(*Received* 10 *February* 1993; *accepted* 30 *March* 1993)

Abstract—The series of lanthanide(III) complexes $Ln(NCS)_3(THF)_4$ [Ln = lanthanide(III) ion, THF = tetrahydrofuran] has been synthesized and examined by X-ray diffractometric methods. The study has shown that four oxygen atoms (THF) and three nitrogen atoms (NCS) are arranged around the Ln^{3+} ions according to well-defined coordination geometries: the square antiprism (SQA) for eight-coordination and the pentagonal bipyramid (PB) for seven-coordination. The dimeric square antiprismatic structures (Ln = Nd, Gd, Eu, Dy and Er) have been previously described. Here we report the crystal structure of $Yb(NCS)_3(THF)_4$. The coordination geometry of the metal ion consists of a slightly distorted pentagonal bipyramid, in which two nitrogen atoms (NCS) are in the apical positions and four oxygens atoms (4THF) and one nitrogen (NCS) lie in the equatorial plane. A correlation between the two coordination arrangements (SQA) and (PB) is discussed.

A preliminary X-ray analysis of the lanthanide series of the complexes $Ln(NCS)_3(THF)_4$ has recently revealed two isomorphous groups of crystal structures.[1a] The former includes the elements from La to Er; to the second belongs Yb and very likely the elements Tm and Lu, with completely different crystallographic features. (It was impossible to obtain crystals of Tm and Lu complexes suitable for an X-ray crystal analysis.)

The first group of complexes has already been described;[1b] it is characterized by a square antiprismatic octa-coordination about the metal ions; their geometrical features change regularly with the atomic number of the element according to the lanthanide contraction.[2]

The crystallographic data observed for the Yb complex are completely different; they are related to the smaller ionic size of the element and are attributable to a change into a seven-coordination. It is well known that such change is determined by the steric requirements of the ligands. For instance, the interconversion from octa- to seven-coordination occurs with Er in the case of $Ln(2,6\text{-dimethyl-4-pyrone})_7(ClO_4)_3$[3] and with Sm in the case of $Ln[(S_2P(OEt)_2]_2(\text{triphenylphosphine oxide})_3[S_2P(OEt)_2]$.[4] In the present case it takes place with Yb (or very likely with Tm). However, this behaviour has never been described on the basis of a systematic analysis of the full series of the lanthanide elements.

The seven coordination seems not to be favoured in all the periodic system[5] and is mostly char-

* For Part I see ref. 1(b).

‡ On sabbatical leave from Dipartimento di Chimica, Università di Napoli, 80134 Napoli, Italy.

acterized by a capped octahedral or trigonal geometry,[6] specifically in complexes with non-equivalent ligands of the type (unidentateA)$_4$Me(unidentateB)$_3$.[7] As for the lanthanide metals only a few complexes are known with different unidentate ligands and all have three-fold symmetry or capped octahedral stereochemistry.[8]

Here we report the crystal and molecular structure of the complex Yb(NCS)$_3$(THF)$_4$, which shows a seven-coordination in the less common bipyramidal pentagonal configuration.[6]

A comparison will also be attempted with the molecular geometry found for the octa-coordinated homologous complexes already reported.[1]

The failure to obtain single crystals of the Tm complex is very likely attributable to the simultaneous presence of both the octa- and seven-coordination species in the product. Actually Tm is at the border line between the two series of these lanthanide complexes. For Lu the problem is related to its small ionic dimensions with respect to the donor ligands employed and its particular electronic configuration.

EXPERIMENTAL

The procedures for the preparation and manipulation of the ytterbium complex are exactly the same as adopted for the preparation of the dimeric square antiprismatic complexes (L = Nd, Eu and Er).[1] Moisture and oxygen were rigorously excluded using the glove-box technique. Anhydrous $YbCl_3$ was prepared according to reported methods.[9] Potassium thiocyanate was purified according to ref. 10. The solvents (THF and pentane) were purified by distillation from $LiAlH_4$ and K-benzophenone under nitrogen. The analysis of the metal was performed according to ref. 11. The Nujol IR spectrum was obtained with a Nicolet FTIR instrument.

Synthesis of Yb(NCS)$_3$(THF)$_4$

$YbCl_3$ and KSCN (molar ratio 1:3) were suspended in THF. The mixture was stirred for 1 day at room temperature and refluxed for 3 h under nitrogen. The resulting solution was centrifuged, the solid removed and the crude product isolated by evaporation of the solvent under reduced pressure. Crystals suitable for X-ray data collection were obtained by adding pentane to a THF solution of the compound. Found: Yb, 27.7. Calc. for $YbS_3O_4N_3C_{19}H_{32}$: Yb, 27.2%.

The Nujol IR spectrum of the title complex shows the frequencies characteristic of the N-monodentate group: ν(CN) 2037, ν(CS) 834, δ(NCS) 485 cm^{-1}.

Collection of X-ray data and structure solution

To prevent decomposition single crystals of Yb(NCS)$_3$(THF)$_4$ were sealed in Lindemann capillaries under nitrogen. Suitable crystals for an X-ray analysis were mounted on a Philips PW100 computer-controlled four-circle diffractometer with a graphite monochromator. Standard centring and auto-indexing procedures indicated the primitive monoclinic lattices $P2_1/a$. The orientation matrix and accurate unit cell dimensions were determined from a least-square fit of 25 symmetry-related reflections.

Intensity data were collected at 25°C using the θ–2θ scan method; two standard reflections, monitored every 150 reflection measurements, indicated a sensible decay of the crystals under X-ray radiation. Three crystals were used for data collection. The intensities were corrected for Lorentz and polarization effects, but not for absorption owing to the relatively low value of μ. Crystal data and details of intensity collection are reported in Table 1.

The positions of the lanthanide atoms were determined from three-dimensional Patterson syntheses. The light atoms were located from subsequent Fourier maps. The positions of the hydrogen atoms were geometrically calculated, assigned isotropic thermal parameters [with $U(H) = 1.2U_{eq}(C)$] and allowed to ride on their parent carbon atom. They were included in the final calculations, but not refined. Except for the carbon atoms of the THF groups anisotropic thermal parameters were used

for the non-hydrogen atoms. Blocked-cascade least-squares refinements were used; they converged to the conventional R index of 0.059. A unitary weighting scheme was used. Scattering factors for the atoms were taken from Cromer and Waber;[12] the scattering factors for Yb were corrected for the real and imaginary parts of anomalous dispersion using Cromer's values.[13] All computations were performed on a Cyber 76 computer using the SHELX-76 program.[14] Additional material available from the Cambridge Crystallographic Data Center comprises the final positional parameters of the non-hydrogen atoms, hydrogen atom coordinates and a full list of the bond lengths and angles.

DISCUSSION

The relevant molecular parameters are reported in Table 2 with reference to Fig. 1. The structural unit consists of two independent molecules of $Yb(NCS)_3(THF)_4$: **A** and **B**. They exhibit a slightly distorted bipyramidal pentagonal seven-coordination. The largest deviations from a symmetrical polyhedron concern the apical positions of the axial ligands in molecule **B**, for which some angles, L_{eq}—Yb′—L_{ax}, are *ca* 107–110°, as against the theoretical value of 90° and L_{ax}—Yb′—L_{ax}, is 166°. For both **A** and **B** the four THF ligands are disposed in the equatorial girdle with bond distances Yb—O of *ca* 2.36–2.40 Å, for THF groups inserted between two THF groups, and of *ca* 2.22–2.25 Å, for THF groups inserted between one THF and the equatorial NCS group, which indicates the dependence of these parameters upon sterical influences. The apical positions are occupied by NCS groups, giving rise to an idealized molecular C_2 symmetry with the pseudo-two-fold axis passing through the equatorial bond; Yb—N(1) and Yb′—N(1)′ for **A** and **B**, respectively (Fig. 1). The values of the Yb—ligand bonds are much more influenced by the coordination mode rather than the ionic radium of the metal; therefore, no simple correlation with the

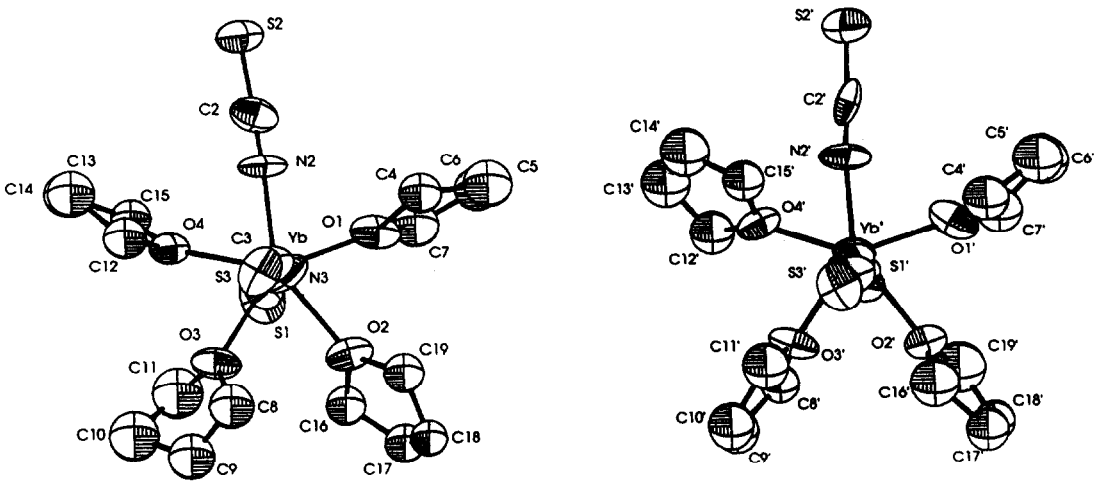

Fig. 1. Two molecules of $Yb(NCS)_3(THF)_4$ forming an independent structural unit, as viewed orthogonally to the equatorial YbL_5 girdle.

corresponding values observed in the octa-coordinated homologous series from Nd to Er is possible. The five atoms bonded to Yb in the equatorial girdle lie within ± 0.04 Å in a plane, the metal ion being way above this plane (*ca* 0.10 Å); in the case of molecule **B** the $Yb'L_5$ girdle is more distorted and only the oxygen atoms lie in a plane within ± 0.06 Å; N(2) and Yb′ are far above this plane (up to *ca* 0.20 Å). These facts and the sensible difference in the axial bond lengths Yb′—N(1)′ and Yb′—N(3)′ (2.25 and 2.31 Å, respectively) in unit **B** cannot be evidence of some *trans* effect[15] since the axial ligands here are identical; they can be ascribed only to intra- and/or intermolecular stereochemical influences.

In Table 3 some coordination parameters about

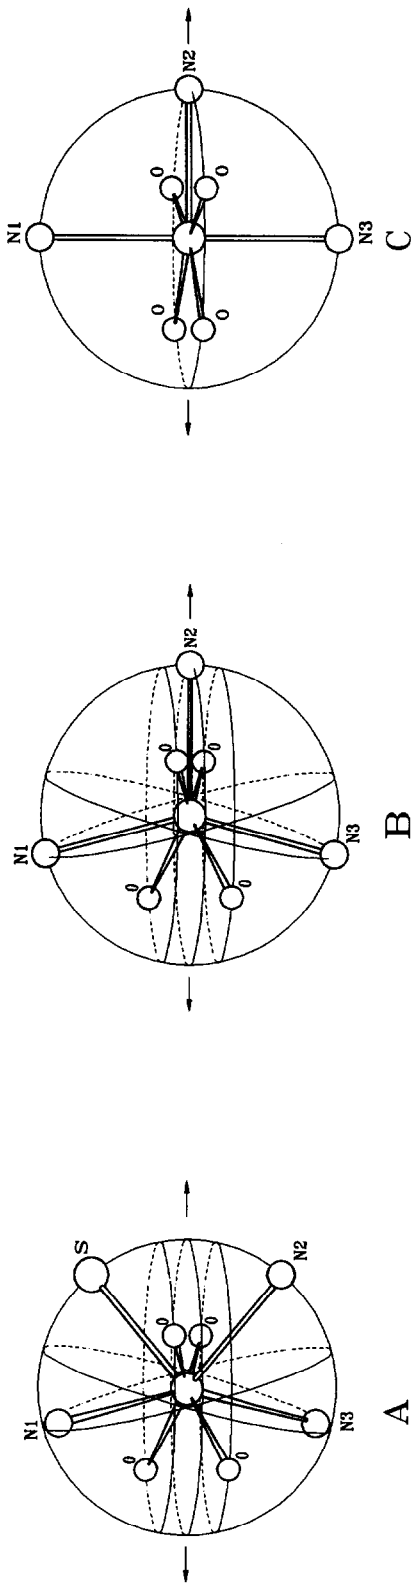

Fig. 2. Schematic interconversion path from square antiprism to pentagonal bipyramid with the retention of a two-fold symmetry axis. (A) Idealized symmetrical SQA coordination sphere; (B) the sites of S and N(2) coalesce in a single position on the equatorial plane, producing a distorted PB coordination; and (C) the oxygen atoms move towards the equatorial plane and N(2) and N(3) towards the meridional plane of the coordination sphere. A regular PB geometry is obtained.

the central ion, averaged between the values found for **A** and **B**, are compared with the corresponding values of a square antiprismatic, octa-coordinated homologous complex. As an example we have selected the complex $Er(NCS)_3(THF)_4$,[1] which is the closest to the Yb complex in this lanthanide series. It is noteworthy that the transformation from octa- to seven-coordination requires little geometrical rearrangement of the coordination sites, mainly involving the three positions occupied by the NCS groups; thus, we estimate that the bipyramidal pentagonal geometry is the seven-coordination mode closest to a square antiprismatic arrangement.

All these facts, together with the presence of two molecules in the structural unit, seem in some way to indicate a reminiscence in this structure of the dimeric nature of the complexes of the preceding lanthanide elements and their octa-coordination in the SQA configuration.[1]

A possible interconversion path from SQA to PB geometry for idealized symmetrical polyhedra is schematically shown in Fig. 2, assuming the retention of a two-fold symmetry axis [a pseudo-C_2 symmetry is present also in the molecular unit of $Er(NCS)_3(THF)_4$[1]].

Likely, such an interconversion does not require an appreciable change in energy,[16] which enhances the suggestion that in the case of the Tm complex both these geometries are present, so preventing or making difficult its crystallization from the mother solution.

The seven-coordination assumed by the Yb complex is the consequence of further contraction of the ionic radium from Er to Yb (*ca* 0.023 Å).[17]

Assuming an octa-coordination, with a sulphur atom of an adjacent molecular unit in the eighth site, we would expect a bond length of Yb—S (see ref. 1) larger than 3.28 Å, as found for the Er complex, that is too weak, and shorter bond lengths of Yb—O and Yb—N, giving rise to a much overcrowded coordination sphere around the central ion.

Acknowledgements—We thank Mr M. Griggio for the computer elaboration of the figures and for the technical assistance.

(*Received* 8 *October* 1992; *accepted* 30 *March* 1993)

Abstract—New complexes of hydrated lanthanide(III) nitrates with 2,6-bis(benzimidazol-2′-yl)pyridine (BBP) having the formulae $[Ln(BBP)_2(NO_3)_2]NO_3 \cdot nH_2O$ (where Ln = La–Nd, Sm–Tb, n = 1, 2), $[Ln(BBP)(BBP—H)(NO_3)(OH_2)]NO_3 \cdot nH_2O$ (where Ln = Dy, Er, n = 3, 4) and $[Ln(BBP—H)(NO_3)_2(OH_2)] \cdot 2H_2O$ (where Ln = Lu) have been prepared and characterized by elemental analyses, IR and electronic spectra, molar conductance, thermal analyses and X-ray powder diffraction patterns. The emission spectra of all the complexes have also been examined. It has been found that all the complexes show the luminescence of the ligand. The Sm, Eu and Tb complexes also show the corresponding metal ion luminescence.

Luminescent lanthanide complexes are a subject of increasing interest, mainly due to their possible applications in bioinorganic chemistry.[1–5] To obtain luminescent lanthanide complexes it is necessary to bind lanthanide cations with chromophonic ligands, which are able to absorb energy and then transfer it effectively to the cation or shield the lanthanide ion from interaction with solvent (water) molecules which deactivate the luminiscent excited state. The tridentate ligand 2,6-bis-(benzimidazole-2′-yl)pyridine (BBP) (see Fig. 1), in which two benzimidazole and one pyridine rings can form an extensive conjugated system by coordination to a metal ion, may fulfil these requirements.[6] Although its complexes with some transition metals have been reported,[6–12] no paper concerning the study of lanthanide(III) complexes with BBP has been reported. Therefore, to investigate whether the BBP ligand would be effective in yielding ionic luminescence we have synthesized several lanthanide(III) complexes with BBP and discuss their luminescence properties.

EXPERIMENTAL

Reagents

The hydrated lanthanide(III) nitrates were prepared by dissolving the respective oxides (99.95%) in 50% nitric acid. The ligand 2,6-bis(benzimidazol-2′-yl)pyridine was prepared according to the literature method.[13] The other chemicals were analytical reagent grade.

[a] L = BBP.

[b] Required values are given in parentheses.

Preparation of the complexes

To a solution of BBP (20 mmol) in Me_2CO (40 cm^3) was added dropwise a solution of hydrated lanthanide(III) nitrates (10 mmol) in Me_2CO (10 cm^3) with stirring at room temperature. A precipitate was formed in a few minutes. After stirring for several hours the product was collected by filtration, washed several times with Me_2CO and Et_2O and dried in a vacuum desiccator over P_4O_{10}. The elemental analyses of these complexes are listed in Table 1.

Measurements

Carbon, nitrogen and hydrogen analyses were determined using a Carlo–Erba 1106 elemental analyser. The IR spectra were recorded on a Nicolet-170SX FT-IR spectrophotometer in CsI discs in the range 4000–200 cm^{-1}. Electronic spectra were recorded on a UV-240 spectrophotometer in the 190–900 nm region using a solution in methanol. Thermal characterization studies were performed with a Du Pont 1090 thermal analyser. Metal analyses were determined by titration with EDTA. Conductivity measurements were obtained using a 10^{-4} M solution in methanol on a DDS-II A conductometer at 25°C. The powder spectra were recorded on a Phillips PW 1700 automated powder diffractometer using Cu-K_α radiation ($\lambda = 1.54051$) with a diffracted-beam curved graphite monochromator. The experimental conditions were: focusing geometry with a θ–2θ scanning mode, stationary flat specimen, divergence slit (1°C), peak angle range 1–60°C, range in d spacing 2.34–14.33 Å, generator settings 40 KV, 100 mA. Electronic emission and excitation spectra were recorded with an 850 spectrophotofluorometer.

RESULTS AND DISCUSSION

The stoichiometries of the solid products obtained from the reaction of Me_2CO solutions of BBP and lanthanide(III) nitrates depend upon the lanthanide ion employed. Use of the lighter lanthanide ions (La–Tb except for Pm) gave the compounds $[Ln(BBP)_2(NO_3)_3 \cdot nH_2O]$ ($n = 1, 2$); the heavier lanthanide ions (Dy and Er) gave complexes of stoichiometry $[Ln(BBP)(BBP—H)(NO_3)_2(OH_2) \cdot H_2O]$ ($n = 3, 4$); whereas the Lu ion yields the 1:1 (metal:ligand) complex $[Lu(BBP—H)(NO_3)_2(OH_2)2H_2O]$. In the Dy, Er and Lu complexes an N proton on the benzimidazole ring of a ligand is lost, as indicated in the literature[12] and in the $Cd(BBP—H)_2$ complex, whose crystal structure has been determined by X-ray diffraction techniques.[14] These results indicate that the size of the metal ions affects the stoichiometry of the complexes. Besides, this change in stoichiometry most probably also results from the steric requirements of the nitrate ligands, which become increasingly forbidding from larger metal ions to smaller metal ions. The complexes are air-stable at room temperature, solution in CH_3OH, DMF and DMSO, slightly soluble in Me_2CO and insoluble in water and non-polar organic solvents. The molar conductances of the complexes (Table 2) indicate that the complexes, except for the Lu

complex, behave as 1 : 1 electrolytes in methanol, whereas the Lu complex is a non-electrolyte.

Thermal analysis

The TG curves of the complexes show a weight loss between 46 and 118°C. The weight loss corresponds to one water molecule for La–Nd and Eu–Tb complexes, two water molecules for Sm and Lu complexes, three water molecules for the Er complex and four water molecules for the Dy complex. These results are in accordance with the compositions of the complexes determined by elemental analyses and also show that the water molecules in these complexes are present as crystal water. The other water molecule (corresponding dehydrated temperature in the range 118–196°C) in the Dy, Er and Lu complexes is present as coordinated water. The complexes undergo decomposition within the temperature range 298–600°C, which shows that the complexes are more thermally stable than the parent ligand (decomposition temperature 250°C). The final products are metal oxides in all cases.

IR spectra

The important IR data of the complexes are listed in Table 2. The appearance of new bands at 3361–3480 cm^{-1} in the spectra of Ln complexes (Ln = La–Nd, Sm–Tb) indicates the antisymmetric and symmetric $OH(H_2O)$ stretching and N—OH bending modes. In the spectra of Dy, Er and Lu complexes the bands assigned to $\nu(H_2O)$ modes in the region 3401–3584 cm^{-1} are split or broadened, which indicates that the complexes contain both coordinated and cystal water, in agreement with the results of thermal studies. A broad band at 3184 cm^{-1} in the free ligand, assigned to the N—H group of the benzimidazole ring, is shifted to lower frequencies by *ca* 120 cm^{-1} in all complexes. This shift may be indicative of stronger hydrogen bonding between the ligand and the anions in the complexes than the intermolecular hydrogen bonding in the ligand in the solid state.[15,16] A new band at *ca* 361 cm^{-1} in the spectra of these complexes may be assigned to the metal–nitrogen stretching vibrations.

The bands characteristic of the ligand vibrations (C=C, C=N stretching) in the 1625–1500 cm^{-1} range are shifted towards high energy (*ca* 5–20 cm^{-1}) by complexation to the lanthanide(III) ions. The in-plane deformation mode of the pyridine ring appears at *ca* 635 cm^{-1}.[18,19] These indicate that the pyridine nitrogen and the nitrogens of the benzimidazole rings coordinate to lanthanide(III) ions. Presumably BBP acts as a tridentate ligand to lanthanide(III) ions.

Table 2 summarizes the IR spectral data of the nitrate groups. It can be seen that the IR spectra of the nitrate complexes exhibit four bands at *ca* 1496, 1288, 1038 and 825 cm^{-1}, which can be assigned to the vibrational modes of the coordinated (C_{2v}) nitrate groups. The magnitude of the splitting of the two bands at higher energies is *ca* 208 cm^{-1}, suggesting that the nitrate groups are present as bidentate ligands.[20] Meanwhile, the band at *ca* 1389 cm^{-1} due to ionic nitrate groups in the IR spectra of the complexes was also observed except for the Lu complex. This shows that these complexes have both ionic and coordinated nitrate groups. However, no band indicative of the ionic nitrate group at *ca* 1389 cm^{-1} in the Lu complex was observed, which shows that the Lu complex has only coordinated nitrate groups.

On the basis of the above discussion these complexes are formulated as: $[Ln(BBP)_2(NO_3)_2]NO_3 \cdot nH_2O$ (where Ln = La–Nd, Sm–Tb, n = 1, 2), $[Ln(BBP)(BBP—H)(NO_3)(OH_2)]NO_3 \cdot nH_2O$ (where Ln = Dy, Er, n = 3,4) and $[Ln(BBP—H)(NO_3)_2(OH_2)] \cdot 2H_2O$ (where Ln = Lu). The metal ion seems to be 10-coordinate for La–Nd and Sm–Tb, nine-coordinate for Dy and Er and eight-coordinate for Lu. The coordination number of central ions is variable (from 10 to 8) from the larger to the smaller lanthanide(III) ions, i.e. the coordination number of the central ion decreases due to lanthanide contraction.

Powder spectra

The X-ray powder patterns were recorded for selected Ce, Eu, Er and Lu complexes for comparison and are shown in Fig. 2. Comparison of the powder spectra of the complexes shows that Eu and Ce complexes are isomorphous, while as expected those of the Er and Lu complexes are different. Also, the powder spectra of the Er complex are different from those of the Lu complex. These results further support the above conclusion.

Electronic spectra

The electronic absorption spectra of all the complexes recorded in methanol (10^{-4} M) show similar features, containing an intense band at 324–328 nm with two shoulders at 306–309 and 331–334 nm attributable to an intraligand $\pi \rightarrow \pi^*$ transition. No absorption bands due to interconfiguration f–f transitions were observed due to their very low molar absorptivities ($\varepsilon < 3$).[21]

Lu	354	385	Ligand

[a] Relative intensity given in parentheses.

Emission spectra

The emission spectra of all the complexes and the ligand were recorded using a compound concentration of 1.0×10^{-4} M in methanol at room temperature. The emission data and their assignments are summarized in Table 3. The results indicate that the only Sm^{III}, Eu^{III} and Tb^{III} complexes show corresponding metal luminescence, whereas

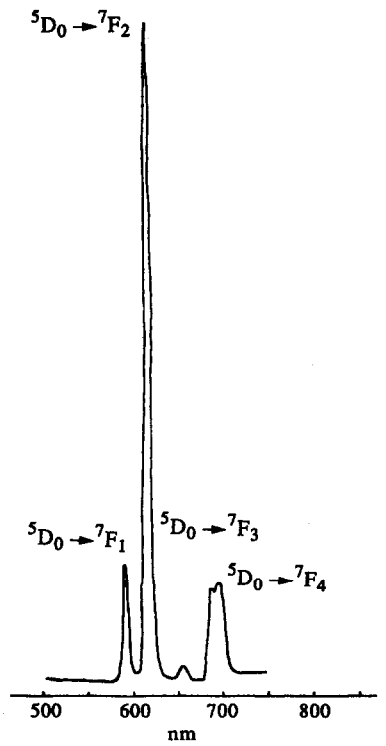

Fig. 3. Emission spectrum of $[EuL_2(NO_3)_2]NO_3 \cdot H_2O$ in methanol (10^{-4} M) at room temperature (λ_{ex} = 355 nm).

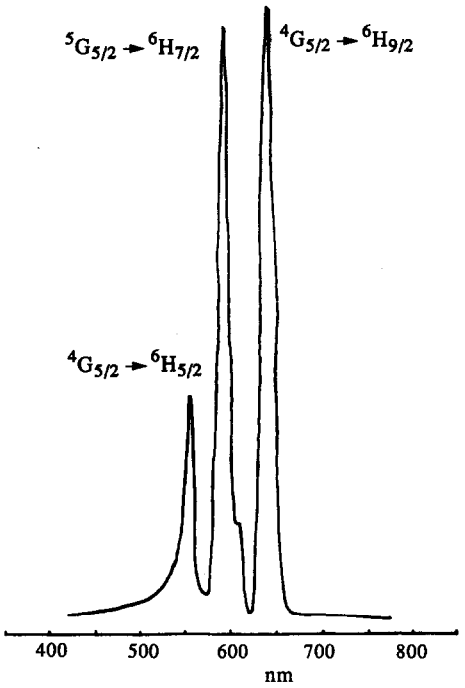

Fig. 4. Emission spectrum of $[SmL_2(NO_3)_2]NO_3 \cdot 2H_2O$ in methanol (10^{-4} M) at room temperature (λ_{ex} = 355 nm).

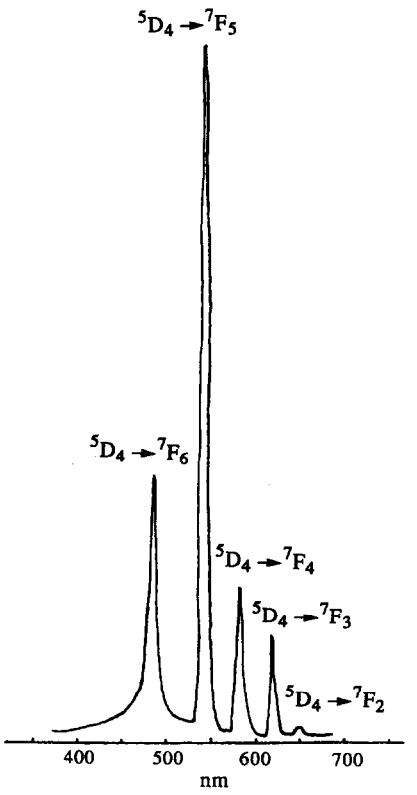

Fig. 5. Emission spectrum of $[TbL_2(NO_3)_2]NO_3 \cdot H_2O$ in methanol (10^{-4} M) at room temperature (λ_{ex} = 365 nm).

the other lanthanide(III) complexes do not. However, all the complexes exhibit luminescence of the ligand by excitation at *ca* 355 nm radiation. Figure 3 shows the emission spectrum of the Eu complex. It can be seen that the emisson arises mainly from a transition originating at the $^5D_0$ level and terminating in the $^7F_1$, $^7F_2$, $^7F_3$ and $^7F_4$ levels. The most intense band at 618 nm is due to the $^5D_0 \rightarrow {}^7F_2$ transition. The transition $^7D_0 \rightarrow {}^7F_3$ at 651 nm is of low intensity and can be reasonably taken as forbidden. The $^5D_0 \rightarrow {}^7F_4$ transition at 695 nm is slightly split into two almost equal intensity lines. The Sm complex shows weak metal ion luminescence and its emission spectrum (Fig. 4) exhibits three bands. Two stronger bands at 597 and 645 nm are assigned to $^4G_{5/2} \rightarrow {}^6H_{7/2}$ and $^4G_{5/2} \rightarrow {}^6H_{9/2}$, respectively. The intensity of the $^4G_{5/2} \rightarrow {}^6H_{5/2}$ transition at 560 nm is so low that this transition can be taken as forbidden. The emission spectrum of the Tb^{III} complex is depicted in Fig. 5. The most intense band at 545 nm is assigned to a $^5D_4 \rightarrow {}^7F_5$ transition. The three relatively weak bands at 490, 585 and 620 nm, assigned to $^5D_4 \rightarrow {}^7F_6$, $^5D_4 \rightarrow {}^7F_4$ and $^5D_4 \rightarrow {}^7F_3$ transitions, respectively, appear in the spectrum of this complex. A very weak band at 650 nm due to the $^5D_4 \rightarrow {}^7F_2$ transition can be taken as forbidden. Further developments about the luminescence properties of the lanthanide(III) complexes with BBP are in progress.

Acknowledgements—We thank Ms X. Lu for drawing the diagrams and helpful assistance.

PREPARATION AND CHARACTERIZATION OF HETEROLEPTIC TETRAISOPROPOXOALUMINATO-YTTRIUM(III) COMPLEXES

UPENDRA M. TRIPATHI, ANIRUDH SINGH* and RAM C. MEHROTRA†

Department of Chemistry, University of Rajasthan, Jaipur 302004, India

(*Received* 28 *January* 1993; *accepted* 1 *March* 1993)

Abstract—Novel heteroleptic tetraisopropoxoaluminato-yttrium(III) complexes $[\{Cl_2Y\{Al(OPr^i)_4\}\cdot 1.5Pr^iOH\}_2]$ **(I)** and $[\{Y\{Al(OPr^i)_4\}_2(\mu\text{-}Cl)(Pr^iOH)\}_2]$ **(II)**, synthesized by the reaction of $YCl_3\cdot 3Pr^iOH$ with $KAl(OPr^i)_4$ in 1 : 1 and 1 : 2 molar ratios, gave on prolonged evacuation the unsolvated complexes $[\{Y\{Al(OPr^i)_4\}(\mu\text{-}Cl)Cl\}_2]$ **(Ia)** and $[\{Y\{Al(OPr^i)_4\}_2(\mu\text{-}Cl)\}_2]$ **(IIa)**, respectively. Derivatives **Ia** and **IIa** have been used as precursors for the synthesis of interesting hetero-(bi- and tri-)metallic isopropoxides of yttrium of the type $[L_{3-x}Y\{Al(OPr^i)_4\}_x]$ [x = 1 and 2; L = OPr^i and $Zr_2(OPr^i)_9$]. All the new derivatives have been characterized by elemental analyses, IR, multinuclear (^1H, ^{13}C, ^{27}Al and ^{89}Y) NMR spectral studies and ebullioscopic molecular weight measurements.

In continuation of our investigations on the chemistry of alkoxides of the lanthanides,[1–4] we report here some interesting results on heteroleptic tetraisopropoxoaluminates of yttrium(III), particularly in view of the applications of alkoxides of yttrium, barium and copper as soluble molecular precursors in the sol–gel process[5–14] for the synthesis of high-temperature superconductors such as $YBa_2Cu_3O_{7-\delta}$.

For a comparative study of lanthanide chemistry, yttrium provides a convenient diamagnetic probe for ^1H, ^{13}C and even ^{89}Y NMR spectroscopy, which assumes significance particularly in view of the difficulties in obtaining single-crystals suitable for X-ray structural studies.

Heterometallic alkoxide chemistry of yttrium remains unexplored,[3,4,15] except for the synthesis of $[Y\{Al(OPr^i)_4\}_3]$,[16] and doubts have been cast recently even on the identity of the simple tris-isopropoxide $Y(OPr^i)_3$.[17,18] The product obtained by the dissolution of metallic yttrium in refluxing isopropyl alcohol has been recently characterized as $Y_5O(OPr^i)_{13}$. The authors have further reported that $Y_5O(OPr^i)_{13}$ does not interact with $Al(OPr^i)_3$ to give $[Y\{Al(OPr^i)_4\}_3]$, whereas the same can be obtained in a high yield by the addition of the required amount of $Al(OPr^i)_3$ to the initially obtained mother liquor, followed by distillation of the bimetallic isopropoxide. Mehrotra[19] has commented that the above observations indicate: (1) the presence of mainly tris-isopropoxide, $Y(OPr^i)_3$, in the mother liquor and (2) high stability of $[Y\{Al(OPr^i)_4\}_3]$. Hubert-Pfalzgraf *et al.*[20] have recently reported that the reaction of neodymium chips with isopropyl alcohol affords the major product $Nd(OPr^i)_3(Pr^iOH)$ in *ca* 76% yield as a first crop, while the second crop in *ca* 15% yield was established by X-ray diffraction to correspond to an oxoisopropoxide solvate, $Nd_5O(OPr^i)_{13}(Pr^iOH)_2$.

In view of the above the synthesis of a number of stoichiometric heteroleptic tetraisopropoxoaluminates of yttrium, $L_xY\{Al(OPr^i)_4\}_{3-x}$ [where L = Cl, OPr^i and $Zr_2(OPr^i)_9$; x = 1 and 2], are reported herein.

EXPERIMENTAL

Stringent precautions were taken to exclude moisture from the solvents, reactants as well as glassware employed throughout the investigations.

$YCl_3 \cdot 3Pr^iOH$,[21] $Zr(OPr^i)_4 \cdot Pr^iOH$[22] and $Al(OPr^i)_3$[23] were prepared by literature methods.

Zirconium in the reactant, $Zr(OPr^i)_4 \cdot Pr^iOH$, as well as in the derivatives was estimated as ZrO_2 after precipitation as mandelate and ignition to oxide. Similarly aluminium was estimated by the oxinate method. Yttrium was estimated by complexometric titration with EDTA using xylenol orange as an indicator. The isopropoxy content was estimated by oxidimetric methods.[24] Chloride was estimated by Volhard's method.[25] IR spectra (4000–200 cm^{-1}) were recorded as Nujol mulls using CsI plates on a Perkin–Elmer 557 spectrophotometer. ^1H (89.55 MHz), ^{27}Al (29.5 MHz) and ^{13}C (22.49 MHz) NMR were recorded at probe temperature on a Jeol FX 90Q FT NMR spectrometer in $CDCl_3$ or C_6H_6. ^1H and ^{13}C NMR spectra were referenced to tetramethylsilane. ^{27}Al NMR spectra were referenced to $Al(NO_3)_3 \cdot xH_2O$ (external). ^{89}Y NMR spectra were obtained using long pulse delay times (4 s) at a frequency of 4.37 MHz and were referenced to $\{Y(H_2O)_6\}Cl_3$. Better response signals were observed with 1 M solutions of yttrium(III) complexes containing *ca* 1% (by mole ratio) of analogous gadolinium complex. The paramagnetic gadolinium derivatives act as a relaxation reagent without appreciable alteration of the chemical shifts at these mole ratios; the number of scans generally required was *ca* 40.

Synthesis of the complexes

$[\{Cl_2Y\{Al(OPr^i)_4\} \cdot 1.5Pr^iOH\}_2]$ (**I**). A solution of $KAl(OPr^i)_4$ [freshly prepared by the reaction of potassium (0.33 g, 8.40 mmol) with isopropanol (*ca* 5 cm^3) containing benzene (*ca* 10 cm^3), followed by the addition of $Al(OPr^i)_3$ (1.70 g, 8.35 mmol) and refluxing the reaction mixture for 2 h] was added slowly to a suspension of $YCl_3 \cdot 3Pr^iOH$ (3.13 g, 8.35 mmol) in benzene (*ca* 20 cm^3) and stirred at 60°C for 12 h. Separation of precipitated KCl (0.61 g, 8.18 mmol) by filtration, followed by removal of the volatiles under reduced pressure (30°C/1 Torr) affords the title compound (**I**) (3.97 g, 99.2%). Found: Y, 17.3; Al, 5.4; Cl, 13.9; OPr^i, 63.2. Calc. for $C_{33}H_{80}Al_2Cl_4O_{11}Y_2$: Y, 17.3; Al, 5.3; Cl, 13.8; OPr^i, 63.6%.

The unsolvated compound, $[\{Cl_2Y\{Al(OPr^i)_4\}\}_2]$ (**Ia**), could be isolated by heating **I** at 60°C under reduced pressure for 4 h. Found: Y, 21.1; Al, 6.4; Cl, 16.7; OPr^i, 55.7. Calc. for $C_{24}H_{56}Al_2Cl_4O_8Y_2$: Y, 21.0; Al, 6.4; Cl, 16.7; OPr^i, 55.8%.

$[\{ClY\{Al(OPr^i)_4\}_2 \cdot Pr^iOH\}_2]$ (**II**). To a benzene (*ca* 15 cm^3) suspension of $YCl_3 \cdot 3Pr^iOH$ (2.54 g, 6.77 mmol) a solution of $KAl(OPr^i)_4$ [prepared by the interaction of potassium (0.53 g, 13.60 mmol) with isopropanol (*ca* 4 cm^3), followed by addition of a benzene (*ca* 20 cm^3) solution of $Al(OPr^i)_3$ (2.77 g, 13.57 mmol) and refluxing for 2 h] was added with continuous stirring. After stirring the reaction mixture at 60°C for 5 h, it was allowed to stir overnight at room temperature (*ca* 30°C). The precipitated KCl (1.00 g, 13.60 mmol) was separated by filtration. Volatiles were removed from the filtrate under reduced pressure (30°C/1 Torr) to yield the product (**II**) (4.74, 98%), which was recrystallized in *ca* 60% yield from an n-hexane–dichloromethane (2:1) mixture. Found: Y, 12.6; Al, 7.7; Cl, 5.0; OPr^i, 74.2. Calc. for $C_{54}H_{128}Al_4Cl_2O_{18}Y_2$: Y, 12.5; Al, 7.6; Cl, 5.0; OPr^i, 74.7%.

However, recrystallization of **II** from n-hexane–dichromethane (2:1) in the presence of isopropanol (1 cm^3) gave a product of composition $[\{ClY\{Al(OPr^i)_4\}_2(HOPr^i)_2\}]$ (**III**) in 55% yield. Found: OPr^i, 76.4; Cl, 4.7; Y, 11.5; Al, 7.0. Calc. for $C_{30}H_{72}Al_2ClO_{10}Y$: OPr^i, 76.6; Cl, 4.6; Y, 11.5; Al, 7.0%. ^1H NMR spectrum of **III** exhibits peaks (with the expected integration ratios) due to α- and β-protons as a septet and a doublet ($J = 6$ Hz) centred at δ 4.27 and 1.25 ppm, respectively, and a broad peak due to the hydroxyl proton of the coordinated isopropanol at δ 2.52 ppm.

Distillation of **II** at 203°C/0.1 Torr affords the unsolvated complex $[\{ClY\{Al(OPr^i)_4\}_2\}_2]$ (**IIa**) in 65% yield. Found: Y, 13.7; Al, 8.2; Cl, 5.5; OPr^i, 72.3. Calc. for $C_{48}H_{112}Al_4Cl_2O_{16}Y_2$: Y, 13.7; Al, 8.3; Cl, 5.4; OPr^i, 72.6%.

$[\{ClY\{Al(OPr^i)_4\}_2 \cdot THF\}_2]$ (**IVa**). To a benzene (*ca* 20 cm^3) solution of $[\{ClY\{Al(OPr^i)_4\}_2 \cdot Pr^iOH\}_2]$ (2.61 g, 3.67 mmol) was added THF (*ca* 3 cm^3) and the reaction mixture was stirred for *ca* 7 h at room temperature. Removal of the volatiles under reduced pressure, followed by recrystallization from an n-hexane–dichloromethane (2:1) mixture results in the product of composition $[\{ClY\{Al(OPr^i)_4\}_2 \cdot THF\}_2]$ in 60% yield. Found: Y, 12.4; Al, 7.5; Cl, 4.9; OPr^i, 65.1. Calc. for $C_{56}H_{120}Al_4Cl_2O_{18}Y_2$: Y, 12.3; Al, 7.4; Cl, 5.0; OPr^i, 65.3%.

$[\{ClY\{Al(OPr^i)_4\}_2 \cdot Py\}_2]$ (**IVb**). Adopting a similar procedure, interaction of $[\{ClY\{Al(OPr^i)_4\}_2 \cdot Pr^iOH\}_2]$ (1.95 g, 2.68 mmol) with pyridine (*ca* 1 cm^3) affords **IVb** in 98.3% yield. It was crystallized by n-hexane at −20°C in 60% yield. Found: Y, 12.3; Al, 7.4; Cl, 4.9; OPr^i, 64.3. Calc. for $C_{58}H_{122}Al_4Cl_2N_2O_{16}Y_2$: Y, 12.2; Al, 7.4; Cl, 4.8; OPr^i, 64.7%.

$[\{(OPr^i)Y\{Al(OPr^i)_4\}_2\}_2]$ (**Va**). A solution of $KAl(OPr^i)_4$ [freshly prepared by reacting potassium (0.61 g, 15.57 mmol) with isopropanol (*ca* 5 cm^3) containing benzene (*ca* 10 cm^3) followed by reflux-

ing after adding $Al(OPr^i)_3$ (3.18 g, 15.58 mmol)] was added slowly to a suspension of $YCl_3\cdot 3Pr^iOH$ (2.93 g, 7.79 mmol) in benzene (*ca* 15 cm^3). After stirring the reaction mixture for 6 h at 60°C a solution of $KOPr^i$ [prepared by reacting potassium (0.30 g, 7.67 mmol) with isopropanol (*ca* 2 cm^3) in benzene (*ca* 10 cm^3)] was added and the resulting reaction mixture was allowed to stir for 6 h. Separation of the precipitated KCl (1.72 g, 22.8 mmol) followed by removal of volatiles affords (**Va**) as a colourless solid (5.22 g, 99.0%), which was distilled unchanged in *ca* 70% yield at 163°C/0.05 Torr. Found: Y, 13.3; Al, 7.9; OPr^i, 78.2. Calc. for $C_{54}H_{126}Al_2O_{18}Y_2$: Y, 13.2; Al, 8.0; OPr^i, 78.8%.

Following a similar procedure interaction of $YCl_3\cdot 3Pr^iOH$, $KAl(OPr^i)_4$ and $KOPr^i$ in a 1:1:2 molar ratio affords $[\{(OPr^i)_2Y\{Al(OPr^i)_4\}\}_x]$ (**Vb**) in 99% yield as a white solid, which could be recrystallized from n-hexane in 60% yield.

$[\{Zr_2(OPr^i)_9\}Y\{Al(OPr^i)_4\}_2]$ (**Vd**). A solution of $KAl(OPr^i)_4$ [prepared by the interaction of potassium (0.27 g, 6.88 mmol) with isopropanol (*ca* 3 cm^3) and $Al(OPr^i)_3$ (1.40 g, 6.88 mmol) in benzene (*ca* 15 cm^3) followed by refluxing for 2 h and removal of volatiles in benzene (*ca* 20 cm^3)] was added slowly to a suspension of $YCl_3\cdot 3Pr^iOH$ (1.29 g, 3.45 mmol) in benzene (*ca* 15 cm^3). After stirring the resulting reaction mixture at 60°C for 10 h a benzene (*ca* 15 cm^3) solution of $KZr_2(OPr^i)_9$ [freshly prepared from potassium (0.13 g, 3.43 mmol) and $Zr(OPr^i)_4\cdot Pr^iOH$ (2.66 g, 6.86 mmol) in isopropanol (*ca* 2 cm^3) and benzene (*ca* 20 cm^3) mixture, followed by stripping off the volatiles] was added in a small proportion and then allowed to stir at 55°C for *ca* 12 h. Removal of precipitated KCl (0.77 g, 10.38 mmol) by filtration and volatiles from the filtrate under reduced pressure (0.9 Torr) affords the title compound (**Vd**) (4.56 g, 99.6%) as a colourless viscous mass. The product (**Vd**) was distilled in 80% yield unchanged at 193°C/0.5 Torr. Found: Y, 6.6; Al, 4.1; Zr, 14.8; OPr^i, 75.1. Calc. for $C_{51}H_{119}Al_2O_{17}YZr_2$: Y, 6.7; Al, 4.0; Zr, 14.7; OPr^i, 75.5%.

Adopting a similar procedure, interaction of $YCl_3\cdot 3Pr^iOH$, $KAl(OPr^i)_4$ and $KZr_2(OPr^i)_9$ in 1:1:2 molar ratios, affords the product of composition $[\{Zr_2(OPr^i)_9\}_2Y\{Al(OPr^i)_4\}]$ (**Vc**) in 99% yield, which could be distilled at 195°C/0.5 Torr in *ca* 90% yield. Found: Y, 4.9; Al, 1.6; Zr, 20.7; OPr^i, 72.6. Calc. for $C_{66}H_{154}AlO_{22}YZr_4$: Y, 5.0; Al, 1.5; Zr, 20.5; OPr^i, 73.0%.

RESULTS AND DISCUSSION

Reactions of $YCl_3\cdot 3Pr^iOH$ with $KAl(OPr^i)_4$ in 1:1 and 1:2 molar ratios yield products **I** and **II**, respectively:

$$YCl_3\cdot 3Pr^iOH + n KAl(OPr^i)_4 \longrightarrow 1/2[\{Cl_{3-n}Y\{Al(OPr^i)_4\}_n(Pr^iOH)_x\}_2] + (3-x)Pr^iOH + nKCl\downarrow$$

I: $n = 1, x = 1.5$

II: $n = 2, x = 1.$

Recrystallization of **II** from n-hexane–dichloromethane in the presence of isopropanol gave $[ClY\{Al(OPr^i)_4\}_2(Pr^iOH)_2]$.

The coordinated isopropanol in **I** and **II** could be removed on prolonged evacuation (1 Torr) at 60°C, yielding the unsolvated products **Ia** and **IIa**, respectively. Alternatively **IIa** can be obtained by distillation (at 203°C/0.1 Torr) of the derivatives (**II**) under reduced pressure.

The coordinated isopropanol in **II** can easily be displaced with comparatively stronger donor ligands, such as THF or pyridine (Py):

$$II + 2L \longrightarrow [\{ClY\{Al(OPr^i)_4\}_2\cdot L\}_2] + 2Pr^iOH$$

IVa: L = THF

IVb: L = Py.

Interestingly, yttrium(III) complexes of the type $[\{YCl(N(SiMe_3)_2)_2(THF)\}_2]$[26] could not be isolated in view of a facile tendency to disproportionate into symmetrical YCl_3 and $Y\{N(SiMe_3)_2\}_3$. Thus, the stability of complexes **II**, **IIa**, **IVa** and **IVb** may be due to the combined effects of steric crowding, coordinative saturation and the chelating effect of the bidentate tetraisopropoxoaluminate ligand.

In situ reactions of $YCl_3\cdot 3Pr^iOH$, $KAl(OPr^i)_4$ and $KOPr^i$ or $KZr_2(OPr^i)_9$ in appropriate molar ratios yield novel hetero-(bi- or tri-)metallic isopropoxides of yttrium(III) according to the following reaction:

$$YCl_3\cdot 3Pr^iOH + (3-x)KL \longrightarrow [L_{(3-x)}Y\{Al(OPr^i)_4\}_x] + 3KCl\downarrow$$

Va: $x = 2$, L = OPr^i

Vb: $x = 1$, L = OPr^i

Vc: $x = 1$, L = $Zr_2(OPr^i)_9$

Vd: $x = 2$, L = $Zr_2(OPr^i)_9$.

These new heterometallic isopropoxides are highly moisture sensitive, colourless solids or viscous liquids, soluble in common organic solvents, generally volatile under reduced pressure, and depict dimeric behaviour (ebullioscopically) in benzene, except the heterotrimetallic isopropoxides **Vc** and **Vd** which tend to be monomeric.

Spectroscopic studies

The characteristic IR frequencies of these new heteroleptic isopropoxometallates of yttrium(III) have been assigned on the basis of published data on metal alkoxides.[1,4,27] The $(CH_3)_2C<$ skeletal vibrations have been observed in the range 1170–1105 cm^{-1}. The ν(C—O) have been found to exhibit absorptions in the range 1085–935 cm^{-1}. Medium to strong broad absorptions displayed in the range 710–410 cm^{-1} may be related to ν(Al—O) (710–640 cm^{-1}), ν(Zr—O) (570–535 cm^{-1}) and ν(Y—O) (460–410 cm^{-1}). The chloro derivatives exhibited additional absorptions in the range 290–205 cm^{-1}, which may be tentatively assigned to Y—Cl stretching frequencies.

Despite the possibility of the inequivalent nature of the isopropoxy groups in plausible structures for the new derivatives, the room-temperature ^{1}H NMR spectra (in $CDCl_3$) of **I**, **Ia**, **II**, **IIa**, **III**, **IVa**, **IVb**, **Va** and **Vb** exhibit a doublet (J = 6 Hz) at δ 1.27, 1.21, 1.25, 1.27, 1.25, 1.24, 1.26, 1.26, 1.24 and a septet (J = 6 Hz) at δ 4.22, 4.03, 4.24, 4.24, 4.27, 4.23, 4.18, 4.31, 4.26 ppm, respectively, due to *gem*-dimethyl (β-H) and methine (α-H) protons. Derivatives **I**, **II** and **III** showed additional broad signals at δ 3.06, 3.40 and 2.52 ppm, respectively, due to OH of the coordinated isopropyl alcohol. The presence of coordinated THF in the derivative **IVa** is indicated by the signals at δ 1.83 (β-CH_2) and 3.69 (α-CH_2), while the appearance of three ^{1}H NMR signals at δ 7.22, 7.58 and 8.66 ppm in the case of the derivative **IVb** is characteristic of coordinated pyridine. The presence of pyridine in the complex **IVb** is further corroborated by the peaks at δ 124.5, 139.6 and 148.4 ppm in its ^{13}C NMR spectrum.

Interestingly, the ^{1}H NMR spectrum of **Vc** exhibits three doublets (J = 6 Hz) centred at δ 1.24, 1.39 and 1.62 ppm, respectively, due to terminal-, μ_2- and μ_3-OPr^i groups, which is consistent with a structure involving bidentate ligation modes of both the groups $Zr_2(OPr^i)_9^-$ and $Al(OPr^i)_4^-$ with a further possibility for a $Zr_2(OPr^i)_9$ unit to coordinate through an appropriately situated isopropoxy group. By contrast, the methine protons appear as an average septet (J = 6 Hz) at δ 4.39 ppm. The above structural possibility is further supported by its ^{13}C NMR spectrum with the appearance of the peaks at δ 25.74, 26.66, 27.31 (β-carbons) and 65.83, 69.03, 72.06 (α-carbons).

By contrast, the spectrum of **Vd** exhibits only two doublets (J = 6 Hz) centred at δ 1.22 and 1.23 ppm due to gem-dimethyl protons, while methine protons appear as an average septet (J = 6 Hz) at δ 4.27 ppm.

The ^{13}C NMR spectrum of the product **I** exhibits two signals at δ 24.9 and 26.5 ppm due to β-carbons and two signals at δ 65.65 and 66.12 ppm ascribable to α-carbons of the isopropoxy groups. The formulation of the product **I** as $[(Pr^iO)_2Al(\mu\text{-}OPr^i)_2Y(Cl)(Pr^iOH)(\mu\text{-}Cl)_2(\mu\text{-}Pr^iOH)Y(Cl)(Pr^iOH)(\mu\text{-}OPr^i)_2Al(OPr^i)_2]$ involving a hepta-coordinated environment around yttrium is supported by the elemental analyses, molecular weight measurements, integrated intensity ratio of the ^{1}H NMR signals at δ 1.27, 3.07 and 4.22 ppm and appearance of a single ^{89}Y NMR peak at δ 313.3 ppm.

The ^{13}C NMR spectrum of **Vb** shows a single peak at δ 26.97 (β-carbons) and two peaks at δ 64.51 and 66.14 (α-carbons) ppm of the isopropoxy groups.

The ^{89}Y NMR spectra of **I**, **Ia**, **II**, **IIa** and **Va** exhibit single peaks at δ 313.3, 361.9, 214.6, 256.9 and 195.1 ppm, respectively. The ^{89}Y NMR spectrum of the product **Vb** exhibits four sharp peaks at δ 219.26, 195.79, 157.20 and 155.01 ppm, probably due to the presence of yttrium(III) in different coordination (five, six or higher) geometries.[28]

In view of the available spectroscopic data and the observed molecular weight (molecular complexity 2.4), 1128 against 470 (calculated value for monomeric derivative), it appears that there might be an equilibrium of the type indicated below:

$$\underset{^{89}\text{Y NMR}:\,\delta\,157.2,\,155.01\text{ ppm}}{[\{Y\{Al(OPr^i)_4\}(OPr^i)(\mu\text{-}OPr^i)\}_2]\,(\mathbf{Vb})} \rightleftharpoons$$

$$\underset{^{89}\text{Y NMR}:\,\delta\,195.79}{(Pr^iO)Y\{Al(OPr^i)_4\}_2} + 1/n\underset{^{89}\text{Y NMR}:\,\delta\,219.26\text{ ppm}}{[Y(OPr^i)_3]_n}^{29}$$

(n = 4 or 5)

These data in conjunction with the recent X-ray crystallographic authentication of a praseodymium analogue,[2] $[\{Pr\{Al(OPr^i)_4\}_2(\mu\text{-}Cl)(Pr^iOH)\}_2]$, tend to support a dimeric type structure (Fig. 1) for the products **II**, **IVa**, **IVb**, **IIa** and **Va**.

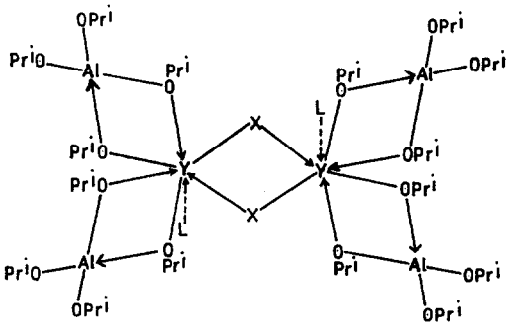

Fig. 1. Proposed structures of the derivatives $[\{XY\{Al(OPr^i)_4\}_2 \cdot L\}_2]$ [when X = Cl and L = Pr^iOH (**II**), THF (**IVa**), Py (**IVb**), absent (**IIa**); when L is absent and X = OPr^i (**Va**)].

The facile removal of coordinated isopropyl alcohol from **II** *in vacuo* is understandable in terms of steric congestion around the smaller Y^{3+} (0.881 Å) compared with that of the larger Pr^{3+} (1.013 Å). This is also reflected in the observed molecular weight (1319), which tends to suggest dissociation of the coordinated isopropyl alcohol in refluxing benzene.

The structural formulation of **IIa** and **Va** as dimeric species (Fig. 1) is mainly based on (1) their molecular weight measurements and (2) ^{89}Y NMR chemical shifts[30] (δ 191.8 ppm) for the derivative **Va**, in which each yttrium atom is surrounded by six oxygens. Interestingly, the ^{80}Y NMR spectrum of $[Y\{Al(OPr^i)_4\}_3]$, for which an octahedral geometry has been suggested on the basis of molecular weight measurements and ^1H NMR studies, exhibits a single sharp peak at δ 192.18 ppm.

The appearance of a single peak at δ 256.87 ppm in the ^{89}Y NMR spectrum of **IIa** is interpretable in terms of the lower electronegativity of Cl (3.0) compared with that (3.5) of O, causing a deshielding effect.

Further, it is interesting to note that (1) the ^1H NMR spectral studies of almost all the products indicate fast exchange (on the NMR time-scale) between bridging and terminal isopropoxy groups; (2) in agreement with the structural formulation depicted in the preceding account, the products **I**, **II**, **IIa**, **IVa**, **IVb**, **Va**, **Vb**, **Vc** and **Vd** exhibit rather broad ^{27}Al NMR signals centred respectively at δ 70.18, 75.15, 66.70, 75.00, 75.50, 80.86, 66.10, 56.05 and 58.58 ppm, characteristic of four-coordinated aluminium(III) species,[31–33] which is the form generally adopted by the $\{Al(OPr^i)_4\}^-$ ligand, as shown in the structures of $Al\{Al(OPr^i)_4\}_3$,[34,35] $\{C_6H_{11}NH_3\}^+\{Al(OPr^i)_4\}^-$[36] and $[\{Pr\{Al(OPr^i)_4\}_2(\mu\text{-}Cl)(Pr^iOH)\}_2]^2$; and (3) the labile nature of solvated products is in agreement with the tendency of yttrium(III) to attain an octahedral environment of the monodentate oxygen ligand.[37–40].

Attention may be finally drawn towards rather a novel dimension depicted in the extraordinary stability of volatile bi- and trimetallic alkoxide derivatives, which appear to involve chlorine/alkoxy bridges (without any metal–metal bonds, often characteristic of polymetal systems).

Acknowledgements—We (RCM & AS) thank the DST, New Delhi, for support of this work. We are grateful to Prof. C. L. Khetrapal, Indian Institute of Science, Bangalore, for his valuable assistance in connection with ^{89}Y NMR studies. We would also like to acknowledge the technical assistance of Mr Suman Gupta in recording ^{89}Y NMR spectra. UMT acknowledges the UGC, New Delhi, and the Rajasthan Government for providing JRF under the Special Assistance Programme.

Abstract—Air-sensitive bivalent europium, samarium and ytterbium complexes have been prepared with the hydrotrispyrazolylborate and hydrotris(3,5-dimethyl-pyrazolyl)borate ligands and some reactions with CO, propene and $(Me_2NCS_2)_2$ investigated.

Since the first homoleptic polypyrazolylborate complexes $[Ln\{HBpz_3\}_3]$ [Ln = Y, La, Ce, Pr, Sm, Gd, Er, Yb, Lu; $HBpz_3$ = hydrotris(pyrazol-1-yl)borate] were reported by Bagnall and Takats,[1] a variety of compounds of the general formula $[Ln\{HBpz_3\}_2X]$ (X = a bidentate monoanionic chelating ligand) have been reported.[2–11] All of these compounds contain lanthanide ions in the tervalent state and some provide analogues of corresponding complexes containing cyclopentadienyl or pentamethylcyclopentadienyl ligands in place of $HBpz_3$.[12–16] However, the sterically demanding nature of $HBpz_3$ tends to produce monomeric species rather than the dimers or oligomers often obtained with the cyclopentadienyl ligands. A consideration of steric angle factors indicates that tridentate $HBpz_3$ is more sterically demanding than C_5Me_5.[8] This suggests that $HBpz_3$ would be a suitable ligand for the bivalent state lanthanide ions since it should be more effective than C_5Me_5 in achieving steric saturation in complexes of 2:1 ligand:metal stoichiometry. Thus, analogues of $[Sm(\eta^5\text{-}C_5Me_5)_2(THF)_2]$[17,18] and $[YB(\eta^5\text{-}C_5Me_5)_2(THF)]$[19] might be obtained using $HBpz_3^-$ or $HB(Me_2pz)_3^-$ in place of $C_5Me_5^-$. Three of the lanthanide elements have accessible bivalent states, samarium, europium and ytterbium.[20] Bivalent lanthanide complexes are generally highly air-sensitive; the most stable being the europium complexes, which are water stable in some cases. The diiodides LnI_2 (Ln = Sm, Yb) offer a convenient starting material for the synthesis of bivalent complexes.[21] They are soluble in THF and are readily formed by the reaction of the metallic element (Sm or Yb) with 1,2-diiodoethane.

The reaction between LnX_2 (Ln = Sm, Yb, X = I; Ln = Eu, X = Cl) and $K\{HBpz_3\}$ in a 2:1 molar ratio in THF leads to the formation of soluble brown, red and yellow complexes containing samarium, ytterbium and europium, respectively. The yellow europium complex was also prepared in aqueous media by the reaction of Eu^{2+} ions, gen-

*Present address: School of Science, Staffordshire University, College Road, Stoke on Trent, Staffordshire ST4 2DE, U.K.

† Author to whom correspondence should be addressed.

erated *in situ* from Eu^{3+} with amalgamated zinc, with $K\{HBpz_3\}$. However, the reaction product was unstable in acidic water and could not be isolated using this approach. As with their pentamethylcyclopentadienyl-containing counterparts, these complexes are all extremely air-sensitive.

The ^1H NMR spectrum of the samarium(II) complex contains signals attributable to coordinated THF. In addition, there are three singlets of area ratio 1:1:1 at δ_{TMS} 11.71, 4.10 and 0.09 ppm, attributable to the $HBpz_3$ ligands which are undergoing rapid exchange. The mass spectrum of this compound contains a molecular ion for $[Sm\{HBpz_3\}_2]^+$ as the most intense peak; other fragment ions observed correspond to $[Sm\{HBpz_3\}pz]^+$ (80%), $[Sm\{HBpz_3\}]^+$ (9%) and $[Smpz_2]^+$ (45%). The ^1H NMR spectrum of the red complex containing the diamagnetic ($4f^{14}$) ytterbium(II) ion exhibits three pyrazolyl resonances of equal area at δ_{TMS} 7.75(d), 7.40(d) and 6.09(t) ppm. The mass spectrum contains the molecular ion for $[Yb\{HBpz_3\}_2]^+$ at 28% of the intensity of the most intense ion, $(pzH)^+$. Other fragments observed correspond to $[Yb\{HBpz_3\}pz]^+$ (37%), $[Yb\{HBpz_3\}]^+$ (8%), $[Ybpz_2]^+$ (10%) and $[Ybpz]^+$ (7%). This compound could also be prepared from the direct reaction of the known complex $Yb\{HB(pz)_3\}_3$ with ytterbium metal in THF. The orange europium(II) complex could not be studied by ^1H NMR because of the highly paramagnetic nature of the $4f^7$ Eu^{2+} ion.

The IR spectra for the samarium(II) and europium(II) complexes are virtually identical suggesting that, like the samarium compound, the europium complex contains coordinated THF. The IR spectrum of the ytterbium compound is similar to those of the samarium and europium compounds, but shows slight differences which may be attributed to the absence of coordinated THF. All of the compounds exhibit ν(BH) at 2440 cm^{-1} and ν(CN) at 1500 cm^{-1}.

The reaction of LnX_2 (Ln = Sm, Yb, X = I; Ln = Eu, X = Cl) with $K\{HB(Me_2pz)_3\}$ [potassium hydrotris(3,5-dimethylpyrazolyl)borate] in a 1:2 molar ratio in THF affords air-sensitive, insoluble purple complexes for samarium and ytterbium and an insoluble orange complex for europium. The IR spectrum of all three solids contains a B—H stretching band at 2530 cm^{-1} and other characteristic ligand bands. These insoluble complexes are intimately mixed with alkali metal halide, but can be purified by sublimation at 200°C under dynamic high vacuum (10^{-6} Torr = 1.3×10^{-4} Nm^{-2}). However, attempts to prepare crystals of $[Sm\{HB(Me_2pz)_3\}_2]$ by heating at 200°C in a sealed evacuated (5×10^{-7} Torr = 7×10^{-5} Nm^{-2}) tube led to the formation of a green melt after 6 h. The orange europium complex can also be prepared from the reaction between $HB(Me_2pz)_3^-$ and Eu^{2+} in water, the orange precipitate being obtained free from alkali metal halide impurities.

In view of the novel reactivity observed[22–26] for the bispentamethylcyclopentadienyl samarium(II) complexes we were interested in determining whether a similar reactivity might be associated with the polypyrazolylborate lanthanide(II) complexes. However, we have not so far succeeded in establishing this. Unlike $[(\eta^5\text{-}C_5Me_5)_2Sm(THF)_2]$[22] a suspension of the samarium(II) trispyrazolylborate complex in toluene does not react with carbon monoxide at 6 atm. In an attempt to prepare a heteroleptic allyl complex, again following the precedent of $[(\eta^5\text{-}C_5Me_5)_2Sm(THF)_2]$,[27] it was found that both the samarium(II) and ytterbium(II) trispyrazolylborate complexes react with propene at 2.7 atm. and 20°C to give the insoluble $[Sm\{HBpz_3\}_3]$ and the soluble $[Yb\{HBpz_3\}_3]$, respectively, as the only characterizable products. In a similar reaction, performed in an attempt to demonstrate their reducing power, these bivalent complexes were reacted with $(Me_2NCS)_2S_2$ in THF. However, again $[Ln\{HBpz_3\}_3]$ (Ln = Sm, Yb) were isolated as the only characterizable products. This failure to establish a parallel to the chemistry of the pentamethylcyclopentadienyl complexes may reflect the relative thermodynamic stability of $[Ln\{HBpz_3\}_3]$ (Ln = Sm, Yb), which can be formed by ligand exchange reactions following oxidation of the oxidation state(II) complex.

BOOK REVIEW

Electron Paramagnetic Resonance of *d* Transition Metal Complexes. By F. E. Mabbs and D. Collison. (Studies in Inorganic Chemistry, Vol. 16). Elsevier, Amsterdam, 1992 (obtainable in U.S.A./Canada from Elsevier, PO Box 882, Madison Square Station, NY 10159). ISBN 0-444-89852-2, xx + 1326 pp., $622/Dfl995.

EPR can be a very powerful technique for the study of paramagnetic transition metal compounds but, as the authors remark in their introduction, existing texts on EPR fall between the two stools of concentrating on free radicals (the majority) or treating the subject at an advanced level (e.g. Griffith, Abragam and Bleaney). This book is an attempt to produce a text that bridges that gap.

The early chapters are devoted to introducing the reader to basic EPR concepts; thus, the first nine (of 18) chapters only deal with $S = 1/2$ systems. Chapters 1 and 2, indeed, are concerned with the basics of the EPR experiment together with logistical problems, such as observing signals, sample handling, effect of spectrometer frequency and showing the reader ways of obtaining g values from powder and frozen solution spectra. The "hard bits" begin with Chapter 3, introducing the concept of the spin-Hamiltonian and the use of perturbation theory, subsequently discussing some simple single-crystal spectra; the ensuing chapters bring in the concept of nuclear hyperfine interaction, treated qualitatively then quantitatively, followed by quadrupole and Zeeman effects. Throughout the book lavish use is made of illustrative spectra, both "real" and simulations; this is a real strength of the book and their use will be a real help in the interpretation of spectra to any non-specialist. Chapter 7 goes into considerable detail in discussing simulation methods, including a worked example showing how matches between real and simulated spectra can be achieved (demonstrating the importance, even for an $S = 1/2$ system, of working at more than one frequency). Several groups' simulation techniques are discussed.

The second part of the book begins with a brief résumé of crystal field theory and then goes on to relate electronic structure to the spin-Hamiltonian parameters for $S = 1/2$ systems, including cases such as low-spin iron(III) and cobalt(II) as well as the more usual examples of copper(II) and titanium(III).

From Chapter 10 onwards the book discusses the less familiar systems with $S > 1/2$. Individual chapters are devoted to $S = 1$, $S = 3/2$, $S = 2$ and $S = 5/2$ cases, with plenty of simulated spectra shown at the end of each chapter showing how spectra vary with changes to the Hamiltonian parameters D and λ, as well as temperature, and the very useful frequency independent resonance (FIR) diagrams where resonance positions are shown as graphs of D against magnetic field; these enable approximate choices of D and λ to be made as preliminaries to accurate fitting.

Chapter 15 examines polynuclear complexes (including a limited number of simulated spectra for $S > 5/2$), whilst Chapter 16 goes through how to simulate spectra for the cases where $S > 1/2$. These are most valuable, for example, for $S = 5/2$ systems in those cases where the zero-field splitting is comparable to $h\nu$, as the observed spectrum is very sensitive to factors like the spin-Hamiltonian parameters. (Here the caveat is that at present computation times, even on a mainframe computer, can apparently run to hours in these "difficult" cases, in contrast to the situations where $D \gg h\nu$, often computable on a PC.) The book does not neglect factors like off-axis turning points, "forbidden" transitions, D- and A-strain. Chapter 17 looks at the effect of extended electron exchange on spectra, whilst Chapter 18 considers the factors responsible for line broadening in solids and solutions. The book is completed by useful appendices listing properties of solvents, physical constants and conversion factors, isotopic spins and abundances, mathematical relationships and expanded FIR diagrams. There are very thorough subject and chemical indexes.

Transition-metal EPR represents one of the "hard bits" of inorganic chemistry. The book is not intended as a guide to the literature of transition metal EPR, although plenty of references to the primary literature are given with, very commendably, a number of 1992 references. Misprints seem very few [e.g. J. S. Griffiths on p. 337, oxovanadium(V) on p. 438]. The immense number of simulated spectra make the book tremendously valuable for this alone (particularly with the cost of computing some of these). This book should go to a second edition, so here are some suggestions for inclusion! Although the concept of determining the sign of D is set out, it would have been nice to see the mathematical principles elucidated, with a real example. Likewise, I missed seeing an example of the application of EPR to spin-equilibrium situations. There are some of the conventional scatter plots of g vs A for ions like vanadyl and copper(II) indicating the dependence of g and A on ligand donor atoms, as well as a table of g values for low-spin d^5, but I think that a rather greater amount of tabulated data, for example, spin-Hamiltonian parameters for high-spin chromium(III) and iron(III), would have been valuable (although it may seem unfair to cavil with a book of over 1300 pages, collecting some data in a further appendix would have been very useful).

This work should be a *sine qua non* for inorganic chemistry departments, although the price will give librarians some sleepless nights.

SYNTHESIS AND REACTIVITY OF BIS-4-PYRONE AND BIS-4-PYRIDINONE DICHLOROTIN(IV) COMPOUNDS

J. BURGESS* and S. A. PARSONS

Department of Chemistry, University of Leicester, Leicester LE1 7RH, U.K.

(*Received* 20 *April* 1993; *accepted* 30 *April* 1993)

Abstract—A number of tin(IV) complexes, $Sn(LL)_2X_2$, have been prepared in which LL is a 4-pyronate or 4-pyridinonate ligand and X is chloride or alkoxide. UV–vis, IR and NMR (^1H, ^{13}C, ^{119}Sn) spectra are reported for these complexes. Reactivities have been established through kinetic studies of nucleophilic substitution in acetonitrile solution. Ligand effects on spectra and reactivity are discussed and compared with those for similar metal(IV) complexes, especially of titanium.

The pyrones kojic acid (**1**) and maltol (**2**) are naturally occurring ligands. Maltol was first isolated from larch bark; kojic acid is derived from bacterial fermentation of carbohydrates, for instance of starch by *Aspergillus oryzae*.[1] Maltol (**2**) and ethylmaltol (**3**) are permitted food additives (E636 and E637) used in the baking industry. They are thus attractive ligands for use either in controlling metal ion concentrations in the human body, or for the introduction of appropriate isotopes for diagnosis or therapy.[2] In practice the closely related 4-pyridinones (e.g. **4**–**6**) are proving more suitable,[3] both since they form significantly more stable complexes and also since, with two variable groups R and R′, they can be tailored more readily than the pyrones.[4] Almost all present and potential applications involve the tris-ligand complexes of metal(III) cations, as for example in the administration of iron(III) complexes for the treatment of anaemia, the use of the ligand L1 (**4**) in clinical trials for dealing with iron overload in thalassaemia[3] and the proposal to use such ligands in the control of aluminium levels in the hope that the progress of senile dementias might at least be slowed.[5] Ligands of these types may also prove of value for the introduction of, for instance, complexes containing gadolinium(III) to act as contrast-enhancing agents in magnetic resonance imaging (MRI)[6] or $^{90}Y^{3+}$ for tumour targetting and destructive irradiation.[7] The most recent application of promise involves vanadium(IV), with the bis-maltolato complex $VO(malt)_2$ claimed to be of value in the treatment of diabetes.[8] In all these applications one of the biggest attractions is the possibility of oral administration.

Several β-diketone complexes of metal(IV) ions of the $M(\beta\text{-dik})_2X_2$ type have shown promise as anti-tumour agents.[9] In particular the benzoylacetonate (bzac) (**7**) compound $Ti(bzac)_2(OEt)_2$, budotitane, is showing considerable promise in the treatment of colon cancers.[10] A number of tin(IV) compounds,[11,12] including the dibenzoylmethanato complex $Sn(bzbz)_2Cl_2$,[13] have also shown some promise in this respect. We therefore felt that synthesis and study of a series of tin(IV) compounds, $Sn(LL)_2X_2$, with LL = a pyronate or pyridinonate ligand [known to form stable complexes, $Si(LL)_3^+$, with silicon[14]] and X = halide or alkoxide, would be interesting and possibly provide one or more compounds of pharmacological value. A further matter of interest to us was the kinetic behaviour of this type of complex, for which rather little information appears to be available. There is rate constant, activation parameter ($\Delta H^\ddagger$, $\Delta S^\ddagger$, $\Delta V^\ddagger$) and solvent effect information on racemization of $Ge(acac)_3^+$ (acacH = acetylacetone = pentane-2,4-dione, **8**)[15] and some kinetic information on intramolecular rearrangements within $Sn(\beta\text{-diketonate})_2Cl_2$ complexes,[16–18] but very little on kinetics of ligand replacement. For tin the only such data appear to be a few results on the relatively slow chloride exchange at $Sn(acac)_2Cl_2$ in chloroform[19] and kinetic parameters for hydrolysis of six dihalogenotin(IV) β-diketonates.[20]

We have, therefore, prepared a number of complexes of the $Sn(LL)_2Cl_2$ type, with LL = 4-pyronate or 4-pyridinonate, and characterized them, particularly by NMR and IR spectroscopy. We have also measured rates of ligand replacement in a range of conditions. We report our results here and discuss them in relation to other complexes, particularly of similar bidentate ligands such as β-diketonates (e.g. **7** and **8**), tropolonate (**9**) and hydroxamates (**10** and **11**).

EXPERIMENTAL

Preparation of complexes

The ethylmaltolate complex $Sn(etmalt)_2Cl_2$ was prepared from tin tetrachloride. Ethylmaltol (2.8 g, 0.02 mol) was dissolved in anhydrous acetone at room temperature. $SnCl_4$ (2.6 g, 0.01 mol) was added dropwise with stirring. The solution was refluxed for 30 min during which time a white precipitate formed. This was filtered and washed with diethyl ether. The crude product was recrystallized from dichloromethane/40–60 petroleum ether, to give 3.4 g of white crystals (85% yield). All the other complexes were prepared in an analogous manner. Their melting points, CHN analyses and UV–vis absorption maxima are given in Table 1, IR frequencies in Tables 2 and 3 and NMR data in Table 4.

Apparatus and techniques

IR spectra were obtained using Nujol mulls on a Perkin–Elmer FTIR instrument, NMR spectra on a Bruker AM300 and UV-vis spectra on a Pye–

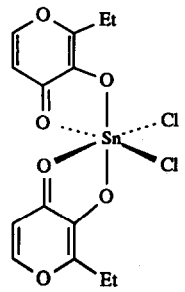
Unicam SP1800. This last instrument, which was equipped with a thermostatted cell holder and PC for data analysis, was also used for the kinetic measurements.

RESULTS AND DISCUSSION

In all cases the product obtained was *cis*-bis-pyronato- or bis-pyridinato-dichlorotin(IV), as was clear from analysis (see above) and from IR and NMR spectroscopy (see below). In the case of the ethylmaltol (**3**) derivative a crystal of product of suitable quality for X-ray structural determination[21] was obtained. This was confirmed to be the expected *cis*-dichloro isomer, with its unsymmetrical bidentate ligands disposed as shown in **12**.



12

IR spectroscopy

IR frequencies and their assignments are given in Table 2, while tin–chloride stretching frequencies for these and a number of related complexes are

collected together in Table 3.[22–25] In all cases, except for the broad band observed for the acethydroxamate complex and the single Sn—Cl stretch for $SnCl_6^{2-}$, two distinct bands assignable to ν(Sn—Cl) in *cis* geometry are found. The ν(Sn—Cl) for our complexes are similar to those for Sn(β-diketonate)$_2Cl_2$ and indeed for $Sn(cp)_2Cl_2$ and $SnCl_6^{2-}$, as is clear from the following order of mean ν(Sn—Cl) values (pyrone and pyridinone complexes in bold type) for complexes $Sn(LL)_2Cl_2$:

aha > **etmalt** > **memalt** > cp > bzbz > **koj** =

trop > bzac > **depp** > **empp** > acac > **dmpp**.

The more weakly bonding pyronate ligands produce higher ν(Sn—Cl) than pyridinonates; the most strongly bonding pyridinonate, dmpp, is associated with the lowest ν(Sn—Cl). The values for the β-diketonate complexes are consistent with this sequence. These IR results are correlated with kinetic results in the appropriate section later.

Discussion of ν(Sn—O) is potentially more complicated, since the bonds in question are incorporated in chelate rings. In practice ν(Sn—O) values are identical within experimental uncertainty for all the pyrone and pyridinone complexes (Table 2; values for the kojate complex are available already[22]). There are, however, significant differences between this very short range of values for the pyrone and pyridinone complexes and the ranges characteristic of tropolonates,[26] β-diketonates[27] and 8-hydroxyquinolinates[28] in complexes $Sn(LL)_2XY$.

NMR spectroscopy

The ^1H, ^{13}C and ^{119}Sn chemical shifts are listed in Table 4, which also includes $^{119}Sn—^{13}C$ coupling constants. Very few direct comparisons with published data appear to be possible.[29] ^1H, ^{13}C and ^{119}Sn chemical shifts and coupling constants are available for one $Sn(koj)_2X_2$ compound,[22,30] but here X = methyl rather than chloride. There is only limited proton NMR information on β-diketonate complexes, Sn(β-dik)$_2X_2$.[16,18]

Kinetics and mechanism

The complexes are indefinitely stable in solution in dry acetonitrile, but addition of water, thio-

cyanate, pyrazine or other potential nucleophiles results in instant reaction. Such reactions are complete within the time needed to mix solutions and run their UV–vis spectra on a conventional spectrophotometer. Thereafter, there is a much slower second reaction, occurring on a time scale appropriate for kinetic monitoring. The products of the second stage are the bis-nucleophile complexes $Sn(LL)_2(nucl)_2$; we are able to obtain rate constants for the reactions:

$$Sn(LL)_2Cl(nucl)^+ + nucl \rightarrow Sn(LL)_2(nucl)_2^{2+} + Cl^-.$$

As both reactants on the left-hand side of this equation vary with the nature of the nucleophile it is not possible to establish relative reactivities for various incoming groups in the way that we were able to do with titanium(IV) analogues.[31] We have, therefore, carried out only a few runs comparing reactivities of water, thiocyanate and pyrazine as nucleophiles and have concentrated our kinetic investigations on the effects of the nature of the non-leaving ligands LL on reactivities with one nucleophile, viz. thiocyanate.

All kinetic runs were conducted in acetonitrile solution, at 298.2 K, with the incoming nucleophile present in considerable excess over the tin compound. First-order kinetics were followed in every run; observed first-order rate constants, computed from absorbance data collected over the first 2.5 half-lives, are reported as a function of nucleophile concentration in Table 5. In each series of runs over a range of nucleophile concentrations a plot of observed rate constant against nucleophile concentration was linear, but with a positive intercept

on the y (rate constant) axis:

$$k_{obs} = k_1 + k_2[\text{nucleophile}].$$

This is illustrated for the series of reactions with thiocyanate in Fig. 1 and for reaction of the ethylmaltol complex with thiocyanate, pyrazine and water in Fig. 2. Values of k_1 and k_2 are collected together, with their uncertainties, in Table 6.

All the values of k_1 (Table 6) are remarkably similar. For the series of thiocyanate reactions these rate constants correspond to solvolytic dissociation of the second chloride:

$$Sn(LL)_2(NCS)Cl + NCS^- \rightarrow Sn(LL)_2(NCS)_2 + Cl^-.$$

As the ligands LL are all two-oxygen chelators of rather similar properties, it is not unreasonable that non-leaving ligand effects on chloride loss should be small. It is rather more surprising that k_1 values for chloride loss from the three complexes Sn(etmalt)$_2$Cl(NCS), Sn(etmalt)$_2$Cl$(OH_2)^+$ and Sn(etmalt)$_2$Cl(pz)$^+$ are also so similar in value. However, a similarly small range of rate constants has recently been found for analogous titanium(IV) complexes.[31]

The relative reactivities of the series of complexes $Sn(LL)_2(NCS)Cl$ towards nucleophilic attack by thiocyanate (Fig. 1), i.e. the order of k_2 values (Table 6), is the same as that in analogous reactions of titanium(IV) complexes.[31] Indeed rate constants for nucleophilic attack at the tin and titanium complexes correlate well, as shown in Fig. 3. The slope of the correlation line in Fig. 3 is 30, indicating that

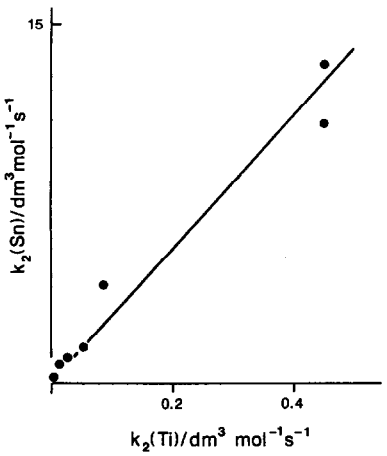

Fig. 3. Correlation of second-order rate constants for thiocyanate attack at tin(IV) and titanium(IV) complexes, $M(LL)_2(NCS)Cl$, under comparable conditions.

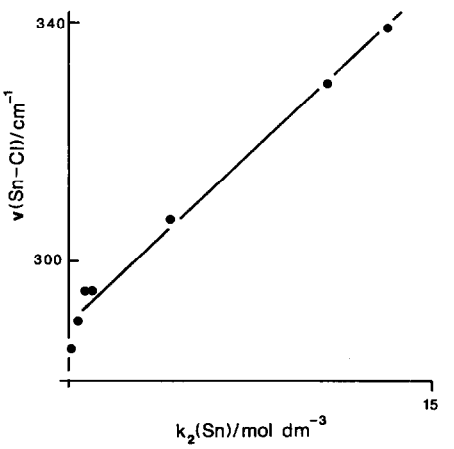

Fig. 4. Correlation of second-order rate constants for thiocyanate attack at complexes of $Sn(LL)_2(NCS)Cl$ with tin–chloride stretching frequencies for the respective complexes $Sn(LL)_2Cl_2$.

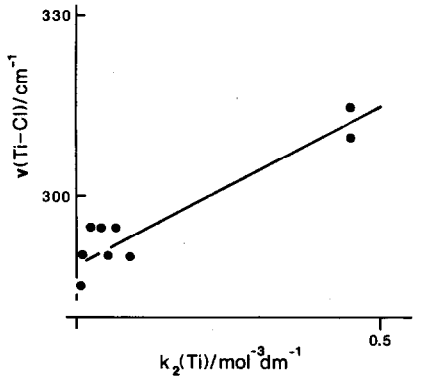

Fig. 5. Correlation of second-order rate constants for thiocyanate attack at complexes of $Ti(LL)_2(NCS)Cl$ with titanium–chloride stretching frequencies for the respective complexes $Ti(LL)_2Cl_2$.

the tin(IV) centre is considerably more reactive than titanium(IV) in this type of complex. This reactivity difference can be ascribed to the different sizes of the tin and the titanium, whose notional ionic radii in six-coordination differ by 8.5 pm, according both to the original Shannon estimates[32] (Sn 69, Ti 60.5 pm) and to the later Shannon and Prewitt values[33] (Sn 83, Ti 74.5 pm). Frazer and Haines found that second-order rate constants were very similar for the three β-diketonate complexes, $Sn(\beta\text{-dik})_2Cl_2$ ($k_2 = 8.8$ for β-dik = acac, 10.3 for bzac and 7.5 $dm^3\ mol^{-1}\ s^{-1}$ for bzbz, in chloroform at 30°C).[20] These values are remarkably close to ours for the ethylmaltol analogue, especially when allowance is made for the differences in solvent (chloroform vs acetonitrile) and in temperature. Frazer and Haines reported activation entropies of around $-50\ J\ K^{-1}\ mol^{-1}$ for the reactions of their three β-diketone complexes, which is consistent with bimolecular water attack at the tin.

Figure 4 shows that there is a strong correlation between IR stretching frequencies, ν(Sn—Cl), and second-order rate constants for thiocyanate attack. Stronger tin–chloride bonding makes attainment of the transition state harder since the bond to the leaving group has to be extended considerably to form the S_N2 transition state. There is a similar correlation for the analogous titanium complexes and reactions.[31]

Anti-tumour activity

The complex $Sn(empp)_2Cl_2$ was tested against a number of cell lines. It was found to have significant but rather modest activity against K562 leukemia and MAC13 murine tumour cells, and rather small activity against two other murine lines and HCT18 and HRT18, human colon and rectal carcinoma lines, respectively. It is interesting that the tin complex shows most activity against the leukemia cells, whereas analogous titanium complexes only appear to show significant activity against colon tumours. Earlier reports[11,34] also suggested greatest activity of complexes of the R_3SnOH, R_2SnO and $R_2SnOSnR_2$ type against P388 leukemia.

A ROUTE LEADING TO A STABLE M—H—B UNIT (M = Si, Ge, Sn). THE BIDENTATE AND TRIDENTATE BEHAVIOUR OF TETRAHYDROBORATE

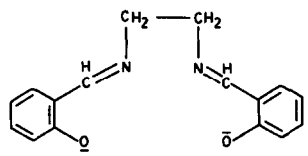
K. S. SIDDIQI,* FATHI M. A. M. AQRA, S. A. SHAH and S. A. A. ZAIDI

Department of Chemistry, Aligarh Muslim University, Aligarh 202 002, India

(*Received* 27 *January* 1993; *accepted* 30 *April* 1993)

Abstract—The complex $[MLCl_2]$ [M = Si, Ge and Sn, L = NN′-ethylene bis-(salicylideneiminate)] reacts with KBH_4 in THF to give $[ML(BH_4)_2]$. The results indicate that the BH_4^- ion behaves as a bidentate ligand and the central metal atom possesses eight-coordination. The conductivity measurements reveal their covalent nature. Another series of compounds of the types $[R_2Sn(BH_4)_2]$ (R = Me, Bu and Ph) and $[R_3Sn(BH_4)]$ (R = Bu and Ph) have been synthesized by the direct interaction of R_2SnCl_2 and R_3SnCl with excess KBH_4 in THF, respectively. In this case it is found that the tetrahydroborate group acts as a tridentate ligand implying eight- and six-coordination of the tin atom, respectively. The molar conductance value ascertains their non-electrolytic character.

It is a conspicuous feature that a polydentate ligand provides unusual stabilization of different oxidation states as well as rigid coordination spheres for the metal.[1,2] Redox reactions carried out on transition metal chelate complexes lead either to a change in the oxidation state of the metal or to the generation of electrophilic and nucleophilic sites on the ligand.[3–8] Since a group(IV) metal in a low oxidation state is able to promote the coordination and the activation of small molecules,[9–11] our interest was focussed on some precursors of low-valent group(IV) metal complexes, containing ligands such as NN′-ethylene bis-(salicylideneiminate) (Fig. 1), which stabilize various oxidation states of these metals.[12]



NN′-ethylene bis (Salicylideneiminate)

Fig. 1.

Transition metal tetrahydroborates are important as precursors to solid metal borides,[13] to metal hydrides[14] as well as alkyls.[15] From the structural point of view they are intriguing for the versatility displayed by the BH_4 group in the mode of its ligation to the metal centre, which may entail triple,[16] double[16] or single[17] hydrogen bridges.

The present paper reports two types of compounds: (1) $[ML(BH_4)_2]$ [M = Si, Ge, and Sn; L = NN′-ethylene bis-(salicylideneiminate)] and (2) $[R_2Sn(BH_4)_2]$ (R = Me, Bu, Ph) and $[R_3Sn(BH_4)]$ (R = Bu, Ph) with a view to exploring the nature and mode of bonding of the BH_4^- ion and to establish a group(IV) metal hydrido complex.

EXPERIMENTAL

Ethylenediamine (Koch Light), salicylaldehyde (E. Merck), $SiCl_4$, $GeCl_4$, $SnCl_4$ and KBH_4 (BDH), R_2SnCl_2 (R = Me, Bu, Ph) and R_3SnCl (R = Bu, Ph) (Fluka) were used as supplied. All the solvents were distilled and dried before use. Microanalyses were made on a Carlo–Erba analyser model 1106. Molar conductances were measured at room temperature on a Digisun electronic conductivity bridge. The IR spectra (200–4000 cm^{-1}) were recorded on a Carl Ziess Specord M-80 spectrophotometer as Nujol mulls. Chlorine and tin were estimated gravimetrically.

* Author to whom correspondence should be addressed.

Synthesis of the Schiff base

A methanolic solution (15 cm^3) of ethylene diamine (0.01 mol) was added dropwise to a methanolic solution (15 cm^3) of salicylaldehyde (0.02 mol). An immediate yellow precipitate was obtained which was filtered, washed, recrystallized from methanol and dried *in vacuo*.

Synthesis of the complexes $[MLCl_2]$ **(1)**

The Schiff base (0.01 mol) was taken in THF and added to MCl_4 (0.01 mol) (M = Si, Ge, Sn) in toluene. The mixture was refluxed along with stirring for 2 h and the yellow product obtained was filtered and washed with toluene and dried *in vacuo*.

Synthesis of the complexes $[ML(BH_4)_2]$

To a THF solution of excess KBH_4 (0.02 mol) was added a chloroform solution (0.01 mol) of **1**. The solution was refluxed for 4 h and after cooling for some time a coloured precipitate settled, which was washed with THF and dried *in vacuo*.

Synthesis of the complexes $[R_2Sn(BH_4)_2]$ *and* $[R_3Sn(BH_4)]$

R_2SnCl_2 (0.01 mol) or R_3SnCl (0.01 mol) was added to a THF solution of excess KBH_4 (0.02 mol or 0.01 mol), respectively. The mixture refluxed for 6 h yields a powdery compound after cooling, which was washed with THF and dried *in vacuo*.

RESULTS AND DISCUSSION

The analytical data (Table 1) agree well with the composition of the complexes. The molar conductance values of 10^{-3} M solutions of the complexes at room temperature in DMF (10–15 Ω^{-1}) fall well below those quoted for uni-univalent electrolytes, indicating their non-ionic nature.[18]

$[ML(BH_4)_2]$ *type*

The complex $[MLCl_2]$ reacts with a THF solution of KBH_4 according to eq. (1) yielding brown, green and yellow powders for tin, silicon and germanium complexes, respectively.

$$[MLCl_2]+2KBH_4 \xrightarrow{THF} [ML(BH_4)_2] + 2KCl \quad (1)$$

This reaction must be performed with excess KBH_4 since a KBH_4:M ratio lower than 2:1 results in the reduction of the metal atom.

The most significant spectroscopic information on these complexes comes from the IR spectrum. Strong bands occur at 2560, 2510, 2269 and 2220 cm^{-1}. These are attributed to B—H stretching modes, the higher two being due to the terminal hydrogens, while the lower two belong to the bridging hydrogens (the presence of the B—H_t stretching frequency rules out the possibility of polymerization). The stretching bands at 1990 and 1825 cm^{-1} must be considered as asymmetric and symmetric vibrations due to the MH_2 unit. The absence of the ν(M—Cl) band in the far-IR region suggests the replacement of Cl^- by the BH_4^- ion. Sharp absorption bands are observed in the 490–500 cm^{-1} range, assignable to ν(M—O). Since the ν(C=C) and ν(C=N) absorption bands generally appear in the same region, it is difficult to distinguish them. A strong band at 1520 cm^{-1} has been assigned to ν(C=N), but it may be due to ν(C=C) also. On this basis we suggest that the reaction of $[MLCl_2]$ with KBH_4 involves the substitution of Cl^- by BH_4^- and then the ligation of BH_4^- to the group(IV) metal in a bidentate manner (Fig. 2), as is the case with $Al(BH_4)_3$.[19] The characteristic IR bands are listed in Table 2. Since these compounds are not soluble in hydrocarbons (benzene, hexane and chloroform) and they are decomposed by coordinating solvents (when the compounds are dissolved in dry DMSO, DMF, THF and CH_3CN the evolution of hydrogen gas was not observed, but the colour of the solution changed probably indicating the chemical deformation of the compounds), any dynamic inspection of them by NMR spectroscopy is prevented.

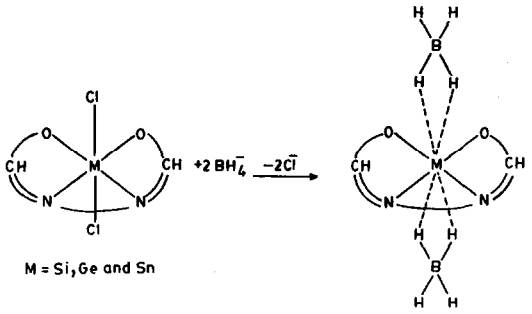

Fig. 2.

Table 2. The important characteristic IR bands of the complexes

Complex	Peak position (cm^{-1})						
	ν(B—H_t)	ν(B—H_b)	ν(M—H_b)	ν(M—C)	ν(M—O)	ν(M—N)	ν(Sn(μ—H)$_3$B)

$[R_2Sn(BH_4)_2]$ and $[R_3Sn(BH_4)]$ type

The reaction of R_2SnCl_2 and R_3SnCl with excess KBH_4 in THF can be represented in accordance with eqs (2) and (3). All the synthesized compounds are air stable.

$$R_2SnCl_2 + \text{excess } KBH_4 \xrightarrow{THF} R_2Sn(BH_4)_2 + 2KCl \quad (2)$$

$$R_3SnCl + \text{excess } KBH_4 \xrightarrow{THF} R_3Sn(BH_4) + KCl \quad (3)$$

The relevant bands of the IR spectra are given in Table 2. The first salient point is the observation of a single intense absorption at 2587 cm^{-1}, taken in conjunction with the absence of any doublet near 2500 cm^{-1}, assigned to $\nu(B—H_t)$, which suggests the presence of only one terminal hydrogen. This is characteristic of tridentate tetrahydroborate groups.[16,19] Other features diagnostic of tridentate binding of the tetrahydroborate group include the appearance of a doublet near 2200 cm^{-1} and an intense band near 1200 cm^{-1}.[16,20] Such tridentate behaviour of BH_4^- was found in the cases of $Zr(BH_4)_4$,[21] $Hf(BH_4)_4$[22] and the actinide derivatives $M(BH_4)_3$[23] (M = Np and Pu). There is no sign of the features characteristic of bidentate binding, as exhibited by $Al(BH_4)_3$,[19] which gives us good grounds for believing that the tetrahydroborate groups are bound to tin exclusively via triple hydrogen bridges (Fig. 3).

The absorptions in the range 1000–1400 cm^{-1} are almost certainly due to fundamentals in which $H_b—B—H_t$ bending is the predominant motion.[21] Another band located near 450 cm^{-1} is assigned to the deformation of the $\nu(Sn(\mu\text{-}H)_3B)$ bridges.[21] The bands observed around 2585–2400 cm^{-1} are assigned to $\nu(B—H_t)$ and those at 2230–2155 cm^{-1} are assigned to $\nu(B—H_b)$. Two distinct bands appeared at 1160 and 500 cm^{-1}, definitively attributed to $\nu(Sn—H_b)$ and $\nu(Sn—C)$. It is noteworthy that the BH_4^- ligand can have a bidentate coordination mode in which only two orbitals are effective in donating electron density to the metal (C_{2v} symmetry), whereas in the tridentate coordination mode three orbitals are effective in this way (C_{3v} symmetry). Very recently the tridentate behaviour of the BH_4^- ion has been explored in the case of $Ti(BH_4)_3$.[24] It has been shown that the tetrahedral BH_4^- anion is characterized by four filled B—H bonding MOs and four vacant B—H antibonding MOs. When coordinated to a metal the local symmetry about the boron atom is reduced, to C_{3v} in the case of the tridentate mode and C_{2v} in the case of the bidentate mode of binding.

(*Received* 27 *January* 1993; *accepted* 27 *April* 1993)

Abstract—The crystal structure of the adduct of copper(II) octanoate with pyridine, $(Cu_2(C_7H_{15}COO)_4)(C_5H_5N)_2$, has been determined by X-ray diffraction. The complex forms discrete centrosymmetric tetracarboxylate-bridged dimers with pyridine moieties in the apical positions.

Copper(II) carboxylate adducts with a large variety of ligands have been extensively investigated and results have been summarized in several publications.[1–5] Investigations on copper(II) complexes with higher carboxylic acids apart from acetates, propionates and butyrates are rare. In spite of increased interest in copper(II) alkanoates containing linear chains and related adducts exhibiting a thermotropic columnar mesophase,[6,7,8] only two crystal structures of copper(II) complexes with higher carboxylic acids have been hitherto determined: anhydrous copper(II) octanoate[9] ($R = 0.159$) and anhydrous copper(II) decanoate[10] ($R = 0.134$).

It was the intention of this work to obtain crystallographic data on the copper(II) octanoate adduct with pyridine.

EXPERIMENTAL

Preparation

The complex was prepared by dissolving $Cu_2(C_7H_{15}COO)_4$ (0.7 g) in pyridine (5 cm^3). The addition of water (300 cm^3) resulted in the precipitation of small blue crystals, presumably monomeric species of copper(II) octanoate adduct with pyridine. The crystals were filtered off. Dark green crystals grew from the filtrate after standing in air for a period of 1 month at room temperature. Found: C, 58.6; H, 8.2; Cu, 15.0; N, 3.3. Calc. for $C_{42}H_{70}Cu_2N_2O_8$: C, 58.8; H, 8.2; Cu, 14.8; N, 3.3%.

Crystal data

$C_{42}H_{70}Cu_2N_2O_8$, $M_r = 858.1$, triclinic, $a = 8.379(3)$, $b = 10.921(6)$, $c = 13.286(6)$ Å, $\alpha = 108.42(4)$, $\beta = 96.21(4)$, $\gamma = 92.06(4)°$, $V = 1143.5$ Å^3, $D_m = 1.23$, $D_c = 1.246$ g cm^{-3}, $Z = 1$, Mo-K_α radiation, $\lambda = 0.7107$ Å, μ(Mo-K_α) $= 9.78$ cm^{-1}, space group $P\bar{1}$, $F(000) = 458$, $T = 293$ K.

Data collection, structure solution and refinement

Data were collected on an Enraf–Nonius CAD-4 diffractometer (crystal monochromatized Mo-K_α radiation, $\lambda = 0.7107$ Å) from a prismatic crystal of dimensions $0.14 \times 0.24 \times 0.32$ mm. Of 6651 reflections collected up to $2\theta_{max} = 60°$, 3036 with

* Author to whom correspondence should be addressed.

$I > 2.5\sigma(I)$ were used in structure refinement. Intensity variation of not greater than 2.5% in three standards monitored during the data collection period indicated negligible crystal decay. The structure was solved by a routine Patterson method followed by subsequent electron-density map calculations. Full-matrix least-squares refinement with anisotropic thermal parameters on all non-hydrogen atoms gave $R[=\Sigma\|F_o|-|F_c\|/\Sigma|F_o|]$ and $R_w[=\Sigma w(\|F_o|-|F_c\|^2/\Sigma w|F_o|^2)^{1/2}]$ of 0.049 and 0.061, respectively, with a value of $w = 1.85\ [\sigma^2(F_o)+0.0014(F_o)^2]^{-1}$. Hydrogen atom positions were generated and their positional and common isotropic thermal parameters were refined. Neutral

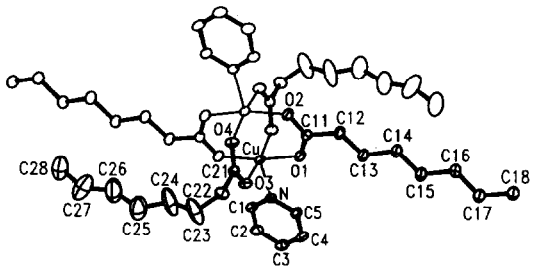

Fig. 1. ORTEP view of the dimeric complex with the atomic-numbering scheme. Thermal ellipsoids are drawn at 30% probability level.

atom scattering factors were used.[11] The system of computer programs NRCVAX,[12] adapted for the PC 386 computer, was used throughout the data reduction, determination, refinement and interpretation. The SHELX-76[13] program was used for the final refinement cycles.

Atomic fractional coordinates, hydrogen atom coordinates, anisotropic thermal parameters, intraligand bond distances and angles, and observed and calculated structure factors tables are deposited with the Editor as supplementary material, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

DISCUSSION

The structure of the title compound is shown in Fig. 1. The important bond lengths and angles are presented in Table 1. Pairs of copper ions are bridged by four n-octanoate ligands, forming a dimeric structure of the acetate hydrate type with pyridine rings instead of water molecules in the apical positions. The Cu—Cu separation of 2.651(1) Å and Cu—N distance of 2.194(4) Å compare well with 2.641(1) and 2.191(2) Å, respectively,

in the orthorhombic copper(II) acetate-pyridine adduct.[14] Cu—O(equatorial) distances range from 1.976(3) to 2.038(3) Å and are considered to be normal for this type of system. The distance of copper from the plane consisting of four equatorial oxygen atoms has a value of 0.209(3) Å and is comparable with the value of 0.19 Å for copper acetate dihydrate.[5] As similarly found in anhydrous copper(II) octanoate[9] and decanoate[10] one pair of hydrocarbon chains in each dimer has the common plane zigzag conformation and the other pair of chains is distorted by rotations about the bonds C(21)—C(22) and C(22)—C(23) (Table 2), presumably because the long hydrocarbon chains if extended in directions at right angles to each other could not pack efficiently together. The structural parameters of the carboxylate groups are usual. C(23)–C(28) hydrocarbon chains are affected by high thermal motion and their bond distances and angles are less reliable. Angles and bond distances in pyridine are normal. The dihedral angle between best planes through C(11)–C(18) carbon atoms ("normal" chain) and C(23)–C(28) carbon atoms (part of the "distorted" chain) is 72.5(19)°.

The packing of the dimers in the unit cell involves no significant inter-dimer associations (Fig. 2). The distance of 3.435(12) Å between the C(3) atom from the pyridine moiety and the C(5) atom from the pyridine ring of a neighbouring molecule represents the closest interaction between discrete dimeric units.

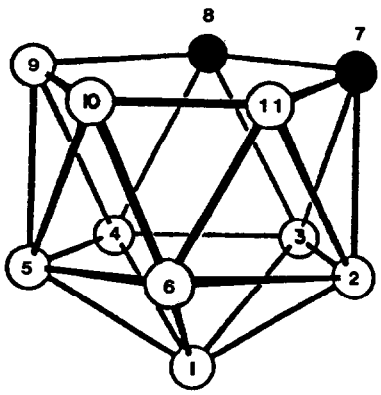
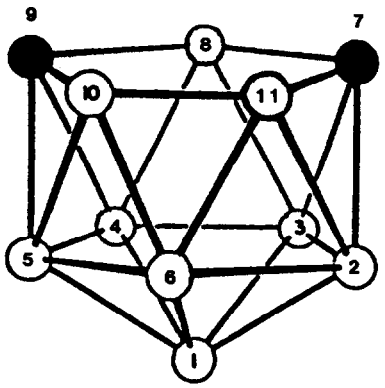
Abstract—The structure of *nido*-$Se_2B_9H_9$ has been determined unambiguously to be the 7,9-isomer by ultra high-field (192.48 MHz) ^{11}B NMR spectroscopy. The He(I) PE spectrum of 7,9-$Se_2B_9H_9$ is compared with the results of an MNDO MO calculation of the dithiaborane analogue 7,9-$S_2B_9H_9$.

The two possible structures of *nido*-$Se_2B_9H_9$ shown in diagrams **I** and **II** are the 7,8- and 7,9-isomers, respectively. The former structure has been suggested for $Se_2B_9H_9$,[1,2] whilst the latter was



(I)



(II)

suggested for $SSeB_9H_9$.[3] All previous attempts to identify the correct structure of $Se_2B_9H_9$ have been unsuccessful. In the present work we have used ultra high-field two-dimensional NMR to resolve this problem and to completely assign the ^{11}B and ^{1}H spectra. The compound is the 7,9-isomer, diagram **II**. In order to better understand the cluster bonding

* Author to whom correspondence should be addressed.

in this type of compound we have investigated the electronic structure of the analogous thiaborane 7,9-$S_2B_9H_9$ using the MNDO programme[4] and compared the results with the published PE spectrum of $Se_2B_9H_9$.[5]

RESULTS AND DISCUSSION

NMR spectroscopy

The present study used a combination of ^{11}B, $^{11}B\{^1H\}$, homonuclear ^{11}B COSY[6] and ^{11}B—^1H HETCOR[7] to establish the structure of $Se_2B_9H_9$ as the 7,9-isomer and assign the resonances in the ^1H and ^{11}B spectra. The 192.48 MHz ^{11}B and $^{11}B\{^1H\}$ NMR spectra show six different boron signals at δ values of +2.1, +1.6, −0.6, −1.0, −8.6 and −34.6 ppm with relative intensities 1:2:2:2:1:1, as shown in Fig. 1. These signals are consistent with either of the structures shown in diagrams **I** and **II**, as each has a plane of symmetry passing through the B—H units in positions (1), (3) and (10) or (1), (6) and (8), respectively. To distinguish between these possibilities a 192.48 MHz ^{11}B COSY experiment was performed, Fig. 2. Of the three resonances with unit relative intensity the two at $\delta = +2.1$ and −34.6 ppm have three cross-peaks, whilst that at $\delta = -8.6$ ppm exhibits only one. In structure **I** B(1) would be expected to have three cross-peaks and B(3) and B(10) two each. For structure **II** B(1) and B(6) would be expected to show three correlations and B(8) only one. Thus, **II** is the correct structure. The signal at δ −8.6 is, therefore, assigned to B(8) and using this information the ^{11}B assignments can be extracted from the COSY data, Table 1. The boron and proton chemicals shifts were correlated from a ^{11}B—^1H HETCOR experiment. The results are summarized in Table 1.

Electronic structure of $X_2B_9H_9$ (X = S *or* Se)

Both the 7,9- and 7,8-isomers of $S_2B_9H_9$ were calculated with the MNDO programme.[4] In both molecules the contributions of the sulphur atoms to the molecular orbitals were notably diffuse, much more so than the contributions from the boron atoms. In general, this diffuseness makes specific comments about particular orbitals difficult. However, in both the isomers the four most stable orbitals were clearly seen to be cluster bonding in nature, even though the other nine cluster bonding orbitals which were expected were not so easily located. The heat of formation of the 7,9-isomer was calculated to be −28.2 kcal mol^{-1}, which was 48.2 kcal mol^{-1} more stable than the 7,8-isomer. The energies of the 14 highest occupied orbitals

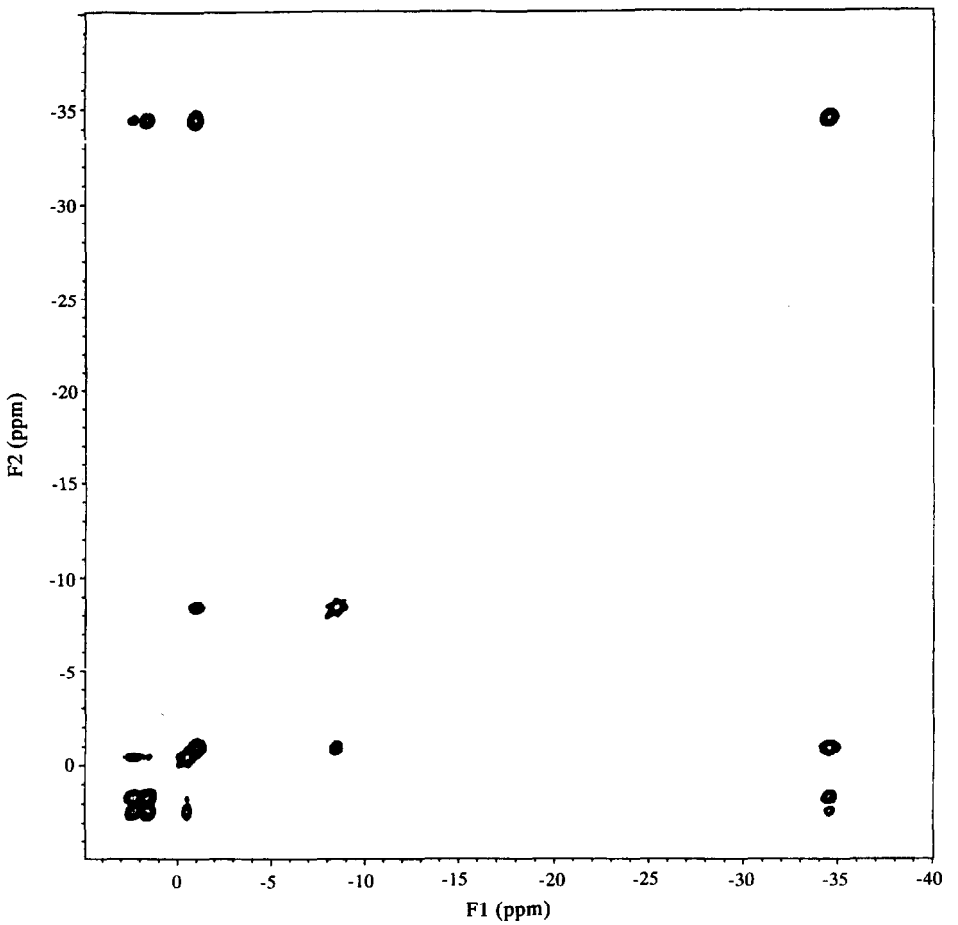

Fig. 2. 192.48 MHz $^{11}B\{^1H\}$ COSY plot for 7,9-$Se_2B_9H_9$. During the experiment 512 increments, each of 384 transients, were collected. Recycle delay 0.3 s; spectrum width 10,500 Hz in both dimensions; final data matrix 2048 × 2048 points. Pseudo-echo window functions were used in both dimensions.

in 7,9-$S_2B_9H_9$ are compared with data from the published PE spectrum[5] of 7,9-$Se_2B_9H_9$ in Table 2. The difference of *ca* 2 eV between the MNDO calculated and observed PE energies in Table 2 is typical of calculations which contain third row atoms.[8] In a previous study of 12-atom heteroborane clusters, 1-$XB_{11}H_{11}$ (X = S or Se), it was concluded that the contribution to cluster bonding from selenium was remarkably similar to that from sulphur.[5] The PE spectra of both 12-atom clusters were essentially the same and showed three broad bands, although there was a slight shift of the band maxima of 1-$SeB_{11}H_{11}$ to lower energies (by 0.5 to 0.7 eV) compared with 1-$SB_{11}H_{11}$. In the present study there is reasonably good agreement between the calculated and experimental data for the first three bands in terms of (a) the differences in energy between successive bands and (b) the number of energy levels or ionization processes. However, the energies of the subsequent ionization processes giving rise to the fourth band are not separated sufficiently well for a detailed analysis to be made. It appears from the calculation that there may be up to eight energy levels in the fourth band. The fifth band is separated by 1.5 eV from the previous one and appears to contain two ionization processes. This feature is reproduced in the calculation, Table 2.

(III)

orbitals four are two-centre S—B localized, one is two-centre B—B, two are three-centre B—S—B, five are three-centre B—B—B and one is a four-centre B—B—B—B orbital. All the two-centre orbitals are located around the open B_3S_2-face. The remaining 12 localized orbitals comprise nine two-centre B—H and two lone-pair sulphur orbitals. The last mentioned correspond to filled 3*s* orbitals at very low energy. Hence, the sulphur atoms can be expected to show no donor properties. On the contrary, the positive charge calculated for the sulphur atoms (+0.34) suggests that these atoms are electrophilic. Some experimental evidence for their electrophilic nature comes from the observation of a compound postulated to be $[Se_2B_9H_{10}O]^-$, which was obtained by Friesen *et al.* from the reaction between $Se_2B_9H_9$ and $[OH]^-$.[3]

Finally, it is noteworthy that while there are many examples of heteroboranes with two or more hetero-atoms from groups IV/14 or V/15 in adjacent positions, apparently there are no heteroboranes with two adjacent atoms from group VI/16 nor any metal-heteroborane derivatives with two adjacent group VI/16 atoms.

EXPERIMENTAL

A sample of 7,9-$Se_2B_9H_9$ was prepared and purified according to a literature method.[3]

NMR spectroscopy

Experiments were performed using a Varian VXR600S spectrometer operating at 14.1 T and a Bruker WH360 spectrometer operating at 8.46 T. The solvent was toluene-d_8 and the spectrometer temperature was 50°C. All ^{11}B chemical shifts are quoted relative to external $BF_3 \cdot OEt_2$ and ^1H chemical shifts relative to internal TMS. The ^{11}B homonuclear correlation experiment (COSY) was performed on the VXR600S instrument, for which the ^{11}B resonance frequency is 192.48 MHz. Details are given in the caption to Fig. 1. The ^{11}B—^1H heteronuclear correlation experiments were performed with the WH360 instrument (for which the ^{11}B frequency is 115.55 MHz and the ^1H frequency is 360.13 MHz) using the sequence XHCORRD.AU provided by Bruker Spectrospin Ltd.

Acknowledgement—We wish to thank the SERC for provision of the ultra high-field NMR facility at the University of Edinburgh.

A CONVENIENT ROUTE TO IRON(III)-THIOLATES: SYNTHESIS AND CHARACTERIZATION OF LOW-SPIN ($S = 1/2$) IRON(III) COMPLEXES HAVING THE CHROMOPHORE $FeN_2S_2^*S_2$ (S* = THIOETHER)

RAMESHWER SHUKLA and PARIMAL K. BHARADWAJ†

Department of Chemistry, Indian Institute of Technology, Kanpur, Kanpur 208016, India

(*Received* 5 *April* 1993; *accepted* 22 *April* 1993)

Abstract—Three air-stable iron(III) complexes with homoleptic hexadentate ligands with the donor set $N_2S_2^*S_2$ (S* = thioether, S = thiolate) have been isolated. The two thiol groups present in each ligand are initially protected as their t-butyl derivatives. When iron(III) chloride is allowed to reflux with any of these thiol-protected ligands the S—Bu^t linkages are cleaved forming the corresponding iron(III)-thiolates in high yields. The complexes are characterized by electronic absorption, EPR and room-temperature Mössbauer spectroscopic as well as room-temperature magnetic susceptibility studies. As the spectral data indicate each complex has a pseudo-octahedral coordination geometry around the metal ion. The effective magnetic moment values at 300 K lie in the range 2.24–2.30, corresponding to low-spin iron(III) ($S = 1/2$) complexes with significant orbital contribution. One of the complexes exhibits a quasi-reversible Fe^{III}/Fe^{II} couple at $E_f = -1.66$ V (vs S.C.E.), while another complex shows a quasi-reversible Fe^{IV}/Fe^{III} couple at $E_f = 0.86$ V (vs S.C.E.).

A number of proteins contain[1–3] iron in different oxidation states with donations mainly from sulphur. Besides these, a bacterial enzyme nitrile hydratase from *Brevibacterium* R312[4] and *Pseudomonas chlororaphis* B23[5] contains iron coordinated to sulphur and nitrogen/oxygen in an octahedral fashion. Detailed spectroscopic studies[6] on this enzyme indicate that iron is present in the +3 oxidation state with low spin ($S = 1/2$). In order to model these sites low molecular weight complexes of iron with sulphur ligation are necessary. A number of polynuclear Fe—S complexes are known,[7,8] where iron exists in different formal oxidation states. In contrast, studies on mononuclear iron complexes in the +3 oxidation state with sulphur ligation are somewhat sparse.[9,10] This is because of the facile redox decomposition of such systems. As a matter of fact, no general synthetic method for iron(III)-thiolates is available. In our quest to find a synthetic strategy to circumvent such redox instability, we present here a synthetic route to iron(III)-thiolates. The method involves cleavage of the S—Bu^t linkage(s) present in a multidonor ligand (as shown in Fig. 1) utilizing the Lewis acidity of the metal ion.[11] Previously, we had reported[12] the synthesis of stable copper(II)-thiolates from these ligands. We, therefore, started with the idea that the iron(III) ion, being a better Lewis acid compared with the copper(II) ion, should be able to cleave the S—Bu^t linkage. Once the free thiolate is formed it should be able to occupy the vacant coordination site on the iron(III). Herein, we describe this method of synthesis of iron(III)-thiolates and their characterization by different spectroscopic and electrochemical techniques.

EXPERIMENTAL

Materials

2-Nitrobenzaldehyde, 2-mercaptoaniline, 1,2-dibromoethane, mercaptoacetic acid, thiosalicyclic acid, t-butylthiol (Aldrich), ethyl chloroformate and iron(III) chloride (Merck) were used as received. All solvents were from Glaxo laboratories

† Author to whom correspondence should be addressed.

and were purified prior to use following standard methods.[13]

The electronic absorption, IR, proton NMR, EPR spectroscopic and room-temperature magnetic susceptibility studies were made as reported earlier.[12] The electrical conductivity of the complexes in acetonitrile solutions were measured using an Elico model CM-82T conductivity bridge. Cyclic voltammograms of the complexes were obtained on a PAR model 370-4 electrochemistry system using freshly purified DMF. The working electrode was glassy carbon and the standard electrode was a saturated calomel electrode. Under our experimental conditions the reversible[14] ferrocenium/ferrocene couple had $\Delta E_p = 80$ mV at $E_f = 0.360$ (mV vs S.C.E.) $[E_f = 0.5\ (E_{pa} + E_{pc})]$. Transmission Mössbauer spectra at 295 K were recorded with a Wiessel Mössbauer spectrometer (Wissel Electronik GmbH, Germany) operating in constant acceleration mode and a ^{57}Co/Rh source. The elemental analyses were performed at the Central Drug Research Institute, Lucknow, India.

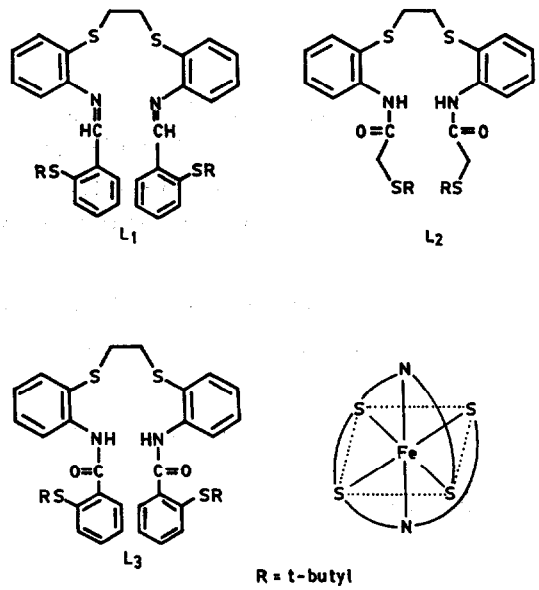

Fig. 1. Ligands used in the present study.

Synthesis of the ligands and complexes

The ligands shown in Fig. 1 were synthesized as described earlier.[12b,c]

Synthesis of complex **1**. To the ligand L_1 (1.25 g, 2 mmol) taken in ethanol (50 cm^3) was added an ethanolic solution (10 cm^3) of iron(III) chloride (0.33 g, 2 mmol) under dinitrogen. The colour of the solution changed to dark red in 5 min upon heating the mixture. After refluxing for 30 min the dark red solution was filtered in air, reduced in volume to *ca* 25 cm^3 in a rotary evaporator and finally allowed to evaporate at room temperature. A dark-red polycrystalline solid appeared overnight, which was collected and air-dried; yield 41%.

Synthesis of complex **2**. This complex was synthesized with L_2 following the method as described above; yield 46%.

Synthesis of complex **3**. Synthesis of this complex was achieved with L_3 as above in 43% yield.

Analytical data for the complexes are collected in Table 1.

RESULTS AND DISCUSSION

The complexes are readily formed as mononuclear cationic species by refluxing an iron(III) salt with the ligand in ethanol under a dinitrogen atmosphere. The reaction cleanly forms the desired products in high yields. They are air-stable both in the solid state as well as in solution (acetone, acetonitrile). In DMF the complexes are stable at least up to 2 h. This stability arises due to the hexadentate chelating ligand occupying all the six coordination sites on the iron(III) ion. The corresponding PF_6^-

Table 1. Cyclic voltammetric[a] and analytical[b] data of the complexes

1	2.29	2.01 (solid, 298 K) 2.03 (solid, 77 K) 2.12 (soln, 298 K) 2.01 (soln, 77 K)	770(410), 625(950), 305(6065)
2	2.24	2.01 (solid, 298 K) 2.01 (solid, 77 K) 2.03 (soln, 298 K) 2.01 (soln, 77 K)	810(280), 640(1450), 310(6135)
3	2.30	2.01 (solid, 298 K) 2.02 (solid, 77 K) 2.06 (soln, 298 K) 2.01 soln, 77 K)	750(180), 625(495), 380(3010)

salts are less soluble in solvents such as acetonitrile as they are precipitated when the chloride salts are treated with $NaPF_6$. The IR spectra of the PF_6^- salts are, however, not diagnostic of the presence of this anion as the ligand itself absorbs strongly in the same region. These complexes, having either PF_6^- or chloride counterions, afford only polycrystalline products. Isolation in single-crystal forms suitable for X-ray crystallography remained unachievable.

The solution electronic spectra for all the hexadentate complexes are quite similar (Table 2) and confirm the presence of iron(III)-thiolate bonds. Each exhibits a strong band in the UV region around 300 nm and one broad band centred near 620 nm with a low energy shoulder. Only a few authentic mononuclear iron(III)-thiolate complexes are known. The electronic spectra of the X-ray crystallographically characterized $[Fe^{III}S_4]$ cores exhibit[9] two charge-transfer bands at 280 and 350 nm, while the pseudo-octahedral FeN_3S_3 complex[10] shows two strong bands near 300 nm. Hence, the two bands around 300 nm are assigned as ligand-to-metal charge-transfer transitions involv-

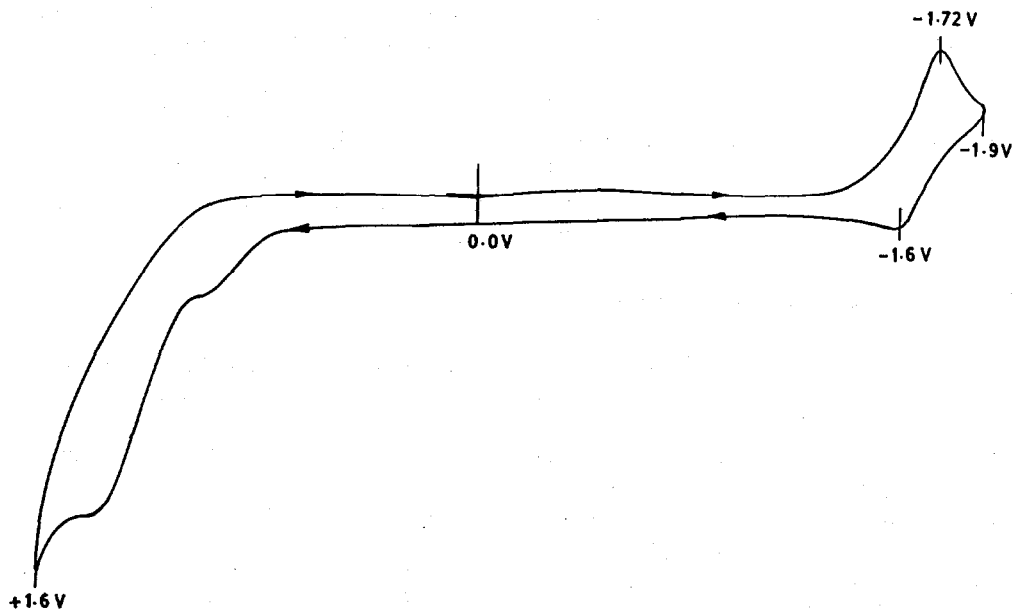

Fig. 2. Cyclic voltammogram (100 mV s^{-1}) of **1** in DMF at a glassy carbon electrode.

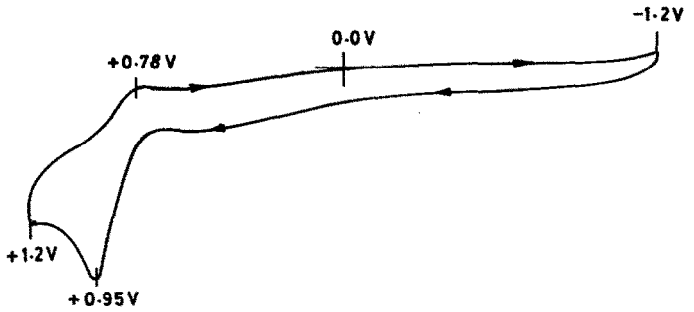

Fig. 3. Cyclic voltammogram (100 mV s^{-1}) of **2** in DMF at a glassy carbon electrode.

ing thiolate and iron(III). Unlike the $[Fe^{III}S_4]$ chromophores, which show a strong and broad band centred around 500 nm, each of the three complexes **1–3** shows one strong band centred near 620 nm with a low energy shoulder attributable to the ligand field transitions. The higher intensity of the ligand field transitions should be due[15] to increased metal–ligand covalency.

The electron-transfer properties of the complexes in DMF were probed by room-temperature cyclic voltammetry. Cyclic voltammograms are shown in Figs 2 and 3, while the redox data are given in Table 1. Complexes **1** and **2** show cyclic responses which are quasi-reversible. The copper(II) complexes of these ligands[12b,c] also exhibit cyclic responses, although at very different potentials. Therefore, the cyclic responses are concluded to be metal-centred. The response in **1** is due to the Fe^{III}/Fe^{II} couple, as eq. (1) below suggests:

$$[Fe(L_1)]^+ + e = [Fe(L_1)] \quad (1)$$

On the other hand, in **2** the response is due to the Fe^{IV}/Fe^{III} couple [eq. (2)]:

$$[Fe(L_2)]^{2+} + e = [Fe(L_2)]^+ \quad (2)$$

It is of relevance to note here that the copper(II) complex of the ligand L_2 shows[12c] a reversible Cu^{III}/Cu^{II} couple at $E_f = 0.55$ V (vs S.C.E.), suggesting the ability of this ligand to stabilize high oxidation states.

The effective magnetic-moment values (μ_{eff}/μ_B) for the complexes range between 2.24 and 2.30 (Table 1) at 300 K. Recently an $Fe^{III}N_3S_3$ complex has been reported[10] that has a pseudo-octahedral geometry around iron(III), consisting of three amino nitrogens of the 1,4,7-triazacyclononane backbone and three thiophenolato sulphurs. This complex shows temperature-dependent magnetic moments with predominantly low-spin (2.4 μ_B at 77 K and 2.9 μ_B at 300 K) at ambient temperatures. The magnetic data for **1–3** are consistent[16,17] with low-spin ($S = 1/2$) iron(III) complexes with significant orbital contributions. The *X*-band EPR spectra of the complexes also corroborate the low-spin nature of the complexes. All the complexes exhibit broad EPR signals near $g = 2$ at 298 or 77 K and no signal is seen near $g = 4$ under any circumstances. Resolved EPR spectra could not be observed either in the solid state or in dilute acetonitrile solutions. Lack of hyperfine splittings and the g value deviating from the free electron g value are indicative[18,19] of delocalization of the odd electron into the four bound sulphurs of the ligand moiety. Studies of molecular models indicate that the binding mode, as illustrated in Fig. 1, leads to the least strained conformation of the ligands as found earlier in the case of copper(II) complexes with these ligands.[12b,c] Thus, the singly occupied metal orbital of the t_{2g} set overlaps with the four equatorially-bound sulphur atoms in the complex leading to increased covalency of the metal–ligand bond.

In order to further confirm the presence of the low-spin iron(III) centres in **1–3** Mössbauer spectra were recorded at 295 K. Table 3 lists the relevant data; characteristic spectra are shown in Fig. 4. The zero-field spectra of the complexes display symmetrical quadrupole doublets. Both the isomer shifts and quadrupole splittings of the complexes are quite comparable with each other. This is attributed to the similar coordination environments

Table 3. Room-temperature Mössbauer spectral data of the complexes

Compound	Isomer shift (Fe, mm s^{-1})	Quadrupole splitting ΔE_q (mm s^{-1})
1	0.49	0.84
2	0.42	0.72
3	0.42	0.86

around the iron(III) ion. Also, the magnitude of these parameters is consistent[10,20,21] with low-spin ($S = 1/2$) octahedral iron(III) complexes.

CONCLUSIONS

The present study shows that it is possible to have a general synthetic route to stable octahedral iron-(III)-thiolates. Both the thiolate sulphurs and the amines, being strong donors, form low-spin iron-(III) complexes. Interestingly, the ligand donor set for iron(III) is quite similar to the one present in the enzyme nitrile hydratase and in both the cases iron(III) is in the low-spin ($S = 1/2$) state. Mimicking the active sites of nitrile hydratase with different types of ligands having thiolate donors is in progress.

(*Received* 23 *March* 1993; *accepted* 22 *April* 1993)

Abstract—$[Cu(bzac)(OC_2H_4OCH_3)]_4$† (**I**) and $[Cu(dbm)(OC_2H_4OCH_3]_4$† (**II**) have been shown to be tetrameric in the solid state. Compound **I** has a pseudo-cubane type structure with μ_3-alkoxide oxygens occupying four bridging positions. Two methoxy oxygens are also within bonding distance of copper(II) ions. Compound **II** has a stepped configuration with a chelate ring and alkoxide oxygens as bridging centres. None of the methoxy oxygens is clearly chelating. Magnetic susceptibility data versus temperature data to 4 K for the complexes show antiferromagnetic coupling which can be treated by "pairs of equal dimers" procedures. The complexes decompose in stages at temperatures below 350°C at atmospheric pressure to give CuO.

The search for suitable precursors for the preparation of layers of CuO or lanthanoid-Ba—Cu superconducting oxides by hydrolytic or MOCVD processes[1,2] has turned attention to the synthesis of soluble or volatile copper(II) complexes[3,4] involving alkoxides Cu(L)(OR'), particularly alkoxy-alkoxides.

Studies of their structural and other properties[5] are, therefore, important in the search for correlations which can predict combinations of ligand and alkoxide which give appropriate solubility, volatility, thermal stability and hydrolytic behaviour.

A substantial number of copper(II) complexes containing a β-diketonate[3,4,6,7] or related ligand, such as a hydroxy benzaldehyde[8] and an alkoxide group [Cu(lig)(OR)], have been reported since the initial study of the $[Cu(acac)(OCH_3)]$ complex by Bertrand and Kaplan.[9] However, only seven structural studies have been reported for such compounds,[7,10] five appearing in 1992.[4,11] The results have identified three types of structure with some variation within each type. Type 1 structures are dimers with alkoxide groups defining essentially square-planar arrays of Cu_2O_6 atoms (**i**). The copper ions can achieve square-pyramidal coordination by coordinating with other Lewis bases as in the sole example of this type so far reported, $[Cu(tfac)(OC_6F_5)(THF)]_2$.[4] Related alkoxy-bridged complexes have also been characterized, of the form $[M(acac)_2(OR)]_2$, R = CH_3, M = Fe^{III},[12] Cr^{III},[13,14] where each M ion is six-coordinate. Type 2 structures are formed by association of pairs of dimers to form tetramers of Cu_4O_4 core units and two subclasses have been reported. In type 2(a) (**ii**) association occurs between dimeric units with inter-dimer bonding between oxygens of chelate rings on one dimer and copper(II) ions on the other, together with additional inter-dimer bonding between bridging alkoxide oxygens (now μ_3-O) and copper(II)

† Ligand abbreviations used for β-diketonate anions are as follows: bzac = benzoylacetonato(1-phenyl-1,3-butanedionato); tfac = 1,1,1-trifluoroacetylacetonato (1,1,1-trifluoro-2,4-pentanedionato); hfac = 1,1,1-5,5,5-hexafluoroacetylacetonato(1,1,1 - 5,5,5 - hexafluoro - 2,4-pentanedionato); acac = acetylacetonato(2,4-pentanedionato); pvac = dipivaloylacetonato(2,2,6,6-tetramethyl-3,5-heptanedionato); and dbm = dibenzoylmethanato (1,4-diphenyl-1,3-propanedionato).

ions as in the first characterized species, $[Cu(acac)(OCH_2Ph)]_4$[10] and $[Cu(tfac)(OCH_2CH_2OCH_3)]_4$.[4] Type 2(b) structures (**iii**) only involve inter-dimer bridging through alkoxide oxygens, as in the dipivaloylmethane-methoxide derivative $[Cu(dpm)(OCH_3)]_4$.[7] There are no chelate—O—Cu distances reported or commented on in this latter work and it is possible that further weak interactions do occur involving these ligands, making the structure similar to type 2(a). However, the bulky tert-butyl groups of the β-diketone ligands may prevent easy coordination. Such structures have been termed "stepwise"[10] or "ladder-like".[7]

The third type of structure (**iv**) also contains a tetrameric Cu_4O_4 core formed by the association of dimer units, but is of the pseudo-cubane type with axes of the pairs of copper ion in each "dimer" subunit arranged at approximately 90° to each other. The alkoxy oxygens act as μ_3-bridging groups. Three complexes having this type of structure have now been structurally characterized, $[Cu(hfac)(OCH_3)(THF)]_4$,[4] $[Cu(hfac)(OC_2H_4OCH_3)]_4$[4] and $[Cu(acac)(OC_2H_4OCH(CH_3)_2)]_4$.[11] The copper ions may be further coordinated to other Lewis bases, as in the first of the three examples, of the methoxy oxygen of $(OCH_2CH_2OCH_3)^-$.

A study[15] of the related cobalt(II) and nickel(II) derivatives, $[M(acac)(OCH_3)(CH_3OH)]$, shows them to have similar cubane-like structures with a molecule of methanol coordinated to each metal centre. Magnetic susceptibility vs temperature studies[6,16] on a number of such copper compounds have shown that the copper(II) ions are coupled antiferromagnetically, leading to values for room-temperature moments per copper ion less than the spin only value for one unpaired electron. However, the paucity of structural data on these types of complexes has not permitted any comparisons of the extent of coupling and structure. The recently[4] demonstrated structural variety of this class of copper(II) complexes strongly suggests that steric factors arising from ligand or alkoxide group substituents can determine the final molecular structure observed and hence the degree of magnetic coupling.

We wish to report further structural, magnetic and thermal studies of copper complexes containing the methoxyethoxide group and the non-symmetrically substituted ligand 1-phenyl-1,3-butanedione (benzoylacetone, bzac) and the symmetrical, bulkier variant 1,3-diphenyl-1,3-propanedione (bidenzoylmethane, dbm) to test the influence of ligand structure on complex structure type and hence on the degree of magnetic coupling. In addition ligand influence on whether the methoxyethoxide group can chelate to copper was sought

in the light of the differing situations in [Cu(acac)($OC_2H_4OCH(CH_3)_2$)]$_4$[11] (no chelation) and [Cu(hfac)($OC_2H_5OCH_3$)]$_4$[4] (chelation).

EXPERIMENTAL

The copper complexes are susceptible to hydrolysis in air in the solid state as well as in solution and all operations were performed using standard Schlenk manipulations under an atmosphere of dry nitrogen. IR spectral measurements were obtained with either Perkin–Elmer FT1600 or JASCO A100 spectrometers. Molecular weights were obtained at 60° in benzene using a Knauer Type II vapour phase osmometer (VPO). Microanalyses were by the National Analytical Laboratories. Thermogravimetric measurements were obtained on a Stanton Redcroft Model STA 1500 thermal analyser at heating rates of 10° min^{-1} and a nitrogen flow rate of 15 cm^3 min^{-1}.

Measurements of magnetic susceptibility

Powdered specimens were used and measurements of susceptiblity obtained at a field strength of 10,000 G between 300 K and 4.2 K using a Quantum Design M.P.M.S. Squid magnetometer. The calibration of the instrument was checked regularly against pure palladium and AR $CuSO_4 \cdot 5H_2O$. Samples were enclosed in gelatine capsules which were suspended at the middle of a plastic drinking straw, which was rigidly fixed to the end of the sample rod.

Syntheses

[Cu(bzac)($OC_2H_4OCH_3$)]$_4$ **(I)** *and* [Cu(acac)($OC_2H_4OCH_3$)]$_4$. Initial attempts to prepare the complexes by refluxing Cu(bzac)$_2$ or Cu(acac)$_2$ with KOH in 2-methoxyethanol yielded red Cu_2O. An alternate successful procedure was subsequently developed involving exchange of the methoxide group in [Cu(bzac)(OCH_3)] or [Cu(acac)(OCH_3)] for the 2-methoxyethoxide ion. The methoxide complexes were readily prepared by refluxing Cu(bzac)$_2$ or Cu(acac)$_2$ in methanol in the presence of 1 molar equivalent of KOH. A general procedure is described for the bzac derivative.

A solution of Cu(bzac)(OCH_3) (1.28 g, 5 mmol) in 2-methoxyethanol (10 cm^3) was refluxed for 5 min, during which time the solution colour changed from green to bright blue. The hot solution was filtered through a Celite pad and then allowed to cool. Blue–green dichroic crystals were formed (1.0 g, 60% yield). Further recrystallization of this material from 2-methoxyethanol gave crystals suitable for X-ray studies. Found: C, 52.1; H, 5.2. Calc. for $C_{13}H_{16}O_4Cu$: C, 52.1; H, 5.4%. IR (Nujol, cm^{-1}): 1020 m [ν(Cu—OR)], 505 s [ν(Cu—OR)], 460 [ν(Cu—O)]. Mol. wt (benzene, 60°): 0.0255 M, 1176±80; 0.058 M, 1076±80. Calc. for [Cu(bzac)($OC_2H_4OCH_3$)]$_4$, 1198. μ_{eff} = 1.48 B.M. (300 K).

[Cu(acac)($OC_2H_4OCH_3$)]. Found: C, 40.4; H, 5.9. Calc. for $C_8H_{14}O_4Cu$: C, 40.5; H, 6.1%. IR (Nujol, cm^{-1}): 1020 m [ν(Cu—OR)], 519 s (ν(Cu—OR)), 445 [ν(Cu—O)]. μ_{eff} = 1.39 B.M. (300 K).

[Cu(dbm)($OC_2H_4OCH_3$)]$_4$ **(II)**. Cu(dbm)$_2$ is insoluble in methanol, preventing direct formation of [Cu(dbm)(OCH_3)]$_4$ and hence negating the exchange route. However, 2-methoxyethanol, at reflux temperature, reacts with Cu(dbm)$_2$ in the presence of KOH and after filtration of the brown solid formed initially [Cu(dbm)$_2$ contaminated by traces of Cu_2O] the desired blue–green compound crystallized from the filtrate on cooling. Reycrystallization from 2-methoxyethanol gave material suitable for X-ray study. Found: C, 59.6; H, 5.0. Calc. for $C_{18}H_{18}O_4Cu$: C, 59.7; H, 5.0%. IR (Nujol, cm^{-1}): 1020 m [ν(Cu—OR)], 517 [ν(Cu—OR)], 457 [νCu—O]. μ_{eff} = 1.52 B.M. (300 K). The complex was also prepared by reaction of Cu(dbm)$_2$ with an equimolar quantity of preformed Na($OC_2H_4OCH_3$) in 2-methoxyethanol. The mixture was refluxed for 1–2 h under nitrogen and the complex crystallized out on cooling.

Crystallographic studies of [Cu(bzac)($OC_2H_4OCH_3$)]$_4$ **(I)** *and* [Cu(dbm)($OC_2H_4OCH_3$]$_4$ **(II)**

Crystals of approximate dimensions 0.17×0.20×0.11 mm **(I)** and 0.24×0.16×0.22 mm **(II)** were used for data collection. Intensity measurements were obtained on a Philips PW1100 diffractometer using graphite monochromated Cu-K_α radiation. Crystallographic data are collected in Table 1. Three standard reflections monitored every 4 h for each complex showed no significant variation over the data collection periods. Intensity data were processed as previously described.[17] Face-indexed numerical absorption corrections were applied, the maximum and minimum transmission factors, respectively, being **(I)** −0.804 and 0.540 and **(II)** −0.765 and 0.632. The atomic scattering factors for neutral atoms were taken from literature values[18] and corrected for anomalous dispersion. Calculations were performed on VAX 11/780 **(I)** and VAX 6250 **(II)** computers, the program for least-squares refinement being that due to Sheldrick.[19] The structures were solved by direct

methods. Full-matrix least-squares refinements employed anisotropic thermal parameters for copper and oxygen and isotropic thermal parameters for all other atoms, including single isotropic thermal parameters for hydrogen [which refined to 0.094(3) Å^2 for **I** and 0.08 Å^2 for **II** positioned in geometrically idealized positions: C—H (**I**) = 0.97 Å, C—H (**II**) = 0.96 Å. $R' = \Sigma w^{1/2}(||F_o|-|F_c||)/\Sigma w^{1/2}|F_o|$ and $\omega = [\sigma^2(F_o)]^{-1}$. The goodness-of-fit values $([\Sigma w(|F_o|-|F_c|)^2/(N_{obs}-N_{para})]^{1/2})$ were 2.10 (**I**) and 1.81 (**II**), respectively. The highest peaks in the difference-Fourier syntheses were 0.58 (**I**) and 0.30 e Å^{-3}.

RESULTS AND DISCUSSION

Syntheses

A general method for the synthesis of copper β-diketone–alkoxide complexes involves reaction of alkoxide anions formed by reaction of KOH[9,20] or alkali metals alone[4,11] with an alcohol and the bis copper complex $Cu(lig)_2$. Reaction between 3,5-substituted salicylaldehydato-copper complexes and alcohols alone have been reported[8] to form OCH_3 and OC_2H_5 derivatives, but the salicylaldehyde complex requires a base to be present for reaction to occur. Although the copper-dbm-methoxyethoxide compound was prepared for the present study by the KOH method, reactions with $Cu(bzac)_2$ and, for comparison, $Cu(acac)_2$ produced red Cu_2O as the main product. Indeed the yield of $[Cu(dbm)(OC_2H_4OCH_3)]_4$ was low and the recovered $Cu(dbm)_2$ appeared to be contaminated with traces of the copper(I) oxide. This complex was however readily prepared by reaction of the preformed sodium alkoxide. A more general reaction involves exchange of one alkoxide group for another by reacting a preformed [Cu(lig)(OR)] complex with another alcohol, preferably of higher boiling point than ROH to facilitate its removal. The Cu-bzac-OCH_3 and analogous acac complex were readily prepared by reaction of $Cu(bzac)_2$ or $Cu(acac)_2$ with methanol and both compounds underwent ready replacement of the methoxide group by methoxyethoxide when refluxed in that alcohol. This synthetic route was introduced by Mehrotra[21] for the preparation of nickel β-diketone–alkoxide compounds and clearly obviates complications due to the reducing properties of

alcohols in strongly basic solution. Each complex showed a comparable IR absorption at 1020 cm^{-1}, which was associated with the presence of the alkoxide group.

The structures of the complexes

[Cu(bzac)($OC_2H_4OCH_3$)]$_4$ (**I**). A diagram of the structure determined by a single-crystal X-ray study is shown in Fig. 1 with selected bond lengths and angles in Table 2 and angles of intersection of the various planes of interest in Table 3. The molecule may be considered to consist of two dimeric units, [Cu(bzac)($OC_2H_4OCH_3$)]$_2$, in which the copper(II) ions are bridged by alkoxy groups, associated into a tetrameric pseudo-cubane (type 3) structure by further, longer bonds between the alkoxide oxygens of each dimer with copper(II) ions in the other. The Cu···Cu axes in each dimeric unit lie at 96.4° to each other. The "intra-dimer" Cu—alkoxy O bonds average 1.954 Å compared with the larger, "inter-dimer" Cu—O linkages averaging 2.436 Å. This indicates weaker coordination between "dimers" than between the monomer units [Cu(bzac)(OR)]. These distances are comparable with those found for the other tetrameric examples described previously (Table 4). The distances between two of the methoxyl-oxygen atoms and two copper(II) ions are short enough to indicate weak bonding [Cu(2)—O(10), 2.865(5) Å; Cu(4)—O(14), 2.867(5) Å] giving six-coordinate copper at these sites. The remaining Cu–methoxyl O distances are much longer (4.76 Å) and no significant bonding interaction would seem possible leaving these copper(II) ions five-coordinate. This situation can be compared with that in [Cu(hfac)($OC_2H_4OCH_3$)]$_4$,[4] where a bonding interaction is indicated between methoxyl oxygens and each copper(II) ion. The Cu—methoxyl O distances (2.67 and 2.56 Å) are shorter than those in the present case. In the third example known having this type 3 structure, [Cu(acac)($OC_2H_4OCH(CH_3)_2$)]$_4$,[7] the isopropoxy oxygen atoms are not within bonding distances of the copper(II) ions. In the bzac compound the planes defined by the Cu_2O_2 dimer units Cu(I)—O(II)—O(9)—Cu(2) and Cu(3)—O(13)—O(15)—Cu(4) are not parallel, but inclined at an angle of 5.5°. Similarly the various benzoylacetonate chelate rings are inclined at angles to these planes. For each "dimer unit" one chelate plane (C_3O_2Cu) intersects at *ca* 23° and the other at *ca* 10° (Table 4), i.e. each is deflected away from the Cu_2O_2 plane and the Cu_4O_4 core. The phenyl rings in each dimer have a *trans* relationship to each other. In the tetramer, however, the arrangement of the two dimers brings pairs of phenyl groups in each dimer towards one another, causing the phenyl rings to incline at angles of *ca* 18° or 30° to their respective chelate rings (Table 3). A view of the molecule through the Cu(1)—O(9)—O(13)—Cu(3) face (Fig. 2) displays this arrangement and shows how the methoxy oxygens of the two alkoxy-methoxide groups are turned away from Cu(1) and Cu(3), while the remaining two are able to interact with Cu(2) and Cu(4).

gram of one dimer segment of the dibenzoylmethane complex is given in Fig. 3 and bond length and angle data in Tables 2 and 3. The complex in contrast to the monophenyl substituted β-diketone has a step structure of type 2(a), as shown in Fig. 4, with chelate ring oxygens being involved in coordinating the two dimer units as well as two bridging alkoxy oxygens. The inter-dimer Cu—O_{chel} bonds are longer than the inter-dimer Cu—O_{alkox} bonds by *ca* 0.4 Å. There is a centre of symmetry in the molecule. The methoxy oxygens of two of the alkoxide groups are certainly beyond even weak bonding interactions with the nearest copper ions with Cu—O > 4.6 Å. The remaining methoxy oxygens are 3.020(2) Å from the nearest copper ions, almost 0.2 Å further away than in compound **I**. [Cu(tfac)($OC_2H_4OCH_3$)]$_4$, where all four methoxyethoxide groups are considered to be in bonding distance with copper ions, has these Cu—O distances at 2.766 Å. Any bonding interaction must therefore be very weak if it may be considered at all.

Given the structural variety now disclosed for [Cu(lig)(OR)] compounds it is logical to expect that the type of structure adopted depends on the steric properties of both β-diketone and bridging alkoxide involved in a given compound. The possibility of alkoxyalkoxide groups chelating to copper ions as

well as acting as bridging ligands may also further influence the final structure adopted. Although alkoxyalkoxide groups are known to chelate readily in molecules such as [$Y(OC_2H_4OCH_3)_3]_{10}$[22] and [$Mo(O)_2(OC_2H_4OCH_3)_2$],[23] steric features of individual molecules no doubt can prevent such bonding occurring in specific instances. Thus, with only one bulky CF_3 group on the diketone a type 3 pseudo-cubane structure results and chelation occurs at each copper via the methoxy oxygen in [Cu(tfac)($OC_2H_4OCH_3$)]$_4$.[4] Replacing this CF_3 group by a phenyl as in compound **I** allows the

type 3 structure to be retained, but chelation by the alkoxyalkoxide group is restricted to two of the four copper ion sites. With two phenyl substituents, as in compound **II**, a type 2(a) structure results and chelation is prevented at each copper site although two alkoxy oxygens can approach two copper sites more closely than the others. The phenyl rings in this compound are set at angles to the chelate ring planes (Table 3). In each dimer unit three rings are rotated in the same direction as each other, while the fourth is turned in the opposite direction. The phenyl ring diametrically opposite to this latter is rotated through only half the angle of the other two. The overall effect is to prevent easy access of the methoxy groups to any copper ion site.

Dimer–tetramer equilibrium in solution

It is of interest to know whether the tetrameric forms of these types of complexes are retained in

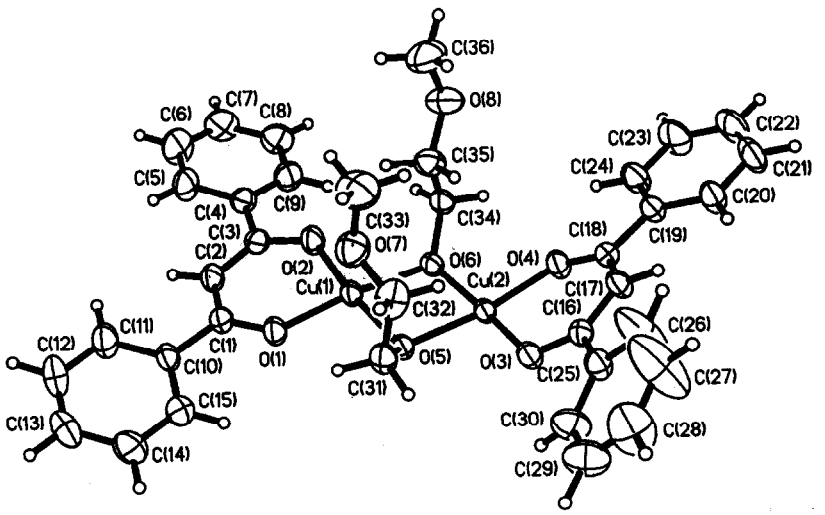

Fig. 3. ORTEP diagram of one dimer segment of the molecular structure of $[Cu(dbm)(OC_2H_4OCH_3)]_4$ (II) showing the atom-labelling scheme. Thermal ellipsoids at 50% probability.

solution. Previous measurements of molecular weights of other copper β-diketonate-alkoxide complexes[4,9] have generally found values much closer to the dimer composition even for complexes shown to be tetrameric in the solid state, indicating that dissociation must be relatively easy. This could be correlated with the long Cu—O inter-dimer bonds. Interestingly the only dimer to be characterized so far by an X-ray diffraction study, [Cu(tfac)(OC_6F_5)THF]$_2$,[24] has a molecular weight in $CHCl_3$ indicating some degree of higher (presumably tetrameric) molecular weight species has formed. Berke *et al.*[4] also report molecular weight data showing that [Cu(hfac)($OC_2H_4OCH_3$)]$_4$ retains the tetrameric form in solution. The low solubility of the dibenzoylmethane complex (II) prevented measurement of its molecular weight by VPO, but the molecular weight of [Cu(bzac)($OC_2H_4OCH_3$)]$_4$ at 60°C in benzene indicates a substantial portion of that complex is still in the tetrameric form. Since the inter-dimer Cu—O distances are of similar dimensions in all the tetramer units so far examined, it is not clear what other factors determine the extent of the tetramer–dimer equilibrium in addition to the long inter-dimer Cu—O distances. Molecular weight studies on [Ni(lig)(OR)ROH] analogues[21] show them to be tetrameric in solution with little tendency to dissociate into constituent dimers. The limited X-ray data on such compounds indicate that the inter-dimer distances are much closer to the intra-dimer distances than is the case in the copper compounds.

Magnetic susceptibility measurements

The copper benzoylacetone and dibenzoylmethane-methoxyethoxide complexes show reduced magnetic moments at 300 K of 1.48 and 1.55 B.M., respectively, as do other such copper(II) complexes.[6,16] This indicates Cu···Cu magnetic coupling and a plot of susceptibility vs temperature from 300 to 4.2 K (Fig. 5) for [Cu(bzac)(OC_2H_4

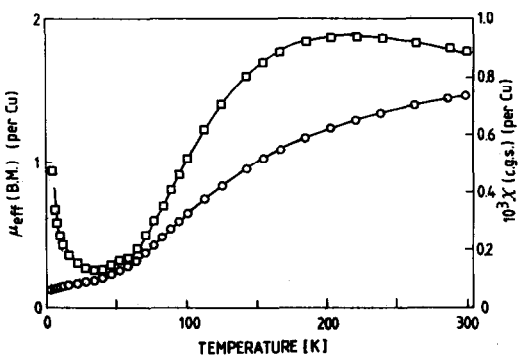

Fig. 5. Plots of magnetic susceptibility (□) and moments (○) vs temperature for [Cu(bzac)($OC_2H_4OCH_3$)]$_4$ (I). Solid lines are the calculated values using a "pair of equal dimers" model with $g = 2.01$, $J_{12} = -120.4$ cm^{-1}, TIP = 60×10^6 cm^3 mol%, copper(II) monomer = 0.5.

$OCH_3)]_4$ shows the typical curve expected for an antiferromagnetically coupled system with a χ_{max} value at *ca* 210 K. The corresponding μ_{eff} value falls to 0.1 B.M. at 4.2 K.

The observed data can be fitted very well by using an isolated "pair of equal dimers" model[24] (i.e. $J_{12} = J_{34}$; $J_{14} = 0$, etc.) with parameters $g = 2.01$, TIP $= 60 \times 10^{-6}$ cm^3 mol and $J_{12} = -120.4$ cm^{-1}. The small increase in χ observed at very low temperatures in the χ/T plot can be accounted for by assuming the presence of a trace amount ($\leqslant 0.5\%$) of a monomer copper(II) "impurity". Previous magnetic studies[6,16] on a range of other copper(β-diketone)(OR) complexes have used a similar model to treat the χ/T data down to 80 K and comparable g and J values have been obtained. The use of a "pair of equal dimers" model appears reasonable in view of the large inter-dimer Cu—alkoxide axial distances (Table 2), which should render any out-of-plane interactions very weak. Indeed, we found that fitting the data to models appropriate to the pseudo-cubane symmetry (type 3), in a manner similar to that previously used by Haase[24,25] and Hatfield[26] for chelating alkoxo species of the type $[Cu(X)(OCH_2CH_2NEt_2)]_4$ (X = NCO, NCS, halide), yielded the same value of J_{12} and a zero value for the cross-coupling parameters J_{14}. In these other studies[24–26] it was found necessary to incorporate non-zero values of the cross J terms, often ferromagnetic in sign, in order to get good fits and sensible values for g. However, the inter-dimer Cu—alkoxide distances were generally much shorter (*ca* 2.1 Å) than those observed here for **I** and the deduced intra-dimer J_{12} parameters were also of a much smaller negative value. The variable-temperature magnetic data for the dbm analogue (**II**) are broadly similar to those of **I**, although the room-temperature μ_{eff} value per copper, of 1.55 B.M., is slightly larger. The corresponding J value, again deduced from an excellent fit using a "pair of equal dimers" model, is a little less than in **I**, viz. $J = -104.3$ cm^{-1} ($g = 2.06$, TIP $= 60 \times 10^{-6}$ cm^3 mol^{-1}, % monomer = 0.5%). The use of a tetranuclear model,[27] appropriate to the symmetry of a stepped structure [type 2(a)] once more yielded the same values of g and J_{12} as found in the dimer model as well as a zero value for J_{14}, etc. Blake *et al.*[6] also found that cross-coupling terms were not required to fit the susceptibility data in a related type 2(b) complex, $[Cu(acac)(OCH_2Ph)]_4$, the J_{12} value being much larger (-313 cm^{-1}) in that case.[16] In other related type 2(a) systems we,[28] and others,[27,29] have found that non-zero inter-dimer interactions do occur and are sometimes ferromagnetic in nature, but this is not the case in complex **II**. Hubert-Pfalzgraf *et al.*[11] commented that preliminary measurements on $[Cu(acac)(OC_2H_4OCH(CH_3)_2)]_4$ might indicate a ferromagnetic contribution, but no further details have been published. In striving to sort out the many factors which might influence the size and sign of J_{12} values in di-μ-alkoxo copper(II) fragments complexes **II** and $[Cu(acac)(OCH_2Ph)]_4$ provide two structurally characterized type 2(a) analogues.[10] The geometrics of the $Cu_2(OR)_2$ bridging moieties are shown in Fig. 6. The main difference is the shorter Cu···Cu distance in **II** with correspondingly smaller Cu—O—Cu angles. This broadly correlates with the r (Cu···Cu) and average Cu—O—Cu angle (ϕ) dependencies noted some years ago by Melnik.[30] Use of Melnik's relation, $2J_{calc} = -101.5(\phi) + 9830$ cm^{-1}, yields J_{calc} values of -110 (**I**), -131 (**II**) and -287 cm^{-1} ($[Cu(acac)(OCH_2Ph)]_4$), in quite good agreement with the fitted values. Magnetic data for the other structurally characterized analogues now known (Table 4) would further test this structural relationship.

Also, di-μ-alkoxo systems displaying very large negative J values[6,31] (i.e. close to diamagnetism) require further structure/magnetism studies to be made in order to confirm an anticipated (ϕ) angle of *ca* 105°, predicted by the linear relationship given above.

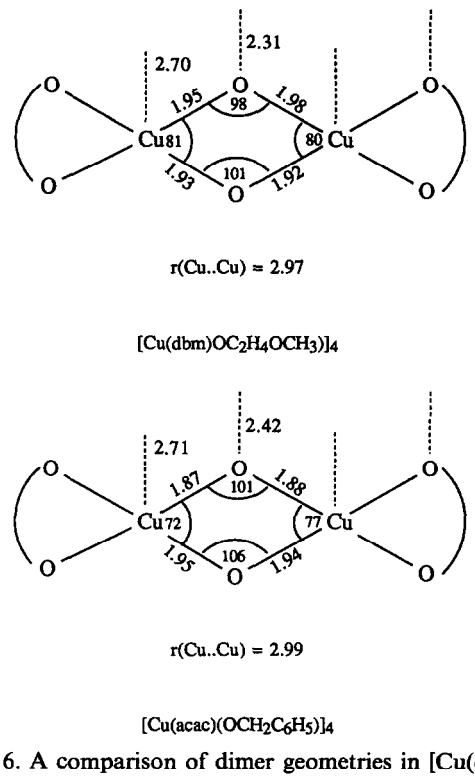

Fig. 6. A comparison of dimer geometries in $[Cu(dbm)(OC_2H_4OCH_3)]_4$ (**II**) and $[Cu(acac)(OCH_2C_6H_5)]$.

Thermal stability

A comparison of the thermal decomposition of compounds **I** and **II** with [Cu(acac)($OC_2H_4OCH_3$)]$_4$ has been made at atmospheric pressure under a dynamic nitrogen atmosphere. The TG and DTG curves for **I** (Fig. 7) show the first decomposition occurs near 100°C (where the weight loss is close to that of one $OC_2H_4OCH_3$ group per tetrameric unit (obs. 6.8%, theor. 6.25%). Further decomposition occurs around 200°C and the additional weight loss is just less than for two further OR groups (obs. 16.6%, theor. for a total of 3 OR groups, 18.7%). Further thermal decomposition has occurred by 280–290°C when a total 62.1% weight loss has taken place. Continuing heating to 500°C finally produces pure CuO (confirmed by XRD) as a film which firmly adheres to the surface of the rhodium sample container. Compound **II** shows somewhat more clearly two decomposition stages (Fig. 7). The first weight loss, *ca* 200°C, corresponds to removal of virtually the entire methoxyethoxide group (obs. 20.1%, calc. 20.7%). The second stage (*ca* 350°C) corresponds to the loss of the remaining organic material and formation of metal oxide is completed by *ca* 480°C. The final material (by XRD examination) was found to be a mixture of CuO and Cu_2O in almost equal proportions, together with a small amount (< 5%) of metallic copper. [Cu(acac)($OC_2H_4OCH_3$)] shows a broadly similar TG curve to those of the benzoyl compounds, without the clearer definition of the stages of decomposition shown by them. However, pure CuO was eventually produced by heating to 400°C a temperature lower than for either of the other complexes. CuO in this case was formed as a powder, which did not adhere to the floor of the sample container. Attempts to sublime [Cu(acac)($OC_2H_4OCH_3$)]$_4$ and [Cu(bzac)($OC_2H_4OCH_3$)]$_4$

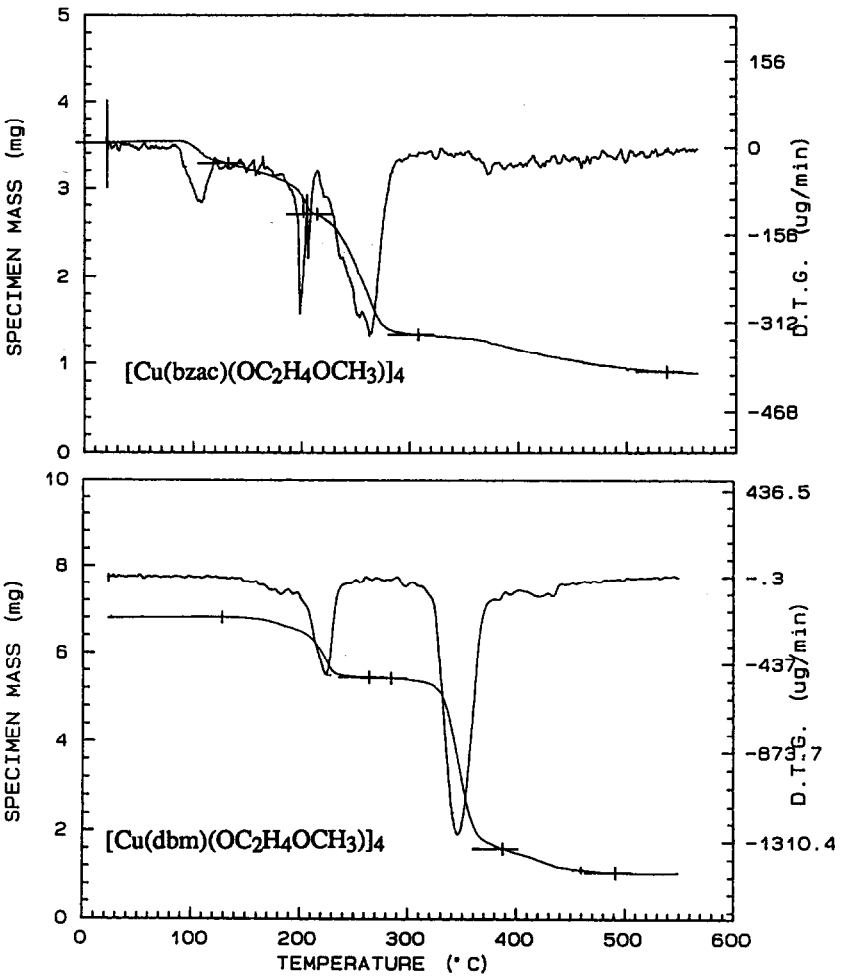

Fig. 7. TG and DTG curves for [Cu(bzac)($OC_2H_4OCH_3$)]$_4$ (**I**) and [Cu(dbm)($OC_2H_4OCH_3$)]$_4$ (**II**). Heating rate 10° min^{-1}, dinitrogen flow 15 cm^3 min^{-1}.

at 10^{-3} mm of Hg resulted in deposits of the bis $Cu(lig)_2$ complexes being obtained at 110°C [$Cu(acac)_2$] and 190°C [$Cu(bzac)_2$]. These latter complexes were identified by their IR spectra, which showed only bands for the $Cu(lig)_2$ compounds. There was no evidence for a band at 1020 cm^{-1} which is characteristic of the copper diketone-alkoxyalkoxides. Other solid decomposition products remained in the sublimation vessel. The [Cu(acac)$(OC_2H_4OCH(CH_3)_2)]_4$ complex is reported to sublime readily at 10^{-3} mm Hg/80°C, but the authors did not specifically refer to examination of the sublimate observed.

SYNTHESIS AND MOLECULAR STRUCTURE OF $[Zn_2(CH_3COO)_3(OCH_3)]$

C. D. CHANDLER, G. D. FALLON and B. O. WEST*

Centre for Chemical Synthesis and Department of Chemistry, Monash University, Clayton, Victoria 3168, Australia

(*Received* 23 *March* 1993; *accepted* 22 *April* 1993)

Abstract—The compound $Zn_2(CH_3COO)_3(OCH_3)$ has been prepared by an exchange reaction between $Zn(CH_3COO)_2$ and $Sn(Bu^n)_2(OCH_3)_2$ in methanol and structurally characterized as a three-dimensional polymer.

There is considerable interest in the identification of heteronuclear complexes that can be formed by the interaction between alkanoate and alkoxide derivatives of metallic elements since they may have utility in the preparation of mixed metal oxides by hydrolysis, the so-called "sol–gel process".[1] When main group elements form the metals involved their compounds are usually labile and given the variety of coordinations possible with carboxyl and alkoxide groups (bridging, terminal coordination, chelation), the particular heteronuclear complex isolated will depend to a large degree on the relative solubilities of the various possible complexes that could form in solution. This in turn could lead to a different molar ratio of the RCOO and R'O groups in the product eventually isolated to that in the reaction mixture. Thus, the compound $[Cd_4Sn_4(\mu\text{-}O)_2(CH_3COO)_{10}(OCH_2Bu^t)_{10}]$ has resulted[2] from reaction between equimolar amounts of $Cd(CH_3COO)_2$ and $Sn(OCH_2Bu^t)_4$ which makes the isolated product "shorter" on alkoxide and "richer" in acetate than the initial mixture. The complex $Pb_2Ti_4(\mu_4\text{-}O)_2(CH_3COO)_2(OC_2H_5)_{14}$ is a more extreme example having been isolated[3] from an equimolar mixture of $Pb(CH_3COO)_2$ and $Ti(OC_2H_5)_4$. Such results raise the question as to whether homonuclear intermediates can form by exchange of alkanoate and alkoxide groups between the reactants before a more complex heteronuclear species is created. We present structural evidence for such a zinc compound of the empirical formula $Zn_2(CH_3COO)_3(OCH_3)_2$, formed by the reaction between $Zn(CH_3COO)_2$ and the alkoxide of restricted bridging ability, $Sn(Bu^n)_2(OCH_3)_2$.

EXPERIMENTAL

All manipulations were conducted using standard Schlenk procedures under an atmosphere of dry nitrogen. Spectral measurements: IR—Perkin–Elmer, FTIR 1600; NMR—Bruker AM-300; mass—VG Micromass 7070F; electron microprobe measurements—Cambridge S410 SEM, with NEC X-ray detector and Packard multichannel analyser. $Sn(Bu^n)_2(OPr^i)_2$ was prepared[4] by reaction of $Sn(Bu^n)_2Cl_2$ with $NaOPr^i$ in *iso*-propanol. The compound was finally distilled at 80°C 1 mm^{-1} Hg (lit.[5] 87°C/1.5 mm Hg). M.S.: *m/z* 293 $Sn(Bu)2(OPr)^+$, 235 $Sn(Bu)(OPr)^+$. ^1H NMR ($CDCl_3$): δ, 4.26 (CH); 1.7–0.8 mult. (CH_3, CH_2). Anhydrous $Zn(CH_3COO)_2$ was obtained by drying the dihydrate (BDH LR grade) at 100°C and 10^{-3} mm Hg for 2 h. IR examination of such material showed no evidence for OH absorptions and its spectrum agreed with that of another reported preparation.[6]

Reaction of $Sn(Bu^n)_2(OCH_3)_2$ *with* $Zn(CH_3COO)_2$

$Sn(Bu^n)_2(OPr^i)_2$ (0.75 g, 2 mmol) was dissolved in methanol (20 cm^3), stirred for 20 min and then evaporated rapidly under reduced pressure, yielding an oil. This was redissolved in methanol (40 cm^3) and anhydrous $Zn(CH_3COO)_2$ (0.4 g, 2 mmol) was added. The solid rapidly dissolved but within several minutes a white precipitate reappeared. The

* Author to whom correspondence should be addressed.

mixture was heated to redissolve the precipitate and then allowed to cool slowly. The clear, colourless crystals which formed were filtered, washed with cold methanol and dried in a stream of nitrogen. Crystals suitable for X-ray studies were obtained by a further recrystallization from methanol. The compound is reasonably soluble in methanol, but very sparingly soluble in chloroform or toluene. Found: C, 24.7; H, 3.5. Calc. for $C_7H_{12}O_7Zn_2$: C. 24.7; H, 3.5%. Electron microprobe showed no evidence for tin in the product. IR (Nujol): 1604(s) 1551(s), 1542(s), 1445(s), 1417(m), 1405(s), 1377(vs), 1364(sh), 1350(sh), 1053(m), 1028(m), 1014(m), 958(m), 702(s), 672(w), 663(w), 609(m) cm^{-1}. ^1H NMR ($CDCl_3$): δ, 3.88 (OCH_3), 3H; 2.12 (CH_3COO), 9H.

Crystallographic studies of $Zn_2(CH_3COO)_3(OCH_3)$

A representative fragment of a large clear crystal sealed in a Lindemann glass capillary was used for data collection. Intensity measurements were made on a Nicolet R3m/V diffractometer using graphite monochromated Mo-K_α radiation. Crystallographic data are collected in Table 1. Cell parameters were derived by least-squares calculations from angular settings of 29 reflections measured in the range $8° < 2\theta < 27°$. Three standard reflections monitored every 197 reflections showed no significant variation in intensity over the data collection period. Intensity data were corrected for Lorentz and polarization effects. Due to difficulty indexing the irregular crystal no absorption correction was applied. The atomic scattering factors for neutral atoms were taken from literature values.[7] All calculations were performed on a VAX11/780 computer, the program for least-squares refinement being that due to Sheldrick.[8] The structure was solved by Patterson methods and refined by full-matrix least-squares employing anisotropic thermal parameters for zinc and isotropic thermal parameters for all other atoms, including a single isotropic thermal parameter for hydrogen (which refined to 0.16(3) $Å^2$), positioned in geometrically idealized positions: C—H 0.96 Å. This treatment reduced R to 0.034 and R' to 0.045, respectively, at convergence where $R' = (\Sigma w(\|F_o\| - |F_c\|)^2/\Sigma w|F_o|^2)^{1/2}$ and $w = [\sigma^2(F_o) + 0.000267F_o^2]^{-1}$. The goodness-of-fit value $([\Sigma w(|F_o| - |F_c|^2/(N_{obs} - N_{para})]^{1/2})$ was 1.85. Refinement with the sense of the polar axis reversed resulted in $R = 0.036$ and $R' = 0.053$. The highest peak in the difference-Fourier synthesis was 0.48 $eÅ^{-3}$.

RESULTS AND DISCUSSION

Crystal structure of $Zn_2(CH_3COO)_3(OCH_3)$

The X-ray structural study has shown the compound to be a three-dimensional polymer in the solid state (Fig. 1). Each zinc atom is four-coordinate, surrounded by a distorted tetrahedron of oxygen atoms derived from three acetate groups and one alkoxide. The zinc atoms are linked in pairs by a bridging OCH_3 and a bridging acetate forming six-membered rings while each zinc atom is in turn linked to a zinc atom on a neighbouring "ring" by further bridging acetates. A list of relevant bond distances and angles is given in Table 2. The compound has a mirror plane through the middle of the six-membered ring, bisecting the bridging methoxide and acetate groups. Anhydrous $Zn(CH_3COO)_2$ is also polymeric in the solid state[9] with zinc atoms in distorted tetrahedral environments, although the departure from 109.5° angles is much less than in the present complex. Each zinc in $Zn(CH_3COO)_2$ is coordinated to four acetates, which in turn bridge to other zinc atoms. Thus, the structure of $Zn_2(CH_3COO)_3(OCH_3)$ can be regarded as derived from that of $Zn(CH_3COO)_2$ with the replacement of one acetate in four by the OCH_3 group. The more limited ability of the latter group to bridge through only one oxygen instead of the two available to the acetate then causes the change in structure. The Zn—O methoxide distances, 1.932 Å, are shorter than the acetate Zn—O distances, which range from 1.948 to 1.974 Å, and the acetate Zn—O

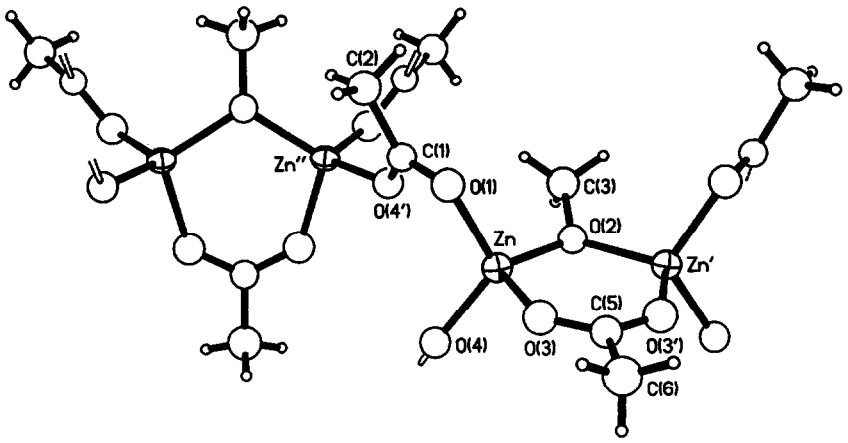

Fig. 1. Molecular structure diagram of $[Zn_2(CH_3COO)_3(OCH_3)]$, showing the atom labelling scheme. Thermal ellipsoids at 50% probability.

distances are longer than the average such bond in $Zn(CH_3COO)_2$. The bond distances are closer to those in basic zinc acetate,[10] $Zn_4(\mu_4\text{-O})(CH_3COO)_6$, where Zn—($\mu_4$-O) is 1.936(1) Å, and the Zn—O (bridging acetate) bonds average 1.946(4). The alkoxide $(CH_3ZnOCH_3)_4$ displays notably longer Zn—O distances (2.039–2.114 Å)[11] than in the present compound (1.932 Å), which can be ascribed to the μ_3 nature of each oxygen in the former. There are two types of acetate group in the alkoxy-acetate compound. One forms six-membered rings with OCH_3 groups and two zinc atoms, while the other bridges between such rings. The difference shows in the O—C—O angles, the former averaging 125° and bridging in a *syn–syn* mode while "ring bridging" acetate groups have O—C—O angles of 120.4° and are coordinated in a *syn–anti* mode. This latter mode of coordination is apparently necessary in order to bridge the long distances between the six-membered rings. The O—C—O angles in $Zn_4(\mu_4\text{-O})(CH_3COO)_6$ are also 125° and there is a striking geometric similarity between the six-membered rings in this compound involving the μ_4-O atom and in $Zn_2(CH_3COO)_3(OCH_3)$ involving the μ_2-OCH_3 group.

Spectroscopic properties

The bridging acetate carboxylate group in basic zinc acetate, $Zn_4(\mu_4\text{-O})(CH_3COO)_6$, gives rise to asymmetric and symmetric vibration frequencies of the CO_2 unit variously reported as $\nu_{asym} = 1600$[6] and 1639 cm^{-1}[12] and $\nu_{sym} = 1441$[6] and 1489 cm^{-1}.[12] The differences, Δ(asym–sym) = 159 or 150 cm^{-1}, are of the right order of magnitude suggested as a correlation for bridging acetate group frequencies.[13] The present complex shows absorptions of similar value which may be assigned to the bridging acetate in the six-membered $Zn_2(CH_3COO)(OCH_3)$ rings at $\nu_{asym} = 1604$ and $\nu_{sym} = 1445$ cm^{-1} ($\Delta = 159$ cm^{-1}). Since a second type of bridging acetate exists in the structure of the complex one further pair of frequencies in the asymmetric and symmetric regions is expected to

be observed. There are indeed other strong absorptions at 1557 and 1542 cm^{-1} (ν_{asym} region) and 1417 and 1405 cm^{-1} (ν_{sym} region), the latter pair being distinguished from the Nujol peak by a structure subtraction procedure. The crystallographic evidence indicates that the acetates in this bridging mode are identical and a clear assignment of an appropriate pair of frequencies, therefore, cannot be made. Frequencies due to the methoxide group are also difficult to assign with confidence amongst the acetate bands. The clearest indication appears to be a band at 1014 cm^{-1} in the alkoxide stretching region beside the probable CH_3 rocking frequency of the acetate group (1053 cm^{-1}).

The ^1H NMR spectrum of $Zn_2(CH_3COO)_3(OCH_3)$ shows only one acetate and one methoxide resonance. If the ring formulation was retained in solution two acetate resonances could be expected in the ratio 2 : 1. The resultant spectrum indicates that rapid exchange is taking place between acetate groups whatever molecular species finally forms.

CONCLUSION

This study confirms that group exchange can take place between labile zinc and tin species to form the type of homo-binuclear ring system detected in larger heteronuclear species and suggests that such entities can form initially and act as building blocks in the formation of such large heteronuclear entities.

A STUDY ON THE SCHIFF BASE Cu_2Zn_2SOD MODEL COMPLEXES—THE RELATIONSHIP BETWEEN STRUCTURE AND ACTIVITY

QIN LU, CHENG-YU SHEN and QIN-HUI LUO*

Coordination State Key Laboratory, Nanjing University, Nanjing 210008, P.R.C.

(*Received* 5 *April* 1993; *accepted* 22 *April* 1993)

Abstract—2-Acetylpyridine was condensed with $NH_2(CH_2)_nNH_2$ (n = 2,3,4). The di-Schiff base complexes of copper(II) were obtained for simulating superoxide dismutase. Studies on the relationship between dismutase O_2^- ability and coordination configuration were made. Linear relationships were obtained between $E_{1/2}$ of $Cu^{II}L/Cu^{I}L$, $g_\parallel/A_\parallel$ and catalytic activities of these complexes, respectively.

Superoxide dismutase (SOD) is a scavenger of the superoxide anion (O_2^-) and it plays an important role in protecting cells from the toxic effects of the superoxide ion, or some products derived from it.[1–3] The active site of Cu_2Zn_2SOD is similar to the imidazolate-bridged copper(II), zinc(II) binuclear complex. In Cu_2Zn_2SOD copper(II) is centred in a distorted square plane coordinated to four nitrogen atoms of four imidazolate radicals (His-44, His-46, His-118 and His-61), in which His-61 is bridged to the zinc(II) atom. His-69 and His-78 provide two more imidazolate nitrogens and the oxygen of the carboxylate group of Asp-81 acts as the fourth ligand to zinc(II), forming a distorted tetrahedral structure[4] (Fig. 1). The main function of the zinc(II) atom is to make the structure stable and has little effect on enzyme activity. Studies on the structure and function of SOD model compounds can lead to a profound understanding of the enzyme as well as to the coordination chemistry and biological medicine chemistry.[5] Up until now some copper (II) complexes have been synthesized with salicylate,[6] amino acids,[7] polypeptides[8] and other[9,10] ligands, but the relationship between structure and function has rarely been discussed.[9,11] In this work 2-acetylpyridine was condensed with ethanediamine, propane diamine-1,2 and butanediamine-1,2 to form three new Schiff base ligands (apen, appn and aptn). After their reaction with $Cu(ClO_4)_2$, we obtained three copper(II) complexes: [N,N′-ethylene bis-(2-acetylpyridine iminato)copper(II)] diperchlorate ([Cu(apen)]$(ClO_4)_2$ (**1**); [N,N′-propylene bis-(2-acetylpyridine iminato)copper(II)] diperchlorate ([Cu(appn)]$(ClO_4)_2$) (**2**); and [N,N′-butylene bis-(2-acetylpyridine iminato)copper(II)] diperchlorate ([Cu(aptn)]$(ClO_4)_2$) (**3**) (formula shown in Fig. 2). Among these three [Cu(aptn)]$(ClO_4)_2$ has been found in our early paper to have a high SOD activity.[12] In this work, the relationship between the structure and SOD activity was determined by the riboflavin illumination method, UV, EPR, electrochemistry and other techniques.

Xiahe Pharmaceutical Factory, specific activity 3000 units mg^{-1} protein. KH_2PO_4 and K_2HPO_4 (A.R) were recrystallized twice in deionized water. Nitrotetrazolium blue (NBT), L-methionine and B.R. riboflavin were analysed by literature methods.[13]

Preparation of complexes

[Cu(apen)]$(ClO_4)_2$. To a methanol solution (30 cm^3) of 2-acetylpyridine (0.5 g, 4.13 mmol) ethanediamine was added dropwise (0.125 g) (distilled before use) with stirring. After refluxing for 20 min a methanol solution (20 cm^3) of $Cu(ClO_4)_2 \cdot 6H_2O$ (0.76 g, 2.07 mmol) was added and refluxing continued for another 30 min. On cooling blue–black microcrystals precipitated in 44% yield (0.52 g). Found: C, 35.1; H, 3.2; N, 10.1; Cu, 11.3. Calc. for $C_{16}H_{18}CuCl_2N_4O_8 \cdot H_2O$: C, 35.1; H, 3.7; N, 10.2; Cu, 11.6%. Λ_M (DMF, 298 K): 138 Ω^{-1} cm^2 mol^{-1}.

[Cu(appn)]$(ClO_4)_2$. The complex was obtained as heavy blue needle crystals in a similar manner using 2-acetylpyridine (0.5 g, 4.13 mmol) propanediamine-1,2 (0.153 g, 2.07 mmol) and $Cu(ClO_4)_2 \cdot H_2O$ (0.76 g, 2.07 mmol); yield 43% (0.48 g). Found: C, 37.2; H, 3.4; N, 9.9; Cu, 11.2. Calc. for $C_{17}H_{20}CuCl_2N_4O_8$: C, 37.6; H, 3.7; N, 10.3; Cu, 11.7%. Λ_M (DMF, 298 K): 144 Ω^{-1} cm^2 mol^{-1}.

[Cu(aptn)]$(ClO_4)_2$. The complex was obtained as heavy blue microcrystals in a similar manner; yield 50%. Found: C, 38.7; H, 4.2; N, 10.2; Cu, 11.2. Calc. for $C_{18}H_{22}CuCl_2N_4O_8$: C, 38.8; H, 3.9; N, 10.1; Cu, 11.4%. Λ_M (DMF, 298 K): 140 Ω^{-1} cm^2 mol^{-1}.

Measurements

Cyclic voltammetry was performed with a 79-1 electrochemical apparatus, connected to an *X–Y* recorder. A three-electrode system was used. The working electrode was glass carbon and platinum coil was used as the counter electrode. The reference electrode was a saturated calomel electrode (S.C.E.). Solutions were prepared using twice distilled water and the concentration of complexes was *ca* 1×10^{-3} mol dm^{-3}. In KCl (0.08 mol dm^{-3}) (A.R., recrystallized before use) a flow of high purity nitrogen was bubbled through the solution for 15 min before measurement. The procedure was performed at room temperature. The half-wave potential, $E_{1/2}$ of $Cu^{II}L/Cu^{I}L$ was obtained from an average of E_{pc} and E_{pa}.

X-band EPR spectra were recorded on a 200D-SRC spectrometer at 110 K with a frequency modulation of 100 kHz. The frequency was calibrated with Mn^{2+} ions in MgO powder.

Electronic spectra were recorded on a Shimadu UV-200 spectrophotometer in methanol solution.

Activity was assayed by illumination[14] of a solution containing 3.40×10^{-6} mol dm^{-3} riboflavin, 4.66×10^{-5} mol dm^{-3} NBT, 0.01 mol dm^{-3} methionine and various concentrations of complexes and SOD, prepared with pH = 7.8 phosphate buffer. The solution was illuminated by a fluorescent lamp with constant light strength at 25°C. The optical density of the solution with and without the complexes (Δ and Δ_0, respectively) was measured at 560 nm to determine their variations with time. The percentage of inhibiting NBT reduction was determined as $f\% = [(\Delta_0 - \Delta)/\Delta_0] \times 100\%$.

RESULTS AND DISCUSSION

Conductivity and electronic spectrum

In DMF the conductivity of all three complexes was *ca* 140 Ω^{-1} cm^2 mol^{-1}, behaving as a 1:2 electrolyte, which is consistent with the chemical formula predicted by elemental analysis (Fig. 2).

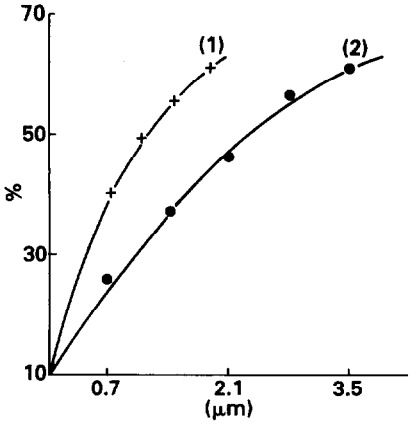

Fig. 3. Plots of percentage of inhibiting NBT reduction vs concentration of the complexes.

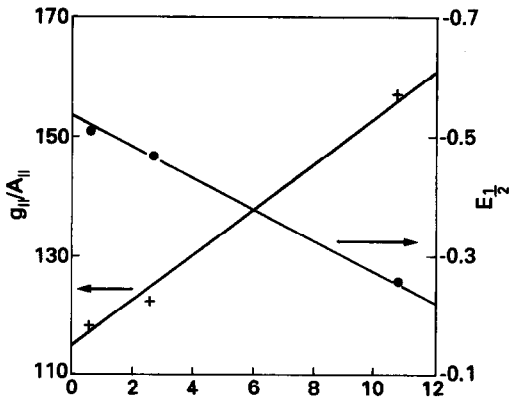

Fig. 4. Plots of $E_{1/2}$ and $g_{\parallel}/A_{\parallel}$ vs relative activity.

The electronic spectra data in Table 1 show that the maximum *d–d* absorption shifted from 620 nm to 705 nm as the carbon chain of the ligand increased. Their absorption intensity increased as well. $[Cu(aptn)](ClO_4)_2$ had a maximum *d–d* wavelength, which is between Cu_2Zn_2SOD and Cu_2ESOD [740(140)].[15] The red shift of absorption implies a distortion from square-planar to tetrahedron for copper(II) configuration.

EPR spectrum

We recorded the EPR spectra of the three compounds and their parameters are listed in Table 1. As previous scholars have reported[16] $g_{\parallel}/A_{\parallel}$ can be used as an empirical rule of configuration distortion. When $g_{\parallel}/A_{\parallel}$ falls between 105 and 135 cm CuN_4 forms a square planar configuration, whereas if $135 < g_{\parallel}/A_{\parallel} < 258$ a distorted tetrahedral configuration results. The $g_{\parallel}/A_{\parallel}$ values of complexes **1** and **2** in Table 1 indicates a square-planar structure. Whilst complex **3** is a distorted tetrahedron, its EPR parameter is very close to that of Cu_2Zn_2SOD.[17] The covalence parameters α^2 and α'^2 were obtained by the literature method[18] and we can see that the covalence of the complexes increases as the structure distortion increases.

Table 2. Electrochemistry data of $Cu^{II}L/Cu^{I}L$ compounds (S.C.E. is standard)

Complexes[a]	E_{pc}(V)	E_{pa}(V)	ΔE_p(V)	$E_{1/2}$(V)
1	−0.564	−0.443	−0.121	−0.504
2	−0.529	−0.414	−0.115	−0.472
3	−0.321	−0.207	−0.114	−0.264

[a] See footnote to Table 1.

Activity

The activity data in Table 1 were obtained by plotting the percentage of inhibiting NBT reduction against concentration of the complex (Fig. 3). The activity for dismuting superoxide ion (O_2^-) increased as the carbon chain of the diamine increased. Among them complex **3** was the highest, its spectral data were the closest to Cu_2Zn_2SOD, implying a close coordination environment of copper(II) to Cu_2Zn_2SOD.

Electrochemistry

Listed in Table 2 are the redox half-wave potentials of the three complexes obtained by cyclic voltammetry. The redox of $Cu^{II}L/Cu^{I}L$ was a quasi-reversible process. When the distortion of CuN_4 increased ($g_{\parallel}/A_{\parallel}$ increased) its reduction potential shifted positively and its activity also increased. Two straight lines were obtained when plotting half wave potential and $g_{\parallel}/A_{\parallel}$ against relative activity (Fig. 4). Former researchers have indicated[19] that the distortion of copper(II) from square planar toward tetrahedral was in favour of the reduction of copper(II) to form a $Cu^{I}L$ complex. In the dismutase reaction of O_2^- the easier $Cu^{I}L$ complex forms, the value of $E_{1/2}$ for $Cu^{II}L/Cu^{I}L$ is more positive and the catalytic activity will be higher. From this point of view, it is easy to understand why $[Cu(aptn)](ClO_4)_2$ gave the best result in simulating superoxide dismutase.

Abstract—The interaction of trimesityliridium(III) with trimethylamine oxide gives quantitative yields of the green iridium(V) complex $Ir(O)(mes)_3$, whose X-ray crystal structure has been determined. The oxo compound is also obtained by interaction of dioxygen with $Ir(mes)_3$ and $Ir(mes)_4$. A similar oxo species has also been obtained from $Ir(2,6\text{-}Me_2C_6H_3)_4$. The molecular structure of $Ir(O)(mes)_3$ is distorted tetrahedral with Ir=O and Ir—C bond lengths of 1.725(9) and 1.989–2.034(13) Å, respectively.

We have described[1] the syntheses and X-ray crystal structures of $Ir(mes)_3$, mes = mesityl, 2,4,6-trimethylphenyl, $Ir(mes)_4$ and $[Ir(mes)_4]^+$, the latter two being the first examples of tetrahedral Ir^{IV} and Ir^V, respectively.

It was noted[1] that brown solutions of $Ir(mes)_3$, which unlike its rhodium analogue is exceedingly air-sensitive, and also of $Ir(mes)_4$ react with dioxygen, the latter only on heating, becoming green. Since the formation of an oxo species was evident, a better procedure for the product, $Ir(O)(mes)_3$, was the interaction of $Ir(mes)_3$ with Me_3NO.

Neutral iridium(V) compounds are relatively rare,[2] being limited to tertiary phosphine and η^5-cyclopentadienyl polyhydrides and related compounds [2a,b] and to (triso)$Ir(H)_2SiR_2R'$ species,[2c] triso = tris(diphenyloxophosphoronyl methanide), R = Ph, R′ = Me and R,R′ = Et. Some aqua cationic dimeric species of Ir^V have been proposed in solution, but they have not been isolated.[2d]

No compounds with Ir=O groups have been previously characterized.

RESULTS AND DISCUSSION

From the reaction of $Ir(mes)_3$ and Me_3NO in diethylether, a quantitative reaction, small greenish-black air-stable crystals of $Ir(O)(mes)_3$ (**1**) can be obtained with some difficulty. The structure as determined by X-ray diffraction is shown in Fig. 1; selected bond lengths and angles are given in Table 1.

The molecular geometry is distorted tetrahedral. The O—Ir—C and C—Ir—C angles each show a considerable spread of *ca* 15° and this feature is probably due to steric interactions linked to the fitting of the bulky aryl groups into the coordination sphere. In addition, for each of the rings the aryl ring coordination is tilted, with Ir—C—C_α angles of 128 and 113; 127 and 117; 122 and 120(1)° for rings 1, 2 and 3, respectively. This feature is commonly found in the *o*-tolyl, 2,6-xylyl and mesityl derivatives previously studied.[1,3] The orientations of the rings relative to the Ir=O bond also vary, with angles between the lines of this bond and the perpendiculars to the ring planes of 40.7, 25.6 and 80.8° for rings 1, 2 and 3, respectively.

The Ir—C distances of 1.99–2.03(1) Å are to be compared with those found in the neutral tetra-

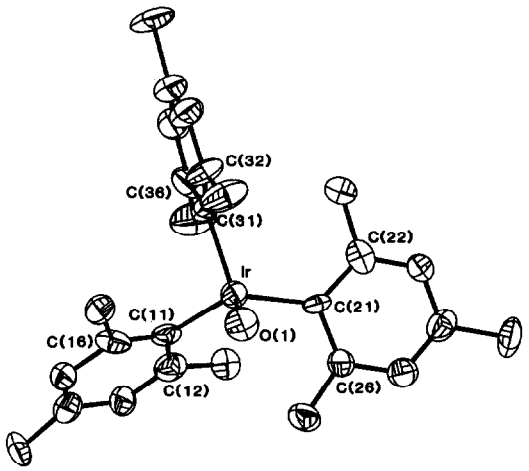

Fig. 1. The structure of oxotrimesityliridium(V).

hedral $Ir(mes)_4$ molecule, 1.99–2.04(1) Å, and the cation $[Ir^V(mes)_4]^+$, 2.00–2.04(1) Å. The Ir=O distance of 1.725(9) Å is significantly longer than Re=O distances[4] in the Re^{VI} complexes $(mes)_2ReO_2$ [Re=O = 1.688(5) Å] and $(mes)_4Re{=}O$ [1.646, 1.679(8) Å], where the Re—C distances [2.062(6) and 2.089(8)–2.194(8) Å] are somewhat longer than the Ir—C distances here, indicating a relative weakening of the Ir=O double bond. This weakening is reflected in the loss of the oxygen atom in the FAB mass spectrum, where only $Ir(mes)_3$ was observed.

The spectroscopic data for **1** are consistent with the solid-state structure. The ^1H NMR spectrum shows only mesityl group resonances, while the IR spectrum has a band at 802 cm^{-1} that can be assigned to Ir=O in addition to mesityl bands.

The compound is soluble in common solvents giving green solutions. Treatment of an Et_2O solution of **1** with aqueous sodium dithionite, $Na_2S_2O_4$, gives a clean reduction to $Ir(mes)_3$, which can be isolated from the ether layer and characterized by ^1H NMR. The compound does not react with CO_2 and from reactions with CO and with HCl in Et_2O no clean products could be isolated. Attempts to convert the Ir=O group to Ir=NR using isocyanates, RNCO, R = Ph, Bu^t, c-C_6H_{11} or $(Me_3Si)N_3$, gave only $Ir(mes)_3$ and decomposition products.

The rapid reaction of $Ir(mes)_3$ in d_6-benzene with dioxygen diluted with dinitrogen on injection via a syringe can be followed by ^1H NMR. The initial spectrum for $Ir(mes)_3$[1] changes (to br s at 2.27, 9H, Me; s, 6.51, 2 aromatic H) and there is clearly an intermediate, labile species which we have been unable to isolate or characterize; it is possibly an η^2-oxygen adduct. The final product has the spectrum of $Ir(O)(mes)_3$. The reaction is presumably of the type

$$Ir(mes)_3 \overset{O_2}{\rightleftharpoons} Ir^V(mes)_3(\eta^2\text{-}O_2) \xrightarrow{Ir(mes)_3} Ir^V(O)(mes)_3$$

involving cleavage of the O—O bond in the intermediate.

The reaction of $Ir(mes)_4$, which is air-stable both in the solid state and in solutions, and oxygen occurs only on heating to *ca* 60°C in toluene or hexane, and the green solution contains $Ir(O)(mes)_3$. When $Ir(mes)_4$ is heated at 60°C in d_8-toluene for 14 h in the absence of air $Ir(mes)_3$ and mesitylene-d_1 only are formed, the latter being detected in the solvent by GC/MS spectra: presumably this reaction involves a radical abstraction of deuterium from the solvent. The tetramesityl does not react with Me_3NO under similar conditions.

Although earlier attempts to obtain homoleptic species with other aryl groups were unsuccessful,[1] we have found that interaction of Li-2,6-dimethylphenyl in Et_2O with a partially dehydrated iridium chloride prepared by the action of $SOCl_2$ on "chloroiridic acid", $(H_3O)_2IrCl_6 \cdot 2H_2O$, using the work-up as for $Ir(mes)_4$,[1] gave $Ir(2,6\text{-xylyl})_4$ (**2**) as a brown solid in low yield (*ca* 6%). It is much less stable than $Ir(mes)_4$ decomposing even in the reaction mixture to give $Ir(2,6\text{-xylyl})_3$, which was characterized only by ^1H NMR; the latter was exceptionally sensitive to air giving $Ir(O)(2,6\text{-xylyl})_3$ identified by IR and NMR spectra. The *X*-band

EXPERIMENTAL

Analysis by Medac, Brunel University and Imperial College Laboratories. General methods and instrumentation are as previously described.[1] All reactions were performed under argon and solvents degassed and dried.

Oxo(trimesityl)iridium(V)

To a solution of Ir(mes)$_3$[1] (0.4 g, 0.07 mmol) in Et_2O (10 cm^3) was added dried Me_3NO (0.009 g, 0.12 mmol). The solution immediately turned bright green but stirring was continued for 12 h at room temperature. After filtration and removal of volatiles in vacuum the residue was extracted with petroleum (2×20 cm^3, 40–60°C) and the extracts reduced to *ca* 10 cm^3. After cooling at −20°C the yield of solid Ir(O)(mes)$_3$, m.p. 130–131°C, was essentially quantitative. Very small X-ray quality crystals were grown from petroleum. Found: C, 57.1; H, 6.0. Calc. for $C_{27}H_{33}IrO$: C, 57.3; H, 5.9%. ^{1}H NMR (C_6D_6, 270 MHz): δ 2.35 (s, 3H, *p*-Me); 2.52 (s, 6H, *o*-Me); 6.79 (s, 2H, aromatic-H).

2,6-*Dimethylphenyliridium compounds*

To Johnson Matthey "chloroiridic acid" (*ca* 1 g) was added thionyl chloride (20 cm^3) and the mixture refluxed under nitrogen (2 h) when the $SOCl_2$ was removed. The black residue (0.3 g) was stirred in Et_2O (15 cm^3) and a solution of 2,6-dimethylphenyl lithium (0.75 g in 15 cm^3 of Et_2O) added. After stirring (20 min) the Et_2O was removed and the residue extracted with petroleum (40–60°C, 2×15 cm^3). Reduction in volume (to *ca* 3 cm^3) and cooling (−20°C) yielded a brown crystalline solid (**2**) (0.04 g, 6.5% yield). We have been unable to obtain satisfactory analyses due to decomposition. In the presence of air the brown solutions become green over 2 h, but the oxo species is much less stable than **1**.

On attempting to prepare **2** from partially dehydrated $IrCl_3 \cdot nH_2O$ as for Ir(mes)$_4$[1] the brown solution was exceedingly sensitive to traces of air and on cooling gave a black powder that was unstable. The ^{1}H NMR spectrum (C_6D_6) taken rapidly corresponded to that of the intermediate found in the Ir(mes)$_3$ + O_2 reaction (δ 6.6, br.s, 3H, aromatic H; 2.2, s, 6H, *o*-Me), while the NMR of the final green solution corresponded to that of **1**. The final product isolated as a solid had an IR (Nujol mull) band at 803 cm^{-1} due to Ir=O, while the ^{1}H NMR spectrum was similar to that for **1**; in C_6D_6: δ 6.9 (d, $J = 7.3$ Hz, 1H aromatic *p*-H); 6.5 (t, $J = 7.3$ Hz, 2H aromatic, *m*-H); 2.4 (s, 6H *o*-Me).

X-ray crystallography

X-ray data were recorded on a FAST TV area detector diffractometer with Mo-K_α radiation ($\lambda = 0.71069$ Å) as previously described,[5] using a crystal of dimensions $0.2 \times 0.15 \times 0.1$ mm^3. The structure was solved via the heavy atom method and refined by full-matrix least-squares. The data were corrected for absorption using the DIFABS[6] method at the isotropic refinement stage. All non-hydrogen atoms were refined in the anisotropic approximation, whilst hydrogens were included in idealized positions and assigned group U_{iso} values. Crystal data and experimental details are as follows.

Formula: $C_{27}H_{33}OIr$, $M_r = 565.78$. Monoclinic, $a = 8.299(1)$, $b = 15.828(3)$, $c = 18.235(7)$ Å, $\beta = 101.21(3)°$, $V = 2349.6$ Å^3, space group $P2_1/a$, $Z = 4$, $D_c = 1.599$ g cm^{-3}, $F(000) = 1120$, μ(Mo-K_α) = 56.7 cm^{-1}. From the ranges scanned 11,805 data were recorded and merged to give 5747 unique ($R_{int} = 0.038$), 2531 observed [$F_o > 3(F_o)$]. $R = 0.039$, $Rw = 0.042$, 304 parameters. Tables of atomic coordinates, displacement factor coefficients, full lists of bond lengths and angles and F_o/F_c values have been deposited as supplementary material with the Editor. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

(*Received* 23 *March* 1993; *accepted* 22 *April* 1993)

Abstract—The compound $WCl_2(PMe_3)_4$ undergoes an oxidative-addition reaction with excess *o*-phenylenediamine (1,2-diaminobenzene) in refluxing toluene to give the tungsten(IV) imido complex *cis,mer*-W(*o*-$NC_6H_4NH_2$)$Cl_2(PMe_3)_3$ (**1**). A chloride substitution reaction of **1** with $NaBPh_4$ leads to the seven-coordinate tungsten(VI) complex {WCl[*o*-$(HN)_2C_6H_4]_2(PMe_3)_2$}(BPh_4) (**2**). Interaction of $MoOCl_2(PMePh_2)_3$ with excess *o*-phenylenediamine in the presence of base (Et_3N) gives the imido complex *mer,trans*-Mo(*o*-$NC_6H_4NH_2$)$Cl_3(PMePh_2)_2$ (**3**). X-ray structures of the compounds listed in the title have been determined. In **1** and **3** the pseudo-octahedral complexes contain unidentate near-linear imido groups, derived from the *o*-phenylenediamine ligand, whereas in complex **2** the geometry is distorted capped octahedral with chelating $(HN)_2C_6H_4$ groups.

In previous studies on *o*-phenylenediamine or its deprotonated compounds of Cr, Mo and W we have described the synthesis and X-ray crystal structures of a number of *o*-phenylenediamine compounds of chromium(II), (III) and (IV),[1] such as the tetra-triflate complex $Cr(O_3SCF_3)_4[(H_2N)_2C_6H_4]$, as well as the *o*-phenylenediamide complex $CrCl_2[(HN)_2C_6H_4](PMe_2Ph)_2$[2] and the binuclear tungsten complex $\{WCl_3[(HN)(H_2N)C_6H_4]\}_2[\mu$-1,2-$(N)_2C_6H_4]$,[3] in which the bridging ligand acts as a bis imido function.

We now describe the synthesis and characterization of the mono-imido complexes *cis,mer*-W(*o*-$NC_6H_4NH_2$)$Cl_2(PMe_3)_3$ and *mer,trans*-Mo(*o*-$NC_6H_4NH_2$)$Cl_3(PMePh_2)_2$. The only previous example[4] of a complex involving an imido group and "free" amino group derived from an *o*-phenylenediamine ligand is Mo(*o*-$NC_6H_4NH_2$)$Cl_2(S_2CNEt_2)_2$. The interesting seven-coordinate bis chelate {WCl[*o*-$(HN)_2C_6H_4]_2(PMe_3)_2$}(BPh_4) is also described.

RESULTS AND DISCUSSION

Tungsten complexes

Interaction of $WCl_2(PMe_3)_4$[5] with *o*-phenylenediamine in refluxing toluene yields large dark needles of *cis,mer*-W(*o*-$NC_6H_4NH_2$)$Cl_2(PMe_3)_3$ (**1**) in good yields (50–55%). Similar oxidative-addition reactions have been reported for the complexes $WCl_2(PR_3)_4$, PR_3 = $PMePh_2$, PMe_3, with hetero-cumulenes such as R′NCO, R′ = Bu^t, Ph,[6] and

† Authors to whom correspondence should be addressed.

the main group azides[7] (mesityl)$_2$B(N)$_3$ and (*o*-tolyl)$_3$Si(N$_3$). The IR spectrum of **1** has a strong ν(N—H) stretch at *ca* 3420 cm^{-1}, indicative of an uncoordinated NH$_2$ group,[8] together with a strong ν(C—N) stretch at *ca* 1279 cm^{-1}. In addition, the strong band at 1263 cm^{-1} can be attributed to the C—N stretch of a coordinated group. Confirmation of the unidentate nature of the ligand is provided by X-ray (see below) and NMR data. In the ^{1}H NMR spectrum the unsymmetrical nature of the bonding results in four distinct multiplets for the aromatic ring protons (see Experimental); a broad band at *ca* 4.9 ppm can be assigned to the NH$_2$ group, whilst the methyl signals of the PMe$_3$ ligands appear as a doublet [δ = 1.9, J(P—H) = 7.9 Hz, 9H] and a triplet [δ = 1.6, J(P—H) = 37 Hz, 18H]. In the ^{13}C NMR spectrum all six imido ligand carbon atoms appear at different chemical shifts (115.1–145.8 ppm). The ^{31}P NMR spectrum consists of two singlets, however, there is no phosphorus–phosphorus coupling between the two inequivalent phosphorus atoms; ^{183}W satellites are present.

Figure 1 depicts the *cis*-chlorine, *mer*-phosphine pseudo-octahedral geometry of one of the three crystallographically independent molecules of **1**. Selected bond lengths and angles for all three molecules are given in Table 1. An "inverse" *trans* influence is exerted by the near-linear (W$\widehat{\text{N}}$C = 177.2 Å) NC$_6$H$_4$NH$_2$ ligand in this complex. The *trans*-W—Cl bond distances are actually shorter than the W—Cl bond *cis* to the NC$_6$H$_4$NH$_2$ group in all three molecules. This effect, or at least the absence of a *trans* lengthening influence, seems to be common for tungsten(IV) species. Similarly no *trans* lengthening influence was reported for the phenylimido group in the related tungsten(IV) complex, W(NPh)Cl$_2$(PMe$_3$)$_3$.[9] There is also evidence of a *trans*-phosphine influence in **1**: the mutually *trans* phosphine distances (2.494 and 2.509 Å) are *ca* 0.04 Å longer than the remaining (*trans* to Cl) W—P distance (2.455 Å). Similar phosphine effects have been reported for the complex Mo(N-*p*-tol)Cl$_2$(PMe$_3$)$_3$[10] and may be ascribed to competitive π-back-bonding.

On the basis of the above X-ray data the compound previously reported[3] as WCl$_2$[1,2-(HN)$_2$C$_6$H$_4$](PMe$_3$)$_3$ is now best regarded as being compound **1** also.

Interaction of **1** with NaBPh$_4$ (2 equivalents) in refluxing MeCN (12 h) yields, after work-up, deep red prisms of {W[*o*(HN)$_2$C$_6$H$_4$]$_2$Cl(PMe$_3$)$_2$}BPh$_4$ (**2**). The IR spectra of **2** contains a sharp band at 3308 cm^{-1}, characteristic of the monoarylamide group.[11] There are no strong bands above 3300 cm^{-1} (uncoordinated NH$_2$). In the ^{1}H NMR spectrum a broad band at *ca* 11.7 ppm can be assigned to the NH protons;[12] the wide range of shifts observed for amido proton resonances, *ca* 2.2–16.8 ppm, has been noted.[12] The aromatic region is complex, whilst a triplet at *ca* 1.0 ppm can be assigned to PMe$_3$ resonances. The ^{31}P NMR spectrum contains

two major peaks [$\delta = -1.1$ and $+8.6$ ppm singlet with satellites J(P—W) = 109 Hz]. The crystal structure of **2** is shown in Fig. 2, with bond lengths and angles given in Table 2. Most interestingly, the unidentate $NC_6H_4NH_2$ imido ligand in **1** has been converted to the chelating diamido of **2**.

Hydrogen atoms were experimentally located, one on each of the *o*-pda nitrogens and so the complex is clearly identified as a tungsten(VI) species. The W—N distances of 2.008(7) to 2.068(7) Å are slightly longer than might be expected for a tungsten(VI)–amido link where N → W $p\pi$–$d\pi$ donation might be expected. However, only limited π-bonding will occur since the metal electron count via sigma interactions is already 14e and a total of only two π-interactions are required. The *ca* 0.05 Å spread in W—N distances may reflect this and the different environments of the nitrogens in the

unsymmetrical coordination sphere. There is, however, some evidence of delocalization of the nitrogen lone pairs into the aromatic ring system. In fact the geometry is difficult to define, partly as a result of the bite restrictions of the *o*-pda ligands, but might reasonably be described as a distorted capped octahedron with N(3) as the capping atom. An alternative description would identify P(1) and P(2) as axial ligands in a distorted pentagonal bipyramidal geometry with considerable equatorial puckering.

Molybdenum. Addition of excess *o*-phenylenediamine to $MoOCl_2(PMePh_2)_3$ gives the paramagnetic complex *mer,trans*-$Mo(o\text{-}NC_6H_4NH_2)Cl_3(PMePh_2)_2$ (**3**), which can be isolated as red–brown crystals in low yield.

The IR spectrum of **3** again contains a ν(N—H) stretch at *ca* 3407 cm^{-1}, indicative of an uncoordinated NH_2 group, together with bands in the ν(C—N) region consistent with the presence of a coordinated group.

The *X*-band EPR spectrum (toluene, 298 K) is sharp with $g_{iso} = 1.978$; super-hyperfine coupling is observed to two equivalent ^{31}P nuclei (*ca* 27 G) comparable to those observed for the complexes $M(N\text{-}p\text{-tol})Cl_3(PR_3)_2$, R = $EtPh_2$, Me and Ph.[13] However, the hyperfine coupling to $^{95,97}Mo$ for **3** (*ca* 44 G) is double that observed by Maatta *et al.*[13] (21.4–22.4 G), but is comparable with that observed for the reduction product of $Mo(NC_6H_4S)Cl(S_2CNEt_2)_2$ (40 G)[14] and the value of 38 G reported for $Mo(S_2CNEt_2)(NHC_6H_4S)_2$.[15] This may be a reflection of the greater contribution of the bent compared with linear bonding in the MNR group in **3**. There is no observable hyperfine isotropic splitting to nitrogen for **3**.

The molecular structure of **3** is shown in Fig. 3, and important bond lengths and angles are given in Table 3. The molecule possesses a *mer* arrangement of chlorines with the phosphine ligands occupying *trans* positions, presumably to minimize steric constraints ($PMePh_2$, cone angle = 136°); whereas in the complex $Mo(N\text{-}p\text{-tol})Cl_2(PMe_3)_3$[10] containing the less sterically demanding PMe_3 ligand (cone angle = 118°) a *cis, mer* geometry is adopted. The molecule lies on a two-fold rotation axis passing through Cl(2), Mo(1), N(1) and the attached $C_6H_4NH_2$ group is disordered. The near-linear imido ligand [Mo—N(1)—C(121) = 169.9(2)°] in **3** shows a *trans* influence with Mo—Cl(2), *ca* 0.1 Å, longer than Mo—Cl(1). This is similar to the situation in the related molybdenum(V) complex $Mo(N\text{-}p\text{-tol})Cl_3(EtPh_2P)_2$.[10]

EXPERIMENTAL

Microanalyses were performed by the University College, London, and Medac Ltd, Brunel University.

The spectrometers and general techniques have

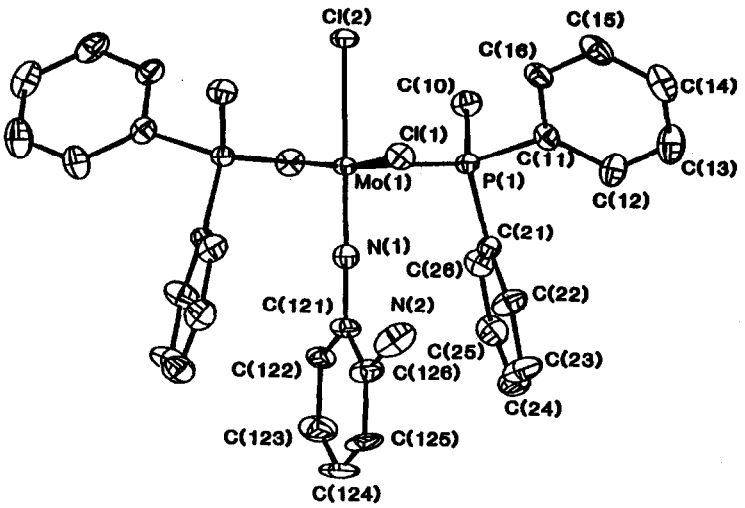

Fig. 3. The structure of *mer*-Cl, *trans*-$PMePh_2[Mo^{V}(o\text{-}NC_6H_4NH_2)Cl_3(PMePh_2)_2]$ (3).

been previously described.[16] The precursors $WCl_2(PMe_3)_4$[5] and $MoOCl_2(PPh_2Me)_3$[17] were prepared as described. Trimethylphosphine was prepared by the method of Wolfsberger and Schmidbaur.[18] Commercial chemicals are from Aldrich; $C_6H_4(NH_2)_2$-1,2 was recrystallized from toluene prior to use. All operations were performed under oxygen-free nitrogen or argon. NMR spectra: Bruker WM 250 Hz (^1H, ^{13}C and ^{31}P), δ in ppm referenced to Me_4Si, solvent and 85% H_3PO_4 (external), respectively. IR spectra as Nujol mulls (in cm^{-1}) and mass spectra by fast atom bombardment.

[(2 - *Aminophenyl*)*imido*]*dichlorotris*(*trimethylphosphine*)*tungsten*(IV) (1)

To $WCl_2(PMe_3)_4$ (1.0 g, 1.79 mmol) in toluene (*ca* 40 cm^3) was added 1,2-$C_6H_4(NH_2)_2$ (0.39 g, 3.6 mmol). The solution was refluxed for 12 h then filtered (hot) and allowed to stand at room temperature when large black needles formed. Yield: 50–55%; m.p. 254–258°C. Found: C, 30.9; H, 5.3; N, 4.8; Cl, 13.6. Calc. for $WC_{15}H_{33}Cl_2N_2P_3$: C, 30.6; H, 5.6; N, 4.8; Cl, 12.0%. Mass spectrum: *m/z* 589(M), 553(M − Cl), 513(M − PMe_3), 437(M − 2PMe_3). IR: 3420s, 3312s, 3205w, 2727w,

Crystallographic studies

X-ray diffraction data were recorded for the three compounds using a FAST TV area detector diffractometer and graphite monochromated Mo-K_α radiation following previously described procedures.[19] Crystals for compounds **2** and **3**, coated with silicone oil, were mounted on the end of glass fibres and the data collected at 150 K, using a CRYOSTREAM cooling device. Data for compound **1** were recorded at room temperature using a capillary mounted crystal. The structures were solved and developed via the heavy atom method and refined by full-matrix least-squares. During the refinement process the data for each structure were corrected for absorption using the DIFFAST program.[20] Crystal data and details of the data collection and structure refinement are given in Table 4.

CHELATE COMPLEXES OF 1,3-BIS-(1′-PHENYL-3′-METHYL-5′-PYRAZOLONE-4′)-1,3-PROPANEDIONE AND 1,10-PHENANTHROLINE WITH LANTHANIDE

XIAOJING LI, LAN YAN,* HUI WANYAN and RUDONG YANG

Department of Chemistry, Lanzhou University, Lanzhou 730000, P.R.C.

