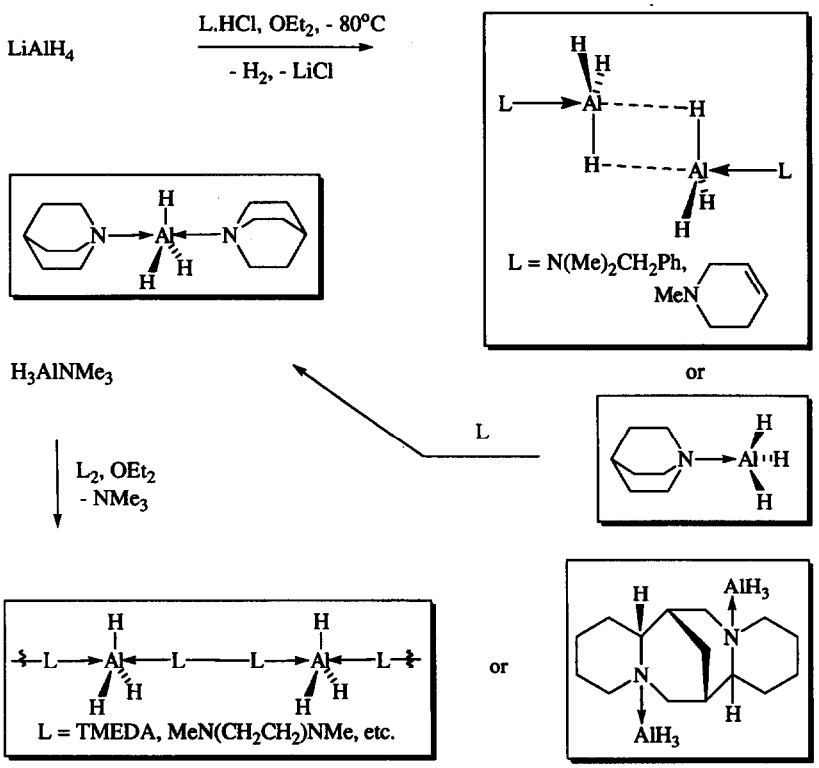
2. SYNTHESIS OF ALANE AND GALLANE ADDUCTS

2.1. *Tertiary and secondary amine adducts*

Synthesis of tertiary amine adducts of alane and gallane mainly follows the methods developed by earlier workers.[11] For alane this involves treating $LiAlH_4$ with the hydrochloride of the amine (salt elimination)[37,38] and ligand displacement whereby etherates, e.g. H_3AlOEt_2, or amine adducts are treated with an amine. This takes advantage of the greater affinity of N-donors to alane,[39] amine base strength differences,[40] e.g. quinuclidine > trimethylamine, and the tendency for alane to form five-coordinate adducts with multidentate amines. Indeed, ligand displacement involving readily available H_3AlNMe_3 is the preferred method for the synthesis of multidentate tertiary amine adducts of alane, thus removing problems associated with the ability of these amines to solubilize the LiCl generated in the salt elimination method using $LiAlH_4$.[41] Less common methods of preparation include (i) the reduction of aluminium halide adducts using a hydride source, e.g. in the synthesis of H_3AlNMe_3 from Cl_3AlNMe_3 and LiH,[42] (ii) the direct synthesis from aluminium powder and amine under high pressure of hydrogen, as in the synthesis of polymeric $[H_3Al\{N(CH_2CH_2)_3N\}]_\infty$,[43] and (iii) the more recent treatment of $LiAlH_4$ with a tertiary amine, e.g. eq. (1), although it is seemingly of limited scope since NEt_3 fails to react and the loss of some aluminium hydride as the by-product.[1]

$$3LiAlH_4 + 2NMe_2Et \xrightarrow{\text{Toluene}} 2H_3AlNMe_2Et + Li_3AlH_6 \quad (1)$$

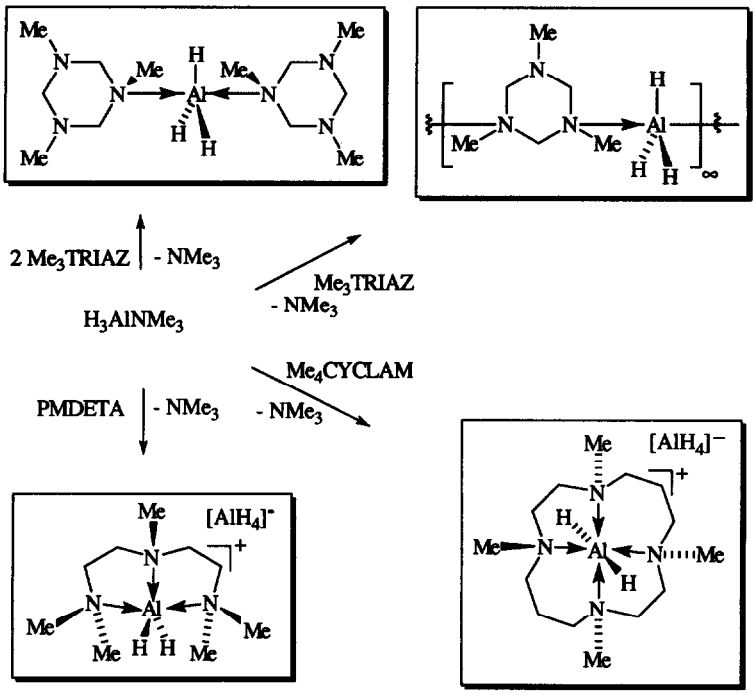
Bidentate tertiary amines afford five-coordinate species, (−)sparteine excepted which forms an alane rich compound possibly because of steric impediment at the N-centres.[40] Five-coordinate bis(monodentate amine) compounds are limited to the well-known trimethylamine adduct and the quinuclidine adduct.[40] Five-coordination is possible for monodentate amines via hydride bridging, at least in the solid state. Aspects of recent work in this area, including the synthesis of the (−)sparteine adduct, are shown in Schemes 1 and 2.[38,40,44,45] In many synthesis of H_3AlNMe_3, which is a key starting material for preparing a variety of amine adducts, as well as mixed donor species,[45] a significant amount of chloride is often present in the product and in some cases has resulted in the isolation of partially chlorinated species, e.g. $H_{2-x}Cl_xAl\{NMe(CH_2CH_2)_2O\}$, see Section 3.1.[40] This appears to arise from hydride/chloride exchange between preformed H_3AlNMe_3 and LiCl derived from $LiAlH_4$ and $NMe_3 \cdot HCl$, and work-up of reaction mixtures using this salt elimination route should follow immediately after evolution of hydrogen gas has ceased. Similarly, close attention to stoichiometry should be paid as excess hydrochloride salt can also result in partial chlorination.



Scheme 1.

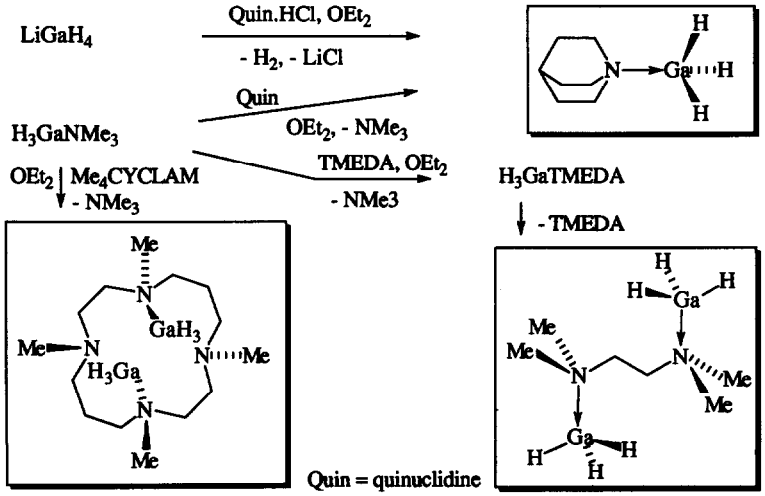
Treatment of H_3AlNMe_3 with the polydentate tertiary amines, Me_3TRIAZ (1,3,5-trimethylhexahydro-1,3,5-triazine), PMDETA (N,N,N′,N″,N″-pentamethyldiethylenetriamine) or $Me_4CYCLAM$ (N,N′,N″,N‴-tetramethylcyclam), yield either neutral, five-coordinate adducts or the first examples of cationic aluminium hydride species, Scheme 2.[44,46] For Me_3TRIAZ the formation of four-membered chelate rings, and thus ionic species, is favourable and additional uptake of alane by the polymeric $[H_3Al(Me_3TRIAZ)]_\infty$ is not observed.

Several methods have been reported for the synthesis of tertiary amine adducts of gallane. Some of these outlined below include the reaction of $LiGaH_4$ with a hydrochloride salt of the amine.[15] The ligand displacement method which is common for alane is limited to a few examples for gallane. These are shown in Scheme 3, along with examples of the salt elimination route. The 1 : 1 reaction of TMEDA (N,N,N′,N′-tetramethylethylenediamine) with H_3GaNMe_3 yields the unstable intermediate $H_3GaTMEDA$,[46] which may be five-coordinate like the TMEDA adduct of alane, but it readily loses half an equivalent of TMEDA *in vacuo* affording the "gallane rich" species.[9,46] A 2 : 1



Scheme 2.

adduct of H_3GaNMe_3 and $Me_4CYCLAM$ has been prepared, but attempts to isolate higher adducts result in rapid decomposition to gallium metal, hydrogen and the free ligand. Indeed, attempts at preparing a range of other tertiary amine gallane adducts of PMDETA and of the mixed donor ligands N-methylmorpholine and N-methylthiomorpholine results in decomposition above *ca* $-20°C$.



Scheme 3.

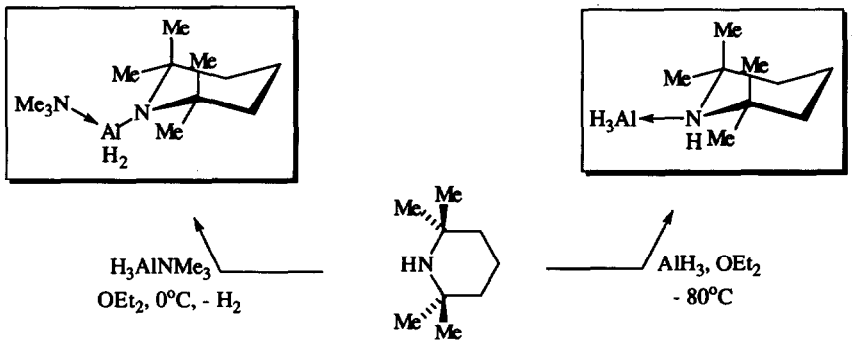
Significant differences in the synthesis of tertiary amine adducts of alane and gallane relate to the tendency for alane to form stable five-coordinate and ionic species and the tendency for polydentate amines to yield inherently unstable adducts of gallane. While the reaction of uncoordinated gallane with trimethylamine at low temperature results in symmetrical cleavage of Ga—H—Ga bridges, affording five-coordinate $H_3Ga(NMe_3)_2$, loss of amine takes place at $> -20°C$, eq. (2).[19] A novel route to H_3GaNMe_3 has recently been described by Downs *et al.*,[47]

eq. (3).

$$1/n[GaH_3]_n \xrightarrow[-95°C]{2NMe_3} H_3Ga(NMe_3)_2 \xrightarrow[-NMe_3]{> 20°C} H_3GaNMe_3 \quad (2)$$

$$H_2Ga(\mu\text{-}H)_2BH_2 \xrightarrow[-95°C]{NMe_3} H_2GaBH_4(NMe_3)_n \xrightarrow{23°C} H_3GaNMe_3 + H_3BNMe_3 \quad (3)$$

Secondary amine adducts are less common because of their tendency to eliminate hydrogen above *ca* −20°C and 20°C for alane and gallane, respectively, affording amido alane and gallane species with amido groups bridging the metal centres.[15] However, the bulky amine 2,2,6,6-tetramethylpiperidine provides an example of a stable alane-secondary amine adduct. Ethereal solutions of AlH_3 and 2,2,6,6-tetramethylpiperidine in diethyl ether afford the adduct (solid decomposes > 145°C), but ethereal solutions of H_3AlNMe_3 result in the formation of a novel monomeric amide at 0°C, Scheme 4.[48] The kinetic stability of the adduct arises from poor donor properties of diethyl ether towards alane, compared with NMe_3.



Scheme 4.

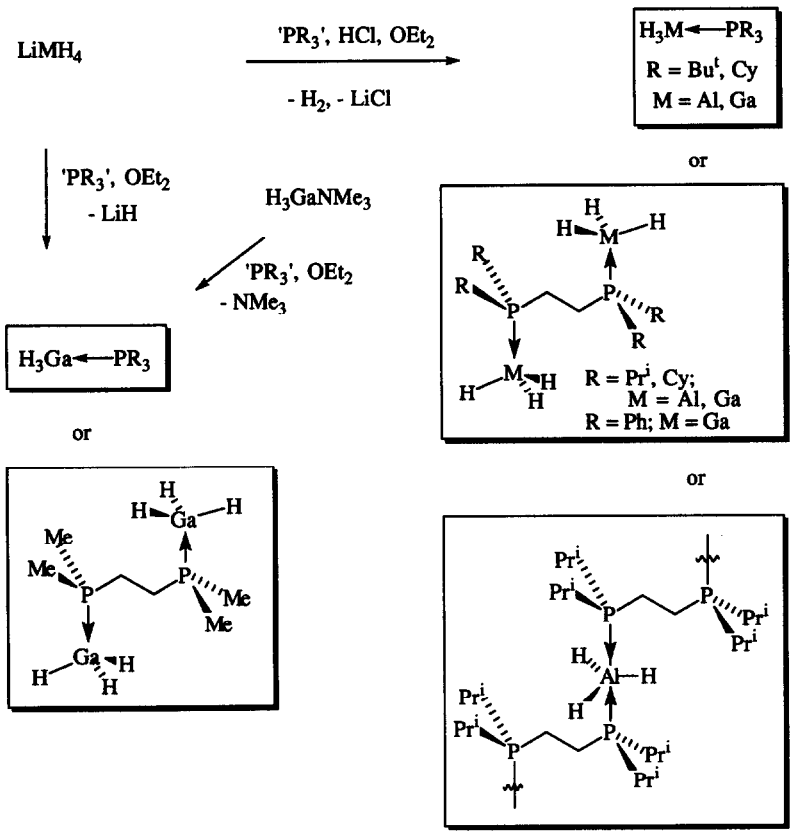
2.2. *Tertiary phosphine adducts*

Stable tertiary phosphine adducts require the use of bulky trialkyl phosphines to circumvent the formation of polymeric alane at low temperature, e.g. H_3AlPEt_3 decomposes at −20°C.[49] Synthetic procedures involve treating ethereal solutions of $LiAlH_4$ with dry HCl and phosphine; $(Pr^i_2PCH_2)_2$ gives the only example of a five-coordinate species, Scheme 5.[50] The ligand displacement method involving H_3AlNMe_3 either fails, notably for aryl substituted phosphines, or gives mixed donor adducts. These can decompose *in vacuo* to simple phosphine adducts, e.g. in the synthesis of $H_3AlPBu^t_3$ (Section 2.3).[45,51,52] Interestingly, the formation of "alane rich" adducts of bifunctional phosphines has only one parallel with tertiary amines, viz the adduct of (−)sparteine. In the case of amines polymeric material normally results with an alane-to-ligand ratio of 1 : 1, with the polymer formed in the presence of excess amine even when the ratio is 2 : 1.

The synthesis of phosphine adducts of gallane is simpler; the ligand displacement method is not complicated by the formation of five-coordinate bis(phosphine) or mixed donor adducts, in accordance with the tendency for gallane to only form stable four-coordinate species. Typically, the starting material is H_3GaNMe_3.[9,51,53] Addition of phosphines to $LiGaH_4$ can yield the adduct directly with the extrusion of LiH in some cases, although the yields are not as high.[53] There is no evidence for the formation of the intermediate 1 : 1 compound, $H_3Ga(PMe_2CH_2)_2$, of the type found in the analogous displacement reaction involving TMEDA, Scheme 3.[46]

Tertiary phosphine adducts of gallane have similar stabilities to tertiary amine adducts, in consequence of the comparable donor strength of the bases towards gallane, established for the equilibrium in eq. (4), $K = 2.94$ (benzene). This suggests that back-donation from filled gallium 3*d* orbitals to vacant phosphorus 3*d* orbitals may explain the anomalously high stability of the P—Ga bond.[54]

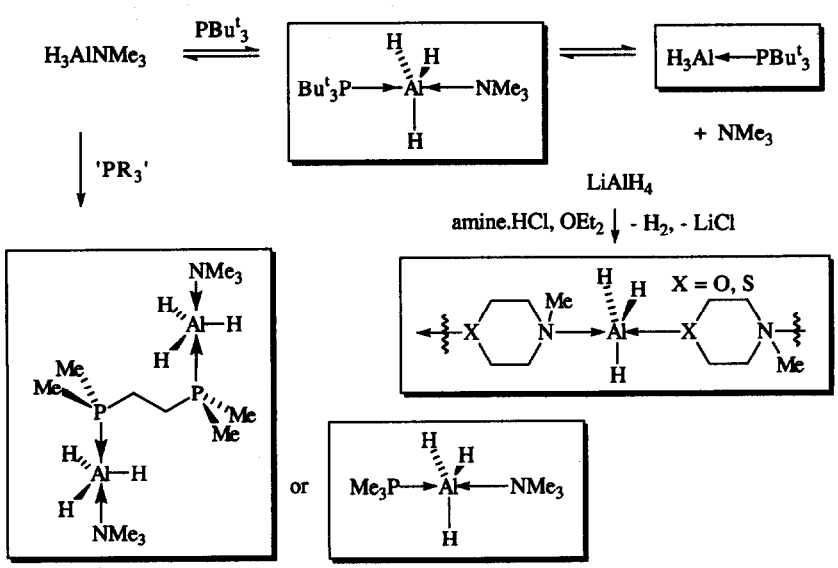
$$H_3GaPMe_3 + NMe_3 \rightleftharpoons H_3GaNMe_3 + PMe_3 \quad (4)$$



Scheme 5.

2.3. *Mixed donor adducts and others*

Mixed tertiary phosphine/amine adducts of alane have been briefly mentioned in Section 2.2. Treatment of H_3AlNMe_3 with a trialkyl phosphine can result in these novel species, Scheme 6.[45,51]



Scheme 6.

The loss of trimethylamine from the tri-t-butyl adduct *in vacuo* is unusual given the donor strengths of the ligands towards alane and theoretical considerations.[38,44,50] Presumably, the exceptionally

large steric demand of the phosphine coupled with the volatility of the amine shifts the equilibrium in favour of $H_3AlPBu^t_3$.[51] Mixed donor species have not been identified for gallane, although they are likely intermediates in ligand displacement reactions. In general ligand displacement reactions of alane or gallane are likely to proceed via complexation as the primary process, even for reactions with secondary and primary amines, phosphines, thiols, etc., where ultimately ligand displacement and hydrogen evolution is possible.[15]

Alane also forms mixed donor adducts with N-methylmorpholine[45] and N-methylthiomorpholine,[40] containing N and heteroatom interactions in the solid state, Scheme 6. The amide $[H_2Al\{N(CH_2CH_2)_2S\}]_2$ results from the reaction of thiomorpholine with trimethylamine alane and can be considered to be a mixed donor complex by virtue of the weak intermolecular Al···S interactions observed in the solid state structure of the amide, Fig. 1.

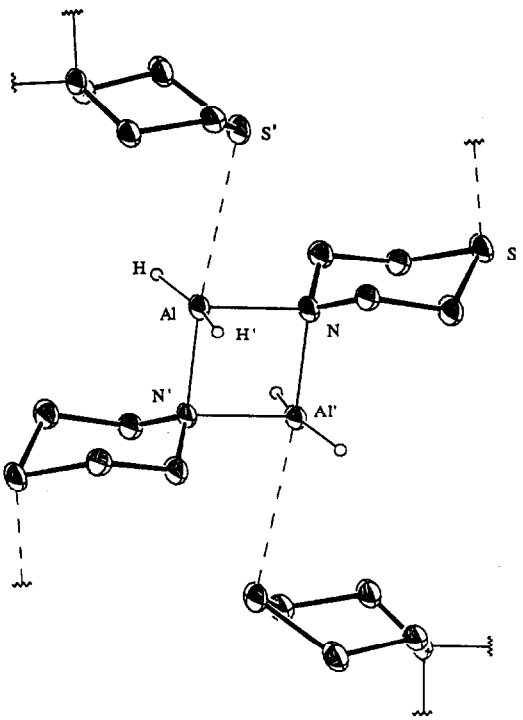


Fig. 1. Molecular structure of $[AlH_2(Thiomorph)]_2$; Al—S′ 3.26(1) Å.

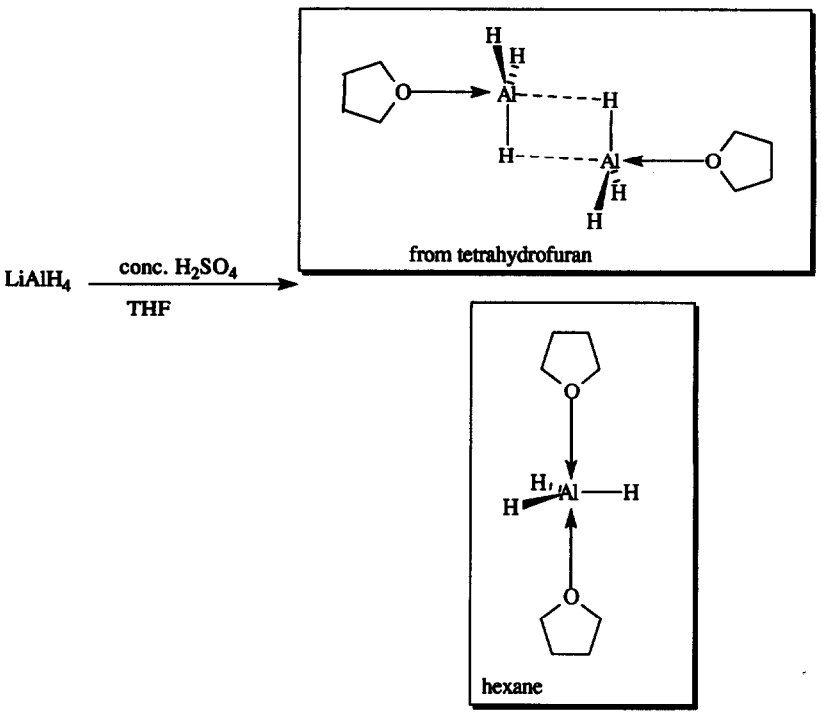
The mixed donor adduct of N-methylmorpholine can be regarded as (i) a model compound for surface binding of H_3AlNMe_3 to oxidized silicon (see Section 6), (ii) as a model intermediate for the displacement of weakly bound etherates to alane[12] and (iii) as a model for Wiberg and Nöth's hydrolysis of amine adducts of alane, where complexation precedes hydrolysis of $H_2O(H)_3AlNR_3$.[55] In one report[56] the complex $Et_2O(H_3Al)NMe_3$ is postulated for the dissolution of H_3AlNMe_3 in diethyl ether. More recently, Smith *et al.* have structurally characterized tetrahydrofuran (THF) adducts of alane.[57] $[H_3Al(THF)]_2$ and $[H_3Al(THF)_2]$ are accessible either from the displacement of NMe_3 from $[H_3Al(NMe_3)]_2$ by THF or the action of concentrated sulphuric acid on lithium aluminium hydride[57] in THF solvent. The hydride-bridged dimer is in equilibrium with the bis-THF monomer and the position of the equilibrium can be disturbed by the addition of excess petrol in the crystallization process giving the monomer. The dimer is favoured by excess THF.[57] $[H_3Al(THF)]_2$ is unstable with respect to loss of THF, in the absence of excess THF, giving $[H_3Al(THF)]_2$ which itself loses the ether donor under dynamic vacuum at 60°C to give polymeric alane, Scheme 7.

Treatment of H_3GaNMe_3 with BF_3 in the presence of SMe_2 is an effective method for generating S-donor adducts of gallane, eq. (5);[58] claims that uncoordinated gallane is formed in the absence of SMe_2[59] have been disputed. It is now thought that some hydride–halide exchange takes place,

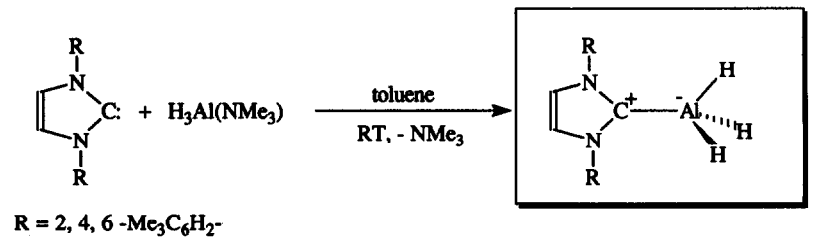


Scheme 7.

giving rise to compounds of the type $[GaH_xF_{3-x}]_n$ in the condensed phase[19] and GaH_2F in the gas phase.[60]

$$H_3GaNMe_3 + BF_3 \overset{SMe_2}{\rightleftharpoons} H_3GaSMe_2 + F_3BNMe_3 \qquad (5)$$

A remarkably stable adduct of alane results from the treatment of 1,3-bis(2,4,6-trimethylphenyl)imidazol-2-ylidene with $[H_3Al(NMe_3)]_2$, Scheme 8.[61] This carbene alane adduct has a melting point of 246–247°C and contains a tetrahedral aluminium centre.



Scheme 8.

3. STABILITY CONSIDERATIONS

Thermal decomposition pathways for tertiary amine adducts of alane and gallane are poorly understood, despite their emerging importance as precursors in CVD technology. The primary process for the decomposition of $H_3Al(NMe_3)_2$ is the loss of one amine group at 100°C.[27] In contrast, the bis(quinuclidine) adduct $H_3Al\{N(CH_2CH_2)_3CH\}_2$ sublimes without decomposition at >120°C and the greater stability here relates to the greater donor strength of the amine. Only above 190°C does it decompose directly to the metal, hydrogen and amine, possibly with the loss of one amine as the limiting process. The five-coordinate mixed donor compound $\{Me_3N(H_3Al)(PMe_2CH_2)_2\}_2$ is also thermally robust and can be sublimed without the loss of either amine or phosphine at 50°C.[45] Theoretical studies (HF/DZP-ECP) on model systems show that $H_3Al(NH_3)_2$

is only 10.74 kcal mol^{-1} more stable relative to fragmentation to H_3AlNH_3 and NH_3[44] and *ab initio* studies of the dissociation energy of H_3AlNH_3 was predicted to be 26 kcal mol^{-1}, after zero point energy corrections.[62] For gallane (D95*+DZP) $H_3Ga(NH_3)_2$ is only 7.8 kcal mol^{-1} more stable relative to H_3GaNH_3 and NH_3,[63] in accordance with the preference for gallane to form four-coordinate species, $H_3Ga(NMe_3)_2$ excepted which is stable below -23.4°C.[59] Similarly, the stabilization energy (D95*//D95*) of $Me_3P(H_3Al)NH_3$ relative to H_3AlNH_3 and PMe_3 is low, at 2.72 kcal mol^{-1} and 9.02 kcal mol^{-1} relative to NH_3 and H_3AlPMe_3,[51] and thus the origin of the stability of $\{Me_3N(H_3Al)(PMe_2CH_2)_2\}_2$ is uncertain. As to the mixed N,O-donor complex based on N-methylmorpholine, the stabilization energy of the model compound $H_2O(H)_3AlNH_3$(D95P) relative to H_3AlNH_3 and OH_2 is only 4.71 kcal mol^{-1} and 13.16 kcal mol^{-1} relative to H_3AlOH_2 and free amine.[64] The compound $H_3Al(PR_3)_2$, modelling the only example of a bis(phosphine) adduct of alane, viz. polymeric $H_3Al\{(PPr^i_2CH_2)_2\}$, Scheme 5, has a low stabilization energy relative to H_3AlPR_3 and free phosphine, 1.82 or 2.26 kcal mol^{-1}, when R = H or Me, respectively (D95*).[64]

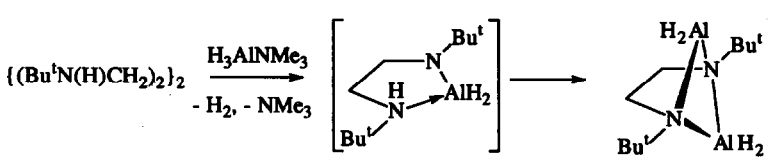
The mono-tertiary amine adducts of alane decompose with the formation of aluminium mirrors between 100 and 170°C,[38,40] whereas bidentate tertiary amines have higher temperatures for the same process, *ca* 170–215°C.[40,44] The enhanced stability of these compounds relates to their polymeric structures, with a reluctance to undergo Al—N cleavage and form monomeric species, as evidenced by their low vapour pressures. For higher amines, which form ionic species predominantly, there is also greater thermal stability relative to monodentate species; the PMDETA and Me_4CYCLAM complexes, Scheme 2, decompose at 182 and 243°C, respectively.[65]

Mono(amine) alane adducts are thought to decompose via an initial and irreversible amine dissociation yielding polymeric alane, which further decomposes to its constituents.[12,27] However, at reduced pressure thermal decomposition of H_3AlNMe_3 yields the highly reactive monomeric alane species AlH_3,[7] which spontaneously decomposes to aluminium and hydrogen before association to dialane and higher aggregates of alane. Thermodynamic studies show that decomposition of AlH_3 to aluminium and hydrogen is favoured by 11 kcal mol^{-1}.[66]

While polydentate tertiary amines enhance the stability of alane, there is no improvement for gallane; H_3GaNHe_3 slowly decomposes to its constituents at room temperature, whereas the "gallane rich" TMEDA compound, Scheme 3, Me_4CYCLAM and PMDETA derivatives decompose rapidly at the same temperature. Seemingly, there is no advantage in having additional donor sites, because of the preference for four-coordinate species. The higher stability of gallane adducts is imparted by the use of stronger Lewis bases such as quinuclidine. This yields an adduct of remarkably high thermal stability, decomposing to its constituents above *ca* 100°C.[67] Tertiary amine adducts of gallane decompose at lower temperatures than analogous alane species, due to weaker metal–nitrogen bonds in gallane adducts, in turn a consequence of the lower acidity of the GaH_3[22] and also because of the frailty of Ga—H bonds.[68]

In adducts containing ligands with methylene linkages between the N-donor groups there is cleavage of N—C bonds, as in tetramethylmethylenediamine (ambient temperature)[69] and alane Me_3TRIAZ adducts, Scheme 2.[44] The monomeric Me_3TRIAZ adduct decomposes at 123°C via the polymeric adduct, yielding on hydrolysis NMe_3, $CH_2(NMe_2)_2$ and some Me_3TRIAZ.[44]

Ammonia will also form a thermally unstable 1 : 1 adduct with alane.[70] This loses 1 equivalent of hydrogen at -40°C, with a further loss at room temperature and at 150°C cross-linked aluminium nitride results. Primary and secondary amine adducts of alane are thermally unstable, the tetramethylpiperidine adduct excepted, Scheme 4,[48] a consequence of the reactivity of hydride substituents towards acidic amine protons resulting in hydrogen elimination and the formation of N-bridging oligomeric amides.[12,71,72] The stability of the piperidine adduct, Scheme 4 (decomposition > 145°C), relates to the steric demand of the amine, disfavouring amido bridges. Steric demand is also important in the formation of the alane-rich amido species in eq. (6); the intermediate amido/amine complex is proposed on the basis of the isolation of the corresponding hydrido/chloro species.[73]



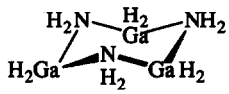
(6)

Free gallane and excess ammonia, at low temperature, afford an ionic ammonia-gallane adduct, eq. (7),[19] which remarkably is stable to hydrogen loss at room temperature. The proposed ionic structure of the product is directly comparable with $[AlH_2(PMDETA)]^+[AlH_4]^-$ and $[AlH_2(Me_4CYCLAM)]^+[AlH_4]^-$.[65]

$$2/n[GaH_3]_n + 2NH_3 \xrightarrow{-78°C} [H_2Ga(NH_3)_2]^+[GaH_4]^- \quad (7)$$

Ammonia condenses with the trimethylamine adduct of gallane yielding the hydrogen elimination product as a cyclic trimer, $[(H_2GaNH_2)]_3$, in the solid state,[35] although earlier reports claimed it was polymeric, eq. (8).[74] As for aluminium (above) heating the trimer above 150°C results in the formation of the metal nitride, as cubic GaN. Secondary amine adducts of gallane usually decompose via hydrogen elimination yielding gallane amides, cf. eq. (8),[75] and typically this takes place at *ca* 20°C, which compares with *ca* −20°C for secondary amine alane adducts, which is higher on account of the greater polarity of the Al—H bond.

$$H_3GaNMe_3 + NH_3 \xrightarrow[-H_2]{ca\ 20°C} \quad (8)$$



Tertiary aryl phosphine adducts of alane based on PPh_3, $(Ph_2PCH_2)_2$ and $(Ph_2PCH_2CH_2)_2PPh$ rapidly decompose to polymeric alane at room temperature or lower. Trialkyl phosphine adducts similarly decompose, unless the alkyl groups are bulky. Decomposition then occurs at *ca* 160°C for both four- and five-coordinate species, Scheme 5, yielding the metal, hydrogen and the ligand.[50,51] In accordance with theoretical considerations the association of alane and release of phosphine are favoured, but for bulky alkyl groups they are kinetically inhibited.[50]

Tertiary phosphine adducts of gallane are in general more stable than alane analogues. Aryl phosphine adducts slowly decompose at room temperature, yielding the metal, hydrogen and the ligand, e.g. $\{H_3Ga(PPh_2CH_2)_2\}_2$,[55] unlike alane analogues which yield polymeric alane and phosphine. Steric hindrance is not necessary to stabilize trialkylphosphine adducts of gallane; $[\{H_3Ga(PMe_2CH_2)_2\}_2]$ and the tricyclohexylphosphine adduct decompose to their constituents at 100 and 130°C.[51] Lower stabilities of aryl phosphine adducts of gallanes (and alanes) are consistent with the lower base strength of aryl-substituted ligands.

Computed stabilization energies (D95*) for various complexation reactions of model phosphine adducts of alane and gallane include:[51]

$$AlH_3 + PH_3 \longrightarrow H_3AlPH_3 \qquad -10.65\ kcal\ mol^{-1}$$

$$AlH_3 + PMe_3 \longrightarrow H_3AlPMe_3 \qquad -21.54\ kcal\ mol^{-1}$$

$$GaH_3 + PH_3 \longrightarrow H_3GaPH_3 \qquad -8.06\ kcal\ mol^{-1}$$

$$GaH_3 + PMe_3 \longrightarrow H_3GaPMe_3 \qquad -16.01\ kcal\ mol^{-1}$$

The trimethylphosphine adducts have greater stabilization energies relative to PH_3, in accordance with donor strength considerations. The potential energy hypersurface of $(H_3AlPH_3)_2$ (6-31G*+DZP) results in convergence on dialane $H_2Al(\mu\text{-}H)_2AlH_2$ and free PH_3, favoured by 5.84 kcal mol^{-1} relative to H_3AlPH_3,[50] Fig. 2. This is consistent with the instability of phosphine adducts of alane relative to polymeric alane, unless the phosphine is bulky enough to suppress association via hydride bridges. Similar calculations on H_3AlNH_3 give a dimer, $H_3N(H)_2Al(\mu\text{-}H)_2Al(H)_2NH_3$, favoured by just 0.4 kcal mol^{-1},[38] and thus the finding of both dimers and monomers for mono(tertiary) amine adducts of alane is not unreasonable.[38,45] No hydride-bridged dimers have detectable energy minima for H_3GaXH_3, X = N or P, with or without binding of the group 15 centres. Indeed, H_3GaPH_3 has been isolated as a colourless solid [m.p. *ca* −50°C (decomposition > −30°C)] by treatment of gallane with excess phosphine[19] and the absence of IR bands diagnostic of Ga—H—Ga bridging suggests it is monomeric in the condensed phase, in agreement with theory.[51,53] Theory also predicts that H_3GaAsH_3 should be a stable monomeric species.[76] Secondary phosphine adducts of gallane are poorly characterized oils of the type H_3GaPHR_2.[75] These are generally unstable to hydrogen elimination and phosphide formation in a similar fashion to that seen for secondary amine gallane adducts.

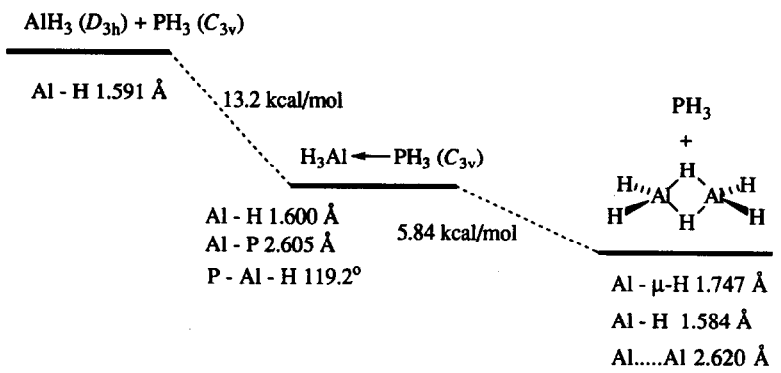


Fig. 2. Computed structures and energies (6–31 G*+DZP) for interaction of AlH_3 and PH_3.

The stability of Lewis base adducts in air varies considerably. In general, adducts of gallane are less reactive than alane due to the lower polarity of the Ga—H bond. Mono(amine) adducts of alane are very reactive and can spontaneously ignite in air, e.g. H_3AlNMe_3. In contrast, bis(amine) and mixed donor adducts decompose slowly due to steric protection of the metal centres/blocking of complexation by reactive species such as water and oxygen (see Section 2.3). Bulky alkylphosphines also impart higher stability in air, even though there is in principle a vacant coordination site available, polymeric $H_3Al\{(PPr^i_2CH_2)_2\}$ expected. Bulky alkylphosphine adducts of gallane also have improved stability in air, to the extent that the tricyclohexylphosphine adduct is air stable.[77]

4. STRUCTURAL STUDIES

4.1. *Alane derivatives*

Four structural types have been identified for adducts of alane: viz (i) monomeric four-coordinate species; (ii) dimeric mono-Lewis base adducts with unsymmetrical hydride bridges, at least for tertiary amines; (iii) five-coordinate bis-Lewis base adducts; and (iv) ionic compounds based on five- or six-coordinate cationic species, $H_2Al(ligand)^+$, and the ubiquitous AlH_4^- ion. X-ray diffraction and electron diffraction studies provide the most definitive structural assignments. However, ^1H NMR and to a lesser extent ^{27}Al NMR spectroscopy is informative, as is the position of ν(Al—H) IR bands, which for example are typically 1680 cm^{-1} for bis(amine) adducts and 1760 cm^{-1} for mono(tertiary amine) adducts.[40,78,79] While the ^1H NMR hydride resonances are broad they are usually *ca* 0.3 ppm upfield, at *ca* 3.8 ppm, for four five-coordinate bis(amine) adducts relative to mono(amine)adducts.[40]

The quinuclidine[45] and tri-n-butyl[26] adducts of alane are monomeric in the solid. The gas phase electron diffraction structure of H_3AlNMe_3[28] shows it to also be monomeric, although there is a discrepancy between the Al—N distance, 2.063(8) Å, in this structure with those in the solid, 1.991(4) and 1.98(2) Å, respectively. Typical Al—H distances are close to 1.60 Å, which are close to theoretical values for H_3AlNH_3.[38,62] The greater basicity of the amines, and thus greater metal centre electron saturation, in monomeric solid state structures relative to those amines found in the bridging hydride adducts, Scheme 1, may account for the existence of monomeric species. However, the difference in energy, monomer versus dimer, is comparable to crystal packing forces.[38] The structure of the alane rich (−)sparteine adduct has been modelled using Chem 3D, Fig. 3.

