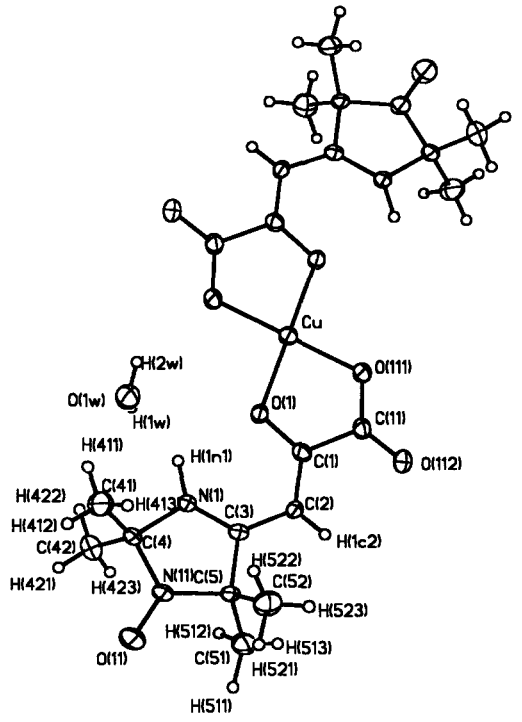

Fig. 2. Structure and atomic numbering of $Cu(HL)_2(H_2O)_2$.

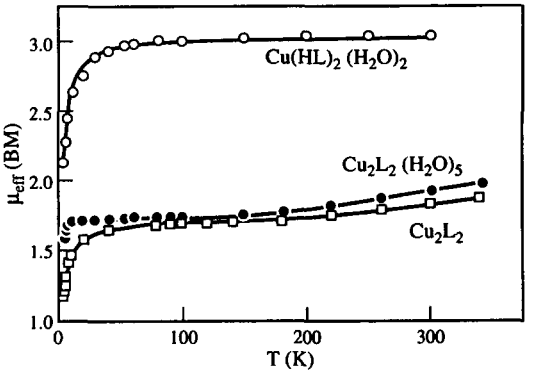

Fig. 3. Experimental magnetic data plotted as μ_{eff} *vs* temperature for $Cu(HL)_2(H_2O)_2$ (○), $Cu_2L_2(H_2O)_5$ (●) and Cu_2L_2 (□). The solid lines are the least-squares fits of the experimental data by the expressions given in the text. [For $Cu_2L_2(H_2O)_5$ and Cu_2L_2, μ_{eff} were calculated per half molecule, $CuL(H_2O)_{2.5}$ and CuL, respectively.]

[14]. The weak intramolecular exchange interaction ($-2.5\ cm^{-1}$) is in good agreement with the sufficiently large intramolecular distance between Cu^{2+} and the N—•O group. The very small value of zJ' accounts for the weak intercluster exchange interactions resulting from the very large intermolecular separation of the paramagnetic centers (> 5.1 Å).

Binuclear complex

Interaction between H_2L and $Cu(CH_3COO)_2(H_2O)$ (1 : 1) gave solid $Cu_2L_2(H_2O)_5$ in 40–50% yield. Addition of a base to the reaction mixture increased the yield to 70–85%. The enamineketone proton is much less acid than the carboxylate one ($pK_1 = 3.73 \pm 0.05$; $pK_2 = 11.85 \pm 0.05$) [15], therefore, the addition of a base shifts the equilibrium toward the formation of $Cu_2L_2(H_2O)_5$ and increases its yield. Without base, the yield of $Cu_2L_2(H_2O)_5$ is lower and the solid contains an insignificant admixture of $Cu(HL)_2(H_2O)_2$. However, since both $Cu_2L_2(H_2O)_5$ and $Cu(HL)_2(H_2O)_2$ appear as well-shaped single crystals of different colors and shapes, unit $Cu(HL)_2(H_2O)_2$ crystals can be mechanically separated from the bulk of $Cu_2L_2(H_2O)_5$. The $Cu_2L_2(H_2O)_5$ complex can also be obtained by the reaction between $Cu(HL)_2(H_2O)_2$ [or $Cu(HL)_2(C_2H_5OH)_2$] and $Cu(CH_3COO)_2(H_2O)$, followed by adding a base to the reaction mixture. The base hydrolysis of CuA_2, followed by the addition of $Cu(CH_3COO)_2(H_2O)$ to the resulting solution, also yielded $Cu_2L_2(H_2O)_5$. Thus, in all cases under consideration, when the Cu : L ratio approached 1 : 1, solid $Cu_2L_2(H_2O)_5$ was obtained.

Crystal structure and magnetic properties of $Cu_2L_2(H_2O)_5$

X-ray diffraction data for $Cu_2L_2(H_2O)_5$ suggest the binuclear structure of the complex (Fig. 4). In $Cu_2L_2(H_2O)_5$ the tridentate bridging L binds two copper atoms to form a five-membered chelate ring [similar to that in $Cu(HL)_2(H_2O)_2$] with one Cu atom and a six-membered chelate ring with the other Cu atom. The donor enamineketone oxygen acts as a bridge between the two metal atoms. The Cu—O and Cu—N bond lengths are, on average, 1.950 and 1.966 Å, respectively. In the five- and six-membered cycles, the average chelate angles are 81.37 and 91.09°, respectively. In the binuclear molecule, each copper atom coordinates one water molecule, i.e. the copper atom has a distorted trigonal bipyramidal environment. The equatorial planes of the bipyramids involve the O(111), O(2) and O(1w) atoms for Cu(1) and the O(611), O(1) and O(2w) atoms for Cu(2). The axial positions are occupied by O(1) and N(2) in the Cu(1) bipyramid and by O(2) and N(1) in the Cu(2) bipyramid.

It should be noted that all coordinated water molecules are located on one side of the $[Cu_2L_2]$ fragment and are far removed from the metal atoms (Table 3). Three noncoordinated water molecules form many different hydrogen bonds with the binuclear fragments $[Cu_2L_2(H_2O)_2]$ to bind them in a frame. In $Cu_2L_2(H_2O)_5$ the water molecules are held not as tightly as those in $Cu(HL)_2(H_2O)_2$. The TG and DTA curves show that heating $Cu_2L_2(H_2O)_5$ to 60–115°C leads to the complete one-step loss of water to form Cu_2L_2 quantitatively. Therefore, Cu_2L_2 can readily be obtained by keeping $Cu_2L_2(H_2O)_5$ *in vacuo* at 70–80°C for 5–6 h. Losing water molecules is a reversible

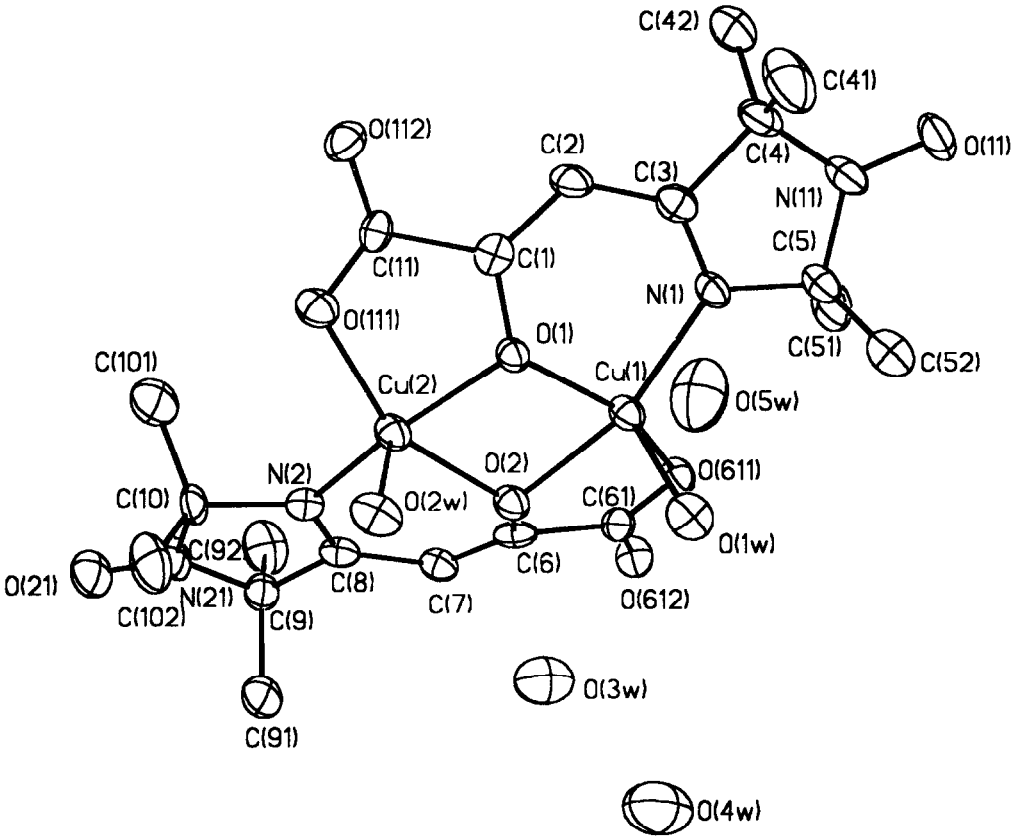

Fig. 4. Structure and atomic numbering of $Cu_2L_2(H_2O)_5$.

process. When stored in a moist atmosphere for 24 h, Cu_2L_2 transforms into $Cu_2L_2(H_2O)_5$. The $Cu_2L_2(H_2O)_5$ complex and the product of its thermolysis, saturated with water, have identical IR spectra. The IR spectrum of $Cu_2L_2(H_2O)_5$ exhibits an intense ν(OH) band at 3427 cm^{-1}, which corresponds to water molecules and is broadened due to the hydrogen bonds. In the IR spectrum of Cu_2L_2, this band is not observed. The presence/absence of this band allows one to easily monitor the presence/absence of water molecules in the solid compound.

In the intramolecular binuclear fragment, the Cu···Cu distance is 3.0588 Å. It is the shortest distance between the paramagnetic centers in $Cu_2L_2(H_2O)_5$. All intermolecular Cu···Cu distances are significantly longer. Within the binuclear molecule, the shortest Cu···—•O distance is 5.370 Å. The intermolecular distances —•O···O•— are not less than 6.542 Å. Therefore, the main exchange interactions occur in the Cu$\langle^{O}_{O}\rangle$Cu fragments. The $\mu_{eff}(T)$ and $\chi^{-1}(T)$ curves (Figs 3 and 5) suggest that both $Cu_2L_2(H_2O)_5$ and Cu_2L_2 exhibit two exchange interactions between the paramagnetic centers, which significantly differ in value. These are the strong antiferromagnetic exchange interactions (J) through the bridging oxygen atoms in the intramolecular fragments Cu$\langle^{O}_{O}\rangle$Cu and the much weaker exchange interactions between the N—•O groups (J_1). The condition $J \gg J_1$ allows the isolation of two temperature regions, $T < 150$ K and $T > 150$ K, on the $\mu_{eff}(T)$ and $\chi^{-1}(T)$ curves. In the low-temperature region the magnetic properties are determined mainly by the interactions between the unpaired electrons of the >N—•O groups, since at low temperatures the spins of metal ions in the Cu$\langle^{O}_{O}\rangle$Cu fragment are fully paired. In the low-temperature region, χ obeys the Curie–Weiss law $[C/(T-\theta)]$ and C is close to that for two weakly coupled electrons (Table 4, Fig. 5). At

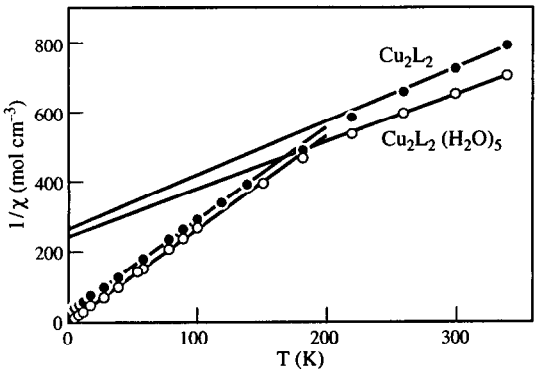

Fig. 5. $1/\chi$ as a function of temperature for $Cu_2L_2(H_2O)_5$ (○) and Cu_2L_2 (●) [$1/\chi$ were calculated per half molecule, $CuL(H_2O)_{2.5}$ and CuL, respectively.]

Table 4. Fitting parameters of the magnetic data

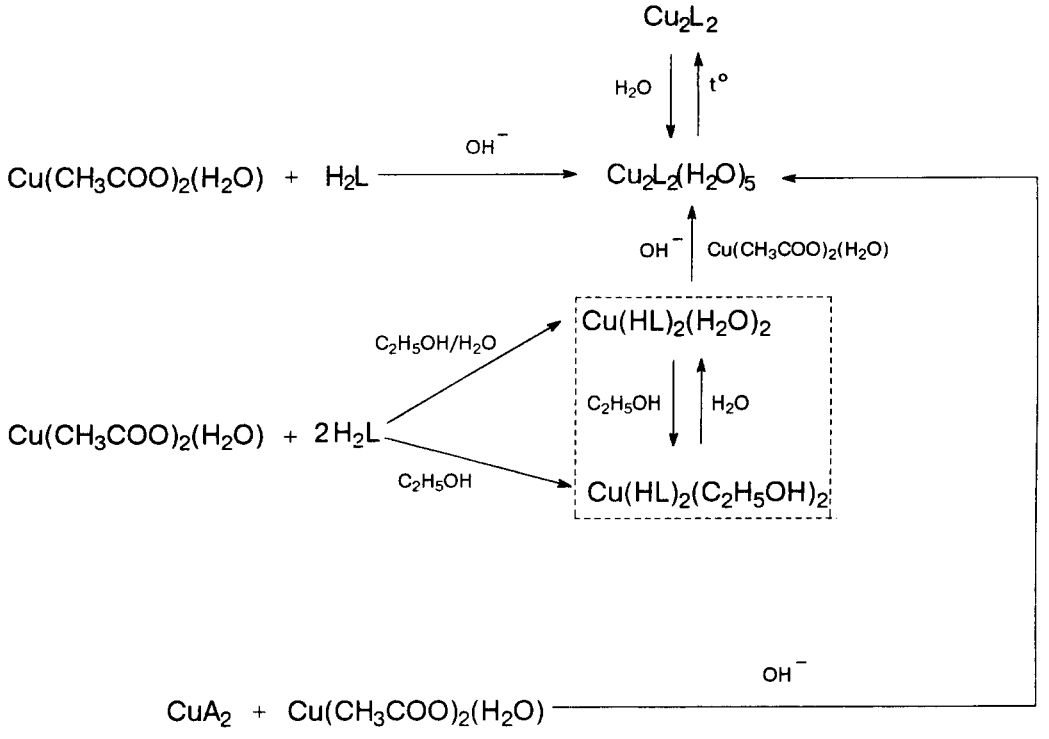
	C (cm^3 K mol^{-1})	θ (K)	g_{Cu}	J (cm^{-1})	zJ' (cm^{-1})
$Cu_2L_2(H_2O)_5$	0.757	−0.6	2.13	−292	−0.8
Cu_2L_2	0.749	−4.2	2.08	−360	−5.8

high temperatures, the strong antiferromagnetic exchange interaction in the Cu<O>Cu fragment, whose magnetic susceptibility is well described by the Bleaney–Bowers equation [16], makes a considerable contribution to the magnetic susceptibility of the compound. Thus, the magnetic susceptibility of each of the complexes can be represented as a sum of two contributions:

$$\chi_M(T) = \frac{C}{(T-\theta)} + \frac{2N\beta^2 g_{Cu}^2}{3kT}(1+\tfrac{1}{3}e^{-2J/kt})^{-1} + N\alpha,$$

where the second term is the Bleaney–Bowers equation and $N\alpha$ is the temperature-independent paramagnetism of Cu^{II}, which was taken equal to 60×10^{-6} cm^3 mol^{-1}. The optimal parameters obtained for $Cu_2L_2(H_2O)_5$ and Cu_2L_2 using the above equation are listed in Table 4. Table 4 also gives values for the parameter of the exchange interaction between the radical centers (zJ'), estimated by the equation $\theta = 2zJ'S(S+1)/3k$ [17] (where z is the number of the nearest neighbors of the radicals) in the molecular field approximation.

It can be seen from Table 4 that removing water from $Cu_2L_2(H_2O)_5$ contracts the magnetic system, which increases the energy of exchange interactions (zJ') between the nitroxides. This is consistent with the well known fact that in the complexes of transition metals with nitroxides the efficiency of H_2O molecules in the spin density transfer is extremely low [18–21]. In addition, removing water increases the value of $|J|$ in the exchange cluster, which points to a certain deformation of the exchange cluster Cu<O>Cu on going from $Cu_2L_2(H_2O)_5$ to Cu_2L_2. In the binuclear fragments, the value of J is determined by the Cu—O—Cu angle [22]. For $Cu_2L_2(H_2O)_5$, these angles are 102.36(7) and 103.74(7)°. The value of J determined for $Cu_2L_2(H_2O)_5$ is in good agreement with the familiar dependence of the exchange parameters on the Cu—O—Cu angle [22].



DISCUSSION

The general scheme of the complex formation in the interactions between Cu and H_2L at different Cu : L ratios and under different synthesis conditions could be presented as in Scheme 3.

The interaction of Cu^{II} with H_2L at a 1 : 2 ratio yields the solvated bischelate $Cu(HL)_2(H_2O)_2$ [or $Cu(HL)_2(C_2H_5OH)_2$]. The sufficiently high acidity of the pseudo-oxalate fragment of H_2L provides the formation of $Cu(HL)_2$ without adding a base. Thus, the first step of the complex formation involves the coordination of the nitroxide by type (b) (Scheme 1). It should be noted that in solid $Cu(HL)_2(H_2O)_2$ the water molecules are not coordinated by the metal ions, but form strong hydrogen bonds with the protons of the secondary amino groups and with the noncoordinated oxygens of the carboxylate groups of neighboring molecules. It is not unlikely that in $Cu(HL)_2(C_2H_5OH)_2$ the ethanol molecules are bonded in a similar manner. However, the low stability and twinning of the $Cu(HL)_2(C_2H_5OH)_2$ crystals did not allow us to determine the structure of this complex.

Changing the Cu^{II} : L ratio to 1 : 1 and increasing pH in the reaction mixture are favorable to the formation of the binuclear complex $Cu_2L_2(H_2O)_5$. The structure rearrangement observed in the transition from mononuclear $Cu(HL)_2$ to binuclear Cu_2L_2 is rather unexpected, since it involves the movement of the polyfunctional ligands toward each other (Scheme 2), which is an unusual process in the coordination chemistry. We designate this process as caterpillar-like reaction. For metal complexes with organic radicals, this process is reported for the first time. It should also be noted that in the available literature on metal complexes with diamagnetic organic ligands of a similar structure, we failed to find a description of a similar structural rearrangement of the mononuclear complex into the binuclear one. The Cambridge Structural Database [23] also contains no information about structural rearrangement of this type. However, a search through the above database has shown that the formation of polynuclear compounds in caterpillar-like reactions, which occur during interactions between polyfunctional organic ligands and metal ions, can be observed not only through processes traditional for the coordination chemistry, but also in biochemical processes [24–27].

It can be seen from Scheme 3 that binuclear $Cu_2L_2(H_2O)_5$ is formed regardless of the method of reaching that ratio Cu^{II} : L = 1 : 1. We would like to place particular emphasis upon the interaction between CuA_2 and copper acetate. In the first step of the reaction, the formation a six-membered enamineketone chelate ring through a direct interaction between Cu^{2+} and H_2L is impossible. Therefore, to synthesize the layered polymer by the scheme shown in Fig. 1, we used CuA_2 as an initial compound. (The presence of two six-membered enamineketone rings in CuA_2 was shown in the previous work [9].) However,

Scheme 3.

all interactions of CuA_2 with copper acetate, hydroxide and chloride (with and without base, in hydrated media, in anhydrous organic solutions, and in heterophase syntheses in water–chloroform mixtures) proceed to form the binuclear $Cu_2L_2(H_2O)_5$, which points to the high stability of the complex.

In the introduction we mentioned that the heterospin systems based on transition metal complexes with organic radicals are currently synthesized using progressively complicated nitroxide derivatives with several functional groups. In this context it is not impossible that caterpillar-like molecular processes will be observed more often. At least, they should be taken into account in developing the synthesis procedures for chain, layered and frame heterospin polymers in solid.

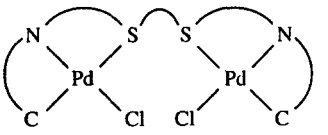
Synthesis and spectroscopic characterization of binuclear thioazomethine palladacycles

P. Chattopadhyay, M. K. Nayak, S. P. Bhattacharyya and C. Sinha*

Department of Chemistry, The University of Burdwan, Burdwan 713 104, India



(Received 3 April 1996; accepted 22 August 1996)

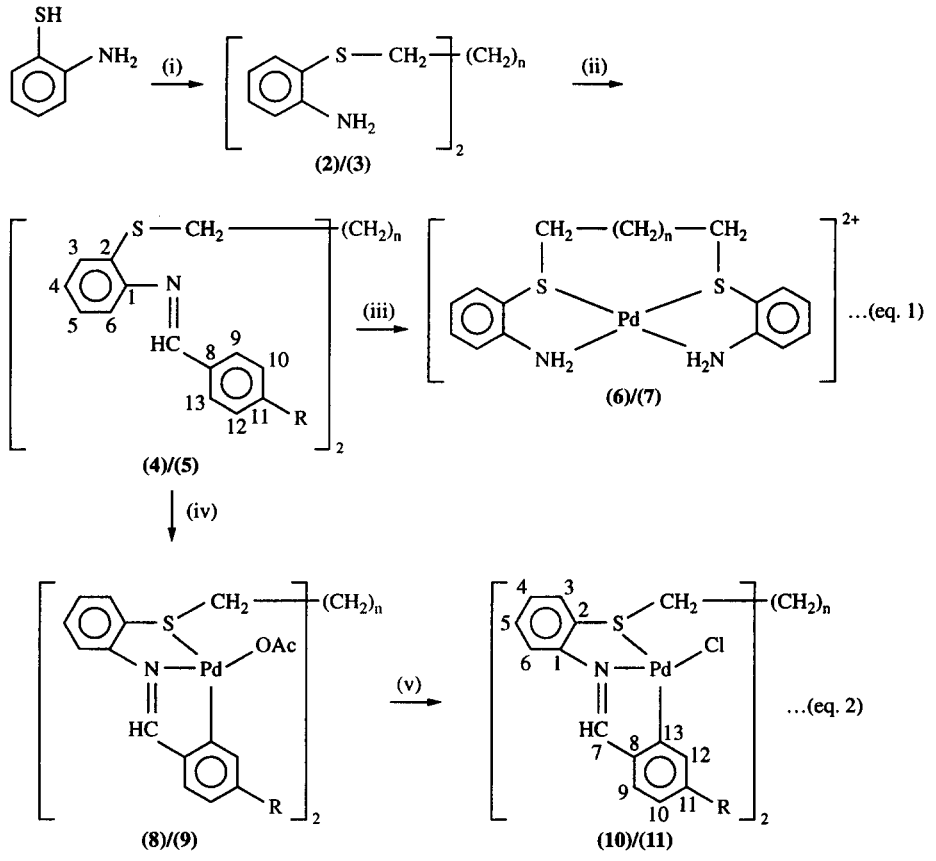
Abstract—Several 1,2-bis(2-thio(*N*-benzylidene)anilines)ethane [$(RC_6H_4CH = NC_6H_4SCH_2)_2$] (**4**) and 1,3-bis(2-thio(N-benzylidene)anilines)propane [$(RC_6H_4CH = NC_6H_4SCH_2)_2CH_2$] (**5**), R = H (a), 11-CH_3 (b), 11-OCH_3 (c), 11-Cl (d) and 11-NO_2 (e)] have been synthesized and reacted with $Pd(OAc)_2$ in boiling benzene. The binuclear cyclopalladated acetato complexes (8/9) thus obtained reacted with LiCl, giving the chloro complexes having the coordination sphere $[Pd(C, N, S)Cl_2]_2$ (**10/11**). The mode of ligand binding was established using high-resolution ^1H NMR and IR data. Copyright © 1997 Elsevier Science Ltd

Keywords: thioazomethines; cyclopalladation; dinuclear.

Cyclometallated organopalladium compounds have been extensively studied [1,2] because of their potential utility in the activation of C—H bonds and several reviews on their synthesis and characterization have appeared [3–10]. Various applications of cyclopalladated complexes to organic synthesis are known [11]. Many such reactions are useful in the synthesis of regio- and stereo-selected organic and heterocyclic compounds [9,11], optically active molecules [1,2], resolution of chiral substrates [13], estimation of optical purity [14] and catalysts for hydrogenations.

Cyclopalladated complexes containing Pd—C σ-bonds stabilized by the additional coordination via a suitably substituted N-donor centre, *viz.* amines [1–3], imines [3,5,6], azobenzenes [7,8,11], arylhydrazones [16], are of particular interest. The imines bearing an additional donor group at a suitable position to maintain chelate structure provide extra stability to the cyclopalladated complexes [6]. Herein we describe binuclear organometallics of coordination type $Pd(C, N, S)Cl_2$ (**1**) of 1,2-bis(2-thio(N-benzylidene)anilines)ethane (**4**) and 1,3-bis(2-thio(N-benzylidene)anilines)propane (**5**). The ligand systems have been designed on our familiarity [7] with the binuclear cyclometallated platinum metal chemistry of hexadentate (C, N, S)-type azoligands.

1



RESULTS AND DISCUSSION

Synthesis

The Schiff bases and their cyclopalladation described in this work are shown in Scheme 1 along with the methods used for synthesis and atom-numbering scheme. The ligands are of effective hexadentate (C, N, S)-type. They were synthesized in good yields by condensation of *para*-substituted benzaldehydes with 1,2-bis((2-aminophemyl)thio)ethane (**2**) or 1,3-bis((2-aminophemyl)thio)propane (**3**). These ligands are new and are systematically named as 1,2-bis(2-thio(*N*-benzylidene)anilines)ethane (**4**) or 1,3-bis(2-thio(*N*-benzylidene)anilines)propane (**5**). The reaction of Schiff bases with Na_2PdCl_4 in aqueous ethanol turns to a suspension and a brown salt is separated quickly by the addition of $NaClO_4$ into the solution, which is characterized as imine-hydrolysed thioamine palladium(II) perchlorate [eq. (1)].

A similar reaction using $Pd(OAc)_2$ in benzene in 1:2 mole proportion gave an orange–brown precipitate after refluxing for a period of 1 h or more. The

acetate derivatives (**8**/**9**) on metathesis in chloroform : acetone (1 : 1, v/v) by adding LiCl produced the chloro derivatives (**10**/**11**) [eq. (2)].

Spectral and binding mode

The appearance of sharp strong bands in IR spectra at 1600–1625 cm^{-1} in the ligands (**4**/**5**) is suggestive of the ν(C=N) mode [17]. This band is red shifted by $\Delta\nu$ = 20–25 cm^{-1} on complexation, suggesting coordination of the metal ions to the azomethine nitrogen [18]. The acetato complexes (**8**/**9**) exhibit strong bands ν_{as} (COO) at 1550–1560 cm^{-1} and ν_s (COO) 1320–1340 cm^{-1} ($\Delta\nu$ = 220–230 cm^{-1}), which correspond to the unidentate character of the bonded —COO groups [17–20]. The chloro complexes (**10**/**11**) are characterized by a sharp single (Pd—Cl) mode at 320–340 cm^{-1} [21].

The complexes are sparingly soluble in common organic solvent and the UV–vis spectra are recorded in DMSO. The absorptions around 450 nm (absent in free ligand) may be assigned to the characteristic of *ortho*-palladation and probably represent transitions localized on the metalated fragment [7,8]. Two other absorptions at 345–390 and 280–295 nm may be ascribed to intraligand charge transfer transitions [20]. The spectral data are collected in Table 1.

In the ^{1}H NMR spectra, all aromatic protons of the ligand (**4**/**5**) and cyclopalladated complexes (**10**/**11**) are unambiguously assigned on the basis of spin–spin structure and changes therein on substitution. The spectra of the ligands in $CDCl_3$ and the complexes in DMSO-d_6 are in complete agreement with the structures in which the halves of the molecule are magnetically equivalent to each other (e.g. 6 = 6′, etc.) The aromatic region displays a group of left–right symmetrical multiplet peaks (4-H_2, b–e) characterizing the four-spin AA′BB′ system (9-H, 13-H; 10-

H, 12-H) at lower field. These signals vary considerably with different R substituents in the aromatic aldehyde. It is quite clear that the electron-releasing groups [Me (b), OMe (c)] shift the signal upfield and withdrawing groups [1 (d), NO_2 (e)] shift them downfield. These signal movements are in accord with the inductive and resonance effects of the R substituent [22]. The signals (4-H) at higher field correspond to *N*-phenyl protons and almost remain unperturbed on substitution. The imine proton (7-H) is expected to appear to the most downfield position as a sharp singlet and moves slightly in either direction depending on the nature of substitution at the C-phenyl ring. The aliphatic protons move to higher field; 14, 14′-H appear as triplet and 15-H as quintet protons. The *N*-phenyl protons are systematically deshielded on palladation: 3-H to 6-H protons are shifted downfield by 0.6–0.7 ppm. The substitution on the C-phenyl ring (11th position) has little influence on these protons.

Sulfur coordination to palladium is reflected by

downfield shifting of the —S—CH_2— signal from the free ligand position. In the complexes the signal of 14, 14′-H protons appear at 0.3 ppm downfield from those of the ligands and the 15-H signal is shifted downfield by 0.7 ppm. The azomethine proton (7-H) shows downfield shifting on metallation of *ca* 0.8 ppm. This accounts for the chelation of the imine nitrogen. On metallation all the protons suffer downfield shifts. The most perturbed protons are the *C*-phenyl protons and the significant feature is the loss of resonance due to 13-H of the *C*-phenyl ring from the NMR spectra and the appearance of new singlet in **10 b–e**. The spectral data are collected in Table 2.

EXPERIMENTAL

Disodium tetrachloropalladate was prepared by treating palladium(II) chloride with sodium chloride in water and evaporating the aqueous solution [7]. Palladium(II) acetate was recrystallized from benzene solution before use. All other chemicals were reagent grade and were used as received. The solvents used in the reactions were dried by reported procedures [23].

UV–vis spectra were recorded on a Shimadzu UV 160A spectrophotometer and IR (4000–200 cm^{-1}) spectra on a Perkin–Elmer 783 and 883 spectrometer. ^{1}H NMR spectra were recorded in $CDCl_3$ and DMSO-d_6 solution on varian Gemini 300 MHz FT NMR spectrometers. Elemental analyses were obtained using a Perkin–Elmer 240c elemental analyser.

Synthesis of ligands

1-2-*Bis*(2-*thio*(N-*benzylidene*)*aniline*)*ethane*, (**3a**). 1,2-Bis((2-aminophenyl)thio)ethane (**2**) was first synthesized by a reported procedure [7]. To a dry ethanolic solution (20 cm^3) of **2** (2 g, 7.25 mmol) was added benzaldehyde (1.54 g, 14.50 mmol) and the solution was refluxed for 2 h on a steam bath. The orange–yellow solution was cooled to room temperature and a dark-coloured gummy mass was separated slowly. The light-yellow supernatant was decanted off. The mass was further boiled with dry ethanol on a steam bath, cooled and the supernatant was decanted off twice as described earlier. It was evaporated at reduced pressure and dried over $CaCl_2$. The yield was 0.98 g (30%). Other Schiff bases were prepared similarly and the yield varied from 30–60%. The solid products obtained for **3c–e** and **4c–e** were purified by recrystallization from a chloroform : ethanol (1 : 4 v/v) mixture. The physical properties are set out in Table 1.

Synthesis of complexes

Dichloro [1,2-*bis*(2-*thio*(N-*benzylidene*)*aniline*) *ethane*)-C^{13}, N, S, $C^{13'}$, N', S',-*dipalladium* (II) (**10a**). To a benzene solution (10 cm^3) of **3a** (0.2 g, 0.48 mmol) was added slowly a warm benzene solution (5 cm^3) of $Pd(OAC)_2$ (0.24 g, 1.07 mmol) and the mixture was refluxed for 1 h. The deposited orange–brown solid was filtered and washed with cold benzene. The dry mass was dissolved in chloroform : acetone (8 cm^3, 1 : 1, v/v) and LiCl (2.5 mmol) was added with continuous stirring. The volume of the mixture was half reduced by slow evaporation at reduced pressure and the separated brown crystals were filtered, washed with a cold chloroform : acetone (1 : 1, v/v) mixture (5 $cm^3 \times 2$) and dried over $CaCl_2$. The yield was 0.18 g, 50%.

Other complexes were also prepared similarly and the yield varied between 45 and 55%. The physical properties are collected in Table 1.

Acknowledgements—The authors are thankful to Professor A. Chakravorty, Calcutta, for elemental analyses and spectral measurements. We thank Dr N. K. Bag, Michigan State University, and Dr P. Basu, Arizona State University, U.S.A., for recording the ^1H NMR spectra. Financial assistance from the Department of Science and Technology and University Grants Commission, New Delhi, is gratefully acknowledged.

(Received 31 January 1996; accepted 22 August 1996)

Abstract—Di-hydrotris(3,5-dimethylpyrazol-1-yl)borate Zn^{II} was prepared from $KHB(3,5\text{-Me}_2\text{pz})_3$ and $Zn(NO_3)_2\cdot 6H_2O$ in acetone, characterized by elemental analysis and ^1H NMR. Crystal structure determination shows that the configuration around the Zn^{II} center is a slightly distorted octahedron. Copyright © 1997 Elsevier Science Ltd

Keywords: synthesis; characterization; crystal structure; zinc complex; poly-nitrogen ligand.

Zinc as an essential element has many physiological functions in living systems. There are more than 160 zinc enzymes which are now known. It is an integral component of many proteins which participate in various metabolic processes. Zinc is also known to be one of the essential inorganic ions which contribute to the catalytic activity and the stability of many metalloenzymes, polynucleotides and membranes [1]. It was of interest to study the model complexes of zinc with poly-nitrogen ligands. In the title compound, the ligand is hydrotris(3,5-dimethylpyrazol-1-yl)borate. It is favourable for the preparation of the transition metal complex [2]. Its geometry as well as strong electron-donating property are valuable in the synthesis of model compounds of several metalloproteins, since coordination of multi-histidyl nitrogen atoms is often observed in metalloproteins. In this paper we describe the preparation, characterization and crystal structure of the title complex.

EXPERIMENTAL

Preparation and analyses of the complex

All chemicals in the reaction were of reagent grade. The preparation of the title compound was in acetone. C, H, N were determined by a Cardo Erba 1106 Element analyser; ^1H NMR spectra were obtained on a Bruker MSL 300 MHz spectrometer using $CDCl_3$ as solvent and TMS as an internal reference. The ligand, potassium hydrotris(3,5-dimethylpyrazol-1-yl)borate, $KHB(3,5\text{-Me}_2\text{pz})_3$, was prepared according to the literature [3]. KBH_4 was reacted with 4.0 equiv. of 3,5-dimethylpyrazol at 204°C for 1 h, with the evolution of 3.0 equiv. of H_2, and filtration followed by washing with hot toluene several times. White crystalline $KHB(3,5\text{-Me}_2\text{pz})_3$ was obtained in 74% yield. $KHB(3,5\text{-Me}_2\text{pz})_3$ was reacted with 1 equiv. of $Zn(NO_3)_2\cdot 6H_2O$ in acetone for 2 h, then the precipitate was filtered, washed with water and acetone many times. The filtrate recrystallized from toluene and left standing for several days. Then the crystal was collected. Found: C, 55.1; N, 24.6; H, 7.0. Calc. for $C_{31.5}H_{47}B_2O_{0.5}N_{12}Zn$ (mol. wt. 688.0). C, 54.9; N, 24.4; H, 6.9%. ^1H NMR ($CDCl_3$): δ ppm 1.37 (s, 18H, Me); 2.42 (s, 18H, Me); 5.58 (s, 6H, pz). The peak at 2.42 ppm was assigned to the methyl near the zinc atom, while the peak at 1.37 ppm to the methyl near the boron atom.

Crystal structure determination

Crystals of the title compound were obtained by slowly cooling the hot toluene solution to room tem-

perature and a colorless platelet of dimensions 0.2 × 0.2 × 0.3 mm was chosen for the measurement. All crystallographic data was collected with a Rigaku AFC7R diffractmeter using Mo-$K\alpha$ radiation (λ = 0.71069 Å) in the ω–2θ scan mode. Of the 2295 collected, 2133 reflections were independent and 1978 reflections with $I > 3.00\ \sigma\ (I)$ were used for the calculation after an empirical absorption based on ψ scans. The structure was solved by direct methods. The non-hydrogen atoms were refined anisotropically. The final cycle of full-matrix least-squares refinement was converged with $R = 0.052$, $Rw = 0.076$ (unweighted and weighted agreement factors resp.) for 269 parameters.

RESULTS AND DISCUSSION

The title compound was prepared according to the following equation:

$$2KHB(3,5\text{-}Me_2pz)_3 + Zn(NO_3)_2 \cdot 6H_2O$$
$$= 2KNO_3 + 6H_2O + [HB(3,5\text{-}Me_2pz)_3]_2Zn$$

The reaction was carried out in acetone and the zinc complex was recrystallized from toluene. The compound was transparent and thermally stable. It was characterized by elemental analysis and ^{1}H NMR spectra. The crystal cell of the complex consists of discrete monomeric molecules, each zinc complex being accompanied by two solvent molecules. The crystallographic data collections and refinement details are listed in Table 1, selected bond distances and angles are given in Tables 2 and 3. The ORTEP plot and unit packing diagram are presented in Figs 1 and 2, respectively.

The Zn atoms are coordinated by six nitrogen atoms of the six pyrazol rings. As evidenced by the N(2)—Zn—N(2) angle (180°), other angles of N—Zn—N (not in a line) are from 85.3(1) to 94.7(1)° and the bond lengths of Zn—N are between 2.160(4) and 2.197(4) Å. The coordination environment of the Zn is a slightly distorted octahedron. The deviation from the ideal configuration can be explained by the steric effect caused by the methyls of the ligands. The boron atoms was coordinated with three nitrogen atoms of the pyrazol rings. The three B—N bond lengths are almost the same (1.55 Å) and so are the N—B—N angle values (109°). It shows that the boron

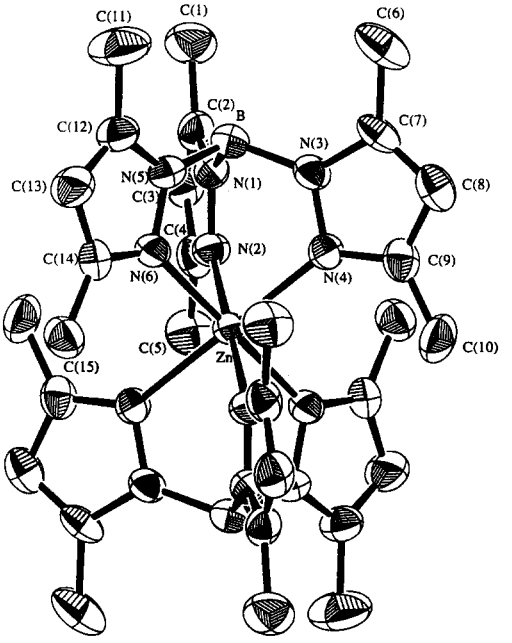

Fig. 1. The ORTEP plot of the crystal.

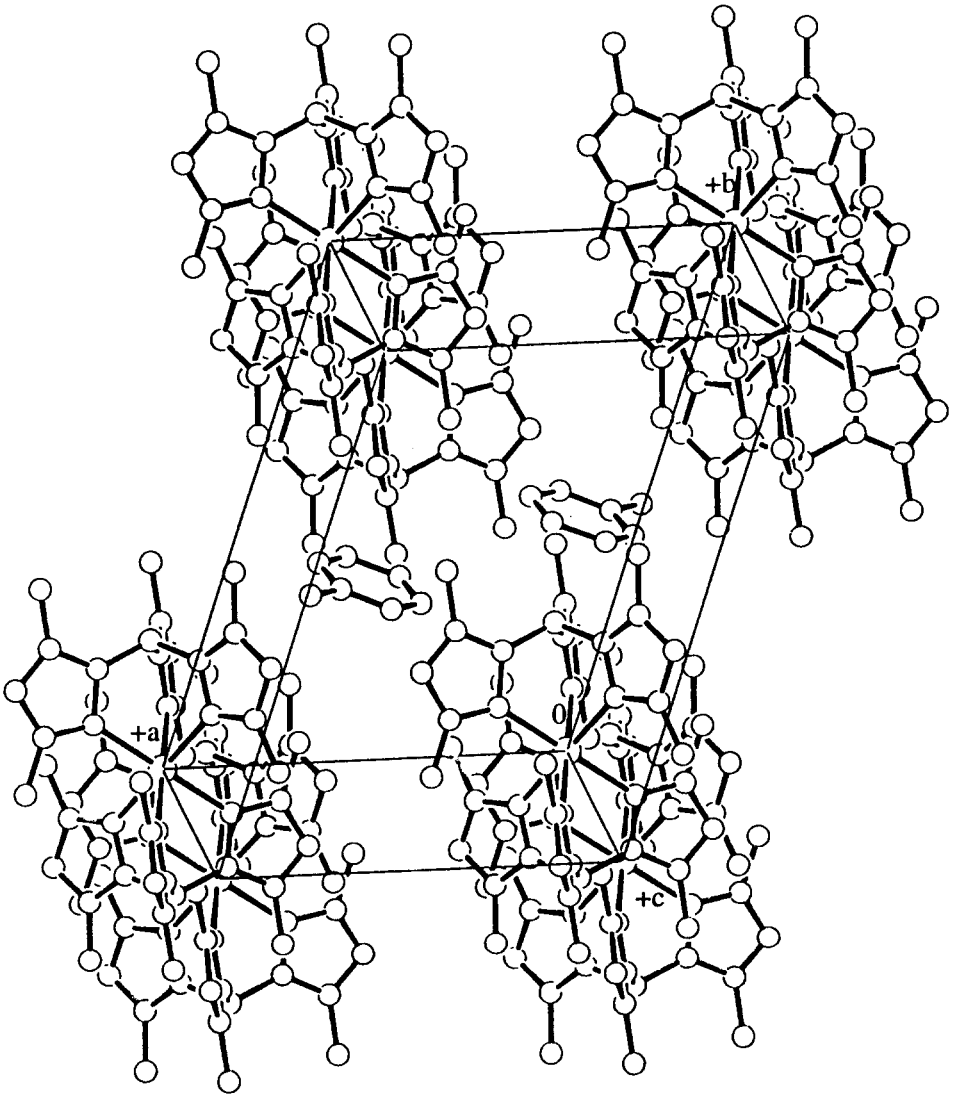

Fig. 2. The unit cell packing diagram of the crystal.

atom retains a strictly tetrahedral configuration. The three N—N lines are parallel, approximately, and the six-membered $B(NN)_2Zn$ ring takes the boat form.

The Zn—N bond distances [average 2.177(1) Å] are longer than the values found in $[\eta^3$-HB(3-Phpz)$_3]$ZnBr [4], [average 2.043(3) Å]. The Zn—N bond lengths are also longer than the Cu—N bond lengths of the compound $[HB(3,5\text{-}Me_2pz)_3CuPPh_3]$ [2.066(5)–2.092(5) Å] [5] and the compound $[pz_2\text{-}(\mu\text{-}pz)_2\text{-}Cu(PPh_3)_2]$ [2.051(3)–2.087(3) Å] [6]. The difference may be the result of the different coordination environments of the metal ions. It is remarkable that the configuration of the title compound is octahedral. Many of the zinc complexes with nitrogen-donor ligands adopt the tetrahedral configuration [7] with Zn—N bond distances (about 2.04 Å) which are shorter than in the title compound. In the title complex the Zn—N bond distances are typical for zinc in octahedral coordination [8] and they are within the ranges found in other octahedral zinc complexes [9].

There are six pyrazol rings in the complex, and they are almost planar. The maximum displacement is 0.001(6) Å for ring N(1)—C(2)—; 0.002(5) Å for

Table 4. Dihedral angles between planes (°)

Plane	1	2	3	4	5

ring N(3)—C(7)— and 0.005(6) Å for ring N(5)—C(13)—. The $(NN)_2$ are almostly in a plane, the maximum displacement is 0.028(4) Å [ring N(1)—N(2)—N(5)—N(6)]. The dihedral angles between the rings are listed in Table 4, in which the planes were defined in the way as the note shows. The biggest dihedral angle is the angle between plane 1 and 4 (150.28°), while the smallest one is the angle between plane 2 and 4 (29.36°).

(Received 4 June 1996; accepted 16 August 1996)

Abstract—Four binuclear cadmium(II) cryptates have been synthesized by [2+3] Schiff-base condensation of tris(3-aminopropyl)amine with sodium 2,6-diformyl-4-R-phenolates (R = OCH_3, CH_3, Br and Cl) in the presence of $Cd(ClO_4)_2 \cdot 6H_2O$. The crystal structure of the cryptate of macrocyclic L^3 (R = Br) $[CdL^3](ClO_4)$ was determined by X-ray diffraction. Each cadmium(II) atom is bonded to three μ_2-phenoxy oxygen atoms and three imine atoms. The coordination geometry of Cd^{II} is considered an irregular distorted octahedron.

Keywords: cadmium(II); binuclear complexes; cryptates; crystal structure; oxygen bridge; irregular distorted octahedron.

The polyaza macrocycles have strong coordination ability and recognition functions for transition metal ions [1–5]. A new kind of macrocyclic ligand has been obtained [6] by template condensation of 2,6-diformyl-4-substituted-phenol with various diamines. These ligands have strong donor atoms, namely, phenoxy oxygen atoms as well as amine nitrogen atoms, and therefore play excellent roles in catalysis and biological simulation [7,8] owing to the special coordination ability with transition metal ions. Recently Gagne and co-workers [9], Nelson and co-workers [10] and others [11] have synthesized several transition metal cryptates by [2+3] condensation of tris(3-aminoethyl)amine (tren) with 2,6-diformyl-4-methylphenol (dmp) in the presence of transition metal ions. But so far there have been few reports of cryptates synthesized by condensation of tris(3-aminopropyl)amine (trpn, the analogue of tren) with dmp or its derivatives. It would be expected that these cryptates would have more plentiful host–guest properties as a result of the flexible long chain of trpn. For example, we have obtained an interesting pentanuclear silver(I) cluster [12] by condensation of trpn with dmp in the presence of silver(I). This paper reports four μ-oxo-bridged binuclear cadmium(II) cryptates synthesized by [2+3] Schiff-base condensation of trpn with 2,6-diformyl-4-R-phenol (R = OCH_3, CH_3, Br, Cl) in the presence of $Cd(ClO_4)_2 \cdot 6H_2O$. The X-ray crystal structure of the cryptate for R = Br shows that the coordination geometry of the Cd^{II} is an irregular distorted octahedron (Fig. 1), being different from the analogues reported up to now in which the coordination geometry of Cd^{II} is an irregular capped octahedron.

EXPERIMENTAL

Materials

2,6-Diformyl-4-R-phenols (R = CH_3O, CH_3, Br, Cl) were prepared by the literature method [13]. Sodium 2,6-diformyl-4-R-phenolates were obtained by mixing equimolar amounts of 2,6-diformyl-4-R-phenol and NaOH in ethanol. Tris(3-ami-

nopropyl)amine was prepared by a modified literature method [14] with a purity of over 99%. All starting materials were of chemical purity.

Physical measurements

The solution electrical conductivity was measured by a BDS-A numerical conductometer (Jiangsu, China) with solution concentrations of *ca* 10^{-4} mol dm^{-3} in acetonitrile. IR spectra were measured as KBr discs using a Nicolet 5DX FT-IR spectrophotometer. Electronic spectra were recorded on a Shimadzu UV-240 spectrophotometer.

Preparation of the cryptates

$[Cd_2L^1](ClO_4)\cdot H_2O$. To a stirred solution of sodium 2,6-diformyl-4-methoxylphenolate (0.1515 g, 0.75 mmol) and $Cd(ClO_4)_2\cdot 6H_2O$ (0.2621 g, 0.625 mmol) in absolute methanol (30 cm^3) was added dropwise a solution of tris(3-aminopropyl)amine (0.094 g, 0.5 mmol) in 15 cm^3 absolute methanol at 0°C. After stirring for 2 h at 35°C, yellowish microcrystals were precipitated and filtered off, washed with methanol and dried *in vacuo*, (yield 75%). Found: C, 47.3; H, 5.5; N, 9.7; Cd, 19.7. Calc. for $C_{45}H_{59}N_8O_{11}ClCd_2$: C, 47.2; H, 5.2; N, 9.8; Cd, 19.7%. IR (cm^{-1}, KBr): 3466 br, [$\nu_{(OH)}(H_2O)$]; 1630 s, ($\nu_{(C=N)}$); 1537 s, ($\nu_{(Ar\text{-}O)}$); 1103 s, ($\nu_{(ClO_4^-)}$). UV–vis [λ_{max} (nm), CH_3CN]: 240 (9310 mol^{-1} dm^3 cm^{-1}); 440 (2724). Λ_M (CH_3CN, 291 K): 104.6 S cm^2 mol^{-1}.

$[Cd_2L^2](ClO_4)\cdot 2CH_3OH$. Similar to $[Cd_2L^1](ClO_4)\cdot H_2O$, $[Cd_2L^2](ClO_4)\cdot 2CH_3OH$ was obtained as a yellowish crystalline product (yield, 65%). Found: C, 49.7; H, 5.2; N, 9.6; Cd, 19.3. Calc. for $C_{47}H_{65}N_8O_9ClCd_2$: C, 49.2; H, 5.7; N, 9.8; Cd, 19.6%. IR (cm^{-1}, KBr): 3452 br, [$\nu_{(OH)}(CH_3OH)$]; 1631 s, ($\nu_{(C=N)}$); 1539 s, ($\nu_{(Ar\text{-}O)}$); 1096 s ($\nu_{(ClO_4^-)}$). UV–vis [λ_{max} (nm), CH_3CN]: 240 (14,000 mol^{-1} dm^3 cm^{-1}); 430 (5000). Λ_M (CH_3CN, 301 K): 100 S cm^2 mol^{-1}.

$[Cd_2L^3](ClO_4)\cdot 3H_2O$. By a similar procedure, $[Cd_2L^3](ClO_4)\cdot 3H_2O$ was obtained as a yellowish crystalline product (yield, 80%). Found: C, 37.6; H, 4.0; N, 8.6; Cd, 17.5. Calc. for $C_{42}H_{54}N_8O_{10}Br_3ClCd_2$: C, 37.9; H, 4.1; N, 8.4; Cd, 16.9%. IR (cm^{-1}, KBr): 3450 br, [$\nu_{(OH)}(H_2O)$]; 1638 s, ($\nu_{(C=N)}$); 1537 s, ($\nu_{(Ar\text{-}O)}$); 1096 s ($\nu_{(ClO_4^-)}$). UV–vis [λ_{max} (nm), CH_3CN]: 420 (3643 mol^{-1} dm^3 cm^{-1}); 238 (15,178). Λ_M (CH_3CN, 291 K): 114 S cm^2 mol^{-1}. The yellowish crystals $[Cd_2L^3](ClO_4)$ suitable for X-ray structure determination were obtained by slow evaporation of the filtrate at ambient temperature.

$[Cd_2L^4](ClO_4)\cdot 0.5H_2O$. By a similar procedure, $[Cd_2L^4](ClO_4)\cdot 0.5H_2O$ was obtained as a yellowish crystalline product (yield, 69%). Found: C, 44.0; H, 4.6; N, 9.8; Cd, 19.2. Calc. for $C_{42}H_{49}N_8O_{7.5}Cl_4Cd_2$: C, 43.8; H, 4.3; N, 9.4; Cd, 19.5%. IR (cm^{-1}, KBr): 3480 br, [$\nu_{(OH)}(H_2O)$]; 1637 s, ($\nu_{(C=N)}$);

1539 s, ($\nu_{(Ar\text{-}O)}$); 1103 s ($\nu_{(ClO_4^-)}$). UV–vis [λ_{max} (nm), CH_3CN]: 410 (3428 mol^{-1} dm^3 cm^{-1}); 240 (9407). Λ_M (CH_3CN, 291 K): 90.7 S cm^2 mol^{-1}. ***CAUTION!*** Perchlorate salts of metal complexes with organic ligands are potentially explosive. Only small amounts of material should be prepared, and these should be handled with caution. The complexes described in this report have, so far, been found to be safe when used in small quantities.

X-ray crystal structure determination of $[Cd_2L^3](ClO_4)$

Crystal data. $C_{42}H_{48}N_8O_7Br_3ClCd_2$, F.W. = 1276.88, monoclinic, space group $C2/c$ (No. 15), a = 21.374(8), b = 12.340(2), c = 18.961(4) Å, β = 112.09(2)°, Z = 4, V = 4634(4) Å^3, $F(000)$ = 2520, D_c = 1.83 g cm^{-3}, μ = 35.91 cm^{-1}, R = 0.052, R_w = 0.063.

Data collection and refinement of the crystal structure. A single crystal of dimension 0.38 × 0.22 × 0.08 mm was mounted on a glass fibre. The crystal data were collected on an Enraf–Nonius CAD4 four circle diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å, T = 296 K) using an ω–2θ scan mode with ω scan width, 0.50 + 0.350 tanθ, scan rate <5.49° min^{-1}; a total of 4304 independent reflections were collected in the range of $2 < 2\theta < 50°$, of which 2600 reflections with $I > 3\sigma(I)$ were used in the structure determination and refinement after Lp corrections. The structure was solved by the MITHRIL direct method. Additional non-hydrogen atoms were located from a difference Fourier map. Hydrogen atoms were introduced in calculated positions but not refined. The final least-squares cycle gave R = 0.052, R_w = 0.063 [w = $1\sigma^2(F)$]. The maximum and minimum residuals had values of 0.89 and −1.34 eÅ^{-3}, respectively. All calculations were performed using the programs contained in the TEXSAN package.

RESULTS AND DISCUSSION

Characterization of the cryptates

All the four cryptates possess similar spectral features. In the infrared spectra the strong peaks appeared at *ca* 1630 cm^{-1} corresponding to the stretching vibration of imino C=N bonds, and neither symmetric and asymmetric stretching frequencies at 3280 and 3330 cm^{-1} for NH_2 groups, nor strong peaks at 1650–1700 cm^{-1} for the carbonyl groups were present. This means that all the NH_2 and CO groups have been condensed into C=N bonds. A broad band at *ca* 3400 cm^{-1} characteristic of the OH group of CH_3OH or H_2O showed that CH_3OH or H_2O molecules existed in the cryptates, in agreement with the elemental analysis. But the three water molecules were lost during the growth of the single crystal of $[Cd_2L^3](ClO_4)$ for X-ray structure determination. The strong peak at *ca* 1090 cm^{-1}, without splitting, showed that the ClO_4^- did not take part in coordination with the Cd^{II} atom. This was also confirmed by the molar conductivity of the cryptates (Λ_M values are 90–114 S cm^2 mol^{-1}) which was attributable to 1 : 1 electrolytes [15]. It implies that the three phenol groups in the ligand lost hydrogen atoms during coordination. Two intense absorptions at about 240 and 400 nm in the electronic spectra of the cryptates were designated as π–π^* transitions of the K-band of the benzene rings and of the C=N groups [6], respectively. The substituents hardly gave any effects on the peak positions of the π–π^* transitions of the benzene rings, but positions of the maxima for the C=N bonds depended on the electron-attracting ability of the substituents. For the cryptates with different substituents, the values for the wavelengths of the C=N peaks have the following sequence: $OCH_3 > CH_3 > Br > Cl$; namely, the strong electron-attracting ability of substituents make the charge transfer require high energy, as a result, the peaks are blue-shifted.

Description of the structure of $[Cd_2L^3](ClO_4)$

A perspective view of the cation $[Cd_2L^3]^+$ and a packing diagram are shown in Figs 2 and 3, respectively. The selected bond distances and angles are given in Tables 1 and 2, respectively.

Figure 3 shows that each unit cell contains four molecular units, each consisting of one molecule of the cryptate cation $[Cd_2L^3]^+$ and one perchlorate anion. It may be seen from Fig. 2 that the cryptate cation has crystallographic C_2 symmetry. The C_2 axis passes through one of the benzene rings, the phenoxy group and the bromide. Each cadmium atom lies in the centre of an irregular distorted octahedron composed of three imino nitrogen atoms, N(2), N(3a), N(4), and three bridging phenoxy oxygen atoms, O(1), O(1a), O(2). Of these N(2) and O(1a) are located approximately at the axial sites and N(3a), O(1), O(2) and N(4) lie in equatorial positions of the octahedron. The

distances between Cd and each imino nitrogen are very close to each other, being about 2.33 Å. The Cd-μ-OPh distances are ranged from 2.32 to 2.30 Å. The distance Cd(1)···Cd(1a) is 3.452 Å and, apparently, there is no interaction between the two metals. The distance between Cd(1) and N(1) (tertiary nitrogen) is 3.051 Å, implying that there is no chemical bond between them. The Cd(1)···N(1) distance is longer than that of its analogue $[Cd_2L^2]^+$ in which the substituent on the benzene ring is a methyl group instead of the bromide and another analogue, whose ligand was synthesized by condensation of tren with dmp, their corresponding distances are 2.65 and 2.79 Å, respectively. Therefore, in our cryptate the substituent Br rendered the coordination environment of Cd^{II} different from that in the methyl substituent in which Cd^{II} is located in the centre of a seven-coordinate capped octahedron. The perchlorates are disordered and lie on a centre of inversion in the unit cell.

Abstract—The rhodium(III) complexes *trans*-$[Rh(L\text{-}L)_2X_2]^+$ [L-L = *o*-$C_6H_4(PMe_2)_2$ or *o*-$C_6H_4(AsMe_2)_2$, X = Cl, Br or I] have been prepared from $RhX_3 \cdot nH_2O$ and L-L, and converted to the *cis*-$[Rh(L\text{-}L)_2X_2]^+$ by sequential treatment with Li_2CO_3 and HX. Both series of compounds have been characterized by analysis, UV–vis and multinuclear (^1H, $^{31}P\{^1H\}$ and ^{103}Rh) NMR spectroscopy. The trends in the ^{103}Rh chemical shifts with L-L, X and stereochemistry are discussed. The crystal structures of *trans*-$[Rh\{o\text{-}C_6H_4(PMe_2)_2\}_2Cl_2]Cl$ and *trans*-$[Rh\{o\text{-}C_6H_4(AsMe_2)_2\}_2I_2]BF_4$ have been determined. Copyright © 1997 Elsevier Science Ltd

Keywords: rhodium; NMR; diphosphine; diarsine.

The kinetic inertness of low-spin d^6 ions in pseudo-octahedral environments often allows the isolation of geometric isomers and for Rh^{III} many examples of *mer* and *fac* and *cis* and *trans* isomers with particular ligand sets have been characterized [1]. Despite a number of reports of *trans*-$[Rh(L\text{-}L)_2X_2]^+$ (L-L = diphosphine or diarsine, X = Cl or Br) [2–7], systematic studies of the *cis* isomers are lacking, little has been reported about the complexes with X = I and a recent paper [8] which characterized *cis*-$[Rh(L\text{-}L)_2Cl_2]^+$ [L-L = $Me_2P(CH_2)_nPMe_2$, n = 2 or 3] cast doubt on some previous reports of *cis* isomers. We report here a systematic study of the syntheses and properties of both *cis* and *trans* isomers of the structurally related ligands *o*-$C_6H_4(PMe_2)_2$ and *o*-$C_6H_4(AsMe_2)_2$ and show that ^{103}Rh NMR spectroscopy is a powerful way of identifying the isomers.

RESULTS AND DISCUSSION

The reaction of hydrated rhodium(III) trihalides $RhX_3 \cdot nH_2O$ (X = Cl, Br, or I; n usually *ca* 3)† with the ligands in ethanol–H_2O mixtures gave the rhodium(III) cations $[Rh(L\text{-}L)_2X_2]^+$ [L-L = *o*-$C_6H_4(PMe_2)_2$ or *o*-$C_6H_4(AsMe_2)_2$] isolated either as X^- or BF_4^- salts. Examination of the crude products by ^1H or in the case of the diphosphine complexes by $^{31}P\{^1H\}$ NMR spectroscopy showed that the *trans* isomer was the major product in each case, usually $\geqslant 80\%$, and pure *trans* isomers were easily obtained by recrystallization. The only exception was $[Rh\{o\text{-}C_6H_4(PMe_2)_2\}_2Br_2]^+$, where the *cis* isomer was present to $\leqslant 40\%$. The *cis* isomers were made from the *trans* by heating with excess Li_2CO_3 in aqueous ethanol for 48 h, which generates the η^2-carbonato complex, followed by treatment with aqueous HX. This method was developed by Bosnich *et al.* to prepare *cis*-$[Co(L\text{-}L)_2X_2]^+$ from the corresponding *trans* isomers [9]. The complexes are generally poorly soluble in chlorocarbons and alcohols, but more soluble in *N*, *N*-dimethylformamide or dimethylsulfoxide.

The ^1H NMR spectra (Table 1) of the *trans*-$[Rh\{o\text{-}C_6H_4(AsMe_2)_2\}_2X_2]^+$ isomers each show a single sharp

† Commercial samples (Johnson Matthey Ltd) were used as received. ^{103}Rh NMR studies on the chloride have shown that mixtures of chloro-aquo complexes are present in varying amounts [10]. The bromide is probably similar. The black $RhI_3 \cdot nH_2O$ is very slightly soluble in water, but dissolves on heating with the ligands in EtOH–H_2O mixture.

The ^{1}H δ(Me) resonances of the diphosphine complexes are ill-defined second-order multiplets due to strong P—P couplings. d = doublet, d.t = doublet of triplets.

δ(Me) resonance, which shift to high frequency Cl < Br < I. Those of the diphosphines are similar, although the resonances are broader due to poorly resolved phosphorus couplings. The corresponding *cis* isomers exhibit four δ (Me) resonances of equal intensity. For the *trans*-$[Rh\{o\text{-}C_6H_4(PMe_2)_2\}_2X_2]^+$ the $^{31}P\{^{1}H\}$ NMR spectra are doublets with ^{1}J (^{31}P—^{103}Rh) = 80–85 Hz, whilst the *cis* isomers exhibit two doublets of triplets (Table 1) with the higher frequency d. of t. due to P_{transX} with ^{1}J (^{31}P—^{103}Rh) *ca* 105 Hz and ^{2}J (^{31}P—^{31}P) *ca* 15 Hz, whilst the second d. of t. is due to P_{transP} with ^{1}J (^{31}P—^{103}Rh) *ca* 83 Hz.

The ^{103}Rh NMR spectra are listed in Table 2 and Fig. 1 shows typical examples. The spectra were recorded by direct observation from saturated solutions of the complexes in $HCONMe_2$ or CH_2Cl_2 containing a free radical relaxation agent and with a 2 s pulse delay. For the diphosphine complexes relatively poor solubilities necessitated *ca* 70–100,000 scans to clearly resolve the couplings. The data in Table 2 reveal relatively systematic shifts with donor atoms and with the isomer present. Thus, for a particular ligand–halide combination the resonance of the *cis* isomer is always to low frequency of the *trans*, whilst for a particular geometric isomer the $\delta(^{103}Rh)$ of the diphosphine complexes are *ca* 400–500 ppm to low frequency of the diarsine analogues. The effect of changing the halide is also a systematic shift to low frequency Cl→Br→I. The literature data on ^{103}Rh NMR chemical shifts are very limited for group 15 donor complexes [10], but the trends in chemical shift observed in this work with isomer and donor atom are consistent with published data. It is, however, notable that the shifts observed in the present series of complexes are to low frequency of those observed for corresponding complexes of type *cis*- and *trans*-$[RhL_4X_2]^+$ (L = PMe_3 or $AsMe_3$) [10]

or (*cis*-) $[Rh\{As(o\text{-}C_6H_4AsMe_2)_3\}X_2]^+$ [11]. The diphosphine and diarsine ligands used in the present study produce very large ligand fields [3] and since in the Ramsay equation the ^{103}Rh chemical shift varies inversely with the electronic exitation energy between the filled and empty *d*-orbitals [10], this correlates with the substantial low-frequency shifts observed. Comparisons can also be made with the ^{59}Co NMR shifts of the *trans*/*cis*-$[Co(L\text{-}L)_2X_2]^+$ [L-L = $o\text{-}C_6H_4(PMe_2)_2$ and $o\text{-}C_6H_4(AsMe_2)_2$] [12,13]. The broad lines

[a] CH_2Cl_2 solutions.

($W_{1/2} \leqslant 20{,}000$ Hz) resulting from the fast relaxation of the quadrupolar ^{59}Co nucleus ($I = 7/2$, 100%) limit the precision of the shifts to *ca* ±30 ppm, but whilst the same low frequency shift on replacing arsenic by phosphorus is found, the halide dependence is reversed with the iodide complexes having the highest frequency resonance and with chloride and bromide having similar shifts. The $\delta(^{59}Co)$ resonances of corresponding *cis* and *trans* isomers for X = Cl or Br are also the same within *ca* 50 ppm (*cis* isomers have not been made for X = I).

The UV–vis spectra of the complexes are listed in Table 3. The *d–d* spectra of low-spin d^6 ions in an octahedral L_6 environment are expected to contain two transitions from the $^1A_{1g}$ ground state to (in order of increasing energy) $^1T_{1g}$ and $^1T_{2g}$. In *trans*-L_4X_2 environments (local D_{4h} symmetry) the $^1T_{1g}$ splits into ^1E_g and $^1A_{2g}$, but the higher energy transition to $^1T_{2g}$ is rarely detectably split. The same states occur for the *cis* isomers, but the splitting of the $^1T_{1g}$ state is much smaller and often not resolved [14]. For the *trans*-$[Rh(L\text{-}L)_2X_2]^+$ (Table 3) the lowest energy band in each case is clearly the $^1A_{1g} \rightarrow {}^1E_g$ transition. Except for *trans*-$[Rh\{o\text{-}C_6H_4(PMe_2)_2\}_2Cl_2]^+$ all the complexes also show a second band $< 30{,}000$ cm^{-1} which are the $^1A_{1g} \rightarrow {}^1A_{2g}$ transition. The very high extinction coefficients reported are due to the fact that these bands lie in the tails of the very intense features $> 30{,}000$ cm^{-1} which are $\pi \rightarrow \pi^*$ of the Ph rings and $\pi(X) \rightarrow e_g(Rh)$ and σ (P/As) $\rightarrow e_g$ (Rh). The *d–d* transitions of the corresponding *cis* isomers, which are expected to lie at higher energy than those in the *trans* complexes, are mostly obscured by the charge transfer transitions.

Cyclic voltammetry studies in CH_2Cl_2 solutions containing 0.1 mol dm^{-3} $[Bu^n_4N][BF_4]$ revealed that all the complexes undergo completely irreversible reductions in the range −0.6 to −0.9 V (*vs* Fc/Fc^+ at +0.57 V) presumably to Rh^I, but no oxidative activity was seen out to the solvent limit at *ca* +2 V. The irreversibility no doubt reflects the change in coordination number, since Rh^I is likely to be four- or five-coordinate, whilst the great stability of the $4d\text{-}t_{2g}^6$ configuration with strong field ligands precludes oxidation to Rh^{IV} [15].

Crystallographic results

The structures of both complexes reported are of *trans* isomers, despite numerous attempts we were unable to obtain suitable crystals of the *cis* isomers. The structures of one cation in *trans*-$[Rh\{o\text{-}C_6H_4(AsMe_2)_2\}_2I_2]BF_4$ is shown in Fig. 2 and bond lengths and angles are given in Table 4. Despite some problem with the choice of crystal system (see Experimental),

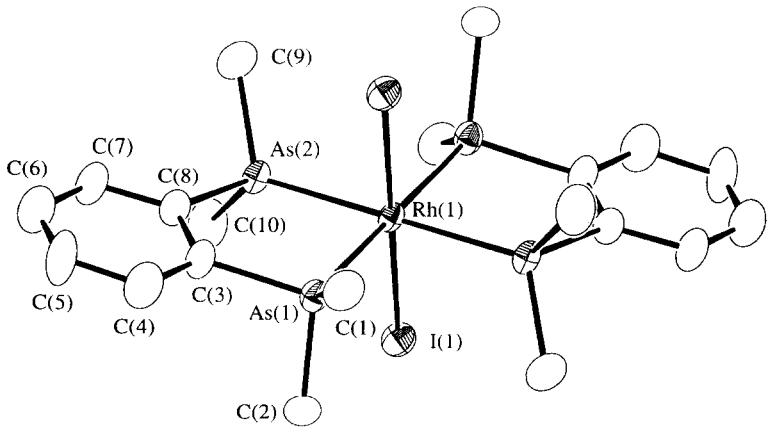

Fig. 2. One of the two cations in $[Rh\{o\text{-}C_6H_4(AsMe_2)_2\}_2I_2]BF_4$ with ellipsoids drawn at the 50% level. The second cation is very similar.

Table 4. Selected bond lengths (Å) and angles (°) for $[Rh\{o\text{-}C_6H_4(AsMe_2)_2\}_2I_2]BF_4$

Rh(1)—I(1)	2.679(1)	Rh(2)—I(2)	2.680(1)
Rh(1)—As(1)	2.426(2)	Rh(2)—As(3)	2.422(2)
Rh(1)—As(2)	2.424(2)	Rh(2)—As(4)	2.424(2)
	As—C	1.90(2)–1.96(2)	
	C—C	1.37(3)–1.43(2)	
	B—F	1.32(3)–1.61(3)	
As(1)—Rh(1)—As(2)	84.80(5)	As(3)—Rh(2)—As(4)	84.72(5)
I(1)—Rh(1)—As(1)	92.88(5)	I(2)—Rh(2)—As(3)	92.38(5)
I(1)—Rh(1)—As(2)	92.31(5)	I(2)—Rh(2)—As(4)	92.85(5)

in chemical terms the geometry is established. The cations lie on a centre of symmetry with Rh—I distances of 2.679(1) and 2.680(1) Å compared with 2.629(1)–2.755(1) Å in $[RhI_3(dppm)(CH_3CN)]$ [16] and Rh—As distances of 2.422(2)–2.426(2) compared with 2.345(4) to 2.454(4) Å in three $[Rh(L\text{-}L)_2Cl_2]^+$ [L-L = $Me_2As(CH_2)_3AsMe_2$] species [7]. The angles between the plane of the C_6 ring and the $RhAs_4$ residue are both 12°. The structure of the cation in *trans*-$[Rh\{o\text{-}C_6H_4(PMe_2)_2\}_2Cl_2]Cl$ is shown in Fig. 3 and bond lengths and angles are given in Table 5. Both *cis* and *trans* isomers of $[Rh(L\text{-}L)_2Cl_2]^+$ [L-L = $Me_2P(CH_2)_nPMe_2$, $n = 2$ or 3] species have been characterized [7,8] and the Rh—Cl [2.359(1) Å] and Rh—P distances [2.333(1), 2.328(1) Å] in the present compound can be compared with values from *trans*-$[Rh(Me_2P(CH_2)_3PMe_2)_2Cl_2]PF_6$, Rh—Cl 2.359(1), Rh—P 2.363(1), 2.364(1) Å] [8]. The Rh is positioned on a centre of symmetry and the angle between the C_6 ring and the RhP_4 residue is 9.1°.

EXPERIMENTAL

Physical measurements were made as described previously [17]. ^{103}Rh $\{^1H\}$ NMR data were recorded at

11.4 MHz on a Bruker AM360 spectrometer at 300 K, from concentrated solutions of the complexes in CH_2Cl_2 or $HCONMe_2$ in 10 mm o.d. tubes containing the free radical TEMPO as a relaxation agent and with a 2 s pulse delay. Typically 50–100,000 scans were accumulated. Due to the long accumulation times the temperature was maintained at 300 K *via* the variable temperature unit of the spectrometer, otherwise variations in room temperature broadened or split the resonances observed [10]. Chemical shifts are reported to high frequency of $\Xi = 3.16$ MHz [10]. Hydrated rhodium(III) halides were obtained from Johnson Matthey and used as received.

Preparations and characterizations

Trans-$[Rh\{o\text{-}C_6H_4(PMe_2)_2\}_2Cl_2]Cl$. To a solution of $RhCl_3 \cdot 3H_2O$ (0.26 g, 1.0 mmol) in aqueous ethanol (50 cm^3 1:2 H_2O: EtOH, v/v) was added the ligand (0.42 g, 2.1 mmol) under nitrogen. The mixture was refluxed for 2 h when a clear yellow solution formed. The solution was concentrated under reduced pressure and the pale yellow solid which separated was recrystallized from CH_2Cl_2/EtOH (0.36 g, 60%). Found: C, 39.9; H, 5.2. Calc. for $C_{20}H_{32}Cl_3P_4Rh$: C, 39.6; H, 5.3%.

Trans-$[Rh\{o\text{-}C_6H_4(PMe_2)_2\}_2X_2]X$ (X = Br or I) were made similarly. Found: C, 31.9; H, 4.1. Calc. for $C_{20}H_{32}Br_3P_4Rh$: C, 32.4; H, 4.3%. Found: C, 27.0, H, 3.5. Calc. for $C_{20}H_{32}I_3P_4Rh$: C, 27.3; H, 3.6%.

Trans-$[Rh\{o\text{-}C_6H_4(AsMe_2)_2\}_2Cl_2]BF_4$. To a solution of $RhCl_3 \cdot 3H_2O$ (0.39 g, 1.5 mmol) in ethanol (50 cm^3) was added the ligand (0.86 g, 3.0 mmol) under nitrogen and the mixture refluxed for 3 h. The solution was concentrated to 10 cm^3 and 40% HBF_4 (5 cm^3) added. The yellow precipitate was filtered off, rinsed with diethyl ether and recrystallized from hot ethanol (0.58 g, 70%). Found: C, 28.4; H, 3.8. Calc. for $C_{20}H_{32}As_4BCl_2F_4Rh$: C, 28.8; H, 3.8%.

Trans-$[Rh\{o\text{-}C_6H_4(AsMe_2)_2\}_2I_2]BF_4$ was made similarly. Found: C, 23.8; H, 3.3. calc. for $C_{30}H_{32}As_4BF_4I_2Rh$: C, 23.6; H, 3.1%. *trans*-$[Rh\{o\text{-}C_6H_4(AsMe_2)_2\}_2Br_2]Br$ was made by the same method but omitting the HBF_4. Found: C, 26.6; H, 3.4. Calc. for $C_{20}H_{32}As_4Br_3Rh$: C, 26.2; H, 3.5%.

Cis-$[Rh\{o\text{-}C_6H_4(PMe_2)_2\}_2Cl_2]Cl$. A slurry of the *trans* isomer (0.36 g, 0.6 mmol) in ethanol (30 cm^3) was treated with Li_2CO_3 (0.18 g, 2.4 mmol) in water (30 cm^3) and the mixture refluxed for 48 h under nitrogen. The resulting pale solution was cooled, filtered and then concentrated hydrochloric acid (3 cm^3) added slowly. The ethanol was removed *in vacuo* and the yellow precipitate filtered off, rinsed with distilled water and diethyl ether. It was recrystallized from ethanol/CH_2Cl_2 (0.16 g, 45%). Found: C, 40.1; H, 5.5. Calc. for $C_{20}H_{32}Cl_3P_4Rh$: C, 39.6; H, 5.3%. The corresponding bromide and iodide were made similarly. Found: C, 32.9; H, 4.5. Calc. for $C_{20}H_{32}Br_3P_4Rh$: C, 32.4; H, 4.3%. Found: C, 27.2, H, 3.6. Calc. for $C_{20}H_{32}I_3P_4Rh$: C, 27.3; H, 3.6%.

The *cis*-$[Rh\{o\text{-}C_6H_4(AsMe_2)_2\}_2X_2]X$ were made from the *trans* isomers and Li_2CO_3 (as above) yields *ca* 50%. (X = Cl) Found: C, 28.2; H, 3.8. Calc. for $C_{20}H_{32}As_4Cl_3Rh$: C, 28.8; H, 3.8%. (X = Br) Found: C, 26.7; H, 3.8. Calc. for $C_{20}H_{32}As_4Br_3Rh$: C, 26.2; H, 3.5%. (X = I) Found: C, 22.5; H, 3.1. Calc. for $C_{20}H_{32}As_4I_3Rh$: C, 22.7; H, 3.0%.

Crystal structure determinations

Diffracted intensities were recorded on a Rigaku AFC7S diffractometer fitted with Mo radiation and graphite monochromator. Crystals of $[Rh\{o\text{-}C_6H_4(AsMe_2)_2\}_2I_2]BF_4$ were obtained from CH_2Cl_2/Et_2O by slow evaporation and the intensity data recorded at 150 K. The initial unit cell [$a = 12.983(2)$, $b = 36.789(6)$, $c = 11.084(2)$ Å, $\alpha = 92.81(1)$, $\beta = 109.35(1)$, $\gamma = 84.00(2)°$] and measured intensities (18353) gave a solution containing the unusual number of six cations per unit cell ($Z = 6$). Inspection of a packing diagram of the unit cell and the atomic coordinates strongly suggested that the chosen cell was too large by a factor of three and that a smaller cell with $Z = 2$ could be chosen. An identical effect has been commented on before [18]. The transformation resulted in a large amount of discarded very weak reflection data and that remaining was used to obtain a structure from the crystal of less than ideal quality. It was noted that the Niggli matrix [19] for this smaller cell indicated that it could be transformed into a monoclinic C-lattice [18] and an alternative solution was explored in the higher symmetry system. The likely space groups are $C2/c$ or $C2/m$, both being centrosymmetric, the choice being governed by the $h0l$ reflections for which a number had $I \gg \sigma(I)$. No solution emerged in $C2/m$ and while $C2/c$ adequately described the cation it failed to produce a plausible BF_4^- anion. The structure solution was therefore described in terms of the triclinic ($Z = 2$) cell with details given in Table 6. The Rh atoms are positioned on a centre of symmetry; Rh, As, I and C atoms were given anisotropic thermal parameters; no H atoms were included in the model and the BF_4^- anion shows the commonly encountered disorder problems. The structure solution and refinement on F^2 were carried out using SHELXS86 [20] and SHELXL93 [21], respectively.

Crystals of $[Rh\{o\text{-}C_6H_4(PMe_2)_2\}_2Cl_2]Cl$ were obtained from CH_2Cl_2/Et_2O by slow evaporation and the intensity data recorded at 150 K. The structure emerged from the heavy atoms located using SHELXS86 [20], and subsequent atoms were found from structure factor and electron density calculations. The rhodium is positioned on a centre of symmetry; all the non-hydrogen atoms were given anisotropic thermal parameters and the H atoms were located in the electron-density maps. Hydrogen atom

Metal supported macrocycles: synthesis and characterization of some new 1,3-bis(benzimidazol-1-yl-methylene)benzene and 1,4-bis(benzimidazol-1-yl-methylene)benzene-bridged metal(II) cation complexes

Sukhvinder K. Chawla* and Beerpal K. Gill

Department of Chemistry, Guru Nanak Dev University, Amritsar 143005, India

(Received 30 July 1996; accepted 12 August 1996)

Abstract—Two new non-chelating bidentate ligands 1,3-bis(benzimidazol-1-yl-methylene)benzene, hereafter 1,3-BIX, and 1,4-bis[benzimidazol-1-yl-methylene]benzene, hereafter 1,4-BIX, have been synthesized and their complexes with M^{II} salts (M = Co, Ni, Cu, Zn, Pd and Pt) have been prepared and characterized using elemental analysis, magnetic moment measurement, IR, UV–vis and ^{13}C NMR and FAB-MS (in some cases) studies. Cu^{II}, Pd^{II} and Pt^{II} metal ions yield dinuclear square-planar complexes *viz.* $[enM(BIX)]_2X_4$ (en = 1,2 diaminoethane; M = Pd or Pt, X = NO_3; M = Cu, X = ClO_4, BIX = 1,3- or 1,4-BIX). Co^{II} chloride forms dimeric tetrahedral $[Co(BIX)Cl_2I_2$, whereas Ni^{II} and Zn^{II} chlorides yield polymeric $[M(BIX)Cl_2]_n$ complexes.

Keywords: non-chelating; macrocycle; metal supported; supramolecule.

Currently there has been particular interest in the synthesis of macrocycles by the self-assembly of ligands around the metal ion in which the metal → ligand coordinate bond replaces the conventional covalent C—C or C—X bond of organic macrocycles. Access to supramolecules *via* non-covalent interactions is presently at the forefront of modern chemistry. Moreover, metal supported macrocycles can be conveniently generated *via* one pot synthesis in contrast to their organic counterparts which involve cumbersome multistep synthesis.

In the past two decades, there have been scattered accounts of the late transition metal ions forming di-, tri-, and tetranuclear complexes enclosing a cavity in the middle. For example, bis-pyrazoles, imidazoles, pyridazines and 3,5-bis[2-pyridyl]pyridazine form multinuclear complexes with Co^{II}, Ni^{II}, Cu^{I}, Cu^{II} and Au^{I} metal ions [1–5]. All these ligands have one thing in common that they disfavour binding to the same metal centre. However, Fujita *et al.* [6] were the first to recognize the potential of such molecules to act as inorganic hosts and used them for molecular recognition. These and other workers have prepared a series of cationic dimeric and tetrameric complexes by interaction of square-planar metal ion species *viz.* $[L_2MX_2]$ [L_2 = en or 1,3-bis(diphenylphosphino)propane or bis-triphenylphosphine; X = OSO_2CF_3, NO_3 or ClO_4] by reacting a variety of linear bidentate ligands such as 4,4′-bipyridine [6], diazapyrene, dicyanobenzene [7], 1,2-bis(4-pyridyl)ethane, 1,4-bis[4-pyridylmethylene]-2,3,5,6-tetrafluorobenzene [8] and 1,4-bis(4-pyridylmethylene)benzene [9] and evaluated some of these complexes for charged and neutral organic guests.

We are interested in linear biosimulating nitrogen-based potentially bidentate ligands because of the ease with which one can achieve variation in pre-organization, cavity size, rigidity and electronic effects of macrocycle. Complexes of 1,3-BIX and 1,4-BIXX (Fig. 1) have been prepared and characterized with a variety of metal ions *viz.* Co^{II}, Ni^{II}, Cu^{II}, Zn^{II}, Pd^{II} and Pt^{II}.

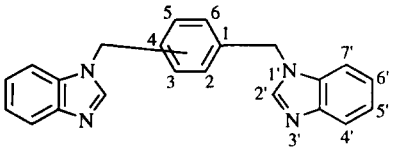

Fig. 1. 1,3- or 1,4-BIX ligand.

EXPERIMENTAL

Physical measurement

Elemental analysis of the complexes were carried out by Regional Sophisticated Instrumentation Centre of Punjab University, Chandigarh, on a Carlo Erba Model 1106. The FAB-MS studies on some complexes were made on POS FAB NBA at the Department of Biochemistry, Washington State University, U.S.A. The ^1H and ^{13}C NMR spectra of ligands and their Pd^{II} and Pt^{II} complexes were recorded on a Bruker A.C. 200 MHz instrument. Mass spectra of the ligands were obtained on Shimadzu-GCMS-OP 2000A. UV–vis spectra of the complexes as solutions were recorded in the range 200–1100 nm using UV-160A recording type Shimadzu spectrophotometer. IR spectra of complexes were recorded on FTIR 8101 M Shimadzu and SP3-300 spectrophotometers as KBr pallets. The ESR spectra of the Cu^{II} complexes were studied at room temperature on an FE-3XG JEOL X-band instrument. The magnetic field in the range 3000 ± 2500 G at a constant microwave frequency of 9.44 GHz was applied. The magnetic susceptibility measurements were made on powdered samples using Evan's method on the magnetic susceptibility balance, Johnson Matthey Engineered Products, England.

Materials

Benzoyl peroxide, *m*-and p-xylenes, *N*-bromo-succinimide were procured from Loba, Bombay. Benzimidazole and metal salts were purchased from Glaxo Laboratories, Bombay or Ranbaxy Chandigarh.

Solvent ether was dried over sodium metal, while acetonitrile was distilled over phosphorus pentoxide immediately before use. All other materials and solvents were used as such without further purification.

m-xylene dibromide and *p*-xylene dibromide were prepared by a reported method [10].

Preparation of 1,3-*bis*(*benzimidazol*-1-*yl-methylene*) *benzene*

A mixture of benzimidazole (3.57 g, 0.03 M), potassium-*tert*-butoxide (3.57 g, 0.032 M) and the catalyst 18-crown-6 (3–4 mg) was stirred for 15 min in dry ether and *m*-xylene dibromide (4 g, 0.015 M) was quickly added to the reaction mixture. The contents were stirred for 25 h (TLC monitored) and filtered. The residue was washed twice with dry ether and refluxed with acetonitrile (30 cm^3) for 1 h to extract the product. It was then filtered and washed with two portions of acetonitrile (10 cm^3). The combined filtrate was concentrated to half its volume, which on cooling gave crystals of the product. The crude product was further purified by recrystallization from acetonitrile; m.pt 109°C, yield 61%. MS data *m/z* 338 (M^+). ^1H NMR (d_6-DMSO-$CDCl_3$-TMS); δ 7.28–7.13 (m, 10H) and 8.16–7.69 (m, 4H) (heterocyclic/phenylene protons), 5.11 (s, 4H, —CH_2 protons).

Preparation of 1,4-*bis*(*benzimidazol*-1-*yl-methylene*) *benzene*

It was prepared by the analogous method discussed above; m.p. = 124°C, yield = 60%. MS data *m/z* 338 (M^+). ^1H NMR (d_6-DMSO-$CDCl_3$-TMS): δ 7.40–7.19 (m, 10H) and 8.49–7.9 (m, 4H) (heterocyclic/phenylene protons), 5.12 (s, 4H, —CH_2 protons).

Preparation of complexes

Preparation of $[M(BIX)Cl_2]_n$, [(BIX) = 1,3-BIX *and* 1,4-BIX; M = Co, n = 2; *and* M = Zn, n = x]. Treatment of aqueous solutions (10.0 cm^3) of metal (II) chloride (0.002 M) with a methanolic solution (10.0 cm^3) of the ligand (675 mg, 0.002 M) at room temperature resulted in the immediate separation of a quantitative precipitate of the complex, which was filtered off and washed several times with water, followed by methanol and dried *in vacuo*. Yield: *ca* 90%.

Repeated attempts to prepare $[Cu(BIX)Cl_2]_2$ under the above conditions resulted in the formation of polymer of stoichiometry $[(BIX)_2Cu_3Cl_6]$.

Preparation of $[Ni(BIX)Cl_2]_n$. The reaction mixture obtained by mixing methanolic solution (15.0 cm^3) of 1,3-BIX (675 mg, 0.002 M) and aqueous solution of nickel(II) chloride (237 mg, 0.002 M in 10 cm^3) was refluxed for 1 h, which on concentration yielded a mixture of two components which were separated by dissolving in CH_3OH. The insoluble green component A (*ca* 80%) could be easily separated from soluble pale brownish component B (*ca* 20%). The component A was washed several times with water and methanol and dried *in vacuo*.

However, repeated attempts to prepare 1,4-BIX analogue of the above complex in the pure state under similar experimental conditions failed and only an impure green product could be isolated.

Preparation of $[enCu(BIX)]_2(ClO_4)_4$. The solutions of $Cu(ClO_4)_2 \cdot 6H_2O$, [0.02 M (standardized against EDTA)], ethylenediamine (0.02 M) and BIX ligands (0.02 M) were prepared in acetonitrile. $Cu(ClO_4)_2 \cdot 6H_2O$ and ethylenediamine solutions were mixed in equal volumes (20 cm^3 each) to prepare

$[enCu(H_2O)_4](ClO_4)_2$ as a bright blue solution *in situ*, which on addition of either ligand (20 cm^3, 0.02 M) turned dark blue. The reaction mixture on standing at room temperature for 2–3 days yielded blue precipitate of the complex, which was filtered off, washed several times with acetonitrile and dried *in vacuo*. Yield *ca* 80%.

Preparation of $[enM(BIX)]_2(NO_3)_4$ [M = Pd *and* Pt]. The complexes $[enPdCl_2]$ [11] and $[enPtCl_2]$ [12] were prepared by the reported methods starting from $PdCl_2$ and H_2PtCl_6, respectively.

An aqueous suspension (5 cm^3) of $[enMCl_2]$ (0.002 M) was treated with a solution of $AgNO_3$ (680 mg, 0.004 M in 5 cm^3 of water). The reaction mixture was stirred for 10 min, and the white precipitate of AgCl was filtered off and a pale brownish solution of $[enM(NO_3)_2]$ was used for the preparation of the complexes. The methanolic solution (10 cm^3) of 1,3-BIX (675 mg, 0.002 M) was added to the above solution of $[enM(NO_3)_2$ and stirred for 10 min. The pale yellow precipitate of $[enM(1,3\text{-}BIX)_2]$ $(NO_3)_4$ separated out on concentration, which was filtered off, washed twice with methanol and dried *in vacuo*. Yield 75%.

The analogous complexes $[enM(1,4\text{-}BIX)]_2(NO_3)_4$ were prepared following the above procedure. Yield 75%.

RESULTS AND DISCUSSION

Cobalt(II) *complexes*

Treatment of $CoCl_2 \cdot 6H_2O$ with either ligand (1 : 1) in $H_2O : CH_3OH$ at room temperature resulted in the separation of an immediate blue precipitate of the complex, which corresponds to $[(BIX)CoCl_2]$ stoichiometry, as indicated by CHN analysis (Table 1). Both the complexes are insoluble in H_2O, CH_3OH, $CHCl_3$ and CH_3CN, but moderately soluble in DMF, DMA and DMSO. The magnetic moment values for $[Co(1,3\text{-}BIX)Cl_2]$ and $[Co(1,4\text{-}BIX)Cl_2]$ complexes are found to be 4.3 and 4.4 B.M., respectively [13], which are suggestive of tetrahedral stereochemistry around the Co^{II} ion.

The visible spectral studies on the complexes as DMF solutions record a broad band at *ca* 635 nm (15,748 cm^{-1}) with a shoulder on the higher energy side *ca* 575 nm (17,391 cm^{-1}) (Table 2, Fig. 2). The position of the band corresponds to the $^4A_2 \rightarrow {}^4T_1(P)$ transition of the tetrahedral complex. The spectra of the complexes in the present case closely resemble tetrahedral Co (imidazole)$_2Cl_2$ [14]. A peak at 615 nm (16,260 cm^{-1}) with shoulders at 585 (17,090 cm^{-1}) and 630 nm (15,070 cm^{-1}) is observed. However, the spectra are vastly different from octahedral Co (imidazole)$_6Cl_2$, which records a band at 487 nm [20,500 cm^{-1}, $^4T_{1g}(F) \rightarrow {}^4T_{1g}(P)$] with a very weak shoulder *ca* 613 nm (16,300 cm^{-1}) due to the spin forbidden $^4T_{1g}(F) \rightarrow {}^2T_{1g}$ transition. Hence, the visible spectral studies of both complexes support the tetrahedral stereochemistry of the Co^{II} ion. The other two transitions *viz.* $^4A_2 \rightarrow {}^4T_1(P)$ and $^4A_2 \rightarrow {}^4T_2(F)$, could not be assigned because these transitions occur beyond the range of the instrument used (above 1000 nm). Furthermore, as the ligands are deliberately designed not to bind to the same metal centre, a ligand-bridged dimeric tetrahedral structure is assigned to these complexes (Fig. 3).

The FAB-MS of $[Co(1,4\text{-}BIX)Cl_2]_2$ in 3-nitrobenzyl alcohol shows a pair of peaks corresponding to $[M^+ + H - Cl]$ at m/z values 900 and 902 (Scheme 1), which first loses HCl (m/z = 864) and then Co (m/z = 806), HCl (m/z = 770) and Cl (m/z = 735) generating $(BIX)_2Co$. This fragment further loses a molecule of ligand (m/z = 397) and Co (m/z = 338) to record the fragment of the ligand at m/z 338 as a base peak. Hence, FAB-MS strongly support the given structural assignment to these complexes.

Table 1. CHN analysis, colour and magnetic moment of the complexes

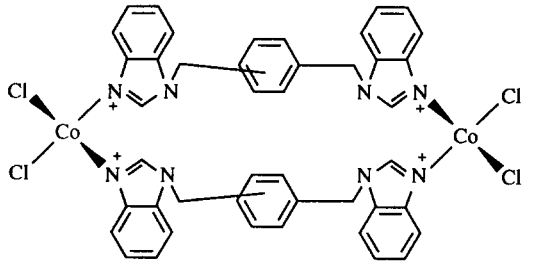
Nickel(II) *complexes*

$NiCl_2 \cdot 6H_2O$ does not react with either ligand at room temperature. However, refluxing a 1 : 1 mixture of metal salt and 1,3-BIX ligand in $CH_3OH : H_2O$ (1 : 1) for 1 h, on concentration yielded a mixture of two components. The insoluble green component A was separated from the soluble brown component B by treating the mixture with methanol. However, prior to isolation both the components are completely soluble in the reaction mixture. However, once isolated, component A becomes highly insoluble. The CHN analysis of this component corresponds to 1:1 (L/M) stoichiometry (Table 1). Its magnetic moment value has been found to be 3.6 B.M. The component B was not studied further.



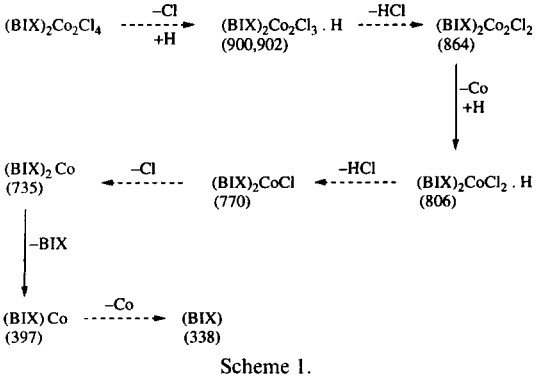


Fig. 3. Co^{III} driven self-assembly of 1,3- and 1,4-BIX ligands.

Reaction of 1,4-BIX with $NiCl_2 \cdot 6H_2O$ under analogous conditions yielded an insoluble green complex,

Scheme 1.

which, however could not be isolated in an analytically pure state. The magnetic moment of the crude product was found to be 3.7 B.M. The tetrahedral ground state $^3T_1(F)$ has much inherent orbital angular momentum and, therefore, the magnetic moment of a truly tetrahedral Ni^{II} complex should be around 4.2 B.M. However, small distortion reduces the μ value to 3.5–4.0 B.M. For all the octahedral and more distorted tetrahedral complexes the range is 3.0–3.5 B.M. [15]. Hence, the magnetic moment values suggest either distorted tetrahedral or octahedral structure for the complexes.

The VIS spectra of the reaction solutions were recorded before isolation of the product. Both spectra show transitions at *ca* 350 nm (28,571 cm^{-1}), a second band in the region of 650 nm (15,385 cm^{-1}) with a shoulder at 735 nm (13,605 cm^{-1}) and another band above 1100 nm (90,909 cm^{-1}, beyond the range of the instrument used), (Table 2, Fig. 2). These transitions correspond to $^3A_{2g} \rightarrow {}^3T_{1g}(P)$, $^3A_{2g} \rightarrow {}^3T_{1g}(F)$ and $^3A_{2g} \rightarrow {}^3T_{2g}(F)$, respectively, of octahedral complexes [16]. The blue shift of the visible transition in the present case compared with the octahedral $[Ni(H_2O)_6]Cl_2$ complex [715 nm, (13,986 cm^{-1})] is a consequence of the replacement of H_2O by N donors which lie towards the stronger end of the spectrochemical series.

Hence, it is concluded that these complexes exist as dimers (because the bidentate ligand is non-chelating) with octahedral stereochemistry around each nickel(II) ion in solution (the other two ligands may be H_2O), which became converted into ligand-bridged polymers in the solid state. The high insolubilities of these complexes in various solvents further support polymeric nature of these complexes.

Copper(II) *complexes*

Reactions of both ligands with $CuCl_2 \cdot 2H_2O$ in $CH_3OH : H_2O$ in a 1 : 1 molar ratio resulted in the immediate separation of a green precipitate of the complexes. Both the complexes correspond to 2 : 3 (L/M) stoichiometry (Table 1). These complexes are found to be highly insoluble in all common solvents and their structure has been discussed elsewhere [17].

To prepare dimeric Cu^{II} complexes, the $[enCu(H_2O)_4](ClO_4)_2$ complex was used as a source of Cu^{II} ions. As expected, the reaction of $[enCu(H_2O)_4](ClO_4)_2$ with 1,3-BIX or 1,4-BIX under highly dilute conditions in acetonitrile generated the square-planar $[enCu(BIX)]_2(ClO_4)_4$ (Fig. 4). The magnetic moment values for 1,3-BIX and 1,4-BIX complexes are found to be 2.1 and 1.9 B.M., respectively. As the magnetic moment values of all the Cu^{II} complexes lacking Cu—Cu interactions fall in the range 1.75–2.20 B.M. [18], the μ values, therefore, do not give any clue regarding the stereochemistries of the complexes, but indicate that the Cu—Cu interaction is absent in the present case.

The visible spectra of these complexes in acetonitrile

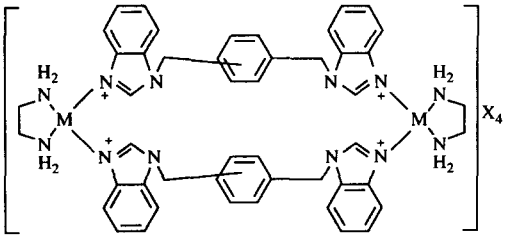

Fig. 4. Metal(II) assisted self-assembly of 1,3- and 1,4-BIX ligands (M = Cu^{II}, Pd^{II} and Pt^{II}).

(Fig. 2, Table 2) record a broad unsymmetrical band in the region *ca* 580 and 590 nm (17,214 and 16,949 cm^{-1}) for the 1,3- and 1,4-BIX complexes, respectively. This band position is of the general type found for planar or tetragonally distorted octahedral copper(II) complexes [19]. Here the four N atoms lie approximately in the plane and bulky ClO_4 anions are placed out of the plane. As in the case of $Cu(benzimidazole)_4(ClO_4)_2$, here again the ClO_4 anions are uncoordinated. Due to the steric reasons the benzimidazole ring and en ring are forced to lie at an angle with the CuN_4 plane, which offer steric hindrance to the approach of large ClO_4 anions. The positions and shapes of IR spectral bands [1100 cm^{-1} (ν_3) unsplit and 620 cm^{-1} (ν_1)] again support that the ClO_4 are uncoordinated (Table 3) [20].

The g_x and g_y values of Cu^{II} complexes which have usual $d_x^2 - y^2$ ground state typically lie between 2.04 and 2.07, while the g_z value falls in the 2.15–2.40 range. In contrast, one of the g values of g_z is close to 2.002, which is indicative of d_z^2 ground state [21]. In the present case the ESR spectrum of $[enCu(1,3\text{-}BIX)]_2(ClO_4)_4$ shows three peaks corresponding to the g values *viz.* $g_1 = 2.01$, $g_2 = 2.075$ and $g_3 = 2.12$ (Fig. 5), which suggest a rhombic elongated structure with $d_x^2 - y^2$ ground state. The $[enCu(1,4\text{-}BIX)]_2(ClO_4)_4$ complex records $g_\parallel$ at 2.43 and shows evidence of a nuclear hyperfine splitting (A = 120 G which can be accounted for due to the presence of the large ClO_4 anion) and $g_\perp = 2.10$. The range of g values again supports an axially enlongated structure with $d_{x^2-y^2}$ ground state [22,23]. As the phenyl rings of the xylene spacer are expected to be planar, some distortion of the CuN_4 chromophore towards tetrahedral may be expected.

Zinc(II) *complexes*

Highly insoluble material separated out on mixing either ligand with $ZnCl_2 \cdot H_2O$. The CHN analysis of the complexes correspond to 1 : 1 (M/L) stoichiometry (Table 1). A ligand-bridged tetrahedral polymeric structure has been proposed for the complexes.

Palladium(II) *and Platinum*(II) *complexes*

As discussed previously for the Cu^{II} complexes, *cis*-$[enM(NO_3)_2]$, [M = Pd or Pt], complexes were reacted

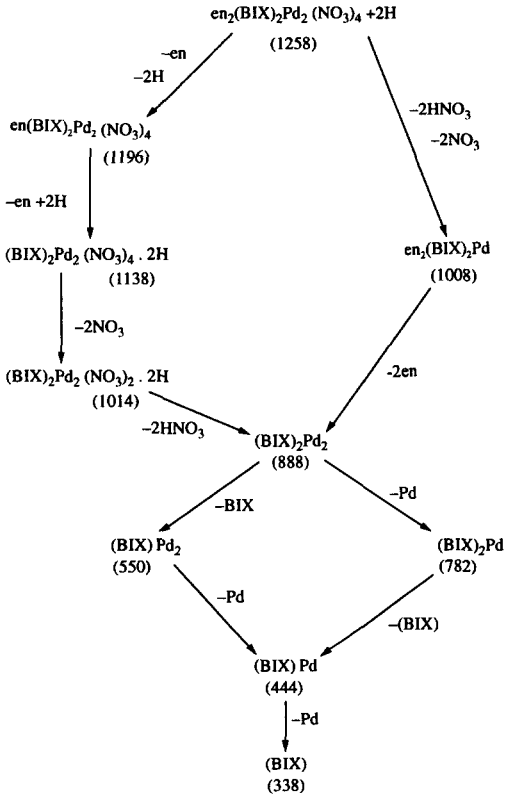
with 1,3- or 1,4-BIX in CH_3OH–H_2O in 1 : 1 molar ratio to generate dinuclear square $[enM(BIX)]_2(NO_3)_4$ (Fig. 4) complexes. These complexes are soluble in hot water, DMSO, DMF and DMA.

IR spectral data (Table 3) corresponds to vibrational bands for the ethylene diamine at 3450, 3100 [ν NH_2, 1620–1600 ($\delta_d NH_2$) 1200–1120 (δ_s) and 920–800 cm^{-2} (ρ_r)]. The bands due to the uncoordinated nitro group appear at 1380–1320 (ν_3), 1105–1045 (ν_1) [20]. These bands are in addition to various vibrational bands due to benzimidazole ligands.

^{13}C NMR data for the ligands as well as complexes are reported in Table 4. In the complexes the positions of the C-2 carbon is shifted downfield, confirming the coordination of the benzimidazole N atom to the metal ion.

The FAB-mass study of $[enPd(1,4\text{-}BIX)]_2(NO_3)_4$ confirms the macrocyclic dinuclear structure for these complexes. It shows a parent ion peak at m/z 1258 $[M^+ + 2H]$. A peak for $[en_2(BIX)_2Pd_2]$ due to the loss of all the four NO_3 $[M^+ - 4NO_3]$ groups is recorded at m/z 1008, which further loses both molecules of ethylene diamine to generate a peak at m/z 888 corresponding to the fragment $(BIX)_2Pd_2$. Successive loss of Pd, BIX and Pd from $(BIX)_2Pd_2$ yields fragments at m/z 782.444 and 338, respectively. In another series of fragmentation pattern, first the loss of both ethylene diamines and then $4NO_3$ is observed to give a peak at m/z at 888 corresponding to $(BIX)_2Pd_2$ (Scheme 2). A base peak for $(BIX)Pd_2$ is shown at m/z 550 from which one Pd dissociates to give (BIX)Pd at m/z 444. Loss of the second Pd gives a free ligand at m/z 338.



CONCLUSION

The formation of these unique complexes clearly shows the success achieved in the self-assembly of the ligands around the metal ion by reacting appropriately designed ligands and carefully selected the metal ion species.

(Received 23 July 1996; accepted 12 August 1996)

Abstract—The new complexes $[MoO_2(BINO)(acac)]^-$ (H_2BINO = 1,1′-bi-2-naphthol and acac = acetylacetonate), $[Mo_2O_5(BINO)_2]^{2-}$, $[MO_2(BINO)_2]^{2-}$ (M = Mo, W, Os) and $[M(PPh_3)_2(BINO)]$ (M = Pd, Pt) have been prepared. The X-ray crystal structures of the title compounds **1** and **2** are described and the vibrational spectra of the complexes reported. Copyright © 1997 Elsevier Science Ltd

Keywords: molybdenum; 1,1′-bi-2-napthol; X-ray crystal structure; Raman spectra.

The ligand 1,1′-bi-2-naphthol (H_2BINO) has potential uses as a chiral auxiliary in oxidation catalysis [1]. In the course of our work on peroxometalates as epoxidation catalysts [2] we have prepared a number of new complexes containing BINO for possible use as chiral epoxidation catalysts. In this paper we report the X-ray crystal structures of $(Bu^n_4N)[MoO_2(acac)(BINO)]$ (**1**) and $(Bu^n_4N)_2(H_2BINO)_2[Mo_2O_7]$ (**2**), and also the syntheses and vibrational spectra of other new complexes of BINO with tungsten, osmium, palladium and platinum.

Four X-ray crystal structures of H_2BINO complexes with titanium and lanthanides have been reported, for [Ti{ethylene-bis(4,5,6,7-tetrahydro-(*S*)-1-indenyl)}((*S*)-BINO)] [3] and $Na_3[Ln((S)\text{-}BINO)_3]\cdot 6THF\cdot H_2O$ [4] (Ln = Pr, Nd or Eu). A number of BINO complexes of tungsten [5,6,7] and titanium [3,8,9] have been isolated, including $[W_2(BINO)_2(OBu^t_2)_2]$ [7], $[W_2(BINO)_3]$ [7] and $[W(BINO)_2Cl_2]\cdot H_2O$ [5], the latter having been used as a catalyst for the ring opening polymerization of alkenes. The complex $[W(BINO)_3]$ was used as a precatalyst in polymerization catalysis [6].

RESULTS AND DISCUSSION

Preparations and X-ray crystallography

Synthesis of the complexes. The molybdenum complexes were made from the tetrabutylammonium or tetramethylammonium salts of 1,1′-bi-2-naphthol and *cis*-$[MoO_2(acac)_2]$ (acac = acetylacetonate); the tungsten complex from 1,1′-bi-2-naphthol and $Na_2[WO_4]$ with tetrabutylammonium chloride; the osmium complex from *trans*-$K_2[OsO_2(OCH_3)_4]$ and 1,1′-bi-2-naphthol; and the palladium and platinum complexes from $[M(PPh)_3)_2Cl_2]$ and 1,1′-bi-2-naphthol with triethylamine.

X-ray crystal structure of **1**. Orange crystals of the compound, suitable for X-ray analysis, were obtained after recrystallization in acetonitrile.

The X-ray analysis of **1** reveals a MoO_2 *cis*-dioxo coordination, the remaining coordination sites being occupied by *cis*-coordinated binaphthol and acetylacetonate ligands, as shown in Fig. 1. The octahedral coordination at molybdenum is severely distorted with angles at Mo ranging between 78.3(1) to 104.5(2)°, and 162.4(1) to 169.2(1)°. The bite angles associated with the chelating ligands are markedly reduced from orthogonal to 82.8(1) and 81.1(1)° for the binaphthol and acetylacetonate groups, respec-

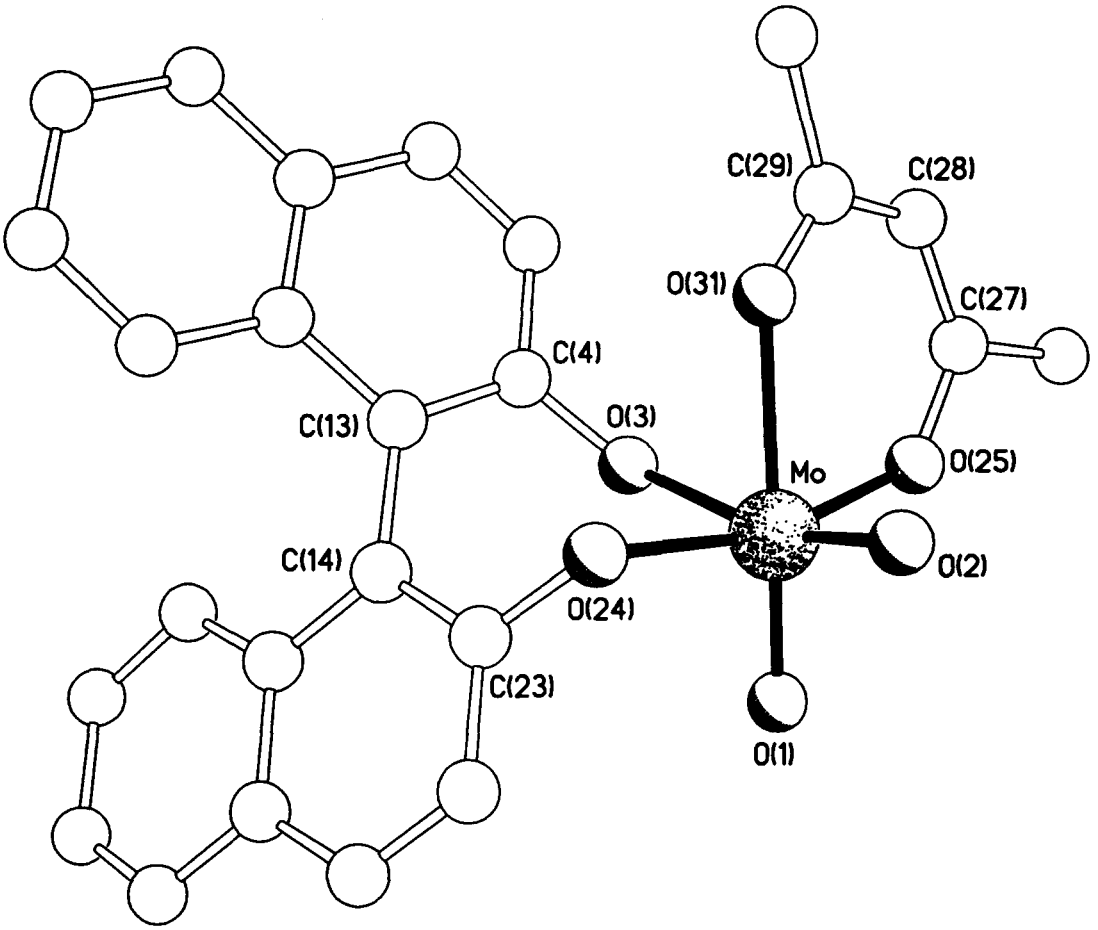

Fig. 1. The molecular structure of the anion in **1**.

tively. There are characteristic displacements of the molybdenum atom towards the oxo substituents out of the plane of the atoms normal to these directions of 0.25 and 0.17 Å for O(1) and O(2), respectively; the two associated Mo—O distances, 1.698(3) [O(1)] and 1.701(3) Å [O(2)], are normal with the O—Mo—O angle being 104.5(2)°.

For both chelating ligands there is a noticeable asymmetry in their Mo—O coordination distances reflecting the powerful *trans* influence of the oxo ligands. In the case of the binaphthol unit [which exhibits a mean torsional twist of *ca* 58° about the C(13)—C(14) linkage] the two Mo—O distances differ by 0.13 Å and in the acetylacetonate moiety the difference is 0.16 Å. Furthermore, these asymmetries extend to include the adjacent C—O bonds in both ligands (Table 1); indeed in the acetylacetonate ligand a pattern of alternation of bond lengths extends throughout the whole ligand (with the exception of the terminal methyl groups), which maintains a coplanar geometry (to within 0.04 Å) with the molybdenum atom.

The only significant non van der Waals packing interaction is a C—H···O hydrogen bond between one of the binaphthol C—H groups in one molecule and the O(1) oxo atom of a *c*-glide-related molecule, thereby forming a loosely-linked chain that extends in the crystallographic *c* direction [C···O, H···O distances 3.26, 2.34 Å; C—H···O angle 176°], Fig. 2.

X-ray crystal structure of **2**. Recrystallization of the orange crystals of **1** from acetonitrile gave beige crystals which were found by X-ray analysis to be $(Bu^n_4N)_2(H_2BINO)_2[Mo_2O_7]$ (**2**). The structure comprises an Mo_2O_7 core hydrogen-bonded to two binaphthol units (*vide infra*), Fig. 3. Thus, unlike **1** where the binaphthol acts as a bidentate ligand, here no coordination has occurred. Initial analysis of the structure indicated a linear geometry for the Mo—O—Mo linkage (with somewhat short Mo—O distances), the bridging oxygen atom being positioned on a crystallographic inversion centre. However, the bridging atom exhibited significant thermal anisotropy normal to the Mo···Mo direction, indicating that a more realistic model is one in which there is a superimposition of two half occupancy non-linear geometries related by the centre of symmetry. Splitting of the position of this bridging oxygen atom resulted in more realistic thermal parameters, and bridging

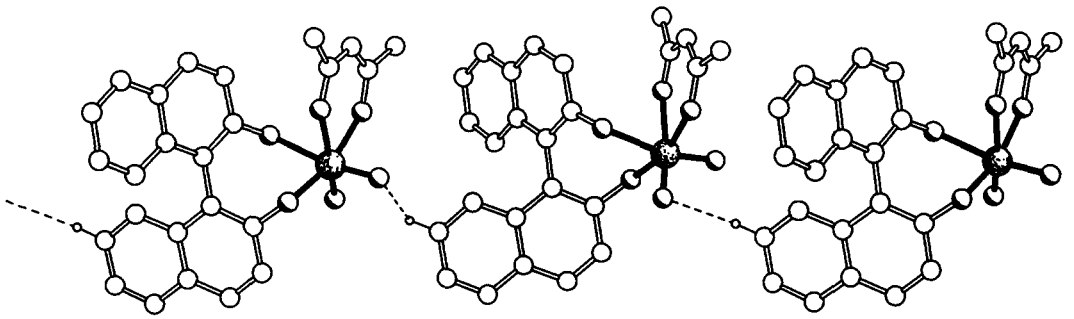

Fig. 2. Part of one of the loosely hydrogen-bonded chains present in the crystal structure of **1**.

Mo—O distances and a Mo—O—Mo angle [155(2)°] comparable to those found in other related systems such as $(Bu^n_4N)_2[Mo_2O_7]$ [10] and $[(\eta\text{-}C_5H_4CH_3)Mo(CO)_2(\mu\text{-dppm})Pt(dppm)]_2[Mo_2O_7]$ [11]. The remaining Mo—O distances are unexceptional, Table 2. A detailed analysis of the angular geometry at molybdenum is not justified in view of the disorder described above. The binaphthol unit exhibits a characteristic skewed geometry with a mean torsional twist about the bond linking the two naphthalene rings of *ca* 85°, a value substantially larger than that observed for the coordinated counterpart of **1**.

An inspection of the packing shows that the pattern of hydrogen-bonding between the binaphthol units and the Mo_2O_7 core alluded to above extends to form chains of molecules, which propagate in the crystallographic *a* direction (O···O distances 2.68 and 2.70 Å), Fig. 4. Adjacent chains are interleaved and stabilized by T-type edge to face aromatic–aromatic interactions between naphthyl rings (centroid··· centroid distance between C_6H_4 rings 5.02 Å).

Vibrational and ^{1}H *NMR spectra*

IR and Raman spectroscopic data for the free ligand and the complexes are listed in Table 3. General assignments of the IR spectrum of 1,1′-bi-2-naphthol have been reported [12,13]. The existence of two bands of the O—H stretch, ν(O—H), at 3485 and 3401 cm^{-1}, was ascribed [12] to the asymmetry of 1,1′-bi-2-naphthol in the solid state, since the two naphthyl rings lie in two different planes. In the IR spectra of our BINO complexes the band corresponding to ν(O—H) was not observed due to loss of protons on coordination and the ν(C—O) band is shifted from 1382 cm^{-1} in H_2BINO to approximately 1366 cm^{-1} in the complexes, suggesting coordination through the oxygen atoms of the hydroxyl groups (similar effects are noted for the IR spectra of catecholato complexes [14,15]). The C—C stretch bands of H_2BINO are only slightly shifted in the complexes. A new band at approximately 1557 cm^{-1}, assigned to ν(C—C), is also seen in the Raman spectrum of **1**, together with

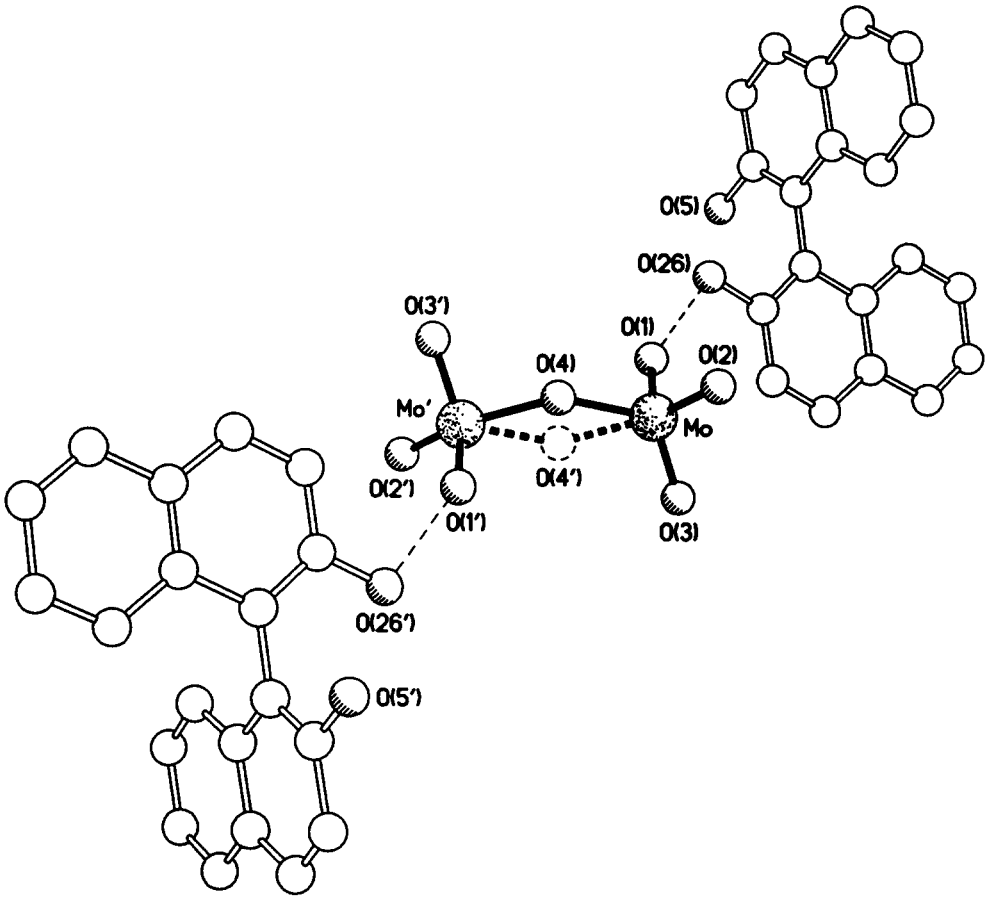

Fig. 3. The Mo_2O_7 core and adjacent hydrogen-bonded binaphthol units in the structure of **2**; the broken bonds correspond to the alternative orientation of the Mo—O—Mo bridge.

Table 2. Selected bond lengths (Å) for **2**

Mo—O(1)	1.693(9)	Mo—O(2)	1.718(7)
Mo—O(3)	1.647(14)	Mo—O(4)	1.90(2)
Mo'—O(4)	1.88(2)	Mo···Mo'	3.701(2)

acetylacetonate bands in both IR and Raman spectra. In **2** the O—H stretch of 1,1'-bi-2-naphthol is shifted from 3485 and 3401 cm^{-1} to 3124 cm^{-1}. In this compound the ν(C—O) band is shifted to 1370 cm^{-1}, an intermediate position between the values for the complexes (shifted to lower wave-numbers) and for H_2BINO.

^1H NMR data for H_2BINO were measured and the data agree well with those of Puga *et al.* [16], there was, however, relatively little change in the spectra on complexation.