(*Received* 30 *September* 1992; *accepted* 22 *April* 1993)

Abstract—A new ligand, 1,3-bis-(1′-phenyl-3′-methyl-5′-pyrazolone-4′)-1,3-propanedione (H_2L), and its chelated complexes, $Ln_2L_3(Phen)_2 \cdot nH_2O$ (where Phen = 1,10-phenanthroline, Ln = lanthanide and Y, n = 3–6), have been prepared by the reaction of H_2L and Phen with the relative metal nitrate in an aqueous alcoholic solution. The binuclear structure of the complexes is proposed according to the discussions of the elemental analyses, molar conductance, IR and ^1H NMR spectra. Fluorescence spectra prove Pr, Sm, Eu, Tb, Dy and Tm complexes have line emissions of metal ions.

4-Acyl-pyrazolones are thought of as ideal chelating agents and their complexes are also of interest to investigate the interaction between metal ions and complexing agents, catalytic activity and NMR shift reagents.[1–3] However, 4-acyl-bis-pyrazolones with four oxygen donors are also potential chelating agents for metal ions and are superior in extraction than monopyrazolone.[4] They are also able to form mononuclear, polynuclear or heteronuclear complexes with ions under differing conditions. These complexes, especially with some of the lanthanides, exhibit excellent fluorescence, which provides an opportunity to study their application in analysis of optical materials. Recently some 4-acyl-bis-pyrazolines and their complexes with lanthanide ions have been investigated,[5–9] but much less work has been performed with the new 4-acyl-bis-pyrazolone-1,3-bis-(1′-phenyl-3′-methyl-5′-pyrazolone-4′)-1,3-propanedione (noted H_2L) and its complexes. In this paper the preparation and various interesting properties of novel mixed-ligand complexes of lanthanide ions with H_2L and 1,10-phenanthroline (noted Phen) are reported.

EXPERIMENTAL

Physical measurements and analyses

The metal content of the reported complexes was obtained by the literature method.[9] Microanalyses for carbon, hydrogen and nitrogen contents were determined using a 1106 elemental analyser. The analytical data for the complexes are given in Table 1. Electrolytic conductance measurements were obtained with a DDS-11A molar conductometer. IR spectra were recorded on an FT-170SX IR spectrophotometer as KBr discs in the 4000–200 cm^{-1} region. ^1H NMR spectra in dimethyl sulphoxide-d_6 were measured with an FT-80A 80 MHz spectrometer; the chemical shifts are reported in ppm downfield from TMS. The UV and fluorescence spectra were obtained using a UV-730 spectrophotometer and a Hitachi-850 fluorescence spectrophotometer, respectively. Thermogravimetric and differential thermal analyses were performed in air at a heating rate of 10°C min^{-1}, using a PCT-2 precision thermobalance analyser.

Materials

Lanthanide nitrate solutions were obtained from the respective metal oxides and HNO_3. Propanedionyl chloride was the chemical reagent. 1-Phenyl-3-methyl-5-pyrazolone, Phen and other chemicals were analytical reagents.

Synthesis of 1,3-*bis*-(1′-*phenyl*-3′-*methyl*-5′-*pyrazolone*-4′)-1,3-*propanedione*

1-Phenyl-3-methyl-5-pyrazolone (21 g) was dissolved in dioxane (40 cm^3) at 75–80°C and calcium hydroxide (10 g) and propanedionyl chloride (5.5

[b] Calculated values in parentheses.

g) were added dropwise within 1 min with rapid stirring. The reaction mixture became a thick paste. After stirring for 5 min the mixture was heated to reflux for 1 h and was decomposed by pouring into dilute hydrochloric acid (200 cm^3, 2 N), which caused brown–yellow coloured crystals to separate. The crystals were collected on a Buchner funnel, washed with distilled water until the washing was neutral, recrystallized from chloroform–petroleum ether (3:2) and dried *in vacuo*. Yield: 4.2 g (35.5%); m.p. 200–201°C. Found: C, 66.1; H, 4.8; N, 13.5. Calc. for $C_{23}H_{20}N_4O_4$: C, 66.3; H, 4.8; N, 13.5%.

Preparation of complex compounds

A solution of H_2L (0.25 g, 0.6 mmol), which was dissolved in 95% alcohol (35 cm^3) by adding NaOH solution (1.2 mmol), was mixed together with Phen · H_2O · ethanol (0.06 g, 0.3 mmol) solution and stirring for a few minutes. Lanthanide nitrate (0.35 mmol) aqueous solution was added dropwise to the above solution and a precipitate appeared gradually. After stirring and refluxing the mixture for 3 h the precipitate was centrifugally separated, washed thoroughly with dilute aqueous HNO_3 solution (pH = 3–4), distilled water and warm chloroform until the washing did not contain Ln^{3+} or NO_3^- and was neutral, and dried *in vacuo*. All the compounds were obtained in high yield: 75–85%.

RESULTS AND DISCUSSION

According to the elemental analyses of the complexes their composition agrees with the general formula $Ln_2L_3(Phen)_2 \cdot nH_2O$ (Ln = Y, $n = 6$; Ln–La, $n = 3$; Ln = Pr, Nd, Sm, Eu, Gd, Tb, Dy, Ho, Er, Tm and Yb, $n = 4$). All the complexes are yellowish–brown. They are soluble in dimethylsulphoxide and chloroform, slightly soluble in ethanol and methanol and insoluble in water and petroleum ether.

The molar conductance values of the complexes (see Table 1) in dimethylsulphoxide lie in the range 8–15 Ω^{-1} cm^2 mol^{-1}. This indicates that in the DMSO solvent complexes are non-ionic in nature.[10]

IR spectra

The ligand H_2L contains a large number of bands in the region 3400–200 cm^{-1}, which rendered frequency assignment somewhat difficult. It is possible, however, to obtain some useful information regarding the metal–ligand bonding. For example, the IR spectra of the enolic form of H_2L shows a broad band at 2600 cm^{-1}, which is evidently due to hydrogen bonded OH, and this band disappears after chelation. The reason is that the intramolecular hydrogen bond is broken after chelating with lanthanide ions. The H_2L band at 1612 cm^{-1} is shifted to lower frequency, 1064 cm^{-1}, in the metal chelates and thus can be related to the C=O stretching. On the other hand, the bands at 2954–2915 and 1597 cm^{-1} in H_2L remain unaltered in the chelates and are, therefore, due to methyl-methylene and phenyl ring stretching. Similarly, another unaffected band at 1574 cm^{-1} appears to be due to C=C/C=N stretching. The H_2L band at 1551 cm^{-1}, which is displaced to 1535 cm^{-1}, and the strength of the vibration which decreases in the chelates provide major contributions to C=O stretching. The 1642 cm^{-1} band due to the stretching vibration of C=N of free Phen is absent in these chelates, whereas a new band is observed at 1623 cm^{-1}. The out-of-plane band frequencies [δ(C—H)] range from 855 and 737 cm^{-1} in Phen to 845 and 731 cm^{-1} in the complexes. All these facts can be taken as evidence of Phen being bonded to the lanthanide ions. The broad band in the chelates observed at 3400–3380 cm^{-1} is due to the water molecules. Low-frequency IR spectroscopy has been used to examine metal–ligand bonds. In the far-IR region new bands appear at 410–420 and 270–285 cm^{-1}, which we infer are due to metal–ligand vibrations. As the metal–nitrogen bond is expected to be weaker than the metal–oxygen bond the 270–285 cm^{-1} bands are assigned to γ(Ln—N) and the bands at 410–420 cm^{-1} to γ(Ln—O). Indeed, the literature[11,12] also refers to Ln—N and Ln—O stretching vibrations appearing at 270–316 and 400–420 cm^{-1}, respectively.

UV spectra

The UV data of the compound dissolved in chloroform are listed in Table 2. It can be seen that the UV spectra of all the complexes are similar, but they are different from those of the ligands. The intense absorption bands of the complexes at 236–243 and 269–272 nm are ascribed to the *B* band ($\pi \rightarrow \pi^*$ transition) of the benzene and phenanthrene ring.[13] These absorption maxima remain either unchanged or suffer slight shifts compared with the ligands. However, the molar extinction coefficients measured at identical wavelengths show significant differences. The band at 375 nm in H_2L is also attributed to the *K* band ($\pi \rightarrow \pi^*$ transition), but in the complexes a bathochromic shift of *ca* 45 nm is observed. It is possible that the *f*-orbital of

the metal atom and the *p*-orbital of H_2L overlap each other to form a greater conjugated system after enolizing and complexing.

^{1}H *NMR spectra*

The ^{1}H NMR spectra of the ligands and some complexes have been investigated using $(CD_3)_2SO$ as a solvent (see Table 3). The proton signals of the free ligand Phen are observed as multiplets at *ca* 7.98–9.12 ppm (8H). The benzene ring proton signals of the ligand H_2L are found as multiplets at *ca* 7.40–7.88 ppm (10H) and methyl and methylene proton signals as singlets at 2.54 (6H) and 4.05 ppm (2H), respectively. The enol proton signal is not observed. The ^{1}H NMR spectra of diamagnetic Y^{3+} and La^{3+} complexes undergo large shifts and changes in comparison with the spectra of the ligands. Almost all the protons show upfield shifts. The proton signals of Phen in the chelate which has also shifted upfield appears at 7.82–9.15 ppm (16H). This indicates that the deshielding effect of electron density in the phenanthrene ring decreases after complexation of the nitrogen atoms in Phen with the Ln^{3+} ion. The complex shows more signals in the region of 7.18–7.80 ppm (30H), which can be assigned to the phenyl protons. Water proton signals are present at 3.41 ppm (12H), which may be exchanged by D_2O. The methylene proton signals have shifted from 4.05 to 3.80 ppm (6H). In addition there are two distinctly different sets of methyl resonances, one set at *ca* 2.23 ppm (6H) and another at *ca* 2.08–1.95 ppm (12H), with a ratio of *ca* 1:2 which indicates that the structures of the complexes have non-equivalent ligands.

In the paramagnetic complexes the proton signals of the Pr^{3+} complex become much weaker and broader. The methyl and methylidyne signals have disappeared and the proton signals of the benzene and phenanthrene ring become a broad multiplet appearing at 6.20–9.20 ppm. The broadening may be ascribed to spin–spin relaxation processes.[14,15] With the Gd^{3+} complex no signal is observed due to extensive broadening of the signals, since Gd^{3+} has the maximum number of unpaired electrons and is, therefore, strongly paramagnetic.

Fluorescenes

Although many lanthanide chelates of β-diketonates fluoresce, the phenomenon of emission line fluorescence, that many lanthanide ions in the same chelate series exhibit, can be seen only in the lanthanide chelates of 4-acyl-bispyrazolone. In our ligands and complexes the fluorescence and assignments are as follows: —Phen, 361,179 nm (line emission ex. = 320 nm); H_2L, Nd, Gd, Ho and Er, 480 nm (band emission ex. = 360 nm). Pr, 604 $^3P_0 \rightarrow {}^3H_6$ (ex. = 359 nm); Sm, 566 $^4G_{5/2} \rightarrow {}^6H_{5/2}$; 646 $^4G_{5/2} \rightarrow {}^6H_{9/2}$; 714 $^4G_{5/2} \rightarrow {}^6H_{11/2}$ (ex. = 370 nm). Eu, 590 $^5D_0 \rightarrow {}^7F_1$; 612 $^5D_0 \rightarrow {}^7F_2$ (ex. = 363 nm). Tb, 490 $^5D_4 \rightarrow {}^7F_6$; 545 $^5D_4 \rightarrow {}^7F_5$; 586 $^5D_4 \rightarrow {}^7F_4$; 622 $^5D_4 \rightarrow {}^7F_3$ (ex. = 354 nm). Dy, 481 $^4F_{9/2} \rightarrow {}^6H_{15/2}$; 575 $^4F_{9/2} \rightarrow {}^6H_{13/2}$ (ex. = 365 nm). Tm, 478 $^1D_2 \rightarrow {}^3H_4$ (ex. = 360 nm). These luminescence phenomena of the lanthanide complexes have been discussed in the literature.[16] In addition terbium and samarium complexes in the solid state have no fluorescence when they are irradiated with UV light (λ = 254 nm), but in DMSO exhibited excellent green and red fluorescence, respectively.

Thermal analysis

In order to investigate the behaviour of the heated compounds we measured the TG–DTA

Table 4. The values of thermal peaks and total weight loss of the complexes

$Yb_2L_3(Phen)_2 \cdot 4H_2O$	101	354	389	509	569	80.6 (80.5)

[a] Calculated values in parentheses.
[b] The products of decomposition for Pr and Tb complexes are Pr_3O_{11} and Tb_4O_7, respectively.

curves of the ligands and the complexes and found: H_2L begins to melt and decompose at 200°C and continuously decomposes at 245, 342, 430 and 597°C; Phen·H_2O loses water at 104°C and then melts at 123°C, until finally it decomposes in the temperature range 217–318°C.

The TG and DTA measurements of the complexes show that all of the complexes exhibit similar thermal analysis diagrams. They have a small endothermal peak on the DTA curve and on the TG curve have a weight-loss equal to the weight of the water molecules in the complexes. These types of complexes have no melting point, and thus after losing water molecules the compounds begin to decompose. There are mainly four exothermal peaks which appear successively on the DTA curve and obvious weight loss occurs on the TG curve between 300 and 750°C. The endothermal and exothermal peak temperatures of the complexes are summarized in Table 4.

It can be seen from Table 4 that the total weight loss of the complexes is nearly equal to that calculated and the complexes are more thermostable than the ligands.

CONCLUSIONS

Summarizing the above analysis we propose a binuclear structure for these complexes in which each of two Ln^{3+} ions combines with two complexing nitrogen atoms in each Phen and three H_2L as tetradentate ligands in the enolic form chelating two Ln^{3+} ions.

(*Received* 18 *December* 1992; *accepted* 20 *April* 1993)

Abstract—Complex formation between the copper(II) ion and ephedrine and norephedrine has been studied potentiometrically and spectrophotometrically. A spectral–structural correlation has been investigated for the complexes. Copper ephedrine and norephedrine complexes possessed a geometry which varied from octahedral to tetragonal to square planer depending on the experimental conditions. Semi-empirical MO calculations were performed on a model "copper–ephedrine complex" with different geometries, with satisfactory results.

Ephedrine and norephedrine are sympathomimetic agents with direct and indirect effects on adrenergic receptors.[1] They possess adrenergic activity and pronounced stimulating effects on the central nervous system.

Transition metal complexes of ephedrine are used as antiallergic drugs. The free energy of formation of such complexes has been related to their medical activity. Copper(II) ephedrine complexes are important, interesting and have drawn much attention. These complexes have some peculiar properties: they are readily soluble in non-polar solvents and react at room temperature with halogenated hydrocarbons.

Different complexes of copper(II) and some ephedrines were prepared and their crystal structure has been studied. Deep violet crystals were obtained from benzene with the structure $(C_{10}H_{14}ON)_2Cu \cdot \frac{2}{3}C_6H_6$,[2] whereas crystallization from cyclohexane led to crystals which have the composition $(C_{10}H_{14}ON)_2Cu \cdot \frac{1}{3}C_6H_{12}$.[3] The crystals from hexane have the composition $(C_{10}H_{14}ON)_2Cu \cdot \frac{1}{6}C_6H_{14}$.

The structure of the copper(II) norephedrine complex, $(C_9H_{12}NO)_2Cu \cdot 3H_2O$, was determined by X-ray diffraction.[4] The crystals were monoclinic where the two norephedrine groups were *trans* and coordinated through their nitrogen and oxygen atoms. The coordination was square pyramidal.

Ephedrine hydrochloride was obtained from the copper complex in alkaline medium[5] and by forming metal diaralkyldithiocarbamate with carbon disulphide and ammoniacal copper(II) and nickel (II) solutions.

Ephedrine and amine complexes of copper(II) combine reversibly with carbon dioxide and yield singly- and multiply-charged copper carbamate complexes.[6] The formation of unstable carbamate complexes was confirmed by EPR studies.[7]

The acid dissociation constant as well as the thermodynamic functions of dissociation were determined for ephedrinium ions by thermometric titration[8] and potentiometry.[9] A value of 9.014 was obtained for the pK_a of norephedrine in aqueous media at 25°C.

In this work the process of complex formation between copper(II) ephedrine and norephedrine was studied potentiometrically and spectrophotometrically and spectral/structural correlations were investigated. The variation of the spectrum with the proposed geometry is discussed. Molecular orbital

calculations have been performed on octahedral, tetragonal and square-planar copper(II) ephedrine complexes. The results showed the variation of *d*-orbital splitting as a function of the geometry of the complex.

EXPERIMENTAL

All materials used were of BDH analar grade. L-ephedrine and D-norephedrine hydrochloride were supplied by Alderich Gillingham, Dorset, U.K. The free base of D-norephedrine was obtained by extracting from alkaline solution (5% ammonium hydroxide).

Preparation of complexes

Copper(II) ephedrine and norephedrine complexes were prepared by adding an aqueous solution of copper sulphate to an aqueous solution of ephedrine or norephedrine hydrochloride, respectively, followed by the dropwise addition of dilute sodium hydroxide solution until a blue violet colouration or precipitate was obtained. The copper(II) ephedrine complex was extracted by benzene, hexane or cyclohexane. Elemental analysis gave the following results: Found: C, 63.3; H, 7.1; N, 6.7; Cu, 13.5. Calc. for $(C_{10}H_{14}ON)_2Cu \cdot \frac{2}{3}C_6H_6$: C, 64.9; H, 7.2; N, 6.3; Cu, 14.3%. Crystals from hexane accounted for the formula $(C_{10}H_{14}ON)_2Cu \cdot \frac{1}{6}C_6H_{14}$. The deep blue–violet precipitate of the copper norephedrine complex was crystallized from methanol. Elemental analysis gave: Found: C, 52.5; N, 6.8; H, 6.9; Cu, 16.5. Calc. for $(C_6H_{12}ON)_2Cu \cdot 3H_2O$: C, 52.2; N, 6.7; H, 7.2; Cu, 15.3%.

Apparatus

pH titration and pH measurements were performed using an Orion 920 digital pH meter and the spectra were scanned on a Perkin–Elmer Lambda 4B spectrophotometer.

RESULTS AND DISCUSSION

1. *Complex formation*

1.1. *Formation constant.* The process of complex formation between copper(II) and ephedrine and norephedrine was studied using pH titration procedures.[10] The pK_a values for the protonated ligand, for the equilibrium:

$$HL^+ \rightleftharpoons H^+ + L,$$

were 8.74 ± 0.21 for norephedrine and 9.18 ± 0.14 for ephedrine. These results compare satisfactorily with values reported in the literature. At 37°C the

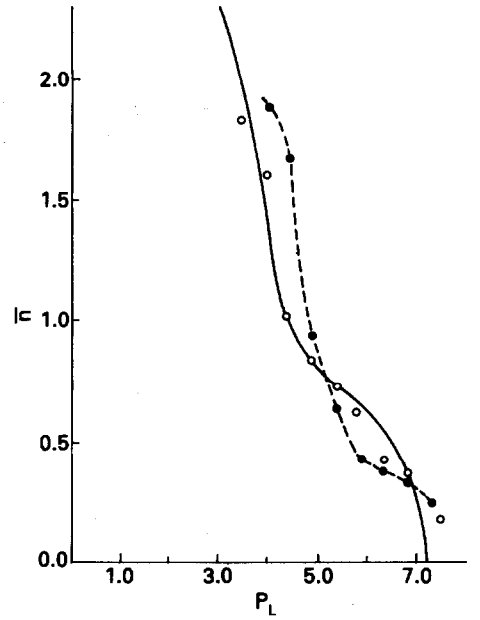

Fig. 1. The formation curves of copper(II) ephedrine (---) and copper(II) norephedrine (O--O) systems.

pK_a value for the ephedrinium ion is *ca* 9.2,[11] whereas that for the norephedrenium ion in aqueous solution is *ca* 9.014[9] at zero ionic strength.

Figure 1 shows the formation curves of copper complexes with ephedrine and norephedrine. Preliminary values of log K_1 and log K_2 for the formation of 1:1 and 1:2 copper complexes were obtained from Fig. 1. Accurate values were obtained from the relations

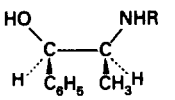
$$\log K_1 = \log \frac{n}{(1-n)[L]_n} \quad (1)$$

$$\log K_2 = \log \frac{(n-1)}{(2-n)[L]_n}, \quad (2)$$

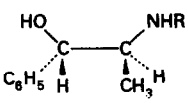
where $1 > n > 0$ in eq. (1) and $2 > n > 1$ in eq. (2). For copper norephedrine complexes log K_1 and log K_2 were 6.39 ± 0.10 and 3.88 ± 0.90, respectively. For copper ephedrine complexes log K_1 and log K_2 were 5.64 ± 0.15 and 4.59 ± 0.05, respectively.

1.2. *Spectral–structural correlation.*

1.2.1. Copper(II) ephedrine system. The optically active alkaloids, ephedrines, occur naturally in the form of different isomers, namely, (−)-ephedrine(I), (−)-norephedrine(II), (+)-pseudo-ephedrine(III) and (+)-pseudo-nonrephedrine(IV) whose absolute configurations are:

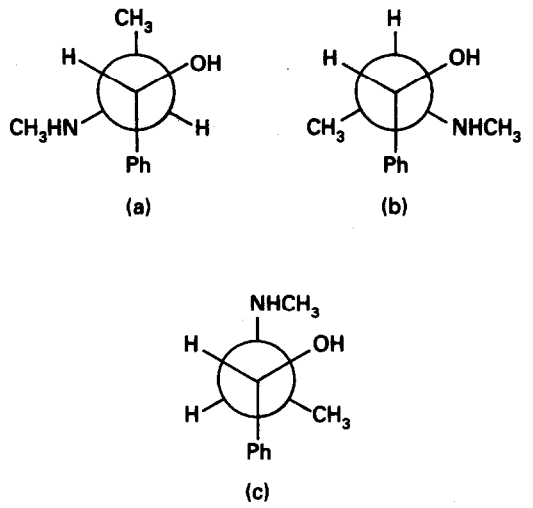


I. R = CH_3; (—) -ephedrine
II. R = H; (—) -norephedrine



III. R = CH_3; (+) -ψ-ephedrine
IV. R = H; (+) -ψ-norephedrine

For an isolated molecule ephedrine has three possible conformations:



Conformation (a) has been proposed for free ephedrine,[12] whereas conformation (c) is found in the crystal structure of copper(II) ephedrine complex.[2]

The reaction between copper(II) and ephedrine is sensitive to the reaction medium. It was easier to prepare the neutral bis-copper(II) complexes of (+)-Hψ ephedrine than the corresponding complexes of (+)-H ephedrine.[13] Amano *et al.*[2] could identify three different copper(II) ephedrine complexes: pale violet–blue crystals, bis((−)-eph)diaquocopper(II), reddish–violet plates, bis((−)-eph)copper(II), and the violet hexagons which were shown by crystal structure to consist of trimeric units of the bis complex by intermolecular hydrogen bonding. The absorption spectra of a crystal of the latter complex and its solution in hexane were identical, which suggests that the trimer nature is retained in solution.

Gillard and Wootton[14] prepared copper(II) ephedrine which was extracted from aqueous medium by petroleum ether. The absorption spectra of the solution of the complex were solvent dependent and did not obey Beer's law. The spectra show two bands around 500–600 nm, the first band was assigned to the *d–d* transition in non-polar solvents. The monomer is considered to dominate in polar solvents, particularly water and the band around 500 nm became weaker. An equilibrium was assumed to exist between the monomer and the trimer.

The diastereoisomeric complex of ephedrine with copper(II) was precipitated in two forms, bis[(+)-ψ-eph]Cu^{II} and the tris form Cu[(+)-ψ-eph]$_2$(+)-Hψ-eph·$2H_2O$, which had identical reflectance spectra,[14] indicating that the third ψ-ephedrine molecule is not involved in coordination. Crystal structure determination establishes this formulation.[15]

Figure 2 shows the absorption spectra of copper(II) ephedrine solutions at a total constant concentration of 2.5×10^{-2} M, with pH ranging from

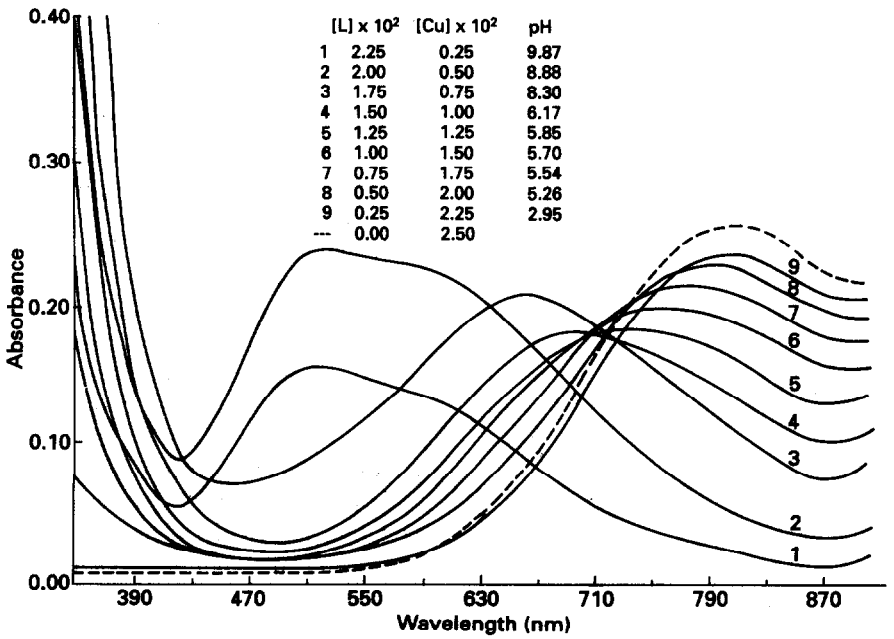


Fig. 2. Absorption spectra of copper(II) ephedrine solutions with a constant total concentration of 2.5×10^2 M.

2.95 to 9.87. The distribution curves for the formation of the different complexes are given in Fig. 3. The 1 : 1 copper(II) ephedrine complex starts to be formed at pH = 5.0 and is predominant in the pH range 5.3–7.5. The 1:2 complex biaquobisephedrinocopper(II) starts to be formed at pH = 7.5 and predominates at pH higher than 8.0. In the pH range 2.95–5.54 there is no indication of complex formation, Fig. 2, whereas in the pH range 5.7–8.30 the spectra of copper(II) ephedrine solutions show a broad band characteristic of tetragonal copper(II) complexes. The broad band has a maximum which ranges from 750–720 to 690–660 nm, depending on the pH of the solution. As the pH increases to 8.88 and 9.78 the spectra differ basically from those at lower pH. It is suggested that only the 1 : 1 Cu : ephedrine complex is formed in the pH range 5.7–8.30 as predicted by the distribution curve, Fig. 2, whereas the 1:2 copper: ephedrine complex is formed at higher pH. Both complexes are tetragonal. In the former complex four water molecules are in the inner coordination sphere, whereas in the latter two, water molecules are in the inner coordination sphere and are along the *z*-axis.

The variation of band maximum with the increase in the pH of the solution, which is attained by the increase in [eph], is due to the distortion of the geometry of the formed complex. Distortion is of the "*z*-out" type and in the limit when the two water molecules along the *z*-axis are removed a square-planar bisephedrinocopper(II) complex is formed. When one applied Job's[16] method to the results of Fig. 2 using the absorbance at $\lambda = 520$, 660 and 740 nm the existence of 1:1 and 1:2 copper(II) ephedrine complexes was evident.

The results of X-ray crystal analysis confirmed

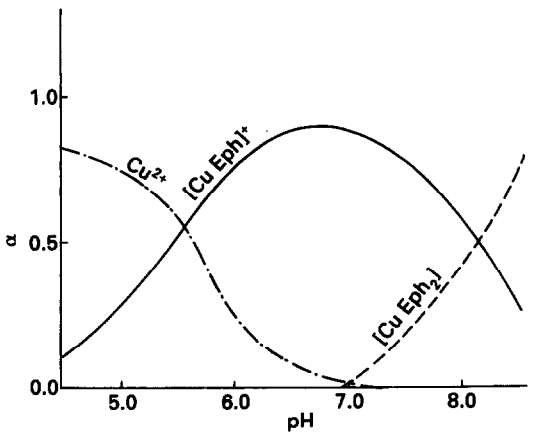

Fig. 3. Distribution curves for the copper(II) ephedrine complex.

that the hydrogen atom of the alcoholic hydroxyl group of the ephedrine molecule was replaced by the copper ion in chelate formation and that the chelate ring was built up by a four-coordinated square planar configuration.[2] No atoms were detected between the copper atoms in the adjacent unit cells in the direction perpendicular to the plane of the square. Based on the Jahn–Teller effect, most of the copper complexes have distorted octahedral configuration. The configuration of ephedrine copper chelate is considered as a limiting case of the usual distorted octahedral configuration with two ligands completely removed.

Figure 4 shows the absorption spectra of copper (II) ephedrine solutions where the ratio of $[Cu^{2+}]$:[eph] varies from 1 : 1 to 1 : 10 and the pH ranges from 6.27 to 10.08. It is clear that each solution has its own spectrum. Up to pH 8.70 the ratio $[LH^+]/[L]$ is of the order of 10, which means that the predominant complex is monoephedrinotetraaquocopper(II). The difference in the spectra for different solutions, Fig. 4, is attributed to different degrees of distortion from octahedral to tetragonal geometry. In a tetragonal field both ^2E_g and $^2T_{2g}$ states split and the single transition in the octahedral geometry splits into three transitions, ν_1 ($^2A_{1g} \leftarrow {}^2B_{1g}$), ν_2 [$^2B_{2g}(T) \leftarrow {}^2B_{1g}(E)$] and ν_3 ($^2E_g \leftarrow {}^2B_{1g}$). This splitting is quite evident on investigating the spectra in Fig. 4. The broad band, for example, in solution 3, is easily resolved to three overlapping bands which are assigned to $^3A_{1g} \leftarrow {}^2B_{1g}$ at 12,820 cm^{-1} (ν_3), $^2B_{2g} \leftarrow {}^2B_{2g}$ at 15,625 cm^{-1} (ν_2) and $^2E_{1g} \leftarrow {}^2B_{1g}$ at 18,518 cm^{-1} (ν_1). The calculation of the physical parameters Δ_0, δ and ρ gives 11,145, 1930 and 6410 cm^{-1}, respectively. The splitting of the ground state (2ρ = 12,820 cm^{-1}) is much larger than that of the excited $^2T_{2g}$ state ($\frac{3}{2}\delta$ = 2893 cm^{-1}). The appearance of three electronic transitions in the 400–800 nm region is quite apparent and there is a gradual blue shift of band maximum and ν_2 overlaps ν_1, which is an indication of the transformation from octahedral to square planar geometry. The spectrum of the aqueous solution of the prepared copper ephedrine complex is very much similar to that of aqueous solution prepared by mixing Cu^{2+} and ephedrine in the ratio 1 : 5 or 1 : 10. The prepared complex proved (elemental analysis) to be the bisephedrinocopper(II) complex.

Conformational effects on the stability of the chelate ring have been reviewed. The chelate ring in the bisephedrine copper(II) complex is subjected to different conformational effects which determine its stability.[17,18] The chelate ring is puckered to minimize the steric repulsions. A number of confomers have been suggested for bisephedrinocopper(II),

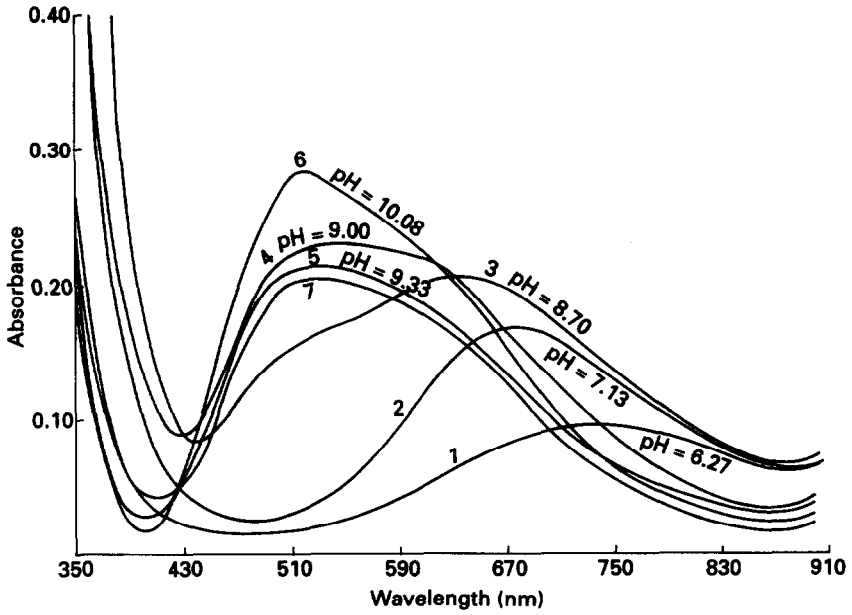

Fig. 4. Absorption spectra of copper(II) ephedrine solutions of varying [Cu^{II}]:[eph] ratios, 1 (1:1), 2 (1:2), 3 (1:3), 4 (1:4), 5 (1:5), 6 (1:10), 7 (free copper).

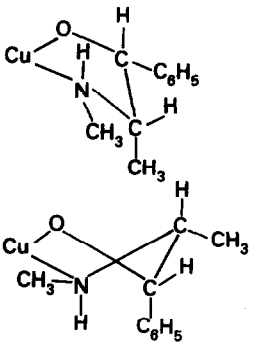
the most stable of which are:



Each of the above conformers has an isomer whereby the substituents, H and $-CH_3$, on the totally asymmetric nitrogen atom exchange positions. Copper(II) complexes with ephedrine and ψ-ephedrine are optically active.[19,20] In a square copper(II) complex the copper atom is not asymmetric and the optical activity in the band of the *d–d* transitions[21] of the metal has been interpreted to result from the vicinal effect of an asymmetric atom in the ligand. The vicinal interaction on the visible optical rotatory dispersion, as measured by the Cotton effect amplitudes, was found to be very sensitive to the substituent in a number of amino acid copper (II) complexes. A large mixing of *d–d* transitions with charge transfer transition from ligand-to-metal or metal-to-ligand has been suggested to lead to the optical activity of these complexes.[21]

The CD spectra of copper(II) complexes with ephedrine and pseudoephedrine, in benzene solution, were almost enantiomeric.[14] The most stable conformations of the ligand describe opposite helicities about the copper atom. The (+)-Hψ-eph complex retains the same signs of Cotton effects in going from non-polar to polar solvents, whereas the Cotton effects of the (−)-H eph complex apparently change sign under the same circumstances; in water the two complexes have almost the same CD spectrum. This was attributed to the ligand having a different conformation when the complex is dissolved in different solvents compared to that adopted in aqueous solution.

Figure 5 shows the absorption spectra of the pre-

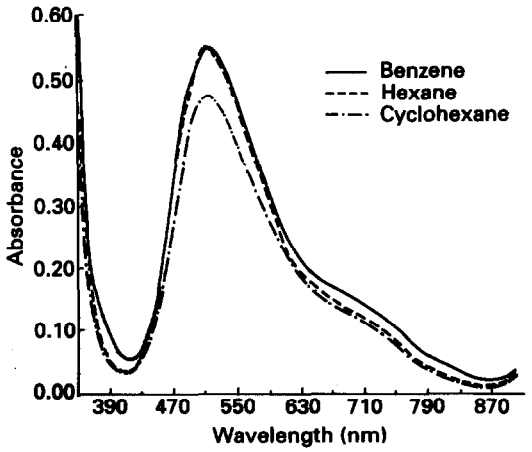


Fig. 5. Absorption spectra of the bisephedrinecopper(II) complex in different solvents.

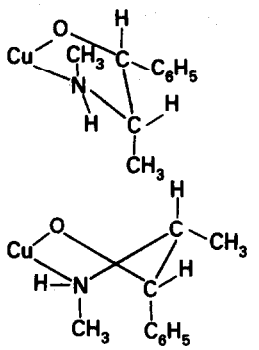
pared bisephedrine copper(II) complex dissolved in benzene, hexane and cyclohexane. The spectra are for the square bisephedrinocopper(II) complex. The similarity of the spectra when benzene and cyclohexane are the solvents indicates the absence of any π-bonding between benzene and the metal ion in the formed chelate. The broad contour of the absorption band is resolved (Gaussian analysis) into three bands with λ_{max} at 520, 630 and 700 nm. The copper ephedrine complex crystallized from benzene had a 1 : 2 square planar geometry.

1.2.2. Copper(II) norephedrine system. On adding an aqueous solution of Cu^{2+} ion to an aqueous solution of norephedrine the copper complex precipitates immediately. However, when methanol was the solvent precipitation did not occur.

Figure 6 shows the absorption spectra of mixtures of copper perchlorate and norephedrine solutions with a constant total concentration of 1.25×10^{-2} M and using methanol as a solvent. The pH of the solutions (after correction) varied from 4.54 to 11.39. The process of complexation becomes clearer at higher concentrations of norephedrine and a gradual blue shift of band maxima is observed with increasing ligand concentration. One starts with a tetragonal tetraaquomononorephedrinocopper(II) complex and finishes up with the square bisnorephedrinocopper(II) complex. The gradual blue shift of band maxima (corresponding to a gradual change from tetragonal to square geometry of the complex) is evident on investigating Fig. 7, where the spectra of solutions containing constant $[Cu^{2+}]$ and varying [norephedrine] are given. For comparison the spectrum of a prepared bisnorephedrinocopper(II) complex, dissolved in methanol, is given.

The gradual change in the geometry of the complex is nicely reflected in the spectra. For the square bisnorephedrinocopper(II) complex one has the following assignment: ν_1 ($d_{xz}, d_{yz} \rightarrow d_{x^2-y^2}$) is observed at 19,610 cm^{-1}, ν_2 ($d_{z^2} \rightarrow d_{x^2-y^2}$) at 16,650 cm^{-1} and ν_3 ($d_{xy} \rightarrow d_{x^2-y^2}$) at 13,330 cm^{-1}.

The square bisnorephedrine copper(II) complex can exist only in two conformers:



Both do not contain an asymmetric atom and the complex would be optically inactive.

2. *Molecular orbital calculation*

It is interesting to investigate theoretically the energy level splitting as the distortion from a pure octahedral geometry increases, via "z-out" dis-

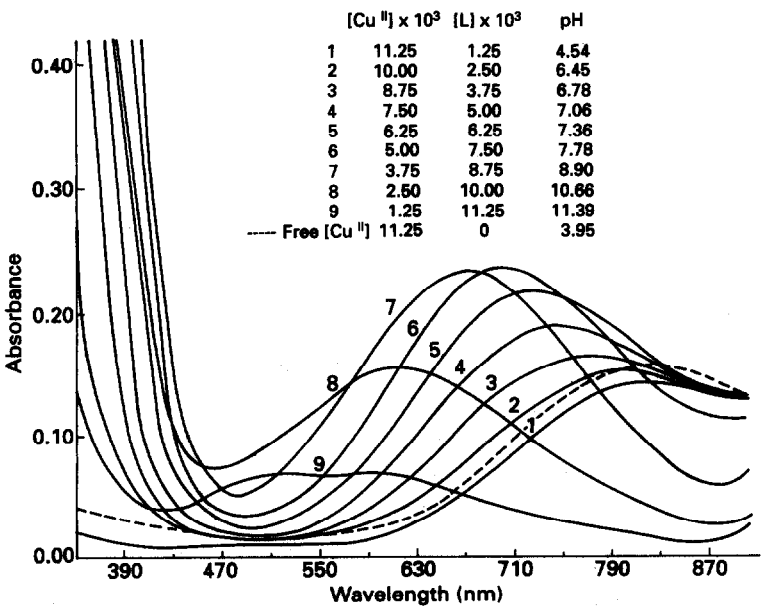


Fig. 6. Absorption spectra of copper(II) norephedrine complexation using methanol as a solvent, with a constant total concentration of 1.25×10^{-2} M.

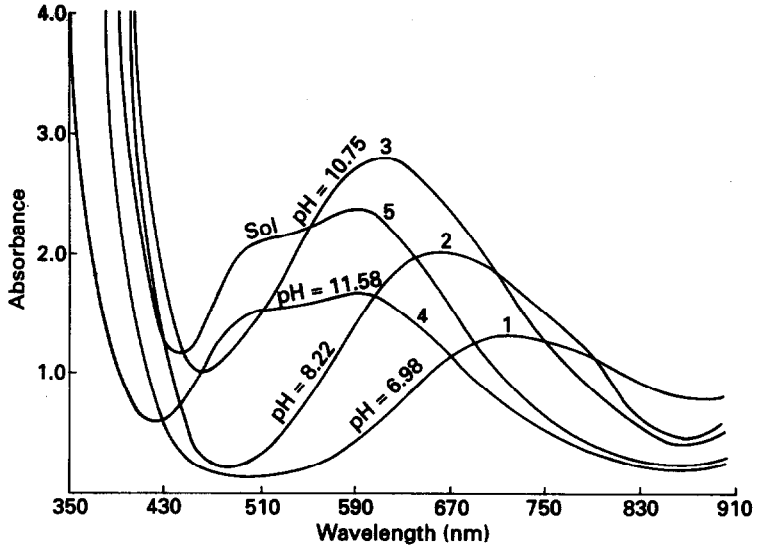

Fig. 7. Absorption spectra of copper(II) norephedrine solutions of varying [Cu^{II}]:[noreph] ratios, 1 (1:1), 2 (1:2), 3 (1:3), 4 (1:4), 5 (methanol solution of solid complex).

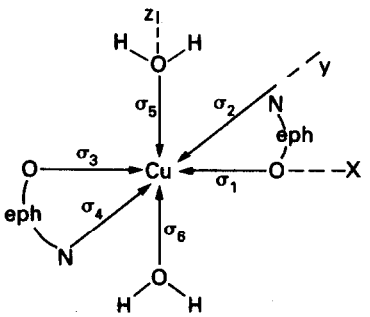
tortion until it arrives at a square planar geometry. The O_h complex of biaquobisephedrinocopper(II) is assumed to have the geometry shown. Assuming a D_{2h} local symmetry for the complex, the symmetry orbitals are given in Table 1.



The general form of the molecular orbital is

$$\psi_i = \sum_j C_{ij} M(\phi_{ij}) + \sum_l C_{il} L(\phi_{il})$$

where CM is the coefficient of the metal ion orbital, ϕ_j, CL is the coefficient of the ligand atomic orbital, ϕ_l.

A symmetry secular determinant is set up and solved for each symmetry species. The diagonal and off-diagonal elements were calculated as

$$H_{ii} = \int \psi_i \hat{H} \psi_i \, d\tau$$

$$H_{ij} = \int \psi_i \hat{H} \psi_j \, dj$$

$$= 0.875[H_{ii} - H_{jj}]\delta_{ij}$$

$$S_{ij} = \int \psi_i \psi_j \, d\tau.$$

The value of H_{ii} is taken as the valence state ionization energy of orbital i and S_{ij} is the group overlap integral between orbital i and j. The values of H_{ij} are calculated using the Wolfsberg–Helmholz relation.[22]

Valence state ionization energies, VSIE, for the ligand orbital, were taken from charge transfer data.[23] The value of H_{ii} for the nitrogen atom of ephedrine was taken as -7.60 eV and that of the hydroxyl oxygen atom of ephedrine as -11.18 eV. A value of -12.16 eV was taken for the ionization energy of the n-electron of the water molecule.[23] The VSIE for the different atomic orbitals on Cu^{2+} ions are charge dependent. Assuming a $+0.25$ charge on the copper ion and a starting configuration of $3d^{9.25}\ 4s^{1.0}\ 4p^{0.5}$ the calculated VSIE were:[24]

$3d = 64{,}000\,cm^{-1}$,

$4s = 54{,}500\,cm^{-1}$ and $4p = 29{,}000\,cm^{-1}$.

Solving the different symmetry determinants one obtains the different eigenvalues and eigenfunctions for the O_h biaquobisephedrinocopper(II) complex. A complete MO energy level diagram is shown in Fig. 8.

Molecular orbital calculations were repeated where the bond length between copper ion and oxygen atom of water molecule was elongated from 1.93 to 2.3 Å. This elongation has its effect on the values of S_{ij} and H_{ij} and on the splitting of energy levels as shown in Fig. 9.

Finally, MO calculations were performed on the square $[Cu(eph)_2]^0$. Results are given in Fig. 10.

In spite of the approximation of the method of

Table 1. Orbital scheme for the biaquobis(ephedrine)copper(II) complex

Symmetry species	Copper(II) orbital	Ligand orbital	S_{ij}
a	$3d_{z^2}$	$\frac{1}{\sqrt{2}}(\sigma_5+\sigma_6)$	0.466
	$3d_{x^2-y^2}$	$\frac{1}{\sqrt{2}}(\sigma_1+\sigma_3-\sigma_2-\sigma_4)$	0.365
		$\frac{1}{\sqrt{2}}(\sigma_1+\sigma_2+\sigma_3+\sigma_4)$	−0.173
	$4s$	$\frac{1}{\sqrt{2}}(\sigma_1+\sigma_3)$	0.048
		$\frac{1}{\sqrt{2}}(\sigma_2+\sigma_4)$	0.107
		$\frac{1}{\sqrt{2}}(\sigma_5+\sigma_6)$	0.137
b_3	$3d_{yz}$	—	—
	$4p_x$	$\frac{1}{\sqrt{2}}(\sigma_3-\sigma_1)$	0.149
b_2	$3d_{xz}$	—	—
	$4p_y$	$\frac{1}{\sqrt{2}}(\sigma_2-\sigma_4)$	0.279
b_1	$3d_{xy}$	—	—
	$4p_z$	$\frac{1}{\sqrt{2}}(\sigma_5-\sigma_6)$	0.197

MO calculations used, some interesting and informative results were obtained. The molecular orbital energy diagram, Fig. 8, for biaquobisephedrinocopper(II) shows a tetragonal splitting of the *d*-orbital. It also shows an extensive mixing between the ligand and both the d_{x^2} and $d_{x^2-y^2}$ metal ion orbitals. The observed transition possesses a partial charge-transfer character, which explains the relatively high intensity of the observed transitions.

As the two water molecules are pulled "out" the MO energy-level diagram turns to that characteristic of a distorted tetragonal complex. A pronounced lowering in the energy of the d_{z^2} orbital is observed as compared with that of $d_{x^2-y^2}$, Fig. 9. Removal of the two water molecules along the *z*-axis leaves a square bisephedrinocopper(II) complex. In this case the MO energy-level diagram, Fig. 10, is characterized by the lowering of the d_{z^2} orbital, even lower than the d_{xy}, d_{xz} and d_{yz} orbitals. The $d_{x^2-y^2}$ orbital is extensively mixed with the ligand orbital. Three low-lying electronic transitions are predicted for the square complex compared with four transitions for the tetragonal complex.

CONCLUSIONS

Spectral–structural correlations have been investigated for the copper(II) ephedrine and norephedrine systems. In the case of the copper(II) ephedrine system both the 1:1 and 1:2 metal:ligand complexes showed spectra characteristic of distorted tetragonal geometry. As the ligand concentration increases the observed spectrum varied significantly and this was interpreted to be due to the increase in the extent of distortion via pulling out the two water molecules along the *z*-axis. The calculation of the crystal field parameters Δ_0 and δ showed an increase in the splitting of the ground

state, a decrease in the splitting of the ground state and a decrease in the splitting of the excited state as the concentration of ephedrine increased with respect to that of Cu^{2+} ions. A further increase in the ligand concentration led to the formation of the bisephedrinocopper(II) complex, which gave an absorption spectrum characteristics of a square complex. The same spectral behaviour, a blue shift of λ_{max} with ligand concentration, was observed for the copper(II) norephedrine system using methanol as a solvent.

(*Received* 22 *February* 1993; *accepted* 1 *April* 1993)

Abstract—The novel salt $[emim]_2[VOCl_4]$ ($[emim]^+$ = 1-ethyl-3-methylimidazolium cation) has been prepared and characterized, both spectroscopically and crystallographically. The $[VOCl_4]^{2-}$ anion has an approximately square pyramidal structure in the solid state. This structure is maintained when the salt is dissolved in the [emim]Cl—$AlCl_3$ ambient-temperature ionic liquid.

Ambient-temperature chloroaluminate(III) ionic liquids have been used as solvents to study the spectroscopy and electrochemistry of a wide range of transition metal chloro complexes.[1] During these investigations a number of oxochloro complexes have been observed.[1–3] They have, generally, been treated as impurities rather than as interesting species in their own right. However, the ambient-temperature chloroaluminate(III) ionic liquids provide an ideal opportunity to observe these species, free from the distortions caused by solvation and solvolysis phenomena.[1]

The chemistry of vanadium(IV) is dominated by the vanadyl group (VO^{2+}). Hence, its roles in redox catalysis and oxo transfer reactions are of some interest.[4,5] As part of a wider investigation of oxygen atom transfer chemistry in ambient-temperature chloroaluminate(III) ionic liquids, we have prepared the salt 1-ethyl-3-methylimidazolium tetrachlorooxovanadate(IV) {$[emim]_2[VOCl_4]$}. We present here the X-ray crystal structure of the salt, together with a spectroscopic investigation of its structure in a basic (excess [emim]Cl) [emim]Cl—$AlCl_3$ ionic liquid.

EXPERIMENTAL

Solvents and starting materials

Dichloromethane (ex. B.D.H.) and ethanenitrile (ex. Aldrich) were distilled from phosphorus(V) oxide, under dinitrogen, immediately before use; thionyl chloride (ex. Aldrich) was distilled *in vacuo* prior to use. Anhydrous $VOCl_2$ was prepared from the dihydrate (ex. B.D.H.), using $SOCl_2$.[6] The non-stoichiometric $VOCl_2(CH_3CN)_x$ ($x \approx 2.5$) was prepared from the reaction of $VOCl_2$ with ethanenitrile.[6] [emim]Cl was prepared by the reaction of 1-methylimidazole with chloroethane.[7]

Preparation of $[emim]_2[VOCl_4]$

1-Ethyl-3-methylimidazolium chloride (2.6 g) and $VOCl_2(CH_3CN)_x$ (2.0 g) were added to dry dichloromethane (75 cm^3). The mixture was heated under reflux, under dry dinitrogen, for 48 h. The resulting mixture was allowed to cool to room temp-

† Author to whom correspondence should be addressed.

Supplementary data are deposited at the Cambridge Crystallographic Data Centre.

erature. After standing overnight green needle crystals were formed, from a green oil. The crystals were isolated by filtration, under dry dinitrogen, and washed with aliquots (10×10 cm^3) of dry dichloromethane. Finally the green crystals were dried *in vacuo*. Yield: 2.54 g (65%), m.p. 99°C. Found: C, 33.76; H, 5.22; N, 12.05%. Calc. for $C_{12}H_{22}Cl_4N_4OV$: C, 33.43; H, 5.14; N, 13.00%.

Spectra

IR spectra were recorded on a Nicolet Magna 550 IR spectrometer. Electronic absorption spectra were recorded on a Perkin–Elmer Lambda 2 spectrophotometer, using 1 cm path length cells.

Crystallographic data collection

A crystal of $[emim]_2[VOCl_4]$ ($0.5 \times 0.3 \times 0.2$ mm) was isolated and mounted in a Lindemann capillary tube. Data were collected on an Enraf–Nonius CAD4 diffractometer. There was no crystal decay. Non-hydrogen atoms were located by direct methods and refinement was by full-matrix least-squares, using an Enraf–Nonius SDP program, with anisotropic temperature factors. Hydrogen atoms were located on a difference map and refined isotropically. Other details of the methods are summarized in Table 1.

RESULTS AND DISCUSSION

IR spectra

The tetrachlorooxovanadate(IV) anion has six atoms and, therefore, 18 Cartesian vectors ($3n$) and 12 molecular vibrations ($3n-6$). Group theory can be used to find the symmetries of these vibrations. The ion has C_{4v} symmetry (*vide infra*); a reducible representation can be obtained by applying the symmetry operations of the group on the Cartesian vectors of the ion.

C_{4v}	E	$2C_4$	C_2	$2\sigma_v$	$2\sigma_d$

This representation may then be reduced, using the C_{4v} character table, to give the irreducible representation.

$$\Gamma = 4A_1 + A_2 + 2B_1 + B_2 + 5E \quad (1)$$

From this, the translations (A_1+E) and the rotations (A_2+E) are subtracted to reveal the normal vibrations.

$$\Gamma_{vib} = 3A_1 + 2B_1 + B_2 + 3E \quad (2)$$

It can be shown that the V=O stretch has A_1 symmetry, whilst there are three V—Cl stretches with A_1, B_1 and E symmetries. Of these only A_1 and E are IR active.

The IR spectrum (2000–225 cm^{-1}) of the solid $[emim]_2[VOCl_4]$ as a Nujol mull is shown in Fig. 1. It can be seen that ν(V=O) is observed as a single strong sharp peak at *ca* 1001 cm^{-1} (cf. 1000 cm^{-1} for $[Et_4N]_2[VOCl_4]$[8]). In the far-IR spectrum a strong band is observed that can be attributed to ν(V—Cl). In the spectrum shown (Fig. 1) this band has resolved into two peaks at 361 and 340 cm^{-1}, in spectra where these peaks are not resolved the band is found at *ca* 350–355 cm^{-1} (cf. 350 cm^{-1} for $[Et_4N]_2[VOCl_4]$[8]). Group theory shows that, for C_{4v} symmetry, the ion $[VOCl_4]^{2-}$ should have both symmetric and asymmetric V—Cl stretches. The two peaks observed at 340 and 361 cm^{-1} can be assigned to the symmetric (A_1) and the asymmetric (E) stretches, respectively. The other peaks in the spectrum are due to the $[emim]^+$ cation and have been discussed elsewhere.[9]

A spectrum of a solution of $[emim]_2[VOCl_4]$ in a basic [emim]Cl—$AlCl_3$ ionic liquid shows a peak due to ν(V=O) at 993 cm^{-1}; ν(V—Cl) is obscured by the spectrum of the ionic liquid itself.

Electronic absorption spectra

The $[VOCl_4]^{2-}$ ion is a d^1 system and hence might be expected to have a simple electronic absorption spectrum. In fact, the spectra of oxovanadium(IV) compounds have been a source of some controversy. However, low-temperature polarized single-crystal measurements[8] of a number of oxovanadium(IV) compounds have led to definitive assignments of electronic absorption spectra. For $[Et_4N]_2[VOCl_4]$[8] three bands were observed at wave numbers below 30,000 cm^{-1}, all of which were assigned to *d–d* transitions, the energies increasing in the order I < II < III. The transitions occur due to an electron being excited from a singly occupied b_2 orbital, which arises from an interaction between the metal d_{xy} orbital and a ligand (Cl) π-orbital, and is weakly antibonding.[8,10]

Band I $b_2 \longrightarrow b_1$

Band II $b_2 \longrightarrow e$

Band III $b_2 \longrightarrow a_1$

Using the single-crystal spectra as a guide the electronic absorption spectrum of a solution of $[emim]_2[VOCl_4]$ (Fig. 2, Table 2) in basic ionic liquid can be analysed. It can be seen that the spectrum is dominated by a broad absorption in the visible region (λ_{max} = 739 nm, 13,530 cm^{-1}), its overall

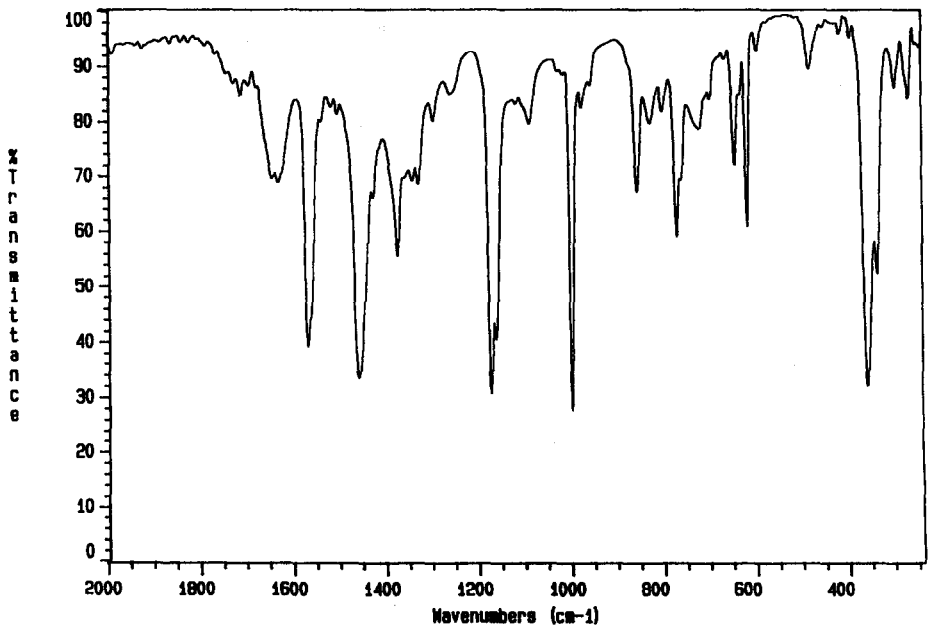

Fig. 1. The IR spectrum (2000–225 cm^{-1}) of $[emim]_2[VOCl_4]$.

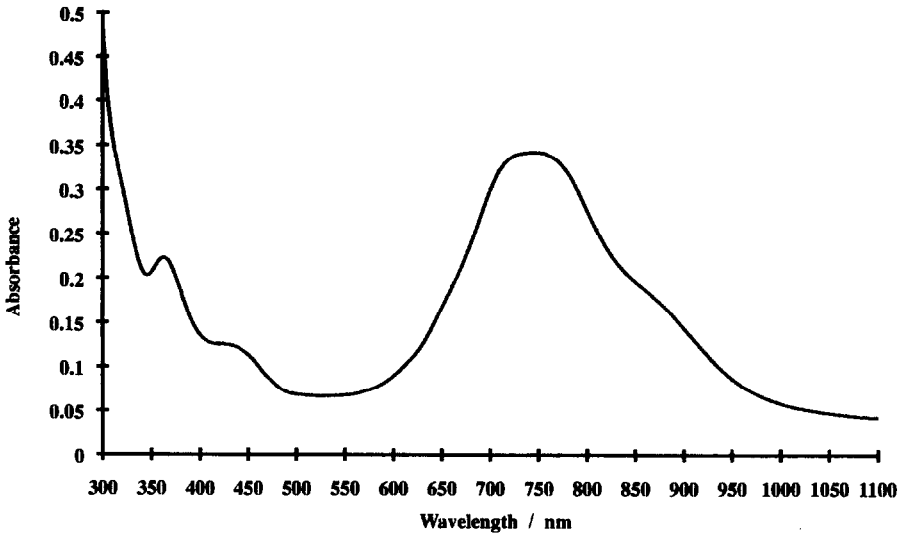

Fig. 2. The electronic absorption spectrum of $[emim]_2[VOCl_4]$ in a basic [emim]Cl—$AlCl_3$ ionic liquid.

appearance being similar to that of the room-temperature single-crystal spectrum of $[Et_4N]_2[VOCl_4]$.[8] The shoulder at 859 nm (11,640 cm^{-1}) can be attributed to the $b_2 \longrightarrow b_1$ transition (band I). The rest of this complicated absorption can be assigned to the $b_2 \longrightarrow e$ transition (band II). The remaining absorptions at 430 and 364 nm (23,280 and 27,470 cm^{-1}) are the beginning of the progression due to the $b_2 \longrightarrow a_1$ transition (band III). Most of this band is obscured by the solvent cut-off, which arises from a π–π^* transition of the imidazolium ring. The spectrum is entirely consistent with the ion maintaining C_{4v} symmetry in the basic ionic liquid.

The crystal structure

The crystal structure of $[emim]_2[VOCl_4]$ is presented in Figs 3 and 4. In this structure the $[VOCl_4]^{2-}$ ion is approximately square pyramidal (C_{4v} symmetry). In the anion there are two longer and two shorter V—Cl bonds (Table 3). However, it can be seen from the bond angles (Table 3) that the ion is not distorted toward trigonal bipyramidal symmetry. The anions lie on crystallographic inversion centres, with the vanadium atoms displaced off the inversion centre such that they, and the oxygen atoms, are disordered equally between both sides of the Cl_4 plane (Fig. 4). Disorder of this nature has been observed for other square pyramidal oxovanadium(IV) compounds.[11]

Although no other crystal structures of the $[VOCl_4]^{2-}$ ion have been recorded, the structures of a number of square-pyramidal complexes of the type $[VOCl_2L_2]$ are known.[11–13] The mean V—Cl bond length in these structures of 0.2326(14) nm is in good agreement with that found for the $[VOCl_4]^{2-}$ ion. However, the mean V=O bond length of 0.1600(12) nm is somewhat longer in these neutral molecules than that in the $[VOCl_4]^{2-}$ ion.

Table 2. The electronic absorption spectrum of $[emim]_2[VOCl_4]$

Transition	λ_{max} (nm)	ν_{max} (cm^{-1})	ε (dm^3 mol^{-1} cm^{-1})
$b_2 \longrightarrow b_1$	859	11,640	shoulder
$b_2 \longrightarrow e$	739	13,530	34.87
$b_2 \longrightarrow a_1$	430	23,280	7.33
	364	27,470	12.87

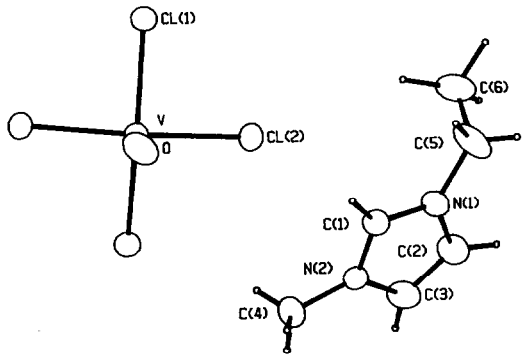

Fig. 3. A single cation and anion of the $[emim]_2[VOCl_4]$ unit, showing the numbering scheme employed.

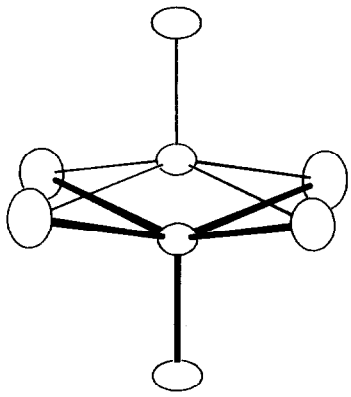

Fig. 4. The site disorder found in $[emim]_2[VOCl_4]$.

The structure of the hexachlorodioxodivanadate(IV) anion ($[V_2O_2Cl_6]^{2-}$) has been recorded[14] and the ion has been shown to consist of two distorted square-pyramidal VCl_4O units sharing a basal edge. As might be expected the V=O bond length of 0.1564(13) nm is in excellent agreement with that found here of 0.1560(5) nm. In $[V_2O_2Cl_6]^{2-}$ the square pyramids are distorted by the presence of both bridging [0.2403(4) nm] and terminal [0.2293(5) nm] V—Cl bonds.

Finally, it is useful to compare the structure of $[emim]_2[VOCl_4]$ with those of known tetrachlorooxovanadate(V) salts. Like the $[VOCl_4]^{2-}$ ion the $[VOCl_4]^-$ ion has a square-pyramidal, C_{4v}, structure. Of the three published structures[15–17] one $\{[P_2NCl_6][VOCl_4]\}$ is the result of diffraction by twinned crystals[17] and is not used for the comparison here. The remaining two structures are in good agreement, showing mean V=O and V—Cl distances of 0.1550 and 0.2252 nm, respectively. The molecular orbital description for $[VOCl_4]^{2-}$ shows that the ground state is $^2B_2$ with a b_2 antibonding HOMO. Oxidation of $[VOCl_4]^{2-}$ to $[VOCl_4]^-$ involves the removal of the electron from the antibonding orbital. Since this orbital has no oxygen character, little difference in the V=O bond lengths is expected. The HOMO does, however, have V—Cl antibonding character, hence the V—Cl bond length in $[VOCl_4]^{2-}$ (0.2330 nm) is expected to be longer than in $[VOCl_4]^-$ (0.2252 nm). This is indeed the case.

A survey of closest interionic contacts reveals that it is unlikely that any of the protons of the cation are involved in hydrogen bonding with the anion. This is consistent with conclusions previously drawn, on the hydrogen-bond acceptor properties of chlorometallate complexes.[18]

The internal dimensions of the $[emim]^+$ ion are unremarkable and in good agreement with those of other salts of this cation.[18,19]

CONCLUSIONS

In the salt $[emim]_2[VOCl_4]$ the anion has C_{4v} symmetry (square pyramidal), at room temperature. This symmetry is maintained when the salt is dissolved in basic compositions of the [emim]

Cl—$AlCl_3$ ionic liquid. The electronic absorption spectrum of the salt dissolved in the ionic liquids was markedly better resolved than spectra recorded in conventional non-aqueous solvents (cf. ref. 10) and is of a quality comparable to that of single-crystal spectra.[8] This confirms the usefulness of [emim]Cl—$AlCl_3$ for the investigation of these interesting oxochloride systems.

(*Received* 5 *January* 1993; *accepted* 1 *April* 1993)

Abstract—The synthesis and characterization of some *cis*-dioxomolybdenum(VI) complexes with bidentate and tetradentate Schiff base ligands derived from reactions of 1-phenyl-3-methyl-4-benzoyl-5-pyrazolone with amines, such as *p*-anisidine, *m*-phenitidine, *m*-toluidine, *o*-, *m*- and *p*-phenylenediamine, and benzidine are reported. Reaction of the bi- and tetradentate Schiff bases with $MoO_2(acac)_2$ in 2:1 and 1:1 ratios, respectively, gave diamagnetic molybdenum(VI) mononuclear complexes with the general formulae *cis*-$MoO_2(L)_2$ (L = bidentate Schiff base), *cis*-$MoO_2(L^1)$ (L^1 = tetradentate Schiff base with *o*- and *m*-phenylenediamine) and the ligand-bridged dinuclear complexes $Mo_2O_4(L^2)(S)_x$ (L^2 = tetradentate Schiff base with *p*-phenylenediamine and benzidene, $S = C_2H_5O^-$ and $x = 2$ or 4). These complexes were characterized by elemental analysis, molar conductance, IR, UV–vis, ^1H NMR and cyclic voltammetry.

The coordination complexes of molybdenum have gained considerable research interest due to their activity in biochemical redox reactions associated with several enzymes.[1–4] The valence of molybdenum varies depending on the nature of the enzyme and the function of some redox enzymes is dependent on variable-valence molybdenum cofactors. The coordination chemistry of the molybdenum(VI) state is based on oxo complexes to a large extent, which are important in oxidations catalysed by metals.[5,6] Most molybdenum(VI) coordination complexes contain *cis*-dioxo MoO_2^{2+} and an octahedral structure. Although many precursors are available, $MoO_2(acac)_2$ is a convenient source of MoO_2^{2+}.[7–9] In this paper we report the synthesis and characterization of some *cis*-dioxomolybdenum(VI) complexes with bi- and tetradentate Schiff bases. The bidentate Schiff bases form mononuclear molybdenum(VI) complexes having the general formula $MoO_2(L)_2$, where L = a bidentate Schiff base, namely, 1-phenyl-3-methyl-4-benzoyl-*p*-anisidine-5-pyrazolone (PMBP-A), 1-phenyl-3-methyl-4-benzoyl-*m*-phenitidine-5-pyrazolone (PMBP-P) and 1-phenyl-3-methyl-4-benzoyl-*m*-toluidine-5-pyrazolone (PMBP-T). The Schiff base ligand of *o*-phenylenediamine forms a mononuclear complex, *cis*-$MoO_2(L^1)$ [L^1 = 1-phenyl-3-methyl-4-benzoyl-*o*-phenylenediamine-5-pyrazolone (PMBP-*o*-phd)]. The Schiff base ligand of *m*-phenylenediamine behaves as a tridentate ligand and forms the mononuclear five-coordinate *cis*-$MoO_2(L^1)$ [L^1 = 1-phenyl-3-4-benzoyl-*m*-phenylenediamine-5-pyrazolone (PMBP-*m*-phd)]. The molyb-

* Author to whom correspondence should be addressed.

denum(VI) complexes of *p*-phenylenediamine and benzidine Schiff bases are five- and six-coordinate dinuclear complexes, respectively, bridging through azomethine nitrogens, represented as $(Mo_2O_4)(L^2)(S)_x$, where L^2 = 1-phenyl-3-methyl-4-benzoyl-*p*-phenylenediamine-5-pyrazolone (PMBP-*p*-phd) and 1-phenyl-3-methyl-4-benzoyl-benzidine-5-pyrazolone (PMBP-bz), $S = C_2H_5O^-$ and $x = 2$ or 4. Elemental analysis, molar conductance, spectroscopic (IR, UV–vis and ^{1}H NMR) and cyclic voltammetry data are given for all the complexes.

EXPERIMENTAL

Materials

All reagents required for compound preparation were of analytical grade. 1-Phenyl-3-methyl-5-pyrazolone was procured from Johnsons Chemical Company, Bombay, India. Ammonium molybdate, acetylacetone and the amines used in this study were procured from B.D.H., U.K.

Synthesis of the ligands

1-Phenyl-3-methyl-4-benzoyl-5-pyrazolone (PMBP) was prepared according to the reported method.[10] The synthesis of bidentate Schiff base ligands, namely 1-phenyl-3-methyl-4-benzoyl-*p*-anisidine-5-pyrazolone (PMBP-A) (**1a**), 1-phenyl-3-methyl-4-benzoyl-*m*-phenitidine-5-pyrazolone (PMBP-P) (**2a**) and 1-phenyl-3-methyl-4-benzoyl-*m*-toluidine-5-pyrazolone (PMBP-T) (**3a**), has been reported earlier.[11] The tetradentate Schiff bases were prepared by a general method wherein 2:1 ethanolic solutions of PMBP and *o*-, *m*- and *p*-phenylenediamine and benzidine were taken and refluxed with stirring for 4–5 h. The volume of the solution was reduced (*ca* 10 cm^3) by concentrating on a water bath. On cooling the solutions to room temperature crystals of yellow 1-phenyl-3-methyl-4-benzoyl-*o*-phenylenediamine-5-pyrazolone (PMBP-*o*-phd) (**4a**), greenish-yellow 1-phenyl-3-methyl-4-benzoyl-*m*-phenylenediamine-5-pyrazolone (PMBP-*m*-phd) (**5a**), yellow 1-phenyl-3-methyl-4-benzoyl-*p*-phenylenediamine-5-pyrazolone (PMBP-*p*-phd) (**6a**) and 1-phenyl-3-methyl-4-benzoyl-benzidine-5-pyrazolone (PMBP-bz) (**7a**) separated out from their respective solutions. The crystals thus obtained were filtered and recrystallized from ethanol (yield 70–75%).

Synthesis of the complexes

$MoO_2(acac)_2$ was prepared according to the reported method.[12] The *cis*-dioxomolybdenum bidentate Schiff base complexes $\{MoO_2(PMBP\text{-}A)_2\}$ (**1b**), $\{MoO_2(PMBP\text{-}P)_2\}$ (**2b**) and $\{MoO_2(PMBP\text{-}T)_2\}$ (**3b**) and tetradentate Schiff base complexes $\{MoO_2(PMBP\text{-}o\text{-}phd)\}$ (**4b**), $\{MoO_2(PMBP\text{-}m\text{-}phd)\}$ (**5b**), $\{Mo_2O_4(PMBP\text{-}p\text{-}phd)(C_2H_5O^-)_2\}$ (**6b**) and $\{Mo_2O_4(PMBP\text{-}bz)(C_2H_5O^-)_4\}$ (**7b**) were prepared by adding a hot ethanolic solution of the ligand to a hot ethanolic solution of $MoO_2(acac)_2$ in 2:1 and 1:1 ratios, respectively. The resulting solution was refluxed for 6–7 h when the colour of the solution changed to dark green. The volume of the solution was reduced (*ca* 10 cm^3) by concentrating on a water bath. Green complexes were obtained on cooling which were filtered, washed with small aliquots of ethanol to remove unreacted ligand and $MoO_2(acac)_2$ and then dried *in vacuo* (yield 60–65%).

Physical measurements

Microanalyses (C, H, N) of the ligands and the complexes were performed on a Carlo–Erba 1106 elemental analyser. Solution electrical conductivity was measured at 298 K using a Digisun Electronics Conductivity bridge. IR spectra were recorded at 298 K on an FT-IR (Bio-Rad) spectrometer as Nujol mulls/KBr pellets. Electronic spectra were recorded on a Shimadzu model UV-160 spectrophotometer. The ^{1}H NMR spectra were recorded at 298 K on a Jeol FX-100 FT-NMR spectrometer. Cyclic voltammetry traces of the complexes were recorded on a Princeton Applied Research Model 384 Polarographic Analyser.

RESULTS AND DISCUSSION

The elemental analyses, UV–vis, ^{1}H NMR and IR data of the bidentate Schiff base ligands (**1a–3a**) have been reported earlier,[11] whereas the data for the tetradentate Schiff base ligands (**4a–7a**) is presented in Table 1. The ^{1}H NMR spectra of all the Schiff base ligands (**1a–7a**) except **5a** and **7a**, show a peak at δ 12.4–12.8 ppm, which is due to the —OH proton, suggesting their existence in the enolic form. In the case of **5a** and **7a** the absence of the —OH proton and the presence of the —CH proton (δ 2.17 ppm) suggest their existence in the keto form. This is further supported by the IR spectra, wherein a band at 3476 cm^{-1} characteristic of ν(OH) is present in all the ligands except **5a** and **7a**. Further, the spectral data suggest that condensation to form tetradentate Schiff bases occurred at both the amino groups present in the diamines. The IR spectra of the ligands show ν(C=N) in the region 1592–1647 cm^{-1}, ν(C—O) at 1137–1165 cm^{-1} and in the case of **5a** and **7a** ν(C=O) appears at 1657 and 1642

cm^{-1}, respectively. On the basis of the data in Table 1 the structure of the bi- and tetradentate Schiff base ligands in general can be written as shown in structure **I**(a and b), respectively.

$MoO_2(acac)_2$ reacts with these bi- and tetradentate Schiff base ligands in ethanol to form stable molybdenum(VI) mononuclear (**1b–5b**) and ligand-bridged dinuclear complexes (**6b–7b**). That both the "acac" ligands in $MoO_2(acac)_2$ were displaced by these ligands was supported by the absence of characteristic peaks of "acac" groups in the IR and NMR spectra for these complexes.

The analytical data for the mononuclear and dinuclear *cis*-dioxomolybdenum(VI) Schiff base complexes (**1b–7b**) is presented in Table 1. The conductivities of freshly prepared solutions of **1b–3b** in acetone and **4b–7b** in DMF are in the range 2–7 $\Omega\ cm^{-1}\ mol^{-1}$, indicating that they are non-electrolytes.

The IR spectra of the complexes (**1b–7b**) (Table 1) exhibit bands in the regions 860–910 and 906–960 cm^{-1} due to ν_{as}(O=Mo=O) and ν_s(O=Mo=O), respectively.[13,14] This indicates the O=Mo=O species to be in the *cis* form as the *trans*-O=Mo=O species would exhibit only a single band in this region.[15,16] In the case of complex **6b** the peaks at 891 and 955 cm^{-1} due to the O=Mo=O species show a split, indicating the presence of two O=Mo=O moieties, one of which is probably present in a slightly different coordination environment. However, only two strong peaks attributable to *cis*-MoO_2^{2+} were seen in complex **7b**. The observed carbon, hydrogen and nitrogen analysis data for complexes **6b** and **7b** fit the ligand-bridged dinuclear complexes only. From the absence of new peaks in the regions 750–770 and 460–490 cm^{-1} in their IR spectra, the possibility of the formation of $\{O_2Mo—O—MoO_2\}^{4+}$ type[14] complexes could be excluded. Further, in the IR spectra of complexes **6b** and **7b** one new peak appeared at 844 and 854 cm^{-1}, respectively. This may be attributed to the M—OC_2H_5 vibration.[13]

The formation of a dinuclear complex may be due to the *para* position of the azomethine nitrogens in **6a** (PMBP-*p*-phd) and **7a** (PMBP-bz), wherein coordination of both azomethine nitrogens to the same metal atom is difficult. In complexes **1b–7b** the bands in the region 1592–1647 cm^{-1} due to the azomethine group of the ligand undergo a shift to lower frequency[17] (1574–1616 cm^{-1}) after complexation, indicating the coordination of azomethine nitrogen to molybdenum. In complex **5b** the ligand **5a** behaves as a tridentate ligand, one of the azomethine nitrogens being unable to coordinate to the metal due to its *meta* position. This is shown by the presence of ν(C=N) at 1647 cm^{-1} (as in the ligand) and the appearance of a new band at 1629 cm^{-1} due to coordinated ν(C=N). The coordination of both the azomethine nitrogens in **5b** to the same metal centre requires the bending of bonds of the phenylenediamine ring. In complex **5b** the band due to ν(C=O) at 1657 cm^{-1} is absent, indicating the enolization of the C=O group.[18] Instead, a new band appears at 1173 cm^{-1} due to coordinated ν(C—O)(enolic). The coordination of enolic oxygen to the metal centre in complexes **1b–6b** is indicated by the increase in ν(C—O) (1166–1180 cm^{-1}) compared with that of the free ligand (1137–1165 cm^{-1}).[11] The cyclic carbonyl coordination to the metal centres in **7b** is indicated by the decrease[19] in ν(C=O) (1635 cm^{-1}) compared with that of the free ligand (1642 cm^{-1}).[18]

The electronic spectra of complexes **1b–7b** (Table 1) were studied in the concentration range 1×10^{-4}–

1×10^{-3} M in acetone (**1b–3b**) and DMF (**4b–7b**). For the bidentate Schiff base complexes (**1b–3b**) a blue shift (327–332 nm) was observed for the ligand band at 347 nm. All the complexes (**1b–7b**) show an additional intense band in the region 424–443 nm, which may be due to ligand-to-metal charge transfer transitions. In the cases of the tetradentate Schiff base complexes **4b–7b**, except **5b**, an additional broad band of low intensity was also observed in the region 680–730 nm. The band appearing at such a low energy is unexpected for $4d^0$ molybdenum(VI) complexes. However, this has also been observed in the case of the tetradentate Schiff base complex *cis*-MoO_2(3-OCH_3-Saltrien).[20]

The mononuclear and dinuclear *cis*-MoO_2(VI) Schiff base complexes were found to be diamagnetic by ^{1}H NMR spectroscopy. The chemical shifts of various protons of the ligands in the molybdenum(VI) complexes **1b–7b** are shown in Table 1. The absence of —OH protons in complexes **1b–6b** suggests coordination through the enolic oxygen to the metal centre. The presence of —CH protons (δ 2.13 ppm) in complex **7b** suggests coordination through the cyclic carbonyl to the metal centre. In the case of complexes **6b** and **7b** the signals due to $-CH_3$ and $-CH_2$ protons (of OC_2H_5) appear as a quartet and a triplet in the regions 2.73–3.09 and 1.23–1.37 ppm, respectively, indicating coordination of the ethoxo group to the metal centre. Further, in the spectrum of complex **7b** two quartets and two triplets are seen in this region, indicating the variation in coordination environment of the two ethoxo groups per metal atom.

The cyclic voltammograms (scan range +1.3 to −1.5 V) vs Ag/AgCl for the bidentate Schiff base complexes **1b–3b** in acetone consist of an irreversible reduction wave at −1.01 V (±0.02 V) vs Ag/AgCl (Fig. 1). When cyclic voltammetry for these complexes was performed in DMF the irreversible reduction wave was found to shift to positive potentials (*ca* 0.05–0.1 V). This irreversible process is attributed to Mo^{VI}/Mo^{V} reduction.[21,22] The reoxidation of Mo^{V} to Mo^{VI} was not observed in **1b–3b**, instead dimerization of Mo^{V} species was seen, forming Mo^{V}—O—Mo^{V}, for which an oxidation wave was observed at +0.2 V (±0.02 V). However, on increasing the scan rate (0.1–2.5 V s^{-1}) it was seen that the anodic peak current at +0.2 V diminished and simultaneously the reoxidation wave of Mo^{V} to Mo^{VI} at −0.95 V tended to appear, especially at the highest scan rate used in this study. Such dimerization of molybdenum(V) species is well known.[22] However, when the scan was reversed at a potential relatively positive to the reduction wave at −1.01 V the oxidation peak at +0.2 V was not seen, indicating that the peak at +0.2 V is a consequence of the reduction peak at −1.01. The cyclic voltammetry of complexes **4b–7b**, except **5b**, showed a reversible redox couple at $E_{1/2} = 0.55$ V[22] (±0.02 V, $0.07 < \Delta E < 0.1$ V) (Fig. 1). In complex **5b** an irreversible reduction ($Mo^{VI} \rightarrow Mo^{V}$) wave was seen at −0.88 V. The reversible redox couple is attributed to $Mo^{VI} \rightarrow Mo^{V}$ reduction and reoxidation to Mo^{VI} in **4b**, **6b** and **7b**. Comparison of the cyclic voltammetry data of the bi- and tetradentate Schiff base complexes **1b–7b** reveals that the $Mo^{VI} \rightarrow Mo^{V}$ reduction is not only facile, but also reversible in the case of tetradentate Schiff base complexes. This may be due to the change in ligand structure,[23,24] wherein the phenylenediamine ring in the ligands **4a–7a** appears to delocalize the electron density effectively from the metal centre causing its easier reduction. In the bidentate Schiff base complexes it appears that the added electron during $Mo^{VI} \rightarrow Mo^{V}$ reduction is located on one of the Mo=O bonds (due to poor delocalization by the bidentate Schiff base ligand) and thus the reduced species may participate in the proton equilibrium leading to dimerization.

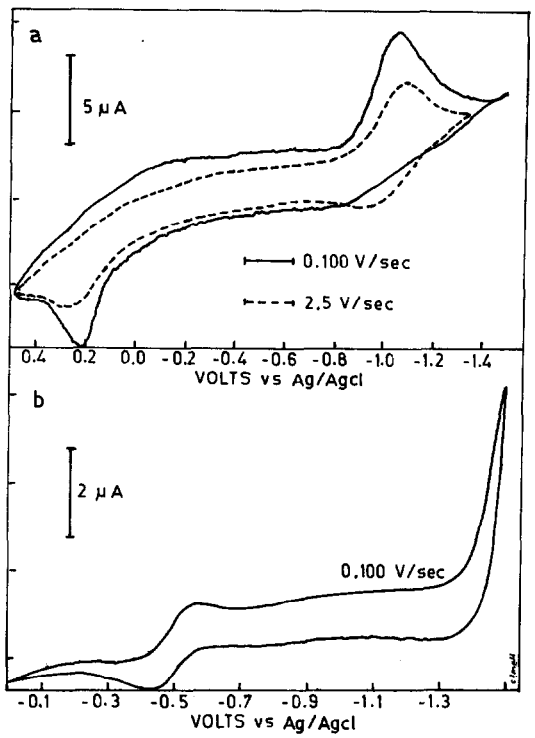

Fig. 1. Cyclic voltammograms of (a) MoO_2(PMBP-P)$_2$, representing bidentate Schiff base complexes, and (b) Mo_2O_4(PMBP-bz)$(C_2H_5O^-)_4$ (**7b**), representing tetradentate Schiff base complexes.

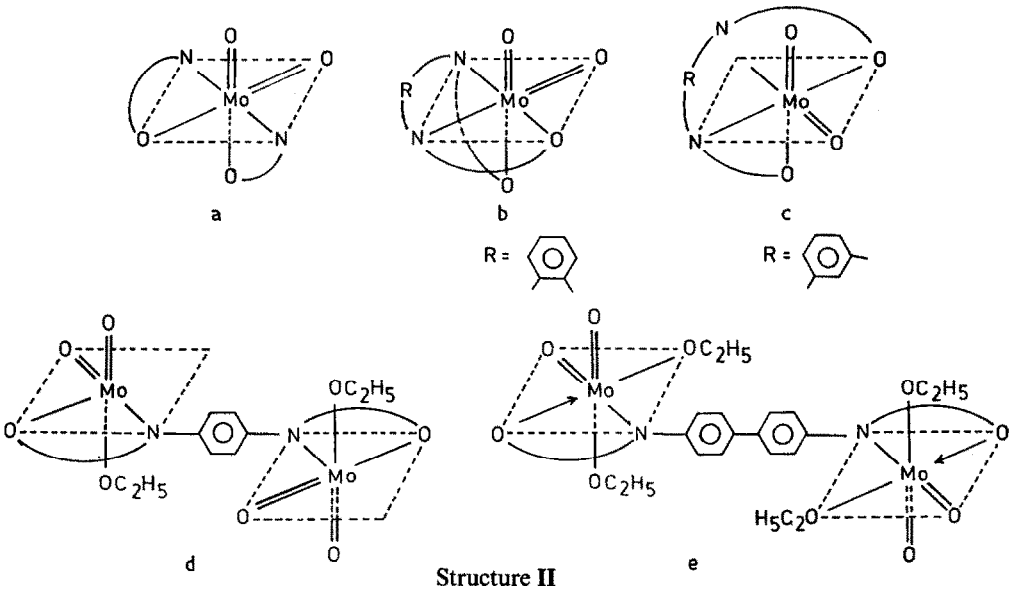
Thus, on the basis of the above data it is evident that the ligands coordinate through the azomethine nitrogen and enolic oxygen to the central metal



Structure II

atom in complexes **1b–6b** and through the cyclic carbonyl in **7b**. Complexes **6b** and **7b** are dinuclear complexes bridging through the azomethine nitrogen. In general, the structure of the bidentate Schiff base complexes *cis*-MoO_2^{VI} (**1b–3b**) can be represented as shown in structure **IIa**. The six- and five-coordinate complexes **4b** and **5b** can be written as shown in structures **IIb** and **IIc**, respectively. The binuclear five- and six-coordinate bridging complexes **6b** and **7b** can be represented as shown in structures **IId** and **IIe**, respectively. For complexes **6b** and **7b** the structures **IId** and **IIe** are preferred, wherein the two MoO_2 moieties are *trans* with respect to phenylenediamine and benzidine rings, in which the steric hindrance of the *p*-hydrogens of the phenyl rings attached to azomethine carbons is avoided. Efforts were made to obtain the crystals of these molybdenum(VI) complexes to study their X-ray crystallography, but due to their poor solubility in most of the organic solvents the desired results could not be attained. However, the work is still being continued in the same direction to obtain positive results.

Abstract—The preparation and characterization of [Fe(C_5Ph_5)(C_5H_5)] by single-crystal X-ray diffraction are reported. The compound crystallizes from chlorobenzene as a chlorobenzene solvate. The (C_5H_5) ring is planar to within 0.002 Å, whilst the C_5 ring of the (C_5Ph_5) ligand is planar to within 0.004 Å. The Fe—(ring centroid) distances are both 1.652 Å. The phenyl substituents of the (C_5Ph_5) ring are canted relative to the cyclopentadienyl frame at angles between 44.3° and 61.8°. The structure of [Fe(C_5Ph_5)(C_5H_5)] is compared with the structures of ferrocene, 1,2,3,4,5-pentamethylferrocene and 1,2,3,4,5-penta(*p*-tolyl) ferrocene. The synthesis and characterization of [Fe(C_5Ph_5)$(CO)_2]_2$ is also reported. [Fe(C_5Ph_5)$(CO)_2]_2$ is assigned a *trans* configuration on the basis of its IR spectrum.

Complexes of the pentaphenylcyclopentadienyl ligand are of considerable current interest, particularly in the context of the emerging field of supracyclopentadienyl chemistry.[1,2] The ligand is capable of conferring novel steric and electronic properties on metal centres. Thus, for example, the two parallel C_5 planes of [Sn(C_5Ph_5)$_2$] contrast with the bent structures of [Sn(C_5H_5)$_2$] and [Sn(C_5Me_5)$_2$].[3–5] [(C_5Ph_5)PdNO] is a purple solid, indefinitely stable at room temperature under dinitrogen, whereas the red oil [(C_5H_5)PdNO] is reported to be unstable at room temperature under an argon atmosphere.[6–8] Diamagnetic decaphenylnickelocene contrasts with paramagnetic nickelocene;[9–11] the dimer [{Ni(μ-Br)(C_5R_5)}$_2$] is unknown for R = H, must be stored below +10°C for R = Me and melts with decomposition above 200°C when R = Ph,[12] and the pentaphenylcyclopentadienyl anion stabilizes 17-, 19- and 20-electron species.[13–15] To date, the crystal structures of pentaphenylcyclopentadiene,[16] pentaphenylcyclopentadien-1-ol[17] and 14 complexes of the pentaphenylcyclopentadienyl anion have been reported.[3,12,18–28] Of these complexes only [Sn(C_5Ph_5)$_2$] has more than one pentaphenylcyclopentadienyl anion coordinated to a single metal atom and only [Ti(C_5Ph_5)(C_5H_5)Cl_2] and [Sn(C_5Ph_5)(C_5H_5)] have an additional cyclopentadienyl ligand. The crystal structure of the closely related [Fe(C_5(*p*-tol)$_5$)(C_5H_5)] has been reported recently.[29] However, there have been few opportunities to study the comparative structural chemistry of the ligands $(C_5R_5)^-$ (R = H, Me, *p*-tol, Ph) in analogous compounds.

We report here the structure and additional properties of pentaphenylferrocene, [Fe(C_5Ph_5)(C_5H_5)], and a comparison with the structures of the complexes [Fe(C_5R_5)(C_5H_5)] (R = H, Me, *p*-tol) and [Fe(C_5Ph_5)$(CO)_2$)Br].[20,29–31] In the course of synthesizing [Fe(C_5Ph_5)(C_5H_5)] we have unexpectedly prepared a pure sample of the elusive [Fe(C_5Ph_5)$(CO)_2]_2$, which is also reported here.

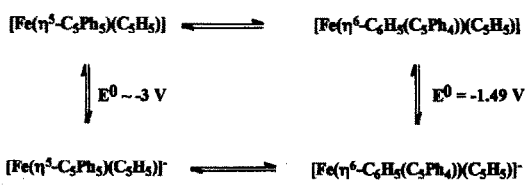
RESULTS AND DISCUSSION

[Fe(C_5Ph_5)(C_5H_5)] was prepared by thermolysis of the product of the reaction between [Fe(C_5Ph_5)$(CO)_2$Br] and cyclopentadienylsodium, as reported

* Authors to whom correspondence should be addressed.

previously.[32] We have recently reported that $[Fe(C_5(p\text{-tolyl})_5)(\eta^1\text{-}C_5H_5)(CO)_2]$ can be isolated as a deep red, air-stable solid from the reaction between $[Fe(C_5(p\text{-tolyl})_5)(CO)_2Br]$ and cyclopentadienyl sodium and is thermally converted to $[Fe(C_5(p\text{-tolyl})_5)(\eta^5\text{-}C_5H_5)]$.[29] The preparation of $[Fe(C_5Ph_5)(C_5H_5)]$ presumably follows an analogous route, as postulated previously by Pauson.[32] At a scan rate of 100 mV s^{-1} $[Fe(C_5Ph_5)(C_5H_5)]$ undergoes a reversible oxidation at $E_{1/2} = +0.240$ V ($\Delta E_p = 65$ mV) and a quasi-reversible reduction at $E_{1/2} = -1.491$ V ($\Delta E_p = 132$ mV). The stabilization of $[Fe(C_5Ph_5)(C_5H_5)]^-$ is unusual for ferrocene and its substituted derivatives and the reduction is almost certainly due to a small equilibrium concentration of the linkage isomer $[Fe(\eta^6\text{-}C_6H_5(C_5Ph_4))(C_5H_5)]$. The analogous compound, $[Fe(\eta^6\text{-}C_6H_5(C_5Ph_4))(\eta^5\text{-}C_5Ph_5)]$, is known[33] and the reduction potential of -1.49 V is typical of those observed for $[Fe(\eta^6\text{-arene})(\eta^5\text{-}C_5Ph_5)]^+$ complexes.[28] Since the reduction of $[Fecp_2]$ complexes typically occurs at *ca* -3 V,[34] it is most likely that the linkage isomer is responsible for the observed reduction behaviour. This can be explained by the processes of Scheme 1, in which the linkage isomerization occurs as a rapid pre-equilibrium and favours the parent complex, $[Fe(C_5Ph_5)(C_5H_5)]$, in the iron(II) oxidation state and the linkage isomer, $[Fe(\eta^6\text{-}C_6H_5(C_5Ph_4))(C_5H_5)]^-$ in the iron(I) oxidation state.

$[Fe(C_5Ph_5)(C_5H_5)]$ has a small (1.3 D) but significant dipole moment. It is not possible to differentiate between the dipole moments of $[Fe(C_5R_5)(C_5H_5)]$ (R = Me,[35] Ph) on the basis of the precision of the present measurements. 1,2,3,4,5-Pentamethylferrocene was shown by microwave absorption measurements to have a small (0.90 D) dipole moment directed along the molecular symmetry axis from the pentamethylcyclopentadienyl ligand towards the cyclopentadienyl ligand (at the negative end of the dipole), in accord with the electron donating properties of methyl groups.[35] The finite dipole moment of pentaphenylferrocene suggests that a small amount of electron charge transmission occurs between the substituent phenyl groups and the ferrocene system. The electrochemical results suggest that the phenyl groups are electron withdrawing and hence that the pentaphenylcyclopentadienyl ligand is at the negative end of the dipole.



Scheme 1.

During an attempted preparation of $[Fe(C_5Ph_5)(CO)_2Br]$ a green crystalline solid which analysed as $[Fe(C_5Ph_5)(CO)_2]_2$ was isolated. The compound is assigned as *trans*-$[Fe(C_5Ph_5)(CO)_2]_2$ on the basis of its IR spectrum.[36] Although observed as a transitory species in the past,[32,37] pure *trans*-$[Fe(C_5Ph_5)(CO)_2]_2$ has not hitherto been isolated. The preparation of *trans*-$[Fe(C_5Ph_5)(CO)_2]_2$ by this route is not reproducible and the mechanism of its formation during the synthesis of $[Fe(C_5Ph_5)(CO)_2Br]$ is unclear. The most obvious difference in the preparations of the two materials is that $[Fe(C_5Ph_5)(CO)_2Br]$ is produced after 2 h reflux, whereas *trans*-$[Fe(C_5Ph_5)(CO)_2]_2$ was isolated after a similar solution had been refluxed for 18 h.

$[Fe(C_5Ph_5)(C_5H_5)]$ crystallizes as discrete molecules in which the iron atom is sandwiched between two near parallel five-membered rings. Final atomic positional coordinates, with estimated standard deviations, bond lengths and angles and anisotropic thermal parameters are deposited.* Selected interatomic bond distances and angles, with standard deviations derived from the refinement, are given in Tables 1 and 2. The atomic nomenclature is defined in Fig. 1. Figures 1 and 2 illustrate the molecular geometry viewed along, and perpendicular to, the normal to the C_5 planes of the ligands, respectively.

No intermolecular contacts of significance were observed in the solid; the closest intermolecular non-bonding approach between molecules being 3.494 Å.

$[Fe(C_5Ph_5)(C_5H_5)]$ crystallizes as a chlorobenzene solvate. There are no significant contacts between the chlorobenzene and the $[Fe(C_5Ph_5)(C_5H_5)]$ molecules in the solid. Disorder of the

chlorobenzene was obvious from the temperature factors. However, the type of disorder could not be deduced from the data refinement.

The $[Fe(C_5Ph_5)(C_5H_5)]$ *molecule*

The C_5 rings of $[Fe(C_5Ph_5)(C_5H_5)]$ are not significantly distorted from planarity (maximum deviation of the C_5C atoms from the C_5R_5 rings, 0.004 Å, R = C_6H_5; 0.002 Å, R = H). The two rings are almost parallel (angle between the normals to the rings 2.8°) and are nearly eclipsed in the solid state. All C—C bond distances are normal within statistical significance [av. 1.438 Å, (C_5Ph_5), 1.418 Å, (C_5H_5)], but may be slightly long by comparison with other iron cyclopentadienyl derivatives. Those of the $(C_5Ph_5)^-$ ligand are similar to those in $[Fe(C_5Ph_5)(CO)_2Br]$.[20] The bond angles within the C_5 rings are normal for the C_5 rings of cyclopentadienyl and substituted cyclopentadienyl derivatives. The Fe—(ring centroid) distances are 1.652 Å (C_5H_5) and 1.652 Å (C_5Ph_5), with the average Fe—C distances being 2.046 Å (C_5H_5) and 2.056 Å (C_5Ph_5). Thus, the separation between the ligand planes is 3.304 Å. These are within the ranges observed for substantially undistorted $[Fe(C_5R_5)$

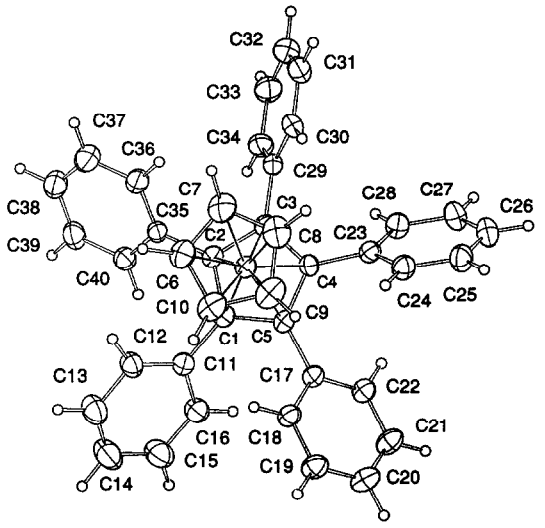

Fig. 1. ORTEP (50% probability) illustration of the molecular structure of $[Fe(C_5Ph_5)(C_5H_5)]$, showing the atom numbering. Viewed along the normal to the C_5Ph_5 plane.

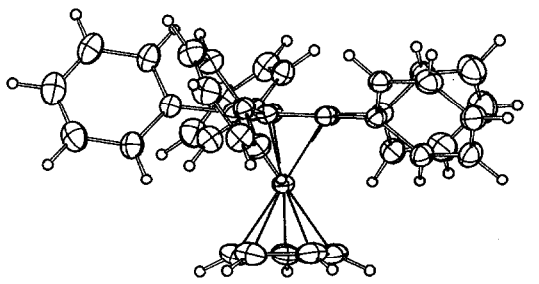

Fig. 2. ORTEP (50% probability) illustration of the molecular structure of $[Fe(C_5Ph_5)(C_5H_5)]$, showing the atom numbering. Viewed perpendicular to the normal to the C_5Ph_5 plane.

Table 3. Comparisons between $[Fe(C_5R_5)(C_5H_5)]$ (R = H, Me, *p*-tolyl, Ph)

Bond	Distance (Å) H[44]	Me[45]	*p*-tolyl[29]	Ph[a]
Fe—C_5H_5	1.654	1.663	1.660	1.651_8
Fe—C_5R_5	1.654	1.641	1.645	1.652_2
C_5H_5—C_5R_5	3.308	3.304(9)	3.305 Eclipsed	3.304 Eclipsed
C—C (C_5H_5)	1.389	1.399(6)	1.400	1.418
C—C (C_5R_5)	1.389	1.408(6)		1.438

[a] Ref: this work.

($C_5R'_5$)] derivatives [Fe—C *ca* 2.04 Å, Fe—(ring centroid) *ca* 1.645–1.66 Å] and outside the range observed for $[Fe(C_5H_5)L_1L_2L_3]$ derivatives [Fe—C *ca* 2.10 Å, Fe—(ring centroid) *ca* 1.74 Å]. The *ipso*-carbon atoms of each of the phenyl rings are displaced slightly from the C_5 plane by between 0.01 and 0.1 Å, with the average distance being 0.09 Å. These *ipso*-carbon atoms and the iron atom are on the opposite sides of the C_5 plane, similar to the configuration in $[Fe(C_5Ph_5)(CO)_2Br]$.[20] The phenyl rings are all also planar with normal dimensions and are oriented at between 44.3° and 61.8° to the C_5 ring of the $(C_5Ph_5)^-$ ligand. The average deviation of the phenyl rings from coplanarity with the C_5 ring of the $(C_5Ph_5)^-$ ligand is 52.0°. Selected bond distances of $[Fe(C_5R_5)(C_5H_5)]$ (R = H, Me, *p*-tolyl, Ph) are compared in Table 3.

EXPERIMENTAL

All synthetic manipulations were performed under an atmosphere of dinitrogen using standard inert-atmosphere techniques. All solvents used were analytical grade. Benzene (Merck) and THF (Merck) were pre-dried over sodium wire, distilled from sodium benzophenone ketyl under an atmosphere of dinitrogen and degassed for at least 30 min prior to use. Chlorobenzene (Fluka) was dried, distilled and stored over calcium hydride. Iron pentacarbonyl (Aldrich) was used as received. 1-Bromo-1,2,3,4,5-pentaphenylcyclopenta-2,4-diene was prepared as described previously.[38] Bromodicarbonylpentaphenylcyclopentadienyliron, $[Fe(C_5Ph_5)(CO)_2Br]$, was prepared by literature methods and was characterized spectroscopically.[20,32]

NMR spectra were recorded on a Bruker AC200F spectrometer. Spectra were referenced internally against the residual solvent resonances [CD_2Cl_2 ^1H NMR δ 5.30 ppm; ^{13}C NMR δ 54.20 ppm; $(CD_3)_2CO$ ^1H NMR δ 2.05 ppm]. IR spectra were recorded using a Digilab FTS-80 Fourier transform spectrometer with 20/80 FTS optics. Electrochemical experiments were performed using a BAS-100 electrochemical analyser. Data were transferred to an Osborne-PC Executive Microcomputer using BAS File Transfer software. A three-electrode configuration was used. The working electrode was a BAS glassy carbon disc (3 mm diameter), which was polished with an alumina (0.25 μm grade) suspension before each cyclic voltammogram was recorded. The auxiliary electrode was a platinum wire (0.5 mm diameter, 4 cm length) and the reference electrode was a BAS Ag/AgCl/KCl(sat.) electrode. All samples were thoroughly degassed with high purity argon (CIG), which was prebubbled through a Cr^{2+} scrubber (0.2 M Cr^{2+}/0.5 M $HClO_4$) and a sulphuric acid (18 M) bubbler tower to remove any traces of oxygen and water, respectively. All potentials are quoted relative to the ferrocinium/ferrocene redox couple, which was observed at +627 mV against the reference electrode. Samples were examined as *ca* 1 mM solutions in THF with tetra(1-butyl) ammonium tetrafluoroborate (*ca* 0.1 M) as the supporting electrolyte. The tetra(1-butyl) ammonium tetrafluoroborate was prepared from tetrafluoroboric acid (35% (v/v) Merck) and aqueous tetra(1-butyl)ammonium hydroxide (40% (w/w) Aldrich).

Solution densities were determined using a Paar precision density meter, model DMA-602 at 25.00 ± 0.01°. Refractive indices of solutions at the sodium D-line were determined using an Abbe 60 refractometer at 25.00 ± 0.05°. Solution dielectric constants were determined by measuring the capacitance at 100 kHz of a condenser filled alternatively with sample solution, solvent and air. A heterodyne beat method was used with a Sullivan precision variable condenser and a glass and nickel cell at 25.00 ± 0.05°.

X-ray diffraction data were recorded using an Enraf–Nonius CAD4-F diffractometer with Mo-K_α radiation, λ = 0.71069 Å.

Melting points were recorded on a Reichert hot platform in air and are uncorrected.

Synthesis of 1,2,3,4,5-*pentaphenylferrocene*

1,2,3,4,5-Pentaphenylferrocene was prepared following a variation on the procedure of McVey and Pauson.[32] A THF solution of cyclopentadienylsodium (2 cm^3, 0.15 g, 6.5 mmol sodium, 0.44 g, 6.8 mmol cyclopentadiene) was added to a stirred solution of $[Fe(C_5Ph_5)(CO)_2Br]$ (4.0 g, 6.3 mmol) in THF (75 cm^3) at room tem-

perature. After 3 h the solution was filtered and the solvent stripped from the filtrate. The combined dried solids were heated at 200°C under vacuum for 5 h and the cooled residue extracted with hot benzene (250 cm^3). The extract was filtered and the solvent evaporated to produce an orange–brown residue with weak IR absorptions at 2007 and 1955 cm^{-1}, consistent with the presence of a small amount of [Fe(η^5-C_5Ph_5)(η^1-C_5Ph_5)$(CO)_2$].[32] The products were separated by chromatography on flash silica (60–400 mesh) using a 1 : 1 (v/v) mixture of petroleum ether (40/60) and benzene as an eluent. The orange fraction, pentaphenylferrocene, was separated from colourless pentaphenylcyclopentadiene by fractional crystallization from chlorobenzene. After several recrystallizations from chlorobenzene, pentaphenylferrocene was obtained as orange tubular crystals, which were suitable for X-ray crystal structure analysis. Yield 2.04 g, 57%; m.p. >300°C (lit.[32] 356–358°C). ^{1}H NMR (CD_2Cl_2, 200.13 MHz): δ 7.1–7.0 (m, 25H, Ar—*H*), 4.3 (s, 5H, C_5H_5) ppm. ^{13}C NMR (CD_2Cl_2, 50.33 MHz): δ 136.6 (quaternary Ar—*C*) 132.7, 127.5, 126.5 (Ar—*C*H). 88.2 (quaternary Cp—*C*), 75.4 (C_5H_5) ppm. IR (KBr) ν_{max}: 1599(m), 1502(s), 1478(w), 1443(m), 1402(s), 1108(w), 1073(w), 1027(w), 1005(w), 814(m), 801(w), 742(s), 709(s), 699(s), 688(m) cm^{-1}.

Synthesis of trans-*bis(pentaphenylcyclopentadienyl)di(μ-carbonyl)dicarbonyldiiron*

A solution of pentaphenylcyclopentadienyl bromide (5.00 g, 9.55 mmol) was prepared by stirring the solid in freshly distilled benzene (100 cm^3) under an atmosphere of nitrogen for 4 h. Iron pentacarbonyl (2.4 g, 12 mmol) was added via a syringe to the orange solution. The deep purple colour characteristic of the pentaphenylcyclopentadienyl radical rapidly developed. The reaction mixture was refluxed for 18 h and cooled to room temperature to give an extremely deep green solution and a fine precipitate, which was separated by filtration. The solvent was stripped from the green filtrate leaving a brown solid, which was identified as [Fe(η^5-C_5Ph_5)$(CO)_2$Br] on the basis of its IR spectrum.[20] The residue in the reaction flask was a layered mixture of an orange–brown solid and a deep green microcrystalline solid. A sample of the green solid was mechanically separated, thoroughly dried under high vacuum and analysed by elemental analysis, IR and ^{1}H NMR spectroscopy. This sample was not sufficiently stable in solution to permit the acquisition of a ^{13}C NMR spectrum. The green material was formulated as the iron dimer, *trans*-[Fe(η^5-C_5Ph_5)$(CO)_2$]$_2$. Yield *ca* 0.4 g, 8%; m.p. 215–20°C (dec.). Found: C, 79.5; H, 4.7. Calc. for $C_{74}H_{50}Fe_2O_4$: C, 79.7; H, 4.5%. ^{1}H NMR [$(CD_3)_2CO$, 200.13 MHz]: δ 7.2–7.0 (m, Ar—*H*), 2.8 (s, broad) ppm. IR (KBr) ν_{max}: 2033(w), 1951(vs), 1913(m), 1787(vs), 1754(m), 1601(w), 1503(m), 1475(w), 1444(m), 1402(m), 1182(w), 1076(w), 1023(w), 802(w), 741(s), 703(s), 679(s), 597(s) cm^{-1}.

Structure determination

Cell constants were determined by a least squares fit to the θ values of 25 independent reflections, measured and refined on an Enraf–Nonius CAD-4 diffractometer with a graphite monochromator. Data were reduced and Lorentz, polarization and decomposition corrections were applied using the Enraf–Nonius Structure Determination Package.[39] The structure was solved by direct methods within the SHELXS-86 program.[40] Non-hydrogen atoms were refined anisotropically and hydrogen atoms were included at calculated sites (C—H 0.97 Å) with group isotropic thermal parameters. Blocked-matrix least-squares refinement was performed using the program SHELX-76.[41] Scattering factors and anomalous dispersion corrections for iron were taken from the International Tables,[42] and for all others the values supplied in SHELX-76 were used. Full tables of bond lengths and angles and listing of atom coordinates, thermal parameters, details of least-squares planes calculations and observed and calculated structure factor amplitudes have been deposited.* Figures were drawn using the program ORTEP.[43]

Crystal data

$C_{40}H_{30}Fe$, M = 566.5, monoclinic, space group, $C_{2/c}$, a = 42.646(8), b = 10.314(3), c = 14.655(4) Å, β = 96.16(2), U = 6408 $Å^3$, D_c (Z = 8) = 1.178 g cm^{-3}, $F(000)$ = 2368, μ(Mo-K_α) = 4.93 cm^{-1}. DINUCLEAR RUTHENIUM(III) COMPLEXES AND THEIR REACTIONS WITH CO AND NOCl: SYNTHESIS, CHARACTERIZATION AND ELECTROCHEMICAL STUDIES

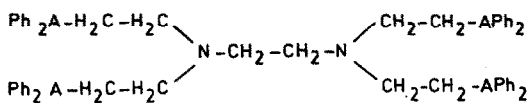
PARIMAL PAUL

Discipline of Coordination Chemistry and Homogeneous Catalysis, Central Salt and Marine Chemicals Research Institute, Bhavnagar 364002, India

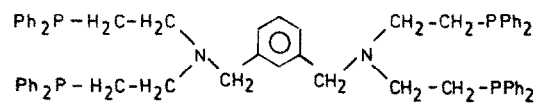
(*Received* 5 *January* 1993; *accepted* 30 *March* 1993)

Abstract—A series of dinuclear ruthenium(III) complexes was synthesized by the reaction of $RuCl_3(AsPh_3)_2MeOH$ with the hexadentate ligands BDPE, BDAE and BDPX, with N_2P_4/N_2As_4 donor sites [BDPE = α,α′-bis(bis(2-(diphenylphosphino)ethyl)amino)ethane, BDAE = α,α′-bis(bis(2-(diphenylarsino)ethyl)amino)ethane and BDPX = α,α′-bis(bis(2-(diphenylphosphino)ethyl)amino)-*m*-xylene). In some cases the mixture of products was separated by column chromatography and characterized. By passing CO through the dichloromethane solution of the above complexes for 20 h the CO adducts were formed with the reduction of ruthenium(III) to ruthenium(II). The reactions of NOCl with ruthenium(III) complexes resulted in the displacement of one Cl or $AsPh_3$ per metal by NO and the ruthenium(III) was reduced to ruthenium(II). The geometry of the complexes was established by $^{31}P\{^1H\}$ NMR spectral data. The cyclic voltammetric behaviour of these complexes was also reported.

The chemistry of transition metal complexes with chelated tertiary phosphine or arsine ligands has gained considerable interest in recent years. Among many reports the chemistry of ruthenium with the ligands having donor sets P_3, NP_2 and NAs_2 are of special interest due to their interesting structural features and reactivities.[1–11] A number of such complexes were also reported from this laboratory with ruthenium and with other transition metal ions.[3–6,12–14] For extensive studies in this area three hexadentate ligands having σ-donor and π-acidic mixed donor sites (N_2P_4 and N_2As_4) have been synthesized and their chemistry with copper(I),[15–19] ruthenium(II),[20] nickel(II) and cobalt(II)[21] have been reported recently. This paper reports the synthesis and characterization of a number of dinuclear ruthenium(III) complexes with the ligands BDPE, BDAE and BDPX and their reactions with CO at normal pressure and ambient temperature and with NOCl [where BDPE = α,α′-bis(bis(2-(diphenylphosphino)ethyl)amino)ethane, BDAE = arsenic analogue of BDPE and BDPX = α,α′-bis(bis(2-(diphenylphosphino)ethyl)amino-*m*-xylene]. The cyclic voltammetric behaviour of these complexes is also reported.



A=P (BDPE)
A=As (BDAE)



(BDPX)

EXPERIMENTAL

Materials

The ligands BDPE, BDAE and BDPX were synthesized by the procedure recently developed in this laboratory.[15] $RuCl_3(AsPh_3)_2MeOH$ was prepared by the published procedure.[22] CO gas was obtained by the dropwise addition of concentrated H_2SO_4 into sodium formate. NOCl was generated *in situ*

by the reaction of sodium nitrite with hydrochloric acid. All solvents used were of reagent grade and were purified and dried before use. All preparations, except reactions with CO, were performed under nitrogen.

Physical measurements

Elemental analyses were performed on a Carlo–Erba elemental analyser model 1106. A digisum Electronics digital conductivity meter model D1-909 was used for conductivity measurement. Magnetic measurements were performed with a PAR model 155 vibrating sample magnetometer. IR spectra were recorded on a Carl–Zeiss Specord M80 spectrometer, as KBr pellets. $^{31}P\{^{1}H\}$ NMR spectra were recorded on a Jeol FX-100 FT NMR using a 10 mm spinning tube with a capillary of deuterium oxide for the internal lock. The UV–Vis spectra were recorded on a Shimadzu UV-160 spectrometer. Electrochemical measurements were performed with a PAR electrochemical instrument; for cyclic voltammograms a PAR 175 Universal programmer coupled with the PAR 174A analyser was used with a glassy carbon working electrode. All potentials were measured against S.C.E. at 25°C and tetrabutylammoniumperchlorate was used as a supporting electrolyte.

Synthesis of metal complexes

$[Ru_2(BDPE)(AsPh_3)_2Cl_6]$ (**1**) *and* $[Ru_2(BDPE)Cl_6]$ (**2**). To a boiling solution of $RuCl_3(AsPh_3)_2MeOH$ (0.426 g, 0.5 mmol) in dichloromethane (50 cm^3) was added dropwise BDPE (0.227 g, 0.25 mmol) dissolved in dichloromethane (10 cm^3) and after complete addition refluxing was continued for 3 h. The solvent from the reaction mixture was removed by a rotary evaporator and the solid mass washed with benzene. The residue was passed through a silica gel column using a dichloromethane–methanol (9 : 1) solvent mixture; the first fraction of the eluant gave complex **1** (yield 0.24 g) and the second fraction yielded **2** (yield 0.1 g).

Complex **2** was also obtained as a single product in good yield when the above reaction was conducted in benzene. The reaction mixture was refluxed for 6 h and during this period complex **2** was separated by filtration and washed with benzene; yield 80%.

$[Ru_2(BDAE)Cl_6]$ (**3**) *and* $[Ru_2(BDPX)Cl_6]$ (**4**). These compounds were synthesized following the same procedure as described for **2** in benzene. Complexes **3** and **4** were recrystallized from a dichloromethane–n-hexane solvent mixture; yield 70–80%.

$[Ru_2(BDPE)(CO)_2Cl_4]$ (**5**, **5a**) $[Ru_2(BDAE)(CO)_2Cl_4]$ (**6**) *and* $[Ru_2(BDPX)(CO)_2Cl_4]$ (**7**). To a dichloromethane solution of complexes **1–4** (0.2 mmol) CO gas was passed through for 20 h at ambient temperature with stirring. During this period the colour of the solution changed from green to brown. The solution was then concentrated to *ca* 5 cm^3 and n-hexane was added dropwise with stirring. The brown microcrystalline compounds that deposited were collected by filtration and recrystallized from a dichloromethane–n-hexane solvent mixture; yield 85–90%.

$[Ru_2(BDPE)(NO)_2Cl_6]$ (**8**), $[Ru_2(BDPE)(NO)_2Cl_4]Cl_2$ (**8a**), $[Ru_2(BDAE)(NO)_2Cl_4]Cl_2$ (**9**) *and* $[Ru_2(BDPX)(NO)_2Cl_4]Cl_2$ (**10**). Complexes **1–4** (0.2 mmol) were taken in a suspension of methanol (50 cm^3) and to this mixture $NaNO_2$ (0.03 g) and concentrated HCl (0.2 cm^3) were added. The reaction mixture became clear after refluxing for 5 h. The solution was concentrated to *ca* 30 cm^3 and kept at room temperature overnight. The brown compounds which separated were collected by filtration, washed with water and ethanol and dried *in vacuo*; yield 65–70%.

RESULTS AND DISCUSSION

The reaction of $RuCl_3(AsPh_3)_2MeOH$ with BDPE in a 2 : 1 molar ratio in CH_2Cl_2 resulted in the formation of a mixture of two complexes of compositions $[Ru_2(BDPE)(AsPh_3)_2Cl_6$ (**1**) and $[Ru_2(BDPE)Cl_6]$ (**2**), separated by column chromatography. The same reaction when conducted in benzene gave complex **2**, which precipitated during the reaction. The ^{31}P NMR spectra of the filtrate indicated the formation of **1**, but the yield was so poor that the pure compound could not be isolated. Similar reactions with the ligands BDAE and BDPX in benzene gave dinuclear complexes $[Ru_2(BDAE)Cl_6]$ (**3**) and $[Ru_2(BDPX)Cl_6]$ (**4**), respectively. To a dichloromethane solution of complexes **1–4** CO gas was passed through for 20 h at ambient temperature. During this period the colour of the solution changed from green to brown and the isolated products were diamagnetic [low-spin ruthenium(II)] with the composition $[Ru_2L(CO)_2Cl_4]$, where L = BDPE (**5** and **5a**), BDAE (**6**) and BDPX (**7**), obtained from **1**, **2**, **3** and **4**, respectively. The reactions of complexes **1–4** with NOCl in methanol resulted in the formation of dinuclear diamagnetic complexes of the compositions $[Ru_2(BDPE)(NO)_2Cl_6$ (**8**) and $[Ru_2L(NO)_2Cl_4]Cl_2$, where L = BDPE (**8a**), BDAE (**9**) and BDPX (**10**), obtained from **1**, **2**, **3** and **4**, respectively. The compositions of all the complexes were confirmed by elemental analysis, presented in Table 1.

Table 1. Analytical data for the complexes[a]

Complex	Analysis (%) C	H	N
$[Ru_2(BDPE)(AsPh_3)_2Cl_6]$ (**1**)	58.5 (58.3)	4.8 (4.7)	1.4 (1.5)
$[Ru_2(BDPE)Cl_6]$ (**2**)	52.3 (52.6)	4.4 (4.5)	2.0 (2.1)
$[Ru_2(BDAE)Cl_6]$ (**3**)	46.1 (46.4)	3.9 (4.0)	1.8 (1.9)
$[Ru_2(BDPX)Cl_6]$ (**4**)	55.2 (54.9)	4.4 (4.6)	1.9 (2.0)
$[Ru_2(BDPE)(CO)_2Cl_4]$ (**5**)	54.9 (55.1)	4.7 (4.6)	2.0 (2.1)
$[Ru_2(BDPE)(CO)_2Cl_4]$ (**5a**)	55.0 (55.1)	4.5 (4.6)	2.0 (2.1)
$[Ru_2(BDAE)(CO)_2Cl_4]$	48.3 (48.5)	4.1 (4.0)	1.8 (1.9)
$[Ru_2(BDPX)(CO)_2Cl_4]$ (**7**)	57.4 (57.2)	4.7 (4.6)	1.9 (2.0)
$[Ru_2(BDPE)(NO)_2Cl_6]$ (**8**)	49.8 (50.3)	4.1 (4.3)	3.9 (4.1)
$[Ru_2(BDPE)(NO)_2Cl_4]Cl_2$ (**8a**)	50.0 (50.3)	4.2 (4.3)	4.0 (4.1)
$[Ru_2(BDAE)(NO)_2Cl_4]Cl_2$ (**9**)	44.9 (44.6)	3.8 (3.9)	3.4 (3.6)
$[Ru_2(BDPX)(NO)_2Cl_4]Cl_2$ (**10**)	52.2 (52.6)	4.3 (4.4)	3.7 (3.8)

[a] Calculated values are given in parentheses.

Conductivity measurements in DMF show that complexes **1–8** are non-electrolytes and **8a–10** correspond to 1 : 2 electrolytes (Table 2). These results indicate that in complexes **1–8** all of the chloride ions are coordinated to the metal ion and in **8a–10** two chlorides in each complex are not involved in coordination.

Magnetic susceptibility measurements showed that complexes **1–4** are paramagnetic (μ_{eff} in the range 1.8–1.96 B.M. per metal) and the moments correspond to one unpaired electron, as expected for low-spin octahedral ruthenium(III)-d^5 complexes. Complexes **5–10** are diamagnetic, as expected for spin-paired ruthenium(II)-d^6 octahedral complexes. These results indicate that the reaction of CO and NOCl with complexes **1–4** resulted in a reduction of ruthenium(III) to ruthenium(II) with the coordination of CO and NO^+ to the metal ion. A similar reductive addition of CO has also been reported for a number of ruthenium(III) complexes with π-acidic ligands such as PPh_3 and $AsPh_3$.[23]

Some selected IR bands of the complexes are shown in Table 2. The IR spectra of all the complexes having BDPE or BDPX as the ligand exhibit a band of medium intensity in the range 510–518 cm^{-1}, which is assigned to ν(Ru—P).[3,4,6,20] For the complexes of BDAE the band in the range 478–482

Table 2. Selected IR bands[a] and conductivity data[b] for the complexes

Complex	IR data (cm^{-1})[a] ν (Ru—P/As)	ν (Ru—Cl)	ν (CO)	ν (NO)	Conductivity[b] Λ_M ($\Omega^{-1}cm^2mol^{-1}$)	Comment
1	510 m, 480 m	320 w, 310 w			8	Non-electrolyte
2	515 m	318 w, 305 w			12	Non-electrolyte
3	482 m	320 w, 305 w			6	Non-electrolyte
4	515 m	330 w, 316 w			7	Non-electrolyte
5	515 m	322 w	1960 s		10	Non-electrolyte
5a	512 m	330 w, 318 w	1960 s		10	Non-electrolyte
6	480 m	328 w, 315 w	1982 s		12	Non-electrolyte

[a] As KBr pellets.
[b] In DMF.
s = strong, m = medium, w = weak.

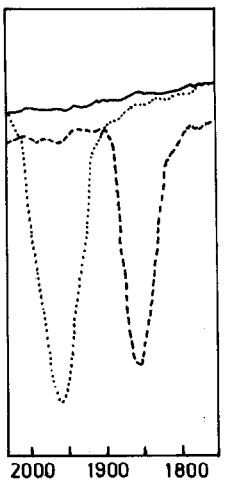

Fig. 1. IR spectra of the complexes **2**, **5a** and **8a** in the range 1750–2050 cm^{-1}, recorded as KBr pellets. (——) $[Ru_2(BDPE)Cl_6]$ (**2**), (·····) $[Ru_2(BDPE(CO)_2Cl_4]$ (**5a**) and (- - - -) $[Ru_2(BDPE)(NO)_2Cl_4]Cl_2$ (**8a**).

cm^{-1} is due to ν(Ru—As).[3,4,20] In all complexes two weak bands appeared in the range 305–332 cm^{-1}, which may be assigned to ν(Ru—Cl).[3–6,20] The bonding of CO or NO^+ in complexes **5–10** is confirmed by IR spectral data. Complexes **5–7** show a strong band in the range 1955–1982 cm^{-1} and **8–10** show a strong band in the range 1850–1875 cm^{-1}, which may be assigned to ν(CO)[7,10,23] and $\nu(NO^+)$,[24–26] respectively. The IR spectra of complex **2** and its CO (**5a**) and NO (**8a**) adducts in the range 1750–2050 cm^{-1} are shown in Fig. 1.

The electronic spectral data of complexes **1–10** in the range 700–300 nm in DMF are presented in Table 3. In this range all complexes exhibit four absorption bands. Similar observations were also reported for a number of ruthenium(III) and ruthenium(II) complexes with tertiary phosphine and arsine ligands.[3,6,20,27] The first two bands may be due to *d–d* transitions,[3,20] whereas the other higher energy bands can be assigned to LMCT; the charge-transfer involving phosphorus or arsenic lone pairs.

Geometry

The $^{31}P\{^1H\}$ NMR spectral data (Table 3) are extremely useful for geometrical assignment. All the complexes except **8** showed a singlet in the range δ 27.37–45.11, suggesting that all the phosphorus atoms in each complex are magnetically equivalent. Complex **1** shows a singlet at δ 45.11, whereas **2** and **4** exhibit singlets at δ 32.33 and 31.52, respectively. The δ value at 45 ± 2 is usually found for the phosphorus atoms of PPh_2 *trans* to chloride in ruthenium complexes with NP_2 donor sets.[3,4,6,20] With a similar donor set the δ value of 30 ± 2 was reported for a number of complexes where the phosphorus atoms of PPh_2 are *trans* to each other.[3,4,6,20] The data, therefore, suggest that in complex **1** two PPh_2 groups bonded to each metal ion are *trans* to chloride and in complexes **2** and **4** *trans* to each other. With this information and other data a dinuclear octahedral geometry for **1** with $AsPh_3$ and Cl in axial positions, as shown in structure **I**, is suggested. For complexes **2** and **4** an octahedral

geometry with a *trans* disposition of phosphorus atoms of PPh_2 in the square plane of the octahedron and two Cl in axial positions, as shown in structure **II**, are suggested. For complex **3** a similar geometry is expected. The CO adducts **5**, **5a** and **7** show singlets at 32.64, 28.37 and 29.00, respectively. For complexes **5a** and **7** there is no remarkable change in chemical shift of the phosphorus atom compared with the parent compounds, therefore, a similar geometry as found for **2** and **3** with the displacement of one Cl by CO in the axial position, as shown in structure **III**, is suggested. The displacement of Cl by CO in the axial position is also supported by the IR data, which exhibit two bonds of ν(Ru—Cl) indicating a *cis* disposition of Cl. In the case of complex **5** there is a considerable upfield shift of the ^{31}P signal compared with the parent compound (**1**). This result indicates that the replacement of $AsPh_3$ by CO with the reduction of ruthenium(III) to ruthenium(II) changes the geometry of the metal ion. The δ value (32.64) indicates that the position of the phosphorus atoms *trans* to chloride is unlikely and again the geometry is not the same as shown in structure **III** since the other physicochemical data of **5** and **5a** are not identical. This possibility is shown in structure **IV**. For complex **6** a similar geometry as shown in structure **III** is proposed. The NO complex (**8**) shows two broad signals at 5.33 and 34.27 with equal intensity, indicating the presence of two types of non-equivalent phosphorus atoms. The signal at 5.33 is assigned to the phosphorus atom *trans* to NO and a notable upfield shift of this signal may be due to the strong *trans* effect of NO^+. The splitting of the signals into a doublet, as expected from two non-equivalent phosphorus atoms, could not be observed at room temperature. The proposed geometry is shown in structure **V**. Complexes **8a** and **10** show singlets at δ 30.03 and 29.25, respectively, indicating the equivalence of all phosphorus atoms in each complex. This observation is similar to that of the CO adduct and, therefore, an octahedral geometry with NO in the axial position, as shown in structure **VI**, is suggested. For complex **9** one can expect a similar geometry as found for **8a**.

Electrochemical study

The cyclic voltammetric behaviour of complexes **1–10** was studied in the potential range 0 to +1.5 V (vs S.C.E.) in DMF at 25 ± 1°C, with scan rates of 100–500 mV s^{-1}. In this range all complexes show two quasi-reversible one-electron redox potentials (Table 4). The differences in potential for the anodic and cathodic peaks (ΔE_p) were in the range 80–110 mV, consistent with a quasi-reversible one-electron process. The two waves can be attributed to the sequential one-electron transfer process for the Ru^{III}/Ru^{II} couple, as found for other dinuclear complexes of different transition metal ions with the same ligands.[18–21] Similar observations were also reported for a number of dinuclear ruthenium complexes and are often used to calculate the stability of the mixed-valence species,[28] expressed in terms of the comproportionation constant K_{com}:

$$K_{com} = \mathrm{Exp}\,(nF(\Delta E/RT));$$

where ΔE is the difference between the two potentials in V. The K_{com} values thus calculated are presented in Table 4. The K_{com} values indicate that the mixed-valence species are moderately stable and

Table 4. Cyclic voltammetry data of the complexes in DMF

Complex	$E^1_{1/2}$	$E^2_{1/2}$	K_{com}
$Ru_2(BDPE)(AsPh_3)_2Cl_6]$ (1)	0.56	1.12	2.99×10^9
$[Ru_2(BDPE)Cl_6]$ (2)	0.48	0.92	2.79×10^7
$[Ru_2(BDAE)Cl_6]$ (3)	0.38	0.80	1.28×10^7
$[Ru_2(BDPX)Cl_6]$ (4)	0.40	0.86	6.07×10^7
$[Ru_2(BDPE)(CO)_2Cl_4]$ (5)	0.60	1.08	1.32×10^8
$[Ru_2(BDPE)(CO)_2Cl_4]$ (5a)	0.60	1.06	6.07×10^7
$[Ru_2(BDAE)(CO)_2Cl_4]$ (6)	0.52	1.02	2.88×10^8
$[Ru_2(BDPX)(CO)_2Cl_4]$ (7)	0.56	1.00	2.79×10^7
$[Ru_2(BDPE)(NO)_2Cl_6]$ (8)	0.76	1.18	1.31×10^7
$[Ru_2(BDPE)(NO)_2Cl_4]Cl_2$ (8a)	0.73	1.16	1.94×10^7
$[Ru_2(BDAE)(NO)_2Cl_4]Cl_2$ (9)	0.65	1.10	4.24×10^7
$[Ru_2(BDPX)(NO)_2Cl_4]Cl_2$ (10)	0.70	1.14	2.87×10^7

this is probably due to the presence of σ-donor and π-acceptor coordinating atoms in the principal ligands.

(*Received* 23 *March* 1993; *accepted* 25 *June* 1993)

Abstract—The interaction of a racemic mixture of N,N′-bis[*o*-(diphenylphosphino)benzylidene-2,2′-diimino-1,1′-binaphthyl (Binap-P_2N_2) (**I**) with 1 equivalent of $Cu(Ph_3P)_2Br$ and $[Cu(CH_3CN)_4]PF_6$ in CH_2Cl_2 gave Cu(Binap-P_2N_2)Br (**II**) and [Cu(Binap-P_2N_2)]PF_6 (**III**) in 60 and 74% yield, respectively. The structure of **II** was established by X-ray diffraction and can be described as distorted tetrahedral with the bromide ion and the two phosphino groups and one of the two imino groups of **I** coordinated to the copper. Variable temperature $^{31}P\{^1H\}$ NMR study of **II** shows that the coordinated and the uncoordinated imino groups of the tridentate Binap-P_2N_2 ligand undergo a facile intramolecular exchange even at −55°C.

The potential of polydentate ligands having both soft and hard centres being good bridging ligands for the preparation of heterobimetallic complexes containing an oxophilic metal and late transition metal has led to extensive study on the synthesis and reactivities of polydentate ligands containing both phosphine and nitrogen base groups.[1–3] Recently, we have examined the reactivity of N,N′-bis[*o* - (diphenylphosphino)benzylidene]ethylenediamine, (P_2N_2), toward transition metal complexes and have shown that the P_2N_2 ligand can act as bridging, bi-, tri-, or tetra-dentate ligand depending on the reaction conditions.[4–6] In this communication, we report the reactivity of the analogous diiminodiphosphine ligands, N,N′-bis[*o*-(diphenylphosphino)benzylidene]-2,2′-diimino-1,1′-binaphthyl (Binap-P_2N_2) (**I**) toward copper(I) complexes.

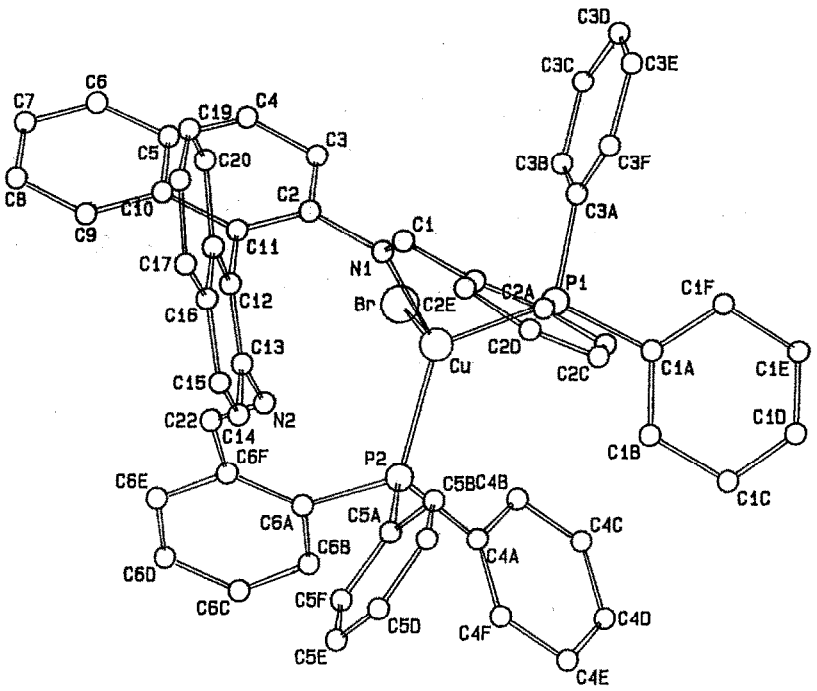

Fig. 1. A perspective view of the molecular structure of $Cu(C_{58}H_{42}N_2P_2)Br$. Selected bond lengths (Å) and bond angles (°): Cu—Br, 2.446(2); Cu—P(1), 2.261(4); Cu—P(2), 2.270(4); Cu—N(1), 2.28(1); C(1)—N(1) 1.27(2); C(22)—N(2), 1.24(2); Br—Cu—P(1), 118.3(1); Br—Cu—P(2), 104.1(1); Br—Cu—N(1), 108.5(3); P(1)—Cu—P(2), 122.0(2); P(1)—Cu—N(1), 82.6(4); P(2)—Cu—N(1), 120.5(3).

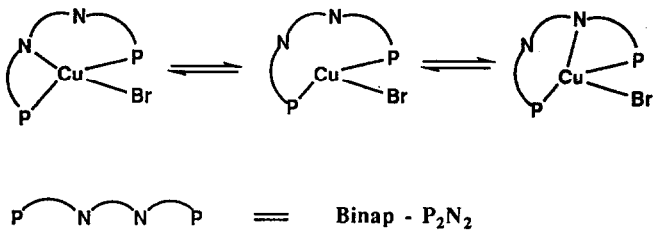
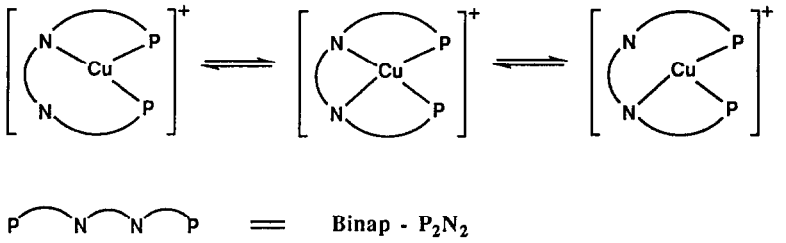
When a racemic mixture of Binap-P_2N_2 was treated with 1 equivalent of $Cu(Ph_3P)_2Br$ in refluxing dichloromethane for 12 h, work up gave orange crystals of stoichiometry $Cu(Binap\text{-}P_2N_2)Br \cdot CH_2Cl_2$ (**II**), in moderate yield (60%) after recrystallization from a CH_2Cl_2/Et_2O mixture.[7] The structure of **II** was established by an X-ray diffraction study. Crystals of stoichiometry $[Cu(Binap\text{-}P_2N_2)Br]2.5CHCl_3$ suitable for X-ray diffraction study were grown from a mixture of $CHCl_3$/hexane.* A perspective drawing and selected bond lengths and bond angles of **II** are shown in Fig. 1 and its caption. All bond lengths and bond angles are normal. The structure can be described as a distorted tetrahedral with the bromide ligand and the two phosphino groups and one of the two imino groups of the Binap-P_2N_2 ligand coordinated to the copper. The dihedral angle between the two least planes of the naphthene units in the binaphthenene moiety is 74.8°. The non-bonding distance between Cu and N(2) is 3.35(1) Å. ^1H NMR spectrum of **II** exhibits a singlet at δ 8.21 ppm for the imino protons and a complex multiplet at δ 6.80–7.75 ppm for the phenyl and binaphthyl protons. The ambient temperature $^{31}P\{^1H\}$ NMR spectrum of **II** exhibits a broad singlet (width at half-height is 150 Hz) which broadens slightly on cooling to −55°C (width at half-height is 160 Hz) at δ −12.4 ppm. This suggests that the coordinated imino group and the uncoordinated imino group of **II** undergo a facile intramolecular exchange as shown in Scheme 1. Similar dynamic behaviour has been reported for $[Cu(P_2N_2)(t\text{-}BuNC)]ClO_4$.[8]

When a racemic mixture of Binap-P_2N_2 was treated with 1 equivalent of $[Cu(CH_3CN)_4]PF_6$ in refluxing dichloromethane for 12 h, work up gave

* Crystal data for $C_{58}H_{42}N_2P_2CuBr \cdot 2.5CHCl_3$: F_w = 1270.82, monoclinic, $P2_{1/c}$ (No. 14), a = 14.114(3), b = 15.633(8), c = 27.429(9) Å, β = 99.56(4)°, V = 5968.1(4) Å^3, Z = 4, $F(000)$ = 2572, D_c = 1.414 g cm^{-3}, μ = 14.6 cm^{-1}. Crystal dimensions: 0.20 × 0.20 × 0.41 mm. Intensity data were collected on an Enraf–Nonius CAD-4 diffractometer with graphite monochromated Mo-K_α radiation (λ = 0.71073 Å) using ω–2θ scans ($2\theta_{max}$ = 45°). The structure was solved by a combination of Patterson and direct methods (DIRDIF) after an absorption correction (transmission factors 0.935–0.998) was applied and refined by full-matrix least-squares to give R = 0.089, R_w = 0.112 for 4069 independent observed reflections [$I \geqslant 3\sigma(I)$].



Scheme 1. Proposed mechanism for the dynamic behaviour of **II**.



Scheme 2. Possible intramolecular exchange process for **III**.

orange crystals of stoichiometry [Cu(Binap-P_2N_2)]PF_6 (**III**) in good yield (74%) after recrystallization from a CH_2Cl_2/Et_2O mixture.[9] ^1H NMR spectrum of **III** exhibits a singlet at δ 8.28 ppm for the imino protons and a complex multiplet at δ 6.50–7.80 ppm for the phenyl and binaphthyl protons. The ambient temperature $^{31}P\{^1H\}$ NMR spectrum of **III** exhibits a broad singlet (width at half-height is 75 Hz) and a heptet [J(P—F) = 712.3 Hz] which remain unchanged on cooling to $-55°C$ at δ -11.6 and -145.1 ppm for the phosphorus of the Binap-P_2N_2 ligand and the PF_6^- anion, respectively. The spectroscopic data suggest that **III** is a tetrahedral complex with the Binap-P_2N_2 ligand acting as a tetradentate ligand. However, a recent X-ray diffraction study on the analogous silver complex, [Ag(Binap-P_2N_2)]BF_4, reveals that the silver is tri-coordinated with the two phosphino groups and one of the two imino groups of the Binap-P_2N_2 ligand coordinated to the silver.[10] Thus, one cannot rule out the possibility that **III** is a tri-coordinated complex having the coordinated and the uncoordinated imino groups of the tridentate ligand Binap-P_2N_2 undergoing a facile intramolecular exchange as shown in Scheme 2. We are in the process of growing crystals suitable for an X-ray diffraction study to confirm the solid state structure of **III**. Preliminary studies also show that **III** is an effective catalyst for aziridination of styrene by PhINTs (Ts = tosylate) at room temperature.

THE REMARKABLE POLYMETALLATE CLUSTER: CRYSTAL STRUCTURE OF $Na_6[H_6Mo_{57}Fe_6O_{183}(NO)_6(H_2O)_{18}]\cdot 91H_2O$

GUI-QING HUANG, SHI-WEI ZHANG* and MEI-CHENG SHAO

Institute of Physical Chemistry, Peking University, Beijing, 100871, P.R.C.

(*Received* 2 *June* 1993; *accepted* 15 *June* 1993)

Abstract—The crystal structure of $Na_6[H_6Mo_{57}Fe_6O_{189}(NO)_6(H_2O)_{18}]\cdot 91H_2O$ has been determined and shown to consist of three 17-molybdate subunits connected by six FeO_6 octahedra and three $\{Mo_2O_9\}$ groups.

Understanding the driving force for the formation of high-nuclearity clusters is still a formidable challenge.[1] We recently reported the structure with the largest polymetallate cluster involving mixed-valence molybdenum and vanadium(IV).[2] In this communication, we report another remarkable polymetallate also involving mixed valence molybdenum with iron(III) instead of vanadium(IV).

The compound was prepared according to the method described by Zhang *et al.*[2,3] a mixture of $Na_2MoO_4\cdot 2H_2O$ (1.92 g), FeS (0.33 g) and NH_2OH–HCl (2.56 g) in water (40 cm^3) and 1 mol dm^{-3} HCl (2 cm^3) was heated under nitrogen at reflux temperature with stirring for 2 h. The resultant dark solution was opened to the air after it was cooled to room temperature. The dark orange hexagonal and yellow needle crystals were obtained from the filtered solution after a few days and the former was characterized by elemental analysis, IR† and single-crystal X-ray structure analysis.‡

The title compound consists of three 17-molybdate subunits connected by six FeO_6 octahedra and three $\{Mo_2O_9\}$ groups, each of which are linked by one bridging oxygen atom and two bridging water molecules, and the subunits related to each other by a three-fold rotation axis; the cluster centre sits on a special position with $\bar{6}m2$ crystallographic symmetry and each individual subunit has internal C_{2v} symmetry (see Figs 1 and 2). In the centre cavity there are 12 water molecules, which are situated around a $\bar{6}$ axis and are coordinated to six molybdate and six iron groups, respectively. Moreover, these 12 water molecules are linked to each other by hydrogen bonding to form two six-membered rings.

The 17-molybdate subunit consists of one compact group of five predominantly edge-sharing MoO_6 octahedra and two $MoO_6(NO)$ pentagonal bipyramids viewed as an $\{Mo_7O_{24}(NO)_2\}$ unit of C_{2v} symmetry, characteristic of the heptamolybdate structure; the $\{Mo_7O_{24}(NO)_2\}$ unit is circled by a ring of 10 corner-sharing distorted MoO_6 octahedra to form a 17-molybdate unit. Such linking may give an indication about the possible mechanism of formation for the 17-molybdate subunit and polymolybdate clusters, which may involve an intact compact unit link $\{Mo_7O_{24}(NO)_2\}$ as a starting nucleus.

The most remarkable feature of the structure, however, is the manner of linking of the 17-mo-

† Found: Fe, 3.1; Mo, 50.0; Na, 0.9. Calc. for $Fe_6H_{250}Mo_{57}N_6Na_6O_{590}$: Fe, 3.0; Mo, 49.6; Na, 1.2%. IR (cm^{-1} in KBr): 3139s, 1618s, 1400vs, 944m, 880vs, 773s, 535m, 469m.

‡ Crystal data: single crystals of $Na_6[Mo_{57}Fe_6O_{183}H_6(NO)_6(H_2O)_{18}]\cdot 91H_2O$ at 293 K are hexagonal, space group $P6_3/mmc$, $a = 23.843(4)$, $c = 27.797(9)$ Å, $V = 13{,}685(7)$ Å^3 and $Z = 2$, $D_c = 2.69$, $D_x = 2.70$ g cm^{-3}. A total of 2602 independent reflections ($1 < 2\theta < 41$) were collected using $\omega/2\theta$ scans with graphite-monochromated Mo-K_α radiation. The structural parameters have been refined to convergence R (based on F^2) = 0.049 for 2076 observed reflections [$F > 4\sigma(F)$].

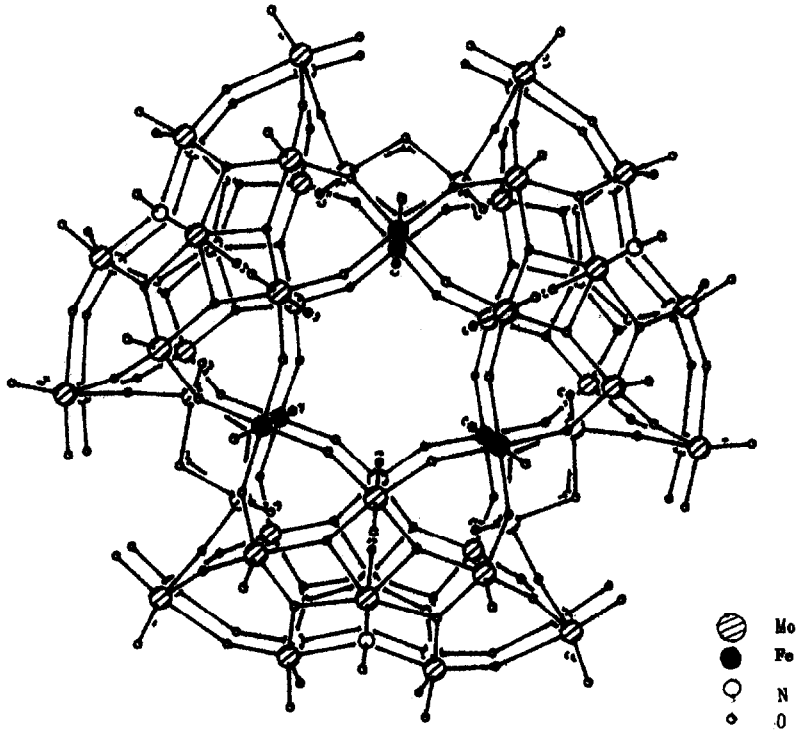

Fig. 1. Perspective drawing of the $[H_6Mo_{57}Fe_6O_{183}(NO)_6(H_2O)_{18}]^{6-}$ anion, viewed along the three-fold rotation axis.

lybdate subunits. In the Mo_{36} isopoly,[4] two 17-molybdate subunits are linked by two $Mo^{VI}O_6$ octahedra with four Mo—O bonds in $\bar{1}$ symmetry, but in the title high-nuclearity anions three 17-molybdate subunits are linked to each other by six $Fe^{III}O_6$ octahedra with four equatorial Fe—O bonds in C_{2v} symmetry, and three $\{Mo_2O_9\}$ groups occupy the three cavities of the anion.

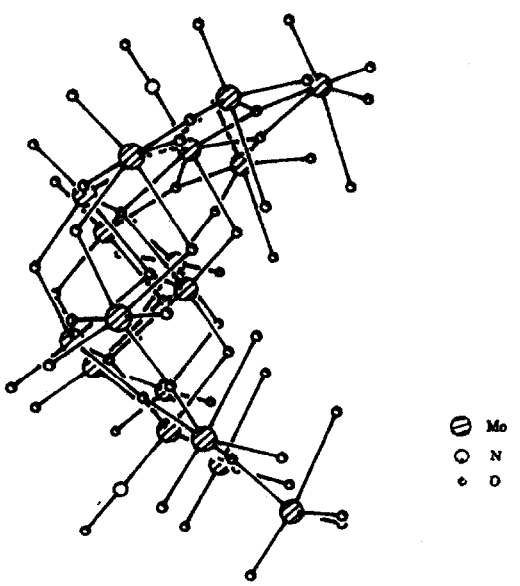

Fig. 2. The 17-molybdate subunit of the $[H_6Mo_{57}Fe_6O_{183}(NO)_6(H_2O)_{18}]^{6-}$ anion, viewed along the $2/m$ axis of the anion.

The same 17-molybdate unit exists in two polyanions also reported,[4] so we supposed that such a 17-molybdate unit is a relatively stable entity.[2] The title compound supports our idea. Moreover, we have synthesized the third high-nuclearity anion $[H_8MO_{57}Fe^{II}{}_6O_{185}(NO)_6(H_2O)_{16}(MoO)_2]^{6-}$, where the 17-molybdate subunit is linked by $Fe^{II}O_6$ instead of $Fe^{III}O_6$ or VO_6 octahedra by controlling the degree of oxidation.

Abstract—The reaction of the unexpectedly formed ligand 2-(2′-pyridyl)quinoxaline (L) with $CuCl_2$ in ethanol, followed by recrystallization from methanol, yields the dinuclear copper (II) complex $[Cu_2Cl_4L_2]$. The crystal structure of this compound shows a bidentate chelating behaviour of L and different (terminal, asymmetric bridging) chloride coordination modes. Some properties of the dimer are also described.

We wish to report the first X-ray crystal structure of a complex containing the ligand 2-(2′-pyridyl)quinoxaline (L). We believe this molecule has great potential as a generally-useful new polyfunctional ligand in metal chemistry and that it will thus prove attractive to a variety of inorganic chemists. Compound L, which may combine the chelating properties of 2,2′-bipyridine[1] with the bridging properties of quinoxaline,[2] belongs to a class of aromatic nitrogen heterocycles whose coordination chemistry is currently a subject of intense research.[3–5] The study of complexes of such ligands is important in developing our understanding of the theory of electron transfer processes, of mixed-valence compounds, of excited-state acid–base properties of inorganic compounds and of magnetic coupling interactions. Such compounds are also used to model important bioinorganic systems and are finding applications as photosensitizers,

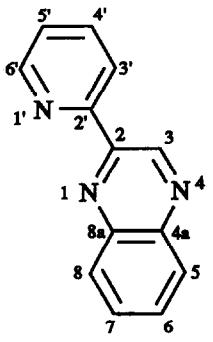
catalysts and in low-dimensional coordination polymers.



L

2-(2′-Pyridyl)quinoxaline was derived unexpectedly from an unusual cyclization reaction of 1,2-diaminobenzene and 2-acetylpyridine;[6] its identity was confirmed by microanalyses and spectroscopic techniques, including various types of mass spectroscopy and two-dimensional COSY NMR. A few 1 : 1 coordination compounds of L with transitional metal chlorides were also isolated and characterized by powder physical and spectroscopic methods.[6] In spite of many efforts neither the crystal structure of L nor that of any complex were known when we submitted our findings concerning the unexpected formation of this ligand.[6] During this period we did not stop seeking the crystal structure of a complex containing L, and we recently succeeded in growing single crystals of $[Cu_2Cl_4L_2]$ (**1**).

For the preparation of the complex, to a solution containing $CuCl_2$ (2.0 mmol) in ethanol (8 cm^3) was added dropwise a warm ethanol solution (10 cm^3) of L (1.9 mmol). Upon addition of the ligand a yellow precipitate was formed. Stirring was continued for 30 min. The solid was collected by filtration, washed with ethanol and diethyl ether and dried in air. The yield was 70–80%. The analytical data corresponded to the formula $CuCl_2L$. Brown crystals of **1** were obtained by recrystallization of the yellow material from hot methanol.*

The structure† of a molecule of **1** is shown in Fig. 1. The structure consists of two Cu^{II} centres bridged by two chloro ligands; a terminal chloro ligand and a bidentate chelating L molecule complete five-coordination at each metal. The molecules of **1** are well separated from each other. The bridging Cu_2Cl_2 is constrained to be planar by the presence of the crystallographic inversion centre in the middle of the dimer. Analysis of the shape-determining angles using the approach of Reedijk *et al.*[7] yields a value for trigonality index, τ, of 0.42 for Cu^{II} ($\tau = 0$ and 1 for perfect *sp* and *tbp* geometries, respectively). Thus, the geometry at each copper can be described as either a distorted square-pyramidal or a distorted trigonal-bipyramidal arrangement. With use of the *tbp* description the apical sites are occupied by Cl(2″) and N(1) with atoms Cl(1), Cl(2), N(1′) and Cu making up the equatorial plane with deviations from the best least-squares plane being −0.027(2), −0.023(2), 0.067(1) and −0.017(5) Å, respectively. The apical atoms, Cl(2″) and N(1), are located 2.310(2) and −1.931(5) Å, respectively, on either side of this plane. For the *sp* description the base plane would consist of the atoms Cl(1), Cl(2), Cl(2″) and N(1) with N(1′) occupying the apical site. The four basal atoms are not co-planar; N(1) and Cl(2″) lie 0.392(5) and 0.348(2) Å, respectively, above the best least-squares plane through the four atoms while Cl(1) and Cl(2) lie 0.356(2) and 0.384(2) Å,respectively, below it. The copper atom is 0.358(1) Å above the plane, i.e. toward the apical atom N(1′). These distortions from the ideal square-pyramidal geometry appear greater than in the trigonal-bipyramidal model. Using the distorted *tbp* description the axial Cu—N(1) distance was found to be shorter than the equatorial Cu—N(1′) distance; this variation of Cu—N as a function of axial *vs* equatorial location at copper is typical of trigonal-bipyramidal Cu^{II}/2,2′-bipyridine complexes.[8] Within the ligand L the angle between the plane of the pyridine ring and the plane of the quinoxaline ring is 7.1°.

Complex **1** joins only a handful of structurally characterized complexes of the type $[Cu_2X_2(\mu\text{-}X)_2(\text{bidentate ligand})_2]$ (X = Cl, Br), in which the geometry at copper is trigonal bipyramidal with the bridging ligands occupying apical and equatorial

* Far-IR, UV-vis and ESR data indicate that the yellow material is structurally different from the brown dinuclear complex. The yellow complex is believed to be a six-coordinate polymer with a mixed bidentate chelating N(1), N(1′)-monodentate N(4) coordination mode of L.[6]

† Crystal data: $C_{26}H_{18}N_6Cl_4Cu_2$, $M_r = 683.4$, monoclinic, space group $P2_1/n$, $a = 8.385(6)$, $b = 14.708(7)$, $c = 10.44(6)$ Å, $\beta = 92.59(5)°$, $V = 1283(1)$ Å^3, $Z = 2$, $D_c = 1.763$ g cm^{-3}, μ(Mo-K_α) = 21.075 cm^{-1}, $T = 25°C$, $2.5° < \theta < 25.0°$, $R(R_w) = 0.038(0.048)$ for 1175 unique reflections with $F > 2.5\sigma$ (F_o). The structure was solved by Patterson and Fourier techniques and refined by full-matrix least-squares analysis. All non-hydrogen atoms were readily located and refined with anisotropic thermal parameters. The contribution of the hydrogen atoms in their calculated positions was taken into account but not refined. All calculations were performed using the Enraf–Nonius crystallographic package MOLEN. Atomic coordinates, thermal parameters and bond lengths and angles have been deposited as supplementary data with the Editor.

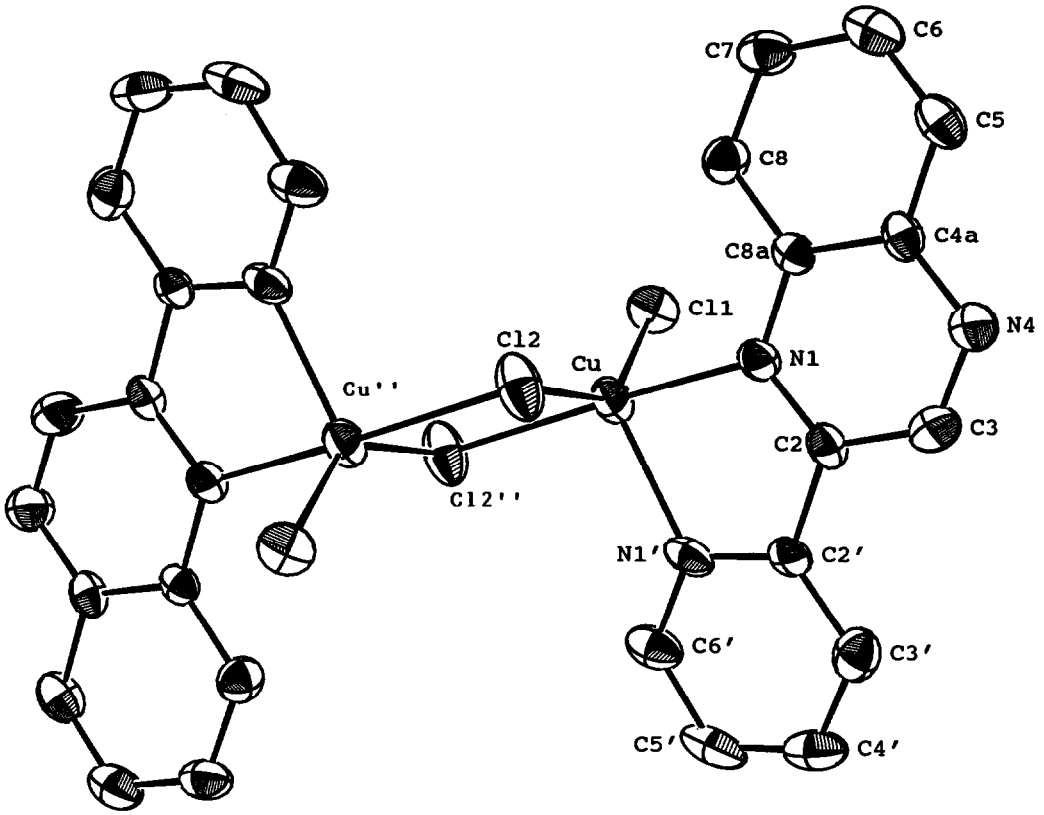


Fig. 1. The molecular structure of $Cu_2Cl_4L_2$ and atom numbering scheme. Double primed atoms are related to those unprimed by the symmetry operation $-x, -y, -z$. Selected bond distances (Å) and angles (°) are: Cu···Cu″ 3.522(1), Cu—N(1) 2.021(5), Cu—N(1′), 2.106(5), Cu—Cl(1), 2.272(2), Cu—Cl(2) 2.473(2), Cu—Cl(2″) 2.274(2); Cl(1)—Cu—Cl(2) 144.2(1), Cl(1)—Cu—Cl(2″) 96.0(1), Cl(1)—Cu—N(1) 94.0(2), Cl(1)—Cu—N(1′) 114.1(1), Cl(2)—Cu—Cl(2″) 84.3(1), Cl(2)—Cu—N(1) 86.1(1), Cl(2)—Cu—N(1′) 101.2(2), C(2″)—Cu—N(1) 169.7(2), Cl(2″)—Cu—N(1′) 98.5(1), N(1)—Cu—N(1′) 79.7(2), Cu—Cl(2)—Cu″ 95.7(1).

sites of each copper ion.[9–11] This structural type is relatively uncommon for halogen-bridged copper(II) dimers, which evidently prefer to form apical–basal bridges with square pyramidal geometry at copper.[9,10] Adopting the above described *sp* viewpoint complex **1** is the only known example, to our knowledge, of a dihalogen-C bridged square-pyramidal $[Cu_2X_4(\text{bidentate ligand})_2]$ complex in which the bridging halogens occupy two basal coordination sites of each copper(II).

The room-temperature effective magnetic moment of **1** is 1.87 B.M. per copper atom. The ESR spectrum obtained at 77 K from a powdered sample shows two poorly resolved lined at $g = 2.09$ and $g = 2.27$; in addition, a $\Delta M_S = 2$ transition is seen at $g = 4.20$. The latter transition is diagnostic of copper(II) dimers.[12] Detailed variable-temperature ESR and magnetic susceptibility studies on complex **1** are currently in progress. The appearance of a very sharp single band at 935 cm^{-1} in the IR spectrum of **1** characterizes a monodentate coordination of the quinoxaline system.[13]

In summary, the chelating N(1) and N(1′) behaviour of L has been confirmed in **1**. The mixed bidentate N(1), N(1′)-monodentate N(4) ligation mode is clearly possible. It is clear that the nature of L makes it a versatile new ligand for use with a variety of metals and for a variety of objectives/advantages, including variable metal oxidation states, bridging vs terminal modes, possible high-nuclearity aggregate formation and/or the linking of aggregates into polymeric arrays, and interesting types of magnetic exchange interactions. Such matters are currently under further investigation. Finally, it is worth noting that the coordination chemistry of the parent pyrazine ligand 2-(2′-pyridyl)pyrazine is also completely unexplored.[3]

OXIDATIVE ADDITION REACTIONS AND REVERSE YLIDE FORMATION INVOLVING MACROCYCLIC (TMTAA, $C_{22}H_{22}N_4$) COMPLEXES OF GERMANIUM(II) AND TIN(II)

DAVID A. ATWOOD, VICKI O. ATWOOD, ALAN H. COWLEY* and HALA R. GOBRAN

Department of Chemistry and Biochemistry, The University of Texas at Austin, Austin, TX 78712, U.S.A.

(*Received* 12 *April* 1993; *accepted* 25 *May* 1993)

Abstract—The germanium(II) and tin(II) macrocyclic complexes Ge(tmtaa) (**1**) and Sn(tmtaa) (**2**) (tmtaa = dibenzotetramethyltetraaza[14]annulene) undergo facile oxidative addition reactions and reverse ylide formation with MeI and C_6Fe_5I, respectively.

In comparison with main-group porphyrin and phthalocyanine complexes very little is known about other tetraaza macrocycles, such as the dibenzotetramethyltetraaza[14]annulene (tmtaa) ligand.[1] Use of the tmtaa ligand in the context of main-group chemistry is, in fact, limited to the elements Al,[2] Ga,[3,4] In,[3] Si,[5] Ge,[3] Sn[3,5] and Zn.[6] One of our objectives in using this ligand is to create unprecedented coordination environments and hence unusual reactivity patterns for main-group element fragments. In a previous communication[3] we have described the synthesis of Ge(tmtaa) (**1**) and Sn(tmtaa) (**2**). The structures of both molecules involve a unique square pyramidal geometry in which the $M^{(II)}$ centre lies 0.91 Å (Ge) and 1.15 Å (Sn) above the N_4 plane of the saddle-shaped tmtaa ligand. The purpose of the present communication is to report that the availability of an axially situated $M^{(II)}$ lone pair in **1** and **2** permits facile oxidative addition and reverse ylid formation to take place.

An excess of MeI was added to a stirred THF solution of either **1** or **2** at −78°C, following which the reaction mixture was allowed to warm slowly (8–12 h) to 25°C. Removal of the excess MeI and solvent under reduced pressure afforded virtually quantitative yields of the oxidative addition products Ge(tmtaa)(Me)(I) (**3**) and Sn(tmtaa)(Me)(I) (**4**). The foregoing formulations for **3** and **4** are in accord with the elemental analyses and mass spectroscopic data.† As noted by Cotton and Czuchajowska,[1] the coordination sphere of M(tmtaa)XY complexes can be regarded as a distorted trigonal prism in which the X and Y ligands adopt a mutually *cis* arrangement. Such a view is consistent with the ^{1}H NMR data for the tin com-

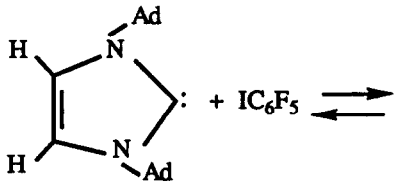
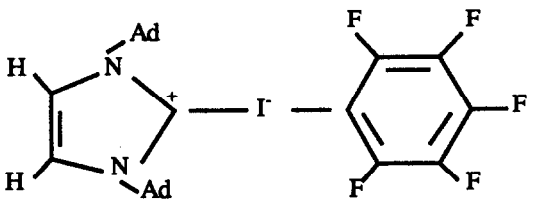
plex **4**. Thus, the methyl and methine protons are inequivalent while the aryl protons, being at the periphery of the complex, remain equivalent. Interestingly, in the case of the germanium analogue **3** the methyl and methine resonances remain equivalent down to −78°C. We attribute this observation to the existence of a rapid ionic-covalent equilibrium in solution.

$$Ge(tmtaa)(Me)(I) \rightleftharpoons [Ge(tmtaa)Me]^{+}I^{-}.$$

A recent report by Arduengo *et al.*[7] indicates that nucleophilic carbenes are capable of forming "reverse ylides" (**5**) with C_6F_5I in the sense that the formal charges at carbon and the halogen are inverted. It was, therefore, of interest to determine whether **1** and **2**, which are heavier carbene analogues, would undergo oxidative addition or reverse ylide formation.



Ad = Adamantyl



5

Compounds **1** and **2** react readily with C_6F_5I upon warming THF solutions of the reagents from −78°C to ambient temperature. Removal of the solvent and excess C_6F_5I affords virtually quantitative yields of products of composition

(*Received* 20 *May* 1993; *accepted* 14 *May* 1993)

Abstract—The new compound $BaCo_2Si_2O_7$ was obtained by heating the mixture $BaCO_3$, $CoCO_3$ and SiO_2 to 1300°C for 48 h. The material was characterized by single-crystal X-ray diffraction and magnetic susceptibility measurements. Each cobalt ion is surrounded by four oxygen atoms arranged in a distorted tetrahedral shape. These tetrahedra are linked into chains through the sharing of one of the oxygen atoms. The CoO_4 chains are cross-linked by bridging Si_2O_7 groups. The barium ions occupy channels that run parallel to the crystallographic *c*-axis. The effective magnetic moment, $\mu_{eff} = 4.70$ B.M., at 25°C is consistent with Co^{2+} in a tetrahedral environment having three unpaired electrons. Antiferromagnetic coupling of the electrons occurs between the nearest neighbour cobalt ions, as indicated by the sign of the Weiss constant, $\theta_p = -46$ K, and by the presence of a broad maximum in the susceptibility curve. At 26 K it undergoes a three-dimensional magnetic transition into a field-induced weak ferromagnet that is characteristic of a one-dimensional metamagnet.

Low-dimensional materials having anisotropic transport and magnetic properties have been the source of great interest.[1] Efforts to synthesize these materials have recently attracted considerable attention.[2] We now report the preparation, structural characterization and magnetic properties of the new material, $BaCo_2Si_2O_7$. Pure $BaCo_2Si_2O_7$ was obtained from the solid-state reaction of $BaCO_3$, $CoCO_3$, and SiO_2 by heating to 1300°C for 48 h.† Its three-dimensional structure was estab-

* Authors to whom correspondence should be addressed.

† A mixture of $BaCO_3$ (0.789 g, 4 mmol), $CoCO_3$ (0.9515 g, 8 mmol) and SiO_2 (0.4816 g, 8.01 mmol) was ground thoroughly in a mortar and then transferred to a platinum crucible. The crucible was placed in the oven (Lindberg Model 51333) and heated in air to 1300°C for 48 h. After this period the oven was cooled slowly (approx. 1°C min^{-1}) to 1000°C, and then allowed to cool quickly to 500°C. At this temperature the sample was removed from the oven.

lished by a single-crystal X-ray diffraction analysis. A projection of the crystallographic unit cell perpendicular to the *bc*-plane is shown in Fig. 1. Each cobalt ion is surrounded by four oxygen atoms arranged in the form of a distorted tetrahedron. These are represented by the tetrahedral shapes in the figure. The tetrahedra are linked into chains through the sharing of one of the oxygen atoms. Tetrahedral CoO_4 ions are exceedingly rare and there are no previous examples of such groupings that are linked to form chains.[3] The CoO_4 chains are cross-linked by Si_2O bridges that form Si_2O_7 groups by using the oxygen atoms surrounding the cobalt ions. The barium ions occupy channels that run parallel to the *c* crystallographic axis.*

Magnetic susceptibility measurements of $BaCo_2Si_2O_7$ show that it is paramagnetic with an effective magnetic moment, μ_{eff}, of 4.70 B.M. at 25°C.† This value is typical of a cobalt(II) ion in a tetrahedral environment with three unpaired electrons.[4] Antiferromagnetic coupling was indicated by a negative Weiss constant, $\theta_p = -46$ K, derived from the linear dependence of the inverse susceptibility, χ^{-1} vs *T*, and by the presence of a broad maximum in the susceptibility curve, near 35 K, which is typical of a low-dimensional antiferromagnet, see Fig. 2. At low temperatures the magnetic properties are very unusual. At 27 K the magnetic response increases rapidly and reaches a broad maximum at approximately 10 K, see Fig. 2. Isothermal magnetization measurements, shown in Fig. 3, have established that the transition is due to a weak *field-induced* ferromagnetic response. Above the transition temperature at 40 K only the anticipated linear paramagnetic response is observed, but at 12 K and 18 K the magnetization increases rapidly to a maximum of approximately 0.4 B.M./Co atom as soon as the magnetic field is applied. At 2.5 K and 5 K the magnetization initially increases slowly to

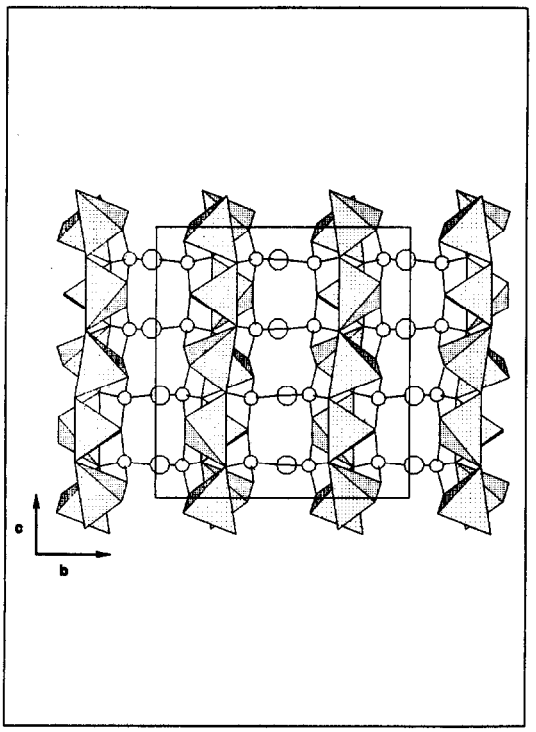

Fig. 1. A projection of the *bc*-plane of the solid-state structure of $BaCo_2Si_2O_7$ showing the chains of CoO_4 tetrahedra running parallel to the *c*-axis. CoO_4 tetrahedra are represented by the shaded polyhedra. Bonds between the silicon (small circles) and oxygen atoms are shown but the oxygen atoms are not drawn. The connectivities of the barium atoms (large circles) are not shown.

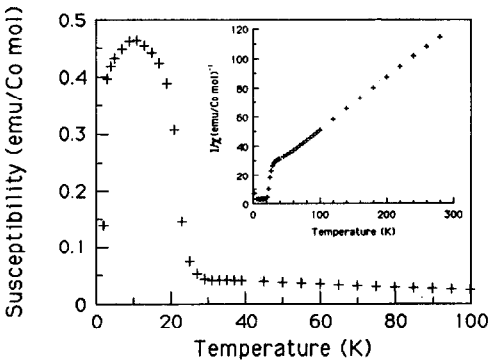

Fig. 2. A plot of the magnetic susceptibility of $BaCo_2Si_2O_7$ measured a 5 kOe in the range 2–100 K shows the broad 1D maximum at *ca* 35 K and the weak ferromagnetic response below 27 K. The insert shows a plot of the inverse susceptibility over the temperature range 2–280 K.

* A deep royal blue crystal was cleaved from the bulk and analysed by single-crystal diffractometry. Space group = *C*2/*c*, $a = 7.2131(6)$, $b = 12.781(1)$, $c = 13.762(1)$ Å, $\beta = 90.299(8)°$, $Z = 8$, 1370 reflections [$I > 3.0\sigma(I)$], $R = 0.042$. Diffraction measurements at 20°C were made on a Rigaku AFC6S four-circle diffractometer using Mo-K_α radiation. The structure solution and refinement was made by using the TEXSAN structure solving program library (v5.0) of the Molecular Structure Corp., The Woodlands, TX. An empirical absorption correction was applied to the data. An X-ray powder analysis showed the bulk sample to be pure $BaCo_2Si_2O_7$.

† Magnetic measurements were performed on a Quantum Design SQUID magnetometer using $BaCo_2Si_2O_7$ (41.9 mg), randomly-oriented small single crystals. The measurements were corrected for diamagnetism and effects of the sample holder. The sample was first cooled in the absence of an applied field. The susceptibility was then measured upon warming in a static field of 5 kOe. The Curie–Weiss law is obeyed in the region 120–220 K. The Curie constant $C = 2.8$ emu K^{-1} mol^{-1} and corresponds to $\mu_{eff} = 4.70$ B.M.

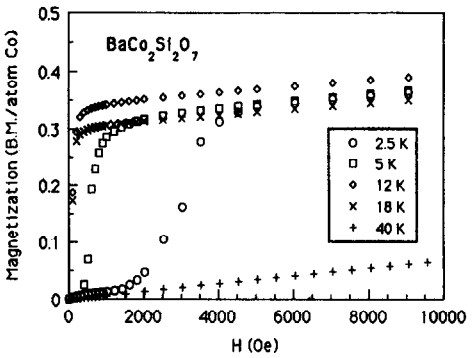

Fig. 3. Isothermal magnetization plots of $BaCo_2Si_2O_7$, μ (B.M./Co atom) vs H (Oersteds), at five different temperatures.

threshold values of 2000 Oe and 500 Oe, respectively, and then rapidly to approximately the same maximum value observed at 12 K and 18 K. Field-induced ferromagnetic phase transitions are characteristic of low-dimensional metamagnets and can be explained by a canting of the electron spins away from the principal magnetic axis.[5] The observation of the threshold fields cannot be attributed to spin-flop behaviour since neither saturation effects nor a weak ferromagnetic response of χ would have been observed for a spin-flop co-linear antiferromagnet.[6]

Supplementary materials available. Tables of crystal data, positional parameters, interatomic distances and angles, anisotropic thermal parameters and tables of structure factors (16 pages) for the structural analyses are available from the author RDA.

FIRST *ORTHO*-PALLADATION OF UNSUBSTITUTED BENZYLAMINE BY PALLADIUM(II) ACETATE

YOSHIO FUCHITA* and HAJIME TSUCHIYA

Laboratory of Chemistry, College of General Education, Kyushu University, Ropponmatsu, Chuo-ku, Fukuoka 810, Japan

(*Received* 27 *April* 1993; *accepted* 11 *May* 1993)

Abstract—The first *ortho*-palladation of unsubstituted benzylamine, achieved by the reaction of palladium(II) acetate with benzylamine in benzene at 60°C, is reported.

In 1968 Cope and Friedrich discovered that N,N-dimethylbenzylamine undergoes *ortho*-metallation on reaction with $PdCl_4^{2-}$, but that benzylamine itself did not.[1] Later Lewis and co-workers showed that disubstitution at the benzylic carbon also promotes *ortho*-palladation.[2] Shaw suggested that the reason for the different behaviour is that the disubstituted compounds lose less internal entropy on cyclization compared with the parent compounds, namely *gem*-disubstituted effect.[3] Furthermore, 10 years before Avshu and co-workers succeeded in preparing the *ortho*-palladated complex of benzylamine, $[\{PdI(C_6H_4CH_2NH_2)\}_2]$, by treating the adduct $[PdI_2(PhCH_2NH_2)_2]$ with a silver(I) salt. This finding is of value in a sense that *ortho*-palladation proceeds via a three-coordinate intermediate which was formed by abstraction of iodide by silver(I),[4] but did not change the general fundamental rule that direct activation of C—H bonds by palladium(II) to afford corresponding palladacycles is the most feasible in the case of tertiary amines, whereas primary and secondary amines are usually inert toward such activation.

Recently, we have found that N-methylbenzylamine can *ortho*-palladate on reaction with palladium(II) acetate, showing the higher ability for C—H bond activation of palladium(II) acetate compared with $PdCl_2$ or $PdCl_4^{2-}$.[5] This experience prompted us to investigate the reaction with benzylamine and we have found that even unsubstituted benzylamine can be *ortho*-palladated by palladium(II) acetate.

Palladium(II) acetate reacted with benzylamine in benzene at 60°C for 1 day to give yellow crystals $[\{Pd(C_6H_4CH_2NH_2)(\mu\text{-}O_2CMe)\}_2]$ (**1**). Its IR spectrum showed characteristic bridging acetato bands at 1570 and 1410 cm^{-1}. The ^1H NMR spectrum of **1** exhibited only one acetato-methyl signal at δ 2.09, indicating that **1** has the *anti* structure **A** and excluding the presence of the *syn* isomer **B** (Fig. 1). If complex **1** has the *syn* structure the two non-equivalent acetato-methyl groups are expected to have different chemical shifts. Reflecting the characteristic folded structure of the acetato-bridged dimer, two protons of the methylene group and those of the amino group were observed non-equivalently at δ 3.2 (complex) and 3.9 (complex) and at δ 2.95 (br) and 3.6 (br), respectively. As for the aromatic protons they appeared at δ 6.7–7.0 (8H) as multiplets. On the basis of these results and elemental analysis **1** was assigned to the dinuclear cyclopalladated complex of benzylamine having the *anti* configuration **A**.

The acetato bridged complex **1** reacted with NaCl to give the chloro-bridged analogue $[\{Pd(C_6H_4CH_2NH_2)(\mu\text{-}Cl)\}_2]$ (**2**), which was almost insoluble in common organic solvents. However, soluble mononuclear complexes $[PdCl(C_6H_4CH_2NH_2)$(3,5-lutidine)] (**3**) and $[PdCl(C_6H_4CH_2NH_2)$(2-picoline)] (**4**) were obtained on treatment of **2** with 3,5-lutidine and 2-picoline, respectively. The ^1H NMR spectrum ($CDCl_3$) of **3** exhibited aromatic protons in the *o*-phenylene moiety at

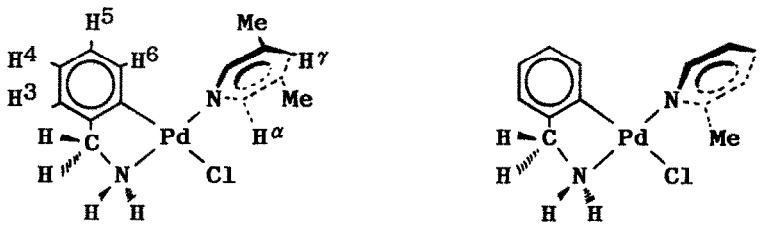
Fig. 1. Structure of $[\{Pd(C_6H_4CH_2NH_2)(\mu\text{-}O_2CMe)_2\}]$ (1).



3 4

Fig. 2. Structures of $[PdCl(C_6H_4CH_2NH_2)(3,5\text{-lutidine})]$ (3) and $[PdCl(C_6H_4CH_2NH_2)(2\text{-picoline})]$ (4).

δ 6.41 [d, ^3J(HH) = 8.3 Hz, 1H], 6.6 (m, 1H) and 7.0 (m, 2H), together with two singlets due to H^α (δ 8.53) and H^γ (δ 7.42) of the 3,5-lutidine ligand. The doublet was assigned to H^6 of the *o*-phenylene moiety, in consideration of the magnetic anisotropy of the pyridine ring (Fig. 2). The benzylic protons were observed as a triplet owing to the coupling with NH_2 at δ 4.24 [^3J(HH) = 5.9 Hz], whereas NH_2 appeared as a broad signal at δ 3.8. As for the ^{1}H NMR spectrum ($CDCl_3$) of **4**, reflecting the unsymmetrical structure of the 2-picoline ligand which coordinates to the palladium atom perpendicular to the palladium square planar plane (Fig. 2), two protons of the amino group resonated separately at δ 3.8 and 4.3 as broad signals, while the benzyl-methyl protons were observed as a triplet at δ 4.25 [^3J(HH) = 5.4 Hz]. The above NMR data of **3** and **4** confirmed unambiguously the *ortho*-palladated structure of benzylamine and the formation of the 2-aminomethylphenyl-C^1, N chelate ring.

In conclusion our results show that palladium(II) acetate is a much better palladium(II) species for direct C—H bond activation than $PdCl_4^{2-}$. This difference might come from the enhanced electrophilicity of palladium(II) acetate itself and/or easier generation of coordinatively unsaturated species by losing one benzylamine from the initially formed bis-adduct $[Pd(O_2CMe)_2(PhCH_2NH_2)_2]$ compared with the adduct $[PdCl_2(PhCH_2NH_2)_2]$, owing to a relatively bulkier acetato ligand compared with the chloro ligand. Details are currently being investigated.

THE SYNTHESES AND STRUCTURES OF TWO LARGE IODOANTIMONATE ANIONS

CLAIRE J. CARMALT and NICHOLAS C. NORMAN*

Department of Chemistry, The University of Newcastle upon Tyne, Newcastle upon Tyne NE1 7RU, U.K.

and

LOUIS J. FARRUGIA

Department of Chemistry, The University of Glasgow, Glasgow G12 8QQ, U.K.

(*Received* 6 *April* 1993; *accepted* 10 *May* 1993)

Abstract—The structures of two iodoantimonate anions are reported, viz. $[Sb_8I_{28}]^{4-}$ and $[Sb_5I_{18}]^{3-}$ both of which resulted from hydrolysis in reactions between SbI_3, $AgBF_4$ and two equivalents of either DMPU or HMPA, respectively. The cations in the former case are $[H(DMPU)_2]^+$ and in the latter case are $[H(HMPA)_2]^+$, both of which contain O···H···O hydrogen bonds. The structure of a similar cation $[H(OPPh_3)_2]^+$, as its $[ICl_4]^-$ salt, is also described.

Antimony and bismuth trihalides readily form adducts with extra halide ions to give halogenoanions, for which a large number of structural types are known.[1] Most of the discrete anions which have been characterized (as opposed to polymeric forms) contain between two and four antimony or bismuth atoms, but in recent years a number of ionic complexes have been isolated in which anions containing up to eight antimony or bismuth atoms are present. Notable in this regard is the work of Pohl, to which we will refer later in more detail. Herein we describe the structures of two iodoantimonate anions, $[Sb_8I_{28}]^{4-}$ and $[Sb_5I_{18}]^{3-}$, the latter having an unprecedented structure, obtained as a result of adventitious hydrolysis in reactions involving antimony tri-iodide and two-electron, oxygen-donor ligands.

RESULTS AND DISCUSSION

The reaction between antimony tri-iodide, SbI_3, 1 equivalent of $AgBF_4$ and 2 equivalents of N,N′-dimethylpropylene urea (DMPU) in THF solution afforded, after work-up, an orange crystalline product. Spectroscopic and analytical data indicated, however, that no BF_4^- was present and, therefore, that a product of, or similar to, the anticipated formula $[SbI_2(DMPU)_2][BF_4]$ had not been formed. The nature of the crystalline material was established by X-ray crystallography (on crystals obtained by recrystallization of the orange powder from chlorobenzene/Et_2O mixtures) and found to be ionic with the formula $[H(DMPU)_2]^+_4[Sb_8I_{28}]^{4-}\cdot xC_6H_5Cl$ (**1**), the origin of which is clearly due to hydrolysis, most probably from traces of moisture associated with $AgBF_4$ which is hygroscopic.

The unit cell of **1** contains a crystallographically centrosymmetric $[Sb_8I_{28}]^{4-}$ anion, four $[H(DMPU)_2]^+$ cations (two per asymmetric unit) and two disordered C_6H_5Cl molecules (one per asymmetric unit) with no significantly short intermolecular or interionic contacts; selected bond lengths and angles for the anion are given in Table 1. A view of one of the two crystallographically independent cations ($\mathbf{1}^+$) is shown in Fig. 1 and in the diagram (the second is similar in all respects). Each cation consists of two DMPU molecules and a proton which, although not directly located, is assumed to lie between the two oxygen atoms in the form of an O···H···O hydrogen bond, in view

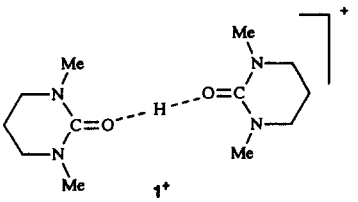
of the short O···O distances observed [2.37(2) and 2.39(2) Å] which are typical of such hydrogen bonded systems.

The structure of the $[Sb_8I_{28}]^{4-}$ anion ($\mathbf{1}^{4-}$) is shown in Fig. 2 and diagramatically. The simplest description of the structure is in terms of three layers



$\mathbf{1}^{+}$

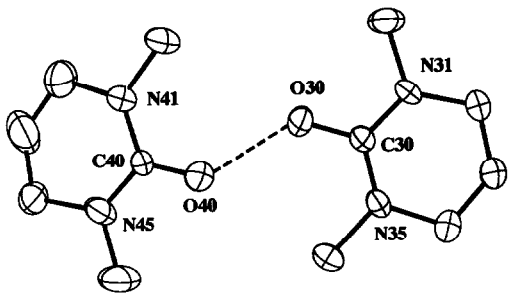


Fig. 1. A view of one of the $[H(DMPU)_2]^+$ cations in **1** ($\mathbf{1}^+$) showing the atom numbering scheme. Hydrogen atoms are omitted and the O···H···O interaction is indicated as a dotted line. Ellipsoids are drawn at the 20% probability level.

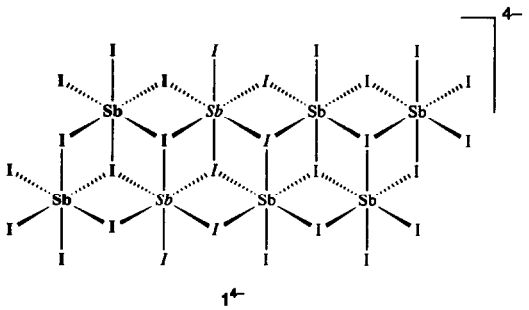
of closely packed iodine atoms with the antimony atoms occupying all of the octahedral holes. The iodines are present in terminal positions as well as in μ_2- and μ_3-bridging sites with Sb—I bond lengths in the ranges 2.753(1)–2.798(1), 2.822(1)–3.580(1) and 3.000(1)–3.494(1) Å, respectively; all of which are usual and deserve no special comment. The structure of $\mathbf{1}^{4-}$ is the same as that found in the salt $[Ph_4P]_4[Sb_8I_{28}]$ (**2**) reported by Pohl *et al.*,[2] although a different isomeric form is found in the structures of $[Me_4N]_4[Sb_8I_{28}]$ (**3**) and $[Me_3S]_4[Sb_8I_{28}]$ (**4**).[3] In **3** and **4** the $[Sb_8I_{28}]^{4-}$ anions have a more three-dimensional structure which is based on an approximately planar $[Sb_6I_{22}]^{4-}$ unit with additional SbI_3 groups coordinated on either site.

We will not comment in detail here on the structural complexity of iodoantimonate anions or related species (see ref. 1 for a general discussion and also refs. 2 and 3), but we draw attention to the fact that the structure of the $[Sb_8I_{28}]^{4-}$ anion found in **1** and **2** can be considered as the fourth member of a series with the general formula $[E_{2n}X_{6n+4}]^{4-}$. Examples of anions for $n = 1$ include $K_4[Bi_2Br_{10}]\cdot 4H_2O$,[4] $[C_2H_{10}N_4S]_2[Bi_2Cl_{10}]\cdot 4H_2O$,[5] $[C_2H_5N_4S]_4[Bi_2Br_{10}]$[6] and $[Sr(H_2O)_8]_2[Bi_2Br_{10}]$[7] and for $n = 2$ include $[Fe(\eta\text{-}C_5H_5)_2]_4[Bi_4Br_{16}]$,[8] $[C_2H_4N_3S]_4[Bi_4Br_{16}]$[9] and $[Mg(MeCN)_6]_2[Bi_4Cl_{16}]$.[10] For $n = 3$ the only examples so far characterized are $[Et_4P]_4[Bi_6I_{22}]$[11] and $[Fe(\eta\text{-}C_5H_5)_2]_4[Sb_6I_{22}]$,[12] although an isomeric form is found in the structure of $[Fe(phen)_3]_2[Sb_6I_{22}]\cdot 2MeCN$.[13]



The structural relationship within this series is illustrated in the diagram of $\mathbf{1}^{4-}$. Complexes of the general formula $[E_2X_{10}]^{4-}$ (i.e. for $n = 1$) have an edge-shared bi-octahedral structure, as shown for the atoms on the left-hand side in bold face. Addition of an E_2X_6 unit, shown in italic face, affords the next member of the series $[E_4X_{16}]^{4-}$, where $n = 2$, and the third and fourth members of the series are constructed accordingly. Judicious choice of the cation(s) will no doubt allow structures with $n > 4$ to be synthesized. The isomeric structures of the form $[E_6X_{22}]^{4-}$ and $[E_8X_{28}]^{4-}$ result from a less symmetrical addition of successive E_2X_6 units; in fact these structures are based on the preceding $[E_{2n}X_{6n+4}]^{4-}$ structure, i.e. for $n-1$, where

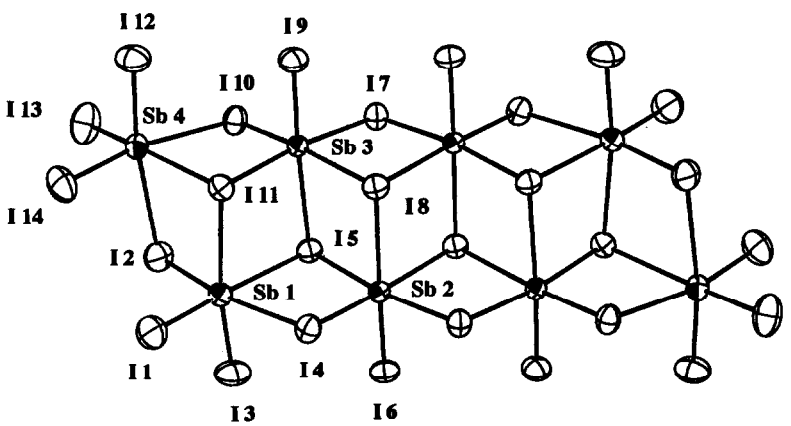


Fig. 2. A view of the centrosymmetric $[Sb_8I_{28}]^{4-}$ anion ($\mathbf{1}^{4-}$) showing the atom numbering scheme. Non-labelled atoms are related to the labelled atoms by a centre of symmetry at 0, 0, 0. Ellipsoids are drawn at the 50% level.

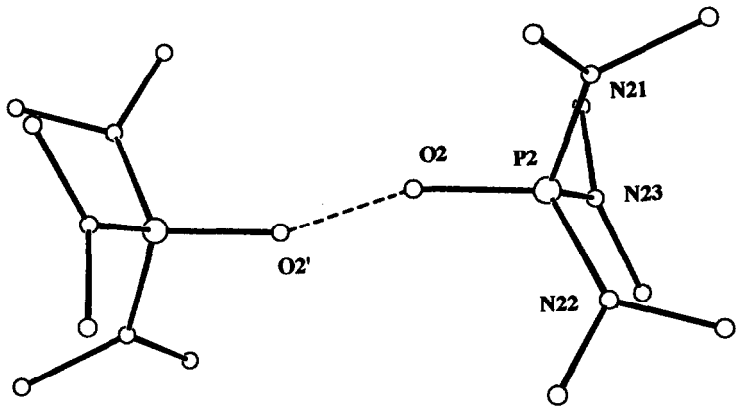

Fig. 3. A view of one of the $[H(HMPA)_2]^+$ cations in **5** (5^+) showing the atom numbering scheme. Hydrogen atoms are omitted and the O···H···O interaction is indicated as a dotted line. Atoms are drawn as circles of arbitrary size due to the large thermal motion associated with the NMe_2 groups.

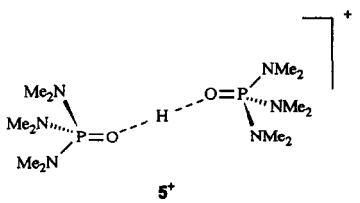
the final E_2X_6 unit is added as separate EX_3 groups above and below the $[E_{2n}X_{6n+4}]^{4-}$ plane.

The analogous reaction between SbI_3, $AgBF_4$ and 2 equivalents of HMPA [hexamethylphosphoramide, $OP(NMe_2)_3$] also afforded an orange crystalline product, the nature of which was established by X-ray crystallography. The results of this analysis revealed an ionic compound having a similar constitution to **1** with the formula $[H(HMPA)_2]_3[Sb_5I_{18}]$ (**5**) and undoubtedly resulting from a similar hydrolysis reaction. The unit cell is centrosymmetric and contains one formula unit of **5** with each of the two asymmetric units containing one and a half cations $[H(HMPA)_2]^+$ (5^+) and half of the anion $[Sb_5I_{18}]^{3-}$ (5^{3-}). A picture of the cation lying on the centre of symmetry is shown in Fig. 3 and in the diagram. In neither of the cations were the protonic hydrogen atoms directly located, although, as in the case of the cations in **1**, their presence between the oxygen atoms is implied by the short O···O distances [O(1)—O(3) 2.41(2), O(2)—O(2′) 2.17(3) Å];* the P—O distances are P(1)—O(1) 1.552(13), P(2)—O(2) 1.515(19) and P(3)—O(3) 1.464(15) Å, and the P—O···O—P torsion angles are P(1)—O(1)—O(3)—P(3) 115(2) and P(2)—O(2)—O(2′)—P(2′) 180°.



5^+

The structure of the anion 5^{3-} (shown in Fig. 4) has crystallographic C_i symmetry, although the molecular symmetry is close to D_{2h}. An illuminating description of the structure, particularly in terms of its electronic structure, is as an octahedral SbI_6^{3-} core in which four faces of the octahedron are capped by SbI_3 groups. This is reflected in the Sb—I bond lengths which are presented in Table 2. The shortest bonds are between the six terminal iodines, I(4)–I(9), and the antimony atoms to which they are bonded, Sb(2) and Sb(3), which range from 2.756(2) to 2.787(2) Å. The next longest bonds are to the central antimony, Sb(1), which range from 3.015(1) to 3.046(1) Å, with the longest interactions being between the face capping antimony atoms, Sb(2) and Sb(3), and the iodines I(1)–I(3), 3.393(1)–3.646(2) Å. The constraints of the structure are such that the iodines I(1)–I(3) are all triply bridging, although I(3) and the symmetry related I(3′) have a rather unusual T-shaped coordination geometry.† There is also a fairly close contact between I(5) and I(9), 3.866(1) Å.

We are not aware of any structures analogous to 5^{3-}, but an isomeric form is found in the structure

* The O(2)—O(2′) distance of 2.17(3) Å is very short, significantly more so than the other O···H···O bonds in **1**, **5** and **7** and O···H···O bonds in general. However, in view of the high thermal motion of the HMPA ligands and possible disorder (see Experimental) we cannot be confident of the accuracy of this value.

† A similar T-shaped geometry for a triply-bridging bromine and iodine is found in the structures of the halogenoarsenic anions in $[Et_3NH]_3[As_3Br_{12}]$ and $[Me_3NH]_3[As_3I_{12}]$, respectively.[26] Both of these anions are isostructural and, by analogy with the description given for 5^{3-}, can be viewed as a central, octahedral AsX_6^{3-} unit capped on two adjacent faces by AsX_3 molecules (X = Br, I).

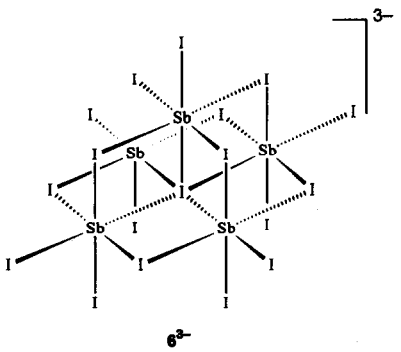
of $[Me_4N]_3[Sb_5I_{18}]$ (**6**) reported by Pohl *et al.*[12] The structure of the $[Sb_5I_{18}]^{3-}$ anion in **6** ($\mathbf{6}^{3-}$) is shown in the diagram and has approximate C_{4v} symmetry with a μ_5-iodine in the basal plane. In terms of the structural description given above for $\mathbf{5}^{3-}$, we can look upon the structure of $\mathbf{6}^{3-}$ in terms of an SbI_6^{3-} octahedron with four edge-bridging SbI_3 groups, in which the four edges share a common vertex. The requirements of octahedral coordination around the bridging antimony atoms mean that each has two terminal iodines and two shared, μ_2-bridging iodines.



$\mathbf{6}^{3-}$

The structure of $\mathbf{5}^{3-}$, together with those of other iodoantimonate anions found in previous studies, illustrates the structural diversity in this field and this is almost certainly controlled by the nature of the cation and, probably to a lesser extent, by the solvent. In this regard we note the parallel with the structural chemistry of copper(I) halogenoanions,[14] wherein there is evidence that the species present in solution are relatively simple, the complex solid-state structures being a mani-

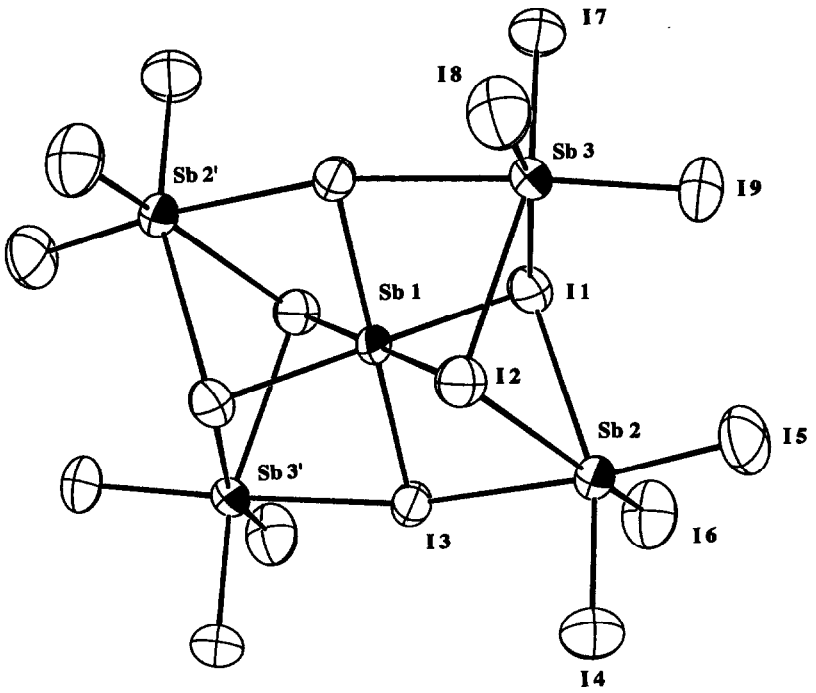


Fig. 4. A view of the centrosymmetric $[Sb_5I_{18}]^{3-}$ anion (5^{3-}) showing the atom numbering scheme. Non-labelled atoms are related to the labelled atoms by a centre of symmetry at 0, 0, 0, i.e. Sb(1). Ellipsoids are drawn at the 20% level.

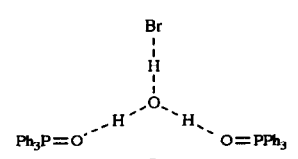
festation of the crystallization process in which the nature of the cation (size and shape, etc.) is crucial.

The cation in **5** (5^+) is an example of a protonated phosphine oxide, which is hydrogen bonded to another phosphine oxide to give a complex cation of the form $R_3P{=}O\cdots H\cdots O{=}PR_3$. We obtained another example of this type of cation, viz. $[H(OPPh_3)_2]^+[ICl_4]^-$ (**7**), from the reaction between ICl_3 and two equivalents of Ph_3PO in CH_2Cl_2 resulting, as in the case of **5**, from partial hydrolysis, the structure of which is reported for comparison. The iodine of the $[ICl_4]^-$ anion in **7** resides on a crystallographic two-fold axis (0.0, *y*, 0.25), giving crystallographic C_{2v} symmetry although the actual molecular structure is very close to the expected D_{4h}, square-planar geometry. The only significant deviation from the idealized structure is in the I—Cl bond lengths, which differ by 0.037 Å (*ca* 18σ); I—Cl(1), 2.471(2), I—Cl(2) 2.508(2) Å. The cation $[H(OPPh_3)_2]^+$ (shown in Fig. 5) lies about a crystallographic inversion centre at 0.5, 0.0, 0.5. The presence of a hydrogen bonding interaction between the two phosphine oxides was indicated by the short O···O separation [O(1)—O(1′) 2.387(6) Å], which is comparable to the distances found in 5^+. However, in this case the hydrogen atom was located and the thermal parameter successfully refined, the O—H distance being 1.194(3) Å (the positional parameters are fixed at 0.5, 0, 0.5). Structurally characterized protonated phosphine oxides are not particularly common, but we note the structures of $Ph_3PO\cdots HF$,[15] $Ph_3PO\cdots HCl$[16] and $Ph_3PO\cdots HBr$.[17] The HBr complex with Ph_3PO has also been characterized as a hydrate (**8**), in which two Ph_3PO groups are hydrogen-bonded to an H_2O molecule which is, in turn, hydrogen bonded to HBr as shown below.[18] The P=O···O distances are 2.470(7) and 2.398(8) Å, although the protonic hydrogens were not detected.



8

Other examples of O···H···O hydrogen bonds where one of the oxygen atoms is from a phosphine oxide are $Ph_3PO\cdots HOC(O)CH_2OC_6Cl_5$ [O···O 2.541(4) Å],[19] tri-*p*-tolylphosphine oxide hemihydrate [O···O 2.810(4) Å][20] and triphenylphosphine oxide hemihydrate [O···O 2.856(3) Å];[21] the O···O distances are understandably shorter in the cationic complexes.

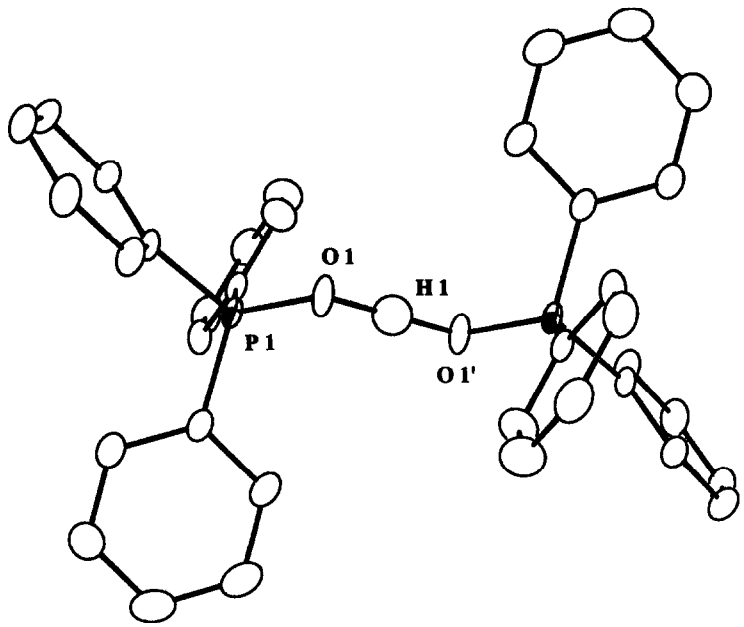


Fig. 5. A view of the $[H(OPPh_3)_2]^+$ cation in **7** showing the atom numbering scheme. Primed atoms refer to the symmetry operation $1-x, -y, 1-z$. Ellipsoids are drawn at the 20% level.

EXPERIMENTAL

General procedures

All reactions were performed using standard Schlenk techniques under an atmosphere of dry, oxygen-free dinitrogen. All solvents were distilled from appropriate drying agents immediately prior to use (sodium-benzophenone for THF, Et_2O and hexanes; CaH_2 for CH_2Cl_2; 4 Å molecular sieves for pyridine, nitromethane, chlorobenzene and 1,2-dichloroethane). SbI_3 (99%+), ICl_3, HMPA, DMPU, Ph_3PO and $AgBF_4$ were procured commercially and used without further purification. Microanalytical data were obtained at The University of Newcastle.

Preparations

$[H(DMPU)_2]_4[Sb_8I_{28}]$ **1**. DMPU (0.097 cm^3, 0.802 mmol) was added to a solution of of SbI_3 (0.201 g, 0.400 mmol) in THF (10 cm^3) resulting in a colour change from yellow to orange. $AgBF_4$ (0.078 g, 0.401 mmol) dissolved in THF (6 cm^3) was then added, which resulted in the formation of a pale yellow precipitate. The solution was stirred for 1 h and then filtered through Celite. The volume of the orange filtrate was reduced to *ca* 10 cm^3 by vacuum and hexane (25 cm^3) was added as an overlayer. Solvent diffusion over a period of days at $-30°C$ resulted in an orange oil. Crystallizations were attempted from CH_2Cl_2/hexane, pyridine-hexane and nitromethane/Et_2O, but X-ray quality crystals of **1** are finally obtained by solvent diffusion of Et_2O over a period of days into a chlorobenzene solution of the orange oil at room temperature (0.092 g, 32% based on antimony). Found: C, 12.1; H, 1.7; N, 3.5. Calc. for $C_{48}H_{100}I_{28}N_{16}O_8Sb_8 \cdot (C_6H_5Cl)_2$: C, 12.4; H, 1.9; N, 3.9%.

$[H(HMPA)_2]_3[Sb_5I_{18}]$ (**5**). HMPA (0.12 cm^3, 0.690 mmol) was added to a solution of SbI_3 (0.173 g, 0.344 mmol) in THF (10 cm^3), resulting in a colour change from yellow to orange. $AgBF_4$ (0.067 g, 0.344 mmol) dissolved in THF (6 cm^3) was then added, which resulted in the formation of a pale yellow precipitate. The solution was stirred for 1 h and then filtered through Celite. The volume of the orange filtrate was reduced to *ca* 10 cm^3 by vacuum and hexane (25 cm^3) was added as an overlayer. Solvent diffusion over a period of days at $-30°C$ resulted in an orange solid. Crystallizations were attempted from CH_2Cl_2/hexane, CH_2Cl_2/Et_2O and 1,2-dichloroethane/hexane, but X-ray quality crystals of **5** were finally obtained by solvent diffusion of Et_2O over a period of days into a CH_2Cl_2 solution of the orange solid at toom temperature (0.083 g, 30% based on antimony). Found; C, 11.3; H, 2.5; N; 5.8. Calc. for $C_{36}H_{111}I_{18}N_{18}O_6P_6Sb_5$: C, 11.1; H, 2.9; N, 6.5%.

$[H(OPPh_3)_2][ICl_4]$ (**7**). Ph_3PO (0.120 g, 0.431 mmol) was dissolved in CH_2Cl_2 (5 cm^3) and cooled to 0°C with an ice-bath. A solution of ICl_3 (0.050

g, 0.214 mmol) in CH_2Cl_2 (3 cm^3) was then added, which resulted in the formation of a bright yellow solution (ICl_3 is orange in CH_2Cl_2). Hexane (15 cm^3) was then layered over this solution and solvent diffusion over a period of days at −30°C afforded yellow crystals of **7** (0.087 g, 49% based on iodine). Some of these crystals were suitable for X-ray diffraction. Found: C, 51.7; H, 3.5. Calc. for $C_{36}H_{31}Cl_4IO_2P_2$: C, 52.3; H, 3.8%.

KBr disc IR spectra for all complexes showed absorptions due to the DMPU or phosphine oxide groups, but absorptions due to the O···H···O fragments were not detected.

X-ray crystallography

Crystallographic data and details of the data collection procedures and structure refinement for all structures are presented in Table 3. The following section deals with the structure of **1**; data for **5** where different are given in square brackets and data for **7** curly brackets. Data were collected on an Enraf–Nonius Turbo-CAD4 diffractometer, running under CAD4-Express software {Enraf–Nonius CAD4 diffractometer}, and with graphite monochromated *X*-radiation ($\lambda = 0.71069$ Å). Accurate unit cell parameters were determined by refinement of setting angles ($20.7° < \theta < 23.7°$) [$17.5° < \theta < 20.7°$] {$\theta \sim 12°$} of 25 reflections. Standard reflections were measured every 2 h during data collection and no significant variation in intensities was noted {a 6% decay was noted and corrected for}. Corrections were applied for Lorentz–polarization and absorption (DIFABS[22]) effects. {The systematic absences indicated either the centrosymmetric space group $C2/c$ or the non-centrosymmetric Cc. The former was chosen on the basis of E statistics and this choice was subsequently confirmed by successful solution and refinement.} The structure was solved for all antimony and iodine atoms by direct methods (SHELX86[23]) {the structure was solved by heavy atom methods for the iodine atom}. Subsequent difference syntheses gave all other atomic positions. All atoms were allowed anisotropic thermal motion. Hydrogen atoms were included at calculated positions (C—H 0.96 Å) and assigned thermal parameters 1.2 times that of the attached carbon atom [due to the extremely high thermal motion of the HMPA ligands, possibly disorder although this could not be modelled, no hydrogen atoms were included in the structure factor calculations]. {Phenyl hydrogens were included at calculated positions with C—H = 1.0 Å and were refined as rigid groups with idealized geometry (C—C = 1.395 Å), and allowed to ride on their attached carbon atoms during refinement. One common isotropic thermal parameter for all phenyl H atoms was refined.} The protonic hydrogens were not detected {the protonic hydrogen H(1) at the centre of inversion (0.5, 0, 0.5) was suspected from the short O···O contact and was observed in a difference map as a peak at 0.36 e $Å^{-3}$; a separate thermal parameter was refined for this hydrogen atom}. There was a severely disordered solvent molecule in the unit cell (presumably C_6H_5Cl), but it was not possible to model this satisfactorily. The electron density was finally modelled using a set of carbon atoms of full and half occupancy; atoms C(100)–C(110) [no solvent was present in crystals of **5** and **7**]. Refinement was by full matrix least-squares, with the function $\Sigma w(|F_o| - |F_c|)^2$ minimized, and with the weighting scheme $w = [\sigma^2(F_o)]^{-1}$ used and judged satisfactory. $\sigma(F_o)$ was estimated from counting statistics. Neutral atom scattering factors were taken from ref. 24 with corrections for anomalous dispersion. All calculations were carried out on a MicroVAX 3600 computer using the Glasgow GX suite of programs.[25]

Supplementary material available from the Cambridge Crystallographic Data Centre comprises complete tables of bond lengths and angles, atomic positional parameters, thermal parameters and hydrogen atom coordinates.

(*Received* 5 *April* 1993; *accepted* 10 *May* 1993)

Abstract—The mixed-metal species $[Gd_2Zr_6(\mu_4\text{-}O)_2(\mu\text{-}OAc)_6(\mu\text{-}OPr^i)_{10}(OPr^i)_{10}]$ (**1**) was obtained by reacting anhydrous gadolinium acetate with $[Zr(OPr^i)_4(Pr^iOH)]_2$. Its X-ray structure analysis reveals two $Zr_3Gd(\mu_4\text{-}O)(\mu\text{-}OAc)_2(OPr^i)_{10}$ tetrahedral clusters associated via Gdμ-OAc linkages. The zirconium and gadolinium centres are hexa- and hepta-coordinated, respectively. The analogous yttrium derivative (**2**) was obtained by a similar route and characterized by microanalysis, IR, ^1H and ^{13}C NMR spectroscopies. Control of the stoichiometry between the metals can be achieved by varying the nature of the alkoxo group. Hydrolysis–polycondensation reactions proceed via differential hydrolysis and offered cubic zirconia containing various amounts of lanthanide oxides depending on the stoichiometry between the metals.

Ternary or complex metal oxides represent an important part of advanced materials due to their wide range of technical applications. Lanthanide oxides are involved in various advanced complex oxide materials such as electro-optical ceramics and high-temperature protonic or super conductors. Chemical routes such as the sol–gel process are versatile methods for obtained ceramics in a variety of shapes and are based on hydrolytic condensation reactions.[1] Molecular precursors of oxides mostly remain limited to alkoxides, which are oligomeric and difficult to handle especially for oxophilic metals and materials science purposes. The use of metal alkoxides in conjunction with less reactive and more easily accessible metal oxide precursors (β-diketonates, acetates) is a common alternative in the approach of mixed-metal oxide materials by chemical routes.[2] However, the molecular constitution of such solutions is not well known and a better understanding is required as a means to a better control of the passage from molecules to materials and a better selection of the homo- and heterometallic precursors for a given material.[3] Lanthanides are associated with zirconium in electro-optical ceramics, high-temperature protonic conductors, electrodes, etc. The most commonly used lanthanide alkoxides, isopropoxides, are generally pentanuclear $Ln_5(\mu_5\text{-}O)(OPr^i)_{13}$ clusters (Ln = Y, La, Yb, Pr)[4] and although they are reported to form mixed-metal alkoxides, for instance with $[Zr(OPr^i)_4(Pr^iOH)]_2$, their structural characterization turned out to be difficult.[5]

acterization of mixed-metal lanthanide–zirconium acetatoalkoxides and the molecular structure of $Gd_2Zr_6(\mu_4\text{-}O)_2(\mu\text{-}OAc)_6(\mu\text{-}OPr^i)_{10}(OPr^i)_{10}$, the first heterometallic Ln—Zr species structurally characterized.

EXPERIMENTAL

All manipulations were routinely performed under argon using Schlenk tubes and vacuum-line techniques with solvents purified by standard methods. $[Zr(OPr^i)_4(Pr^iOH)]_2$[6] and anhydrous $Ln(OAc)_3$ (Ln = Y, Gd)[7] were obtained according to the literature. ^1H and ^{13}C NMR and IR spectra were obtained using Bruker WH-90, AC-200 and IR-FTS 45 spectrometers, respectively. IR spectra were obtained as Nujol mulls. Analytical data were obtained from the Centre de Microanalyses du CNRS.

Synthesis of $Ln_2Zr_6O_2(OAc)_6(OPr^i)_{20}$ [Ln = Gd (**1**), Y (**2**)]

$Gd(OAc)_3$ (0.6 g, 1.77 mmol) added to a solution of $[Zr(O^iPr)_4(Pr^iOH)]_2$ (2 g, 2.64 mmol) in toluene (40 cm^3). The reaction medium was then heated at reflux for 20 h leading to the progressive dissolution of the acetate. After evaporation to dryness the crude product was recrystallized at 5°C in a toluene–hexane mixture (10:1); yield: 2 g (90%) of **I**. The product is soluble in aliphatic and aromatic hydrocarbons and THF. Its solubilization in isopropanol is slow (1 h). Found: C, 34.9; H, 6.1; Gd, 12.9; Zr, 22.5. Calc. for $C_{36}H_{79}O_{17}GdZr_3$: C, 35.6; H, 6.5; Gd, 14.5; Zr, 22.6%. IR (cm^{-1}): 1637sh, 1610vs [$\nu_{as}(CO_2)$]; 1544sh, 1454, 1436 [$\nu_s(CO_2)$]; 553sh, 526vs, 487s, 437m, 519m [ν(M—OR)]. ESR (room temperature, toluene): $\langle g \rangle = 2.016$, $\mu = 11.8\ \mu_B$.

A similar procedure applies to the synthesis of the yttrium analogue **2** obtained in a 75% yield, but no crystals suitable for X-ray analysis could be grown. Found: C, 36.5; H, 6.4; Y, 8.1; Zr, 24.0. Calc. for $C_{36}H_{79}O_{17}YZr_3$: C, 37.8; H, 6.9; Y, 7.8; Zr, 23.9%. IR (cm^{-1}): 1645sh, 1616m, 1574vs [ν_{as}(CO)]; 542s, 499m, 465s [μ(M—OR)] ^1H (C_6D_6, ppm): 4.88 (m, 2H, CH), 4.45 (sep, $J = 6$ Hz, 8H, CH); 1.99s (6H, OAc), 1.94s (3H, OAc); 1.65d 1.59d, 1.51d, 1.45d ($J = 6$ Hz, 60H, CH_3). $^{13}C\{^1H\}$ ($CDCl_3$, ppm): 73, 71.8, 70.9, 70.1, 69, 64.7 (CH); 29.8, 26.6, 26, 25.6, 25, 23.8, 19.9, 19 (CH_3).