Solid state structures of H_3AlPR_3, R = Cy,[50] Bu^t,[51] $\{H_3Al(PR_2CH_2)\}_2$, R = Cy,[50] Pr^i,[51] all possess four-coordinate species, with the distances in the range Al—P 2.460(2)–2.467(1) Å. The computed structure at the MP2/D95* level of theory for H_3AlPMe_3, C_{3v} symmetry, is longer, 2.498 Å, which is a common result for phosphine adducts of alane and gallane.[51] The lack of dimeric structures with bridging hydrides is predetermined by the necessity to use hindered ligands to block formation of polymeric alane, Fig. 2.[50,51]

The X-ray crystal structures of the trimethylamine, dimethylbenzylamine, 4-methyltetrahydropyridine and tetrahydrofuran adducts of alane, Schemes 1 and 7, have the unsymmetrical hydride bridge structure, illustrated by the methyltetrahydropyridine adduct in Fig. 4.[38] In each

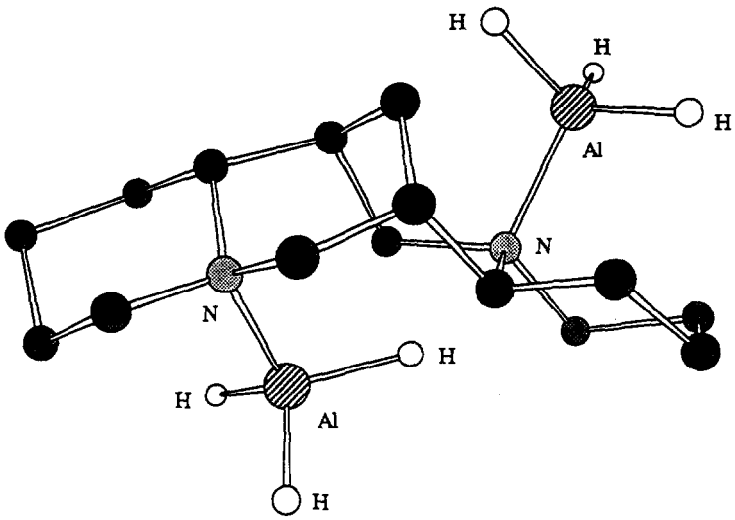

Fig. 3. Chem 3D structurally minimized molecular model of $(H_3Al)_2(-)$sparteine.

case the aluminium coordination environment can be considered as pseudo-trigonal bipyramidal. The Al—N distances are significantly longer than in the four coordinate species, 2.08 Å, with the Al—O distance 1.967(2) Å. The Al···H contact at *ca* 2.05 Å was long and no significant elongation occurred of the associated short distance, *ca* 1.59(4) Å—amine adducts; *ca* 1.39 Å—THF adducts, relative to terminal Al—H distances. The computed structure for the model compound $(H_3AlNH_3)_2$ agrees well with these structures, as does the computed structure of H_3AlNH_3 with the above monomers, DZP,[38] TZ2P+*f*basis.[62] Prior to the finding of a dimeric structure in the solid for H_3AlNMe_3, originally proposed by Ruff and Hawthorne,[12] the generally accepted view was that complexes of the type H_3AlNR_3 were monomeric in the solid state.

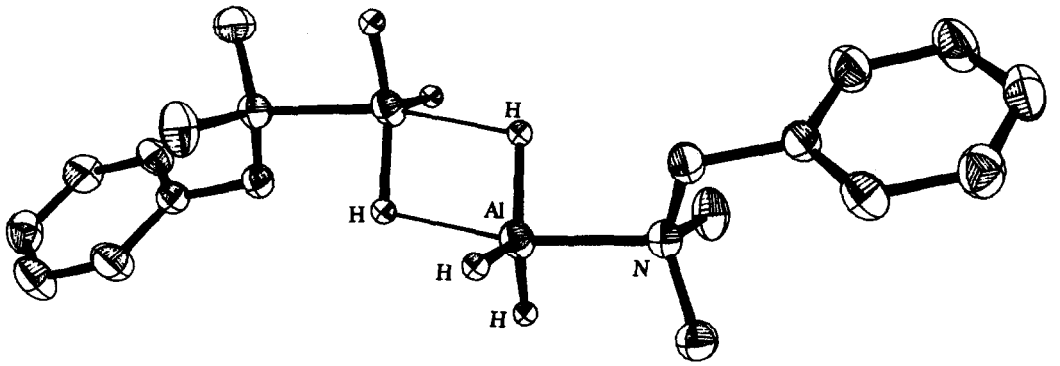

Fig. 4. Dimeric structure of $H_3Al(NMe_2CH_2Ph)$; Al—H 2.088(2) Å; Al—μ-H 1.56, 2.07 Å; Al—H 1.56 Å (mean); Al···Al 2.883 Å; H—Al—H 122(1)°; Al—μ-H—Al 104.7(5)°; μ-H—Al—μ-H 75(1)°.

The foregoing dimeric structures can be considered as tertiary amine stabilized adducts of the as yet unknown dialane $[H_2Al(\mu\text{-}H)]_2$. Theory predicts a binding energy comparable to that of the well-known diborane $[H_2B(\mu\text{-}H)]_2$.[80] Vaporization cleaves the hydride bridges, at least for H_3AlNMe_3 which is monomeric in the gas phase,[28] and the dimeric nature of this compound in the solid explains why it has a lower vapour pressure than the monomeric bis(amine) adduct.[32] The degree of association of the solid state dimers in benzene is close to 1.40,[27,40] cf. with 1.21 for the mono(quinuclidine) adduct which is monomeric in the solid.[16,45] The degree of association of the 3-chloroquinuclidine adduct of alane in benzene is higher, 1.64,[40] possibly in consequence of the chloro group acting as a weak donor rather than association via hydride bridging. This is also supported by IR and ^{27}Al NMR studies.[40]

Davidson and Wartik[37] had previously reported the TMEDA adduct having a high vapour

pressure and a dimeric structure was proposed for the gas phase in which the TMEDA was thought to adopt a bidentate coordination mode. Structurally characterized $[H_3Al\{Me_2N(CH_2)_nNMe_2\}]_\infty$ [$n = 2$ (TMEDA),[29] 3 (TMPDA),[41] 4 (TMBDA)[44]] are all polymeric in the solid state, the alane moiety defining a trigonal plane and N-centres in apical positions of a trigonal bipyramid, as shown by the structure of the TMEDA analogue in Fig. 4.[44,81] Thus, it seems unlikely that TMEDA would adopt a bidentate mode of bonding with octahedral aluminium as previously suggested.[37] More likely is a gas phase cyclic dimer in which the aluminium atoms are five-coordinate with nitrogen atoms in apical positions, as suggested for the solution state structure of $[H_3Al\{Me_2N(CH_2)_3NMe_2\}]_\infty$.[41] The structures of the Me_3TRIAZ derivatives, Scheme 2, have a similar coordination environment, as has the earlier structure of the TMEDA adduct, albeit for space group $P2_12_12_1$[29] cf. $P2_1/c$, and the structure of $H_3Al(NMe_3)_2$.[27] The range of Al—N distances for all five-coordinate species is 2.183(4)–2.24(2) Å, which encompasses the distance for the computed structure for $H_3Al(NH_3)_2$, 2.20 Å. This has D_{3h} symmetry and thus a linear N—Al—N arrangement, cf. experimental values for the foregoing structures $>174.9(2)°$.[44] Placing the nitrogen centres in apical positions is supported by theory (HF/DZP-ECP); starting with the C_{2v} and C_s trigonal bipyramidal isomers of $H_3Al(NH_3)_2$ resulted in fragmentation to H_3AlNH_3 and NH_3.[44]

Related structures include (i) those of the mixed donor species, the alane adduct of N-methylmorpholine and $\{Me_3N(H)_3Al(PMe_2CH_2\}_2$[45] and (ii) the structure of polymeric $H_3Al(PPr^i{}_2CH_2)_2$, Fig. 5.[50] All have the trigonal bipyramidal structure with the donor atoms in apical positions, as predicted by theory on model compounds (D95P),[50] D95*//D95*[51] and D95*,[51] respectively. The adduct of N-morpholine crystallizes in $P2_12_12_1$, but with *ca* 17% chloride content (see Section 2.0) it crystallizes in $P2_1/c$;[43] the chloride replaces hydride groups at only one site/metal centre for the two independent strands and thus without disruption to the polymeric structure. The Al—N distance is slightly shorter than for the above compounds, 2.15 Å, and Al—O is 2.19 Å. The mixed P—N— donor adduct has a similarly short Al—N distance, 2.155(9) Å, which is offset by an exceptionally long Al—P distance, 2.688(5) Å. In fact this distance is more akin to that in polymeric $H_3Al(PPr^i{}_2CH_2)_2$, mean 2.755(3) Å,[51] Fig. 6, some 0.3 Å longer than in monophosphine adducts of alane (see above) and some 0.5 Å longer than in bis(amine) adducts, which reflects very weak solvation of alane by P-donors and the tendency of unhindered phosphine adducts of alane to decompose to polymeric alane under mild conditions, via association.

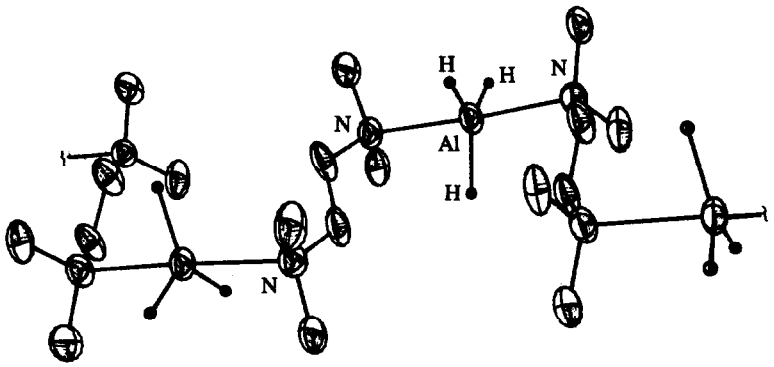

Fig. 5. Polymeric structure of H_3Al(TMEDA) [Al—N 2.24(2) and Al—H 1.55 Å (mean), N—Al—N 178.4(2)°].

Five- and six-coordination is achieved in the cationic species H_2AlL^+, L = PMDETA (trigonal bipyramidal with hydrogen atoms in the trigonal plane) and L = Me_4CYCLAM, *trans*-octahedral, Fig. 7.[65] ν(Al—H) reflect complex structures, both with a band at 1660 cm^{-1} for $[AlH_4]^-$ and another at 1822 cm^{-1}, L = PMDETA; 1740 cm^{-1}, L = Me_2CYCLAM.[65]

4.2. *Gallane derivatives*

Unlike alane, gallane has only one authenticated structural type, monomeric four-coordinate species. The ^{1}H NMR chemical shifts for the hydrides are typically 4.5–5.0 ppm and ν(Ga—H)

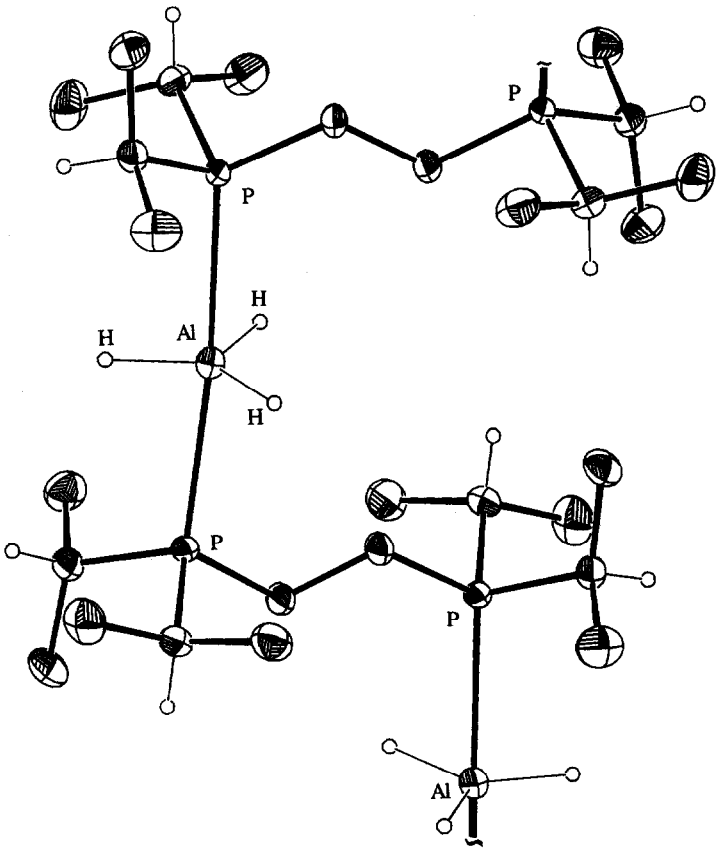

Fig. 6. Polymeric structure of $H_3Al(PPr^i_2CH_2)_2$ [Al—P 2.724 and Al—H 1.59 Å (mean), P—Al—P 175.0(3)°].

1800–1850 cm^{-1}, both significantly higher than for alane adducts. The 1 : 1 gallane adduct of TMEDA, Scheme 3, has a lower ν(Ga—H) band at 1790 cm^{-1}, which suggests it has a polymeric structure, as for the alane analogue,[81] and along with $H_3Ga(NMe_3)_2$ (< 23.4°C) are seemingly the only examples of five-coordinate species. Interestingly, theory predicts five-coordinate $H_2O(H)_3GaNH_3$ has a stabilization energy of 7.8 kcal mol^{-1} relative to H_3GaNH_3 and H_2O (D95* + DZP),[63] so that mixed N–O-donor five-coordinate species are possibly accessible.

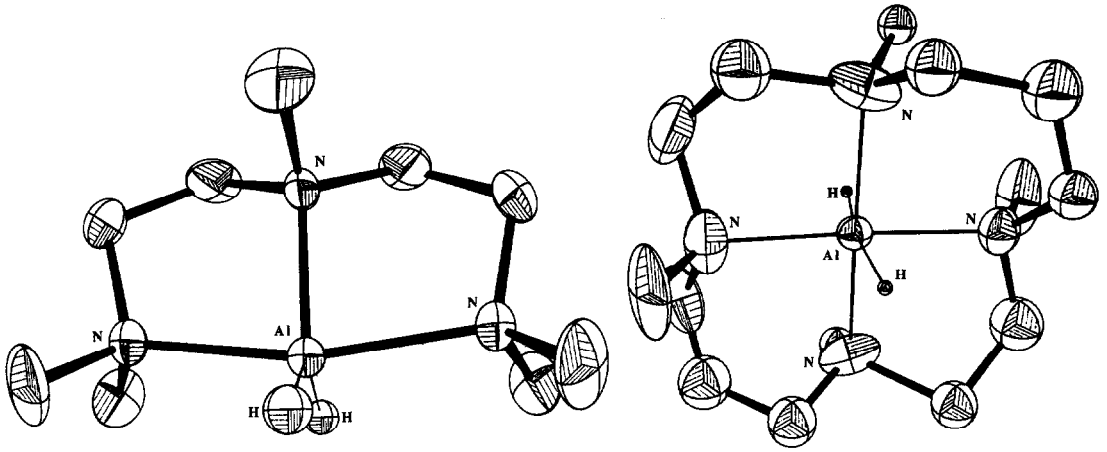

Fig. 7. Structures of the cationic alanes, $H_2Al(PMDETA)^+$ and $H_2Al(Me_4CYCLAM)^+$.

Tertiary amine adducts structurally characterized include $(H_3Ga)_2$TMEDA, Ga—N 2.094(4) Å,[9,67] and the quinuclidine adduct, Ga—N 2.063(4) Å,[46] with the difference in Ga—N reflecting the

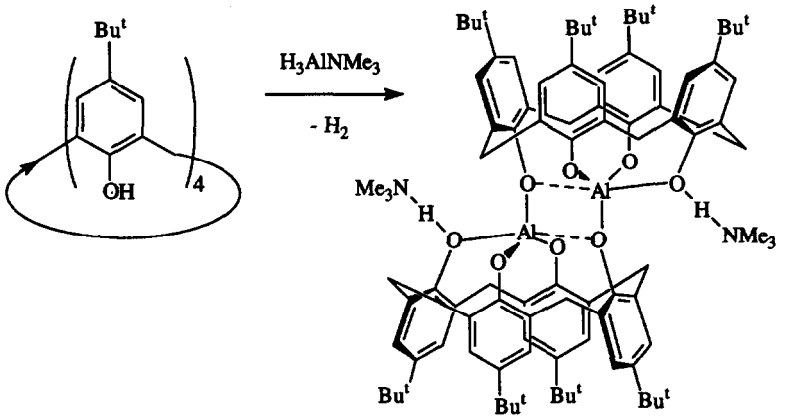
high difference in stabilities of the two compounds (Section 3). The gas-phase structure of H_3GaNMe_3 has Ga—N of 2.124 Å.[22] [An inaccurate and incomplete X-ray structure determination of this compound gives Ga—N 1.97(9) Å.[82]] The STO-3G/ECP-DZ level of theory on H_3GaNH_3 yields a slightly flattened tetrahedron environment around the metal centre, N—Ga—H 99.57° with Ga—N 2.074 Å, Ga—H 1.57 Å,[53] which is close to the solid state structures.[67]

H_3GaPMe_3 is X-ray sensitive, but other compounds have been authenticated in the solid: H_3GaPR_3, R = Cy[53] or Bu^t,[51] and $\{H_3Ga(PMe_2CH_2)\}_2$,[9,53] Ga—P 2.460(2), 2.444(6) and 2.399(4) Å, respectively. The agreement with theory for both H_3GaPH_3 (MP2/DZP) and H_3GaPMe_3 (RHF/DZP) for the Ga—P distance is poor, 2.576 and 2.550 Å, respectively, but there is reasonable agreement for other geometries.

5. REACTIONS

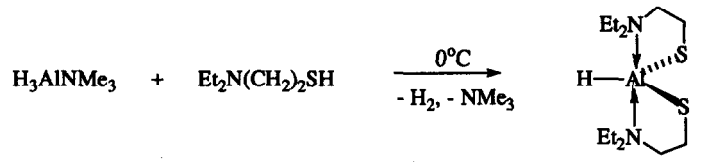
5.1. *Metallation*

Metallation reactions have in part been discussed in Section 3, dealing with the stability of secondary and primary amine adducts of alane, for example, Scheme 4, eq. (6). N,N′-Dimethylethylenediamine and H_3GaNMe_3 afford a novel gallane-rich metal amide, $[H_5Ga_3\{(NMeCH_2)_2\}_2]$.[67] Alcohols and thiols react with H_3AlNMe_3, yielding alkoxy- or mercapto-alanes.[67,83,84] Reaction with *p*-tert-butylcalix[4]arene results in trimetallation and deprotonation by the tertiary amine, yielding a bis(calix[4]arene), eq. (9), which included methylene chloride "hydrogen-bonded" to the centroids of opposing arene rings.[77] Reaction of H_3MNMe_3, M = Al or Ga, with 1,3-diketones, $X_3CC(O)CH_2C(O)CX'_3$, X = X′ = H; X = H, X′ = F; X = X′ = Me, affords exclusively the metallation products, as tri(acetylacetonato)metal(III) species, but for X = X′ = F metallation and addition prevails (see below).[85]



(9)

A monomeric mercaptoalane has been authenticated (X-ray structure) for an N-functionalized thiol, eq. (10).[48]

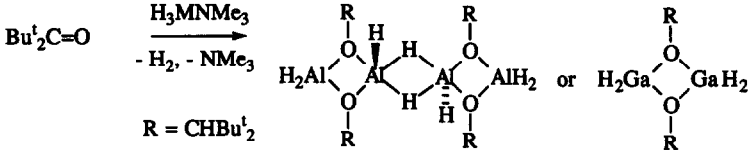


(10)

5.2. *Hydrometallation/reduction*

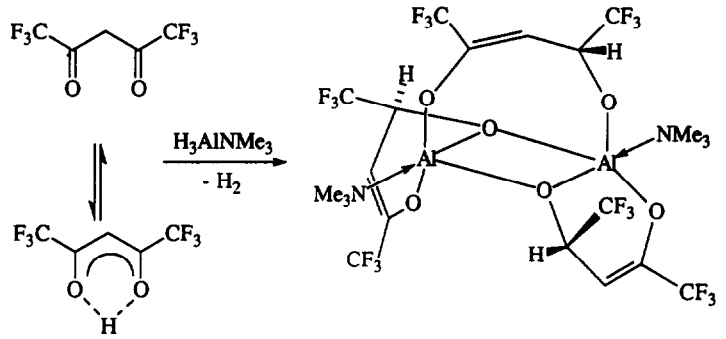
Tertiary amine adducts of alane reduce a variety of functional groups, often in high yield and with selectivity,[1] e.g. H_3AlNEt_2Me reduces carboxylic acids to alcohols and nitriles and amides to amines, but will not attack alkyl or halide groups. There is little work on synthetic applications of gallane, although recent work suggest some differences with alane analogues.[86] For example, H_3GaNMe_3 does not reduce ethylbenzoate, whereas H_3AlNMe_3 reduces the same compound to benzyl alcohol. Di-t-butylketone is reduced by both the trimethylamine adducts of alane and gallane,

although the isolated compounds have different solid state structures, further reflecting the tendency for gallane to achieve four fold coordination, e.g. (11).[48]



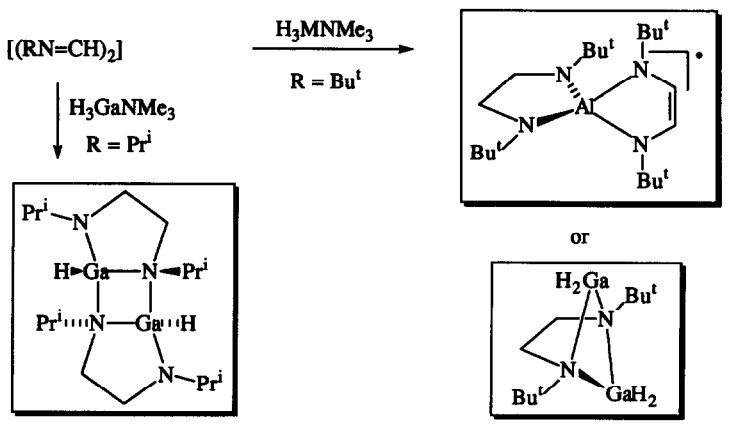
(11)

Metallation and addition prevails on treating H_3AlNMe_3 with $F_3CC(O)CH_2C(O)CF_3$, eq. (12), but metallation only for other 1,3-diketones (see below).[85]



(12)

1,4-Di-t-butyldiazabutadiene reacts differently with the trimethyl amine adducts of alane and gallane; alane affords a paramagnetic species, whereas gallane results in complete hydrometallation, Scheme 9,[10,87] isolated as a "gallane-rich" species which is isolobal with the aluminium compound derived from metallation of N,N′-di-t-butylethylenediamine, eq. (6).[72] 1,4-Di-i-propylbutadiene also gives addition, but as a dimeric species, Scheme 9. Interestingly, the treatment of 1,4-di-t-butylbutadiene with a mixture of metal powder, M′, and $LiMH_4$ gives radical species, $[M\{(NBu^tCH)_2\}_2]^{\bullet}$, with one ligand reduced to a dianion, the other to a radical, M = M′ = Ga or Al, M′ = Al or Ga, M = Ga.[10,87,88]



Scheme 9.

Addition to C=C bonds requires rather forcing conditions, even for intramolecular addition, e.g. hydrometallation of $H_3AlN(Me)_2CH_2CH{=}CH_2$, yielding a polymer—$\{(H)_2AlNMe_2(CH_2)_3\}^-$.[27]

5.3. *Miscellaneous*

Lithium hydride will displace the amine from H_3AlNMe_3 yielding $LiAlH_4$.[89] Similarly, mercury or lithium alkyls will displace hydrides in H_3AlNMe_3, affording amine adducts of alkylalanes,[31,90] and mercury(II) halides afford haloalane compounds.[31] Monoalkylgallane can also be prepared from mercury alkyl and H_3GaNMe_3.[91]

6. SURFACE CHEMISTRY

Tertiary amine adducts have found applications in materials science as precursors for delivering aluminium metal to surfaces. In addition to the useful vapour pressure of these adducts the absence of metal–carbon bonds in the precursors results in little deleterious carbonaceous material in the metal deposits.[7] Moreover, the compounds are less air-sensitive than trialkylaluminium compounds which have been used extensively in CVD technology.[6,8,92]

Both H_3AlNMe_3 and $H_3Al(NMe_3)_2$ have been successfully used to prepare thin films of aluminium using laser induced CVD,[7] low pressure CVD[6,8,92,93] and molecular beam epitaxy MBE.[94] They have also been used in electroless[95] and electrosolution aluminium plating.[13] More recently the mixed group 13 tertiary amine adduct $Me_3N(H)_2Al(\mu\text{-}H)_2BH_2$ has been used in depositing high purity aluminium under mild conditions, 100°C or 25°C with substrates pretreated with $TiCl_4$.[96].

Studies on the surface reactivity of H_3AlNMe_3 and $H_3Al(NMe_3)_2$ pecursors on Si, Al and GaAs substrates have yielded the following reactions, eqs (13)–(16), with the assumption that for $H_3Al(NMe_3)_2$ the primary process is the formation of NMe_3 and H_3AlNMe_3 prior to any surface adsorption.[38,92,93]

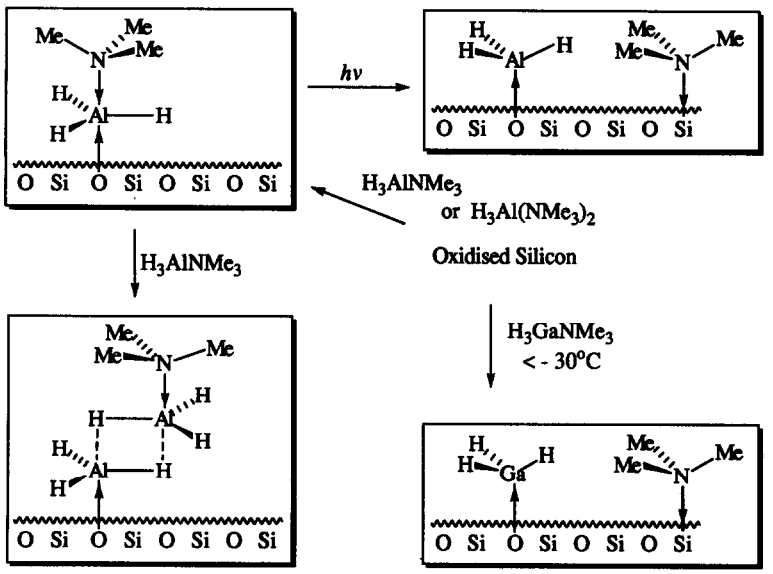
$$H_3AlNMe_3(g) \longrightarrow H_3AlNMe_3(ads) \qquad T = 150\,K$$

$$H_3AlNMe_3(ads) \longrightarrow AlH_3(ads) + NMe_3(g) \qquad T = 200\text{–}400\,K$$

$$AlH_3(ads) \longrightarrow Al(m) + H_2(g) + H(ads) \qquad T = 500\,K$$

$$2H(ads) \longrightarrow H_2(g) \qquad T = 600\,K$$

The adsorption of H_3AlNMe_3 on thermally grown oxidized silicon under UHV conditions has at least two pressure dependent processes, Scheme 10.[64] Molecular adsorption prevails at the dosing pressure *ca* 5.0×10^{-7} mbar with the aluminium centres becoming five-coordinate via binding to surface oxygen centres. High XPS X-ray flux (>240 W) results in migration of NMe_3 to silicon centres, ascertained by comparison of adsorption of NMe_3 gas. At dosing pressures of H_3AlNMe_3 *ca* $>10^{-7}$ mbar an aluminium rich species is formed, with the Al : N close to 2 : 1, possibly with hydride bridge formation, Scheme 10. Similar results are obtained for dosing of bis-trimethylamine alane, $H_3Al(NMe_3)_2$.



Scheme 10.

Calculations on H_3AlNH_3 and H_2O, and H_3AlOH_2(HF/D95*), as model systems for the interaction of H_3AlNMe_3 with surface oxygen centres have the formation of $H_3AlNH_3(OH_2)$ as energetically favoured by 4.53 kcal mol^{-1} and its fragmentation to H_3AlOH_2 and NH_3 requiring 13.16 kcal mol^{-1}; association of H_3AlOH_2 and H_3AlNH_3 to $H_2(H_3N)Al(\mu\text{-}H)_2Al(OH_2)H_2$, as a model

for the aluminium rich species, is also favoured, by 3.39 kcal mol^{-1}. At the higher dosing pressure where there is greater chance of molecular encounter of H_3AlNMe_3 with adsorbed H_3AlNMe_3, dissociation of $H_3Al(NMe_3)_2$ yielding surface bound "$H_3Al{\leftarrow}O{=}$" is possible, eq. (13). Association of such species with H_3AlNMe_3 via hydride bridges, of the type found in the solid for H_3AlNMe_3, is then possible, eq. (14).

$$H_3AlNMe_3(g) + Me_3N(H)_3Al{\leftarrow}O{=} \rightleftharpoons H_3Al(NMe_3)_2 + H_3Al{\leftarrow}O{=} \quad (13)$$

$$H_3AlNMe_3(g) + H_3Al{\leftarrow}O{=} \rightleftharpoons H_2(NMe_3)Al(\mu\text{-}H)_2Al{\leftarrow}O{=} \quad (14)$$

Adsorption characteristics for the trimethylamine adduct of gallane on oxidized silicon, also under UHV conditions, are different. For temperatures below *ca* −30°C dissociative adsorption occurs, with some of the trimethyl amines trapped on silicon sites. This is consistent with the preference for gallane to form four-coordinate species, although the primary process is likely to be the formation of a five-coordinate "mixed-donor" species. Calculations (D95* + DZP) show the five-coordinate species $H_2O(H)_3GaNH_3$ to be energetically favoured relative to (i) H_3GaNH_3 and H_2O by 0.67 kcal mol^{-1} and (ii) H_3GaOH_2 and NH_3 by 7.8 kcal mol^{-1}.[63]

7. CONCLUSIONS

Overall, the differences between Lewis base adducts of alane and gallane are: (i) a stronger tendency of aluminium to form "hyper"-valent structures compared to gallium; gallane forms four-coordinate species in the gas phase and the solid, even with potentially polydentate ligands such as TMEDA; (ii) the frailty of Ga—H bonds compared with Al—H bonds; and (iii) the polarizing influence/back-bonding participation of the d^{10} core for gallium. Recent rapid developments in the chemistry of Lewis base adducts of alane and gallane include applications in synthesis and materials science. Further developments in the former are likely because of differences in the reactivity of alanes and gallanes between various functional groups, viz differences in stereo-, chemo- and regioselectivity. Moreover, with a careful choice of optically active Lewis base there is scope for developing chiral reducing agents of gallane, possibly with different enantioselectivity than reagents based on alane. New applications in materials science are possible in developing volatile hetero-bimetallic compound for CVD generation of alloys, such as aluminium or gallium transition metal materials which have favourable lattice parameters relative to group 13–15 compound semiconductor materials, to circumvent breakdown of the interface and corruption of the device characteristics.[97] The incorporation of boron in aluminium is advantageous in high current density and deposition of such a material has recently been achieved using $Al(BH_4)_3$.[96] There is also scope for: (i) using alanes (and gallanes) as precursors for Ziegler Natta catalysts, along the lines developed for aluminium alkyls; (ii) developing arsine, and other heavier main group element adducts of alane and gallane; (iii) developing the chemistry of indane; and (iv) developing mixed group 13 hydride species, as well as gallane aggregates similar to the extensive types developed for borane, noting the nexus between borane and gallane and the distinctiveness of alane.

PROPOSED STRUCTURE OF THE FIRST *HYPHO* CARBABORANE, $C_3B_4H_{12}$

MARK A. FOX, ROBERT GREATREX,* NORMAN N. GREENWOOD and MARTIN KIRK

School of Chemistry, University of Leeds, Leeds LS2 9JT, U.K.

(*Received* 23 *March* 1993; *accepted* 20 *April* 1993)

Abstract—The reaction between *arachno*-B_4H_{10} and propyne under hot/cold conditions affords in low yield the first unsubstituted neutral *hypho* carbaborane, $C_3B_4H_{12}$, a colourless volatile liquid. The new tricarbaborane has been characterized by high-resolution mass spectrometry and ^1H, $^1H\{^{11}B\}$, $^1H\{^{11}B$ selective$\}$, 2D ^1H—$^1H\{^{11}B\}$ COSY, $^1H\{^{11}B\}$ n.O.e., ^{11}B, $^{11}B\{^1H\}$, 2D ^{11}B—$^{11}B\{^1H\}$ COSY and ^{13}C NMR spectroscopy. The data imply a mirror-plane symmetry and are consistent with an unprecedented open seven-vertex carbaborane framework.

A continuing and important theme in polyhedral borane chemistry is that of establishing relationships between cluster geometry and bonding.[1] Species belonging to the *closo*, *nido* and *arachno* classes have been well studied, but boranes having *hypho* electron counts (i.e. containing $n+4$ framework electron pairs, where n is the number of cluster atoms) are sparse and consequently their structural and bonding patterns are less well understood. Known examples, including a new series of eight- and nine-vertex dithiaborane clusters, have been summarized recently.[2]

Perhaps surprisingly, among the thousands of known carbaboranes the only authenticated example that falls into the *hypho* category is $Me_3N \cdot CB_5H_{11}$,[3] in which the 3,4-H-bridge of B_5H_{11} is replaced by the —$CHNMe_3$— linkage. The main route into carbaborane chemistry has been through the reactions of boranes with unsaturated hydrocarbons,[4] the type of product depending on the conditions employed. High-temperature "flash" reactions or electric discharges tend to form *closo*-carbaboranes, whereas less energetic conditions lead to *nido* clusters. It is tempting to speculate that *hypho*- and *arachno*-carbaboranes might occur as unstable intermediates in the formation of the more familiar *closo* and *nido* species, and that the hot/cold reaction technique might offer a viable method of isolating them. Interestingly, the classic compound $B_4H_8 \cdot C_2H_4$, obtained from the hot/cold reaction between B_4H_{10} and ethene,[5] has a *hypho* formula and electron count, but is generally regarded as being simply a dimethylene-substituted derivative of *arachno*-B_4H_{10}. No diffraction data have yet been published for this compound,[6] but IR[7] and NMR[8] data have been interpreted in terms of a symmetrical "basket-like" structure of C_{2v} symmetry and recent *ab initio*/IGLO/NMR calculations are in agreement with this.[9] The idea that an analogous molecule having a bridging unsaturated C=C function could be formed in the reaction between B_4H_{10} and alkynes has been suggested,[4e] but does not appear to have been followed up.

In view of the fact that the hot/cold technique has not previously been applied generally to reactions between boranes and acetylenes we decided to embark on a systematic study in this area in an attempt to generate new carbaborane intermediates and to shed further light on the mechanisms involved in these reactions. We have recently communicated preliminary results on the new *hypho*-carbaborane $C_3B_4H_{12}$;[10] in this fuller account we present additional NMR data on this interesting compound and discuss their structural implications.

Dedicated to Professor Heinz Nöth on his 65th birthday.

EXPERIMENTAL

Reactions were performed in standard high-vacuum systems fitted with greaseless O-ring taps and spherical joints [J. Young (Scientific Glassware) Ltd]. MeC≡CH was obtained commercially (Cambrian Gases) and B_4H_{10} was produced by the action of BF_3 on $[NMe_4]B_3H_8$, as described in the literature.[11] The hot/cold reactor was of the concentric tube type,[12] constructed of Pyrex and having a reaction volume of approximately 650 dm^3.

In a typical reaction B_4H_{10} (5 mmol) and MeC≡CH (4 mmol) were measured manometrically, condensed into the vessel and then allowed to warm to the temperature of the acetone/CO_2 slush bath maintained at −35°C surrounding the reactor. Silicone fluid (Dow Corning 550) was added to the inner reservoir, heated rapidly with a 1000 W heater to 100°C and controlled at that temperature for the desired period. The hot oil was then removed, the vessel cooled to −196°C and the volatile products pumped into a U-trap held at −196°C as the vessel was allowed to warm to room temperature. The volatiles were subjected to fractionation on a low-temperature column[13] and the distillate monitored directly by low-resolution mass spectrometry on a Kratos MS30 instrument. A species with a mass cut-off at *m/z* 92, which left the column at −60°C, was isolated in low yield (*ca* 1%) and characterized by high-resolution mass spectrometry (on a VG AutoSpec operated by Mr D. Singh) and by NMR spectroscopy. Attempts to improve the yield of this species by altering the reaction conditions have so far proven unsuccessful. Samples for NMR spectroscopy were pumped under vacuum into 5 mm soda-glass traps, which were sealed off and used as NMR tubes. Low-field measurements were made at 2.35 Tesla (100 MHz ^1H; 32 MHz ^{11}B) on a Jeol FX100 instrument. High-field spectra were obtained at 9.4 Tesla (400 MHz ^1H; 128 MHz ^{11}B; 100 MHz ^{13}C) on a Bruker AM-400 instrument. The $^1H\{^{11}B$ selective$\}$ and 2D ^1H—$^1H\{^{11}B\}$ COSY experiments were performed as described in previous publications from this laboratory.[14]

RESULTS AND DISCUSSION

High-resolution mass-spectrometric measurements on the new product with a mass cut-off at *m/z* 92 confirmed the assignment of this fragment to the parent molecular ion $[^{12}C_3{}^{11}B_4{}^1H_{12}]^+$ (observed *m/z* 92.1306, calc. *m/z* 92.1311). The 128 MHz $^{11}B\{^1H\}$ NMR spectrum in $CDCl_3$ at 223 K of the purest sample consisted essentially of two signals of equal integrated intensity [Fig. 1(i) and Table 1]. Significantly there were no cross peaks between these two boron resonances in the 2D ^{11}B—$^{11}B\{^1H\}$ COSY NMR spectrum. In the line-narrowed, undecoupled spectrum [Fig. 1(ii)] the peak at δ −20.1 (relative to $BF_3 \cdot OEt_2$) comprised a doublet of doublets of doublets [J(BH) = 165, 63, 37 Hz] and the peak at δ 1.60 appeared as a broadened doublet [J(BH) = 145.0 Hz].