EXPERIMENTAL

All starting materials were supplied by Aldrich and used without further purification. The complexes $[MoO_2(acac)_2]$ [17], *trans*-$K_2[OsO_2(OCH_3)_4]$ [18], $[Pd(PPh_3)_2Cl_2$ [19] and $[Pt(PPh_3)_2Cl_2]$ [20] were made by the cited literature procedures. The salts (Bu^n_4N)(HBINO) and (Me_4N)(HBINO) were prepared by refluxing ethanolic solutions of H_2BINO and Bu^n_4NCl or Me_4NCl in equimolar proportions, filtered and cooled.

Preparation of $(Bu^n_4N)[MoO_2(acac)(BINO)]$

To a solution of $[MoO_2(acac)_2]$ (0.16 g, 0.5 mmol) in acetone (5 cm^3) was added a solution of (Bu^n_4N)(HBINO) (0.26 g, 0.5 mmol) in acetone (10 cm^3). The yellow precipitate formed was filtered, washed with acetone and dried in a desiccator over silica gel. Yield = 0.32 g, 0.24 mmol, 49%. Orange crystals of the compound were obtained by recrystallization in acetonitrile.

Preparation of $(Bu^n_4N)_2(H_2BINO)_2[Mo_2O_7]$

The orange crystals obtained by recrystallization of $(Bu^n_4N)[MoO_2(acac)(BINO)]$ were left in acetonitrile for a week. The colour faded and beige crystals of $(Bu^n_4N)_2(H_2BINO)_2[Mo_2O_7]$ were obtained.

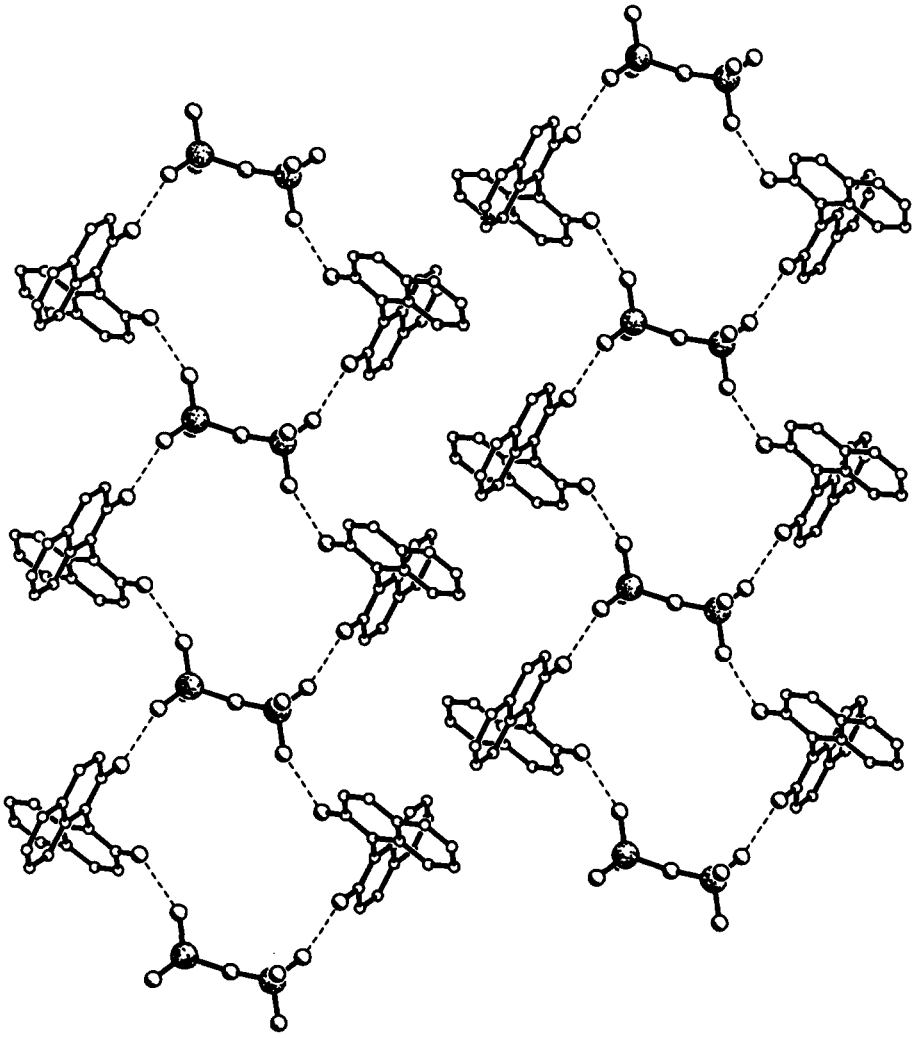

Fig. 4. Part of a pair of interleaved hydrogen-bond chains of Mo_2O_7 and binaphthol molecules in the structure of **2**.

Preparation of $(Me_4N)_2[MoO_2(BINO)_2]\cdot 2MeOH$

To a solution of $[MoO_2(acac)_2]$ (0.16 g, 0.5 mmol) in methanol (20 cm^3) was added 1,1′-bi-2-naphthol (0.29 g, 1.0 mmol) and tetramethylammonium chloride (0.11 g, 1.0 mmol). The resulting yellow solution was heated to reflux for 2 h, filtered hot and reduced to approximately half of the volume by rotary evaporation. Beige crystals were obtained after refrigeration for 4 days, filtered and dried in a desiccator with silica gel. Yield = 0.050 g, 0.055 mmol, 11%.

Preparation of $(Me_4N)_2[Mo_2O_5(BINO)_2]$

To a solution of $[MoO_2(acac)_2]$ (0.082 g, 0.25 mmol) in acetone (3 cm^3) was added a solution of $(Me_4N)(HBINO)$ (0.18 g, 0.5 mmol) in acetone (10 cm^3). The yellow suspension obtained was stirred for 1 h. The yellow precipitate was filtered and dried in a desiccator over silica gel. Yield = 0.13 g, 0.24 mmol, 49%.

Preparation of $(Bu^n_4N)_2[WO_2(BINO)_2]\cdot 2H_2O$

To an aqueous solution of sodium tungstate (0.17 g, 0.5 mmol, 10 cm^3 of water) was added an ethanolic suspension of 1,1′-bi-2-naphthol (0.29 g, 1.0 mmol, 20 cm^3 of ethanol) and an aqueous solution of tetrabutylammonium chloride (0.28 g, 1.0 mmol, 2 cm^3 of water). The resulting light yellow solution (with some 1,1′-bi-2-naphthol suspended) was heated at reflux for 3 h and filtered. Beige crystals were obtained after refrigeration for 3 days, filtered, washed with ethanol and dried in a desiccator with silica gel. Yield = 0.279 g, 0.21 mmol, 43%.

Preparation of $K_2[OsO_2(BINO)_2]\cdot 6H_2O$

To a stirred solution of *trans*-$K_2[OsO_2(OCH_3)_4]$ (0.20 g, 0.47 mmol) in methanol (15 cm^3) was added a methanolic solution of 1,1′-bi-2-naphthol (0.29 g, 1.0 mmol, 5 cm^3 of methanol). The resulting dark green solution was left stirring for *ca* 10 min, a dark-

brown precipitate started to form and then diethyl ether (20 cm^3) was added. The solution turned darker and upon filtration a brown solid was isolated. The solid was washed with diethyl ether and dried in a desiccator with silica gel. Yield = 0.23 g, 0.23 mmol, 50%.

Preparation of $[Pd(PPh_3)_2(BINO)]\cdot EtOH$

To a stirred suspension of $[Pd(PPh_3)_2Cl_2]$ (0.35 g, 0.5 mmol) in ethanol (10 cm^3) was added a methanolic solution of 1,1′-bi-2-naphthol (0.29 g, 1.0 mmol, 4 cm^3 of methanol) and triethylamine (0.6 cm^3, 4.0 mmol). The resulting yellow suspension was stirred for 7 days and a suspension of a yellow solid in a red solution was obtained. It was centrifuged and the red solution isolated. To this solution was added the same volume of water and an orange solid was formed. It was centrifuged and the orange solid isolated and dried in a desiccator over silica gel. Yield = 0.13 g, 0.14 mmol, 27%.

Preparation of $[Pt(PPh_3)_2(BINO)]\cdot EtOH$

To a stirred suspension of $[Pt(PPh_3)_2Cl_2]$ (0.40 g, 0.5 mmol) in ethanol (10 cm^3) was added a methanolic solution of 1,1′-bi-2-naphthol (0.29 g, 1.0 mmol, 4 cm^3 of methanol) and triethylamine (0.6 cm^3, 4.0 mmol). The resulting white suspension was stirred for 7 days and a yellow suspension was obtained. It was centrifuged and the yellow solid isolated and dried in a desiccator over silica gel. Yield = 0.39 g, 0.37 mmol, 74%. Yellow crystals of the compound were obtained by recrystallization in acetonitrile.

Crystal structure determinations

Crystal data for **1**. $[C_{25}H_{19}O_6Mo][(C_4H_9)_4N]$, $M = 753.8$, monoclinic, space group $P2_1/c$, $a = 10.708(2)$, $b = 18.451(2)$, $c = 19.439(3)$ Å, $\beta = 91.92(1)°$, $V = 3838(1)$ Å^3, $Z = 4$, $D_c = 1.30$ g cm^{-3}, μ(Cu-K_α) = 31.6 cm^{-1}, $F(000) = 1592$. An orange/yellow plate of dimensions $0.33 \times 0.20 \times 0.05$ mm was used.

Data collection and processing. Data were measured on a Siemens P4/PC diffractometer with Cu-K_α radiation (graphite monochromator) using ω-scans. 5351 independent reflections were measured ($2\theta \leqslant 116°$) of which 4443 had $|F_o| > 4\sigma(|F_o|)$ and were considered to be observed. The data were corrected for Lorentz and polarization factors, and a Gaussian absorption correction (face-indexed numerical) was applied; the maximum and minimum transmission factors were 0.851 and 0.539, respectively.

Structure analysis and refinement. The structure was solved by the heavy atom method and the non-hydrogen atoms were refined anisotropically. The hydrogen atoms of the methyl groups attached to sp^2 centres were located from ΔF maps and subsequently optimized. The positions of the remaining hydrogens were

idealized, assigned isotropic thermal parameters, [U(H) = 1.2U_{eq}(C); U(H) = 1.5U_{eq}(C—Me)], and allowed to ride on their parent carbon atoms. Refinement was by full-matrix least-squares based on F^2 to give $R_1 = 0.042$, $wR_2 = 0.105$ for the observed data and 443 parameters. The maximum and minimum residual electron densities in the final ΔF map were 0.58 and −0.64 e Å^{-3}, respectively. The mean and maximum shift/error ratios in the final refinement cycle were 0.003 and −0.023, respectively.

Crystal data for **2**. $[Mo_2O_7][(C_4H_9)_4N]_2 \cdot [C_{20}H_{14}O_2]_2$, M = 1361.4, triclinic, space group $P\bar{1}$, a = 10.371(3), b = 10.759(3), c = 16.759(5) Å, α = 103.84(2), β = 102.89(2), γ = 92.73(2)°, V = 1759.9(8) Å^3, Z = 1 (the molecule has crystallographic C_i symmetry), D_c = 1.29 g cm^{-3}, μ(Cu-K_α) = 33.8 cm^{-1}, F(000) = 718. A clear prismatic plate of dimensions 0.21 × 0.12 × 0.01 mm was used.

Data collection and processing. Data were measured on a Siemens P4/PC diffractometer with Cu-K_α radiation (graphite-monochromator) using ω-scans. 2851 independent reflections were measured ($2\theta \leqslant 120°$), of which 2177 had $|F_o| > 4\sigma(F_o|)$ and were considered to be observed. The data were corrected for Lorentz and polarization factors and a Gaussian absorption correction (face-indexed numerical) was applied; the maximum and minimum transmission factors were 0.961 and 0.729, respectively.

Structure analysis and refinement. The structure was solved by the heavy-atom method and the non-hydrogen atoms were refined anisotropically. The hydroxyl hydrogen atoms were located from a ΔF map and were refined isotropically subject to an O—H distance constraint. The positions of the remaining hydrogens were idealized, assigned isotropic thermal parameters, [U(H) = 1.2U_{eq}(C), U(H) = 1.5U_{eq}(C—Me)] and allowed to ride on their parent carbon atoms. Refinement was by full-matrix least-squares based on F^2 to give $R_1 = 0.061$, $wR_2 = 0.149$ for the observed data and 405 parameters. The maximum and minimum residual electron densities in the final ΔF map were 0.53 and −0.66 e Å^{-3}, respectively. The mean and maximum shift/error ratios in the final refinement cycle were 0.000 and 0.000, respectively.

For both structures, computations were carried out on 50 MHz 486 PC computers using the SHELXTL-PC program system [21]. Additional material available from the Cambridge Crystallographic Data Centre comprises fractional atomic coordinates, H-atom coordinates, thermal parameters and remaining bond lengths and angles.

Characterization

IR spectra were measured as KBr discs on a Perkin–Elmer 1720 FT instrument. Raman spectra were recorded on as powders on a Perkin–Elmer 1760 X FT-IR instrument fitted with a 1700 X NIR FT-Raman accessory (Spectron Nd:YAG laser, 1064 nm excitation). ^{1}H NMR spectra were measured on a Jeol EX-270 spectrometer (^{1}H, 270.05 MHz). Microanalyses were measured by the Microanalytical Department, Imperial College.

(Received 18 July 1996; accepted 12 August 1996)

Abstract—Three new nickel(II) dinuclear oxalato-bridged compounds Ni(TAA)(ClO_4)·0.5ox (**1**), Ni_2(APO-sal_2)ox·$2H_2O$ (**2**) and Niphen$_2$oxNiacac$_2$·$4H_2O$ (**3**) have been characterized [TAA = $N(CH_2CH_2NH_2)_3$ ox = oxalate, phen = 1,10-phenanthroline, acac = acetylacetonate and APO-sal_2 is the Schiff base formed by the condensation of salicylaldehyde and 1,3-diamino-2-propanol]. The crystal structure of **1** has been determined by a single-crystal X-ray analysis. The nickel atom is coordinated by two oxygen atoms of an oxalato ligand and four nitrogen atoms belonging to TAA in an octahedral arrangement. The intermetallic distance of Ni(1)—Ni(2) is 5.412(1) Å. Magnetic measurements (77–300 K) show that three compounds are antiferromagnetically coupled, $J = -14.4$, -11.25 and -19.3 cm^{-1} for **1**, **2** and **3**, respectively. Copyright © 1997 Elsevier Science Ltd

Keywords: nickel(II) complexes; (μ-oxalato) complexes; magnetic properties.

The magnetic behaviour of nickel(II) dimers, in which the oxalate anion acts as a bis-bidentate bridging ligand, is a well-known subject and the general trends of their magnetic properties are well established, the oxalato bridge is very efficient in propagating antiferromagnetic interactions between the two paramagnetic centres of dinuclear compounds. In these compounds the nickel(II) shows octahedral coordination in all the [Ni–ox–Ni] pairs reported to date and the Ni–oxalao–Ni fragment is rigid and planar, and only small differences in the bond parameters can be found in the bridge fragment. However, this generalization should be assumed only for compounds in which four remaining coordination positions of the nickel atom have similar properties—such as aminate ligands (NiN_4O_2 environment). The NiN_4O_2 nickel–oxalato dinuclear compounds contain tetraaza macrocycles, tetraaza amines or two diamines [1–5]. The aim of this study is to characterize the nickel–oxalato dimer with tetraaza amine (TAA) and to compare the magnetic properties of this compound with those of [phen$_2$Ni–ox–Niacac$_2$] with NiN_4O_2 and NiO_6 environment. In fact, linear trimeric bis(acetylacetonato)nickel(II) has been reported [6] to have both ferromagnetic coupling ($J = +26$ cm^{-1}) between adjacent nickel atoms and antiferromagnetic coupling ($J = -7$ cm^{-1}) between the terminal nickel atoms. The third studied compound is a monomeric binuclear nickel(II) complex based on Schiff base derivative of 1,3-diaminopropan-2-ol with oxalate as bridging ligand.

EXPERIMENTAL

All chemicals were of reagent grade and used as purchased from commercial sources. Niphen$_2$$Cl_2$·$4H_2O$ [7] and Niacac$_2$ [8] were prepared according to literature methods.

Preparation of Ni(TAA)(ClO_4)·0.5ox

$N(CH_2CH_2NH_2)_3$ (1.66 mmol, 0.25 cm^3) was added to a solution of $Ni(ClO_4)_2$·$6H_2O$ (1.6 mmol, 0.6 g) in water (5 cm^3). After stirring for a few minutes, a

* Author to whom correspondence should be addressed.

solution of Na_2ox (0.8 mmol, 0.11 g) in water (5 cm^3) was added. The reaction mixture was stirred at 80°C for 15 min, then filtered and the blue solution was allowed to stand for 5 days. The precipitated deep blue crystals were filtered off and washed with cold water. Found: C, 24.3; H, 5.1; N, 15.9; Cl, 10.4. Calc. for $C_7H_{18}ClN_4O_6Ni$: C, 24.1; H, 5.2; N, 16.1; Cl, 10.2%.

Preparation of $Ni_2(APO\text{-}sal_2)ox \cdot 2H_2O$

Salicylaldehyde (5 mmol, 0.52 cm^3) and 1,3-diamino-2-propanol (2.5 mmol, 0.15 g) were refluxed in methanol (8 cm^3) for 2 h. After cooling to room temperature triethylamine (14 mmol, 2 cm^3) was added. Then the solution of $NiCl_2 \cdot 6H_2O$ (5 mmol, 1.2 g) in 10 cm^3 methanol and oxalic acid (2.8 mmol, 0.25 g) in 10 cm^3 methanol was added while stirring. The mixture was heated under reflux for 1 h and then was allowed to stand overnight. The solids formed were filtered off and washed with ethanol and ether. Found: C, 41.8; H, 4.15; N, 5.1; Ni, 22.2. Calc. for $C_{19}H_{20}N_2O_9Ni_2$: C, 42.4; H, 3.8; N, 5.2; Ni, 21.8%.

Preparation of $Niphen_2oxNiacac_2 \cdot 4H_2O$

Separated methanolic solutions (10 cm^3) of $Niphen_2Cl_2 \cdot 4H_2O$ (1 mmol, 0.6 g) and oxalic acid (1 mmol, 0.09 g) were added to a hot ethanolic solution (15 cm^3) of $Niacac_2$ (1.2 mmol, 0.3 g) under continuous stirring. Triethylamine (4.4 mmol, 0.6 cm^3) was after 5 min added to this solution and the resulting reaction mixture was left to stand at room temperature. Blue microcrystals, which were not suitable for X-ray analysis, were deposited in a few hours. Found: C, 51.4; H, 4.3; N, 7.1; Ni, 14.5. Calc. for $C_{36}H_{38}N_4O_{12}Ni_2$: C, 51.7; H, 4.6; N, 6.7; Ni, 14.0%.

Physical measurements

The carbon, hydrogen and nitrogen analyses were determined on an EA1108 instrument (Fisons). IR spectra were measured on a Specord M80 (Carl Zeiss, Jena) using Nujol mulls within the region ν = 4000–400 cm^{-1}. Electronic absorption spectra were obtained on a Specord M40 (Carl Zeiss, Jena). The magnetic susceptibility of powdered complexes were measured by the Faraday method in the temperature range 77–300 K. The apparatus was calibrated with $HgCo(NCS)_4$. Corrections for the diamagnetism were estimated from Pascal's constants [9]. Thermal decomposition was studied with a Q1500 Derivatograph (MOM Budapest) with a sample weight of 130–180 mg over a temperature range 20–800°C at a heating rate of 2.5°C min^{-1}.

Structural characterization

Crystals suitable for a single-crystal X-ray analysis were obtained by recrystallization of the studied complex from a water solution.

Data collection and processing. The intensity data were collected on a KUMA KM-4 diffractometer at 153(2) K using graphite monochromated Mo-K_α radiation and an ω–2θ scan technique. From 2483 measured reflections, 2093 with $I > 2\sigma(I)$ were considered observed. Lattice parameters and orientation matrix for data collection were obtained from least-squares refinement on setting angles for 25 reflections ($17.1 < 2\theta < 26.1°$). Periodics checks on two standard reflections indicated no crystal instability during data collection. Absorption and extinction effects were ignored.

Structure analysis and refinement. The structure was solved by heavy-atom method (SHELXS-86) [10] and refined anisotropically by full-matrix least-squares procedure (SHELXL-93) [11] with weight: $w = 1/[\sigma^2(F_0^2) + (0.0636P)^2 + 0.7843P]$, where $P = (F_0^2 + 2F_c^2)/3$. The H atoms were located from difference-Fourier maps and all their parameters were refined. Largest differences in the peak and hole on a final difference electron density map were 0.611 and -0.876 e $Å^{-3}$, respectively. All structure determination calculations were carried out on IBM RS/6000 98F and PC AT 486 computers. Crystal data and refinement parameters for $Ni(TAA)(ClO_4) \cdot 0.5ox$ are summarized in Table 1.

RESULTS AND DISCUSSION

Structure of $Ni(TAA)(ClO_4) \cdot 0.5ox$

The structure consists of the binuclear $[(TAA)Ni\text{–}ox\text{–}Ni(TAA)]^{2+}$ cation and perchlorate anions. A view of the cation is shown in Fig. 1. Principal bond distances are listed in Table 2. The binuclear cation consists of two $(TAA)Ni^{II}$ units bridged by a bis-bidentate oxalate anion. The geometry at the two nickel(II) centres is octahedral, with ligation provided by the four nitrogen atoms of the TAA ligand and the oxygen atoms of the bridging oxalate. As usual the Ni—C_2O_4—Ni fragment is practically planar, deviations from the least-square plane fitted through the Ni(1)—C(1)—O(1)—O(2)—C(1a)—O(1a)—O(2a)—Ni(1a) atoms are lower than 0.010 Å. The Ni(1)···Ni(2) separation of 5.412(1) Å falls within the range found for similarly coordinated μ-oxalato-nickel(II) complexes.

Spectroscopic and magnetic properties of $Ni(TAA)(ClO_4) \cdot 0.5ox$

The electronic spectrum in water solution shows the three characteristic absorptions of octahedral nickel(II) at 27,950, 17,700 and 10,000 cm^{-1}.

Largest difference peak and hole (e Å^{-3})	0.611 and −0.876

The IR spectrum of the complex is consistent with the structural data presented above. It shows the sharp bands at 3200 (s), 3180 (s) and 3120 (s) cm^{-1} assigned to the N—H stretching vibrations. The band at 1625 cm^{-1} (s) is attributed to the antisymmetric NH_2-bending vibration and NH_2-twisting vibrations which appear at 1040 (s) and 1000 (s) cm^{-1}. The absorptions at 880 (m) and 906 cm^{-1} (m) may be assigned to the

Symmetry transformations used to generate equivalent atoms: (a) $-x+1$, $-y$, $-z+1$.

CH_2-rocking, at 1268 cm^{-1} (w) to the CH_2-wagging and at 1382 cm^{-1} (s) to the CH_2-bend vibrations [12]. The occurrence of tetradentate oxalate is clearly observed in the IR spectrum of the title compound: the ν_{asym}(CO) 1644 (s), ν_{sym}(CO) 1355 (s), 1312 (s), δ(CO) 796 cm^{-1} bands agree very well with those reported [13] for Nitrien(ClO_4)·0.5ox (trien = triethylenetetramine). The bands at 1090 (s) and 624 (s) cm^{-1} belong [14] to anion ClO_4^-.

The effective magnetic moment of 2.94 B.M. at 297 K per Ni^{2+} is typical for octahedrally coordinated nickel(II). The variable-temperature magnetic moment and magnetic susceptibility in the range 78–300 K for a solid sample of the title compound is shown in Fig. 2. The magnetic moment is temperature dependent and decreases from 4.23 B.M. mol^{-1} (2.94 B.M. per Ni^{2+}) at 297 K to 3.57 B.M. at 77.9 K. This proves that there is antiferromagnetic coupling across the oxalate bridge. The magnetic behaviour of the title complex could be interpreted using isotropic spin Hamiltonian $H = -2JS_1S_2$, where $S_1 = S_2 = 2/2$ and J is the exchange integral. The experimental data have been fitted to the expression [2]:

$$\chi_M = \frac{\mu_0 N g^2 \beta^2}{3kT} \times \left(\frac{30\exp(6J/kT) + 6\exp(2J/kT)}{5\exp(6J/kT) + 3\exp(2J/kT) + 1} \right) + N_\alpha \quad (1)$$

by using Klička's program [15] for the HDVV-dimer model. In this expression N, β, k and T have their usual meaning, J is the exchange integral and it is assumed that $g_x = g_y = g_z = g$. The last term in this equation, N_α, is the temperature-independent paramagnetism (TIP). The best fit parameters obtained are: $J = -14.4\ cm^{-1}$, $g = 2.25$. For Ni^{II} complexes in octahedral geometry, the metal x^2-y^2 orbital is half occupied and is aligned to allow overlap with the oxalate σ-orbitals. For present complex, the observed J value of $-14.4\ cm^{-1}$ is very similar to those of [Ni_2trien_2ox](ClO_4)$_2$ ($J = -15.1\ cm^{-1}$, our result, or [2] $J = -15.7\ cm^{-1}$) or [3] [Ni_2en_4ox](NO_3)$_2$ ($J = -16\ cm^{-1}$).

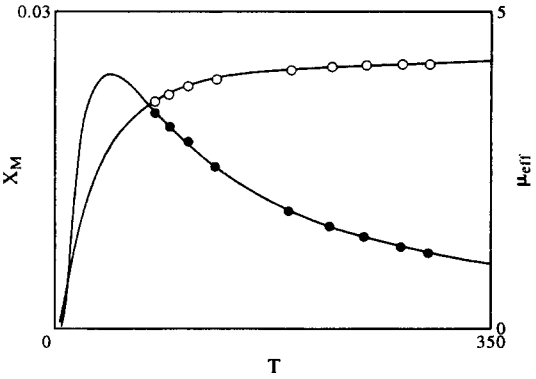

Fig. 2. The paramagnetic susceptibility (●—in cgs) and effective moment (○—B.M.) *vs* temperature curves for Ni(TAA)(ClO_4)·0.5ox. The circles are the experimental points, the solid lines are theoretical lines.

Properties of $Ni_2(APO\text{-}sal_2)ox \cdot 2H_2O$

The binuclear nickel(II) oxalato-bridged complex of the ligand (APO-sal_2) precipitates from the solution as a brown powder, which was not suitable for X-ray study. The thermal behaviour of the compound has been deduced from its TG and TGA curves. The removal of the water molecules starts at 75°C and the corresponding small endothermic peak at approximately 150°C is broad. The weight loss continues in the temperature range 210–400°C with two exothermic peaks at 290 and 340°C. A constant mass is achieved at 400°C. The last observed solid product was identified by its X-ray powder diffraction pattern as NiO (Δm_{th} 72.2%, Δm_{exp} 72.5%).

The IR spectrum shows a strong absorption band at 1620 cm^{-1}. This frequency corresponds to the ν(C=N), which is typical for Schiff bases. The (C=O) at 1670 cm^{-1} of the salicylaldehyde disappears as a result of condensation. The phenolic (C—O) band (1270 cm^{-1}) of the ligand shifts to a higher frequency [1290 cm^{-1} (s)] in the complex due to the bonding [16] to nickel. The occurrence of oxalate is observed in the IR spectrum of this complex at 1640 (m) – ν_{asym}(CO), 1365 (s), 1300 (s) – ν_{sym}(CO) and δ(C—O) at 755 cm^{-1} (m).

The effective magnetic moment at room temperature (296 K) is 4.00 B.M. mol^{-1}; i.e. 2.79 B.M. per Ni^{II}. The temperature dependence of the magnetic moment of this compound is displayed in Fig. 3. On lowering of the temperature, μ_{eff} decreases from 4.00 B.M. at 296 K to 3.47 B.M. at 77.5 K. This magnetic behaviour is characteristic of an antiferromagnetically coupled Ni^{II}–Ni^{II}. The value of the exchange parameter $J = -11.25$ cm^{-1} ($g = 2.04$) based on Eq. (1) is a little smaller than that in the previous compound.

Properties of $Niphen_2oxNiacac_2 \cdot 4H_2O$

This compound was obtained as blue microcrystals almost insoluble in organic solvents.

The thermal analysis shows that the compound starts its decomposition above 60°C, losing its water molecules in an endothermic process. A weight loss of 8.5% in the TG curve corresponds to the loss of four water molecules (Δm_{th} 7.5%). The anhydrous salt is stable from 120 up to 210°C, above this temperature the thermal decomposition continued in one step. A constant mass is achieved at 440°C, at which temperature the weight of the residue was in accordance with this calculated for NiO (NiO was identified by X-ray powder diffraction pattern).

The IR data of this complex show the characteristic bands of the oxalate bridging ligands. Three peaks ν_{asym}(C—O), ν_{sym}(C—O) and δ(C—O) of oxalate are found at 1652 (w), 1312 (s) and 770 (w) cm^{-1}. The ν(C=C) and ν(C=O) bands of the acetylacetone ion [17,18] are found at 1592 (m) and 1520 (m) cm^{-1}, respectively, and for phenanthroline complexes are found following typical peaks [19] 1442 (s), 1345 (s), 1156 (m) and 850 (w) cm^{-1}.

At 295 K the magnetic moment μ_{eff}/molecule is 4.61 B.M., the μ_{eff}/Ni^{2+} is 3.18 B.M., which is in the range expected for an octahedral Ni^{II} atom. The thermal dependence of χ_M and μ_{eff} for this complex in the temperature range 78.5–295 K is shown in Fig. 4. From room temperature, the μ_{eff} value decreases to 3.54 B.M. mol^{-1} at 78.5 K. The value of $J = -19.4$ cm^{-1} and $g = 2.38$ have been evaluated from the best fit of the experimental data to Eq. (1). This value is a bit higher value, but not greatly deviated from this ($J = -14.3$ cm^{-1}) reported [17] for μ-oxalato-bis[(acetylacetonato)(*N*,*N*,*N*′,*N*′-tetramethylethylenediamine)nickel(II)].

The exchange integrals J found for all three compounds studied are in the -11.25 to -19.4 cm^{-1} range. The data obtained in this study show that the main factor influencing the strength of the antiferromagnetic coupling is the extent of overlap between the magnetic orbitals of the paramagnetic nickel ions and those of the μ-oxalato bridging ligand. In other words, there is only small influence of the

(Received 28 June 1996; accepted 12 August 1996)

Abstract—The reaction of Me_3Al with 1 and 2 equiv. of 2-aminoacetophenone yielded $Me_2Al[O{=}C(Me)C_6H_4\text{-}2\text{-}NH]$ (**1**) and $MeAl[O{=}C(Me)C_6H_4\text{-}2\text{-}NH]_2$ (**2**), respectively. Compound **2** was also obtained in the reaction of **1** with 1 equiv. of 2-aminoacetophenone. The addition of 4-methylpyridine (py-Me) to **1** produced the Lewis acid–base adduct $Me_2Al[O{=}C(Me)C_6H_4\text{-}2\text{-}NH]\cdot$ py-Me (**3**). The resulting compounds have been characterized by elemental analysis, cryometric molecular weight determination and ^1H and ^{27}Al NMR spectroscopy. These studies revealed that compound **1** has a four-coordinated chelate structure in solution, while **2** and **3** are five-coordinated monomeric complexes. The molecular structure of **2** has been confirmed by single-crystal X-ray crystallography. Copyright © 1997 Elsevier Science Ltd

Keywords: organoaluminum compound; O,N-chelate complex.

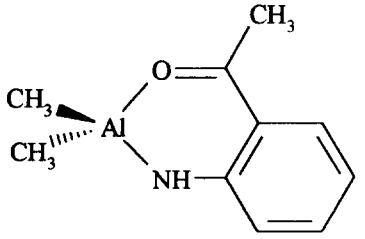
The reactions of organoaluminum compounds with O,O′-bidentate ligands, and the structure and reactivity of alkylaluminum chelate complexes, have been the subject of intense studies recently [1–5]. We succeeded in synthesizing and structural characterizing of the first simple five-coordinated alkylaluminum chelate complex, $RAl(O,O')_2$, [3] and also characterized a number of new $R_2Al(O,O')$-type complexes and showed that the structure of dialkylaluminum chelate compounds in solution depends on the nature of the O,O′-chelate ligand [4,5]. For example, if both chelating oxygen atoms are involved in the conjugated bond system of the O,O′-chelate, the $R_2Al(O,O')$ complexes occur as monomeric compounds in solution. Studies have been carried out by us on the reactions of monohydroxy O.O′-bidentate ligands. Similarly, the structurally characterized dialkylaluminum O,N-chelate complexes described in the literature concerned only the derivatives of the O,N-bidentate ligands bearing a hydroxy group [6–10].

In this paper we report the interactions of trimethylaluminum with 2-aminoacetophenone as an O,N-bidentate ligand bearing an acidic proton bonded to a nitrogen atom, and structural studies of the four- and five-coordinated monomeric alkylaluminum O,N-chelate complexes.

RESULTS AND DISCUSSION

The interaction of Me_3Al with 1 and 2 equiv. of 2-aminoacetophenone (amketH) leads to the formation of $Me_2Al(amket)$ (**1**) and $MeAl(amket)_2$ (**2**), respectively, and evolution of methane [Eqs. (1) and (2)], Compound **2** may also be prepared directly from the reaction of **1** with 1 equiv. of amketH [Eq. (3)].

* Author to whom correspondence should be addressed.



$$Me_3Al + amketH \rightarrow Me_2Al(amket) + MeH \quad (1)$$

$$Me_3Al + 2\,amketH \rightarrow MeAl(amket)_2 + 2\,MeH \quad (2)$$

$$Me_2Al(amket) + amketH \rightarrow MeAl(amket)_2 + MeH \quad (3)$$

Compound **1** is a deep-red solid and is soluble in hydrocarbon solvents, while **2** is an orange solid and is soluble in methylene chloride and aromatic solvents.

Elemental analysis, cryometric molecular weight determinations, ^{27}Al and ^1H NMR and IR spectroscopy are consistent with the formulae of compound **1** and **2** as given, and the monomeric chelate structures in solution. The ^{27}Al NMR spectrum of **1** consists of one resonance at δ 152.0, indicative of a four-coordinated aluminum atom. This is in the same range as the signals for monomeric $R_2Al(O,O')$ chelate compounds recently reported [4,5]. In the ^1H NMR spectrum three singlets corresponding to Me—Al, Me—C and N—H amide protons, as well as four multiplets of aromatic protons are observed, which is consistent with the tetrahedral chelate structure **I**.

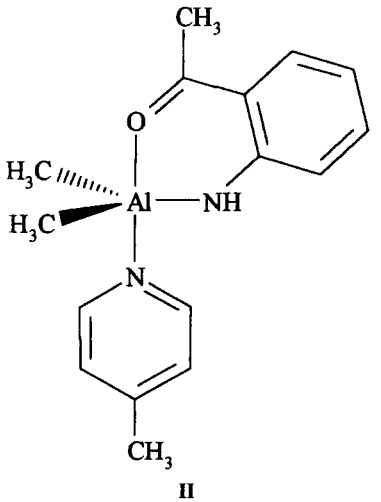
I

The results concerning structure **I** in solution are in agreement with those of our earlier findings for $R_2Al(O,O')$ complexes; namely that the presence of a conjugated bond system in the chelating ligand favours the formation of monomeric dialkylaluminum chelate complexes [4,5]. Unfortunately, we have been unable to perform X-ray diffraction studies on **1** at ambient temperature.

The ^{27}Al NMR shift for **2** (δ 74) is similar to that previously observed by us for the monomeric five-coordinated methylaluminum O,O'-chelate compound [3]. In the ^1H NMR spectrum one methylaluminum peak and a single set of resonances for the amket ligands are observed. The structure of **2** has been confirmed by X-ray crystallography.

The molecular structure of **2** is shown in Fig. 1 and selected bond lengths and angles are given in Table 1. The complex comprises a five-coordinated aluminum atom with an idealized trigonal bipyramid coordination sphere. The aluminum atom lies exactly in the $CAlN_2$ equatorial plane determined by the methyl group carbon atom and two amide nitrogen atoms. The angles between the bonds in this plane are close to 120°. The carbonyl group oxygen atoms of the chelating ligand are in axial positions.

Simultaneously, the deviation of the axial bonds from an ideal position, as shown in Fig. 2, probably results from strains in the O,N-chelating ligand. Chelating ligands form deformed six-membered AlNCCCO heterocyclic rings in the shape of an open envelope with a dihedral angle defined by NAlO and NCCCO atoms equal to 14.4°. The mean length of the Al—N bonds is 1.865 Å and is comparable with corresponding bond lengths in five-coordinated alkylaluminum complexes with O,N-macrocyclic ligands [11,12]. The lengths of the axial Al—O bonds are comparable with those observed for axial bonds lengths in an analogous compound with an O,O'-ligand, $MeAl(mesal)_2$ [3]. The structurally characterized compound **2** is the first simple five-coordinated alkylaluminum chelate complex with an O,N-bidentate ligand.



The reaction of **1** with 4-methylpyridine (py-Me) results in the formation of the Lewis acid–base adduct $Me_2Al(amket)(py\text{-}Me)$ (**3**) in quantitative yield [Eq. (4)].

$$Me_2Al(amket) + py\text{-}Me \rightarrow Me_2Al(amket) \cdot py\text{-}Me \quad (4)$$

Compound **3** is a deep red liquid insoluble in hydrocarbon solvents and soluble in methylene chloride and aromatic solvents. It is unstable at ambient temperature and slowly decomposes within 1–2 days to yield **2** and $Me_3Al \cdot py\text{-}Me$ [Eq. (5)].

$$Me_2Al(amket) \cdot py\text{-}Me \rightarrow MeAl(amket)_2 + Me_3Al \cdot py\text{-}Me \quad (5)$$

Compound **3** has been characterized by elemental analysis, cryometric molecular weight determinations and ^{27}Al and ^1H NMR spectroscopy. The ^{27}Al NMR spectrum of **3** consists of one resonance at δ 73 with a chemical shift similar to that observed for **2** indicative of a five-coordinated aluminum atom.

II

The ^1H NMR spectrum of this complex shows four singlets in an intensity ratio of 6:3:3:1, which can be easily assigned to Me—Al, Me—C, Me-py and N—H protons, respectively. The data obtained for **3**

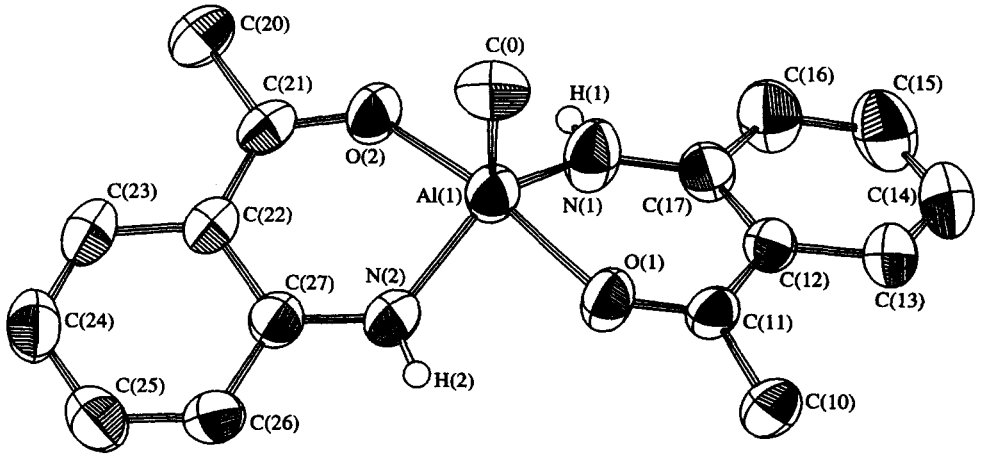


Fig. 1. Molecular structure of $MeAl[O{=}C(Me)C_6H_4\text{-}2\text{-}NH]_2$ (**2**) with the atom labelling scheme. Thermal ellipsoids are drawn at the 50% level. Hydrogen atoms, except NH groups, have been omitted for clarity.

are therefore consistent with the monomeric Lewis acid–base adduct and its structure can be described as depicted in **II**. Adduct **3** is the first example of a monomeric five-coordinated dialkylaluminum compound to be isolated and spectroscopically characterized. Further studies on the structure and reactivity of alkylaluminum O,N -chelate complexes are under way.

EXPERIMENTAL

All operations were carried out under nitrogen. Solvents were purified and dried by standard techniques. Me_3Al and 2-aminoacetophenone were distilled before use. Standard Schlenk line techniques were employed. NMR spectra were recorded on a Varian VXR-300 spectrometer.

Preparation of $Me_2Al[O{=}C(Me)C_6H_4\text{-}2\text{-}NH]$ (**1**)

2-Aminoacetophenone was dissolved in toluene (8 cm^3) and Me_3Al (0.44 g, 3.3 mmol) was added dropwise at −78°C. After the addition was completed the reaction mixture was allowed to warm up to room temperature. The solvent was then removed *in vacuo*, leaving an orange solid that was crystallized from a toluene/hexane solution at 0°C. Yield: 85%. Found: C, 62.5; H, 7.6; N, 7.0. Calc. for $C_{10}H_{14}NOAl$: C, 62.8; H, 7.4; N, 7.3; Al, 14.1%. Molecular weight

X-ray crystal structure determination of **2**

A yellow crystal of compound **2** was sealed inside a Lindemann capillary and mounted on the goniometer head of a Siemens P3 diffractometer employing graphite-monochromated Mo-K_α, radiation. Crystal data, data collection and refinement parameters are summarized in Table 2. The cell parameters were obtained by least-squares refinement of measured setting angles of 28 randomly selected reflections with $7 < 2\theta < 30°$. Intensity data were collected using the ω–2θ technique with variable scan speed. Two check reflections (2 0 0; 0 1 3) measured every 70 reflections revealed drastic crystal decay of 60% and intensities were corrected accordingly. Lorentz and polarization corrections were applied to the data set; no corrections were applied for absorption.

The crystal of **2** was monoclinic and assigned to the $P2_1/c$ (No. 14) space group on the basis of systematic absences. The structure was solved by direct methods using SHELXS-86, [13] which revealed the positions of all non-hydrogen atoms. Refinement was per-

formed by the full-matrix least-squares method on F^2 using the SHELXL-93 program. [14] All non-hydrogen atoms were refined with anisotropic thermal parameters. The aromatic and methyl H-atoms were placed in calculated positions and refined isotropically with a riding model. Hydrogen atoms of the methyl group bonded to the Al atom were refined as a disordered group with two positions rotated from each other by 60°. It was possible to identify on the difference Fourier map and successfully refine the positions of hydrogen atoms of both amide NH groups. An extinction correction was applied to all data during the final stages of refinement, and the extinction coefficient x was refined by leastsquares according to the equation $F_c^* = kF_c[1+0.001xF_c^2\lambda^3/\sin(2\theta)]^{-1/4}$, where k was the overall scale factor. Refinement of the structure led to convergence, and the maximum shift of the parameter was less than 0.01 of its estimated standard deviation. The largest peak in the final difference Fourier map had an electron density of 0.155 eÅ^{-3}, and the lowest excursion -0.156 eÅ^{-3}. The weighting scheme was of the form $w^{-1} = \sigma^2(F_o^2)+(0.365P)^2+0.6559P$, where $P = (2F_c^2+F_o^2)/3$. Residuals are defined as $wR_2 = \{\Sigma[w(F_o^2-F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$ for all data and conventional $R_1 = \Sigma||F_o|-|F_c||/\Sigma|F_o|$ for reflections with $F_o^2 > 2\sigma(F_o^2)$, the latter for comparison with conventional refinements based on F values. Full lists of atomic coordinates, thermal parameters, bond lengths and bond angles have been deposited at the Cambridge Crystallographic Data Centre.

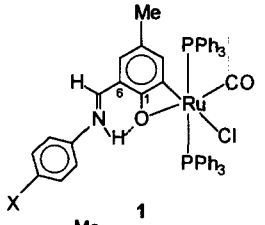
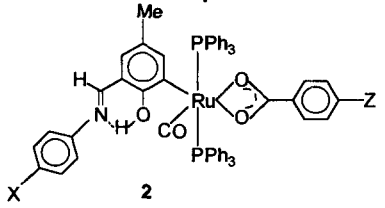
A four-membered C,O-chelate: two families of ruthenium organometallics incorporating N···O hydrogen bonding

Prasanta Ghosh



Department of Inorganic Chemistry, Indian Association for the Cultivation of Science, Calcutta 700 032, India

(Received 6 June 1996; accepted 6 August 1996)



Abstract—The reaction of mono-Schiff bases of 4-methyl-2,6-diformylphenol and primary amines (p-$XC_6H_4NH_2$, X = OMe, Cl, CO_2Et and NO_2) with $Ru(PPh_3)_3Cl_2$ in boiling ethanol afforded violet diamagnetic complexes, $[Ru(\eta^2\text{-}p\text{-}XC_6H_4L)(PPh_3)_2(CO)Cl]$ (η^2-p-XC_6H_4L = [4-methyl-6-(*N*-p-Xphenyliminiomethyl) phenolato-C^2,O] incorporating the unprecedented orthoruthenated phenolato function, which is hydrogen-bonded with the uncoordinated imine nitrogen. These complexes were found to react with sodium benzoates (p-ZC_6H_4COO, Z = Me, Cl) to generate the new aryl complexes of ruthenium, $[Ru(\eta^1\text{-}p\text{-}XC_6H_4L)(PPh_3)_2(CO)(\eta^2\text{-}p\text{-}ZC_6H_4COO)]$. The spectral (IR, UV–vis and ^1H NMR) features of these two types of complexes and the effect of the X substituent on electronic and ^1H NMR spectra are scrutinized. The effect of PPh_3 ring currents on the chemical shifts of the metallated ring protons is semiquantitatively estimated. In these complexes different types of novel intramolecular N···O interaction and the conformational orientation of p-XC_6H_4L ligands are noted. The redox behaviour of these complexes is reported. The $E_{1/2}$ values of Ru^{III}/Ru^{II} couple correlate linearly with the Hammett constants (σ) of X substituent in the halo complexes. A spectro-electrochemical correlation in these complexes is also observed. Copyright © 1997 Elsevier Science Ltd

Keywords: ruthenium; decarbonylation; C,O-chelation; carboxylate chelation; N···O hydrogen bonding; spectroelectrochemical correlation.

Recently it has been reported that the reaction of $Ru(PPh_3)_3Cl_2$ with 4-methyl-2,6-diformylphenol in the presence of primary amines affords the novel organometallics of type **1** (X = H, Me) [1]. Complex **1** was found to react with carboxylates affording **2** (X = H, Me; Z = H) [2].

1

2

In this work the synthesis and characterization of a more complete series of compounds (X = OMe, Cl, CO_2Et and NO_2; Z = Me and Cl) and their spectral (IR, UV–vis and ^1H NMR), redox and the intramolecular N···O hydrogen-bonding features are reported. This has provided an opportunity for studying the substituent effects in a logical manner.

EXPERIMENTAL

Materials

The starting materials $Ru(PPh_3)_3Cl_2$ [3] and the 4-methyl-2,6-diformylphenol [4] were prepared by the reported procedures. The reactions of 4-methyl-2,6-diformylphenol and the aromatic primary amines (p-$XC_6H_4NH_2$) in 1:1 and 1:2 ratios in boiling ethanol affords, respectively, the Schiff bases **4** and **5**. The sodium benzoates (Na-p-ZC_6H_4COO) were prepared by neutralizing the corresponding acid with 0.1 N

NaOH solution. The purification of dichloromethane and the preparation of tetraethylammonium perchlorate (TEAP) for electrochemical work were carried out as before [5]. All other chemicals and solvents were of analytical grade and used without further purification.

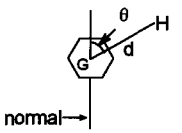
Preparation of complexes

The complexes **1** were synthesized in excellent yields by reacting $Ru(PPh_3)_3Cl_2$ with the Schiff mono-bases **4**. The reaction of **1** with sodium benzoates generated **2** in high yields. Details are given for representative cases.

Carbonylchloro[4-*methyl*-6-(N-p-*chlorophenyliminiomethyl*)*phenolato-C*^{2},*O*]*bis*(*triphenylphosphine*) *ruthenium*(II), **1** (*X* = Cl). To a solution of 2-formyl-4-methyl-6-(*N*-*p*-chlorophenylimine)phenol (**4**, X = Cl; 45 mg, 0.15 mmol) in hot ethanol (30 cm^3) was added $Ru(PPh_3)_3Cl_2$ (100 mg, 0.10 mmol). The mixture was heated to reflux for 1 h and then cooled. A dark violet solid separated which was collected by filtration. It was washed thoroughly with cold ethanol and dried *in vacuo*. Yield: 80 mg [82% on the basis of $Ru(PPh_3)_3Cl_2$]. Found: C, 65.5; H, 4.5; N, 1.4. Calc. for $C_{51}H_{41}NO_2P_2Cl_2Ru$: C, 65.5; H, 4.4; N, 1.5%.

Complexes **1** with X = OMe, CO_2Et and NO_2 were synthesized similarly in 80–85% yields. Found: C, 67.2; H, 4.8; N, 1.4. Calc. for $C_{52}H_{44}NO_3P_2ClRu$ (**1**, X = OMe): C, 67.2; H, 4.7; N, 1.5%. Found: C, 66.7; H, 4.7; N, 1.4. Calc. for $C_{54}H_{46}NO_4P_2ClRu$ (**1**, X = CO_2Et): C, 66.7; H, 4.8; N, 1.4%. Found: C, 64.8; H, 4.4; N, 2.9. Calc. for $C_{51}H_{41}N_2O_4P_2ClRu$ (**1**, X = NO_2): C, 64.8; H, 4.4; N, 3.0%.

Carbonyl(p-*chlorobenzoato*)[4-*methyl*-6(N-p-*tolyiminomethyl*)*phenol-C*^{2}]*bis*(*triphenylphosphine*) *ruthenium*(II), **2** (*X* = Me; *Z* = Cl). To a vigorously stirred solution of **1** (X = Me) [6] (50 mg, 0.05 mmol) in dichloromethane (20 cm^3) and acetone (20 cm^3) was added dropwise an aqueous solution of Na-*p*-ClC_6H_4COO (60 mg, 0.34 mmol). The mixture was stirred for 0.5 h. The dark violet solution turned yellow. The organic solvents were then removed under reduced pressure, leaving an aqueous suspension of a yellow residue. This was isolated by filtration, washed thoroughly with water and dried *in vacuo*. Yield: 48 mg (85% on the basis of chloro precursor). Found: C, 68.5; H, 4.7; N, 1.3. Calc. for $C_{59}H_{48}NO_4P_2ClRu$: C, 68.5; H, 4.7; N, 1.3%.



Complexes **2** with X = H, Z = Cl and X = H, Me, Z = Me, were similarly prepared in high yields (85–90%). Found: C, 68.3; H, 4.5; N, 1.4. Calc. for $C_{58}H_{46}NO_4P_2ClRu$ (**2**, X = H; Z = Cl): C, 68.3; H, 4.5; N, 1.4. Found: 70.8; H, 4.9; N, 1.4. Calc. for $C_{59}H_{49}NO_4P_2Ru$ (**2**, X = H; Z = Me): C, 70.9; H, 4.9; N, 1.4%. Found: C, 71.0; H, 5.1; N, 1.3. Calc. for $C_{60}H_{51}NO_4P_2Ru$ (**2**, X = Me; Z = Me): C, 71.1; H, 5.1; N, 1.4%.

Physical measurements

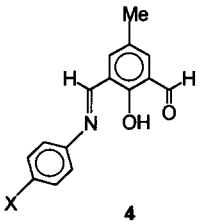
Electronic and IR spectra were recorded on Hitachi 330 and Perkin–Elmer 783 IR spectrophotometers. For ^{1}H NMR spectra a Bruker 270-MHz FT NMR spectrometer was used (tetramethylsilane as internal standard). Microanalyses (C, H, N) were obtained using a Perkin–Elmer 240C elemental analyser. The diamagnetic behaviour of the samples was established using a PAR 155 vibrating-sample magnetometer fitted with a Walker Scientific magnet. Electrochemical measurements were performed under nitrogen on a PAR 370-4 electrochemistry system, as reported earlier [5]. All the reported potentials are uncorrected for junction contributions. Solution ($\sim 10^{-3}$) electrical conductivities were measured with the Philips PR 9500 bridge. The following Hammett σ values [7] for *para*-substituents were used: H, 0.00; Me, −0.17; OMe, −0.27; Cl, +0.23; CO_2Et, +0.45; NO_2, +0.78.

Computation of chemical shift due to PPh_3 *ring currents*

The crystallographic data of **1** (X = Me) have been used [1b]. The computed parameters are d and θ. These are defined in **3**: d = distance of the concerned

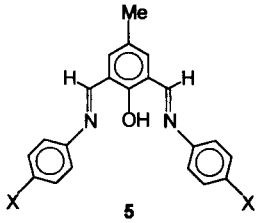
3

proton from the centroid (G) of each PPh_3 phenyl ring and θ = angle between d vector and the normal to the plane of the phenyl ring at G. From these distances (d) and angle (θ) parameters, the cylindrical coordinates [8] ρ and z of the concerned proton were calculated in units of the radius of the benzene hexagon [9] as follows:



$$\rho = d\cos(90-\theta)/1.39 \quad z = d\sin(90-\theta)/1.39.$$

The ρ and z values were then used to compute the shift with the help of available isoshielding plots [9]. The net shift was estimated by summing up individual contributions.



RESULTS AND DISCUSSION

Synthesis and characterization

Complexes **1** and **2** will be abbreviated as [Ru(η^2-*p*-XC_6H_4L)$(PPh_3)_2$(CO)Cl] and [Ru(η^1-*p*-XC_6H_4L)$(PPh_3)_2$(CO)(η^2-*p*-ZC_6H_4COO)], respectively. The [Ru(η^2-*p*-XC_6H_4L)$(PPh_3)_2$(CO)Cl] complexes were synthesized in excellent yields by the stoichiometric reaction of the mono-Schiff bases **4** and $Ru(PPh_3)_3Cl_2$ in boiling ethanol [eq. (1)]. The Schiff bases **4** were

4

5

obtained by reacting 4-methyl-2,6-diformylphenol with the appropriate amine in ethanol. The reaction of eq. (1) affords **1** when

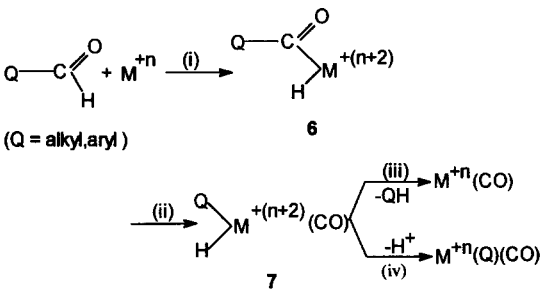
$$Ru(PPh_3)_3Cl_2 + \mathbf{4} \rightarrow Ru(\eta^2\text{-}p\text{-}XC_6H_4L)(PPh_3)_2(CO)Cl + HCl + PPh_3 \quad (1)$$

1

$$\mathbf{1} + Na\text{-}p\text{-}ZC_6H_4COO \rightarrow [Ru(\eta^1\text{-}p\text{-}XC_6H_4L)(PPh_3)_2(CO)(\eta^2\text{-}p\text{-}ZC_6H_4COO)] + NaCl \quad (2)$$

2

the di-Schiff base **5** was used in place of **4**. This proceeds *via* hydrolysis of **5** by the water present in the solvent.



The reaction of the complexes **1** with the aqueous substituted sodium benzoates in dichloromethane–acetone mixture at room temperature afforded the $[Ru(\eta^1\text{-}p\text{-}XC_6H_4L)(PPh_3)_2(CO)(\eta^2\text{-}p\text{-}ZC_6H_4COO)]$ (Z = Me and Cl) complexes in nearly quantitative yields [eq. (2)]. The transformation causes a complete colour change from dark violet to yellow.

The complexes synthesized in this work are listed in Table 1. Complexes **1** and **2** are violet and yellow crystalline solids, respectively.

All the complexes are diamagnetic and non-electrolytic in organic polar solvents. They are soluble in dichloromethane, chloroform, benzene and acetone.

Formation path

Ruthenium [10] and rhodium [11] promoted decarbonylation reaction of aldehydes generally proceeds by the following steps [(i), (ii) and (iii)] [12]. However, in this reaction step (iii) does not occur. The inherently unstable Ru^{IV} carbonyls [13] with two PPh_3 ligands

(Q = alkyl,aryl)

6

7

easily eliminate the hydride from **7** as H^+ and are reduced to stable Ru^{II} carbonyl complexes [14], incorporating the four membered C,O-chelate ring (**1**). Step IV leading to the final product is a complete novelty for decarbonylative metallation reactions. The eliminated proton from **7** is then unsymmetrically bridged by the imine nitrogen and the phenolate to form the zwitter-ionic iminium-phenolato function.

Table 1. UV–vis spectral data and cyclic voltammetric reduction potentials at 298 K

[a] In CH_2Cl_2.

[b] Extinction coefficient.

[c] Conditions: solvent, dichloromethane; supporting electrolyte, TEAP (0.1 M); working electrode, platinum; reference electrode, SCE; solute concentration, $\sim 10^{-3}$ M; $E_{1/2} = 0.5(E_{pa} + E_{pc})$ at scan rate 50 mV s^{-1}, where E_{pa} and E_{pc} are anodic and cathodic peak potentials respectively; $\Delta E_p = E_{pa} - E_{pc}$.

In the absence of the imine function the reaction does not occur implying the formation of the iminium-phenolato motif makes the reaction feasible. No considerable effect of the substituent (X) is observed in the yield and the time of the reaction.

UV–vis spectra

The four-membered chelate chromophore in **1** displays characteristic spectral features in the visible region. Three allowed bands are observed in the range 300–700 nm (Table 1, Fig. 1). The band around 550 nm is obviously due to the metal-to-ligand charge-transfer (MLCT). The value of the λ_{max} of this band increases (red-shifted) with increasing order of electronegativity of X, i.e. $\lambda_{max}(NO_2) > \lambda_{max}(CO_2Et) > \lambda_{max}(Cl) > \lambda_{max}(H) > \lambda_{max}(Me) > \lambda_{max}(OMe)$, and correlates linearly with the Hammett constant (σ) of the X substituent [6]. This significant and systematic effect of p-XC_6H_4 substituent strongly suggests that the acceptor antibonding orbital has significant iminium character.

In this region the dramatic change of the spectral feature is noted when the hapticity of the p-XC_6H_4L ligand changes from η^2 to η^1 in the [Ru(η^1-p-XC_6H_4L)(PPh_3)$_2$(CO)(η^2-p-ZC_6H_4COO)] complexes. These benzoato complexes display two bands near 400 and 330 nm in dichloromethane solution (Fig. 1). The latter band is more intense than the former. The maxima of these bands are not shifted either varying the X or the Z substituents.

IR spectra

In the [Ru(η^2-p-XC_6H_4L)(PPh_3)$_2$(CO)Cl] complex the Ru—Cl stretching vibration occurs near 340 cm^{-1} with medium intensity. In [Ru(η^1-p-XC_6H_4L)(PPh_3)$_2$(CO)(η^2-p-ZC_6H_4COO)] the asymmetric and symmetric stretching vibrations of the carboxyl function appear as distinct bands of medium intensity in the region 1450–1530 cm^{-1}. The relatively low separation between the two stretching modes is consistent with the presence of chelated carboxyl function [15]. The C≡O stretching vibration in these complexes occurs in the region 1910–1920 cm^{-1}.

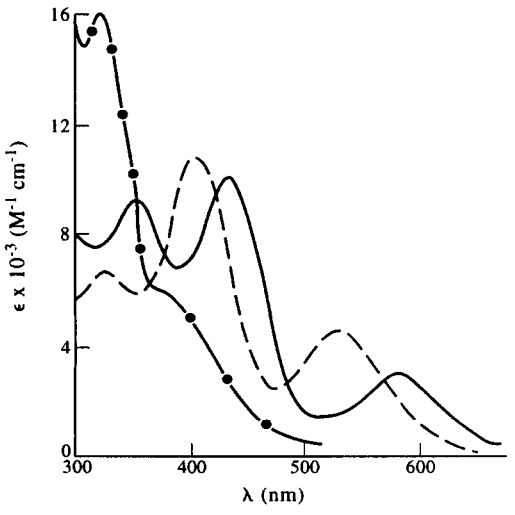

Fig. 1. Electronic spectra of [Ru(η^2-p-$O_2NC_6H_4L$)(PPh_3)$_2$(CO)Cl](——), [Ru(η^2-p-$MeOC_6H_4L$)(PPh_3)$_2$(CO)Cl] (– – –) and [Ru(η^1-PhL)(PPh_3)$_2$(CO)(η^2-p-MeC_6H_4COO)] (–·–·–) in dichloromethane.

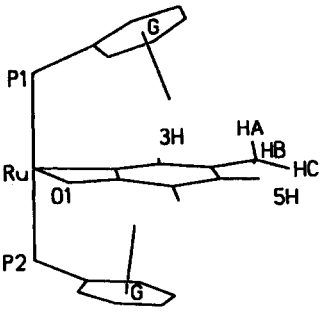

^{1}H *NMR spectra*

Free ligands. The 3-H (*ortho* to —CHO) and the 5-H protons in **4** (X = Cl) resonate as sharp singlets at 7.85 ppm and 7.51 ppm (Table 2).

The 4-Me and the aldimine (—CH=N—) signals appear at ~2.40 and ~8.7 ppm, respectively. The phenolic OH signal arises as a relatively sharp peak at ~13.7 ppm.

Complexes **1**. In **1** the —CHO (in **4**) or —CH=N— (in **5**) function *ortho* to the 3-H in free ligands is replaced by the ruthenium centre, which is bonded to PPh_3 ligands. C2 is potentially a carbanionic centre in these complexes. Due to the shielding effects of the C2 centre and the ring currents of the PPh_3 phenyls [1,16], the chemical shifts of the metallated ring protons are significantly low (Table 2). The signal at ~5.9 is assigned to 3-H which lies *ortho* to C2. The 5-H singlet appears at ~6.06 ppm. The azomethine function lying *ortho* to 5-H is attached to the p-XC_6H_4 substituent. This substituent has a small but significant effect on the 5-H resonance. The resonance shifts to lower field as the X substituent becomes more electron-withdrawing (Table 2). The chemical shift (~1.7 ppm) of the 4-Me signal is also considerably low. The effect of the PPh_3 ring currents to this group and the 3-H and 5-H proton signals may be interpreted by the following observations on the [Ru(η^2-p-MeC_6H_4L)(PPh_3)$_2$(CO)Cl] structure [1b].

In [Ru(η^2-p-MeC_6H_4L)(PPh_3)$_2$(CO)Cl] two phenyl rings of the PPh_3 ligands orient nearly parallel to the metallated benzene ring (**8**). The distances of 3-H, 5-

8

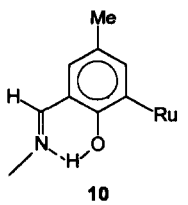
[a] TMS internal standard, PPh_3 signals at 7.23 and 7.66 ppm. Abbreviations: s = singlet; rs = relatively sharp singlet; br = broad; d = doublet; t = triplet; q = quartet; in **2**, aromatic signals (Ar—H) are non-resolvable.

H and 4-Me protons from the centroids (*G*) of the two rings and the angles at *G* with distance vectors show that these protons lie in the shielding region of the rings. Using these distance and angle parameters and the isoshielding ρ-*z* plots [9] the estimated upfield shielding of these protons are: 3-H, 1.00; 5-H, 0.75; 4-Me, 0.50 ppm.



In the carboxylates rotation of the RL (here, R = *p*-XC_6H_4) ligand around the Ru—C axis is not restricted and in solution the effective shielding due to the PPh_3 ring currents is low. The 5-H signal merges with the other aromatic signals and the 3-H and 4-Me protons appear at ~6.2 ppm and 2.0 ppm respectively (Table 2).

Intramolecular $N^+H\cdots O^-$ *and* $OH\cdots N$ *hydrogen bonding*

The heteronuclear asymmetric $NH\cdots O$ hydrogen bonding plays an important role in the amide and peptide chemistry [17]. The reported $OH\cdots N$ interaction is rare [18]. However, both are important in enzyme catalytic phenomena [19]. The $N\cdots O$ interaction in the chloro complexes is illustrated in **9** in which the H atom is unsymmetrically bridged. In the IR spectra the N^+—H vibration is observed as a relatively broad band in the region 3400–3450 cm^{-1} (Table 1), indicating the presence of weak hydrogen bonding [20]. In ^{1}H NMR the N^+—H proton displays characteristically broad band (width at half height ~0.5 ppm) at ~12 ppm (Table 2).

9

10

Transformation of the complexes **1** to **2** leads to a tautomeric change of the hydrogen-bonded iminium-phenolato function (**9**) to the asymmetrically hydrogen-bonded imine-phenol function (**10**). In IR and ^{1}H NMR spectra this is clearly observable. In contrast to the presence of the N^+—H vibration in **9**, **10** displays a very broad feature in the region 3200–3600 cm^{-1} as observed in the case of free ligands (**4** and **5**). Instead of having any nitrogen quadrupole broadened N^+—H signal, **10** shows a relatively sharp O—H signal (width at half height ~0.1 ppm) at 12.6 ppm in the ^{1}H NMR spectra. The feature of this OH signal compares very well with the O—H signal in free ligands.

The intrinsic difference of the ^{1}H NMR signal of the aldimine proton in **1** and **2** is also consistent with the two forms of interactions. The aldimine proton of the —CH=N$^+$ function is expected to appear at higher field [21]. In **9** it appears at ~7.4 ppm, but in **10** it occurs at ~8.1 ppm. As expected [20a,22], the C=N stretching frequency is higher in **9** (~1630 cm^{-1}) than that (~1590 cm^{-1}) in **10**.

X-ray structure determination of [Ru(η^2-*p*-MeC_6H_4L)$(PPh_3)_2$(CO)Cl] [1b] and [Ru(η^1-*p*-MeC_6H_4L)$(PPh_3)_2$(CO)(η^2-$MeCO_2$)] [2], in which bridged H atoms have been located directly by difference Fourier maps, provide us the distance and angle parameters of $N^+H\cdots O^-$ and $OH\cdots N$ units, respectively [$N^+H\cdots O^-$: $N\cdots O$, 2.665(12) Å; N—H, 0.99(6) Å; $H\cdots O$, 1.75(5) Å; N—$H\cdots O$, 144(1)° and for $OH\cdots N$: $O\cdots N$, 2.592(10) Å; O—H, 1.14(3) Å; $H\cdots N$, 1.52(3) Å and O—$H\cdots N$, 156(1)°]. It shows that the O—$H\cdots N$ interaction in the tautometer **10** is stronger and the O—$H\cdots N$ angle is more close to 180°. However, the $N^+H\cdots O$ bridge (in **9**) is more unsymmetrical.

Conformational reorganization

The CO molecule in **1** lies *trans* to the phenolate, but in **2** it is positioned *cis* to that. In the transformation

1 → **2** the coordinated phenolate and the chloride are displaced by the benzoato oxygens. To avoid strong repulsive interaction [2] between the phenolic oxygen and one of the benzoato oxygens, the monodentate RL ligand rotates ~180° around the Ru—C axis resulting in the orientation as in **2**.

These two distinct orientations of the RL ligand having different modes of binding with the ruthenium centre incorporate the distinctive N···O interaction (**9** and **10**). However, these are easily interconvertible. The ruthenium centre with RL, CO and PPh_3 ligands has strong affinity towards

$$\mathbf{2} \underset{R'COO^-}{\overset{Cl^-}{\rightleftharpoons}} \mathbf{1} \qquad (3)$$

the chloride as well as the carboxylate, eq. (3). Upon treating with excess chloride **2** transforms to **1** and in the presence of HCl the carboxylate displacement is very fast and quantitative.

Interestingly it is noted that the tautomerization of the —CH=N$^+$H···O$^-$ to the —CH=N···HO$^-$ with a concomitant geometrical isomerization is the crucial occurrence in the photochemically induced cycle in the chromophore of the visual and bacterial rhodopsins [20a].

Metal redox and spectroelectrochemical correlation

In dichloromethane solution the [Ru(η^2-*p*-XC_6H_4L)$(PPh_3)_2$(CO)Cl] and the [Ru(η^1-*p*-XC_6H_4L)$(PPh_3)_2$(CO)(η^2-*p*-ZC_6H_4COO)] complexes display a characteristic quasi-reversible cyclic voltammetric response corresponding to the Ru^{III}/Ru^{II} couple, eqs (4) and (5). Current height data suggests that

$$\mathbf{1}^+ + e \rightarrow \mathbf{1} \qquad (4)$$

$$\mathbf{2}^+ + e \rightarrow \mathbf{2} \qquad (5)$$

the process involves the transfer of one electron. The high instability of the oxidized species did not permit their isolation.

In ^{1}H NMR it is observed that the X substituent has significant electronic influence on the metallated ring. It also has a measurable effect on the $E_{1/2}$ values (Table 1; Fig. 2). The reduction potential ($E_{1/2}$) of the couple, eq. (4), increases as the electron-withdrawing character of X increases [6]. A linear correlation of the $E_{1/2}$ values with the Hammett constants (σ) of X was found. No significant effect of the Z substituent on the couple of eq. (5) was noted. The $E_{1/2}$ values of the benzoates are lower than those of the chloro complexes.

The ease of charge transfer (MLCT) from the ruthenium(II) centre to the acceptor antibonding orbital of the metallated ring is a measure of the stability of the ruthenium(II) valence in the C,O-chelate. With the higher electronegative substituent (X), the acceptor orbital is more stabilized and the energy of the MLCT band becomes lower. This charge delocalization stabilizes the filled t_2-shell of ruthenium(II) in higher extent and it is reflected in the $E_{1/2}$ values of the Ru^{III}/Ru^{II} couple. The lower the energy of the band maxima $t_2 \rightarrow \pi^*$ the higher is the $E_{1/2}$ value and these two parameters have a linear spectroelectrochemical correlation [23].

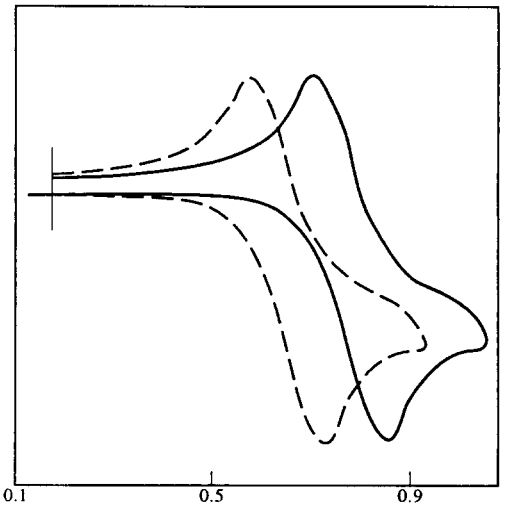


Fig. 2. Cyclic voltammograms of ~10^{-3} mol dm^{-3} solutions in dichloromethane for [Ru(η^2-*p*-$MeOC_6H_4L$)$(PPh_3)_2$(CO)Cl] (– – –) and [Ru(η^2-*p*-$O_2NC_6H_4L$)$(PPh_3)_2$(CO)Cl] (——).

In this work, a new family of *ortho*-ruthenated phenolates has been synthesized. The inherently unstable four-membered C,O-chelate ring of this type is stabilized in these complexes in the presence of two PPh_3, CO, Cl as coligands and a crucial —CH=NR (R = *p*-XC_6H_4) function (*ortho* to OH group) which is hydrogen-bonded (NH$^+$···O$^-$) to the coordinated phenolato oxygen. The *p*-XC_6H_4 substituent has indirect but considerable electronic influence on the chelate chromophore and the metal centre. The Hammett constants of X correlate linearly with the energy of the MLCT band and the $E_{1/2}$ values of the Ru^{III}–Ru^{II} couple. Expectedly the spectroelectrochemcial correlation is linear.

The new arylbenzoato complexes generated from these halo precursors incorporate the uncoordinated phenolic group and the substituents of imine and benzoato functions have no significant effect on the metal centre. In these benzoates the OH···N hydrogen bonding a tautometer of NH$^+$···O$^-$ constitutes a rare example.

Acknowledgements—I am thankful to Professor A. Chakravorty for providing facilities and useful suggestions. Financial support from the DST, New Dehli, is acknowledged.

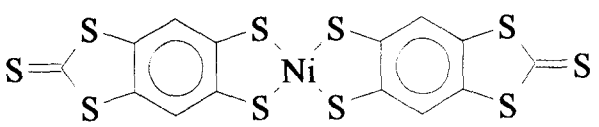
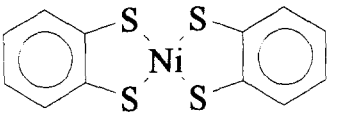
(Received 4 June 1996; accepted 6 August 1996)

Abstract—X-ray absorption near-edge structure (XANES) and extended X-ray absorption fine structure (EXAFS) studies on the tetra(*n*-butyl)ammonium salt of $[Ni(dmbit)_2]^{x-}$ ($x = 2, 1$ and 0.29) and $[Ni(dmbbip)_2]^-$ have been performed in order to reveal the structural parameters of the $[NiS_4]^{x-}$ core along with the chemical state. The central nickel ion is confirmed to have coordination number four with square-planar geometry. The [Ni—S] bond distance in $[Ni(dmbit)_2]^-$ (2.154 Å) is identical with that of $[Ni(dmbbip)_2]^-$, but shorter than those of $[Ni(dmbit)_2]^{2-}$ (2.178 Å) and $[Ni(dmbit)_2]^{0.29-}$ (2.165 Å). Copyright © 1997 Elsevier Science Ltd



Keywords: X-ray absorption near-edge structure (XANES); extended X-ray absorption fine structure (EXAFS); molecular-based organic conductor; nickel-1,2-dithiolene.

Recently we have studied the synthesis, magnetic and electrical properties of $Ni(dmbit)_2$ and $Ni(dmbbip)_2$ complexes [1–5] (dmbit: 5,6-dithio-benzo[*d*]-1,3-dithiole-2-thione; dmbbip: 1,2-di(isopropylthio) benzene-4,5-dithiole) which have ligands with an expanded π-electron system (Scheme 1): Dmbit and dmbbip ligands can be regarded in the family of bdt (benzene-1,2-dithiolate) with a peripheral isotrithione [$(—S)_2C{=}S$] and isopropylthiol [$—SCH(CH_3)_2$] groups, respectively. Alternatively, the dmbit ligand can be considered as an analogue of the dmit ligand in which the C=C bond is substituted with the benzene ring. The bdt type ligand, however, behaves differently to the ethylenedithiolate type ligands, such as dmit (4,5-dimercapto-1,3-dithiole-2-thione) and mnt (maleonitriledithiolate), because the resonance energy of benzene is much higher than that of the isolated double bond in ethylenedithiolate (Scheme 2). Hence, there is a difference in stability between the dianionic ligands ($dmit^{2-}$ and bdt^{2-}) relative to the dithioketo forms, which are derived by a reversible oxidation of dianionic ligands.



Monoanionic salts of $Ni(dmbit)_2$ and $Ni(dmbbip)_2$, which are insulators with pressed pellet conductivities of 10^{-9} and 10^{-11} S cm^{-1}, respectively, at room temperature, [1] show the antiferromagnetic coupling among nickel ions and the magnetic moments of 1.74 and 1.75 B.M., respectively, corresponding to low-spin d^7 state of nickel(III) [2]. The partially oxidized complex, $[Ni(dmbit)_2]^{0.29-}$, shows a metallic behaviour from 300 to 220 K at which it has the maximum conductivity of 1.35 S cm^{-1}. This is not a single crystal conductivity because attempts to grow single crystals suitable for electrical conductivity measurement were unsuccessful. X-ray crystal structure analysis has not been performed due to the same reason.

Extended X-ray absorption fine structure (EXAFS) spectroscopy using a synchrotron radiation source is a useful method for determining the local environment of a selected atom (e.g. interatomic distance, coordination number), although it is limited to the information with the near-neighbouring atoms. X-ray absorption near-edge structure (XANES) spec-

troscopy also gives valuable data on the oxidation state and local geometry of a selected atom. Above all, these techniques are applicable to the powdered samples as in our case [4]. Here we report the results of EXAFS and XANES studies on $[Ni(dmbit)_2]^{2-}$ and its oxidized complexes, $[Ni(dmbit)_2]^{x-}$ ($x = 1$ and 0.29), along with its analogue $[Ni(dmbbip)_2]^{-}$.

EXPERIMENTAL

Sample preparation

$(n\text{-}Bu_4N)_x[Ni(dmbit)_2]$ ($x = 2$, 1 and 0.29) and $(n\text{-}Bu_4N)[Ni(dmbbip)_2]$ complexes were prepared and confirmed as described in the previous paper, [1–2] in which the partial oxidation was performed by chemical method using $(n\text{-}Bu_4N)Br_3$ in CH_3CN.

XAS measurements

XANES and EXAFS experiments have been carried out on the beam-line 10B at the Photon Factory of the National Laboratory for High Energy Physics (2.5 GeV, 260 ~ 360 mA) by using a Si(311) channel-cut monochromator. Data were collected at room temperature in the transmission mode using ionization chambers filled with N_2 and $N_2(75\%) + Ar(25\%)$ gas for the measurements of incident X-ray intensity (I_0) and transmitted (I), respectively. Powder samples were finely ground with Nujol in a mortar and suspended homogeneously onto adhesive tape and the folded appropriately in order to be free from the thickness effect ($\Delta\mu t \cong 1$). Ni metal foil ($\phi = 0.5$ μm) was used as a standard to calibrate the energy of the samples. The inherent background in the data was removed by fitting a polynomial to the pre-edge

region, and extrapolated through the entire spectrum, from which it was subtracted.

Data reduction

The data were normalized to an edge jump of unity for comparing the XANES features directly. The energy positions of the edge features were determined from the positions of the half-width at half-maximum of the second derivatives. The data reduction of raw EXAFS spectra was carried out as described elsewhere [6]. The EXAFS function $\chi(k)$ is given by the equation, $\chi(k) = \{\mu(k) - \mu_0(k)\}/\mu_0(k)$, where k is the photoelectron wave-vector ejected given as $\{8\pi m(E-E_0)\}^{1/2}/h$. E represents the energy of the incident X-rays and E_0 is the threshold energy of a k-shell electron. A curve fitting procedure in the k space for the refinements of structure parameters was applied to the Fourier filtered $k^3\chi(k)_{obs}$ values to minimize the following error-squares sum, $\Sigma\ k^6(\chi(k)_{obs} - \chi(k)_{calc})^2/n$, where n represents the number of data points.

The model function $\chi(k)_{calc}$ was obtained according to the single-electron and single-scattering theory:

$$\chi(k)_{calc} = \Sigma\{n_j/(kr_j^2)\}F_j(\pi,k)\exp(-2\sigma_j^2k^2) \times \exp(-2r_j/\lambda)\sin(2kr_j+\phi_j(k)).$$

Here for the backscattering amplitude $F_j(\pi,k)$, the total scattering phase shift $\phi_j(k)$ and the mean free path of a photoelectron λ were used the values of the FEFF code (version 5.03). The interatomic distance r, the Debye–Waller factor σ_j the coordination number n and E_0 were optimized as variables in the course of the structural analysis.

RESULTS AND DISCUSSION

The Ni K-edge XANES spectra for $(n\text{-}Bu_4N)_x[Ni(dmbit)_2]$ ($x = 2, 1$ and 0.29) and $(n\text{-}Bu_4N)[Ni(dmbbip)_2]$ are shown in Fig. 1, in which the changes of peak position and intensity upon oxidation, $[Ni(dmbit)_2]^{2-} \rightarrow [Ni(dmbit)_2]^{-} \rightarrow [Ni(dmbit)_2]^{0.29-}$, are clearly shown and comparable with $[Ni(dmbbip)_2]^{-}$. The overall shape of spectra is very similar to that of coordination complexes with square-planar local symmetry around central metal, such as metalloporphyrin [7] and M[B(3-isopropylpyrazole-1-yl)$_4$]$_2$ (M = Fe, Co, Ni, Cu and Zn) [8]. Four peaks labelled A, B, C and D are recognized in the near-edge absorption region and the first EXAFS oscillation is followed at higher energy region. The energy positions of these peaks are estimated from their second derivatives and listed in Table 1. Among these, peak A at 8330 eV in the pre-edge region corresponds to the transition of the nickel 1s electron to its empty 3d-orbitals. Their intensities are very small compared with the other peaks, because this transition is principally forbidden by dipole selection rule ($\Delta l = \pm 1$). Peaks C and D correspond to the $1s \rightarrow 4p_\pi$ and $1s \rightarrow 4p_0$ transitions, respectively, and are also characteristics of the transition metal complexes with square-planar local symmetry. In addition, the second peak (B) in the spectra shows the most apparent difference in its intensity as well as the chemical shift among four peaks. This peak is attributed to the transition from the initial state, $|1s^2 3d^n 4p_\pi^0\rangle$, to the final state, $|1s^1 3d^{n+1} 4p_\pi^1 L\rangle$, where l denotes the ligand hole, and a simultaneous shake-down process through the ligand-to-metal charge-transfer (LMCT), which gives the core-hole screening effect in the final state. Therefore, this peak might be well modified by the electronic environment such as the ligand field and the chemical bonding because d-orbitals are most susceptible to the bonding nature of the ligands. If the nickel ion is located in the square-planar local geometry and therefore its electronic configurations of 3d-orbitals could be written as $(xz)^2(yz)^2(z^2)^2(xy)^2(x^2-y^2)^0$ and $(xz)^2(yz)^2(z^2)^2(xy)^1(x^2-y^2)^0$ for $[Ni(dmbit)_2]^{x-}$, where $x = 2$ and 1, respectively, a charge-transfer should occur from 3p-orbitals of ligating sulfur to the lowest empty orbitals of nickel, $(x^2-y^2)^0$ and $(xy)^1$, for $[Ni(dmbit)_2]^{2-}$ and $[Ni(dmbit)_2]^{1-}$, respectively. However, a charge-transfer to the $(xy)^1$-orbital for the compound $[Ni(dmbit)_2]^{1-}$ needs an additional spin-pairing energy, which might result in the lowering of transition probability and, as a consequence, the depression of peak intensity of B. Upon partial oxi-

Table 1. The energies (eV) of the XANES transitions

Complex	Transition Peaks A	B	C	D
$(n\text{-}Bu_4N)_1[Ni(dmbbip)_2]$	8330	8335.0	8339.0	8344.0
$(n\text{-}Bu_4N)_2[Ni(dmbit)_2]$	8330	8334.5	8338.5	8343.2
$(n\text{-}Bu_4N)_1[Ni(dmbit)_2]$	8330	8335.3	8339.0	8344.0
$(n\text{-}Bu_4N)_{0.29}[Ni(dmbit)_2]$	8330	8336.2	8339.0	8344.0

dation of the monoanionic complex, only peak B related to the LMCT process shifts to higher energy by 0.9 eV, while peaks C and D remain unchanged in energy. These three peaks, however, shift by 0.5–0.8 eV due to the oxidation of the dianionic complex (Table 1). XANES transition energies of the $[Ni(dmbbip)_2]^-$ complex are almost the same as those of $[Ni(dmbit)_2]^-$, indicating that the electronic state of $[NiS_4]^{1-}$ core is nearly unaffected by the peripheral groups on the ligand and therefore could be considered with as almost identical electronic state in both monoanionic complexes [9].

The k^3-weighted EXAFS oscillations are shown in Fig. 2 and the magnitudes of Fourier transform of $k^3\chi(k)$ are in Fig. 3, where the first peak corresponds to the shell of the nearest-neighbour (ligating sulfur) around nickel. In order to compare the change of the [Ni—S] bond distance upon oxidation of $[Ni(dmbit)_2]^{2-}$, EXAFS curve fits were performed in the Fourier-filtered oscillation of the [Ni—S] shell (Fig. 3), using the curved-wave XAFS simulation program (FEFF). The fitting results are summarized in Table 2. Nickel ions in these complexes have the coordination number 4 within a typical error range, indicating the square-planar local symmetry. $[Ni(dmbit)_2]^{1-}$ exhibits a shorter [Ni—S] bond distance than that for $[Ni(dmit)_2]^{2-}$, as can be seen in the X-ray crystallographic analysis of nickel dithiolene complexes such as $[Ni(dmbit)_2]^{x-}$, where [Ni—S] bond distances are 2.156 ($x = 1$) [10] and 2.216 Å ($x = 2$) [11] and $[Ni(mnt)_2]^{x-}$, 2.146 ($x = 1$) [12] and 2.166 Å ($x = 2$) [13]. As for $[Ni(dmbbip)_2]^{1-}$, it is also identical with those of $[Ni(dmbit)_2]^{1-}$ (2.154 Å), and $[Ni(bdt)_2]^{1-}$ (2.151 Å) [14], which can be easily understood from the fact that three ligands (dmbit, dmbbip

Table 2. Curve fitting results of Fourier-filtered EXAFS spectra for the first shell[a]

Complex	R(Å)[b]	C.N.[c]	σ^2(Å^2)[d]	ΔE_0(eV)
$(n\text{-}Bu_4N)_1[Ni(dmbbip)_2]$	2.154	4.1	3.53	−4.7
$(n\text{-}Bu_4N)_2[Ni(dmbit)_2]$	2.178	4.1	4.11	−5.3
$(n\text{-}Bu_4N)_1[Ni(dmbit)_2]$	2.154	4.2	2.82	−4.0
$(n\text{-}Bu_4N)_{0.29}[Ni(dmbit)_2]$	2.165	3.5	3.11	−6.3

[a] Typical accuracies are ±0.02 Å for R and ±25% for coordination number and Debye–Waller factor. A curve fitting procedure in the k space for the refinements of structure parameters was applied to the Fourier filtered $k^3\,\chi(k)_{obsd.}$ values over the k range 3.0–14.2 Å^{-1} of dk = 1.0 Å^{-1} and the R range 1.4–2.3 Å of dr = 1.0 Å.

[b] R is the [Ni—S] bond distance.

[c] Coordination number (C.N.) corresponds to the values when amplitude reduction factor is fixed to unit.

[d] Debye–Waller factor ($\times 10^{-3}$).

and bdt) belong to benzene-1,2-dithiolate group with the same $[NiS_4]^{1-}$ core.

Consequently, it is clear that the redox process is mainly centred on the $[NiS_4]^{x-}$ core during the oxidation of $[Ni(dmbit)_2]^{2-}$. The [Ni—S] bond distance of the partially oxidized complex (2.165 Å), however, is in between those of mono- and dianionic Ni-dmbit complexes. The metal–sulfur bond distance of conductive nickel-dithiolene is not easy to predict, but it could be assumed with these data that nickel(IV) was not generated by the partial oxidation; if so, the [Ni—S] distance should become shorter after partial oxidation, because the radius of the nickel(IV) ion is shorter than nickel(III) [15]. Therefore, the dmbit ligand can be thought to be oxidized in this step so that conducting electrons are delocalized all over the metal complex, which may cause the [Ni—S] bond distance to be longer than that of monocationic complex. Upon oxidation of $[Ni(dmbit)_2]^{2-}$, the Debye–Waller factor (σ^2), which contains information on the disorder of the interatomic distances, decreases by 31% associated with the decrease of the [Ni—S] bond distance and an increase up to 110% was observed in the partially oxidized complex, as can be expected in [Ni—S] bond distance variation.

CONCLUSIONS

The central nickel ion within the $[NiS_4]^{x-}$ core of the $[Ni(dmbit)_2]^{x-}$ and $[Ni(dmbbip)_2]^{1-}$ complexes is confirmed to have coordination number four with square-planar geometry. The LMCT process and electronic transition in the nickel ion were affected by the oxidation of $[Ni(dmbit)_2]^{2-}$ to $[Ni(dmbit)_2]^{1-}$ accompanying the [Ni—S] bond distance decrease (*ca* 0.024 Å). It seems that the oxidation process is mainly centred at the $[NiS_4]^{2-}$ core and therefore an insulator $[Ni(dmbit)_2]^{1-}$ was produced. Upon partial oxidation, however, only the LMCT process was affected (peak B) and the [Ni—S] bond distance became longer (*ca* 0.013 Å), resulting in the conductive $[Ni(dmbit)_2]^{0.29-}$ complex.

(Received 28 May 1996; accepted 6 August 1996)

Abstract—The title complex was synthesized in aqueous solution and its crystal structure was determined by X-ray diffraction. The complex is binuclear, with copper and yttrium ions connected by four bridging carboxyl groups from four alanine molecules. The yttrium ion is coordinated by four oxygen atoms from four carboxyl groups and four oxygen atoms of four water molecules with the coordination number eight, taking a square antiprism arrangement. Copyright © 1997 Elsevier Science Ltd

Keywords: copper and yttrium; crystal structure; alanine complex.

Lanthanide ions are often used as spectroscopic probes for calcium ions in the studies of biological systems, dyeing promoters in the textile dyeing industry and additive elements of fertilizers in agriculture [1–3]. Since these applications are related to the interactions between lanthanide ions and biological ligands, the study of the bond models of lanthanide ions with amino acids is of interest. Recently, the crystal data of a series of lanthanide complexes with alanine have been reported [4–9]. Here we present the X-ray diffraction data for a heteronuclear complex of copper and yttrium with alanine.

EXPERIMENTAL

Preparation

The title complex was prepared by mixing $Cu(ClO_4)_2$ and $Y(ClO_4)_3$ in an aqueous solution of alanine at pH 4 in a 1 : 1 : 4 molar ratio. A blue single crystal was then obtained by slow evaporation at room temperature. After washing with water and air-drying, the composition of the crystal was determined by elemental analysis. Found: N, 5.1; C, 13.1; H, 4.0. Calc. for $[CuY(Ala)_4(H_2O)_5](ClO_4)_5 \cdot 3H_2O$: N, 4.9; C, 12.5; H, 3.9%. This formula is approximately consistent with the result of diffraction analysis.

IR spectra

IR spectra of the complex and alanine were obtained from KBr pellets at room temperature using a Nicolet Magna-IR 750 spectrophotometer. Compared with the IR spectrum of alanine, the ν_s(carboxyl) band at 1431 cm^{-1} of the complex is shifted 21 cm^{-1} to higher wavenumbers from 1410 cm^{-1}. This shows that the carboxyl groups of the ligand have been coordinated with the metal ion [10]. A broad absorption band for ν(hydroxyl) appears at 3400 cm^{-1} after complexation, showing the presence of water molecules in the complex.

X-ray analysis

In air, the crystals quickly turn opaque due to the loss of water molecules. For this reason, a crystal of approximate dimension $0.26 \times 0.28 \times 0.36$ mm was mounted in a thin-walled capillary for structure determination. Intensity data were collected on a Siemens P4 diffractometer. 4487 independent reflections were collected, of which 3451 reflections with $F > 4.0(F)$ were used for structure refinement. Intensities were not corrected for absorption. All calculations were performed in the Siemens SHELXTL P4/PC system. The structure was solved by direct methods and difference-Fourier syntheses, respectively. Crystal data, details of data collection and refinement are listed in Table 1.

RESULTS AND DISCUSSION

The crystal structure of the title complex and its coordination polyhedra are shown in Figs 1 and 2, respectively. Selected bond lengths and bond angles are listed in Table 2.

The complex exists as binuclear molecules with copper and yttrium ions connected by four bridging carboxyl groups from four alanine molecules. The yttrium ion is coordinated by four oxygen atoms from four alanine molecules and four oxygen atoms from four water molecules. Thus, the coordination number of yttrium ion is eight and the coordination polyhedron is a square antiprism. The copper ion, with coordination number 5, is coordinated by one oxygen atom from a water molecule and four oxygen atoms from the four bridging carboxyl groups, giving a square-pyramidal coordination polyhedron. The average bond lengths of Y—O(carboxyl) and Y—O(water) are 2.325 and 2.386 Å, respectively. The distance between Cu^{2+} and Y^{3+} is 3.491 Å. The perchlorate anions reside in the cavities of the crystal and stabilize the crystal packing by forming hydrogen bonds (Fig. 3).

The crystal structure of the complex $[CuY(Ala)_4(H_2O)_5](ClO_4)_5 \cdot 3H_2O$ has some similarities with the complexes $[Ln_2(Ala)_4(H_2O)_8](ClO_4)_6 \cdot nH_2O$ (Ln = Y, Ho, Er) [4–6]. They are all dimeric molecules and completely different from $[Dy(Ala)(H_2O)_6]Cl_3$, which is a one-dimensional infinite chain [8].

Abstract—The title complex, $K[KLa(HTTHA)(H_2O]\cdot 8H_2O$, was synthesized in aqueous solution and its crystal structure was determined by X-ray diffraction. In the complex, the ten-coordinated lanthanum ion is bonded by four nitrogen atoms and six carboxyl oxygen atoms of the same triethylenetetraaminehexaacetic acid (H_6TTHA) molecule. The coordination polyhedron of lanthanum can be described as a distorted bicapped square antiprism. The crystal is composed of one dimensional infinite chains. Copyright © 1997 Elsevier Science Ltd

Keywords: lanthanum complex; crystal structure; triethylenetetraaminehexaacetic acid.

Paramagnetic metal ion complexes are finding many applications in biomedicine, especially as bioconjugates for monoclonal antibody radioisotope labeling and as magnetic resonance imaging (MRI) agents [1,2]. Polyaminecarboxylic acids and their derivatives are very important chelating agents for metal ions. They form stable complexes with trivalent lanthanide metal ions and the diethylenetriaminepentaacetic acid (H_5DTPA) complex with gadolinium has been used as a MRI agent in the NMR diagnosis of tumors [3,4]. Having similar coordination ability with H_5DTPA towards lanthanide ions, triethylenetetraaminehexaacetic acid (H_6TTHA) can also strongly chelate with lanthanides and its complex with gadolinium may also be used as an image enhancing agent. So far, studies on lanthanide complexes with H_6TTHA in solution have been carried out to determine the thermodynamic stability constants [5,6] and there is no crystallographic study on them. Here we report the synthesis and crystal structure of the title complex.

EXPERIMENTAL

Preparation

Lanthanum oxide (La_2O_3) and triethylenetetraaminehexaacetic acid (H_6TTHA) were mixed in a 1:2 molar ratio in water. The mixed solution was refluxed for *ca* 5 h under stirring. Then the solution was neutralized with KOH solution to *ca* pH6 and filtrated. The filtrate was concentrated on a water bath and the clear solution obtained was allowed to evaporate slowly at room temperature, yielding colorless prismatic crystals suitable for X-ray diffraction. The composition of the complex was deduced from the elemental analysis. Found: N, 6.4; C, 24.5; H, 3.9. Calc. for $K[KLa(HTTHA)(H_2O]\cdot 8H_2O$: N, 6.5; C, 24.9; H, 4.9%. The formula is approximately consistent with the results of diffraction analysis. The

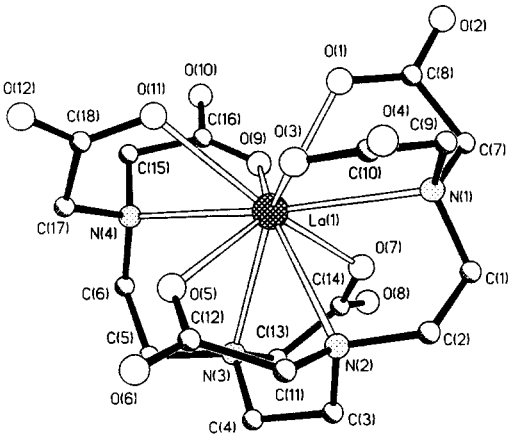

Fig. 1. Structure of K[KLa(HTTHA)(H_2O)]·8H_2O.

hydrogen content found is a little lower than that of the real composition of the complex. This may be caused by the efflorescent of the crystal before elemental determination.

IR spectra

IR spectra of the complex and free ligand were obtained from KBr pellets at room temperature using a Nicolet Magna-IR 750 spectrophotometer. Compared with the IR spectrum of free ligand, the ν_{as} (carboxyl) band of the complex is shifted 44 cm^{-1} to lower wave-numbers from 1642 cm^{-1} and the ν_s (carboxyl) band of the complex is shifted 6 cm^{-1} to higher frequency from 1398 cm^{-1}. This indicates that the carboxyl groups of the ligand have been coordinated with the metal ion [7,8]. A broad absorption band for ν(hydroxyl) appears at 3400 cm^{-1} after complexation, showing the presence of water molecules in the complex.

X-ray analysis

A colorless crystal of the title compound was mounted in a thin-walled capillary for structure determination. The reflections were collected on a Siemens P4 diffractometer. There were some small crystallites on the surface of the main crystal, so we used the program CHDU to calculate the cell parameters (CHDU is programmed by us, which is used to eliminate the influence of the small crystallites on the calculation of the cell parameters). Intensities were corrected for absorption by a semi-empirical method. The structure was solved by the heavy-atom method. Lanthanum-ion coordinates were determined by analysis of the Patterson map and all non-hydrogen atoms were determined by Fourier syntheses. Hydrogen atoms were located either from difference Fourier

syntheses or by theoretical method. The refinement was made by full-matrix least-squares. Crystal data, details of data collection and refinement are listed in Table 1.

RESULTS AND DISCUSSION

The crystal structure of the title complex and its coordination polyhedron are shown in Figs 1 and 2, respectively. Selected bond lengths and bond angles are listed in Table 2.

In the complex, each La^{3+} ion is encapsulated by one H_6TTHA molecule and coordinated by six oxygen atoms from the six carboxyl groups and four nitrogen atoms of the H_6TTHA molecule with coordination number 10, making a distorted bicapped square antiprism arrangement. The average bond lengths of La—O and La—N are 2.557 and 2.807 Å, respectively. There are two kinds of potassium ions in the crystal, K(1) and K(2). K(1), with coordination number seven, is coordinated by six oxygen atoms from two neighboring H_6TTHA molecules and one oxygen atom from a water molecule. Completely different from K(1), K(2), with coordination number 6, is coordinated by six water molecules only.

The crystal structure can be described as having a one-dimensional infinite chain, where the metal atoms are arranged in the order K(1)···La(1)··· K(1a)···La(1a)···. The connecting diagram of the metal ions is shown in Fig 3. K(1)···La(1)···K(1a) are connected by four carboxyl groups. Two bridging

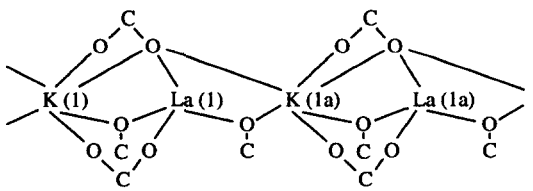

Fig. 3. Sketch map of the metal connection in K[KLa(HTTHA)(H2O)]·8H2O.

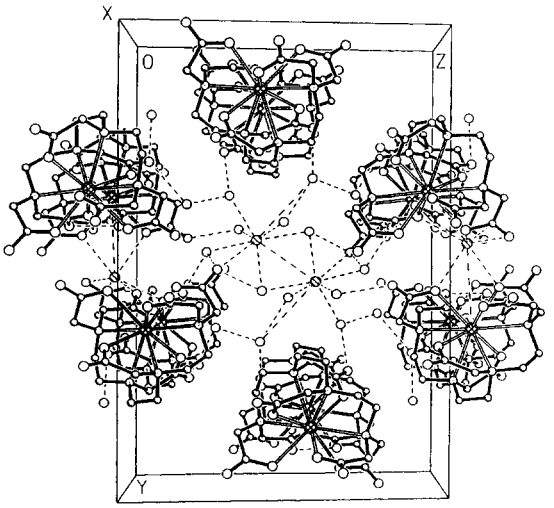

Fig. 4. Arrangement of K[KLa(HTTHA)(H_2O)·8H_2O.

carboxyl groups and a μ_2-O from a third carboxyl group connected to K(1) and La(1). One of the bridging carboxyl groups has an oxygen atom, acting as μ_3-O and bonding with La(1), K(1) and also K(1a). In contrast to the connection of K(1)···La(1), La(1) and K(1a) are connected only by the μ_3-O and a μ_2-O from the fourth carboxyl group. Therefore, there are two carboxyl bridges and two oxygen bridges between La(1) and K(1), but only two oxygen bridges between La(1) and K(1a). This is in good agreement with the distance data: K(1)···La(1), 4.154; K(la)···La(1), 4.378 Å.

In addition to the six-coordinated water molecules, there are still two uncoordinated water molecules in the crystal. They reside in the cavities of the crystal and stabilize the crystal packing through hydrogen bonds (Fig. 4).

Synthesis and crystal structure of a novel manganese(III)–molybdenum(IV) hetero-octametallic cluster, $Na_2Mn_2[Mo_3O_4(O_2CEt)_8]_2$

Li Xu,* Zaofei Li and Jinshun Huang*

State Key Laboratory of Structural Chemistry and Fujian Institute of Research on the Structure of Matter, Chinese Academy of Sciences, Fuzhou, Fujian 350002, P.R. China

(Received 24 May 1996; accepted 6 August 1996)

Abstract—A mixture of $Na_2MoO_4{\cdot}2H_2O$, $Mo(CO)_6$, $Mn(CH_3CO_2)_3{\cdot}2H_2O$ and $(EtCO)_2O$ was heated at 120°C to produce the novel manganese(III)–molybdenum(IV) hetero-octanuclear cluster $Na_2Mn_2[Mo_3O_4(O_2CEt)_8]_2$ (**1**) as green–black crystals in *ca* 15% yield. The X-ray structure determination reveals the presence of the two incomplete cubane-type cluster units, $[Mo_3O_4(O_2CEt)_8]^{4-}$ bridged by two Mn^{III} ions. The centrosymmetric octanuclear dianions are linked by Na^+ into infinite chains. It is surprising that each Mn^{III} ion has a rather regular O_6 octahedral coordination sphere with O—Mn—O angles within 5° of the expected octahedral value and six similar Mn—O bond lengths [1.963(4)–2.001(5) Å], showing little Jahn–Teller distortion. Copyright © 1997 Elsevier Science Ltd

Keywords: cluster; manganese complex; molybdenum complex; octanuclear complex; crystal structure; Jahn–Teller effect.

This is the continuing study of the chemistry of the hetero-octametallic cluster series $Na_2M'_2[M_3O_4(O_2CR)_8]_2$ established in this laboratory [1–5]. Such species consist of the two incomplete cubane-type cluster units $[M^{IV}_3O_3O_4(O_2CR)_8]^{4-}$ (M = Mo, W) bridged by two trivalent metal ions (M′), such triangular metal–metal bonded clusters having been extensively studied over the past two decades [6–8]. Bridging oxides and carboxylate oxygen atoms from the two trinuclear units just constitute two rather regular O_6 octahedra for the M′ bridging metal ions. We have reported V^{III}-, Cr^{III}-, Fe^{III}-, Mo^{III}- and Al^{III}-bridged clusters **2**–**13** of this series. Herein we present the new Mn^{3+}-bridged derivative, $Na_2Mn^{III}_2[Mo^{IV}_3O_4(O_2CEt)_8]_2$ (**1**). As will be illustrated later, it provides an unprecedented example of little Jahn–Teller distortion for octahedral Mn^{III} complexes [9,10].

EXPERIMENTAL

Preparative reactions were carried out in the air. $Mn(CH_3CO_2)_3{\cdot}2H_2O$ was prepared according to [11]. Other reagents were used as supplied without special purification.

Synthesis of $Na_2Mn_2[Mo_3O_4(O_2CEt)_8]_2$ (1)

A mixture of $Na_2MoO_4{\cdot}2H_2O$ (0.63 g, 2.60 mmol), $Mo(CO)_6$ (0.40 g, 1.50 mmol), $Mn(CH_3CO_2)_3{\cdot}2H_2O$ (0.35 g, 1.30 mmol) and propionic anhydride (60 cm^3) was heated at 120°C for 3 days. After cooling to room temperature, well-formed black crystals of **1** were obtained (0.20 g, 15%).

X-ray crystallography

The crystallographic data for cluster **1** are summarized in Table 1. The reflection intensities were collected on a Rigaku AFC5R diffractometer, using graphite-monochromated Mo K_α radiation (λ = 0.71069 Å) at room temperature and $\omega/2\theta$ scan mode ($3 < 2\theta < 50°$) with scan speed 8° min^{-1}. The structures were solved by direct methods using MULTAN11/82 and refined by full-matrix least-squares with all nonhydrogen atoms anisotropic. The weighting scheme w was $1/[\sigma(F_o)^2 + (0.02 \times F_o)^2 + 1.000]$. All

calculations were performed on a PC-486 using the Molen-PC program package with scattering factors taken from the International Tables.

RESULTS AND DISCUSSION

Synthesis

The synthesis of the Mn–Mo hetero-octametallic cluster **1** is convenient and straightforward. The redox reaction of MoO_4^{2-} and $Mo(CO)_6$ in propionic anhydride in the presence of $Mn(O_2CCH_3)_3$ produced the trinuclear unit $[Mo_3O_4(O_2CEt)_8]^{4-}$, which is trapped by Mn^{3+} ions to form the hetero-octanuclear anion $Mn_2[Mo_3O_4(O_2CEt)_8]^{2-}$. The dianion is further linked by Na^+ ions in the reaction into the insoluble infinite chain cluster **1**, which is believed to be essential to the successful preparation of this type of cluster. It should

be mentioned that the use of the freshly prepared Mn^{III} acetate [11] is necessary, otherwise, the yield of **1** will be substantially lowered presumably due to the facile disproportionation of Mn^{III} to Mn^{III} and Mn^{IV}. All attempts to prepare the Mn^{IV} derivative using Mn^{4+} compounds in place of $Mn(O_2CCH_3)_3$ were unsuccessful. This indicates that the correspondingly required 7e (metal *d* electrons are counted only) $[Mo_3O_4(O_2CEt)_8]^{5-}$ is unstable. In fact, the electrochemical reduction of the 6e $[Mo_3O_4(O_2CEt)_8]^{4-}$ always afforded 2e- or 3e-reduced derivatives [8]. It was also not possible to prepare Mn^{II} derivatives such as $Mg_2Mn^{II}[Mo_3^{IV}O_4(O_2CEt)_8]$ using $Mn(O_2CCH_3)_2$ to replace the Mn^{III} complex.

X-ray crystal structure

The structure of the cluster dianion of **1**, $Mn_2[Mo_3O_4(O_2CCH_3)_8]_2^{2-}$, is shown in Fig. 1. Selected bond lengths and angles in **1** are given in Tables 2 and 3 and a comparison of structural parameters in **1** and 12 related compounds are listed in Table 4. The structure consists of the two incomplete cubane-type cluster units, $[Mo_3O_4(O_2CCH_3)_8]^{4-}$, which is depicted in Fig. 2, with two Mn^{III} ions. An unusual feature in the cuboidal units shown in Fig. 2 is the single bridging ligand μ-$EtCO_2$, which has not been found in previously reported $[Mo_3O_4]^{4+}$-type species [6–8]. As shown in Table 3, the Mo—Mo and Mo—O bond

lengths in the $[Mo_3O_4(O_2CEt)_8]^{4-}$ unit of **1** and **2–8** are almost the same, indicating that the same oxidation state +4 of the Mo atoms in these species. By deduction, Mn has the oxidation state of +3 rather than +4, which requires a corresponding lowering of Mo oxidation states and thus change of the bond lengths about the Mo, in agreement with the experimental results described above. As shown in Fig. 1, each Mn is bound to two bridging oxides and four propionate oxygen atoms from the two trinuclear units in an octahedral arrangement. It can be seen from Table 2 that the resultant MnO_6 octahedron is rather regular with the O—Mn—O angles within 5° of the expected octahedral values. It is surprising that the anticipated tetragonal distortion has not occurred in the MnO_6 octahedron, as indicated by the six similar Mn—O bonds [1.963(4), 1.970(5), 1.982(5), 1.983(5), 1.993(4), 2.001(5) Å] given in Table 2. The averaged value of 1.989(5) Å for the six Mn—O bond lengths in the present cluster is close to the 1.981(8) and 1.994(3) Å in β-Mn(acac)$_3$ [9] and γ-Mn(acac)$_3$ [10], respectively. The reason for the lack of Jahn–Teller distortion in **1** is not clear, but the resulting instability of the MnO_6 octahedral is believed to be responsible for the low yield of **1**.

The mean Mn—O_b^* (bridging Mo and Mn) bond length [1.978(4) Å] which is close to the averaged Mn—O_{ba} (O_2CEt) distance [1.984(5) Å] is remarkably longer than the Mn—μ_3O bond in $[Mn_3O(O_2CH)_9]_2$ [av. 1.90(2) Å] [12], indicating very weak Mn—O_b^* d–p π-bonds. This is similar to the cases in the V, Fe and Al clusters, but unlike those in the Cr clusters where significant Cr—O_b^* d–p π-bonding has been observed.

As shown in Fig. 3, the octanuclear cluster dianions are linked by Na^+ ions into an infinite chain structure with the mean Na—O bond of 2.315(8) Å, responsible for the insolubility in water and common organic solvents and easy formation.

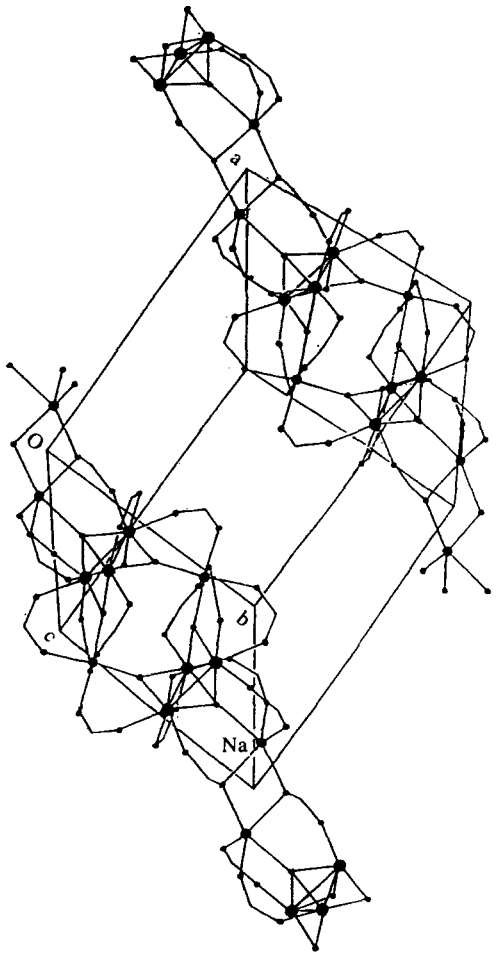

Fig. 3. Perspective view of the infinite chain of **1** with the Et groups omitted for clarity.

(Received 21 April 1996; accepted 6 August 1996)

Abstract—A new oxo-centred heterotrinuclear complex $[Cr_2MnO(PhCOO)_6Py_3][CrO_3Cl]$ was synthesized, which exhibited weak antiferromagnetic interaction between three atoms Cr^{III}, Cr^{III} and Mn^{III}. The J values for Cr^{III}—Mn^{III} and Cr^{III}—Cr^{III} have been estimated; the central O atom provides the main superexchange pathway. It indicated that the distance of M—(μ_3-O) is an important factor for metal–metal superexchange interaction. Copyright © 1997 Elsevier Science Ltd

Keywords: crystal structure; magnetic susceptibility; heteronuclear complex; chromium–manganese complex; oxo-centred complex; trinuclear complex.

Oxo-centred trinuclear complexes were the first polynuclear complexes to be investigated magnetically [1–2] and the first [2] in which the magnetic interactions were found. X-ray crystal structure [3] demonstrated that they contained an essentially equilateral triangle of metal ions surrounding a central O atom. Trinuclear complexes [4–7] $M_3O(RCOO)_6L_3$ and $[M_3O(RCOO)_6L_3]X$ were known for a wider range of metal ions, such as V, Cr, Mn, Fe, Co, Ni, Ru, Rh and Ir. The mixed-metal clusters [8–12] have attracted particular attention because spin-coupling interactions between different metal atoms may be investigated in almost the same geometric framework. It was possible to answer such questions as: is the exchange interaction mediation by the central atom, the bridging ligand or both? Although heterotrinuclear complexes had been known for more than half a century, $[Fe_2^{III}M^{II}O(MeCOO)_6L_3]$ complexes (L: H_2O, M: Co, Ni or Zn; L: Py, M: Co, Ni) were originally prepared in 1928 by Weinland and Holtmeier [8] and the structure was proved in 1980 by Yokubov [9]. The complexes of $Cr_2^{III}M^{II}$, $Cr^{III}Fe^{III}Mn^{II}$ analogues were reported in 1982 [10], these heterotrinuclear complexes exhibited antiferromagnetic exchange interactions and the central O atom provided the main superexchange pathway [13], in which p-orbitals of oxygen atom in the M_3O plane were especially effective. It is apparent that the number of d-electrons in $M_2^{III}M'^{III}O$ compounds is one less than that in $M_2^{III}M'^{II}O$ compounds, so the magnetic properties of those complexes may appear quite different, but few heterotrinuclear $M_2^{III}M'^{III}O$ complexes [14] have been studied. In this paper we report the synthesis of a new heterotrinuclear compound $[Cr_2MnO(PhCOO)_6Py_3][CrO_3Cl]$ and the crystal structure and magnetic properties of the compound.

EXPERIMENTAL

Preparation of materials

Preparation of NBu_4MnO_4. *Described by T. Sale* [15].

$[Cr_2MnO(PhCOO)_6Py_3][CrO_3Cl] \cdot 2/3Py$.

* Author to whom correspondence should be addressed.

$CrCl_3 \cdot 6H_2O$ (2.17 g) and benzonic acid (7.5 g) were dissolved in pyridine (20 cm^3), while stirring NBu_4MnO_4 (1.14 g) was slowly added. After stirring for 30 min, pyridine was evaporated under reduced pressure and a viscous slurry was obtained, then absolute alcohol (50 cm^3) was added and stirred, then the precipitate was produced. The mixture was filtered, washed three times with a little absolute alcohol. The product was a brown solid, yield 80% (calculated according to Cr).

The brown solid was redissolved in a little acetonitrile and brown–black single crystals were obtained after evaporating slowly in the air for several days. Found: C, 54.8; H, 3.8; N, 4.0; Cr, 11.8; Mn, 4.4. Calc. for $C_{60.3}H_{48.3}N_{3.7}O_{16}ClCr_3Mn$: C, 54.6; H, 3.7; N, 3.9; Cr, 11.7; Mn, 4.1%.

Identification of the anion $[CrO_3Cl]^-$. There are three Cr atoms and one Mn atom in the title compound. It must be confirmed which metal atom (Cr or Mn) is in the anion. A single crystal structure analysis cannot distinguish this, because the atomic numbers of Cr and Mn are very close. In this case chemical methods are useful.

The acetonitrile solution containing KPF_6 was added with stirring to the acetonitrile solution of the title compound and the yellow precipitate obtained was then filtered out and washed three times with CH_3CN. The filter liquor was evaporated at room temperature and a few days later brown crystals were obtained. The data from the inductively coupled plasma atomic emission spectrum showed that the yellow precipitate contained the elements Cr and K and the brown crystals contained the elements Mn, Cr and P. These results with X-ray crystal structure analysis data indicated that the yellow precipitate is $KCrO_3Cl$, composed of the coordination anion CrO_3Cl^- and K^+ ion and the brown crystals were composed of PF_6^- anion and the large cation $[Cr_2MnO(PhCOO)_6Py_3]^+$.

Crystallographic studies

A deep black–brown single crystal (dimensions: $0.30 \times 0.50 \times 0.90$ mm^3) was mounted on a Rigaku AFC 5R diffractometer.

X-ray diffraction data were collected at 296 K with Mo-K_α radiation (0.71073 Å) and ω–2θ scan mode in the range $0 < 2\theta < 49.9°$. Of the 1881 independent reflections collected, 1119 reflections with $I > 3\sigma$ were used in structure calculation. All data were corrected for Lp factors and empirical absorption. The structure was solved by direct methods.

$[Cr_2MnO(PhCOO)_6Py_3][CrO_3Cl] \cdot 2/3Py$, M = 1326.69, hexagonal, space group $P6_3/m$, $a = b$ = 12.92(1), c = 21.35(2) Å, V = 3089(4) $Å^3$, Z = 2, D_x = 1.43 g cm^{-3}, $F(000)$ = 1356, μ = 8.02 cm^{-1}. The refinement converged at the final R = 0.050 and R_ω = 0.063. $R = \Sigma \| F_o | - | F_c \| / \Sigma | F_o |$; $R_\omega = [\Sigma\varepsilon(| F_o | / | F_c |)^2 / \Sigma\omega | F_o |^2]^{1/2}$; $\omega = 1/\sigma^2 F$.

RESULTS AND DISCUSSION

Structural description

The compound consists of a cation and an anion. The cation structure is shown in Fig. 1. Selected bond distances and angles of the compound are given in Table 1. In the cation unit three metal atoms form an equilateral triangle with μ_3-O located at the centre of this planar triangle and the three-fold axis is normal to the plane and through the μ_3-O atom. The bond distances of M(2)—(μ_3-O) are 1.903(2) Å, in agreement with the M—(μ_3-O) distance in $[M_3O(RCOO)_6]^+$, which lie within a fairly narrow range (1.90 ± 0.01 Å) [13]. The distance is longer than that of Cr—(μ_3-O) in the Cr_3O complex (1.89 Å) [5] and shorter than that of Mn—(μ_3-O) in the Mn_3O complex (1.936 Å) [16]. It is reasonable that the M(2)—(μ_3-O) distance in the title compound is the average value of two Cr—O bonds and one Mn—O bond. It means that two Cr^{III} ions and one Mn^{III} ion occupy the three M(2) ions sites, statistically. As compared with neutral M_3—(μ_3-O) type compounds, in which the formal oxidation numbers were II, III and III, the bond distances of M—(μ_3-O) in the title compound are shorter than the neutral one, because the formal oxidation number is higher in the latter (+3) than in the former (+2.7); both the ionic radius and static electronic contribute to a shorter bond distance of M—(μ_3-O). In the complex, the coordination geometry of each metal ion is a slightly distorted octahedral with five oxygen atoms from bridging benzonic acid groups and μ_3-O and a nitrogen atom from a terminal pyridine. The pyridine rings are almost perpendicular to the M_3O plane, probably due to greater steric interactions with the benzoate groups. The M(2)—N distance is 2.109(6) Å, which is shorter than that of the heterotrinuclear $Cr^{III}_2Ni^{II}O$ complex (2.137–2.149 Å) [11],

O(2)—M(2)—O(3)	169.9(2)	M(2)—O(1)—M(2)	119.9996(7)

M(1) = 1/2Cr+1/2Cl, M(2) = 2/3Cr+1/3Mn.

because the positive charge in M(2) is higher than in the latter. The M(2)—M(2) distances are all 3.296(3) Å, so there are no M—M bonds between the metal ions. As a comparison, selected data of $Cr_3O(CF_2HCOO)_6Py_3$ (**A**) [17], $[Cr_3O(CH_3COO)_6(H_2O)_3]^+$ (**B**) [17] and $[Cr_2MnO(PhCOO)_6Py_3]^+$ (**C**) are listed in Table 2.

As we can see in Table 2, there are some composition differences between compound **A** and cations **B** and **C**. The different bridging ligands CH_3COO, CHF_2COO and PhCOO only have small effects. The equatorial ligands and formal oxidation numbers of the metals are more important. H_2O is a weaker base than pyridine, so the Cr—(μ_3-O) bond is stronger in cation **B** than in cation **C**. The formal oxidation number is +3 in cations **B** and **C**, but +2.67 in compound **A**. This is the reason that the distance between atoms are shorter in cations **B** and **C** than in compound **A**.

The structure of the anion $[CrO_3Cl]^-$ is shown in Fig. 2. The existence of $[CrO_3Cl]^-$ was proved by the chemical method as above. In the unit cell the CrO_3Cl ion is disordered over a centre of inversion, such that an ethane-like structure is produced (Fig. 3), with the Cl and Cr atoms half occupying the M(1) site, Fig. 2. The M(1)—M(1A) length appears to be shorter [2.145(5) *vs* 2.16 Å] and the M—O distances longer [1.554(8) *vs* 1.53 Å] than in $KCrO_3Cl$ [16], probably as a consequence of the disorder. The geometry of the anion is a pyramidal with Cl and three oxygen atoms located on the each apexes.