Synthesis of $Y_2Zr_2O(OAc)6(OC_2H_4OMe)_6$ (**3**)

$Y(OAc)_3$ (0.8 g, 3 mmol) was dissolved at room temperature in a solution of zirconium 2-methoxyethoxide (obtained by refluxing $[Zr(OPr^i)_4(Pr^iOH)]_2$ (1.04 g, 2.68 mmol) with $MeOC_2H_4OH$) in toluene (20 cm^3) over a period of 20 h. After elimination of the excess $Y(OAc)_3$ the filtrate was concentrated and crystallization of **3** was achieved by adding hexane (1.4 g, 89%). The product is soluble in toluene, THF, 2-methoxyethanol, but insoluble in aliphatic hydrocarbons. Found: Y, 15.0; Zr, 15.4. Calc. for $C_{30}H_{60}O_{25}Y_2Zr_2$: Y, 15.1; Zr, 15.5%. IR (cm^{-1}): 1616sh, 1560vs [ν(C—O)]; 588s, 514vs, 467s [ν(M—OR)]. ^1H (C_6D_6, ppm): 3.44 m (2H, $MOCH_2$), 3.1t ($J = 6.2$ Hz, 2H, CH_2); 3.01s (3H, OMe), 2.13s (3H, OAc). $^{13}C\{^1H\}$ ($CDCl_3$, ppm): 129.0, 128.2, 125.3 (CO_2); 73.7, 61.8, 58.9 (CH_2, OMe); 29.7, 24.5, 21.5 (OAc).

If the same reaction was achieved at refluxing toluene a different oxo compound was obtained. IR (cm^{-1}): 1583 [$\nu_{as}(CO_2)$], 1448 [$\nu_s(CO_2)$]; 585, 511, 464 [ν(M—OR)].

X-ray diffraction study of $Gd_2Zr_6(\mu_4\text{-}O)_2(\mu\text{-}OAc)_6(\mu\text{-}OPr^i)_{10}(OPr^i)_{10}$ (**1**)

A crystal grown from toluene–hexane solutions at 5°C was introduced into a Lindeman capillary and mounted onto an Enraf–Nonius CAD-4 automatic diffractometer. Systematic absences indicate monoclinic symmetry and space group $C2/c$. The lattice parameters were determined from 25 computer-centred reflections. The unit cell parameters and basic information about data collection are as follows.

Crystal data for $C_{66}H_{158}O_{34}Gd_2Zr_6,C_6H_{14}$. $M = 2357.8$, monoclinic, space group $C2/c$, $a = 39.55(2)$, $b = 12.274(7)$, $c = 22.91(1)$ Å, $\beta = 103.20(4)$, $U = 10827$ Å^3, $D_c = 1.415$ g cm^{-3} for $Z = 4$, μ(Mo-K_α) = 18.22 cm^{-1}. 3458 data were collected at low temperature (−100°C) using graphite-monochromated Mo-K_α radiation ($\lambda = 0.71073$ Å). Metal atoms were found by direct methods using SHELXS.[8] All remaining non-hydrogen atoms were located on successive difference electron density maps. The structure was refined by least-squares with an approximation (in three blocks) to the normal matrix using CRYSTALS.[9] 2760 reflections with $I > 3\sigma(I)$ were used to solve and refine the structure: $R = 0.0529$, $R_w = 0.0617$, 357 variables. The weighting scheme w was defined as $w = w'*[1-(\Delta F/6\sigma(F))^2]^2$, with $w' = 1.0/\Sigma_{r=1,n}\mathrm{ArTr}(x)$, where $x = F_c/F_c(\max)$ and three coefficients of Ar (7.32, −0.218, 4.42) for the Chebyshev polynomial Tr(x).[10] In view of the low ratio of variables/data only metals and oxygen atoms were refined anisotropically. Some of the carbon atoms of the alkoxide ligands have high

isotropic thermal parameters. For three of them a disordered distribution of the carbon atoms could be found, but other attempts to define possible disordered sites failed. Anomalous dispersion terms were applied. Empirical absorption corrections using DIFABS[11] were made. Positional parameters and equivalent isotropic thermal parameters are given as supplementary material.

RESULTS AND DISCUSSION

By contrast with lanthanide alkoxides, acetates of the compounds studied are easily accessible but poorly soluble. However, they can be activated by metal alkoxides, although they appear less reactive towards $M(OR)_n$ species than metal acetates of other elements such as lead(II) or magnesium.[3a] The reaction between anhydrous $Ln(OAc)_3$ (Ln = Y, Gd) and $[Zr(OPr^i)_4(Pr^iOH)]_2$ requires refluxing in toluene for 20 h and is evidenced by the dissolution of the acetate. In both cases compounds analysing as $Ln(OAc)_3 \cdot Zr_3O(OPr^i)_{10}$ [Ln = Gd (**1**), Ln = Y (**2**)] have been obtained in high yield (80%). These compounds are air-sensitive, soluble in non-polar media (hexane, toluene) and non-volatile. Their IR spectra show three stretching frequencies for the acetate ligands, shifted to higher frequencies with respect to $Gd(OAc)_3$ (1546 cm^{-1}) or to $Y(OAc)_3$ (1536 cm^{-1}). ^1H and ^{13}C NMR spectra of the yttrium derivative **2** display two types of acetate ligands in a 1 : 2 surface area and are quite complex for the isopropoxo region, while the paramagnetism of **1** results in poorly resolved NMR spectra. Suitable crystals could be obtained for **1** and its structure was thus elucidated by X-ray studies, which established its mixed-metal character as well as the presence of the oxo ligands.

Compound **1** appears to be an octanuclear heterometallic oxoacetatoalkoxide of the formula $Gd_2Zr_6(\mu_4\text{-}O)_2(\mu\text{-}OAc)_6(\mu\text{-}OPr^i)_{10}(OPr^i)_{10}$. Its molecular structure results from two $GdZr_3(\mu_4\text{-}O)(OAc)_2(OR)_{10}$ aggregates assembled by the two gadolinium atoms via bridging acetato ligands into the discrete centrosymmetric molecule shown in Fig. 1. Selected bond distances and angles are summarized in Table 1. The gadolinium atoms are hepta-coordinated, while all zirconium centres are hexa-coordinated. The tetranuclear $GdZr_3(\mu_4\text{-}O)(OAc)_2(OR)_{10}$ unit can be viewed either as a distorted flattened tetrahedron or as two cubane units (in which one metal apex is missing) sharing a face [Zr(1), Gd and the oxo ligand O(15)]. The gadolinium atom occupies the "apical" position of the distorted tetrahedron, while the zirconium atoms form an isosceles triangular unit: the distances Zr(1)···Zr(2) and Zr(1)···Zr(3) are comparable (3.42 Å av.), but Zr(2)···Zr(3) opens up to 4.074(2) Å. The oxo ligand O(15) is located at 0.46 Å from the plane of the three zirconium atoms and is the only ligand connecting the Zr(2) and Zr(3) atoms. The salient feature is the coordination of the μ_4-oxo O(15) ligand; this ligand is "concave" [Zr(2)—O(15)—Zr(3) 137.3(4)°] and thus drawn towards Gd and Zr(1). Such a stereochemistry contrasts with most $M_4(\mu_4\text{-}X)$ (X = C, N, O)[12] units, but is analogous with that of $Ce_4(\mu_4\text{-}O)(OPr^i)_{13}(Pr^iOH)$[13] or $Al_4(\mu_4\text{-}O)(OPr^i)_5Cl_4(Pr^iOH)$[14] species; in the latter the stereochemistry around the

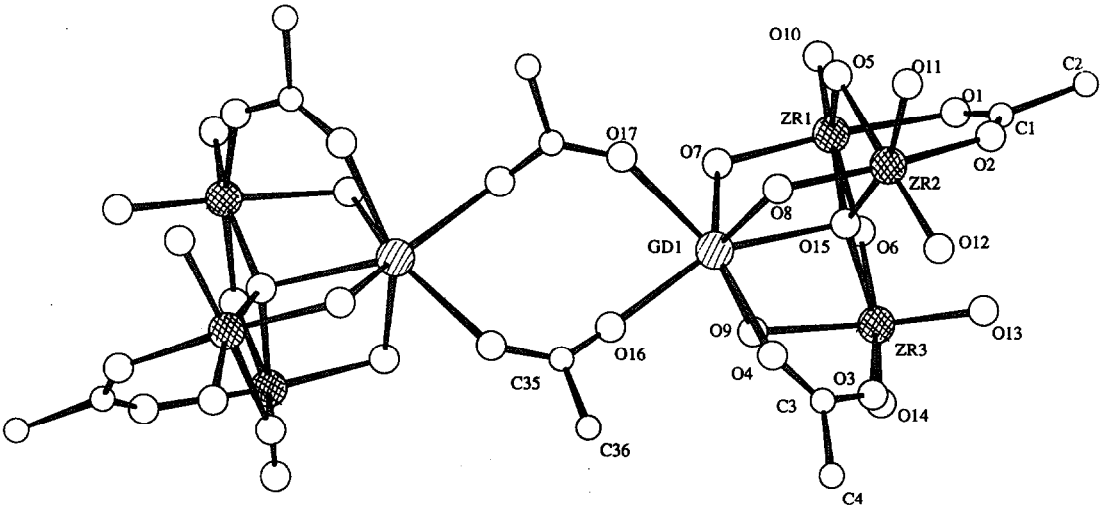

Fig. 1. Ball and stick view of the molecular structure of $Gd_2Zr_6(\mu_4\text{-}O)_2(\mu\text{-}OAc)_6(\mu\text{-}OPr^i)_{10}(OPr^i)_{10}$ showing the atom labelling.

[a] Prime-related by an inversion centre.

oxo ligand is supported by a bridging $H(OPr^i)_2^-$ ligand resulting from hydrogen bonding. With the exception of the long Zr(2)···Zr(3) distance the tetranuclear unit is quite regular, with Gd···Zr distances of 3.57 Å av., and thus close to the Zr···Zr distances. A similar tetranuclear framework has also been observed for a mixed-metal lead–zirconium derivative, $PbZr_3(\mu\text{-}OAc)_2(\mu\text{-}OPr^i)_5(OPr^i)_5$.[3,15] The tetranuclear aggregates of **1** are connected by acetate ligands, thus resulting in hepta-coordination of the gadolinium centres and quite long Gd···Gd distances (5.58 Å). The M—O bond distances follow the pattern Zr—OR < Zr—μ-OR Zr—μ_4-O Zr—OAc and Gd—μ-OR < Gd—μ-OAc < Gd—μ-4O and range from 1.904(9) to 2.274(9) Å for zirconium and from 2.277(8) to 2.421(8) Å for gadolinium. The gadolinium–oxygen bond lengths are longer than the Zr—O ones, as expected on the basis of the larger gadolinium covalent radius. Quite large variations are observed for the Zr—μ-OR (2.10–2.27 Å) as well as for the Gd—OAc linkages (2.27–2.41 Å). Angles Zr—O—C to terminal alkoxide ligands are large (167.7° av.) and account for the short Zr—O bond lengths (av. 1.91 Å) with respect to the sum of the covalent radii (2.18 Å). The various metal–oxygen distances are in the range of the values reported for zirconium isopropoxide derivatives[16] or the gadolinium alkoxides structurally characterized so far, $Cp_5Gd(\mu_5\text{-}O)(OMe)_8$ and $Na_2Gd_4(\mu_6\text{-}O)(OBu^t)_{12}$.[17] Although both types of zirconium centres—depending on the number of terminal and bridging alkoxides—are hexa-coordinated, they depart from octahedral geometry. Gadolinium, like other lanthanides, can commonly accommodate high coordination numbers such as eight; however, only hexa-coordination has been observed so far in its alkoxide derivatives,[17] while the metal is six- or seven-coordinate in Gd_2O_3. The stereochemistry of the hepta-coordinated gadolinium centres of **1** correspond to a triangular prism capped by an acetate oxygen, O(4). The increase in the gadolinium coordination number in the acetatoalkoxide illustrates a common tendency of acetate ligands.

The NMR spectra of the yttrium derivative **2** account for a structure similar to that of compound **1** in solution. In view of the large yield of **1** and **2** and of the absence of formation of isopropylacetate (as shown by IR monitoring and by NMR), the origin of the oxo ligand most probably results from the alkoxide groups giving an oxo $Zr_3O(OR)_{10}$ unit. Such an oxo fragment has also been detected by mass spectrometry studies.[5] Reactions between metal alkoxides and acetates do not necesssarily proceed by elimination of an ester, since derivatives resulting from simple addition reactions such as $MNb_2(\mu\text{-}OAc)_2(\mu\text{-}OPr^i)_4(OPr^i)_6$ (M = Cd, Mg) have been obtained and structurally characterized.[3a,18]

Hydrolysis of **1** gives a powder still containing acetate ligands [$\nu_{as}(CO_2)$ 1541, $\nu_s(CO_2)$ 1404 cm^{-1}] and hydroxyl residues [ν(OH) 3375 cm^{-1}], as a result of the lower hydrolytic susceptibility of the carboxylate ligands as compared with alkoxides,[1] which are further eliminated by thermal treatment at 300°C as shown by thermogravimetric analysis. Temperatures as high as 700°C are usually required for the conversion of gadolinium acetate into the oxide.[19] After crystallization (starting at 600°C), cubic ZrO_2 containing 25% of Gd_2O_3 is obtained as a result of the existence of ZrO_2–Gd_2O_3 solid solutions over a large range of compositions.[20] Comparable results are obtained in the case of the yttrium derivative **1** {IR after hydrolysis 3382 [ν(OH)], 1558 [$\nu_{as}(CO_2)$], 1412 [$\nu_s(CO_2)$] cm^{-1}}.

The Ln—Zr stoichiometry of the mixed-metal species can be modified by varying the nature of the OR ligand. Heterometallic species in which the two metals, Ln and Zr, display a 1 : 1 stoichiometry[21] are obtained if zirconium 2-methoxyethoxide is used instead of the isopropoxide. The zirconium 2-methoxyethoxide is also more reactive and dissolution of the anhydrous $Ln(OAc)_3$ proceeds readily at room temperature. By contrast with the reactions with zirconium isopropoxide, refluxing leads in this case to the elimination of an ester, $MeOC_2H_4OAc$, detected by IR [$\nu(CO_2)$: 1726 cm^{-1}]. These condensation reactions result in species having a higher proportion of oxo ligands and which are also less soluble than **1** or **2**.

The overall data establish that the poor reactivity and insolubility of acetates can be overcome in the presence of a metal alkoxide, giving a soluble mixed-metal species. The reaction proceeds with redistribution of the acetate ligands, which act as assembling ligands between the different metals. The use of soluble—but less favourable in terms of ceramic yields—carboxylates such as 2-ethylhexanoates is thus not a prerequisite. The metal introduced via classical alkoxides such as isopropoxides or ethoxides is always predominant.[3a] Another interesting feature lies in the assistance of the organic residues, which allow thermal elimination of the acetate ligands (which remain after hydrolysis) in quite mild conditions as compared with the parent acetates.

THE SYNTHESIS AND CHARACTERIZATION OF NOVEL DIOXIMES AND THEIR HETERONUCLEAR COMPLEXES CONTAINING CROWN ETHER MOIETIES

YASAR GOK,* HALIT KANTEKIN and ISMAIL DEGIRMENCIOGLU

Department of Chemistry, Karadeniz Technical University, 6180 Trabzon, Turkey

(*Received* 27 *April* 1993; *accepted* 7 *May* 1993)

Abstract—A novel vic-dioxime S,S′-bis[2-(4′-benzylidenamino-benzo-15-crown-5)]dithioglyoxime (**6**), with crown ether groups has been synthesized from the reaction of 4′-formylbenzo(15-crown-5) and S,S′-bis(2-aminophenyl)dithioglyoxime (**4**), which has been synthesized from the potassium salt of 2-aminothiophenol and dichloroglyoxime. Mononuclear complexes with a metal : ligand ratio of 1 : 2 have been isolated for nickel(II) and cobalt(III). The reaction of mononuclear complexes with copper(I) and cadmium(II) gives heterotrinuclear complexes. The structure of dioximes and their complexes are proposed according to elemental analyses, ^{1}H and ^{13}C NMR, IR, UV–vis and mass spectra.

Crown ether compounds which were first synthesized by Pedersen, who described their ion-binding properties,[1] have been the focus of a great deal of interest for the past 35 years. This is because of the possible chemical and biological applications of their unusual ion-binding capability, solvation and transport effect.[2] A number of investigations of these processes have been carried out,[3] as well as studies of the molecular structures of the complexes using IR, ^{1}H and ^{13}C NMR spectroscopy[4] and X-ray crystallography.[5] Recently, crown ether groups have also been extensively employed to construct new compounds with extraordinary properties; ion channels formed by the superposition of crown ether macrocycles in tetrakis(crown ether) substituted phthalocyanines.[6] Bis(crown ether) Schiff base[7] and quinoxaline,[8] and imidazoline[9] ligands containing recognition sites for alkali and transition metal guest cations have been reported.[10] The design and synthesis of macropolycyclic molecules containing more than one recognition site for binding several guest species is of considerable current interest in the chemical literature.[7b,11] These multisite receptors may exhibit allosteric properties[12] by binding sequentially two or more guest metal cations in close proximity to one another.

vic-Dioximes have received considerable attention as model compounds to mimic biofunctions such as reduction of vitamin B_{12}.[13] Their complexes have been the continuous source, through the decades, of many interesting reports. The reaction of thiols with (*E,E*)-dichloroglyoxime or cyanogen di-N-oxide yielded various symmetrically substituted dithioglyoxime derivatives.[14] The (*E,E*)- and (*E,Z*)-stereoisomers of *vic*-dioximes are capable of coordinating through N,N or N,O sites of the oxime groups, and only in a few cases is it possible to realize the interconversion of (*E,E*) and (*E,Z*) complexes.[9,15] The transition metal complexes of these vicinal dioximes are essentially N,N-coordinated square-planar structures.[16]

Especially the chemistry and molecular structure of bis(dioximato)cobalt(III) complexes have been extensively explored in the last few years[17] due to interest in them as models for important biochemical complexes, as well as to their usefulness as catalysts in many chemical processes[18] or as templates in many organic syntheses.[19]

Furthermore, the relevance of bimetallic compounds to bioinorganic systems has been one of the reasons for the increase in the amount of research on polynuclear compounds. In addition to these resulting polynuclear complexes may facilitate electron-transfer studies and serve as models of relevance to biological redox processes.

In the present paper we describe symmetrically substituted dithioglyoxime and its derivative carrying symmetrical benzylidenamino benzo(15-crown-5) units. The preparation of a bis-benzo

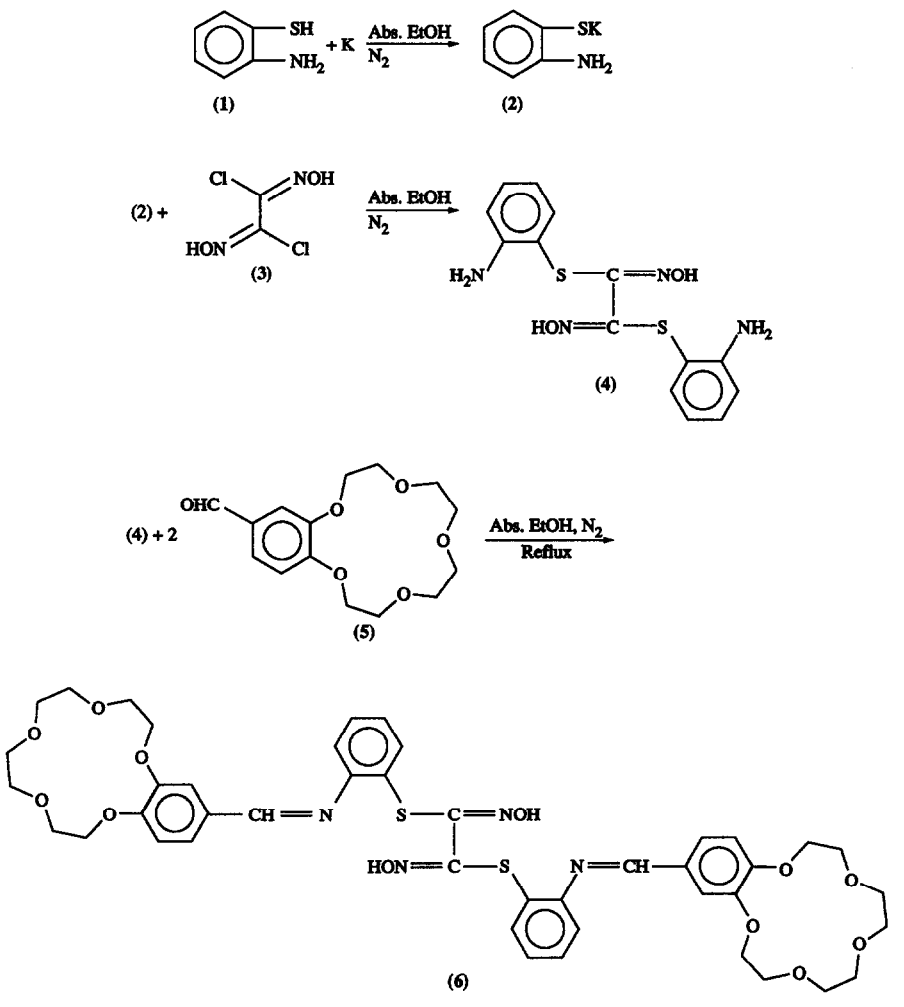
crown ether ligand(6) containing a Schiff base diothioglyoxime linkage and its heteronuclear complexes has been achieved.

RESULTS AND DISCUSSION

The ligand used for this study, namely S,S′-bis(2-aminophenyl)dithioglyoxime (**4**), contains an amine and two sulphur donors and a *vic*-dioxime group. Its synthesis was accomplished in 62.8% yield by the reaction of dichloroglyoxime and the potassium salt of 2-aminothiophenol as shown in Scheme 1. The condensation reaction of **4** with 4′-formylbenzo(-15-crown-5) (**5**)[20] (2 mol) gave the Schiff base bis-crown ether (**6**), which is named S,S′-bis[2-(4′-benzylidenamino - benzo - 15 - crown - 5)]dithioglyoxime, as a white crystalline solid in good yield (24.94%) (Scheme 1). Both structures were verified by elemental analyses, mass spectrometry, ^{1}H and ^{13}C NMR, IR and UV–vis spectroscopy. The two novel *vic*-dioxime ligands **4** and **6** contain three recognition site for transition metals, whereas **6** contains two crown ether sites for alkali metal cations.

In the ^{1}H NMR spectrum of **4** a singlet which belongs to the thiol group disappears; a new resonance at $\delta = 11.77$ ppm is formed after the addition of (*E,E*)-dichloroglyoxime (Scheme 1). This resonance indicates that the OH protons are present in this compound (**4**). The =N—OH protons are also identified easily by D_2O exchange. The presence of only one singlet for the OH protons is consistent with the assumption that **4** has an *S-trans*-configuration, as do all known symmetrically substituted *vic*-dioximes.[21] A singlet at $\delta = 5.06$ and multiplets at $\delta = 6.54$–7.26 ppm corresponding to NH_2 and aromatic protons are not shifted considerably compared with the starting material (**1**). More detailed information about the structure of **4** is provided by the ^{13}C NMR spectrum. The signal



Scheme 1.

for the benzene carbon, C(1) with *ortho*-C—S substituents, is observed at $\delta = 143.97$ ppm,[22] while the other carbon [C(2)] having a proton with *ortho*-C—N and *meta*-C—S substituents is seen at $\delta = 109.51$ ppm. The other signals which belong to benzene carbons C(3), C(4), C(5) and C(6) are observed at $\delta = 128.36$, 114.57, 126.58 and 116.22 ppm, respectively. In addition to the chemical shifts of the carbon atoms (4) oxime groups exhibit a new signal belonging to C(7) (Table 1). The presence of only one resonance for oxime carbons in the ^{13}C NMR spectrum of **4** can be interpreted for the formation of an *S-trans*-configuration of **4**.[15] The carbon resonances of oximes in this compound are found at higher fields than values given for aldo- and keto-oximes.[22] The mass spectrum of **4**, which shows a molecular ion at *m/z* 334, confirms the proposed structure and rules out any polymeric form. In the IR spectrum of **4** the disappearance of the S—H stretching vibration along with the appearance of new vibrations at 3210 [(OH)], 1650 [(C=N)] and 980 cm^{-1} [(N—O)] are in agreement with the structure in Table 1. The aromatic and amine stretching and bending vibrations of **4** are very close to those of both **4** and **1**. In the ^1H NMR spectra of **6** OH protons appear as a singlet at $\delta = 12.21$ ppm, which disappears upon D_2O exchange. This result indicates that the structure of **6** is of the *S-trans* form[23] (Table 2). The singlets at $\delta = 5.06$ ppm, which belong to NH_2 protons of **4**, disappear after the condensation reaction with **5**. The chemical shifts which belong to aromatic and etheral protons were observed at $\delta = 8.05$, 7.62–7.38, 7.10 and 3.65–4.19 ppm, respectively. The carbonyl protons were shifted upfield[12a] as expected and appeared at $\delta = 9.84$ ppm. In the ^{13}C NMR spectrum of **6** all the carbon atoms of the aliphatic ether groups show absorptions between $\delta = 68.27$ and 70.46 ppm, as previously reported.[9b] The protonated benzene carbons with the *ortho*-carbonyl and O—CH_2 substituents appear at $\delta = 114.20$ ppm. The aromatic carbon atom attached to the carboxy group appears at $\delta = 128.22$ ppm. The chemical shifts for the azomethine carbons and carbohydroxyamide carbon atom are found at $\delta = 167.07$ and 151.28 ppm, respectively. These equivalent carbon atoms also confirm the *S-trans* configuration[24] and are also found at lower fields than values given for aldo- and keto-oximes. The mass spectrum of **6** did not exhibit a molecular ion;[8] however, peaks at *m/z* 841 (30), 804 (48), 708 (14), 589 (85), 440(8) and 402 (68) were observed. The observed chemical shifts either in ^1H or ^{13}C NMR for **6** reveal that upon condensation the HC=N, C=N—O, aromatic and O—CH_2 carbon bonds shift by a small degree. Little change in the positions of the above-mentioned absorptions were evidence suggesting Schiff base formation of **4**.

In the IR spectrum of **6** the stretching and bending vibrations at 3350 and 1630 cm^{-1}, respectively, disappear after the formation of the Schiff base and the new resonances, which belong to C=N group, appear at 1670 cm^{-1} as a broad band. The O—H, N—O and C=N vibrations which belongs to the oxime group were observed at 3220, 965 and 1640 cm^{-1}, respectively. In addition the stretching vibration (C=O) for **5** disappears after the condensation reaction of **4** with **5**. This result indicates that the formation of the Schiff base is completed.

The reaction of **4** with a salt of nickel(II) gives a product with a metal–ligand ratio of 1:2. This mononuclear complex was obtained even when the metal ion was used in an equivalent amount. Since a distinct lowering in the pH of the solution was observed during the complex formation, in the case of nickel(II) complex (**7**), deprotonation of (**4**) with subsequent N,N′-chelation with the *vic*-dioxime groups probably occurs (Fig. 1).

In the ^1H NMR spectrum of the diamagnetic nickel(II) complex (**7**) the resonances of intramolecular binding OH···O protons shifted to $\delta = 17.15$ ppm, which disappear by D_2O exchange. The usual hydrogen bridges of the square-planar vic-dioxime complexes were also characterized by the weak deformation bands[25] around 1730 cm^{-1}. Weak bands at *ca* 1730 cm^{-1} indicate OH···O bridges,[16a] while the C=N vibrations are at lower wave numbers, as expected for N,N-chelated vicinal dioxime complexes. This mononuclear complex **7** is diamagnetic, as expected for a square-planar d^8 metal ion.[26]

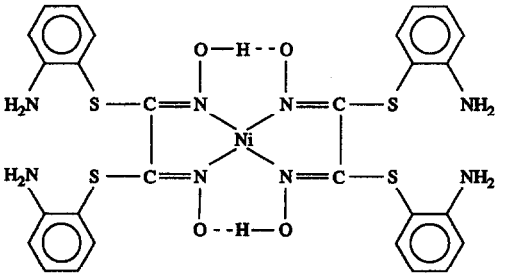
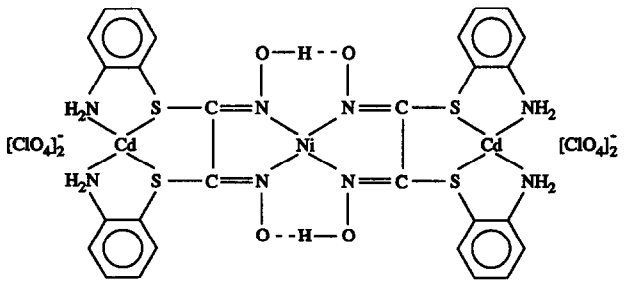
To prepare the cadmium(II) complex of **7** a suspension of **7** in ethanol was refluxed for 17 h. Thus, the cadmium(II) complex (**8**) was obtained. This trinuclear complex is diamagnetic. The stability of the dithiadiamino complex of two cadmium(II) metal ions in solvents such as water and ethanol is the most important reason for the formation of this tri-nuclear complex. The difference in the ^1H NMR spectrum of **8** is the presence of small shifts for the NH_2 protons, which can be interpreted as the formation of the new complex. A close look at the IR spectrum of **8**, taken as KBr pellets, shows a high degree of similarity which suggests that it has the same geometrical configuration. The [(NH_2)] mode of **7** occurs at 3300 cm^{-1} and a band at 1605 cm^{-1} is attributed to [$\delta(NH_2)$]. This band is lowered to 3200–3265 cm^{-1} in the complex, suggesting Cd—N through the amine nitrogen atom. The [(S—C)] vibrations in the free ligand (**4**) appear as a split band at 690 and 585 cm^{-1}, a mode which is shifted in the spectra of the trinuclear complex of **4** and which appears at 663 and 572 cm^{-1} suggesting the bonding of the metal ion to the ligand sulphur atom. This is further supported by the presence of bands in the lower frequency region which can be attributed to Cd—S bonding. With regard to the nature of the perchlorate ion in **8**, the complex shows a strong band centred at 1095 cm^{-1}, a weak one at 960



(7)

Fig. 1.



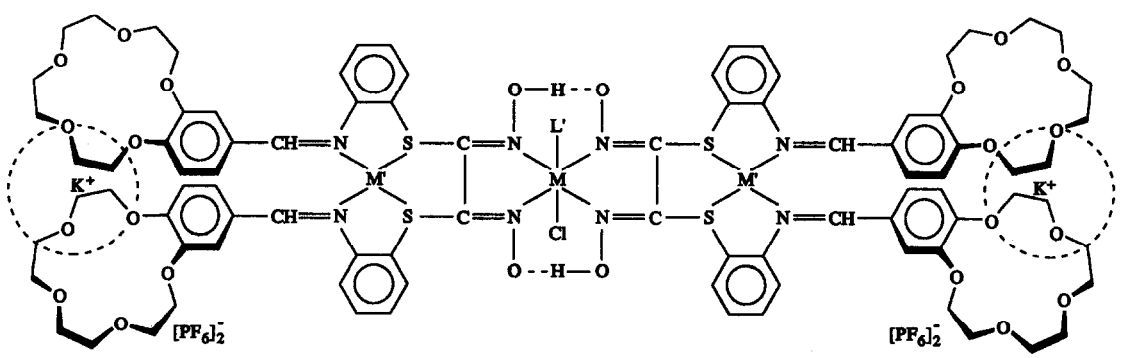
(8)

Fig. 2.

and a sharp one at 620 cm^{-1}, features typical of ionic perchlorates.[27a,b] The lack of appreciable splitting of the strong perchlorate bands supports a structure in which the perchlorate ions are not coordinated to the metal ions.[27c] A structural feature of this complex system is the presence of fused benzo groups, which serve to reduce the flexibility of the system.[28] The X-ray analysis indicates that in $[Cd(gly)_2]\cdot H_2O$[29] two glycino anions coordinate to the metal by forming a square-planar structure. The IR spectrum of the d^{10} complex of L-cysteine[30] shows that the structure of the complexes is square-planar, as shown in Fig. 2.

The cobalt(III) complex of **6** was prepared as previously reported[9a]. In the ^1H NMR spectrum of this complex the deuterium is exchangeable; intramolecular bridging, O—H · · · O protons appear as a singlet at $\delta = 14.35$ ppm for the pyridine derivative. ^{13}C NMR spectra of this compounds are very similar to those of the free ligand (**6**). The small shifts that take place in these spectra are due to complexation. The complex exhibits [(C=N)] absorptions at 1630 and 1660 cm^{-1}. In addition, after the complexation reaction of **6** the [(O—H)] vibrations at 3220 cm^{-1} disappear. These facts suggest that ligand **6** is N,N′-coordinated to cobalt(III) to look like the proposed structure (**9**) shown in Fig. 3.

The reaction of $[Cu(I)(CH_3CN)_4][PF_6]$[31] with **6** gave the corresponding diamagnetic copper(I) complex as a dark-yellow microcrystalline solid. This complex is especially suited for non-aqueous media syntheses of copper(I) compounds and the complex is moderately soluble in polar solvents and remarkably stable to air oxidation in CH_3CN solution. In this complex with **9** tetradentate coordination is achieved by the use of the two imino nitrogen and two sulphur atoms. Comparing the respective solutions, the ^{13}C NMR spectra of **9** and its copper(I) complex (Table 2) reveal that upon complexation shifts of the HC=N, SC and NC carbons by up to 5–7 pm result. Little change (0.7–1.0 ppm) in the position of the crown ether absorptions were evident, supporting the structure of the copper(I) cation in complex **10**. Subsequent complexation of the copper(I) complex with potassium hexafluorophosphate gave the respective heteropolymetallic complexes **10**, with the copper(I) cation in a square-planar coordination environment



9:M = Co^{III},L′ = pyridine
10:M = Co^{III},L′ = pyridine
M′ = Cu^{I}

Fig. 3.

and (Fig. 3) the potassium cations bound by crown ether moieties. The structures of these sandwich complexes are proposed in Fig. 3. In the IR spectrum **10** shows small shifts for the stretching vibrations of the imine groups. The [(C=N)] vibrations of **10** appear at 1638 cm^{-1}. This azomethine stretch occurs at slightly lower energy in complex **9**, which indicates coordination of the imine nitrogen atom. As expected, shifts of the imine stretching vibrations to lower wave numbers are observed by complexation of copper(I) and potassium hexafluoro phosphate. In addition to these shifts of [(C=N)] suggest the bound alkali metal cations are influencing the electron density at the respective cobalt-bound copper(I) metal centres. The bands (850 and 557 cm^{-1}) which belong to [PF_6] support the structure in which the hexafluorophosphate ions are not coordinated to the centred copper(I) atom.[31]

EXPERIMENTAL

The ^1H and ^{13}C NMR spectra were recorded with a Bruker 200-AC instrument in DMSO-d_6 and the chemical shifts are reported in δ values relative to Me_4Si as an internal standard. IR spectra were recorded with a Perkin–Elmer 1600 FT-IR instrument. Mass spectra were measured on a Concept H Series Mass spectrometer. The metal contents of the complexes were determined by a Hitachi 180-80 atomic absorption spectrophotometer in solutions prepared by decomposing the compounds in the aqua regia and then subsequently digesting in concentrated HCl. 4′-Formylbenzo(15-crown-5)[32] (**5**) and dichloroglyoxime[33] were prepared as in the reference cited.

S,S′-Bis(2-aminophenyl)dithioglyoxime (**4**)

A solution of the potassium salt of 2-aminothiophenol was prepared by portionwise addition of the latter (2.5 g, 20 mmol) to KOEt solution, obtained by dissolving potassium metal (0.78 g, 20 mmol) in absolute ethanol (40 cm^3). This solution, together with a solution of (*E,E*)-dichloroglyoxime (1.57 g, 10 mmol) in absolute ethanol (40 cm^3), was simultaneously added dropwise over 6 h to absolute ethanol (180 cm^3) stirred at room temperature under nitrogen; stirring was continued overnight. The pale yellow reaction mixture was then filtered off and the filtrate volume was reduced to 30 cm^3 to precipitate the rest of the crude product. The crude product was filtered off, washed with water, cold ethanol and diethylether, respectively, and dried *in vacuo* over P_4O_{10}. After recrystallization from ethanol, yield; 2.10 g (62.8%) of needle crystals; m.p. 199°C (dec.). IR (KBr) = 3550, 3295, 3210, 3070, 2950, 1650, 1610, 1600, 1590, 1570, 1480, 1435, 1320, 1295, 1240, 1160, 980, 690, 585 cm^{-1}. ^1H NMR [D_6] DMSO: δ = 11.77 (s, 2H), 5.06 (s, 4H), 7.26–6.24 (m, 8H). ^{13}C NMR [D_6] DMSO: δ = 150.15, 143.97, 128.36, 126.58, 116.22, 114.57, 109.51. MS (E.I.), *m/z* (%): 334 (12) (M^+), 316 (16), 302 (10), 283 (100). UV–vis (DMF), λ_{max} (log ε): 276 (4.87), 306 (4.55), 323 (4.48), 348 (4.36), 364 (4.30). Found: C, 50.0; H, 4.1; N, 16.6. Calc. for $C_{14}H_{14}N_4O_2S_2$: C, 50.3; H, 4.2; N, 16.8%.

S,S-Bis[2-(4′-benzylidenamino-benzo-15-crown-5)] dithioglyoxime (**6**)

A solution of 4′-formylbenzo(15-crown-5) (2.96 g, 10 mmol) in absolute ethanol (35 cm^3) was added dropwise to a solution of compound **4** (1.67 g, 5 mmol) in absolute ethanol for a 30 min period at room temperature under nitrogen. The reaction mixture was refluxed and stirred for 22 h. The reaction was monitored by thin layer chromatography [*Rf* = 0.79, $CHCl_3$: CH_3—OH : H_2O (73 : 25 : 3)]. The mixture was cooled and the solvent was removed *in vacuo*. After crystallization of the product from ethanol, yield 1.11 g (24.9%) of white product; m.p. 117°C (dec.). IR (KBr): 3200, 3065, 2920, 2850, 1670, 1640, 1600, 1580, 1510, 1435, 1280, 1160, 1130, 1050, 965, 686, 582 cm^{-1}. ^1H NMR [D_6] DMSO: δ = 12.21 (s, 2H), 9.84 (s, 2H), 8.05 (s, 4H), 7.62–7.38 (m, 8H), 7.10 (s, 2H), 4.19–3.65 (m, 32H). ^{13}C NMR [D_6] DMSO: δ = 167.07, 153.48, 151.28, 148.67, 144.19, 134.04, 130.43, 128.22, 122.07, 118.24, 114.20, 113.17, 112.20, 111.05, 70.46, 69.55, 68.50, 68.27. MS (FAB.), *m/z* (%): 842 ($M^+ - NOH - OH$), 804 (45), 664 (18), 708 (12), 589 (85), 537 (90), 154 (100). UV–vis (DMF) (nm): λ_{max} (log ε) 270 nm (4.58), 305 nm (4.83), 361 nm (4.97), 391 nm (4.85). Found: C, 59.2; H, 5.5; N, 6.2. Calc. for $C_{44}H_{50}N_4O_{12}S_2$: C, 59.3; H, 5.6; N, 6.3%.

{*Bis[S,S′-bis(2-aminophenyl)dithioglyoximato]*} *nickel*(II) *complex* (**7**)

A solution of $NiCl_2 \cdot 6H_2O$ (0.474 g, 2 mmol) in ethanol (30 cm^3) was added to a solution of **4** (1.336 g, 4 mmol) in ethanol (60 cm^3) at room temperature, a distinct change in colour from colourless to red and a decrease in the "pH" of the solution was observed. While heating the mixture to 70°C $(C_2H_5)_3N$ (0.505 g, 5 mmol) in ethanol (5 cm^3) was added and an orange precipitate formed (**7**). After heating the mixture for 2 h the precipitate was filtered off, washed with water, ethanol and diethyl ether and then dried *in vacuo* over P_4O_{10}. Yield:

1.425 (98.3%); m.p. 297°C (dec.). IR (KBr): = 3305, 3030, 1730, 1635, 1605, 1595, 1565, 1480, 1440, 1310, 1235, 1190, 1160, 1130, 1060, 960, 910, 681, 583 cm^{-1}. ^1H NMR [D_6]DMSO: δ 5.13 (s, 8H), 7.35–6.68 (m, 16H), 17.35 (s, 2H). UV–vis (DMF), λ_{max} (nm) ($\log\varepsilon$): 275 (4.69), 304 (4.58), 322 (4.85), 342 (4.88), 395 (4.30), 516 (4.12). Found: C, 46.2; H, 3.4; N, 15.3; Ni, 7.9. Calc. for $C_{28}H_{26}N_8O_4S_4Ni$: C, 46.4; H, 3.6; N, 15.4; Ni, 8.1%.

Trinuclear complex of **4**

A solution of $Cd(ClO_4)_2 \cdot 6H_2O$ (0.836 g, 2 mmol) in ethanol (20 cm^3) was added to a suspension of **7** (0.724 g, 1 mmol) in ethanol (100 cm^3) and the mixture was refluxed for 17 h with vigorous stirring. The end of the reaction was determined by thin layer chromatograhy [$Rf = 0.65$, n-BuOH : CH_3COOH : H_2O (4 : 1 : 5)]. The precipitate was filtered off, washed with cold ethanol and diethyl ether and then dried *in vacuo* over P_4O_{10}. Yield (**8**): 1.112 g (82.5%); m.p. 319°C (dec.). IR (KBr): 3305, 3020, 1710, 1630, 1600, 1590, 1560, 1475, 1450, 1310, 1240, 1195, 1160, 1130, 1095, 960, 915, 663, 625, 572 cm^{-1}. ^1H NMR [D_6] DMSO: δ = 5.22 (br, 8H), 7.38–6.71 (m, 16H), 17.28 (s, 2H). UV–vis (DMF) (nm) λ_{max} ($\log\varepsilon$): 276 (4.82), 305 (4.50), 332 (4.81), 345 (4.76), 393 (4.15), 426 (3.94), 450 (3.63). Found: C, 24.6; H, 1.7; N, 8.2; Ni, 4.1; Cd, 16.4. Calc. for $[C_{28}H_{26}N_8O_4S_4NiCd_2][ClO_4]_4$: C, 24.9; H, 1.9; N, 8.3; Ni, 4.3; Cd, 16.7%.

The cobalt(III) *complex of* **6**

A solution of $CoCl_2 \cdot 6H_2O$ (0.1185 g, 0.5 mmol) in absolute ethanol (20 cm^3) was added to a solution of **6** (0.890 g, 1 mmol) in absolute ethanol (60 cm^3). While heating pyridine (0.395 g, 5 mmol) in ethanol (5 cm^3) was added to the above solution and dioxygen was bubbled through the mixture for 2 h at 70°C. The pale brown precipitate was filtered off, washed with water, ethanol and diethyl ether and then dried *in vacuo* over P_4O_{10}. Yield: 0.928 g, (95.1%); m.p. 326°C (dec.). IR (KBr): 3050, 2920–2845, 1660, 1630, 1600, 1580, 1470, 1440, 1310, 1300, 1245, 1160, 1140, 1030, 975, 940, 684, 584 cm^{-1}. ^1H NMR [D_6] DMSO: δ = 9.95 (s, 4H), 8.18–8.01 (m, 8H), 7.71 (s, 2H), 7.68–7.35 (m, 16H), 7.07 (s, 2H), 7.13 (s, 4H), 14.35 (s, 4H). ^{13}C NMR [D_6] DMSO: δ 167.06, 153.49, 151.32, 148.71, 143.87, 134.20, 126.40, 126.15, 125.82, 125.63, 124.79, 121.04, 117.92, 114.05, 113.27, 111.24, 111.03, 70.45, 69.59, 68.55, 68.33. UV–vis (DMF) (nm), λ_{max} ($\log\varepsilon$) = 272 (4.09), 303 (4.52), 322 (4.86), 365 (4.67), 420 (4.27), 525 (3.84). Found: C, 7.0; H, 5.2; N, 6.3; Co, 2.9. Calc. for $C_{93}H_{103}N_9O_{24}S_4ClCo$: C, 57.2; H, 5.3; N, 6.4; Co, 3.0%.

Trinuclear complex of **6**

A suspension of the mononuclear cobalt(III) complex of **6** (0.4878 g, 0.25 mmol) in dry acetonitrile (100 cm^3) was treated with excess $Cu(CH_3CN)_4PF_6$ (0.1829 g, 0.5 mmol) in dry acetonitrile (50 cm^3) under nitrogen and the mixture was refluxed for 18 h with stirring. The end of the reaction was determined by thin layer chromatography ($Rf = 0.68$, BAW 4 : 1 : 5). After the addition of KPF_6 (0.1104 g, 0.6 mmol) dissolved in dry acetonitrile (40 cm^3) under nitrogen the mixture was stirred at room temperature for 4 h and the solvent volume was reduced (30 cm^3) *in vacuo*. The precipitate was filtered off, washed with cold water, cold ethanol and diethyl ether and then dried *in vacuo* over P_4O_{10}. Yield (**10**): 0.627 g (87.87%), m.p. 380°C. IR (KBr): 3035, 2190–2840, 1720, 1638, 1625, 1600, 1580, 1560, 1530, 1450, 1430, 1380–1350, 1340, 1290, 1260, 1240–1210, 1175, 1030, 975, 895, 850, 667, 575, 557 cm^{-1}. ^1H NMR [D_6] DMSO: δ 9.91 (s, 4H), 8.25–8.03 (m, 8H), 7.78 (s, 2H), 7.68–7.43 (m, 16H), 7.22 (s, 4H), 7.12 (s, 2H), 15.64 (s, 4H). ^{13}C NMR [D_6] DMSO: δ 172.73, 153.56, 151.53, 150.58, 143.63, 134.51, 127.22, 126.17, 125.45, 124.68, 124.16, 121.18, 117.69, 113.96, 113.61, 113.47, 110.87, 70.25, 69.16, 68.21, 68.08. UV–vis (DMF) (nm), λ_{max} ($\log\varepsilon$): 278 (4.17), 302 (4.49), 331 (4.81), 348 (4.74), 366 (4.48), 444 (4.08) 536 (3.97). Found: C, 40.6; H, 3.6; N, 4.4; Co, 2.0; Cu, 4.4; K, 2.5. Calc. for $[C_{93}H_{103}N_9O_{24}S_4ClCoCu_2K_2][PF_6]_4$: C, 40.8; H, 3.8; N, 4.6; Co, 2.1; Cu, 4.6; K, 2.8%.

(*Received* 27 *April* 1993; *accepted* 7 *May* 1993)

Abstract—Reaction of equimolar quantities of $[WI_2(CO)(NCMe)(\eta^2\text{-}MeC_2Me)_2]$ and $Ph(H)CNNHCONH_2$ or $R(R^1)CNNHCSNH_2$ ($R = R^1 = Me$, Et; $R = H$, $R^1 = Ph$; $R = Me$, $R^1 = Et$, Pr^n, Bu^t, Ph) in CH_2Cl_2 at room temperature gave the cationic bis(but-2-yne) complexes $[WI(CO)\{Ph(H)CNNHCONH_2\}(\eta^2\text{-}MeC_2Me)_2]I$ or $[WI(CO)\{R(R^1)CNNHCSNH_2\}(\eta^2\text{-}MeC_2Me)_2]I$ in good yield. The cationic nature of these complexes was confirmed by reaction of $[WI(CO)\{Me(Ph)CNNHCSNH_2\}(\eta^2\text{-}MeC_2Me)_2]I$ with $Na[BPh_4]$ in acetonitrile to afford the tetraphenylborate exchanged product $[WI(CO)\{Me(Ph)CNNHCSNH_2\}(\eta^2\text{-}MeC_2Me)_2][BPh_4]$. Refluxing a $CHCl_3$ solution of $[WI(CO)\{Et_2CNNHCSNH_2\}(\eta^2\text{-}MeC_2Me)_2]I$ for 14 h gave the mono(but-2-yne) complex $[WI_2(CO)\{Et_2CNNHCSNH_2\}(\eta^2\text{-}MeC_2Me)]$.

Although a wide range of "classical" transition metal complexes containing semicarbazones and thiosemicarbazones have been described,[1–3] very few examples of organotransition metal complexes containing these attached ligands have been reported. The π-allyl molybdenum thiosemicarbazone complexes $[MoX(CO)_2\{R^1(R^{11})CNNHCSNH_2\}(\eta^3\text{-}C_3H_4R)]$ ($X = Cl$ or Br; $R = H$ or Me; $R^1 = H$ or Me; $R^{11} = Me$, Et, Pr^n or Ph)[4,5] and the closely related semicarbazone complexes $[MoX(CO)_2\{R^1(R^{11})CNNHCONH_2\}(\eta^3\text{-}C_3H_4R)]$ ($X = Cl$, Br or I; $R = H$ or Me; R′, R″ = H or Me and Me, Et, Pr^n or Ph)[6,7] have been prepared and characterized. Tripathi and coworkers[8] have described the synthesis of some zirconium cyclopentadienyl thiosemicarbazone complexes. The iron complexes $[Fe(CO)_2L(\eta^5\text{-}C_5H_5)][PF_6]$ [$L = R^1(R^{11})CNNHCSNH_2$, where $R^1 = R^{11} = Me$; $R^1 = H$, $R^{11} = Ph$; $R^1 = H$, $R^{11} = p\text{-}NO_2Ph$; $R^1 = Me$, $R^{11} = p\text{-}MePh$; $R^1R^{11} = C_5H_{10}$] have been prepared[9,10] and crystallographically characterized[10] for $R^1 = H$, $R^{11} = Ph$. The seven-coordinate thiosemicarbazone complexes $[WI_2(CO)_3\{R(R^1)CNNHCSNH_2\}]$ ($R = R^1 = Me$ or Et; $R = Me$, $R^1 = Pr^i$; $R = Ph$, $R^1 = H$) and $[Mo(\mu\text{-}I)I(CO)_2\{R(R^1)CNNHCSNH_2\}]_2$ have also been reported.[11]

In recent years we have been investigating the chemistry of the bis(alkyne) tungsten complexes $[WI_2(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$ ($R = Me$ or Ph),[12] which are prepared by reacting the bis(acetonitrile) complex $[WI_2(CO)_3(NCMe)_2]$ with an excess of RC_2R in CH_2Cl_2 at 0°C. In this paper we describe the reactions of the bis(but-2-yne) complex $[WI_2(CO)(NCMe)(\eta^2\text{-}MeC_2Me)_2]$ with benzaldehydesemicarbazone and thiosemicarbazones.

EXPERIMENTAL

The reactions were performed under dry nitrogen using standard Schlenk-line techniques. The compound $[WI_2(CO)(NCMe)(\eta^2\text{-}MeC_2Me)_2]$ was prepared by the published method.[12] The ligands benzaldehydesemicarbazone and the thiosemicarbazones $R(R^1)CNNHCSNH_2$ ($R = R^1 = Me$, Et; $R = H$, $R^1 = Ph$; $R = Me$, $R^1 = Et$, Pr^n, Bu^t, Ph) were synthesized by the method of Sah and Daniels.[13] All other chemicals used were purchased from commercial sources. IR spectra were recorded as $CHCl_3$ films between NaCl plates on a 1430 ratio recording IR spectrophotometer. Elemental analyses (carbon, hydrogen and nitrogen) were determined using a Carlo–Erba elemental analyser MOD 1106 (using helium as a carrier gas). ^1H and ^{13}C NMR spectra were recorded either on a Bruker AC 250 or a Bruker WH 400 MHz NMR spec-

trometer (all spectra were calibrated against tetramethylsilane).

Preparation of [WI(CO){H(Ph)CNNHCONH$_2$}(η^2-MeC$_2$Me)$_2$]I (**1**)

To a stirred solution of [WI$_2$(CO)(NCMe)(η^2-MeC$_2$Me)$_2$] (0.5 g, 0.813 mmol) in CH_2Cl_2 (20 cm^3) was added H(Ph)CNNHCONH$_2$(0.13 g, 0.813 mmol). After stirring for 18 h the solution was filtered and the solvent removed *in vacuo* to give brown crystals of [WI(CO){H(Ph)CNNHCONH$_2$}(η^2-MeC$_2$Me)$_2$]I (**1**), which were recrystallized from CH_2Cl_2/Et_2O. Yield of pure complex = 0.24 g, 40% (see Table 1 for physical and analytical data).

Preparation of [WI$_2$(CO){Me(Ph)CNNHCSNH$_2$}(η^2-MeC$_2$Me)$_2$]I (**8**)

To a stirred solution of [WI$_2$(CO)(NCMe)(η^2-MeC$_2$Me)$_2$] (0.5 g, 0.813 mmol) in CH_2Cl_2 (20 cm^3) was added Me(Ph)CNNHCSNH$_2$ (0.16 g, 0.813 mmol). After stirring for 18 h the solution was filtered and the solvent removed *in vacuo* to give brown crystals of [WI(CO){Me(Ph)CNNHCSNH$_2$}(η^2-MeC$_2$Me)$_2$]I (**8**), which were recrystallized from CH_2Cl_2/Et_2O. Yield of pure complex = 0.32 g, 52%.

Similar reactions of [WI$_2$(CO)(NCMe)(η^2-MeC$_2$Me)$_2$] with an equimolar quantity of R(R^1)CNNHCSNH$_2$ [R = R^1 = Me (**2**), Et (**3**); R = H, R^1 = Ph (**4**); R = Me, R^1 = Et (**5**); Pr^n (**6**); Bu^t (**7**)] in CH_2Cl_2 at room temperature gave [WI(CO){R(R^1)CNNHCSNH$_2$}(η^2-MeC$_2$Me)$_2$]I (**2–7**). For physical and analytical data see Table 1.

Preparation of [WI(CO){Me(Ph)CNNHCSNH$_2$}(η^2-MeC$_2$Me)$_2$][BPh$_4$] (**9**)

To a stirred suspension of [WI$_2$(CO)(NCMe)(η^2-MeC$_2$Me)$_2$] (0.5 g, 0.813 mmol) in acetonitrile (25 cm^3) was added Me(Ph)CNNHCSNH$_2$ (0.16 g, 0.829 mmol) and Na[BPh$_4$] (0.28 g, 0.819 mmol). After stirring for 18 h removal of the solvent *in vacuo* afforded a yellow/white slurry, which was redissoved in CH_2Cl_2 (20 cm^3) and the solution was filtered twice to remove NaI. Finally, removal of the solvent *in vacuo* gave red/brown crystals of [WI(CO){Me(Ph)CNNHCSNH$_2$}(η^2-MeC$_2$Me)$_2$][BPh$_4$] (**9**), which were recrystallized from CH_2Cl_2/Et_2O. Yield of pure product = 0.37 g, 47%.

Preparation of [WI$_2$(CO){Et$_2$CNNHCSNH$_2$}(η^2-MeC$_2$Me)] (**10**)

To a stirred solution of [WI$_2$(CO)(NCMe)(η^2-MeC$_2$Me)$_2$] (0.5 g, 0.813 mmol) in $CHCl_3$ (40 cm^3)

[a] Calculated values in parentheses.

was added $Et_2CNNHCSNH_2$ (0.13 g, 0.813 mmol). After refluxing for 14 h at 69°C cooling the solution, filtration and removal of the solvent *in vacuo* gave brown crystals of $[WI_2(CO)\{Et_2CNNHCSNH_2\}(\eta^2\text{-}MeC_2Me)]$ (**10**), which were recrystallized from CH_2Cl_2/Et_2O. Yield of pure product = 0.29 g, 53%.

RESULTS AND DISCUSSION

Equimolar quantities of $[WI_2(CO)(NCMe)(\eta^2\text{-}MeC_2Me)_2]$ and $Ph(H)CNNHCONH_2$ or $R(R^1)CNNHCSNH_2$ (R = R^1 = Me, Et; R = H, R^1 = Ph; R = Me, R^1 = Et, Pr^n, Bu^t, Ph) in CH_2Cl_2 at room temperature eventually gave the cationic complexes $[WI(CO)\{Ph(H)CNNHCONH_2\}(\eta^2\text{-}MeC_2Me)_2]I$ (**1**) and $[WI(CO)\{R(R^1)CNNHCSNH_2\}(\eta^2\text{-}MeC_2Me)_2]I$ (**2–8**) *via* displacement of an acetonitrile ligand and an iodide. Confirmation of the cationic nature of **1–8** was obtained by reacting equimolar amounts of $[WI(CO)\{Me(Ph)CNNHCSNH_2\}(\eta^2\text{-}MeC_2Me)_2]I$ and $Na[BPh_4]$ in acetonitrile to give the anion exchanged product $[WI(CO)\{Me(Ph)CNNHCSNH_2\}(\eta^2\text{-}MeC_2Me)_2][BPh_4]$ (**9**). Refluxing $[WI(CO)\{Et_2CNNHCSNH_2\}(\eta^2\text{-}MeC_2Me)_2]I$ (**3**) in chloroform (69°C) for 14 h eventually gave the neutral diiodo complex $[WI_2(CO)\{Et_2CNNHCSNH_2\}(\eta^2\text{-}MeC_2Me)]$ (**10**). All the new complexes **1–10** were characterized by elemental analysis (carbon, hydrogen and nitrogen) (Table 1), IR and ^1H NMR spectroscopy (Tables 2 and 3). Complexes **1–10** are moderately soluble in chlorinated solvents such as CH_2Cl_2 and $CHCl_3$, however, they are more soluble in acetone and dimethylsulphoxide. Complexes **1–10** are air-sensitive both in the solid state and in solution, however, they can be stored under nitrogen for several days. The reactions described in this paper are shown in Scheme 1.

The IR spectra of complexes **1–9** showed a strong single carbonyl band between 2020 and 2050 cm^{-1}, which was expected since the previously reported[14] bidentate nitrogen donor complexes $[WI(CO)(\widehat{N\,N})(\eta^2\text{-}RC_2R)_2]I$ (R = Me or Ph; $\widehat{N\,N}$ = 2,2′-bipy, 1,10-phen or *o*-phenylenediamine) have similar CO stretching bands in their IR spectra. The molecular structure of the tetraphenylborate complex $[WI(CO)(2,2'\text{-bipy})(\eta^2\text{-}MeC_2Me)_2][BPh_4]$ was crystallographically determined[14] and the structure of the related complexes described in this paper are likely to be similar, as shown in Fig. 1. The ^1H NMR spectra for **1–9** generally also show four but-2-yne methyl resonances, expected for the structure shown in Fig. 1. In the cases where there are three but-2-yne resonances the intensity ratio is 2:1:1, which indicates two of the resonances are overlapping. For the complexes $[WI(CO)(\widehat{O\,S}$ or $\widehat{N\,S})(\eta^2\text{-}MeC_2Me)_2]I$ (**1–8**) to obey the effective atomic number rule the two but-2-yne ligands in **1–8** must donate a total of six electrons to the metal, i.e. one four-electron and one two-electron donor to the tungsten centre. This was confirmed by the ^{13}C NMR spectrum obtained for $[WI(CO)\{Et_2CNNHCSNH_2\}(\eta^2\text{-}MeC_2Me)_2]I$ (**3**), which showed alkyne contact carbon resonances at $\delta(CDCl_3, +25°C)$ = 148.3, 156.3, 163.8 and 176.3 ppm, which from Templeton and Wards'[15] correlation suggest that the but-2-yne ligands are donating an average of "three" electrons each to the tungsten. However, it is likely that four- and two-electron alkynes are rapidly equilibrating on the NMR time-scale. Attempts to obtain the ^{13}C NMR spectra of all complexes **1–10** was unsuc-

cessful due to moderate solubility and instability in solution. It should be noted that we attempted the reactions of the more sterically crowded benzophenonethiosemicarbazone with [WI_2(CO)(NCMe)(η^2-MeC_2Me)$_2$] without success.

We have previously described[16] the reaction of the bidentate phosphines, $Ph_2P(CH_2)_nPPh_2$ (n = 1–6) with [WI_2(CO)(NCMe)(η^2-RC_2R)$_2$] (R = Me or Ph) to give the mono(alkyne) complexes [WI_2(CO){$Ph_2P(CH_2)_nPPh_2$}(η^2-RC_2R)]. Hence, we attempted to prepare the analogous mono(but-2-yne) complexes [WI_2(CO){Ph(H)CNNHCONH$_2$}(η^2-MeC_2Me)] and [WI_2(CO){R(R^1)CNNHCSNH$_2$}(η^2-MeC_2Me)] by refluxing **1–8** in CH_2Cl_2 or $CHCl_3$. In the case of R = R^1 = Et the neutral mono(but-2-yne) complex [WI_2(CO){Et_2CNNHCSNH$_2$}(η^2-MeC_2Me)] (**10**) was obtained in 53% yield, after refluxing [WI(CO){Et_2CNNHCSNH$_2$}(η^2-MeC_2Me)$_2$]I in $CHCl_3$ for 14 h. The carbonyl stretching band for **10** at 1960 cm^{-1} is at a considerably lower wave number than the bis(but-2-yne) complexes **1–9** and in a similar position to the bidentate phosphine complexes [WI_2(CO){$Ph_2P(CH_2)_nPPh_2$}(η^2-MeC_2Me)].[16] The differing behaviour of the $\widehat{N\,S}$ donor ligands and the $\widehat{P\,P}$ type ligands is likely to be due to the more electron-rich donor ability of $\widehat{N\,S}$, which helps to stabilize the bis(but-2-yne) complexes [WI(CO)($\widehat{N\,S}$)(η^2-MeC_2Me)$_2$]I. It should be noted that several unsuccessful attempts were made to prepare

(*Received* 23 *March* 1993; *accepted* 7 *May* 1993)

Abstract—Mononuclear diphenolato complexes [M(NO)L*X(OQOH)] and binuclear complexes [{M(NO)L*X}$_2$(μ-OQO)] {M = Mo, W; L* = [HB(3,5-$Me_2C_3HN_2$)$_3$]$^-$; X = Cl, I; Q = C_6H_4, 4,4′-$C_6H_4C(O)C_6H_4$, 4,4′-$C_6H_4S(O)_2C_6H_4$ or $C_6H_4C(O)(C_6H_4)_2C(O)C_6H_4$} were prepared. Some have been reported before; the new complexes were thoroughly characterized. Electrochemical interactions between the metal centres in the binuclear complexes with the three longer bridging ligands are small. The binuclear molybdenum complexes (which contain two 16-electron metal centres) with 4,4′-$OC_6H_4C(O)C_6H_4O$ or 4,4′-$OC_6H_4S(O)_2C_6H_4O$ as bridging ligands were reduced to dianionic species (two 17-electron centres), whose EPR spectra indicate pairwise electron exchange at or near the fast limit; with the longer bridging ligand $OC_6H_4C(O)(C_6H_4)_2C(O)C_6H_4O$ the more complex EPR spectrum of the reduced dianionic complex indicates that electron exchange is no longer "fast", but occurs at an intermediate rate. With the shortest bridging ligand OC_6H_4O the electrochemical interaction is sufficiently large to allow selective preparation of the mixed-valence 16-electron/17-electron species, whose EPR spectrum indicates that it is valence trapped; fast exchange is only initiated when *both* metal centres have a 17-electron configuration. The EPR spectra of the corresponding bimetallic tungsten dianions cannot be used to examine electron exchange processes since they show no resolved hyperfine signals.

In earlier papers[1,2] we reported that the bimetallic molybdenum complexes [{Mo(NO)L*X}$_2$E] [L* = tris(3,5-dimethylpyrazolyl)borate, HB(3,5-$Me_2C_3HN_2$)$_3$; E = *para*- or *meta*-OC_6H_4O; X = Cl or I] and [{Mo(NO)L*X}$_2$($OC_6H_4YC_6H_4O$)] (X = Cl or I; Y = nothing, O, S, SO_2, CO, $COC_6H_4C_6H_4CO$) underwent two one-electron reductions, affording a mono- and a di-anion. The $E_{1/2}$ data indicated that in those systems containing relatively short bridges, e.g. *para*-OC_6H_4O, the electrochemical interaction between the two redox centres was very strong (as measured by $\Delta E_{1/2}$, the difference between first and second reduction potentials), whereas in the complexes containing more extended bridges such as $OC_6H_4YC_6H_4O$ (above)

† Authors to whom correspondence should be addressed.

the interaction was weak or negligible. In the case of $[\{Mo(NO)L^*Cl\}_2(p\text{-}OC_6H_4O)]$ the two one-electron reductions are sufficiently well separated to permit selective one-electron reduction with a reducing agent of the appropriate potential;[1] with longer bridging ligands this is not possible. Whereas the neutral bimetallic complexes formally contain two 16-electron metal centres, the mixed-valence mono-anions have one 16- and one 17-electron centre and the dianions contain two 17-electron centres. The mixed-valence 16-electron/17-electron species could be either valence-trapped, if the asymmetry due to solvation differences at the two ends is sufficiently large, or delocalized with the electron "hopping" between the ends. The doubly-reduced 17-electron/17-electron species could have either singlet (coupled 17-electron centres) or triplet (uncoupled centres) states. The EPR properties of these paramagnetic species have not hitherto been studied in detail.

More recently we have found that analogous complexes containing bridging ligands such as 4,4′-bipyridines[3] and the "extended" α,ω-di(4-pyridyl)-polyenes[3,4] of the type $[\{Mo(NO)L^*Cl\}(pyr\text{–}E\text{–}pyr)]$ [E = $(CH_2)_n$, n = 0–3; $(CH{=}CH)_n$, n = 1–5; C_6H_4, N=N, etc.] contain two 17-electron molybdenum centres. The electrochemical interactions between those centres are substantial, being in fact an order of magnitude larger than the interactions found between $\{Ru(NH_3)_5\}^{2+}$ centres with the same bridging ligands.[5] EPR spectroscopy has shown that the two unpaired electrons in these species are apparently in fast exchange across the bridging ligand. This interaction can even occur across a saturated bridge,[3] its facility being explained partly by the fact that, unlike one-electron charge-transfer processes, there is no solvent reorganization required since both metals have the same number of electrons before and after any exchange.

Use of asymmetric bridging ligands, with one phenol terminus and one pyridyl terminus, has enabled the preparation of binuclear complexes with one 17-electron and one 16-electron terminus, e.g. $[\{Mo(NO)L^*Cl\}_2(OC_6H_4C_5H_4N)]$.[6,7] Due to the difference of 800 mV in redox potential between the two ends the single unpaired electron is "valence trapped", but one-electron reduction of the 16-electron terminus to give the *asymmetric* (17 + 17)-electron complex initiates apparent fast exchange of electrons between the two ends despite the asymmetry.

A re-examination of the doubly-reduced bimetallic complexes containing extended phenolic bridges, viz. $[\{Mo(NO)L^*X\}_2(OQO)]^{2-}$, has shown

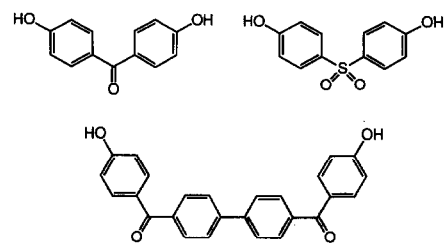

Fig. 1. Structures of the bridging ligands used in this paper.

that these species have EPR spectral characteristics analogous to their neutral bipyridyl analogues $[\{Mo(NO)L^*Cl\}(pyr\text{–}E\text{–}pyr)]$ and to $[\{Mo(NO)L^*Cl\}_2(OC_6H_4C_5H_4N)]^-$; all three types of system contain two 17-electron metal centres. In this paper we describe the full characterization of some neutral bi-molybdenum species and some tungsten analogues with the extended di-phenol bridging ligands shown in Fig. 1; some related mono-metallic compounds, $[Mo(NO)L^*X(OQOH)]$, are also described. In addition we describe a solution EPR spectroscopic study of the singly-reduced (16-electron/17-electron) and doubly-reduced (17-electron/17-electron) forms of $[\{Mo(NO)L^*Cl\}_2)p\text{-}OC_6H_4O)]^{n-}$ (n = 1, 2) and of the doubly-reduced (17-electron/17-electron) dianionic species $[\{Mo(NO)L^*X\}_2(OQO)]^{2-}$ with the longer bridging ligands. These new species now allow us to examine apparent fast exchange of electrons between phenolate-substituted molybdenum centres with bridging ligands from short to very long, i.e. we can compare dianionic [(17 + 17)-electron] species containing OC_6H_4O, $OC_6H_4COC_6H_4O$, $OC_6H_4S(O)_2C_6H_4O$ and $OC_6H_4CO(C_6H_4)_2COC_6H_4O$ as bridging ligands. We have previously established a lower limit of *ca* 100 MHz for the exchange interaction J between the electrons with relatively short bridging ligands;[1,6] the real rate is probably much faster. With sufficiently long bridging ligands, however, and provided intermolecular electron exchange does not occur, there must come a point at which the intramolecular exchange becomes slow and spectra characteristic of electrons localized at one metal centre may be observed.

EXPERIMENTAL

^1H NMR spectra were recorded on Jeol GX90 or GX270 spectrometers. Electron-impact (E.I.) mass spectra were measured on a Kratos MS9 instrument and fast-atom bombardment (FAB) mass spectra on a VG-Autospec at the SERC Mass Spectrometry Service Centre, Swansea, with 3-nitrobenzylalcohol

as a matrix. EPR spectra were recorded at room temperature on a Bruker ESP-300E spectrometer. Electrochemical experiments were performed using an EG&G PAR model 273A potentiostat. A standard three-electrode configuration was used, with platinum-bead working and auxiliary electrodes and a saturated calomel electrode (S.C.E.) reference. Ferrocene was added at the end of each experiment as an internal standard; all potentials are quoted vs the ferrocene/ferrocenium couple (Fc/Fc^+). The solvent was CH_2Cl_2, purified by distillation from CaH_2, containing $[NBu_4][PF_6]$ (0.1 mol dm^{-3}) as a base electrolyte.

Controlled-potential reductions *in situ* in the EPR cavity were performed using a platinum gauze working electrode in an EPR flat cell. The platinum wire working electrode and S.C.E. reference were positioned in a reservoir of solvent (CH_2Cl_2 containing 0.1 mol dm^{-3} $[NBu_4][PF_6]$) attached to the top of the EPR flat cell. The potential at the working electrode was applied using an EG&G PAR model 264A polarographic analyser. Alternatively, the reduced (17-electron/17-electron) forms of some complexes could be prepared by addition of cobaltocene to a solution of the neutral (16-electron/16-electron) species in distilled MeCN under nitrogen. After immersion of the mixture in a sonic cleaning bath for a few minutes a sudden and obvious colour change, from deep red/brown to a much paler brown, occurred. A few drops of the solution were then added by syringe to a nitrogen-flushed EPR tube; the reduced solutions were stable for several hours.

4,4′-Dihydroxybenzophenone ($HOC_6H_4COC_6H_4OH$), bis(4-hydroxyphenyl)sulphone ($HOC_6H_4S(O)_2C_6H_4OH$) and hexamethylenetetramine were obtained from Aldrich and used as received; $HOC_6H_4CO(C_6H_4)_2COC_6H_4OH$ was kindly donated by Dr H. Colquhoun of ICI Mond division. [{Mo(NO)L*Cl}$_2$(p-OC_6H_4O)] was prepared according to the published method.[1]

General procedure for syntheses of complexes

A mixture of [ML*(NO)X$_2$] (M = Mo, X = Cl, I; M = W, X = Cl), the appropriate ligand (5 equivalents) and hexamine (5 equivalents, except for [{Mo(NO)L*Cl}$_2$($OC_6H_4COC_6H_4C_6H_4CO$ C_6H_4OH)] where an excess of Et_3N was used) in dry toluene was heated to reflux under nitrogen. The reactions were monitored by thin-layer chromatography, the reaction times required for complete consumption of the starting metal complex being given in Table 1. After cooling the reaction mixture hexane was added (half the volume of the toluene solution) and the solution was refrigerated overnight to precipitate the unreacted ligand and the excess of hexamethylenetetramine and its salts. After filtration the residual solution was evaporated to dryness *in vacuo* and purified by column chromatography on silica. Initial elution with CH_2Cl_2 removed traces of unreacted [ML*(NO)X$_2$] and the green μ-oxo dimer, which always appeared as a by-product. The major two fractions were then collected, the first being the bimetallic complex [{ML*(NO)X}$_2$(μ-L)] and the second the monometallic complex [ML*(NO)X(HL)]. Addition of up to 2% THF to the CH_2Cl_2 was sometimes necessary to elute the more polar mononuclear complexes. The fractions from the columns were evaporated to dryness *in vacuo*, recrystallized from CH_2Cl_2/hexane (M = W) or CCl_4/hexane (M = Mo), collected by filtration and dried *in vacuo*. If necessary, fractions collected in this way could be purified further on a second short silica column.

Analytical and mass spectroscopic data are given in Table 1.

RESULTS AND DISCUSSION

Synthesis and characterization of complexes

All of the complexes with the "extended" ligands (Fig. 1) were prepared by reaction of [ML*(NO)X$_2$] (M = Mo, X = Cl, I; M = W, X = Cl) with $HOC_6H_4EC_6H_4OH$ (E = CO or SO_2) and $\{HOC_6H_4COC_6H_4\}_2$ in toluene at reflux with hexamethylenetetramine or Et_3N present as base. Due to the very low solubility of these ligands in hot toluene a large excess was always used. On chromatographic purification the relatively non-polar binuclear complexes eluted ahead of the much more polar mononuclear complexes, which have free pendant phenol groups and so could be separated easily. With $HOC_6H_4S(O)_2C_6H_4OH$ no mononuclear complexes were formed; only a binuclear complex was isolated in each case (Table 1). The three binuclear complexes [{Mo(NO)L*Cl}$_2$($OC_6H_4EC_6H_4O$)] [E = CO, SO_2, $CO(C_6H_4)_2CO$] have been mentioned earlier and their electrochemistry was described in some detail.[2] However, complete details of their characterization were not given, so they are included here for the sake of completeness. All of the complexes were characterized by elemental analysis and FAB mass spectrometry, strong molecular ions being seen in every case. Owing to the presence of a large number of possible isotope combinations of the elements Mo, W, Cl and B the molecular ion clusters span a wide mass range and the most intense peak of the cluster does not always cor-

respond exactly to the value calculated from the most abundant isotopes.

In addition all complexes were characterized by ^{1}H NMR spectroscopy (Table 2). The pyrazolyl methyl protons occur as singlets between 2 and 2.7 ppm. In many cases all six signals were resolved, which is consistent with the low symmetry of the [ML*(NO)X(phenoxide)] centre; each pyrazolyl ring is *trans* to a different group (nitrosyl, halide, phenoxide) and are, therefore, all inequivalent. The fact that only six signals were ever observed for the binuclear complexes confirms that they have two-fold symmetry in solution, with each metal centre equivalent. The pyrazolyl protons, between 5.7 and 6.0 ppm, behave similarly. The protons of the aromatic ligands in the bridging ligands occur between 6.9 and 8.1 ppm in each case. In the mononuclear complexes [M(NO)L*X($OC_6H_4COC_6H_4OH$)] (M = Mo, X = Cl, I; M = W, X = Cl) the inequivalence of the coordinated and pendant aromatic rings is clear; in the binuclear complexes the signals due to the bridging ligand protons simplify consistent with the two-fold symmetry.

All of the tungsten complexes have ν(NO) at *ca* 1650 cm^{-1} in the IR spectrum; for the molybdenum complexes the nitrosyl stretch is at just above 1680 cm^{-1}. These values are to be expected by comparison with other phenoxide-substituted molybdenum and tungsten complexes and further confirm the identities of the complexes.

Electrochemistry

The complexes were examined by cyclic voltammetry and the results are summarized in Table 1. The results show that the metal–metal interactions across these long bridges in the binuclear complexes are fairly weak. In no cases are two waves resolved by cyclic voltammetry. Accordingly, the positions of the centres of the (rather broad) voltammetric waves are given in each case. No attempt has been made to deconvolute the electrochemical response to give separate $E_{1/2}$ values for the two closely-spaced reductions in the new binuclear complexes. For [{Mo(NO)L*Cl}$_2$(O$C_6H_4EC_6H_4O$)] [E = CO, SO_2 and $CO(C_6H_4)_2CO$] the electrochemical properties were reported earlier in some detail and the separate $E_{1/2}$ values estimated by analysis of the shapes of differential-pulse polarograms.[2] They showed separations of 85, 75 and 56 mV, respectively, between the two reductions. This is in marked contrast to complexes with bis(4-pyridyl) bridging ligands of similar lengths, where the electrochemical interactions were typically several hundred millivolts.[3,4]

EPR spectroscopy of molybdenum complexes

First, we examined the EPR properties of the reduced forms of [{Mo(NO)L*Cl}$_2$(p-OC_6H_4O)], in which the two metal-centred reductions are sufficiently far apart to allow selective one-electron or two-electron reductions by controlled-potential electrolysis. A controlled-potential reduction at -0.9 V vs Fc/Fc$^+$ generated the 16-electron/17-electron mixed-valence mono-anion. The EPR spectrum of the resultant solution is shown in Fig. 2(a). This spectrum clearly shows that the unpaired electron is localized on one molybdenum centre; since about 25% of molybdenum atoms have nuclear spin $I = 5/2$, there is a sextet ($A_{Mo} = 50 \pm 1$ Gauss) superimposed on a central singlet at $g = 1.97$. This spectrum is identical to those of several *mono-nuclear*, 17-electron molybdenum complexes.[1,3,4,8] The mixed-valence state is, therefore, valence-trapped on the EPR time-scale, i.e. it exhibits Class I behaviour according to the Robin and Day classification.[9]

Reduction at a potential more negative than the

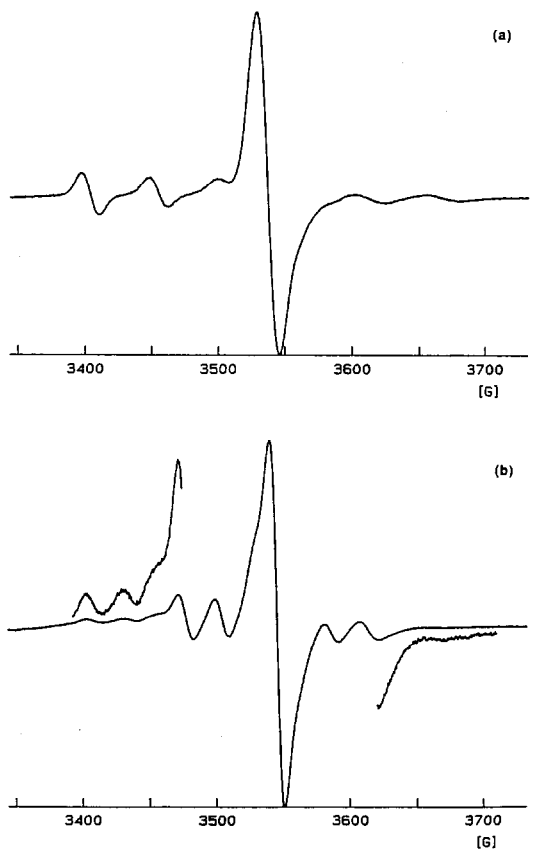

Fig. 2. EPR spectra of [{Mo(NO)L*Cl}$_2${OC_6H_4O}] after (a) one-electron reduction and (b) two-electron reduction, in MeCN at room temperature.

second reduction process—either electrochemically or by addition of cobaltocene—afforded a solution of the 17-electron/17-electron dianion, whose EPR spectrum is in Fig. 2(b). This spectrum clearly shows that the exchange interaction between the two unpaired electrons has been initiated. The apparent hyperfine splitting of the sextet (arising from the isotopomer containing one $I = 0$ and one $I = 5/2$ nucleus) has halved to 26 ± 1 Gauss, which is consistent with each electron coupling to two equivalent metal centres,[10] and additional outlying lines consistent with the presence of a 1:2:3:4:5:6:5:4:3:2:1 11-fold multiplet (arising from the isotopomer containing two nuclei which both have $I = 5/2$) are evident. The limit of "fast" electron exchange is the situation where the electron exchange interaction $|J|$ is much greater than the hyperfine coupling frequency;[10] with $A_{Mo} = 51 \pm 1$ Gauss, the signal centre at 3537 Gauss and a microwave frequency of 9.77 GHz, this means that $|J|$ must be *much greater* than $(51/3537) \times 9.77 \times 10^9$ Hz, i.e. 140 MHz, to give a first-order spectrum consistent with both electrons coupling equally to both molybdenum nuclei. This behaviour is identical to that observed with the asymmetric 16-electron/17-electron complex [{Mo(NO)L*Cl}$_2$($OC_6H_4C_5H_4N$)] where the single unpaired electron is also valence-trapped, but on reduction to the 17-electron/17-electron monoanion fast exchange is initiated.[6,7]

We next examined the EPR properties of the reduced mononuclear complexes [Mo(NO)L*Cl($OC_6H_4COC_6H_4OH$)]$^-$ and [Mo(NO)L*Cl{O$C_6H_4CO(C_6H_4)_2COC_6H_4OH$}]$^-$, and of the reduced binuclear complexes [{Mo(NO)L*Cl}$_2$(O$C_6H_4EC_6H_4O$)]$^{2-}$ [E = CO, SO_2 and $CO(C_6H_4)_2$CO], all of which contain 17-electron {MoL*(NO)Cl(OAr)} cores, in order to see whether or not the exchange interaction could be sustained over relatively long distances. Although we have shown that the exchange interaction is maintained (i.e. $|J| \gg A_{Mo}$, where $|J|$ is the electron–electron interaction and A_{Mo} the hyperfine coupling) over a long distance using α,ω-di(4-pyridyl)-polyenes and related ligands as bridges,[3,4] with diphenols as bridging ligands the mesomeric linkage between the metal centres is removed by the presence of formally sp^3-hybridized oxygen atoms in the bridge. The effect of this is illustrated by the observation that the inter-metal electrochemical interactions with diphenol bridges are substantially weaker than those in binuclear complexes with 4,4′-bipyridyl-type bridges of comparable lengths.

The reduction potentials of the molybdenum complexes are sufficiently anodic that complete two-electron reduction to the 17-electron species may be effected simply by addition of cobaltocene to the sample in acetonitrile solution. We have previously used this technique with CH_2Cl_2 as the solvent,[6,7] but with these rather large complexes the dianions slowly precipitated from solution (presumably as the cobalticenium salts) resulting in very poorly resolved EPR spectra. Accordingly we used MeCN, in which the reduced dianions are fully soluble.

The 17-electron mononuclear complexes [Mo(NO)L*Cl($OC_6H_4COC_6H_4OH$)]$^-$ and [{Mo(NO)L*Cl}$_2$($OC_6H_4CO(C_6H_4)_2COC_6H_4OH$)]$^-$ gave spectra which are essentially identical to the spectra of valence-localized 16-electron/17-electron complexes, such as in Fig. 2(a); these spectra indicate the presence of an unpaired electron localized at one molybdenum atom. Anisotropic broadening, due to the slow tumbling rate of the long molecules in solution, means that the high-field components of the sextet are poorly resolved. These spectra are identical to several other mononuclear, 17-electron molybdenum complexes.[1,3,4,8]

The reduced binuclear complexes [{Mo(NO)L*Cl}$_2$($OC_6H_4EC_6H_4O$)]$^{2-}$ (E = CO or SO_2) give spectra which are very similar to those we have observed for other 17-electron/17-electron biradicals such as in Fig. 2(b); halving of the apparent hyperfine splitting and the appearance of outlying components from the expected 11-fold multiplet are again evident. Although these spectra are slightly perturbed from ideality in that the intensities of the outlying components are not exactly as predicted (e.g. the first three weak components are predicted to have intensity ratios of 1:2:3), the positions and

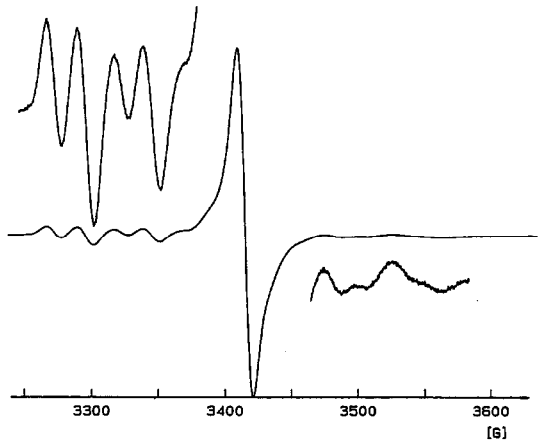

Fig. 3. EPR spectrum of [{MoL*(NO)Cl}$_2${OC_6H_4C(O)$(C_6H_4)_2$(CO)C_6H_4O}]$^{2-}$ (with two 17-electron centres) in MeCN at room temperature.

multiplicities of the signals confirm that the value of $|J|$ is still very large relative to A_{Mo}.

The EPR spectrum of $[\{Mo(NO)L^*Cl\}_2\{OC_6H_4CO(C_6H_4)_2COC_6H_4O\}]^{2-}$, which contains a much longer bridging ligand, is shown in Fig. 3. It is quite different from both of the previous two, showing five resolved peaks to the left of the central peak with separations of 18–20 Gauss between them. It appears that in this complex the exchange interaction between the unpaired electrons is sufficiently decreased by the greater length of the bridging ligand to give an intermediate situation where $|J|$ is now of the same order as A_{Mo}. This is expected to lead to a more complicated, second-order spectrum with several additional lines appearing (depending on the nuclear spin) and apparent line separations of less than either of the two simple extremes,[10] which is what we observe. In addition, the separation between the most outlying hyperfine component and the signal centre is larger than we observed for either extreme, which is another indication of second-order behaviour. We are currently attempting to simulate these EPR spectra and the preliminary results clearly show that a spectrum very similar to that of $[\{Mo(NO)L^*Cl\}_2\{OC_6H_4CO(C_6H_4)_2COC_6H_4O\}]^{2-}$ may be obtained with a value of $|J|$ of approximately 50 MHz (c.f. $A_{Mo} \approx 140$ MHz); a detailed report of the spectral simulation studies will be made in due course.[11]

In order to rule out intermolecular electron exchange processes contributing to the appearance of the spectrum we also performed a variable-temperature EPR study of $[\{Mo(NO)L^*Cl\}_2\{OC_6H_4CO(C_6H_4)_2COC_6H_4O\}]^{2-}$ in MeCN, from 240 to 340 K. No significant variation in the appearance of the spectrum was observed apart from a slight broadening of all of the lines at low temperatures as the solvent viscosity increased. This proves that inter-molecular electron exchange is not occurring, and that therefore the appearance of the spectrum is solely due to the intramolecular electron exchange interaction across $\{OC_6H_4COC_6H_4C_6H_4COC_6H_4O\}$.

EPR spectroscopy of tungsten complexes

The molybdenum complexes are particularly suitable for these studies since changes in the appearance of the hyperfine satellites is an excellent diagnostic tool for examining electron exchange interactions in the biradicals. In order to see if we could observe similar behaviour with tungsten complexes we examined the EPR spectra of the reduced 17-electron and 34-electron mono- and binuclear complexes. Electrochemical reduction of the mononuclear complex $[W(NO)L^*Cl(OC_6H_4COC_6H_4OH)]$ *in situ* in the EPR cavity yielded a paramagnetic species whose spectrum just consisted of a broad, single line at $g = 1.89$. Similar behaviour was observed with the corresponding binuclear complex $[\{W(NO)L^*Cl\}_2(OC_6H_4COC_6H_4O)]^{2-}$; the signal did not become much stronger with time, and after about an hour a small signal appeared at the free-spin value with a hyperfine coupling of 2.5 Gauss, i.e. an organic free radical with resolved hydrogen coupling, probably resulting from decomposition of $[\{W(NO)L^*Cl\}_2(OC_6H_4COC_6H_4O)]^{2-}$ and partial reduction of the free bridging ligand. Neither $[W(NO)L^*Cl(OC_6H_4COC_6H_4OH)]^-$ nor $[\{W(NO)L^*Cl\}_2(OC_6H_4COC_6H_4O)]^{2-}$ showed any evidence of clearly resolved hyperfine coupling to ^{183}W ($I = 1/2$, 14.4% natural abundance), which means unfortunately that electron-exchange between tungsten centres in the biradicals such as $[\{W(NO)L^*Cl\}_2(OC_6H_4COC_6H_4O)]^{2-}$ cannot be easily examined.

CONCLUSIONS

We have demonstrated that on addition of one electron to binuclear complexes of the type $[\{Mo(NO)L^*Cl\}_2(\mu\text{-}L)]$ (where H_2L is a *p*-diphenol-type bridging ligand) the odd electron is localized at one molybdenum terminus; addition of a second electron initiates delocalization. This delocalization (pairwise electron exchange) can also occur in biradicals containing $\{OC_6H_4COC_6H_4O\}$ and $\{OC_6H_4S(O)_2C_6H_4O\}$ as bridging ligands between $\{Mo(NO)ClL^*\}$ centres. With $\{OC_6H_4COC_6H_4C_6H_4COC_6H_4O\}$ as a bridging ligand, however, the EPR spectrum is second-order, consistent with a weaker exchange interaction between the two electrons; we are, therefore, seeing the first indications of control of the magnitude of $|J|$ with the length of the bridging ligand. The EPR spectra of the analogous tungsten complexes show no clearly-defined hyperfine satellites and are, therefore, unsuitable for examination of pairwise electron exchange.

Acknowledgements—We are grateful to the SERC for support of this work through a fellowship (AW) and via funds to purchase the EPR spectrometer, and to the Politechnika Krakowska, Poland, for leave of absence for AW while part of this work was completed. We thank Mr Dariusz Rams for technical assistance.

METAL COMPLEXES OF FUNCTIONALIZED PHOSPHINES—II.* SYNTHESIS OF HYDROXYMETHYL- AND AMINOMETHYLDIPHENYLPHOSPHINE COMPLEXES OF PLATINUM. CRYSTAL STRUCTURE OF *cis*-[$PtCl_2(Ph_2PCH_2OH)_2$]

(*Received* 22 *April* 1993; *accepted* 5 *May* 1993)

Abstract—The phosphine Ph_2PCH_2OH reacts with (COD)$PtCl_2$ to form *cis*-[$PtCl_2(Ph_2PCH_2OH)_2$], the structure of which has been determined by X-ray crystallography. Similarly, the phosphines Ph_2PCH_2NHR (R = Bu^t, C_6H_4Me-4) react with (COD)$PtCl_2$ to form *cis*-[$PtCl_2(Ph_2PCH_2NHR)_2$], although for R = C_6H_4Me-4 this complex is unstable and [$PtCl_2\{(Ph_2PCH_2)_2NR\}$] (R = C_6H_4Me-4) is isolated. The complexes [$PtCl_2\{(Ph_2PCH_2)_2NR\}$] can be prepared directly from (COD)$PtCl_2$ and $(Ph_2PCH_2)_2NR$.

In recent years functionalized phosphines containing one or more functional groups of various types have been synthesized and their properties investigated.[2] The ligands Ph_2PCH_2XH (X = O, NR) are formally analogous to the diphosphine $Ph_2PCH_2PPh_2$, which is most commonly found as a bridging ligand rather than as a chelate.[3] To our knowledge there are no examples of Ph_2PCH_2XH (X = O, NR) acting as chelates. This is presumably due to the strain involved in forming a four-membered ring since the related ligands $Ph_2PCH_2CH_2XH$ (X = O, NR) will form chelate complexes when bound to platinum.[1,4] Hydroxymethyldiphenylphosphine has been used as a bridging ligand to form early–late heterobimetallic complexes,[5] whilst aminomethyldiphenylphosphine ligands have also been used to form bimetallic platinum complexes.[6]

In this paper we report the synthesis of some hydroxymethyl- and aminomethyldiphenylphosphine complexes of platinum. Reaction of (COD)$PtCl_2$ with Ph_2PCH_2OH resulted in the formation of *cis*-[$PtCl_2(Ph_2PCH_2OH)_2$] (**1**). This complex has been made previously by hydrolysis of [$PtCl_2\{Ph_2PCH_2OCOMe\}_2$] with HCl.[7] The ^1H NMR spectrum exhibits a multiplet due to the phenyl protons at δ 7.6–7.0 and a broad, unresolved multiplet at δ 4.5, which also has broad platinum satellites and is assigned to the methylene protons. A broad signal at δ 3.9 is assigned to the hydroxyl protons. As pointed out previously the absence of P—CH_2 coupling makes determination of the stereochemistry of these complexes in solution difficult from ^1H NMR data. However, we now report the $^{31}P\{^1H\}$ NMR data which allows unequivocal assignment of stereochemistry. The $^{31}P\{^1H\}$ NMR spectrum displays a singlet at δ +7.3, with platinum satellites [J(Pt—P) = 3687 Hz]. The magnitude of the coupling constant indicates that the phosphine ligands are *trans* to chloride, in a mutually *cis* configuration.[8]

A single-crystal X-ray diffraction study of **1** was performed to establish the molecular geometry and whether there was any interaction of the hydroxyl groups with platinum or hydrogen bonding with the chlorides. In $Ni(CN)_2$ complexes of this phosphine there were found to be intermolecular hydrogen bonds between the hydroxyl protons and the nitrogens of cyanides in adjacent molecules.[9] The molecular structure of **1** is illustrated in Fig. 1, together with the crystallographic numbering system. A summary of important bond lengths and angles is

* For part I see ref. 1.

† Author to whom correspondence should be addressed.

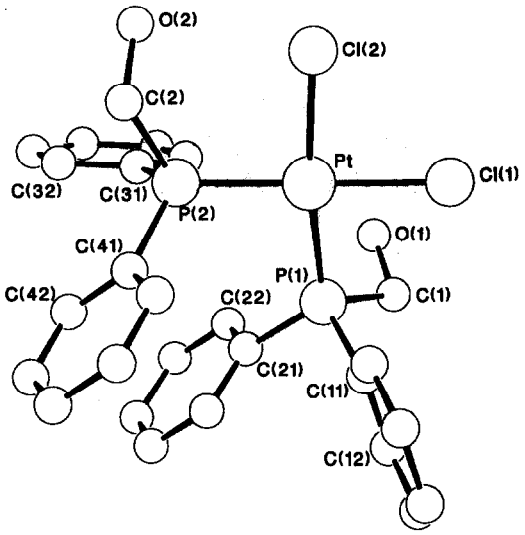

Fig. 1. Molecular structure of *cis*-$[PtCl_2(Ph_2PCH_2OH)_2]$ (**1**).

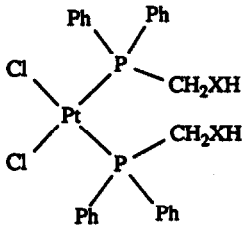
given in Table 1. The geometry around the platinum is effectively square planar. The molecule exists as the *cis* isomer with the phosphine ligands *trans* to the chloride ligands. The Pt—Cl and Pt—P bond lengths are of a similar magnitude to those reported for *cis*-$[PtCl_2(PPh_3)_2]$,[10] which has average Pt—Cl and Pt—P bond lengths of 2.345(16) and 2.258(10 Å, respectively. The Cl—Pt—Cl and P—Pt—P bond angles are slightly smaller than those recorded for *cis*-$[PtCl_2(PPh_3)_2]$ of 87.1(1)° and 97.8(1)°, respectively. The O(1)—Pt separation of 3.484 Å is too large for any bonding interaction. The hydroxyl hydrogens were located in the difference-Fourier map. The O—H bond lengths are 0.78 [O(1)—H(5)] and 1.39 Å [O(2)—H(6)], respectively. Both these hydrogen atoms have short separations from a chlorine atom. Thus, H(5) is 2.46 Å from a chlorine in an adjacent molecule with an O(1)—H(5)—Cl angle of 164°, both of which are consistent with an intermolecular hydrogen bond. For H(6) the intramolecular distance to Cl(2) is 2.05 Å, which is very short, and the O(2)—H(6)—Cl(2) angle is 123°, suggesting a bent hydrogen bond. This may also explain the rather long O(2)—H(6) bond length mentioned above. Thus, the structure of **1** shows evidence of inter- and intramolecular hydrogen bonding between chlorine atoms and hydroxyl hydrogens.

The reaction of $Ph_2PCH_2NHBu^t$ with (COD)$PtCl_2$ in a 2:1 ratio gave *cis*-$[PtCl_2(Ph_2PCH_2NHBu^t)_2]$ (**2a**). The $^{31}P\{^1H\}$ NMR spectrum of **2a** exhibits a signal at δ +4.0 ppm with platinum satellites [J(Pt—P) = 3710 Hz], consistent with phosphorus coordinated *trans* to chloride; hence, the two phosphorus ligands are in a mutually *cis* configuration. The ^1H NMR spectrum displays a multiplet in the region δ 8.0–7.1 due to the phenyl protons, a multiplet at δ 3.5 due to the methylene protons, as well as signals due to the tert-butyl and N—H protons.



1 X=O

3a R=Bu^t
3b R=C$_6$H$_4$Me-4

Reaction of $Ph_2PCH_2NHC_6H_4Me$-4 with (COD)$PtCl_2$ gave a mixture of two products, as determined by $^{31}P\{^1H\}$ NMR spectroscopy. It is probable that a signal observed at δ +5.9 [J (Pt—P) = 3693 Hz] is due to *cis*-$[PtCl_2(Ph_2PCH_2$

Table 1. Selected bond lengths (Å) and angles (°) for *cis*-$[PtCl_2(Ph_2PCH_2OH)_2]$

Bond length	(Å)	Bond angle	(°)

$NHC_6H_4Me\text{-}4)_2$] (**2b**), since the chemical shift and size of J(Pt—P) are similar to those found in **2a**. The second signal of δ −6.1 [J(Pt—P) = 3417 Hz] is due to the chelate complex [$PtCl_2\{(Ph_2PCH_2)_2NR\}$] (**3b**), which was identified by comparison of its $^{31}P\{^1H\}$ NMR spectrum with that of an independently prepared sample, see below.

Reaction of $(COD)PtCl_2$ with $(Ph_2PCH_2)_2NR$ (R = Bu^t, C_6H_4Me-4) gave the complexes [$PtCl_2\{(Ph_2PCH_2)_2NR\}$] (**3a,b**). The $^{31}P\{^1H\}$ NMR spectra of **3a** and **3b** each display one signal at δ −5.9 and −6.1, respectively, with J(Pt—P) values of *ca* 3420 Hz. The coupling constant indicates that the phosphine ligands are *trans* to chloride, i.e. in a mutually *cis* configuration. The reduction in magnitude of J(Pt—P) going from complexes **2** to complexes **3** containing a six-membered chelate ring, is consistent with related platinum complexes containing diphenylphosphinoalkyl ligands.[11] The ^1H NMR spectra of **3a** and **3b** display broad multiplets at δ 3.4 and 3.9, respectively, due to the methylene protons, and signals due to the phenyl groups, Bu^t and C_6H_4Me-4, respectively.

The conversion of *cis*-[$PtCl_2(Ph_2PCH_2NHC_6H_4Me\text{-}4)_2$] (**2b**) to *cis*-[$PtCl_2\{(Ph_2PCH_2)_2NC_6H_4Me\text{-}4\}$] (**3b**) is in contrast to the previous reaction of $Ph_2PCH_2NHBu^t$ when only the non-chelate complex *cis*-[$PtCl_2(Ph_2PCH_2NHBu^t)_2$] (**2a**) is formed. The difference in reactivity of the two ligands is unlikely to be due to their nucleophilicity since Bu^t is the more nucleophilic, but it may be that the electron-withdrawing C_6H_4Me-4 group activates the α-C towards nucleophilic attack. It is interesting that complex **3a** can also be formed by refluxing **2a** in toluene with aqueous formaldehyde for 24 h. A similar transformation has been reported for the analogous *cis*-[$Mo(CO)_4(Ph_2PCH_2NHR)_2$] complexes.[12]

Further studies are in progress to investigate the effect of substituents on the reactivity of the phosphines and also the use of complexes **1** and **2a** as precursors to bimetallic species.

EXPERIMENTAL

Petroleum ether and toluene were all dried by refluxing over purple sodium/benzophenone in a nitrogen atmosphere. Dichloromethane was purified by refluxing over calcium hydride. The phosphines[12] and $(COD)PtCl_2$[13] were prepared by the literature methods. The syntheses of phosphorus-containing compounds were performed in deoxygenated solvents under a nitrogen atmosphere. Once isolated as pure solids, all new phosphine compounds are relatively air-stable and precautions for their storage are unnecessary.

^1H NMR spectra were recorded on a Bruker AM300 or Varian EM390 spectrometer as $CDCl_3$ solutions with internal $SiMe_4$ as a reference. $^{31}P\{^1H\}$ NMR spectra were recorded on a Jeol FX60 instrument at 24.15 MHz in CH_2Cl_2 solution and were referenced to external 85% H_3PO_4 with shifts to high frequency being positive. Microanalyses were performed by Butterworth Laboratories Ltd, Middlesex.

Reaction of $(COD)PtCl_2$ *with* Ph_2PCH_2OH

A mixture of Ph_2PCH_2OH (819 mg, 3.79 mmol) and $(COD)PtCl_2$ (650 mg, 1.79 mmol) in dichloromethane (50 cm^3) was stirred for 0.5 h at room temperature, after which time the solvent was removed under vacuum giving a white solid. The solid was crystallized from dichloromethane and petroleum ether to give white crystals of *cis*-[$PtCl_2(Ph_2PCH_2OH)_2$] (**1**) (1.6 g, 85%). Found: C, 44.5; H, 3.7. Calc. for $C_{26}H_{26}Cl_2O_2P_2Pt$: C, 44.7; H, 3.7%. ^1H NMR ($CDCl_3$): δ3.9 (s, br, 2H, OH), 4.5 (m, 4H, CH_2), 7.3 (m, 20H, Ph). $^{31}P\{^1H\}$ NMR: +7.3 [J(Pt—P) 3687 Hz].

Reaction of $(COD)PtCl_2$ *with* $Ph_2PCH_2NHBu^t$

A solution of $(COD)PtCl_2$ (750 mg, 2.0 mmol) in dichloromethane (40 cm^3) was added to a solution of $Ph_2PCH_2NHBu^t$ (0.99 mg, 4.05 mmol) in toluene (4 cm^3). The mixture was stirred for 0.5 h at room temperature, after which time the solvent was removed under vacuum to give a pale yellow solid. Crystallization of the solid from dichloromethane and petroleum ether afforded pale yellow crystals of *cis*-[$PtCl_2(Ph_2PCH_2NHBu^t)_2$] (**2a**) (1.11 g, 69%). Found: C, 50.6; H, 5.6; N, 3.2. Calc. for $C_{34}H_{44}Cl_2N_2P_2Pt$: C, 50.5; H, 5.5; N, 3.5%. ^1H NMR ($CDCl_3$): δ1.00 (s, 18H, Bu^t), 2.00 (s, br, 2H, NH), 3.50 (m, 4H, CH_2), 7.5 (m, 20H, Ph). $^{31}P\{^1H\}$ NMR: +4.0 [J(Pt—P) 3711 Hz].

Reaction of $(COD)PtCl_2$ *with* $Ph_2PCH_2NHC_6H_4Me$-4

A mixture of $Ph_2PCH_2NHC_6H_4Me$-4 (461 mg, 1.51 mmol) and $(COD)PtCl_2$ (221 mg, 0.59 mmol) in dichloromethane (50 cm^3) was stirred for 1 h at room temperature, after which time the solvent was removed under vacuum affording a white solid. The solid consisted of a mixture of two complexes, as determined by $^{31}P\{^1H\}$ NMR spectroscopy, *cis*-[$PtCl_2(Ph_2PCH_2NHC_6H_4Me\text{-}4)_2$] (**2b**), $^{31}P\{^1H\}$ NMR +5.9 [J(Pt—P) 3693 Hz], and [$PtCl_2\{(Ph_2PCH_2)_2NC_6H_4Me\text{-}4\}$] (**3b**) (see below).

Reaction of $(COD)PtCl_2$ *with* $(Ph_2PCH_2)_2NR$ (R = Bu^t, C_6H_4Me-4)

A mixture of $(COD)PtCl_2$ (200 mg, 0.54 mmol) and $(Ph_2PCH_2)_2NBu^t$ (251 mg, 0.54 mmol) in dichloromethane (50 cm^3) was stirred for 1 h, after which time the solvent was removed under vacuum giving a white solid. The solid was crystallized from dichloromethane and petroleum ether affording white crystals of $[PtCl_2\{(Ph_2PCH_2)_2NBu^t\}]$ (**3a**) (313 mg, 79%). Found: C, 45.9; H, 4.3; N, 1.8. Calc. for $C_{30}H_{33}Cl_2NP_2Pt\cdot(CH_2Cl_2)$: C, 45.3; H, 4.3; N, 1.7%. ^1H NMR ($CDCl_3$): δ0.8 (s, 9H, Bu^t), 3.4 (m, 4H, CH_2), 7.6 (m, 20H, Ph). $^{31}P\{^1H\}$ NMR: −5.9 [J(Pt—P) 3428 Hz].

Using a similar procedure starting from $(COD)PtCl_2$ (100 mg, 0.27 mmol) and $(Ph_2PCH_2)_2NC_6H_4Me$-4 (140 mg, 0.28 mmol) gave, after crystallization from dichloromethane and petroleum ether, $[PtCl_2\{(Ph_2PCH_2)_2NC_6H_4Me\text{-}4\}]$ (**3b**) as white crystals (153 mg, 74%). Found: C, 45.2; H, 3.4; N, 1.5. Calc. for $C_{33}H_{31}Cl_2NP_2Pt\cdot(2CH_2Cl_2)$: C, 44.8; H, 3.8; N, 1.5%. ^1H NMR ($CDCl_3$): δ2.2 (s, 3H, Me), 3.9 (m, 4H, CH_2), 7.5 (m, 24H, Ph). $^{31}P\{^1H\}$ NMR: −6.1 [J(Pt—P) 3418 Hz].

Crystal structure determination

Crystal data for *cis*-$[PtCl_2(Ph_2PCH_2OH)_2]$ (**1**). M = 698.4. Monoclinic, space group $P2_1/n$, a = 17.452(5), b = 15.878(5), c = 9.379(6) Å, β = 100.1(1)°, U = 2559 $Å^3$, z = 4, μ = 55.89 cm^{-1}, λ(Mo-K_α) = 0.7107 Å, $F(000)$ = 1360, D_c = 1.81 g cm^{-3}. Crystal dimensions 0.08 × 0.1 × 0.2 mm.

The crystal used for data collection was mounted in air and the unit cell parameters were determined by least-squares refinement of ω-measurements of different layers.[14] Data were collected on a Stöe STADI-2 diffractometer with an ω-scan technique in the range $7° < 2\theta < 60°$. The intensities of 4935 unique reflections were measured and these data were corrected for Lorentz and polarization effects to give 4706 unique reflections with $I > 3\sigma(I)$. The structure was solved by conventional Patterson techniques using SHELXS-86 and all subsequent calculations were performed with the computer programme SHELX-76.[15] Scattering factors were taken from ref. 16. An absorption correction was applied to the data, the maximum and minimum transmission factors being 0.7484 and 0.6443, respectively. The phenyl rings were included as rigid groups with D_{6h} symmetry and C—C distances of 1.395 Å. All hydrogen atoms were included in calculated positions (C—H = 0.95 Å) and refined with group isotropic thermal parameters, with the exception of the two hydroxyl hydrogen atoms which were located in a difference-Fourier map and their positional coordinates and isotropic parameters were refined. All non-hydrogen atoms were refined anisotropically. Final cycles of refinement employed a weighting factor w calculated from $w = k/(\sigma^2F + gF^2)$, where k = 0.95 and g = 0.0047, and gave final values of R = 0.0580 and R_w = 0.0627.

Abstract—Reactions of $Al_2R'_4[N(C_2H_5)_2]_2$ ($R' = CH_3$, C_2H_5) with ethylenediamine or N,N′-dimethylethylenediamine yield air-sensitive trialuminium products $[AlR'_2]_2[RNCH_2CH_2NR]_2[AlR']$ (**1a**: $R' = CH_3$, $R = H$; **1b**: $R' = CH_3$, $R = CH_3$; **2a**: $R' = C_2H_5$, $R = H$; **2b**: $R' = C_2H_5$, $R = CH_3$). Reactions of $Al_2R'_4[N(C_2H_5)_2]_2$ with diethylenetriamine, $[(NH_2CH_2CH_2)_2NH]$, yield air-sensitive tetraaluminium products, $(AlR'_2)_2[(HNCH_2CH_2)_2N]_2(AlR')_2$ (**3**: $R' = CH_3$; **4**: $R' = C_2H_5$). The polyaluminium complexes are well characterized. Some structures have been determined by X-ray crystallography. For both **1a** and **1b** the penta-coordination sphere around the central aluminium conforms to a square-pyramidal configuration and the tetra-coordination for the outer two aluminium atoms is a tetrahedral configuration. Complex **4** has two central aluminium atoms with a penta-coordinate square-pyramidal configuration and the outer aluminium atoms in a tetrahedral configuration.

The utilization of organo main group compounds as precursors to ceramic materials is currently a very popular area of study. Noteworthy are the organo aluminium–nitrogen compounds, which are precursors for aluminium nitride.[1–10] Smith *et al.* have reported a considerable amount of organoaluminium with primary and secondary monodentate amines.[1–5] We have been studying the selective synthesis of $R_4Al_2(NR'_2)_2$ in high yields, the Al_2N_2 framework being similar to cyclobutane.[11] As the chemistry of Al_2N_2 towards donor ligands has not been explored we have attempted reactions of the Al_2N_2 frame with multidentate nitrogen donor ligands to see to what extent a maximization of aluminium coordinate number occurs by association to different aggregations. The interaction of aluminium multidentate containing N—H ligands involving Al—C, Al—N and N—H bond cleavages via intermolecular condensation has been documented in the literature.[12–18]

EXPERIMENTAL

Apparatus and materials

All operations were performed in a nitrogen-flushed glove-bag, dry-box or in a vacuum system. All solvents were distilled prior to use. IR, mass, nuclear magnetic resonance and X-ray single diffraction data were obtained using a Hitachi 26030 IR spectrometer, VG-7025S spectrometer, Varian VXR-300 MHz FT-NMR spectrometer and Enraf–Nonius CAD4 spectrometer. Elemental analyses were performed at Galbraith Laboratory, U.S.A.

Reactions of bis(di-μ-diethylamino-dialkylaluminium) with ethylenediamine

Ethylenediamine (0.24 cm^3, 12 mmol) was added slowly to a solution containing an ether solution (100 cm^3) of bis(di-μ-diethylamino-dialkylaluminium) (6 mmol) (R′ = CH_3, C_2H_5) under nitrogen. The reaction took place immediately and released heat and gases. The colourless solution became turbid, but cleared at later stages. After 4 h the residue $Al(alkyl)_3(NHCH_2CH_2NH)_2$ (R′ = CH_3, **1a**, and C_2H_5, **2a**) was obtained after removal of ether.

The complex (**1a**) (solid) was purified by sublimation at 80°C, 10^{-3} Torr; m.p.: 84.5–86°C. IR (Nujol mull): 3330(w), 3280(w), 2980(s), 2960(s), 2910(s), 2860(s), 2810(m), 1460(m), 1370(m), 1185(br), 1055(br), 690(br). Found: C, 39.8; H, 10.5; N, 19.1. Calc.: C, 39.7; H, 10.0; N, 20.6%. Characteristic fragment ions occur at *m/z* (E.I.: 70 eV, assignment in parentheses): 257 $(Al_3Me_4HC_4H_{12}N_4)^+$, 241 $(Al_3Me_3HC_4H_{11}N_4)^+$, 228 $(Al_3Me_2C_4H_{12}N_4)^+$, 199 $(Al_3Me_4C_2H_6N_2)^+$, 170 $(Al_2Me_2C_7H_{14}N_2)^+$, 141 $(Al_2Me_2C_2H_7N_2)^+$, 99 $(AlMeC_2H_5N_2)^+$, 84 $(AlC_2H_5N_2)^+$, 69 $(Al_2Me)^+$, 57 $(AlMe_2)^+$. The complex (**2a**) (liquid) was purified by distillation at 170°C; 10^{-3} Torr. IR(in KBr pellets): 3330(m), 3290(m), 1370(m), 1330(m), 1290(m), 1230(m), 1190(m), 1165(s), 1160(m), 1120(w), 1065(m), 800(br), 640(br) cm^{-1}. Their NMR chemical shifts are listed in Tables 1 (^1H) and 2 (^{13}C and ^{27}Al).

Reactions of bis(di-μ-diethylamino-dialkylaluminium) with N,N′-dimethylethylenediamine

A diethyl ether solution of N,N′-dimethylethylenediamine (68.2 mmol) was added slowly to an ether (50 cm^3) solution of bis(di-μ-diethylamino-dialkylaluminium) (34.1 mmol) (R′ = CH_3, C_2H_5) under nitrogen with stirring for 6 h and its colour turned to deep yellow. The residue $Al(alkyl)_3(MeNCH_2CH_2NMe)_2$ (alkyl = CH_3, **1b**, and C_2H_5, **2b**) was obtained after removal of ether.

The complex (**1b**) (solid) was purified by sublimation at 90°C, 10^{-3} Torr; m.p.: 200°C sublimated. IR (Nujol mull): 2950(m), 2880(m),

Their NMR chemical shifts are listed in Tables 1 (^1H) and 2 (^{13}C and ^{27}Al).

Reactions of bis(di-μ-diethylamino-dialkylaluminium) with diethylethylenediamine

Diethylethylenediamine (0.69 cm^3, 6 mmol) was added to an ether solution (50 cm^3) of bis(di-μ-diethylamino-dialkylaluminium) (6 mmol) (R′ = CH_3, C_2H_5) under nitrogen, causing immediate reaction with the release of heat and gases. After stirring for 4 h the solution was decanted by centrifugation and the solid $Al_4R_6(HNCH_2CH_2NCH_2CH_2NH)$ (R = CH_3, **3**, C_2H_5, **4**) was obtained.

The complex (**3**) (solid) was purified by sublimation at 140°C, 10^{-3} Torr; m.p.: dec > 315°C, IR (Nujol mull): 3340(w), 3290(w), 2950(m), 2920(s), 2850(w), 1460(m), 1370(w), 1295(w), 1190(s), 1105(w), 1065(m), 1050(m), 1010(w), 925(m), 840(m), 760(br), 690(br), 650(w) cm^{-1}. Characteristic fragment ions occur at *m/z* (E.I.: 70 eV, assignment in parentheses): 398$(M)^+$, 384 $(Al_4Me_5HC_8H_{20}N_6)^+$, 383 $(Al_4Me_5C_8H_{20}N_6)^+$, 367 $(Al_4Me_4C_8H_{19}N_6)^+$, 354 $(Al_4Me_3HC_8H_{20}N_6)^+$, 311 $(Al_3Me_2C_8H_{20}N_6)^+$, 282 $(Al_4Me_5C_4H_9N_3)^+$, 183 $(Al_2Me_2C_4H_{10}N_3)^+$, 73 $(HAlMe_3)^+$, 57 $(AlMe_2)^+$. The complex (**4**) (solid) was purified by recrystallization (ether) m.p.: 139.5–140°C. Found: C, 49.2; H. 9.2. Calc.: C, 49.8; H, 9.5%. Characteristic fragment ions occur at *m/z* (E.I.: 20 eV, assignment in parentheses): 453 [bass peak, $(Al_4Et_5CH_2C_8H_{17}N_6)^+$], 339 [bass peak, $(Al_4Et_5C_8H_{20}N_6)^+$], 57 $(HAlEt)^+$, 393 $(Al_4Et_3C_8H_{18}N_6)^+$, 85 $(AlEt_2)^+$, 455 $(Al_4Et_3C_8H_{22}N_6)^+$, 212 $(Al_4Et_2C_4H_{10}N_3)^+$, 423 $(Al_4Et_4C_8H_{20}N_6)^+$, 154 $(Al_2C_4H_{10}N_3)^+$, 125 $(AlC_4H_{10}N_3)^+$. Their NMR chemical shifts are listed in Table 1 (^1H) and Table 2 (^{13}C and ^{27}Al).

X-ray structure analysis

Single crystals suitable for X-ray diffraction were obtained by thermal gradient vacuum sublimation

(**1a** and **1b**) or slow recrystallization from a suitable solvent (**4**, from ether). Data crystals were sealed in lithium glass capillaries to avoid decomposition by oxygen or moisture. Reflections were collected on a Enraf–Nonius CAD-4 automated diffractometer using graphite-monochromated Mo-K_α radiation for data up to $2\theta \leqslant 45°$. Structures were solved with MULTAN[19] and refined with a weighted full-matrix least-squares routine, NRCVAX,[20] on a Micro VAX 3600. Atomic scattering curves were derived from data taken from the International Tables, Vol. IV.[21] Crystal data and refinement details are listed in Table 3. The initially non-disordered models of **1a** and **1b** finished with very unreasonable C—C bond lengths (1.25–1.33 Å) for N—CH_2—CH_2—N, in addition to large thermal motions. Hence, 1 : 1 disordered structures were constructed later, resulting in much more reasonable thermal parameters for carbon atoms and C—C single bond distances. The R values were significantly decreased. For **4** no disorder has been found in the structure. We have obtained the crystal structure of **1a**, which is very similar to the structure reported earlier.[22] However, we believe that we obtained a different form of the crystal. Since it does not convey any more chemical information than what has already been published, we decided not to present the crystallographic data of **1a** here. Selected bond distances and angles of **1b** and **4** are listed in Tables 4 and 5, respectively.

RESULTS AND DISCUSSION

The bidentate ligands ethylenediamine or N,N′-dimethylethylene diamine were allowed to react with $Al_2R'_4(NEt_2)_2$ (R′ = Me, Et) to produce $[AlR'_2]_2[(HNCH_2CH_2)_2N]_2[AlR']$. Compounds **1a** and **1b** were the only aluminium containing products isolated besides the gaseous product and volatile amine. The overall reaction is given in eq. (1). Crystal data and refinement details of **1a** and **1b** are listed in Table 3, with bond lengths and angles in Tables 4 and 5, respectively.

$$3Al_2(NEt_2)R'_4 + 4RHNCH_2CH_2HNR \rightarrow 2[AlR'_2]_2(NHCH_2CH_2NR)_2 [AlR'] + 6Et_2NH + 2R'H \quad (R' = Me, Et;\ R = H, Me) \qquad (1)$$

The complexes (**1b**, **2a**, **2b**) display two different environments for the aluminium atoms and the ethylenediamines are bridged to three organoaluminium groups, such that two Al_2N_2 cores are linked by the central aluminium atom, as shown in Fig. 1. The coordination environment of the two

outer aluminium atoms is in the usual tetrahedral coordination. The central aluminium atom is bonded to four nitrogen atoms from two bidentate ligands and a methyl carbon atom. The penta-coordination of the central aluminium atom is obviously in a square-pyramidal configuration. The distances of central Al(2)—N(1), 2.029(4), and Al(2)—N(2), 2.043(4) Å bonds in **1b** are consistent with the mean Al—N distance of 2.022(3) Å in the published data,[15] and are slightly longer than the distances of the outer Al—N, Al(1)—N(1), 1.926(4), and Al(1)—N(2), 1.923(4) Å, in **1b**. The Al—N lengths of a penta-coordinate aluminium, therefore, are longer than those of a tetra-coordinate aluminium. The Al—C distances are similar in **1b**. The Al(1)···Al(2) contacts of 2.911(2) Å in **1b** are not indicative of any metal–metal interaction. The distance of C(1)—C(1′) = 1.526(20) Å in **1b** as extracted from the disordered five-membered ring AlN_2C_2 are consistent with a single bond distance of 1.55 Å. The tridentate diethylenetriamine was allowed to react with $Al_2R'_4(NEt_2)_2$(R′ = Me, Et) and $[AlR'_2]_2[(HNCH_2CH_2)_2N]_2[AlR']$ was isolated as the aluminium-containing products. The crystal data and structural parameters are listed in Tables 3, 4 and 5. The overall reaction is given in eq. (2)

$$2Al_2(NEt_2)_2R'_4 + 2(H_2NCH_2CH_2)_2NH \rightarrow Al_4R'_6[(HNCH_2CH_2)_2N]_2 + 4Et_2NH + 2R'H \quad (R' = Me, Et) \qquad (2)$$

The spectral data of **3** were consistent with the

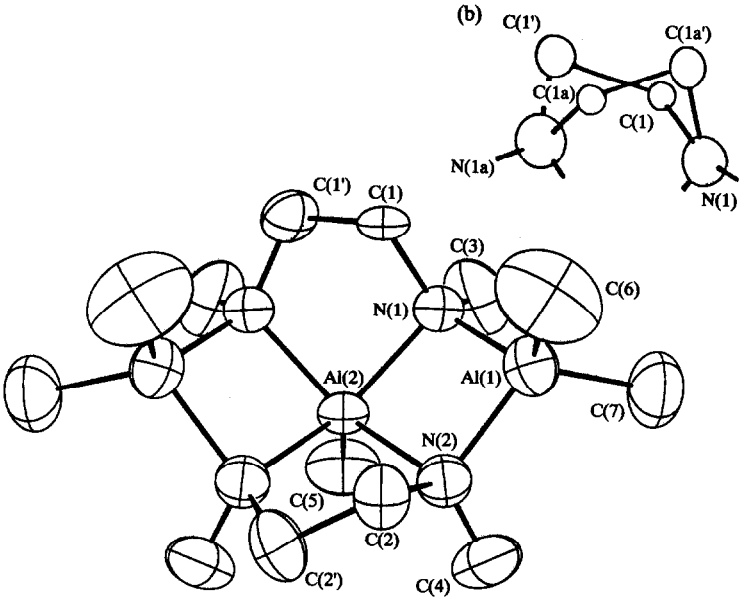

Fig. 1. Molecular structure of $[AlR'_2]_2[RNCH_2CH_2NR]_2[AlR']$ (**1b**, R′ = CH_3, R = CH_3).

published results.[5] Herein, we also report the X-ray crystal structure of **4**, which is similar to the work published by Robinson *et al.* Complex **4** consists of two different environments for the aluminium atoms and the diethylenetriamines bridge four organoaluminium groups, revealing three Al_2N_2 cores connected consecutively by two central aluminium atoms as shown in Fig. 2. The two outermost aluminium atoms are in the usual tetrahedral coordination and the two inner aluminium atoms are bonded to four nitrogen atoms and to a methyl carbon atom in a square-pyramidal configuration. The distances of Al(1)—N(1) = 2.083(3), Al(1)—N(2) = 1.980(3), Al(1)—N(3) = 2.034(2) and Al(1)—N(3)′ = 1.987(2) Å for square-pyramidal configuration are slightly longer than the distances of Al(2)—N(1) = 1.904(3) and Al(2)—N(2) = 1.912(3) Å for tetrahedral aluminium. The distances of Al(1)—C(8) = 1.976(4), Al(2)—C(10) = 1.960(4) and Al(2)—C(12) = 1.971(4) Å are essentially the same, despite the bonding geometry variations. The contacts of Al(1)···Al(2) = 2.919(1) and Al(2)···Al(1A) = 3.025(1) Å exclude any significant metal–metal interactions.

Alkanes and secondary amines were released due to cleavage of N—H, Al—R and Al—N bonds via an intermolecular condensation reaction, giving products possessing Al_2N_2 fragments. The for-

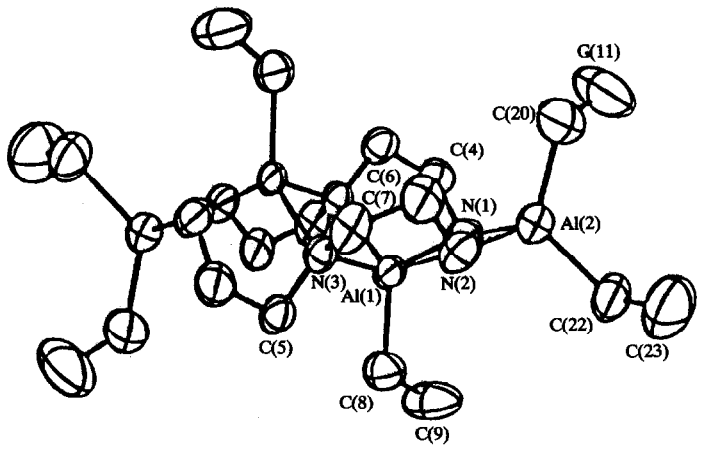

Fig. 2. Molecular structure of $[AlEt]_2[C_6H_{20}N_6]_2[AlEt_2]_2$.

mation of trialuminium or tetraaluminium organocomplexes depends on the number of nitrogen atoms present in the polydentate amines. Each nitrogen atom is able to donate two electron pairs to two different aluminium atoms after the cleavage of one N—H bond. The outer aluminium accepts two electron pairs from nitrogen atoms, keeping a tetrahedral configuration, and the central aluminium accepts four electron-pairs from four nitrogen atoms, forming a square-pyramidal configuration. Hence, substitutions of ethylenediamine and diethylenetriamine reactants on the Al_2N_2 skeleton result in the formation of trinuclear and tetranuclear aluminium complexes, respectively.

(*Received* 27 *October* 1992; *accepted* 5 *May* 1993)

Abstract—The crystal and molecular structure of the first cyclometallated platinum(II) complex of 1,1,2,2-tetraacetylethane {bis(2,4-pentanediones)-3,4-diacetyl-2,4-hexadiene-2,5-diol (H_2-dahd)}, [Pt(dahd-C^3,O)(PMe_2Ph)$_2$], was determined by X-ray analysis.

The β-dicarbonyl and β-ketoesters, which have active methylene groups, have been widely known to function as versatile ligands to transition metal ions and a number of their bonding modes in a variety of metal complexes have been reported.[1,2] While the L-ascorbate platinum(II) complex with the Pt—C bond has been prepared, which is of interest as an antitumor reagent,[3] its structure interestingly resembles in its skeleton the central carbon-bonded platinum(II) complex of β-dicarbonyl. In contrast to these previous findings any function of γ,γ′-bis(β-dicarbonyls)[4] with the second- or third-row transition metals has strangely been elusive. 1,1,2,2 - Tetraacetylethane{3,4 - diacetyl - 2,4 - hexadiene-2,5-diol(H_2-dahd)} and the bis(β-diketones) with connecting links of L_2 (L = S, Se: 2,3 - disubstituted 1,1,4,4 - tetraacetylbutane) between the two β-diketones are always in the dienol form with six-membered hydrogens chelated intramolecularly, and their central carbons of the β-dicarbonyl groups are stabilized as quarternary carbons.[5,6] Nevertheless, we have recently found that the central carbons of the bis(β-dicarbonyls) are relatively readily activated under basic conditions to form a metallacycle to platinum(II) with a (C,O)-linkage (1,1,2,2-tetraacetylethane),[7–9] while the 2,3-disubstituted 1,1,4,4-tetraacetylbutane undergoes S—S, S—C and Se—C bond cleavage producing 3 - substituted 2,4 - pentanedionate dianions which relatively readily form unusual platinum(II) complexes with five-membered (S,O)-[10] and four-membered (η^2-L_2)-linkages (L = S, Se),[11] respectively. An analogous platinum(II) complex with an (Se, O) bond has been prepared by an oxidation reaction of $Pt(PPh_3)_4$ with 2,2,4,4-tetraacetyl-1,3-diselenetane.[12] Here, [Pt(dahd-C^3,O′)(SEt_2)$_2$] is interesting since inversion of one sulphur atom has been found to proceed via an unusual bond breakage (an intermolecular path-

* Authors to whom correspondence should be addressed.

way) from ^{1}H NMR, which may be accounted for as a relatively large *trans* influence of the metallated carbon (C^3).[9] In addition, the cyclometallated platinum(II) complex of 1,1,2,2-tetraacetylethane unusually activates the C—H bond of the monosubstituted acetylene to afford the dialkynyl complexes, as described previously.[13] The crystal and molecular structure of [Pt(dahd-C^3,O)(PMe_2Ph)$_2$] has thus been determined by X-ray analysis in this paper and it reveals that the five-membered metallacycle of 1,1,2,2-tetraacetylethane is approximately planar. The structure retains an almost square-planar configuration with a slight distortion towards tetrahedral, while large steric repulsions between PMe_2Ph and the C-bonded 2,4-pentanedione group from 1,1,2,2-tetraacetylethane has been observed. This is the first report of a structure of a cyclometallated platinum(II) complex of 1,1,2,2-tetraacetylethane crystallographically determined.

EXPERIMENTAL

[Pt(dahd-C^3,O′)(PMe_2Ph)$_2$]

The preparation of this compound has been described previously.[8]

X-ray crystal structural analysis of [Pt(dahd-C^3,O′)(PMe_2Ph)$_2$]

Pale yellow crystals were grown from an acetone–ethanol mixed solution under isothermal vaporization. A crystal of dimensions *ca* 0.1 × 0.13 × 0.20 mm was used during the measurements. Throughout the experiment Mo K_α radiation ($\lambda = 0.71069$ Å) was used with a graphite crystal monochromator on a Rigaku AFC four-circle diffractometer.

Crystal data of [Pt(dahd-C^3,O′)(PMe_2Ph)$_2$], $C_{26}H_{34}O_4P_2Pt$

$Mr = 667.59$, monoclinic, $a = 13.897(2)$, $b = 18.987(4)$, $c = 11.164(1)$ Å, $\beta = 112.471(9)$; $U = 2722.2(8)$ Å^3, space group $P2_1/n$, $Z = 4$, $D_x = 1.629$ g cm^{-3}, $F(000) = 1320$, μ(Mo K_α) = 5.62 mm^{-1}. The cell parameters were refined by least-squares for 25 reflections in the range $33° < 2\theta < 38°$. The space group was determined from the systematic absences ($0k0$; k odd, $h0l$; $h+l$ odd). The intensity data were measured using the ω–2θ scan technique, with a scan speed of 2° s^{-1}. The intensity of the incident beam was monitored throughout the data collection by measuring three reference reflections, (1,1,1), (1,0,1) and (0,−1,1), which showed no significant change in intensities ($0.97 < I_0 < 1.06$). A total of 5373 reflections were measured, ($0 \leqslant h \leqslant 16$, $0 \leqslant k \leqslant 22$, $-13 \leqslant l \leqslant 13$). Among these zero intensities were 417 and 681 were weak [$|F_0| < 3\sigma(F_0)$]. Non-zero unique reflections from 4275 planes were corrected for Lorentz and polarization, but not absorption effects. The position of the platinum atom was obtained by a Patterson synthesis. All other atoms were located by Fourier and difference syntheses. The structure was refined by the full-matrix least-square method with anisotropic thermal parameters for non-hydrogen atoms and isotropic factors for hydrogen atoms. The function minimized was $\Sigma w(|F_0| - |F_c|)^2$ with $w = 1/[\sigma^2(F_0)]$. The R values of the final refinement were $R = 0.045$ with $Rw = 0.049$. Goodness-of-fit, S, was 2.5. The maximum and minimum heights in the final difference-Fourier map were ±0.2 e Å^{-3}. A FACOM-M782 computer at the Data Processing Center, Kyoto University, and the UNICSII computation program system[14] were used for all calculations in the data reduction and the structure analysis. The atom scattering factors were taken from the International Tables for X-ray Crystallography.[15]

RESULTS AND DISCUSSION

A perspective view of [Pt(dahd-C^3,O′)(PMe_2Ph)$_2$] [dahd^{2-}-3,4-diacetyl-2,4-hexadiene-2,5-diolate dianion {bis(2,4-pentanediones)-1,1,2,2-tetraacetylethane}] with the numbering scheme is shown in Fig. 1. The bis(2,4-pentanedione) ligand forms a five-membered metallacycle, in which the 3-carbon atom and the carbonyl oxygen atom at the 5-position from the dahd^{2-} bond to platinum(II). The bond lengths and bond angles are shown in Fig. 2. Bond angles P(1)—Pt—C(3) and P(2)—Pt—O(1) are 165.8° and 177.2°, respectively, and P(1) and C(3), and P(2) and O(1) are displaced up to 0.1 Å out of the best plane in opposite directions. These show that the complex still retains an approximate square planar geometry, but with a slight tetrahedral distortion.[2] The Pt—C(3) bond distance 2.143 Å may be normal and comparable with the corresponding bond distance observed in the Pt—C bonded complex of a β-ketoester, *trans*-bis{methyl(α-methoxycarbonyl)[pyridine]-2-propanoate-C,N} platinum(II).[3] In the present case the bond distance C(3)—C(4), 1.549 Å, is slightly elongated from the corresponding bond length of the free ligand 1,1,2,2-tetraacetylethane (1.496 Å),[5,6] while C(4)—C(5), 1.368 Å, is so shortened that it is sufficiently close to a C=C bond length, 1.360 Å, found in the cyclometallated compound of the 2,4-pentanedionate dianion, [Pt(tfa-C,O)(Me_2-py)(PPh_3)] (tfa =

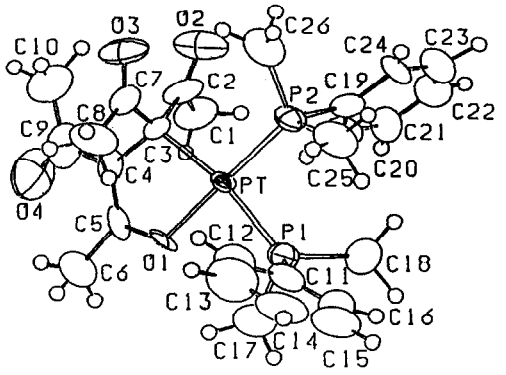

Fig. 1. A perspective view of the molecular structure of [Pt(dahd-C³,O)(PMe₂Ph)₂].

1,1,1-trifluoro-2,4-pentanedione) with a six-membered chelate ring.[16] The five-membered chelate ring Pt, O(1), C(5), C(4) and C(3) in the present case is in the envelope conformation, where the torsion angle C(3)—C(4)—C(5)—O(1) is −1.8°, C(4)—C(3)—Pt—O(1) −8.03° and C(5)—O(1)—Pt—C(3) 8.39°, respectively. Bond angles in the five-membered chelate ring, Pt—C(3)—C(4) 104.3° and C(3)—C(4)—C(5) 117.0°, are alternatively 5° and 3° less than the ideal bond angles 109° and 120° and these are probably the distortions due to the ring strain. The two carbonyls of the carbon-bonded 2,4-pentanedione group of 1,1,2,2-tetraacetylethane are in the same direction, opposite to the chelate ring with torsion

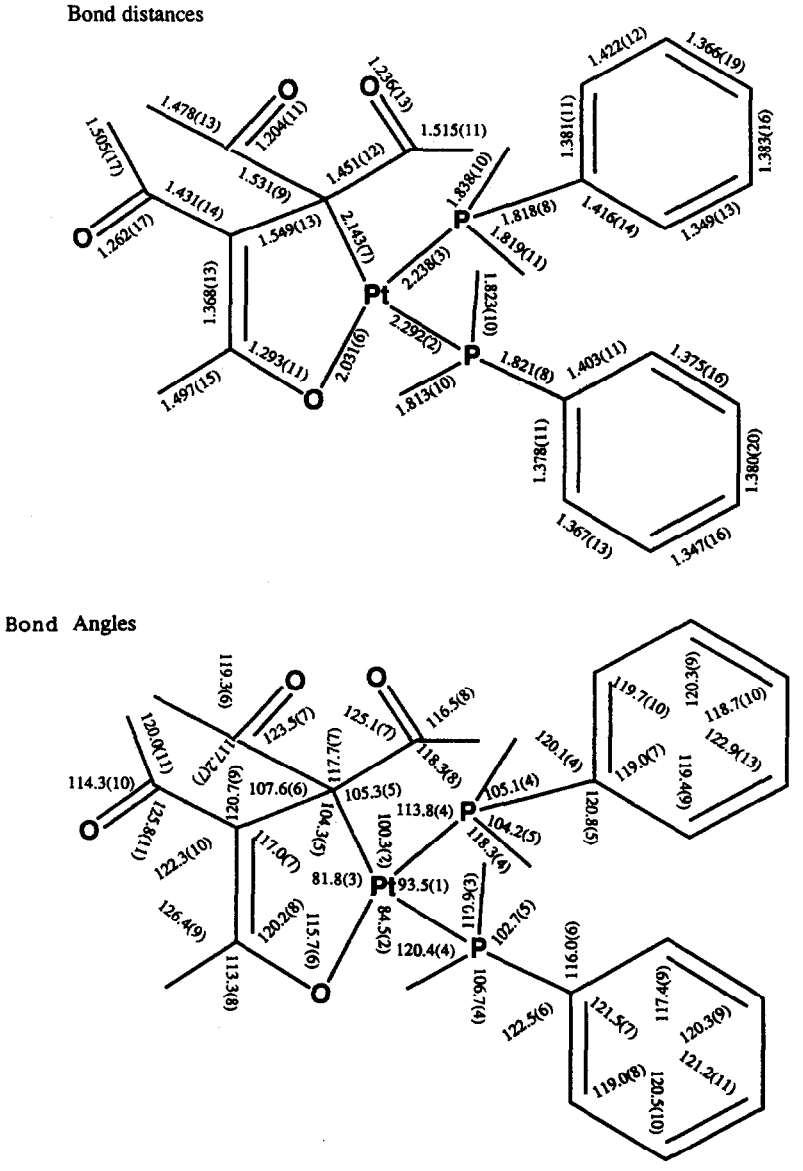

Fig. 2. Bond distances (Å) and angles (°) in [Pt(dahd-C³,O)(PMe₂Ph)₂].

angles C(2)—C(3)—C(7)—O(3) 1.7° and O(2)—C(2)—C(3)—C(7) 20.8°.

The steric size of PMe_2Ph and 1,1,2,2-tetraacetylethane is significant and an unusual short interatomic contact has been observed for O(2)···C(26), 2.99 Å, which is much shorter than the sum of the van der Waals radii of the methyl group (2.0 Å) and oxygen atom (1.5 Å). The bond angle C(3)—Pt—P(1), 100.3°, is also extraordinary being expanded from the ideal bond angle 90°, which may cause repulsion of C(3) in a direction towards O(1). As a result the interatomic contact O(2)···C(26), 2.82 Å, is considerably short and the bond angle O(1)—Pt—P(1) is 5.5° less than the ideal bond angle 90°.

The two phenyl rings of PMe_2Ph ligands orient in mutually opposite directions to the coordination plane and the dihedral angles between each phenyl ring and the coordination plane are 59.9° and 99.6°, respectively.

Although the lengths of the four carbonyl bonds from 1,1,2,2-tetraacetylethane were unfortunately accompanied with relatively large deviations and any significant differences were not clearly distinct, the bond length C(9)—O(4), 1.262 Å, seems to be slightly longer than the others in the keto form, C(7)—O(3) 1.204 and C(2)—O(2) 1.2364 Å, and it rather approaches that of the enol C(5)—O(1), 1.293 Å. Any elongation of bond distance C(9)—O(4) may not, however, be significant since its oxygen atom is apart by more than 7.8 Å from the adjacent platinum atom and an intermolecular interaction can be excluded. On the other hand, the IR carbonyl stretching vibrations in $[Pt(dahd\text{-}C^3,O')(PMe_2Ph)_2]$[8] have been observed as three distinct bands at 1515(s), 1627(s) and 1673(vs) cm^{-1} and these absorptions could be assigned as due to the O-bonding carbonyl in the enol form [$\nu(C^5—O^1)$], the acetyl group [$\nu(C^9=O^4)$] attached to the five-membered chelate ring and the C-bonded 2,4-pentanedione group [$\nu(C^7=O^3)$ and $\nu(C^2=O^2)$]. In the latter two bands the frequency at 1627 cm^{-1} is in the lower frequency region relative to the keto carbonyl, which may not, however, be unusual and is comparable with 1613–1621 cm^{-1} already found in $[Rh(acac\text{-}O)(CO)(PPr^i_3)_2]$[17] possessing an O-unidentate 2,4-pentanedione and $[Pt(M\text{-}ac\text{-}M,O)(PR_2Ph)_2]$ (M = S, R = Me;[9] M = Se, R = Ph;[11] M-ac = 3-mono-substituted-2,4-pentanedione).

In the present case a large *trans* influence related with a metallated carbon (3) could not be observed and the difference in bond lengths between Pt—P(2), 2.238 Å, and Pt—P(1), 2.292 Å, is not as pronounced as 2.24 and 2.34 Å found in $[PtCl(PMe_3)_3)]Cl$.[18]

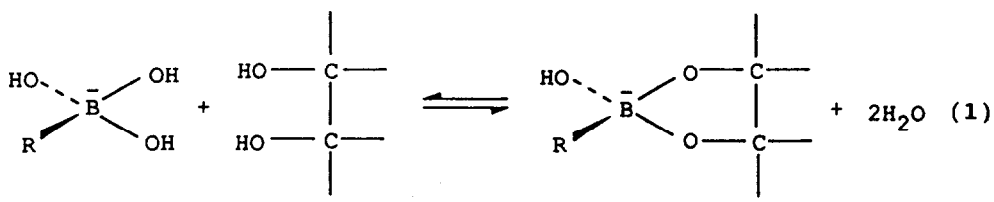
(*Received* 28 *January* 1993; *accepted* 4 *May* 1993)

Abstract—Borate ions, $RB(OH)_3^-$, react with polyols to form anionic complexes via the reaction $RB(OH)_3^- + H_2L \rightleftharpoons Cx^- + 2H_2O$. In the present study thermodynamic parameters of several such reactions were determined by variable-temperature ^{1}H and ^{11}B NMR spectroscopy. The systems studied were: $B(OH)_4^-$/1,2-ethanediol; $B(OH)_4^-$/1,2-propanediol; $C_6H_5B(OH)_3^-$/1,2-ethanediol; $CH_3B(OH)_3^-$/1,2-propanediol; and $CH_3B(OH)_3^-$/1,2-dihydroxybenzene. The first four systems have very similar stability constants and thermodynamic parameters. The reactions are all exothermic ($\Delta H° \sim -20$ kJ mol^{-1}) and values of $\Delta S°$ are quite negative ($\Delta S° \sim -60$ J mol^{-1} K^{-1}). The negative entropy is attributed primarily to a loss of configurational entropy in the ligand on complexation. This assertion was further investigated by studying the complexation of $CH_3B(OH)_3^-$ with the rigid ligand 1,2-dihydroxybenzene. The $CH_3B(OH)_3^-$/1,2-dihydroxybenzene reaction is characterized by a stability constant which is greater by four orders of magnitude than those of the other systems and this increase is shown to be entirely due to a much more positive value of $\Delta S°$.

Molecular recognition of carbohydrates and other polyhydroxy compounds by boron acids has been a subject of long and continuing interest.[1] The basis of this recognition is the formation of covalent bonds between the boron acid and appropriately oriented hydroxyl groups on the ligand. The overall reaction in basic media is a condensation reaction between borate ion and the ligand [eq. (1)]. In our continuing study of the mechanism of boron acid complexation reactions we have recently shown that polyols react only with borate ions,[2] while more acidic ligands such as dihydroxybenzenes[3] can react with trigonal boron acids, $RB(OH)_2$, as well.

We report here our first determination of thermodynamic parameters for these reactions. Although there have already been several reports[4–11] of thermodynamic parameters for borate/polyol complexation reactions in the literature, significant disagreement among the various studies is common and, as a result, the thermodynamic parameters remain somewhat uncertain. The two techniques used in these studies have been the measurement by pH techniques of stability constants as a function of temperature[4–8] and calorimetry.[9–11] One reason for the lack of agreement is that both techniques used in the determination of the thermodynamic



* Author to whom correspondence should be addressed.

parameters are dependent on accurate values of the reaction stability constants and here, too, differences exist in the literature.

The present paper demonstrates the efficacy of variable-temperature ^1H and ^{11}B NMR spectroscopy for the accurate determination of stability constants and thermodynamic parameters for boron acid complexation reactions. Although ^{11}B NMR spectroscopy has been used in the determination of stability constants for the reactions,[12-14] its use has not previously been extended to include a thermodynamic study.

EXPERIMENTAL

Boric acid, methylboronic acid, phenylboronic acid, 1,2-ethanediol, 1,2-propanediol, 1,2-dihydroxybenzene and D_2O (Aldrich) were all used as received. Stability constants for the various reactions were determined as a function of temperature by pH titration (NaOH titration), ^1H NMR spectroscopy and ^{11}B NMR spectroscopy. pH titrations were performed on a Fisher Accumet 950 pH meter and pH measurements were made in a thermostated cell under a nitrogen atmosphere. The activity coefficient of the hyrdogen ion was calculated using the Davies equation[15] as appropriate for each temperature and ionic strength. The pH meter was restandardized at each temperature. ^1H and ^{11}B NMR spectra were obtained using a Bruker IBM 250 MHz FT NMR spectrometer equipped with a Bruker BVT-1000 variable-temperature unit; 10 mm quartz NMR tubes were used in all ^{11}B experiments. The Bruker BB VSP 250 broad-band probe was modified to contain only quartz glassware. Therefore, there was no background boron signal. The accuracy of the ^{11}B NMR integration was checked by preparing a solution containing known (gravimetric) concentrations of $CH_3B(OH)_2$, $B(OH)_3$ and $C_6H_5B(OH)_2$ and comparing the NMR integrated areas with the gravimetric molar ratio. No measurable difference was observed. All solutions were prepared using D_2O/H_2O as the solvent mixture and the pH was adjusted by addition of deuterated NaOH or deuterated HCl. ^1H NMR spectra were recorded in 100% D_2O and ^{11}B NMR spectra were usually recorded in 30% D_2O. Solution pH was measured before and after recording each spectrum using a Fisher Ag/AgCl Microprobe combination pH electrode. In the case of ^{11}B NMR spectra these measurements were made directly in the NMR sample tube. pH measurements and NMR spectra were recorded over a temperature range from 276 to 318 K. Boron acid concentrations in various experiments ranged from 0.05 to 0.20 M and ligand concentrations ranged from 0.07 to 0.35 M. Ionic strength was adjusted by addition of the requisite amount of KNO_3 and it was typically maintained at 0.10 M.

RESULTS

Stability constants for the reactions at 25°C were variously determined by pH titration, ^{11}B NMR spectroscopy and ^1H NMR spectroscopy and agreement between the first two techniques has been previously demonstrated.[2,16] ^1H NMR spectroscopy also yields identical results.

Variable-temperature ^1H and ^{11}B NMR spectroscopy were used to determine the stability constants as a function of temperature. Since the ^{11}B NMR signals of $RB(OH)_3^-$ are relatively broad and often overlap with the resonances of the borate complex ions, ^1H NMR spectroscopy is frequently the method of choice for these systems. ^{11}B NMR spectroscopy is particularly useful for $B(OH)_4^-$ systems because the borate resonance is quite sharp and adequate separation of the resonances makes integration much more accurate. Both techniques were used in the $B(OH)_4^-$/1,2-propanediol study and representative spectra are shown in Figs 1 and 2.

The ^{11}B NMR spectrum of the system is presented in Fig. 1. The peak at -18 ppm is due to $B(OH)_4^-$ and the downfield peak (-14 ppm) is assigned to the 1 : 1 complex. Although $B(OH)_4^-$ is

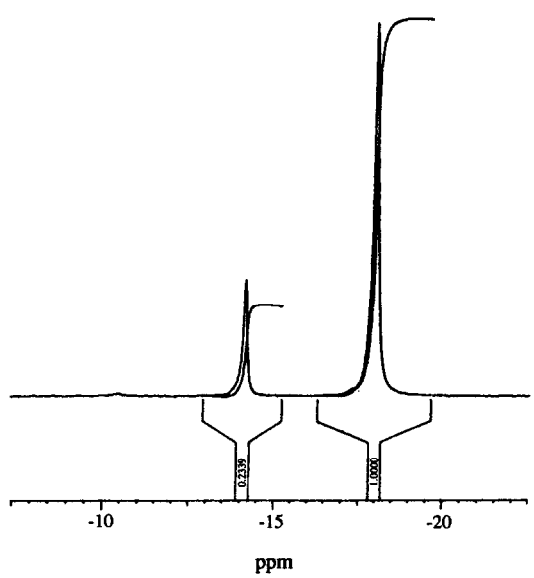


Fig. 1. ^{11}B NMR spectrum: $[B(OH)_4^-] = 0.10$ M; [1,2-propanediol] = 0.10 M; pH(D) = 12.0 in 30% D_2O/H_2O; $T = 25$°C. Chemical shifts are relative to external 0.15 M $B(OH)_3$ in 30% D_2O/H_2O at pH(D) = 2.0. The bracketed numbers are the relative integrations.

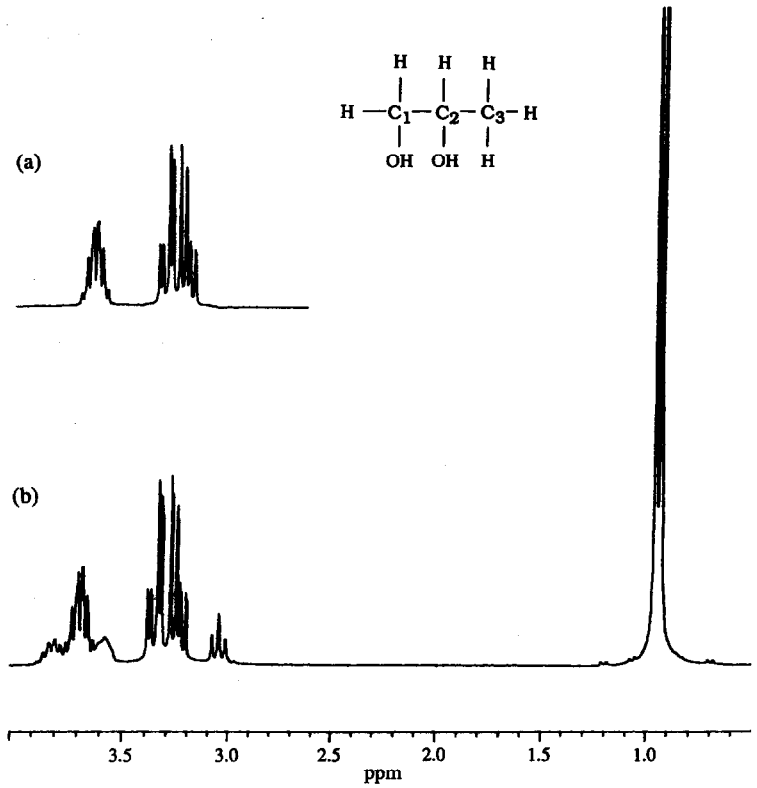

Fig. 2. ^{1}H NMR spectra: (a) The methylene/methyne [C(1)/C(2)] region of [1,2-propanediol] = 0.13 M in D_2O; pD = 12.0; T = 25°C. (b) $[B(OH)_4^-]$ = 0.10 M; [1,2-propanediol] = 0.13 M in D_2O; pD = 12.0; T = 25°C. The solvent H_2O/D_2O peak at 4.63 ppm is not shown. All ^{1}H NMR chemical shifts are relative to external 3-(trimethylsilyl)propionic acid in D_2O; pD = 12.0; T = 25°C.

also capable of forming bis complexes with diols,[17] reactant concentrations in our experiments were kept sufficiently low that only 1 : 1 complexes are formed in measurable concentration. An NMR signal due to the bis complex (−11 ppm) can be easily seen at higher reactant concentrations. Direct integration of the peaks in Fig. 1 allows a calculation of the reaction stability constant [eq. (1)].

The ^{1}H NMR spectrum of the same system is shown in Fig. 2. The spectrum of free 1,2-propanediol is presented in Fig. 2(a). The multiplet at 3.3 ppm is assigned to the two protons on C(1) and the multiplet at 3.7 ppm is due to the one proton on C(2). The spectrum with added $B(OH)_3$ is presented in Fig. 2(b). The methyl protons (1 ppm) are unaffected by complexation. The three non-methyl protons in the complex are non-equivalent and they give rise to three new multiplets in the spectrum. The new triplet at 3.1 ppm is well separated from the free ligand multiplet at 3.3 ppm and the stability constant can be calculated from the integration of these two multiplets.

Since ^{1}H and ^{11}B NMR experiments are performed in solvents which differ in D_2O concentration, this variable was also studied. ^{11}B NMR experiments were performed in 20%, 50% and 100% D_2O and results were obtained which agreed within experimental error. Similarly, although the ionic strength was maintained at 0.10 M by addition of the requisite amount of KNO_3, in a few experiments reactant concentrations alone provided an ionic strength in excess of 0.10 M. Therefore, the effect of ionic strength was evaluated. Ionic strength was increased up to 0.60 M by addition of KNO_3 and no measurable effect on either stability constants or thermodynamic parameters was observed. Our complete results on the $B(OH)_4^-$/1,2-propanediol system are presented in Fig. 3.

All of the NMR experiments except 1,2-dihydroxybenzene were performed at pH 12. At pH 12 the boron acids are all present predominantly as $RB(OH)_3^-$ and the various diols are unionized. Integration of the appropriate NMR signals provides a direct determination of the reaction stability constant [eq. (1)]. The $CH_3B(OH)_2$/1,2-dihydroxybenzene system, however, was studied at pH 6. This lower pH was selected to avoid problems associated with ligand oxidation in basic media.[3]

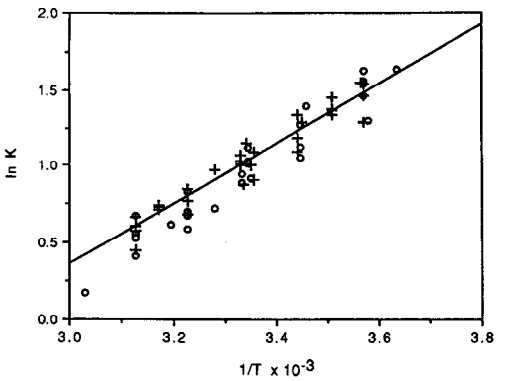

Fig. 3. van't Hoff plot of the $B(OH)_4^-$/1,2-propanediol system; ○ = ^1H NMR (experimental points); + = ^{11}B NMR (experimental points).

At this pH both $CH_3B(OH)_2$ and 1,2-dihydroxybenzene are unionized. Integration of the ^{11}B NMR spectrum at the measured pH allows the direct calculation of the stability constant for the reaction of trigonal $CH_3B(OH)_2$. The stability constant and thermodynamic parameters for the analogous reaction of $CH_3B(OH)_3^-$ with 1,2-dihydroxybenzene can be calculated from the $CH_3B(OH)_2$ values and the acid dissociation constant and thermodynamic parameters of $CH_3B(OH)_2$ ionization. The latter parameters were determined by pH titration of $CH_3B(OH)_2$ at several temperatures.

Stability constants and thermodynamic parameters for the various reactions are presented in Table 1. The error associated with the stability constants and the $CH_3B(OH)_2$ acid dissociation constant is ±10%. The values of ΔG° were calculated from the reported values of the equilibrium constants at 25°C and have an error of ±0.25 kJ mol^{-1}, which corresponds to the ±10% error in each of these constants. Errors associated with the other thermodynamic parameters were determined from the variances[18] of the slope and intercept of the appropriate van't Hoff plots (Fig. 3) and are specifically included in Table 1.

DISCUSSION

Although there have been several determinations of thermodynamic parameters of borate/polyol reactions in the literature,[4-11] significant disagreement among the various studies is not uncommon. For example, the reaction of $B(OH)_4^-$ with 1,2-dihydroxybenzene has been the subject of three investigations[5-7] and reported values of ΔH° vary from −0.24[5] to −23 kJ mol^{-1},[6] while determinations of ΔS° vary from +77[5] to −1.7 J mol^{-1} K^{-1}.[6] There have also been three different studies[7-9] of both the $B(OH)_4^-$/1,2-ethanediol and $B(OH)_4^-$/1,2-propanediol systems. The last of these[9] is a calorimetric investigation. Again, reported values of ΔH° vary widely (from −5.8[9] to −15.1 kJ mol^{-1}[8] for 1,2-ethanediol and from −9.3[9] to −21.4 kJ mol^{-1}[8] for 1,2-propanediol), as do values of ΔS° (−15[9] to −45.6 J mol^{-1} K^{-1}[8] for 1,2-ethanediol and −22[9] to −62 J mol^{-1} K^{-1}[8] for 1,2-propanediol). Several thermodynamic studies of more complex polyols[5,8-11] produce similar or greater differences.

Perhaps the most important reason for these large differences in reported thermodynamic parameters is the lack of accurate values of the reaction stability constants. Accurate stability constants are needed even if a calorimetric method is used,[9-11] because these reactions do not go to completion at any pH. The most common method which has been used in the determination of the stability constants is one in which the pH change on addition of diol to a borax buffer is measured.[17] It has been pointed out[7,17,19] that the equations which relate the pH change to the reaction stability constants can be solved exactly only for cases in which just one com-

Table 1. Thermodynamic parameters for several $RB(OH)_3^-$/1,2-diol reactions

Reaction	K^a	$\Delta G^{\circ a}$ (kJ mol^{-1})	ΔH° (kJ mol^{-1})	ΔS° (J mol^{-1} K^{-1})	NMR method
$B(OH)_4^-$ + 1,2-ethanediol	1.4	−0.83	−18(±2)	−58(±8)	^1H, ^{11}B
$B(OH)_4^-$ + 1,2-propanediol	2.8	−2.6	−17(±1)	−50(±2)	^1H, ^{11}B
$C_6H_5B(OH)_3^-$ + 1,2-ethanediol	2.4	−2.2	−20(±3)	−60(±9)	^1H
$CH_3B(OH)_3^-$ + 1,2-propanediol	6.0	−4.4	−26(±4)	−74(±10)	^1H
$CH_3B(OH)_3^-$ + 1,2-dihydroxybenzene[b]	4.0×10^4	−26	−28(±2)	−11(±10)	^1H

[a] Values of K and ΔG° are given at 25°C. The errors in K and ΔG° are ±10% and ±0.25 kJ mol^{-1}, respectively.

[b] Calculated from the values for the reaction of $CH_3B(OH)_2$ with 1,2-dihydroxybenzene and the thermodynamic parameters for the ionization of $CH_3B(OH)_2$. For $CH_3B(OH)_2$: $K_a = 4.0 \times 10^{-11}$; $\Delta G^\circ = -59$ kJ mol^{-1}; $\Delta H^\circ = 28 \pm 2$ kJ mol^{-1}; $\Delta S^\circ = -105 \pm 8$ J mol^{-1} K^{-1}.

plex is formed. An approximation must be made when bis complexes are also formed.[7,17] The determination of stability constants by ^{11}B NMR spectroscopy[12–14] involves no similar approximation. A tabulation[12] of pH change and ^{11}B NMR results shows that ^{11}B NMR spectroscopy leads to smaller values of stability constants in most cases. Given the uncertainty in the literature values of the stability constants, it is to be expected that the thermodynamic parameters determined using them would also be uncertain.

Reactions of $RB(OH)_3^-$

The study of simple 1,2-diols was chosen as a first test of the use of variable-temperature ^{11}B and ^1H NMR spectroscopy for the determination of thermodynamic parameters for borate complexation reaetions. The two $B(OH)_4^-$ systems involve a redetermination of previously reported[7–9] values of $\Delta H°$ and $\Delta S°$. The $CH_3B(OH)_3^-$ reactions complement some of our earlier kinetic studies.[2,3] The principal result (Table 1) is that the thermodynamic parameters for the reactions of aliphatic diols with the various borate ions are quite similar. The reactions are all exothermic with an average value of $\Delta H° \sim -20$ kJ mol^{-1}. All of the entropy changes are quite negative ($\Delta S° \sim -60$ J mol^{-1} K^{-1}) and this can be attributed to a loss of ligand configurational entropy on complexation. This assertion is supported by a comparison of the reactions of $CH_3B(OH)_3^-$ with 1,2-propanediol and 1,2-dihydroxybenzene, a rigid ligand. 1,2-Dihydroxybenzene is much more acidic than 1,2-propanediol and the reaction stability constant for this system exceeds that for the 1,2-propanediol system by four orders of magnitude. Surprisingly, this difference in stability constant turns out to be entirely related to a much more positive value of $\Delta S°$ and not at all to any real difference in $\Delta H°$. It is interesting to note that our previous kinetic study[3,20] concluded that the complexation reactions of 1,2-dihydroxybenzenes are likely to be characterized by a much more positive entropy of activation in the forward direction as compared with less rigid ligands. The present thermodynamic result is entirely in accord with the consequences of that idea. It should also be noted that a recent thermodynamic analysis[21] estimates the "entropic cost of restricting a rotor, within a hydrocarbon chain, as -1.6 to -3.6 kJ mol^{-1} ($T\Delta S°$ at 300 K)". Our results on the $CH_3B(OH)_3^-$/1,2-propanediol and $CH_3B(OH)_3^-$/1,2-dihydroxybenzene systems yield a comparable value of -1.9 kJ mol^{-1} if the difference in $\Delta S°$ between the two systems is attributed solely to the loss of configurational entropy in 1,2-propanediol. Although the comparison is certainly not exact (the —$CHOHCH_2OH$ moiety of 1,2-propanediol is not simply a hydrocarbon chain), it is significant to acknowledge the quantitative similarity between the two results.

The wide variation in previously reported thermodynamic parameters for borate/aliphatic 1,2-diol reactions has obscured the fact that these reactions are all very similar thermodynamically. Now that variable-temperature ^{11}B and ^1H NMR spectroscopy has been shown to be an accurate and reliable method for the determination of these parameters, we will extend its use to more complex polyols and also to the thermodynamic study of bis borate complexes.[22]

19. We have used a method similar to the pH change method in previous studies.[3,16] In some cases where

bis complexes are formed it is possible to avoid the necessity of making approximations in the data analysis. In these particular studies the pH change technique was complemented by additional methods of stability constant determination.

PREPARATION AND THE UNIQUE ACIDIC PROPERTY OF A HEXAFLUORO-2,4-PENTANEDIONATOCOBALT(III) COMPLEX WITH ADDITIONAL ANIONIC LIGANDS

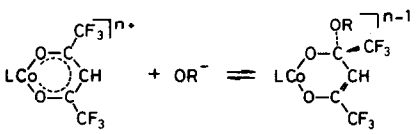
Y. KITAMURA† and A. SHIBATA

Department of Chemistry, Faculty of Science, Ehime University, Matsuyama 790, Japan

(*Received* 5 *April* 1993; *accepted* 30 *April* 1993)

Abstract—15 title complexes were newly prepared. Omitting the water of crystallization, these are: $[Co(hfac)L]ClO_4$, with L = *fac*(N)-(β-ala)(bpy), *fac*(N)-(L-ala)(bpy), *fac*(N)-(gly)(bpy), *mer*(N)-(gly)(en), *mer*-(NO_2)(dien), *mer*(N)-(pico)(en), *mer*(N)-(pico)(tn); [Co(hfac)L], with L = *cis*(O)-aeida, *trans*(O)-aeida, *cis*(O)-apida, β-eddp, C_2-*cis*(O)-$(gly)_2$, *cis*-$(ox)(NH_3)_2$, (ox)(en); and K[Co(hfac)(nta)], where the hfac acts as a bidentate and L is a mix of ligands occupying the residual four coordination sites. The abbreviations for the ligand are: Hhfac = hexafluoro-2,4-pentanedione, H(β-ala) = β-alanine, bpy = 2,2′-bipyridine, H(L-ala) = L-alanine, Hgly = glycine, en = ethylenediamine, dien = diethylenetriamine, Hpico = picolinic acid, tn = 1,3-propanediamine, H_2aeida = aminoethyliminodiacetic acid, H_2apida = aminopropyliminodiacetic acid, H_2eddp = ethylenediamine-N,N′-dipropionic acid, H_2ox = oxalic acid and H_3nta = nitrilotriacetic acid. The geometric structures of these complexes were assigned on the basis of UV–vis, proton NMR and fluorine NMR spectra. All these complexes show a pH-dependent rapid and reversible colour change in water and in methanol, which is ascribed to covalent bond formation and fission between a lyate anion and one of the carbonyl carbon atoms of the coordinating hfac ligand. The thermodynamic constants for this equilibrium in water, K_{OH}, and in methanol, K_{OMe}, were estimated spectrophotometrically. The pK_{OH} ranged from −7.4 to −4.8 and the pK_{OMe} from −8.4 to −4.2. Possible explanations are given for the following observations: K_{OH} and K_{OMe} are large when L involves a coordinating oxygen atom on the hfac plane in $[Co(hfac)L]^{n+}$, when L involves a pico or bpy ligand or when L is a tripod-type ligand. K_{OMe} is large when L is quadridentate. For a monopositive complex $K_{OH} < K_{OMe}$, whereas for a zero-valent complex $K_{OH} > K_{OMe}$.

In 1979 Kuroda found a pH-dependent rapid and reversible colour change of an aqueous solution of $[Co(hfac)(en)_2](ClO_4)_2$; orange in acid and violet in base.[1] He proposed a deprotonation of the methylidyne group of the coordinating hfac ligand as an origin for this phenomenon. Later, NMR spectra of this complex in D_2O were studied.[2] The methine proton signal shifted on addition of NaOD, but it returned to the original position without losing intensity on the subsequent reacidification by DCl. The ^{13}C signals in basic D_2O revealed that the two CF_3 and the two C—O groups are not equivalent. On these bases a reversible addition of an OH^- to one of the carbonyl carbon atoms of the coordinating hfac ligand was proposed [L = $(en)_2$, R = H and $n = 2$ in eq. (1)].[2]



(1)

Subsequently, an analogous colour change was also observed for several related complexes, $[Co(hfac)L]^{n+}$, with L = $(NH_3)_4$, trien, i-dtma and edda (trien = 1,8-diamino-3,6-diazaoctane, Hi-dtma = 4-diethylenetriaminemonoacetic acid, H_2edda = ethylenediamine-N,N′-diacetic acid).[3] The fluorine NMR spectra of these complexes in basic D_2O indicated that two or four dia-

† Author to whom correspondence should be addressed.

stereoisomers are formed, except for the case of the highly symmetrical L = $(NH_3)_4$. This was consistent with eq. (1) (R = H) and eliminated the alternative possibility of the formation of $[Co(hfac)(OH)L]^{n-1}$ or $[Co(hfacOH)L(H_2O)]^{n-1}$, in which hfac or hfacOH coordinates to cobalt(III) as a monodentate ligand.[3] A single crystal of $[Co(hfacOH)(cn)_2]Br \cdot H_2O$ was obtained on addition of NaOH to an aqueous solution of $[Co(hfac)(en)_2]Br_2$.[4] It was studied by X-ray diffraction and the structure of the complex ion as given on the right of eq. (1) [L = $(en)_2$, R = H, $n = 2$] was confirmed.[4] The proton NMR spectrum of $[Co(hfac OH)(en)_2]Br \cdot H_2O$ in CH_3OD indicated that substitution of OH^- by OCH_3^- occurs and $[Co(hfac OCH_3)(en)_2]^+$ is formed.[4] The X-ray crystallographic study of crystals of β-$[Co(hfacOCH_3)(trien)]ClO_4$ and $[Co(hfacOCH_3)(en)_2]ClO_4$ confirmed the structure of these complexes, as given on the right of eq. (1) [R = CH_3, L = $(en)_2$ or β-trien, $n = 2$].[5,6] The thermodynamic equilibrium constants of eq. (1), K_{OH} in water (R = H) or K_{OMe} in methanol (R = CH_3), were determined by titration or from the UV–vis absorption intensity of the complex in appropriate buffers.[3,5,7,8] It was pointed out that in the case of 25 $[Co(hfac)L]^{2+}$ with tetraamine L ligands their values critically depend on the involvement as L ligands of a bpy or a phen ligand (phen = 1,10-phenanthroline).[8] $pK_{OH} \fallingdotseq -6.6$ and $pK_{OMe} \fallingdotseq -8.7$ when L does not involve bpy or phen ligands. $pK_{OH} \fallingdotseq -8.7$ and $pK_{OMe} \fallingdotseq -11.0$ when L involves either a bpy or a phen ligand. $pK_{OH} \fallingdotseq -11.5$ and $pK_{OMe} \fallingdotseq -14.6$ when L involves two bpy or phen ligands.

In the present report we are further interested in the effect of anionic L ligands on the magnitudes of K_{OH} and K_{OMe}. We have recently prepared 15 new complexes and estimated their K_{OH} and K_{OMe} values by UV spectrophotometry. Their geometric structures are assigned on the bases of UV–vis, proton NMR and fluorine NMR spectra.

EXPERIMENTAL

A Unisoku RS-450 stopped-flow apparatus, JEOL-GSX-270-FT-NMR instrument and a Shimadzu UV-2200 UV–vis spectrophotometer were used. The experimental procedures were similar to those described in a previous report.[5] In the proton and fluorine NMR measurements 2-methyl-2-propanol ($\delta = 0$ ppm) and trifluoroacetic acid ($\delta = -76.5$ ppm) were used as internal standard, respectively.

CAUTION! Although we have experienced no difficulty with the perchlorate salts described here, these should be regarded as potentially explosive and handled accordingly.

Cis(O)-Na[Co(aeida)$(NO_2)_2$]·$2H_2O$ (1)

This substance was prepared by a slight modification of a published method.[9] During the air-oxidation of the solution containing $CoCl_2$ and H_2aeida the pH value was controlled at *ca* 7 by the occasional addition of acetic acid. This prevented the decomposition of the complex and improved the yield by a magnitude of 1.5.

Cis(O)-M^1[Co(aeida)$(NO_2)_2$]·nH_2O ($M^1 = NH_4^+$, K^+, Rb^+, Cs^+; $n = 0$ or 1). A hot aqueous solution of **1** (38 g) was mixed with a saturated aqueous solution of CH_3COOM^1 (0.2 mol). Brilliant orange–brown crystals separated on cooling the solution and washed with methanol; yield 90%. *Cis*(O)-K[Co(aeida)$(NO_2)_2$]·H_2O was identified. Found: C, 18.9; H, 3.2; N, 14.7. Calc.: C, 19.1; H, 3.2; N, 14.9%. UV–vis absorption maxima: λ_{max} (nm) (ε) = 470 (252), 334 (6290).

Trans(O)-[Co(aeida)$(H_2O)_2$]NO_3 (2)

A mixture of *cis*(O)-NH_4[Co(aeida)$(NO_2)_2$] (10 g), acetic acid (60 cm^3) and H_2O (20 cm^3) was contained in an evaporating dish covered with a watch glass and was warmed on a water bath until the solid dissolved and the evolution of the gas stopped. The resultant solution was treated with 2 M HNO_3 (20 cm^3) and evaporated on a water bath by air blow (M = mol dm^{-3}). The tarry product was diluted by water (100 cm^3) and evaporated again. These dilution and evaporation procedures were repeated three times, while acetic acid escaped in the vapour. The final tarry product was dissolved in water (50 cm^3) and treated by 2 M HNO_3 (10 cm^3). It was evaporated at 70°C until crystal separation and left at room temperature overnight. The resultant red–violet crystals (5 g) were collected and washed with methanol. Found: C, 21.8; H, 4.2; N, 12.2. Calc.: C, 21.8; H, 4.3; N, 12.7%. λ_{max} (nm) (ε) = 538 (185), 382 (178).

Na[Co(apida)$(NO_2)_2$] (3)

This yellow–brown crystal was prepared analogously to **1** using tn; yield 30%.

H[$CoCl_2$(eddp)] (4)

An aqueous suspension (40 cm^3) of H_2eddp·2HCl (2.7 g) and $CoCO_3$ (1.3 g) was stirred at 50°C. The resultant red–brown solution was treated with NaOH (0.8 g) and oxidized by the addition

of 30% H_2O_2 (20 cm^3). The deep red solution was treated with HCl (20 cm^3) and evaporated on a water bath. Red–brown crystals (2 g) were obtained and washed with ethanol and ether.

[Co(β-ala)(CO_3)(bpy)] (**5**)

This substance (1.5 g) was prepared analogously to **6** using β-alanine (0.9 g). The crystal was washed with ethanol and ether (1 : 1).

[Co(L-ala)(CO_3)(bpy)] (**6**)

An aqueous solution of K[Co(CO_3)$_2$(bpy)] (3.8 g) and L-alanine (0.9 g) was stirred at 40°C for 2 h and evaporated to near dryness.[8] The residue was extracted with methanol and insoluble salts were removed. These evaporation and extraction procedures were repeated three times. Crystals separated on the final evaporation of the methanolic solution and were washed with ethanol and ether; yield 1.5 g.

[Co(CO_3)(gly)(bpy)] (**7**)

Glycine (0.8 g) was added to an aqueous solution (20 cm^3) of K[Co(CO_3)$_2$(bpy)] (4 g).[8] This solution was stirred at 50°C for 1 h. Red–violet precipitates were obtained and washed with ethanol and ether.

[Co(CO_3)(NO_2)(dien)] (**8**)

An aqueous solution (20 cm^3) of *mer*-[$CoCl_3$(dien)] (2.7 g) and Li_2CO_3 (1 g) was stirred at 60°C for 1 h.[10] After filtration the filtrate was treated with $NaNO_2$ (1 g), stirred at 60°C for 30 min and evaporated in the air to 10 cm^3. Inorganic salts were removed. An orange–yellow precipitate (2 g) separated on treatment of this filtrate by ethanol (10 cm^3), which was collected and washed with ethanol and ether. This complex is soluble in water and slightly soluble in methanol.

[Co(CO_3)(pico)(tn)] (**9**)

An aqueous solution of K[Co(CO_3)$_2$(tn)] (2.9 g) was slowly treated with an aqueous solution of Hpico (1.2 g).[8] This mixture was stirred at 50°C for 30 min and evaporated by air blow to near dryness. The resultant solid was separated by filtration and dissolved in methanol. This was evaporated giving violet crystals which were washed with methanol and ether (1 : 1).

K[Co(CO_3)(gly)$_2$] (**10**)

Glycine (7.5 g) was neutralized by KOH. This solution was added to a tricarbonatocobaltate solution prepared from $CoCl_2 \cdot 6H_2O$ (12 g).[11] The mixture was stirred at 50°C for 2 h and cooled. Salts were removed and the filtrate was treated with an equal volume of ethanol. The resultant violet crystals were recrystallized from water by the addition of ethanol and washed with ethanol and ether; yield 5 g.

Fac(N)-[Co(β-ala)(hfac)(bpy)]ClO_4

This substance (1 g) was prepared analogously to **11** using **5** (1.2 g). Found: C, 35.3; H, 2.5; N, 6.7. Calc.: C, 35.5; H, 2.5; N, 6.9%.

Fac(N)-[Co(L-ala)(hfac)(bpy)]ClO_4 (**11**)

Compound **6** (1.2 g) in water was decarbonized by 2 M $HClO_4$ (3 cm^3) and treated with drops of Hhfac (0.7 g) and 2 M NaOH (1.6 cm^3). The mixture was stirred at 50°C for 1 h and cooled. The resultant precipitates were recrystallized from acetone and washed with ethanol and ether (2 : 8) and ether; yield 1 g. Found: C, 35.5; H, 2.5; N, 7.2. Calc.: C, 35.5; H, 2.5; N, 6.9%.

Fac(N)-[Co(gly)(hfac)(bpy)]ClO_4

Compound **7** (3.5 g) was decarbonized in 2 M $HClO_4$ (10 cm^3) and combined with Hhfac (2.1 g) and 1 M NaOH (10 cm^3). The mixture was then stirred at 50°C for 1 h. The resultant orange–red crystals were recrystallized from methanol and water (9 : 1); yield 2 g. Found: C, 34.2; H, 2.2; N, 7.3. Calc.: C, 34.3; H, 2.2; N, 7.1%.

Mer(N)-[Co(gly)(hfac)(en)](ClO_4)$\cdot 2H_2O$

Mer(N)-[Co(CO_3)(gly)(en)]$\cdot H_2O$ (2.7 g) was decarbonized with 2 M $HClO_4$ (10 cm^3).[12] The resultant solution was treated with Hhfac (2.1 g) and NaOH (0.4 g) and stirred at 50°C for 1 h. Deep orange crystals separated on the addition of $HClO_4$, which were recrystallized from methanol containing drops of $HClO_4$ and washed with ethanol and ether (2 : 8); yield 3.7 g. Found: C, 19.9; H, 3.0; N, 7.9. Calc.: C; 20.2; H, 3.2; N, 7.9%.

Mer-[Co(hfac)(NO_2)(dien)]ClO_4

Compound **8** (1.4 g) was decarbonized by 1 M $HClO_4$ (10 cm^3). The solution was treated at 45°C with an aqueous solution of Hhfac (1 g) and NaOH

(0.2 g). The resultant yellow–orange precipitates were collected by filtration and extracted with acetone (30 cm^3) containing drops of $HClO_4$. The final product (1.6 g) was obtained by evaporation of the extract and washed with ethanol and ether (2:8). Found: C; 20.8; H, 2.8; N, 10.7. Calc.: C, 21.0; H, 2.7; N, 10.9%.

Mer(N)-[Co(hfac)(pico)(en)]ClO_4

This substance was prepared analogously to **12** using $K[Co(CO_3)_2(en)]$.[8] Found: C; 28.3; H, 2.6; N, 7.7. Calc.: C, 28.5; H, 2.4; N, 7.7%.

Mer(N)-[Co(hfac)(pico)(tn)]ClO_4 (**12**)

Compound **9** (3.3 g) was decarbonized with 2 M $HClO_4$ (10 cm^3). The solution was treated with Hhfac (2.1 g) and NaOH (0.4 g) and stirred at 50°C until the colour changed from violet to red–violet. The solution was evaporated to near dryness and the residue was extracted with acetone. The extracts were treated with drops of $HClO_4$ and evaporated and the resultant precipitates were extracted by methanol and water (9:1) with drops of $HClO_4$. The extracts were evaporated. These extraction and evaporation procedures were repeated three times and the product was obtained. Found: C, 25.8; H, 2.6; N, 7.4. Calc.: C, 25.8; H, 2.7; N, 7.5%.

Trans(O)-[Co(aeida)(hfac)]·$0.5H_2O$

An aqueous solution (40 cm^3) of **2** (6.7 g) was treated with an aqueous solution (5 cm^3) of Hhfac (4.2 g) and NaOH (0.9 g) and was stirred at 40°C for 2 h. Crystals appeared in the solution, which was then treated with 2 M HNO_3 (1 cm^3), concentrated at 40°C to half volume and left overnight. The resultant crystals were collected and washed with ether. This mixture of *trans*(O) and *cis*(O) products was then extracted with ethanol (25 $cm^3 \times 5$). The extracts were treated with water (10 cm^3) containing a few drops of 2 M HNO_3 and were evaporated at 50°C to near dryness. The resultant precipitates were extracted with ethanol and the extracts treated with water (quarter volume of the extracts) containing a drop of 2 M HNO_3 and evaporated to near dryness. These extraction, dilution and evaporation procedures were repeated three times. The resultant brown–violet crystals (1.8 g) were collected, washed with ethanol:ether (1:9), then ether and finally air-dried. Found: C, 29.4; H, 2.5; N, 6.1. Calc.: C, 29.4; H, 2.7; N, 6.2%.

Cis(O)-[Co(aeida)(hfac)]·$0.5H_2O$

The ethanol extraction residues in the above procedure for the *trans*(O) isomer were collected and dissolved in hot methanol and water (1:1). This solution was filtered and the filtrate was treated with a few drops of 2 M HNO_3. The mixture was evaporated at 60°C until the solution colour turned from red to violet and was left at room temperature. The resultant deep red crystals were collected by filtration. The filtrate containing the *trans*(O) product can be utilized through evaporation and ethanol extraction. It was recrystallized twice from methanol, washed with ethanol, acetone and air-dried; yield 4.5 g. Found: C, 29.4; H, 2.5; N, 6.4. Calc.: C, 29.4; H, 2.7; N, 6.2%.

Cis(O)-[Co(apida)(hfac)]·$1.5H_2O$

Compound **3** (8 g) was dissolved in warm 80% acetic acid (70 cm^3). The violet solution obtained was treated with 2 M $HClO_4$ (20 cm^3) and evaporated. The oily product was treated with ethanol and the resultant precipitates were collected by filtration and washed with ethanol. This product (4.5 g), which we presumed to be crude $[Co(apida)(H_2O)_2]ClO_4$, was dissolved in water (10 cm^3) and treated with a mixture of Hhfac (2.1 g) and 1 M NaOH (10 cm^3) and stirred at 60°C for 1 h. The resultant red–violet crystals were recrystallized from methanol and water (9:1); yield 1.5 g. This substance is sparingly soluble in water. Found: C, 30.3; H, 3.4; N, 5.8. Calc.: C, 30.0; H, 3.4; N, 5.8%.

β-[Co(eddp)(hfac)]·$2H_2O$

An aqueous solution (10 cm^3) of **4** (1.7 g) was neutralized with 2 M NaOH (2.5 cm^3) to pH = 4–5. The solution was then combined with Hhfac (1.0 g) and 1 M NaOH (5 cm^3) and stirred at 50°C for 1 h. The resultant red oily product was extracted with acetone. After filtration, the extracts were evaporated and the resultant oily substance was dissolved in ethanol. Red–violet crystals separated on evaporation of this ethanolic solution, which were washed with ethanol:ether (1:9) and ether; yield 0.5 g. Found: C, 30.9; H, 3.6; N, 5.6. Calc.: C, 31.0; H, 3.8; N, 5.6%.

C_2-cis(O)-[Co(hfac)$(gly)_2$]·$0.5H_2O$

This red–orange substance (2 g) was prepared analogously to **13** using **10** (3.4 g). Found: C, 25.5; H, 2.3; N, 6.4. Calc.: C; 25.6; H; 2.4; N, 6.6%.

Cis-$[Co(hfac)(ox)(NH_3)_2]\cdot 0.5H_2O$

An aqueous solution (10 cm^3) of *cis–cis*-$[Co(ox)(NH_3)_2(H_2O)_2]NO_3$ (2.8 g) was treated at 50°C with Hhfac (2.1 g) and 2 M NaOH (5 cm^3).[13] The resultant violet crystals were recrystallized from methanol containing drops of $HClO_4$ and washed with ethanol : ether (2 : 8); yield 2 g. This substance is light sensitive and should be kept in a refrigerator in the dark. Found: C; 20.9; H, 1.8; N, 7.1. Calc.: C, 21.2; H, 1.8; N, 7.1%.

$[Co(hfac)(ox)(en)]\cdot 1.5H_2O$ (13)

$K[Co(CO_3)(ox)(en)]\cdot H_2O$ (3.2 g) was decarbonized at 40°C by 1 M H_2SO_4 (10 cm^3).[11] The solution was treated by an aqueous solution (10 cm^3) of Hhfac (2.1 g) and NaOH (0.5 g) and stirred at 45°C for 1 h. The mixture was then acidified using drops of 3 M H_2SO_4 and evaporated. The resultant red–violet crystals were recrystallized twice from methanol and washed with ethanol : ether (2 : 8) and ether; yield 1.5 g. Found: C, 24.4; H, 2.2; N, 6.5. Calc.: C, 24.5; H, 2.7; N, 6.4%.

$K[Co(hfac)(nta)]\cdot 2H_2O$

An aqueous suspension (10 cm^3) of K[Co(OH)(nta)(H_2O)] (3.2 g) was treated with a methanolic solution (10 cm^3) of Hhfac (2.1 g).[14] The mixture was stirred at 30°C for 10 h and evaporated slowly at 30°C to dryness. The residue was washed with ether and extracted with ethanol. The extracts were evaporated at 30°C to dryness and the residue was extracted with ethanol and left at room temperature. The resultant red–violet crystals (1 g) were washed with ethanol : ether (2 : 8) and ether. Found: C, 24.9; H, 1.9; N, 2.4. Calc.: C, 25.0; H, 2.1; N, 2.7%.

RESULTS AND DISCUSSION

Preparations

The general preparative course for $[Co(hfac)L]^{n+}$ is that Nahfac reacts with the corresponding diaqua complex, which is derived from the carbonato, dichloro or dinitro precursor. $[Co(hfac)(nta)]^-$ is prepared by the reaction between Hhfac and the corresponding hydroxoaqua precursor.

Proton NMR spectra

The isomerism of the cobalt(III)-aeida complex can be assigned by the glycinate ring proton resonance spectra (Table 1). One pair of doublets with 4H intensity corresponds to the *trans*-(O) isomer, where the two glycinate rings are equivalent. Two pairs of doublets, each of which is of 2H intensity, corresponds to the *cis*(O) isomer, where the two glycinate rings are inequivalent.

UV–vis spectra

All the $[Co(hfac)L]^{n+}$ complexes obtained in this work show a distinct, rapid and reversible colour change with variation of the pH in water and methanol. Typical spectra are shown in Fig. 1 and the absorption maxima are summarized in Table 2. In acidic medium the first band and the charge transfer band around 350 nm are observed. In basic medium the first band shifts by 30–60 nm to lower energy and the charge-transfer band disappears. This disappearance is consistent with eq. (1), where a localization of the π-electron system occurs on the right. When L coordinates through three nitrogen and one oxygen atoms [L = (β-ala)(bpy), (L-ala)(bpy), (gly)(bpy), (gly)(en), (pico)(en) and (pico)(tn)] the *mer*(N) or *fac*(N) coordination mode of L can

length. The examples are: among L = *fac*(N)-(β-ala)(bpy), *fac*(N)-(L-ala)(bpy) and *fac*(N)-(gly)(bpy); between L = *mer*(N)-(pico)(en) and *mer*(N)-(pico)(tn); between L = *cis*(O)-aeida and *cis*(O)-apida.

Fluorine NMR spectra

The fluorine NMR spectra in D_2O are summarized in Table 3. One can interpret these results by considering the symmetry aspect of $[Co(hfac)L]^{n+}$.[3,8] The two CF_3 groups are equivalent in $[Co(hfac)L]^{n+}$ with C_{2v}, C_2 or $C_s(\perp)$ symmetry. They are inequivalent in $[Co(hfac)L]^{n+}$ with other symmetry or in $[Co(hfacOH)L]^{n-1}$. When $[Co(hfac)L]^{n+}$ is of C_2, $C_s(\perp)$ or $C_s(\parallel)$ symmetry two diastereoisomeric $[Co(hfacOH)L]^{n-1}$ are possible. When $[Co(hfac)L]^{n+}$ is of C_1 symmetry four diastereoisomeric $[Co(hfacOH)L]^{n-1}$ are possible. Thus, the point group of $[Co(hfac)L]^{n+}$ and, therefore, the coordination mode of the L ligand are assigned from the observed spectra and are given in Table 3. Symmetry types of alternative isomers are: $C_s(\perp)$ with L = *sym–fac–cis*-(NO_2)(dien), C_1 with L = *unsym–fac–cis*-(NO_2)(dien), C_2 with L = α-eddp, $C_s(\parallel)$ with L = *trans*(O)-(apida), C_1 with L = C_1-*cis*(O)-$(gly)_2$ and C_{2v} with L = *trans*-$(ox)(NH_3)_2$ (Fig. 2). The spectra with L = β-eddp indicate that two isomers co-exist with a mole ratio of 12:88 in acidic D_2O 20 min after dissolution, where the meridional secondary NH proton is either adjacent to or remote from the coordinated hfac oxygen.[15] On the other hand, the spectra with L = *mer*-(NO_2)(dien) indicate that only one of the two possible isomers with respect to the disposition of the meridional secondary NH proton exists in the solution.

Equilibrium constant

Values of K_{OH} and K_{OMe} were estimated from the absorption intensity at 350 nm of the complex in appropriate buffers as described elsewhere.[8] A typical example is shown in Fig. 3. In water tris was used as a buffering agent. In methanol tris (pK_b = 6.53) was used with $[Co(hfac)L]^+$ and 5,5-diethyl-

barbituric acid ($pK_b = 4.26$) with [Co(hfac)L] or $[Co(hfac)(nta)]^-$. In certain cases where the lyate anion combined species was labile the absorption intensity was measured immediately after mixing the complex with the base using a stopped-flow apparatus. The results are summarized in Table 4. The following deductions can be inferred, where we denote the K_{OH} and K_{OMe} values of $[Co(hfac)L]^{n+}$ as $K_{OH}(L)$ and $K_{OMe}(L)$, respectively.

(1) K_{OH} and K_{OMe} are large when a coordinating oxygen atom of the L ligand exists on the hfac plane in $[Co(hfac)L]^{n+}$. Examples are: K_{OH}(*fac*(N)-i-dtma) < K_{OH}(*mer*(N)-i-dtma); K_{OH}(α-edda) < K_{OH}(β-edda); K_{OH}(*trans*(O)-aeida) < K_{OH}(*cis*(O)-aeida); K_{OH}(*trans*(O)-aeida) or K_{OH}(α-edda) < K_{OH}(C_2-*cis*(O)-$(gly)_2$). One possible explanation for this may be that the back-donation of the *d* electrons of the cobalt(III) centre to the carbonyl π*-orbital co-planar with the hfac plane makes the carbonyl carbon atoms of the hfac ligand electron-deficient. This electron deficiency could be the driving force for the bond formation between one of the carbonyl carbon atoms and the lyate anion.

(2) K_{OH} and K_{OMe} are large when L involves a coordinating pyridine ring. Examples are: K_{OH}(*fac*(N)-i-dtma) < K_{OH}(*fac*(N)-(gly)(bpy)), K_{OH}(*fac*(N)-(β-ala)(bpy)) or K_{OH}(*fac*(N)-(L-ala)(bpy)); K_{OH}(*mer*(N)-i-dtma) < K_{OH}(*mer*(N)-(pico)(en)) or K_{OH}(*mer*(N)-(pico)(tn)). This may be explained analogously to the above by back-donation to the pyridine ring π*-orbital, which is, however, not co-planar with the hfac plane. The effect of a bpy ligand on the magnitude of K_{OH} or K_{OMe} is not so remarkable, as with L = tetraamine (see the introduction).[8] It may be that K_{OH} or K_{OMe}(*fac*(N)-i-dtma) is comparatively large owing to the tripod structure of the i-dtma ligand, as described below.

(3) K_{OH} and K_{OMe} are large when L is a tripod-type ligand. Examples are: K_{OH}(β-edda) < K_{OH}(*cis*(O)-aeida); K_{OH}(α-edda) < K_{OH}(*trans*(O)-aeida); K_{OH}(α-trien) or K_{OH}(β-trien) < K_{OH}(tren), where tren = tris-(2-aminoethyl)amine.[8]

(4) K_{OMe} is large when L is quadridentate. Examples are: K_{OMe}((ox)(en)) < K_{OMe}(*cis*(O)-aeida) or K_{OMe}(β-edda); K_{OMe}(*mer*(N)-(gly)(en)) < K_{OMe}(*mer*(N)-i-dtma); K_{OMe}(*cis*-(ox)$(NH_3)_2$) < K_{OMe}(*cis*(O)-aeida) or K_{OMe}(β-edda).

(5) The relatively small values of K_{OH} and K_{OMe} with $[Co(hfac)(nta)]^-$ are explained by the electronic repulsion between the anionic complex and lyate anion. The tripod structure of the nta ligand and the oxygen atom of nta existing on the hfac plane may overcome this repulsion.

(6) For a mono-positive complex $K_{OH} < K_{OMe}$, whereas for a zero-valent complex $K_{OH} > K_{OMe}$. The only exception is β-[Co(hfac)(eddp)]. This tendency can be explained by the change, ΔG_{el}, in the electrostrictive solvation free energy of the complex in eq. (1), as already indicated in a previous report.[5] According to the Drude–Nernst aproximation ΔG_{el}

in methanol is smaller than that in water for a mono-positive complex, whereas the former is larger than the latter for a zero-valent complex.

(*Received* 5 *April* 1993; *accepted* 30 *April* 1993)

Abstract—Direct reaction of the metallated compound $Rh_2(\mu^2\text{-}O_2CCH_3)_3[\mu^2\text{-}(C_6H_4)PPh_2]\cdot(H_2O)_2$ with PPh_2Fc [$Fc = (C_5H_4)Fe(C_5H_5)$] in chloroform solution yields the corresponding mono-adduct $Rh_2(O_2CCH_3)_3[(C_6H_4)PPh_2]\cdot(PPh_2Fc)$ (**1**), which has been characterized by ^{31}P NMR spectroscopy. Photochemical irradiation of **1** in chloroform gives the compound $Rh_2(\mu\text{-}O_2CCH_3)_2(\eta^2\text{-}O_2CCH_3)[\mu^2\text{-}(C_6H_4)PPh_2][PPh_2Fc]\cdot(H_2O)$ (**2**) in practically quantitative yield. Compound **2**, by thermal treatment in chloroform solution, yields cleanly the doubly-metallated compound $Rh_2(\mu^2\text{-}O_2CCH_3)_2[\mu^2\text{-}(C_6H_4)PPhFc][\mu^2\text{-}(C_6H_4)PPh_2]\cdot(H_2O)_2$ (**3**). Complex **3** acts as a multiple electron-transfer system, showing by cyclic voltammetry in CH_2Cl_2 two well-defined one-electron oxidation processes: the first at 0.52 V, assigned to the redox couple Fe^{II}/Fe^{III}, and the second at 1.00 V, due to the redox couple Rh_2^{+4}/Rh_2^{+5}.

Orthometallation reactions of P-donor ligands in dirhodium(II) compounds have been extensively studied.[1] Reaction intermediates have been isolated and in some cases kinetic studies of single steps of the metallation process have been performed.[2] One intermediate step of the metallation reaction consists of the rearrangement of one phosphine from axial to equatorial coordination (step I → II in Scheme 1). This rearrangement can be selectively promoted by photochemical irradiation of the mono-adduct species **I**.[2]

We have recently studied the metallation of redox active phosphines such as PPh_2Fc ($Fc = \{(C_5H_4)Fe(C_5H_5)\}$) and $Fe\{(C_5H_4)PPh_2\}_2$ on $Rh_2(\mu^2\text{-}O_2CCH_3)_4$ as a new route to obtain complexes with two or more redox centres.[3] Crystal structures of the doubly-metallated complexes $Rh_2(\mu^2\text{-}O_2CCH_3)_2[\mu^2\text{-}(C_6H_4)PPhFc]_2(HO_2CCH_3)_2$ and $Rh_2(\mu^2\text{-}O_2CCH_3)_2\{[(C_6H_4)PPh(C_5H_4)]_2Fe\}(HO_2CCH_3)(CH_2Cl_2)$ have been determined by X-ray diffraction methods.[3]

The crystal structure of the acetic acid bis-adduct of complex **3**, $Rh_2(\mu^2\text{-}O_2CCH_3)_2[\mu^2\text{-}(C_6H_4)PPhFc][\mu^2\text{-}(C_6H_4)PPh_2]\cdot(HO_2CCH_3)_2$, has been recently reported.[4]

We describe in this paper the details of the synthesis of the mixed doubly-metallated complex $Rh_2(\mu^2\text{-}O_2CCH_3)_2[\mu^2\text{-}(C_6H_4)PPhFc][\mu^2\text{-}(C_6H_4)PPh_2]\cdot(H_2O)_2$ (**3**) from the intermediate product $Rh_2(\mu^2\text{-}O_2CCH_3)_2(\eta^2\text{-}O_2CCH_3)[\mu^2\text{-}(C_6H_4)PPh_2][PPh_2Fc]\cdot(H_2O)$ (**2**). The electrochemical behaviour of complex **3** as a new ferrocene-labelled dinuclear rhodium(II) complex is also discussed.

EXPERIMENTAL

All solvents were of analytical grade and were degassed prior to use by standard procedures. All the reactions were performed under argon using the Schlenk technique, although the isolated compounds were air-stable solids.

Preparation of the compounds

$Rh_2(\mu^2\text{-}O_2CCH_3)_4(MeOH)_2$,[5] $Rh_2(\mu^2\text{-}O_2CCH_3)_3[\mu^2\text{-}(C_6H_4)PPh_2](H_2O)_2$[1e] and $Rh_2(\mu^2\text{-}O_2CCH_3)_3[\mu^2\text{-}(C_6H_4)PPhFc]\cdot(HO_2CCH_3)_2$[3] were prepared according to literature methods.

L= H_2O, CH_3CO_2H

Scheme 1.

(a) $Rh_2(\mu^2\text{-}O_2CCH_3)_3[\mu^2\text{-}(C_6H_4)PPh_2]\cdot(PPh_2Fc)$ (**1**). This adduct was obtained in solution by adding the phosphine ligand PPh_2Fc to $Rh_2(\mu^2\text{-}O_2CCH_3)_3[\mu^2\text{-}(C_6H_4)PPh_2]\cdot(H_2O)_2$ ($[Rh_2]/[PPh_2Fc] = 1:1$) in $CHCl_3$. The ^{31}P NMR spectra were recorded from the resulting solution. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ P1 = 21.2 ppm, [^1J(Rh—P) = 156.1 Hz]; δ P2 = −8.5 ppm [^1J(Rh—P) = 109.4, ^2J(Rh—P) = 27.9, ^3J(P—P′) = 7.4 Hz).

(b) $Rh_2(\mu^2\text{-}O_2CCH_3)_2(\eta^2\text{-}O_2CCH_3)[\mu^2\text{-}(C_6H_4)PPh_2][PPh_2Fc]\cdot(H_2O)$ (**2**). $Rh_2(\mu^2\text{-}O_2CCH_3)_3[\mu^2\text{-}(C_6H_4)PPh_2]\cdot(H_2O)_2$ (100 mg, 0.13 mmol) and PPh_2Fc (48.1 mg, 0.13 mmol) were introduced in a photochemical reactor with a mercury vapour lamp (OSRAM-125). The solid mixture was dissolved in $CHCl_3$ (100 cm^3) yielding a brown–orange solution. After 45 min of irradiation the reaction was stopped and the solvent was removed under reduced pressure. The resulting crude solid was dissolved in a mixture of CH_2Cl_2: hexane (5 cm^3: 5 cm^3); slow evaporation of the solvent gave a brown crystalline product; yield 86%. Spectroscopic data: ^1H NMR ($CDCl_3$), δ (ppm): 1.05 (3H, s, Me), 1.21 (3H, s, Me), 1.41 (3H, s, Me) 3.6–4.9 (9H, m, C_5H_5; C_5H_4), 6.4–8.7 (24H, m, aromatics). $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ P1 = 17.32 ppm [^1J(Rh—P) = 138.14, ^2J(Rh—P) = 8.7 Hz], δ P2 = 38.42 ppm [^1J(Rh—P) = 172.34 Hz]. Found: C, 52.8; H, 4.5. Calc. for $C_{46}H_{44}FeO_7P_2Rh_2$: C, 53.5; H, 4.3%.

(c) $Rh_2(\mu^2\text{-}O_2CCH_3)_2[\mu^2\text{-}(C_6H_4)PPhFc][\mu^2\text{-}(C_6H_4)PPh_2]\cdot(H_2O)_2$ (**3**). Compound **2** (100 mg, 0.091 mmol) was dissolved in chloroform (40 cm^3) and the solution was refluxed for 1 h when the colour changed to red–brown. The solvent was evaporated to dryness under vacuum and the resulting red–solution solid was dissolved in CH_2Cl_2. This solution was transferred to a chromatography column (30 × 2 cm) packed with silica gel in hexane. Elution with hexane: CH_2Cl_2: acetone (10:5:1) separated a yellow band, which was discarded. Further elution with hexane: CH_2Cl_2: acetone (2:1:2) separated a brown–red band, which was collected. This solution was evaporated to dryness and the solid was dissolved in a CH_2Cl_2: hexane (1:1) (5 cm^3) mixture. Red–brown crystals were obtained by slow evaporation of the solvent; yield 85%. Spectroscopic data: ^1H NMR ($CDCl_3$) δ (ppm): 1.18 (3H, s, Me), 1.23 (3H, s, Me), 2.41 (4H, b, H_2O), 3.47 (1H, s, C_5H_4), 3.77 (5H, s, C_5H_5), 4.07 (1H, s, C_5H_4), 4.43 (1H, s, C_5H_4), 4.55 (1H, s, C_5H_4), 6.19–7.92 (24H, m, aromatics). $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ P1 = 17.24 ppm [^1J(Rh—P) = 167.5, ^2J(Rh—P) = 7.1 Hz], δ P2 = 14.92 ppm [^1J(Rh—P) = 160.5, ^2J(Rh—P) = 7.5 Hz]. Found: C, 53.5; H, 4.3. Calc. for $C_{44}H_{42}FeO_6P_2Rh_2$: C, 53.4; H, 4.3%.

Compound **3** can be recrystallized from a mixture of CH_2Cl_2: hexane: acetic acid (5:5:1) yielding quantitatively the acetic acid adduct $Rh_2(\mu^2\text{-}O_2CCH_3)_2[\mu^2\text{-}(C_6H_4)PPhFc][\mu^2\text{-}(C_6H_4)PPh_2](CH_3CO_2H)_2$.[4]

Instrumental

NMR measurements were recorded on Varian Unity-300 and Unity-400 spectrometers.

The electrochemical experiments were performed in a three-electrode cell; the working and auxiliary electrodes were platinum, the reference electrode was a saturated calomel electrode electrically connected to the solution by a "salt bridge" containing a saturated solution of the supporting electrolyte and the solvent. Cyclic voltammograms were obtained with a programming function generator 305 HQ instrument connected to a AMEL potentiostat and were recorded on a Riken–Denshi F-35 *X–Y* recorder. The solvent was CH_2Cl_2, which had been freshly distilled from P_2O_5. The supporting electrolyte, Bu_4NPF_6, was recrystallized from ethanol and dried at 80°C *in vacuo* for 48 h. Potential-controlled electrolysis was performed in a three-compartment cell separated by fritted glass. Working and auxiliary electrodes were a platinum mesh. The charge transferred was calculated by recording intensity vs the time and carrying out

a further integration. The system was calibrated against ferrocene.

RESULTS AND DISCUSSION

Rhodium(II) complexes containing a metallated arylphosphine react with additional amounts of phosphine yielding rhodium(II) doubly-metallated compounds. This thermal reaction generally yields a complex mixture of doubly-metallated compounds.[1d,3]

In the present case the first attempts to obtain the doubly-metallated compound $Rh_2(\mu^2\text{-}O_2CCH_3)_2[\mu^2\text{-}(C_6H_4)PPhFc][\mu^2\text{-}(C_6H_4)PPh_2](H_2O)_2$ (**3**) from the singly-metallated compounds $Rh_2(\mu^2\text{-}O_2CCH_3)_3[\mu^2\text{-}(C_6H_4)PPh_2](H_2O)_2$ or $Rh_2(\mu^2\text{-}O_2CCH_3)_3[\mu^2\text{-}(C_6H_4)PPhFc]\cdot(H_2O)_2$ with PPh_2Fc and PPh_3, respectively, by the thermal method, failed because a very complicated mixture of metallated compounds was obtained.

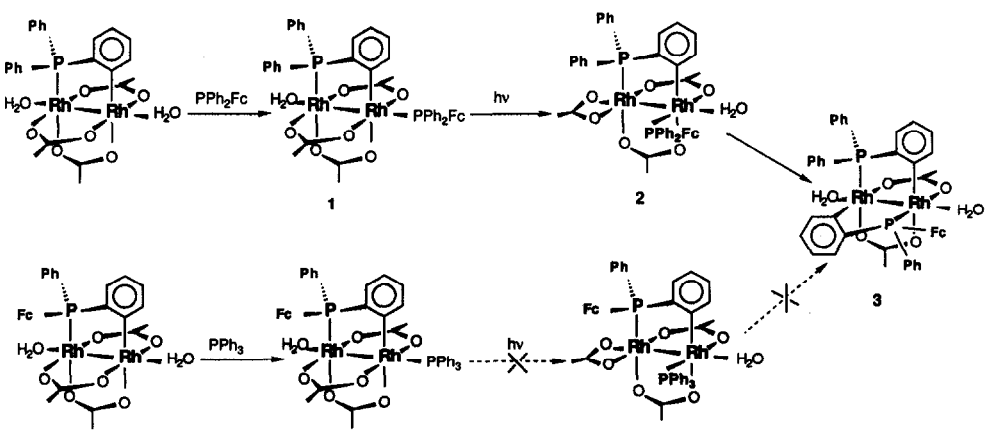
The photochemical irradiation of the phosphine mono-adduct $Rh_2(\mu^2\text{-}O_2CCH_3)_3[\mu^2\text{-}(C_6H_4)PPh_2](PPh_2Fc)$ (**1**) in chloroform promotes the rearrangement of the axial PPh_2Fc to an equatorial coordination yielding $Rh_2(\mu^2\text{-}O_2CCH_3)_2(\eta^2\text{-}O_2CCH_3)[\mu^2\text{-}(C_6H_4)PPh_2][PPh_2Fc](H_2O)$ (**2**). This reaction can be easily monitored by ^{31}P NMR spectroscopy, showing no other intermediates between the starting and the final compounds. The ^{31}P NMR spectrum of **2** shows a low-field resonance (38.42 ppm) characteristic of an equatorial phosphine[2,6] and another in the region of the metallated bridging phosphines (17.32 ppm). However, by irradiating the mono-metallated compound $Rh_2(\mu^2\text{-}O_2CCH_3)_3[\mu^2\text{-}(C_6H_4)PPhFc]\cdot(H_2O)_2$ with an equimolecular amount of PPh_3 in similar conditions a mixture of different metallated compounds is formed, together with small amounts of the intermediate compound containing the equatorial non-metallated phosphine, which, in this case, could not be isolated. The metallation of the intermediate compound $Rh_2(\mu^2\text{-}O_2CCH_3)_2(\eta^2\text{-}O_2CCH_3)[\mu^2\text{-}(C_6H_4)PPh_2][PPh_2Fc]\cdot(H_2O)$ (**2**) to give the doubly-metallated compound **3** occurs cleanly and selectively. This reaction can be easily followed by ^{31}P NMR spectroscopy. These results are summarized in Scheme 2.

Electrochemical results

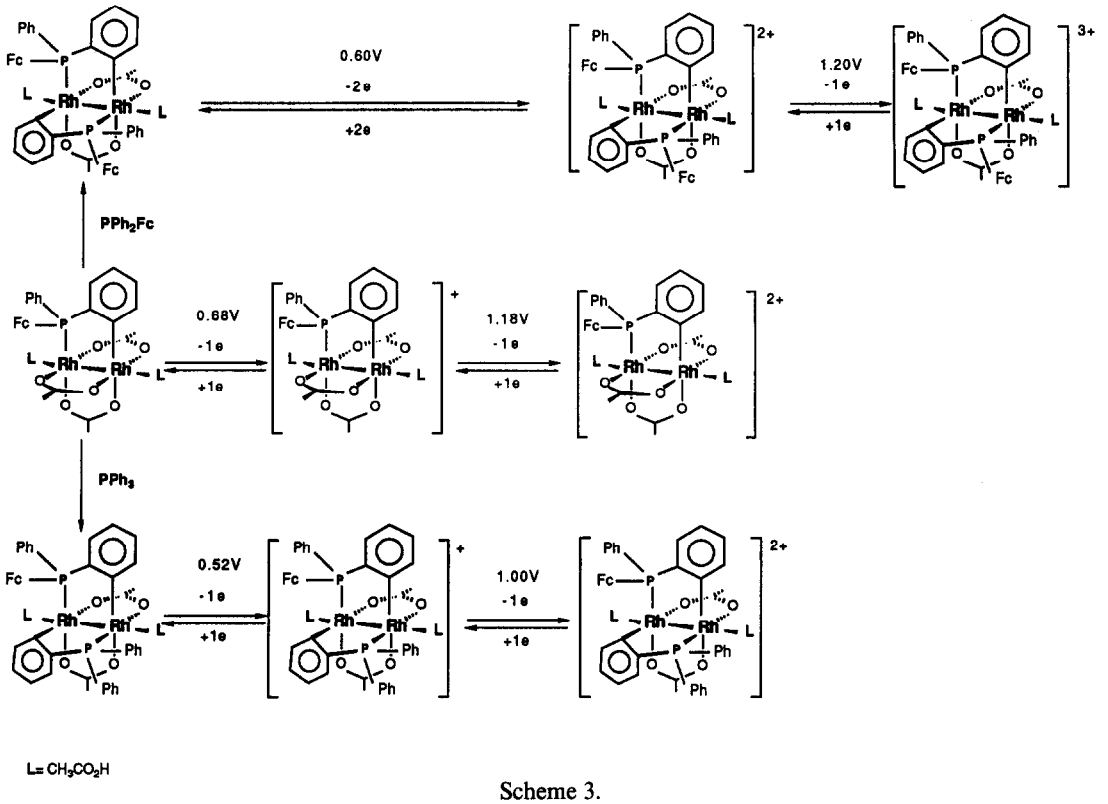
Compound **3** shows by cyclic voltammetry [in CH_2Cl_2 $(NBu_4)PF_6$, 0.2 M, as a supporting electrolyte] two well-defined one-electron reversible oxidation peaks at 0.58 and 1.04 V (Fig. 1). The first peak must be associated to the redox couple Fe^{II}/Fe^{III} of the ferrocenyl ligand, whereas the second oxidation process must be due to the Rh_2^{4+}/Rh_2^{5+} couple. Both processes are electrochemically reversible at the sweep rate of 0.1 V s^{-1}. The voltammogram of **3** as the acetic acid bis-adduct $Rh_2(\mu^2\text{-}O_2CCH_3)_2[\mu^2\text{-}(C_6H_4)PPhFc][\mu^2\text{-}(C_6H_4)PPh_2](CH_3CO_2H)_2$ shows no important differences (E_p $[Fe^{II}/Fe^{III}] = 0.52$ V; E_p $[Rh_2^{4+}/Rh_2^{5+}] = 1.00$ V).

For compound **3** the oxidation value for the couple Rh_2^{4+}/Rh_2^{5+} is intermediate between those of the doubly-metallated complexes $Rh_2(\mu^2\text{-}O_2CCH_3)_2[\mu^2\text{-}(C_6H_4)PPhFc]_2\cdot(CH_3CO_2H)_2$ and $Rh_2(\mu^2\text{-}O_2CCH_3)_2[\mu^2\text{-}(C_6H_4)PPh_2]\cdot(CH_3CO_2H)_2$ previously reported.[3] The oxidation value for the couple Rh_2^{4+}/Rh_2^{5+} is lower in **3** than in the related ferrocene-labelled monometallated compound $Rh_2(\mu^2\text{-}O_2CCH_3)_3[\mu^2\text{-}(C_6H_4)PPhFc]\cdot(CH_3CO_2H)_2$, in good agreement with the trend that doubly-metallated compounds oxidize more easily than mono-metallated compounds.[3]

These differences show the influence that the more easily oxidizable couple produces on the



Scheme 2.



Scheme 3.

potential value of the second redox centre and with complex **3** a series of complexes which undergoes multiple electron-transfer processes is completed, as is summarized in Scheme 3.

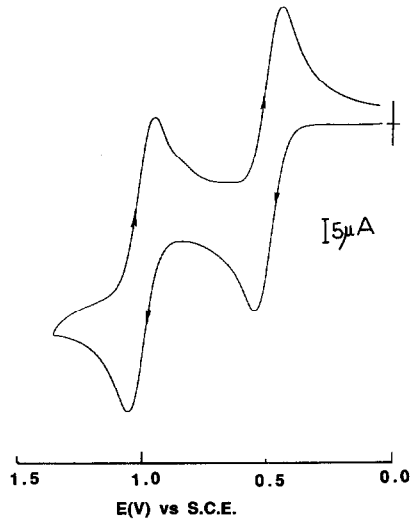


Fig. 1. Cyclic voltammogram of **3**, in CH_2Cl_2 (NBu_4PF_6 supporting electrolyte, sweep rate 0.1 V s^{-1}).

(*Received* 6 *April* 1993; *accepted* 22 *April* 1993)

Abstract—Reaction of decaborane(14) with compounds of the type $(\eta^5\text{-}C_5H_5)_2ZrX_2$ and $(\eta^5\text{-}C_5H_5)_2ZrXY$, where X and Y are H^-, CH_3^- or BH_4^-, leads to a range of compounds, which include $[(\eta^5\text{-}C_5H_5)_2Zr(\mu\text{-}H)]B_{10}H_{13}$, $(\eta^5\text{-}C_5H_5)_2ZrB_{10}H_{10}$, $[(\eta^5\text{-}C_5H_5)_2Zr(\mu\text{-}H)]_2B_{10}H_{10}$ and probably $[(\eta^5\text{-}C_5H_5)_2Zr(BH_4)]B_{10}H_{13}$. All of these compounds exhibit three-centre/two-electron Zr—H—B interactions between $(\eta^5\text{-}C_5H_5)_2Zr^{2+}$ and the terminal hydrogen atoms on their (formal) anionic borane moieties. The formation of $B_{10}H_{10}^{2-}$ in the reactions when X and Y are both CH_3^- was found to be attributable to a previously unknown disproportionation/rearrangement reaction of $B_{10}H_{12}^{2-}$, which occurs above *ca* 60°C, i.e. $2B_{10}H_{12}^{2-} \rightarrow B_{10}H_{10}^{2-} + B_{10}H_{14}^{2-}$. When X and/or Y is BH_4^-, then at higher temperatures borane cluster anion enlargement occurs to give a mixture of species which contain the borane anions $B_{12}H_{12}^{2-}$, $B_{11}H_{11}^{2-}$ and $B_{10}H_{10}^{2-}$, again exhibiting Zr—H—B interactions from $(\eta^5\text{-}C_5H_5)_2Zr^{2+}$ to these anions through their terminal hydrogen atoms. It is suggested that these products arise through the agency of a metal-mediated disproportionation reaction(s), probably with the involvement of Zr—H—B interactions. The extent of Zr—B interaction in the Zr—H—B linkages was investigated using extended-Hückel LCAO–MO calculations in the case of $(\eta^5\text{-}C_5H_5)_2ZrB_{10}H_{10}$ and indicate a significant contribution from Zr—B overlap in the bonding. Finally, the ability of an $(\eta^5\text{-}C_5H_5)_2Zr$ fragment to act as a cluster vertex in a metallaborane is discussed in light of the types of metal to borane anion interactions observed for the species synthesized in this study.

An examination of the literature shows that, with the exception of tetrahydroborates, very few metallaboranes of the early transition metals have been reported.[1–4] Known examples include $(\eta^5\text{-}C_5H_5)_2TiB_3H_8$ and $(\eta^5\text{-}C_5Me_5)_2Ta_2(\mu\text{-}Br)_2(B_2H_6)$.[5,6] In the former the (formal) $B_3H_8^-$ ion is regarded as being linked to titanium by two Ti—H—B three-centre/two-electron bonds, while in the latter the bridging diborane unit is asymmetrically bound, with three Ta—H—B bridges, one direct Ta—B bond and a single B—H—B bridge. By way of comparison several metallacarbaborane species have been synthesized. These include compounds of the type $(\eta^8\text{-}C_8H_8)_2M(Et_2C_2B_4H_4)$, where M = Ti and V, which are cyclooctatetraene metal-carbaborane sandwich compounds,[7] and the species $(Et_4N)_2[M(C_2B_{10}H_{12})_2]$, M = Zr or Hf, and their related dimethyl analogues[8,9] (M also includes Ti[10]), which involve two metal-linked 13-vertex metallacarbaboranes. However, no large early transition metal species derived from decaborane(14), $B_{10}H_{14}$, are currently known.

The acidic nature of the bridging protons in $B_{10}H_{14}$ is well established. Indeed, $B_{10}H_{14}$ acts as a strong monoprotic acid in aqueous ethanol[11] (and in other organic solvents, e.g. CH_3CN). Of synthetic relevance to this study is the fact that $B_{10}H_{14}$ reacts with 1 equivalent of NaH in ether to give $B_{10}H_{13}^-$ and H_2.[12] With 2 equivalents of NaH a second mole

* Author to whom correspondence should be addressed.

of H_2 is evolved and $B_{10}H_{12}^{2-}$ is reported to form.[13] Similar reactions occur with $LiBH_4$ and $NaBH_4$ to give $B_{10}H_{13}^-$, H_2 and B_2H_6.[12,14] However, at higher temperatures (80–90°C in dioxane) cluster enlargement occurs with the formation of $B_{11}H_{14}^-$ and H_2,[14] while at even higher temperatures (160°C in diglyme) $B_{12}H_{12}^{2-}$ and H_2 are produced.[15] All of these reactions rely wholly or, in part, on the combination of protic and hydridic hydrogens to eliminate H_2. This approach should, in turn, be applicable to transition metal systems containing (hydridic) hydrogen and their reactions with decaborane. Condensation of the transition metal and borane fragments should, after elimination of H_2, lead to metallaboranes.