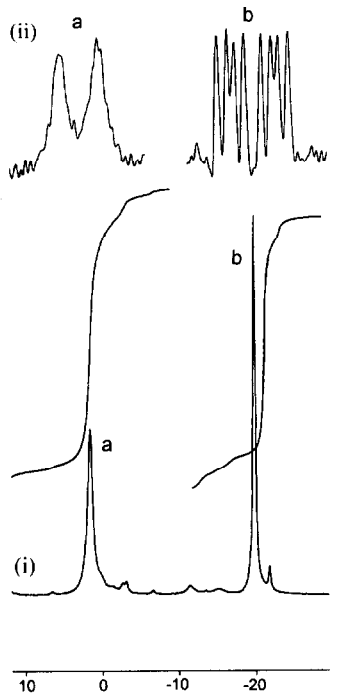

Fig. 1. Boron NMR spectra of *hypho*-$C_3B_4H_{12}$: (i) 128 MHz $^{11}B\{^1H\}$, (ii) 128 MHz line-narrowed ^{11}B. Chemical shifts referenced to $BF_3 \cdot Et_2O$ = 0.00 ppm.

The 400 MHz boron-decoupled ^1H NMR spectrum in $CDCl_3$ at 223 K consisted of seven signals of approximate relative intensity 2:2:2:2:1:1:2 at δ values (relative to Me_4Si) of 3.25, 2.23, 1.61, 0.68, −0.90, −1.40 and −2.16, respectively (labelled c–j in Fig. 2). Comparison of proton spectra with and without boron decoupling allowed peaks e, g and h at δ 1.61, −0.90 and −1.40 to be assigned to C—H protons. The $^1H\{^{11}B$ selective$\}$ experiments have revealed that the resonances from the two bridging hydrogen atoms are in fact coincident and comprise the peak at δ −2.16, despite the fact that the integrated intensity of this peak is nearer 1.6 than 2 (relative to peaks g and h which are both of intensity 1). The signal labelled with an asterisk at δ 0.24 was originally thought to be part of the main spectrum and was assigned to the hydrogen atom bridging the two boron atoms B_a.[10] However, this peak has since been shown to vary in intensity from sample to sample, and is now

Table 1. NMR data of *hypho*-$C_3B_4H_{12}$

Boron	δ (ppm)[a]	J(BH) (Hz)[b]

j			b	quintet	$J(H_jB_bH_f)$	$H_f = 8.7$

[a] In ppm ($BF_3\cdot Et_2O$ = 0.00 ppm); 128 MHz $^{11}B\{^1H\}$ spectrum; solvent $CDCl_3$, 230 K. There were no cross peaks relating these two boron resonances in the 2D ^{11}B—$^{11}B\{^1H\}$ NMR.

[b] In Hz; 128 MHz line-narrowed ^{11}B spectrum.

[c] In ppm (Me_4Si = 0.00 ppm); 100 MHz $^{13}C\{^1H\}$ spectrum; solvent $CDCl_3$, 230 K.

[d] Number of protons attached to each carbon; $^{13}C\{^1H\}$ A.P.T. (attached proton test) spectrum. The δ −24.5 peak is too broad for assignment.

[e] In ppm (Me_4Si = 0.00 ppm); 400 MHz ^1H spectrum.

[f] In ppm; 400 MHz $^1H\{^{11}B\}$ spectrum.

[g] Boron atom to which the proton is bonded; 400 MHz $^1H\{^{11}B$(selective)$\}$—^1H spectra.

[h] In Hz; 100 MHz line-narrowed ^1H spectrum; solvent CD_2Cl_2 233 K. The peak appearance is also described.

[i] By cross peaks; 2D ^1H—$^1H\{^{11}B\}$ COSY spectrum; solvent $CDCl_3$, 233 K.

[j] Peaks of other protons observed, with relative intensities; 400 MHz $^1H\{^{11}B\}$ n.O.e. (nuclear Overhauser effect) spectra.

[k] Protons unknown.

attributed to a minor impurity. In the ^1H—^1H COSY spectrum very strong cross-peaks were observed between H_f and H_j, H_f and H_d and H_g and H_h, but none between H_d and H_j or H_c and H_i.

These NMR data point to a structure of C_s mirror-plane symmetry with B_2H_5, B_2H_3, CH_2 and two equivalent CH groups. The favoured structure and a corresponding (2243) topological diagram are shown in Figs 3(i) and (ii). Each pair of symmetry-related boron atoms is associated with a bridging hydrogen atom and the CH_2 group has non-identical protons. The lack of connectivity between the two sets of boron atoms is indicated by the absence of cross-peaks in the ^{11}B—$^{11}B\{^1H\}$ COSY NMR spectrum.

The boron signal at δ 1.60 is attributed to the two boron atoms B_a, for which the coupling to the bridging hydrogen H_i is unresolved, even in the line-narrowed spectrum. The complex splitting of the boron signal at δ −20.1 is attributed to the coupling of boron atoms B_b to the three sets of protons H_f, H_d and H_j. The coupling constants of 165 and 37 Hz (revealed in the line-narrowed ^{11}B NMR spectrum [Fig. 1(ii)]) are typical of *exo*-terminal and bridg-

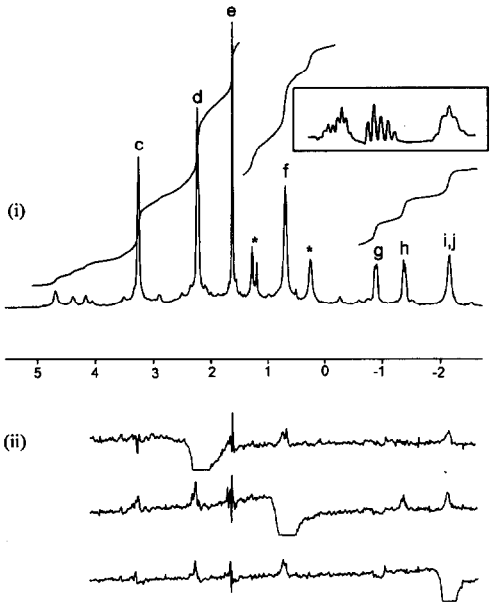

Fig. 2. Proton NMR spectra of *hypho*-$C_3B_4H_{12}$: (i) 400 MHz $^1H\{^{11}B\}$ (* = impurities); inset: 100 MHz line-narrowed $^1H\{^{11}B\}$ of peaks H_g, H_h and $H_{i,j}$; (ii) 400 MHz $^1H\{^{11}B\}$ n.O.e. spectra with irradiation at H_d, H_f and $H_{i,j}$ peak positions, respectively. Chemical shifts referenced to Me_4Si = 0.00 ppm.

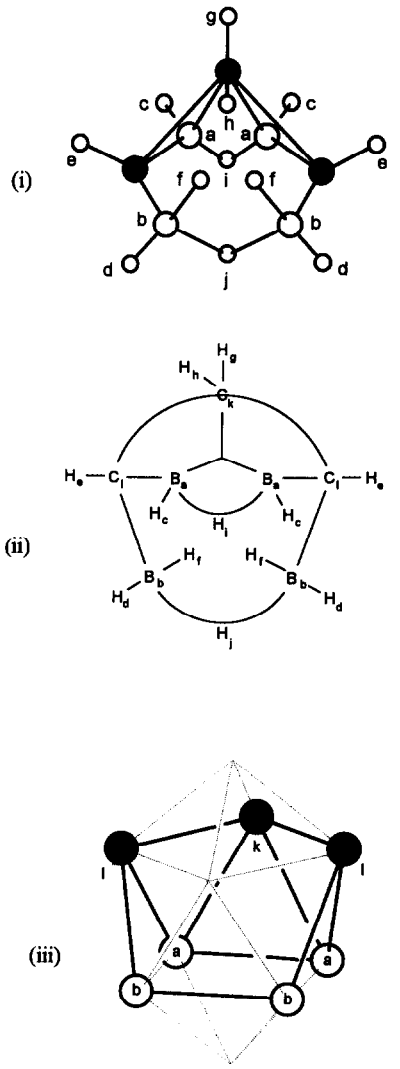

Fig. 3. (i) The proposed molecular structure of $C_3B_4H_{12}$, see text. (ii) A possible (2243) topological description of the bonding in *hypho*-$C_3B_4H_{12}$. An alternative (and effectively equivalent) bond network involves two closed three-centre CBC bonds in place of the closed three-centre BCB and open three-centre CCC bonds shown. (iii) Formal relationship between the cluster framework geometry of *hypho*-$C_3B_4H_{12}$ and *closo*-$B_{10}H_{10}^{2-}$. Large open circles B, shaded circles C, small open circles H.

ing hydrogen atoms, respectively, and these are assigned to H_d and H_j. The coupling constant of 63 Hz is unusual, but a similar value (J = 55–60 Hz[15]) has been obtained for the coupling constant associated with the unique *endo*/face-capping hydrogen atom in pentaborane(11)[16] and it therefore seems likely that the two H_f protons in $C_3B_4H_{12}$ are also *endo* in character. The possibility that they might be bridging between B_b and C_l is rejected because any such structure would feature too many three-centre bonds to enable a topological description to be formulated in which all 11 framework electron pairs were accommodated. Moreover, the observation that a ^1H n.O.e. enhancement was observed for protons H_h and H_c when proton H_f was irradiated, but not when H_d or $H_{i,j}$ are irradiated [Fig. 2(iii)], strongly suggests that the H_f protons are indeed disposed towards H_h, whereas the terminal H_d protons and the bridge protons $H_{i,j}$ point away from H_h. The 100 MHz $^{13}C\{^1H\}$ spectrum showed peaks at δ 18.0 and −24.5, assigned to C_l and C_k, respectively, by an attached proton test.

The cluster framework geometry, which conforms to 2243 *styx* topology, can be formally viewed as a seven-atom fragment of a closed triangular 10-vertex bicapped Archimedean antiprism [Fig. 3(iii)]. This description of the molecule is consistent with the Williams–Wade electron counting rules for *hypho*-$C_3B_4H_{12}$, which require a contribution of 11 electron pairs to the framework bonding. However, the absence of any direct bonding between the two sets of boron atoms, revealed in the COSY data, suggests considerable flexibility in the structure and an alternative description of the *molecular* geometry would be as a 1,2,5-tricarbapentaborane fragment in which the C(2) and C(5) atoms are bridged by a

B_2H_5 fragment, giving an overall *hypho* electron count. It is also noteworthy that the compound is isoelectronic with the non-classical norbornene carbocation $C_7H_9^+$. By contrast, the view that the framework geometry is that of a *hypho* six-vertex trigonal prismatic C_2B_4 cluster with a μ_2-bridging CH_2 group can be confidently rejected: proton peaks g and h in Fig. 2(i), each of which features geminal coupling, are at unusually high field for a normal methylene grouping, suggesting that the latter is not acting simply as a pendant moiety. Such a description would also be impossible to formulate topologically.

The reaction mechanism by which the *hypho*-tricarbaborane $C_3B_4H_{12}$ is formed from propyne and tetraborane is not obvious. It is noteworthy that the product has three contiguous carbon atoms —CH—CH_2—CH—, but there is no sign of the methyl group initially present in propyne, $CH_3C{\equiv}CH$.

Acknowledgements—We thank the SERC, the U.S. Army Research and Standardization Group (Europe) and Borax Research for financial support, Dr X. L. R. Fontaine for recording some of the high-field NMR data, Ellen Leuschner for help in preparing a sample of the compound for the ^{11}B—^{11}B COSY measurement and Professor P. Paetzold (Aachen) for useful comments on this work.

LOW-TEMPERATURE SOLID-STATE ROUTES TO TRANSITION METAL OXIDES VIA METATHESIS REACTIONS INVOLVING LITHIUM OXIDE

A. HECTOR and I. P. PARKIN*

Department of Chemistry, The Open University, Milton Keynes MK7 6AA, U.K.

(*Received* 18 *March* 1992; *accepted* 19 *April* 1993)

Abstract—Thermolysis of a mixture of lithium oxide and anhydrous transition metal halide, MX_n (M = Ti, Zr, Hf, V, Nb, Ta, Cr, Mo, W, Fe, Co, Ni, Cu, Zn, X = Cl; M = Mn, X = I), at oven temperatures of 450°C for 5 h produces crystalline transition metal oxide via a solid-state metathesis reaction. DSC studies show that the reaction is initiated at 300°C for M = Hf and Nb. When M = Ta or Nb the product is $LiMO_3$. The metal oxides and lithium-metal oxides were characterized by X-ray powder diffraction, S.E.M., EDAX, FT-IR and magnetic moment measurements.

Metal oxides of various formulations are known for all the transition elements.[1] They have widespread technological importance as powders for catalysts,[2] ceramics,[3] engineering materials[4] and as thin films for reflectance coatings. Recently the use of mixed metal oxides as high-temperature superconductors[5] has seen rapid growth and could lead to great improvements in power transmission.

Metal oxides have been made by heating the metal in air, often at high temperature. The refractory nature of some metal oxides means that annealing has often been required to produce a crystalline material. New developments in metal oxide and mixed metal oxide synthesis have involved the use of either molecular precursors or hydrothermal processes.[6] The thermal decomposition of metal nitrates or alkoxides has allowed lower temperature preparation of oxides either as bulk solids or as thin films via MOCVD. Occasionally competitive degradation pathways incorporate other elements in the oxide lattice in these lower temperature preparations.[7] Hydrothermal processes have allowed lower temperature mixed-metal oxide synthesis and have several advantages, including intimate mixing of the reagents and stoichiometric composition control.

Solid-state "self-propogating high-temperature synthesis" (SHS) routes to ceramic materials including nitrides, sulphides, phosphides and oxides have been developed by Russian workers.[8] Kaner[9–12] has elegantly developed this work for metathesis type reactions and has synthesized a range of main group and transition metal pnictides, mixed pnictides and mixed chalcogenides. Solid-state metathesis routes have some advantages when compared to traditional methods of metal oxide synthesis: firstly, no solvent is involved in the reaction; secondly, low synthesis temperatures are required often with the reaction exhibiting high exothermicity once initiated; thirdly, the by-products in the reactions are removeable from the oxide lattice allowing ready separation of products. Additionally, stoichiometric control of the reagents allows the possibility of making a range of mixed metal oxides.

An early example of a metathesis route to metal oxides was developed in 1932 by Hilpert and Wille,[13] who reported the preparation of mixed-metal ferrates at moderate temperature (400–500°C) by reaction of metal dichlorides with lithium ferrate. Recently, reaction[10,14] of sodium peroxide with CuF was found to produce Cu_2O.

We report here the reaction of lithium oxide with anhydrous transition metal halides, to produce crystalline transition metal oxides.

EXPERIMENTAL

All reactions and preparations were conducted under vacuum or in a dinitrogen filled dry-box. Glass ampoules were made out of either pyrex, borosilicates or quartz glass and were either flame dried under vacuum or heated to 400°C for 6 h prior to reaction. All solvents were degassed; THF was distilled from sodium/benzophenone and stored over 4 Å molecular sieves prior to use. Metal halides and lithium oxide were purchased from Aldrich Chemical Company. The metal halides were dried over thionyl chloride prior to use. X-ray powder diffraction patterns were obtained using a Siemens D5000 diffractometer using nickel filtered Cu-K_α radiation (1.5406 Å); SEM and EDAX analyses were obtained on a Jeol JSM 820 instrument equipped with the Kevex program;[15] FT-IR spectra were obtained as pressed KBr pellets on a Nicolet 205(CsI); GC were obtained on a Pye–Unicam 204 with 5 Å molecular sieves using a thermal conductivity detector with helium carrier gas; magnetic moment measurements were determined by a Johnson–Matthey balance. DSC analyses were performed in open aluminum pans under argon flow on a Polymer Laboratories DSC using a ramp rate of 5°C min^{-1} from 200 to 620°C. Thermal initiation of the reactions was performed in a Lenton Thermal Design tube furnace. Microanalyses were performed by Medac LTD, Brunel University.

Transition metal oxide preparation (M = Ti, Zr, Hf, V, Cr, Mo, W, Mn, Fe, Co, Ni, Cu, Zn, Hg)

Lithium oxide (50–100 mg) and anhydrous metal halide, MX_y (equimolar quantities of lithium and halide), were ground together using an agate pestle and mortar in a nitrogen filled dry-box. The powder was added to a thick-walled glass ampoule, sealed under vacuum and sonicated with ultrasound for 10 min. The ampoule was then wrapped in glass wool and placed in a conventional oven at 450°C for 2–10 h, during which time the solids invariably fused into a large lump and changed colour. The ampoule was removed from the oven, allowed to cool to room temperature and broken open in a dinitrogen filled glove-box. Trituration of the fused solid with THF (3×20 cm^3) for 10 h produced a coloured precipitate and a cloudy THF layer. Evaporation of the THF filtrate produces lithium chloride. The coloured powders were identified as transition metal oxides by X-ray powder diffraction (Table 1), EDAX analysis, FT-IR and magnetic moment measurements. Ceramic yields, based on the metal after THF trituration varied from 60 to 90% dependent on the sample.

Table 1. Crystalline phases observed from reaction of MX_n and Li_2O

Initial metal halide	Crystalline phase detected	Colour	Yield (%)	Reaction time (h)	Observed lattice *a* spacing[20]	Literature lattice *a* spacings
$TiCl_4$	TiO_2 (Li_2TiO_3)	White	60	2	4.585 (5.06)	4.593 (5.072)
$TiCl_3$	TiO_2	White/grey	60	2	5.069	5.067
$ZrCl_4$	ZrO_2	Grey	65	2	5.32	5.313
$HfCl_4$	HfO_2	Grey	65	2	5.12	5.12
VCl_4	VO_2 (Li_3VO_4)	Black	55	2	9.083 (5.499)	9.083 (5.447)
VCl_3	V_2O_3 ($LiVO_2$)	Black	60	2	5.42	5.43
$NbCl_5$	$LiNbO_3$	Light grey	90	2	5.149	5.149
$TaCl_5$	$LiTaO_3$	Grey	90	2	5.167	5.153
$CrCl_3$	Cr_2O_3	Grey	60	10	4.955	4.958
$MoCl_5$	MoO_2	Brown	65	10	5.609	5.607
$MoCl_3$	MoO_2	Black	70	10	5.610	5.607
WCl_4	WO_2	Black	70	2	5.575	5.575
MnI_2	MnO (Mn_3O_4)	Brown	85	2	4.440	4.445
$FeCl_3$	Fe_3O_4 (Fe_2O_3)	Dark brown	80	2	8.396	8.396
$CoCl_2$	CoO	Brown	85	10	5.040	5.036
$NiCl_2$	NiO	Light green	75	10	4.277	4.260
CuI	Cu_2O	Yellow	40	2	4.177	4.176
$ZnCl_2$	ZnO	Light grey	90	2	4.271	4.270
$HgCl_2$	HgO	Yellow	45	10	3.257	3.350

Note: not all lattices are cubic; only the *a* value is reported. Minor phases detected are shown in parentheses.

Alternative procedure

(1) An identical procedure to that outlined above can be carried out by initiating the reaction using a 750 W industrial microwave oven with a variable heating period dependent on the sample. The work-up and properties of the materials obtained were identical to those initiated in the conventional oven.

(2) The metal oxides could also be washed free of lithium chloride by-products by washing with degassed water for 10 min.

(3) Attempts at making mixed metal oxides were investigated under the same reaction and work-up conditions as above, except equimolar quantities of the starting metal halide powders were ground together before mixing in the ground lithium oxide powder.

CAUTION! Reaction of hydrated metal halides with lithium oxide can lead to an explosion of the ampoules on thermolysis. Care must be taken in the reactions of Li_2O with metal halides because a vigorous exothermic reaction can result. All preparations should be routinely performed behind a toughened glass safety screen.

RESULTS AND DISCUSSION

Reaction of ground powders of Li_2O and anhydrous transition metal halides at an oven temperature of 450°C in sealed ampoules produce crystalline transition metal oxides and lithium halides via a solid state metathesis reaction, eqs (1), (2), (3) and (4).

$$MCl_4 + 2Li_2O \longrightarrow MO_2 + 4LiCl \quad (M = Hf, Zr, W) \quad (1)$$

$$MX_2 + Li_2O \longrightarrow MO + 2LiX \quad (M = Zn, Hg, Cd, Co, Ni, X = Cl; M = Mn, X = I) \quad (2)$$

$$FeCl_3 + Li_2O \longrightarrow Fe_2O_3 + Fe_3O_4 + 3LiCl \quad (3)$$

$$2CuI + Li_2O \longrightarrow Cu_2O + 2LiCl \quad (4)$$

The product of the reactions [eqs (1), (2), (3) and (4)] was often contained as a fused grey lump and a small amount of a white solid was sublimed onto the walls of the ampoule. The white sublimed solid was analysed as lithium halide (either LiCl or LiI dependent on the initial reagents) by X-ray powder diffraction (XRPD), lithium flame test and EDAX analysis. The grey fused material showed a smooth morphology by S.E.M., Fig. 1(a); metal, oxygen and a small amount of halide (15 mol%) by EDAX analysis, both of which are consistent with the formation of a metal oxide that is coated with sublimed lithium halide. The metal oxide was purified by either washing with THF or water; this removed the co-product lithium halide. The metal oxides after trituration were characterized by X-ray powder diffraction (Table 1), FT-IR, magnetic moment measurements, S.E.M., EDAX analysis and microanalysis.

The S.E.M. profile of the triturated metal oxides showed micron sized particles with sharp angles and faces as illustrated in Fig. 1(b), whilst the EDAX analysis revealed only metal and oxygen with no halides present (2–3% detection limit). The samples of ZnO and Cr_2O_3 made in this study showed less than 0.5% lithium by microanalysis, indicating that the metal oxide lattices do not contain appreciable amounts of LiX after trituration. The FT-IR spectra of the metal oxides showed a broad band at *ca* 450 cm^{-1} due to M—O stretches. The magnetic moment measurements were typical for each of the metal oxides and showed no deviation from literature values.[16]

The X-ray powder diffraction data for the transition metal oxides formed from reaction of Li_2O and metal halide are summarized in Table 1. In general, after a reaction time of 5 h at 450°C a crystalline transition metal oxide was formed, however, the degree of crystallinity as judged by the Scherrer equation[17] varied from crystallite sizes of 800 Å (ZnO) to 150 Å (HfO_2). The metal oxides after trituration showed no lithium halide present and only one phase of metal oxide (by XRD), with the exception of iron and manganese where two phases, Fe_2O_3, Fe_3O_4 and MnO, Mn_3O_4, were detected. Representative XRD patterns for ZnO and MnO, Mn_3O_4 made in this study, are shown in Figs 2(a) and 2(b).

The phase of metal oxide detected by XRD invariably showed the metal in the same oxidation state as in the initial metal halide. In general no reduction or oxidation of the metal occurred and no gases (O_2) were detected from the reaction by GC, however, for reactions involving $TiCl_3$ and $MoCl_3$, TiO_2 and MoO_2 were detected indicating an oxidation at the metal. For reactions involving VCl_3 and VCl_4 the metal oxides formed were V_2O_3 and VO_2, respectively. A small amount of the phases associated with $LiVO_2$ and Li_3VO_4 were also detected in these reactions by XRD. Analogous solid-state reactions of Li_3N and metal halides do lead to reduction at the metal and formation of dinitrogen,[18] with the tendency increasing across the periodic table such that when starting with $HfCl_4$ partial reduction occurs at the metal and HfN and N_2 are formed. To the right of the *d*-block reduction becomes increasingly more important

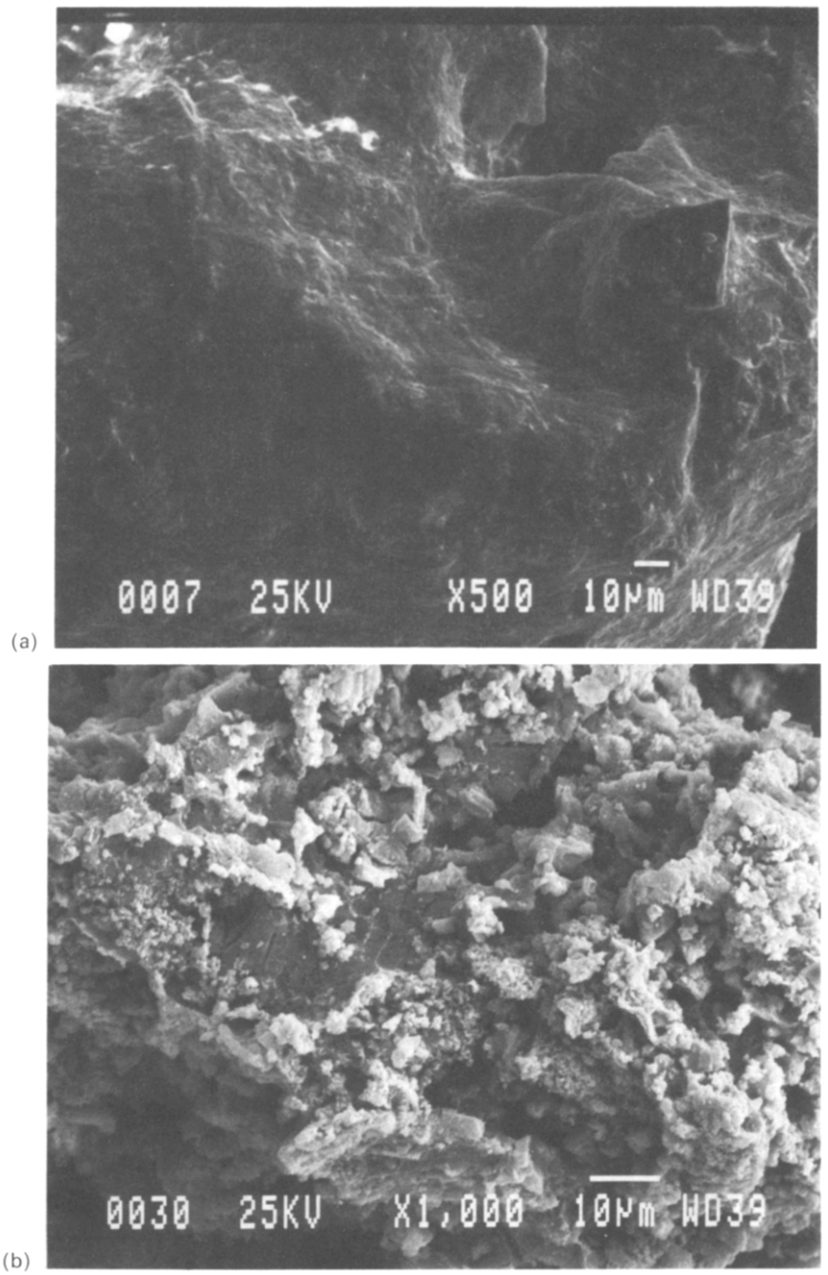

Fig. 1. S.E.M. profiles of the solid produced by reaction of MnI_2 and Li_2O (a) without and (b) after trituration with water.

and the reaction between $ZnCl_2$ and Li_3N yields only zinc metal and dinitrogen. This trend is not seen for the reactions of Li_2O and transition metal halides where metal oxides (or lithium metallates) are formed for all the metal halides studied independent of the position of the metal in the periodic table. The reason for the difference in reactivity for similar solid-state reactions involving Li_2O and Li_3N and metal halides may be due to the fact that many of the late transition metal nitrides are thermally unstable and undergo facile reduction to metal and dinitrogen, whereas metal oxides are comparatively more thermally stable.

The reaction of $HfCl_4$ with Li_2O was studied by DSC, which revealed a large exotherm at 310–325°C (Fig. 3). Similar results were also obtained for reaction of $NbCl_5$ and Li_2O. The energy released (120–300 kJ mol^{-1}) corresponds to the expected heat of reaction on forming metal oxide and LiCl. Interestingly the exotherm takes place over a time scale of a few minutes, indicating that the reaction is not as violently exothermic as reactions of $MoCl_5$–

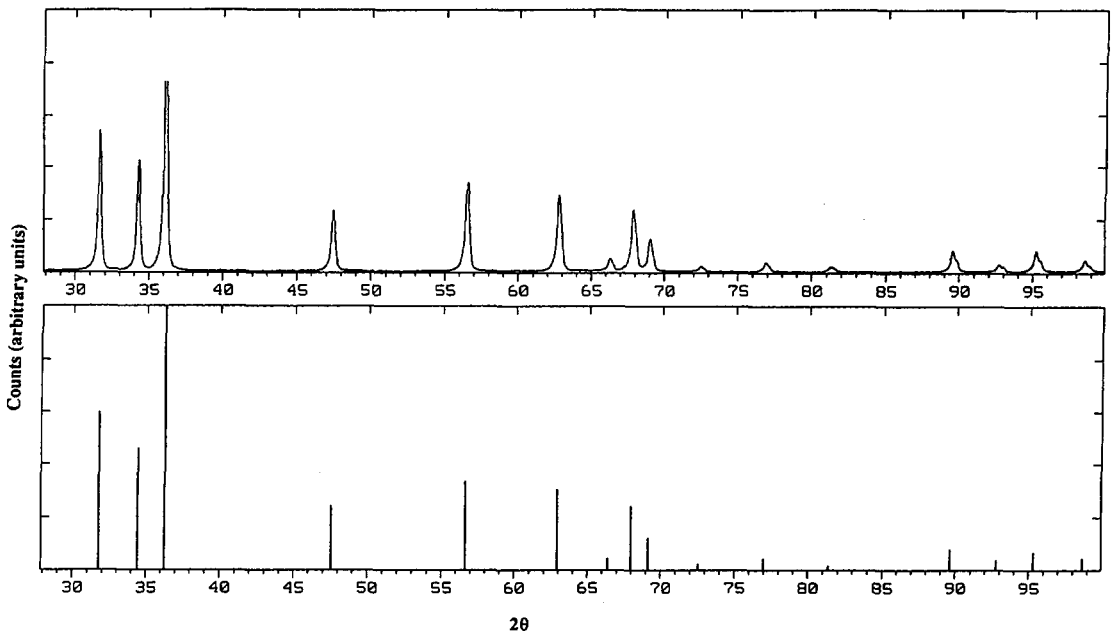

Fig. 2(a). Upper trace X-ray powder diffraction pattern for the solid produced from reaction of $ZnCl_2$ and Li_2O; lower trace standard X-ray powder diffraction line pattern for ZnO.

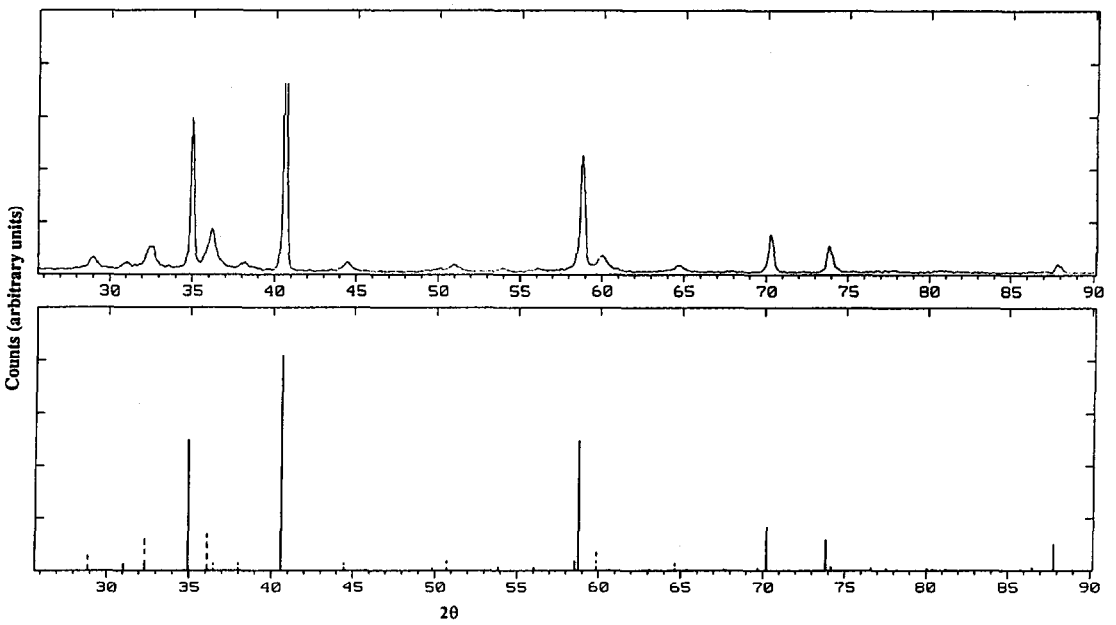

Fig. 2(b). Upper trace X-ray powder diffraction pattern for the solid produced from reaction of MnI_2 and Li_2O; lower trace standard X-ray powder diffraction line pattern form MnO (——) and Mn_3O_4 (– – – –).

Na_2S and Li_3N–$HfCl_4$ which are over in a few seconds.[9,18] However, the reaction of $ZnCl_2$ and Li_2O is extremely exothermic with the products spraying the inside of the DSC cell; initiation temperature in this case proved to be around 250°C. It is probable that heat transfer in the DSC cell is easier than in the glass ampoule reactions and that the observed tube furnace initiation temperatures of 400–450°C actually correspond to 310–325°C at the sample surface after the effects of thermal gradient through the glass and the bulk sample are taken into account. Blank runs of Li_2O and $HfCl_4$

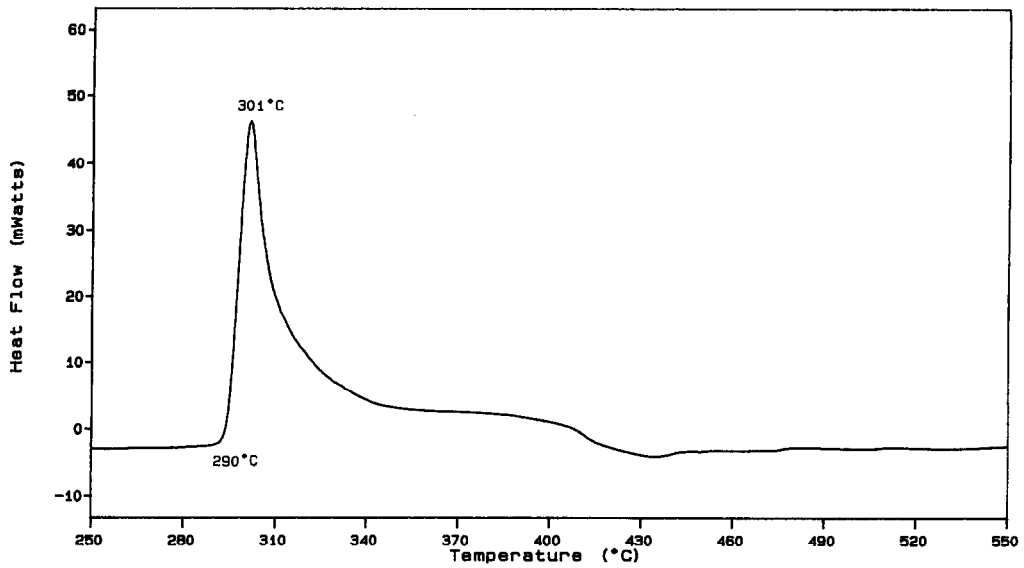

Fig. 3. Differential scanning calorimetry trace for reaction of $HfCl_4$ and Li_2O.

in the same apparatus showed no features of the same magnitude from 200 to 650°C. A sample of $HfCl_4$ and Li_2O held at 295°C showed heat evolved over a 15 min period, corresponding approximately to the calculated heat of reaction. The heat evolved from the reaction suggests high temperatures are generated; this is confirmed by the crystallinity of the product. Analogous reactions of lithium nitride or lithium sulphide with transition metal halides are very exothermic, inducing temperatures[9,18] in excess of 1000°C.

Hess' Law calculations[19] of the reaction of Li_2O with metal halides indicate that the reaction is exothermic with ΔH_f varying from -100 to -600 kJ mol^{-1} dependent on the metal. Initiation of the reaction in a small region of the solid may occur, but propagation throughout the bulk material may not be as facile in these uncompressed mixed Li_2O/MX_n powders than with analogous Li_3N reactions. Thus, a number of independent propagations throughout the solid could account for the observed fused crystalline product and partially sublimed metal halide.

The major exceptions to the formation of metal oxides in the reactions of Li_2O with transition metal halides were those involving niobium and tantalum pentachlorides, where $LiNbO_3$ and $LiTaO_3$ were the only phases detected [eq. (5)]. However, in reactions involving titanium and vanadium halides with Li_2O a small amount of crystalline lithium metallate was observed in addition to the main metal oxide phase by XRPD. The X-ray powder diffraction patterns of $LiTaO_3$ and $LiNbO_3$

$$MCl_5 + 3Li_2O' LiMO_3 + LiCl \quad (M = Ta, Nb) \qquad (5)$$

were phase pure (Fig. 4) after THF trituration and the EDAX analysis showed only metal and oxygen with no chlorine present (lithium could not be determined by EDAX analysis on the instrument used). The samples of $LiMO_3$ were diamagnetic as expected, indicating that the metals had not been reduced.

Attempts at making mixed-metal oxides, $M_xM_yO_z$, by reaction of preground metal halides and lithium oxide did not prove successful at oven temperatures of 450°C. This is illustrated in Fig. 5 for the reaction of equimolar amounts of $ZnCl_2$ and MnI_2 with Li_2O, which produced both ZnO and MnO rather than a mixed metal oxide, Zn_xMn_yO.

The oxygen incorporated in the transition metal oxides formed from metathesis reactions involving Li_2O comes predominantly from the lithium oxide, because blank experiments under exactly the same conditions produced only unreacted metal halide (as demonstrated by XRPD and EDAX analysis). However, for the reactions involving $TiCl_3$ and $MoCl_3$, where oxidized products TiO_2 and MoO_2 are produced, some oxygen is probably incorporated in the product either due to work-up or from the glassware. One specialist utility of this reaction could be in incorporating isotropically labelled oxygen into a metal oxide lattice by starting with initially labelled lithium oxide.

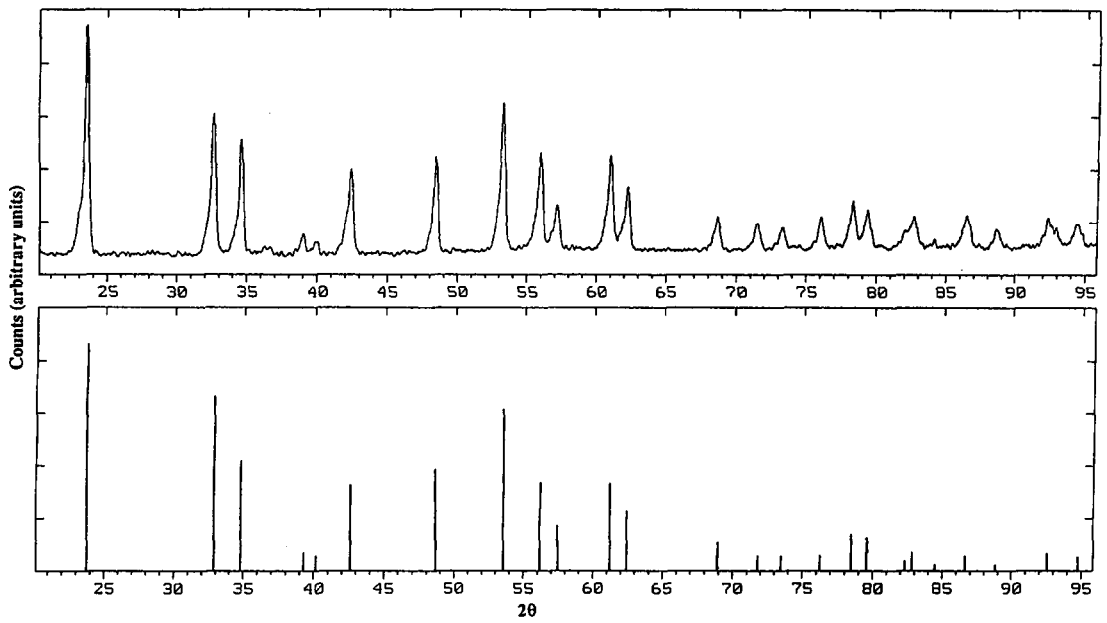

Fig. 4. Upper trace X-ray powder diffraction pattern for the solid produce from reaction of $TaCl_3$ and Li_2O; lower trace standard X-ray powder diffraction line pattern for $LiTaO_3$.