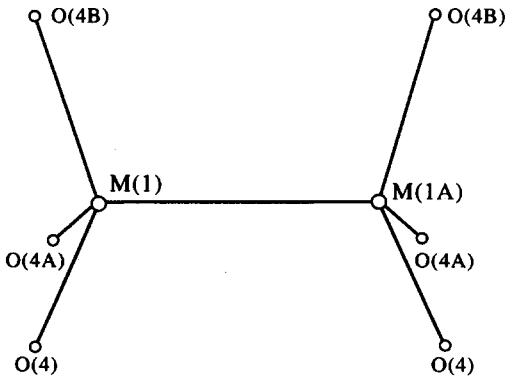

Fig. 2.

The solvent pyridine molecule is disordered about the three-fold axis parallel to the C direction and the C and N atoms are statistically distributed over all sites.

IR spectroscopy

Canon *et al.* [12] have convincingly assigned the IR spectra of a series of trinuclear Cr^{III} acetate and for-

mate complexes and identified the vibrational modes of the central Cr_3O model, and found that when one of the Cr^{III} ions is replaced with Fe^{III} the band at 640–660 cm^{-1} splits.

As shown in Table 3, there are similar IR spectra for complexes $[Cr_3O(PhCOO)_6Py_3]ClO_4$ (**1**) [17], $[Cr_3O(PhCOO)_6Py_3]Cl$ (**2**) [17] and $[Cr_2MnO(PhCOO)_6Py_3][CrO_3Cl]^-$ at 935 cm^{-1} appears.

Magnetic properties

Variable-temperature (1.5–300 K) magnetic susceptibility data were recorded for powder samples of the compound using a CF-1 ESM magnetic balance. The effective magnetic moment (μ_{eff}) per molecule decreased slowly down to 54 K (6.9μ_B), below which it decreased quite rapidly (5.6μ_B at 51 K to 2.9μ_B at 1.5 K).

As can be seen in Fig. 4, the variable-temperature magnetic susceptibility of the sample follows the Curie–Weiss law with a slight deviation at the lower temperature. The Weiss constant $\theta = -37$ K and the Curie constant $C = 5.90$. There is an antiferromagnetic exchange interaction in the compound.

The spin-Hamiltonian which describes the isotropic magnetic exchange interaction in a triangular trinuclear complex is given in eq. (1).

$$H = -2[J_{12}(s_1s_2)+J_{23}(s_2s_3)+J_{31}(s_3s_1)] \quad (1)$$

here, $J_{12} = J_{31} = J_1$, $J_{23} = J_2$.

With the assumption that the g values of Cr^{III} and Mn^{III} are equal to 2.00, HDVV model leads to the expression of the molar magnetic susceptibility as follows

Table 3. IR spectra (cm^{-1}) of selected complexes

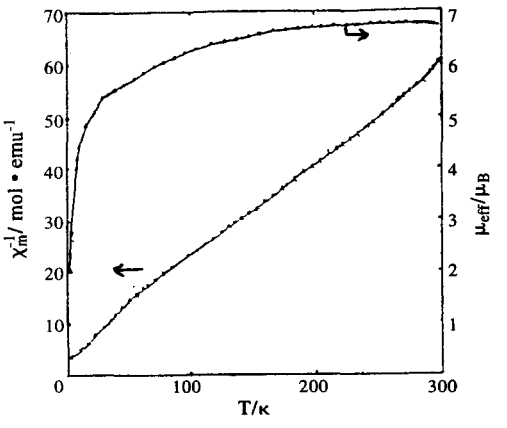

Fig. 4.

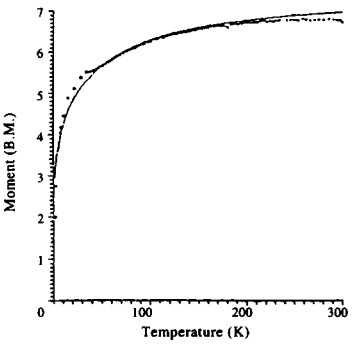

Fig. 5.

$$\chi_m = \frac{Ng^2\mu_B^2}{12kT}\cdot\frac{A}{B}. \quad (2)$$

Here, $A = 330\exp(18x+12y)+180\exp(8x+12y)+180\exp(14x+6y)+84\exp(12y)+84\exp(6x+6y)+84\exp(10x+2y)+30\exp(-6x+12y)+30\exp(6y)+30\exp(4x+2y)+30\exp(6x)+6\exp(-10x+12y)+6\exp(-4x+6y)+6\exp(2y)$; $B = 11\exp(18x+12y)+9\exp(14x+6y)+9\exp(8x+12y)+7\exp(12x)+7\exp(6x+6y)+7\exp(10x+2y)+5\exp(-6x+12y)+5\exp(6y)+5\exp(4x+2y)+5\exp(6x)+3\exp(-10x+12y)+3\exp(-4x+6y)+3\exp(2y)+\exp(-6x+6y)$; $x = J_1/kT$, $y = J_2/kT$.

The magnetic susceptibility data for the complex is fitted to eq. (2) with the fitting parameters $J_1 = -7.03$, $J_2 = -13.4$ cm^{-1} and Curie constant $C = 6.06$, the solid line in Fig. 5 represents this fitting.

It is indicated that there are weak antiferromagnetic interactions between three metal atoms, Cr, Cr and Mn, and the interaction of Cr—Cr is almost twice as large as that of Cr—Mn. According to the molecular structure, there are no M—M bonds between the metal ions and two possible superexchange pathways in the complex: the central O atom and the bridging benzoate groups. Vincent *et al.* [15] recently reported the oxo-centred trinuclear Mn^{III} complex, with J values of -10.2 cm^{-1} and the majority of this interaction is propagated by the central oxygen atom, not by the acetate bridges. It can be seen in Table 4 that the distance of M—(μ_3-O) is a very important factor.

The shorter the M^{III}—O distance, the larger is the J value. The short M^{III}—O distance could raise the energy of the dz^2 orbital directed along the M^{III}—O bond vector. In the Cr_2MnO complex the M^{III}—O bond length is an average value in crystallography, but they are different at the molecular level, so the J_1 and J_2 values are not equal.

(Received 6 October 1995; accepted 6 August 1996)

Abstract—A new mixed-valence heterotrinuclear complex [Mn^{III} Co^{III} $Mn^{II}O(PhCOO)_6Py_3$] was first synthesized by using NBu_4MnO_4 as the oxidizer. In the reaction, Co^{II} ions were oxidized to Co^{III}, while Mn^{VII} were reduced to Mn^{II} and Mn^{III}. The oxidation number of three metal ions were +3, +3 and +2, which was proved by the electrical conductivity. There are two types of trinuclear species in the single cell. One is valence delocalized in which the bond distance Co(2)—O(2) is 1.85(2) Å and the distance M—O is 1.933(9) Å, which is an average value of Mn^{II}—O and Mn^{III}—O; another is valence-localized in which the bond distance of Co^{III}—O is 1.84(1), Mn^{III}—O, 1.86(1), Mn^{II}—O, 1.99(1) Å. Variable temperature (1.5–300 K) magnetic susceptibility indicated that there is antiferromagnetic exchange interaction among the three metal ions.

Keywords: crystal structure; mixed-valence complex; heteronuclear complex; manganese–cobalt complex; magnetic properties; oxo-centred complex.

Trinuclear, oxo-centred carboxylate complexes of transition metals have been of interest for several years [1]. The oxo-centred [2] heterotrinuclear complexes have special interests, because the magnetic exchange interaction of different nuclei could be studied under almost same geometry, but little work has been done. Blake [3] previously reported magnetic and spectroscopic properties of some heterotrinuclear basic acetic acids of $Cr_2^{III}M^{II}$ and $Fe_2^{III}M^{II}$ (M = Mg, Fe, Co, Ni, Mn). A series of mixed-metal and mixed-valence compounds, $[Cr_2MnO(PhCOO)_6Py_3][CrO_3Cl]$ [4], $Cr_2^{III}Mn^{II}O(CH_3COO)_6Py_3$ and $Mn_2^{III}M^{II}O(CH_3COO)Py_3$ [5], had been reported recently. These compounds had the similar oxo-centred structure and weak antiferromagnetic interaction between the metal ions.

Using Bu_4NMnO_4 as an oxidizer, the heterotrinuclear mixed-valence complex [$Mn^{III}Mn^{II}Co^{III}O$] was synthesized and the molecular structure and variable-temperature susceptibility were determined.

EXPERIMENTAL

Preparation of materials

Benzoic acid, $Co(OAc)_2$, pyridine, absolute ethanol and CH_3CN were used as received. The elemental analyses for carbon, hydrogen and nitrogen were determined on a Perkin–Elmer 240C analyser. X-ray photoelectron spectra (XPS) was performed on a VG MK II spectrometer using Mg-K_α radiation and charge-transfer correction referred to the binding energy of C_{1s}. The variable-temperature (1.5–300 K) magnetic susceptibility measurement of the title

* Author to whom correspondence should be addressed.

complex was obtained on a CF-1 ESM magnetic balance at 1.2T magnetic field.

Preparation of NBu_4MnO_4. Followed reference [6]. $Mn_2Co(PhCOO)_6(Py)_3$. $Co(OAc)_2$ (2.88 g) and benzoic acid (15 g) dissolved in pyridine (40 cm^3) forming a violet–red solution, to which NBu_4MnO_4 (2.28 g) was slowly added with stirring. After reacting for 10 min, pyridine was evaporated under reduced pressure and a brown oily slurry was obtained. Then, 200 cm^3 of absolute alcohol was added with stirring and some precipitates were deposited, filtered and washed three times with a little absolute alcohol. The brown solid was obtained and redissolved in a minimum amount of acetonitrile, then filtered. The filtrate was evaporated at room temperature for a few days, then black crystals were obtained. Found: C, 59.6; H, 3.9; N, 4.0; Mn, 8.5; Co, 5.0. Calc. for $C_{57}H_{45}N_3O_{13}Mn_2Co$: C, 59.6; H, 4.0; N, 3.7: Mn, 9.6; Co, 5.1%.

Variable-temperature (1.5–300 K) magnetic susceptibility data have been recorded for the microcrystal sample of the title complex using a CF-1 ESM magnetic balance.

Determination of electrical conductivity

The title compound and Et_4NBr were dissolved in acetonitrile, which was treated with CaH_2, P_2O_5 and K_2CO_3 before use. The conductivity data were determined using a DDS-11A electrical conductivity instrument at 20.00 ± 0.02°C.

The molar conductivity of the title compound (in CH_3CN) is 3.15 $\omega^{-1}cm^{-2}mol$, which corresponds to non-electrolytic behaviour. This means that the valences of three metal ions were +3, +3 and +2.

X-ray crystallography

A black prism crystal ($0.5 \times 0.3 \times 0.3$ mm) was used for X-ray diffraction (see Table 1). Data were collected on a Rigaku AFC5R diffractometer at 296 K using graphite-monochromatic Mo-K_α (0.71073 Å) radiation and $\omega/2\theta$ scan mode. 3790 observed reflections with $I > 3\sigma(I)$ were used in structure calculation and all data were corrected for Lp factors and empirical absorption. The structure was solved by direct methods. Successive Fourier syntheses gave the coordinates of all the non-hydrogen atoms refined with anisotropic thermal parameters. All calculations were performed on a Micro-VAX II computer using TEXSAN programs. Atomic coordinates and thermal parameters, together with observed and calculated structure factors, have been deposited with the Editor, from whom copies are available on request.

RESULTS AND DISCUSSION

The acetate bridging $Mn_2^{III}Co^{II}O$ species had been prepared by Cannon [5] recently using oxygen as the oxidizer. The title compound $Mn^{III}Co^{III}Mn^{II}$ was synthesized by using Bu_4NMnO_4 as oxidizer. The Co^{II} ion was oxidized to Co^{III}, while Mn^{VII} ions were reduced to Mn^{II} and Mn^{III}. X-ray photoelectron spectra of the title complex have been determined and display two peaks at 781.7 and 642.4 eV. The former belongs to $Co2P_{3/2}$ and the latter belongs to $Mn2P_{3/2}$.

The molecular structure is shown in Fig. 1, and selected bond distances and angles are given in Table 2. Every metal atom has a slightly distorted octahedral coordination geometry with four oxygen atoms from bridging benzoate groups, the μ_3-oxygen atom and a nitrogen atom of terminal pyridine. The pyridine rings are essentially perpendicular to the trinuclear complex, probably as a result of increased steric interactions between the pyridine rings and the benzoate phenyl group. There are two kinds of Mn_2CoO species in the unit cell. One is valence localized, in which the distances of three metal atoms to μ-O atom are 1.84(1), 1.86(1) and 1.99(1) Å, respectively [Fig. 1(a)]. Considering the oxidation state of the metal atoms in the title compound and the bond distances of M—O in references [7]–[9], we could classify three bonds of M—O as follows: 1.84(1) Å belongs to the bond distance of Co^{III}—O, 1.86 Å to Mn^{III}—O and 1.99 Å to Mn^{II}—O. Another one is valence delocalized (Fig. 1(b)), in which the distance Co(2)—O(2) is 1.85(2) Å and the distance Mn(3)—O(2) [1.933(9) Å] is a statistical average value of Mn^{III}—O [1.86(1) Å] and Mn^{II}—O [1.99(1) Å]. This is disorder stack as shown below:

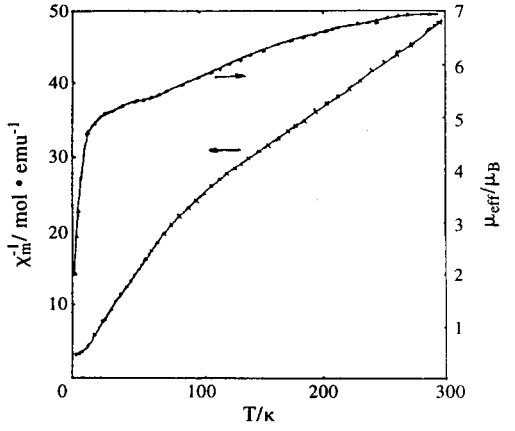

Fig. 2.

There are eight asymmetry units in a single cell and each unit contains 1.5 trinuclear complex units, $[Mn_2CoO(PhCOO)_6Py_3]$, of which the complete molecule has a bond delocalized structure [Fig. 1(b)] and the other 'half' which is part of a molecule sited on a two-fold axis has a bond localized structure [Fig. 1(a)].

Magnetic properties

As can be seen in Fig. 2, the effective magnetic moment (μ_{eff}) per molecule decreased 7.0μ_B at 300 K, 5.0μ_B at 80 K, 4.8μ_B at 17 K and 1.95μ_B at 1.5 K. This suggests that there is an antiferromagnetic exchange among the three metal atoms: Co^{III}, Mn^{III} and Mn^{II}.

(Received 12 July 1996; accepted 2 August 1996)

Abstract—A series of ternary mixed ligand 4-acyl pyrazolone lanthanide complexes: $Ln(L)_3 \cdot 2H_2O$ [where Ln = Tb^{3+} or Gd^{3+}, L = 1-phenyl-3-methyl-4-acetyl-pyrazolone-5 (PMAP), 1-phenyl-3-methyl-4-propionyl-5-pyrazolone (PMPP), 1-phenyl-3-methyl-4-isobutyryl-5-pyrazolone (PMIP), 1-phenyl-3-methyl-4-neovaleryl-pyrazolone-5 (PMNP) and 1-phenyl-3-methyl-4-benzoyl-pyrazolone-5 (PMBP)] were synthesized and characterized by FT-IR spectra, UV–vis spectra and DTA-TG analysis. Room-temperature phosphorescence was observed from the Gd^{3+} complexes by excitation of the sample with the fourth harmonic frequency of a Nd: YAG laser beam (λ = 266 nm) and the triplet energies of the pyrazolone ligands were evaluated. Both the fluorescence intensity and fluorescence lifetime of the Tb^{3+} complexes depend on the structure of the ligands and explanations are presented. The crystal structure $[Tb(PMPP)_3 \cdot 2H_2O] \cdot EtOH$ was determined by X-ray diffraction. The structure was refined to $R = 0.064$ ($R_w = 0.073$). The complex is mononuclear and the central terbium ion is coordinated by eight oxygen atoms to form a square-antiprism coordination polyhedron, six of which are from the three bidentate pyrazolone ligands and the other two are from the two coordination water molecules. Keywords: fluorescence; pyrazolone lanthanide; crystal structure; ligand; β-diketones.

β-Diketones have received extensive attention as important lanthanide extractants in solvent extraction. Among them, 1-phenyl-3-methyl-4-benzoyl-5-pyrazolone (HPMBP) was one of the most commonly used [1]. In recent years several other pyrazolones were synthesized, such as halogen substituted 4-acyl pyrazolones [2], bis-4-acyl pyrazolones [3] and these substituted pyrazolones have been found to be good chelating extractants in the separation of trivalent lanthanide ions [4]. Despite intense attempts, however, very few crystal structure of pyrazolone lanthanide extractants have been reported. Bombieri reported the crystal structure of tris(1-phenyl-3-phenyl-4-acetyl-5-pyrazolone)ytterbium dihydrate, $Yb(DPAP)_3 \cdot 2H_2O \cdot 3EtOH$ [5], while Huang *et al.* reported several trifluoro substituted 4-acyl pyrazolone lanthanide complexes [6]. The crystal structure of a lanthanide 4-acyl pyrazolone complex has not yet been reported. In this paper, we report the synthesis and crystal structure of tris(1-phenyl-3-methyl-4-propionyl-5-pyrazolone) terbium dihydrate, $[Tb(PMPP)_3 \cdot 2H_2O] \cdot EtOH$.

Some of the lanthanide β-diketonate complexes have interesting luminescence properties [7,8]. When irradiated with ultraviolet light, these lanthanide β-diketonate complexes exhibit narrow line emissions in the visible region characteristic of the metal ion. This phenomenon enables them to have many important

* Author to whom correspondence should be addressed.

practical applications, such as their use as fluorescence probes in biochemistry [9], and in the determination of trace amounts of trivalent lanthanide ions in solution [10]. Fluorescence methods are also used to obtain information about the structure of lanthanide complexes, their formation constants, symmetry, etc. [11]. Recently, they have been used in electroluminescent devices [12] and also as thresholdless microcavity laser materials [13]. Although there have been studies on the fluorescence properties of lanthanide β-diketonate complexes, there are still very few studies on 4-acyl pyrazolone lanthanide complexes of lanthanides [14]. The most commonly used pyrazolone (PMBP) complex with Tb^{3+} or Eu^{3+} was found to exhibit only very weak fluorescence and so it was supposed that the triplet energy of PMBP is too low to transfer energy efficiently to the central ion to obtain lanthanide fluorescence [14b]. We believe that the substitution of the benzoyl group with acyl can minimize the conjugation in the ligand, which may lead to a higher triplet energy such that a much higher fluorescence efficiency may be achieved. Room-temperature phosphorescence measurements on samples of Gd^{3+} with 4-acyl pyrazolone ligands confirmed our suggestion and as expected, strong green fluorescence from the 4-acyl pyrazolone terbium complexes was observed.

EXPERIMENTAL

Material and synthesis

The four 4-acyl pyrazolone ligands: 1-phenyl-3-methyl-4-acetyl-pyrazolone-5 (HPMAP), 1-phenyl-3-methyl-4-propionyl-pyrazolone-5 (HPMPP), 1-phenyl-3-methyl-4-iso-butyryl-pyrazolone-5 (HPMIP) and 1-phenyl-3-methyl-4-neovaleryl-pyrazolone-5 (HPMNP) were synthesized according to the procedure of Jensen [1]. 1-Phenyl-3-methyl-4-benzoyl-pyrazolone-5 (HPMBP) was analytical grade product purchased from the Beijing Chemical Factory (Beijing, China). Tb_4O_7 (>99.9%) and Gd_2O_3 (>99.9%) were purchased from Yuelong Chemical Factory (Shanghai, P.R. China). Aqueous solutions of $Tb(ClO_4)_3$ and $Gd(ClO_4)_3$ were prepared by dissolving Tb_4O_7 or Gd_2O_3 in perchloric acid to obtain a concentration of 0.40 M, (pH = 4.0). Other reagents were all analytical grade chemicals from the Beijing Chemical Factory.

The lanthanide complexes $Ln(L)_3 \cdot 2H_2O$ (where Ln = Tb, Gd and L = 4-acyl pyrazolones) were all synthesized by a similar method. A typical example for $Tb(PMAP)_3 \cdot 2H_2O$ is given as follows: A solution of HPMAP (3.00 mmol) in ethanol (30 cm^3) was neutralized by NaOH (3.00 mmol) aqueous solution under heating and stirring, then an aqueous solution of $Tb(ClO_4)_3$ (1.00 mmol) was added dropwise and refluxed for 20 min. When the resulting solution was cooled to room temperature, white solids were formed and filtered out. The crude product was recrystallized from mixed solvents of ethanol and water to obtain the sample as small crystals, then it was filtered and dried at 80°C for 4 h. Found: C, 51.4; H, 4.6; N, 9.8; Tb, 19.0. Calc. for $Tb(PMAP)_3 \cdot 2H_2O$ ($C_{36}H_{37}N_6O_8Tb$, denoted as compound **A**): C, 51.2; H, 4.8; N, 10.0; Tb, 18.8%. Found **C**: 53.0; H, 4.8; N, 9.5; Tb, 18.2. Calc. for $Tb(PMPP)_3 \cdot 2H_2O$ ($C_{39}H_{43}N_6O_8Tb$, denoted as compound **B**): C, 52.9; H, 5.2; N, 9.5; Tb, 17.9%. Found: C, 54.5; H, 5.2; N, 9.0; Tb, 17.3. Calc. for $Tb(PMIP)_3 \cdot 2H_2O$ ($C_{42}H_{49}N_6O_8$, denoted as compound **C**). C, 54.4; H, 5.65; N, 9.16; Tb, 17.19. Found: C, 56.0; H, 5.7; N, 8.6; Tb, 16.35. Calc. for $Tb(PMNP)_3 \cdot 2H_2O$ ($C_{45}H_{55}N_6O_8Tb$, denoted as compound **D**): C, 55.7; H, 6.0; N, 8.7; Tb, 16.4.). Found: C, 59.5; H, 4.1; N, 7.9; Tb, 15.6. Calc. for $Tb(PMBP)_3 \cdot 2H_2O$ ($C_5H_{43}N_6O_8Tb$, denoted as compound **E**): C, 59.5; H, 4.5; N, 8.2; Tb, 15.4.

Single crystals of $[Tb(PMPP)_3 \cdot 2H_2O] \cdot EtOH$ were obtained by dissolving the solid powder of $Tb(PMPP)_3 \cdot 2H_2O$ in a mixture of ethanol and water to obtain a clear solution. Then the solution was allowed to evaporate slowly and after 1 week, colorless single crystals suitable for X-ray diffraction studies were obtained. The crystals are stable and no changes were observed after storing under ambient atmosphere for 3 days.

Instruments and measurements

IR spectra of the ligands and complexes were recorded on a Magna 750 FT-IR spectrophotometer, using the KBr pellets in the range of 4000–400 cm^{-1}. Thermoanalysis measurements were carried out on a LCT-1 type DTA and TG analyser system under an air atmosphere. α-Al_2O_3 was used as the reference and the temperature was raised at a rate of 10°C min^{-1}. The UV–vis spectra were recorded on a Shimadazu UV-3100 spectrophotometer with a slit width of 2 nm. Fluorescence excitation and emission spectra were recorded on a Hitachi 850 fluorescence spectrophotometer, using a 430 nm excitation cut-off filter. Excitation and emission bandwidths of 5 nm were employed and the fluorescence spectra were corrected for nonlinear instrumental response and blank solvents [15].

The fluorescence lifetime determination was performed on a SLM 48000 Multi-Frequency Phase Fluorometer, using the frequency-domain method with glycogen as the reference. A 540 nm interference filter was placed in the emission path to eliminate interference from solvent and stray light. The modulated frequency used ranges from 200 to 5000 Hz. At each frequency both the phase shift and the relative modulation values were measured six times and the average values were used to evaluate the fluorescence lifetime in order to minimize the experimental error. A total of 10 different frequencies were used and the final fluorescence lifetime was determined by least-squares analysis of the 10 data that lead to the minimum value of R [16,17].

$$R = (1/2)\{\Sigma((\phi_\omega - \phi_\omega^c)/\delta_\phi)^2 + \Sigma((M_\omega - M_\omega^c)/\delta_M{}^2\}, \quad (1)$$

where ϕ_ω and ϕ_ω^c are the measured and the calculated phase shift, M_ω and ξM_ω^c are the measured and the calculated modification, and δ_ϕ and δ_M are the average phase error (0.5°) and modulation error (0.005).

The room-temperature phosphorescence of the $Gd(L)_3 \cdot 2H_2O$ samples, where L = 4 acyl pyrazolones, was measured by excitation of the samples with the fourth harmonic of the pulsed GCR-4 Nd : YAG laser (λ = 266 nm) with 30 Hz repetition rate and 6 ns pulse width. The laser irradiated on the powder samples with energy of 10 μJ pulse^{-1} at an area of 0.15 cm^2. The emissions from the samples were collected by a set of focus lenses, dispersed by the 500 nm focal length monochromator with a 1200 grooves mm^{-1} grating and detected by the R955 photomultiplier tube (Hamamatsu). To reduce the laser scattering light, a BG40 filter (Schott) was placed in front of the slit of the monochromator. The output of the photomultiplier was sent to the 4100 boxcar system (EG & G) for averaging, then transferred to the 286 personal computer *via* GPIB bus. The HP54510A digital oscilloscope was employed and the averaged real-time signal was transferred to a 386 SX/25 computer *via* GPIB bus in lifetime measurement [18].

X-ray data collection, structure solution and refinement

The crystal and refinement data of $[Tb(PMPP)_3 \cdot 2H_2O] \cdot C_2H_5OH$ are summarized in Table 1. A single crystal having approximate dimensions 0.2 × 0.2 × 0.2 mm^3 was mounted on an Enraf–Nonius CAD4 diffractometer. Data were collected in the ω–2θ scan mode at room temperature (26 ± 1°C) in the range $2 \leqslant \theta \leqslant 23°$. All the intensities were corrected for Lorentz and polarization effects and an absorption correction was also used. The crystal structure was solved by direct methods (MULTAN 82), the coordinates of the terbium atom were determined from an *E*-map and the coordinates of other nonhydrogen atoms were defined by successive Fourier synthesis. The coordinates of all nonhydrogen atoms and their anisotropic thermal parameters were refined by full-matrix least-squares and the structure converged to yield R and R_W factors of 0.064 and 0.073, respectively. All the calculations were carried out on a PDP 11/44 computer using a SDS-PLUS computer program package [19,20].

Maximum residual hole, $\Delta\sigma_{min}$ (e Å^{-3})	−1.12

RESULTS AND DISCUSSION

Characterization of the complexes

All free pyrazolone ligands exhibit two types of strong C=O bond stretching vibrations in their FT-IR spectra. The positions of these two peaks differ slightly from ligand to ligand as listed in Table 2. The higher-frequency peak shifts to lower wavenumber and *vice versa* upon complexation. The stretching frequency difference ($\Delta\nu$) between the two carbonyl bands is smaller in the metal complex than that in the corresponding free ligands. The former (higher energy) peak is assigned to $\nu_{C=O}$ vibration at the 5-position of the pyrazolone ring. The coordination of the terbium ion to the oxygen atom of this carbonyl group weakens the C=O bond, resulting in a red shift. The latter (low-energy) peak is assigned to the vibration of the acyl carbonyl in the 4-position of the pyrazolone ring, which has some single bond character due to keto–enol tautomerization of the β-diketone group. The acyl carbonyl group is strengthened by equalization of single-double bond length upon complexation, leading to an increase in vibrational frequency. This assignment is supported by the crystal structure analysis of $Tb(PMPP)_3 \cdot 2H_2O$, in which the average bond length of the 5-pyrazolone carbonyls (1.276 Å) is slightly longer than that of the 4-acyl carbonyls (1.230 Å). The C=O band at the 5-position is weaker than in the 4-position, in agreement with our assignment. The process can be diagrammatically described as follows [21]:

(Enol) (Keto) (Complex)

The five ligands in ethanol solution all exhibit two broad strong absorption bands around 230–240 and 260–280 nm, with absorption maxima differing slightly from ligand to ligand in the UV–vis spectra (Table 2). The two bands are assigned to the $\pi \rightarrow \pi^*$ electronic transitions of the conjugated carbonyl and the phenyl ring group [21]. The absorption maximum of the first band in HPMBP is red-shifted by *ca* 6 nm compared with other 4-acyl pyrazolones. The second band is further red-shifted by *ca* 15 nm (except for HPMNP, whose position is also the same as HPMBP). The difference may be caused by the electron-donating ability of the alkyl groups and a lowering of conjugation caused by substitution of the benzoyl group with acyl groups. The complexes also exhibit two absorption bands in ethanol solution. It is clear that these two absorption bands are contributed by the ligands. In addition, the molar absorption coefficiencies of the complexes are *ca* three times larger compared with those of the free ligands, but this is expected since one mole of the complex contains three moles of the ligands.

The DTA-TG curves of compounds **B** and **D** are similar. Their TG curves both exhibit a weight loss around 120°C and the corresponding DTA curves exhibit an endothermic peak. This process corresponds to the complexes losing two water molecules. The weight loss percentages (experimental/theoretical) are 6.7/4.1 for **B** and 6.0/3.7 for **D**. An endothermic peak at 191°C for **B** and 220°C for **D** appears in their DTA curves, however, no weight loss appears in the corresponding TG curves. The peaks may be assigned to the melting point of the dehydrated complex. The dehydrated complexes undergo a series of complex oxidation and decomposition reactions and finally form Tb_4O_7 in the 310–550°C region. The DTA curves exhibit a small and large exothermic band around 330 and 500°C, while the TG curves exhibit a series of weight loss. There are no changes both in the TG and DTA curves when the temperature is higher than 550°C. The overall weight loss percentages are 80.0/78.8% for **B** and 75.7/80.6% for **D**, respectively. The experimental values are in agreement with the theoretical ones within the experimental error.

Room-temperature fluorescence and phosphorescence

The shapes of the fluorescence excitation spectra of the five terbium complexes are similar. They all exhibit a broad excitation band from 250 to 370 nm with maxima varying from sample to sample for powdered samples (Table 3). The excitation spectra of the complexes in dimethylformamide (DMF) solution, however, are quite different from those of the powdered samples. In DMF solution, they all exhibit a weak band around 260 nm and a strong band around 340 nm, with the intensity of the former band being only *ca* 1/15 of the latter. The excitation peak intensities for **A, B** or **C** are much stronger than that for **D** or **E**. A typical fluorescence excitation spectra for compound **A** in these two states are shown in Fig. 1. We

$Tb(PMNP)_3 \cdot 2H_2O$(powder)	266, 334	547.2	109	130
$Tb(PMNP)_3 \cdot 2H_2O$(in DMF)	266, 332	546.2	0.21	[a]
$Tb(PMBP)_3 \cdot 2H_2O$(powder)	264, 332	547.8	0.66	0.32
$Tb(PMBP)_3 \cdot 2H_2O$(in DMF)	304	558.9	0.015	[a]

[a] The fluorescence lifetime of $Tb(PPMNP)_3 \cdot 2H_2O$ and $Tb(PMBP)_3 \cdot 2H_2O$ in DMF cannot be measured correctly due to their weak fluorescence intensity. The concentration of the DMF solutions were all 1.00×10^3 mol l^{-1}.

consider the difference in excitation as the result of the difference environments between the two states. In solution the complex molecules are isolated, so the effects between the complex molecules are weak, but they may have strong interactions with the solvent molecules. In the solid state the molecules are closely packed so that they have a much stronger interaction [22].

The fluorescence emission spectra of the complexes are very similar and are all characteristic of Tb^{3+} ion emission spectra. They all exhibit five emission bands at 496, 546, 587, 624 and 655 nm, corresponding to the $^5D_0 \rightarrow {}^7F_j (j = 6, 5, 4, 3, 2)$ electronic transitions. Among these transitions, that which is located around 546 nm ($^5D_0 \rightarrow {}^7F_5$) is the strongest, in accordance with the spectra of other Tb^{III} complexes. Although the shapes of the emission spectra are similar, however, the fluorescence intensities are quite difference, as listed in Table 3. The emission intensity for compounds **A, B** or **C** are three orders of magnitude stronger than that for compound **E,** either in the solid state or in DMF solution. We believe that this is due to the different triplet energy level of the ligands. The PMBP ligand has a relatively low triplet energy level and thus it cannot efficiently transfer UV excitation energy to the lowest excited state of the terbium ion ($^5D_4$) to obtain the characteristic emission of Tb^{3+} [14]. The substitution of the benzoyl group with an acyl group may decrease the electron conjugate system to yield a ligand with a higher triplet energy level, so that ligand-to-metal energy transfer may proceed much more easily.

The above expectation was confirmed by the room-temperature phosphorescence spectra of the

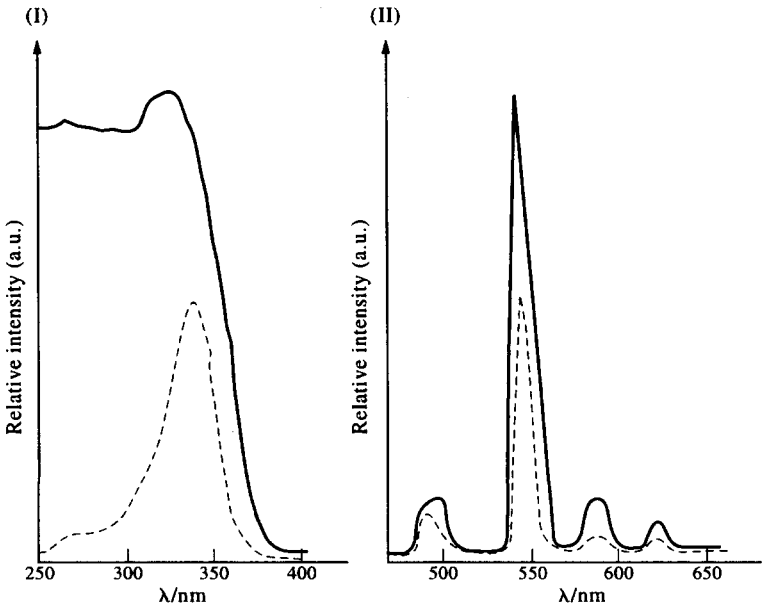

Fig. 1. The fluorescence excitation (**I**) and emission spectra (**II**) of $Tb(PMAP)_3 \cdot 2H_2O$ in the solid powderous state (solid line) and in DMF solution (broken line).

$Gd(L)_3 \cdot 2H_2O$ samples. It is well known that intramolecular energy transfer from the triplet state to the resonance level of a lanthanide ion is spin-forbidden. The energy is transferred by resonant exchange and the role of the triplet state is very important. Although there have been many reports on the phosphorescence of lanthanide complexes at low temperature (77K) [23], at room temperature phosphorescence of a lanthanide complex is very rare. The phosphorescence spectra of the $Gd(L)_3 \cdot 2H_2O$ complexes excited by a 266 nm laser beam are shown in Fig. 2. The phosphorescence spectra were obtained by setting the delay at 300 ns with a gate width of 1000 ns, except for $Gd(PMPB)_3 \cdot 2H_2O$, which was obtained by setting the gate delay at 300 ns with a gate width of 200 ns. All five spectra are very broad and structureless. The shapes of the former three ligands (PMAP, PMPP and PMIP) are similar both in intensity and peak position. However, when the methyl group in PMAP is substituted by a tert-butyl group (PMNP) or a phenyl group (PMBP), the spectra are red-shifted significantly. This indicates that the latter two ligands have much lower triplet energies. The triplet energies of the five ligands are estimated to be 20,580 cm^{-1} for PMAP, 20,750 cm^{-1} for PMPP, 20,370 cm^{-} for PMIP, 19,340 cm^{-1} for PMNP and 18,180 cm^{-1} for PMBP by choosing the positions of the emission maxima as the triplet energy level. In good agreement with expectations, the substitution of the benzoyl group with acyl groups increases the triplet energy in the pyrazolone ligands, which then strongly affects the fluorescence properties of the complexes. It is well known that the $^5D_4$ excited state of Tb^{3+} is *ca* 20,500 cm^{-1} [7]. The triplet energies of PMAP, PMPP and PMIP are slightly higher or almost the same as the $^5D_4$ excited state of Tb^{3+}, thereby increasing the efficiency of energy transfer and yielding strong Tb^{3+} ion fluorescence. However, the triplet energies of PMNP and PMBP are significantly lower than the $^5D_4$ excited state, thus the energy transfer cannot proceed smoothly (because of the width of the band, the phosphorescence spectra of PMNP and PMBP have some overlap with the $^5D_4$ excited state of Tb^{3+}). This leads to a much weaker fluorescence intensity, in good agreement with the fluorescence data.

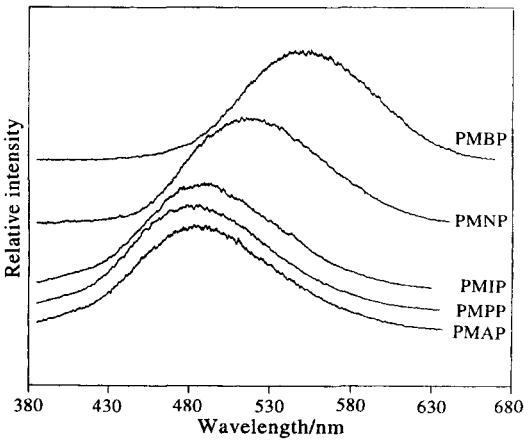

Fig. 2. Room-temperature phosphorescence spectra of $Gd(L)_3 \cdot 2H_2O$ excited by a 266 nm laser beam. L = PMAP, PMPP, PMIP, PMNP, PMBP.

Due to the time lag between absorption and emission, the emission is delayed to the modulated excitation. The fluorescence lifetime could be evaluated by measuring the phase shift and the relative modulation of the samples at different modulated excitation frequency. The basic equations in the frequency-domain method to determine the fluorescence lifetime are as follows [16,17]:

$$\tau_\phi = \tan\phi/\omega, \tag{2}$$

where ϕ is the phase shift caused by a sample of lifetime τ_ϕ and ω is the circular frequency of excitation (equals 2π times the excitation frequency in Hz)

$$\tau_M = (1/\omega)([1/D^2]-1)^{0.5}, \tag{3}$$

where D is the ratio of the relative modulation of the fluorescent sample and the glycogen reference solution.

By measuring the phase shift and the relative modulation of the samples at different frequency and using the methods described above, least-squares analysis of the 10 sets of data showed that the fluorescence lifetimes of the complexes are quite different at different states, as given in Table 3. All the samples exhibit only one fluorescent component. The lifetimes of **D** and **E** cannot be determined exactly due to their weaker fluorescence intensity. In the solid powdered states **A, B** and **C** have almost the same lifetime of *ca* 200 μs, much longer than for **D** or **E**. It is noteworthy that the lifetimes of **A, B** and **C** in DMF solution are much longer than those of the solid powders. This may be due to the strong coordination effect of the DMF molecules, which can substantially replace the two coordinated water [24]. The replacement can avoid the high-frequency O—H bond vibration and thus greatly decrease the energy loss through the coordination water to obtain a much longer fluorescence lifetime. All these emphasize that the triplet energy of the ligand is the key factor in determining the fluorescence intensity and lifetime of the complex, but the coordination environment also plays an important role.

Description of the structure of $[Tb(PMPP)_3 \cdot 2H_2O] \cdot EtOH$

Selected bond lengths and bond angles for $Tb(PMPP)_3 \cdot 2H_2O$ are listed in Table 4. The molecular structure is shown in Fig. 3. The complex is mononuclear, as expected. The central terbium ion is coordinated with eight oxygen atoms, six of which are from the three bidentate PMPP ligands and the other two are from the two coordinated water molecules. The eight oxygen atoms form a square-antiprism coordination

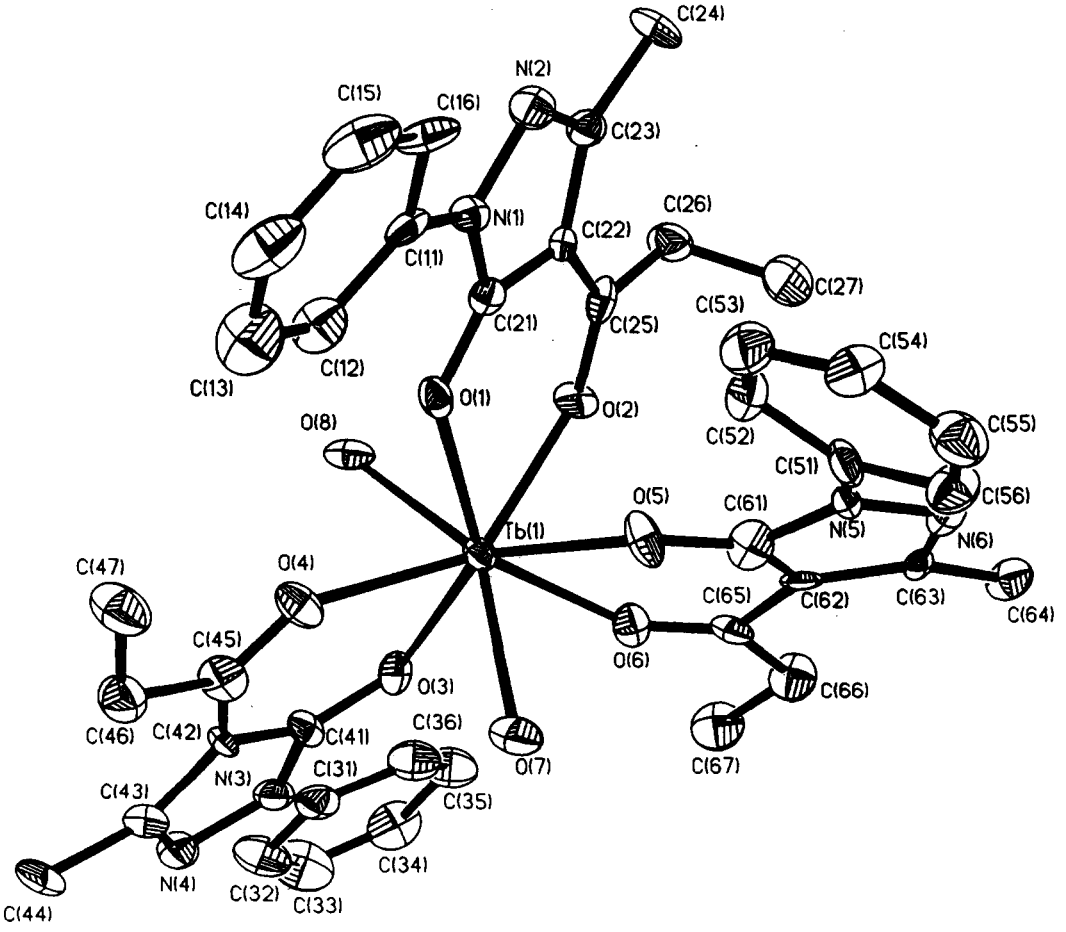

Fig. 3. The molecular structure of $Tb(PMPP)_3 \cdot 2H_2O$.

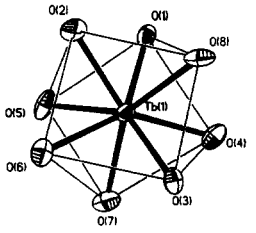

Fig. 4. The coordination polyhedron around the central terbium atom.

polyhedron around the central terbium ion (Fig. 4). The O(2), O(8), O(3) and O(4) oxygen atoms form the upper plane and the O(1), O(4), O(7) and O(5) atoms form the bottom plane. The distances of the oxygen atoms from the planes are less than 0.13 (10) Å and the dihedral angle between the two planes is 2.86(9)°, reflecting the fact that the deviation from the ideal square-antiprism coordination polyhedron is very small. The average bond length between the terbium ion and the pyrazolone oxygen atom is 2.338 Å, which is slightly shorter than that between the terbium and water oxygen atom (2.450 Å). This may be the result of the negative charge of the pyrazolone oxygen, which could be more strongly coordinated to the terbium ion due to electrostatic effects. The PMPP chelating mode is rather asymmetric, the terbium-to-carbonyl-oxygen distances being systematically longer on the side adjacent to the ethyl group (2.360 Å) than those from the pyrazolone ring (2.316 Å). This asymmetric chelation is similar to those found in the structures of lanthanide β-diketonate complexes, such as $Yb(acac)_3 \cdot H_2O$ [25], $Yb(DPAP)_3 \cdot 2H_2O$ [5]. The close proximity of the ethyl group to a coordinated oxygen atom could be consistent with the observed lengthening if electronic factors cannot in principle be ruled out. The PMPP ligands coordinate to the terbium ion in the enol form to form stable six-membered rings and the sum of the internal angles of the six-membered ring for the three ligands are 716.5, 717.6 and 718.8°, respectively. These angles are very close to 720°, suggesting that the six-membered rings are almost planar. The average C=C bond distance of the enol anion in the complex is 1.385 Å, a value which falls between the typical C=C double bond distance (1.33 Å) and C—C single bond distance (1.54 Å), reflecting a certain amount of electron delocalization upon complexation. All of the five-membered pyrazolone rings and the phenyl rings are planar and the dihedral angles between the pyrazolone ring and the phenyl ring are quite different in the three ligands, ranging from 9.28 to 145.06°.

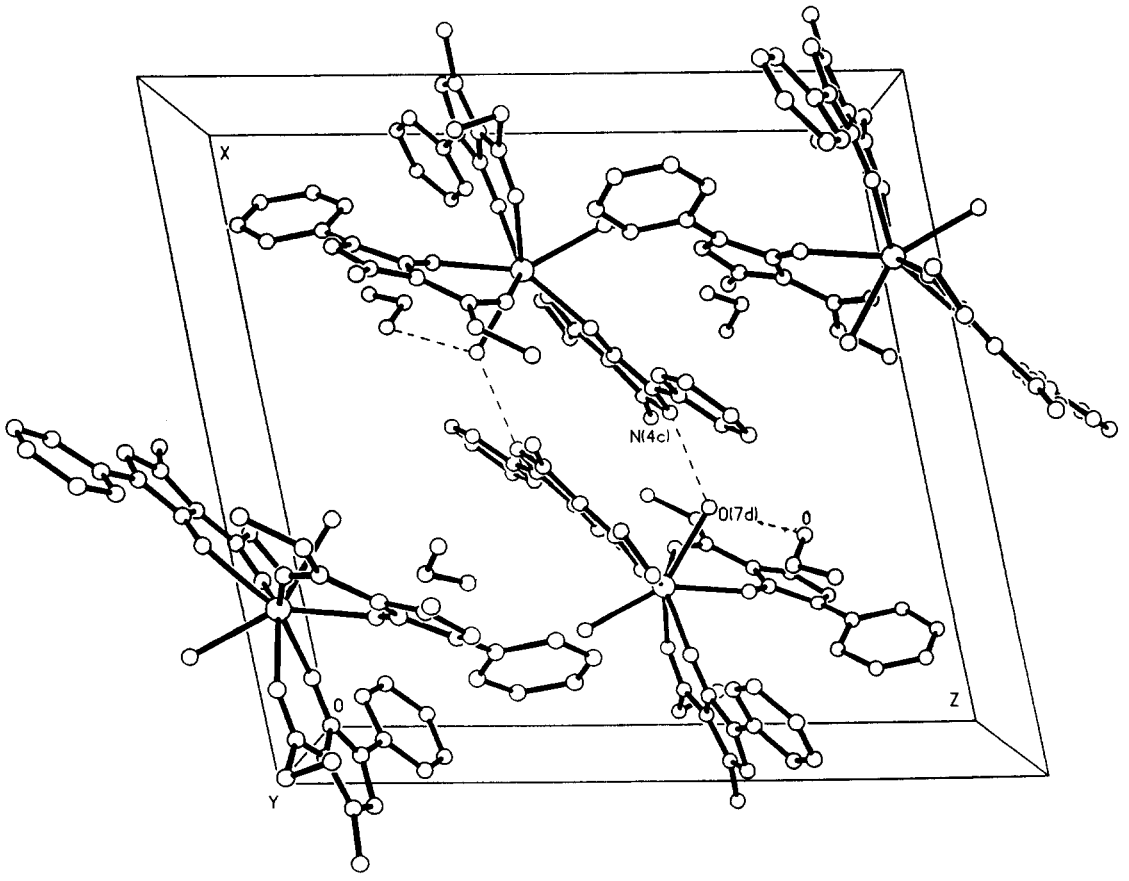

Fig. 5. The molecular packing diagram in the unit cell.

The molecular packing diagram of the unit cell is shown in Fig. 5. There are no disordered ethanol solvent molecules in the crystal, even though the ethanol oxygen atoms do not coordinate to the central terbium atom. This is different compared with the structure of $Yb(DPAP)_3 \cdot 2H_2O \cdot 3EtOH$, in which there are some disordered ethanol molecules in the unit cell, in agreement with the observation that the crystal does not lose solvent under ambient atmosphere. The distance between the coordinated water oxygen O(7d) and the ethanol oxygen is 2.884 Å and that between O(7d) and the pyrazolone nitrogen N(4) is 2.820 Å, indicating that the ethanol is connected to the complex molecule *via* hydrogen bonding [26]. The angles of N(4c)—O(7d)—O, N(4c)—O(7d)—Tb and Tb—O(7d)—O are 119.0, 129.0 and 108.0°, respectively. The crystal contains mainly isolated complex molecules, except for hydrogen bonding.

Supplementary materials. Tables of the atomic coordinates, equivalent isotropic and isotropic displacement coefficients of non hydrogen atoms, the bond distances and bond angles of the complex, the observed and calculated structure factors and the table of least-square planes and the dihedral angles between the planes are all submitted as supplementary materials.

Hydrotris(pyrazolyl)borate molybdenum chemistry: spin triplet 16-electron carbonyl derivatives of molybdenum(II), and the X-ray structure of the Mo(V) oxo compound $\{HB(3,5\text{-}Me_2C_3N_2H)_3\}MoOI_2$

Akila A. Saleh,‡ Brett Pleune, James C. Fettinger and Rinaldo Poli†

(Received 23 May 1996; accepted 31 July 1996)

Abstract—The hydrotris(3,5-dimethylpyrazolyl)borate complexes $Tp^*Mo(CO)_2X$ (X = Cl, I) are rare examples of 16-electron carbonyl derivatives with a spin triplet ground state, which exhibit relatively sharp contact-shifted ^1H NMR spectra. Oxidation of $Tp^*MoI(CO)_2$ led to the isolation and crystallographic characterization of Tp^*MoOI_2. Copyright © 1997 Elsevier Science Ltd

Keywords: molybdenum; hydrotris(pyrazolyl)borate; paramagnetic organometallic compounds.

The hydrotris(pyrazolyl)borate (Tp) ligand provides a structurally rigid and chemically inert capping ligand, which in many respects resembles (but in many other aspects it differs from) the ubiquitous cyclopentadienyl ring. We were interested in extending some of the chemistry we have recently explored for intermediate oxidation state cyclopentadienylmolybdenum compounds to the Tp ligand system. Although Tp systems of Mo have been studied extensively in low-oxidation states [1–10], much less work has been carried out in high oxidation states [11–13] and the only reported compound of Mo^{III} appears to be a salt of $[Tp^*MoCl_3]^-$[Tp* = hydrotris(3,5-dimethylpyrazolyl)borate] [14].

We have focused our attention on the sterically more demanding Tp*. In an attempt to access higher-valent Tp*Mo halide derivatives by oxidative decarbonylation of lower-valent derivatives, a technique which successfully provides an entry into higher-valent CpMo halides ($Cp = \eta^5-C_5H_5$)[15], we have investigated the reaction of excess halogen with $[Tp^*Mo(CO)_3]^-$. During the course of this study we have been able to isolate and fully characterize the product of partial oxidation, $[Tp^*MoX(CO)_2]$ (X = Cl, I). Such a compound (for X = I) was first mentioned by Templeton, but neither it nor the corresponding tricarbonyl derivative were isolated nor spectroscopically characterized other than by *in situ* IR spectroscopy [4]. More recently, the compound $Tp^*MoI(CO)_2$ has been isolated from the reaction between $[MoI_2(CO)_3(MeCN)_2]$ and KTp*, and has been described as a diamagnetic compound, showing well-defined ^1H NMR spectroscopic properties [16]. The latter publication prompted us to submit the results of our own investigations, since they substantially differ from those therein reported. We also describe here the X-ray structure of Tp^*MoI_2O, a product of further aerobic oxidation of $Tp^*MoI(CO)_2$.

EXPERIMENTAL

General data

All operations were carried out under dinitrogen with standard Schlenk-line techniques. Solvents were distilled directly from the drying agent (toluene and heptane from Na, THF from Na/K/benzophenone,

† Author to whom correspondence should be addressed.

CH_2Cl_2 from P_4O_{10}) under argon prior to use. FT-IR spectra were recorded with KBr cells on a Perkin–Elmer 1800 spectrophotometer. ^1H NMR spectra were recorded on Bruker WP200 and AF200 spectrometers; the peak positions are reported with positive shifts downfield of TMS as calculated from the residual solvent peaks. The magnetic susceptibility measurements were carried out with a Johnson Matthey magnetic balance, which operates by a modified Gouy method whereupon the effect of the immersion of a sample in the magnetic field gradient is measured by a change of the magnet weight rather than by a change of the sample weight. The magnetic moments were calculated by the formula $\mu_b = 2.828 \cdot (\chi_M T)^{-1}$, the molar susceptibility χ_m being corrected by the diamagnetism of the ligands by using Pascal's constants. The elemental analyses were carried out by M-H-W Laboratories, Phoenix, AZ. Compounds KTp* [17] and $PhICl_2$ [18,19] were prepared as previously described. $Mo(CO)_6$ (Aldrich) was used without any further purification.

Preparation of Tp*MoI(CO)$_2$

A solution of $[Tp^*Mo(CO)_3]^-$ was prepared *in situ* by refluxing $Mo(CO)_6$ (2.63 g, 10.0 mmol) and KTp* (3.36 g, 10.0 mmol) in THF (85 cm^3). To this solution I_2 (2.54 g, 10.0 mmol) was added. Immediately after the I_2 addition, the IR spectrum of the reaction mixture exhibited CO stretching vibrations at 2025 (s), 1998 (m), 1937 (s) and 1922 (s) cm^{-1}. After stirring overnight at room temperature, the absorptions at 2025 and 1937 cm^{-1} had disappeared, while those at 1937 and 1922 cm^{-1} had grown in intensity. The mixture was concentrated to *ca* 20 cm^3 and *n*-heptane (50 cm^3) was added. The red–brown precipitate was filtered off, washed with heptane and dried *in vacuo*. Yield: 4.26 g (74%). Found: C, 35.2; H, 4.0; N, 14.5. Calc. for $C_{17}H_{22}BIMoN_6O_2$: C, 35.4; H, 3.8; N, 14.6% IR (THF, cm^{-1}): 1999 s, 1920 s. ^1H NMR ($CDCl_3$, δ, 298 K): 87.8 (s, CH_3, 3H), 70.5 (s, CH_3, 3H), 47.2 (s, CH_3, 6H), 34.8 (s, CH_3, 6H), 8.6 (s, CH, 2H), −2.3 (br, BH, 1H), −7.2 (s, CH, 1H). $\mu_{eff} = 3.00$ μ_B.

Preparation of Tp*MoCl(CO)$_2$

By a procedure analogous to that reported above, a solution of KTp*Mo(CO)$_3$ (2.83 mmol) was prepared from $Mo(CO)_6$ and KTp* in THF (50 cm^3). To this solution $PhICl_2$ (0.779 g, 2.83 mmol) was added. Immediately after the addition of $PhICl_2$, the IR spectrum of the reaction mixture exhibited CO stretching vibrations at 2007 (s) and 1923 (s) cm^{-1}. After stirring overnight at room temperature, the IR spectrum had not changed. The mixture was concentrated to *ca* 10 cm^3 and *n*-heptane (30 cm^3) was added. The orange precipitate was filtered off, washed with heptane and dried *in vacuo*. Yield: 0.869 g (63%). IR (THF, cm^{-1}): 2007 s, 1923 s. ^1H NMR ($CDCl_3$, δ, 298 K): 96.9 (s, CH_3, 3H), 71.5 (s, CH_3, 3H), 41.9 (s, CH_3, 6H), 31.7 (s, CH_3, 6H). $\mu_{eff} = 2.81$ μB.

Reaction of Tp*MoI(CO)$_2$ *with* I_2

Formation of Tp*MoI$_2$O. Tp*MoI(CO)$_2$ (0.542 g, 0.941 mmol) and I_2 (0.239 g, 9.42 mmol) were dissolved in toluene (30 cm^3). The mixture was stirred at room temperature overnight. Monitoring by IR spectroscopy revealed the complete loss of the CO stretching absorptions. The mixture was evaporated to dryness and the residue was used for several recrystallization attempts. A small amount (< 20 mg) of single crystals which were suitable for an X-ray structural determination was obtained from a toluene/*n*-heptane layer. Found: C, 31.5; H, 3.6; N, 11.6. Calc. for $C_{18.5}H_{26}BI_2MoN_6O$ ($Tp^*MoOI_2 \cdot 1/2C_7H_8$): C, 31.3; H, 3.7; N, 11.8%.

X-ray crystallography for Tp*MoI$_2$O·C_7H_8

A dark purple, nearly black colored crystal with dimensions $0.400 \times 0.125 \times 0.100$ mm was placed on the Enraf–Nonius CAD-4 diffractometer. The cell parameters and crystal orientation matrix were determined form 25 reflections in the range $35.2 < 2\theta < 40.64°$ and confirmed with axial photographs. Data were collected [Mo−K_α] with $\omega/2\theta$ scans over the range $2.23 < \theta < 24.98°$ with a scan width of $(0.64 + 0.56 \tan\theta)°$ and a variable scan speed of 2.3–2.7° min^{-1} with each scan recorded in 96 steps with the outermost 16 steps on each end of the scan being used for background measurement. The diffractometer was controlled with a Digital Equipment Corporation Micro VAX II (MVII) computer and the automated Enraf–Nonius control program Express (version 5.1). Three nearly orthogonal standard reflections were monitored at 1 h intervals of X-ray exposure with minimal variations in intensity being observed. Data were collected with the indices *-hkl*; resulting in the measurement of 2461 unique reflections. Data were corrected for Lorentz and polarization factors, and for absorption based on nine ψ-scan reflections in the range $5.1 < \theta < 15.3°$, with transmission factors ranging from 0.3809–0.5015. Systematic absences indicated the centrosymmetric space group *Pnma* (no. 62) or the noncentrosymmetric space group $Pna2_1$ (no. 33); intensity statistics clearly favored the centric case. The structure was determined by direct methods, with the successful location of the three heavy atoms and several carbon and nitrogen atoms. The remaining nonhydrogen atoms were found from two subsequent difference-Fourier maps. The toluene molecule was found to be disordered with two of the atoms nearly overlapping with their symmetry equivalents that represented other positions of the ring, namely, the C12, C16 pair and the C11 and C17 pair. AFIX commands were used to impose the

molecular geometry as a six-membered ring with C17 as the methyl group. Hydrogen atoms were placed in calculated positions, these being dependent on both the type of bonding at the carbon atom, with the aromatic hydrogen atoms calculated with d(C—H) = 0.950 Å and U_H set equal to $1.2U_{(parent)}$, whereas the methyl hydrogen atoms were initially determined with a rotational difference-Fourier map about the central carbon atom that was further optimized for tetrahedral geometry with d(C—H) = 0.980 Å and U_H set equal to $1.5U_{(parent)}$. The hydrogen atom attached to the boron atom was placed in an idealized tertiary position with d(B—H) = 1.00 Å and U_H set equal to $1.2U_{(parent)}$. All nonhydrogen atoms were refined anisotropically during the final series of cycles and to convergence [$\delta/\sigma \leqslant 0.001$] with $R(F) = 4.47\%$, $wR(F^2) = 7.23\%$ and GOF = 1.075 for all 2460 unique reflections [$R(F) = 3.10\%$, $wR(F^2) = 6.67\%$ for those 2000 data with $F_0 > 4\sigma(F_0)$]. A final difference-Fourier map was essentially featureless with the largest peaks being within 1 Å from a heavy atoms and $|\Delta\rho| \leqslant 0.65$ e Å^{-3}. The function minimized during the full-matrix least-squares refinement was $\Sigma w(F_0^2 - F_0^2)$, where $w = 1/[\sigma^2(F_0^2) + (0.0320*P)^2 + 4.4833*P]$ and $P = (\max(F_0^2, 0) + 2*F_0^2)/3$. An empirical correction for extinction was also attempted but found to produce a negative value and was not applied.

Crystal data and refinement parameters are listed in Table 1, and selected bond distances and angles are collected in Table 2 (the atomic positions have been deposited with the Cambridge Crystallographic Data Centre).

RESULTS

The reaction between $Tp^*Mo(CO)_3^-$ and the halogenating agents $PhICl_2$ and I_2 provide a simple and high yield synthesis of the Mo^{II} 16-electron derivatives $Tp^*MoX(CO)_2$(X = Cl, I), see Eqs (1) and (2). Both derivatives have been isolated as crystalline solids and characterized by elemental analysis (C, H, N, for X = I only), ^{1}H NMR, IR and magnetic susceptibility.

$$Tp^*Mo(CO)_3^- + PhICl_2 \rightarrow Tp^*MoCl(CO)_2 + Cl^- + PhI \quad (1)$$

$$Tp^*Mo(CO)_3^- + I_2 \rightarrow Tp^*MoI(CO)_2 + I^- \quad (2)$$

The iodo derivative has already been reported twice in the literature, but in one case it was not isolated [4], whereas in the other case it has been mischaracterized [16]. Templeton *et al.* carried out the same reaction reported here and reported the initial formation of the tricarbonyl derivative, $Tp^*MoI(CO)_3$, which is characterized by IR absorptions at 2025 and 1937 cm^{-1} in THF [4]. Upon further stirring for 20 h in THF, a gradual conversion to the dicarbonyl compound, which is characterized by absorptions at lower energy (i.e. 1998 and 1921 cm^{-1}) [4],

Largest difference peak and hole (eÅ^{-3})	0.655 and −0.413

was reported by these authors. It was also reported that the CO loss process is inhibited by a CO atmosphere. No further characterization data were provided in that work. Our IR observations fully match those reported in the above mentioned contribution. The IR absorptions of the isolated solid, which was crystallized from the THF solution by addition of *n*-heptane, are 1999 and 1920 cm^{-1} in THF. We have also established that the exposure of $Tp^*MoI(CO)_2$ to an atmosphere of CO does not produce any observable amounts of the tricarbonyl derivative.

Cano and coworkers on the other hand, have prepared the compound by an alternative route, namely the reaction of KTp* with $MoI_2(CO)_3(MeCN)_2$. They have obtained a crystalline solid, for which they report satisfactory C, H, N analyses for the formulation $Tp^*MoI(CO)_2 \cdot 2MeCN$, directly from the reaction medium (MeCN) after only 30 min stirring at room temperature [16]. The formulation of this product was based on the observation of only two IR stretching vibrations (at 2000 and 1850 cm^{-1} in KBr pellet), whereas a tricarbonyl derivatives with a four-legged piano stool structure and C_s symmetry should exhibit three absorptions ($2A' + A$), as is indeed observed for the related $TpMoI(CO)_3$ complex [2]. This assignment is, however, dubious because broad and sometimes shifted bands are usually observed in polycrystalline samples; the lower frequency absorption does not match either of those observed by Templeton *et al.* for the tricarbonyl and dicarbonyl complexes. Although mention is made of the solubility of the isolated product in common organic solvents, no IR data in solution were reported.

The most critical discrepancy between the previously reported [16] characterization of $Tp^*MoI(CO)_2$ and ours is related to the ^1H NMR properties. The previously reported spectrum [16] was characterized by the expected pattern for a Tp* ligand sitting on a mirror plane, the resonances being in a region of the spectrum which is typical for *diamagnetic* compounds. However, the compound isolated by us is paramagnetic, the solid-state magnetic moment being 3.00 μ_B in agreement with a spin triplet state and shows relatively sharp but highly contact-shifted resonances in the ^1H NMR spectrum, see Fig. 1. The simplest explanation that we can advance is that the relatively rapid precipitation and isolation of the product from MeCN by the previous workers [16] did not allow a complete conversion of the tricarbonyl derivative to the dicarbonyl derivative. Although the composition of the reported product may indeed be close to that of the dicarbonyl, the observed resonances in the diamagnetic region are probably due to residual amounts of the diamagnetic tricarbonyl derivative.

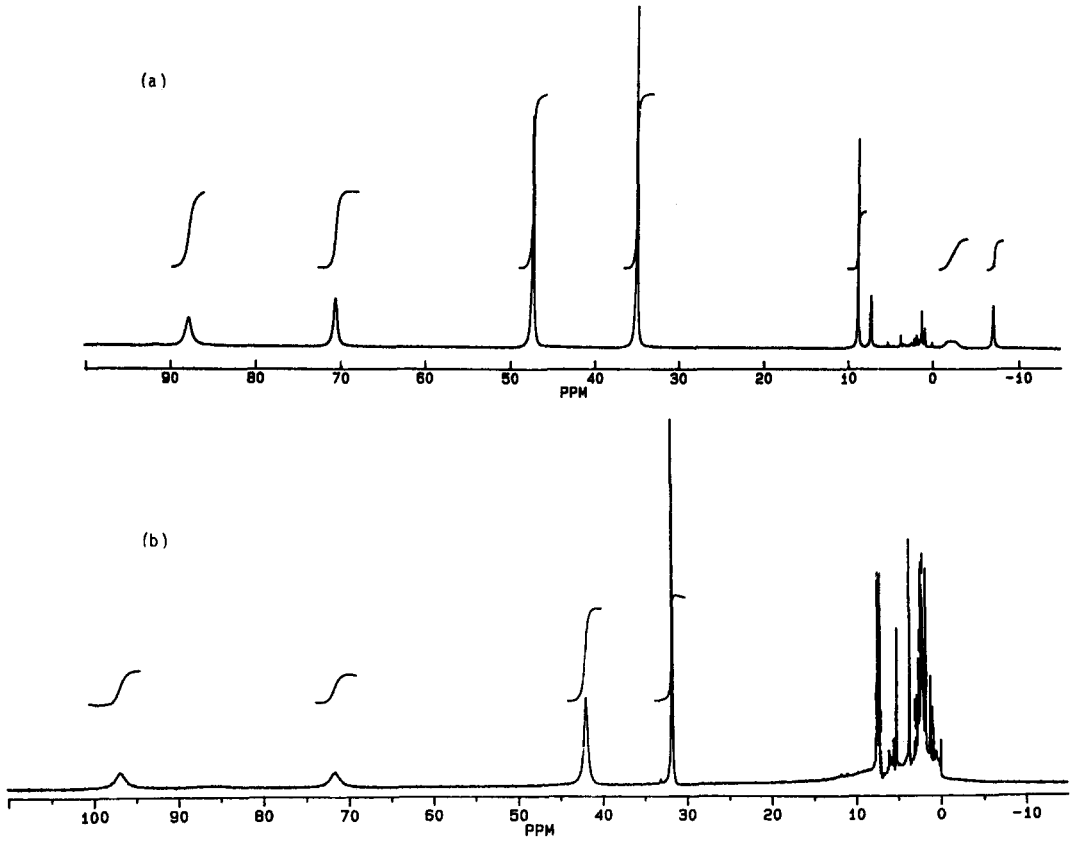

Fig. 1. Room-temperature ^1H NMR spectra of compounds $Tp^*MoX(CO)_2$ [(a) X = I; (b) X = Cl]. Solvent = $CDCl_3$.

The ^{1}H NMR spectrum of Tp*MoI(CO)$_2$ clearly shows two sets of resonances in a 2 : 1 ratio for each type of TP* proton, consistent with the structural rigidity of the C_s pseudo-octahedral structure. There is greater spin density transmitted to the unique pyrazole ring with respect to the other two, the resonance for each type of proton of this ring being shifted to a much greater extent (δ 87.8 and 70.5 for the two ME groups and -7.2 for the ring H, with respect to 47.2, 34.8, and 8.6 for the corresponding protons of the two equivalent rings). A much broader resonance at δ -2.3 is assigned to the B—H proton. Resonances in the diamagnetic region are quite small, attesting to the purity of the compound, and resonances that may be assigned to the tricarbonyl derivative, equivalent to those reported by Cano and coworkers are not visible [16].

The spectroscopic properties of the chloro compound, which has not been described before, parallel those of the iodo analog. The magnetic moment of this derivative is 2.81 μ_B. The ^{1}H NMR resonances are broader relative to those of the iodo analogue, a phenomenon which is commonly observed in the ^{1}H NMR spectra of paramagnetic halide derivatives [20]. The pyrazole ring CH and the BH protons are not visible in this case (see Fig. 1).

Further diiodine oxidation of compound Tp*MoI(CO)$_2$ in THF afforded, after workup and crystallization from toluene/heptane, single crystals of compound Tp*MoOI$_2$, the oxygen atom being possibly provided by adventitious moisture or air. This reaction was monitored by ^{1}H NMR spectroscopy, showing a complex behavior with the formation of several reaction intermediates, none of which has been isolated to date. A similar process has been described in the literature for the oxidation of Tp*Mo(CO)$_3^-$ with thionyl chloride, followed by exposure to air, to afford Tp*MoOCl$_2$ [13,14].

Compound Tp*MoOI$_2$ exhibits a broad EPR resonance ($w_{1/2}$ = 57 G at the X-band; g = 2.045), in agreement with its d^1 configuration. The formulation of this oxo product is confirmed by X-ray crystallography (see Fig. 2). The geometry parallels that established for the related TpMoOCl$_2$. There is no

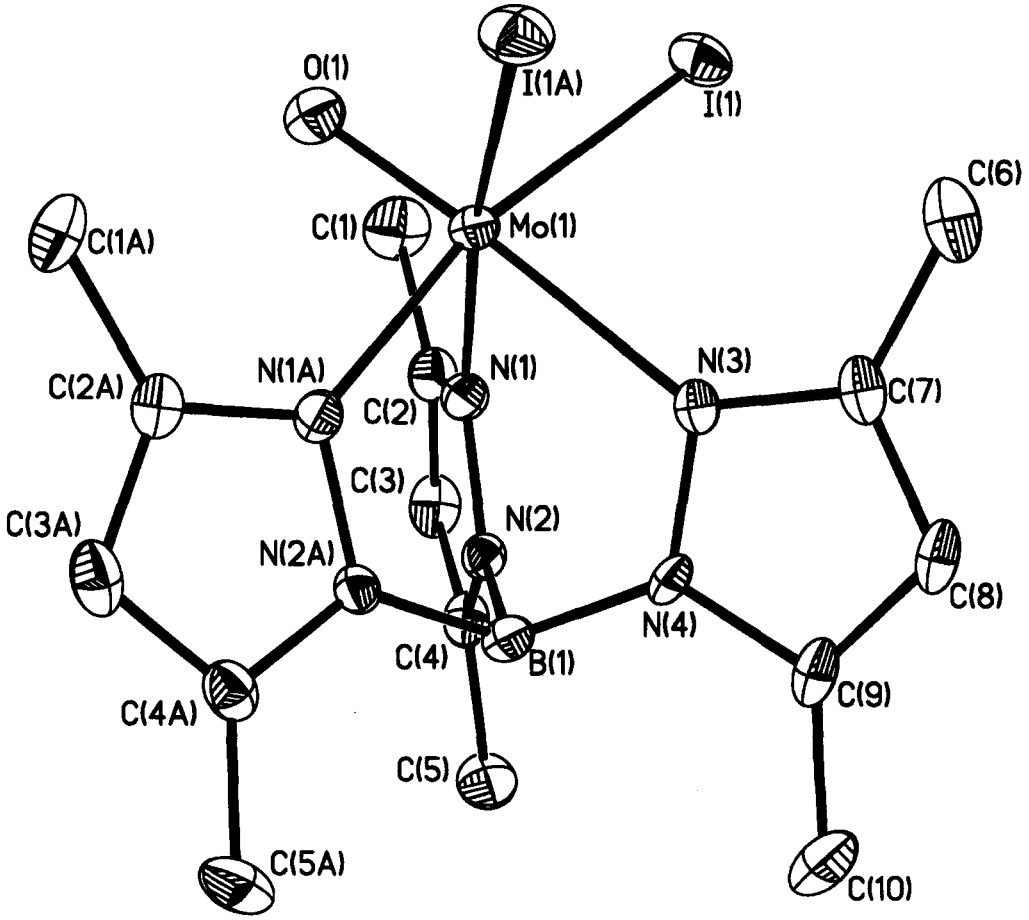

Fig. 2. An ORTEP view of the Tp*MoOI$_2$ molecule with the numbering scheme used. Ellipsoids are shown at the 40% probability level.

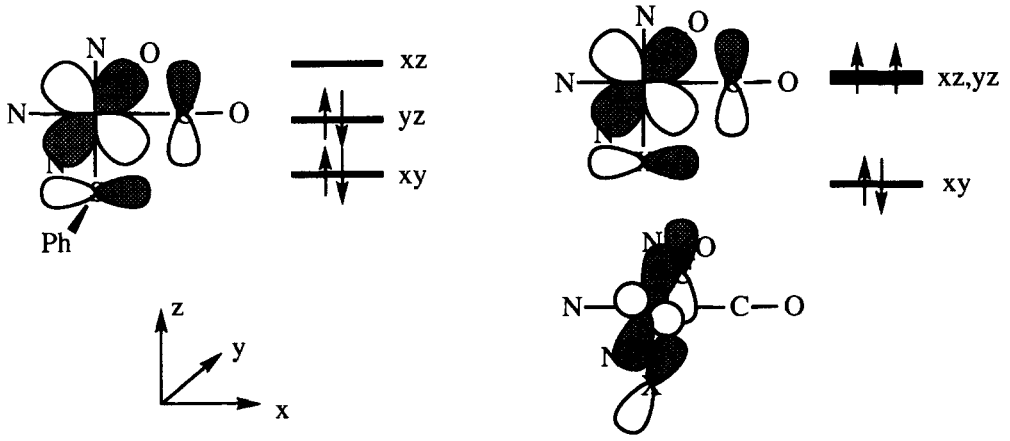
sign of positional disorder between the smaller oxygen and the bigger iodine atoms, whereas a O/Cl positional disorder was observed for $TpMoOCl_2$ [12]. The oxygen atom exerts a greater *trans* influence than the iodine atoms, lengthening the Mo—N(3) distance by *ca* 0.2 Å with respect to the Mo—N(1) distance. The other distances in the molecule are quite typical, including the short Mo—O distance, which is close to that reported for the terminal Mo—O bonds in $[TpMoOCl]_2O$ [1.67(4) Å] [12]. The I—Mo—I and I—Mo—O angles are slightly greater and all N—Mo—N angles are smaller than the ideal octahedral angle.



DISCUSSION

The spontaneous CO loss from hydrotris (pyrazolyl)boratotricarbonylhalomolybdenum(II) is a phenomenon first observed by Templeton for $Tp^*MoI(CO)_3$. No analogous process has been reported for the corresponding $TpMoX(CO)_3$ at room temperature, while mild thermolysis of $TpMoI(CO)_3$ in MeCN has been shown to lead to disproportionation products [2]. These observations suggest that the greater steric encumbrance of the Tp* ligand contributes significantly to the thermodynamics of the CO dissociation process. The $Tp^*WI(CO)_3$ compound, on the other hand, yielded the decarbonylated $Tp^*WI(CO)_2$ product only upon reflux for several hours in THF [21,22], attesting to the stronger W—CO bond relative to the Mo—CO bond. Another related literature report concerns compound $\{HB(3,5\text{-}Me_2C_2N_3)_3\}MoI(CO)_3$, i.e. a system completely analogous to $Tp^*MoI(CO)_3$, except for the formal substitution of the pyrazole rings CH groups with N atoms to yield 1,2,4-triazole rings. This compound was isolated from the I_2 oxidation of $[\{HB(3,5\text{-}Me_2C_2N_3)_3\}Mo(CO)_3]^-$ in MeCN and gas evolution was observed upon dissolution in other organic solvents [9]. The decarbonylated product, however, was not isolated or characterized.

Stable low-oxidation state organometallic compounds with an open-shell configuration are rare, especially for metals of the 4*d* and 5*d* series. Compounds with a 16-electron configuration are often stabilized by ligands that are capable of providing two additional electrons from a lone pair *via* a π-donation mechanism [23]. In order for this interaction to be most effective, the lone pair must interact with an empty metal orbital, thus leading to a spin-paired (diamagnetic) configuration. Half-sandwiched Mo(II) compounds such as $CpMo(CO)_2(AsBu^t_2)$ [24], $CpW(CO)_2[P(OCMe_2CMe_2O)]$ [25] and $Cp^*Mo(PPh_2)(PMe_3)_2$ [26] ($Cp^* = \eta^5-C_5Me_5$), can be rationalized in this light. We have recently provided the first example of a spin triplet analogue of the above compounds, namely $Cp^*MoCl(PMe_3)_2$ [27]. The chloride ligand is apparently a less efficient π-donor than phosphido or arsenido groups. Analogous complexes with carbonyl ligands, however, have always been found to be diamagnetic, even with weak π-donors such as halides. Examples are $MoBr_2(CO)_2(PPh_3)_2$ [28], $Mo(OBu^t)_2(CO)_2(py)_2$ [29] and $Mo(S_2CNPr^i_2)_2(CO)_2$ [30]. Octahedral complexes of d^4 centers can in principle adopt two spin configurations: a high-spin (quintet) $t^3_{2g}e^1_g$ or a low-spin (triplet) t_{2g} [4]. Both are observed for complexes of Cr(II) and the spin triplet configuration is adopted by carbonyl-free Mo^{II} complexes, e.g. $MoCl_2(PMe_3)_4$ [31]. In carbonyl complexes, however, the Jahn–Teller unstable (for d^4) octahedral geometry undergoes remarkable distortions to maximize the π-interactions and lead to diamagnetic ground states [32]. The $Tp^*MoX(CO)_2$(X = Cl, I) compounds described here are the first reported examples of octahedral carbonyl derivatives of Mo^{II} with a spin triplet ground state. They are also rare examples of spin triplet carbonyl complexes for any element, especially heavier metals of the 4*d* and 5*d* series. The only other magnetically characterized example known to us is $ReI_3(CO)_3$ [33]. The compound $Tp^*WI(CO)_2$, i.e. a W(II) analog of the Mo compounds discussed here, has also been described as paramagnetic [22], but no magnetic susceptibility nor NMR data for this compound have been reported. Given that severe distortions of the octahedral coordination geometry for Mo^{II} complexes are related to the electrons being paired in a singlet state, we postulate that the geometry of the $Tp^*MoX(CO)_2$ should describe a relatively undistorted octahedron (e.g. bond angles close to 90°). We were unfortunately unable to grow suitable single crystals of this compound.

It is interesting to compare the paramagnetism of $Tp^*MoX(CO)_2$(X = Cl, I) with the diamagnetism of the related $Tp^*M(SPh)(CO)_2$(M = Mo, W) [1,22] and other W^{II} derivatives, e.g. $Tp^*W(NR_2)(CO)_2$ [34]. The halide on one side, and the thiolato and amido ligands on the other side, differ in the strength and symmetry of the π-interactions. While SPh (if bent) and NR_2 are single-sided π-donors, a halide ligand has two equivalent and orthogonal lone pairs. Thus, in an undistorted octahedral structure, the SPh and NR_2 ligands will be able to remove the degeneracy of the metal d_{xz} and d_{yz} orbitals (see Scheme 1, left) and lead to a spin paired ground state, while the halide ligands, even if they engage in a significant π interaction, will not (Scheme 1, right). The imido ligand in complex $[Tp^*W(NPh)(CO)_2]^+$ also has the ability of participating in M—N π-bonding with both lone pairs. The structure shows a linear W—N—Ph moiety and a relatively undistorted octahedral geometry, but the reported NMR properties of the compound indicate diamagnetism [34].

(Received 23 July 1996; accepted 12 August 1996)

Abstract—The 1:2:1 reaction of $CdCl_2\cdot 2.5H_2O$ with 3,4-dihydroxybenzoic acid ($3,4\text{-}H_3dhb$) and KOH in Pr^nOH–H_2O gave the unique, seven-coordinate cadmium(II) complex $[Cd(3,4\text{-}H_2dhb)_2(H_2O)_3]\cdot HCl\cdot(3,4\text{-}H_3dhb)\cdot 2.5H_2O$ as one of the products. Crystal structure and ^{113}Cd NMR studies showed that $3,4\text{-}H_2dhb^-$ behaves as a bidentate chelate with ligated atoms being the carboxylate oxygens, but that seven-coordination is not retained in aqueous solution. Keywords: Cd^{II} complex; seven-coordinate complex; ^{113}Cd NMR; 3,4-dihydroxybenzoato(-1) Cd^{II} complex; crystal structure.

Several groups have been exploring the coordination chemistry of dihydroxybenzoic acids [1–7] and related ligands [8–10]. They have been motivated chiefly by the fact that in living systems, like plants or microorganisms, simple aromatic compounds bearing phenolic and carboxylic groups serve as versatile ligands to chelate toxic and nutrient metal ions. Many of these compounds are also present in the natural environment as by-products of degradation and metabolic processes and they act as nonspecific ligands toward metal ions in terrestrial and aquatic systems [11]. This family of ligands can provide an efficient chelating ability through several potential donor sets, e.g., of salicylato or catecholato type; mixed coordination modes are also possible. Polynuclear or polymeric species may also be formed with ligands able to bind a metal ion through a donor set while retaining further donor groups to coordinate another metal; these complexation processes may be significant due to their involvement in the natural processes leading to the formation of humic and fulvic matter [11]. we have developed an interest in cadmium complexes of dihydroxybenzoic acids, an area hitherto unexplored for this otherwise well studied metal and we report herein the preparation and characterization of $[Cd(3,4\text{-}H_2dhb)_2(H_2O)_3]\cdot HCl\cdot(3,4\text{-}H_3dhb)\cdot 2.5H_2O$ ($3,4\text{-}H_3dhb$ = 3,4-dihydroxybenzoic acid), a seven-coordinate cadmium(II) complex presenting a bidentate carboxylato-type coordination of $3,4\text{-}H_2dhb^-$. The X-ray structure of this complex is the first such reported for metal complexes containing any anionic form of $3,4\text{-}H_3dhb$.

The Cd^{II} complex is one of the two products from the 1 : 2 : 1 reaction* between $CdCl_2$, $3,4\text{-}H_3dhb$ and KOH in Pr^nOH–H_2O. Crystals suitable for a crystal structure analysis were obtained by slow cooling of a concentrated solution of the complex in H_2O.

Crystallographic studies† indicated the formula $[Cd(3,4\text{-}H_2dhb)_2(H_2O)_3]\cdot HCl\cdot(3,4\text{-}H_3dhb)\cdot 2.5H_2O$. The structure of the $[Cd(3,4\text{-}H_2dhb)_2(H_2O)_3]$ molecule (Fig. 1) proves conclusively that the $3,4\text{-}H_2dhb^-$ anion functions as a bidentate chelate with ligated atoms being the carboxylate oxygens [O(1), O(2) and O(11), O(12)]; the oxygen atoms [O(5), O(6), O(7)] from three terminal H_2O molecules complete seven-coordination at the metal atom. The chelating $3,4\text{-}H_2dhb^-$ anions are asymmetrically ligated [Cd(1)—O(1) 2.513(4), Cd(1)—O(2) 2.304(4); Cd(1)—O(11) 2.481(4), Cd(1)—O(12) 2.314(4) Å], while the Cd(1)—O_{aquo} bond lengths are similar [2.290(5), 2.309(4) and 2.291(4) Å]. The geometry around Cd(1) can be described as distorted pentagonal bipyramidal. Atoms O(1), O(2), O(6), O(11) and O(12) comprise the equatorial plane around Cd(1), while atoms O(5) and O(7) form the pyramidal apices [O(5)—Cd(1)—O(7) 170.5(2)°]. Cd(1) lies 0.061(3) Å above the least-squares equatorial plane [from which the maximum deviation of atoms concerned is 0.096(7) Å by O(11) towards O(5)]. The regularity of the arrangement is necessarily broken by the chelation angles subtended at Cd(1) by the rigid four-membered chelate rings [54.0(1), 54.3(1)°], the regular pentagon value being 72°. The present compound joins a relatively small family of seven-coordinate Cd^{II} species [13–19]. It is interesting to note that the coordination of each atom is not forced by the geometry of other coordinating atoms, although there are examples of apparent seven-coordination forced by geometrical demands of polydentate ligands [13,15–17]. The crystal structure is stabilized through a complex scheme of intra- and intermolecular hydrogen bonds involving the coordinated and lattice H_2O molecules, —OH groups, chloride ion and the carboxylic group of the noncoordinated $3,4\text{-}H_3dhb$ molecule.

In the IR spectrum, complex $[Cd(3,4\text{-}H_2dhb)_2(H_2O)_3]\cdot HCl\cdot(3,4\text{-}H_3dhb)\cdot 2.5H_2O$ exhibits bands at 3480, ~3350, 3190, ~2900, 1661, 1554, 1480, 1448, 1404, 1287 and 1265 cm^{-1}, assignable‡ to $\nu(O—H)_{bound\ H_2O}$, $\nu(O—H)_{lattice\ H_2O}$, $\nu(O—H)_{phenolic}$, $\nu(O—H)_{-COOH}$, $\nu(C{=}O)_{-COOH}$, ν_{asym} (CO_2), a ring stretching mode characteristic of free catechole-type ligands and their metal complexes, ν_{sym} (CO_2), $\delta(OH)_{-COOH}$, $\nu(C—O)_{-COOH}$ and $\nu(C—O)_{phenolic}$, respectively [1,3,4]. The small ν_{asym} (CO_2)-ν_{sym} (CO_2)

* To a stirred solution of $CdCl_2\cdot 2.5H_2O$ (0.34 g, 1.5 mmol) in Pr^nOH (25 cm^3) was added solid $3,4\text{-}H_3dhb$ (0.46 g, 3.0 mmol). Addition of a solution of KOH (0.084 g, 1.5 mmol) in H_2O (10 cm^3) led to the rapid precipitation of a Cd^{II}-containing cream microcrystalline material. After *ca* 15 min, the mixture was filtered and the essentially colorless mother liquor soon began to deposit well-formed crystals of the product. The crystals were collected by filtration, washed with Pr^nOH–H_2O (1 : 1) and acetone, and dried in air; yield *ca* 21% based on available Cd. Found: C, 35.8; H, 4.1; Cl, 4.8; Cd, 16.3. $C_{21}H_{28}ClCdO_{17.5}$ requires: C, 35.6; H, 4.0; Cl, 5.0; Cd, 15.9%).

† Crystal data: $C_{21}H_{28}ClCdO_{17.5}$, M = 708.31, monoclinic, space group $C2/c$, a = 27.925(14), b = 11.484(2), c = 19.908(6) Å, β = 126.49(2)°, U = 5133(3) Å^3 (by least-squares refinement of the setting angles of 24 automatically centered reflections in the 2θ range 30–40°, λ = 0.70930 Å), Z = 8, $F(000)$ = 2872, D_c = 1.83 g cm^{-3}, T = 296 K, colorless crystals, 0.47 × 0.21 × 0.14 mm, μ = 1.04 mm^{-1}, 9231 reflections measured, 4526 unique, giving 3389 with $I > 2.0\sigma(I)$ [R_{int} = 0.041], 366 refined parameters, $[\Delta/\sigma]_{max}$ = 0.060, $[\Delta\rho]_{max}$, $[\Delta\rho]_{min}$ = 1.690, −0.630 e Å^{-3}, $R(=\Sigma\|F_o|-|F_c\|/\Sigma|F_o|)$ = 0.047, $R'(=[\Sigma w(|F_o|-|F_c|)^2/\Sigma w|F_o|^2]^{1/2})$ = 0.043 for 3389 independent observed reflections, weights based on counting-statistics.

Intensity data, collected on a Rigaku AFC6S diffractometer using the $\omega/2\theta$ scan mode to $2\theta_{max}$ = 50°, were corrected for decay (−1.08%) and absorption (Ψ scans, transmission factors range: 0.684951–0.795685). The structure was solved by direct methods and refined on $|F|$ by full-matrix least-squares. The main molecule as well as two of the H_2O molecules and the extra neutral ligand are in general position giving eight of each in the unit cell. The chlorine atom Cl(1) sits on the two-fold axis (Z = 4), chlorine atom Cl(2) and H_2O molecule OW(3) are disordered about an inversion center and have site occupancy factors of 1/2. While chlorine is present on one side of the inversion center, water is present on the opposite side. The two partial chlorines cannot be present simultaneously, since they would be too close to one another. Hence, there are 2.5 solvation H_2O molecules per Cd^{II} atom and two half Cl atoms. The extra proton required to balance the charge could not be located; hydrogens on OW(3) and —OH hydrogens on free ligand were not found either and have not been included in the model. Nonhydrogen atoms were refined with anisotropic thermal parameters, except disordered atoms which were kept isotropic. Hydrogen atoms were located in difference maps, distances being normalized to 0.95 Å. Residual electron density in the area of the disordered atoms likely reflects extra components to the disorder that were not resolved. Attempts were made to introduce partial Cl or O atoms on that side, but standard uncertainties in bond lengths and angles as well as R factors did not improve; solution described above was retained. All computing was done using the NRCVAX system of crystallographic software [12]. Atomic coordinates, thermal parameters and bond lengths and angles have been deposited at the Cambridge Crystallographic Data Center.

‡ Details will be reported in the full paper.

An ORTEP [21] representation of the molecule $[Cd(3,4\text{-}H_2dhb)_2(H_2O)_3]$ in complex $[Cd(3,4\text{-}H_2dhb)_2(H_2O)_3]\cdot HCl\cdot(3,4\text{-}H_3dhb)\cdot 2.5H_2O$: Cd (1)—O(1) 2.513(4), Cd(1)—O(2) 2.304(4), Cd(1)—O(5) 2.290(5), Cd(1)—O(6) 2.309(4), Cd(1)—O(7) 2.291(4), Cd(1)—O(11) 2.481(4), Cd(1)—O(12) 2.314(4), C(7)—O(1) 1.251 (7), C(7)—O(2) 1.272(7), C(17)—O(11) 1.257(8), C(17)—O(12) 1.268(8) Å; O(5)—Cd(1)—O(7) 170.5(2), O(5)—Cd(1)—O(1) 84.6(2), O(5)—Cd(1)—O(6) 90.3(1), O(1)—Cd(1)—O(2) 54.0(1), O(1)—Cd(1)—O(12) 144.5(1), O(2)—Cd(1)—O(11) 144.9(1), O(2)—Cd(1)—O(6) 130.9(1), O(11)—Cd(1)—O(12) 54.3(1), O(6)—Cd(1)—O(11) 83.8(1), O(6)—Cd(1)—O(12) 137.6(1), O(7)—Cd(1)—O(11) 92.6(1), O(7)—Cd(1)—O(12) 91.7(2), O(6)—Cd(1)—O(7) 82.6(2)°.

separation is as expected for the bidentate chelating mode of the carboxylate ligation of $3,4\text{-}H_2dhb^-$ [20].

^{13}Cd NMR is a very useful tool for the study of Cd^{II} complexes due to the sensitivity of the ^{113}Cd chemical shift to the nature of donor atoms, their coordination geometry and bond length [22]. The complex reported here has an isotropic chemical shift at 45.9 ppm in D_2O solution (Fig. 2). The coordination number of Cd^{II} in complexes with exclusively oxygen ligation is six, seven or eight, while the isotropic chemical shifts span the range δ 140 to −115 [23,24]. From these systematic studies, a pattern has emerged [23] showing that six-coordinate Cd^{II} has a chemical shift ranging from δ 140 to −70, seven-coordinate cadmium(II) spans the range δ 0 to −70, and eight-coordinate cadmium(II) a range δ 0 to −115. Based on such data, the chemical shift at δ 45.9 is assigned to a six-coordinate cadmium(II) atom, indicating that the

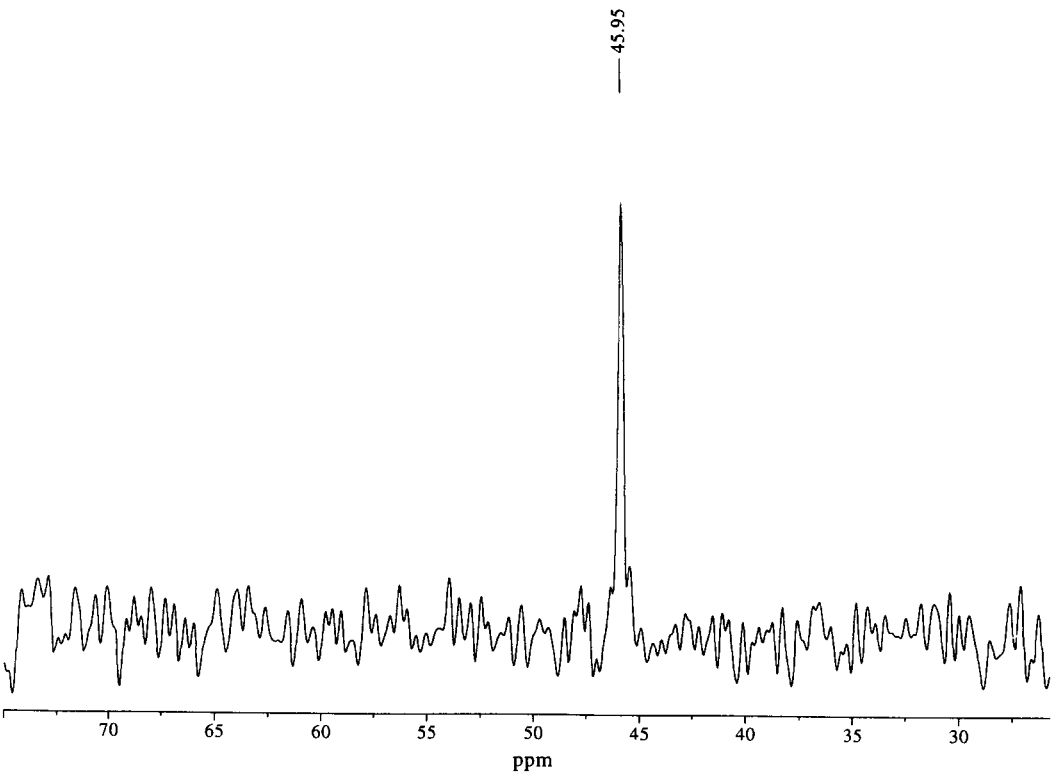

Fig. 2. ^{113}Cd NMR spectrum (88.7 MHz) of $[Cd(3,4\text{-}H_2dhb)_2(H_2O)_3]\cdot HCl\cdot(3,4\text{-}H_3dhb)\cdot 2.5H_2O$ in D_2O; chemical shift is referenced to an external sample of 0.1 M $Cd(ClO_4)_2$ in D_2O at 23°C.

solid-state structure of the $[Cd(3,4\text{-}H_2dhb)_2(H_2O)_3]$ molecule does not persist in solution. We are studying this and related complexes by solid-state ^{113}Cd NMR in order to determine the shifts of the individual tensors and anticipate direct structure/shielding correlations from these experiments.

A better understanding of the course of the reaction reported here must await identification of the other major product, the initial cream microcrystalline precipitate. This material seems to contain (IR evidence) doubly deprotonated 3,4-dihydroxybenzoic acid. Additional Cd^{II}-dihydroxybenzoato species—including high nuclearity clusters—are under investigation.

The production of hydrogen peroxide from dioxygen using hydroxylamine as substrate catalysed by Mn^{2+}-exchanged montmorillonite clay

Bhupinder Hothi, Virginie Lechene, Joseph Robinson and Tippu S. Sheriff*

Inorganic Research Laboratories, Department of Physical Sciences, University of Hertfordshire, College Lane, Hatfield, Hertfordshire AL10 9AB, U.K.

(Received 24 May 1996; accepted 6 August 1996)

Abstract—Mn^{2+}-exchanged montmorillonite clay, in milligramme quantities, efficiently catalyses the production of hydrogen peroxide from dioxygen (or air) and hydroxylamine at pH 8.0 in aqueous solution; concentrations of hydrogen peroxide > 0.40 mol dm^{-3} (~1.5% w/v H_2O_2, ~86% based on hydroxylamine) in 50 min and turnover numbers $[H_2O_2]/[Mn^{2+}] > 10^5$ were obtained. The mechanism for hydrogen peroxide production in this system is discussed together with the possibilities of developing a dual system to use the *in situ* generated hydrogen peroxide to effect some organic oxidation transformations. Copyright © 1997 Elsevier Science Ltd

Keywords: hydrogen peroxide; dioxygen; manganese; clay; catalysis; hydroxylamine.

Hydrogen peroxide is seen as the ideal oxidant from an environmental point of view, producing only water as a byproduct. It has been estimated [1] that of the 900,000 tonne per annum production of hydrogen peroxide, only 10% is used in the synthetic organic industry, mostly for epoxidation reactions and the paucity of practical applications contrasts with the clear environmental advantages. Solutions to the problems of the activation of hydrogen peroxide which results in this under-use are being found [2] and it is envisaged that the use of hydrogen peroxide will increase markedly in the coming decade.

The oxidation of organic molecules usually requires the use of fairly concentrated solutions of hydrogen peroxide or organic peroxides (30%), but recently dilute solutions of hydrogen peroxide (~2%) have been used to epoxidise alkyl-substituted alkenes [3]. Other important potential applications in the generation of dilute solutions of hydrogen peroxide from air or dioxygen in aqueous solution include the formulation of liquid laundry detergents and the disinfection of process waters and water used for air-conditioning etc. The *in situ* generation of hydrogen peroxide has additional environmental advantages in terms of the transport, storage and handling problems associated with hydrogen peroxide.

There has been a number of reports of the production of hydrogen peroxide by reaction of dioxygen and transition metal ions or complexes, although in the majority of these systems the peroxide rapidly disappears by further reaction or catalytic decomposition. In the presence of a reducing substrate, catalytic production of hydrogen peroxide is possible. Thus, it has been shown by one of us that manganese(II)/4,5-dihydroxybenzene-1,3-disulfonate (Tiron) provides an efficient homogeneous catalyst for the reduction of dioxygen to hydrogen peroxide with hydroxylamine in the pH range 7.5–8.6 [4]. Peroxide concentrations greater than 0.20 mol dm^{-3} and

turnover numbers $[H_2O_2]/[Mn^{2+}] > 10^4$ were obtained. Unpublished data suggest that the overall process can be represented as follows:

$$O_2(air) + 2NH_2OH = H_2O_2 + N_2 + 2H_2O \quad (1)$$

Preparation of modified clay

Sodium bentonite (MPS-1), a montmorillonite supplied by Volclay, was dried for several hours at 105°C and then cooled in a desiccator. A 5% (w/v) suspension of the clay (20 g) in a 0.1 M aqueous solution of $MnCl_2 \cdot 4H_2O$ was stirred overnight, the supernatent liquid discarded and the clay washed several times with distilled water. The clay was isolated by centrifugation and again washed with distilled water until all the excess $MnCl_2$ had been removed (tested with $AgNO_3$). The Mn^{2+}-exchanged clay was dried (as before) and then crushed and powdered and sieved through a 500 micron mesh. Analysis of both Mn^{2+}-exchanged clay and sodium bentonite for manganese content was achieved by ICP with XRD being used to provide basal spacings data.

Hydrogen peroxide production and analysis

Accurately weighed portions of the clay were added to a Dreschel bottle (in a water bath) containing deionized water (100.0 cm^3) containing ACS grade $NH_2OH \cdot HCl$ (0.5 or 1.0 mol dm^{-3}) and Tiron (6×10^{-4} mol dm^{-3}), buffered using 4-(2-hydroxyethyl)-l-piperazinepropanesulfonic acid (EPPS, 0.1 mol dm^{-3}) to pH 8.0 using semiconductor grade, carbonate-free aqueous NaOH. A good supply of dioxygen from a cylinder or air *via* a vacuum created by a water pump were supplied to the stirred solution. Aliquots of the solution were removed at defined periods and analysed for hydrogen peroxide concentration using the colorimetric method based on titanium (IV) sulfate [5,6]. A Philips UV–vis spectrophotometer PU 8720 was used for colorimetric measurements.

The results are shown in Fig. 1. The yields of H_2O_2 produced with Mn^{2+}-clay, ~0.23 mol dm^{-3} (~90% based on NH_2OH) were consistent with earlier results using homogeneous catalysis [4], but the rate of production of hydrogen peroxide, $[H_2O_2]_{max}$ in ~30 min, was found to be a marked improvement. With NH_2OH (1.0 mol dm^{-3}) and using Mn^{2+}-clay (0.0074 g), remarkable concentrations of H_2O_2 of ~0.43 mol dm^{-3} (~1.5% w/v H_2O_2, ~86% based on NH_2OH) could be obtained in only *ca* 50 min.

In the absence of added clay (Fig. 1) only slow formation of H_2O_2 was observed which can probably be attributed to catalysis by adventitious traces of Mn^{2+} [7]. With sodium bentonite, there is also a slow (but slightly higher) formation of H_2O_2, which presumably results from catalysis by small quantities of manganese present within the clay, measured by ICP to be 0.15 mmol of total manganese per 100 g of clay. The Mn^{2+}-exchanged clay is catalytic in milligramme quantities with "saturation" being observed at weights of exchanged clay of 5 mg (per 100 cm^3 of reaction solution). The amount of Mn^{2+} exchanged in the clay was determined by ICP to be 33.95 mmol per 100 g of clay, corresponding to a cation exchange capacity (CEC) of the clay of 67.6 meq (mmol) per 100 g, giving turnovers of $[H_2O_2]/[Mn^{2+}] \sim 10^5$.

Previously "saturation" was achieved at levels of 1×10^{-4} mol dm^{-3} when using aqueous $MnCl_2$ [4], corresponding to a weight of manganese(II) of *ca* 50 mg. This clearly shows the greater efficiency of Mn^{2+} within the clay support to catalyse the process. This result can be either explained by the effect of the restricted two-dimensional space within a layered clay structure, thus allowing a greater probability for reactants to meet [8], or the effect of the reactants proximity adsorbed on the outer surface of the modified clay.

X-ray powder diffraction (XRD) analysis of sodium bentonite (undried) and Mn^{2+}-clay both produced sharp peaks implying an interlayer structure with basal spacings (d_{001}) of 1263 and 1281 pm, respectively. These results would give an interlayer (interlamellar) spacing of approximately 300 pm and 320 pm for the Na^+- and Mn^{2+}-clay, respectively [9]. In the aqueous reaction medium used, it would be expected that the Mn^{2+}-clay would fully hydrate, increasing the interlayer space to approximately 800 pm and this space would be important in especially enabling the intercalation and binding of the ligand (Tiron), and also the substrate (hydroxylamine) and dioxygen.

The rate of formation of hydrogen peroxide in air using Mn^{2+}-exchanged clay was approximately 1/5 that in pure dioxygen, indicating that dioxygen is involved in the rate-determining step. A mechanism for the homogeneous process has been proposed [4], whereby both dioxygen and hydroxylamine become bound to a square-planar assembly of manganese(II) and catecholate ligand with the resulting complex acting as an "electron sink" for the transfer of electron density from the bound substrate to dioxygen. The faster rates of hydrogen peroxide production with this partial heterogeneous system imply that the presence of manganese(II) adsorbed either onto the surface or within the interlamellar space of the clay facilitates this process.

Recently Uemura and *et al.* have reported the use of Mn^{2+}-clay to catalyse the oxidation of alkanes with *tert*-butyl hydroperoxide [10]. With the system described here, there is the possibility of developing a dual process which cannot only generate hydrogen peroxide *in situ*, but also catalyse important organic oxidation processes. Work is also continuing to search for alternative substrates to hydroxylamine to make this process more economically viable and for which some success has been achieved. This system is also of

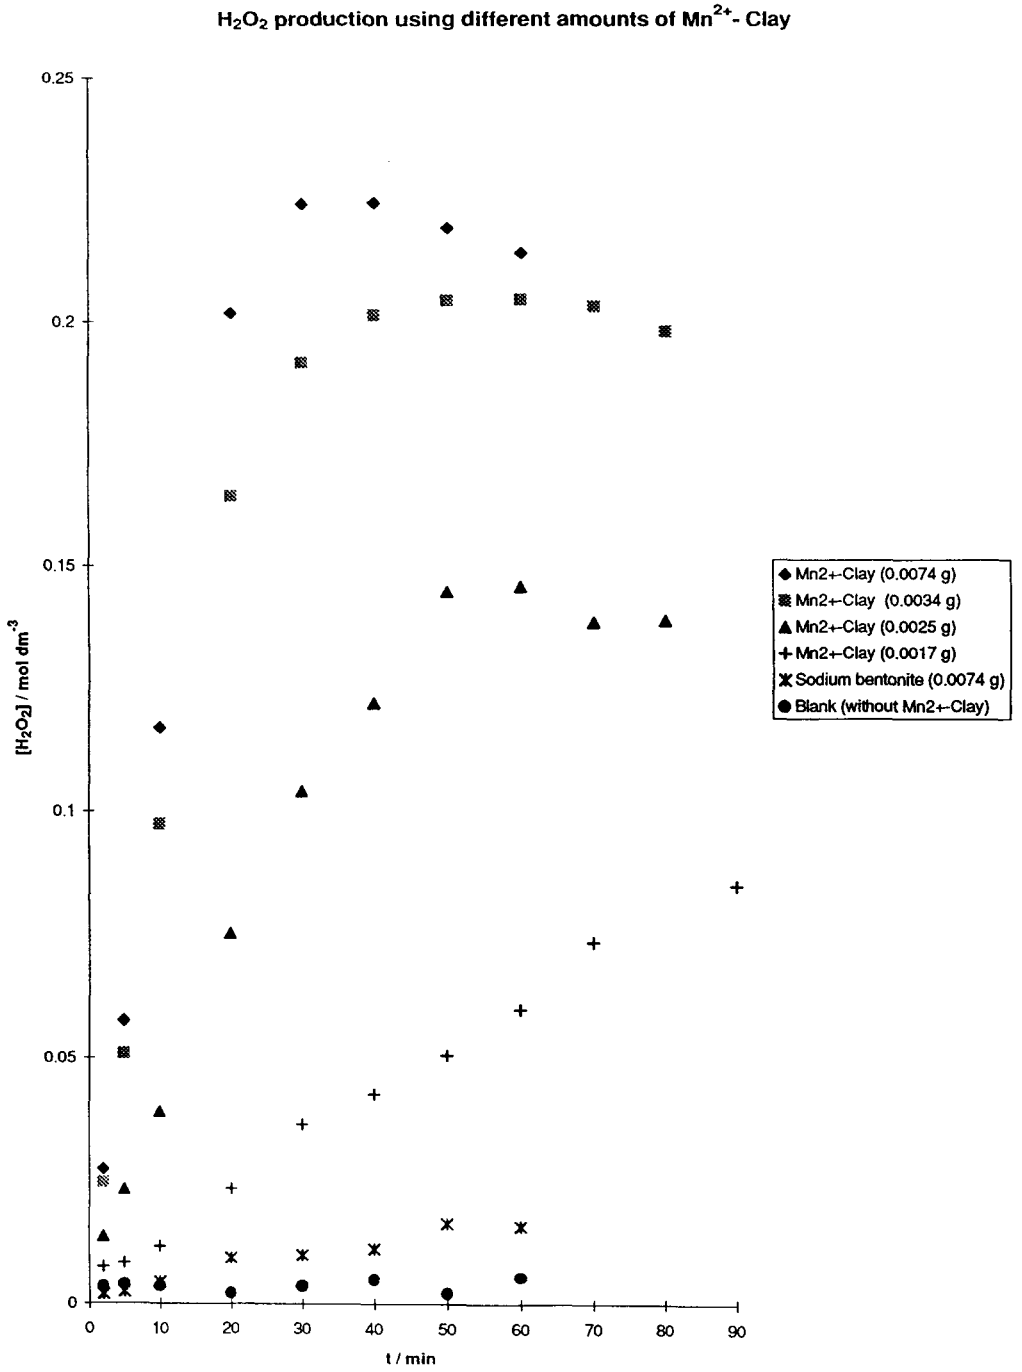

Fig. 1. The production of H_2O_2 in the Mn^{2+}-clay/Tiron/NH_2OH system in the presence of O_2 at $25 \pm 0.5°C$ and different weights of Mn^{2+}-clay. In all runs, the [Tiron] was 6×10^{-4} mol dm^{-3}, the initial [NH_2OH] was 0.5 mol dm^{-3} and the pH was 8.0 [0.1 mol dm^{-3}, 4-(2-hydroxyethyl)-l-piperazinepropanesulfonate (EPPS) buffer].

interest in modelling natural systems such as galactose oxidase [11].

(Received 24 May 1996; accepted 6 August 1996)

Abstract—The monooxo-capped trimolybdenum carboxylate cluster $Na_2[Mo_3O(O_2CCH_3)_8(H_2O)] \cdot 2H_2O$, with an unusual set of Mo—Mo bonds [2.441(5), 2.786(5), 2.808(6) Å] has been synthesized and structurally characterized. Copyright © 1997 Elsevier Science Ltd

Keywords: molybdenum; carboxylate; cluster; trinuclear complex; crystal structure.

Triangular metal–metal bonded cluster compounds of molybdenum have been extensively studied over the past two decades [1–9]. Three Mo—Mo bonds in all these reported species are, however, similar with the differences less than 0.1 Å. Herein we wish to present the novel monooxo-capped trimolybdenum carboxylate cluster $Na_2[Mo_3O(O_2CCH_3)_8(H_2O)] \cdot 2H_2O$ (**1**) with an unusual set of Mo—Mo bonds. It is also the first monooxo-capped hexacarboxylato-bridged cluster of molybdenum, while such clusters of tungsten have been reported more than 10 years ago [3,8].

Cluster **1** has been characterized by X-ray crystallography [10]. The structure of the cluster anion, $[Mo_3O(O_2CCH_3)_8(H_2O)]^{2-}$, is shown in Fig. 1. Its most important structural feature is an unprecedented set of Mo—Mo distances, one short [2.441(5) Å] and two long [2.786(5), 2.808(6) Å], the former being the shortest Mo—Mo bond length in reported trinuclear molybdenum clusters. The Mo—Mo bond difference of up to 0.356(5) Å is surprising because the greatest difference thus far reported for trimolybdenum clusters is less than 0.1 Å [2,9]. To understand this, a comparison of M—M bonds in **1** and the tritungsten cluster $[W_3O(O_2CMe)_5(OCMe)(H_2O)_3]^{2+}$ (**2**) [2.495(1), 2.684(1), 2.687(1) Å] [8b], may be helpful due to the structural similarity and almost the same bond radius. According to the compositions, **1** and **2** have 10 and 8 electrons, respectively, available for M—M bonding. The two more electrons in the former cluster function as shortening the short M—M bond and lengthening the long ones. This indicates that they occupy a Mo—Mo molecular orbital of Mo(1)—Mo(2) π-bonding and Mo(1) [or

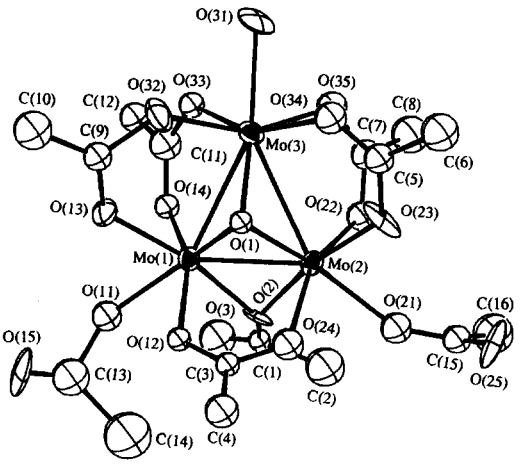

Fig. 1.

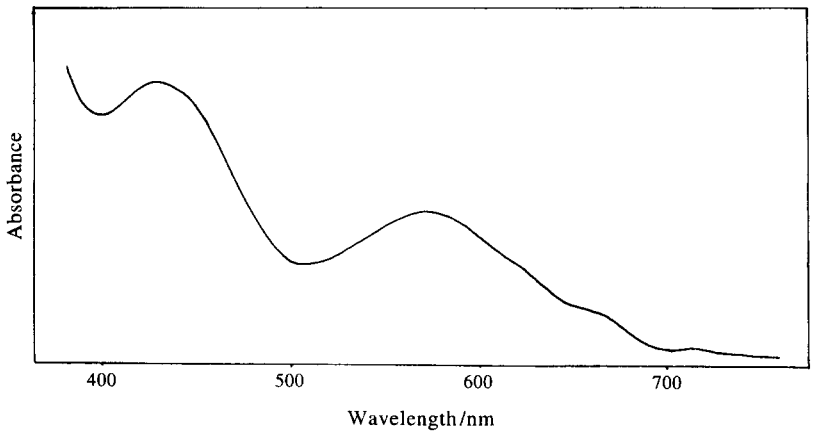

Fig. 2.

Mo(2)]—Mo(3) antibonding character. The asymmetry of the structure caused by the unidentate bridging acetate, η^1, μ_2-O_2CMe, is believed to be responsible for the occurrence of such an unusual set of Mo—Mo bonds, since the other symmetric 10e Mo_3 clusters $Mo_3HI_7L_3$ possess three almost equal Mo—Mo bonds [7].

The preparation of the crystalline **1** was as follows. A solution obtained by refluxing $Na_2MoO_4 \cdot 2H_2O$ in $(EtCO)_2O$ was added with Et_2O to produce a precipitate. A mixture of the precipitate, $Mo(CO)_6$ and Ac_2O was heated for 2 days to yield the green–black crystals of **1**. It is noteworthy that, by similar methods, we have prepared a novel series of hetero-octanuclear clusters of the formula $A_2M'_2[M_3O_4(O_2CR)_8]_2$ (A = Li, Na, K, M′ = V^{3+}, Cr^{3+}, Mn^{3+}, Fe^{3+}, Al^{3+}, Mo^{3+}, M = Mo, W, R = Me, Et) [11–16]. Cluster **1** is extremely sensitive to air. It dissolves in water or organic solvents (e.g. MeCN, EtOH) to give a green solution whose UV–vis spectrum is shown in Fig. 2. In the case of water, the solution becomes red in color after exposure to air for several hours. When added with a mixture of HBr and $ZnBr_2$, one can readily obtain red crystals of the oxidized product with the composition $[Mo_3O_2(O_2CCH_3)_6(H_2O)_3]ZnBr_4 \cdot 8H_2O$ [17].

(Received 25 June 1996; accepted 12 September 1996)

Abstract—An isophthalate-bridged manganese(II) chain complex of the formula $[Mn_2(bipy)_4(m\text{-phth})]_n[ClO_4]_{2n}\cdot 4nH_2O$, where bipy is 2,2′-bipyridine and *m*-phth is isophthalate (dianion of benzene-1,3-dicarboxylic acid), has been prepared and characterized by X-ray crystallography and magnetic measurements. The structure consists of cationic isophthalate-bridged $[Mn_2(bipy)_4(m\text{-phth})]^{2+}$ chains, non-coordinated perchlorate anions and water molecules of crystallization. Each isophthalate ligand is bound to four manganese atoms through carboxylate oxygens with the *syn–syn* bridging mode, affording manganese(II) pairs that are linked by the isophthalate group to yield a one-dimensional chain running along the *c*-axis. The manganese(II) ion displays a distorted octahedral coordination being linked to four nitrogen atoms of two bipy ligands and two oxygen atoms of two carboxylate groups from two isophthalate ligands. The variable temperature magnetic susceptibility of the title complex in the temperature range 4–300 K has been interpreted in terms of a Mn^{II} dimer with a molecular field approximation, and the values obtained for J, g(fixed) and zJ' being -0.98 cm^{-1}, 2.00 and -0.03 cm^{-1}, respectively, indicating a weakly antiferromagnetic exchange coupling between the Mn^{II} ions.

Keywords: manganese complexes; chain complexes; crystal structures; magnetism; isophthalate; 2,2′-bipyridine.

Magnetic properties of polynuclear transition metal complexes with extended bridging ligands have been of interest for some years [1–8]. Many papers have been published on binuclear and chain copper(II) complexes containing the bridging benzene dicarboxylate ligands [2–6], but polynuclear manganese(II) complexes with bridging benzene dicarboxylate ligands have been very rare up to now [7–9]. In the present paper we describe the synthesis, crystal structure and magnetic properties of another manganese(II) chain complex with a bridging isophthalate ligand, $[Mn_2(bipy)_4(m\text{-phth})]_n[ClO_4]_{2n}\cdot 4nH_2O$, where bipy and *m*-phth correspond to 2,2′-bipyridine and isophthalate (dianion of benzene-1,3-dicarboxylic acid).

EXPERIMENTAL

Preparations

2,2′-Bipyridine and other common chemicals were purchased from Sigma Chemical Co. and used as received. The piperidinium salt of isophthalic acid was prepared in a similar method to the piperidinium salt of terephthalic acid [4].

A methanolic solution (20 cm^3) of bipyridine (0.8 mmol) and piperidinium isophthalate (0.2 mmol) was slowly added to a solution (20 cm^3) of manganese(II) perchlorate hexahydrate (0.4 mmol) in the same solvent with continuous stirring. The light yellow powder separated during the addition was filtered off. Small yellow rectangular crystals of the title complex suitable for X-ray analysis were obtained after a month by slow evaporation of the mother liquor at 280±2

K. These were filtered off and air dried. Found: C, 49.5; H, 3.8; N, 9.8; Mn, 9.8. Calc. for $C_{24}H_{22}N_4O_8ClMn$: C, 49.3; H, 3.8; N, 9.6; Mn, 9.4%.

Physical measurements

Magnetic measurements on powder samples were carried out with a CF-1 type extracting sample magnetometer in the temperature range 4–300 K. The apparatus was calibrated with $Hg[Co(NCS)_4]$. Corrections for diamagnetism were estimated from Pascal's constants.

X-ray crystallography

Diffraction data were collected at 290±2 K on a P4 four-circle diffractometer with graphite-monochromated Mo-K_α radiation ($\lambda = 0.71073$ Å) by using the ω–2θ scan technique. Details of the crystal data are listed in Table 1. The lattice parameters were obtained from a least-squares refinement using the setting angles of 20 carefully centred reflections in the 2θ range 5.92–28.3°. Intensity data were collected in the 2θ range 3.32–48°. A total of 4252 reflections were collected and 3587 of them were considered as observed [$I > 2\sigma(I)$] and used for refinement of the structure. The intensities were corrected for Lorentz-polarization and absorption. The structure was solved by heavy-atom Patterson methods and expanded using Fourier techniques. The six oxygen atoms in the ClO_4 group from O(3) to O(6) and O(7) and O(8) of two crystallization water molecules, were found to exhibit locally positional disorder. All hydrogen atoms except H(19) and H(19) were created using Fourier techniques, while H(18) and H(19) were set in calculated positions. Hydrogen atoms were refined isotropically. Four hydrogen atoms of the two crystallization H_2O molecules were included but not refined. The final cycle of full-matrix least-squares refinement on F^2 was based on 3587 observed reflections [$I > 2\sigma(I)$] and 408 variable parameters and converged with unweighted and weighted agreement factors of $R = \Sigma||F_o| - |F_c||/\Sigma|F_o| = 0.059$, $R_w = [(\Sigma w(|F_o| - |F_c|)^2/\Sigma wF_o^2] = 0.1474$; $GOF = 0.867$ (on F^2). The maximum and minimum peaks on the final difference Fourier map corresponded to 0.501 and −0.356 e Å^{-3}, respectively. Selected bond distances and angles are given in Table 2.

RESULTS AND DISCUSSION

Description of the crystal structure

The structure of the complex consists of polymeric cationic chains composed of $[Mn_2(bipy)_4(m\text{-phth})]^{2+}$ units, non-coordinated perchlorate anions and crystallization water molecules. One of the independent structural units is shown in Fig. 1 together with the atom-numbering scheme. The isophthalate group acts as a tetrakis(monodentate) ligand which is bound on each side to two manganese(II) ions through the carboxylate oxygens in a *syn–syn* configuration, yielding a chain that runs parallel to the *c*-axis, as shown in Figs 1 and 2. The interchain metal–metal separations are 4.84, 9.72 and 7.06 Å for Mn···Mn(A), Mn···Mn(B) and Mn(A)···Mn(B), respectively (see Fig. 1).