A related approach is to combine a borane with a metal alkyl or aryl (R), followed by elimination of RH and metallaborane formation as above. Such an approach has, however, been used infrequently. Some examples do exist; for example, $B_{10}H_{14}$ reacts with the dialkyls and diaryls of zinc and cadmium (where R = Me, Et, Ph) in ethereal solvents to yield RH and solvates of the formula $MB_{10}H_{12}\cdot nS$, where M = Zn, Cd and S = Et_2O, THF.[16,17] A more recent example involves the reaction of $B_{10}H_{14}$ and $(Et_3P)AuMe$ [and also $(Ph_3P)AuMe$] to give methane, H_2 and, ultimately, the triple gold and boron cluster $[(H_{12}B_{10}Au)(\mu\text{-}AuPEt_3)_4(AuB_{10}H_{12})]$.[18]

For the early transition metals a range of accessible hydride, methyl and tetrahydroborate ligand species is provided by the $(\eta^5\text{-}C_5H_5)_2MX_n$ compounds, where X is H^-, CH_3^- or BH_4^- and n may be 1, 2 or 3 depending on the metal and its formal oxidation state (III → V). Not all compounds are known, but many mixed-ligand species can also be synthesized, e.g. $(\eta^5\text{-}C_5H_5)_2Zr(H)CH_3$. Reaction of these organo-transition metal hydride-, methyl- and tetrahydroborate-containing species with $B_{10}H_{14}$ should, therefore, give rise to new metallaboranes of the early transition metals. Varing the transition metal, for the same oxidation state, will allow exploration of the effect of electron configuration (in conjunction with frontier orbital considerations) on metallaborane formation, although the reducing nature of the boranes may make some oxidation states unattainable. Moreover, in the case of (formally at least) H^- as a ligand the $(\eta^5\text{-}C_5H_5)_2MH_n$ compounds of groups IV and V exhibit hydridic character, whereas organo-transition metal hydrides of the latter transition metals are generally neutral or acidic in nature.[19] At the outset of these studies it was expected that these features would play some role in metallaborane formation and in this study only the results of our investigations into the zirconium system are reported.

EXPERIMENTAL

All operations and manipulations were performed under nitrogen or in a vacuum so as to exclude oxygen and water, using Schlenk apparatus or an inert atmosphere glove-box. All reagents were used as received, while $B_{10}H_{14}$ (Strem Chemical Co.) was sublimed under vacuum before use. Solvents were dried using standard methods and distilled either under nitrogen or in a vacuum immediately prior to use, and were transferred using gastight syringes or under a vacuum.

The compounds $(\eta^5\text{-}C_5H_5)_2ZrH_2$, $(\eta^5\text{-}C_5H_5)_2Zr(CH_3)_2$, $(\eta^5\text{-}C_5H_5)_2Zr(BH_4)_2$ and $(\eta^5\text{-}C_5H_5)_2Zr(H)BH_4$ were prepared as described in the literature,[20–22] while $(\eta^5\text{-}C_5H_5)_2Zr(H)CH_3$ was prepared from $(\eta^5\text{-}C_5H_5)_2Zr(Cl)CH_3$, which was prepared in turn from $[(\eta^5\text{-}C_5H_5)_2ZrCl]_2O$.[23,24] The compound $(\eta^5\text{-}C_5H_5)_2Zr(BH_4)CH_3$, previously characterized in solution by ^1H and ^{11}B NMR,[25] was obtained by reaction of $(\eta^5\text{-}C_5H_5)_2Zr(Cl)CH_3$ with $LiBH_4$ (in a 1 : 2 mole ratio, respectively) in toluene for 4 h, followed by filtration and removal of the solvent. Examination by ^1H NMR indicated no evidence of any starting material, while IR examination (Nujol mull) gave ν(B—H) at 2436, 2395 and 2102 cm^{-1} and $\delta(BH_2)$ at 1124 cm^{-1}.

IR spectra were recorded on a Bio-Rad FTS-7 spectrophotometer as either Nujol mulls between NaCl plates or as (dried) KBr discs. Gas-phase spectra were recorded using a 10 cm gas cell fitted with NaCl windows. All NMR spectra were recorded on a JEOL FX-90Q instrument operating at 28.75 and 89.60 MHz for ^{11}B and ^1H, respectively, and were referenced to $BF_3\cdot Et_2O$ and TMS. Acetonitrile (AR grade) for conductivity work was refluxed over CaH_2 for 3 days, then doubly distilled in an all-glass still under nitrogen. This resulted in CH_3CN of specific conductivity better than 8×10^{-8} S cm^{-1} at 25°C. Conductivities were measured using a Philips PR 9500/01 conductivity-measuring bridge with a PW 9512 cell. Microanalyses were performed by the Analytical Unit, Research School of Chemistry, at the Australian National University.

Reactions and preparations

$(\eta^5\text{-}C_5H_5)_2ZrH_2$ and $B_{10}H_{14}$; preparation of $[(\eta^5\text{-}C_5H_5)_2Zr(\mu\text{-}H)]B_{10}H_{13}$. In a typical reaction a solution of $B_{10}H_{14}$ (0.144 g, 1.18 mmol, 5% excess) in benzene (20 cm^3) was added to a well-stirred slurry containing $(\eta^5\text{-}C_5H_5)_2ZrH_2$ (0.25 g, 1.12 mmol) in benzene (30 cm^3) under nitrogen. A gas (presumably hydrogen) formed immediately and the slurry changed from white to yellow. The mix-

ture was stirred for a further 3 h, but to ensure completion of the reaction heating to 40–50°C for a period of *ca* 30 min was found to be necessary. The resulting solid was collected by filtration, washed with benzene and dried *in vacuo* (typical yield >90%). Found: C, 36.4; H, 7.5. Calc. for $[(\eta^5\text{-}C_5H_5)_2ZrH]B_{10}H_{13}$: C, 34.9; H, 7.0%. In a separate reaction, using similar quantities of reactants, $B_{10}H_{14}$ was added to $(\eta^5\text{-}C_5H_5)_2ZrH_2$ in benzene in an evacuated glass reaction vessel. After completion of the reaction the gas generated was transferred to a calibrated volume using a Toepler pump, giving 0.98 mol of hydrogen formed per mole of $(\eta^5\text{-}C_5H_5)_2ZrH_2$ consumed.

$(\eta^5\text{-}C_5H_5)_2Zr(CH_3)_2$ and $B_{10}H_{14}$; preparation of $(\eta^5\text{-}C_5H_5)_2ZrB_{10}H_{10}$ and $[(\eta^5\text{-}C_5H_5)_2Zr(\mu\text{-}H)]_2B_{10}H_{10}$.

(a) $(\eta^5\text{-}C_5H_5)_2Zr(CH_3)_2$ to $B_{10}H_{14}$, mole ratio 1:1 and 1:2. To a stirred solution of $B_{10}H_{14}$ (0.241 g, 1.97 mmol) in toluene (20 cm^3) was added a toluene solution (20 cm^3) of $(\eta^5\text{-}C_5H_5)_2Zr(CH_3)_2$ (0.500 g, 1.97 mmol). No reaction was observed and the solution temperature was raised slowly to *ca* 105°C, at which point the solution turned yellow, quickly followed by the formation of a bright yellow precipitate. Evidence of gas evolution was also noted. Using a gas-tight syringe a gas sample was taken from the reaction vessel at this point for IR examination, which indicated the presence of CH_4. After refluxing (*ca* 110°C) for 30 min the products were allowed to cool and the yellow product filtered, washed with toluene and dried *in vacuo* (yield 0.366 g, 78%). An identical product was also obtained with a mole ratio for $(\eta^5\text{-}C_5H_5)_2Zr(CH_3)_2$ to $B_{10}H_{14}$ of 1:2. Found: C, 36.1; H, 6.3. Calc. for $(\eta^5\text{-}C_5H_5)_2ZrB_{10}H_{10}$: C, 35.4; H, 5.9%. In two independent reactions measurement of the volume of non-condensable gas (CH_4+H_2) generated in this reaction indicated that 2.43 and 2.56 mol per mole of $(\eta^5\text{-}C_5H_5)_2Zr(CH_3)_2$ were formed.

(b) $(\eta^5\text{-}C_5H_5)_2Zr(CH_3)_2$ to $B_{10}H_{14}$, ratio 2:1. A solution of $(\eta^5\text{-}C_5H_5)_2Zr(CH_3)_2$ (0.570 g, 2.27 mmol) and $B_{10}H_{14}$ (0.140 g, 1.15 mmol) in toluene (45 cm^3) was heated to *ca* 105°C, at which point the solution turned yellow, gas evolution was observed and an orange solid formed. A sample taken for IR analysis indicated the presence of CH_4 but not, definitely, evidence of C_2H_6. After refluxing for *ca* 1 h the bright orange solid product was filtered, washed with toluene and dried in a vacuum (yield 0.375 g, 59%). Found: C, 42.5; H, 5.7. Calc. for $[(\eta^5\text{-}C_5H_5)_2ZrH]_2B_{10}H_{10}$: C, 42.7; H, 5.7%.

$(\eta^5\text{-}C_5H_5)_2Zr(BH_4)_2$ and $B_{10}H_{14}$. In a typical reaction a solution of $B_{10}H_{14}$ (0.122 g, 1.00 mmol) in benzene (20 cm^3) was added to a solution of $(\eta^5\text{-}C_5H_5)_2Zr(BH_4)_2$ (0.251 g, 1.00 mmol) in benzene (30 cm^3). No reaction was observed. The solution was then heated to *ca* 80°C, at which the first signs of reaction occurred. The mixture was subsequently refluxed for 3 h, yielding an orange precipitate. After cooling the product was filtered, washed with benzene (30 cm^3) and dried in a vacuum (yield 0.299 g). The reaction was repeated several times using different stoichiometries [both 1:1 and 1:2 $(\eta^5\text{-}C_5H_5)_2Zr(BH_4)_2$ to $B_{10}H_{14}$], variable reaction times (1–5 h) and also at a different temperature using refluxing toluene as the solvent. A reaction was also conducted in a closed, evacuated system, which demonstrated the formation of large quantities of a permanent gas (presumably hydrogen) and also the formation of B_2H_6 (by IR spectroscopy).

$(\eta^5\text{-}C_5H_5)_2Zr(H)CH_3$ and $B_{10}H_{14}$. A solution of $B_{10}H_{14}$ (0.149 g, 1.22 mmol) in benzene (25 cm^3) was added to a slurry of $(\eta^5\text{-}C_5H_5)_2Zr(H)CH_3$ (0.276 g, 1.16 mmol) in benzene (20 cm^3) in an evacuated glass vessel. No reaction was observed initially, but the solid turned yellow within 15 min with evidence for the formation of a yellow solution. After 24 h the mixture was heated to 50°C for 1 h to ensure complete reaction. IR examination of the gas generated in the reaction indicated the presence of CH_4. The yellow solution was decanted and the insoluble yellow product washed with benzene and dried in a vacuum (yield 0.269 g, 66%). IR and ^{11}B NMR examination established that the insoluble product was $[(\eta^5\text{-}C_5H_5)_2ZrH]B_{10}H_{13}$.

$(\eta^5\text{-}C_5H_5)_2Zr(H)BH_4$ and $B_{10}H_{14}$.

(a) Reaction at room temperature. A solution of $B_{10}H_{14}$ (0.155 g, 1.27 mmol) in benzene (20 cm^3) was added to $(\eta^5\text{-}C_5H_5)_2Zr(H)BH_4$ (0.301 g, 1.27 mmol) in benzene (30 cm^3). No reaction was observed initially, but the solution slowly turned yellow with time and a pale yellow precipitate also formed. At various stages the atmosphere above the solution was sampled and subject to IR examination, which indicated the generation of B_2H_6. After 4 days the solid was collected by filtration, washed with benzene (30 cm^3) and dried *in vacuo* (yield 0.233 g).

(b) Reaction at *ca* 80°C. A solution containing $(\eta^5\text{-}C_5H_5)_2Zr(H)BH_4$ (0.255 g, 1.07 mmol) and $B_{10}H_{14}$ (0.131 g, 1.07 mmol) in benzene (50 cm^3) was refluxed (*ca* 80°C) for 4 h, resulting in the formation of an orange solid. This material was isolated by filtration, washed with benzene (25 cm^3) and dried *in vacuo* (yield 0.310 g).

$(\eta^5\text{-}C_5H_5)_2Zr(BH_4)CH_3$ and $B_{10}H_{14}$. A solution of $(\eta^5\text{-}C_5H_5)_2Zr(BH_4)CH_3$ (0.203 g, 0.808 mmol) in toluene (30 cm^3) was added to one containing $B_{10}H_{14}$ (0.100 g, 0.818 mmol) in toluene (20 cm^3). No reaction was observed at room temperature. On heating reaction occurred at *ca* 90°C with evidence

of gas generation and the formation of a yellow orange solid. The reaction vessel and contents were subsequently refluxed for 2 h. On cooling the yellow–orange insoluble product was isolated, washed with toluene and dried in a vacuum (yield 0.193 g). IR and ^{11}B NMR spectroscopy indicated that the major component of this solid was $(\eta^5\text{-}C_5H_5)_2ZrB_{10}H_{10}$.

Extended-Hückel molecular orbital calculations

Molecular orbital calculations were made using the extended-Hückel approach, as described by Hoffmann.[26,27] The basis set used for zirconium consisted of single Slater orbitals for both the 5*s* and 5*p* functions, while the 4*d* function was taken as a linear combination of two Slater type functions. The Slater exponents (ζ) and valence-state ionization potentials (H_{ii}) for zirconium, as well as those of H, C and B, were as reported in the literature.[27,28] Off-diagonal elements of the Hamiltonian, H_{ij}, were calculated using a modified Wolfsberg–Helmholtz formula with K equal to 1.75.[29] Calculations were made on an isolated $(\eta^5\text{-}C_5H_5)_2Zr^{2+}$ group and on $(\eta^5\text{-}C_5H_5)_2ZrB_{10}H_{10}$ (see below).

RESULTS AND DISCUSSION

Reactions of $B_{10}H_{14}$ *with* $(\eta^5\text{-}C_5H_5)_2ZrX_2$ *and* $(\eta^5\text{-}C_5H_5)_2ZrXY$, *where* X, Y = H^-, CH_3^-, BH_4^-

In many ways the zirconium system represents an ideal case. Every compound (six in all) arising from all possible combinations of the ligands H^-, CH_3^- and BH_4^- has been synthesized for $(\eta^5\text{-}C_5H_5)_2ZrX_2$ and $(\eta^5\text{-}C_5H_5)_2ZrXY$ species. Moreover, reduction of zirconium from oxidation state IV to III is relatively difficult compared with titanium and most other group V and VI elements, while hafnium does not show the range of compounds exhibited by zirconium. This also pertains to the group V and VI $(\eta^5\text{-}C_5H_5)_2MX_n$ species.

The reactions of the six $(\eta^5\text{-}C_5H_5)_2ZrX_2$ and $(\eta^5\text{-}C_5H_5)_2ZrXY$ compounds produce a diverse array of products depending on the temperature of reaction and the ratio of reactants. In general, H^- was found to react at room temperature or just above, BH_4^- at 80–90°C and CH_3^- at 100–110°C, although some variation was observed with the mixed-ligand species. For each reaction product the boron-containing fragment(s) could be related to one of the known decaborane anions (e.g. $B_{10}H_{10}^{2-}$, $B_{10}H_{13}^-$) or, in the case of BH_4^- as a ligand, to borane cluster enlargement under the appropriate high-temperature reaction conditions. The reactions and their products can be conveniently arranged in three groups, which depend on the temperature at which reaction occurred, the borane anion to which the resulting boron-containing fragment of the product species is related and whether or not borane cluster enlargement occurred.

$(\eta^5\text{-}C_5H_5)_2ZrH_2$, $(\eta^5\text{-}C_5H_5)_2Zr(H)CH_3$ *and* $(\eta^5\text{-}C_5H_5)_2Zr(H)BH_4$: *reactions at* ca *room temperature; products related to the* $B_{10}H_{13}^-$ *ion*

The reaction between $(\eta^5\text{-}C_5H_5)_2ZrH_2$ and $B_{10}H_{14}$ occurs at room temperature in a 1 : 1 mole ratio to produce 1 mol of H_2 (hence implying $B_{10}H_{13}^-$ formation) and a compound of composition $[(\eta^5\text{-}C_5H_5)_2ZrH]B_{10}H_{13}$. The product does not have the "ionic" formulation suggested by this representation but is, rather, polymeric with Zr—H—Zr and Zr—H—B linkages. It is insoluble in non-polar solvents like benzene and toluene and is only slightly soluble in more polar solvents such as CH_3CN and DMF, which attests to its polymeric nature.

The IR spectrum of $[(\eta^5\text{-}C_5H_5)_2ZrH]B_{10}H_{13}$ in the range 2600–1900 cm^{-1} is shown in Fig. 1(a) and indicates a B—H_{ter} stretch (*ca* 2515 cm^{-1}) showing some structure, along with two bands at 2172 and 2135 cm^{-1}, which may be assigned as Zr—H—B stretches based on assignments for $(\eta^5\text{-}C_5H_5)_2Zr(BH_4)_2$, $(\eta^5\text{-}C_5H_5)_2Zr(H)BH_4$ and $(\eta^5\text{-}C_5H_4Me)_2Hf(BH_4)_2$ (see also the next section below).[22,30,31] Another weaker band occurred at *ca* 2298 cm^{-1} and this is also likely to be a Zr—H—B stretch. No evidence of a terminal Zr—H stretch was observed, as found in $[(\eta^5\text{-}C_5H_5)_2ZrH_2]_n$ (1520 cm^{-1}), $[(\eta^5\text{-}C_5H_4Me)_2Zr(\mu\text{-}H)H]_2$, (1565 cm^{-1}) and in monomeric $(\eta^5\text{-}C_5Me_5)_2ZrH_2$ (1555 cm^{-1}).[20,32,33] However, a strong band was observed at 1314 cm^{-1}, which can be assigned as a Zr—H—Zr stretch, based on assignments for this feature in the spectra of $[(\eta^5\text{-}C_5H_5)_2ZrH_2]_n$ (1300 cm^{-1}) and in $[(\eta^5\text{-}C_5H_4Me)_2Zr(\mu\text{-}H)H]_2$ (1330 cm^{-1}), the latter also subject to a structural study.[32] Two possible structures for this compound can be envisaged. The first is based on the hydrogen-bridged $Zr(\mu\text{-}H)_2Zr$ unit found in $[(\eta^5\text{-}C_5H_4Me)_2Zr(\mu\text{-}H)H]_2$ and is shown in **A** below. In this case the two terminal hydrogens bound to zirconium in the dimeric unit of $[(\eta^5\text{-}C_5H_4Me)_2Zr(\mu\text{-}H)H]_2$ have been replaced by two $B_{10}H_{13}^-$ groups, with zirconium bound to what would be in an isolated $B_{10}H_{13}^-$ ion terminal hydrogen atoms on boron. The second structure **B** also has $B_{10}H_{13}^-$ groups attached to zirconium, but is built around a non-linear $\cdots Cp_2Zr\text{—}H\text{—}Cp_2Zr\text{—}H\cdots$ backbone. However, this is considered less likely based on the known presence of the $Zr(\mu\text{-}$

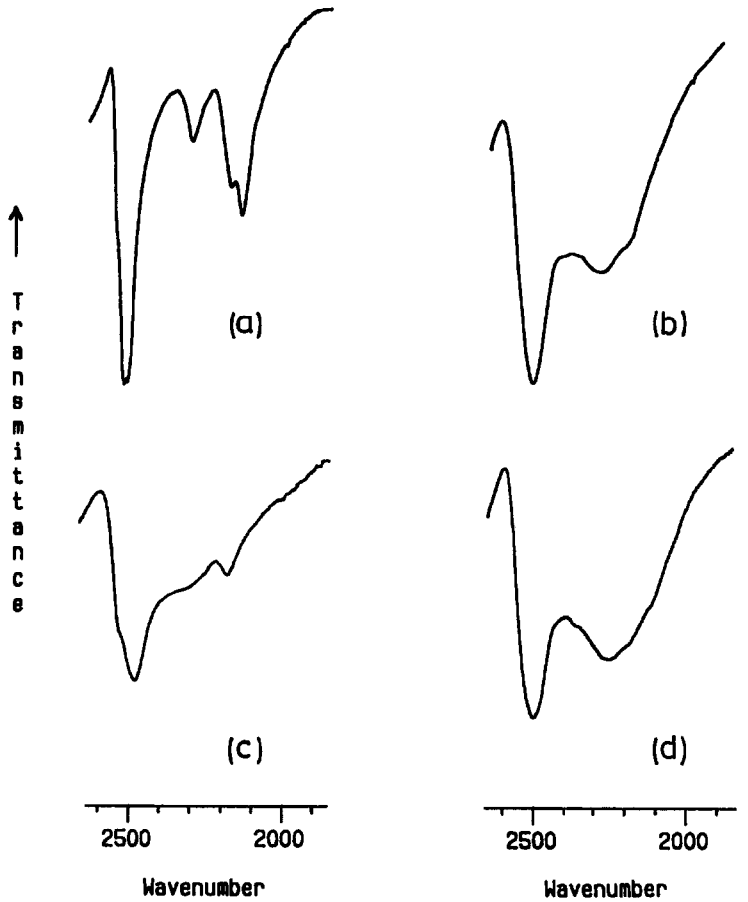

Fig. 1. IR spectra in the ν(B—H) and ν(Zr—H—B) stretching regions (2600–1900 cm^{-1}) of (a) $[(\eta^5\text{-}C_5H_5)_2Zr(\mu\text{-}H)]B_{10}H_{13}$, (b) $(\eta^5\text{-}C_5H_5)_2ZrB_{10}H_{10}$, (c) $[(\eta^5\text{-}C_5H_5)_2Zr(\mu\text{-}H)]_2B_{10}H_{10}$ and (d) the reaction product of $(\eta^5\text{-}C_5H_5)_2Zr(BH_4)_2$ and $B_{10}H_{14}$ (1 : 1 mole ratio) after refluxing in toluene for 2 h.

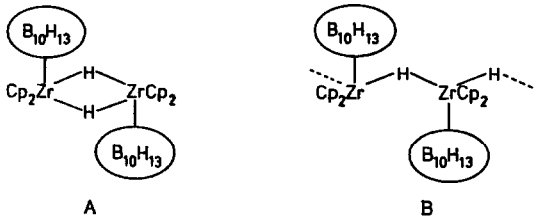
H)$_2$Zr unit in $[(\eta^5\text{-}C_5H_4Me)_2Zr(\mu\text{-}H)H]_2$ and, as established by ^{1}H NMR studies, in the precursor $[(\eta^5\text{-}C_5H_5)_2Zr(\mu\text{-}H)H]_2$.[34]



In both **A** and **B** due consideration has been given to the three frontier orbitals of an $(\eta^5\text{-}C_5H_5)_2Zr$ group (i.e. $1a_1$, b_2, $2a_1$; local C_{2v} symmetry) as discussed by Lauher and Hoffmann,[35] resulting in coordinatively saturated zirconium(IV) in either structural proposal, as is found in $[(\eta^5\text{-}C_5H_4Me)_2Zr(\mu\text{-}H)H]_2$. Without a structural study, however, it is not possible to tell which hydrogen atoms are involved in Zr—H—B bonding. While no calculations have been made on $B_{10}H_{13}^-$, *ab initio* SCF–MO calculations on isolated $B_{10}H_{12}^{2-}$ and on $B_{10}H_{14}$ have shown that the charge on the terminal hydrogens varies by only a small amount in each case (+0.04 to +0.08 e^- and +0.17 to +0.18 e^-, respectively[36]) so that, assuming an even charge distribution also pertains to $B_{10}H_{13}^-$, it is likely that more than one type of terminal hydrogen is involved in Zr—H—B bonding. This is the probable source of the many Zr—H—B bands found in the IR spectrum and use of different hydrogens in Zr—H—B bonding is probably related to at least two geometric packing arrangements for $B_{10}H_{13}^-$ within the structure. The possibility of bonding through a bridging hydrogen on $B_{10}H_{13}^-$ would seem unlikely as these would be the most positively charged hydrogen atoms in this species, while breakdown of a B—H—B unit to give a single Zr—H—B bond would leave the remaining boron electron deficient.

Although the compound was not highly soluble, ^{11}B NMR studies in acetonitrile and N,N-dimethylformamide showed the presence of free $B_{10}H_{13}^-$,[37] indicating breakdown of the polymeric structure in solution. Moreover, the ^1H NMR spectrum in d_3-CH_3CN exhibited a resonance at 6.33 ppm, which corresponds to the η^5-C_5H_5 protons, as well as a resonance at 3.29 ppm which can only be assigned as a terminal hydrogen on zirconium. The latter value may be compared with values of 3.85 and 3.75 ppm for the terminal hydrogen atoms in $[(\eta^5\text{-}C_5H_5)_2Zr(\mu\text{-}H)H]_2$ and $[(\eta^5\text{-}C_5H_4Me)_2Zr(\mu\text{-}H)H]_2$, respectively (the bridging hydrogens occur at -3.45 and at -2.98 ppm).[32,34] Presumably, the $[Cp_2Zr(\mu\text{-}H)_2ZrCp_2]^{2+}$ unit has also broken down to give solvated $(\eta^5\text{-}C_5H_5)_2ZrH^+$ ions, which have terminal hydrogen atoms. In agreement with this the molar conductivity of a 1.0×10^{-3} M solution of $[(\eta^5\text{-}C_5H_5)_2Zr(\mu\text{-}H)]B_{10}H_{13}$ in CH_3CN at 25°C was 108 S cm^2 mol^{-1}, slightly lower than the range expected for a 1:1 electrolyte (120–160 S cm^2 mol^{-1})[38] in this solvent. The low value may perhaps be associated with the fairly large sizes of the ions, leading to reduced ionic mobilities, or perhaps to some residual cation–anion (or even cation–cation) interactions in solution.

Reaction of $(\eta^5\text{-}C_5H_5)_2Zr(H)CH_3$ and $B_{10}H_{14}$ occurred between room temperature and 50°C to produce the same product, $[(\eta^5\text{-}C_5H_5)_2Zr(\mu\text{-}H)]B_{10}H_{13}$, as described above, as well as CH_4. The formation of the hydrogen-bridged zirconium species in this reaction is not surprising as the precursor $(\eta^5\text{-}C_5H_5)_2Zr(H)CH_3$ is also known to be polymeric with Zr—H—Zr bridging, with a ν(Zr—H—Zr) stretch (1310 cm^{-1}) evident in the IR spectrum.[24]

The reaction between $(\eta^5\text{-}C_5H_5)_2Zr(H)BH_4$ and $B_{10}H_{14}$ at room temperature was similar to that between $NaBH_4$ (or $LiBH_4$) and $B_{10}H_{14}$, in that the ultimate boron-containing products were compounds containing the $B_{10}H_{13}^-$ ion as well as B_2H_6.[12,14] The initial compound that formed appeared to be $[(\eta^5\text{-}C_5H_5)_2Zr(BH_4)]B_{10}H_{13}$ based on the formulation of the species $[(\eta^5\text{-}C_5H_5)_2Zr(\mu\text{-}H)]B_{10}H_{13}$ described above, in conjunction with IR data. The IR data showed a strong B—H_{ter} stretch at 2523 cm^{-1} and evidence of a doubly-bridged BH_4^- group,[22,30,31] with bands at 2429, 2384, 2156(sh) and 2124 cm^{-1}. Also, there was a strong peak at 1119 cm^{-1}, which is assignable as the $\delta(BH_2)$ mode. However, B_2H_6 was observed as a product in the reaction after several days and the IR spectrum of the solid product always indicated the presence of a strong, broad band at 1317 cm^{-1}, characteristic of the Zr—H—Zr stretch found in $[(\eta^5\text{-}C_5H_5)_2Zr(\mu\text{-}H)]B_{10}H_{13}$. It would thus appear that the initial product, that is $[(\eta^5\text{-}C_5H_5)_2Zr(BH_4)]B_{10}H_{13}$, decomposes slowly to $[(\eta^5\text{-}C_5H_5)_2Zr(\mu\text{-}H)]B_{10}H_{13}$ and B_2H_6. As the actual reaction between $(\eta^5\text{-}C_5H_5)_2Zr(H)BH_4$ and $B_{10}H_{14}$ is itself quite slow, taking several days, pure $[(\eta^5\text{-}C_5H_5)_2Zr(BH_4)]B_{10}H_{13}$ can never be obtained without the presence of some $[(\eta^5\text{-}C_5H_5)_2Zr(\mu\text{-}H)]B_{10}H_{13}$. The $^{11}B\{^1H\}$ NMR spectrum in CH_3CN of a typical product of this reaction after 3 days indicated the presence of free $B_{10}H_{13}^-$ and a resonance at -26.0 ppm, which is assignable to BH_4^- bound to zirconium based on a comparison with the BH_4^- resonance (-14.4 ppm) found in $(\eta^5\text{-}C_5H_5)_2Zr(BH_4)_2$.[20]

$(\eta^5\text{-}C_5H_5)_2Zr(CH_3)_2$: *reactions at* ca 105°C; *products related to the* $B_{10}H_{10}^{2-}$ *ion*

Reaction between $(\eta^5\text{-}C_5H_5)_2Zr(CH_3)_2$ and $B_{10}H_{14}$ produced two different products depending on the reaction stoichiometry. With a mole ratio for $(\eta^5\text{-}C_5H_5)_2Zr(CH_3)_2$ to $B_{10}H_{14}$ of 1:1 or 1:2 only $(\eta^5\text{-}C_5H_5)_2ZrB_{10}H_{10}$ was formed, while with a mole ratio of 2:1 $[(\eta^5\text{-}C_5H_5)_2Zr(\mu\text{-}H)]_2B_{10}H_{10}$ was isolated. The formation of $B_{10}H_{10}^{2-}$ in all of these reactions was initially surprising and will be addressed below, but its presence was established by ^{11}B NMR studies in N,N-dimethylformamide and dimethyl sulphoxide, in which both compounds are quite soluble, each compound exhibiting (see Fig. 2) signals at *ca* +1 and -28 ppm (with integrated intensities of 1:4) in agreement with the data reported for the $B_{10}H_{10}^{2-}$ ion.[39]

The IR spectra of both compounds, Figs 1(b) and (c), indicated considerable interaction between the $(\eta^5\text{-}C_5H_5)_2Zr^{2+}$ or $[(\eta^5\text{-}C_5H_5)_2Zr(\mu\text{-}H)]_n^{n+}$ cations and $B_{10}H_{10}^{2-}$ anions. In $(\eta^5\text{-}C_5H_5)_2ZrB_{10}H_{10}$, for example, there was a strong B—H_{ter} stretch at 2502 cm^{-1} with a very broad (*ca* 300 cm^{-1}) medium intensity band to lower frequencies, centred at 2300 cm^{-1}. The presence of broad, weak bands in the region 2400–2100 cm^{-1}, which are absent in alkali metal salts of $B_{10}H_{10}^{2-}$, are indicative of M—H—B bonding. This has been established on the basis of IR studies[40–42] on $\{[(C_6H_5)_3P]_2Cu\}_2B_{10}H_{10}$ and $Cu_2B_{10}H_{10}$, both of which exhibit Cu—H—B interactions in their solid-state structures.[42,43] In each case the Cu—H—B bridges involve both axial and equatorial BH interactions of the *closo*-$B_{10}H_{10}^{2-}$ ion with Cu(I). Evidence for similar interactions are also found for $[(\eta^5\text{-}C_5H_5)_2Zr(\mu\text{-}H)]_2B_{10}H_{10}$. In this case there is a broad, medium intensity band centred at 2280 cm^{-1} and a second, well-developed peak at 2177 cm^{-1}. One further feature in the IR spectrum of the latter compound is a strong band at 1194 cm^{-1}, which is

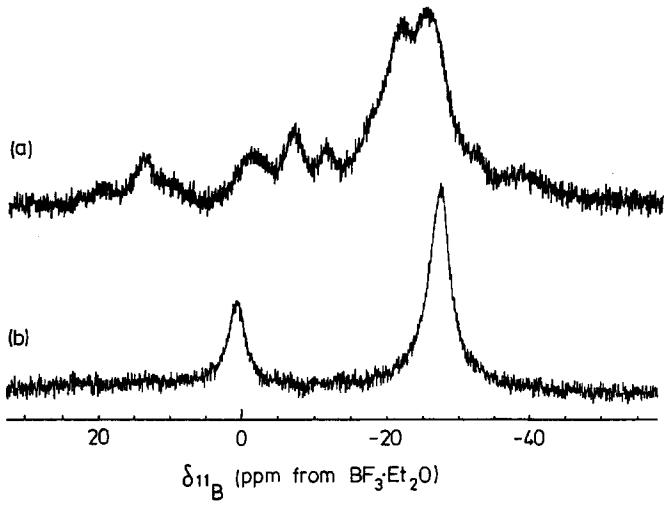


Fig. 2. $^{11}B\{^1H\}$ NMR spectra (at 27°C) of $(\eta^5\text{-}C_5H_5)_2ZrB_{10}H_{10}$ in (a) acetonitrile and (b) dimethyl sulphoxide.

assigned as a Zr—H—Zr stretch (see the previous section), leading to a polymeric structure.

Further evidence for strong Zr—H—B interactions in both compounds came from ^{11}B and ^1H NMR studies. Although both compounds dissociate on dissolution in DMF and DMSO to give free $B_{10}H_{10}^{2-}$, in CH_3CN their $^{11}B\{^1H\}$ spectra are considerably more complicated, exhibiting multiple boron environments. The interaction of one $(\eta^5\text{-}C_5H_5)_2Zr^{2+}$ group with a bidentate, "chelating" $B_{10}H_{10}^{2-}$ ion (a bicapped Archimedian antiprismatic structure) can occur in three ways, involving one axial–equatorial and two types of equatorial–equatorial linkages to the anion. These would lead, in turn, to a maximum of seven, seven and five boron environments, respectively, assuming no coincidences of chemical shifts. If some $B_{10}H_{10}^{2-}$ is also bound through only one of its terminal hydrogen atoms then the resulting spectra would be even more complex. The $^{11}B\{^1H\}$ NMR spectra of these compounds (see, for example, Fig. 2) are more complicated than might be expected, based on the presence of a single species in solution containing one bidentate $B_{10}H_{10}^{2-}$ ion, and suggest that more than one type of linkage is present and, by inference, also in the solid state. Indeed, it is likely that one $(\eta^5\text{-}C_5H_5)_2Zr^{2+}$ group could even link two $B_{10}H_{10}^{2-}$ ions in solution and in the solid state, as found in the structure of $Cu_2B_{10}H_{10}$.[43] It should be noted that different Pt—H—B linkages have been invoked to explain two (geometric) isomers of *cis*-$[(PPh_3)_2Pt(B_{10}H_{10})]$.[44] However, in *cis*-$[(PPh_3)_2Pt(B_{10}H_{10})]$ and also in $[(PPh_3)_2Cu]_2B_{10}H_{10}$ the $^{11}B\{^1H\}$ spectra are recognizably that of $B_{10}H_{10}^{2-}$, except for the increased width of the signals (with $w_{1/2} = 330$ Hz in the platinum compound) compared with free $B_{10}H_{10}^{2-}$ ($w_{1/2} = 51$ Hz).[41,44] This is not the case for the two zirconium-containing species obtained in this study, where multiple boron environments were observed.

The ^1H NMR spectra of $(\eta^5\text{-}C_5H_5)_2ZrB_{10}H_{10}$, $[(\eta^5\text{-}C_5H_5)_2Zr(\mu\text{-}H)]_2B_{10}H_{10}$, $[(PPh_3)_2Cu]_2B_{10}H_{10}$ and *cis*-$[(PPh_3)_2Pt(B_{10}H_{10})]$ also provide an interesting comparison, as well as strong evidence for Zr—H—B interactions. For $[(PPh_3)_2Cu]_2B_{10}H_{10}$ the ^1H NMR spectrum has been reported to show just *single*, broadened axial and equatorial resonances, consistent with a fluctional system, with chemical shifts (axial at 3.65 and equatorial at 0.85 ppm[41]) not too different from $B_{10}H_{10}^{2-}$ itself (4.3 and 0.9 ppm, respectively). For *cis*-$[(PPh_3)_2Pt(B_{10}H_{10})]$, on the other hand, the $^1H\{^1B\}$ NMR spectrum shows multiple axial and equatorial signals, consistent with a rigid species in solution.[44] In the case of $(\eta^5\text{-}C_5H_5)_2ZrB_{10}H_{10}$ the ^1H NMR spectrum shows two $\eta^5\text{-}C_5H_5$ resonances (6.45 and 6.38 ppm) and a broad ($w_{1/2} = 20$ Hz) resonance at 2.19 ppm. The two $\eta^5\text{-}C_5H_5$ resonances are of unequal integrated intensities, ruling out the possibility of two magnetically inequivalent $\eta^5\text{-}C_5H_5$ groups on a single $(\eta^5\text{-}C_5H_5)_2Zr$ group, and is consistent with at least two species in solution. The resonance at 2.19 ppm is tentatively assigned to axial hydrogens involved in Zr—H—B bonding, which are now observable in a non-^{11}B decoupled spectrum because of changed electric field gradient conditions operative in the Zr—H—B three-centre/two-electron bonds. For $[(\eta^5\text{-}C_5H_5)_2Zr(\mu\text{-}H)]_2B_{10}H_{10}$, there is only a single $\eta^5\text{-}C_5H_5$ resonance (6.38 ppm) and the axial hydrogens now

involved in Zr—H—B bonding appear at 2.16 ppm. There is also a sharp resonance at 2.35 ppm, which is assignable as a terminal hydrogen on zirconium formed by breakdown of the Zr—H—Zr link on dissolution in CH_3CN.

The presence of strong Zr—H—B linkages for $(\eta^5\text{-}C_5H_5)_2ZrB_{10}H_{10}$ was also supported by conductivity measurements in CH_3CN, which showed a Λ_M of only 27 S cm^2 mol^{-1} for a 1.0×10^{-3} M solution at 25°C, indicative of substantial cation–anion interactions even in this dilute solution (relative to the concentrations used in the NMR studies in CH_3CN, which were saturated solutions).

The formation of $B_{10}H_{10}^{2-}$ in the above reactions was surprising given that it is a *closo* species, while the precursor $B_{10}H_{14}$ is a *nido* species. Thus, conversion of $B_{10}H_{14}$ (i.e. "$B_{10}H_{10}^{4-}$") to $B_{10}H_{10}^{2-}$ is an oxidation process, but no change in metal oxidation state was observed. In the reaction between $(\eta^5\text{-}C_5H_5)_2Zr(CH_3)_2$ and $B_{10}H_{14}$ in a 1 : 1 mole ratio, after initial formation of CH_4 (i.e. "$CH_3^- + H^+$") to give $B_{10}H_{12}^{2-}$ as a likely intermediate based on the initial reaction stoichiometry, this suggests that one or more of the following reactions may operate:

$$2B_{10}H_{12}^{2-} \rightarrow B_{10}H_{10}^{2-} + B_{10}H_{14}^{2-} \quad (1)$$

$$B_{10}H_{12}^{2-} \rightarrow B_{10}H_{10}^{2-} + H_2 \quad (2)$$

$$B_{10}H_{14}^{2-} \rightarrow B_{10}H_{10}^{2-} + 2H_2. \quad (3)$$

Previously, it has been shown that pyrolysis of solid $Na_2B_{10}H_{12}$ or $Rb_2B_{10}H_{14}\cdot nH_2O$ at *ca* 240°C produces a mixture of $B_{10}H_{10}^{2-}$ and $B_9H_9^{2-}$.[45] However, no information on the thermal stabilities of $B_{10}H_{12}^{2-}$ and $B_{10}H_{14}^{2-}$ in solution is currently available.

A solution of $Na_2B_{10}H_{12}$ in THF was, therefore, prepared in a sealed, evacuated NMR tube and the thermal stability of $B_{10}H_{12}^{2-}$ investigated using ^{11}B NMR. Reaction began at *ca* 60°C and was subsequently monitored at 65°C, giving $B_{10}H_{10}^{2-}$ and $B_{10}H_{14}^{2-}$ in approximately equal amounts over several (*ca* 6) hours. Likewise, when $B_{10}H_{14}$ and excess NaH were vigorously refluxed in THF under nitrogen only $B_{10}H_{10}^{2-}$ and $B_{10}H_{14}^{2-}$ in approximately equal amounts (together with a small amount of BH_4^- <1%) were observed after 3 h by ^{11}B NMR. This suggests that the reaction between $(\eta^5\text{-}C_5H_5)_2Zr(CH_3)_2$ and $B_{10}H_{14}$ in a 1 : 1 mole ratio occurs according to the steps:

$$Cp_2Zr(CH_3)_2 + B_{10}H_{14} \rightarrow [Cp_2ZrB_{10}H_{12}] + 2CH_4 \quad (4)$$

$$2[Cp_2ZrB_{10}H_{12}] \rightarrow Cp_2ZrB_{10}H_{10} + Cp_2ZrB_{10}H_{14}. \quad (5)$$

The presence of $B_{10}H_{14}^{2-}$ as a product in this reaction was established (amongst other species) in the toluene-soluble fraction of the products by ^{11}B NMR in DMSO. However, the yield of toluene-insoluble $(\eta^5\text{-}C_5H_5)_2ZrB_{10}H_{10}$ was always 70–80%, while reaction (5) above would imply a maximum yield of 50%. A subsequent ^{11}B NMR investigation into the thermal stability of $B_{10}H_{14}^{2-}$ (a solution of $Cs_2B_{10}H_{14}\cdot CsCl$[46] in DMSO showed no decomposition up to 150°C, well above the reaction temperature of $(\eta^5\text{-}C_5H_5)_2Zr(CH_3)_2$ with $B_{10}H_{14}$. The reaction between $(\eta^5\text{-}C_5H_5)_2Zr(CH_3)_2$ and $B_{10}H_{14}$ (in a 1 : 1 mole ratio) was, therefore, studied under conditions whereby the total amount of gaseous product could be measured using a Toepler system. The amount of evolved gas was 24% greater (average of two determinations; see Experimental) than that based on the amount of CH_4 generated according to reaction (4) above, indicating formation of a further permanent gas (presumably hydrogen). Thus, it would appear that, under the reaction conditions, direct thermal decomposition of the "intermediate" $[(\eta^5\text{-}C_5H_5)_2ZrB_{10}H_{12}]$ also occurs, in addition to the rearrangement/disproportionation reaction given in (5) above, which may be written:

$$[Cp_2ZrB_{10}H_{12}] \rightarrow Cp_2ZrB_{10}H_{10} + H_2. \quad (6)$$

Reactions (5) and (6) would, therefore, appear to be competing reactions, leading to the observed yields of $(\eta^5\text{-}C_5H_5)_2ZrB_{10}H_{10}$ and H_2. Analogous reactions presumably occur when $B_{10}H_{14}$ reacts with $(\eta^5\text{-}C_5H_5)_2Zr(CH_3)_2$ in a 1 : 2 stoichiometry, although in this case C_2H_6 is also a likely product according to the equation:

$$2(\eta^5\text{-}C_5H_5)_2Zr(CH_3)_2 + B_{10}H_{14} \rightarrow [(\eta^5\text{-}C_5H_5)_2Zr(H)]_2B_{10}H_{10} + 2CH_4 + C_2H_6. \quad (7)$$

However, attempts to identify C_2H_6 in the presence of excess CH_4 by IR spectroscopy were not definitive in this case.

$(\eta^5\text{-}C_5H_5)_2Zr(BH_4)_2$, $(\eta^5\text{-}C_5H_5)_2Zr(H)BH_4$ *and* $(\eta^5\text{-}C_5H_5)_2Zr(BH_4)CH_3$: *reactions at* 80–110°C; *borane cluster enlargement*

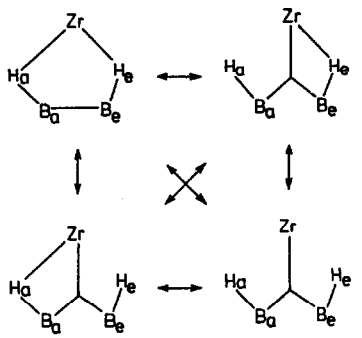
When the reactions between $(\eta^5\text{-}C_5H_5)_2Zr(BH_4)_2$, $(\eta^5\text{-}C_5H_5)_2Zr(H)BH_4$ and $(\eta^5\text{-}C_5H_5)_2Zr(BH_4)CH_3$ with $B_{10}H_{14}$ were performed in refluxing benzene or toluene over an extended period, an orange solid always formed in each case. The IR spectra of these materials [see Fig. 1(d) for a typical spectrum] were essentially identical to that of $(\eta^5\text{-}C_5H_5)_2ZrB_{10}H_{10}$, except for an increase in the size of the Zr—H—B stretching mode(s)

relative to that of the B—H_{ter} stretch. This again indicates strong interactions between zirconium and the product borane anions. The $^{11}B\{^1H\}$ NMR spectra of these solids in DMF or DMSO indicated the presence of $B_{10}H_{10}^{2-}$ as well as two resonances at −15.8 and −16.9 ppm. The relative intensities of these two peaks were dependent on the temperature at which the reaction was performed as well as the time scale. These resonances, therefore, belong to different species and are not attributable to $B_{11}H_{14}^-$, which has two resonances of equal intensity at similar chemical shifts [for $B_{11}H_{14}^-$ in glyme; δ ppm (intensity): −12.5(1), −14.1(5) and −14.9(5)[47]]. The two resonances may be assigned to $B_{12}H_{12}^{2-}$ (−15.8 ppm) and $B_{11}H_{11}^{2-}$ (−16.9 ppm)[48,49] and likely arise from the initial formation of $B_{11}H_{13}^{2-}$ (or $B_{11}H_{14}^-$), followed by decomposition to $B_{11}H_{11}^{2-}$ and H_2, with $B_{10}H_{10}^{2-}$ and $B_{12}H_{12}^{2-}$ formed either directly from $B_{11}H_{13}^{2-}$ (or $B_{11}H_{14}^-$) or by thermal decomposition of $B_{11}H_{11}^{2-}$. Indeed, the method reported for the preparation of $B_{11}H_{11}^{2-}$ involves the pyrolysis of solid $Cs_2B_{11}H_{13}$ above 250°C, followed by repeated recrystallizations from aqueous solution to remove $Cs_2B_{10}H_{10}$ and $Cs_2B_{12}H_{12}$.[49,50] The salt, $Cs_2B_{11}H_{11}$, is itself stable to 400°C but decomposes at 600°C to give $Cs_2B_{10}H_{10}$ and $Cs_2B_{12}H_{12}$.[50] The data on $B_{11}H_{14}^-$ are less accessible, but this anion (as the Cs^+ salt) appears to be pyrolytically unstable above 185°C, giving $B_nH_n^{2-}$ (where $n = 12, 10, 9$).[51] The reaction behaviour described above for the simple caesium salts parallels that observed in the present study, but at considerably higher temperatures. The markedly reduced decomposition temperatures (in solution) observed in this work may be associated with the presence of $(\eta^5\text{-}C_5H_5)_2Zr^{2+}$, that is, to a metal-mediated decomposition process(es). This is likely associated with Zr—H—B interactions between $(\eta^5\text{-}C_5H_5)_2Zr^{2+}$ and the proposed intermediate borane anions (i.e. $B_{11}H_{13}^{2-}$ or, less likely, $B_{11}H_{14}^-$, based on the products formed) of the type established in the compounds described in the two previous sections. While metal-mediated decomposition reactions of the boranes have not previously been reported, metal-mediated oligomerization reactions involving a $(\eta^5\text{-}C_5H_5)_2Mo$ moiety are known leading to metallaboranes containing two, five and nine boron atoms from a [BH_3·THF] substrate.[52]

Zr—H—B *bonding interactions and the* $(\eta^5\text{-}C_5H_5)_2Zr$ *group as a cluster vertex*

The three lowest-lying frontier orbitals of an $(\eta^5\text{-}C_5H_5)_2M$ group with local C_{2v} symmetry (the cyclopentadienyl groups being eclipsed) are, as described by Lauher and Hoffmann,[35] primarily metal based and are, in order of increasing energy, $1a_1$ (58% $d_{x^2-y^2}$ and 30% d_{z^2}), b_2 (73% d_{xz}) and $2a_1$ [35% d_{z^2}, 19% $d_{x^2-y^2}$, 17% s and 16% p_z; data calculated for $(\eta^5\text{-}C_5H_5)_2Zr^{2+}$]. The three orbitals are located in the plane bisecting the two cyclopentadienyl groups and do not transform as do the three frontier orbitals of a BH or $Fe(CO)_3$ skeletal vertex ($A_1 + E$, local C_{3v} symmetry), so that a $(\eta^5\text{-}C_5H_5)_2M$ group and a BH [or $Fe(CO)_3$] vertex are not isolobal. Disregarding skeletal electron contributions the $(\eta^5\text{-}C_5H_5)_2M$ group can be like, for example, an $Mn(CO)_4$ fragment if only two of the three frontier orbitals of the $(\eta^5\text{-}C_5H_5)_2M$ group are used in bonding. An $Mn(CO)_4$ group is actually isolobal with BH_2 or $Cu(PR_3)_2$ and would be expected to bridge two atoms in a cluster provided that the "bite" angle of the frontier orbitals was commensurate with the separation of the two cluster atoms and their (unused) attendant orbitals and that these orbitals were of the appropriate symmetry (and energy) to interact with the frontier orbitals of the $Mn(CO)_4$ group. An $(\eta^5\text{-}C_5H_5)_2M$ fragment is really more complex in that there are three, not two, frontier orbitals. However, true 16-electron systems are quite common for group IV elements and may involve, for example, the $(\eta^5\text{-}C_5H_5)_2Zr^{2+}$ group. Examples using just σ-bonding ligands (which removes the possibility of π-bonding through higher energy ligand donor orbitals) include $(\eta^5\text{-}C_5H_5)_2Zr(CH_3)_2$, $(\eta^5\text{-}C_5H_5)_2Zr(CH_2CMe_3)_2$ and $(\eta^5\text{-}C_5Me_5)_2ZrH_2$. The effective "bite" angle [as given by the X—M—X angle in $(\eta^5\text{-}C_5H_5)_2MX_2$ compounds], which gives rise to the most favourable overlaps of the three frontier orbitals with those of the two X groups (interaction with b_2 and some combination of $1a_1$ and $2a_1$), actually varies depending on the d-orbital population.[35] This angle is 94–97° for d^0, 85–88° for d^1 and 76–82° for d^2 systems. Assuming an average "bite" angle of 96° for $(\eta^5\text{-}C_5H_5)_2Zr^{2+}$ (a d^0 system) and covalent radii for zirconium and boron of 1.45 and 0.79 Å, respectively, the B—B distance in a borane cluster required to support two two-centre/two-electron Zr—B bonds would be 3.32 Å, well in excess of any two adjacent boron atoms in such a species, even though these atoms may be linked by a three-centre/two-electron B—B bond. Considering the distance required an $(\eta^5\text{-}C_5H_5)_2Zr^{2+}$ fragment is thus likely to bond symmetrically along one side of a formal $B_{10}H_{12}^{2-}$ fragment, if the latter is derived from $B_{10}H_{14}$ by loss of two bridging protons from just one side of the parent molecule. This type of interaction is observed in the $[M(B_{10}H_{12})_2]^{2-}$ ions, where M = zinc(II) and nickel(II),[53,54] and the $B_{10}H_{12}^{2-}$ group can be regarded as acting as a

tetrahapto ligand. In the present study, however, $B_{10}H_{12}^{2-}$ was not observed as a boron-containing product. Rather, boron-containing anionic species were obtained which exhibited three-centre/two-electron bonding interactions with $(\eta^5\text{-}C_5H_5)_2Zr^{2+}$ through their terminal hydrogen atoms. The extent of actual Zr—B interaction in these linkages was investigated using extended-Hückel LCAO–MO calculations for an axial–equatorial interaction of $(\eta^5\text{-}C_5H_5)_2Zr^{2+}$ with $B_{10}H_{10}^{2-}$, as is likely to occur in the case of $(\eta^5\text{-}C_5H_5)_2ZrB_{10}H_{10}$. An idealized ($D_{4d}$) geometry for the $B_{10}H_{10}^{2-}$ ion was assumed,[55] taken from that found in $[(PPh_3)_2Cu]_2B_{10}H_{10}$, together with a $(\eta^5\text{-}C_5H_5)_2Zr^{2+}$ fragment so that the H—Zr—H angle was 96°. With Zr—H distances of 1.91 and 2.08 Å, not too different to those found in the three-centre/two-electron Zr—H—Zr bonds in $[(\eta^5\text{-}C_5H_4Me)_2Zr(\mu\text{-}H)H]_2$ (1.94 and 2.05 Å), this gave equal Zr—B distances of 2.39 Å to the axial and equatorial boron atoms, an arrangement similar to that observed for the Cu—B distances (in this case both 2.30 Å) in $[(PPh_3)_2Cu]_2B_{10}H_{10}$.[42] The resulting Zr—B orbital overlaps (absolute values) varied from 0.393 to 0.023, disregarding those restricted to zero by symmetry constraints, and involved all of those orbitals indicated above that contribute strongly to the three lowest-lying frontier orbitals of the $(\eta^5\text{-}C_5H_5)_2Zr^{2+}$ group. In comparison, the Zr—H orbital overlaps varied from 0.331 to 0.039 with the major overlap occuring between $Zr(5p_y)$ and $H(1s)$—the y direction being perpendicular to the vector from zirconium to the middle of the B_a—B_e bond and in the plane bisecting the two cyclopentadienyl groups. Thus, the bonding between zirconium and the borane anion is best described using the following representation:



Scheme 1.

A similar array of interactions has been proposed previously in the case of $[(PPh_3)_2Cu]_2B_{10}H_{10}$, although as pointed out in that study the relative contributions of the Cu—H and Cu—B interactions cannot be extracted from the interatomic distances themselves.[42] The $(\eta^5\text{-}C_5H_5)_2Zr^{2+}$ and $(PPh_3)_2Cu^+$ groups are effectively acting like a BH_2 vertex, a commonly found feature in *arachno*-boranes, although in each case they require electron supplementation from the terminal B—H two-centre/two-electron bonds of $B_{10}H_{10}^{2-}$ to create the three-centre/two-electron M—H—B bonds, while a (neutral) BH_2 vertex is a source of one skeletal electron.

Given the frontier orbitals extant, the likely metal–borane interactions involving an $(\eta^5\text{-}C_5H_5)_2Zr$ fragment are of the type proposed to occur in the compounds obtained in this study. As such, these will involve relatively weak three-centre/two-electron bonds (Zr—H—B with a considerable Zr—B contribution, as pertains to this study). For a general $(\eta^5\text{-}C_5H_5)_2M$ fragment the strength of the M—H—B (and M—B) interactions are likely to vary depending on the transition metal, its formal oxidation state and, therefore, the electron population of the frontier orbitals. This will, in turn, affect the bite angle of the frontier orbitals in their interaction with a borane cluster, which may lead to different types of interactions between the $(\eta^5\text{-}C_5H_5)_2M$ fragments and the borane itself. In general, as the interactions are likely to be relatively weak, as found in this study, the metal atoms should exert little influence on aspects of the chemistry of the neutral borane or borane ion(s) in question. Exceptions include, for example, possible borane reduction of the metal and changes in the site of nucleophilic or electrophilic attack caused by electron density changes as a result of formation of the M—H—B bonds, provided that these are retained in solution. The result, as found in this study, was that in its reactions with the zirconium-containing species used, the chemistry of $B_{10}H_{14}$ was recognizably that of its reactions with free (i.e. ionic) H^- and BH_4^-. Evidence of metal intervention was noted, however, in the proposed metal-promoted disproportionation/rearrangement reaction which always occurred at elevated temperatures (above 80°C) when BH_4^- was present. In the absence of a metal these same reactions only occur at much higher temperatures. It should be noted that in cases where an $(\eta^5\text{-}C_5H_5)_2M$ group does act to alter chemistry, such as in the metal-mediated oligomerization of $[BH_3\cdot THF]$ by $(\eta^5\text{-}C_5H_5)_2MoH_2$,[52] photolysis and thermolysis have been used to promote reaction. The resulting higher borane species actually involved incorporation of one cyclopentadiene ring into the cluster geometry so that the $(\eta^5\text{-}C_5H_5)_2Mo$ fragment no longer remained intact.

51. This information may be inferred from the observation that while CsB_3H_8 when pyrolysed at 185°C gives $Cs_2B_{10}H_{10}$, $CsB_{11}H_{14}$ (34% yield), $CsBH_4$ and H_2, at 230°C the products are $Cs_2B_nH_n$ (n = 12, 10, 9) and H_2; data reported by J. M. Makhlouf, W. V. Hough and G. T. Hefferan, *Inorg. Chem.* 1967, **6**, 1196 and ref. 47. The conclusion is also consistent with the observation that no reaction occurs between $Me_3NH^+B_{11}H_{14}^-$ and Et_3N at 180°C, both com-

pounds being recovered unchanged after 1 h, implying that no pyrolysis of $B_{11}H_{14}^-$ occurs at this temperature; H. C. Miller, N. E. Miller and E. L. Muetterties, *Inorg. Chem.* 1964, **3**, 1456.

55. The assumed geometry of $B_{10}H_{10}^{2-}$ had an axial–equatorial B—B distance of 1.68 Å, with equatorial–equatorial distances of 1.82 Å (within the square planes) and 1.80 Å (between the planes) and a B—H distance of 1.11 Å. The H_a—B_a—B_e and H_e—B_e—B_a angles were 130° and 122°, respectively (where a = axial, e = equatorial). For the $(\eta^5\text{-}C_5H_5)_2Zr^{2+}$ fragment the Zr—Cp(centroid) distance was 2.21 Å, with a Cp(centroid)—Zr—Cp(centroid) angle of 130°.

Abstract—Reaction of $Mn(ClO_4)_2 \cdot xH_2O$ and $Mn(CH_3CO_2)_3 \cdot xH_2O$ with 2,2′:6′,2″:6″,2‴-quaterpyridine (QP) in acetonitrile or methanol gave the complexes $[Mn(QP)(H_2O)_2](ClO_4)_2$ and $[Mn(QP)(CH_3CO_2)(H_2O)](ClO_4)$, respectively. X-ray crystal structure determination revealed that the manganese atom is six-coordinated in the former, but seven-coordinated in the latter. Both complexes catalysed oxidation of alkenes by PhIO.

The coordination chemistry of polypyridine ligands is an active and important area of research.[1,2] Despite the fact that 2,2′-bipyridine and 2,2′:6′-2″-terpyridine and their substituted derivatives have been subjected to extensive works, there are only a few studies on the ligand 2,2′:6′,2″:6″,2‴-quaterpyridine (QP).[3–5] This ligand is expected to be more oxidation resistant and has a low energy orbital for a metal-to-ligand charge transfer transition to occur in the visible region. As part of our program in the design of new oxidative and photochemical catalysts we explore the coordination chemistry of quaterpyridine with transition metal ions. Herein is described the synthesis and structural determination of six- and seven-coordinated manganese(II) complexes of QP. A preliminary study of catalytic epoxidation will be presented.

EXPERIMENTAL

Materials

$Mn(CH_3CO_2)_3 \cdot xH_2O$ and $Mn(ClO_4)_2 \cdot xH_2O$ from Aldrich were used as received. The ligand QP was prepared by literature methods.[3] All solvents for syntheses and recrystallizations were of analytical grade.

Physical measurements and instrumentation

IR spectra were measured in KBr pellets on a Nicolet 20 SXC FT-IR spectrometer. UV–vis spectra were obtained on a Milton Roy Spectronic 3000 spectrophotometer.

Cyclic voltammograms were measured using a Princeton Applied Research (PAR) model 175 universal programmer, model 173 potentiostat and model 179 digital coulometer coupled to a Houston 2000 *X–Y* recorder. A conventional two-compartment cell was used in electrochemical measurements. A silver–silver nitrate (0.1 M in acetonitrile) reference electrode was used in degassed acetonitrile [0.1 M in $(CH_3(CH_2)_3)_4NPF_6$] with a ferrocenium–ferrocene ($Fc^{+\cdot}/Fc$) couple as the internal standard. The working electrode was glassy carbon, which was pre-treated as described previously.[6]

$[Mn(QP)(CH_3CO_2)(H_2O)](ClO_4)$ (**1**). A mixture of $Mn(CH_3CO_2)_3 \cdot xH_2O$ (0.2 g) and QP (0.1 g) in methanol (30 cm^3) was heated at 50°C for 1/2 h, after which the mixture was filtered. The filtrate was

† Author to whom correspondence should be addressed.

treated with $LiClO_4$ to give a pale yellow solid, which was then filtered and air dried.

$[Mn(QP)(H_2O)_2](ClO_4)_2$ (**2**). Excess $Mn(ClO_4)_2 \cdot xH_2O$ and QP were mixed in acetonitrile (50 cm^3) at 70°C. The resulting solution was stirred for 15 min, filtered and concentrated to *ca* 10 cm^3. Ether diffusion afforded greenish-yellow needles. IR (cm^{-1}): 1597m, 1575m, 1490m, 1466m, 1440m, 1314w, 1249w, 1192w, 1110s, 1088s, 1016w, 777s, 652w, 625m, 429w. UV–vis in CH_3CN (λ_{max}, $10^{-3}\varepsilon$): (235, 35.2), (294, 18.1), (301, 26.1), (332, 16.2), (342, 16.9).

X-ray crystallography

Yellow crystals of $[Mn(QP)(CH_3CO_2)(H_2O)](ClO_4)$ (**1**) and $[Mn(QP)(H_2O)_2](ClO_4)_2$ (**2**) were obtained by diffusion of diethyl ether into the corresponding acetonitrile solution. The intensity data were measured on an Enraf–Nonius CAD4 diffractometer equipped with graphite monochromatized Mo-K_α radiation ($\lambda = 0.7093$ Å) using a θ–2θ scan mode at 297 K with $2\theta_{max} = 50°$. Cell parameters and the space group were obtained from 24 strong reflections with 2θ in the ranges 18–27° and 19–25° for complexes **1** and **2**, respectively. For complex **1** a total of 8678 reflections were measured, 8295 of which were considered unique and 5486 of these had $I > 2\sigma(I)$; while for complex **2** a total of 2233 reflections were collected, in which 592 reflections with $I > 2\sigma(I)$ were considered out of 2142 unique reflections. All data were corrected for Lorentz and polarization effects. Empirical absorption corrections were applied. In the final cycle of refinement convergence was reached at $R = 0.045$, $R_w = 0.033$, $S = 2.56$ for complex **1** and $R = 0.070$, $R_w = 0.070$, $S = 1.99$ for complex **2**. Final difference densities were in the range -0.62–0.86 e $Å^{-3}$ for complex **1** and -0.56–0.70 e $Å^{-3}$ for complex **2**. A summary of crystallographic data is listed in Table 1. Selected bond lengths and bond angles are listed in Table 2.

Alkene oxidation by iodosobenzene catalysed by complex **2**

The reaction was conducted in degassed CH_2Cl_2/CH_3CN solution (3 : 1 volume) and under nitrogen. A mixture of complex **2** (7 mg), alkene (40 mg) and PhIO (30 mg) was stirred for 3–6 h. Excess sodium sulphite (100 mg) was added in water (3 cm^3). After excess PhIO was decomposed the organic layer was separated. The aqueous layer was extracted with 3×2 cm^3 of CH_2Cl_2. The combined organic layer was evaporated to dryness under reduced pressure. 3-Methylbenzoic acid (3 mg) was added as an internal standard. The mixture was extracted with 3×5 cm^3 petroleum ether (40–60°C), filtered through a cotton plug and evaporated under reduced pressure. NMR spectra were taken on the residues obtained.

[a] There are two independent manganese complexes in an asymmetric unit of **1**.

RESULTS AND DISCUSSION

X-ray structure determination

The reaction of quaterpyridine with $Mn(CH_3CO_2)_3 \cdot xH_2O$ in methanol or ethanol rapidly gave $[Mn(QP)(CH_3CO_2)(H_2O)]^+$, which was isolated as the perchlorate salt in high yield. A similar reaction with $Mn(ClO_4)_2$ in acetonitrile gave the six-coordinated $[Mn(QP)(H_2O)_2](ClO_4)_2$. The IR spectrum of **1** shows strong absorption bands at 3400 and 3230 cm^{-1}, attributed to $\nu(OH_2)$ stretches. The UV–vis absorption spectrum of **1** or **2** in acetonitrile is featureless, being dominated by the intraligand $\pi \rightarrow \pi^*$ transitions at 342, 333 and 302 nm.

The structures of the manganese complexes **1** and **2** have been determined by X-ray crystallography. There are two independent molecules of complex **1** in an asymmetric unit, but these are not significantly different from each other (see Table 2). A perspective view of one cation of **1** with its atomic numbering scheme is shown in Fig. 1. The central manganese atom adopts the common coordination geometry for seven-coordinated manganese(II) complexes—distorted pentagonal-bipyramidal.[7] The equatorial sites are occupied by the four nitrogen atoms of quaterpyridine and one of two oxygen atoms of the chelating acetate ligand. The N_4O donor set of atoms, which form the pentagon, are approximately co-planar with the acetate oxygen atom slightly deviating from the plane defined by N(1)–N(4). The measured ∠O(1){acetate}—Mn—O(5){water} of 156.2(1)–162.2(1)° is substantially deviated from linearity. Such bending is probably a result of the presence of the chelating

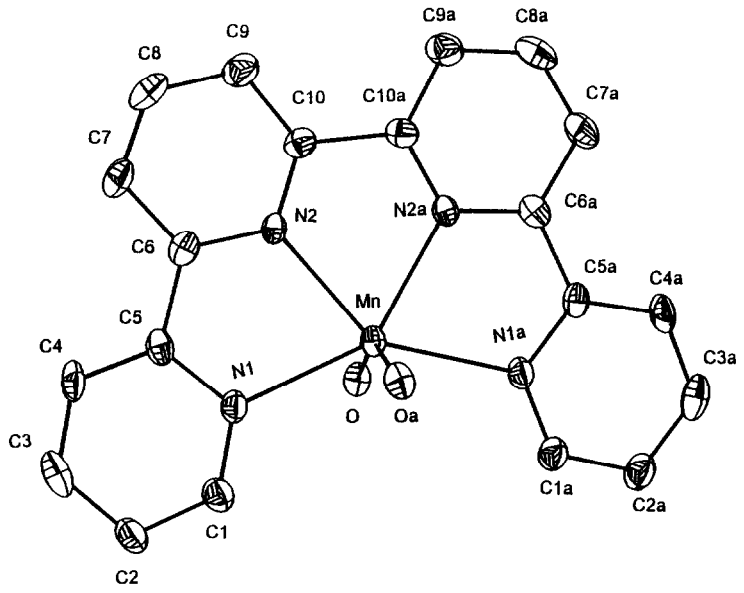

Fig. 2. ORTEP view of $[Mn(QP)(H_2O)_2]^{2+}$.

acetate ligand and the large void angle defined by N(1)—Mn—N(4), similar to the situation in **2**.

A comparison between the reported structure with that of $[Ni(QP)(CH_3CN)_2][PF_6]_2$,[3] $[Pt(QP)](ClO_4)_2$[4b] and $[Co(QP)(H_2O)(SO_3)](NO_3)]\cdot H_2O$[5] reveals much smaller N(1)—M—N(4) void angles for the nickel(II), platinum(II) and cobalt(II) complexes. This is in accord with previous works which indicated that seven-coordinated metal complexes of QP have much larger N(1)—M—N(4) void angles.

The structures of six-coordinated **2** can best be described as a skew-trapezoidal-bipyramid (see Fig. 2). The short edge is comprised of two central pyridyl rings, while the long edge can be imagined as two terminal pyridyl rings and the void between them. Upon coordination the water molecules in the axial positions skew towards the long axis of the trapezoid, i.e. the open end of QP, with ∠O(1)—Mn—O(1A) at 150.0(2)°. Furthermore, the absence of a fifth equatorial coordinated atom in complex **2** allowed closer approach of the axial oxygen atoms and the equatorial nitrogen atoms.

In these structures two mirror planes were retained and the quaterpyridines are essentially coplanar.

The two central Mn—N bonds in both **1** and **2** are slightly shorter than the two outer Mn—N bonds. This may be due to the constrained effect of the quaterpyridine ligand. Nevertheless, these Mn—N distances are normal and comparable to those values of 2.276(4)–2.328(4) Å found in [Mn(dapb)(H_2O)Cl]Cl [dapb = 2,6-diacetylpyridinebis-(benzoylhydrazone)].[6] The Mn—O(5) {water} distance of **1** is somewhat shorter than the average Mn—O(1),(2) {acetate} distance, probably due to the limited ∠O(1)—C(1)—O(2) bite angle of acetate.

As the extent of QP distortions in both **1** and **2** are almost the same [∠N(1)—C(15)—C(16) = 114.9(3)–115.6(3), ∠N(2)—C(20)—C(21) = 115.2(4)–115.4(4); ∠N(1)—C(5)—C(6) = 116.4(6), ∠N(2)—C(10)—C(10A) = 114.3(6)] the almost equal magnitude of void angles in coordinated QP for both seven- and six-coordinate manganese(II) indicates that isolation of the seven-coordinated manganese(II) quaterpyridine complex is possible as long as suitable chelating molecules are present. Furthermore, the larger void angle of complex **2** compared with $[Pt(QP)](ClO_4)_2$[4b] suggests strong interaction of QP with third row transition elements.

Interestingly enough, the quinquepyridine manganese(II) complex was not available from direct synthesis, which was found to be retarded by water.[8] This result was consistent with the fact that manganese(II) generally has a stronger preference for oxygen than nitrogen. The isolation of quaterpyridine manganese(II) complexes again demonstrates the unique chelating strength of four rigidly bridged equatorial pyridyl units.

Electrochemistry

The generation of manganese(III) from complex **2** using the cyclic voltammetric method was unsuccessful as complex **2** was unstable towards decomposition in aqueous solution. A voltammograph was recorded in degassed acetonitrile

Table 3. Epoxidation catalysed by $[Mn(QP)(H_2O)_2](ClO_4)_2$ (**2**)

	Cis-stilbene[a]	*Trans*-stilbene[a]	Styrene[b]	Norbornene[b]
Turnover	1[c] 0.3[f]	4[c]	16[d]	3[e]

[a] Reaction time 6 h.
[b] Reaction time 3 h.
[c] *Trans*-stilbene oxide.
[d] Styrene oxide.
[e] *Exo*-2,3-epoxynorbornane.
[f] *Cis*-stilbene oxide.

solution [0.1 M $(CH_3(CH_2)_3)_4NPF_6$], which can afford an oxidative scan up to +2.5 V. However, no oxidative wave was observed within this condition. Reduction of **2** was observed at *ca* −1.7 V (vs $Fc^{+\cdot}/Fc$), which was believed to be ligand-centre reduction.[9]

Alkene epoxidation by PhIO

Complex **2** was found to catalyse alkene epoxidation by PhIO. A lightly coloured suspension of the reaction mixture turned into a dark green solution within minutes. The reaction was found to be non-stereospecific as *cis*-stilbene gives both *trans*- and *cis*-stilbene oxide with more than 70% *trans*-isomer (see Table 3). Oxo-transfer was more effective with less sterically hindered alkenes as the turnover number for styrene was four times greater than that of *trans*-stilbene and about 20-fold to that of *cis*-stilbene. A small amount of benzaldehyde was detected for styrene oxidation.

AN EXAFS STUDY OF GRIGNARD COMPOUNDS IN SOLUTION

T. S. ERTEL* and H. BERTAGNOLLI

Institut für Physikalische Chemie, Universität Stuttgart, Pfaffenwaldring 55, D-7000 Stuttgart 80, F.R.G.

(*Received* 5 *April* 1993; *accepted* 2 *June* 1993)

Abstract—The results of an EXAFS study of the Grignard compounds methyl, ethyl and phenyl magnesium bromide in diethyl ether and vinyl magnesium bromide in tetrahydrofuran are presented in this paper. The degree of molecular association and the local structure around the central magnesium atoms are deduced from the determined distances and coordination numbers.

Grignard compounds in general are probably the most popular organometallic substrates. Since their detection in 1900 by Victor Grignard,[1] their widespread applicability as precursors in synthetic organic and inorganic chemistry have increased over the decades. Grignard reagents can be successfully employed, e.g. in the synthesis of alcohols, aldehydes, ketones, carboxylic acids, esters, amines and mercaptans. The synthesis of ligands or organometallic complexes is also a field of application. Although the Grignard reagents have been used for over 90 years, considerable confusion exists as to their precise nature in solution.[2–8] Almost all methods of physical chemistry have been used to shed some light on the possible equilibria and the species contributing to it.

Molecular weight studies provided the existence of dimeric and oligomeric species in solution.[9] These results, however, are questionable. On the one hand, contamination by oxygen and water was not sufficiently considered.[10–12] On the other hand, this method does not provide any information about the degree of solvation and the geometry of this species.[13]

The question of how dimers are existing, either as R_2MgX_2Mg or $RMgX_2MgR$, was studied by tracer experiments. Former studies showed no exchange of ^{28}Mg.[14] Therefore, the dimer should be written as R_2MgX_2Mg. Recent studies, however, showed a statistical exchange of ^{28}Mg and the former results were not reproduced.[15]

Measurements of the electrolytic conductivity revealed the existence of ionic species.[16–21] The results, however, show that the amount of ions is very small. Therefore, ionic species must not be taken into account for the description of the character of Grignard compounds in solution.

The existence of dimers of the type R_2MgX_2Mg with coordinating diethyl ether was derived from the IR spectroscopic data of CH_3CH_2MgBr.[22,23] C_6H_5MgI in diethyl ether is supposed to be a monomer, besides some small amounts of $(C_6H_5)_2MgI_2$ and $(C_6H_5)_2Mg$. THF solutions of alkyl magnesium bromides and chlorides can be described in terms of an equilibrium between two RMgX and R_2Mg/MgX_2.[24]

^1H NMR studies of alkyl magnesium halogenides in diethyl ether suggest that R_2MgX_2Mg is the predominant species, because their spectra are very similar to those of the corresponding dialkyl magnesium compounds.[25,26] Solutions of aryl magnesium compounds showed a dependence of the equilibrium constant on the type of aryl group. Furthermore, the contribution of the R_2Mg species increases with the coordinating ability of the solvent.[27–29] The only ^{25}Mg NMR study of CH_3CH_2MgBr in THF provided evidence of CH_3CH_2MgBr, $MgBr_2$ and $(CH_3CH_2)_2Mg$.[30] For reasons of completeness ^{13}C NMR studies of various organomagnesium bromides and chlorides should be mentioned.[31–34] However, all these inves-

* Author to whom correspondence should be addressed.

tigations did not provide any information about the possible structures of the species.

Although X-ray diffraction studies have been performed on ethyl and phenyl magnesium bromide dietherates in the solid state,[35-37] only little information is available on structural features such as the intra- and interatomic distances of Grignard reagents in solution. Extended X-ray absorption fine structure (EXAFS) and large angle scattering (LAXS) were used to determine the structure of magnesium bromide and iodide in diethyl ether and THF.[38] The structure of methyl, ethyl and phenyl magnesium bromide in diethyl ether in the concentration range 0.1–1.0 M was also investigated with these two spectroscopic methods.[39]

We decided to perform EXAFS measurements on methyl, ethyl and phenyl magnesium bromide in diethyl ether and vinyl magnesium bromide in THF with concentrations of 3.12, 3.04, 2.96 and 1.56 M. Since in the EXAFS study mentioned above the existence of a second shell could not be observed,[39] we investigated more highly concentrated solutions, thereby increasing the probability of detecting a second or even higher shell, which are a prerequisite for a reasonable structural proposal.

The EXAFS phenomenon is based upon the absorption of X-rays in a particular absorbing atom and the oscillatory variation of the X-ray absorption coefficient μ as a function of the photon energy E beyond an absorption edge. The resulting modulation of $\mu(E)$ provides information about the kind, number and distance of neighbours surrounding the absorbing atom.[40,41]

EXPERIMENTAL

The EXAFS experiment was performed at the bromine K-edge at 13474.0 eV at the beamline RÖMO II at the Hamburger Synchrotronstrahlungslabor (HASYLAB) at DESY, Hamburg, at 20°C, using a Si⟨311⟩ crystal monochromator under ambient conditions (5.4 GeV, beam current 50 mA). Data were collected in the transmission mode with ion chambers. The first ion chamber, monitoring I_0, with a length of 15 cm was continuously flushed with a mixture of 7% argon and 93% nitrogen. The second and third ion chambers, recording I_1 and I_2, respectively, with a length of 30 cm were flushed with 100% argon. The fill of the ion chambers was chosen in such a way that *ca* 10% of the incident X-rays were absorbed in the first ion chamber and about 80% in the sample itself.[42] Energy calibration was monitored with a 30 μm thick anhydrous $MgBr_2$ sample as a reference. All measurements were performed under an inert gas atmosphere. A sample cell suitable for measuring air- and moisture-sensitive compounds was used. We first calculated the sample thickness and, after a test scan, adjusted it to the optimal values depending on the investigated sample.

Data reduction

The common data reduction procedure involves fitting the pre-edge absorption with a Victoreen-type polynomial, extrapolating beyond the edge and subtraction from the total absorption coefficient to give the corrected absorption coefficient. The next step is background removal, which was performed by the use of a modified smoothing spline algorithm, and subsequent normalization with the determined spline. Following Fourier transformation and Fourier filtering in the relevant ranges provides the contribution of one or more backscatterers to these separated coordination shells.[40,41] The background removal of spectra of liquid compounds is very demanding. On the one hand, the high noise level of the data caused by the static disorder is a problem. On the other hand, a high flexibility of the smoothing spline increases the risk of removing part of the few EXAFS oscillations, typical for spectra of liquid compounds. The way of successfully dealing with all the problems and a very detailed description of the used program package with an example of the data analysis for methyl magnesium bromide in diethyl ether are given in ref. 43. In order to determine the coordination number N more accurately, the $\chi(k)$ functions were deconvoluted with the monochromator resolution as a response function. This procedure compensates for the decrease of the $\chi(k)$ amplitude caused by the limited and energy-dependent resolution of the monochromator. In order to determine the degree of association the accuracy to which the coordination number is known plays an important role. The applied weighting scheme and the ranges for Fourier transformation and Fourier filtering for the compounds methyl (MeMgBr), ethyl (EtMgBr), phenyl magnesium bromide (PhMgBr) in diethyl ether and vinyl magnesium bromide (ViMgBr) in THF are shown in Table 1. The background-corrected $k^3\chi(k)$ functions and the Fourier transforms are shown in Fig. 1.

RESULTS

Interpretation and curve fitting with EXCF

The Fourier transforms of all Grignard compounds show a well pronounced first coordination shell (Fourier filtering range 2). It was found that this peak contains the contribution of a single mag-

Table 1. Table of the applied weighting scheme and the ranges of Fourier transformation and Fourier filtering

3	2.74–3.34	2.76–3.38	2.60–3.38	2.56–3.38

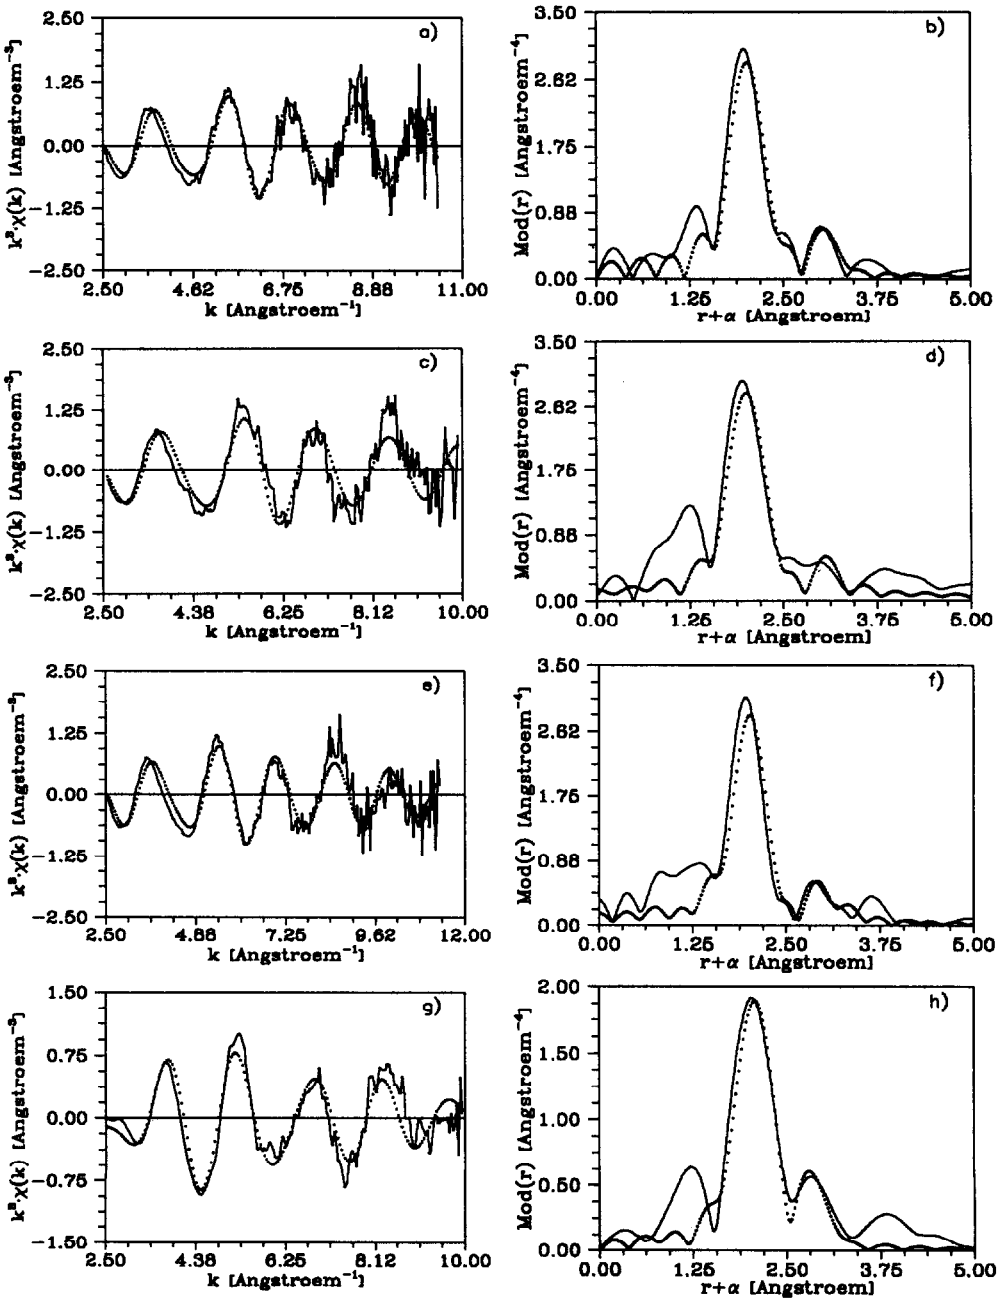

Fig. 1. Experimental (solid line) and theoretically calculated (dots) $k^3\chi(k)$ functions by FEFF, the Fourier transforms and the Fourier transformed best fits (dots) for MeMgBr (a, b), EtMgBr (c, d) and PhMgBr (e, f) in diethyl ether and ViMgBr (g, h) in tetrahydrofuran.

nesium backscatterer to the $k^3\chi(k)$ function. Furthermore, the Fourier transforms show a small second maximum (Fourier filtering range 3). The question now is whether the second peak is an artefact, i.e. a side lobe of the first coordination shell, or a real contribution of other backscatterers. To settle this question the Fourier transforms of the k^n ($n = 0, 1, 2, 3$) weighted $\chi(k)$ functions, multiplied by five different window functions, were compared. The second peak, however, was found in all 20 Fourier transforms of the respective Grignard compound. More proof of the existence of a second coordination shell is that the Fourier filtered ranges of the first peak do not provide a satisfactory description of the $\chi(k)$ functions, i.e. there is a lack of a further frequency component. How many and which kind of backscatterers contribute to this second coordination shell? Only in the case of ViMgBr in THF a single oxygen backscatterer provides the best fit. For all the other compounds the description with a single oxygen backscatterer was insufficient. We tried all reasonable combinations of backscatterer pairs and the oxygen/bromine pair yielded the best results. χ^2, a measure for the agreement of the experimental and theoretically calculated function,[43] was *ca* 200% lower than for other pairs. The improvement reached with a third backscatterer was not significant. Therefore, the existence of a further backscatterer could be ruled out with a high probability. One of the concepts of EXAFS, however, is to achieve a maximum of agreement between theoretically calculated and experimental functions with a mininum of parameters. The curve fitting procedure was performed

with theoretical amplitude and phase functions by McKale,[44] as well as with those calculated by the program FEFF (V3.1).[45,46] With McKale phases and amplitudes, $\lambda(k)$ is approximated by the universal curve for inorganic compounds and the amplitude reducing factor $S_0^2(k)$ was set to 1.0. The program FEFF provides the possibility of exactly calculating $\lambda(k)$ and $S_0^2(k)$, which are used in the least-squares refinement to fit the EXAFS data. The first and the second coordination shell were refined separately, as well as in combination. It is a matter of fact that due to the correlation of the shells and termination of series effects caused by the Fourier filtering, the values obtained by both methods differ marginally.

The results of the least-squares refinement for the combination of the first and second coordination shell—with theoretical amplitude and phase functions calculated by FEFF–are shown in Fig. 1. The structural parameters for the Grignard compounds—i.e. absorber–backscatterer distance r (Å), the corresponding coordination number N, the Debye–Waller factor σ (Å) and the shift of the threshold energy ΔE_0 (eV) obtained with the amplitude and phase functions of FEFF and McKale for the combination of the first and second coordination shell—are shown in Table 2.

Curve fitting with EXCURV90

The structural parameters obtained with EXCURV90 are given in Table 3. The first and second coordination shell were refined together. The results obtained with EXCURV90 provide

[a] Only one shift of the threshold energy ΔE_0 for all backscatterers is calculated within EXCURV90. The fit-index is a measure for the agreement with the experimental data.

additional evidence that the second maximum of the Fourier transform is a real peak. In analogy to the curve-fitting process with EXCF it was tried to describe the Fourier filtered EXAFS functions (Fourier filtering range 1, see Table 1) with one Mg, Br and O backscatterer (MeMgBr, EtMgBr, PhMgBr) or with only one Mg and O backscatterer (ViMgBr). With these backscatterers a good agreement between experimental and theoretically calculated function was achieved. EXCURV90, however, provides the possibility of calculating the significance of added shells when iterations are carried out after adding a new shell. On the contrary to the results of the iterations obtained with EXCF[43] there is a 99% probability for the existence of a further oxygen backscatterer contributing to the second maximum for MeMgBr, EtMgBr and PhMgBr, but not for ViMgBr. For further information concerning the Joyner statistic test see the manual of EXCURV90 and ref. 47.

Curve fitting with model amplitudes and phases

The fit for the experimental data with theoretical amplitude and phase functions yields values of the coordination numbers, which are unexpectedly low, even for the first coordination shell. This is caused by the shortcomings of the used theoretical amplitude and phase functions. Therefore, we tried $MgBr_2$ as a model compound, whose EXAFS spectrum at the bromine *K*-edge was measured as a reference. However, it was impossible to isolate the Br—Mg model amplitude and phase from the first peak in the radial distribution function, because oxygen backscatterers contribute to this peak ($MgBr_2$ is extremely moisture sensitive). Therefore, we decided to use NaBr as a model compound for the Br—Mg pair* for reasons of phase transferability.[48–53] The coordination number for the Br—Na pair was of course corrected for monochromator resolution, too.

With the extracted amplitude and phase functions for the Br—Na absorber–backscatterer pair the number of magnesium atoms in the first shell of bromine in methyl, ethyl, phenyl and vinyl magnesium bromide is 1.60 ± 0.07, 1.62 ± 0.08, 1.33 ± 0.09 and 0.97 ± 0.10. The distances changed to 2.556 ± 0.013, 2.560 ± 0.014, 2.546 ± 0.014 and 2.607 ± 0.015 Å. The deduced standard errors for the distances and coordination numbers are a consequence of possible errors in the extracted model amplitudes and phases.

DISCUSSION

Based upon the structural parameters obtained with the described curve fitting procedures a structural model for the Grignard compounds MeMgBr, EtMgBr and PhMgBr in diethyl ether and ViMgBr in tetrahydrofuran may now be developed. The values of the Br and O coordination numbers will not be discussed, because the contribution of this second coordination sphere to the EXAFS is very small and no model amplitude and phase functions were available. Additionally, the error for the determination of coordination numbers for second shells is *ca* $\pm30\%$.[54] The interpretation of the magnesium coordination numbers, however, is rather reliable. First, the coordination number of the first coordination sphere of the bromine atom calculated with model amplitude and phase functions has considerable confidence. Secondly the first maximum in the radial distribution function contains the contribution of only one kind of backscatterer at a defined distance. With the extracted model amplitude and phase functions for the Br—Na absorber–backscatterer pair, the Mg coordination numbers for methyl, ethyl and phenyl magnesium bromide in diethyl ether and vinyl magnesium bromide in tetrahydrofuran are 1.60 ± 0.07, 1.62 ± 0.08, 1.33 ± 0.09 and 0.97 ± 0.10. The fact that the magnesium coordination numbers are higher than one is an indication of an association of the compounds MeMgBr, EtMgBr and PhMgBr in diethyl ether. This is supported by molecular weight studies.[12,55,56] The existence of a Br—Br pair, as it is deduced from the simulation of the second shell, confirms the association too. However, a Br—Br distance of about the deduced value could also be the result of an equilibrium between $MgBr_2$, MgR_2 and RMgBr. The coordination number of bromine with respect to magnesium, however, would in the case of an equilibrium strictly be one. Considering the structural parameters only, higher associates like oligomers cannot be excluded. However, the following discussion is restricted to monomers and dimers for reasons of clarity. According to the Br—Mg coordination number the percentage of dimers in the ethereal solutions is $60\pm7\%$, $62\pm8\%$ and $33\pm9\%$, respectively. Large angle X-ray scattering (LAXS) investigations revealed a degree of dimerization of 54%, 45% and 34% for 2.7 M, 2.7 M and 1.5 M solutions of methyl, ethyl and phenyl magnesium iodide in diethyl ether, basing upon the

* A normalization of the coordination number of the Br—Br and Br—O pairs seemed to be useless, because the contribution of these pairs to the experimental $k^3\chi(k)$ function is too small. The coordination numbers of these pairs will be discussed only qualitatively and are not used to derive a structure model.

deduced Mg—I coordination numbers.[39] Assuming that the tendency to form associates for organomagnesium ioides is lower than for organomagnesium bromides,[12,55,56] the proposed degree of dimerization of the bromides is in very good agreement with those results. The lower degree of dimerization of phenyl magnesium bromide is caused by the higher steric demands of phenyl groups in common.

Molecular weight studies of organomagnesium bromides in tetrahydrofuran provided no evidence of the existence of associated species, even at very high concentrations.[57,58] The Br—Mg coordination number of 0.97 ± 0.10 for the solution of vinyl magnesium bromide in tetrahydrofuran confirms the existence of monomers, too. Also, no Br—Br absorber–backscatterer pair was found by analysing the EXAFS data.

Summarizing these results, the samples in diethyl ether are mixtures of monomers and dimers. In tetrahydrofuran, however, only monomers are formed. The structure of the monomeric species is now deduced from the obtained Br—Mg and Br—O distances.*

With the results obtained with the programs EXCF (see Table 2) and EXCURV90 (see Table 3) for three backscatterers (Mg, Br, O), Br—Mg—O bond angles of 120.0°, 109.48° and 90.0° and the corresponding Mg—O distances were calculated. The average Mg—O distance in crystalline Grignard compounds is 2.10 ± 0.07 Å.[35–37,59–61] Assuming that there is no considerable change of this distance in solution, the deduced Mg—O distances should be about 2.10 ± 0.30 Å, depending on the calculated Br—Mg—O angle. For the compounds methyl, ethyl and phenyl magnesium bromide in diethyl ether values of Mg—O distances in the mentioned range were reproduced for a Br—Mg—O bond angle of 109.48°. A bond angle of 90° is the only reasonable one for vinyl magnesium bromide in tetrahydrofuran (see Table 4). The conclusion is that the systems in diethyl ether and ViMgBr in tetrahydrofuran are most likely to have tetrahedral or octahedral monomeric structure, respectively.

A Br—Br absorber–backscatterer pair was only found in the etheral solutions, but not for ViMgBr in tetrahydrofuran. Up to now all investigations of Grignard compounds exclude an *inter*molecular Br—Br interaction between monomeric species. In associated structures, the halogen atoms commonly function as bridging atoms. Therefore, we assume that the Br—Br pair belongs to a dimer species. Nevertheless, an EXAFS spectroscopical detection of an intermolecular Br—Br contact is very unlikely due to the high static and thermal disorder in these solutions and the resulting high Debye–Waller factors.[62]

From the experimentally determined values of Br—Mg and Br—Br distances a Br—Mg—Br bond angle of $89.9 \pm 1.6°$ was deduced (see Table 4). Since the compounds in diethyl ether are most likely to have a tetrahedral monomer geometry, the monomer subunits could form distorted tetrahedral dimers. However, such a distorted tetrahedral dimer in solution is very unlikely. X-ray diffraction studies showed that Grignard compounds crystallize as monomer tetrahedral dietherates and do not have any tendency to form distorted tetrahedral dimers.[35–37,60] A more probable structure model with a Br—Mg—Br bond angle of $89.9 \pm 1.6°$ is provided by the formation of octahedral dimers. Assuming such an octahedral dimer, an additional and shorter Br—O distance than this one we found with EXCF should have been detected. Indeed, when we performed iterations with EXCURV90 a further and distinctively shorter Br—O distance with a 99% probability for its existence was determined.

With the results for the Br—Mg and the short Br—O distances, the calculation of Mg—O distances for Br—Mg—O bond angles of 120.0°, 109.48° and 90.0° was repeated. Only a bond angle of 90.0° provides a reasonable Mg—O distance (see Table 4). The determined bond angle favours the proposed octahedral dimers, but does not exclude the existence of octahedral monomers.

The Grignard compounds methyl, ethyl and phenyl magnesium bromide are existing as monomers of the type T_m and O_m as well as dimers of the type O_d (see Fig. 2). The percentage of dimer species is $60 \pm 7\%$, $62 \pm 8\%$ and $33 \pm 9\%$. For methyl and ethyl magnesium bromide the equilibrium is on the side of the dimer and for phenyl magnesium bromide on the side of the monomer species due to steric reasons. The structure of vinyl magnesium bromide in THF can best be described as an octahedral monomer of the type O_m.

It should be noted here that the EXAFS-spectroscopical results do not give any information concerning the *position* of the organic residues at the magnesium atom of the dimers. Therefore, a distinction between octahedral dimers of the types R_2MgBr_2Mg and $RMgBr_2MgR$ (with supporting molecules of solvation) is not possible. The ^1H NMR studies of methyl and ethyl magnesium bromide in diethyl ether[25,26] provided evidence for octahedral dimers of the type R_2MgBr_2Mg,

* The errors for absorber–backscatterer distances of second or higher shells are only *ca* 5%.[54]

Table 4. The derived Br—Mg—Br bond angles and Mg—O distances, deduced from the obtained Br—Mg, Br—Br and Br—O distances (the standard errors, if indicated, are a consequence of the combination of *all* iteration results, i.e. multi-shell fits with EXCF as well as with EXCURV90)

Compound		∠Br—Mg—Br (°)	Mg—O (Å) 120.0°	Mg—O (Å) 109.48°	Mg—O (Å) 90.0°

			1.44	1.70	2.38
PhMgBr	Three shell fits	89.4±0.1	1.76±0.02	2.03±0.03	2.72±0.03
	Four shell fit	89.7	1.74	2.01	2.70
			1.41	1.66	2.33
ViMgBr	Two shell fits	—	1.31±0.01	1.55±0.01	2.24±0.02

whereas phenyl magnesium bromide in diethyl ether exists as a mixture of R_2MgBr_2Mg and $RMgBr_2MgR$.[27-29] Our MOPAC V6.0[63,64] calculations with the Hamilton operator PM3, however, showed that octahedral dimers of the type $RMgBr_2MgR$ are more stable than the R_2Mg Br_2Mg species *independent* from the kind of the organic residue R.

The deduced Mg—O distance for an octahedral geometry (O_m, O_d) is 2.35±0.03 Å for the samples dissolved in diethyl ether, for vinyl magnesium bromide in tetrahydrofuran it is 2.24±0.02 Å. Such an Mg—O distance in tetrahydrofuran can only be assigned to the structure model O_m, whereas this distance for the compounds in diethyl ether can be assigned to the complexes of the type O_m and O_d or O_d only. The structure model O_d is very reasonable

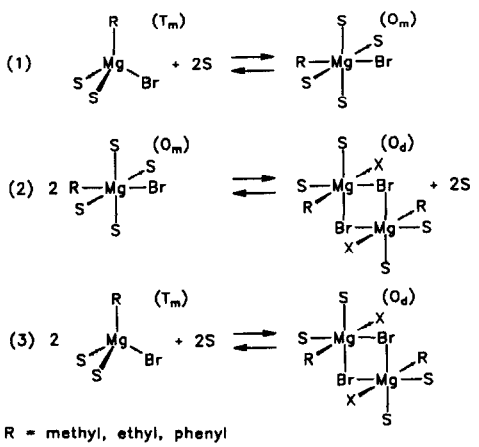

Fig. 2. Proposed equilibria for the compounds methyl, ethyl and phenyl magnesium bromide in diethyl ether.

owing to the determined coordination numbers and the exisence of a Br—Br pair. The structure model for the monomer of the type O_m, however, does not provide an explanation for the increase of 0.11±0.05 Å for the Mg—O distance when the solvent is changed from diethyl ether to tetrahydrofuran. On the contrary, X-ray diffraction studies suggest that the Mg—O distance decreases about 0.08±0.02 Å when changing the coordinated solvent from diethyl ether to tetrahydrofuran.[35-37,59-61] A possible explanation is that the systems in diethyl ether do not have an octahedral monomer (O_m), but only an octahedral dimer geometry of the type O_d. Therefore, the increase of the Mg—O distance is a consequence of the steric demands in the structure model O_d. For the mentioned reasons, a satisfactory description of the systems in diethyl ether is given by the equilibrium 3 in Fig. 2.

A further question is why the monomers in diethyl ether have a tetrahedral structure whereas in tetrahydrofuran they have an octahedral geometry. X-ray diffraction studies reveal that Grignard compounds in diethyl ether preferably crystallize in a tetrahedral geometry.[35-37,60] In tetrahyrofuran, however, mainly five- and six-fold coordination around magnesium is found.[59,61] The authors make the lower steric demand of tetrahydrofuran responsible for that phenomenon.

Considering the structure models T_m and O_d one might ask the question why no contribution of a C backscatterer to the second coordination sphere has been detected. The EXAFS measurements, however, have been performed at 20°C and referring to the results of NMR investigations, there is a very fast exchange of the alkyl and aryl groups at

this temperature. At *ca* −60°C the exchange is slow enough to distinguish between RMgX and R_2Mg species.[27–29] As mentioned before, high exchange rates cause relatively high Debye–Waller factors and, therefore, an EXAFS spectroscopical detection of such near neighbour distances is quite impossible.

The number of organic substituents R is much lower than the number of coordinated solvent molecules. For example, the structure models T_m, O_m and O_d have two, four or six oxygen atoms close to the bromine atom, respectively. Therefore, the detection of oxygen backscatterers in the second coordination sphere is much more probable, although the Debye–Waller factors of these absorber–backscatterer pairs are very high too.

The following section contains some concluding remarks concerning the shift of the threshold energy $\Delta E_0 = E_0^{ref} - E_0$, where E_0^{ref} is the threshold energy of the reference compound $MgBr_2$. These shifts contain some information about the reactivity and the carbanionic character of the respective Grignard compound. The negative shifts of methyl, ethyl and phenyl magnesium bromide (−7.1, −4.6 and −3.3 eV) confirm that the partial negative charge of the bromine atom is partially transferred to the organic group R, thereby increasing the energy required to eject a photoelectron. This fact is supported by UV spectroscopical studies.[65] The carbanionic character and the reactivity of the Grignard compounds increases with Me > Et > Ph, which is in very good agreement with the calculated shifts of the threshold energy. Vinyl magnesium bromide has the lowest reactivity of all the investigated Grignard compounds. This supports the positive shift of 0.4 eV. Assuming that the bromine atom in $MgBr_2$ should have the most negative partial charge, a *positive* shift is very surprising. An explanation can be a stronger +I and +M-effect of the vinyl group compared with the phenyl group. Furthermore, the existence of monomers only in the tetrahydrofuran solution makes a delocalization of the charge more difficult.

CONCLUSION

The structure models, the obtained distances, the deduced degree of dimerization for the Grignard compounds methyl, ethyl and phenyl magnesium bromide in diethyl ether and vinyl magnesium bromide in tetrahydrofuran are summarized in Fig. 3. The standard errors are a consequence of the combination of the results obtained with different theoretical amplitude and phase functions, i.e. McKale, FEFF and those of EXCURV90 and the empirical model amplitude and phase functions.

The simulation of the EXAFS spectra of the Grignard compounds with only one of the named amplitude and phase functions would be rather incomplete and of an unscientific nature, because none of them can claim to be the best one.

Abstract—The solvation structure of the iron(III) ion in N,N-dimethylacetamide (DMA) has been determined by means of EXAFS (extended X-ray absorption fine structure) spectroscopy and the complex formation between iron(III) and thiocyanate ions has been calorimetrically and spectrophotometrically studied in DMA containing $(C_2H_5)_4NClO_4$ (0.4 mol dm^{-3}) as a constant ionic medium at 25°C. The iron(III) ion is surrounded with six DMA molecules and has an octahedral $[Fe(dma)_6]^{3+}$ structure. Calorimetric and spectrophotometric titration data were well explained in terms of the formation of $[Fe(SCN)_n]^{(3-n)+}$ (n = 1–6) and their formation constants, reaction enthalpies and entropies were determined. Electronic spectra of individual iron(III) thiocyanato complexes in DMA were also extracted. The complexation of iron(III) with thiocyanate ions in DMA is more favorable than that in N,N-dimethylformamide (DMF). The favorable formation is mainly due to the more negative reaction enthalpies in DMA than those in DMF, which is resulting from the larger steric interaction between the ligating DMA molecules around the iron(III) ion than the DMF ones.

We have studied calorimetrically and spectrophotometrically the complex formation reactions between iron(III) and thiocyanate ions in water and N,N-dimethylformamide (DMF).[1,2] The $[Fe(SCN)]^{2+}$, $[Fe(SCN)_2]^{+}$, $[Fe(SCN)_3]$, $[Fe(SCN)_4]^{-}$ and $[Fe(SCN)_5]^{2-}$ complexes are formed in DMF,[2] while the formation of only three complexes, $[Fe(SCN)]^{2+}$, $[Fe(SCN)_2]^{+}$ and $[Fe(SCN)_3]$, was observed in water.[1] The complexation in DMF is accompanied by large and positive entropies and is markedly enhanced compared with that in water. The large and positive entropies result from weak solvent–solvent interactions, as generally seen in aprotic solvents.[3,4]

N,N-Dimethylacetamide (DMA) is an aprotic donor solvent and has a molecular structure and solvent properties similar to those of DMF, e.g. relative dielectric constants ε(DMA) = 37.8, ε(DMF) = 36.7; donor numbers D_N(DMA) = 27.8, D_N(DMF) = 26.6; acceptor numbers A_N(DMA) = 13.6, A_N(DMF) = 16.0.[5,6] However, the structure and properties of the metal complexes in DMA are markedly different from those in DMF. The zinc(II) ion has an octahedral structure in DMF, while a solvation equilibrium, $[Zn(dma)_4]^{2+} + 2dma = [Zn(dma)_6]^{2+}$, is established in DMA.[7] The nickel(II) ion has an octahedral structure and forms a series of the $[NiCl_n]^{(2-n)+}$ (n = 1–4) complexes both in DMF and DMA.[7–9] However, the structure of the chloro complexes is significantly different in the two solvents. The octahedral $[NiCl(dmf)_5]^{+}$ and $[NiCl_2(dmf)_4]$ complexes and the tetrahedral $[NiCl_3(dmf)]^{-}$ and $[NiCl_4]^{2-}$ ones are formed in DMF.[8] The tetrahedral $[NiCl_3(dma)]^{-}$ and $[NiCl_4]^{2-}$ complexes are also formed in DMA, while the following equilibria are present for the mono- and dichloro complexes: $[NiCl(dma)_4]^{+} + dma = [NiCl(dma)_5]^{+}$ and $[NiCl_2(dma)_2] + dma = [NiCl_2(dma)_3]$.[9] These strongly indicate that the coordination of DMA molecules to metal ions is sterically hindered by the presence of an acetyl methyl group within a DMA molecule.

In this report we describe the complexation of iron(III) with thiocyanate ions in DMA in order to obtain more information on the solvent effect of DMA. The solvation structure of the iron(III) ion in DMA was first determined by means of EXAFS (extended X-ray absorption fine structure) spectroscopy because the solvation structure of metal ions in solution is essential to interpret the thermodynamics of complexation. The thermodynamic parameters for the formation of the iron(III) thiocyanato complexes were then determined in DMA containing $(C_2H_5)_4NClO_4$ (0.4 mol dm^{-3}) as a constant ionic medium by calorimetry and spectrophotometry at 25°C. The thermodynamic parameters thus obtained in DMA are compared with those in water and DMF.

EXPERIMENTAL

Reagents

All chemicals used were of reagent grade. Iron(III) perchlorate was recrystallized once from an aqueous perchloric acid solution. The DMA solvate of iron(III) perchlorate was prepared by dissolving the hydrate of iron(III) perchlorate in DMA and then recrystallized once from DMA and finally dried at room temperature in a vacuum oven. Tetraethylammonium perchlorate was recrystallized once from water. Tetraethylammonium thiocyanate was used without further purification. These compounds were dried at room temperature in vacuum. N,N-Dimethylacetamide was purified as described elsewhere.[7] All DMA solutions were prepared and treated under a dry nitrogen atmosphere.

Calorimetric and spectrophotometric measurements

Calorimetric measurements were carried out by using a fully automatic on-line calorimetry system,[10] consisting of a twin-type calorimeter (Tokyo Riko, Japan). Test solutions contained $(C_2H_5)_4NClO_4$ (0.4 mol dm^{-3}) as a constant ionic medium. An iron(III) perchlorate DMA solution (40 cm^3) was placed in a stainless-steel vessel, the inside wall of which was coated with Teflon, and was titrated with a $(C_2H_5)_4NSCN$ DMA (0.4 mol dm^{-3}) solution using an APB-118 autoburet (Kyoto Electronics, Japan) under a dry nitrogen atmosphere. The vessel was inserted in an aluminum block thermostated at (25.0±0.0001)°C in an air bath. Heats of complexation ranging from 0.2 to 2.0 J at each titration point were measured with a certainty of ±0.02 J and were corrected for heat of dilution of the titrant, which had been determined in advance by separate experiments and was found to be very small.

Electronic spectra were measured at 25°C using a UV-2100 spectrophotometer (Shimadzu, Japan) equipped with a PC-9801VM computer (NEC, Japan), which recorded absorbance data in 1 nm intervals over the wavelength range 300–700 nm. A flow cell with a path-length of 0.5 cm was connected to a titration vessel through Teflon and glass tubes. An iron(III) perchlorate DMA solution placed in the vessel was titrated with a $(C_2H_5)_4NSCN$ DMA (0.4 or 0.04 mol dm^{-3}) solution under a dry nitrogen atmosphere. Spectrophotometric data at 50 selected wavelengths over the range 300–600 nm were employed for the subsequent least-squares calculation.

The overall formation of the $[Fe(SCN)_n]^{(3-n)+}$ complex can be defined as eqs (1) and (2) if the formation of only mononuclear species is assumed.

$$Fe^{3+} + nSCN^- = [Fe(SCN)_n]^{(3-n)+} \quad (1)$$

$$\beta_n = [Fe(SCN)_n^{(3-n)+}]/[Fe^{3+}][SCN^-]^n \quad (2)$$

A heat q_i measured at a titration point i is represented by the overall formation constant β_n and the enthalpy $\Delta H^0_{\beta n}$ of $[Fe(SCN)_n]^{(3-n)+}$ as eq. (3), where V_i denotes the volume of the test solution.

$$q_i = -(V_i \Sigma \beta_n (\Delta H^0_{\beta n})[Fe^{3+}]_i [SCN^-]_i^n - V_{i-1} \Sigma \beta_n (\Delta H^0_{\beta n})[Fe^{3+}]_{i-1}[SCN^-]_{i-1}^n) \quad (3)$$

Similarly, an absorbance A_{ij} measured in a solution i at a given wavelength λ_j is expressed by the formation constant β_n and the molar absorption coefficient $\varepsilon_n(\lambda_j)$ of $[Fe(SCN)_n]^{(3-n)+}$ as eq. (4).

$$A_{ij} = \Sigma \varepsilon_n(\lambda_j) \beta_n [Fe^{3+}]_i [SCN^-]_i^n + \varepsilon_{Fe}(\lambda_j)[Fe^{3+}]_i + \varepsilon_{SCN}(\lambda_j)[SCN^-]_i \quad (4)$$

The concentrations of free Fe^{3+} and SCN^- are related to their total concentrations, $C_{Fe,i}$ and $C_{SCN,i}$, in a solution i by the following mass-balance equations.

$$C_{Fe,i} = [Fe^{3+}]_i + \Sigma \beta_n [Fe^{3+}]_i [SCN^-]_i^n \quad (5)$$

$$C_{SCN,i} = [SCN^-]_i + \Sigma n \beta_n [Fe^{3+}]_i [SCN^-]_i^n \quad (6)$$

Formation constants and enthalpies were obtained simultaneously by minimizing the error-square sum $\Sigma(q_{i,obs} - q_{i,calc})^2$, formation constants and molar absorption coefficients by $\Sigma\Sigma(A_{ij,obs} - A_{j,calc})^2$ using a non-linear least-squares program according to an algorithm proposed by Marquardt.[11]

EXAFS measurements

EXAFS spectra were measured around the iron K edge in the transmission mode using the BL6B

station at the Photon Factory of the National Laboratory for High Energy Physics (KEK).[12] White synchrotron radiations were monochromatized by an Si(111) double crystal. The two crystals were detuned by 50% to the fundamental above the edge in order to eliminate higher order harmonics. Two sample solutions were prepared by dissolving the DMA solvate and hydrate of iron(III) perchlorate in DMA and water, respectively. Concentrations of iron(III) are *ca* 0.2 and *ca* 0.4 mol dm^{-3} in DMA and water, respectively. The aqueous solution contained perchloric acid (3 mol dm^{-3}) in order to prevent the hydrolysis of iron(III). A glass fibre filter, which had been dried at 100°C in an air bath, was immersed in a sample solution and then sealed in a Mylar bag in order to prevent the evaporation of solvent and to avoid moisture. An effective jump at the absorption edge was obtained by changing the number of filters. The apparent absorbance was obtained as $\ln(I_0/I)$, where I and I_0 are X-ray intensities with and without a sample, respectively. The intensities I_0 and I were simultaneously measured by ionization chambers filled with nitrogen and nitrogen(85%)+argon(15%) gas, respectively.

Details of the data reduction procedure of the raw EXAFS spectra have been described elsewhere.[2,7,13–15] The threshold energy of a K-shell electron E_0 was selected as the position of the half-height of the edge jump in each sample and was 7.125 keV in the present study. The structure parameters were finally determined in the k space by comparing the observed EXAFS spectrum and the model function $\chi(k)_{calc}$ according to the single-electron and single-scattering theory.[16–19] The back-scattering amplitude $F(\pi,k)$ and the total scattering phase shift $\alpha(k)$ were quoted from the literature.[20] To minimize the error-square sum $\Sigma k^6(\chi(k)_{obs}-\chi(k)_{calc})^2$, the E_0 value and the mean free path of the photoelectron λ were first evaluated from a standard sample of known structure (an aqueous iron(III) perchlorate solution containing $[Fe(H_2O)_6]^{3+}$).[21] The parameters were then kept constant in the course of the subsequent structural analysis of unknown samples, while the bond length r, the Debye–Waller factor σ and the coordination number n were optimized as variables.

RESULTS

Calorimetry and spectrophotometry

Figure 1 depicts calorimetric titration curves for the iron(III) thiocyanato system in the $(C_2H_5)_4NClO_4$ DMA (0.4 mol dm^{-3}) solution. The heat of complexation q measured at each titration point is normalized with the volume of titrant added δv and the concentration of the ligand in the titrant $C_{SCN,tit}$ and the term $-q/(\delta v C_{SCN,tit})$ is plotted against C_{SCN}/C_{Fe}, where C_{SCN} and C_{Fe} denote the total concentration of the thiocyanate and iron(III) ions, respectively, in solution.

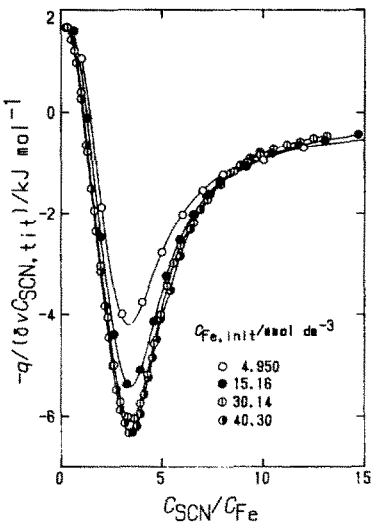

Fig. 1. Calorimetric titration curves for the iron(III) thiocyanato system in N,N-dimethylacetamide containing 0.4 mol dm^{-3} $(C_2H_5)_4NClO_4$ at 25°C. Concentrations of iron(III) ion in initial test solutions, $C_{Fe,init}$ (mmol dm^{-3}), are given. The solid lines are calculated by using constants in Table 1.

The calorimetric titration curves were analysed by assuming the formation of plausible sets of mononuclear complexes and the results are given in Table 1. The calorimetric titration curves were not reproducible by an assumption of the formation of four complexes, i.e. $[Fe(SCN)]^{2+}$, $[Fe(SCN)_2]^+$, $[Fe(SCN)_3]$ and $[Fe(SCN)_4]^-$, because of large R and σ values [see the set (1–4) in Table 1]. The set (1–5), assuming the formation of $[Fe(SCN)]^{2+}$, $[Fe(SCN)_2]^+$, $[Fe(SCN)_3]$, $[Fe(SCN)_4]^-$ and $[Fe(SCN)_5]^{2-}$, gave small R and σ values. The set (1–6), considering the formation of $[Fe(SCN)]^{2+}$, $[Fe(SCN)_2]^+$, $[Fe(SCN)_3]$, $[Fe(SCN)_4]^-$, $[Fe(SCN)_5]^{2-}$ and $[Fe(SCN)_6]^{3-}$, gave appreciably smaller R and σ values than the set (1—5). Furthermore, a significant improvement of uncertainties involved in the formation constants resulted for the set (1–6). Hence, we finally propose the formation of the $[Fe(SCN)]^{2+}$, $[Fe(SCN)_2]^+$, $[Fe(SCN)_3]$, $[Fe(SCN)_4]^-$, $[Fe(SCN)_5]^{2-}$ and $[Fe(SCN)_6]^{3-}$ complexes in DMA. As seen in Fig. 1, the solid lines calculated by using the parameter values for the set (1–6) reproduce well the experimental points over the whole range of C_{SCN}/C_{Fe} examined.

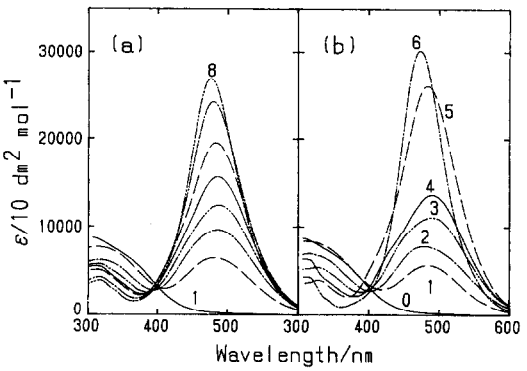

Fig. 2. (a) Typical variation of electronic spectra of iron(III) thiocyanate N,N-dimethylacetamide solutions with varying C_{SCN}/C_{Fe} ratios in the range 300–600 nm. The total concentrations of iron(III) and thiocyanate ions, C_{Fe} and C_{SCN} (mmol dm^{-3}), in measured solutions are (1) 0.3076 and 0, (2) 0.3038 and 0.5004, (3) 0.2965 and 1.466, (4) 0.2734 and 4.505, (5) 0.2121 and 12.58, (6) 0.1025 and 27.02, (7) 0.09500 and 90.34 and (8) 0.04117 and 260.9. (b) Electronic spectra of individual iron(III) thiocyanato complexes in N,N-dimethylacetamide. The number n represents $[Fe(SCN)_n]^{(3-n)+}$.

Figure 2(a) shows the typical variation of electronic spectra measured with varying the C_{SCN}/C_{Fe} mole ratios in the $(C_2H_5)_4NClO_4$ DMA (0.4 mol dm^{-3}) solution, where absorbances were normalized with a unit concentration of the iron(III) ion.

The spectrophotometric titration data were analysed in a similar manner to that employed for the calorimetric data. However, a least-squares calculation failed to derive reliable formation constants because of the monotonous variation of the spectra as shown in Fig. 2(a). We then analysed the spectrophotometric data on the basis of the formation constants calorimetrically obtained and the results are compared in Table 2. As seen in the table, the set (1–6), considering the formation of $[Fe(SCN)]^{2+}$, $[Fe(SCN)_2]^+$, $[Fe(SCN)_3]$, $[Fe(SCN)_4]^-$, $[Fe(SCN)_5]^{2-}$ and $[Fe(SCN)_6]^{3-}$, gave the smallest R and σ values and satisfactorily reproduced variation of the spectra. The spectrophotometric titration data thus confirmed the presence of the $[Fe(SCN)]^{2+}$, $[Fe(SCN)_2]^+$, $[Fe(SCN)_3]$, $[Fe(SCN)_4]^-$, $[Fe(SCN)_5]^{2-}$ and $[Fe(SCN)_6]^{3-}$ complexes in DMA. Figure 2(b) shows the electronic spectra of individual iron(III) thiocyanato complexes extracted.

Figure 3 depicts the species distribution of the iron(III) thiocyanato complexes in the $(C_2H_5)_4NClO_4$ DMA (0.4 mol dm^{-3}) solution, along with that in DMF and water.

EXAFS

The extracted EXAFS oscillations in the form $k^3\chi(k)$ and their Fourier transforms $|F(r)|$ (uncorrected for the phase shift) are shown in Figs 4(A) and (B), respectively. Considering that DMA and

water are oxygen-donor solvents, the first intense peaks at 160 pm in the $|F(r)|$ curves are due to Fe—O bonds in the first coordination sphere of the iron(III) ion. The position and height of the first peaks in the $|F(r)|$ curves are virtually the same for the two solutions. The octahedral structure of the hydrated iron(III) ion has been established in water.[21] The iron(III) ion is thus expected to have an octahedral structure in DMA as well as in water.

The structural parameters r, σ and n of the iron(III) ion in DMA were finally determined by a non-linear least-squares calculation. The least-squares method was applied to the Fourier filtered $k^3\chi(k)$ values over the k range 4.0×10^{-2}–13.5×10^{-2} pm^{-1}. The inverse Fourier transformation was performed over the r range 85–210 pm. The E_0 and λ values were estimated in advance from an aqueous iron(III) perchlorate solution involving the $[Fe(H_2O)_6]^{3+}$ ion of known structure.[21] The Fe—O bond length within the $[Fe(H_2O)_6]^{3+}$ ion was also allowed to vary in order to check the reproducibility of the value. The r, σ and n values for the iron(III) ion in DMA were then refined by adopting the E_0 and λ values determined. The best fit values are listed in Table 3. The solid lines calculated using the parameter values thus obtained reproduce well the experimental points, as depicted in Fig. 4(C). The Fe—O bond length within the $[Fe(H_2O)_6]^{3+}$ ion agrees well with the literature values[21] and the E_0 and λ values are well approximated in the present study. The solvation number of nearly six was obtained for the iron(III) ion in DMA and the least-squares calculation thus derived a conclusion that the iron(III) ion has an octahedral $[Fe(dma)_6]^{3+}$ structure.

DISCUSSION

A series of $[Fe(SCN)_n]^{(3-n)+}$ (n = 1–6) complexes are extensively formed in DMA. The stepwise thermodynamic quantities for the formation of the complexes are summarized in Table 4, together with those in DMF and water.

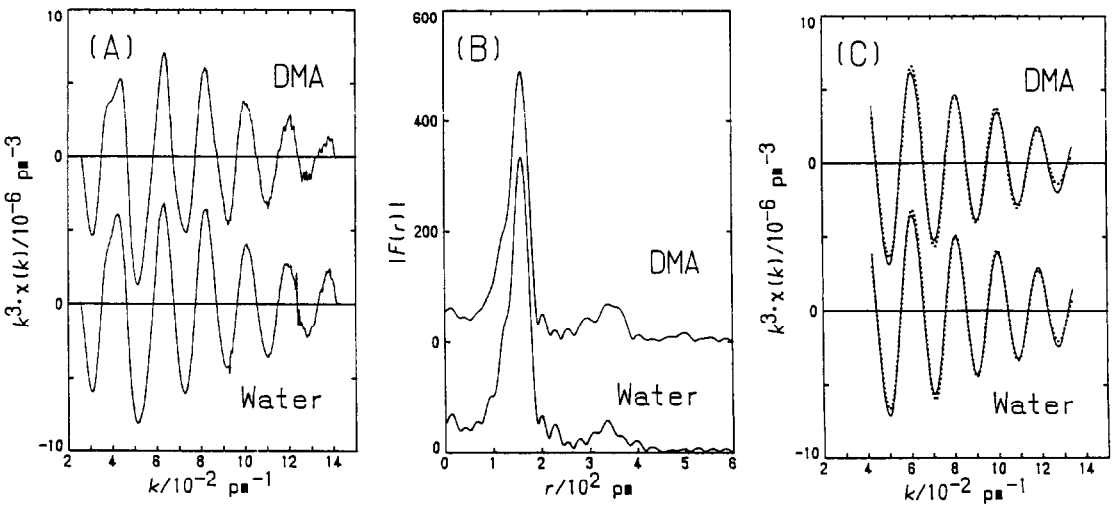

Fig. 4. (A) The EXAFS spectra $\chi(k)$ weighted by k^3 for DMA and aqueous solutions of iron(III) perchlorate. (B) The Fourier transforms $|F(r)|$ of the $k^3\chi(k)$ values shown in (A), uncorrected for the phase shift. (C) The Fourier filtered $k^3\chi(k)$ curves for the samples solutions. The observed values are shown by dots and calculated ones using parameter values in Table 4 are shown by solid lines.

Species	r (pm)	σ (pm)	n
$[Fe(dma)_6]^{3+}$	200(1)	6.0(0.1)	5.9(0.1)
$[Fe(H_2O)_6]^{3+}$	200(1)	5.6(0.1)	6[c]

[a] The values in parentheses refer to standard deviations.

[b] E_0 = 7133.6(2) eV and λ = 646(12) pm.

[c] The values were kept constant during the calculations.

The thiocyanate ion can bind to metal ions through either the nitrogen or sulphur atom, depending on the nature of the metal ions. First-row divalent transition metal ions, which are relatively hard acceptors, prefer a hard nitrogen donor to form N-coordinated isothiocyanato complexes.[22-24] The relatively soft mercury(II) ion prefers a soft sulphur donor to form S-coordinated thiocyanato complexes.[23,24] We expect that the thiocyanate ion binds to the iron(III) ion with its nitrogen donor site in DMA because iron(III) is a hard acceptor.

The iron(III) ion is coordinated with six DMA molecules and has an octahedral $[Fe(dma)_6]^{3+}$ structure in DMA, according to the present EXAFS measurements. The $[Fe(SCN)_6]^{3-}$ complex is also expected to have an octahedral structure. If any of the $[Fe(SCN)_n]^{(3-n)+}$ (n = 1–5) complexes has either a five- or four-coordination structure, extensive desolvation occurs at a certain step of complexation accompanied by large and positive enthalpy and entropy changes. Also, large and negative enthalpy and entropy values should be observed at a higher step of complexation, since the iron(III) ion finally forms the six-coordinate $[Fe(SCN)_6]^{3-}$ complex. However, the stepwise thermodynamic quantities show a monotonous change as seen in Table 4 and thus no structural change occurred at any step of complexation. It is thus concluded that the $[Fe(SCN)_n]^{(3-n)+}$ (n = 1–5) complexes have a six-coordinate octahedral structure like the $[Fe(dma)_6]^{3+}$ ion.

The formation of the iron(III) thiocyanato complexes in aprotic DMA and DMF is more favorable than that in protic water (see Fig. 3 and Table 4). The favorable formation in DMA and DMF than that in water is mainly due to the more positive entropy values in these two solvents. On the other hand, the enthalpy changes are less negative and thus less favorable in the former two solvents than in the latter. The iron(III) ion is octahedrally solvated in the three solvents and the Fe—O bond

[a] The values in parentheses refer to three standard deviations.

lengths are all 200 pm.[1,2] The electron-pair donating ability of DMA and DMF [e.g. the donor number D_N(DMA) = 27.8, D_N(DMF) = 26.6] is stronger than that of water (14.8).[5,6] The less negative enthalpy values in DMA and DMF than those in water is thus attributed to the stronger solvation of the iron(III) ion in the former two solvents than in the latter.

The $[Fe(SCN)_n]^{(3-n)+}$ (n = 1–5) complexes are all more stable in DMA than in DMF. However, the enthalpic and entropic contributions to the free energy terms are different in each step.

The formation of $[Fe(SCN)]^{2+}$ in DMA is associated with larger entropy than that in DMF, while the entropy values for the formation of $[Fe(SCN)_2]^+$, $[Fe(SCN)_3]$ and $[Fe(SCN)_4]^-$ are rather similar both in DMA and DMF. The presence of an acetyl methyl group in a DMA molecule causes large steric repulsion between DMA molecules around the iron(III) ion, which restricts the motion of DMA molecules. The DMA molecules in the first coordination sphere of the hexa-solvated iron(III) ion may lose freedom of motion to a greater extent than DMF and thus the formation of $[Fe(SCN)]^{2+}$ in DMA is associated with larger entropy than that in DMF. Once $[Fe(SCN)]^{2+}$ is formed in DMA, DMA molecules in the complex as well as in the higher complexes have similar freedom of motion to the relevant complexes in DMF. Hence, the entropy values for each step of the formation of $[Fe(SCN)_n]^{(3-n)+}$ (n = 2–4) are similar both in DMA and DMF.

The formation of $[Fe(SCN)]^{2+}$, $[Fe(SCN)_2]^+$, $[Fe(SCN)_3]$ and $[Fe(SCN)_4]^-$ in DMA are all enthalpically preferred over DMF. Moreover, the difference in the ΔH_n^0 values increases with increasing the ligand number n. Judging from the electron-pair donating properties of DMA and DMF, energies needed for breaking the Fe—O bonds must be slightly larger for DMA than for DMF. In the crystal the metal—O—C—N torsion angles largely deviate from 180° in a DMA solvate,[25] while in a DMF solvate the metal—O—C—N torsion angles are close to 180°.[26] Hence, DMA molecules are conformationally unstable compared with DMF molecules in the first coordination sphere. As a result of a replacement of a DMA molecule with a thiocyanate ion, the liberated DMA molecule is stabilized in the bulk, which causes the more negative enthalpies in DMA than in DMF. Also, the conformational stabilization of DMA molecules within complexes increases with increasing the ligand number n by the stepwise replacement with the thiocyanate ion. Thus, the stepwise formation of $[Fe(SCN)_n]^{(3-n)+}$ (n = 1–4) in DMA is enthalpically more favorable than in DMF.

In $[Fe(SCN)_4]^-$, in which the coordination of solvent molecules to the central metal ion may not be sterically hindered, the electron-pair donating ability of the solvents may be reflected in the stepwise formation of $[Fe(SCN)_5]^{2-}$. Thus, the more exothermic stepwise formation of $[Fe(SCN)_5]^{2-}$ in DMF than in DMA results.

Acknowledgements—EXAFS measurements were performed under the approval of the Photon Factory Program Advisory Committee (Proposal No. 91-005).

Abstract—The heavier lanthanide nitrate complexes with DB30C10 have been prepared in acetonitrile. These new complexes with the general formula $[Ln(NO_3)_2(OH_2)_2(DB30C10)]_2 \cdot [Ln(NO_3)_5] \cdot CH_3CN$ (Ln = Sm–Lu) have been characterized by means of elemental analysis, IR spectra and conductivity measurement. The crystal and molecular structure of $[Lu(NO_3)_2(OH_2)_2(DB30C10)]_2 \cdot [Lu(NO_3)_5] \cdot 5CH_3NO_2$ has been determined by single-crystal X-ray diffraction. The asymmetric unit contains three independent ions: two cations, $[Lu(NO_3)_2(OH_2)_2(DB30C10)]^+$, with nine-coordinate lutetium ions and one anion, $[Lu(NO_3)_5]^{2-}$, with a 10-coordinate lutetium(III) ion. The coordination geometries of the cations and anion are distorted tricapped trigonal prism and distorted bicapped square antiprism, respectively.

Many rare earth-crown ether complexes have been investigated and some have been studied by single-crystal X-ray diffraction methods.[1,2] Among these studies the rare earth complexes with large cavity crown ethers have been less reported.[3] In order to investigate the coordination ways of large cavity crown ethers with rare earth ions we previously synthesized a series of complexes of the heavier lanthanide nitrates with dibenzo-24-crown-8 (DB24C8) and studied their molecular structure.[4] We found that the lanthanide nitrates and DB24C8 formed the hydrogen bonding complexes $[Ln(NO_3)_3(OH_2)_3] \cdot (DB24C8)$ (Ln = Gd–Lu), in which the lanthanide(III) ions were not directly coordinated to the crown ether, but coordinated to three bidentate nitrate groups and three water molecules, the crown ether molecule was hydrogen bonded to the water molecules.[4] As an extension of our previous work we recently synthesized the heavier lanthanide nitrate comlexes with DB30C10 and studied their composition and structure.

EXPERIMENTAL

Reagents

Hydrated lanthanide nitrates were prepared by dissolving Ln_2O_3 (AnalaR) in 1:1 nitric acid. DB30C10 was purchased from TJCRF (China). All other chemicals were AnalaR grade.

Chemical and physical measurements

The metal ion contents was determined by EDTA titration using xylenol-orange as an indicator. Carbon, nitrogen and hydrogen contents were determined using a Carlo–Erba 1106 elemental analyser. The IR spectra were recorded in the 4000–200 cm^{-1} region using KBr pellets and a 170 SX FTR spec-

* Author to whom correspondence should be addressed.

trometer. The crystals data were collected on a R3M/E diffractometer.

Preparation of the complexes

A solution of lanthanide nitrate (0.63 mmol) in acetonitrile (2 cm^3) was added dropwise to a solution of DB30C10 (0.4 mmol) in acetonitrile (2 cm^3). The mixture was stirred at room temperature for 24 h. The precipitated solid complex was filtered, washed with ethylacetate and dried in a desiccator (0.1 mm Hg) over P_4O_{10} for 2 days. All the complexes are powdered solids with the characteristic colour of the corresponding lanthanide nitrates.

All the complexes are hardly soluble in benzene and tetrachloromethane, slightly soluble in ethyl ether and ethyl acetate and soluble in acetonitrile, nitromethane and acetone.

Single crystals of the lutetium complex were obtained by dissolving the powdery solid complex in nitromethane and leaving the solution in a desiccator over $CaCl_2$ at room temperature. After about 1 month the colourless, air-sensitive crystals of the complex formed from the solution.

Crystal structure analysis

X-ray diffraction intensities were collected at 20°C on an R3M/E diffractometer with graphite-monochromated Mo-K_α radiation, using the $\theta/2\theta$ scan technique. The intensities were corrected for Lorentz–polarization effects and for empirical absorption. The crystal data are listed in Table 1.

The structure was solved by the Patterson method and a subsequent difference-Fourier technique and refined by full-matrix least-squares methods with anisotropic thermal factors for all non-hydrogen atoms. All calculations were performed using the SHELXTL system of computer programs.

RESULTS AND DISCUSSION

The composition of the complexes

The analytical data for the newly synthesized complexes, listed in Table 2, indicate that all the complexes conform to a 3:2 metal ion-to-crown ether stoichiometry.

[a] L = DB30C10.

IR spectra

Compared with those of the free ligand the absorptions of ν(Ar—O—R) and ν(R—O—R) of the complexes showed shifts of -7 to -10 and -17 to -19 cm^{-1}, respectively; this indicates that the crown ether coordinates to the lanthanide(III) ion.

In the IR spectrum of the complexes the absorptions appearing in the 3410–3440, 1629–1633 and 602–603 cm^{-1} regions are clearly due to ν(OH), δ(HOH) and ρ_r(HOH), respectively, indicating that coordinated water molecules exist in the complexes.[5]

The characteristic frequencies of coordinating nitrate groups appear in the 1765–1781 ($\nu_2+\nu_5$), 1730–1734 ($\nu_2+\nu_6$), 1506–1507 (ν_1), 1282–1291 (ν_4), 1047–1051 (ν_2) and 815–863 (ν_3) cm^{-1} regions in the IR spectrum of the complexes; the difference between the two strongest absorptions (ν_1 and ν_4) of nitrate groups is *ca* 200 cm^{-1}, indicating that the nitrate groups in the complexes coordinate to the metal ions as a bidentate ligand.[5] The absence of the absorptions around 1360 cm^{-1} indicates that all the nitrate groups in the complexes coordinate to the lanthanide ions.[5]

structure of $[Lu(NO_3)_2(OH_2)_2(DB30C10)]^+$ cations and the $[Lu(NO_3)_5]^{2-}$ anion, whilst Fig. 2 illustrates the molecular packing arrangement in the unit cell.

The structure contains two independent $[Lu(NO_3)_2(OH_2)_2(DB30C10)]^+$ cations, one $[Lu(NO_3)_5]^{2-}$ anion and five uncoordinated nitromethane molecules. In the cations the $Lu_{(1)}^{III}$ and $Lu_{(2)}^{III}$ ions are both nine-coordinated with three crown ether oxygen atoms, two bidentate nitrate groups and two water molecules. The coordination geometries of these two cations are distorted tricapped trigonal prisms[6] (Fig. 3). The distances between lutetium(III) ions and oxygen atoms lie in the ranges: $Lu_{(1)}$—O (crown), 2.382–2.404 (av. 2.395); $Lu_{(2)}$—O (crown), 2.358–2.422 (av. 2.395);

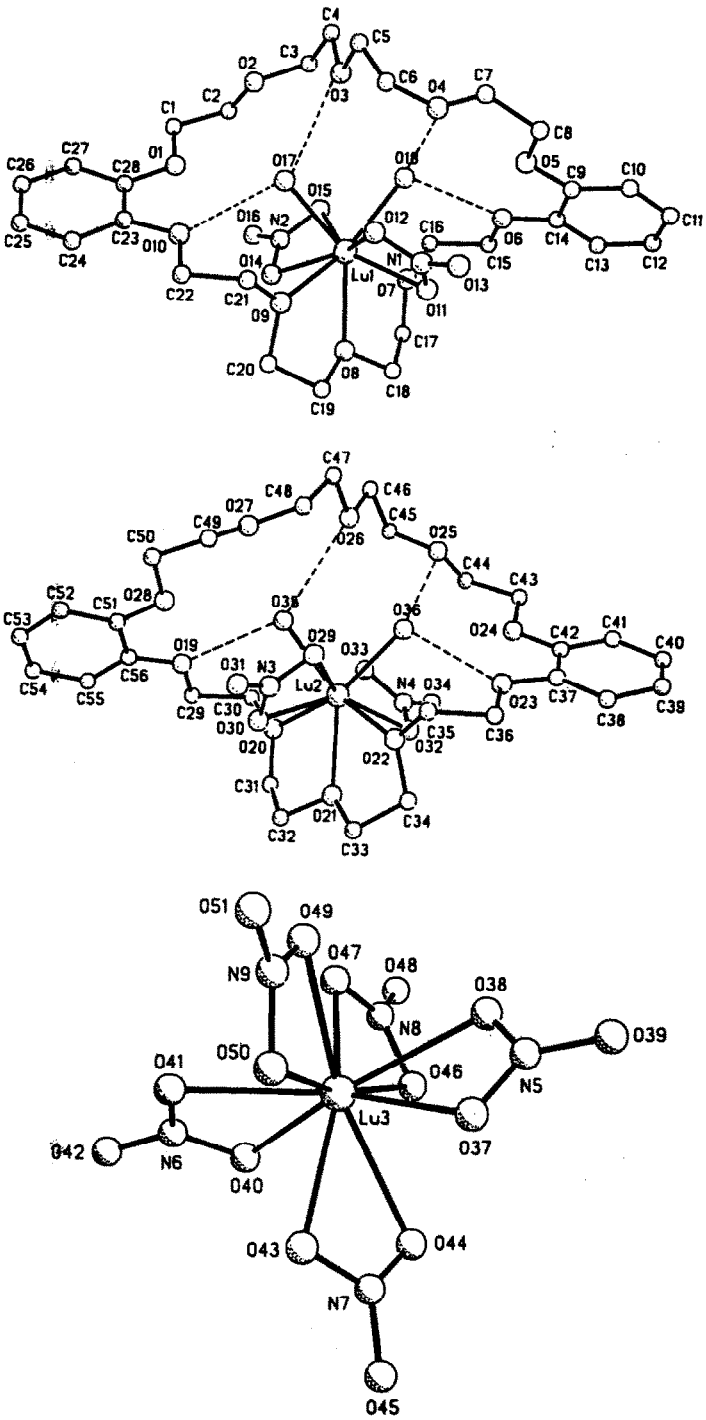

Fig. 1. The structures of the complex cations and complex anion.

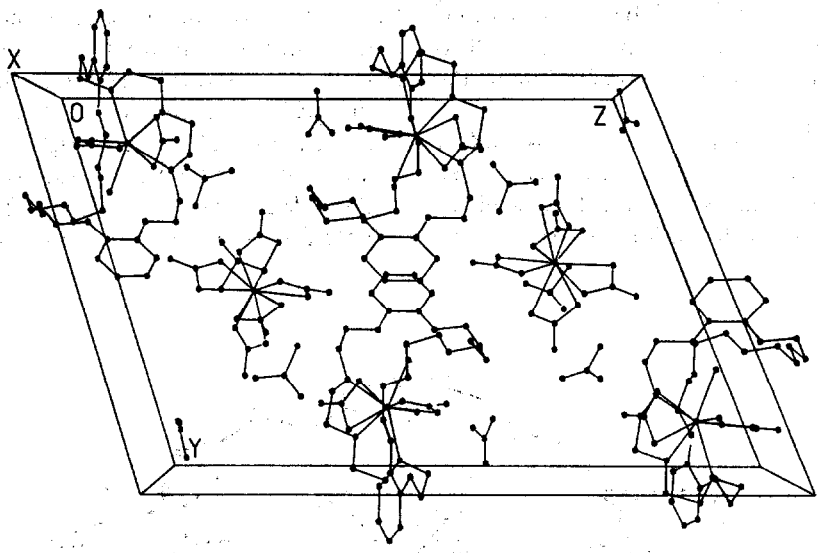

Fig. 2. The molecular packing arrangement in the unit cell.

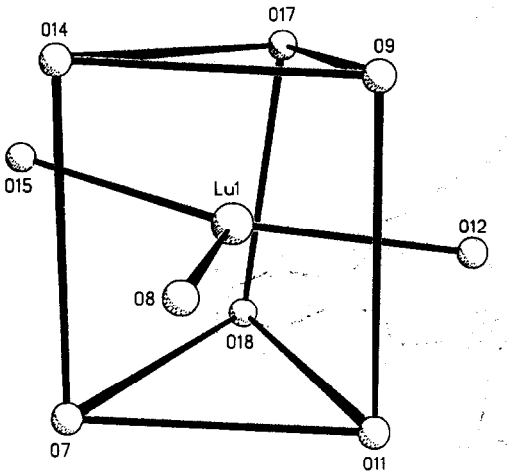

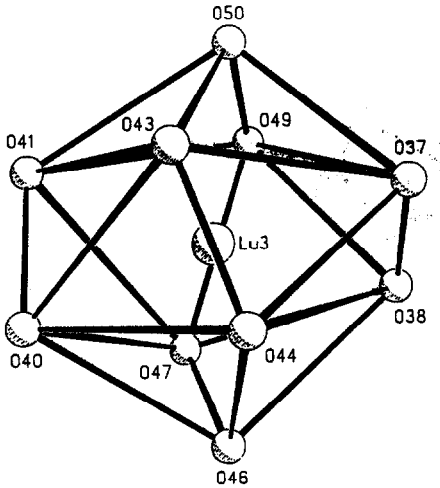

Fig. 3. The coordination geometries of the $Lu_{(1)}^{III}$ cation and $Lu_{(3)}^{III}$ anion.

$Lu_{(1)}$—O (nitrate), 2.354(10)–2.439(11) (av. 2.406); $Lu_{(2)}$—O (nitrate), 2.353(10)–2.426(9) (av. 2.395); $Lu_{(1)}$—O (water), 2.281(10)–2.285(8) (av. 2.283); and $Lu_{(2)}$—O (water), 2.286(8)–2.326(11) Å (av. 2.306 Å). In the anion the 10-coordinated lutetium(III) ion is bonded to five bidentate nitrate groups, forming a distorted bicapped square antiprism[6] (Fig. 3). The $Lu_{(3)}$—O (nitrate) bond lengths lie in the range 2.321–2.464 Å (av. 2.394 Å).

It can be seen from Table 5 that some O(water)···O(crown) distances range from 2.811 to 2.997 Å; these values lie in the range of hydrogen bonding distances.[7] This suggests that the hydrogen bonding occurs between coordinated water molecules and some of the crown ether oxygen atoms.

CONCLUSIONS

In comparison with DB24C8, DB30C10 is more flexible and so it can achieve the correct M—O(crown) distances and directly coordinate to the lanthanide ions. Owing to the too small ionic radius of the lutetium(III) ion the ligand cannot absorb the steric crowding arising from the large

Table 5. Some O(water)···O(crown) distances (Å)

O(17)···O(3)	2.826	O(35)···O(19)	2.889
O(17)···O(10)	2.811	O(35)···O(26)	2.997
O(18)···O(4)	2.867	O(36)···O(25)	2.907
O(18)···O(6)	2.853	O(36)···O(23)	2.812

cavity diameter, so all of the crown ether oxygen atoms in DB30C10 cannot simultaneously coordinate to the metal ion and DB30C10 can only bond to Lu^{3+} ion through part of the ether oxygen atoms.

(*Received* 20 *April* 1993; *accepted* 11 *May* 1993)

Abstract—The title compound $Te^{II}LI$ [L = diethyl dithiocarbamate, $(C_2H_5)_2NCS_2^-$] was synthesized by the reduction of $Te^{IV}L_2I_2$ with elemental tellurium. Its structure has been determined and is found to be polymeric, with I being the bridging ligand. The polymeric chain adopts a helical configuration which runs parallel to the *c*-axis of the tetragonal unit cell. Each tellurium is bonded to two sulphurs of a chelating dithiocarbamate group and to two iodines in a planar configuration. The bond distances of Te—S(1), Te—S(2), Te—I and Te—I′ are 2.536(4), 2.483(5), 3.108(1) and 3.279(1) Å, respectively, and the bond angles of I—Te—S(1), S(1)—Te—S(2), S(2)—Te—I′ and I′—Te—I are 149.6(2), 70.7(2), 151.1(2) and 129.2(2)°, respectively.

During our continuing studies on mixed halide-dithiocarbamate complexes of tellurium in +2 and +4 states we have prepared the novel compound TeLI. Crystal structures of many tellurium(II) bisdithiocarbamates, $Te[R_1(R_2)NCS_2]_2$ [$R_1 = R_2 = C_2H_5$,[1] $(OH)C_2H_4$,[2] C_3H_7,[3] i-C_3H_7[4] and morpholyl,[5] have been determined. In all these cases tellurium(II) exhibits a planar trapezoidal four-fold coordination of sulphur atoms with highly anisobidentate dithiocarbamate chelation. Even though tellurium(II) mixed-ligand complexes of xanthate with dithiocarbamate[6] and halides (Br, Cl and I)[7] have been prepared earlier, preparation of complexes containing both dithiocarbamate and halide was elusive. Recently using suitable synthetic strategies we were able to report on the synthesis and structure determination of adducts of TeLX (where L is a dithiocarbamate group and X a thiocyanate or iodide ion) with TeL_2[8] and TeL_2I_2.[9] In this paper is reported the synthesis and structure of the pure phase iododiethyldithiocarbamato tellurium(II).

The structure determination reveals a novel helical polymeric arrangement of atoms to satisfy the common four-fold coordination of tellurium(II).

EXPERIMENTAL

The title compound was prepared by stirring a solution of $Te^{IV}L_2I_2$ (0.678 g, 1 mmol) with freshly prepared powdered elemental tellurium (0.190 g, 1.5 mmol) for 12 h. The unreacted tellurium powder was filtered and evaporation of the filtrate gave dark brown needle-shaped crystals of TeLI. TeL_2I_2 was prepared by the procedure reported earlier[10] and tellurium powder was obtained by hydrazine reduction of tellurium(IV) chloride in 2 N HCl medium.

The composition of the compound was confirmed from elemental analysis results. The percentage weight calculated is given in parentheses. Found: C, 15.0; N, 3.5; H, 2.6; Te, 31.4; I, 31.5. Calc.: C, 14.9; N, 3.5; H, 2.5; Te, 31.7; I, 31.5%.

Crystal data

The crystallographic data are as follows: $Te(C_4H_{10}NCS_2)I$, $Mr = 402.75$, tetragonal, space group $I\bar{4}$, $a = b = 20.107(3)$, $c = 6.283(4)$ Å, $V = 2540.15$ Å^3, $Z = 8$, $D_x = 2.11$, $D_m = 2.14$ mg m^{-3}, λ(Mo-K_α) = 0.71069 Å, $\mu = 4.717$ mm^{-1}, $F(000) = 1471.98$. The density was measured by the flotation method.

Data collection

A single crystal of dimensions $0.5 \times 0.5 \times 0.5$ mm^3 was mounted on an Enraf–Nonius CAD4 diffractometer. Lattice parameters with ESDs were obtained from 24 reflections in the θ range 11.5–15.6°. The intensity data were collected by the ω–2θ scan technique for 2θ range between 4° and 55° with Mo-K_α radiation; the *hkl* range being h: $-17 \rightarrow 18$, k: $0 \rightarrow 26$, l: $0 \rightarrow 8$. Three standard reflections were measured every 2 h for an intensity check and three reflections remeasured after every 200 reflections for an orientation check, which showed no significant variation in the intensity. 3266 reflections were measured, of which 1591 reflections with $I > 3\sigma(I)$ were considered unique. The intensity data were corrected for Lorentz and polarization effects. An absorption correction was applied using the program ABSORB.[11]

Solution and refinement

The structure was solved by the heavy atom method. Tellurium and iodine positions were obtained from the Patterson map and the successive Fourier maps based on tellurium and iodine positions gave the locations of all non-hydrogen atoms. The full-matrix least-squares method using SHELX76[12] gave the positions of non-hydrogen atoms and their anisotropic thermal parameters. Maximum shift per e.s.d. was 0.04 when the refinement was terminated and 286 parameters were refined. Residuals at convergence were $R = 0.057$ and $Rw = 0.056$ for 1591 unique reflections, where $w = 1/[\sigma^2|F_o| + 0.0012|F_o|^2]$. The final difference-Fourier map showed no unusual features with the largest peak maximum being 1.3 e Å^{-3}, which is in proximity to tellurium and has no chemical significance. Hydrogen atoms did not appear in the final difference-Fourier map. Atomic scattering factors for non-hydrogen atoms were taken from Cromer and Mann[13] and anomalous dispersion correction factors were taken from Cromer and Liberman.[14]*

RESULTS AND DISCUSSION

Crystals of the title compound, TeLI, are stable indefinitely under ambient conditions in air. In the characteristic C⟛N IR absorption region for the dithiocarbamates, TeL_2 shows absorptions at 1478, 1446 and 1414 cm^{-1} and TeLI at 1510 and 1420 cm^{-1}. TeLI is highly soluble in dichloromethane, but unlike TeL_2 is very sparingly soluble in carbon tetrachloride. Whereas solutions of TeL_2 in dichloromethane are unaffected by triphenylphosphine, solutions of TeLI in the same solvent undergo immediate decomposition to tellurium on addition of this reagent.

In the tellurium(II) dithiocarbamates generally the coordination around tellurium is four and planar. Tellurium, in the title compound, if it were to exist as a monomer would be coordinately unsaturated, being bound to two sulphur atoms of the dithiocarbamate group and an iodine atom. There are three different possibilities by which four coordination can be attained. In the first possibility the tellurium atom can bind to another tellurium atom to form a dimer having a Te—Te bond. This kind of Te—Te interaction is observed in $Te_2L'_3(SCN)$ [$L' = (OHCH_2CH_2)_2NCS_2^-$],[8] where the "unsaturated" TeL'(SCN) moiety achieves the saturation by bonding to Te of the TeL'_2 group. The inter tellurium bond distance reported therein is 3.221 Å. In the second possibility the dithiocarbamate group(s) can act as a bridging ligand(s), binding to two tellurium atoms. A number of bridged dithiocarbamates have been reported in the complexes of many transition elements, e.g. $(MoL_3)_2$,[15] $(ZnL_2)_2$[16] and $(Ru_2L_5)^+BF_4^-$.[17] In the third possibility the coordination around tellurium can be enhanced by bridging through iodine atoms. Such iodine-bridged structures have been reported for the tellurium(IV) complexes TeL'_2I_2[18] and TeL_2I_2[10] and mixed-valence Te^{II}–Te^{IV} complex, $Te_2L_3I_3$.[9] The present structure determination shows that in the title compound iodine bridging occurs and instead of a dimeric structure, a polymeric structure is obtained. Such halogen-

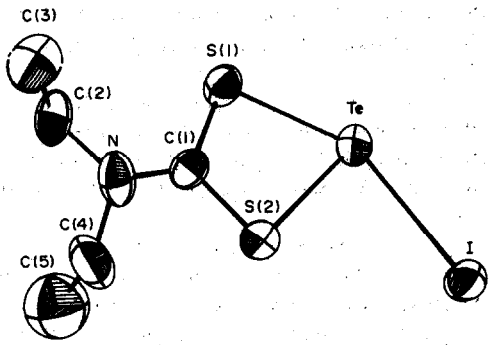

Fig. 1. The ORTEP plot of the fragment of TeLI with 50% probability ellipsoid.

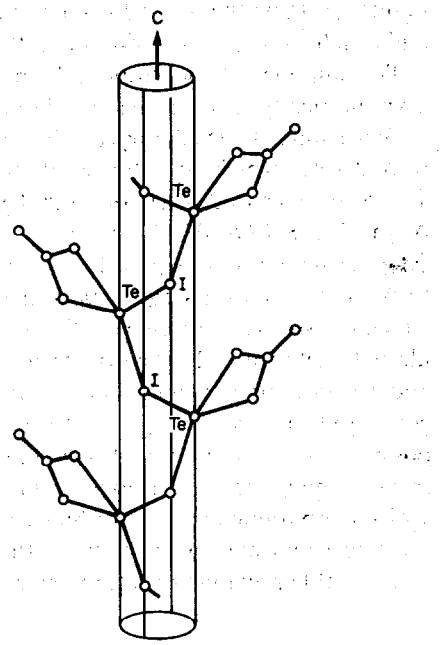

Fig. 2. The helical arrangement of the molecule.

bridged polymeric structures have been found in $[Te(S_2COC_2H_5)Br]_n$[7] and $(OC_4H_8NCSe_3)I$.[19] The ORTEP[20] diagram of the molecule is shown in Fig. 1.

The helical arrangement adopted by the tellurium and iodine atoms, running parallel to the *c*-axis, is shown in Fig. 2, with two pairs of tellurium and iodine atoms forming a repeating unit with a period of 6.283(4) Å. There are four helices within a unit cell, with the shortest separation between two inter-helical tellurium atoms being 9.363(1) Å.

Tellurium atoms in the helix are at a distance of 3.879(2) Å from two other tellurium atoms. This distance is smaller than the sum of the van der Waals radii of 4.12 Å. Similarly two iodine atoms in the helix are at a distance of 5.772 Å from two other iodine atoms.

Each tellurium displays a planar arrangement of two sulphurs and two iodines, the RMS deviation from the mean plane being 0.07 Å. The two pairs of non bonding electrons on the tellurium would lie above and below this plane.

There are two different Te—I bonds (see Table 1), with distances of 3.108(1) and 3.279(1) Å, both being larger than the sum of the individual covalent radii of tellurium and iodine (2.70 Å). This is so because of the appreciable *trans* influence of the dithiocarbamate sulphurs and in addition the bridging of the iodines. The angle subtended at the

Table 1. Bond lengths (Å) and angles (°)

S(1)—C(1)—S(2)	115.1(8)	C(5)—C(4)—N	111(2)
Te—S(1)—C(1)	86.7(6)		

(′) = (0.5−*x*, 0.5−*y*, −0.5+*z*).

iodine, bridging the two tellurium atoms, is 74.7(1)° and at tellurium by the iodines is 129.2(2)°.

The sulphurs of the dithiocarbamate group are asymmetrically bound, having bond lengths of 2.536(4) and 2.483(5) Å for Te—S(1) and Te—S(2), respectively, which are shorter than the average Te—S distance of 2.69 Å found in TeL_2[1] and 2.65 Å in $TeL(S_2COC_2H_5)$[6] and other tellurium(II) dithiocarbamate complexes. This may be attributed to the presence of a single dithiocarbamate group which is a stronger complexing ligand than the iodide with tellurium(II). The difference in Te—S(1) and Te—S(2) bond lengths in this compound is less compared with that in TeL_2. In the asymmetrically bound Te—S the shorter Te—S bond is present *trans* to the longer Te—I bond and *vice versa*. The molecular parameters of the dithiocarbamate group are unexceptional and similar to those found in innumerable previous structure determinations.

THE REDOX SYNTHESIS, STRUCTURE AND MAGNETIC PROPERTIES OF THE HETEROBIMETALLIC μ-OXO COMPOUND [(py)(TPP)CrOFe(tmtaa)]

PETER J. NICHOLS, GARY D. FALLON, BOUJEMAA MOUBARAKI, KEITH S. MURRAY and BRUCE O. WEST*

Centre of Chemical Synthesis and Department of Chemistry, Monash University, Clayton, Victoria 3168, Australia

(*Received* 20 *April* 1993; *accepted* 11 *May* 1993)

Abstract—The oxidation of Fe^{II}(tmtaa)† by $Cr^{IV}O$(TPP)† in pyridine-tetrahydrofuran solution leads to the formation of the heterobimetallic complex [(py)(TPP)CrOFe(tmtaa)]. Crystal structure determination of the bis-tetrahydrofuran solvate shows that the CrOFe linkage is almost linear [176.6(9)°], while the Fe-tmtaa stereochemistry differs from that previously known for five-coordinate tmtaa complexes. Mössbauer spectra and magnetic data (to 4 K) are reported for the solvent free complex. The $S = 3/2 : S = 5/2$ complex shows strong antiferromagnetic coupling with a $2J$ value of -299 cm^{-1}.

Oxo-bridged heterobinuclear complexes have been prepared[1] by one-electron redox reactions between $Cr^{IV}O$ porphyrin derivatives and a variety of other metal complexes of iron(II),[2–4] molybdenum(IV),[3,5] manganese(II)[3] and vanadium(IV).[6] Heterotrinuclear species can also be formed by two-electron redox reactions between $Ru^{VI}(O)_2$ porphyrins and iron(II)[7] complexes. Ligands used have involved porphyrins, phthalocyanine, salicylaldimines and dithiocarbamates. In contemperaneous work acetate-bridge "supported" heterobinuclear μ-oxo bridged complexes $[(L)M(\mu\text{-}O)(\mu\text{-}CH_3COO)_2M'(L')]^+$ (L and L′ are triazacyclononane type ligands) have also been prepared by Wieghardt *et al.*[8] using hydrolytic procedures in aqueous solution for several combinations of first row transition elements. A number of these compounds have been structurally characterized including $[(L)Cr^{III}(\mu\text{-}O)(\mu\text{-}CH_3COO)_2Fe^{III}(L')]PF_6$[8] (L = 1,4,7-triazacyclononane, L′ = 1,4,7-trimethyl-1,4,7-triazacyclononane). Although an X-ray structural study has been successfully carried out[7] on the trinuclear species Ru^{IV}(TPP)[OFe^{III}(salmah)]$_2$, similar characterizations of singly oxo-bridged compounds have proved elusive because of difficulties in growing suitable single crystals of any of the compounds previously reported.[1–6] One factor contributing to this is their ability to undergo further hydrolysis in the presence of traces of water. Magnetic studies have provided the principal evidence for their constitution so far,[1] since the majority of the complexes show strong to medium antiferromagnetic coupling via the oxo bridge. One incomplete structure determination[2] has been reported for the complex [(py)(TPP)CrOFe(TMP)], which disclosed the gross coordination features of the molecule, including an essentially linear CrOFe linkage, but crystal imperfections prevented refinement of the data to an acceptably low R factor.

A variety of structural studies of metal tmtaa compounds has appeared in recent literature,[9] suggesting that the presence of that ligand may lead to ready crystallization of coordination complexes. Fe^{II}(tmtaa) has been shown[10,11] to react readily with molecular oxygen to form a homobimetallic μ-oxo bridged complex, $[Fe^{III}(tmtaa)]_2O$, and such reactivity has been found to indicate complexes which can reduce $Cr^{IV}O$(P) and form heterobimetallic oxo-bridged complexes.[1] We have accordingly reacted Fe^{II}(tmtaa) with $Cr^{IV}O$(TPP) in the presence

* Author to whom correspondence should be addressed.

† Ligand abbreviations: tmtaa is the dianion of 5,7,12,14-tetramethyldibenzo[b,i][1,4,8,11]tetraazacyclotetradeca-2,4,7,9,11,14-hexaene. TPP is the dianion of 5,10,15,20-tetraphenylporphyrin. TMP is the dianion of 5,10,15,20-tetra-*p*-methoxyphenylporphyrin.

of pyridine and have isolated the complex [(py)(TPP)$Cr^{III}OFe^{III}$(tmtaa)] as a tetrahydrofuran solvate. Crystals of an appropriate quality to enable an X-ray structural study to be completed have been obtained and we wish to report the result of that study. The variation with temperature of the magnetic susceptibility and the Mössbauer spectrum of the complex have also been measured for comparison with CrOFe complexes previously isolated, which have different ligands attached to iron(III).[2,4] There is presently considerable interest in making magnetostructural correlations on heterometallic species not only in order to advance knowledge of superexchange mechanisms, but also because of the occurrence of mixed metal clusters in certain biological systems. Wieghardt and Girerd[8] have recently put forward a superexchange model which has some new features and the magnetic data for the present compound are analysed in this context.

EXPERIMENTAL

Materials and techniques

All manipulations were performed in dry solvents under purified nitrogen as previously described.[2] Spectra were recorded as follows: IR, PE 1600 FTIR; mass, V.G. Micromass; visible, Varian SuperScan 3. (Intensities indicated thus; vs, very strong; s, strong; m, medium; w, weak.)

Microanalyses were performed by the Australian Microanalytical Service and the National Analytical Laboratories Pty Ltd.

Variable-temperature magnetic susceptibility measurements were made using a Quantum Design MPMS Squid magnetometer. The calibrations of field and temperature performed by the manufacturer were also checked against a calibrated palladium sample as well as $Hg[Co(NCS)_4]$ and $CuSO_4 \cdot 5H_2O$. An applied field of 10 kOe was employed for the present measurements. Samples were finely ground and placed in gelatin capsules for measurements. The equipment and procedures for Mössbauer spectral measurements have been described previously.[2]

CrO(TPP) was prepared by the oxidation of Cr(TPP)Cl with iodosylbenzene.[12] Fe^{II}(tmtaa) was prepared following the reported procedure,[11] except that $Fe(py)_4(NCS)_2$ was substituted for Fe(*o*-phenylenediamine)$_2(NCS)_2$. Microanalytical and mass spectral data indicated no incorporation of pyridine or acetonitrile. Selected IR absorption bands (Nujol mull): 1592m, 1566m, 1524m, 1186vs, 1027s, 738vs cm^{-1}. Dry solid Fe(tmtaa) exposed to air overnight gave rise to the following 112 absorption bands (Nujol mull): 1538vs, 1192s, 1027s, 811vs, 742s cm^{-1}. A toluene solution of the complex kept under nitrogen with a slow "leak" of dry oxygen formed the oxo complex $[Fe^{III}(tmtaa)]_2O$, which could be crystallized as a toluene solvate. Found: C, 67.6; H, 5.8; N, 12.3. Calc. for $C_{51}H_{52}Fe_2N_8O$: C, 67.3; H, 5.8; N, 12.4%. Selected IR absorption bands (Nujol mull): 1538vs, 1192s, 1027s, 810vs, 742s cm^{-1}. The 810 cm^{-1} absorption appears most likely to relate to the FeOFe vibration. The band at 890 cm^{-1} assigned to this vibration[10] was not observed and may have been a printing error for 809 cm^{-1}. $\mu_{eff} = 2.5\mu_B$ (lit.[10,11] $1.96\mu_B$). In contrast to the low solubility reported[11] for the analogous CH_3CN adduct the toluene product is soluble in a range of solvents, but these solutions, including that in toluene, decompose rapidly when exposed to moist air forming high-spin iron(III) products showing strong OH IR absorption.

Synthesis of [(py)(TPP)CrOFe(tmtaa)]·2THF

CrO(TPP) (0.36 g, 0.53 mmol) and Fe(tmtaa) (0.21 g, 0.53 mmol) were dissolved in a deoxygenated THF/pyridine (50 : 1; 50 cm^3) solution and stirred at room temperature for 1 h. The red–green solution was filtered, cooled to 0°C and layered with hexane (100 cm^3). After standing at 0°C for 1 week with careful exclusion of air, purple crystals separated and these were collected, washed with hexane and dried under a flow of nitrogen (yield $\approx$ 0.2 g, 30%). A suitable crystal was selected from the batch for an X-ray diffraction study. Found: C, 72.5; H, 5.7; N, 9.5. Calc. for $C_{71}H_{55}CrFeN_9O \cdot 2C_4H_8O$: C, 72.9; H, 5.5; N, 9.7%. UV–vis absorption spectrum (toluene): 380, 436 (Sôret), 548 nm. Selected IR absorption bands (Nujol mull): 1596m, 1562m, 1524m, 1191m, 1068s, 1006vs, 879s, 795s, 746s cm^{-1}. On standing the purple crystalline compound gradually changes to a green powder through loss of THF. Coordinated pyridine is not evolved, however, as is evident from mass spectral examination of the solvent-free residue and its microanalysis. Found: C, 73.5; H, 5.2; N, 10.8. Calc. for $C_{71}H_{55}CrFeN_9O$: C, 73.6; H, 4.8; N, 10.9%. The THF-free compound was used for variable-temperature magnetic and Mössbauer spectral measurements because of the greater reproducibility of the composition of this form of the complex. The loss of THF does not affect the spectral or magnetic properties of the complex.

X-ray crystallography of [py(TPP)CrOFe(tmtaa)]·2THF

A representative purple acicular crystal was used for data collection. Intensity measurements on the

compound were made on a Nicolet R3m/V diffractometer using graphite-monochromated Mo-K_α radiation. Cell parameters were derived by least-squares calculations from 18 angular settings of reflections. The data collection and crystal parameters are given in Table 1. Three standard reflections monitored every 197 reflections did not show any significant variation in intensity over the collection period. Intensity data were processed as described previously.[13] Numerical absorption corrections[14] were applied to each data set. The maximum and minimum transmission factors were 0.959 and 0.936, respectively. The atomic scattering factors for neutral atoms were corrected for anomalous dispersion.[15] All calculations were performed on a MicroVax 2000 computer using the program due to Sheldrick[14] for least-squares refinement. The structure was solved by direct methods. Full-matrix least-squares refinement employing anisotropic thermal parameters for iron, chromium and the oxygen and carbon atoms of the THF solvate molecules and isotropic thermal parameters for all other atoms (single isotropic thermal parameter for hydrogen fixed at 0.08 Å^2—positioned in geometrically idealized positions: C—H 0.96 Å) reduced R to 0.076 and R_w to 0.099, respectively, at convergence, where $R_w = (\Sigma w(||F_o|-|F_c||)^2/\Sigma w|F_o|^2)^{1/2}$ and $w = [\sigma^2(F_o)+0.00040F_o^2]^{-1}$. The highest peak in the difference-Fourier synthesis was 1.07 e Å^{-3}.

RESULTS AND DISCUSSION

Syntheses

Fe^{II}(tmtaa) undergoes ready reaction with Cr^{IV}(O)(TPP) in THF solution to yield the heterobimetallic oxo-bridged complex [(TPP)Cr^{III}OFe^{III}(tmtaa)]. In the presence of pyridine the complex [(py)(TPP)CrOFe(tmtaa)] is formed, which can be isolated from solution as a di-tetrahydrofuran solvate. IR spectral bands indicating the presence of both porphyrin and tmtaa ligands are observed for the compound, while a strong band at 879 cm^{-1} which has no counterpart in the spectra of the reactants is tentatively assigned to the asymmetric CrOFe stretching vibration. The electronic absorption spectrum is dominated by the absorption of the porphyrin with a Sôret band at 436 nm.

The structure of [(py)(TPP)Cr^{III}OFe^{III}(tmtaa)]·2THF

A diagram of the molecular structure of [(py)(TPP)CrOFe(tmtaa)] is given in Fig. 1 with a list of relevant bond distances and angles in Table 2. The molecule consists of a six-coordinate chromium porphyrin unit with a pyridine molecule coordinated to the metal linked by an oxo group to a five-coordinate Fe-tmtaa unit. Tetrahydrofuran

molecules occupy lattice cavities formed by the loose packing of the complex molecules and there is no bonding interaction between either of the THF molecules and a molecule of [(py)(TPP)CrO Fe(tmtaa)]. The closest distance of approach between any atom of the tetrahydrofuran molecules and any atom of the complex is 3.619 Å between a carbon atom of a THF molecule and N(7) of the tmtaa ring. Only nine other interatomic contacts are at less than 3.8 Å. The porphyrin ring is ruffled with two of the four *meso*-carbons, C(20) and C(10), displaced from the N_4 plane towards the bridging oxygen atom and the remaining two, C(5) and C(15), displaced away from the oxygen. The coordinated pyridine molecule lies in the fold created by the displacements of C(20) and C(10) at an angle to the line between them. The torsion angle N(1)—Cr—[N(5)—C(49)] is 35.2°. Even with an excess of pyridine in the reaction mixture the iron(III) ion appears unable to accept a further ligand. $[Fe(tmtaa)]_2O$ has been previously shown[11] to be unable to coordinate additional Lewis bases, as has been observed with many other iron(III) μ-oxo compounds involving tetradentate ligands.[16] The earlier[2] incomplete crystallographic study of [(py)(TPP)CrOFe(TMP)] also showed pyridine attached to chromium but not to iron when porphyrin ligands were attached to both metals. The phenyl rings of tetraphenylporphyrin are inclined to the N_4 plane of the porphyrin ring in the propellor form well established for such tetraaryl derivatives. The angles are greatest for the phenyl groups overlain by the benzenoid rings of tmtaa (118° and 116°) and least for those nearer the pentanediimino segments (106° and 108°).

The CrOFe bridge is virtually linear with an angle of 176.6(9)°. Other homobimetallic $Cr^{III}OCr^{III}$ derivatives have shown essentially linear oxo bridges whereas FeOFe compounds display a range of angles from *ca* 140° to 180°. (Table 3 lists a selection of data. Additional references may be found in Table 1 of ref. 1.) The value observed for a particular Fe_2O complex is mainly influenced by inter-ligand steric interactions.[16] While we shall proceed to analyse the magnetic data of the CrOFe and FeOFe molecules in terms of the essentially non-bonding Heisenberg ($-2J\bar{S}_1 \cdot \bar{S}_2$) model (*vide infra*) it is nevertheless interesting to examine an alternative structural correlation developed on the assumption that π-bonding occurs in oxo-bridged species. Thus, such a molecular orbital picture of the bonding in MOM systems first put forward by Dunitz and Orgel[18] and extended by others[19–21] has been successful in correlating linear or bent MOM bonds with the total number of electrons which needs to be accommodated in the available

bonding, *anti*-bonding and non-bonding orbitals of the system. For complexes with up to eight metal electrons to be placed in the bonding and non-bonding levels a linear bond structure results as found for d^3–d^3 $Cr^{III}OCr^{III}$ and d^4–d^4 $Ru^{IV}ORu^{IV}$ compounds, whether containing large or small ligands (Table 3). $Fe^{III}OFe^{III}$ derivatives with a total of 10 metal electrons to be accommodated will require the use of anti-bonding levels for placement of the additional electrons and this causes the resultant bond systems to be bent.[16] If, however, interligand steric interactions are sufficiently great the FeOFe bond can approach linearity as in $[Fe(TPP)]_2O$[17b] and $[Fe(3\text{-}^t\text{Busaltmen})]_2O$.[17c] Application of this correlation to the present heterobimetallic $Cr^{III}OFe^{III}$ system with eight electrons to be accommodated would predict an essentially linear system as observed.

The Cr—O and Fe—O bond lengths are each comparable to those observed in homobimetallic

derivatives of those elements (Table 3). While the chromium ion is essentially located in the plane of the porphyrin ring (0.075 Å towards the oxo bridge from the N_4 plane of the porphyrin) the iron ion is displaced 0.646 Å from the N_4 plane of tmtaa towards the bridging oxygen. Such displacements towards the bridging oxo group are commonly found for five-coordinate iron(III)-μ-oxo complexes,[16] including the homobinuclear compound $[Fe(tmtaa)]_2O$[11] where the displacement is 0.698 Å.

The tmtaa ligand has a "saddle-shaped" conformation in the complex with the pentanediimine rings directed towards the porphyrin ligand and the benzenoid rings directed away (Fig. 2). The displacement of the iron atom from the N_4 plane towards the oxo group thus places it between the pentanediimine rings rather than the benzenoid, an arrangement which is opposite to that found in all other tmtaa coordination compound structures so far determined.[9] In the FeOCr complex the angles between the tmtaa N_4 plane and the pentanediimino planes are considerably smaller by about 13–16°, while the benzenoid rings lie at angles approximately 10° greater than their $[Fe(tmtaa)]_2O$ counterparts (Table 4; the planes being compared are identified in Fig. 3). The particular conformation found in the FeOCr complex allows the close fitting of the porphyrin and tmtaa ligands at the relatively short approach distance required by the oxo bridge, whereas a "normal" conformation of the tmtaa ligand with benzenoid rings directed towards the porphyrin would result in such intermolecular repulsion that the oxo-bridged assembly could probably not form. In $[Fe(tmtaa)]_2O$[11] the benzenoid rings lie towards the oxo group with iron out of the N_4 plane also towards oxygen, but the combination of a bent FeOFe bond and a rotation of the tmtaa molecules about each Fe—O axis allows the ligands to "fit" together without strain. The relative rigidity of the porphyrin molecule and the orientations of its phenyl substituents prevents any such arrangement in the case of the FeOCr complex. The resulting conformation indicates that tmtaa is capable of utilizing its nitrogen lone pairs in a much more flexible manner than has been recognized hitherto. There is further evidence of the minimization of steric interactions between the two ligands in this compound in that each tmtaa nitrogen atom is rotated about the Fe—Cr axis with respect to the eclipsed position with the corresponding porphyrin nitrogen by small angles in the range 6–12° (Table 2). The

Cr^{IV}—O distance[22] of 1.62(2) Å in the parent molecule CrO(TPP) is shorter, as expected, than the Cr^{III}—O distance in the heterobimetallic product of 1.776(11) Å.

Mössbauer effect spectra and magnetism

The Mössbauer spectral parameters are shown in Table 5. Sharp, symmetrical quadrupole doublets are observed at 4.2 and 77 K, while a slight asymmetry is evident at 295 K. The parameters are typical of those expected for an $S = 5/2$ iron(III) ion having five-coordinate geometry, as disclosed by the structural data.

The compound shows a magnetic moment of $3.51\mu_B$ at room temperature, considerably reduced from the spin-only value of $7.07\mu_B$ expected for an uncoupled $S = 3/2 : S = 5/2$ system of chromium(III), d^3 and iron(III), d^5 ions (assuming $g_{Cr} = g_{Fe} = 2.0$). A study of the variation of magnetic susceptibility with temperature down to 4.2 K shows the same type of antiferromagnetic behaviour, as was observed with other [(TPP)CrO Fe(Lig)] complexes.[2,4] Thus, the magnetic moment decreases gradually from $3.51\mu_B$ at 300 K to $3.25\mu_B$ at *ca* 120 K and then remains constant until 20 K at which point it decreases rapidly, because of zero-field splitting effects, reaching a value of $2.82\mu_B$ at 4.2 K (Fig. 4). The plateau value of $3.25\mu_B$ corresponds to population of the ground $S' = 1$ spin-state, but is higher than expected (viz. $2.83\mu_B$). We have experienced this before in a few other CrOFe systems, including [(TPP)CrOFe(TMP)],[2] which required $g_{Fe} = 2.05$ to fit the observed μ_{eff} value. Most other examples that have been studied, e.g. [(N–Me–Im)Cr(TPP)OFe(salmah)],[4] as well as the recently reported μ-oxo-di-μ-carboxylato Cr—Fe triazacyclonane compounds of Wieghardt,[8] show plateau values of *ca* $2.9\mu_B$ with a gradual

increase in the μ_{eff} then occurring at higher temperatures, eventually reaching *ca* $3.2\mu_B$ at room temperature. It is possible that a fraction of a further paramagnetic species showing Curie-like behaviour is present in the present complex and is responsible for the slightly enhanced μ_{eff} values. The Mössbauer spectra of the samples used for magnetic susceptibility studies did not show any evidence for an additional, monomeric iron(III) species which might have resulted from a degree of hydrolysis of the samples examined, but the presence of small quantities of chromium(III) and iron(III) monomers arising from such a process cannot be completely ruled out. The microanalytical data for the samples examined also indicated that the samples were "pure", but a hydrolytic process leaving equimolar amounts of Cr(TPP) and Fe(tmtaa) units in the samples would not be detected by such analyses. Despite this problem with the magnitude of "plateau" μ_{eff} values, it was possible to fit the data well to the sample $S = 3/2 : S = 5/2$ dimer model of the type used by Wieghardt *et al.*[8] A best-fit value of $2J = -299$ cm^{-1} was obtained, similar in value to those obtained for (P)CrOFe(P′)[2] compounds (-274 to -300 cm^{-1}), and for triply-bridged, μ-oxo, di-μ-carboxylato complexes[8] (-275 cm^{-1}). The best-fit g value of 2.30 for the present compound is higher than the expected 2.0 because the g acts as a scaling factor, taking into account the factors discussed above. The rapid decrease in μ_{eff} at very low temperatures could be simulated by the incorporation of a $(T-\theta)$ term into the χ equation. A best-fit θ value of -1.2 K was indicative of zero field splitting or perhaps intermolecular exchange effects occurring.

It is interesting to briefly consider the similarities of the $2J$ values in the linear CrOFe complexes and

the "non-linear" $Cr(O)(O_2CR)_2Fe$ compounds in terms of the recent localized "magnetic" orbital model proposed by Wieghardt *et al.*[8] In their treatment the short M—O direction was defined as z and the M—O—M′ pathway was considered to be the principal magnetic exchange pathway. In order of increasing energy the electronic configurations of the localized metal orbitals are iron(III)—$(x^2-y^2, xz, yz, xy, z^2)$, each singly occupied, and chromium(III)—(x^2-y^2, xz, yz), also singly occupied. The strong overall antiferromagnetism in $Cr(O)(O_2CR)_2Fe$ compounds was ascribed[8] to the antiferromagnetic pathways $Fe(z^2)$—$Cr(xz)$ and $Fe(yz)$—$Cr(yz)$ dominating over the ferromagnetic pathways $Fe(xz)$—$Cr(yz)$, $Fe(xz)$—$Cr(xz)$ and $Fe(xz)$—$Cr(x^2-y^2)$. In opening the CrOFe angle from 121° in the $Cr(O)(O_2CR)_2Fe$ system[8] to 177° in the present CrOFe system the yz-yz overlap will be unaffected, but the z^2-xz overlap will decrease towards zero. The xz-xz overlap should correspondingly increase. All of this would suggest that the angle change should also lead to a J value change, unless there is an accidental cancelling out of the constituent J(AF) and J(F) values. An additional influence due to the bridging ligand has been observed in studies on the homobinuclear doubly-bridged species $[(tpa)M(O)(O_2CR)M(tpa)]^{3+}$, where M = Cr^{III}[21] or Fe^{III}[23] and tpa = tris(2-pyridylmethyl)amine. The J values in the Cr···Cr series are very sensitive to changes in the RCO_2^- group as well as to the CrOCr bridge angle and this has been interpreted[21] in terms of a molecular-orbital model with significant π-bonding in the CrOCr unit being affected by variations in the $Cr(O_2CR)Cr$ moiety.

Thus, it can be seen from the above discussion that some of the Wieghardt–Girerd proposals are supported by some studies while others, e.g. ignoring the influence of μ-RCO_2^-, are not. In the case of linear μ-oxo species recent results from our laboratories on Mn^{III}—O—Mn^{III} phthalocyanine complexes[24] and from Holwerda *et al.*[25] on $[X(tpa)CrOCr(tpa)X]^{2+}$ compounds show very large negative J values. Indeed, room-temperature diamagnetism is displayed by the Cr···Cr complex, where X = NCSe. These various pieces of data suggest that while the Wieghardt–Girerd model[8] provides a good guide to the sign of J, effects due to the non-bridging ligands and from π-bonding within the μ-oxo bridge will combined to "fine-tune" the actual values of J. It is noteworthy that Gorun and Lippard[26] were unable to obtain a correlation between J and the superexchange distance in FeOFe systems, but were able to do so for complexes with a "supported" oxo linkage Fe(O)(Y)Fe, where Y = RCO_2^-, etc.

$[Fe(tmtaa)]_2O \cdot$ *toluene*. In the course of this work a new toluene solvate of the homobinuclear compound $[Fe(tmtaa)]_2O$ was isolated and is magnetic susceptibility vs temperature behaviour recorded, since only a room-temperature moment per iron ion of $\mu_{eff} = 1.96\mu_B$ had previously been reported for the CH_3CN adduct.[10] This value is comparable with that found for most μ-oxo iron(III) complexes.[16] Despite many preparations of the toluene solvate in the present work it was not possible to isolate a sample with a moment lower than $2.5\mu_B$ and many samples gave higher values. It is concluded that the ease of hydrolysis of the oxo complex referred to in the Experimental prevented the isolation of a sample of the oxo complex completely free of a high spin Fe—OH species. Confirmation of a monomer impurity is seen in the variable-temperature magnetic data which showed a Curie–Weiss-like increase in χ as the temperature decreases, rather than the anticipated decrease.[27] Even at 4.2 K the μ_{Fe} value had only decreased to *ca* $1\mu_B$, rather than zero, indicative of the presence of *ca* 8% of an $S = 5/2$ monomeric species. The data could be fitted well to an $S = 5/2$ dimer model using the parameters $g = 1.88$, $J = -80$ cm^{-1}, % monomer = 8.3 and $\theta = -4.4$, where θ in the $(T-\theta)$ term allows for possible weak intermolecular effects. The value of J is close to that in $[Fe\ salen]_2O$, which has a very similar FeOFe angle.

Acknowledgements—This work was supported by grants from the Australian Research Council (to B.O.W. and K.S.M.) and the award of an ARC Postdoctoral Research Fellowship (to B.M.). The authors are grateful to Professor J. Cashion. for providing access to Mössbauer spectral facilities and to Yasser Korbatieh for recording and fitting the spectra.

(*Received* 20 *April* 1993; *accepted* 11 *May* 1993)

Abstract—The complexes $[Ru(NH_3)_5(NCC_2H_5)](PF_6)_n$ ($n = 2, 3$) have been isolated and characterized by microanalysis, cyclic voltammetry, UV–vis and IR spectroscopies. In acidic media, $C_{H^+} = 1 \times 10^{-3}$ M, $\mu = 0.10$ M ($NaCF_3COO$) at (25.0 ± 0.1)°C, the complex ion $[Ru(NH_3)_5(NCC_2H_5)]^{2+}$ undergoes aquation yielding the *trans*-$[Ru(NH_3)_4(NCC_2H_5)(H_2O)]^{2+}$ ion, with k_{-NH_3} equal to $(1.2 \pm 0.1) \times 10^{-5}$ s^{-1}. The specific rates k_1, k_{-1} and K_{eq} for the reaction:

$$trans\text{-}[Ru(NH_3)_4(NCC_2H_5)(H_2O)]^{2+} + pz \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} trans\text{-}[Ru(NH_3)_4(NCC_2H_5)(pz)]^{2+} + H_2O$$

are, respectively, 8.6×10^{-3} M^{-1} s^{-1}, 1.6×10^{-5} s^{-1} and 5.4×10^2 M^{-1}, under the same experimental conditions described above. The value for the pK_a of the acid *trans*-$[Ru(NH_3)_4(NCC_2H_5)(pzH)]^{3+}$ was calculated as (1.6 ± 0.1), $\mu = 0.1$ M ($NaCF_3COO$) at (25.0 ± 0.1)°C. The complex ion $[Ru(NH_3)_5(NCC_2H_5)]^{3+}$ undergoes hydrolysis in alkaline medium yielding the propanamide complex of pentaammineruthenium(III), with k_{OH} equal to $(1.9 \pm 0.1) \times 10^2$ M^{-1} s^{-1}.

Using ruthenium(II),(III) tetraammines as probes we are carrying out a systematic study[1,2] in order to understand the metal–ligand interactions. Besides the interest in the *trans* effect and *trans* influence of the ligands, we are spending a considerable effort to learn how the perturbation of charge density in the metal centre and ligands as a consequence of coordination is reflected in their chemical reactivities.

As part of this work it appears particularly attractive to investigate the ruthenium(II),(III) nitrile systems. This paper describes the behaviour of propionitrile as a ligand in ruthenium(II) and ruthenium(III) tetraammines.

EXPERIMENTAL

Chemicals

The solvents employed were freshly distilled before use. Propionitrile (Aldrich) was purified by treatment with phosphorus pentoxide followed by distillation.[3] Doubly distilled water was used throughout. Pyrazine, pz (Aldrich Puriss Grade), was used as supplied.

All of the preparations were carried out under argon. The argon (White Martins S.A.) was purified using $Cr(ClO_4)_2$ solutions and zinc amalgam.

Synthesis of ruthenium compounds

$[Ru(NH_3)_5Cl]Cl_2$ and $[Ru(NH_3)_5(H_2O)](PF_6)_2$ were prepared as described in the literature.[4–6]

$[Ru(NH_3)_5(NCC_2H_5)](PF_6)_2$ (**I**) was prepared by adding $[Ru(NH_3)_5Cl]Cl_2$ (0.2 mmol) to trifluoracetic acid (0.2 M, 9 cm^3) in the presence of zinc amalgam. The zinc amalgam reduces the ruthenium(III) to ruthenium(II) and the chloride ion is fastly aquated,[6] generating the $[Ru(NH_3)_5(H_2O)]^{2+}$ species "*in situ*". When all the $[Ru(NH_3)_5Cl]^{3+}$ species was converted to $[Ru(NH_3)_5(H_2O)]^{2+}$ (*ca* 30 min), propionitrile (3.0 mmol in 0.5 cm^3 methanol) was added to the reaction flask. The mixture was allowed to react in the dark for *ca* 30 min. The complex (**I**) was precipitated by the addition of saturated NH_4PF_6 solution (2 cm^3) and cooling. The resulting yellow solid was filtered and washed with chloroform to remove the excess ligand. Yields better than 80% Found: C, 6.5; N; 15.8; H, 3.8. Calc.: C, 6.8; N, 15.8; H, 3.8%.

$[Ru(NH_3)_5(NCC_2H_5)](PF_6)_3$ (**II**) was obtained by exhaustive electrochemical oxidation of $[Ru(NH_3)_5(NCC_2H_5)]^{2+}$ in aqueous solution. In a typical preparation the $[Ru(NH_3)_5(NCC_2H_5)](PF_6)_2$ salt (40–50 mg) was dissolved in degassed 10^{-3} M CF_3COOH (20–30 cm^3) aqueous solution. Electrochemical oxidation was performed at +0.26 V (vs. S.C.E.). When the oxidation was complete the volume of the solution was reduced through rotaevaporation to 4–5 cm^3. A solid was obtained upon the addition of saturated NH_4PF_6 solution (1 cm^3). The solid was filtered off and washed with cold degassed dry ether (5 cm^3). The yield was better than 60%. Found: C, 5.3; N, 12.0; H, 2.9. Calc.: C, 5.3; N, 12.4; H, 2.9.

Apparatus and techniques

UV and visible spectra were recorded using a Hewlett–Packard Model 8452A Diode Array spectrophotometer. IR spectra were recorded on KBr pellets using a Nicolet Model 5SXC-FT-IR spectrophotometer.

The ^1H NMR spectra were recorded at 200 MHz on a Bruker AC200 instrument; the spectra of the ligand and complexes were obtained in CD_3COCD_3.

The TG/DTG and DSC curves were obtained using a Du Pont Thermal Analyser Model 9900 combined with a Du Pont TGA 951 and DSC 910. The measurements were performed using a dynamic nitrogen atmosphere at a flow rate of 60 $cm^3\ min^{-1}$ up to 600°C. The heating rate was 10°C min^{-1} and sample sizes ranged in mass from 9 to 10 mg.

Electrochemical measurements were made vs the saturated potassium chloride calomel electrode (S.C.E.). The measurements were performed using a Parc Modal 173 potentiostat, a Parc Model 175 universal programmer and a model RE-0091 *X–Y* recorder. A glassy carbon electrode (area 0.51 cm^2), platinum wire and S.C.E. were used in cyclic voltammetric experiments as the working, auxiliary and reference electrodes, respectively. During the electrolysis a platinum net (area 13.6 cm^2) was used as the working elecrode. The number of moles of electrons transferred per mole of complex in an exhaustive electrolysis, at constant potential, was calculated by measuring the total area under the current vs time curves for complete electrolysis. The reversibility of the Ru^{III}/Ru^{II} redox couple was verified on the basis of the ratio of cathodic to anodic peak currents (i_{pa}/i_{pc})[7] and the peak-to-peak potential separation ($\Delta E_{p/a,c}$)[8].

A Corning model 130 pH meter and a Methron EA 147 microglass electrode were used for the pH determinations.

All the measurements were performed at 25.0 ± 0.1°C.

Kinetic measurements

The reactions were followed by monitoring changes in absorbance at fixed wavelengths as a function of time. Pseudo-first-order rate constants (k_{obs}) were determined graphically from plots of $\ln(A_\infty - A_t)$ vs time. The k_{obs} were then used to determine k_1, k_{-1} and K_{eq}, by substitution into the following equation:

$$k_{obs} = k_{-1}[L] + k_{-1} \text{ and } K_{eq} = k_1/k_{-1}.$$

The rate of loss of NH_3 from $[Ru(NH_3)_5(NCC_2H_5)]^{2+}$, k_{-NH_3}, was measured using a high concentration (1.0 M) of a competitor ligand (pz). The study was performed by dissolving **I** in a concentrated aqueous solution of pyrazine (with the pH, ionic strength and temperature previously adjusted) and monitoring the formation of the pz derivative spectrophotometrically at 440 nm.

The hydrolysis of the coordinated propionitrile from $[Ru(NH_3)_5NCC_2H_5)]^{3+}$ to give the propanamide complex was studied in slightly basic solution at 25.0 ± 0.1°C over a range of pH values controlled with $[CO_3^{2-}/HCO_3^-]$ buffer mixtures according to Zanella's procedure.[9]

pK_a *determination*

The pK_a of the acid *trans*-$[Ru(NH_3)_4(NCC_2H_5)(pzH)]^{3+}$ (**III**) was determined spectrophotometrically. The elecronic spectra of **III** (4.8×10^{-4} M) solution at constant ionic strength ($NaCF_3COO/CF_3COOH$, $\mu = 0.10$ M) were recorded as a function of the solution hydrogen ion concen-

tration. The pK_a values were calculated using the relationship:[10]

$$pK_a = pH + \log \frac{A' - A}{A - A^0},$$

where A', A^0 and A are, respectively, the absorbances of the fully protonated complex, the deprotonated complex and a mixture of both at 534 nm (where the protonated species absorbs) at a given pH.

RESULTS AND DISCUSSION

The identity of the propionitrile complex (**I**) has been established through microanalysis, electronic, vibrational and nuclear magnetic resonance spectroscopies and cylic voltammetry.

The electronic spectrum of solutions of **I** shows absorptions at $\lambda_{max} = 262$ ($\varepsilon = 1.5 \times 10^4\ M^{-1}\ cm^{-1}$) and $\lambda_{max} \cong 350$ nm ($\varepsilon = 2.4 \times 10^2\ M^{-1}\ cm^{-1}$), attributed to metal-to-ligand charger-transfer (MLCT) and ligand-field (LF) transitions, respectively (see Table 1). The electronic spectrum of the **II** ion in aqueous solutions exhibits one intense band at 238 nm, attributable to ligand-to-metal charge transfer (LMCT) (see Table 1). These attributions have been proposed by analogy with those described for related complexes.[11]

The cyclic voltammogram of aqueous solutions of **I** or **II** shows a reversible, one-electron process corresponding to the Ru^{III}/Ru^{II} couple at $E^{0\prime} = 0.19 \pm 0.01$ V vs S.C.E.; $\mu = 0.10$ ($(NaCF_3COO)/(CF_3COOH)$), 25.0 ± 0.1°C.

The IR spectra of **I** displays one intense band in the nitrile region at 2260 cm^{-1}, attributed to the stretching frequency ν(CN), which is shifted [$\Delta\nu(CN) = +14\ cm^{-1}$] from the free ligand value.

There has been some controversy in the literature regarding the position of ν(CN) for ruthenium(II) complexes. Ford *et al.*[11] reported that ν(CN) is shifted to lower energy when nitriles are coordinated to the $Ru(NH_3)_5^{2+}$ moiety and ascribed his results to $Ru^{II} \rightarrow NCR$ back-bonding. Chatt *et al.*[12] reported ν(CN) shifts to higher energies for nitriles coordinated to a ruthenium(II) centre. These authors[11] pointed out that besides back-bonding arguments the polarization ability of the counter-ion should also be considered. This seems to be the case for our compound.

For complex **II** ν(CN) is observed at 2294 cm^{-1} [$\Delta\nu(CN) = +48\ cm^{-1}$]. This shift of ν(CN) is expected as a consequence of the σ-bond $Ru^{III} \leftarrow NCR$ and is in agreement with the ν(CN) values reported for related systems in the literature.[11]

The proton magnetic resonance spectrum of propionitrile coordinated to pentaammineruthenium(II) is characterized by a decrease in chemical shielding[13] for the nitrile protons relative to the free ligand. The methyl protons are deshielded much less than the methylene (0.07 and 0.50 ppm, respectively).

As judged from TG/DTG data complex **I** is stable up to 140°C. A small loss of weight (1.17%) is observed before 140°C, probably due to the escape of adherent moisture present in the sample. At temperatures higher than 140°C samples of **I** exhibit a two-step weight loss. The first step, *ca* 9% weight loss, occurs in the range 140–250°C and is enveloped by a well defined second step 250–500°C corresponding to a weight loss of 54%.

Table 1. Band maxima, molar absorption[a] and formal reduction potential[a]

Complex	λ_{max} (nm)[b]	ε ($M^{-1}\ cm^{-1}$)	$E^{0\prime}$ (V vs S.C.E.)
$[Ru(NH_3)_5(NCC_2H_5)]^{2+}$	262	1.5×10^4	0.19 ± 0.01
	$\cong 350$	2.4×10^2	
Trans-$[Ru(NH_3)_4(NCC_2H_5(H_2O)]^{2+}$	262	4.4×10^3	0.20 ± 0.01
	378[b]	3.6×10^2	
Trans-$[Ru(NH_3)_4(NCC_2H_5)(pz)]^{2+}$	442[b]	8.0×10^2	0.64 ± 0.01
$[Ru(NH_3)_5(NCC_2H_5)]^{3+}$	238	1.2×10^3	
	$\cong 290$	4.0×10^3	0.19 ± 0.01
	382	2.6×10^2	
$[Ru(NH_3)_5(NHCOC_2H_5)]^{2+}$	238	3.3×10^3	0.74 ± 0.01[c]
	382[b]	2.4×10^3	

[a] Hexafluorophosphate salt.
[b] ± 2 nm.
[c] Irreversible E_{pa}.

The reaction:

$$[Ru(NH_3)_5NCC_2H_5]^{2+} + H_2O \xrightarrow{k_{-NH_3}} trans\text{-}[Ru(NH_3)_4(NCC_2H_5)(H_2O)]^{2+} + NH_3$$

has been followed spectrophotometrically, using pyrazine as an auxiliary ligand, and the decrease in the solution hydrogen ion concentration was potentiometrically monitored. A good agreement was observed for the specific rate k_{-NH_3} measured by both techniques: $(1.2 \pm 0.1) \times 10^{-5}$ s^{-1}; at 25.0 ± 0.1°C, $\mu = 0.10$ M ($NaCF_3COO/CF_3COOH$).

The characteristics of the electronic spectra of the *trans*-$[Ru(NH_3)_4(NCC_2H_5)(H_2O)]^{2+}$ ion in aqueous solutions are summarized in Table 1. The absorptions at 262 and 378 nm have been attributed to MLCT and LF transitions, respectively.

The cyclic voltammogram of the *trans*-$[Ru(NH_3)_4(NCC_2H_5)(H_2O)]^{3+/2+}$ system in aqueous solution is reversible and the formal potential, $E^{0\prime}$, for the Ru^{III}/Ru^{II} couple in this complex is (0.20 ± 0.01) V vs S.C.E., $\mu = 0.10$ ($NaCF_3COO/CF_3COOH$), $C_{H^+} = 3.0 \times 10^{-4}$ M; at 25.0 ± 0.1°C.

The reaction:

$$trans\text{-}[Ru(NH_3)_4(NCC_2H_5)(H_2O)]^{2+} + pz \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} trans\text{-}[Ru(NH_3)_4(NCC_2H_5)(pz)]^{2+} + H_2O$$

has been studied kinetically as a function of the pyrazine concentration, see Table 2.

From the data in Table 2, it is possible to calculate values for k_1, k_{-1} and K_{eq} of 8.6×10^{-3} M^{-1} s^{-1}; 1.6×10^{-5} s^{-1} and 5.4×10^{-2} M^{-1}, respectively.

Evidence for rate saturation was observed in plots at k_{obs} vs C_{pz} for $C_{pz} > 1.0 \times 10^{-1}$ M, suggesting that the substitution reaction is controlled by a dissociative pathway.[1] The same behaviour has been described before for substitution reactions on ruthenium(II) tetra- and pentaammine centres.[1,14,15]

Table 2. Substitution in *trans*-$[Ru(NH_3)_4(NCC_2H_5)(H_2O)]^{2+}$ by pyrazine (pz)[a]

10^2 [pz] (M)	$10^4 k_{obs}$ (s^{-1})
0.50	0.60
1.6	1.6
4.0	3.6
5.0	4.5
6.0	5.3
7.5	6.4
8.0	6.8
10.0	9.0
15.0	9.8
20.0	10.0

[a] $\mu = 0.10$ ($NaCF_3COO$), $C_{H^+} = 3.0 \times 10^{-4}$ M, $C_{Ru^{II}} = 5.0 \times 10^{-4}$ M, each value a mean of at least three independent determinations, agreeing within ±4%.

When the NH_3 ligand in a *trans* position to H_2O, in the coordination sphere of $[Ru(NH_3)_5(H_2O)]^{2+}$, is replaced by propionitrile the substitution rate of the water molecule by pz is reduced about seven fold. Based on the second-order specific rate data for water substitution by pyrazine (k_1) in the *trans*-$[Ru(NH_3)_4L(H_2O)]^{2+}$ complexes, see Table 3, the relative *trans* effect series of L[1] can be written as follows:

$$NCC_2H_5 < SbPh_3 < NH_3 \cong AsPH_3 < SO_2 < PPh_3 < P(OEt)_3 < SO_3^{2-}.$$

The position of the propionitrile in the above series is in agreement with the good π-acid and weak σ-base properties of the NCC_2H_5 molecule. As reported by Isied in a related work[15] this class of ligand exhibits weak *trans* labilizing effects.

Assuming $k_{-1}/k_1 = 1/K_{eq}$ as an indicator of the relative *trans* influence of L[1] and based on the data of Table 3 the following series can be deduced:

$$NH_3 \ll SO_3^{2-} < SbPh_3 < AsPh_3 \leqslant NCC_2H_5 < SO_2 < PPh_3 \ll P(OEt)_3.$$

The extent of the $Ru^{II} \rightarrow$ pz back-bonding is well accepted[1,14-18] and is an indicator of the degree of the competition between L and pz for the 4*dπ*-electrons. Therefore, the stronger the back-bonding interaction $Ru^{II} \rightarrow L$, the weaker will be the $Ru^{II} \rightarrow$ pz bond. The above *trans* influence series of ligands L suggests that NCC_2H_5 is a π-acid as good as $AsPh_3$, but weaker than SO_2.

Another parameter used[1,14,15,17] to evaluate the 4*d*-electron availability upon coordination of the metal centre to L is the pK_a value for *trans*-$[Ru(NH_3)_4L(pzH)]^{3+}$ species. In strongly acidic solution it is possible to protonate reversibly the pyrazine ligand in the *trans*-$[Ru(NH_3)_4(NCC_2H_5)(pz)]^{2+}$ complex. The pK_a value for the *trans*-$[Ru(NH_3)_4(NCC_2H_5)(pzH)]^{+}$ acid was determined as equal to 1.6 ± 0.1, see Experimental.

This pK_a value, between the pK_a[17] of the free pyrazine molecule (0.50) and that[17] for the pyrazine coordinated to the $[Ru(NH_3)_5]^{2+}$ moiety (2.5), reflects the competition for the 4*dπ*-electrons between NCC_2H_5 and pz (see Table 3).

Based on the pK_a values of Table 3, the position of propionitrile in the increasing series of π-acidity for selected ligands is as follows: $NH_3 < SbPh_3 < AsPh_3 < NCC_2H_5 < PPh_3$.

At this point some comments seem in order regarding the reactivity of species **II**.

Table 3. Data on substitution reactions:

trans-$[Ru(NH_3)_4L(H_2O)]^{2+}$ [a] + pz $\rightleftharpoons$ *trans*-$[Ru(NH_3)_4Lpz]^{2+,0} + H_2O$

and pK_a for *trans*-$[Ru(NH_3)_4L(pzH)]^{3+}$ acids

L	k_1 (M^{-1} s^{-1})	k_{-1} (s^{-1})	K_{eq} (M^{-1})	pK_a	Ref.
PPh_3	1.15	3.9×10^{-2}	29.5	1.3	16

NCC_2H_5	8.6×10^{-3}	1.6×10^{-5}	5.4×10^{2}	1.6	This work

[a] At 25 ± 0.2°C; $\mu = 0.10$.

Species **I**, in basic medium in the absence of oxygen, only undergoes the aquation reaction described earlier in this paper. If oxygen is present the oxidation of the ruthenium(II) centre occurs followed by the formation of the amide complex:

$$[Ru(NH_3)_5(NCC_2H_5)]^{3+} \xrightarrow[k_{OH}]{[B]} [Ru(NH_3)_5(NHCOC_2H_5)]^{2+}.$$

The k_{OH} for the above reaction $(1.9\pm0.1)\times10^2$ M^{-1} s^{-1} ($\mu = 1.0$ M, $NaClO_4$, $[B] = [CO_3^{2-}/HCO_3^-]$, at 25.0 ± 0.1°C) is very close to those reported in the literature[9] for related ligands.

Fast aquation of the ligand $NHCOC_2H_5$ is observed if the metal centre is reduced to ruthenium(II):

$$[Ru(NH_3)_5(NHCOC_2H_5)]^{2+} \xrightarrow[\text{Fast}]{Zn/Hg} [Ru(NH_3)_5(H_2O)]^{2+} + NH_2COC_2H_5.$$

The ruthenium complex is quantitatively regenerated as $[Ru(NH_3)_5(H_2O)]^{2+}$ and the coordinated nitrile quantitatively converted in the corresponding amide.

Work on related systems is in progress at our Laboratory and results will be reported later.

(*Received* 7 *April* 1993; *accepted* 11 *May* 1993)

Abstract—$[Cu(PPh_3)I]_4$ reacts with heterocyclic thiones (L) [L = pyrimidine-2-thione (pymtH), 1,3-thiazoline-2-thione (tzdtH), 1,3-imidazoline-2-thione (imtH), benz-1,3-imidazoline-2-thione ($bzimtH_2$) and benz-1,3-thiazoline-2-thione (bztztH)] in the presence of triphenylphosphine to give mononuclear complexes of the general formula $[Cu(PPh_3)_2(L)I]$. These complexes have been characterized by various physicochemical methods. The crystal structure of $[Cu(PPh_3)_2(pymtH)I]$ has been determined by single-crystal X-ray diffraction methods. The molecule is mononuclear, with a distorted tetrahedral geometry and bond lengths Cu—S = 2.338(4), Cu—I = 2.674(2), Cu—P = 2.296(4) and 2.303(4) Å.

A considerable amount of work has been done in the past two decades on the synthesis and characterization of metal complexes containing heterocyclic thiones as ligands.[1] In particular, owing to the high tendency of copper(I) to form metal–sulphur bonds, a large set of compounds resulting from copper(I) halides and heterocyclic thiones were presented.[2] During our previous studies in this area much attention has been given to understanding the factors that govern the coordination geometry of the metal atom. Working on this problem we used various arylphosphines as a second bulky π-acceptor ligand to induce changes on copper geometry.[3] The structures of the copper(I) complexes we have obtained consist generally of monomeric or dimeric species constructed by bridging halogen or thione ligands. In the case of monomerics triphenylphosphine has been shown to form four-coordinate complexes, while the size of the thione ligand seemed not to play a significant role. Thus, it was believed that three-coordinate complexes should be possible to prepare if more bulky tertiary phosphines were to be employed. Indeed, that has been observed using the sterically more hindered triorthotolylphosphine, as exemplified by the structures of $[Cu(totp)(tzdtH)Br]$[3f] and $[Cu(totp)(pymtH)Cl]$[3h]. In general it has been shown that the geometry of complexes of univalent coinage metals is determined by steric rather than by electronic properties of the phosphine ligands.[4] On the other hand, the reasons for the formation of dimeric complexes as well as the cause of the bridging of the two copper(I) centres either by halogen or by thione-S atoms was not fully understood. As a contribution towards the elucidation of the questions about the stereochemical properties of this very interesting class of complexes, we report here the syntheses and characterization of a new series of mononuclear complexes of the general formula $[Cu(PPh_3)_2(L)I]$.

EXPERIMENTAL

Materials and instruments

CuI and PPh_3 were purchased from Merck and used as received. All thiones (Merck or Aldrich) used in this work were recrystallized from hot ethanol, while the solvents were of reagent grade and were used without further purification. $[Cu(PPh_3)I]_4$ was prepared by the method of Costa *et al.*[5]

IR, electronic and NMR spectra, conductivities, melting points, magnetic susceptibility measurements and elemental analyses of carbon, nitrogen and hydrogen were performed as described previously.[3d] Thermogravimetric analyses were performed on a TGS-2 Perkin–Elmer DTG/TG thermobalance in air with a heating rate of 10°C min^{-1}. Sample sizes were *ca* 10 mg.

Preparation of the complexes

A solution of $[Cu(PPh_3)I]_4$ (1 mmol) in acetonitrile (20 cm^3) was treated with a solution (50 cm^3) of the appropriate thione (4 mmol) in the same solvent. The reaction mixture was stirred for 2 h at 40–50°C, filtered and allowed to evaporate slowly at room temperature. The microcrystalline solid thus formed was collected by filtration, washed with small amounts of ethanol and ether and dried *in vacuo*. The yields observed were 35–40%.

All prepared complexes, with their elemental analyses and some physical properties, are given in Table 1.

Crystal structure determination

A crystal of size $0.1 \times 0.2 \times 0.4$ mm was used for the measurement on a Syntex $P2_1$ diffractometer. Cell parameters were obtained from least-squares treatment of setting angles of 15 reflections in the range $19 \leqslant 2\theta \leqslant 22°$. Intensities were collected using graphite monochromatized Mo-K_α radiation in the θ–2θ scan mode and peak profile analysis according to Lehman and Larsen.[6] Only reflections with $I \geqslant 4\sigma(I)$ were classified observed. Intensities were corrected for Lorentz and polarization factors. The structure has been solved by the heavy atom method and refined by full-matrix least-squares calculations on *F*s, with atomic scattering factors from SHELX76.[7] The refinement was carried out, first with isotropic and then with anisotropic temperature factors. Positions of hydrogen atoms were calculated from geometric conditions and refined using a riding model with fixed isotropic *U*. Molecular illustrations were drawn using the ORTEP program.[8] Other experimental conditions and residual factors are listed in Table 2. Main bond distances and angles are given in Table 3. See also "supplementary material".

RESULTS AND DISCUSSION

In previous work monomeric mixed-ligand complexes of copper(I) halides were generally prepared by the simple reaction between the heterocyclic thiones and a 1:2 mixture of CuX and PPh_3 in chloroform or acetone solutions. On the other hand, when a "cubane-like" complex, $[Cu(PPh_3)X]_4$ or $Cu_2X_2(ttp)_n$ (ttp = tritolylphosphine, $n = 2$ or 3),[9] was used as a starting material the reactions resulted, under the same conditions, in the formation of dimers with either sulphur or halogen as bridging atoms. However, compositions and spectroscopic investigations of the compounds discussed here confirm their monomeric nature, although they were synthesized using the method for preparing the dimeric complexes in acetonitrile solution as the only modification. Since CuI forms weak complexes with acetonitrile,[10] it can be suggested that such an unstable complex, probably formed by dissolving $[Cu(PPh_3)I]_4$ in acetonitrile, acts as an intermediate in which CH_3CN ligands

Table 1. Analytical data and some physical properties of the complexes

Complex	Φ_i max[a]	Colour	Melting point (°C)	Elemental analysis: found (calc.) (%) C	H	N
1 $[Cu(PPh_3)_2(pymtH)I]$	0.164	Yellow	209	57.6 (58.1)	4.0 (4.1)	3.5 (3.4)

may be readily displaced by thione and phosphine ligands.

All the complexes are microcrystalline solids soluble in chloroforom, methanol, ethanol, acetone and acetonitrile. According to the analytical results, the composition of the complexes is CuI · 2PPh$_3$ · L. Their solutions are non-conducting in acetone and chloroform. Room-temperature magnetic measurements confirmed the diamagnetic nature of the compounds studied.

Information concerning the structure of the investigated complexes, as well as the coordination mode of the ligands, can be provided on the basis of IR spectra. The presence of ν(NH) bands at 3200–3130 cm^{-1},[11a] the absence of ν(SH) absorptions in the 2500–2600 cm^{-1} region[11b] and the production of characteristic "thioamide" bands[11c] in the solid state IR spectra of both complexes and the corresponding free ligands exhibit the dominance of the thione form of the ligands investigated. The coordination through the sulphur atom is indicated by the shifts of the "thioamide" vibrations upon metal coordination.[3b]

The UV–vis spectra of the complexes in chloroform solutions show two main broad bands in the regions 255–262 and 290–335 nm, respectively, accompanied by another one at 280 nm. The two higher energy bands can be attributed to intraligand transitions of the phosphine ligand, since the spectrum of the free phosphine consists of three bands, at 287, 280 and 262 nm, for which the bands at 262 and 280 nm are found to have log ε values similar to their counterparts in the complexes.

The ^{1}H NMR spectra of the complexes are diagnostically of minor importance, since the protons of the heterocyclic thiones fall in the region of the triphenylphosphine peaks. However, the dominance of the thione form of the ligands in all complexes under investigation can be deduced by the presence of a broad peak in the region 10–14 ppm, assigned to the NH group, connected with the absence of the peak for the thiol (SH) proton at δ = 3–5 ppm.

Thermal analysis in flowing air shows the complexes decompose in two or three stages. Figure 1 illustrates TG and DTG data curves for the complex [Cu(PPh_3)$_2$(pymtH)I]. The thermal decomposition of the compound is a typical example of a two-stage process. The first stage (250–345°C) is connected with two very strong endothermic effects and involves a 76% mass loss, consistent with the evolution of the thione and the two PPh_3 molecules (theoretical mass loss 77%). The second stage (470–570°C) is accompanied by a strong endothermic effect and involves a 14% mass loss corresponding to the evolution of the iodine atom and oxidation of the copper(I) to CuO (theoretical mass loss 13.4%).

Room temperature irradiation of the complexes in chloroform at the maximum of the band in the region 290–335 nm causes the decomposition of the complexes in two photoproducts, as we can estimate according to Coleman's method.[12] The decomposition occurs within minutes and can be checked periodically by comparison of the intensities of the bands in the UV spectra, since no evolution of new bands or significant shifts could be observed during the experiment. In accordance with our earlier observations in mixed-ligand complexes there is no difference in the decomposition mechanism of the complexes, on the grounds of the lability of the phosphine ligand in solution.[13–15] Quantum yields of these complexes have been determined at room temperature and are reported in Table 1.

Description of the structure

Main bond lengths and angles are given in Table 3. Figure 2 shows a view of the molecular structure with hydrogen atoms omitted; molecular packing is shown in Fig. 3. The crystal structure of [Cu

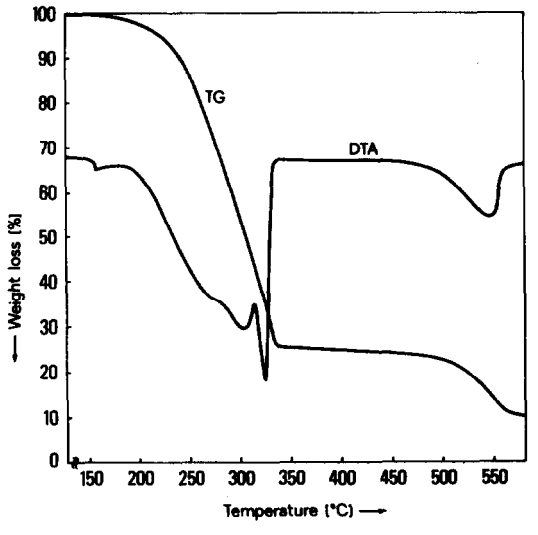

Fig. 1. TG and DTG curves for [Cu(PPh_3)$_2$(pymtH)I].

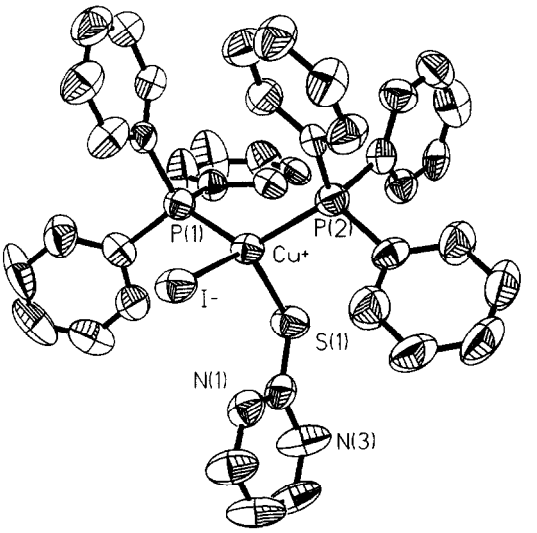

Fig. 2. An ORTEP drawing showing the main atom numbering scheme.

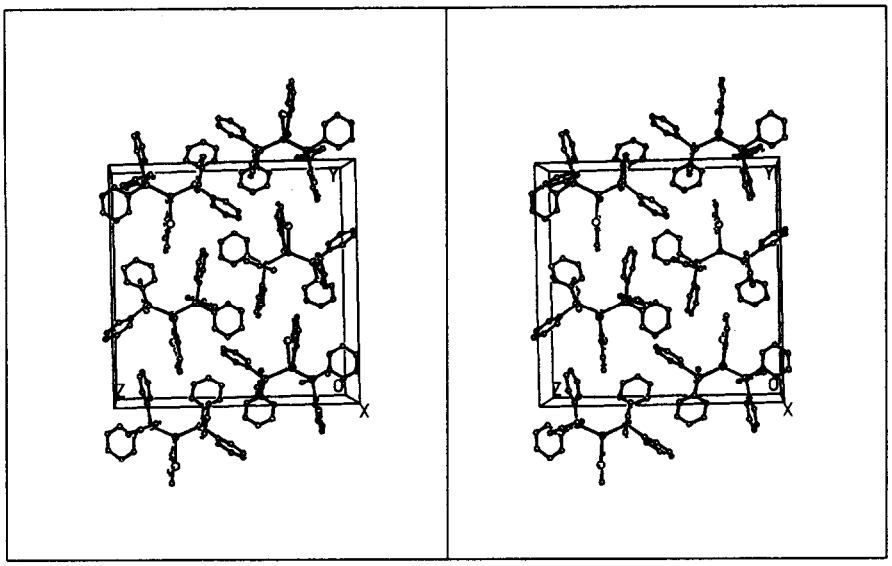

Fig. 3. Packing diagram. A stereoview down the *a*-axis.

$(PPh_3)_2(pymtH)I]$ is built up from well-separated discrete molecules with no crystallographically imposed symmetry. The coordination around the metal is tetrahedral with two phosphorus atoms of the phosphine, one sulphur of the thione and one iodine atom. According to the Cambridge Structural Database this is the first known structure with a $CuIP_2S$ core. This arrangement is considerably distorted since the phosphorus angle at the metal site, P(1)—Cu—P(2) with a value of 125.3(1)°, is much larger than the tetrahedral value, 109.4°. This higher angle is counterbalanced by the bond angles I—Cu—P(1), I—Cu—P(2) and S—Cu—P(2), whose values are lower than 109.4° [103.5(1), 103.6(1) and 103.4(1)°, respectively]. The tetrahedral distortion is due to steric imposition of the bulky phosphine ligands and was previously observed in a series of analogous complexes, e.g. in $[Cu(PPh_3)_2(meimtH)Br]$ [P—Cu—P = 130.9(0)°][3c] and in $[Cu(PPh_3)_2(pymtH)Br]$ [P—Cu—P = 125.0(2)°].[3a]

The Cu—S distance of 2.338(4) Å is somewhat longer than in the bromine isomorph [2.302(4) Å],[3a] but shorter than in $[Cu(PPh_3)_2(meimtH)Br]$ [2.375(1) Å][3c] or in $[Cu(PPH_3)_2(bzimtH_2)Cl]$ and $[Cu(PPh_3)_2(nbzimtH_2)Cl]$ [2.377(1) and 2.381(2) Å, respectively].[3e] This shortening of the Cu—S distance upon coordination reflects the increase of the π-character in this bond. The Cu—P(1) and Cu—P(2) distances of 2.296(4) and 2.303(4) Å, respectively, are significantly longer than those observed in the isomorphous structure of $[Cu(PPh_3)_2(pymtH)Br]$ [2.263(4) and 2.267(4) Å], but closer to those found in other triphenylphosphine complexes.[16,17] The Cu—I distance of 2.674(2) Å is within the range of values (2.622–2.785 Å) previously reported for copper(I) complexes[18] and exactly the same found in $[Cu(py2SH)_2I]_2$.[2c] The short non-bonding distance in the molecule H(1A)···I(1) can be accepted as an intramolecular hydrogen bond with the geometry: N(1)···I(1) = 3.549 Å, H(1A)···I(1) = 2.65 Å and N(1)—H(1A)—I(1) = 176°.