CONCLUSIONS

Current routes to metal oxides either by direct combination of the elements or by hydrothermal molecular precursor routes often involve high-temperature pyrolysis of the materials or prolonged annealing to produce a crystalline material. The solid-state metathesis routes described here to form metal oxides are at a reasonably low initiation temperature (300°C) and comparatively short reaction times (5 h for ampoule reactions, 6–10 min in a DSC cell). Unfortunately mixed-metal oxides seem

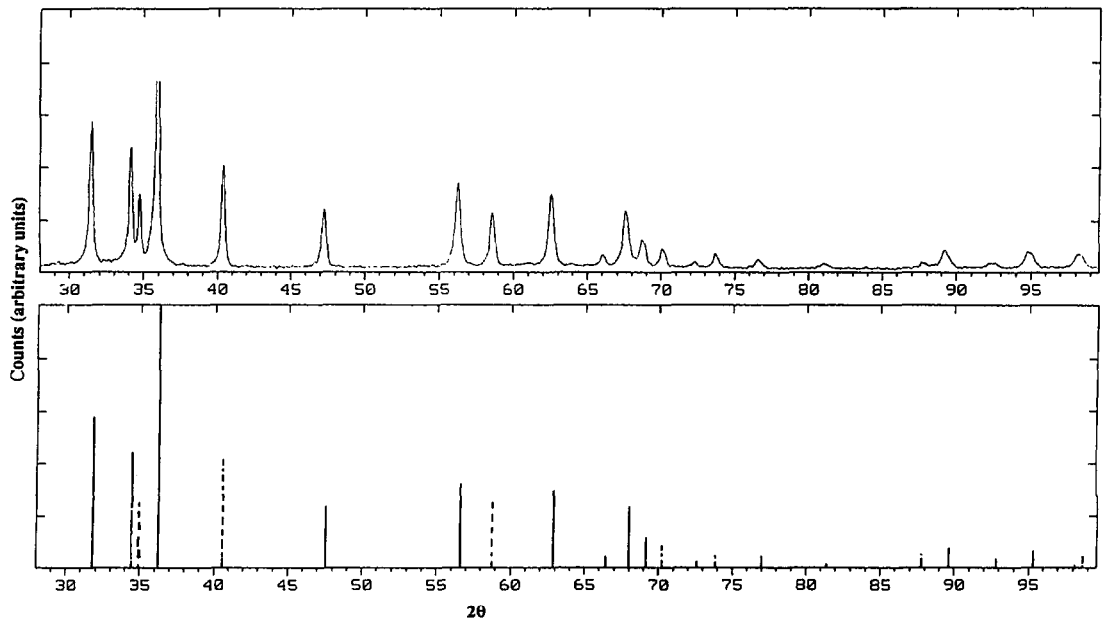

Fig. 5. Upper trace X-ray powder diffraction pattern for the solid produce from reaction of equimolar amounts of $ZnCl_2$ and MnI_2 with Li_2O; lower trace standard X-ray powder diffraction line pattern for ZnO (——) and MnO (– – – –).

difficult to form by this low external energy route, probably because of a lack of intimate mixing of the reagents. All the transition metal halides studied react with Li_2O to form metal oxide with little redox chemistry at the metal, however, for Ta and Nb the only phase produced is $LiMO_3$ and for V and Ti a small amount of $LiMO_x$ phases are also seen. The solid-state metathesis reaction of Li_2O and MX_n offers a convenient, rapid, low external energy route to industrially useful metal oxides such as TiO_2 and ZnO.

(*Received* 2 *February* 1993; *accepted* 19 *April* 1993)

Abstract—Two mixed ligand complexes of quinaldic acid and manganese(II) azide or thiocyanate, namely azido(N,O-quinaldato)triaquamanganese(II) monohydrate (**1**) and thiocyanato(N,O-quinaldato)(O-quinaldic acid)diaquamanganese(II) (**2**), have been prepared and characterized by single-crystal X-ray methods. The coordination environment of the manganese(II) atom in complex **1** is a distorted octahedron. Each metal atom is chelated by a quinaldate anion [via its nitrogen atom, Mn—N = 2.292(3) Å, and a carboxylate oxygen atom, Mn—O = 2.147(3) Å] and links three aqua molecules [Mn—O distances from 2.189(3) to 2.217(3) Å] and a terminal azido ligand [Mn—N = 2.181(3) Å]. The structure of complex **2** features distorted octahedral manganese(II) coordination geometry, chelated quinaldate anion [Mn—N = 2.271(7) Å and Mn—O = 2.158(5) Å], O-bonded neutral quinaldic acid molecule [Mn—O = 2.228(5) Å], two aqua molecules [Mn—O = 2.180(5) and 2.203(6) Å] and a terminal N-thiocyanato group at an Mn—N distance of 2.119(7) Å. The IR spectra of these two complexes are presented and discussed in relation to their structures.

Quinaldic acid (hereafter abbreviated as H-quin) has long been accepted as a chelating ligand for many di- and trivalent metal ions forming five-membered rings through the ligation of the quinaldate anion.[1–17] Quinaldic acid, however, was found to function as a neutral monodentate ligand in its gold(III) complex, $[(H_3O)(H\text{-quin})_2][AuBr_4]$, coordinating via its carbonyl oxygen with long Au—O bonds (av. = 3.414 Å).[18] Elman *et al.*[19,20] and Csöregh *et al.*[21] studied the effects of various substituents on the coordinating properties of pyridine- and quinoline-carboxylic acids and the stereochemistry of the resulting complexes.

It is well known that the azide group may function as a terminal monodentate or bridging bi-, tri- or tetradentate ligand with a variable manner of binding.[22,23] Recently we described the synthesis and X-ray structural characterization of a polymeric complex of manganese(II) azide with picolinic acid, otherwise called 2-pyridinecarboxylic acid, which crystallizes with an additional water molecule.[24] We now report our investigation of the corresponding complex of quinaldic acid (**1**), along with the manganese(II) thiocyanato complex of quinaldic acid (**2**). We anticipated that a comparative

* Author to whom correspondence should be addressed.

study of these mixed ligand complexes might yield interesting results. The present work constitutes part of our continuing study of metal pseudohalides containing substituted pyridine and quinoline ligands;[25,26] further impetus is derived from the recent surge of interest in the structural features of azide binding to biological metals.[27]

EXPERIMENTAL

Quinaldic acid was obtained from Aldrich. The other chemicals were of analytical grade quality.

Preparation of [Mn(quinaldato)$(N_3)(H_2O)_3]\cdot H_2O$

This complex was prepared by dissolving $MnCl_2\cdot 4H_2O$ (0.52 g, 5 mmol) in ethanol (10 cm^3). Quinaldic acid (1.73 g, 10 mmol) dissolved in warmed ethanol was then added dropwise. This mixture was filtered off. To the clear solution NaN_3 (0.65 g, 10 mmol) in distilled water (5 cm^3) was also added dropwise with stirring and the mixture became a yellow solution. Yellow crystals were obtained by slow evaporation in a desiccator charged with anhydrous $CaCl_2$, kept in the dark for several days. The same yellow crystals were obtained by the same procedure using an aqueous medium instead of ethanol. Found: C, 35.3; H, 4.2; N, 16.2; Mn, 16.3. Calc.: C, 35.2; H, 4.1; N, 16.4; Mn, 16.1%.

Preparation of [Mn(quinaldato)(quinaldic acid) $(NCS)(H_2O)_2$]

This complex was prepared by dissolving $MnCl_2\cdot 4H_2O$ (0.52 g, 5 mmol) in ethanol (10 cm^3). Upon addition of quinaldic acid (1.73 g, 10 mmol) dissolved in warmed ethanol (10 cm^3) the solution became turbid. Drops of distilled water were added until the solution became clear. To this solution KSCN (0.97 g, 10 mmol) in distilled water (3 cm^3) was added and the mixture became very faint yellow. Upon allowing this final solution mixture to stand in an open conical flask over several days red crystals were obtained. These crystals were filtered off and the filtrate allowed to stand over several days more to produce the title complex as yellow crystals or needles. Found: C, 51.2; H, 3.4; N, 8.3; Mn, 11.3. Calc.: C, 51.0; H, 3.5; N, 8.5; Mn, 11.1%.

X-ray crystallography

Lattice parameters of both compounds have been determined by least-squares refinement of X-ray powder patterns at 298(1) K (Philips APD 1700

The structures were solved by direct methods. Anisotropic displacement parameters were only applied to the non-hydrogen atoms in blocked-matrix least-squares refinements. Hydrogen atoms with bonds to carbon atoms were geometrically generated; the positions of the remaining hydrogen atoms were located from difference fourier maps and included in the final refinement cycles with isotropic displacement values. The programs DIFABS,[28] SHELX-76,[29] SHELXS-86,[30] PLATON[31] and THE XRAY SYSTEM[32] were used for computations. Analytical expressions of neutral-atom scattering factors were employed and anomalous dispersion corrections were incorporated.[33] Selected bond distances and bond angles are given in Table 2, hydrogen bonding systems are collected in Table 3. Positional parameters, anisotropic thermal parameters, a full list of bond lengths and angles and observed and calculated structure factors have been deposited with the Editor as supplementary material.

Physical measurements

The IR absorption spectral bands of free and coordinated ligands are collected in Table 4. The experimental procedures and instruments used for spectral and other measurements have been given previously.[34]

DISCUSSION

The reaction between manganese(II) ion and quinaldic acid in the presence of azide ions in aqueous or aqueous ethanolic medium afforded only the title complex (**1**), whereas the same reaction in the presence of thiocyanate anion afforded two complexes, a yellow complex (**2**) and red crystals of a complex that has not yet been investigated. Trials to prepare crystals suitable for X-ray structure determination of the red complex are in progress. Complexes **1** and **2** are insoluble in cold or hot water, ethanol and acetone, but soluble in boiled DMF and DMSO giving rise to non-conducting solutions in these solvents.

The principal structural features of [Mn(quin)$(N_3)(H_2O)_3]\cdot H_2O$ (**1**) are illustrated in Figs 1 and 2. The coordination environment of each manganese(II) atom is distorted octahedron. The quinaldate anion chelates a metal atom via its ring nitrogen atom [Mn–N(1) = 2.292(3) Å] and a carboxylate oxygen atom [Mn—O(1) = 2.147(3) Å] to form a five-membered ring. The chelate ring deviates only 0.075(5) Å from planarity. Each manganese atom is further bonded to three aqua molecules at Mn—O distances from 2.189(3) to 2.217(3) Å. The coordination number six of the manganese atom is completed through its binding to a terminal azido group at an Mn—N(11) bond length of

[a] Split band.

2.181(3) Å, which is shorter than Mn—N(quin) but comparable with the corresponding distances [2.161(23) Å] found in the complex [Mn(3-pic)$_2$(N$_3$)$_2$(H$_2$O)$_2$][35] (**3**) also containing terminal azido groups. The terminal azido ligand in the title complex is linear [angle N—N—N = 179.4(5)°] and slightly asymmetric [N(11)—N(12) = 1.167(4) and N(12)—N(13) = 1.157(4) Å]. The maximum deviation [0.088(5) Å] from planarity within the quinaldato ligand anion shows the non-coordinated oxygen atom O(2). The isolated manganese(II) polyhedra are linked via hydrogen bonds of the types O—H···N and O—H···O to form a two-dimensional layer structure extended along the *ab*-plane of the unit cell. In this hydrogen bond system the oxygen atoms O(3)–O(6) of the water molecules act as donor atoms forming hydrogen bonds to the N(13) atom of the azide group, to both oxygen atoms of the quinaldate ligand and also to O(6) of the lattice water molecule (Table 3).

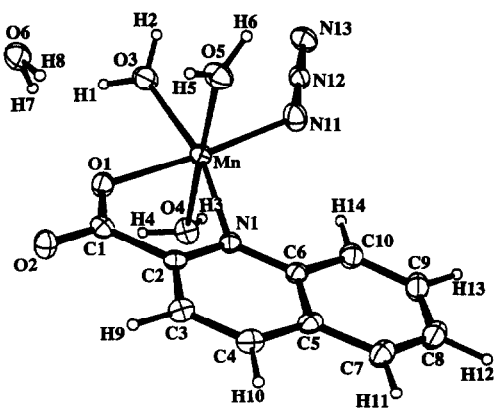

Fig. 1. Molecular structure and atom numbering scheme of Mn[(quin)(N$_3$)(H$_2$O)$_3$]H$_2$O (**1**).

The title complex (**1**) differs from the polymeric [Mn(picolinato)(N$_3$)(H$_2$O)] complex **4**, although both have octahedral manganese atoms. While the quinaldate anion acts as an N,O-bidentate ligand in complex **1**, the picolinato anion behaves as a tridentate ligand in complex **4**; it chelates a manganese atom via its nitrogen and carboxylate oxygen atom. This coordinated carboxylate oxygen atom further bridges another manganese atom giving rise to cyclic Mn$_2$O$_2$ units. These centrosymmetric dimeric units are connected by bridging μ(1,3) azido groups to form a two-dimensional layer structure along the *ab*-plane (Fig. 2, see ref. 24).

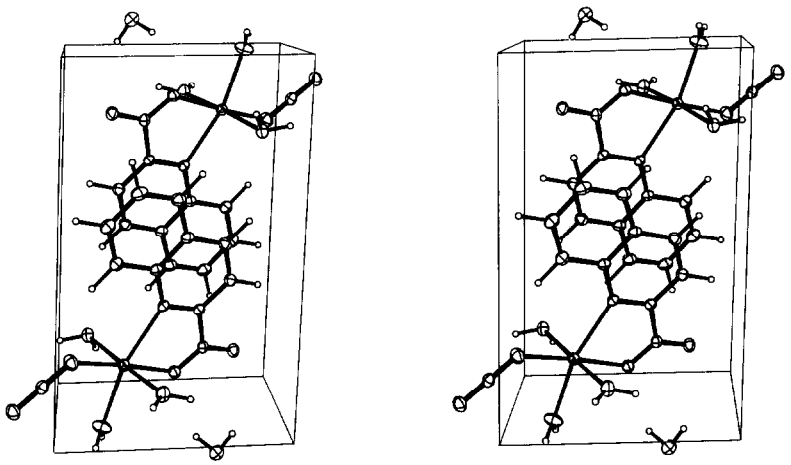

Fig. 2. Packing plot of $Mn[(quin)(N_3)(H_2O)_3]H_2O$ (**1**), viewed down the *b*-axis of the unit cell.

A plot with the atom numbering scheme of the $[Mn(quin)(H\text{-}quin)(NCS)(H_2O)_2]$ complex (**2**) is given in Fig. 3. The coordination geometry of the manganese(II) atom is also distorted octahedral. The quinaldate anion chelates a manganese atom, as in complex **1**, through its heterocyclic nitrogen atom [Mn—N(1) = 2.271(7) Å] and a carboxylate oxygen atom [Mn—O(1) = 2.158(5) Å]. These bond lengths are similar to the corresponding values in complex **1**. The manganese atom further links an O-monodentate neutral quinaldic acid molecule via its carboxylic oxygen at an Mn—O(4) distance of 2.228(5) Å, which is longer than the corresponding Mn—O distance with the quinaldate anion and two aqua molecules at Mn—O bond lengths of 2.180(5) and 2.203(6) Å, which are very close to those found in complex **1**. The octahedral geometry of the manganese atom is completed through its binding to a terminal N-thiocyanato group [Mn—N = 2.119(7) Å]. The thiocyanate group is linear [angle N—C—S = 178.7(7)°]. The manganese(II) atom is almost co-planar [0.039(4) Å] to the quinaldato anion molecule. The heteroatomic ring system of the quinaldate ligand is planar within experimental error, but its carboxylate group has a distortion of approximately 9(1)° from the ring plane. The maximum deviation from planar geometry within the neutral quinaldic acid molecule has the oxygen atom O(4) [0.09(1) Å]. Intermolecular hydrogen bonds of the type O—H···O between the water molecules and the oxygen atoms of the carboxylic groups of both heteroatomic ring ligands link manganese(II) polyhedra to form one-dimensional chains along the *a*-axis of the unit cell. In addition, possible intramolecular hydrogen bonds of the type N—H···O occur (Table 3).

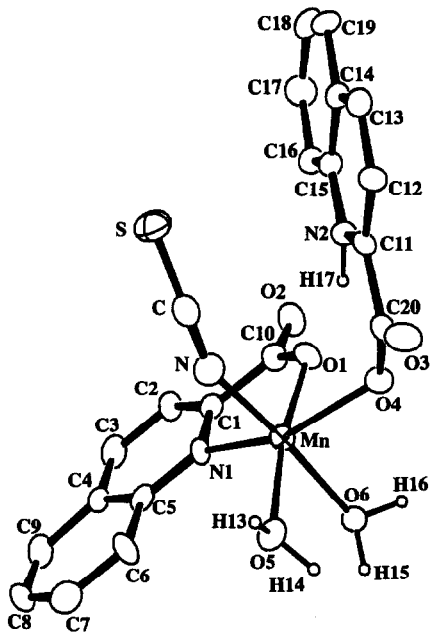

Fig. 3. Molecular structure and atom numbering scheme of $Mn(H\text{-}quin)(quin)(NCS)(H_2O)_2$ (**2**). H(1)–H(12) are omitted for clarity.

It is of interest to compare the mixed-ligand complexes **1**–**4** and $Mn(pyridine)_2(N_3)_2$ (**5**).[36] A common structural feature of this series is a six-coordination about the manganese atoms. In complexes **3** and **5** with monodentate picoline and pyridine, respectively, the azido groups function as $\mu(1,3)$ bridging in **5**, whereas in **3** the presence of two aqua molecules hinders the bridging mode of the azido ligands enforcing them to act as terminal groups. In complex **4** the picolinato anion acts as a chelating

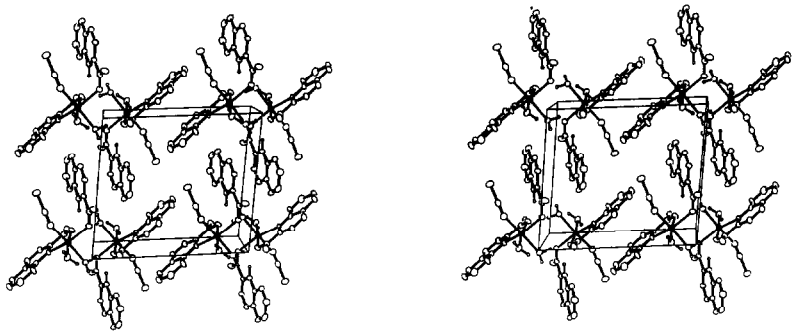

Fig. 4. Packing plot of Mn(H-quin)(quin)(NCS)(H$_2$O)$_2$ (**2**), viewed down the *a*-axis of the unit cell. H(1)–H(12) are omitted for clarity.

bridging tridentate ligand and the fourth coordination site is occupied by an aqua molecule, therefore, the other two sites are satisfied by bridging the azido ligand in the fashion $\mu(1,3)$ between two metal centres. In complexes **1** and **2** a quinaldate anion acts as a bidentate chelating ligand. The remaining four sites are occupied by three aqua molecules and a terminal azido group in complex **1**, whereas two aqua molecules and a terminal N-thiocyanato ligand occupies three sites in complex **2** which makes the neutral quinaldic acid molecule act as a monodentate ligand. It is noticeable that in all manganese(II) azido complexes known up until now the azido ligands act either as terminal or as $\mu(1,3)$ bridging ligands. Bridging azido ligands of the type $\mu(1,1)$ were observed only once before in the structure of [(CO)$_3$Mn(N$_3$)$_3$Mn(CO)$_3$].[37]

Previous studies have shown that no bands due to the C=O stretching vibration could be observed in the vicinity of 1700 cm^{-1} in the IR spectrum of free quinaldic acid as a result of hydrogen-bond formation between carboxylic hydrogen and the nitrogen atoms.[38] In accordance with this a weak-to-medium intensity band is observed at 1690 cm^{-1} in the IR spectrum of our sample. The hydrogen-bond formation is indicated by the appearance of the N—H stretching vibrations[39] around 3200–2400 and 1950–1900 cm^{-1}. Examination of Table 4 shows that a medium band at 1690 cm^{-1} due to ν(C=O) appears only in the spectrum of complex **1**. In the IR spectra of both complexes, however, a very strong band is observed around 1620 cm^{-1} due to the COO$^-$ stretching vibration. The C—O stretching vibration which appears at 1320 cm^{-1} in the IR spectrum of free acid is shifted to higher frequencies and appears at 1365 cm^{-1} in complex **1**. The appearance of two very strong bands at 1370 and 1350 cm^{-1} associated with ν_s(C—O) in the spectrum of complex **2** indicates the existence of a coordinated quinaldate anion as well as a neutral quinaldic acid molecule. The vibration frequencies related to the quinoline ring are shifted to higher frequencies in the spectrum of complex **1** as compared with the corresponding frequencies in the spectrum of free quinaldic acid. These results suggest that the quinaldate anion acts as an N,O-bidentate ligand in complex **1**. The IR spectrum of complex **2**, on the other hand, shows quinoline ring vibrations at higher frequencies as well as vibrations at more or less the same frequencies for free H-quin. This result suggests that complex **2** contains N,O-bidentate as well as O-monodentate ligand molecules. Free and coordinated water molecules as well as hydrogen-bonded carboxylic groups are indicated by the appearance of strong and broad bands in the range 3500–2500 cm^{-1}.[40] The above results are consistent with the X-ray structures given above for both complexes (Figs 2 and 4).

The ν_{as}(N$_3$) mode which appears as a very strong and sharp band at 2060 cm^{-1} in the spectrum of the manganese(II) azide complex is consistent with a structure containing only terminal azide ligands. The medium band at 1335 cm^{-1} associated with the ν_s(N$_3$) mode supports the asymmetric nature of the azide group.[41] In the IR spectrum of complex **2** ν(CN) which appears as a very intense band at 2040 cm^{-1} is consistent with the terminal N-bonded thiocyanato group.[42] This conclusion is supported by the appearance of δ(NCS) at 480 cm^{-1}.

In the far-IR region we tentatively assigned to the metal–ligand vibrations the following frequencies;[42] bands around 370 cm^{-1} to ν[Mn—O(H$_2$O)], those around 350 cm^{-1} due to ν[Mn—N(N$_3$ or NCS)], bands around 270–250 cm^{-1} to ν[Mn—O(quin)] and 240–220 cm^{-1} to ν[Mn—N(quin)].

(*Received* 22 *February* 1993; *accepted* 2 *April* 1993)

Abstract—Complexes of the types $M(H\text{-}Quin)_2 \cdot 2H_2O$ (M = Mn, Co, Ni and Zn) and $M(H_2\text{-}Quin)(Quin) \cdot 2H_2O$ (M = Fe and Co), where H_2-Quin = quinolinic acid, have been prepared and characterized. The spectral results suggest that all these complexes contain distorted octahedral metal atoms. The crystal structures of the nickel(II) and manganese(II) complexes were determined by single-crystal X-ray diffraction methods. The nickel atom in centrosymmetric $Ni(H\text{-}Quin)_2 \cdot 2H_2O$ is octahedrally coordinated by two nitrogen atoms [Ni—N = 2.030(2) Å] and two oxygen atoms [Ni—O = 2.027(2) Å] belonging to the two $H\text{-}Quin^-$ anions and two *trans*-aqua molecules at Ni—O distances of 2.117(2) Å. The structure is consolidated by intra- and intermolecular O—H···O hydrogen bonds. X-ray analysis of the $Mn(H\text{-}Quin)_2 \cdot 2H_2O$ complex revealed that it should be formulated as $[Mn(H_2O)_6][Mn(H\text{-}Quin)_3]_2$. The octahedral $[Mn(H\text{-}Quin)_3]^-$ and $[Mn(H_2O)_6]^{2+}$ units lie on different three-fold axes and are connected together by O—H···O hydrogen bonds between the aqua ligands and the non-coordinated oxygen of a carboxylato group or oxygen atoms of the carboxy group in position 3 in the pyridine ring.

The reaction of some metal(II) salts with quinolinic acid, otherwise called pyridine-2,3-dicarboxylic acid, have been reported to produce complexes of the type $M(quinolinato) \cdot nH_2O$, where M = Mn, Fe, Co, Ni, Cu and Zn and n = 0–2, and the thermal properties of these solid complexes were studied.[1] Other metal(II) complexes of this ligand, either anhydrous or hydrated, have also been mentioned in the literature,[2–7] but definitive crystallographic data are lacking for these materials. X-ray structure determination has been performed only for the dihydrated silver(II) complex of quinolinic acid.[7] Recently we have been interested in the study of metal complexes of pyridine dicarboxylic acids[8] and described the structure of $[AuBr_4][K(dinicotinic\ acid)_6]$.[9] In this paper we report the synthesis and characterization of Mn^{II}, Fe^{II}, Co^{II}, Ni^{II} and Zn^{II} complexes of quinolinic acid (hereafter abbreviated as H_2-Quin) and X-ray structures of the nickel and manganese complexes.

EXPERIMENTAL

Quinolinic acid was obtained from Aldrich and the other chemicals were of analytical grade.

Preparation of the complexes

Complexes of the type $M(H\text{-}Quin)_2 \cdot 2H_2O$ were generally prepared by mixing metal(II) nitrate or

sulphate (5 mmol) and the ligand (12 mmol) in water (30 cm^3) and boiling the mixture for several minutes until a clear solution was obtained. The mixture was then allowed to stand over several days until a crystalline product of the complex separated. In the case of the manganese complex $MnCl_2 \cdot 3H_2O$ was used and the final mixture allowed to stand in the dark.

Complexes of the type $M(H_2\text{-}Quin)(Quin) \cdot 2H_2O$ (M = Fe or Co) were prepared in the same manner except that ethanol was used as a solvent instead of water. The products were filtered off, washed with hot water or ethanol and dried *in vacuo*.

Elemental analyses of the complexes isolated are given in Table 1.

Physical measurements

Magnetic susceptibility measurements were performed on the modified Faraday balance SUS 10 (A. Paar KG, Graz, Austria). The accuracy and reproducibility of the data is about 2%. Corrections were made using Pascal's constants. IR and electronic spectra and other measurements were performed as described previously.[10]

Table 2 contains the magnetic moments as well as spectral data of the isolated complexes.

X-ray structure analysis

The nickel(II) and manganese(II) complexes are handled in the same manner. Diffraction measurements were made on a Nicolet R3m/V four-circle diffractometer (graphite-monochromatized Mo-K_α radiation, $\lambda = 0.71069$ Å) and determination of the crystal class, orientation matrix and accurate unit cell parameters were performed according to established procedures.[11] Intensities were recorded at 18°C and data collection and processing parameters are summarized in Table 3. The raw inten-

sities were processed with a learnt-profile procedure[12] and absorption corrections were applied using a pseudo-ellipsoidal fit to azimuthal scans of selected strong reflections.[13,14]

The structure was solved by Patterson superposition and Fourier methods. All non-hydrogen atoms in the asymmetric unit were subjected to anisotropic refinement. The aromatic hydrogen atoms were generated geometrically (C—H fixed at 0.96 Å), allowed to ride on their respective parent carbon atoms and included in structure factor calculations with assigned isotropic thermal parameters. The carboxyl and aqua hydrogen atoms were located from difference maps. All computations were performed using a DEC MicroVAX-II computer with the SHELXTL-PLUS system.[15,16] Analytical expressions of neutral atom scattering factors incorporating the real and imaginary components of anomalous dispersion were employed.[17] Least-squares refinement converged to the R indices and other parameters listed in Table 3. Selected bond distances and bond angles are given in Table 4. Anisotropic thermal parameters and structure factors are available from the last author upon request and have also been deposited with the Editor and the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

The reactions between Mn^{II}, Co^{II}, Ni^{II} and Zn^{II} salts and H_2-Quin in aqueous solution afforded complexes of the type $M(H\text{-}Quin)_2\cdot 2H_2O$. On the other hand, reactions in ethanolic media led to the

Symmetry transformation: a $(-y, x-y, z)$, b $(y-x, -x, z)$.

isolation of $M(H_2\text{-Quin})(Quin)\cdot 2H_2O$ only in the case of M = Fe and Co. Complexes of the first type are insoluble in cold water, alcohol, acetone and chloroform, but slightly soluble in hot water and DMF and reprecipitated upon cooling. Those of the other type are soluble in water and ethanol.

IR spectral data (Table 2) of the solid complex differentiate between the two types of compounds. Complexes of the type $M(H\text{-Quin})_2\cdot 2H_2O$ (M = Mn, Co, Ni and Zn) exhibit spectra which are consistent with $H\text{-Quin}^-$ coordination. In this case ν(C=O) of the carboxyl group in position 3 appears as a medium to strong band just below 1700 cm^{-1} and $\nu_{as}(COO^-)$ of the α-carboxylate group as a shoulder or medium band around 1635 cm^{-1}. On the other hand, ν_s(COO) which appeared at 1305 cm^{-1} in the free acid is shifted to higher frequencies in the spectra of these complexes and appears around 1360–1380 cm^{-1}. Complexes of the other type exhibit at least two IR bands above 1700 cm^{-1}, similar to those observed for coordinated neutral dipicolinic acid,[18] in addition to a band around 1630 cm^{-1}. In the region 1300–1280 cm^{-1} where ν_s(COO) appears, several bands corresponding to H_2-Quin and $Quin^{2-}$ are observed. Crystal structure determination has shown that bis(pyridine-2,6-dicarboxylate)silver(II) monohydrate contains two different ligand molecules, namely anionic dipicolinate and neutral dipicolinic acid.[19] Both ligands, however, have the same tridentate coordination modes. One may assume a similar composition for the pyridine-2,3-dicarboxylic acid molecules in complexes of the type $M(H_2\text{-Quin})(Quin)\cdot 2H_2O$. The typical upward shift of the major pyridine ring bands is indicative of coordination of the ring nitrogen in all complexes of both types. A strong broad band centred at *ca* 3450 cm^{-1} appears in the spectra of all complexes due to the presence of aqua molecules.[20,21] The extremely broad band in the 3100–2400 cm^{-1} range due to hydrogen bonded COOH groups in H_2-Quin or $H\text{-Quin}^-$ appears in the spectra of the above complexes.

The electronic spectra of the complexes are summarized in Table 2. Spectra of nickel(II) and cobalt (II) complexes are typical of six-coordinate species, most of the absorption bands having clearly defined shoulders that suggest distortions from octahedral symmetry. The iron(II) complex shows the broad spin-allowed $^5T_{2g}$–$^5F_{2g}$ transition band in O_h symmetry,[22] which is similar to other iron(II) complexes.[23]

Room-temperature magnetic data (Table 2) are consistent with high-spin six-coordinate $M(H\text{-Quin})_2\cdot 2H_2O$ and $M(H_2\text{-Quin})(Quin)\cdot 2H_2O$ com-

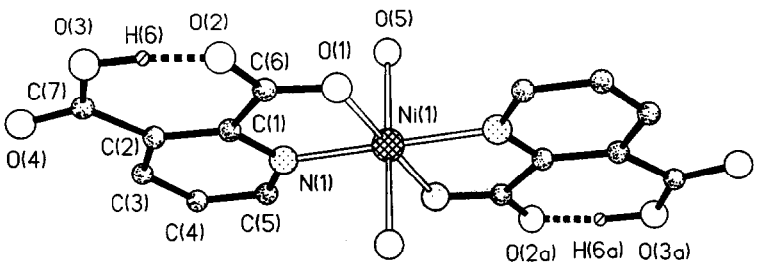

Fig. 1. The coordination environment of the nickel(II) atom in the complex $Ni(H\text{-Quin})_2\cdot 2H_2O$ (1), along with the atom numbering scheme.

plexes. The observed magnetic moments are similar to those of $M(H\text{-dipic})_2 \cdot 3H_2O$, $M(dipic) \cdot nH_2O$ and $M_2(dipic)(H\text{-dipic})_2 \cdot nH_2O$.[24,25] The magnetic susceptibility of the $Ni(H\text{-Quin})_2 \cdot 2H_2O$ complex was measured over the range 78–296 K. The χ_M data obey very well the Curie–Weiss law and $1/\chi_M$ vs T gives a straight line. The small θ value (-1.1 K) is indicative of the absence of magnetic interaction between nickel centres. These results are consistent with the results of crystal structure determination of the nickel(II) complex.

Figure 1 illustrates the structural features of the centrosymmetric $Ni(H\text{-Quin})_2 \cdot 2H_2O$ complex **1**. The (2 + 2 + 2) coordination about the nickel atom can be described as an elongated octahedron with aqua ligands occupying the axial positions. The Ni—N bond length of 2.030(2) Å is a little longer, whereas Ni—O(L) distances of 2.027(2) Å a little shorter than the corresponding distances reported for $Ni(H\text{-dipic})_2 \cdot 2H_2O$ [1.974(14) Å for Ni—N and 2.105(15)–2.207(6) Å for Ni—O].[26,27] Structurally the present complex is very similar to *trans*-diaquabis(pyridine-2-carboxylato)nickel(II) tetrahydrate, which has a comparable axial Ni—O(aqua) bond of 2.100(11) Å and longer equatorial Ni—L bonds [Ni—O = 2.053(7), Ni—N = 2.068(10) Å].[28]

The structure of complex **1** differs from that of $Ag(H\text{-Quin})_2 \cdot 2H_2O$ (**3**).[7] The latter complex consists of $Ag(H\text{-Quin})_2$, where each ligand molecule is strongly bonded to the silver(II) atom through the nitrogen atom and an oxygen atom of the carboxy group in the 2-position. The ketonic oxygen atoms of the twisted 3-carboxy groups form weak interactions [2.98 Å] with the silver atom in adjacent molecules, giving rise to a tetragonally distorted octahedron. The lattice water molecules are in positions to form hydrogen bonds with the oxygen atoms of the carboxy groups in the 2- and 3-positions.

A perspective view of the crystal structure of **1** along the *b*-axis is shown in Fig. 2. There are two kinds of hydrogen bonding interactions: an intramolecular O(3)—H···O(2) hydrogen bond similar to that in the crystal structure of free quinolinic acid [O···O = 2.398(3) Å][29] and an intermolecular O(5)—H···O(4) hydrogen bond linking the aqua ligand of one complex with the carboxy group of an adjacent complex. The structure is consolidated by intermolecular hydrogen bonds that are arranged in spirals along the two axes in the unit cell.

The X-ray structural analysis revealed that the complex $Mn(H\text{-Quin})_2 \cdot 2H_2O$ (**2**) should be reformulated as $[Mn(H_2O)_6][Mn(H\text{-Quin})_3]_2$, as seen from Fig. 3 which illustrates the essential structure components. The structure consists of a packing of octahedral $[Mn(H\text{-Quin})_3]^-$ and $[Mn(H_2O)_6]^{2+}$ ions that lie on different three-fold axes in the unit cell. The two independent anionic units exhibit different Mn—N bond lengths [2.286(3) and 2.257(4) Å], but nearly equal Mn—O bond lengths [2.142(3) and 2.131(3) Å]. The Mn—O distances in the hexaaqua cation [2.168(3) and 2.173(4) Å] are longer than the Mn—O(Quin) distances in the anions. The non-coordinated oxygen of the carboxy group in position 2 in the pyridine ring forms two hydrogen bonds of the type O···H—O, the first with the OH group of the non-coordinated carboxy

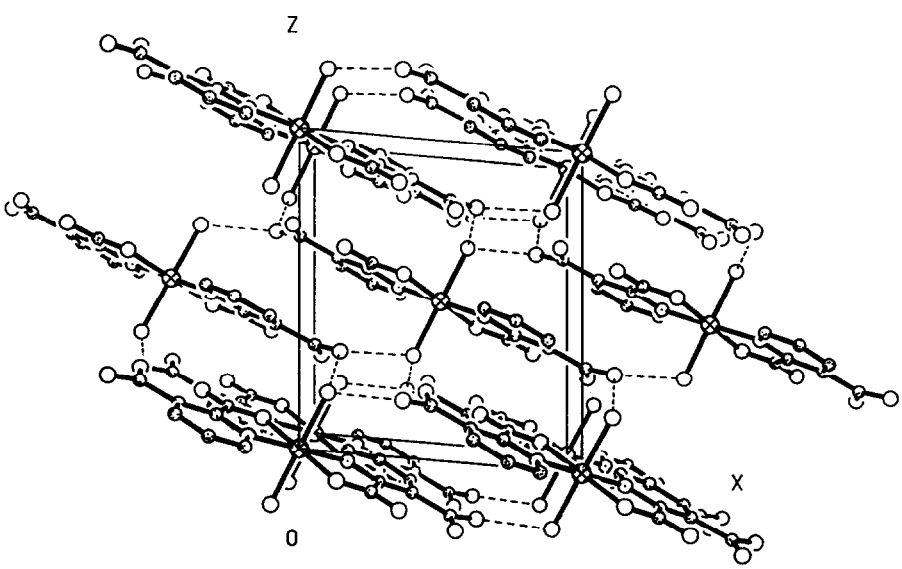

Fig. 2. Perspective view of the crystal structure of complex **1** along the *b*-axis.

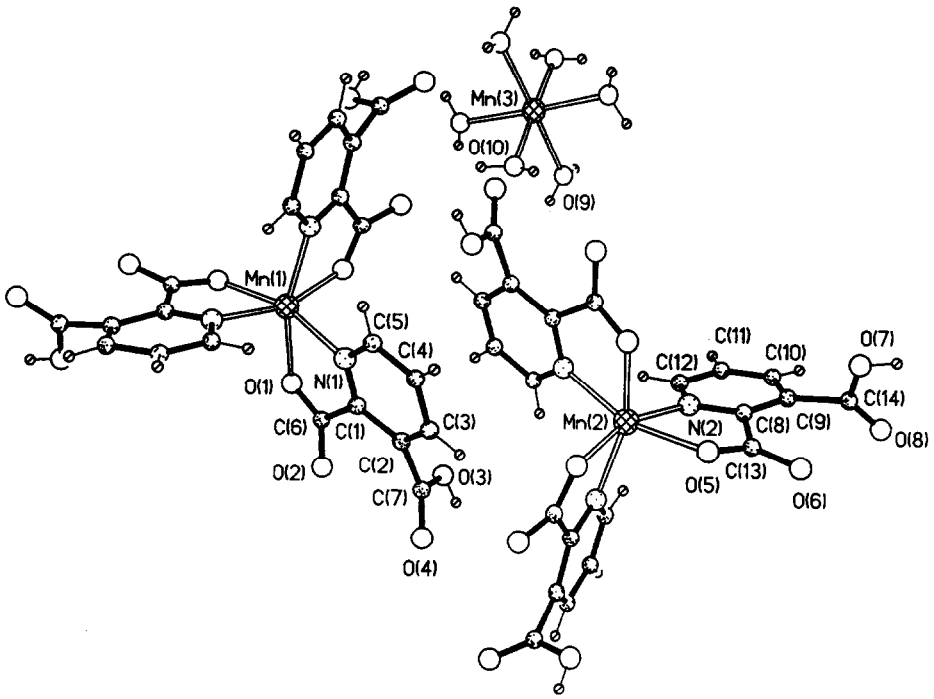

Fig. 3. The coordination environments of the manganese(II) atoms in the cation and anions in the complex $2[Mn(H\text{-}Quin)_3]\cdot[Mn(H_2O)_6]$ (**2**), along with the atom numbering scheme.

group (position 3) of another anionic unit and the second with an aqua molecule from the cationic unit. A third hydrogen bond of the same type exists between the cationic oxygen of the non-coordinated carboxy group from an anionic unit and the oxygen atom of a water molecule of the cation. These hydrogen bonds, therefore, connect the anions and the cation together into a three-dimensional network structure (Fig. 4).