The Mn ion is six coordinate and possesses an N_4O_2 environment by virtue of two carboxylate oxygen atoms [O(1) and O(2)] from two isophthalate ligands that occupy *cis* positions, and four nitrogen atoms [N(1), N(2), N(3) and N(4)] from two chelating bipy groups. The Mn—N (bipy) average bond length is 2.265 Å while the Mn—O(carboxylate) average bond length is 2.125 Å. These bond distances are in agreement with those in the structures of $[Mn_2(bipy)_4(ta)]_n[ClO_4]_{2n}$ (bipy = 2,2′-bipyridine; ta = terephthalate) [10], and $[Mn_4(o\text{-phth})_2(bipy)_8][ClO_4]_4\cdot 3H_2O$ (*o*-phth = phthalate) [9]. Large deviations of bond angles from 90° of the idealized octahedral geometry are found for angles N(1)—Mn(1)—N(2) [71.8(2)°] and N(3)—Mn(1)—N(4) [72.4(2)°] which are restricted by the bipy five-membered chelate ring. So the Mn ion has a distorted octahedral coordination sphere. The best equatorial plane is defined by atoms O(1), N(2), N(3) and N(4). The largest deviation from the mean plane is 0.216 Å for N(4) and the Mn atom is 0.109 Å out of this plane. The dihedral angle between the benzene ring of the isophthalate and the equatorial plane of the Mn octahedron is 83.68°. The Mn atom and all atoms of the bridging isophthalate are coplanar [largest deviation from the mean plane 0.61 Å for O(1A)]. Each bipy ligand is coplanar, and the dihedral angle between two bipy mean planes is 91.74°.

The perchlorate groups have their expected tetrahedral geometry.

Magnetic properties

The temperature dependence of the molar magnetic susceptibility and magnetic moment per two Mn^{II} ions unit of the title complex in the form of χ_M versus T and μ_{eff} versus T are shown in Fig. 3a and b. The effective magnetic moment per two Mn^{II} ions unit of $[Mn_2(bipy)_4(m\text{-phth})][ClO_4]_2 \cdot 4H_2O$ at 300 K is 8.34 B.M. which is close to the spin-only value of 8.36 B.M. expected for two uncoupled high-spin Mn^{II} ions.

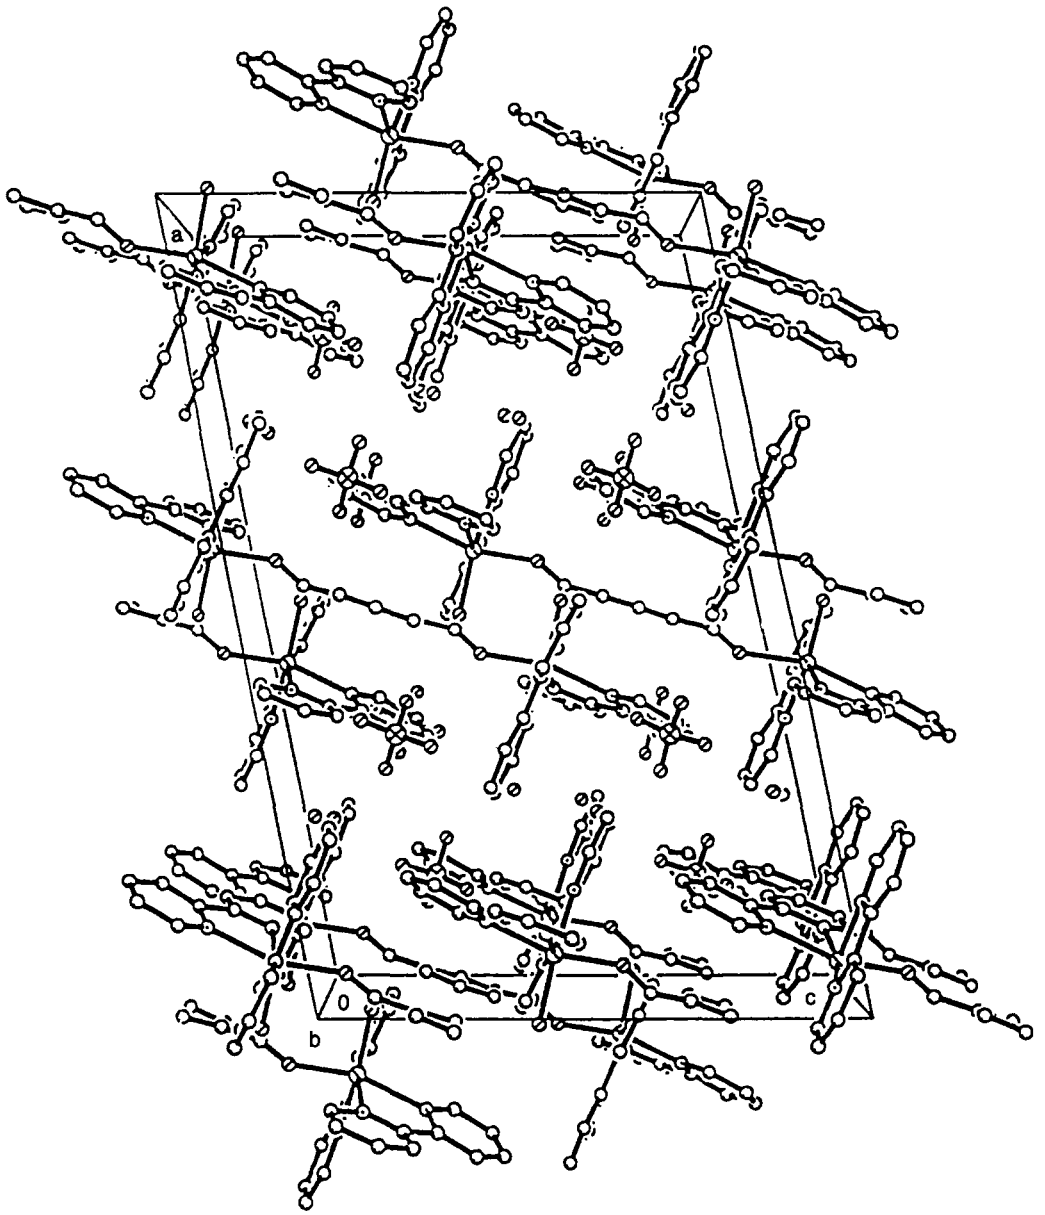

Fig. 2. Unit cell and packing diagram for $[Mn_2(bipy)_4(m\text{-phth})]_n[ClO_4]_{2n} \cdot 4nH_2O$.

When the temperature is lowered, the magnetic moment value decreases steadily from 8.34 B.M. at 300 K to 7.05 B.M. at 28.17 K and to 3.46 B.M. at 4.54 K, showing the presence of weak antiferromagnetic spin-exchange interactions between high-spin Mn^{II} ions through the double carboxylate and the extended isophthalate bridges.

The magnetic behaviour of the chain manganese(II) complex is quite complicated by exchange interactions, low-symmetry ligand field and g-tensor anisotropy. As can be seen in other cases, the single-ion zero-field splitting D and rhombic splitting parameter E for Mn^{II} ions are small and can be negligible [8,9,11]. We attempted to interpret this magnetic system for the title complex by using the Heisenberg–Dirac–Van Vleck $S_A = S_B = \frac{5}{2}$ spin-coupled dimer model ($H = -JS_AS_B$). For the two Mn^{II} dimers bridged by two carboxylate groups respectively, there must be separated J values, but to the first approximation, they were considered as the same. The expression of magnetic susceptibility [12] of the title complex is

$$\chi_M = 2Ng^2\beta^2/kT[(e^x + 5e^{3x} + 14e^{6x} + 30e^{10x} + 55e^{15x})/(1 + 3e^x + 5e^{3x} + 7e^{6x} + 9e^{10x} + 11e^{15x})] \quad (1)$$

where N, g, β, x are the Avogardro's number, g-factor, Bohr magneton, and $x = J/kT$, respectively, and J is the exchange coupling constant within the Mn^{II} dimer with double carboxylates in the *syn–syn* conformation.

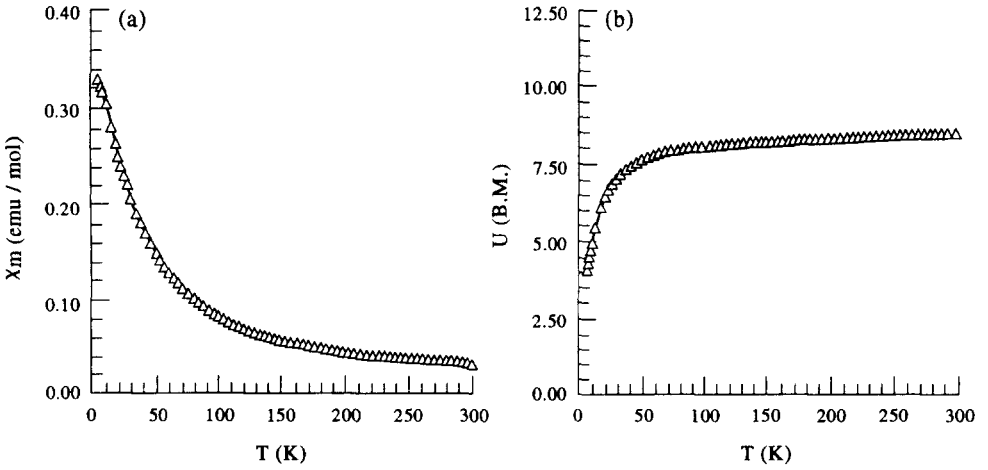

Fig. 3. Experimental (△) and calculated (-) temperature dependent molar magnetic susceptibility (a) and effective magnetic moment (b) per two Mn^{II} ions unit of $[Mn_2(bipy)_4(m\text{-path})][ClO_4]_2 \cdot 4H_2O$.

A molecular field (zJ') [8,13], representing intrachain Mn^{II} ions (through the extended bridging isophthalate) and interchain Mn^{II} ions magnetic interactions, was added to account for the actual nature of the compound. Thus the expression for the magnetic susceptibility of the title complex becomes

$$\chi_M' = \chi_M/[1-2zJ'\chi_M/Ng^2\beta^2] \quad (2)$$

Using Eq. (2), the least-squares fit to the magnetic susceptibility data gives the parameters: $J = -0.98$ cm^{-1}, $zJ' = -0.03$ cm^{-1} and $R = 2.9 \times 10^{-4}$ $[R = \Sigma(\chi_{calc}-\chi_{obs})^2/\Sigma(\chi_{obs})^2]$, assuming $g = 2.0$. The J value indicates a weakly antiferromagnetic exchange coupling within the manganese(II) dimer while the zJ' value reflects very weakly antiferromagnetic interactions.

The nature of the magnetic coupling within the Mn^{II} dimer for the title complex is similar to that of the Mn^{II} chain complex bridged by terephthalate (weak antiferromagnetic, $J = -1.35$ cm^{-1}) and most other triply and doubly bridged carboxylate Mn^{II} complexes [10].

Lanthanide(III) complexes with bidentate biheterocyclic ligands

P. Thakur, V. Chakravortty and K. C. Dash*

Department of Chemistry, Utkal University, Bhubaneswar 751004, India

(Received 24 May, 1996; accepted 12 September 1996)

Abstract—Eight lanthanide thiocyanate complexes of the type $[Ln(NCS)_3(PBH)_2]$ and $[Ln(NCS)_3(MPB)_2]$, where Ln = La, Pr, Nd, Sm, Eu, Gd, Dy and Y and PBH and MPB are 2-(2-pyridylbenzimidazole) and 1-methyl-2-(2′-pyridyl)benzimidazole, respectively, have been synthesized and characterized by various physicochemical techniques such as conductance and thermogravimetric studies, electronic, IR, NMR (^1H and ^{13}C), EPR, CV and fluorescence spectral investigations. The $\nu(C{\equiv}N)$ of the thiocyanate group indicates N coordination in all cases. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: lanthanide complexes; EPR; NMR; fluorescence spectra; thermogravimetric analysis; cyclic voltammetry.

The trivalent lanthanide ions have very specific spectroscopic and magnetic properties which make them ideal as probes in studies of a wide variety of chemical, biological and environmental systems [1,2]. Imidazole and its derivatives are biologically significant. The ligand 2-(2′-pyridyl)benzimidazole (PBH) has aroused considerable interest because of its structural similarity to the widely studied 2,2′-bipyridine, 1,10-phenanthroline, 2,2′-biimidazole, *etc.*, in containing the —N=C—C=N— group. The ligand acts as a powerful bidentate chelating agent [3,4] and has been found to form stable complexes with various transition metal ions [5–7]. However, the literature is quite scarce in dealing with the various aspects involving different physicochemical properties and complexation behaviour of its N-methylated analogue 1-methyl 2-(2′-pyridyl)benzimidazole (MPB). Substituted pyridyl benzimidazoles can act as very good coordinating agents [8]. Substituents in the ring effect the electronic distribution and consequently the coordinating ability of its derivatives. The ligand 1-methyl-2-(2′-pyridyl)benzimidazole (MPB) was synthesized by condensation of *N*-methyl-*o*-phenylene diamine with picolinic acid in polyphosphoric acid (PPA) or by refluxing in HCl [9]. The ligand has been recommended as a suitable reagent for the spectrophotometric determination of Fe^{II} [10]. MPB has a lower melting point than its unsubstituted derivative PBH, owing to the absence of intermolecular hydrogen bonding. The fluorescence spectra [11] in ethanol and prototropic equilibria [12] in aqueous solution of MPB have been reported. The lanthanide complexes of PBH and MPB have not hitherto been reported. Earlier work from this laboratory dealt with complexes of U^{VI} and Th^{IV} with related 1,2-diamine ligands such as PBH [13], 2,2′-bi-imidazole (H_2Biim) [14] and 1,1′-dimethyl-2,2′-biimidazole (DMBIm) [15]. In order to understand the coordination chemistry of lanthanides, we report here the synthesis and characterization of complexes with the novel bidentate biheterocyclic ligands PBH and MPB.

EXPERIMENTAL

Hydrated metal nitrates (Indian Rare Earths Ltd; 99.90% pure) were used as received. Methanolic solutions of metal thiocyanates were obtained by metathesis of the respective metal nitrates with stoichiometric amounts of KNCS. Physical measurements were carried out as reported earlier [13,14]. ^1H and ^{13}C NMR spectra of the ligand and its coordination complexes were obtained using Bruker 400 MHz AMX and 270 MHz FTNMR instruments, respectively. Fluorescence spectra of the complexes were recorded using a Shimadzu spectrofluorophotometer RF-510. Electronic spectra were

* Author to whom correspondence should be addressed.

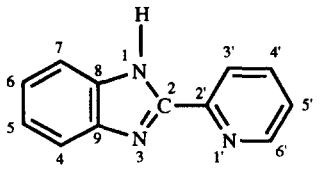
recorded on a Beckmann DU-640B spectrophotometer; EPR and CV were recorded on Varian E-4 spectrometer and Polarecord E-506 (Metrohm), respectively. The metal ion was determined by EDTA titration using xylenol-orange as indicator.

Syntheses of ligands PBH and MPB

The ligand PBH was prepared as reported earlier [9]. The preparation of MPB from PBH is as follows: 1.5 cm^3 (15 mmol) of dimethyl sulfate (DMS) was added dropwise to a well stirred suspension of powdered NaOH (2.357 g, 60 mmol), PBH (1.95 g, 10 mmol) and tetrabutyl ammonium bromide (0.19 g, 4 mol%), (TBAB, used as a phase transfer catalyst) in dioxane (25 cm^3). Stirring at room temperature was continued for 30 min and the reaction was monitored by TLC. The mixture was filtered, washed with ethyl acetate and the combined washings along with the filtrate were treated with a 1:1 aqueous ammonia solution to remove excess DMS. The volume of the resultant solution was reduced to 5–10 cm^3 and was stored at 4°C for about 2 h. The orange-red oily liquid was washed with hexane and the light yellow washings were cooled to give colourless crystals of MPB. These were filtered, washed with the minimum amount of hexane and finally dried in air. Yield: 1.01 g (48%). M.p. 62°C (lit. 64–65°C) [11]. Found: C, 74.3; H, 5.2; N, 19.9; Calc. for MPB ($C_{13}H_{11}N_3$): C, 74.6; H, 5.3; N, 20.1%: MS: *m/z* 209.

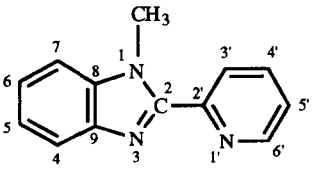
Syntheses of complexes

Both types of complexes $[Ln(NCS)_3(PBH)_2]$ and $[Ln(NCS)_3(MPB)_2]$, were synthesized by refluxing methanolic solutions of the ligands (PBH or MPB) and the corresponding metal salts in stoichiometric amounts at 70–80°C for 4 h. The solid complexes were filtered off and washed with small aliquots of methanol followed by diethyl ether, recrystallized from methanol and finally dried *in vacuo*.



RESULTS AND DISCUSSION

The bidentate chelating ligand 2-(2′-pyridyl) benzimidazole (**I**) and 1-methyl-2-(2′-pyridyl) benzimidazole (**II**) interact with lanthanide ions to form well-defined complexes which are presented in Tables 1 and 2 along with relevant characterizing data. The IR and ^1H NMR spectra of the complexes suggest coordination of the ligands in a bidentate manner. The complexes are sparingly soluble in common organic solvents and the molar conductances of the complexes show them to be non-electrolytes [16,17]. A higher conductivity value for the complexes is observed in MeOH or Me_2SO, which may be owing to solvolysis of the complexes. The increase in molar conductivity of the complexes in the presence of added TOPO (trioctyl phosphine oxide) further suggests coordination of the anion to the metal ions.



The reported coordination complexes are insoluble in organic solvents such as benzene, nitrobenzene, bromoform, c-hexane, *etc.* with which cryoscopic measurements are usually done and hence, molecular mass determination of these complexes could not be made. These complexes are, however, soluble in methanol, acetone, acetonitrile, *etc.* It is speculated that they are monomeric in nature in which case the lanthanide ion would be seven coordinate and possible structures are monocapped octahedron [18], monocapped trigonal prism [19] or pentagonal bipyramid [20].

Electronic and IR spectra

The electronic spectra of all the complexes were recorded in methanol. In the UV region an intense band at 302–308 nm with one shoulder at 274–280 nm was attributable to an intraligand π–π^* transition. Visible spectra indicate that in lanthanide ions the 4*f* orbitals are effectively shielded by $5s^25p^6$ electrons and lines that appear in the absorption spectra arise from electronic transitions within the 4*f* levels. These transitions are normally forbidden, but become allowed when degeneracy in the 4*f* orbitals is removed by applying an external crystal field [21,22]. The absorption bands in the Pr^{III}, Nd^{III}, Sm^{III} and Dy^{III} complexes were recorded at 1×10^{-3} mol dm^{-3} in absolute methanol. The spectra of the complexes (Table 3) show a shift of the bands towards lower energy, compared with those of the aqua ions [23] owing to the nephelauxetic effect. The bonding parameter ($b^{\frac{1}{2}}$), the covalency parameter (δ) and the nephelauxetic parameter ($\bar{\beta}$) are less than unity, while Sinha's parameter (δ) is positive, indicating a moderate covalent character for the bond between the metals and ligands [24].

Table 3. Important *f–f* bands and their tentative assignments[a]

Complex	λ_{max} (cm^{-1})	Tentative assignments	Calculated spectral parameters
$[Pr(NCS)_3(MPB)_2]$	22,421	$^3H_4 \rightarrow {}^3P_2$	$\bar{\beta} = 0.997$
	21,276	$^3H_4 \rightarrow {}^3P_1$	$b_{\frac{1}{2}} = 0.041$
	20,661	$^3H_4 \rightarrow {}^3P_0$	$\delta = 0.341$
	16,778	$^3H_4 \rightarrow {}^1D_2$	
	13,297	$^3H_4 \rightarrow {}^1G_4$	
$[Nd(NCS)_3(MPB)_2]$	19,531	$^4I_{\frac{9}{2}} \rightarrow {}^2G_{\frac{9}{2}}$	$\bar{\beta} = 0.992$
	19,083	$^4I_{\frac{9}{2}} \rightarrow {}^2G_{\frac{7}{2}}$	$b_{1/2} = 0.063$
	17,182	$^4I_{\frac{9}{2}} \rightarrow {}^4G_{\frac{5}{2}}, {}^2G_{\frac{7}{2}}$	$\delta = 0.81$
	13,495	$^4I_{\frac{9}{2}} \rightarrow {}^4F_{\frac{9}{2}}$	
	13,333	$^4I_{\frac{9}{2}} \rightarrow {}^4F_{\frac{5}{2}}$	
	12,468	$^4I_{\frac{9}{2}} \rightarrow {}^4F_{\frac{3}{2}}$	
$[Sm(NCS)_3(MPB)_2]$	24,875	$^6I_{\frac{5}{2}} \rightarrow {}^4P_{\frac{9}{2}}$	$\bar{\beta} = 0.987$
	20,746	$^6I_{\frac{5}{2}} \rightarrow {}^4I_{\frac{9}{2}}$	$b_{1/2} = 0.08$
	15,197	$^6I_{\frac{5}{2}} \rightarrow {}^4I_{\frac{11}{2}}$	$\delta = 0.50$
$[Dy(NCS)_3(MPB)_2]$	20,491	$^6I_{\frac{15}{2}} \rightarrow {}^6F_{\frac{11}{2}}$	$\beta = 0.995$
	15,197		$b_{1/2} = 0.062$
			$\delta = 0.72$

[a]The covalence factors were calculated by the relations $\bar{\beta} = \nu$ (complex)/ν (aqua), $b_{1/2} = [1/2(1-\beta)]^{1/2}$ and $\delta = 100(1-\bar{\beta})/\beta$.

The IR spectra of ligands PBH and MPB and its complexes were recorded and prominent vibrations are presented in Tables 4 and 5. The spectra of the ligands and complexes are virtually identical except for the appearance of additional bands owing to the coordinated anion. The absorption bands in the region 3400–3045 cm^{-1} of the free ligand (PBH) and its metal complexes are assigned to N—H stretching frequencies [25]. Bands observed in the region 3170–3200 cm^{-1} and 2930–2860 cm^{-1} are assigned to the aromatic ν(C—H) and ν(C—H) of the N—CH_3 group, respectively. An intense band observed at *ca* 1637 cm^{-1} is due to the ν(C=N) stretching of the ligand. Appearance of this band at a lower frequency region in the complexes suggests coordination of the ligands through the nitrogen atom. Pyridine ring vibrations are observed as a weak band in the region 1500–1560 cm^{-1}. The in-plane deformation mode of the pyridine ring appears at *ca* 645 cm^{-1} [26,27] which indicates that the pyridine nitrogen and the nitrogen of the benzimidazole rings coordinate to lanthanide(III) ions.

The highly intense ν(C≡N) band in the region 2080–2040 cm^{-1} and ν(C—S) at *ca* 825 cm^{-1} [28,29] suggest the presence of a nitrogen-bonded isothiocyanate. A new band at *ca* 365 cm^{-1} in the far-IR

region of the complexes may be assigned to the metal–nitrogen stretching vibrations [30].

NMR spectra

The NMR (^1H and ^{13}C) spectra of the ligands and complexes in DMSO-d_6 and acetone-d_6 provide evidence in favour of bonding of the ligand to Ln^{3+}. The aromatic protons were observed as a complex multiplet in the region δ 7.22–8.68 in the ligand, which was shifted to δ 7.26–8.22 in the complexes. The observed downfield shift of the signals is a good indication of complex formation [31]. No pseudo-contact shift was, however, observed for paramagnetic lanthanide complexes.

The ^1H NMR spectrum of the ligand MPB in acetone-d_6 showed a multiplet in the region δ 7.26–8.67 [9]. The signal observed at δ 7.3 corresponded to the 5, 6, 3′ and 5′ protons. The signal corresponding to H(4) and H(7) was observed at δ 7.8. The doublets observed at δ 8.3 and 8.6 corresponds to H(4′) and H(6′), respectively. The methyl proton observed at δ 4.3 was shifted to δ 3.92 in the complexes. However, when the spectra were taken in DMSO-d_6 the N—CH_3 proton signal appeared at δ 4.3; i.e. there was no shift in the complexes.

The ^{13}C NMR chemical shifts of the ligands at δ 152.51, 143.40, 138.71, 124.62, 123.59, 123.23 and 122.51 correspond to the C(2), C(9), C(8), C(5), C(6), C(4) and C(7) atoms of the benzimidazole moiety, whereas the signals observed at δ 151.14, 149.54, 120.89 and 110.81 are assigned to C(2′), C(6′), C(3′, 5′) and C(4′) of the pyridine moiety of the ligand. The signal owing to 1—CH_3 is observed at δ 33.58. In DMSO-d_6 the corresponding ^{13}C signals are observed at δ 152.25, 143.02, 138.45, 124.34, 123.28, 122.27, 151.01, 149.36, 120.49, 110.38 and 33.42 and undergo a downfield shift.

Thermal behaviour

The TG technique has been used to follow the thermal behaviour of the ligand and the complexes. According to the results obtained, the complexes are not volatile and their decomposition commences only above 200°C, which indicates the absence of coordinated or lattice water. The final product of the decomposition was the lanthanide(III) oxide in all cases.

Fluorescence spectra

The solid fluorescence spectra of the complexes of Sm^{3+}, Eu^{3+} and Dy^{3+} with MPB are shown in Table 6 along with their assignments. These spectra exhibit the following attributes: in the spectra of $Eu(NCS)_3(MPB)_2$, the $^5D_0 \rightarrow {}^7F_0$ transition observed as a weak band at 575 nm existing as a single peak indicates the presence of only one site for the Eu^{3+} ion [2] the $^5D_0 \rightarrow {}^7F_1$ transition around 593 nm is separated into two bands (585.0, 590.0 nm) and the strong band appearing at *ca* 602 nm is assigned to the $^5D_0 \rightarrow {}^7F_2$ transition. The transition $^5D_0 \rightarrow {}^7F_3$ at 650 nm is of low intensity and can be reasonably taken as forbidden and the $^5D_0 \rightarrow {}^7F_4$ transition appears at 698 nm. The electric dipole transition $^5D_0 \rightarrow {}^7F_2$ is clearly stronger than the magnetic dipole transition $^5D_0 \rightarrow$

Table 6. The fluorescence data for solid Sm^{III}, Eu^{III} and Dy^{III} complexes with MPB

Complex	E_x (nm)	E_m (nm)	Assignments
MPB	308	425	
$[Sm(NCS)_3(MPB)_2]$	305	580	$^5D_0 \rightarrow {}^7F_2$
		620	$^5D_0 \rightarrow {}^7F_1$
		640	$^5D_0 \rightarrow {}^7F_4$
$[Eu(NCS)_3(MPB)_2]$	305	575	$^5D_0 \rightarrow {}^7F_0$
		593	$^5D_0 \rightarrow {}^7F_1$
		602	$^5D_0 \rightarrow {}^7F_2$
		698	$^5D_0 \rightarrow {}^7F_4$
$[Dy(NCS)_3(MPB)_2]$	305	574	$^4D_{\frac{7}{2}} \rightarrow {}^6F_{\frac{5}{2}}$
		481	$^4D_{\frac{7}{2}} \rightarrow {}^6F_{\frac{13}{2}}$

$^7F_1$ and this indicates the absence of inversion symmetry at the Eu^{3+} site.

The Sm complex shows weak metal ion luminescence and its emission spectrum exhibits three bands (Table 6). It is found that the fluorescence properties are in tune for each lanthanide ion.

Magnetic susceptibility and cyclic voltammetry

The observed magnetic moments of the complexes are close to those given by the Van Vleck equation indicating that the lanthanides in the complexes remain in the +3 oxidation state and the 4*f* electrons are little influenced by the ligands.

The cyclic voltammetry of the MPB complexes in acetonitrile solution shows two reduction waves, as illustrated in Fig. 1. For the Sm complex the first wave at −1.349 versus ($Ag/AgCl_{(s)}$, Cl^-) is reversible and has been assigned to the complexes Sm^{III}/Sm^{II} couple (see Table 7). The second wave is presumed to be a ligand-based reduction. The other redox potential values are attributed to the redox behaviour of the ligands.

EPR spectra

The EPR spectra of the Gd^{3+} complexes in the solid state and in solution (DMSO) were recorded both at room (303 K) and liquid nitrogen temperature (77 K). The "*g*" values calculated from the spectra are presented in Table 8. The following conclusions can be drawn from the spectra.

1. Each formula unit contains one Gd^{3+} ion with spin–spin interactions that cause excessive Gaussian broadening of the EPR lines in the solid phase, both at low temperature and room temperature. It is impossible to extract the zero field splitting features.
2. The high concentration of Gd^{3+} in the solution gives rise to line broadening due to spin–spin relaxation.
3. The intensity of the low field line, being almost the same as that of the high field line, indicates a large zero-field splitting [2,32].
4. In some cases two types of spectra are observed: those with relatively narrow symmetric peaks and those with broad symmetric peaks, in accordance with the work of Geraldes and Williams [33].

(Received 5 July 1996; accepted 10 September 1996)

Abstract—The reaction of $Na[Co(CO)_4]$ with PyS–(2-mercapto-pyridine) in THF at room temperature gave a dark crystalline product $[Co_5(CO)_2(\mu_3\text{-}S)_3(SC_5H_4N)_7]$ (**1**). The crystal structure of **1** determined by single crystal X-ray diffraction, revealed a pentanuclear metallic core, $Co_5(\mu_3\text{-}S)_3(\mu\text{-}S)_4(\mu\text{-}C)$, which can be described as a skeleton comprising three incomplete cubane-like structural units, two SCo_3S_3 and a SCo_3S_2C, in an inversion arrangement sharing two rhombic CoS_2Co faces or, in other words, as a raft-type structure consisting of fused $Co_3(\mu\text{-}S)$ units. The geometry around each Co atom is a distorted octahedron and the octahedra are divided into four types according to the different coordination environments. The three Co—Co bond distances of 2.72–2.80 Å indicate weak metal–metal interactions. The formal oxidation states of the five cobalt atoms are one Co^{I} and four Co^{III}. The formation of **1** is discussed and the cyclic voltammetry of **1** has been measured. Interestingly, **1** contains three inorganic μ_3-S atoms notwithstanding the absence of inorganic S^{2-}source in the synthetic reaction system, implying a process related to desulfurization of 2-mercaptopyridine in the preparative reaction. © 1997 Elsevier Science Ltd. Keywords: cobalt–sulfur; raft cluster; $Co_3(\mu_3\text{-}S)$ unit; structure; cyclic voltammetry.

The chemistry of cobalt–sulfur compounds has been significant with regard to hydrogenation, hydroformylation and hydrodesulfurization catalysis. As part an investigation of the effect of various organosulfur compounds on both hydrogenation and hydroformylation of olefins, a large number of unusual polymeric cobalt carbonyl sulfur complexes [1–18] have been produced by the reaction of dicobalt octacarbonyl with sulfur or sulfur-containing reagents and characterized by X-ray crystallography; most of the complexes contain $Co_3(\mu_3\text{-}S)$, $Co_4(\mu_4\text{-}S)$ and $Co_2(\mu\text{-}S)$ units. As part of our studies on the chemistry of transition metal–sulfur complexes containing low- and mixed-valence metal atoms, we report herein a novel pentanuclear cobalt–sulfur cluster compound with a raft-type structure consisting of fused $Co_3(\mu_3\text{-}S)$ units.

EXPERIMENTAL

Materials and methods

THF was distilled from $LiAlH_4$, $Co_2(CO)_8$ and PySH were purchased from Aldrich. All the procedures were carried out under nitrogen using the Schlenk technique.

IR spectra were recorded on a Perkin–Elmer 577 IR spectrometer.

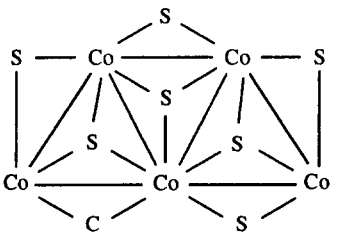
Cyclic voltammetry (CV) measurements were carried out with a three-electrode cell using 0.1 M Bu_4NF_4 as the supporting electrolyte and MeCN as solvent. The working electrode was a glassy carbon and the reference electrode was an aqueous SCE separated from the sample solution by a salt bridge. Solutions were deoxygenated and blanketed with nitrogen and the potentiostat was a CV-1B from BAS (Bioanalytical System).

Synthesis of $Co_5(\mu_3\text{-}S)_3(CO)_2(SC_5H_4N)_7$ **(1)**

A mixture of $Co_2(CO)_8$ (0.34 g, 1 mmol), NaOH (0.40 g, 10 mmol) in THF (40 cm^3) was stirred at room temperature overnight, resulting in a light yellow solution with a purple precipitate. After filtering off the precipitate, to the filtrate was added Et_4NCl (0.33 g, 2 mmol) and PySH (0.22 g, 2 mmol) and the reaction mixture was stirred at room temperature giving a bright yellow solution with a white precipitate. The reaction mixture was stirred at 40°C for another 2 h, resulting in a brown–yellow solution. After filtering off the white residue and removing the solvent by pumping nearly to dryness, the nearly dry residue was dissolved in EtOH (30 cm^3) giving a brown solution. A small amount (0.1 g) of dark brown crystals was obtained after cooling the solution at 4°C for several weeks. The IR spectrum of **1** (KBr pellet) showed besides the characteristic absorptions of the PyS ligands, two strong bands at 1810 and 1930 cm^{-1} indicating the existence of carbonyls and a weak band at 450 cm^{-1} which might be the stretching vibrational frequency of a metal-bridging sulfur bond. In fact, the X-ray crystal structure determination verifies that **1** contains two carbonyl ligands and three μ_3-S atoms. After filtering off the crystalline product **1**, a little air was added to the filtrate and the resulting filtrate was cooled at 4°C for 24 h, and another crystalline product, $[Et_4N][Co(PyS)_3]$ **(2)**, was obtained which has been previously characterized by X-ray crystallography [19].

X-ray crystal structure determination of **1**

A single crystal of **1** having dimensions of $0.30 \times 0.30 \times 0.40$ mm^3 was mounted on a glass fibre with epoxy cement. Data collection was performed on an Enraf–Nonius CAD4 computer-controlled kappa diffractometer utilizing graphite-monochromated Mo-K_α radiation ($\lambda = 0.71073$ Å) at room temperature. All calculations were performed on a VAX computer using the MOLEN program [20]. Compound **1** crystallizes in the monoclinic space group $P2_1/n$ with $a = 12.852(2)$, $b = 20.991(3)$, $c = 19.691(3)$ Å; $\beta = 100.14(4)°$; $V = 5229.3$ $Å^3$; $Z = 4$; $D_{calc} = 1.55$ g cm^{-3}. A total of 9926 reflections, of which 9903 reflections were unique, were collected in the range $0 \leqslant 2\theta \leqslant 50°$ using ω–2θ scan technique. Lorentz and polarization corrections were applied to the data and the linear absorption coefficient is 19.7 cm^{-1} for Mo-K_α radiation. No absorption correction was made. The structure was solved by direct methods. A total of eight atoms were located from an *E*-map and the remaining atoms were located in succeeding difference Fourier syntheses. Hydrogen atoms were not included in the calculations. The structure was refined in full-matrix least-squares where the function minimized was $w(\Sigma[F_o] - [F_c])$ and the weight w is defined as by the Killean and Lawrence method with terms of 0.020 and 1.0 [21]. Only the 7197 reflections having $I \geqslant 3\sigma(I)$ were used in the refinements. The final cycle of refinement included 550 variable parameters and converged with unweighted and weighted agreement factors of $R = \Sigma(|[F_o] - [F_c]|)/\Sigma[F_o] = 0.042$ and $R_w = [\Sigma w(F_o - F_c)^2/\Sigma w(F_o)^2]^{1/2} = 0.058$.



The estimated standard deviation of observation of unit weight was 1.04 and the highest peak in the final difference Fourier map was 0.71 e $Å^{-3}$.

A list of atomic coordinates and calculated thermal parameters have been deposited at the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

The structure and mixed-valence metal atoms of $[Co_5(\mu_3\text{-}S)_3(CO)_2(SC_5H_4N)_7]$ **(1)**

The bond distances and angles of complex **1** are listed in Tables 1 and 2, and the molecular structure of **1** is depicted in Fig. 1. As shown in Tables 1 and 2 and Fig. 1, the molecule of **1** contains a pentanuclear Co—S skeleton, $[Co_5(\mu_3\text{-}S)_3(\mu\text{-}S)_4(\mu\text{-}C)]^{3+}$ **(A)** consisting of three incomplete cubane-like cluster units, two Co_3S_4 and a Co_3S_3C, in an inversion arrangement to each other, sharing two rhombic CoS_2Co faces. Around the skeleton can be found four bridging PyS (five-electron donor), three terminal PyS (three-electron donor) and one terminal carbonyl ligand, resulting in six coordination of each cobalt atom. Interestingly, the five cobalt atoms in the molecule are in a raft geometry, where three Co_3 triangles are aligned linearly sharing their edges. Each Co_3 triangle is capped by an inorganic sulfur atom and each peripheral Co—Co edge is bridged by a sulfur atom from PyS except for one which is bridged by a carbon atom from a bridging carbonyl.

A

Although the three Co_3 triangles are not exactly coplanar (the dihedral angles between Co(1), Co(2), Co(5) and Co(5), Co(3), Co(2) and between Co(5), Co(3), Co(4) and Co(5), Co(3), Co(2) are 9.6 and 2.5°, respectively), it is obvious that the two capping sulfur atoms of the two terminal Co_3 triangles [Co(1), Co(2), Co(5) and Co(3), Co(4), Co(5)] are located at the opposite side of the capping sulfur atom of the central Co_3 triangle [Co(2), Co(3), Co(5)]. The capping and bridging atoms form two layers and the

Numbers in parentheses are estimated standard deviations.

cobalt atoms are sandwiched between them. This is the first example of a Co—S compound containing a raft geometry consisting of fused $Co_3(\mu_3\text{-}S)$ units, although a similar geometry of Mo atoms has been found in the Mo—S cluster compound, $[Mo_6S_{10}(SH)_2(PEt_3)_6]$ [22]. The Co—Co distances are 2.72, 2.73, 2.80, 2.89, 2.90, 2.91 and 3.03 Å. The three shorter Co—Co distances [Co(5)—Co(4), Co(5)—Co(3) and Co(5)—Co(2)] seem to indicate a somewhat weak metal–metal interaction although the 90 skeletal electrons have occupied the whole 45 orbitals of the five Co atoms. The Co—μ_3-S bond distances are 2.321(2)–2.382(2) Å, the Co—μ_2-S(PyS) bond lengths are 2.443(2)–2.512(2) Å and the Co—S(PyS) distances are 2.490(3)–2.580(3) Å. The irregularity of the Co—S and Co—Co bond distances implies the complicated electron structure of the cobalt atom centres and the possibility of the existence of mixed-valence cobalt atoms in the cluster compound. Carefully inspecting the coordination environment of each cobalt atom in the molecule it is evident that all the five cobalt atoms are different from each other. However, considering the sort of atoms around the cobalt atoms, the five cobalt atoms in the cluster could be divided into three groups: (i) Co(2), Co(3) and Co(4) atoms (which contain S and N as surrounding atoms); (ii) Co(5) which has a bridging C atom from a carbonyl ligand besides the S and N atoms as surrounding atoms; and (iii) Co(1), which possesses a carbon atom from a terminal carbonyl ligand in addition to bridging C, S and N atoms as surrounding atoms. Considering the unsymmetric bridging carbonyl between the Co(1) and Co(5) atoms [Co(1)—C(2) and Co(5)—C(2) bond distances are 1.91(1) and 2.53(1) Å, respectively] then Co(5) should be included in the group of Co(2), Co(3) and Co(4) atoms. However, it is worth pointing out that because of the existence of an unsymmetric bridging carbonyl ligand leading to the transfer of a pair of electrons on the Co(5) atom to the carbon atom, the Co(5) atom may vacate its one orbital to form metal–metal bonds with neighbouring Co atoms. This is probably the reason why the bond distances of Co(5)—Co(2), Co(5)—Co(3) and Co(5)—Co(4) are shorter than the others and could be considered as being a result of metal–metal interaction. This fact, perhaps, implies the existence of some electron transfer of Co → μ_3-S.

In connection with the different coordination environments of the cobalt atoms and the electric charge equilibrium of the neutral molecule there are, at least, two oxidation states of Co atoms in the molecule and, reasonably, the Co(2), Co(3), Co(4) and Co(5) atoms are in the oxidation state +3 and the Co(1) atom is in the +1 state. The fact that the Co(1) atom contains two carbonyls for stabilizing its low oxidation state supports the above suggestion.

Interestingly, the incomplete cubane-like Co_3S_4 structural units in **1** are configurationally similar to Fe_3S_4 units [23], which are of special interest owing to the more general significance of the 3 Fe sites in the Fe—S protein, *D. gigas* ferredoxin II [24] and are similar to the Mo_3S_4 units [25], which exhibits some aromaticity with d–p π conjugation like benzene and special reactivities [25–28].

Formation and cyclic voltammetry of **1**

According to the X-ray crystal structure of **1**, there are several conspicuous features: (i) the oxidation states of the cobalt atoms in **1** are higher than that in the starting material, cobalt carbonyls; (ii) there are three inorganic sulfur atoms, μ_3-S, in **1**. This implies that the formation of **1** involves the oxidation of cobalt atoms and hydrodesulfurization of 2-mercapto-pyridine(PyS) because of the lack of an in-

organic sulfur source of S^{2-} or S^{2-}-containing compound as starting material in the preparative reaction. As a reactant, the yellow solution obtained from the reaction of $Co_2(CO)_8$ with NaOH in THF at room temperature is, in fact, the $Na[Co(CO)_4]$ [29] with a lower oxidation state of the cobalt atom. Thus the formation of **1** is mainly due to the reaction of $[Co(CO)_4]^-$ with PySH. However, it cannot be excluded that existence of the higher valence cobalt compound with PySH is a result of the $Co_2(CO)_8$ in THF leading to the formation of $Co(THF)_6[Co(CO)_4]_2$ [30–32]. The synthetic reaction, beyond doubt, is so complicated that the yield of **1** is low and there are other products besides **1** in the reaction mixture. However, in the light of the structural features of **1** and the formation of the Co^{II} compound, $[Co(PyS)_3]^-$, by addition of a little air into the synthetic reaction solution [19], it appears that the precursor compounds are $[Co(CO)_x(PyS)_y]^{n-}$ ($x = 1$–4; $y = 1$–4 and $n = 0$–3), formed by reaction of different valent Co compounds with PySH, and the hydrodesulfurization of PyS^- is completed by cooperation of certain precursor compounds resulting in the formation of polynuclear cluster compounds containing inorganic μ_3-S atoms. Interestingly, a similar result, whereby the reaction of iron pentacarbonyl with PySH or dithiocarbamate results in a trinuclear iron–sulfur–carbonyl complex containing an inorganic μ_3-S atom, $[Fe_3S(CO)_9]^{2-}$, has been found [33]. This seems to imply that the formation of μ_3-S, containing cluster compounds is essential to hydrosulfurization. These μ_3-S-containing cluster compounds formed following the hydrodesulfurization would be advantageous to understanding the hydrodesulfurization and looking for highly effective hydrodesulfurization catalysts.

The cyclic voltammograms of **1** in acetonitrile are shown in Fig. 2. There is a redox couple at *ca* −0.12 V *vs* SCE (−0.09 V/−0.15 V) (Fig. 2a). With reference to the electrochemical data of the cobalt ion and PySH [34], it is apparent that this event is not the redox of the simple cobalt ion or PyS ligand and should reflect the electrochemical behaviour of the whole cluster compound **1** as in Eq. (1),

$$[Co_5(\mu_3\text{-}S)_3(CO)_2(SC_5H_4N)_7]^0 \underset{-e}{\overset{+e}{\rightleftharpoons}} [Co_5(\mu_3\text{-}S)_3(CO)_2(SC_5H_4N)_7]^- \quad (1)$$

However, the redox couple at −0.12 V *vs* SCE disappeared and oxidation peaks at +0.56 and 0.81 V *vs* SCE appeared when the positive scan went to +1.4 V *vs* SCE (Fig. 2b). This indicated that **1** decomposed and chemical reaction took place in the solvent under this higher potential.

(Received 10 April 1996; accepted 5 September 1996)

Abstract—Mo–Cu–Se complexes with cubane-like cores $\{MoCu_3Se_3X\}$, $[\{MoCu_3Se_3X\}(PPh_3)_3Se]$ (X = Cl, Br, I) have been synthesized from CuX, $MoSe_4^{2-}$ and PPh_3 in appropriate conditions and characterized by IR, ^{31}P NMR, ^{95}Mo NMR and UV–vis electronic spectra. The structure of $[\{MoCu_3Se_3Cl\}(PPh_3)_3Se]$ has been determined by X-ray single crystal diffraction analysis. The structure contains a strongly distorted cubane-like $\{MoCu_3Se_3Cl\}$ core. Each Cu centre is bonded tetrahedrally to one P, one Cl and two Se atoms and the Mo centre is bonded tetrahedrally to four Se atoms. The mean Mo—Cu distance is 2.749(5) Å. The ^{95}Mo NMR spectra of the title compounds along with $[Ph_4P]_2MoSe_4$ consist of one single resonance in the range of δ = 1303–3145 ppm. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: Mo–Cu–Se complexes; cubane-like; syntheses; crystal structure; NMR spectra; IR and UV–vis spectra.

Transition metal cluster compounds that contain sulfur donor ligands have been an active area of research for many years, especially in the chemistry of thiometalates [1]. Much of this interest is generated by efforts to model both biological systems [2] and industrial catalysts used for hydrodesulfurization processes [3]. However, the research on the corresponding chemistry of transition metal selenides has been carried out only in the last few years [4,5]. That some of the coordination chemistry of metal selenides parallels that of metal sulfides has been confirmed by several recent results [4].

Because of the lone-pair electrons and unsaturated coordination in the complex ion MS_4^{2-} (M = Mo, W), several different structural types of polynuclear complexes have been obtained from soft acids, such as the coinage-metal cations Cu^+ and Ag^+, and thiometalates in the presence of ligands like PPh_3, R_2NCS_2. Several interesting structural types such as linear, cage, cubane-like and double cubane-like have been studied in detail [6–10]. However, studies of their selenium analogues are limited. In the Cu(Ag)/WSe_4^{2-} system, a few compounds have been reported [11–15]. However, in the Cu(Ag)/$MoSe_4^{2-}$ system, surprisingly few complexes have been characterized [15–17]. As part of our interest in Mo(W)–Cu(Ag) cluster compounds, we have isolated a series of Mo(W)–Cu–S compounds with different structural types, such as $[M(CuL)_nS_4]^{2-}$ (M = Mo, W; n = 1–3) [8–20], $[M_2Cu_4S_6E_2(L)_2]^{2-}$ [21], $[M_2Cu_5S_6E_2(L)_3$ [2–10,22] (L = R_2dtc) and $[MoCu_{10}S_4Cl_{12}]^{4-}$ [23]. Recently, we have begun to explore the chemistry of the Mo(W)–Cu(Ag)–Se system, and obtained a cubane-defect or so-called "string bag" cluster compound, $[Ph_4P]_2\{MoCu_3Se_3Cl_3(Py)\}O$ [24]. In this paper, we report the syntheses and spectroscopic properties of cubane-like cluster compounds, $[\{MoCu_3Se_3X\}(PPh_3)_3Se]$, X = Cl, (**1**); X = Br, (**2**); X = I, (**3**), and the crystal structure of (**1**) is also described.

EXPERIMENTAL

All operations were carried out under dinitrogen. Solvents and reagents were degassed by repeated

* Author to whom correspondence should be addressed.

evacuation and flushing with pure dinitrogen before use. $Cu(PPh_3)_3Br$ was prepared according to literature methods [25]. The reagents and solvents used were purchased as AR grade. Elemental analyses were carried out by the Elemental Analysis Laboratory in our Institute. The visible and UV electronic spectra were recorded on a Shimadzu UV-3000 spectrophotometer. IR spectra were obtained on a Digilab FTS-40 spectrophotometer. ^{31}P and ^{95}Mo NMR data were measured on a Varian Unity-500 spectrometer, relative to 85% H_3PO_4 acid and 2 mol dm^{-3} Na_2MoO_4 in D_2O, respectively.

Preparation of $[Ph_4P]_2MoSe_4$

$[Ph_4P]_2MoSe_4$ was prepared by a modification of the literature method [26]. $Mo(CO)_6$ (1.32 g, 5 mmol) was added to the fresh slurry of Na_2Se_x, prepared from heating selenium powder (1.58 g, 20 mmol) and sodium (0.25 g, 10 mmol) in 50 cm^3 of DMF solution. After the reaction solution was heated at about 80°C for 0.5 h, Ph_4PBr (4.19 g, 10 mmol) was added, and the solution filtered. An equal volume of THF was added, and, after storage at 4°C overnight, the product as blue–purple crystals was isolated. Yield: 3.28 g (60.2%). IR (KBr, cm^{-1}): 341.2(s): ^{95}Mo NMR (ppm): δ 3145.

Synthesis of $[\{MoCu_3Se_3Cl\}(PPh_3)_3Se]$ (**1**)

A suspension of CuCl (0.075 g, 0.75 mmol) in CH_2Cl_2 (10 cm^3) was added with stirring to a solution of $[PPh_4]_2MoSe_4$ (0.28 g, 0.25 mmol) in CH_2Cl_2 (10 cm^3). The deep blue solution turned brown immediately and a precipitate formed. Then an excess of PPh_3 (0.53 g, 2.0 mmol) was added to bring the resulting precipitate into solution. After the reaction mixture was stirred for *ca* 1 h at room temperature, a reddish brown filtrate was collected. The filtrate was diffused by diethyl ether vapour and X-ray-quality crystals of **1** as dark-red blocks were obtained after several days. Yield: 0.218 g (59.6%). Found: C, 45.3; H, 3.1; P, 7.0; Cu, 13.8; Mo 7.1. Calc. for $C_{54}H_{45}ClCu_3MoP_3Se_3$: C, 45.5; H, 3.2; P, 6.5; Cu, 13.4; Mo, 6.7%. IR (KBr, cm^{-1}): 1479.1 vs, 1434.6 vs, 1095.5 vs, 744.2 vs, 703.9 vs, 691.5 vs, 512. 6 vs, 505.8 vs, 492.6 vs, 383.3 s, 329.9 s.

Synthesis of $[\{MoCu_3Se_3Br\}(PPh_3)_3Se]$ (**2**)

$Cu(PPh_3)_3Br$ (0.70 g, 0.75 mmol) in CH_2Cl_2 (10 cm^3) was added to a CH_2Cl_2 solution (10 cm^3) of $[Ph_4P]_2MoSe_4$ (0.28 g, 0.25 mmol). The resulting brown solution was stirred for 1 hour at room temperature and subsequently filtered to afford a reddish brown filtrate. Black–red crystals of **2** were obtained over several days by layering the filtrate with THF. Yield: 0.157 g (41.6%). Found: C, 43.8; H, 3.2; P, 6.9; Cu, 13.5; Mo, 6.5. Calc. for $C_{54}H_{45}BrCu_3MoP_3Se_3$: C, 44.1; H, 3.1; P, 6.3; Cu, 13.0; Mo, 6.5%. IR (KBr, cm^{-1}): 1478.8 vs, 1434.4 vs, 1095.1 vs, 744.2 vs, 703.8 vs, 691.3 vs, 521.3 vs, 505.5 vs, 491.8 vs, 384.8 s, 329.3 s.

Synthesis of $[\{MoCu_3Se_3I\}(PPh_3)_3Se]$ (**3**)

A clear CH_2Cl_2 (10 cm^3) solution of CuI (0.15 g, 0.75 mmol) and PPh_3 (0.59 g, 2.25 mmol) was slowly added to a solution of $[PPh_4]_2MoSe_4$ (0.28 g, 0.25 mmol) in CH_3CN (10 cm^3), then stirred for a while. After filtering, Pr^iOH (2 cm^3) was added. The filtrate was kept at the room temperature and black–red crystals of **3** were obtained the next day. Field: 0.176 g (45.2%). Found: C, 42.3; H, 3.1; P, 6.4; Cu, 13.1; Mo, 7.1. Calc. for $C_{54}H_{45}ICu_3MoP_3Se_4$: C, 42.7; H, 3.0; P, 6.1; Cu, 12.6; Mo, 6.3%. IR (KBr, cm^{-1}): 1479.3 vs, 1432.3 vs, 1095.5 vs, 740.9 vs, 704.7 vs, 691.4 vs, 521.3 vs, 503.9 vs, 489.1 vs, 381.4 s, 323.9 s.

Crystallographic structure determination

A selected single crystal of compound **1** with dimensions $0.4 \times 0.15 \times 0.15$ mm^3 was mounted on a glass fibre and the cell dimensions were obtained by a least-squares fit of setting angles for 25 reflections. Diffraction data were collected on an Enraf–Nonius CAD4 diffractometer using graphite-monochromated Mo-K_α ($\lambda = 0.71073$ Å) radiation. The scan mode was ω–2θ. A total of 5156 independent reflections were collected in the range $1 \leqslant \theta \leqslant 25°$ and 2943 observed reflections with $I \geqslant 3\sigma(I)$ were used for further computation.

All calculations were performed on a COMPAQ 486 computer with MOLEN/PC program package [27] and the hydrogen atoms were not included in the calculations. Non-hydrogen scattering factors were taken from Cromer and Waber [28]. Intensity data were corrected for Lorentz and polarization effects and empirical absorption based on Ψ-scans. The coordinates of the metal atoms were determined by direct methods and all the remaining non-hydrogen atoms were located from successive difference Fourier syntheses. The structure was refined by full-matrix least-squares techniques with anisotropic thermal parameters for the non-hydrogen atoms. The crystal and refinement data for the complex are shown in Table 1, together with some experimental details.

The important bond lengths and bond angles for the complex are given in Tables 2 and 3, respectively.

RESULTS AND DISCUSSION

Synthesis

In the present reaction system of $MoSe_4^{2-}$, CuX and phosphine in CH_2Cl_2, the neutral complexes CuX (X = Cl, Br, I) coordinate to the $MoSe_4^{2-}$ anion in a

Mo : Cu ratio of 1 : 3 to yield the Mo–Cu–Se–X compounds as the first step:

$$[Ph_4P]_2MoSe_4 + 2CuX \rightarrow (Ph_4P)_2[MoSe_4(CuX)_3] \quad (1)$$

The reaction occurred very rapidly and the resulting compound was nearly insoluble in CH_2Cl_2. Addition of a phosphine to the reaction system caused the products to dissolve at the second step. It is possible that the PPh_3 ligands, which are highly soluble in CH_2Cl_2, substitute Cl^- ions and that the $\{MoSe_4Cu_3(PPh_3)_3\}^+$ produced is dissolved. In the presence of the released Cl^- ion, the distorted cubane-like complexes are formed:

$$(Ph_4P)_2[MoSe_4(CuX)_3] + PPh_3 \longrightarrow [MoSe_4(CuPPh_3)_3X] + 2Ph_4PX \quad (2)$$

From the reaction mechanism mentioned above based on experimental phenomena, excess PPh_3 ligands should increase the yield of the title compound.

Moreover, when a phosphine-substituted Cu^+ species is added to $[Ph_4P]_2MoSe_4$ in a similar or identical condition, the same results can be obtained, the reaction requiring only one step:

$$[Ph_4P]_2MoSe_4 + 3Cu(PPh_3)_3X \longrightarrow [MoSe_4(CuPPh_3)_3X] + 2Ph_4PX + 6PPh_3 \quad (3)$$

However, the yield of the title complexes is much lower than that in the two-step reaction.

Structure of $[\{MoCu_3Se_3Cl\}(PPh_3)_3Se]$ (**1**)

The molecular structure of compound **1** is shown in Fig. 1. The structure is the same as that previously reported SOWKEU [17] but with an improvement. The compound possesses a stronger distorted cubane-like core $\{MoCu_3Se_3Cl\}$. Examples of related cubanes containing different MoS_4^{2-} moieties are known [6,7,11,15,16]. In the core of $\{MoCu_3Se_3Cl\}$, both the Cu and Mo atoms are tetrahedrally coordinated. Each Cu centre is bonded tetrahedrally to one P, one Cl and two Se atoms, and the Mo centre is bonded tetrahedrally to four Se atoms. The title compound presents two kinds of Cu—Cl bond distance, one short Cu—Cl bond [2.430(9) Å] and two long Cu—Cl bonds [av. 2.708(9) Å], which is different from the $\{MoAg_3S_3Cl\}(PPh_3)_3E'$ (E′ = O,S) cluster [8,9], with three long Ag—X bonds. The Mo—Cu interactions of 2.736(5), 2.768(5) and 2.743(5) Å with an average value of 2.749 Å, are approximately the same as those for $\{MoCu_3S_3Cl\}(PPh_3)_3S$ [8]. In general, the trends in bond distances and angles in Tables 2 and 3 parallel those observed in earlier analogous structures [7,11].

Spectroscopy

In the Mo(W)–Cu(Ag)–S compounds, both infrared and electronic spectroscopy was of use in characterization of products, but their usefulness in the Mo(W)–Cu(Ag)–Se compounds was more limited. The small differences in the bond distances of the three Cu—P [2.200(9), 2.219(8), 2.232(9) Å] are shown in the IR spectra, in which the vibrational stretches appear at 513, 506 and 493 cm^{-1}. The Mo—Se and Cu—Se vibrations are observed in the IR spectra in the range 280–385 cm^{-1} and cannot be easily distinguished from one another. The terminal Mo—Se absorption at 385 cm^{-1} of the title compound is blue shifted, compared with that of Mo—Se in $MoSe_4^{2-}$ (ν = 341 cm^{-1}): however, the bridge Mo—Se vibrations at 330 cm^{-1} are red shifted compared with

[a] In DMF.
[b] In CH_2Cl_2.

that in $MoSe_4^{2-}$, which is owing to coordination of the Cu atoms to $MoSe_4^{2-}$. The title compound in solution has an intense band at 200–500 nm in its absorption spectra, typically a very intense peak at 268 nm ($\varepsilon = 2.9 \times 10^4$ M^{-1} cm^{-1}) and a broad peak at 373 nm ($\varepsilon = 6.8 \times 10^3$ M^{-1} cm^{-1}). The charge transfer bands inferred in the region are owing to π(Se) $\rightarrow$ d(Mo) arising from the $MoSe_4^{2-}$ moiety and a relatively weak ligand $d(MoSe_4^{2-}) \rightarrow d(Cu^+)$ interaction [11]. Very similar results can be found in the other two compounds.

As opposed to electronic and infrared spectra, both ^{95}Mo and ^{31}P NMR spectra provide useful characterization of the Se present in the compounds. Since Cu^+ is a d^{10} system, the deshielding effect may result from orbital overlap. As the radius of the Se atom is larger than that of S, the orbital overlap between Cu and Se, Mo and Se can increase. The chemical shift in the ^{95}Mo NMR spectrum changes from δ 3145 in $MoSe_4^{2-}$ to δ 1302 for the title compound in CH_2Cl_2 solution. The chemical shift upfield from anion to complex in selenium is larger than that for the sulfido complex. The ^{31}P NMR resonances (Table 4) for the title complexes shows a single peak downfield from that of the free PPh_3 ligand, and the ^{31}P resonances shift upfield on going from Cl^- to I^-, a trend that can again be ascribed to a smooth increase in orbital overlap.

Trimetallic complexes containing nickel or palladium and two molybdenum nitrosyl groups

Stanley M. Kagwanja,* Christopher J. Jones† and Jon A. McCleverty‡

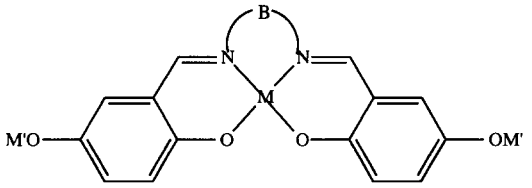
School of Chemistry, University of Bristol, Cantocks Close, Bristol BS8 1TS, U.K.

(Received 20 August 1996; accepted 3 September 1996)

Abstract—The reaction of $[Mo(NO)\{HB(dmpz)_3\}Cl_2]$ [$HB(dmpz)_3$ = tris(3,5-dimethylpyrazolylborate] with nickel(II) and palladium(II) Schiff-base complexes derived by condensation of two mole equivalents of 2,5-dihydroxybenzaldehyde with α,ω-diamines [1,2-$C_6H_4(NH_2)$, $NH_2(CH_2)_nNH_2$, n = 2–4 for Ni, n = 2 for Pd) affords trimetallic species. From cyclic, square wave and differential pulse voltammetric data it is shown that the species may be reduced to a dianion and that the sites of reduction are probably the two molybdenum nitrosyl fragments. From the electrochemical and limited EPR spectral data obtained from reduced species, it is clear that there is very weak electronic and minimal magnetic interaction between the redox centres. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: tris(pyrazolyl)borate; nitrosyl; molybdenum; redox-active; trimetallic.

In oxidizable and/or reducible complexes where the two metal centres are connected by a multiatom bridge, the redox behaviour of the two centres can be very strongly mediated by the coligands, be they bridging or peripheral. This is particularly so in compounds containing bipyridyls or quinones, where the ligands themselves are capable of redox activity [1]. Such redox behaviour offers the opportunity to study unusual mixed-valence compounds, and to generate electron-rich or -poor species with relevance to biomimetic and/or molecular electronic behaviour [2]. The now well-characterized and readily manipulated tris(3,5-dimethylpyrazolyl)molybdenum nitrosyls, $[Mo(NO)\{HB(dmpz)_3\}XY]$ afford a particularly convenient vehicle for generating binuclear species exhibiting interesting photochemical, second-order nonlinear optic or unusual but controllable magnetic properties [3]. However, there are relatively few studies of the redox behaviour of trinuclear species, particularly heterometallic systems, especially those in which one of the three metal centres is part of a multiatom bridge between the other two. We have described some compounds derived from the ferrocenyl group with two molybdenum nitrosyls centres [4], and recently reported the construction and characterization of complexes containing a single copper(II) centre attached to two $\{Mo(NO)\{HB(dmpz)_3\}Cl\}^+$ groups [5]. In this last study, we found that the copper atom had a small but detectable influence on the redox behaviour of molybdenum centres, which themselves were only weakly interacting electrochemically. This trimetallic system was based on a near-planar Schiff-base ligand system derived from 2,4-dihydroxybenzaldehyde and α,ω-diamines [**1**, M = Cu, M′ = $Mo(NO)\{HB(dmpz)_3\}Cl$; B = hydrocarbyl]. A possible reason why the electrochemical interaction between the two remote molybdenum nitrosyl centres was not substantially enhanced by the implantation of the copper ion in the centre of the ligand array could be that there is a slight distortion of these copper Schiff-base complexes from planarity, thereby perturbing the potential delocalization across the trimetallic species. In order to probe this view, we have prepared a series of analogous nickel(II) and palladium(II) species, where planar coordination is more likely to be maintained and potential delocalization is maximised.



EXPERIMENTAL

The compound $[Mo(NO)\{HB(dmpz)_3\}Cl_2]$ and the Schiff-base ligands were prepared as described pre-

{**1**; M = Ni or Pd, M' = H or Mo(NO){HB(dmpz)$_3$Cl; B = hydrocarbyl}

viously, and all general work-up and spectroscopic procedures were also as previously reported [5]. FAB-mass spectral data were obtained using a NOBA matrix. Cyclic voltammetry, differential pulse and square wave voltammetry were carried out using an EC & G PAR 273A galvanostat and potentiostat. Solutions in acetonitrile and dichloromethane were *ca* 1×10^{-3} mol dm^{-3} in the complex, with [Bu$^n_4$N][PF$_6$] (0.1 mol dm^{-3}) as the base electrolyte and the saturated calomel electrode (SCE) as the reference electrode. The working and counter electrode was a Pt bead and Pt wire, respectively, and all formal potentials were taken as the average of anodic and cathodic peak potentials. Differential pulse voltammetry was carried out using a pulse amplitude of 10 mV and the Δi *vs* E relationship was recorded. To obtain ΔE_f values from these waves, the separation between the two reduction potentials was calculated using the graphical method developed by Richardson and Taube [6].

Synthesis of nickel and palladium Schiff-base precursors (**1**, M = Ni *or* Pd; M' = H; B = *hydrocarbyl*)

In general, the nickel complexes were prepared by refluxing a mixture of nickel chloride hexahydrate or nickel acetate with the Schiff base in absolute ethanol. The palladium compounds were obtained similarly, using palladium acetate, either in methanol or ethanol.

[**1**, M = Ni; M' = H; B = C_6H_4]. A dark red precipitate formed immediately when $NiCl_2 \cdot 6H_2O$ (0.21 g, 0.86 mmol) dissolved in ethanol (10 cm^3) was refluxed with the appropriate Schiff base (0.3 g, 0.86 mmol) in ethanol (20 cm^3). Refluxing was maintained for 3 h, and the mixture was then cooled, the red precipitate filtered off and washed thoroughly with ethanol and diethyl ether and dried *in vacuo* (0.19 g, 52%). Mass spectrum (FAB): Found m/z = 405. Calc. for compound 405. IR (KBr disc, cm): 1610 ($\nu_{C=N}$). ^{1}H NMR [$(CD_3)_2SO$]: δ 8.83 (C*H*=N, s, 2H), 8.73 (O*H*, s, 2H), 8.15 (C_6H_4, dd, 2H), 7.30 (C_6H_4, dd, 2H), 6.93 (part of C_6H_3, m, 4H), 6.57 (part of C_6H_3, m, 4H, J_{HH} = 9.9 Hz). UV–vis (DMSO): λ_{max} nm (ε) 263 (2699), 298 (1449), 385 (1786), 519 (704).

[**1**, M = Ni; M' = H; B = CH_2CH_2]. This compound was prepared similarly, using $NiCl_2 \cdot 6H_2O$ (0.12 g, 0.5 mmol) and the appropriate Schiff base (0.15 g, 0.5 mmol). The brown product was collected, washed as before and dried *in vacuo* (0.13 g, 66%). Mass spectrum (FAB): Found m/z = 357. Calc. for compound 357. IR (KBr disc, cm^{-1}): 1629 ($\nu_{C=N}$). ^{1}H NMR [$(CD_3)_2SO$]: δ 8.63 (C*H*=N, s, 2H), 8.5 (O*H*, s, 2H), 7.84 (part of C_6H_3, s, 2H), 6.76 (part of C_6H_3, d, 2H, J_{HH} = 7.42 Hz), 6.60–6.53 (part of C_6H_3 and hydrogen-bonded H of OH, distorted t, 4H), 3.38 (CH_2CH_2, s, 4H).

[**1**, M = Ni; M' = H; B = $CH_2CH_2CH_2$]. This compound was prepared in the same way as (**1**, M = Ni; M' = H; B = C_6H_4), using $NiCl_2 \cdot 6H_2O$ (0.23 g, 0.96 mmol) and the appropriate Schiff base (0.3 g, 0.96 mmol). The mixture was refluxed for 2 days and the red–brown solution was filtered, cooled and the filtrate evaporated *in vacuo*. The brown residue was treated with diethyl ether and the precipitate formed was filtered off, washed with diethyl ether and dried *in vacuo* (0.25 g, 71%). Mass spectrum (FAB): Found m/z = 371. Calc. for compound 371. IR (KBr disc, cm^{-1}): 1608 ($\nu_{C=N}$). ^{1}H NMR [$(CD_3)_2SO$]: δ 8.63 (C*H*=N, s, 2H), 8.50 (O*H*, s, 2H), 6.90 (part of C_6H_3, d, 2H, J_{HH} = 6.53 Hz), 6.56 (part of C_6H_3, s, 2H), 6.48 (part of C_6H_3, d, 1H, J_{HH} = 9.1 Hz), 6.45 (part of C_6H_3, d, 1H; J_{HH} = 9.1 Hz), 4.37 (CH_2N, s, 2H), 4.76 (CH_2N, s, 2H), 1.79 ($CH_2CH_2CH_2$, s, 2H).

[**1**, M = Ni; M' = H; B = $(CH_2)_4$]. This compound was prepared in a way similar to that of (**1**, M = Ni; M' = H; B = C_6H_4), but using nickel acetate (0.22 g, 0.88 mmol) and the Schiff base (0.29 g, 0.88 mmol) in ethanol (50 cm^3). The mixture was refluxed overnight, filtered while hot and the filtrate cooled and evaporated *in vacuo*. The green–yellow solid that precipitated was washed thoroughly with ethanol and diethyl ether and dried *in vacuo* (0.25 g, 66%). Mass spectrum (FAB): Found m/z = 385. Calc. for compound 385. IR (KBr disc, cm^{-1}): 1616 ($\nu_{C=N}$). The compound was paramagnetic and no ^{1}H NMR spectrum could be recorded.

[**1**, M = Pd; M' = H; B = C_6H_4]. A solution of palladium acetate (0.32 g, 1.41 mmol) in methanol (20 cm^3) was added to a solution of the appropriate Schiff base (0.49 g, 1.41 mmol) in methanol (40 cm^3). This mixture was refluxed, and after 15 min a red precipitate had formed. Refluxing was continued for a further 5 h, whereupon the mixture was cooled and the red solid that had formed was filtered off, washed thoroughly with methanol and then diethyl ether and dried *in vacuo* (0.52 g, 82%). Mass spectrum (FAB): Found m/z = 452. Calc. for compound 452. IR (KBr disc, cm^{-1}): 1603 ($\nu_{C=N}$). ^{1}H NMR [$(CD_3)_2SO$]: δ = 9.07 (O*H*, 2, 2H), 8.87 (C*H* = N, s, 2H), 8.34 (C_6H_4, dd, 2H), 7.41 (C_6H_4, dd, 2H), 7.06–6.88 (C_6H_3, m, 6H).

[**1**, M = Pd; M' = H; B = CH_2CH_2]. This compound was prepared in a way similar to that of (**1**, M = Pd; M' = H; B = C_6H_4), using palladium acetate (0.31 g, 1.37 mmol) and the appropriate Schiff base (0.41 g, 1.37 mmol) in ethanol (80 cm^3). The mixture was refluxed for 1 h, and after the usual work-up afforded a yellow solid (0.36 g, 65%). Mass spec-

trum (FAB): Found m/z = 405. Calc. for compound 404. IR (KBr disc, cm^{-1}): 1627 ($\nu_{C=N}$). ^1H NMR [$(CD_3)_2SO$]: δ 8.60 (O*H*, s, 2H), 8.09 (C*H* = N, s, 2H), 6.87 (part of C_6H_3, s, 2H), 6.70 (part of C_6H_3, d, 2H, J_{HH} = 11.97 Hz), 6.70 (part of C_6H_3, s, 2H), 3.79 (CH_2CH_2, s, 4H).

Bis-molybdenum complexes, [**1**, M = Ni *or* Pd; M′ = Mo(NO){HB(dmpz)$_3$}Cl; B = *hydrocarbyl*]

In general, these complexes were prepared by treatment of one mole equivalent of the nickel or palladium Schiff-base complexes, i.e. (**1**, M = Ni or Pd; M′ = H; B = hydrocarbyl) with [Mo(NO){HB(dmpz)$_3$Cl$_2$] in dry toluene to which a few drops of triethylamine had been added. The mixture was then refluxed either overnight (when M = Ni) or for several days (M = Pd). On evaporation of the solvent *in vacuo* followed by chromatography of the residue over silica gel (60, 70–230 mesh) using dichloromethane and/or dichloromethane/THF mixtures as eluant, various fractions could be collected, the solvent partially evaporated *in vacuo* and the desired compound precipitated as a solid on addition of n-hexane. Details of particular compounds are given below.

[**1**, M = Ni; M′ = Mo(NO){HB(dmpz)$_3$}Cl; B = C_6H_4]. A suspension of (**1**, M = Ni; M′ = H; B = C_6H_4) (0.09 g, 0.22 mmol) in dry toluene (50 cm^3) containing some triethylamine and [Mo(NO){HB(dmpz)$_3$}Cl$_2$] (0.22 g, 0.45 mmol) was treated as described in the general discussion, affording a blue solution. On chromatography using dichloromethane, three fractions were collected, the first yellow and the second green ([{Mo(NO){HB(dmpz)$_3$}Cl}$_2$O] identified by mass spectrometry) being discarded, the third and major blue fraction being completely eluted using dichloromethane containing 1% THF. On partial reduction of the volume *in vacuo* to *ca* 10 cm^3, and on addition of n-hexane, the compound was precipitated as a blue solid (0.09 g, 31%). Mass spectrum (FAB): Found m/z = 1321. Calc. for complex 1320. IR (KBr disc, cm^{-1}): 2553 (ν_{BH}), 1677 (ν_{NO}), 1602 ($\nu_{C=N}$), 1574 ($\nu_{C=C}$). ^1H NMR (CD_2Cl_2): δ 8.434 (C*H* = N, s, 2H), 7.56 (C_6H_4, distorted A_2B_2 multiplet, 4H), 7.56 (part of C_6H_3, d 2H, J_{HH} = 8.8 Hz); 7.18 (part of C_6H_3, d, 2H, J_{HH} = 2.5 Hz), 7.15 (part of C_6H_3, s, 2H), 5.93 ($Me_2C_3HN_2$, s, 2H), 5.88 ($Me_2C_3HN_2$, s, 2H), 5.78 ($Me_2C_3HN_2$, s, 2H), 2.63 [$(CH_3)_2HN_2$ s, 6H], 2.42–2.40 [$(CH_3)_2C_3HN_2$), m, 18H], 2.23 [$(CH_3)_2C_3HN_2$, s, 6H], 2.04 [$(CH_3)_2C_3HN_2$, s, 6H].

[**1**, M = Ni; M′ = Mo(NO){HB(dmpz)$_3$}Cl; B = CH_2CH_2]. Prepared similarly to the compound above, using (**1**, M = Ni; M′ = H; B = CH_2CH_2) (0.09 g, 0.31 mmol), toluene (20 cm^3), triethylamine and [Mo(NO){HB(dmpz)$_3$}Cl$_2$] (0.31 g, 0.62 mmol). A green–blue mixture was formed which was worked-up as described above, affording the compound as a blue solid (0.15 g, 45%). Mass spectrum (FAB): Found m/z = 1272. Calc. for complex 1272. IR (KBr disc, cm^{-1}): 2553 (ν_{BH}), 1667 (ν_{NO}), 1614 ($\nu_{C=N}$), 1584 ($\nu_{C=C}$). ^1H NMR (CD_2Cl_2): δ 7.75 (C*H* = N, s, 2H), 7.43 (part of C_6H_3, t, 3H), 7.04 (part of C_6H_3, m, 6H), 5.93 ($Me_2C_3HN_2$, s, 2H), 5.86 ($Me_2C_3HN_2$, s, 2H), 5.76 ($Me_2C_3HN_2$, s, 2H), 3.48 NCH_2CH_2N, s, 4H), 2.60 [$(CH_3)_2C_3HN_2$, s, 6H], 2.41–2.31 [$(CH_3)_2C_3HN_2$, m, 18H], 2.20 [$(CH_3)_2C_3HN_2$, s, 6H], 2.02 [$(CH_3)_2C_3HN_2$, s, 6H].

[**1**, M = Ni; M′ = Mo(NO){HB(dmpz)$_3$}Cl; B = $CH_2CH_2CH_2$]. Prepared as above, using (**1**, M = Ni; M′ = H; B = $CH_2CH_2CH_2$) (0.17 g, 0.45 mmol), toluene (40 cm^3), triethylamine and [Mo(NO){HB(dmpz)$_3$}Cl$_2$] (0.45 g, 0.91 mmol). The blue solution that formed afforded, on chromatography, red, green–yellow and blue fractions, and after work-up as described above, the desired compound was isolated as a blue solid (0.32 g, 54%). Mass spectrum (FAB): Found m/z = 1285. Calc. for complex 1286; 1227 ([M − Ni]$^+$). IR (KBr disc, cm^{-1}): 2554 (ν_{BH}), 1668 (ν_{NO}), 1617 ($\nu_{C=N}$), 1586 ($\nu_{C=C}$). ^1H NMR (CD_2Cl_2): δ 7.47 (C*H* = N, s, 2H), 7.39 (part of C_6H_3, d, 2H, J_{HH} = 2.54 Hz), 6.99 (part of C_6H_3, m, 4H), 5.92 ($Me_2C_3HN_2$, s, 2H), 5.86 ($Me_2C_3HN_2$, s, 2H), 5.76 ($Me_2C_3HN_2$, s, 2H), 3.60 (NCH_2, s, 4H), 2.60 [$(CH_3)_2C_3HN_2$, s, 6H], 2.40–2.38 [$(CH_3)_2C_3HN_2$ and CH_2CH_2N, m, 22 H, 6H], 2.18 [$(CH_3)_2C_3HN_2$, s, 6H], 2.04 [$(CH_3)_2C_3HN_2$, s, 6H].

[**1**, M = Ni; M′ = Mo(NO){HB(dmpz)$_3$}Cl; B = $(CH_2)_4$]. Prepared as described above using [**1**, M = Ni; M′ = H; B = $(CH_2)_4$] (0.14 g, 0.32 mmol), toluene (40 cm^3), triethylamine and [Mo(NO){HB(dmpz)$_3$}Cl$_2$] (0.32 g, 0.64 mmol). The purple solution that formed was chromatographed as described previously, giving red, purple and blue fractions, and the desired compound was isolated from the blue fraction as a blue solid (0.2 g, 44%). Mass spectrum (FAB): Found m/z = 1303. Calc. for complex 1300; 1243 ([M − Ni]$^+$). IR (KBr disc, cm^{-1}): 2554 (ν_{BH}), 1672 (ν_{NO}), 1623 ($\nu_{C=N}$), 1581 ($\nu_{C=C}$). The complex was paramagnetic and did not afford a ^1H NMR spectrum.

[**1**, M = Pd; M′ = Mo(NO){HB(dmpz)$_3$}Cl; B = C_6H_4]. A suspension of (**1**, M = Pd; M′ = H; B = C_6H_4) (0.13 g, 0.28 mmol) in dry toluene (40 cm^3) containing some triethylamine and [Mo(NO){HB(dmpz)$_3$}Cl$_2$] (0.28 g, 0.57 mmol) was refluxed for 3 days. The purple mixture was filtered while hot and the filtrate cooled and evaporated *in vacuo*, affording a purple powder. This was dissolved in the minimum volume of dichloromethane and chromatographed on alumina. The first red fraction was eluted with hexane (40% v/v) in dichloromethane, but the second fraction, which contained a mixture of green and red species, was discarded. The third major blue fraction was eluted with pure dichloromethane. This last was concentrated to *ca* 10 cm^3 and n-hexane added to precipitate a blue solid which was filtered off, thoroughly washed with hexane and dried *in vacuo* (0.12 g, 31%). Mass spectrum (FAB): Found m/z = 1368. Calc. for complex 1367. IR (KBr disc,

cm^{-1}): 2550 (ν_{BH}), 1672 (ν_{NO}), 1649 ($\nu_{C=N}$), 1587 ($\nu_{C=C}$). ^1H NMR (CD_2Cl_2): δ 8.42 (CH = N, s, 2H), 7.84 (C_6H_4, A_2B_2 multiplet, 4H), 7.54 (part of C_6H_3, d, 2H, J_{HH} = 2.91 Hz), 7.19 (part of C_6H_3, m, 4H), 5.99 ($Me_2C_3HN_2$, s, 2H), 5.94 ($Me_2C_3HN_2$, s, 2H), 5.94 ($Me_2C_3HN_2$, s, 2H), 2.59 [$(CH_3)_2C_3HN_2$, s, 6H], 2.44–2.43 [$(CH_3)_2C_3HN_2$, m, 18H], 2.19 [$(CH_3)_2C_3HN_2$, s, 6H], 2.08 [$(CH_3)_2C_3HN_2$, s, 6H].

[**1**, M = Pd; M′ = Mo(NO){HB(dmpz)$_3$}Cl; B = CH_2CH_2]. Prepared as described above, using (**1**, M = Pd; M′ = H; B = CH_2CH_2) (0.15 g, 0.38 mmol), toluene (20 cm^3), triethylamine and [Mo(NO){HB(dmpz)$_3$}Cl_2] (0.37 g, 0.75 mmol), the mixture being refluxed for 3 days. The purple solution that formed afforded, on chromatography, two purple and one blue fraction. The latter gave the desired compound as a blue solid (0.23 g, 46%). Mass spectrum (FAB): Found m/z = 1321. Calc. for complex 1319. IR (KBr disc, cm^{-1}): 2552 (ν_{BH}), 1668 (ν_{NO}), 1624 ($\nu_{C=N}$), 1587 ($\nu_{C=C}$). ^1H NMR (CD_2Cl_2): δ 8.01 (CH = N, s, 2H), 7.48 (part of C_6H_3, d, 2H, J_{HH} = 2.90 Hz), 7.30 (part of C_6H_3, dd, 2H), 7.05 (part of C_6H_3, d, 2H, J_{HH} = 9.44 Hz), 5.98 ($Me_2C_3HN_2$, s, 2H), 5.93 ($Me_2C_3HN_2$, s, 2H), 5.82 ($Me_2C_3HN_2$, s, 2H), 3.88 (NCH_2CH_2N, s, 4H), 2.57 [$(CH_3)_2C_3HN_2$, s, 6H], 2.44–2.42 [$(CH_3)_2C_3HN_2$, m, 18H], 2.17 [$(CH_3)_2C_3HN_2$, s, 6H], 2.06 [$(CH_3)_2HN_2$, s, 6H].

RESULTS AND DISCUSSION

Synthetic studies

The trimetallic species [**1**, M = Ni, M′ = Mo(NO){HB(dmpz)$_3$}Cl; B = C_6H_4, $(CH_2)_n$, n = 2–4] and [**1**, M = Pd, M′ = Mo(NO){HB(dmpz)$_3$}Cl; B = C_6H_4 or CH_2CH_2] were obtained by reaction of the preformed nickel or palladium Schiff base complexes (**1**, M = Ni or Pd, M′ = H) with [Mo(NO){HB(dmpz)$_3$}Cl_2] in a 1:2 molar ratio in the presence of triethylamine. The amine can act in two ways: either by reduction of [Mo(NO){HB(dmpz)$_3$}Cl_2] to a labile monoanion that readily undergoes substitution [7], or by facilitating elimination of HCl in the reaction. The reaction mixture was refluxed overnight (Ni species) or for 2–3 days (Pd), and purification of the compounds was achieved by column chromatography using dichloromethane as eluant. There was evidence for the formation of other compounds during these reactions, and we know from other work that these can be [Mo(NO){HB(dmpz)$_3$}$(OH)_2$] and/or [{Mo(NO){HB(dmpz)$_3$}$(\mu$-OH)$\}_2$], and [{Mo(NO){HB(dmpz)$_3$}Cl$\}_2(\mu$-O)] [8]. The first two species are coloured pink/red and the last green. None were specifically isolated for purification, and there is probably also decomposition of the Schiff base species, although we did not isolate identifiable fragments. The trimetallic species were obtained as blue solids in yields ranging from 31–54%. Elemental analyses (Table 1) and FAB mass spectral data (Experimental section) are in general agreement with our formulations.

Spectroscopic studies and magnetic properties

The IR spectra of the new complexes contain absorptions consistent with the presence of the tetradentate ligands and, where appropriate, the HB(dmpz)$_3$ ligands (ν_{BH} 2250–2254 cm^{-1}). The NO stretching frequencies of the trimetallic nickel complexes occur in the range 1667–1677 cm^{-1} and those of their palladium analogues fall in the range 1668–1672 cm^{-1}, whereas those in the copper species occurs at 1678–1685 cm^{-1} [5]. The very slight increase in ν_{NO} of [**1**, M = Cu; M′ = Mo(NO){HB(dmpz)$_3$Cl;

Table 1. Analytical data obtained from mono- and tri-metallic Schiff-base complexes [**1**, M = Ni or Pd; M′ = H or Mo(NO){HB(dmpz)$_3$}Cl; B = hydrocarbyl}] · xH_2O

B = hydrocarbyl] is not thought to be significant, and so the central metal atom has little effect on ν_{NO} of the molybdenum fragments. The NO stretching frequencies fall in a region typical of a {Mo(NO){HB(dmpz)$_3$}Cl} fragment bonded to a phenolic ligand although they occur at values slightly lower than those in simple related monophenolate complexes [9]. The stretching frequency of azomethine —C=N— linkages decreases on complexation of the Schiff base ligand by nickel or palladium as expected, and on incorporation of the {Mo(NO){HB(dmpz)$_3$}Cl} fragments, $\nu_{C=N}$ occurs in the range 1602–1623 cm^{-1} for the Ni complexes and 1649–1624 cm^{-1} for the Pd complexes.

The majority of the complexes are diamagnetic and their ^1H NMR spectra details are recorded in the Experimental section. However [**1**, M = Ni, M′ = H, B = $(CH_2)_4$] and [**1**, M = Ni, M′ = Mo(NO){HB(dmpz)$_3$}Cl; B = $(CH_2)_4$] are paramagnetic (see below). The ^1H NMR spectra of the diamagnetic nickel and the two palladium complexes are broadly consistent with our formulations, and require no special comment. It should be noted that the azomethine resonances occur as singlets, indicating the symmetrical nature of these complexes. In the molybdenated complexes [**1**, M = Ni; M′ = Mo(NO){HB(dmpz)$_3$}Cl; B = C_6H_4, $(CH_2)_n$, n = 2, 3] and [**1**, M = Pd; M′ = H; B = C_6H_4, $(CH_2)_2$], the 4-H protons of the pyrazolyl rings in HB(dmpz)$_3$ appear as three closely equivalent resonances of relative area six, owing to the overall symmetry of the trimetallic species and to the lack of a plane of symmetry within each octahedral {Mo(NO){HB(dmpz)$_3$}Cl(O—)} fragment.

The electronic spectra were recorded in the range 1100–200 nm. The monometallic diamagnetic nickel complexes (**1**, M = Ni; M′ = H; B = C_6H_4 and CH_2CH_2), exhibit relatively weak absorptions at 519 and 550 nm in DMSO. Similar Ni^{II} Schiff base complexes have absorptions between 540 and 585 nm [10], which are assigned to *d–d* transitions. The spectrum of [**1**, M = Ni; M′ = H; B = $(CH_2)_3$] is somewhat different, with a broad shoulder at *ca* 600 nm, and while this complex is diamagnetic in DMSO, its analogue [**1**, M = Ni; M′ = H; B = $(CH_2)_4$] has a similar spectrum but is paramagnetic both in solution (DMSO) and the solid state. A magnetic susceptibility measurement of [**1**, M = Ni; M′ = H; B = $(CH_2)_4$] confirmed that it is paramagnetic in the solid state (μ_{eff} = 1.53 B.M.). The value of μ_{eff} is significantly lower than that expected for a six- or five-coordination, or pseudo-tetrahedral Ni^{II} centre, although there are two water molecules of crystallization present in the compound (Table 1). The species analyses well, but the electronic spectrum is ambiguous, is not consistent with a NiN_2O_4 or NiN_2O_3 chromophore and cannot be used to determine the nature of this Ni species in solution or the solid state. However, it is possible that the length of B is sufficient to permit some flexibility within the tetradentate ligand system, leading to some distortion either towards a tetrahedral geometry or by formation of a five-coordinate species (in DMSO). Such distortions would cause some perturbation of magnetic properties without substantial electronic spectral changes, and this has been detected in other Ni^{II} Schiff-base complexes [10]. Some evidence of distortion from planar towards tetrahedral or five-coordinate species was detected in the electronic spectra of the related copper(II) complexes (**1**, M = Cu; M′ = H; B = hydrocarbyl) [5].

The electronic spectra of the trimetallic species [**1**, M = Ni or Pd; M′ = Mo(NO){HB(dmpz)$_3$Cl; B = C_6H_4, $(CH_2)_n$, n = 2–4] are dominated by two moderately intense absorptions. In the nickel complexes these occur in the ranges 740–750 nm and 612–630 nm, both somewhat stronger than expected for *d–d* transitions in Ni^{II}. We have observed an absorption associated with the molybdenum fragment in the region 600–750 nm before, and believe that it is due to a ligand-to-metal charge transfer [11]. The palladium complexes exhibit broadly similar spectra. The ^1H NMR spectrum showed that [**1**, M = Ni; M′ = Mo(NO){HB(dmpz)$_3$}Cl; B = $(CH_2)_4$] is paramagnetic in solution, but insufficient material was available for solid state susceptibility measurements.

Electrochemical studies

The complexes (**1**, M = Ni or Pd; M′ = H; B = hydrocarbyl) have relatively low solubility in dichloromethane and acetonitrile and so their electrochemical properties were investigated by cyclic (CV) and square wave voltammetry (SWV) in DMSO. The CV of all the nickel compounds, with the exception of (**1**, M = Ni; M′ = H; B = CH_2CH_2), exhibited an irreversible reduction process between −1.47 and −1.60 V as shown by detection of a cathodic peak (E_p^c) in their CVs and by SWV. Only (**1**, M = Ni; M′ = H; B = C_6H_4), exhibited a second reduction process, at −2.05 V, which was detected by SWV. On reverse sweep, the CVs of these complexes exhibited one or two anodic peaks, the first of which may have been associated with reoxidation of a species generated by reductive decomposition of the complexes near −1.50 V. Some of the complexes exhibited a further oxidation process, E_p^a varying from +0.43 to +0.65 V. For comparison purposes, we investigated the electrochemistry of (**1**, M = Ni; M′ = Me; B = C_6H_4), in order to determine whether the presence of the hydroxyl groups in (**1**, M = Ni; M′ = H; B = C_6H_4) had any influence on the electrode behaviour of this compound (for example, oxidation to quinone fragments). Again, an irreversible reduction was observed, at −1.54 V, but in the CV the anodic sweep showed only one oxidative electrode reaction, at −0.65 V, so methylation of the hydroxyl groups has little influence on the electrode reactions of the nickel Schiff-base complex. The CVs of the palladium complexes (**1**, M = Pd; M′ = H; B = C_6H_4 and CH_2CH_2) showed

that they underwent quasi-reversible (B = C_6H_4) or reversible (B = CH_2CH_2) reductions at −0.52 V. Their SWVs similarly revealed reduction, at −0.56 V (B = C_6H_4) and −0.51 V (B = CH_2CH_2). From these data, it is not possible to establish precisely what these electrode processes represent, although the reductions may be owing to formation of M^I from M^{II}.

The CVs of the molybdenated species, [**1**, M = Ni or Pd; M′ = Mo(NO){HB(dmpz)$_3$}; B = hydrocarbyl] were determined in acetonitrile and revealed only one significant electrode process, an apparent two-electron reduction at *ca* −0.50 V. This is due to reduction of the molybdenum centres, the E_f values for the Ni complexes occurring at −0.52 to −0.53 V, those of the Pd analogues being slightly more anodic, at −0.49 and −0.45 V; the E_f values being consistent with those obtained from other phenoxy-substituted Mo(NO){HB(dmpz)$_3$} fragments [11]. No other significant electrode behaviour was detected in these compounds. That this electrochemical behaviour is a result of a two-electron reduction was not determined directly by coulometry but by comparison of the electrode behaviour of related bimetallic species such as [{Mo(NO){HB(dmpz)$_3$}Cl$_2$(OC$_6$H$_4$CH=NC$_6$H$_4$N=CHC$_6$H$_4$O)] [12] and [**1**, M = Cu; M′ = Mo(NO){HB(dmpz)$_3$Cl; B = hydrocarbyl] [5]. The difference in peak potentials, ΔE_f ($E_f^c - E_f^a$), in acetonitrile fell in the range 100–137 mV for the nickel complexes and 106–117 mV for the palladium species, the values being virtually independent of scan rate. For a reversible one-electron process ΔE_f should be 59 mV, and for a two-electron transfer process it should either be of the order of 120 mV for sequential electrode reactions ($E_f^1 < E_f^2$ or $E_f^1 > E_f^2$, where < means less cathodic than) or 29 mV for a synchronous process. ΔE_f for the oxidation of ferrocene, used as internal reference in all the species studied, varies from 62 to 122 mV, a deviation from the ideal indicating that there is uncompensated solution resistance and a non-ideal electrochemical cell configuration. However, ΔE_f for the trimetallic complexes is reasonably close to the theoretical value for two sequential electron transfers, in which there is very weak interaction between the two redox centres. This is consistent with the previously observed behaviour of the copper analogues [5]. The data in Table 2 show that the reduction potential for the molybdenum nitrosyl fragments is influenced only slightly by the central metal, the palladium complexes (*ca* −0.47 V) being reduced at a potential *ca* 60 mV more anodic than their nickel counterparts (*ca* −0.53 V). The reduction potentials of the related copper complexes [**1**, M = Cu; M′ = Mo(NO){HB(dmpz)$_3$}}Cl; B = hydrocarbyl] average −0.46 V, showing that while the LUMO in this class of complexes is influenced by M, that influence is small. The reduction potentials of the molybdenated nickel complexes, like their copper analogues, show no significant dependence on the nature of B.

Because of the suggestion of two sequential one-electron reductions in the cyclic voltammograms of [**1**, M = Ni or Pd; M′ = Mo(NO){HB(bmpz)$_3$}Cl; B = hydrocarbyl], we conducted pulse voltammetry (DPV) in the range −0.4 to −0.6 V. Richardson and Taube [6] have derived a relationship between E_f and the width at half-height ($w_{1/2}$) of a differential pulse voltammetric peak for systems where the interaction between two redox centres in the same molecule is small. In the complexes described here, this interaction is going to be between 36 mV (the theoretically calculated separation of E_f^1 and E_f^2 for two non-interacting centres is 35.6 mV) and *ca* 180 mV. The data in Table 3 shows ΔE_f for the trimetallic species varying between 68 and 90 mV, broadly comparable to that in the copper analogues, consistent with weakly interacting redox sites. The coproportionation constants (K_c) for the equilibrium

[**1**, M = Ni, Pd; M′ = Mo(NO){HB(dmpz)$_3$}Cl]

+ [**1**, M = Ni, Pd; M′ = Mo(NO){HB(dmpz)$_3$}Cl]$^{2-}$

$\rightleftharpoons$ 2[**1**, M = Ni, Pd; M′ = Mo(NO){HB(dmpz)$_3$}Cl]$^-$

determined using the relationship $\Delta E_f = 59.16 \log K_c$, show that the monoreduced species have small but significant stabilities, the general electrochemical behaviour being consistent, as stated already, with weak interaction between the two molybdenum nitrosyl centres. The K_c data are broadly similar to the copper analogues [5] and it appears that the reduced species containing palladium are marginally more stable than their nickel analogues.

We had previously attempted to reduce [**1**, M = Cu; M′ = Mo(NO){HB(dmpz)$_3$}Cl; B = hydrocarbyl], primarily with the intention of generation a dianion containing, in principle, three unpaired electrons, one owing to Cu^{II} and two associated with the monoreduced [Mo(NO){HB(dmpz)$_3$}Cl] fragments. This was unsuccessful because the reduced species decomposed [5].

However, cobaltocene reduction of [**1**, M = Ni; M′ = Mo(NO){HB(dmpz)$_3$}Cl; B = $(CH_2)_n$, n = 3 and 4] in dichloromethane afforded EPR-active species that exhibited g = 1.97, consisting of a sextet (A_{Mo} = 50 ± 1 G; *ca* 25% of molybdenum atoms have nuclear spin I = 5/2) superimposed on a central singlet. This spectrum is not inconsistent with a dianion, [**1**, M = Ni; M′ = Mo(NO){HB(dmpz)$_3$}Cl; B = $(CH_2)_n$, n = 3 and 4)]$^{2-}$ in which the two unpaired spins on the molybdenum nitrosyl centres do not correlate with each other. Non-correlation of the two unpaired spins in paramagnetic binuclear molybdenum nitrosyl species containing dipyridyl bridging ligands is rare but has been observed [13], and seems to be mainly a function of twist within the dipyridyl fragment separating the isolated electrons. The complexes described here are not significantly twisted, nor are the two reduced molybdenum centres particularly far apart (minimum separation of 13 bonds) although the electrochemical interaction between them is very small. However, since the

reduced species are very unstable in solution, we cannot rule out the possibility that decomposed fragments give rise to EPR signals consistent with *monometallic* paramagnetic ($S = \frac{1}{2}$) molybdenum nitrosyl species whose spectra are similar to that detected here.

CONCLUSIONS

We have shown that the diamagnetic trimetallic species [**1**, M = Ni or Pd; M′ = Mo(NO){HB(dmpz)$_3$}Cl; B = hydrocarbyl] are very similar to their paramagnetic copper analogues, undergoing detectable redox behaviour localized on the molybdenum nitrosyl fragments. The central metal atom (Ni or Pd) has a small influence on the peripheral molybdenum nitrosyl groups, leading to a slight increase in charge density on them. However, there is only a weak interaction between the two molybdenum redox centres, detected primarily by differential pulse voltammetry. The EPR spectra of the reduced trimetallic species [**1**, M = Ni; M′ = Mo(NO){HB(dmpz)$_3$}Cl; B = $(CH_2)_n$, $n = 3$ and 4]$^{2-}$, are consistent with unpaired spins isolated on each molybdenum nitrosyl centre.

(Received 23 April 1996; accepted 3 September 1996)

Abstract—Reaction of $Nb(OEt)_5$ with 2-mercapto-4-methylphenol ($mmpH_2$) in the presence of triethylamine gave the mononuclear tris complex $(Et_3NH)[Nb(mmp)_3]$ which was structurally characterized. The coordination geometry around the niobium is between octahedral and trigonal prismatic, with a twist angle of 41.5°. The mercaptophenolate ligands are arranged around the metal in a "propeller" fashion. $(Et_3NH)[Nb(mmp)_3]$ was characterized by IR, ^1H NMR and UV–vis spectroscopies, and cyclic voltammetry. A reversible reduction wave found at −1.03 V is for reduction to the Nb^{IV} complex. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: niobium; mercaptophenolate; 2-mercapto-4-methylphenol.

The coordination of V, Nb and Ta to sulfur donors, either inorganic sulfide or thiolate, is no longer considered especially unusual, in view of the range of such molecular complexes prepared and structurally characterized in the past 10 years [1]. We have recently reported [2] the structure and properties of the mononuclear V^{IV} complex of 2-mercapto-4-methylphenol ($mmpH_2$, $mmp^{2-} = CH_3C_6H_3OS^{2-}$), a mixed O,S-donor ligand related to catechol [o-$C_6H_4(OH)_2$] and to benzene-1,2-dithiol [o-$C_6H_4(SH)_2$]. Catecholate [3] and dithiolene [4] complexes of both main group and transition metals have attracted much attention on account of their intriguing structural, electronic and redox properties, and their numerous applications. Tris-dithiolene complexes display a range of geometries from octahedral to trigonal prismatic [5], as well as other distorted polyhedra [6], and the factors influencing these geometries have been vigorously debated in the literature [7].

Wishing to extend our studies of the complexes of the mercaptophenolate ligand to the heavier congeners of vanadium we have synthesized the niobium(V) tris complex anion, $Nb(mmp)_3^-$. While a brief report of $HNb(mp)_3$ (mp = 2-mercaptophenolate) has appeared [8], no structural or spectroscopic characterization was included. This paper describes the synthesis, X-ray structure, ^1H NMR, IR, UV–vis and cyclic voltammetry of $[Et_3NH][Nb(mmp)_3]$.

EXPERIMENTAL

All operations were carried out under purified nitrogen or argon using standard inert atmosphere techniques. 2-Mercapto-4-methylphenol was prepared by a literature synthesis [9]. Reagents niobium(V) ethoxide and triethylamine, were purchased from Aldrich Chemical Co. and used as received. Solvents were distilled under nitrogen using conventional drying agents [MeOH over $Mg(OMe)_2$, MeCN and CH_2Cl_2 over CaH_2, Et_2O over sodium/benzophenone].

Elemental analyses (C, H and N) were performed by Oneida Research Services, Whitesboro, NY. Metal analysis was performed in-house using ICP-AES on acidic aqueous digests.

Preparation of $(Et_3NH)[Nb(mmp)_3]$

A solution of $Nb(OEt)_5$ (1.0 g, 3.1 mmol) in MeOH (5 cm^3) was added to a solution containing 2-mercapto-4-methylphenol (1.35 g, 9.6 mmol) and Et_3N (0.61 g, 6.0 mmol) in MeOH (1 cm^3). The orange–brown mixture was stirred for 1 h, and the solvent subsequently removed *in vacuo* to leave a brown oil. This was stirred vigorously with Et_2O for several hours, then the mixture was filtered, affording 1.9 g of brown solid, $(Et_3NH)[Nb(mmp)_3]$. The product was recrystallized from $MeCN/Et_2O$ to yield 1.3 g of analytically pure dark brown microcrystalline solid (67% yield), which was used for subsequent measurements. Found: C, 52.7; H, 5.5; N, 2.3; Nb, 15.4. Calc. for $C_{27}H_{34}NO_3S_3Nb$: C, 53.2; H, 5.6; N, 2.3; Nb, 15.2%. ^1H NMR (CD_3CN, 300 MHz): δ 6.3–6.9 (arom. $CH_3C_6H_2OS$), 2.2 (s, 9H, $CH_3C_6H_2OS$), 1.2 [t, 9H, $(CH_3CH_2)_3NH$], 3.1 [q, 6H, $(CH_3CH_2)_3NH$]. Slow diffusion of Et_2O into a MeCN solution of the product afforded dark brown crystals suitable for X-ray diffraction measurements.

Physical measurements

Infrared spectra were obtained as KBr pellets on a Nicolet 5PC FTIR spectrometer. Electronic spectra were obtained on MeCN solutions in gas-tight quartz cuvettes using a HP 8453 spectrophotometer. ^1H NMR measurements were conducted on a Varian Gemini 300 spectrometer with TMS as internal standard. Electrochemical measurements were performed on CH_2Cl_2 solutions (*ca* 4 mM) using a BAS 100B electrochemical analyser; a glassy carbon working electrode was used in conjunction with a platinum wire auxiliary electrode and a saturated calomel reference electrode. The solutions contained 0.1 M tetra-n-butylammonium perchlorate as supporting electrolyte. IR compensation was employed. The ferrocene/ferrocenium couple was used as internal standard.

X-ray diffraction and structure solution

A single black crystal of dimensions $1.3 \times 0.5 \times 0.5$ mm was mounted in a glass capillary under an inert atmosphere. Intensity data were taken at room temperature (293 K) using a Rigaku AFC6 diffractometer on a Rigaku R200X rotating anode with Cu-K_α radiation ($\lambda = 1.5418$ Å) at 50 kW, and were corrected for absorption empirically using psi-scans, and for Lorentzian and polarization effects. Three standard reflections were monitored every 100 data points, showing less than 1% variation. Direct methods using SHELX-86 [10] revealed only the Nb, S, O and some of the aromatic ring carbons; however, no clear distinction between the sulfur and oxygen atoms was evident at this point. Therefore, initial phases were determined based on the Nb atom alone and F^2 difference Fourier analysis using SHELX-93 [11] revealed the rest of the structure, including a two-fold disorder of the cationic methylene group. All non-hydrogen atoms, including the disordered methylene, were refined anisotropically. Hydrogen atom positions were idealized and allowed to ride on the atoms to which they were attached. Hydrogen atoms were assigned an isotropic U value corresponding to the atoms of attachment.

Crystal data. $C_{27}H_{34}NO_3S_3Nb$, $M = 609.64$, trigonal, space group $P\bar{3}$, $a = b = 13.122(4)$, $c = 9.591(2)$ Å, $V = 1430.2(7)$ Å^3, $Z = 2$, $D_{calc} = 1.416$ g cm^{-3}, $F(000) = 632$, $\mu = 5.698$ mm^{-1}, scan type $\omega, 2\theta$ range 3.5–45°, reflections collected = 817, unique reflections = 686, observed reflections [$F_0 > 2\sigma(F_0)$ = 650], refinement parameters = 114, final R (on F) = 0.0496, R_w (on F^2; all data) = 0.1414, goodness-of-fit (all data) = 1.312.

The asymmetric unit consists of one-third of the formula, with the Nb and N atoms found on special positions along the triad, and the nitrogen H constrained to the threefold axis. The unit cell, therefore, contains two $(Et_3NH)[Nb(mmp)_3]$ units, with the anion and cation clearly separated.

Atomic coordinates have been deposited at the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

Synthesis of $(Et_3NH)[Nb(mmp)_3]$

The synthesis of $(Et_3NH)[Nb(mmp)_3]$ was accomplished by the reaction of $Nb(OEt)_5$ with the protonated form of the ligand, $mmpH_2$, in the presence of mild base, Et_3N, to provide the Et_3NH^+ countercation, as in the equation below:

$$Nb(OEt)_5 + 3mmpH_2 + Et_3N \rightarrow [Nb(mmp)_3]^- + Et_3NH^+ + 5EtOH$$

This simple, clean acid–base procedure avoids potential side reactions which might ensue from reaction of niobium(V) halides with the ligand or salts of the ligand, and generates the product in high yield with minimal work-up. There was no evidence for oxo or sulfido niobium species, nor for reduced niobium complexes, all of which have been previously observed in reactions of niobium halides with thiolates [12].

$(Et_3NH)[Nb(mmp)_3]$ is sensitive to oxygen in solution, but no visible decomposition occurs in crystals exposed to the air over several days.

Structure of $(Et_3NH)[Nb(mmp)_3]$

The molecular structure and atomic-numbering scheme for the anion $[Nb(mmp)_3]^-$ are shown in Fig. 1. The view is along the crystallographic threefold axis; this axis generates two of the three mmp ligands

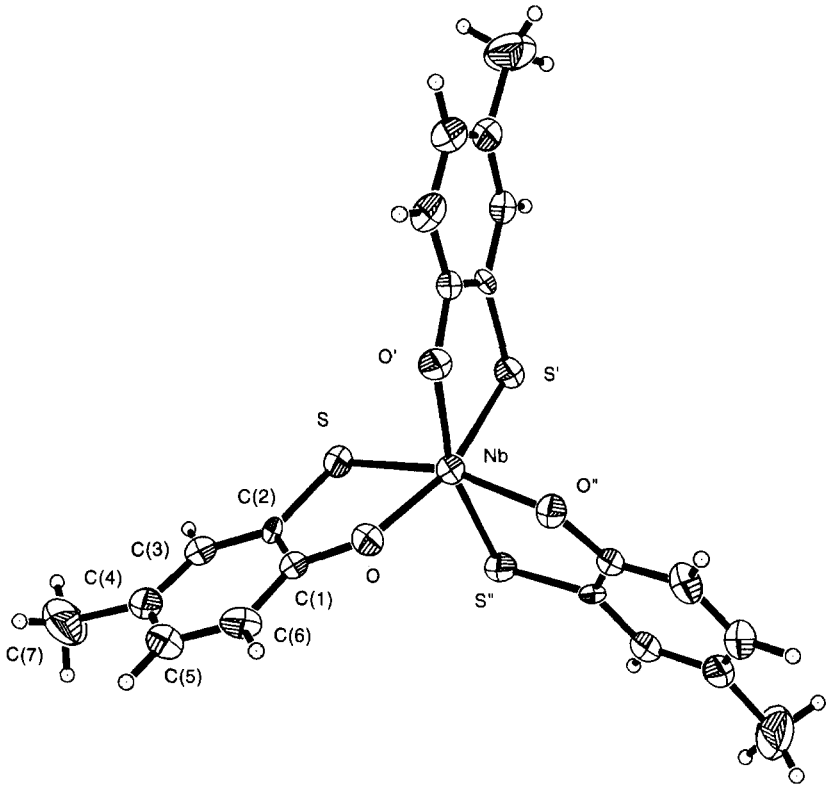

Fig. 1. Structure and numbering scheme of the anion in $(Et_3NH)[Nb(mmp)_3]$. Thermal ellipsoids are drawn at the 50% probability level.

from the asymmetric unit. Selected bond lengths and angles are in Table 1.

The complex anion consists of three bidentate chelating mmp ligands coordinated to niobium through three oxygen and three sulfur atoms in a facial arrangement, with crystallographically imposed C_3 symmetry. As a result of the symmetry the two triangular planes defined by the three sulfur atoms and three oxygen atoms are rigorously parallel. The twist angle between these S_3 and O_3 planes is 41.5°, indicating a geometry intermediate between octahedral (twist angle of 60°) and trigonal prismatic (twist angle of 0°). An assignment of distorted octahedral geometry is also supported by the *trans* angle of 160.6°, which is between the values of 136° for a trigonal prism and 168.1° for an octahedron (corrected for a bite angle of 78.1°). The geometry of $[Nb(mmp)_3]^-$ is close to that of $[V(mmp)_3]^{2-}$ [2], but differs from the dithiolene $[Nb(S_2C_6H_4)_3]^-$ [5], which is a slightly distorted trigonal prism with a twist angle of only 0.7°. While no structural information on simple tris-catecholates of Nb^V could be found in the literature for comparison with $[Nb(mmp)_3]^-$, such complexes are generally [13] octahedral or distorted octahedral in the absence of ligand constraints that favour another coordination geometry. In $[Nb(S_2C_6H_4)_3]^-$ the three ligand aromatic rings are in a "paddle-wheel" [5] arrangement around the central metal atom, with the ring planes lined up with the pseudo-threefold axis. In contrast, in $Nb(mmp)_3$ the twist towards octahedral geometry causes the three ligand planes to rotate into a "propeller" arrangement around the Nb, with an angle of 62.7° between the threefold axis and the normal to the aromatic ring planes (this angle would be 90° in a "paddle-wheel" arrangement). The Nb falls almost exactly in the projected planes of the aromatic rings, with only a very slight bending of 4.2° about the O–S vectors. This is substantially less than the bending observed in $[V(mmp)_3]^{2-}$ (average of 10.0°) and trigonal prismatic

Table 1. Selected bond lengths (Å) and angles (°)

Nb—O	1.943(5)	Nb—S	2.475(2)
O—C(1)	1.356(8)	S—C(2)	1.754(7)
C(1)—C(2)	1.402(10)	C(2)—C(3)	1.378(9)
C(3)—C(4)	1.377(10)	C(4)—C(5)	1.386(11)
C(5)—C(6)	1.396(10)	C(6)—C(1)	1.359(9)
C(4)—C(7)	1.532(10)		
O—Nb—S	78.14(15)	O—Nb—S′	160.56(15)
O—Nb—S″	99.45(14)	O—Nb—O′,O″	99.9(2)
S—Nb—S′,S″	83.07(7)	C(2)—S—Nb	98.3(3)
C(1)—O—Nb	129.9(5)	twist angle[a]	41.5

[a] Owing to the symmetry, the calculation of the twist angle reduces to the angle between O—Nb—S when all are projected onto the same *xy*-plane.

dithiolenes [5] such as $[Nb(S_2C_6H_4)_3]^-$ (22.4°) and $Mo(S_2C_6H_4)_3$ (21.4°).

The Nb—S distance in $[Nb(mmp)_3]^-$ is unusually long at 2.475(2) Å, in comparison with averaged values of 2.441 Å in $[Nb(S_2C_6H_4)_3]^-$ [5] 2.405 Å in $[Nb(SPhMe\text{-}p)_6]^-$ [1g] and 2.450 Å in $[Nb(SCH_2CH_2S)_3]^-$ [14], all of which contain Nb^V. It is not much shorter than the Nb^{IV}—S distance in $[Nb(SPh)_6]^{2-}$ [1g], at 2.488 Å. However, the C—S, C—O and C(1)—C(2) distances indicate that the ligands are in a fully reduced state and are not consistent with a Nb^{IV} + semiquinone/thione formulation. Furthermore, the Nb—O distance at 1.943 Å is short, and in keeping with other Nb^V—O bond lengths, such as in Nb(HTrencam) [15] (Nb—O_{av} = 2.03 Å). The long Nb—S distance in $[Nb(mmp)_3]^-$ may be a consequence of optimization of the Nb—O bond strengths at the expense of the Nb—S bonds. The bite angle of 78.1° is similar to that in $[V(mmp)_3]^{2-}$ (82.0°) and other six-coordinate complexes of mercaptophenolate [16].

^{1}H *NMR, IR and UV–vis spectroscopies*

The mid-IR spectrum of $[Nb(mmp)_3]^-$ displays ligand vibrations at 1467 (C—C ring stretch) and 1236 cm^{-1} (C—O). A sharp band at 3122 cm^{-1} is assigned to the cation N—H stretch. In $(Et_3NH)(PNP)[V(mmp)_3]$, where the Et_3NH^+ cation is hydrogen bonded to the anion, this band appears at lower frequency (3053 cm^{-1}) and is of lower intensity. The shift to higher frequency and intensity in $(Et_3NH)[Nb(mmp)_3]$ is consistent with the lack of hydrogen bonding shown in the X-ray structure.

Intense LMCT bands occur in the UV–vis spectrum at 288 nm (ε = 26,800 M^{-1} cm^{-1}), 367 (ε = 11,400) and *ca* 430 (sh; *ca* 7600 M^{-1} cm^{-1}). These are at higher energy than the charge transfer bands seen in $[V(mmp)_3]^{2-}$ reflecting the higher energy of the Nb unoccupied orbitals compared with V. The bands are also of higher energy than LMCT bands in dithiolenes [5,17] such as $[Nb(S_2C_6H_3CH_3)]^-$ and $[Nb(DDDT)_3]^-$, suggesting a greater stability of ligand orbitals in the mixed O,S ligand as compared to the S,S analogues.

The diamagnetic nature of the complex is established by the observation of an NMR spectrum (see Experimental section), with ^{1}H signals observed from the ligand and cation.

Cyclic voltammetry

Figure 2 shows the cyclic voltammogram of $[Nb(mmp)_3]^-$. The reversible reduction at $E_{1/2}$ = −1.03 V (*vs* SCE; −1.49 V *vs* Fc^+/Fc internal standard [18]. $E_{pa} - E_{pc}$ = 90.0 mV for the $[Nb(mmp)_3]^-/[Nb(mmp)_3]^{2-}$ wave; $E_{pa} - E_{pc}$ = 62.0 mV for the Fc^+/Fc wave) corresponds to conversion to the Nb^{IV} complex, while the irreversible oxidation

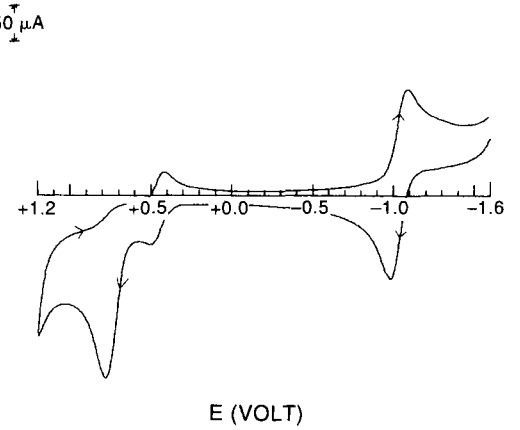

Fig. 2. Cyclic voltammetry of $(Et_3NH)[Nb(mmp)_3]$ in CH_2Cl_2 solution at room temperature (scan speed 200 mV s^{-1}; reference electrode SCE). Wave at +0.46 V is the ferrocene internal standard.

waves at positive potentials are ligand-based processes. These latter irreversible oxidation waves are also seen in the electrochemistry of $[V(mmp)_3]^{2-}$. The $[V(mmp)_3]^-/[V(mmp)_3]^{2-}$ couple [2] is at a more positive potential (−0.27 V *vs* Ag/AgCl) than that of $[Nb(mmp)_3]^-/[Nb(mmp)_3]^{2-}$, consistent with the well-known greater stability of higher oxidation states for the second transition metal series.

Acknowledgements—We thank Professor Fred L. Urbach and Shawn Swavey for assistance with electrochemical measurements.

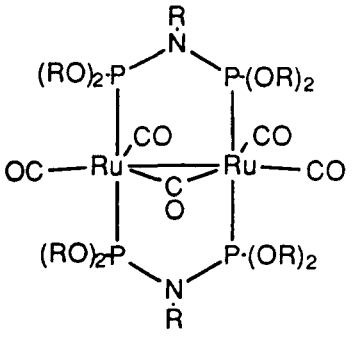
(Received 17 June 1996; accepted 29 August 1996)

Abstract—The high-pressure (1300 psi CO, 120°C) reactions of $Ru_3(CO)_{12}$ with the diphosphines $R_2PCH_2PR_2$; R = CH_3 (dmpm), C_6H_5 (dppm), and C_6H_{11} (dcypm), are reported. In the case of dppm, the disphosphine-bridged dinuclear ruthenium complex $[Ru_2(\mu\text{-dppm})_2(\mu\text{-CO})(CO)_4]$ was obtained. The corresponding reaction with dcypm afforded the mononuclear chelated diphosphine complex $[Ru(dcypm)(CO)_3]$. The mixed ligand system $[Ru_2(\mu\text{-dppm})(\mu\text{-dmpm})(\mu\text{-CO})(CO)_4]$ was obtained by employing a 1 : 1 mixture of dppm and dmpm. The crystal and molecular structures of $[Ru_2(\mu\text{-dppm})_2(\mu\text{-CO})(CO)_4]$ and $[Ru(dcypm)(CO)_3]$ were also determined. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: dinuclear ruthenium; complex; diphosphine; high-pressure synthesis; crystal structure.



Diphosphine and diphosphazane-bridged dinuclear ruthenium complexes have been the subject of considerable study [1–10]. The chemistry of dinuclear ruthenium diphosphazane complexes, **1** (R = Me, tPr[i] or Ph), has been pursued extensively in the laboratories of Haines and co-workers [1–6]. The study of these complexes has led to a detailed model system for the stepwise oxidation of CO to CO_2 [6] as well as to a novel photochemical Michaelis–Arbuzov-type rearrangement [11]. We have therefore sought to expand the scope of this class of dinuclear transition metal complexes.

The high-pressure synthesis of the bis(dimethylphosphino)methane (dmpm)-bridged complex **2** was reported by Johnson and Gladfelter [7]. The bis(diphenylphosphino)methane (dppm)-bridged complex $[Ru_2(\mu\text{-dppm})_2(\mu\text{-CO})(CO)_4]$ (**3**) was first synthesized by the photochemical reaction of $Ru_3(CO)_{12}$ with dppm [8]. More recently, **3** was also prepared by the reduction of ruthenium acetate in the presence of carbon monoxide, although the structure of this material has yet to be reported [9]. We report studies of the high-pressure (1300 psi CO, 120°C) reactions of $Ru_3(CO)_{12}$ with the diphosphines $R_2PCH_2PR_2$; R = CH_3 (dmpm), C_6H_5 (dppm) and C_6H_{11} (dcypm), including the preparation of the mixed-ligand system

$[Ru_2(\mu\text{-dppm})(\mu\text{-dmpm})(\mu\text{-CO})(CO)_4]$ (**4**) and the mononuclear complex $[Ru(dcypm)(CO)_3]$ (**5**). The crystal and molecular structures of **3** and **5** are also described.

EXPERIMENTAL

All manipulations were carried out under nitrogen in a VAC glove-box, or using standard Schlenk techniques. Toluene was distilled from sodium prior to use. Hexane was used as purchased from Fisher Scientific. $Ru_3(CO)_{12}$ and dmpm [bis(dimethyl-phosphino) methane] were purchased from Strem. Dppm [bis (dimethylphosphino)methane] was purchased from Aldrich. Dcypm [bis(dicyclohexylphosphino)methane] was obtained from Dr. I. P. Rothwell (Purdue University). The complex $[Ru_2(\mu\text{-dmpm})_2(\mu\text{-CO})(CO)_4]$ was prepared according to the literature procedure [7]. IR spectra of compounds as KBr pellets were recorded using a Perkin–Elmer 1710 Fourier transform infrared spectrometer. ^1H and ^{31}P-[^1H] NMR spectra were recorded on either Varian XL-200 or General Electric 300 spectrometers.