Supplementary material. List of atomic coordinates, positional and isotropic thermal parameters of the hydrogen atoms, the bond lengths and angles and the anisotropic thermal parameters are available from the authors on request.

A SECONDARY REACTION IN THE OXIDATION OF L-METHIONINE BY CHROMIUM(VI) IN ACIDIC MEDIUM*

L. F. SALA,† C. PALOPOLI, V. ALBA and S. SIGNORELLA

Departamento de Ciencias Exactas, Facultad de Ciencias Bioquímicas (UNR), Suipacha 531, 2000 Rosario, Argentina

(*Received* 22 *February* 1993; *accepted* 11 *May* 1993)

Abstract—The reaction mechanism of the oxidation of L-methionine by chromium(VI) in perchloric acid has been reviewed. Secondary reaction products formed by methionine C(1)—C(2) bond scission were observed, besides the major oxidation product: methionine sulphoxide. Methionine sulphoxide and methional (3-[methylthio]-propionaldehyde) were found to be produced by two parallel redox steps. Ammonia and carbon dioxide have been identified and their yields determined. Free radicals were detected during the reaction course and the yield of carbon dioxide was found to be independent of the amount of free radical scavenger. When the amino group was blocked by an acetyl group the N-acetylmethionine sulphoxide was the only oxidation product. The mechanism with the associated reaction kinetics are presented and discussed.

In recent years several studies have reviewed the toxicity and carcinogenicity of chromium compounds.[1–3] Chromium(VI) compounds pose serious dangers to biological systems and many small molecules found within the cell are redox active and should be able to reduce them. These compounds may be important to the cellular metabolism of chromium(VI).[4,5]

Amino acids containing a thiol group are strong reductants of chromium(VI).[6] We have undertaken a study of the reaction between chromium(VI) and methionine, which contains a thio ether group, under acidic conditions. These reactions had previously been investigated[7,8] and the N-methionine sulphoxide was the only product detected by the authors. In this work we demonstrate that C—C scission occurs leading to the formation of carbon dioxide and ammonium ions by a competitive reaction path and that carbon dioxide yield increases as the pH rises. This parallel reaction implies a reformulation of the kinetic law and mechanism with respect to those proposed previously and suggests that amino and carboxylic groups should be coordinated to chromium(VI) to form an intermediate ester, previous to the slow redox step.

EXPERIMENTAL

Materials

(−)-L-methionine (Sigma), potassium dichromate (Cecarelli), sodium perchlorate (Sigma), perchloric acid (Merck, 70% reagent), acetic anhydride (Merck) and 2,4-dinitrophenylhydrazine (Aldrich) were used without further purification. N-acetylmethionine and methionine sulphoxide were synthesized by methods described in the literature.[9,10] Mixtures of sodium perchlorate and perchloric acid were used to maintain a constant ionic strength of 0.4 M at different hydrogen ions concentrations.

Kinetic measurements

Reaction rates were determined spectrophotometrically by monitoring chromium(VI) decay at 350 nm on a Guildford Response II recording spectrophotometer with a thermostated cell-holder. No chromium(V) was observable by EPR spectroscopy under the experimental conditions used, indicating that changes in absorbance at

*The present work has been presented at the XIX Latin American Meeting on Chemistry, Buenos Aires, Argentina (1990).

† Author to whom correspondence should be addressed.

350 nm reflected changes in chromium(VI) concentrations without interference from chromium(V). Rate constants obtained from multiple determinations were within ±5% of each other.

For all the kinetic measurements the concentration of chromium(VI) was kept constant at 6×10^{-4} M, while the L-methionine and N-acetylmethionine concentrations were varied from 1.75×10^{-2} to 0.14 M and from 7.3×10^{-3} to 0.172 M, respectively, at a constant ionic strength of 0.4 M. The reactants were found to be stable over the time course of the kinetic measurements. In every experiment perchloric acid was used as a source of hydrogen ions. Over the course of the reactions the pH was constant to within 0.1 pH unit. In the range of pH used the protonated form of L-methionine ($pK_{a_1} = 2.28$)[11] is the main species in solution.

Test for free radicals

A solution of potassium dichromate (1.2×10^{-3} M, 2 cm^3) in 0.01 M $HClO_4$ was added to a mixture of 0.1 M methionine in 0.01 M $HClO_4$ and 23% p/p acrylonitrile (0.5 cm^3), at 60°C. After 30 min a white precipitate of a polymer appeared slowly. Under the same conditions in a reaction mixture of N-acetylmethionine, potassium dichromate and acrylonitrile a white precipitate appeared after 50 min. The blank experiments in the absence of methionine, N-acetylmethionine or potassium dichromate did not show the formation of any such precipitate.

In a series of experiments increasing amounts of acrylonitrile (11 to 22 mmol) were added to a mixture of L-methionine and potassium dichromate in $HClO_4$ (the same conditions as above) and the carbon dioxide yielded was measured. For all the experiments the yield of carbon dioxide was found to be constant (*ca* 30%), indicating that carbon dioxide radicals should not be formed over the course of the methionine oxidation.

Products analysis

In excess of oxidant. In a typical experiment a solution (25 cm^3) of methionine (0.123 M) in 1 M $HClO_4$ was added to a potassium dichromate solution (25 cm^3, 0.611 M) in 1 M $HClO_4$, at 60°C. The solution was continuously flushed with pure nitrogen. The gaseous products were taken in a 0.3% 2,4-dinitrophenylhydrazine acid solution and in a sodium hydroxide solution.

After 6 h the 2,4-dinitrophenylhydrazone acid solution was filtered out and the yellow residue was analysed by ^1H and ^{13}C NMR. The compound was identified as the 2,4-dinitrophenyl hydrazone of acetaldehyde by comparing the spectra with those of an authentic sample.

The sodium hydroxide solution was titrated against 0.07 N HCl solution to determine the carbon dioxide yielded. Quantitative amounts of carbon dioxide were obtained.

A sample of the reaction mixture (10 cm^3) was alkalinized with NaOH and heated. Distilled ammonia was swept into a 0.2 N HCl solution and titrated against standard NaOH solution. In this way a quantitative yield of ammonia was found.

Unreacted chromium(VI) was determined spectrophotometrically at 350 nm after complete degradation of the organic compound; 2 mol of chromium (VI) were consumed per mole of methionine.

From these experimental data the stoichiometry for the total oxidative degradation of methionine by chromium(VI) is:

$$CH_3S(CH_2)_2CH(NH_3^+)COOH + 2Cr^{VI} \rightarrow (CH_3)_2SO + CH_3CHO + NH_4^+ + CO_2 + 2Cr^{III}. \quad (1)$$

No attempt was made to determine dimethylsulphoxide in the reaction mixture.

In excess of organic substrate. A mixture (25 cm^3) of L-methionine (0.598 M) and potassium dichromate (0.010 M) in 0.78 M $HClO_4$ was allowed to react at 60°C. After the reaction proceeded to completion the mixture was used to charge a Dowex 50W-X8, 100–200 mesh cation exchange column. Continued elution with increasing amounts of $HClO_4$–$NaClO_4$ mixtures resulted in the separation of two fractions. The first was purple in colour and could be eluted with 1 M $HClO_4$. The second had a blue colour and was eluted with 2 M $HClO_4$.

For the blue fraction bands at 410 and 570 nm were observed ($\varepsilon = 13$ and 16 M^{-1} cm^{-1}, respectively), attributable to the octahedral $^4A_{2g} \rightarrow {}^4T_{1g}$ and $^4A_{2g} \rightarrow {}^4T_{2g}$ transitions in O_h symmetry, respectively which are distinctive of the free chromium(III) aqua-ion.

Given the close agreement (*vide infra*) of both visible and UV spectral maxima and the intensities between the observed species in the purple fraction and those of authentic samples independently prepared,[12,13] this fraction might consist of a mixture of binary complexes of methionine/chromium(III) (395 nm, $\varepsilon = 40.5$ and 530 nm, $\varepsilon = 33$) and methionine sulphoxide/chromium(III) (410 nm, $\varepsilon = 25$ and 561 nm $\varepsilon = 24$). Since these absorption bands are strongly pH dependent,[13] absorbances of the synthesized samples were measured in $HClO_4$ solutions of the same concentration as those of the reaction products in the purple fraction.

Carbon dioxide and ammonia were determined

Table 1. Yields of CO_2 (NH_3) in the oxidation of L-methionine by chromium(VI) at different pH. $[Cr^{VI}]_0 = 0.075$ M; $[Met]_0 = 0.7621$ M, $T = 60°C$

pH	$\%CO_2$ (NH_3)
0.77	24
1.23	31
1.55	35
2.51	48

by the same method as described before. Table 1 shows CO_2 (NH_3) yields at different pH, under excess organic substrate.

In a parallel reaction set methionine sulphoxide was determined by the same method described by Olatunji *et al.*[8] However, the yield obtained was substantially lower than reported because of the co-precipitation of unreacted methionine, even when the same conditions described by the authors were employed.

2,4-Dinitrophenylhydraqzine (1 cm^3) in HCl (2 N) was added to the reaction mixture (3 cm^3) and extracted with ethyl acetate. After adding a solution of Na_2CO_3 the aqueous layer was made alkaline with NaOH and methional was detected spectrophotometrically as the 2,4-dinitrophenylhydrazone ($\lambda_{max} = 432$ nm).[14]

RESULTS AND DISCUSSION

Rate studies

Over the whole range of pH used in the kinetic measurements UV–vis studies showed that the reaction of methionine and chromium(VI) resulted in an absorption band at 350 nm and a shoulder at 420–500 nm, characteristic of the $Cr_2O_7^{2-}$ ion.[15] Under our experimental conditions no spectral evidence of a methionine-chromium(VI) ester was obtained.

The observed rate constants were calculated from the absorbance data obtained at 350 nm. The pseudo-first-order rate constants were calculated at various $[Cr^{VI}]_0$, but at constant $[S]_0$, $[H^+]_0$, ionic strength ($I = 0.4$ M) and temperature. The rate was found to be constant with increasing amounts of $[Cr^{VI}]_0$ (Table 2), indicating that the total chromium(VI) concentration must be used in the rate law.

Table 3 summarizes values of k_{obs} for various concentrations of L-methionine at a fixed concentration of perchloric acid. Plots of k_{obs} vs [methionine] at constant acidity gave straight lines (Fig. 1), from which values of k_1 were determined (Table 3). The plot of k_1 vs $[HClO_4]^2$ gave a straight line with a positive intercept, showing that the first-order rate constant k_1 may be expressed as consisting of an acidity independent and an acidity dependent term:

$$k_1 = a + b[H^+]^2, \quad (2)$$

where $a = 0.01402\ M^{-1}\ s^{-1} \pm 8.66 \times 10^{-3}$ and $b = 26.34\ M^{-3}\ s^{-1} \pm 2.02$.

The complete rate law is then given by:

$$-d[Cr^{VI}]/dt = k_{obs}[Cr^{VI}] = (a + b[H^+]^2)[Met][Cr^{VI}] \quad (3)$$

where Cr^{VI} represents the total chromium(VI) concentration and Met = L-methionine.

For the N-acetylmethionine derivative (NAM) a different kinetic law was derived. k'_{obs} values obtained for different $[HClO_4]$ at fixed NAM concentrations are summarized in Table 4. Plots of k'_{obs} vs $[HClO_4]^2$ gave a good straight line (Fig. 2), from which k_2 values were obtained (Table 4). The plot of k_2 vs [NAM] gave a straight line with a positive intercept, showing that k_2 may be expressed as consisting of a term independent of [NAM] and of another with a first-order dependence. The complete rate law is then given by:

$$-d[Cr^{VI}]/dt = k'_{obs}[Cr^{VI}] = (c + d[NAM])[H^+]^2[Cr^{VI}], \quad (4)$$

where $c = 2.53 \times 10^{-3}\ M^{-2}\ s^{-1} \pm 3.4 \times 10^{-4}$ and $d = 9.48\ M^{-3}\ s^{-1} \pm 0.74$ and Cr^{VI} refers to the total chromium(VI) concentration.

Mechanism

A mechanism consistent with all experimental data obtained for the oxidation of methionine with

$$Met^{\cdot+} + Cr_2O_7^{2-} \rightarrow H_3CSO(CH_2)_2CHNH_3^+COOH + Cr^V + HCrO_4^- \quad (8)$$

(MetSO)

$$2HCrO_4^- \rightleftharpoons Cr_2O_7^{2-} + H_2O \quad (9)$$

Scheme 1.

The first step represents the formation of an anionic complex between chromium(VI) and L-methionine acting as a tridentate ligand.[16] This complex may decompose to the aldehyde, ammonium ion and carbon dioxide assisted by another molecule of L-methionine, or may be protonated to a new complex which interacts with another molecule of methionine in the slow step to yield the sulphoxide.

According to the proposed mechanism the full rate law for the chromic oxidation of L-methionine, under conditions studied in the kinetic measurements, can be derived:

$$-\frac{d[Cr^{VI}]}{dt} = k_6[Met][I] + k_7[Met][I][H^+]^2$$

$$= (k_6K_5[Met]^2 + k_7K_5[Met]^2[H^+]^2)[Cr_2O_7^{2-}] \quad (10)$$

since

$$[Cr^{VI}]_T = [Cr_2O_7^{2-}] + [I]$$

$$= [Cr_2O_7^{2-}](1 + K_5[Met]). \quad (11)$$

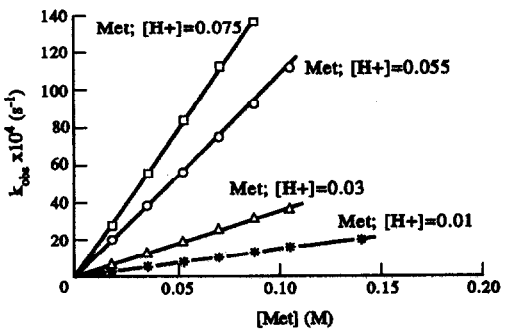

Fig. 1. k_{obs} as a function of [Met] at different [$HClO_4$]; T = 30°C; I = 0.4 M; $[Cr^{VI}]_0 = 6 \times 10^{-4}$ M.

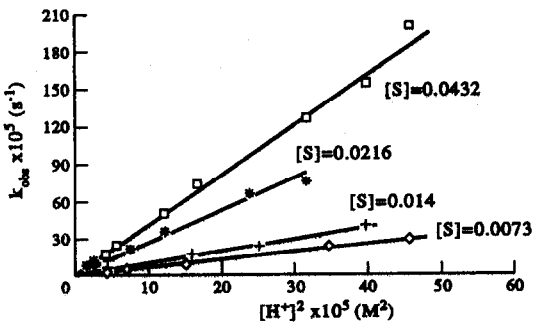

Fig. 2. k'_{obs} as a function of $[HClO_4]^2$ at different [NAM]; T = 30°C; I = 0.4 M; $[Cr^{VI}]_0 = 6 \times 10^{-4}$ M.

Table 4. Observed pseudo-first-order rate constants and calculated k_2 for the oxidation of N-acetyl-L-methionine by chromium(VI); $T = 30°C$; $I = 0.4$ M, $[Cr^{VI}]_0 = 6 \times 10^{-4}$ M

$[HClO_4]$ (M)	$k_{obs} \times 10^5$ (s^{-1}) at [NAM] (M) 0.0073	0.014	0.0216	0.0432	0.0644

0.0724	34.0				
k_2 (M^{-2} s^{-1}) $\times 10^3$	65.85	101.20	255.96	411.50	605.80

Replacing $[Cr_2O_7^{2-}]$ in (10):

$$-\frac{d[Cr^{VI}]}{dt} = \frac{(k_6 + k_7[H^+]^2) K_5 [Met]^2}{1 + K_5 [Met]} [Cr^{VI}]_T. \quad (12)$$

If K_5 [Met] $\gg$ 1, eq. (12) becomes:

$$-\frac{d[Cr^{VI}]}{dt} = (k_6 + k_7[H^+]^2)[Met][Cr^{VI}]_T$$

$$= k_{obs}[Cr^{VI}]_T, \quad (13)$$

eq. (13) is in full agreement with the experimental findings.

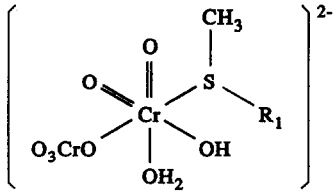
In Scheme 1 the intermediate I differs from those reported previously by other authors who proposed the sulphur atom as the only coordination site.[7,8] The two different oxidation products observed in this work, methionine sulphoxide (oxidation of the sulphur atom) and methyl-3-propionaldehyde thioether [C(1)—C(2) bond scission], suggest that the amino and carboxylate groups should bind chromium(VI) in the intermediate complex. Moreover, the presence of the sulphur function seems to be necessary for amino and carboxylate group coordination and further oxidation. A precedent for suggesting a six-coordinate chromium(VI) intermediate has already been reported for oxidation processes where chromium(VI) acts as a catalyst.[16] To verify the last assumption the reactivity of two structurally related amino acids was checked. Homoserine (4-hydroxy-2-amino-butanoic acid) and isoleucine (3-methyl-2-amino-pentanoic acid) were reacted with chromium(VI) under the same experimental conditions employed to oxidize methionine. As expected, no reaction was detected with either homoserine or isoleucine, indicating that sulphur is essential to yield the redox products.

Sulphur-containing amino acids have been proposed to react by a thioester intermediate with the sulphur as the only atom bound to chromium(VI). However, the possibility of binding by the three coordination sites should not be discarded, even when the main redox product arises from oxidation of the sulphur atom.

The alternative mechanism in Scheme 2 provides another suitable explanation for the formation of

two different oxidation products and also fits the experimental kinetic law well.

$$\text{Met} + Cr_2O_7^{2-} \overset{K_{14}}{\rightleftharpoons} \text{II} \quad (14)$$



where R_1 is $(CH_2)_2CH(NH_2)COOH$

$$\text{II} + 2H^+ + \text{Met} \xrightarrow[\text{slow}]{k_{15}} H_3CS^{\cdot+}(CH_2)_2CH(NH_3^+)COOH + Cr^V + HCrO_4^- \quad (15)$$

$$\text{II} \overset{K_{16}}{\rightleftharpoons} \text{I} \xrightarrow[\text{Met (slow)}]{k_{16}} H_3CS(CH_2)_2CHO + NH_4^+ + CO_2 + Cr^{IV} \quad (16)$$

Scheme 2.

By this mechanism two intermediate complexes between methionine and chromium(VI) are formed. In complex **II** methionine binds chromium(VI) through the sulphur atom. This complex decomposes towards the sulphoxide in the acid catalysed step. Complex **II** is in equilibrium with complex **I**, in which methionine acts as a tridentate ligand, which slowly yields the decarboxylated-deaminated product. Equations (8) and (9) also constitute this mechanism.

If this second scheme is correct those sulphur-containing amino acids for which K_{16} is negligible should produce the sulphur-oxidized product through complex **II**, e.g. penicillamine[17] and cysteine.[18] In this way this second scheme should represent a more general mechanism which comprises those reported previously.

The fact that the yield in CO_2 increases with pH is in agreement with the formation of CO_2 by a path independent of pH, whereas methionine sulphoxide is formed by an acid catalysed step, such as proposed in both mechanisms.

Two consecutive steps involving oxidation of methionine to methionine sulphoxide and further oxidation to the methional sulphoxide may be ruled out on the basis of the absence of reaction when methionine sulphoxide was reacted with chromium(VI) under the same experimental conditions employed to oxidized methionine.

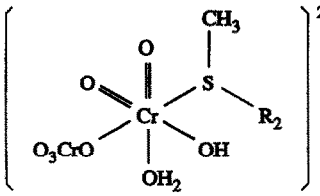
To explain the decarboxylation path it might be thought that the oxidized sulphur function oxidizes the amino group in a subsequent fast step. This N-oxidation might be sterically assisted with the participating sulphur and nitrogen centres adopting a favourable five-membered ring configuration. The oxidized amino radical, regarded as a protonated imine, may be subject to hydrolysis forming the corresponding aldehyde and ammonia. Two reasons may be given to rule out this intramolecular oxidation. First, this oxidation is favoured in basic or slightly acid solutions and no longer takes place in strong acid solutions.[19] This is in clear contrast with the increasing amounts of carbon dioxide observed as the pH rises. Second, if decarboxylation was assisted by the oxidized sulphur function, yield of carbon dioxide should be affected by adding increasing amounts of acrylonitrile to the reaction mixture. On the contrary, the yield of carbon dioxide remained constant.

The spectrophotometric analysis of the chromium(III) products showed a mixture of chromium(III)-methionine and chromium(III)-methionine sulphoxide binary complexes. Some authors[20] have concluded that initial one-electron reduction of chromium(VI) leads to chromium(III) entrapment of the oxidized substrate, whereas initial two-electron reduction leads to chromium(III) entrapment of excess substrate. If this generalization were accepted then the spectrophotometric observation of the chromium(III)-methionine complex as a product would imply an initial two-electron reduction of chromium(VI) by methionine; whereas the chromium(III)-methionine sulphoxide complex suggests an initial one-electron reduction of chromium(VI) by methionine in the acid catalysed pathway.

The constant yield of carbon dioxide observed after adding increasing amounts of acrylonitrile, and radicals observed in the N-acetyl-methionine-$Cr_2O_7^{2-}$ mixtures (in this case the sulphoxide is the only reaction product, as discussed below), lead us to suggest that radicals formed in the oxidation of methionine might take part in the sulphoxide formation, presumably through a sulphur-centred radical-cation.[19] This radical ion may react with another molecule of $Cr_2O_7^{2-}$ in a fast step [eq. (8)] to yield the methionine sulphoxide and chromium(V). $HCrO_4^-$ produced in the slow redox steps rapidly associates to another $HCrO_4^-$ to form $Cr_2O_7^{2-}$, the predominant species of chromium(VI) in the solution [eq. (9)].[15] Finally, intermediate chromium(V) may react with excess methionine in later steps to yield chromium(III) and the oxidation products.

From the experimental data obtained for the oxidation of NAM with chromium(VI) the mechanism in Scheme 3 was deduced:

$$CrO_7^{2-} + NAM \overset{K_{17}}{\rightleftharpoons} \left[\text{III} \right]^{2-}$$



III

(17)

where R_2 is $(CH_2)_2CH(NOAc)COOH$.

$$\text{III} + 2H^+ \xrightarrow[\text{slow}]{k_{18}} H_3CS^{\cdot+}(CH_2)_2CH(NHOAc)COOH + Cr^V \quad (18)$$

$$\text{III} + NAM + 2H^+ \xrightarrow[\text{slow}]{k_{19}} \underset{(NAM^{\cdot+})}{H_3CS^{\cdot+}(CH_2)_2CH(NHOAc)COOH} + Cr^V + NAM \quad (19)$$

$$NAM^{\cdot+} + Cr_2O_7^{2-} \rightarrow H_3CSO(CH_2)_2CH(NHOAc)COOH + Cr^V + HCrO_4^- \quad (20)$$

$$NAM + Cr^V \rightarrow H_3CSO(CH_2)_2CH(NHOAc)COOH + Cr^{III} \quad (21)$$

Scheme 3.

In this case the N-acetyl group blocks the amino group and enables the coordination site at the nitrogen atom. NAM acts then as a monodentate ligand bound to chromium(VI) through the sulphur atom to yield $NAM^{\cdot+}$, through two competitive pathways [eqs (18) and (19)]. Chromium(V) and $NAM^{\cdot+}$, formed in the slow steps, yield the final chromium(III) and the sulphoxide by two later fast steps [eqs (20) and (21)]. This is in agreement with radicals observed when acrylonitrile was added to a reaction mixture. However, the sulphoxide might be formed by a two-electron step, followed by a fast reaction between chromium(IV) and NAM to yield chromium(III) and sulphur-centred radicals responsible for the white precipitate observed with acrylonitrile.

CONCLUSIONS

Methionine reacts with chromium(VI) at a significant rate only at pH < 2; e.g. at pH = 7 it reacts only after prolonged incubation at 37°C.[21] This suggests that the reductant reacts with chromium(VI) especially when protonated to form the intermediate ester, with the ammonium group playing an important role in its rate of formation.[6] At higher pH the rate of formation of this ester is too slow and the oxidation is not significant. At low pH the ester is formed rapidly and the redox steps are rate limiting.

Since decarboxylation viewed as a later oxidation by the oxidized sulphur function was ruled out (discussed above), methionine C(1)—C(2) bond scission reveals that the nitrogen and oxygen atoms might participate in the ester formation. This secondary reaction becomes more important as pH rises and its competitive path becomes slow. It seems reasonable to suppose that this secondary reaction should be more evident for methionine, or any other sulphur-containing amino acid with appropriate structural and configurational characteristics, able to form a strain-free tricyclic intermediate complex with the chromium metal centre.

Abstract—The synthesis of *trans*-2-styrylbenzothiazole (L) and of its complexes with mercury(II) halides is reported. Complexes with the formulae $[Hg_2(L)Cl_4]$, $[Hg(L)Br_2]$, $[Hg(L)_2I_2]$ and $[Hg(L)I_2]$ were isolated and characterized by conventional chemical analysis, electronic and IR spectra and by thermal analysis. For one of these complexes, $[Hg(L)_2I_2]$, the X-ray crystal structure was also determined. The complex consists of discrete $[Hg(L)_2I_2]$ units in which mercury, located on a two-fold axis, shows a distorted tetrahedral coordination and the ligand molecules are bonded via nitrogen atoms with Hg—I = 2.61(2) Å and Hg—N = 2.36(1) Å bond distances.

A large number of benzothiazole derivatives are of considerable biological and chemical interest. Their pharmaceutical and agrochemical applications are of particular relevance and they have attained technological importance in the field of thermoplastic polymers having high thermal stability.[1] This class of compounds is also interesting from a coordinative point of view, since these molecules contain both S and N heteroatoms and a π-donor aromatic system showing a wide variety of complexes.[2–12] This paper reports the synthesis of *trans*-2-styrylbenzothiazole (L) and the results of a study on its coordinating ability with some mercury(II) halides.

EXPERIMENTAL

Physical measurements

Carbon, nitrogen, hydrogen and sulphur were determined with a Carlo–Erba 1106 elemental analyser; IR spectra were recorded in the solid state with a Bruker IFS 113v Fourier-transform spectro-

* Author to whom correspondence should be addressed.

photometer using KBr pellets (4000–400 cm^{-1}) and polythene pellets (500–50 cm^{-1}). Electronic spectra were recorded at room temperature with a Shimadzu MPS 50L spectrophotometer with solid samples on filter paper or on polythene sheets or as Nujol mulls. Differential scanning calorimetric analyses were performed on a Perkin–Elmer DSC-2C calorimeter equipped with IBM PS 2/30 automatic data acquisition and processing software using sealed aluminium pans.

Syntheses

2-*Styrylbenzothiazole.* Sodium (0.1 mol) was slowly added to absolute ethanol (25 cm^3) in a 100 cm^3 flask and refluxed for *ca* 1 h with stirring. Absolute ethanol (15 cm^3) was then added to complete the reaction; benzaldehyde (10.6 cm^3, 0.1 mol) and 2-methyl-benzothiazole (12.7 cm^3, 0.1 mol) were then added dropwise. The stirred mixture became yellow and upon heating a yellow–orange solid precipitated. The solution was then left at room temperature for 14 h and the solid 2-styryl-benzothiazole was collected by vacuum filtration. The solid was suspended in water (10 cm^3) and acetic acid was added to pH 6.5, the pale yellow solid was filtered again and dried at 50°C for 4 h *in vacuo*. The product was twice recrystallized from ethanol/water (1.5/1), filtered by vacuum and dried at 50°C *in vacuo* (yield 6.21 g, 27%); m.p. 111–112°C. Found: C, 75.9; H, 4.7; N, 5.9. Calc. for $C_{15}H_{11}NS$: C, 75.9; H, 4.7; N, 5.9%.

$[Hg_2(L)Cl_4]$. The complex, as a microcrystalline ivory product, was obtained by mixing warm chloroform solutions of mercury(II) chloride and of the ligand with molar ratios ranging from 2/1 to 1/2; m.p. 204°C; λ_{max} = 390 nm. Found: C, 23.2; H, 1.4; N, 1.9; S, 4.0. Calc. for $C_{15}H_{11}NSCl_4Hg_2$: C, 23.1; H, 1.4; N, 1.8; S, 4.1%.

$[Hg(L)Br_2]$. The compound, as a microcrystalline pale yellow powder, was precipitated by adding with stirring a small amount of n-hexane to a warm ethylbenzene solution of mercury(II) bromide and of the ligand in molar ratios as above; m.p. 183°C; λ_{max} = 395 nm. Found: C, 29.9; H, 1.8; N, 2.4; S, 5.1. Calc. for $C_{15}H_{11}NSBr_2Hg$: C, 30.1; H, 1.8; N, 2.3; S, 5.4%.

$[Hg(L)_2I_2]$. The complex was obtained by slow addition with stirring of warm ethanolic solutions of mercury(II) iodide and the ligand with metal/ligand ratios ranging from 1/2 to 1/3. After some days yellow prisms separated; m.p. 130°C; λ_{max} = 400 nm. Found: C, 38.6; H, 2.4; N, 3.0; S, 6.8. Calc. for $C_{30}H_{22}N_2S_2I_2Hg$: C, 38.8; H, 2.4; N, 3.0; S, 6.9%.

$[Hg(L)I_2]$. The synthesis was performed as above with a 1/1 molar ratio; yellow powder; m.p. 150°C; λ_{max} = 410 nm. Found: C, 25.9; H, 1.6; N, 2.1; S, 4.6. Calc. for $C_{15}H_{11}NSI_2Hg$: C, 26.0; H, 1.6; N, 2.0; S, 4.6%.

Crystal data, solution of the structure and refinement

The crystal of the $[Hg(L)_2I_2]$ compound was mounted in a random orientation on the diffractometer: the resulting crystal data with the details of the intensity data collection and refinements are quoted in Table 1. Intensity data were corrected for Lorentz and polarization effects and an empirical correction for absorption was applied.[13] The structure was solved by Patterson and Fourier methods and refined by full-matrix least-squares with iso-

tropic and anisotropic (for Hg, I and S atoms) thermal parameters. Hydrogen atoms were not located but were introduced at the calculated positions only in the final geometrical calculations. Final atomic coordinates and thermal parameters are quoted in the supplementary material; the atomic scattering factors with the anomalous scattering coefficients were taken from International Tables.[14] The calculations were performed on the Gould 32/77 computer of the Centro di Studio per la Strutturistica Diffrattometrica del C.N.R. (Parma) using the SHELX76,[15] ORTEP[16] and PARST[17] programs.

RESULTS AND DISCUSSION

DSC measurements show that all the complexes are very stable up to melting points, following immediately the decomposition, and, therefore, their melting enthalpies are not experimentally accessible. The electronic spectra of the solid complexes show a distinct broad band in the range 390–416 nm, which may be assigned to the CT transition (ligand to metal). The IR spectra of benzothiazoles in the range 1650–1470 cm^{-1} can only be associated with the overall ring-skeleton vibrations, no other specific assignments are possible.[18–20] The identification of the bands in the complexes reported here are made more difficult by the presence of the olefinic double bond of the styryl unit and the possible shifts due to the ligand coordination, therefore, no clear evidence of this fact can be obtained. In the 1320–850 cm^{-1} range, into which fall the CH in-plane deformation and ring-breathing,[19] the spectra of the free ligand and its complexes do not show marked differences. The strong band at 755 cm^{-1} attributable to the CH out-of-plane deformation and the ν(C—S) stretching frequency at 682 cm^{-1} for the free ligand are unchanged in all the complexes, indicating that the metal is not coordinated through the sulphur atom. The far-IR spectrum (500–50 cm^{-1}) of the free ligand exhibits bands at 480, 434, 361, 264, 210, 177 and 100 cm^{-1}: in all the complexes the bands at 480, 430 and 210 cm^{-1}, assignable to the "ring out-of-plane" frequencies, are unchanged. In the chloride and bromide compounds the bands at 339 and 229 cm^{-1}, respectively, are attributable to the mercury–halogen terminal stretching and the band at 361 cm^{-1} of the ligand shifts to 370 cm^{-1}, but no correlation with the structure may be made. $[Hg_2(L)Cl_4]$ shows a band at 353 cm^{-1} which, in agreement with the literature,[21] could suggest the presence of a linear $HgCl_2$ unit and of two non-equivalent $HgCl_2$ molecules. A very strong band at 162 cm^{-1} for the two HgI_2 compounds falls in the region typically associated with the terminal Hg—I vibrations in tetrahedral complexes. All compounds show a band at 270–272 cm^{-1} of medium intensity and absent in the free ligand, tentatively assigned to a ν(Hg—N) mode.

The structure of the complex molecule $[Hg(L)_2I_2]$ is shown in Fig. 1: the mercury atom, located on a two-fold axis is bonded with two iodines and two nitrogen atoms of the ligands. The resulting geometry is very distorted tetrahedral with the angles at the metal N—Hg—N′ 89.9(4)°, I—Hg—I′ 127.4(1)° (′ = $-x,y,1/2-z$) and I—Hg—N 104.5(3)° (Table 2); these values appear to be influenced mainly by the steric hindrance of the bulky iodine atoms. The values found in some tetrahedral N,I-containing mercury compounds are: I—Hg—I 142.7(1), 128.9(1), 122.5(1)° and N—Hg—N 93.7(5), 72.9(5), 102.3(5)°, respectively, in diiodobis(pyridine)mercury(II),[22] (N,N,N′,N′-tetra-

$ii = -x, -y, -z$
$iii = -x-1/2, 1/2-y, -z$

methyl - *o* - phenylenediamine - N,N′)diiodomercury(II)[23] and diiodo(2,3 : 12,13-dibenzo-1,14,17 - trioxa - 5,10 - diaza - 2,3 : 4,5 : 10,11 : 12,13 - cycloenneadecatetraene)mercury(II).[24] The two Hg—I bond distances, 2.61(2) Å, compare favourably with those found in a relevant number of compounds: an inspection carried out using the Cambridge Structural Database (CSD) system[25] considering only the compounds with Hg—I bonds falling in the range 2.50–270 Å gave the result of 37 crystal structures, in which some of the closely related values are 2.603(4) and 2.611(4) Å in (μ_2-tetramethylthiotetrathia - fulvalene - S,S′,S″,S‴)bis [diiodomercury(II)];[26] 2.623(5) Å in 1,4,7,10,13, 16 - hexaoxa - cyclooctadecanediiodomercury (II);[27] and 2.594(4) and 2.605(4) Å in 1-acetyl-1-methyl-2-[1-(2)-iodomercury-2,2-dimethyl-2-silapropylidene]cyclopentene.[28] Also for the Hg—N bonds 2.36(1) Å similar distances are found in 27 crystal structures of CSD (range 2.33–2.39 Å); some of the close related examples are 2.376(6) and 2.379(6) Å in chloro(1,4,8,11-tetraazacyclotetradecane) mercury (II) tetrachloromercury (II)[29] and 2.369(5) Å in bis(μ_2-5-nitro-1,2,3,4-tetrathiazole-N^1,N^3,N^6,N^9-)mercury.[30] Bond distances and angles in the organic molecule show no abnormal features, in particular those related to the five-membered ring are in good agreement with the mean values calculated using 145 observations obtained from CSD: C=S = 1.745(3), 1.743(3) Å;

C—N = 1.328(4) Å, N—C = 1.396(3) Å and C—S—C = 89.7(2)°. The 2-styrylbenzothiazole molecule is only roughly planar [maximum deviation from the least-squares plane 0.08(1) Å; mercury is out of this plane, 0.214(2) Å]; the dihedral angle formed by the phenyl ring and the benzothiazole moiety is only 2.3(4) Å. Styrylbenzothiazoles show different behaviour because of the free rotation of the aromatic ring. Compounds in which the ligand is nearer to the planarity, as in the present structure, include tetraethylammonium tribromo[2 - (2′ - chloro - 4′ - nitrosil) - 6 - methoxybenzothiazole]platinate(II) with a dihedral angle between the aromatic ring and benzothiazole of 6(4)° and 6.7(2)° in 2-(2′-chlorostyryl) benzothiazole;[31] the reasons for these differences could be due to packing forces.

Abstract—The electrochemical oxidation of anodic metal (nickel, zinc or cadmium) in acetonitrile solutions of benzothiazole-2-thione (Hbztz) gave the compounds $[M(bztz)_2]$ [M = nickel(II), zinc(II) and cadmium(II)]. When the oxidations were repeated in the presence of neutral ligands L′ (2,2′-bipyridine or 1,10-phenanthroline) the complexes $[M(bztz)_2L']$ were obtained. The crystal structure of 2,2′-bipyridine bis(benzothiazole-2-thionato)zinc(II) was determined by X-ray diffraction. This compound consists of monomeric molecules in which the central ZnS_2N_2 unit has a slightly distorted tetrahedral environment. The electronic, IR and ^1H and ^{13}C NMR spectra of the complexes are discussed and related to their structure.

Electrochemical procedures have been widely used for the synthesis of metallic complexes, especially those with weakly acid organic ligands, in which the acidic group is usually a hydroxyl,[1,2] pyrrole NH[3,4] or thiol group.[5,6] Of particular relevance to the present work are metal thiolates obtained starting from thiols or disulphides.[2,7] Metallic complexes of these ligands are of interest in a wide range of fields, which in the case of nickel, zinc and cadmium compounds include biochemical applications.

As part of our continuing interest in thiolate complexes, in this work we prepared electrochemically a series of nickel(II), zinc(II) and cadmium(II) complexes with benzothiazole-2-thione (Hbztz), a versatile molecule that can behave either (a) as a neutral ligand through the exocyclic sulphur atom (1),[8] or (b) as an anionic ligand, in which case it can act as a monodentate through the exocyclic sulphur atom (2)[9] or through its nitrogen atom (3),[10] and (c) as a chelating ligand (4)[11] and as a two- (5)[12] or three-way (6)[13] bridging ligand through its nitrogen and exocyclic sulphur atoms. We also prepared mixed complexes containing $bztz^-$ and either 2,2′-bipyridine(bipy) or 1,10-phenanthroline (phen) and determined the crystal of 2,2′-bipyridine bis(benzothiazole-2-thionato)zinc(II).

Although $[M(bztz)_2]$ compounds have been prepared before by non-electrochemical methods, the other compounds reported in this article have not, as far as we know, been synthesized before.

EXPERIMENTAL

All solvents, benzothiazole-2-thione, 2,2′-bipyridine and 1,10-phenanthroline were commercial products used without further purification. The metals (Ega Chemie) were used as plates (*ca* 2 × 2 cm).

Preparation of the complexes

The electrochemical method used in the synthesis of the compounds is similar to that described by Tuck.[14] The cell was a 100 cm^3 tall-form beaker fitted with a rubber bung through which the electrochemical leads entered into the cell. The anode, in foil form, was suspended from a platinum wire and the cathode was another platinum wire. The benzothiazole-2-thione was dissolved in acetonitrile (*ca* 50 cm^3) and a small amount of tetramethylammonium perchlorate (*ca* 10 mg) was added to the solution. For the synthesis of mixed compounds, 2,2′-bipyridine or 1,10-phenanthroline was added. Hydrogen was evolved at the cathode and the formation of an insoluble compound was generally visible in a few minutes. At the end of electrolysis, the solid product was collected, washed with acetonitrile and dried *in vacuo*.

The cells can be summarized as Pt(−)/CH_3N+Hbztz/M(+) and Pt(−)/CH_3CN+Hbztz+L′/M(+), where L′ is bipy or phen and M nickel, zinc or cadmium. Details of solution composition and electrochemical conditions are given in Table 1.

Physical measurements

Microanalyses were performed using a Carlo–Erba EA1108 microanalyser and the results are given in Table 2. IR spectra were recorded in KBr mulls on a Perkin–Elmer 180 spectrophotometer and the optical spectra on a Perkin–Elmer Lambda 9 spectrophotometer. ^1H and ^{13}C NMR spectra were recorded on a Bruker WM 250 MHz spectrometer using DMSO-d_6 as solvent; chemical shifts were determined against TMS as an internal standard. Magnetic measurements were performed using a SQUID.

Crystal structure determination

Crystal data for [Zn(bztz)$_2$bipy)]. $C_{24}H_{16}N_4S_4Zn$, $M = 554.04$, triclinic, space group $P\bar{1}$, $a = 11.27(1)$, $b = 14.14(1)$, $c = 8.64(1)$ Å, $\alpha = 105.60(8)$, $\beta = 106.37(9)$, $\gamma = 102.29(8)°$, $V = 1208(2)$ Å^3, $Z = 2$, $D_c = 1.524$ g cm^{-3}, $F(000) = 564$, λ(Mo-K_α) = 0.71069, $\mu = 13.93$ cm^{-1}.

crystal of approximate dimensions $0.25 \times 0.20 \times 0.20$ mm was mounted on a glass fibre. All measurements were made on a Rigaku AFC5R diffractometer with graphite monochromated Mo-K_α radiation. Cell constants and an orientation matrix for data collection (obtained from a least-squares refinement using the setting angles of 19 carefully centred reflections in the range $9.45 < 2\theta < 21.12°$) corresponded to a triclinic cell.

The data were collected at room temperature using the $\omega/2\theta$ scan technique with scan widths $(1.15+0.30 \tan \theta)°$ and a scan speed of 4.0° min^{-1} (in omega).

Of the 4488 reflections collected 4253 were unique ($R_{int} = 0.053$). An empirical absorption correction applied using the program DIFABS[15] resulted in transmission factors ranging from 0.87 to 1.00. The data were corrected for Lorentz and polarization effects.

Structure solution and refinement. The structure was solved by direct methods.[16] The non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included in idealized positions. The final cycle of full-matrix least-squares refinement was based on 1672 observed reflections [$I > (2.00\sigma(I)$] and 298 variable parameters and converged to $R = \Sigma(|F_o| - |F_c|)/\Sigma|F_o| = 0.047$ and $Rw = [(\Sigma w (|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2} = 0.053$. The maximum and minimum peaks on the final difference Fourier map were to 0.43 and -0.37 e $Å^{-3}$.

Neutral atom scattering factors were taken from Cromer and Waber.[17] Anomalous dispersion effects were those of Cromer.[18] All calculations were performed using the TEXSAN[19] crystallographic software package of Molecular Structure Corporation. The atomic positions full lists of bond lengths and angles and other crystallographic data have been deposited as Supplementary Publication No. CSD 57074. Copies can be obtained through the Fachinformation-zentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen.

RESULTS AND DISCUSSION

The electrochemical method successfully produced the complexes $[M(bztz)_2]$ and $[M(bztz)_2L']$ (M = Ni, Zn or Cd; L′ = bipy or phen). All these compounds are solid, insoluble in common non-

Table 2. Analytical data

polar organic solvents (including chloroform and acetonitrile) and soluble in more polar solvent such as DMSO.

The electrochemical efficiency, *Ef*, defined as the amount of metal dissolved per Faraday of charge, was found to be *ca* 0.5 mol F^{-1} in all cases. This and the evolution of hydrogen at the cathode suggest that the reaction mechanism can be written as:

$$\textit{Cathode}\quad 2\,Hbztz + 2e^- \rightarrow 2bztz^- + H_2(g)$$

$$\textit{Anode}\quad 2bztz^- + M \rightarrow [M(bztz)_2] + 2e^-$$

$$2bztz^- + M + L' \rightarrow [M(bztz)_2L'] + 2e^-$$

$$M = Ni, Zn \text{ or } Cd;\ L' = phen \text{ or } bipy.$$

Structure of $[Zn(bztz)_2(bipy)]$

$[Zn(bztz)_2(bipy)]$ crystals consist of monomeric units in which a tetra-coordinate zinc atom is bound to the exocyclic sulphur atoms of two monodentate thiolate ligands and to the two nitrogen atoms of a bidentate chelating bipyridine molecule (Fig. 1). The tetrahedral environment of the zinc atom is distorted due to the small bite of the bipyridine [N(21)—Zn—N(32) = 78.9°; see Table 3], which also results in secondary deviation of the other perinuclear angles from the ideal value of 109°.

The $Zn—N_{bipy}$ bond lengths, 2.100(8) and 2.088(7) Å, are very similar to those found in another complex containing tetrahedral zinc and bipyridine, $[Zn(S\text{-}2,4,6\text{-}Pri_3C_6H_2)_2bipy]$.[20] The Zn—S distances, 2.294(5) and 2.321(4) Å, are within the range found in other thiolates with distorted

tetrahedral geometry, 2.25–2.36 Å.[21,22] Note that both the Zn—N and Zn—S distances are very similar to those found in [Zn(S-*p*-tolyl)$_2$phen],[22] which in a recent EXAFS study[23] has been used as a model of the zinc centre of Transcription factor IIIA (TFIIIA); this raises the possibility that [Zn(bztz)$_2$(bipy)] might likewise be considered as a model of this protein.

The bipyridine ligand is essentially planar, with no atom deviating from the least-squares plane by more than 0.011 Å. The bond lengths and angles within the ligand are similar to those found in other bipyridine complexes.[4,5,24] The benzothiazole portion of the benzothiazole-2-thionate ligands is also planar, with the largest deviations from the least-square planes being 0.016 Å and the deviations of the exocyclic sulphur atoms from this plane being 0.15 Å for S(10) and just 0.005 Å for S(20). The zinc atom is also practically on the plane of the benzothiazole group to which S(20) it is bound, the deviation being only 0.037 Å, but lies 0.303 Å above the plane of the other benzothiazole portion.

The N—C distances of benzothiazole-2-thionate are shorter in the complex than in the free ligand.[25] The C—S_{exo} distances, on the contrary, are longer in the complex, 1.70(1) Å as against the 1.662 Å that in the free ligand has been considered as indicating a degree of double bond character. The two bztz$^-$ ligands, therefore, appear to have a greater degree of thiolate character in the complex than in the free ligand.

Vibrational spectra

The IR spectra of the complexes (Table 4) lack the bands at *ca* 3100 and 750 cm^{-1}, which in the spectrum of Hbztz are attributed to ν(NH) and δ(NH), respectively.[26] Of the bands appearing at 1032, 1011, 605, 527, 393 and 300 cm^{-1} in the spectrum of the free ligand, i.e. those which on the basis of an S_{exo}-selenation study[26] (substitution of thioketonic sulphur with selenium) have been attributed the greatest ν(C=S) character, only those at 1032 and 1011 cm^{-1} show, in the spectra of the complexes, the shift to smaller wave numbers expected to result from reduction of the C—S bond order. The shift is greater for the 1032 cm^{-1} band, probably due to its having a greater ν(C=S) contribution.

In addition, the spectra show bands due to ν(M—S)[27] in the 380–320 cm^{-1} region. All the mixed complexes exhibit IR bands typical of coordinated bipy and phen.[28,29]

NMR spectra

The ^{1}H NMR spectra of the complexes (Table 5) show signals for all the bztz$^-$ hydrogen atoms except the NH proton, which in the spectrum of the free ligand appears as a broad signal at *ca* 13.4 ppm. This confirms the deprotonation of the ligand during electrosynthesis of the complex. In the spectra of some of the complexes the signals for several different protons appear jointly as a multiplet (as do the signals for H_5, H_6 and H_7 in the spectrum of the free ligand), whereas in those of other complexes the same signals are well differentiated and have the expected multiplicities.

The mixed complexes containing bipy have the expected four bipy signals, all of them shifted downfield, as a result of coordination, with respect to their position in the spectrum of the free ligand. This finding is in keeping with the X-ray diffraction results for [Zn(bztz)$_2$(bipy)]. Similarly, the mixed complexes containing phen show the expected signals, of which those for $H_{2,9}$ and $H_{3,8}$ are shifted downfield as a result of deshielding due to coordination to the metal.[30]

The ^{13}C NMR spectra (Table 6) also show all of the expected signals. The bztz$^-$ C_2 signal is shifted upfield in the spectra of all the complexes as a result of reduced C—S bond order,[31] which is further

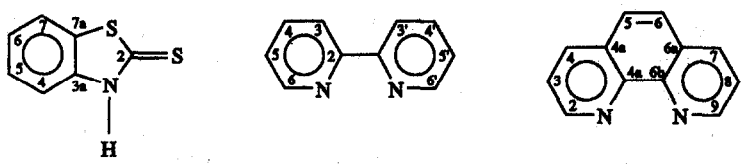
[a] Integrated relative intensities in parentheses.



evidence that bztz$^-$ is closer to its thiolate form in the complexes than in Hbztz.

Magnetic moments and electronic spectra

The magnetic moment of the [Ni(bztz)$_2$] complex shows that this compound is essentially diamagnetic and is consistent with square-planar coordination around the nickel(II) centre. This interpretation is compatible with the solid-state electronic spectrum of this compound, which shows two bands at *ca* 16,950 and 21,700 cm^{-1} which can be attributed to $^1B_{1g} \rightarrow {}^1A_{1g}$ and $^1E_{1g} \rightarrow {}^1A_{1g}$ transitions, respectively, in a square-planar field.[32]

The effective room-temperature magnetic moments, μ_{eff}, of [Ni(bztz)$_2$bipy] and [Ni(bztz)$_2$phen], 3.4 and 2.9, respectively, lie in the range expected for octahedral nickel(II) complexes.[33] The diffuse reflectance spectra of these complexes show two *d–d* bands at *ca* 8800 and 16,500 cm^{-1} with a clearly discernible shoulder at *ca* 8000 cm^{-1}. These bands can be respectively attributed to the $^3A_{2g} \rightarrow {}^3T_{2g}$ and $^3A_{2g} \rightarrow {}^3T_{1g}$(F) transitions in an octahedral field.[32] The shoulder may be due to the low energy

(*Received* 3 *March* 1993; *accepted* 5 *May* 1993)

Abstract—Tris(2-aminoethyl)aminecopper(II) perchlorate complexes, $[Cu(tren)L](ClO_4)_2$ [tren is tris(2-aminoethyl)amine and L are neutral N-donor ligands including imidazoles, pyridines and amines], have been synthesized and characterized. The X-ray crystal structures of $[Cu(tren)(achmH)](ClO_4)_2$ (**1**) and $[Cu(tren)(2MImH)](ClO_4)_2$ (**2**) (achmH = N-acetylhistamine; 2MImH = 2-methylimidazole) have been determined. Their structures consist of discrete perchlorate anions and distorted trigonal-bipyramidal $[Cu(tren)(N\text{-donor})]^{2+}$ cations with the three primary amine groups of the tren ligand forming the equatorial plane, where one of the equatorial angles is larger than the other two and the Cu—N bond opposite the largest equatorial N—Cu—N angle is significantly longer than the other two. Electronic and EPR spectra are reported for these complexes. The LF spectra are analysed in trigonal-bipyramidal symmetry with the Jahn–Teller effect being considered in the excited state and the effect of geometric distortions. The *d*-orbitals are assigned in a sequence of $d_{z^2} \gg d_{x^2-y^2} > d_{xy} > d_{xz} \sim d_{yz}$. The bonding properties of the CuN_5 chromophores are elucidated and discussed with reference to the electronic structures of the complexes, suggesting no π-interaction in the axial Cu—N bonds.

Penta-coordinate copper(II) complexes exhibit a wealth of stereochemistry[1] and lead to difficulties in correlating the electronic properties and the geometries of the complexes.[2,3] The [tris(2-aminoethyl)amine]copper(II) diperchlorate complex $[Cu(tren)(NH_3)](ClO_4)_2$,[4] which exhibits a nearly regular trigonal-bipyramidal structure, is ideal for electronic structure studies, because complications due to possible π-bonding between the central copper ion and the ligands, and due to non-equivalent donor atoms of the ligands, are eliminated. In these studies difficulties are usually encountered in deciding the effective symmetry group for the complexes,[5] particularly when chelating ligands are in use. However, by analysis of the electronic spectra, the electronic structures are usually assignable with proper effective local symmetry for the complexes. The NH_3 complex was suggested having a D_{3h} symmetry with the *d*-orbital sequence as $d_{z^2} > d_{x^2-y^2}$, $d_{xy} > d_{xz}$, d_{yz} to account for the two *d–d* bands observed. An angular-overlap model analysis for this complex by reproducing the two band maxima was reported.[6]

† Author to whom correspondence should be addressed.

In a theoretical paper by Hoffmann *et al.*[7] the π-substituent effects on penta-coordinate complexes have been elucidated. In our investigation of bonding properties of Cu—N chromophores in trigonal-bipyramidal complexes we feel that with reference to the electronic structure of the NH_3 complex it would be beneficial to study the π-interactions between the central copper ion and the axial ligand by introducing a neutral N-donor, single-faced π-ligand to the fifth site of the tren-copper(II) moiety. We anticipate that the energy level of one of the d_π-orbitals, d_{xz} or d_{yz}, should be decreased or increased by a π-acceptor or a π-donor, respectively, with respect to the degenerate d_{xz} and d_{yz} orbitals of the NH_3 complex. In this regard Gaussian analyses were performed to assure the *d–d* component band positions for these complexes including the NH_3 complex. Surprisingly, we found that there were three, rather than two, *d–d* components for the NH_3 complex. Herein, we report the stereochemistry and the electronic spectra for tren-copper(II) complexes containing amines, imidazoles and pyridines and elucidate their electronic structures and bonding properties.

EXPERIMENTAL

Materials and preparations

N-Methylimidazole (Merck), 2-methylimidazole (Merck), 4-methylimidazole (Aldrich), imidazole (Merck), N-acetylhistamine (Aldrich), pyridine (Merck), 4-methylpyridine (Merck), piperidine (Merck), pyrrolidine (Merck), $Cu(ClO_4)_2 \cdot 6H_2O$ (Merck) and organic solvents of reagent grade and spectrograde were used as received. The tren complexes were prepared by the following general procedure: To a methanol solution of $Cu(ClO_4)_2 \cdot 6H_2O$ and the unidentate ligand (molar ratio 1 : 3) was added dropwise a stoichiometric amount of tren in methanol. The reaction mixture was stirred at room temperature for 2 h. The blue precipitates were filtered and washed with ether and then dried *in vacuo* over P_4O_{10}. The crystals of the title complexes suitable for X-ray structure determination were obtained from a CH_3CN and CH_3OH solution containing an excess amount of the imidazole derivatives and $NaClO_4$.

Physical measurements

Electronic spectra were recorded on a Perkin–Elmer Lambda 9 spectrophotometer. Solid samples were measured as Nujol mulls on Whatman No. 1 filter paper. The deconvolution of the visible spectra into Gaussian component bands was performed on a VAX 6510 computer using the profile-fitting program CUVFIT.[8] EPR spectra were obtained using a Bruker ER 200D spectrometer and calibrated with DPPH ($g = 2.0037$). IR spectra were recorded as Nujol mulls or KBr pellets on a BIO-RAD FTS-40 FTIR spectrometer. A Micro Vax II computer-

controlled Siemens R3m/V diffractometer was used for crystal and molecular structure determination. Elemental analyses were performed by the microanalysis laboratories of Taiwan University, Taipei.

Structure determination and refinement

Details of crystal data and intensity collection are summarized in Table 1. 16 independent reflections with $8° \leqslant 2\theta \leqslant 29°$ for complex **1** and 15 with $9° \leqslant 2\theta \leqslant 25°$ for complex **2** were used for least-squares determination of the cell constants. Diffractometer examination of the the reciprocal lattice showed the space group to be $P2_1$ for **1** from the systematic absences $0k0$, $k \neq 2n+1$, and *Pnma* for **2** from the systematic absences $0kl$, $k+l \neq 2n+1$; $hk0$, $h \neq 2n+1$. Intensity data ($\theta/2\theta$ scan, $2.5° \leqslant 2\theta \leqslant 50.0°$, $(\sin\theta/\lambda)_{max} \simeq 0.6$) were collected at 296 K for two octants of the sphere ($-13 \leqslant h \leqslant 12$, $0 \leqslant k \leqslant 9$, $0 \leqslant l \leqslant 15$, for **1** and $0 \leqslant h \leqslant 18$, $0 \leqslant k \leqslant 9$, $0 \leqslant l \leqslant 18$ for **2**) and corrected for Lorentz and polarization effects, but not for absorption. Three standard reflections were monitored every 50 reflections and showed no signs of crystal deterioration. The structures were solved by direct methods using the SHELXTL PLUS program[9] and refined by full-matrix least-squares on F values. Scattering form factors and anomalous dispersion correction terms were taken from the International Tables for X-ray Crystallography.[10] All hydrogen atoms included in the refinement were placed in idealized positions (C—H = 0.96 Å, H—C—H = 109.4°) after non-hydrogen atoms were refined anisotropically. All calculations were done on a Micro Vax II-based Nicolet SHELXTL PLUS system. Additional material deposited comprises structure factors, atomic coordinates, anisotropic thermal parameters, hydrogen atom coordinates and a full list of bond lengths and angles.

RESULTS AND DISCUSSION

X-ray structure of $[Cu(tren)(achmH)](ClO_4)_2$ (**1**)

The unit cell contains two $[Cu(tren)(achmH)]^{2+}$ cations and four $[ClO_4]^-$ anions interconnected by hydrogen bonds. The structure of the N-acetylhistamine complex is shown in Fig. 1 and the unit cell arrangement in Fig. 2. Selected bond lengths and angles are listed in Table 2.

The copper ion is in a distorted trigonal-bipyramidal geometry with the three primary amine groups of the tren ligand forming the equatorial plane and the tertiary amine and the imidazole moiety of the achmH ligand on the apical positions. The equatorial plane is not strictly triangular; one of the N—Cu—N angles of 129.7(6)° is significantly larger than the other two; the distance of the Cu—N(4) bond [2.137(9) Å] opposite the largest N—Cu—N angle is somewhat longer than the other

two Cu—N bonds. The copper atom is removed from the equatorial plane towards the imidazole ligand because the tren chelate bite angles are less than 90°. The axial Cu—N(2) bond is shorter than the equatorial Cu—N bonds, while the axial Cu—N(5) bond is even shorter. The tren ligand has one λ [N(4)] and two δ [N(1) and N(3)] chelate rings with small torsion angles (7.4°, 3.6° and 6.7°, respectively) and exhibits large thermal vibrations on the C(1), C(4) and C(6) atoms. The bond lengths and angles of the tren ligand are generally normal, except the ethylene C—C bonds which are shorter than the normal C—C single bond, probably due to anisotropic thermal motion effects.

The amide moiety of the N-acetylhistamine is in the "*trans*" configuration[11] and the C(11)—N(7)—C(12)—O(9) skeleton is co-planar. The imidazole moiety has normal bond distances and

angles with short C(7)—N(5) and C(9)—N(6) bonds. The dihedral angle between the imidazole ring and the N(4)—Cu—N(2) plane is 13.4°. The imidazole N(6) is connected to the amide O(9) of the neighboring molecule by a hydrogen bond. The perchlorate anions are in tetrahedral geometry with large thermal vibrations.

X-ray structure of $[Cu(tren)(2MImH)](ClO_4)_2$ (**2**)

The unit cell contains four $[Cu(tren)(2MImH)]^{2+}$ cations and eight $[ClO_4]^-$ anions. The structure of the 2-methylimidazole complex is shown in Fig. 3 and the cell arrangement in Fig. 4. Selected bond lengths and angles are listed in Table 2.

The copper(II) ion is in a distorted trigonal-bipyramidal geometry with the equatorial sites occupied by the primary amine groups of the tren ligand and the axial sites by the tertiary amine and the 2-methylimidazole. The distorted equatorial plane contains the longest Cu—N(3) bond [2.137(13) Å] opposite the largest N(5)—Cu—N(5a) angle [132.7(7)°] and the Cu—N(3) bond is tilted towards the tertiary amine with a bite angle of 80.8(5)°. This

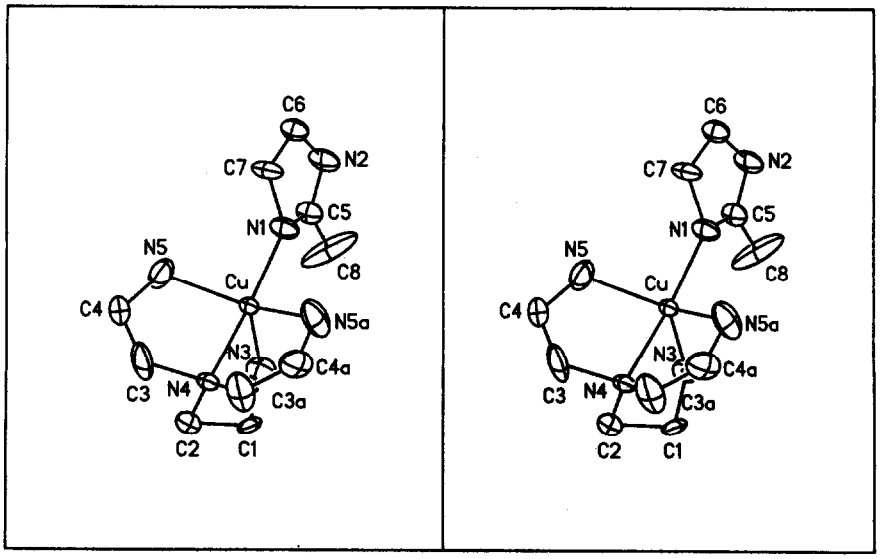

Fig. 3. Stereoscopic drawing of the copper coordination of $[Cu(tren)(2MImH)]^{2+}$.

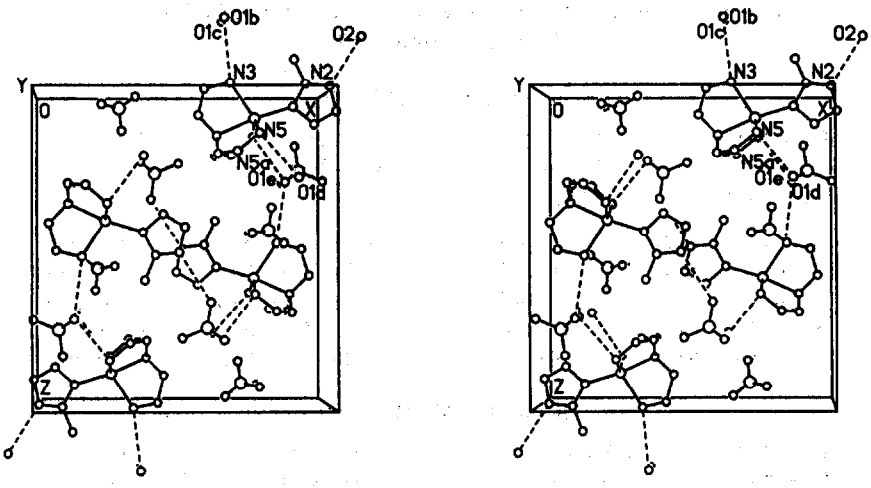

Fig. 4. Stereoscopic drawing of the molecular packing of $[Cu(tren)(2MImH)](ClO_4)_2$ in the unit cell. Hydrogen bonds: N(2)···O(2) 2.966, N(5)···O(1d) 3.179 and N(5a)···O(1e) 3.179 Å, and bifurcated hydrogen bonds, N(3)···O(1b) 3.256 and N(3)···O(1c) 3.256 Å.

chelate ring, in λ conformation with a torsion angle of 29.7°, is seriously disordered so that a mirror plane through Cu—N(3)—N(4) is effected. The other two chelates related by this mirror plane have one λ and one δ conformation with small torsion angles of 4.6°. The N(5), C(3), N(5a) and C(3a) atoms have large thermal parameters, suggesting that the chelate rings are fluctional. The dihedral angle between the 2-methylimidazole ring and the Cu—N(3)—N(4) plane is 14.1°. The dimensions of the 2-methylimidazole ligand are generally normal, except that the C(8) atom is in serous disorder. Note that the 2-methyl group is sitting close to the $N(3)H_2$ group. The ClO_4^- anions have expected tetrahedral geometry although some degree of disorder is apparent. The cations and the anions are interconnected by hydrogen bonds, as shown in Fig. 4.

Electronic and EPR spectroscopy

The visible and EPR spectral data of the tren complexes are listed in Table 3. It is noteworthy that the spectral contours of both the solid state and the solution visible spectra are extremely similar for the tren complexes containing a neutral N-donor unidentate ligand including the NH_3 complex, as illustrated in Fig. 5. This fact suggests that no dissociation of the neutral ligands occurs in solution. The spectra feature a broad band with λ_{max} at 780–810 nm, an apparent flanking high energy shoulder at 650 nm and a low energy shoulder at 900–950 nm. With the exception of the NH_3 complex, which exhibits an isotropic powder EPR spectrum, the powder EPR spectra of the tren complexes are of the reversed type with $g_\perp > g_\parallel \sim 2.00$. However, all of the complexes showed the reversed glass spectra with resolved hyperfine coupling in the $g_\perp$ and $g_\parallel$ regions.

Stereochemistry and bonding properties

The structures of the tripod tren complexes **1** and **2** are not strictly trigonal-bipyramidal. Rather, they are distorted towards a square-pyramidal structure with approximate C_{2v} local symmetry. In fact, among the structurally confirmed tren-copper(II) complexes compiled in Table 4 $[Cu(tren)(NH_3)](ClO_4)_2$[4] is the only compound having regular tbp geometry. It is obvious that the nature of the unidentate ligand plays an important role here. Since the pK_a values of the unidentate ligands in Table 4 vary considerably and randomly with respect to the distortion angles, distortion of the tbp structure due to the σ-donating abilities of the unidentate ligands can be ruled out. It is, then, necessary to consider the effects of π-interactions.

Two structural features of complexes **1** and **2** relevant to π-interactions are discussed here. First, the bond distance of the axial Cu—N(2MImH) [2.001(12) Å] bond of complex **2** obviously resulted from steric congestion, as is evident from the short C(8)—N(3) distance [3.407 Å] and the large bond angles of ∠Cu—N(1)—C(5) [135.8(11)°] and ∠N(1)—Cu—N(3) [106.8(5)°]. One may suspect that in complex **1** π-interactions may participate in the short Cu—N(achmH) bonding [1.957(13) Å], which lies at the short limit of the previously reported Cu—N(imidazole) distances of imidazole copper(II) complexes.[17] However, the short axial

bond lengths usually observed for tren complexes are attributable to the occupancy of a single electron in the d_{z^2} orbital. Secondly, the imidazole rings of complexes **1** and **2** are offset by 13.4° and 14.1°, respectively, to the longest equatorial Cu—N bond. Geometrically, π-interactions between the metal d_π orbitals and the ligand π-orbitals cannot be ruled out if the *x*- or *y*-axis must coincide with the elongated equatorial Cu—N bond. Nevertheless, based on the structural features π-interactions cannot be unambiguously clarified.

In order to reveal the bonding properties of the tren complexes the visible spectra were deconvoluted into their Gaussian component bands. Starting from a set of three or four trial peaks, computer iteration processes were performed until a minimum value of the reliability factor, *R*,[18] was reached. Each complex had an excellent fit, with the *R* factor ranging from 0.23% to 0.67%, and showed a resulting set of three Gaussian component peaks as typical examples, shown in Fig. 6; the peak positions and their half-height widths and relative peak areas are listed in Table 5. Attempts to fit with two component bands were unsuccessful. In order to

assure the reliability of the computer-fitting processes for the solid-state visible spectra the corresponding solution spectra were also deconvoluted into the Gaussian component peaks. The results are given in Table 5 and some examples are shown in Fig. 7.

The three component peaks resolved for the NH_3 complex are consistent with the single-crystal polarized spectra observed for the trigonal-bipyramidal $Cu(NH_3)_2Ag(SCN)_3$.[19] The appearance of three bands has been explained mainly by the effect of spin-orbit coupling.[19-21] However, the spin-orbit coupling cannot properly account for the resolved peaks of the NH_3 complex here. First, the energy difference between the two low energy peaks (corresponding to the $^2\Gamma_9$ and $^2\Gamma_7$ energy levels[19]) of 2.17 kK is much too large for the anticipated $2k\lambda$, where λ is the spin-orbit coupling constant, -0.829 kK, and k is the spin-orbit reduction parameter and is numerically < 1. An average value of 2.09(8) kK is observed for the tren complexes studied here. Secondly, the peak area of the highest energy peak is nearly the same as the sum of the two low energy peaks, suggesting that the highest energy peak consists of two degenerate bands and does not split at all in contrast to the anticipated splitting by a value of $\sim k\lambda$. Moreover, the highest energy peak of each of the other tren complexes studied here also shows

a large peak area, which is greater than the sum of the other two peaks and likely consists of two component bands. These results suggest that the large highest energy peak of the NH_3 complex and other tren complexes as well is the degenerate d_{xz}, $d_{yz} \rightarrow d_{z^2}$ transition.

We propose that the Jahn–Teller effect in the excited states is more appropriate for interpretation of the spectra here.[22] The five *d*-orbitals are subject to the tbp symmetry field to give a sequence of $d_{z^2} \gg d_{x^2-y^2}$, $d_{xy} > d_{xz}$, d_{yz}, where the d_{z^2} ground state is consistent with the EPR spectral data. The in-plane degenerate $d_{x^2-y^2}$ and d_{xy} orbitals are further affected by the Jahn-Teller instability in the excited states, whilst this effect on the out-of-plane d_{xz} and d_{yz} orbitals is not apparently observable. The areas of the two low energy peaks are nearly equal for the NH_3 complex. However, for other tren complexes the intensity of the central peak is less than half of that of the lower energy peak. This fact is attributable to the geometric distortion towards C_{2v} local symmetry. Accordingly, the *d*-orbital sequence is best arranged in $d_{z^2} \gg d_{x^2-y^2} > d_{xy} > d_{xz} \sim d_{yz}$.

In the trigonal-bipyramidal tren-copper(II) complexes the d_{xz} and d_{yz} orbitals are degenerate if the fifth axial ligand has no π-orbital, such as NH_3. However, for complexes with a single-faced π-ligand at the fifth axial site, π-interaction between the central copper and the ligand should cause one of the d_π-orbitals, d_{xz} or d_{yz}, to ascend or descend, depending on the ligand being a π-donor or a π-acceptor, respectively. In other words, π-interaction should result in lifting the degeneracy of the d_{xz} and d_{yz} orbitals. Here, all of the complexes showed a slightly broadened highest energy peak corresponding to the transition of d_{xz}, d_{yz} to d_{z^2}, irrespective of the difference of the π-bonding capabilities of the axial unidentate ligands, i.e. pyridines are generally considered as π-acceptors and imidazoles are π-donors.[7,23–25] It is, therefore, conceivable that no π-interaction is involved in the axial bonding for the trigonal-bipyramidal tren-copper(II) complexes.

[c] Half-width at $E_{max}/2$.
[d] Reliability factor defined as $R = \Sigma|y_{obs,i} - y_{calc,i}|/\Sigma y_{obs,i}$.

In conclusion, we have demonstrated the importance of utilizing Gaussian deconvolution techniques to analyse the LF spectra of the tren-copper(II) complexes and to elucidate the sequence of the *d*-orbitals. The weak d_{xy} to d_{z^2} transition peak can only be revealed from the resolved Gaussian component peaks. We have further explored the π-bonding capabilities of the ligands by comparison of the energy levels of the d_π-orbitals of a series of structurally analogous complexes and concluded that no π-interaction participates in the axial Cu—N bonding for the tren complexes, despite the fact that such an interaction is symmetry allowed. Moreover, unlike the generally recognized copper(II) complexes, the axial ligand is not labile. Finally, the deviation of the tren-copper(II) complexes from regular tbp structure is possibly due to the non-cylindrically symmetric unidentate ligand, which effectively lifts the C_3 axis in the tbp geometry.

(*Received* 5 *January* 1993; *accepted* 5 *May* 1993)

Abstract—A new complex, $Co_2Cl_5(py)_5$ was obtained by the reaction of $CoCl_2 \cdot 6H_2O$ with $Bu^n_4NMnO_4$ in pyridine in the presence of benzoic acid. The structure consists of a discrete octahedral $[Co^{III}Cl_2(py)_4]^+$ cation and a tetrahedral $[Co^{II}Cl_3py]^-$ anion. The compound was also characterized by elemental analyses, IR, XPS spectra and variable-temperature magnetic susceptibility measurements. The reaction conditions indicate that when the molar ratio of benzoic acid : $CoCl_2 \cdot 6H_2O$ is below 0.75 the title complex cannot be obtained.

An important current area of research is the development of synthetic methodologies for preparing new inorganic compounds. Recently, Vincent *et al.* have reported that the $Bu^n_4NMnO_4$ is a useful oxide reagent for the synthesis of mixed-valent polynuclearmanganese complexes in non-aqueous solvents.[1–4] In order to enlarge the applied scope of this reagent and to prepare the mixed-valent polynuclear cobalt complexes, we herein first report the synthesis and X-ray crystal structure of the mixed-valent cobalt complex $Co_2Cl_5(py)_5$ using $Bu^n_4NMnO_4$ as an oxide reagent in pyridine.

EXPERIMENTAL

Material and measurements

Benzoic acid, $CoCl_2 \cdot 6H_2O$, pyridine, absolute ethanol and CH_3CN were used as received. $Bu^n_4NMnO_4$ was prepared from $KMnO_4$ and Bu_4NBr as described earlier[5] and used without recrystallization. All operations were performed under aerobic conditions at ambient temperature.

The elemental analyses for carbon, hydrogen and nitrogen were performed on a Perkin–Elmer 240C analyser. The metal analysis for cobalt was measured on a Jarrell–Ash 1100+2000 ICP apparatus. The chlorine analysis was performed using Volhard's method. IR spectra were obtained on a Nicolet FT 170SX spectrometer using KBr pellets. X-ray photoelectron spectra were performed on a VG MK II spectrometer using Mg-K_α radiation and a charge-transfer correction referred to the binding energy of C_{1s}. The variable-temperature (74–300 K) magnetic susceptibility measurements of crystal samples of the title complex (75.24 mg) were obtained on a Shimadzu MB-2 magnetic balance at 1.2 T magnetic field.

Synthesis of $Co_2Cl_5(py)_5$

$CoCl_2 \cdot 6H_2O$ (1.94 g, 8.15 mmol) and benzoic acid (1.00 g, 8.15 mmol) were dissolved in pyridine (40 cm^3) to give a violet–red solution. This was stirred while solid $Bu^n_4NMnO_4$ (1.14 g, 3.15 mmol)

* Author to whom correspondence should be addressed.

was added in small portions over approximately 20 min; the reaction solution turned deep brown. After stirring for 20 min the reaction solution was evaporized to remove the pyridine solvent and a brown oil product was obtained, which was redissolved in absolute ethanol (70 cm^3). The ethanol solution was concentrated by evaporization and stood overnight in a refrigerator at *ca* 5°C to give a green solid product, which was collected by filtration, washed three times with small portions of ethanol and dried in air to give the product (1.10 g, yield 39.1%). This material was redissolved in CH_3CN and stood in air, for 3 days, to give green crystals of the title complex which were suitable for X-ray structure studies. Found: C, 43.0; H, 3.6; N, 10.1; Co, 17.2; Cl, 25.0. Calc. for $C_{25}H_{25}N_5Cl_5Co_2$: C, 43.4; H, 3.6; N, 10.1; Co, 17.0; Cl, 25.6%. IR data: 3112w, 3048w, 1605s, 1489m, 1445s, 1212s, 1149w, 1063s, 1016m, 759s, 695s, 641w, 467w, 423w, 353w. XPS (eV) data: N_{1s} (399.0), $Co2P_{3/2}$ (779.0).

X-ray crystallography

A prismatic green crystal (0.4 × 0.2 × 0.2 mm) was used for X-ray diffraction. Data were collected on a Rigaku AFC5R diffractometer at room temperature using graphite monochromated Mo-K_α (0.71069 Å) radiation. The intensities were corrected for the Lp factor and empirical absorption. A summary of data collection parameters is given in Table 1.

The structure was solved by direct methods. Successive Fourier syntheses gave the coordinates of all the non-hydrogen atoms refined with anisotropic thermal parameters. The hydrogen atoms were placed in geometrically calculated positions with a C—H distance of 0.95 Å and refined with isotropic thermal parameters. The final cycle of refinement led to a final convergence at $R = 0.041$. All calculations were performed on a Micro VAXII computer using TEXSAN programs. Atomic coordinates and thermal parameters, together with observed and calculated structure factors, have been deposited with the Editor, from whom copies are available on request; copies have also been deposited with the Cambridge Crystallographic Data Center.

RESULTS AND DISCUSSION

The use of permanganate for inorganic syntheses in aqueous solvents is common. In recent years $Bu^n_4NMnO_4$ has been successfully used for preparing the mixed-valent polynuclear manganese complexes in non-aqueous solvents.[1–4] We attempt to synthesize the mixed-valent cobalt polynuclear complex by using $Bu^n_4NMnO_4$ to oxidize the divalent cobalt salt $CoCl_2 \cdot 6H_2O$ in pyridine in the presence of benzoic acid. However, the unexpected product $Co_2Cl_5py_5$ was obtained instead of the desired polynuclear complex. Apparently, the benzoic acid does not actually play an important role in this reaction. Although the reaction is not particularly sensitive to the amount of benzoic acid, it is to the molar ratio of benzoic acid: $CoCl_2 \cdot 6H_2O$ used. When the ratio was lower than 0.75 the title complex could not be obtained. Other organic acids are not suitable for the synthesis of the title complex.

Description of the X-ray crystal structure of $Co_5Cl_5(py)_5$

Figure 1 shows a view of the complex molecule $Co_2Cl_5(py)_5$. Selected bond distances and angles are listed in Table 2. The structure contains the crystallographically discrete cation $[Co^{III}Cl_2(py)_4]^+$ and anion $[Co^{II}Cl_3py]^-$ in the ratio 1:1. The six-

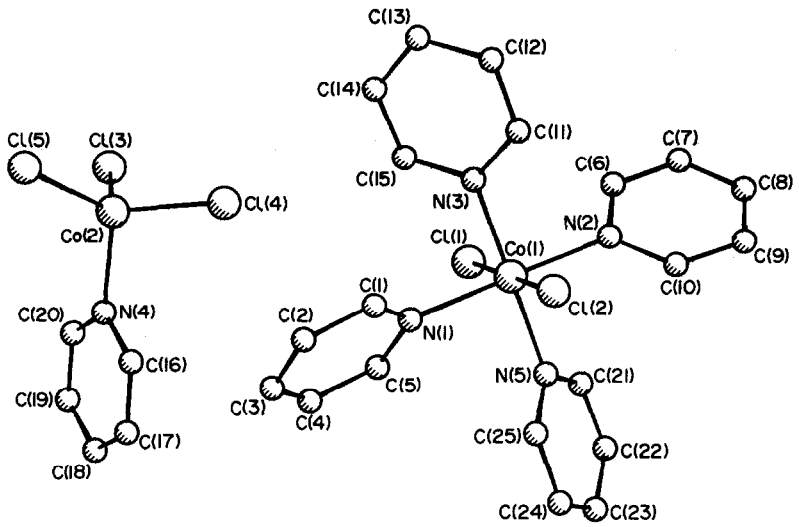

Fig. 1. The structure of $Co_2Cl_5(py)_5$.

coordinated cobalt(III) atom in the cation is bonded to the nitrogen atoms from four pyridine molecules, with Co—N distances of 1.974(5)–1.984(4) Å (average 1.978 Å), and to the two chlorine atoms, with Co—Cl bonds of 2.253(2) and 2.249(2) Å, forming a tetragonal-bipyramid with the chloride atoms in axial directions and nitrogen atoms on the equatorial plane. The four-coordinate cobalt(II) atom in the anion is bonded to three chloride atoms at distances of 2.243(2)–2.258(2) Å (average 2.251 Å) and to the nitrogen atom of the pyridine molecule at a bond length of 2.039(5) Å. The coordination geometry around the cobalt(II) atom is a tetrahedron.

The Co(2)—N(4) bond distance [2.039(5) Å] is longer than Co(1)—N_{av} [N(1)—N(3) and N(5)] [1.978(4) Å] due to the larger radius for Co^{II} vs Co^{III}. This result can be confirmed by a comparison of the Co—N(py) bond lengths in some different valent cobalt–pyridine complexes, such as $[Co^{I}(py)_2(Bph_4)]$, 2.096(9) Å;[6] $[Co^{II}(S\text{-}2.4.6\text{-}Pr_3C_6H_2)_2(py)_2]$, 2.038(9) Å;[7] $[Co^{III}(dpgH)_2Cl(py)]\cdot CH_3OH$, 1.965(3) Å.[8] By comparison, one can find that the Co—Cl bond lengths in the two kinds of ions are similar. Taking the difference in the metal ion radius into account, however, the Co^{II}—Cl bond distance should be longer than the Co^{III}—Cl bond. The reason for this can be ascribed to the

Table 2. Selected bond distances (Å) and angles (°)

Co(1)—Cl(1)	2.253(2)	Co(1)—N(1)	1.984(4)
Co(1)—Cl(2)	2.249(2)	Co(1)—N(2)	1.978(4)

N(2)—Co(1)—N(3)	90.9(2)	N(2)—Co(1)—N(5)	89.3(2)
N(3)—Co(1)—N(5)	179.4(2)		

following. Since the coordination ability of pyridine is stronger than the chlorine anion and four pyridine molecules coordinate to the cobalt(III) ion, compared with one to the cobalt(II) ion, the effective nuclear charge of the cobalt(III) ion should decrease more than that of the cobalt(II) ion. Therefore, the attraction between the cobalt (III) ion and chlorine anion will be weakened more compared with the Co^{II}—Cl bond, thus leading to the lengthening of the Co^{III}—Cl bond and similar distances of Co—Cl bonds in the two kinds of ions. This result has been confirmed by the XPS studies below.

Spectroscopic characterization and magnetic properties of $Co_2Cl_5(py)_5$

The IR spectra of the title complex has been measured. It displays the characteristic absorption peaks of pyridine molecules at 3048w, 1605s, 1498m, 1445s, 1016s, 759s, 641w and 423w cm^{-1} and an absorption at 353 cm^{-1} for Co—Cl bond stretching.[9] The Co—N bond stretching occurs at 256 cm^{-1}.[9] It is well known that upon complex formation the pyridine vibrations in the high frequency region are not shifted appreciably, whereas those at 604 (in-plane ring deformation) and 405 cm^{-1} (out-of-plane ring deformation) are shifted to higher frequencies.[9] In the IR spectra of the title complex the frequencies of these two bands (641 and 423 cm^{-1}) are higher than those of free pyridine molecule, indicating the presence of coordinated pyridine molecules in the complex.

The nature of the complex also was verified by XPS spectra. In view of the XPS data we found that the N_{1s} binding energy of the nitrogen atom of pyridine molecules increased compared with that of the free pyridine molecule (398.6 eV). This shows that the electrons in the nitrogen atoms partially shift to the cobalt atoms due to coordination. This result is consistent with that mentioned in the IR spectra. Due to the presence of cobalt(II) and cobalt (III) ions in the complex the XPS spectra usually display two peaks of $Co2P_{3/2}$ binding energy. However, in the spectra of the title complex only one peak was found. We suppose that this is probably due to the presence of four-coordinate pyridine molecules around the cobalt(III) ion, whereas only one pyridine molecule coordinates to the cobalt(II) ion. Thus, the binding energy of the cobalt(III) ion should decrease much more than that of cobalt(II) ion, thus leading to the similar binding energy of cobalt(III) and cobalt(II) ions.

The variable-temperature magnetic susceptibility measured at 1.2 T in the range 78–300 K for a polycrystalline sample of the title complex obeys the Curie–Weiss expression $\chi = C/(T-\theta)$, with $\theta = 0$, suggesting no magnetic-exchange interaction between the two cobalt ions. The effective magnetic moment of the complex is consistent with that of the cobalt(II) ion. This further verified the composition of the mixed-valent cobalt complex.

(*Received* 18 *December* 1992; *accepted* 5 *May* 1993)

Abstract—By the one-pot reaction of lanthanide trichloride with 2 equivalents of sodium cyclopentadienyl and 1 equivalent of sodium 2-methoxyethylcyclopentadienyl in THF, the mixed tricyclopentadienyl lanthanide complexes $(C_5H_5)_2Ln(CH_3OCH_2CH_2C_5H_4)$ (Ln = La, Sm, Gd, Er, Yb, Y) were obtained. The compound $(CH_3OCH_2CH_2C_5H_4)Y(C_5H_5)_2$ (**6**) crystallized from THF. The central metal Y is coordinated to three cyclopentadienyl ring centroids and the ether oxygen forming a distorted tetrahedron. The average Y—C(η^5) bond distance and Y—O bond distance of **6** are 2.702 and 2.414 Å, respectively.

Tris-cyclopentadienyl lanthanide complexes were first reported by Birmingham and Wilkinson in 1956.[1] The X-ray structure study shows that the solid-state structure of trivalent lanthanide metallocenes, $(C_5H_5)_3Ln$, are polymeric involving μ-$\eta^5:\eta^2$-C_5H_5 or μ-$\eta^5:\eta^1$-C_5H_5 units.[2–6] The polymers can be destroyed by Lewis bases to form monomeric Lewis base adducts with a formal coordination number 10[7] or 11.[8,9] Recently, using 2-methoxyethylcyclopentadienyl ($CH_3OCH_2CH_2C_5H_4^-$) as a ligand we have successfully prepared the solvent-free monomeric tris-cyclopentadienyl lanthanides $(CH_3OCH_2CH_2C_5H_4)_3Ln$,[10] in which only two of the ether oxygen atoms coordinate to the metal, whose coordination number is 11. Moreover, the studies on crystal structure of the above compounds show that the average bond lengths of Ln—O are longer than the related bond lengths of the compound $(C_5H_5)_3Ln \cdot THF$.[7,11–13] This result prompted us to propose that the solvent-free monomeric tris-cyclopentadienyl lanthanides might also be obtained by forming one intramolecular coordination bond. Therefore, we have investigated the syntheses of the new mixed tris-cyclopentadienyl lanthanide complexes $(CH_3OCH_2CH_2C_5H_4)Ln(C_5H_5)_2$ and the X-ray crystal structure of $(CH_3OCH_2CH_2C_5H_4)Y(C_5H_5)_2$ has been determined.

Although a few mixed tris-cyclopentadienyl lanthanides have been reported,[14–16] to our knowledge the structural information on mixed tris-cyclopentadienyl lanthanides containing intramolecular coordination bond has not been reported up to now.

EXPERIMENTAL

All operations were performed under purified argon by using Schlenk techniques. All solvents were refluxed and distilled either over finely divided $LiAlH_4$ or over blue sodium benzophenone under argon immediately before use. C_5H_5Na was prepared by the usual method. IR spectra were recorded on Perkin–Elmer 983 and Digilab FTIS-20/E Fourier-transform IR spectrometers with Nujol and fluorolube mulls and were examined between disc-shaped CsI crystals. Mass spectra were recorded on a Finnigan 4021 spectrometer at E.I., $T = 50$–$300°C$, E.M. = 1.3 kV. ^1H NMR spectra were obtained on a FX-90Q (90 MHz) spectrometer referenced to external Me_4Si in THF-d_8.

Metal analyses of the complexes were accomplished using a direct complexometric titration procedure with disodium EDTA.[14] Carbon and hydrogen analyses were performed by the combustion method in an aluminium tude.

Preparation of $CH_3OCH_2CH_2C_5H_4Na$ (7)

The sodium 2-methoxyethylcyclopentadienyl was prepared according to the previous description.[23] ^1H NMR (90 MHz, C_4D_8O) δ: 2.50 (t,2H), 3.05 (s,3H), 3.28 (t,2H), 5.18 (t,2H), 5.31 (t,2H). IR (cm^{-1}): 3060(m), 2922(s), 1458(v), 1095(s), 1077(s), 1022(m), 786(v), 677(s), 385(w), 340(w), 250(m), 225(s).

Preparation of $(CH_3OCH_2CH_2C_5H_4)La(C_5H_5)_2$ (1)

A THF solution of 1 equivalent of $(CH_3OCH_2CH_2C_5H_4)Na$ (0.45 M, 9.3 cm^3) and 2 equivalents of C_5H_5Na (1.07 M, 7.9 cm^3) were, respectively added to a suspension of $LaCl_3$ (1.05 g, 4.2 mmol) in THF (15 cm^3), which had been cooled to $-50°C$. The reaction mixture was warmed to room temperature and stirred overnight. The solvent was removed *in vacuo* and the residue was sublimed at 170–$220°C/4 \times 10^{-4}$ mm Hg giving 0.75 g of a white solid of $(CH_3OCH_2CH_2C_5H_4)La(C_5H_5)_2$ (1) in 45% yield. ^1H NMR (90 MHz, C_4D_8O) δ: 2.48 (t,2H), 3.45 (s,3H), 3.73 (t,2H), 5.57 (s,10H), 5.78 (s,4H). IR (cm^{-1}): 3069(s), 2920(vs), 2851(s), 1452(s), 1439(s), 1043(s), 1035(s), 1009(s), 963(m), 829(m), 780(s), 760(s), 665(m), 395(m), 321(vw), 250(w), 220(m). Found: C, 55.0; H, 5.3; La, 35.4. Calc. for $C_{18}H_{21}OLa$ (1): C, 55.1; H, 5.4; La, 35.4%. MS (E.I., 50–300°C): *m/z* 392 (21.77) M^+, 327 (100) $[M-C_5H_5]^+$, 124 (7.76) $[CH_3OCH_2CH_2C_5H_5]^+$, 66 (26.15) $[C_5H_6]^+$.

Preparation of $(CH_3OCH_2CH_2C_5H_4)Sm(C_5H_5)_2$ (2)

A THF solution of 1 equivalent of $(CH_3OCH_2CH_2C_5H_4)Na$ (0.45 M, 7.8 cm^3) and 2 equivalents of C_5H_5Na (1.07 M, 6.6 cm^3) were, respectively added to a suspension of $SmCl_3$ (0.91 g, 3.54 mmol) in THF (15 cm^3), which had been cooled to $-20°C$. The reaction mixture was warmed to room temperature and stirred overnight. The solvent was removed *in vacuo* and the residue was sublimed at 170–$220°C/4 \times 10^{-4}$ mm Hg giving 0.83 g of a yellow solid of $(CH_3OCH_2CH_2C_5H_4)Sm(C_5H_5)_2$ (2) in 58% yield. IR (cm^{-1}): 3078(s), 2924(vs), 2831(vs), 1437(s), 1057(s), 1045(s), 1032(m), 1011(s), 965(s), 834(s), 785(s), 761(s), 660(m), 382(m), 321(m), 240(m), 210(s). Found: C, 53.7; H, 5.3; Sm, 37.3. Preparation of $(CH_3OCH_2CH_2C_5H_4)Er(C_5H_5)_2$ (4)

The procedure followed was similar to that for **2**. A pink solid (**4**) was obtained by sublimation (170–$220°C/4 \times 10^{-4}$ mm Hg) in 40% yield. IR (cm^{-1}): 3080(s), 2930(s), 2840(s), 1452(s), 1437(s), 1060(s), 1045(s), 1035(m), 1011(s), 965(m), 837(m), 770(sh), 665(s), 391(s), 321(s), 240(w), 220(m). Found: C, 51.3; H, 4.9; Er, 40.0. Calc. for $C_{18}H_{21}OEr$ (4): C, 51.4; H, 5.0; Er, 39.8%. MS (E.I., 50–300°C): *m/z* 419 (1.69) $[M]^+$, 354 (100) $[M-C_5H_5]^+$, 124 (6.30) $[CH_3OCH_2CH_2C_5H_5]^+$, 66 (4.30) $[C_5H_6]^+$.

Preparation of $(CH_3OCH_2CH_2C_5H_4)Yb(C_5H_5)_2$ (5)

The procedure followed was similar to that for **2**.

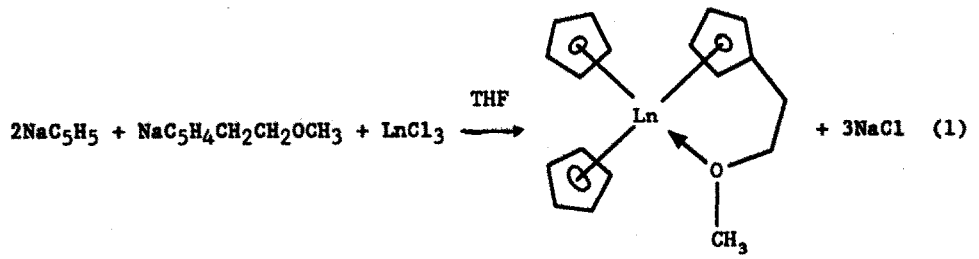
A dark green solid (**5**) was obtained by sublimation (170–220°C/4×10^{-4} mm Hg) in 46% yield. IR (cm^{-1}): 3074(vs), 2935(s), 2833(s), 1453(s), 1440(s), 1060(sh), 1045(s), 1035(m), 1011(s), 965(m), 837(m), 769(s,sh), 665(s), 391(s), 321(vw), 240(w), 220(m). Found: C, 50.0; H, 4.8; Yb, 40.9. Calc. for $C_{18}H_{21}OYb$ (**5**): C, 50.7; H, 5.0; Yb, 40.6%. MS (E.I., 50–300°C): 427 (5.29) $[M]^+$, 362 (100) $[M-C_5H_5]^+$, 124 (19.85) $[CH_3OCH_2CH_2C_5H_5]^+$, 66 (86.74) $[C_5H_6]^+$.

factors for non-hydrogen atoms were refined anisotropically.

RESULTS AND DISCUSSION

Synthesis

The new mixed tris-cyclopentadienyl lanthanide complexes (**1–6**) were synthesized by a one-pot reaction as shown in eq. (1).



Ln = La(1), Sm(2), Gd(3), Er(4), Yb(5), Y(6)

Preparation of $(CH_3OCH_2CH_2C_5H_4)Y(C_5H_5)_2$ (**6**)

The procedure followed was similar to that for **2**. A white solid (**6**) was obtained by sublimation (170–220°C/4×10^{-4} mm Hg) in 46% yield. ^1H NMR (90 MHz, C_4D_8O) δ: 2.60 (t,2H), 3.45 (s,3H), 3.73 (t,2H), 5.37 (s,10H), 5.89 (t,2H), 6.00 (t,2H). IR (cm^{-1}): 3081(s), 2939(s), 2833(s), 1452(s), 1437(s), 1054(s), 1042(s), 1035(m), 1011(s), 965(m), 837(m), 790(s), 765(s), 632(m), 394(m), 330(w), 259(s), 214(m). Found: C, 62.9; H, 6.1; Y, 25.9. Calc. for $C_{18}H_{21}OY$ (**6**): C, 63.2; H, 6.2; Y, 26.0%. MS (E.I., 50–300°C): 342 (5.60) $[M]^+$, 277 (100) $[M-C_5H_5]^+$, 124 (8.19) $[CH_3OCH_2CH_2C_5H_5]^+$, 66 (39.61) $[C_5H_6]^+$.

X-ray structure analysis

A suitable single crystal, which was obtained through recrystallization from a THF solution of sublimate **6**, was sealed under argon in a thin-walled glass capillary. Intensity data were collected on a Siemens R3m/v diffractometer with Mo-K_α ($\lambda = 0.71073$ Å) radiation in the 2θ–θ scan mode. Final lattice parameters were obtained by a least-squares refinement of the values of reflections. The space group $P21/c$ for compound **6** was identified from the systematic absences. The crystallographic parameters are listed in Table 1. The intensities were corrected for Lorentz and polarization, but not for absorption effects. The Y atom was located by direct methods and all non-hydrogen atoms were obtained from successive Fourier syntheses. Hydrogen atoms were added according to theoretical models. All positional parameters and temperature

All of the new complexes are easily purified by sublimation at 170–220°C/10^{-4} mm Hg, to give solids which were moderately soluble in toluene and very soluble in THF.

In the E.I. mass spectra all of the complexes showed a parent molecular ion, M^+, and related

Table 1. Crystallographic parameters for **6**

Compound	$C_{18}H_{21}OY$

fragments; no m/z greater than M^+ was detected. This indicates that the complexes are monomeric and the Ln—C_5H_5 bond is first cleaved, giving the base peak of $[M-C_5H_5]^+$.

The IR spectra of these new complexes exhibit absorption peaks typical of η^5-cyclopentadienyl at *ca* 775, 1020, 1440 and 3085 cm^{-1}.[17–19] Moreover, the IR spectrum analyses imply the presence of an intramolecular coordination bond from the oxygen atom of the ether-substituted cyclopentadienyl to the lanthanide metal, because the absorption peak of the C—O—C asymmetric stretching vibration in the new complexes is shifted to lower frequency ($\Delta\nu = 35$–53 cm^{-1}) compared with those of $NaC_5H_4CH_2CH_2OCH_3$ (**7**).[14–20]

The ^1H NMR data of complexes **1**, **6** and **7** were measured in perdeuterotetrahydrofuran. It is noteworthy that the proton signals of OCH_3 and OCH_2 shift to lower field compared with those of the sodium salt (**7**). These results show that an intramolecular coordination bond, Ln—O, is formed.[20,21]

Structure

The crystallographic parameters, selected bond lengths and angles of complex **6** are listed in Tables 1 and 2. The molecular and crystal structure of **6** is shown in Fig. 1.

The crystal structure analysis shows that the distorted tetrahedron around the yttrium ion is formed with three centroids of the cyclopentadienyl rings and the oxygen atom of the ligand. Complex **6** is a monomer with an intramolecular coordination bond. However, the formal coordination number of Y^{3+} is 10. The Y—C(η^5) bond distances range from 2.535(20) to 2.793(26) Å and average 2.702 Å. This is similar to the value reported for $(C_5H_5)_3Y$ THF (**8**), 2.71(3) Å.[13] The Y—O bond length in **6** is 2.414(13) Å, which is 0.04 Å shorter than that in **8**. Since the coordination environment of the metal ion in **6** is different from that in $(CH_3OCH_2CH_2C_5H_4)_3Pr$ (**9**),[10] the Y—O distance is significantly shorter than the mean Pr—O distance in **9**, even if the difference in metal ion size is taken

Cent(1)—Y—Cent(2)	117.9	Cent(2)—Y—Cent(3)	115.4
Cent(1)—Y—Cent(3)	120.4	Cent(1)—Y—O(1)	91.3
Cent(2)—Y—O(1)	101.3	Cent(3)—Y—O(1)	102.8

[a] Cent(1) is the centroid of the cyclopentadienyl ring defined by C(4)–(8); Cent(2), C(9)–(13); Cent(3), C(14)–(18).

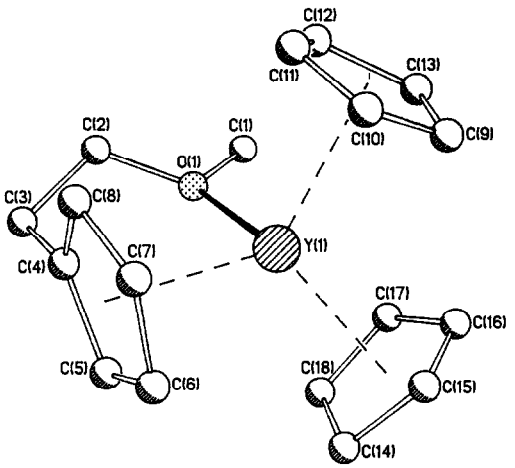

Fig. 1. Molecular structure of $(CH_3OCH_2CH_2C_5H_4)Y(C_5H_5)_2$ (**6**).

into account.[22] This reveals that coordination of the central metal is saturated in the new monomeric complexes $(CH_3OCH_2CH_2C_5H_4)Ln(C_5H_5)_2$, but is over-saturated in the complexes $(CH_3OCH_2CH_2C_5H_4)_3Ln$, resulting in the longer Ln—O distance in the latter.

Three cent—Y—cent angles are 120.4, 117.9 and 115.4°, respectively, and the sum of three angles is 353.7° in **6**, which are comparable with the angles 119.2, 117.5, 115.4 and 352.1° in **8**, respectively. This shows that the arrangement of three cyclopentadienyl rings in **6** is analogous to the arrangement in **8**. The angles of O(1)—Y—cent(1), O(1)—Y—cent(2) and O(1)—Y—cent(3) are 91.3, 101.3 and 102.8° in **6**, respectively. It is noteworthy that the smallest angle O(1)—Y—cent(1) (91.3°) is 5.1° smaller than that of O—Y—cent in **8**. The difference is the result of forming an intramolecular coordination bond.

KINETICS OF THE SUBSTITUTION REACTION BETWEEN AQUAOXOTETRACYANOMOLYBDATE(IV) AND CYANIDE/HYDROGEN CYANIDE

JAAP P. SMIT, WALTER PURCELL, ANDREAS ROODT* and JOHANN G. LEIPOLDT

Department of Chemistry, University of the Orange Free State, Bloemfontein 9300, South Africa

(*Received* 28 *January* 1993; *accepted* 20 *April* 1993)

Abstract—The kinetics of the substitution reaction between aquaoxotetracyanomolybdate (IV) ions and CN^- and HCN, as an important intermediate step in the formation of the $[Mo(CN)_8]^{4-}$ complex, was studied by stopped-flow spectrometry. The aqua ligand in the $[MoO(H_2O)(CN)_4]^{2-}$ complex is substituted by both CN^- ions and hydrogen cyanide according to the reaction:

$$[MoO(H_2O)(CN)_4]^{2-} + CN^-/HCN(L) \underset{k_{-L}}{\overset{K_L, k_L}{\rightleftharpoons}} [MoO(L)(CN)_4]^{n-} + H_2O.$$

At 15.0°C and $\mu = 1.0$ M (KNO_3) the equilibrium, forward and reverse rate constants of the reaction with CN^- ions were determined as 92(5) M^{-1}, 83(1) $M^{-1}\,s^{-1}$ and 0.87(3) s^{-1}, and for HCN as 3(1) M^{-1}, 458(5) $M^{-1}\,s^{-1}$ and 140(30) s^{-1}, respectively. Coordination of the HCN to the metal centre results in a decrease in the pK_a value of hydrogen cyanide by approximately 1.5 pH units to *ca* 7.6(2).

It was shown over the past few years that the protonation of the dioxotetracyano complexes of molybdenum(IV), tungsten(IV), rhenium(V) and technetium(V) results in the formation of the $[MO(OH)(CN)_4]^{(n+1)-}$ and $[MO(H_2O)(CN)_4]^{n-}$ complexes.[1] These protonated species undergo substitution reactions with mono- (aqua substitution) and bidentate[2] (aqua and cyano substitution) ligands. The protonation behaviour of these systems has recently been the subject of carbon-13 and oxygen-17 NMR[3,4] studies in order to investigate the water exchange of these complex ions.

Previous studies of monodentate substitution reactions on the $[MO(H_2O)(CN_4]^{n-}$ complexes for the tungsten(IV) and rhenium(V) systems[1] included different ligands such as F^-, N_3^- and NCS^- ions, pyridine and substituted thioureas. However, for the molybdenum(IV) system the only monodentate ligand substitution reaction that could be studied was that of fluoride ions as a result of the high lability of the coordinated aqua in the $[MoO(H_2O)(CN)_4]^{2-}$ ion. Although it is known that the HCN entity can act as a monodentate ligand,[5–8] this fact was only recently observed in our laboratory for these dioxotetracyano systems. We have therefore, taken interest in the substitution behaviour of these systems in CN^-/HCN medium in order to investigate the formation of the higher coordinated cyano complexes {i.e. $[M(CN)_8]^{4-}$ (for M = Mo^{IV} and W^{IV})} since the mechanism of such a process is not known at this stage. The results of the kinetic study of the molybdenum(IV) system in aqueous CN^-/HCN medium, forming the oxopentacyanomolybdate(IV) complex as an important intermediate in the formation of the octacyano species, is reported herein.

EXPERIMENTAL

General

All chemicals used were of analytical reagent grade and double distilled water was used in all

* Author to whom correspondence should be addressed.

these experiments. All pH measurements were obtained on an Orion 701 pH meter with a combined glass/calomel electrode.

CAUTION. Cyanide is extremely toxic and HCN is generated throughout these experiments. Care should therefore be taken to perform all manipulations in a fume hood as far as possible.

Preparation of the starting complex

$K_3Na[MoO_2(CN)_4]\cdot 6H_2O$ was prepared in the following way: $Na_2MoO_4\cdot 2H_2O$ (7.0 g, 0.03 mol), KBH_4 (3.0 g, 0.063 mol) and KCN (5.0 g, 0.077 mol) were dissolved in water (100 cm^3) and cooled to *ca* 5°C, followed by the dropwise addition of acetic acid (5 cm^3, 0.08 mol) over *ca.* 10 min. More KCN (5.0 g, 0.077 mol) was then added, followed by the dropwise addition of another aliquot of acetic acid (5 cm^3, 0.007 mol) over *ca* 10 min. A mixture of NaOH (10 g, 0.25 mol) and KOH (14 g, 0.25 mol) (as solids) was added slowly to the molybdenum(IV) solution followed by the slow addition of ethanol (30 cm^3). The pink crystals were washed successively in small portions with an ethanol/water (9:1) (600 cm^3) mixture. Recrystallization was performed by dissolving the crystals in a minimum of water, addition of NaOH and KOH (*ca* 1 g of each) and precipitation of $K_3Na[MoO_2(CN)_4]\cdot 6H_2O$ by the slow addition of ethanol (yield 7.5 g, >50%). The purity was confirmed as described previously.[1]

Data collection and other measurements

The kinetics were obtained at 600 nm on a Durrum D-110 stopped-flow spectrophotometer coupled with a personal computer capable of performing least-squares analyses on the absorbance vs time data obtained from the kinetic runs. All kinetic runs were performed under pseudo-first-order conditions in carbonate/bicarbonate buffer medium with $\mu = 1.0$ M (KNO_3). Selective variation of the molybdenum(IV) concentration throughout these experiments showed no detectable changes in the rate constants observed. Other spectrophotometric measurements were performed on a Hitachi 150-20 double beam instrument, while all temperatures are reported to ±0.1°C accuracy. The solid lines in Figs 1–6 represent the computer least-squares fits of the data to the respective functions. In all calculations the acid dissociation constant for HCN has been taken as 9.20(6), which was confirmed potentiometrically at 10.0°C in $\mu = 1.0$ M (KNO_3). The reported value in 0.1 ionic strength is 9.20[5–9] at 25°C.

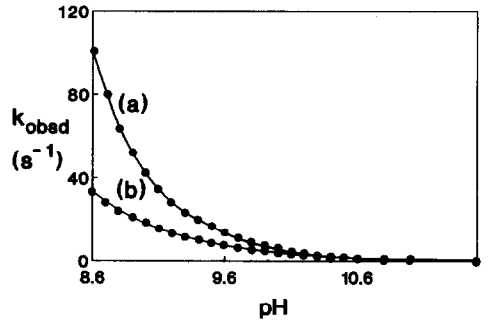

Fig. 1. pH dependence of pseudo-first-order rate constant at 10.0°C, $[Mo^{IV}] = 4.22\times10^{-3}$ M, $\mu = 1.0$ M (KNO_3), for (a) $[CN^-] = 0.05$ M and (b) $[CN]_{tot} = 0.050$ M.

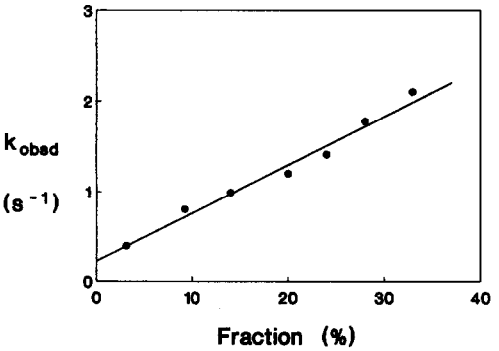

Fig. 2. Dependence of the pseudo-first-order rate constant on the fraction of $[MoO(H_2O)(CN)_4^{2-}]$ as a function of $[Mo^{IV}]_{tot}$ at 10.0°C, $\mu = 1.0$ M (KNO_3), $[CN^-] = 0.050$ M and $[Mo^{IV}] = 4.22\times10^{-3}$ M.

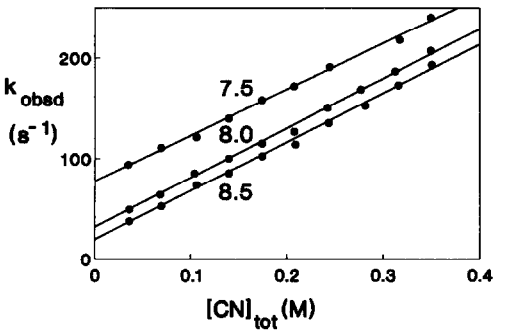

Fig. 3. Dependence of pseudo-first-order rate constant on $[CN]_{tot}$ at pH (a) 7.5, (b) 8.0 and (c) 8.5, at 15.0°C, $[Mo^{IV}] = 4.22\times10^{-3}$ M $\mu = 1.0$ M (KNO_3).

RESULTS

We have taken care to perform the different experiments described here in such a way as to ensure the most complete analysis of this complex system. The following important results from previous research on these systems have to be kept in

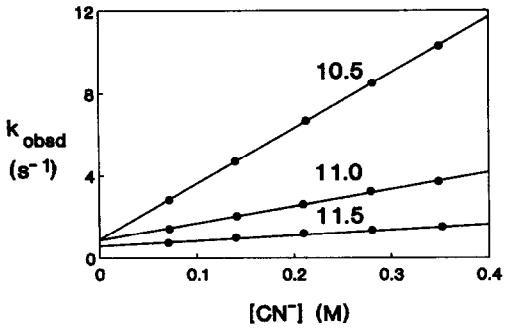

Fig. 4. Dependence of pseudo-first-order rate constant on [CN^-] at pH (a) 10.5, (b) 11.0 and (c) 11.5, at 15.0°C, $[Mo^{IV}] = 4.22 \times 10^{-3}$ M, $\mu = 1.0$ M (KNO_3).

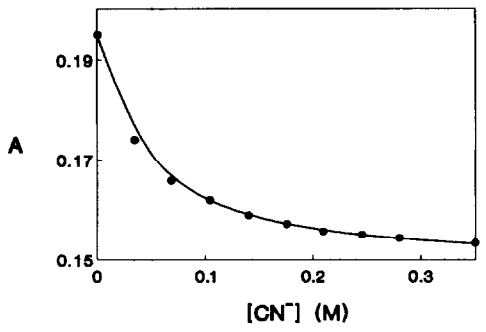

Fig. 6. Absorbance change ($\lambda = 600$ nm) dependence on [CN^-] at 15.0°C, $[Mo^{IV}] = 4.22 \times 10^{-3}$ M, $\mu = 1.0$ M (KNO_3), pH = 10.5.

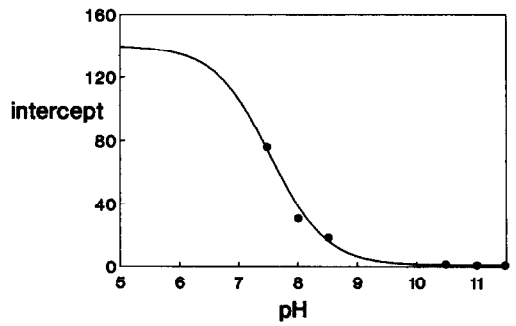

Fig. 5. pH dependence of y-intercept [eqs (4) and (5)] at 15.0°C, $[Mo^{IV}] = 4.22 \times 10^{-3}$ M, $\mu = 1.0$ M (KNO_3), $[CN]_{tot} = 0.050$ M.

mind: (1) The $[MO(H_2O)(CN)_4]^{n-}$ complex is the only protonated species of the dioxotetracyano complexes of molybdenum(IV), tungsten(IV), technetium(V) and rhenium(V) which is reactive towards monodentate substitution, i.e. no replacement of the hydroxo ligand in the $[MO(OH)(CN)_4]^{m-}$ complexes was observed in all the systems studied.[1] (2) In the rhenium(V) system, and some other complexes studied, protonated forms of different ligands, for example, HN_3[10] and specifically HCN,[5-8] can act as monodentate ligands. (3) The oxopentacyanomolybdate(IV) complex, $[MoO(CN)_5]^{3-}$,[11,12] and very recently also the HCN complex, $[MoO(CN)_4(HCH\text{-}\kappa N)]^{2-}$,[13] have already been isolated as the PPh_4^+ salts and characterized crystallographically, confirming the formulation of the reaction products.

These observations, coupled with the fact that the $[MoO(H_2O)(CN)_4]^{2-}$ complex reacts with cyanide at pH values below the pK_a value of HCN (9.2), enables the construction of Scheme 1 for the ligation of $[MoO(H_2O)(CN)_4]^{2-}$ by CN^-/HCN. The coordination mode of the HCN in the $[MoO(HCN)(CN)_4]^{2-}$ complex is via the nitrogen atom,[12,14-16] which has been confirmed recently by the crystal structure determination of $(PPh_3)_2[MoO(NCH\text{-}\kappa N)(CN)_4]\cdot H_2O$.[13] The effect of isomerization is not addressed separately in this system and is assumed to be incorporated in the K_{aNCH} value. It is, however, reasonable to assume that the isomerization is rapid since no deviation from first-order kinetics was observed. This is in agreement with the fast isomerization observed for cobalt(III) ($[Co(CN)_5NC]^{3-} \rightarrow [Co(CN)_6]^{3-}$, $k_{iso} = 0.2$ s^{-1}), even though the normal substitution reactions on the cobalt(III) centre are very slow.[14]

Figure 1(a) illustrates the effect of pH on the observed reaction rate constant for the reaction between $[MoO(H_2O)(CN)_4]^{2-}$ and CN^-/HCN in the pH range 8–12, at constant [CN^-] = 0.05 M (calculated, pK_{aHCN} = 9.20). Similarly, Fig. 1(b) shows the pH dependence of k_{obs} at constant *total* cyanide concentration, i.e. $[CN]_{tot} = 0.050$ M.

The rapid increase in k_{obs} below the pK_a value of HCN from both plots in Fig. 1 is quite obvious. It

$$[MoO(H_2O)(CN)_4]^{2-} + CN^- \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [MoO(CN)_5]^{3-} + H_2O$$

$$+H^+ \; \updownarrow \; -H^+, K_{aHCN} \qquad +H^+ \; \updownarrow \; -H^+, K_{aNCH}$$

$$[MoO(H_2O)(CN)_4]^{2-} + HCN \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} [MoO(HCN)(CN_4]^{2-} + H_2O$$

Scheme 1.

is clear that the concentration of the aqua complex increases with a decrease in pH from 12 to 9. Using the data in Fig. 1, and the definition of the acid dissociation constant for the $[MoO(H_2O)(CN)_4]^{2-}$ complex ($pK_{a1} = 10.0$[1]), the fraction concentration of the *aqua* complex in the pH range 10.3–11.5 can be calculated. Figure 2 shows the relationship between the observed rate constant and the fraction of the $[MoO(H_2O)(CN)_4{}^{2-}]$ ion with respect to the total $[Mo^{IV}]$, clearly illustrating a negligible contribution of $[MoO(OH)(CN)_4]^{3-}$ to the observed rate constant (*y*-intercept represents only the contribution of the reverse step, k_{-1}, see Discussion). This observation is in direct correlation with the proposed reaction in Scheme 1, i.e. that the aqua $[MoO(H_2O)(CN)_4]^{2-}$ complex is the only reactive species towards substitution by CN^-/HCN.

The rate law for the complete reaction in Scheme 1 is given by eq. (1)

$$\text{Rate} = k_1[MoH_2O][CN^-] + k_2[MoH_2O][HCN] - k_{-1}[MoCN] - k_{-2}[MoNCH] \quad (1)$$

In eq. (1) MoH_2O, MoCN and MoNCH represent the $[MoO(H_2O)(CN)_4]^{2-}$, $[MoO(CN)_5]^{3-}$ and $[MoO(NCH)(CN)_4]^{2-}$ species, respectively. Before integration of the rate equation the total concentration of molybdenum(IV) reactant ($[Mo^{IV}]_{tot} = [MoO(H_2O)(CN)_4{}^{2-}] + [MoO(OH)(CN_4{}^{3-}]$) and that of the products ($[MoCN]_{tot} = [MoO(CN)_5{}^{3-}] + [MoO(NCH)(CN)_4{}^{2-}]$) was incorporated in eq. (1). The definitions of the first acid dissociation of $[MoO(H_2O)(CN)_4]^{2-}$, K_{a1}, as well as the acid dissociation constant of HCN, K_{aHCN}, and that of the coordinated hydrogen cyanide, K_{aNCH}, were also included. Expressions for the observed first-order rate constant, k_{obs}, were consequently obtained upon integration of the rate law ($[CN^-]$, $[CN^-]_{tot} \gg [Mo]_{tot}$) in terms of the total cyanide concentration, $[CN]_{tot} = ([CN^-] + [HCN])$ [eq. (2)], or in terms of $[CN^-]$ [eq. (3)].

$$k_{obs} = \frac{[(k_1 K_{aHCN}/[H^+]) + k_2][CN]_{tot}}{(1 + K_{a1}/[H^+])(1 + K_{aHCN}/[H^+])} + \frac{k_{-2} + k_{-1}K_{aNCH}/[H^+]}{1 + K_{aNCH}/[H^+]} \quad (2)$$

$$k_{obs} = \frac{[(k_1 K_{aHCN}/[H^+]) + k_2](1 + [H^+]/K_{aHCN})[CN^-]}{(1 + K_{a1}/[H^+])(1 + K_{aHCN}/[H^+])} + \frac{k_{-2} + k_{-1}K_{aNCH}/[H^+]}{1 + K_{aNCH}/[H^+]} \quad (3)$$

The solid line in Fig. 1(b) represents the least-squares fit of the k_{obs} vs pH data to eq. (3) (constant $[CN]_{tot} = 0.050$ M). Similarly, the solid line in Fig. 1(a) gives the least-squares fit of the k_{obs} vs pH data to eq. (2) (constant $[CN^-] = 0.050$ M). The approximate values obtained from both computer fits in Fig. 1 for k_1, k_{-1}, k_2, k_{-2} and K_{aNCH} are 140(20) M^{-1} s^{-1}, $-0.2(2)$ s^{-1}, 300(50) M^{-1} s^{-1}, 180(70) s^{-1} and $2(1) \times 10^{-8}$. Equation (3) has too many parameters to produce accurate results from a single fit to the data in Fig. 1, but good estimates for the different constants could nevertheless be obtained therefrom. More accurate values for the different constants were determined as described below.

At pH values 7–8, where $[H^+] \gg K_{a1}$, K_{aHCN}, eq. (2) simplifies to eq. (4).

$$k_{obs} = k_2[CN]_{tot} + \frac{k_{-2} + k_{-1}K_{aNCH}/[H^+]}{1 + K_{aNCH}/[H^+]} \quad (4)$$

Figure 3 illustrates the dependence of the pseudo-first-order rate constant on the total cyanide concentration (primarily in the form of HCN) at pH values 7.5–8.5 (lower pH values could not be studied due to the small effective equilibrium constant, see Fig. 3). It is clear that the increase in k_{obs} is primarily a result of the increase in the intercept, i.e. the reverse rate constant, and that the kinetics at these pH values are adequately described by eq. (4). It is further obvious that the value of k_2 can be obtained from the slope of the lines in Fig. 3 and the average value obtained from the three pH values is reported in Table 1.

At pH values 11–11.5, where $[H^+] \ll K_{a1}$, K_{aHCN}, eq. (2) simplifies to eq. (5).

$$k_{obs} = \frac{k_1[H^+][CN]_{tot}}{K_{a1}} + \frac{k_{-2} + k_{-1}K_{aNCH}/[H^+]}{1 + K_{aNCH}/[H^+]} \quad (5)$$

Figure 4 shows the dependence of k_{obs} on the total cyanide (primarily in the form of CN^- ions) at pH values 10.5–11.5. It is clear from eq. (5) that k_1 is obtained from the slope upon incorporation of the pH and K_{a1}. The average value for k_1 thus obtained is given in Table 1.

The contribution to the total pseudo-first-order rate constant provided by the reverse path, given in eqs (4) and (5), is at lower pH values, primarily as a function of the acid dissociation constant of the coordinated HCN, i.e. K_{aNCH}. Assuming $pK_{aNCH} < 8$ the reverse reaction in eq. (5) can be simplified even further ($k_{-1} > k_{-2}[H^+]/K_{aNCH}$, as confirmed by the similarity in the intercepts of the lines in Fig. 4) and the expression for the pseudo-first-order rate constant (pH *ca* 11) is given by eq. (6).

$$k_{obs} = \frac{k_1[H^+][CN]_{tot}}{K_{a1}} + k_{-1} \quad (6)$$

At high pH values the intercept in eq. (6), therefore, provides values for the reverse rate constant for the

CN^- pathway, of which the results obtained for k_{-1} are given in Table 1.

The pH dependence of the intercept at lower pH values is described by eq. (7), with the contribution of k_{-1} being relatively small at pH < 10 and the intercept is primarily determined by k_{-2}.

$$\text{Intercept} = \frac{k_{-2}[H^+] + k_{-1}K_{aNCH}}{[H^+] + K_{aNCH}} \qquad (7)$$

The pH dependence of the intercept is shown in Fig. 5 [the least-squares fit to eq. (7) given by the solid line], from which a fairly accurate estimated pK_a value of the coordinated HCN could be determined, see Table 1.

A more accurate definition of the complete curve in Fig. 5 is restricted by the decrease in the reaction yield at pH < 7.5. The accurate determination of k_{-2} is limited accordingly.

The equilibrium constants for neither the HCN nor the CN^- pathways can be determined individually as a result of the complexity of the equation defining the reaction equilibria, see Scheme 1. However, at high pH the CN^- pathway dominates and the absorbance dependence on $[CN^-]$ for this system (pH = 10.5), upon incorporation of Beer's law,

mass balance and the definitions of K_1 ($= k_1/k_{-1}$) and K_{a1}, can be described by eq. (8). The results are shown in Fig. 6 and the K_1 value obtained is reported in Table 1.

$$A = \frac{A_m + A_{ml}K_1[CN^-]}{(1+K_{a1}/[H^+])(1+K_1[CN^-])} \quad (8)$$

In eq. (8) A_m and A_{ml} represent the absorbance contributions due to the unsubstituted and substituted complexes, respectively.

A temperature dependence study was undertaken to determine the activation parameters for both the HCN (at pH = 7.5) and CN^- (at pH = 11.0) pathways. The results of the studies showed the normal dependence similar to that given in Figs 3 and 4 and the forward and reverse rate constants and the activation parameters calculated therefrom are given in Table 1. The temperature changes in the pK_a values of the molybdenum(IV) complexes were assumed to be negligible compared with that of the other parameters.

DISCUSSION

The oxopentacyanomolybdate(IV) complex has been obtained previously and is well characterised,[11,12] while reactions of HCN as a ligand have been described previously in aqueous systems such as $[Ni(CN)_4]^{2-}$, $[Ni(trien)]^{2+}$ (trien = triethylenetetramine),[5] $[Ni(daco)_2]^{2+}$ [8] (daco = 1,5-diazicyclooctane), $[Ni(EDTA)]^{2-}$,[8] aqua-cobalamin[7] and [Rh(TPPS)$(H_2O)_2$] [TPPS = tetrakis(4-sulphonatophenyl)porphyrin].[6] It was found that CN^- ions may react more rapidly than HCN,[6] but the opposite also holds true.[8] The HCN coordinates to the metal centre via the nitrogen, as has very recently been crystallographically verified by the structure determination of $(PPh_4)[MoO(CN)_4(NCH\text{-}\kappa N)]\cdot H_2O$.[13] Evidence from the literature concerning the coordination ability of the nitrogen atom in the HCN entity is quite abundant, i.e. the crystal structure determination of $[(NH_3)_5Co NCCo(CN)_5]\cdot H_2O$[15] showed that CN^- can act as an ambidentate ligand, i.e. coordinate with either the carbon or nitrogen atom; the structure determinations of, for example, $[(NH_3)Co(NCacac)](Cl)(ClO_4) \cdot 2H_2O$[16] (NCacac = 3-cyanoacetylacetonato) and $[(PPh_3)_2N]_2[MoO(CN)_4(NCCH_3)]$[12] showed that cyanide can in principle coordinate to a metal centre via the nitrogen atom; the existence of dimeric $[(CN)_6W—NC—W(CN)_6]^-$ and trimeric $[(CN)_7W—CN—W(CN)_6—CN—W(CN)_7]^{6-}$ ions, as has been suggested recently,[17] further illustrates this point.

It is of significance that hydrogen cyanide has been found to react in the case of the $[MoO(H_2O)(CN)_4]^{2-}$ system, providing a possible route for the formation of the octacyano complexes at lower acidity values. Equally important, however, is the fact that in spite of the HCN reacting with the aquaoxotetracyanomolybdate(IV) complex, the stability constant of the pentacyano-oxo complex at pH values less than 8.5 is too low to ensure appreciable amounts of $[MoO(CN)_5]^{3-}$ present, a prerequisite for the formation of the $[Mo(CN)_8]^{4-}$ complex. This is in agreement with the observed fact that the octacyanomolybdate(IV) does not form around these pH values.

In the molybdenum(IV) system it is of significance that the HCN actually reacts approximately five times more rapidly than the CN^- ion, see k_2 and k_1 in Table 1. Since a dissociative mechanism has been assumed for the tungsten(IV) system based on the high pressure kinetic study for the reaction between the $[WO(H_2O)(CN)_4]^{2-}$ complex and N_3^- ions ($\Delta V^* = +10.6$ cm^3 mol^{-1}),[1] a similar mechanism is anticipated for the molybdenum(IV) system. Furthermore, the large *trans* influence of the oxo ligand as observed in the metal–aqua bond distances in the $[MO(H_2O)(CN)_4]^{n-}$ complexes, as well as the mode of distortion (displacement of the central metal atom by 0.3 Å towards the oxo from the plane formed by the four cyano carbon atoms), will promote a dissociative activation.[1] In the aforementioned tungsten(IV) system the difference between the ligation constants for the monodentate ligands NCS^-, N_3^- and py is only a factor of 2 (2.9, 4.1 and 6 M^{-1} s^{-1} at 25°C, respectively) and an acceptable linear free energy relationship was obtained for these three ligand systems. The anation rate constant for the reaction with fluoride ions was, however, only 0.14 M^{-1} s^{-1}, in which case a contribution from hydrogen bonding was assumed. In the case of the tungsten(IV) system the reaction with F^- ions was *ca* 20–40 times slower than the average of the other three ligands. In the case of the molybdenum(IV) system in the present study the reaction with F^- ions is only 10 times slower than the reaction with CN^- ions, but 50 times slower than the reaction with HCN.

By considering the reaction between $[MoO(H_2O)(CN)]^{2-}$ and HCN/CN^- ions in the present study, it is clear that the reverse rate constants (i.e. hydrolysis) differ by more than two orders of magnitude where there is only a five times difference in the aqua substitution rate constants. This is in direct agreement with a dissociative mechanism. The five-fold increase in reaction rate with

the HCN (compared with that of the CN^- ions) observed in this study might be attributed to a better association capability, being a neutral entity, and experiencing less electrostatic repulsion than the negatively charged CN^- ion during the rate-determining step. In fact, slightly increases rates were observed in both the tungsten(IV) (py compared to NCS^- and N_3^-, see previous paragraph) and rhenium(V)[2] (k_1 for the neutral ligands thiourea and hydrazoic acid were between 2 and 10 times larger than the reaction with NCS^- ions) systems when less negative incoming ligands were used. Although negative activation entropy values for both the HCN and CN^- pathways were calculated, this does not necessarily imply an associative mechanism, as has been shown previously on a number of occasions by high pressure kinetic studies.

The fact that the HCN does coordinate in this present system poses similar problems to those observed previously,[5] i.e. the coordination mode and the behaviour of the hydrogen cyanide once coordinated. According to that proposed in Scheme 1 the acid dissociation of the coordinated HCN results in the almost simultaneous isomerization to the carbon-coordinated cyano complex. It might be anticipated that the combination of this dissociation/isomerization still can result in a pK_a value for the coordinated HCN that is more acidic than the free acid in aqueous solution, since the coordination of the HCN via the nitrogen atom is expected to weaken the H—C bond, resulting in a stronger acid.

This study has confirmed the reaction of both free cyanide ions and hydrogen cyanide with the $[MoO(H_2O)(CN)_4]^{2-}$ complex and has described the kinetics of this complex system, which is an important step in the elucidation of the mechanism by which the octacyanometalate complexes form. We are currently in the process of extending these studies to the other dioxotetracyano systems already studied in our laboratories, i.e. tungsten(IV) and also rhenium(V) and technetium(V). The $[TcO(CN)_5]^{3-}$ complex is already known, but no formation kinetics have been reported.[18] The cyanide exchange on these systems by high-field NMR and the formation of higher-coordinated cyano complexes are also under investigation.

REACTIONS OF 1-ADAMANTYLPHOSPHINE AND BIS-(1-ADAMANTYL)PHOSPHINE WITH CARBONYLS OF GROUP 6, 8 AND 10 METALS. REACTIVITY OF THE P—H BOND IN 1-ADAMANTYLPHOSPHINE COMPLEXES*

(*Received* 4 *January* 1993; *accepted* 19 *April* 1993)

Abstract—The reactions between $(1\text{-Ad})_nPH_{3-n}$ (1-Ad = 1-adamantyl; $n = 1, 2$) and $M(CO)_6$ (M = Cr; Mo, W), $Fe_2(CO)_9$ and $Ni(CO)_4$ led to mononuclear derivatives of the type $(OC)_mM[(1\text{-Ad})_nPH_{3-n}]$ ($m = 5$, M = Cr, Mo, W; $m = 4$, M = Fe; $m = 3$, M = Ni; $n = 1, 2$). Although rather unreactive, as a result of the 1-adamantyl substitution, some of these compounds were employed for further synthesis under more vigorous conditions. Thus, pyrolysis of $(1\text{-AdPH}_2)Fe(CO)_4$ (**7**) furnished the binuclear cluster $(1\text{-AdPH})_2Fe_2(CO)_6$ (**11**), whereas substitution of a PH proton in the chromium complex $(1\text{-AdPH}_2)Cr(CO)_5$ (**1**) by a diisopropylphosphino group led to the diphosphine complex $(OC)_5Cr(1\text{-AdPH—P}^i\text{Pr}_2)$ (**15**), which isomerized at elevated temperatures to $(1\text{-AdPH—P}^i\text{Pr}_2)Cr(CO)_5$ (**15a**) with liberation of the diphosphine $1\text{-AdPH—P}^i\text{Pr}_2$ (**16**). The crystal structure of **15** is described; the P—P bond length is 223.6(1) pm. 1-AdPH_2 reacted with $Fe_3(CO)_{12}$ with the formation of a mixture of bi- and trinuclear iron carbonyl clusters.

Primary and secondary phosphines resemble the majority of phosphorus(III) compounds in that they react with metal carbonyls, substituting carbon monoxide.[1] As a result of the reactivity of the $—PH_2$ or the —PH group these compounds can serve as versatile precursors in the synthesis of new compounds. The synthesis of species that are unknown or unstable in an uncoordinated state may be realized in the coordination sphere of a transition metal. Thus, based on phosphine complexes, Treichel and his co-workers[2–4] have described the synthesis of phosphido complexes; Stelzer and his co-workers[5] have synthesized di-, tri- and tetraphosphines coordinated to metal carbonyl fragments; Mathey and his co-workers[6–9] have reported the synthesis of phosphaalkene and phosphirane complexes from coordinated phosphine precursors. Complexes involving PH phosphines have also been used in the synthesis of oligonuclear transition metal clusters.[10,11]

A variety of metal complexes involving primary and secondary phosphines as ligands are known, but the substituents were always aromatic or sterically undemanding alkyl groups. In the course of our studies on tertiary, bulky hydrocarbon group substituents at phosphorus[12–14] the question arose whether the comparatively unreactive 1-adamantyl-substituted phosphines of the type $(1\text{-Ad})_nPH_{3-n}$ ($n = 1, 2$) could be employed as ligands and, if so, whether further chemical reactions at the coordinated phosphine ligands would be possible.

RESULTS AND DISCUSSION

Reactions of 1-adamantylphosphine and bis-(1-adamantyl)phosphine with carbonyls of group 6, 8 and 10 metals

The reaction of 1-adamantyl- and bis-(1-adamantyl)phosphine with a slight excess of the hexa-

* Dedicated to Professor R. W. Parry on the occasion of his 75th birthday.

† Author to whom correspondence should be addressed.

carbonyls of chromium(0), molybdenum(0) and tungsten(0) in high-boiling solvents at 110–140°C was found to lead, selectively, to the monosubstituted derivatives with the loss of carbon monoxide [eq. (1)]. Reactivities and yields were found to decrease from chromium to tungsten carbonyl.

$$R^1R^2PH + M(CO)_6 \xrightarrow[-CO]{\Delta} (R^1R^2PH)M(CO)_5 \quad (1)$$

R^1	R^2	Cr	Mo	W
1-Ad	H	**1**	**2**	**3**
1-Ad	1-Ad	**4**	**5**	**6**

Products **1–6** are colourless solids that are stable in air for hours. They may be purified by recrystallization from THF. The $\delta(^{31}P)$ values of **1–6** exhibit a significant low-field shift from those of the starting phosphines [1-$AdPH_2$, −81.6 ppm and $(1\text{-Ad})_2PH$, 18.71 ppm] (Table 1).

The deshielding effect increases from the tungsten to the chromium complexes. This could be a result of the decrease in the number of electrons at the metal atom and, consequently, a weakened shielding effect. In the ^1H NMR spectra of **1–6**, besides the signals due to the 1-adamantyl groups, the resonances of the phosphine protons are observed in the region 3.81–4.08 ppm (Table 1). Both $\delta(^{31}P)$ and $^1J(PH)$ (302.50–321.00 Hz)[15] lie in the expected region. In the ^{13}C NMR-spectra the *cis*- and *trans*-CO groups may be distinguished on the basis of

[a] *Cis/trans* only for the octahedral complexes **1–6**.
[b] X-part of an ABX spectrum.

their $\delta(^{13}C)$ and $^2J(PC)$ values:[16] the $\delta(^{13}C)$ values of *trans*-CO groups are observed consistently at lower field than those of the *cis*-CO groups. In the case of the molybdenum and tungsten complexes $^2J(PC)_{trans}$ is always larger than $^2J(PC)_{cis}$, while the opposite is true for the chromium complexes **1** and **4** (Table 2), in accord with expectation.[16]

Belonging to the point group C_{4v}, for complexes **1–6** in the IR spectra three IR-active bands are expected in the CO region[17] and are indeed observed. ν(PH) is observed in all IR spectra in the region 2299–2321 cm^{-1} (Table 1).[18] The mass spectra of **1–6** are found to exhibit the molecular ion peaks resulting from the successive loss of five CO groups and a peak at m/z 135 from the 1-adamantyl fragment. In the mass spectra of **4–6** signals from the free ligand, $(1\text{-Ad})_2PH$, are observed.

The mononuclear derivatives of iron pentacarbonyl, **7** and **8**, were synthesized from $(1\text{-Ad})_nPH_{3-n}$ and $Fe_2(CO)_9$ in toluene as an inert solvent at room temperature [eq. (2)]. The products are orange–brown solids, melting with decomposition.

$$R^1R^2PH + Fe_2(CO)_9 \xrightarrow[-Fe(CO)_5]{\text{toluene}} (R^1R^2PH)Fe(CO)_4 \quad (2)$$

$R^1 = 1\text{-Ad}, \quad R^2 = H$: **7**

$R^1 = R^2 = 1\text{-Ad}$: **8**

For **7** $\delta(^{31}P)$ is shifted by *ca* 86 ppm and for **8** by *ca* 64 ppm to high field, compared with the free ligands. The $\delta(^1H)$ and $^1J(PH)$ values of the phosphine protons are in accord with expectation and are closely similar to those of **1–6** (Table 1). In the ^{13}C NMR spectra of both compounds only one resonance, a doublet due to $^{31}P—^{13}C$ coupling, is observed for the carbonyl groups (Table 2). Assuming trigonal-bipyramidal geometry at Fe(0) a pseudo-rotation process, too fast to be followed by ^{13}C NMR spectroscopy, would account for this observation. The mass spectra of **7** and **8** exhibit the molecular ion with low intensity and the successive loss of the four carbonyl groups is seen. The IR spectra of **7** and **8** display the expected three bands in the carbonyl region, consistent with the

C_{3v} point group[17] and ν(PH) bands at 2325 (**7**) and 2310 cm^{-1} (**8**).

The reaction of primary phosphines with $Fe_3(CO)_{12}$ and $Ru_3(CO)_{12}$ has been studied.[10,19,20] In all cases oligonuclear phosphinidene clusters were obtained. In the case of osmium the primary reaction product, $Os_3(CO)_{11}(RPH_2)$ (R = Ph, *c*-C_6H_{11}) is well known.[20,21] It was thus of interest to determine whether the comparatively unreactive 1-$AdPH_2$ would yield products analogous to the osmium complexes in its reaction with $Fe_3(CO)_{12}$. Three signals in the ^{31}P NMR spectra of the reaction mixture [$\delta(^{31}P)$ 458.95, 400.85 and 150.88 in a 3 : 8 : 1 ratio] were assigned to the clusters **9**, **10** and **11**. These assignments are based on those of the analogous ^{t}butyl-substituted compounds, from the work of Huttner,[10,23] Vahrenkamp[11] and Stelzer[22] [eq. (3)]. There was no evidence for a primary substitution product, $Fe_3(CO)_{11}$(1-$AdPH_2$). Of the three components of the reaction mixture **9** and **10** could be isolated in a pure state. The phosphido cluster (**11**), present here solely as one of the symmetric isomers, was subsequently synthesized by a different method (*vide infra*).

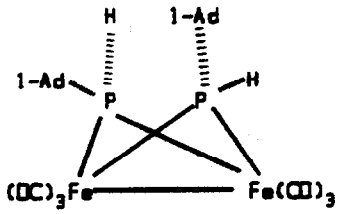
10



11

$$1\text{-}AdPH_2 + Fe_3(CO)_{12} \xrightarrow[-CO,\,-H_2]{\Delta} \mathbf{9} + \mathbf{10} + \mathbf{11} \quad (3)$$

The singlet absorption at 458.95 ppm in the ^{31}P NMR spectrum of **9** is typical of a μ^3-phosphido ligand. Compared with the signal of the analogous ^{t}butyl compound[10] there is a high-field shift of *ca* 8 ppm. A difference of this magnitude in $\delta(^{31}P)$ between analogous ^{t}butyl- and 1-adamantyl-phosphorus compounds is almost always observed, irrespective of the coordination number of phosphorus.[13] $\delta(^1H)$ for the bridging hydrogen atoms is −24.09 ppm, with $^2J(PH)$ = 27.41 Hz. In the ^{13}C NMR spectra of **9** only one signal is observed for the resonance of the carbonyl groups, suggesting a dynamic structure. For the 1-adamantyl cage the expected four signals are observed, with an unusually small value for $^1J(PC)$ of 6.81 Hz, as against a larger $^3J(PC)$ value of 10.42 Hz. The mass spectrum exhibits the molecular ion at *m/z* 588, fragments from the successive loss of nine carbonyl groups and the fragments $[Fe_3PH]^+$, $[Fe_3P]^+$ and $[Ad]^+$. The IR spectrum, similar to that of the analogous ^{t}butyl compound,[10] shows six bands in the carbonyl region, suggesting a similar structure.

A resonance, $\delta(^{31}P)$ = 400.85 ppm, shifted by *ca* 5 ppm to high field, relative to the analogous ^{t}butyl compound,[23] is observed for **10** in the region typical of μ^3-phosphido ligands. Stelzer and his co-workers have obtained such compounds as stable products of the thermally initiated reaction of primary phosphines with $Fe(CO)_5$.[22] The ^{13}C NMR spectrum of **10** in the carbonyl region shows a single line for the carbonyl groups at 213.90 ppm. The ^{13}C NMR resonances of the atoms C^1 and C^3 of the 1-adamantyl cage appear as X parts of ABX spectra, as a result of coupling with the two non-equivalent phosphorus atoms of the molecule. The mass spectrum of **10** shows a low intensity molecular ion at *m/z* 752 and fragments originating from successive loss of the nine carbonyl groups. In addition, signals due to the fragments $[Fe_3P_2Ad]^+$, $[Fe_2P_2Ad]^+$, $[Fe_3P_2]^+$, $[Fe_3P]^+$ and $[Ad]^+$ are observed.

As for the analogous ^{t}butyl compound[23] five bands are observed in the carbonyl region of the IR spectrum of **10**, their wave numbers differing only slightly from those of the ^{t}butyl analogue. The number and position of these bands confirm the assumed structure.

For the synthesis of mononuclear nickel(0)-phosphine derivatives a large excess of $Ni(CO)_4$ was added to solutions of the phosphines $(1\text{-}Ad)_nPH_{3-n}$ (n = 1, 2) in THF. The reaction mixtures were

stirred at room temperature until the evolution of carbon monoxide ceased [eq. (4)].

$$R^1R^2PH + Ni(CO)_4 \xrightarrow[-CO]{\text{THF, room temperature}} (R^1R^2PH)Ni(CO)_3 \quad (4)$$

R^1 = 1-Ad, R^2 = H: **12**

$R^1 = R^2$ = 1-Ad: **13**

Compound **12** was obtained as a colourless oil, crystallizing at −18°C, while **13** was a colourless solid. As expected there is a marked low-field shift of $\delta(^{31}P)$ (Table 1). In the ^1H NMR spectra signals typical of P*H* protons are observed at 3.85 (**12**) and 3.66 ppm (**13**), with $^1J(PH)$ = 298.11 and 301.14 Hz, respectively (Table 1). In the ^{13}C NMR spectra of both complexes only single resonances are observed for the carbonyl groups. There is a conspicuous high field shift of the ^{13}C NMR resonances of the C^1 atoms of the 1-adamantyl group. In the mass spectrum of **12** the molecular ion is seen at *m/z* 310, whereas for **13** the heaviest fragment arises from the loss of one carbonyl group from the parent molecule. Further characteristic fragments are the result of the successive loss of carbon monoxide. The base peak, in both cases, is the adamantyl cation (*m/z* 135). The IR spectra (C_{3v} molecular symmetry) reveal two bands[17] in the carbonyl region, in agreement with reports on mononuclear nickel carbonyl complexes of other phosphines.[24] IR absorptions due to ν(PH) are seen at 2319 (**12**) and 2299 cm^{-1} (**13**).[18]

Reactions of metal carbonyl-phosphine complexes

As mentioned above, we succeeded in isolating the two trinuclear iron(0) clusters **9** and **10** from the reaction mixture of 1-$AdPH_2$ and $Fe_3(CO)_{12}$, whereas the isolation of a third product [$\delta(^{31}P)$ 150.88] failed. Based on the comparison of the $\delta(^{31}P)$ values to those of other, structurally analogous compounds,[11,22] this signal is assigned to an isomer of the phosphido cluster (**11**). In order to ascertain its identity an alternative synthesis of **11** was realized, following a previously reported procedure,[11] by refluxing a solution of the phosphine complex **7** in toluene [eq. (5)]. A 1 : 1 ratio of **7** : **11** was determined (^{31}P NMR) after a 6 h reflux period.

$$\underset{\mathbf{7}}{2(1\text{-}AdPH_2)Fe(CO)_4} \xrightarrow[-2CO,\ -H_2]{\text{toluene, reflux}} \underset{\mathbf{11}}{(1\text{-}AdPH)_2Fe_2(CO)_6} \quad (5)$$

This ratio remained unchanged upon continued refluxing. Upon work-up by column chromatography **11** was obtained as a yellow solid, consisting of a 1 : 1 mixture of the isomers **11a** and **11b**. From the $\delta(^{31}P)$ value of **11a** (150.88 ppm) it was concluded that it was one of the products obtained in the reaction of 1-$AdPH_2$ with $Fe_3(CO)_{12}$. The ^{31}P NMR spectrum of **11b**, due to the non-equivalence of the two phosphorus atoms, shows a higher order AB type NMR pattern. Presumably as a result of the steric demand of the bulky 1-adamantyl group, isomer **11c** is not observed (Fig. 1).

In contrast, Stelzer and his co-workers obtained a mixture of all three possible isomers[22] from the reaction of $Fe(CO)_5$ with $PhPH_2$, presumably because of the lower steric demand of the phenyl group. The ^1H NMR spectrum of our mixture of isomers, **11a** and **11b**, is found to exhibit numerous lines in the region 2.81–5.15 ppm, which originate

Fig. 1. Newman projection of compounds **11a**, **11b** and **11c**.

from the higher order spectra to be expected for the protons of the phosphido bridges. A precise assignment of the partially overlapping signals was unsuccessful. The mass spectrum of **11a/11b** shows the molecular ion at *m/z* 614, fragments originating from the successive loss of six CO groups and the ions $[Fe_2P_2]^+$ and $[Ad]^+$. Four bands are observed in the carbonyl region of the IR spectrum; they are shifted to slightly lower wave numbers than those of the analogous ^{t}butyl compound.

The formation of heterometallic clusters in the reaction of coordinated phosphines with oligonuclear metal carbonyls has been described in the literature.[10,11,25-27] Employing the conditions described by Huttner and his co-workers,[10] an equimolar mixture of $Fe_3(CO)_{12}$ and **1** in toluene was heated for 12 h at 80°C. An inspection by ^{31}P NMR spectroscopy revealed only the signal of **1** and there was no indication of possible product signals[27] after another 3 h reflux period. The reason for the failure of this reaction under the conditions employed may be the comparatively low reactivity of 1-adamantyl-substituted phosphorus compounds.

In analogy to reports by Stelzer and his coworkers[5] an attempt was made to substitute one or two of the phosphino protons in **2** by diphenylphosphino groups, forming coordinated di- or triphosphines. However, ^{31}P NMR gave no evidence for any reaction, either after stirring a mixture of **2** and diphenylchlorophosphine in toluene in the presence of triethylamine for several days at room temperature or after a 5 h reflux period. The failure of the reaction, in contrast to the analogous reaction of the phenylphosphine-substituted molybdenum pentacarbonyl derivative, is again thought to be due to the reduced reactivity of the 1-adamantyl phosphine derivative **2**.

A successful attempt at the formation of a PP bond in the coordination sphere of a metal was based on the reaction of $(1\text{-AdPH}_2)Cr(CO)_5$ (**1**) with n-butyl lithium, forming the yellow lithium phosphido complex **14**; subsequent addition of diisopropylchlorophosphine gave compound **15**, the chromium pentacarbonyl derivative of the unknown unsymmetrical diphosphine **16**, in high yield [eqs (6) and (7)]. The ^{31}P NMR spectrum of **15** is found to exhibit a higher order pattern, with $\delta(^{31}P)$ ($^iPr_2P$) = 6.22 ppm, $\delta(^{31}P)$ (1-Ad*P*H) = 2.45 ppm, $^1J(PP)$ = 245.97 Hz.[28] The ^{1}H NMR spectrum shows a doublet at 3.92 ppm

$$\underset{\mathbf{1}}{(1\text{-AdPH}_2)Cr(CO)_5} + {}^n\text{BuLi} \xrightarrow[-{}^n\text{BuH}]{-78°C} \underset{\mathbf{14}}{(1\text{-AdPHLi})Cr(CO)_5} \quad (6)$$

$$1\text{-Ad(H)PLi} + {}^i\text{Pr}_2\text{PCl} \xrightarrow[-\text{LiCl}]{} 1\text{-Ad(H)P—P}^i\text{Pr}_2$$
$$\downarrow \qquad\qquad\qquad\qquad \downarrow$$
$$\underset{\mathbf{14}}{Cr(CO)_5} \qquad\qquad \underset{\mathbf{15}}{Cr(CO)_5} \quad (7)$$

[^1J(PH) = 297.49 Hz]. A ^2J(PH) coupling constant cannot be discerned in the spectrum. The protons of both isopropyl groups in the ^{1}H NMR spectrum give rise to partially overlapping higher-order spin systems and while an exact assignment is impossible, the isopropyl groups appear to be non-equivalent. This finding is supported by the observation of six lines for the two isopropyl groups in the ^{13}C {^{1}H, ^{31}P} NMR spectrum. For the carbon atoms of the carbonyl groups two resonances at $\delta(^{13}C)$ = 217.26 ppm, $^2J(PC)$ = 9.39 Hz (*cis*-CO), and $\delta(^{13}C)$ = 221.23 ppm, $^2J(PC)$ = 4.36 Hz (*trans*-CO), are observed. The mass spectrum exhibits the molecular ion at *m/z* 476, fragment ions caused by the successive loss of carbonyl groups and the fragments $[1\text{-AdP(H)P}^i\text{Pr}_2]^+$, $[1\text{-AdP(H)P}]^+$ and $[Ad]^+$. IR bands are observed for ν(PH) at 2307 cm^{-1} and in the carbonyl region at 2060, 1979 and 1937 cm^{-1}.

In order to confirm the structure and identity of **15**, and to exclude the possibility of a migration of the $Cr(CO)_5$ group to the more nucleophilic diisopropyl-substituted phosphorus atom, a single-crystal X-ray diffraction study of **15** was conducted (Fig. 2, Table 3). This confirms the presence of an adamantyl-substituted and pentacarbonyl-chromium-coordinated diphosphine. The main distortion from ideal octahedral coordination geometry

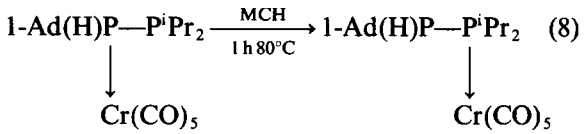
is indicated by the angles P(1)—Cr—C(20) [100.6(1)°] and C(19)—Cr—C(20) [170.8(1)°]. These wide angles are probably caused by the bulky isopropyl substituents at P(2), which lie approximately synclinal (skew) and synperiplanar (partially eclipsed) relative to the pentacarbonyl-chromium grouping [torsion angles: Cr—P(1)—P(2)—C(11) 93.7°; Cr—P(1)—P(2)—C(14) −13.4°]. The P(1)—P(2) bond length is normal [223.6(1) pm]. The P(1)—C(1) bond length [188.4(2) pm] is slightly greater than P—C bonds in species involving less bulky alkyl substituents, but is comparable with P—C bond lengths in other adamantyl phosphines.[13] The adamantyl group shows, as expected, a narrow range of values for the C—C bond lengths [152.1(2) C(6)—C(7) to 154.6(3) C(5)—C(10); av. 153.2 pm]. P(1) shows a considerably distorted tetrahedral coordination geometry associated with the bulky substituents $Cr(CO)_5$ and $P(^iPr)_2$, which effect a widening of the angle Cr—P(1)—P(2) [128.3(1)°]. The less bulky part of the diisopropylphosphine substituent faces the adamantyl substituent and the angle P(2)—P(1)—C(1) is thus small [100.2(1)°]. The coordination geometry at P(2) is pyramidal; the average angle at P(2) is 103.2°.

Finally, a solution of **15** in methylcyclohexane was heated to 80°C. Within 1 h the resonances of compound **15** disappeared in the ^{31}P NMR spectrum and a new AB spin system was observed. This was assigned to the isomeric complex **15a**, the result of the migration of the $Cr(CO)_5$ group to the diisopropyl-substituted phosphorus atom. The following ^{31}P NMR parameters are observed for **15a**: $\delta(^{31}P)$ (1-Ad*P*H) = 5.03 ppm, $\delta(^{31}P)$ ($^iPr_2P$) = 6.89 ppm, $^1J(PP) = 244.65$ Hz.[28] Additional doublets at $\delta(^{31}P) = -46.61$ and 69.33 ppm [$^1J(PP) = 295.92$ Hz] are assigned to the thermally liberated free ligand 1,1-diisopropyl-2-(1-adamantyl)diphosphine **16**; the signal at lower field



(8)

15 **15a**

+ 1-Ad(H)P—P^{i}Pr$_2$

16

	δ_P(1-Ad(H)*P*)	δ_P($^iPr_2P$)	^1J(PP)
15	2.45	6.22	245.97
15a	5.03	6.89	244.65
16	−46.61	69.33	295.92

arises from the $^{i}Pr_2P$ group, the one at higher field from the 1-Ad*P*H group [eq. (8)]. After a 6 h heating period (80°C) ^{31}P NMR signals of **15a** and **16** are no longer observed. Instead complicated, partially overlapping patterns due to higher order spectra are seen and the signals can no longer be unambiguously assigned.

EXPERIMENTAL

All experiments were conducted in an atmosphere of dry, oxygen-free nitrogen in conventional glass apparatus.[29] Solvents were purified by standard procedures, dried and stored over molecular sieves.[30,31] The following compounds were synthesized according to procedures given in the literature: 1-adamantylphosphine,[32] bis-(1-adamantyl)-phosphine,[33] diiron enneacarbonyl,[34] triiron dodecacarbonyl,[35] diphenylchlorophosphine[36] and diisopropylchlorophosphine.[37]

NMR spectra ($CDCl_3$). Bruker AC-200 (^1H at 200.1 MHz, ^{13}C at 50.3 MHz, ^{31}P at 81.0 MHz). Chemical shifts are given in ppm vs int. $CDCl_3$ (^1H, ^{13}C) and 85% H_3PO_4 ext. (^{31}P), coupling constants are listed in Hz. Chemical shift values were given a positive sign when the absorption, relative to the standard, was at low field and *vice versa*. Multiplicities: s = singlet, d = doublet, m = multiplet.

IR spectra. Beckman IR 4260 and Nicolet FT-IR 740. Except for **15** (solution in chloroform), the IR spectra were recorded on hexane solutions. Absorption frequencies are quoted in wave numbers (cm^{-1}). Intensities: vw = very weak, w = weak, m = medium, s = strong, vs = very strong.

Mass spectra. Finnigan MAT 8430. Samples were introduced into the mass spectrometer via a direct inlet septum (EI ionization).

Analyses. Microanalytical Laboratory Beller (Göttingen) and Analytical Laboratory of the Institut für Anorganische und Analytische Chemie der Technischen Universität, Braunschweig.

Abbreviations. MCH = methylcyclohexane. THF = tetrahydrofuran.

Synthesis of the phosphine complexes **1–6** (*Table* 4)

General procedure. Approximately equimolar amounts of the phosphine and of the appropriate metal carbonyl were dissolved or suspended in the

degassed solvent and heated until the evolution of CO ceased. Subsequently, the reaction mixtures were kept at −18°C overnight. The precipitate thus obtained was collected by filtration and was purified by recrystallization from THF.

Mass spectra. **1**: 360 (10) $[M]^+$, 332 (1) $[M-CO]^+$, 304 (6) $[M-2CO]^+$, 276 (10) $[M-3CO]^+$, 248 (30) $[M-4CO]^+$, 220 (100) $[M-5CO]^+$, 135 (10) $[Ad]^+$. **2**: 406 (24) $[M]^+$, 378 (20) $[M-CO]^+$, 350 (60) $[M-2CO]^+$, 322 (38) $[M-3CO]^+$, 294 (100) $[M-4CO]^+$, 266 (60) $[M-5CO]^+$, 135 (85) $[Ad]^+$. **3**: 492 (6) $[M]^+$, 464 (12) $[M-CO]^+$, 436 (100) $[M-2CO]^+$, 408 (14) $[M-3CO]^+$, 380 (16) $[M-4CO]^+$, 352(6) $[M-5CO]^+$, 15 (12) $[Ad]^+$. **4**: 494 (4) $[M]^+$, 466 (3) $[M-CO]^+$, 438 (3) $[M-2CO]^+$, 410 (6) $[M-3CO]^+$, 382 (20) $[M-4CO]^+$, 354 (100) $[M-5CO]^+$, 302 (10) $[Ad_2PH]^+$, 135 (70) $[Ad]^+$. **5**: 540 (1) $[M]^+$, 512 (2) $[M-CO]^+$, 484 (5) $[M-2CO]^+$, 456 (3) $[M-3CO]^+$, 428 (1) $[M-4CO]^+$, 400 (1) $[M-5CO]^+$, 302(18) $[Ad_2PH]^+$, 135 (100) $[Ad]^+$. **6**: 626 (10) $[M]^+$, 598 (25) $[M-CO]^+$, 570 (40) $[M-2CO]^+$, 542 (8) $[M-3CO]^+$, 514 (6) $[M-4CO]^+$, 486 (10) $[M-5CO]^+$, 302 (4) $[Ad_2PH]^+$, 135 (100) $[Ad]^+$.

Synthesis of **7** *and* **8** *(data for* **8** *in square brackets)*

A mixture of $Fe_2(CO)_9$ (5 g, 13.7 mmol) [0.55 g, 1.5 mmol] and 2.25 g/13.3 mmol (0.45 g/1.5 mmol) of the appropriate phosphine in degassed toluene (60 cm^3) [70 cm^3] was stirred for 16 h [96 h] at room temperature. Subsequently, the reaction mixtures were filtered and the solvent removed *in vacuo* (0.1 mm). The crude products thus left were recrystallized from THF.

7: Yield: 3.94 g (88.1%): m.p.: 92°C (dec.). Found: C, 50.1; H, 5.4; Fe, 16.7. Calc. for $C_{14}H_{17}FeO_4P$ (336.107): C, 50.0; H, 5.1; Fe, 16.6%. Mass spectrum: 336 (12) $[M]^+$, 308 (12) $[M-CO]^+$, 280 (10) $[M-2CO]^+$, 252 (90) $[M-3CO]$, 224 (100) $[M-4CO]^+$, 135 (40) $[Ad]^+$. **8**: Yield: 0.52 g (73.7%); m.p.: 117°C. Found: C, 61.5; H, 6.7; Fe, 12.0. Calc. for $C_{24}H_{31}FeO_4P$ (470.327): C, 61.3; H, 6.6; Fe, 11.9%. Mass spectrum: 470 (3) $[M]^+$, 442 (5) $[M-CO]^+$, 414 (1) $[M-2CO]^+$, 386 (60) $[M-3CO]^+$, 358 (40) $[M-4CO]^+$, 302 (14) $[Ad_2PH]^+$, 279 (10) $[M-2CO-Ad]^+$, 135 (100) $[Ad]^+$.

Preparation of **9**, **10** *and* **11**

A mixture of 1-AdPH$_2$ (5 g, 29.7 mmol) and $Fe_3(CO)_{12}$ (15 g, 29.8 mmol) in toluene (170 cm^3) was heated at 100°C for 14 h. The reaction mixture was allowed to cool to room temperature and was filtered through 5 g of silica gel. The solvent was removed from the filtrate at 0.1 mm. A ^{31}P NMR spectrum ($CDCl_3$) showed signals due to **9**, **10** and **11**. This material was sublimed at 100°C (0.1 mm) until no more **9** was deposited on the cold finger. The residue was twice recrystallized from hexane and **11** was obtained as dark red rhombohedral crystals.

9: Yield: 3.54 g (20.3%, based on 1-AdPH$_2$): m.p.: 200°C (dec.). Found: C, 38.7; H, 3.1: Fe, 28.4. Calc. for $C_{19}H_{17}Fe_3O_9P$ (587.853): C, 38.8, H. 2.9; Fe, 28.5. Mass spectrum: 588 (22) $[M]^+$, 560 (12) $[M-CO]^+$, 532 (16) $[M-2CO]^+$, 504 (100) $[M-3CO]^+$, 474 (44) $[M-4CO]^+$, 446 (38) $[M-5CO]^+$, 418 (90) $[M-6CO]^+$, 390 (20) $[M-7CO]^+$, 362 (12) $[M-8CO]^+$, 334 (30) $[M-9CO]^+$, 200 (36) $[Fe_3PH]^+$, 199 (34) $[Fe_3P]^+$, 135 (14) $[Ad]^+$. **10**: Yield: 7.26 g (65.0%, based on 1-AdPH$_2$); m.p.: >240°C. Found: C, 46.9; H, 4.0; Fe, 21.8. Calc. for $C_{29}H_{30}Fe_3O_9P_2$ (752.039): C, 46.3; H, 4.0; Fe, 22.3%. Mass spectrum: 752 (<1) $[M]^+$, 724 (5) $[M-CO]^+$, 696 (12) $[M-2CO]^+$, 668 (10) $[M-3CO]^+$, 640 (<1) $[M-4CO]^+$, 612 (14) $[M-5CO]^+$, 584 (16) $[M-6CO]^+$, 556(10) $[M-7CO]^+$, 528(8) $[M-8CO]^+$, 500 (24) $[M-9CO]^+$, 444 (12) $[Fe_2P_2Ad_2]^+$, 365 (13) $[Fe_3P_2Ad]^+$, 309 (6) $[Fe_2P_2Ad]^+$, 230 (11) $[Fe_3P_2]^+$, 199 (5) $[Fe_3P]^+$, 135 (100) $[Ad]^+$.

Synthesis of **12** *and* **13** *(data for* **13** *in square brackets)*

A mixture of $Ni(CO)_4$ (2.07 g, 12 mmol) [2.55 g, 15 mmol] and 1-AdPH$_2$ [1.69 g, (10 mmol)] or (1-Ad)$_2$PH) [1.51 g, 5 mmol] was stirred in THF (40 cm^3) over 5 h at room temperature until the evolution of CO had ceased. Upon removal of the solvent *in vacuo* (0.1 mm) **12** was left as a colourless oil, **13** as a colourless solid.

12: Yield: 2.17 g (69.9%). Found: C, 49.8; H, 5.5; P, 10.1. Calc. for $C_{13}H_{17}NiO_3P$ (310.949): C, 50.2; H, 5.5; P, 10.0%. Mass spectrum: 310 (1) $[M]^+$, 282 (12) $[M-CO]^+$, 254 (20) $[M-2CO]^+$, 226 (28) $[M-3CO]^+$, 168 (4) $[AdPH_2]^+$, 135 (100) $[Ad]^+$. **13**: Yield: 1.51 g (67.8%); m.p.: 94–96°C. Found: C, 61.8; H, 7.4; P, 7.0. Calc. for $C_{23}H_{31}NiO_3P$ (445.170): C, 62.1; H, 7.0: P, 7.0%. Mass spectrum: 416 (6) $[M-CO]^+$, 388 (10) $[M-2CO]^+$, 360 (16) $[M-3CO]^+$, 302 (10) $[Ad_2PH]^+$, 135 (100) $[Ad]^+$.

Preparation of **11a**/**11b**

A solution of **7** (1.35 g, 4 mmol) in toluene (70 cm^3) was refluxed for 6 h. A product/educt ratio

of 1 : 1 was determined by ^{31}P NMR spectroscopy. This ratio was unchanged after a further 2 h reflux period. The reaction mixture was cooled to room temperature, filtered through 2 g of silica gel and the solvent removed *in vacuo* (0.1 mm). The reaction mixture was separated by column chromatography (10 g of silica gel; mobile phase n-pentane). The mixture of **11a/11b** was obtained as the first, bright yellow fraction. Unreacted **7** (orange–brown) was recovered as a second fraction. Subsequently, the solvent was removed from both fractions *in vacuo* (0.1 mm).

11a/11b: Yield: 0.53 g (43.1%); m.p.: 140°C (dec). Found: C, 50.9; H, 5.4; Fe, 18.2. Calc. for $C_{26}H_{32}Fe_2O_6P_2$ (614.177): C, 50.8; H, 5.2; Fe, 18.2%. ^1H NMR: δ 1.67–2.07 [m, 1-Ad], 2.82–5.15 [m, P—H]. IR spectrum: ν = 2052 (m), 2015 (vs), 1983 (s), 1973 (s). Mass spectrum: 614 (16) $[M]^+$, 586 (14) $[M-CO]^+$, 558 (40) $[M-2CO]^+$, 530 (50) $[M-3CO]^+$, 502 (12) $[M-4CO]^+$, 474 (4) $[M-5CO]^+$, 446 (60) $[M-6CO]^+$, 394 (18) $[M-3CO-AdH]^+$, 366 (22) $[M-4CO-AdH]^+$, 338 (23) $[M-5CO-AdH]^+$, 310 (22) $[M-6CO-AdH]^+$, 174 (100) $[Fe_2P_2]^+$, 135 (24) $[Ad]^+$.

Attempted reaction of **7** *with* $Fe_3(CO)_{12}$

A mixture of **7** (1.8 g, 5.7 mmol) and $Fe_3(CO)_{12}$ (2.52 g, 5 mmol) in toluene (60 cm^3) was heated, first at 80°C for 12 h, then refluxed for a further 3 h. At both stages only the signal of unchanged **7** was observed in the ^{31}P NMR spectrum.

Attempted reaction of **2** *with* Ph_2PCl/NEt_3

A mixture of **2** (1.01 g, 2.5 mmol), Ph_2PCl (1.20 g, 5.4 mmol) and NEt_3 (1.1 g, 11 mmol) in toluene (60 cm^3) was stirred, first at room temperature for 7 days, then heated at reflux for a further 5 h. No precipitation of $[HNEt_3]Cl$ was observed, nor was there a change in the ^{31}P NMR spectrum.

Preparation of **15**

To a suspension of **1** (0.75 g, 2.1 mmol) in a mixture of 10 cm^3 each of diethyl ether and toluene, held at −196°C, was added a 15% solution of ^nBuLi (0.9 g, 2.1 mmol) in hexane *ca* 6 g of a 15% solution via a syringe. The temperature of the reaction mixture was allowed to increase to −78°C. During 0.5 h of stirring the reaction mixture turned orange, accompanied by evolution of a gaseous product (^nBuH). Subsequently, $^iPr_2PCl$ (0.4 g, 2.6 mmol) in toluene (5 cm^3) was added dropwise over 5 min. The mixture was warmed to room temperature, stirred for 2 h and filtered to remove the LiCl. The solvent was removed from the filtrate *in vacuo* (0.1 mm) and the remaining yellow product recrystallized from hexane, giving crystals suitable for the X-ray crystal structure determination.

15: Yield: 0.77 g (77%); m.p.: 121–124°C. Found: C, 53.0; H, 6.4; P, 12.8. Calc. for $C_{21}H_{30}CrO_5P_2$ (476.41): C, 52.9; H, 6.3; P, 13.0%. NMR spectra: ^1H: δ 1.10–1.29 [m, —CH_3], 1.71–2.10 [m, 1-Ad], 2.12–2.32 [m, —$CH(CH_3)_2$], 3.92 [d, P*H*, ^1J(PH) = 297.49]. $^{13}C\{^1H, ^{31}P\}$: δ 20.19, 23.25 [s, —*C*H$(CH_3)_2$], 20.40, 21.09, 22.41, 24.28 [s, —CH(*C*$H_3)_2$], 29.11 [s, C^3 (1-Ad)], 35.94 [s, C^1(1-Ad)], 36.17 [s, C^4(1-Ad)], 41.89 [s, C^2(1-Ad)], 217.29 [s, CO_{cis}], 221.20 [s, CO_{trans}]. $^{13}C\{^1H\}$: δ 19.89–24.51 [m, {*C*$H_3)_2$*C*H—], 28.98–35.88 [m, C^1(1-Ad), C^3(1-Ad)], 36.14 [s, C^4(1-Ad)], 41.83 [d, C^2(1-Ad), ^2J(PC) = 7.09], 217.26 [d, CO_{cis}, ^2J(PC) = 9.39], 221.23 [d, CO_{trans}, ^2J(PC) = 4.36]. IR spectrum: ν = 2307 (w), 2060 (s), 1979 (m), 1937 (vs). Mass spectrum: 476 (3) $[M]^+$, 448 (19) $[M-CO]^+$, 364 (32) $[M-4CO]^+$, 336 (100) $[M-5CO]^+$, 284 (9) $[M-5CO-Cr]^+$, 242 (6) $[M-5CO-Cr-C_3H_6]^+$, 200 (52) $[M-5CO-Cr-2C_3H_6]^+$, 135 (31) $[Ad]^+$.

X-ray crystal structure determination of **15**: Crystal data: $C_{21}H_{30}CrO_5P_2$. M = 476.4, triclinic, space group $P\bar{1}$, a = 1019.2(3), b = 1077.7(3), c = 1125.7(3) pm, α = 84.10(3), β = 74.61(3), γ = 78.10(3), U = 1.165 nm^3, Z = 2, D_x = 1.358 mg m^{-3}. λ(Mo-K_α) = 0.71069 Å, μ = 0.66 mm^{-1}, T = 173 K, F(000) = 500.

Data collection and reduction. A cut yellow prism 1.0 × 0.65 × 0.50 mm was mounted on a glass fibre and transferred to the cold gas stream of the diffractometer (Siemens R3 with LT-2 low-temperature attachment). Data were collected to $2\theta_{max}$ 55°. Cell constants were refined from setting angles of 50 reflections in the range 2θ 20–23°. An absorption correction based on ψ-scans was applied (transmission factors: 0.62–0.66). Of 9018 reflections 5374 were unique (R_{int} = 0.025) and 4727 > $4\sigma(F)$ were used for all calculations (Program system "Siemens SHELXTL PLUS").

Structure solution and refinement. The structure was solved by direct methods. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included using a riding model. The hydrogen bonded to phosphorus was then the second largest peak in a difference Fourier synthesis and was kept fixed at the peak position during the final cycles. Refinement proceeded to R = 0.030, wR = 0.041. The weighting scheme was $w^{-1} = \sigma^2(F) + 0.0002F^2$. 262 parameters; S = 1.8; max, Δ/σ = 0.003; max, $\Delta\rho = 0.8 \times 10^{-6}$ e pm^{-3}. Full details of the structure determination have

been deposited at the Fachinformationszentrum Karlsruhe, Gesellschaft für Wissenschaftlich-technische Information mbH, D-76344 Eggenstein-Leopoldshafen 2, Federal Republic of Germany. Any request for this material should quote a full literature citation and the reference number CSD 57330.

Thermolysis of **15**, *formation of* **15a** *and* **16**

A solution of **15** (50 mg, 0.1 mmol) in MCH (6 cm^3) was heated at 80°C for 6 h. ^{31}P NMR spectra of the reaction mixture were recorded at the beginning of the heating period, after 1 h and after 6 h. The experiment was terminated after 6 h because signals from unknown decomposition products were observed.

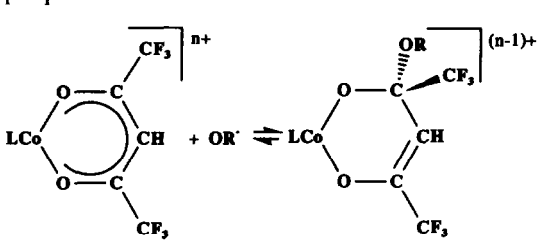
(*Received* 27 *April* 1993; *accepted* 8 *June* 1993)

Abstract—The crystal structures of $[Co(hfac)(en)_2](ClO_4)_2$ (**I**) and β-$[Co(hfac)(trien)](ClO_4)_2$ (**II**) have been determined by X-ray diffraction at ambient temperature, where Hhfac = hexafluoro-2,4-pentanedione, en = ethylenediamine and trien = 1,8-diamino-3,6-diazaoctane. The relative configuration of the cation in **II** is *rel*-Δ-β-*RR*. Their molecular structures are compared with those previously reported for $[Co(hfacOH)(en)_2]^+$, $[Co(hfacOH_3)(en)_2]^+$ and β-$[Co(hfacOCH_3)(trien)]^+$, in which an OH^- or OCH_3^- anion is covalently combined with one of the carbonyl carbon atoms on the hfac ligand. The quasiaromaticity of the coordinating hfac ligand in **I** and **II** was structurally characterized.

A cobalt(III) complex with a bidentate hfac ligand shows a pH dependent rapid and reversible colour change in water and in methanol.[1,2] This phenomenon was studied by UV and NMR spectroscopy and a reversible addition of a lyate anion onto one of the carbonyl carbon atoms in the hfac ligand was proposed



(1)

where L represents ligands occupying the residual four coordination sites and $R = H$ in water and $R = CH_3$ in methanol.[3,4] This mechanism was unequivocally underlined by the X-ray structure analysis of crystals obtained from basic solutions. In $[Co(hfacOH)(en)_2]Br \cdot H_2O$,[5] $[Co(hfacOCH_3)(en)_2]ClO_4$[6] and β-$[Co(hfacOCH_3)(trien)]ClO_4$,[4] an OH^- or OCH_3^- anion is combined with the hfac ligand by a covalent bond as shown on the right side of eq. (1). In the present report, we carry out the X-ray structure analysis for $[Co(hfac)(en)_2](ClO_4)_2$ (**I**) and β-$[Co(hfac)(trien)](ClO_4)_2$ (**II**). We compare their molecular structures with those of the corresponding OR^- combined complexes. We are also interested in the two possible configurations of β-$[Co(hfac)(trien)]^{2+}$; *rel*-Δ-β-*RR* and *rel*-Δ-β-*RS* where the meridional secondary NH proton is remote from or adjacent to a coordinated hfac oxygen atom. In a previous ^{19}F NMR study of **II**, it was indicated that the solid sample was composed of unspecified single isomer.[7]

EXPERIMENTAL

Compounds **I** and **II** were prepared as described elsewhere and recrystallized from water by addition of a slight excess of sodium perchlorate.[1,8]

Structure determination

Crystal data, details of data collection and structure refinement are listed in Table 1. The intensity data were collected using an automated Rigaku four-circle diffractometer AFC5R with graphite monochromatized Mo-K_α radiation ($\lambda = 0.71069$ Å) at the Advanced Instrumentation Center for Chemical Analysis, Ehime University. The cell dimensions for **I** and **II** were obtained using 22 reflections ($28.3° \leqslant 2\theta \leqslant 29.6°$) and 25 ones ($29.4° \leqslant 2\theta \leqslant 29.9°$), respectively. The ω–2θ scan mode with a scan rate 16°/min (in ω) was employed. Corrections were made for the Lorentz and polarization factor. Empirical correction for the absorption was made based on azimuthal (ψ) scans of three reflections.[9]

The structures were solved by a combination of Patterson method and direct methods. During the refinement the structures showed orientational disorder at perchlorate anions in **I** and at trifluoromethyl group in **II**. Partial occupancy factors for these disordered atoms were refined. The coordinates and anisotropic thermal parameters for the non-hydrogen atoms were refined by the full-matrix least-squares procedure based on F with weight $w = 1/\sigma^2(F_o)$. The positions of the hydrogen atoms were calculated from those of the non-hydrogen atoms and were included in F_c calculation. All calculations were performed on a VAXstation 3200 computer with TEXSAN program[10] which used the atomic scattering factors taken from "International Tables for X-ray Crystallography".[11] Anomalous dispersion effects were included in the F_c calculation. The final atomic parameters, together with observed and calculated structure factors have been deposited with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

Structure of $[Co(hfac)(en)_2](ClO_4)_2$ **(I)**

There are four $[Co(hfac)(en)_2]^{2+}$ cations and eight ClO_4^- anions in the unit cell. The anions showed an orientational disorder. Large thermal parameters for trifluoromethyl groups suggested similar disorder, but they could not be modelled with split sites. A perspective view of the cation and the atom labelling scheme are shown in Fig. 1.

The quasiaromatic ring is coplanar, Co(1) deviating by 0.094 Å from the plane defined by O(1), C(1), C(2), C(3) and O(2), whereas trifluoromethyl carbon atoms, C(4) and C(5), deviate by 0.043 Å and −0.180 Å from this plane, respectively. The deviations of Co(1) from the xy, yz and zx coordination plane were less significant, where each of the planes is defined by four atoms binding to Co(1). Selected bond distances and angles are summarized in Tables 2 and 3.

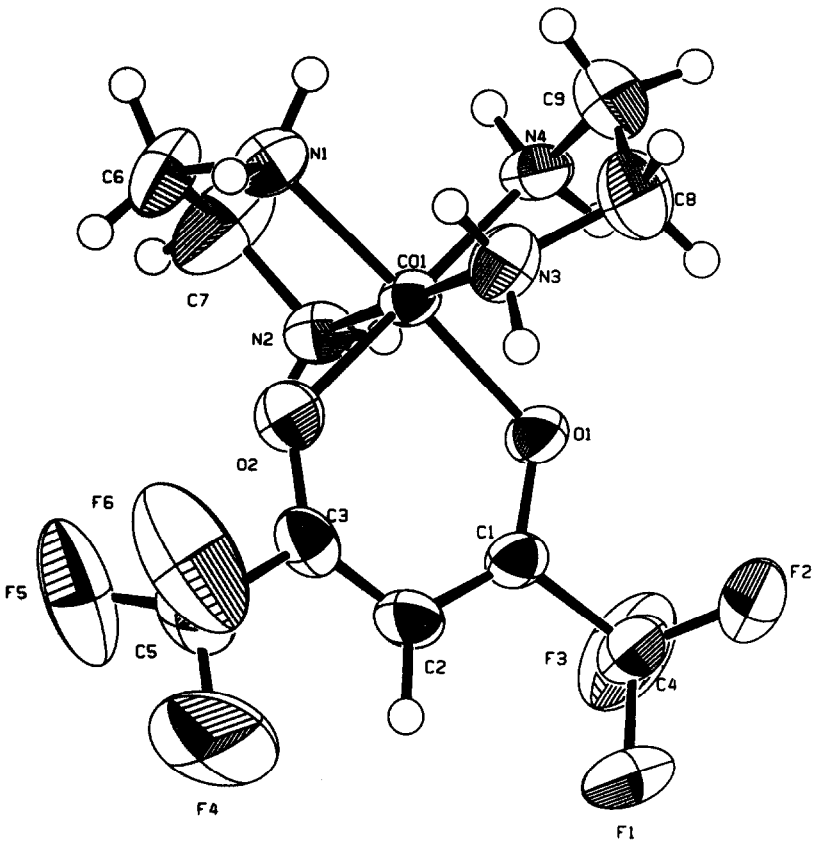

Fig. 1. Perspective view of $[Co(hfac)(en)_2]^{2+}$ cation. Open circles represent hydrogen atoms. Ellipsoids have been drawn at 50% probability.

All the amino groups are hydrogen bonded to the perchlorate ions. The shortest N—H···O bond distance is 2.86(2) Å for N(3). There are nine hydrogen bonds with the distance shorter than 3.30 Å. All the other intermolecular distances are in ordinary van der Waals contacts.[12]

Structure of $[Co(hfac)(trien)](ClO_4)_2$ **(II)**

There are two crystallographically independent cations of β-$[Co(hfac)(trien)]^{2+}$, or **1** and **2**. One of them contains Co(1) and the other cation Co(2). A perspective view of the cations and the atom labelling scheme are shown in Figs 2 and 3. The configurations of **1** are Δ-β-*RR* and Λ-β-*SS* and those of **2** are also Λ-β-*SS* and Δ-β-*RR*. Thus, the relative configuration of this complex is *rel*-Δ-β-*RR*.

The structure of **2** with Λ-β-*SS* configuration is essentially the same as the reflected structure of **1** with Δ-β-*RR* configuration. The noticeable difference stems from the rotation of the trifluoromethyl groups containing C(4) or C(24). The trifluoromethyl group with larger occupancy factor (0.870) in **1** occupies at the position which is rotated around the C—C bond by 120° from that in **2**. Pertinent bond lengths and bond angles are shown in Tables 2 and 3.

The atomic deviations of Co(1) and Co(2) from the respective *xy*, *yz* and *zx* coordination plane range from 0.017 to 0.023 Å, except for one deviation of 0.008 Å. The former values are small but significant. These deviations may be attributed to the existence of the tetradentate ligand trien.

All the nitrogen atoms are hydrogen bonded with the perchlorate oxygen atoms. The shortest hydrogen bond distances are 2.954(9) Å and 2.946(8) Å for N(4) and N(23) atom, respectively. There are fourteen hydrogen bonds with distances shorter than 3.30 Å. All the other intermolecular distances are ordinary van der Waals contacts,[12] except for 2.640(7) Å and 2.95(1) Å for the contacts between F(4) and F(23) and between F(24) and the perchlorate oxygen.

Comparison with the structure of the OR^- *combined complex*

The $[Co(hfac)(en)_2]^{2+}$ is approximately of C_2 symmetry. The average length of the equivalent bonds [i.e. N(1)—C(6) and N(4)—C(9)] was com-

pared with the corresponding bond length in the $[Co(hfacOR)(en)_2]^+$, where we assumed OR^- is combined with the carbon atom corresponding to C(3) in **I** (Fig. 1). The β-$[Co(hfac)(trien)]^{2+}$ is apparently of C_1 symmetry. In the previously presented structure of *rel*-Δ-*β*-*RR*-$[Co(hfacOCH_3)(trien)]ClO_4$, the OCH_3^- is combined with the carbon atom corresponding to C(3) in cation **1** or to C(23) in cation **2**. The average length of the corresponding bonds in cations **1** and **2** [i.e. C(6)—C(7) and C(26)—C(27)] is compared with the corresponding bond length in the *rel*-Δ-*β*-*RR*-$[Co(hfacOH_3)(trien)]^+$. The significant differences are summarized in Table 4.

C(3)—C(5)		0.03	−0.06
C(6)—C(7)		0.09	−0.05
C(8)—C(9)	−0.06	−0.04	−0.03

[a] See text. The composite standard deviation for the difference is below 0.01.

The Co—O bond lengths of **I** and, in particular, **II** are longer than those of the corresponding OR^- combined complexes. In contrast the Co—N bond lengths of **I** and **II** are shorter than those of the OR^- combined complexes. The O(1)—C(1), C(2)—C(3) and O(2)—C(3) bonds are significantly shorter and C(1)—C(2) bond is slightly longer than the corresponding one in the OR^- combined complexes. This is consistent with the disappearance of the pseudoaromaticity of the hfac ligand on the right side of eq. (1). In the OR^- combined complex, the bonds corresponding to the O(1)—C(1), C(2)—C(3) and O(2)—C(3) bond are single bonds and that corresponding to C(1)—C(2) is a localized double bond. The differences for the other bonds cannot be attributed clearly to the intramolecular electronic interaction, because the same extent of variation in the bond length will be caused by the intermolecular interaction. Nevertheless these differences might be related to the fact that the equilibrium constant of eq. (1) depends significantly on the variation of L ligand and that for certain L ligands the OR^- combined complexes are labile.[2,13] Most bond angles are similar to the corresponding ones in the OR^- combined complex. Only the N(2)—Co(1)—N(3) angle in **I** (173.8°) is slightly smaller than the corresponding angles in the OR^- combined complexes (177.8° and 178.4°).

Abstract—Reaction of [$ReCl_3$(MeCN)(PPh_3)$_2$] with the planar pentadentate diacetylpyridinebis(benzoylhydrazone) ligands $DAPBH_2$ and DAP-Me-BH_2 and triethylamine in isopropanol under reflux gave the dark brown seven-coordinate complexes [ReCl(L)PPh_3], containing the doubly deprotonated pentadentate ligand [L = DAPB(2−) (**1**); L = DAP-Me-B(2−) (**2**)]. Complex **1** has been characterized by crystallography. The central rhenium atom in **1** is seven-coordinate, with pentagonal bipyramidal geometry with the axial positions being occupied by the chloride ion and the triphenylphosphine ligand. The DAPB coordinates in a pentadentate manner in the equatorial plane of the complex and the five donor atoms of the doubly deprotonated DAPB(2−) ligand form an approximately planar pentagon. The rhenium atom is slightly displaced out of the ligand plane towards the phosphorus atom. Reaction of **2** with Ag[BF_4] in CH_2Cl_2 at room temperature gave a black complex of stoichiometry [Re(DAP-Me-B)(PPh_3)][BF_4] (**3**). Reaction of [$MoCl_4$(MeCN)$_2$] with DAP-Me-BH_2 and Et_3N in dry CH_2Cl_2 under reflux gave deep green [$MoCl_2$(DAP-MeB_2)] (**4**), formulated as a seven-coordinate molybdenum(II) complex containing the doubly deprotonated pentadentate DAP-$MeBH_2$ ligand in the equatorial plane of the complex. The Mössbauer spectra of the complexes [$FeCl_2(DAPBH_2)$]·H_2O (**5**) and [FeCl(DAPMe-B)(H_2O)] (**6**) were investigated as a function of temperature. The spectrum of **5** was consistent with high-spin seven-coordinate iron(II) and **6** was shown to contain two distinct iron(III) sites; possible structures are discussed.

The planar pentadentate 2,6-diacetylpyridine bis(benzoylhydrazone) ligands ($DAPBH_2$ and DAP-Me-BH_2, Fig. 1) and similar ligands formed from DAP and a variety of other aroylhydrazines have the ability to behave as neutral or deprotonated ligands and produce stereochemistries with

* Chloro(triphenylphosphine)(2,6 - diacetylpyridinebis[benzoylhydrazonato(2−)]rhenium(III), dichloro-2,6-diacetylpyridinebis(benzoylhydrazone)iron(II), monohydrate, aquochloro-2,6-diacetylpyridinebis[4-methylbenzoylhydrazonato(2−)]iron(III).

high coordination numbers.[1,2] The coordination chemistry of these interesting ligands has been extensively studied with first row transition metals and some main group elements, but comparatively little with second and third row transition metals. It is not straightforward to predict the capacity of such metal ions to accommodate pentagonal bipyramidal geometry, or the ways in which multidentate ligands of varying conformational flexibility will respond to the stereochemical preferences of different metal ions. We report here the synthesis and characterization of some rhenium(III) and molybdenum(II) complexes of these ligands, and in order to investigate the detailed coordinate geometry of these complexes we have determined the crystal structure of the seven-coordinate rhenium(III) complex [ReCl(DAPB)(PPh_3)] (**1**). We have also investigated the Mössbauer spectroscopy of the iron(II) and iron(III) complexes **5** and **6** of these ligands.

RESULTS AND DISCUSSION

Preparation and properties of $DAPBH_2$ *and* DAP-Me-BH_2 *complexes*

Table 1 gives analytical and spectroscopic data for the pentadentate ligands and the complexes of rhenium, molybdenum and iron. The rhenium(III) complexes **1** and **2** were prepared in good yield by heating [$ReCl_3$(MeCN)(PPh_3)$_2$] and the appropriate pentadentate ligand in isopropanol under reflux in the presence of triethylamine. The seven-coordinate complexes are non-electrolytes and are soluble in most of the common organic solvents with the exception of alcohols, ethers and alkanes. There is no evidence in the IR spectrum for ν(NH) or ν(C=O), which suggests that the coordinated planar pentadentate ligands are doubly deprotonated in these rhenium(III) complexes. The imino stretching frequency, ν(C=N), for the coordinated ligand appears at 1520 and 1580 cm^{-1} for **1** and **2**, respectively, indicative of coordination by the imino nitrogens. Characteristic bands for coordinated triphenylphosphine appear at 700–750 cm^{-1}. The ^1H

NMR spectra of the two pentadentate ligands are generally little changed on coordination to the rhenium(III). The $^{31}P\{^1H\}$ NMR spectra of the rhenium(III) complexes in $CH_2Cl_2/CDCl_3$ (80 MHz, δ TMP) consist of singlet resonances at -9.0 (**1**) and -9.2 ppm (**2**), respectively, corresponding to the singly coordinated triphenylphosphine ligand.

The black rhenium(III) complex formulated as $[Re(DAP\text{-}Me\text{-}B)(PPh_3)][BF_4]$ (**3**) was prepared in virtually quantitative yield by reacting [ReCl(DAP-Me-B)(PPh_3)] (**2**) with excess $Ag[BF_4]$ under inert atmosphere in dry CH_2Cl_2. The elemental analysis of **3** confirms the absence of chlorine and suggests the formulation $[Re(DAP\text{-}Me\text{-}B)(PPh_3)][BF_4]$. The product is soluble in chlorinated solvents, DMF, DMSO and acetone. The ^1H NMR spectrum of (**3**) was rather broad, but the integral ratio of the barely resolved singlets (CH_3—) vs the aromatic proton multiplet agreed with the formulation for **3** above. The $^{31}P\{^1H\}$ spectrum of **3** shows a single resonance at -1.8 ppm, which indicates a downfield shift in the ^{31}P spectrum of **3** vs that of complex **2**, and indicates retention of a single PPh_3 group. Complex **3** was found to be a 1 : 1 electrolyte in DMF solution by determination of conductivity measurements over a concentration range; the results compare favourably with those obtained for other 1 : 1 electrolytes. The IR spectrum of **3** shows no evidence of ν(NH) or ν(C=O) and bands due to η(C=N) appear at 1600 and 1580 cm^{-1}, which suggests that the planar pentadentate ligand has been retained. The structure of this complex is uncertain and a six-coordinate structure appears to be unlikely since there is no precedent in the literature. So far attempts to grow crystals suitable for an X-ray structure determination have not been successful.

Reaction of $[MoCl_4(MeCN)_2]$ with DAP-Me-BH_2 and Et_3N in CH_2Cl_2 under reflux gave $[MoCl_2$(DAP-Me-B)] (**4**) in good yield. The neutral complex $[MoCl_2$(DAP-Me-B)] (**4**) is hygroscopic and soluble in DMF, DMSO, CH_2Cl_2, $CHCl_3$ and acetone. The product gave a single HPLC peak (retention time 5.6 min). This complex is related to the Schiff's base derivative $[MoCl_2(sal)_2]$ (sal = 2-OC_6H_4CH=NPh), which is six-coordinate.[3] The diamagnetism of the seven-coordinate molybdenum(IV) (d^2) complex is not unexpected and has precedent in $[MoCl(S_2CNMe_2)_3]$.[4]

The neutral dark green complex $[FeCl_2(DAPBH_2)]\cdot H_2O$ (**5**) was prepared from anhydrous $FeCl_2$ and $DAPBH_2$ in dry methanol. It is soluble in DMF, DMSO and slightly soluble in $CHCl_3$, CH_2Cl_2 and acetone, and conductivity measurements in DMF showed the complex to be neutral. The IR spectrum shows the presence of ν(OH) at 3340 cm^{-1}, indicative of the presence of water. The shift of the amide ν(C=O) band by 30 cm^{-1} to lower wave number compared with the free ligand $DAPBH_2$ and the appearance of ν(NH) bands suggest that the ligand is coordinating as a neutral doubly protonated pentadentate yielding a seven-coordinate pentagonal bipyramidal iron(II) complex with the two chlorides occupying axial positions. $DAPBH_2$ ligands are known to coordinate in this fashion in other $[M^{II}Cl_2(DAPBH_2)]$ (M = Mn, Co, Ni, Zn) complexes. The magnetic moment of 5.46 B.M. and the Mössbauer data for **5** are consistent with the formulation as a high-spin iron(II) species. The elemental analysis is in reasonable agreement with the stoichiometry containing a water of crystallization.

The brown complex [FeCl(DAP-Me-B)(H_2O)] (**6**) was prepared by reaction of anhydrous $FeCl_3$ with DAP-Me-BH_2 in absolute ethanol in the presence of triethylamine as base. Elemental analysis suggests the formulation as the iron(III) complex [FeCl(DAP-Me-B)(H_2O)]. The neutral complex **6** is soluble in DMF, DMSO and slightly soluble in CH_2Cl_2. There is no ν(NH) nor ν(C=O) in the IR spectrum, which suggests that the ligand in complex **6** is doubly deprotonated and coordinating in a pentadentate(2−) manner. Peaks at 3160, 3240, 3300 and 3410 cm^{-1} can be assigned to OH stretches of a water molecule. The Mössbauer spectrum and magnetic moment of 5.65 B.M. confirms the assignment as high-spin iron(III). The suggested structure based on Mössbauer studies (see below) is dimeric, with one pentagonal bipyramidal iron with one chloride and the oxygen of another FeCl(DAPMe-B) unit in the axial sites.

Description of the molecular structure of [ReCl(DAPB)(PPh_3)]

The molecular structure of [ReCl(DAPB)(PPh_3)] is shown in Fig. 2 and important bond lengths and angles are given in Table 2. The coordination about the central rhenium atom is essentially pentagonal bipyramidal, with the axial positions being occupied by one chloride ion and the triphenylphosphine ligand. The $DAPBH_2$ ligand on being doubly deprotonated, therefore, coordinates as a planar pentadentate ligand. The pentagonal bipyramidal nature of the complex is more apparent from Fig. 3, which gives a representation of the equatorial ligand with the axial ligands omitted for clarity. The five donor atoms N(2), N(12), N(23), O(1) and O(3) form an approximately planar pentagon around the metal atom. The angles at the metal in the plane are O(1)—Re—N(12), 72.3(1)°; N(12)—Re—N(2), 70.9(1)°; N(2)—Re—N(23), 71.4(1)°; N(23)—Re—O(3), 72.4(1)°; O(1)—Re—O(3), 72.9(1)°; which

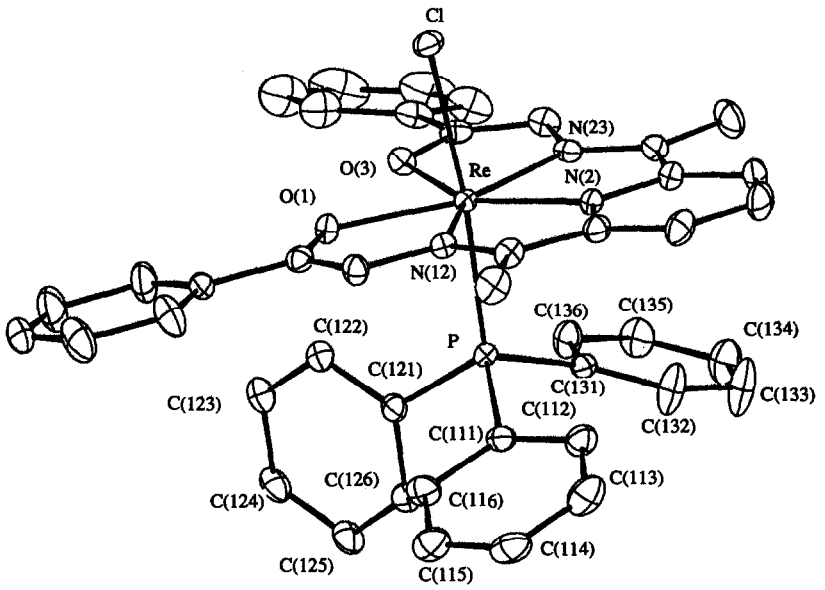

Fig. 2. A representation of the molecular structure of [ReCl(DAPB)(PPh_3)], showing a partial atom-labelling scheme.

confirms the symmetrical, approximately planar pentagonal coordination of the pentadentate ligand. There is no evidence for a water of crystallization or other solvent molecule in the structure.

The pentadentate doubly deprotonated equatorial ligand in complex **1** appears reasonably coplanar on the basis of the bond angle data. However inspection of the data for the least squares plane through the ligand donor atoms reveals small but significant deviations of the five donor atoms in the ligand from planarity. The rhenium atom lies 0.054 Å below the O(1)—N(12)—N(2)—N(23)—O(3) plane.

$(H_2O)]Cl$,[1c] where the fully protonated ligand coordinates as a neutral pentadentate ligand, the N_3O_2 donor set of atoms which form the pentagon are also approximately co-planar, the maximum deviation from the least squares plane being 0.13 Å, the manganese atom being 0.12 Å above this plane. Other seven-coordinate, pentagonal bipyramidal $DAPBH_2$ complexes which may be compared with the present one are $[Co(DAPBH_2)(H_2O)(NO_3)]NO_3$ and $[Ni(DAPBH_2)(H_2O)_2][NO_3]_2\cdot 2H_2O$.[5] Small structural differences involve mainly the N—N bond distances, which are longer in the rhenium compound [N(3)—N(23), 1.388(5) and N(1)—N(12), 1.390(5) Å] than in those of the manganese compound [1.380(5) and 1.390(5) Å], and in those of the cobalt [1.365(4) and 1.376(4) Å] and nickel compounds [1.369(6) and 1.366(6) Å]. The two $M—O_{ligand}$ bonds differ by 0.050, 0.079 and 0.195 Å in the compounds of manganese, cobalt and nickel, respectively. In the rhenium complex this difference is much smaller at 0.008 Å. The geometry of the doubly deprotonated ligand in [ReCl(DAPB)(PPh_3)] thus compares quite well with that found for the smaller first row transition metal ions.

Calculated least-squares planes through the two phenyl rings of the ligands (not given in this work) show that the two phenyl rings are not in the equatorial plane of the pentadentate ligand but are rotated some 15–16° from the equatorial plane and about 16° from each other. This may well be a function of crystal packing constraints.

Mössbauer spectroscopic studies of **5** *and* **6**

Mössbauer data and magnetic measurements are given in Table 3. Compound **5** has Mössbauer parameters consistent with a high-spin iron(II) elec-

tronic environment. The isomer shift of 78 K is 1.28(1) mm s^{-1} and quadrupole splitting (QS) of 2.51(1) mm s^{-1} would not be inconsistent with a seven-coordinate environment as assumed for **5**. The change in the QS at room temperature is consistent with a thermal population of one or more of the four singly electron-occupied 3d orbitals by the sixth electron originally lying in the lowest energy orbital of an ^{5}A state. There is some evidence from the Mössbauer spectra of **5** for the presence of a small iron(III) impurity.

Complex **6** poses more of a problem, as there are clearly two distinct iron sites A and B at both 298 and 78°, and the computer fit is consistent with two symmetric doublets. The last is consistent with two iron sites that are antiferromagnetically coupled. However, the magnetic moment is only slightly lower than the values found for other high-spin

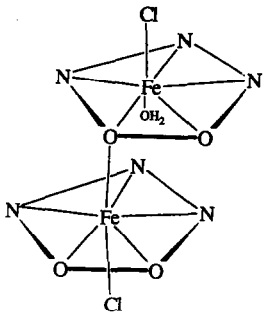

Fig. 4. The proposed structure for $[FeCl(DAPB)]\cdot H_2O$.

iron(III) systems and suggests that any coupling must be small.

There is little data in the literature on seven-coordinate iron(III) complexes for comparison. However, some data on six-, seven- and eight-coordinate complexes with ethylenediaminetetraacetic acid (H_4EDTA) and diethylenetriaminepentaacetic acid (H_5DTPA) have appeared[6,7] and are also summarized in Table 3. The isomer shift values for both sites are consistent with high-spin iron(III). The assignment of coordination number is more difficult as there is no obvious correlation with the isomer shift values and the quadrupole splittings also reflect the changes in symmetry as the donor atoms are varied. Nevertheless, the parameters for site A are in accord with seven-coordination, while those for B are more suggestive of an octahedral geometry.[8-14]

The observation of two different sites is intriguing and as indicated above, the symmetry of the peaks suggests antiferromagnetic coupling. We therefore tentatively assign the complex the dimeric structure shown in Fig. 4 in which an oxygen provides a bridge between the two iron atoms. The chloride analysis corresponding to one chlorine per iron would appear to rule out structures involving bridging oxo- or hydroxo-ligands.

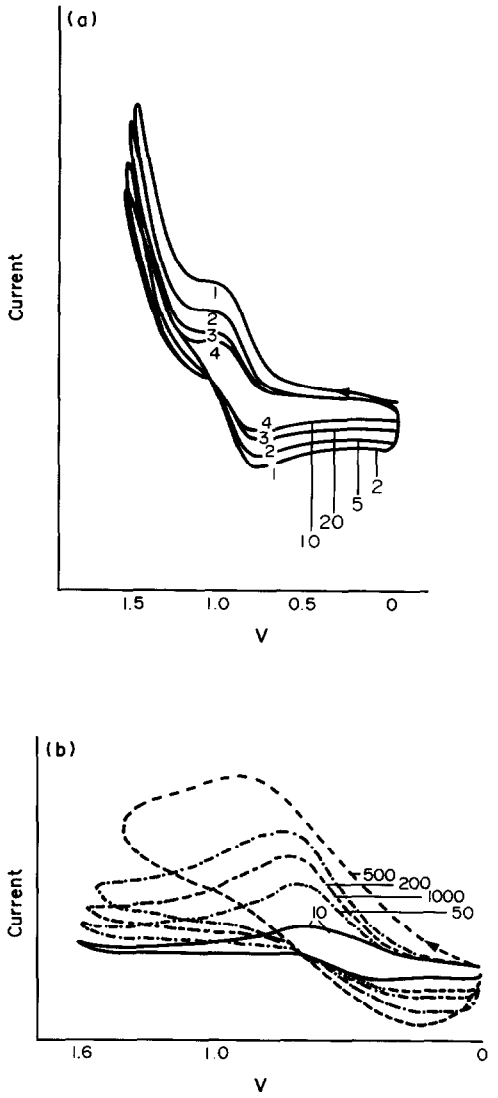

Fig. 5. The cyclic voltammograms of complexes (a) **1** and (b) **5** recorded in CH_2Cl_2 at a gold working electrode vs a silver wire pseudo-reference electrode with $[Bu^n{}_4N][BF_4]$ as a supporting electrolyte at various scan rates ($mV\ s^{-1}$, indicated on the voltammograms).

Redox properties of **2** *and* **5**

The redox properties of the seven-coordinate rhenium(III) complex **1** was studied in 0.2 M $[Bu_4N][BF_4]$/DMF at a gold disc electrode. Figure 5 shows the cyclic voltammograms of the observed single reversible oxidation process at various scan rates. The oxidation ($E_{1/2} = +0.87$ V vs S.C.E.) corresponds to the formation of the cation $[ReCl(DAP\text{-}Me\text{-}B)(PPh_3)]^+$ and lies close to the oxidation limit accessible for a gold electrode.

The electrochemistry of $[FeCl_2(DAPBH_2)]\cdot H_2O$ (**5**) was studied in 0.2 M $[Bu_4N][BF_4]$/DMF at a gold disc electrode. Figure 5 shows the oxidation process at various scan rates. The process is more reversible at high scan rates. The very large ΔE_p values (approximately 500 mV at 500 mV s^{-1}) are indicative of slow heterogeneous electron transfer for the iron(II) complex. Ferrocene showed normal ΔE_p values of 65 mV under similar conditions indicating that uncompensated internal cell resistance is not responsible. The overall process corresponds to oxidation of iron(II) to iron(III), but the simultaneous rapid deprotonation of the ligand cannot be ruled out. Since this would be very fast it would not affect the overall cyclic voltammetric processes.

EXPERIMENTAL

Materials and methods

All experimental manipulations were carried out under an atmosphere of dry nitrogen gas unless stated otherwise. Standard Schlenk-tube, vacuum line and syringe techniques were employed throughout where appropriate. Melting points were determined using an electrothermal melting point apparatus. Elemental analyses were carried out by the Microanalytical Laboratories of Manchester and Sussex Universities. IR spectra were recorded on a Perkin–Elmer 1330 IR spectrophotometer in the range 200–4000 cm^{-1} as Nujol mulls on KBr plates. ^1H and ^{13}C NMR spectra were recorded either on Jeol PMX 60SYS or Bruker WP80SY spectrometers with TMS as an internal standard using the solvents indicated. ^{31}P NMR spectra were recorded on the Bruker WP80SY spectrometer using TMP as the internal standard. Electronic spectra were recorded on a Beckman DU-7 spectrophotometer. Conductivity measurements were made either in DMF or CH_2Cl_2 using a Jenway conductivity meter. Magnetic susceptibility determinations were made in the solid state using a Johnson–Matthey automatic recording magnetic susceptibility balance calibrated with mercury cobalt thiocyanate. The solution state values were obtained using the Evans method. Solvents were dried by standard methods. All other materials and reagents were obtained commercially (Fisons, Aldrich) and used without further purification. $[ReOCl_3(PPh_3)_2]$ was prepared from rhenium metal using the published procedure.[15]

Mössbauer measurements

Mössbauer spectroscopic measurements were carried out on solid samples in aluminium holders. The samples were placed into a cryostat under dinitrogen after quenching at 78 K. The spectrometer (previously described) was calibrated with a natural iron absorber 25 μm thick, which was used as zero for the isomer shift measurements. The spectra were computer fitted.[16]

Electrochemical measurements

Cyclic voltammetry experiments were typically carried out in 0.2 M solutions of $[Bu_4N][BF_4]$ in either CH_2Cl_2 or DMF under a nitrogen atmosphere at room temperature using a three-electrode cell configuration. The working electrode was either a gold or platinum disc. The reference electrode was normally a silver wire arranged such that a luggin capillary was in close proximity to the working electrode. $E_{1/2}$ values were quoted vs S.C.E., against which the ferrocene/ferrocinium couple $[Fc/Fc^+]$ has an $E_{1/2}$ value of 0.54 V in THF–0.2 M $[Bu_4N][BF_4]$. Cyclic voltammetric measurements were made on an EG and G Par model 362 scanning potentiostat. The current and potential values were stored on floppy disk via the EG and G twin channel data recorder. The data was manipulated on an OPUS™ microcomputer using EG and G's CONDECON 300™ software.

Determination of X-ray crystal structure

Full details of the data collection and structure solution are summarized in Table 4.

Preparation of the ligands

Benzoylhydrazine and 4-methylbenzoylhydrazine were prepared by boiling under reflux a 1 : 1 mixture of hydrazine hydrate and either methyl benzoate or 4-methyl benzoate.[17] 2,6-Diacetylpyridinebis(benzoylhydrazone) ($DAPBH_2$) and 2,6-diacetylpyridinebis(4-methylbenzoylhydrazone) (DAP-Me-BH_2) were prepared in about 85% yield by condensation of 2,6-diacetylpyridine and 2 equivalents of the corresponding benzoylhydrazine in absolute ethanol under reflux.[1c] Analytical and spectroscopic data for the ligands and complexes are given in Table 1.

Preparation of the complexes

$[ReCl(DAPB)(PPh_3)]$ (**1**). $DAPBH_2$ (0.5 g, 1.25 mmol), $[ReCl_3(MeCN)(PPh_3)_2]$ (1.08 g, 1.25 mmol) and triethylamine (2 cm^3, 27 mmol) in dry isopropanol (50 cm^3) were stirred at 40°C for 13 h. After cooling the dark brown solid was separated by filtration, washed with ether and dried *in vacuo* (yield 0.60 g, 55%). The product was recrystallized from CH_2Cl_2/Et_2O to yield black crystals suitable for X-ray structure determination.

$[ReCl(DAP\text{-}Me\text{-}B)(PPh_3)]$ (**2**). DAP-Me-BH_2 (0.5 g, 1.17 mmol), $[ReCl_3(MeCN)(PPh_3)_2]$ (1 g, 1.17 mmol) and triethylamine (1.5 cm^3, 20 mmol) were heated under reflux in isopropanol (45 cm^3) for 3 h. After cooling and reducing the volume of the mixture to approximately half, the dark brown solid was filtered off, washed with dry ether and dried *in vacuo* (yield 0.73 g, 67%).

$[Re(DAP\text{-}Me\text{-}B)(PPh_3)][BF_4]$ (**3**). Solid $Ag[BF_4]$ (0.09 g, 0.46 mmol) was added to $[ReCl(DAP\text{-}Me\text{-}B)(PPh_3)]$ (0.21 g, 0.22 mmol) in dry CH_2Cl_2 (30 cm^3).

The mixture was stirred at room temperature in the dark for 45 h before filtration into a clean flask. The solvent was evaporated to dryness to yield a black solid (yield 0.2 g, 98%). The product was soluble in DMF, DMSO, CH_2Cl_2, $CHCl_3$ and acetone.

$[MoCl_2(DAP\text{-}Me\text{-}B)]$ (**4**). $[MoCl_4(MeCN)_2]$ (0.37 g, 1.16 mmol) in dry CH_2Cl_2 (30 cm^3) was added to DAP-Me-BH_2 (0.41 g, 1.57 mmol) in dry CH_2Cl_2 (30 cm^3) and triethylamine (0.6 cm^3, 4.3 mmol) was added. The mixture was heated under reflux (3 h) before cooling to room temperature. The deep green product was collected by filtration under nitrogen, washed with CH_2Cl_2 (10 cm^3) and then dried *in vacuo* (yield 0.5 g, 76%).

$[FeCl(DAP\text{-}Me\text{-}B)]\cdot H_2O$ (**5**). Anhydrous $FeCl_3$ (0.3 g, 1.85 mmol) was added to DAP-Me-BH_2 (0.8 g, 1.85 mmol) in dry methanol (20 cm^3) and triethylamine (0.5 cm^3, 3.7 mmol) was added. The mixture was heated under reflux for 3 h. On cooling a brown solid precipitated, which was collected by filtration and recrystallized from $MeOH/CH_2Cl_2$ (yield 0.65 g, 66%).

$[FeCl_2(DAPBH_2)]\cdot H_2O$ (**6**). Freshly made $FeCl_2$ (0.17 g, 1.25 mmol) in dry methanol (20 cm^3) was added to $DAPBH_2$ (0.5 g, 1.25 mmol) in dry methanol (30 cm^3) under nitrogen. The mixture was heated under reflux (3 h). After cooling the green solid was collected by filtration under nitrogen, washed with ether and dried *in vacuo* (yield 0.39 g, 57%).

THE SYNTHESIS AND CHARACTERIZATION OF A BARIUM SILYL-PHOSPHIDE BY A LOW TEMPERATURE ROUTE

SIMON R. DRAKE,* PHILLIP HALL and ROGER LINCOLN

Department of Chemistry, Imperial College of Science, Technology and Medicine, South Kensington, London SW7 2AY, U.K.

(*Received* 7 *May* 1993; *accepted* 3 *June* 1993)

Abstract—The reaction of tetramethylsilane and sodium hydride in a mixed solvent of THF and HMPA (2:1 by volume), at reflux for 40 h, followed by the addition of PCl_3 yielded $(Me_3Si)_3P$ (**1**) in excellent yield by a simple, non-hazardous and facile route. This phosphine was readily converted into the known phosphide $(Me_3Si)_2PH$ (**2**) by controlled hydrolysis. Reaction of this ligand with barium granules in a mixed liquid ammonia-THF solvent system at −40°C yielded the first barium silylphosphide, $[Ba(P\{SiMe_3\}_2)_2(THF)_2]_n$ (**3**), which was characterized by IR, ^1H, ^{13}C and ^{29}Si NMR spectroscopy.

Alkali metal derivatives of organophosphides are well known, and they have found extensive applications as crystalline sources of PR_2^- in both main group and transition metal chemistry.[1,2] Recent studies have focused predominantly on lithiated silyl phosphines complexed with either mono- or polydentate Lewis bases,[3] or alternatively base free.[4] Investigations into several of the heavier alkali metal complexes (e.g. Na or K) have used these materials as building units for iso-tetraphosphines.[5]

In stark contrast to the situation for the alkali metals there have been few reports of group IIA phosphido complexes, save for two early reports on beryllium diorganophosphides.[6] This apparent dearth of synthetic and structural knowledge may be contrasted with recent advances in our understanding of the trimethylsilylamides of the heavier group IIA metals.[7,8] For these amido complexes there is now a rapidly growing reservoir of knowledge both in solution, the vapour phase and also in the solid state.

Silylphosphides have received considerable attention over the last 30 years, since their first synthesis in 1959 via the reaction of alkyl-chlorosilanes and sodium dialkyl-phosphides.[9] Alternative routes have since included the use of sodium phosphide (Na_3P) and Me_3SiCl in monoglyme[10] and Me_3SiCl and Mg in a range of polar solvents,[11,12] but to date, save for the use of Na_3P,[10] there are presently no simple and safe high-yield routes to these useful ligands. Silyl phosphines and phosphides have found extensive applications as starting materials for reaction with lithium alkyls,[13] carbonyl compounds,[14] boranes[15,16] and unsaturated organic substrates.[17]

We have previously utilized our innovative mixed ammonia-ethereal solvent route to prepare a wide range of group IIA organometallic complexes by this low-temperature facile route, including the solvated and homoleptic trimethylsilylamides. In this paper we wish to report a simple new route to $(Me_3Si)_3P$ and an extension of our ammonical-ethereal solvent route to the hitherto unknown alkaline earth trimethylsilylphosphide, $[Ba(P\{SiMe_3\}_2)_2(THF)_2]_n$ (**3**).

EXPERIMENTAL

General procedures

All manipulations were carried out under dry (molecular sieves) argon (using standard dry-box and Schlenk techniques). All hydrocarbon and ethereal solvents were rigorously dried and then distilled from sodium benzophenone ketyl by standard methods. Elemental analyses were performed by the microanalytical departments of Imperial College and Butterworth Laboratories. Combustion aids

* Author to whom correspondence should be addressed.

were used in an effort to discourage carbide formation. The results for carbon, hydrogen and nitrogen analysis were found to be extremely variable and it was found that experimentally determined carbon contents were often low compared with the expected values. The melting points were measured under argon in sealed capillaries and are uncorrected values.

Instrumentation

NMR data were recorded on a Jeol GS 270 NMR spectrometer, using the protio impurities of the deuterated solvent as reference for ^1H spectra and the ^{13}C resonance of the solvent as a reference for ^{13}C spectra. Chemical shifts were also independently referenced to tetramethylsilane (< 1%) added by volume. The NMR samples were prepared in Wilmad 5 mm NMR tubes, equipped with J. Youngs valves to ensure reproducibility of NMR spectra and ensure sample stability. All chemical shifts are positive to high frequency of the standard.

IR spectra were recorded on a Perkin–Elmer FTIR 1720 spectrometer as Nujol mulls between 25 × 4 mm KBr plates. The Nujol was pre-dried with 4 Å molecular sieves prior to use and the Nujol samples were protected from the atmosphere by an O-ring-sealed Presslok holder. The listing of bands observed at 3000 and 1400 cm^{-1} has been omitted due to overlapping with the C—H stretching frequencies of Nujol.

Starting materials

Barium metal granules were purchased from Alfa Chemicals and stored in an inert atmosphere glovebox. Sodium hydride, tetramethyl silane and phosphorus trichloride were obtained from Aldrich Chemicals and used as supplied. The materials described here are all exceptionally air- and moisture-sensitive and as such they should be routinely prepared under dry argon using thoroughly degassed and dry solvents.

Preparation of $P(SiMe_3)_3$ **(1)**

CAUTION: Hexamethylphosphoramide is a carcinogen and phosphorus trichloride is toxic and must be handled in a well ventilated fume-hood.

Tetrahydrofuran (200 cm^3) and hexamethylphosphoramide (100 g, 0.6 M) were transferred into a dry 1 dm^3, three-necked flask by use of a cannula. The flask was also equipped with an overhead mechanical stirrer, pressure-equalized dropping funnel and water cooled coil condenser. Solid NaH (27.2 g, 1.13 M) was then placed into the flask under argon and tetramethylsilane (100 g, 1.13 M) added dropwise over 1 h at 20°C, stirring the mixture at high speed. The resulting reaction mixture was heated to reflux and held at this temperature for 4 h until a yellow–orange solution persists with a deep grey finely divided solid remaining at the bottom of the flask.

The reaction mixture, which now contains the presumably HMPA solvated sodium trimethylsilyl salt $[Me_3SiNa(HMPA)_x]_n$, was allowed to cool to room temperature and PCl_3 (37.8 cm^3, 51.7 g, 0.376 M) added dropwise over 1 h. The reaction flask was then refluxed for 40 h to ensure maximum conversion to the tris-trimethylsilylphosphine. The progress of the reaction was monitored by ^1H and ^{31}P NMR and stopped when peaks due to the intermediate $(Me_3Si)_2PCl$ had all but disappeared (*ca* less than 4–7% of the reaction mixture by NMR).