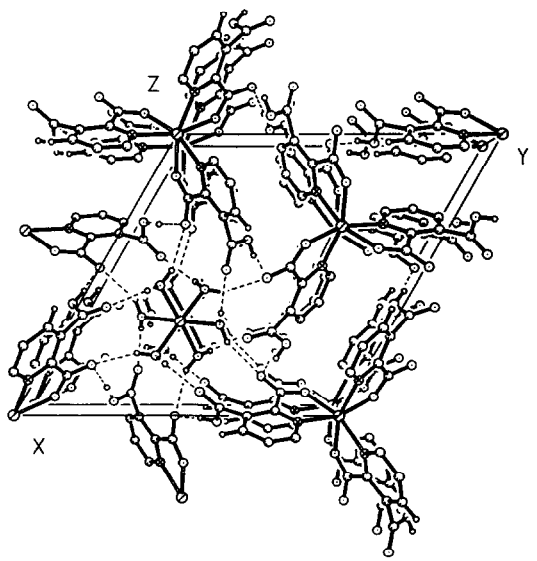

Fig. 4. Packing in the unit cell of complex **2** viewed down the *c*-axis.

The structure of the anionic unit $[Mn(H\text{-}Quin)_3]^-$ in complex **2** may be compared with that of Mn(picolinato)$_3\cdot H_2O$,[30] in which the picolinato anions function as N,O-bidentate ligands and are arranged in a very similar way in both compounds. The Mn^{III}—N distances in the picolinate complex vary from 2.059(5) to 2.254(5) Å, which are shorter than the Mn^{II}—N bond lengths found for the quinolinato anions (Table 4). The Mn^{II}—N distances, however, are very close to that observed [2.278(3) Å] in Mn(picolinato)$(N_3)(H_2O)$.[31] The above Mn—N distances are all longer than the Mn^{IV}—N bond lengths of 2.006(4) Å found in the Mn_2O_2(picolinato)$_4\cdot$MeCN complex.[32] This comparison demonstrates a progressive decrease in the Mn—N bond length as the oxidation state of the manganese atom increases.

(*Received* 22 *February* 1993; *accepted* 30 *March* 1993)

Abstract—Complexes of the types $MAuX_4\cdot 4(pic\text{-}H)\cdot 2H_2O$ (M = Na for X = Cl and M = K for X = Br), $NaAu(pic)_2X_2\cdot 2H_2O$ (where X = Cl or I) and $NaAuCl_4\cdot Na(pic\text{-}H)\cdot(pic)\cdot 2H_2O$ (where pic-H = picolinic acid) have been prepared and characterized. Picolinic acid functions as a neutral N,O-bidentate ligand in the first type and as an O-monodentate picolinate anion in the second type. The IR results suggest that the last complex contains both neutral and anionic organic moieties. The conductivities of these complexes were measured and are discussed. X-ray single-crystal analysis of the $KAuBr_4\cdot 4(pic\text{-}H)\cdot 2H_2O$ complex revealed that it should be formulated as $[K(pic\text{-}H)_2(H_2O)_2]\cdot[AuBr_4]\cdot(pic\text{-}H)_2$. The potassium atom in the centrosymmetric cation is octahedrally coordinated by two *trans*-N,O-bidentate neutral picolinic acid molecules [K—N = 2.790(6) Å and K—O = 2.888(5) Å] and two aqua ligands at K—O distances of 2.769(4) Å. The other two picolinic acid molecules are involved in hydrogen bonding with the oxygen atoms of the coordinated pic-H and aqua molecules.

The broad spectrum of physiological effects of picolinic acid, also known as 2-pyridinecarboxylic acid, and its derivatives on activity functions of both animal and plant organisms has been attributed to their ability to form complexes with transition metals.[1] In this regard many complexes of picolinic acid together with their crystal structures have been reported.[2–10]

Alkali metal complexes, on the other hand, play vital roles in biological systems, many of which are not fully understood as yet. Speakman[11] has reviewed the structures of "acid salts" formed by alkali metals and carboxylic acids, such as MHX_2, where M = K, Rb, NH_4 and HX = salicylic acid, and drawn attention to the very short hydrogen bonds which generally occur in these compounds. Although some of the "acid salts" of potassium formed by inorganic[12] or organic acids[13,14] have been structurally characterized, to our knowledge potassium compounds containing both organic acids and inorganic anions have been reported only once in hexa(3,5-dicarboxypyridine)potassium tetrabromoaurate(III).[15] In the present study, we prepared some gold(III) halide complexes of picolinic acid (hereafter abreviated as pic-H) and determined the crystal structure of $KAuBr_4\cdot 4(pic\text{-}H)\cdot 2H_2O$ by X-ray diffraction.

EXPERIMENTAL

Picolinic acid was obtained from Aldrich and the other chemicals were of analytical grade quality.

† Authors to whom correspondence should be addressed.

Preparation of the complexes

(1) $NaAu(pic)_2Cl_2 \cdot 2H_2O$. A mixture of sodium tetrachloroaurate(III) dihydrate (0.40 g, 1 mmol) and picolinic acid (0.248 g, 2 mmol) in acetone (30 cm^3) was boiled for *ca* 10 min. The mixture was allowed to stand overnight to produce the complex.

(2) $NaAu(pic)_2I_2 \cdot 2H_2O$. A mixture of sodium tetrachloroaurate(III) dihydrate (0.42 g, *ca* 1 mmol) and picolinic acid (0.27 g, 2.2 mmol) in ethanol (*ca* 40 cm^3) was boiled and reduced to half its original volume. After cooling NaI (0.9 g, 6 mmol) dissolved in the least amount of distilled water was added and the final mixture allowed to stand for *ca* 2 weeks.

(3) $NaAuCl_4 \cdot 4(pic\text{-}H) \cdot 2H_2O$. $NaAuCl_4 \cdot 2H_2O$ (4.3 g, *ca* 1 mmol) in ethanol (10 cm^3) and picolinic acid (0.62 g, 5 mmol) in warmed ethanol (20 cm^3) were mixed together and the mixture reduced to *ca* half of its original volume by boiling, and allowed to stand in an open beaker for several days.

(4) $KAuBr_4 \cdot 4(pic\text{-}H) \cdot 2H_2O$. This complex was prepared by mixing $NaAuCl_4 \cdot 2H_2O$ (0.41 g, 1 mmol) and picolinic acid (0.55 g, 4.5 mmol) in ethanol (30 cm^3). The mixture was boiled for *ca* 15 min and after cooling an aqueous solution of KBr (0.72 g, 6 mmol) was added. The final mixture was allowed to stand for *ca* 2 weeks to produce the complex. Alternatively, $NaAuCl_4 \cdot 2H_2O$, picolinic acid and KBr were mixed together in the above molar ratio, using acetone instead of ethanol. The mixture was boiled for *ca* 10 min and then allowed to stand over several days, after which the brown colour of the solution disappeared. Several days later the complex was separated as dark brown crystals.

(5) $NaAuCl_4 \cdot Na(pic\text{-}H)(pic) \cdot 2H_2O$. This complex was prepared according to procedure (3), except that water was used as a medium instead of ethanol.

Elemental analysis results of the isolated complexes together with some of their physical properties are given in Table 1.

Physical measurements

The IR absorption bands of free and coordinated ligands and the gold–halogen stretching vibrations are given in Table 2. Conductivity measurements were performed using 10^{-3} mol of each complex in acetone solution. The experimental procedures and instruments used for various physical measurements are as described previously.[16,17]

X-ray structure analysis of $[AuBr_4][K(pic\text{-}H)_2(H_2O)_2] \cdot (pic\text{-}H)_2$

Details of the crystal parameters, data collection and structure determination are given in Table 3. The raw intensities collected on a Nicolet R3m/V four-circle diffractometer at room temperature (294 K) were processed with the profile-fitting procedure of Diamond[18] and corrected for absorption using ψ-scan data.[19] The gold and bromine atoms were located by the Patterson method and the coordinates of the other non-hydrogen atoms were determined from successive difference-Fourier syntheses. All non-hydrogen atoms were subjected to anisotropic refinement and the hydrogen atoms of the pyridyl groups were generated geometrically (C—H bonds fixed at 0.96 Å) and assigned the same isotropic temperature factor of $U = 0.08$ Å^2. Computations were performed using the SHELTXL-PLUS program package[20] on a DEC MicroVAX-II computer. Analytic expressions of atomic scattering factors were employed and anomalous dispersion corrections were incorporated.[21] The residual maxima in the last difference map all lie

in the neighborhood of the $[AuBr_4]^-$ anion. Selected bond lengths and angles are given in Table 4. Anisotropic thermal parameters and structure factors are available from the last author and along with atomic coordinates have been deposited with the Editor and the Cambridge Crystallographic Data Centre.

DISCUSSION

The reaction between picolinic acid and gold(III) halides in different media afforded complexes of the types $MAuX_4 \cdot 4(pic\text{-}H) \cdot 2H_2O$, NaAu $(pic)_2X_2 \cdot 2H_2O$ and $NaAuCl_4 \cdot Na(pic)(pic\text{-}H) \cdot 2H_2O$. These complexes differ from nicotinic acid and isonicotinic acid complexes formulated as AuL_nX_3, where $n = 1$, 2 or 3,[16,17] as well as from those of quinaldic acid for the formula $[(H_3O)(quin\text{-}H)_2][AuBr_4]$.[22]

Pertinent IR data for the products of interaction of pic-H with gold(III) halides are given in Table 2. Complexes of the type $MAuBr_4 \cdot 4(pic\text{-}H) \cdot 2H_2O$ exhibit the ν(C=O) band around 1745 cm^{-1} and no absorption due to ν(COO), whereas those of the type $NaAu(pic)_2X_2 \cdot 2H_2O$ show only very strong bands around 1645 cm^{-1} [ν(COO)]. The result for these latter complexes is indicative of O-picolinate anions, since the vibrations of the pyridine ring are not influenced by coordination. However, the IR spectrum of 3,5-pyridinedicarboxylic acid coordinated to potassium atom *via* its carbonyl oxygen exhibits a shift of ν(C=O) to higher frequencies.[15,23] Accordingly picolinic acid in its complexes of the former type is coordinated via its carbonyl oxygen to an alkali metal atom. The strong shoulder at 1710 cm^{-1} indicates the existence of picolinic acid molecules that are similar to free pic-H. This conclusion is supported by the appearance of pyridine ring vibrations at higher frequencies, in addition to bands at more or less the same frequencies as in free pic-H. These results suggest that $MAuX_4 \cdot 4(pic\text{-}H) \cdot 2H_2O$ complexes possess N,O-bidentate pic-H molecules as well as uncoordinated pic-H, as found in $[Mg(H_2O)_6]$ (nicotinate)$_2 \cdot (H_2O)_4$.[24] The existence of hydrogen bonds of the types O—H···O and N···H—O between aqua molecules and/or carboxylic groups and nitrogen atoms of the pyridine moiety are indicated by broad bands in the region 3500–2000 cm^{-1} (Table 2).[25–27] The spectra of $MAuX_4 \cdot 4(pic\text{-}H) \cdot 2H_2O$ exhibit ν(Au—X) bands at 360, 345 and 265 cm^{-1} for X = Cl and Br, respectively, which are very similar to those found for other complexes containing $[AuX_4]^-$ anions.[23,28,29] Complexes of this type may, therefore, be formulated as $[M(pic\text{-}H)_2(H_2O)_2][AuX_4] \cdot (pic\text{-}H)_2$. This formulation is consistent with the molar conductivities of these complexes in acetone (Table 1), which are indicative of 1 : 1 electrolytes.[30] In the case of the NaAu $(pic)_2Cl_2 \cdot 2H_2O$ complex no bands are attributable to ν(Au—Cl), so that ionic or bridging halogen atoms may be present. As these complexes behave as 1 : 1 electrolytes in acetone (Table 1) one

may suggest the $Na[Au(pic)_2X_2] \cdot 2H_2O$ formulation, in which the gold atom is in a square planar arrangement of four bridging halogen atoms and further ligated at long Au—O distances by a pair of *trans*-O-monodentate picolinate groups. Six-coordinate gold atoms are found in the structure of $[(H_3O)(quin\text{-}H)_2][AuBr_4]$.[22] The IR data of the $NaAuCl_4 \cdot Na(pic)(pic\text{-}H) \cdot 2H_2O$ complex (Table 2) suggest that it contains O,N-bidentate pic^- and uncoordinated pic-H and may, therefore, be formulated as $Na[AuCl_4] \cdot [Na(pic)(H_2O)_2] \cdot (pic\text{-}H)$. This formula is consistent with the conductivity measurement (Table 1) and the far-IR results, which exhibit ν(Au—Cl) bands at 378 and 333 cm^{-1}. The IR spectral results given above for $MAuX_4 \cdot 4(pic\text{-}H) \cdot 2H_2O$ are confirmed by the X-ray structure analysis of the bromide complex.

The X-ray structure analysis of $KAuBr_4 \cdot 4(pic\text{-}H) \cdot 2H_2O$ revealed that it should be formulated as $[K(pic\text{-}H)_2(H_2O)_2][AuBr_4] \cdot (pic\text{-}H)_2$. Figure 1 illustrates the principal structural features of the complex, which consists of $AuBr_4^-$ anions, $[K(pic\text{-}H)_2(H_2O)_2]^+$ cations and pic-H molecules. The potassium atom is located at an inversion centre and six-coordinated by pairs of *trans*-N,O-bidentate chelating picolinic acid molecules [K—N = 2.790(6) and K—O = 2.888(5) Å] and aqua ligands at K—O distances of 2.769(4) Å. The remaining independent picolinic acid molecules form acceptor hydrogen bonds with the coor-

Symmetry transformations: a $(-x, -y, 1-z)$; b $(1-x, -y, 1-z)$; c $(-1+x, -1+y, z)$.

dinated oxygen atom O(1) of the picolinic acid ligand and an oxygen atom of an aqua molecule (Fig. 1). A similar situation exists in the structure of $[Mg(H_2O)_6]\cdot(\text{nicotinate})_2(H_2O)_2$, in which the nicotinate molecules are hydrogen-bonded to the water molecules and not coordinated directly to magnesium.[24] Other hydrogen bonds of the types O(3c)—H···O(1W) and O(1W)—H···N(2b) between the aqua ligand and the uncoordinated picolinic acid link the latter with the cations to form a thick layer concentrated about the plane $z = 1/2$ (Fig. 2). The C=O and C—OH bonds of the carboxy group in either the coordinated or uncoordinated picolinic acid molecule are clearly distinguishable, so that the donor and acceptor atoms in all hydrogen bonds can be assigned, although the carboxy and aqua hydrogen atoms could not be located from the final difference map.

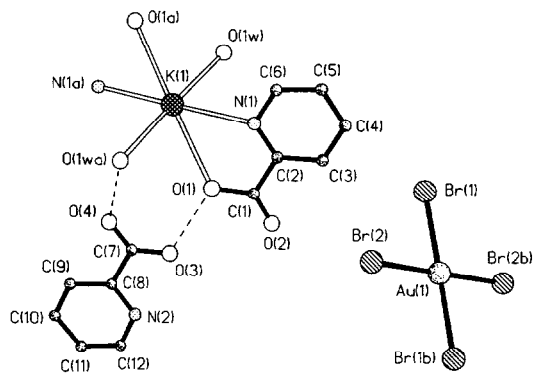

Fig. 1. The coordination environments of the potassium and gold(III) atoms in the complex $[K(\text{pic-H})_2(H_2O)_2][AuBr_4]\cdot(\text{pic-H})_2$ along with the atom numbering scheme.

The mode of bonding of picolinic acid in the present complex is similar to that found in the structure of Mn(pic-H)(pic)Cl.[31] The K—O distances are much longer than those [2.56(1) Å] in $[K(3,5\text{-dicarboxypyridine})_6][AuBr_4]$,[15] but agree very well with those (2.71–2.86 Å) in other KO_6 octahedra.[13] Likewise, the K—N distances of 2.790(6) Å are close to those in other KN_6 coordination

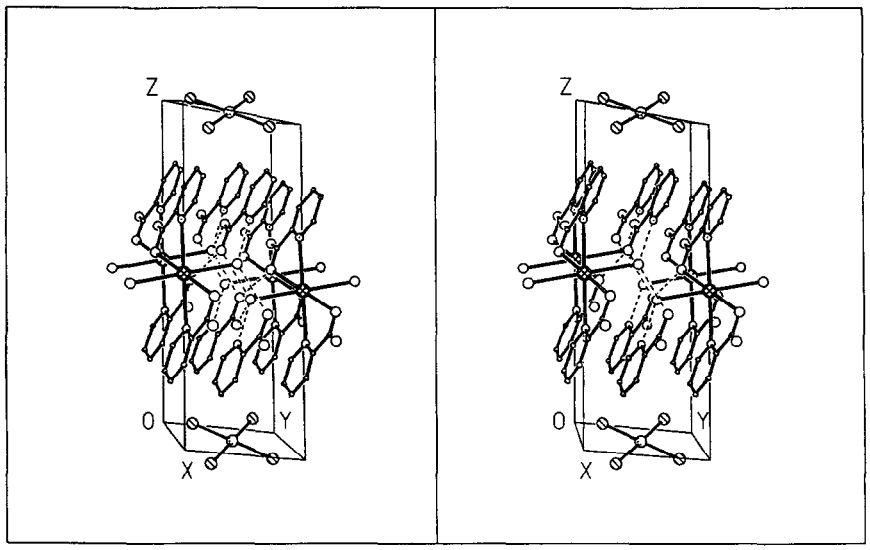

Fig. 2. A stereoview of the crystal structure. Hydrogen bonds are represented by broken lines.

octahedra,[14,32,33] but longer than those (2.556–2.603 Å) found in the structure of $KCr(pyridine)_4(N_3)_4$.[34]

(*Received* 14 *January* 1993; *accepted* 7 *April* 1993)

Abstract—A nickel(II) complex of acetylpyrazine ^{4}N-dimethylthiosemicarbazone, $[Ni(Pz4DM)_2]$, has been synthesized and characterized by its spectral properties. Its crystal structure shows the two ligands coordinated in a *mer*-configuration and bond lengths and angles are compared with other thiosemicarbazone complexes. The complex, in contrast to the uncoordinated thiosemicarbazone, shows no growth inhibition against two human pathogenic fungi, *Aspergillus niger* and *Paecilomyces variotii*.

Heterocyclic thiosemicarbazones, as well as their metal complexes, are important because of potentially beneficial biological activity.[1] Although there have been numerous studies involving the isolation of complexes and their spectral and magnetic characterization,[2,3] comparatively few crystal structures of these complexes have been determined. Results of studies of bis(ligand)chromium(III) and -iron(III) complexes that are relevant are: The thione $\{=^1N-^2NH-C(=S)^4NH_2\}$ and thiol $\{=N-N=C(-S^-)NH_2\}$ forms of pyruvic acid thiosemicarbazone are coordinated to chromium(III) as tridentate ligands in a meridional conformation with the expected bond length differences for the metal–ligand and thiosemicarbazone moiety.[4] Bis(salicylaldehyde thiosemicarbazonato)-chromium(III) perchlorate has two equivalent tridentate ONS ligands arranged in a meridional conformation,[5] as does an iron(III) complex with two anionic 2-acetylpyridine 3-azabicyclo-[3.2.2]nonylselenosemicarbazones (i.e. loss of ^{2}NH).[6] However, the structure of bis(isoquinoline-1-carboxaldehyde thiosemicarbazonato)nickel(II) monohydrate was reported[7] with small differences in the bond lengths of the two coordinated ligands.

Most crystal studies have been reported for four-coordinate nickel(II) and copper(II) thiosemicarbazone complexes, that demonstrated the most biological activity.[8] A tetrahedral nickel(II) complex, NiS_2Cl_2, with two acetophenone thiosemicarbazone ligands, does not have the imine nitrogens coordinated.[9] *Cis*-bis(acetonethiosemicarbazonato)nickel(II) has been found to have con-

† Author to whom correspondence should be addressed.

siderable tetrahedral distortion from planar stereochemistry.[10] Planar nickel(II) complexes have been reported for complexes of 2-acetylpyridine azabicyclo[3.2.2]nonylthiosemicarbazone,[11] salicylaldehyde ^{4}N-phenylthiosemicarbazone[12] and two acetylpyrazine ^{4}N-substituted thiosemicarbazones.[13] Representative copper(II) complexes of heterocyclic thiosemicarbazones are the following: [Cu(HPictsc)H_2O]Cl·H_2O, where H_2Pictsc is 3-hydroxy-5-hydroxymethyl-4-formyl-2-picoline thiosemicarbazone,[14] the dinuclear complex of 2-formylpyridine thiosemicarbazone,[15,16] the mononuclear complex formed from the aforementioned dinuclear copper(II) complex and saccharin,[17] as well as additional complexes of 2-formylpyridine thiosemicarbazone.[18] The structure of a 2-acetylpyridine-3-hexamethyleneiminylthiosemicarbazone nickel(II) complex has also been reported.[19] Here we report the structure and spectral properties of bis(acetylpyrazine ^{4}N-dimethylthiosemicarbazonato)nickel(II) dichloromethane, [Ni(Pz4DM)$_2$]·CH_2Cl_2.

EXPERIMENTAL

Syntheses and materials

The yellow thiosemicarbazone was prepared by adding ^{4}N-methyl-^{4}N-phenyl thiosemicarbazide to an ethanolic-aqueous mixture of acetylpyrazine and dimethylamine followed by gentle refluxing for 2 h as described previously.[20] The bis complex [Ni(Pz4DM)$_2$] was prepared by refluxing for 2 h an anhydrous ethanol 1:2 mixture of nickel(II) acetate (Alfa) and acetylpyrazine ^{4}N-dimethylthiosemicarbazone. The brown product (*ca* 70% yield), which formed on cooling, was filtered after about half of the solvent was evaporated, washed with cold isopropanol and dried on a warm plate (35°C). The crystal was grown from dimethyl sulphoxide by slow diffusion of methylene chloride into the solution.

Physical measurements

The spectral, physical and biological measurements of the powder sample were made as previously reported.[2]

Determination of the crystal structure of [Ni($C_9H_{12}N_5S$)$_2$]·CH_2Cl_2([Ni(Pz4DM)$_2$]·CH_2Cl_2)

A brown prismatic crystal of approximate dimensions 0.25 × 0.20 × 0.50 mm was mounted on a glass fibre and used for data collection on a CAD4 Enraf–Nonius four-circle automatic diffractometer. Cell constants and an orientation matrix for data collection were obtained by least-squares refinement of the diffraction data from 25 reflections in the range 18–29°. The systematic absences observed suggested the space group to be $P2_1/n$. Data were collected at 293 K using Cu-K_α radiation (λ = 1.54056 Å) and the $\omega/2\theta$ scan technique. The intensities were corrected for Lorentz and polarization effects, and for absorption by an empirical method.[21] The structure was solved by direct methods,[22] which revealed the position of all non-hydrogen atoms. The positional and individual displacement (initially isotropic then anisotropic) parameters were refined by full-matrix least-squares.[23] The positions of the pyrazine hydrogen atoms were found from a difference map and those of methyl groups and of the dichloromethane were calculated from geometry. All hydrogen atoms were included in the structure factor calculations with B_{iso} = 4.0 Å^2, but not refined. A secondary extinction correction was applied[24] and the final coefficient, refined in the last cycle, was 8.248(1) × 10^{-7}. The final R value was 0.062, with R_w = 0.069 (weighting scheme $w^{-1} = \sigma^2(F)$; 326 parameters; S = 2.260; maximum Δ/σ in final cycle 0.001; maximum $\Delta\rho$ = 1.009 e Å^{-3}). Computations were performed on a DEC MicroVAX 3500 computer. For a summary of crystal data, see Table 1.

RESULTS AND DISCUSSION

Structure of $[Ni(Pz4DM)_2]$

The most important bond lengths and angles are included in Tables 2 and 3, respectively. Both tables are arranged in order to allow for a convenient comparison of the two ligands. A complete list of bond distances and angles, as well as final atomic coordinates, equivalent isotropic temperature factors and lists of F_o/F_c values are included in the supplementary material deposited with the Editor. A view of the structure of the molecule is shown in Fig. 1.[25]

The nickel(II) ion is octahedrally coordinated by the two approximately planar tridentate ligands arranged in a *mer*-configuration and a single isomer of this chiral molecule is present. Coordination for both ligands is via a pyrazinyl nitrogen, the azomethine nitrogen and the thiolato sulphur atoms. The greatest difference between the two ligand's metal donor atom bond lengths, 0.029 Å, occurs for the Ni—S bonds. This is larger than the 0.013 Å found for bis(isoquinoline-1-carboxaldehyde thiosemicarbazonato)nickel(II), $[Ni(Iq4DH)_2]$, which had a difference in the Ni—N(12) and Ni—N(22), azomethine nitrogen, bond lengths of the same magnitude.[7] The Ni—N(12) and Ni—N(22) bonds in $[Ni(Pz4DM)_2]$ are quite similar, but Ni—N(11) and Ni—N(21), pyrazinyl nitrogens, differ by 0.014 Å, while the analogous isoquinonyl Ni—N bonds differed by only 0.004 Å. The two complexes have similar distances for the S(11)—C(16) and S(21)—C(26) bonds; for $[Ni(Iq4DH)_2]$ 1.719 and 1.735 Å and for $[Ni(Pz4DM)_2]$ 1.714 and 1.729 Å. There is similar agreement between the bond distances for the remaining thiosemicarbazonato moieties of the two complexes.

Table 4 is a more complete compilation of some

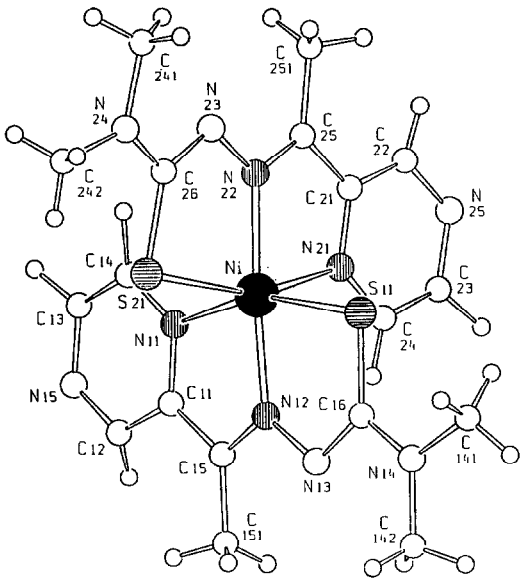

Fig. 1. Schakal diagram of $[Ni(Pz4DM)_2]$.

of the relevant bond lengths of the thiosemicarbazone moiety in the various nickel(II) complexes, as well as examples of copper(II) and chromium(III) complexes. The copper(II) complex has a coordinated heterocyclic thiosemicarbazonato ligand and displays considerable growth inhibition against a range of fungi.[19,26] The thiosemicarbazone bond lengths that would be expected to be most affected by coordination would be the imine C=N and thiolato C—S bonds and, therefore, the largest differences in these bonds would also be expected in the complexes listed in Table 4. There is small variation in C=N with $[Ni(Pz4DM)_2]$ having somewhat shorter bonds and, therefore, weaker bonding to the nickel(II) centre in the six-coordinate complex than for the four-coordinate nickel(II) complexes, except for *cis*-$[NiAc4DH)_2]$. $[Ni(Pz4DM_2]$ has longer C=N bonds than $[Ni(Iq4DH)_2]$, which has the bulkier isoquinoline rings which would presumably weaken imine nitrogen coordination. The bonds are of comparable length to those of $[Cr(HSal4DH)_2]^+$, but considerably longer than found for the four-coordinate copper(II) complex. Similar trends are found for the C—S bond length, except that $[Cr(HSal4DH)_2]^+$ has shorter bonds indicating that the soft sulphur donor atom does not bond as strongly to the hard chromium(III) ion as the nitrogen donor. Also, in contrast to the C=N bond, the C—S bond is considerably longer in the four-coordinate copper(II) complex, indicating stronger bonding of the sulphur donor; most of the four-coordinate nickel(II) complexes also have long C—S bonds. The remaining complexes listed in Table 4 show less differences in the thiosemicarbazone moiety's bond lengths, since they change to a lesser degree on complexation.

Table 4. Comparison of the thiosemicarbazone moiety and metal–donor atom bond lengths (Å) for metal complexes (e.s.d.s range from 0.003 to 0.009 Å)

	1.288	1.388	1.344	1.707	1.307	2.425	2.041		

[a] Iq4DH = anion (loss of ^{2}N proton) of isoquinoline thiosemicarbazones.
[b] Ac4DH = anion (loss of ^{2}N proton) of acetone thiosemicarbazone.
[c] Lbcn = anion (loss of ^{2}N proton) of 2-acetylpyridine 3-azabicyclo[3.2.2]nonylthiosemicarbazone.
[d] Pz4M = anion (loss of ^{2}H proton) of acetylpyrazine ^{4}N-methyl-thiosemicarbazone.
[e] Sal4Ph = dianion (loss of hydroxy and ^{2}N proton) of salicylaldehyde ^{4}N-phenylthiosemicarbazone.
[f] Lhexim = anion (loss of ^{2}N proton) of 2-acetylpyridine 3-hexamethyleneiminylthiosemicarbazone.
[g] HSal4DH = monoanion (loss of hydroxy proton) and salicylaldehyde thiosemicarbazone.

As expected and consistent with the discussion of the bond lengths of the thiosemicarbazone moiety, the six-coordinate complexes all have significantly longer M—S and M—N bonds (Table 4) than the four-coordinate complexes. Somewhat surprising is that the metal–thiosemicarbazone ligand bonds for $[Cr(HSal4DH)_2]ClO_4$ are longer than the metal–sulphur and metal–nitrogen bonds for [Ni(Pz4DM)$_2$]. Additional studies of complexes having different ^4N {i.e. $=^1N—^2NH—C(=S)^4NR_2$} substituents are needed to establish this function's effect on the M—S and C=S bond lengths. Note that there is considerable difference in the M—S bond lengths between [Ni(Pz4M)Cl] and [Ni(Pz4DM)Cl] with a change from ^4NHMe to $^4NMe_2$ (Table 4), but the two compounds have identical C—S bond lengths.

The metal–thiosemicarbazone ligand bond angles (Table 5) also show a difference with a change in coordination number; the six-coordinate complexes have similar bond angles and the angles are smaller for the six-coordinate complexes than for the four-coordinate complexes. A comparison of the angles between [Ni(Pz4DM)$_2$] and [Ni(Pz4DM)Cl] shows a large difference in the S—Ni—N(ring) bond angle, *ca* 159.0° and 158.2° vs 170.6°, respectively. The much smaller angles found for [Ni(Pz4DM)$_2$] must be due to an inter-ligand steric effect, as are the *ca* 5° differences in the other metal–ligand bond angles.

Spectroscopic studies of HPz4DM *and* [Ni(Pz4DM)$_2$]

A decrease in the energy of ν(C=N) from 1605 cm^{-1} in the spectrum of HPz4DM to 1565 cm^{-1} in the spectrum of [Ni(Pz4DM)$_2$] is consistent with coordination of the azomethine nitrogens, as is the presence of a band at 430 cm^{-1} which is assignable to ν(Ni—N).[27] A second band at 1600 cm^{-1} assignable to ν(C=N) is expected in this complex's spectrum since the anionic ligands formally have a double bond between ^2N and ^3C {i.e. $=^1N—^2NH—C(=S)^4NR_2$}. Coordination of the thiol sulphurs is indicated by a decrease in energy of the thioamide IV band at 857 to 749 cm^{-1}, as well as a band at 335 cm^{-1} assignable to ν(NiS).[28] We recorded the spectrum of acetylpyrazine to aid us in assigning the ring deformation band in the 600 cm^{-1} region of the spectrum of the uncomplexed ligands; this band increases by 30 cm^{-1} in the spectrum of [Ni(Pz4DM)$_2$] on coordination of one of the ring nitrogens. The ν(NiN) band for a pyrazinyl nitrogen is expected below 250 cm^{-1} and we are unable to assign it with our spectrometer. Pyrazine derivatives have bands assignable to the ring's $\pi \rightarrow \pi^*$ and $n \rightarrow \pi^*$ transitions at *ca* 38,500 and 30,500 cm^{-1}, respectively.[29] A DMSO solution of acetylpyrazine shows its ring's $\pi \rightarrow \pi^*$ and $n \rightarrow \pi^*$ transitions at 36,900 and 32,890 cm^{-1}, respectively, with $\log \varepsilon = 2.911$ for the latter band. A third band in the spectrum at 29,410 cm^{-1} is assignable to the $n \rightarrow \pi^*$ band involving the acetyl oxygen's lone electron pair(s). In the solution spectrum of HPz4DM the ring's $n \rightarrow \pi^*$ band must merge with the $n \rightarrow \pi^*$ band of the azomethine group to give a $\log \varepsilon$ value of 4.33 for a band at 31,350 cm^{-1}. Lower energy $n \rightarrow \pi^*$ bands at 23,040 and 18,520 cm^{-1}, which involve the thiosemicarbazone moiety, are present in the solid-state spectra of HPz4DM, as well as [Ni(Pz4DM)$_2$] (24,510 and 20,620 cm^{-1}).

In DMSO solution, other than the intense $n \rightarrow \pi^*$

[a] Identification of the ligands is under Table 4.

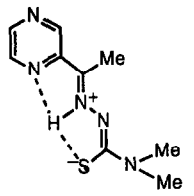

Fig. 2. Bifurcated isomer of HPz4DM with extended conjugation.

band at *ca* 30,000 cm^{-1}, only a single band at *ca* 23,000 cm^{-1} is present for HPz4DM. This coupled with ^1H NMR results[13] indicate that HPz4DM possesses a significant percentage of the bifurcated isomer (Fig. 2) with its conjugated thiosemicarbazone moiety. The DMSO spectrum of $[Ni(Pz4DM)_2]$ has bands at 28,990, 25,640 and 21,740 cm^{-1} with $\log \varepsilon$ values of 4.47, 4.28 and 4.34, respectively. The highest energy band is due to an intraligand $n \rightarrow \pi^*$ transition, while the next band includes the thiosemicarbazone moiety's $n \rightarrow \pi^*$ and $Ni^{II} \rightarrow$ ring charge transfer transitions. The lowest energy band is likely due to an $S \rightarrow Ni^{II}$ charge transfer transition, since it is too intense for a *d–d* band. Weak bands are found in the mull transmission spectrum at 6760 and 13,160 cm^{-1}, which can be assigned as $^3A_{2g} \rightarrow {}^3T_{2g}$ and $^3A_{2g} \rightarrow {}^3T_{1g}(F)$, respectively. However, their ratio falls outside the values normally associated with octahedral symmetry[30] and do not yield meaningful ligand field parameters.

Antifungal activity of HPz4DM *and* $[Ni(Pz4DM)_2]$

Although HPz4DM strongly inhibits the growth of *Paecilomyces variotii* (i.e. a 22 mm diameter of growth inhibition is achieved by a 1000 $\mu g\ cm^{-3}$ solution), and to a slightly lesser extent *Aspergillus niger* (i.e. 19.5 mm at 1000 $\mu g\ cm^{-3}$), $[Ni(Pz4DM)_2]$ shows no activity against either fungus. The four-coordinate nickel(II) complexes of this ligand, [Ni(Pz4DM)Cl] and [Ni(Pz4DM)Br] also showed no activity.[13] Copper complexes of NPz4DM show significant activity against both fungi,[20] indicating that ease of reduction of the metal centre and the thiosemicarbazone ligand may be important for antifungal activity.[31]

Abstract—Time-averaged chemical shifts in the ^{1}H NMR spectra of aniline, pyridine and some derivatives, induced by coordination in 1:1 complexes to the paramagnetic $5f^2$ uranium(IV) as its complex with the thenoyltrifluoroacetonato anion [U(TTA)$_4$], have been used to find equilibrium constants in benzene and acetone solution. The bound chemical shifts are shown to be solvent independent. In acetone the equilibrium constant for the formation of U(TTA)$_4$·H$_2$O was found to be 4.0±0.2 dm^3 mol^{-1} from ^{1}H NMR spectroscopy. Equilibrium constants have also been determined by electronic spectroscopy in benzene solution, in which U(TTA)$_4$ itself is eight-coordinate. The results were correlated with the basicity of the substrate and the effects of steric hindrance were evaluated. U(TTA)$_4$ is nine-coordinate in acetone through solvent coordination and the addition of substrate caused no or small changes to the electronic spectrum.

The addition of a neutral donor ligand, S, to a benzene solution of U(TTA)$_4$ containing excess HTTA caused[1] changes in the shape and intensity of an *f–f* absorption near 670 nm, which were interpreted in terms of a change in coordination number at uranium(IV) from eight to nine. There is no published evidence that U(TTA)$_4$ forms 10-coordinate adducts.

$$U(TTA)_4 + S \rightleftharpoons U(TTA)_4S \quad (1)$$

with

$$\beta_1 = [U(TTA)_4S]/[U(TTA)_4][S] \quad (2)$$

and

$$L_0 = U_{total} = [U(TTA)_4] + [U(TTA)_4S] \quad (3)$$

$$S_0 = S_{total} = [S] + [U(TTA)_4S] \quad (4)$$

With triphenylphosphine oxide (TPPO), for example,[1] successive additions produced a set of spectra with two isosbestic points from which the equilibrium constant β_1 [eqs (1) and (2)] was calculated with the mass balance equations (3) and (4). The extinction coefficients of U(TTA)$_4$, ε_1, and the adduct U(TTA)$_4$S, ε_2, were found when the TPPO concentration was zero (ε_1) and when further addition of TPPO caused no change to the spectrum (ε_2), i.e. when the nine-coordinate U(TTA)$_4$·TPPO was fully formed. Between 450 and 500 nm $\varepsilon_2 > \varepsilon_1$ and the nine-coordinate adduct has a characteristic absorption maximum near 670 nm. Oxidation of uranium(IV) to uranium(VI) was said to be prevented by the addition of a 10-fold excess of HTTA. The Th(TTA)$_4$ adduct with trioctylphosphine oxide is nine-coordinate in the solid state.[2]

The computer program SQUAD[3–5] used in the present work for the calculation of β_1 from electronic spectroscopy requires no predetermined values of ε_1 and ε_2, which are calculated at each analytical wavelength. This provides a useful internal validation of the results since ε_1 is readily found from solutions where the concentration of S is zero.