Preparation of $[Ru_2(\mu\text{-dppm})_2(\mu\text{-CO})(CO)_4]$ (**3**)

Complex **3** was prepared by a modification of Gladfelter's method [7] for the synthesis of $[Ru_2(\mu\text{-dmpm})_2(\mu\text{-CO}(CO)_4]$. $Ru_3(CO)_{12}$ (0.940 g, 1.47 mmol) and dppm (1.697 g, 4.41 mmol) were placed in a 500 cm^3 high-pressure Parr reactor to which 100 cm^3 of toluene was added. The reactor was charged and sealed in the dry-box and then placed in a heating well and pressurized with CO to *ca* 1000 psi. Upon heating to 120°C, the reactor pressure rose to *ca* 1300 psi. The reaction was stirred under these conditions using a mechanical stirrer for 16 h, after which it was cooled to room temperature and vented. The reactor was then returned to the dry-box where the reaction contents were transferred to a round-bottomed flask and reduced in volume under vacuum to *ca* 50 cm^3 and precipitated with *ca* 200 cm^3 hexane. A yellow solid was recovered by filtration, rinsed with hexane and dried *in vacuo*. Yield: 2.06 g (84%). ^1H NMR (200 MHz, C_6D_6): δ_H 3.4 (4H, m, CH_2), 6.7–7.7 (40H, m, CH). ^{31}P-[^1H] NMR (81 MHz, C_6D_6): δ_P 39.9 (s). IR (KBr) ν(CO) cm^{-1}: 1964 s, 1918 vs, 1894 vs, 1872 s, 1700 s.

Preparation of $[Ru_2(\mu\text{-dppm})(\mu\text{-dmpm})(\mu\text{-CO})(CO)_4]$ (**4**)

Complex **4** was prepared by a similar method to that for **3** but equimolar amounts of dppm and dmpm were used; $Ru_3(CO)_{12}$ (470 g, 736 mmol), dmpm (0.18 cm^3, 1.1 mmol) and dppm (425 g, 1.11 mmol). The final reaction mixture contained essentially a statistical mixture of **4**, **3** and $[Ru_2(dmpm)_2(CO)_5]$.

Reducing the solution volume to *ca* 30 cm^3 resulted in precipitation of $[Ru_2(dmpm)_2(CO)_5]$. This was removed by filtration and then through successive addition of hexane and filtration, **4** and then **3** were isolated and dried *in vacuo*. For **4**: Yield: 0.33 g (30%). $^{31}P-\{^1H\}$ NMR (81 MHz, C_6D_6(: δ(AA'BB') 15.3 (m), 39.4 (m). IR (KBr)ν(CO) cm^{-1}: 1951 s, 1912 vs, 1895 vs, 1867 s, 1682 s.

Preparation of [Ru(dcypm)$(CO)_3$] (**5**)

Complex **5** was prepared by a similar method to that for **3**, but dcypm was substituted for dppm; $Ru_3(CO)_{12}$ (266 mg, 416 mmol) and dcypm (510 mg, 1.25 mmol). Light yellow needles of **5** crystallized upon reducing solvent volume. For **5**: ^1H NMR (200 MHz, C_6D_6) : δ_H 2.7 (2H, t, CH_2), 1.0–2.1 (44H, broad overlapping m, cyclohex). $^{31}P-\{^1H\}$ NMR (81 MHz, C_6H_6): δ_P −3.30 (s) ppm. IR (KBr) ν(CO) cm^{-1}: 1981 vs, 1899 vs, 1880 vs.

Crystal data for [$Ru_2(\mu$-dppm$)_2(\mu$-CO)$(CO)_4$] (**3**)

X-ray quality crystals of $\mathbf{3}\cdot 2CH_3CN$, ($C_{59}H_{50}N_2O_5P_4Ru_2$), were grown by slow evaporation from CH_3CN. An orange plate having approximate dimensions of $0.24\times0.20\times0.13$ mm^3 was mounted in a glass capillary. Data collection were performed at 293 ± 1 K with Cu-K_α radiation (λ = 1.54184 Å) on an Enraf–Nonius CAD4 computer-controlled kappa-axis diffractometer equipped with a graphite crystal, incident beam monochromator. The crystal data and data collection parameters are given in Table 1. Cell constants and an orientation matrix for data collection were obtained from least-squares refinement, using the setting angles of 25 reflections in the range $24 < \theta < 47°$, measured by the computer-controlled diagonal slit method of centring. As a check on the crystal quality, omega scans of several intense reflections were measured; the width at half-height was 0.40° with a take-off angle of 6.0°, indicating good crystal quality. Lorentz and polarization corrections were applied to the data. The linear absorption coefficient is 63.8 cm^{-1} for Cu-K_α radiation. An empirical absorption correction based on the method of Walker and Stuart was applied [12]. Relative transmission coefficients ranged from 0.478 to 1.000 with an average value of 0.639. The structure was solved using the structure solution program SHELX-86 [13]. The remaining atoms were located in succeeding difference Fourier syntheses. Hydrogen atoms were located and added to the structure factor calculations but their positions were not refined. The structure was refined in full-matrix least-squares where the function minimized was $\Sigma w\ (|F_o|-|F_c|)^2$ and the weight w is defined as by the Killean and Lawrence method with terms of 0.020 and 1.0 [14]. Scattering factors were taken from Cromer and Waber [15]. Anomalous dispersion effects were included in F_c [16]; the values for f' and f'' were those of Cromer [17]. All calculations were performed on a VAX computer. Refinement was done using MolEN [18]. Crystallographic drawings were done using programs ORTEP [19].

Crystal data for [Ru(dcypm)$(CO)_3$] (**5**)

X-ray quality crystals of **5**, ($C_{28}H_{46}O_3P_2Ru$), were grown by solvent evaporation from toluene. A colourless needle having approximate dimensions of $0.50\times0.35\times0.25$ mm^3 was mounted in a glass capillary. The crystal data and data collection parameters are given in Table 1. Structural analysis was similar to that described for **3** with the following modifications. Cell constants and an orientation matrix for data collection were obtained from least-squares refinement, using the setting angles of 25 reflections in the range $17 < \theta < 21°$, measured by the computer-controlled diagonal slit method of centring. As a check on the crystal quality, omega scans of several intense reflections were measured; the width at half-height was 0.43° with a take-off angle of 3.0°, indicating good crystal quality. The structure was solved using the Patterson heavy-atom method which revealed the position of the Ru atom.

RESULTS AND DISCUSSION

The reaction of $[Ru_3CO_{12}]$ with dppm under 1000 psi CO in toluene led to the formation of [$Ru_2(\mu$-dppm$)_2(\mu$-CO$)(CO)_4$] (**3**). In the presence of a 1 : 1 mixture of dppm and dmpm the mixed-ligand system [$Ru_2(\mu$-dmpm$)(\mu$-dppm$)(\mu$-CO$)(CO)_4$] (**4**) was formed in essentially a statistical yield, along with **2** and **3**. Complex **4** was isolated by fractional crystallization from toluene/hexane solutions. Upon continued addition of hexane, complex **2** crystallizes first, followed by **4** and then **3**.

Table 2 compares the carbonyl infrared stretching frequencies of complexes **2–4** and the related diphosphazanes. As expected, increasing the basicity of the ligand from phosphazane to phosphine leads to a decrease in carbonyl stretching frequencies owing to increased π backbonding. Similarly, the less basic **3** shows higher stretching frequencies than **2**. The mixed ligand system **4** exhibits ν(CO) bands at frequencies that are intermediate between the bis(dmpm) and bis(dppm) compounds, **2** and **3**. Complex **3**, like **2**, shows a singlet in the ^{31}P NMR spectrum while the mixed-ligand system, **4**, shows an AA'BB' pattern owing to the different phosphorus chemical environments of dmpm and dppm.

An ORTEP view of [$Ru_2(\mu$-dppm$)_2(\mu$-CO$)(CO)_4$] (**3**) is shown in Fig. 1, and crystal data and data collection parameters are summarized in Table 1. Selected bond distances and angles are given in Table 3. the structure consists of two five-coordinate ruthenium centres separated by a Ru—Ru distance of

[b] KBr pellet.

2.9073(9) Å, as compared with 2.8928(8) for **2** [7]. Similarly Ru—C and Ru—P bond distances are rather similar for **3** and **2**. Generally, core bond distances are longer in **3** than in the related diphosphazane, [$Ru_2\{\mu$-$(MeO)_2PN(Et)P(OMe)_2\}_2(\mu$-CO$)(CO)_4$] [5].

Substituting dcypm in the high-pressure synthesis resulted in the formation of the mononuclear ruthenium complex [Ru(dcypm)$(CO)_3$] (**5**). This is likely to be the result of the steric bulk of the cyclohexyl rings. Dinuclear dcypm-bridged complexes do, however, exist [20]. Complex **5** shows a singlet in the ^{31}P NMR at $\delta -3.3$ and three ν(CO) bands in the IR at 1981, 1899 and 1880 cm^{-1}. This is characteristic of axial, equatorial coordinated ruthenium bis(phosphine) complexes [21–23]. The ν(CO) bands occur lower in energy than the similar bis(diphenylphosphino)ethane (dppe) complex, [Ru(dppe)$(CO)_3$ (ν(CO) = 1997, 1942, 1885 cm^{-1}) [21] owing to the increased basicity of dcypm. The large shift of the ^{31}P NMR signal of **5** higher field (−3.3 ppm) compared with the bridging diphosphine complexes **2**–**4** is characteristic of the four-membered RuP_2C ring of a chelating methylene diphosphine. The ring contributions, Δ_R, to the ^{31}P chemical shifts of chelating methylene diphosphine complexes can be greater than −50 ppm [24].

An ORTEP view of [Ru(dcypm)$(CO)_3$] (**5**) is shown in Fig. 2. Crystal data and data collection parameters are given in Table 1. Selected bond distances and angles are given in Table 4. The complex is mononuclear and five-coordinated about ruthenium. The Ru—C bond distances are 1.884(7), 1.894(6) and

P(2)—Ru—C(3)	95.7(2)		

1.909(7) Å and the Ru—P distances are 2.370(1) and 2.378(1) Å, not significantly different from those reported for [Ru$(PMe_3)_2(CO)_3$] and [Ru$(PPh_3)_2(CO)_3$] [13,14]. The P—Ru—P angle is quite narrow at 70.71(4)°.

We have thus shown the generality of the high-pressure synthesis of mono- and di-nuclear ruthenium complexes from [Ru$(CO)_{12}$] and bis(dialkylphosphino)- or bis(diarylphosphino)-methanes. The novel mixed-ligand complex [Ru_2(μ-dmpm)(μ-dppm)(μ-CO)$(CO)_4$] has also been prepared by this method. The selectivity of this method for preparing mononuclear *vs* dinuclear products appears to depend on the steric requirements of the diphosphine ligand.

(Received 29 July 1996; accepted 27 August 1996)

Abstract—The crystal and molecular structure of the first copper(II) complex of (2-{[3-(trifluoromethyl) phenyl]amino}-3-pyridinecarboxylate with 3-pyridylmethanol as neutral ligand was determined by X-ray analysis. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: fenamate; copper(II) niflumate; 3-pyridylmethanol; crystal structure; X-ray diffraction analysis; bond valences.

(2 - {[3 - (Trifluoromethyl)phenyl]amino} - 3 - pyridinecarboxylic acid (niflumic acid) and other fenamates (flufenamic acid and mefenamic acid) are believed to act through the inhibition of prostaglandin biosynthesis, like other anti-inflammatory analgesics [1]. The interaction of the copper(II) atom, which plays a vital role in a number of quite different biological processes, with therapeutically administrated drugs is a subject of considerable interest.

X-ray crystallographic studies of the 1 : 1 complex between niflumic acid and ethanolamine showed deprotonation of one carboxylic oxygen atom [2]. The bond valences [3] of the niflumate anion calculated by the formula $s = (R_0/R)^N$ are shown in Fig. 1. R is the bond length, R_0 and N are fitted constants. Available atom valences of the terminal atoms were calculated as the difference between the theoretical atomic valence and the sum of bond valences around the atom. The greatest available valence of one oxygen atom indicates the preferred coordination of niflumate ligand to the metal cation through one carboxylic oxygen atom. On the basis of spectroscopic and magnetic properties of $Cu(nif)_2(3\text{-pyMe})_2$ (nif = niflumate, 3-pyMe = 3-pyridylmethanol) the polymeric structure with a pseudo-octahedral environment about the Cu^{II} atom was proposed.

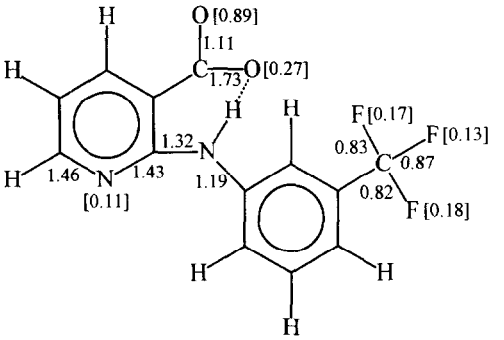

Fig. 1. Bond valences (in valence units, v.u.) of niflumic acid anion. Valences of C—C bonds are in the range 1.20–1.71 v.u. Available valences of the terminal atoms are enclosed in square brackets.

In order to understand better some aspects of metal ion–drug interactions, we have studied the structure of the title compound at room temperature.

EXPERIMENTAL

The copper(II) niflumate was prepared as described elsewhere [4]. The 3-pyridylmethanol adduct of cop-

* Author to whom correspondence should be addressed.

per(II) niflumate was prepared by adding the ligand 3-pyMe (2.73 g, 0.025 mol) to 100 cm^3 of a methanol suspension of $Cu(nif)_2$ (3.43 g, 0.01 mol). After heating to boiling, a solution was obtained which was left to cool and stand at room temperature. The precipitated product was isolated, washed with cold methanol and then dried at room temperature. The crude product was recrystallized from hot methanol to yield green crystals. Found (Calc.) for $Cu(nif)_2(3\text{-pyMe})_2$: Cu, 7.5 (7.5); C, 53.5 (54.0); H, 3.9 (3.9); N, 5.5 (5.6)%.

Crystal data for $Cu(nif)_2(3\text{-pyMe})_2$, $C_{38}H_{30}F_6N_6O_6Cu$

The density of the crystals measured by flotation in CCl_4/benzene mixture is $D_m = 1.52\ g\ cm^{-3}$, calculated $D_x = 1.53\ g\ cm^{-3}$. $M_r = 844.23$, monoclinic, $a = 11.806(3)$, $b = 22.856(6)$, $c = 7.101(8)$ Å, $\beta = 106.7(3)^\circ$; $V = 1835(2)$ Å^3, space group $P2_1/n$, $Z = 2$, $F(000) = 862$, $\mu(\text{Mo-}K_\alpha) = 0.68\ mm^{-1}$. A crystal of dimensions *ca* $0.25 \times 0.20 \times 0.20\ mm^3$ was measured on a Syntex $P2_1$ diffractometer, with graphite-monochromated Mo-K_α radiation ($\lambda = 0.71069$ Å). The cell parameters were refined by least squares for 15 reflections in the range $11.0 \leqslant 2\theta \leqslant 32.1^\circ$. 3308 reflections in total were measured using the $\omega/2\theta$ scan technique, $2\theta_{max} = 110^\circ$, time per reflection *ca* 60 s, index range $0 \leqslant h \leqslant 15$, $0 \leqslant k \leqslant 25$, $-9 \leqslant l \leqslant 8$, two standard reflections with variation 2%, $R_{int} = 0.036$. Correction for empirical absorption was applied. The maximum and minimum transmission factor values were 1.0 and 0.825, respectively. 2219 unique reflections obeying the condition $F > 3\sigma(F)$ were estimated. All non-hydrogen atoms were localized by direct methods, using the SHELXS86 program [5]. The atom-scattering factors and f', f'' values were obtained from *International Tables for X-ray Crystallography* [6]. The structure was refined by the least-squares method, using the SHELX76 program [7]. After the anisotropic refinement all hydrogen atoms were located from difference maps, but not refined. The final values were $R = 0.048$ and $Rw = 0.048$, $w = 0.3802/[\sigma(F_o) + 0.001(F_o)^2]$. Goodness-of-fit, S, was 0.06. The maximum and minimum heights in the final difference Fourier map were 0.5 and -0.3 e Å^{-3}, respectively. All calculations were performed on a PC 386 computer.

RESULTS AND DISCUSSION

The molecular structure of $[Cu(nif)_2(3\text{-pyMe})_2]$ is shown in Fig. 2. Selected bond lengths and bond angles are summarized in Table 1. *Trans* coordination of the Cu atom is formed by two carboxylic oxygen atoms from two niflumic ligands and two nitrogen atoms from two 3-pyridylmethanol ligands. This almost square-planar coordination of the Cu atom is supplemented by two methanolic oxygen atoms of the neighbouring structural units, forming a pseudo-octahedral coordination connecting the units $[Cu(nif)_2(3\text{-pyMe})_2]$ into infinite chains along the Z-direction (Fig. 3). The chains are held mutually by the van de Waals forces.

Using the data in refs [8,9] for Cu—N(1) bond valence, according to Brown and Shannon [10] the predicted bond length Cu^{II}—O(3) is 2.61 Å, which is very close to the observed value (Table 1). The coordination of the Cu^{II} atom may therefore be described as pseudo-octahedral and the Cu···O(2) contact, being 3.231(3) Å, should be regarded as non-bonding. The dihedral angle between the rigid car-

boxylate group [the sum of the bond angles around the C(7) atom is 359.93(7)°] and the equatorial plane of the copper coordination sphere is 93.5(2)°. The intramolecular ligand hydrogen bond N(2)—H(15)···O(2) [the interatomic distances are N(2)···O(2) 2.657(5) and H(15)···O(2) 1.851(3) Å, and the bond angle N(2)—H(15)···O(2) is 135.4(3)°] encloses a pseudo-ring in the niflumic ligand (Fig. 2).

Both benzene and pyridine rings of the niflumic ligand deviate significantly from planarity (χ^2 values of 45.0 and 84.4, respectively). The dihedral angle created by the least-squares planes of both rings is 11.7(1)°. The torsion angle C(8)—C(12)—N(2)—C(13) (Table 2) does not differ from the corresponding angle for the niflumic acid anion (174.1°) [2]. The other two torsion angles defining the conformation of the niflumic ligand differ significantly from the values for niflumic acid (−177.2 and −4.5°). Such deformation is in agreement with the stabilization effect of the hydrogen bond N(2)—H(15)···O(2) occurring in the niflumic acid anion, too. The pyridine ring of the 3-pyridylmethanol ligand is planar. Mean C—C and C—N bond lengths in the niflumic and 3-pyridylmethanol ligands exhibit no significant differences from mean bond lengths of the same type in the structures of morpholinoethyl niflumate [11] and bis(salicylato)-bis(3-pyridylmethanol)copper(II) [12]. The dihedral angle between the plane of pyridine ring and the equatorial plane of the copper atom coordination is 97.3(1)°.

Acknowledgements—We thank Professor G. M. Sheldrick and Dr E. Irmer from the University of Göttingen, Germany, for useful discussions. This work was supported by the

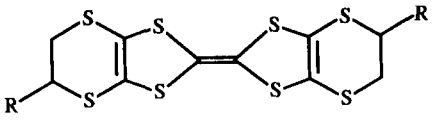
(Received 28 June 1996; accepted 27 August 1996)

Abstract—Two neutral nickel complexes of multi-sulfur 1,2-dithiolenes, [Ni(MEDT)$_2$], **1** (MEDT = 5,6-dihydro-5-methyl-1,4-dithiin-2,3-dithiolate), and [Ni(PHDT)$_2$], **2** (PHDT = 5,6-dihydro-5-phenyl-1,4-dithiin-2,3-dithiolate) have been prepared and characterized. The X-ray structure analysis of **1** reveals that the molecules are arranged as two different oriented "stacks" along the *a* axis. The shortest intrastack S···S contact is 3.9312 Å. © 1997 Elsevier Science Ltd. All rights reserved.



Keywords: crystal structures; nickel complexes; 1,2-dithiolenes; conductors.

Since the metal complexes DMIT ligand (DMIT = 4,5-dimercapto-1,3-dithiole-2-thionate) were first reported to exhibit superconduction, a massive research effort has centred on the design and synthesis of similar complexes [1–2]. The crystal structures of these complexes reveal that intermolecular interactions through the sulfur–sulfur interatomic contact is the basic requirement for high conductivity. Following this, the multi-sulfur 1,2-dithiolene complexes $[Ni(DDDT)_2]^-$ [3] (DDDT = 5,6-dihydro-1,4-dithiin-2,3-dithiolate) and $[Ni(PDDT)_2]^-$ [4] (PDDT = 6,7-dihydro-5H-1,4-dithiepin-2,3-dithiolate) have been synthesized and studied. In our previous work we reported the syntheses, properties of the nickel complexes of MEDT and PHDT ligands (MEDT = 5,6-dihydro-6-methyl-1,4-dithiin-2,3-dithiolate; PHDT = 5,6-dihydro-5-phenyl-1,4-dithiin-2,3-dithiolate) and the crystal structure of $[Bu_4N][Ni(MEDT)_2]$ [5].

In a continuation of this work, we have synthesized the two neutral complexes of MEDT and PHDT ligands, [Ni(MEDT)$_2$] (**1**) and [Ni(PHDT)$_2$] (**2**, see Scheme 1), which are "inorganic analogues" of the organic donor molecules BMeDT-TTF [6] and BPhDT-TTF [7] (BMeDT-TTF = bis(5,6-dihydro-5-methyl-1,3-dithiol-[4,5-*b*][1,4]-dithiocyclohexen-2-ylidene); BPhDT-TTF = bis(5,6-dihydro-5-phenyl-1,3-dithiol-[4,5-*b*][1,4]-dithiocyclohexen-2-ylidene). We also report the crystal structure of [Ni(MEDT)$_2$] (**1**).

EXPERIMENTAL

Reagents

$[Bu_4N][Ni(MEDT)_2]$ and $[Bu_4N][Ni(PHDT)_2]$ were prepared according to the literature method [3]. All the chemicals used were analytically pure without further purification.

Syntheses

$[Ni(MEDT)_2]$ (**1**) and $[Ni(PHDT)_2]$ (**2**) were prepared by I_2 oxidation of $[Bu_4N][Ni(MEDT)_2]$ and $[Bu_4N][Ni(PHDT)_2]$ in acetone, respectively.

The black needle-shaped crystals of $[Ni(MEDT)_2]$ were obtained by recrystallization in CS_2 through slow evaporation. Found: C, 27.0; H, 2.8. Calc. for $C_{10}H_{12}S_8Ni$: C, 26.9; H, 2.7%. IR (KBr): 1257(s), 1214(s), 1144(s), 1076(m), 873(m), 483(m) Cm^{-1}.

$[Ni(PHDT)_2]$ was recrystallized from CS_2 or benzene. Found: C, 42.3; H, 3.1. Calc. for $C_{20}H_{16}S_8Ni$: C, 42.0; H, 2.8%. IR (KBr): 1234(s), 1174(s), 1134(m), 886(m), 469(m) cm^{-1}.

Physical measurements

IR spectra were measured on a Nicolet FT-IR 170SX spectrophotometer using KBr pellets. UV–vis and NIR spectra were recorded on a UV3100 spectrophotometer. Elemental analyses were performed using a Perkin–Elmer 240 analytical instrument.

Single-crystal analysis

A representative crystal of $[Ni(MEDT)_2]$ (**1**) was surveyed. A data set was collected using a Siemens P4 diffractometer equipped with graphite-monochromated Mo-K_α radiation ($\lambda = 0.71073$ Å). A psi-scan was used for an empirical absorption correction [8]. Pertinent crystal survey, data collection and structure refinement are summarized in Table 1.

The structure was solved by direct method using SHELXL-86 [9] and refined by full-matrix least-squares method on F^2 using SHELXL-93 [10]. The H atoms located from difference maps and refined isotropically.

RESULTS AND DISCUSSION

The neutral complexes of $[Ni(DDDT)_2]$ [11], $[Ni(DMIT)_2]$ [12] and $[Ni(PDDT)_2]$ [13] are very insoluble in CS_2, benzene and other organic solvents. Attachment of a bulky group, such as phenyl in **2** and methyl in **1**, did indeed increase the solubility in CS_2 and benzene enabling us to obtain good crystals of **1** and **2** for structure determination.

The complexes **1** and **2** in benzene solution show strong broad absorption at 1029 ($\varepsilon = 36{,}000$) and 1028 nm ($\varepsilon = 43{,}000$), respectively. This low energy near-IR absorption is due to the $\pi \rightarrow \pi$ transition of

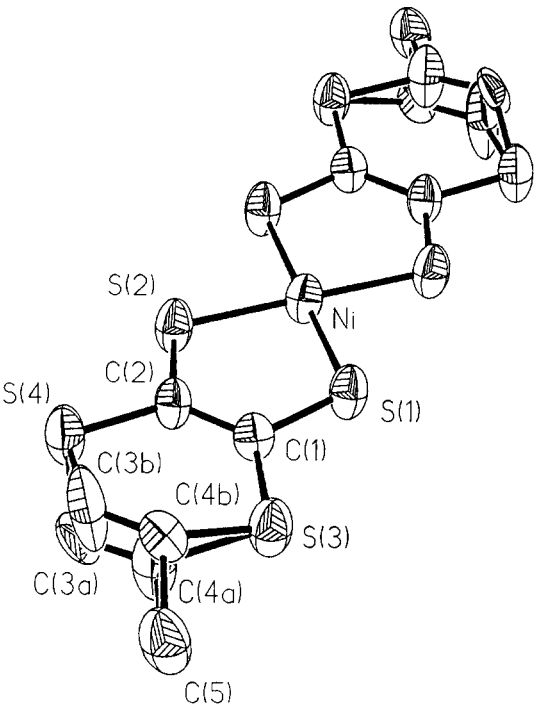

Fig. 1. Structure of $[Ni(MEDT)_2]$ with the numbering scheme.

the delocalized ligand. While the monoanion, $[Ni(MEDT)_2]^-$ and $[Ni(PHDT)_2]^-$, exhibit this band at 1177 and 1172 nm, respectively [5].

The three IR absorption bands of **1** at 1257, 1274 and 873 cm^{-1} are ascribed to ν(C=C), ν(C—S) and ν(R—C≪), respectively. While in complex **2,** these bands are around 1234, 1174 and 840 cm^{-1}.

Figure 1 shows the structure and labelling scheme of [Ni(MEDT)$_2$ (**1**). Selected bond lengths and angles for the complex are listed in Table 2. A comparison of the structural features of [Ni(MEDT)$_2$] to other selected monoanionic and neutral nickel dithiolenes is shown in Table 3.

The four sulfur atoms surrounding the nickel atom yield a square-planar environment with an average S—Ni—S angle of 91.30(9)°. The average Ni—S, C—S and C=C bond lengths in the five-membered ring containing the nickel atom are 2.128(3), 1.703(5) and 1.399(12) Å, respectively, while in the monoanion, $[Bu_4N][Ni(MEDT)_2]$, these values are 2.126, 1.73 and 1.34 Å, respectively. The shorter C—S bond lengths in [Ni(MEDT)$_2$] are indicative of double-bond character. This is the same in other similar complexes, as [Ni(PDDT)$_2$ [13] [1.711(4) Å], [Ni(PHDT)$_2$ [14] (1.706 Å) and [Ni(DDDT)$_2$] [1.68(2) Å]. It suggests that oxidation occurs essentially on the 1,2-multi-sulfur dithiolene ligand rather than the metal centre.

The external —$CH_2CH(Me)$— groups exist in a *trans* configuration. C(3), C(4) and C(5) are highly uncharacteristic, which are certainly due to the conformational disorder of the non-planar outer ring. The partial occupancies for C(3A), C(3B), C(4A) and C(4B) are 0.5, respectively.

A stereoview of the unit cell packing of the [Ni(MEDT)$_2$] molecules viewed down the *b* axis (Fig. 2) shows the molecules forming a layered structure along the *c* axis. From Fig. 3 we can see the molecules are arranged as two differently oriented "stacks" along the *a* axis. This is similar to the structure of [Ni(PHDT)$_2$ [14].

The shortest intrastack S···S contact in this structure is 3.9312 Å, occurring between S(3) and S(3) $(-X+1, -Y+1, -Z+1)$. There is no close S···S

(Received 18 June 1996; accepted 27 August 1996)

Abstract—The first dodecanuclear manganese aggregate containing heterocarboxylate ligands $[Mn_{12}O_{12}(O_2CMe)_4(O_2CEt)_{12}(H_2O)_4]$ (**1**) has been prepared and structurally characterized. The single crystal X-ray diffraction of **1** shows that it is similar to $[Mn_{12}O_{12}(O_2CR)_{16}(H_2O)_4]$ (**2a**, R = Me or **2b**, R = Ph) in its skeletal structure but it has a different crystal structure. Primary magnetism studies imply that **1** has an $S = 9$ spin ground state. A clear hysteresis loop was also observed for a polycrystalline sample of $\mathbf{1}\cdot 2H_2O\cdot 4EtCOOH$, but there was no anomaly in susceptibility down to 1.5 K. The cluster **1** represents another example of nanometre-sized molecular superparamagnets without particle size distribution. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: manganese-oxo cluster; nanomolecule; molecular bistability; superparamagnet; molecular magnetism; mesoscopic physics and chemistry.

An important development in molecular magnetism is the progress from the study of the paramagnetic properties of isolated molecules to the design and synthesis of the so-called molecular ferromagnets—molecular materials exhibiting spontaneous magnetization below a critical temperature [1,2]. A fundamental step in the preparation of molecular ferromagnets is the synthesis of molecular species possessing large spin ground states, which are ferromagnetically arranged in the solid structure. Recently, synthetic methodologies for clusters of increasing complexity [3–10] have opened a new road to preparing this kind of molecule, with large spin ground state, because high nuclearity spin clusters could stabilize high-spin ground states. To date, several aggregates with high-spin ground states have been reported [9,11–18] and superparamagnetic-like behaviour has been proven in some of these aggregates [9,14,19]. Our research group began work on this project in 1993 and a ferromagnetic transition at $T_c = 3.3$ K in a manganese-containing high-spin cluster was observed in our laboratory and communicated in this journal recently [20]. In this communication, we report a manganese-containing mesoscopic molecular superparamagnet **1** with an $S = 9$ spin ground state.

To a clear solution of $Mn(O_2CMe)_2\cdot 4H_2O$ (2 g, 8.15 mmol) in 20 cm^3 60% (v/v) $EtCO_2H/H_2O$ was slowly added, dropwise, $KMnO_4$ (0.5 g, 3.15 mmol) with caution, followed by slow heating to 60°C. On cooling to room temperature, the resulting black-brown solution was filtered and allowed to stand in air without disturbance. After about 3 weeks, black crystals of $\mathbf{1}\cdot 2H_2O\cdot 4EtCO_2H$, were deposited in 60% yield based on Mn^{VII}. Elemental analyses of this sample are in agreement with the indicated formulation.

Cluster **1** crystallizes in the space group $I\bar{4}$ with two water and four propionic acid molecules and the corresponding crystallographic data for $\mathbf{1}\cdot 2H_2O\cdot 4EtCO_2H$ are given in Table 1. Unlike the cluster **2** [13,21], there are two discrete molecules of **1** in the asymmetric unit with essentially identical structures. As shown in Fig. 1, cluster **1** has a dimension of 1 nm owing to the longest metal–metal distance of 8.49 Å,

and is made up of a central $Mn^{IV}_4O_4$, almost ideal, cubane held within a non-planar ring of eight Mn^{III} atoms by μ_3-oxide atoms. However, peripheral ligation is by twelve μ_2-propionate, four μ_2-acetate and four H_2O groups. Besides μ_3-oxide bridges, the four Mn(1) and four Mn(2) atoms are linked by four μ_2-acetate bridges, but the four Mn(2) and four Mn(3) atoms are linked by eight μ_2-propionate bridges instead of the acetate groups as in **2a**. Octahedral Mn^{III} should be Jahn–Teller distorted, and this is apparent in the Mn(2) atoms with tetragonal elongation along the axes parallel to the principal molecular $\bar{4}$ axis. The Jahn–Teller effect also occurs in the Mn(3) atoms but this is probably an orthorhombic distortion. The four H_2O ligands are located on the four Mn(3) atoms to complete their octahedral coordination.

Variable-temperature magnetic susceptibility data were recorded at 10 kG in the range 1.5–300 K for a polycrystalline sample of cluster **1**, and are presented in Fig. 2. In Fig. 3 the effective magnetic moment per molecule versus temperature is shown. From this figure we find that the effective magnetic moment per molecule drops slightly from $12.03\mu_B$ at 300 K to $11.65\mu_B$ at 195 K, then it steadily increases with decreasing temperature to reach a maximum of $22.70\mu_B$ at 9.2 K, below which it drops again sharply to $5.17\mu_B$ at 1.5 K. This behaviour clearly indicates that there are appreciable intramolecular magnetic exchange interactions in this cluster and not all of the spin states of the cluster are equally thermally populated, because if there were no magnetic exchange interactions present in a mixed valency $Mn^{IV}_4Mn^{III}_8$ aggregate, or all the spin states were equally thermally populated, the spin-only effective magnetic moment with $g = 2$ should be equal to $15.87\mu_B$. Apparently, the principal interaction in this cluster is ferromagnetic, owing to the increase in effective moment per molecule with decreasing temperature below 195 K and the cluster has a maximum average spin state of 11 at 9.2 K. However, there must be some competing antiferromagnetism as well, owing to the decrease in the effective moment per molecule and the smaller values than $15.87\mu_B$ with decreasing temperature in the range from 300–195 K. Furthermore, the shape of Fig. 3 and the average spin state of 11 at 9.2 K suggest that all of the clusters are populated in some large spin ground states which are net ferromagnetic at low temperature. The decline in effective magnetic moment below 9 K reflects zero-field splitting in the ground state which is associated with the single-ion anisotropy of the Jahn–Teller-distorted manganese(III) ions.

In order to determine the spin of the ground state, bulk magnetization (M) measurements were performed for this compound at 1.5 K in fields in the range 0–70 kG. The bulk reduced magnetization ($M/N\beta$) is shown in Fig. 4, plotted as a function of H/T. This curve should follow a Brillouin function [22], and at large H/T (i.e. spin saturation), $M/N\beta$ approaches a maximum value of $2S$ with $g = 2$. Figure 4 shows clearly that the cluster **1** has an $S = 9$ ground state because the value of $2S$ goes towards 18 when H/T is greater than 2. Additionally, a break was observed in this curve at $H/T \approx 1$, which suggests that there should be a transition of molecular origin relative to the applied magnetic field and temperature in this cluster.

Interestingly, this cluster exhibits a clear hysteresis loop below 3 K, as shown in Fig. 5, although its curve of initial magnetization is not surrounded by this loop. This hysteresis effect is totally different from that of a three-dimensional ordered ferromagnet, which shows an anomaly in the susceptibility (see Fig. 2) and specific heat curves at the Curie temperature, and appears to be of molecular origin. We feel that this magnetic hysteresis may result from the applied field-induced molecular states transition between the two stable states $M_S = \pm 9$ of this cluster and this kind of transition could indeed be observed in the initial magnetization curve near the "coercive" field, where there is a break in this curve (Figs 2 and 5). Similarly to cluster **2a**, a superparamagnetic-like property should be responsible for the magnetic behaviour of this cluster.

To conclude, the present results indicate that cluster **1** represents the first example of a dodecanuclear manganese aggregate containing mixed carboxylate ligands structurally characterized by single crystal X-ray diffraction and is another interesting compound with mesoscopic structure, which is a new field between micro- and macroscopic structures, and has a dimension of several to hundreds of nanometres, and molecular superparamagnetic properties. Since there is no molecular weight distribution, it is a better model system for mesoscopic physics and chemistry.

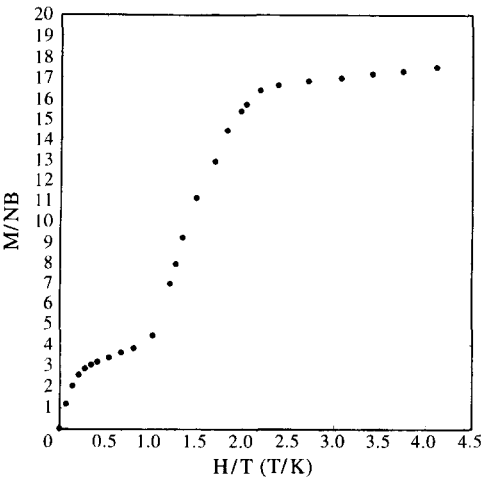

Fig. 4. Plot of reduced magnetization, $M/N\beta$ versus H/T for $1 \cdot 2H_2O \cdot 4EtCO_2H$, where N is Avogadro constant number, β is the Bhor magneton, and H is the magnetic field.

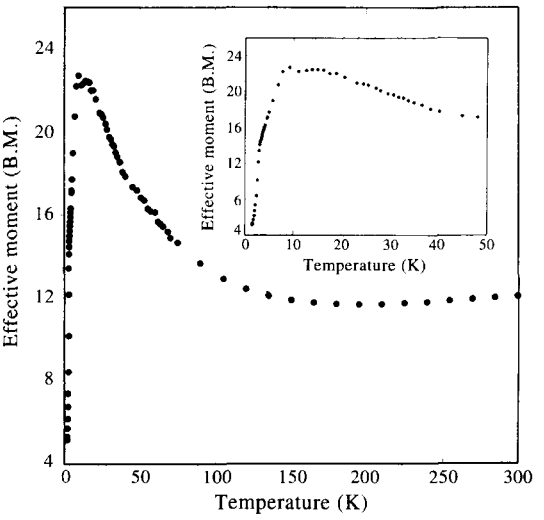

Fig. 3. Plot of effective magnetic moment per molecule (μ_{eff}/molecule) measured at 10 kG versus temperature for $1 \cdot 2H_2O \cdot 4EtCO_2H$.

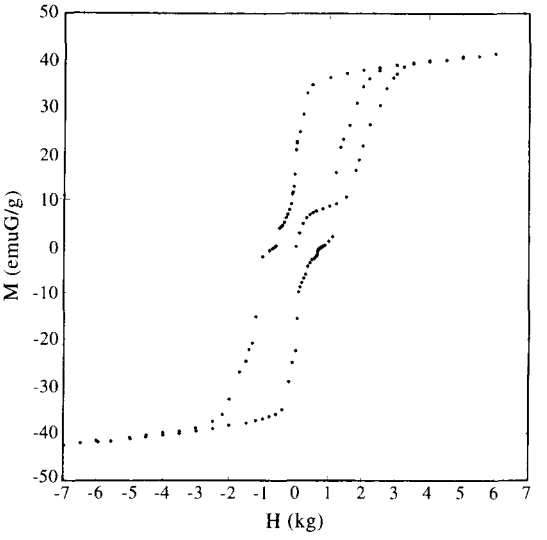

Fig. 5. Hysteresis loop of a powder sample of $1 \cdot 2H_2O \cdot 4Et$-CO_2H at 1.5 K.

In addition, the observed hysteresis for individual molecules implies that there are two stable states in some molecular systems which could be frozen under an applied magnetic field. This molecular bistability opens a new road to store information at the molecular level.

(Received 12 July 1996; accepted 23 August 1996)

Abstract—The reaction of $CuCl_2 \cdot 2H_2O$ with 1-(2-carboxybenzoyl)thiosemicarbazide (H_3L) and imidazole (HIm) in NaOH gave a Cu^{II} complex, which was crystallized from pyridine (Py) to give complex **1**, $[Cu_3L_2(Py)_6(HIm)](H_2O)_2$. The complex molecule contains a linear Cu_3 array in which the central copper atom at the crystallographic inversion centre has an octahedral environment and the other two Cu atoms are square pyramidal, each bridged to the central Cu atom *via* the L group, with the atoms O(1) and N(2) chelating to Cu(1), and the atoms N(1), S and O(2) to Cu(2). The carboxylate groups coordinate to the metal atoms in a unidentate fashion. Complex **2**, $[Cu_2(H_3L)_2Cl_2](H_2O)_3$, obtained by the reaction of $CuCl_2 \cdot 2H_2O$ with H_3L has been characterized by IR, UV, NMR (^1H and ^{13}C) spectra, and TGA and molar conductance measurements. The ESR and magnetic moment measurements show that the Cu atoms in complex **2** are in the Cu^I oxidation state. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: syntheses; crystal structure; Cu^{II} complex; Cu^I complex; 1-(2-carboxybenzoyl)thiosemicarbazide; pyridine.

Substituted phthalamidic acids are important for their many kinds of pharmacological activities and analytical uses [1,2]. It has been reported that their metal complexes could exhibit more efficient actions. Up to now, many substituted phthalamidic acids and their transition metal complexes have been reported [3]. However, most of the published work has focused on ligands with only oxygen and nitrogen donor atoms. In recent years, metal complexes with sulfur-containing ligands such as thiosemicarbazone and its derivatives have been given great attention because of their biological and magnetic properties [4,5]. It is also thought that the N,N,S-tridentate ligand system is a common feature for carcinostatic potency. In particular, the copper complexes of pyridine-2-carbaldehyde thiosemicarbazone have been shown to be stable in biological systems [4] and have *in vitro* cytotoxic effects against Ehrlich cells, and a second mechanism of interaction has been suggested involving the binding of the copper(II) drug to the nitrogen bases of DNA or RNA [6].

In our previous work, a series of lanthanide complexes with an amido acid derived from 4-pheynylthiosemicarbazide were reported [7], and the biological activity studies showed that some of them (Ce, Sm and Tm) demonstrated definite antiarthritic activities *in vivo*. However, no X-ray crystallographic data on such complexes have yet been reported. In order to study the structural properties of complexes with these kinds of ligands, and to extend the study on the relationship between the coordination behaviour and the biological activities, we have synthesized two copper complexes with a new ligand derived from thiosemicarbazide (Fig. 1).

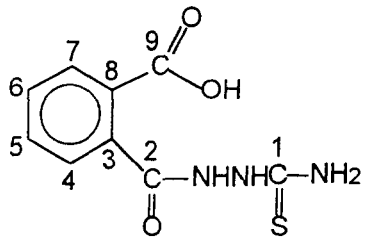

Fig. 1. 1-(2′-carboxybenzoyl)thiosemicarbazide (H_3L) (m.f. $C_9H_9O_3N_3S$) (the numbers in the figure are denoted for ^{13}C NMR assignments).

EXPERIMENTAL

All the chemicals are of A.R. grade and used without further purification.

Synthesis of the ligand H_3L

To 100 cm^3 of acetonitrile solution containing phthalic anhydride (3.8 g, 25.3 mmol) was added thiosemicarbazide (2.3 g, 25.3 mmol). This reaction mixture was stirred at 60–70°C for 2 h, then was refluxed for one more hour. The precipitate formed was filtered and recrystallized from methanol–ethanol (2:1, v/v), and dried *in vacuo*. Yield, 1.54 g (85%). Found: C, 45.1; H, 4.1; N, 17.7. Calc. for $C_9H_9N_3O_3S$: C, 45.2; H, 3.8; N, 17.6%.

Synthesis of complex **1** $[\{Cu_3L_2(Py)_6\}(HIm(H_2O)_2]$

To 30 cm^3 of an aqueous solution of NaOH (0.1 g, 3.0 mmol) and H_3L (0.3 g, 1.0 mmol) was added $CuCl_2 \cdot 2H_2O$ (0.3 g, 1.5 mmol). After stirring at room temperature for 1 h, imidazole (0.1 g, 1.5 mmol) was added. The mixture was then stirred continuously for two more hours. The brown solid precipitated was isolated by filtration, washed repeatedly with water and anhydrous methanol and dried *in vacuo*. After slow evaporation of the pyridine solution of the solid (0.2 g in 10 cm^3 of pyridine) over a period of a few weeks (the volume was reduced to about 3 cm^3), deep green crystals deposited, which were filtered and dried in air. Yield, 0.1 g. Found: C, 49.1; H, 4.5; N, 16.2. Calc. for $C_{51}H_{50}N_{14}O_8S_2Cu_3$: C, 49.3; H, 4.0; N, 15.8%.

Synthesis of complex **2** $[\{Cu_2(H_3L)_2Cl_2\}(H_2O)_3]$

To 25 cm^3 of an anhydrous methanolic solution containing H_3L (0.6 g, 2.5 mmol) was added $CuCl_2 \cdot 2H_2O$ (0.4 g, 2.5 mmol). After stirring for 3–4 h at room temperature, a white product precipitated and was collected, washed thoroughly with anhydrous methanol and dried *in vacuo*. Yield, 0.5 g (57%). Found: C, 29.4; H, 3.0; Cl, 10.1; N, 11.4; S, 9.2. Calc. for $C_{18}H_{24}N_6O_9S_2Cu_2Cl_2$: C, 29.6; H, 3.3; Cl, 9.7; N, 11.5; S, 8.8%.

Physical measurements

Elemental analyses (C, H and N) were performed on a Carlo–Erba 1106 elemental analyser. The contents of Cl and S were analysed in our group. IR spectral data were recorded on a Magna 750 spectrometer as KBr disks in the range of 4000–200 cm^{-1}. UV spectra were collected by a Shimadzu UV-300 spectrophotometer. NMR (^1H and ^{13}C) spectra were recorded on a Bruker AM 500 spectrometer in DMSO-d_6 solution. ESR spectra were measured with a Bruker 2000-SRC spectrometer. Magnetic susceptibility measurements were carried out at room temperature with a CTP-F_{82} Faraday balance, and by the Guoy method with $CuSO_4 \cdot 5H_2O$ ($\chi_g = 6.06 \times 10^{-6}$ c.g.s. μ) as calibrant. Molar conductance values were collected on a Shanghai-11A molar conductometer in DMSO solution. TGA data were recorded in nitrogen between room temperature and 450°C by a Shimatzu TGA 50 thermogravimetric analyser.

Crystal structure determination

Crystallographic details for complex **1** are listed in Table 1. The unit-cell parameters were determined by a least-squares treatment obtained with $10.09 < \theta < 10.93°$. The single crystal was mounted on an Enraf–Nonius CAD4 diffractometer for data collection. Three reflections were chosen as intensity standards and were remeasured every 400 reflections. No significant intensity decay was found during the data collection. Data were corrected for Lorentz, polarization and absorption effects. All the calculations were performed on a VAX 785 computer using the TEXSAN program package. The structure was solved by heavy-atom methods with some of the non-hydrogen atoms located by successive difference Fourier syntheses, and was refined by the full-matrix least-squares method with anisotropic thermal parameters for all the non-hydrogen atoms. Hydrogen atoms were included as fixed contributions and not refined. The solvent imidazole molecule was disordered over two positions and atom N(8) is the statistical distribution of C and N atoms. The occupancy percentage for H(25), which would be attached to the C atom is 50%.

RESULTS AND DISCUSSION

The syntheses of the two complexes can be described by the following two equations:

$$2H_3L + 3CuCl_2 \cdot 2H_2O \xrightarrow[2.Py]{1.NaOH/H_2O} \text{Complex } \mathbf{1}$$

$$H_3L + CuCl_2 \cdot 2H_2O \xrightarrow{MeOH} \text{Complex } \mathbf{2}$$

Complex **1** is a deep green crystalline solid, while complex **2** is a white powder. Both are insoluble in common solvents such as alcohol, chloroform and

acetonitrile, but soluble in DMF, DMSO and Py. The low molar conductance values of 13.58 $\mu s \cdot cm^{-1}$ for complex **1** and 7.32 $\mu s \cdot cm^{-1}$ for complex **2** imply a non-electrolytic nature for these neutral complexes.

The TGA data show that complex **2** began to lose three water molecules at about 53–70°C, corresponding to the weight loss of 7.82% (Calc. 7.40%). Because of the low temperature, such water molecules can be regarded as lattice water. At about 296°C, this complex tends to decompose.

For complex **1**, the ESR spectrum at 286 K consists of one band with $g = 2.0866$, $\Delta H = 178.2$ G, and at 77 K, it is composed of one band with $g = 2.0910$, $\Delta H = 177.0$ G, showing that the copper ions in complex **1** remain in the 2+ oxidation state. For complex **2**, there are no signals in the ESR spectra at the above two temperatures, and the result of the magnetic susceptibility measurement at room temperature showed that complex **2** was diamagnetic in nature, confirming that the Cu ions in complex **2** are in the Cu^I state.

Description of the structure of complex **1**

The molecular structure and packing in the unit cell for complex **1** are depicted in Figs 2 and 3, respectively. Selected bond distances and angles are summarized in Table 2.

As shown in Fig. 1, the three copper atoms are linked together linearly by two μ_2-bridged L groups. The central Cu(1) atom is located on the crystallographic inversion centre with either of the other two copper atoms located 4.738(2) Å away. The Cu(1) atom is in a six-coordinated octahedral geometry with the two pyridine molecules in axial positions and the two amido-carbonyl oxygen atoms [O(1), O(1a)] in the equatorial plane. The terminal Cu(2) atom is coordinated in a trigonal-bipyramidal geometry composed of two nitrogen atoms from two pyridine molecules and one sulfur atom from the thiourea, as well as one oxygen atom from the carboxylate. Thus, the L group forms two five-membered chelate rings with the Cu atoms, ring Cu(1)O(1)C(1)N(1)N(2) and ring Cu(2) SC(9)N(2)N(1), with a dihedral angle of 7.5(1)°. A third seven-membered ring, Cu(2)O(2)C(8)C(7)C(2) C(1)N(1), is puckered along atoms N(1) and C(8), with a dihedral angle of 106.9(4)° between the two least-squares planes N(1)C(1)C(2)C(7)C(8) and C(8)O(2)Cu(2)N(1). Therefore, the ligand L is η^2(O,N)-chelated to Cu(1) and η^3(N,S,O)-chelated to Cu(2).

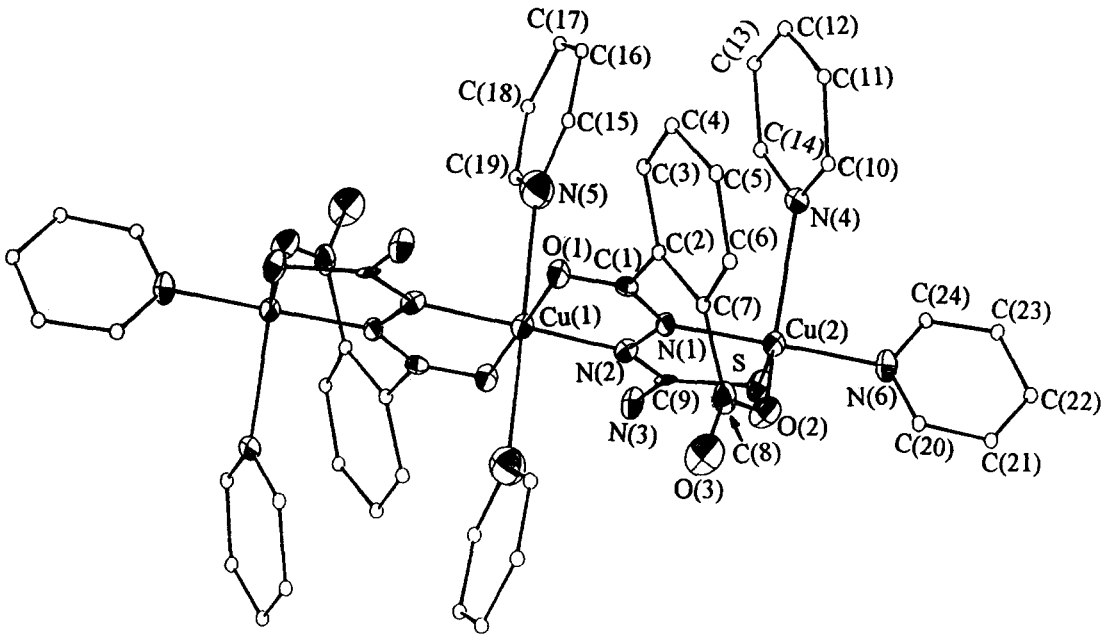

Fig. 2. Structure of the $[Cu_3L_2(Py)_6]$ core of complex **1** with the hydrogen atoms omitted for clarity.

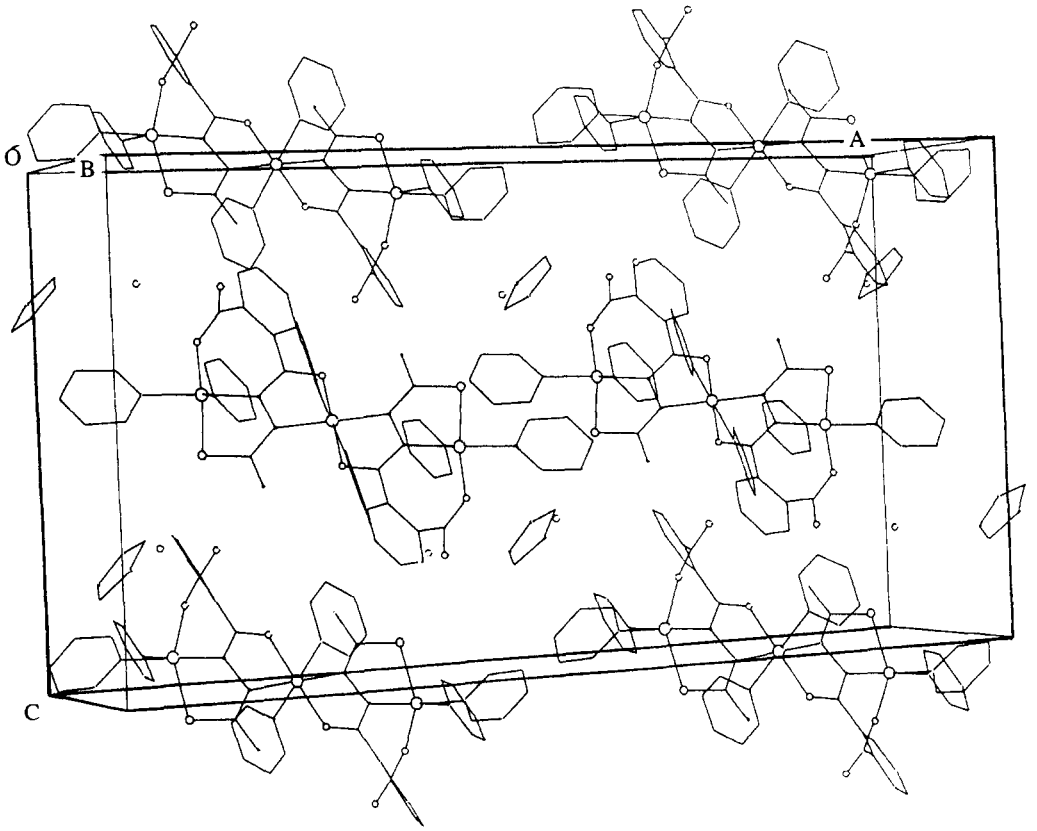

Fig. 3. The unit cell packing of complex **1** $[\{Cu_3L_2(Py)_6\}(HIm)(H_2O)_2]$.

the complex is: Py(5) > Py(4) > Py(6) as shown by the order of the Cu—N_{Py} distances Cu(1)—N(5) > Cu(2)—N(4) > Cu(2)—N(6). The Cu(1)—O(1) and Cu(1)—N(2) distances are 1.960(5) and 1.991(7) Å, respectively, both of which are slightly longer than those in a previously reported dinuclear copper(II)

semicarbazone compound with a similar coordination mode [8], probably owing to the steric effect of the pyridine molecules. The distances Cu(2)—S [2.277(3) Å] and Cu(2)—N(1) [1.974(6) Å] agree well with the corresponding bonds in the Cu^{II} complexes containing thiosemicarbazone ligands [5]. The bond Cu(2)—O(2) [1.992(6) Å] involving the carboxylate group is within the normal range of unidentate coordination of a carboxylate to Cu^{II} [9]. The bonds C(1)—N(1), N(2)—C(9), O(1)—C(1) and C(9)—S are well within the range of published results for thiosemicarbazone complexes [5], indicating the existence of C(1)=N(1), N(2)=C(9), O(1)—C(1) and C(9)—S bonds. It is noted that the N—N bond distance of 1.415(8) Å is slightly longer than those reported in the literature for thiosemicarbazone copper(II) compounds [5,10], which might be owing to their different coordination mode. The non-coordinated carboxylate oxygen atom O(3) is hydrogen-bonded with both the solvate water molecule [O(1w)···O(3) = 2.91(1) Å, O(1w)—H_{23}—O(3) = 156.0(1)°] and the NH_2 group [O(3)···N(3) = 2.96(1) Å, O(3)—H_2—N(3) = 166.9(1)°]. The imidazole molecule adopts a space-filling role only.

NMR (^1H, ^{13}C)

Because of the strong paramagnetic nature of complex **1**, it is hard to interpret its NMR spectral data.

In the ^1H NMR spectrum of the free ligand H_3L, the proton signal at δ 13.73 is attributed to OH(COOH), while the two peaks at δ 10.36 and 9.44 are ascribed to NH[1H, C(O)NH] and NH[1H, NHC(S)], respectively. The proton signals for the phenyl ring are found at δ 8.23, 7.90, 7.68 and 7.60. The peak for NH(2H, C(S)NH_2) appears at δ 7.43.

In the ^1H NMR spectrum of complex **2**, most of its proton signals are observed shifted downfield relative to those of the free ligand H_3L. The peak at δ 13.63 is ascribed to OH(1H, COOH), which is much closer to that of the ligand H_3L, suggesting that in complex **2** the carboxylate group is not involved in coordination to the metal ion. In comparison with the free ligand H_3L, the two slightly downfield-shifted proton signals of NH[1H, C(O)NH] and NH[1H, NHC(S)] at δ 10.68 and 10.24, respectively, indicate that neither of these two nitrogen atoms binds to the metal atom, and the slightly downfield shift effect might be due to the coordination of the S and the O atom of the amido-carbonyl group to the metal ion, which can be confirmed further by the IR spectra. Unlike for the free ligand, two proton signals at δ 8.89 and 7.54 appear for C(S)NH_2 in complex **2**.

In the ^{13}C NMR spectrum of the ligand H_3L, the signal at δ 182.94 is ascribed to C_1 (atom labelling is given in Fig. 1), and δ 168.32 to C_2 and C_9. The other six peaks at δ 137.36, 132.80, 130.24, 130.17, 129.33 and 128.62 are attributed to C_3, C_5, C_7, C_6, C_8 and C_4, respectively.

With respect to complex **2**, all the signals have been found to shift to higher fields compared with those of the ligand. The signal for C_1 is observed to shift to a higher field at δ 179.01, such a high-field shift effect may be ascribed to the existence of the M → S back donation in complex **2**. Unlike in the free ligand H_3L, C_2 and C_9 are found separately at δ 167.60 and 167.95, respectively. The signals for the phenyl ring are observed at δ 136.26 (C_3), 132.31 (C_5), 129.89 (C_7), 129.74 (C_6), 128.88 (C_8) and 128.16 (C_4).

IR and UV spectra

For all three compounds (H_3L, **1** and **2**) bands in the region 3390–3180 cm^{-1} are usually attributed to the stretching frequencies ν(NH), and bands in the region 3530–3540 cm^{-1} in the two complexes can be assigned to ν(OH) from water. The intense band arising from the amide-I stretching vibration at 1655 cm^{-1} in the free ligand undergoes changes in frequency and intensity when compared with those of the two complexes. In complex **1**, it shifts to 1548 cm^{-1}, while in complex **2**, it appears at 1630 cm^{-1}, suggesting the complexation of the oxygen atom of the amido-carbonyl to the metal ion in these two complexes. As regards the mode of the C=S group, this band at 840 cm^{-1} in the free ligand H_3L has changed to 735 cm^{-1} in complex **1**, suggesting coordination *via* the thiolate sulphur atom, which is also indicated by the presence of a band of 345 cm^{-1} assignable to ν(Cu—S) [11]. For complex **2**, the ν(C=S) band has shifted to 785 cm^{-1}, indicating engagement of the thionyl sulfur atom in the complex formation, and the band at 257 cm^{-1} is assigned to ν(Cu—S) [12]. Additionally, in complex **1**, coordination of the nitrogen and oxygen atoms to Cu atoms is observed by the presence of bands at 450–480 cm^{-1}, assignable to ν(Cu—N) [13] and ν(Cu—O) [4].

The UV spectral diagrams of the ligand H_3L and the two complexes are shown in Fig. 4. The absorption at about 272 nm for the compounds is assigned to the $^1L(a)$ absorption of the aromatic ring. The absorption peak at 330.4 nm for the free ligand H_3L is attributed to a $\pi \rightarrow \pi^*$ transition. In the case of the spectra of the two complexes, there is no absorption above 300 nm, implying coordination of the oxygen atom of the amido-carbonyl to the metal ion in the complexes. The absorption band at 300 nm in complex **1** is ascribed to $^1L(b)$ of the aromatic ring.

Therefore, based on the aforementioned facts and known preference of Cu^I for the tetrahedral structure [15], the proposed structure of complex **2** can be tentatively described as that shown in Fig. 5.

(Received 12 August 1996; accepted 22 August 1996)

Abstract—The mutagenic activity of the rhodium(III) complexes with 2,2′-biquinoline(biq) and 2-(2′-pyridyl)quinoline(pq) namely, *mer*- and *fac*-$[Rh(pq)Cl_3(H_2O)]$, *cis*-$[Rh(NN)_2X_2]X$ (NN = biq or pq; X = Cl, Br) and *cis*-$[Rh(pq)_2Cl_2]$ $[Rh(CO)_2Cl_2]\cdot H_2O$, was investigated in strains of *Salmonella typhimurium* TA1530 (hisG46, Δgal, Δuvr, R^-) and TA98 (hisD3052, ΔuvrB, rfa, R^+). All of the complexes studied appear to be active in inducing both base substitution and frame shift mutations. The complex *cis*-$[Rh(biq)_2Cl_2]Cl$ exhibits the highest activity in both strains and has the lowest toxicity. © 1997 Elsevier Science Ltd. All rights reserved.

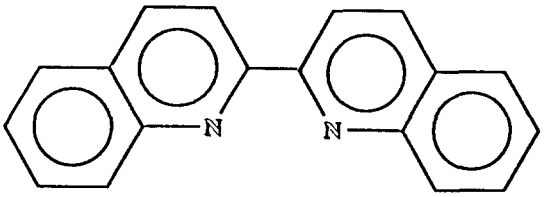
Keywords: mutagenic activity; rhodium(III); 2,2′-biquinoline; 2-(2′-pyridyl)quinone; *Salmonella typhimurium* TA1530 and TA98; base substitution; frame shift mutations.

In 1969 complexes of rhodium(III) of the type *trans*-$[RhL_4X_2]Y$ (L = substituted pyridine; X = Cl, Br; Y = Cl, Br, NO_3, ClO_4) were reported to have high levels of antibacterial activity [1]. During the same year, Rosenberg *et al.* reported that cisplatin, *cis*-$[Pt(NH_3)_2Cl_2]$, was a potential antitumour complex [2]. Since that time, the biological properties of many complexes of Group VIIIB metals, especially rhodium, ruthenium, iridium and palladium, in addition to platinum have been investigated (for example, see [3–10]).

The antitumour property of cisplatin was based upon the observation that this complex induced filamentous growth in strains of *Escherichia coli* [8]. When this microbiological property was used to test the biological activity of a series of platinum-group metal complexes, rhodium(III) complexes were found to be the most active [8].

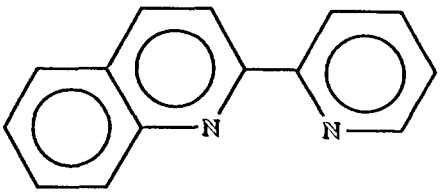
Complexes of rhodium(III) of the type *cis*-$[Rh(NN)_2X_2]X$ (NN = 2,2′-bipyridine (bpy) or 1,10-phenanthroline (phen) and X = Cl, Br, I) have also attracted great interest for their possible use as antibacterial and antitumour agents [11]. Moreover, complexes of rhodium(III) with 2,6-diaminopyridine and its substituted derivatives have been reported to exhibit biological properties [12]. The biological activity of rhodium(III) complexes with *N*-heterocyclic ligands has been suggested to be due to the generation of rhodium(I) species [13]. In fact, rhodium(I) complexes have also been found to produce filamentous growth of *E. coli* and to induce lamda prophage in lysogenic bacteria [7, 14].

All these considerations prompted us to investigate the biological properties of rhodium(III) complexes with *N*-donor ligands. We have recently reported the synthesis and characterization of a series of rhodium(III) complexes with 2,2′-biquinoline(biq) and 2-(2′-pyridyl)quinoline(pq) [15–19]. We now report the mutagenic activity of some of these complexes on *S. typhimurium* TA1530 and TA98.



EXPERIMENTAL

Materials



All solvents used were AR grade. The chemicals used were purchased from Laborat, Aldrich, Fluka or BDH. The ligands biq and pq were recrystallized from PhMe and CH_3OH, respectively. The rhodium(III)

biq

pq

complexes used are: *mer*- and *fac*-$[Rh(pq)Cl_3(H_2O)]$, *cis*-$[Rh(NN)_2X_2]X$ (NN = pq, bis; X = Cl, Br) and *cis*-$[Rh(pq)_2Cl_2][Rh(CO)_2Cl_2]\cdot H_2O$. They were prepared as described earlier [15–19].

The rhodium(III) complexes were dissolved in small amounts (200–500 μL) of dimethylsulfoxide then mixed with deionized water up to 1 cm^3 and filter sterilized before use.

Bacterial strains

The strains of *S. typhimurium* TA1530 (hisG46, Δgal, Δuvr, R^-) and TA98 (hisD3052, ΔuvrB, rfa, R^+) used were a generous gift from Bruce Ames, Berkeley, U.S.A.

Mutagenesis assay

The mutagenicity of the rhodium(III) complexes was tested without metabolic activation, according to Ames *et al.* [20]. The tester strains were cultured daily from frozen permanents [21] and were incubated overnight on a gyratory shaker at 37°C.

The test was briefly carried out as follows: an appropriate amount of each rhodium complex solution and 0.1 cm^3 of the bacterial culture were gently mixed with 2 cm^3 of molten top agar and spread over a Petri dish containing 20 cm^3 of Vogel–Bonner agar [20]. Each treatment was carried out in duplicate. Plates were allowed to solidify, incubated at 37°C for 48 h and then screened for colonies of histidine revertants. Control plates were prepared using the proper concentrations of the solvents.

The number of revertants per plate, expressed as the mean value of at least two independent experiments, was used as an indication of the mutagenic activity of the tested complexes. A complex was considered mutagenic whenever the number of revertant colonies was at least double that of the spontaneous revertants in the control plates. The mutagenic effects were also confirmed by demonstrating a dose–response relationship whereby various concentrations (10–400 μg complex/plate) were used.

RESULTS AND DISCUSSION

The mutagenic activity of some rhodium(III) complexes with biq and pq was tested on *S. typhimurium* TA1530 and TA98. The results are presented in Table 1. It can be concluded that all the complexes tested are able to raise the number of histidine revertants over the spontaneous level when both bacterial strains are used. This means that the rhodium(III) complexes used possess mutagenic activity for bacteria; they induce both base substitution and frame shift mutations. They appear, however, to have different levels of biological activity.

Based on their activity to induce base substitution mutations, the complexes may be arranged in the following order:

cis-$[Rh(biq)_2Cl_2]Cl$ > *cis*-$[Rh(pq)_2Br_2]Br$ > *cis*-$[Rh(pq)_2Cl_2]Cl$ > *cis*-$[Rh(biq)_2Br_2]Br$ > *fac*-$[Rh(pq)Cl_3(H_2O)]$ > *cis*-$[Rh(pq)_2Cl_2][Rh(CO)_2Cl_2]\cdot H_2O$ > *mer*-$[Rh(pq)Cl_3(H_2O)]$.

The complexes *cis*-$[Rh(biq)_2Cl_2]Cl$ and *cis*-$[Rh(pq)_2Br_2]Br$ are highly mutagenic; *cis*-$[Rh(pq)_2Cl_2]Cl$ and *cis*-$[Rh(biq)_2Br_2]Br$ are moderately mutagenic while *fac*- and *mer*-$[Rh(pq)Cl_3(H_2O)]$ and *cis*-$[Rh(pq)_2Cl_2][Rh(CO)_2\ Cl_2]\cdot H_2O$ are slightly mutagenic.

However, when *S. typhimurium* TA98 was used, the complexes *cis*-$[Rh(pq)_2Cl_2]Cl$, *cis*-$[Rh(pq)_2Cl_2][Rh(CO)_2Cl_2]\cdot H_2O$ and *cis*-$[Rh(biq)_2X_2]X$ (X = Cl, Br) were found to be highly mutagenic *via* frame shifts, while *mer*-$[Rh(pq)Cl_3(H_2O)]$ and *cis*-$[Rh(pq)_2Br_2]Br$ were moderately mutagenic.

It seems that the complexes used in this study (Table 1) are more active *via* frame shift than base substitution mechanisms. Complexes of platinum with bidentate amines have been reported to show the same behaviour [6]. The absence of detailed reports on the structural aspects of the interactions of biologically active rhodium(III) compounds with bacterial DNA makes it difficult to relate the activity of our complexes to their structures. However, some conclusions can be drawn since both rhodium and platinum are heavy transition metals and bind to similar types of ligands [22, 23]. One has to keep in mind, however, that the majority of rhodium(III) and platinum(IV) complexes are octahedral, while those of platinum(II) are square-planar [22,23].

It has been reported that most biologically active platinum complexes, whether octahedral or square-planar, have two moderately labile *cis* leaving groups

[a] Histidine revertants are counted and calculated as the average number of colonies/plate after a 48 h incubation at 37 C in the presence of the indicated amounts of complexes. Each data is an average of at least two independent experiments, each of which included duplicate plates.

[b] These values refer to revertants of *S. typhimurium* TA98; control value = 28±2.

and two *cis* nitrogen donor amine ligands [24]. All the bis-biq and -pq rhodium(III) complexes used have *cis* configurations [15–19]. The *mer*- and *fac*- isomers also satisfy this requirement.

The toxicity of the complexes used in this study (Table 1) seems to depend on the bacterial strains used. The complex *cis*-[Rh(biq)$_2Br_2$]Br is toxic to strains TA1530; *cis*-[Rh(pq)$_2X_2$]X (X = Cl, Br) are highly toxic to strains TA98, while all the other complexes are not significantly toxic to both strains within the concentration range used (Table 1).

The toxicity of cisplatin, *cis*-[Pt$(NH_3)_2Cl_2$], has been related to its ease of hydrolysis; the hydrolysis products were found to oligomerize and form toxic products [8]. Complexes with bidentate amine ligands, such as ethylenediamine or 1,2-diaminocyclohexane, have been reported to be less toxic than cisplatin. The complexes used in this study have the advantage of containing bidentate N-donor chelating agents (biq and pq). Moreover, platinum(II) and platinum(IV) have been reported to form their most stable complexes with the most polarizable ligands (I > Br > Cl > N ~ O) [5]. The toxicity of *cis*-[Rh$(NN)_2Br_2$]Br (NN = biq, pq) could be due to their instability in solution, which is caused by the repulsions between the bulky biq or pq and the Br ligands.

Finally, it can be concluded from this study that the chloro complex *cis*-[Rh(biq)$_2Cl_2$]Cl exhibits the highest mutagenic activity and the lowest toxicity among all complexes tested and is expected to be the most promising candidate for further biological studies.

Direct synthesis and crystal structure of tetrameric copper(I) iodide with trimethylamine $[CuI(NMe_3)]_4$

Olga A. Babich and Vladimir N. Kokozay*

Department of Chemistry, Kiev Shevchenko University, 252033 Kiev, Ukraine

(Received 23 July 1996; accepted 22 August 1996)

Abstract—The tetrameric cluster $[CuI\{N(CH_3)_3\}]_4$ has been synthesized directly from copper powder and trimethylammonium iodide in non-aqueous solutions (acetonitrile, *N*,*N*-dimethylformamide) and characterized by X-ray crystallography. The compound $[CuI\{N(CH_3)_3\}]_4$ possesses a molecular structure. A tetrahedral Cu_4 cluster with short Cu—Cu distances (2.67 Å) is surrounded by an I_4 tetrahedron, thus each face of the Cu_4 tetrahedron is centred by a μ_3-bridging iodine atom. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: tetrameric copper(I) complex; crystal structure; direct synthesis.

Direct synthesis involving metal powder provides an opportunity to prepare various types of coordination compounds [1]. In this paper we report the details of the preparation and the results of the structure determination of the first compound of cluster type obtained by direct method. Tetrameric copper(I) compounds of stoichiometry $[CuI(L)]_4$ (where L = Lewis base) have been described previously in the literature [2–5], but the cluster compound $[CuI\{N(CH_3)_3\}]_4$ is the first one prepared by the direct synthesis.

EXPERIMENTAL

All chemicals were commercial products of reagent grade and used without further purification. Trimethylammonium iodide was synthesized from trimethylammonium chloride and potassium iodide in methanol solution by exchange reaction and recrystallized from isopropanol. All experiments were carried out in air.

Synthesis of $[CuI\{N(CH_3)_3\}]_4$

The following method was used for the preparation of the complex: Cu (0.63 g, 10 mmol), $(CH_3)_3N \cdot HI$ (3.71 g, 20 mmol) and acetonitrile (70 cm^3) were placed in a flask in the above order. The mixture was stirred at ambient temperature over 5–6 h and left overnight. Next morning the colourless crystals were separated from the pale brown solution. Yield: 0.95 g (76%). Found: C, 13.9; H, 3.2; N, 6.0; Cu, 25.1; I, 51.0. Calc. for $C_{12}H_{36}Cu_4I_4N_4$: C, 14.4; H, 3.6; N, 5.6; Cu, 25.5; I, 50.8%.

Crystal structure determination

Crystallographic measurements were obtained at 20°C using an Enraf–Nonius CAD-4 diffractometer operating in the ω–2θ scan mode (the ratio of the scanning rates was $\omega/\theta = 1.2$). The intensity data were collected within the range $1.60 \leqslant \theta \leqslant 21.97°$ using graphite-monochromated Mo-K_α radiation. The accurate unit-cell constants and the orientation matrix for data collection were obtained from least-squares refinement, using the setting angles of 24 reflections in the range $13 < \theta < 15°$. The structures were solved by direct methods and refined by full-matrix least-squares techniques on F^2 in the anisotropy approximation using SHELX-93 [6]. The positions of the hydrogen atoms were idealized and included in the calculations of the structure factors as the fixed contributions. The non-centrosymmetric space group $P\bar{4}3n$ was chosen during the structure solution. Transition to the centrosymmetric space group $Pm3n$ is impossible because the molecule of complex does not

possess the symmetry centre. The density measured by the floatation method is 2.27 g cm^{-3} and to be compared with the calculated density of 2.283 g cm^{-3}. The crystallographic data are summarized in Table 1. Convergence was reached at the agreement factor listed in Table 1.

Selected bond distances and angles are given in Table 2. A fragment of the unit-cell packing of $[CuI\{N(CH_3)_3\}]_4$ is shown in Fig. 1. Atomic coordinates, anisotropic thermal parameters, full list of bond distances and angles are given in the supplementary material.

DISCUSSION

The crystal of $[CuI\{N(CH_3)_3\}]_4$ complex consists of the discrete tetrameric molecules. Two independent complex molecules are present in the unit cell. Figure 2 shows the labelling scheme for atoms in one of the two molecules, and a view of the Cu_4I_4 core. The coordination environments of Cu(1) and Cu(2) atoms are topologically similar, but differ somewhat from each other geometrically (Table 2). The Cu(2), N(2) and I(2) atoms occupy special positions at three-fold axes, while the other atoms occur in general positions.

The base of the complex molecule is a tetrahedral Cu_4 cluster surrounded by a tetrahedron of iodine atoms, thus each face of the Cu_4 tetrahedron has been centred by a μ_3-bridging iodine atom [Fig. 1(b)]. The significant distortion of the Cu_4I_4 core from regular cubic geometry involves symmetric and opposing distortions of the Cu—I—Cu and I—Cu—I angles (the average value I—Cu—I = 112.86° and Cu—I—Cu = 60.5°) and it may be caused by the repulsion between the iodine atoms [7]. The iodine $\cdots$ iodine contacts within the $[CuI\{N(CH_3)_3\}]_4$ molecule range from 4.392 to 4.505 Å, which is similar to the I $\cdots$ I contacts in the corresponding $[CuI(L)]_4$ complexes with the nitrogen-donor ligands [2,5].

The coordination environment of the copper(I) atoms is formed by three iodine atoms and one nitrogen atom of the trimethylamine molecule

Symmetry transformations used to generate equivalent atoms: (a) $-x, 1-y, z$; (b) $1/2-y, 1/2+x, 1/2-z$; (c) $-1/2+y, 1/2-x, 1/2-z$; (d) $1-x, 1-y, +z$; (e) $1-x, +y, 1-z$; (f) $+x, 1-y, 1-z$.

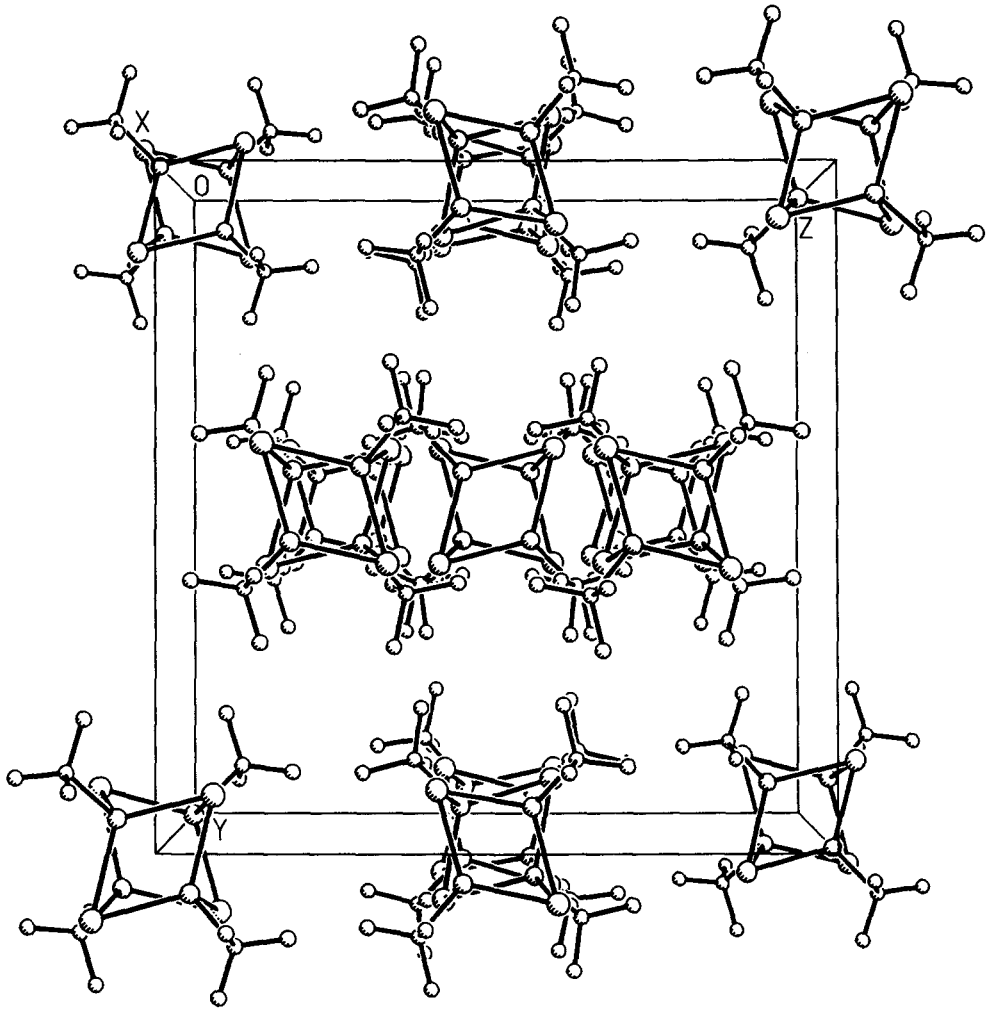

Fig. 1. Fragment of the unit-cell packing of $[CuI\{N(CH_3)_3\}]_4$.

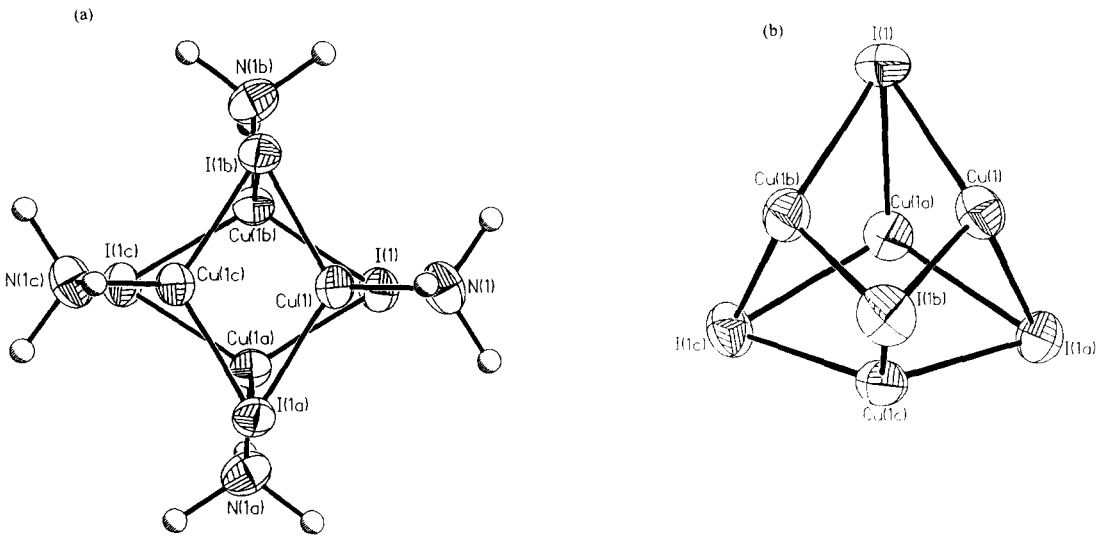

Fig. 2. (a) One of the two complex molecules in $[CuI\{N(CH_3)_3\}]_4$ with the atom-labelling scheme ("a", "b" and "c" refer to the $-x, 1-y, z$; $1/2-y, 1/2+x, 1/2-z$; $-1/2+y, 1/2-x, 1/2-z$, respectively; the carbon atoms are unlabelled) and (b) a view of the Cu_4I_4 core.

[Cu—N = 2.09(2)–2.13(5) Å] and represents a slightly distorted tetrahedron.

The average distance between copper atoms (2.678 Å) is greater than the value for standard copper–copper bonds (2.56 Å). However, it is significantly shorter than the average Cu···Cu distance in complexes with phosphine or arsine-donor ligands and comparable to those found in other nitrogen-donor cubic $[CuI(L)]_4$ structures [8]. Investigation of the emission spectra [4] has shown that if the copper···copper distance in $[CuI[L]]_4$ systems is less than 2.8 Å some metal–metal interaction may be assumed.

The local geometry of each nitrogen atom corresponds to C_{3v} symmetry. N—C bond lengths range from 1.43(3) to 1.50(3) Å; C—N—C angles vary from 107(2) to 111(2)°.

(Received 5 July 1996; accepted 22 August 1996)

Abstract—Reaction of erbium picrate with N,N,N′,N′-tetraphenyl-3,6,9-trioxaundecanediamide (TTD) yielded [Er(Pic)$_3$(TTD)]. Its crystal structure shows that the Er^{III} ion is coordinated to five oxygen atoms of TTD, three oxygen atoms of two picrates and one oxygen atom of H_2O giving a coordination number of nine. The TTD molecule acts as a multidentate ligand forming a ring-like coordination structure similar to those of crown compounds. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: erbium picrate; TTD; complex; synthesis; structure.

Noncyclic polyethers show a high complexation selectivity which makes them suitable reagents for the extraction and analysis (ion-selective electrodes) of the lanthanide ions [1–5]. The extraction of fission products by N,N,N′,N′-tetraphenyl-3,6,9-trioxaundecanediamide (TTD) has been studied by an isotopic tracer technique and the extractability of alkaline earths and lanthanide ions by nitrobenzene solution of TTD is very high when picrate is used as an accompanying ion [5]. In addition, TTD was used as an active material for barium ion-selective electrode, showing an excellent electromotive force stability [6,7]. In this work, we describe the synthesis and crystal structure of the Er^{III} picrate complexes with TTD.

Structure 1. N,N,N′,N′-Tetraphenyl-3,6,9-Trioxaundecanediamide (TTD)

EXPERIMENTAL

Erbium(III) picrate [8] and TTD [9] were prepared according to the literature methods. All solvents used were purified by standard methods.

Synthesis of [Er(Pic)$_3$(TTD)]

A solution of TTD (0.1 mmol) in anhydrous ethanol (15 cm^3) was added dropwise to a solution of

* Author to whom correspondence should be addressed.

erbium(III) picrate (0.1 mmol) in anhydrous ethanol (20 cm^3). The mixture was stirred at room temperature for 2 h. The precipitated solid complex was filtered, washed with anhydrous ethanol and dried *in vacuo* over P_4O_{10} for 48 h. Found: C, 43.7; H, 2.8; N, 11.3; Er, 12.5. Calc. for $[Er(Pic)_3(TTD)]$: C, 43.6; H, 2.8; N, 11.2; Er, 12.2%. The solid complex was recrystallized from a solution of MeCN by slow evaporation to obtain the transparent yellow crystals of $[Er(Pic)_2(TTD)\cdot H_2O]\cdot Pic\cdot CH_3CN$.

X-ray diffraction analysis for $[Er(Pic)_2(TTD)\cdot H_2O]\cdot Pic\cdot CH_3CN$

Data collection was performed on an R3M/E four-circle diffractometer with Mo-K_α radiation ($\lambda = 0.71073$ Å) using the $\omega/2\theta$ scan mode. Correction for LP factors was applied. The structure was solved by the Patterson method and subsequent difference Fourier techniques and refined by full-matrix least-squares procedures based on F. All non-hydrogen atoms were refined anisotropically. The coordinates of the hydrogen atoms were fixed by theoretical models and refined only with isotropic thermal factors. All calculations were performed on an Eclipse S/140 computer with the SHELXTL program. Crystal data and a summary of intensity data collection and structure refinement parameters are listed in Table 1.

Positional parameters, anisotropic displacement parameters, hydrogen atom coordinates, a full list of bond lengths and angles and observed and calculated structure factors have been deposited as supplementary material with the Cambridge Crystallographic Data Centre. Selected bond lengths and bond angles are given in Table 2.

RESULTS AND DISCUSSION

The structure for $[Er(Pic)_2(TTD)\cdot H_2O]\cdot Pic\cdot CH_3CN$ is illustrated in Fig. 1. Figure 2 shows the molecular packing arrangement in the unit cell.

The crystal structure is composed of a $[Er(Pic)_2(TTD)(H_2O)]^+$ cation, one picrate anion and one MeCN molecule linked by electrostatic attraction and weak van der Waals forces. The Er^{III} ion is nine-coordinated by oxygen atoms, five from TTD, three from one bidentate and one unidentate picrates and one from H_2O. The coordination polyhedron is a monocapped tetragonal antiprism (Fig. 3). The TTD molecule wraps around the metal ion with its oxygen atoms and forms a ring-like coordination structure together with the bidentate picrate [O(14)] situated at the open side of the TTD chain (Fig. 4). The four oxygen atoms of TTD [O(2), O(3), O(4), O(5)] are not quite coplanar, their deviations from the mean plane being in the range of 0.0345–0.9754 Å. O(1) lies out of this plane by 1.5036 Å and the erbium atom by 0.2867 Å. Obviously TTD is distorted to some extent in order to maintain the Er—O distances at suitable lengths for coordination.

The average distance between the erbium atom and the coordinated oxygen atoms is 2.393 Å, where the Er—O(7) distance is the shortest probably due to the higher electron density on the oxygen anion of the picrate, while the Er—O [phenolic, O(14)] distance is shorter than the Er—O [nitro, O(15)] one in the bidentate picrate. The Er—O (C=O) distances (mean 2.344 Å) are significantly shorter than the Er—O (C—O—C) ones (mean 2.471 Å). This suggests that the Er—O (C=O) bond is stronger than the Er—O (C—O—C) one.

In conclusion, the TTD molecule acts as a multidentate ligand forming a ring-like coordination structure. The internal cavity formed by coordinating oxygen atoms is suited for the uptake of a cation, while the nonpolar groups (CH_2 groups, aliphatic rings) form a lipophilic shell around the coordination sphere. The TTD molecule, therefore, shows high selectivity complexation and lipophilicity, which make it a useful extract of lanthanide ions and a component in sensors for Ba^{2+}.

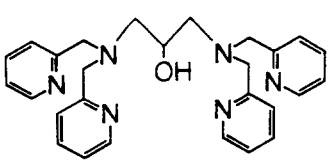
High activity for oxidation reaction by peroxide adduct of binuclear iron(III) compound with (μ-η^1 : η^1)-coordination mode

Tetsuya Akamatsu, Teruyuki Kobayashi, Yumiko Sasaki, Sayo Ito and Yuzo Nishida*

Department of Chemistry, Faculty of Science, Yamagata University, Yamagata 990, Japan

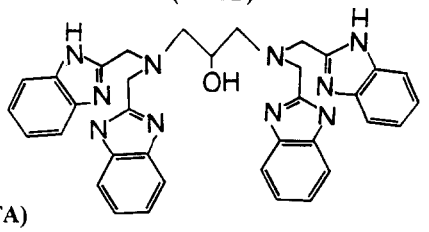
(Received 28 June 1996; accepted 22 August 1996)

Abstract—Reactivities of the peroxide adducts of the iron(III) compounds with binucleating ligands, $Fe_2(HPTP)(OH)(NO_3)_2^{2+}$, $Fe_2(HPTB)(OH)(NO_3)_2^{2+}$ and $Fe_2(HXTA)(CH_3COO)_2^{-}$, were compared in the reaction with hydrogen peroxide (catalase-like function) and in the oxidation reactions of phenols and 2′-deoxyribose, (where H(HPTP), H(HPTB) and H_5(HXTA) denote N,N,N′,N′-tetrakis(2-pyridylmethyl)-1,3-diamino-propane-2-ol, N,N,N′,N′-tetrakis(2-benzimidazolylmethyl)-1,3-diamino-propane-2-ol and N,N′-2-hydroxy-5-methyl-1,3-xylylenebis[*N*-(carboxymethyl)]glycine, respectively). The peroxide adduct of the H(HPTP) complex exhibited the highest activity in all the reactions described above and the origin of the results are discussed in terms of the electrophilic nature of the peroxide adduct, electronic structure of the reactant, Lewis acidity of an iron(III) ion, orbital correlationship between metal peroxide adduct and the substrate and the steric hindrance of the ligand system. Based on these facts, we have proposed a new scheme for the catalase-like function catalysed by a binuclear iron(III) complex. © 1997 Elsevier Science Ltd. All rights reserved.



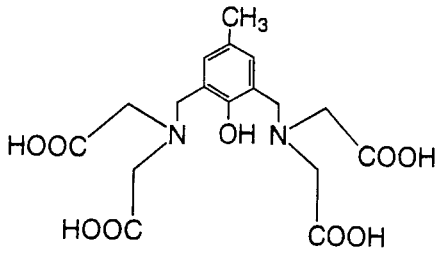
Keywords: binuclear iron(III); peroxide adduct; oxidative reaction; electrophilic peroxide adduct.

The reaction of the O_2 molecule at a diiron(II) center to give a binuclear iron(III)-peroxide adduct is sometimes observed in biological systems and several proteins known or believed to share this functional motif include hemerythrin (the O_2 carrier protein of certain marine invertebrates), methane monooxygenase from methanotrophic bacteria and stearoyl-CoA Δ9 desaturase from yeast and plants, and ribonucleotide reductase (DNA synthesis) [1–6]. For each of the diiron proteins, the chemical outcome of the O_2-reaction is distinct; in hemerythrin O_2 is reversibly bound in a hydroperoxidediferric complex [7–9], in methane monooxygenase O_2 is activated for the two-electron oxidation (hydroxylation) of an unactivated hydrocarbon [10,11], in stearoyl-CoA Δ9 desaturase O_2 is activated for the unhydrogenation of stearoylthioether [12], and in ribonucleotide reductase (RR), O_2 is activated for the one-electron oxidation of an endogenous tyrosine residue [13]. An objective which is central to the study of these diiron proteins is to identify structural and electronic features of the iron clusters and their protein chelators, which allow similar centers to mediate very different reactions with O_2.



In our previous papers we have pointed out that the metal-peroxides play an important role in some biological systems [14] and proposed a meaningful understanding of structure–function relationships in these peroxide adducts, which may require knowledge of both the structure and chemical mechanism [15]. Until now, three diiron(III) compounds are known to give a peroxide adduct in the reaction with hydrogen peroxide; there are those with H(HPTB) [16], H(HPTP) [17] and H_5(HXTA) [18], where H(HPTP), H(HPTB) and H_5(HXTA) represent N,N,N′,N′-tetrakis(2-pyridylmethyl)-1,3-diaminopropane-2-ol, N,N,N′,N′-tetrakis(2-benzimidazolylmethyl)-1,3-diaminopropane-2-ol and N,N′-2-hydroxy-5-methyl-1,3-xylylenebis[N-(carboxymethyl)glycine], respectively [see Scheme 1]. For the case of $[Fe_2(HPTB)(OH)(NO_3)_2]^{2+}$, two possible structures

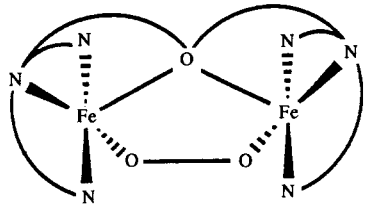
* Author to whom correspondence should be addressed.



H(HPTP)

H(HPTB)

H_5(HXTA)



Scheme 1

have been postulated as a peroxide adduct, (a) and (b) as illustrated in Fig. 1 [19], and recent studies have suggested that the former, *cis*-μ-$\eta^1:\eta^1$ mode, should be most likely [20]. We have already reported that the peroxide adduct with H(HPTP) exhibited much higher activity for the formation of a phenoxo radical in the reaction with phenols [21], which is a model reaction for tyrosine radical formation observed in ribonucleotide reductase, however, the origin for the negligible activity of the other compounds, H(HPTB) and H_5(HXTA), is unknown.

In our recent papers we have observed that the oxidation and oxygenation reactions catalysed by the binuclear iron(III)-peroxide adduct are carried out by a different peroxide adduct and different reactivity (oxidation and oxygenation) is attributed to the different orbital phase-relationship between the metal-peroxide adduct and reactant [15,22]. In this study we have compared the reactivities of three peroxide adducts of H(HPTP), H(HPTB) and H_5(HXTA) compounds in the reaction of hydrogen peroxide, i.e. catalase-like function, and in oxidation reactions of phenols and 2′-deoxyribose. Based on these results, we propose a new scheme for the reactivity of the peroxide adduct of the binuclear iron(III) compound, and attempt to give a clear understanding of the origin of high activity for oxidation reaction by the peroxide adduct of binuclear iron(III) compounds with the (μ-$\eta^1:\eta^1$)-coordination mode.

(a)

(b)

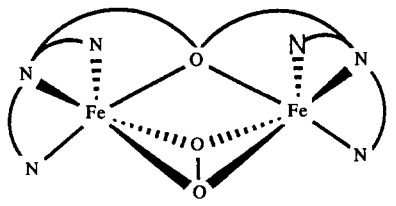


Fig. 1. Two possible structures for peroxide adduct of binuclear iron(III) compound.

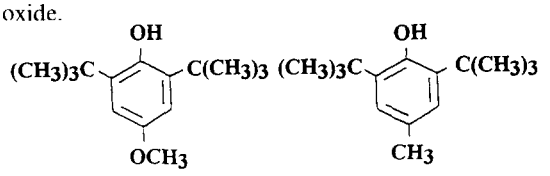
EXPERIMENTAL



Materials

The binuclear iron(III) complexes used in this study were prepared according to the published methods [16–18].

ESR signal due to the formation of phenoxo radical

ESR spectra of the reaction mixture containing the iron(III) compound (1 cm^3, 1/500 mol dm^3 of ethanol/water = 1/1 solution), phenol (1 cm^3, 1/25 mol dm^{-3} ethanol/water = 1/1 solution) and hydrogen peroxide (1 cm^3, 1/50 mol cm^{-3} ethanol/water = 1/1 solution) were measured at 298K. The intensity of the ESR signal was normalized in terms of that of MnO used as an internal standard. Phenols used in this study were 2,6,di-*tert*-butyl-4-hydroxy-anisole (DTBHA) and 2,6-di-*tert*-butyl–4-methylphenol (BHT), and the ESR study on these phenoxo radicals has already been reported [23]. In addition to these

cases, we have also measured the ESR signal due to the phenoxo radical by adding NADH (1cm^3, 3/500 mol dm^{-3} aqueous solution) instead of hydrogen peroxide.

DTBHA BHT

Catalase-like function

All reactions were performed at 25°C in a 10 cm^3 reactor containing a stirring bar under air. The flask containing a binuclear iron(III) compound (10μmol) solution (5 cm^3) was closed with a rubber septum. Hydrogen peroxide solution (1 cm^3, commercial 30% aqueous solution was diluted to 1 M solution by water) was injected through the septum with a syringe. The reactor was connected with a graduated burette filled with water and the dioxygen evolved was measured at appropriate times by volumetry. In the case of MnO_2 as a catalyst, *ca* 16 cm^3 of dioxygen evolved under our experimental conditions.

TBARS (thiobarbituric acid reactive substance) formation in the reaction mixture containing 2′-deoxyribose [24]

To an iron(III) compound solution (20 cm^3 aqueous solution of $[Fe^{3+}] = 5 \times 10^{-2}$ mol dm^{-3} containing 2′-deoxyribose (50 mg) was added hydrogen peroxide solution (10cm^3 1×10^{-1} mol dm^{-3}) and the resulting solution was treated with 2-thiobarbituric acid (TBA, 20 mg), as described in the previous paper [25], and the absorbance at 532 nm of the mixture was measured according to the usual work-up. In this case, the pink material should be due to the formation of malondialdehyde in the solution, which should be derived from oxidative degradation of 2′-deoxyribose [24].

RESULTS

Phenoxo radical formation

As shown in Fig. 2, the solution of DTBHA and hydrogen peroxide gives a negligible ESR signal (trace A) and it is thus clear that the formation of phenoxo radical (g-value, 2.0039 and peak-to-peak separation, 0.082 mT) [23] observed in the reaction mixture of hydrogen peroxide and binuclear iron(III) complexes (see Fig. 2, traces B, C and D) should be due to its reaction with the peroxide adduct of a binuclear iron(III) compound. This radical formation is greatly enhanced by the presence of a binuclear iron(III) complex with H(HPTP), which are much stronger than those of H(HPTB) and H_5(HXTA). The ESR signal strength of the phenoxo radical observed in this experiment is generally time-dependent, one of the examples observed for the H(HPTP) complex being illustrated in Fig. 3 and schematically shown in Fig. 4. This shows that the phenoxo radical formed may be quenched by a phenoxo radical or peroxide adduct of the iron(III) complex. The results obtained for the BHT are also

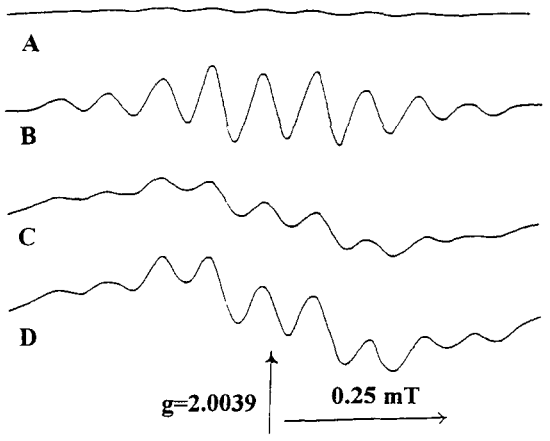


Fig. 2. ESR spectra of solution containing iron(III) complex, hydrogen peroxide and DTBHA (X-band, 25°, measured at 10 min after addition of hydrogen peroxide). (A) No iron(III), gain ×100; (B) Fe_2(HPTP)(OH)$(NO_3)_2^{2+}$, gain ×1; (C) Fe_2(HPTB)(OH)$(NO_3)_2^{2+}$, gain ×20; (D) Fe_2(HXTA)$(CH_3COO)_2^-$, gain ×100.

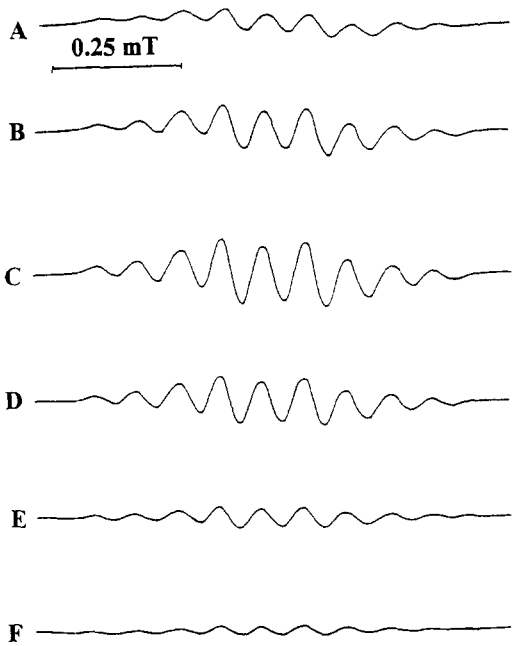

Fig. 3. Time course of the ESR spectra of solution containing Fe_2(HPTP)(OH)$(NO_3)_2^{2+}$, hydrogen peroxide and DTBHA (X-band, 25°C, gain ×1). Measured after addition of hydrogen peroxide at (A) 1, (B) 2, (C) 10, (D) 15, (E) 20 and (F) 25 min.

represented in Fig. 5; in these cases, the H(HPTP) also shows the highest activity for the formation of the radical as observed for the DTBHA system.

In Fig. 6, the ESR signal due to the phenoxo radical formation by the addition of NADH is shown, in this case, the activity of compound with H(HPTP) is also the highest, suggesting that an active species for phenoxo radical formation should be similar to that in the binuclear iron(III)/hydrogen peroxide system. Thus, it seems quite likely that in solution the following reaction proceeds and the formation of the peroxide adduct is responsible for the radical formation:

$$Fe_2^{II}(HPTP)(OH)^{4+} \xrightarrow[NADH]{} Fe_2^{III}(HPTP)^{3+} \xrightarrow[O_2]{}$$

Peroxide adduct of binuclear Fe^{III}

The last process has been investigated by Lippard and co-workers in detail [26].

Catalase-like function

In Fig. 7, the time course of dioxygen evolution in the presence of binuclear iron(III) compound and hydrogen peroxide is shown. It should be noted here that among the three compounds, the H(HPTP) complex exhibits the highest activity and that of the H(HPTB) complex is negligible in water.

Activity for TBARS Formation

In Fig. 8 the absorption spectra of the solutions treated by TBA are shown. It is well known that TBA reacts with malondialdehyde to give the following substance (see the figure below) [25], which shows a strong absorption band at 532 nm; these are called the thiobarbituric acid reactive substances, abbreviated as TBARS. Figure 8 shows that the iron(III) complex with H(HPTP) produced a much larger quantity of TBARS than those of the H(HPTB) and H_5(HXTA); this suggests that the former compound exhibits much

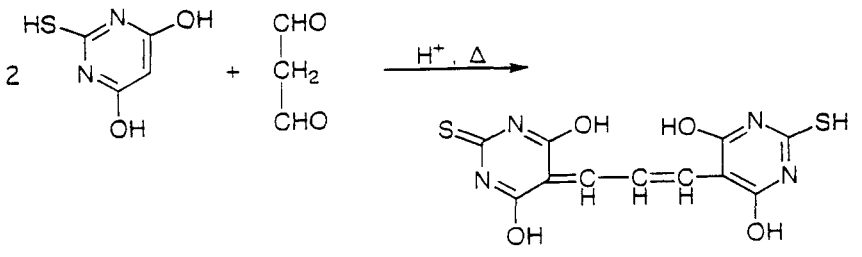
higher activity for oxidative degradation of 2′-deoxyribose in the presence of hydrogen peroxide.



DISCUSSION

Active species for oxidation of phenols

It is well known that the binuclear iron(III) compound with H(HPTB), $[Fe_2(HPTB)(OH)(NO_3)_2]^{2+}$ reacts with hydrogen peroxide, to give a blue peroxide adduct [16]. At present, although the precise structure of the peroxide adduct is not established, it may be of *cis*-μ-η^1:η^1 type, as shown in Fig. 1 (a) [19]. A similar peroxide adduct formation was already pointed out for the compound with H(HPTP) and H_5(HXTA).

As shown in Fig. 2, this peroxide adduct should be an intrinsically active species for the oxidation of phenol, because no radical formation was observed in the presence of only free hydrogen peroxide or an iron(III) compound. This shows that some binuclear iron(III)-peroxide adducts exhibit an oxidation activity. Oxidation activity should be due to its electron acceptor power and thus it seems quite likely that the formation of a phenol radical should be due to the electrophilic nature of the peroxide adduct, as emphasized in the previous papers [21,22], and the occurrence of the electrophilic nature of the metal-peroxide adducts has been rationalized in terms of the MO scheme of the compounds [14,15]. A few years ago, several authors have reported that an active species for the formation of tyrosine radical observed in ribonucleotide reductase should be an FE^{IV}-oxo-species, which is derived from the binuclear iron(III)-peroxide adduct [27,28]. However, the above consideration seems unlikely on the basis of the discussion that the negligible activity of the Fe_2(HXTA) compound for the formation of phenoxo radical clearly excludes the possible participation of an Fe^{IV} =oxo species in the reaction, because the formation of an Fe^{IV}=oxo species is expected to be more preferable for the H_5(HXTA) complex than those of the H(HPTP) and H(HPTB) complexes according to the electrochemical data [17]. Our conclusion is quite consistent with the recent discussion developed for the ribonucleotide reductase [13].

The electrophilic nature of the peroxide adduct should be enhanced when the energy of the orbital which interacts with the occupied orbital of the substrate is lower; the energy of the MO containing *d*-orbital and orbital of the peroxide adduct may be controlled by the Lewis acidity of an iron(III) ion [14], which may be evaluated in terms of the reduction potential of the metal ion observed in the CV data. CV data shows that reduction potential ($Fe^{III} \rightarrow Fe^{II}$) of the iron(III) ions are similar to each other in the compounds with H(HPTP) and H(HPTB), but more negative in the H_5(HXTA) compound [17]; this predicts simply that the electrophilic nature of the peroxide adduct should be in the order

H(HPTP) ≈ H(HPTB) > H_5(HXTA). On the basis of the above discussion, much of the difference observed in the activity for phenoxo radical formation of H(HPTP) and H_5(HXTA) compounds can be rationalized. The different reactivity observed for the H(HPTP) and H(HPTB) compounds should be due to the large steric hindrance due to the benzimidazole moiety in the H(HPTB) compound, which may prevent the approach of the phenol, leading to the lower activity for the formation of a phenoxo radical.

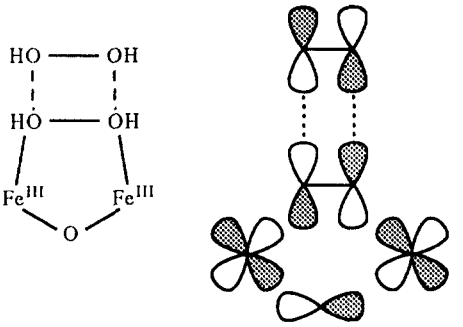


Fig. 10. Orbital relationship for facile electron transfer between the peroxide ion and the peroxide adduct of the binuclear iron(III) complex.

Chemical mechanism in catalase-like function

There may be two pathways for the evolution of dioxygen in the reaction mixture of hydrogen peroxide and a binuclear iron(III) compound; (1) electron transfer from the peroxide to an iron(III) ions through the formation of the peroxide adduct and (2) electron transfer from a peroxide ion to the peroxide adduct of binuclear iron(III) complex, as depicted in Fig. 9. In pathway (1) the oxidation–reduction cycle between Fe^{II} and Fe^{III} occurs, and in the latter case, the oxidation state of the Fe^{III} is settled throughout the reaction. As the reduction potential of the H(HPTB) and the H(HPTB) compounds are essentially the same, the results in Fig. 7 completely exclude the possibility of pathway (1), because negligible activity of the H(HPTB) compound cannot be explained by this pathway. This also excludes the possible participation of an iron(IV)=oxo species in the catalase-like function. The above discussion leads to the conclusion that the evolution of dioxygen observed in the present systems should proceed *via* pathway (2). In pathway (2), the coincidence between the orbital phases of the electron donor and acceptor, as depicted in Fig. 10, should be very important. In the case of the H(HPTB) compound, the steric hindrance as described above should also be responsible for the negligible activity observed and the lower activity of the (HXTA) compound should also be explained in terms of the lower Lewis acidity of an iron(III) ion than that in the H(HPTP) compound.

Origin for high activity for oxidation reaction

We already reported that the reactivity of the peroxide adduct of the metal complex with side-on coordination mode is highly dependent on the electronic structure of the reactants [22], for example, the Mn^{III}-peroxide adduct exhibits high reactivity for the acid anhydride, on the other hand, its reactivity towards the acid ester is almost negligible. Based on these facts, the importance of the electrophilic nature of the peroxide adduct and of the orbital correlationship between the peroxide adduct (unoccupied) and the substrate (occupied) were pointed out. This con-

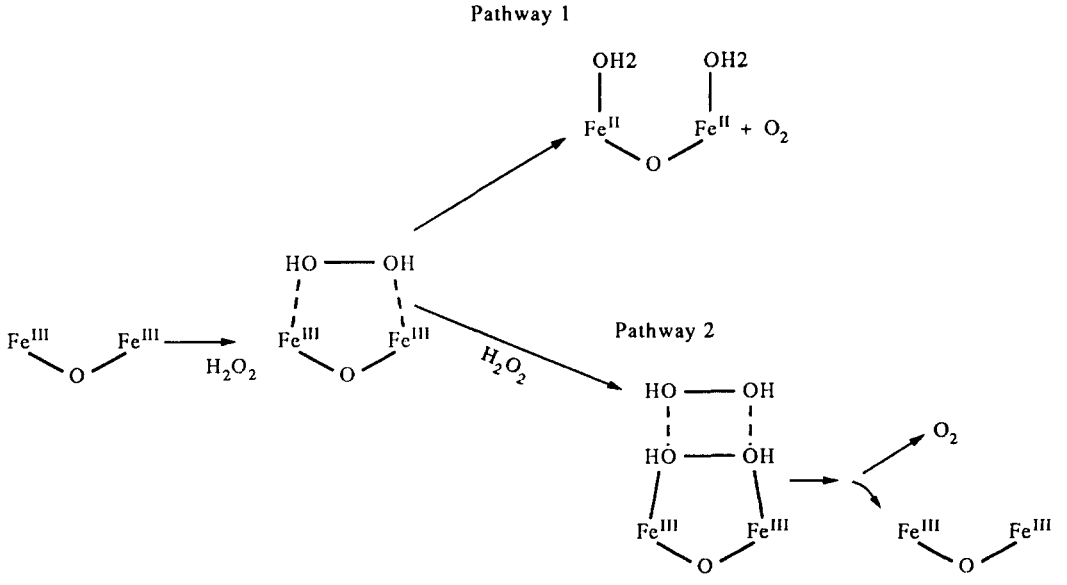

Fig. 9. Two possible pathways for dioxygen evolution.

sideration may give a reasonable explanation for the facts that in general these peroxide adducts exhibit much lower activity for alkane functionalization and for high activity for catalase-function of the (HPTP) complex as shown in Fig. 10. The oxidation reaction of phenol should proceed with the loss of a hydrogen atom from phenolic group *via* electron transfer and thus the orbital relationship between donor and acceptor does not control the reaction, which may explain the high activity of the peroxide adduct of the (HPTP) complex for oxidation reactions of phenols and 2′-deoxyribose and may support our previous conclusion that oxidation and oxygenation reactions are carried out by a different peroxide adduct than described before; peroxide adducts with an end-on η^1-coordination mode are proposed to be active for the oxygenation reaction [29].

(Received 25 June 1996; accepted 22 August 1996)

Abstract—A new tetradentate ligand 1,4-bis(5′-methyl-2,2′-bipyridine-5-ethyl)-benzene(p-bpy) and its Cu^{II} and Ag^{I} complexes were synthesized. In complex **1**, $Cu(p\text{-bpy})[ClO_4]_2 \cdot 0.5MeCN$, the four nitrogen atoms of the ligand coordinate with one Cu^{II} to form a flattened tetrahedron. The metal ion also has weak interactions with two ClO_4^- ions, which link the Cu^{II} ions in a one dimensional fashion to make an infinite chain. In complex **2**, $Ag(p\text{-bpy})[ClO_4]$, the coordination geometry of Ag^{I} is flattened tetrahedron. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: helical complex; molecular assembly; copper(II) complex; silver(I) complex; substituted bipyridene.

There is considerable interest in molecular topology, with particular emphasis being placed on the ability of metal ions to control the configuration of organic ligands [1]. Several groups have been involved in studies on the formation of helical complexes [2–5]. It was reported that oligobipyridines containing 6,6′-disubstituted bpy units spaced by $—CH_2OCH_2—$ and $—CH_2CH_2—$ form with Cu^{I} and Ag^{I} double helical complexes [6,7,8], while the ligand 1,2-bis(2,2′-bipyridyl-6-yl)ethane (*o*-bpy) forms with both Cu^{II} and Cu^{I} only mononuclear complexes [9]. The mononuclear complexes of Ru^{II} and Re^{V} of *o*-bpy has also been studied recently [10,11] on the interest of photochemistry. Nevertheless, Lehn and coworkers [8,12] observed that a slight modification of the steric effects by shifting from a 6,6′- to a 5,5′-disubstitution results in the formation of triple helical complexes and a 4,4′-disubstitution results in a triply bridged dinuclear Fe^{II} complex [13]. In order to further illustrate the effects by the linking positions and properties of spacer groups (flexibility and length), we combined the effects of preparing a new tetradentate ligand based on 5,5′-disubstituted bpy using $—CH_2CH_2—C_6H_4—CH_2CH_2—$ as the spacer. The results showed that the coordinating behaviour of the ligand are unexpectedly not similar to the above 6,6′- or 5,5′ disubstituted bpy-based ligands, but similar to *o*-bpy, forming mononuclear complexes with Ag^{I} and Cu^{II}. The synthesis of the tetradentate ligand 1,4-bis(5′-methyl-2,2′-bipyridine-5-ethyl)-benzene(*p*-bipy), the preparation, X-ray structure and properties of its Cu^{II} and Ag^{I} complexes are reported.

EXPERIMENTAL

Preparation of the ligand (p-*bpy*)

1,4-Bis(bromomethyl)benzene was prepared according to the literature [13], 50%, m.p. 142.5–144.5°C.

5,5′-Dimethyl-2,2′-bipyridine was prepared according to the literature [14,15], m.p. 115.5–116.5°C (literature value 114.5–115°C), ^{1}H NMR results: δ2.39 (6H,s,-CH_3), δ7.62 (2H,d,H_4,$H_{4'}$), δ8.26 (2H,d,H_3,$H_{3'}$), δ8.49 (2H,s,H_6,$H_{6'}$).

1,4-Bis(5′-methyl-2,2′-bipyridine-5-ethyl)-benzene (*p*-bpy): Lithium diisopropylamide was prepared by addition of butyllithium (14.4 mmol, 1.7 M solution in ether) to diisopropylamine (2.10 cm^3, 14.86 mmol) in dry THF (40 cm^3) under argon at −78°C. This solution was added slowly by cannula to 5,5′-dimethyl-2,2′-bipyridine (2.66 g, 14.44 mmol) in dry THF (40 cm^3) at −78°C. The dark reddish brown reaction mixture was stirred for about 2.5 h. 1,4-Bis(bromomethyl)benzene (1.85 g, 6.8 mmol) in THF (60 cm^3) was added dropwise with stirring within *ca* 40 min, during the period the temperature was allowed to increase slowly but not above 0°C. Stirring at 0°C was continued for 30 min and then water (20 cm^3) was added to quench the reaction. THF was removed *in vacuo* and the yellow precipitate filtered off, suspended in MeOH (50 cm^3) and filtered again. The remaining solid was chromatographed on a silica column with chloroform/methanol = 95 : 5. Colourless crystal needles were obtained with condensation. Yield 900 mg (30%), m.p. 242.0–244.0°C, FAB+, *m/z* 471. Found: C, 82.1; H, 6.7; N, 12.1. Calc. for $C_{32}H_{30}N_4$: C, 81.7; H, 6.4,N,11.9%, ^{1}H NMR results: δ2.39 (6H,s,—CH_3), δ2.94 (8H,m,—CH_2—), δ7.07 (4H,s,—C_6H_4—), δ7.55 (2H,d,H_4), δ7.62 (2H,d,$H_{4'}$), δ8.26 (4H,d,H_3, $H_{3'}$), δ8.45 (2H,s,H_6), δ8.49 (2H,s,$H_{6'}$). All results indicate that the title ligand has been obtained.

Preparation of the complexes

Cu(*p*-bpy) $[ClO_4]_2 \cdot 0.5MeCN$ (**1**) was prepared by refluxing a suspension solution of *p*-bpy (25.4 mg, 0.054 mmol) in methanol (20 cm^3) containing an equivalent of $Cu(ClO_4)_2 \cdot 6H_2O$ (20 mg, 0.054 mmol) for *ca* 2 h. Green precipitates were obtained upon concentration. The micro-elemental analysis of the dried powder sample is consistent with the unsolvated formula: Found: C, 51.6; H, 4.3; N, 7.4. Calc. for $C_{32}H_{30}N_4CuCl_2O_8$: C, 52.4; H, 4.1; N, 7.6%. Suitable crystals were recrystallized from a acetonitrile/toluene (1 : 1) solution of the precipitates at room temperature by slow evaporation of the solvent.

Ag(*p*-bpy) $[ClO_4]$ (**2**): Refluxing of the suspension solution of the ligand *p*-bpy (27.8 mg, 0.059 mmol) in methanol with an equivalent of $AgNO_3$ (10 mg, 0.059 mmol) gave a colourless solution. Precipitates were obtained upon the addition of saturated methanolic $LiClO_4$ solution and filtration. Suitable crystals were recrystallized from a methanolic solution of the complex by slow evaporation of the solvent. The micro-elemental analysis is consistent with the unsolvated formula: Found: C, 56.2; H, 4.1; N, 8.5. Calc. for $C_{32}H_{30}N_4AgClO_4$: C, 56.8; H, 4.4; N, 8.3%.

X-ray crystallography

Crystals of the complexes were mounted on a Rigaku RAXIS IIc diffractometer equipped with highly oriented graphite-monochromatized Mo-K_α radiation (λ = 0.71073 Å). Reflection data were collected at 292 K using an imaging plate system in the variable ω-scan technique. The refinement of the coordinates and anisotropic thermal parameters of the non-hydrogen atoms was carried out by the full-matrix least-squares analysis. The hydrogen atoms of the ligands were placed in their calculated positions and assigned fixed isotropic thermal parameters and allowed to ride on their respective parent atoms. Analytic expressions of atomic scattering factors were employed and anomalous dispersion corrections were incorporated [16–18]. All calculations were performed on a PC 486 computer.

Summary of data collection and crystal data for both complexes are listed in Table 1. Selected bond lengths and bond angles are listed in Tables 2 and 3 for complex **1** and complex **2**, respectively.

ESR spectrum

The ESR spectrum were recorded at 110 K on a Bruker 2000-SRC spectrometer operating at 9.4884 GHz in frozen acetonitrile.