The THF was then distilled off under an inert atmosphere and the remaining reaction mixture distilled under reduced pressure, collecting the fraction boiling between 45 and 80° at 0.1 mm. This fraction was then redistilled collecting the fraction boiling between 50 and 63° at 0.1 mm, which contained approximately 100 cm^3. To ensure that no HMPA was present in the product (due to very similar boiling points of these compounds) the solution was fractionated two more times using a vacuum-jacketed Vigreux multi-plate column collecting the fraction boiling at 64°C at 0.2 mm. This yielded a colourless product, $(Me_3Si)_3P$ (59.4 g, 81.2%). Found: C, 42.9; H, 10.8. Calc. for $C_9H_{27}Si_3P$: C, 42.7; H, 10.7%. ^1H NMR (270 MHz, C_6D_6, 20°C): δ 2.32 [d, 9.24 Hz, J(PSiCH) of 4.5 ± 0.1 Hz and δ 0.4 lit]. ^{13}C NMR (67.94 MHz, C_6D_6, 20°C): δ 36.25 (d, 3.7 Hz). ^{31}P NMR (109.37 MHz, C_6D_6 at 20°C): δ 251 ± 1 [J(SiCH) of 6.6 ± 0.1 Hz]. ^{29}Si NMR (53.6 MHz, C_6D_6 at 20°C): δ 2.32 [d, 9.24 Hz, J(PCH) of 4.5 ± 0.1 Hz]. Mass spectra (E.I.) molecular ion at 253 a.m.u.

Synthesis of $(Me_3Si)_2PH$ **(2)**

Into a 250 cm^3 two-necked round bottomed flask, flame dried, evacuated and flushed with argon gas, was added THF (50 cm^3) and tris-trimethylsilylphosphine (30 cm^3, 25.8 g, 0.0103 M). To this stirred solution freshly distilled water (11 cm^3) and KOH in THF (50 cm^3) was added at 50°C and Stp. The desired fraction of bistrimethylsilylphosphide, $(Me_3Si)_2PH$, distilled at 79°C and 36 torr pressure (11.3 g, 63.5 mmol), 62%. A second higher fraction was subsequently collected, which was found to be unreacted $(Me_3Si)_3P$. Found: C, 40.3; H, 10.8. Calc. for $C_6H_{19}Si_2P$: C, 40.0; H, 10.5%. ^1H NMR (270 MHz, C_6D_6, 20°C): δ 2.32 [d, 9.24 Hz,

J(PSiCH) of 4.5±0.1 Hz and δ 0.4 lit]. ^{13}C NMR (67.94 MHz, C_6D_6, 20°C): δ 36.25 (d, 3.7 Hz). ^{31}P NMR (270 MHz, C_6D_6, 20°C): δ 251±1 [J(SiCH) of 6.6±0.1 Hz]. ^{29}Si NMR (53.6 MHz, C_6D_6, 20°C): δ 2.32 [d, 9.24 Hz, J(PCH) of 4.5±0.1 Hz]. Mass spectrum (E.I.) shows a molecular ion at 180 a.m.u.

Synthesis of $[Ba(P\{SiMe_3\}_2)_2(THF)_2]_n$ **(3)**

Into a thoroughly flame-dried Schlenk tube (with three vacuum-purge cycles) was placed barium metal granules (1.37 g, 10 mmol) inside a glove-box under a nitrogen atmosphere. The top was then greased and placed on top of the Schlenk tube and the vessel attached to a vacuum line in a well-ventilated fume cupboard. The Schlenk was then evacuated and back-flushed three times with nitrogen.

THF (25 cm^3), toluene (5 cm^3) and bis-trimethylsilylphosphide (5.40 cm^3, 30.0 mmol, 50% excess) were added to the Schlenk tube via a carefully degassed syringe. The top of the Schlenk was then removed under a positive gas flow and quickly replaced with a rubber suba-seal. At this point the *rapidly* stirred suspension was cooled by means of an external dry ice–acetone bath to *ca* −40°C. The fume hood sash was pulled down as far as possible for the remainder of the experiment. Ammonia gas was then slowly bubbled into the solution for 10–12 min, during which time the solution turned a grey colour. The reaction mixture was then slowly allowed to warm to room temperature. Initially, bronze pieces of $Ba(NH_3)_6$ were formed as the metal reacted, but these readily dissolved over a period of 1–2 h. No further flush with NH_3 was necessary.

The rate of stirring of the solution was then reduced to a minimum and the reaction mixture allowed to stir for *ca* 8–12 h at ambient temperature. After this period of time the solution may have a pale grey colour, at this point the stirrer is turned off and the reaction mixture allowed to stand to allow a small amount (*ca* 50 mg) of finely divided metal to settle out. The solution was then carefully filtered through a celite pad and all the solvent removed *in vacuo*. The resulting residue was dissolved in the minimum of n-hexane/THF and left to stand in the freezer at −25°C, which yielded a large amount of white microcrystalline solid. This was isolated using a filter stick and taken into a glove-box. Yield: 2.71 g, 43.2%. Found: C, 38.9; H, 8.6. Calc. for $C_{20}H_{52}P_2O_2Si_4Ba$: C, 39.8; H, 8.7%. IR (Nujol, ν cm^{-1}) 1243 (st), 1246 (vs), 1088 (vs), 1036 (st), 870 (st), 819 (st), 821 (vs), 754 (st), 650 (st), 602 (st). ^1H NMR (270 MHz, C_6D_6, 20°C): δ 0.23 (s, 36H), δ 1.38 (m, 8H), δ 3.52 (m, 8H). ^{13}C NMR (67.94 MHz, C_6D_6, 20°C): δ 5.20 (s, Me), δ 25.46 (s, THF), δ 68.62 (s, THF). $^{29}Si\{^1H\}$ NMR (53.6 MHz, C_6D_6, 20°C): δ −14.88 (refd. TMS).

RESULTS

Synthesis

Prior to this study synthetic routes to tris-trimethylsilylphosphine, $(Me_3Si)_3P$, were rather limited, generally using the hazardous Na_3P as the phosphorus precursor which may then be reacted *in situ* with a trimethylsilyl halide.[9–12] Given these limitations we have developed an alternative high yield synthetic route. Our strategy involves the reaction of tetramethylsilane and sodium hydride in a mixed solvent of THF and HMPA (2 : 1 by volume), these two materials are held at reflux for 40 h to yield a deep yellow–orange solution of presumably $[NaSiMe_3 \cdot x\text{HMPA}]_n$, see eq. (1).

$$Me_4Si + NaH \xrightarrow[\Delta]{\text{THF/HMPA}} [Me_3SiNa(HMPA)_x]_n + CH_4 \quad (1)$$

To the solution is added phosphorus trichloride, dropwise over a period of 1 h at room temperature, which is then followed by a 40 h reflux and the reaction monitored by NMR. It is stopped when peaks due to the intermediate $(Me_3Si)_2PCl$ have virtually disappeared (*ca* less than 5% of the reaction mixture by multinuclear NMR). The product was finally separated by repeated vacuum distillation from the THF and HMPA in > 80% yield, see eq. (2).

$$[Me_3SiNa(HMPA)_x]_n + PCl_3 \longrightarrow (Me_3Si)_3P + 3NaCl + x\text{HMPA} \quad (2)$$

Separation of the residual HMPA from the $(Me_3Si)_3P$ proved to be best accomplished by repeated distillation, which yielded the final product in good yield and high purity. Attempts at reducing the amount of HMPA in the reaction mixture (due to its carcinogenic nature) were unsuccessful and resulted in mixtures of silyl phosphines, which proved very difficult to separate. Therefore, the 2 : 1 ratio of THF to HMPA is the recommended one for the synthesis of the tris-trimethylsilylphosphine.

The tris-trimethylsilylphosphine is readily converted into the bis-trimethylsilylphosphide by controlled hydrolysis in THF to yield $(Me_3Si)_2PH$, 62%, with some unreacted phosphine remaining. Given the ease and comparative safety behind this preparative route, this has now facilitated a preliminary study of the metallation of the phosphide ligand $(Me_3Si)_2PH$ by the heavier alkaline earth

metals, and in particular by barium granules suspended in ammonical-THF.

We have found that barium metal reacts rapidly with trimethylsilylphosphide at temperatures between −35 and −45°C in THF in the presence of ammonia to yield $[Ba\{P(SiMe_3)_2\}_2(THF)_2]_n$ (**3**) in moderate yield and isolated as a white highly air-sensitive crystalline solid. This material is readily soluble in toluene and THF (and other polar coordinating solvents, e.g. dme, CH_3CN, HMPA, etc.).

DISCUSSION

We have previously reported the application of our ammonia-ethereal solvent route to a wide range of alkaline earth organometallic complexes and more recently extended it to related homoleptic compounds, via the use of ammonical-hydrocarbon solvent synthesis.[7] These routes have been shown to operate via the intermediacy of solvated electrons (either at ambient temperature or at −40°C). We have previously noted that liquid ammonia will form a mixed solvent system with a wide range of organic solvents, both above and below its boiling point.[7]

Up to five years ago many of the heavier alkaline earth complexes were thought to be either polymeric or insoluble in most organic solvents. More recent studies[8,18-19] have revealed that this need not be the case, indeed several studies have recently demonstrated that suitably bulky ligands such as $(Me_3Si)_2NH$, OAr′, etc. will solubilize a wide range of group IIA based compounds. A notable feature of these metals is their strong Lewis acidity, which ensures that in the absence of Lewis base solvents they will generally form polymeric insoluble materials. However, on the addition of suitable Lewis base solvents the polymeric ensembles may be cleaved to yield simpler molecular species. A wide variety of molecular geometries are available, provided that judicious choice of ligands and or Lewis bases are used to achieve coordinative saturation of the large M^{2+} cations.

Using a similar aproach to that of Caulton *et al.*[18] with a small modification,[19] we have been able to isolate the related phosphide complex $[Ba\{P(SiMe_3)_2\}_2(THF)_2]$ (**3**). The ^1H and ^{13}C NMR spectra of this material in C_7D_8 reveal the presence of only one methyl environment on the trimethylsilylphosphide ligand. A similar observation is also observed for the ^{29}Si NMR spectrum, implying that this compound either contains only one distinct type of phosphide environment or as seems more likely a rapid fluxional process is occurring, equilibrating the different ligand environments (both THF and phosphide). A similar situation to this has previously been reported by Westerhausen in his variable-temperature NMR study of $[Ba(N\{SiMe_3\}_2)_2(THF)_2]$.[8] Caulton *et al.*[18] have previously shown by single-crystal X-ray crystallography that this barium trimethylsilamide is monomeric with a distorted tetrahedral structure.[18] Attempts to date at cryoscopic molecular mass measurements in benzene have been unsuccessful with this complex due to its exceptional air- and moisture-sensitivity and its rapid decomposition.

CONCLUSIONS

In this work we have demonstrated a novel and efficient route to trimethylsilylphosphide via use of the readily available starting materials tetramethylsilane and sodium hydride in a mixed solvent of THF and hexamethylphosphoramide at reflux. Reaction of the postulated *in situ* intermediate $[Me_3SiNa(HMPA)_x]_n$ with PCl_3 and subsequent work-up yields $P(SiMe_3)_3$ in excellent yield. Such a facile synthesis of a silylphosphine is noteworthy and promises to ensure that the chemistry of this ligand will now be further explored, especially as a precursor ligand for metal phosphides, e.g. Zn_3P_2. Indeed, the possibility of extending this route to other silyl phosphides, i.e. $(R_3Si)_3P$ (where R is Ph, Et, etc.) looks very promising using simple alkyl or aryl silanes as suitable starting materials.

The synthetic strategy used here to prepare the barium phosphide complex $[Ba(P\{SiMe_3\}_2)_2(THF)_2]$ will find further extension to a wide range of other organic substrates with moderately acidic protons and a pK_a of < 30. Careful manipulation of experimental conditions may allow us to eventually isolate the analogous phosphide complexes of $[Ba(N\{SiMe_3\}_2)_2(THF)]_2$ and $[Ba(N\{SiMe_3\}_2)_2]_2$.[18] Indeed, given the dearth of alkaline earth metal phosphide and phosphine based complexes a study of their fundamental coordination chemistry is long overduc.

(*Received* 5 *May* 1993; *accepted* 3 *June* 1993)

Abstract—Combined ^{31}P, ^{1}H and ^{13}C NMR studies show the course of the reaction of amines with formaldehyde and phosphorous acid in hydrochloric acid solutions. For symmetrical di- and tri-aza macrocycles, piperazine and 1,4,7-triazacyclononane, the products formed according to the stoichiometry, with all nitrogens apparently derivatized at similar rates; partial derivatization is thus not easily achieved. Primary amines once substituted were disubstituted at a much greater rate than the initial substitution. One asymmetric macrocycle, 1,4,8-triazacyclododecane, was substituted sequentially, showing that it is possible to prepare a partially substituted version in some purity. Guanidineacetic acid was the only one of a series of guanidines to react under Moedritzer–Irani conditions. This may have mechanistic significance.

Since the first attempts to prepare azacrown macrocycles with pendant arms,[1] there have been many publications on the subject. The expressive names lariat ether[2] and bibracchial ether[3] were later coined to describe these and similar entities. In this paper we describe the progress of reactions to derivatize NH groups of small aza macrocycles selectively with methylenephosphonate residues. The coordinating properties of aminoalkyl phosphonates[4] (AAP) have been studied in great detail[5] and their suitability as crystallization inhibitors, peroxide stabilisers, herbicides and builders for detergents is now well established. AAP ligands are usually prepared using the Moedritzer–Irani reaction,[4] shown in eq. (1), for the case of a simple primary amine.

$$RNH_2 + 2H_3PO_3 + 2CH_2O \longrightarrow RN(CH_2PO_3H_2)_2 \quad (1)$$

Commercial products made by this route are often very impure. There is no detailed study of the reaction or its mechanism in the literature. It is not established whether or not partial substitution is favoured by any set of conditions. The major advantages of the Moedritzer–Irani reaction are the availability and inexpensive nature of the starting materials, and the one-step procedure, offset somewhat by the difficulty in purifying the final products, which is especially true of water-soluble derivatives. The difficulties arise because of the presence of partially substituted AAP derivatives or unreacted phosphorous acid starting material in the reaction mixture. Qualitative comparison has been made here between the progress of the reaction and the amounts of partially substituted products formed, in selected reactions involving macrocyclic secondary amines and also some involving open-chain primary amine starting materials. If all N—H groups in a molecule react at the same, or closely similar, rates, it should be difficult to obtain pure partially substituted derivatives, but if differential rates are observed then partially substituted derivatives may be isolable.

The amines 1,4,7-triazacyclononane (**1a**), piperazine (**2a**), 1,4,8-triazacyclododecane (**3a**), 1,3-propanediamine (**4a**) and benzylamine (**5a**) were used as the amine starting materials. To the best of our knowledge macrocycle **3a** has not been prepared before. Its synthesis using the Richman and Atkins method[6] and subsequent AAP derivatisation will be reported elsewhere.[7]

EXPERIMENTAL

Monitoring the reaction

An example of the procedure used to follow the reactions is decribed.

Reaction of triazacyclononane **1a**, reaction I. The temperature of a *ca* 5 mol dm^{-3} DCl solution (16 cm^3) under nitrogen, containing the amine trihydrochloride (0.38 g, 1.59 mmol) and phosphorous acid (0.39 g, 4.78 mmol), was initially raised to 92°C using a water bath. Paraformaldehyde (0.29 g, 9.56 mmol) was added in one portion, the flask was shaken vigorously to dissolve the solid and the timing of the reaction was started. Samples were taken by means of a pipette, transferred to an NMR tube and then cooled rapidly in an ice–water bath.

All other reactions were carried out in a similar manner except for that involving **4a**, which was run in an HCl/H_2O solvent and a further reaction IX with **1a**, which was run with aqueous formaldehyde added dropwise over a period of 1 h. Aliquots were removed and cooled, then used directly for NMR. The ^{31}P NMR spectra of the first aliquots taken from each reaction revealed that a significant amount of phosphorous acid had been converted to phosphoric acid,* a side reaction noted in the original Moedritzer–Irani publication.[4] The concentration of H_3PO_4 in the reaction mixture effectively remained constant after the addition of paraformaldehyde and initiation of the AAP forming reaction. The signals are poorly defined and

* The chemical shift of the (internal) H_3PO_4 formed in the reaction is different from that of external standard $H_3PO_4(\delta_P O)$ because of the different acidities of the solutions in which they were measured.

it is difficult to differentiate the multiplicities of overlapping signals. This is probably due to a slower rate of proton exchange between particular ionisable protons. Where convenient, ^1H and ^{13}C spectra were obtained on the same sample, except for reaction VII, for which selected ^1H and ^{13}C spectra were obtained in the following manner. The HCl/H_2O solvent mixture was removed on a rotary evaporator. Repeated additions of D_2O and removals of solvent were carried out in an effort to deuterate the exchangeable protons. As a result, the spectra for each sample cannot be compared directly with the corresponding ^{31}P spectra because the initial warming to remove the HCl/H_2O is likely to have raised the temperature sufficiently to cause the reaction to continue.

Guanidines. The series of guanidines **6–8** was also subjected to similar studies. The only guanidine successfully derivatized was guanidineacetic acid (**8**); the others did not appear to be phosphonated at all.

NMR spectra were run on Brüker WP200, AC200, WB300, AMX500 and JEOL FX90Q spectrometers.

RESULTS AND DISCUSSION

The Moedritzer–Irani reaction [shown in eq. (1)] was monitored for a series of amines **1a–5a** using NMR spectra of quenched samples from the reaction mixtures. One aim of the study was to ascertain if phosphonation was sequential, with subsequent steps of different rate, which could permit partial functionalization. Qualitative inferences may be obtained from the results of this study.

The new ^{31}P signals which appeared during the reaction were assigned using several arguments. The signals present in maximum concentration at the end of a reaction were assigned to the most fully phosphonated product allowed by stoichiometry. Secondly, signals were differentiated in terms of known shielding patterns consequent on protonation.[8–10] The relevant integrals from the phosphorus spectra assisted the assignment of ^1H and ^{13}C NMR signals, together with ^{31}P coupling patterns of the NCH_2P signals. Spectra were normally taken in 5 M acid solutions, but sometimes the pH was raised to neutral to shift the overlapping signals; the latter were also assigned by decoupling experiments and the highest resolution work at 500 MHz for ^1H. Transient signals were also observed and assigned to intermediate species, not identified, and by-products.

In Table 1 are shown the ratios of reagents chosen for each amine studied, together with temperature and an approximate half-life based on the disappearance of initial H_3PO_3. Tables 2 and 3 show the assignment of the signals in ^{31}P and ^1H spectra, respectively, to characteristic groups in the reagents and products, identified in Scheme 1. Results for the several amines are discussed in turn.

Triazacyclononane (**1a**)

For the first amine chosen, triazacyclononane, the reaction was run at three different ratios of

reagents in an attempt to maximize the amounts of mono-, di- and tri-substituted products, respectively (as shown in Table 1): adventitious oxidation of the phosphorous acid prior to formaldehyde addition altered the ratios originally chosen. The ^{31}P chemical shifts of the signals for mono- and di-substituted 1,4,7-triazacyclononane are very similar and the multiplets are superimposed. The values quoted in Table 2 were obtained from well-resolved spectra from reaction IX.

Peaks observed in the ^1H NMR spectra have been tentatively assigned as shown in Table 3. After 180 min of reaction II the signal for the unsubstituted amine starting material disappeared. The methylene of the R groups appears as a doublet δ_H 3.60, J(P—H) $\approx$ 13.8 Hz. The line-widths of this doublet and the adjacent signal in the final spectrum (after 180 min) suggest that these correspond to R_1 and R_2 of mixtures of partially substituted AAP derivatives (which have non-equivalent protons

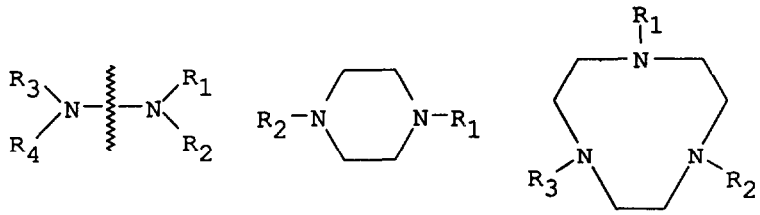

Scheme 1. Definitions of R_1–R_4 for reactions I–IX.

both in the methylenephosphonate groups and the macrocyclic ring).

In the final ^{13}C NMR spectrum from reaction mixture III (after 180 min) remnant formaldehyde appears as a single peak (δ_C 81.77). Two CH_2—P doublets were identified by their J(P—C) coupling constants (Table 4); the most intense doublet was assigned to the tri-substituted product on comparison of this spectrum with the corresponding ^{31}P spectrum [δ_C 51.77, J(P—C) 143.5 Hz]. The macrocyclic ring CH_2 carbon atoms appear as a large single peak (δ_C 50.76) and two much smaller peaks (δ_C 51.63, 49.79). This indicates that most of the amine is fully substituted and in that situation the ring carbon atoms are equivalent. The other ^{13}C spectra are much more difficult to interpret. A number of signals appear upfield from the signals due to ring CH_2 and CH_2—P carbon atoms (δ_C 41.97–45.10). At least four signals are observed at the beginning of the reaction (1–3 min), but only one remains after 180 min (δ_C 45.06). A number of unidentified signals were also observed upfield of the ring CH_2 and CH_2—P proton peaks in the ^1H spectra obtained from reaction II (δ_H 3.0–3.4). The disappearance of the upfield ^{13}C signals in reaction III suggests that these species may be intermediates in the reaction. If the mechanism proposed by Redmore[12] and Vincens *et al.*[13] applies, these signals may be due to the corresponding methylol derivatives (RNR′) (CH_2OH) and/or iminium ions.

A comparison can be made between the reaction in which formaldehyde was added as solid paraformaldehyde in one portion at the beginning (III) and that in which aqueous formaldehyde was added dropwise over a period of 1 h (IX). The initial ratio of [H_3PO_3]/[amine] was roughly the same in each case. The time-scales shown in Table 1 indicate that the time taken for 50% reaction of H_3PO_3 was similar to reactions III and IX. Although the tri-substituted product was only present as 25% of total ^{31}P after 60 min in reaction IX (compared with 41% in reaction III), the concentrations of the fully substituted product are effectively the same after 3 h ($\approx$ 54% in each case). Therefore, the products obtained in the Moedritzer–Irani reaction are essentially the same, irrespective of whether the formaldehyde is added as an aqueous solution or as solid paraformaldehyde. One ephemeral signal appeared in the ^{31}P NMR spectrum of initial samples; this had disappeared before the end of the reaction and thus may be an intermediate. The phosphorus shift and coupling constant were very similar to those of hydroxymethylphosphonic acid, which in other reactions accumulated at the end of the reaction and was thought not to be an intermediate. The identity of the ephemeral signal was not discovered.

Piperazine (**2a**), *reaction* IV

The di-substituted product was found to precipitate from the samples taken during the latter stages of the reaction; assignment of its NMR signals is thus straightforward. The spectra indicate that the initially formed mono-substituted product is gradually converted to the di-substituted product.

Triazacyclododecane (**3a**)

To circumvent the difficulties of distinguishing the signals for partially substituted products in the ^1H and ^{31}P NMR, the macrocyclic ligand **3a**, which contains three chemically distinct nitrogens and also bridging methylenes with differing chemical shifts, was examined. The formation and decay of the various components, traced via the ^{31}P and ^1H NMR signals at various reaction times, are shown in Figs 1 and 2 and are discussed below. The ^{31}P plot shows the fast incorporation of two methylphosphonate groups (R_1 and R_2, see Scheme 1) with the final one forming much later. The A′B′ signals (see key in Scheme 2) are seen to form more slowly than the composite signal for the rest of the ring protons, from the plot in Fig. 2.

^{31}P *studies*

Three sets of signals (Fig. 3) corresponding to product **3b** are seen in the final spectrum of this stack of low-resolution ^{31}P spectra, obtained at

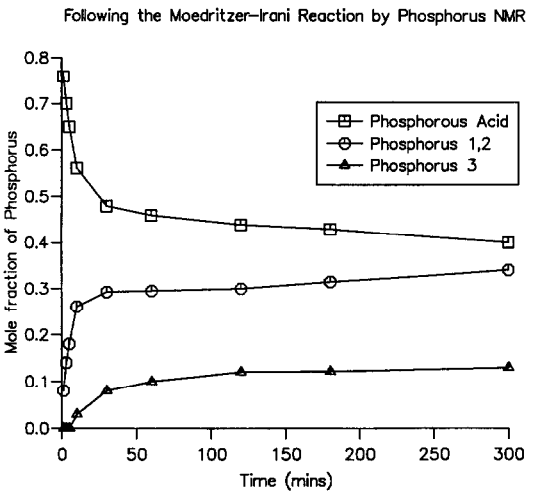

Fig. 1. Decay and build-up of ^{31}P signals for the conversion of **3a** to **3b** (taken from low-resolution 36.2 MHz spectra).

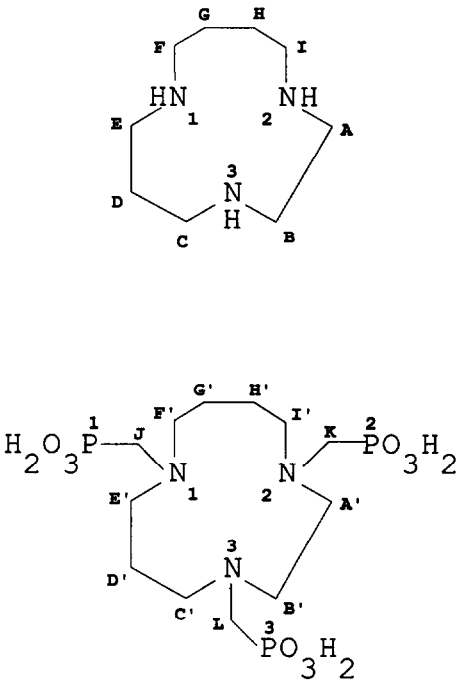

Scheme 2. Labelling scheme for the conversion of **3a** to **3b**.

36.20 MHz. The decay of the phosphorous acid signal in the early stages of the reaction is matched with the rapid increase in signals 1 and 2 as the ligand is phosphonated. The plot shows that one nitrogen of the macrocycle **3a** (labelled as shown in Scheme 2), probably N(1), is slightly more reactive than a second, probably N(2). These undergo rapid reaction in comparison to the third nitrogen, N(3). The assignment of the phosphorus signals was verified by higher resolution spectra and the spectrum of the tri-substituted product, obtained also at neutral pH, together with ^{1}H and ^{31}P decoupling experiments. The evolution of ^{31}P signals (obtained at higher resolution and an RF of 121.496 MHz) with time made clear that several signals with well-resolved triplet couplings to adjacent methylene hydrogens were observed (10.82, 10.70, 10.58 and 10.46 ppm). Downfield, and partly overlapping these signals, was a set of blurred signals, from which accurate coupling constants could not be extracted. There was a third, very blurred, signal, which appeared at 13.5 ppm after a much greater lapse of time. It can be seen (Scheme 3) that the stepwise substitution of **3a** can in principle give three mono-substituted products, of which A1 is more likely than the other two, three di-substituted products of which B12 and B13, are more likely than B23 (which involves substitution of the two least basic nitrogens) and one tri-substituted product C123. The signals in the final spectrum are readily assigned to ligand C123, 13.5, 10.7 and 10.3 ppm to the methylenephosphonate residues on N(3), N(1) and N(2), respectively. The number of sharply resolved multiplets (*ca* 10.9–10.4 ppm) is equal to the number of phosphorous environments expected for N(1) groups on A1, B12, B13 and C123. The number of blurred multiplets (three) is equal to the number of phosphorus environments on N(2) required for B12, A2 and C123. The unique phosphorus environment for N(3) in C123 is at 13.5 ppm in the acid spectra. Since some of the signals [including those for the phosphorus N(1) environments and the remnant phosphorous acid] were quite sharp, it is likely to be a kinetic effect, with

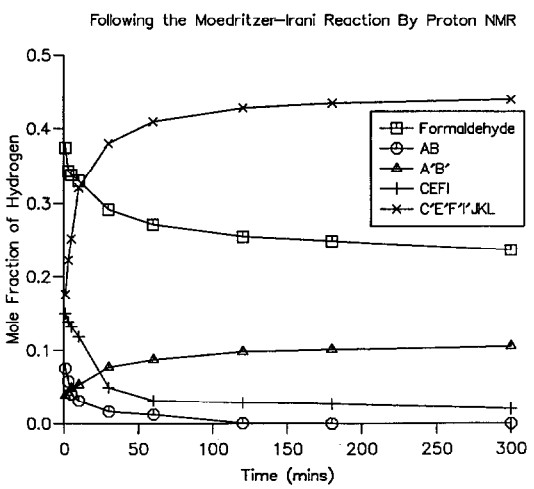

Fig. 2. Decay and build-up of ^{1}H signals for the conversion of **3a** to **3b** (taken from 200 MHz spectra).

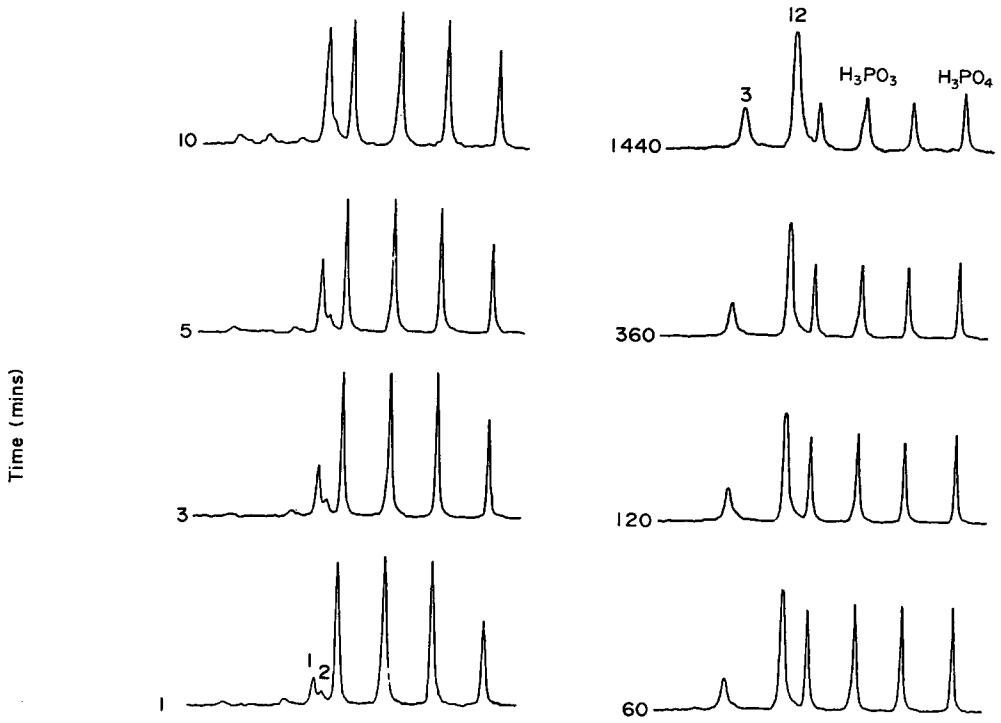

Fig. 3. ^{31}P NMR traces for the conversion of **3a** and **3b** over a period of 24 h (36.2 MHz, ambient temperature).

exchange of protons between particular nitrogens in the macrocyclic ring varying the chemical shifts of attached groups, but with incomplete averaging. This effect was probed in neutral solution, when a sharp triplet was observed for the phosphorus environment attached via N(1).

Most phosphorus spectra were taken in 5.5 M HCl with $H_0 \approx -2$, at which acidity one could expect that the third nitrogen, with a pK_a of *ca* 0–2, although almost fully protonated, would be liable to fast proton exchange which could cause the blurring effect (averaging over sites of different chemical shift) seen in the NMR spectra. The second nitrogen (pK_a *ca* 6) could also be in an intermediate exchange

region and certainly, for spectra run at pH 7, protons on the two least basic nitrogens would be expected to be in a state of intermediate exchange on a typical NMR time-scale, with resultant effect on NMR signals.

^{1}H *studies*

From the selection of ^{1}H spectra shown in Fig. 4 (and obtained at 200 MHz Rf), initially free ligand is the major component, whose signals are observed. The labels shown on the lowest trace correspond to the proton labels shown in Scheme 2. Similar labels are used for the triphosphonate **3b**, distinguished by a prime where the ring protons are involved. As phosphonate groups are added the DGH/D'G'H' signals lose their fine structure with changing chemical environment. The time-dependent loss of free ligand and growth of phosphonated ligand signals is also quite evident.

The mole fractions of species are plotted against time in Figs 1 and 2, both for the phosphorus and for the proton signals. From the plots of ^{1}H signals (Fig. 2), the decay of the formaldehyde is clearly similar to that of the phosphorous acid in the ^{31}P spectra. It is simpler to consider the growth of the methylene signals on the phosphonated macrocycle A'B', C'E', F'I', J, K, L rather than the decay of the free ligand signals, since the former signals are better resolved. Again the rapid formation of the phosphonate groups on nitrogens N(1), and N(2) is shown by the growth of the C'E'J/F'I'K signal, these being the methylenes adjacent to the nitrogens involved, whereas the A'B' signal does not appear until the 10th minute. This signal only becomes significant after 60 min, subsequent to the first two phosphonations. This appearance at 10 min corresponds to the appearance of the corresponding peak in the ^{31}P spectrum.

These results show a sequential formation of phosphonate groups as hoped, with the phosphonation of the first two nitrogens being clearly faster than that for the third. However there is no large difference in the reactivity of nitrogens N(1) and N(2) (see

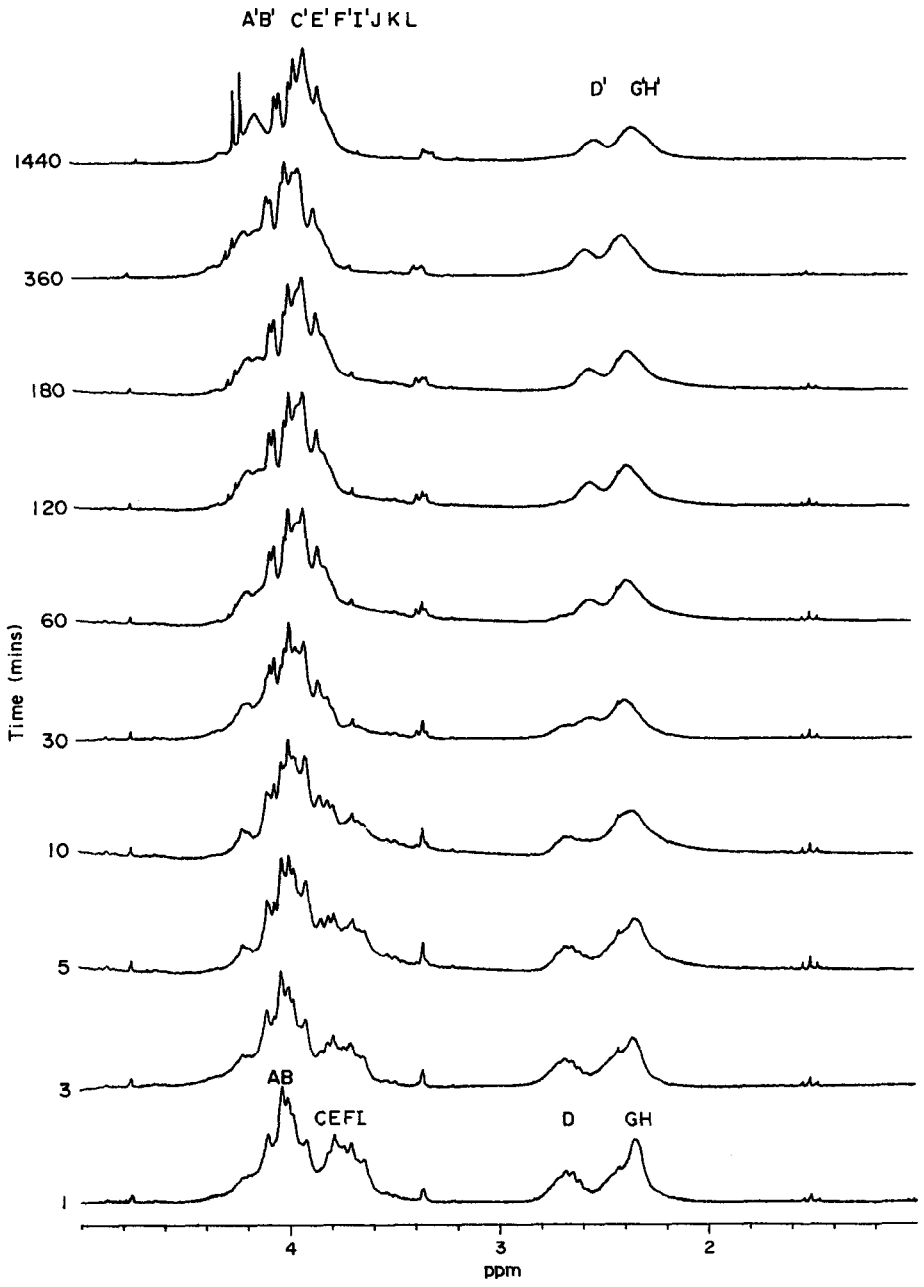

Fig. 4. ^{1}H NMR traces for the conversion of **3a** to **3b** over a period of 24 h (200 MHz, ambient temperature).

Scheme 3 and Fig. 1). The origin of these differences may lie in the pK_a values of the macrocyclic nitrogens. Although no data could be found for ligand **3a**, values from potentiometric studies on similar ligands **1a**, **10** and **11**[14–16,20,21] are shown in Table 5, along with the collected pK_a data for all the amines and guanidines used, where available from the literature.[17–19] For each of the macrocycles, two of the nitrogens are much more basic than the third. This is thought to be caused[7] by a combination of electrostatic repulsion and hydrogen bonding, i.e. the second protonated nitrogen is able to form a hydrogen bond with the unprotonated third nitrogen leaving it less susceptible to protonation. The close proximity of the protonated nitrogen also gives rise to electrostatic repulsion of an incoming proton. These factors make the third nitrogen much more difficult to protonate. In the early stages of the reaction the first two nitrogens are much more reactive to phosphonation. However, once the first two become phosphonated the chemical environment around the third nitrogen will have changed,

Table 5. pK_a values of amine starting materials

Ligand	pK_{a1}	pK_{a2}	pK_{a3}
1a[14]	11.03	7.37	0.7

11[14]	12.2	8.79	4.76
11[21]	9.79	8.13	4.18

which will in turn change the basicity and therefore reactivity towards phosphonation. The knowledge of the higher reactivity of the first two nitrogens could be very beneficial in reactions where basicity of the nitrogens is a factor. It should also allow the functionalization of two nitrogens leaving the third one free.

Also relevant are the guanidine reactions. In general guanidine reactions gave no N-methylene phosphonate derivatives by this route, although it is known that guanidines react with formaldehyde under acid conditions.[22] From the pK_as quoted in Table 5 it may be seen that guanidineacetic acid alone has a first pK_a value in the range of the macrocyclic amines, while guanidine is much more basic than any of the amines studied. The fact that guanidine **8** does not undergo the Moedritzer–Irani reaction may be associated with its very high pK_a or with the double-bond character of the C—N links, which may prevent formation of an imine from the methylol as required in the Vincens mechanism.[13]

Primary amines

The Moedritzer–Irani reaction was followed using both 1,3-diaminopropane (**4a**) (reaction VII) and benzylamine (**5a**) (reaction VIII) as the amine starting materials. The diamine was selected because the AAP derivatives were found to be very soluble, permitting the reaction to be carried out at high concentration without problems of precipitation in quenched samples. Six new signals, falling into two shift ranges, observed in the ^{31}P NMR spectra are quoted in Table 2.

The first sample taken after $1\frac{1}{2}$ min shows the presence of a tri- and/or tetra-substituted product, but there is no detectable signal for a mono- or di-substituted AAP derivative. The rapid build-up of signals for R_3 and R_4 (in comparison to those for R_1 and R_2) provides evidence for the increased rate of reaction of a mono- or di-phosphonomethylated primary amine nitrogen atom relative to the precursor amine. The final sample, taken after 1 day, indicated 22% of the mono- and di-substituted and 70% of the tri- and tetra-substituted AAP derivatives. Two signals were observed for the methylene protons in the ^1H spectrum of 1,3-diamino-propane tetrahydrochloride [δ_H: $CH_2CH_2CH_2$ 1.62 (p), $CH_2CH_2CH_2$ 2.66 (t)] and two singlets were observed in the corresponding ^{13}C spectrum (δ_C: $CH_2CH_2CH_2$ 28.81, $CH_2CH_2CH_2$ 38.54). The ^{13}C signal due to the CH_2 group in the middle of the propane diamine chain appears to be split into at least three peaks in all samples taken from the reaction, becoming sharper and less broad towards the end of the reaction as most of the amine starting material is converted to the tri- and tetra-substituted AAP derivatives.

Characteristic C—P coupling constants for all the spectra taken are shown in Table 4. The presence of hydroxy methylphosphonic acid (**9**) in the later samples from several reactions was confirmed by characteristic doublets in both the ^{13}C and ^1H spectra [δ_H: 3.34 J(P—H) 7.1 Hz, δ_C: 57.62 J(P—C) 159.0 Hz]. The significant amount of hydroxymethylphosphonic acid still present after ≈80% of reaction VII provides further evidence that this species is formed as a by-product.

Benzylamine **5a**

Reaction VIII was undertaken in an attempt to obtain simpler, more easily interpretable ^1H spectra. The first products were observed in the ^{31}P spectra after 20 min. Four new species appear to have been formed in the reaction. After 30 min the mono- and di-substituted AAP derivatives are both present as ≈ 0.5% of the total phosphorus in the sample (δ_P: mono- 13.03, di- 10.59 ppm). The amount of the di-AAP derivative then increases until it is present as 32% (of total ^{31}P) after 5 h. The concentration of the mono-AAP derivative is at a maximum after 3 h (1.8%) and this decreases to 1.1% after 5 h. This indicates that, once formed, the mono-AAP derivative is *rapidly* converted to the fully substituted derivative. These results are in agreement with those obtained by Redmore *et al.*[23] These workers detected only trace amounts of the mono-substituted benzylamine derivative after reacting 1 mole equivalent of benzylamine, phosphorous acid and formaldehyde. The amount of hydroxymethylphosphonic acid (**9**) increases

throughout the reaction and it is present as 2.5% (of total ^{31}P) after 5 h ($\delta_P = 23.37$ ppm). The di-substituted AAP derivative was found to be poorly soluble, precipitating from some of the later samples taken from the reaction mixture. This facilitated the assignments of the spectra.

The reaction between benzylamine, H_3PO_3 and formaldehyde (in the ratio 1:2:4) resulted in the almost exclusive formation of the fully substituted derivative (32%) relative to that of the mono-substituted product (1.1%). It was concluded that the rate of reaction of a mono-phosphonomethylated primary amine nitrogen atom was faster than that of the precursor amine. This is probably due to the increased positive charge on the nitrogen atom in the mono-substituted AAP derivative. The amount of partially substituted products (mono- and di-) formed in the reaction between 1,3-diaminopropane, H_3PO_3 and formaldehyde (1:4:8) was greater than the amount formed in the above reaction but tri- and tetra-substituted AAP derivatives were always present at higher concentrations, finishing at 70% of the total phosphorus in the reaction mixture.

In the reaction between piperazine (**2a**), phosphorous acid and formaldehyde (in the ratio 1:2:2), the ratio of fully to partially substituted products was $\approx 1.5:1$, which is much lower than that obtained in the reaction using benzylamine as the amine starting material. All three reactions using 1,4,7-triazacyclononane were carried out using a deficit of phosphorous acid. No fully substituted AAP derivative was formed in reaction I (0.34 mole equivalent of H_3PO_3). The amount of fully substituted product was found to increase with an increase in H_3PO_3, but significant concentrations of partially substituted products were still present in reactions II and III (0.78 and 2.06 mole equivalents of H_3PO_3, respectively). This increase in rate is not as large as that observed with the primary amines. This is probably because the substitutions are occurring on different nitrogen atoms in the secondary amines rather than the same nitrogen atom in the primary amines. With the triazacyclododecane, the differential basicities of the three nitrogens permit sequential formation of phosphonates with the first two nitrogens phosphonating on a shorter time-scale than the third.

NICKEL COMPLEXES OF TRIDENTATE LIGANDS INCORPORATING THIOETHER AND TRIAZENE-1-OXIDE FUNCTIONS. SYNTHESIS, STRUCTURE AND METAL REDOX

SOMA KARMAKAR, SURANJAN BHANJA CHOUDHURY, DEBASHIS RAY and ANIMESH CHAKRAVORTY*

Department of Inorganic Chemistry, Indian Association for the Cultivation of Science, Calcutta 700 032, India

(*Received* 20 *April* 1993; *accepted* 3 *June* 1993)

Abstract—The reaction of nickel(II) acetate with $RN(O)NNHC_6H_4SMe$ (HL^1: R = Me; HL^2: R = Pr^n; general abbreviation HL) in aqueous ethanol affords $[NiL_2]$ as brown crystalline solids. The X-ray structure of $[NiL^2{}_2]$ is reported. Each ligand acts in the tridentate meridional SNO fashion. The $Ni(SNO)_2$ coordination sphere is severely distorted from octahedral geometry. The Ni—S distances, 2.519(2) and 2.549(2) Å, constitute the longest nickel(II)–thioether bonds reported so far. Due to low symmetry, the octahedral ν_1 band of the complexes are split into components lying at *ca* 1400 and 1000 nm. The complexes display quasireversible cyclic voltammograms corresponding to the metal redox couple $[Ni^{III}L_2]^+/[Ni^{II}L_2]$, $E_{1/2} \sim 0.75$ V (vs S.C.E.). Coulometrically generated $[Ni^{III}L_2]^+$ displays rhombic EPR spectra, the g values of the perpendicular components being larger than that of the parallel component corresponding to the $(d_{z^2})^1$ ground state.

This work forms part of our programme on the synthesis, structure and redox behaviour of nickel(II) complexes incorporating thioether ligation.[1–4] The nickel(II)–thioether link is intrinsically weak[5–7] and we have used polydentate ligation as the stabilizing principle. Ligands having both thioether and triazene-1-oxide functions are well-suited[8] for nickel(II) binding and we have recently reported the case of hexadentate coordination (**1**).[4] In this concluding study on the thioether triazene-1-oxide complexes we examine the case of tridentate ligands, which have two disadvantages compared with hexadentate ligands: diminished chelate effect and potentially easier dissociation of the terminally placed thioether site. Nevertheless, complexes of coordination type **2** have, however, been isolated and one of these has been structurally characterized. Redox activity of nickel–sulphur complexes are of bioinorganic interest.[9,10] The present complexes are oxidisable in solution affording EPR-active nickel(III) species.

EXPERIMENTAL

Materials

2-Methylthioaniline was prepared by methylating 2-aminothiophenol by methyl iodide in alkaline media. The hydroxylamines were made by reduction of the corresponding nitro compounds.[11] All reagents used were of commercial grade. Tetraethylammonium perchlorate and pure dichloromethane for electrochemical and spectroscopic work were obtained as before.[12]

* Author to whom correspondence should be addressed.

Physical measurements

Electronic and IR spectra were measured with Hitachi model 330 and Perkin–Elmer model 783 spectrometers. Electrochemical data were collected with a PAR 370-4 electrochemistry system as before.[13] Magnetic measurements were performed with a PAR-155 vibrating sample magnetometer and EPR spectra were recorded with a Varian E-109 C spectrometer (*X*-band) fitted with a quartz Dewar.

Synthesis of ligands and complexes

The ligands HL^1 and HL^2 were synthesized by similar methods and details are given for HL^2, *o*-(1-*n*-propyl triazene-1-oxide)methyl thiobenzene. A solution of 2-(methylthio)aniline (1.39 g) in concentrated HCl (1.7 cm^3) and water (2 cm^3) was diazotized at 0°C with $NaNO_2$ (1.38 g) dissolved in water (5 cm^3). The diazotized solution was added with stirring to 1.12 g of N-*n*-propylhydroxylamine hydrochloride in water (15 cm^3) and cooled to 0°C. The pH of the reaction mixture was kept in the range 3–5 by gradual addition of an aqueous solution (20 cm^3) of sodium acetate (6 g). The ligand separated out as a pale yellow precipitate. This was filtered and recrystallized from alcohol to yield pale yellow needles. Yield: 75%. Found: C, 53.2; H, 6.6; N, 18.8. Calc. for $C_{10}H_{15}N_3OS$: C, 53.3; H, 6.7; N, 18.7%. The ligand HL^1 was synthesized in 68% yield. Found: C, 48.8; H, 5.6; N, 21.2. Calc. for $C_8H_{11}N_3OS$: C, 48.7; H, 5.6; N, 21.3%.

To a hot ethanolic solution of the ligand HL^2 (388 mg, 2.0 mmol) was added an aqueous solution of nickel(II) acetate tetrahydrate (250 mg, 1.0 mmol). The mass was then refluxed for 30 min and on concentration $[NiL^2_2]$ was precipitated as a brown crystalline solid, which was collected by filtration, washed successively with alcohol and water and finally dried over P_4O_{10}. Yield: 72%. Found: C, 47.4; H, 5.6; N, 16.7. Calc. for $C_{20}H_{28}N_6O_2S_2Ni$: C, 47.3; H, 5.5; N, 16.6%. The complex $[NiL^1_2]$ was synthesized similarly and obtained in 70% yield. Found: C, 42.6; H, 4.5; N, 18.4. Calc. for $C_{16}H_{20}N_6O_2S_2Ni$: C, 42.6; H, 4.4; N, 18.6%.

X-ray structure determination of $[NiL^2_2]$

Single crystals of $[NiL^2_2]$ were grown by slow diffusion of hexane into the dichloromethane solution. Cell dimensions were determined with the help of 25 machine centred reflections. Data were collected at 296 K on a Nicolet R3m/V diffractometer with graphite monochromated Mo-K_α (λ = 0.71073 Å) radiation in the ω–2θ scan mode. Two check reflections measured after every 98 reflections showed no significant variations. Lorentz and polarization corrections and semi-empirical absorption correction[14] were performed.

The structure was solved by direct methods and was refined by full-matrix least-squares procedures. All the non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included at the calculated positions in the final refinement cycle with an isotropic thermal parameter (0.08 $Å^2$). Crystal data and other details are collected in Table 1. Computations were performed on a MicroVAX II computer using the SHELXTL-PLUS program system.[15]

Tables of atomic coordinates, anisotropic thermal parameters, full listing of bond lengths and angles and observed and calculated structure factors are available as supplementary material from the Editor.

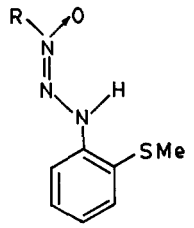
RESULTS AND DISCUSSION

Synthesis and structure

The ligands (3) used in the present work are HL^1 and HL^2 (general abbreviation HL). The brown crystalline $[NiL_2]$ complexes were prepared in high



R

HL^1 Me

HL^2 n-Pr

(3)

yields by reacting HL with nickel(II) acetate tetrahydrate in aqueous ethanol. Selected characterization data, shown in Table 2, will be considered further in a later section. For the present we note that the complexes are paramagnetic with two unpaired electrons. The characteristic N_3 and NO vibrations[16] of the chelate rings are present.

The X-ray structure of $[NiL^2_2]$ has been determined. A view of the molecule is shown in Fig. 1 and selected bond distances and angles are listed in Table 3. Each ligand acts in the tridentate meridional SNO fashion. The angle between the two

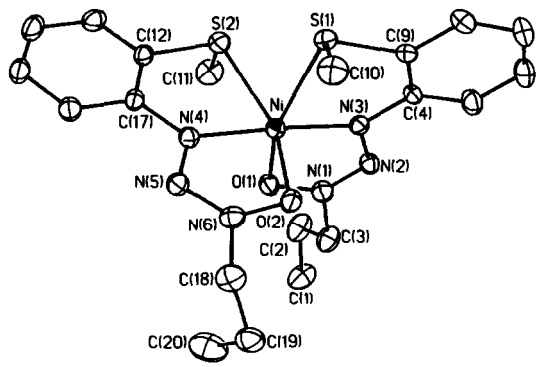


Fig. 1. Perspective view and atom labelling scheme of $[NiL^2_2]$. Atoms are shown as 50% thermal probability ellipsoids.

meridional planes formed by the two ligands is 91.3(2)°. The $Ni(SNO)_2$ coordination sphere is, however, severely distorted from octahedral geometry, the *trans* S—Ni—O angles being 157.7(1)° and 158.2(1)°. The interchelate N(3)—Ni—N(4) *trans* angle, 176.2(2)° is, however, close to 180°. The distortions are created mainly by the constraints of ligand chelation. All the five-membered chelate rings are good planes with mean deviations lying in the range 0.01–0.05 Å. The sulphur atoms are pyramidal and the non-bonded S···S length is 3.519(2) Å.

In nickel(II)–thioether complexes the Ni—S distances usually lie in the range 2.39–2.44 Å.[1,2,17] In a hexadentate thioether triazene-1-oxide complex

[a] Estimated standard deviations are given in parentheses.

of type **1** the Ni—S lengths, 2.494(4) and 2.526(3) Å, were found to lie outside the above range.[4] In the present complex the distances are even longer, 2.519(2) and 2.549(2) Å. There is thus a subtle weakening of the Ni—S(thioether) bond due to a diminished chelate effect on going from **1** (five chelate rings) to **2** (four chelate rings). To our knowledge the average Ni—S length in $[NiL^2_2]$ represents the longest nickel(II)–thioether bond reported so far.

In the triazene-1-oxide chelate rings the N(1)—N(2) and N(5)—N(6) distances are *ca* 0.03 Å shorter than the N(2)—N(3) and N(4)—N(5) distances, respectively. Thus, in the π-delocalization of the N_3O ligand frame, the triazene-1-oxide valence form —N(O)=N—$\bar{N}$— has higher weightage than the hydroxy triazene, —N($\bar{O}$)—N=N—. Consistent with this the Ni—N lengths are *ca* 0.07 Å shorter than the Ni—O lengths.

Spectra and metal redox

The highly distorted coordination sphere observed in the X-ray structure is directly reflected in the ligand field spectra of the complexes, Table 2. Thus, the octahedral ν_1 band is split into two components lying at *ca* 1400 and 1000 nm (Fig. 2).

The complexes are electroactive at platinum and a quasireversible cyclic voltammetric response corresponding to the metal redox couple of eq. (1) is observed (dichloromethane solution). The reduction potentials (Table 2) lie at the higher end of the range observed for thioether ligated nickel complexes.[1-3,18] The brown trivalent cation $[NiL_2]^+$ has been generated in solution coulometrically and such solutions display the same cyclic peaks as $[NiL_2]$, showing that no immediate decomposition occurs.

$$[Ni^{III}L_2]^+ + e \rightleftharpoons [Ni^{II}L_2] \quad (1)$$

The description of $[NiL_2]^+$ as a nickel(III) complex is corroborated by the frozen glass (77 K) EPR spectra of the electrooxidized solutions. The representative case of $[NiL^2_2]^+$ is displayed in Fig. 2. Three signals are observed at $g_1 = 2.221$, $g_2 = 2.083$ and $g_\parallel = 2.078$, the latter two overlapping seriously. To achieve consistency with the spectra of the hexadentate complexes,[4] we assign g_1 and g_2 to components of $g_\perp$ and g_3 to $g_\parallel$. The rhombic splitting is larger in the present tridentate complexes compared with the reported[4] hexadentate case ($g_\perp$ components of 2.199, 2.138, $g_\parallel = 2.035$). The $g_\perp > g_\parallel$ inequality corresponds to a $(d_{z^2})^1$ ground state.[19,20] The EPR parameters of $[NiL^1_2]^+$ with $g_\perp$ components of 2.217, 2.082 and $g_\parallel = 2.076$ are similar to those of $[NiL^2_2]^+$.

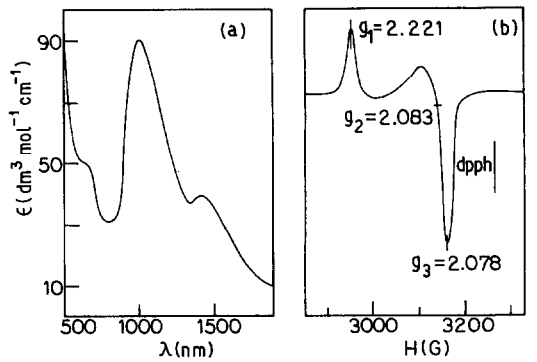

Fig. 2. (a) Electronic spectrum of $[NiL^2_2]$ in dichloromethane solution. (b) *X*-band (9.11 GHz) EPR spectrum of $[NIL^2_2]^+$ in frozen (77 K) dichloromethane.

CONCLUSIONS

Two tridentate ligands (HL) having thioether and triazene-1-oxide functions have afforded nickel(II) complexes of the type $[NiL_2]$. The octahedral ν_1 band shows a large splitting. Structure determination in one case has revealed the presence of a highly distorted $Ni(SNO)_2$ coordination sphere. The Ni—S (thioether) bonds are the longest observed so far among thioether complexes. The bonds are weaker in $[NiL_2]$ compared with those in complexes of hexadentate ligands bearing the same functions. Electrochemical oxidation of $[NiL_2]$ affords $[NiL_2]^+$, which has a $(d_{z^2})^1$ ground state with a large rhombic distortion.

Acknowledgements—Crystallography was performed in the National Single Crystal Diffractometer Facility established at the Department of Inorganic Chemistry, Indian Association for the Cultivation of Science, by the Department of Science and Technology, New Delhi. Financial support received from the Council of Scientific and Industrial Research is also acknowledged.

Abstract—Treatment of Ru(TMP)(CO) with *m*-CPBA in CH_2Cl_2/EtOH afforded Ru(TMP)$(OH)_2$, isolated as air-stable violet crystals. Ru(TMP)$(OH)_2$ is paramagnetic (μ_{eff} *ca* 2.7 B.M.) and displays broad ^{1}H NMR signals with paramagnetic isotropic shifts. The IR spectrum shows a band at 760 cm^{-1} assignable to the Ru—O stretch. Ru(TMP)$(OH)_2$ is capable of catalysing aerobic epoxidation of alkenes under mild conditions.

Oxo complexes of ruthenium porphyrins have received much attention because of their resemblance to active species of mono-oxygenase enzymes[1] and their applications in organic oxidations.[2–4] Recently, Groves and co-workers reported that Ru(TMP)O_2 (TMP = tetramesitylporphyrin dianion) is able to catalyse the aerobic epoxidation of alkenes under mild conditions. The suggested mechanism involves the intermediacy of an unstable oxo-ruthenium(IV) species, which disproportionates to dioxo-ruthenium(VI) and ruthenium(II).[2] The Ru(TMP)O intermediate, which was characterized by ^{1}H NMR spectroscopy, could be obtained by reaction of Ru(TMP)O_2 with 1 equivalent of PPh_3 or aerial oxidation of Ru(TMP)$(MeCN)_2$.[2b] However, attempts to isolate pure Ru(TMP)O have so far been unsuccessful. In a previous paper, we described the synthesis of Ru(OEP)O(EtOH) (OEP = octaethylporphyrin dianion) which was, however, incapable of catalysing the aerobic oxidation of alkenes due to rapid dimerization in non-polar solvents. In our continuing effort to develop metal catalysts for organic oxidation we herein report the synthesis and reactivity of Ru(TMP)$(OH)_2$, which could be a key intermediate in the Ru(TMP)-based oxidations.

EXPERIMENTAL

Ru(TMP)CO was prepared according to the literature method.[1b] *m*-Chloroperoxybenzoic acid (*m*-CPBA) was purchased from Merck and used as received. Tetrakis(2,6-dichlorophenyl)porphyrin, H_2(2,6Cl_2TPP), was synthesized by a modified procedure of Rothemund's method using 1-methyl-2-pyrrolidinone instead of pyridine.[4] All solvents used were of analytical grade. ^{1}H NMR spectra were obtained on a Jeol EX 270 NMR spectrometer and chemical shifts (δ, in ppm) were reported referenced to Me_4Si. IR spectra (Nujol) were obtained on a Nicolet Model 20 FXC FT-IR spectrometer. Reduction potential was determined by cyclic voltammetry using a Princeton PAR 173/179 potentiostat equipped with a model 175 universal pro-

grammer. A glassy carbon electrode was used as the working electrode and the reduction potential was reported referenced to the ferrocenium/ferrocene couple.

Preparation of Ru(TMP)$(OH)_2$ (**1**)

To a CH_2Cl_2/EtOH (1:2, 25 cm^3) solution of Ru(TMP)CO (50 mg) was added *m*-CPBA (50 mg). The resulting solution was filtered and left to stand at room temperature overnight. The dark violet crystals formed were collected and washed with a small amount of cold ethanol (yield: 25 mg). Concentration of the filtrate gave a second crop of product, which was contaminated with some unreacted *m*-CPBA. ^1H NMR (CD_2Cl_2/CD_3OD, 1:1): 2.62 (*p*-Me), 3.09 (*o*-Me), 7.54 (*meta*-phenyl), −30.58 (pyrrolic); all broad singlets. UV–vis (CH_2Cl_2/EtOH), λ_{max}/nm ($\varepsilon/10^3\ M^{-1}\ cm^{-1}$): 660 (1.29), 600 sh (2.66), 522 (9.33), 408 (93.3), 320 (15.8).

Preparation of Ru(2,6-Cl_2TPP)CO(EtOH) (**2**)

A mixture of $Ru_3(CO)_{12}$ (100 mg), H_2(2,6-Cl_2-TPP) (100 mg) and naphthalene was heated at 220°C under a nitrogen atmosphere for 72 h. After cooling to room temperature the solidified melt was dissolved in toluene and loaded onto a column of neutral alumina. Naphthalene, unreacted $Ru_3(CO)_{12}$ and free porphyrin were eluted with toluene. The ruthenium porphyrin was eluted with $CHCl_3$/EtOH (yield: 20%). ^1H NMR ($CDCl_3$): −1.07 (s br, 2H, H_3CH_2OH), 0.93 (s br, 3H, CH_3CH_2OH), 7.73 (m, 12H, *para*- and *meta*-phenyl), 8.44 (s, 8H, pyrrolic). UV–vis (CH_2Cl_2), λ_{max} (nm) ($\varepsilon/10^3\ M^{-1}\ cm^{-1}$): 410 (252), 530 (20), 558 sh (4.6).

Preparation of Ru(2,6-Cl_2TPP)O_2 (**3**)

To a solution of **2** (50 mg) in CH_2Cl_2 (50 cm^3) at room temperature was added *m*-CPBA (50 mg). After stirring at room temperature for 3 min the resulting solution was loaded onto a column of neutral alumina. The purple product was eluted with CH_2Cl_2 and was recrystallized from CH_2Cl_2/hexane (yield: 40%). ^1H NMR ($CDCl_3$): 7.81 (m, 12H, *para*- and *meta*-phenyl), 8.88 (s, 8H, pyrrolic). UV–vis (CH_2Cl_2), λ_{max} (nm) ($\varepsilon/10^3\ M^{-1}\ cm^{-1}$): 420 (309), 511 (14.4), 566 sh (4.0).

Aerobic epoxidation with ruthenium porphyrins

Typically a mixture of ruthenium porphyrin (3 mg) and norbornene (0.3 cm^3) in benzene (5 cm^3) was stirred under oxygen (4 bar) in an autoclave. After reaction, the organic products were analysed and quantified by gas chromatography using the internal standard method.

RESULTS AND DISCUSSION

Oxidation of Ru(TMP)CO with excess *m*-CPBA in CH_2Cl_2/EtOH afforded Ru(TMP)$(OH)_2$ (**1**), isolated in its pure form. It seems likely that the oxidation of Ru(TMP)CO by *m*-CPBA initially gave Ru(TMP)O_2, which is soluble in CH_2Cl_2 and is gradually reduced by EtOH to give Ru(TMP)$(OH)_2$ (Scheme 1).

Compound **1** was found to be unstable in non-polar solvents such as CH_2Cl_2, in which it is air-oxidized to diamagnetic Ru(TMP)O_2, as indicated by ^1H NMR spectroscopy. However, in the presence of alcohol aerobic oxidation of **1** is completely inhibited presumably because the alcohol molecule blocks the vacant coordination site of Ru^{IV}-TMP (see later section), which is essential for aerobic oxidation of the complex. It might be noted that the dimerization of the related Ru(OEP)O(EtOH) complex can also be inhibited by alcohol.[3a] Therefore, the following studies and characterization of **1** were performed in the presence of alcohol.

The measured magnetic moment of *ca* 2.7 B.M. (by Evans' method[5] in $CDCl_3/CD_3OD$) for **1** is close to the spin-only value for two unpaired electrons, suggesting an $S = 1$ ground-state configuration. Similar magnetic moments have been found for other related paramagnetic ruthenium(IV) porphyrins with π-donating axial ligands such as O^{2-}, Br^- and Cl^-. Ru(porph)R_2 (porph = OEP, TPP; R = Me, Ph) are, however, diamagnetic.[6] The ^1H NMR spectrum of **1** in CD_2Cl_2/CD_3OD shown in Fig. 1 consists of four paramagnetically shifted broad resonance signals assignable to the *para*- and *ortho*-methyl and *meta* protons of the *meso*-phenyl groups and the pyrrolic protons. Peaks at *ca* 1.2 (t) and 3.7 (q) ppm due to unligated EtOH molecules were also found. The observation of a single *ortho*-methyl resonance (down to −50°C) is indicative of the D_{4h} symmetry of the molecule. Formulation of the prepared complex to be Ru(TMP)O(EtOH) or Ru(TMP)O(OH_2) is therefore not preferred. According to our previous work Os(porph)$(OEt)_2$ (porph = OEP, TPP) show paramagnetically shifted ^1H NMR signals for the coordinated ethoxy ligands.[7] No signals due

$$\text{Ru(TMP)CO} + 2m\text{-CPBA} \longrightarrow \text{Ru(TMP)O}_2$$

$$\text{Ru(TMP)O}_2 \xrightarrow{\text{EtOH, H}_2\text{O}} \text{Ru(TMP)(OH)}_2$$

Scheme 1.

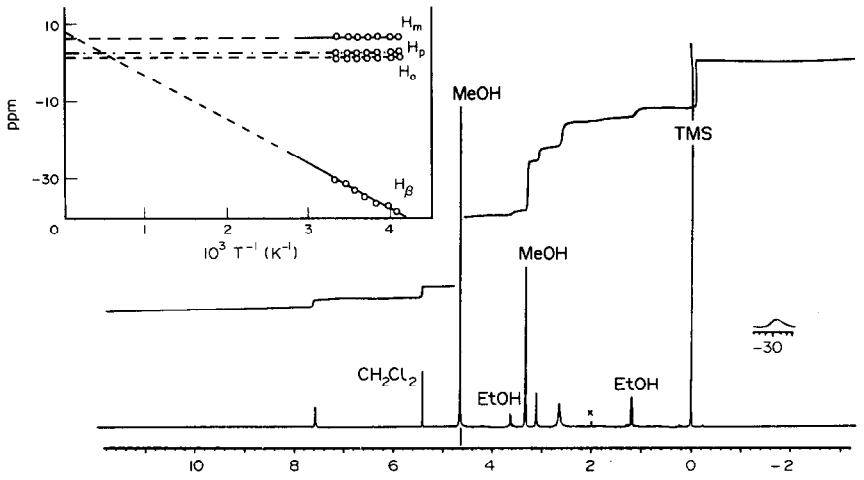

Fig. 1. ^{1}H NMR spectrum of Ru(TMP)$(OH)_2$ in CD_2Cl_2/CD_3OD.

to the coordinated ethoxy group have been found for **1**, thus excluding the possibility of the prepared complex to be Ru(TMP)(OEt)(OH) or Ru(TMP)$(OEt)_2$.

Similar to Ru(TMP)O,[2b] the paramagnetic isotropic shifts for **1** vary inversely with temperature from +50 to −40°C (inset of Fig. 1). The extrapolated intercepts to $T^{-1} = 0$ for all of the resonances are very close to the respective positions expected for diamagnetic TMP complexes. Since there is no evidence for anti-ferromagnetic coupling, the possibility of a dimeric structure for **1** is ruled out. The adherence to the Curie relationship is indicative of the existence of a single spin state throughout the temperature range. The upfield pyrrolic shift (at *ca* −30 ppm), which is typical for paramagnetic ruthenium(IV) porphyrins, suggests that the isotropic shift mainly results from π-delocalization.[6b]

The IR spectrum of **1** does not show any intense band around the 800 cm^{-1} region,[2b] suggesting that no oxo group is present. A new band which is absent in the starting Ru(TMP)CO appears at 760 cm^{-1}. This band is assigned to the Ru—OH stretch. In accordance with this assignment this band shifts to 726 cm^{-1} after isotopic labelling of the compound with ^{18}O.[8] The oxidation-state marker[9] at 1011 cm^{-1} is consistent with the IV oxidation state.[2b,3a]

In order to unambiguously confirm the structure of **1** an X-ray diffraction study was performed. The result indicated that **1** is a Ru^{IV}-TMP complex with an average Ru—O bond distance of 1.929(9) Å.[10] Unfortunately, we have not been able to solve the crystal structure completely due to disorder of the two axial ligands and solvent molecules.

The cyclic voltammogram of **1** in CH_2Cl_2/MeOH (1 : 1) shows a quasi-reversible couple at −0.8 V and an irreversible oxidation wave at 0.80 V vs $Cp_2Fe^{+/0}$. The reduction couple was tentatively assigned to the metal-centred $Ru^{IV}/^{III}$ couple.

Aerobic epoxidation with **1**

Compound **1** is an active catalyst for aerobic epoxidation of alkenes under mild conditions. For example, *ca* 20 equivalents of *exo*-norbornene oxide (determined by GLC) along with an unidentified paramagnetic ruthenium compound were obtained when a benzene solution of **1** and norbornene was stirred at room temperature under 4 bars of oxygen for 35 min (entry 1, Table 1). Consistent with the observation by Groves and co-workers,[2a] the yield of epoxide is rather insensitive to oxygen pressure. It is noteworthy that Ru(TMP)$(OH)_2$ is a more efficient aerobic epoxidation catalyst than Ru(TMP)O_2, although the overall yields for both systems are more or less identical.

We believe that Ru(TMP)O, which is equilibrium with **1**, is the active intermediate for the catalytic aerobic epoxidation. In fact, the conversion of $Ru^{IV}(OH)_2$ to Ru^{IV}=O (possibly catalysed by water) is not without precedence. Previously, we have established a similar equilibrium between $Ru^{IV}(OH)_2$ and $Ru^{IV}O(OH_2)$ for a cationic ruthenium(IV) compound of a non-porphyrinic macrocycle.[11] Of note, recrystallization of [Ru{3,4,5-$(MeO)_3$TPP}$(OH)_2$] from CH_2Cl_2/ETOH solution in air led to the isolation of a structurally characterized ruthenium(III)-aquo(hydroxo) compound, Ru[3,4,5-$(MeO)_3$TPP](OH)(OH_2) [3,4,5-$(MeO)_3$TPP = tetrakis(3,4,5-trimethoxyphenyl)porphyrin dianion].[12] This indicates that oxo and hydroxo ligands of ruthenium porphyrins can be protonated and deprotonated quite easily and exchange rapidly with water in solvent.

Table 1. Aerobic epoxidation of alkenes by ruthenium porphyrins[a]

Catalyst	Reaction time[b]	Substrate	Product (turnover)[c]
1. $Ru(TMP)(OH)_2$	35 min	Norbornene	*Exo*-norbornene oxide (20)
2. $Ru(TMP)O_2$	2.5 h	Norbornene	*Exo*-norbornene oxide (22)
3. $Ru(2,6\text{-}Cl_2\text{-}TPP)O_2$	6 h	Norbornene	*Exo*-norbornene oxide (19)

[a] Reaction conditions: ruthenium porphyrin (3 mg) and norbornene (300 mg) were stirred in benzene (5 cm^3) at room temperature.

[b] Time required for completion of reaction (monitored by GLC).

[c] Turnover based on ruthenium porphyrins used.

In an attempt to develop a long-lived and robust aerobic oxidation catalyst we have also investigated the aerobic oxidation of alkenes catalysed by $Ru(2,6\text{-}Cl_2TPP)O_2$ [2,6-Cl_2TPP = tetrakis(2,6-dichlorophenyl)porphyrin dianion] (entry 3, Table 1). Although the overall turnover of *ca* 19 is similar to that found for the TMP analogues, the rate of aerobic epoxidation by $Ru(2,6\text{-}Cl_2TPP)O_2$ is rather slow. It seems likely that the ruthenium(II) complex of 2,6-Cl_2TPP is so electron-deficient that it is reluctant to undergo aerobic oxidation to dioxo-ruthenium(VI). Therefore, two stereoelectronic factors seem to be critical to aerobic epoxidation catalysed by ruthenium porphyrins. First, the porphyrin must be sterically encumbered so as to prevent bimolecular reactions such as μ-oxo formation. Previously, we have shown that the oxo-ruthenium(IV) compounds of non-sterically demanding OEP are incapable of aerobic oxidation due to rapid dimerization of oxo-ruthenium(IV). Second, the porphyrin must be electron-rich so that aerobic oxidation to dioxo-ruthenium(VI) is energetically favourable. The delicate balance between these two factors in the TMP system makes Ru(TMP) a unique catalyst for aerobic epoxidation.

In summary, we have successfully isolated a monomeric ruthenium(IV)-dihydroxo compound of tetramesitylporphyrin, which catalyses aerobic epoxidation of alkenes via $Ru(TMP)O_2$. The observation of direct interaction of dioxygen with ruthenium(IV) porphyrin provides evidence for a new mechanism for the Ru(TMP)-based aerobic oxidation that involves interconversion of oxo-ruthenium(IV) and dioxo-ruthenium(VI).

THE SYNTHESIS AND CRYSTAL STRUCTURE OF $[CrF(NH_3)_5]ZnCl_4$

DONALD A. HOUSE*

Chemistry Department, University of Canterbury, Christchurch, New Zealand

and

VICKIE McKEE*

Chemistry Department, Queen's University, Belfast BT9 5AG, Northern Ireland

(*Received* 6 *April* 1993; *accepted* 2 *June* 1993)

Abstract—Salts of $[CrF(NH_3)_5]X_2$ (X = NO_3, $1/2ZnCl_4$) are readily prepared from the reaction between $[Cr(NCO)(NH_3)_5](NO_3)_2$ and 40% HF. The structure of $[CrF(NH_3)_5][ZnCl_4]$ has been determined by single-crystal X-ray analysis.

We are currently interested in the trends observed for Cr—X (X = halide ion) bond lengths in chromium(III) ammine and polyamine complexes. In particular, the observed trends in Cr—Cl bond lengths in $[CrCl(RNH_2)_5]^{2+}$ (R = H, Me, Et) have been correlated with acid hydrolysis rates[1,2] and there is much current debate on the mechanism of the substitution.[3]

Although salts of $[CrF(NH_3)_5]^{2+}$ have been known for many years, the synthetic route via fluoride anation of $[Cr(NH_3)_5(OH_2)](NO_3)_3 \cdot NH_4NO_3$[4,5] is often poorly described[6] and gives variable yields.[7,8]

We describe here a simple, high yield preparation of the $[CrF(NH_3)_5]^{2+}$ cation and the single-crystal X-ray structural analysis of $[CrF(NH_3)_5]ZnCl_4$.

EXPERIMENTAL

$[Cr(NCO)(NH_3)_5](NO_3)_2$ was synthesized by the method of Schmidtke and Schönherr.[9,10] We obtained a 60% yield, with equal weights of urea and $Cr(NO_3)_3 \cdot 9H_2O$ (15 g each) in an aluminium foil covered beaker (250 cm^3) and an oven temperature of 135–140°C for 42 h. A green residue was separated from the orange crystals by washing the solid with warm (40°C) 50:50 ethanol:water (50 cm^3). Decantation of this wash solution gave the crude product, quite suitable for the next step, without further purification.

Fluoropentaamminechromium(III) *nitrate*, $[CrF(NH_3)_5](NO_3)_2$

The orange $[Cr(NCO)(NH_3)_5](NO_3)_2$ (5 g, crude) was suspended in 40% HF (20 cm^3) in a plastic beaker and the mixture was heated at 80°C (water bath) for *ca* 10 min, until all effervescence ceased and a clear, wine-red solution was obtained. **CAUTION:** Use gloves and an efficient fume hood. HF(g) can cause serious burns on contact with wet skin. Solid $NaNO_3$ (3 g) was added and ethanol (20 cm^3) added dropwise to the hot solution giving a pink precipitate. The product was collected from the ice cooled solution and recrystallized from water (25 cm^3, 80°C) by addition of $NaNO_3$ (3 g) and ethanol (25 cm^3), as above. Slow cooling to room temperature and then in ice gave 4.2 g (92%) of $[CrF(NH_3)_5](NO_3)_2$ as orange needles, which were washed with ethanol and air dried.

Fluoropentaammine chromium(III) *tetrachlorozincate*(II), $[CrF(NH_3)_5]ZnCl_4$

The nitrate salt (0.2 g) was dissolved in 0.01 M HCl (10 cm^3) at room temperature and a solution of $ZnCl_2$ (0.5 g) in HCl (5 cm^3, 1 M) was added.

* Authors to whom correspondence should be addressed.

An orange–red microcrystalline precipitate formed immediately (0.24 g, 90%) and this was collected, washed with ethanol and air dried. This solid was dissolved in water (10 cm^3) and X-ray quality, orange–red crystals formed as the solution evaporated at room temperature (3 days).

Fluoropentaamminecobalt(III) *tetrachlorozincate*(II), $[CoF(NH_3)_5]ZnCl_4$

Fluoropentaamminecobalt(III) nitrate (1 g)[11] was dissolved in warm (60°C) 0.01 M HCl (50 cm^3 and saturated $ZnCl_2$ solution (3 cm^3) was added. Sparkling, rose-red, crystalline platelets deposited from the warm solution and these were collected after 14 h at room temperature.

Visible absorption spectral data in 0.01 M $HClO_4$: λ (nm), [ε, (M^{-1} cm^{-1})]: 352 max [38.9], 402 min [7.7], 512 max [45.6].

The X-ray powder diffraction patterns (Phillips PW1729) of $[CoF(NH_3)_5]ZnCl_4$ and $[CrF(NH_3)_5]ZnCl_4$ show that these compounds are isomorphous. Positions ($2\theta°$) for several of the major peaks are, Co(Cr, Cr_{calc}): 10.35 (10.43, *10.36*), 15.95 (15.90, *15.81*), 20.88 (20.81, *20.81*), 21.79 (21.68, *21.64*), 27.02 (26.87, *26.87*), 29.07 (28.79, *28.74*), 31.56 (31.35, *31.94*), 44.44 (44.68, *44.10*). Numbers in italics are those predicted[11a] from the crystallographic parameters obtained for $[CrF(NH_3)_5]ZnCl_4$.

X-ray structure determination (Table 1)

X-ray diffraction data for an orange–red crystal of $[CrF(NH_3)_5]ZnCl_4$ were collected under the conditions described in Table 1. The space group was determined by systematic absences and confirmed by the structure analysis. The non-unique data were averaged and the resulting data were corrected for Lorentz polarization, anomalous dispersion, check reflection fluctuations and adsorption effects (Table 1).

The structure was solved by direct methods. In the final cycles of refinement, and in the structure factor calculations (supplementary tables), hydrogen atoms were included in idealized calculated positions (supplementary tables). Bond lengths and angles are listed in Table 2. Tables of supplementary data have been deposited with the Editor and are available from the authors on request. Coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

$[Cr(NCO)(NH_3)_5](NO_3)_2$ is easily prepared by thermal decomposition of urea in the presence of $Cr(NO_3)_3 \cdot 9H_2O$.[9,10] This has proved to be a most useful precursor for several $[CrX(NH_3)_5]^{n+}$ complexes, e.g. X = Cl or NH_3[12] and we have now extended the series to include X = F. In this regard, it should be noted that the decomposition of $[Cr(NCO)(NH_3)_5](NO_3)_2$ in > 6 M HCl gives $[CrCl(NH_3)_5]Cl_2$ and not $[CrCl(NH_3)_4(OH_2)]Cl_2$ as previously reported.[12]

The nature of the product resulting from the hydrolysis of the coordinated cyanate is markedly acid dependent as dilute acids give mainly $[Cr(NH_3)_6]^{3+}$,[9,12] while higher acid concentrations result in complete cyanate loss and anion anation, possibly via $[Cr(NH_3)_5(OH_2)]^{3+}$. We cannot, however, completely eliminate some sort of associative or strong ion-pair pathway in the presence of such high anion concentrations. This is not the first time that acid dependent products have been observed in chromium(III) ammine chemistry, as $[Cr(ox)(NH_3)_4]^+$ forms $[Cr(ox)(NH_3)_3(OH_2)]^+$ in

dilute acid and $[CrX(NH_3)_4(OH_2)]X_2$ (X = Cl, Br) in > 6 M HX.[8,13,14]

Although the Cr—F bond distance[15] has been measured in a number of fluorochromium(III) amine complexes (Table 3) this is the first time, to our knowledge, that a salt of fluoropentaamminechromium(III) has been structurally characterized by a single-crystal X-ray analysis.

The salt consists of octahedral $[CrF(NH_3)_5]^{2+}$ cations and tetrahedral $ZnCl_4^{2-}$ anions (Figs 1 and 2). The mean Cr—NH_3 distance, 2.081(19) Å, lies within the range observed for other $[CrX(NH_3)_5]^{n+}$ complexes, e.g. 2.074(4) Å in $[CrCl(NH_3)_5]Cl_2$

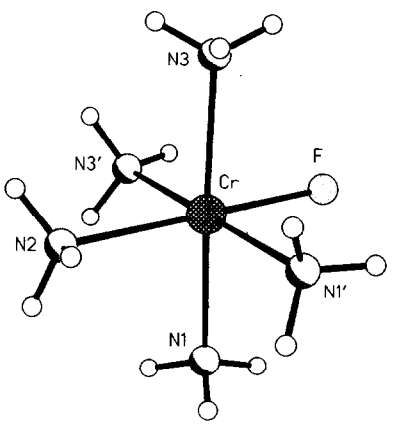

Fig. 1. A view of the $CrF(NH_3)_5^{2+}$ cation showing the numbering scheme used in Tables 2 and 3.

Table 4. M—X distances (Å) in $M^{III}X(NH_2R)_5^{2+}$ complexes (X = halide ion)

Complex	M—X	Ref.
$[CrF(NH_3)_5]ZnCl_4$	1.863(4)	This work

$[OsCl(NH_3)_5]Cl_2$	2.369(2)	49

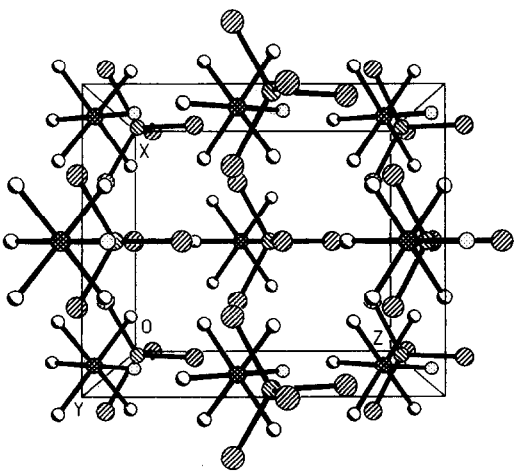

Fig. 2. A packing diagram for $[CrF(NH_3)_5]ZnCl_4$.

(Table 4) or from 2.0592(57) to 2.080(4) Å in various salts of $[Cr(NH_3)_6]^{3+}$.[16] There may be a hint of a solid-state *trans* effect insofar as the Cr—N(2) distance (Fig. 1) is long at 2.099(6) Å, but there are other *cis*-Cr—NH_3 distances of 2.093(4) Å. The Cr—F distance of 1.863(4) Å is one of the shortest observed for a fluoro ligand *trans* to a coordinated nitrogen donor (Table 3), but is similar to that found in *trans*-$[CrF(NH_3)(en)_2]^{2+}$ [Cr—F = 1.862(4)]. Bond lengths and angles in the $ZnCl_4^{2-}$ anion (Fig. 2) are quite within the range observed for other tetrachlorozincate(II) salts with complex ion cations.[17–29]

In view of the current debate[1–3] with regard to

[a] Rate law is $k_{obs} = k_1k_2[H^+]$.
[b] In *ca* 0.1 M $HClO_4$.
[c] The sign of $\Delta S^{\#}$ is correctly cited in ref. 57.
[d] k_{obs} in 2.0 M $HClO_4$, ref. 59.
[e] k_{obs} in 1.0 M $HClO_4$, ref. 59.

the relationship between $MX(N_5)^{2+}$ bond length and the mechanism of M—X solvolysis, we have attempted to correlate Cr—F bond distances with reactivity (Table 5). The analysis is complicated by the paucity of data for Cr—F solvolysis rates and the fact that Cr—F solvolysis is an acid-catalysed process.

The normal rate law is $k_{obs} = k_1 + k_2[H^+]$ and plots of k_{obs} vs $[H^+]$ are used to determine k_1 (Table 5) from the intercept. Unfortunately, these systems are difficult to work with (two detailed studies on the solvolysis of $[CrF(NH_3)_5]^{2+}$ give conflicting results at high temperatures[30,31]) as Cr—N bond rupture is competitive with Cr—F bond rupture.[32–34]

Despite the lack of comparative kinetic information, it is evident from the data in Table 5 and the literature[35] that *trans*-difluorochromium(III) systems are very inert to solvolytic fluoride loss; much more so than their *cis*-difluoro analogues. This difference in kinetic lability is not reflected in any pattern of Cr—F bond length in Table 5, as Cr—F distances in *cis* and *trans*-isomers seem to be randomly distributed throughout.

(*Received* 6 *April* 1993; *accepted* 2 *June* 1993)

Abstract—A number of new ruthenium(II) complexes, $[Ru(PPh_3)_2L_2]$ (L = monoanions of Schiff bases formed from 2,3-dihydroxybenzaldehyde, 3,5-dibromosalicylaldehyde and salicylaldehyde with aniline or its *p*-substituents), have been prepared. They were characterized by spectroscopic techniques and investigated by cyclic voltammetry. The effective catalytic oxidation of alcohols by these complexes in the presence of N-methylmorpholine-N-oxide or molecular oxygen gas as co-oxidants is reported.

Reaction of dichlorotris(triphenylphosphine) ruthenium(II) with the sodium salts of various Schiff bases, L, derived from aliphatic dianions and β-diketones or aromatic aldehydes gives the octahedral species *trans*-$[Ru^{II}(PPh_3)_nL_m]$ (n = 2, m = 1, 2).[1] It has been briefly noted[2] that the bidentate salicylaldimine Schiff bases *o*-$HOC_6H_4CH{=}NR$ [R = Ph, Bz, *o*- or *p*-$Y \cdot C_6H_4$ (Y = Me, Cl, Br or NO_2)] react with $[RuCl_2(PPh_3)_3]$ under anaerobic conditions and in the presence of triethylamine to give the complexes $[Ru^{II}(PPh_3)_2(OC_6H_4CH{=}NR)_2]$. Recently,[3] the complexes $[Ru^{III}X_2(AsPh_3)_2(HL)]$ (X = Cl, Br; H_2L = Schiff base ligand formed from 2,3-dihydroxybenzaldehyde and aniline or its *o*- and *p*-substituted derivatives, H_2R-Phb) have been prepared and characterized and their use as catalytic oxidants of both alcohols and 3,5-di(tert-butyl)catechol has also been studied.

In continuation of work on catechol Schiff base ligands, H_2L (H_2R-Phb),[3] we now report the preparation of the complexes $[Ru^{II}(PPh_3)_2(HL)_2]$ and also of other Schiff bases derived from 3,5-dibromosalicylaldehyde (HR-BPhSal) or salicylaldehyde (HR-PhSal; R = H, *p*-Me, *p*-MeO, *p*-Cl, *p*-Br or *p*-NO_2). We also report their spectroscopic and electrochemical behaviour and study the catalytic oxidation of alcohols by such complexes in the presence of N-methylmorpholine-N-oxide (NMO) or dioxygen as co-oxidants, since $[RuCl_2(PPh_3)_3]$[4] and $[Ru^{II}Cl_2(PPh_3)_2L]$[5] (L = O,N-neutral donor ligand) have been previously used in this way.

RESULTS AND DISCUSSION

Schiff base ligands are prepared by condensation of aniline (or *p*-substituted aniline) with the corresponding aldehyde in ethanol. Salicylaldimine Schiff bases, HR-PhSal (R = H, *p*-Me, *p*-MeO, *p*-Cl, *p*-Br and *p*-NO_2) were reacted under nitrogen gas with $[RuCl_2(PPh_3)_3]$ in refluxing degassed benzene and in the presence of Et_3N with a 1 : 3 metal : ligand molar ratio. Brown or red solutions were formed during 1–2 h. Evaporation of the solution to low bulk under nitrogen, followed by the addition of degassed methanol gave red–brown

* Author to whom correspondence should be addressed.

microcrystals of the corresponding complexes, which were then thoroughly washed with methanol to remove Et_3NHCl salt. The complexes of the salicylaldimine Schiff bases derived from *p*-methoxyaniline and *p*-nitroaniline were formed during reaction in refluxing benzene as brown or green compounds, respectively. Analytical data (Table 1) indicate that the formulae of these complexes are identical with previously mentioned[2] species, $[Ru(PPh_3)_2(R\text{-}PhSal)_2]$. The complexes of Schiff bases derived from 3,5-dibromosalicylaldehyde (HR-BPhSal) or 2,3-dihydroxybenzaldehyde (H_2R-Phb) were similarly prepared and the analyses are also consistent with the formulae $[Ru(PPh_3)_2(R\text{-}BPhSal)_2]$ and $[Ru(PPh_3)_2(HR\text{-}Phb)_2]$. The tropolonato complex $[Ru^{II}(PPh_3)_2(trop)_2]$ (Htrop- = tropolone, 2-hydroxy-2,4,6-cycloheptatrienone) prepared previously[6] from $[RuH_2(PPh_3)_4]$ is now obtained easily by the same procedure. Most of the complexes are fairly soluble in CH_2Cl_2 and their molar conductivities in this solvent are very low; the complexes are found to be diamagnetic at room temperature.

Spectroscopic properties

The IR spectra of the Schiff bases HR-PhSal and HR-BPhSal show boad bands near 3450 cm^{-1} and strong bands near 1620 cm^{-1}, attributed to ν(O—H) and ν(C=N) vibrations, respectively. The former band was found to disappear, while the latter was shifted to lower wave numbers (10–40 cm^{-1}) in the corresponding complexes. The catecholato Schiff base ligands, H_2R-Phb, show two medium bands near 3400 and 3300 cm^{-1}, due to the ν(O—H) vibrations of the free and hydrogen bonded

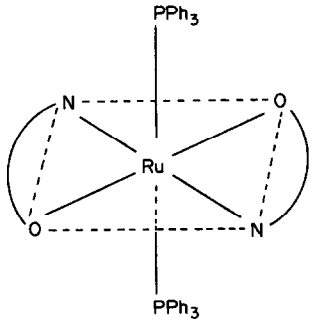
[a] Underlined data refer to the corresponding free Schiff base ligands.

hydroxyl groups,[3] respectively. The lower wave number ν(O—H) vibration disappears in the present complexes as do those found for $[Ru^{III}X_2(AsPh_3)_2(HR\text{-}Phb)]$ (X = Cl, Br).[3] The ν(C=N) vibration is also shifted to lower wave numbers, which is contrary to the case for higher oxidation state metal complexes, $[RuX_2(AsPh_3)_2(HR\text{-}Phb)]$ and $[M^{VI}O_2(HR\text{-}Phb)_2]$ (M = Mo, U).[3] This is due to d_π–p_π back-bonding between ruthenum-d_π and azomethine-p_{π^*} orbitals, since ruthenium(II) is well known to be a strong π-donor.[7] The band observed near 1365 cm^{-1} in the free ligand (H_2R-Phb) assigned to δ(OH)[3] does appear in the corresponding ruthenium(II) complexes, while its disappearance was noted in catecholato[8–10] and naphthalene-2,3-diolato[11] complexes. Distinct bands are also observed in the complexes $[Ru(PPh_3)_2(HR\text{-}Phb)_2]$ and lie in the range 1220–1265 cm^{-1}, consistent with the phenolic ν(C—O) vibration.[12,13] This confirms the participation of the azomethine nitrogen and C(2) hydroxyl oxygen atoms in coordination. Also all of the complexes show bands due to coordinated triphenylphosphine and there are no bands attributed to ν(Ru—Cl) modes around 300 cm^{-1}. The most important IR bands are listed in Table 1; the deep colour of the complexes makes them unsuitable for Raman studies.

The UV–vis spectra of the ruthenium(II) complexes were obtained in CH_2Cl_2 (Table 1) in the concentration range 10^{-3}–10^{-5} M at ambient temperature. A broad band near 700 nm of low molar absorptivity (ε = 300 M^{-1} cm^{-1}) is observed in some complexes within the concentrations used. This band is probably assigned to *d–d* transitions of ruthenium(II), as expected, since a low intensity band near 600 nm characteristic of ruthenum(III) was reported in similar complexes.[14–18] For the green ruthenium complexes derived from the catecholato Schiff base ligands, $[Ru(PPh_3)_2(HR\text{-}Phb)_2]$, an intense band around 700 nm is found, due to ligand(π)–metal(*d*) charge-transfer while the weaker ligand field may be obscured by such transitions.[14–16,19] The peak near 370 nm is likely to be due to metal (*d*)–ligand(π^*) charge transfer.[3,20–24] The bands or shoulders below 300 nm are of the interligand π–π^* type.[3,19,23,24]

The ^{1}H NMR for $[Ru(PPh_3)_2(p\text{-}ClPhSal)_2]$ in $CDCl_3$ showed a multiplet at δ 6.75–7.25 ppm, attributed both to protons of triphenylphosphine and two protons of the coordinated Schiff base ligand; the remaining protons of the latter, including those of the azomethine group, appear as a broad doublet at δ 7.45–7.75 ppm. The proton resonances of the same ligand (*p*-ClPhSal) have been found in the same shift range as for $[Ru^{II}Cl(\eta^6\text{-}p\text{-cymene})(p\text{-}ClPhSal)]$.[25] The ^{31}P NMR spectra[26] of the complexes $[Ru^{II}(PPh_3)_2(R\text{-}PhSal)_2]$ prepared similarly by our method showed a singlet resonance at δ 31–32 ppm, indicating a *trans*-phosphine geometry. A recent study on the X-ray crystal structure of the complex $[Ru^{II}(PPh_3)_2(o\text{-}Cl_4SQ)_2]$ [o-Cl_4SQ = tetrachloro-*o*-benzosemiquinonate(−1)] revealed a *trans*-geometry of the phosphine ligands.[7] On the basis of spectroscopic data and by analogy with related complexes[1,2,26] we tentatively assign the structure shown below for these ruthenium(II) complexes.



O – N = Schiff base anion (−1)

Redox properties

The electrochemistry of the complex was investigated by cyclic voltammetry. Voltammetric data vs the silver electrode for 0.1 M $(Bu^n_4N)PF_6$–CH_2Cl_2 solution (containing *ca* 10^{-3} M of the complex) are presented in Table 2. The voltammograms of the complexes $[Ru(PPh_3)_2(R\text{-}PhSal)_2]$ do not show any reduction wave (or peak) at negative potentials, but do show two oxidation waves and the current height of the second wave is twice that of the first wave which is reversible (ΔE = 60–80 mV), close to that anticipated for a Nernstian one-electron process [ΔE = 59 mV).[27] The second wave was quasi-reversible (ΔE = 140–160 mV) and is comparable to that observed for $[Ru^{III}Br_2(AsPh_3)_2(8\text{-}hq)]$ (H8-hq = 8-hydroxyquinoline).[5] These two oxidation waves probably correspond to Ru^{II}/Ru^{III} and Ru^{III}/Ru^{IV} oxidation, respectively. The complexes $[Ru(PPh_3)_2(R\text{-}BPhSal)_2]$ show similar voltammograms, but the two oxidation waves have similar current height, presumably due to Ru^{II}/Ru^{III} and Ru^{III}/Ru^{IV} oxidations, respectively. An irreversible oxidation peak at a positive potential due to Ru^{II}/Ru^{III} oxidation was found for $[Ru^{II}(PPh_3)_2(HR\text{-}Phb)_2]$, similar to those observed for $[Ru^{II}Cl_2(HA)]$ (HA = arylazo-oxime),[28] $[Ru^{II}Cl_2(PPh_3)_2L]$ (L = phenylacetic hydrazide)[5] and $[Ru^{II}H(terpy)(PPh_3)_2](Sal)$ [terpy = 2,2′,2″-terpyridine; Sal = salicylate anion(−1)].[29]

For scan rates (SR) between 20 and 100 $mV\ s^{-1}$ the ratio $i_p/(SR)^{1/2}$ (i_p = peak current) was constant and the ratio of anodic to cathodic current (i_{p_c}/i_{p_a}) was approximately one, the peak separation being independent of the scan rate. This indicates that the electron transfer is reversible or approaches reversibility and that mass transfer is limited. However, at slow scan rates (e.g. 5 $mV\ s^{-1}$) the current function $i_{p_a}/(SR)^{1/2}$ is larger than the constant value found at faster scan rates and i_{p_c}/i_{p_a} is smaller than unity. The electrochemical behaviour of the complex $[Ru(PPh_3)_2(p\text{-MeBPhSal})_2]$ (**IIb**) was studied on adding 2-propanol (2% v/v), Table 3 and Fig. 1(a). At slow scan rate the anodic peak current is larger than that found in the absence of 2-propanol and the current ratio (i_{p_c}/i_{p_a}) reduces more with decreasing the scan rates, as in the case for $[Ru^{III}Cl_2(TMEA)_2][ClO_4]$ (TMEA = N,N,N′,N′-tetramethyl-1,2-ethanediamine).[30] These results (Table 3) are much more pronounced for the Ru^{III}/Ru^{IV} couple than that for Ru^{II}/Ru^{III} and show that 2-propanol could be catalytically oxidized by complex **IIb** at the electrode surface. For the complex $[Ru^{II}(PPh_3)_2(trop)_2]$ (**IV**), whose cyclic voltammogram[6] is similar to that of **IIb**, we found that its Ru^{III}/Ru^{IV} couple completely disappeared on adding 2-propanol, while the Ru^{II}/Ru^{III} oxidation couple is still displayed [Fig. 1(b)]. This study can be used as a test for the applicability of ruthenium complexes as useful electrochemical oxidative catalysts, since complex **IIb** was found to be an effective catalytic oxidant for alcohols (as shown below) while the tropolonato complex (**IV**) is weak and considered to be an inert catalytic oxidant over several hours in CH_2Cl_2.[6]

Catalytic oxidation

In continuing attempts to find new ruthenium(II) and ruthenium(III) complexes that act as efficient

catalysts in the presence of N-methylmorpholine-N-oxide (NMO) for selective oxidation of primary alcohols to aldehydes and secondary alcohols to ketones.[3,5,14,19] we find that these ruthenium complexes are better catalytic oxidants than those of dioxo-ruthenium,[31-34] as they are easy to prepare in high yields. They are also less expensive, selective towards catalytic oxidation of alcohols and more efficient catalysts to achieve high turnovers. It has been reported that the complexes $[Ru^{II}Cl_2(PPh_3)_3]$ and $[Ru^{III}Cl_2(EPh_3)_2L]$ [E = As or P; L = O,O-donor ligand anion (−1)] in the presence of excess NMO are good catalytic oxidants for alcohols with turnovers 50–100.[4,14,19] The present Schiff base ruthenium(II) complexes have been used for such catalytic activity in the presence of NMO or O_2 gas as co-oxidants and results are summarized in Table 4. The oxidations were performed at room temperature in CH_2Cl_2, from which water was removed using powdered molecular sieves. Acetonitrile was also used instead of CH_2Cl_2 for the oxidation of *p*-methoxybenzyl alcohol and a similar yield was obtained. There was no detectable oxidation of alcohol in the absence of any ruthenium complex. All complexes (using NMO as a co-oxidant) oxidize primary alcohols to the corresponding aldehydes and secondary alcohols to ketones with high yield and turnovers (up to 160). Also, the catalysts in the presence of NMO are effective towards oxidation of unsaturated alcohol, e.g. cinnamyl alcohol without competing double bond attack. It is clear from the oxidation of *p*-methoxybenzyl alcohol (Table 4) that the coordinated Schiff base derived from salicylaldehyde (R-PhSal) which contains an electron attracting group (R = *p*-Cl) increases the rate of oxidation, contrary to those obtained with the electron repelling group (R = *p*-Me), although the $E_{1/2}$ values of the oxidation waves for their corresponding ruthenium(II) are close. This observation is similar to that found for the $[Ru^{II}Cl_2(PPh_3)_2L]$/NMO system (L = O,N-neutral donor ligand).[5] These ruthenium(II) complexes in the presence of oxygen gas as co-oxidant also effect such oxidations of primary alcohol to aldehyde

Fig. 1. Underlined data refer to catalytic oxidation by the complexes/O_2.
[a] A = corresponding aldehyde, K = corresponding ketone.
[b] Turnover = moles of product/moles of catalyst.

while secondary alcohols, α-tetralol, are hardly oxidized. The complex derived from the catechol Schiff base ligand **IIId** is a better catalyst towards such oxidation. Turnovers of 25 were obtained with the complex **IIId** when oxygen gas was bubbled through solutions of the primary alcohol overnight, similar to those found by *trans*-dioxo-ruthenium(VI) complexes $[RuO_2Cl_3(4\text{-}t\text{-But-py})]^-$ and $[Ru_2O_6py_4]$.[31] Reaction of ruthenium(III) Schiff base complexes with O_2[35–37] or PhIO (iodosobenzene)[37] was suggested to form ruthenium(IV) superoxo complexes[35,36] or oxo-ruthenium(V) complexes.[37] The formation of oxo-ruthenium(V) species was also reported for $RuCl_3$/NMO[38,39] or PhIO[40] systems and the mechanism was mentioned for the oxidation of alcohols, where ruthenium(III) is regenerated.[38]

It is interesting to note that the complexes $[Ru(PPh_3)_2(R\text{-}PhSal)_2]$ (**I**) are more efficient oxidants than those of **III** and **II**. The efficiency of such catalysts increases in the order **II** < **III** < **I**, which is consistent with their difference in electrochemical behaviour. Although the complexes **II** and **I** have a similar reversible wave (due to Ru^{II}/Ru^{III} oxidation), their second oxidation wave is reversible (due to Ru^{III}/Ru^{IV}) and irreversible (due to Ru^{III}/Ru^{V}), respectively. Complex **III** has only an irreversible oxidation peak, as described above. We believe that this lack of reversibility for such oxidation waves reflects the reason for the more efficient catalytic cycle of oxidation[5,6] and consequently the ease of the oxidation reaction with high turnovers. It is relevant from the cyclic voltammetric data that oxidation effected by catalysts is likely to occur via ruthenium high oxidation states (Ru^{IV} or Ru^{V}), which should be accessible through chemical oxidation with the common co-oxidants.[14,15,19,41]

EXPERIMENTAL

Preparation of complexes

Preparation of $[Ru(PPh_3)_2(R\text{-}PhSal)_2]$ (**I**). The complex $[RuCl_2(PPh_3)_3]$[42] (0.25 mmol) was dissolved in dry benzene (20 cm^3) under nitrogen and

then the Schiff base ligand, HR-PhSal (0.65 mmol) and Et_3N (0.5 cm^3) were added, respectively. The mixture was refluxed under nitrogen for 2 h forming a red–brown solution, then evaporated to low bulk under nitrogen, followed by the addition of degassed methanol (20 cm^3) after which time red microcrystals were isolated for the corresponding compounds of R = H, *p*-Me, *p*-Cl and *p*-Br. In the case of the derivatives, R = *p*-MeO and *p*-NO_2, the corresponding brown and green complexes are precipitated after 1–1.5 h during reflux of the benzene solution. The products were filtered off, washed with degassed methanol (3×25 cm^3) to remove triethylamine hydrochloride and finally dried *in vacuo* for a few days after grinding. Some compounds appeared to retain considerable amounts of benzene solvent before they became sufficiently dry (as shown by ^1H NMR spectroscopy).

Similar procedures were used to prepare red–brown microcrystals of $[Ru(PPh_3)_2(R\text{-}BPhSal)_2]$ and $[Ru(PPh_3)_2(trop)_2]$[6] and the green complexes $[Ru(PPh_3)_2(HR\text{-}Phb)_2]$.

Catalytic oxidation by complexes. The oxidation of piperonyl alcohol by $[Ru(PPh_3)_2(Hp\text{-}ClPhb)_2]$ (**IIId**) is typical. To a solution of piperonyl alcohol (1 mmol) was added NMO in CH_2Cl_2 (20 cm^3) and 10^{-2} mmol of compound **IIId**. The solution was stirred for 3 h in the presence of 4 Å molecular sieves (0.5 g). The mixture was then evaporated to dryness and extracted with ether (2×25 cm^3). The combined ethereal extracts were filtered and evaporated to give piperonal which was characterized and quantified as its 2,4-dinitrophenylhydrazone derivative.

A similar procedure was used for aerobically assisted oxidation using molecular oxygen as the co-oxidant instead of NMO. Oxygen gas was bubbled through the solution of piperonyl alcohol (1 mmol) and compound **IIId** (4×10^{-2} mmol) in CH_3CN (20 cm^3). The reaction continued for 24 h.

IR spectra were measured on a Perkin–Elmer 883 spectrometer as paraffin mulls between CsI plates and KBr discs. ^1H NMR spectra were measured on a Brucker AT-FT 100. The electronic spectra were measured on a Varian 634 UV–vis spectrophotometer. Cyclic voltammetric studies were carried out on a potentiostat/wave generator (Oxford Electrodes) using a platinum working electrode in conjunction with a Philips PM8043 *X–Y* recorder. Magnetic measurements were made on a Johnson–Matthey magnetic susceptibility balance.

(*Received* 6 *April* 1993; *accepted* 2 *June* 1993)

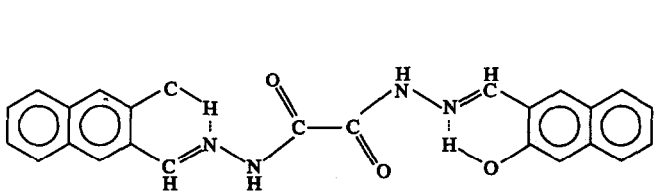
Abstract—The monometallic complexes $[M(napoxlhH_2)(H_2O)_2]_n \cdot 2nH_2O$ [where $M = UO_2^{2+}$ and Zn^{2+}, and $napoxlhH_4$ = bis(*o*-hydroxynaphthalde)oxaloyldihydrazone] have been synthesized and characterized on the basis of the results obtained from molar conductance data, electronic, IR and ^1H NMR spectral studies. It is proposed that the complex $[UO_2(napoxlhH_2)(H_2O)_2]_n \cdot 2nH_2O$ involves eight coordinated uraniums with six ligand atoms arranged in the equatorial plane perpendicular to the linear uranyl group involving dihydrazone in the enolic form with *cis* configuration, whereas $[Zn(napoxlhH_2)(H_2O)_2]_n \cdot 2nH_2O$ is octahedral involving enolic dihydrazone in the staggered configuration. The phenolic-OH groups remain uncoordinated.

Acyl-, aroyl- and phthaloyldihydrazones containing azomethine, amide and phenolic functions are polyfunctional ligands.[1] These are capable of yielding polymeric polynuclear complexes involving ligand bridging and oxo-bridging.[2,3] Metal complexes of salicylaldehyde dihydrazones, which yield high molecular weight oligomeric products by polymerization, have been studied in some detail, but those containing relatively bulkier aromatic aldehydes and ketones have been much less studied. By the introduction of bulky fragments into the dihydrazone skeleton[4] it is possible to prepare polynuclear homo- and heterobimetallic complexes of dihydrazones having discrete molecularity. Bis (*o*-hydroxynaphthaldehyde)oxaloyldihydrazone is one such ligand capable of holding two or more metal atoms in close proximity, depending upon the preparation conditions. To the best of our knowledge, there is no report on a single complex formed by this ligand. The present paper reports the results of an investigation into the reaction of uranyl acetate and zinc acetate with bis(*o*-hydroxynaphthaldehyde)oxaloyldihydrazone, capable of existing in the staggered (A) and *cis* (B) conformations, and the structural assessment of the resultant products.

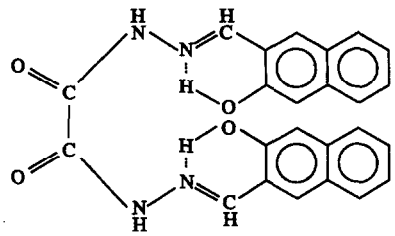
RESULTS AND DISCUSSION

The complexes isolated in the present study (Table 1) are air stable and decompose above 300°C. They are soluble in DMSO and DMF only. The complexes showed weight loss corresponding to two water molecules at *ca* 110°C and two water molecules at *ca* 180°C, respectively. The water molecules lost at *ca* 110°C suggest that they are part of the lattice structure, while those lost at 180°C suggest that they are part of the coordination sphere. Their molar conductance values in DMSO are 2.5

* Author to whom correspondence should be addressed.



Staggered A



Cis B

and 1.2 Ω^{-1} cm^2 mol^{-1}, indicating that they are non-electrolytes in this solvent.[5] The fact that the complexes are single-phase species has been confirmed by the fact that the DMSO solutions of all the complexes show a uniform spot on a TLC plate covered with silica gel and developed using a mixture of petroleum ether, ether and methanol in the ratio 2 : 2 : 1.

The dihydrazone shows bands at 330 and 370 nm in DMSO solution. A DMSO solution of the zinc complex shows bands at 320, 329, 375 and 450 nm, while the uranyl complex shows two bands at 340 and 405 nm, respectively. The bands in the region 320–375 nm have their origin due to electronic transitions within the ligand, while those in the region 400–450 nm have their origin due to ligand-to-metal charge transfer transitions. In the uranyl complex the band characteristic of the uranyl ion is obscured by ligand-to-metal charge transfer transitions.[6]

The IR and ^{1}H NMR spectral data for the dihydrazone and its complexes are summarized in Table 2. The IR spectrum of the napoxlhH_4 shows bands in the regions 3500–3300sbr, 3382s, 3332s, 3278s, 1655vs, 1616s and 1528 cm^{-1} due to ν(NH)+ν(OH), ν(C=O), ν(C=N) and amide II+ν(C—O)(phenolic). The ^{1}H NMR spectrum of the free ligand in DMSO-d_6 exhibits four and two proton signals at δ 12.72 and 9.75 ppm downfield of TMS, assigned to δ(NH)+δ(OH) and δ(—C=N), respectively.[3] The multiplet due to the naphthyl protons appears in the region δ 7.15–8.20 ppm. The signal at δ 12.72 ppm is relatively broad, indicating the presence of hydrogen bonding in the free dihydrazone.

The absence of the strong amide I band and the appearance of a strong to very strong band in the region 1602–1580 cm^{-1} and a very strong band in the region 1535–1533 cm^{-1} confirm the enolization of the ligand on complexation. The C=N band shows a negative shift by *ca* 14–36 cm^{-1}, indicating azomethine nitrogen coordination. The $[UO_2(napoxlhH_2)(H_2O)_2]_n \cdot 2nH_2O$ complex shows a strong band at 937 cm^{-1} corresponding to the ν_3 stretching frequency of UO_2^{2+}.

The complex $[UO_2(napoxlhH_2)(H_2O)_2]_n \cdot 2nH_2O$ shows doublets at δ 12.65, 12.79 ppm and 9.79, 9.97 ppm, corresponding to two phenolic-OH and two azomethine protons; the corresponding peaks in $[Zn(napoxlhH_2)(H_2O)_2]_n \cdot 2nH_2O$ appear as singlets at δ 12.70 ppm and δ 9.70 ppm. The average δOH peak position in $[UO_2(napoxlhH_2)(H_2O)_2]_n \cdot 2nH_2O$ remains almost at the same position or slightly upfield shifted in the $[Zn(napoxlhH_2)(H_2O)_2]_n \cdot 2nH_2O$ complex compared with that in

the free ligand, thus ruling out the possibility of involvement of the phenolic-OH group in coordination.[7] The average azomethine proton peak position in uranyl complex is downfield shifted by *ca* 0.13 ppm, while in the zinc complex it is slightly upfield shifted by *ca* 0.05 ppm. Such a feature associated with the δ —C=N signal in the complexes indicates coordination through the nitrogen atom of the azomethine group to the metal centre. The downfield shift of δ —C=N in the uranyl complex suggests that there is a drainage of electron density from the nitrogen atom of the azomethine grouping to the metal centre, while in the zinc complex the naphthyl ring electron density flows through the azomethine nitrogen atom to the metal centre.

The splitting of the δ OH and δ —C=N signals into doublets in the uranyl complex is related to the ability of the UO_2^{2+} ion to assemble the dihydrazone in the equatorial plane, which forces a *cis* conformation on the dihydrazone,[8] whereas the zinc ion is unable to do so and the dihydrazone coordinates to the zinc centre in the staggered configuration.

On the basis of the physicochemical data presented and discussed above the uranyl complex maybe suggested to involve an eight-coordinate uranium atom[9] with dihydrazone in *cis* conformation in the enolic form, while the zinc complex may be proposed to be octahedral involving a staggered arrangement of the dihydrazone in the enolic form around the zinc ion, respectively.

EXPERIMENTAL

$UO_2(OAc)_2 2H_2O$, $Zn(OAc)_2 2H_2O$, diethyl oxalate, hydrazine hydrate and *o*-hydroxynaphthaldehyde were BDH, AR or E Merck grade reagents. Oxaloyldihydrazine was prepared by reacting diethyl oxalate (1 mol) with hydrazine hydrate (2 mol). Bis(*o*-hydroxynaphthaldehyde)oxaloyldihydrazone was prepared by refluxing a hot dilute ethanol solution of oxaloyldihydrazine (1 mol) with *o*-hydroxynaphthaldehyde (2 mol). The yellow precipitate obtained was recrystallized from ethanol and dried in an electric oven at *ca* 70°C, m.p. > 300°C. Found: C, 68.0; H, 4.2; N, 13.3. Calc. for $C_{24}H_{18}N_4O_4$: C, 67.6; H, 4.2; N, 13.1%.

Uranium and zinc in the complexes were determined by standard literature methods. Carbon, hydrogen and nitrogen were determined by microanalysis. Water molecules were determined by heating the samples in an electric oven at *ca* 110°C

and 180°C, respectively, and passing the vapour through a trap containing anhydrous copper sulphate, which turned blue, and estimating the weight loss. The molar conductance of the complexes at 10^{-3} M dilution in DMSO was measured using a Direct Reading Conductivity meter 303 with a dip-type conductivity cell. IR spectra were recorded on a Perkin–Elmer 983 spectrophotometer in the range 4000–180 cm^{-1} using KBr discs. The ^1H NMR spectra were recorded on a CFT-20, 90 MHz spectrometer using DMSO-d_6 solution. Electronic spectra were recorded on a Shimadzu MPS-5000 multipurpose spectrophotometer in DMSO.

Preparation of the complexes

The complexes were prepared by the following general method. $M(OAc)_2 \cdot 2H_2O$ (UO_2^{2+}, Zn^{2+}) (0.05 M, 50 cm^3) in ethanol containing a trace of acetic acid was dissolved by gentle heating and stirring. Oxaloyldihydrazine (0.05 M, 55 cm^3) in hot distilled water was added to the above solution accompanied by stirring for a period of 10 min. The reaction mixture was refluxed for 1 h and then filtered under hot conditions, washed with hot water, ethanol and finally with ether.

The precipitate obtained above was suspended in ethanol, to which *o*-hydroxynaphthaldehyde solution (0.1 M, 75 cm^3) in ethanol was added. The reaction mixture was refluxed. The progress of the reaction was followed with the help of TLC. The reaction was complete after 6 h in the case of the uranyl complex, while it required 20 h in the case of the zinc complex. The product was filtered in hot conditions, washed with hot ethanol, ether and dried in an air oven at *ca* 70°C.

^1H AND ^{13}C NMR RELAXATION INVESTIGATION OF THE COPPER(II) COMPLEX OF AMITRAZ, A FORMAMIDINE PESTICIDE

ELENA GAGGELLI, NICOLA GAGGELLI and GIANNI VALENSIN*

Department of Chemistry, University of Siena, Siena 53100, Italy

and

ALESSANDRO FRANCHI

USL 30, Siena, Siena 53100, Italy

(*Received* 23 *March* 1993; *accepted* 2 *June* 1993)

Abstract—The copper(II) complex of amitraz, a formamidine pesticide, was investigated by measuring ^1H NMR spin-lattice relaxation rate enhancements (PRRE) in [$^2H_6$]-DMSO solution. The occurrence of fast exchange conditions was demonstrated by the temperature dependence of the PRRE. The PRRE was interpreted by the Solomon–Bloembergen–Morgan approach; the number of solvent molecules in the coordination shell was calculated at $q = 2$; the reorientational correlation time in the 1 : 1 metal complex was assumed to be the same as in the free ligand and calculated at $\tau_c = 69$ ps. The metal ion was shown to stabilize a *cisoid* conformation of the ligand.

Amitraz, {N,N′[(methylimino)dimethylidyne]di-2,4-xylidine} (Fig. 1), is a formamidine acaricide and insecticide effective against a wide variety of phytophagous mites and insects. It is synthesized from 2,4-dimethylaniline and it reverts to several products on mammalian metabolism and environmental degradation.[1–3]

Extensive use in agriculture has raised the question of its toxicity, especially in light of its interaction with the hepatic mixed-function oxidase systems[1] and also with components of the biogenic amine system.[4]

In this communication we present NMR evidence that amitraz can act as an effective ligand for metal ions, such as Cu^{2+}, forming stable complexes that may play a significant role in eliciting the biochemical activity.

EXPERIMENTAL

Materials

Amitraz (standard analysis reagent) was obtained from Ehrenstorfer Lab. (Augsburg) and used without further purification. Solutions were made in [$^2H_6$]-DMSO or in H_2O and carefully deoxygenated by bubbling nitrogen gas through. The desired copper concentration was obtained using stock solutions of $Cu(ClO_4)_2$ in [$^2H_6$]-DMSO or in H_2O.

Methods

NMR experiments were performed on a Varian VXR-200 spectrometer at controlled temperature (±1 K). Chemical shifts were referenced to internal TMS. Spin-lattice relaxation rates were measured with inversion recovery pulse sequences. Spin–spin relaxation rates were measured with the Carr–Purcell–Meiboom–Gill pulse sequence. The rate values were calculated, in both cases, by linear regression analysis of the recovery or decay curves of longitudinal or transverse magnetization components. $^{13}C\{^1H\}$ nuclear Overhauser effects were measured with gated decoupling techniques.

RESULTS AND DISCUSSION

Different proton spin-lattice relaxation rate enhancements (PRRE) were measured in the pres-

* Author to whom correspondence should be addressed.

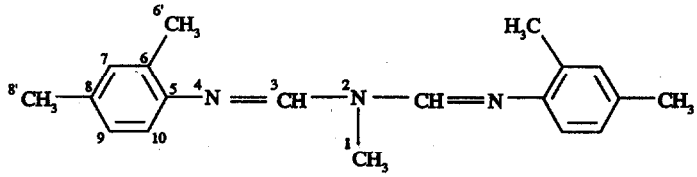

Fig. 1. Molecular formula of amitraz.

ence of copper(II) ions (Table 1). The experimental paramagnetic contributions to the relaxation rates, R_{ip}, were calculated by:

$$R_{ip} = R_{iobs} - R_{if} \quad (i = 1, 2), \tag{1}$$

where R_{iobs} and R_{if} are the rate values measured in the presence and in the absence, respectively, of relatively small concentrations of the paramagnetic ion.

Consideration of the temperature dependence of such PRRE (Fig. 2) suggests that fast exchange conditions apply, such that:

$$R_{ip} = qfR_{iM} \quad (i = 1, 2), \tag{2}$$

where q is the number of coordinated ligand molecules and f is the fraction of bound ligand, the relaxation rate of which is given by R_{iM}. In such situations the PRRE can be interpreted in terms of the Solomon–Bloembergen–Morgan theory;[5–7] since $R_{2p} \gg R_{1p}$ was measured (Table 1) it was concluded that R_{2p} is contributed by the scalar interaction, whereas the paramagnetic contribution to the spin-lattice relaxation rate, R_{1p}, is mainly determined by the dipolar electron spin–nuclear spin interaction given by:[8,9]

$$R_{ip} = \frac{1}{10} qf \frac{\gamma_H^2 g_e^2 \beta_e^2}{r^6} \left\{ \frac{3\tau_c}{1 + \omega_H^2 \tau_c^2} \right\}, \tag{3}$$

where r is the ion-proton distance measured in Å; $\omega_H = 1.257 \times 10^9$ rad s^{-1} is the proton Larmor frequency; τ_c is the correlation time modulating the nuclear spin–electron spin dipole–dipole interaction; $\gamma_H = 2.6753 \times 10^4$ rad s^{-1} G^{-1} is the proton magnetogyric ratio; $g_e = 2.002322$ is the electronic g factor; $\beta_e = 0.92731 \times 10^{-20}$ erg G^{-1} is the Bohr magneton.

The motional correlation time, in the case of copper(II) complexes with small ligands, is a rotational correlation time[8,9] which can be reasonably assumed to be the same as for the free ligand. The validity of this assumption might be questioned but only at a superior level of accuracy, which is not required in this case (a large error in τ_c in fact only yields small uncertainties in evaluating distances). The motional correlation time was, therefore, calculated by measuring the ^{13}C spin-lattice relaxation rates of the free ligand, summarized in Table 2. Since the ^{13}C—^{1}H dipolar interaction may not provide the unique relaxation mechanism, especially for methyls, the spin-lattice relaxation rates were scaled down with the measured nuclear Overhauser effect (n.O.e.) through:

$$R_1^{dip} = R_{1obs} \frac{\eta_{obs}}{\eta_{max}}, \tag{4}$$

where η_{max} (the maximum observable n.O.e. when

Table 1. Paramagnetic proton relaxation rates for amitraz (0.1 mol dm^{-3}) in [^{2}H$_6$]-DMSO at $T = 295$ K in the presence of [Cu^{2+}] = 4.3×10^{-4} mol dm^{-3} and calculated ion-proton distances

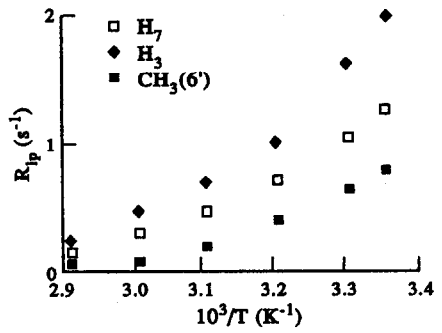

Fig. 2. Temperature dependence of PRRE for selected protons of amitraz (0.1 mol dm^{-3}) in [$^2H_6$]-DMSO.

the relaxation rate is dominated by the dipolar interaction) = 1.98.

From the calculated dipolar relaxation rates, R_1^{dip}, an effective reorientational correlation time of 69.3 ± 15.3 ps for modulation of the internuclear vectors of the four methynes was calculated.[10] As for the methyls the same calculations yield correlation times in the range 6.1–8.5 ps, suggesting "unlocked" free rotation.[11]

The number of ligands in the coordination sphere was evaluated by measuring the solvent proton relaxation rates, shown in Table 3. A large PRRE (R_{1p} = 3.88 s^{-1}) is measured for DMSO protons in the presence of [Cu^{2+}] = 0.43 mmol dm^{-3}, which is reduced (R_{1p} = 1.64 s^{-1}) by the presence of ligand (0.1 mol dm^{-3}). The reduction is due to a decreased number of solvent molecules in the metal coordination sphere. Application of eq. (3) would yield q = 2.5, as compared with q = 6 for the free solvated ion, suggesting that speciation may occur in DMSO. However, repetition of the measurements in H_2O, where the presence of the ligand (0.1 mol dm^{-3}) lowered the solvent PRRE from its free hexaaquo ion value (R_{1p} = 20.6 s^{-1}) to R_{1p} = 13.7 s^{-1}, yields q = 4.0 for the complex. It is concluded that the major species existing in water solution is a metal complex, $ML(H_2O)_4$, having four solvent molecules in the first coordination shell and that preferential solvation by water molecules gives, in the partially hydrated DMSO solvent, metal complexes having mixed solvation shells, $ML(DMSO)_x(H_2O)_{4-x}$.

Since q = 2 for the amitraz molecule that contains pairs of symmetric protons, we can conclude that the main species is a chelated ML complex in which the two imino nitrogens of one ligand molecule coordinate the copper ion. The effective formation of a predominant ML_2 species, in which the coordinating atom is the methylamino nitrogen, can be excluded with the aid of computer graphics molecular modelling. If coordination were occurring via the sp^3 nitrogen there would be no possibility of bringing the aromatic protons close enough to the metal to account for the observed PRRE.

These observations were ratified by calculating ion–proton distances (Table 1). Agreement with the proposed structure becomes very good, especially if the calculations are performed taking into account the correlation time for methyls as in the free state. It is concluded that the ligand retains the same motional flexibility in the bound and in the free state.

Metal binding evidently stabilizes a *cisoid* conformation around the N_4—C_5 bond, thus bringing H_3 and H_{10} quite close to each other. In order to ascertain whether this conformation was also somehow stabilized in the free state selective and double-selective proton spin-lattice relaxation rates were measured for H_3 and H_{10} in order to obtain the dipolar cross-relaxation rate ($\sigma_{3,10}$) between the two:[12,13]

$$\sigma_{3,10} = \sigma_{10,3} = R_3^{3,10} - R_3^{sel} = R_{10}^{3,10} - R_{10}^{sel}, \quad (5)$$

Table 2. ^{13}C NMR parameters of amitraz (0.1 mol dm^{-3}) in [$^2H_6$]-DMSO at T = 295 K

	0.1	—	0.75
	—	4.3×10^{-4}	21.06
	0.1	4.3×10^{-4}	14.47

where R_i^{sel} is the spin-lattice relaxation rate after selective excitation of the i resonance and $R_i^{i,j}$ is the rate measured for proton i after double-selective excitation of i and j resonances. The H_3—H_{10} internuclear distance was calculated at 2.54 Å for amitraz in the free state using the measured value of $\sigma_{3,10}$ ($\sigma_{3,10} = 0.07\ s^{-1}$) in the following equation:[14]

$$\sigma_{3,10} = \frac{1}{10}\frac{\gamma_H^4 h^2}{r_{3,10}^6}\left\{\frac{6\tau_c}{1+4\omega_H^2\tau_c^2} - \tau_c\right\}, \qquad (6)$$

where $\tau_c = 69.2$ ps was assumed. From the molecular model it is calculated that, at values of 0° and 90° for the C_3—N_4—C_5—C_{10} torsional angle, the H_3—H_{10} distance is found at 2.1 and 3.5 Å, respectively, whereas a distance of 2.5 Å corresponds to a torsional angle of about 45°. It is concluded that the free ligand in solution exists in some "preferential" conformation, which is further stabilized by coordination with divalent copper ions.

NOVEL μ-TEREPHTHALATO OXOVANADIUM(IV) BINUCLEAR COMPLEXES WITH AN ANTIFERROMAGNETIC EXCHANGE INTERACTION

SHU-LIN MA,* JUAN SHI, DAI-ZHENG LIAO,† ZONG-HUI JIANG, SHI-PING YAN and GENG-LIN WANG

Department of Chemistry, Nankai University, Tianjin 300071, P.R.C.

(*Received* 23 *March* 1993; *accepted* 2 *June* 1993)

Abstract—Three novel oxovanadium(IV) binuclear complexes have been synthesized, namely $[(VO)_2(TPHA)(H_2O)_2(L)_2](Ac)_2$ [L = 2,2′-bipyridyl (bipy), 4,4′-dimethyl-2,2′-bipyridyl (Me_2bipy) and 1,10-phenanthroline (phen); TPHA is the dianion of terephthalic acid]. Based on IR, elemental analyses and magnetic moments at room temperature these complexes are proposed to have extended TPHA-bridged structures and consist of two vanadium(IV) atoms in a distorted square-pyramidal environment. The temperature dependence of the magnetic susceptibility of $[(VO)_2(TPHA)(H_2O)_2(L)_2](Ac)_2$ has been studied, giving the exchange integral $J = -47.75$ cm^{-1}. This indicates an antiferromagnetic exchange interaction between the VO^{2+} ions.

Binuclear metal complexes with extended bridged structure are of current interest due to spin-exchange and charge-transfer between metal ions and in the domains of metalloenzymes and novel magnetic materials.[1] Many works have been published on binuclear copper(II) complexes containing the μ-terephthalato ligand.[2–7] The bridging function of terephthalate dianions and the long-distance antiferromagnetic exchange interactions of these complexes have been revealed by single-crystal X-ray and magnetic analyses.[2,6,7] Recently complexes of this kind with various terminal ligands and other metal ions, such as $[M_2(TPHA)(L)_4](ClO_4)_2$ (M = Ni, Co, L = bipy, phen and Me_2bipy),[8–10] were synthesized in our laboratory and their magnetic properties and some crystal structures were studied. As an extension of that investigation in this paper we report the synthesis, characterization and magnetism of three new complexes, $[(VO)_2(TPHA)(H_2O)_2(L)_2](Ac)_2$ [L = 2,2′-bipyridyl (bipy), 4,4′-dimethyl-2,2′-bipyridyl (Me_2bipy) and 1,10-phenanthroline (phen); TPHA is the dianion of terephthalic acid].

EXPERIMENTAL

Preparation of $[(VO)_2(TPHA)(H_2O)_2(bipy)_2](Ac)_2$

Piperidinium terephthalate was synthesized by the literature method.[2] Bipy, Me_2bipy and phen were of analytical grade.

A solution of piperidinium terephthalate salt (134.4 mg, 0.4 mmol) and 2,2′-bipyridyl (125 mg, 0.8 mmol) in methanol (10 cm^3) was added slowly to a methanol solution (10 cm^3) of $VO(Ac)_2$ (148 mg, 0.8 mmol). After further stirring for 24 h at 60°C. A yellow powder formed with diethyl ether and was dried *in vacuo*. Found: C, 50.0; H, 3.6; N, 7.7. Calc. for $C_{32}H_{30}N_4O_{12}V_2$: C, 50.3; H, 3.7; N, 7.3%.

Preparation of $[(VO)_2(TPHA)(H_2O)_2(Me_2bipy)_2](Ac)_2$

This complex was obtained as a yellow powder by the same procedure as above, but using Me_2bipy

* Tianjin College of Commerce.
† Author to whom correspondence should be addressed.

instead of bipy. Found: C, 52.7; H; 4.8; N, 7.1. Calc. for $C_{36}H_{38}N_4O_{12}V_2$: C, 52.7; H, 4.7; N, 6.8%.

Preparation of $[(VO)_2(TPHA)(H_2O)_2(phen)_2](Ac)_2 \cdot 0.5H_2O$

This complex was obtained as an apricot–yellow powder by the same procedure as above, but using phen instead of bipy. Found: C, 52.5; H, 3.5; N, 7.4. Calc. for $C_{36}H_{30}N_4O_{12}V_2 \cdot 0.5H_2O$: C, 52.6; H, 3.8; N, 6.8%.

Measurements

Analyses for carbon, hydrogen and nitrogen were performed on a Perkin–Elmer analyser, Model 240. The IR spectra were recorded with an IR-408 IR spectrophotometer on KBr disks. Room-temperature magnetic susceptibilities were measured by the Gouy method; the apparatus was calibrated with $[Ni(en)_3]S_2O_3$. Variable-temperature magnetic susceptibility was measured on a vibrating sample magnetometer, Model CF-1. Diamagnetic corrections were made with Pascal's constants for all the constituent atoms and the magnetic moments were calculated using the equation $\mu_{eff} = 2.828(\chi T)^{1/2}$.

RESULTS AND DISCUSSION

General characterization

Elemental analyses have indicated that the reaction of TPHA with $VO(Ac)_2$ and bipy, Me_2bipy or phen yielded the binuclear complexes. For the three $[(VO)_2(TPHA)(H_2O)_2(L)_2(Ac)_2$ complexes the significant bands in the IR spectra are given in Table 1. In the IR region of the spectrum the complexes exhibited the two characteristic strong and broad bands in the 1700–1300 cm^{-1} region, attributed to the $\nu_{as}(COO^-)$ and $\nu_s(COO^-)$ stretching vibrations of the carboxylato groups. An asymmetrical stretching vibration (ν_{as}) of the carboxylato group at 1575 cm^{-1} for the terephthalato was shifted to higher frequencies in the binuclear complexes. However, the symmetrical stretching vibration (ν_s) of the carboxylato group at 1400 cm^{-1} for the terephthalato was shifted to lower frequencies in the binuclear complexes. In addition, the separation between $\nu_{as}(COO^-)$ and $\nu_s(COO^-)$ has often been used to diagnose the coordination modes of the carboxylato groups, that is, bidentate carboxylato groups show a separation smaller than 200 cm^{-1} whereas unidentate carboxylato groups show a separation larger than 200 cm^{-1}. The $\nu_{as}(COO^-) - \nu_s(COO^-)$ values for the present complexes are larger than 200 cm^{-1}, suggesting a unidentate coordination mode for both carboxylato groups.[3] Based on the discussion above these complexes are proposed to have an extended TPHA-bridged structure, in which the TPHA ligand bridges in a bis-unidentate fashion and each vanadium(IV) is in a distorted square-pyramidal environment, as shown in Fig. 1.

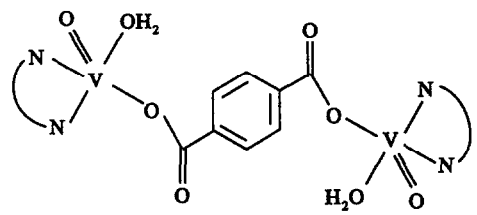

Fig. 1. Proposed chemical structure of the complexes.

Magnetic properties

The observed magnetic moment for the binuclear complexes at room temperature (see Table 1) is considerably less than the spin-only value (2.45 B.M.). This suggests the operation of an antiferromagnetic spin-exchange interaction in these complexes.[10] Variable-temperature (4.2–300 K)

Table 1. Physical data for the complexes

Compounds[a]	Colour	IR (cm^{-1}) $\nu_{as}(COO^-)$	$\nu_s(COO^-)$	$(\nu_{as} - \nu_s)$	μ_{eff} (B.M.) (per dimer unit)
1	Yellow	1630	1325	305	2.06
2	Yellow	1620	1330	290	2.18
3	Apricot–yellow	1625	1345	280	2.18

[a] **1** = $[(VO)_2(TPHA)(H_2O)_2(bipy)_2](Ac)_2$; **2** = $[(VO)_2(TPHA)(H_2O)_2(Me_2bipy)_2](Ac)_2$; **3** = $[(VO)_2(TPHA)(H_2O)_2(phen)_2](Ac_2 \cdot 0.5H_2O$.

magnetic susceptibility data were collected for $[(VO)_2(TPHA)(H_2O)_2(bipy)_2](Ac)_2$ and the magnetic analysis was performed using the susceptibility equation based on the Heisenberg spin operator ($\hat{H} = -2J\hat{S}_1\hat{S}_2$, $S_1 = S_2 = 1/2$):[11]

$$\chi_M = \frac{2N\beta^2g^2}{KT}\left[3+\exp\left(-\frac{2J}{KT}\right)\right]^{-1}, \qquad (1)$$

where χ_M denotes the susceptibility per binuclear complex and the remaining symbols have their usual meanings. As shown in Fig. 2 good fits to the experimental data are attained with eq. (1). The magnetic parameters thus determined are $J = -47.75\ cm^{-1}$ and $g = 2.01$. The agreement factor F, defined here as $\Sigma[(\chi_M)_{obs}-(\chi_M)_{calc}]^2/\Sigma(\chi_M)_{obs}$, is then equal to 9.49×10^{-6}. This result ($J < 0$) indicates that the complexes undergo a moderately strong antiferromagnetic spin-exchange interaction between the VO^{2+} ions.

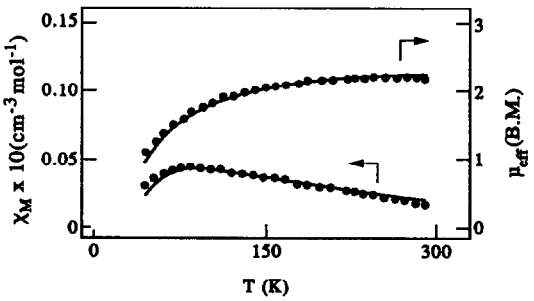

Fig. 2. Temperature variations of the magnetic susceptibility and magnetic moment for $[(VO)_2(TPHA)(H_2O)_2(bipy)_2](Ac)_2$. The curve is drawn based on eq. (1), using the magnetic parameters given in the text.

SYNTHESIS AND CHARACTERIZATION OF PLATINUM(II) AZOPHENOLATES INCORPORATING THIOETHER/SULPHINYL DONOR SITES

CHITTARANJAN SINHA

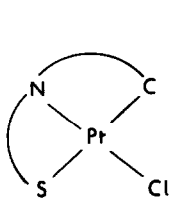
Department of Chemistry, University of Burdwan, Burdwan 713 104, India

(*Received* 27 *January* 1993; *accepted* 2 *June* 1993)

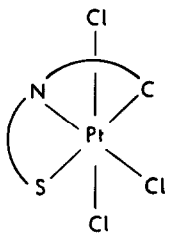
Abstract—Oxygen insertion into the Pt—C bond has been examined. Both thioether and sulphinyl azobenzene platinum(II) complexes (**5** and **6**) undergo metalloxylation by *m*-chloroperbenzoic acid (*m*-CPBA) when stirred in acetonitrile solution for a long time. Usually the reactions in chlorocarbon solvents form platinum(IV) organometallics, unlike isomorphous palladium(II) complexes. The reaction was confirmed by non-oxidative synthesis using hydroxyazobenzenes (**9** or **10**) liberated via reductive elimination of the metal from the corresponding palladium(II) complexes. Platinum(II) azophenolates (**7** or **8**) were characterized by spectroscopic techniques.

There has been growing interest in the chemotherapeutic treatment of platinum compounds, particularly *cis*-platin, *cis*-$Pt(NH_3)_2Cl_2$ and related systems.[1] Currently it is believed that the formation of Pt—S bonds by sulphur containing biomolecules like proteins or peptides is responsible for the inactivation of *cis*-platin and for the observed nephrotoxocity.[2,3]

Our current interest is in designing sulphur coordinated platinum(II) cyclometallates and their interaction with peracids.[4] The platinacycles of coordination type **1**, Pt(C,N,S)Cl, are susceptible to oxidative addition by halogens/peracids in chlorocarbon solvents to form cyclometallated platinum(IV) systems **2**. Herein we describe the reaction of **1** with *m*-chloroperbenzoic acid (*m*-CPBA) in acetonitrile for a long period of time to lead to oxygen insertion into the Pt—C bond giving azophenolato Pt(O,N,S)Cl. These have been structurally characterized with the help of spectroscopic techniques.



1



2

RESULTS AND DISCUSSION

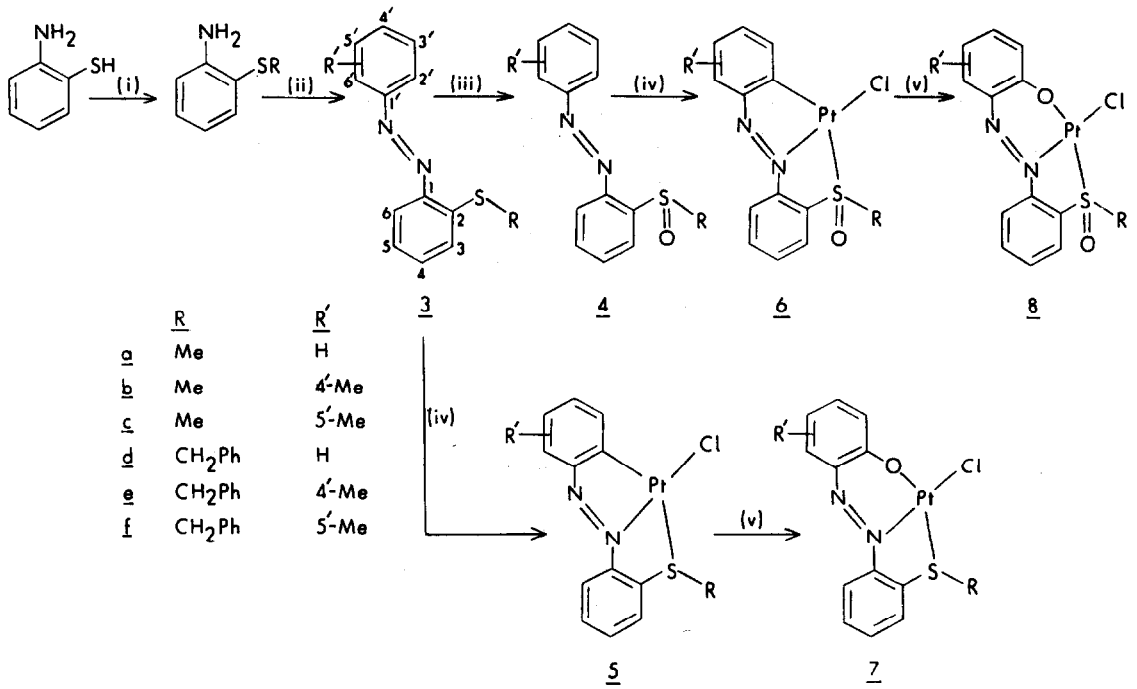
Synthesis

The azobenzenes and complexes described in this work are shown in Scheme 1, along with the methods used for synthesis. The azobenzenes contain the donor substituents —SR or —S(O)R at the *ortho* position to the azo function. They are effective tridentate chelating ligands of (C,N,S) types. The thioazobenzenes are formed by the condensation of nitrosoaromatics with anilines and the sulphinyl analogous are synthesized by oxidizing the corresponding sulphides with hydrogen peroxide in acetic acid.

The reaction of azobenzenes with K_2PtCl_4 proceeds smoothly in hot aqueous methanol to give brown coloured platinum(II) complexes in excellent yields. These compounds have been structurally characterized previously.[4]

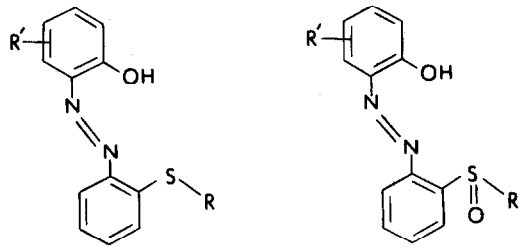
Upon addition of *m*-CPBA to solutions of **5** (or **6**) in acetonitrile the colour changes immediately from brown to orange–yellow and finally to pink–violet after 5 days of continuous stirring. Removal of the solvents followed by chromatographic purification afforded **7** (or **8**) in high yield. Characterization of the orange–yellow substance has been unsuccessful.

The reaction results in metalloxylation, which is confirmed by non-oxidative synthesis using the



Scheme 1. (i) CH_3I or $PhCH_2Cl/Na/EtOH$; (ii) *m*-/*p*-$RC_6H_4NO/AcOH$; (iii) $H_2O_2/AcOH$; (iv) $K_2PtCl_4/MeOH–H_2O$; (v) *m*-CPBA/MeCN.

hydroxyazobenzene ligand **9** (or **10**) liberated via the demetallation of palladium(II) azophenols by hydrazine hydrate.[5]



9 10

An interesting feature of the reaction is that the coordinated thioether function is unaffected by peracid, even when the latter is present in excess. The coordinated chloride is also inactive, as in other cases,[4,5] although the free chloride is highly reactive.[6] Free thioethers are easily oxidized by peroxo reagents, yielding sulphoxides and sulphones via nucleophilic attack on the peroxo group by sulphur.[7,8]

Spectral and binding mode

IR and UV–vis spectra. The IR spectra of these complexes display a single N=N stretch around 1380–1390 cm^{-1} and a Pt—Cl stretch near 340 cm^{-1} (Table 1). In the free ligands ν(N=N) occurs in the range 1450–1475 cm^{-1}. The decrease in ν(N=N) on complex formation is characteristic of Pt-azo π-back-bonding.[5,9] Sulphinylazophenolato complexes exhibit another strong band at *ca* 1140–1155 cm^{-1}. This is characteristic of the S=O group.[4,5] The free ligands show the strong band near 1040 cm^{-1} and upon complexation this is shifted to higher frequencies. The specific frequencies are: 1140 in **8a**, 1145 in **8b**, 1145 in **8c**, 1145 in **8d**, 1155 in **8e** and 1155 cm^{-1} in **8f**. The shift to higher energies is an indication of S-bonding. The O-binding shifts ν(S=O) to lower energies (*ca* 900 cm^{-1}).[5,10–12] Confirmatory NMR evidence is presented below.

The complexes afford pink–violet solutions in organic solvents and display characteristic spectra in the UV–vis region (Table 1). The spectra of cyclometallated and azophenolato platinum(II) complexes in the UV–vis region are significantly different (Fig. 1). The spectral differences are diagnostic of the binding mode in the complexes, as in the case of isomorphous palladium complexes.[5]

High-resolution ^1H *NMR spectra.* Sulphur coordination of thioether and sulphinyl ligands to metals in cyclometallated platinum(II) and platinum(IV) complexes is well established.[4] In the present case the hydroxy-azobenzene platinum(II)

complexes are classified in two ways:

(1) S—Me *cases*. The S-binding is reflected in high-resolution ^1H NMR spectra by downfield shifting of the S—Me signal from the free ligand position and the presence of coupling between ^{195}Pt and ^1H(SMe). Selected chemical shift data ($CDCl_3$ solvent) are collected in Table 2. The S—Me signal of **7c** occurs at *ca* 0.45 ppm downfield from those of **9c** and of **8c** at *ca* 1.00 ppm downfield from those of **10c**. This again undergoes a downfield shift by *ca* 0.8 ppm in the sulphinyl complexes, **8a–c**, from thioether complexes, **7a–c**. This may be due to the electron-withdrawing effect of the S=O function.[4] Although sulphur centre oxidation supports the downfield shift of the S—Me signal (by *ca* 0.25 ppm), it is to a lesser extent than their corresponding platinum complexes (by *ca* 0.80 ppm). The coupling between ^{195}Pt ($I = 1/2$, abundance 33.7%) and ^1H (S—Me) is another strong indication of sulphur coordination to the metal centre.[4,13] The coupling constant ^3J(Pt—H) of thioazophenolates (50 Hz) is *ca* 2.5 times that of the sulphinylazophenolates (20 Hz) (Table 2). The coupling constant [^3J(Pt—H)] is largely reduced in cycloplatinates than in the analogous azophenolato complexes (cf. **5b**, 20.1;[4] **7b**, 50 Hz), possibly due to the *trans* influence of the Pt—C bond. The protons of the phenolate ring suffer sizeable upfield shifts compared with the other ring. The differences in δ values of **5b** and **7b** are 3-H, 0.08; 4-H, 0.04; 5-H, 0.04; 6-H, 0.06; 3′-H, 0.52; 5′-H, 0.34 and 6′-H, 0.01, respectively. This is expected in view of the electron releasing effect of the phenolic ring.[5]

All aromatic signals of **7a–c** and **8a–c** have been completely assigned on the basis of chemical shifts; spin–spin structures and the effect of substituents (Table 2). The aromatic protons are systematically deshielded in going from **7** to **8**; the effect being particularly prominent in the case of 3-H, 4-H and 5-H. Assignments are shown schematically in Fig. 2.

(2) S—CH_2Ph *cases*. Evidence in support of S-

binding to metals is the appearance of the inequivalence of the methylene protons of S—CH_2Ph and its increase compared with the free ligand value.[5] The methylene protons of the complexes appear as AB quartets (Table 3). The geminal coupling constant is 13.5 Hz. The quartets display greater separation in the thio compared with the sulphinyl azophenolato complexes (cf. **7d–f**, 0.3 ppm; **8d–f**, 0.2 ppm). This is shown in Fig. 3. The coupling constant ^3J(Pt—H) of the thioazophenolates (**7d–f**,

ca 80 Hz) is larger than for the sulphinyl azophenolates (**8d–f**, *ca* 52 Hz) (Table 3). The origin of the differences is unclear at present, but the larger steric demand[10] of the sulphinyl function (compared with the thioether function) may have a role to play. The methylene chemical shifts of the azophenolato platinum(II) complexes (**8d–f**) lie *ca* 0.7 ppm downfield from analogous thioazophenolato platinum(II) complexes (Table 3).

The platinacycles display a very small separation

[*ca* 0.05 ppm ^3J(Pt—H) *ca* 13 Hz] of AB quartets for the $PhCH_2S(O)$-coordinated complexes **6d–e** and a broad band for **5d–e**,[4] which are significantly large in the phenolato complexes. This is because of the *trans* influence of the Pt—C bonds in the former, which is absent in phenolato systems. The aromatic region is complicated by signals from the CH_2Ph substituent and hence is not assigned.

EXPERIMENTAL

Dipotassium tetrachloroplatinate was prepared by a published procedure.[4] 2-(Alkylthio) azobenzenes, their sulphinyl derivatives and platinum(II) complexes were prepared as previously described.[4] 2-Hydroxy-azobenzenes were liberated via the demetallation of palladium azophenolates by 99% hydrazine hydrate.[5] *m*-Chloroperbenzoic acid and hydrazine hydrate (99%) were commercially available. The active oxygen content of *m*-CPBA was measured iodometrically.[14] All other common chemicals were reagent grade and were used as received. Commercially available BDH silica gel (60–120 mesh) was used for column chromatography.

Physical measurements

IR and UV–vis spectra were recorded on Perkin–Elmer 783 and Hitachi 333 spectrophotometers, respectively. ^{1}H NMR data were collected in $CDCl_3$ solvent using Varian XL 200 and Brcker 270 MHz FT NMR spectrometers.

Synthesis of 2-(*methylthio*)*azophenolato platinum*(II) (**7a**)

Direct synthesis. To an aqueous methanolic solution of 2-(methylthio)-2′-hydroxyazobenzene (**9a**) (0.05 g, 0.21 mmol) was added an aqueous solution of K_2PtCl_4 (0.1 g, 0.24 mmol) dropwise with continuous stirring at room temperature. The stirring was continued for 2 h. The colour of the solution was changed from light yellow to pink–violet. The reaction mixture was then evaporated to dryness *in vacuo*. The residue was thoroughly washed with 50% (v/v) water–methanol (5×5 cm^3). The residue was dissolved in dichloromethane (5 cm^3) and chromatographed over a silica gel column (45×1 cm) prepared in benzene. Acetonitrile-benzene (10%, v/v) eluted the desired pink–violet compound. Evaporation of the solvent *in vacuo* afforded the pure crystalline product in 80% yield.

Other complexes were also prepared similarly with 75–85% yield.

By m-*CPBA oxidation*: **5a** → **7a**. A solution of *m*-CPBA (0.052 g, 0.30 mmol) in degassed acetonitrile (10 cm^3) was added dropwise to a magnetically stirred solution of complex **5a** (0.12 g, 0.26 mmol) in the same solvent (25 cm^3). The solution colour immediately changed from brown–red to orange–yellow. The stoppered degassed solution was magnetically stirred continuously for 5 days. The orange–yellow solution very slowly changed to pink–violet. The reaction mixture was then evaporated to dryness *in vacuo*. The residue was thoroughly washed with 50% (v/v) water–ethanol (5×8 cm^3) and then chromatographed using dichloromethane solution over a silica gel column (45×1 cm) prepared in petroleum ether. A small amount of an orange–yellow band was eluted first by benzene and then rejected. The desired pink–violet band was eluted by acetonitrile–benzene (10%, v/v) and evaporated to dryness *in vacuo*. Evaporation of the solvent yielded a pure crystalline compound in 50% yield. Recrystallization from a dichloromethane–hexane layer yielded shining needle-shaped crystals.

Other complexes were also prepared similarly with 45–65% yield. Microanalytical data are given in Table 1.

(*Received* 19 *February* 1993; *accepted* 19 *May* 1993)

Abstract—Alkylation of the rhenium(VII) dichloro compound of the formula $MeRe(NR')_2Cl_2Py$ (**1**) with MeMgCl, Et_2Zn and Pr^iMgCl yields the d^0 trialkyl diimido complexes of the formula $MeR_2Re(NR')_2$ (**2a–c**) (R = Me, Et, Pr^i; R′ = 2,6-dimethylphenyl). Compound **2a** is stable at 25°C, while compounds **2b** and **c** decompose within a few hours. In a similar manner the alkylation of the new tert-butyl imido derivative $MeRe(NBu^t)_2Cl_2$ (**4**) [prepared from $MeRe(NBu^t)_3$ (**3**) by hydrochlorination] yields the trialkyl complexes of the formula $MeR_2Re(NBu^t)_2$ (**5a–c**) (R = Me, Et and Pr^i), of which the mixed-alkyl species are again thermolabile. Analysis of the gas-phase decomposition products revealed a rather complex decomposition pathway, in which the β-hydrogen elimination is likely to play a minor role. Reaction of the polymeric oxo species of the formula $Me_3SnOReO_3$ (**6**) with the silylamine $Bu^tNHSiMe_3$ gives, surprisingly cleanly, the monomeric tris-imido compound of the formula $Me_3SiORe(NBu^t)_3$ (**7**) in 93% yield.

High oxidation state alkyl rhenium complexes containing multiply-bonded ligands such as oxo (=O) or organoimido (=NR) functionalities have received increased attention in the past few years.[1] The stability of these compounds often depends on the nature of the alkyl group. However, it is not yet a settled question as to which decomposition pathways apply for d^0 metal alkyl complexes.[2] Organorhenium(VII) oxides have been shown to catalyse olefin epoxidation and olefin metathesis very efficiently.[3] However, it is not clear how a rhenium-alkylidene unit (Re=CH_2)—known to induce olefin metathesis[4]—is being formed in this system.[5] While several alkyl rhenium oxo and imido compounds are in the literature, very little is known about mixed-alkyl metal derivatives. It was therefore necessary to prepare and study mixed-alkyl rhenium complexes containing alkyl groups with and without β-hydrogen atoms.

RESULTS AND DISCUSSION

Synthesis of trialkyl diimido rhenium(VII) *complexes*

Alkylation of $MeRe(NR')_2Cl_2Py$ (**1**) with neopentyl magnesium chloride yields the mixed-alkyl species $Me(Np)_2Re(NR')_2$ (R′ = 2,6-dimethylphenyl, Np = CH_2CMe_3), which exists in two isomeric forms.[6] One of the isomers was structurally

† Authors to whom correspondence should be addressed.

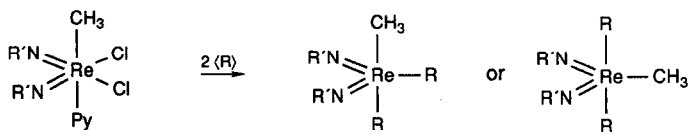
characterized. It exhibits a *tbp* structure with equatorial imido ligands as well as axial neopentyl groups. The compound is stable at ambient temperature. Alkylation of **1** with MeMgCl, Et_2Zn and Pr^iMgCl in a similar manner yields the corresponding species of the formula $MeR_2Re(NR')_2$ (R = Me, Et, Pr^i) (**2a–c**) in 70–80% isolated yield according to Scheme 1.

The trimethyl species **2a** is a low-melting solid which is indefinitely stable at room temperature, like the known imido congener $Me_3Re(NBu^t)_2$.[7] However, the mixed-alkyl derivatives **2b** and **c** decompose within a few hours at room temperature. Although ^1H NMR spectroscopy has its limitations and cannot always be used unambiguously for the determination of organoimido structures,[8,9] the following structures can be proposed for complexes **2a–c**: Since the 2,6-dimethylphenylimido groups are equivalent in all three penta-coordinated compounds, their equatorial position seems likely in the light of the strong competition of these ligands (through the π-bonding) for the empty *d*-orbitals of the metal.[10] The two methyl signals of **2a** (ratio 2/1) give proof of inequivalent methyl groups, two of which must occupy the axial positions of the trigonal-bipyramid while the third is in the equatorial position (Scheme 1). Compound **2b** is a yellow oil that contains two inequivalent ethyl groups (^1H NMR) corresponding to a *tbp* structure with *one* axial and *one* equatorial ethyl ligand. Interestingly, **2c** has two *equivalent* Pr^i ligands that must then occupy the axial positions of the trigonal-bipyramid. This structural difference between **2b** and **2c** can possibly be explained by the bulkiness of the isopropyl as compared with the ethyl group. It is reasonable to assume that two isopropyl groups favour positions *trans* to each other in order to minimize steric repulsion. Although square-pyramidal structures are, in principle, possible for compounds **2a–c**, their close similarity with $Me(Np)_2Re(NR')_2$ (where Np = CH_2CMe_3, R′ = 2,6-dimethylphenyl) of a crystallographically determined *tbp* solid-state structure[6] makes this possibility unlikely. As far as penta-coordinate d^0 rhenium(VII) complexes are concerned, there is a surprisingly great number of species with *tbp* ground-state geometry, e.g. $(Bu^tN)_2ReCl_3$ and $(Bu^tN)_2ReCl_2Ph$,[9] $ReO_2(CH_2CMe_3)_3$,[11a] $MeReO_2(1,2\text{-}O_2C_2Me_4)$,[11b] $RReO_3$(quinuclidine) (R = Et, CH_2SiMe_3),[11c] $[MeReO_3Cl]^-$[11d] and $MeReO_3(H_2NC_6H_5)$.[11e] However, the square-pyramidal geometry does not occur frequently, cf. $(Bu^tN)_2ReCl_2(2\text{-}MeC_6H_4)_2$,[8] $Re(NPPh_3)(SPh)_4$[12a] and $Re(CHBu^t)(N\text{-}2,6\text{-}C_6H_3Pr^i_2)(O\text{-}2,6\text{-}C_6H_3Cl_2)$.[12b] On the other hand, some penta-coordinated d^2-oxo alkyl complexes, e.g. $O{=}Os(CH_3)_4$[13] and $O{=}Os(CH_2CHMe_2)_4$,[14] exhibit even a rigid non-dynamic square-pyramidal geometry.

Reaction of **1** with mesityl- and 2-methylallyl Grignard reagents did not cleanly yield the expected mixed-alkyl compounds of the formula $MeR_2Re(NR')_2$. Instead, decomposition was observed, although neither the alkyl group nor the mesityl group contains a β-hydrogen.

In a similar manner the alkylation of the new di(t-butylimido) dichloro rhenium(VII) complex $MeRe(NBu^t)_2Cl_2$ (**4**) [synthesized from $MeRe(NBu^t)_3$[15] and dry etheral HCl (3 mol)] with MeMgCl, Et_2Zn and Pr^iMgCl gives the corresponding trialkyl diimido rhenium species $MeR_2Re(NBu^t)_2$ (**5a–c**) (R = Me, Et, and Pr^i) in 70–80% yield according to Scheme 2.

Compound **5a** has already been isolated from the reaction of $Re(NBu^t)_2Cl_3$ and $AlMe_3$[7] and a monomeric *tbp* structure was proposed. In contrast, the mixed-alkyl species **5b** and **c** are again thermolabile. Nevertheless, their structure can be assigned on the basis of the ^1H NMR spectra. Thus, the spectrum of **5b** shows *one* Bu^t signal assigned to equivalent t-butylimido groups in equatorial positions as well as *two* different ethyl signals for axial and equatorial positions at the trigonal bipyramid. The ^1H NMR spectrum of **5c** contains *one* Bu^t signal and *two* inequivalent Pr^i signals, indicating a *tbp* structure where the Pr^i groups occupy an equatorial as well as an axial position (Scheme 2). The difference in the configurations of **2c** and **5c** (e.g. *trans* and *cis* Pr^i groups, respectively) is likely

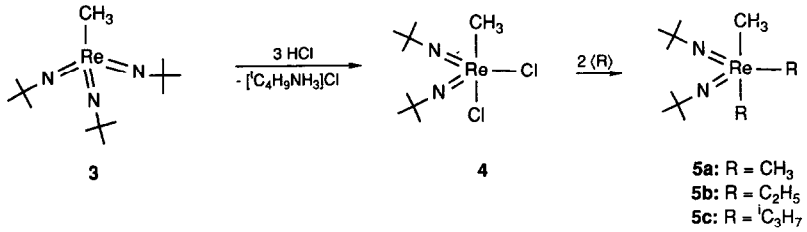


1
R′= 2,6-$C_6H_3(CH_3)_2$

2a: R = CH_3
2b: R = C_2H_5

2c: R = $^iC_3H_7$

Scheme 1. R represents the alkylating reagents CH_3MgCl (for **2a**), $(C_2H_5)_2Zn$ (for **2b**) and $^iC_3H_7MgBr$ (for **2c**).



Scheme 2. For R, see Scheme 1.

to arise from the different steric demand of the *aryl*- and *alkyl*imido ligands. The t-butylimido group is spherically bulkier than the disk-shaped 2,6-dimethylphenylimido group, therefore, one of the isopropyl groups is positioned in the equatorial plane (where it is further away from the t-butylimido groups than in the axial position). Steric constraint is thus relieved. This reasoning only holds if the Pr^i group is smaller than the t-butylimido group, which is probably the case.

Decomposition of the mixed-alkyl rhenium(VII) *complexes*

GC analysis of the gaseous decomposition products of neat **2b** and **c** and **5b** and **c** at 25°C (*ca* 4 h) revealed a rather complex decomposition pattern. In all cases except **2c** the main product is the corresponding C_2 or C_3 alkane (ethane, propane), respectively. The C_2 and C_3 alkene is also formed (20–50% of alkane). The amount of methane is smaller. These results suggest that the homolytic cleavage of the Re—C bond, with concomitant reduction of rhenium(VII) to rhenium(VI), followed by disproportionation of the alkyl radical is not the dominant decomposition pathway, since in this case the amount of alkanes and alkenes should be equal. The β-hydrogen elimination-type decomposition pathway does not play a significant role either, since C_2 or C_3 alkenes, respectively, were expected in this case as the main products.

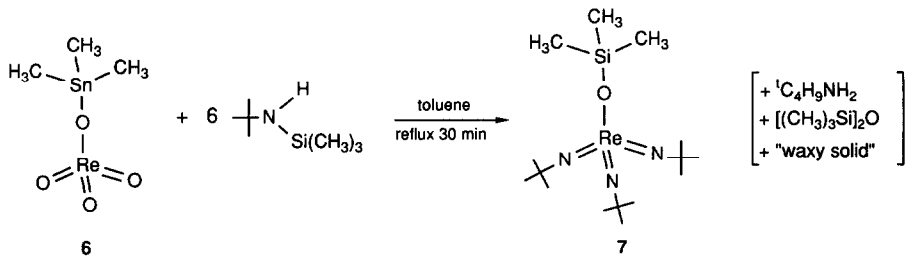
Note that the decomposition was studied without solvent (neat samples). This means that the possibility of hydrogen abstraction from the solvent can be excluded. Also note that **2c** was the only case where more alkene (e.g. propene) than alkane was detected; here, the two isopropyl groups are probably *trans* to each other (^{1}H NMR evidence), a situation that is less likely to result in α-hydrogen abstraction from the other isopropyl group. In this case β-hydrogen elimination could explain the dominant formation of the propene. The ^{1}H NMR spectra of the solid decomposition products gave no clarifying results. It seems obvious that the decomposition behaviour of these mixed alkyl rhenium species is complex. Further efforts must be made to obtain a clear, unambiguous picture. We believe, however, that β-hydrogen elimination is not the major pathway here since the metal (although in its highest oxidation state) is electronically saturated through the strongly π-donating imido ligands.

Synthesis of $MeRe(NBu^t)_2Cl_2$ (**4**) *and* $Me_3SiORe(NBu^t)_3$ (**7**)

The new compound $MeRe(NBu^t)_2Cl_2$ (**4**), used for the preparation of **5a–c**, was synthesized from $MeRe(NBu^t)_3$[15] and 3 equivalents of dry etheral HCl (Scheme 2). The ^{1}H NMR spectrum shows equivalent t-butylimido groups. Since organoimido groups are strong π-donor ligands, we assign them equatorial positions. In contrast to the compound $[R'NH_3]^+[MeRe(NR')_2Cl_3]^-$, formed by hydrochlorination of $MeRe(NR')_3$ (R = 2,6-dimethylphenyl),[6] **4** does not form chloride adducts with the alkylammonium salt formed in the reaction. This result reflects the more electrondonating and/or sterically more demanding character of the t-butylimido group in **4** as compared with the 2,6-dimethylphenylimido ligand.

The synthesis of $MeReO_3$ starting from Re_2O_7 and Me_4Sn also yields the stannoxy complex $Me_3SnOReO_3$ (**6**).[16] The chemistry of this compound is underdeveloped as compared with the siloxy congener, which is mainly due to the polymeric structure of **6**.[17] A facile, simple reaction has now been found to convert this by-product to the more useful tris-imido rhenium(VII) derivative $Me_3SiORe(NBu^t)_3$ (**7**)[18] in excellent yield [eq. (1)].

The other products of this reaction are Bu^tNH_2, $Me_3SiOSiMe_3$ (identified by GC–MS) and a hardly tractable waxy solid that has not been identified due to the difficulty of purification. In theory the stoichiometric reaction of **6** with $Bu^tNHSiMe_3$ (6 mol) produces **7**, Bu^tNH_2 (3 mol), $Me_3SiOSiMe_3$ (2 mol) and "$Me_3SiOSnMe_3$" (1 mol). The ^{1}H NMR spectrum of the waxy solid shows two signals at 1.59 ppm and 3.4 ppm, as in the ^{13}C NMR



6 7

Equation 1. New synthesis of $(CH_3)_3SiORe[N(^tC_4H_9)]_3$(**7**) from (polymeric) $(CH_3)_3SnOReO_3$ (**6**). The "waxy solid" (unidentified) contains the tin introduced through **6**.

spectrum (26.5 and 70.6 ppm). However, further characterization by MS and elemental analysis gave ambiguous results. The only other known reaction of **6** is conversion to $MeReO_3$ by consecutive treatment with trifluoro or trichloroacetic anhydride and tetramethyltin in acetonitrile.[19,20]

EXPERIMENTAL

General data

All experiments were performed under nitrogen or argon atmosphere using standard Schlenk techniques. Solvents were dry and oxygen-free. The starting compounds $MeRe(NR')_2Cl_2Py$ (**1**), $MeRe(NBu^t)_3$ (**3**) and $Me_3SnOReO_3$ (**6**) were prepared according to the literature methods.[6,15,16] Complexes **2a**, **4**, **5a** and **7** gave satisfactory elemental analysis, while in the case of the mixed-alkyl species the results were influenced by the decomposition and also by the high solubility of these oils which made purification difficult. ^{1}H NMR spectra were recorded at 25°C, 400 MHz (JEOL JNM GX-400) and 300 MHz (Varian Unity 300). The amount of the gaseous decomposition products are expressed as the percentage of the total C_1–C_4 fraction.

Preparations

2a–c. To **1** (510 mg, 1.0 mmol) in toluene (15 cm^3) was added at −78°C MeMgCl (2.0 mmol, 1.0 cm^3, 2.0 M Et_2O solution), Et_2Zn (1.0 mmol, 0.8 cm^3, 1.25 M hexane solution) or Pr^iMgCl (2.0 mmol, 2.0 cm^3, 1.0 M THF solution). The mixture was stirred and the temperature was raised slowly to 25°C. Stirring was continued for 1 h and then the solvents were evaporated *in vacuo*. The residue was extracted with pentane. The pentane solution was filtered and evaporated to dryness *in vacuo* yielding compounds **2a–c** as viscous yellow oils. Compound **2a** solidified to an amorphous "semi-solid".

2a. ^{1}H NMR ($CDCl_3$): δ 1.62 (s, 3H, CH_3); 2.04 (s, 6H, CH_3); 2.30 [s, 12H, 2,6-$C_6H_3(CH_3)_2$]; 6.95–7.05 (m, 6H, 2,6-$C_6H_3Me_2$). IR (cm^{-1}, KBr): 2968 m, 2915 m, 1463 m, 1306 vs, 772 vs. MS (*m/z*, rel. int. %): 455 ($[M-CH_3]^+$, 100).

2b. ^{1}H NMR ($CDCl_3$): δ 1.73 [t, J(H—H) = 7 Hz, 3H, CH_2CH_3], 1.96 [t, J(H—H) = 7 Hz, 3H, CH_2CH_3], 2.14 (s, 3H, CH_3), 2.33 [s, 12H, 2,6-$C_6H_3(CH_3)_2$], 2.44 [q, J(H—H) = 7 Hz, 2H, CH_2CH_3], 3.22 [q, J(H—H) = 7 Hz, 2H, CH_2CH_3], 6.95–7.05 [m, 6H, 2,6-$C_6H_3(CH_3)_2$]. GC analysis: CH_4 8%, C_2H_6 68%, C_2H_4 12%.

2c. ^{1}H NMR ($CDCl_3$): δ 1.78 [d, J(H—H) = 7 Hz, 12H, $CH(CH_3)_2$], 1.96 (s, 3H, CH_3), 2.45 [s, 12H, 2,6-$C_6H_3(CH_3)_2$], 3.77 [septet, J(H—H) = 7 Hz, 2H, $CH(CH_3)_2$], 6.95–7.05 [m, 6H, 2,6-$C_6H_3(CH_3)_2$]. GC analysis: CH_4 8%, C_3H_8 34%, C_3H_6 51%.

4. To **3** (830 mg, 2.0 mmol) in Et_2O (15 cm^3) was added dry HCl (3.1 mmol, 3.1 cm^3, 1.0 M Et_2O solution) at −78°C, with stirring. A yellowish precipitate separated and the mixture was allowed to warm slowly to room temperature. After 1 h of stirring the mixture was filtered and the filtrate was concentrated *in vacuo* until most of the product separated as a yellow solid. The remaining small amount of ether was decanted while it was still cold and the product was dried *in vacuo*. Yield 73%. ^{1}H NMR ($CDCl_3$): δ 1.50 [s, 18H, $C(CH_3)_3$], 1.9 (s, 3H, CH_3). ^{13}C NMR ($CDCl_3$): δ 23.6 (s, $ReCH_3$), 28.9 [s, $C(CH_3)_3$], 75.2 [s, $C(CH_3)_3$]. IR (KBr, cm^{-1}): 2960 s, 2905 m, 1440 m, 1360 m, 1255 m (Re=NR), 1290 s.

5a–c. These species were prepared in an analogous manner to **2a–c**, starting from **4** (414 mg, 1.0 mmol) and MeMgCl (2.0 mmol), Et_2Zn (1.0 mmol) as well as Pr^iMgCl (2.0 mmol), respectively.

5a. Identical to $Me_3Re(NBu^t)_2$ reported in the literature.[7]

5b. ^{1}H NMR ($CDCl_3$): δ 1.30 [s, 18H, $C(CH_3)$], 1.45 (s, 3H, CH_3), 1.61 [t, J(H—H) = 7 Hz, 3H, CH_2CH_3], 1.69–1.79 (m, 5H, CH_2CH_3 and

CH_2CH_3), 2.6 [q, J(H—H) = 7 Hz, 2H, CH_2CH_3]. GC analysis: CH_4 14%, C_2H_6 53%, C_2H_4 24%.

5c. ^{1}H NMR ($CDCl_3$): δ 1.3 [s, 18H, $C(CH_3)$], 1.45 (s, 3H, CH_3), 1.71 [d, J(H—H) = 7 Hz, 6H, $CH(CH_3)_2$], 1.79 [d, J(H—H) = 7 Hz, 6H, $CH(CH_3)_2$], 2.5 [septet, J(H—H) = 7 Hz, 1H, $CH(CH_3)_2$], 3.1 [septet, J(H—H) = 7 Hz, 1H, $CH(CH_3)_2$]. GC analysis: CH_4 8%, C_3H_8 60%, C_3H_6 27%.

7. To a suspension of **6** (4.14 g, 10 mmol) in toluene (40 cm^3) was added $Bu^tNHSiMe_3$ (12 cm^3, 63 mmol). The reaction mixture was then refluxed for 30 min. The clear yellow solution was cooled to room temperature and evaporated to dryness *in vacuo*. The residue was extracted with pentane, filtered and the pentane was removed *in vacuo* leaving a yellow oil which quickly crystallized. Yield 93%. The compound is identical to the one prepared by Nugent from $Me_3SiOReO_3$ and $Bu^tNHSiMe_3$.[18] ^{1}H NMR ($CDCl_3$): δ 0.07 [s, 9H, $Si(CH_3)_3$], 1.33 [s, 27H, $C(CH_3)_3$]. MS (m/z, %) 489 ($[M]^+$, 10), 474 ($[M-CH_3]^+$, 98), 418 ($[M-CH_3-C_4H_8]^+$, 35), 362 ($[M-CH_3-2C_4H_8]^+$, 80), 57 ($[C_4H_9]^+$, 100).

(*Received* 20 *April* 1993; *accepted* 11 *May* 1993)

Abstract—Trimethylplatinum(IV) complexes of the type [$PtMe_3X(Me_2NCH_2CH_2ER)$] (X = Cl, Br, I; ER = SBu^t, SC_6H_4Me-4, SPh, SePh, TePh) have been prepared and characterized by elemental analysis and NMR (^1H and ^{13}C) spectral data. The structure of [$PtMe_3Br(Me_2NCH_2CH_2SC_6H_4Me$-4)] has been determined by single-crystal X-ray diffraction. The central platinum atom is coordinated by three *fac*-methyl groups and nitrogen, sulphur and bromine atoms. The five-membered chelate ring PtNCCS is non-planar.

The chemistry of organoplatinum(IV) has attracted much attention in recent years.[1] A wide variety of complexes with nitrogen donors[2–6] and organochalcogenides[7–12] have been synthesized and studied. The organochalcogenide complexes possess interesting dynamic stereochemistries[13,14] and in several cases chalcogen inversion energies have been determined by NMR spectroscopy. However, complexes with hybrid ligands containing one nitrogen and a chalcogen donor have received little attention.[1,15] In this paper we report the synthesis of bidentate hybrid ligands and their complexes with trimethylplatinum halides.

RESULTS AND DISCUSSION

Treatment of trimethylplatinum halides with stoichiometric quantities of $Me_2NCH_2CH_2ER$ gave complexes of the type [$PtMe_3X(Me_2NCH_2CH_2ER)$] (X = Cl, Br, I; ER = SBu^t, SC_6H_4Me-4, SPh, SePh, TePh). ^1H and ^{13}C NMR data are given in Tables 1 and 2. Assignments of NMR chemical shifts and coupling constants are made by comparison with those of the free ligand and complexes of the types [$PtMe_3X(NN)$][2,3,6] and [$PtMe_3X(RE\ ER)$][7,8,10] (E = chalcogen atom). The ^1H and ^{13}C NMR spectra exhibited three Pt—Me resonances in a 1 : 1 : 1 ratio, each flanked with platinum satellites. This suggests that either only one isomer having all three Pt—Me groups *trans* to

[a] s = singlet; d = doublet; t = triplet; m = multiplet; br = broad.

three different ligands, *i.e.* N, E and X, exist at room temperature or interconversion between different isomers is rapid on the NMR time scale. The most shielded resonance in the ^1H NMR spectrum was assigned to the Pt—Me *trans* to halide, while the most deshielded resonance was attributed to the methyl group *trans* to the chalcogen atom. The remaining third resonance appearing between these two resonances was assigned to Pt—Me *trans* to nitrogen. The $^2J(^{195}Pt—^1H)$ lies in the range 69–73 Hz.

The ^1H NMR spectra of the free ligand exhibited a singlet for NMe_2 protons, two triplets or multiplets for methylene protons and expected resonances for ER residue. On complexation the methyl groups of the NMe_2 moiety became anisochronous, since two signals flanked with platinum satellites were observed. One of the methyl signals was little affected in its position from the free ligand and showed larger $^3J(^{195}Pt—^1H)$ (*ca* 15 Hz). The other resonance with a smaller value of $^3J(^{195}Pt—^1H)$ (*ca* 10 Hz) was considerably deshielded; it showed marked halogen dependence and moved to higher frequencies with increasing size of the halogen atom. The magnitude of $^3J(^{195}Pt—^1H)$ has been reported in the range 10–28 Hz, depending on the nature of the ligand.[6,12,16] The ligand methylene protons appeared as a complex multiplet.

For six-coordinate *fac*-$PtMe_3XNE$ complexes two enantiomers (**A** and **B**) with opposite configuration around the metal centre are possible; each one can exist in two isomeric forms (**A**, **C** and **B**, **D**) depending on the orientation of the R group on the chalcogen atom. The room-temperature NMR data discussed above indicate that only one form is present in solution. However, at room temperature a rapid interconversion between these forms is likely. Thus, the low-temperature ^1H NMR spectrum of $[PtMe_3I(Me_2NCH_2CH_2SBu^t)]$ was recorded in CD_2Cl_2 at 500 MHz (Fig. 1). Except the PtMe resonance *trans* to N, all the resonances

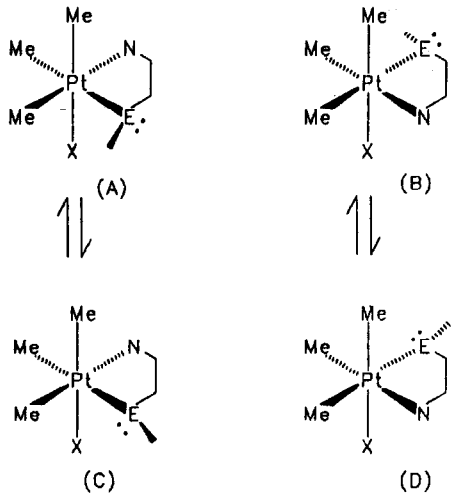
[a] Values in parentheses are $^1J(^{195}Pt—^{13}C)$ in H_3.

showed broadening at various temperatures and on further lowering the temperature resonances separated into two peaks attributable to two isomeric forms, which are present in a 2:3 ratio. Room-temperature ^1H NMR in CD_2Cl_2: δ 1.00 [^2J(Pt—H) = 70.0 Hz, *trans* to I]; 1.40 [^2J(Pt—H) = 70.9 Hz, *trans* to N], 1.52 [^2J(Pt—H) = 72.3 Hz, *trans* to S] (Pt—Me); 1.50 (s, SBu^t); 2.29 [^3J(Pt—H) = 14.6 Hz], 3.02 [^3J(Pt—H) = 11.0 Hz] (NMe_2). At −60°C, isomer **I** (40%): 1.15 [^2J(Pt—H) = 72.5 Hz *trans* to I], 1.25 [^2J(Pt—H) = 71.0 Hz *trans* to N], 1.34 [^2J(Pt—H) = 71.6 Hz *trans* to S] (Pt Me); 1.33 (s, Bu^t); 2.31 [^3J(Pt—H) = 14.8 Hz], 2.86 (NMe_2). Isomer **II** (60%): 0.75 [^2J(Pt—H) = 69.4 Hz, *trans* to I]; 1.25 [^2J(Pt—H) = 71.0 Hz *trans* to N]; 1.32 [^2J(Pt—H) = 71.5 Hz *trans* to S] (Pt Me); 1.46 (s, Bu^t); 2.13 [^3J(Pt—H) = 14.8 Hz], 3.00 (NMe_2). This suggests that these molecules have dynamic stereochemistry in solution and interconversion between two forms is rapid on the NMR time scale at room temperature. The Pt—Me signal *trans* to N did not broaden in the temperature range 27 to −60°C, but was gradually shielded by 0.15 ppm on cooling the solution down to −60°C. For both the isomers the Pt—Me *trans* to N has the same chemical shift.



As is evident from Table 2 the platinum–methyl

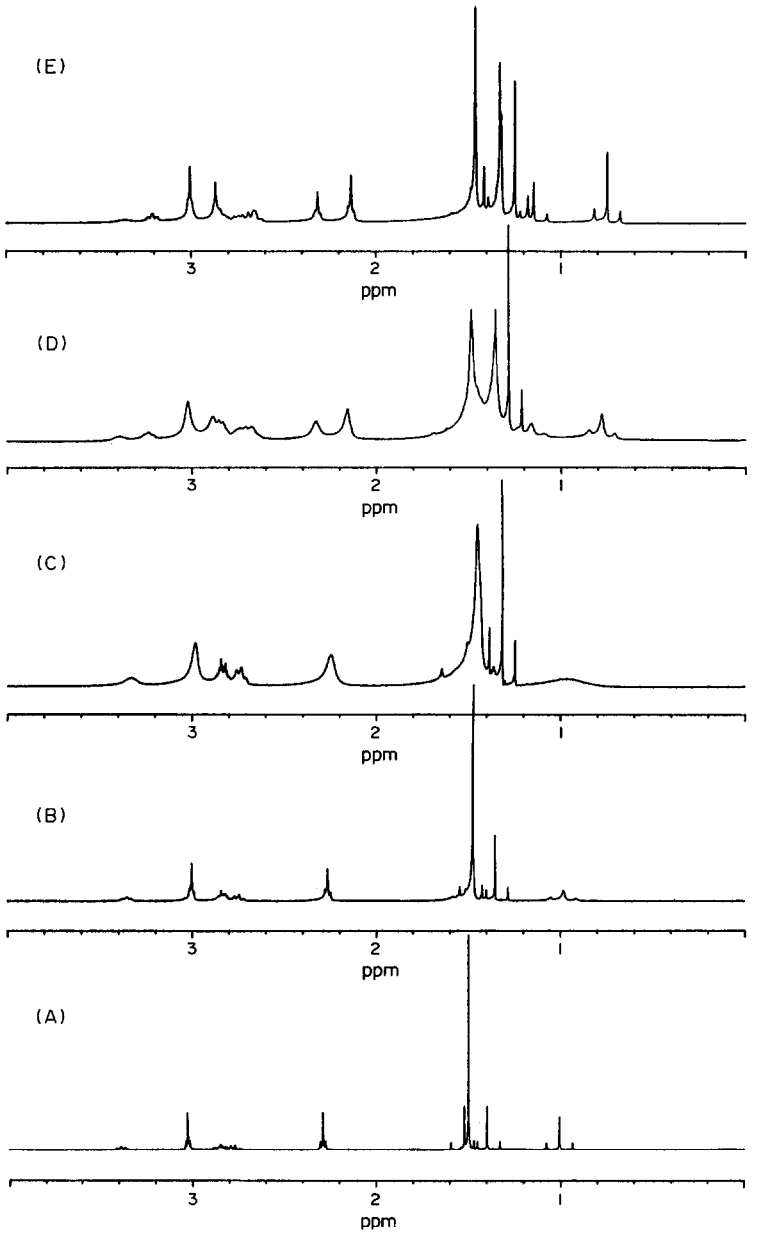


Fig. 1. Variable-temperature ^1H NMR spectra of [$PtMe_3I(Me_2NCH_2CH_2SBu^t)$] in CD_2Cl_2; (A) 27°C; (B) 0°C; (C) −20°C; (D) −40°C; (E) −60°C.

carbon resonances show halogen dependence. The magnitude of $^1J(^{195}Pt—^{13}C)$ for the methyl group *trans* to X is significantly greater than the value observed for the methyl group *trans* to nitrogen or *trans* to the chalcogen atom. The observed values of ^1J(Pt—C) reflect the *trans* influence of various ligands.[17] The magnitude of ^1J(Pt—C) for the methyl group *trans* to halogen also varies with the nature of the halogen atom and follows a trend of ^1J(*trans*-Cl) > ^1J(*trans*-Br) > ^1J(*trans*-I). This is consistent with the *trans* influence of the halogen atoms.[6,10,17]

As with the ^1H NMR spectra $^{13}C\{^1H\}$ displayed two resonances for the NMe_2 carbons with vanishingly small $^2J(^{195}Pt—^{13}C)$. The magnitude of ^2J(Pt—C) in platinum(IV) complexes varies between 3.4 and 108 Hz.[8,10,16] The methylene carbon attached to the ER group was progressively shielded on going from sulphur to selenium to tellurium. This is consistent with the trend of higher shielding with decreasing electronegativity of the atom in analogous compounds.[18]

The structure deduced from NMR data has been established by a single-crystal X-ray study of one

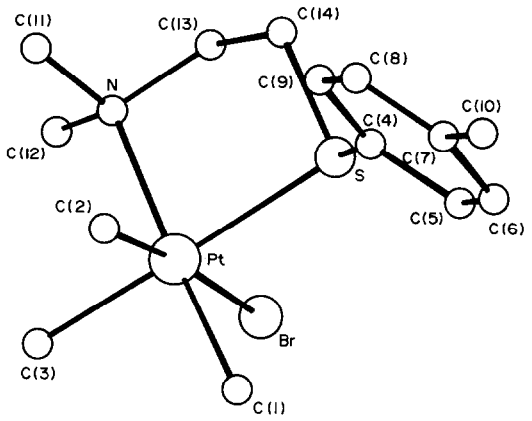

Fig. 2. PLUTO plot of $[PtMe_3Br(Me_2NCH_2CH_2SC_6H_4Me\text{-}4)]$.

representative molecule. The structural analysis of $[PtMe_3Br(Me_2NCH_2CH_2SC_6H_4Me\text{-}4)]$, shown in Fig. 2, revealed that the molecule crystallizes in isomeric form **C**. The central platinum atom is coordinated by three *fac* methyl groups and the nitrogen, sulphur and bromine atoms with the SC_6H_4Me-4 group *cis* to bromide. The configuration about platinum is distorted octahedral with interbond angles in the range 83.9(2)–96.8(4)° for right angles and 174.8(4)–177.4(4)° for linear arrays. The geometry around sulphur is distorted tetrahedral, angles being CH_2SPt 97.7°, CH_2S—tol 104.3° and tol—S—Pt 113.6°. Selected bond lengths and angles are given in Table 3.

The Pt—C distances *trans* to sulphur or bromide are essentially identical, however, the Pt—C distance *trans* to N is shorter. The Pt—C distances are in agreement with those reported earlier for methylplatinum(IV) complexes.[2,10,19,20] The Pt—S distance [2.437(3) Å] is similar to the values found for the trimethyl platinum(IV) complexes with thioether ligands.[10,21] The Pt—N distance [2.310(9) Å] is significantly longer than the values reported for $[PtMe_3I\{(Me_2pz)_2CH_2\}]$ [2.236(4) Å][2] and $[PtMe_3(SSPPh_2)(py)]$ [2.239(9) Å].[20] The Pt—Br distance [2.618(2) Å] is slightly shorter than the distance reported in $[(PtMe_3Br)_2(MeSeSeMe)]$ (mean value 2.629 Å).[22]

The plane defined by PtC(1)C(3)NS atoms (plane **I**) is nearly planar. The five-membered PtNC(13)C(14)S ring (plane **II**) is distinctly non-planar; the maximum deviation of one of the atoms being −0.358 Å. This lies more or less perpendicular to the planar tolyl ring (dihedral angle 78.0°). The dihedral angle between planes **I** and **II** is $4.71 \pm 1.22°$.

EXPERIMENTAL

Trimethylplatinum iodide,[23] $[PtMe_3X]_4$,[24] Ph TeTePh[25] and MeC_6H_4SH were prepared as described in the literature. Diphenyldiselenide (PhSeSePh) (Aldrich), PhSH (Fluka), Bu^tSH (Fluka) and $Me_2NCH_2CH_2Cl \cdot HCl$ were obtained from commercial sources. Analytical grade solvents were used throughout. ^1H NMR spectra were re-

corded on a Bruker AC-200 or Bruker AMX-500 NMR spectrometer. Variable-temperature ^1H NMR experiments were performed in CD_2Cl_2 on a Bruker AMX-500 NMR spectrometer. ^{13}C NMR spectra were recorded on a Bruker AC-200 NMR spectrometer operating at 50 MHz. Chemical shifts are relative to an internal chloroform peak (δ 7.26 ppm for ^1H and δ 77.0 ppm for ^{13}C). Microanalyses were provided by the Analytical Chemistry Division of B.A.R.C. Melting points were determined in capillary tubes and are uncorrected.

Synthesis of $Me_2NCH_2CH_2SPh$

To a solution of NaSPh [prepared from sodium (427 mg, 18.6 mmol) in methanol and thiophenol (2 cm^3, 19.5 mmol)] was added freshly distilled and dried $Me_2NCH_2CH_2Cl$ (2.01 g, 18.7 mmol)[26] with vigorous stirring under nitrogen atmosphere. This was stirred at room temperature for 15 h and filtered. The filtrate was dried *in vacuo* to give a pale yellow liquid which was stored in the fridge. Similarly $Me_2NCH_2CH_2SBu^t$ and $Me_2NCH_2CH_2SC_6H_4Me$-4 were prepared.

Synthesis of $Me_2NCH_2CH_2TePh$

To a benzene–methanol solution of NaTePh [prepared from PhTeTePh (786 mg, 1.92 mmol) and methanaolic $NaBH_4$ solution[25]] was added an excess of $Me_2NCH_2CH_2Cl$ (622 mg, 5.79 mmol) with stirring under nitrogen atmosphere. The reactants were stirred at room temperature for 3 h. The solvents were evaporated *in vacuo*. The residue was extracted with hexane and filtered under a nitrogen atmosphere. The solvent was stripped off *in vacuo*

[a] All complexes were recrystallized from an acetone–diethylether–hexane mixture at 0°C as white or cream coloured solids.

to give an orange–red liquid, which was used immediately. $Me_2NCH_2CH_2SePh$ was similarly prepared, however, only 1 equivalent of 2-dimethylaminoethylchloride was used.

Synthesis of $[PtMe_3I(Me_2NCH_2CH_2SPh)]$

To a benzene solution of $[PtMe_3I]_4$ (107 mg, 0.073 mmol) was added a solution of $Me_2NCH_2CH_2SPh$ (53 mg, 0.29 mmol) with stirring. The reactants were stirred for 4 h and the solvent was evaporated under vacuum. The residue was dissolved in an acetone–ether–hexane mixture (1 : 1 : 2 v/v), which on cooling at 0°C afforded cream-coloured crystals of the title complex in 47% yield. Other complexes were prepared similarly and pertinent data are summarized in Table 4.

Crystallography

All diffraction measurements were performed at room temperature on an Enraf–Nonius CAD-4 diffractometer using graphite monochromatised Mo-K_α radiation, $\lambda = 0.71069$ Å. The unit cell was determined from 25 ($6° < \theta < 11°$) randomly selected reflections using the automatic search, index and least-squares routines. The refined cell constants and other relevant crystal data for the colourless plates of $[PtMe_3Br(Me_2NCH_2CH_2SC_6H_4Me\text{-}4)]$ (size $0.15 \times 0.30 \times 0.30$ mm) are presented in Table 5. All the data were corrected for Lorentz and polarization effects. An empirical absorption correction was applied to the data by measuring the intensities of four reflections with θ near 90° for different ψ values ($0° < \psi < 360°$, every 10°) and using the EAC program, from the Enraf–Nonius package. The maximum and minimum transmission were 0.99 and 0.23, respectively. Two standard reflections (2, 2–27 and 4, 2–7) measured every 1800 s showed no intensity variation.

$R = [\Sigma w(\|F_o\| - \|F_c\|)/\Sigma\|F_o\|$	0.043
$R_w = [\Sigma w(\|F_o\| - \|F_c\|)^2/\Sigma w\|F_o\|^2]$	0.059
Scan technique	θ–2θ

The structure was solved by routine heavy-atom methods and refined by full-matrix least-squares with non-hydrogen atoms anisotropic. Hydrogen atoms were omitted. The weighting scheme was $w = 1/\sigma^2(F)$. A final difference map had a maximum density of 1.37 e Å^{-3} near platinum. Programs from the Enraf–Nonius SDP plus package[27] were run on a PDP 11/73 computer.

SPECTROSCOPY OF LANTHANIDE SINGLE CRYSTALS WITH GLYCYLGLYCINE, $Ln(Gly–Gly)_2(ClO_4)_3 \cdot 4H_2O$ (Ln = Nd, Eu)

E. HUSKOWSKA and J. LEGENDZIEWICZ*

Institute of Chemistry, University of Wrocław, 50-383 Wrocław, Poland

(*Received* 27 *April* 1993; *accepted* 7 *May* 1993)

Abstract—The lanthanide(III) compound with a simple dipeptide (glycylglycine) of the formula $Ln(Gly–Gly)_2(ClO_4)_3 \cdot 4H_2O$ was obtained in the form of mono-crystals. These are the first known single crystals of lanthanides with a dipeptide. Well-resolved absorption and luminescence spectra at room and helium temperatures are reported and analysed. The bonding mode of the Ln^{3+} ions with a simple peptide is compared with the available X-ray data for the calcium compounds with diglycine and triglycine. Absorption spectra were measured along the *a*-axis in the region 9000–40,000 cm^{-1}. The probabilities of *f–f* transitions were analysed and the temperature effect on the intensities considered. Single-ion relaxation processes and cooperative effects are discussed. Stark components were determined and point symmetry was assigned. Energy level diagrams for $^4I_{9/2}$ and $^4I_{11/2}$ states are proposed. Spectroscopy results are compared with the X-ray data.

The lanthanide ions are used as isomorphic substitutes for the Ca^{2+} ion in studies of biological systems. Our recent X-ray data and spectroscopic results of model systems (Ln—amino acids), however, show that this kind of substitution could sometimes not be isomorphic.[1]

In all the cases presented the lanthanide ions create the dimeric or polymeric forms in the structure.[1–10] The type of polymer depends on the Ln : A (A = amino acid) ratio in the compounds and on the amino acid (mono-carboxylate or di-carboxylate). No similar data for lanthanide mono-crystals with simple peptides have been reported as yet. It is of course extremely important to establisih what changes, if any, occur upon metal ion substitution in systems of biological importance. In the studies of calcium bonding proteins the rather isomorphic substitution of Ca^{2+} ions by Ln^{3+} ions was stated in few cases.[11]

To solve the problem of the interaction of lanthanide ions with a simple peptide in detail we have undertaken the X-ray[1–3] and spectroscopic studies of mono-crystals with diglycine. A comparison of Ca^{2+} and Nd^{3+} ion interaction with simple peptides is made.

EXPERIMENTAL

Mono-crystals of the title compounds were obtained from $Ln(ClO_4)_3$ aqueous solutions at pH ≈ 4; the glycylglycine concentration was maintained well below the lanthanide concentration in accordance with the method described in ref. 4. Mono-crystals of composition $Ln(Gly–Gly)_2(ClO_4)_3 \cdot 4H_2O$ precipitated from the solutions.

The concentration of the lanthanide ions in the mono-crystals was determined complexometrically. The density D_m (g cm^{-3}) = 2.089 was found using the flotation method in a mixture of 1,2-dibromoethane and chloroform.

Spectroscopic measurements

Absorption spectra of the neodymium single crystal were measured using a Cary–Varian spectrophotometer at 300 and 5 K. Stark components were determined in the spectra obtained at 5 K. The absorption spectra obtained at room temperature were used for the *f–f* transition intensity analysis. Oscillator strength values of the electronic transitions were calculated over the measured spectral range by the graphical integration method. These values were used in the calculation of τ_λ parameters

from the Judd relation.[12] The calculation procedure is described in refs 7–9.

The fluorescence spectra of the neodymium and europium compounds were measured using a GDM 100 grating monochromator with a cooled photomultiplier tube. An ILA 120 argon laser was used as the excitation source (λ_{exc} = 488, 514 nm); Eu^{3+} ions were excited by a xenon lamp (λ_{exc} = 395 nm); the spectrum were recorded at 77 K on an SLM "Aminco" SPF 500 spectrofluorometer.

RESULTS AND DISCUSSION

The results of the spectroscopic studies of the monocrystals of the title compounds are presented in Tables 1–3 and Figs 1–4. The problems we

wanted to solve by spectroscopic studies and by comparison with the results from the X-ray analysis in this paper are the following: (1) To elucidate how possible changes in the structure are reflected in such spectroscopic properties of a single crystal as intensity of the hypersensitive transition, point symmetry of the lanthanide ions, splitting and broadening of the electronic lines, the appearance of sidebands of the main electronic lines, etc. (2) Discussion of similarities and differences between the title compound and other lanthanide systems with amino acids. (3) Finally, we would like to consider the mechanism of the radiative transition intensity, based on the room and helium temperature measurements, vibronic coupling and cooperative effect.

Before analysing the spectroscopic results of the title compound let us recall the X-ray data. We obtained a series of single crystals of lanthanides with amino acids[1–10] and found the dimeric or polymeric forms in the solid state, although none involved the hydroxide linkages. The reason for such a situation was probably precipitation from the solution at $pH \leqslant 4$. The results of the lanthanide interaction with glycine and polyglycine in solution were reported recently by Brittain.[13] He found that the degree of association by hydroxide linkages was less for complexes with diglycine compared with those of glycine and also suggested that the steric nature of the amino acid ligand played a dominant role in determining the degree of association.

In our studies of the formation of polymeric

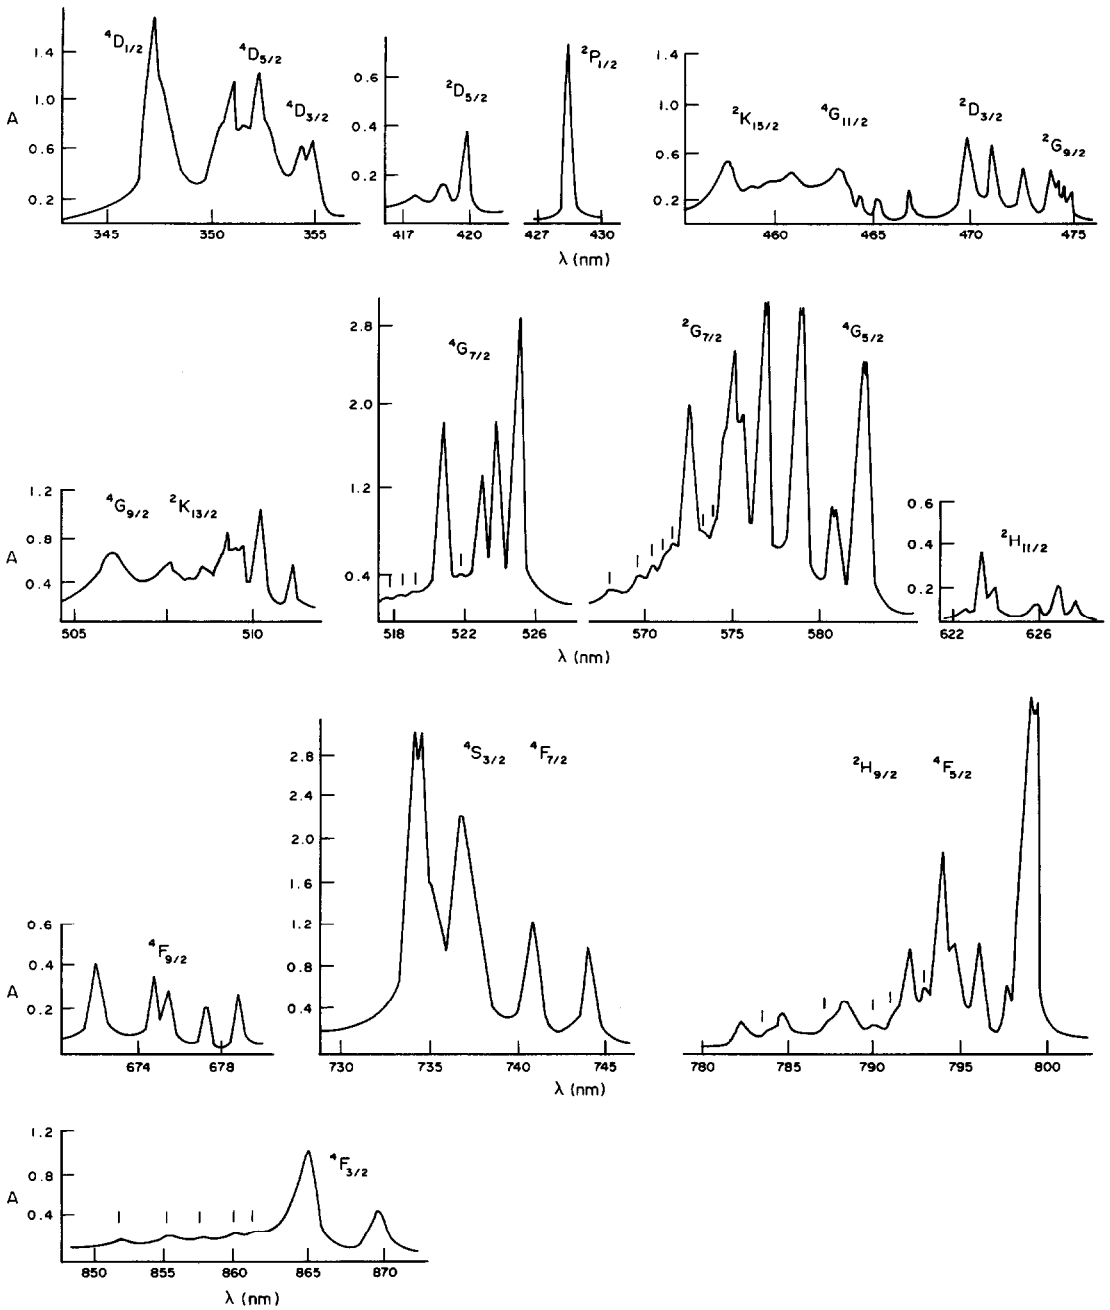

Fig. 2. Absorption spectrum of the neodymium single crystal at 5 K (|—vibronic lines).

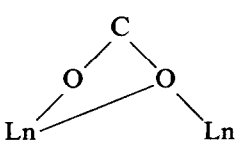
species (even in the case of mono-carboxylate amino acids) the carboxyl bridges of Ln—O—C—O—Ln or



types always participate.[4]

Comparison of the available crystal structure data for Ca^{2+} complexes with glycylglycylglycine[14] with the respective data of $Nd(Gly–Gly)_2(ClO_4)_3 \cdot 4H_2O$[1–3,15] leads to the following statement: in both mono-crystals containing the peptide the Ca^{2+} and Ln^{3+} ions are bonded by the carboxyl and carbonyl group oxygens. However, the coordination numbers are different. The Ca^{2+} ions are bonded to seven oxygen atoms forming approximately a pentagonal bipyramid, but the Ln ions

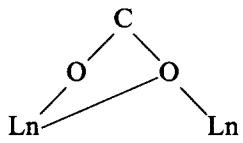
create the nine-coordinate polyhedra with oxygen atoms which belong to the carboxyl groups of different peptides, carbonyl groups and water molecules.[3] Although in both compounds similar carboxyl bridges of the (a) type bond to two different



metal ions, the addition of two Ln—O—C—O—Ln (b) type bridges strengthens the bonding between the two lanthanide ions.[1–3] Such a situation can influence the rate of the exchange of lanthanide ions in the peptide and can lead to differences in exchange rates for Ca^{2+} and Ln^{3+} ions. It could also explain the immediate exchange of Ca^{2+} ions by Ln^{3+} ions after their addition to the calcium binding protein. However, in the case of diglycine calcium ions are coordinated in a different manner and the coordination number is 6.

The X-ray studies of lanthanide compound with diglycine indicate the formation of polymeric forms in the structure involving the carboxyl bridge and the carbonyl group in coordination, thus forming the infinite polymeric chains.[1,3] In such a way the fragments of lanthanide ion pairs, coordinated as in single crystals of complexes with glycine and glutamic acid,[4,8] are repeated in the structure. The differences are given by the chelating properties of the carboxyl and carbonyl oxygens existing in the dipeptide simultaneously.

Since lanthanide ions are treated as spectroscopic probes in studies of biological systems in solution and the solid state, it seemed important to study how those structural factors would influence the spectroscopic properties of the lanthanide ion. The intensity analysis data presented in Table 1 show that the oscillator strength values for some f–f transitions remain almost unchanged in comparison to other lanthanide systems with amino acids[1–10] and aqua ions, but a significant increase was observed for hypersensitive transitions (that obey the selection rule $\Delta J \leqslant 2$ and $\Delta S = 0$) and some transitions observed in the IR region ($^4I_{9/2} \rightarrow {}^4F_{5/2}$, $^2H_{9/2}$; $^4S_{3/2}$, $^4F_{7/2}$), see Table 1. The oscillator strength of the hypersensitive transition is similar to that in the single crystal spectra (in one orientation) of the glutamic acid complex.[1,5] This means that although there are differences observed in the coordination of the Nd^{3+} ion, bonding lengths and point symmetry remain similar. However, a precise comparison will be achieved when a big enough single crystal of the title compound is obtained and spectroscopic data at the different crystal orientations can be measured (since the crystals are biaxial). Up to now, however, we have not been able to obtain a crystal suitable for such studies.

The bonding mode of the carboxyl group in both cases remains the same. The additional chelate

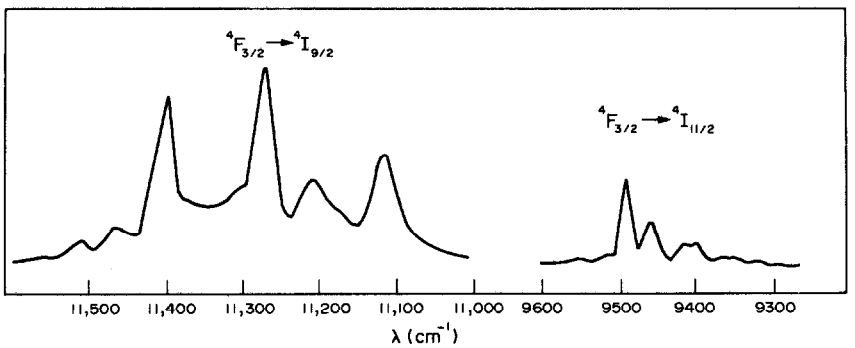


Fig. 3. Fluorescence spectrum of the neodymium single crystal at 5 K.

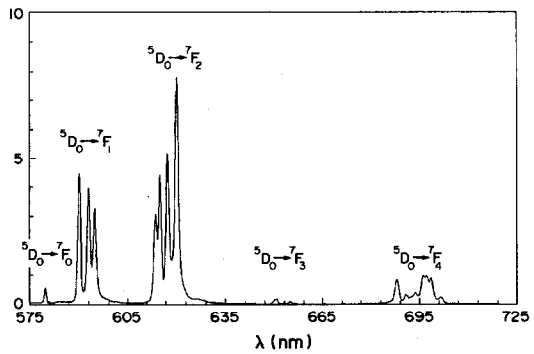

Fig. 4. Fluorescence spectrum of the europium compound at 77 K.

coordination of the CO group of the peptide, however, does not cause a significant change in the direct Nd^{3+} ion environment, so the spectroscopic properties and intensity of these two systems are comparable at room temperature. A subtle distortion of molecular symmetry for four sites of Nd^{3+} in the glutamic acid compounds is not detectable in the room temperature spectra.[5,8]

It is worth noting that in both the absorption and luminescence spectra significant broadening of the optical lines is observed, being, however, less than that observed in the spectra of single crystals with DL-alanine[5,6,15] (Figs 2–4). The differences between the structures are as follows: in the former structure the polymeric chain is formed by linking the dimeric subunits; in the latter dimers are only formed with equivalent lanthanide ions positions, so only one site is occupied. Ln—Ln distances are 3.996 and 4.439 Å, respectively. In both systems the ion pair interactions could lead to the broadening of the optical lines or to the appearance of additional lines (see Figs 2–4).

Regarding the subject of the splitting patterns of luminescence bands (see Fig. 4), $^5D_0 \rightarrow {}^7F_J$ transitions show the C_{2v} point symmetry[16] for the Eu^{3+} ion and also for the Nd^{3+} ion, since the neodymium and europium single crystals are isomorphic. Figure 4 pictures the luminescence spectrum in the region 5780–7500 Å with the Stark components found for 0–0, 0–1, 0–2, 0–3 and 0–4 transitions. The group theory consideration allowed us to assign for 0–0 A_1, 0–1 A_2, B_1, B_2, 0–2 $2A_1$, B_1, B_2, 0–3 A_1, $2B_1$, $2B_2$ and for 0–4 $3A_1$, $2B_1$, $2B_2$ components.[16] The spectroscopy data obtained at 5 K in the region of the $^4I_{9/2} \rightarrow {}^2P_{1/2}$ transition indicate that only one position is occupied by the Nd^{3+} ion, thus confirming the X-ray crystallography data (Fig. 2). These results differ significantly from those for the glycine complex with neodymium, where two different symmetry positions were stated, and for the L-glutamic acid complex with neodymium, where four symmetry sites were found at 5 K.[1,15] Those four positions were not exhibited in the spectra at 77 K.[8]

On the basis of absorption spectra at 300 and 5 K and luminescence spectra at 5 K (see Fig. 3) the energy level diagrams are proposed (Table 2). It was found that splitting of the $^4I_{9/2}$ ground state is equal to 378 cm^{-1} and is almost the same as for other systems with coordination number = 9.[17] Table 2 includes the Stark components of transitions observed in measured spectral regions. The

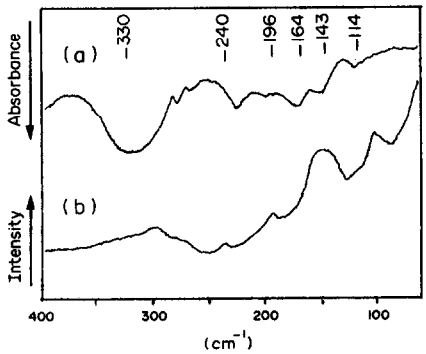

Fig. 5.(a) IR and (b) Raman spectra of the Nd(Gly–Gly)$_2$(ClO$_4$)$_2$·4H$_2$O crystal.

splitting pattern corresponds to the energy level scheme determined by Carnall *et al.* in the absorption spectra of Nd^{3+} ions doped into single crystals of LaF_3 with C_{2v} point symmetry.[18] Figure 2 shows the absorption spectrum of a single crystal of $Nd(Gly–Gly)_2(ClO_4)_3 \cdot 4H_2O$ at 5 K. The complex structure of bands is striking, mainly of those related to the transitions which obey the selection rule $|\Delta J| = 2, 0$; $^4I_{9/2} \rightarrow {}^4G_{5/2}$, $^2G_{7/2}$; $^4F_{5/2}$, $^2H_{9/2}$. This structure is accompanied by the greatest intensity differences as a function of temperature (Table 1).

The weak satellite lines in the high energy range of these bands result from vibronic coupling and ion pair interactions. The electron–phonon interactions were observed in the spectra of coordination compounds with organic ligands by Caro *et al.*[19,20] and by us.[15,21–23] The mechanisms of these transitions were interpreted as interference between respective energy differences of Stark components and phonons of organic molecules. The vibronic components in emission and excitation spectra of europium and gadolinium inorganic systems were widely investigated by Blasse and co-workers.[24–26] They discussed the vibronic transition probabilities in the systems under investigation in terms of the existing theories.

The ion pair interaction has been experimentally studied for lanthanide ionic compounds by Buisson,[27] Malinowski,[28,29] Stręk,[30] Blasse[31,32] and others, but lanthanide molecular systems only by Güdel[33] and by us.[15,21–23,34] Theoretical investigation of this phenomenon was reported by Dahl[35] in the PrF_3 system. Elucidation of the two effects (cooperative effect and vibronic coupling) needs spectroscopic studies of diluted $La_{1-x}Nd_x(Gly–Gly)_2(ClO_4)_3 \cdot 4H_2O$ single crystals. In spite of our efforts up to now we have not been successful in preparing this type of crystal.

Let us analyse the results of the spectroscopic data of fully concentrated single crystals. In the energy region of $^4I_{9/2} \rightarrow {}^2G_{7/2}$, $^4G_{5/2}$; $^4F_{5/2}$, $^2H_{9/2}$; $^4F_{3/2}$; $^4G_{7/2}$ transitions the vibronic sidebands corresponding to the transitions described in Table 3 appear. We have attributed only those lines which were repeated in the composition with all the Stark components observed in the analysed transition. These results correspond quite well to the phonons observed in the IR and Raman spectra (Fig. 5). All bands below *ca* 100 cm^{-1} should be assigned to the odd phonon transitions connected with librational and torsional vibrations of the Ln—O—C—O—Ln ribbon. Besides these sidebands additional strong lines appear for the $^4I_{9/2} \rightarrow {}^4G_{5/2}$, $^2G_{7/2}$ and $^4I_{9/2} \rightarrow {}^4F_{5/2}$, $^2H_{9/2}$ transitions. Their number is irrelevant to the one symmetry site of the Nd^{3+} ions. They result from Davydov splitting. The mechanism of interaction between the Ln^{3+} ion pair can be different: EPI, EMI, MDD, EDD or EX.[35] Vial and Buisson[36] have found exchange to be the most important mechanism for the excitations with higher energies. Dahl and Schaack have reported the magnetoelastic effect in the PrF_3 crystal.[35] At this stage it is difficult to decide which mechanism is predominant. A doublet structure was observed by Caro in neodymium complexes with organic ligands[19] and by us in almost all the polymeric single crystals, thus confirming the close relationship between polymeric structures and the nature of this kind of spectra.[15] This means that two mechanisms are most probable, EPI or EX. The former is close to that proposed by Davydov in polymeric biological systems, and called the solitons mechanism.[37]

A comparison of the neodymium complex with glycine and diglycine leads to the following statements: the Nd^{3+} ion creates, with glycine, triclinic mono-crystals of the formula $Nd(Gly)_3(ClO_4)_3 \cdot 4.5H_2O$.[5] Although in the structure similar coordination modes of carboxyl groups were found and the coordination number of 9 for Nd^{3+} ions is identical to the diglycine complex, only linear polymers in the structure are formed to engage the dimeric pairs of type (a) linked by the weaker bridge of type (b). The point symmetry of Nd^{3+} seems to be C_{2v}, similar to the case of diglycine mono-crystal.

Note that the type of lanthanide coordination in the dipeptide remains the same as in glycine. A similar rule can be found in another complex with glycyl-L-tyrosine.[38] Probably the coordination of the Ln^{3+} ion with particular amino acid residues of peptides will be the same as by a single amino acid.[3,4,7,15]

STUDIES ON MIXED LIGAND COMPLEXES OF RUTHENIUM(II) CHIRAL SCHIFF BASES WITH NITROGEN DONORS

R. I. KURESHY† and N. H. KHAN

Discipline of Coordination Chemistry and Homogeneous Catalysis,
Central Salt and Marine Chemicals Research Institute, Bhavnagar 364002, India

(*Received* 23 *March* 1993; *accepted* 5 *May* 1993)

Abstract—Mixed ligand complexes of the ruthenium(II) ion using chiral Schiff bases derived from salicylaldehyde, chloro- and methoxysalicylaldehyde and L-histidine with mono- or bidentate nitrogen bases such as azide, imidazole and 2,2-bipyridyl have been synthesized. The characterization was performed by microanalysis, IR, UV–vis $\{^1H\}$, $^{13}C\{^1H\}$ and $^{31}P\{^1H\}$ NMR spectroscopy, conductance measurement, optical rotation, CD spectral studies and electrochemistry. The conformational aspects regarding the asymmetric carbon atom and the nitrogen containing ligands around the ruthenium(II) metal ion have been discussed. The complexes show quasi-reversible behaviour in cyclic voltammetry and the redox potentials of the Ru^{II}/Ru^{I} couplies lie in the range -0.12 to -0.29 V.

The study of mixed ligand complexes is relevant in the field of analytical chemistry, where the use of mixed ligand complexes allows the development of increased selectivity and sensitivity; also it has great importance in the fields of biological and environmental chemistry. Metal chelates of aminoalcohols play important roles in nature, e.g. in the hormones adrenaline and noradrenaline and in amino polysaccharide chemistry.[1] Orthohydroxycarboxylic acid has biological significance and is considered as a model compound in the study of humic and fulvic acids in soils.[2,3] They also have pharmaceutical applications[4,5] owing to the anti-inflammatory properties of their transition metal complexes.[6,7] Mixed ligand complexes of platinum,[8] palladium,[9] ruthenium(II) and ruthenium(III), such as $[(DMSO)_4RuCl_2]$[10] and $[(NH_3)_4RuCl_2]Cl$,[11] are known to possess anti-tumour and antibacterial activity. In view of the importance of these ruthenium complexes we have undertaken the studies of mixed ligand complexes of ruthenium(II) using chiral ligands derived from L-histidine and salicylaldehyde, 5-chloro- and 5-methoxysalicylaldehyde with mono- and bidentate nitrogen bases, viz. azide imidazole and 2,2-bipyridyl with the exception that both types of ligand may deeply affect the known properties, viz. electronic and dichroic behaviour of these mixed ligand complexes.