In addition to electronic spectroscopy it is also possible to find β_1 from an analysis[6,7] of the ^{1}H NMR spectra of S, which are shifted but little broadened by the presence of the paramagnetic $5f^2$ uranium(IV). This method should be applicable in solvents which bind to U(TTA)$_4$, e.g. acetone, where changes in the electronic spectrum might be too small for the determination of β_1 because no

* Author to whom correspondence should be addressed.

change in coordination number occurs on the addition of S.

Here, we extend the electronic spectroscopic method to organic nitrogen bases and further demonstrate the usefulness of ^{1}H NMR techniques for β_1 and the bound chemical shifts of S, Δ_B.

EXPERIMENTAL

Materials

4-Picoline (BDH) was purified by distillation and 4-toluidene (Aldrich) by recrystallization (petroleum ether). Pyridine (BDH, 99.5%, AnalaR), 3,5-lutidene (Aldrich, 98%), 3,4-lutidene (Aldrich, 98%), 2,4,6-collidine (Aldrich, 99%), aniline (BDH, 99.5%, AnalaR), 3-chloroaniline (Aldrich, 99%), 4-nitroaniline (BDH), $UO_2SO_4 \cdot 3.5H_2O$ (BDH), HTTA (Aldrich, 99%), benzene (BDH, AnalaR, water content 0.04% Karl Fischer), acetone (BDH, AnalaR, water content 0.2%, chromatography), benzene-d_6 (Merck, 99.6 atom %D) and acetone-d_6 (CEN, 99.8 atom %D) were used as supplied.

Tetrakis(thenoyltrifluoroacetonato)uranium(IV), U(TTA)$_4$

Uranyl sulphate in dilute hydrochloric acid was reduced with zinc amalgam. Caesium chloride and concentrated hydrochloric acid were added to the reduced solution, which was then saturated with gaseous hydrogen chloride. On cooling green crystals of Cs_2UCl_6 precipitated. HTTA in ethanol was added to a suspension of Cs_2UCl_6 in ethanol. The dark brown precipitate of U(TTA)$_4$ which eventually formed was recrystallized from toluene. Found: C, 34.6; H, 1.6. Calc. for $C_{32}H_{16}F_{12}O_8S_4U$: C, 34.3; H, 1.4%. ^{1}NMR (C_6D_6), 293 K: σ 5.25, 5.20, 5.16 (1H, m), δ 7.02, 6.96 (1H, m), δ 7.43, 7.39 (1H, m), 13.71 (1H, singlet), m = multiplet.

Use of nitrogen box

Solutions of U(TTA)$_4$ and the adducts were prepared by conventional degassing procedures in an atmosphere of purified nitrogen using a Faircrest glove-box. These solutions were transferred under nitrogen to sealed cells for use in the spectrophotometer.

Spectrometric measurements

Electronic spectra were recorded with a Pye–Unican SP8-100 between 445 and 500 nm (determination of $\log_{10}\beta_1$) and 620–700 nm (to monitor oxidation) in matched quartz cells at 20 ± 1°C using pure solvent as the reference. The nitrogen bases did not absorb at these wavelengths. Equilibrium constants were determined with SQUAD. The conditions are summarized in the footnote to Table 1.

In a system $A + nB \rightleftharpoons AB_n$, if $n = 1$ then a plot of $A_T B_T/\Delta A_s$ against $A_T + B_T$ will be linear,[9] where A_T = total concentration of A, B_T = total concentration of B, ΔA_s = absorbance at a given wavelength (at which B does not absorb) minus $\varepsilon_A A_T$ (ε_A = extinction coefficient of A at the same wavelength). This behaviour was found at 450 nm for U(TTA)$_4$ adducts and helps confirm the stoichiometry of the reaction.

^{1}H NMR spectra were recorded in d_6-benzene and d_6-acetone using a Bruker WH90 FT spectrometer operating at 90.0229 MHz. Chemical shifts (ppm) relative to the internal standard TMS for the coordinated and free ligand were subtracted to give values of $\sigma\Delta$. The experimental conditions are summarized in the footnotes to Table 2.

The upfield, experimental chemical shifts, $\sigma\Delta$, observed when various amounts of S were added to solutions containing a fixed concentration of U(TTA)$_4$ were used to find β_1 and ΔB, the bound chemical shift of any proton on S.

(1) A graphical method was used which employed the relationship:[6]

$$S_0(1-\sigma\Delta/\Delta B) = L_0\Delta B/\sigma\Delta - (\beta_1^{-1} + L_0), \quad (5)$$

where L_0 = constant concentration of U(TTA)$_4$ and S_0 = variable concentration of S.

A value of ΔB was guessed to calculate $S_0(1-\delta\Delta/\Delta B)$, which was plotted against $1/\sigma\Delta$. The slope ($L_0\Delta B$) of the plot was found using linear least-squares analysis and the new value of ΔB was used to recalculate S_0 $(1-\delta\Delta/\Delta B)$, which in turn was replotted against $1/\sigma\Delta$. This process was repeated until the difference in successive values of ΔB was insignificant (less than 1 part in 1000 for both slope and intercept). The final value of the intercept was used to find β_1.

(2) The general relationship[6–8]

$$\sigma\Delta = [\mathrm{U(TTA)_4S}]\Delta B/S_0 \quad (6)$$

was analysed with eqs (2)–(4) using the Newton-Raphson method with a locally-written program which gave values of β_1 and ΔB with their standard deviations and the degree of formation of the complex.

The results from SQUAD and the two NMR methods, eqs (5) and (6), are given in Tables 1 and 2 with one standard deviation given in parentheses. Allowing for systematic and other experimental errors the true uncertainty is likely to be at least two to three times greater than these values.

Equilibrium constant and bound chemical shift for water

The ^{1}H NMR spectrum of a sample (1 cm^3) of d_6-acetone was recorded and the H_2O resonance recognized. Known amounts of H_2O were added to samples (1 cm^3) of d_6-acetone and the spectra recorded. By measuring the peak areas it was then possible to find the amount of H_2O initially present in the d_6-acetone. D_2O at various concentrations was then added to solutions of U(TTA)$_4$ at fixed concentration in d_6-acetone. The ^{1}H NMR spectra of these solutions were recorded and the shifts analysed using eqs (5) and (6) as before. Results are given in Table 3. Similar experiments could not be conduced in d_6-benzene because of the low solubility of water in the solvent. There was no evidence from the electronic spectra in benzene to suggest that water coordination was significant in this solvent.

RESULTS AND DISCUSSION

Oxidation of uranium(IV)

Uranium(IV) is oxidized to uranium(VI) by atmospheric dioxygen in non-aqueous solvents.[10–12] There is no consistent kinetic pattern, but the rate of oxidation may depend[10–12] on (1) the initial concentration of uranium(IV), (2) the partial pressure

Table 3. Complexation of water with $U(TTA)_4$ in acetone[a]

Range of H_2O/D_2O concentration (mol dm^{-3})	Number of solutions	Degree of formation	ΔB (ppm) Eq. (5)	Eq. (6)	β_1 (dm^3 mol^{-1}) Eq. (5)	Eq. (6)
5.590×10^{-1}–6.450×10^{-2}	7	2–6% based on H_2O	46.8(1.4)	48.1(1.0)	4.0(0.2)	4.0(0.2)

of O_2, (3) the solvent and its water content, (4) the nature of the coordinated ligands and (5) exposure to light. In solution the oxidation of $U(TTA)_4$ and its adducts can be readily followed between 610 and 720 nm, since uranium(VI) does not absorb appreciably above 500 nm.

We made preliminary experiments in which uranium(IV) absorbances near 660 nm were measured using benzene and acetone solutions of $U(TTA)_4$ and its adducts. Solutions were prepared in air and a nitrogen box, but with no excess HTTA. In general, the rate of oxidation was acceptably slow in air (Table 1). The percentage oxidation of $U(TTA)_4$ in unit time increased with a decrease in the initial $U(TTA)_4$ concentration and with an increase in the total concentration of S. We found that $U(TTA)_4$ alone was less susceptible to oxidation in benzene where it is eight-coordinate than in acetone where nine-coordination is achieved with a solvent molecule as ligand; on the addition to acetone and benzene solutions of a ligand S at a concentration which would result in the complete formation of a nine-coordinate adduct in benzene, the oxidation was more rapid but became much less solvent dependent.

Although the rate of oxidation decreased for solutions prepared in a nitrogen box it could not be totally prevented in our hands. All of the results presented here refer to solutions made up in the air.

Our purpose was to find conditions under which oxidation was minimized in subsequent studies to find equilibrium constants and NMR parameters. Measurements were made rapidly and were always complete within 30 min of solution preparation. Initial rates of oxidation are recorded in Table 1. The good agreement found between calculated and experimental values of extinction coefficients of $U(TTA)_4$ and the small standard deviations in $\log_{10}\beta_1$ (Tables 1 and 2) suggested that oxidation was relatively unimportant. Experiments with results showing marked variation in extinction coefficients or with high standard deviations in $\log_{10}\beta_1$ or with absorption spectra with weak shoulders below 500 nm typical of uranium(VI), or with new, weak resonances indicative of uranium(VI) complexes in the ^1H NMR spectra, were repeated. No excess HTTA was used in our experiments since this produced many additional resonances in the ^1H NMR spectra, which made it difficult to monitor shifts in the resonances of S protons and, in addition, results from NMR and electronic spectroscopy could be compared under very similar experimental conditions.

Electronic spectroscopy in benzene solution

The analysis (Table 1) gave values of $\log_{10}\beta_1$ with small standard deviations, indicating a good fit to the experimental data. There was also good agreement between the calculated and experimental values for the extinction coefficients of $U(TTA)_4$.

In general, $\log_{10}\beta_1$ increases with an increase in the pK_a of the nitrogen bases, except when steric hindrance is present (Table 1). Thus, 2,4,6-collidene and 2-picoline have $\log_{10}\beta_1$ at least an order of magnitude smaller than might be expected from the pK_a values.

The method becomes less satisfactory as $\log_{10}\beta_1$ decreases since large excesses of the base are required to give a wide range in the degree of formation of the complex (see footnote to Table 1 and Experimental). For 4-nitroaniline no changes in the spectrum of $U(TTA)_4$ were observed.

There is good evidence that the uranium(IV) absorption maximum near 670 nm is sensitive to a change in coordination number,[1] which was confirmed in the present work through comparison between benzene and acetone solutions. The peak at 656 nm in benzene shifts to that found in acetone at 662 nm and the pronounced shoulder near 685 nm declines as base is added. These are accompanied by changes in the overall shape of the band envelope. Adding the base to an acetone solution caused small or no change in λ_{max} and the

shape of the envelope, although we do know from ^{1}H NMR measurements that complex formation takes place. Our conclusion is that U(TTA)$_4$ is eight-coordinate in benzene and nine-coordinate in acetone.

Experiments for a given base with variation in the initial uranium(IV) concentration gave consistent values of $\log_{10}\beta_1$, indicating that no polymeric species were present.

The use of carefully-dried benzene had little effect on the values of $\log_{10}\beta_1$. For example, a value of 2.44 ± 0.03 was found for 4-picoline in dry benzene, which is the same as that given in Table 1 for which the water content was 0.04%.

The bound chemical shift (ΔB) *and* β_1 *from* ^{1}H *NMR studies*

For 3,5-lutidene the bound chemical shifts of equivalent protons are solvent independent (Table 2) within experimental error, as might be expected for complexes of similar structure. ΔB (ppm) decreased as the number of bonds separating a proton from the metal centre increased; two bonds, NH_2 in 4-tol 96, H in H_2O 47; three bonds, 2-H in 4-pic 34, 2-H in 3,5-lut 31; four bonds, 2-H in 4-tol 13, 3-H in 4-pic 12.5; five bonds, 3-H in 4-tol 11, CH_3 in 3,5-lut 6, 4-H in 3,5-lut 7; six bonds, CH_3 in 4-pic 7; seven bonds, CH_3 in 4-tol 2. These results do not provide evidence for a predominant contact shift mechanism. There are through-space relationships (r^{-3}, θ) with ΔB decreasing with an increase in r as expected for a pseudo-contact mechanism. A simple analysis using r^{-3} only found from known bond lengths reproduced the correct order of ΔB, but overestimated the relative values in most cases. Nothing is known of the true symmetry of these complexes in solution. We are currently undertaking a full analysis in selected cases using ^{13}C in addition to ^{1}H NMR spectroscopy.

The values for ΔB obtained by the two methods of data analysis agree within the likely experimental errors in all cases.

There is also reasonable agreement between values of $\log_{10}\beta_1$ obtained from benzene solutions using both the electronic and NMR spectroscopic methods (Tables 1 and 2, for 3,5-lutidene 2.37 and 2.30, for 4-toluidene 1.09 and 0.97, respectively). The values of $\log_{10}\beta_1$ found in acetone are rather less than an order of magnitude smaller than those found in benzene and could reflect the nine-coordination of U(TTA)$_4$ itself in acetone.

^{1}H NMR spectroscopy is thus established as a satisfactory method for the determination of an equilibrium constant for uranium(IV) complexes, particularly in cases where changes in the electronic spectrum are too small for use in the determination. The method is limited in terms of the range in the degree of formation of complex across the experiments because of the decrease in intensity of the resonances of the base as the concentration is reduced (see Experimental). For example, ΔB for the amine protons of 4-toluidene was found to be 96 ppm, which is very much larger than the observed shifts $\delta\Delta$. Nonetheless, relatively small (10%) standard deviations were observed.

Comparison with values of $\log_{10}\beta_1$ *found previously*

Previously values of $\log_{10}\beta_1$, with U(TTA)$_4$ in benzene solution,[13] were found to be 2.55 for N,N-diethylacetamide and 3.02 for triethylphosphate and for U(acac)$_4$ in benzene β_1 (kg mol^{-1}) was found[14] to be 63.8 for dimethyl sulphoxide at 40°C from a ^{1}H NMR kinetic study ($\log_{10}\beta_1 \cong 1.80$). With oxygen donor ligands and U(TTA)$_4$ in benzene the values shown below for $\log_{10}\beta_1$ are reported,[1,15,16] determined by electronic spectroscopy.

tri-n-octylphosphine oxide	6.23
tri-phenylphosphine oxide	4.72
di-n-butyl n-butylphosphinate	4.04
dioctyl sulphoxide	3.64
dihexyl sulphoxide	3.62
dimethyl sulphoxide	3.23
dibenzyl sulphoxide	3.10
tri-n-butyl phosphate	3.04
tri-iso-octylthiophosphate	1.04
methyl-iso-butylketone	0.1

The values for triethyl phosphate[13,15] are in good agreement.

Using SQUAD[3-5] we found $\log_{10}\beta_1$ in benzene to be 3.14 ± 0.01 for tri-n-butyl phosphate and 4.00 ± 0.01 for di-n-butyl n-butylphosphonate from electronic spectroscopy. The very different values for dimethyl sulphoxide[14,16] may be attributed[17] to the apparent poorer acceptor properties of U(acac)$_4$ compared with U(TTA)$_4$. As far as we know there are no comparable values for the nitrogen bases with uranium(IV).

Complexation between U(TTA)$_4$ *and water in acetone solution*

Nine-coordinate adducts of thorium(IV) with one molecule of water are well-established in the solid state. The structures[18,19] of aquatetrakis(1,1,1-trifluoropentan-2,4-dionato)thorium(IV) and the corresponding tropolonato complex are based on the nine-coordinate monocapped square antiprism.

The ^1H NMR method was modified (see Experimental) to allow estimations of β_1 and ΔB for water (Table 3). The value of β_1 is at the lower limit of the useful range for the method, as indicated by the degree of formation of the complex. The concentration of water in the experimental solutions cannot be conveniently lowered whilst the concentration of $U(TTA)_4$ is limited by solubility. Nonetheless, satisfactory standard deviations were obtained for β_1 and ΔB with very similar values from the two methods of data analysis. The value of ΔB was large, as expected (see results for the $-NH_2$ group in 4-toluidene, Table 2). As far as we know this is the first determination of β_1 for complexation of water with a uranium(IV) complex.

Abstract—New potentially tridentate ferrocenylphosphines have been prepared by the lithiation of diphenylphosphinoferrocene (dppf) followed by reaction of the dilithiated products with chlorodiphenylphosphine. The reaction of the new ligands with $Pd(COD)Cl_2$ has been studied using ^{31}P NMR to determine the preferential bidentate coordination modes.

The tertiary alkyl- and aryl-phosphines are probably the most widely used class of ligands in organometallic chemistry. One of the ligands in this class, dppe, diphenylphosphinoethane (diphos), is the prototype for the bidentate series of ligands and is probably the most commonly used bidentate ligand for complexation of *soft* transition metal centres. The ferrocenylphosphine ligands constitute a subgroup of the aforementioned general ligand class and in their own right are among the most widely used in active homogeneous catalysis. The prototype ligand of this group, bis-diphenylphosphinoferrocene,† bdppf[1–5] (**2**), the ferrocenyl analogue of dppe, was first described by Davison in 1972.[1]

The advantage of ferrocene-based ligands over more conventional linear alkyl based ligands is that they are amenable to chemical modification by incorporation of different functionalities into the ferrocenyl side-chain with consequent changes in the overall steric, electronic and solubility properties.

There are very surprisingly few tridentate trisphosphine ligands available for use in inorganic chemistry. Of these triphos, bis-(2-phenylphosphinoethyl)phenylphosphine, is probably the most well known. There is a significant literature database covering the chemistry of triphos complexes and in many cases the chemical reactivity of such complexes is very different from that of closely-related complexes containing bidentate phosphine ligands. It would be useful to prepare an equivalent series of ferrocene based ligands with the prototype **3** as shown in Fig. 1, with the inherent advantages allowing the possibility of further facile chemical modification. With this in mind several years ago

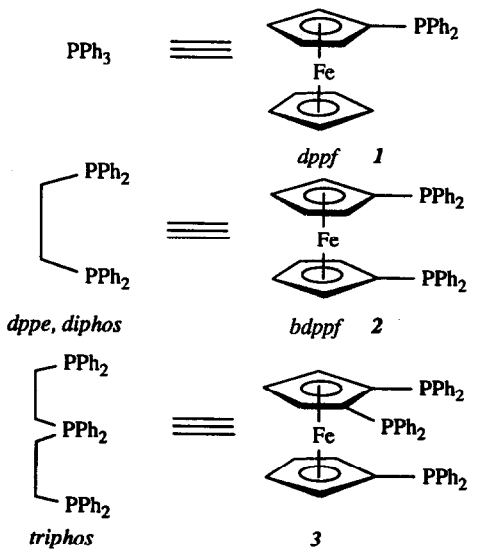

Fig. 1. Common tertiary phosphines and their ferrocenyl analogues.

† The acronyms dppf and bdppf are used to represent diphenylphosphinoferrocene and 1,1′-bis-diphenylphosphinoferrocene, respectively, in this paper, although in the literature currently dppf is commonly used to represent the latter compound, which can cause confusion.

we investigated the lithiation of diphenylphosphinoferrocene, but we were unable to effectively isolate individual isomers of the derived substituted products from crude reaction mixtures. In view of the differences observed between the chemistries of dppe and triphos complexes which have developed since that time we felt this area of work should be further explored. This paper describes initial results in this area.

EXPERIMENTAL

All reactions were performed under an inert atmosphere of dry nitrogen or argon. Chromatographic separations were performed in a glovebox, although minimal oxidation occurs under normal aerobic chromatography. ^{1}H NMR spectra were obtained using Bruker WH-400 or WM-250 instruments. ^{31}P NMR spectra were recorded at 101.26 MHz. Mass spectra were recorded using the solid probe on a Finnegan 1020 instrument.

Preparation of tris-diphenylphosphinoferrocenes

A solution of diphenylphosphinoferrocene (dppf) in diethylether was treated with 2 molar equivalents of an n-butyllithium solution (2.5 M) and 1 molar equivalent of tetramethylethylenediamine, TMED. After stirring for 16 h the solution was treated with 2 mol equivalents of chlorodiphenylphosphine. After refluxing for 1 h the reaction mixture was hydrolysed with a dilute solution of sodium carbonate. The mixture was extracted with dichloromethane (until no more yellow product was extracted) and the combined extracts concentrated to a small volume, dried over anhydrous $MgSO_4$ and filtered. Following solvent removal a yellow oil was obtained. This was then chromatographed carefully on a neutral alumina column: a series of fractions were collected eluting with n-hexane and diethyl ether (increasing polarity), the solvent was removed from each fraction and the ^{31}P{H} NMR spectrum of each was recorded. Following identification of the product containing fractions which were still mixtures at this stage, fractions containing identical products were combined and these were rechromatographed on a silica gel column to give the following products in order of elution: 1,1′-bis-diphenylphosphinoferrocene (bdppf), 1,3,1′-tris-diphenylphosphinoferrocene (tdppf-**3**) and finally 1,2,1′-tris-diphenylphosphinoferrocene (tdppf-**2**). The solvents used for elution were increasingly polar mixtures of hexane and diethyl ether. The yields tend to vary with the scale of the reaction; however, as an example the reaction when carried out on a 10 mmol scale of dppf gave the following approximate product composition based on integration of ^{31}P resonances: unreacted dppf 22%, bdppf 15%, tdppf-**3** 51% and tdppf-**2** 6%. A similar reaction performed using neat TMED as a solvent gave slightly higher product yields of tdppf-**3** (54%) and tdppf-**2** (6%). The isolated yields are somewhat lower especially for tdppf-**2**, which is typically only about 4%.

tdppf-**2**. ^{1}H NMR ($CDCl_3$): 3.73 (q, 2H, Hc), 4.06 (1:2:2:2:1 ddd, 2H, Ha), 4.18 (t, 1H, Hb), 4.40 (t, 2H, Hd). ^{31}P{H} ($CDCl_3$): −18.36 δ (mono-substituted ring), −25.35 δ (di-substituted ring). Mass spectrum *m/z*: 738 (mass ion, 2), 662 (3), 586 (4), 570 (3), 569 (2), 553 (15), 476 (8), 381 (12), 370 (20), 355 (19), 321 (30), 183 (100). Found: C, 74.7; H, 5.1. Calc. for $C_{46}H_{37}FeP_3$: C, 74.8; H, 5.0%.

tdppf-**3**. ^{1}H NMR ($CDCl_3$): 3.89 (q, 2H, Hc), 4.04 (bq, 2H, Ha), 4.07 (bm, 1H, Hb), 4.10 (t, 2H, Hd), 7.20–7.40 (ms, 30H). ^{31}P{H} ($CDCl_3$): −18.86 (s). Mass spectrum *m/z*: 740 (2), 738 (4), 678 (5), 662 (9), 630 (2), 553 (13), 476 (8), 370 (18), 226 (23), 215 (28), 185 (100). Elemental analysis: Found: C, 75.11; H, 5.15. Calc. for $C_{46}H_{37}FeP_3$: C, 74.81; H, 5.05.

Reaction of tdppf-**2** *and* -**3** *with* $Pd(COD)Cl_2$

In 3 mm NMR tubes containing either tdppf-**2** or tdppf-**3** was added a filtered solution of $Pd(COD)Cl_2$ (0.5 molar equivalents) in $CDCl_3$. After a few minutes the ^{31}P{H} NMR spectrum was recorded, then again after 2 h and again after 1 week. The new resonances located are as listed in Table 1.

The resultant solutions were then further treated with a deutero-chloroform solution of $Pd(COD)Cl_2$ to give a slight molar excess of the palladium complex and the reaction mixtures were crystallized by slow diffusion of a hexane top layer to give nodules

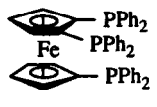
Table 1. ^{31}P NMR data of tdppf-**2**·$PdCl_2$ and tdppf-**3**·$PdCl_2$

Ligand	Original resonances	New resonances on addition of $Pd(COD)Cl_2$
tdppf-**2**	−18.36, −25.35	−18.49, 41.85
tdppf-**3**	−18.86	32.57 (2 resonances), 27.65, −18.91, −19.94

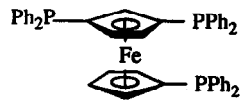
in the case of tdppf-**3**·$PdCl_2$ or microcrystals in the case of tdppf-**2**·$PdCl_x$. ^{1}H NMR: 7.90–8.10 (bm, 4H), 7.20–7.70 (bm, 26H), 4.48–4.56 (bm, 2H), 3.50–3.70 (bm, 2H), three other broadened resonances present of low intensity. ^{31}P NMR: 41.75(bs), 25.64(bs). tdppf-**3**·$PdCl_2$ ^{1}H NMR: 4.03 (bs, [m], 2H), 4.12 (bs, 2H), 4.23 (bs, 1H), 4.29 (bs, 1H), 4.45 (bs, 1H), 7.10–7.60 (ms, 22H), 7.70–8.00 (ms, 8H). ^{31}P NMR: −19.76 (s), 32.45 (s).

RESULTS AND DISCUSSION

The ferrocene based ligands dppf and bdppf are prepared either by Friedel–Crafts procedures or by reaction of lithioferrocenes with chlorodiphenylphosphine.[6–8] The dilithiation of dppf is known to give mixtures of 2,1′- and 3,1′-dilithiodiphenylphosphinoferrocene, albeit in rather poor yields as observed by trapping experiments with sulphur.[9] By a simple modification of the experimental conditions the yield of these dilithiated intermediates can be increased and, therefore, subsequent reaction with chlorodiphenylphosphine results in the formation of the tris-diphenylphosphinoferrocenes. The separation of the isomers **3a** and **3b** from each other and from reaction by-products on a large scale posed the greatest experimental problem, since on TLC they have almost identical R_f values in a range of solvent mixtures. This was overcome by repeated careful chromatography using both neutral alumina and silica gel supports. The products **3a** and **3b** were identified by ^{1}H NMR spectroscopy, since their spectra are diagnostic of the substitution pattern on the cyclopentadienyl rings, Fig. 2. Compound **3b** which elutes first from the column shows only minor shifts in its ^{1}H NMR spectrum in comparison to bdppf (**2**). The mono-phosphorus substituted ring



3a, tdppf-2



3b, tdppf-3

protons of **3b** are observed at 3.89 and 4.10 δ and the di-substituted ring protons at 4.04 and 4.07 δ, respectively, the latter being the unique proton. The ferrocenyl proton region in the spectrum of **3a** exhibits a greater chemical shift spread: 3.73 and 4.40 δ for the mono-substituted ring protons and 4.06 and 4.18 δ for the di-substituted ring protons, the

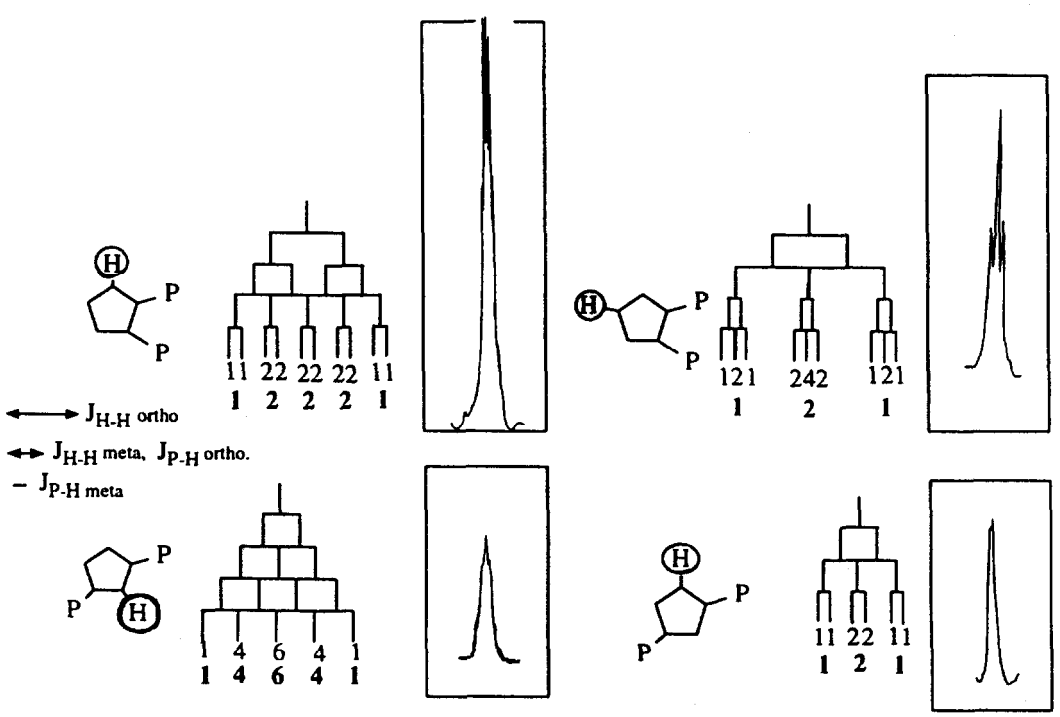


Fig. 2. The predicted resonance line shapes for individual proton resonances of the di-substituted cyclopentadienyl rings, assuming that J(H—H)(*ortho*) values are approximately double those of J(H—H)(*meta*) and J(H—P)(*ortho*) with J(H—P)(*meta*) not resolved. In the boxes are the experimentally observed resonances.

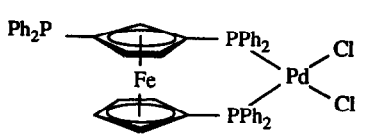
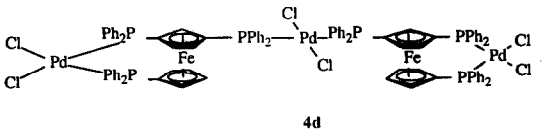
latter shift value being that of the unique proton. The $^{31}P\{H\}$ NMR of **3b** is interesting in that only one singlet is observed at -18.86 δ at MHz, with only a minor shift when compared to bdppf (-17.75 δ) or dppf (-16.82 δ). This result infers that there is very little steric or electronic effect on 1,3 di-substitution of the ferrocenyl ring. The similar $^{31}P\{H\}$ NMR spectrum of **3a** is as expected with two resonances observed at -18.36 and -25.35, the latter of which is due to the di-substituted ring. The significant chemical shift difference in this case is presumably due to the proximity of the two phosphorus atoms and the phenyl rings. This is also mirrored to some extent in the ^1H NMR resonance of the phenyl protons, which also show a wider chemical shift range in comparison to both bdppf and compound **3b**. There is also evidence both in the crude reaction mixture and in the fractions collected following column chromatography for the presence of 1,2- and 1,3-diphenylphosphinoferrocenes. This is corroberated by the proton ^1H NMR data: these are two additional singlets in the ferrocenyl region of early fractions collected following column chromatography indicative of unsubstituted cyclopentadienyl rings and in the ^{31}P NMR there are three unassigned peaks at -24.99, -17.94 and -17.82 δ.

The reaction of tdppf-**3** with $Pd(COD)Cl_2$ gave a mixture of products. The initial $\{H\}^{31}P$ singlet resonance at -18.86 δ was slowly replaced by new resonances at 32.57 (2s) and -19.94 δ, respectively, with low intensity resonances observed at 27.65 and -18.91. The complex **4c** would be expected to show three different ^{31}P NMR resonances, two of which would be of very similar chemical shift and intensity. This is, therefore, indeed what is observed with the two closely spaced resonances at $+32.57$ δ, being assigned to the palladium-bound phosphorus atoms. This chemical shift value compares well with that of the ^{31}P resonance of $(bdppf)PdCl_2$, which,



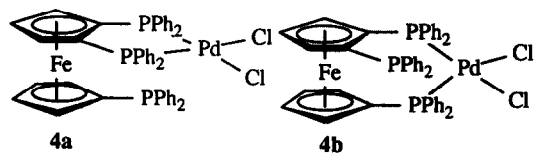
4c

under the same conditions, appears at $+33.36$ δ. It is not, however, altogether clear if the other low-field, low-intensity resonance is due to a palladium-bound species or not, since it is unlikely that complexes of the type $(tdpff\text{-}3)_2(PdCl_2)_3$ (**4d**) would be formed under these reaction conditions. On standing spherical nodules of $(tdpff\text{-}3)PdCl_2$ can be isolated, which show one broad ^{31}P resonance at 32.45 δ and a second sharper resonance at -19.75 δ, the latter being due to the uncoordinated phosphorus



4d

atom. The ^1H NMR spectrum of the latter indicates the expected non-equivalence of all three di-substituted ring protons. This is also evidence for an oligomeric product since a brown insoluble powder is also deposited. In the case of the reaction of tdpff-**2** with $Pd(COD)Cl_2$ there should be two distinct possibilities for coordination modes as shown below:



4a **4b**

In the case of **4b** there should be three phosphorus resonances, two of which again should be similarly shifted of roughly equal intensity, while in the case of **4a** only two resonances should be observed, one of which should be shifted downfield. The observation is that both complexes **4a** and **4b** are obtained, however, **4a** predominates initially since a high intensity singlet is rapidly observed at 41.85 δ following addition of $Pd(COD)Cl_2$, with the expected two low-field singlets due to **4b** at 32.57 δ present in only minor concentration. Associated with this resonance is the weaker resonance at -18.49, which is due to the uncoordinated phosphorus atom. However, on addition of a stoichiometric amount of the palladium complex and prolonged standing leads to the formation and isolation of a small quantity of a solid sample, which exhibits two low-field singlets in approximately a 1:2 ratio at 25.64 and 41.75 δ, respectively. The resonance at 41.75 δ is clearly due to coordinated phosphorus atoms as was observed in the reaction mixture; however, it is not clear whether the uncoordinated phosphorus atom is bound to a second palladium atom or simply oxidized (the phosphine oxides of dppf and bdppf are observed at similar chemical shift values, *ca* 28.47and 27.57 δ, respectively). The ^1H NMR spectrum is extremely broad and, therefore, another possibility is that all three phosphorus atoms are bound to one palladium centre with chloride dissociation, although this will obviously produce a different coordination mode compared with the normal square planar coordination geometry.

Our studies on the coordination chemistry of these new ligands and the related series of tetradentate tetra-diphenylphosphinoferrocenes is con-

tinuing and will be the subject of following publications in this series.

(*Received* 26 *February* 1993; *accepted* 2 *April* 1993)

Abstract—From the reactions of $(CF_3)_2CHOH$ (hfip.H), $(CF_3)Me_2COH$ (tftb.H) and $(CF_3)_2MeCOH$ (hftb.H) with $Y\{N(SiMe_3)_2\}_3$ in benzene, thf or diethyl ether as solvents the following compounds have been isolated and characterized by elemental analysis, IR, NMR and mass spectroscopy: $[Y\{OCMe_2(CF_3)\}_3]_n$ (**1**), $[Y\{OCMe_2(CF_3)\}_3(thf)_{2.5}]$ (**2**), $[Y\{OCMe(CF_3)_2\}_3]_n$ (**3**), $[Y\{OCMe(CF_3)_2\}_3(NH_3)_{0.5}]$ (**4**), $[Y\{OCMe(CF_3)_2\}_3(NH_3)_3]$ (**5**), $[Y\{OCMe(CF_3)_2\}_3(thf)_3]$ (**6**), $[Y\{OCMe(CF_3)_2\}_3(Et_2O)_{0.33}]$ (**7**), $[Y\{OCMe(CF_3)_2\}_3$ (diglyme)] (**8**), $[Y\{OCMe(CF_3)_2\}_3(Bu^tOH)_3]$ (**9**), $[Y\{OCH(CF_3)_2\}_3(NH_3)_{0.5}]$ (**10**) and $[Y\{OCH(CF_3)_2\}_3(thf)_3]$ (**11**). Sublimation *in vacuo* is usually accompanied by loss of some of the neutral ligand, but **8** sublimes intact. Single-crystal X-ray structures of **6** and **8** showed that these mononuclear octahedral complexes have the facial configuration. ^{89}Y NMR chemical shifts were obtained for **2**, δ 93.66; **6**, 66.44; **8**, 78.63; and **11**, 82.78.

Recently we reported the synthesis and characterization of a number of tris-tertiary alkoxides of yttrium and lanthanum as part of a programme aimed at developing suitable precursors for depositing metal oxides by the MOCVD technique.[1]

Volatility in metal alkoxides, $[M(OR)_3]_x$, is usually limited because of their oligomeric nature ($x > 2$), which is caused by μ_2-OR of μ_3-OR bridges.[2] With tetravalent or pentavalent metals volatile mononuclear alkoxides, $M(OR)_4$ or $M(OR)_5$, are readily obtained by using tertiary butoxide ligands to prevent oligomerization by steric hindrance,[2] but with trivalent metals much bulkier (higher tertiary alkoxide) ligands are required. Thus, yttrium tert-butoxide was obtained as the trinuclear species $[Y_3(\mu_3\text{-}OBu^t)_2(\mu\text{-}OBu^t)_3(OBu^t)_4(Bu^tOH)_2]$, which could be sublimed (with loss of Bu^tOH) at 235°C/10^{-2} Torr and even with the very bulky OCMeEtPr^i ligand a dimer, $[Y_2(OCMeEtPr^i)_6]$, subliming at 170°C/10^{-3} Torr resulted.[1] In terms of enhancing volatility by increasing the bulk of the ligand, there is a trade-off between lowering the degree of oligomerization (x) and increasing the total number of atoms in the molecule. Thus, Lappert *et al.*[3] obtained mononuclear species, $M(OC_6H_2Bu^t_2\text{-}2,6\text{-}Me\text{-}4)_3$, by using the very bulky aryloxo ligand, but due to the large number of atoms in the molecule (one metal, three oxygens, 45 carbons and 69 hydrogens) the volatility was comparatively low (sublimes 250–260°C/10^{-3} Torr). In a further effort to enhance volatility we have explored the use of fluorinated alkoxide ligands. Thus, by replacing CH_3 groups by CF_3 groups we anticipated that three factors would be operating. Firstly there would be a small increase in bulkiness because the CF_3 group is slightly larger than CH_3; secondly the inductive effect of the electron attracting fluoro derivative will make the oxygen a weaker electron donor (e.g. pK_a values: Bu^tOH, 19.2; $C_4F_9{}^tOH$, 5.4) and thus a weaker bridging ligand; and thirdly the abnormally weak intermolecular forces between CF_3 groups would lower the enthalpy of vaporization.

† Present address: Department of Chemistry and Applied Chemistry, University of Wales—Cardiff, PO Box 912, Cardiff CF1 3TB, U.K.

Unfortunately, perfluoro-tert-butanol ($C_4F_9{}^tOH$) is not commercially available, so we were restricted to the use of three partially fluorinated alcohols; one secondary alcohol, $(CF_3)_2CHOH$ (hexafluoroisopropyl, hfip), and two tertiary alcohols, $(CF_3)(Me)_2COH$ (trifluoro-tert-butyl, tftb) and $(CF_3)_2MeCOH$ (hexafluoro-tert-butyl, htfb). Encouraged by our previous success in preparing yttrium tris-tert-alkoxides by the reaction of the tert-alcohol with the chloride-free three-coordinated silylamido-derivative $Y\{N(SiMe_3)_2\}_3$ [eq. (1)]

$$Y\{N(SiMe_3)_2\}_3 + 3R^tOH \longrightarrow Y(OR^t)_3 + 3(Me_3Si)_2NH \quad \textbf{(1)} \quad (1)$$

we adopted the same approach for the synthesis of the fluoroalkoxides. Some preliminary results on these and other metal fluoroalkoxides have already been published[4] and we now report full details.