RESULTS AND DISCUSSION

Structural description and discussion

The structure of complex **1** is characterized by a half occupancy of the solvent acetonitrile molecule. Two crystallographically non-equivalent complex molecules are observed (Fig. 1). Copper(II) was found to coordinate with only one ligand molecule in a flattened tetrahedral geometry. The two terminal pyridine nitrogen atoms in each ligand have shorter bonds with the metal ion Cu(1): Cu(1)—N(1) = 1.968(1), Cu(1)—N(4) = 1.948(2), Cu(1)—N(2) = 1.995(2), Cu(1)—N(3) = 1.991(1) Å, similar to the complex of *o*-bpy [8]; but the situation is different in the case of Cu(2): Cu(2)—N(5) = 1.996(2) Å is the longest and Cu(2)—N(6) = 1.972(2), Cu(2)—N(8) = 1.974(2) Å, while the shortest is Cu(2)—N(7) = 1.945(2) Å. The pyridine rings within the 2,2′-bipy subunits are not completely coplanar, with dihedral angles 1/2, 8.4°; 3/4, 13.8°; 5/6, 11.8°; 7/8, 7.5° (the pyridyl rings are

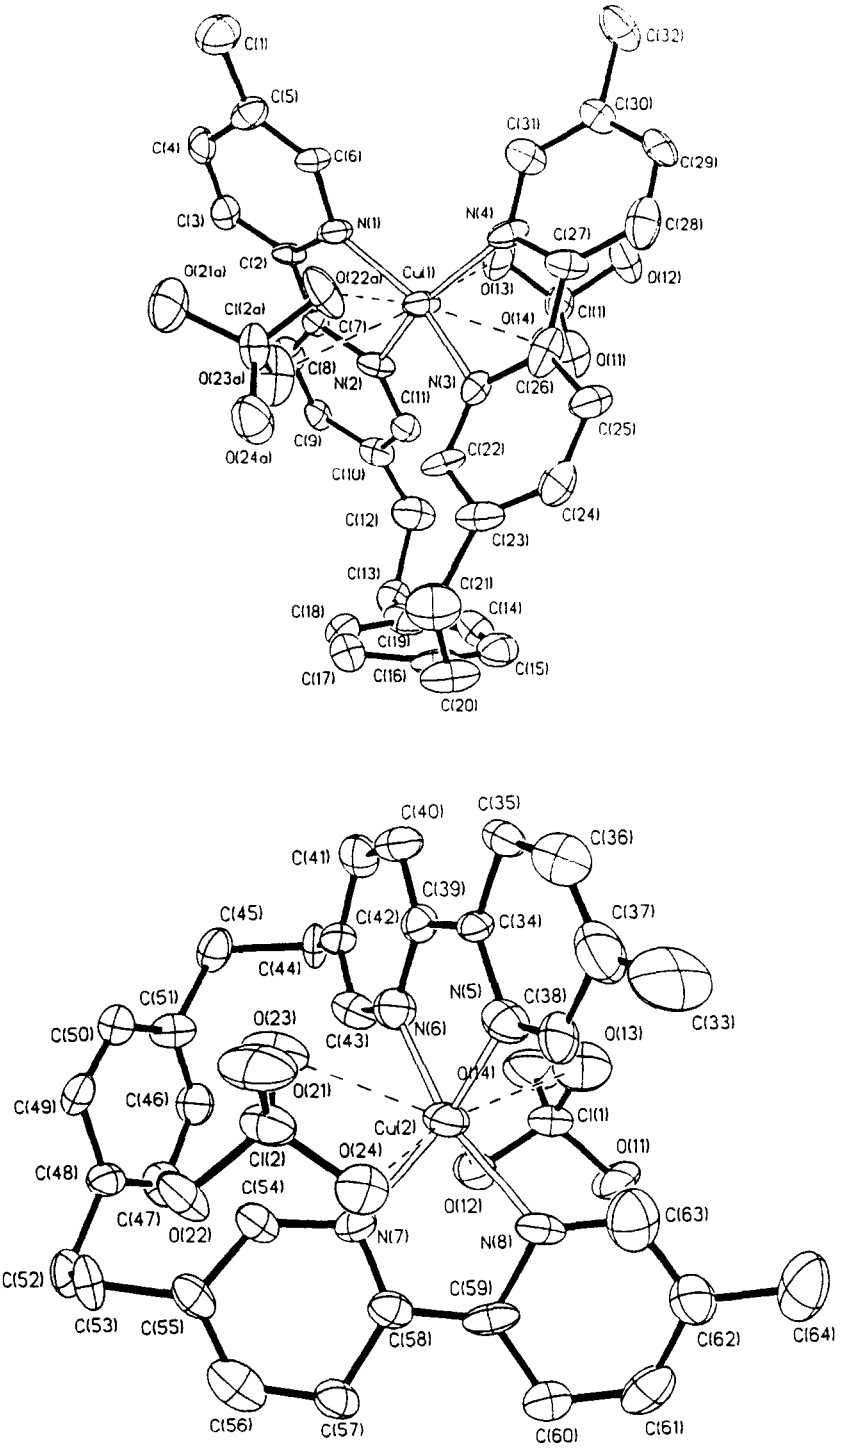

Fig. 1. The molecular structure of complex **1** with atom numbering scheme.

numbered after the nitrogen atoms they contain). The bond angles involving the five-membered chelation, N(1)—Cu(1)—N(2) = 83.6°, N(3)—Cu(1)—N(4) = 82.3°, N(5)—Cu(2)—N(6) = 84.1°, N(7)—Cu(2)—N(8) = 82.5° are slightly larger than the value of 81.6° reported for the *o*-bpy complex. The Cu(1)—Cu(2) distance is 7.605 Å. The angle between intramolecular plane normals of the two bipyridines is *ca* 60° in both molecules and the phenyl ring has dihedral angles of *ca* 61° with both bipy normals in molecules containing Cu(1), but in the second molecule the dihedral angles are different: 64 and 55°, respectively, for normals containing N(5), N(6) and N(7), N(8). The phenyl plane of the ligand and the coordination least-squares plane are perpendicular to each other with a dihedral angle of 89.3°.

The molecular structure of complex **2** is depicted in Fig. 2 with atom numbering scheme. Similar to complex **1**, two independent mononuclear molecules of the formula Ag(*p*-bpy)ClO_4 are identified in the lattice. No aromatic stacking is observed between them. The coordination geometry of silver(I) is a flattened tetrahedron. The major difference between the two unique molecules is the different bond angles (see Table 3). The dihedral angle values in the same molecules between pyridyl rings are Ag(1): 1/2 13.9° ; 3/4, 2.3 ; Ag(2): 5/6, 3.7°; 7/8, 2.9° (the pyridine ring planes numbered after the nitrogen atoms they contain). The distance Ag(1)—Ag(2) = 15.247 Å and the angle between intramolecular plane normals of the two bipyridine(bpy) is 69 and 60°, respectively, for that containing Ag(1) and Ag(2).

Several ligands that have comparable structures have been reported. For 6,6′-disubstituted 2,2′-bipyridine-based ligands, 1,2-bis(6′-methyl-2,2′-bipyridyl-6-yl)ethane(*o*-dmbpy) forms with a Cu^{I} double helical complex, as does the ligand using 1,10-phenanthroline as a replacement of the bipyridyl segments [8]. The other series of ligands using —CH_2OCH_4— as the spacer can also form with Cu^{I} and Ag^{I} double helical complexes [7]. The literature [19,20] reports the syntheses of several knotted molecules in which the key step is the synthesis of Cu^{I} dinuclear double helical complexes. A flexible spacer as long as —CH_2CH_2 CH_2CH_2— was used in the synthesis. However, when the 6′-methyl group is removed, the ligand 1,2-bis(2,2′-bipyridyl-6-yl)ethane(*o*-bpy) can only form with Cu^{II} and Cu^{I} mononuclear complexes [9]. Lehn and co-workers found that a slight steric modification from 6,6′- to 5,5′-disubstituents results in the formation of a triple helical complex of 1,2-bis(5′-methyl-2,2′-bipyrid-5-yl)ethane with Fe^{II} [8]. And the tris-(bipyridyl) ligand 5,5′-bis(5′-methyl-2,2′-bipyridyl-5-ethyl)-2,2′-bipyridine forms with Ni^{II} a trinuclear triple helical complex, the X-ray structure of which has been determined [12].

It can be seen that the structures of both of the Ag^{I} and Cu^{II} complexes with the newly synthesized ligand *p*-bpy in this paper are different from all the above two cases of 6,6′- and 5,5′-disubstituted bpy based ligands. On the first hand, these facts indicate the steric effects of the 6′-methyl in *o*-dmbpy is most important in the formation of the Cu^{I} double helix for 6,6′-disubstituted bpy-based ligands. The methyl substitution of *p*-bpy at the 5′-position, not at the crucial 6′-position, creates no steric repulsion when the ligand adopts the near planar all-*cis* conformation to form a ring cavity. On the other hand, the significant difference between the 6,6′- and 5,5′-disubstituted ligands spaced by —CH_2CH_2— is perhaps

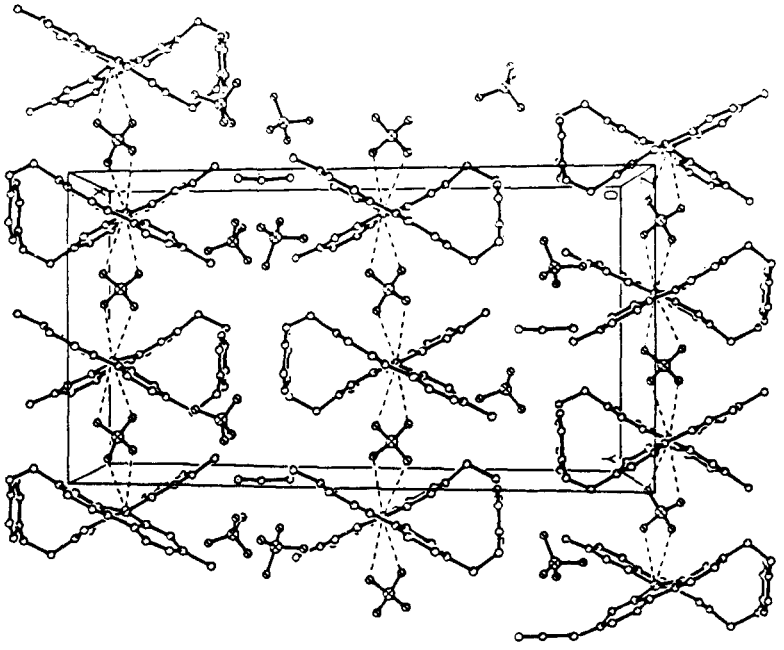

Fig. 2. The crystal packing of complex **1**.

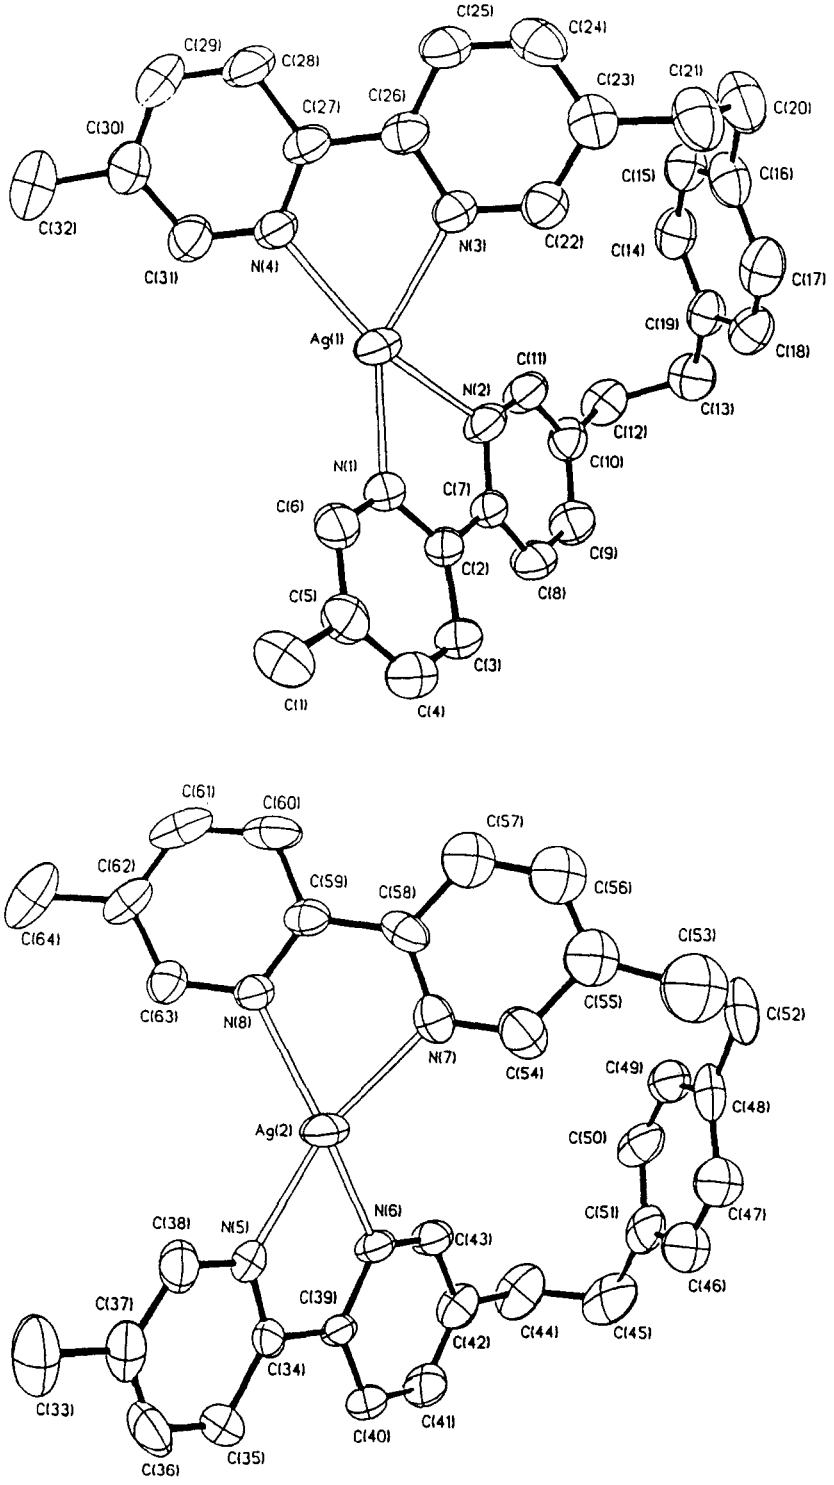

Fig. 3. The molecular structure of complex **2** with atom numbering scheme.

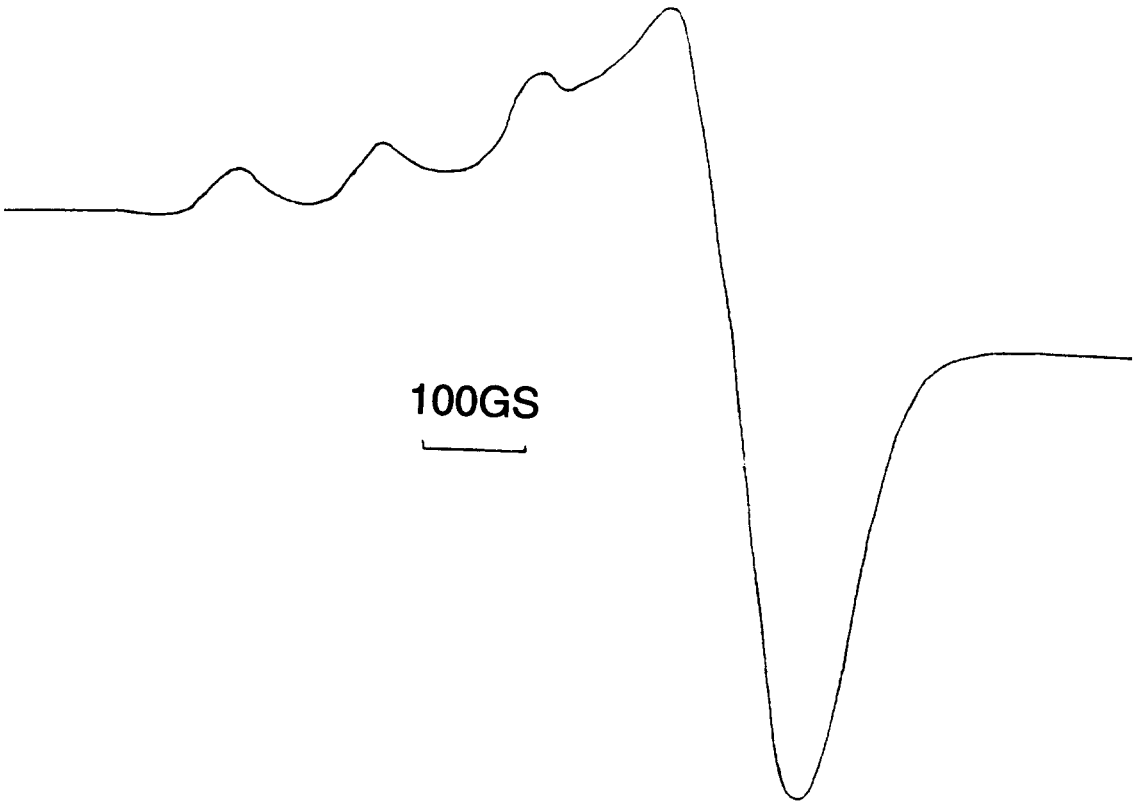

Fig. 4. ESR spectrum of complex **1** in solvent acetonitrile at 110 K.

caused by the facts that the 5,5′-disubstituted ligands has a larger planar cavity than the 6,6′-disubstituted ones and the metal ions with smaller ionic radius, such as Ni^{II} and Fe^{II}, cannot fit in. However, when a helical conformation was adopted by the ligand molecules, they can coordinate simultaneously with two metal ions to establish the octahedral geometric requirement of the cations and form a triple helix. However, the change of the spacer from $—CH_2CH_2—$ to $—CH_2CH_2—C_6H_4—CH_2CH_2—$ also disfavours the formation of multiple helicates, because the length and flexibility of the spacer made is possible for the ligand to act as a tetradentate ligand coordinating with only one Cu^{II} or Ag^{I} ion.

Therefore, it can be concluded that for ligands based on substituted bpy, both flexibility, length of the spacer group and the steric groups at crucial positions can control the formation of helical complexes. The flexibility, the longer spacer group and the absence of steric groups at the terminal 6′-positions are responsible for the failure in forming double or triple helixes in this paper.

The structure of the two complexes are essentially similar apart from the weak coordination of perchlorate ions in complex **1**. This difference results from the tendency of Cu^{II} to form six-coordinate octahedral geometry. In complex **1**, the ClO_4^- anions act as bidentate ligands and occupy positions relative to the CuN_4 chromophore, such that four long Cu—O distances (ranging from 2.962 to 3.303 Å) are present to yield a distorted eight-coordinate CuN_4O_4 dodecahedral chromophore. The Cu—O distances are longer than that in Cu(*o*-bpy) $(ClO_4)_2$ (2.7 Å), but shorter than that of Cu—F in $Cu(bpy)_2(PF_6)_2$ (3.3 Å). As the Cu—O distances are too long [21], the copper stereochemistry is best considered as compressed tetrahedral in the title complex **1**. The longest reported bond length of Cu—O, to our knowledge is 2.932 Å in a bis(2-pyridylcarbonyl)amido complex [22]. Most recently weak $Cu\cdots OClO_3$ bonds were observed ranging from 2.992 to 3.348 Å [23]. Therefore, it is appropriate to say that ClO_4^- has weak coordinating interactions with Cu^{II}. The structure is in a one-dimensional infinite chain form (Fig. 3). The crystal packing is perhaps the main cause of the existence of the two molecules with a different coordination situation in both complexes.

ESR spectrum

The ESR spectrum (Fig. 4) can best be described as isotropic with a weak $g_{\|}$ component located at 2.268 and a $g_{\perp}$ located at 2.081. The spectrum is similar to that of $[Cu(o\text{-bpy})](ClO_4)_2$ [8].

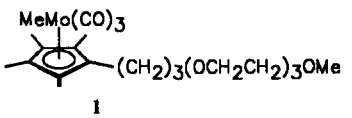
Organometallic compounds as complexing agents: a rare example of a crystalline alkali metal podate

Ulrich Siemeling

Fakultät für Chemie, Universität Bielefeld, Universitätsstraße 25, D-33615 Bielefeld, Germany



(Received 12 August 1996; accepted 21 August 1996)

Abstract—The tentacle-bearing ferrocenes $[Fe\{R_4C_5SiMe_2(OCH_2CH_2)_nOMe\}_2]$ (**4a**: R = H, $n = 2$; **4b**: R = Me, $n = 2$; **4c**: R = H, $n = 3$; **4d**: R = Me, $n = 3$) and $[Fe\{Me_4C_5(CH_2)_3(OCH_2CH_2)_3OMe\}_2]$ (**5**) act as podands for alkali metal cations; **4b, 4d,** and **5** are much better podands than **4a** and **4c**. Compound **5** and $[(C_5H_5)Fe\{Me_4C_5(CH_2)_3(OCH_2CH_2)_3OMe\}]$ (**8**) are oxidized to $\mathbf{5}^+$ $[PF_6]^-$ and $\mathbf{8}^+$ $[PF_6]^-$, respectively, which both show no tendency to crystallize. The cobaltocenium species $[Co\{Me_4C_5(CH_2)_3(OCH_2CH_2)_3OMe\}_2]^+[PF_6]^-$ ($\mathbf{11}^+$ $[PF_6]^-$) is a selective podand, which prefers potassium over lithium cations; its potassium podate $\mathbf{11}^+$ $[PF_6]^- * K^+[PF_6]^-$ is the first example of a crystalline oligoethylene glycol ether podate, whose crystallinity does not rely on the rigid end-group principle. © 1997 Elsevier Science Ltd. Keywords: cyclopentadienyl ligand, functionalized; ferrocene, functionalized; oligoethylene glycol ether; podate; crystalline; organometallic chemistry, supramolecular; tentacle.

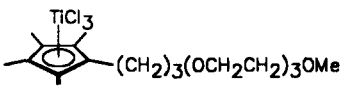
We have recently described a series of cyclopentadienes of the type HR_4C_5-Z-$(OCH_2CH_2)_nOMe$ (Z = spacer group) functionalized with a pendent oligoethylene glycol ether "tentacle" [1]. These compounds have been utilized for the preparation of a wide variety of cyclopentadienyl complexes such as, for example, the carbonyl complexes **1** [2] and **2** [1b], the titanium half-sandwich complex **3** [2] and the ferrocenes **4a–d** [3] and **5** [1b], which show extraordinarily high solubilities in organic solvents of all polarities due to the amphiphilic nature of the tentacle substituent.



We have also been able to synthesize rather unusual compounds such as, for example, the half-sandwich iron(II) chloride complex **6** [4] and the primary α-ferrocenyl carbocation $\mathbf{7}^+$ [5]; the stabilising influence of the tentacle on these otherwise very unstable species is based on a predominantly intramolecular coordination of the tentacle to the unsaturated position present in these compounds.

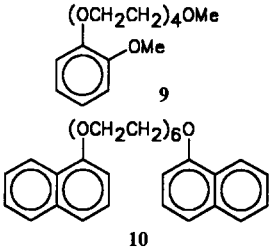
This paper focuses on a supramolecular aspect of tentacle-functionalized cyclopentadienyl compounds, which is based on the well-known ability of oligoethylene glycol ether units to act as podands [6].

RESULTS AND DISCUSSION

The podand abilities of the ferrocenes **4a–d** and **5** towards alkali metal cations were determined by using the well-established picrate extraction method developed by Peterson [7]. The results of this investigation are summarised in Table 1.

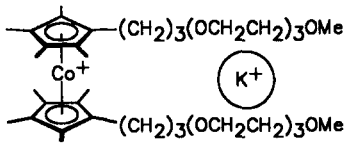


Two effects can be made out quite clearly. The first effect is based on the ring substitution of the ferrocenes: The ferrocenes with permethylated cyclopentadienyl rings (**4b, 4d** and **5**) are much better podands than the unmethylated ferrocenes **4a** and **4c**. The second effect is based on the tentacle length: Considering the ferrocenes of type **4**, it is evident that among the pairs with identical ring methylation the ferrocene with the longer tentacle is the better podand. Not surprisingly, the podand abilities of **4d** and **5**, which have the same ring methylation and tentacle length, are almost identical.

Generally, tentacle-bearing molecules are oils which show no tendency to crystallize [8]. This is even true for ionic compounds such as $[Fe\{Me_4C_5(CH_2)_3(OCH_2CH_2)_3OMe\}_2]^+[PF_6]^-$ (**5**$^+[PF_6]^-$), which is a viscous oil, and $[(C_5H_5)Fe\{Me_4C_5(CH_2)_3(OCH_2CH_2)_3OMe\}]^+[PF_6]^-$ (**8**$^+[PF_6]^-$), which is a waxy semi-solid (this may reflect the presence of only one tentacle in this species); both compounds were obtained in essentially quantitative yields by oxidation of **5** and $[(C_5H_5)Fe\{Me_4C_5(CH_2)_3(OCH_2CH_2)_3OMe\}]$ (**8**) [5], respectively, with 1 equiv. of ferrocenium hexafluorophosphate in acetonitrile.

Table 1. Relative extractabilities (in %) of alkali metal cations from the aqueous into the organic phase by the ferrocenes **4a–d** and **5**. Concentrations: 10^{-2} M for **4a–d** and **5** (in dichloromethane); 7×10^{-5} for picric acid and 10^{-1} M for the alkali metal chlorides (in water)

	Li	Na	K	Rb	Cs
4a	0.2	2.2	3.1	2.5	2.3
4b	12.6	20.2	21.1	20.2	18.2
4c	2.3	3.0	3.8	4.4	5.4
4d	76.1	85.6	87.2	88.5	89.5
5	72.0	84.8	89.7	89.7	89.5



The great reluctance of such compounds to crystallize is due to the high flexibility of the tentacles, which is substantially reduced upon complexation of metal cations. Crystalline podates of simple oligoethylene glycol ethers $Me(OCH_2CH_2)_nOMe$ are indeed known for a variety of transition metal and alkaline earth metal cations [6b], but not for alkali metal cations, for which crystalline podates could be obtained only with oligoethylene glycol ethers such as **9** [9] and **10** [10], which bear rigid aromatic end-groups.

9

10

Owing to the presence of a spacer group between the tentacle and the ferrocenyl nucleus the ferrocenes **4a–d** and **5** cannot be regarded as oligoethylene glycol ethers bearing a rigid aromatic end-group. Not unexpectedly, attempts to crystallize their alkali metal podates failed. Surprisingly, however, **11**$^+$, which is the isoelectronic cobaltocenium analogue of **5**, yielded a beautifully crystalline potassium podate. Complex **11**$^+$ was synthesized by air oxidation of an acidified THF solution of the corresponding cobaltocene $[Co\{Me_4C_5(CH_2)_3(OCH_2CH_2)_3OMe\}_2]$ (**11**) prepared *in situ* from $Li[Me_4C_5(CH_2)_3(OCH_2CH_2)_3OMe]$ and cobalt(II) chloride in THF. Precipitation of the cobaltocenium species with an excess of potassium hexafluorophosphate afforded yellow crystals of the stoichiometry **11**$^+[PF_6]^- * K^+[PF_6]^-$ in good yield. Remarkably, lithium cations, which were also present in the solution in approximately the same concentration as potassium cations, could not be detected in the solid complex. Complex **11**$^+$ therefore appears to be a selective podant with a pronounced preference for potassium over lithium cations in aqueous solution. The podate **11**$^+[PF_6]^- * K^+[PF_6]^-$ is very soluble in acetone, acetonitrile and nitromethane. It may be recrystallized quite conveniently from aqueous acetone by slow evaporation of the organic solvent. Obviously, the cooperation of an increased ionicity with respect to the potassium podates of the ferrocenes **4a–d** and **5** and a decreased flexibility of the two tentacles with respect to the ferrocenium salt **5**$^+[PF_6]^-$ leads to facile crystallization. Crystals suitable for a single-crystal X-ray diffraction study could not be obtained so far, because the compound forms very thin platelets. It is therefore as yet uncertain whether each potassium ion is coordinated by the two tentacles of one cobaltocenium ion (as shown in Fig. 1) or whether they are coordinated by one tentacle each of two

$11^+[PF_6]^- * K^+[PF_6]^-$

Fig. 1. Possible structure of the podate $11^+[PF_6]^- * K^+[PF_6]^-$.

cobaltocenium units leading to a polymeric arrangement.

The compound $11^+[PF_6]^- * K^+[PF_6]^-$ is the first example of a crystalline alkali metal podate which does not rely on the rigid end-group principle. The cooperative behaviour of the two tentacles present in this species seems to be facilitated by the cobaltocenium hinge, which reduces the flexibility of the system by allowing only rotational motion around the C_5 ring centroid-C_5 ring centroid axis; the closely related di(O_4-tentacle) species $MeO(CH_2CH_2O)_3$-$(CH_2)_5(OCH_2CH_2)_3OMe$ has an association constant of less than 1.25 for the complexation of K^+ and no corresponding podate can be isolated.

EXPERIMENTAL

All reactions were performed in an inert atmosphere (purified argon or dinitrogen) by using standard Schlenk techniques unless stated otherwise. Solvents and reagents were appropriately dried and purified by using standard procedures. NMR spectra were recorded at 300 K with a Bruker DRX 500 instrument operating at 500.13 MHz for ^1H. Elemental analyses were performed by Mikroanalytisches Laboratorium Beller, Göttingen, and the Microanalytical Laboratory of the University of Bielefeld.

Synthesis of $5^+[PF_6]^-$

A solution of ferrocenium hexafluorophosphate (364 mg, 1.10 mmol) in acetonitrile (10 cm^3) was added to a solution of **5** [1b] (777 mg, 1.10 mmol) in acetonitrile (10 cm^3). The solution was stirred for 14 h. The solvent was removed *in vacuo*. Ferrocene was removed by sublimation (70°C/10^{-3} mbar) leaving $5^+[PF_6]^-$ (936 mg, 100%) as a dark green, viscous oil. Found: C, 53.7; H, 7.9. $C_{38}H_{66}F_6FeO_8P$ requires: C, 53.6; H, 7.8.

Synthesis of $8^+[PF_6]^-$

A solution of ferrocenium hexafluorophosphate (364 mg, 1.10 mmol) in acetonitrile (10 cm^3) was added to a solution of **8** [3] (491 mg, 1.10 mmol) in acetonitrile (10 cm^3). The solution was stirred for 14 h. The solvent was removed *in vacuo*. Ferrocene was removed by sublimation (70°C/10^{-3} mbar) leaving $8^+[PF_6]^-$ (650 mg, 100%) as a dark green, waxy semi-solid. Found: C, 48.7; H, 6.6. $C_{24}H_{38}F_6FeO_4P$ requires: C, 48.7; H, 6.5%.

Synthesis of $11^+[PF_6]^- * K^+[PF_6]^-$

Bu*n*Li (5.00 cm^3 of a 1.58 M solution in hexane, 7.90 mmol) was added dropwise with stirring to a solution of $HMe_4C_5(CH_2)_3(OCH_2CH_2)_3OMe$ [1b] (2.58 g, 7.90 mmol) in THF (30 cm^3) cooled to 0°C. The resultant solution of $Li[Me_4C_5(CH_2)_3(OCH_2CH_2)_3OMe]$ was added dropwise with stirring to a solution of $CoCl_2$ (520 mg, 4.00 mmol) in THF (50 cm^3) cooled to −60°C. The mixture was allowed to warm to room temperature overnight. Hydrochloric acid (0.1 N; 80 cm^3, 8.00 mmol) was added to the dark brown solution of the cobaltocene **11** thus obtained. A stream of air was passed through the mixture over a period of 2 h. The aqueous layer was separated, extracted with diethyl ether (2 × 20 cm^3) and was subsequently filtered into a solution of $K^+[PF_6]^-$ (1.47 g, 8.00 mmol) in water (30 cm^3). The solution was allowed to stand in a large Petri dish overnight. The yellow crystals of $11^+[PF_6]^- * K^+[PF_6]^-$ (2.58 g, 62%) were collected by filtration, washed with cold water (2 × 5 cm^3) and dried *in vacuo*. Found: C, 44.0; H, 6.5; Co, 5.5; F, 22.0. $C_{38}H_{66}CoF_{12}KO_8P_2$ requires: C, 43.9; H, 6.4; Co, 5.7; F, 21.9%. ^1H NMR (CD_3NO_2): δ 1.70 ("t", 4H, $CH_2CH_2CH_2$), 1.80 and 1.82 (2s, 24H, C_5Me_4), 2.32 (t, J = 7.2 Hz, 4H, $C_5Me_4CH_2CH_2CH_2OR$), 3.32 (s, 6H, OMe), 3.45 (t, J = 6.4 Hz, 4H, $C_5Me_4CH_2CH_2OR$), 3.50–3.61 [m, 24H, $(OCH_2CH_2)_3$]; $^{13}C\{^1H\}$ NMR (CD_3NO_2): δ 8.4 (C_5Me_4), 20.7 and 29.6 ($C_5Me_4CH_2CH_2CH_2OR$), 59.2 (OMe), 71.0, 71.1, 71.3 and 72.8 [$CH_2(OCH_2CH_2)_3$], 95.4, 96.4 and 98.5 (C_5Me_4); ^{19}F NMR (CD_3NO_2): δ −72.6 [d, J(PF) = 707 Hz]; $^{31}P\{^1H\}$ NMR (CD_3NO_2): δ −143.2 [sept, J(PF) = 707 Hz].

Determination of the relative extractabilities of alkali metal cations from the aqueous into the organic phase by the ferrocenes **4a–d** and **5**

Equal volumes (5 cm^3) of a solution of the respective ferrocene (10^{-2} M) in dichloromethane and of picric acid (7×10^{-5} M) and the respective alkali metal chloride (10^{-1} M) in water were equilibrated at room temperature by vigorous shaking. The respective aqueous solutions and pure dichloromethane were equilibrated likewise. The extinction of each equilibrated aqueous phase was determined at λ = 357 nm (absorption maximum of picrate). The relative extractability (in %) for a specific alkali metal cation by a specific ferrocene corresponds to the value $[(E_0 - E)/E_0] \times 100$ (E_0: extinction for the extraction of the aqueous solution of the respective alkali metal chloride and picric acid with pure dichloromethane; E: extinction for the corresponding extraction with

10^{-2} M of the respective ferrocene in dichloromethane).

(Received 6 August 1996; accepted 21 August 1996)

Abstract—New vanadyl(IV) complexes of tetradentate Schiff-base dianions containing one, two or three carbon atoms between the two iminato-nitrogen atoms are described. The compounds are either mononuclear or polymeric, as shown by the value of $\nu(V{=}O)$, and depending upon the Schiff-base dianion. There is no evidence for electron delocalization along the polymeric chains. Some vanadium(III) complexes of bidentate Schiff-base monoanions have also been isolated; the crystal structure of $[VO(2\text{-}OC_6H_4CHNH)_2]$ and preliminary data on the structure of $[V(Prhap)_3]\cdot$toluene [HPrhap = $2\text{-}HOC_6H_4C(Me)NCH_2CH_2Me$] are reported. © 1997 Elsevier Science Ltd. Keywords: vanadium; Schiff bases; low oxidation states; complexes; X-ray structures; preparations.

We have recently described [1,2] preparations and structures of cations consisting of vanadium–oxygen chains, all containing the tetradentate $(salen)^{2-}$, $(OC_6H_4CH:NCH_2CH_2N:CHC_6H_4O)^{2-}$. We have now extended the scope of these reactions to oxovanadium(IV) complexes with similar Schiff base ligands. In the course of this work we have prepared several new Schiff bases and their oxovanadium(IV) complexes which present several features of interest. We have also attempted, without much success, to reduce vanadyl(IV) and dichlorovanadium(IV) complexes of tetradentate Schiff base anions to vanadium(III) complexes, but we succeeded in preparing vanadium(III) complexes of bidentate Schiff-base monoanions, using sodium or lithium reduction.

RESULTS AND DISCUSSION

Complexes of vanadium(IV) *and tetradentate Schiff-base dianions*

Most of the tetradentate Schiff bases described here have either ethylene (—CH_2CH_2—) or 2,2-dimethyl-(trimethylene) (—$CH_2CMe_2CH_2$—) bridges between their two nitrogen atoms. Metal complexes derived from these two types of Schiff base will have five- or six-membered central chelate rings, respectively. All the Schiff bases used are detailed in Table 1. The new vanadyl(IV) complexes are listed in Table 2.

Ethylene-bridged complexes

Oxovanadium(IV) complexes with ethylene bridges may be divided into two classes. A typical example of

[a] Required values in parentheses.

[b] These have been previously reported in the given references, but all the data are from our preparations.

[c] No deviation from ideal behaviour down to 87 K.

the first class is [VO(salen)], which forms green crystals, is fairly soluble in solvents such as acetonitrile and dichloromethane, has ν(V=O) in its solid-state IR spectrum at 980 cm^{-1} and is monomeric in the solid state [3,4]. The class also includes a complex with a ligand derived from ethylenediamine and 2-hydroxybenzophenone, which has ν(V=O) at 981 cm^{-1} [5]. The only difference from the salen complex is that the CH=N motif is replaced by CPh=N. However, an analogous complex made in the same way with a ligand derived from ethylenediamine and 2-hydroxy-5-chlorobenzophenone is gold, not green, relatively insoluble and has ν(V=O) at 881 cm^{-1}. This is representative of the second class, with ν(V=O) *ca* 100 cm^{-1} to lower frequency compared with the first. These are all apparently polymeric in the solid state, forming chains $\cdots V{=}O \rightarrow V{=}O \rightarrow \cdots$. The shift of *ca* 100 cm^{-1} in ν(V=O) between apparently similar compounds is also found in the chemistry of vanadyl(IV) complexes with bidentate and tridentate ligands and at least one compound is known which exists in both forms with different crystal shapes [6]. The two forms are apparently isomers.

If we assume that the green vanadyl(IV) complexes are all square pyramidal and five-coordinate, as in [VO(salen)] [3], the difference between the ν(V=O) values can easily be rationalized [7] in terms of the infinite chain polymerization of the orange or gold compounds in the solid state. No structural studies showing such polymeric chains in ethylene-bridged complexes (except [1] for the cation [V(salen)OV(salen)O]$^+$ with ν(V=O) at 880 cm^{-1}) have been reported, although [VO{$OC_6H_4CH:N(CH_2)_3N:CHC_6H_4O$}] has a chain structure and a low value of ν(V=O) [7].

The reason for the changeover from "normal" ν(V=O) values at 980 cm^{-1} "low" values at 880 cm^{-1} must be in part electronic, because substitutions in the phenyl rings should not influence sterically the geometry round the vanadium atom [5]. The electronic effects of aromatic substituents might most simply be assessed using the pK_A values of the related 3- and 4-substituted benzoic acids; pK_A values in acetonitrile (the solvent most frequently used in this work) include 20.7 for benzoic acid, 19.5 for 3-bromobenzoic acid, 19.2 for 3-nitrobenzoic acid and 18.7 for 3,5-dichlorobenzoic acid [8].

We have therefore made [VO{$(MeO)_4$salen}], [VO(Cl_2salen)], [VO(Br_2salen)], [VO(Cl_4salen)], [VO(Br_4salen)] and [VO{$(NO_2)_2$salen}] using Schiff bases prepared from ethylenediamine and 4,6-dimethoxysalicylaldehyde, 5-chlorosalicylaldehyde, 5-bromosalicylaldehyde, 3,5-dichlorosalicylaldehyde, 3,5-dibromosalicylaldehyde and 5-nitrosalicylaldehyde, respectively. The first three form green crystals with higher ν(V=O), the last two form insoluble powders with low ν(V=O). The sixth complex, derived from Cl_4salen is unique among tetradentate Schiff base derivatives in being apparently obtainable in both polymeric and monomeric forms, although we were unable to confirm this by X-ray structure analysis. The green solid, ν(V=O) = 991 cm^{-1}, was isolated from acetonitrile after heating the preparative reaction mixture in acetonitrile for 20 min at reflux. Upon prolonged exposure to acetonitrile solution or upon exposure to solvents such as diethyl ether, acetone, dichloromethane and methanol, or even upon heating the solid *in vacuo*, the green form changes to the orange form, with ν(V=O) = 868 cm^{-1}. We believe that the only other example of such isomerism is the complex bis[(*N*-(4-chlorophenyl)salicylideneaminato) oxovanadium(IV)] [6,7].

The data seem to suggest that within a given class of compound (monomeric or polynuclear) some lowering of ν(V=O) is favoured by electron-withdrawing substituents such as chloro, bromo and nitro. The known [VO{$(MeO)_2$salen}] has a high ν(V=O) and is presumably monomeric. There are no intermediate values of ν(V=O), which suggests a sudden switch in structure induced by the electronic effects of the substituents and the change between monomeric and polymeric structures seems a reasonable explanation.

However, this may not be in the whole story. Kuska and Yang [5] studied a series of analogous complexes based on the Schiff base 4,5-$R^1R^2C_6H_2$(OH)CPh=N-CH_2CH_2—N=CPhC_6H_2(OH)R^1R^2-4,5. They plotted ν(V=O) against the Hammett σ factors for R^1 and R^2, and showed that ν(V=O) increases with the electron-withdrawing power of the substituents within the "high-frequency" group, which is observed for: R^1 = H, R^2 = Cl; R^1 = CH_3, R^2 = Cl; R^1 = R^2 = H and R^1 = H, R^2 = CH_3 in solution in $CHCl_3$. However, in Nujol mulls, the first two compounds are in the "low-frequency" group. Our data, within the "high-frequency" and "low-frequency" groups, show that electron-withdrawing substituents have no consistent effect on ν(V=O), but the overall effect, as with Kuska and Yang, is hardly significant and certainly not comparable with the effect of polymerization on ν(V=O). However, the observations do imply that steric effects have a secondary influence. The fact that heavily substituted aromatic rings and bridges other than ethylene tend to favour polymerization hints at a crystal-packing effect. However, the low solubility of the polymeric compounds has prevented sensible solution studies.

The magnetic moments of all the complexes are close to the spin-only values for vanadium(IV) complexes. As the unpaired electron is believed to be in an orbital orthogonal to the V=O axis [9], it should not be affected by polymerization along V—O—V—O chains. The effective magnetic moment of [VO{$(NO_2)_2$salen}] exhibits normal Curie–Weiss behaviour down to 87 K.

2,2-*Dimethyl(trimethylene)-bridged complexes*

Alone among compounds of formula [VO($OC_6H_4CH:N(CH_2)_nN:CHC_6H_4O$)] ($n$ = 2–10) the complex

with $n = 3$ has a "low" ν(V=O) [4] and that with $n = 4$ shows two values of ν(V=O). The X-ray structure for $n = 3$ shows that this material is polymeric [7]. This may be a consequence of distortions in the coordination sphere of the vanadium atom upon lengthening the bridge rather than electronic factors, since there are no substituents on phenyl rings.

We report here syntheses of several dimethyl (trimethylene)-bridged complexes which also contain six-membered central chelate rings, with a geometry about the vanadium atom similar to that of trimethylene-bridged complexes. All these complexes, i.e. [VO(salnptn)], [VO{$(MeO)_2$salnptn}], [VO(nalnptn)] and [VO{$(MeO)_4$salpn}] from 2,2-dimethylpropane-1,3-diamine and salicylaldehyde, 3-methoxysalicylaldehyde and 2-hydroxy-1-naphthaldehyde, respectively, and from 4,6-dimethoxysalicyaldehyde and propane-1,3-diamine show a "low" ν(V=O) value and are presumably polymeric. This was confirmed for [VO(salnptn)] by an X-ray study [10]. Unlike its trimethylene-bridged analogue, the dimethyl(trimethylene) derivative [VO(salnptn)] is soluble in common organic solvents and several protonation, oxidation and reduction reactions of it have been carried out. Details of these reactions are being published separately. The effective magnetic moment of [VO(salnptn)] was found to be virtually independent of field and temperature from 293 K down to 87 K and the compound exhibits normal Curie–Weiss behaviour. Even though the compound is apparently polymeric, there is no indication of electron delocalization, consistent with the unpaired electron being in the d_{xy} orbital and orthogonal to the V—O chain.

Yields of dimethyl(trimethylate)-bridged complexes were usually considerably smaller than those of ethylene-bridged complexes made by the same route. The attempted synthesis of [VO($OC_6H_4CMe:NCH_2CMe_2CH_2N:CMeC_6H_4O$)] and of its trimethylene-bridged analogue from [VO(acac)$_2$] and the Schiff base failed altogether, while the synthesis of its ethylene-bridged analogue by the same route proceeded in good yield.

Methylene-bridged complexes

A Schiff base with a methylene bridge would be accessible from methylenediamine if this existed. A compound derived from this Schiff base with molybdenum, but synthesized from hexamethylenetetramine, salicylaldehyde and, presumably, traces of water, has recently been reported [11]. Unexpectedly, the tetradentate Schiff base is dinucleating. We have, however, prepared $HOC_6H_4CH:NCH_2N:CHC_6H_4OH$ (H_2salmn) for the first time by reaction of salicylaldehyde, methylenediamine dihydrochlorine and triethylamine.

Treatment of H_2salmn with [VO(acac)$_2$] or with $VOSO_4$ under various conditions gave products which could not be characterized. However, treatment of H_2salmn with [{VO(OMe)(acac)}$_2$] under very mild conditions gave a yellow powder, soluble in dichloromethane and acetonitrile, analysing for [VO(salmn)] · MeOH with an IR band at 986 cm^{-1} characteristic of a terminal ν(V=O) and a magnetic moment of 1.73 BM. Due to the colour it seems unlikely that this is the simple monomer of its empirical formula and a crystal structure analysis is needed to elucidate its nature.

Attempted synthesis compounds of vanadium(II) with tetradentate Schiff-base dianions

Attempts were made to prepare vanadium(II) complexes of $(hapen)^{2-}$ and $(happn)^{2-}$ by reaction of the sodium or lithium salts of the Schiff bases with $VCl_2(thf)_2$ [12], $VBr_2(MeOH)(thf)$ [13] or [$VCl_2(py)_4$] [14]. In no case was an unequivocal vanadium(II) product obtained. Attempts were also made to reduce the vanadium(IV) complexes [VCl_2(hapen)] and [VCl_2(sal-1,2-pn)] with sodium sand. These dihalides were prepared from the corresponding vanadyl species by standard routes. This method was also unsuccessful, although in the latter case a vanadium(III) complex, [{VCl(sal-1,2-pn)}$_2$], was obtained and characterized. All these halo-compounds are detailed in Table 3. This formulation is based upon the usual analytical and spectroscopic data and analogy with [{VCl(salen)}$_2$], which has been suggested to be dinuclear [15].

Compounds of vanadium(IV) with bidentate Schiff-base monoanions

Schiff bases are made in 1 : 1 reactions between aldehydes and primary amines.

$$ArCHO + RNH_2 \longrightarrow ArCH:NR$$

However, when R = H (i.e. with ammonia), three molecules of aromatic aldehyde react with two molecules of ammonia giving hydroamides, whereas aliphatic aldehydes yield polymers (aldol condensation) and/or aldehyde-ammonias.

$$3ArCHO + 2NH_3 \longrightarrow ArCH:NCHArN:CHAr$$

$$AlkCHO + NH_3 \longrightarrow AlkC(H)(OH)(NH_2)$$

We made hydrosalicylamide (Ar = C_6H_4OH), from salicylaldehyde and ammonia, to react with $VOSO_4$. We hoped to obtain an analogue of [VO(salmn)] substituted in the methylene bridge by a —C_6H_4OH group, but we isolated green crystals analysing as $C_{14}H_{12}N_2O_3V$ with a strong IR band at 980 cm^{-1}, ν(V=O), and sharp bands at 3360 and 3240 cm^{-1} ν(NH). We assign the structure [VO($OC_6H_4CH:NH)_2$] to this compound; it contains a sali-

[a] Analytical figures in parentheses are calculated values.

cylideneiminato-ligand whose free acid (salicylaldeimine, $HOC_6H_4CH:NH$) is unknown, and it is the previously unreported parent compound of all oxovanadium(IV) bis(bidentate) Schiff base complexes.

X-ray studies of similar complexes $[VO(OC_6H_4CH:NR)_2]$ [16] ($R \neq H$) show that the two N donor atoms take *trans* positions to one another to minimize interactions between their R groups. In our compound where R = H these interactions would be small and there seems no reason why these two atoms should not be *cis* to one another, with one N—H group above and one below the plane formed by the N_2O_2 atom donor set, as happens to the methylene groups in [VO(salen)]. This would result in two slightly different N—H stretching frequencies. In fact, the NH groups are indeed *trans*, but different. An X-ray structure analysis has clarified the situation. The structure is shown in Fig. 1 and selected bond lengths and angles are in Table 4.

The vanadium atom is five-coordinate with the expected square pyramidal pattern, similar to that in [VO(salen)] [3], the vanadyl oxygen O(3) is in the apical position and the two bidentate ligands form the base plane. However, whereas in [VO(salen)] the two halves are related by pseudo-mirror plane symmetry, here the two ligands are related by a pseudo-two-fold symmetry axis along the V—O(3) bond. The difference in the two imido groups, at opposite corners of the square base plane, arises from their contacts with adjacent molecules; H(29) forms a good hydrogen bond with the vanadyl oxygen atom of the next molecule down the *a* axis (thus linking the molecules in infinite chains parallel to this axis); in contrast, H(19) has no close neighbours.

Dimensions around the V atom are as expected. The V—O(3) vanadyl distance is short, at 1.589(4) Å. The two V—O distances in the base plane are virtually identical, as are the two V—N distances. All the distances are very similar to those found in [VO(salen)].

Complexes of vanadium(II) *and vanadium*(III) *with bidentate Schiff-base anions*

An attempt to prepare a vanadium(II) complex from $VCl_2(thf)_2$ and the sodium salt of the Schiff base formed from 2-hydroxyacetophenone and *n*-propylamine, Na(Prhap), gave, instead of $[V(Prhap)_2]$, $[V(Prhap)_3]$ (see Experimental). This has been characterized as an octahedral vanadium(III) complex with a tris(chelate) structure by a single-crystal X-ray determination. The resolution obtained was finally only to $R = 0.10$ and therefore serves only to confirm the essential octahedral structure nature of the material (Fig. 2). We include experimental details below only for the record and do not propose to discuss the structure further.

Since considerable care was taken to exclude adventitious oxygen during this work, the oxidation of vanadium(II) to vanadium(III) might have been due to the Schiff base. However, reactions of saturated compounds, such as $[VCl_2(py)_4]$, with heavily substituted bidentate Schiff base anions, in the hope that the pyridine would block otherwise reactive sites, gave only poorly characterized blue materials. We cannot claim to have prepared with certainty any vanadium(II) compounds.

The vanadium(III) complexes (Table 5) presumably all have a structure similar to that of $[V(Prhap)_3]$. Their effective magnetic moments are close to the spin-only value at room temperature (2.83 μ_B), and they decrease considerably with temperature. This is the usual behaviour of mononuclear, distorted,

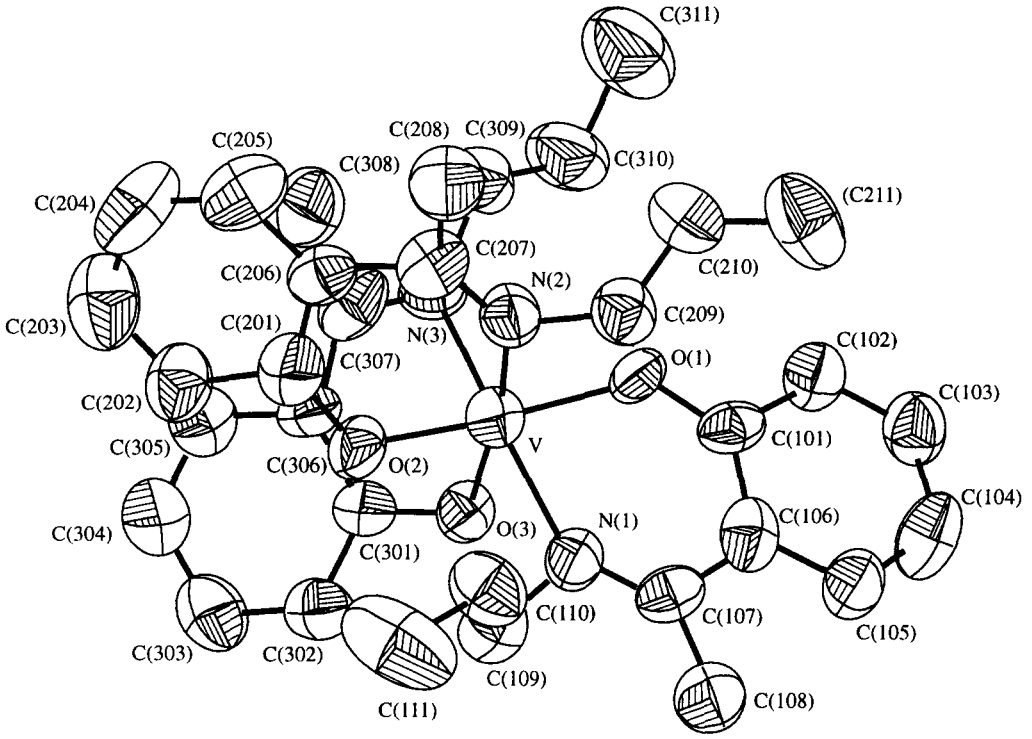

Fig. 2. Structure of the vanadium complex in $[V(Prhap)_3] \cdot C_7H_8$. Thermal ellipsoids are drawn at 50% probability.

octahedral six-coordinate vanadium(III) complexes [17].

EXPERIMENTAL

Reactions involving vanadium complexes were carried out using standard Schlenk techniques in dried solvents under N_2. C,H,N analyses were carried out at the Universities of Sussex and Surrey, or by Butterworth Microanalytical Laboratories. IR spectra were obtained using a Perkin–Elmer 883 spectrometer and magnetic moments at 20°C were determined by the Faraday method using $Hg[Co(CNS)_4]$ as standard and making diamagnetic corrections using Pascal's constants. Variable-temperature magnetic moments on two compounds were made on a Gouy balance. Aldehydes, amines, $VOSO_4$ and $[VO(OCMeCHCOMe)_2]$, and $[VO(acac)_2]$ were purchased from Aldrich or Lancaster Synthesis. $[VCl_2(py)_4]$ [14], $VCl_2(thf)_2$ [12] and $VBr_2(MeOH)(thf)$ [13] were prepared by literature methods.

Schiff bases (Table 1) were generally prepared by mixing boiling methanol solutions of aldehydes and amines and their vanadium compounds (Table 2) by ligand exchange with $[VO(acac)_2]$, as described [3]. All exceptions to this are given below. Analyses, yields, colours, V—O stretching frequencies $\nu(V{=}O)$ and magnetic moments (μ_B) are given in the Tables.

Ethylene-N,N′-*bis*(*salicylideneiminato*)*oxovanadium* (IV)–*methanol*(1/1)

The Schiff base H_2salen (0.53 g, 2 mmol) and $[VO(acac)_2]$ (0.53 g, 2.0 mmol) were dissolved in dichloromethane (20 cm^3) and methanol (20 cm^3) was added. After 24 h the volume was slowly reduced *in vacuo* to ~10 cm^3, when green crystals (0.59 g, 81%) were formed, washed with methanol and diethyl ether and dried *in vacuo*.

Methylene-N,N′-*bis*(*salicylideneimine*)

Methylenediamine bishydrochloride (3.0 g, 25 mmol) dissolved in methanol (40 cm^3) was cooled to −60°C. Salicylaldehyde (6.1 g, 50 mmol) and triethylamine (10 cm^3, ~75 mmol) were added and the solution allowed to warm with stirring overnight, giving a light yellow crystalline precipitate which was filtered off, washed with diethyl ether and dried in air, yield 4.0 g, 62%.

Methylene-N,N′-*bis*(*salicylideneiminato*)*oxovanadium* (IV)–*methanol*(1/1)

The Schiff base H_2salen (0.51 g, 2 mmol) and $[\{VO(OMe)(acac)\}_2]$ (0.78 g, 2 mmol) were dissolved in dichloromethane (20 cm^3) and methanol (20 cm^3) was added. The volume was reduced *in vacuo* after 24

[a] Required values in parentheses.

h to ~10 cm³ when a yellow powder precipitated. This was filtered off and dried *in vacuo*; yield 0.31 g, 44%.

Hydrosalicylamide

Ammonia (2.0 M in methanol, 20 cm³, 40 mmol) was added to salicylaldehyde (7.3 g, 60 mmol) giving a yellow solid. The mixture was warmed briefly to 60°C when all dissolved to give a clear solution and then allowed to cool giving yellow crystals (5.0 g, 72%).

Oxobis(salicylideneiminato)vanadium(IV)

$VOSO_4\cdot H_2O$ (0.9 g, 5 mmol), hydrosalicylamide (1.8 g, 5 mmol) and methylamine (2 cm³, 15 mmol) were heated under reflux in aqueous ethanol (1 : 1, 50 cm³) for 1 h giving a green solid which was filtered off, washed with water, ethanol and diethyl ether and recrystallized from acetonitrile (100 cm³).

Tris(2-*phenolato*-N-*benzylacetophenoneimine*)*vanadium*(III)

Toluene (150 cm³) was added to Hbzhap (3.44 g, 15.27 mmol) under nitrogen forming a clear yellow solution. This was cooled in an ice-bath and LiMe (11.0 cm³, 1.4 M solution in diethyl ether) was syringed in forming a red solution after much effervescence. After stirring for 5 min, $[VCl_3(MeCN)_3]$ (1.43 g, 5.10 mmol) was added producing a mixed suspension of the green starting material and the white lithium salt Li(bzhap), but on stirring a deep red solution formed and the $[VCl_3(MeCN)_3]$ slowly dissolved. The mixture was heated under reflux for 3 h, allowed to cool and then the white precipitate (LiCl) was filtered off and the deep red solution was reduced slightly in volume. Flame red microcrystals separated, which were filtered off and dried *in vacuo*.

Tris(2-*phenolato*-N-4-*methylbenzylacetophenoneimine*)*vanadium*(III)

To an ice-cold solution of the Schiff base HMebzhap (3.40 g, 14.2 mmol) in toluene (100 cm³), LiMe (10.2 cm³, 14.2 mmol, 1.4 M solution in diethyl ether) was added. Much efferverscence occurred and the yellow solution became dark red, but upon complete addition of the LiMe a white precipitate formed with a pale orange solution. Then $[VCl_3(MeCN)_3]$ (1.33 g, 4.73 mmol) was added and the mixture heated under reflux for 1 h. The red–brown microcrystals which appeared from the deep red solution on cooling were filtered off on a sintered disc and extracted with the mother liquor. A white solid (LiCl) remained on the sinter and the red filtrate was held at −15°C. Very little solid precipitated, so the solution was taken to

dryness and the red–brown solid washed with and finally suspended in diethyl ether. The solid was filtered off and dried *in vacuo*. The analyses suggest that some LiCl is associated with the complex.

Tris(salicylaldehydatobenzylimine)vanadium(III)

The Schiff base Hbzsal (3.35 g, 15.9 mmol) was dissolved in toluene (100 cm^3) to give a clear yellow solution. This was cooled in solid CO_2 ice/acetone and LiMe (11.4 cm^3, 47.6 mmol, 1.4 M solution in diethyl ether) added slowly, forming a white precipitate in an opaque solution. On warming to room temperature and after much effervescence the colour of the solution had changed to pink but the white precipitate remained. $[VCl_3(MeCN)_3]$ (1.33 g, 4.73 mmol) was added and the suspension stirred overnight. Next day a red precipitate had formed; this was filtered off and extracted from the sintered disc by the mother liquor. The red product which appeared on cooling was filtered off and dried *in vacuo*.

Tris(2-*phenolato*-N-n-*propylacetophenoneimine*)*vanadium*(III)–*toluene*(1/1)

Na(Prhap) was prepared by the careful addition of sodium hydride (2.21 g, 92.1 mmol) to a solution of HPrhap (16.1 g, 90.8 mmol) in thf (70 cm^3). The white product which precipitated after much effervescence was filtered off and dried *in vacuo*.

To a yellow solution of Na(Prhap) (1.85 g) in thf (100 cm^3) was added the vanadium(II) species $VBr_2(MeOH)(thf)$ (0.93 g, 2.62 mmol). On stirring, a red solution formed almost immediately and stirring was continued at room temperature overnight. The white solid (NaCl) which precipitated was filtered off and the deep red filtrate was concentrated to dryness yielding a dark red product.

Toluene (70 cm^3) was added to give a deep red solution. A little toluene was pumped off until some solid began to form. Then the mixture was left to stand at room temperature for *ca* 3 weeks during which time bright red crystals appeared. They were filtered off and dried *in vacuo*. The crystals changed to green on exposure to air.

Halocomplexes of vanadium(III) *and vanadium*(IV)

Dichloro[*propan*-1,2-*diyl*-N,N′-*bis*(*salicylideneiminato*)]*vanadium*(IV) The HCl gas used in this preparation was prepared by the careful dropwise addition of concentrated H_2SO_4 to concentrated HCl. The vanadyl derivative [VO(sal-1,2-pn)] (2.01 g, 5.79 mmol) was dissolved in acetonitrile (50 cm^3) forming a green solution. The HCl gas was bubbled through this solution, which changed rapidly from green to deep blue, for *ca* 30 min. The deep blue microcrystalline solid which formed on standing at 4°C overnight was filtered off, washed with methanol and dried in a vacuum desiccator.

Dibromo[*propan*-1,2-*diyl*-N,N′-*bis*(*salicylideneiminato*)]*vanadium*(IV). The HBr gas used in this preparation was generated from bromine and tetralin. The HBr gas was bubbled through a green acetonitrile of [VO(sal-1,2-pn)] (0.5 g, 1.4 mmol) which became blue–purple within 5 min. The gas was bubbled through the reaction mixture for a further 25 min. The deep blue solid which formed on standing at 4°C overnight was filtered off, washed with methanol and dried in a vacuum desiccator.

Diiodo[*propan*-1,2-*diyl*-N,N′-*bis*(*salicylideneiminato*)]*vanadium*(IV). A flask containing [VO(sal-1,2-pn)] (1.74 g, 5.01 mmol) was evacuated, dinitrogen was admitted and the solid dissolved in freshly distilled dichloromethane (100 cm^3), forming a green solution. Trimethylsilyl iodide (1.43 cm^3, 10.0 mmol) was added forming a brown–black solution with the rapid precipitation, on stirring, of a tan solid. This was filtered off and dried *in vacuo*.

Chloro[*propan*-1,2-*diyl*-N,N′-*bis*(*salicylideneiminato*)]*vanadium*(III). The dark blue crystalline $[VCl_2(sal\text{-}1,2\text{-}pn)]$ (0.7 g, 1.7 mmol) was added to thf (30 cm^3) forming a blue–black suspension in a blue solution. An excess of sodium sand (0.13 g, 5.6 mmol) was added and after stirring the mixture at room temperature for 3 days, a dark red solution and white precipitate resulted. The white solid, presumably NaCl, was filtered off and the filtrate was taken to dryness, yielding a dark red semicrystalline solid.

Dichloro[*ethylene*-N,N′-*bis*(*acetophenoneiminato*)]*vanadium*(IV). A green solution of [VO(hapen)] (0.5 g, 1.4 mmol) in acetonitrile (50 cm^3) was treated with HCl gas. The solution changed rapidly from green to deep blue and gas was bubbled through the reaction mixture for a further 25 min. The deep blue microcrystalline solid which formed on standing at 4°C overnight was filtered off, washed with methanol and dried in a vacuum desiccator.

Dibromo[*ethylene*-N,N′-*bis*(*acetophenoneiminato*)]*vanadium*(IV). This was made by bubbling HBr gas through an acetonitrile solution (50 cm^3) of [VO(hapen)] (0.5 g, 1.4 mmol) until the colour changed from green to a deep blue. On standing at 15°C overnight, a dark grey–blue solid precipitated which was filtered off, washed with methanol and dried in a desiccator.

Crystal structure analysis of $[VO(OC_6H_4CHNH)_2]$

Crystal data. $C_{14}H_{12}N_2O_3V$, $M = 307.2$. Orthorhombic, space group $P2_12_12_1$ (no. 19), $a = 5.5475(6)$, $b = 11.797(1)$, $c = 20.494(3)$ Å, Vol. = 1341.1 $Å^3$. $Z = 4$, $D_c = 1.521$ g cm^{-3}, $F(000) = 628$, μ(Mo-K_α) = 7.2 cm^{-1}, λ(Mo-K_α) = 0.71069 Å.

Crystals are very long, fine, grey needles. One, cut down to *ca* 0.36 × 0.13 × 0.04 mm, was mounted on a glass fibre and, after photographic examination, was

transferred to an Enraf–Nonius CAD4 diffractometer (with monochromated radiation) for determination of accurate cell parameters (by refinement from the settings of 25 reflections, having θ in the range 10–12°, each reflection centred in four orientations) and measurement of diffraction intensities (to $\theta_{max} = 25°$).

During processing, the intensity data were corrected for Lorentz–polarization effects and were adjusted to eliminate negative net intensities (by Bayesian statistical methods). There was no deterioration of the crystal during examination. Of the 1410 unique reflections input to the SHELX program system for structure analysis, 1196 had $I > 2\sigma_I$.

The structure was determined by the heavy atom method and refined by full-matrix least-squares procedures. All the non-hydrogen atoms were allowed anisotropic thermal parameters. The two imido hydrogen atoms were located in difference maps and their coordinates were refined independently; the remaining H atoms were included in idealized positions. The isotropic thermal parameters of all the H atoms were refined freely. Refinement converged with $R = 0.060$ and $R_g = 0.073$ [20] for all 1410 reflections weighted $w = (\sigma_F^2 + 0.00341\,F^2)^{-1}$. In a final difference map, the largest peaks, at *ca* 0.7 e Å^{-3}, were around the vanadium atom.

Refinement of the opposite enantiomeric structure produced R and R_g [20] values of 0.064 and 0.077 and slightly higher e.s.d.s throughout. We are confident, therefore, that we are reporting the absolute configuration for that particular crystal.

Scattering factors for neutral atoms were taken from reference [21]. Computer programs used in this analysis have been noted above and in Table 4 of reference [22], and were run on a DEC MicroVAX 3600 machine currently in the Chatt Laboratory.

Crystal structure determination of $[V(Prhap)_3] \cdot C_7H_8$

Crystal data. $C_{33}H_{42}N_3O_3V \cdot C_7H_8$, $M = 671.8$. Monoclinic, space group $P2_1/c$ (no. 14), $a = 12.434(27)$, $b = 18.418(25)$, $c = 16.529(11)$ Å, $\beta = 101.16(12)°$, Vol. = 3714 Å^3. $Z = 4$, $D_c = 1.201$ g cm^{-3}, $F(000) = 1432$, μ(Mo-K_α) = 2.9 cm^{-1}, $T = 295$ K. λ(Mo-K_α) = 0.71073 Å.

The intensity data were collected from a crystal with dimensions $1 \times 0.45 \times 0.45$ mm using an Enraf–Nonius CAD4 diffractometer with graphite monochromated Mo-K_α radiation. The resulting unit cell, obtained from 25 reflections, had larger than usual errors, probably as a result of the crystal size but also arising from a lack of crystal quality due to the disorder present in the structure. This has been reflected in the relatively high final R value ($R = 0.10$) at the end of the refinement.

The Lorentz–polarization correction was applied to the diffraction intensities. An empirical absorption correction based upon Ψ-scan data gave minimum/maximum corrections of 0.30/0.99, average 0.66, which so badly distorted the intensity data that refinement was impeded. The correction was later ignored and this is justified as the absorption coefficient is only 2.9 cm^{-1}.

The position of the V atom together with four oxygen atoms was obtained from the Patterson map. The usual heavy atom method produced the remainder of the molecule, now identified as $[V(Prhap)_3]$, together with some disordered atoms indicative of a solvent molecule. Convergence was slow, reaching an R value of 0.22 with difficulty. The decision was made at this stage to ignore the empirical absorption corrected data and to use the uncorrected set, when R improved to 0.18. At the same time, effort was expended to establish the exact nature of the solvent molecule and whether it was only a fractional molecule or a full molecule. It was concluded after trial refinements of the occupancy factors that the solvent was that of a full toluene molecule. Hydrogen atoms were also added to the atoms list, but not refined, in calculated positions using $d_{C-H} = 1.0$ Å.

Anisotropic refinement of the vanadium complex, the toluene molecule remaining isotropic, allowed R to converge to 0.10, $R_w = 0.14$ and $S = 1.291$ using a weighting scheme $w^{-1} = [\sigma_F^2 + (0.08F)^2 + 8.0]$. The highest peak in the final difference map was 0.55 electrons. The isotropic temperature factors, B_{iso}, of the toluene atoms are very high, ranging from 16 to 34 Å^2, indicating substantial disorder in the structure.

(Received 2 August 1996; accepted 21 August 1996)

Abstract—A range of complexes has been prepared by reaction of thiacycloalkynes with Ag^{I}, Cu^{I} and Hg^{II} cations and cationic MPR_3 (M = Ag, Cu, Hg) fragments. ^1H NMR studies reveal that coordination of 1,4,7-trithiacycloundec-9-yne (L^1) to Ag^{I} results in a change of ligand conformation from exodentate in the free ligand to endodentate in the coordinated ligand implying involvement of the thioether functionalities in coordination. Participation of the alkyne linkage in coordination is less certain and a polymeric structure is suggested in the solid state. Reaction of $AgSbF_6$ with L^1 and PPh_3 or PMe_2Ph afforded complexes in which the silver is coordinated by a phosphine and an endodentate η^3-L^1. Similar studies with Cu^{I} and Hg^{II} showed a reduced tendency for thioether coordination reflected in a reduced denticity of L^1. Studies with a range of dithiacycloalkynes and a tetrathiacyclodiyne show that Ag^+ and Cu^+ can be successfully coordinated by ligands containing a combination of two thioether donors and one alkyne. © 1997 Elsevier Science Ltd. Keywords: silver; copper; mercury; thioether; alkyne; phosphine.

The ability of polythioether macrocycles to coordinate metal ions and metal–ligand fragments has been extensively studied in recent years [1,2]. Interest has focused on 1,4,7-trithiacyclononane (9S3), which forms a remarkable range of stable complexes due to its endodentate conformation, but several other thiacrown ethers which are not preorganized for facial coordination, such as 2,5,8-trithia[9]-*o*-benzenophane (TTOB), display good ligating properties and useful selectivity [3]. We have reported the synthesis of 1,4,7-trithiacycloundec-9-yne (L^1) *via* decomplexation from a hexacarbonyldicobalt fragment [4] or *via* a high dilution method [5]. Several other ligands L^2–L^7 have also been prepared by the high dilution method [5,6]. Selective coordination of the alkyne functionality in such systems has been illustrated by their reactions with $[Co_2(CO)_8]$ to form monoalkynehexacarbonyldicobalt complexes [5,6] and with $[Mo(CO)_2(S_2CNMe_2)_2]$ to afford bisalkynebis(dithiocarbamate)molybdenum complexes [5]. In this paper we report the complexation of the soft metal centres Cu^{I}, Ag^{I} and Hg^{II} by thiacycloalkynes L^1–L^7.

EXPERIMENTAL

All reactions were carried out under nitrogen using standard Schlenk tube and vacuum line techniques, and all solvents were freshly distilled under nitrogen and over appropriate drying agents. Light petroleum (boiling point 40–60°C) and acetonitrile were distilled over calcium hydride and tetrahydrofuran and diethyl ether were distilled over potassium. The ligands were prepared by literature methods [5]. Fast atom bombardment (FAB) mass spectra were recorded from a NOBA matrix by the EPSRC mass spectrometry service at the University of Swansea with a VG ZAB-E instrument. Raman spectra were recorded with an SA multichannel Raman spectrometer model HF640 with a CCD detector. NMR spectra were recorded with a JEOL GX 270 instrument. Molecular-mechanics calculations were carried out using HYPERCHEM (Release 3) [7]. Structures were minimized with conjugate gradients (Polak–Ribiere algorithm) using the MM+ force field until the gradients were less than 0.01 kcal mol^{-1} $Å^{-1}$. Elemental analyses were performed by Mr A. J. Fassam at the University of Kent. Analytical and physical data for the new compounds is given in Table 1.

[a] Raman spectroscopy.
[b] Calculated values are given in parentheses.
[c] Fast atom bombardment (FAB) mass spectroscopy.

Preparation of [AgL^1][BF_4](**1**)

To a solution of $AgBF_4$ (0.162 g, 0.83 mmol) in THF (50 cm^3) was added 1 equiv of L^1 (0.17 g, 0.83 mmol), which caused the immediate formation of a white precipitate. After stirring for 3 h, Et_2O (50 cm^3) was added and the mixture left overnight at −25°C before the product was isolated by filtration and dried *in vacuo* to afford [AgL^1][BF_4] (0.33 g, 99%). Compounds **2**, **3**, **11**, **13**, **15**, **17**, **19** and **21** were prepared by similar procedures.

Preparation of [$AgL^1(PPh_3)$][SbF_6] (**4**)

To a stirred solution of L^1 (0.10 g, 0.49 mmol) and PPh_3 (0.13 g, 0.49 mmol) in THF (20 cm^3) was gradually added $AgSbF_6$ (0.17 g, 0.49 mmol). After 3 h the solution was filtered and the product precipitated by addition of light petroleum (60 cm^3). The white precipitate was isolated by filtration and dried *in vacuo* to afford [$AgL^1(PPh_3)$][SbF_6] (0.34 g, 85%).

Preparation of [$AgL^1(PMe_2Ph)$][SbF_6] (**5**)

$AgSbF_6$ (0.34 g, 0.98 mmol) was gradually added to a stirred solution of L^1 (0.20 g, 0.98 mmol) in THF (30 cm^3) followed by addition of PMe_2Ph (0.14 cm^3, 0.98 mmol). After 3 h the solution was filtered and the product precipitated by addition of light petroleum (60 cm^3). The white precipitate was isolated by filtration and dried *in vacuo* to afford [$AgL^1(PMe_2Ph)$][SbF_6] (0.45 g, 67%).

Preparation of [CuL^1][PF_6] (**6**)

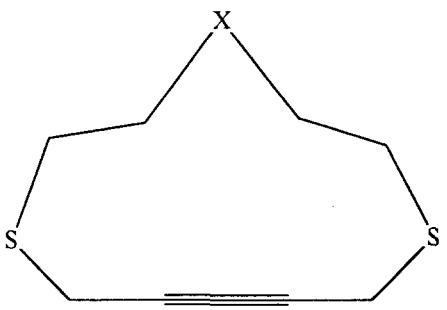
To a suspension of [$Cu(NCMe)_4$][PF_6] (0.20 g, 0.54 mmol) in THF (50 cm^3) was added 1 equiv of L^1 (0.11 g, 0.54 mmol), which caused the immediate formation of a white precipitate. After stirring for 5 h, Et_2O (50 cm^3) was added and the mixture left overnight at −25°C before the product was isolated by filtration and dried *in vacuo* to afford [CuL^1][PF_6] (0.22 g, 100%). Compounds **12**, **14**, **16**, **18**, **20** and **22** were prepared by similar procedures.

Preparation of [$CuL^1(PPh_3)$][PF_6] (**7**)

To a stirred solution of L^1 (0.10 g, 0.49 mmol) and PPh_3 (0.12 g, 0.49 mmol) in MeCN (15 cm^3) was added [$Cu(NCMe)_4$][PF_6] (0.18 g, 0.49 mmol). Stirring was continued overnight and then the solvent removed *in vacuo*. The residue was dissolved in hot THF (15 cm^3)

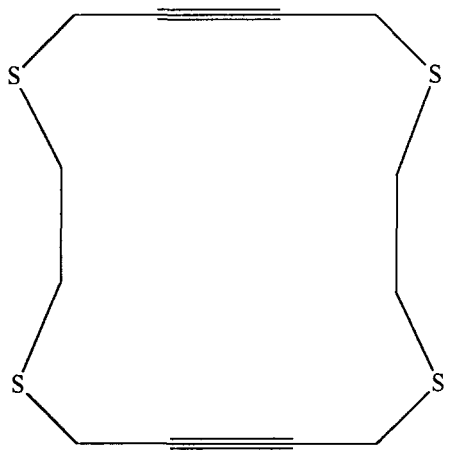
and filtered before precipitation of the product by addition of light petroleum (50 cm^3). The white precipitate was isolated by filtration and dried *in vacuo* to afford $[CuL^1(PPh_3)][PF_6]$ (0.18 g, 55%). Compound **8** was prepared in a similar manner except PMe_2Ph was added to a solution of L^1 and $[Cu(NCMe)_4][PF_6]$.

Preparation of $[Hg(L^1)_2]Cl_2$ (**9**)



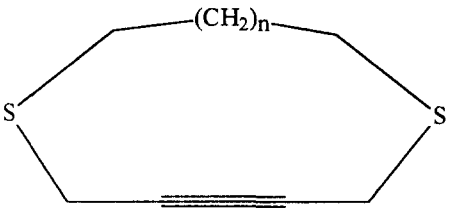
$HgCl_2$ (0.13 g, 0.49 mmol) was added to a stirred solution of L^1 (0.20 g, 0.98 mmol) in THF (20 cm^3). After 3 h the solvent was removed *in vacuo* and the residue precipitated from THF (15 cm^3) by addition of light petroleum (60 cm^3) to afford $[Hg(L^1)_2]Cl_2$ (0.58 g, 87%).

Preparation of $[HgL^1(PPh_3)]Cl_2$ (**10**)

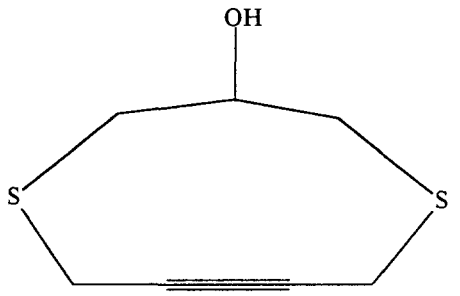


A solution of L^1 (0.10 g, 0.49 mmol) and PPh_3 (0.13 g, 0.49 mmol) in 1 : 1 MeCN : Et_2O (20 cm^3) was mixed with a solution of $HgCl_2$ (0.13 g, 0.49 mmol) in 1 : 1 MeCN : Et_2O (10 cm^3). A precipitate formed immediately which after 2 h was collected by filtration, washed with light petroleum (60 cm^3) and dried *in vacuo* to afford $[HgL^1(PPh_3)]Cl_2$ (0.25 g, 69%).

RESULTS AND DISCUSSION



Treatment of a THF solution of $AgBF_4$ with L^1 affords $[AgL^1][BF_4]$ (**1**) in quantitative yield. Its formulation was confirmed by elemental analysis and by FAB mass spectrometry with observation of an isotope envelope at m/z 313 corresponding to $[AgL^1]^+$ (Table 1). The formation of a 1 : 1 product contrasts with the 1 : 2 products formed between Ag^+ and TTOB[3] and 9S3, although a 1 : 1 trimer $[Ag_3(9S3)_3]^{3+}$ has also been characterized [8]. The ^1H NMR spectrum of **1** contains a singlet at 3.42 ppm assigned to the four acetylenic methylene protons and a single AA′BB′ pattern due to the $CH_2CH_2SCH_2CH_2$ fragment. Simulation and iterative fitting of the spectrum using LAOCOON PC [9] resulted in values for the vicinal coupling of $J = 8.34(4)$ and $J' = 3.27(4)$, which indicates an equilibrium containing pre-



L^1 X = S
L^7 X = O

L^2

L^3 n = 1
L^4 n = 2
L^5 n = 3

L^6

dominantly *gauche* S—C—C—S fragments [10]. This can be compared with the NMR spectrum of L^1 in the same solvent (CD_3CN), which has values of $J = 11.14(2)$ and $J' = 5.13(2)$, indicating an equilibrium of containing predominantly *anti* S—C—C—S fragments in accord with the solid-state structure of L^1 as determined by X-ray crystallography [4]. It appears that L^1 adopts an endodentate conformation to coordinate to Ag^+, but **1** is highly fluxional with both sides of the ring being made equivalent on the NMR timescale. Molecular-mechanics calculations suggest that an endodentate conformation of L^1 is accessible with an energy of 8.97 kcal mol^{-1} compared with the exodentate conformation observed in the free ligand which has an energy of 8.29 kcal mol^{-1}. The ^{13}C NMR spectrum of **1** is very simple and contains four resonances corresponding to the four different carbon environments in the complex. The acetylenic carbon resonance at 84.5 ppm is shifted to the lower field by 4.8 ppm compared with L^1, while the other resonances are shifted by *ca* 3–4 ppm. Relatively few alkyne complexes of silver have been reported [11–15]. The interaction is typically weak and causes only small chemical shift changes to the alkyne carbons so a shift of 4.8 ppm could indicate an interaction between the triple bond and silver in solution. Unfortunately we were unable to grow crystals suitable for X-ray crystallography to determine the solid-state structure of **1**. Coordination of the alkyne would be expected to reduce the tripe bond strength and hence its stretching frequency. For example, coordination of silver(I) triflate to 1,6-cyclodecadiyne results in a change of $\nu(C{\equiv}C)$ from 2282, 2224 cm^{-1} to 2230, 2160 cm^{-1} [14]. The triple bond of L^1 gives a strong absorption in the Raman spectrum at 2227 cm^{-1}, but unfortunately the corresponding resonance for **1** could not be observed in either the IR spectrum, presumably because it is very weak, or in the Raman spectrum, due to fluorescence. However, the spectra did indicate that the counter-ion BF_4^- was not coordinated. In order to gain further information complexes $[AgL^1][SbF_6]$ (**2**) and $[AgL^1][O_3SCF_3]$ (**3**) were prepared containing different counter-ions. Both complexes gave NMR spectra similar to **1** and also produced poor Raman spectra, but resonances could be observed at 2231 and 2238 cm^{-1}, suggesting negligible interaction of the alkyne with the metal. The FAB mass spectrum of **2** contains an isotope envelope at m/z 517 corresponding to $[Ag(L^1)_2]^+$ suggesting a polymeric structure in the solid state. Figure 1 illustrates a possible polymeric solid-state structure for compounds **1–3** involving μ-η^3-η^1-L^1 ligands. A similar bonding mode is exhibited by 9S3 in $[Ag_3(9S3)_3]^{3+}$ [8].

Reaction of $AgSbF_6$ with L^1 and PPh_3 affords the complex $[AgL^1(PPh_3)][SbF_6]$ (**4**). The mass spectrum shows an isotope envelope at m/z 575 corresponding to $[AgL^1PPh_3]^+$. The vicinal coupling constants (Table 2) reveal that the ring is adopting an endodentate confirmation similar to that observed in

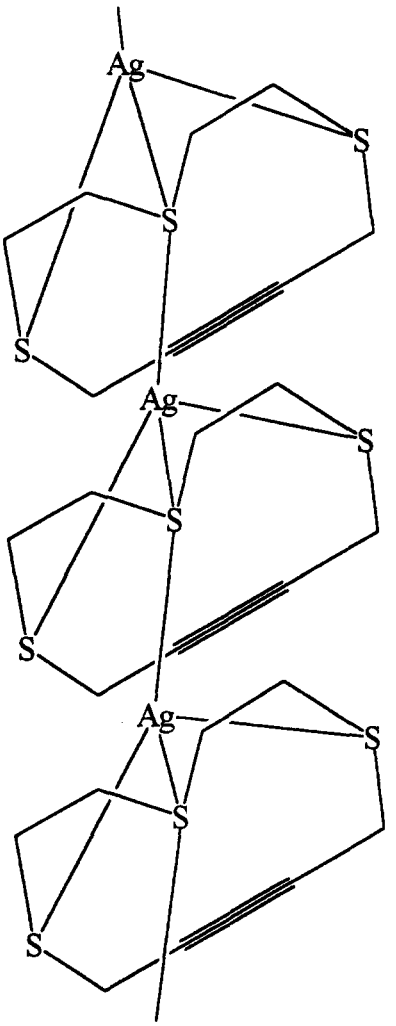


Fig. 1. Proposed structure for compounds **1–3**.

$[Co_2(CO)_6L^1AgPPh_3]$ [16]. Strong absorptions are observed in the Raman spectrum at 2252 and 2222 cm^{-1}, possibly indicating two different environments for the alkyne linkage in the solid state but neither indicating a significant weakening of the bond as might be expected if metal coordination had occurred. Similar results were obtained with PMe_2Ph in the formation of $[AgL^1(PMe_2Ph)][SbF_6]$ (**5**). Both **4** and **5** display only a single resonance at room temperature in the ^{31}P NMR spectra at 14.1 and −21.5 ppm, respectively. The spectrum of **5** was also recorded at 212 K and appears as a four line pattern due to coupling to ^{107}Ag and ^{109}Ag [J(AgP) = 600 and 690 Hz], indicating that phosphine exchange is rapid at room temperature.

Reaction of L^1 with $[Cu(NCMe)_4][PF_6]$ affords $[CuL^1][PF_6]$ (**6**). Elemental analysis supports the formulation and confirms that no acetonitrile ligands remain coordinated to the copper centre. In acetonitrile the vicinal coupling constants indicate an equilibrium containing equal amounts of *anti* and *gauche* S—C—C—S segments, suggesting that L^1 is acting as

[a] Chemical shifts (δ) in ppm, coupling constants in Hz, e.s.d.s in parenthesis. Measured in CD_3CN.

a didentate (η^2) ligand with possibly rapidly exchanging acetonitrile as a co-ligand.

Reaction of L^1 and PPh_3 or PMe_2Ph with $[Cu(NCMe)_4][PF_6]$ affords compounds $[CuL^1(PPh_3)][PF_6]$ (**7**) and $[CuL^1(PMe_2Ph)][PF_6]$ (**8**). The vicinal coupling constants (Table 2) indicate that in both compounds the ligand has maintained its exodentate conformation. Raman spectroscopy (Table 1) shows changes of less than 4 cm^{-1} in $\nu(C{\equiv}C)$ consistent with no interaction between the alkyne and the metal centre. A possible structure of **7** and **8** would be linear with L^1 coordinated in a unidentate (η^1) fashion *via* the central sulfur atom.

Reaction of L^1 with $HgCl_2$ affords compound $[HgL^1_2]Cl_2$ (**9**). Again the vicinal coupling constants indicate an exodentate conformation and the Raman spectrum suggests that the alkyne is not involved in coordination, so a linear two-coordinate structure is suggested. Reaction of L^1 and PPh_3 with $HgCl_2$ affords **10**, which was too insoluble for NMR measurements and is formulated as $[HgL^1(PPh_3)]Cl_2$ on the basis of FAB mass spectroscopy (Table 1).

The reactions of several other thiacycloalkynes (L^2–L^7) were investigated in less detail and the results tabulated in Tables 1 and 2. The results indicate that Ag^+ and Cu^+ can be successfully coordinated by ligands containing a combination of two thioether donors and one alkyne. Ligand L^2 with four thioethers and two alkynes can coordinate two metal ions simultaneously.

Acknowledgements—We thank Dr J. A. Creighton for recording the Raman spectra and H. A. Bower for experimental assistance. The EPSRC provided a studentship (GFM) and access to the mass spectrometry service.

The reactivity of CuX_2 ($X^- = Cl^-$, Br^-, $MeCO_2^-$) salts towards *tris*-pyrazolyl-borates of differing steric requirements. The single crystal X-ray structure of $[CuCl(pz^{Ph}H)(HB\{pz^{Ph}\}_3)] \cdot CH_2Cl_2$

(Received 31 July 1996; accepted 20 August 1996)

Abstract—Treatment of CuX_2 ($X^- = Cl^-$, Br^-) with one molar equivalent of $K[HB\{pz^{Ph}\}_3]$ ($pz^{Ph}H$ = 3-phenylpyrazole) in CH_2Cl_2 : MeCN (4 : 1) at room temperature afforded $[CuX(pz^{Ph}H)(HB\{pz^{Ph}\}_3)]$ ($X^- = Cl^-$, **I**; $X^- = Br^-$, **II**) in moderate to good yields. The crystal structure of the title compound shows a square-pyramidal copper(II) centre, with Cu—Cl = 2.2740(13) Å and Cu—N = 2.010(3), 2.031(3), 2.038(3), 2.241(3) Å. The complex exhibits an intramolecular N—H···Cl hydrogen bond, with N···Cl = 3.034(4) Å, N—H···Cl = 119.4°, and an intramolecular graphitic interaction between the $pz^{Ph}H$ pyrazole ring and a phenyl group from the tripodal ligand. Steric repulsions between this phenyl group and the bound Cl^- cause substantial distortions from an ideal square-pyramidal geometry. Reaction of $K[HB\{pz^{Ph}\}_3]$ with $Cu_2(O_2CMe)_4 \cdot 2H_2O$ yields $[Cu(O_2CMe)(HB\{pz^{Ph}\}_3)]$ (**III**). The EPR and UV-vis spectroscopic properties of **I**–**III** are consistent with a $\{d_{x^2-y^2}\}^1$ configuration at copper. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: copper; *tris*-pyrazolylborate; B—N cleavage; crystal structure.

There has been widespread use of *tris*-pyrazolylborates as protecting ligands in synthetic inorganic chemistry [1]. This popularity has resulted from their ease of preparation and the facility with which their steric and electronic properties can be varied by use of different pyrazole ring substituents [1c]. We report here the syntheses of $[CuX(pz^{Ph}H)(HB\{pz^{Ph}\}_3)]$ ($pz^{Ph}H$ = 3-phenylpyrazole; $X^- = Cl^-$, Br^-), which we have encountered while preparing starting materials for our biomimetic copper coordination chemistry studies [2], and the crystal structure of the chloro complex. These compounds are different from the previously reported products of reactions of CuX_2 salts with other *tris*-pyrazolylborates and offer a good example of how the coordination chemistries of these ubiquitous ligands can vary with their steric bulk.

EXPERIMENTAL

All manipulations were carried out in air. All solvents, $CuCl_2$ and $CuBr_2$ were used as supplied, while $pz^{Ph}H$ and $K[HB\{pz^{Ph}\}_3]$ were prepared by the literature procedure [3]. $Cu_2(O_2CMe)_4 \cdot 2H_2O$ was prepared from $CuCO_3$ and acetic acid and recrystallized from hot water.

Synthesis of (hydrido-tris-{3-phenylpyrazol-1-yl}borato)(5-phenylpyrazole)chlorocopper(II) (I)

Anhydrous $CuCl_2$ (0.28 g, 2.08×10^{-3} mol) and $K[HB\{pz^{Ph}\}_3]$ (1.00 g, 2.08×10^{-3} mol) were stirred in CH_2Cl_2 : MeCN (4 : 1; 50 cm^3) at room temperature for 16 h, yielding a deep green solution and pale green precipitate. The mixture was filtered and the filtrate reduced to an oil. Trituration with a minimum volume of Et_2O immediately yielded green microcrystals; after

addition of an equal volume of hexanes and overnight storage at −30°C, the product was filtered and dried *in vacuo* (yield 1.0 g, 70%). Found: C, 62.5; H, 4.43; N, 16.4. Calc. for $C_{36}H_{30}N_8BClCu$: C, 63.2; H, 4.42; N, 16.4%. IR (cm^{-1}): 3223m, 2518w, 1556w, 1524w, 1493s, 1458m, 1424w, 1362m, 1298w, 1259m, 1195s, 1139m, 1119w, 1094m, 1072m, 1046m, 1028w, 960m, 918w, 792m, 760s, 737m, 727w, 694m, 661w, 509w. UV–vis ($CHCl_3$): λ_{max} = 244 nm (ε_{max} = 48,800 M^{-1} cm^{-1}), 248 (sh), 313 (sh), 708 (103), 925 (sh). X-ray structure determination of **I** · CH_2Cl_2

Slow diffusion of hexanes into a CH_2Cl_2 solution of **I** yielded X-ray quality crystals, which lost solvent upon exposure to air. Experimental details of the structure determination are given in Table 1. The structure was solved by direct methods (SHELXTL-PLUS [4]) and refined by full-matrix least-squares on F^2 (SHELXL-93 [5]). During refinement, the CH_2Cl_2 molecule was found to be disordered over three equally occupied orientations, which were modelled using a common C—Cl distance and tetrahedral Cl—C—Cl angle; one Cl atom, Cl(52), is common to two of these fragments. All non-H atoms except the C atoms of the disordered solvent were refined anisotropically, and all hydrogen atoms were included in calculated positions.

Other measurements

IR spectra were obtained as Nujol mulls pressed between KBr windows between 400 and 4000 cm^{-1} using a Perkin–Elmer Paragon 1000 spectrophotometer. UV–vis spectra were obtained with a Perkin–Elmer Lambda 12 spectrophotometer operating between 200 and 1100 nm, in 1 cm quartz cells. Positive-ion fast atom bombardment (FAB) mass spectra were performed on a Kratos MS50 spectrometer using a 3-NOBA matrix. CHN microanalyses were performed by the University of Cambridge Department of Chemistry microanalytical service. X-band EPR spectra were obtained using Varian E103E and Bruker ECS160 instruments. All electrochemical measurements were carried out using an Autolab PGSTAT20 voltammetric analyser, in CH_2Cl_2 containing 0.5 M $Bu^n_4NPF_6$ (prepared from Bu^n_4NOH and HPF_6) as supporting electrolyte. Cyclic voltammetric experiments involved the use of a double platinum working/counter electrode and a silver wire reference electrode; all potentials quoted in the text are referenced to an internal ferrocene/ferrocenium standard and were obtained at a scan rate of 100 mV s^{-1}.

RESULTS AND DISCUSSION

Treatment of CuX_2 ($X^- = Cl^-$, Br^-) with one molar equivalent of $K[HB\{pz^{Ph}\}_3]$ [3] in 4:1 CH_2Cl_2:MeCN at room temperature afforded a blue–

green solution and pale green precipitate, from which a green microcrystalline solid was isolated after filtration, evaporation of the filtrate to an oil and extraction with Et_2O. The yields of these reactions are 70% ($X^-=Cl^-$) or 34% ($X^-=Br^-$) based on the amount of $K[HB\{pz^{Ph}\}_3]$ employed; lower yields of the same products were obtained from analogous reactions carried out in MeOH or acetone. The IR spectra of these new compounds show, in addition to the expected weak ν_{B-H} absorption at *ca* 2515 cm^{-1}, a medium intensity band close to 3200 cm^{-1} attributable to a N—H or O—H stretching vibration, while microanalysis suggests their formulation as $[CuX(pz^{Ph}H)(HB\{pz^{Ph}\}_3)]$ ($X^-=Cl^-$, **I**; $X^-=Br^-$, **II**). The FAB mass spectra of **I** and **II** are complex, containing many peaks assignable to mono-, di- and tri-copper molecular ions, but confirm the presence of $[HB\{pz^{Ph}\}_3]^-$, $pz^{Ph}H$ and X^-.

The EPR spectra of **I** and **II** in CH_2Cl_2, which are very similar, are distinct from those of tetrahedral copper(II)/*tris*-pyrazolylborate complexes [6,7] and exhibit the pseudoaxial symmetry typical of a tetragonal $\{d_{x^2-y^2}\}^1$ electronic structure [8] (for **I** at 77 K; $g_\parallel=2.26$, $A_\parallel\{^{63,65}Cu\}=163$ G, $g_\perp=2.08$; at 293 K; $\langle g\rangle=2.14$, $\langle A\rangle=62$ G: for **II** at 77 K; $g_\parallel=2.24$, $A_\parallel\{^{63,65}Cu\}=167$ G, $g_\perp=2.09$; at 293 K; $\langle g\rangle=2.16$, $\langle A\rangle=65$ G). The spectra of **II** are rather broad, however, suggesting the presence of fluxionality and/or multiple species in solution. Superhyperfine coupling to ^{14}N or halogen nuclei was not detectable under these conditions. The UV–vis spectra of **I** and **II** in $CHCl_3$ show *d*–*d* maxima at 708 and 715 nm, respectively, both bands exhibiting shoulders at higher wavelength; this is again typical of tetragonal copper(II) centres [8]. In addition to these bands, both complexes exhibit absorptions close to 310 nm. For **I** this region forms a broad and undefined shoulder, but in the spectrum of **II** it is resolved into two distinct bands at $\lambda_{max}=352$ (sh) and 306 nm ($\varepsilon_{max}=2{,}950$ M^{-1} cm^{-1}). We assign these peaks to $X\rightarrow Cu$ ($X^-=Cl^-$, Br^-) LMCT bands [8,9]. Intra-pz^{Ph} $\pi\rightarrow\pi^*$ transitions are observed at $\lambda_{max}=251$ and 244 nm [10].

The source of $pz^{Ph}H$ in the syntheses of **I** and **II** is not an impurity in the $K[HB\{pz^{Ph}\}_3]$ starting material employed, which contains <5% free $pz^{Ph}H$ by ^1H NMR. Rather, the formation of these compounds involves the Cu^{2+}-assisted cleavage of the $[HB\{pz^{Ph}\}_3]^-$ B—N bonds. Such Lewis or Brønsted acid-catalysed degradations of pyrazolylborates to their parent pyrazoles are well known and present a common decomposition pathway for their metal complexes [11]. The feasibility of such a process in this system is suggested by the FAB mass spectra of **I**–**III** (*vide infra*) and other $Cu/[HB\{pz^{Ph}\}_3]^-$ complexes that we have examined [2], which uniformly show a very intense peak at $m/z=361$, corresponding to $[^{63}Cu(H^{11}B\{pz^{Ph}\}_2)]^+$. The syntheses of the related compounds $[MCl(pz^{i\text{-}Pr2}H)(HB\{pz^{i\text{-}Pr2}\}_3)]$ ($pz^{i\text{-}Pr2}H$ = 3,5-di-iso-propylpyrazole; M = Mn, Fe) have been reported, although these preparations involve the addition of excess pyrazole to the reaction mixture [12]. Addition of 1 molar equivalent of $pz^{Ph}H$ to preparations of **I** and **II** increases the rate of reaction (which is now complete in 15 min), but only marginally improves the final yield of products in terms of the amount of CuX_2 employed.

The isolation of **I** and **II** contrasts with previous reports of reactions of other *tris*-pyrazolylborates with $CuCl_2$. Thus, treatment of $CuCl_2$ with one molar equi-

valent of $Na[HBpz_3]$ (pzH = pyrazole) yields $[Cu(HBpz_3)_2]$ [6] or the dimer of square pyramidal copper(II) ions $[Cu(\mu\text{-}Cl)(HBpz_3)]_2$ [13], depending on reaction conditions, while analogous reactions employing $K[HB\{pz^{i\text{-}Pr2}\}_3]$ or $K[HB\{pz^{t\text{-}Bu}\}_3]$ ($pz^{t\text{-}Bu}H$ = 3-*tert*-butylpyrazole) give tetrahedral complexes of form $[CuCl(HB\{pz^R\}_3)]$ ($pz^RH = pz^{i\text{-}Pr2}H$, $pz^{t\text{-}Bu}H$) [1b,6,14]. The driving force for the formation of **I** and **II** presumably arises from a combination of several factors, namely: the high Lewis acidity of the Cu^{2+} ion; the desire of the copper(II) centre to maximize its coordination number; the intermediate steric properties of the $[HB\{pz^{Ph}\}_3]^-$ ligand, which permit five-coordination at copper; and the steric bulk of the pendant pyrazolyl phenyl substituents, which prevents the dimerization of the $[CuCl(HB\{pz^{Ph}\}_3)]$ unit.

A single crystal X-ray structure determination of $\mathbf{I}\cdot CH_2Cl_2$ shows that **I** adopts an irregular five-coordinate geometry in the solid state (Fig. 1, Table 2), which might be described as trigonal bipyramidal with N(3) and N(25) as axial donors [N(3)—Cu(1)—N(25) = 171.40(12)° or as square pyramidal with N(36) apical. Given the observed pattern of Cu—N distances [Cu(1)—N(3) = 2.010(3), Cu(1)—N(14) = 2.031(3), Cu(1)—N(25) = 2.038(3), Cu(1)—N(36) = 2.241(3) Å] and the spectroscopic data described above, the latter description of the complex seems more justified. By comparison with the related square pyramidal complex $[CuCl(DMF)(HB\{pz^{i\text{-}Pr2}\}_3)]$ [6], **I** exhibits a rather distorted molecular structure. Firstly, Cl(2) is displaced from the least squares plane of the three basal N-donors by 1.23 Å, although the Cu(1)—Cl(2) bond is only lengthened by 0.014 Å compared with the literature compound. Secondly, there is a weak intramolecular N—H···Cl hydrogen bond between the chloride ligand and $pz^{Ph}H$ pyrrolic proton [Cl(2)···N(4) = 3.034(4) Å, Cl(2)···H(4)—N(4) = 119.4°]. Thirdly, the orientation of the $pz^{Ph}H$ ligand in the molecule is fixed by a graphitic interaction between the $pz^{Ph}H$ pyrazole ring and a phenyl substituent from the tripodal ligand, which lie 3.17 Å apart at their closest approach (the dihedral angle between the planes of the two groups is 10.5°). Finally, Cu(1) is displaced from the basal N-donor plane by 0.097 Å *away* from the apical N-donor.

The origin of the molecular distortions in $\mathbf{I}\cdot CH_2Cl_2$ is evident from examination of a space-filling diagram of the complex (Fig. 2). The apical phenyl group, which is fixed in orientation by the aforementioned graphitic interaction with the $pz^{Ph}H$ ligand, is twisted so that one edge is in close contact with the bound chloride [Cl(2)···C(42) = 3.450(4) Å]. It is the steric demands of this interaction, rather than the N—H···Cl hydrogen bond, that force Cl(2) out of the ligand basal plane.

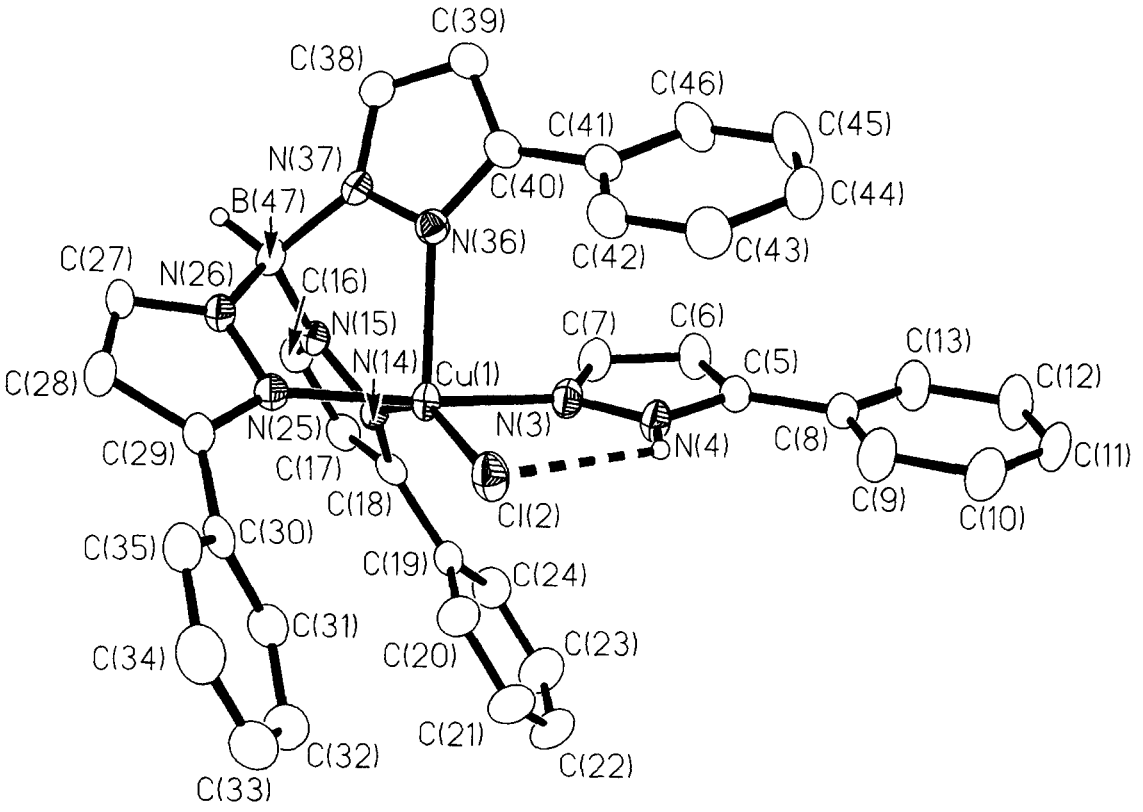

Fig. 1. Solid-state structure of $[CuCl(pz^{Ph}H)(HB\{pz^{Ph}\}_3)]$ (**I**), showing the atom numbering scheme employed. Thermal ellipsoids are at the 50% probability level. For clarity, all carbon-bound hydrogen atoms have been omitted.

Intramolecular N—H···X hydrogen bonds have been previously observed in the solid-state structures of pyrazole complexes of formula *trans*-$[MX_2(pzH)_4]$ [15] (e.g. for M = Ni and $X^- = Cl^-$; N···Cl = 3.10(1), 3.17(1) Å [15a,b]). Such interactions have also been described for the square pyramidal species $[MnX(pz^{i\text{-}Pr2}H)(HB\{pz^{i\text{-}Pr2}\}_3)]$ ($X''^- = \eta^1$-$PhCO_2^-$, η^2-O_2^{2-}) [16]. The manganese complex with $X^- = Cl^-$ has been suggested not to show such an interaction, however, although its IR spectrum shows a $\nu_{N\text{-}H}$ absorbance close to those of **I** and **II** and no structural study was reported [16a]. Intramolecular graphitic interactions of the type found in $\mathbf{I}\cdot CH_2Cl_2$ are also reported in the solid-state structures of the octahedral complexes $[M(HB\{pz^{Ph}\}_3)_2]$ (M = Mn, Fe) [3b].

Attempts to synthesize other complexes of the formula $[CuX(pz^{Ph}H)(HB\{pz^{Ph}\}_3)]$ ($X^- = N_3^-$, NCS^-) by reacting $K[HB\{pz^{Ph}\}_3]$ with $Cu(BF_4)_2\cdot xH_2O$ in the presence of one molar equivalent of NaX were unsuccessful, affording dark green microcrystalline solids consisting of at least two different $[HB\{pz^{Ph}\}_3)]^-$ and X^--containing products by IR, which we were unable to separate by crystallization. While we have not unambiguously identified the products of these reactions, it is possible that dimerization competes with the $[HB\{pz^{Ph}\}_3]^-$ cleavage reaction under these conditions as a method of achieving five-coordination at

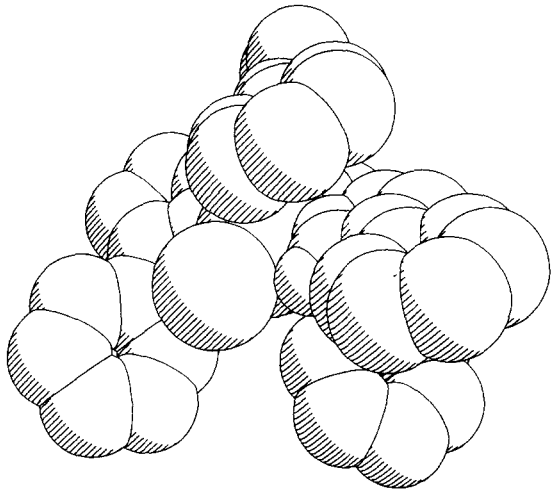

Fig. 2. Space-filling model of the solid-state structure of **I** showing the steric interactions between Cl(2) and the apical phenyl substituent, and the N(4)—H(4)···Cl(2) hydrogen bond. For clarity, all carbon-bound hydrogen atoms have been omitted. The view is approximately parallel to the Cu···B vector, with B(47) lying directly behind Cu(1).

copper. It is notable in this regard that the single crystal structure (but not the synthesis or spectroscopic properties) of $[Cu_2(\mu\text{-}N_3)_2(HB\{pz^{i\text{-}Pr2}\}_3)_2]$ has been reported [17]. However, reaction of $K[HB\{pz^{Ph}\}_3]$ with $Cu_2(O_2CMe)_4 \cdot 2H_2O$ cleanly yields green microcrystals analysing as $[Cu(O_2CMe)(HB\{pz^{Ph}\}_3)]$ (**III**). The IR spectrum of **III** shows ν(O—C—O) at 1514 and 1470 cm^{-1}, consistent with the presence of a chelating acetato ligand [18], while UV–vis ($CHCl_3$) and EPR (CH_2Cl_2) spectroscopies are similar to those of other reported $[Cu(O_2CR)(HB\{pz\}_3)]$ complexes [19] and again suggest a $\{d_{x^2-y^2}\}^1$ configuration at copper (at 77 K; $g_\parallel = 2.29$, $A_\parallel\{^{63,65}Cu\} = 148$ G, $g_\perp = 2.08$: at 293 K; $\langle g \rangle = 2.16$, $\langle A\{^{63,65}Cu\} \rangle = 44$ G). We therefore assign **III** as a square pyramidal complex, containing a (probably asymmetric) bidentate acetate ligand.

The cyclic voltammogram (CV) of **I** in CH_2Cl_2/0.5M $Bu^n_4NPF_6$ at 293 K shows a *quasi*-reversible couple at $E_{1/2} = -0.44$ V *vs* ferrocene/ferrocenium ($\Delta Ep = 380$ mV at 100 mV s^{-1}) assignable to the $Cu^{II/I}$ couple. The oxidative wave of this process is considerably sharper than the reductive peak, suggesting a significant kinetic barrier to the reductive process, which presumably involves concomitant decoordination of Cl^- or $Pz^{Ph}H$ to afford a tetrahedral copper(I) centre. This oxidation exhibits minimal decay upon repeated scanning, while $Ip_c : Ip_a$ is almost invariant between scan rates of 10 and 1000 mV s^{-1}. The CVs of **II** and **III** under identical conditions, while still showing *quasi*-reversible $Cu^{II/I}$ reductions at $E_{1/2} = -0.36$ (**II**) and -0.20 V (**III**), exhibit additional minor peaks indicative of the presence of several species at the electrode. In addition to these processes, **I**–**III** exhibit an additional, irreversible reduction at $Ep_c = -1.11$ (**I**), -1.31 (**II**) and -1.02 V (**III**), which does not have a detectable daughter wave or desorption spike; the identity of this process is unclear.

(Received 30 July 1996; accepted 20 August 1996)

Abstract—Two incomplete cubane-like clusters, $[\{MoAg_2S_3C_5H_5NS\}(PPh_3)_2(S)]\cdot CH_2Cl_2$ (**I**) and $[\{WAg_2Se_3C_5H_5NS\}(PPh_3)_2(Se)]\cdot CH_2Cl_2$ (**II**), were obtained from the reaction of $MoS_4Ag_2(PPh_3)_3$ and $WSe_4Ag_2(PPh_3)_3$ with excess C_5H_5NS in CH_2Cl_2 solvent. The X-ray crystallography analysis shows that **I** and **II** have incomplete cubane-like structures, in which the Mo(W) and Ag atoms are tetrahedrally coordinated.

Keywords: incomplete cubane-like cluster; crystal structure; molybdenum; tungsten; pyridine-2-thiol.

The incomplete cubane-like cluster compounds have attracted much attention, due to their relationship to the novel quasi-aromaticity [1] and the nitrogenase models [2,3]. Many molybdenum and tungsten compounds with incomplete cubane-like M_3S_4 cores have been reported [4], for instance, $Mo_3S_4(dtp)_4\cdot(H_2O)$ and $W_3S_4(dtp)_4\cdot(H_2O)$ [5,6]. However, only a few heterometallic compounds with incomplete cubane-like structure are known, such as MoW_2 and Mo_2W cores [7]. During the past few years, some incomplete cubane-like clusters with M_2Cu (M = Mo, W) and M_2Ag (M = Mo, W) cores have been synthesized in our laboratory [8–10]. Here we report the syntheses and crystal structures of two heterometallic incomplete cubane-like compounds with $MoAg_2$ and WAg_2 cores. It is interesting that these two clusters crystallize in an acentric space group on which is the essential condition for nonlinear optical frequency doubling materials.

EXPERIMENTAL

Synthesis

All chemical reagents are of A.R. grade and used as purchased. $MoS_4Ag_2(PPh_3)_3$ and $WSe_4Ag_2(PPh_3)_3$ are prepared according to the literature methods [11]. IR spectra were recorded on FTS-40 and Magna 750 spectrophotometers and UV–vis electronic spectra on a Shimadzu UV-3000 spectrophotometer.

Preparation of $[\{MoAg_2S_3C_5H_5NS\}(PPh_3)_2(S)]\cdot CH_2Cl_2$. $MoS_4Ag_2(PPh_3)_3$ 0.2 g, 0.163 mmol was dissolved in CH_2Cl_2 (10 cm^3) and to the solution C_5H_5NS (0.15 g, 1.35 mmol, excess) was added. After stirring for *ca* 5 min, the resulting solution was filtered. Then *i*-propanol (1 cm^3) was added to the orange filtrate, it was allowed to stand at ambient temperature for 2 days, when 0.05 g of black needle crystals were obtained (yield: 26.4%). Found: C, 43.7; H, 3.3; N, 1.4. Calc. for $C_{42}H_{37}Ag_2Cl_2MoNP_2S_5$: C, 43.5; H, 3.2; N, 1.2% IR (KBr pellet, cm^{-1}): 1562.1, 1496.5, 1477.2, 1432.9, 1126.2, 1093.5, 744.4, 723.2, 692.3, 516.8, 503.3, 490.2, 482.1, 459.0, 451.3, 410.8. UV–vis

(in DMF) $\lambda(\varepsilon)$(nm/10^{-3} M^{-1} cm^{-1}): 485(7.0), 320(18), 270(35).

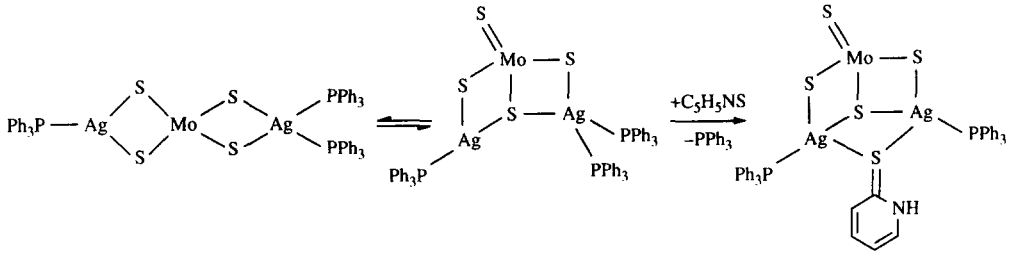
Preparation of $[\{WAg_2Se_3C_5H_5NS\}(PPh_3)_2(Se)]\cdot CH_2Cl_2$ (**II**). The preparing procedure is similar to the synthetic method for **I**, using $WSe_4Ag_2(PPh_3)_3$ (0.2 g) rather than $MoS_4Ag_2(PPh_3)_3$; 0.07 g of black block crystals were obtained (yield: 36.6%). Found: C, 35.4; H, 2.6; N, 1.0. Calc. for $C_{42}H_{37}Ag_2Cl_2Se_4NP_2SW$: C, 35.1; H, 2.6; N, 1.0%. IR (KBr pellet, cm^{-1}): 1560.3, 1496.1, 1477.5, 1432.9, 1123.7, 1093.4, 741.8, 722.7, 693.0, 518.7, 492.3, 445.1, 333.1, 303.1, 292.9. UV–vis (in DMF) $\lambda(\varepsilon)$(nm/10^{-3} M^{-1} cm^{-1}): 475(4.9), 350(25), 290(36), 270(35).

X-ray structure determinations

The crystal data for compounds **I** and **II** are summarized in Table 1, together with some experimental details. Data were collected on an Enraf–Nonius CAD4 diffractometer using Mo-K_α radiation (λ = 0.71073 Å) at 296 K. Three standard reflections were measured every 120 min.

The structures were solved by direct methods; the Mo(W) atom was located in the E map. The remaining atoms were located in succeeding difference-Fourier syntheses. Hydrogen atoms were not included. The structures were refined by the full-matrix least-squares technique with anisotropic thermal parameters, except for the phenyl C atoms. Final $R = \Sigma||F_o| - |F_c||/\Sigma|F_o| = 0.049$ (0.055), $wR = [\Sigma w(|F_o - F_c|)^2/\Sigma wF_o^2]^{1/2} = 0.055$ (0.057) and $S = [\Sigma w(|F_o - F_c|)^2/(N_o - N_v)]^{1/2} = 1.37$ (1.30); N_o = number of observations, N_v = number of variables) for cluster **I** (cluster **II**). The weighting scheme was $w = 1/\sigma^2(F_o)$ for **I** and **II**. All calculations were performed on a COMPAQ PL4/50 computer using the MoLEN/PC program package [12]. Scattering factors were taken from Cromer and Waber [13].

RESULTS AND DISCUSSION



Synthesis

The precursors for synthesizing the clusters have the linear configuration and have been used to prepare some single cubane-like and double cubane-like clusters [14]. Here, two incomplete cubane-like clusters were obtained from these two precursors. The reactions are easily performed in CH_2Cl_2 with excess C_5H_5NS. The possible reaction pathway is illustrated in Scheme 1.

The linear precursor can have a reversible butterfly configuration; as C_5H_5NS attaches to the framework, one PPh_3 ligand is detached, which results in the formation of the incomplete cubane structure.

Crystal structure

The important bond lengths and bond angles for the two compounds are given in Tables 2–5, respectively.

The crystal structure of cluster **I** consists of a neutral molecule $[\{MoAg_2S_3C_5H_5NS\}(PPh_3)_2(S)]$ and a solvent CH_2Cl_2. Figure 1 gives the ORTEP drawing of $[\{MoAg_2S_3C_5H_5NS\}(PPh_3)_2(S)]$. The cluster core $\{MoAg_2S_3C_5H_5NS\}$ is an incomplete cubane-like type structure, which contains a terdentate MoS_4^{2-}, two

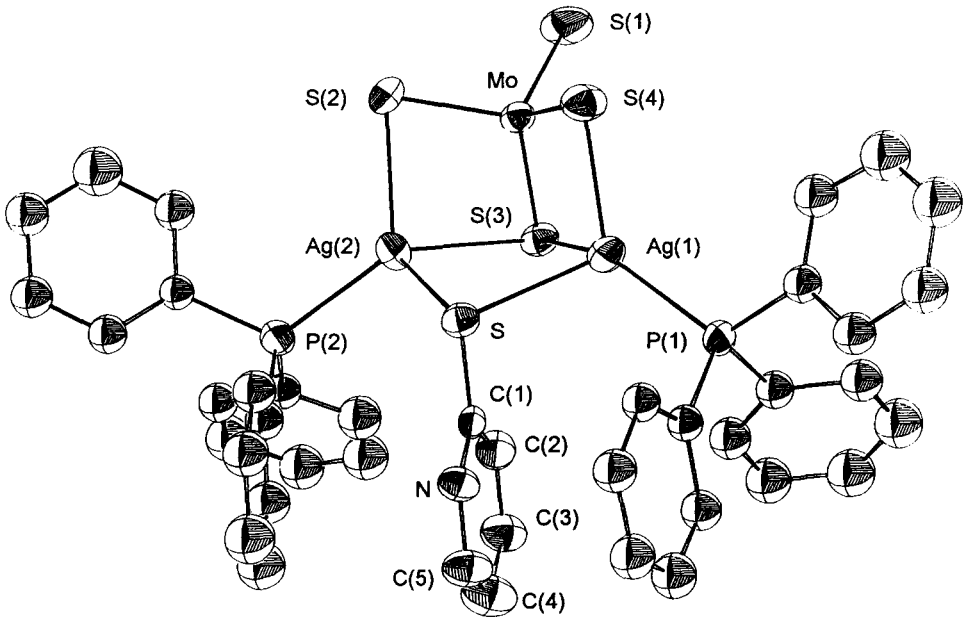

Fig. 1. The ORTEP drawing of $[\{MoAg_2S_3C_5H_5NS\}(PPh_3)_2(S)]$ with 50% probability level.

Ag atoms and a C_5H_5NS ligand. Two PPh_3 ligands are terminally attached to the two Ag atoms, respectively. The S atom of C_5H_5NS bridges the two Ag atoms. The Mo atom maintains its tetrahedral coordination geometry, with the S—Mo—S bond angles ranging from 106.8(2) to 113.0(1)°. The bond lengths of Mo—S range from 2.128(4) to 2.264(3) Å. The two Ag atoms have distorted tetrahedral coordination, with each Ag coordinated by one P and three S atoms. The S—Ag—S(P) bond angles are in the range 89.7(1)–132.9(1)°. The Mo—Ag distances are slightly different, one is 2.972(1) and the other is 2.966(1) Å.