RESULTS AND DISCUSSION

The complexes were prepared by the replacement of water molecules in terdentate (ONO) chiral ruthenium(II) Schiff base complexes by mono- or bidentate nitrogen denors, such as azide, imidazole and 2,2-bipyridyl (Scheme 1), with a colour change from green to brown or brownish-red for the complexes **1–3** and **7–9**, while **4–6** are all dark green. The analytical and molar conductance data are presented in Table 1. Complexes **1–3** are 1 : 1 electrolytes in methanol, while complexes **4–9** are non-electrolytic in nature.

The IR spectra of the complexes show intense bands near 1605–1590 cm^{-1}, due to the coordinated azomethine group which overlaps with the $(COO^-)_{asym}$ stretching mode. The $(COO^-)_{sym}$ stretching mode lies at 1440 cm^{-1}. A broad band at 3300–3400 cm^{-1} in complexes **1–6** is due to coordinated water occupying the axial position and the bands due to coordinated linear azide appear near 2030, 1325, 630 and 425 cm^{-1}, which are assigned to the asymmetric, symmetric, N_3^- stretching, N_3^- bending and Ru—N_3^- stretching

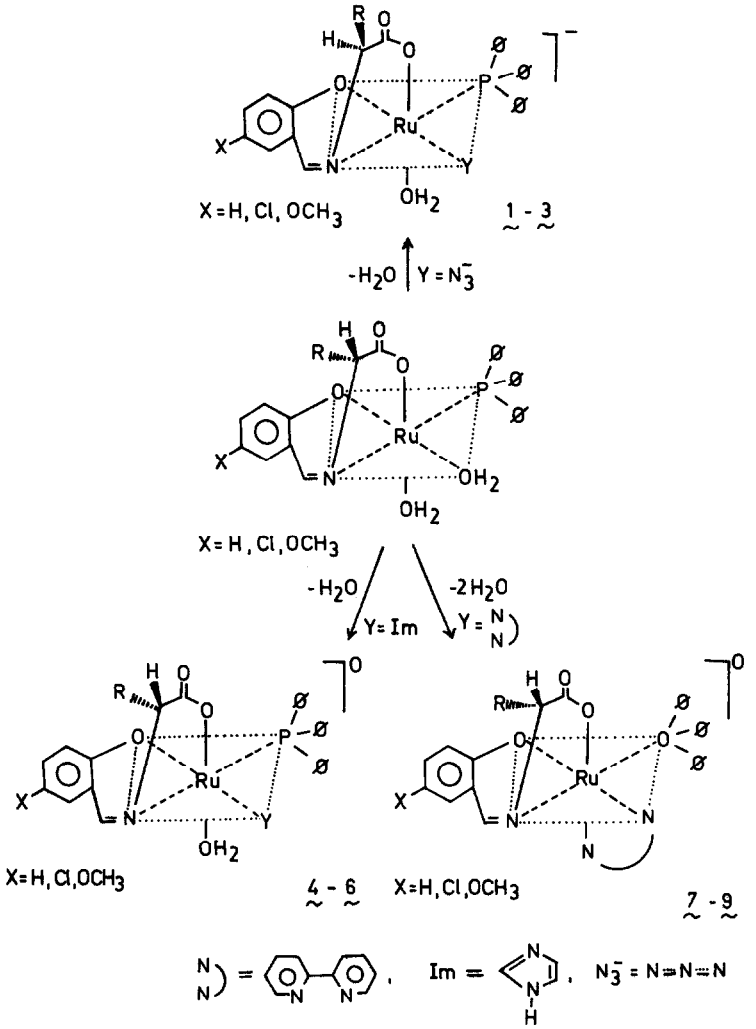

Scheme 1.

modes, respectively,[12] in **1–3**. However, the mixed ligand complexes **4–6** show bands at 618, 650 and 1060 cm^{-1}, due to coordinated imidazole (Table 2). Complexes **7–9** show bands near 1600, 1575, 1460, 1242, 1160 and 770 cm^{-1} due to the coordinated 2,2 bipyridyl ligand.[13] Some of the bands are merged with IR bands of the symmetric or asymmetric COO^- group, azomethine group and ring vibrations. In the far-IR region bands at 550 and 345 cm^{-1} are assigned to ν(Ru—P) and ν(Ru—N), respectively.

The electronic spectra of the complexes recorded in methanol show a high intensity charge-transfer band at 372 ($\varepsilon = 2162$) to 395 nm ($\varepsilon = 2500$) along with the intraligand bands at 320 nm ($\varepsilon = 2500$). The $d \rightarrow \pi^*$ L band in all the complexes lies in the range 604 ($\varepsilon = 878$) to 798 ($\varepsilon = 1171$) nm (Table 3). The position of this band depends on the donating nature of the substituents attached to the metal ion in the chelating ring.[14] The energy of this band decreases in the order N_3^- > Im > 2,2 bipy.

Since complexes **1–6** have an optical centre at metal also so it is possible to investigate the dichroic behaviour of LMCT and *d-d* transitions.

The CD spectra of the complexes in methanol show CD λ_{max} LMCT bands red shifted with respect to the electronic absorption maximum (Table 3). The large red shifts are accompanied by a marked increase in dichroic behaviour. In equatorial binding a blue shift in the *d-d* bands is seen (Table 3) with increased intensity due to substituted azide and imidazole as compared with 2,2-bipyridyl, because the ligand-field transition borrows intensity from the low energy azide or imidazole-to-ruthenium(II) LMCT transition.

Two representative CD spectra, Fig. 1(A), of 5MeOSal[L-hisazidotriphenylphosphinoaquoruthenate(II) and 5ClSal[L-histriphenylphosphino-2,2-

bipyruthenate(II), [Fig. 1(B)] in methanol show that complexes **A** and **B** have different geometrical configurations and that complex **A** is stereospecifically coordinated to ruthenium metal ion so that the *gauche* chelate ring is located in the λ form, while complex **B** is an equilibrium mixture of the two isomers (λ and δ) with more of the δ-form. Molecular model construction reveals that complexes **1–3** tend to acquire the *S* configuration because of the steric hindrance created by the free rotation of azide with that of the —CH_2 group of the histidine moiety on one side and PPh_3 on the other (Fig. 2), which is also evidenced by the presence of a positive value of the optical rotation (Table 3), while no such steric interaction occurs in the case of complexes **4–9** and they acquire the *R* configuration. Similar interactions were also reported earlier.[15,16]

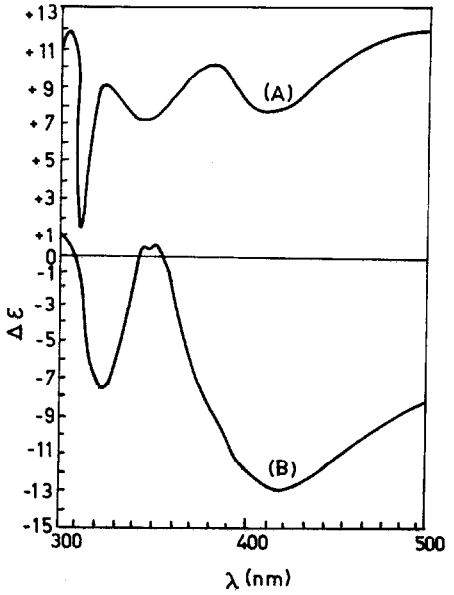

Fig. 1. CD spectra of (A) 5MeOSal[L-hisazidotriphenyl phosphinoaquoruthenate(II)] and (B) 5ClSal[L-histriphenyl phosphino-2,2-bipyridylruthenate(II)] in MeOH.

^{1}H NMR spectra of the complexes in DMSO-d_6 show resonance signals at 2.5–2.04 and 1.13–1.15 ppm due to the proton on the asymmetric carbon and —CH_2 protons. The resonance signal due to the OCH_3 protons is merged with the signal of DMSO-d_6 at 3.39 ppm in complexes **3**, **6** and **9**, while the signals near 6.10–7.00 and 8.12–8.20 ppm are due to aromatic and azomethine protons. A singlet at 14.10–14.50 ppm is due to the NH proton of imidazole, which is confirmed on shaking complexes **4–6** with D_2O; this signal disappears due to fast exchange of protons. Complexes **7–9** show resonance signals around 9.6–10.2 ppm due to the coordinated 2,2-bipyridyl ligand, which is also reported elsewhere.[17]

$^{13}C\{^1H\}$ NMR spectra of the complexes in DMSO show signals at 48.94 and 55–55.9 ppm due to carbon atoms of the —CH_2 and —CH groups, while complexes **3**, **6** and **9** show a singlet at 85.83

[a]A platinum electrode is the working electrode, the solvent is MeOH, the supporting electrolyte is tetrabutyl ammonium perchlorate (0.001 M), the reference electrode is Ag/AgCl and the scan rate is 200 mV s^{-1}.

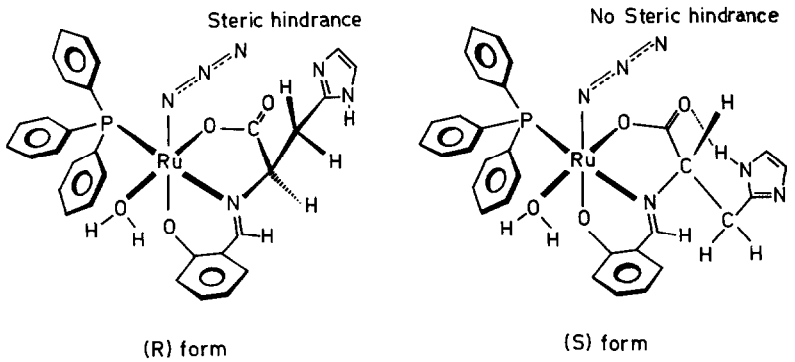

Fig. 2. Configurational aspects regarding azide in the vicinity of the complexes **1–3**.

ppm due to the carbon atom of the methoxy group. The resonance signals in the range 126.31–132.00 ppm are due to carbon atoms of the aromatic rings and a signal at 197.21–200.22 ppm is due to the carbon atom of the coordinated carboxylato group (Table 4). Signals in the range 151–154 ppm are due to the carbon atom directly attached to the nitrogen of 2,2-bipyridyl[18] and resonance signals near 124.6 ppm are due to other carbon atoms in complexes **7–9** (Table 4).

$^{31}P\{^{1}H\}$ NMR spectra of the complexes in DMSO show a singlet in the region 32 ppm due to the presence of only one triphenylphosphino group *trans* to the nitrogen of the azomethine group.[19,20]

The cyclic voltammogram of the complexes in methanol show quasi-reversible (Table 5) one-electron Ru^{II}/Ru^{III} oxidation couples in the potential range +0.65 to +0.94 V vs Ag/AgCl. From the cyclic voltammogram and differential pulse voltammogram the $E_{1/2}$ values of the Ru^{II}/Ru^{I} couple lie in the range −0.12 to −0.29 V. The shift in the redox couple is due to the coordinated nitrogen containing ligands to the ruthenium metal ion.

EXPERIMENTAL

$RuCl_3 \cdot 3H_2O$ was obtained from Johnson Matthey; triphenylphosphine, sodium azide, imidazole, 2,2-bipyridyl (Sisco), salicylaldehyde, 5-chlorosalicylaldehyde, 5-methoxysalicylaldehyde and L-histidine (Aldrich) were used as received. All the chiral Schiff bases were synthesized by a reported procedure.[21] The metal complex $[RuCl_2(PPh_3)_3]$[22] and the chiral ruthenium(II) Schiff base complexes were synthesized by a reported method.[23]

Microanalyses of the complexes were performed on a Carlo Erba Analyser model 1106. Molar conductance was measured at room temperature on a Digisun electronic conductivity bridge DI-909. The IR spectra were recorded on a Carl–Zeiss Specord M-80 spectrophotometer in Nujol mulls/KBr. Electronic spectra were recorded in a Shimadzu UV–vis recording spectrophotometer model 160. ^{1}H, $^{13}C\{^{1}H\}$ and $^{31}P\{^{1}H\}$ NMR spectra were obtained on a Jeol FX-100 NMR spectrometer in DMSO-d_6 and DMSO using $[Si(CH_3)_4]$ as an internal standard and operating at 99.55, 24.99 and 40.27 MHz, respectively. Cyclic voltammograms, and differential pulse voltammograms were recorded with a Princeton Applied Research (PAR) instrument using tetrabutylammonium perchlorate as the supporting electrolyte in methanol. The optical rotation of the complexes in methanol was measured using a polarimeter (Atago Japan). The CD spectra were recorded in methanol by Jasco Machine Model J-20, Japan.

Synthesis of $[RuL(PPh_3)(N_3)^-(H_2O)]^-Na^+$ (1–3)

A hot solution of the complexes $[RuL(PPh_3)(H_2O)_2]$ (0.01 mmol) in dichloromethane/methanol was refluxed with sodium azide (0.013 mmol) for 8–10 h under constant stirring. After completion of reaction the solutions were filtered and concentrated on a rotaevaporator to a small volume and then precipitated by diethyl ether. They were filtered, washed and dried *in vacuo*; yield 60–62%.

$[RuL(PPh_3)(Im)(H_2O)]$ (4–6) *and* $[RuL(PPh_3)(2,2\text{-bipy})]$ (7–9)

Complexes $[RuL(PPh_3)(H_2O)_2]$ (0.01 mmol) were dissolved in dichloromethane/methanol and refluxed with imidazole or 2,2-bipyridyl (0.01 mmol) for 8–9 h. The resulting solutions were filtered, concentrated on a rotaevaporator and precipitated by diethyl ether. They were filtered, recrystallized in CH_2Cl_2/MeOH and dried *in vacuo*; yield 74–75%.

Abstract—^{115}In NMR studies are reported for InX_3 (X = Cl, Br, I) solutions in hexamethylphosphoramide (HMPA). The resonances of InX_4^- anions are observed for tribromide and triiodide solutions. Mixed $InBr_{4-n}I_n^-$ anions may be obtained for the mixtures of InI_3 and $InBr_3$. A trigonal-bipyramidal complex, $InCl_3(HMPA)_2$, is formed from $InCl_3$–HMPA solutions. Diiodotetrakis(hexamethylphosphoramide)indium(III) iodide has been prepared from an InI_3–HMPA system and fully characterized by elemental analysis, IR and NMR spectroscopy and X-ray crystallography. The cation is *trans*-octahedral. ^{19}F NMR spectra of $In(NO_3)_3$–F^-–HMPA systems demonstrate the formation of six-coordinate mixed $InF_n(HMPA)_m(H_2O)_{6-n-m}^{3-n}$ species.

The high donor number (DN_{SbCl_5} = 38.8) of hexamethylphosphoramide (HMPA) makes it a strong ionizing solvent. Besides this, the shape and dimensions of the HMPA molecule cause different steric interactions in the adducts solvated by it and so complexes with unusual stereochemistry may be formed.

The coordination chemistry of indium(III) halide compounds with HMPA has not been studied intensively. There are no data on solution chemistry of indium species in HMPA and only two works are devoted to the solid-state chemistry of indium adducts with HMPA.[2,3] When studying coordination compounds of aminophosphine oxides Bolster obtained a number of indium(III) halide adducts with HMPA–$InX_3(HMPA)_2$ (X = Cl^-, Br^-, I^-).[2] Based on the data of vibrational spectroscopy Bolster proposed a dimeric structure for these compounds, $[InX_2(HMPA)_4]^+[InX_4]^-$ with *trans*-geometry of the cation. Later, a chloride complex with the same composition was characterized by X-ray crystallography.[3] Indium was shown to be in a trigonal-bipyramidal arrangement with hexamethylphosphoramide molecules in axial positions and three chloride ions in equatorial positions.

The present paper concerns the investigation of a number of complexes formed from InX_3–HMPA (X = Cl^-, Br^-, I^-) and $In(NO_3)_3$–F^-–HMPA–H_2O systems, both in solution and in the solid state, and also continues the consideration of the stereochemical aspects and mutual influence of ligands in mixed halo species of indium(III).

EXPERIMENTAL

Materials

Indium trichloride was prepared by chlorination of indium(III) oxide with CCl_4 at *ca* 450°C. Indium triiodide was obtained according to the literature procedures.[4,5] $(C_4H_9)_4NInX_4$ salts were prepared as insoluble precipitates when mixing aqueous solutions of InX_3 and $(C_4H_9)_4NX$ and their subsequent

* Authors to whom correspondence should be addressed.

recrystallization was achieved from acetonitrile followed by drying *in vacuo*. Indium trinitrate was obtained by dissolving indium(III) oxide of a stoichiometric quantity of nitric acid.

The salts of $InBr_3$, $InF_3 \cdot 3H_2O$, NH_4F and $(CH_3)_4NF$ were obtained from commercial sources without further purification.

Hexamethylphosphoramide was rigorously dried and distilled by standard methods and was used as a solvent for preparing the solutions. All operations with InX_3 ($X = Cl^-$, Br^-, I^-) salts and HMPA were performed under nitrogen.

Preparation of the compounds

X-ray quality crystals of **I** and **II** were grown by slow evaporation of $InCl_3$ and InI_3 solutions, respectively, in HMPA in a vacuum desiccator. The crystals were washed with a small amount of CCl_4 to remove the excess HMPA. The crystals of both **I** and **II** are colourless and transparent. The crystals of **II** are very unstable and completely decompose in air in a few minutes.

Spectra

IR spectra of samples **I** and **II** were run on a Specord 715 IR spectrometer between 400 and 4000 cm^{-1}. ^{115}In, ^{31}P, ^{19}F and ^{1}H NMR spectra were obtained with a Bruker AC-200 P spectrometer. All samples were run as solutions. The main experimental conditions are given in Table 1.

X-ray structure determinations

An Enraf–Nonius CAD-4 diffractometer using graphite-monochromated Mo-K_α radiation was used for structure determinations.

The unit cell parameters of crystals of **I** indicated absolute similarity with the penta-coordinated complex $InCl_3(HMPA)_2$ described in ref. 3.

For preserving, a single crystal of **II** was cemented to a glass fibre and mounted into a sealed Pyrex capillary (under nitrogen) and was then examined on a diffractometer.

Data were collected at 200(2) K for $2\theta_{max} = 50°$. The crystals of **II** belong to the triclinic space group $P\bar{1}$. The unit cell parameters and other crystal data for **II** are: $a = 14.053(3)$, $b = 17.621(3)$, $c = 20.920(4)$ Å; $\alpha = 73.89(1)$, $\beta = 89.25(2)$, $\gamma = 80.05(2)°$; $V = 4899(2)$ Å^3; $Z = 4$, $\mu = 25.1$ cm^{-1}. A total of 8104 independent reflections were measured, of which 6213 with $I \geqslant 2\sigma$ were used for calculation.

The positions of indium and iodine atoms were derived from the heavy-atom procedure; the positions of the remaining non-hydrogen atoms were revealed by a sequence of the difference-Fourier syntheses. The coordinates of the hydrogen atoms were determined for geometrically idealized positions (C—H, 1 Å). Block-diagonal least-squares anisotropic refinement for all non-hydrogen atoms (866 refined parameters) with regard to the hydrogen atoms ($U_{eq} = 0.06$ Å^2) converged to values of $R = 0.057$, $R_w = 0.056$, GOOF = 1.97, $w = (\sigma^2(F_0) + 0.0001F_0^2)^{-1}$.

RESULTS AND DISCUSSION

The ^{115}In NMR spectra of InX_3 ($X = Br^-$, I^-) solutions in HMPA show bands almost identical in frequencies to those found for the corresponding InX_4^- anions (Table 2). A similar situation has been observed when dealing with acetonitrile solutions of indium trihalides also displaying resonances of InX_4^- ($X = Cl^-$, Br^-, I^-) species (Table 2).[6] This was interpreted as being a result of a disproportionation reaction which leads to mixed six-coordinate cationic complexes that share the same anion InX_4^-. As for acetonitrile solutions, no bands for the cationic complexes were observed for InX_3–HMPA systems. It seems reasonable that lowering of the symmetry of the cations causes large quadrupole broadening[7] and thus they are undetectable in ^{115}In NMR. Therefore, it might be assumed that the balance between the ionic charges of the species in solutions of HMPA is reached by forming only unsymmetrical $InX_n(HMPA)_{6-n}^{(3-n)+}$ ($X = Br^-$, I^-; $n = 1, 2$) cationic species because $In(HMPA)_6^{3+}$ could be detected as $In(H_2O)_6^{3+}$.[8]

[a] R = $(C_6H_5)_4P$ for $InCl_4^-$ and $InBr_4^-$; $(C_4H_9)_4N$ for InI_4^-.

The formation of InX_4^- anions in InX_3–HMPA ($X = Br^-$, I^-) systems allowed us to obtain $InBr_nI_{4-n}^-$ species when mixing $InBr_3$ and InI_3 solutions. The case of an equimolar mixture of $InBr_3$ and InI_3 solutions illustrates well these findings; the spectrum consists of five distinct lines with chemical shifts (−278, −439, −619, −813 and −1018 ppm) corresponding to the ^{115}In NMR frequencies in $InBr_nI_{4-n}^-$ anions.[6,7]

In view of the much better electron donor properties of HMPA compared with acetonitrile (DN_{SbCl_5} = 38.8 and 14.1, respectively) it is somewhat surprising that no ^{115}In NMR resonances are observed for $InCl_3$ solutions in HMPA in contrast to CH_3CN (Table 2). It is apparent that, in this case, interaction between indium trichloride and the solvent does not lead to salt disproportionation to $InCl_n(HMPA)_{6-n}^{(3-n)+}$ and $InCl_4^-$ complex ions. We can assume that some uncharged mixed $InCl_3(HMPA)_n$ solvates, with thermodynamic stabilities appreciably greater than the ionic complexes, are formed. Taking into account the tendency of indium(III) to form complexes with high coordination numbers with oxygen-donor ligands species with $n = 2$ and 3 seem to be preferred.

This was indeed confirmed when compound **I** was prepared from $InCl_3$–HMPA solution. Elemental analyses (Table 3), IR spectrum and X-ray diffraction of sample **I** indicated it to be the penta-coordinated complex *trans*-$InCl_3(HMPA)_2$.[3] Thus, in spite of the difference in preparative techniques (ours and ref. 3) only one product from the interaction of $InCl_3$ and HMPA is formed. Usually small changes in preparative conditions cause the formation of different products because of the lability of indium(III) complexes. The case of $InCl_3(HMPA)_2$ is an exception to this rule. The trigonal-bipyramidal arrangement of ligands with three halide atoms in equatorial positions is not rare for indium(III) chemistry. Compounds with this type of structure InX_3L_2, where L = $(CH_3)_3N$,[9] $(CH_3)_4N_2CO$,[10] $\{(CH_3)_2N\}_3PO$,[3] $(CH_3)_4N_2CS$,[10] $(CH_3)_3PS$, $(CH_3)_3AsS$,[11] $(CH_3)_3P$, $Ph_2P(CH_2)_2PPh_2$[12] and $(C_6H_5)_3P$,[13] are known. Among a total of 11 complexes, eight are chlorides. Moreover, a comparison of the bond lengths between indium and atoms in the axial positions for complexes with different X indicates that the distances for chloride species are significantly shorter. Considering all these facts we must assume that $InCl_3L_2$ species are more stable compared with other halides, which can circumstantially explain the formation of $InX_3(HMPA)_2$ only for the $InCl_3$–HMPA system.

^{115}In NMR resonances of InX_4^- species for indium tribromide and triiodide solutions in HMPA, together with the data indicating an ionic dimeric structure of $InX_3(HMPA)_2$ adducts,[2] led us to expect the formation of $[InX_2(HMPA)_4]^+$ $[InX_4]^-$ complexes from InX_3–HMPA ($X = Br^-$, I^-) systems.

No crystal phase was yielded from $InBr_3$ solution in HMPA due to glass formation.

Crystals of **II** were obtained from the InI_3–HMPA system. Table 3 indicates that the elemental analysis of this compound differs from that expected for $InI_3(HMPA)_2$.

The IR spectrum of sample **II** contains characteristic bands due to coordinated HMPA molecules and indicates that coordination occurs via the oxygen atom (Table 4).[2,3]

The structure of **II** involves the complex cations $[InI_2(OP\{N(CH_3)_2\}_3)_4]^+$ and I^- anions. The two crystallographically independent cations (a and b) have the same configuration, which is illustrated in Fig. 1. The indium atoms are hexa-coordinated to four HMPA molecules via oxygen and to two *trans*-

arranged iodine atoms in an octahedral geometry (Fig. 1, Table 5). The packing of **II** is extraordinarily loose; for one non-hydrogen atom there is a value of 25.5 $Å^3$. The shortest contacts are I···I = 7.20, I···C = 3.45, C···C = 3.45 Å.

Careful analyses of the solid phase from InI_3–HMPA solution demonstrates that compound **II** is the only product formed in this system. We can, therefore, conclude that despite the unequivocal formation of the InI_4^- anion in solution the balance between the ionic charges in the solid is reached by iodide ions which are displaced by HMPA molecules from the inner coordination shell of indium.

To date all known ionic structures containing the six-coordinate indium cation $InX_2L_4^+$, where L = Me_3PO for X = Cl^-, Br^-; Ph_2MePO for X = Br^-; Ph_3PO for X = Cl^-, Br^-; Ph_3AsO for X = Cl^- [14] and Me_2SO for X = I,[15] have InX_4^- species as an anion and thus compound **II** is the first example of mixed indium(III) complexes containing an acido ligand in the outer coordination sphere.

Previous authors[14] have tried to analyse reasons for the appearance of ionic structures and assumed preferential formation of ionic derivatives by a heavier halogen and the structure of $InI_3(HMPA)_4$ verifies this assumption.

One more interesting feature of the structure of $InI_3(HMPA)_4$ is the *trans* configuration of the cation. Recently we analysed the stereochemical features of pseudo-octahedral complexes of indium(III) halides.[16] Both VSEPR (valence-shell electron-pair repulsion)[17] and electronic-vibrational[18] concepts predict stabilization of the *trans* isomer for InX_2L_4 species when the difference between the electronegativity and geometrical parameters of donor atoms X and L are significant.

According to these approaches the arrangement of iodide ions in $[InI_2(HMPA)_4]^+$ should also be *trans*. It should, however, be noted that the same composition of donor atoms in the coordination sphere (I and O) gives the *cis* isomer for the cation in $[InI_2(Me_2SO)_4]^+[InI_4]^-$.[15] Authors[19] have assumed the dominant role of steric effects of ligands. Calculations of the steric angles of donor iodine and oxygen atoms (based on average bond lengths In—I 2.80 and In—O 2.18 Å) give values of 91° and 80°, respectively. Sums of the steric angles show that the *trans* isomer is destabilized since two of three octahedral planes, in contrast to one for *cis*, contain the larger iodine atoms. In—I and In—O distances in $[InI_2(HMPA)_4]^+$ (Table 5) are almost the same and so the values of the steric angles are equal, but the configuration is *trans* nevertheless. There seems to be two reasons influencing the geometry of the cation, notably (1) that the stabilization of the isomer is a function of the anion present in the lattice (I^- or InI_4^-) and (2) that, as was pointed out in ref. 19, steric stabilization of the *cis* species may disappear for bulky ligands where L—L non-bonded repulsions become predominant and *trans*-ML_2X_4 species may become favoured. HMPA should be undoubtedly considered as a bulky ligand due to the downwards-spreading umbrella geometry of the $\{(CH_3)_2N\}_3PO$ molecule, which invalidates the above arguments by producing an effective steric angle greater than that of the monatomic donor.

The arrangement of four bulky HMPA molecules in one plane and thus the contribution to the cation stability is enabled by an increase in the P—O—In angles, to *ca* 164° in $InI_2(HMPA)_4^+$ compared with 153° for $InCl_3(HMPA)_2$.[3] This oxygen angle value is the greatest for known oxo ligands coordinated to indium and even larger than that for *trans*-$[InCl_2(Ph_3PO)_4]^+$ (160°) with a ligand as large as triphenylphosphine oxide,[14] which indicates the more ionic nature of the indium–oxygen linkage in the adduct with HMPA.

The last assumption can be circumstantially confirmed by ^1H and ^{31}P NMR values. The coordination of HMPA molecules to indium [benzene solution of $InI_3(HMPA)_4$ was analysed] causes a small high-field shift of the NMR lines of both ^1H [1.38 ppm, J(H—H) = 9.5 Hz compared with 1.44 ppm and 9.3 Hz, respectively, for HMPA–C_6H_6 solution] and ^{31}P (22.86 ppm compared to 24.49 ppm for HMPA–C_6H_6 solution). This sharply contrasts with ^{31}P lines of phosphine oxide[14] and phosphate[20] molecules in indium complexes, which are usually shifted downfield by *ca* 5–13 ppm.

In a number of recent papers concerning complex fluorides of group III(13) metals—aluminium, gallium and indium—with various O- and N-donor molecular ligands we have suggested some relation between shielding of the ^{19}F nucleus and the electronegativity of an atom in the *trans* position to fluorine.[21,22] It has been shown that oxygen causes greater transfer of electron density than nitrogen from the ligand donor atom through metal to fluorine, leading to a high-field shift. A similar situation seems to be observed for $InI_3(HMPA)_4$ because the complex cation comprises oxygen atoms in O—In—O fragments, which results in a strong *trans* effect and an increase in electron density on all atoms of the HMPA molecule.

Regarding ^{31}P NMR spectroscopy of indium complexes it should be noted that in contrast to aluminium, for which $Al(HMPA)_4^{3+}$ displays a sharp quintet by ^{27}Al NMR and a sextet for ^{31}P showing clear evidence for a tetrahedral arrangement of four HMPA ligands around Al^{3+},[23] it is not possible to observe couplings between ^{115}In and ^{31}P nuclei. Line broadening must be attributed in the first place to quadrupolar relaxation of the metallic nucleus and then to the low symmetry of the complex.

We have not managed to prepare adducts of InF_3 with HMPA due to the insolubility of $InF_3 \cdot 3H_2O$ in this solvent. In spite of this some interesting information about indium complexes with such

ligands as F^- and HMPA may be obtained when investigating the $In(NO_3)_3$–F^-(NH_4F, $(CH_3)_4NF$)–HMPA–H_2O systems using ^{19}F NMR spectroscopy.

Fast exchange between various indium fluoride species slowed down only at *ca* 258 K, allowing the observation of the separate ^{19}F lines (40–80 Hz) of individual complexes. Varying the HMPA/$In(NO_3)_3$ molar ratio over the range 6–10 when $F^-/In(NO_3)_3$ was kept close to 1 allowed us to detect eight resonances of mixed-fluoro/HMPA/aqua species. We have no direct evidence for the coordination number of indium in these complexes, but the number of bands observed together with the results we obtained when dealing with ^{19}F NMR spectra of In^{3+}–F^-–L–H_2O [L = Cl^-, Br^-, I^-, NCO^-, NCS^-,[24] $(NH_2)_2CO$, NH_2CH_3CO, $(NH_2)_2CS$ and NH_2CH_3CS[25]] systems allowed us to consider the interval of chemical shifts (−150 to −175 ppm) corresponding to the six-coordinate species. The assignment of lines (Table 6) was performed in accordance with both the tendency of the ligands to cause deshielding of ^{19}F nuclei in the complex and the dependence of the integration curves on HMPA concentration. Chemical shifts (δ) of the complexes show the additivity of δ when substituting water molecules in $InF_n(H_2O)_6^{3-n}$ by HMPA (*ca* 2.5 ppm per substitution). The corresponding values for acido ligands (17, Cl^-; 15, Br^-; 7, NCS^-) are significantly higher and demonstrate a stronger influence of ionic ligands compared with neutral molecules on coordinated fluoride.

The consideration of interactions of various indium halide salts with hexamethylphosphoramide leads to several conclusions, notably: HMPA molecules can be combined with atoms of all halides (from F to I) in the coordination sphere of indium(III).

The coordination numbers of indium in mixed-halide complexes with HMPA differ. The same preparative technique leads to five-coordinate chloride species, whereas the coordination number for the iodide complex cation is six. This result is rather unexpected because the opposite situation should be more likely. The reasons for the preference of trigonal-bipyramidal chloride structure has been discussed earlier. It can be assumed that the formation of similar iodide species is hindered by the arrangement of three large iodine atoms in the equatorial plane. The systematic discussion of this observation needs more structural information and quantitative thermodynamic data on mixed indium complexes. Work on this is proceeding.

Table 6. ^{19}F resonances for mixed $InF_n(HMPA)_m(H_2O)_{6-n-m}^{3-n}$ species in aqueous solution

Complex	$-\delta$ (ppm)
$InF(HMPA)(H_2O)_4^{2+}$	174.2
$InF(HMPA)_2(H_2O)_3^{2+}$	171.4
$InF(HMPA)_3(H_2O)_2^{2+}$	169.2
$InF(HMPA)_4(H_2O)^{2+}$	167.0
$InF(HMPA)_5^{2+}$	164.7
$InF_2(HMPA)(H_2O)_3^+$	163.6
$InF_2(HMPA)_2(H_2O)_2^+$	160.6
$InF_2(HMPA)_3(H_2O)^+$	157.3

SYNTHESIS AND CHARACTERIZATION OF SOME LANTHANIDE(III) PERCHLORATO COMPLEXES OF HYDRAZONES OF ISONICOTINIC ACID HYDRAZIDE

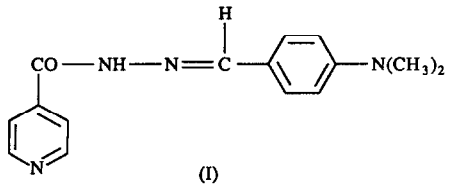
RAM K. AGARWAL* and RAJENDRA K. SARIN

Department of Chemistry, Lajpat Rai (Post-Graduate) College, Sahibabad 201005 (Ghaziabad), India

(*Received* 28 *January* 1993; *accepted* 27 *April* 1993)

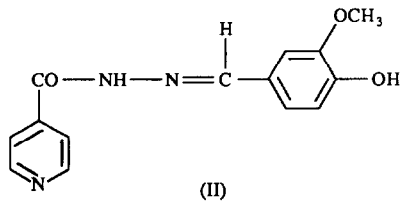
Abstract—The lanthanide(III) perchlorato complexes of hydrazones of isonicotinic acid hydrazide, viz. N-isonicotinamido-*p*-dimethylaminobenzalaldimine (INH-PDAB) and N-isonicotinamido-3-methoxy-4-hydroxybenzalaldimine (INH-VAN) of the type $Ln(ClO_4)_3 \cdot 4$(INH-PDAB) or $Ln(ClO_4)_3 \cdot 4$(INH-VAN) (Ln = La, Pr, Nd, Sm, Gd, Tb or Dy) have been synthesized and characterized by analytical, magnetochemical, IR and UV–vis spectral methods. The thermal stabilities of these compounds have also been investigated.

The remarkable biological activity of acid hydrazides, R—CO—NH—NH_2, their corresponding aroylhydrazones, R—CO—NH—N=CH—R′ and the dependence of their mode of chelation with transition metal ions present in the living system have been of significant interest in recent years.[1–4] The coordination compounds of aroylhydrazones have been reported to act as enzyme inhibitors[5] and are useful due to their pharmacological applications.[6–8] In view of the increasing interest in hydrazones, on account of the structural, analytical and pharmacological importance of their metal complexes, the synthesis of two hydrazones, i.e. N-isonicotinamido-*p*-dimethylaminobenzalaldimine (INH-PDAB) (I) and N-isonicotinamido-3-methoxy-4-hydroxybenzalaldimine (INH-VAN) (II) and their lanthanide(III) perchlorato complexes are described.



(I)

N-Isonicotinamido-p-Dimethylaminobenzalaldimine (INH-PDAB) (m.f. $C_{15}H_{16}N_4O$)



(II)

N-Isonicotinamido-3-Methoxy-4-Hydroxybenzalaldimine (INH-VAN) (m.f. $C_{14}H_{13}N_2O_3$)

EXPERIMENTAL

Reagents

The lanthanide oxides were obtained from Rare Earths Products Ltd (India) and were used without further purification. The perchlorates were prepared by heating the corresponding oxides with perchloric acid (A.R.) and evaporating off the excess acid.[9] The ligands INH-PDAB and INH-VAN were synthesised in the laboratory as follows: isonicotinic acid hydrazide (0.01 mol) was dissolved in 95% ethanol (30 cm^3). To this solution was added the aromatic aldehyde *p*-dimethylaminobenzaldehyde or vanillin (0.01 mol) in 95% ethanol (40 cm^3). The reaction mixture was refluxed on a water bath for *ca* 2 h. The partial removal of solvent on a water bath followed by cooling produced a crystalline product, which was suction filtered, washed with cold alcohol and dried *in vacuo*. The purity of the ligands was checked by elemental analysis, TLC and m.p. determination (INH-PDAB, $C_{15}H_{16}N_4O$,

yellow, m.p. 209°C; INH-VAN, $C_{14}H_{13}N_3O_3$, yellow, m.p. 191°C).

Synthesis of the complexes

$[Ln(ClO_4)_3 \cdot 4(INH\text{-}PDAB)]$ (Ln = La, Pr, Nd, Sm, Gd, Tb or Dy). All the perchlorato complexes were prepared by mixing hot ethanolic solutions of ligand and metal perchlorate in a 4:1 molar ratio. The mixture was refluxed on a water bath for 2 h and then concentrated. On cooling the complexes were filtered, washed with ethanol and diethyl-ether and dried *in vacuo* over anhydrous $CaCl_2$.

$[Ln(ClO_4)_3 \cdot 4(INH\text{-}VAN)]$ (Ln = La, Pr, Nd, Sm, Gd, Tb or Dy). Lanthanide(III) perchlorate (2 mmol) and INH-VAN (8.1 mmol) were dissolved separately in hot ethanol (20 cm^3 each). The reaction mixture was refluxed for *ca* 3 h and the solution was concentrated to a viscous mass, which was washed several times with small portions of hot benzene to remove the excess ligand. The finely divided solid mass was finally washed with diethyl-ether and collected and dried *in vacuo* over P_4O_{10}.

Analytical methods

The complexes were analysed for the metals by the conventional method.[10] Microanalyses for carbon, hydrogen and nitrogen were performed on a Perkin–Elmer 23 CHN elemental analyser. The perchlorate was estimated by the Kurz method.[11] The molecular weight of the complexes was determined cryoscopically in freezing nitrobenzene using a Beckmann thermometer of accuracy ± 0.01°C in the laboratory. The conductivity measurements were obtained using a Toshniwal conductivity bridge (type CL 01/01) and a dip-type cell operating at 220 V on an AC mains. All the measurements were performed at room temperature in $PhNO_2$. The magnetic measurements were obtained at room temperature with a Gouy's balance and $[HgCo(SCN)_4]$ was used as a calibrant. The IR spectra of the complexes were recorded on a Perkin–Elmer IR spectrophotometer model-521 in CsI_2 in the range 4000–200 cm^{-1}. A Hilger Uvispek spectrophotometer with a 1 cm quartz cell was employed for recording the visible spectra of these complexes. TG analyses were performed in static air with open sample holders and a small platinum boat; the heating rate was 6°C min^{-1}.

RESULTS AND DISCUSSION

The reaction of non-aqueous solutions of lanthanide(III) perchlorate with INH-PDAB and INH-VAN resulted in the formation of complexes of the composition $Ln(ClO_4)_3 \cdot 4L$ (L = INH-PDAB or INH-VAN; Ln = La, Pr, Nd, Sm, Gd, Tb or Dy). The analytical data of the present complexes are summarized in Table 1. Most of the complexes are fairly stable and could be stored for a long time and are non-hygroscopic in nature. All the complexes are generally soluble in common organic solvents, but partially soluble in diethyl-ether. TG curves indicate no changes up to 130°C, suggesting the absence of coordinated or uncoordinated water molecules in these complexes. The molar conductivity values in nitrobenzene fall in the range 76–82 $\Omega_m\ \Omega^{-1}\ cm^2\ mol^{-1}$, suggesting that these complexes behave as 1:3 electrolytes. Data on the molecular weight of the complexes in nitrobenzene are presented in Table 1, along with values calculated on the basis of established formulae of the complexes. The ratio of molecular weight observed for $Ln(ClO_4)_3 \cdot 4L$ to that calculated is found to be 0.25. This data provide further support that four species are formed in these complexes.

IR spectra

A study and comparison of the IR spectra of the ligands and its complexes imply that both the ligands are bidentate with the carbonyl-oxygen and azomethine-nitrogen as the two coordination sites. In INH-VAN the —OH group is not taking part in the coordination. The presence of various ring vibrations and C—H absorption makes the spectra fairly complicated for complete assignments of individual bands. Tentative assignments to several absorptions associated with C—H, C=C, C—N and ring stretchings have been made; these absorptions are a little sensitive to complexation. Similarly, the absorption and ring breathing mode in the ligands and their Ln^{3+} complexes are very close to each other.

The ligands are expected to be tridentate, the possible coordination sites being the pyridine-nitrogen, the azomethine-nitrogen and the amide group. The amide-I band in the INH derivatives appears at 1660–1640 cm^{-1}. In the IR spectra of the complexes a considerable negative shift in ν(C=O) is observed, indicating a decrease in the stretching force constant of C=O as a consequence of coordination through the carbonyl-oxygen atom of the free base. The amide-II band appears at the normal position in the NH deformation rather than the C—N link. In the INH derivatives the absorption in the 1565–1560 cm^{-1} region has been assigned to amide-II absorption. The NH stretching absorption[12] in the free ligands occurs at *ca* 3290 and 3220 cm^{-1}, which remains unaffected after complexation. This precludes the possibility of coordination

through the imine nitrogen atom. Another important band occurs at *ca* 1590 cm^{-1}, attributed to ν(C=N) (azomethine mode[13,14]). In the spectra of all the complexes this band is shifted to a lower wave number and appears in the 1550–1530 cm^{-1} region, indicating the involvement of the nitrogen atom of the azomethine group in coordination.[13,14] The strong bands observed at 1575–1520 cm^{-1} and 1080–1000 cm^{-1} are tentatively assigned[14–16] to antisymmetric and symmetric ν(C=C)+ν(C=N) bands of the pyridine ring, but the pyridine ring breathing and deformation bands remain practically unchanged in frequency and band intensities, thus revealing the non-involvement of the pyridine nitrogen in coordination. However, this assignment[17] is not unambiguous because the N—N group of the ligands also absorbs in the region 1000–890 cm^{-1}. In the spectra of INH-VAN the stretching frequency around 3400–3200 cm^{-1} is attributed to ν(OH). In the complexes of INH-VAN the —OH group frequency appears in the same region as in the free ligand, clearly indicating that the —OH group is not taking part in coordination. The overall IR spectral evidence suggests that both the ligands act as bidentate ligands and coordinate through the amide-oxygen and azomethine-nitrogen atoms, forming a five-membered chelate ring. The bands in the region 440–360 cm^{-1} in the complexes under study are tentatively assigned to ν(Ln—O)/ν(Ln—N) modes.[17–19]

In all the complexes only two strong ν_3 and ν_4 bands are observed in the regions 1110–1080 cm^{-1} and 630–620 cm^{-1}, respectively, for the perchlorate ion, indicating that tetrahedral symmetry has not been disturbed on complexation and the perchlorate ions are not bonded to the metal ions.[20,21] This conclusion is also supported by conductance and molecular weight data.

Electronic spectra

The electronic spectra in the visible region of the solid lanthanide(III) complexes exhibit changes in the intensity and shifts in position of the absorption bands relative to the solid lanthanide(III) salts. These shifts have been ascribed to a nephelauxetic effect. The extent of the red shifts of the hypersensitive bands is related to covalance in the metal–ligand bonds and is assessed by the nephelauxetic ratio (β), bonding parameter ($b^{1/2}$), Sinha's parameter [$\delta(\%)$] and covalency angular overlap parameter (η).[22–24] The values of the covalent parameters are presented in Table 2. The values of the nephelauxetic ratio (β) are smaller than 1 and the positive values of the bonding parameter ($b^{1/2}$) and Sinha's parameter indicate the occurrence of some covalent character in the metal–ligand bond.[25] The comparatively smaller magnitude of the $b^{1/2}$ values also show the involvement of the 4*f*-orbital in the metal–ligand bond to a very small degree.[24]

Thermal studies

The analyses of the thermolysis curves suggest that these complexes do not show the presence of water molecules either in or out of the coordination sphere. There is a change in the curves within the temperature region 285–330°C, due to the loss of mass corresponding to 2.5 mol of organic ligands and at 440°C all the organic ligands are lost. Finally, at *ca* 810°C stable lanthanide oxides are formed.[26]

Stereochemistry

The solution studies in $PhNO_2$ suggest the ionic nature of these complexes. They behave as 1 : 3 electrolytes on $PhNO_2$. The molecular weight determined cryoscopically in freezing $PhNO_2$ suggests that four species are formed in these complexes. This is further confirmed by IR data. IR spectra and TG studies of all the complexes further indicate the absence of water. Thus, in these complexes the central metal ion is surrounded by four oxygen atoms and four nitrogen atoms and thus the coordination number eight applies to these complexes.[27] This is in analogy with other lanthanide perchlorato complexes of 2,2′-bipyridine-1,1′-dioxide,[28] $[Ln(BipyO_2)_4]\ (ClO_4)_3$, or octamethylpyrophosphoramide,[29] $[La(OMPA)_4]\ (ClO_4)_3$. Based on the elemental analyses and various physicochemical

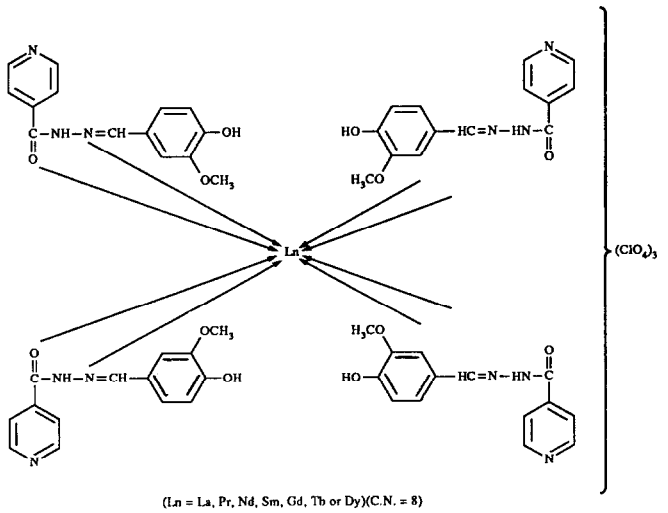

Fig. 1. Probable structures of lanthanide(III) perchlorato complexes of INH-VAN.

studies the following structure may be tentatively proposed for the present complexes (Fig. 1).

(*Received* 5 *April* 1993; *accepted* 22 *April* 1993)

Abstract—The paramagnetic tungsten(V) complex $Cp^*WCl_2[1,2\text{-}(HN)_2C_6H_4]$, $Cp^* = C_5Me_5$, has been obtained by interaction of Cp^*WCl_4 with *o*-phenylenediamine (1,2-diaminobenzene, *o*-pdaH$_2$). The X-ray crystal structure shows a pseudo-square pyramidal geometry with the chelating diamido group and chlorine atoms forming the base and a slipped (3e) Cp* group occupying the axial site.

A number of tungsten complexes with deprotonated ligands derived from 1,2-diaminobenzene were obtained during unsuccessful attempts[1] to obtain the still unknown $W[1,2\text{-}(HN)_2C_6H_4]_3$, which would be isoelectronic with the rhenium(VII) cation $\{Re[1,2\text{-}(HN)_2C_6H_4]_3\}^+$.[2] A number of diamagnetic monoimido compounds with C_5Me_5(Cp*) ligands have been made for niobium and tantalum,[3] $Cp^*M(NR)Cl_2$, R = Me, $C_6H_3Pr^i_2$-2,6, molybdenum and tungsten,[4] $Cp^*M(NBu^t)_2Cl$, rhenium,[5] $Cp^*Re(NR)Cl_2$, R = Me, Bu^t, and iridium, $Cp^*Ir(NBu^t)$.[6]

The paramagentic tungsten (d^1) 1,2-diamido complex $Cp^*WCl_2[1,2\text{-}(HN)C_6H_4]$ (**1**) is obtained by interaction of Cp^*WCl_4[7] with 2 equivalents of *o*-phenylenediamine in refluxing toluene. Alternatively Cp^*WCl_4 and the hydrochloride, *o*-pdaH$_2$ · 2HCl in toluene containing excess NEt_3 are refluxed as before. The EPR spectrum of **1** (*X*-band, 25°C in THF) is sharp with $g = 1.933$, a value typical for tungsten(V);[8] coupling to ^{183}W was observable (82 G), but no hyperfine isotopic coupling due to nitrogen. The IR spectrum has a sharp NH band at *ca* 3300 cm^{-1}. Compound **1** is soluble in polar solvents such as THF and MeCN, but is insoluble in hydrocarbons.

A diagram of the molecule is shown in Fig. 1; selected bond lengths and angles are given in Table 1. The coordination geometry is best described as pseudo-square pyramidal with the Cp* ligand occupying the axial site. The molecule lies on a crystallographic mirror plane through W(1), C(4) and C(7).

The diamido ligand chelates symmetrically (by symmetry) and the metal atom lies close to the least-squares plane of the ligand; the displacement from the plane of 0.21 Å gives an envelope fold about the N···N vector of *ca* 8°. Apart from this small amount of bending the nitrogens are essentially planar,[9a] as is commonly found for amido ligands; indeed, pyramidal amides are quite rare.[9b] On this basis it would be usual to look for evidence of $p\pi$–$d\pi$ donation of the nitrogen lone pairs to the metal, but in the present case the W—N distances of 1.998(8) Å are not unusually short. For example, they are longer than the W^V—N (amido) bond [1.924(14) Å] in $\{WCl_3[1\text{-}(HN)2\text{-}(H_2N)C_6H_4]\}_2\{\mu\text{-}1,2\text{-}(N)_2C_6H_4\}$.[1] There is, however, some indication

* Authors to whom correspondence should be addressed.

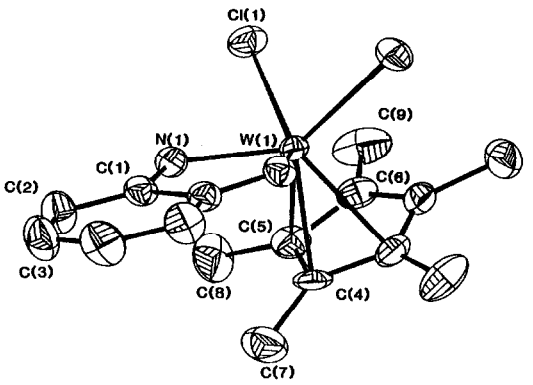

Fig. 1. The structure of $(C_5Me_5)WCl_2[1,2\text{-}(HN)_2C_6H_4]$.

of delocalization of the nitrogen lone pairs into the aromatic ring, since the unique C—N distance is quite short at 1.37(1) Å, but there seems to be little disturbance of the ring aromaticity, with the bonds all within the range 1.38–1.42(2) Å.

One interesting feature of the structure is the bonding of the Cp* ring, for which the W—C distances differ significantly, from 2.27 to 2.46(1) Å. Such distortions may be described in terms either of "tilting"[10] or "slippage".[11] In many instances the two descriptions refer to the same feature, which is fundamentally characterized by a non-orthogonal angle between the vector for the metal atom to the centroid of the Cp (or Cp* or indenyl-C_5) ring and the ring plane. Thus, we defined[10] a "tilt angle" τ as in structure **1(a)**, whilst various authors have proposed alternative ways[11] of measuring slippage; a typical definition is that of Atwood,[11b] as shown in structure **1(b)**.

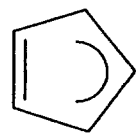
C(5)—W(1)—C(5a)	58.9(5)

Key to symmetry operations relating designated atoms to reference atoms at (x, y, z): (a) $1.0+x, y, z$.

Geometrically, Atwood's Ψ angle is equivalent to our τ. In fact, simple geometrical considerations show that slippage must also be accompanied by tilting. The origin and importance of "slippage" has been much discussed in terms of electronic effects and the importance of the feature to fluxional systems, particularly in indenyl complexes. We ascribed the tilting in our manganese complexes[10] to steric interactions in a rather crowded coordination sphere, but this may not always be the case.

One important factor is the electron count on the metal in the complex in question and the potential ability of the Cp type ligand to act as a 5,3 or 1 electron ligand. Slippage is then associated with the lower electron provision, with a $1e,\eta^1$ ligand—essentially a simple alicyclic sigma ligand—as the limiting extreme. However, the η^3 case is not so straightforward. On the one hand we have a clear $3e,\eta^3$ bonding mode characterized by a C_5 ring, which is not only slipped but also folded, such as the classic structure described by Huttner *et al.*[12] Here the C—C bond geometry was also consistent with a disruption of the fully delocalized pi-system to give a form as in structure **2**.



2

On the other hand there are numerous examples of slipped rings in which the planarity and delocalization of the C_5 ring is preserved. The much studied Cp_2Be[13] structure is a classical example and many others are found both within main group and transition metal chemistry.

Our complex is an example of the latter type. The

slippage of the ring is well defined ($\delta = 0.22$ Å, τ or $\Psi = 6.2°$), but the ring remains accurately planar (maximum deviation 0.011 Å) and the C—C distances are equal [1.41–1.43(1) Å] within the limits of experimental error. In view of the presence of different kinds of ligand atoms in the base of the suggested square pyramidal geometry ($2x$ amide N+$2x$Cl) it is difficult to define the true "axial direction" and thus provide the slippage, or tilt, with a firmer reference axis.

Our discussion of slippage here is pertinent since we have a case of "competitive π-donation", as indeed has been featured in previous discussions of the phenomenon.[14] Thus, we have a basic W^V electron count of 11—one metal *d*-electron, two W—N, two W—Cl and one "W—Cp" sigma bonding pairs. Supplementation may then occur via $2x$N—W $p\pi$–$d\pi$ donation, as discussed above, plus a further two or four electrons from the Cp* corresponding to Cp* acting as η^3 or η^5. The latter case would lead to a 19e configuration.

A similar situation occurs in the complex 1,2-W_2(indenyl)$_2$$(NMe_2)_4$, where the indenyl is distinctly η^3 and for which the authors assigned a greater π-donating ability to the NMe_2 group vs the indenyl.[14] It is intriguing to note that in the directly related W(η-$C_5H_4Pr^i$)Cl_4[15] the ($C_5H_4Pr^i$) group is close to η^5, with W—C(Cp) distances differing by no more than 0.033 Å. The balance between various electronic and indeed steric factors is clearly very fine.

EXPERIMENTAL

Analyses were by Imperial College and University College, London, laboratories. General techniques and instrumentation are as described previously.[1]

Synthesis of *CpWCl_2{1,2-$(HN)_2C_6H_4$}

In a typical reaction *$CpWCl_4$ (0.3 g, 0.65 mmol) and *o*-pdaH_2 (0.15 g, 1.38 mmol) in toluene (*ca* 20 cm^3) were refluxed for 12 h. The collected dark precipitate was washed with degassed water (*ca* 10 cm^3), Et_2O (2×15 cm^3) and dried in vacuum (yield *ca* 40%). X-ray quality, black, needle crystals were grown from MeCN. Found: C, 38.7; H, 4.2; N, 5.7. Calc. for $WCl_2N_2C_{16}H_{21}$: C, 38.7; H, 4.3; N, 5.6%. MS(E.I): $m/z = 497$, M^+.

X-ray crystallography

X-ray data were recorded at 298 K on a FAST TV area detector diffractometer with Mo-K_α radiation ($\lambda = 0.71069$ Å), as previously described,[16] using a crystal of dimensions $0.22 \times 0.18 \times 0.04$ mm^3. The structure was solved via the heavy atom method and refined by full-matrix least-squares. The data were corrected for absorption using the DIFABS[17] method at the isotropic refinement stage. All non-hydrogen atoms were refined in the anisotropic approximation whilst hydrogens were identified from the difference map and different U_{iso} values were assigned. Crystal data and experimental details are as follows.

Formula: $C_{16}H_{19}Cl_2N_2W$, $M_r = 494.096$, orthorhombic, $a = 8.105(1)$, $b = 16.001(2)$, $c = 12.939(1)$ Å, $V = 1680.95$ $Å^3$, space group *Pnam* (no. 53, non-standard), $Z = 4$, $D_c = 1.9524$ g cm^{-3}, $F(000) = 948$, μ(Mo-K_α) = 73.363 cm^{-1}. From the ranges scanned 10,447 data were recorded and merged to give 2269 unique ($R_{int} = 0.057$), 1780 observed [$F_o > 3(F_o)$]. $R = 0.0306$, $R_w = 0.0365$, 146 parameters. Tables of atomic coordinates, displacement factor coefficients, full lists of bond lengths and angles and F_o/F_c values have been deposited as supplementary material with the Editor. Atomic coordinates have also been deposited with the Cambridge Crystallograpohic Data Centre.

CRYSTAL STRUCTURE OF POLY[{TRIS-μ-IODO-BIS⟨(2,2′,2″-NITRILODIETHOXYETHANOL)DILEAD(II)⟩}-μ-IODO] OBTAINED BY DIRECT METHODS USING LEAD(II) OXIDE AS A STARTING MATERIAL

VLADIMIR KOKOZAY* and ALEXANDER SIENKIEWICZ

Department of Chemistry, University of Kiev, Kiev 252017, Ukraine

(*Received* 4 *January* 1993; *accepted* 7 *April* 1993)

Abstract—A direct method of obtaining $(Pb_4I_4L_2)_n$, where L is twice deprotonated 2,2′,2″-nitrilotriethanol (triethanolamine), is reported. The crystal structure of the compound was determined by X-ray techniques. The crystallographically independent fragments of $Pb_4I_4L_2$ are associated by bridging oxygen and iodine atoms in endless layers parallel to the *bc*-plane of the crystal. Tetradentate twice deprotonated triethanolamine is coordinated to lead(II) via oxygen and nitrogen atoms.

It was reported[1] that the direct method of synthesis leads to the preparation of coordination compounds of unusual composition and original crystal structure, for example, $Cuen_2I_2 \cdot 0.33DMF$ (where en = ethylendiamine, DMF = N,N-dimethylformamide).

The present paper describes the preparation and X-ray investigation of PbI · 0.5L, which assumes an unusual crystal structure.

EXPERIMENTAL

For the preparation of this complex the following method was used: PbO (2.23 g, 0.01 mol), NH_4I (1.45 g, 0.01 mol), DMFA (15 cm^3) and triethanolamine (1.33 cm^3, 0.01 mol) were heated to boiling and stirred until total dissolution of PbO was observed (3–5 min). The clear colourless solution obtained was allowed to stand at room temperature for 2 h after which crystals separated from the solution. The crystals were filtered, washed with dry isopropanol and finally dried *in vacuo* at room temperature; yield 3.0 g (74%). The colourless crystalline compound obtained is sparingly soluble in water and organic solvents. Found: C, 8.7; H, 1.6; Pb, 49.9; I, 31.0; N, 1.6. Calc. for PbI · 0.5L: Pb, 50.7; I, 31.1; N, 1.7; C, 8.8; H, 1.7%.

Crystallographic measurements were obtained at 20°C using an Enraf–Nonius CAD-4 diffractometer operating in the $\omega/2\theta$ scan mode (the ratio of the scanning rates was $\omega/\theta = 1.2$). The intensity data were collected within the range $1 \leqslant \theta \leqslant 27°$ using graphite-monochromated Mo-K_α radiation ($\lambda = 0.71073$ Å). Intensities of 3348 unique reflections were measured. The structure was solved by direct methods and refined by full-matrix least-squares techniques in the anisotropic approximation. In the refinement 2206 reflections with $I > 3\sigma(I)$ were used. About 40% of the hydrogen atoms were located in the Fourier maps; the positions of the remaining atoms were calculated. All hydrogen atoms were included in the final refinements with the fixed positional and thermal ($B_{iso} = 5$ Å^2) parameters. Convergence was obtained at $R = 0.036$ and $R_w = 0.0357$, G.O.F. = 1.15 (252 refined parameters; largest shift/ESD after final cycle < 0.29; the largest peak in the final difference map was 1.17 e Å^3). For the inverted structure $R = 0.0374$, $R_w = 0.0445$, G.O.F. = 1.15. The weighting scheme $w = (\delta^2 F + 0.0016\ F^2)^{-1}$ was used. Corrections for the Lorentz and polarization effects as well as the empirical correction for absorption using the DIFABS program[2] were applied. All structural calculations were performed with a PDP-11/23+ computer using the SDP-PLUS program package.[3] Full crystallographic data have been deposited at the Cambridge Crystallographic Data Centre.

Crystal data for compound of composition $C_{12}H_{30}I_4N_2O_6Pb_4$: $Fw = 1634.8$, orthorombic, $a = 18.555(2)$, $b = 17.914(1)$, $c = 8.119(1)$ Å, $V = 2698.7$ Å^3, $Z = 4$, $d = 4.02$ g cm^{-3}, space group $Pna2_1$; $\mu = 296.3$ cm^{-1}, $F(000) = 2816$.

Bond distances and angles are given in Tables 1 and 2. Atomic coordinates, anisotropic thermal parameters, observed and calculated structure factors and torsion angles are given in the supplementary material.

DISCUSSION

The complex forms an inorganic polymer of composition $(Pb_4I_4L_2)_n$: crystallographically independent units [fragment of Fig. 1 without I(4a), O(5b) and O(3c) atoms] are associated by bridging oxygen and iodine atoms in endless layers parallel to the *bc*-plane (Fig. 2). The coordination of the lead atoms is clear from Fig. 1 and Tables 1 and 2.

Unsymmetrical five-coordination of Pb(1) and Pb(4) atoms is induced by ligand constraints, different functions of oxygen atoms [only O(2) and O(6) are terminal atoms, others are bridging] and the influence of stereochemically-active lone pairs of electrons. Close contacts of atoms O(5b) [$0.5-x$, $y-0.5$, $z-0.5$) and O(3c) ($0.5-x$, $0.5+y$, $0.5+z$) with Pb(1) and Pb(4) are $r\langle$Pb(1)—O(5b)$\rangle = 2.695$ Å and $r\langle$Pb(4)—O(3c)$\rangle = 2.725$ Å; the angles N(1)—Pb(1)—O(5b) and N(2)—Pb(4)—O(3c) are approximately equal at 128 and 120°, respectively.

Conditionally it is possible to divide the co-

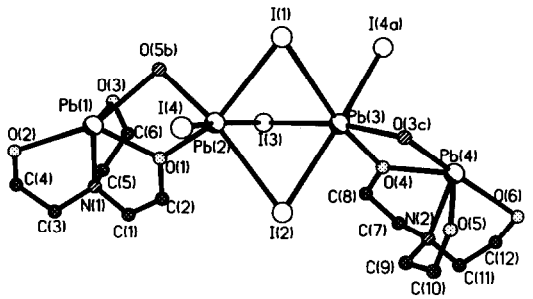

Fig. 1. A fragment of the crystal structure (hydrogen atoms were omitted for clarity).

ordination of Pb(2) and Pb(3) atoms into two spheres. The inner sphere is formed by atoms O(1) and O(5b) $(0.5-x,\ y-0.5,\ z-0.5)$ for Pb(2) [$r\langle$Pb(2)—O(5b)$\rangle$ = 2.468 Å] or O(4) and O(3c) $(0.5-x,\ 0.5+y,\ 0.5+z)$ for Pb(3) [$r\langle$Pb(3)—O(3c)$\rangle$ = 2.442 Å]; hence, the two-coordinate "bent" geometry occurs or, in other words, coordination of the named lead atoms possess ψ-trigonal configuration,[4] where a lone pair occupies one equatorial coordination site. The angles O(1)—Pb(2)—O(5b) and O(4)—Pb(3)—O(3c) are approximately equal (73° and 74°). Outer coordination spheres of Pb(2) and Pb(3) are comprised

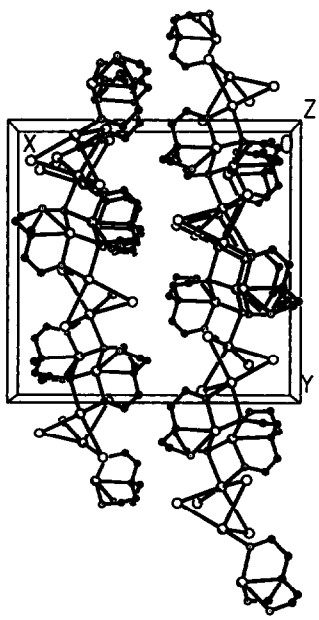

Fig. 2. Perspective view of the packing in the unit cell along the normal to the *ab*-plane.

of iodine atoms, as seen in Fig. 1; $r\langle$Pb(3)—I(4a) $(x,\ y,\ 1+z)\rangle$ = 3.111 Å. From this point of view the coordination polyhedra of atoms Pb(2) and Pb(3) are strongly distorted octahedra.

The atom I(4), as with other iodine atoms, shown in Fig. 1, possesses a bidentate-bridging nature and connects the atoms Pb(2) and Pb(3d) $(x,\ y,\ z-1)$, the latter not being marked in Fig. 1. The atom I(4a) $\{x,\ y,\ 1+z\}$ completes the same function for Pb(3) and Pb(2a), also omitted in Fig. 1.

Metal–metal interatomic close contacts in the complex are equal: $r\langle$Pb(1)—Pb(2)$\rangle$ = 3.866, $r\langle$Pb(2)—Pb(3)$\rangle$ = 3.844 and $r\langle$Pb(3)—Pb(4)$\rangle$ = 3.869 Å; these values exceed the nearest neighbouring lead–lead distance (3.49 Å) in the crystal lattice of lead metal.

Tetradentate twice deprotonated triethanolamine is coordinated to lead via oxygen and nitrogen atoms. Although the coordinates of hydrogen were not refined, the composition of the complex and the structural data [in particular, Pb—O—bond lengths, non-bridging nature of O(2) and O(6) atoms] indicate that the hydroxylic hydrogen atoms are attached to O(2) and O(6).

Puckered five-membered PbOCCN rings possess the *gauche* conformation, with the exception of O(1) and O(4)-containing rings which have envelope conformations. Each PbL of crystallographically independent units have opposite rotational configurations looking along the N—Pb bond. In certain cases the carbon–carbon interatomic distances in the rings are shorter than the normal aliphatic C—C bond length (1.54 Å).[5] This is a common property of chelate complexes containing five-membered rings.

DICOPPER(I) COMPLEXES OF THE NOVEL PHOSPHORUSBIPYRIDYL LIGAND 6-DIPHENYLPHOSPHINO-2,2′-BIPYRIDYL

JOHN S. FIELD, RAYMOND J. HAINES,† CAMPBELL J. PARRY and SADESH H. SOOKRAJ

Department of Chemistry, University of Natal, P.O. Box 375, Pietermaritzburg 3200, Republic of South Africa

(*Received* 1 *April* 1993; *accepted* 19 *July* 1993)

Abstract—Reaction of 6-diphenylphosphino-2,2′-bipyridine (Ph_2Pbipy) with copper(I) precursors such as $[Cu(MeCN)_4]^+$ and $[Cu(2,2'\text{-bipy})(MeCN)_2]^+$ affords dinuclear phosphorusbipyridyl ligand-bridged dicopper products and in particular $[Cu_2(\mu\text{-}Ph_2Pbipy)_2(MeCN)_2]^{2+}$ (**1**) and $[Cu_2(2,2'\text{-bipy})(\mu\text{-}Ph_2Pbipy)_2]^{2+}$ (**2**), respectively. The ligand coordinates head-to-tail in **1**, and head-to-head in **2**, as established by single crystal X-ray diffraction studies.

Transition metal complexes of polypyridyl ligands have been widely investigated as homogeneous electrocatalysts for the reduction of carbon dioxide.[1] Mechanistic studies have indicated that the low-lying and vacant π^*-orbitals of the polypyridyl ligand provide the site for the initial reduction and at relatively low cathodic potentials, i.e. the ligand mediates in the transfer of electrons from the electrode surface to a CO_2 molecule bound to a metal atom. As part of a programme for the development of dinuclear, rather than mononuclear, homogeneous electrocatalysts for CO_2 reduction we have synthesised the hitherto unreported phosphorusbipyridyl ligand, 6-diphenylphosphino-2,2′-bipyridine (Ph_2Pbipy),‡ and have studied its coordination behaviour towards a variety of metal-containing precursors. Electronically this ligand can be considered as being derived from the ubiquitous triphenylphosphine and the equally ubiquitous 2,2′-bipyridine.[3] Alternatively, in terms of its coordination properties, it can be considered as a tridentate equivalent of the widely studied bridging phosphoruspyridyl ligand 2-diphenylphosphinopyridine.[4] As such, the ligand not only contains a chelating bipyridyl fragment, but overall will preferentially adopt a bridging coordination mode thereby stabilizing dinuclear compounds to fragmentation. This communication reports the results of an investigation of the coordination behaviour of this ligand towards two copper(I) precursors.

Treatment of $[Cu(MeCN)_4]PF_6$[5] with one mole equivalent of Ph_2Pbipy in acetonitrile was indeed found to lead to the formation in high yield of a yellow dinuclear product characterized by X-ray

† Author to whom correspondence should be addressed.

‡ The synthesis of the ligand involved the treatment of 2,2′-bipyridine with methyl iodide to produce N-methyl-2,2′-bipyridyl iodide, oxidation of the latter with ferricyanide ions in the presence of sodium hydroxide to give *N*-methyl-2,2′-bipyridin-6-one, chlorination of the oxidized product with phosphoryl chloride and phosphorus pentachloride to afford 6-chloro-2,2′-bipyridine and reaction of the latter with $LiPPh_2$ to give the final product in *ca* 25% overall yield. Details of this synthesis have been reported elsewhere.[2]

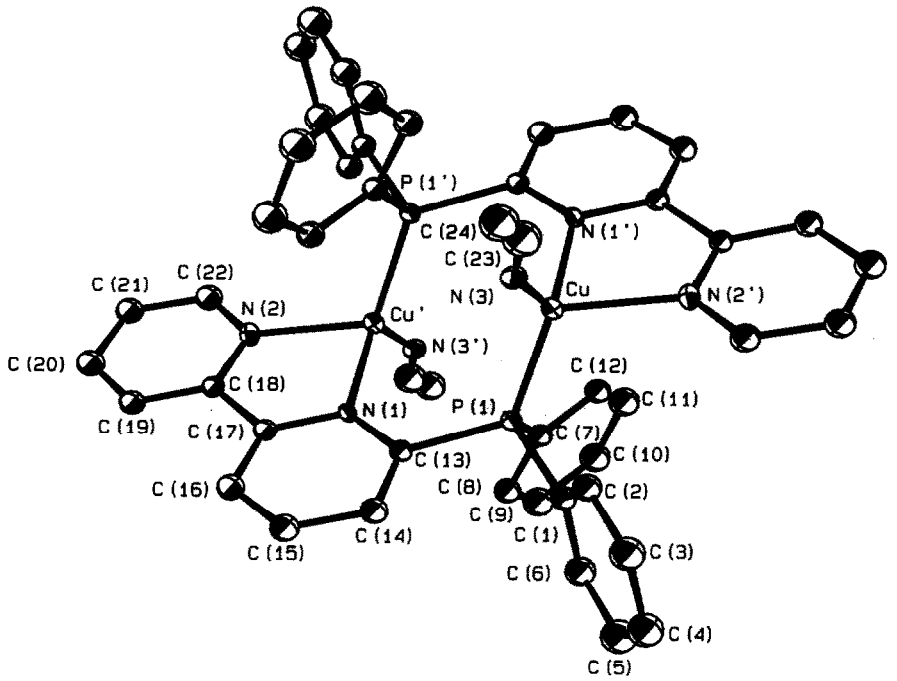

Fig. 1. ORTEP plot (20% probability) of the cation of $[Cu_2(\mu\text{-}Ph_2Pbipy)_2(MeCN)_2](PF_6)_2$ {**1**,$(PF_6)_2$}. Selected interatomic distances (Å) and angles (°): Cu···Cu', 3.941(2); Cu—P(1), 2.191(3); Cu—N(1'), 2.070(9); Cu—N(2'), 2.106(9); Cu—N(3), 2.073(9); P(1)—Cu—N(1'), 123.3(2); P(1)—Cu—N(2'), 113.9(2); P(1)—Cu—N(3), 116.5(2); N(1')—Cu—N(2'), 79.9(3); N(1')—Cu—N(3), 114.7(3); N(2')—Cu—N(3), 98.7(3).

crystallography† as well as by conventional methods‡ as $[Cu_2(\mu\text{-}Ph_2Pbipy)_2(MeCN)_2](PF_6)_2$ {**1**,$(PF_6)_2$}. The stereochemistry of the dication is illustrated in Fig. 1. The two copper atoms which are separated by a non-bonding distance of 3.941(2) Å, are bridged by the two Ph_2Pbipy ligands coordinated head-to-tail; the two ligands are in fact related through a crystallographically imposed centre of symmetry. Each copper atom has coordinated to it a phosphorus atom of the one bridging ligand, a chelating bipyridyl fragment of the other bridging ligand and an acetonitrile molecule. The stereochemistry about each copper atom is considerably distorted from tetrahedral as reflected by the P(1)—Cu—N(1') and N(1')—Cu—N(2') angles of 123.3(2) and 79.9(5)°, respectively. The acetonitriles are very weakly bound and are readily displaced by a wide range of neutral and anionic ligands including water, alcohols, hydrogen sulphide, diphenylphosphine, bis(diphenylphosphino)methane and -ethane, benzonitrile, pyridine and various substituted pyridines, 2,2'- and 4,4'-bipyridine, 1,10-phenanthroline, pyrido[2,3-b]pyrazine, 7-azaindole and halide, cyanide, thiocyanate, hydrogensulphido, dithiocarbamate, carboxylate and borohydride ions.[7] The dication **1** exhibits two reversible one-electron reduction waves at $E_{1/2} = -1.34$ and -1.55 V, vs Ag/AgCl, in its cyclic voltammogram recorded in benzonitrile at a platinum electrode. Significantly, the neutral species formed at the latter potential has been shown to catalyse the electrochemical reduction of CO_2 to CO and CO_3^{2-}. Details are being reported separately.[8]

Reaction of the copper(I) bipyridyl derivative

† *Crystal Data*: $C_{48}H_{40}N_6P_4F_{12}Cu_2$, $M = 1179.85$, monoclinic, space group $P2_1/c$, $a = 11.671(8)$, $b = 9.424(5)$, $c = 22.885(8)$ Å, $\beta = 93.71(6)°$, $U = 2511.8$ Å^3, $D_c = 1.56$ g cm^{-3} for $Z = 2$, $F(000) = 596$, λ(Mo-K_α) = 0.71069 Å, μ(Mo-K_α) = 11.17 cm^{-1}. 3027 unique reflection intensities were measured on a Nonius CAD-4 diffractometer using the ω–2θ scan mode in the range $3 < \theta < 23°$, 2386 of which were classed as observed [$I > 3\sigma(I)$]. These data were corrected for Lorentz and polarization effects and for absorption using the empirical method. The structure was solved by using standard Patterson and Fourier techniques and refined (SHELX-76[6]) by full-matrix least-squares methods (265 parameters) to $R = 0.0777$ {$R' = 0.0853$, $w = 1.0/[\sigma^2(F) + 0.003F^2]$, max. (shift/ESD) = 0.13} with anisotropic thermal factors assigned to all the non-hydrogen atoms except for the phenyl carbon atoms. Hydrogen atoms were not located. Atomic co-ordinates, thermal parameters and interatomic distances and angles have been deposited as supplementary material at the Cambridge Crystallographic Data Centre.

‡ Satisfactory microanalytical data were obtained for the new compounds synthesised.

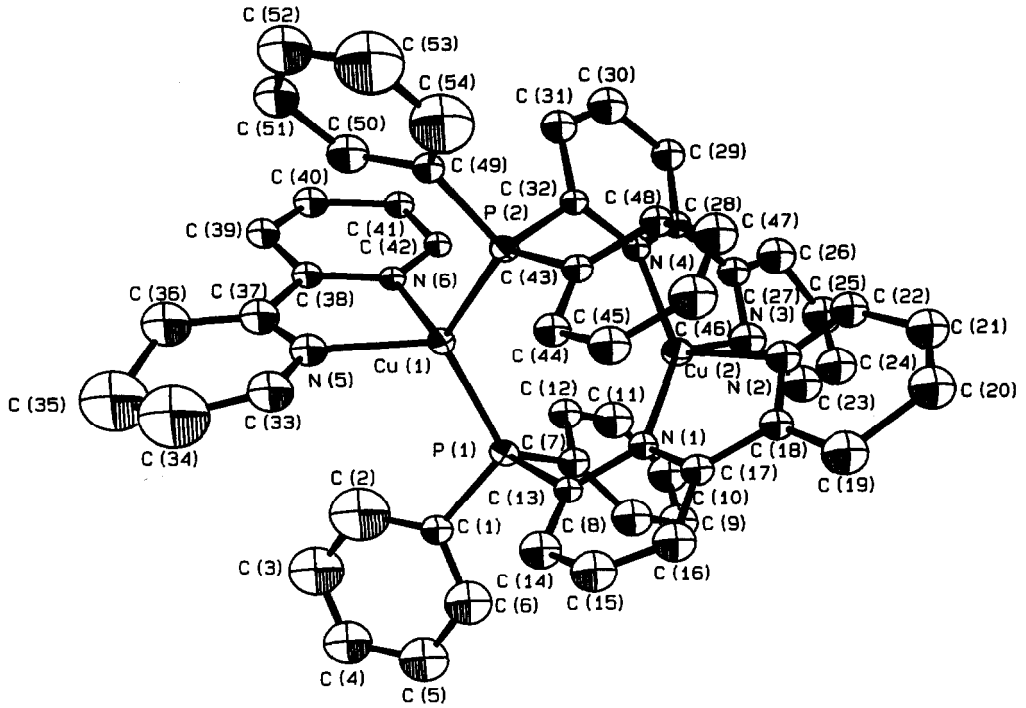

Fig. 2. ORTEP plot (20% probability) of the cation of $[Cu_2(\mu\text{-}Ph_2Pbipy)_2(2,2'\text{-bipy})](PF_6)_2$ {**2,(PF$_6$)$_2$**}. Selected interatomic distances (Å) and angles (°): Cu(1)···Cu(2), 3.692(2); Cu(1)—P(1), 2.234(6); Cu(1)—P(2), 2.237(6); Cu(1)—N(5), 2.03(2); Cu(1)—N(6), 2.14(2); Cu(2)—N(1), 1.96(2); Cu(2)—N(2), 2.10(2); Cu(2)—N(3), 2.13(3); Cu(2)—N(4), 2.03(2); P(1)—Cu(1)—P(2), 121.7(2); P(1)—Cu(1)—N(5), 113.0(6); P(1)—Cu(1)—N(6), 118.3(5); P(2)—Cu(1)—N(5), 112.3(4); P(2)—Cu(1)—N(6), 104.5(6); N(5)—Cu(1)—N(6), 79.3(7); N(1)—Cu(2)—N(2), 81.9(8); N(1)—Cu(2)—N(3), 130.5(9); N(1)—Cu(2)—N(4), 143.8(7); N(2)—Cu(2)—N(3), 96.8(9); N(2)—Cu(2)—N(4), 119.0(8); N(3)—Cu(2)—N(4), 79.2(9).

$[Cu(2,2'\text{-bipy})(MeCN)_2]PF_6$[9] with an equimolar amount of Ph_2Pbipy was found to lead, on the other hand, to the formation of $[Cu_2(\mu\text{-}Ph_2Pbipy)_2(2,2'\text{-bipy})](PF_6)_2$ {**2,(PF$_6$)$_2$**} in which, as established by X-ray crystallography† (Fig. 2), the bridging phosphorusbipyridyl ligands are coordinated head-

† *Crystal data*: $C_{54}H_{42}N_6P_4F_{12}Cu_2$, $M = 1253.93$, monoclinic, space group $C2$, $a = 23.212(2)$, $b = 19.333(3)$, $c = 13.717(2)$ Å, $\beta = 100.06(1)°$, $U = 5799.6$ Å^3, $D_c = 1.44$ g cm^{-3} for $Z = 4$, $F(000) = 634$, $\lambda(\text{Mo-}K_\alpha) = 0.71069$ Å, $\mu(\text{Mo-}K_\alpha) = 9.569$ cm^{-1}. 3888 unique reflection intensities were measured on a Nonius CAD-4 diffractometer using the ω–2θ scan mode in the range $3 < \theta < 23°$, 2948 of which were classed as observed $[I < 3\sigma(I)]$. These data were corrected for Lorentz and polarization effects and for absorption using the empirical method. The systematic absences $h+k = 2n+1$ for all *hkl* in the monoclinic system indicated the space group to be $C2$, Cm, or $C2/m$. Analysis of the intensity distribution strongly suggested that the space group is non-centrosymmetric i.e., $C2$ or Cm. The Patterson showed intense vectors corresponding to copper atoms in different asymmetric units being related by a two-fold axis (but not by a mirror plane); accordingly solution of the structure proceeded in $C2$. Solution of the Patterson allowed the location of the copper and phosphorus atoms of the cation and a difference Fourier synthesis phased on these atoms revealed the positions of the remaining non-hydrogen atoms of the cation. A difference Fourier phased on all the non-hydrogen atoms of the cation indicated that the distribution of PF_6^- anions is as follows: one on a general equivalent position, a second on a two-fold axis and a third on a general equivalent position but disordered such that the site occupation factor is 0.5. The structure was refined (SHELX-76[7]) by full-matrix least-squares techniques (313 parameters) to $R = 0.1075$ $\{R' = 0.1146$, $w = 1.00/[\sigma^2(F) + 0.019F^2]$, max. (shift/ESD) $= 0.09\}$ with anisotropic thermal factors assigned to the copper and phosphorus atoms and isotropic temperature factors to the remaining non-hydrogen atoms. The phenyl rings were refined as rigid groups. Hydrogen atoms were not located. Refinement of the structure in the other hand of $C2$ gave a higher R' value. Some of the isotropic thermal factors of the lighter atoms are very high suggesting that they are partially disordered and that their positional parameters should be treated with circumspection; nevertheless the main features of the structure are correct. Attempts to grow crystals which give a better-defined diffraction pattern are continuing; lack of facilities precluded a data collection at a lower temperature. Atomic coordinates, thermal parameters and bond lengths and angles have been deposited at the Cambridge Crystallographic Data Centre.

to-head. The two copper atoms which are separated by a non-bonding distance of 3.692(2) Å again adopt irregular tetrahedral geometries (see caption to Fig. 2). By careful control of the reaction conditions an intermediate in the formation of **2,$(PF_6)_2$**, viz. $[Cu(bipy)(\eta^1\text{-}Ph_2Pbipy)_2]PF_6$, could be isolated. This compound reacts readily with $[Cu(MeCN)_4]PF_6$ to produce **2,$(PF_6)_2$** and is, in fact, an ideal precursor for the synthesis of a wide range of asymmetric dinuclear compounds. The dication **2** exhibits two reversible one-electron reduction waves at $E_{1/2} = -1.24$ and -1.48 V, and a third partly reversible ($i_{pa}/i_{pc} < 1.0$) wave at $E_{1/2} = -1.85$ V, *vs* Ag/AgCl, in its cyclic voltammogram recorded in benzonitrile under argon at a platinum electrode. When the cyclic voltammogram is recorded under an atmosphere of CO_2 again a significant current enhancement of the second reduction wave is observed indicating that, similar to that observed for **1**, species produced by the reduction of **2** catalyse the electrochemical reduction of CO_2.

Studies of the coordination chemistry of the Ph_2Pbipy ligand are continuing with the eventual aim of producing a range of dinuclear Ph_2Pbipy ligand-bridged complexes which are effective electrocatalysts for the reduction of CO_2 to useful products. Indeed, the efficacy of this ligand for affording dinuclear compounds is illustrated by the range of dinuclear compounds that we have thus far isolated and characterized crystallographically and which include $[Ru_2\{\mu\text{-}OC(Me)O\}(CO)_2(\mu\text{-}Ph_2Pbipy)_2]PF_6$,[10] $[\{Ag_2(\mu\text{-}Ph_2Pbipy)_2\}(\mu'\text{-}4,4'\text{-}bipy)]_n(PF_6)_{2n}$[10] and $[Ni_2(CO)_2(\mu\text{-}Ph_2Pbipy)_2](BF_4)_2$.[11]

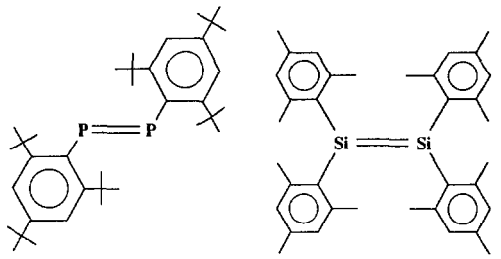
1. INTRODUCTION

In Dasent's 1965 monograph entitled *"Nonexistent Compounds"*,[1] molecules of the heavier main group elements containing $p\pi$—$p\pi$ multiple bonds warranted a chapter to themselves, the point being made that whilst multiple bonding was common for the first row elements carbon, nitrogen and oxygen, it was conspicuous by its absence in the chemistry of the heavier congeners (with the exception, to some extent, of sulphur). This was the situation not for lack of effort on the part of synthetic chemists, but rather because many of the compounds which had been described in the early literature as having multiple bonds were later shown to be cyclic oligomeric species containing only single bonds. For example, the compound, described in 1877 by Köhler and Michaelis as

"phosphobenzene", was formulated as PhP=PPh by analogy with the well known azobenzene, PhN=NPh, but it was later shown to adopt cyclic pentameric and hexameric forms in the solid state.[2] Similarly, compounds which were once thought to contain As=As, Si=Si and Si=C double bonds were also later shown to be oligomeric. Not surprisingly, perhaps, these results led to a belief in a "double bond rule" whereby elements of the second and subsequent rows were deemed not to form stable $p\pi$—$p\pi$ multiple bonds.[3] This was the state of affairs which existed until a little over ten years ago and it is possible that it was the belief in a double bond rule which was largely responsible for the stagnation in this field. In this regard, the parallel with the stories of perbromate[4] and noble gas chemistry[5] are illuminating since the important discoveries in each of these cases were preceded by a period in which many reasons for their nonexistence were advanced; it is also noteworthy how many of the compounds in Dasent's book have, in fact, now been synthesized.

The situation changed dramatically, however, in the early 1980s with the synthesis and characterization of the first stable* compounds with a phosphorus–phosphorus (diphosphenes, RP=PR) and a silicon–silicon (disilenes, $R_2Si{=}SiR_2$) double bond, (**1**)[6] and (**2**),[7] respectively, together with examples of stable phospha-alkenes ($RP{=}CR_2$)[8] and silenes ($R_2Si{=}CR_2$).[9]



1 2

The area has expanded considerably since this time and is very much part of the renaissance of main-group chemistry which has occurred during this same period. In this review, we shall look back over the first decade of the subject addressing first some thermodynamic aspects regarding the strengths of single and double bonds for the *p*-block elements, followed by an overview of some of the important compounds which have been synthesized, specifically, those in groups 14 and 15 which contain isolated (i.e. non-conjugated) multiple bonds which can be described as of the $p\pi$—$p\pi$ type. Conjugated compounds and the extensive chemistry of multiply bonded sulphur species will not be discussed. Particular emphasis is given to structure and bonding; details on the methods of synthesis and on reactivity studies can be found in the various review articles which are referenced.

2. ASPECTS OF SINGLE AND DOUBLE BOND ENERGIES

In seeking an explanation for the varying stability of $p\pi$—$p\pi$ multiple bonds between the *p*-block elements, we must look first at the strengths of the various bonds involved and an illuminating way in which this can be done is to examine the σ and π-bond increments for particular pairs of atoms. Table 1 lists such increments for several pairs of elements, and is derived largely from the recent work of Kutzelnigg,[10] although the origin of this approach goes back to Pauling.[11] The values in Table 1 are defined such that the first value is that for a typical E—E single or σ-bond; for example the value of 335 kJ mol^{-1} for carbon is that of the C—C bond in ethane. The second value is the difference in energy between a double, or $\sigma+\pi$-bond and that of the single bond given by the first value and this can be taken as a measure of the strength of the π-bond. For carbon, the difference is that between the bond energy of the C=C double bond in ethene (630 kJ mol^{-1}) and the single C—C bond in ethane. Clearly the σ-bond in ethane is not the same as the σ-bond in ethene but the

* The term "stable" is used here to imply that the compounds can be isolated, characterized and stored under ambient conditions of temperature and pressure; in other words, that they are stable with respect to dimerization or oligomerization and/or other facile reaction types.

Table 1. Approximate bond increments (kJ mol^{-1}) for σ/π bonds adapted from ref. 10

C—C	N—N	O—O	C—O	N—O
(335/295)	(160/395)	(145/350)	(335/380)	(190/370)

Ge—Ge	As—As	Se—Se	C—S	S—O
(165/110)	(175/120)	(210/125)	(280/265)	(275/250)

differences are likely to be small; moreover, it is broad comparisons between different types of bonds that are important rather than a means of quantitatively predicting particular bond energies.

If we first consider homonuclear bonds, an important point to emerge from Table 1 is that the π-bond increment for the first row or $2p$ elements is considerably greater than that for the elements of the second and subsequent rows. In other words, π-bond strengths are much larger for the first row elements and by a factor of between two and three. The standard explanation for this feature is that the second and subsequent row elements, being larger, have correspondingly larger and therefore more diffuse orbitals. Overlap between these bigger orbitals is poorer which results in weaker bonds, particularly in the case of π-bonds in which the atomic orbitals overlap side-on rather than the head-on overlap of σ-orbitals. Whilst this is probably broadly correct, and is an example of a defining feature of p-block chemistry, wherein bond strengths generally decrease down a group, it is only part of the explanation for the absence of extensive π-bonding in the chemistry of the heavier elements. The other aspect which we must consider is the strengths of the single or σ-bonds between the first row elements. Thus for nitrogen and oxygen, the N—N and O—O single bonds (like the F—F bond) are exceptionally weak as is clear from Table 1. This feature is usually associated with the small size of the first row atoms, leading to significant repulsions between nonbonded pairs of electrons, and to the fact that relatively high energy π^*-orbitals are occupied. These factors are of much lesser importance for the larger, heavier elements, the latter in particular since any factors which result in weak π bonding will also mitigate the effects of occupation of π^*-orbitals. As a result, P—P and S—S single bonds are considerably stronger than N—N and O—O bonds, respectively. In considering both of these factors, it is therefore apparent that for groups 15 and 16, as the values in Table 1 clearly indicate, the combination of a $\sigma+\pi$ bond is more stable than two σ-bonds for the first row elements whereas the reverse is true for the elements of the second and subsequent rows.

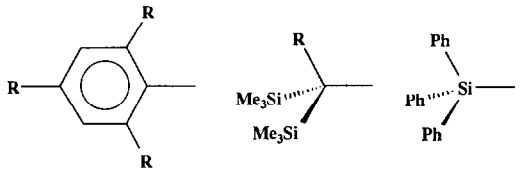
In group 14 the comparison is a little different in that the strength of the C—C single bond is greater than that of the Si—Si bond since there are no nonbonded electron pairs associated with the carbon atoms. The absence of an extensive chemistry of multiply bonded silicon compounds is due, as before, to the weakness of π-bonding for this element (two σ-bonds are stronger than one σ and one π-bond) and it is noteworthy that Si—Si π-bonding is the weakest of the $3p$ elements (see Table 1) consistent with the larger size of the silicon atom (vs P or S). The occurrence of π-bonding in carbon chemistry, however, is not associated with any weakness of the C—C σ-bond but much of the extensive and rather special organic chemistry of carbon is the result of the similarity in the strengths of the C—C σ and π-bonds. With this final point in mind, it is also clear from the values for group 14 in Table 1 that, in absence of factors which weaken the first row σ-bond, the ratio of the σ/π bond strengths drops markedly between the first and second row (0.88 vs 0.61) but then remains nearly constant for the second and third row (0.61 vs 0.66).

An examination of σ and π increments for heteronuclear bonds is also instructive. For example, Table 1 reveals that the π-bond increment is large where both elements are from the first row although the σ-bond strengths are also large where one of the elements is carbon. Heteronuclear bonds where a second row element is involved, for example Si—O and P—O, are similar to the homonuclear second row element cases in having a small π increment but we should note the rather special case of sulphur wherein the σ and π increments for both C—S and S—O bonds are about equal. This is mainly the result of a large π increment (as opposed to weak σ-bonding, cf. C—C) and in this sense, sulphur is acting (as far as π-bonding is concerned) more like a first row element. This is undoubtedly due to the relatively small size of the sulphur atom and the consequent better

π overlap, and it is therefore not surprising that $p\pi$—$p\pi$ multiple bonding is important in the chemistry of this element.

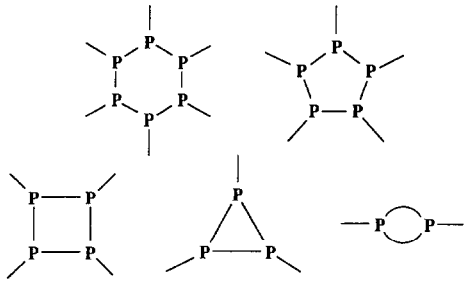
3. STERIC PROTECTION

In the previous section it was shown, on the basis of bond energy considerations, why single bonding is expected to be much more common than $p\pi$—$p\pi$ multiple bonding for the heavier *p*-block elements. However, an analysis which deals only with strengths of particular bonds does not encompass other important features. The synthesis of stable compounds containing isolated multiple bonds, which are the subject of this report, was, in fact, achieved by employing sterically bulky substituents, typical examples of which are $C_6H_2R_3$-2,4,6 (R = Me, Et, Pr^i, Bu^t, CF_3), $(Me_3Si)_3C$, $(Me_3Si)_2CH$ and Ph_3Si as shown below.



R = Me, Et, Pr^i, Bu^t, CF_3 R = Me_3Si, H

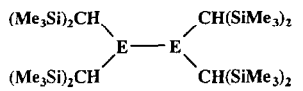
The efficacy of such groups in this regard has often been stated to be kinetic in origin with the implication that they protect an unstable functional group from oligomerization by means of their size. However, whilst there is much truth in this assertion, it is not really kinetic stabilization. If we take as an example some compounds which have already been mentioned, then for the RP or phosphinidene unit, when R is phenyl, cyclic pentameric and hexameric species are formed whereas when R is the much more bulky aryl substituent $C_6H_2Bu^t_3$-2,4,6 (hereafter Ar′ and often referred to as supermesityl), it is a diphosphene which is obtained. If we now consider various possible ring sizes and also that a diphosphene can be thought of, albeit somewhat perversely, as a two-membered ring, it is clear from the diagrams below that more bulky substitutents will favour smaller ring sizes since the R—P—P angle(s), and hence the R···R separation, increase as the ring size decreases. This argument assumes that the P_n rings are planar and that the bonded atoms of the R groups are coplanar with the P_n ring which will not generally be the case, but the basic point of the argument remains in that smaller rings will more readily accommodate larger R groups.



On this basis, it is apparent that the stabilization of a diphosphene by sterically demanding substituents is not really kinetic stabilization but it is a form of thermodynamic stabilization since it is certainly not the case that **1** is a kinetic product which is somehow prevented (by a large activation energy) from forming a larger, and thermodynamically more stable, P_n ring. Thus, π-bonded compounds (two membered rings) can be rendered quite stable if the σ-bonded alternatives (larger rings) are made less stable by using large and bulky side groups; in effect, these large groups exert thermodynamic control over oligomerization and kinetic control over other reactions which may occur at the double bond.

There is an interesting parallel to note here between the use of sterically demanding groups used to stabilize P=P and Si=Si double bonds in diphosphenes and disilenes, respectively, and the

similar use of such groups to stabilize element–element single bonds in group 13 chemistry. Thus compounds of the type R_2E—ER_2 containing two-centre, two-electron E—E single bonds are particularly uncommon in the chemistry of the group 13 elements, especially for the heavier elements. This instability is likely to be associated with the presence of a vacant *p*-orbital at each element centre rather than with any inherent weakness of the E—E bonds; the B—B single bond, for example, has a substantial bond energy of about 300 kJ mol^{-1}. For boron, the use of strong π-donors is efficacious in this regard[12] whereas for aluminium, gallium and indium, the sterically demanding group $(Me_3Si)_2CH$ has been utilised by Uhl and co-workers[13] to effect the isolation of such compounds; Cowley *et al.* have also described a di-indium compound stabilized by four $C_6H_2(CF_3)_3$-2,4,6 groups.[14]



E = Al, Ga, In.

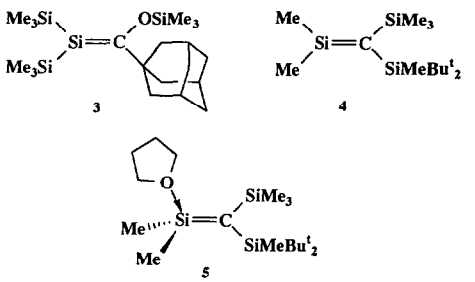
In this case, the sterically bulky $(Me_3Si)_2CH$ groups probably are effective in stabilizing the E—E bond for kinetic reasons in that they inhibit reactions which would degrade the E—E bond, particularly disproportionation reactions.

Having looked at some general properties which affect the stability of multiply bonded compounds in the *p*-block, we will now look at some specific examples. This is certainly not a comprehensive or exhaustive list but the compounds described serve to illustrate some of the general features associated with this subject.

4. GROUP 14

4.1. *Compounds involving double bonds to a first row element*

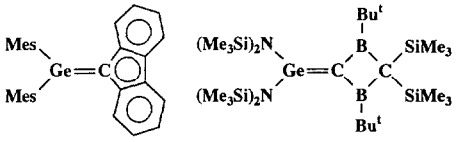
(i) *Silenes* (Si=C) *and their heavier congeners.* The first stable compound in this class to be structurally characterized was $(Me_3Si)_2Si{=}C(OSiMe_3)$(1-ad) (**3**) (ad = adamantyl) described by Brook and co-workers[15] in 1982. Key features of this compound include a Si=C bond which is approximately 10% shorter than a typical Si—C single bond, and the near coplanarity of the Si=C unit and the atoms to which it is bonded. Other important features, derived from NMR spectroscopy, are the inequivalence of the Me_3Si groups, which indicates hindered rotation about the Si=C bond, a deshielded ^{29}Si NMR chemical shift and a large ^1J(SiC) coupling constant. All of these features are important in establishing the presence of double bonding akin to that commonly encountered for the first row elements.



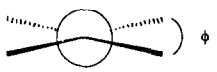
An additional and important structural feature of **3** is the presence of four bulky groups surrounding the Si=C unit which is undoubtedly responsible, in large part, for the stability of **3** with regard to dimerization, a usually facile reaction for less hindered silenes. However, the subsequent isolation and structural characterization of complex **4** by Wiberg and co-workers[16a] shows that massive steric protection is not always a necessary condition, at least as far as the silicon

centre is concerned, for stability towards dimerization; there are other examples of complexes (see later) where steric factors alone are unlikely to prevent dimerization. It is also noteworthy that the silicon centre in **4** is quite Lewis acidic and readily accommodates a coordinated thf (tetrahydrofuran) molecule to give complex **5**.[16b] Lewis acidity is commonly associated with three-coordinate, multiply bonded silicon centres in silenes, silanimines (see later) and in transition metal silylene complexes, $L_nM{=}SiR_2$.[17]

Compounds containing Ge=C double bonds (germenes) are fewer in number and have been reviewed by Barrau *et al.*[18] Two examples, **6**[19] and **7**[20,21] have been structurally characterized and both contain Ge=C bonds which are significantly shorter than typical Ge—C single bonds in accord with that found for silenes. However, whilst in **6** the atoms to which the Ge=C unit is bonded are nearly coplanar, in **7** the average twist angle, ϕ, defined in the diagram below, is 36°. Relatively large twist angles are sometimes encountered in complexes of this and related types (see later) which reflects the relative weakness of the π-bond. It should also be noted that in both **6** and **7** there is the possibility of π-conjugation with the substituents which may enhance their stability.

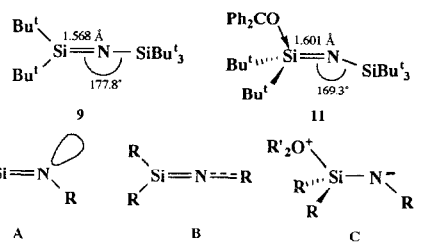


6 7



Stannenes (compounds with Sn=C double bonds) related to **6**[22] and **7**[23] have also been reported (the latter characterized by X-ray crystallography) together with the stannaketenimine $(C_6H_2(CF_3)_3$-2,4,6$)_2$Sn=C=N(mes) (**8**),[24] the structure of which will be discussed later.

(ii) *Silanimines* (Si=N) *and their heavier congeners.* The first stable silanimine $(Bu^t)_2Si{=}N(SiBu^t_3)$ (**9**) was described by Wiberg and co-workers[25] in 1986. The Si=N bond distance (1.568 Å) is significantly shorter than typical Si—N single bonds and is also shorter than the N—$SiBu^t_3$ bond length in **9** (1.695 Å), but of more interest is the almost linear coordination about the nitrogen atom (Si=N—Si 177.8°). Such a geometry is clearly inconsistent with a bonding scheme as represented in **A** with a localized lone pair on the nitrogen atom; some degree of delocalization involving a vacant orbital on the $SiBu^t_3$ silicon centre, as shown in **B**, is implied and in which the nitrogen is better described as *sp* hybridized rather than sp^2. Delocalization of nitrogen lone pairs onto adjacent silicon centres is not uncommon and is seen, for example, in the planar structure of silyl substituted amines such as $N(SiMe_3)_3$ and related compounds.[26] As with the silenes, the three-coordinate silicon centres in silanimines are appreciably Lewis acidic and readily coordinate (albeit weakly) a Lewis base. The structure of the thf adduct Me_2(thf)Si=N($SiBu^t_3$) (**10**)[25] reveals a Si=N bond (av. 1.581 Å for two independent molecules) slightly lengthened compared to **9** due to the fact that the acceptor orbital on silicon is probably the Si=N π^*-orbital, and also that the nitrogen centre is now noticeably bent (Si=N—Si av. 161.3°). Additional structures of Lewis base adducts (with Si=N distances and Si—N—Si angles in parentheses) are $Bu^t_2(Ph_2CO)$Si=N($SiBu^t_3$) (**11**) (1.601 Å, 169.3°)[27] and Bu^t_2(thf)Si=N($SiBu^t_2$Me) (**12**) (1.596 Å, 174.3°).[28] Moreover, it is apparent when comparing the structures of the similarly substituted compounds **11** and **12**, that a longer Si=N bond correlates with a smaller Si—N—Si angle which is in accord with a limiting, zwitterionic structure **C**.



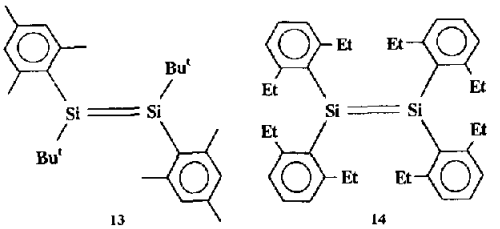
9 11

A B C

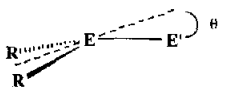
Many stable germanimines (Ge=N) have been described and the topic has been reviewed[18] although the only crystal structure determinations that have been reported are those for $\{(R)(Me_3Si)N\}_2Ge{=}N(R)$ (R = mes, $C_6H_3Pr^i_2$-2,6).[29] Both compounds have short Ge=N bonds and planar structures consistent with the presence of $p\pi$—$p\pi$ Ge=N bonds.

4.2. *Compounds involving double bonds without a first row element*

(i) *Disilenes*[30] (Si=Si) *and their heavier congeners.* The first stable disilene **2** was reported in 1981 by West, Fink and Michl[7] and the crystal structure determination of **2** was reported in 1984[31] together with that of the *E* isomer of (mes)(Bu^t)Si=Si(mes)(Bu^t) (mes = $C_6H_2Me_3$-2,4,6) (**13**),[31] the structures of $(C_6H_3Et_2\text{-}2,6)_2Si{=}Si(C_6H_3Et_2\text{-}2,6)_2$ (**14**)[32] and (*E*)-$(C_6H_2Pr^i_3\text{-}2,4,6)$(R)Si=Si$(C_6H_2Pr^i_3\text{-}2,4,6)$(R) (**15**) (R = Bu^t, $SiMe_3$) have also been described[33] together with those of the air stable compound $(C_6H_2Pr^i_3\text{-}2,4,6)_2Si{=}Si(C_6H_2Pr^i_3\text{-}2,4,6)_2$[34] and *E*-(mes)(1-ad)Si=Si(mes)(1-ad).[35] In all complexes, the Si=Si bond length is around 2.15±0.01 Å which is about 10% shorter than typical Si—Si single bond lengths consistent with double bond character for the Si=Si unit (C=C bonds are typically about 10–12% shorter than C—C bonds with comparably sized substituents). Moreover, in complexes **13** and **15**, the Si=Si unit and the atoms to which it is bonded are coplanar where the twist angle ϕ and the pyramidalization angle θ are zero (θ is defined as the angle made by the E—E′ vector to the RRE plane as shown in the diagram below). Maximum deviations from planarity are found in **2** for which θ is 18° and in **14** for which ϕ is 10°.



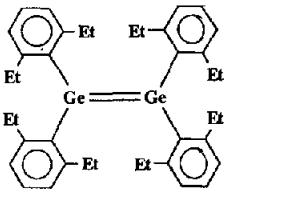
13 14



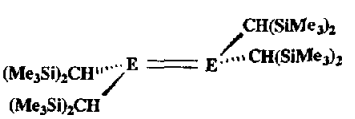
Other factors consistent with a double bond formulation for disilenes are the deshielded ^{29}Si NMR chemical shifts and large ^1J(SiSi) coupling constants. Moreover, for **13**, *E* and *Z* isomers can be isolated (although these equilibrate in solution, especially under photochemical conditions), NMR data for which establish a barrier to rotation about the Si=Si bond of 131 kJ mol^{-1}. This can be compared with the rotational barrier in stilbene which is 179 kJ mol^{-1}, i.e. about 30% larger.

Tetra-alkylated disilenes are $\{(Me_3Si)_2CH\}_2Si{=}Si\{CH(SiMe_3)_2\}_2$[36] and $Bu^t_2Si{=}SiBu^t_2$[37] the former being air stable and rather unreactive due to the extremely large substituents.

Digermenes which have been structurally characterized are $(C_6H_3Et_2\text{-}2,6)_2Ge{=}Ge(C_6H_3Et_2\text{-}2,6)_2$ (**16**)[38] and (mes)$(C_6H_3Et_2\text{-}2,6)$Ge=Ge$(C_6H_3Et_2\text{-}2,6)$(mes) (**17**)[39] by Masamune *et al.*, together with $\{(Me_3Si)_2CH\}_2Ge{=}Ge\{CH(SiMe_3)_2\}_2$ (**18**)[40] and the distannene, $\{(Me_3Si)_2CH\}_2Sn{=}Sn\{CH(SiMe_3)_2\}_2$ (**19**)[40] which have been described by Lappert and co-workers.

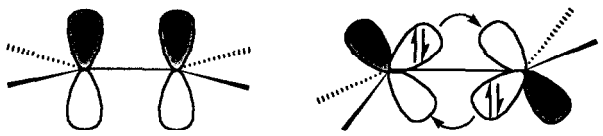


16



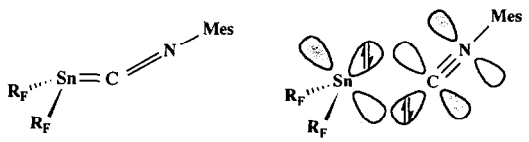
18, E = Ge; **19**, E = Sn.

In **16**,[38,39] the twist angle, ϕ, is 10° and the pyramidalization angle, θ, is 12° neither of which is significantly larger than those found in disilenes. In **17**, however, the germanium atoms are markedly pyramidal ($\theta = 36°$, $\phi = 7°$)[39] and compounds **18** and **19** are significantly distorted from a planar geometry such that whilst ϕ is zero in both cases, they adopt strongly *trans* bent structures, where θ is 32° and 41°, respectively.[40] Clearly a standard $\sigma+\pi$ bonding description applicable to olefins is reasonable for the disilenes and the digermene **16** but is not appropriate for the digermenes **17** and **18** and the distannene **19**. The bonding in these latter two species has been addressed by Lappert *et al.*[40] Pauling[41] and in a series of papers by Trinquier and co-workers.[42] The basis of the argument is that a planar structure as shown in **D** is only feasible if the triplet state of the ER_2 fragment is energetically accessible. For carbon, this is certainly the case (the triplet state of CH_2 is slightly lower in energy than the singlet state) but as the group is descended (C, Si, Ge, Sn), not only is the singlet state more stable, but the singlet–triplet energy separation, ΔE_{ST}, increases. In the situation where $\Delta E_{ST} > 1/2E—E(\sigma+\pi)$, where $E—E(\sigma+\pi)$ is the double bond energy, a *trans* bent structure should be preferred. For germanium and certainly for tin, ΔE_{ST} is sufficiently large and the planar structure of type **D** is no longer the energy minimum. The bonding in the resultant *trans* bent structure may therefore be represented as an interaction of two singlet states as shown in **E**.



D **E**

In the stannaketenimine **8**,[24] the tin atom is also markedly pyramidal (sum of angles = 290.9°) and this compound may be thought of as linked, singlet stannylene (R_2Sn) and isocyanide (C≡NR) species as shown in the diagram below. Consistent with this view is the bent geometry at the carbon atom (153.9°) and the near linear coordination (175.0°) at nitrogen.

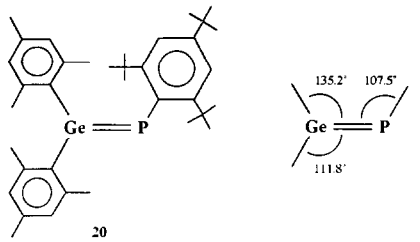


8, $R_F = C_6H_2(CF_3)_3$-2,4,6

An alternative, although complementary, description is provided by Albright, Burdett and Whangbo[43] wherein the change in structure from type **D** to type **E** as group 14 is descended, is considered in terms of a second order Jahn–Teller distortion due to mixing of the $b_{1u}\pi$ and $b_{2g}\pi^*$ levels with the $3b_u\sigma^*$ and $3a_g\sigma^*$ levels, respectively. These levels become closer in energy as the group is descended leading to greater mixing and hence to a larger *trans* bent distortion. In this sense, the increasing pyramidalization is seen as a special case of pyramidalization in eight-electron EX_3 species reasons for which are also discussed. Similar reasons for an increase in bending for six-electron EX_2 species with a concomitant increase in ΔE_{ST} are also addressed. The % bond shortenings in **18** and **19** compared with typical single bond values are 4 and 2%, respectively which also indicates that the standard $\sigma+\pi$ double bonding model is not appropriate in these cases.

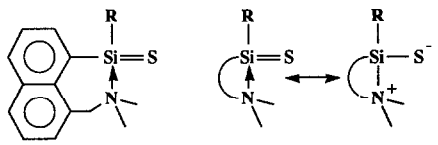
(ii) *Silaphosphenes* (Si=P) *and their heavier congeners.* The following compounds which are examples of silaphosphenes, germaphosphenes (Ge=P) and stannaphosphenes (Sn=P) have been described: RR′Si=PAr′ (R = R′ = $C_6H_2R''_3$-2,4,6 for R″ = Me, Et, Pr^i; R = $C_6H_2Pr^i_3$-2,4,6, R′ = Ph, mes, Bu^t),[44a–c] $(mes)_2Ge$=PAr′ (**20**)[45] and $\{(Me_3Si)_2CH\}_2Sn$=PAr′[46] together with the cumulene Ar′P=Si=PAr′.[47] Compound **20** has been structurally characterized[45] and has a Ge=P bond length which is about 8% shorter than a typical Ge—P single bond. Moreover, the coordination around the Ge=P unit is essentially planar with important interbond angles as shown below, and it is noteworthy that there is no appreciable pyramidalization at the germanium centre, similar to the situation found for **16**; the uneven angles to the mesityl groups are clearly a consequence of the

supermesityl *cis* to one mesityl group. There has been one report of a sila-arsene, $(C_6H_2Pr^i_3$-2,4,6)$_2$Si=AsSiPr^i_3[48] which has been characterized spectroscopically.



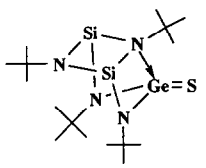
20

(iii) *Thiosilanones or silanethiones* (Si=S). The only compounds to have been reported in this class[49] are of the form shown below in which the silicon centre is additionally coordinated, intramolecularly, by an amine function; the electrophilic nature of three-coordinate silicon was encountered with silenes and silanimines. Possible canonical forms are also represented.



R = Ph, Naphthyl

Compounds of this type have also been isolated with Si=NBu^t and Si=PPh units[50] and brief mention should also be made of a compound containing a base stabilized Ge=S bond, **21** see below,[51] and also of ESR evidence for the radical anion species $[Bu^t_2Si{=}O]^{-\bullet}$[52] although no data is yet available for stable neutral silanones, $R_2Si{=}O$.

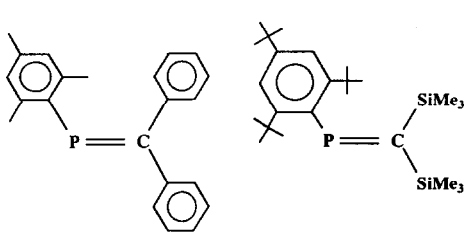


21

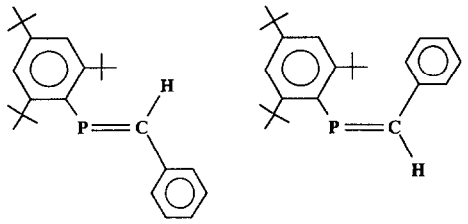
5. GROUP 15

5.1. *Compounds involving double and triple bonds to a first row element*

(i) *Phospha-alkenes* (P=C), *phospha-alkynes* (P≡C) *and related compounds.* Phospha-alkenes[8] are one of the most extensively studied class of compound containing multiply bonded phosphorus. The first report of stable non-conjugated phospha-alkenes was by Becker in 1976[53] who described the complexes RP=CR′(OSiMe$_3$) (R = R′ = Bu^t; R = *c*-hexyl, R′ = Bu^t; R = Ph, R′ = Bu^t) and examples of complexes which have subsequently been structurally characterized are (mes)P=CPh_2 (**22**)[54] and Ar′P=C$(SiMe_3)_2$ (**23**)[55] which are shown below. Of particular interest are the structures of the *E* and *Z* isomers of Ar′P=CH(Ph) (**24**);[56a–c] both of these isomers are also configurationally rigid in solution under ambient conditions indicating hindered rotation about the P=C bond.



22 23

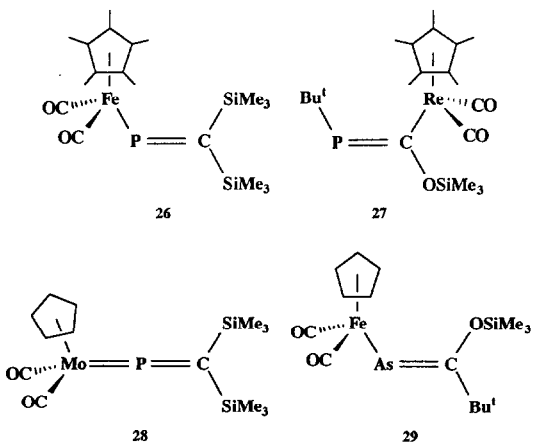


E, 24a *Z*, 24b

In general, a degree of steric protection is required in order for compounds containing isolated P=C bonds to be stable (with respect to dimerization) but this condition is relaxed somewhat when the P=C unit is part of a conjugated system or when the phosphorus is bonded to an electronegative atom or group. Examples of the former class of compound are the phosphabenzenes $C_5H_2R_3$-2,4,6-P (R = H and Ph)[57] whilst the latter is exemplified by $ClP{=}C(SiMe_3)_2$ (**25**).[58] In **25**, and a series of related compounds, the chlorine atom, by virtue of its electronegativity, probably leads to a phosphorus centre with a greater δ^+ charge which in turn results in a contraction of the phosphorus *p*-orbital which overlaps more effectively with the carbon *p*-orbital.

An important class of phospha-alkene is the metalla-phospha-alkene of which two basic types have been characterized depending on the position of the organotransition metal fragment, viz $(L_nM)P{=}CR_2$ and $RP{=}CR(ML_n)$. Structurally characterized examples are $(\eta\text{-}C_5Me_5)(CO)_2Fe{-}P{=}C(SiMe_3)_2$ (**26**)[59] and $Bu^tP{=}C(OSiMe_3)\{Re(CO)(NO)(\eta\text{-}C_5Me_5)\}$ (**27**)[60] in which the metal atoms are bonded to phosphorus and carbon, respectively.

Further derivatives of this class of compound are the phosphavinylidene complex $(\eta\text{-}C_5H_5)(CO)_2Mo{=}P{=}C(SiMe_3)_2$ (**28**)[61] reported by Cowley *et al.* which is an example where the phosphorus is multiply bonded to the metal atom as well as to carbon, and the arsa-alkene complex $(\eta\text{-}C_5H_5)(CO)_2Fe{-}As{=}CBu^t(OSiMe_3)$ (**29**)[62] described by Weber and co-workers, one of only very few examples of an arsenic–carbon double bond.

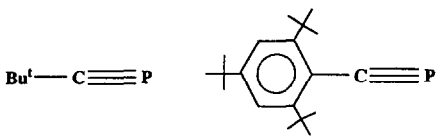


26 **27**

28 **29**

Important structural features associated with all the phospha-alkenes are a P=C bond length which is about 8–10% shorter than a P—C single bond and the coplanarity of the atoms bonded to the P=C unit. Angles at phosphorus are usually about 100°, except for some of the P-bonded metalla-phospha-alkenes in which these angles are often a little larger. NMR parameters are also consistent with the presence of a P=C double bond.

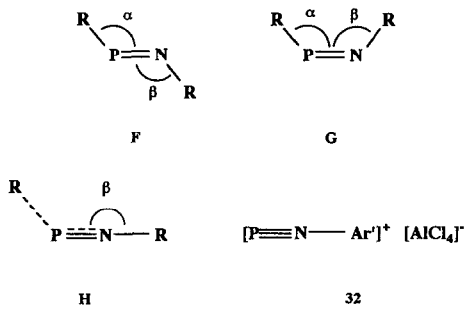
The first phospha-alkyne stable to polymerization, $Bu^tC{\equiv}P$ (**30**) was described in 1981 by Becker[63] and the chemistry of this and related species has been extensively reviewed.[64] The structure of **30** and other compounds RC≡P (R = H, Me, Ph) have been determined by microwave spectroscopy[65] whilst the structure of the crystalline compound $Ar'C{\equiv}P$ (**31**) has been determined by X-ray crystallography;[66] in all cases, the P≡C bond distances are short and consistent with a P≡C triple bond. The arsenic analogue of **31**, $Ar'C{\equiv}As$, has been reported by Märkl[67] although no structural details are available.



30 31

Finally in this section, it is important to mention a number of cumulenes involving P=C double bonds. This area, which has been reviewed by Appel,[8] has developed to include a large range of compounds, examples of which are 1,3-phospha-allenes RP=C=PR, 1-phospha-allenes RP=C=CR_2 and phosphaketenes RP=C=O.

(ii) *Phospha-imines* (P=N). The chemistry of phospha-imines has a slightly longer history than many of the other classes of compound described in this review, dating back to 1973, and the subject has recently been reviewed by Niecke.[68] Of particular interest are the structures of these compounds (all of which contain at least one bulky group) which can be classified according to three general classes. The first type, **F**, involves a *trans* and planar arrangement about the P=N bond and is defined by a RP=NR torsion angle of about 180°. The P=N bond distances are all close to 1.55 Å with the angle at phosphorus (α) typically between 100 and 110° and the angle at nitrogen (β) between 115 and 125°. The second type, **G**, has a *cis* configuration for which the RP=NR torsion angle is close to 0°. Compounds of this type have similar P=N bond lengths to those of type **F** and also similar values for the angle α, but values for β are larger falling in the range 130–145°. In the final type, **H**, the nitrogen atom adopts a nearly linear coordination in which β ranges from 155 to 180°. An examination of the structural data indicates that there is essentially a continuum between types **G** and **H** in which the angle at nitrogen increases from 130 to 180°. Moreover, this increase in β correlates with a decrease in the P=N bond length from about 1.55 to 1.48 Å. This latter observation is consistent with the view that type **H** compounds are best represented as incipient ionic species of the form $[RN{\equiv}P]^+[R]^-$ in which the PN linkage has substantial triple bond character. Not surprisingly, therefore, type **H** compounds are found when the $[R]^-$ group is electron withdrawing such as halide, $Bu^t{}_3CO$ or $Bu^t{}_2HCO$ and complete ionization occurs in the complex $[Ar'N{\equiv}P]^+[AlCl_4]^-$ (**32**). Compound **32** and related species are analogous to organic diazonium cations and isoelectronic with phospha-alkynes.



F G

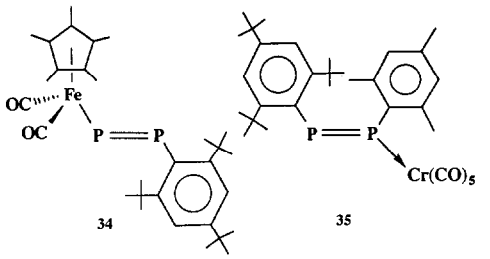
H 32

5.2. *Compounds involving double bonds without a first row element*

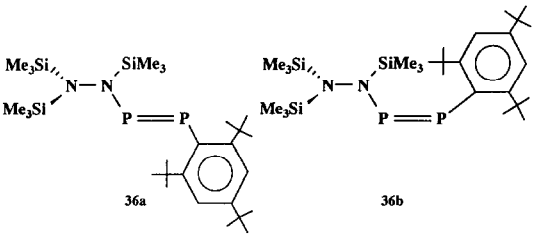
(i) *Diphosphenes* (P=P) *and their heavier congeners.* The first stable diphosphene, **1**, was reported in 1981 by Yoshifuji[6] and the subject has been reviewed a number of times by Cowley,[69] Yoshifuji[70] and Weber.[71] In all cases, sterically bulky groups on at least one of the phosphorus atoms (mostly both) are required in order to stabilize these compounds with salient structural features being a P=P bond length of about 2.03 Å, which is 8–10% shorter than typical P—P single bonds, and angles at the phosphorus atoms which range from 100 to 110° (c.f. phospha-imines). In **1**, for example, the C—P—P angle is 102.8° which is considerably smaller than an angle of 120° which might be anticipated from a bonding model involving sp^2 hybridization at the phosphorus centre. Such a model is much more appropriate for the diazo analogue of **1**, Ar'N=NAr' (**33**),[72] for which the bond angles at nitrogen are 113.5° (av.), and for the nitrogen centres in some phospha-imines.

In fact, a trend wherein the bond angles decrease as the group is further descended is apparent when diarsenes are considered (see below).

Most of the diphosphenes which have been structurally characterized to date, including the metalla-diphosphene (η-C_5Me_5)$(CO)_2$Fe—P=PAr′ (**34**)[73] adopt a *trans* or *E* configuration analogous to **1** and for a long time it was considered that this was the only isomer which was likely to be observed since a *cis* or *Z* form would present no obvious steric barrier to dimerization. The first indication of a *cis* diphosphene was obtained by Koenig and co-workers[74] from laser irradiation studies of **1**, and also by Yoshifuji *et al.*[75] who isolated the $Cr(CO)_5$ complex Ar′P=P[$Cr(CO)_5$](mes) (**35**), but subsequently, the uncoordinated *cis* diphosphenes Ar′P=PR (R = Bu^{t}NH, 1-adNH) were isolated and structurally characterized by Niecke and co-workers who later reported the structural characterization of both the *cis* and *trans* isomers of Ar′P=P{N($SiMe_3$)[N($SiMe_3$)$_2$]} (**36a,b**).[76]



34 35



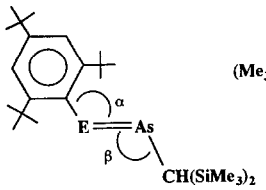
36a 36b

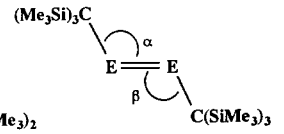
If one considers the stabilization of diphosphenes to be due to steric protection alone, then the isolation of uncoordinated *cis* isomers, which are also stable in solution albeit in equilibrium with the *trans* form,[76] presents a difficulty since, as mentioned above, the attached groups present no obvious barrier to dimerization. The reason for their stability undoubtedly lies not so much with steric effects but with electronic factors. For example, in **36b**, the nitrogen atom to which one of the phosphorus atoms is bonded adopts a trigonal planar geometry in which this plane is coplanar with the NPP plane. There is, therefore, the possibility of conjugation between the nitrogen lone pair and the P=P bond giving rise to a three-centre, four-electron system which is undoubtedly associated with their stability. Nevertheless, the consequences of having two large groups *cis* to each other is evident from a comparison of the angles at phosphorus in compounds **36a** and **36b**. In **36a** the two angles N—P—P and P—P—C are 106.1 and 97.6°, respectively whereas in **36b** they are 126.3 and 121.4°.

The angle of 97.6° in **36a** is one of the smallest observed for a diphosphene, but even smaller angles are found in diarsenes in which the relevant bond angles are usually a few degrees less than those in the analogous phosphorus compounds. Two diarsenes $(Me_3Si)_3CAs{=}AsC(SiMe_3)_3$ (**37**)[77a] and Ar′As=AsCH($SiMe_3$)$_2$ (**38**)[77b] and a phospha-arsene Ar′P=AsCH($SiMe_3$)$_2$ (**39**)[77c] prepared by Cowley and co-workers have been structurally characterized, important angles for which are shown below and which illustrate the trend to decreasing interbond angles as the group is descended. This trend to smaller angles on descending the group is not unexpected and can be considered as a special case of the same trend observed in other EX_2 species. The rationale for this effect is similar to that offered for the increasing pyramidalization in compounds of group 14 and is described in detail in ref. 43. It is important to note, however, that in the group 15 compounds, the π-bonding orbitals are not involved in the orbital mixing associated with the change in geometry. Thus, whereas in group 14 the increase in pyramidalization leads to a weakening of the E—E bond and a decrease in the per cent bond shortening (compared to a single bond), in group 15 no such weakening occurs

and the bond lengths found in phospha-arsenes and diarsenes are, like diphosphenes, 8–10% shorter than typical single bonds.

No structural data is available for an antimony containing compound although spectroscopic data have been reported for $Ar'P{=}SbCH(SiMe_3)_2$.[77c]





E = P, $\alpha = 101.2$, $\beta = 96.4°$ E = P, $\alpha,\beta = 108.5°$ (av.)
E = As, $\alpha = 99.9$, $\beta = 93.6°$ E = As, $\alpha,\beta = 106.3°$ (av.)

6. CONCLUSION AND GENERAL FEATURES

In concluding this perspective, it will be useful to recapitulate briefly the salient features associated with the multiply bonded compounds described herein. In the early years of the subject there was much discussion as to whether "true" double bonds were really present. In most cases, the answer to this question must now be seen to be yes inasmuch as the spectroscopic and structural features are those expected for multiply bonded species. For example, in all compounds where a suitable NMR nucleus is available, the chemical shifts and coupling constants are usually consistent with the presence of a multiple bond; the solid state NMR studies of Zilm and co-workers[78] are a particularly elegant example in this regard.

Moreover, the structural studies on which this report has focused are also consistent with multiple bonding in that percentage bond shortenings of between 8 and 10% (for double bonds) are commonly observed in conjunction with a planar or near planar environment around the E=E unit. The only major exceptions are found for the digermenes and distannenes (and other tin containing species) in which the standard $\sigma + \pi$ model is clearly not appropriate in most cases. Some of the structural features of the silanimines and the phospha-imines are also unusual. Nevertheless, we must exercise a little caution in the discussions of bond lengths particularly with respect to the percentage shortenings observed. Thus, in an insightful paper, Power *et al.*[79] have shown that comparisons between bond lengths must take due account of the formal hybridizations of the elements involved. For example, typical P—P single bonds in compounds such R_2P—PR_2 are about 2.2 Å whereas the P=P bonds in diphosphenes are about 2.03 Å, a shortening of about 8%. However, the phosphorus hybridization in diphosphines and diphosphenes is sp^3 and sp^2, respectively and Power has estimated that a bond shortening of about 0.1 Å (i.e. about 4%) is due to this change in hybridization alone. It is therefore likely that only half of the shortening observed for P=P bonds is due to the presence of the π-bond, the other half being due simply to the different hybridization of the phosphorus atoms. Analogous examples from nitrogen chemistry, however, suggest that the shorter distances found for N=N double bonds vs N—N single bonds are mostly due to the presence of the π-bond (about 75%) and less to the different hybridization of the nitrogen (25%). These observations are consistent with the relatively stronger π-bonding expected for nitrogen vs phosphorus as outlined earlier.

Finally, it is worth mentioning some of the types of compound which have yet to be synthesized. Clearly there is a paucity of data for species involving the heaviest elements, particularly the 6*p* elements lead and bismuth although it is likely that even more sterically bulky ligands will be needed to afford stability in these cases. An alternative strategy is to exploit the Lewis acidity of these elements and to use groups which are both bulky and which contain Lewis basic sites in order to form intramolecular acid–base complexes. However, the concomitant increase in coordination number means that a description of the bonding in terms of a pure $p\pi$—$p\pi$ interaction is no longer entirely appropriate.

In the chemistry of the group 14 elements, the isolation of triply bonded compounds has so far eluded researchers in the field. Thus whilst C≡C and C≡N bonds are well characterized, there are no stable examples of sila-alkynes, RSi≡CR, silanitriles, RSi≡N, disilyenes, RSi≡SiR or analogous

compounds involving the heavier congeners. This is in contrast to group 15 where the chemistry of phospha-alkynes is now well established and this probably reflects the fact that phosphorus forms somewhat more stable π bonds than silicon due to its smaller size. Success in the field of heavier element triple bonds is also likely to require new and even more bulky ligands, particularly those with the ability to stabilize what are likely to be extremely electrophilic silicon centres. It is probable that conjugatively stabilized compounds and transition metal complexes will be prepared before uncoordinated compounds are isolated as has happened before in this field.

Note added at proof

Since the submission of the manuscript, X-ray crystal structures have been reported for the stannaimine complex $\{(Me_3Si)_2N\}_2Sn{=}N(C_6H_3Pr^i_2\text{-}2,6)$[80] and for the phosphasilene complex $(C_6H_2Bu^t_3\text{-}2,4,6)P{=}Si(Bu^t)\{P(C_6H_2Bu^t_3\text{-}2,4,6)(PPh_2)\}$.[81]

Acknowledgements—I would like to thank Drs Paul D. Lickiss and A. Guy Orpen and Professor Alan H. Cowley FRS for their comments and advice in preparing this manuscript.

SYNTHESIS AND CHARACTERIZATION OF ALKYL-2,2,2-TRIFLUOROETHYL SULPHITES

SURAJ P. NARULA,* SUKHJEEVAN KAUR, RAVI SHANKAR and SURINDER K. SHARMA

Department of Chemistry, Panjab University, Chandigarh-160014, India

(*Received* 2 *June* 1993; *accepted* 7 *July* 1993)

Abstract—Some new asymmetric organic sulphites, $R'CH_2OS(O)OCH_2CF_3$ ($R' = H$, CH_3, CH_2Cl, C_2H_5 or C_3H_7) were prepared and characterized by elemental analyses, IR, mass and multinuclear (^1H, ^{13}C, ^{19}F) NMR spectral studies. The quantitative increase of ^1H NMR chemical shift difference of non-equivalent protons with bulk of the R′ substituent is reported.

Organic sulphites have such practical uses as: (i) insecticides;[1] (ii) non-aqueous solvents[2] and (iii) polymerization catalysts.[3] These compounds have also been investigated for reasons of their chemical reactivity[4–8] and structural features.[4,9–13] The structure of these compounds has been studied from the standpoint of non-equivalence of α-methylene protons located in the vicinity of oxygen atoms, linked to the asymmetric centre S=O. In these studies attention has mainly been focussed on the structure of cyclic sulphites while only a few acyclic organic sulphites are characterized;[10–12] and even amongst them very little is known about the nature of asymmetrical sulphites, ROS(O)OR′. Therefore, alkyl-2,2,2-trifluoroethyl sulphites $R'CH_2OS(O)OCH_2CF_3$ ($R' = H$, CH_3, CH_2Cl, C_2H_5, C_3H_7) are isolated, characterized by molecular spectroscopy and the results obtained are reported in this paper.

EXPERIMENTAL

All reactions were performed under dry nitrogen. Thionyl chloride (Fluka) was distilled over mercury before use. Methyl/ethyl/n-propyl/n-butyl alcohols were dried by standard methods given in the literature.[14]

2-Chloroethyl/2,2,2-trifluoroethyl alcohols (Fluka) were used as such. Sulphur and chlorine were estimated by gravimetric methods.[15]

Elemental analyses of the samples were obtained using a Perkin–Elmer (Model 2400) CHN Analyser. Gas Chromatographic analyses were performed on a Perkin–Elmer (Sigma 300) instrument using 6m × 1/8″ long SE-52 column and helium as carrier gas with recorder rate 0.5 cm min^{-1}. IR spectra were recorded as thin films using KBr optics on a Perkin–Elmer 1430 ratio recording spectrophotometer. ^1H and ^{13}C NMR spectra were obtained on Brüker AMX-400 instrument using TMS as internal standard; while ^{19}F NMR spectra were recorded on Varian EM-390 with Freon-11 as external reference. Mass spectra were recorded at 70 eV on VG-Analytical 70-S Spectrometer.

Preparative methods

Methyl/ethyl/2-chloroethyl/n-propyl/n-butyl chlorosulphites were prepared by the reaction of thionyl chloride (40.0 mmol) and the corresponding alcohol (40.0 mmol) as reported earlier.[4] The purity of these compounds was checked by elemental analyses, IR and ^1H NMR spectral data.

Preparation of methyl/ethyl/2-chloroethyl/n-propyl/n-butyl-2,2,2-trifluoroethyl sulphite

A slow addition of 2,2,2-trifluoroethanol (13.7 mmol) was carried out separately into methyl/ethyl/2-chloroethyl/n-propyl or n-butyl chlorosulphite (13.7 mmol) at 50–60°C with constant stirring. A slow stream of dry nitrogen was bubbled into the reaction mixture to expel the HCl gas

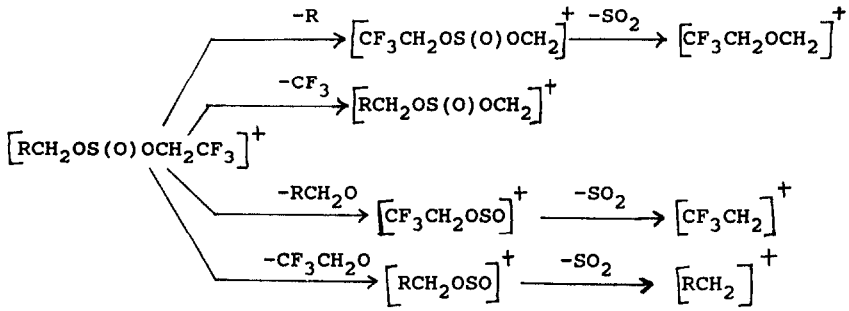

Scheme 1.

formed. After the addition was complete, the contents were heated at 80–90°C for 8–10 h until evolution of HCl gas ceased. The crude mixture was distilled under partial vacuum using a 2 ft long silvered glass column containing glass helices. The constant boiling fractions at 28, 43, 74, 48, 54°C/2 mm Hg, respectively, were collected (% Yield: 70.2, 74.0, 80.7, 82.0, 85.0, respectively) and analysed. Found: C, 20.6; H, 2.7; S, 18.2. Calc. for $C_3F_3H_5O_3S$: C, 20.2; H, 2.8; S, 18.0%. Found: C, 24.9; H, 3.7; S, 16.1. Calc. for $C_4F_3H_7O_3S$: C, 25.0; H, 3.7; S, 16.7%. Found: C, 21.4; H, 2.6; S, 14.4. Calc. for $C_4ClF_3H_6O_3S$: C, 21.2; H, 2.7; S, 14.1%. Found: C; 29.3; H, 4.6; S, 15.1. Calc. for $C_5F_3H_9O_3S$: C, 29.1; H, 4.4; S, 15.5%. Found: C, 32.9; H, 5.2; S, 14.8. Calc. for $C_6F_3H_{11}O_3S$: C, 32.7; H, 5.0; S, 14.5%.

RESULTS AND DISCUSSION

Methyl/ethyl/2-chloroethyl/n-propyl/n-butyl-2,2,2-trifluoroethyl sulphites were prepared separately by the reaction of 2,2,2-trifluoroethanol with the appropriate alkyl chlorosulphite.[4] This

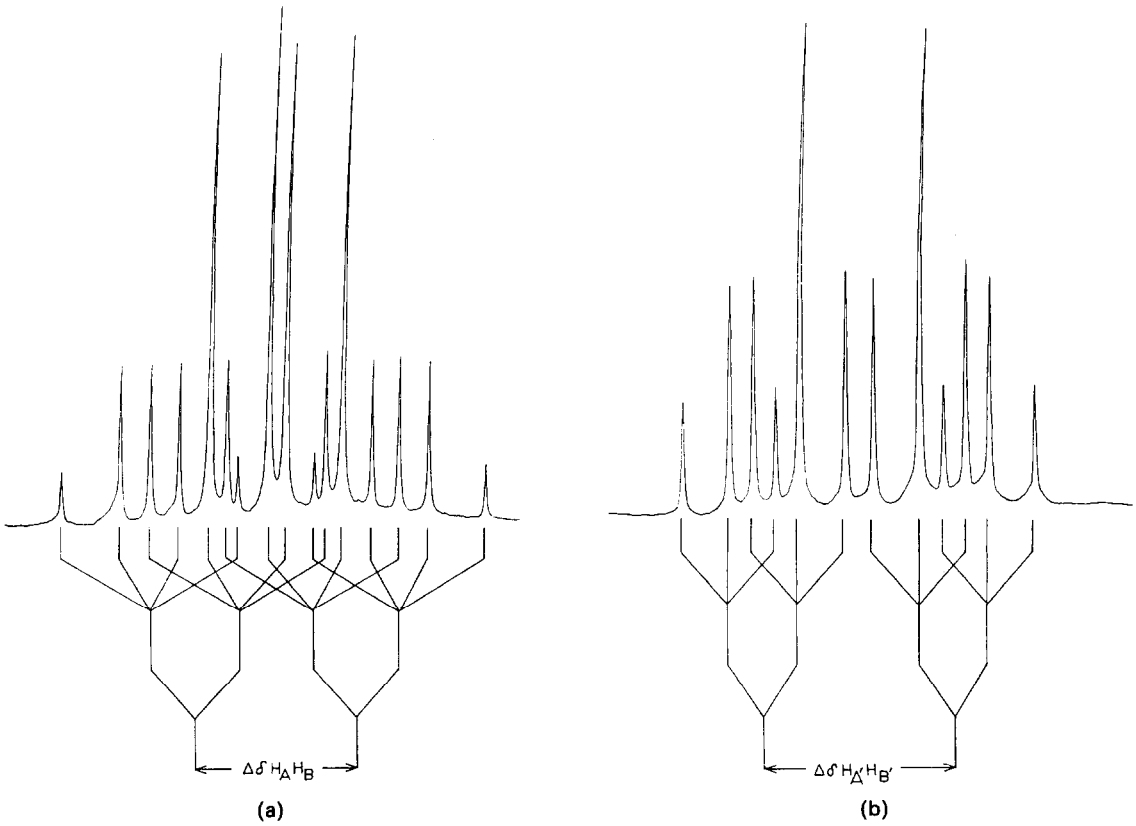

Fig. 1. (a) Splitting pattern for the α-methylene protons of 2,2,2-trifluoroethyl group in $C_3H_7OS(O)OCH_2CF_3$. (b) Splitting pattern for the α-methylene protons of n-propyl group in $C_3H_7OS(O)OCH_2CF_3$.

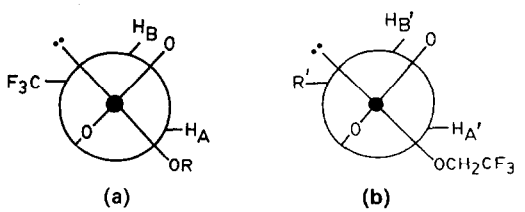

Fig. 2. (a and b) The central atom represents sulphur atom with the lines connecting the oxygen, the lone pair, alkoxy/2,2,2-trifluoroethoxy groups. The large circle represents the α-methylene carbon bonded with two hydrogens, the oxygen and the CF_3/R′ groups.[20]

direct method gives higher yields (70–85%) of the products than the one in which "alcohol–amine"[16] adduct is used (30–40%). All these compounds are colourless, distillable liquids and contain only minor amounts (< 1%) of dialkyl sulphites as evidenced by GLC.

Spectral data

Infrared spectra of these sulphites give important absorptions at 1270–1260, 1215–1210, 1180–1160, 960–920 and 550–530 cm^{-1} assignable to $\nu_{as}CF_3$, $\nu S{=}O$, $\nu_{sy}CF_3$, $\nu SO(C)$ and δSO_2 modes, respectively.[13,17]

Mass spectra of these compounds show molecular ion peak M^+ in each case. The major fragments and their origin (Scheme 1) suggest that the titled sulphites fragment in the manner partially similar to both the symmetrical analogs.[13,18]

^1H NMR spectra of the compounds give the distinct quartets/triplets in the region 4.4–4.2 and 4.2–4.0 ppm (Fig. 1a,b). The spectral pattern can be rationalized on the basis of non-equivalence of α-methylene protons of CF_3CH_2O and $R'CH_2O$ groups (R′ = H, CH_3, C_2H_5 and C_3H_7), respectively.[12,19] The chemical environments of each set of protons may be diagrammatically represented as shown in Fig. 2a,b. The assignments of the chemical shift values are made in accordance with the reported trends[21,22] and are recorded in Table 1. The spectrum of 2-chloroethyl 2,2,2-trifluoroethyl sulphite could not be analysed unambiguously due to extensive overlapping of signals.

A perusal of Table 1 reveals that the chemical shift difference of each set of non-equi-

valent protons, i.e. $\Delta\delta H_AH_B/\Delta\delta H_A'H_B' = \delta(H_B-H_A)/\delta(H_B'-H_A')$ increases with increasing the size of R′ group. The variation of anisochronism with the bulk of R group in symmetrical sulphites, $(RCH_2O)_2SO$ is reported;[23] however, quantitative assessment of the steric effect of straight chain alkyl groups on the non-equivalent protons of both the α-methylene groups separately are being reported for the first time.

^{13}C and ^{19}F NMR chemical shifts along with the observed coupling constant data[13,24] (Table 2) are also consistent with the structure of these compounds.

(*Received* 23 *June* 1993; *accepted* 1 *July* 1993)

Abstract—The treatment of tetraphenylporphyrinatoiron(III)hexafluoroantimonate (**1**), $FeTPPSbF_6$, with peroxylauric acid, to form high-valent μ-oxo dimers of FeTPP, and *t*-butylhydroperoxide, leading to the isolation of μ-oxo bridged high-valence iron(IV) porphyrin and a *t*-butylperoxo substituted isoporphyrin cation, is described.

Cytochrome P-450 is a family of remarkable heme-containing proteins that perform a number of monooxygenation transformations on a great variety of substrates.[1–3] These include the insertion of an oxygen atom into an alkane C—H bond, hydroxylation of arenes, epoxidation of olefins and oxidation as well as dealkylation of heteroatoms.[3] It is now widely accepted that the nature of the active species responsible for the oxygenations by cytochrome P-450 is an oxo-ferryl porphyrin π-cation radical.[4] This is formally an oxoferryl intermediate, Fe(V)=O, two oxidation equivalents above the native ferric heme, similar to compound I species of horse-radish peroxidase whose structures have been established as Fe(IV)-oxo porphyrin π-cation radicals.[5] Extensive model studies of simple synthetic hemins with various oxygen atom transfer agents such as iodosylbenzene, peracids and hydroperoxides have not only accomplished the oxygen atom transfer reactions performed by cytochrome P-450, but also strongly support the above formalization of the active oxidant.[4,6–11]

We have described the generation of tetraphenylporphyrinatoiron(III)hexafluoroantimonate, (**1**), $FeTPPSbF_6$, along with some of its properties.[12] It was anticipated that such an iron(III) porphyrin system free of axial ligands might be reactive toward superoxide ion and peroxides and thus serve as a possible model for the

active sites of biological systems responsible for oxygen activation, such as cytochrome P-450, peroxidase[5,13] and catalase.[5,13] The reactions of **1** with superoxide ion has previously been described,[12] but in the present report the treatment of **1** with peroxylauric acid and *t*-butylhydroperoxide is described.

RESULTS AND DISCUSSION

When **1** was treated with an excess of peroxylauric acid in benzene at 0°C a black glistening solid, **2**, was isolated by centrifugation in 62% yield. The material was insoluble in hydrocarbon solvents, but dissolved readily in dichloromethane. Its electronic absorption spectrum in this solvent displayed a very broad Soret band at 396 nm with shoulders at 325 and 450 nm as demonstrated in Fig. 1. After dithionite reduction of **2** in pyridine the pyridine hemochrome, $FeTPP(pyr)_2$, spectrum[12] was observed confirming the presence of an iron porphyrin moiety in the compound. Thin-layer chromatography of **2** on alumina produced a μ-oxo dimer, FeTPP-O-FeTPP,[14] again suggesting the presence of an iron porphyrin. The infrared spectrum of the solid had absorption bands appropriate to the TPP skeleton, to SbF_6^- (655 and 290 cm^{-1})[15] and a very strong Fe–O stretch[14] at 860 cm^{-1}, all indicative of a possible oxidized form of a μ-oxo dimer, $[Fe(TPP\text{-}O\text{-}FeTPP]^{+n}(SbF_6^-)_n$. Treatment of μ-oxo dimer, $(FeTPP)_2O$, with silverhexafluoroantimonate in dichloromethane solution at room temperature resulted in a solution showing an identical electronic spectrum to that of **2**, providing further evidence for the presence of an oxidized μ-oxo dimer adduct and demonstrating that silver ions are capable of oxidizing $(FeTPP)_2O$ to **2**.

Electrochemical oxidation of the μ-oxo dimer, $(FeTPP)_2O$, is known to proceed in two one-electron steps.[16] The first oxidation step was assigned as the production of a mixed-valence oxidation state μ-oxo dimer of iron(III) and iron(IV), which could be isolated as a perchlorate salt, [Fe(III)TPP-O-

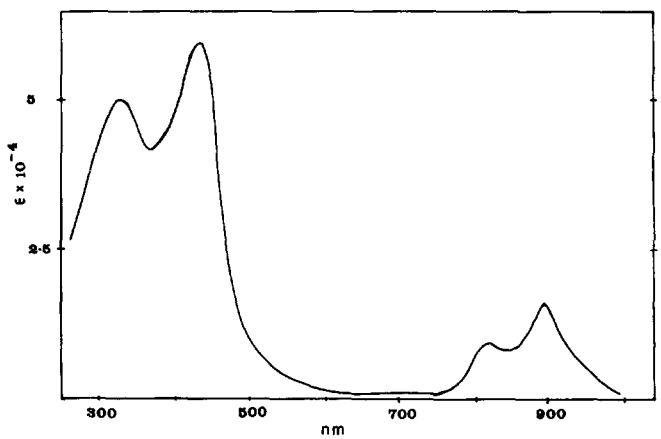

Fig. 2. The electronic spectrum of **4** in dichloromethane.

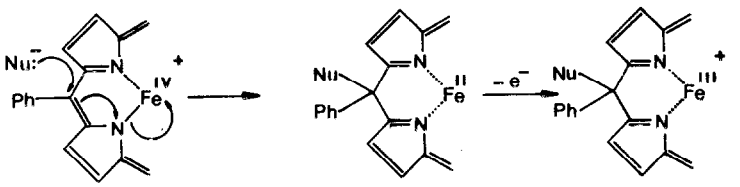
Fe(IV)TPP]$^{+}ClO_4^{-}$, and the second was assigned as the bis-oxidized dimer of two iron(IV) centres, which has also, more recently,[17] been isolated as a perchlorate salt, [Fe(IV)TPP-O-Fe(IV)TPP]$^{+2}$ $(ClO_4^{-})_2$. Strong evidence supporting Fe(III) porphyrin π-cation radical assignments for these high-valent dimers has been put forward.[18] The electronic spectrum of **2** (Fig. 1) was found to be identical to that of the bis-oxidized μ-oxo bridged dimers described above. Polarographic studies of **2** and the μ-oxo dimer with tetra(n-hexyl) ammonium hexafluoroantimonate as supporting electrolyte further strengthened the assignment of **2** as the bis-oxidized μ-oxo dimer, [Fe(IV)TPP-O-Fe(IV)TPP]$^{+2}(SbF_6^{-})_2$. Two reversible oxidation waves at 0.70 and 1.00 V were observed of equal height and a wave double that height at 1.54 V for the μ-oxo dimer. The first two waves were ascribed to the formation of [Fe(III)TPP-O-Fe(IV)TPP]$^{+}$ and [Fe(IV)TPP-O-Fe(IV)TPP]$^{+2}$, respectively, but the two-electron wave must either correspond to the iron centres going to iron(V) simultaneously, or more accurately, both porphyrin rings being oxidized to radical π-cations simultaneously with both metals remaining at the Fe(IV) oxidation state. When **2** was subjected to polarography under the same conditions, reduction waves were observed at 0.65–0.70 V and 0.96–1.10 V, and an oxidation wave at 1.55 V. These results are therefore consistent with the proposed structure, and agree with the similar polarographic studies of Felton *et al.*[16] and Phillippi and Goff.[17,18]

The compound was stable for 24 h in solution under anhydrous aprotic conditions. Attempted crystallizations of **2** failed due to the reduction of the compound to the mixed-valence dimer or the μ-oxo dimer. When the peroxylauric acid oxidation was carried out in refluxing benzene a different compound, **3**, was obtained as a brown solid in reduced yields. This compound, readily soluble in dichloromethane, was substantially more stable both in solution and in the solid state than **2**. Electron absorption spectroscopy in dichloromethane showed the presence of a Soret band at 408 nm, a band at 330 nm and a very broad band centred around 500 nm as shown in Fig. 1. This spectrum was identical to that of the mixed-valence μ-oxo dimer,[16-18] [Fe(III)TPP-O-Fe(IV)TPP]$^{+}ClO_4^{-}$. That **3** was indeed the mixed-valence oxidation state dimer, [Fe(III)TPP-O-Fe(IV)TPP]$^{+}SbF_6^{-}$, was further supported by polarographic studies of the compound which were consistent with those cited above for [Fe(III)TPP-O-Fe(IV)TPP]$^{+}ClO_4^{-}$: a reduction wave at 0.70 V, an oxidation wave of a similar height at 1.00 V and another oxidation wave twice that height as expected at 1.55 V. Field desorption mass spectrometry provided the required molecular ion of **3** at m/z 1587 and another more stable one at 1352 amu corresponding to [Fe(III)TPP-O-Fe(IV)TPP]$^{+}$. Infrared spectroscopy showed the characteristic Fe–O stretching frequency at 865 cm^{-1} as well as bands characteristic of SbF_6^{-}.

Further support for the mixed-valence formulation came from the reaction of equimolar amounts of $(FeTPP)_2O$ with **2** in dichloromethane at room temperature. The product displayed an electronic spectrum identical to that of **3**. When the peroxylauric acid oxidation was carried out at room temperature, a mixture of **2** and **3** was afforded as detected by optical absorption spectroscopy and polarographic studies. By varying the temperature of the reaction it became possible to control the preparation of either of these compounds in pure state. All this, together with the fact that attempted recrystallizations of **2** normally failed and a product having an optical spectrum identical to **3** resulted, highlights the close relationship between the μ-oxo dimer, **2** and **3**.

Excess *t*-butylhydroperoxide reacted with **1** in benzene at 0°C to provide a pale-brown precipitate, **4**, which was isolated by centrifugation in almost quantitative yield. Its optical spectrum in dry dichloromethane as shown in Fig. 2 displayed a Soret band at 415 nm, another maximum at 320 nm and the near-infrared region had absorption bands at 898 and 815 nm, characteristic of isoporphyrin cations.[19] Attempted crystallization of **4** in various solvents was unsuccessful and resulted in conversion variously to the postulated adducts [Fe(IV)TPP-O-Fe(IV)TPP]$^{+2}(SbF_6^{-})_2$ and [Fe(IV)TPP-O-Fe(III)TPP]$^{+}SbF_6^{-}$, the μ-oxo dimer, $(FeTPP)_2O$, and an FeTPPX-type adduct. Spectroscopic studies showed that both [Fe(IV)TPP-O-Fe(IV)TPP]$^{+2}(SbF_6^{-})_2$ and [Fe(IV)TPP-O-Fe(III)TPP]$^{+}SbF_6^{-}$, but also $(FeTPP)_2O$, could be converted to **4** upon addition of *t*-butylhydroperoxide in dichloromethane at room temperature, indicating a higher oxidation state and further highlighting the structural resemblance between the μ-oxo dimer, **2** and **3**, and also **4**. Reduction of **4** by dithionate/pyridine resulted in the pyridine hemochrome[12] and reduction by aqueous iodide solution resulted in the formation of $(FeTPP)_2O$. Atomic absorption spectroscopic results showed an Fe : Sb ratio of 1 : 1 within experimental error.

On the basis of this evidence the structure shown in Fig. 3 is proposed for **4**. This is an iron(III) *t*-butylperoxide substituted isoporphyrin cation bridged to an iron(IV) porphyrin unit by a μ-oxo bridge. This structure was further supported by gas



Scheme 1.

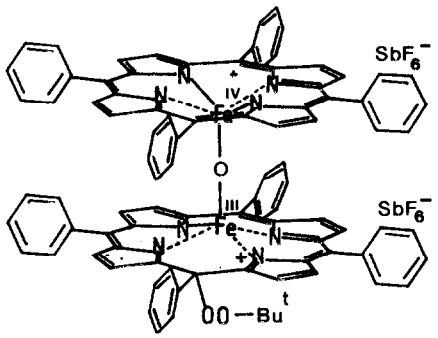


Fig. 3. The proposed structure for **4**.

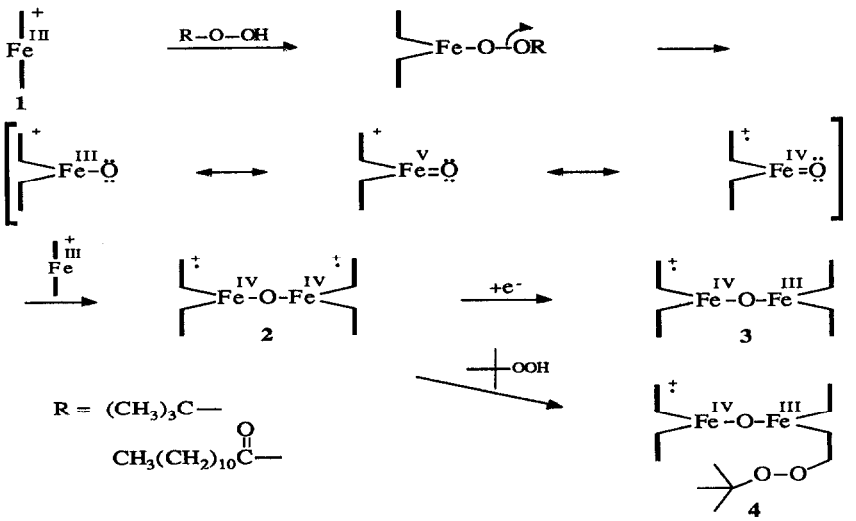
chromatography studies indicating that **4**, when reduced with ethane thiol produces *t*-butyl alcohol. Cyclic voltammetry conducted on **4** in dichloromethane with tetra(n-hexyl)ammonium hexafluoroantimonate as supporting electrolyte showed the compound to behave quite differently electrochemically from the family based on $(FeTPP)_2O$. Two reduction waves of equal height were observed with $E_{1/2}$-values of -0.05 and 0.26 V, together with an oxidation wave at 1.54 V. It is thus a much less powerful oxidant in free-energy terms than $[Fe(IV)TPP\text{-}O\text{-}Fe(IV)TPP]^{+2}$, though more powerful in terms of oxidizing equivalents for the conversion of iodide to iodine in aqueous solution.

An isoporphyrin of the type reported here has not previously been prepared. The mechanism for its formation is coherently believed to involve the formation of the bis-oxidized μ-oxo adduct, $[Fe(IV)TPP\text{-}O\text{-}Fe(IV)TPP]^{+2}(SbF_6^-)_2$, formed in a similar manner to that of the peroxylauric acid case. *t*-Butylhydroperoxide, a substantially better nucleophile than peroxylauric acid, attacks at the *meso*-position of one of the $Fe(IV)TPP^+$-units of the dimer. The excess *t*-butylhydroperoxide oxidizes the resulting iron(II) species to iron(III) as demonstrated in Scheme 1.

Finally, Scheme 2 illustrates the proposed mechanism for the formation of **2**, **3** and **4**. Although this mechanism has not been well established it has features similar to the mechanism proposed by LaMar and co-workers[20,21] for the irreversible μ-oxo dimer formation of ferrous porphyrins in the presence of dioxygen. It involves a heterolytic cleavage of a peroxo bond in the intermediate peroxy iron(III) species, resulting in the formation of an electron deficient oxygen species which is formally equivalent to an iron(V) ferryl intermediate,[22-24] Fe(V)=O. This intermediate would presumably be stabilized by the π-cation radical assignment orig-



Scheme 2.

inally postulated by Dolphin *et al.*[25-27] but should be a far more potent oxidizing agent than the corresponding Fe(IV)=O intermediate proposed by LaMar *et al.* (*vide supra*). It also lacks a stabilizing electron-donating axial ligand. Consequently, its concentration would never be expected to reach any detectable levels and it reacts instantaneously with a second free cation, $FeTPP^+$, to form the bis-oxidized μ-oxo dimer.

EXPERIMENTAL

Electronic absorption spectra were measured on a Perkin–Elmer 555 UV–VIS spectrophotometer. When included, $\log\varepsilon$ follows each λ_{max} in parentheses. Infrared spectra were recorded on either a Perkin–Elmer 521 Grating IR spectrophotometer or a Perkin–Elmer 297 IR spectrophotometer. Field desorption mass spectra were recorded on a VG-16F instrument. All solvents were Analytical Reagent grade or redistilled commercial grade and were always dried. Measurements at stationary and rotating platinum electrodes were carried out in dry dichloromethane using 0.01 M $(n\text{-hexyl})_4N^+SbF_6^-$ as supporting electrolyte and a Princeton Applied Research 174 polarographic analyser. Gas chromatography was performed on a Varian instrument under the following conditions: injector 250°C, detector 275°C; H_2 5 lbs, He 40 lbs, air 40 lbs; column SE 30 $12' \times 1/8''$, 40°C. Iodometric titrations were performed using standard procedures with $KI/Na_2S_2O_3$ and starch as an indicator. Peroxylauric acid was prepared according to the procedure of Swern.[28] *t*-Butylhydroperoxide (90%) (Aldrich) was dried by the procedure of Sharpless *et al.*[29]

The preparation of the proposed μ-oxo-bis(tetraphenylporphyrinatoiron(IV) bishexafluorantimonate, $[Fe(IV)TPP\text{-}O\text{-}Fe(IV)TPP]^{+2}(SbF_6^-)_2$, **2**

To a stirred ice-cooled dry benzene solution (35 cm^3) of peroxylauric acid (0.2 g, 0.93 mmol) under nitrogen was added $FeTPPSbF_6$, **1**, (0.05 g, 0.55 mmol) dissolved in minimum amount of dry dichloromethane (1–2 cm^3). No effervescence was noted and after stirring for 15 min at 0°C a solid precipitated from solution. Centrifugation afforded a black glistening solid, which was washed twice with dry benzene and twice with pentane. The product was dried *in vacuo* for 3 h to yield an initial product (22 mg). A second crop was obtained by adding pentane to the centrifugate (8 mg; total 31 mg, 62%). [Found: C, 54.8; H, 3.4; N, 5.7; F, 11.7; Fe, 5.8. Calc. for $C_{88}H_{56}N_8OF_{12}Fe_2Sb_2$: C, 57.9; H, 3.1; N, 6.1; F, 12.5; Fe, 6.1%. λ_{max} (CH_2Cl_2) 325 (sh, 4.63), 396 (4.90), 450 (sh, 4.53) nm. ν_{max} (KBr) 3040 (s, C—H), 1595 (s, C=N), 860 (s, Fe—O—Fe), 655 (s, SbF_6^-), 290 (s, SbF_6^-) cm^{-1}. Polarographic results: reduction waves recorded at 0.65–0.70 and 0.96–1.10 V and an oxidation wave at 1.54 V.]

The preparation of the proposed μ-oxo-[5,10,15,20-tetraphenylporphyrinatoiron(III), 5,10,15,20-tetraphenylporphyrinatoiron(IV)] hexafluoroantimonate, $[Fe(III)TPP\text{-}O\text{-}Fe(IV)TPP]^+SbF_6^-$, **3**

The same procedure as for **2** was followed, but after the addition of $FeTPPSbF_6$ at 0°C the stirred solution was transferred to a steam-bath and stirred for 30 min at 65°C. A brown solid precipitated from solution, which after cooling was centrifuged, washed with cold benzene and pentane and finally dried *in vacuo* for 3 h. **3** was obtained as a brown solid (20 mg, 46%). [λ_{max} (CH_2Cl_2) 330 (4.78), 408 (5.25), 500 (sh, 4.24) nm. ν_{max} (KBr) 3040 (s, C—H), 1595 (s, C=N), 865 (s, Fe—O—Fe), 660 (s, SbF_6^-), 290 (s, SbF_6^-) cm^{-1}. *m/z* (FD) 1587 (M^+), 1352 (M—SbF_6^-). Polarographic results: reduction waves recorded at 0.70 V and oxidation waves at 1.00 and 1.55 V.]

The preparation of the proposed μ-oxo-[5-t-butylperoxide-5,10,15,20-tetraphenylisoporphyrinatoiron (III), 5,10,15,20-tetraphenylporphyrinatoiron(IV)], bishexafluorantimonate, **4**

To an ice-cooled stirred solution of dry benzene (500 cm^3) and dry 90% *t*-butylhydroperoxide [13.3 g (12.0 cm^3), 133 mmol] was added $FeTPPSbF_6$ (1.61 g, 1.78 mmol) dissolved in a minimum amount of dry dichloromethane (40 cm^3). Effervescence was noted and the reaction mixture was stirred for approximately 5 min. A precipitate appeared and the reaction mixture was filtered. The residue was washed with benzene and then with pentane, air dried momentarily and finally dried *in vacuo* for several hours affording **4** as a brown solid (1.64 g, 96%). [λ_{max}(CH_2Cl_2) 320 (4.69), 415 (4.78), 815 (3.89), 898 (4.07) nm. λ_{max}(benzene) 320, 385, 420 nm. ν_{max}(nujol) 860 (m, Fe—O—Fe), 655 (m, SbF_6^-), 290 (m, SbF_6^-) cm^{-1}. Atomic absorption: Fe:Sb ratio of 1:1.12, equivalent to 1:1 within experimental error. Polarographic results: reduction waves recorded at −0.05 and 0.25 V and an oxidation wave at 1.54 V.]

Thiol reduction of **4**

The isoporphyrin **4** (20 mg) was dissolved in chloroform (2 cm^3) and ethanethiol was added (20

drops). The mixture was stirred at room temperature for 20 min at which time the solution was injected into the gas chromatograph. *t*-Butyl alcohol was detected in accordance with the proposed structure.

Abstract—A new μ_3-O triiron(III) complex $[Fe_3O(OBZ)_6(CH_3OH)_3](NO_3)(CH_3OH)_2$ (HOBZ = benzoic acid) has been synthesized, its structure has been determined and variable temperature magnetic susceptibility has been measured. In the cation of the complex, three iron atoms form an equilateral triangle with μ_3-O in the centre. An intramolecular antiferromagnetic exchange interaction occurs with $J = -27.06$ cm^{-1}, and a weaker intermolecular antiferromagnetic exchange interaction occurs with $zJ' = -2.59$ cm^{-1}.

Trinuclear basic carboxylate complexes $[M_3^{III}O(RCO_2)_6L_3]^+$ (M = Fe, Mn, Cr) have been used as the materials for synthesis of high nuclearity spin clusters, such as Fe_6, $Fe_{16}M$ (M = Co, Mn), Mn_4, Mn_{12},[1–4] and they also occupy a special place in magnetochemistry.[5] So the studies of their structures, bonding properties and magnetism are a current topic of research. To date the structures of $[Fe_3O(RCO_2)_6L_3]^+$ for R = CH_3, L = H_2O;[6] R = $C(CH_3)_3$, L = CH_3OH;[7] R = $CH_2(NH_2)$, L = H_2O;[8] and $[Fe_3O(MeCO_2)_3(EtCO_2)_3(H_2O)_3]^+$,[9] have been reported, but where R = phenyl have not been reported. In this paper, we report the structure and magnetic properties of the title compound for which R = Ph, L = CH_3OH.

EXPERIMENTAL

Preparation

Basic iron(III) benzoate (which was synthesized by literature procedures[10]) (0.5 g, *ca* 0.5 mmol) was mixed with equiv. nitrate (such as $Ni(NO_3)_2 \cdot 6H_2O$) in 40 cm^3 methanol and refluxed for 20 min, cooled to room temperature and filtered. The filtrate slowly evaporated in the air to give brown–red crystals. The crystals exposed in air lost solvent molecules. Found: C, 49.3; H, 3.6; N, 1.1; Fe, 14.6. Calc. for $C_{46}H_{46}NO_{20}Fe_3$: C, 50.6; H, 3.9; N, 1.3; Fe, 15.3.%.

X-ray crystallography

Cell dimensions were determined on an R3M/E four-circle diffractometer and reflection intensities measured in the ω–2θ scan mode with graphite monochromated Mo-K_α radiation ($\lambda = 0.71069$ Å). The data were not corrected for absorption. The atomic coordinates of the metal atoms were first obtained by analysing the Patterson function. The other non-hydrogen atom coordinates were gradually obtained by Fourier synthesis. After all the coordinates of the non-hydrogen atoms were refined, the hydrogen atom coordinates were obtained from difference Fourier synthesis and analysis of geometry. Finally, the coordinates, anisotropic thermal parameters for non-hydrogen atoms and

$^b R_w = \Sigma[|F_o - F_c| \cdot w^{1/2}]/\Sigma[|F_o| \cdot w^{1/2}]$.
$w = 1/(\sigma^2(F) + |g| \cdot F^2)$.

the isotropic thermal parameters for hydrogen atoms were refined by block diagonal matric least-squares methods. Crystal data for the title complex are given in Table 1.

Mössbauer spectroscopy and magnetic susceptibility measurement

The Mössbauer spectrum of a polycrystalline sample was obtained on a S-600 type spectrometer at room temperature, the quadrupole splitting ΔE_Q and the isomer shift δ were measured relative to iron.

Solid state magnetism measurement of powdered sample was carried out with a CF-1 type extracting sample magnetometer at 50 KOe in the temperature range 1.8–300 K. The diamagnetism has been corrected.

RESULTS AND DISCUSSION

Structure description

The structure of title complex consists of one cation $[Fe_3O(OBZ)_6(CH_3OH)_3]^+$, one NO_3^- anion and two methanol molecules. The structure of the complex is shown in Fig. 1. Selected bond lengths and angles are given in Tables 2 and 3, respectively.

In the cation, the distances of Fe(1)—Fe(2).

O(17)—O(19)	2.695	O(17)—O(20)	2.756

Fe(1)—Fe(3) and Fe(2)—Fe(3) are 3.274, 3.300 and 3.284 Å, respectively. Three iron atoms define an equilateral triangle with the μ_3-O atom in the centre; the μ_3-O atom is within the same plane (ΣFe—O—Fe′ = 359.9°), three methanol O atoms also are located on this plane. Two OBZ^- anions which bridge the same pair of iron atoms lie on each side of the 3Fe—μ_3-O plane, their angles with 3Fe—μ_3-O plane are not equal.

Each iron has an octahedral coordination. The values of $\angle\mu_3$-O—Fe—methanol O are close to 180°. The angles in the plane constructed from coordinated benzoate O atoms, such as $\angle$O(1)—Fe(1)—O(2), are close to 90°, but the values of $\angle\mu_3$-O—Fe—benzoate O are (in the range of 91.8–97.8) larger than 90°. The bond lengths of Fe—benzoate O(1.994–2.030 Å), Fe—μ_3-O(1.890–1.907 Å), Fe—methanol O(2.084–2.015 Å) are in the normal range.[11] The average bond length of Fe—μ_3-O is about 0.2 Å shorter than that of Fe—benzoate O, thus Fe atoms are positioned out from the plane constructed from coordinated benzoate O atoms and towards μ_3-O atom. The fact that three Fe atoms and μ_3-O atoms are coplanar and the distances of Fe—μ_3-O are shorter than Fe—benzoate O indicate that in $[Fe_3O(OBZ)_6(CH_3OH)_3]^+$, there is not only a σ bond, but also a delocalized π interaction around the three iron atoms and μ_3-O atom.

Table 4 shows the oxygen–oxygen distances in the complex. These distances vary from 2.656 Å to 3.000 Å, within the range of hydrogen bond lengths. There are no intermolecular hydrogen bonds.

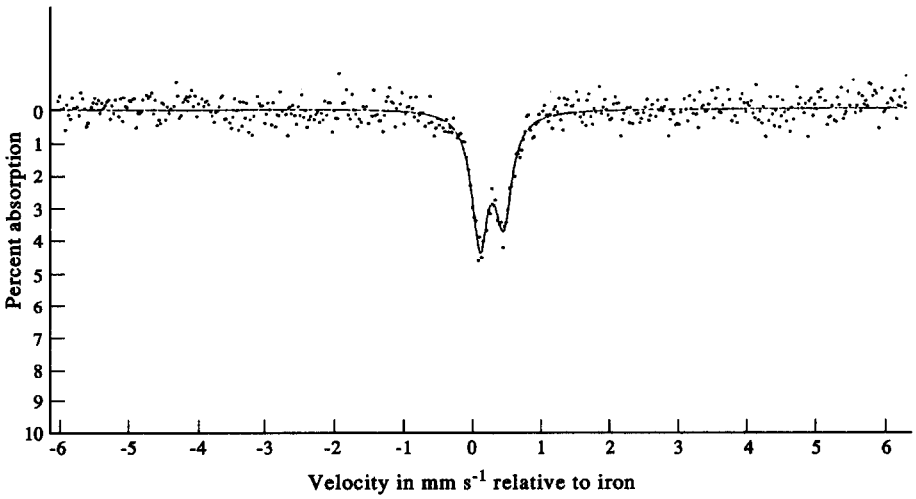

Fig. 2. Mössbauer spectrum of the complex.

Magnetic properties

The Mössbauer spectrum of title complex at room temperature is presented in Fig. 2. A least-squares fit (solid line) to the experiment points, assuming a Loentzian line shape, gives an isomer shift value $\delta = 0.31$ mm s^{-1}, within the range of 0.3–0.6 mm s^{-1} typically observed for high-spin iron(III) complexes.[12] The quadrupole splitting value $\Delta E_Q = 0.346$ mm s^{-1}, which is outside the range of 0.45–0.71 mm s^{-1} that are found for other basic iron carboxylates, shows the title complex is high symmetrical. The other feature of the spectrum which is the asymmetry in intensity that is also observed in other triiron complexes, may be explained by the Goldanskii Karayagin effect.[13,14]

The magnetic properties of $[M_3O(RCO_2)_6L_3]^+$ (R = H, CH_3) have been studied by many people,[14–16] though their structure can be described as consisting of a central oxygen atom surrounded by an equilateral triangle of metal atoms. However, their magnetic behaviour cannot be satisfactorily explained in terms of an intracluster isotropic exchange interaction, involving equivalent coupling constants. Other models such as the isosceles triangle and biquadratic model have been proposed. In the isosceles triangle model, isotropic exchange is also assumed, but one coupling constant is allowed to differ from the other two. This model provides good agreement with experimental data but is in conflict with the crystal structure of an equilateral triangle of metal atoms. The biquadratic exchange model only gives a good fit to the experimental data when it is allowed to be non-Hermitian, however the physical significance of biquadratic exchange is far from clear. The magnetic property of $[Fe_3O(OBZ)_6(H_2O)_3](OBZ)\cdot 6H_2O$ has also been studied, but their is no reasonable fitting of the data.[15] In this paper, we consider intracluster interaction with the isotropic exchange Hamiltonian which involves equivalent coupling constant J[17] [eq. (1)],

$$H = -2J(S_2S_2+S_2S_3+S_1S_3). \tag{1}$$

Then the paramagnetic susceptibility per mole χ_M can be expressed as eq. (2):

$$\chi_M = \frac{Ng^2\beta^2A}{4kTB}, \tag{2}$$

where $A = 1+20\exp(3x)+105\exp(8x)+210\exp(15x)+330\exp(24x)+429\exp(35x)+455\exp(48p)+340\exp(63x)$

$B = 1+4\exp(3x)+9\exp(8x)+10\exp(15x)+10\exp(24x)+9\exp(35x)+7\exp(48x)+4\exp(63x)$

$\chi = J/kT.$

In addition, we also consider intercluster interation with molecular field model[18] which involves intercluster coupling constant zJ' [eq. (3)],

$$\chi' = \frac{\chi_M}{1-(2zJ'/Ng^2\beta^2)\chi_M}. \tag{3}$$

The above mentioned model gives an excellent fit (see Fig. 3) with $g = 2.00$ (not varied in fitting), $J = -27.06$ cm^{-1}, $zJ' = -2.59$ cm^{-1} and $R = 5.9\times10^{-3}$ ($R = \Sigma(\chi_c-\chi_c)^2/\Sigma\chi_c^2$). This J value is consistent with the values obtained from other triiron complexes. These results indicate that the

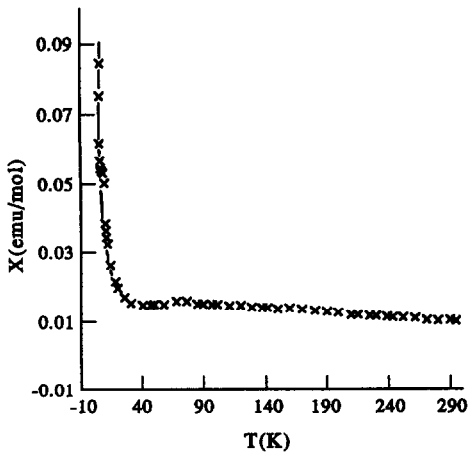

Fig. 3. The fitting of magnetic susceptibility.

J value for $[Fe_3O(RCO_2)_6]^+$ have no apparent relationship with the substituted R group, and also confirm that in these complexes the path of exchange interaction is through μ_3—O.

The intercluster interaction has been considered for complex $[FeO(CH_3CO_2)_6(H_2O)_3](ClO_4)\cdot 2H_2O$, and the resulting slightly positive value of zJ' has been explained by weak exchange occurring through the hydrogen bond network, but there is no structural evidence.[17] In this study, we found slightly negative value of zJ', but the crystal structural data shows no hydrogen bond linkage between clusters. This means that the pathway for intermolecular spin exchange interaction may be not through hydrogen bond network, the interaction between molecules may have another mechanism, such as phase transition in low temperature. However, intensive study on the magnetic properties of these complexes need more structural data, especially at low temperatures.

(*Received* 16 *June* 1993; *accepted* 28 *June* 1993)

Abstract—Iron(III) complexes of hexadentate Schiff base $N_2S_2O_2$ donor ligands, 1,3-di(*o*-salicylaldiminophenylthio)propane (H_2DSALPTP) and 1,2-di(*o*-salicylaldiminophenylthio)xylene (H_2DSALPTX) have been synthesized and characterized. The ligands gave dark green iron(III) complexes [Fe(DSALPTP)]$FeCl_4$ and [Fe(DSALPTX)]$FeCl_4$ when reacted with anhydrous $FeCl_3$. The Mössbauer data of these two complexes suggest the presence of two iron sites, one of which is octahedral and the other tetrahedral. The octahedral site is the complex cationic species and the tetrahedral site is the anion $FeCl_4^-$. On the other hand, $Fe(ClO_4)_3 \cdot 6H_2O$ reacted with the ligands to give the complexes [Fe(DSALPTP)]ClO_4 and [Fe(DSALPTX)]ClO_4. The iron(III) centre in the complex cationic species of the first two complexes are low-spin and for the latter two complexes high-spin. Though a colour change from yellow to green occurred when the ligands reacted with $Fe(NO_3)_3 \cdot 9H_2O$, no compound could be isolated in the solid state from the solution.

Hexadentate ligands, capable of octahedral coordination to a transition metal ion, may encapsulate it in a 1:1 complex whose exterior exhibits the properties of an organic material. Such species generated interest particularly in the production of the metal containing pharmaceuticals and the formation of selective metal ion extractants.[1]

The hexadentate ligand, 1,2-di(*o*-salicylaldiminophenylthio)ethane (abbreviated as H_2DSALPTE), a condensation product of 1,2-di(*o*-aminophenylthio)ethane and salicylaldehyde was first reported by Dwyer and his co-workers,[2] later by Cannon *et al.*[3] Rothin *et al.*[1] and by us.[4] Recently, complexes of iron(II) and iron(III) with certain hexadentate ligands have aroused much interest because of their anomalous magnetic behaviour. The equilibria between high and low spin states in the solid state and in solution have been investigated by variable temperature magnetic moment and Mössbauer spectroscopic measurements.[5–8] Though certain complexes of 1,3-di(*o*-aminophenylthio)propane were studied,[9] and nickel(II) complexes of 1,2-di(*o*-aminophenylthio)xylene prepared through the reaction of the *o*-aminothiophenolato complex with α,α′-dibromo-*o*-xylene,[10] no work was carried out with the Schiff base ligands derived from them through condensation with salicylaldehyde. As a part of our studies with N,S and N,S,O donor ligands and their metal complexes,[4,11–14] we have synthesized the hexadentate ligands (Fig. 1) 1,3-di(*o*-salicylaldiminophenylthio)propane (abbreviated as H_2DSALPTP) and 1,2-di(*o*-salicylaldiminophenylthio)xylene (abbreviated as H_2DSALPTX) and characterized their iron(III) complexes.

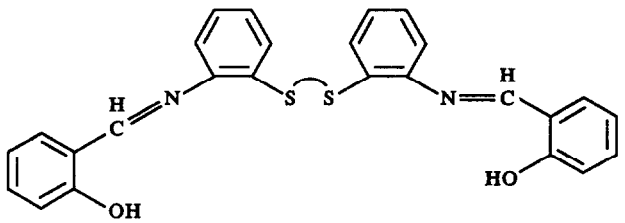

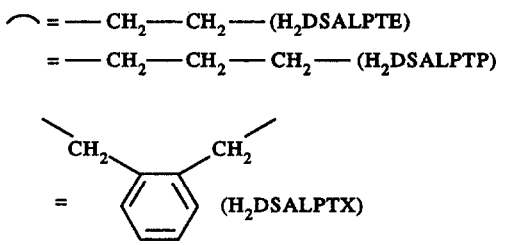

Fig. 1. Structure of the ligands.

EXPERIMENTAL

Synthetic procedures

1,3-*di*(o-*aminophenylthio*)*propane*. This ligand was prepared by a method published earlier.[3]

1,2-*di*(o-*aminophenylthio*)*xylene*. The same preparative procedure as above was adopted, except that α,α′-dibromo-*o*-xylene was used as the difunctional alkylating agent.

1,3-*di*(o-*salicylaldiminophenylthio*)*propane* (*H_2-DSALPTP*). The ligand was prepared by adding an alcoholic solution of 1,3-di(*o*-aminophenylthio)propane (one molecular proportion) to an alcoholic solution of salicylaldehyde (two molecular proportions) and refluxing the mixture for 1/2 h. On cooling the mixture after reflux, yellow crystals separated out. The product was filtered and recrystallized from $CHCl_3$-Pet.ether. (yield 90%, m.p. 70°C)).

1,2-*di*(o-*salicylaldiminophenylthio*)*xylene* (*H_2-DSALPTX*). The ligand was prepared following the same procedure as the previous one, except that 1,2-di(*o*-aminophenylthio)xylene was condensed with salicylaldehyde. Yellow crystals were obtained after recrystallization (yield 90%, m.p. 135°C).

[Fe(*DSALPTP*)][$FeCl_4$] (**1**). A solution of anhydrous $FeCl_3$ (0.162 g, 1 mmol) in dry methanol was added to a stirred solution of H_2DSALPTP (0.498 g, 1 mmol) in chloroform. After the addition, the stirring was further continued for 10 h. Green crystals separated out on adding petroleum ether to the reaction-mixture. The product was filtered and recrystallized from methanol (yield 65%).

[Fe(*DSALPTP*)]ClO_4 (**2**). This was obtained as green crystals by applying the same procedure as above, excepting that $Fe(ClO_4)_3 \cdot 6H_2O$ (0.46 g, 1 mmol) was taken as the starting metal salt (yield 60%).

[Fe(*DSALPTX*)][$FeCl_4$] (**3**). To an ethanolic suspension of H_2DSALPTX (0.56 g, 1 mmol), an ethanolic solution of anhydrous $FeCl_3$ (0.162 g, 1 mmol) was added with stirring. The mixture was further stirred for 8 h, when a green precipitate formed. This was filtered, washed with ether and recrystallized from methanol (yield 70%).

[Fe(*DSALPTX*)]ClO_4 (**4**). This complex was prepared by the similar method as the previous one with $Fe(ClO_4)_3 \cdot 6H_2O$ (0.46 g, 1 mmol) as the starting metal salt. It formed green crystals on recrystallization from methanol. (Yield 80%).

Physical measurements. The analyses of C, H and N of the compounds were carried out in a Perkin–Elmer Model 240C elemental analyser. Elemental analyses of iron were done by conventional method after decomposing the compounds with concentrated mineral acids. Infrared spectra (4000–200 cm^{-1}) in KBr discs were recorded with a Perkin–Elmer 783 spectrophotometer. Electronic spectra were recorded in a Hitachi 330 spectrophotometer. ^{1}H NMR spectra were recorded using a Varian XL-200 spectrometer with tetramethylsilane as the internal standard. The magnetic susceptibility measurements at room temperature were made in a PAR 155 vibrating-sample magnetometer. Mössbauer spectra were recorded in a 2 × 256 channel multiscalar confined to constant acceleration drive system. The source used was 10 mci ^{57}Co in Rh-matrix. A least squares fit programme[15] (LGFIT2) has been used to fit the experimental

data. The data were calculated relative to metallic iron. All the chemicals and solvents used were of A.R. or G.R. grade.

RESULTS AND DISCUSSION

The iron(III) salts react smoothly with the ligands to form the complexes [Fe(DSALPTP)][$FeCl_4$] (**1**), [Fe(DSALPTP)]ClO_4 (**2**), [Fe(DSALPTX)][$FeCl_4$] (**3**) and [Fe(DSALPTX)]ClO_4 (**4**). The ligands function as dibasic hexadentate ones, losing two protons from the two phenolic groups present in them. The anions of the starting salts have a marked influence on the composition of the complexes. Complexes are formed with anhydrous $FeCl_3$ or $Fe(ClO_4)_3 \cdot 6H_2O$, but no stable complex could be isolated with $Fe(NO_3)_3 \cdot 9H_2O$ as the starting metal salt, though there is a distinct colour change from yellow to green during the course of the reaction. Examples where $Fe(NO_3)_3$ does not give isolable products with hexadentate ligands have also been reported earlier.[1] The presence of comparatively larger sulphur atom in the ligand structure places limitations on their ability to fully coordinate to a single metal ion.[1,16] The complexes isolated in the present study are unstable in solution and slowly change colour from deep green to pale yellow after several hours. Elemental analyses for the complexes are given in Table 1.

The ^1H NMR spectrum of H_2DSALPTP shows a singlet at δ 8.6 ppm (2H) attributed to the phenolic protons. The signals for the aromatic and HC=N protons appear as a multiplet at δ 6.9–7.5 ppm (18H), —S—CH_2— protons as a triplet at δ 3.06 ppm (4H) and —CH_2— protons as a quintet at δ 2.05 ppm (2H). For H_2DSALPTX, the signal for the phenolic protons appear at δ 8.46 ppm (2H), aromatic and HC=N protons as a multiplet at δ 6.85–7.4 ppm (22H) and —S—CH_2 protons as a singlet at δ 4.22 ppm (4H).

The IR spectra of the free ligands contained bands at 1610–1600 cm^{-1} which may be assigned to the C=N stretching frequency. A broad band at 3500 cm^{-1} for H_2DSALPTP and 3440 cm^{-1} for H_2DSALPTX may be attributed to ν(OH).[17] The ν(C—O) (aromatic carbon and phenolic oxygen) is observed at 1350 and 1365 cm^{-1} for H_2DSALPTP and H_2DSALPTX, respectively. The ν(—S—CH_2) modes for the free ligands appear at 700–640 cm^{-1}. The ν(C=N) modes in the ligands are lowered by 5–15 cm^{-1} in the complexes which indicates the coordination of the azomethine nitrogen atom to the metal centre.[17] The ν(C—O) modes are shifted by 20–30 cm^{-1} in the higher region in the complexes suggesting thereby Fe—O linkage. Moreover, —S—CH_2— frequencies of the free ligands are lowered by 10–15 cm^{-1} upon complexation suggesting that the thioether moieties take part in coordination. Fe—S linkage in the complexes is substantiated by the appearance of bands below 400 cm^{-1} which are absent in the ligands (generally ν(M—S) appears[17–19] between 350–250 cm^{-1}).

Appearance of strong broad band centred at 1100 cm^{-1} (ν_3), a weak one at 950 cm^{-1} (ν_1) and a sharp one at 625 cm^{-1} (ν_4) for both complexes (**2**) and (**4**) indicate the presence of ionic perchlorates.[19–22] Intense band found at 390 cm^{-1} for both (**1**) and (**3**) is attributed to $\nu_3(FeCl_4)$.[17] However, a very slight shoulder is observed at 375 cm^{-1} for both of these bands, which may be due to steric factors reducing the symmetry from T_d.

Electronic spectral data for the complexes are set out in Table 2. For complexes (**3**) and (**4**), there is no significant difference between band energies, indicating that the electronic transitions of the cations dominate the spectra. A band at 16,949 cm^{-1} ($\varepsilon = 861$) is assigned to $^6A_{1g} \rightarrow {}^4T_{2g}(G)$ transition for octahedral, high-spin iron(III) centre present in complex (**4**). Complex (**3**), shows this band at 15,723 cm^{-1} ($\varepsilon = 2243$). Probably, the band due to cationic species is overlapped with the spin-forbidden transition expected[23] for $[FeCl_4]^-$ between 16,000 and

[a] Found (Calcd.) %.

13,700 cm^{-1}. The cationic part of (**1**) and (**2**) are low-spin. Unfortunately, the electronic spectra of low-spin iron(III) complexes have not been adequately characterized.[24] This is often due to strong charge transfer bands dominating the visible portion of the electronic spectrum. Bands between 15,000 cm^{-1} and 22,000 cm^{-1} in the spectrum are likely due to $d \rightarrow \pi^*$ metal-to-ligand bands[25] as well as sulphur to iron(III) transitions.[26,27] The bands below 15,000 cm^{-1} which can be assigned to *d–d* transitions of the spin-paired cations could not be detected. However, the spin-forbidden transition for $[FeCl_4]^-$ (high-spin anion) may be overlapped within this region in complex (**1**). Bands are observed at 16,393 cm^{-1} ($\varepsilon = 1754$) for complex (**2**) and 18,181 cm^{-1} ($\varepsilon = 352$) and 22,321 cm^{-1} ($\varepsilon = 1950$) in complex (**1**). The higher energy band in complex (**1**) which is not observed in (**2**) may arise because of $^6A_1 \rightarrow {}^4E(D)$ transition.[23(a)]

The electrical conductivity measurements (Table 2) are in conformity with 1:1 electrolytes. The slight lower values observed for (**1**) and (**3**) may probably arise because of ion-association of $[FeCl_4]^-$ anions with solvent molecules.[27] The magnetic moment values at room temperature of the complexes are given in Table 2. It is seen that complex (**2**) is low-spin with a value of 2.03 B.M. Therefore complex (**1**) which has the same complex cation part must involve a low-spin cationic part and a high-spin anionic $[FeCl_4]^-$ part. Thus the magnetic moment observed (4.21 B.M. per iron atom) may be rationalized as an average contribution from low-spin iron(III) site and a high-spin iron(III) site. Direct support for the proposed formulation is provided by the Mössbauer spectrum (Fig. 2) which shows clearly the presence of two iron sites. Complex (**4**) on the other hand has a high-spin iron(III) centre with a magnetic moment of 5.63 B.M. Therefore complex (**3**) has both the cationic part and the anionic part in high-spin states. The measured magnetic moment is 4.82 B.M. per iron atom; the low-value possibly indicating some interaction involving the anionic species. The Mössbauer spectrum (Fig. 3) clearly indicates two iron centres.

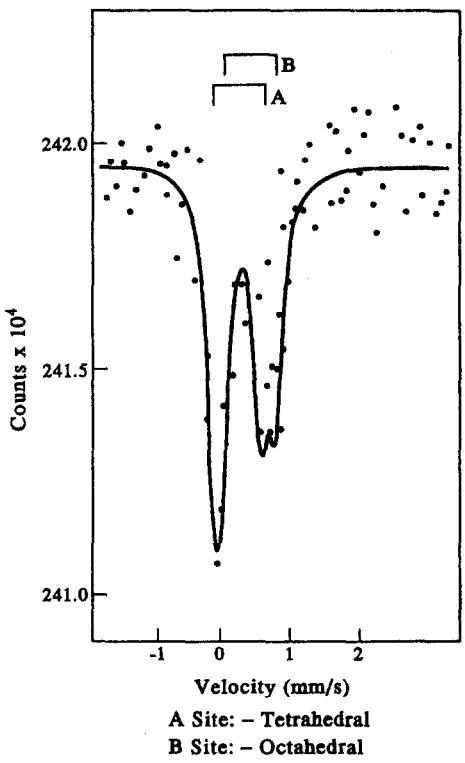

Fig. 2. Mössbauer spectrum of [Fe(DSALPTP)][$FeCl_4$] (**1**).

The Mössbauer spectrum of (**1**) shows a doublet with large bandwidths. Two doublets were fitted to the experimental data; a reasonably good fit is

obtained. The doublet with isomer shift of 0.25 mm s^{-1} and quadrupole-splitting value of 0.67 mm s^{-1} is ascribed to iron(III) centre in tetrahedral environment. The two values are very well in agreement with data available for $[FeCl_4]^-$ ions.[28] The higher q.s. value indicates that $[FeCl_4]^-$ anion is slightly distorted from perfect tetrahedral symmetry, an observation in conformity with the IR spectra. The other doublet has I.S. value of 0.37 mm s^{-1} and q.s. value of 0.71 mm s^{-1} and indicate that this iron(III) centre has an octahedral environment.[28,29] Moreover, assuming same Lamb–Mössbauer factors for both sites, the population ratio of iron(III) centres has been calculated from the corresponding resonance areas and are found to be Fe^{III}_{tet} : Fe^{III}_{oct} = 1 : 1, in fair agreement with the formulation suggested. No spectrum was obtained for (**2**), the reason for which is not clearly understood. For complex (**3**) again, a "two doublet" fit gives good results. The doublet with I.S. value of 0.12 mm s^{-1} and q.s. value of 0.38 mm s^{-1} is in agreement with tetrahedral iron(III) centres and therefore ascribed to $[FeCl_4]^-$. The other doublet with I.S. value of 0.46 mm s^{-1} and q.s. value of 0.91 mm s^{-1} is due to the complex cationic part in octahedral geometry. The population ratio of Fe^{III}_{tet} : Fe^{III}_{oct} = 1 : 1.17. The spectrum of complex (**4**) shows a symmetrical doublet. I.S. value obtained is 0.49 mm s^{-1} and q.s. value 0.64 mm s^{-1}; these indicate iron(III) centre in octahedral geometry.[28] The bandwidth in this spectrum is found to be a bit larger (0.71 mm s^{-1}): but from analytical data, more than one iron(III) site is not possible. This broadening is most probably due to ultrafine nature[28] of (**4**).

Acknowledgement—The authors thank Dr Dipankar Das, Department of Solid State Physics, IACS, for recording the Mössbauer spectra.

SYNTHESIS AND COMPLEXATION CHEMISTRY OF THE NOVEL (1,3)-BIFUNCTIONAL ORGANOPHOSPHORUS(III) ESTERS $[(RO)_2PO]_4Si$ (R = Me, Et)

NIGEL GREENE and TERENCE P. KEE*

School of Chemistry, University of Leeds, Leeds LS2 9JT, U.K.

(*Received* 3 *June* 1993; *accepted* 28 *June* 1993)

Abstract—The new, silylated tetraphosphite compounds $[(RO)_2PO]_4Si$ (R = Me, Et) have been synthesised in high yield from the reactions between $SiCl_4$ and $(RO)_2P(=O)H$ in the presence of NEt_3. These compounds can bridge two metal centres in the form of a bis-bidentate, chelating ligand such as in the compounds $\{M\}\{[P(OMe)_2O]_2Si[O(OMe)_2P]_2\}\{M\}$ $\{M = [Mo(CO)_4]$ and $[PtCl_2]\}$.

We are currently investigating the coordination and organic chemistry of main-group and transition metal phosphito compounds of the general form $[(RO)_2PO]_nM$ where R is an organic residue and M is a main-group or transition metal atom. These types of molecule combine both electrophilic (M) and nucleophilic (P) centres connected via an electronically conducting single atom spacer and as such belong to the general class of 1,3-bifunctional compounds. Consequently, we have found that phosphito compounds are reactive towards both electrophilic and nucleophilic reagents and display chemistries which make them desirable both as ligands to transition metals[1] and as reagents for organic, and in particular asymmetric, synthesis.[2] This paper extends further the uses of main-group phosphito compounds as ligands through the synthesis of novel silylated tetraphosphite esters.

During the course of our investigations we have studied the reactions between secondary phosphites, $(RO)_2P(=O)H$, and mixed organochlorosilanes (eq. 1) which have facilitated access to a range of silylated polyphosphite esters.[1]

$$(R^1O)_2P(O)H + 1/nCl_nSiR^2_{4-n} \xrightarrow{NEt_3} 1/n[(R^1O)_2PO]_nSiR^2_{4-n} + NHEt_3Cl \quad (1)$$

R^1 = Me, Et; R^2 = Me, Ph, CH=CH_2

We have shown that the reaction in eq. (1) can be used to prepare (1,3)-bifunctional monophosphite esters [1a] ($n = 1$), diphosphite esters[1b,c] ($n = 2$) and triphosphite esters[1d] ($n = 3$) and here wish to report the extension of this methodology to the synthesis of (1,3)-bifunctional tetraphosphite esters ($n = 4$).

RESULTS AND DISCUSSION

Synthesis and characterisation of the tetraphosphites $[(RO)_2PO]_4Si$ (R = Me, Et)

The tetraphosphites $[(RO)_2PO]_4Si$ (R = Me **1**, Et **2**) are synthesised in high yields as colourless liquids according to the reaction in eq. (1) ($n = 4$). In practice, since the reactions are slower than those required for diphosphites ($n = 2$) and triphosphites ($n = 3$), we find that the use of five equivalents of the secondary phosphite leads to more reasonable reaction times (Scheme 1).

Mass spectrometry of **1** and **2** locates the molecular ions at m/z 464 and m/z 576, respectively. Infrared spectroscopy reveals no evidence for ν(P=O) vibrations {cf. 1265 cm^{-1} for $(MeO)_2P(=O)H$ and 1255 cm^{-1} for $(EtO)_2P(=O)H$} and NMR spectroscopic data are comparable to those found for other silylated phosphites.[1] Particularly characteristic is the high frequency value[3] of the ^{31}P NMR resonances for **1** and **2**; δ 124.8 and δ 123.4, respectively. Moreover, the observation of quintet resonances in the ^{29}Si NMR spectra of **1** and **2** at δ −108.3 ($^2J_{PSi}$ 6.7; *ca* 1.5 M solution in toluene at 298 K) and δ −109.0 ($^2J_{PSi}$ 5.5; *ca* 1.5 M solution in $CDCl_3$ at 298 K), respectively indicate that four phosphito residues are coordinated to silicon (Fig. 1). These chemical shifts are in the region expected

for siloxanes containing four coordinated oxygen atoms.[4] Furthermore, the $^2J_{PSi}$ values of 6.7 and 5.5 Hz, respectively are also within the range normally observed (+1 to +27 Hz).[4]

In a similar manner to analogous diphosphites and triphosphites, the tetraphosphites **1** and **2** are sensitive to hydrolysis, decomposing to the constituent secondary phosphites upon exposure to moist air at room temperature.

The synthetic strategy outlined in eq. (1) has now been used to prepare silylated mono-, di-, tri- and tetra-phosphites readily and in high yields. With this in mind we have sought to extend the strategy to incorporate elements other than silicon in the backbone of the polyphosphite. We have investigated the reactions of PCl_3, $S(=O)Cl_2$, $S(=O)_2Cl_2$, and $SnCl_4$ with stoichiometric quantities of $(MeO)_2P(=O)H$ and NEt_3 at room temperature. In each case, reaction occurred readily as evidenced by the precipitation of $NHEt_3Cl$ however, in no case could a clean product be isolated. With PCl_3, a pentane soluble liquid was isolated which displayed several resonances in the δ 129–131 region expected for a phosphito compound but we were unable to isolate a pure material.

Reactions of $[(MeO)_2PO]_4Si$ *with transition metals*

The tetraphosphites **1** and **2** have the potential to complex to two transition metal atoms in two different ways, illustrated in Fig. 2 (this does not include the several ways in which such tetradentate ligands can bridge more than two metals) and exemplified by the coordination chemistry of the tetraphosphines $[Ph_2PCH_2]_4C$[5] and $[Ph_2PCH_2]_2CH_2CH_2[CH_2PPh_2]_2$.[6] We were particularly interested to promote bis-bidentate bridging be-

tween two metal centres (Fig. 2a) and in an effort to do so have examined the reactivity between **1** and $Mo(CO)_4$(NBD) and PtX_2(COD) (X = Cl, Me).

A 2 : 1 mixture of $Mo(CO)_4$(NBD) and **1** react at room temperature to afford product mixtures which are dependent upon the order and rate of addition of the reactants. When $Mo(CO)_4$(NBD) is added to **1**, a mixture of compounds is obtained from which it has not been possible to isolate a pure compound. However, when the order of addition of reagents is reversed, a white solid can be isolated in low yield (**3**) which, by ^{31}P NMR analysis, appears to consist of a single phosphorus-containing compound. Specifically, a single resonance at δ 153.7 is consistent with the presence of metal-bound phosphito groups.[1] Infrared spectroscopy reveals ν(CO) stretching vibrations characteristic of a tetracarbonyl system leading to the conclusion that **3** is the dimeric bridged complex, $\{Mo(CO)_4\}_2\{\mu$-$[P(OMe)_2O]_4Si\}$ (Scheme 1). This is further supported by elemental analysis, mass spectrometry and ^{13}C NMR spectroscopy which reveals two carbonyl carbon resonances, an AXX′ multiplet at δ 211.52 due to the carbonyl groups *trans* to phosphorus and a triplet at δ 206.72 ppm due to the carbonyls *cis* to phosphorus, respectively. This pattern is characteristic of the [*cis*-$Mo(CO)_4L_2$] moiety. Interestingly, the ^{13}C resonance for the carbonyls *trans* to the phosphorus atoms is very slightly lower in frequency than those of related diphosphite complexes[1c] of the form $[Mo(CO)_4\{P(OMe)_2O\}_2SiR^1R^2]$ where R^1, R^2 are variously Me, Ph, CH=CH_2 (Table 1) suggesting that the ligands $[P(OMe)_2O]_2Si[OP(OMe)_2]_2$ are slightly less electron-donating towards molybdenum than $[P(OMe)_2O]_2SiR^1R^2$. This result is consistent with the more electronegative coordination environment around silicon in the tetraphosphites.[7]

onances in the regions δ 154–152 and δ 126–124 suggest that not all phosphorus atoms are metal-bound, the latter resonances being indicative of uncoordinated phosphito residues.[1]

$PtCl_2$(COD) reacted smoothly with **1** at room temperature to afford a white, microcrystalline product which was insufficiently soluble in common non-coordinating organic solvents for NMR analysis and apparently decomposed in pyridine. Nevertheless, elemental analysis supports the formulation $\{PtCl_2\}_2\{[P(OMe)_2O]_4Si\}$ **4** in which the tetraphosphite ligand presumably coordinates to both metal atoms as a bis-bidentate bridging ligand (Scheme 1). In an attempt to increase both solubility and crystallinity we subsequently examined the reaction of **1** with $PtMe_2$(COD), but although this did produce products containing platinum-coordinated phosphorus atoms, no pure product was isolated.

We believe that although ligation proceeds readily for the tetraphosphite ester **1**, the degree of flexibility in the backbone permits the compound to coordinate to metal centres in a variety of modes, such as bridging more than two metal centres, thus leading to mixtures of oligomeric products of low solubility which prove difficult to characterise. Consequently, we are currently shifting our attention to more robust, geometrically constrained phosphorus(III) esters which have more electron-releasing properties and these systems will form the basis of future reports.

EXPERIMENTAL

All syntheses were performed under dry dinitrogen using Schlenk and cannula techniques or in an inert-atmosphere filled dry-box. Solvents were dried over either sodium wire, calcium chloride or 4 Å molecular sieves before reflux and subsequent distillation, under dinitrogen, from a suitable drying agent (given in parentheses); pentane (sodium benzophenone ketyl), toluene (sodium metal), dichloromethane (calcium hydride). Deuterated solvents were dried by passage down a column of basic alumina (Brockmann Grade I). All solvents were deoxygenated before use. Elemental analyses and molecular weight measurements were performed by the Microanalytical Laboratory of this department, the latter on a Hitachi Perkin–Elmer 215 Apparatus. IR spectra were recorded between KBr windows on a Perkin–Elmer 257 grating spectrophotometer. NMR spectra were obtained on JEOL FX90Q, JEOL FX100 and Bruker AM 400 instruments; the ^{31}P and ^{13}C spectra being recorded under conditions of broad-band decoupling. Spectra are referenced to TMS or residual $CHCl_3$, C_6D_5H solvent resonances (^1H, ^{13}C, ^{29}Si) or 85% $H_3PO_{4(aq)}$ as 0 ppm. Mass spectra were recorded either in the electron impact (E.I.) or F.A.B. modes on a VG Autospec instrument. The compounds $SiCl_4$, $SOCl_2$, SO_2Cl_2 and $SnCl_4$, were purchased from commercial sources and were used as received. $(RO)_2P(=O)H$ (R = Me, Et) and NEt_3 were purified by passage down a short column of basic alumina (Brockmann Grade I). $Mo(CO)_4$(NBD)[8] and $PtCl_2$(COD)[9] were prepared using published procedures. NBD = norborna-2,5-diene, COD = cycloocta-1,5-diene.

Synthesis of $[(RO)_2PO]_4Si$ (R = Me **1**, Et **2**)

$SiCl_4$ (0.45 g, 2.62 mmol) was added dropwise at room temperature to a stirred mixture of $(RO)_2P(=O)H$ (1.44 g, 13.09 mmol R = Me; 1.81 g, 13.09 mmol R = Et) and NEt_3 (2.2 cm^3, 15.71 mmol) in pentane solvent (40 cm^3). The initially clear solutions became cloudy within seconds of adding the silicon reagent due to the precipitation of $NHEt_3Cl$. After stirring for 72 h, the mixture was filtered, the residue washed with pentane (10 cm^3) and all the volatiles removed under reduced pressure to leave a colourless liquid in which was suspended a small amount of $NHEt_3Cl$. Subsequent extraction into pentane (15 cm^3), re-filtration and removal of the volatiles *in vacuo* afforded the products as clear, mobile liquids. Yields, **1** 1.1 g, (88%); **2** 1.2 g (77%). For **1**: ^1H ($CDCl_3$) 3.46 (m, 24H, J_{PH} 9, CH_3O). ^{13}C ($CDCl_3$) 48.3 (m, J_{PC}, 9 CH_3O). ^{31}P ($CDCl_3$) 124.8 (s). ^{29}Si (toluene) −108.3 (quin, $^2J_{PSi}$ 6.7) i.r. (thin film, cm^{-1}) 979 {s, br, ν(POSi)}. *m/z*; 464 $(M)^+$, 434 $(M-2CH_3)^+$, 356 $[M-OP(OMe)_2]^+$, 246 $[M-2OP(OMe)_2]^+$.

For **2**: ^1H ($CDCl_3$) 3.86 (m, 16H, $^3J_{HH}$ 7, CH_3CH_2O), 1.17 (t, 24H, $^3J_{HH}$ 7, CH_3CH_2O). ^{13}C ($CDCl_3$) 57.2 (m, J_{PC} 6, CH_3CH_2O), 16.6 (s, CH_3CH_2O): ^{31}P ($CDCl_3$) 123.4 (s). ^{29}Si ($CDCl_3$) −109.0 (quin, $^2J_{PSi}$ 5.5) i.r. (thin film, cm^{-1}) 935 {s, br, ν(POSi)}. *m/z*; 576 $(M)^+$, 440 $[M-OP(OEt)_2]^+$.

Reaction of $[(MeO)_2PO]_4Si$ *with* $Mo(CO)_4$(NBD)

A solution of $[(MeO)_2PO]_4Si$ (0.49 g, 1.07 mmol) in pentane (30 cm^3) was added dropwise to a suspension of $Mo(CO)_4$(NBD) (0.64 g, 2.12 mmol) in pentane (30 cm^3) cooled to −78°C. After the addition was complete (*ca* 1 h) the mixture was allowed to warm to room temperature and stirred thus for a further 3 h. During this period a white, free-flowing suspension formed in the reaction vessel along with a small quantity of brown material lining the flask. The mixture was allowed to settle

and the pentane solution decanted off carefully. The residue was washed with a further portion of pentane (10 cm^3) and all extracts combined. Concentration of the pentane solution to *ca* one third volume resulted in precipitation of $\{Mo(CO)_4\}\{\mu\text{-}[P(OMe)_2O]_4Si\}$ **3** as a white crystalline compound in low (< 10%) yield. (Found: C, 22.0; H, 2.7; $C_{16}H_{24}O_{20}MoP_4Si$ requires: C, 21.8; H, 2.8%. ^1H (C_6D_6) 3.29 (m, 24H, J_{PH} 12, CH_3O—); ^{13}C (C_6D_6) 211.52 (m, J_{PC} 24.7, CO_{trans}), 206.72 (t, $^2J_{PC}$ 13.7, CO_{cis}), 49.97 (s, CH_3O—); ^{31}P (C_6D_6) 153.7 (s). i.r. (CH_2Cl_2 solution, cm^{-1}) 2035 {s, ν(CO)}, 1962 {s sh, ν(CO)}, 1942 {s br, ν(CO)}. *m/z*; 879 $[M]^+$.

The same procedure as described above was used with a 1:1 stoichiometric mixture of $Mo(CO)_4$ (NBD) and $[(MeO)_2PO]_4Si$ except that the addition of reagents was reversed; where upon an oily mixture was obtained and analysed by ^{31}P NMR spectroscopy (see text).

Reaction of $[(MeO)_2PO]_4Si$ *with* $PtCl_2(COD)$

A solution of $[(MeO)_2PO]_4Si$ (0.22 cm^3, 0.92 M, 0.20 mmol) in THF was added at room temperature to a solution of $PtCl_2(COD)$ (0.15 g, 0.40 mmol) in THF (15 cm^3). The mixture quickly became cloudy due to a precipitate. After 16 h at ambient temperature, the mixture was allowed to settle and the fine-grained white precipitate, compound **4**, isolated by filtration, washed with pentane (2×5 cm^3) and dried *in vacuo*. (Found: C, 10.0; H, 2.8; Cl, 15.3. Calc. for $C_8H_{24}Cl_4O_{12}P_4Pt_2Si$: C, 9.6; H, 2.4; Cl, 14.2%.

(*Received* 2 *June* 1993; *accepted* 14 *June* 1993)

Abstract—The negative and positive ions of gold and platinum, Au^-, Pt^-, Au^+ and Pt^+, generated by the direct laser ablation of the metals, were reacted with benzene, alkyl substituted benzenes, benzenethiol, H_2S, n-propanethiol and the four butanethiols in a Fourier Transform Ion Cyclotron Resonance Mass Spectrometer (FT–ICR–MS). Reactions were carried out with ions collisionally cooled, to reduce their kinetic energy and deactivate electronic excited states, and with "hot" ions directly after production by the laser. The negative ions of both metals react at a slower rate than the positive ions and their spectra show fewer products. No products were observed for the reaction of metal negative ions with the aromatic hydrocarbons except for the reaction of Pt^- ions with mesitylene to give the $(CH_3)_2C_6H_3CH_2^-$ anion as the major product. The reactions of Au^- ions with most of the aryl and the alkyl thiols produced the SR^- anion as the major product. The reactions of both Au^+ and Pt^+ ions with benzene and the substituted benzenes gave the charge transfer ions L^+ (e.g. $C_6H_6^+$) as the major products. Collisionally cooled Pt^+ ions gave minor product ions identified as Pt-benzyne species ($PtC_6H_4^+$), while "hot" Pt^+ ions gave the Pt-benzyne species as the major ions. Benzenethiol reacted with both Au^+ and Pt^+ to yield the charge transfer ion $C_6H_5SH^+$ as the major product, while the reactions of Au^+ and Pt^+ ions with H_2S both gave addition complexes MH_2S^+ and $M(H_2S)_2^+$, similar to the reactions of Ag^+ and Cu^+. The reactions of n-propanethiol and the four butanethiols with Au^+ and Pt^+ ions generally gave the protonated thiol as the major ion with significant quantities of other ions including addition complexes. These results are different from the previously reported reactions of Cu^+ and Ag^+ ions which gave the addition ions as the major products.

The production of metal ions by laser ablation of a pure metal generally yields[1] the mono cation M^+, which may not be the common positive ion observed in condensed phase chemistry: an example is Pt^+. Further, the ions produced often are in electronically excited states. A few metals also produce negative ions M^- which are in very unusual oxidation states. Gold and platinum form both negative and positive mono-ions, $M^+(g)$ and $M^-(g)$. The Au^+ ion may be considered to be in a normal oxidation state, but the other three ions are in unusual oxidation states.

Our studies of the reactions of metal ions with thiols have included the reactions of $Cu^+(g)$ and $Ag^+(g)$, reported earlier.[2] Now we report the reactions of Au^+ for comparison with those of Cu^+ and Ag^+, and extend to the monoanion of Au. We have also studied the reactions of the positive and negative ions of Pt, for comparison with Au.

An extensive study of the reactions of gold cations with aromatic and aliphatic hydrocarbons was carried out by Chowdhury and Wilkins[3] using Fourier Transform mass spectrometry. They found hydride abstraction to be the major reaction of alkanes higher than ethane. The reaction with arenes gave the charge transfer products ArH^+,

* Authors to whom correspondence should be addressed.

some hydride abstraction products Ar^+ and some addition ($AuArH^+$) products. With alkyl halides the methide ion ($AuCH_2^+$) was a major product. Weil and Wilkins[4] studied the reactions of Au^+ with alcohols, and showed that hydride abstraction was the major reaction pathway, and that loss of water to form the gold-alkene ion was the main secondary pathway. Both studies produced ions by laser ablation, used collisional cooling to reduce the translational energy of the ions and allow excited states of the metal ion to decay to the ground state or be removed by rapid reaction.

In two papers Grady and Bursey[5,6] used a spark source to produce high energy Au^+, and reacted the ions with various hydrocarbons and carbonyl compounds, concluding that there was evidence of the intervention of excited states of the ion in the chemical reactions observed. The simple catonized ion AuL^+ was not observed, and also more fragmentation of the organic species occurred if the metal had low lying excited states. Recently greater attention has been given to how the reactivity of an ion might change if ions in excited states are produced during ionization.[7] Various studies have been undertaken to determine the amounts of excited state ions present after ionization.[7-9] Excited state ions are potentially more important for Au^+ than for Cu^+ and Ag^+, as the first excited state for Au^+ is 1.9 eV above the ground state whereas the energy gap values for Cu^+ and Ag^+ are 2.8 eV ($3d^94s^1$) and 4.9 eV ($4d^95s^1$), respectively.[10]

Only one previous study of the reactions of Pt^+ has been reported, this was with methane,[11] as part of a study of the reactions of third row transition metal ions. Pt^+ has a ground state of ^2D ($5d^9$) but several excited states less than 2 eV above the ground state [^4F 0.59 eV, ^2D ($J = 3/2$) 1.04 eV, ^4F 1.16 eV, ^4P 1.65 eV]. Our principal interest is in the reactions of thiols with these metal ions. Because a thiol can react with gaseous metal ions at either the SH function or the hydrocarbon function, we have included studies of reactions with H_2S and with hydrocarbons for reference purposes in this paper.

EXPERIMENTAL

Mass spectra were obtained using a Spectrospin CMS-47 (FT-ICR) mass spectrometer, equipped with a 4.7T superconducting magnet.[12] The metal was secured to a satellite probe tip and introduced into the ICR cell using a direct insertion probe. A cylindrical ICR cell (radius 30 mm × 60 mm) with six titanium single section plates was used in an ultra high vacuum chamber maintained at a base pressure of 10^{-9} mbar by a turbomolecular pump.

Laser-ablation was performed using a Nd-YAG laser (1064 nm, Spectra Physics DCR-11) focused to an area of 0.1 mm^2 on the metal at the end of the cell, flush and in contact with the ICR trapping plate. The laser was used in the Q-switched mode producing a pulse for 8 ns and a maximum energy at the sample of ~ 1600 MW cm^{-2}. The pulse energy at the sample was modified using neutral density filters; energies of 340 and 150 MW cm^{-2} were most commonly used.[13]

Ions were isolated using an ejection pulse, and a minimum delay of 100 ms was used to allow collisional cooling before the reaction was observed. Positive or negative ions were trapped in the cell by potentials of +4 V or −4 V, respectively. A typical pulse program and the treatment of data have previously been reported.[2] The reactants were degassed by repeated freeze–thawing and introduced through a heated inlet system. The reactants were admitted to give a background pressure of 6.5×10^{-8} mbar (uncorrected) and ablation was performed in the presence of the reactant.

RESULTS

In the following, the symbols Au^+ and Pt^+ are used for the positive ions which were selected and collisionally cooled in the presence of the reactant for 100 ms before the reactions were monitored. Some experiments were carried out without collisional cooling, and the metal ions reacted directly after laser production and are denoted $*Au^+$ and $*Pt^+$.