RESULTS AND DISCUSSION

When the fluorinated alcohols R^tOH were added to $Y\{N(SiMe_3)_2\}_3$ the silylamide groups were completely replaced by fluoroalkoxides but the products obtained were sensitive to experimental details such as solvent and temperature and also depended on the acidity of the fluorinated alcohol. Besides the tris-fluoroalkoxides $[Y(OR^t)_3]_n$ a number of adducts, $\{Y(OR^t)_3\}_xLy$ (where L = NH_3, thf or Et_2O), were also obtained.

Trifluoro-tert-butoxides (tftb)

From the reaction of excess tftb.H with $Y\{N(SiMe_3)_2\}_3$ in benzene the tris-fluoroalkoxide $[Y(tftb)_3]_n$ (**1**) was obtained as a white solid (m.p. 118–120°C), which could not be sublimed *in vacuo* due to thermal decomposition. The ^1H NMR spectrum in C_7D_8 gave a single peak at 333 K (δ 1.49), which broadened and split at lower temperatures. At 253 K a five-line spectrum (δ 1.66, 1.58, 1.48, 1.37 and 1.24) with integral ratios 2 : 2 : 2 : 1 : 2 was obtained. At 233 K the ^{19}F spectrum also gave five lines in the ratios 1 : 2 : 2 : 2 : 2. These NMR spectra were consistent with a trinuclear species, $[Y_3(\mu_3\text{-}tftb)_2(\mu\text{-}tftb)_3(tftb)_4]$, having the same structure as that revealed by single-crystal X-ray analysis for $[Pr_3(tftb)_9]$.[4] This structure consists of a triangle of metal atoms capped by two μ_3-ligands and three bridging ligands distinguishable by symmetry into two types (ratio 2 : 1). One metal has two terminal ligands giving it a distorted octahedral configuration, whilst the other two, which are equivalent, each have one terminal ligand giving a five-coordinate configuration. In the praseodymium compound the X-ray structure showed that the five-coordinated metals were interacting intramolecularly at the vacant octahedral sites with fluorine from CF_3 groups and it is possible that this occurs in **1**.

When the reaction of tftb.H and the silylamide was performed in thf as the solvent, the product **2** obtained after crystallization from toluene had the composition $[Y(tftb)_3(thf)_{2.5}]$ and its ^1H NMR spectrum suggested that more than one species was present. When **2** was redissolved in thf and the excess solvent pumped off *in vacuo* the ^1H NMR spectrum of the residual solid corresponded to $[Y(tftb)_3(thf)_3]$. The NMR data can be interpreted on the basis that the tris-thf complex dissociates reversibly in toluene solution with the formation of a dimeric species, $[Y_2(\mu\text{-}tftb)_2(tftb)_4(thf)_4]$, as depicted in eq. (2).

$$2Y(tftb)_3(thf)_3 \Leftrightarrow Y_2(tftb)_6(thf)_4 + 2thf \quad (2)$$

The product **2** obtained by crystallization from toluene is thus a mixture of the two compounds shown in eq. (2).

Hexafluoro-tert-butoxides (hftb)

When hftb.H (3 mol) was added to $Y\{N(SiMe_3)_2\}_3$ (1 mol) in benzene a white precipitate formed, which redissolved on heating under reflux. The tris-fluoroalkoxide $[Y(hftb)_3]_n$ (**3**) crystallized out on cooling (m.p. 175–177°C) and in contrast to **1** it readily sublimed at 110–120°C/10^{-2} Torr. Unfortunately the low solubility of **3** precluded the collection of reliable NMR spectra, which might have provided structural information. If compound **3** is a dimer or trimer the alkoxide bridges must be very weak to allow such a high volatility compared with $[Y_3(OBu^t)_9(Bu^tOH)_2]$ (sublimed at 235°C/10^{-2} Torr) and $[Y_3(tftb)_9]$ (thermally unstable).

Refluxing yttrium silylamide (1 mol) with excess hftb.H (*ca* 4.5 mol) in benzene gave on cooling a crystalline product (**4**), which had the analysis for $[Y_2(hftb)_6(NH_3)]$. The presence of coordinated ammonia was confirmed by IR [ν(NH), 3396 and 1607 cm^{-1}) and ^1H NMR (δ 0.87) spectra, although the ratio of hftb : NH_3 in the ^1H NMR spectrum was closer to 3 : 1. Compound **4** sublimed at 105–110°C/10^{-2} Torr giving a sublimate with a hftb : NH_3 ratio of 3 : 1. Its mass spectrum gave a series of dinuclear fragmentations, $Y_2F_x(hftb)^+_{5-x}$ (x = 1–5).

Concerning the origin of the ammonia in **4** we presume it is formed in a side reaction involving

$(Me_3Si)_2NH$ liberated in the primary reaction [eq. (1)] and the excess of hftb.H which is acidic (pK_a 9.6), according to eq. (3).

$$2(CF_3)_2MeCOH + (Me_3Si)_2NH \longrightarrow NH_3 + 2Me_3SiOCMe(CF_3)_2 \quad (3)$$

Support for this hypothesis was given by an experiment in which $Y(hftb)_3$ was suspended in benzene to which hftb.H and $(Me_3Si)_2NH$ were than added. The $Y(hftb)_3$ slowly dissolved and after standing overnight the solution was stripped of volatiles *in vacuo* and the residue crystallized from toluene. Analysis of the product (**5**) showed it to be the tris-ammine $[Y(hftb)_3(NH_3)_3]$ [m.p. 130–135°C; ν(NH), 3408 and 1605 cm^{-1}; δ_H 0.63 (9H, NH_3), 1.39 (9H, $O(CH_3)(CF_3)_2$]. Compound **5** sublimed at 80–110°C/10^{-2} Torr with loss of ammonia giving a sublimate similar in properties to that obtained from **4**. The variable-temperature ^1H NMR spectra of **4** and **5** both suggested the presence of more than one species due to dissociation of weakly coordinated ammonia molecules. In view of the formation of the dimer $[Pr_2(hftb)_6(NH_3)_4]$, whose structure was established by single-crystal X-ray diffraction,[4] it is reasonable to suppose that yttrium forms an analogous compound which could be in equilibrium with **5** in solution [eq. (4)].

$$2Y(hftb)_3(NH_3)_3 \Leftrightarrow [Y_2(hftb)_6(NH_3)_4] + 2NH_3 \quad (4)$$

The sublimates obtained from **4** and **5** both gave complex ^1H and ^{19}F NMR spectra at low temperatures, which could be interpreted in terms of trinuclear complexes such as $[Y_3(hftb)_9(NH_3)_2]$ analogous to the known species $[Y_3(OBu^t)_9(Bu^tOH)_2]$ and $[Y_3(OBu^t)_9(thf)_2]$.[1]

When the reaction of $Y\{N(SiMe_3)_2\}_3$ with excess hftb.H was performed in thf solution instead of benzene the product was the tris-thf adduct $[Y(hftb)_3(thf)_3]$ (**6**), which could be crystallized from toluene. It is noteworthy that no ammine was formed under these conditions and it may be that reaction (3) only occurs if $Y(hftb)_3$ is available to complex the ammonia thus produced. When thf is present the stable complex (**6**) is formed because thf is a better ligand than ammonia. Compound **6** was established by elemental analysis, ^1H NMR spectroscopy and a single-crystal X-ray structure determination, which showed that the mononuclear octahedral complex existed as the facial isomer (Fig. 1).

Compound **6** readily sublimed at 110–120°C/10^{-2} Torr with loss of thf and the sublimate had a composition close to that of $[Y_2(hftb)_6(thf)]$ and was sparingly soluble in benzene. It readily dissolved in thf to reform $[Y(hftb)_3(thf)_3]$. The ^1H NMR spectrum of **6** in C_7D_8 at room temperature gave a single resonance for hftb (δ 1.56) and the two multiplets for thf (δ 1.43 and 3.69), but at low temperature (233 K) all three peaks were split (δ 1.13, 1.26, 1.63, 1.73, 3.48, 3.79) suggesting that more than one species was present. An obvious possibility is dissociation of thf giving either a five-coordinated complex, $[Y(hftb)_3(thf)_2]$, or the six-coordinated dimer $[Y_2(hftb)_6(thf)_4]$. The mass spectrum of **6** gave a series of fragment ions, $Y_2F_x(hftb)^+_{(5-x)}$ (x = 1–5), due to abstraction of fluoride by the yttrium, suggesting that loss of thf in the vapour leads to the formation of dinuclear $Y_2(hftb)_6$.

Treatment of $Y\{N(SiMe_3)_2\}_3$ with excess hftb.H in diethyl ether gave an etherate, which was crystallized from toluene as $[Y(hftb)_3(Et_2O)_x]$ (**7**). According to elemental analysis x = 1/3, but from the ^1H NMR spectrum x was closer to 1/2. Compound **7** readily sublimed at 75–100°C/10^{-2} Torr to form the unsolvated $[Y(hftb)_3]_n$ (**3**). Interestingly the mass spectrum of **7** was identical with those of **4** and **6**, which gave the dinuclear species $Y_2F_x(hftb)^+_{(5-x)}$ (x = 1–5).

Since diethyl ether is a weaker ligand than thf, it is not surprising that a tris-etherate was not obtained. Nevertheless, compound **7** proved to be the most volatile complex of $Y(hftb)_3$. Since the tris-thf complex readily lost thf when heated *in vacuo*, it was decided to try the potentially chelating tridentate ether ligand diglyme ($CH_3OCH_2CH_2OCH_2CH_2OCH_3$) in an attempt to prepare an adduct which was thermally stable. Excess diglyme was added to a suspension of $[Y(hftb)_3]_n$ (**3**) in toluene. Compound **3** rapidly dissolved and after concentrating the solution the 1 : 1 adduct $[Y(hftb)_3(diglyme)]$ (**8**) crystallized out. At 140–150°C/10^{-2} Torr compound **8** sublimed completely without loss of diglyme. Its mass spectrum gave the fragment ion $[Y(hftb)_2(diglyme)]^+$ and the species $[YF(hftb)(diglyme)]^+$, in both of which the diglyme remains coordinated to a mononuclear yttrium species. A single-crystal X-ray structure confirmed that **8** is an octahedral complex with facial configuration (Fig. 2).

In another experiment excess htfb.H was added to a solution of $[Y_3(OBu^t)_9(Bu^tOH)_2]$ in benzene. After removal of solvent and tertiary alcohols *in vacuo* the residue was crystallized from toluene giving compound **9**, which was characterized by elemental analysis and ^1H NMR as the tris-alcoholate $[Y(hftb)_3(Bu^tOH)_3]$ [ν(OH) 3572 cm^{-1}]. Compound **9** readily sublimed at 70–120°C/10^{-2} Torr with loss of tertiary alcohols (mainly Bu^tOH). Heating **9** *in vacuo* at 60°C until no more alcohol

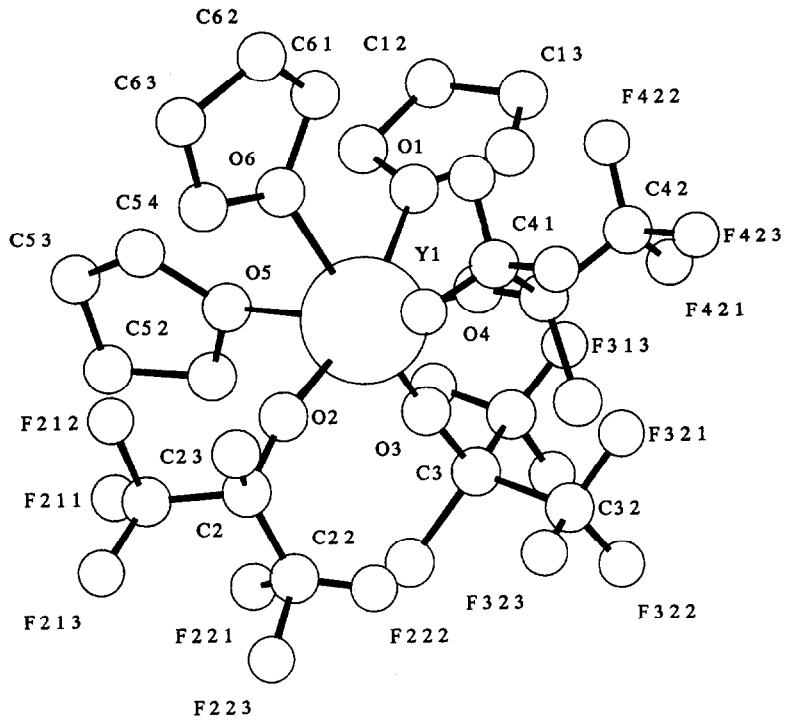

Fig. 1.

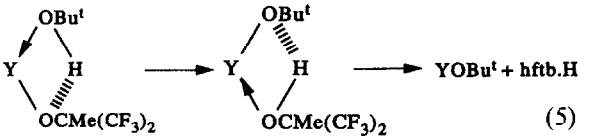
was released and then subliming the residue (110°C/10^{-2} Torr) gave a sublimate which had an analysis corresponding to $[Y_2(hftb)_5(OBu^t)]$.

Although the room-temperature ^1H NMR of **9** gave single peaks for OH (δ 3.13), hftb (δ 1.45) and Bu^tO (1.17) in the correct ratio for $[Y(hftb)_3(Bu^tOH)_3]$, low-temperature (213 K) spectra showed the presence of four OH resonances, three hftb and four Bu^tO resonances indicating a mixture of species. Similarly the ^{19}F NMR spectrum gave a single peak for hftb at room temperature, but split into four peaks (4:2:3:2 ratios) at 193 K.

In formulating compound **9** as $[Y(hftb)_3(Bu^tOH)_3]$ it is assumed that the more electronegative ligand $hftb^-$ is present as the covalently bonded anion in preference to Bu^tO^-. This complex could exist as facial or meridional isomers. In the latter the three hftb ligands have two which are equivalent and *trans* to each other and the third which is *cis* to the other two. Similarly the three Bu^tOH ligands will be distinguishable in a 2:1 ratio. Thus, at low temperatures a mixture of *fac* and *mer* isomers in the absence of fluxional interconversion might be expected to show six different hftb and Bu^tO peaks in the ^1H NMR spectrum and three hftb peaks in the ^{19}F NMR spectrum. Since the ^1H NMR gave seven and the ^{19}F NMR gave four it appears that other species must also be present. It is possible that some $[Y(hftb)_2(OBu^t)(hftb.H)(Bu^tOH)_2]$ is also present, which would give rise to even more isomeric species. One of the OH peaks (δ 6.27) at 213 K could well be due to coordinated hftb.H. Careful removal of coordinated alcohol (60°C/10^{-2} Torr) left a residual compound, whose analysis was close to that required for $[Y_2(hftb)_5(OBu^t)]$. However, it must be remembered that hftb.H (b.p. 60°C) is more readily evaporated *in vacuo* than Bu^tOH (b.p. 82°C) and the action of removing alcohol from **9** may promote the exchange of ligands [eq. (5)].



(5)

Treatment of **9** with thf caused the complete removal of coordinated Bu^tOH, leaving the previously established compound $[Y(hftb)_3(thf)_3]$ (**6**).

Hexafluoro-isopropoxides (hfip)

Although hexafluoro-isopropanol (hfip.H) is not a tertiary alcohol, it was of special interest in view of the fact that yttrium tris-isopropoxide was found to be unstable because of its facile breakdown to give the pentanuclear oxo-species $[Y_5(\mu_5\text{-}O)(\mu_3\text{-}OPr^i)_4(\mu\text{-}OPr^i)_4(OPr^i)_5]$.[6,7] It is very acidic (pK_a 9.3) compared with isopropanol (pK_a 17.1) and more volatile (b.p.: hfip.H, 59°C; Pr^iOH, 82°C).

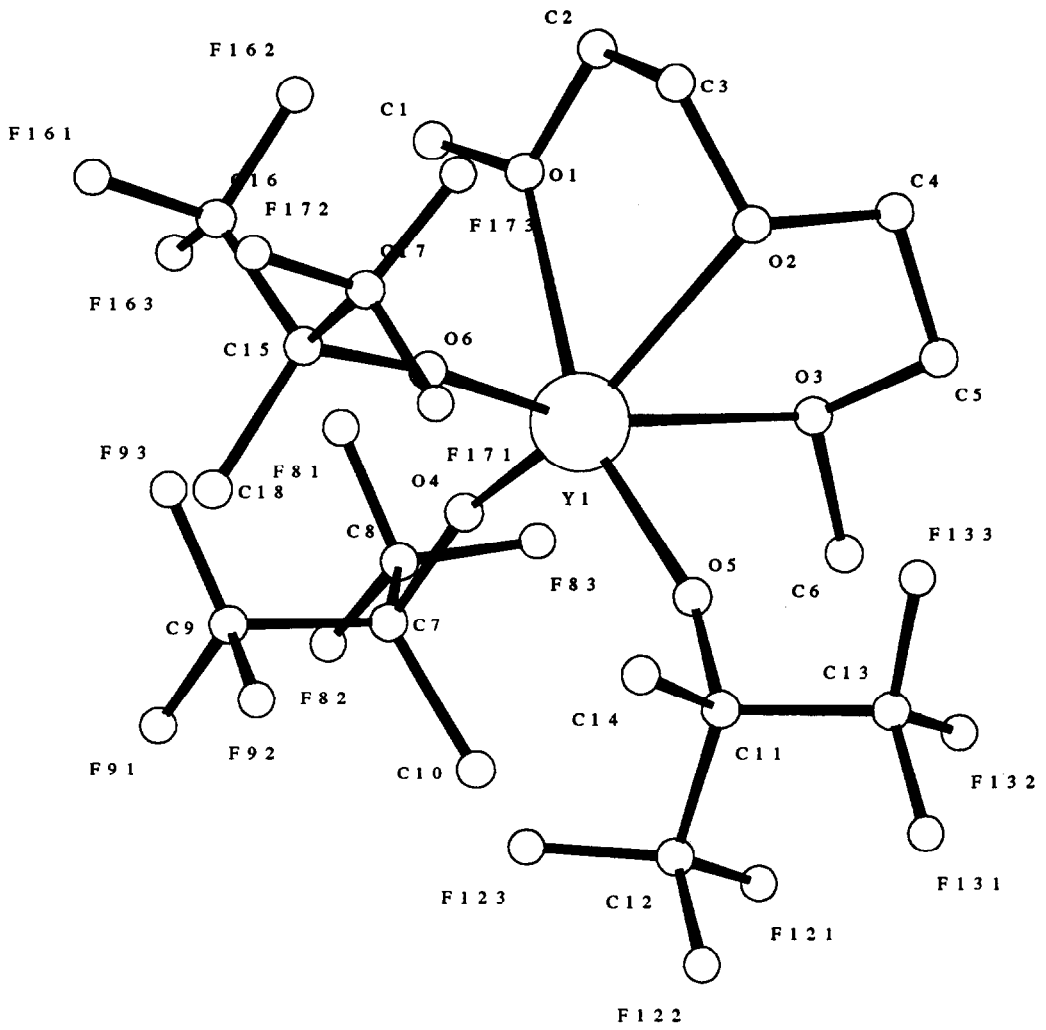


Fig. 2.

From the reaction involving excess hfip.H with $Y\{N(SiMe_3)_2\}_3$ in boiling benzene a product (**10**) crystallized out, which analysed as $[Y_2(hfip)_6(NH_3)]$. The presence of coordinated ammonia was confirmed by IR [ν(NH), 3652, 3394, 1618 cm^{-1}] and ^1H NMR (C_6D_6, δ 0.90, NH_3; 4.65 hfip) spectroscopy. In the mass spectrum peaks were observed corresponding to $[Y_2F_x(hfip)_{(5-x)}]^+$ ($x = 1$, 2 and 4), suggesting that dinuclear species were present in the vapour phase. The compound sublimed with decomposition at *ca* 140°C/10^{-2} Torr. The ammonia was doubtless formed by the side reaction of excess hfip.H with $(Me_3Si)_2NH$ liberated in the primary reaction. The composition of **10** was probably determined by the amount of excess hfip.H present, since according to eqs (1) and (3) an excess of 200% would be needed to convert all the $(Me_3Si)_2NH$ to ammonia, but only 40% excess was used in the experiment.

Mazdiyasni and Schaper[8] obtained the compound $[Y(hfip)_3(NH_3)_2]$ from the reaction of YCl_3 and hfip.H in the presence of excess ammonia, but we assume that it has the dinuclear structure $[Y_2(hfip)_6(NH_3)_4]$ by analogy with the corresponding scandium and praseodymium complexes, whose structures were determined by single-crystal X-ray diffraction analysis.[4]

The formation of ammine was completely suppressed when the reaction was performed in thf and the crystalline adduct $[Y(hfip)_3(thf)_3]$ (**11**) (m.p. 164–169°C) was obtained by crystallizing from toluene. The formula of **11** was confirmed by elemental analysis and ^1H NMR (C_7D_8; δ 4.68 sept. 3H, hfip; 3.74 m. 12H, thf; 1.44 m. 12H, thf) spectroscopy. Sublimation (90–130°C/10^{-2} Torr) occurred with loss of thf and the sublimate, which was sparingly soluble in benzene, had an analysis corresponding to $[Y(hfip)_3(thf)_{0.33}]$. The mass spectrum of **11** con-

tained peaks corresponding to the fragment ions $[Y_2(hfip)_6CF_3]^+$ and $[Y_2(hfip)_5]^+$. Although **11** behaved as a single species in the ^1H and ^{19}F NMR spectra at room temperature, at low temperature both ligands showed evidence of fluxional behaviour (e.g. broadening and splitting into two peaks). At 215 K the ^1H spectrum gave a ratio of 4:7 for the two species of hfip and at 189 K the ^{19}F spectrum gave a ratio of 2:3. Therefore, it appears that in solution either *fac/mer* isomerization or some dissociation of thf is occurring. Formation of a five-coordinate complex, $[Y(hfip)_3(thf)_2]$, or a six-coordinate dimer, $[Y_2(hfip)_6(thf)_4]$, are obvious possibilities as was suggested in the case of the hftb complex (**6**).

The structure of $[Y(hftb)_3(thf)_3]$ (**6**)

The single-crystal X-ray diffraction analysis of **6*** showed that this mononuclear complex has a distorted octahedral structure with the two sets of ligands disposed in the facial configuration (Fig. 1). Some bond lengths and angles relating to the core of the structure are given in Tables 1 and 2. The Y—O(hftb) bond distances (av. 2.10 Å) are notably shorter than those for Y—O(thf) (av. = 2.43 Å). This is as expected because the Y—O(hftb) bond involving the anionic ligand should be a stronger covalent bond than the Y—O(thf) coordinate bond. The very bulky hftb ligands would be expected on steric grounds to adopt the meridional arrangement and the actual adoption of the facial arrangement implies the operation of strong electronic interactions opposing the *mer* configuration. An obvious explanation would be the presence of considerable oxygen-to-metal π-donation from the oxygen lone pairs to the vacant *d*-orbitals (t_{2g}) of the d^0Y^{3+} ion. Both ligands could in principle be π-donors, but so long as one ligand type is a stronger π-donor than the other then the facial configuration will be favoured. If the hftb ligand is strongly π-donating its oxygen lone pairs then the $\widehat{YOC}$ should widen towards the limiting angle of 180°. Inspection of Table 2 shows that the angles are 167.7, 159.2 and 173.5°, which does suggest that π-donation is present. Although the inductive electronic effect of the electronegative CF_3 groups will reduce the donor capability of the oxygen (hftb.H is acidic) the short Y—O σ-bond will assist π-overlap. Turning to the coordinated thf ligands, it is noteworthy that the $\widehat{YOC}$s are all close to 120° (av. 123, 122 and 123° for each thf) and the $\widehat{COC}$s are around 111° so that the sum of the angles at each oxygen is close to 360° (358, 357 and 358°). Thus, the oxygens are in the trigonal planar configuration, which is required for π-donation to the yttrium. Although the structural evidence lends support to π-donation by both hftb and thf ligands it must be remembered that the bulky nature of the hftb ligands may cause distortions in the structure. Caulton *et al.*[5] have reported the structure of the complex $[Y(OSiPh_3)_3(thf)_3]$, which also adopts the facial configuration. The core structure of this complex is strikingly close in detail to that of **6** showing that replacement of hftb by $OSiPh_3$ makes little difference to bond lengths or angles.

Table 1. Some bond lengths (Å) for $[Y(hftb)_3(thf)_3]$ (**6**)

O(1)—Y(1)	2.428(11)	O(2)—Y(1)	2.123(11)

C(64)—O(6)	1.508(20)		

The structure of $[Y(hftb)_3(diglyme)]$ (**8**)

The single-crystal X-ray diffraction analysis of **8** showed it to be a distorted octahedral complex exhibiting the facial configuration (Fig. 2). The bond distances [Y—O(hftb) av. 2.06; Y—O(diglyme) av. 2.47 Å, Table 3] are very close to those found in **6**, as are also the angles $\widehat{YOC}$(hftb) of 160.3, 159.1 and 171.0° (Table 4). The replacement of three thf ligands by the tridentate diglyme has, therefore, had little effect on the structure and bonding of the hftb ligands. In the coordinated diglyme it is noteworthy that whilst O(1) is trigonal planar, the sum of the angles around O(2) and O(3) are 343°, suggesting that diglyme is less effective as a π-donor than thf.

Judging by the Y—O bond lengths [Y—O(thf) 2.43; Y—O(diglyme) 2.47 Å] it appears that diglyme is slightly less strongly bonded to yttrium than thf and, therefore, the greater stability of **8** to dissociation must be due to the chelate effect of diglyme coupled with its lower volatility than thf.

^{89}Y *NMR spectra*

In our previous work on the tertiary alkoxides of yttrium some ^{89}Y NMR data were obtained.[1] It

*The structure of **6** was reported in a preliminary communication[4] and all data have been deposited therein.

was noted that the chemical shifts for the octahedral trinuclear complexes $[Y_3(OBu^t)_9(Bu^tOH)_2]$ (δY 166.8) and $[Y_3(OAm^t)_9(Am^tOH)_2]$ (δY 199.1) were considerably downfield compared with the tetrahedral complexes, which appeared to be in the range δY 36.8–45.6. However, it was recently reported by Coan *et al.*[10] that the tetrahedral complex $[Y_2(OSiPh_3)_6]$ gave a chemical shift of 263.2 ppm, i.e. further downfield than the values for our octahedral complexes. We have now re-determined the spectra of the tetrahedral complexes and found that the values had been incorrectly identified due to "fold-over" of the spectra. The correct values (all in C_7D_8) are: $[Y_2(OCMe_2Pr^i)_6]$ (δ 249.04), $[Y_2(OCMeEtPr^i)_6]$ (δ 237.48) and $[Y_2(OCEt_3)_6]$ (δ 245.42). These values are clearly in the same region as found for $[Y_2(OSiPh_3)_6]$. It is noteworthy that the earlier chemical shifts for $[Y_5O(OPr^i)_{13}]$ reported by Poncelet *et al.*[7] were also shown by Coan *et al.*[10] to be in error due to fold-over. We have now determined the ^{89}Y chemical shifts of the new octahedral complexes of the fluorinated tertiary alkoxides. The following values were obtained: $[Y(tftb)_3(thf)_3]$ (δY 93.66), $[Y(hftb)_3(thf)_3]$ (δY 66.44), $[Y(hftb)_3(diglyme)]$ (δY 78.63) and $[Y(hfip)_3(thf)_3]$ (δY 82.78). These chemical shifts are considerably upfield compared with the octahedral complexes containing unfluorinated tertiary alkoxides. These data are collected together with some of Coan *et al.*'s[10] results in Table 5. The shift to higher fields caused by replacement of CH_3 groups by CF_3 in the tertiary butoxide complexes is evident.

CONCLUSIONS

This work has shown that volatile mononuclear octahedral complexes of yttrium can be synthesized using highly-fluorinated alkoxide ligands. In addition to the steric effect of tertiary alkoxides the electronegative effect of CF_3 groups destabilizes the alkoxide bridges and promotes the formation of stable adducts of the type $[Y(OR^1)_3L_3]$. However, the mass spectra of some of these compounds show evidence of fluorine abstraction by the yttrium under the conditions within the mass spectrometer.

EXPERIMENTAL

All manipulations were performed under dry nitrogen using vacuum-line, glove-box and Schlenk-style apparatus. Solvents were dried using the sodium ketyl of benzophenone and freshly distilled. The fluorinated alcohols (Fluorochem Ltd) were dried over molecular sieves and diglyme (Aldrich) was treated first with sodium then refluxed over CaH_2 (2 h) and finally distilled under reduced pressure. $Y\{N(SiMe_3)_2\}_3$ was prepared as previously described.[9]

NMR spectra were obtained using Bruker WM 250 FT and WH 400 FT spectrometers, using solvent signals from incomplete deuteration for ^1H

and ^{13}C chemical shifts which are quoted relative to TMS. Fluorine chemical shifts are relative to $CFCl_3$ and ^{89}Y chemical shifts are relative to YCl_3.

Mass spectra were obtained using a Kratos MS 50 TC mass spectrometer operating at 70 eV. IR spectra were obtained as Nujol mulls in the range 4000–200 cm^{-1} using a Perkin–Elmer FT 1720 spectrophotometer. Carbon, hydrogen and nitrogen analyses were obtained from the Microanalytical service, University College, London, or from B.M.A.C. Yttrium was determined gravimetrically as Y_2O_3.

Preparation of $[Y\{OCMe_2(CF_3)\}_3]_n$ (**1**)

To a suspension of $Y\{N(SiMe_3)_2\}_3$ (6.5 g) in benzene (180 cm^3) was added $Me_2(CF_3)COH$ (5.8 g) in benzene (40 cm^3), causing the solid to dissolve immediately. After standing overnight the solution was refluxed for a minute and the volatiles removed *in vacuo*. The residue was crystallized from toluene giving **1** (2.5 g, 46% yield, m.p. 118–120°C dec.). Found: Y, 19.0; C, 30.7; H, 3.9. Calc. for $Y\{OCMe_2(CF_3)\}_3$: Y, 18.9; C, 30.6; H, 3.9%. ^1H NMR ($C_6D_5CD_3$): at 333 K (δ 1.49); at 290 K (δ 1.59 br, 1.47, 1.31 br); at 253 K (δ 1.66, 2H; 1.58, 2H; 1.48, 2H; 1.37, 1H; 1.24, 2H). ^{13}C NMR (C_6D_6): δ 26.54. ^{19}F NMR ($C_6D_5CD_3$): ambient temperature (δ −74.70 br, −76.11 br, −78.28 br, −79.80, −80.08 br); at 233 K (δ −75.45, 1F; −74.76, 2F; −75.70, 2F; −80.91, 2F; −82.34, 2F). IR: 1710 vw, 1397 m, 1320 m, 1212 s, 1148 s, 1020 m, 989 m, 876 m, 799 w, 755 m, 616 m, 587 m, 516 m, 497 m, 482 m, 432 w, 404 w, 378 w, 289 w, 228 w cm^{-1}.

Preparation of $[Y\{OCMe_2(CF_3)\}_3(thf)_x]$ (**2**)

$(CF)_3Me_2COH$ (2.18 g) in thf (10 cm^3) was added to a solution of $Y\{N(SiMe_3)_2\}_3$ (2.80 g) in thf (100 cm^3) and left overnight. After removal of the volatiles *in vacuo* the residue was crystallized from toluene giving **2** (2.31 g, m.p. 115–121°C). Found: Y, 13.7; C, 40.1; H, 5.9. Calc. for $Y\{OCMe_2(CF_3)\}_3(thf)_{2.5}$: Y, 13.7; C, 40.6; H, 5.9%. ^1H NMR ($C_6D_5CD_3$): at 297 K [δ 3.72 m, 10H, (thf); 1.49 m, 10H (thf); 1.46, 18H (tftb)]; at 213 K [δ 3.59, 3.53 (thf); 1.68, 1.53 (tftb); 1.33, 1.32 (thf)]. ^{19}F NMR ($C_6D_5CD_3$): ambient temperature (δ −78.51, −81.29, −81.64, −82.04, −82.28 br, −82.58, −83.52); at 268 K (δ −78.58, −81.21, −81.58, −82.09, −82.20, −82.55, −83.20, −83.71). ^{89}Y NMR (thf-d_8): δ 93.66. IR: 1317 s, 1218 s, 1137 vs, 1029 s, 989 m, 921 m, 879 s, 755 m, 672 w, 611 s, 598 m, 482 m, 441 w, 373 m, 345 w, 286 s, 232 m, 222 s, 217 m cm^{-1}.

Compound **2** was redissolved in thf and the solvent pumped off *in vacuo*, leaving a solid residue of $[Y(thb)_3(thf)_3]$. ^1H NMR (C_6D_6): at 297 K (δ 3.73 m, 12H (thf); 1.49, 18H (tftb); 1.46 m, 12H (thf)]; at 213 K ($C_6D_5CD_3$) [δ 3.59 (thf); 1.62, 1.49, 1.48, (tftb); 1.38 (thf)]. Mass spectrum: *m/z*. Found: 871.0413. Calc. for $[Y_2(tftb)_6CF_3]$: 871.0390. Found: 812.9878. Calc. for $[Y_2(tftb)_5]$: 812.9971. Compound **2** was sublimed in small yield (*ca* 20%) at 105–110°C/10^{-2} Torr.

Preparation of $[Y\{OCMe(CF_3)_2\}_3]_n$ (**3**)

Addition of $(CF_3)_2MeCOH$ (2.98 g) in benzene (10 cm^3) to a solution of $Y\{N(SiMe_3)_2\}_3$ (3.11 g) in benzene (190 cm^3) caused immediate precipitation of a white solid which redissolved under reflux. On cooling the product **3** crystallized (2.94, 85% yield, m.p. 175–177°C). Found: Y, 14.3; C, 21.7; H, 1.3. Calc. for $Y\{OCMe(CF_3)_2\}_3$: Y, 14.1; C, 22.8; H, 1.4%. The compound was sparingly soluble in hydrocarbon solvents making NMR measurements unreliable. ^1H NMR (C_6D_6): at 323 K (δ 1.80, 1.54, 1.50, 1.39). IR: 1315 s, 1256 s, 1206 s, 1186 s, 1100 s, 1080 s, 1020 m, 995 m, 980 m, 965 m, 954 m, 866 m, 760 m, 701 s, 681 w, 658 w, 624 m, 534 m, 502 w, 455 w, 430 w, 305 w, 283 w, 227 m, 217 w.

Compound **3** sublimed at 110–120°C/10^{-2} Torr (m.p. 176–178°; Found: Y, 13.4; C, 22.3; H, 1.3%).

Preparation of $[Y\{OCMe(CF_3)_2\}_3(NH_3)_x]$ (**4**)

Addition of $(CF_3)_2MeCOH$ (7.0 g) in benzene (40 cm^3) to a solution of $Y\{N(SiMe_3)_2\}_3$ (5 g) in benzene (180 cm^3) caused a white precipitate which dissolved on warming. After refluxing for 2 h the solution was allowed to cool and deposited needle crystals of **4** (4.7 g; m.p. 108–130°C). Found: Y, 14.2; C, 21.9; H, 1.7; N, 1.2. Calc. for $[Y\{OCMe(CF_3)_2\}_3(NH_3)_{0.5}]$: Y, 13.9; C, 22.5; H, 1.6; N, 1.1%. ^1H NMR (C_6D_6): at 297 K [δ 1.37 (9H, hftb), 0.87 br (3H, NH_3)]. ^{19}F NMR ($C_6D_5CD_3$): at 333 K [δ −77.45 (1F), −78.55 br (3F), −79.37 (1F), −79.48 (6F)]. IR: 3396 w, 1607 w, 1309 s, 1260 s, 1171 s, 1077 s, 993 m, 979 m, 967 m, 865 m, 801 w, 759 m, 701 s, 688 m, 679 m, 656 w, 624 m, 535 m, 503 m, 458 m, 433 w, 384 w, 336 w, 295 w, 280 w, 230 w, 220 w, 215 w, 209 w cm^{-1}. Mass spectra: *m/z*. Found: 758.8275. Calc. for $Y_2F_2\{OCMe(CF_3)_2\}_3$: 758.8350. Found: 596.8282. Calc. for $Y_2F_3\{OCMe(CF_3)_2\}_2$: 596.8246. Found: 434.8177. Calc. for $Y_2F_4\{OCMe(CF_3)_2\}$: 434.8142. Found: 272.8045. Calc. for $[Y_2F_5]$: 272.8116. Found: 250.7975. Calc. for $[Y_2F_3O]$: 250.8019.

Compound **4** sublimed at 105–110°C/10^{-2} Torr (m.p. 125–130°C). Found: Y, 13.6; C, 21.7; H, 1.9; N, 1.7. Calc. for $[Y\{OCMe(CF_3)_2\}_3(NH_3)]$: Y, 13.7; C, 22.2; H, 1.9; N, 2.2%. ^1H NMR ($C_6D_5CD_3$): at 298 K [δ 1.47 (1H), 1.40 (3H), 1.38 (1H), 1.15 (4H)]: at 220 K (δ 1.54, 1.38 br, 0.85): at 333 K (δ 1.50, 1.38, 1.22 br, 0.92 br). ^{19}F NMR ($C_6D_5CD_3$): at 296 K [−77.45 (2F), −78.55 br (6F), −79.37 (2F), −79.62 (9F)]. IR: 3399 w, 1613 w, 1311 s, 1258 s, 1186 s, 1110 s, 1077 s, 977 m, 895 m, 865 m, 802 w, 760 m, 702 s, 629 m, 656 w, 618 m, 534 m, 503 m, 458 w, 384 m, 295 w, 280 m, 231 w cm^{-1}. Compound **4** was refluxed in thf and the volatiles removed *in vacuo*, leaving a residue of $[Y\{OCMe(CF_3)_2\}_3(thf)_3]$ (**6**).

Preparation of $[Y\{OCMe(CF_3)_2\}_3(NH_3)_3]$ (**5**)

To $[Y\{OCMe(CF_3)_2\}_3]_n$ (0.90 g) suspended in benzene was added $(Me_3Si)_2NH$ (1 cm^3) and $(CF_3)_2MeCOH$ (1.3 cm^3). The solid slowly dissolved and was left overnight before evaporating off the volatiles *in vacuo*, leaving a residue which was crystallized from toluene (**5**, 0.73 g, m.p. 130–135°C). Found: Y, 12.1; C, 20.5; H, 2.4; N, 5.4. Calc. for $[Y\{OCMe(CF_3)_2\}_3(NH_3)_3]$: Y, 13.0; C, 21.1; H, 2.6; N, 6.1%. ^1H NMR ($C_6D_5CD_3$): at 297 K [δ 1.39 (9H, hftb), 0.63 br (9H, NH_3)]: at 228 K (major peaks, δ 1.49, 0.28 br; minor peaks, 1.42, 1.16, 0.46). ^{19}F NMR ($C_6D_5CD_3$): δ −79.96. IR: 3408 m, 1605 w, 1306 s, 1202 s, 1110 s, 1072 s, 978 m, 857 m, 762 w, 700 s, 672 m, 614 w, 535 m, 458 w, 379 w, 328 w, 294 w, 284 w, 259 w, 250 w, 240 w, 228 w, 216 w cm^{-1}.