Cluster **II** is isomorphous to cluster **I**. Figure 2 shows the ORTEP drawing of $[\{WAg_2\ Se_3C_5H_5NS\}(PPh_3)_2(Se)]$. Cluster **II** has the same molecular structure as cluster **I**, but the W and Se atoms replace the

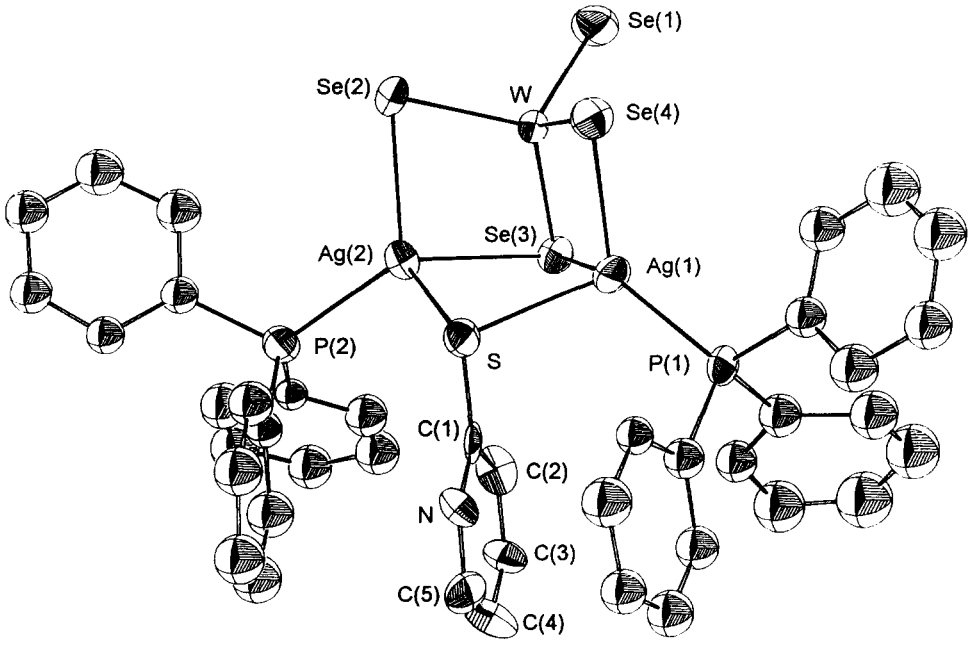

Fig. 2. The ORTEP drawing of [{$WAg_2Se_3C_5H_5NS$}$(PPh_3)_2$(Se)] with 50% probability level.

Mo and S atoms, respectively, which results in a slight increase in bond lengths. The mean bond lengths of cluster **II** are compared with that of the cubane-like cluster $[WAg_3Se_3I](Se)(Ph_3P)_3$ in Table 6; The W—Ag distances of cluster **II** are almost the same as that of $[WAg_3Se_3I](Se)(Ph_3P)_3$ [15], but the W—μ_3-Se and Ag—μ_3-Se bond lengths are a little longer than those of $[WAg_3Se_3I](Se)(Ph_3P)_3$.

The average bond lengths of clusters **I** and **II** as well as some related clusters are provided in Table 6.

As listed in Table 6, the average bond lengths Mo—μ_3-S and Mo—μ-S of **I** are shorter than those of $Mo_3S_4(dtp)_4\cdot(H_2O)$ and $[Et_4N]\{Mo_2AgS_4\}(S_2C_2H_4)_2(PPh_3)$, but the Ag—$\mu_3$-S mean bond length is longer than that of $Mo_3S_4(dtp)_4\cdot(H_2O)$ and $[Et_4N]\{Mo_2AgS_4\}(S_2C_2H_4)_2(PPh_3)$, which indicates that compared with the cores Mo_3 and Mo_2Ag, the incomplete cubane corner S atom of $MoAg_2$ is closer to the Mo atom.

As is well known C_5H_5NS exists in two tautomeric forms: the thione tautomer and the thiol tautomer. For cluster **I** and **II**, S—C bond lengths are 1.70(1) and 1.72(1) Å, respectively, which is fully in accord with thione tautomeric form [16]. The bridging mode of thione C_5H_5NS, has been reported by Constable *et al.* [17].

It is worth noting that these two clusters crystallized in an acentric space group. Recently, much attention has been paid to the study of nonlinear optical properties of W(Mo)—Cu(Ag)—S clusters [18,19], nonlinear absorption and nonlinear refraction have been observed in some W(Mo)—Cu(Ag)—S compounds, but the second harmonic generation (SHG) has not been studied in W(Mo)—Cu(Ag)—S system, because the requirement of a noncentrosymmetric lattice is not easy for the synthetic chemist to achieve. As the title clusters are acentric in the lattice, we intend to study the SHG property with these clusters in the future.

Metal substitution in the cluster $(\mu\text{-H})_2Fe_3(\mu_3\text{-Te})(CO)_9$—III.† Crystal and molecular structure of $[FeMo_2(\mu_3\text{-Te})(CO)_7(\eta^5\text{-}C_5H_5)_2]$

(Received 26 July 1996; accepted 20 August 1996)

Abstract—The reaction of $[(\mu\text{-H})_2Fe_3(\mu_3\text{-Te})(CO)_9]$ with $[CpM(CO)_3]_2$ (M = Mo, W; Cp = η^5-C_5H_5) complexes causes substitution of one and two $HFe(CO)_3$ groups with isolobal $CpM(CO)_2$ fragments. The first-stage substitution derivative $[(\mu\text{-H})Fe_2W(\mu_3\text{-Te})(CO)_8Cp]$ reacts with $[CpMo(CO)_3]_2$ resulting in the heterotrimetal $[FeMoW(\mu_3\text{-Te})(CO)_7Cp_2]$ cluster. The structure of $[FeMo_2(\mu_3\text{-Te})(CO)_7Cp_2]$ has been determined by X-ray analysis. The structures of the other products have been suggested based on ^1H, ^{77}Se and ^{125}Te NMR and IR spectroscopy. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: iron; molybdenum; selenium; tellurium; tungsten; heterometal clusters; synthesis; crystal and molecular structure.

The reaction of $[(\mu\text{-H})_2Fe_3(\mu_3\text{-Se})(CO)_9]$ (**Ia**) with the dimeric $[CpM(CO)_3]_2$ (M = Mo, W) complexes was recently shown to be a convenient method for the synthesis of two types of heterometal clusters: $[(\mu\text{-H})Fe_2M(\mu_3\text{-Se})(CO)_8Cp]$ [M = Mo(**IIa**),‡ W(**IIIa**)] and $[FeM_2(\mu_3\text{-Se})(CO)_7Cp_2]$ [M = Mo (**IVa**), W (**Va**)] [1,3]. Moreover, compound **IIIa** was shown to react with $[CpMo(CO)_3]_2$ resulting in the heterotrimetal $[FeMoW(\mu_3\text{-Se})(CO)_7Cp_2]$ (**VIa**) cluster [2]. These reactions mentioned previously [2] can be regarded as a cooperative decomposition of the initial polynuclear complexes resulting in the spontaneous formation of new compounds, whose structures cannot be predicted *a priori*. After the metal substitution in **Ia** had been studied it became possible to propose the reactions of this type as a general approach to the directed synthesis of a sufficiently large series of parent heterometal derivatives, not only cluster **Ia**, but its telluride analog $[(\mu\text{-H})_2Fe_3(\mu_3\text{-Te})(CO)_9]$ (**Ib**) as well. This work is devoted to an experimental verification of this proposition.

EXPERIMENTAL

All reactions were carried out under argon; the other manipulations were performed in air. All solvents were distilled from appropriate drying agents. The IR spectra were recorded on a Bruker IFS85 spectrometer. The NMR spectra were recorded on Bruker SXP-4-100 (^1H at 90 MHz) and CXP-300 (^{125}Te at 96.4 MHz) spectrometers. The chemical shift of ^{125}Te (positive downfield) was referenced to the 1 M water solution of H_6TeO_6 [δ = 712 ppm from $(CH_3)_2Te$ [4]] as an external standard and counted relative to dimethyltelluride. $[(\mu\text{-H})_2Fe_3(\mu_3\text{-Te})(CO)_9]$ (**Ib**) was obtained by the same procedure as used previously for **Ia** [3]. The NMR spectra parameters are given in Table 1.

Reactions of $[(\mu\text{-H})_2Fe_3(\mu_3\text{-Te})(CO)_9]$ (**Ib**) *with* $[CpM(CO)_3]_2$ (M = Mo, W)

In a typical manner compound **Ib** (0.82 g, 1.5 mmol) and $[CpM(CO)_3]_2$ (1.0 mmol) in *m*-xylene (15 cm^3)

Compound **IIb** (0.128 g, 0.18 mmol) and $[CpMo(CO)_3]_2$ (0.17 g, 0.35 mmol) in *m*-xylene (5 cm^3) were refluxed for 8 h and the volatiles then removed in high vacuum. The solid residue was extracted with several portions of $CHCl_3$ and concentrated *in vacuo*. The mixture of soluble products thus obtained was separated by TLC on "Silufol" plates (hexane : benzene in a 2 : 3 ratio). Four major fractions were collected:

(1) The red fraction—small amounts of unreacted $[CpMo(CO)_3]_2$.

(2) The red–brown fraction—trace amounts of **IVb**.

(3) The red–violet fraction—$[FeMoW(\mu_3\text{-Te})(CO)_7Cp_2]$ (**VIb**), yield 0.054 g (38%). Found: C, 25.7; H, 1.3. Calc. for $C_{17}H_{10}FeMoO_7TeW$: C, 25.9; H, 1.3%. IR ($CHCl_3$, ν_{co}, cm^{-1}): 2020 vs; 1973 s; 1950 vs; 1933 sh; 1879 w, br; 1849 w, br.

(4) The dark red fraction—trace amounts of **Vb**.

X-ray structure determination of **IVb**

Crystal data: $C_{17}H_{10}FeMo_2O_7Te$, mol. weight 701.58, triclinic, space group $P\bar{1}$, $a = 7.296(1)$, $b = 8.207(1)$, $c = 16.434(2)$ Å, $\alpha = 96.77(1)$, $\beta = 76.07(1)$, $\gamma = 111.33(1)^\circ$, V = 889.2(2) Å^3, $D_c = 2.620$ g cm^{-3}, a "Syntex $P2_1$" diffractometer, λ(Cu-K_α), room temperature, $\theta/2\theta$ scans with $V_{min} = 3.5^\circ$ min^{-1} up to $2\theta_{max} = 110^\circ$. Total 1967 (1789 independent, $R_{int} = 0.0518$) reflections were measured. An absorption correction ($\mu = 308.97$ cm^{-1}) was applied using the integration method on a crystal shape: faces ±(100), a perpendicular distance 0.330 mm, ±(010), 0.320, ±(001), 0.056; transmission factors varied from 0.21715 to 0.01331. The structure was solved by direct method (SHELXS-86

* All yields are based on **Ib**.

[5]) and refined by the full-matrix least-squares method on F^2 (SHELXL-93 [6]). The H atoms were calculated geometrically and refined in the rigid body approximation (C—H = 0.96 Å). Final R values: $R(F) = 0.0431$, $wR(F) = 0.1135$ for 1546 $F_{hkl} > 4\sigma(F)$, $R(F) = 0.0489$, $wR(F^2) = 0.1186$ for all 1789 independent reflections used. Atomic coordinates and thermal parameters are deposited in the Cambridge Crystallographic Database.

RESULTS AND DISCUSSION

Synthesis

Cluster **Ib** reacts with dimeric complexes $[CpM(CO)_3]_2$ (M = Mo, W) resulting in metal substituted derivatives, which are analogous to the selenide complexes described previously [1,3] (Scheme 1).

It should be noted that the reactions were performed following the procedure used for the analogous selenide clusters previously described [1,3]. Therefore, one can compare yields of metal substituted products and make some conclusions.

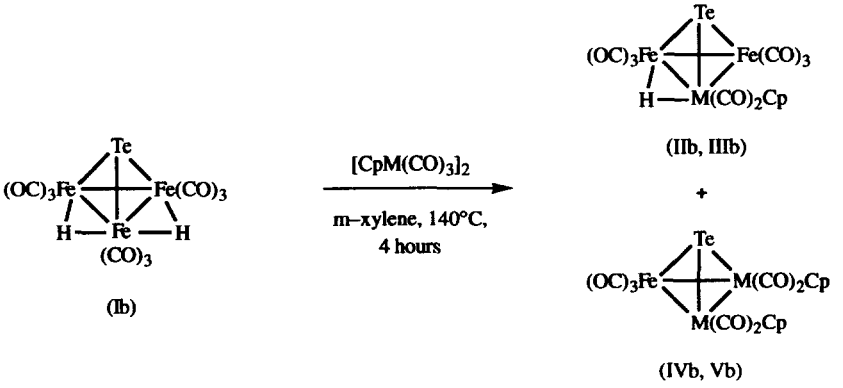
For the first time a difference in reactivity of **Ia** and **Ib** with $[CpMo(CO)_3]_2$ has occurred: the first-step substituted product **IIb** was obtained by the general procedure, but its selenide analog **IIa** was not obtained [3]. In one experiment, **IIa** was isolated in a low yield from the reaction mixture when the process was interrupted after 2 h. In our opinion the difference mentioned reflects that telluride clusters are more stable at the reaction temperature used than selenide and exhibit the lower substitution rate.

An analogous conclusion can be made when the reactions of **Ib**(**Ia**) with the molybdenum dimer complex and with the tungsten one are compared. In contrast to molybdenum clusters, the yield of the first-step tungsten substituted derivative is higher than that of the second-step one. This observation gives evidence suggesting substitution of the $HFe(CO)_3$ fragments with $[CpMo(CO)_2]$ is faster than that with $[CpW(CO)_2]$.

Based on this conclusion the reaction of **IIIB** and $[CpMo(CO)_3]_2$ was chosen to prepare the $[FeMoW(\mu_3\text{-Te})(CO)_7Cp_2]$ (**VIb**) cluster (Scheme 2).

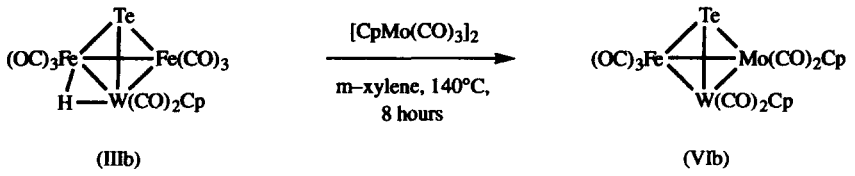
An inversion of the reaction partners (when **IIb** and $[CpW(CO)_3]_2$ were used) required an increased reaction time. It results in the **VIb** yield decreasing, probably, due to the decomposition of the initial complexes and products.

Spectroscopy



A single crystal sample of **IVb** was obtained by the slow diffusion of pentane into the toluene solution of the cluster and its structure has been determined by X-ray crystallography. Single crystals of the other heterometal complexes have not yet been obtained, so their structures are suggested on the basis of spectroscopy (see Experimental).

It was previously mentioned that the conclusion about a number of tungsten atoms in a cluster molecule can be made on the basis of the NMR spectra if the coupling on the ^{187}W nuclei is observed [1]. Based on the natural abundance and the statistical distribution of the ^{187}W isotope one can predict that the ^{125}Te NMR spectra will exhibit three peaks (a superposition of the singlet and the doublet with the same center) in a 1:12:1 ratio for the clusters containing one tungsten atom and in a 1:6:1 ratio for the clusters containing two tungsten atoms [1]. The spectra recorded confirm the number of the W atoms proposed for **IIB, Vb** and **VIb** (Table 1).



The IR spectra of **IVb, Vb** and **VIb** are very similar with only slight differences in the position of the peaks. This is supporting evidence in favour of **Vb** and **Vib** having core structures analogous to **IVb**.

The ^1H NMR spectra of **IVb** and **Vb** exhibit the singlet signals for the Cp ligand protons. In contrast the spectrum of **VIb** exhibits two singlet signals for Cp ligands linked to W and Mo atoms, respectively (Table 1). The fact that **VIb** is an individual compound and not a mixture of **IVb** and **Vb** is confirmed by chromatography (see Experimental).

The ^1H NMR spectra of the first-step substituted products **IIb** and **IIb** exhibit signals for μ-H and Cp

Scheme 1.

(IIIb) (VIb)

Scheme 2.

ligand protons in a 1 : 5 ratio. In the case of **IIIb**, the coupling on the ^{187}W nuclei was observed for the μ-H proton (Table 1). The IR spectrum of **IIb** is very similar to **IIIb**.

The additive decrease of the ^{125}Te chemical shift was observed in the **IVb, VIb, Vb** set as well as the ^{77}Se one in the **IVa, VIa, Va** set [2] (Table 1). The clusters forming each of the sets can be considered formally as the products obtained by the sequential substitution of $CpMo(CO)_3$ with $CpW(CO)_3$.

Ia, IIA and **IVa**; **Ia, IIa** and **Va**; **Ib, IIb** and **IVb**; **Ib, IIIb** and **Vb** represent the sets of the clusters obtained by the sequential substitution of $HFe(CO)_3$ with $CpM(CO)_2$ (M = Mo, W). Both in the case of the selenide clusters and the telluride ones there is no accurate additivity in the chalcogenide chemical shift variation in these rows, but the variation tendencies are very similar (Table 1).

The data mentioned in this section allow one to be sure in the correctness of the structures proposed (Schemes 1 and 2).

Crystal and molecular structures of **IVb**

Compound **IVb** has a molecular structure, as shown in Fig. 1. The crystal packing is illustrated in Fig. 2

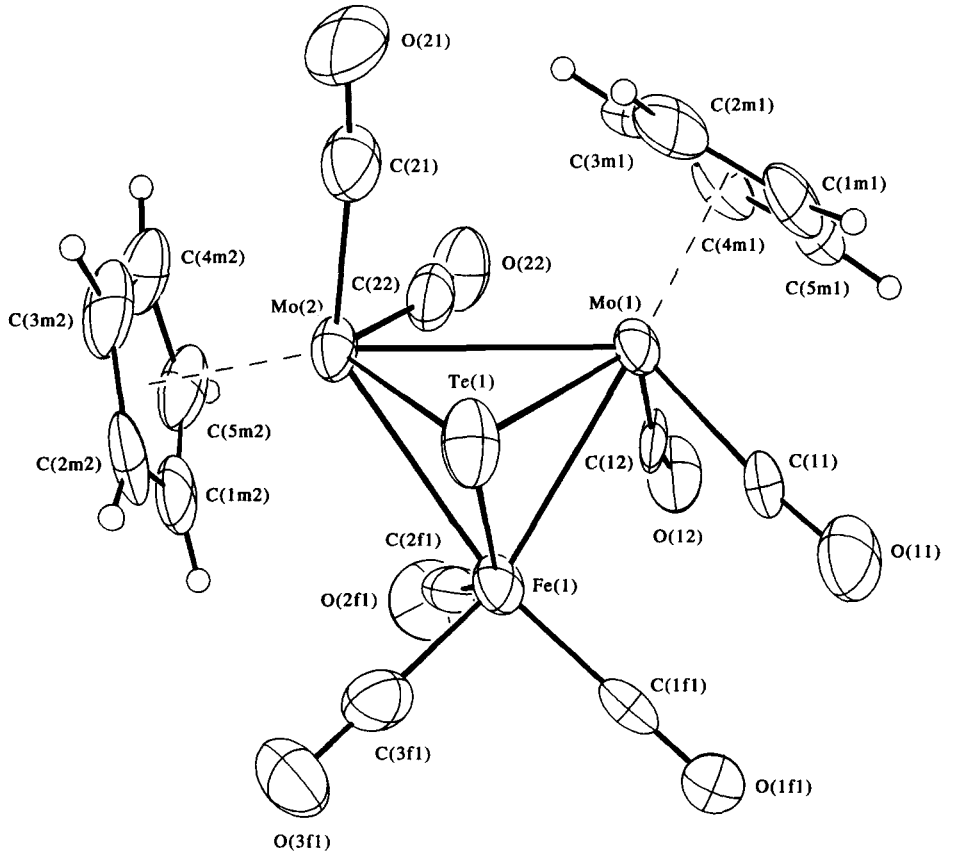


Fig. 1. Molecule **IVb** (50% probability level thermal ellipsoids). Short nonvalence contacts of Te atom are shown by dashed lines. The selected bond distances (Å): Mo(1)—Mo(2), 3.002(1), Mo(1)—Fe(1), 2.704(2), Mo(2)—Fe(1), 2.837(2), Mo(1)—Te(1), 2.700(1), Mo(2)—Te(1), 2.551(1), Fe(1)—Te(1), 2.410(2), Mo(1)—C(11), 1.95(2), Mo(1)—C(12), 1.90(1), Mo(1)—C(1m1), 2.14(1), Mo(1)—C(2m1), 2.24(1), Mo(1)—C(3m1), 2.37(1), Mo(1)—C(4m1), 2.33(1), Mo(1)—C(5m1), 2.22(1), Mo(2)—C(21), 1.89(2), Mo(2)—C(22), 1.94(2), Mo(2)—C(1m2), 2.22(1), Mo(2)—C(2m2), 2.34(1), Mo(2)—C(3m2), 2.28(1), Mo(2)—C(4m2), 2.20(1), Mo(2)—C(5m2), 2.12(1), Fe(1)—C(1f1), 1.78(2), Fe(1)—C(2f1), 1.65(2), Fe(1)—C(3f1), 1.74(2).

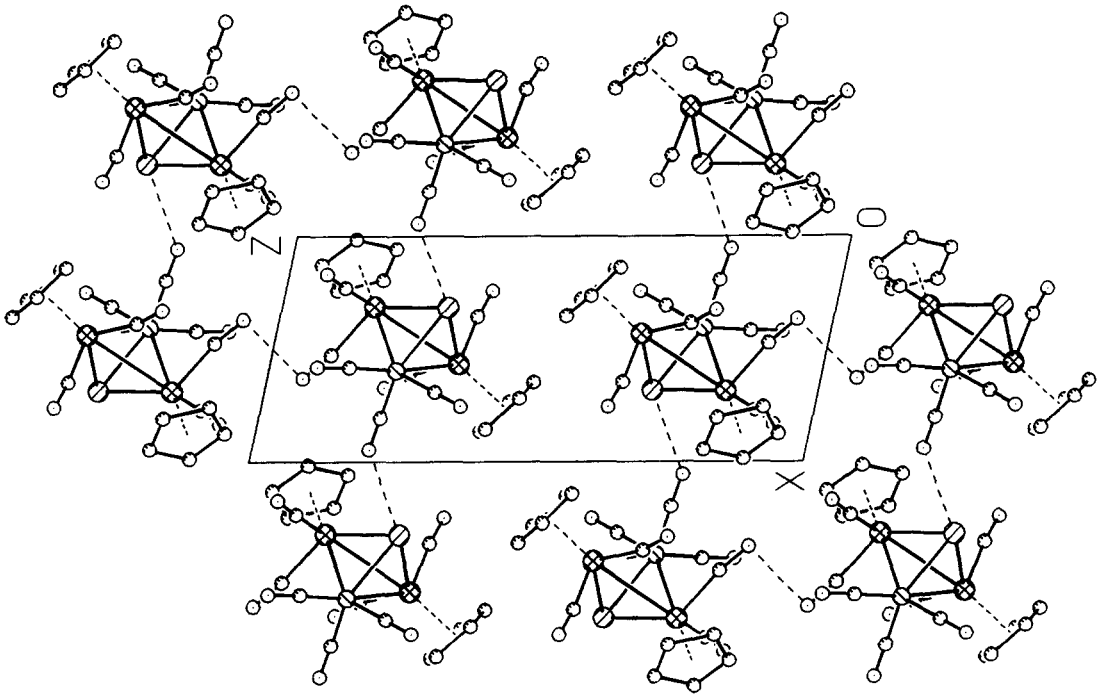

Fig. 2. Crystal packing of **IVb** (view along the *y* axis). Short intermolecular contacts of Te atom are shown by dashed lines.

and selected bond distances are given in the caption of Fig. 1.

In general the molecule of **IVb** seems to be similar to the selenide analogs **IVa** [3] and **Va** [1]. The main difference consists in an unexpected asymmetry of the **IVb** core: the cluster cores of **Va** and **IVa** have almost C_S symmetry [1,3], but the **IVb** core has no mirror plane. The Mo(2)—Te(1) bond length is shorter than Mo(1)—Te(1) by 0.149(1) Å and there is a large difference [0.133(2) Å] in the two Mo—Fe bond lengths.

From our point of view, two reasons are responsible for the core symmetry difference of the telluride clusters from the selenide analogs:

(1) *An asymmetric ligand arrangement of two* Mo atoms. The Cp ligands of Mo(1) and Mo(2) atoms have different orientations relative to the Mo(1)—Mo(2) bond (Fig. 1). This causes some difference in the electronic state of Mo *atoms* and, therefore, the difference in the Mo—Te and Mo—Fe bonding. An analogous asymmetry of the ligand environment takes place in the selenide complexes [1,2,3] also but Te seems to be more "soft" than Se.

(2) *Short non-valence contacts between* Te *and C (intramolecular) and between* Te *and* O *(intermolecular).** It is known that the tellurium atom exhibits a tendency to increase the coordination number by means of this type of contact [8,9]. In the structure of **IVb** the Te atom has only three covalent bonds, but its coordination number is 7 due to four additional nonvalence contacts. The selenium atom exhibits this tendency to a lesser degree. This may explain the core asymmetry of **IVb** and its crystal packing difference from the compounds **IVa** and **Va** (the structures of **IVa** and **Va** are monoclinic, the structure of **IVb** is triclinic).

CONCLUSION

This work and the previous ones [1,2,3] show that the metal substitution in the $[(\mu\text{-H})_2Fe_3(\mu_3\text{-X})(CO)_9]$ (X = Se, Te) clusters is a convenient method of a large-scale heterometal complex preparation.

A search for the elusive red form in substituted Pt^{II} bipyridine complexes

Sudhir Achar and Vincent J. Catalano*

Department of Chemistry/216, University of Nevada, Reno, Reno, NV 89557, U.S.A.

(Received 17 June 1996; accepted 6 August 1996)

Abstract—An expedient method for the synthesis of $[Pt(bu_2bpy)Cl_2]$, **1**, (bu_2bpy) = 4,4′-di-*tert*-butyl-2,2′-bipyridine, is reported. The X-ray crystal structure determination of the complex **1** revealed that the monomers stack in a head-to-tail fashion with the interplanar separation of 3.7 Å. The platinum centers are 5.643 Å apart and the bipyridine portion of the ligands are *anti* to each other and offset. X-ray crystal structure analyses were performed for the complexes $[PtMe_2(bu_2bpy)]$ (**2**), $[PtMe_2(Me_2bpy)]$ (**3**), (Me_2bpy) = 4,4′-dimethyl-2,2′-bipyridine and $[PtMe_2(bpy)]$ (**4**), (bpy) = 2,2′-bipyridine, and various aspects of these structures are discussed.

Keywords: Pt stacking, π–π stacking; red form bipyridine.

Bipyridine and phenanthroline complexes of platinum(II) have drawn considerable attention in the past 25 years because of the tendency of the platinum centers to aggregate in the solid state forming linear chains [1]. These resulting stacks often possess very short platinum–platinum separations (< 3.5 Å) resulting in intensely colored absorptions and emissions. Often these complexes are polymorphic and can be classified into three categories, *viz.* monomers that show no metal–metal interaction, linear chains with Pt^{II} centers stacked equidistant along an axis and discrete dimers dominated by short Pt^{II}–Pt^{II} interactions or by strong π–π stacking of the diimine ligands. For example, the dimorphic nature of the complex $[Pt(bpy)Cl_2]$ (bpy = 2,2′-bipyridine) has generated tremendous interest [2]. The monomer form (yellow) can be converted to the linear chain form (red) either by boiling with HCl or by heating it in pyridine [3]. Further, it is generally accepted that it is possible to control the morphology by altering the nature of the substituent on the auxiliary ligands. In an attempt to understand these factors, we have recently begun to investigate sterically encumbered *cis*-chelating diimine ligands coordinated to the Pt^{II} centers. Central to this study is the role of steric factors over electronic factors in determining the stacking motif.

In this paper we wish to report a convenient method for the synthesis of $[Pt(bu_2bpy)Cl_2]$ (**1**), (bu_2bpy) = 4,4′-di-*tert*-butyl-2,2′-bipyridine [4]. Also reported are the unusual solid-state structure of **1** and the previously unreported structures of $[PtMe_2(bu_2bpy)]$ (**2**) $[PtMe_2(Me_2bpy)]$ (**3**) and (Me_2bpy) = 4,4′-di-methyl-2,2′-bipyridine and $[PtMe_2(bpy)]$ (**4**).

EXPERIMENTAL

The ^1H NMR spectrum was recorded employing a General Electric QE 300 spectrometer. Chemical shifts are reported with respect to TMS. The UV–vis spectrum was recorded using a Perkin–Elmer Lambda 11 UV–Vis spectrometer in acetonitrile. The ligand (bu_2bpy) [5] and the complexes $[Pt(SMe_2)_2Cl_2]$ [6], $[PtMe_2(bu_2bpy)]$ [7], $[PtMe_2(Me_2bpy)]$ and $[PtMe_2(bpy)]$ [8] were prepared by literature methods.

$[Pt(bu_2bpy)Cl_2]$ (1)

To a stirred solution of (bu_2bpy) (0.15 g) in chloroform (10 cm^3) was added a solution of $[Pt(SMe_2)_2Cl_2]$ (0.22 g) in chloroform (10 cm^3), and the yellow solution was heated to reflux for 1 h after which the solvent volume reduced to nearly 3 cm^3 by distillation. On standing at room temperature, the product was precipitated as a yellow microcrystalline solid which was filtered, washed with hexane and dried *in vacuo*. Yield 85%. ^1H NMR in $CDCl_3$ (300 MHz): δ 1.46 (s, 18H,

* Author to whom correspondence should be addressed.

tert-butyl hydrogens), 7.48 [d, 2H, $^3J(H^5,H^6) = 6$ Hz, $^4J(H^5,H^{3'}) = 2$ Hz, $H^5,H^{5'}$ of bu_2bpy], 7.89 (s, 2H, $H^3,H^{3'}$ of bu_2bpy), 9.46 [d, 2H, $^3J(H^6,H^5) = 6$ Hz, $^3J(PtH) = 38$ Hz, $H^6,H^{6'}$ of bu_2bpy]. UV–vis λ_{max}: 376 nm.

X-ray structures

Crystals of $[Pt(bu_2bpy)Cl_2]$ were glued on a glass fiber and mounted on a Siemens P4 four-circle goniometer. Unit-cell parameters were determined from automatic machine centering of 46 reflections ($6.86 < 2\theta < 24.96°$) and refined by least-squares methods. Intensities were collected at 293 K with graphite-monochromated Mo-K_α radiation using ω scanning techniques. 3362 total reflections were collected between $1.89 < \theta < 22.5°$ and merged ($R_{int} = 0.054$) to yield 2437 unique reflections. Two check reflections showed only random fluctuations (<1%) during the data collection. The data were corrected for Lorentz and polarization effects. An empirical absorption correction using azimuthal (Ψ) scans of reflections was applied. Crystal data are provided in Table 1.

The structure was solved using direct methods and refined on F^2 using SHELXTL 5.1 [9] computer programs. All nonhydrogens were refined with anisotropic thermal parameters. Hydrogen atoms were added in calculated positions and refined by use of a riding model and fixed isotropic thermal parameters.

Crystals of **2, 3** and **4** were mounted as described above. Unit-cell parameters were determined by machine centering of 24 reflections for **2** ($9.71 < 2\theta < 24.77°$), 27 reflections for **3** ($9.94 < 2\theta < 24.97$) and 37 reflections for **4** ($5.48 < 2\theta < 24.97°$). For **2,** 3457 reflections were collected ($1.89 < \theta < 22.5°$) and merged to yield 2563 unique data ($R_{int} = 0.0410$), and 2534 ($2.18 < \theta < 22.5°$) reflections were collected for **3** and merged to give 1752 unique data ($R_{int} = 0.0303$). 1049 reflections ($1.89 < \theta < 22.5°$) were collected for **4** and merged to give 548 unique data ($R_{int} = 0.0548$). The data were treated as described above, except for **3** which was corrected for absorption using XABS2.

The structures were solved and refined as described above. The final coordinates, complete bond distances and angles, average temperature factor (U_{eq}), and packing diagrams for all compounds are given in the supporting information (34 pages).

RESULTS AND DISCUSSION

The synthesis of $[Pt(bu_2bpy)Cl_2]$ (**1**) was conveniently accomplished in chloroform by the reaction of (bu_2bpy) with $[Pt(SMe_2)_2Cl_2]$. Using low boiling, easily manipulated solvents makes the present method advantageous over earlier methods, and the product is obtained in high yield after only 2 h. The product was readily characterized by ^1H NMR and by single-crystal structure determination. The ^1H NMR spectrum exhibits a single resonance for the *tert*-butyl protons at $\delta = 1.46$ ppm followed by three peaks at the downfield region characteristic of the bipyridyl ring resonances. In addition, the *ortho*-protons ($H^6,H^{6'}$) also show platinum satellites with $^3J(PtH) = 36$ Hz. The assignments are given in the experimental section and are in close agreement with the reported values [10]. The dimethylplatinum(II) complexes $[PtMe_2(bu_2bpy)]$, $[PtMe_2(Me_2bpy)]$ and $[PtMe_2(bpy)]$ were prepared by the reaction of appro-

priate diimine ligands with $[Pt_2Me_4(\mu\text{-}SMe_2)_2]$ according to the reported methods [6,7].

As shown in Fig. 1 the asymmetric unit contains one molecule of $[Pt(bu_2bpy)Cl_2]$. Selected bond distances and angles are listed in Table 2. The platinum center adopts a nearly square-planar geometry with the sum of the Pt containing angles equaling 360.1°. The contraction of N(1)—Pt—N(2) angle at 78.7(5)° from the ideal 90° is typical for *cis*-chelating bipyridines as is the expansion of the Cl(1)—Pt—N(1) [96.1(4)°] and Cl(2)—Pt—N(2) [96.5(4)°] from 90°. However, the *trans* angles show little deviation from linearity with N(1)—Pt—Cl(2) and N(2)—Pt—Cl(1) being nearly equal at 174.8(4) and 174.6(4)°, respectively. The Pt—Cl distances are nearly equal [Pt—Cl(1), 2.293(3); Pt—Cl(2), 2.287(4) Å] as are the Pt—N separations [Pt—N(1), 2.010(12); Pt—N(2) 2.019(10) Å]. These distances are consistent with other Pt^{II}—Cl and Pt^{II}—N separations and are unremarkable.

Excluding the *tert*-butyl group, the molecule is remarkably planar. The average deviation from planarity is only 0.05 Å. The angle between the least squares planes of the two pyridine subunits is only 4.4° and the $PtCl_2$ fragment is canted only by 2.2°. The most remarkable feature of this structure is the intermolecular interactions shown in Fig. 1. The Pt monomers stack in a head to tail fashion with a separation of 3.7 Å between the two planes. In this arrangement the Pt centers are offset and 5.643 Å apart. The bipyridine portion of the ligand are anti to each other and offset. This arrangement is fairly typical since most π-stacking involves groups which are offset from each other to maximize overlap [11]. There is no evidence of hydrogen bonding between the chlorides and the methyl hydrogens of the *tert*-butyl groups. It appears that a second geometry where Pt—Pt stacking predominates is possible. This would only require a translation of the two Pt centers towards each other. However, such an arrangement would eliminate the possibility of any π–π stacking from the bipyridine groups. The present arrangement may offer a higher packing efficiency by placing the *tert*-butyl groups on opposite sides of each other. This factor alone appears to be more important than Pt···Pt aggregation.

Similar results are seen in the solid state structures of **2, 3** and **4**. These structures are depicted in Figs 2, 3 and 4. For **2** the structure is remarkably similar to that of **1**. The Pt—N(1) and Pt—N(2) separations in **2** are slightly longer at 2.092(8) and 2.093(9) Å owing to the larger *trans* influence of Me over Cl. The corresponding N(1)—Pt—N(2) angle is 77.1(4)°. The sum of the angles around Pt in **1** is 360.1°, while in **2** that number is relaxed to 357.2°. Both are very close to the ideal for a square planar center of 360°.

Table 2. Selected bond distances (Å) and angles (°) for **1, 2, 3,** and **4**

		1

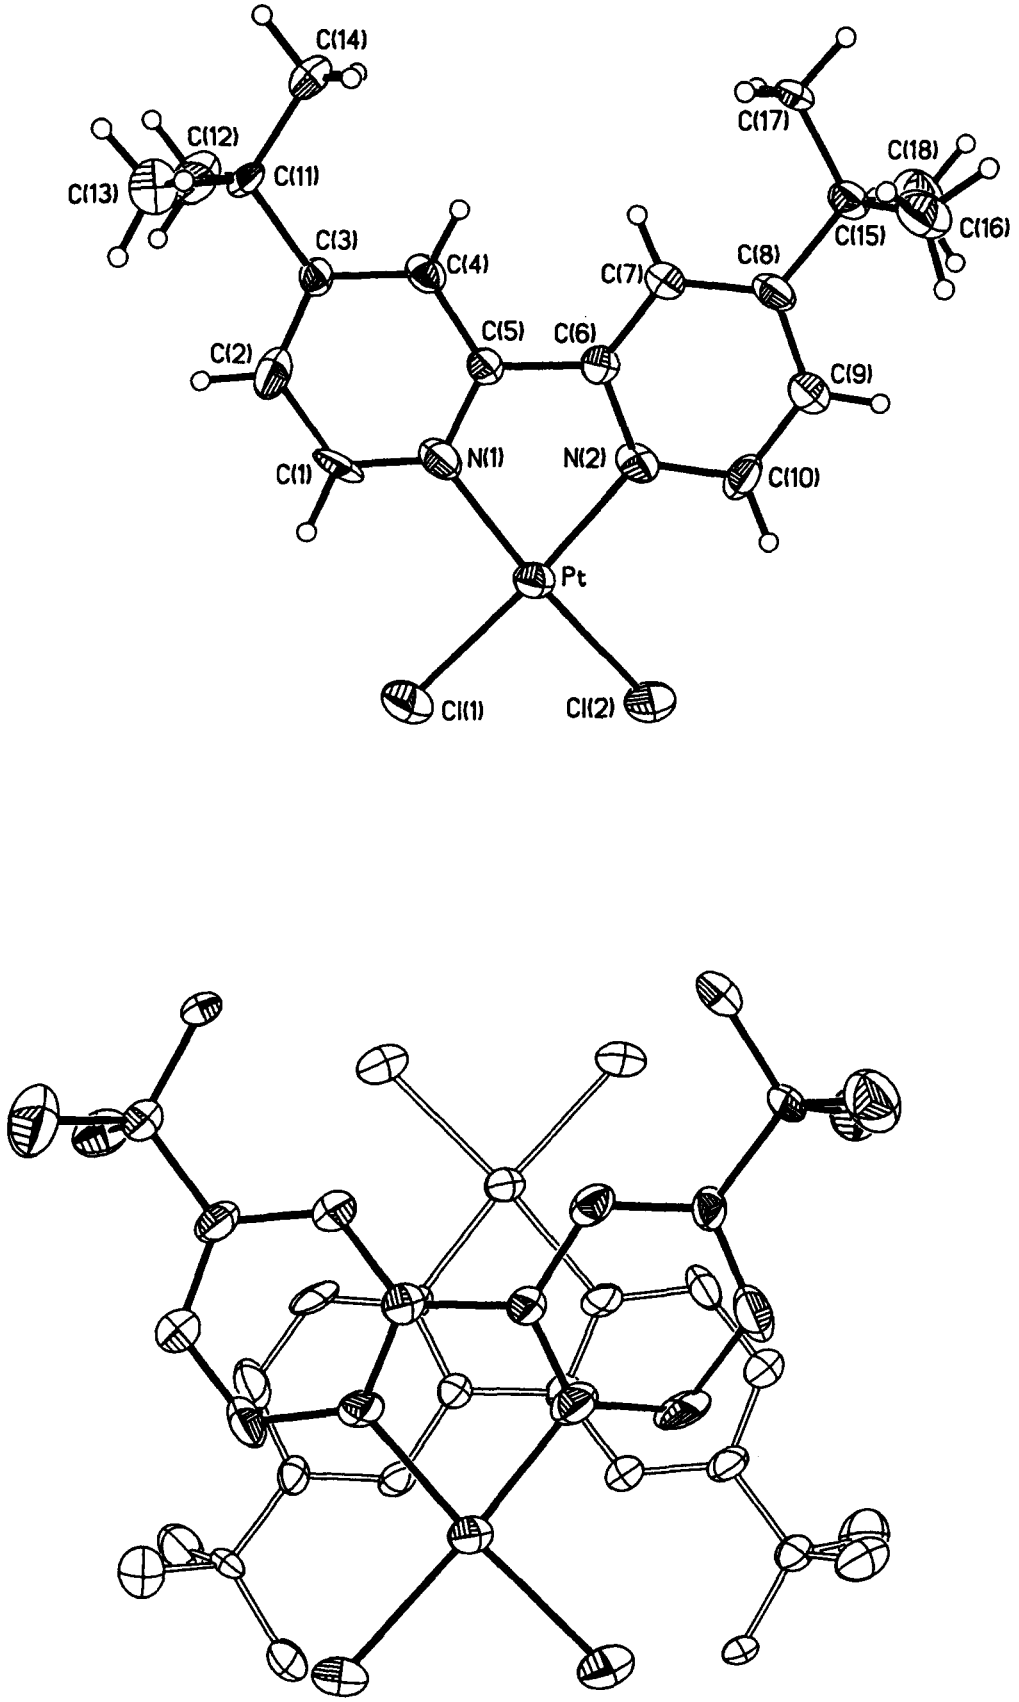

Fig. 1. Thermal ellipsoid (40% probability) drawing of **1** with numbering scheme (top) and plot emphasizing the stacking (bottom).

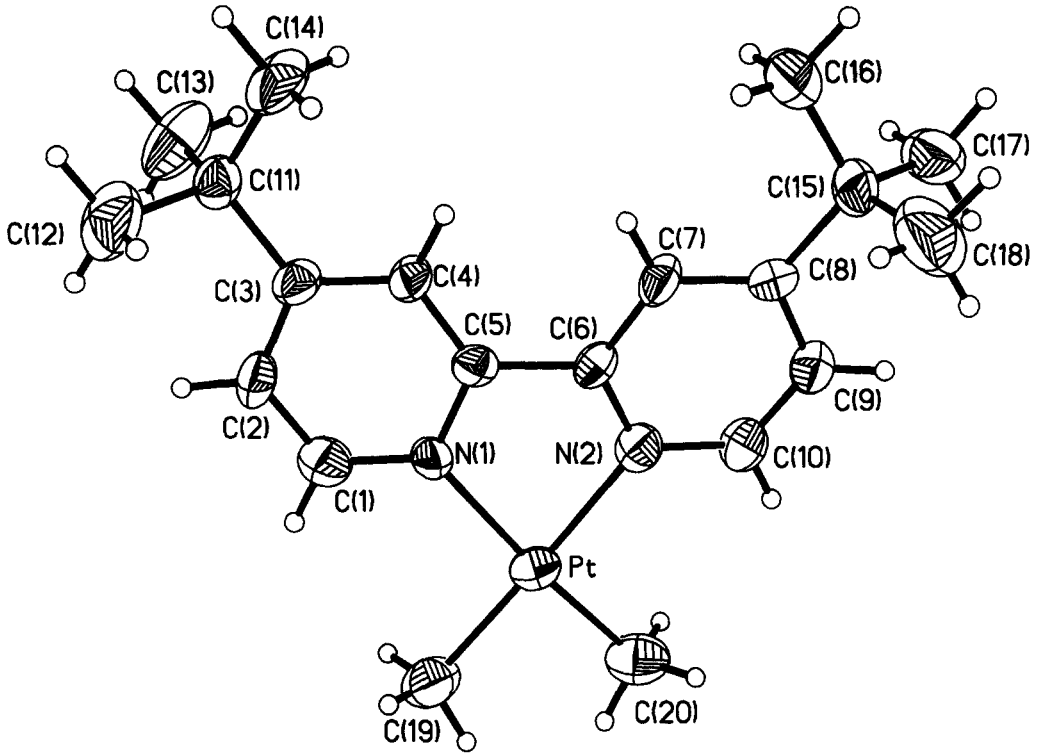

Fig. 2. Thermal ellipsoid (40% probability) drawing of **2** with numbering scheme.

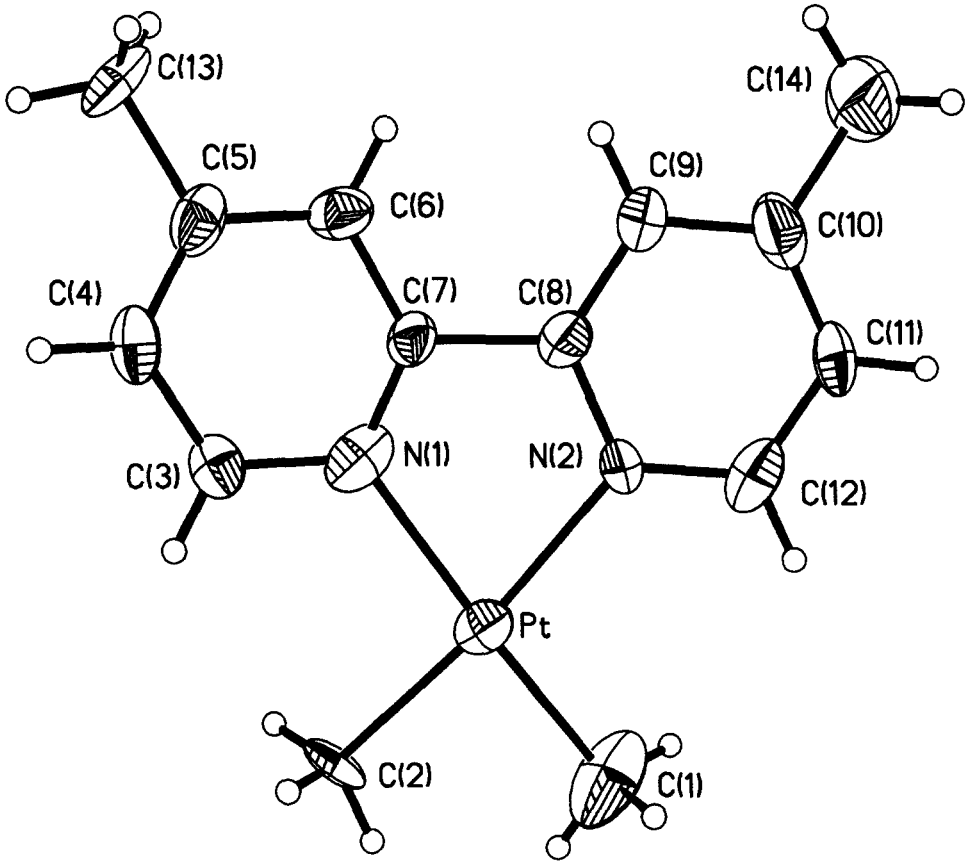

Fig. 3. Thermal ellipsoid (40% probability) drawing of **3** with numbering scheme.

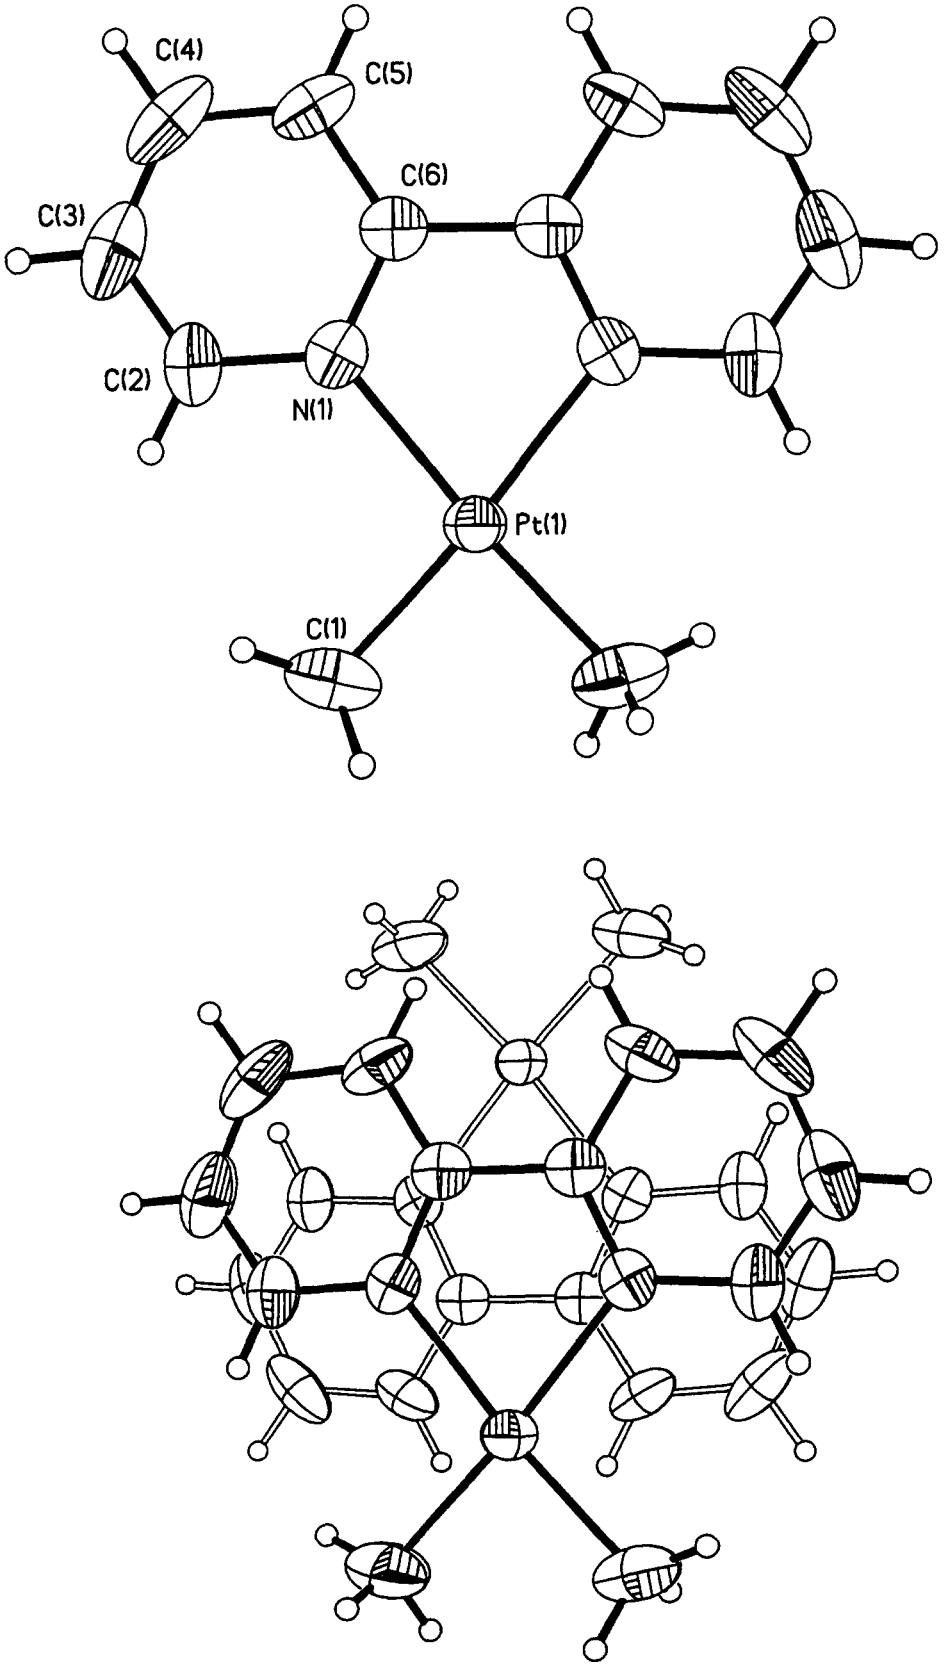

Fig. 4. Thermal ellipsoid (40% probability) drawing of **4** with numbering scheme (top) and plot emphasizing the stacking (bottom).

The structures of **3** and **4** are typical of non-Pt stacked complexes and are remarkable only in their absence of a strong Pt···Pt interaction. The Pt···Pt separations for **3** and **4** are 6.562 and 5.526 Å, respectively. The Pt atom of **4** is situated on a two-fold axis making this structure more rectilinear. Selected bond distances and angles can be found in Table 2. The average interplanar distances for **2, 3** and **4** are 3.7, 3.4 and 3.5 Å, respectively. Clearly the *tert*-butyl groups influence the interplanar separations. Packing diagrams for all compounds are provided in the supporting information.

There was no evidence for formation of the platinum stacked complexes in any of the compounds reported. It is apparent that the elusive red form is very sensitive to even subtle change in ligand sterics and perhaps electronics. $[PtMe_2(bpy)]$ and $[PtMe_2(bu_2bpy)]$ are naturally red from an intense MLCT transition and showed only a single nonstacked morphology [7]. This result is rather surprising since there is very little difference in sterics between **4** and its chloro analog for which the red form is known. From this it appears that electronics must also play a role in the Pt—Pt self association; however, it would seem that the more electron rich Pt center in **4** would be the better candidate for Pt stacking, but none was observed. Attempts to convert the unstacked forms into "red" forms all met with failure.

Acknowledgements—Acknowledgement is made to the donors of the Petroleum Research Fund, administered by the American Chemical Society, for their support of this research and to Johnson Matthey Ltd for their generous loan of platinum salts.

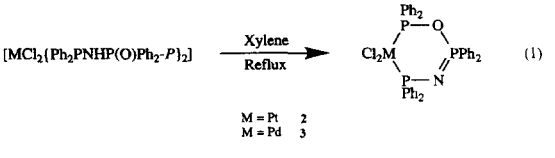
A novel $MNOP_3$ metallacycle. Crystal and molecular structure of *cis*-$[PtCl_2\{Ph_2POP(Ph)_2NPPh_2\text{-}P,P'\}]$

Alexandra M. Z. Slawin, Martin B. Smith and J. Derek Woollins*

Department of Chemistry, Loughborough University, Loughborough, Leics, LE11 3TU, U.K.

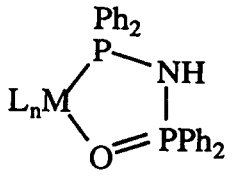


(Received 29 August 1996; accepted 18 September 1996)

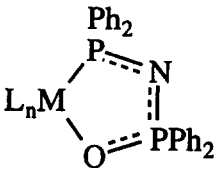
Abstract—Thermolysis of *cis*-$[PtCl_2\{Ph_2PNHP(O)Ph_2\text{-}P\}_2]$ (**1**) in refluxing xylene gives *cis*-$[PtCl_2\{Ph_2POP(Ph)_2NPPh_2\text{-}P,P'\}]$ (**2**) containing the first example of an $MNOP_3$ metallacycle. Compound **2** has been characterized by multinuclear NMR spectroscopy (^1H, $^{31}P\text{-}\{^1H\}$ and $^{195}Pt\text{-}\{^1H\}$), IR spectroscopy and X-ray crystallography. The related palladium(II) complex *cis*-$[PdCl_2\{Ph_2POP(Ph)_2NPPh_2\text{-}P,P'\}]$ (**3**) was similarly prepared. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: metallacycle; synthesis; X-ray structure; mixed P(III)–P(V) ligand.

We recently reported the synthesis of the heterofunctional phosphine $Ph_2PNHP(O)Ph_2$ and described some coordination chemistry of this ligand with various late transition metals [1–3]. In particular we have successfully prepared new five-membered metallacycles of $MN(H)OP_2$ (Type **I**) and $MNOP_2$ (Type **II**) (M = Rh, Ir, Pd and Pt) [1,3] containing the P,O-chelating ligands $Ph_2PNHP(O)Ph_2$ and $[Ph_2PNP(O)Ph_2]^-$, respectively. The $[Ph_2PNP(O)Ph_2]^-$ anion can also behave as a P,O-bridging ligand forming a novel ten-membered $Pd_2N_2O_2P_4$ metallacycle (Type **III**) [2]. Furthermore, we found that refluxing a methanol suspension of *cis*-$[PtCl_2\{Ph_2PNHP(O)Ph_2\text{-}P\}_2]$ (**1**) affords an unsymmetrical complex *cis*-$[PtCl_2\{Ph_2PNHP(O)Ph_2\text{-}P\}(Ph_2POMe)]$ in which one Ph_2P—N bond has been cleaved [4]. Here we describe the first examples of metallacycles of $[MCl_2\{Ph_2POP(Ph)_2NPPh_2\text{-}P,P'\}]$ (M = Pt **2**; Pd **3**) (Type **IV**) of which **2** has been structurally characterized. The coordinated $Ph_2POP(Ph)_2NPPh_2$ ligand is closely related to $[Ph_2PNP(Ph)_2NPPh_2]^-$ (Type **V**) of which only a few examples of transition metal complexes are known [5–7].



Refluxing a suspension of **1** in xylene for 40 min under nitrogen gave, after recrystallization from CH_2Cl_2/Et_2O, the platinum(II) complex *cis*-$[PtCl_2\{Ph_2POP(Ph)_2NPPh_2\text{-}P,P'\}]$ in 82% yield [Eq. (1)]. Compound **2** has the expected $^{31}P\text{-}\{^1H\}$ NMR spectrum (Fig. 1) together with the other anticipated spectroscopic and analytical data. The $^{31}P\text{-}\{^1H\}$ NMR



(1)

spectrum is particularly informative and reveals three unique phosphorus environments consistent with an unsymmetrical $Ph_2POP(Ph)_2NPPh_2$ ligand. The high frequency doublet at δ_P 83.5 [^1J(PtP) 4460 Hz] is typical for a metal-ligated phosphinite group [*cf* *cis*-$[PtCl_2(Ph_2POMe)_2]$ δ_P 85.6, ^1J(PtP) 4175 Hz].

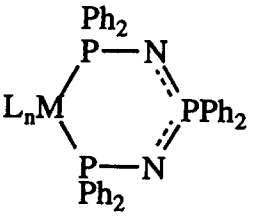
Type I



Type II

Type III

Type IV

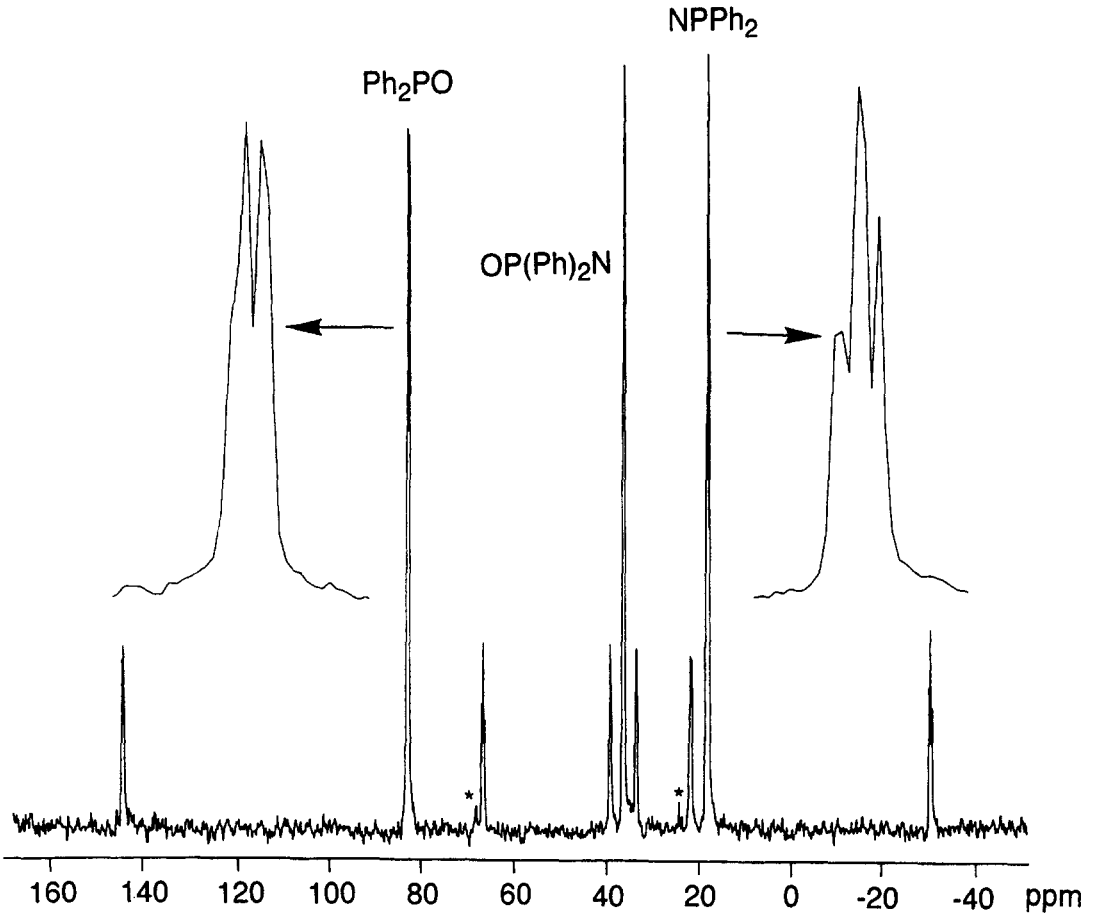
Type V

Furthermore, the small ^3J(PtP) value of 194 Hz associated with the resonance at δ_P 36.7 is assigned to the central $OP(Ph)_2N$ moiety. A small J(PP) coupling constant is indicative of a mutual *cis* arrangement of phosphorus ligands and is further supported by the presence of two ν(Pt—Cl) stretches at 310 and 279 cm^{-1} in the IR spectrum (KBr disc). Examination of the xylene filtrate by ^{31}P-$\{^1H\}$ NMR revealed a major phosphorus species, which has been identified as the elimination product $Ph_2P(O)NH_2$ as anticipated from this thermal transformation. The corresponding palladium(II) analogue *cis*-$[PdCl_2\{Ph_2POP(Ph)_2NPPh_2$-$P,P'\}]$ (**3**) was synthesized from $[PdCl_2\{Ph_2PNHP(O)Ph_2$-$P\}_2]$ and has the expected spectroscopic data.†

Suitable crystals of **2** were grown by slow diffusion of Et_2O into a $CDCl_3$ solution. The X-ray structure‡ of **2** (Fig. 2) reveals the platinum to be almost perfectly square planar [the Pt atom lies 0.07 Å out of the plane of its substituent atoms]. The ring is puckered slightly and could be described as being "boat-like". The central P(1)—O(3)—N(1)—P(3) atoms are approximately planar [mean deviation 0.10 Å] with the prow and stern Pt(1) and P(2) atoms lying 0.43 and 0.48 Å, respectively, from this mean plane. Although the identity of the O and N atoms cannot be established unequivocally from the X-ray study, the evidence is excellent. A number of refinements with O,O; O,N; N,O and N,N were attempted. The lowest R factor was obtained in the O,N case as shown in

† Compounds **2** and **3** gave satisfactory carbon, hydrogen and nitrogen microanalysis. IR spectra (KBr discs), ^1H, ^{31}P-$\{^1H\}$ and ^{195}Pt-$\{^1H\}$ NMR spectra ($CDCl_3$). Selected spectroscopic data: For **2**: ^{31}P-$\{^1H\}$: δ_P 83.5 [^1J(PtP) 4460 Hz, (—PPh_2O)], 36.7 [^3J(PtP) 194 Hz ($OPPh_2N$)], 18.4 [^1J(PtP) 3506 Hz (—$NPPh_2$)]; ^{195}Pt-$\{^1H\}$: δ_{Pt} −4296; ^1H: δ_H 7.91–7.74, 7.56–7.30 (arom. H); IR: 310, 279 cm^{-1} [ν(Pt—Cl)]. For **3**: ^{31}P-$\{^1H\}$: δ_P 106.5 (—PPh_2O), 45.3 (—$NPPh_2$), 36.2 ($OPPh_2N$), 16, 28 Hz [J(PP)]; ^1H: δ_H 7.98–7.80, 7.53–7.28 (arom. H); IR: 305, 277 cm^{-1} [ν(Pd—Cl)].

‡ Crystal data for compound **2**: $C_{36}H_{30}Cl_2NOP_3Pt$, M = 851.56, monoclinic, space group $P2_1/n$, a = 12.351(2), b = 15.669(1), c = 17.507(2) Å, β = 97.007(10)°, U = 3363 Å^3, Z = 4, T = 293 K, D_c = 1.68 g cm^{-3}, $F(000)$ = 1672, λ = 1.54178 Å, μ(Cu-K_α) 11.0 mm^{-1}. Rigaku AFC 7S diffractometer, ω-scans ($2\theta_{max}$ = 120.1°). Crystal dimensions 0.12 × 0.21 × 0.22 mm^3. Of 5279 unique data, 3380 were observed and corrected for absorption [$I > 3.0\sigma(I)$]. The structure was solved by heavy-atom Patterson methods and refined to give R = 0.042 and R_w = 0.043. The structure was refined anisotropically using teXsan [12]. Atomic coordinates, bond lengths and angles and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre.



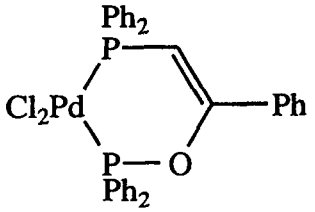


Fig. 1. The $^{31}P-\{^{1}H\}$ NMR spectrum (36.2 MHz) of **2** (*denotes impurity).

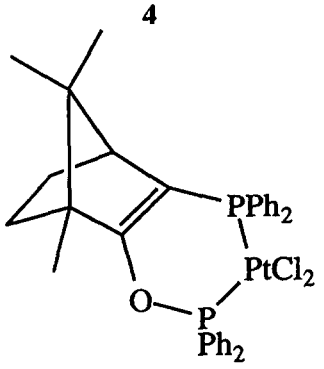

Fig. 2, which is supported by the microanalysis and NMR results. The P—O and P—N bond lengths are statistically indistinguishable, however the P(1)—O(3)—P(2) and P(2)—N(1)—P(3) angles [129.8(4) and 125.5(4)°, respectively] differ markedly. In the structures of $[M\{Ph_2PNP(Ph)_2NPPh_2\text{-}P,P'\}]$ (M = Ni, Pd) [5,6] seven of the eight P—N—P angles lie in the range 122.5(4)–125.2(4)° with one exception of 128.2(4)°. A comparison of equivalent P—N—P and P—O—P angles is not easy but a good example would be $Ph_2P(Se)EP(Se)Ph_2$ [for E = O, 135.8(2); E = NH, 132.3(2)°] [8,9] in which the angle for nitrogen is smaller than that for oxygen, again in agreement with our assignment here. The Pt(1)—P bond lengths are not significantly different but the Pt(1)—Cl bond lengths reflect the difference in *trans* groups with Pt(1)—Cl(2) [2.378(2) Å] being larger than Pt(1)—Cl(1) [2.351(3) Å] illustrating the better π acceptor ability of P(1) as a consequence of its oxygen substituent. Within the $PtNOP_3$ ring there is a substantial degree of localized bonding with the P—O/N bonds at P(2) being appreciably shorter than those at P(1) and P(3). The angles within the ring reflect the puckered geometry. The P(1)—Pt(1)—P(3) angle is slightly enlarged at 95.8(1)° whilst the Pt—P—O/N angles are *ca* 117°. The P(2) centre is close to tetrahedral whilst P(1) and P(3) are quite distorted from ideal geometries. There are no significant intermolecular interactions.

Attempts to liberate $Ph_2POP(Ph)_2NPPh_2$ from **3** with KCN/MeOH were unsuccessful and reflect the instability of this ligand. Several degradation products were identified by $^{31}P-\{^{1}H\}$ NMR spectroscopy, the major products are Ph_2POMe and $Ph_2PNHP(O)Ph_2$.

Palladium(II) and platinum(II) complexes of β-ketophosphines undergo similar transformations to give the phosphine–phosphinite complexes **4** and **5** [10,11]. A possible mechanism for the formation of **2** involves an intramolecular coupling reaction of the two *cis* ligands in **1**. The initial step is Ph_2P—N bond cleavage of one coordinated ligand. The base $[Ph_2P(O)NH]^-$ could rapidly deprotonate the amine of the second $Ph_2PNHP(O)Ph_2$ ligand with concomittant formation of **2** and $Ph_2P(O)NH_2$.

4

5

The M—P—O—P—N—P metallacycle is the first example of a new ring system closely related to the six-membered M—P—N—P—N—P rings of which only a few examples have been documented [5–7]. Further synthetic studies are currently in progress.

Dinuclear and tetranuclear oxo-bridged iron(III) complexes of the ambidentate ligand 3-(2-pyridyl)-pyrazole

Peter L. Jones, John C. Jeffery, Jon A. McCleverty* and Michael D. Ward*

School of Chemistry, University of Bristol, Cantock's Close, Bristol BS8 1TS, U.K.

(Received 20 August 1996; accepted 18 September 1996)

Abstract—The crystal structures of $[Fe_4^{III}(HL)_2(L)_6(\mu\text{-}O)_2[PF_6]_2\cdot 4MeCN$ (**1**·4MeCN) and $[Fe_2^{III}(HL)_4(OSO_3)_2(\mu\text{-}O)]\cdot 2MeOH\cdot 3H_2O$ (**2**·MeOH·$3H_2O$) have been determined [HL is the ambidentate, potentially terdentate ligand 3-(2-pyridyl)-pyrazole]: complex **2** is a conventional μ-oxo-diiron(III) complex in which HL acts as a bidentate chelate and the sulfate ligands are monodentate, but **1** is effectively a dimer containing two μ-oxo-diiron(III) cores linked by deprotonated ligands L^- which are bridging *via* the two N atoms of the pyrazolate rings. © 1997 Elsevier Science Ltd. Keywords: iron–oxo complexes; pyrazolate bridge; polynuclear complexes; crystal structures.

As part of our recent studies on the hexadentate podand ligand tris[{3-(2-pyridyl)-pyrazol-1-yl}hydroborate] (Tp^{Py}) [1, 2], which contains three *N,N'*-bidentate chelating arms linked by an apical boron atom, we observed formation of unusual tetrameric complexes $[M_4^{II}(Tp^{Py})_4]^{4+}$ with first-row transition metal dications (Mn, Fe, Co, Ni, Zn) [2]. Of these the Mn^{II} and Zn^{II} complexes have been crystallographically characterized. Whilst attempting to crystallize the Fe^{II} complex of this series we have observed formation of an unusual tetranuclear Fe^{III} complex **1**, arising from decomposition of the parent Tp^{Py} ligand with concomitant liberation of 3-(2-pyridyl)-pyrazole (HL). HL has been known for a while to be able to act as a simple bidentate chelate in mononuclear, octahedral iron(II) and nickel(II) complexes [3]. There is also the possibility of it being able to act as a terdentate bridging ligand *via* deprotonation of the pyrazolyl NH group and coordination of the pyrazolyl N^1 atom to a second metal ion. This coordination mode for L^- has not been observed until now, although pyrazolate anions are well known to be able to act as bis-monodentate bridges in other contexts [4].

Reaction of $K(Tp^{Py})$ with $FeSO_4\cdot 7H_2O$ in methanol (1 : 1 ratio) followed by precipitation of the complex with KPF_6 afforded a yellow solid†. Electrospray mass spectrometry indicated that it was the desired tetramer $[Fe_4^{II}(Ty^{Py})_4][PF_6]_4$, and an IR spectrum showed the characteristic $\nu_{B\text{-}H}$ band at *ca* 2450 cm^{-1}, con-

* Authors to whom correspondence should be addressed.

† *Preparations*. **1**: A mixture of KTp^{Py} (0.24 g, 0.5 mmol) and $FeSO_4\cdot 7H_2O$ (0.14 g, 0.5 mmol) in MeOH (20 cm^3) was stirred at room temperature to afford a yellow solution. Addition of excess aqueous KPF_6 afforded a yellow precipitate of $[Fe_4^{II}(Tp^{Py})_4][PF_6]_4$ which was filtered off, washed with water and dried *in vacuo*. Slow recrystallization by diffusion of diethyl ether vapour into an MeCN solution of the complex afforded brown crystalline blocks of **1**·4MeCN in 30% yield (based on Fe). FABMS: $m/z = 1555$ $\{M-PF_6^-\}$, 1410 $\{M-2PF_6^-\}$, 1264 $\{M-2PF_6^- - L\}$, 1120 $\{M-2PF_6^- - 2HL\}$, 976 $\{M-2PF_6^- - 2HL-L^-\}$.

2: Addition of a solution of HL (0.29 g, 2.0 mmol) in MeOH (20 cm^3) to a solution of $FeSO_4\cdot 7H_2O$ (0.25 g, 0.9 mmol) in MeOH (20 cm^3) immediately afforded a yellow precipitate. The suspension was stirred for 30 minutes in air, then the solid was filtered off, washed with methanol and dried *in vacuo*. Yield based on Fe: 85%. Recrystallization from $MeOH/H_2O$ afforded X-ray quality crystals. FABMS: $m/z = 924$ $\{M+Na^+\}$, 698 $\{M-Fe-HL\}$, 345 $\{Fe(HL)_2\}$.

Both complexes gave satisfactory elemental analyses. Unambiguous assignment of the asymmetric Fe—O—Fe stretch in the IR spectrum was not possible owing to the large number of other bands in the expected region (*ca* 770–850 cm^{-1}; ref. [7]).

firming that the Tp^{Py} ligand was intact. Recrystallization from MeCN diethyl ether (in air) over several days afforded brown crystals, which on X-ray analysis, were shown to be $[Fe_4^{III}(HL)_2(L)_6(\mu\text{-}O)_2][PF_6]_2\cdot 4MeCN$ (**1**·4MeCN)‡. Mass spectroscopic and analytical characterization of these crystals was in agreement with the crystal structure‡: also, the $\nu_{B\ H}$ band had disappeared from the IR spectrum.

The centrosymmetric complex cation of **1** is depicted in Figs 1 and 2, and has many unusual features. Each metal centre is coordinated by the bidentate pocket of two ligands L (pyridyl N and pyrazolyl N^2), one pyrazolate N^1 atom which acts as a bridge from an adjacent metal and an oxo ligand which acts as a bridge to a different metal, giving a pseudo-octahedral N_5O coordination sphere. The four bridging ligands, L^-, are all terdentate and deprotonated. The remaining four bidentate ligands, one on each metal ion, form two hydrogen-bonded pairs [Fig. 2a]. The separation between N(11) and N(71) [also N(11A) and N(71A)] is 2.78 Å, which is far too short for there to be two N—H bonds. Instead this short N···N separation is consistent with a weak N—H···N hydrogen bond between deprotonated (anionic) and protonated (neutral) pyrazole rings [5]. This was confirmed by the location of *two* very small, closely spaced peaks between N(11) and N(71) in the final Fourier difference map, consistent with the proton being disordered over two positions N—H···N and N···H—N. The formulation of **1** is therefore $[Fe_4(HL)_2(L)_6(\mu\text{-}O)_2][PF_6]_2$, which means that the metal ions must have a combined charge of +12, i.e. four Fe^{III} centres. This oxidation state assignment is confirmed by inspection of the Fe—O distances, which are all 1.77 Å: in contrast, the only structurally characterized $Fe^{II}(\mu\text{-}O)Fe^{III}$ complex has Fe—O distances of 1.999 and 2.069 Å [6]. The structural parameters of the metal–oxo core are in fact entirely typical of high-spin dinuclear Fe^{III} complexes linked by a single oxo bridge [7]. Aromatic π-stacking interactions between overlapping ligand segments are apparent, with inter-ring separations in the range 3.3–4 Å (Fig. 2b). This complex therefore provides an interesting example of a self-assembly process in which aromatic π-stacking and hydrogen bonding interactions, in addition to the normal metal–ligand bonding, contribute to the structure: the ability of L^- to be either bidentate and mononucleating, or terdentate and dinucleating, is also significant.

We attempted to prepare **1** deliberately by reaction of HL with $FeSO_4\cdot 7H_2O$ in methanol†. This afforded a yellow solid in good yield, but its spectroscopic data were not consistent with formation of **1** and accordingly its crystal structure was also determined (Fig. 3)‡. The product of this reaction was shown to be $[Fe_2^{III}(HL)_4(OSO_3)_2(\mu\text{-}O)]$ (**2**), which crystallized as **2**·2MeOH·$3H_2O$. The complex lies on a C_2 axis which passes through the oxo bridge [O(10)]. The two ligands HL on each iron(III) centre are simple bidentate chelates with protons attached to the non-coordinated pyrazolyl N^1 atoms. The structural parameters of the metal–oxo core are again entirely typical of high-spin dinuclear Fe^{III} complexes linked by a single oxo bridge [7]. There is again an aromatic π stacking interaction between two of the HL ligands, which are near-parallel and overlapping with separations of 3.2–3.6 Å from the atoms in one ligand to the mean plane of the other. The most unusual feature of this complex is that the sixth coordination site of each metal is occupied by a monodentate sulfate ion, which is to our knowledge the first time this has been observed in an oxo-bridged diferric complex. The only other structurally characterized $Fe_2^{III}(\mu\text{-}O)$ complex containing sulfate ligands is $[\{(Me_3tacn)Fe\}_2(\mu\text{-}O)(\mu\text{-}1,3\text{-}SO_4)_2]$ (Me_3tacn = *N*,*N*′,*N*″-trimethyl-1,4,7-triazacyclononane) in which the two sulfate ions bridge the iron centres [8]; similarly, $[\{Fe(NN)_2\}_2(\mu\text{-}O)(SO_4)_2]$ (NN = 2,2′-bipyridine or 1,10-phenanthroline) were proposed to have one sulfate ion bridging the two metal centres and one free sulfate, on the basis of their IR spectra [9]. Complex **2** is therefore a typical oxo-bridged diferric complex [7], albeit slightly unusual in having monodentate sulfate ligands.

‡ *Crystal data.* **1**·4MeCN: $C_{72}H_{62}F_{12}Fe_4N_{28}O_2P_2$, M = 1864.8, brown blocks, crystal size 0.8 × 0.5 × 0.3 mm³; triclinic, space group $P\bar{1}$; a = 10.101(3), b = 13.769(3), c = 16.227(5) Å; α = 96.51(2), β = 94.06(2), γ = 105.58(2)°; U = 2147.7(11) Å³; Z = 1; D_c = 1.442 g cm⁻³; $F(000)$ = 948; μ(Mo-$K\alpha$) = 0.786 mm⁻¹. The crystal was mounted in a sealed glass capillary tube with some of the mother liquor present to prevent solvent loss. 8410 data were collected with $2\theta_{max}$ = 46.5° at 293 K using a Siemens SMART diffractometer (Mo-$K\alpha$ radiation, graphite monochromator, λ = 0.71073 Å); after merging these gave 5971 unique data with R_{int} = 0.039.

2·2MeOH·$3H_2O$: $C_{34}H_{42}Fe_2N_{12}O_{14}S_2$, M = 1018.6, yellow blocks, crystal size 0.45 × 0.40 × 0.25 mm³; monoclinic, space group $C2/c$; a = 12.533(3), b = 19.612(2), c = 18.956(3) Å; β = 108.03(1)°; U = 4450.1(11) Å³; Z = 4; D_c = 1.520 mm⁻¹. The crystal was mounted in a sealed glass capillary tube with some of the mother liquor present to prevent solvent loss. 10,552 data were collected with $2\theta_{max}$ = 50° at 293 K using a Siemens SMART diffractometer (Mo-$K\alpha$ radiation, graphite monochromator, λ = 0.71073 Å); after merging these gave 3921 unique data with R_{int} = 0.052.

Both structures were solved by direct methods and refined on all F^2 data using the SHELX suite of programs [11]. All non-hydrogen atoms were refined with anisotropic thermal parameters; hydrogen atoms were included in calculated positions with isotropic thermal parameters. For **1**·4MeCN, refinement of 543 parameters converged at R_1 = 0.065, wR_2 = 0.190. The tetranuclear complex is centrosymmetric so each asymmetric unit contains half of the complex (two independent metal atoms) as well as one hexafluorophosphate anion and two molecules of MeCN. For **2**·2MeOH·$3H_2O$, refinement of 304 parameters converged at R_1 = 0.039, wR_2 = 0.111. The dinuclear complex lies on a C_2 axis so each asymmetric unit contains half of the complex (one independent metal atom) as well as one methanol molecule and 1.5 water molecules (of which the half molecule lies on the C_2 axis).

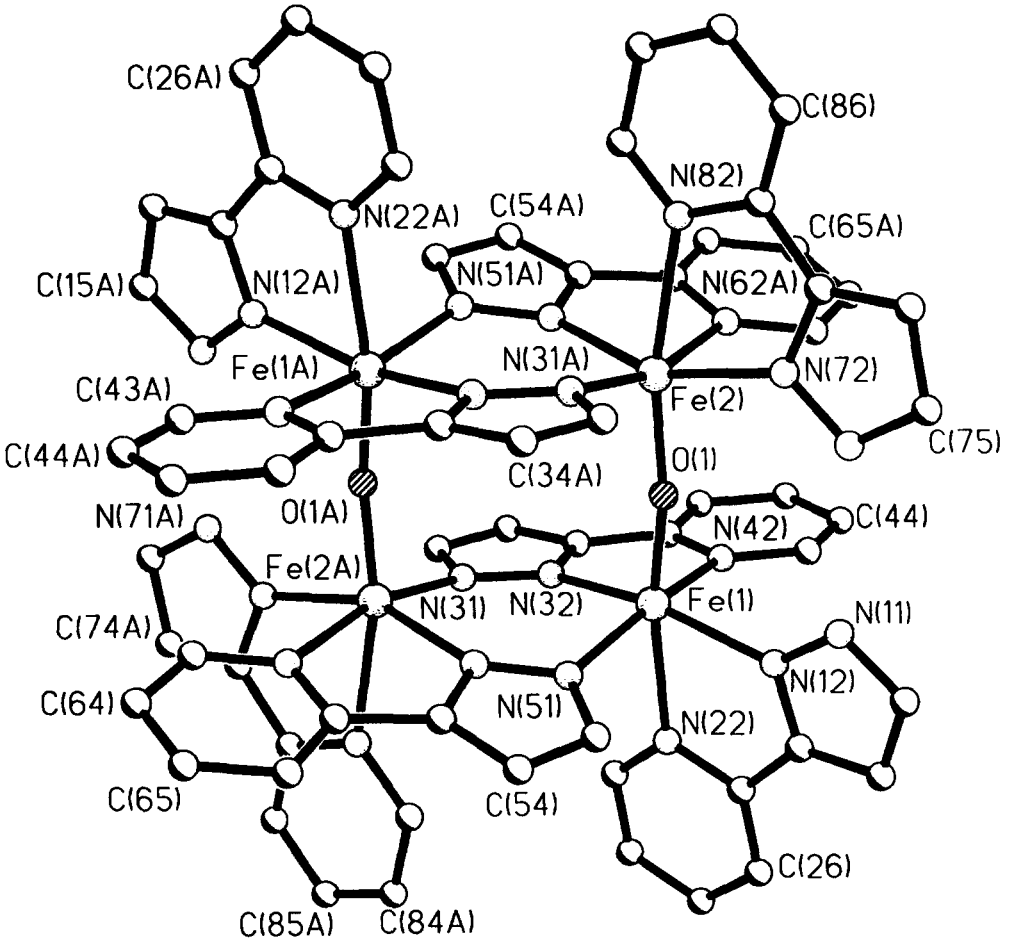

Fig. 1. Crystal structure of the dication of **1**. Selected bond lengths (Å) and angles (°): Fe(1)—O(1) 1.770(3), Fe(1)—N(12) 2.067(4), Fe(1)—N(32) 2.103(4), Fe(1)—N(51) 2.107(4), Fe(1)—N(42) 2.208(5), Fe(1)—N(22) 2.329(4), Fe(2)—O(1) 1.770(3), Fe(2)—N(31A) 2.096(4), Fe(2)—N(72) 2.094(5), Fe(2)—N(52A) 2.099(4), Fe(2)—N(62A) 2.204(5), Fe(2)—N(82) 2.339(5), Fe(1)...Fe(2) 3.517, Fe(1)...Fe(2A) 4.091; N(12)—Fe(1)—N(22) 73.7(2), N(32)—Fe(1)—N(42) 75.9(2), O(1)—Fe(1)—N(22) 169.6(2), O(1)—Fe(1)—N(12) 96.8(2), O(1)—Fe(1)—N(42) 94.4(2), O(1)—Fe(1)—N(32) 101.3(2), O(1)—Fe(1)—N(51) 99.4(2), N(72)—Fe(2)—N(82) 72.5(2), N(52A)—Fe(2)—N(62A) 76.0(2), O(1)—Fe(2)—N(82) 167.2(2), O(1)—Fe(2)—N(72) 94.9(2), O(1)—Fe(2)—N(62A) 95.7(2), O(1)—Fe(2)—N(52A) 106.0(2), O(1)—Fe(2)—N(31A) 98.1(2), Fe(1)—O(1)—Fe(2) 166.8(2).

We tried further to prepare **1** from direct reaction of HL with other iron salts not containing strongly coordinating anions, but without success: so far the only reliable preparation of **1** is by decomposition of $[Fe_4^{II}(Tp^{Py})_4][PF_6]_4$ in air during crystallization. Complex **2** may be considered as half of complex **1**, derived by breaking the bonds between the metal ions and the pyrazolate N^1 atoms, and filling the gaps with monodentate sulfate ligands: alternatively **1** is a dimer of **2**, derived from removal of the sulfate ligands and then allowing the vacancy at each metal site to be filled by a deprotonated bridging pyrazole from one of the ligands on an adjacent metal centre.

These complexes are of interest owing to their possible relevance as models for the active sites of non-heme iron proteins, which are widespread in nature [10]. Very many model complexes have been prepared that mimic the active sites of these metalloproteins, which has resulted in a very thorough understanding of the spectroscopic, electronic and magnetic properties of complexes containing the $Fe_2^{III}(\mu\text{-O})$ core [7]. We are attempting to prepare **1** in larger amounts because its magnetic properties are potentially interesting, with two oxo bridges and two pyrazolate bridges—both of which are known to be highly effective at mediating magnetic exchange interactions—linking the four Fe^{III} centres.

COMMUNICATION

Observations on the constitution of some "dithiocarbamato-bridged heterobimetallic complexes"

George Exarchos and Stephen D. Robinson*

Department of Chemistry, King's College London, Strand, London WC2R 2LS, U.K.

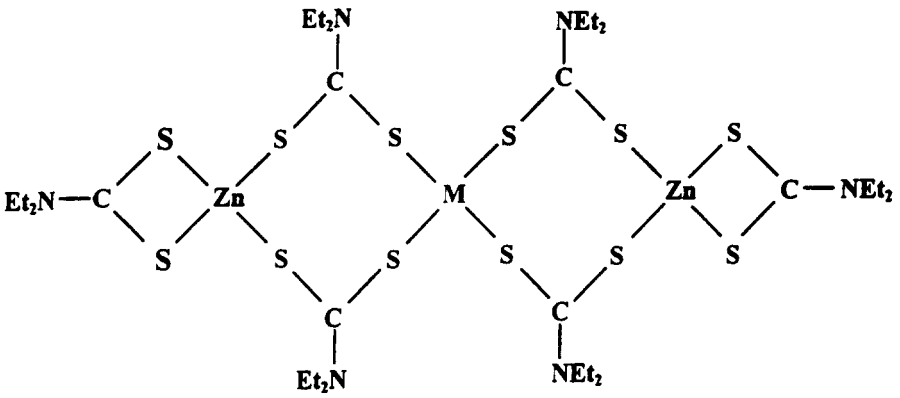
(Received 21 August 1996; accepted 3 September 1996)

Abstract—Some dithiocarbamato-bridged heterobimetallic complexes $[M'\{M(S_2CNR_2)_3\}_2]$ and $[\{M'M(S_2CNR_2)_4\}_n]$, obtained by successive addition of stoichiometric amounts of bivalent metal salts MX_2 (M = Zn, Cd or Hg) and $M'Y_2$ (M′ = VO, Mn, Fe, Co, Ni, Cu or Zn) to a solution of a sodium dithiocarbamate, are reformulated as mixtures of homonuclear complexes involving, in some instances (M′ = Mn, Fe or Co), trivalent $[M'(S_2CNR_2)_3]$ species. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: dithiocarbamate; bimetallic; transition metals.

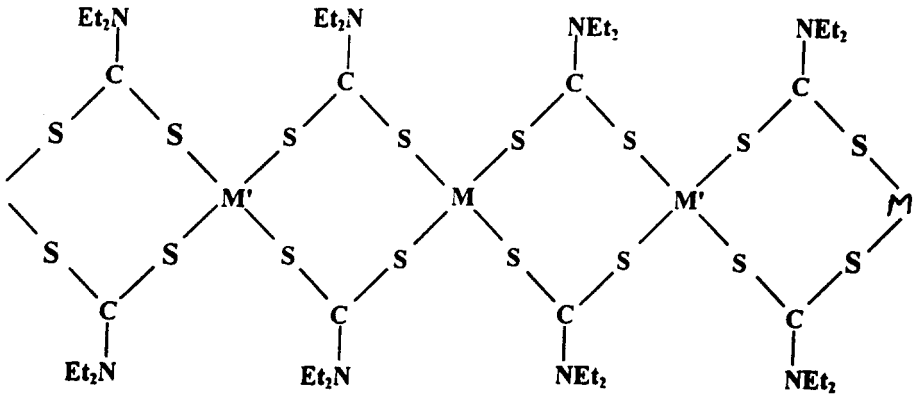
In a series of papers Aggarwal [1], Johri [2], Singh [3] and Sodhi [4] and their colleagues have reported that tri- and poly-nuclear dithiocarbamato-bridged complexes of the general forms **I** and **II** precipitate when stoichiometric amounts of divalent metal salts MX_2 (M = Zn, Cd or Hg; X = $MeCO_2$, NO_3) and $M'Y_2$ (M′ = VO, Mn, Fe, Co, Ni, Cu or Zn; Y = NO_3, Cl, $1/2SO_4$) in 4:1 acetone/water solution are added successively to a solution of a sodium dithiocarbamate salt in the same solvent mixture. The underlying reactions may be formulated as shown in Schemes 1 and 2.

$$3Na(S_2CNR_2) + MX_2 \rightarrow Na[M(S_2CNR_2)_3] + 2NaX$$
$$2Na[M(S_2CNR_2)_3] + M'Y_2 \rightarrow [M'\{M(S_2CNR_2)_3\}_2] + 2NaY$$



Scheme 1.

$$4Na(S_2CNR_2) + MX_2 \rightarrow Na_2[M(S_2CNR_2)_4] + 2NaX$$
$$Na_2[M(S_2CNR_2)_4] + MY_2 \rightarrow [\{M'M(S_2CNR_2)_4\}_n] + 2NaY$$



Scheme 2.

We have re-investigated these reactions and find that, contrary to the conclusions of the previous authors [1–4], the products precipitated are essentially mixtures of bis(dithiocarbamato) complexes $[\{M(S_2CNR_2)_2\}_n]$, $[\{M'(S_2CNR_2)_2\}_n]$ (n = 1 or 2) and, in some instances, the heterobinuclear species $[MM'(S_2CNR_2)_4]$. Furthermore, we find that when divalent salts of manganese, iron or cobalt are involved spontaneous oxidation to the trivalent state occurs leading to the formation of tris(dithiocarbamato) complexes $[M'(S_2CNR_2)_3]$ (M′ = Mn, Fe or Co). Our concerns regarding these reactions were first raised by the novel structures proposed for the products, none of which was supported by X-ray crystallographic evidence. In particular there is no obvious thermodynamic reason why heterometallic dithiocarbamato complexes involving divalent metal ions should adopt tri- or poly-nuclear structures **I** and **II**, respectively, when the corresponding simple divalent metal dithiocarbamates $[\{M(S_2CNR_2)_2\}_n]$ and $[\{M'(S_2CNR_2)_2\}_n]$ (n = 1 or 2) are monomers or dimers [5,6], with the latter tending to dissociate in solution [6–9]. Furthermore, the structural differences can hardly be attributed to kinetic factors since our ^1H NMR studies on the mixed systems $[M(S_2CNEt_2)_2]$/$[M'(S_2CNPr^i_2)_2]$ confirm previous reports [10] that the

(III)

dithiocarbamates of divalent transition metal ions are generally labile with respect to ligand exchange.

In order to confirm our belief that these "heterobimetallic" complexes are simple mixtures, samples of "$[Ni\{Zn(S_2CNEt_2)_3\}_2]$" prepared in the prescribed manner [3] were examined by NMR and X-ray powder diffraction methods. The sharp, well-resolved ^1H and $^{13}C-\{^1H\}$ NMR spectra of "$[Ni\{Zn(S_2CNEt_2)_3\}_2]$" were found to be identical with composite spectra of $[Ni(S_2CNEt_2)_2]$ and $[\{Zn(S_2CNEt_2)_2\}_2]$. Given that the chemical shifts recorded for these two homonuclear species display very significant differences (^1H *ca* δ 0.1–0.3, $^{13}C-\{^1H\}$ δ 5) it is highly unlikely that the NMR spectra of a heterobimetallic dithiocarbamato-bridged species could not be demonstrably different from those observed for the simple complexes. Likewise, we find that the X-ray powder pattern of "$[Ni\{Zn(S_2CNEt_2)_3\}_2]$" is essentially identical with the combined patterns of $[Ni(S_2CNEt_2)_2]$ and $[\{Zn(S_2CNEt_2)_2\}_2]$. We have also investigated the first product deposited from a synthesis of "$[Cu\{Zn(S_2CNEt_2)_3\}_2]$". Here, because of the paramagnetic nature of d^9 copper(II), only broad NMR resonances are observed from which little can be concluded. We therefore sought evidence from X-ray crystallographic data. The X-ray powder photographs of the copper/zinc product do indeed indicate the presence of a single phase. However, the unit cell parameters derived therefrom lie essentially midway between the closely related sets of data reported for $[\{Cu(S_2CNEt_2)_2\}_2]$ and $[\{Zn(S_2CNEt_2)_2\}_2]$. Given that *both* copper [9] and zinc [8] bis(dithiocarbamates) exist as dimers in the solid state we suggest that the lines present in the pattern of the precipitated product are attributable to the mixed *binuclear* species $[CuZn(S_2CNEt_2)_4]$(**III**) which is preferentially deposited because of lower solubility. Such binuclear species have been detected and characterized by Ivanov and co-workers [11–13] in the course of their ESR studies on paramagnetic copper(II) dithiocarbamates doped in low concentrations into the corresponding zinc dithiocarbamate lattices using preparative procedures similar to those employed by Aggarwal [1], Johri [2] and Singh [3] and colleagues.

A second and more serious reservation arises in the case of the species "$[\{MM'(S_2CNR_2)_4\}_\infty]$" (M′ = Mn, Fe or Co). These products, which purport to contain four-coordinate manganese(II), iron(II) and cobalt(II), respectively, were all apparently prepared in open vessels without protection from atmospheric oxygen [1,2]. Given that the simple bis(dithiocarbamato) complexes of manganese(II) [14,15] iron(II) [16] and cobalt(II) [17] are notoriously air sensitive, readily undergoing oxidation to the trivalent state and, in the case of manganese(II), reported pyrophoric [14], it seems highly improbably that heterometallic dithiocarbamato complexes containing these metals in the divalent state would be stable with respect to aerobic oxidation. Indeed, it has been reported that cobalt(II) salts, on treatment with aqueous sodium diethyldithiocarbamate, undergo spontaneous oxidation to the trivalent state *even under strictly anaerobic conditions* [14]. Our belief that oxidation occurs in the syntheses involving manganese, iron and cobalt and that the products are merely mixtures of $[\{M(S_2CNEt_2)_2\}_2]$ (M = Zn, Cd or Hg) and $[M'(S_2CNEt_2)_3]$ (M′ = Mn, Fe or Co) is strongly supported in the case of manganese by the observation that the products isolated are all reported [1,2] to display the violet colour associated with the relatively air-stable manganese(III) dithiocarbamates, rather than the bright yellow characteristic of their very air-sensitive manganese(II) counterparts [15]. Moreover, the electronic spectra (700–200 nm, CH_2Cl_2 solution) of the products "$M'\{Zn(S_2CNEt_2)_2\}_2]$" (M′ = Mn, Fe or Co) are essentially the same as those obtained by combining the spectra of $[\{Zn(S_2CNEt_2)_2\}_2]$ and the corresponding trivalent complexes $[M(S_2CNEt_2)_3]$.

In the case of the cobalt/zinc product "$[Co\{Zn(S_2CNEt_2)_3\}_2]$" the NMR spectra recorded by the previous authors [3] and confirmed in our present work display no evidence of the paramagnetic shifts or line broadenings expected for complexes containing d^7 cobalt(II) [17,18]. On the contrary, they are identical to those obtained by superimposing the spectra of $[Co(S_2CNEt_2)_3]$ and $[\{Zn(S_2CNEt_2)_2\}_2]$. In particular the ^1H NMR spectrum of the supposed heterobimetallic product displays the AB part of an ABX_3 pattern arising from the diastereotopic methylene protons [19], identical to that observed for an authentic sample of octahedral $[Co(S_2CNEt_2)_3]$.

Preliminary studies suggest that a parallel series of "heterobimetallic xanthates" reported by the same authors [20–22] should likewise be reformulated in many instances as mixtures of essentially homometallic complexes. A fuller study of these and some related systems will be reported in due course.

Synthesis and characterization of the first gold(I) complex of reduced epidithiopiperazine-2,5-dione

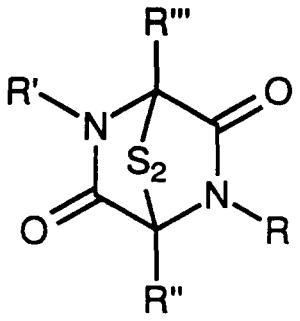
Christina L. L. Chai,* David C. R. Hockless and K. D. Vinindra Weerasuria

Department of Chemistry and the Research School of Chemistry, The Australian National University, ACT 0200, Australia

(Received 12 August 1996; accepted 27 August 1996)

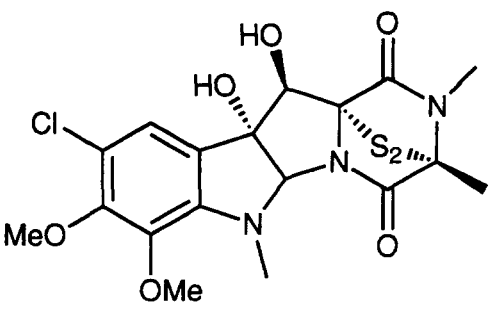
Abstract—1,4-Diethyl-3,6-dithiopiperazine-2,5-dione reacted with triphenylphosphine gold chloride to form the corresponding gold complex, the structure of which was determined by X-ray crystallography. The gold(I) complex reacted with iodine to form 5,7-diethyl-2,3-dithia-5,7-diazabicyclo-[2.2.2]octan-6,8-dione. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: gold(I) complex; epidithiopiperazine-2,5-dione.



Compounds of many transition metals have proved to have medicinal value in both diagnosis and therapy [1]. Metal complexes such as cisplatin and its analogue carboplatin are capable of acting as selective cytotoxic agents [2], whereas auranofin and myocrisin are important gold drugs for the treatment of rheumatoid arthritis [3]. In other cases, biologically active compounds complexed with transition metals have enhanced biological properties [4].

Epidithiopiperazine-2,5-diones (**1**) are a class of compound that displays a wide range of biological activities [5]. For example, sporidesmin (**2**) is a toxin that causes the disease facial eczema in sheep and cattle, whereas gliotoxin (**3**) is a potent immunosuppressant. Studies have shown that the reduced form of the disulfide (i.e. dithiol) is also biologically active but thioalkylation of the sulfurs or desulfurization renders these compounds inactive [6]. The biological effects of these compounds can be abrogated with the use of metals such as zinc, mercury and cadmium and this has been attributed to the formation of metal thiolato complexes [7]. Recently, the detection of sporidesmin dianionic dithiolato complexes with zinc and cadmium by electrospray mass spectrometry was reported [8]. In this paper, we report the first isolated and fully characterized transition metal complex of 1,4-diethyl-3,6-dithiopiperazine-2,5-dione (**4**), the reduced form of a synthetic epidithiopiperazine-2,5-dione. It is hoped that the chemistry and biological properties of this metal complex will provide further insight into the biological mechanism of action of this class of compounds.



1,4-Diethyl-3,6-dithiopiperazine-2,5-dione (**4**) was synthesised following a modification of Trown's synthesis [9]. 1,4-Diethylpiperazine-2,5-dione was brominated with 2 equivalents of *N*-bromosuccinimide, followed by conversion of the corresponding dibromide to the dithioacetate at 0°C. Only the *cis* diastereomer was observed and hydrolysis (HCl/MeOH) gave the corresponding *cis*-dithiol in excellent yields. After extensive drying to remove water and residual acid, the dithiol was treated with triethylamine (2 equiv.) in dichloromethane, followed by the addition

of triphenylphosphine gold chloride (2 equiv.) in dichloromethane. After work-up, the gold(I) dithio complex (**5**) was isolated in excellent yields (95%).†The ^{1}H NMR spectra showed a shift of the methine signal from δ 5.04 in the dithiol derivative to δ 5.4 in the gold complex. The sulfhydryl proton for the dithiol (δ 3.15) also disappeared upon complexation with triphenylphosphine gold chloride. ^{31}P NMR of the complex showed only one signal at δ 37.6. Other spectral data (IR, ^{13}C NMR), as well as combustion analysis, confirms the proposed structure. In addition, recrystallization from dichloromethane/ether gave crystals suitable for X-ray crystal structure analysis.‡

‡Crystal data for compound **5**: $C_{44}H_{42}N_2O_2P_2S_2Au_2$, M = 1150.83, T = 296(1) K, monoclinic, space group $C2/c$; a = 23.854(1), b = 11.812(3), c = 16.768(2) Å, β = 117.067(6)°, U = 4207(1) Å^3, D_c (Z = 4) = 1.82 g cm^{-3}, F(000) = 2224, μ(Cu-K_α) = 150.6 cm^{-1}, semi-empirical absorption correction; 3302 unique data ($2\theta_{max}$ = 120.1°), 2466 with $I > 3\sigma(I)$; R = 0.045, wR = 0.048, GOF = 2.56. Data were measured on a Rigaku AFC6R rotating anode diffractometer (graphite crystal monochromator, λ = 1.54180 Å). Refinement was by full-matrix least squares analysis on F using the teXsan structure analysis software of Molecular Structure Corporation [18].

The structure of the gold dithiolato complex is shown in Fig. 1. The piperazinedione ring is characterized by a boat conformation consistent with conformations observed for *cis*-α,α′-disubstituted piperazinediones [10]. The dithio functionalities adopt pseudoaxial positions and the molecule on the whole possesses a twofold axis of rotation. The conformational parameters [11] were as follows: ψ[N(1*)—C(1)—C(2)—N(1)] −23.8 (15)°, φ[C(1)—C(2)—N(1)—C(1*)] 26.7 (16)°, ω[C(2)—N(1)—C(1*)—C(2*)] −2.5 (17)°. The latter value shows that the deviation from planarity is small. The Hooker parameter β [12], measuring the degree of folding of the piperazinedione ring, is 26°.

The gold complex also possesses a short Au—Au bond distance of 3.0440(9) Å. Typically, short intramolecular Au^I—Au^I distances are observed for complexes in which two 1,2- or 1,3-difunctional bidentate ligands hold a pair of gold(I) atoms, and values as short as 2.76 Å have been reported [13]. For the gold complex **5**, Au—S and Au—P bond lengths of 2.308(3) and 2.267(3) Å are observed. The former is slightly longer than the observed Au—S bond length for auranofin (2.29 Å) [14]. The C—S bond length of 1.85(1) Å is slightly longer than the normal C—S value of 1.82 Å, but is shorter than the C—S bond distances found in gliotoxin (**3**) (1.89 Å) [15] and

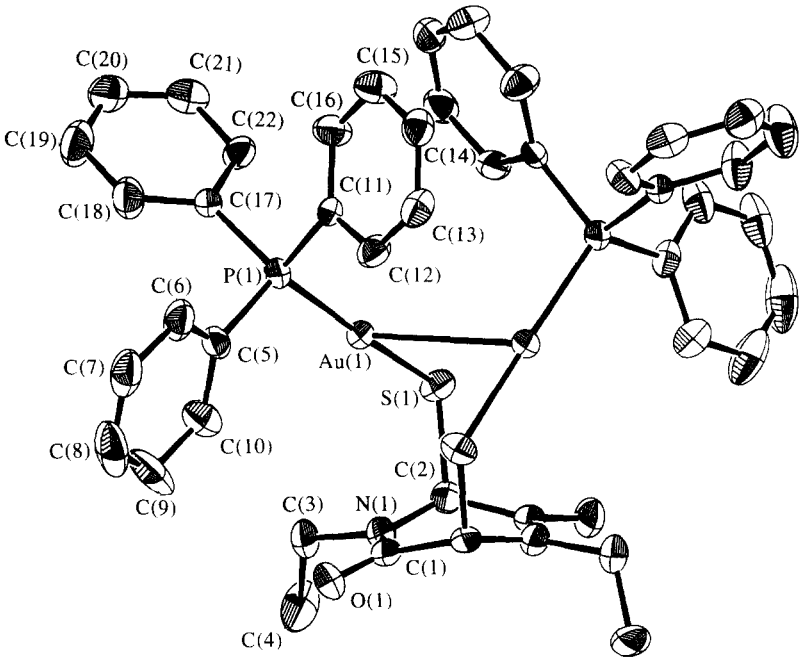

Fig. 1. A perspective view of the gold(I) dithiolato complex (**5**). Selected bond lengths (Å) and angles (°): Au(1)—Au(1) 3.044(9), Au(1)—P(1) 2.267(3), Au(1)—S(1) 2.308(3), S(1)—C(2) 1.85(1), O(1)—C(1) 1.22(1), N(1)—C(1) 1.36(1), N(1)—C(2) 1.45(1), N(1)—C(3) 1.45(1), C(1)—C(2) 1.51(1). Au(1)—Au(1)—S(1) 79.04(9). S(1)—Au(1)—P(1) 172.4(1), Au(1)—Au(1)—P(1) 106.27(8), Au(1)—S(1)—C(2) 107.2(4), C(1)—N(1)—C(2) 124.0(10), N(1)—C(1)—C(2) 117(1), S(1)—C(2)—N(1) 114.5(8), S(1)—C(2)—C(1) 110.0(8), N(1)—C(2)—C(1) 113(1).

sporidesmin (**2**) (1.90 Å) [16]. In addition, it is important to note that the coordination about gold(I) is slightly bent, with P—Au—S angles of 172.4(1) . This value is close to the observed angle for auranofin of 173.6°, but deviates significantly from the ideal value of 180° for linearity.

The ease of oxidative addition of gold centres has been reported [17]. In our studies, dropwise addition of I_2 in chloroform as monitored by NMR spectroscopy did not yield the corresponding Au^{I}/Au^{III} systems, nor Au^{II}/Au^{II} systems. Instead, formation of the disulfide, the epidithiopiperazine-2,5-dione was observed. The ease of oxidation of the gold dithiolato derivative to the disulfide is noted by the quantitative conversion with excess I_2.

The studies here have demonstrated that stable gold(I) dithio derivatives of piperazine-2,5-diones can be synthesized. Owing to the biological importance of these derivatives, it is interesting to examine the biological properties of these new metal piperazinedione complexes. Such studies could lead to the discovery of new and more selective therapeutic drugs, as well as further elucidation into the mechanism of action of epidithiopiperazinedione derivatives.

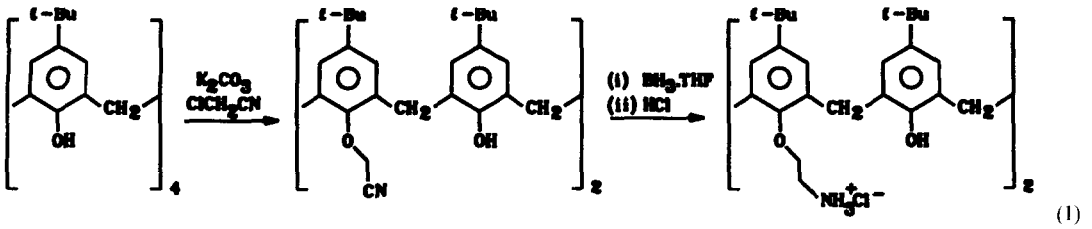
Lower rim alkylammonium-substituted calix[4]arenes as "proton-switchable" extractants for chromate and dichromate anions

Emil M. Georgiev,[a] Nicholas Wolf[b] and D. Max Roundhill[b]*

[a] Department of Chemistry, Tulane University, New Orleans, Louisiana 700118, U.S.A. and
[b] Department of Chemistry and Biochemistry, Texas Tech University, Lubbock, TX 79409-1061, U.S.A.

(Received 16 June 1996; accepted 12 August 1996)

Abstract—The compound 5,11,17,23-tetra-tert-butyl-25,27-bis(2-aminoethoxy)-26,28-dihydroxycalix[4]arene (**2**) has been synthesized by the borane reduction of 5,11,17,23-tetra-tert-butyl-25,27-bis(2-dicyanomethoxy)-26,28-dihydroxycalix[4]arene (**1**). The protonated alkylammonium form of **2** is an effective extractant for transferring the anions CrO_4^{2-} and $Cr_2O_7^{2-}$ from an aqueous into a chloroform layer. The monoanions Cl^-, $CH_3CO_2^-$ and NO_3^-, and dianions SO_4^{2-}, MoO_4^{2-} and WO_4^{2-} have little effect on the extraction of CrO_4^{2-} and CrO_7^{2-}. Deprotonation of the dialkylammonium cation results in reversal with CrO_4^{2-} and $Cr_2O_7^{2-}$ migrating back into the aqueous layer. © 1997 Elsevier Science Ltd. All rights reserved.



Keywords: calixarene; amino; chromate; dichromate.

The synthesis of complexants and hosts for specific metals is an important goal, especially if the metal is a commercially valuable one that is currently an environmental problem. For cations the metal can be directly bound to a ligating group on the host, but for anions or uncharged molecules there may be no direct interaction between the metal centre and the host. Although there are numerous examples of molecules that act as hosts and complexants for cations, there are fewer examples of molecules that act as hosts for anions [1–4]. Recently, however, a number of chemically modified calixarenes have been synthesized that can be used as hosts for simple anions [5]. From an environmental viewpoint, two important anions for which a selective host would be useful are chromate and dichromate. These particular ions are important because of their high toxicity [6–11] and because of their presence in soils and waters [12].

In designing complexants for these particular guest anions a number of structural features can be incorporated into the host molecule that may be important in achieving selective binding. For such a molecule to be effective as a host it is necessary that its structural features are compatible with those of the guest anion. Although there have been some recent reports of chemically modified calixarenes acting as host molecules for simple anions, none has yet been used as host for CrO_4^{2-} and $Cr_2O_7^{2-}$ [13]. Because the periphery of a chemically modified calixarene can be made structurally compatible with these ions we have targeted the synthesis of an extractant for them based on a calix[4]arene framework.

The chromate and dichromate ions CrO_4^{2-} and $Cr_2O_7^{2-}$ are dianions with oxide functionalities at their periphery. Since the metal centre does not bind to additional ligands there is no advantage in designing a host that can act as a complexant to it. Nevertheless, since the periphery of the anions have oxide moieties, these are potential sites for hydrogen bonding to the host molecule. We now report the synthesis of a chemically modified calix[4]arene that is an extractant for both CrO_4^{2-} and $Cr_2O_7^{2-}$ from an aqueous solution into a chloroform layer. This compound is

1 2 (1)

5,11,17,23-tetra-tert-butyl-25,27-bis(2-aminoethoxy)-26,28-dihydroxycalix[4]arene bis hydrochloride. This particular calix[4]arene is a dication for the formation of a neutral ion-paired complex with CrO_4^{2-} and $Cr_2O_7^{2-}$, and it also has both hydroxyl and alkylammonium functionalities that can potentially form hydrogen bonds with these anions.

The synthetic route to this extractant follows that used for other 2-aminoethoxy-substituted calix[4]arenes and is shown in Eq. (1) [14]. The initial compound, 5,11,17,23-tetra-tert-butyl-25,27-bis(2-dicyanomethoxy)-26,28-dihydroxycalix[4]arene (**1**), has been prepared according to the literature procedure [15]. Reduction with a solution of borane in THF, followed by conversion to the amine hydrochloride salt with HCl, gives the product **2**. The compounds **1** and **2** show the following characteristic spectroscopic features: **1**, ^{1}H NMR ($CDCl_3$): δ 0.88 (s, Bu^t), 1.32 (s, Bu^t), 3.45 [d, CH_2, ^2J(HH) = 13.6 Hz], 4.23 [d, CH_2, ^2J(HH) = 13.6 Hz], 4.81 (s, CH_2), 5.57 (s, OH), 6.73 (s, ArH), 7.12 (s, ArH). **2**, ^{1}H NMR (DMSO-d_6): δ 1.12 (s, Bu^t), 1.17 (s, Bu^t), 3.50 [d, CH_2, ^2J(HH) = 12.4 Hz], 4.10 (d, CH_2, ^2J(HH) = 12.4 Hz], 3.51 [t, CH_2, ^3J(HH) = 7 Hz], 4.25 [t, CH_2, ^3J(HH) = 7 Hz], 7.18 (s, ArH), 8.54 (br s, OH + NH_3). Mass spectrum: m/z 735 (M − 2HCl).

Aqueous solutions of Na_2CrO_4 and $K_2Cr_2O_7$ show no extraction into a chloroform layer in the absence of a complexant. Furthermore, the alkylammonium salts of butylamine, *N*,*N*-dimethylbutylamine, tributylamine, ethylenediamine and *N*,*N*,*N*′,*N*′-tetramethylethylenediamine also show no extraction for these anions. However, when the protonated alkylammonium salt of **2** is added, extraction of CrO_4^{2-} and $Cr_2O_7^{2-}$ into the chloroform layer occurs. At ratios of CrO_4^{2-} : **2** of 1 : 0, 1 : 1, 1 : 2 and 1 : 20 the respective partition coefficients ($CHCl_3$: water) are 0, 0.5, 1.0 and 80, showing that the protonated form of **2** is an effective host. The absorption spectra of the guest CrO_4^{2-} and $Cr_2O_7^{2-}$ molecules and the ^{1}H NMR spectrum of the host **2** are unchanged, indicating that no chemical reaction has occurred between them. The extraction of CrO_4^{2-} and $Cr_2O_7^{2-}$ into chloroform by **2** in the presence of a ten-fold excess of Cl^-, SO_4^{2-}, $CH_3CO_2^-$, HPO_4^-, NO_3^-, MoO_4^{2-} and WO_4^{2-}, themselves potential guest anions for **2**, has been inves-

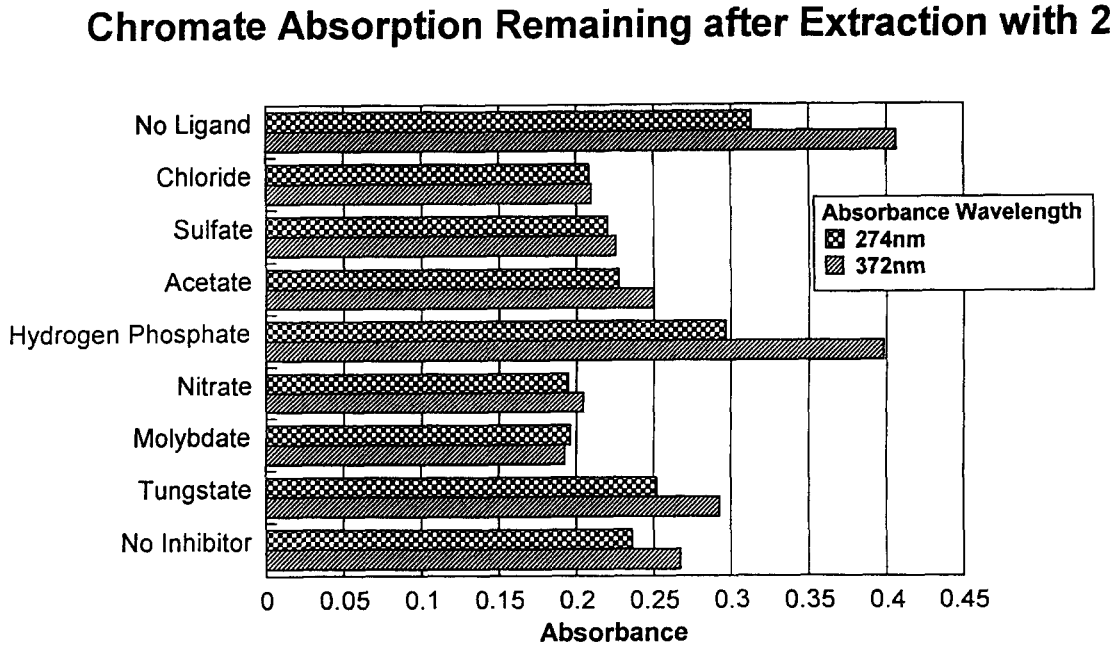

Fig. 1. Quantity of CrO_4^{2-} remaining in aqueous solution after extraction with **2** in chloroform in the presence of potential inhibitors. In each case the ratio of CrO_4^{2-} : **2** is 1 : 1, and the ratio of CrO_4^{2-} : inhibitor is 1 : 10.

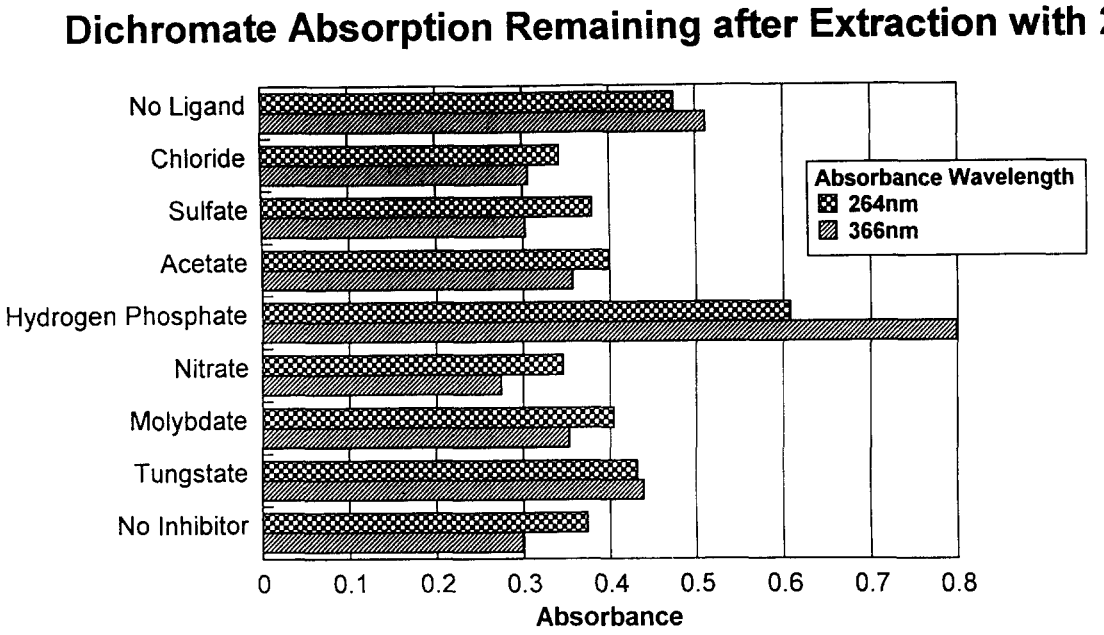

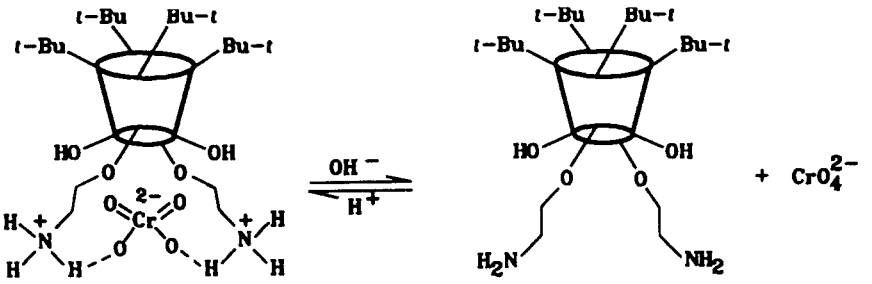

Fig. 2. Quantity of $Cr_2O_7^{2-}$ remaining in aqueous solution after extraction with **2** in chloroform in the presence of potential inhibitors. In each case the ration of $Cr_2O_7^{2-}$: **2** is 1 : 1, and the ratio of $Cr_2O_7^{2-}$: inhibitor is 1 : 10.