The principal reaction types observed in this study are listed below. The symbol L is used for the reactant where the reaction does not involve fragmentation. For other reactions we use the symbol HXYH such that for the hydrocarbons XY is the doubly deprotonated species (e.g. $C_6H_6 = HC_6H_4H$), and for the thiols X = S and YH = R where R is the alkyl or aryl substituent.

Mono-complex formation;

$$M^+ + L \rightarrow ML^+ \text{ or } M^- + L \rightarrow ML^-, \quad (1)$$

Bis-complex formation;

$$ML^+ + L \rightarrow ML_2^+ \text{ or } ML^- + L \rightarrow ML_2^-, \quad (2)$$

Charge transfer;

$$M^+ + L \rightarrow M + L^+, \quad (3)$$

Hydride abstraction;

$$M^+ + HXYH \rightarrow HXY^+ + MH \text{ or}$$
$$M^- + HXYH \rightarrow HXY^- + MH, \quad (4)$$

Elimination of H_2;

$$M^+ + HXYH \rightarrow MXY^+ + H_2, \quad (5)$$

Table 1. Charged products of reactions of the negative ions Au^- and Pt^-

A dash signifies that no ions were detected.

Elimination of H_2Y;

$$M^- + HXYH \rightarrow MX^- + H_2Y, \quad (6)$$

Elimination of H_2X;

$$M^+ + HXYH \rightarrow MY^+ + H_2X, \quad (7)$$

Elimination of Y;

$$M^+ + HXYH \rightarrow MH_2X^+ + Y, \quad (8)$$

Abstraction of HX^-;

$$M^+ + HXYH \rightarrow YH^+ + MHX. \quad (9)$$

The reactions of Au^- *and* Pt^-

The reactions of the anions Au^- and Pt^- are shown in Table 1.

The aromatic hydrocarbons were unreactive towards the metal anions with the exception of mesitylene which reacted with Pt^- by hydride abstraction (eq. 4) to give the anion $C_9H_{11}^-$. There was also a trace of the addition reaction to form the mono-complex (eq. 1).

The reaction of the metal anions with the thiols was hydride abstraction to form MH (eq. 4) in almost all cases, the exceptions being the non-reactivity of Au^- with n-C_3H_7SH, and the reaction of Au^- with t-C_4H_9SH to give mainly S_3^- after long reaction times, S_3^- is a quite stable anion also observed as a minor product in other reactions. Minor pathways in the Pt^- plus thiol reactions involved sulfur abstraction (eq. 6) to form PtS^-, and subsequent addition of the dehydrogenated thiol to give $PtS(SC_4H_9)^-$.

H_2S was unreactive with Au^- but reacted with Pt^- to give the addition products (eqs 1 and 2).

The reactions of Au^+

The major reaction of the collisionally cooled Au^+ ions with the hydrocarbons was the charge transfer reaction (eq. 3). The reactive toluene also gave by hydride abstraction the stable ion $C_7H_7^+$ (eq. 4). This ion was also observed in the reaction of xylene by loss of a methyl group. The reactions of hydrocarbons with $*Au^+$ ions (not collisionally cooled) were studied for benzene and toluene. In both cases the charge transfer reaction (eq. 3) was a secondary pathway and for benzene the addition reactions (eqs 1 and 2) produced the major products, whereas for toluene $C_7H_7^+$ (eq. 4) was the major product ion.

The reaction of benzenethiol with Au^+ ions gave the charge transfer reaction (eq. 3) as the major pathway and the formation of the mono-complex (eq. 1) as the secondary pathway. The reaction of $*Au^+$ with benzenethiol did not alter the main pathway, but one minor product indicated S abstraction

[a] Signifies that the reaction was not investigated.

from the thiol. Only the addition reaction was observed for Au^+ with H_2S (eqs 1 and 2). The reactions of Au^+ with the alkyl thiols gave many similar products not involving Au, namely the protonated thiol RSH_2^+, the charge transfer product RSH^+, and $C_4H_9^+$ formed by the abstraction of SH^- (eq. 9). Two of the thiols were reacted with $*Au^+$ and gave the same major ions but the minor ion $AuC_2H_4^+$ indicated C—C bond cleavage.

The reactions of Pt^+

The major product of the reaction of Pt^+ with the hydrocarbons was the charge transfer ion, RH^+ (eq. 3). Another significant ion (about 15%) was the hydride abstraction product R^+ (eq. 4). Although the major ions contributed ~ 90% of the products, examination of the minor ions using narrow band spectra revealed some interesting products.

In order to establish the compositions of some of the unusual product ions in our reactions we report and interpret representative spectra. For reference, Fig. 1 shows the spectrum of Pt^+ as obtained by our broad band ejection procedure: the ions present agree with the theoretical isotopic distribution (relative to the most abundant isotope) of platinum (^{194}Pt 97%, ^{195}Pt 100%, ^{196}Pt 75%, ^{198}Pt 21%).

After collisionally cooled Pt^+ had reacted with benzene for 2 s, part of the isotopic pattern of the addition products was as shown in Fig. 2. The intensity distribution of the ions at *m/z* of 270, 271, 272 and 274 agree with and can only be due to the benzyne product $PtC_6H_4^+$, while the phenyl addition product $PtC_6H_5^+$ and the benzene

Where L is used there are several products, see text.

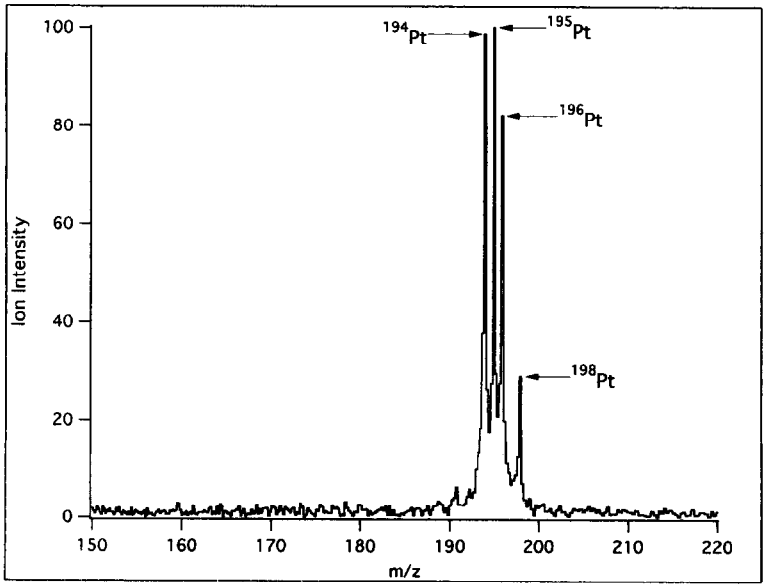

Fig. 1. The spectrum of collisionally cooled Pt^+ ions, obtained by broad-band ejection of all other ions from laser ablated platinum.

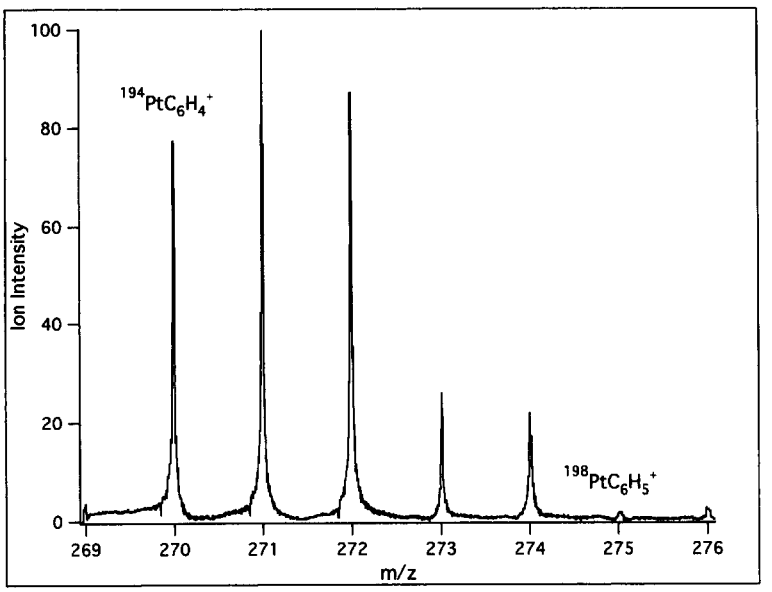

Fig. 2. The narrow band spectrum of the products of reaction of collisionally cooled Pt^+ ions with benzene after 2 s.

addition product, $PtC_6H_6^+$, are unambiguously proven as minor products by the low intensity ions at *m/z* 275 and 276. Thus the peaks at *m/z* 271, 272, 273 and 274 are due to more than one ion, e.g. *m/z* 274 is a mixture of $^{196}PtC_6H_6^+$ and $^{198}PtC_6H_4^+$.

Continuation of the same reaction for 10 s yielded two other sets of minor products, for which the spectra are shown in Figs 3 and 4. The products in Fig. 3 are the bis addition products and involve both benzyne and benzene ligands. For instance the peak at *m/z* 346 is the bis-benzyne product $^{194}Pt(C_6H_4)_2^+$. The peaks at *m/z* 353 and *m/z* 354 indicate the presence of $^{198}Pt(C_6H_6)(C_6H_5)^+$ and $^{198}Pt(C_6H_6)_2^+$, respectively. The other peaks are overlaps and mixed ligand ions.

The spectrum of the tris-complexes shown in Fig.

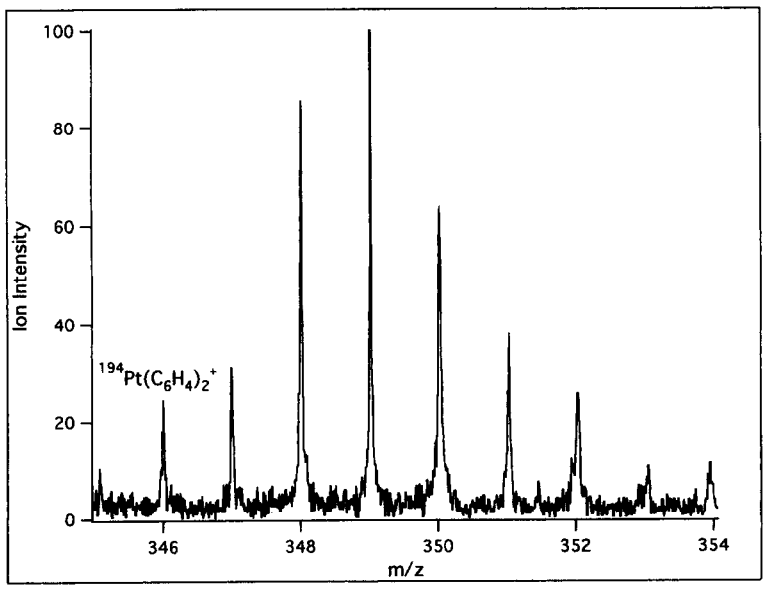

Fig. 3. The narrow band spectrum of the minor products of reaction of collisionally cooled Pt^+ ions with benzene after 10 s.

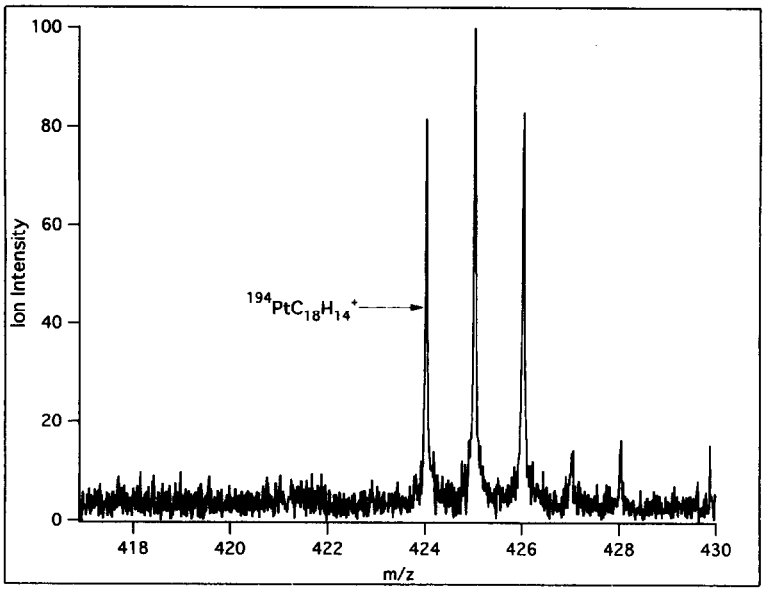

Fig. 4. The narrow band spectrum of the minor products of reaction of collisionally cooled Pt^+ ions with benzene after 10 s.

4 is much simpler and suggests that the ion at m/z 424 is $^{194}Pt(C_6H_4)_2(C_6H_6)^+$ or $^{194}Pt(C_6H_4)(C_6H_5)_2^+$. The isotope pattern in Fig. 4 is similar to the isotope pattern in Fig. 1. The reaction of Pt^+ with toluene gave the charge transfer ion $C_7H_8^+$ as the major product with approximately 15% of the hydrogen transfer product $C_7H_7^+$. Other minor addition products were observed as shown in the narrow band spectra Figs 5 and 6. The mono- and bis-benzyne products $PtC_7H_6^+$ and $Pt(C_7H_6)_2^+$ are at m/z 284 and 374, respectively for the ^{194}Pt ion. The peaks at m/z 283, 372 and m/z 373 indicate the presence of ions having further losses of hydrogen such as $^{194}Pt(C_7H_5)_2^+$ (m/z 372) compared to $^{194}Pt(C_7H_6)_2^+$ (m/z 374).

The reaction of $*Pt^+$ ions afforded greater concentrations of the addition complexes and the hydrogen transfer product. The mono-addition

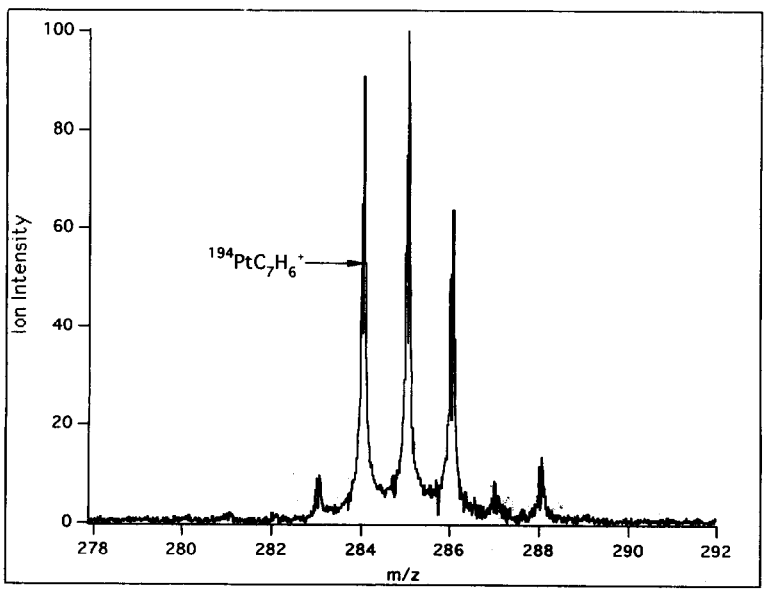

Fig. 5. Narrow band spectrum of the reaction of collisionally cooled Pt^+ ions with toluene, after 1.5 s.

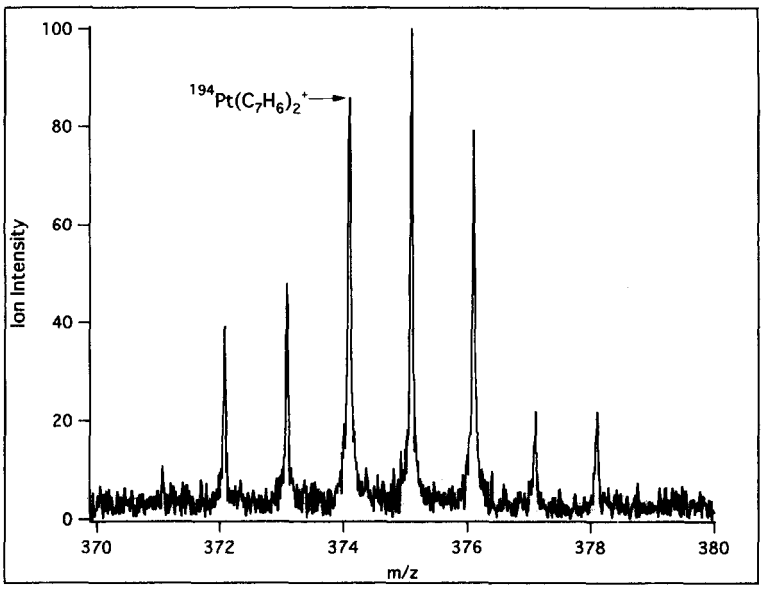

Fig. 6. Narrow band spectrum of the reaction of collisionally cooled Pt^+ ions with toluene, after 1.5 s.

products were the initial major ions rather than the charge transfer product or the hydride transfer product, the $C_7H_7^+$ ion.

The reaction of Pt^+ ions with p-xylene gave the charge transfer product $C_8H_{10}^+$ as the major ion and $C_8H_9^+$ as the second most intense ion, with smaller amounts of $C_7H_7^+$. The addition products were observed in the narrow band spectrum, shown in Fig. 7. The ions at *m/z* 296, 297 and 298 are most probably $^{194}PtC_8H_6^+$, $^{194}PtC_8H_7^+$ and $^{194}PtC_8H_8^+$, respectively with the peaks at *m/z* 297 and 298 having contributions from $^{195}PtC_8H_6^+$ and $^{195}PtC_8H_7^+$, respectively.

The reaction of Pt^+ with mesitylene gave the charge transfer product $C_9H_{12}^+$ as the major ion, and the addition products shown in Fig. 8 as minor products. The ions at *m/z* 310, 311 and 312 are identified as $^{194}PtC_9H_8^+$, $^{194}PtC_9H_9^+$ and $^{194}PtC_9H_{10}^+$, respectively, while *m/z* 311 and 312 have contributions from $^{195}PtC_9H_8^+$ and $^{195}PtC_9H_9^+$, respectively.

Pt^+ reacted cleanly with benzenethiol to produce

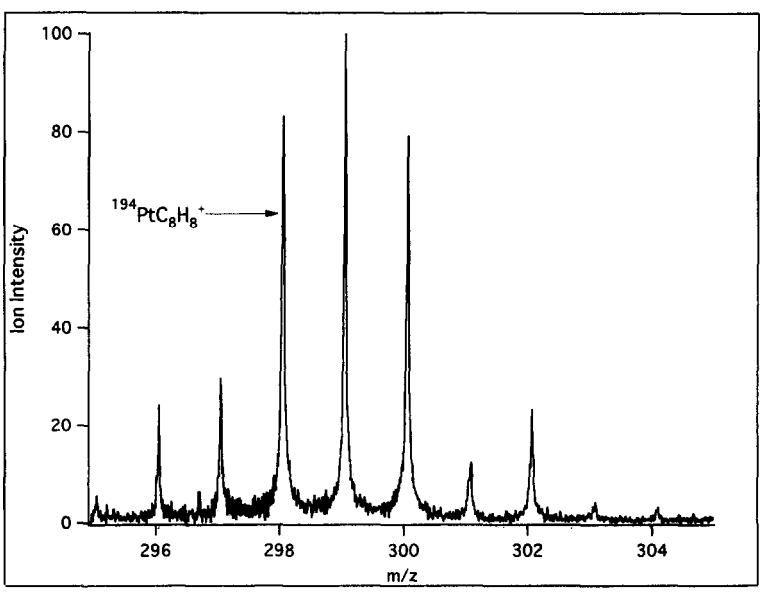

Fig. 7. Part of the spectrum of the reaction of collisionally cooled Pt^+ ions with p-xylene, after 1.5 s.

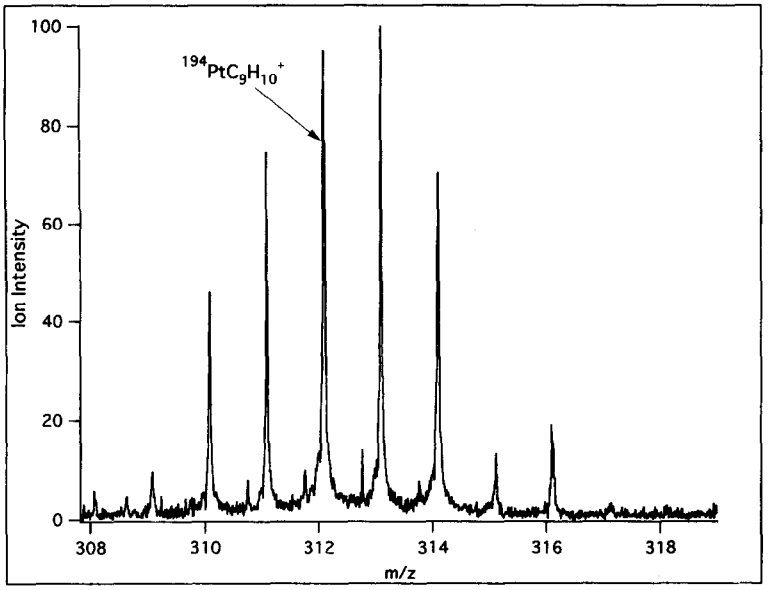

Fig. 8. The narrow band spectrum of the reaction of collisionally cooled Pt^+ ions with mesitylene, after 0.2 s.

the charge transfer ion $C_6H_5SH^+$ as the major product, while the mono-complex ion $PtC_6H_5SH^+$ was a trace product.

*Pt^+ ions were more reactive and this was shown in the variety of products which were obtained at low intensity levels (< 4%). The charge transfer product L^+ was a major ion, and the mono- and bis-complex ions $PtC_6H_5SH^+$ and $Pt(C_6H_5SH)_2^+$ were observed together with other species such as $PtS_n(C_6H_5SH)_m^+$ where n = 1, 2 and m = 1, 2 and $PtS(C_6H_5SH)_3^+$. The reaction of Pt^+ with H_2S gave only the addition products PtH_2S^+ (eq. 1) and $Pt(H_2S)_2^+$ (eq. 2).

The reactions of Pt^+ with all the alkyl thiols (except t-butanethiol) gave the protonated thiol RSH_2^+ as the major ion. The removal of HS^- (eq. 9) to give $C_4H_9^+$ as the major ion occurred for t-butanethiol. An unusual minor ion observed in the reactions of all the butanethiols was $PtC_4H_7^+$ produced by the loss of H_3S.

DISCUSSION

The production of bare metal ions using the laser method is expected to produce ions with high translational energy and also ions in excited electronic states. Collisional cooling using an inert gas or the reacting molecule might be expected to significantly reduce translational energy but may not provide pathways for the deactivation of excited state ions to ground state ions. The excited state ions often have long lifetimes as shown by Ridge[15] or react differently as shown recently by Russell.[7] Russell has used the different reactivity to investigate Fe^+ formed by Electron Impact and found that 65% of the ions formed were in excited states. The production of high energy Au^+ using a spark source[5,6] is obviously a guide to the reactivity of Au^+ in excited states.

The metal negative ions were markedly less reactive than the positive ions. Au^- ($d^{10}s^2$) was a particularly unreactive ion. The major reaction of Au^- and Pt^- with the thiols was the hydride abstraction reaction, eq. 4. The exception was with H_2S, which from solution chemistry would be expected to be more acidic than the thiols, but was unreactive towards Au , and underwent simple addition with the more reactive Pt^-. The time course of the $Pt^- + H_2S$ reactions is shown in Fig. 9.

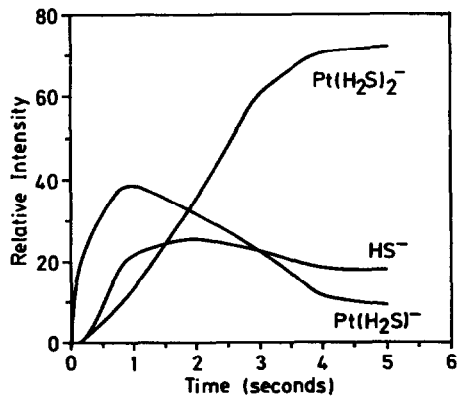

Fig. 9. Time course of the reaction of Pt^- with H_2S.

The ionization energy of Au, 9.225 eV is slightly lower than that of benzene (9.25 eV) but the reaction of collisionally cooled Au^+ with benzene gave the charge transfer reaction. The formation of the addition complexes $AuC_6H_6^+$ and $Au(C_6H_6)_2^+$ with "hot" $*Au^+$ suggests that excited state ions may be reacting to give different products than the charge transfer product produced by the ground state ions. Sato *et al.*[16] using laser ablation and a molecular beam method had observed the addition products and $Au(C_6H_6)_2^+$, but their reactions were carried out at benzene pressures of 60 torr.

The observation of only 30% charge transfer reaction with "hot" Au^+ ions suggest that the excited state ions may be at twice the concentration of the ground state ions, or that ions with higher translational energy may undergo the addition reaction in preference to the charge transfer reaction.

The ionization potentials of the methyl substituted benzenes studied ($\sim$ 8.4–8.8 eV)[17] are significantly lower than the ionization potential of benzene. In the case of toluene the reaction with collisionally cooled Au^+ was the charge transfer reaction as expected. The minor product was the very stable ion $C_7H_7^+$ which involved hydride abstraction (eq. 4).

With "hot" Au^+ ions the major product ion was $C_7H_7^+$ and the minor product ion was the charge transfer ion $C_7H_8^+$. After a reaction time of 2 s the ratio of the ions $C_7H_7^+ : C_7H_8^+$ was approximately 3 : 1. If $C_7H_7^+$ ions were formed by the reaction of excited state Au^+ ions present directly after laser ablation, then the ground state ions were only about 25% of the total ions. The charge transfer ions were the major species observed in the reactions of collisionally cooled Au^+ with xylene and mesitylene as expected from the ionization potentials.[17]

Our results differ in detail from those of Chowdhury and Wilkins who observed the major product of the reaction of Au^+ with benzene to be the addition product $AuC_6H_6^+$ and the charge transfer ion to be the major product for the reaction of toluene.

The reactions of Au^+ with benzene and substituted benzenes also contrast with the reactions of Cu^+ and Ag^+,[2] where the major ions formed were the addition complexes ML^+ and ML_2^+. The ionization potentials of Cu and Ag (7.73 and 7.58 eV, respectively) are significantly lower than the ionization potential of Au, thus the charge transfer process would be highly endothermic for ground state Cu^+ and Ag^+.

The reaction rates of Pt^+ with benzene and the substituted benzenes indicate that this metal ion is more reactive than Au^+. This is possibly due to the filled shell electronic configuration of Au^+ (d^{10}) being a more stable, less reactive species compared with Pt^+ (d^9), but may also be due to long lived excited states of Pt^+. The ionization energy of Pt (9.0 eV) is significantly lower than that of benzene and yet the charge transfer ion and the hydride transfer ion are formed in the reaction of Pt^+ with benzene. This suggests that although the ground state reaction to form the charge transfer products may be endothermic, the participation of excited state Pt^+ ions may involve exothermic reactions. The observation of the benzyne product and other similar products with the substituted benzenes, and the increase in the proportion of these ions when "hot" $*Pt^+$ was used also indicates the presence of excited state ions.

The formation of addition products was greater for the more reactive toluene than for benzene, and also greater for the more reactive "hot" ions. The "benzyne" products could be formed by removal of two aromatic hydrogens (a real benzyne), or involve removal of one or two of the methyl protons: our current experiments cannot distinguish these mechanisms. There was also evidence of the further removal of hydrogens from the benzene ring in the formation of products such as $Pt(C_7H_5)_2^+$ in the reaction of Pt^+ with toluene. It is possible for p-xylene to form a benzyne, but mesitylene cannot easily form a benzyne derivative and so loss of methyl protons must take place in the formation of the products giving ions such as m/z 310, $^{194}PtC_9H_8^+$.

Reactions involving the formation of metal-benzyne complexes from aryl halides have been reported previously, principally with Sc^+, Ti^+, V^+ and Fe^+.[18,19] Platinum benzyne and other metal benzyne compounds have also been prepared in the condensed phase.[20]

The ionization potential of benzenethiol, 8.32 eV suggests that both Au^+ and Pt^+ should give the charge–transfer reaction, as was observed. The production of minor ions particularly with $*Pt^+$ suggests the reactions involve excited state ions. The higher ionization potentials of Au and Pt compared with Cu and Ag are the reason for the completely different reaction pathways in the gas phase reactions of their mono-cations.

H_2S has a high ionization potential (10.5 eV) and so the only reaction observed with the positive ions Au^+, Pt^+ and Cu^+ was the addition reaction. In all cases there was no evidence of metal sulphide formation in contrast to well known solution reactions.

The alkyl thiols have higher ionization potentials (9.2–8.7 eV), but the major ion observed for both Au^+ and Pt^+ was the protonated ligand, which may

arise from the initial charge transfer ion RSH^+ reacting further with the neutral thiol. The minor products formed arise mainly from the rupture of the C—S bond and the elimination of H_2S which may add to the reacting metal ion or be pumped away as a neutral molecule. Pt^+ gave the unusual minor ions $PtC_4H_8S^+$ and $PtC_4H_7^+$ which involve the loss of H_2 (eq. 5) and H_3S, respectively.

In contrast to our previous study of the reactions of Cu^+ and Ag^+ where the formation of addition products with similar molecules was the principal reaction, the reactions of Au^+ and Pt^+ indicated above are very different.

Abstract—Anions (loss of ^{3}N hydrogen) of 2-acetylpyridine azacyclothiosemicarbazones coordinate in a planar conformation to a central nickel(II) or copper(II) ion through the pyridyl N, azomethine N and thiolato S atoms. The fourth coordination site is occupied by a bromo ligand. Their ability to inhibit the growth of two fungi is compared to their structural differences.

Heterocyclic thiosemicarbazones, as well as their metal complexes, are important series of compounds because of potentially beneficial, biological activity.[1] In particular, copper(II) thiosemicarbazone complexes have shown enhanced biological activity compared to uncomplexed thiosemicarbazones.[2] Although there has been considerable effort directed toward the isolation of new complexes and their spectral and magnetic characterization,[3,4] comparatively few crystal structures of nickel(II) and copper(II) thiosemicarbazones have, as yet, been determined. Ferrari *et al.* reported the crystal structure of 3-hydroxy-5-hydroxymethyl-4-formyl-2-picoline thiosemicarbazone, H_2Pictsc, as well as the copper(II) complex, $[Cu(HPictsc)H_2O]Cl \cdot H_2O$, derived from aqueous copper(II) chloride.[5] Bell and Theocharis[6] and Muller *et al.*[7] both reported the crystal structure of the dimeric copper(II) complex derived from 2-formylpyridine thiosemicarbazone and copper(II) acetate. Ainscough *et al.* determined the crystal structure of a monomeric copper(II) complex formed from this dimeric copper(II) acetate complex and saccharin.[8] More recently this same group reported additional copper(II) complexes of 2-formylpyridine thiosemicarbazone.[9]

Few crystal structures have been reported of complexes formed from 2-acetylpyridine ^{4}N-substituted thiosemicarbazones, which may possess more beneficial biological activity than their 2-formylpyridine analogues.[10] The structure of a

nickel(II) complex of 2-acetylpyridine azabicyclo [3.2.2]nonylthiosemicarbazone, [Ni(Lbcn)NCS], was reported a few years ago.[11] More recently, we have reported the molecular structure[12] of a copper(II) complex of 2-acetylpyridine hexamethyleneiminylthiosemicarbazone, HLhexim (Fig. 1), which is one of the more active growth inhibitory agents against *Aspergillus niger* and *Paecilomyces variotii*.[13] Also, a structural study of two nickel(II) complexes of acetylpyrazine N-substituted thiosemicarbazones has just been completed.[14] Here we report the nickel(II) complex of HLhexim, [Ni(Lhexim)Br] and the copper(II) complex of the related 2-acetylpyridine piperidinylthiosemicarbazone (Fig. 1), [Cu(Lpip)Br].

EXPERIMENTAL

HLpip and HLhexim were synthesized according to the method recently reported by Scovill.[15] [Ni(Lhexim)Br] and [Cu(Lpip)Br] were prepared in boiling ethanol and the antifungal studies were carried out as described previously[14] and the crystals were grown by slow evaporation of dimethyl sulphoxide solutions at 35°C. The crystals, a light brown prism of approximate dimensions $0.40 \times 0.30 \times 0.60$ mm for [Ni(Lhexim)Br] and an orange–brown prism of approximate dimensions $0.30 \times 0.15 \times 0.35$ mm for [Cu(Lpip)Br], were measured on a Siemens R3m/V Diffractometer using a 2θ range of 4 to 55°. The structures were solved with a Siemens SHELXTL PLUS (VMS) using direct methods. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included in structure factor calculations in their calculated positions. Refinement of the parameters was accomplished by full-matrix least-squares using a riding model for hydrogen atoms and converged with $R = 0.069$ and $R_w = 0.090$ for the 3782 observed reflections and $R = 0.085$ and $R_w = 0.092$ for the 5358 observed reflections [Ni(Lhexim)Br] and [Cu(Lpip)Br], respectively. The goodness-of-fits were 2.99 and 2.20. For a summary of crystal data, see Table 1.

RESULTS AND DISCUSSION

Interatomic distances and bond angles are compiled in Tables 2 and 3 for [Ni(Lhexim)Br] and [Cu(Lpip)Br], respectively. The supplementary material contains a list of the final positional and equivalent isotropic thermal parameters of the non-H atoms. H-atom coordinates and isotropic displacement coefficients are also included in the supplementary material as are the packing diagrams,

which show no indication of interaction between metal centres. Perspective views of [Ni(Lhexim)Br] and [Cu(Lpip)Br] are shown in Figs 2 and 3.

The anionic thiosemicarbazones each act as a tridentate ligand and coordinate to the central metal atom via the pyridyl nitrogen, N(1); the azomethine nitrogen, N(2); and the thiolato sulphur atom with the fourth coordination site occupied by a bromine atom in each compound, Figs 2 and 3. The hexamethyleneiminyl and pyridinyl rings are bent away from the remainder of the molecule. This is shown in the packing diagrams (Figs 4 and 5): the two

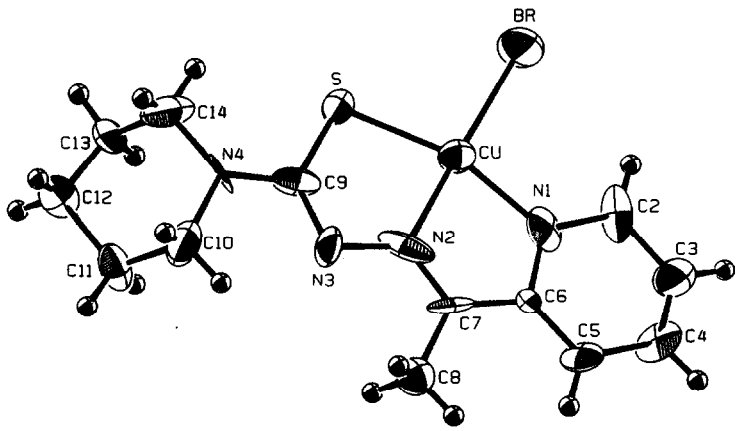

Fig. 3. Ortep diagram for [Cu(Lpip)Br].

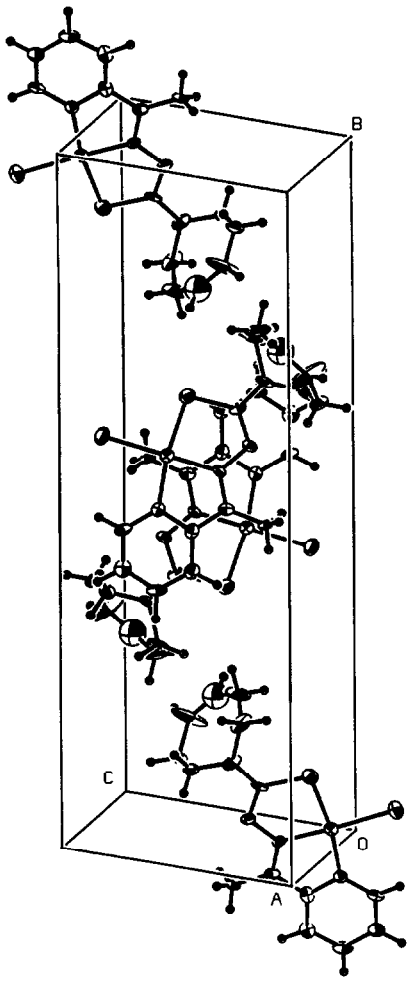

Fig. 4. Packing arrangement for [Ni(Lhexim)Br].

[Ni(Lhexim)Br] molecules in the centre of the cube are rotated 180° from each other to avoid steric interaction, while molecules on the corner have an eclipsed appearance. The bend out of the coordination plane is considerably less for the smaller piperidinyl group in [Cu(Lpip)Br], Fig. 3. For both complexes there seems to be minimal interaction between adjacent metal(II) centres via bromine or sulphur atoms.

In Table 4 is a comparison of the bond lengths for the thiosemicarbazone moiety for [Ni(Lhexim)Br] and [Cu(Lpip)Br] with previously studied copper(II) and nickel(II) thiosemicarbazone complexes. Most of the complexes, except those studied by West *et al.*[11,12,14] involve unsubstituted thiosemicarbazones with two hydrogens attached to ^{4}N in contrast to ^{4}N being a part of a ring. There is little difference in the bond lengths of C=^{2}N between the various thiosemicarbazone complexes although [Ni(Lhexim)Br] has the longest bond, and the nickel(II) complexes generally have longer C=^{2}N bonds than the copper(II) complexes. Comparatively, the 2-acetylpyridine azacyclothiosemicarbazone complexes have long ^{2}N—^{3}N bonds, short ^{3}N—^{9}C bonds, and long ^{9}C—S bonds. This is indicative of the coordinated ligand's greater conjugation and therefore, more delocalized electron density. It then follows that this coordinated ligand also possesses lower energy bonding acceptor orbitals (π^*) and has lower energy metal---→ligand charge transfer bands. [Ni(Lhexim)Br] and [Cu(Lpip)Br] have bands which can be assigned to thiosemicarbazone

moiety---→metal charge transfer bands as low as 20,620 and 22,520 cm^{-1}, respectively.[16,17]

Table 5 shows the metal(II)-donor atom bond lengths for the nickel(II) and copper(II) complexes of tridentate thiosemicarbazones; most have a heterocyclic nitrogen as the third donor atom. Although [Cu(Lhexim)Br] is comparable,[11] [Cu(Lpip)Br] has the shortest Cu—S bond indicating strong bonding of this donor atom. Further, it is the only copper(II) thiosemicarbazone that has a shorter pyridine Cu—N bond than azomethine Cu—N bond although the two bonds are similar in

length to the complexes of 2-formylpyridine thiosemicarbazone.[8,9] The Cu—Br bonds for [Cu(Lpip)Br] is shorter than that of [Cu (Lhexim)Br] which may be due to the reduced bulkiness of the 6-membered piperidinyl ring compared to the 7-membered hexamethyleneiminyl ring.[11]

The nickel(II) thiosemicarbazone complexes have significantly shorter metal–ligand bonds than the copper(II) complexes which is likely due to nickel's smaller number of *d*-electrons and vacant *d* orbital. Comparing [Ni(Lhexim)Br] with [Cu(Lhexim)Br] shows that the bond distances for the two harder donor atoms, the nitrogens, differ the most in the two complexes. This is likely due to the harder nickel(II) center forming stronger bonds with the hard nitrogen donors. Alternatively, back π-bonding of the copper(II) electron to empty *d* orbitals on the bromo and thiol donor atoms may provide some added strength to these ligand–copper(II) bonds. This is evidently not a factor in copper bonding to the pyridyl nitrogen.

A comparison of bond angles of the metal ligand bonds for various thiosemicarbazone complexes is shown in Table 6. The nickel(II) complexes have larger bond angles than the copper(II) complexes for each of the following: S—Cu—^{1}N, S—Cu—^{2}N and ^{1}N—C—^{2}N, which is consistent with the nickel–ligand bonds being shorter. The larger angles reduce interelectronic repulsion for these shorter bonds. Of the angles involving the bromo ligands in [Ni(Lhexim)Br] and [Cu(Lhexim)Br][11] only Br—Cu—S (97.4°) is significantly different from Br—Ni—S (91.6°), so that the only nickel(II) complex's bond angle which is smaller than the copper(II) complex's angle is the one between the two longest metal ligand bonds. Table 6 shows fairly consistent bond angles for the different thiosemicarbazones for both the copper(II) and nickel (II) complexes. Bond angles seem to be less useful in identifying aspects of a complex that would indicate biological activity.

The greater biological activity of copper(II) thiosemicarbazones compared to the uncomplexed ligands, Table 7, is likely due to the extent of conjugation of the coordinated thiosemicarbazone anion. Since the copper(II) complex is more active against both fungi than the analogous nickel(II) complex, which has comparable activity to the uncomplexed ligand, it is likely that the ease of reduction of copper(II) is also significant. Electrochemical studies[20] have shown that the best antifungal agents in this series of compounds are those which have the lowest reduction potential for the copper(II) and for the coordinated thiosemicarbazone. The voltage vs Ag/AgCl for the reduction of the copper(II) in both complexes is -0.425 and for the coordinated thiosemicarbazone -1.225 V and -1.275 V for [Cu(Lpip)Cl] and [Cu(Lhexim)Cl], respectively.[20] Spectroscopic studies[13] indicate that the effectiveness of fungal growth inhibition of these thiosemicarbazone complexes is inversely related to the magnitude of $g_\parallel$ (i.e. inhibition increases with increasing covalency of ligand bonding). The room temperature powder $g_\parallel$ values are 2.159 and 2.145 for [Cu(Lpip)

Cl][17] and [Cu(Lhexim)Cl],[16] respectively, and they are among the lowest for thiosemicarbazone complexes having the general formula (Cu(NNS)Cl]. A further indication of biological activity from this paper study appears to be the short $^{3}N—^{9}C$, long $^{9}C—S$, long $^{9}C—^{4}N$ and short Cu—S bond lengths for [Cu(Lpip)Br] and [Cu(Lhexim)Br] since these two compounds are among the most active antifungal agents of the more than 50 copper thiosemicarbazone complexes tested in this laboratory to date. All are related to the strength of coordination of the thiol sulphur. Further, a copper(II) complex with its weaker metal–ligand bonding compared to the analogous nickel(II) complex would be a stronger Lewis acid, which may be important to the biological activity. For example, the copper(II) complex, through its Lewis acidity, may be able to place the ligand in close proximity to the site of the thiosemicarbazone's inhibitory action against ribonucleotide reductase.[21]

(*Received* 20 *April* 1993 ; *accepted* 8 *June* 1993)

Abstract—The crystal structure of triamterinium tetrachlorocuprate(II), $(C_{12}H_{13}N_7)CuCl_4$, was determined by X-ray diffraction. The crystals are monoclinic, $P2_1/n$, with $a = 13.959(3)$, $b = 7.118(2)$, $c = 17.280(5)$ Å, $\beta = 99.99(2)°$, $V = 1690.9(9)$ Å^3 and $Z = 4$. A final R value of 0.031 was obtained. The structure consists of the $[CuCl_4]^{2-}$ anion and a triamterinium diprotonated cation. The $[CuCl_4]^{2-}$ anion shows a flattened tetrahedral geometry, the two larger Cl—Cu—Cl angles being 133.83 and 143.71°; the dihedral angle is 31.13°. The Cu—Cl distances range from 2.23 to 2.29 Å. The spectroscopic and magnetic results of $[CuCl_4]^{2-}$ and $[CuBr_4]^{2-}$ are in agreement with a high distortion of these ions from the tetrahedral configuration. According to the sites of protonation of the triamterene, the best donor atoms are the endocyclic N(3) and N(8) atoms.

Natural pteridine derivatives such as folic acid and biopterin are important co-factors in biological redox reactions.[1] Pteridines are fused-ring nitrogen heterocyclic compounds that function as co-factors for enzymes involved in hydroxylation[2] and methyl transfer[3] and as redox mediators. Variation of the substituents of the core of the folates has provided a synthetic anticancer drug, methotrexate.[4,5] At this time, two pterin co-factors are known for enzymes that also require a metal for a catalytic activity. Since pterins as co-factors in biological redox reactions are thus associated with metal ions and contribute to electron transfer in biological processes, information on pterin–metal interactions may give clues to the roles of metal ions in the utilization of dioxygen and concomitant electron transfer in relevant enzymatic reactions.

From the pteridine derivatives we have chosen triamterene(triam) (2,4,7-triamino-6-*o*-tolylpteridine ; Fig. 1), which is a potassium retaining diuretic which is widely used in the therapy of hypertension, mainly to prevent the K^+ losses which are caused by stronger natriuretic compounds like thiazides or loop diuretics.[6]

The structure activity relationship of the pteridine diuretics may be rationalized by assuming that the pteridines bind to some active sites at two points. The more important site involves a basic centre which in triamterene may be the N(1) and N(8) atoms. The other site probably involves the

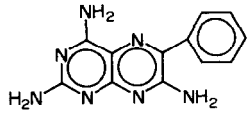

Fig. 1. Triamterene.

† Author to whom correspondence should be addressed.

phenyl substituent of triamterene and may be hydrophobic in nature.[7]

Triamterene has several nitrogen atoms which can behave as donors with metallic ions. The basic centre may be modified by the interaction of the metallic ions and these can increase or diminish the therapeutic activity of the drug. Another important point is that the complex formation can increase the solubility of these insoluble compounds.

Various recent reports exist in the literature for metal interactions with pteridine derivatives,[8–13] but the synthesis and characterization of metal–triam complexes have not yet been reported. On the other hand, there is great interest in the tetrahalocuprates(II) due to the fact that they show a high variety of coordination numbers and geometries[14–17] and, in some cases, a discontinuous reversible thermochromic behaviour.

We have initiated the synthesis and characterization of metal–triam complexes ; in this paper we report the first instance of metal compounds of triam, including the crystal structure of the triamterinium tetrachlorocuprate.

EXPERIMENTAL

Triam was kindly supplied as a powder material by Almirall Laboratories. All reagents used were of analytical grade. Due to the insolubility of triam, the complex formation reactions were investigated in acid media.

Synthesis of $[H_2triam][CuCl_4]$

Solid triam (1 mmol) was dissolved in concentrated HCl (25 cm^3) (35%) with continuous stirring by heating at 35°C. $CuCl_2 \cdot 2H_2O$ (3 mmol) was then added. When the mixture was stirred for *ca* 5 min, an orange microcrystalline precipitate appeared. The solid was collected by filtration and washed with benzene. After a few days single crystals, which were suitable for X-ray diffraction, were obtained in the filtrate. Yield : 68%. Found : C, 32.0 ; H, 3.1 ; N, 21.8 ; Cl, 29.3 ; Cu, 13.6. Calc. for $[H_2triam][CuCl_4]$: C, 31.3 ; H, 2.8 ; N, 21.3 ; Cl, 30.8 ; Cu, 13.8%.

Synthesis of $[H_2triam][CuBr_4]$

To a bromohydric solution of triam [1 mmol in 50 cm^3 of concentrated HBr (48%)] was added $CuBr_2$ (3 mmol) with continuous stirring. From the purple solution a microcrystalline solid precipitated. The precipitate was filtered, washed with benzene and dried at 70°C to constant weight. Yield : 45%. Found : C, 22.8 ; H, 1.9 ; N, 16.2 ; Cu, 10.0. Calc. for $[H_2triam][CuBr_4]$: C, 22.6 ; H, 2.0 ; N, 15.4 ; Cu, 9.9%.

Analyses were performed by elemental analyses for C, H and N and by AAS for copper.

Physical measurements

IR spectra of KBr/CsI pellets were recorded on a Perkin–Elmer 843 instrument. Electronic spectra in the UV–vis range were obtained with a Perkin–Elmer Lambda 15 spectrophotometer. Electronic spectra in the NIR region were registered with a Perkin–Elmer Lambda 9 spectrophotometer. EPR spectra of polycrystalline samples were recorded at *X*-band frequencies with a Bruker ER 200D spectrometer equipped with a liquid nitrogen continuous flow cryostat. Magnetic susceptibility data were collected on powdered samples for the compounds with the use of a Faraday-type magnetometer fitted with a liquid nitrogen continuous flow cryostat. Mercury tetrakis(thiocyanato) cobaltate was used as a susceptibility standard. All data were corrected for diamagnetism with the appropriate Pascal constants.

X-ray powder diffraction patterns were obtained through a Kristalloflex 810 Siemens diffractometer using Cu-K_α radiation.

Crystallographic data collection

Red crystal, size 0.43 × 0.26 × 0.13 mm. Throughout the experimental Mo-K_α radiation was used with a graphite crystal monochromator on an Enraf–Nonius CAD-4 single-crystal diffractometer ($\lambda = 0.71073$ Å). The unit cell dimensions were determined from the angular settings of 25 reflections with θ between 14 and 19°. The space group was determined to be $P2_1/n$ from the systematic absences. The intensity data of 3482 reflections, in the *hkl* range (16, 8, 20) to (0, 0, −20) and θ limits ($0 < \theta < 25°$) were measured using the ω–2θ scan technique and a variable scan rate with a maximum scan time of 60 s per reflection. The intensity of the primary beam was checked throughout the data collection by monitoring three standard reflections every 60 min. The final drift correction factors were between 1.01 and 0.99. On all reflections profile analysis was performed ;[18,19] an empirical absorption correction was applied, using Ψ scans[20] μ(Mo-K_α) = 1.94 mm^{-1} (correction factors were in the range 1.00–0.76). Symmetry equivalent reflections were averaged, $R_{int} = \Sigma(I - \langle I \rangle)/\Sigma I = 0.020$, resulting in 2967 unique reflections, of which only 2414 were observed with $I > 3\sigma(I)$. Lorentz and polarization corrections were applied and the data were reduced to $|F_o|$ values. The structure was solved by

Patterson interpretation using the program SHELXS86[21] and Fourier synthesis. Isotropic least-squares refinement, using SHELXS76,[22] converged to $R = 0.097$. At this stage an additional empirical absorption correction was applied,[23] resulting in a further decrease of R to 0.085. The maximum and minimum absorption correction factors were 1.28 and 0.88, respectively. Further anisotropic refinements followed by a difference-Fourier synthesis allowed the location of all the hydrogen atoms.

During the final stages of the refinement the positional parameters and the anisotropic thermal parameters of the non-hydrogen atoms were refined. All hydrogens were refined isotropically. The final conventional agreement factors were $R = 0.031$ and $wR = 0.031$ for the observed reflections and variables. The function minimized was $\Sigma w(F_o - F_c)^2$, $w = 1/[\sigma^2(F_o) + 0.00010F_o^2]$ with $\sigma(F_o)$ from counting statistics. The maximum shift-to-ESD ratio in the last full-matrix least-squares cycle was less than 0.1. The final difference-Fourier map showed no peaks higher than 0.35 e $Å^{-3}$ or deeper than -0.54 e $Å^{-3}$. Atomic scattering factors were taken from the International Tables for X-ray Crystallography (1974).[24] The plot was made with PLUTO.[25] Geometrical calculations were made with PARST.[26] All calculations were made on a MicroVAX-3400 at the Scientific Computer Center of the University of Oviedo.

RESULTS AND DISCUSSION

The X-ray powder patterns have been recorded showing that the triamterinium tetrahalocuprates are isomorphous.

Description of the $[H_2triam][CuCl_4]$ *crystal structure*

Molecular geometry data are collected in Table 1. The structure, which is shown in Fig. 2, together with the atomic numbering scheme, consists of one independent H_2triam^{2+} cation and one $CuCl_4^{2-}$ anion. In the anion there is a significant deviation

from both of the two ideal geometries, square planar and tetrahedral, so that the Cl—Cu—Cl angles around the metal atom are 143.71(5), 95.91(5), 98.42(5), 93.37(5), 100.10(6) and 133.83(5)°. The Cu—Cl bond lengths are, however, regular at 2.264(1), 2.289(1), 2.249(1) and 2.229(1) Å. Two of the Cu—Cl distances are longer owing to their extensive involvement in hydrogen bonding. Cl(1) is hydrogen bonded to H(N8), Cl(3) is hydrogen bonded to H(N2) and H(N4), Cl(2) is hydrogen bonded to H(N2) and H(N4) and Cl(4) is hydrogen bonded to H(N7) and H(N4), with Cl—H distances of 2.20, 2.40, 2.30 and 2.30, respectively.

In general terms the structure of the $CuCl_4^{2-}$ anion is sensitive to the nature of the cation. Thus, for small cations there is octahedral 4+2 coordination, but with large and non-spherical cations four-coordination, commensurate with a flattened tetrahedral geometry, is found, e.g. [N-(2-ammonioethyl)morpholinium][$CuCl_4$].[27] In a recent publication Halvorson *et al.*[14] have analysed over 60 crystal structure determinations containing the $CuCl_4^{2-}$ anion. Variations in angular deformations of the $CuCl_4^{2-}$ anions between these known structures have been examined from a plot of the *trans*-Cl—Cu—Cl angle against frequency of occurrence, which shows the majority of the structures contain *trans* angles between 125 and 145°. In general, hydrogen bonds tend to remove charge from the chlorine atoms. This reduces the electrostatic repulsions between the chlorine atoms and allows the $CuCl_4^{2-}$ ions to move towards a square planar geometry. Typically values range from 130° for large non-hydrogen bonding cations to 180° for those cations which can form extensive hydrogen bond interactions.

The deformation from the tetrahedral geometry can be expressed by the Cl(1)—Cu—Cl(4)—Cl(2)—Cu—Cl(3) = 31.13(4)° dihedral angle. This dihedral angle indicates a very strong distortion if we take into account that this angle is 90° for tetrahedral geometry and 0° for square planar.[28] The Cl---N interactions may explain the large distortion of the $[CuCl_4]^{2-}$ ion from the tetrahedral configuration.

With respect to the cation, the first aspect to be noted is that the protonation takes place in the endocyclic nitrogen N(3) and N(8) atoms.

Table 2 compares the bond distances and angles of the crystal structure of the triam[29] and the triamterinium cation observed in the structure of the $[H_2triam][CuCl_4]$ compound. We can appreciate an increase of double bond character in the C—NH_2 distances as a consequence of the higher electronic demand of the protonated contiguous endocyclic nitrogen atoms. Furthermore, the protonation increases the C—N—C bond angles (C—N—C 123° in the cation and 117.3°, 116.1° in the triam). Bond angles are less than 120° at the unprotonated N ring atoms.

The torsion angle C(2P)—C(1P)—C(6)—N(5) is 35.4(4)°, similar to that observed in the triamterene. This angle indicates the twist between the phenyl and fused rings and is related to the antifolate activity.[29]

Molecules are linked by an intricate and unusual

Table 2. Comparison of the bond distances of the triam and the triamterinium cation

	Triamterinium	Triam
N(1)—C(8A)	1.335(4)	1.360
C(2)—N(3)	1.376(4)	1.377
C(4)—N(4)	1.307(4)	1.350
C(4A)—N(5)	1.353(4)	1.354
N(5)—C(6)	1.317(4)	1.316
C(7)—N(7)	1.315(4)	1.355
N(8)—C(8A)	1.374(4)	1.358
N(1)—C(2)	1.335(4)	1.327
C(2)—N(2)	1.309(4)	1.351
N(3)—C(4)	1.355(4)	1.320
C(4)—C(4A)	1.427(4)	1.431
C(4A)—C(8A)	1.389(4)	1.398
C(6)—C(7)	1.462(4)	1.441
C(7)—N(8)	1.340(4)	1.338

network of hydrogen bonds (Table 3 and Fig. 3). It is noteworthy that the only intramolecular hydrogen bond in the triamterinium cation is formed by the N(4)—N(5) atoms, the opposite to that found in the triamterene where the stronger hydrogen bonds are formed by N(2) and the N(4) atom forms only one weak hydrogen bond. The cation and anion are linked by strong hydrogen bonding between Cl and the protonated N(3) and N(8) atoms.

As we have indicated the isomorphous character of the tetrabromocuprate complex permits us to suggest a similar distorted tetrahedron around the copper(II) ion.

IR and electronic spectra

The characterization data of the solids can readily be interpreted once the crystal structure is known.

The IR spectra of the dihydrohalide salts show a complex series of absorption bands at 3440–3200 and 2900–2650 cm^{-1}. The first group of bands corresponds to ν(N—H) vibrations and are shifted with respect to those of the ligand, probably due to the different hydrogen bonding arrangement shown in the crystal structures. The second region of bands can be attributed to N—H^+ stretching vibrations; the low frequencies observed is a consequence of the strong hydrogen bonding between the triamterinium cation and the CuX_4^{2-} anion.[28]

The far-IR spectrum of [H_2triam][$CuCl_4$] shows a new band with respect to the ligand at 300 cm^{-1}, which is assigned to a ν(Cu—Cl) vibrations.[28]

The solid reflectance electronic spectrum of [H_2triam][$CuCl_4$] shows two broad *d–d* transitions at 7460 and 10,720 cm^{-1}. The energies of the *d–d* bands are considerably higher than those normally found for flattened tetrahedra and may be explained by the greater distortion toward planarity, which increases the overall splitting of the *d*-orbital energy levels.[30]

Some attempts have been made to correlate

Symmetry code: (1) $-x+1/2, +y+1/2, -z-1/2$; (2) $+x, +y+1, +z$; (3) $-x, -y+1, -z$; (4) $+x-1/2, -y+1/2, +z-1/2$.

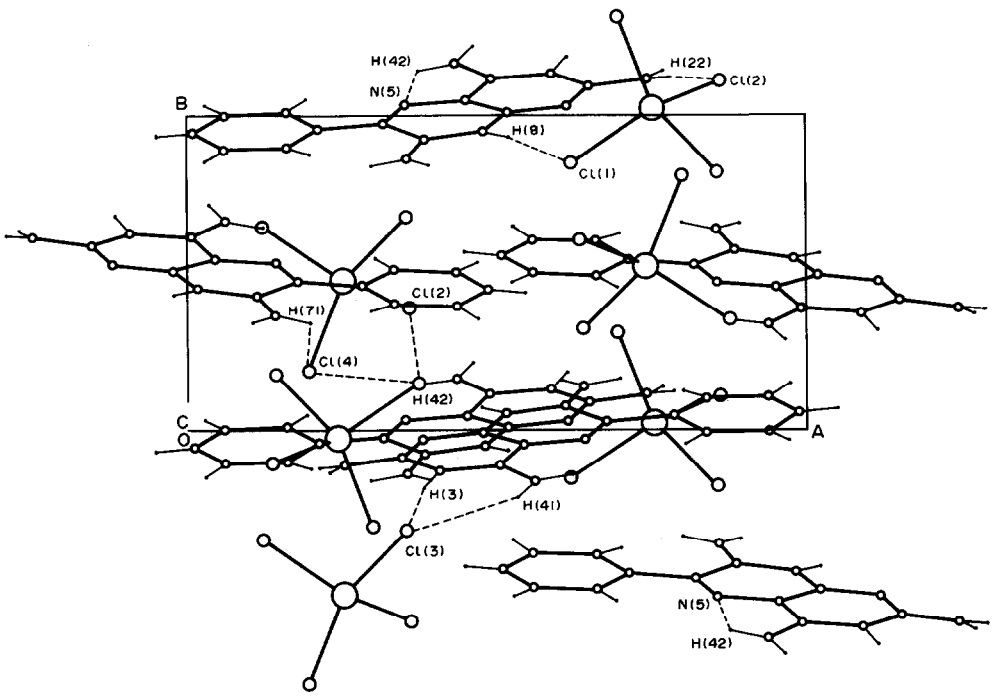

Fig. 3. A view of the molecular packing along the *z*-axis showing the hydrogen bonding network.

empirically the maximum of the *d–d* transition for several tetrachlorocuprate(II) salts with the amount of distortion from T_d symmetry determined from X-ray crystal structure studies. Battaglia *et al.*[28] correlated the maximum *d–d* spectra vs distortion expressed as the Cl—Cu—Cl dihedral angle. Halvorson *et al.*[14] in previously cited work compared the *d–d* electronic absorption energy with the average *trans* angle. If we represent the dihedral angle of $[H_2triam][CuCl_4]$ in the diagram of this work, the value of the maximum energy is 10,800 cm^{-1}, close to 10,720 cm^{-1} observed in the electronic spectrum.

The electronic spectrum of $[H_2triam][CuCl_4]$ also presents broad bands at 21,740, 25,190 and 38,460 cm^{-1} assigned to a $\pi a_2(N) \rightarrow b_2$ MLCT, $\pi \rightarrow \pi^*$(L—L) and $\sigma \rightarrow b_2$ MLCT.[31]

The UV–vis spectrum of $[H_2triam][CuBr_4]$ shows three bands in the visible region at 15,970, 18,830 and 23,580 cm^{-1}. These bands, according to the literature,[32,33] are associated with a ligand-to-metal charge-transfer transition, since the *d–d* transitions are expected in the near-IR region in the case of the $CuBr_4^{2-}$ chromophore.

The *d–d* transitions appear as a broad feature in the 5000–12,500 cm^{-1} region with several peaks. Using a simulation program with Gaussian line shape it was possible to identify all the *d–d* transitions of the $CuBr_4^{2-}$ ion. According to Willet *et al.*[17] the transitions at 10,750, 10,000, 7270 and 6100 cm^{-1} correspond to

$$^2A_{1(dxy)} \longrightarrow {}^2B_{2(dxz)}$$
$$\longrightarrow {}^2A_{2(dx^2-y^2)}$$
$$\longrightarrow {}^2B_{1(dyz)}$$
$$\longrightarrow {}^2A_{1(dz^2)}$$

in the splitting of the ^2E level in the D_{2d} symmetry into non-degenerate $^2B_1$ and $^2B_2$ levels in C_{2v} symmetry due to the orthorhombic distortion.

Magnetism and EPR spectra

The magnetic moment at room temperature of $[H_2triam][CuCl_4]$ is 1.72 B.M., similar to that obtained for other tetrachlorocuprates.[34]

Powder magnetic susceptibility measurements of $[H_2triam][CuBr_4]$ were made in the temperature range 75–300 K. From the plot of the μ_{eff} vs T it can be deduced that the magnetic interactions obey a Curie–Weiss dependence on temperature with $\theta = 24.4$ K.

Figure 4 shows the EPR spectrum of a finely ground powder sample of $[H_2triam][CuCl_4]$ at room temperature. It is an axial copper d^9 EPR spectrum with $g_\parallel = 2.38$ and $g_\perp = 2.09$. No hyperfine structure was observed; the absence of resolved hyperfine structure in the EPR has been attributed to a

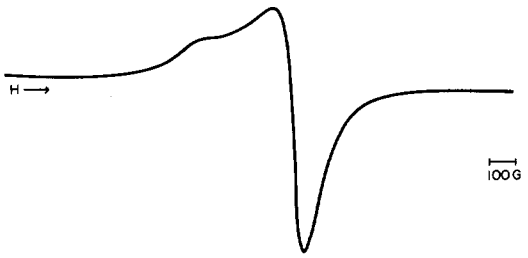

Fig. 4. EPR powder spectrum of $[H_2triam][CuCl_4]$.

strong admixture of the 4*p* state into $3d(t_2)$ orbitals of the copper ion.[35] Sharnoff[36] has reported the EPR spectra of the tetrachlorocuprate(II) ion with a tetrahedral geometry with similar *g* parameters to those found in the EPR of $[H_2triam][CuCl_4]$. Sharnoff has indicated that the values of *g* seem to be those of an octahedral copper(II) polyhedron, in spite of the fact that they are obtained from a distorted copper(II) tetrahedron. This is a result of the presence of the wave functions with a significant amount of central ion orbitals belonging to the 4*p* shell. The LCAO–MO analysis of Cs_2CuCl_4 shows that this orbital contains 70.3% 3*d* character, 11.7% 4*p* character and 18% ligand character. Battaglia *et al.*[37] compared the *g*-values of some tetrachlorocuprates(II) with the *trans* angle and suggest that the discrepancy may be due to that fact that the local pseudo-S_4 axes are not parallel to the tetragonal *c*-axis.

In summary, the resolution of the crystal structure and the study of spectroscopic properties of the tetrahalide salts permits us to identify the best donor atom [endocyclic N(3) and N(8)] of the drug and, as a consequence, to study its behaviour as a ligand.

Supplementary material

Final positional and thermal parameters, anisotropic thermal parameters, hydrogen-atom parameters, distances and angles involving hydrogen atoms, least-squares planes data, principal torsion angles and list of structure amplitudes have been deposited.

DINUCLEAR OXOVANADIUM(IV) COMPOUND WITH ALKOXYALCOHOL: SYNTHESIS AND STRUCTURAL STUDY OF $\{VOCl[OCH(CH_3)CH_2OCH_3]\}_2$

GISELE FOULON, JEAN-DOMINIQUE FOULON and NADINE HOVNANIAN*

Laboratoire de Physicochimie des Matériaux, URA 1312, ENSCM 8 rue Ecole Normale, 34053 Montpellier Cédex 1, France

(*Received* 21 *April* 1993; *accepted* 4 *June* 1993)

Abstract—The reaction between $VOCl_3$ and 3 equivalents of sodium 1-methoxy-2-propanoxide in a mixture of toluene/1-methoxy-2-propanol leads, after removal of the salt and crystallization of the concentrated filtrate, to a vanadium(IV) compound which has been characterized by the usual techniques (elemental analysis, IR, MS, EPR, ^1H and ^{51}V NMR) and X-ray diffraction as a dimeric five-coordinate oxovanadium(IV) chloride dialkoxide, $\{VOCl[OCH(CH_3)CH_2OCH_3]\}_2$. This compound can also be obtained from $VOCl_3$ with 1-methoxy-2-propanol in THF using ammonia gas. One of the two oxygen atoms from each methoxyalkoxo group bridges the vanadium centres yielding a planar V_2O_2 core. Surprisingly, a *cis* configuration around the V—O—V—O ring is adopted both by oxo groups and chlorine atoms.

Oxoalkoxovanadium complexes are attractive sources of molecular oxide precursors for sol–gel processes.[1] They can lead also to vanadium alkoxo compounds of high interest in catalytic and biological applications.[2]

A number of vanadium oxoalkoxides derived from primary, secondary and tertiary monoalcohols have been synthesized from V_2O_5, NH_4VO_3, $VOCl_3$ or by ester-exchange reactions[3]. Some of them have been structurally characterized as polymeric species such as $[VO(OMe)_3]_\infty$[4] or five-coordinate complexes such as $VO(OCH_2CH_2Cl)_3$[5] and $[VO(cyclo\text{-}C_5H_9O)_3]_2$[6]; the main character is that alkoxide ligands often act as bridging groups. The literature also mentions crystallographic data for derivatives with potential polydentate alcohols, particularly diols in dimeric or tetrameric associations. These polymerizations are achieved by two different bridging structural arrangements between the vanadium centre and the diols: either one of the oxygen atoms of each of the diol moieties bridges two vanadium centres[7] or each alkoxide oxygen atom is coordinated to only one metal atom.[8] Note that recently a hydrothermal synthesis based on polyols such as $CH_3C(CH_2OH)_3$ or $CH_3CH_2C(CH_2OH)_3$ yielded hexavanadium polyoxo alkoxide anion clusters.[9]

We have decided to study the reactivity of $VOCl_3$ towards alkoxyalcohols, since these derivatives are used as additives in sol–gel techniques, yielding multicomponent oxides, in order to avoid formation of heterogeneous media, to slow down hydrolysis rates and/or stabilize gels.[10] Alkoxyalcohols have proved to react easily with various transition metals, main group elements or lanthanides yielding stable and highly soluble alkoxide derivatives.[11]

In this paper we describe the synthesis, X-ray crystallographic characterization and spectroscopic study of $\{VOCl[OCH(CH_3)CH_2OCH_3]\}_2$, a five-coordinate oxovanadium (IV) chloride dialkoxide compound obtained from 1-methoxy-2-propanol.

EXPERIMENTAL

All manipulations were routinely performed under argon using Schlenk tubes and vacuum-line techniques with solvents purified by standard methods. $VOCl_3$ was used as received. ^1H and ^{51}V NMR and IR spectra were run on Bruker AC-250 and IR FT Nicolet ZDX spectrometers, respectively. $\delta(^{51}V)$ values are quoted relative to $VOCl_3$ and the

* Author to whom correspondence should be addressed.

spectra in non-deuterated solvents (parent alcohol) were recorded with external lock (D_2O). IR spectra were obtained as Nujol mulls between KBr plates. Mass spectra were recorded on a 300 DX JEOL by Electronic Impact. EPR spectra were recorded on a Bruker ER 200D spectrometer, operating at *X*-band with 100 KHz field modulation; the measurements were made on a solid sample at room temperature. Analytical data were obtained from the Centre de Microanalyses du CNRS.

Synthesis of $\{VOCl[OCH(CH_3)CH_2OCH_3]\}_2$ **(1)**

Pieces of sodium metal rods (1.52 g, 66 mmol) were slowly added under vigorous stirring to a solution of 1-methoxy-2-propanol (8 cm^3, 79.2 mmol) in toluene (15 cm^3). The solution was heated as the reaction slowed down. The mixture was stirred at room temperature overnight until all the sodium metal was consumed. The solution was then cooled at 0°C and vanadium oxytrichloride (2 cm^3, 21.2 mmol) was added dropwise under a slow argon flow. The reaction was exothermic and the colorless solution turned brown–red. The mixture was stirred for 12 h at room temperature and then filtered. After concentration the brown–red filtrate was left to crystallize at 5°C over a few days. Dark blue needle-shaped crystals were formed. Yield: 40% based on vanadium. Found: C, 25.2; H, 4.6; Cl, 17.9; V, 26.3. Calc. for $C_8H_{18}O_6Cl_2V_2$: C, 25.0; H, 4.7; Cl, 18.5; V, 26.6.%. IR (cm^{-1}): 1307, 1258, 1159, 1089, 1019, 962, 864, 801, 723, 674, 541, 462, 354. SM (*m/z*, EI), OR = $OCH(CH_3)CH_2OMe$: $[VOCl(OR)]_2$ (12%), $V_2O_2Cl(OR)_2$ (10%), $V_2OCl(OR)_2$ (7%), $VO_2Cl(OR)_2$ (13%), VO(OR) $Cl(CHCH_2OMe)$ (6%), VO(OR)$(CHCH_2OMe)$ (5%), VO(OR) (5%), $OMeCH_2CH(CH_3)$ (100%), $OMeCH_2$ (30%). ^1H NMR (CD_2Cl_2, ppm): 1.09 m (CH_3, 3H); 3.15 m–3.31 m (CH_2 and CH_3, 5H); 3.9 m (CH, 1H). ^{51}V NMR (1-methoxy-2-propanol, ppm): −573.1 (1); −573.9 (1).

Alternative synthesis of **1**

$VOCl_3$ (2 cm^3, 21 mmol) was added to THF (40 cm^3) immediately yielding a dark red solution. After addition of 1-methoxy-2-propanol (8 cm^3, 79.2 mmol) the dark red solution was stirred. Then ammonia gas was bubbled at intermittent intervals of 2–5 min until the white fog formed above the reaction mixture disappeared. The solution became bright orange, then orange–white. After removal of NH_4Cl by filtration the bright orange filtrate was concentrated and left to crystallize at 5°C. Dark blue crystals were formed.

Crystallographic studies

A suitable crystal of $\{VOCl[OCH(CH_3)CH_2OCH_3]\}_2$ was mounted onto a Siemens P3 automatic diffractometer. Unit cell parameters were obtained from least-squares fit to the automatically centred settings for 20 reflections. The crystal parameters and basic information related to data collection and structure refinement are summarized in Table 1. The profile fitting option of the XDISK program[12] was used during data reduction in order to correct 25% of decay. No correction for absorption was made. All calculations were performed on a VAX 3100. Complex neutral-atom scattering factors were employed. Anomalous dispersion terms were used. Positions for the vanadium and chlorine atoms were obtained from a Patterson syn-

thesis using SHELXS-86[13] and were confirmed by subsequent development of the structure. All remaining non-hydrogen atoms were found by successive electron density map calculations using SHELX 76.[14] Anisotropic temperature factors were introduced for all non-hydrogen atoms. Hydrogen atoms were placed in calculated positions (C—H = 1.08 Å) and were no further refined, but recalculated after each cycle. Positional parameters and anisotropic thermal parameters are given as supplementary material.

RESULTS AND DISCUSSION

The exothermic reaction of $VOCl_3$ with 3 equivalents of sodium 1-methoxy-2-propanoxide in a mixture of toluene/1-methoxy-2-propanol yielded a dark blue solid, $\{VOCl[OCH(CH_3)CH_2OCH_3]\}_2$ (**1**). This compound was also obtained by reaction between $VOCl_3$ and 1-methoxy-2-propanol in THF using ammonia gas. This compound crystallized from the concentrated reaction medium after removal of NaCl or NH_4Cl.

Despite the bubbling of NH_3 through the solution or the reaction with an alkali alkoxide, chloride ligands are still present and a reaction of reduction has occurred. Since solutions of light-sensitive vanadium(V) compounds when they are exposed to diffuse daylight or UV turn to light blue vanadium(IV) simultaneously with a black powder precipitate, we have carried out the syntheses in the dark and reproducible quantities of $\{VOClOCH(CH_3)CH_2OCH_3]\}_2$ were obtained. According to the literature no reduction products are formed by reaction of $VOCl_3$ with functionalized alcohols when methylene chloride is used as a solvent of reaction or of recrystallization.[15] However, some reduction reactions occurred when vanadium(III) and (IV) carboxylates were previously prepared from $VOCl_3$.[16]

$\{VOCl[OCH(CH_3)CH_2OCH_3]\}_2$ is soluble in polar organic solvents such as parent alcohol or DMSO and insoluble in pentane. Its dissolution in chlorinated solvents (CH_2Cl_2) or in toluene or THF is slow and results in a partially clear and blue solution. The oxidation degree of this oxovanadium chloride alkoxide correlates well with its colour, either in the solid state or in solution. Sol–gel investigations have shown us that in the presence of low or high water concentration, in the parent alcohol, compound **I** yields clear and limpid yellow or green solutions without any precipitation. These solutions become blue after many weeks. This observation (stability towards hydrolysis which seems to generate soluble materials) appears at first surprising, considering the known sensitivity of alkoxides towards water. The study of hydrolysis of this oxoalkoxide (by ^{51}V NMR and IR spectroscopies) is in progress.

In order to confirm the vanadium(IV) oxidation state assignment for the bulk sample of **1** an EPR spectrum of **1** was carried out. It consists of an intense and symmetric broad signal, showing a partially resolved hyperfine structure due to the coupling with the vanadium nucleus ($I = 7/2$; eight lines are distinguishable. The direct measurement of g from the EPR spectrum gives a value of 1.95, which is similar to those previously recorded for a number of oxovanadate(IV) complexes.[17]

IR spectroscopy for **1** is consistent with the formulation provided by the X-ray analysis; it exhibits in particular two bands at 1159 and 1089 cm^{-1} which can be assigned to ν(C—O—V) vibrations, while an intense band at 1019 cm^{-1} is attributed to ν(V=O). In the low energy range the peaks located at 674, 541, 462 and 354 cm^{-1} are typical of ν(V—OR) and ν(C—Cl) vibrations, respectively.

Despite the paramagnetism of compound **1**, a ^1H NMR spectrum reveals the characteristic chemical shifts of the alkoxide groups. Nevertheless, no structural information can be provided because of the broadening of the signals due to quadrupolar and paramagnetic effects. The ^{51}V NMR spectrum of **1** shows two very close signals at −573.1 and −573.9 ppm in a ratio 1:1, which reveals a non-absolute equivalence for the ^{51}V resonances. We note that the weak half-line width of these resonances (45 Hz) is not affected by paramagnetic effects. Due to the lack of ^{51}V NMR information about oxovanadium(IV) compounds,[18] conversely to oxovanadium(V) species, no comparison is possible.

The dimeric nature of the compound was first suggested by mass spectral data, which exhibit the parent molecular ion without any ion of higher molecular mass. It has been definitively confirmed by an X-ray structural study.

The X-ray crystal structure of **1** is shown in Fig. 1. Relevant bond lengths and angles are collected in Table 2. The complex consists of a dimeric unit in which the two independent $VOCl[OCH(CH_3)CH_2OCH_3]$ units are held together by the bridging μ_2-O(1) and μ_2-O(2) oxygen atoms. Although no crystallographic symmetry is imposed, a molecule of **1** exhibits an overall symmetry close to C_2, with the approximate C_2 axis passing through the midpoint of a line joining the vanadium atoms and perpendicular to the V—O—V—O plane. Thus, both oxo groups and chlorine atoms adopt a *cis* configuration around the V—O—V—O ring. Such a configuration is rather rare since the *trans* configuration is more often encountered as

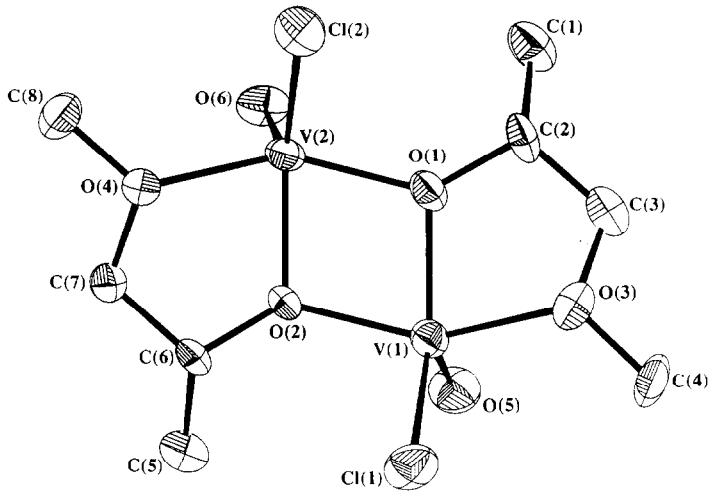

Fig. 1. ORTEP view of the $\{VOCl[OCH(CH_3)CH_2OCH_3]\}_2$ molecule, showing the atomic numbering scheme (thermal ellipsoids drawn at 40% probability level).

in the related vanadium(V) complex $\{VOCl[OC(CH_3)_2]_2\}_2$.[7a] Moreover, the C_2 symmetry of the molecule leads to a boat-like configuration, as evidenced by Fig. 2. This configuration tends to reduce the intramolecular interactions between the alkoxide ligand and both oxo group and chlorine atom. The vanadium atoms are five-coordinate, defining a distorted trigonal bipyramid. Actually, this environment can alternatively be described as a distorted square pyramid. Although important shifts between the ideal angle values and the observed ones are noticed in both descriptions, we tend to prefer the trigonal bipyramid model in the way that deviation from planarity (± 0.17 Å) of the square base in the pyramidal model appear to be consequent. Nevertheless, these two types of environment

are currently encountered in vanadium(IV) complexes.[16a,17a,19]

The V—O and V—Cl bond lengths fall in the range of values previously reported in the literature.[7a,7b,17a]. Worthy of mention is the V—μ_1—O bond length, which is significantly longer than the V—μ_2—O one [average 2.058(7) and 1.957(7) A°, respectively]. This is clearly explained by the fact that the μ_2-O atoms [O(1) and O(2)] are negatively charged, whereas the μ_1-O atoms of the methoxy groups [O(3) and O(4)] are uncharged, allowing a weaker $p\pi$–$d\pi$ donation. The value of the intermetallic distance [V(1)...V(2) = 3.084(3) Å] is in good agreement with the V...V distance observed in the related oxovanadium compounds.[7a,17a,20] At this distance a V—V bonding should not be expected and consequently, the two unpaired electrons should be mainly localized on one V=O unit.

The presence of remaining chloride ligands in complex **1** makes the metal atom functionalizable and may permit the introduction of a second metal (by reaction with a species such as $K[M(OR)_n]$ with salt elimination, for example). Further investigations towards the reactivity of **1** are in progress in this way.

Abstract—The reaction of $Mo(O)(NBu^t)(OSiMe_3)Cl$ or $Mo(O)(NBu^t)(OSiMe_3)_2$ with mesMgBr affords the imido complex $[Mo(NBu^t)(mes)_3(OSiMe_3)]$ (**2**); the crystal structure of **2** indicates that the imido and the siloxy ligands are linear, the Mo—N bond of 1.786(10) Å being one of the longest reported to date for a linear molybdenum imido group.

The chemistry of transition metal complexes possessing oxo or imido ligands has been investigated extensively[1] and is still of considerable current interest. In this research field we have been interested in the behaviour of dioxo and diimido molybdenum(VI) complexes with different small molecules such as phosphorus ylides, isocyanates, carbon monoxide and isocyanides.[2] In most cases the differences in reactivity between the dioxo and the diimido compounds are very important and were explained by the better π-donating properties of imido groups with respect to oxo ligands.[2d] Accordingly, we thought it could be interesting to prepare oxo-imido molybdenum(VI) complexes and to study their reactivity in comparison with that of their dioxo and diimido analogues.

Since the interaction of four equivalents of t-butyltrimethylsilylamine, $Bu^tN(SiMe_3)H$, with $Mo(O)_2Cl_2$ yields, almost quantitatively, $Mo(NBu^t)_2(OSiMe_3)_2$,[3] which upon treatment with mesMgBr (mes = 2,4,6-$C_6H_2Me_3$) affords $Mo(NBu^t)_2mes_2$,[4] we anticipated it might be possible to obtain $Mo(O)(NBu^t)mes_2$ via the following synthetic sequence:

$$Mo(O)_2Cl_2 + 2\,Bu^tN(SiMe_3)H \longrightarrow Mo(O)(NBu^t)(OSiMe_3)Cl + [SiMe_3NH_2Bu^t]^+Cl^-$$

$$Mo(O)(NBu^t)(OSiMe_3)Cl + 2\,mesMgBr \longrightarrow Mo(O)(NBu^t)mes_2 + MgBrCl + MgBrOSiMe_3.$$

In this paper we report on the reactivity of oxoimido molybdenum complexes with mesMgBr along with the X-ray crystal structure of $[Mo(NBu^t)(mes)_3(OSiMe_3)]$.

RESULTS AND DISCUSSION

When $Mo(O)_2Cl_2$ was reacted in hexane with 2 equivalents of $Bu^tN(SiMe_3)H$ a yellow solution was obtained after filtration of $[(SiMe_3)H_2NBu^t]^+Cl^-$. Evaporation of this solution afforded a yellow solid characterized by ^1H NMR as $Mo(O)(NBu^t)(OSiMe_3)Cl$ (**1**). It proved to be impossible to isolate this complex analytically pure owing to slow decomposition in solution into oligomeric species. Oligomer formation was supposed to occur by con-

densation of the $OSiMe_3$ groups to form an oxo bridge and 1 equivalent of $(Me_3Si)_2O$, as shown by the disappearance of the $OSiMe_3$ signal in the NMR spectra of the crystals isolated from solutions containing **1**.

Addition of 2 equivalents of mesMgBr (0.96 M in THF) to freshly prepared **1** dissolved in THF gave a brown–yellow solid after evaporation of the solvent. Crystallization of this solid in Et_2O-hexane afforded yellow crystals. The X-ray structure of this compound has been determined and the molecular structure is shown in Fig. 1 along with the atom numbering scheme. The main bond lengths and angles are given in Table 1. Contrary to our expectations it happened that it was not the hoped-for oxo-imido species, but a t-butylimido(trimesityl) (trimethylsiloxy)molybdenum(VI) complex, [Mo(NBu^t)(mes)$_3$(OSiMe$_3$)] (**2**).

The geometry about the molybdenum atom is a perfect trigonal bipyramid. The three mesityl groups lie in the basal plane of the bipyramid and are twisted with respect to this plane with a 33° angle, as can be seen from the N(1)—Mo—C(5)—C(6) torsional angle of 123°. The existence of a third-order symmetry axis shows that C(2)—N(1)—O(3) and Si are linear. The most striking features of the structure are the following. Although the triply bonded nature of the imido ligand can clearly be seen in the linearity of the Mo—N—C unit, the N(1)—Mo bond length of 1.786(10) Å is expected to be much shorter.[1c,5] It seems to be one of the longest known for a linear imido ligand bound to a high valent transition metal.[4,5] Such a distance of 1.786 Å would imply a Mo—N bond order somewhat smaller than 3.[1c,6] Another striking feature concerns the Mo—O(3) and Si—O(3) distances of 1.904(10) and 1.606(11) Å, the former being shorter and the second slightly longer than normal.[7] This observation provides a clear manifestation of strong oxygen $p\pi$–$d\pi$ donation. The considerable lengthening of the N(1)—Mo bond together with the unprecedented linearity of the Mo—O—Si angle might be due to steric interaction of the bulky mesityl groups with the metal centre. Indeed, short intramolecular contacts (< 2.4 Å) exist between hydrogen atoms of the tert-butyl and of the trimethylsilyl groups and the mesitylene methyl groups:

H(C15)---H(C13) 2.24 Å.

We observed also that whatever the amount of mesMgBr reacted with $Mo(O)(NBu^t)(OSiMe_3)Cl$ the only compound isolated was **2**. Furthermore, **2** could also be formed upon treatment of mesMgBr with freshly prepared $Mo(O)(NBu^t)(OSiMe_3)_2$ (**3**), obtained by reacting $Mo(NBu^t)_2(OSiMe_3)_2$ with 1 equivalent of H_2O and 1 equivalent of HCl as reported for the synthesis of $Cr(O)(NBu^t)(OSiMe_3)_2$.[8]

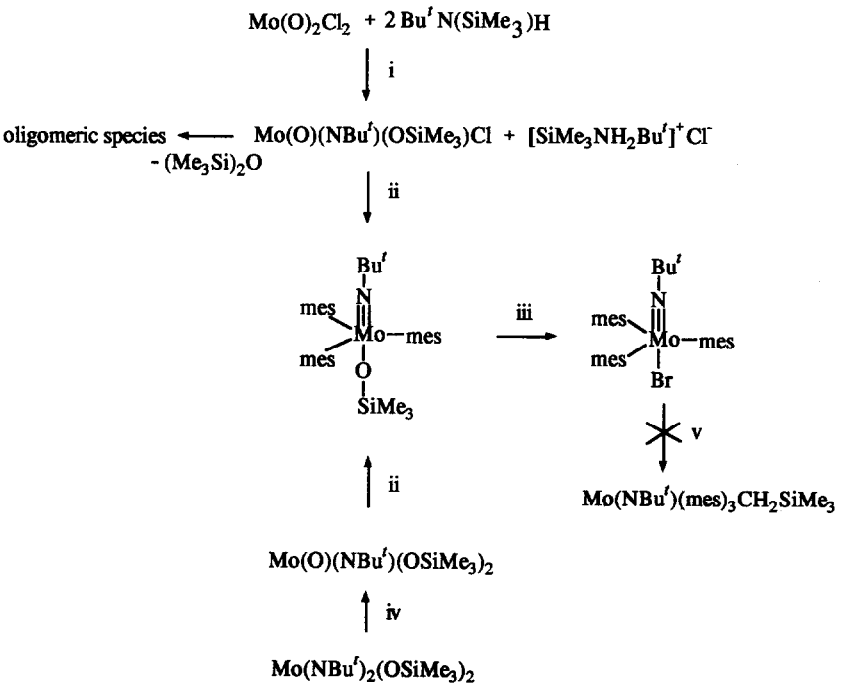
The observed reactivity of these oxo-imido complexes is unusual and, to our knowledge, such a behaviour has been reported only once.[9] Indeed, although alkylation of metal-oxo or further alkylation of oxoalkyls is a way to obtain metal alkyls[10] with the loss of the oxo group, in most cases the oxo group is notoriously inactive, particularly when halogeno or siloxo groups are attached to the metal.[11] Here, the presence of the imido seems to render the reactivity of the oxo groups different from other oxo complexes since, under very mild conditions, it is the oxo functionality which is alkylated rather than the $OSiMe_3$ group.

Substitution of the $OSiMe_3$ ligand was cleanly achieved by reacting **2** with $BrSiMe_3$, affording $Mo(NBu^t)(mes)_3Br$ (**4**) in good yields. However, upon treatment with Me_3SiCH_2MgCl, $Mo(NBu^t)(mes)_3Br$ was recovered unchanged (Scheme 1).

Complexes **2** and **4** appear to be rigid on the NMR time scale at room temperature. For both species, the three mesityl ligands are identical and the three methyls of each aromatic ring are magnetically different in the ^1H and ^{13}C NMR spectrum. The principal features which differentiate these two species are that in the ^1H NMR spectrum of **2** the aromatic protons resonate at the same frequency, whereas they appear at two different chemical shifts for **4**. On the other hand, the *ortho* quaternary carbon atoms of the mesityls are differentiated in the ^{13}C NMR spectrum of **2**, whereas they are not in the case of **4**. The ^{13}C NMR shift differences between the α- and β-carbons in the t-butyl groups of **2** and **4** were found to be 38.3 and 42.6, respectively, showing that π-donation from the nitrogen atom is slightly greater for the latter than for **2**.[1c]

EXPERIMENTAL

All reactions were carried out in an atmosphere of purified nitrogen using standard Schlenk techniques. Solvents were dried over and distilled from the sodium ketyl of benzophenone. Instruments: NMR, Bruker AM-200 and AM-400X; IR, FT-IR



Scheme 1. Synthesis and reactivity of $[Mo(NBu^t)(mes)_3OSiMe_3]$ (**2**). Reagents and conditions: (i) hexane, reflux, 0.5 h; (ii) mesMgBr, THF, −20–23°C, 10 h ; (iii) 1 equivalent of Me_3SiBr in Et_2O, room temperature; (iv) 1 equivalent of H_2O and 1 equivalent of HCl in Et_2O, −78°C; (v) Me_3SiCH_2MgCl, THF, −20–23°C.

Nicolet MX-S. $Mo(O)_2Cl_2$,[12] $Bu^tN(SiMe_3)H$[13] and $Mo(NBu^t)_2(OSiMe_3)_2$[3] were prepared as previously described.

(t-Butylimido)oxo(trimethylsiloxy)chloromolybdenum(VI) (**1**)

A suspension of $Mo(O)_2Cl_2$ (2 g, 10 mmol) in hexane (30 cm^3) was refluxed for 0.5 h in the presence of $NHBu^tSiMe_3$ (3.18 g, 20 mmol). After cooling the yellow solution was filtered, the solid residue was washed with hexane (15 cm^3) and the combined hexane extracts were pumped *in vacuo*, affording crude **1** as a yellow solid. Yield: 2.3 g (75%). NMR: ^1H ($CDCl_3$): δ 1.45 (9H, s, Bu^t), 0.18 (9H, s, $OSiMe_3$).

(t-Butylimido)oxobis(trimethylsiloxy)chloromolybdenum(VI) (**3**)

To a stirred solution of $Mo(NBu^t)_2(OSiMe_3)_2$ (0.49 g, 1.18 mmol) in Et_2O (30 cm^3) at $-78°C$ was successively added water (0.02 cm^3, 1.18 mmol) and ethereal HCl (5.9 cm^3, 0.2 M solution). The solution was allowed to warm to 25°C. Rapid filtration through a medium porosity frit and removal of solvent gave crude **3** as a yellow solid. Yield: 0.297 g, 70%. NMR: ^1H ($CDCl_3$): δ 1.34 (9H, s, Bu^t), 0.06 (18H, s, $OSiMe_3$).

(t-Butylimido)tris(mesityl)(trimethylsiloxy)molybdenum(VI) (**2**)

To a solution of $Mo(O)(NBu^t)(OSiMe_3)Cl$ freshly prepared (2.37 g, 7.7 mmol) in THF (30 cm^3) was added dropwise at $-20°C$ mesMgBr (26.6 cm^3, 0.87 M solution in THF). The yellow solution turned red and was stirred overnight at room temperature. Removal of solvent, extraction of the residue into hexane (3×25 cm^3), filtration and concentration of the orange–brown solution followed by cooling at $-20°C$ afforded yellow crystals of **2**. Yield: 1.19 g, 60%. NMR: ^1H ($CDCl_3$): δ 6.75 [6H, s, 2,4,6-$C_6H_2(CH_3)_3$], 2.46 [9H, s, *2*,4,6-$C_6H_2(CH_3)_3$], 2.31 [9H, s, 2,4,*6*-$C_6H_2(CH_3)_3$], 2.23 [9H, s, 2,*4*,6-$C_6H_2(CH_3)_3$], 1.36 (9H, s, Bu^t), -0.13 (9H, s, $OSiMe_3$). ^{13}C ($CDCl_3$): δ 179.3 (C *ipso*), 140.4, 139.3 (*2*,4,*6*-$C_6H_2CH_3$), 136.5 (2,*4*,6-$C_6H_2CH_3$), 128.9, 129.96 (CH arom), 67.1 [$C(CH_3)_3$], 28.7 [$C(CH_3)_3$], 26.8, 25.2 [*2*,4,*6*-$C_6H_2(CH_3)_3$], 20.9 [2,*4*,6-$C_6H_2(CH_3)_3$], 2.0 [$OSi(CH_3)_3$].

(t-Butylimido)tris(mesityl)bromomolybdenum(VI) (**4**)

To a stirred solution of $Mo(NBu^t)(mes)_3OSiMe_3$ (0.7 g, 1.14 mmol) in hexane (20 cm^3) was added Me_3SiBr (0.15 cm^3, 1.14 mmol) at room temperature. The colour of the solution changed to red

and then to green–brown. After stirring overnight, filtration and removal of the solvent afforded a solid residue, which was extracted into Et_2O (10 cm^3). Addition of hexane (5 cm^3) followed by cooling at −20°C gave yellow crystals of **4**. Yield: 0.3 g, 50%. NMR: ^1H ($CDCl_3$): δ 6.81, 6.76 [2 × 3H, s, 2,4,6-$C_6H_2(CH_3)_3$], 2.48, 2.42 [2 × 9H, s, 2,4,6-$C_6H_2(CH_3)_3$], 2.21 [9H, s, 2,4,6-$C_6H_2(CH_3)_3$], 1.40 (9H, s, Bu^t). ^{13}C ($CDCl_3$): δ 185.7 (C *ipso*), 138.7 (2,4,6-C_6H_2-CH_3), 138.0 (2,4,6-$C_6H_2CH_3$), 131.0, 129.1 (CH arom), 70.2 [$C(CH_3)_3$], 28.4, 26.7 [2,4,6-$C_6H_2(CH_3)_3$], 27.6 [$C(CH_3)_3$], 20.8 [2,4,6-$C_6H_2(CH_3)_3$].

X-ray crystallography

A parallelepiped crystal with dimensions 0.3 × 0.3 × 0.25 mm was used for data collection on a Huber four-circle diffractometer using graphite monochromatized Mo-K_α radiation. Lattice parameters were refined using 24 reflections in the range $4 \leqslant 2\theta \geqslant 27°$. A standard reflection (3 4 −1) was checked every 50 reflections, no significant deviation was observed. The structure was solved by direct methods using SHELXS86.[14] All non-hydrogen atoms were refined with anisotropic displacements factors coefficients (SHELX76[15]). Hydrogen atoms were included in idealized positions and were assigned a common refined temperature factor ($U = 0.14$ Å^2). Atomic scattering factors were calculated from data obtained from ref. 17. Crystal data for **2** are given in Table 2. A disordered mesitylene molecule, statistically distributed on two positions, appears around the symmetry element −3. The occupation factor corresponds to about 1/2 mesitylene for one molecule of complex.

Supplementary material (atomic coordinates, bond lengths and angles, and thermal parameters) have been deposited with the Editor at the Cambridge Crystallographic Data Centre.

(*Received* 7 *May* 1993; *accepted* 3 *June* 1993)

Abstract—Complexes of zinc(II) and cadmium(II) with 2-amino-2-deoxy-D-glycero-D-talo heptonic acid (HMa) and 2-(benzylamino)-2-deoxy-D-glycero-D-talo heptonic acid (BnMa) have been obtained. The complexes were characterized by elemental analysis, IR spectroscopy and X-ray powder diffraction. These complexes have a 1 : 2 metal-to-ligand ratio and an octahedral structure. Coordination occurs through the nitrogen atom of the amino group and oxygen atoms of the bridging carboxylate group. The thermal behaviour of the complexes has also been studied.

Studies of the interactions of carbohydrates and their derivatives with metal ions have increased during the last few years, mainly due to the possible importance of such interactions in a variety of industrial, pharmaceutical and biological processes.[1,2]

The ability of sugar derivatives to sequester metal ions can be utilized for the extraction of metals which are economically important and for the development of new classes of metal-based affinity catalysts. Furthermore, carbohydrates are often highly soluble in water and are usually only weakly immunogenic and of low toxicity. These properties are very useful in developing pharmaceutical agents for the removal of toxic metals or the uptake of essential metals.

Finally, the complexation of metal ions by several carbohydrates derivatives is of great interest in view of their biological role, particularly in the availability of nutrients to plants and in the regulation of the flow of metal ions across cell walls.[3]

It is worth noting that on introduction of a carboxy or amino group (or both) into a sugar molecule the complex-forming ability is enhanced by several orders of magnitude, even in acidic or neutral solution.[4–6]

Our interest in the coordination chemistry of carbohydrate α-amino acids[7–9] prompted us to prepare and characterize the zinc(II) and cadmium(II) complexes of 2-amino-2-deoxy-D-glycero-D-talo heptonic acid (HMa) and 2-(benzylamino)-2-deoxy-D-glycero-D-talo heptonic acid (BnMa) in order to investigate the mode of attachment of the ligand molecules to the metal ions. The ligands used in this study have the structure shown in Fig. 1.

EXPERIMENTAL

Preparation of the ligands and complexes

The ligands 2-amino-2-deoxy-D-glycero-D-talo heptonic acid (HMa) and 2-(benzylamino)-2-deoxy-D-glycero-D-talo heptonic acid (BnMa) were prepared according to the method of Galbis *et al.*[10]

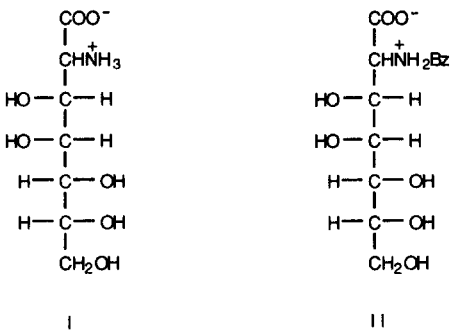

Fig. 1. Structural formulae of the ligands HMa (I) and BnMa (II).

and recrystallized twice from doubly-distilled water. All the remaining chemicals proved to be sufficiently reliable to be used without further purification.

The complexes were synthesized as follows: A freshly prepared aqueous solution of the metal nitrate was added to a hot aqueous solution of the ligand in the metal: ligand stoichiometric ratio of 1:2. The pH of the whole solution was then adjusted at a pH value lower than that of precipitation of the correspondent hydroxide, by dropwise addition of dilute NaOH. When the resulting solutions were stirred during the next few hours and they were either concentrated or cooled, microcrystalline solids were isolated.

All compounds were filtered off by suction, washed consecutively with water, ethanol and diethylether, air-dried and stored *in vacuo* over anhydrous $CaCl_2$

Apparatus and methods

Chemical analysis of carbon, hydrogen and nitrogen were performed by means of microanalytical methods using a Perkin–Elmer 240 microanalyser. The metal content was determined by thermogravimetry.

IR spectra were obtained from KBr pellets (4000–450 cm^{-1}) using a Perkin–Elmer FT-IR 1720 spectrophotometer.

Thermoanalytical data were obtained from TG, DTG and DSC curves. These were recorded on a Mettler TA-3000 system provided with a Mettler TG 50 thermobalance and a Mettler DSC 20 differential scanning calorimeter. The atmospheres used were air (flow = 200 cm^3 min^{-1}) or nitrogen (flow = 200 cm^3 min^{-1}, purity = 99.99% v.v.) for TG and DSC runs. The heating rate was 10°C min^{-1} and the weight of the samples was between 3 and 13 mg.

The X-ray powder diffraction patterns were obtained through a Philips PW-1700 diffractometer using Cu-K_α radiation.

RESULTS AND DISCUSSION

The analytical data and proposed formulae for the complexes are summarized in Table 1. Analyses for nitrate proved negative.

IR spectra

The bonding sites of the ligands that are involved in coordination with the metal ion have been examined by a careful comparison of the IR spectra of the free ligands and their complexes. Besides, the IR spectra of the complexes have been analysed, paying attention to the bands due to the carboxylate and amino groups. The position in the bands corresponding to the stretching vibrations of these groups can illustrate its coordination to the metal ions, because its energy depends on the degree of symmetry of these groups.

The IR spectra of HMa complexes are almost identical, showing their similarity in structure and the type of bonding present. Compared with the spectrum of the free ligand,[11] in the high frequency IR region they show an absorption centred at 3502 [zinc(II) complex] and 3504 cm^{-1} [cadmium(II) complex], which has been identified as being due to the stretching vibrations in hydroxyl groups with intramolecular hydrogen bonds. Besides, the absorption band observed for HMa at 3124 cm^{-1} assigned to the $\nu(NH_3^+)$ stretching vibration is absent in the spectra of the complexes, indicating that the amino group participates in the coordination.

On the other hand, the asymmetric COO^- stretching frequency (ν_{asym}) of the amino acids occurs at 1580–1660 cm^{-1} when the group is coordinated to metals, whereas, a non-coordinated COO^- group

$Cd(BnMa)_2 \cdot 2H_2O$	43.0	5.8	3.6	14.5
	(43.3)	(5.7)	(3.6)	(14.5)

has the $\nu_{asym}(COO^-)$ stretching at lower frequencies.[12,13] The bands at 1606 [zinc(II) complex] and 1587 cm^{-1} [cadmium(II) complex] therefore indicates that COO^- is also coordinating in the complexes.

The presence of the coordinated carboxylate group is supported by similar previous assignments[14] in the complexes of analogous α-amino acids with zinc(II) and cadmium(II), in which the amino group and one oxygen of the carboxylate moiety provide a chelate ring in the equatorial plane with carbonyl substituents at axial positions.

It is generally observed that the value of $\Delta\nu$ corresponding to $(\nu_{asym} - \nu_{sym})$ of the carboxylate group change in the order zinc(II) > cadmium(II). In our case the same occurs and thus the values are 185 and 178 cm^{-1} for the zinc(II) and cadmium(II) complexes, respectively. This could be explained on the basis that as the relation charge/ratio decreases for cadmium(II) with regard to zinc(II) the metal–oxygen bond [C—O···M] is weakened and C—O is strengthened and, consequently, $\Delta\nu$ decreases too.

With regard to the IR spectra data of the BnMa complexes with zinc(II) and cadmium(II) it is worth noting that the same criteria: (a) position of $\nu_{asym}(COO^-)$ stretching[15] and (b) $\Delta\nu$ difference between asymmetric and symmetric carboxylate stretching frequencies, are known in order to decide the coordination behaviour of the carboxylate group. On the basis of these criteria, the carboxylate group coordinates as a bridging bidentate ligand in both complexes. Likewise, coordination of the amino group is supported by the disappearance of the absorption band assigned to N—H bonding with respect to same band in the free ligand.

In this case the $\Delta\nu$ values are greater than those observed for HMa complexes. This behaviour is usual in N-protected amino acids with N-protecting groups showing an electron-withdrawing effect, because these groups reduce the basicity of the amino group. This implies a weakness of the nitrogen–metal bond and a concomitant increase in the strength of the oxygen–metal bond C—O···M, therefore, resulting in greater values.[16]

From these considerations it could be concluded that the coordination behaviour of BnMa in these compounds is the same as that of HMa.

Thermal study

The TG and DSC curves of complexes of the same ligand are very similar, which, having in mind the similar molecular structures, also suggests a similar thermal decomposition mechanism. Table 2

lists the most important features of these diagrams.

The TG curves of $ZnMa_2$ and $CdMa_2$ show an abrupt weight loss which starts at about 200°C and finishes at 300°C; this effect is accompanied by a sharp endothermic effect, at 257°C, clearly differentiated in the DSC plots of the complexes; the relative values of their energies suggest that such pyrolytic processes are similar. The combustion of the remaining sample, in the 300–500°C temperature range, yields the ZnO and CdO residues, respectively.

The thermal behaviour of the zinc(II) and cadmium(II) complexes with BnMa is very similar to that mentioned above for the HMa complexes. The first pyrolytic effect begins at approximately 70°C, finishing around 230°C; it is centred at 168°C for both complexes and with very similar energy. However, in the TG plots, especially in the one corresponding to cadmium(II), a shoulder of this first main effect can be observed that incorporates a weight loss of the order 4.7%, corresponding to the loss of two H_2O molecules.

At temperatures above this first effect, combustion of the sample takes place, finally giving the corresponding oxides that were characterized by IR spectroscopy and X-ray powder diffraction patterns.

X-ray diffraction

The X-ray powder patterns of $Zn(BnMa)_2 \cdot 2H_2O$ and $Cd(BnMa)_2 \cdot 2H_2O$ (Table 3) show that these compounds are isomorphous and crystallize in the monoclinic system. The systematic extinctions, $(0k0)$ absent for k = odd and $(h0l)$ for l = odd, indicate that the most probable space group is $P2_1/c$. The unit cell data were refined by a classical least-squares method, minimizing the $\Sigma(\sin^2\theta_0 - \sin^2\theta_c)^2$ expression. The refined parameters are: $a = 12.521(4)$, $b = 23.126(4)$, $c = 11.024(2)$ Å; $\beta = 89.23(3)°$; $V = 3192(1)$ Å^3 for $Zn(BnMa)_2 \cdot 2H_2O$; and $a = 12.474(3)$, $b = 23.687(5)$, $c = 11.032(2)$ Å; $\beta = 89.57(2)°$; $V = 3259(1)$ Å^3 for $Cd(BnMa)_2 \cdot 2H_2O$. The greater volume of the unit cell of $Cd(BnMa)_2 \cdot 2H_2O$ is consistent with the greater size of the cadmium(II) ion compared with the zinc(II) ion.

(*Received* 20 *April* 1993; *accepted* 3 *June* 1993)

Abstract—Improved preparations of the disecondary phosphines PhHP$(CH_2)_n$PHPh (n = 2, mppe; n = 3, mppp; n = 4, mppb; n = 6, mpph) by the lithium cleavage of the corresponding ditertiary phosphine $Ph_2P(CH_2)_nPPh_2$ are described and various NMR parameters are reported; a $^{12/13}C$ isotope effect upon $\delta(^{31}P)$ is observed in the case of mppe. Reactions of mppe and mppp with $[M(CO)_6]$ (M = Cr, Mo, W) yield 1:1 complexes; both the *meso* and the *rac* isomers are produced, are separated and are unequivocally characterized by elemental analysis, vibrational spectroscopy and ^1H, ^{13}C and ^{31}P NMR spectroscopy.

The ditertiary phosphines $Ph_2P(CH_2)_nPPh_2$ [e.g. dppm (n = 1) and dppe (n = 2)] have been used for many years as bidentate chelating ligands for a wide range of metal substrates,[1,2] but the relatively high symmetry of these ligands and their complexes limits the data readily available from their ^{31}P, ^{13}C and ^1H NMR spectra. Ligands of lower symmetry are therefore of considerable interest and, hitherto, RR′P$(CH_2)_n$PR′R and $R_2P(CH_2)_n$PR′R [R, R′ = H, alkyl, aryl] have been studied with this in mind.[3–22] Of particular potential value in this regard are the disecondary phosphines PhHP$(CH_2)_n$PHPh, both in view of the small size of the hydrogen substituent on phosphorus and the opportunities offered for further reactions, e.g. with BuLi or various unsaturated species. One published synthesis of mppe, [PhHP$(CH_2)_2$PHPh] (**1**), involves the preparation of Ph(Pr^{i}O)P(O)CH_2 CH_2(O)P(Pr^{i}O)Ph followed by its reduction with $LiAlH_4$ and is somewhat inconvenient,[10,11] although another route via the hydrolysis of $[(Li(thf)_2)_2(PhPCH_2CH_2PPh)]$ yielded 58% of the desired product.[24] A different procedure involving the reaction of either NaPPhH or KPPhH with the appropriate n-dihaloalkane has been used to prepare **1**[7] as well as mppp, [PhHP$(CH_2)_3$PHPh][4] (**2**), mppb, [PhHP$(CH_2)_4$PHPh][4] (**3**), and mpph, [PhHP$(CH_2)_6$PHPh][5] (**4**), but is somewhat cumbersome. An attractive alternative is the lithium cleavage of ditertiary phosphines, $Ph_2P(CH_2)_n$ PPh_2, to give PhLiP$(CH_2)_n$PLiPh, which can then be hydrolysed to the desired disecondary phosphine. Unfortunately, this reaction often yields substantial amounts of alternative products owing to cleavage of a P—CH_2 bond,[25–30] but we find that under suitable conditions the formation of these and the consequent Ph_2PH can be minimized. Thus, the reaction offers a convenient, high-yielding route to **1** and also to **2**, **3** and **4**.

* Author to whom correspondence should be addressed.

Although all of these ligands should form complexes with metal substrates, relatively little work has been reported in this area: the main results are for reactions of **1** with chalcogens,[7,10,31,32] methyl iodide,[7,10] nickel and cobalt halides[11] and the organoelement halides R_2ECl_2 and $RECl_2$.[14,33] Similar reactions of **2** have been studied[4,14,31-33] as well as its reactions with $Ni(CO)_4$, $C_7H_8Mo(CO)_4$ and $Mo(CO)_6$.[19]

We report here the improved syntheses of **1**, **2**, **3** and **4** and present their ^{31}P, ^{13}C and ^{1}H NMR parameters. Preparative, NMR and vibrational spectroscopic studies of the reactions between **1** and **2** and group VI transition metal hexacarbonyls are also reported and individual diastereomers (arising from the presence of the phosphorus chiral centres) of the complexes have been isolated as air-stable, microcrystalline solids.

RESULTS AND DISCUSSION

General

The reaction between a thf solution of dppe and metallic lithium was complete within *ca* 24 h at 300 K, but significant cleavage of P—CH_2 bonds occurred so that after hydrolysis substantial amounts (50%) of Ph_2PH were produced and the subsequent yield of the desired product [mppe, (**1**)] was low.[28] However, at 273 K the P—C bond cleavage was more selective and favoured the formation of $PhLiPCH_2CH_2PLiPh$ so that crude yields (^{31}P NMR evidence) of mppe in excess of 95% were achieved, although the reaction now took *ca* 200 h to complete.[28] With other α,ω-bis(diphenylphosphino)alkanes satisfactory yields of the desired disecondary phosphines [mppp, (**2**); mppb (**3**); mpph, (**4**)] were obtained when the cleavage reaction was conducted at 300 K or above and they were therefore complete more rapidly. For **1** and **2** ^{31}P NMR showed that 1:1 mixtures of diastereomeric products were obtained, but these were not separated; presumably **3** and **4** were also diastereomeric mixtures.

The 1:1 diastereomeric mixtures of mppe (**1**) and mppp (**2**) each reacted smoothly in refluxing $MeOCH_2CH_2OCH_2CH_2OMe$ with $M(CO)_6$ [M = Cr, Mo, W] to yield solutions containing the corresponding complexes $M(CO)_4L$ (**5**–**16**) in each case as diastereomeric pairs in the proportions shown in Table 1. For the mppe complexes it was possible to separate the individual *meso* and *rac* isomers in each case by fractional crystallization, and their melting points and analytical data are in Table 1. With mppp each of the diastereomers of the chromium complex was isolated, but only the *meso* forms were obtained pure for molybdenum and tungsten. Attempts to isolate the *rac* forms were thwarted by polymerization; this is consistent with a previous study of the mppp/$Mo(CO)_6$ system.[19]

Unequivocal identification of the *rac* and *meso* diastereomers was obtained from their ^{13}CO NMR spectra since the former yields a triplet (from the two equivalent axial CO groups) and an ABX multiplet (from the equatorial CO groups), whilst the latter gives *two* triplets (from the inequivalent axial CO groups) and an ABX multiplet.[34,35] Representative spectra are shown in Fig. 1. The formation of unequal proportions of the *rac* and *meso* diastereomers from a 1:1 mixture of the two diastereomers of the ligand indicates that inversion of phosphorus must occur at the reaction temperature (435 K).

NMR spectra

Tables 2 and 3 give ^{13}C, ^{31}P and selected ^{1}H data for the disecondaryphosphines **1**–**4**. For **3** and **4** the

centres of chirality are sufficiently far apart for no differences between pairs of diastereomers to be apparent; and for **2** $\delta(^{31}P)$ is the only parameter to show any differences. In the case of **1** there are small differences in the chemical shifts, but not in the coupling constants, and this presumably indicates that any conformational imbalances are relatively small as these molecules have no bulky substituents. Under conditions of broad-band proton decoupling the natural abundance ^{13}C spectra of these species are from ABX spin systems [A, B = ^{31}P, X = ^{13}C] and their appearance is therefore dependent upon J(AB), J(AX) and J(BX), as well as $\nu_0\delta$(AB), which arises from the $^{12/13}$C isotope effect upon $\delta(^{31}P)$. In the absence of this effect the spin system is AA′X and would yield a symmetrical five-line pattern for the X sub-spectrum; most such spectra have previously been analysed on this basis. However, for higher values of $B_0V_0\delta_{AB}$ becomes appreciable and this leads to a splitting of the central X resonance so that a six-line pattern is obtained. This is illustrated in Fig. 2 and provides a convenient and precise indirect method of measuring $^{12/13}$C isotope effects upon ^{31}P shieldings, although it does not yield their signs. There appear to be very few *direct* observations of this effect. For the *ipso*-phenyl carbons of **1** the effect is 0.017 ppm and is 0.02 ppm for the directly bonded backbone carbons.

Although the differences in $\delta(^{31}P)$ for the two diastereomers of **1** and **2** are of undoubted diagnostic value, it is not appropriate to comment in detail upon their origin. However, it is noteworthy that in the complexes of these two ligands (*vide infra*), where the two chiral centres are separated by only two chemical bonds, the differences are much larger (*ca* 3 ppm) and are of similar magnitude for both phosphines. Presumably these differences

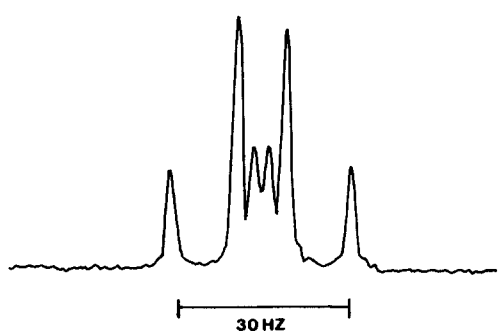

Fig. 2. ^{13}C NMR spectrum of the backbone region of the disecondary phosphine **1** at 50.3 MHz. Equal proportions of the two diastereomers were present, but this had no observable effect upon the spectra, the splitting of the central line being due to the $^{12/13}$C isotope effect upon $\delta(^{31}P)$.

would be retained in similar complexes of $PhHP(CH_2)_nPHPh$ no matter how large the value of n owing to the availability of the two-bond route via the metal atom.

The analysis of the ^{13}C spectra of the ligand parts of the complexes **5–16** proceeded as above and the results are summarized in Table 4. An important feature of this analysis is that it yields $^2J(^{31}P^{31}P)$ [ideally from the $^{13}C_{meta}$ resonances of the phenyl groups for which $^5J(^{31}P^{13}C)$ can be realistically taken as zero] and this then provides the key to the analysis of the carbonyl resonances. For axial carbonyls there are triplets resulting from coupling to the two ^{31}P nuclei and for the equatorial characteristic ABX patterns are obtained. Only in those cases for which the signal-to-noise ratio was sufficient to observe all lines of the X spectrum was it possible to obtain separate values of $^2J(^{31}P^{13}C_{cis})$ and $^2J(^{31}P^{13}C_{trans})$. Although we have previously observed $^{12/13}C$ isotope effects upon $\delta(^{31}P)$ in the carbonyl spectra of metal phosphine complexes[36] the dispersion in the present study was insufficient for this. In a combined NMR and X-ray diffraction study[34] of *meso*-$Ph_2PCHPhCHPhPPh_2Mo(CO)_4$, which has the same local symmetry at molybdenum as **7**, it was possible to make a reasonable assignment of the ^{13}C resonances of the two types of axial carbonyl group on the basis of their large (7.2 ppm) chemical shift difference and a comparison with $[Ph_2P(CH_2)_2PPh_2]Mo(CO)_4$.[35] In the present series the corresponding chemical shift differences are much smaller (*ca* 3 ppm or less) so that no comparable conclusions can be drawn, and the two types of carbonyl are simply styled ax and ax′, with ax being arbitrarily assigned the higher value of $\delta(^{13}C)$.

This study brings out the clear effects of relatively small changes in interbond and dihedral angles upon chemical shifts and particularly coupling constants, since differences in electronic effects should be insignificant between the pairs of diastereomers. In the diphosphines themselves the observed effects are small, presumably because the absence of bulky substituents leads to a high degree of conformational mobility and because the different conformers have approximately equal populations.

The coordination chemical shifts $\Delta\delta(^{31}P)$[37] for the complexes of mppe are less than for dppe[35] with both molybdenum and tungsten, but are more with chromium, whilst those for mppp complexes are greater than for dppp except in the case of the *rac*-$W(CO)_4$ derivative. Coordination chemical shifts in chelate complexes have significant components arising from "ring strain" and the extent to which this can be relieved by ring puckering. This in turn will be affected by the bulk of substituents and should be an easy process in complexes of mppe and mppp; that is the extent of ring strain should be least in these. In conformity with this the differences in various ^{13}C parameters [viz. $\delta(^{13}C)$ and $J(^{31}P^{13}C)$] between diastereomeric pairs are quite small for these complexes and the parameters themselves follow patterns similar to those found for complexes of dppe and dppp.[35] There are, however, interesting differences in certain proton parameters for the members of diastereomeric pairs of the mppe complexes. Specifically, there is a chemical shift difference of *ca* 1.4 ppm in $\delta(^1H)$ for the two types of CH_2 proton in the *rac* isomers, but of only *ca* 0.3 ppm for the *meso* isomers and these are paralleled by values of $^3J(^{31}PCC^1H)$ of *ca* 38 Hz for *one* type of proton in the *rac* isomers. These observations can be understood if account is taken of a high degree of chelate ring puckering, as has been determined for complexes of dppe[38] and $Ph_2PCHPhCHPhPPh_2$.[34] Figure 3 shows four idealized conformers for a $PhHP(CH_2)_2PHPhM(CO)_4$ complex: the two pairs (*a*) and (*b*), and (*c*) and (*d*) represent extremes of the *rac* and *meso* diastereomers, respectively. In the *rac* diastereomer the two conformers have either *both* Ph groups axial or *both* equatorial and will therefore differ in energy so that one form may predominate. Hence, protons A and A′ will be mainly equatorial and B and B′ mainly axial or *vice versa*. In the *meso* diastereomer the two conformers are of equal energy (each has *one* Ph group axial and *one* equatorial) and are thus equally populated; hence, the A,A′ and B,B′ protons will spend equal amounts of time in axial and equatorial positions; thus, the environments are partially averaged and the chemical shift difference is reduced. Also, in the latter diastereomer there will be a greater degree of averaging of dihedral angles relating P and CH_2 and hence smaller values of $^3J(^{31}P^1H)$. Interestingly, this behaviour is also found in the complexes of mppp, despite the presumably greater flexibility of the six-membered chelate ring.

Vibrational spectra

The vibrational characteristics of the dppe derivatives of group VI transition metal hexacarbonyls have previously been reported,[39,40] but no data appear to be available for the mppe homologues. In general, local C_{2v} symmetry in the *cis*-$L_2M[CO]_4$ species leads to four carbonyl stretching modes [$2A_1$, B_1, B_2], each being IR and Raman active. Selected vibrational frequencies for the mppe complexes (**5–10**) are presented in Table 5; the IR solution spectra (in CH_2Cl_2) were all similar with hardly any differences between the cor-

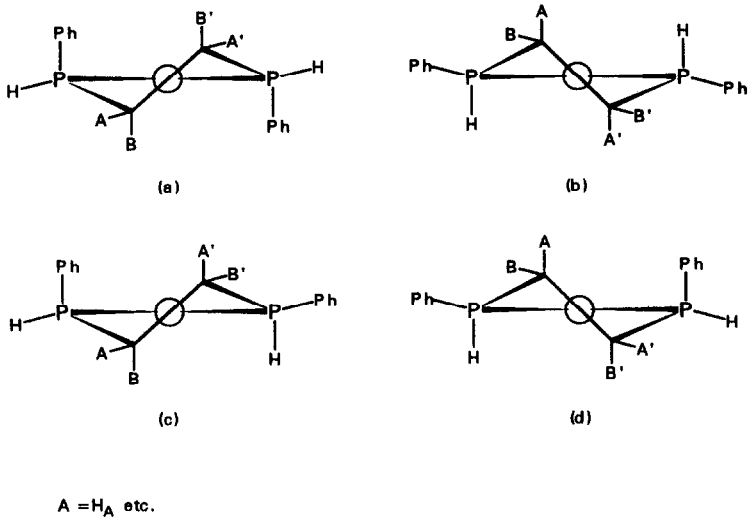

Fig. 3. Four idealized conformers of a $[PhHP(CH_2)_2PHPh]M(CO_4)$ complex: (a) and (b) represent two extremes of the *rac* diastereomer whilst (c) and (d) represent two extremes of the *meso* diastereomer.

responding *rac*/*meso* pairs. In all cases a higher frequency carbonyl band at *ca* 2010–2020 cm^{-1} was observed, together with a group of three overlapping lower frequency carbonyl bands in the 1850–1950 cm^{-1} region. However, the solid-state spectra show marked differences between corresponding *rac* and *meso* pairs in both the ν(CO) and ν(P—H) spectral regions. The carbonyl region spectra were still essentially four-band, but various splittings and shoulders were observed, presumably indicative of differing environments in the crystal. For the chromium complexes **5** (*meso*) and **6** (*rac*), a higher frequency carbonyl mode occurs at 2011 and 2009 cm^{-1}, respectively, in the Raman spectra. The *meso* isomer also has strong bands at 1903, 1899 and 1865 cm^{-1}; the first two of these overlap and are therefore not totally resolved. By contrast, the *rac* isomer (**6**) displays a strong, broad band at 1904 cm^{-1} with a higher frequency shoulder at 1921 cm^{-1}. Additional bands are present at 1881 and

(R) = Raman. × Indicates KBr discs; ° indicates CH_2Cl_2 solution.

1865 cm^{-1}; of these the latter is much less intense than the corresponding one in the spectrum of the *meso* complex. The KBr disc IR spectra of **5** and **6** display similar characteristics, although with much reduced resolution. The molybdenum and tungsten congeners behave similarly and show the same band patterns in both the solid-state IR and Raman spectra. Overall these data indicate that in the solid-state there is undoubtedly some distortion from idealized pseudo-octahedral geometry and there are probably interactions between the phenyl moieties and the equatorial carbonyl groups; such effects have been crystallographically determined for $Ph_2P(CH_2)_2PPh_2Mo(CO)_4$.[38] However, in solution such interactions are presumably much reduced; this would account for the striking similarities between the spectra of corresponding *meso*/*rac* pairs in CH_2Cl_2 solution.

EXPERIMENTAL

^{1}H, ^{13}C and ^{31}P NMR spectra were recorded at room temperature in CH_2Cl_2 solutions contained in either 5 or 10 mm o.d. spinning tubes at field strengths of 2.1 (Jeol FX 90Q), 4.7 (Bruker AC 200F), 7.1 (Bruker WF 300) and 11.8 (Bruker AMX 500) T.

IR spectra were recorded as solutions in CH_2Cl_2 or as KBr discs using either a Perkin–Elmer 1600 or a Nicolet 20 PC FTIR spectrometer. Raman spectra were recorded on solid samples sealed in glass capillaries using a Coderg PHO spectrometer with excitation provided at 514.5 nm by a Coherent Radiation Argon Ion Laser.

All solutions were deaerated prior to use and manipulations were performed under an atmosphere of dry dinitrogen.

1,2-*Bis*(*diphenylphosphino*)*ethane* (*dppe*) *and* 1,3-bis(*diphenylphosphino*)*propane* (*dppp*)

These were prepared by established procedures[3,35,41] involving the reaction of sodium diphenylphosphide and the appropriate dichloroalkane in liquid ammonia. Other α,ω-bis(diphenylphosphino)alkanes were synthesized similarly [yields $>70\%$].

1,2-*Bis*(*phenylphosphino*)*ethane* [*mppe*, (**1**)]

Dppe (70.3 g, 0.176 mol) and thinly cut lithium metal strips (4.9 g, 0.704 mol) were reacted in dry thf (700 cm^3); the mixture was stirred for *ca* 200 h at 273 K when ^{31}P NMR indicated total reaction of the starting diphosphine. To the deep red solution degassed water (250 cm^3) was added (cautiously at first) to hydrolyse the lithiated disecondary phosphine and to remove any dissolved salts. Diethyl ether was added and the organic layer was separated and dried over Na_2SO_4; after filtration, the solvent was removed by distillation. The resulting straw-coloured viscous liquid was distilled [140°C/0.2 mm Hg: literature 161°C/0.8 mm Hg[3,10]] to give a clear product (yield 85%) in which ^{31}P NMR indicated the presence of two diastereomers in a 1:1 ratio, although no separation was attempted.

1,3-*Bis*(*phenylphosphino*)*propane* [*mppe*, (**2**)], 1,4-bis(*phenylphosphino*)*butane* [*mppe*, (**3**)] *and* 1,6-bis(*phenylphosphino*)*hexane* [*mppe*, (**4**)]

These disecondary phosphines were prepared in a similar way to mppe (**1**) using the appropriate bis(diphenylphosphino)alkane; reactions were monitored to completion by ^{31}P NMR. For mppp (**2**), lithiation of dppp was completed within 24 h at room temperature and the product (77% yield) was isolated by distillation [190°C/4.0 mm Hg: literature 196°C/5 mm Hg[3,4]]. The two diastereomers observed by ^{31}P NMR were not separated. The lithiation of dppb to yield mppb (**3**) was effected by stirring at room temperature for 8 h followed by refluxing for 2 h to ensure complete reaction; the product was isolated in *ca* 75% yield by distillation [147°C/0.09 mm Hg; literature 208°C/4.0 mm Hg[3,4]]. Mpph (**4**) was prepared from lithiated dpph (reaction was complete within 8 h at room temperature) and isolated in 80% yield by distillation [165°C/0.05 mm Hg: literature 178°C/0.2 mm Hg[3,5]].

Reactions of mppe (**1**) *and mppe* (**2**) *with* M(CO)$_6$ [M = Cr, Mo, W]

The reactions of either mppe (**1**) or mppe (**2**) with M(CO)$_6$ were conducted in refluxing diglyme. Experimental details are presented in Table 1. After complete reaction (as monitored by ^{31}P NMR) the solvent was removed *in vacuo* and addition of MeOH followed by refrigeration yielded a first crop of crystals (*rac* isomer). Repeated evaporation and refrigeration yielded further crystals (*meso* isomer). Products were recrystallized from CH_2Cl_2/MeOH. From the reactions of mppp (**2**) with molybdenum and tungsten hexacarbonyls only one product—the *meso* isomer—could be isolated.

Acknowledgements—We thank the NAB, the Royal Society, the Leverhulme Trust and the SERC for financial support, the former City of London Polytechnic for facilities, Mr S. Richards and Dr P. N. Gates (Royal

Holloway and Bedford New College) for assistance with vibrational spectroscopy and Dr J. H. Carpenter for helpful comments.

(*Received* 12 *July* 1993; *accepted* 11 *August* 1993)

Abstract—Reaction of Ph(2-Pyr)NH with "$Mg(Bu)_2$", followed by addition of amine substrates, gives heteroleptic magnesium bis(amides), one of which, $[\{Mg[N(Ph)_2][N(Ph)(2\text{-}Pyr)]\}_2]$, has been crystallographically characterized and shown to be a dimer with a central, rectangular azamagnesacyclic ring.

Magnesium is generally regarded as having a "diagonal relationship" with lithium,[1,2] its diagonal neighbour in the periodic table, in view of the many chemical similarities between them. However, as yet, very little research has been done on the magnesium front to test the validity of this relationship, with respect to amides (derived from amines). Lithium amide reagents, epitomized by the hindered kinetic base lithium diisopropylamide (LDA),[3,4] are essential to the synthetic chemist's repertoire, and considerable attention has been paid to establishing their natures, both in solution (where they operate)[5] and in the solid state.[6,7] The chemical utility of magnesium amides has been largely unexplored by comparison, though bromo derivatives $[\{Mg[N(R)_2]Br\}_n]$ have been used to promote self-condensation of certain ethers,[8–10] and bis(amido) species $[\{Mg(NR^1R^2)_2\}_n]$ have been used to generate mono(amido)magnesium hydride stereoselective reducing agents.[11] Structural information on magnesium amides is commensurately scarce.[12] There is a particular dearth of reports concerning bis(amides). This stems in part from the failure of certain bis(alkyl)magnesium compounds to undergo two successive aminations;[13] instead reaction can cease after the initial amination step to give mono(amido)magnesium alkyls, $[Mg(NR^1R^2)R^3]$. Recently, however, it has been shown that such compositions are accessible *via* the hydrocarbon-soluble "dibutylmagnesium" (DBM),† though their structures were not investigated.[14] This reagent was previously shown to be a convenient starting material for generating other organomagnesium compounds including aryloxides and cyclopentadienyls.[15]

In a previous study,[16] we reported making the octahedral bis(amide) $[Mg\{N(Ph)(2\text{-}Pyr)\}_2\cdot(THF)_2]$, **1**, by a procedure expected to produce the mono(amido) analogue $[\{Mg[N(Ph)(2\text{-}Pyr)]Bu^n\}_n]$, **2** (Scheme 1). By comparison with tetrahedral

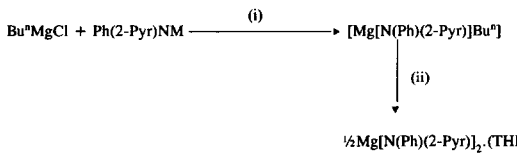
† Developed by the FMC corporation and commercially available from the Aldrich Chemical Co., Ltd. It is essentially $Mg(Bu^n)Bu^s$ with a small amount (typically, 5%) of *n*-octyl groups present. See refs 14 and 15 for more details.

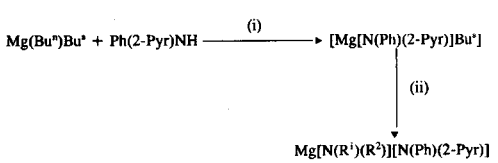


Scheme 1. (i) hexane, THF solvent, M = Li or Na, removal of LiCl or NaCl; (ii) $-1/2[Mg(Bu^n)_2\cdot(THF)_2]$.

$[\{Mg[N(CH_2CH_2NMe_2)CH_2Ph]Bu^n\}_2]$, **3**, made *via* the same Grignard reagent (Bu^nMgCl), we concluded that **1** resulted from the THF-induced disproportionation of the intermediate **2**, which is suspected to be a dimer ($n = 2$) akin to **3**, but with a more sterically exposed Mg centre, accessible to penetration by THF donor solvent molecules. In the belief that intermediates akin to **2** should be open to reaction with other molecules (besides THF), including amines, we substituted DBM for the Grignard reagent, so removing the need for THF, then reacted the resulting solution with different amines. This proved successful and led to the synthesis of hitherto rather elusive heteroleptic bis(amido) magnesium compounds, as reported herein. The crystal structure of a representative compound of this type, $[\{Mg[N(Ph)_2][N(Ph)(2\text{-}Pyr)]\}_2]$, **4**, is also revealed.

EXPERIMENTAL

The general synthetic approach is outlined in Scheme 2. Crystalline **4** was prepared specifically as follows. Freshly standardized dibutylmagnesium (5 mmol in heptane) was introduced to a Schlenk tube under argon gas containing a chilled mixture of the amine Ph(2-Pyr)NH (5 mmol) in hexane. A reaction occurred immediately with evolution of gas. At this stage, for kinetic reasons, the magnesium product is thought to be $[\{Mg[N(Ph)(2\text{-}Pyr)]Bu^s\}_n]$,[17] rather than its isomer $[\{Mg[N(Ph)(2\text{-}Pyr)]Bu^n\}_n]$. Addition of second amine, $(Ph)_2NH$ (5 mmol), caused further gas evolution and the precipitation of a brownish–green solid. The solvent mixture was then removed



Scheme 2. (i) hexane/heptane solvent, $-Bu^nH\uparrow$; (ii) R^1R^2NH (1 equivalent), R^1, R^2 = Ph, Me; $R^1 = PhCH_2$, $R^2 = Me_2NCH_2CH_2$. $-Bu^sH\uparrow$.

in vacuo and replaced with toluene, which on warming dissolved the solid. Allowing the solution to slowly reach ambient temperature by surrounding it with a water bath gave, after 18 h, a crop of yellow cubic crystals. These crystals were washed with toluene, dried *in vacuo*, isolated in a dry box, and identified as the new compound **4**. Yield of **4**, 82%; m.p. 217–218°C; (Found: C, 76.2; H, 5.6; Mg, 6.6; N, 11.2. Calc. for $C_{23}H_{19}MgN_3$: C, 76.4; H, 5.3; Mg, 6.6; N, 11.6%).

5: ^{1}H NMR (400 MHz in C6D6): 7.71 (*d*, 1H, α-H of Pyr); 7.35 (*t*, 2H, *m*-H of Ph); 7.27 (*d*, 2H, *o*-H of Ph); 7.03 (*m*, 1H/1H, γ-H of Pyr/*p*-H of Ph); 6.94 (*t*, 1H, β′-H of Pyr); 6.03 (*t*, 1H, β-H of Pyr); 1.84 (s, 6H, NMe_2). Yield, 4%; m.p. 125–127°C; (Found: C, 64.9; H, 6.0; Mg, 10.2; N, 18.8. Calc. for $C_{13}H_{15}MgN_3$: C, 65.7; H, 6.4; Mg, 10.2; N, 17.7%).

6: ^{1}H NMR (400 MHz in d^8-Toluene): 7.70 (*d*, 1H, α-H of Pyr); 7.57 (*d*, 2H, *o*′-H of Ph); 7.30 (*m*, 2H/2H, *o*-H, *m*-H of Ph); 7.21 (*t*, 2H, *m*′-H of Ph); 7.08 (*t*, 1H, *p*′-H of Ph); 7.00 (*m*, 1H/1H, *p*-H of Ph and γ-H of Pyr); 6.63 (*d*, 1H, β′-H of Pyr); 6.06 (*t*, 1H, β-H of Pyr); 4.27 (*s*, 2H, CH_2Ph); 2.70 (*m*, 2H, CH_2 of Et); 2.27 (*m*, 2H, CH_2 of Et); 1.75 (*s*, 6H, NMe_2). Yield, 5%; m.p. 141–143°C; (Found: C, 72.0; H, 6.9; Mg, 6.6; N, 15.0. Calc. for $C_{22}H_{26}MgN_4$: C, 71.3; H, 7.1; Mg, 6.6; N, 15.1%).

Due to their high solubility in hydrocarbon solvents compounds **5** and **6** were isolated in small yield as impure powders by crashing them out of solution at low temperature (−35°C). Further experiments are being carried out to attempt to prepare crystalline samples for X-ray analysis studies.

Crystallography

4: $C_{46}H_{38}Mg_2N_6$, $0.48\times0.42\times0.37$ mm, $M = 723.44$, monoclinic, space group $P2_1/n$, $a = 8.794(14)$, $b = 22.298(12)$, $c = 9.915(10)$ Å, $\beta = 99.16(11)°$, $U = 1919.4(38)$ Å^3, $Z = 2$, $D_c = 1.252$ g cm^{-3}, $\mu = 0.877$ mm^{-1} (Cu–K_α radiation, $\lambda = 1.54184$ Å), $F(000) = 760$; $R' = 0.2671$ for 245 parameters, including anisotropic displacement parameters for non-H atoms and isotropic displacement parameters for constrained H atoms, by refinement on F^2 from all 2818 measured unique data ($2\theta_{max}$ 120°) measured at 200 K on a Stoe–Siemens diffractometer; weighting scheme, $w = 1/[\sigma^2(F_o^2)+(0.15p)^2+1.48p]$ where $p = (F_o^2+2F_c^2)/3$; conventional $R = 0.0978$ for F values of 2385 reflections with $F_o^2 > 2\sigma(F_o^2)$.[18,19] The rather high R value is due to the highly air and moisture sensitive nature of the crystals.

Atomic coordinates, displacement parameters

and bond lengths and angles have been deposited with the Editor and the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

The centrosymmetric molecular structure of **4** in the solid state (Fig. 1) is dimeric. Its principal feature, a central, planar, four-membered azamagnesacyclic ring, is noteworthy for having perfect right-angled internal corners [90.0(2)°]. So far we are unable to explain why this is so. Related MgNMgN rings in other compounds tend to have angles straddling 90°, with the acute angle at N, e.g. in **2**, 87.6(1)° and 92.4(1)°;[16] in [{[*o*-$(Me_3Si)NC_6H_4(SiMe_3)N]Mg\cdot(OEt_2)\}_2$], 86.1(3)° and 93.9(3)°.[15] N atoms in this ring for **4** belong to the Ph_2N^- amido anions. These formally sp^3-hybridized atoms occupy four coordinate, distorted tetrahedral sites [mean bond angle at N(1), 108.9°]. Both sp^2-N atoms within the terminally attached Ph(2-Pyr)N$^-$ amido anions, in contrast, occupy three-coordinate, distorted trigonal planar sites [mean bond angles: N(2), 120.0°; N(3), 119.6°]. Approximately planar MgNCN rings are formed as a consequence of this bidentate chelation. The (amido)N atom interacts more efficiently with the Mg atom than does the (pyridyl)N atom, as evidenced by the wider C(1)N(3)Mg bond angle [93.7(3)° cf. 90.8(2)° for C(1)N(2)Mg] and the shorter Mg—N(3) bond length [2.025(5) Å cf. 2.107(5) Å for Mg—N(2)]. A similar pattern was previously noted in the structure of **1**,[16] though its MgNCN rings are significantly larger [corresponding bond angles, 94.9(1)° and 91.0(1)°, respectively: corresponding bond lengths, 2.105(2) Å and 2.182(2) Å, respectively] due to the higher coordination (six cf. four in **4**) of its Mg atom. Returning to the central MgNMgN ring of **4**, it is interesting that while the internal bond angles at Mg and N are equal as discussed earlier, the Mg—N μ-bonding is unsymmetrical with short edges of 2.080(5) Å [Mg—N(1)] and long edges of 2.119(5) Å [Mg—N(1′)]. This prompts the thought that the origin of the dimeric set-up lies in two monomeric moieties, which combine in a transoid arrangement with respect to its amido substituents with the new bonds formed being Mg—N(1′) and Mg′—N(1) (i.e. the long edges). These bonds may also be the first to cleave in reactions of this compound, giving coordinatively unsaturated, mononuclear Mg intermediates.

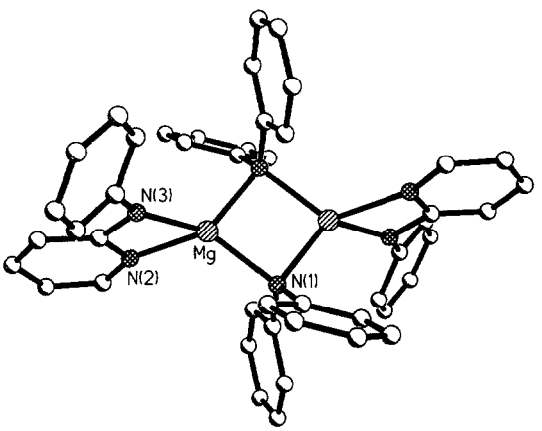


Fig. 1. A view of the structure of **4** with important atoms labelled and hydrogen atoms omitted for clarity. Selected bond lengths (Å) and angles (°): Mg—N(1) 2.080(5), Mg—N(1′) 2.119(5), Mg—N(2) 2.107(5), Mg—N(3) 2.025(5); N(1)—Mg—N(1′) 90.0(2), N(1)—Mg—N(2) 122.2(2), N(1)—Mg—N(3) 134.9(2), N(2)—Mg—N(3) 65.4(2), Mg—N(1)—Mg′ 90.0(2).

Two other heteroleptic bis(amido)magnesium solids were prepared following the synthetic procedure in Scheme 2: [{Mg[N(Me)$_2$][N(Ph)(2-Pyr)]}$_n$], **5** and [{Mg[N(CH$_2$CH$_2$NMe$_2$)CH$_2$Ph][N(Ph)(2-Pyr)]}$_n$], **6**. Produced by adding the amines Me_2NH and $PhCH_2(Me_2NCH_2CH_2)NH$, respectively, at the second stage of the process, both compounds were characterized by microanalysis and by ^{1}H NMR spectroscopy. Structural characterization of **5** and **6** are yet to be carried out. However, the former compound is probably analogous with **4**. The crystal structure of **6**, in contrast, is likely to be monomeric given that both of its amido ligands contain two N atoms, which collectively could saturate the Mg atom in a distorted tetrahedral geometry, obviating the need for aggregation.

THE SYNTHESIS OF $[HB[3,5\text{-}(Bu^tph)_2pz]_3]^-$ ($Bu^tph = p\text{-}C_6H_4Bu^t$), A NEW TRIS(PYRAZOLYL)HYDROBORATO LIGAND: THE CRYSTAL AND MOLECULAR STRUCTURE OF $Tl\{\eta^3\text{-}HB[3,5\text{-}(Bu^tph)_2pz]_3\}$

EMANUELA LIBERTINI,* KEUM YOON and GERARD PARKIN†

(*Received* 22 *June* 1993; *accepted* 6 *August* 1993)

Abstract—The synthesis of a new sterically demanding tris(pyrazolyl)hydroborato ligand, $[HB[3,5\text{-}(Bu^tph)_2pz]_3]^-$ (Bu^tph = *para*-$C_6H_4Bu^t$), is reported. The potassium derivative is prepared by the direct reaction of KBH_4 with 3,5-bis(*para*-tert-butylphenyl)pyrazole. Metathesis with $TlNO_3$ converts the potassium derivative to the thallium complex $Tl\{\eta^3\text{-}HB[3,5\text{-}(Bu^tph)_2pz]_3\}$. The crystal and molecular structures of the pyrazole derivative $[3,5\text{-}(Bu^tph)_2pz]_2ZnI_2$ and the thallium derivative $Tl\{\eta^3\text{-}HB[3,5\text{-}(Bu^tph)_2pz]_3\}$ have been determined.

Since the original report by Trofimenko in 1966,[1] the tris(pyrazolyl)hydroborato ligand system $[HB(3,5\text{-}RR'pz)_3]^-$ (RR'pz = substituted pyrazole), shown in Fig. 1, has found widespread applications.[2,3] Some recent developments have involved the incorporation of a variety of substituents into the 3-position of the tris(pyrazolyl)hydroborato ligand, thereby effectively tailoring the steric environment about a metal centre. For example, the cone angles of the tris(pyrazolyl)hydroborato ligands $[\eta^3\text{-}HB(pz)_3]^-$, $[\eta^3\text{-}HB(3,5\text{-}Me_2pz)_3]^-$ and $[\eta^3\text{-}HB(3\text{-}Bu^tpz)_3]^-$ have been estimated as 184, 224 and 244°, respectively.[4,5] Moreover, the incorporation of substituents such as trifluoromethyl, e.g. $[\eta^3\text{-}HB(3\text{-}CF_3\text{-}5\text{-}Mepz)_3]^-$, may also exert electronic influences.[1]

One of the most appealing attributes of sterically-demanding derivatives such as $[\eta^3\text{-}HB(3\text{-}Bu^tpz)_3]^-$ is that the bulky tert–butyl substituents in the 3-position of the pyrazolyl ring provide a ligand environment that strongly stabilizes four-coordination in preference to higher coordination numbers. Consequently, the ligand has been aptly termed a "tetrahedral enforcer", especially with regard to the first-row transition metals.[4a]

Our specific interest in tris(pyrazolyl)hydroborato ligands has focussed on the use of the sterically-demanding $[HB(3\text{-}Bu^tpz)_3]^-$ [4a] and $[HB(3\text{-}Bu^t\text{-}5\text{-}Mepz)_3]^-$ [6] ligands to stabilize a series of monomeric alkyl, hydride and hydroxide derivatives of the *s*- and *p*-block metals, e.g. Be,[7] Mg,[8] Al,[8a,9] Zn[10] and Cd.[11] Indeed, these ligands sta-

† Author to whom correspondence should be addressed.

bilize such derivatives to the extent that their reactivity may be reduced considerably from that observed in other systems. For example, the zinc alkyl derivatives $\{\eta^3\text{-HB(3-Bu}^t\text{pz)}_3\}\text{ZnR}$ are not particularly reactive towards O_2, whereas the dialkyls ZnR_2 are pyrophoric.[10a] In order to promote the reactivity of these systems we required a ligand that was less sterically-demanding than either of the ligands $[\text{HB(3-Bu}^t\text{pz)}_3]^-$ or $[\text{HB(3-Bu}^t\text{-5-Mepz)}_3]^-$. However, less sterically-demanding ligands such as $[\text{HB(3,5-Me}_2\text{pz)}_3]^-$ and $[\text{HB(3,5-Ph}_2\text{pz)}_3]^-$ suffer from the disadvantage that ligand redistribution (eq. 1) may often be facile, resulting in the formation of the corresponding six-coordinate sandwich complexes $\{\eta^3\text{-HB(3,5-R}_2\text{pz)}_3\}_2\text{M}$, such as $\{\eta^3\text{-HB(3,5-Me}_2\text{pz)}_3\}_2\text{Mg}$[12] and $\{\eta^3\text{-HB(3,5-Ph}_2\text{pz)}_3\}_2\text{M}$ (M = Mn, Fe).[13]

$$2\{\eta^3\text{-HB(3,5-R}_2\text{pz)}_3\}\text{MX} \longrightarrow \{\eta^3\text{-HB(3,5-R}_2\text{pz)}_3\}_2\text{M} + \text{MX}_2 \quad (1)$$

Moreover, even the neopentyl (Np) derivative $[\eta^3\text{-HB(3-Nppz)}_3]^-$ also forms a six-coordinate sandwich complex of nickel, $\{\eta^3\text{-HB(3-Nppz)}_3\}_2\text{Ni}$.[14] In this paper we report the synthesis of the $[\text{HB[3,5-(Bu}^t\text{ph)}_2\text{pz]}_3]^-$ (Bu^{t}ph = *para*-C_6H_4Bu^t) ligand which has been designed with the intentions that : (i) the *para*-tert-butyl substituents will be sufficient to inhibit the formation of six-coordinate $\{\eta^3\text{-HB[3,5-(Bu}^t\text{ph)}_2\text{pz]}_3\}_2\text{M}$ sandwich complexes; but yet (ii) the phenyl substituents in the immediate vicinity of the metal centre will provide a coordination environment that is less sterically-demanding than that of the tert-butyl derivative $[\text{HB(3-Bu}^t\text{pz)}_3]^-$.

Although we are interested primarily in controlling the coordination environment at the metal centre, i.e. the 3-position of the pyrazolyl group, the use of a symmetric 3,5-disubstituted pyrazole derivative offers several advantages : (i) substitution at the 5-position also provides a protective environment about the B–H group that will help prevent ligand degradation, (ii) monosubstituted and asymmetric 3,5-disubstituted pyrazoles may give mixtures of tris(pyrazolyl)hydroborato derivatives, depending upon the selectivity of the reaction with the inequivalent nitrogen centres of the pyrazole, and (iii) asymmmetric $\{\eta^3\text{-HB[3,5-RR'}_2\text{pz]}_3\}\text{MX}$ derivatives may rearrange in order to relieve steric congestion. For example, 3,5-Pr^{i}MepzH reacts with BH_4^- to give a mixture of isomers,[15] and $\{\eta^3\text{-HB(3-Nppz)}_3\}_2\text{Ni}$ rearranges to $\{\eta^3\text{-HB(3-Nppz)}_2\text{(3-Nppz)}\}_2\text{Ni}$ upon heating.[14] Clearly, such problems are avoided with the use of symmetric 3,5-disubstitued pyrazoles.

As with the synthesis of the tris(3,5-diphenylpyrazolyl)hydroborato ligand,[16] the starting material for the synthesis of $[\text{HB[3,5-(Bu}^t\text{ph)}_2\text{pz]}_3]^-$ is 3,5-bis(*para*-tert-butylphenyl)pyrazole. The pyrazole 3,5-(Bu^{t}ph)$_2$pzH* is readily obtained by the reaction of $N_2H_4\cdot(H_2O)$ with the diketone $[\text{(Bu}^t\text{ph)C(O)]}_2\text{CH}_2$† via a procedure analogous to that used for the unsubstituted derivative, 3,5-diphenylpyrazole.[16] 3,5-bis(*para*-tert-butylphenyl) pyrazole has also been characterized by X-ray diffraction as its adduct with ZnI_2, $[3,5\text{-(Bu}^t\text{ph)}_2\text{pzH}]_2\text{ZnI}_2$.‡ The molecular structure of $[3,5\text{-(Bu}^t\text{ph)}_2\text{pzH}]_2\text{ZnI}_2$ is shown in Fig. 2.§

The tris[3,5-(*para*-tert-butylphenyl)$_2$pyrazolyl]hydroborato ligand $[\text{HB[3,5-(Bu}^t\text{ph)}_2\text{pz]}_3]^-$ is readily obtained as the potassium derivative by the direct reaction of KBH_4 with 3,5-bis(*para*-tert-butylphenyl)pyrazole at *ca* 280°C (eq. 2).

$$KBH_4 + 3[3,5\text{-(Bu}^t\text{ph)}_2\text{pzH}] \longrightarrow K\{\text{HB[3,5-(Bu}^t\text{ph)}_2\text{pz]}_3\} + 3H_2 \quad (2)$$

In addition to potassium complexes, thallium derivatives are also useful reagents in the synthesis

---

*Data for 3,5-(Bu^{t}ph)$_2$pzH (m.p. 200–202°C). ^{1}H NMR (C_6D_6): *d* 1.18 [18H, s, 2C(CH$_3$)$_3$], 6.72 [1H, s, CH(pz)], 7.19 [4H, d, $^3J_{H\text{-}H}$ = 8.4, 4H of (*para*-C_6H_4Bu^t)$_2$], 7.74 [4H, d, $^3J_{H\text{-}H}$ = 8.4, 4H of (*para*-C_6H_4Bu^t)$_2$], 12.6 [1H, very broad, NH]. Found : C, 55.7; H, 5.6; N, 6.2. Calc. : C, 56.1 ; H, 5.7; N, 5.7%.

§Crystal data for $[3,5\text{-(Bu}^t\text{ph)}_2\text{pzH}]_2\text{ZnI}_2$ at room temperature : Monoclinic $P2_1/n$ (No. 14), a = 15.348(5), b = 14,577(4), c = 21.413(3) Å, β = 95.59(2)°, V = 4768(2) Å^3, Z = 4, R = 0.0488, R_w = 0.0543. A complete set of tables of crystal and intensity collection data, atomic coordinates, bond distances and angles, and anisotropic displacement parameters, and an ORTEP drawing have been deposited with the Editor as supplementary materials. The atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

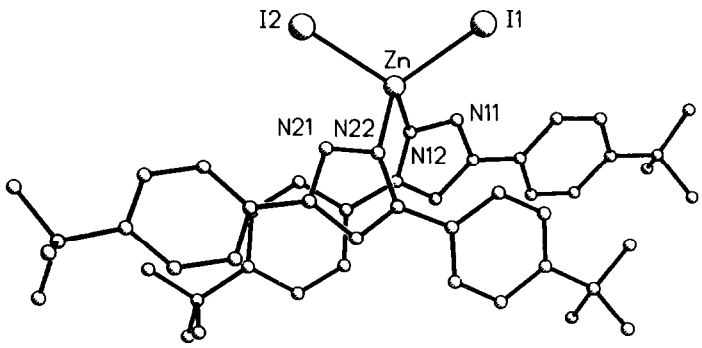

Fig. 2. The molecular structure of $[3,5\text{-}(Bu^t ph)_2pzH]_2ZnI_2$. Other atoms are not labelled for clarity. Selected bond lengths (Å) and angles (°): Zn—I(1) 2.567(2), Zn—I(2) 2.603(2), Zn—N(12) 2.062(7), Zn—N(22) 2.077(8); I(1)—Zn—I(2) 112.2(1), N(12)—Zn—N(22) 99.5(3), I(1)—Zn—N(12) 102.5(2), I(1)—Zn—N(22) 121.7(2), I(2)—Zn—N(12) 120.2(2), I(2)—Zn—N(22) 101.3(2).

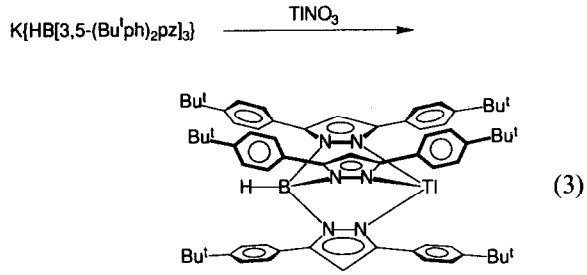
of tris(pyrazolyl)hydroborato complexes. Thus, the potassium derivative is readily converted to the thallium reagent $Tl\{\eta^3\text{-}HB[3,5\text{-}(Bu^t ph)_2pz]_3\}$‖ by metathesis with aqueous $TlNO_3$ (eq. 3).



(3)

The molecular structure of $Tl\{\eta^3\text{-}HB[3,5\text{-}(Bu^t ph)_2pz]_3\}$ has been determined by X-ray diffraction, as shown in Fig. 3.¶ The coordination geometry about thallium is similar to that in the related complex $Tl\{\eta^3\text{-}HB(3\text{-}Bu^t pz)_3\}$.[17] For example, the average Tl—N bond length [2.61(5) Å] and N—Tl—N bond angle [77(2)°] in $Tl\{\eta^3\text{-}HB[3,5\text{-}(Bu^t ph)_2pz]_3\}$ compare well with the values of 2.59(1) Å and 78(3)° in $Tl\{\eta^3\text{-}HB(3\text{-}Bu^t pz)_3\}$. The average Tl—N bond length in $Tl\{\eta^3\text{-}HB[3,5\text{-}(Bu^t ph)_2pz]_3\}$ is longer than the sum of the covalent radii (2.31 Å),** and is presumably a reflection of the fact that overall the bonding between Tl and the tris(pyrazolyl) hydroborato ligand is composed of one normal covalent and two dative covalent interactions.[18]

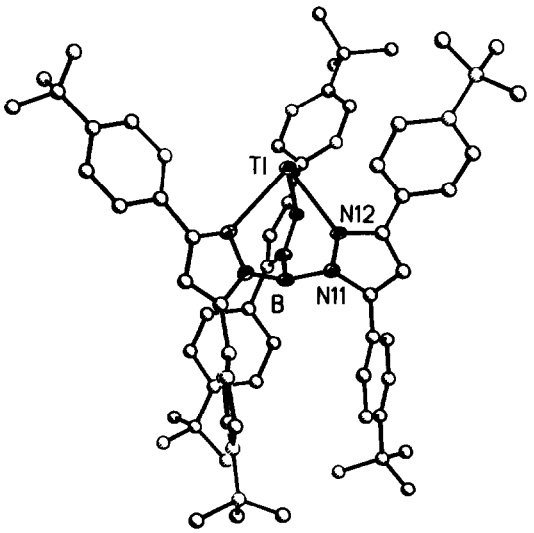


Fig. 3. The molecular structure of $\{\eta^3\text{-}HB[3,5\text{-}(Bu^t ph)_2pz]_3\}Tl$. Other atoms are not labelled for clarity. Selected bond lengths (Å) and angles (°): Tl—N(12) 2.568(10), Tl—N(22) 2.584(10), Tl—N(32) 2.663(15), N(12)—Tl—N(22) 75.2(3), N(12)—Tl—N(32) 77.7(4), N(22)—Tl—N(32) 78.3(4).

‖ Data for $Tl\{\eta^3\text{-}HB[3,5\text{-}(Bu^t ph)_2pz]_3\}$. ^1H NMR (C_6D_6): δ 1.09 [27H, s, $C(CH_3)_3$], 1.29 [27H, s, $C(CH_3)_3$], 6.76 [3H, s, CH(pz)], 6.99–7.23 [18H, m, 18H of *para*-$C_6H_4Bu^t$ groups], 7.69 [6H, d, $^3J_{H-H}$ = 8.2, 6H of *para*-$C_6H_4Bu^t$ groups]. Found: C, 68.4; H, 7.0; N, 7.3. Calc.: C, 68.5; H, 6.8; N, 6.9%.

¶ Crystal data for $Tl\{\eta^3\text{-}HB[3,5\text{-}(Bu^t ph)_2pz]_3\}$ at room temperature: Monoclinic, $P2_1/a$ (No. 14), a = 18.677(5), b = 19.486(5), c = 19.628(4) Å, β = 112.16(2)°, V = 6615(3) Å^3, Z = 4, R = 0.0624, R_w = 0.0825. A complete set of tables of crystal and intensity collection data, atomic coordinates, and bond distances and angles, and an ORTEP drawing have been deposited with the Editor as supplementary materials. The atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

** $r_{cov}(Tl)$ = 1.57 Å, $r_{cov}(N)$ = 0.74 Å. L. Pauling, *The Nature of The Chemical Bond* (3rd edn). Cornell University Press, Ithaca (1960).

In summary, the synthesis of a new tris(pyrazolyl)hydroborato ligand $[\eta^3\text{-HB[3,5-(Bu}^t\text{ph)}_2\text{pz]}_3]^-$ is reported. We believe that this ligand offers considerable potential for supporting metal centres that are less sterically demanding than those obtained by the use of the $[\eta^3\text{-HB(3-Bu}^t\text{pz)}_3]^-$ ligand, while still restricting the formation of sandwich complexes.

BOOK REVIEWS

Nuclear Chemistry. By O. Navrátil, J. Hála, R. Kopunec, F. Macásek, V. Mikulaj and L. Leseticky (translated by J. Hála and P. Huth). Ellis Horwood Ltd, Chichester, U.K. and Academia (Czech. Academy of Sciences), Prague, Czechoslovakia, 1992. ISBN 0-13-626904-4, £50.00.

It is a pleasure to read a new text on Nuclear Chemistry which covers most aspects of the subject thoroughly and which is written in such a clear and comprehensible way. In composition the book is logical, starting with nuclear structure, nuclear reactions and nucleogenesis, then proceeding on to the interaction of radiation with matter and the detection of radioactivity. Further chapters consider the analytical applications of radiation and radioisotopes, the preparation of labelled compounds and the radiochemical aspects of nuclear power generation. This latter topic leads to a consideration of some of the environmental problems posed by the current exploitation of radioactivity, in medicine and in research. There is, however, one grave omission, which detracts from the overall value of the book: no detailed consideration is given to radiological protection, to the international requirements that control the use and disposal of radioactive materials and to the reasons for these controls.

In all other respects, this book is excellent and the structure of each chapter exemplary. The basic concepts, either physical or chemical, are presented first, followed by a detailed exposition and development. Each chapter is brought to a conclusion by a consideration of a series of examples of applications. Thus, for each topic there is a thorough explanation and the interest of the reader is stimulated and maintained. This reflects well both on the Czech authors of the original text and upon the translators. In this book the problem of uneven structure that besets multi-authored texts and an awkwardness of style that so often accompanies translation have both been very successfully avoided.

Due to the breadth of topics covered (with just one exception) and the depth and thoroughness with which each topic is covered, this book should become a widely-used text. Practising radiochemists and those engaged in nuclear chemistry will start out thinking it useful and end up finding if invaluable. Those about to start work with radioactivity will find it an excellent text from which to learn and a mine of useful information.

Gmelin Handbook of Inorganic and Organometallic Chemistry. 8th Ed. Silicon Supplement Volume B7: Binary Species of Silicon and Fluorine. Edited by G. Hönes, H. Keller-Rudek, D. Koschel, P. Merlet, H. Schäfer and F. Schröder. Springer-Verlag, Berlin, 1992, ISBN 3-540-93651-3, 348 + xix pp., DM 1980.

This is the sixth in the ambitious series of updated Gmelin volumes on silicon compounds, the first of which appeared in 1982. As is normal with this series, the book is the result of large-scale collaboration: no less than eleven authors (led by Edwin Hengge and Robert Schlögl) and six editors (with Friedrich Schröder as chief editor) were involved. Literature coverage generally starts where the earlier Main Volume left off, at the end of 1949, although a few earlier key references are included. All relevant references up to January 1992 are included, and even a few later ones, which represents an admirably rapid production schedule.

It needs to be emphasized that this volume deals solely with binary Si_xF_y compounds; species in which elements other than fluorine are bonded to silicon will be dealt with in a forthcoming supplement volume B8. This means that compounds such as $(SiF_3)_2O$ and $SiF_2(NMe_2)_2$ are not covered in detail here, although they are referred to as reaction products derived from SiF_4.

Most chemists would expect to find SiF_2, SiF_4, and Si_2F_6 dealt with in such a volume, and indeed they take up 60% of the book, with 48, 144, and 16 pages devoted to them, respectively. But many other species are here, including neutral SiF_m (m = 1, 3, 5, 6), cations such as SiF^{n+} (n = 1–3) and SiF_m^{n+} (m = 2–4; n = 1,2), anions like SiF_m^- (m = 1–5) and SiF_m^{3-} (m = 1, 5), and various polysilicon derivatives such as $(SiF_2)_n$, $Si_{10}F_{16}$, and Si_mF^+ (m = 2–6). The familiar anion SiF_6^{2-} is treated at some length, and electronic, spectroscopic, structural and chemical properties of hexafluorosilicates with a range of cations are discussed. Possible duplication appears to be an inherent difficulty of the Gmelin system of classification, since Na_2SiF_6, for example, will also appear in the Sodium volumes.

Some of the compounds noted above are only "theoretical"; SiF^- has not been observed experimentally, for instance, but computational methods have provided values for its bond length, dissociation energy, dipole moment and some other properties. Indeed, the book contains numerous impressive illustrations of the power of modern theoretical methods. One striking example involves possible isomers of Si_2F_4: five different computational methods agree in predicting that the most stable arrangement is $(SiF_3)SiF$ rather than $F_2Si{=}SiF_2$.

Besides the expected full accounts of preparations and properties, there are extended discussions of results from more recent and exotic techniques such as multiple photon absorption, ion cyclotron resonance, gas-phase and solid-state NMR, and resonant Auger spectra. It was

Gmelin Handbook of Inorganic and Organometallic Chemistry. 8th Ed. Silicon Supplement Volume B7: Binary Species of Silicon and Fluorine. Edited by G. Hönes, H. Keller-Rudek, D. Koschel, P. Merlet, H. Schäfer and F. Schröder. Springer-Verlag, Berlin, 1992, ISBN 3-540-93651-3, 348 + xix pp., DM 1980.

This is the sixth in the ambitious series of updated Gmelin volumes on silicon compounds, the first of which appeared in 1982. As is normal with this series, the book is the result of large-scale collaboration: no less than eleven authors (led by Edwin Hengge and Robert Schlögl) and six editors (with Friedrich Schröder as chief editor) were involved. Literature coverage generally starts where the earlier Main Volume left off, at the end of 1949, although a few earlier key references are included. All relevant references up to January 1992 are included, and even a few later ones, which represents an admirably rapid production schedule.

It needs to be emphasized that this volume deals solely with binary Si_xF_y compounds; species in which elements other than fluorine are bonded to silicon will be dealt with in a forthcoming supplement volume B8. This means that compounds such as $(SiF_3)_2O$ and $SiF_2(NMe_2)_2$ are not covered in detail here, although they are referred to as reaction products derived from SiF_4.

Most chemists would expect to find SiF_2, SiF_4, and Si_2F_6 dealt with in such a volume, and indeed they take up 60% of the book, with 48, 144, and 16 pages devoted to them, respectively. But many other species are here, including neutral SiF_m (m = 1, 3, 5, 6), cations such as SiF^{n+} (n = 1–3) and SiF_m^{n+} (m = 2–4; n = 1,2), anions like SiF_m^- (m = 1–5) and SiF_m^{3-} (m = 1, 5), and various polysilicon derivatives such as $(SiF_2)_n$, $Si_{10}F_{16}$, and Si_mF^+ (m = 2–6). The familiar anion SiF_6^{2-} is treated at some length, and electronic, spectroscopic, structural and chemical properties of hexafluorosilicates with a range of cations are discussed. Possible duplication appears to be an inherent difficulty of the Gmelin system of classification, since Na_2SiF_6, for example, will also appear in the Sodium volumes.

Some of the compounds noted above are only "theoretical"; SiF^- has not been observed experimentally, for instance, but computational methods have provided values for its bond length, dissociation energy, dipole moment and some other properties. Indeed, the book contains numerous impressive illustrations of the power of modern theoretical methods. One striking example involves possible isomers of Si_2F_4: five different computational methods agree in predicting that the most stable arrangement is $(SiF_3)SiF$ rather than $F_2Si{=}SiF_2$.

Besides the expected full accounts of preparations and properties, there are extended discussions of results from more recent and exotic techniques such as multiple photon absorption, ion cyclotron resonance, gas-phase and solid-state NMR, and resonant Auger spectra. It was

something of a revelation to this reviewer to learn how much punishment some unlikely species have taken: we find, for example, that not only the IR visible, UV, and ESR spectra of SiF_3 have been determined, but also its thermodynamic parameters, structure, bond dissociation energy, ionization energy and cross-section, electron and proton affinity, polarizability, and even some chemical reactions. Some other highlights were the excellent discussions of SiF_2 reactivity and the use of Si—F species in microelectronic device fabrication.

All this information is clearly and critically displayed; it is particularly helpful that inconsistencies both within and between publications are pointed out. Altogether some 3700 references are cited, although there is a good deal of duplication because references are given for each short section. Apart from a very few infelicitous passages of English, it is almost impossible to fault the volume; it is comprehensive, well structured, and authoritative, and the team of authors and editors are to be congratulated on an excellent achievement (but could an author index be considered in future volumes?). If you ask "Is it worth the money?", just consider the cost of *your* time in collecting, checking, marshalling, and critically assessing even part of this mass of information!

(*Received* 10 *May* 1993; *accepted* 12 *July* 1993)

Abstract—The tetramethylurea adducts of tricyclopentadienyl lanthanide(III) complexes, $Cp_3Ln \cdot TMU$ (Ln = La, Ce, Nd, Sm, Eu and Yb, TMU = 1,1,3,3-tetramethylurea), have been isolated by addition of the stoichiometric amount of $(CH_3)_2NCON(CH_3)_2$ to $Cp_3Ln \cdot THF$, in hexane. The compounds were characterized by standard techniques and the molecular structures of $Cp_3Ce \cdot TMU$ and $Cp_3Nd \cdot TMU$ were determined by single crystal X-ray diffraction analysis. The two compounds are isomorphous. The metal centre is tetrahedrally coordinated.

Since the synthesis of the first tricyclopentadienyl lanthanide compounds, Cp_3Ln, by Birmingham and Wilkinson,[1] a large amount of adducts of these complexes with Lewis bases containing C, N, O or P donor ligands have been synthesized. These results have been extensively reviewed.[2] However, oxygen donor adducts are limited to the coordinated solvent where the compounds are prepared, the only exceptions being $Cp_3La \cdot L$ [L = dioxane, DMSO, DMF, $OP(OMe)_3$, $OCMe_2$] reported by Fischer[3] who studied their ^{139}La NMR. In this contribution we describe the synthesis and characterization of some lanthanide tricyclopentadienides with 1,1,3,3-tetramethylurea. The crystal and molecular structures of $CeCp_3 \cdot TMU$ and $NdCp_3 \cdot TMU$ are also reported.

EXPERIMENTAL

Materials and methods

All operations were performed under rigorous oxygen and moisture exclusion in an argon-filled glove-box or using Schlenk and vacuum-line techniques.

Tetrahydrofuran and n-hexane were dried over sodium benzophenone ketyl, under argon, and distilled prior to use. The solvents were degassed on the vacuum line. Deuterated benzene was dried over sodium benzophenone ketyl and distilled. 1,1,3,3-Tetramethylurea was dried with BaO and distilled prior to use. NaCp was prepared by reacting sodium with the stoichiometric amount of cyclopentadiene monomer in THF. The anhydrous lanthanide trichlorides, $LnCl_3$, were prepared according to literature procedures.[4] The compounds $Cp_3Ln \cdot THF$ were synthesized by metathetical reactions of the lanthanide trichlorides with three equivalents of sodium cyclopentadienide in THF.

Metal analyses were carried out by complexometric titration with EDTA. ^1H NMR spectra were recorded using a Bruker SY80FT multinuclear spectrometer and the proton chemical shifts are reported in ppm relative to Me_4Si. IR spectra were recorded on a Perkin–Elmer 577 spectrophotometer using Nujol mulls between CsI plates.

X-ray crystallography of $Cp_3Ln \cdot TMU$ (Ln = Ce, Nd)

The crystals for X-ray diffraction were mounted in quartz capillaries in an argon-filled glovebox.

Data were collected at room temperature on an Enraf–Nonius CAD4 diffractometer with graphite-monochromatized Mo-K_α radiation using the ω–2θ scan mode. The pertinent crystallographic parameters are listed in Table 1. Data were corrected for Lorentz-polarization, linear decay, and for absorption (Ψ scans) using the Enraf–Nonius program. The structure was solved by Patterson and Fourier methods and refined by full-matrix least-squares using SHELX-76.[5] All the non-hydrogen atoms were refined anisotropically and the contribution of the hydrogen atoms were introduced in calculated positions, with group U_{iso} values assigned. In the final difference Fourier map the highest peaks were 0.8 e $Å^{-3}$ for Ce and Nd compounds and were located near the Ln atom.

Atomic scattering factors and anomalous scattering terms were taken from International Tables for X-Ray Crystallography.

Tables of final atomic positional and thermal parameters, full lists of bond lengths and angles, equations of mean least-squares planes and tables of F_o/F_c values have been deposited as supplementary material with the Editor.

Syntheses

$Cp_3La \cdot TMU$ (**1**). All the complexes were prepared in a similar way. In a typical experiment $Cp_3La \cdot THF$ (200 mg, 0.49 mmol) in 10 cm^3 of n-hexane was stirred overnight with $(CH_3)_2NCON(CH_3)_2$ (57 mg, 0.49 mmol). The suspension was decanted and the white solid obtained was washed several times with n-hexane and dried in the vacuum-line. Yield, 96%. Sublimation temperature: 170°C/10^{-3} mm Hg. IR (Nujol, ν cm^{-1}): 3060w, 1580s, 1530w, 1258m, 1232w, 1162s, 1062m, 1009s, 909m, 775vs, 742vs, 580m, 418vw, 360w. Found: La, 30.8. Calc. for $LaC_{20}H_{27}N_2O$: La, 30.8%. ^1H NMR (C_6D_6) (δ ppm *vs* TMS): 6.19 (15H), 2.16 (12H).

$Cp_3Ce \cdot TMU$ (**2**). $Cp_3Ce \cdot THF$ (200 mg, 0.49 mmol) in 10 cm^3 of n-hexane was stirred overnight with $(CH_3)_2NCON(CH_3)_2$ (57 mg, 0.49 mmol). A yellow solid was obtained with a yield of 95%. Sublimation temperature: 150°C/10^{-3} mm Hg. IR (Nujol, ν cm^{-1}): 3060w, 1570s, 1525m, 1255w, 1230w, 1155s, 1060m, 1003s, 905m, 775s, 740vs, 572m, 420vw, 355w. Found: Ce, 30.5. Calc. for $CeC_{20}H_{27}N_2O$: Ce, 31.0%. ^1H NMR (C_6D_6) (δ ppm *vs* TMS): 6.85 (15H), −0.59 (12H).

Yellow crystals suitable for X-ray diffraction were obtained by slow diffusion of n-hexane into a saturated solution of $Cp_3Ce \cdot TMU$, in toluene, at room temperature.

$Cp_3Nd \cdot TMU$ (**3**). $Cp_3Nd \cdot THF$ (200 mg, 0.49 mmol) in 10 cm^3 of n-hexane was stirred with $(CH_3)_2NCON(CH_3)_2$ (57 mg, 0.49 mmol). A pale blue–violet solid was obtained with 96% yield. Sublimation temperature: 145°C/10^{-3} mm Hg. IR (Nujol, ν cm^{-1}): 3062w, 1580s, 1525m, 1249m, 1230w, 1155s, 1062m, 1009s, 910m, 779vs, 745vs, 575s, 410w, 358w. Found: Nd, 31.6. Calc. for $NdC_{20}H_{27}N_2O$: Nd, 31.6%. ^1H NMR (C_6D_6) (δ ppm *vs* TMS): 2.23 (15H), −6.01 (12H).

Crystals suitable for X-ray diffraction were obtained by slow diffusion of n-hexane into a saturated solution of $Cp_3Nd \cdot TMU$, in toluene, at room temperature.

$Cp_3Sm \cdot TMU$ (**4**). An orange solid was obtained from $Cp_3Sm \cdot THF$ (200 mg, 0.48 mmol) and $(CH_3)_2NCON(CH_3)_2$ (54 mg, 0.48 mmol) in 10 cm^3 of n-hexane with a yield of 95%. Sublimation temperature: 122°C/10^{-3} mm Hg. IR (Nujol, ν cm^{-1}): 3080w, 1580s, 1520m, 1260w, 1240w, 1150s, 1060m, 1010s, 900m, 780vs, 740vs, 560m, 420w, 350w. Found: Sm, 33.0. Calc. for $SmC_{20}H_{27}N_2O$: Sm, 32.6%. ^1H NMR (C_6D_6) (δ ppm *vs* TMS): 11.74 (15H), 0.75 (12H).

$Cp_3Eu \cdot TMU$ (**5**). A brown solid was obtained from $Cp_3Eu \cdot THF$ (200 mg, 0.48 mmol) and $(CH_3)_2NCON(CH_3)_2$ (54 mg, 0.48 mmol) in 10 cm^3 of n-hexane with a yield of 94%. Sublimation temperature: 105°C/10^{-3} mm Hg. IR (Nujol, ν cm^{-1}): 3060w, 1578s, 1525m, 1260w, 1232w, 1150s, 1060w, 1009s, 909m, 762s, 745s, 575s, 410vw, 353w. Found: Eu, 32.8. Calc. for $EuC_{20}H_{27}N_2O$: Eu, 32.8%. ^1H NMR (C_6D_6) (δ ppm *vs* TMS): 30.52 (15H), 17.58 (12H).

$Cp_3Yb \cdot TMU$ (**6**). A dark green solid was obtained from $Cp_3Yb \cdot THF$ (200 mg, 0.45 mmol) and $(CH_3)_2NCON(CH_3)_2$ (53 mg, 0.45 mmol) in 10 cm^3 of n-hexane with a yield of 97%. Sublimation temperature; 91°C/10^{-3} mm Hg. IR (Nujol, ν cm^{-1}): 3062w, 1580s, 1530m, 1260w, 1240w, 1150s, 1060m, 1010s, 910m, 740vs, 720vs, 550s, 410w, 350w. Found: Yb, 35.6. Calc. for $YbC_{20}H_{27}N_2O$: Yb, 35.7%. ^1H NMR (C_6D_6) (δ ppm *vs* TMS): −39.85 (15H), 28.06 (12H).

RESULTS AND DISCUSSION

The preparation of the compounds $Cp_3Ln \cdot TMU$ was carried out by adding the stoichiometric amount or a slight excess of TMU to a suspension of $Cp_3Ln \cdot THF$ in hexane.

Complexes were characterized by IR and ^1H NMR spectroscopies and metal analyses.[6] The compounds are air sensitive, especially the cerium compound, and can be stored at room temperature, under argon, during several months without noticeable decomposition; they are soluble in ethers, halogenated and aromatic solvents and slightly soluble in aliphatic solvents. All the compounds can be sublimed without losing the tetramethylurea molecule, suggesting a strong M—O bond in these compounds (see the X-ray crystal structures).

The IR spectra of the complexes are essentially independent of M suggesting similar molecular structures. The bands assigned to Cp ligand appear at 3080–3060, 1010–1003 and 780–762 cm^{-1} indicating a η^5 mode of coordination of the Cp to the metallic centre.[7] The antisymmetric ring stretching frequency located at about 1150 cm^{-1} could not be assigned due to superposition of a strong vibration mode of TMU. Coordination of the base to the lanthanide centre was inferred from the shift to lower frequencies of the band assigned to the ν(C=O) stretching vibration that appears in the 1580–1570 cm^{-1} range (1648 cm^{-1} for the uncoordinated base).

The ^1H NMR spectra of the complexes show one single resonance for the cyclopentadienyl rings and one single resonance for the methyl groups of the TMU ligand.

Crystal structure of $Cp_3Ce \cdot TMU$ *and* $Cp_3Nd \cdot TMU$

The structure analysis shows that the two compounds are isomorphous. Considering that the Cp ligand occupies a single coordination site, the lanthanide centre is four-coordinate with bonding to three η^5-cyclopentadienyl groups and to one σ-bonded TMU and displays a distorted tetrahedral geometry. A PLUTO drawing of $Cp_3Nd \cdot TMU$ molecule is shown in Fig. 1. Selected bond lengths and bond angles are given in Table 2.

The average Ln—C bond length is 2.83(2) Å for the Ce compound and 2.80(2) Å for the Nd compound. The TMU molecule is coordinated to the metal at Ln—O distances of 2.459(7) Å for the Ce compound and 2.437(5) Å for the Nd compound with Ln—O—C(1) angles of 154.8(5)° and 153.6(4)°, respectively. In both compounds the OCN_2 moieties in the TMU are planar with O—C(1) distances of 1.26(1) Å.

Similar tetrahedral structures have been found in the isostructural $Cp_3Ln \cdot THF$ series (Ln = La,[8] Pr,[9] Nd,[9,10] Gd,[11] Dy,[12] Lu[13]). Also in the present case the Ln—O and Ln—C(Cp) distances are in accordance with the general decreasing trend of bond distances as the ionic radius of the metal decreases. A comparison of the structural data of $Cp_3Nd \cdot TMU$ with those of $Cp_3Nd \cdot THF$[9] shows similar average Nd—C distances [2.80(2) and

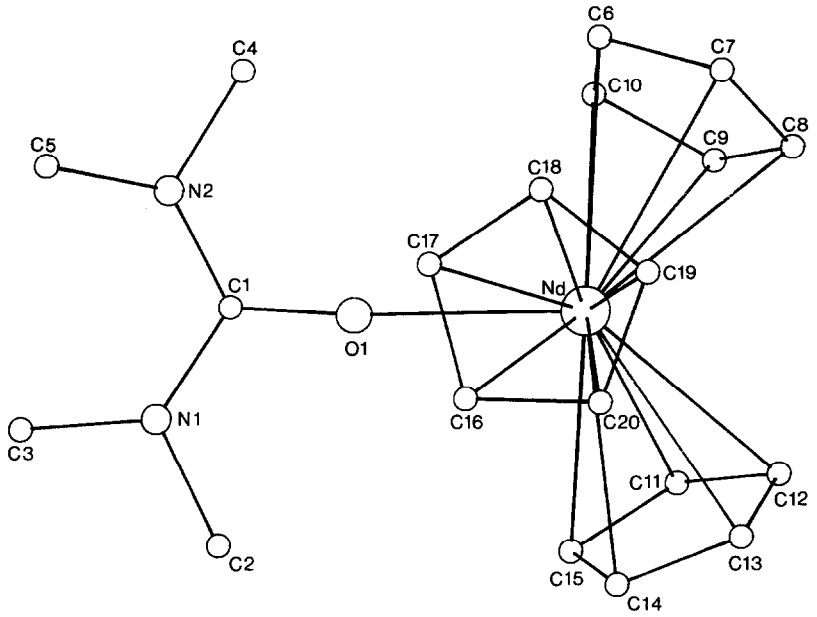

Fig. 1. PLUTO view of $Cp_3Nd \cdot TMU$.

(*Received* 10 *May* 1993; *accepted* 12 *July* 1993)

Abstract—Tridentate and bidentate coordination behaviour of N-(2-hydroxyethyl)-1,2-ethanediamine(L) with PdX_2 (X = Cl or Br) and their isomerization (N,N,O → N,N coordination) both in the solid state and in the solution have been studied by thermal techniques (DSC and TG-DTA), IR and ^{1}H NMR spectroscopy. One of the isomers [PdLCl$_2$] has been characterized by single crystal X-ray analysis. The palladium(II) ion possesses a square planar geometry with the N_2Cl_2 donor set.

A number of investigations have been reported[1–5] on the nature of the complex formation with N-(2-hydroxyethyl)-1,2-ethanediamine(L). The ligand has three potential donor sites (N,N,O), two nitrogens of the diamine and one oxygen of the hydroxyl group. The hydroxy coordination to metal seems to be weaker than the nitrogen. As a result the ligand is bidentate (via two N) when the other coordination sites of the metal are already occupied by strongly coordinating groups (e.g. NO_2^-, ethylenediamine, triethylenetetramine etc.) but is tridentate when those are weakly coordinating (e.g. H_2O, halogens etc). Moreover, it has been reported that there is a tendency of the bidentate form of this ligand to be transformed into the tridentate form in some complexes.[1]

The above propositions were made on the basis of conductance, spectral (electronic, IR and NMR) data and supported by chemical reaction (acetylation). However, due to lack of single crystal X-ray analysis data, the structures of these complexes as well as the flexidentate behaviour of the ligand remain more or less speculative. Moreover, the coordinating power of hydroxy group (—OH) and that of halogens are not very different. Therefore, it may be expected that interchange between these coordination sites (—OH and halogens) in solid state is possible if the potential barrier of the transformation is not very high.[6]

In this paper we report the syntheses of both bidentate and tridentate form of the ligand (L) in

$PdLX_2$ (X = Cl or Br). Isomerization (tridentacy → bidentacy of L) has also been described along with the crystal structure analysis of $[PdLCl_2]$ where L is bidentate.

EXPERIMENTAL

Materials

All the chemicals used were of AR grade and high purity N-(2-hydroxyethyl)-1,2-ethanediamine (L) was purchased from Fluka AG and distilled before use.

Physical measurements

The instruments used for IR and electronic spectra, thermal investigations [thermogravimetry (TG), differential thermal analysis (DTA) and differential scanning calorimetry (DSC)], elemental analyses, X-ray powder diffraction and conductance measurements were the same as reported earlier.[7] The ^1H NMR spectra were obtained on a 270 MHz Bruker 270 FT NMR spectrometer in DMSO-D_6 with TMS as an internal standard at IISc, Bangalore, India.

Preparation of $PdLCl_2$ (**1**) *and* $PdLBr_2$ (**2**)

These compounds were prepared by following the methods reported earlier.[1,5] Found: C, 17.1; H, 4.5; N, 9.9. Calc. for $C_4H_{12}N_2OCl_2Pd$ (**1**): C, 17.0; H, 4.3; N, 9.9%. Found: C, 13.0; H, 3.3; N, 7.4. Calc. for $C_4H_{12}N_2OBr_2Pd$ (**2**): C, 13.0; H, 3.2; N, 7.6%.

Preparation of $[PdLCl_2]$ (**1a**)

After removing $PdLCl_2$ (**1**), the mother liquor was kept at room temperature for 48 h, when rhomboid, pale-yellow crystals were separated out. These crystals were collected by filtration and dried in a desiccator. Yield 10%. Found: C, 17.2; H, 4.5; N, 10.0. Calc. for $C_4H_{12}N_2OCl_2Pd$ (**1a**): C, 17.0; H, 4.3; N, 9.9%.

Preparation of $[PdLBr_2]$ (**2a**)

The desired dazzling yellow coloured complex was obtained on recrystallization of **2** from water. Yield 40%. Found: C, 12.9; H, 3.1; N, 7.6. Calc. for $C_4H_{12}N_2OBr_2Pd$ (**2a**): C, 13.0; H, 3.2; N, 7.6%.

Crystallography

Crystal data. $C_4H_{12}N_2OCl_2Pd$ (**1a**), M = 281.8, monoclinic, $a = 8.646(2)$, $b = 9.746(2)$, $c = 10.388(3)$ Å, $\beta = 99.33(3)°$, $U = 863.8$ Å^3 (by least-squares refinement on diffractometer angles for 20 automatically centred reflections, $\lambda = 0.71069$ Å), space group $P2_1/c$, $Z = 4$, $D_c = 2.17$ g cm^{-3}, $F(000) = 552$, rhomboid light yellow crystals, dimensions $0.30 \times 0.16 \times 0.12$ mm, μ(Mo-K_α) = 24.9 cm^{-1}, $T = 293$ K.

Structure determination

Intensities for 2523 unique reflections ($1.5 < \theta < 30°$) were collected on a Hilger-Watt diffractometer in ω–2θ scan mode using graphite monochromatised Mo-K_α radiation. Data were corrected for absorption (max., min. transmission factor 0.90, 0.65) according to ref. 8. A total of 2123 reflections with $I > 3\sigma(I)$ was considered observed. The structure was solved by Patterson, Fourier methods and refined by full-matrix least-squares. All hydrogen atoms were located from difference maps. Final refinement with all non-hydrogen atoms anisotropic and hydrogen atoms isotropic (OH hydrogen was kept fixed) converged to $R = 0.047$, $R' = 0.048$. The weighting scheme $w = 1/[\sigma^2(F_o) + 0.001|F_o|^2]$ with $\sigma(F_o)$ from counting statistics gave satisfactory agreement analyses. Programs, computer used and sources of scattering factor data are given in ref. 9.

Supplementary material available.

Tables of positional and thermal parameters, interatomic distances and angles, and prominent lines in the X-ray powder diffraction patterns of **1** and **1a** are available from the authors on request.

RESULTS AND DISCUSSION

Structure of complex $[PdLCl_2]$ (**1a**)

The crystal structure consists of discrete monomeric units. An ORTEP[10] plot of **1a** with atom labelling scheme is shown in Fig. 1. Table 1 gives selected bond lengths and bond angles. Four ligand atoms [Cl(1), Cl(2), N(1), N(2)] around the palladium(II) form a distorted square planar arrangement with one bidentate N-(2-hydroxyethyl)-1,2-ethanediamine molecule and two chlorine atoms in *cis* position. The deviations from the weighted mean plane through the coordinated atoms are Cl(1) 0.001(1), Cl(2) −0.001(1), N(1) 0.015(5), N(2) −0.011(4) Å with the palladium atom 0.004(1) Å

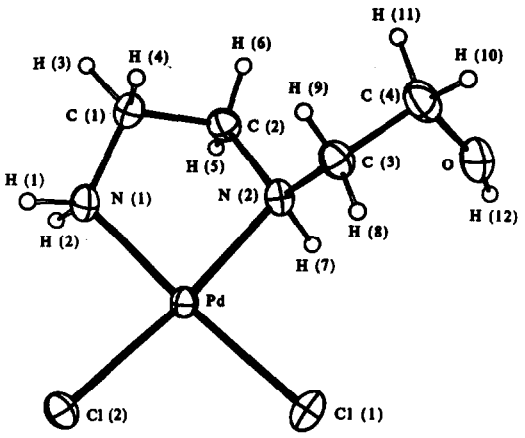

Fig. 1. ORTEP-plot of $[PdLCl_2]$ (**1a**) with atom numbering scheme.

from this plane. The Pd—Cl bond lengths in **1a** [mean value 2.322(1) Å] are in agreement with the values reported for palladium(II) complexes having chloro ligands.[11-13] The Pd—N distances 2.029(4), 2.062(4) Å are comparable to those observed in other palladium amine complexes.[14,15] The bending of Cl(2)—Pd—N(2) angle from linearity [174.2(1)°] can be related to the steric bulk of hydroxyethyl group attached to N(2). Other bond distances and angles are of usual values.

Therefore, it is clearly established that in $PdLCl_2$ (**1a**) the ligand, N-(2-hydroxyethyl)-1,2-ethanediamine in contrast to the earlier reports[1,5] is not tridentate but bidentate (coordinated via two N; the OH group remains uncoordinated).

Synthesis and X-ray powder diffraction study of (**1**)

The X-ray powder diffraction studies of **1** and **1a** reveal that all the prominent lines of **1a** are present in the diffraction pattern of **1** in addition to several other lines. Therefore, it is reasonable to infer that compound **1** which was reported as [PdLCl]Cl by the earlier investigators,[1,5] is not a single compound but admixed with **1a**. In spite of repeated attempts, we could not synthesize **1** in pure form. The relative ratio of these two complexes in the solid phase depends on several procedural factors e.g. temperature, nature of the solvent and even on the time taken for the addition of ligand to the Pd(II) solution during the preparation of the complex **1**. As the temperature of solution of $M_2[PdCl_4]$ (M = Li, Na or K) is lowered during the preparation, the relative percentage of the species [PdLX]X in the mixture is increased and reaches a maximum at *ca* 0–1°C. It is also noticed that the quicker the addition of the ligand to $M_2[PdCl_4]$ solution the lower is the percentage of the $[PdLCl_2]$. However, for the non-aqueous solvent e.g. methanol, ethanol, isopropanol etc. the amount of $[PdLCl_2]$ is always higher than [PdLCl]Cl. The relative ratio of these two species may be qualitatively measured by the relative peak intensity of the powder diffraction lines and the —OH bands appearing in the region 3500–3350 cm^{-1} in the IR spectra as well as by the measurement of the enthalpy change (ΔH) for the isomerization $[PdLCl]Cl \rightarrow [PdLCl_2]$ by DSC in the solid state *vide infra*. Complex **1** having least amounts of **1a** has been used for the following studies.

Isomerization [(**1**) → (**1a**)] *in the solid state and in solution*

Complex **1** on heating undergoes an endothermic irreversible phase transition (peak temp. 180°C) without any mass loss as is evident from the simultaneous TG–DTA and DSC studies (Fig. 2). The species isolated after phase transition appears to be **1a** as is evident from X-ray powder diffraction pattern, IR and NMR spectra. Complex **1a** on the other hand does not show any phase transition before decomposition. Therefore, the enthalpy change for **1** → **1a** non-isothermal transformation, is solely due to isomer **1** and is used to assess the relative amount of the isomers. The structure of

Table 1. Selected bond lengths (Å) and bond angles (°) of $[PdLCl_2]$ (**1a**) with ESDs in parentheses

Pd—Cl(1)	2.327(1)	Pd—Cl(2)	2.318(1)
Pd—N(1)	2.029(4)	Pd—N(2)	2.062(4)
N(1)—C(1)	1.487(7)	N(2)—C(2)	1.506(7)
N(2)—C(3)	1.490(7)	O—C(4)	1.415(9)
Cl(1)—Pd—N(1)	176.3(1)	Cl(2)—Pd—N(2)	174.2(1)
Cl(1)—Pd—Cl(2)	94.0(1)	Cl(1)—Pd—N(2)	91.8(1)
Cl(2)—Pd—N(1)	89.6(1)	N(1)—Pd—N(2)	84.6(2)
Pd—N(2)—C(3)	112.0(3)	C(3)—C(4)—O	107.5(5)

this isomer is proposed to be [PdLCl]Cl where L is tridentate, as is evident from IR and NMR spectra *vide infra*. Earlier reports[1,5] are also in line with this proposed structure.

The **1** → **1a** transformation occurs slowly also at room temperature in presence of high relative humidity (*ca* 70% or more) and becomes complete in one month. However, this transformation has not been found to occur in detectable quantity in a P_4O_{10} desiccator for several months. Complex **1** transforms to **1a** on crystallization from hot water.

Conductance

The electrolytic conductance of the complexes $PdLCl_2$ were measured in DMSO. The complex **1** shows $\Lambda m = 30\ \Omega^{-1}$ mol cm^2 and is very close to the desired value for 1:1 complex,[16] whereas the complex **1a** is non-electrolyte ($\Lambda m = 4\ \Omega^{-1}$ mol cm^2). The conductance value of **1** approaches to that of **1a** on keeping the solution overnight.

Infrared spectra

The complex **1** shows a band at *ca* 3390 cm^{-1} for OH stretching modes (Fig. 3) while in the case of **1a** this band appears at 3458 cm^{-1}. From this shifting it is legitimate to assume that in the former case the hydroxy group is coordinated with palladium but not in the latter case. In the far-IR region, complex **1** shows one strong band for Pd—Cl stretching at *ca* 330 cm^{-1} but the complex [$PdLCl_2$] (**1a**) shows two peaks for Pd—Cl stretching at 350 and 312 cm^{-1}. This splitting is expected as the complex **1a** possesses *cis* gometry.[17,18] From the above discussion it can be assumed that the OH group of the ligand is also coordinated along with the two N in **1**.

Proton NMR spectra

To obtain a greater insight into the mode of coordination of ligand in solid state as well as in solution we studied the palladium(II) halide complexes by ^{1}H NMR spectroscopy.

The [$PdLCl_2$] (**1a**) shows four peaks (Fig. 4) for all the —CH_2— ^{1}H except for —CH_2O— at the region of δ 3.00–2.32, while for —CH_2O— it appears as a multiplet at δ 3.71–3.58. All NH protons appear at lower field than the —CH_2— absorptions (δ 4.75–5.26). The —OH proton appears as a broad peak at δ 5.82. All the —CH_2— including —CH_2—O— in the complexes have the same chemical shift as in the free ligand, whereas the most pronounced change in chemical shift is observed for the protons adjacent to the ligation site, probably due to the decrease in the electron density of the donor atoms on complexation.[19] All the —NH— and —OH protons are almost removed in D_2O.

The complex $PdLCl_2$ (**1**) shows some extra peaks (Fig. 5) in addition to the peaks appearing in the case of [$PdLCl_2$] (**1a**) for the protons attached to the donor atoms. These extra peaks appear at the

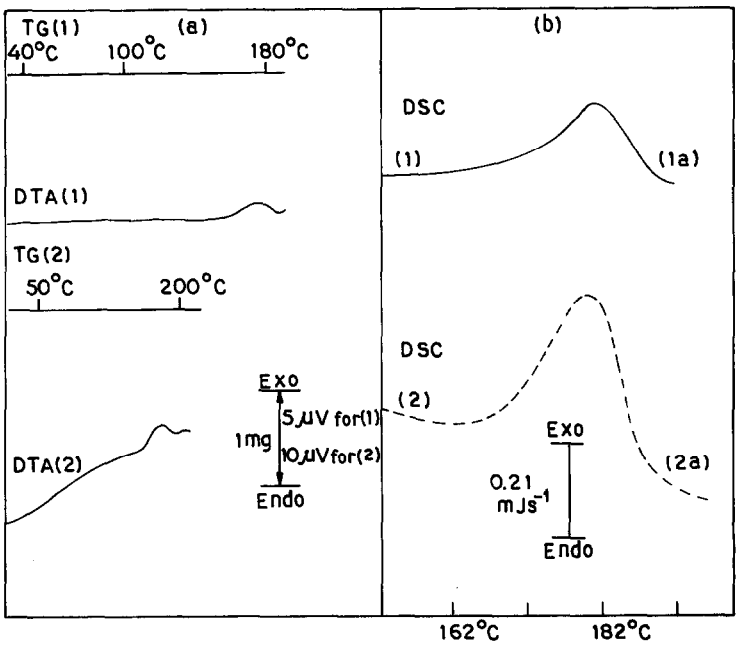

Fig. 2. TG-DTA(a) and DSC(b) runs for the complexes $PdLCl_2$ (**1**) and $PdLBr_2$ (**2**).

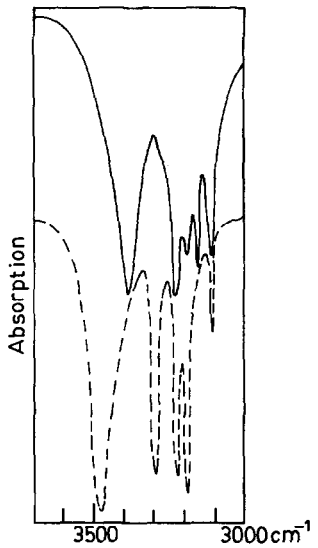

Fig. 3. IR spectra of $PdLCl_2$ (**1**) (——) and $[PdLCl_2]$ (**1a**) (– – –).

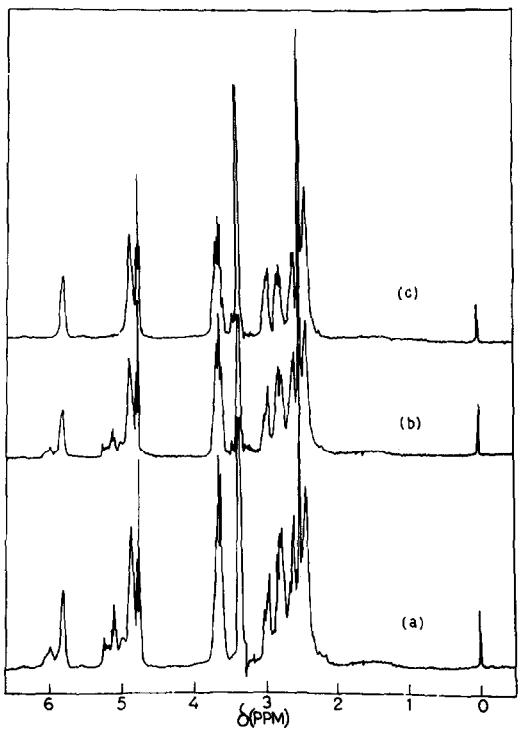

Fig. 5. ^1H NMR spectra of $PdLCl_2$ (**1**) showing the change of positions of the peaks with time, (a) just after dissolving in DMSO-D_6, (b) after 1 h and (c) after 24 h.

lower field than the corresponding peaks appeared in the complex $[PdLCl_2]$ (**1a**). It is interesting to note that these additional peaks are shifted to the higher field with time and ultimately, after *ca* 24 h, they merge with the original peaks of complex **1a** indicating the complete transformation of **1** → **1a**.

The corresponding bromo complex, $PdLBr_2$ behaves quite similarly to chloro complex. However, there are some differences between them which are summarized below. (i) The colour of [PdLBr]Br (**2**) is red and that of $[PdLBr_2]$ (**2a**) is yellow. Therefore on heating of the species **2**, an irreversible thermochromism (red → yellow) is observed along with the endothermic phase transition. (ii) The complex **2** is also not pure. It contains its isomer **2a** as impurity like the corresponding chloro analogue but in higher percentage (evident from X-ray powder diffraction, IR spectra and DSC experiment). (iii) On dissolution in DMSO, complex **2** transforms immediately to **2a** as the NMR spectra of **2** and **2a** in DMSO are observed to be identical.

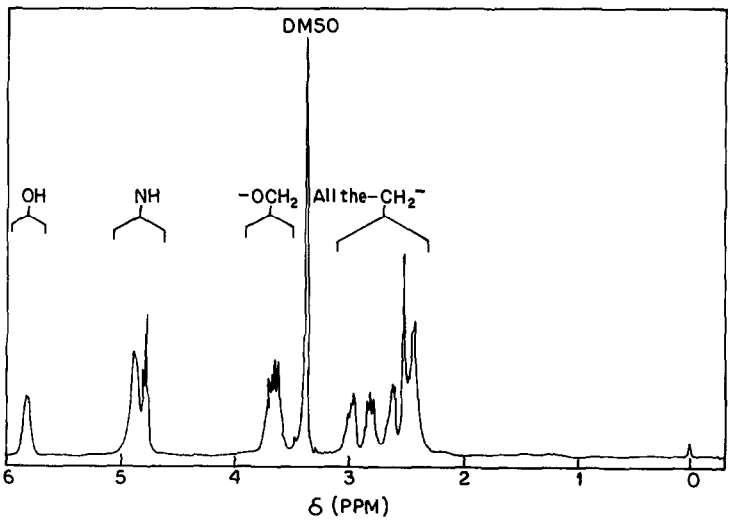

Fig. 4. ^1H NMR spectra of $[PdLCl_2]$ (**1a**).

CONCLUSION

The above studies show that this ligand forms two isomeric 1 : 1 complexes with PdX_2 (X = Cl or Br). One is metastable [PdLX]X and the other is stable $PdLX_2$. The ligand is tridentate in the former and bidentate in the latter. However, the solid product separated immediately after mixing a solution of Pd salt and the ligand (1 : 1) is [PdLX]X admixed with a slight amount of $[PdLX_2]$ indicating that the former is kinetically favoured. The transformation of this metastable [PdLX]X to stable $[PdLX_2]$ can be brought about by three different procedures: (i) on heating in the solid state; (ii) by crystallization/dissolution in suitable solvent and (iii) by keeping the solid complex in the humid atmosphere (relative humidity 70% or more).

Acknowledgement—The authors wish to thank Dr A. R. Chakraborty, Department of Inorganic and Physical Chemistry, IISc, Bangalore for ^1H NMR spectra. We are also grateful to the Department of Physics, University of York, U.K. for allowing two of the authors (AKM, MM) to use the X-ray diffractometer facility.

(*Received* 10 *May* 1993; *accepted* 12 *July* 1993)

Abstract—The complex [NaMn(pyrazinato)$(N_3)_2(H_2O)_2$] has been synthesized and characterized by spectroscopic methods and X-ray crystallography. The infrared and Raman spectral results indicate that the complex contains an N,O-bidentate pyrazinato anion, aqua ligands and asymmetric azido groups. The structure of the complex features an octahedrally coordinated manganese atom as well as six-coordinated sodium atom. Each manganese atom, which links a bridging aqua ligand [Mn—O = 2.244(3) Å] and three μ(1,1,3)-bridging azido ligands [Mn—N from 2.137(3) to 2.257(3) Å], is chelated by a pyrazinato anion [*via* its ring nitrogen atom, Mn—N = 2.297(3) Å, and a carboxylato oxygen atom, Mn—O = 2.148(3) Å]. The sodium atom is bonded to three μ(1,1,3)-bridging azido ligands in a facial arrangement [Na–N from 2.415(4) to 2.517(4) Å] and three water molecules [Na–O from 2.368(3) to 2.440(3) Å] in which two of them act as bridges between two sodium octahedra. The manganese and sodium octahedra have a common edge *via* an aqua ligand and an azido group.

Complexes of first-row transition metal ions with pyridine and its derivatives have been extensively studied.[1] With a carboxy substituent at the 2-position on the pyridine ring, several possibilities arise regarding the mode of interaction between the ligands and the metal ions: the carbonyl oxygen may coordinate alone, or along with the nitrogen of the pyridine ring on the central metal ion to form a five-membered ring, the two oxygen atoms of the carboxy group may coordinate by one or two metal atoms, or the nitrogen atom may function alone as a monodentate ligand. In a search of selective extraction reagents for transition metal ions, Elman *et al.*[2,3] and Csoregh *et al.*[4] studied the effects of various substituents on the coordinating properties of pyridine- and quinoline-carboxylic acids and the stereochemistry of the resulting complexes. On the

* Authors to whom correspondence should be addressed.

other hand, pyrazine and pyrazine-2-carboxylic acid (hereafter abbreviated as H-pyz) combine the coordinating features of the pyridine-2-carboxylic acid, plus the fact that the pyrazine moiety may act as bridge and thus aid the formation of polymeric derivatives.[5]

Recently we studied the interaction between pyridine-2-carboxylic acid and manganese(II) ions in the presence of azide ions and described the crystal structure of the resulting complex Mn (picolinato)(N_3)(H_2O).[6] In the present work we employed pyrazine-2-carboxylic acid in preparing the title manganese(II) azide complex and determined its structures by spectroscopic and X-ray crystallographic methods in order to establish its molecular and coordination geometry.

EXPERIMENTAL

Pyrazinic acid was obtained from Aldrich and the other chemicals were of analytical grade quality.

Preparation of the NaMn(*pyrazinato*)(N_3)$_2$(H_2O)$_2$

The NaMn(pyz)(N_3)$_2$(H_2O)$_2$ complex was prepared by dissolving $MnCl_2 \cdot 3H_2O$ (0.71 g, 5 mmol) in distilled water (20 cm^3). Pyrazinic acid (1.24 g, 10 mmol) dissolved in boiled water (*ca* 10 cm^3) was then added. To the clear solution, NaN_3 (0.65 g, 10 mmol) in distilled water (5 cm^3) was also added dropwise with stirring and the mixture became yellow solution. Transparent yellow crystals were obtained by slow evaporation in a desiccator charged with $CaCl_2$ and kept in the dark for several days. Found: C, 18.6; H, 2.4; N, 34.7; Mn, 17.3. Calc.: C, 18.7; H, 2.2; N, 34.9; Mn, 17.1%.

Physical measurements

Raman spectra were obtained using equipment consisting of a Spex 1301 monochromator, C31034 photomultiplier tube, photon counting electronics and a Spectra-Physics Model 2016 argon-ion laser ($\lambda = 514.5$ nm). The power of the laser beam used was approximately 20 mW. The experimental procedures and instruments used for other measurements are as described previously.[7]

X-ray analysis

A modified STOE four circle diffractometer was used for single crystal X-ray measurements. Lattice parameters were obtained by least-squares refinement of the diffraction data from 28 reflections in the 2θ range 8–15°. Data were collected at 300(1) K using graphite crystal-monochromatized Mo–K_α radiation ($\lambda = 0.71069$ Å) and the ω-scan technique. The intensities were corrected for Lorentz and polarization effects, and for absorption by an empirical method.[8] Crystallographic data are given in Table 1.

Table 1. Crystallographic data and processing parameters

Chemical formula	$C_5H_7MnNaN_8O_4$

The structure was solved by Patterson methods. Anisotropic displacement parameters were only applied to the non-hydrogen atoms in full-matrix least-squares refinements. The hydrogen atoms were included in the final refinement cycles on calculated positions. The programs DIFABS,[8] SHELX-76,[9] SHELXS-86,[10] PLATON[11] and THE XRAY SYSTEM[12] were used for computations. Analytical expressions of neutral-atom scattering factors were employed, and anomalous dispersion corrections were incorporated.[13] Selected bond distances and bond angles are given in Table 2. Positional parameters, anisotropic displacement parameters, hydrogen atom coordinates, a full list of bond lengths and angles and observed and calculated structure factors have been deposited with the Editor as supplementary material.

DISCUSSION

The principal structural features of the title complex are illustrated in Fig. 1. The coordination environment about each manganese(II) atom is a distorted octahedron. The pyrazinato anion chelates a manganese atom *via* its ring nitrogen atom

N(22)—N(21)—Mn(f)	137.0(3)	N(21)—N(22)—N(23b)	179.2(5)
Na—N(23)—N(22a)	147.1(3)	O(1)—C(5)—O(2)	125.8(3)

Symmetry code: (a) $x-1, y, z$; (b) $x+1, y, z$; (c) $-x-1/2, y, -z$; (d) $x-1/2, 1-y, z$; (e) $x+1/2, 1-y, z$; (f) $1/2-x, 1/2-y, 1/2-z$; (g) $-1/2-x, 1/2-y, 1/2-z$.

N(1) and a carboxylate oxygen atom O(1) to form a five-membered chelate ring. The chelate ring deviates only 0.07(1) Å from planarity, the N(1)···O(1) distance is 2.669(7) Å. The manganese atom is further coordinated by three nitrogen atoms from three μ(1,1,3)-bridging azido ligands in a facial arrangement [Mn—N from 2.137(3) to 2.257(3) Å] and a bridging water molecule at Mn—O(3) bond length of 2.244(3) Å. This water molecule further bridges a sodium atom [Na—O(3) = 2.411(3) Å] which is also six-coordinated. The sodium atom is coordinated by two more aqua ligands [Na—O(4) = 2.440(3) and Na—O(4c) = 2.368(3) Å] and three nitrogen atoms (facial) from three μ(1,1,3)-bridging azido ligands [Na—N from 2.415(4) to 2.517(4) Å]. The last two aqua ligands, O(4) and O(4c) act as bridges between two sodium octahedra. Thus two centrosymmetric related manganese polyhedra have a common edge *via* μ(1,1,3) azido ligands, whereas the manganese and sodium octahedra have their common edge *via* the aqua ligand O(3) and the azido group N(11)—N(12)—N(13e). Conforming to the general characteristics of the coordinated azides,[14-16]

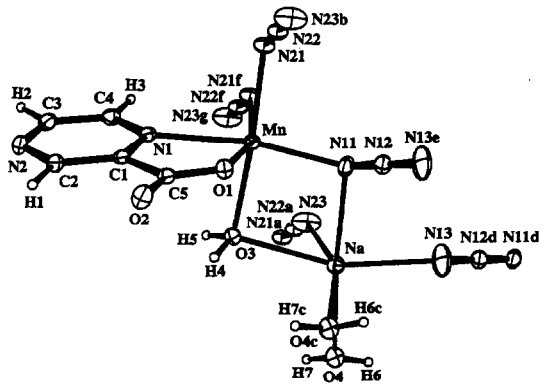

Fig. 1. Molecular structure of NaMn(pyz)$(N_3)_2(H_2O)_2$. Symmetry code according Table 2.

the two $\mu(1,1,3)$ azides are linear, but one of them may be considered as symmetrical within experimental errors [N(11)—N(12) = 1.164(5) and N(12)—N(13e) = 1.150(5) Å] whereas the other is asymmetric [N(21)—N(22) = 1.182(4) and N(22)—N(23b) = 1.124(5) Å]; however, in both of them the longer N—N distance is that between the central nitrogen and the nitrogen coordinated to two metal centres.

The $\mu(1,1,3)$ mode of azide bridging has previously been found in the structures of the polymeric complexes $Cu(NH_3)_2(N_3)_2$,[17] Cu(pyridine)$_2(N_3)_2$[18] and Cu(DENA)$(N_3)_2$ (DENA = diethylnicotinamide).[19] The structure of the title complex, however, is novel in that the $\mu(1,1,3)$ azido bridging occurs between three centres of two different metal atoms (Fig. 2). The Mn—N bond distances given in Table 2 are longer than corresponding values reported for $[(CO_3)Mn(N_3)_3Mn(CO)_3]$ containing only $\mu(1,1)$ azides [2.06(2)–2.11(2) Å],[20] but resemble those reported for polymeric Mn(pyridine)$_2(N_3)_2$ having only $\mu(1,3)$ azides [2.195(5) and 2.217(4) Å].[21]

The present complex differs from that obtained when picolinic acid, also known as 2-pyridinecarboxylic acid, was used instead of pyrazinic acid in a similar reaction, namely Mn(picolinato)$(N_3)(H_2O)$.[6] In the latter complex, the picolinate anion functions differently from the pyrazinate anion, and acts as a tridentate ligand. It chelates a manganese atom *via* its ring nitrogen and carboxylate oxygen atom which is further bridging another manganese atom giving rise to a dimeric Mn_2O_2 unit. The Mn—O distance in the present structure is shorter, whereas the Mn—N distance is little longer than corresponding values in the structure of the picolinato complex [Mn—O(pic) = 2.243(2) and Mn—N(pic) = 2.278(3) Å].[6] In the present structure there are four kinds of hydrogen bonding interactions that consolidate the crystal lattice: O(3)—H(4)···O(2) = 1.81(4) Å and O(4)—H(7)···O(1) = 1.91(4) Å, which link the bridging aqua ligands with coordinated and uncoordinated oxygen atoms, respectively, of a chelated pyrazinato anion, and O(3)—H(5)···N(2) = 1.93(3) Å and O(4)—H(6)···N(13) = 2.23(4) Å which link the same bridging aqua ligands given above with a non-bonded nitrogen atom of a pyz^- anion of an adjacent molecule and a monodentate nitrogen atom of an azido group in the same asymmetric unit, respectively. These hydrogen bonds are non-linear and the O—H···O or O—H···N angles vary from 152(4) to 172(4)°. The Na—N distances of 2.415(4) to 2.517(4) Å within the sodium octahedron (Fig. 1 and Table 2) are shorter than those (2.61–2.64 Å) in other NaN_6 coordination octahedra.[22] Likewise, the Na—O bond lengths of 2.368(3) to 2.440(3) Å found in the present structure are close to those in similar NaO_6 octahedra.[22]

The IR spectrum of free pyrazinic acid exhibits the following absorption bands (cm^{-1}, v = very, m = medium, w = weak, s = strong, br = broad): 1725vs,br [ν(C=O)], 1316vs [ν(C—O)], 1020s, 825m, 789s, 705m, 410/400m (pyrazine ring vibrations).[23] The spectrum of the complex on the other hand shows a substantial decrease of the $\nu_{as}(CO_2^-)$ to 1665s, and an increase of the $\nu_s(CO_2^-)$ to 1377s (IR) and 1377m (Raman). This large separation between the two ν(CO) indicates the unidentate coordination to the metal atom as found for many metal complexes of carboxylic acids.[24–27] Vibrations related to the pyrazine moiety are slightly shifted to higher wave-numbers and appear at 1038m, 855m, 793m, 724m and 432w. These results are indicative of the existence of N,O-bidentate chelate pyrazinate anion. Hydrogen bonding of the type O—H···O in the free acid is indicated by the appearance of broad bands at *ca* 2500 cm^{-1} and at *ca* 1900 cm^{-1}.[28,29] The IR spectrum of the complex shows a strong broad band with several peaks at 3506, 3412, 3354 and 3279 cm^{-1}, due to hydrogen bonded aqua ligands.

The $\nu_{as}(N_3)$ mode appears as a very strong band

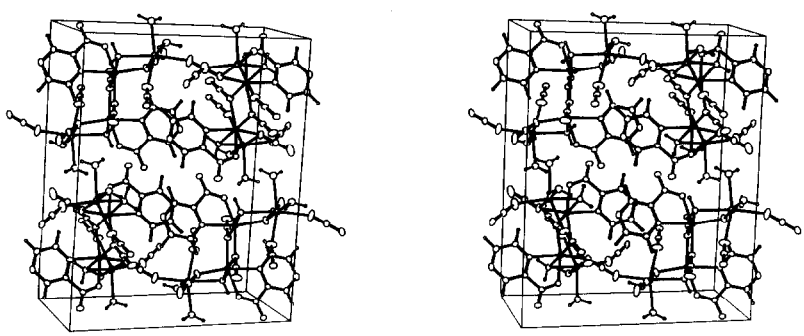

Fig. 2. Stereoplot of the unit cell viewed along the a axis.

at 2086 cm^{-1} together with a shoulder around 2020 cm^{-1}. In the Raman spectrum no band is observed in this region. Considering the significant difference between the two N—N distances (Δd) in each azide group (Table 2), the peak at 2086 cm^{-1} can be assigned to the azide group N(21)—N(22)—N(23b) ($\Delta d = 0.058$ Å) and the shoulder at 2020 cm^{-1} to the more symmetric N(11)—N(12)—N(13e) ($\Delta d = 0.015$ Å) group. The strongest band in the Raman spectrum at 1356 cm^{-1} and the corresponding medium strong band at 1353 cm^{-1} in the IR are associated with the symmetric stretch vibration mode of the azide ligand.[30,31] This is an expected result since the $\nu_s(N_3)$ mode is IR-inactive for entirely symmetrical azide ion. Thus while intensity considerations of such stretch vibration modes are valuable in assigning the slight asymmetric nature of both azide groups, they are of no value in determining the mode of bonding of these azides, i.e. whether they are terminal, $\mu(1,1)$-, $\mu(1,3)$-, or $\mu(1,1,3)$-bridging.

In the far-IR region, we tentatively assign to the metal-ligand vibrations the following frequencies:[32] 407sh and 375vw to ν(Mn—O(H_2O)]; the bands are 291m and 268m to ν(Mn—N(N_3)]; the bands at 314m (at 315 in the Raman spectrum) and 238s to ν[Mn—O(pyz)] and ν[Mn—N(pyz)], respectively. The metal-nitrogen vibrations are also found in the Raman spectrum at 285, 265 and 245 cm^{-1}, respectively.