Compound **5** sublimed with loss of NH_3 at 80–110°C/10^{-2} Torr (m.p. 128–136°C). ^1H NMR ($C_6D_5CD_3$): at 297 K [δ 1.45 (1H), 1.39 (3H), 1.36

(1H), 1.28 (4H) (hftb); 0.89 br (3H) (NH_3)]; at 233 K (δ 1.58, 1.50, 1.40, 1.25, 1.17, 0.93, 0.77, 0.49). IR: 3669 w, 3405 w, 1614 w, 1310 s, 1260 s, 1186 s, 1109 s, 1077 s, 978 m, 864 m, 864 m, 800 m, 761 m, 701 s, 674 m, 616 m, 535 m, 502 m, 456 w, 384 m, 295 w, 280 m, 253 w, 228 m.

Preparation of $[Y\{OCMe(CF_3)_2\}_3(thf)_3]$ (**6**)

To a solution of $Y\{N(SiMe_3)_2\}_3$ (3.91 g) in thf (100 cm^3) was added $(CF_3)_2MeCOH$ (4.5 g) and the solution left overnight. After removal of volatiles *in vacuo* the residue was crystallized from toluene **6** (5.67 g, 98% yield, m.p. 164–182°C). Found: Y, 10.6; C, 33.7; H, 4.0. Calc. for $[Y\{OCMe(CF_3)_2\}_3(thf)_3]$: Y, 10.5; C, 34.0; H, 3.9%. ^1H NMR ($C_6D_5CD_3$): at 297 K [δ 3.69 m (12H, thf); 1.56 (9H, hftb); 1.43 m (12H, thf)]; at 233 K [major peaks: 3.48 m (thf), 1.73 (hftb), 1.26 m (thf); minor peaks: 3.79 m, 1.63, 1.13]. ^{19}F NMR ($C_6D_5CD_3$): at 297 K (δ −74.65); at 203 K (−74.32 plus a small peak at −74.09). ^{89}Y NMR (thf): δ 66.44. IR: 1306 s, 1223 s, 1186 s, 1111 s, 1078 s, 1024 s, 977 s, 925 m, 871 s, 800 w, 761 w, 701 s, 671 m, 614 m, 533 m, 497 m, 380 m, 368 m, 332 w, 291 m, 280 m, 265 m, 227 m, 217 m cm^{-1}. Mass spectra: *m/z*. Found: 920.8556. Calc. for $[Y_2F\{OCMe(CF_3)_2\}_4]$: 920.8454. Found: 758.8436. Calc. for $[Y_2F_2\{OCMe(CF_3)_2\}_3]$: 758.8350. Found: 596.8285. Calc. for $[Y_2F_3\{OCMe(CF_3)_2\}_2]$: 596.8246. Found: 434.8157. Calc. for $[Y_2F_4\{OCMe(CF_3)_2\}]$: 434.8142. Found: 272.8045. Calc. for $[Y_2F_5]$: 272.8116. Found: 250.7997. Calc. for $[Y_2F_3O]$: 250.8019.

Compound **6** sublimed with loss of thf at 110–120°C/10^{-2} Torr (m.p. 170–175°C). Found: Y, 13.2; C, 24.9; H, 2.0. Calc. for $[Y_2(hftb)_6(thf)]$: Y, 13.3; C; 25.2; H, 2.0%. The sublimate was sparingly soluble in benzene giving a poor ^1H NMR spectrum (C_6D_6) (δ 3.81 m and 1.39 m, thf; 1.74 br, 1.44, 1.24, 0.97 br, hftb). The sublimate dissolved in thf and reformed complex **6**.

Preparation of $[Y\{OCMe(CF_3)_2\}_3(Et_2O)_x]$ (**7**)

$(CF_3)_2MeCOH$ (3.75 g) was added to a solution of $Y\{N(SiMe_3)_2\}_3$ (2.83 g) in diethyl ether (150 cm^3) and the solution left overnight. After removing the volatiles *in vacuo* the residue was crystallized from toluene (**7**, 2.97 g, m.p. 126–132°C). Found: Y, 13.7; C, 23.7; H, 1.9. Calc. for $[Y\{OCMe(CF_3)_2\}_3(Et_2O_{0.33}]$: Y, 13.5; C, 24.4; H, 1.9%. ^1H NMR (C_6D_6): at 297 K [δ 3.51 q (4H, Et_2O—CH_2); 1.40 (18H, hftb); 0.98 t (6H, Et_2O—CH_3)]; in ($C_6D_5CD_3$) at 297 K [δ 3.45 q (4H, Et_2O—CH_2); three overlapping broad peaks at 1.41, 1.35 and 1.27 (18H, hftb); 0.99 t (6H, Et_2O—CH_3)]; at 253 K (3.24 q, 1.37, 1.11 t, 0.94). ^{19}F NMR ($C_6D_5CD_3$): at 320 K [−73.14, −74.23, −74.80 br (major peak), −75.41]; at 283 K [−73.13, −74.22 br, −75.07, −75.28]; at 203 K [−72.25 (1F), −72.51 (3F), −73.02 (9F), −73.67 (4F), −73.90 (4F), −74.49 (14F), −74.86 (3F), −75.62 (4F)]. IR: 1314 s, 1259 s, 1175 s, 1079 s, 1042 m, 994 m, 976 m, 954 m, 889 w, 865 m, 799 m, 784 m, 761 m, 702 s, 676 w, 656 w, 619 m, 536 m, 499 m, 454 w, 434 w, 381 m, 281 m, 227 m, 213 m cm^{-1}. Mass spectra: *m/z*. Found: 920.8581. Calc. for $[Y_2F\{OCMe(CF_3)_2\}_4]$: 920.8454. Found: 758.8373. Calc. for $[Y_2F_2\{OCMe(CF_3)_2\}_3]$: 758.8350. Found: 596.8242. Calc. for $[Y_2F_3\{OCMe(CF_3)_2\}_2]$: 596.8246. Found: 434.8131. Calc. for $[Y_2F_4\{OCMe(CF_3)_2\}]$: 434.8142. Found: 272.8030. Calc. for $[Y_2F_5]$: 272.8116. Found: 250.8004. Calc. for $[Y_2F_3O]$: 250.8019.

Compound **7** sublimed at 75–100°C/10^{-2} Torr (m.p. 120–150°C). Found: Y, 13.8; C, 22.1; H, 1.5. Calc. for $Y\{OCMe(CF_3)_2\}_3$: Y, 14.1; C, 22.8; H, 1.4%. ^1H NMR (C_6D_6): at 297 K (δ 1.72, 1.48, 1.42 br, 1.38, 1.26, 0.98 br). IR: 1314 s, 1191 s, 1117 s, 1088 s, 1037, 990 m, 962 m, 869 m, 802 m, 768 m, 761 m, 703 s, 692 m, 653 w, 617 m, 536 m, 501 m, 454 w, 438 w, 381 m, 337 w, 322 w, 296 m, 278 m, 226 m, 219 m, 213 m cm^{-1}. The sublimate was sparingly soluble in hydrocarbon solvents.

Preparation of $[Y\{OCMe(CF_3)_2\}_3(diglyme)]$ (**8**)

Diglyme (3 cm^3) was added to a suspension of $[Y\{OCMe(CF_3)_2\}_3]_n$ (3.41 g) in toluene (100 cm^3) and the solid rapidly dissolved. The solution was concentrated to approximately 50 cm^3 and the product crystallized out (3.42 g, m.p. 201–204°C). Found: Y, 11.7; C, 27.7; H, 2.9. Calc. for $[Y\{OCMe(CF_3)_2\}_3(diglyme)]$: Y, 11.6; C, 28.2; H, 3.0%. ^1H NMR ($C_6D_5CD_3$): at 297 K [δ 3.27 s (6H, CH_3-diglyme); 3.08 m (4H, CH_2-diglyme); 2.90 m (4H, CH_2-diglyme); 1.60 s (9H, hftb)]; at 203 K [3.23 (CH_3-diglyme), 3.28 sh, 2.97 (CH_2-diglyme), 2.32, 2.25 (CH_2-diglyme); 1.69 (hftb)]; at 183 K [3.26, (CH_3-diglyme); {3.12, 3.00, 2.92, 2.88 (CH_2-diglyme)}; {2.26, 2.19 (CH_2-diglyme)}; 1.71, 1.69 (hftb)]. ^{19}F NMR ($C_6D_5CD_3$): at 297 K (δ −79.42); at 194 K (δ −78.14, −78.94, −79.20). ^{89}Y NMR (C_7D_8/diglyme, 2:3 v/v): δ 78.63. IR: 1305 s, 1176 s, 1110 s, 1077 s, 1045 s, 1008 s, 978 s, 931 m, 864 s, 834 m, 809 w, 762 m, 701 s, 675 m, 615 m, 533 m, 499 m, 382 m, 368 m, 332 w, 282 s, 261 m, 222 s, 217 m cm^{-1}. Mass spectra: *m/z*. Found: 585.0175. Calc. for $[Y\{OCMe(CF_3)_2\}_2$

(diglyme)]: 585.0175. Found: 423.0090. Calc. for [YF{OCMe$(CF_3)_2$}(diglyme)]: 423.0074.

Compound **8** completely sublimed at 140–150°C/10^{-2} Torr (m.p. 199–203°C). ^{1}H NMR (C_6D_6): at 297 K [δ 3.29 s (6H, CH_3-diglyme); 3.00 t (4H, CH_2-diglyme); 2.84 t (4H, CH_2-diglyme); 1.67 s (9H, hftb)]. IR spectrum identical with **8**.

Preparation of [Y{OCMe$(CF_3)_2$}$_3$($Bu^tOH)_3$] (**9**)

$(CF_3)_2$MeCOH (3.75 g) was added to a solution of [$Y_3(OBu^t)_9(Bu^tOH)_2$] (1.42 g) in benzene (80 cm^3) and the solution kept at room temperature overnight. After refluxing for 0.5 h the volatiles were removed *in vacuo*, leaving a residue which was crystallized from toluene (**9**, 2.97 g, m.p. 174–184°C). Found: Y, 10.7; C, 32.4; H, 4.1. Calc. for [Y{OCMe$(CF_3)_2$}$_3$($Bu^tOH)_3$]: Y, 10.4; C, 33.7; H, 4.6%. ^{1}H NMR ($C_6D_5CD_3$): at 298 K [δ 3.13 (3H, OH); 1.45 (9H, hftb); 1.17 (27H, Bu^tO)]; at 213 K [6.27 (1H), 4.46 (1H), 4.04 (1H), 3.70 (2H) OH; 1.60 (12H), 1.52 (6H), 1.27 (6H) (hftb); 1.12 sh, 1.11 (45H), 1.04 (18H), 0.94 (18H)]. ^{19}F NMR ($C_6D_5CD_3$): at 293 K (δ −78.59); at 233 K [−78.03 (11F); −78.54 (4F); −78.74 br (3F)]; at 203 K [−77.78 (2F): −78.19 br (1F); −78.44 br (3F)]; at 193 K [−77.71 (4F); −78.11 (2F); −78.33 (3F); −78.39 (2F)]. IR: 3572 m, 1307 s, 1191 s, 1110 s, 1077 s, 1025 m, 975 m, 882 m, 860 m, 803 w, 762 w, 749 m, 702 s, 674 m, 615 w, 533 w, 498 m, 441 w, 382 m, 279 w, 233 w, 223 w, 214 w cm^{-1}.

Compound **9** sublimed with loss of alcohol at 70–120°C/10^{-2} Torr. When **9** was heated at 60°C *in vacuo* until all the coordinated alcohol had been removed the residue sublimed at 110°C/10^{-2} Torr. Found: Y, 15.2; C, 25.1; H, 2.4. Calc. for [Y_2{OCMe$(CF_3)_2$}$_5$(OBu^t)]: Y, 15.4; C, 24.9; H, 2.1%. The sublimate was sparingly soluble in hydrocarbon solvents rendering the NMR measurements unreliable. ^{1}H NMR (C_6D_6): at 298 K [δ 1.49, 1.40 (hftb); 1.12 (OBu^t) approximate ratio hftb: OBu^t, 4:3]. The mixture of alcohols [δ 5.80 (OH), 1.32 sept (hftb); 1.47 (OH), 1.04 (Bu^tO)] pumped off (**9**) appeared to be in the ratio Bu^tOH: hftb.H = 2:1. Found: C, 45.5; H, 7.8. Calc.: C, 43.6; H, 7.9%.

Preparation of [Y{OCH$(CF_3)_2$}$_3$($NH_3)_x$] (**10**)

Addition of $(CF_3)_2$CHOH (6.8 g) in benzene (40 cm^3) to a solution of Y{$N(SiMe_3)_2$}$_3$ (5.5 g) in benzene (180 cm^3) caused immediate precipitation. The precipitate dissolved under reflux (2 h) and on cooling gave a crystalline product (**10**, 4.5 g, m.p. 108–109°C). Found: Y, 15.1; C, 17.3; H, 0.8; N, 1.1. Calc. for [Y_2{OCH$(CF_3)_2$}$_6$(NH_3)]: Y, 14.8; C, 18.1; H, 0.7; N, 1.2%. Compound **10** was sparingly soluble in hydrocarbon solvents, which caused problems in obtaining reliable NMR measurements. ^{1}H NMR (C_6D_6): at 298 K [(δ 4.65 m (hfip); 0.90 (NH_3)]. ^{19}F NMR ($C_6D_5CD_3$): at 296 K [δ −75.91 d (J = 4.2 Hz)]; at 213 K [δ −75.42 d (J = 5.7 Hz)]. IR: 3652 w, 3394 w, 3312 w, 1667 w, 1618 w, 1293 s, 1218 s, 1105 s, 1054 m, 978 w, 890 s, 850 s, 746 s, 690 s, 673 w, 642 w, 536 m, 520 m, 494 w, 455 m, 375 m, 311 m, 292 m, 250 w, 240 w cm^{-1}. Mass spectra: *m/z*. Found: 864.8803. Calc. for [Y_2F{OCH$(CF_3)_2$}$_4$]: 864.7829. Found: 716.7297. Calc. for [Y_2F_2{OCH$(CF_3)_2$}$_3$]: 716.7881. Found: 420.7029. Calc. for [Y_2F_4{OCH(CF_3)}$_2$]: 420.7986.

Compound **10** sublimed with decomposition at 140°C/10^{-2} Torr. It dissolved in thf to form the tris-thf complex (**11**) [^{1}H NMR (thf-d_8) at 298 K, δ 4.72 sept (hfip)].

Preparation of [Y{OCH$(CF_3)_2$}$_3$(thf)$_3$] (**11**)

$(CF_3)_2$CHOH (3.78 g) in thf (10 cm^3) was added to a solution of Y{$N(SiMe_3)_2$}$_3$ (3.8 g) in thf (90 cm^3) and left overnight before removing the volatiles *in vacuo*. The residue was crystallized from toluene (**11**, 4.23 g, 80% yield, m.p. 164–169°C). Found: Y, 11.0; C, 31.2; H, 3.3. Calc. for [Y{OCH$(CF_3)_2$}$_3$(thf)$_3$]: Y, 11.0; C, 31.3; H, 3.4%. ^{1}H NMR ($C_6D_5CD_3$): at 297 K [δ 4.68 sept (3H, hfip); 3.74 m (12H, thf); 1.44 m (12H, thf)]; at 215 K [4.90 (4H) 4.72 (7H) (hfip); 3.67 (32H) 3.46 (15H) (thf); 1.38 (15H) 1.31 (33H) (thf)]. ^{19}F NMR ($C_6D_5CD_3$): at 298 K (δ −77.6 d; J = 7.1 Hz); at 235 K (δ −76.99 br); at 216 K [(−76.86 br (5F); −77.20 br (2F)]; at 189 K [−76.56 br (2F); −77.14 d (J = 4.7 Hz) (3F)]. ^{89}Y NMR (thf): δ 82.78. IR: 1291 s, 1211 s, 1178 s, 1092 s, 1025 s, 928 m, 885 s, 843 s, 742 s, 686 s, 655 m, 528 m, 369 m, 333 w, 281 m, 212 m cm^{-1}. Mass spectra: *m/z*. Found: 871.0413. Calc. for [Y_2{OCH$(CF_3)_2$}$_6$$CF_3$]: 871.0390. Found: 812.9878. Calc. for [Y_2{OCH$(CF_3)_2$}$_5$]: 812.9971.

Compound **11** sublimed with loss of thf at 90–130°C/10^{-2} Torr (m.p. 148–160°C). Found: Y, 14.2; C, 20.4; H, 0.8. Calc. for [Y{OCH$(CF_3)_2$}$_3$(thf)$_{0.33}$]: Y, 14.5; C, 20.2; H, 0.9%. Due to the sparing solubility of the sublimate it was difficult to obtain a reliable NMR spectrum. ^{1}H NMR (C_6D_6): at 297 K [δ 4.91 br (1H, hfip); 3.79 m (2H, thf); 1.23 m (2H, thf)]. IR: 1295 s, 1228 s, 1180 s, 1095 s, 1008 m, 890 s, 848 s, 745 s, 688 s, 521 m, 446 m, 374 m, 354 w, 289 m, 224 w, 218 w cm^{-1}.

X-ray crystallography

The crystal structure of $[Y\{OCMe(CF_3)_2\}_3(thf)_3]$ (**6**) has already been reported[4] and all supplementary data have been deposited with the Cambridge Crystallographic Data Centre.

$[Y\{OCMe(CF_3)_2\}_3(diglyme)]$ (**8**). A single crystal was grown from toluene solution and X-ray measurements were made using a CAD 4 diffractometer operating in the $\omega/2\theta$ mode with graphite-monochromated Mo-K_α radiation.

Details of the crystal data, intensity measurements and structure refinement are given in Table 6.

(*Received* 22 *February* 1993; *accepted* 2 *April* 1993)

Abstract—The reaction of (η^5-cyclopentadienyl)(η^4-tetraphenylcyclobutadiene)cobalt (**1**) with excess $Cr(CO)_6$ leads to four identified heterometallic compounds. They are compounds **2**, **3** (**3′** and **3″**) and **4** with one, two, and three phenyl ring(s) being complexed with $Cr(CO)_3$ fragment(s), respectively. Compounds **3′** and **3″** are two structural isomers with two arene $Cr(CO)_3$ groups in the *trans* and *cis* positions, respectively. These compounds were characterized by mass, IR, E.A. and ^1H and ^{13}C NMR spectra. The X-ray crystal structure of **3′** has been determined and can be regarded as three metals linked by three connected π-rings. It shows that two $Cr(CO)_3$ complexed phenyl rings are about parallel to the cyclobutadiene ring which causes the downfield shift of the Cp signal of **3′** in the ^1H NMR spectrum. Steric effects are more important than electronic effects in **3′** in the interpretation of the geometry of the two arene$Cr(CO)_3$ fragments.

The applications of arene$Cr(CO)_3$ in organic synthesis are well known and numerous derivatives of arene$Cr(CO)_3$ compounds have been made.[1] However, examples of the synthesis of mixed-metal compounds through bridging π-rings are rare.[2] We know that the heteronuclear metal complexes offer the chance to observe cooperative effects of the different metal centres when the metals are held in close proximity by bridging ligands.[3] The cooperative effect should be enhanced through directly joined π-rings. Therefore, it was of interest to prepare this type of compound and examine their physical and chemical properties.

(η^5-Cyclopentadienyl)(η^4-tetraphenylcyclobutadiene)cobalt (**1**) is a sandwich-like compound with four phenyl rings attached to four carbons of the cyclobutadiene ring. It has four active sites, four phenyl groups, for metal π-complexation. The dihedral angle between each phenyl and the cyclobutadiene ring is around 50–60°.[4] It seems that the space between the phenyl rings is too small to accommodate any $Cr(CO)_3$ fragment without significant structural change of **1**. It was therefore of interest to study the possibility of incorporating metal fragment(s) into phenyl rings and to monitor the structural change and effects caused. We now report the preparation of **2**, **3** (**3′** and **3″**) and **4** and the crystal structure of **3′**, which contains mixed metals through the directly joined π-rings.

RESULTS AND DISCUSSION

The reaction of **1** with $Cr(CO)_6$ in dibutyl ether in the presence of a small amount of THF resulted in attachment of $Cr(CO)_3$ fragments to the phenyl groups (Scheme 1).

The yields of **2**, **3′**, **3″** and **4** are 44.2%, 14.0%, 7.3% and 10.8%, respectively. Compounds **3′** and **3″** are structural isomers (Fig. 1). They are both orange and very close in R_f values (0.21 for **3″**, 0.19

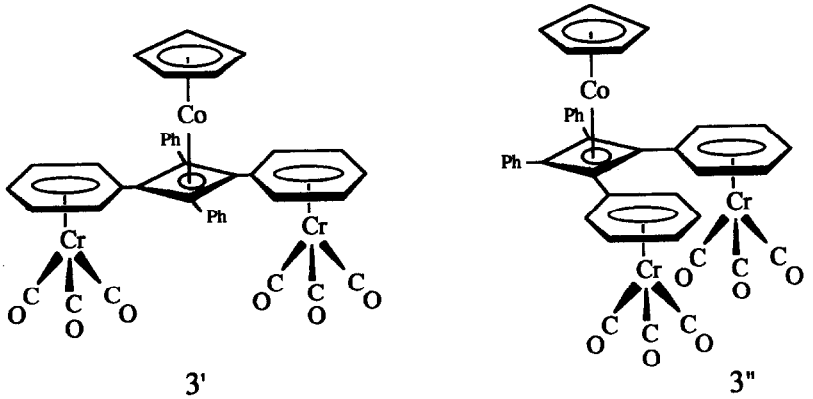
for **3'** in CH_2Cl_2/hexanes = 1 : 1). A slight difference in solubilities makes the separation of these two isomers by CTLC possible; **3"** was eluted first before **3'**. The fact that the yield of **3'** is higher than **3"** is reasonable from the viewpoint of steric effects.

Compound **3'** was crystallized by diffusing CH_2Cl_2 from the solution to the toluene and dark red crystals were obtained. The crystal data of **3'** shows that the dihedral angles between the $Cr(CO)_3$ complexed phenyl rings and cyclobutadiene ring are around 10° (Fig. 2 and Table 3). This is a significant structural change compared with that of **1**. The change in structure might help in releasing the tension between areneCr(CO)$_3$ and non-complexed phenyl rings. Also, the downfield shift of the Cp in ^{1}H NMR from 4.63 in **1** to 4.89 in **3'** can be attributed to this structural change. It can be explained by a better overlap between the cyclobutadiene ring and the two $Cr(CO)_3$ complexed phenyl rings through π-interaction (Fig. 3). By that process the two $Cr(CO)_3$ complexed phenyl rings may donate more electron density to the electron-withdrawing cyclobutadiene ring and then to the Cp ring that causes the downfield shift. It is also supported by the fact that a sequential downfield shift from **2** to **3** to **4** with more $Cr(CO)_3$ complexed **1** (**2**: 4.76, **3'**: 4.89, **3"**: 4.93, **4**: 5.05). ^{1}H NMR also shows an obvious upfield shift for the phenyl ring(s) of arene-$Cr(CO)_3$ and the almost unaffected phenyl group(s) in the same molecule, which is consistent with the well-known observations.[5]

The two $Cr(CO)_3$ fragments are pointed in different directions from the CoCp fragment in **3'**, which might avoid the repulsion between $Cr(CO)_3$ and CoCp. The dihedral angle between cyclobutadiene and one of the non-complexed phenyls, 75.9°, is larger than that in **1**. This might also help to relieve the tension between the phenyl and the $Cr(CO)_3$ fragment. The bond lengths of four cyclobutadiene carbon–carbon bonds in the planar cyclobutadiene ring is about the same, which is around 1.46 Å. The Cp and C_4 rings are almost coplanar [dihedral angle 1.9°]. Compound **3'** can be regarded as three metal fragments that are linked



3' 3"

by a 6–4–6 conjugated π–π ring system, which is rare according to the literature.

Hunter pointed out that the planarity of the arene ring can be distorted by a substituent.[6] An inward distortion, $\delta d < 0$, will take place when the substituent is an electron-withdrawing group. On the other hand, an outward distortion, $\delta d > 0$, is expected for an electron-donating substituent.[7] The above rule is obeyed unless a very bulky substituent is present. The cyclobutadiene ring is an electron-withdrawing group due to its tendency of aromaticity with six π-electrons. It is also supported by the fact that the positive values of $\Delta\pi$ in the ^{13}C NMR spectrum of the η^6-complexed phenyl group (2.04 ppm for **2**, 1.72 ppm for **3′**, 1.66 and 1.36 ppm for **3″**, 2.946, 0.285 and 0.294 ppm for **4**) were observed. According to Hunter, a positive $\Delta\pi$ in ^{13}C NMR indicates that the substituent, a C_4 ring, is an electron-withdrawing group.[8] However, in our case a slightly outward distortion is observed, even though an electron-withdrawing group (C_4 ring) is attached to the arene$Cr(CO)_3$ ring (Table 2). This opposite result to the above rule strongly suggests that the steric effect is more important than the electronic effect in this case. An inward distortion will not be favoured for the strong steric interaction between $Cr(CO)_3$ and the rest of the molecular fragment.

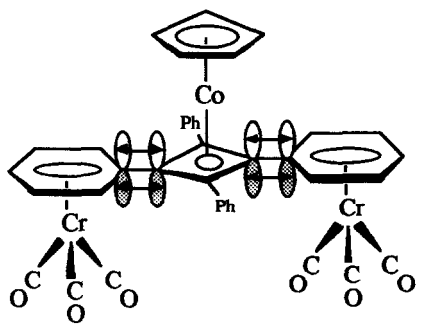

Fig. 3. The enhancement of interaction through the overlap of *p*-orbitals in the π-rings.

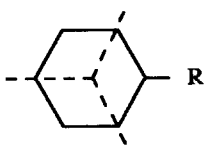
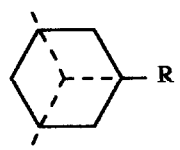
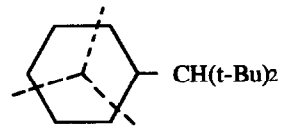
The orientation of $Cr(CO)_3$ in arene$Cr(CO)_3$ has been the subject of extensive studies. An *anti*-eclipsed form is observed for arene$Cr(CO)_3$ with an electron-withdrawing substituent. On the other hand, a *syn*-eclipsed form is observed for arene-$Cr(CO)_3$ with an electron-donating substituent.[9] However, it will be distorted to a nearly staggered structure when the substituent is very bulky. In the structure of (1′-t-butyl-2′,2′-dimethylpropyl)-π-(tricarbonylchromium)benzene the chromium carbonyl group was found to eclipse 44° away from its expected *syn*-eclipsed form due to its bulky substituent.[10] It is about 30° in **3′** for both arene-



anti-eclipse



syn-eclipse



1'-t-butyl-2',2'-dimethylpropyl)-π-(tricarbonylchromium)benzene

$Cr(CO)_3$ fragments. This result also supports the observation that arene$Cr(CO)_3$ is attached by a very bulky, even though electron-withdrawing, group in **3'**.

Compound **4** was obtained in a reasonable amount. It is interesting to find that three $Cr(CO)_3$ fragments are able to insert into the already crowded area. In a related case Grimes was only able to place two $Cr(CO)_3$ fragments into a carborane, nido-2,3-$(PhCH_2)_2C_2B_4H_6$, even though four phenyl groups and more room are available in that compound.[11]

EXPERIMENTAL

Preparation of (η^5-C_5H_5)(PPh_3)Co(C_4Ph_4)

The synthesis of the title compound was patterned on the procedure in the literature.[12]

Preparation of **1**, (η^5-C_5H_5)Co(C_4Ph_4)

By refluxing (η^5-C_5H_5)(PPh_3)Co(C_4Ph_4) in toluene for 12 h one may obtain a quantitative yield of the title compound.

Apparatus and materials

All operations were performed in a nitrogen-flushed glove-box or in a vacuum system. Freshly distilled solvents were used. All processes of separation of the products were performed by Centrifugal Thin Layer Chromtography (CTLC), Chromatotron, Harrison model 8924. ^1H and ^{13}C NMR spectra were recorded on a Varian-300 spectrometer at 300 and 75.46 MHz, respectively. Chemical shifts are reported in ppm downfield from internal TMS. IR spectra were recorded in CH_2Cl_2 on a Hitachi 270-30. Mass spectra were recorded on a Joel JMS-SX/SX 102A GC/MS/MS. Elementary analyses were recorded on a Heraeus CHN-O-S-Rapid. X-ray diffraction data were collected on an Enraf–Nonius CAD4 diffractometer; the essential crystal data of **3'** are given in Table 1. Structure analyses are processed on a microvax computer using NRC VAX software.[13]

Reaction of (η^5-C_5H_5)Co(C_4Ph_4) *with* $Cr(CO)_6$

Into a 250 cm^3 round-bottom flask equipped with a condenser and a magnetic stirrer were placed (η^5-C_5H_5)Co(C_4Ph_4) (0.6 g, 1.24 mmol) and chromium hexacarbonyl (2.74 g, 12.42 mmol). Anhydrous dibutyl ether (120 cm^3) and anhydrous tetrahydrofuran (THF) (12 cm^3) were added and the reaction mixture was refluxed under dry nitrogen for 36 h. The reactor was cooled to room temperature and filtered and the solvent removed *in vacuo*.

The residue was dissolved in a small amount of CH_2Cl_2 and then was loaded onto CTLC for separation. Four bands were collected through the elution of a mixture of solvents. The ratio of solvent mixture (CH_2Cl_2/hexanes) changed from 4:1 to

1 : 1 as the separation proceeded. The first yellow band, R_f (0.66) in 1 : 1 of CH_2Cl_2–hexanes, was identified as a small amount of unreacted **1**. Compound **2**, orange ($R_f = 0.42$), was collected as the second band. The third band contains **3′** and **3″**. Both are orange and are very close in R_fs; 0.21 for **3″** and 0.19 for **3′**. This mixture was separated further by CTLC with a slow solvent injection speed. Compound **3″** was eluted out before **3′**. Compound **4**, orange ($R_f = 0.08$), was collected as the last band. The separation in CTLC was under nitrogen.

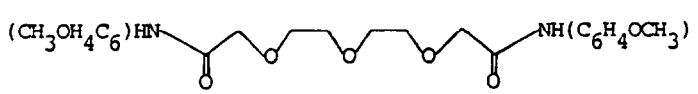
Abstract—Lanthanide nitrate complexes with N,N′-bis(4-methoxyphenyl)tetraglycollic diamide (L) have been prepared in non-aqueous medium. These new complexes with the general formula $[Ln(L)(NO_3)_3]$ (Ln = La, Ce, Pr, Nd and Sm) have been characterized by elemental analysis, conductivity measurements and IR spectra. An X-ray crystallographic structural determination of the praseodymium complex shows that the pentadentate organic ligand wraps around the lanthanide ion which is also bonded to three bidentate nitrate groups, achieving the uncommon undeca-coordination.

Macrocyclic ligands, such as crown ethers, show a high complexation selectivity, which makes them suitable reagents for investigations of separation of lanthanide ions.[1] On the other hand, non-cyclic polydentate ligands, the open-chain analogues of crown ethers,[2] can also be used in the separation and analysis of the rare earths.[3–5] Some polyethylene glycols and their derivatives exhibit a "crown-like" behaviour in the lanthanide complexes[6] and some of them have been studied as lanthanide extractants.[3,4] As part of a systematic investigation on the lanthanide complexes with open chain multidentate ligands[7] this paper reports the preparation and structure of the complexes of lanthanide nitrates with N,N′-bis(4-methoxyphenyl)tetraglycollic diamide.



N,N'-Bis(4-methoxyphenyl)tetraglycollic diamide (L)

EXPERIMENTAL

Reagents

Lanthanide nitrates were prepared by dissolving the corresponding oxides (AR) in 1 : 1 nitric acid. The ligand was obtained from the Lanzhou Institute of Chemical Physics. All other chemicals were AR grade and used without further purification.

Chemical and physical measurements

The metal ions were determined by EDTA titration using xylenol as an indicator. Carbon, nitrogen and hydrogen were determined using a Carlo–Erba 1106 elemental analyser. Conductivity measurements were performed with a DDS-11A type conductivity bridge using 10^{-3} mol dm^{-3} solutions in acetone at 25°C. The IR spectra were recorded on a Nicolet 170 SX FT-IR instrument using KBr discs in the 4000–400 cm^{-1} region. The crystal structure was determined on an R3M/E four-circle X-ray diffractometer.

Preparation of the complexes

A solution of lanthanide nitrate (1 mmol) in ethyl acetate (25 cm^3) was added dropwise to a solution of the ligand (0.432 g, 1 mmol) in ethyl acetate (25 cm^3) under stirring. The complex was precipitated gradually. After being stirred for 10 h the complex was isolated by filtration, washed with ethyl acetate and dried *in vacuo* over P_4O_{10} for 72 h; yield 60–65%. Single crystals of the praseodymium complex suitable for X-ray diffraction were obtained by recrystallizing the powdery complex from a solution of acetonitrile by slow evaporation.

X-ray structure determination

Crystal data. $C_{26}H_{34}N_7O_{16}Pr$, $M = 841.51$, monoclinic, space group Cc, $a = 21.324(8)$, $b = 11.456(4)$, $c = 14.495(4)$ Å, $\beta = 97.37(2)°$, $V = 3512(2)$ Å^3, $Z = 4$, $D_c = 1.59$ g cm^{-3}, λ(Mo-K_α) = 0.71073 Å, $\mu = 14.6$ cm^{-1}, $F(000) = 1704$.

A single crystal of dimensions $0.2 \times 0.4 \times 0.6$ mm was selected for the data collection on an R3M/E diffractometer with graphite-monochromated Mo-K_α radiation, $\theta/2\theta$ scan. 25 reflections were used for measuring lattice parameters and 2232 independent reflections were collected in the range $1° < 2\theta < 42°$. Of these 1777 reflections with $I \geqslant 1.5\sigma(I)$ were used in the structure determination and refinement. Lorentz–polarization corrections were applied. The structure was solved by Patterson methods and Fourier techniques and refined by full-matrix least-squares, with anisotropic thermal factors for all non-hydrogen atoms and isotropic thermal parameters for hydrogen atoms. Final $R = 0.049$, $R_w = 0.045$. Atomic coordinates, thermal parameters and a full set of bond lengths and angles have been deposited with the Editor as supplementary material.

RESULTS AND DISCUSSION

Analytical results are summarized in Table 1. The analytical data show that all of the complexes conform to a 1 : 1 metal-to-ligand stoichiometry.

All complexes are hygroscopic. They are soluble in methanol, ethanol, acetone and acetonitrile, slightly soluble in chloroform, ethyl acetate and nitromethane, and sparingly soluble in benzene, ether and cyclohexane. The molar conductance values of the complexes in acetone (Table 1) indicate that all the

complexes act as non-electrolytes,[8] implying that all the nitrate groups are in the coordination sphere.

IR spectra

The most important IR bands of the ligand and the complexes are reported in Table 1. The ligand has a ν(C—O—C) band at 1130 cm^{-1} in its spectrum. This band appears at 1098–1104 cm^{-1} in the spectra of the complexes with a shift of 26–32 cm^{-1} to the lower frequency region, indicating that the ether oxygen atoms are coordinated to the metal ions. A very strong band assigned to ν(C=O) is observed at 1670 cm^{-1} in the spectrum of the free ligand. This band appears at 1628–1633 cm^{-1} in the spectra of the complexes with a shift of 37–42 cm^{-1}, showing that the C=O groups also take part in coordination to the metal ions. The IR spectral evidence above suggests the ligand is pentadentate, forming a ring-like structure, which is confirmed by the result of crystal structure determination.

Crystal structure of $[Pr(L)(NO_3)_3]\cdot 2CH_3CN$

Selected bond lengths and angles are given in Tables 2 and 3. Figure 1 shows the structure and the numbering scheme for the complex molecules. Figure 2 shows the packing arrangement in the unit cell.

The unit cell consists of the complex molecules and separate uncoordinated acetonitrile molecules. The ligand wraps around the metal ion with its oxygen atoms and assumes a ring-like structure similar to those of the crown ethers.[1] The praseodymium ion in the complex is 11-coordinated by three bidentate nitrate groups and one pentadentate ligand. Six Pr—O(nitrate) distances have values between 2.476 and 2.686 Å (mean 2.572 Å). The Pr—O(L)

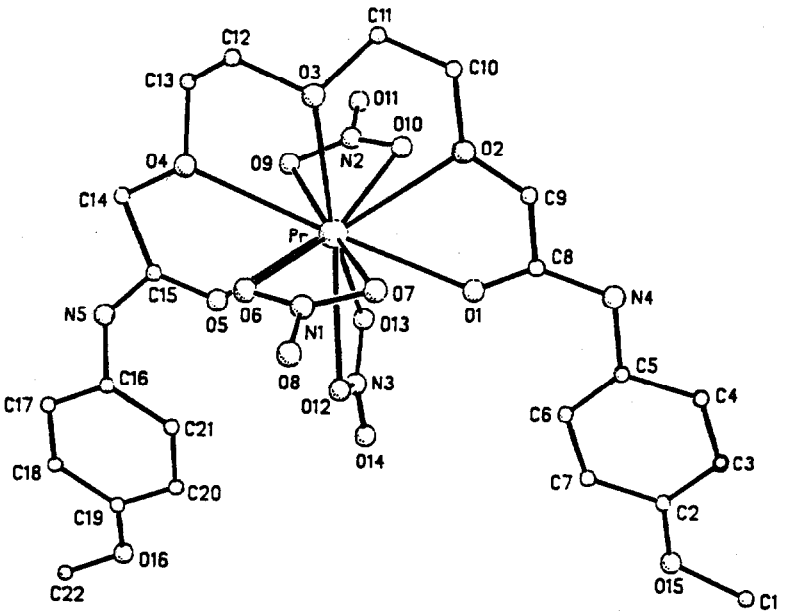

Fig. 1. Molecular structure of the praseodymium complex.

distances are of two types: as expected, the two terminal Pr—O(carbonyl) distances (mean 2.529 Å) are significantly shorter than the three Pr—O (etheric) distances (mean 2.715 Å). This is probably due to the higher electron density on the carbonyl oxygen.

A noteworthy feature of the molecular structure is the 11-coordinate polyhedron around the metal ion. Undeca-coordination is not common in inorganic chemistry.[9,10] The other reported undeca-coordinated lanthanide complexes with organic-type ligands are $[La(15\text{-crown-}5)(NO_3)_3]$,[11] $[La(monoaza\text{-}15\text{-crown-}5)(NO_3)_3]$,[12] $[La(naphtho\text{-}16\text{-crown-}5)(NO_3)_3]$,[13] $[La(TEG)(NO_3)_3]$ (where TEG = tetraethylenglycol),[14] $[La(DAPBAH)(NO_3)_3]$ [where DAPBAH = 2,6-diacetylpyridine-

bis(benzoic acid hydrazone)],[15] [Ce(15-crown-5)$(NO_3)_3$],[16] [Ce(4,4′-bipy)$(NO_3)_4(H_2O)_2]^-$ anion[17] and [Eu(15-crown-5)$(NO_3)_3$].[10] In general, the coordination polyhedra in these complexes are not easily definable or comparable and seem to be more determined by the shapes and characteristics of the bonded ligands than by the common coordination number.[9,14]

In conclusion, the open-chain multidentate ligand N,N′-bis(4-methoxyphenyl)tetraglycollic diamide can react with lanthanide nitrates in non-aqueous medium to form 1:1 (metal-to-ligand) stable solid complexes. The ligand acts as a pentadentate ligand forming a ring-like structure. Similar structures were also found for lanthanide complexes with other non-cyclic polyethers.[6]