(2)

tigated. The data in Figs 1 and 2 show that the monoanions Cl^-, $CH_3CO_2^-$ and NO_3^-, with the exception of HPO_4^-, and the dianions, have little effect on the extraction of CrO_4^{2-} and $Cr_2O_7^{2-}$ [16].

Upon addition of NaOH to the aqueous layer, the deprotonated calixarene in the chloroform is no longer an effective host molecule for CrO_4^{2-} and the dianion then migrates back into the aqueous layer in a reversible process [Eq. (2)] [17].

Abstract—The three-dimensional (3D) polymers $[(Me_3Sn)_3Fe(CN)_6]_\infty$ (**I**) and $[(Me_3pb)_3Fe(CN)_6]_\infty$ (**II**) which have wide internal cavities capable of incapsulating voluminous organic compounds behave as host acceptors forming charge transfer complexes (CTC). Thiazole and benzothiazole derivatives acting as guest donor species are encapsulated within the cavities of the 3D polymeric hosts **I** or **II** forming yellow to green or red CTC having, in some cases, semiconducting properties. Some of the donors containing an amino group undergo polymerization within the cavities of the host polymers forming new molecular composites having pronounced electrical conductivity when doped in 2 M HCl solution. The interesting feature of these composites is the enhanced electronic conductivities exhibited by encapsulation of the conductive polymers within the cavities of the host 3D polymers. © 1997 Elsevier Science Ltd. Keywords: change transfer complexes; thiazole; benzothiazole; molecular composites; 3D-host polymers.

The novel supramolecular polymers of the type $[(R_3E)_nM(CN)_6]_\infty$ (where R = alkyl or phenyl, E = Sn or pb and M = Fe, Co or Ru) have different potential applications as they act as ion exchangers [1–3], oxidative materials [4] and 3D-hosts which serve as templates within which guest molecules are assembled and also as acceptors forming CTC [5–8]. Their structure is based on a 3D network of the octahedral $M(CN)_6$ building blocks and the trigonal bipyramidal (R_3E) connecting units. The octahedral $M(CN)_6$ building blocks are linked to each other *via* the trigonal bipyramidal [···CN—E(R_3)—NC···] configuration. The framework structures create wide parallel channels or cavities with diameters typically of *ca* 9.5 Å [7,9] into which many interesting reactions including electron or charge transfer have been explored.

In this article the reactions involving the intercalation of thiazole and benzothiazole derivatives acting as electron donors within the cavities of the 3D polymers $[(Me_3E)_3Fe(CN)_6]_\infty$, where E = Sn or Pb acting as electron acceptors, have been studied to obtain novel CTC. Thiazoles and benzothiazoles have wide applications in the fields of pharmaceutical, analytical and industrial chemistry [10]. However, although electronically conducting heteroatamic polymers such as polypyrrole and polythiophene have received considerable attention because of their remarkable electronic, magnetic and optical applications, there have been no such studies on thiazoles and benzothiazoles. The present report also reveals the formation of paramagnetic CTCs having conducting properties.

EXPERIMENTAL

Materials and preparations

All reagents used in this study were of the purest grade and purchased from either Aldrich or Sigma

*Author to whom correspondence should be addressed.

and used without further purification. However, thiazole and benzothiazole derivatives were purified by sublimation (solid materials) *in vacuo* or by recrystallization from ethanol and by distillation (liquids) *in vacuo*, and kept under nitrogen while thiazole was used as received. The orange precipitate of the host polymers **I** and **II** were obtained by mixing aqueous solutions of Me_3SnCl or Me_3PbCl, respectively, and $K_3Fe(CN)_6$ in 3 : 1 molar ratio under nitrogen in the dark. Each precipitate was filtered off, washed with water and then CH_2Cl_2. The purity and identity of **I** and **II** were checked by elemental analysis and IR spectroscopy (Tables 1 and 2). The CTCs were prepared by adding the dry freshly prepared **I** or **II** to an excess of the donor, thiazole or benzothiazole derivative, with continuous grinding at 5°C or at room temperature. The reaction rate was greatly increased by addition of a few drops of ethanol, while in the case of thiazole no solvent was added. After the addition of thiazole to **I** or **II** a deep red colour appeared which faded in time (*ca* 24 h) giving a stable yellow product. Thus, the red product was kept under nitrogen while all measurements were carried out directly after preparation. On the other hand, the CTCs **3′**, **8′**, **10′**, **14′** and **16′** were prepared by the method described above in the presence of a few drops of 2 M HCl solution. Also, the 2-aminothiazole and 2-aminobenzothiazole derivatives were subjected to oxidation by the addition of ammonium persulfate in the presence of 2 M HCl at 5°C to produce the corresponding polymers.[11] Only, 2 aminothiazole (**3″**), 2-aminobenzothiazole (**8″**) and 2-amino-6-methylbenzothiazole (**10″**) underwent polymerization under these experimental conditions giving brown or greenish-brown polymers. Since **I** and **II** are photo-and air-sensitive [12] all manipulations were carried out in the dark under nitrogen. The products were washed with ethanol several times and dried *in vacuo*. The colour and the composition of the CTC depended on the type of the donor, the reaction time and grinding (Table 1).

Instruments

All the analytical, spectroscopic and conductivity measurements as well as the instruments are as previously described [5,6].

RESULTS AND DISCUSSION

Analytical data

The stoichiometry of the CTC [moles donor (x) per mole acceptor polymer] was deduced from chemical analysis (Table 1). The results reveal that most of the donor molecules can intercalate within the channels of the polymers **I** and **II** with an amount less than 1 mol ($x < 1$) per mol of polymer while thiazole (compound **2**) reacts in the ratio 1 : 1 ($x = 1$). On the other hand, thiazole and some of the amino derivatives (compounds **1, 3, 8, 10, 13** and **16**) reacted in the ratio 3 : 2 ($x = 1.5$). The results revealed in addition that several samples contained some ethanol amounting to more or less the quantity of the donor species interca-

lated. Although the significance of the presence of the solvent molecules in these CTCs is not clear, it is worth noting that such results have been previously found for several other intercalates of the present polymers and of FeOCl [6,13].

IR spectra

The IR spectra of the CTC exhibit the characteristic bands of the corresponding donor and the acceptor polymer. These bands suffer some changes from those of the free donors [14] and the acceptor polymers (Table 2). The IR spectra of the CTCs **4, 5, 6, 11** and **12** showed broad bands at 3370–3420 cm^{-1} corresponding to ν_{NH}. The solvent molecules absorb around 3430 cm^{-1} due to ν_{OH}. The presence of the solvent molecules in the composition of most of the CTC was also confirmed by TGA where a stoichiometric ratio of one ethanol molecule per mole of the acceptor polymer (Table 1) was released in the temperature range 80–100°C. The ν_{CH} bands of the thiazole and benzothiazole moieties appear at 3048–3097 cm^{-1}, while those of $\nu_{C=N}$ and $\nu_{C=C}$ are located around 1625 and 1520 cm^{-1}. Generally, the IR bands due to the thiazole or benzothiazole donors suffer a shift to lower wavenumbers on CT complexation. On the other hand, the IR spectra of the polymers **I** and **II** exhibit drastic changes on CT complexation. A new strong band appears at 2065–2086 cm^{-1} due to $\nu_{Fe^{II}-CN}$ while the band due to $\nu_{Fe^{III}-CN}$ suffers a shift to lower wavenumbers with a dramatic decrease in relative intensity. Also, a new medium-to-weak band appears at 2180–2190 cm^{-1}, which may be attributed to the stretching frequency of some free terminal cyanide groups. In addition to the medium band at 410 cm^{-1} due to $\nu_{Fe^{III}-CN}$, a weak-to-medium band appears at 445–465 cm^{-1} corresponding to $\nu_{Fe^{III}-CN}$, indicating partial reduction of Fe^{III} to Fe^{II} by the thiazole or benzothiazole donor forming CTC.

In the case of thiazole, 2-aminothiazole, 2-aminobenzothiazole and 2-amino-6-methylbenzothiazole (compounds **1, 3, 8, 10, 13, 14** and **16**) the host polymer **I** or **II** was completely reduced to the isostructural, but anionic homologue $[(Me_3E)_3Fe^{II}(CN)_6]^-$. This is gathered by the disappearance of the bands at 2146–2122, 2110–2115 and 410 cm^{-1} due to $Fe^{III}CN$ building blocks and the appearance of strong-to-medium bands at 2075, 2040 and 450 cm^{-1} due to $Fe^{II}CN$ building blocks. Also the broad band due to ν_{NH_2} disappears and instead a sharp band appears at 3220–3289 cm^{-1}, corresponding to ν_{NH} indicating polymerization of these donors within the channels of the polymers **I** and **II** forming stable 3:2 molecular composites.

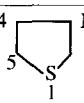
Upon intercalation, the acceptor polymers remain having channels as wide as the donor molecules can accommodate forming CTC as gathered from the presence of the characteristic bands of the (Me_3E) connecting units at 2980, 2900, 2800 and 780 cm^{-1} due to different modes of vibrations of the methyl groups and at 550 and 495 cm^{-1} due to ν_{Sn-C} and ν_{Pb-C}, respectively. The presence of two ν_{CH} bands at 2980 and 2900 cm^{-1} could arise from crystallographic non-equivalence of methyls in the distorted trigonal-bipyramidal structure of the zigzag chains and from methyls in linear chains [15].

NMR spectra

The ^1H NMR spectra of the CTCs were measured in alkaline NaOD solution. The CTCs dissociate after

heating the solution according to the following equation:

$$[(D^+)_x(Me_3E)_3Fe^{II}_xFe^{III}_{1-x}(CN)_6]_\infty \xrightarrow[\text{heating}]{\text{NaOD}} x(D^+)_{solv} + 3[Me_3E(OD)_2]^-_{solv} + x[(Fe(CN)_6]^{4-} + 1 - x[Fe(CN)_6]^{3-}.$$



The NMR spectra of the CTCs (Table 3 and Fig. 1), reveal the signals characteristic of the thiazole and benzothiazole moieties as well as that of the methyl protons of the (Me_3E) connecting units. It is observed that the signals of the donors appear at more or less the same positions as the signals due to the protons of the free donors in DMSO [16]. The NMR spectra of **1, 2** and **13** indicate the polymerization of thiazole *via* the positions 2 and 5 and of 2-aminothiazole (compounds **3** and **14**) *via* position 5, since the signals due to the protons at these positions disappear while that of the proton at position 4 suffers a shift to higher field. The polymerization of 2-aminobenzothiazole and 2-amino-6-methylbenzothiazole was also confirmed by the shift of the multiplet due to the protons of the phenyl moiety to higher field relative to those of the corresponding monomers [16]. These results indicate the intercalation of thiazole and benzothiazole donors within the channels of the 3D polymers **I** and **II** forming CTCs, while the donors of **1, 3, 8, 10, 13, 14** and **16** undergo polymerization forming molecular composites.

Magnetic properties

The EPR spectra of the polymers **I** and **II** show the same behavior exhibiting five absorption signals with g values 1.9784, 2.2003, 2.5005, 2.9164, 3.147 and 4.5872. [5] The first four signals correspond to low-spin iron(III), which has a $(dE)^5$ electronic configuration with one unpaired electron in the d_{yz} orbital forming with the cyanide ions a distorted octahedral structure. [17–20] The last signal at 4.5872 is weak and corresponds to the trace amounts of high-spin iron(III) [21–23].

The EPR spectra of the molecular composites **1, 3, 8, 10, 13, 14** and **16** exhibit one strong symmetrical signal with g value $\sim$2.0 accompanied by the disappearance of the signals of the polymers **I** and **II** (Fig. 2). This signal corresponds to the free radical cation of the corresponding poly-donor and resembles that observed in the EPR spectrum of polyaniline [24,25] and its derivatives [5]. This argument was also supported by the presence of a strong signal at $g \simeq 2.0$ of the authentic samples of the polyaminothiazole and benzothiazole derivatives prepared by the oxidation of the monomers by ammonium persulfate. The polymerization of these donor molecules within the channels of the polymers **I** and **II** yields extremely paramagnetic molecular composites. However, the molecular composite **2** is EPR silent and diamagnetic. On the other hand, the EPR spectra of the CTCs also show a strong signal around g 2.0, in addition to weak signals at g values corresponding to the acceptor polymer **I** or **II**. The presence of the strong signal at

~2.0 is good evidence for the paramagnetic nature of these CTCs, while the weak intensity and the disappearance of some signals of the polymer **I** or **II** substantiate the intercalation of these donors within the cavities of **I** and **II**. Also the magnetic susceptibilities of the CTC (Table 3) confirm their paramagnetic nature.

The electronic absorption spectra

The electronic absorption spectra of the CTC in Nujol mulls (Table 4 and Fig. 3) show the characteristic bands of thiazole derivatives at 248–262 nm ($^1L_b \leftarrow {}^1A$) and those of benzothiazole derivatives at 220, 275–350 nm ($^1L_a \leftarrow {}^1A$ and $^1L_b \leftarrow {}^1A$ of the phenyl ring) and at 245–264 nm ($^1L_b \leftarrow {}^1A$ of the thiazole moiety) [14]. These bands exhibit pronounced blue shifts relative to those of the free donors. The spectra of the CTCs with $X < 1$ reveal a band at 390–415 nm (Π–Π* transitions of the ($Fe^{III}CN$) building blocks) with the appearance of a new broad band at 300–320 nm (Π–Π* transitions of the ($Fe^{II}CN$) building blocks) [5], indicating the partial reduction of iron(III) to iron(II). In the spectra of the CTCs within $X = 1$, the former band disappears due to complete reduction of iron(III) to iron(II). These results indicate the formation of CTC with $\sigma \leqslant 1$, the case which is further supported by the appearance of a new broad band at 430–470 nm corresponding to CT transitions. The Π–Π* nature of this CT band is shown from the photoelectron spectroscopic studies of thiazole deriva-

tives [10]; I_p (Π_3–thiazole) = 9.50 eV and I_p (Π_3–2-aminothiazole) = 9.45 eV, which indicate that the CT transitions are from the highest occupied Π-orbitals of thiazoles as electron donors to the LUMO of the polymer **I** or **II** as an acceptor. On the other hand, HMO calculations of benzothiazale derivatives confirm that the cloud of the phenyl ring has more charge density than in the thiazole moiety. Therefore, in the case of benzothiazoles the Π-donation is from the phenyl ring. Also, the spectra of the CTC in Nujol mulls after the addition of 1 M HCl reveal the CT bands at the same position confirming their Π–Π* nature.

The electron affinity of the polymers **I** and **II** as novel acceptors can be calculated by the equation: $h\upsilon_1 - h\upsilon_2 = E_{A1} - E_{A2}$. Using the reported values of electron affinities E_{A1}, of 1,3-dinitrobenzene (1.26 eV), 2,4-dinitrotoluene (1.17 eV) and 1,3,5-trinitrobenzene (1.73 eV) [26,27] and the energies of the CT bands, $h\upsilon_1$, of these acceptors with some thiazole and benzothiazole derivatives [28]. The electron affinities of the polymers **I** and **II** are equal to 1.52 ± 0.05 and 1.45 ± 0.06 eV, respectively. Using the reported values of the adiabatic ionization potentials of thiazole and benzothiazole derivatives [10,28]. The energy of the CT band can be calculated according to the relation given by Briegleb [29].

$$E_{CT} = I_p - E_A + C_1$$

The mean calculated values of the Coulombic factors, C_1, of the polymers **I** and **II** are equal to 4.5 ± 0.18 and 4.4 ± 0.16 eV. The calculated values of E_{CT} (*ca* 2.56–2.90 eV) are reproducible and satisfactory compared with the experimental ones (*ca* 2.52–2.88 eV), except those of molecular composites where a pronounced deviation was observed between the calculated and the experimental E_{CT} values (Table 5). The broad band observed at the longer wavelength in the spectra of **3, 8, 10, 14** and **16** corresponds to two transitions. The first one can be attributed to CT from the donor to the host polymer acting as an acceptor and is located at positions corresponding to the calculated E_{CT} (Table 5). The second transition at 476–495 nm is due to a charge transfer exciton from the benzonoid [—HN—(C_7H_3NS)—NH—] to the quinoid [—N=(C_7H_3NS)=N—] structures, which is similar to that of polyaniline observed at 510 nm (*ca* 2.43 eV).[11] The presence of this band provides evidence for the polymerization of 2-aminothiazole, 2-aminobenzothiazole and 2-amino-6-methylbenzothiazole within the channels of the host polymers **I** and **II**. On the other hand, the spectra of the protonated molecular composites **3′**, **8′**, **10′**, **14′** and **16′** revealed a broad band at 670–718 nm (1.85–1.74 eV) (Fig. 4 and Table 5), corresponding to polaron lattice with the disappearance of the localized quinoid structure as the band at 476–495 nm disappears. This band resembles the broad band observed at 760 nm (1.6 eV) in the optical spectrum of protonated polyaniline [11,30].

The absorption spectra of the CTCs of thiazole as donor are quite different from those of the remaining donors. Thiazole itself absorbs in Nujol mull at 235 nm, while the spectra of **1** and **13** show bands in the region 285–530 nm (Table 4). The band at 235 nm disappears, indicating that the monomer species are not present and instead polymerization occurs. The new bands at 285 and 385 nm are attributed to neutral oligomers [31] formed within the channels of the host 3D polymers **I** and **II**, which are reduced to the isostructural anionic homologue. The bands are rather broad, which may be composed of contributions from several species. However, the band at 285 nm was definitely considered to be the absorbance of neutral oligomers since its intensity increases upon reduction of the species formed during electrochemical oxidation of thiazole [31] and the band at 385 nm disappears in the spectrum of **2**. The absorbance at 530 nm is due to the absorption of the cation radicals as also indicated by EPR spectra and magnetic results of the molecular composites **1** and **13**. On the other hand, the band at 530 nm is absent in the spectrum of **2**, indicating the formation of neutral oligomers which are EPR silent and diamagnetic. The CT band is observed at 360 and 344 nm for **1** and **13**, where the calculated (*ca* 3.48 and 3.65 eV) and the experimental (*ca* 3.45 and 3.60 eV) E_{CT} values are quite concordant. The CTCs behave as very weak semiconductors or insulators (Table 6), while the protonated forms of the molecular composites have good semiconducting

properties with conductivity higher than the unprotonated ones and than the corresponding authentic samples (Table 5).

This research has shown that the physical properties of the CTC could be varied by changing the host polymer, the donor and conditions of the reaction. Therefore, these CTCs can be tailored to meet specific properties.

(Received 19 September 1995; accepted 25 September 1996)

Abstract—The X-ray crystal structure of $Cu(thd)_2 \cdot Phen$, which is the first adduct of $Cu(thd)_2$ reported to be stable in the vapor phase, was determined. A *cis*-octahedral arrangement of chelate ligands around copper is of low symmetry due to Jahn-Teller distortion and the rigidity of the ligands. Peculiarities of the $Cu(thd)_2 \cdot Phen$ synthesis are discussed. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: copper; β-diketones; adducts; structure; MOCVD; precursors.

2,2,6,6-Tetramethylheptan-3,5-dionates of metals (thd-complexes) have attracted much attention recently as volatile precursors suitable for application in the MOCVD of complex oxides like high T_c superconductors [1,2]. Perspective single source versions of MOCVD require powder mixtures or organic solutions containing some different thd-complexes [3–5]. $Ba(thd)_2 \cdot 2Phen$ (Phen = o-phenanthroline) [6] is essentially more stable to the hydrolysis and polymerization than $Ba(thd)_2$ and is preferable for the application in MOCVD [7]. No chemical interaction in the system $Ba(thd)_2 \cdot 2Phen$-$Y(thd)_3$-$Cu(thd)_2$ used to deposit $YBa_2Cu_3O_{7-x}$ thin films has been reported so far. It is noteworthy that $Y(thd)_3 \cdot Phen$ was described as thermally unstable [8]. Adducts of $Cu(thd)_2$ with Phen have not been reported so far. At the same time, our preliminary study has shown that some chemical interaction involving $Cu(thd)_2$ occurred in the powder mixture under air or after heating *in vacuo* (XRD patterns of $Cu(thd)_2$ disappear, color changes from deep blue to green).

Only a few adducts of $Cu(thd)_2$ with monodentate N-donors have been isolated in the solid state [9]. All the complexes decomposed at room temperature to form $Cu(thd)_2$. The same was valid for adducts of $Cu(acac)_2$ (acac = acetylacetone) or other unfluorinated β-diketonates of copper(II) [10]. On the contrary $Cu(hfa)_2$ (hfa = hexafluoracetylacetonate) gave rise to various adducts stable at room temperature [11–13]. Only fluorinated β-diketonates have been known to form adducts $CuL_2 \cdot Phen$ and $CuL_2 \cdot 2,2'$-Dipy, where L is a β-diketonate [13].

We present here the synthetic procedures related to the preparation of $Cu(thd)_2 \cdot Phen$ as well as results of its crystal structure determination.

EXPERIMENTAL

Synthetic procedures

Two paths were proposed to synthesize the adduct of $Cu(thd)_2$ with Phen: (1) reaction of $Cu(thd)_2$ with Phen; (2) interaction between $Cu(NO_3)_2 \cdot n$Phen with Nathd. Only the former path was successful.

$Cu(thd)_2$ was synthesized by the reaction of stoichiometric amounts of water solution of $Cu(CH_3COO)_2 \cdot H_2O$ and Hthd and purified by vacuum sublimation (160 C).

$Cu(thd)_2 \cdot Phen$. The solution of anhydrous Phen (5 mmole) and $Cu(thd)_2$ (5 mmole) in 35 cm^3 of dry benzene was prepared. Then benzene was evaporated under aspiration. The green precipitate formed was purified by vacuum sublimation (130 C). Needle-like single crystals of $Cu(thd)_2 \cdot Phen$ were grown by slow cooling of a hot benzene solution.

*Author to whom correspondence should be addressed.

A similar procedure with $Cu(acac)_2$ and Phen was carried out. But only some Phen was collected after heating the powder mixture obtained *in vacuo*. No copper was detected in the sublimate.

$Cu(NO_3)_2 \cdot$Phen and $Cu(NO_3)_2 \cdot$2Phen were prepared from ethanol solutions of $Cu(NO_3)_2 \cdot 6H_2O$ and Phen$\cdot H_2O$ according to the procedure described in [14]. $Cu(NO_3)_2 \cdot$2Phen was formed by dehydration of $Cu(NO_3)_2 \cdot$2Phen$\cdot H_2O$ *in vacuo* (120°C).

Benzene solutions of Nathd were mixed with the copper compounds ($Cu(NO_3)_2 \cdot$Phen or $Cu(NO_3)_2 \cdot$2Phen) in the molar ratio 2:1 with subsequent heating and stirring for 3 h. Partial interaction was presumed for both systems judging by color variation of the solution and precipitate (from deep blue to light blue or greenish blue). However, no $Cu(thd)_2 \cdot$Phen was isolated from the benzene solutions.

Crystal structure determination

A crystal selected with approximate dimensions $0.2 \times 0.2 \times 0.6$ mm was not of good quality, being twinned parallel to the needle axis. The data were collected on a STADI4 (Stoe) diffractometer using Mo-K_α radiation with a graphite monochromator (θ-2θ scan method, $\theta_{max} = 21°$). A wide range of scanning (about 2°) was used due to the twinning so that reflections from both components of the twin could be measured. The cell parameters of triclinic crystals are $a = 10.00(1)$ Å, $b = 11.54(2)$ Å, $c = 16.21(2)$ Å, $\alpha = 71.91(8)°$, $\beta = 85.59(8)°$, $\gamma = 68.20(7)°$, $V = 1650$ Å^3, sp. gr. $P\bar{1}$, $Z = 2$, $d_{calc} = 1.229$ g cm^{-3}. From 3203 reflections measured 2349 were with $I \geqslant 2\sigma(I)$. The crystallographic calculations were performed using the SHELXS-86 and SHELXSL-93 program packages [15]. The structure was solved using a combination of direct and Fourier methods and refined by the full-matrix least-squares technique with anisotropic thermal parameters for all non-hydrogen atoms. The position of the hydrogen atoms were calculated and refined as riding atoms. The final R-values were $R_1 = 0.079$ and $wR_2 = 0.201$. Selected bond lengths and angles are listed in Table 1.

RESULTS AND DISCUSSION

In $CuL_2 \cdot Q$, where Q is a monodentate ligand, Cu has square pyramidal coordination [11,16,17]. According to EPR data Q can occupy an apical position (Q = acetonitrile, DMSO, THF) or basal position (Q = Py, PPh_3) in the structure of $Cu(hfa)_2 \cdot Q$. In a similar way octahedral $CuL_2 \cdot Q$ complexes can adopt *cis* or *trans* positions of the monodentate Q. The former takes place for $Cu(tta)_2 \cdot 2\gamma$-pic [18] and $Cu(hfa)_2 \cdot$2Py [19], the latter for $Cu(tta)_2 \cdot$2Py [20] (Table 2).

There are three possible positions for donor atoms of the bidentate Q′ in $CuL_2 \cdot Q'$ with tetragonally distorted octahedral Cu^{II} system (Fig. 1, Table 2): (a) *trans* coordination leading to the chain-like structure $Cu(acac)_2 \cdot$4,4′-Dipy [21,22], (b) *cis*-coordination in the equatorial plane resulting in equal Cu—N distances and equivalent β-diketonate-anions in $Cu(hfa)_2 \cdot$2,2′-Dipy [23], (c) *cis*-coordination not in the equatorial plane with non-equivalent β-diketonate-anions due to Jahn–Teller distortion. No structural data has been available for the latter possibility. So $Cu(thd)_2 \cdot$Phen is the first example of coordination of type (c) for $CuL_2 \cdot Q'$ (Fig. 2). Average values of Cu—O and Cu—N bond lengths are close to the values for complexes of type (b), as can be seen from Table 2, where the basic structural data for $CuL_2 \cdot Q'$ and $CuL_2 \cdot 2Q$ are presented.

Another feature of copper coordination is the shift of donor atoms from the equatorial plane (~0.11 Å) resulting in a very small tetrahedral distortion of the square.

The type (c) possesses the lowest symmetry among Cu coordination types in $CuL_2 \cdot Q'$ due to (1) Jahn–Teller distortion; (2) rigidity of ligands. As a result of the second factor angles D—Cu—D (D is a donor atom) in chelate rings are all markedly below 90°

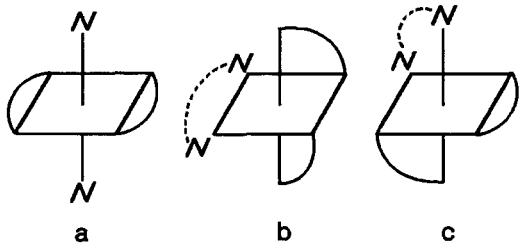

Fig 1. Possible positions for donor atoms in $CuL_2 \cdot Q'$ with tetragonally distorted octahedral Cu^{II} system.

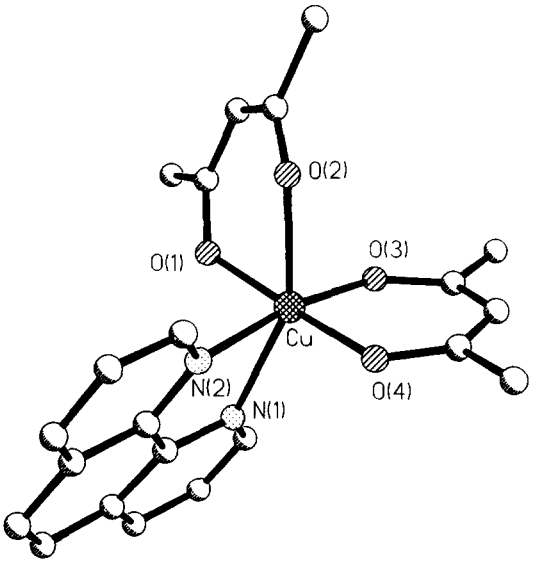

Fig 2. Molecular structure of $Cu(thd)_2 \cdot Phen$.

(especially N(1)—Cu—N(2), 75°). The contribution of the first factor can be demonstrated by comparison with the structure of $Mg(thd)_2 \cdot Phen$ [24] which is without Jahn–Teller distortion. In $Mg(thd)_2 \cdot Phen$ the Mg—O bonds have nearly the same length as Mg—N bonds. Angle distortions are similar too, except those due to the rigidity of ligands. In terms of the same labeling scheme as for $Cu(thd)_2 \cdot Phen$, the maximum deviations are for angles O(1)—Mg—N(2), 100.8° and O(3)—Mg—N(2), 161.2° instead of 90° and 180° respectively for the regular octahedron. The maximal deviating angles in $Cu(thd)_2 \cdot Phen$ are 77° and 155° for *cis* and *trans* positions (Table 1).

It should be also noted that all chelate rings are not planar and bent around D···D lines: 7.8° for Phen-Cu cycle, 11.6° and 30.8° for thd-Cu cycles. The latter value is higher than the usually observed swivel of β-diketonate–metal chelate rings [25].

The knowledge of the molecular structure of $Cu(thd)_2 \cdot Phen$ allows a better understanding of the stability and synthesis of $CuL_2 \cdot Q'$.

Among 3 bidentate chelate ligands in the distorted

tetragonally *cis*-octahedral arrangement around copper atom (types (b) and (c) only one ligand can place both its donor atoms in the equatorial plane. For π-donating ligand this position is most preferable [18] so the competition of ligands for such a position could be expected in the system under investigation. The complex would be stable if one of the competitive configurations is markedly preferable. If no configuration is preferable then both (b) and (c) structures would be unstable. This consideration conforms to the experimental data.

Really Phen or 2,2′-Dipy occupies *cis*-positions in the equatorial plane in octahedral Cu-complexes if other ligands are weaker donors (hfa [23] (Table 2, N7), salicylate [26], anions of inorganic acids [27–29]). On the contrary, stronger donor (thd^-) substitutes Phen in *cis* position of the equatorial plane ($Cu(thd)_2 \cdot Phen$). Judging by the increase of acidity in the sequence Hthd-Hacac-Hhfa one can expect the intermediate behavior for $acac^-$. Actually complexes of (b) or (c) types were not obtained for $Cu(acac)_2$, only (a) type. Moreover stable complexes of general formula $Cu(acac)X \cdot Phen$ (X = anion of strong inorganic acid like NO_3^- or ClO_4^-) with square pyramidal Cu coordination are known with donor atoms of both $acac^-$ and Phen in the basal plane [30].

The idea of competition of π-donating chelate ligands for position in the equatorial plane works well for the choice of synthetic paths to $CuL_2 \cdot Q'$. If the strongest π-donating chelate ligand of $CuL_2 \cdot Q'$ has both its donor atoms in the equatorial plane of the molecular precursor then the synthesis is expected to be successful. If the position is initially occupied by other chelate ligand the kinetic obstacles are possible. Actually $Cu(thd)_2$ with square coordination of copper(II) [31] forms $Cu(thd)_2 \cdot Phen$ easily but $Cu(NO_3)_2 \cdot x Phen$ is not suitable for preparation of the complex.

CONCLUSIONS

The stable complex $Cu(thd)_2 \cdot Phen$ of (c) type has been obtained. The possibility to prepare the adduct $CuL_2 \cdot Phen$ with structure (b) or (c) is determined by competition of π-donating chelate ligands for the position in the equatorial plane of tetragonally distorted octahedral Cu^{II} system.

Some new aspects following from this work are worth further study: (1) possibility of synthesis of adducts of $Cu(thd)_2$ with other chelate bidentate N-donor ligands (2,2′-Dipy, en *et al.*); (2) behavior of $Cu(pta)_2$ (pta = pivaloyltrifluoracetone) to such chelate ligands. Is it similar to $Cu(thd)_2$ or $Cu(hfa)_2$?

(Received 10 September 1996; accepted 25 September 1996)

Abstract—The heterobimetallic complex $[WCl(SnCl_3)(CO)_3(NCMe)_2]$(**1**) reacts with norbornadiene (NBD) at room temperature, liberating two acetonitrile ligands to form the seven-coordinate complex $[WCl(SnCl_3)(CO)_3(\eta^4\text{-NBD})]$(**2**). The compound **2** is the first structurally characterized example of monomeric, halocarbonyls with a tungsten–tin bond in which a diene ligand is present on tungsten. The IR, ^{13}C NMR spectra of **2** are also described and can be correlated with the crystallographically observed geometry. The structure of **2** provides a good model for comparing the *trans* influence of the chlorine and carbon monoxide ligands in this molecule. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: tungsten; tin; norbornadiene; crystal structure; seven-coordinate complex.

There is currently considerable interest in seven-coordinate complexes of tungsten(II), in particular the complexes $[WCl_2(CO)_3L_2]$, L = phosphine, arsine, which have recently been found to be catalysts for the metathesis of alkenes and polymerization of alkenes or alkyne [1–5]. These complexes require Lewis acid activation to be metathesis or polymerization catalysts at room temperature [4,5].

In the course of our investigation of the $W(CO)_6$–Lewis acid interaction we developed a new photochemical method for the preparation of tungsten(II)-Lewis acid adducts. This method has been successfully applied to the preparation of the highly versatile compound $[(CO)_4W(\mu\text{-}Cl)_3W(SnCl_3)(CO)_3]$ [6], which reacts with substances (L) containing nitrogen or phosphorus as donor atoms, to give products of the type $[WCl(SnCl_3)(CO)_3L_2]$ and $[WCl_2(CO)_3L_2]$ [7]. In a previous paper [7,8] we described a new high-yield synthesis of the acetonitrile complex $[WCl(SnCl_3)(CO)_3(NCMe)_2]$(**1**). Studies are in progress to explore the reactivity of that and the other tungsten(II) carbonyl complexes. Olefin binding to the metal centre has often been suggested and tungsten–alkene complexes have been proposed as key intermediates in several catalytic reactions; however, only a few examples of stable tungsten(II) alkene complexes have been reported [9,10].

The first tungsten(II) diene, e.g. norbornadiene, compound was prepared by Davidson and Vasapollo [9] in reaction of the tungsten(II) complex $[WBr_2(CO)_4]_2$ with norbornadiene. Next, from an X-ray crystallographic study, the compound was shown to be $[WBr_2(CO)_2(NBD)]$ [10]. The small number of tungsten(II) alkene complexes known is almost certainly due to the instability of alkene compounds. We now report a new high-yield synthesis of the complex $[WCl(SnCl_3)(CO)_3(\eta^4\text{-NBD})]$(**2**), from the reaction of **1** with norbornadiene. The unknown coordination geometry of the diene compound **2** together with the fact that compounds of this class can be used as a model of a catalytic centre make it an interesting problem for X-ray structure analysis.

Although many studies of seven-coordinate molybdenum(II) compounds of the general formula $MoCl(SnR_nCl_{3-n})(CO)_3(NCMe)_2$, (R = Me, Bu, Ph) have been carried out [11–17] to date there has been no report of these compounds reacting with an alkene or diene. For these reasons we consider it unusually interesting that tungsten(II) species of the $[WCl(SnCl_3)(CO)_3(\eta^4\text{-NBD})]$(**2**) type can be prepared directly from **1**.

EXPERIMENTAL

All reactions were carried out under nitrogen by standard Schlenk line techniques. The solvents and reagents applied were dried, distilled and deoxygenated.

IR spectra were recorded on a Nicolet FT-IR Model-400 spectrometer by means of KBr pellets. Far-IR spectra were recorded (600–100 cm^{-1}) with a Brüker IFSv instrument in a Nujol mull on a polyethylene film. ^1H and $^{13}C\{^1H\}$ NMR spectra were recorded on AMX 300 Brüker spectrometer. An UV-vis absorption spectra were recorded on a Hewlett Packard 8452A spectrophotometer.

$[WCl(SnCl_3)(CO)_3(NCMe)_2]$(**1**) was prepared by a reaction of $[(CO)_4W(\mu\text{-}Cl)_3W(SnCl_3)(CO)_3]$ in acetonitrile according to the literature method [7,8]. To **1** (0.15 g, 0.25 mmol) dissolved in CH_2Cl_2 (25 cm^3) with continuous stirring under a stream of nitrogen a ten-fold excess of norbornadiene (0.3 cm^3, 2.5 mmol) was added *via* syringe. The mixture was stirred for 4 days during which time an orange solution of **1** gradually changed to a reddish-brown colour, while the ν(CO) frequencies of **1** disappeared. After the completion of the reaction, the solution was separated from some insoluble green powder by filtration. The isolation of the product by precipitation with heptane produced the analytically pure yellow crystalline complex of **2** (yield = 0.12 g, 80%).

Crystallography

The yellow crystals of **2** were grown from a CH_2Cl_2/heptane (10:1) solution. The crystals were stable enough when handled in an inert atmosphere or coated with a light hydrocarbon oil to protect them from the atmosphere.

Crystallographic data were obtained using a KM4 κ-axis computer-controlled [18] four-circle diffractometer operating in the ω-2θ scan mode with graphite-monochromated Mo-K_α radiation (λ = 0.71069 Å). Cell dimensions were obtained by a least-squares refinement on setting angles of 36 well-spaced reflections in the range $19.8 < \theta < 35.6°$. The details of the crystal data intensity measurement are given in Table 1.

The structure was solved by heavy-atom methods with the SHELXS-86 program [19] and refined by a full-matrix least-squares method, using the SHELXL program [20]. Neutral atomic scattering factors were taken from the SHELXL-93 program [20]. For non-hydrogen atoms, refinement with anisotropic temperature factors converged to $R_1 = 0.0319$ and $wR_2 = 0.0815$. H atoms were fixed in trigonal or tetrahedral positions at 0.98 or 0.97 Å from the C atoms to which they were bonded.

Supplementary publication material includes positional parameters, remaining dimensions, torsion angles, anisotropic thermal parameters, and hydrogen positions.

RESULTS AND DISCUSSION

The tungsten(II) bis(acetonitrile) complex **1** [7,8] was synthesized by the reaction of $[(CO)_4W(\mu\text{-}Cl)_3W(SnCl_3)(CO)_3]$ [6] with CH_3CN in toluene at room temperature. Upon addition of diene to an orange solution of **1** in CH_2Cl_2 the colour gradually changes to reddish-brown, while the ν(CO) frequencies (2040s, 2020s, 1970m(sh) and 1930vs(br) cm^{-1}) of **1** disappear and the ν(CO) band at about 2080 cm^{-1} characteristic of norbornadiene complex **2** reaches a maximum. In order to drive the reaction to completion a ten-fold excess of the diene was necessary. After the completion of the reaction, isolation

of the product by precipitation with heptane yields moderately air-stable yellow crystals of **2** in an 80% yield. The compound **2** is slowly hydrolysed on exposure to air, but no special precautions seem necessary to exclude air from the solvents to prepare crystals.

The molecule $[WCl(SnCl_3)(CO)_3(\eta^4\text{-NBD})]$(**2**), is shown in Fig. 1 together with the atomic numbering scheme. Table 2 contains selected bond distances and bond angles. The environment of the tungsten atom is a distorted capped trigonal prism with the tin atom occupying the unique capping position above the centre of the quadrilateral face defined by the chlorine and three carbonyl groups, two double bonds of norbornadiene making up the remaining edge. The square face that is capped by the $SnCl_3$ group is distorted. The major distortions from regularity of the prism appear to be associated with the presence of the chlorine atom in the capped quadrilateral face and with the fact that the W—Cl bond, at 2.454(2) Å, is considerably longer than the three W—CO distances (2.04 Å av). The angles subtended at the tungsten atom by the four atoms determining the capped face are in the range 82.1(3)–93.8(4) , whereas the angle subtended at the tungsten atom by the midpoints of the norbornadiene carbon–carbon double bonds is only 63.6(2) . Two CO groups in the capped face are mutually *cis* with C(2)—W—C(3) angle 92.4(4) and almost the same W—C distances, 2.029(9) and 2.032(9) Å, but the third CO group is in a *trans* position with a longer W—C(3) distance equal 2.06(1) Å. The *trans*-$W(CO)_2$ unit is slightly bent at the metal atom, the C—W—C angle being 166.8(4) .

The coordination of norbornadiene ligand is arranged in two types; the C=C *trans* to CO and the C=C *trans* to Cl. This gives rise to a slight difference between the W—C distances; such that W—C(6) = 2.326(8) Å and W—C(7) = 2.306(9) Å are almost 0.1 Å shorter than W—C(4) = 2.407(9) Å and W—C(5) = 2.413(8) Å. The two shorter bonds are both *trans* to chlorine ligand and longer *trans* to carbonyl. The above bond lengths are in excellent agreement with the degree of electron back-donation from the $d\pi$-orbitals of tungsten to the ligands whose π acidity is taken into account. As CO is a better π acid than C=C, back-donation to CO is much preferred. For the C=C and its *trans* Cl pair, the electron density due to back-donation is almost wholly accepted by C=C, resulting in shortened W—C(6) and W—C(7) distances and in a lengthened C(6)—C(7) distance compared to W—C(4), W—C(5) and C(4)—C(5) distances.

The structure of **2** thus provides a good model for comparing the *trans* influence of the chlorine and carbon monoxide ligands in this molecule.

The tungsten–tin bond is short at 2.764(1) Å compared to the sum of the relevant covalent radii of 2.97 Å [21, 22] but the longest of those observed previously. The W—Sn distances of 2.731(1),[6] 2.710(1),[8] 2.711(1) [23] and 2.737(1) [23], 2.759(3) [24] Å have been observed.

The tin atom is four-coordinate with a geometry that is best described as distorted tetrahedral; the mean W—Sn—Cl angle (118.78 av.) is greater than the mean Cl—Sn—Cl angle (98.79 av.), which is consistent with Bent's rule [25] that atomic *p* character

concentrates in orbitals directed towards electronegative substituents. The Sn—Cl distances, one shorter (2.321(3) Å), and two longer (2.344(3) Å), observed in **1** are much shorter than in uncoordinated trichlorostannate: 2.53 Å in $CsSnCl_3$ [26]. This can be explained by coordination of the trichlorostannate to tungsten which removes electron density from tin. This loss of electron density is compensated by π bonding between the tin and the chloride, thus shortening the tin–chlorine bond [27].

A common feature of the structures reported for seven-coordinate complexes containing W—Sn or Mo—Sn bond such as $[WCl(SnCl_3)(CO)_3(NCMe)_2]$ [8] $[WCl(MeSnCl_2)(CO)_3(C_4H_{10}S_2)]$ [24], $[MoCl(SnCl_3)(CO)_3(C_4H_{10}S_2)](CH_2Cl_2)$ [28] and $[MoCl(MeSnCl_2)(CO)_3(C_{10}H_8N_2)]$ [29] is a distorted capped octahedron geometry and the presence of a tin atom in the unique capping position and a chlorine atom bridging the W—Sn or Mo—Sn bond with Sn—μ—Cl distances in the range 2.781–2.958 Å and M—Sn—Cl angles in the range 52.1–55.2°. In contrast, in the structure of **2** the chlorine atom bonded to W is very far from the Sn atom (2.979(2) Å) and W—Sn—Cl angle is only 50.4(2)°. The geometrical arrangement of the seven ligand atoms around the tungsten atom in **2** more closely approximates a capped trigonal prism.

A noticeable feature of **2** is the exceptionally high ν(CO) frequency (2087 cm^{-1}), which is among the highest known for seven-coordinate $[WX_2(CO)_3L_2]$ type compounds, comparable only with that for halocarbonyls $[WX_2(CO)_4]_2$ [6]. This frequency is significantly higher than that of analogous $[WBr_2(CO)_2NBD]$ (2063 cm^{-1} [10]). This indicates that smaller electron density is being back donated into empty π^*-orbitals of the CO ligands. This implies that $SnCl_3^-$ is more electronegative and capable of acting as a more effective π-acceptor than Cl or Br

and as a result there is smaller W—CO back donation in **2**.

The lower frequency region of the infrared spectrum is dominated by the principal absorptions at 352, 336 cm^{-1}, which can be regarded as ν_s and ν_{as} (Sn—Cl) vibration. Tin-halide frequencies of the $[SnCl_3]^-$ ion were observed in, for example, $[Et_4N][SnCl_3]$ at 295(A_1) and 259 cm^{-1} (E) [30] but increase upon coordination of $SnCl_3^-$ to metal or other ligand. The band at 307 cm^{-1} is assigned to the W—Cl stretching vibration.

The ^1H NMR spectrum of **2** shows five well-separated groups of signals consistent with the solid structure of **2**. The absorption at δ 5.04 is protons attached on the same double bond, while the peaks at 3.71 are protons attached to the other double bond. The resonance of olefin protons is at a higher field than that of the free norbornadiene by 1.77 and 3.10 ppm but lower by 0.41 and higher by 0.92 ppm than that of the tungsten(0) complex $[W(CO)_4NBD]$ (4.63 ppm [31]). The ^{13}C NMR spectrum shows two carbonyl resonances at δ 202.28 and 193.47 ppm, in an intensity ratio of 1 : 2 in keeping with the symmetry of **2** in the solid state. The resonance at δ 193.47 ppm can be assigned to the carbonyls that are mutually *trans*. This resonance is slightly highfield compared to the signal of the CO group that is *trans* to the C=C unit of norbornadiene. Carbon signals of coordinated NBD were correctly assigned by observing the $^{13}C-^1H$ coupling constants. One of the double bond resonances (43.11 ppm) shifts more upfield than other carbon signals, yet the coupling constant stays in the range characteristic of double bond carbons (188 Hz). As the most remarkable feature we note the large difference between the two C=C units of norbornadiene, which are separated by 38.7 ppm: $\Delta\delta = 100.1$ and 61.39 ppm. The coordination shift for $[W(CO)_4(NBD)]$ [32] is 74.4 ppm. Thus, we assign the lower field norbornadiene signal of **2** to the two carbons of the C=C unit in the *trans* position to the CO group and the signal at higher field to the two carbons of the double bond *trans* to the chlorine. With regard to the origin of this effect, the coordination shift correlates with the W—C bond distance and with the degree of metal ($d\pi$) → olefin(π^*) back-donation.

(Received 6 August 1996; accepted 25 September 1996)

Abstract—Synthesis of the tris-chelated complexes $[Ru(L)_n(L^3)_{3-n}]^{2+}$ (L = *N*-aryl-pyridine-2-aldimine, L^3 = 2-(*m*-tolylazo)pyridine) based on silver(I) assisted *trans*-metallation is described. The complexes, $[Ru(L)_3]^{2+}$ and $[Ru(L)(L^3)_2]^{2+}$ afford $[Ru(pic)(L)_2]^+$ and $[Ru(pic)(L^3)_2]^+$ (pic = 2-picolinate ion) respectively, on hydrolysis and subsequent oxidation. When $RuCl_2(L)_2$ was reacted with two moles of $[Ag(L^3)_2]^+$, a pink complex of composition $[Ru(L)(L^3)(L^4)]^+$ [L^4 = *N*-aryl-2-picolinamide] was isolated along with the expected brown complex, $[Ru(L^3)(L)_2]^{2+}$. Initial oxidation of the metal ion favours L → L^4 conversion. The complexes have been characterized using spectroscopy and X-ray crystallography. The X-ray structure of $[Ru(pic)(L^1)_2]ClO_4 \cdot CH_2Cl_2$ is reported. The metal oxidation as well as ligand reductions for the complexes have been studied voltammetrically in acetonitrile using platinum as the working electrode. It has been observed that the oxidation of the transformed complexes, *viz.* $[Ru(pic)(L)_2]^+$, $[Ru(pic)(L^3)_2]^+$ and $[Ru(L)(L^3)(L^4)]^+$ occur at lower potentials as compared to their parent $[Ru(L)_n(L^3)_{3-n}]^{2+}$ complexes. All the complexes show metal-to-ligand charge transfer transitions in the visible range and absorption energies linearly correlate with the differences between the metal oxidation and the first ligand reduction potentials. © 1997 Elsevier Science Ltd. Keywords: ruthenium; Schiff-base; structure; ligand transformations; redox and redox-spectra correlation.

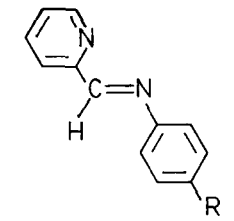
This work stems from our interest in the ruthenium-diimine complexes. This class of compounds is important [1] due to their rich redox and optical properties. In this respect, we have been working [2–4] on the synthesis and reactivities of ruthenium complexes of *N*-aryl-pyridine-2-aldimine (**1**, L). These complexes [2–6] are intensely coloured, undergo multiple electron transfer and most importantly, they show interesting patterns of chemical as well as photochemical reactivities.



Herein we report the synthesis and characterization of the tris-chelated ruthenium complexes involving L and L^3. These may be conveniently synthesized starting from ruthenium bis-chelated dichlorides by the use of silver(I) assisted *trans* metallation reaction route. The study of reactions of ruthenated L in the above complexes forms an important part of the present work. Interestingly, different products were obtained from apparently similar types of reactions. All the relevant species have been fully characterized. The reason for transformation selectivity of L is discussed on the basis of the present findings and other results [3,4] from this laboratory and elsewhere.

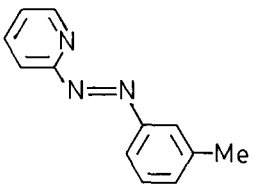
RESULTS AND DISCUSSION



A. *The synthetic reactions*

In the process of synthesizing [2, 7–9] mixed ligand tris-chelated ruthenium complexes of L (**1**) and 2-(*m*-tolylazo)pyridine (L^3, **2**) some unusual products were

R = H : L^1
R = Me : L^2

1, L

L^3

2

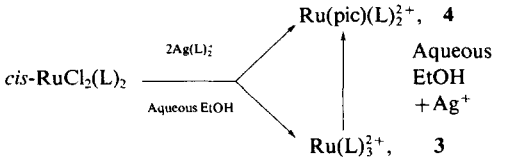
obtained along with the expected products, which are elaborated below. The general reaction which has been studied may be represented as follows:

$$cis\text{-}RuCl_2L'_2 + 2AgL''_2 \xrightarrow[\substack{L',L''\\ L' = L,L^3\\ L'' = L,L^3}]{EtOH} RuL_2L'' + 2AgCl + 3L'$$

(a) (i) *Reaction of cis-*$RuCl_2(L)_2$ *and two moles of* $Ag(L)_2^+$

The bluish green *cis* isomer [3] of $RuCl_2(L)_2$ was reacted with two moles of silver complex [10], $Ag(L)_2^+$, in 1 : 1 aqueous ethanol. In addition to the expected [2] brown tris-chelate, $Ru(L)_3^{2+}$ (**3**), a pink compound was also formed. Interestingly, an aqueous ethanolic solution of pure $Ru(L)_3^{2+}$ in the presence of dilute aqueous $AgNO_3$ quantitatively produced the pink compound. The pink product was purified on a silica gel column eluting with 1 : 5 CH_3CN-CH_2Cl_2 mixture. The brown product was obtained from the column using a more polar solvent (2 : 3 CH_3CN-CH_2Cl_2 mixture) as an eluent.

(ii) *Characterization*



The brown compound was identified as the known [2] $[Ru(L)_3](ClO_4)_2 \cdot H_2O$ (**3**) which we do not discuss any further. The pink compound which analyzed as $[Ru(pic)(L)_2]ClO_4 \cdot CH_2Cl_2$ (**4**) (pic = 2-picolinate anion) is diamagnetic and a 1 : 1 electrolyte in CH_3CN. The IR spectrum showed all the characteristic features [2, 3] of coordinated L and ionic ClO_4^-. Interestingly, it also displayed a moderately strong band at 1650 cm^{-1} indicating the presence [11] of a carboxylic function. Selected characterization data are collected in Table 1.

Fortunately, single crystals of **4** (L = L^1) could be grown as solvates: **4**·CH_2Cl_2 and its structure was successfully solved crystallographically. Molecular views of the complex excluding the solvent of crystallization and the counter anion, ClO_4^- are shown in Fig. 1. Selected bond distances and bond angles are collected in Table 2. The structure solution of **4** unequivocally confirms the composition of **4** as $Ru(pic)(L^1)_2^+$. The geometry of the $Ru(L^1)_2$ fragment in **4** is *trans*, *cis* (*trans* with respect to two N^1(py) and *cis* with in the N^2 (imine) pair). The carboxylic function lies *trans* to one of the two imine nitrogens. In this manner the three pyridine nitrogens are positioned meridionally. We note here that the parent complex **3** exists [2] in the meridional geometry. Therefore, the transformation **3** → **4** is stereoretentive.

In the above structure, Ru—N(5) length agrees [12] well with the Ru—N lengths in $Ru(pic)_2(PPh_3)_2$. Interestingly, the four Ru—N lengths in the $Ru(L^1)_2$ fragment of **4** are not equal. The Ru—N(4) length is notably shorter than other three Ru—N lengths. This must be due to stronger $d\pi$–$p\pi$ interactions [13] between Ru^{II} and π^* of the imine function containing N(4), which lies *trans* to the strong σ-donor carboxylic acid function. Moreover, the average Ru—N (imine) length in **4** is shorter [4] by *ca* 0.03 Å compared to that in *trans*-$Ru^{III}(L^1)(L^4)Cl_2$ (L^4 = N-phenyl-2-picolinamide). This may be attributed to the superior back-bonding in ruthenium(II) complexes.

Finally, it may be noted that the reaction of hydrated $RuCl_3$ and $Ag(L)_2^+$ in 1 : 3 mole ratio also resulted in the formation of a mixture of **3** and **4**. The yield of **4** increases with the increase of the duration of the reaction.

The reactions, described above, are schematically presented in Scheme I.

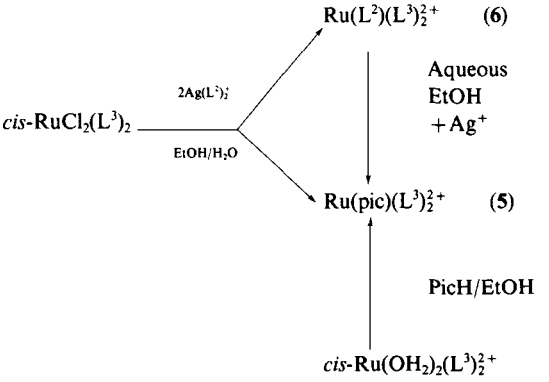
(b)(i) *Reaction of cis-*$RuCl_2(L^3)_2$ *and two moles of* $Ag(L)_2^+$



Similar to the prior reaction, this reaction also resulted in the formation of two major products, one of which is violet and the other one is brown in colour. The compounds were purified on a silica gel column by eluting with solvent mixtures of different polarities. The violet compound may be generated by boiling the brown product in aqueous ethanol in the presence of dilute $AgNO_3$ solution. Interestingly, the reaction [11] of *cis*-$Ru(OH_2)_2(L^3)_2^{2+}$ with PicH in ethanol instantaneously produces the violet product in a high yield.

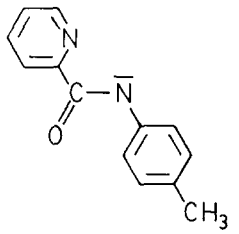
(ii) *Characterization*

The first moving violet band was eluted with 5:2 CH_2Cl_2-CH_3CN mixture and it analyzed as $[Ru(pic)(L^3)_2]ClO_4 \cdot CH_2Cl_2$ (**5**). The brown product, which was eluted with 1:1 CH_2Cl_2–CH_3CN mixture, analyzed as $[Ru(L^2)(L^3)_2](ClO_4)_2 \cdot H_2O$, (**6**). The compound **5** is a 1:1 electrolyte whereas the compound **6** is 1:2 electrolyte in CH_3CN. The compound **5** displayed a moderately strong absorption at 1660 cm^{-1} in the IR spectrum. This band is conspicuously absent in the IR spectrum of **6**. Evidently, the 1660 cm^{-1} absorption indicates the presence [11] of a carboxylic function in **5** (Table 1).

The ^1H NMR spectra of the compounds **5** and **6** were examined. In this case we have used only methyl substituted ligand, L^2 to take advantage of monitoring the methyl resonances in the less crowded region of the ^1H NMR spectrum. The aromatic region of both the spectra are complex due to serious overlapping. Therefore, we concentrated only on the methyl resonances (Table 1). The compound **5** displayed two equally intense resonances at 2.15 and 2.05 δ. The intensities of two resonances correspond to six protons. The compound **6** also displayed two methyl resonances at 2.21 and 2.12 δ, but the ratio of signal intensities is 1:2. Moreover, the total area covered by the two methyl signals of **6** corresponded to nine protons. Therefore, it may be concluded that the two equally intense methyl resonances in **5** is due to the presence of two L^3 ligands. In the spectrum of **6** there are three methyl resonances, two of which are overlapping which are attributed [14] to methyl groups of L^3, and the second signal is due [2] to the *p*-tolyl group of L^2. The spectral data, presented above, clearly demonstrate that the hydrolytic oxidative cleavage of an imine function occurs in the formation of **5**.

Thus, the reaction is similar to the reaction which is described in Section (a).

Scheme II



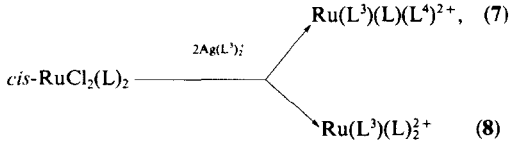
(c) (i) *Reaction of cis-*$RuCl_2(L^2)_2$ *and two moles of* $Ag(L^3)_2^+$

In this reaction bluish green *cis* isomer of $RuCl_2(L^2)_2$ was reacted with two moles [15] of $Ag(L^3)_2^+$ in aqueous ethanol. This reaction also yielded two major products. One of the two products is pink whereas the other one is brown. Unlike the two previously described reactions, the brown product is quite stable in boiling aqueous ethanol. Both the

products were purified by using the column chromatography technique.

(ii) *Characterization*

The pink product was eluted with 1:9 CH_3CN-CH_2Cl_2 solvent mixture and analyzed as $[Ru(L^2)(L^3)(L^4)](ClO_4)_2 \cdot 0.5CH_2Cl_2$ (L^4 = N-*p*-tolyl-2-picolinamide), (**7**). The brown product was then eluted with 1:1 CH_3CN-CH_2Cl_2 mixture. Based on the elemental analyzes the composition was ascertained as $[Ru(L^3)(L^2)_2](ClO_4)_2 \cdot H_2O$ (**8**). The characterization of **7** and **8** were unambiguously made based on their physical data.



L^4

The compounds **7** and **8** are 1:1 and 1:2 electrolytic, respectively, in acetonitrile. Unlike monopicolinates, the compound **7** did not show any characteristic absorption of carboxylic function. Instead, a moderately strong band at 1620 cm^{-1} in the IR spectrum of **7** confirms the presence [4, 13] of an amide function. Fortunately, this compound (**7**) displayed highly resolved ^1H NMR spectrum (Fig. 2) which was conveniently used for its characterization. The spectrum consists of well separated, equally intense three methyl resonances between 2.1–2.3 δ. This clearly reveals the presence of three tolyl groups in **7**. Moreover, there are four doublets of 2H intensities in the range 7.0 to 5.5 δ. Such doublets of two proton intensities can only arise from *p*-tolyl groups in this compound. The rest of the spectrum is complex due to overlapping peaks. The ^1H NMR spectrum of **8**, as expected, consists of two methyl resonances, one of which is double the intensity of the other. The spectral data collectively taken with the analytical data do conform to the proposed composition of the above compounds.

The reaction, described above, may then be summarized below in Scheme III.

We note that a tris-chelated compound with three different bidentate ligands as in **7** is extremely rare [16].

Scheme III

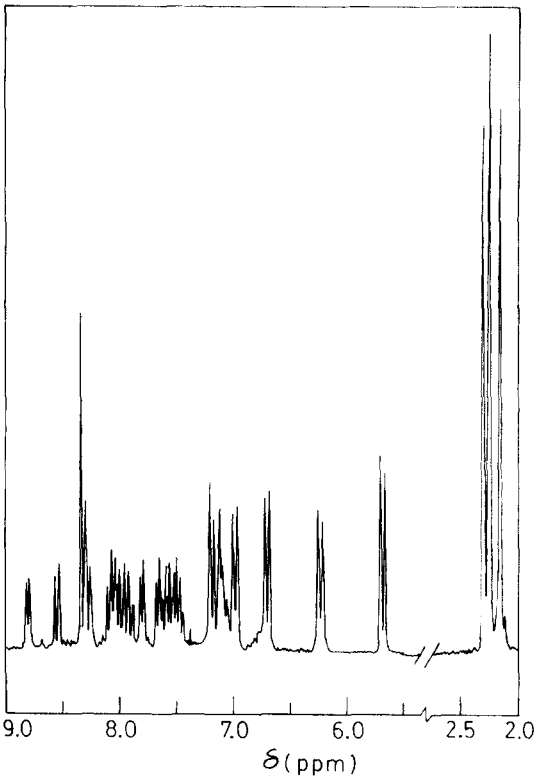


Fig. 2. ^1H NMR spectrum of $[Ru(L^2)(L^3)(L^4)]ClO_4 \cdot CH_2Cl_2$ in $CDCl_3$.

B. *The origin of transformations*

The reactions described above may be broadly classified in two categories: type (i) L → pic (reactions (a) and (b)); type (ii) L → L^4 (reaction (c)). We first consider the reaction (b) of type (i). In this reaction the starting ruthenium compound does not contain L. Therefore, the formation of $[Ru(pic)(L^3)_2]^+$ could, in principle, occur in two ways. Once the coordinated chlorides are precipitated as insoluble AgCl, the solution mixture then contains bis-solvento complex, $RuS_2(L^3)_2^{2+}$ (S = solvent) and four moles of free L. Coordination of L to $Ru(L^3)_2^{2+}$ moiety would produce $Ru(L)(L^3)_2^{2+}$ (**6**). Furthermore, hydrolysis [17] of an imine function in a hydroxylic solvent is a common phenomenon. Thus, hydrolysis of free L followed by oxidation of the aldehyde function would produce PicH in solution which may then react with the labile bis-solvento species to form the monopicolinate, **5**. The second possibility is the same transformation of L occurring after coordination to $Ru(L^3)_2^{2+}$ moiety. We note here that **6** can be easily transformed to **5** and the electrophilicity of L increases upon coordination, which is primary for the hydrolysis of an imine function. Out of the above two possibilities, we therefore propose that L → pic transformation presumably occurs *via* coordination of L. This proposal also applies to the reaction (a).

Table 3. Cyclic voltammetric data[a]

Compound	Metal-centred oxidation $E_{1/2}$(V)[E_p(mV)]	Ligand-based reductions $-E_{1/2}$(V)[ΔE_p(mV)]
$[Ru(L^1)_3](ClO_4)_2 \cdot H_2O$	1.43(75)	0.93(90), 1.16(100), 1.49(110)
$[Ru(pic)(L^1)_2]ClO_4 \cdot CH_2Cl_2$	1.00(75)	1.15(100), 1.48(90)
$[Ru(L^2)_3](ClO_4)_2 \cdot H_2O$	1.44(70)	0.90(90), 1.19(110), 1.52(110)
$[Ru(pic)(L^2)_2]ClO_4 \cdot CH_2Cl_2$	1.00(80)	1.16(100), 1.48(100)
$[Ru(L^2)(L^3)_2](ClO_4)_2 \cdot H_2O$	2.00[b]	0.15(90), 0.65(100), 1.56(170)
$[Ru(pic)(L^3)_2]ClO_4 \cdot CH_2Cl_2$	1.56(70)	0.28(100), 0.85(100), 1.71(180)
$[Ru(L^3)(L^2)_2](ClO_4)_2 \cdot H_2O$	1.81[b]	0.40(90), 1.05(100), 1.57(120)
$[Ru(L^2)(L^3)(L^4)](ClO_4)_2 \cdot CH_2Cl_2$	0.98(70)	0.92(100), 1.27(100)

[a] Cyclic voltammetric experiments were carried out in MeCN at 298 K using 0.1 mol NBu_4ClO_4 as supporting electrolyte and platinum as working electrode. The reported data correspond to scan rate $v = 50$ mV s^{-1}.

[b] Irreversible response, the potential corresponds to E_{pa}.

The other type of transformation, $L \rightarrow L^4$ (type (ii)) must occur with the coordinated L since both L are already coordinated in the starting material. This type of transformation of an imine function has been exemplified [4,13] very recently, in two other ruthenium systems. One such example is the oxidative transformation of *trans*-$Ru^{II}Cl_2(L)_2$ to *trans*-$Ru^{III}Cl_2(L)(L^4)$. It has been shown that initial oxidation of the metal ion followed by partial hydrolysis of coordinated L^1 and subsequent oxidation of the hydrolyzed L are the steps involved in the above transformation. At this stage, comparison of oxidation power of different reactants of reaction (c) is necessary for further discussion. We note that L^3 is a very strong [14] π-acceptor. Consequently, $Ag(L^3)_2^+$ should be a strong oxidant. Furthermore, the oxidation of *cis*-$RuCl_2(L)_2$ may be easily achieved [3] ($E_{1/2}$: 0.32 V). In the reaction (c), initial oxidation of $RuCl_2(L)_2$ by $Ag(L^3)_2^+$ is, therefore, the most plausible one. The oxidation of the metal ion then leads to an identical situation where coordinated $L \rightarrow L^4$ transformation was shown [4] to occur by the oxidation of the metal centre. In contrast to the previously reported examples [4,13], initial oxidation of the metal ion in reaction (c) is not reflected in the oxidation state of the same in the final product. In the present case (**7**) beside being coordinated to L^4, ruthenium is also bound to a very strong π-acceptor, L^3 and a moderate acceptor L. In the environment of L, L^3 and L^4, ruthenium is preferably stabilized in the bivalent state ($E_{1/2}$: Ru^{III}/Ru^{II} 1.0 V *vide infra*).

It may, therefore, be concluded, from the foregoing discussion, that hydrolysis followed by oxidation of coordinated L results in the formation of pic, whereas oxidation of the compound followed by hydrolysis would preferentially transform L to L^4.

C. *Electrochemical properties and redox-spectra correlation*

Electrochemical properties of the compounds **3**–**8** were studied cyclic voltammetrically in CH_3CN using tetrabutyl ammonium perchlorate (TBAP) as supporting electrolyte and platinum as a working electrode. The measurements were carried out in the range 2.2 V to −1.6 V versus SCE (saturated calomel electrode). All the complexes are electroactive, the electrochemical data are presented in Table 3. Representative voltammograms are displayed in Fig. 3.

We first consider the three parent chelates *viz.* **3**, **6** and **8**. Cyclic voltammogram [2] of the reported compound **3** is already discussed. Both **6** and **8** displayed an irreversible oxidation wave at a very high oxidation potential (> 1.6 V) due to $Ru^{II} \rightarrow Ru^{III}$ oxidation. Metal mediated oxidation of coordinated L has recently been discussed in the literature [4]. For the present complexes the oxidation potentials are very high and consequently the chemical reaction succeeding the electrochemical formation of Ru^{III}-L is expected to be very fast and thus the reverse waves were absent in the voltammograms of **6** and **8**. Both the complexes also display reversible, multiple electron transfer reductive responses on the negative of SCE. These are attributed to the reductions of the coordinated ligands. It may be noted that on moving from **3** to **8** *via* **6**, the metal oxidation potential increases in a parallel direction whereas a reverse trend was observed for the ligand reduction. The above trend is as expected, since L^3 stabilizes Ru^{II} better than L due to enhance $d\pi$–$p\pi$ back bonding and also undergoes reduction more easily due to the presence of lower acceptor orbital.

The two monopicolinates **4** and **5** showed reversible oxidative and reductive responses on both positive and negative of SCE. Their metal centered redox potentials are systematically lower than those for the parent diimine compounds. The picolinate ion which is a hard ligand, stabilizes [11] the higher valent state and thus the above shift of redox potential is observed. Moreover, on moving from **4** to **5** the $E_{1/2}$ of Ru^{III}/Ru^{II} couple shifts by about 0.56 V, presumably due to the better stabilisation of lower valent state by L^3 as noted before. For a similar reason, the ligand reductions in

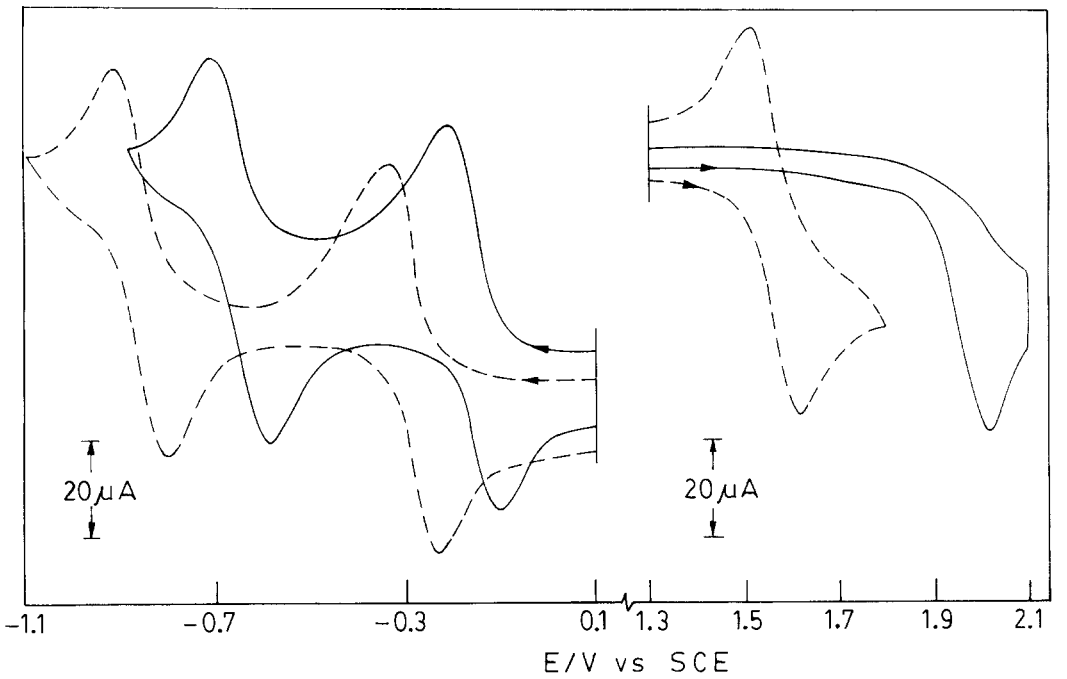

Fig. 3. Cyclic voltammograms of $[Ru(L^2)(L^3)_2](ClO_4)_2 \cdot H_2O$ (——) and $[Ru(pic)(L^3)_2]ClO_4 \cdot CH_2Cl_2$ ( ) in acetonitrile.

5 is easier than that in **4**. The cyclic voltammogram of the monopicolinamide **7** consists of a reversible oxidative response at 1.0 V attributed to Ru^{III}/Ru^{II} couple and two more reductive couples on the negative of SCE due to the ligand reductions.

Interestingly, the metal redox of **4, 5** and **6** are all reversible whereas those of their parents, **3, 6** and **8,** are either irreversible or quasireversible. Irreversibility in the latter group of complexes is due to metal assisted L oxidation reaction. In spite of the fact that both **4** and **6** contain L as coligand their metal redox responses are reversible. It may, therefore, be concluded that partially transformed products, even if they contain additional L, are resistant to further oxidation of L at least in the CV time scale.

The solution absorption spectra of the complexes were recorded in CH_2Cl_2. Representative spectra of the complexes are displayed in Fig. 4 and the data are collected in Tables 4 and 5. Although the complexes retain fairly intense intraligand transitions in the UV region, the key feature is the intense lower energy transitions occurring in the visible region (520–480 nm) those are assigned [2] to $Ru(d\pi) \rightarrow$ ligand (π^*) MLCT transitions. These transition energies for the parent complexes **3, 6** and **8** are systematically higher than those for the monopicolinates **4, 5** and monopicolinamide, **7**. The MLCT absorption energies for all the above complexes, (**3–8**), interestingly, show a linear correlation [2] with ΔE [where, $\Delta E = E_{1/2}(Ru^{III}/Ru^{II}) - E_{1/2}$ (ligand 0/−1)] (Table 5). This correlation, in other words, justifies our assignment of MLCT transitions for the complexes.

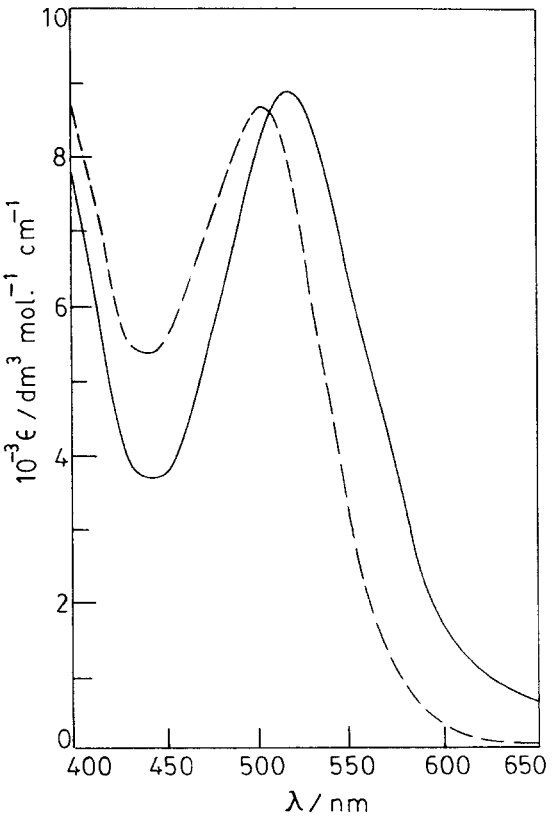

Fig. 4. Visible range absorption spectra of $[Ru(L^2)(L^3)(L^4)]ClO_4 \cdot CH_2Cl_2$ (——) and $[Ru(L^3)(L^2)_2](ClO_4)_2 \cdot H_2O$ (– – –) in CH_2Cl_2.

[c]Ill defined shoulder

Finally we wish to mention here that preliminary luminescence studies on the above complexes reveal that the picolinates and the amides have much stronger emission than their parent diimines in the visible region. Our work in this area is continuing.

EXPERIMENTAL

Materials

The salt, $RuCl_3 \cdot nH_2O$ was obtained from Arora Matthey, Calcutta and was digested thrice with concentrated HCl before use. The silver complexes, $[Ag(L)_2]ClO_4$ (L = L^1 or L^2) and $[Ag(L^3)_2]ClO_4$ were synthesized as before [10, 15]. The complexes *cis*-$[RuCl_2(L)_2]$ and *cis*-$[RuCl_2(L^3)_2]$ were prepared [3] by published procedures. The purification of dry solvents for electrochemical and spectral work was performed as described earlier. All other chemicals and solvents used for the preparative work were of reagent grade and were used as received.

Physical measurements

Spectra were recorded on the following equipment: UV–vis, Hitachi 330 spectrophotometer; NMR spectra, Varian XL 200 MHz FT NMR spectrometer. Electrochemical measurements were performed under nitrogen atomosphere on a PAR 370-4 electrochemistry system as described previously [14]. All potentials reported in this work are uncorrected for junction contribution. Solution (*ca* 1 mmol) electrical conductivity measurements were performed on an Elico CM 82T conductivity bridge.

Reactions

(a) Reaction of *cis*-$RuCl_2(L)_2$ (L = L^1 and L^2) and $[Ag(L)_2]ClO_4$. To a sample of bluish green *cis* isomer of $RuCl_2(L)_2$ (0.5 mmol) suspended in ethanol–water mixture (5 : 1) was added a solution of $[Ag(L)_2]ClO_4$ (1 mmol) in ethanol (10 cm^3) and the mixture was heated to reflux for 1 h. The solution was cooled and filtered through a G-4 sintered glass funnel. The filtrate was evaporated to dryness. The crude mass was then dissolved in CH_2Cl_2 and subjected to column chromatography on a silica gel column eluting with different mixtures of CH_2Cl_2-CH_3CN. A pink band of $[Ru(pic)(L)_2]^+$ was eluted with CH_2Cl_2-CH_3CN (5 : 1) followed by a brown band of $[Ru(L)_3]^{2+}$ eluted with CH_2Cl_2-CH_3CN (3 : 2). These were evaporated and crystallized from CH_2Cl_2-C_6H_{14} (1 : 1). The compounds were obtained as solvates. The yields and analyzes were as follows.

Table 5. Redox spectral data

Compound	$E_{1/2}$(V) Metal oxidation	$-E_{1/2}$(V) First ligand reduction	ΔE(V) Ox/Red	*vc.t.* (cm^{-1})
$[Ru(L^1)_3](ClO_4)_2 \cdot H_2O$	1.43	0.93	2.36	20833
$[Ru(pic)(L^1)_2]ClO_4 \cdot CH_2Cl_2$	1.00	1.15	2.15	19417
$[Ru(L^2)_3](ClO_4)_2 \cdot H_2O$	1.44	0.90	2.34	20833
$[Ru(pic)(L^2)_2]ClO_4 \cdot CH_2Cl_2$	1.00	1.16	2.16	19417
$[Ru(L^2)(L^3)_2](ClO_4)_2 \cdot H_2O$	2.00	0.15	2.15	19417
$[Ru(pic)(L^3)_2]ClO_4 \cdot CH_2Cl_2$	1.50	0.28	1.84	18348
$[Ru(L^3)(L^2)_2](ClO_4)_2 \cdot H_2O$	1.81	0.40	2.21	20000
$[Ru(L^2)(L^3)(L^4)]ClO_4 \cdot CH_2Cl_2$	0.98	0.92	1.90	19230

$[Ru(pic)(L^1)_2]ClO_4 \cdot CH_2Cl_2$: yield 35%. (Found: C, 48.3; H, 3.4; N, 9.1. Calc. for $C_{31}N_5H_{26}O_6Cl_3Ru$: C, 48.2; H, 3.4; N, 9.1%).

$[Ru(L^1)_3](ClO_4)_2 \cdot H_2O$: yield 25%. (Found: C, 50.2; H, 3.7; N, 9.6. Calc. for $C_{36}N_6H_{32}O_9Cl_2Ru$: C, 50.0; H, 3.7; N, 9.7%).

$[Ru(pic)(L^2)_2]ClO_4 \cdot CH_2Cl_2$: yield 37%. (Found: C, 49.3; H, 3.7; N, 8.9. Calc. for $C_{33}N_5H_{30}O_6Cl_3Ru$: C, 49.5; H, 3.7; N, 8.7%).

$[Ru(L^2)_3](ClO_4)_2 \cdot H_2O$: yield 26%. (Found: C, 51.5; H, 4.2; N, 9.3. Calc. for $C_{39}N_6H_{38}O_9Cl_2Ru$: C, 51.6; H, 4.2; N, 9.3%).

(b) Conversion of $[Ru(L^1)_3](ClO_4)_2$ to $[Ru(pic)(L^1)_2]ClO_4$. To a solution of 0.25 mmol of $[Ru(L^1)_3](ClO_4)_2$ in ethanol–water mixture (5:1) was added an aqueous solution of $AgNO_3$ (1 mmol in 5 cm^3 of water) and the mixture was heated to reflux for 2 h. It was then evaporated to dryness and subjected to column chromatography on a silica gel column eluting with different mixtures of CH_2Cl_2-CH_3CN as described in Section (a).

The yields were as follows: $[Ru(pic)(L^1)_2]ClO_4 \cdot CH_2Cl_2$: 76%; $[Ru(L^1)_3](ClO_4)_2 \cdot H_2O$: 19%.

(c) Reaction of *cis*-$RuCl_2(L^3)_2$ and $[Ag(L^2)_2]ClO_4$. This reaction was similarly performed as the reaction described in Section (a) starting from *cis*-$RuCl_2(L^3)_2$ and $[Ag(L^2)_2]ClO_4$. The yields and analyzes of the isolated products are as follows:

$[Ru(pic)(L^3)_2]ClO_4 \cdot CH_2Cl_2$: yield 42%. (Found: C, 46.3; H, 3.5; N, 12.2. Calc. for $C_{31}N_7H_{28}O_6Cl_3Ru$: C, 46.4; H, 3.5; N, 12.2%).

$[Ru(L^2)(L^3)_2](ClO_4)_2 \cdot H_2O$: yield 20%. (Found: C, 49.0; H, 3.9; N, 12.4. Calc. for $C_{37}N_8H_{36}O_9Cl_2Ru$: C, 48.9; H, 4.0; N, 12.3%).

(d) Conversion of $[Ru(L^2)(L^3)_2](ClO_4)_2$ to $[Ru(pic)(L^3)_2]ClO_4$. This was similarly performed as described in Section (c) starting from $[Ru(L^2)(L^3)_2](ClO_4)_2$. The yields were as follows: $[Ru(pic)(L^3)_2]ClO_4 \cdot CH_2Cl_2$: yield 85%; $[Ru(L^2)(L^3)_2](ClO_4)_2 \cdot H_2O$: yield 9%.

(e) Reaction of $[Ru(L^3)_2(OH_2)_2]^{2+}$ and PicH was performed as described previously [11].

(f) Reaction of *cis*-$RuCl_2(L^2)_2$ and $[Ag(L^3)_2]ClO_4$. The above reaction was also similarly performed as described in Section (a) starting from *cis*-$RuCl_2(L^2)_2$ and $[Ag(L^3)_2]ClO_4$. The yields and analyzes were as follows:

$[Ru(L^2)(L^3)(L^4)](ClO_4) \cdot CH_2Cl_2$: yield 40%. (Found: C, 52.3; H, 4.0; N, 11.3. Calc. for $C_{39}N_7H_{36}O_5Cl_3Ru$: C, 52.6; H, 4.0; N, 11.0%).

$[Ru(L^3)(L^2)_2](ClO_4)_2 \cdot H_2O$: yield 17%. (Found: C, 50.5; H, 4.1; N, 10.9. Calc. for $C_{38}N_7H_{37}O_9Cl_2$: C, 50.3; H, 4.1; N, 10.8%).

Crystallography

Single crystals of $[Ru(pic)(L^1)_2]ClO_4 \cdot CH_2Cl_2$ were grown at 298 K by slow diffusion of hexane into dichloromethane solution of the compound. Diffraction measurements were carried out on a Nonius CAD4 fully automated four-circle diffractometer. The unit cell was determined and refined using setting angles of 25 reflections, with 2θ angles in the range 11.60 to 20.82°. The unit cell dimensions are listed in Table 6. Data were collected by $\theta - 2\theta$ scans within the angular range 3–45°. All data reduction and structure refinement were performed using the NRCC-SDP-VAX packages. The structure was solved by the Patterson method. Final cycles of least square refinement converged with discrepancy indices of $R_f = 0.045$ and $Rw = 0.035$. Tables containing full listings of atom positions, anisotropic thermal parameters and hydrogen atom locations are available as supplementary material.

(Received 30 July 1996; accepted 25 September 1996)

Abstract—The tellurium-rich compound $[Re_6Te_{14}I_{14}]$ (**1**) was obtained in high yield by high-temperature reaction (400°C) of the octahedral cluster complex Re_6Te_{15} with I_2 in a 1 : 9 ratio. Compound **1** is diamagnetic, air-stable and insoluble in most common organic solvents. The structure of **1** has been determined by single-crystal X-ray diffraction. The $[Re_6Te_8(TeI_2)_6]^{2+}$ structure is characterized by the presence of the octahedral Re_6 cluster with Re—Re distances at 2.690(1)–2.700(1) Å; the Re—μ_3—Te distances are 2.689(1)–2.698(1) Å. Each Re atom is ligated by neutral TeI_2 group. The Re—TeI_2 distances are 2.670(1)–2.672(1) Å. The Te—I distances in the TeI_2 ligands range from 2.756(2) to 2.785(2) Å. The I—Te—I bond angles are 89.29(5)–92.67(5)° and the Re—Te—I angles span 104.19(4) to 106.56(3)°. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: rhenium tellurium cluster compound; crystal structure.

The chemistry of Te^{IV} halides is well developed, but much less is known about Te^{II} halides. It has not been possible yet to prepare the halides of Te^{II} as pure phases [1]. However, they do exist in solution or in the gas phase as dissociation products of Te^{IV} halides. Tellurium(II) halides demonstrate a very high tendency to be stabilized in solution through the formation of complexes with anionic or with neutral Lewis bases; for halochalcogenate(II) anionic species examples are (i) series of tetrahalotellurates(II), TeX_4^{2-} (X = Cl, Br, I) [2,3], (ii) the dinuclear planar $Te_2I_6^{2-}$ ion [1]. During attempts to prepare transition-metal derivatives of halotellurates(II) only the tetranuclear $Te_4I_{14}^{2-}$ complex was obtained [4].

Recently the first examples of the metal cluster complexes $[Nb_2Te_8I_{12}]$ [5] and $[Mo_3Te_{10}I_{10}]$ [6] containing $Te_2I_6^{2-}$ and TeI_3^- ligands have been described. It is remarkable that halotellurate(II) ions can be obtained in complex form from high-temperature reactions. In 1996 Strähle *et al.* described the synthesis and structure of $Re_4Te_4(TeBr_2)_4Br_8$ [7]. The complex was obtained from the elements at 550°C and contains $TeBr_2$ ligands. Hexanuclear Re_6 tellurohalide cluster compounds $[Re_6Te_6Cl_6(TeCl_2)_2]$ and $[Re_6Te_8(TeBr_2)_6]Br_2$ have been obtained by high-temperature reaction of rhenium halides with elemental Te [8].

In this paper, we report the use of a high-temperature reaction of octahedral tellurium-rich compound Re_6Te_{15} with I_2 for the synthesis of the octahedral cluster compound $Re_6Te_{14}I_{14}$ (**1**) containing terminal TeI_2 ligands coordinated to the rhenium atoms of the $[Re_6(\mu_3\text{-}Te)_8]^{2+}$ cluster fragment.

The inorganic ligands $TeCl_2$, $TeBr_2$ and TeI_2 are new. The number of known complexes with related SCl_2 and $SeCl_2$ ligands is limited and examples are (i) $PdCl_2(QCl_2)_2$ (Q = S, Se) [9, 10], (ii) $PtCl_4(SCl_2)_2$ [10], (iii) $Ru_2Cl_5(SCl_2)_4$ [11], and (iv) $AuCl_3(SCl_2)$ [12].

EXPERIMENTAL

Preparation of $Re_6Te_{14}I_{14}$ (1)

Re_6Te_{15} was prepared by the literature method [13b]. A mixture of Re_6Te_{15} (1.5155 g, 0.50 mmol) and I_2 (1.1548 g, 4.55 mmol) was heated (400°C, 48 h) in an evacuated fused silica tube. The tube was cooled

at 10°C h to promote crystal growth. Excess of iodine and TeI_4 were evaporated *in vacuo* at 160°C, allowing the isolation of hexagonal well-formed crystals of **1**. Yield: 2.25 g (96%). Found: Re, 23.8; Te, 38.2. Calc for $I_{14}Re_6Te_{14}$: Re, 23.9; Te, 38.2%.

In order to ensure product homogeneity, the X-ray powder diffraction diagram of the product was obtained and found to be identical with the one calculated from the single-crystal data.

X-ray data collection and structure solution

Reflection data of $Re_6Te_{14}I_{14}$ (**1**) were collected at 295 K on a Rigaku AFC-5R diffractometer with graphite monochromated Mo-K_α radiation ($\lambda = 0.7107$ Å). The ψ-scan data showed very large absorption effect (relative transmission factor: 0.232–0.983), and an empirical absorption correction was applied. Such a large absorption was inevitable because the crystals grew as hexagonal plates, and the compound had a large μ value ($\mu = 32.6$ mm^{-1}) due to the heavy atoms. The structure could be successfully solved by direct methods (SHELXS86). Successive refinements gave reasonable interatomic distances and angles. However, the R values were high for a crystal with a good quality ($R = 0.126$ and $Rw = 0.124$ for 6035 reflections with $|F_o| > 3\sigma(F_o)$). No large residual peak was found on the Fourier maps. Examination of the discrepancies between $|F_o|$ and $|F_c|$ values revealed that strongly absorbed reflections had larger differences, which indicated that strongly absorbed reflections had not been accurately corrected with the empirical ψ-scan method. Therefore, the accuracy of the atomic parameters was substantially determined by the accuracy of the absorption correction. To obtain more accurate atomic parameters, we removed reflections with the calculated transmission factor less than 0.45 because their intensities were corrected less accurately than those of other reflections. After these reflections were removed, the reflections that could be used for refinements were still abundant. The ratio of the number of reflections to the number of variables was 26.2, and enough to determine the structure accurately. The refinements with the reduced reflection data set gave reasonable R values ($R = 0.036$, $Rw = 0.029$ for 4064 reflections). The differences between the parameters obtained from the refinement with all reflections and the corresponding parameters obtained with reduced reflection data were very small: the ratios of the difference to the estimated standard deviation were all less than 2.0.

Crystal data and refinement results for **1** are given

RESULTS AND DISCUSSION

The hexanuclear Re_6 telluride Re_6Te_{15} is well known [13]. The cluster cores $[Re_6(\mu_3-Te)_8]$ of the compound are connected with each other *via* almost planar butterfly-like $Te_7 \equiv [Te(Te_3)_2]$ units. At room temperature Re_6Te_{15} reacts with Br_2 to form a molecular compound $Re_6Te_4Br_{10} \equiv [Re_6(\mu_3-Te)_4(\mu_3-Br)_4]Br_6$ with terminal Br atoms bonded to each rhenium atom [13b,14]. During the course of our study of controlled reaction of Re_6Te_{15} with I_2 we have obtained complex $[Re_6Te_{14}I_{14}]$ (**1**) containing terminal TeI_2 ligands coordinated to the rhenium atoms of the $[Re_6(\mu_3-Te)_8]^{2+}$ cluster fragment. Complex **1** is the first complex with TeI_2 ligands.

The tellurium-rich compound $[Re_6Te_{14}I_{14}]$ was obtained in high yield by the high-temperature reaction of the octahedral cluster complex Re_6Te_{15} with I_2 in a 1 : 9 ratio. The relevant equation is as in (1).

$$Re_6Te_{15} + 9I_2 \longrightarrow Re_6Te_{14}I_{14} + TeI_4 \qquad (1)$$

Compound **1** is diamagnetic, air-stable and insoluble in most common organic solvents. The structure of **1** has been determined by single-crystal X-ray diffraction. The $[Re_6Te_8(TeI_2)_6]^{2+}$ structure (Fig. 1) is characterized by the presence of the octahedral Re_6 cluster with Re—Re distances at 2.690(1)–2.700(1) Å, which are similar to those of Re_6Te_{15} (2.667(2)–2.682(2) Å) [15]. Each triangular face of the octa-

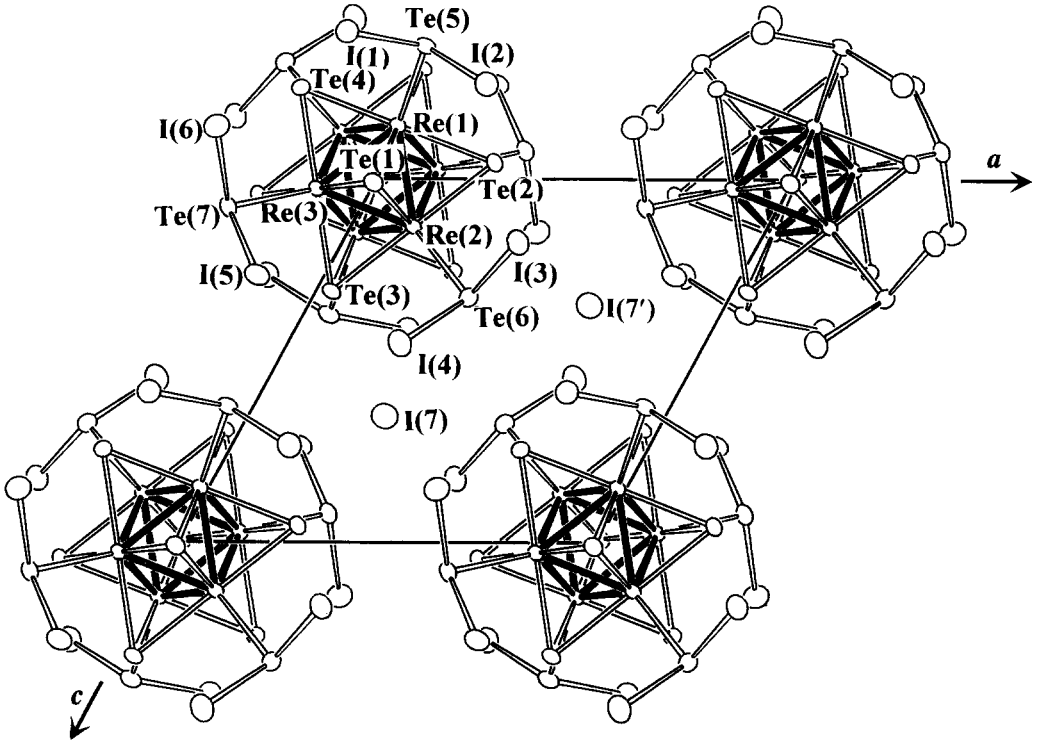

Fig. 2. ORTEP drawing of a cell of $[Re_6Te_8(TeI_2)_6]I_2$ projection on the *a*-*c* plane. Thermal ellipsoids are drawn at the 50% probability level.

hedron Re_6 is capped almost symmetrically by triply bridging telluride ions; the Re—μ_3—Te distances are 2.689(1)–2.698(1) Å. Each Re atom is further ligated by the neutral TeI_2 group. The Re—TeI_2 distances at 2.670(1)–2.672(1) Å are comparable to the Re—μ_3—Te distances. The Te—I distances in the TeI_2 ligands range from 2.756(2) to 2.785(2) Å. The I—Te—I bond angles are 89.29(5)–92.67(5)° and the Re—Te—I angles span 104.19(4) to 106.56(3)°. Tellurium atoms of the neutral ligands TeX_2 (X = Cl, Br, I) of the complexes $Re_6Te_6Cl_6(TeCl_2)_2$, $[Re_6Te_8(TeBr_2)_6]Br_6$ [8], $Re_4Te_4(TeBr_2)_4Br_8$ [7], and $[Re_6Te_8(TeI_2)_6]I_2$ have pyramidal geometry as predicted from VSEPR model consideration. The distortion of the polyhedron around the Te atom is caused by coordination to Re and by stereochemically active lone pairs directed from the Te atoms toward a vertex of tetrahedral polyhedrons.

The bonding in diamagnetic **1** can be rationalized in a straightforward manner. Counting iodine and μ_3-Te ligands as I^- and Te^{2-}, the TeI_2 groups as neutral ligands leads to the formulation $[(Re^{3+})_6(Te^{2-})_8(TeI_2)_6](I^-)_2$, where 24 electrons are shared by six Re atoms. In fact, the Re—Re bond distances in **1** are in good agreement with formal Re—Re single bond distances of the other 24 electron hexanuclear telluro, seleno and thio cluster complexes [15].

In the structure of $[Re_6Te_8(TeI_2)_6]I_2$, the clusters make close-packed layers along the *ac* plane (Fig. 2). All of the triangles in a close-packed layer are centered by iodide anions. Though a single layer has a pseudo-three-fold symmetry, the neighboring layer is shifted approximately along the *c*-axis by 0.3 c, and the whole crystal structure does not have pseudo-three-fold symmetry. A pseudo-three-fold axis passes Te1 atoms in a $[Re_6Te_8(TeI_2)_6]^{2+}$ cluster.

(Received 18 July 1996; accepted 25 September 1996)

Abstract—The new compound benzoato *meso*-tetra(4-methoxyphenylporphyrinato)thallium(III), Tl(tmpp)($C_6H_5CO_2$), has been synthesized and its molecular structure determined by X-ray analysis. The coordination sphere of the Tl^{3+} ion is an approximate square-based pyramid in which the apical site is occupied by an asymmetric-bidentate $C_6H_5CO_2^-$ group. The average Tl—N bond distance is 2.24(1) Å and the Tl atom is displaced 0.811 Å from the porphyrin plane. The Tl(1)—O(5) and Tl(1)—O(6) distances are 2.57(2) and 2.27(2) Å, respectively. Variable temperature ^{13}C NMR measurements show that the benzoato group of Tl(tmpp)($C_6H_5CO_2$) in CD_2Cl_2 solvent undergoes intramolecular exchange. In the slow exchange region, the carbonyl and $C_{1'}$ carbons of the benzoato group are separately located at 167.8 ppm [with ^2J(Tl-^{13}C) coupling constant 212 Hz] and 128.3 ppm [with ^3J(Tl-^{13}C) coupling constant 282 Hz] for Tl(tmpp)($C_6H_5CO_2$) in CD_2Cl_2 at −90°C. In the fast exchange region, the C*OO and $C_{1'}$ carbons of the $C_6H_5CO_2^-$ ligand in CD_2Cl_2 at 21°C are singlets at 168.4 and 130.3 ppm, respectively. The comparison of the ring current effect ($\Delta\delta$) for the benzoate ligand of Tl(tmpp)($C_6H_5CO_2$) and benzoato *meso*-tetra(4-methoxyphenylporphyrinto)tin(IV), Sn(tmpp)($C_6H_5CO_2$)$_2$, is also reported. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: crystal structure; thallium porphyrin complexes; intramolecular exchange; low temperature ^{13}C NMR; benzoato ligand; asymmetric bidentate ligand.

Previously, the synthesis, characterization and dynamic NMR studies of acetato *meso*-tetra(4-methoxyphenylporphyrinto) thallium(III), Tl(tmpp)(OAc), were reported by our group [1]. It turned out that the acetato ligand exchange for Tl(tmpp)(OAc) in CD_2Cl_2 solvent was intramolecular. When the OAc^- of Tl(tmpp)(OAc) was replaced by a bulkier and heavier benzoate group, $C_6H_5CO_2^-$, the complex Tl(tmpp)(OAc) became benzoato *meso*-tetra(4-methoxyphenylporphyrinto)thallium(III) Tl(tmpp)($C_6H_5CO_2$) (**1**). The acetato exchange of Tl(tmpp)(OAc) encouraged us to investigate a similar benzoato exchange for Tl(tmpp)($C_6H_5CO_2$) in CD_2Cl_2 by ^{13}C dynamic NMR method.

Smith *et al.* [2] reported the crystal structure of benzoato *meso*-tetra(4-methoxyphenylporphyrinto) tin(IV), Sn(tpp)($C_6H_5CO_2$)$_2$. Sn(tpp)($C_6H_5CO_2$)$_2$ is a tin(IV) complex with the benzoate, $C_6H_5CO_2^-$, being unidentately coordinated to the Sn atom. When the tpp was substituted by *meso*-tetra-(4-methoxyphenyl)porphyrin (tmpp), it became benzoato-*meso*-tetra-(4-methoxyphenylporphyrinato)tin(IV), Sn(tmpp)($C_6H_5CO_2$)$_2$ (**2**). The synthesis, ^{13}C and ^1H NMR spectroscopic studies of the new complex, Sn(tmpp)($C_6H_5CO_2$)$_2$ (**2**), are also reported.

In this paper, ^1H and X-ray analysis of Tl(tmpp)($C_6H_5CO_2$) (**1**) are reported. The ^{13}C NMR spectra at low temperature are examined to infer the intramolecular apical ligand, $C_6H_5CO_2^-$, exchange for Tl(tmpp)($C_6H_5CO_2$) in CD_2Cl_2. The comparison of

the ring current shielding effect for compounds (**1**), (**2**) is an interesting subject and is also investigated in this paper.

EXPERIMENTAL

Synthesis

Tl(tmpp)($C_6H_5CO_2$) (**1**). Tl(tmpp)Cl (95.5 mg, 0.1 mmoles) [1] in $CHCl_3$ (20 cm^3) was treated with sodium benzoate (155.8 mg) in CH_3OH (10 cm^3) and stirred under reflux for ~13 h. After concentrating, it was dissolved in CH_2Cl_2 and extracted three times with distilled water to remove the excess $C_6H_5CO_2Na$. The CH_2Cl_2 layer was concentrated to dryness and gave purple prisms (91.8 mg, 87.9%). The crystals were grown by diffusion of ether vapour into a $CHCl_3$ solution. It was dissolved in CD_2Cl_2 (99.95% from Aldrich) for ^1H (Table 1, at 21°C) and ^{13}C (Table 2, at 21 and −90°C) NMR measurement.

Sn(tmpp)($C_6H_5CO_2$)$_2$ (**2**). Free base (tmpp; 150 mg, 0.204 mmoles, from Aldrich) and powdered $SnCl_2 \cdot 2H_2O$ (92 mg, 0.408 mmoles) were stirred and refluxed in pyridine (30 cm^3) for 3 h. The solution was cooled to 50°C, then saturated $C_6H_5CO_2H$ (12 cm^3, 32% in NH_3) was added, and heating and stirring were continued for another 3 h. After the solution was cooled, water (150 cm^3) was added, and the solid collected by vacuum filtration, washed with water, and dried by suction. The filter cake was digested *in situ* with CH_2Cl_2, dried with anhydrous Na_2SO_4 and filtered. The filtrate was taken to dryness under reduced pressure by rotatory evaporation and the product obtained was recrystallized from CH_2Cl_2/*n*-hexane yielding blue crystals (181 mg, 81%). It was dissolved in $CDCl_3$ for NMR measurement at 21°C (shown in Tables 1 and 2).

Spectroscopy

^1H and ^{13}C NMR spectra were recorded at 400.13 (or 600.20) and 100.61 (or 150.93) MHz, respectively, on a Bruker AM-400 spectrometer (or Bruker DMX-600) in $CDCl_3$ or CD_2Cl_2. ^{13}C NMR data are relative to the centre line of $CDCl_3$ at 77.0 ppm (or CD_2Cl_2 at 53.6 ppm). ^1H NMR data are relative to $CDCl_3$ at 7.24 ppm (or CD_2Cl_2 at 5.30 ppm).

Crystallography

Crystal data and other information for [Tl(tmpp)($C_6H_5CO_2$)·$CHCl_3$] are given in Table 3. Measurements were made on a Siemens SMART CCD diffractometer using monochromatized Mo-K_α radiation ($\lambda = 0.71073$ Å) *via* the $\omega:2\theta$ scan technique. Absorption correction was based on 3516 symmetry-equivalent reflections using the SHELXTL-PC program package ($T_{min,max} = 0.482, 0.906$). The structure was solved by direct methods (SHELXTL PLUS) and refined by full-matrix least-squares. All non-hydrogen atoms were refined with anisotropic thermal parameters, whereas all hydrogen atom positions were calculated using a riding model and included in the structure factor calculation. Selected bond distances and angles for [Tl(tmpp)($C_6H_5CO_2$)·$CHCl_3$] are given in Table 4.

RESULTS AND DISCUSSION

Molecular structure of [Tl(tmpp)($C_6H_5CO_2$)·$CHCl_3$]

The skeletal framework of the complex [Tl(tmpp)($C_6H_5CO_2$)·$CHCl_3$], with $P2_1/C$ symmetry, is illustrated in Fig. 1. It reveals the six-coordination of the thallium atom with four nitrogen atoms of the porphyrinato group and the asymmetric bidentate $C_6H_5CO_2^-$ ligand; bond distances (shown in Table 4) are: Tl(1)—O(5) = 2.57(2), Tl(1)—O(6) = 2.27(2), O(5)—C(49) = 1.31(3), O(6)—C(49) = 1.17(2), C(49)—C(50) = 1.50(3) and the mean Tl(1)—N = 2.24(1) Å. The $CHCl_3$ molecule C(56)H(56a)Cl(1)Cl(2)Cl(3), in [Tl(tmpp)($C_6H_5CO_2$)·$CHCl_3$] arose from the solvent trapped during the crystal growth.

The thallium atom lies 0.789 and 0.811 Å from the four porphyrin nitrogens and the 24-atom porphyrin plane ($C_{20}N_4$), respectively. The dihedral angles between the mean planes of the skeleton ($C_{20}N_4$) and the planes of the phenyl group are 63.1° [C(24)], 80.7° [C(31)], 70.6° [C(38)] and 71.1° [C(45)].

The radius of the central "hole" ($C_t\cdots N$, the distance from the geometrical centre of the mean plane of the 24-atom core to the porphyrinato-core N atoms) in [Tl(tmpp)($C_6H_5CO_2$)·$CHCl_3$] is 2.096 Å which is larger than 2.01 Å suggested by Collins *et al.* [3]. The thallium(III) atom is bonded in a highly expanded porphyrinato core ($C_{20}N_4$) in [Tl(tmpp)($C_6H_5CO_2$)·$CHCl_3$] and the porphyrin ($C_{20}N_4$ and Tl) can be viewed as a domed shape. The net doming is 0.02 Å (= 0.811–0.789). Figure 2 shows the displacement (in Å) of each atom of the porphyrin ($C_{20}N_4$ and Tl) from the porphyrin mean plane ($C_{20}N_4$).

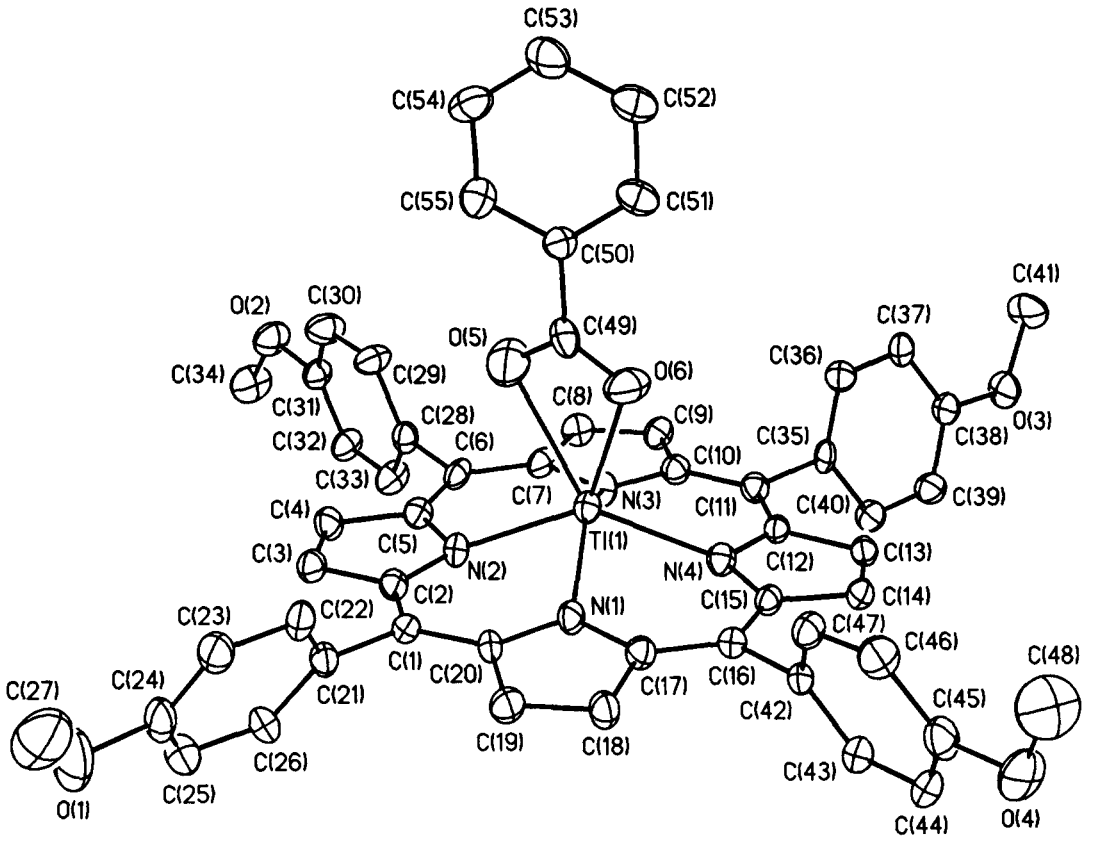

Fig. 1. Molecular configuration and atom labelling scheme for [Tl(tmpp)($C_6H_5CO_2$)·$CHCl_3$]. Hydrogen atoms and solvent C(56)H(56a)Cl(1)Cl(2)Cl(3) are omitted for clarity.

at 21°C and −90°C, respectively, and their ^{13}C data appear in Table 2. At 21°C, intramolecular exchange of the $C_6H_5CO_2^-$ group is rapid, indicated by singlet signals due to carbonyl carbons at 168.4 ppm and $C_{1''}$ carbons at 130.3 ppm shown in Fig. 3(a). At −90°C, the rate of the intramolecular exchange of $C_6H_5CO_2^-$ for Tl(tmpp)($C_6H_5CO_2$) (**1**) in CD_2Cl_2 is slow comparable with the coupling frequency of Tl-^{13}C, i.e. 247 ± 35 Hz. Hence, C*O and $C_{1''}$ carbons of $C_6H_5CO_2^-$ shown in Fig. 3(b) are observed at 167.8 ppm [with ^2J(Tl-^{13}C) = 212 Hz] and 128.3 ppm [with ^3J(Tl-^{13}C) = 282 Hz], respectively.

The intramolecular exchange of the $C_6H_5CO_2^-$ group is rapid for Tl(tmpp)($C_6H_5CO_2$) (**1**) in CD_2Cl_2

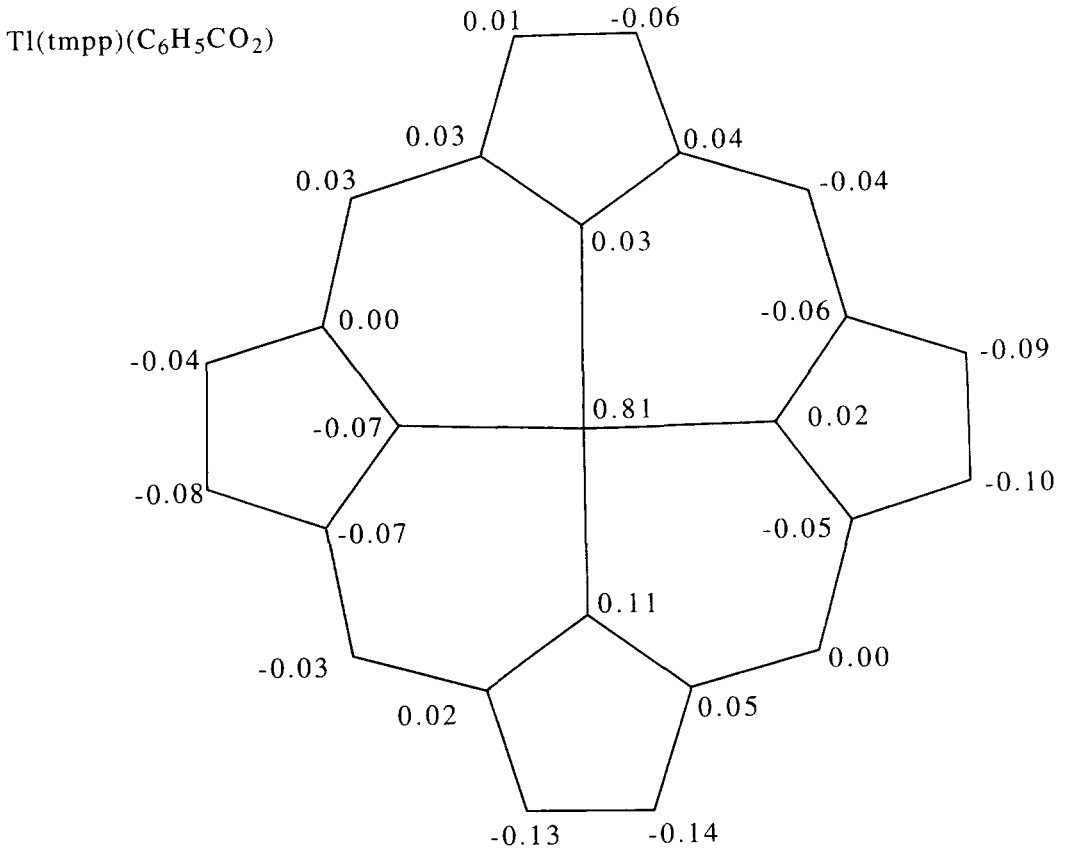

Fig. 2. Formal diagram of the porphyrin core ($C_{20}N_4$ and Tl) of [Tl(tmpp)($C_6H_5CO_2$)·$CHCl_3$] in which each atom symbol is replaced by a number showing the displacement (in Å) of that atom from the mean plane of porphyrin ($C_{20}N_4$).

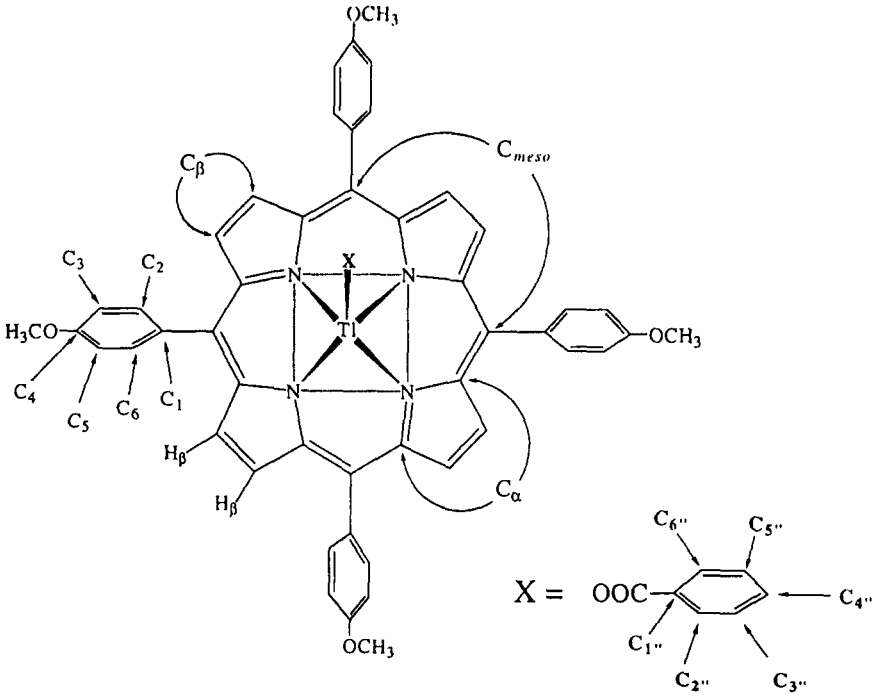
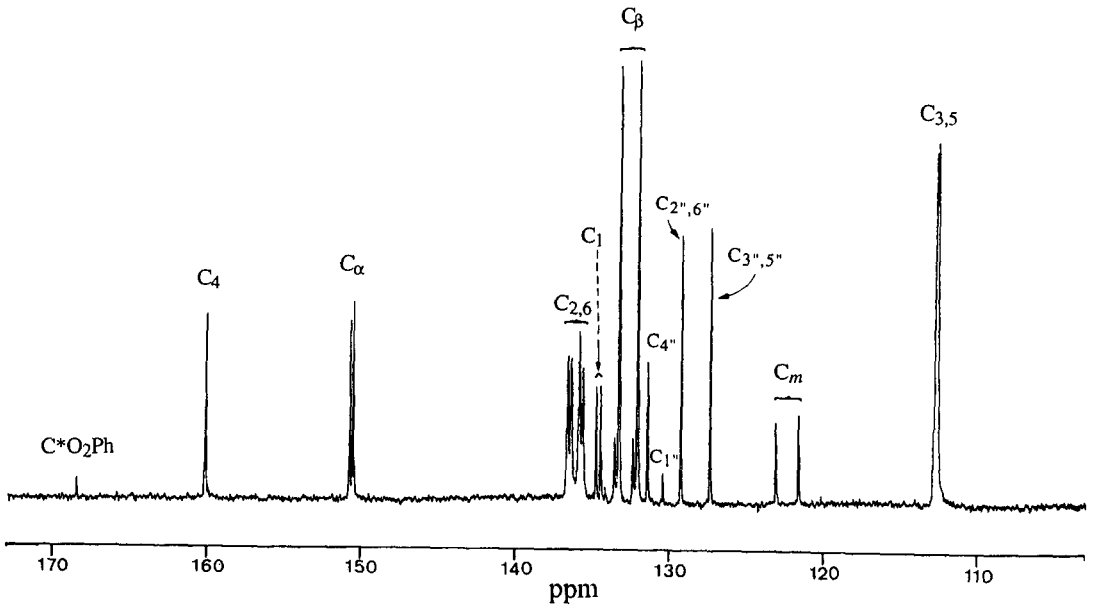


at 21 C, whereas the rotation of anisole group along C_1—C_{meso} bond is slow at the same temperature on the NMR time-scale. It is supported by both the assignment of 136.4, 135.6 ppm to the $C_{2,6}$ carbons and 112.6, 112.5 ppm due to the $C_{3,5}$ carbons (shown in Table 2) and by the assignment of 8.25, 8.06 ppm to $H_{2,6}$ protons (or *ortho*-H) and 7.32, 7.27 ppm due to $H_{3,5}$ protons (or *meta*-H, shown in Table 1).

The singlet signals for carbonyl carbons at 162.9 ppm and $C_{1''}$ carbons at 128.1 ppm (shown in Table 2) for Sn(tmpp)($C_6H_5CO_2$)$_2$ (**2**) in $CDCl_3$ at 21 and −50 C indicates no $C_6H_5CO_2^-$ exchange in compound (**2**). The benzoate might be, as in the case of Sn(tpp)($C_6H_5CO_2$)$_2$ [2], unidentately coordinated to the Sn atom for compound (**2**), and the tin(IV) atom is centered in an expanded porphyrinato core ($C_{20}N_4$).



Compared with compound (**1**), the rotation of the anisole group along C_1—C_{meso} for compound (**2**) is fast at 21°C on the NMR time-scale. It is supported by both the assignment of 135.9 ppm to $C_{2,6}$ carbons and 112.5 ppm due to the $C_{3,5}$ carbons (shown in Table 2) and by the assignment of 8.16 ppm to $H_{2,6}$ protons and 7.32 ppm due to $H_{3,5}$ protons (shown in Table 1).

Due to the ring current effect, upfield shifts for the ^{1}H resonances of $H_{4''}$, $H_{3'',5''}$ and $H_{2'',6''}$ in Tl(tmpp)($C_6H_5CO_2$) (**1**) are $\Delta\delta = -0.68$ [from 7.61 (obtained from C_6H_5COOH) to 6.93 ppm], −0.78 (from 7.47 to 6.69 ppm) and −1.73 ppm (from 8.12 to 6.39 ppm), respectively (shown in Table 1). From the same effect, upfield shifts for the ^{1}H resonances of $H_{4''}$, $H_{3'',5''}$ and $H_{2'',6''}$ in Sn(tmpp)($C_6H_5CO_2$)$_2$ (**2**) are $\Delta\delta = -0.94$ (from 7.61 to 6.67 ppm), −1.14 (from 7.47 to 6.33 ppm) and −3.21 ppm (from 8.12 to 4.91 ppm), respectively (shown in Table 1). All indicate that as the protons of the benzoate ligand become closer to the $C_{t'}$, the shielding gets larger. The porphyrin ($C_{20}N_4$ and Tl) of compound (**1**) is viewed as domed shape whereas that ($C_{20}N_4$ and Sn) of compound (**2**) is planar. $C_{t'}$ (1.3391, 0.14134, 0.13389), of compound (**1**) is different from Tl(1), (1.38291, 0.14291, 0.09151), atom whereas $C_{t'}$ of compound (**2**) is Sn atom. The distances between $H_{4''}$, $H_{3'',5''}$, $H_{2'',6''}$ and $C_{t'}$ are longer in compound (**1**) than in compound (**2**). Hence the ring-current effect $\Delta\delta$ is larger in compound (**2**) than in compound (**1**) with (−0.94 *vs* −0.68 ppm) for $H_{4''}$, (−1.14 *vs* −0.78 ppm) for $H_{3'',5''}$ and (−3.21 *vs* −1.73 ppm) for $H_{2'',6''}$.

In summary, although the bulky benzoate group is asymmetrically and bidentately coordinated to the thallium atom in compound (**1**), it still undergoes the

Abstract—A binuclear Nd^{III} complex of formula $[Nd_2(phen)_2(ONO_2)_2(CH_3COO)_4]$ (phen = phenanthroline) has been prepared and its structure and magnetism have been studied by X-ray diffraction and magnetic susceptibility measurements. The structure consists of two Nd^{III} ions bridged by four-bidentate CH_3COO^- groups and coordinated by two phen and two ONO_2 groups to give a binuclear $[Nd_2(phen)_2(ONO_2)_2(CH_3COO)_4]$ unit. This molecule possesses C_2 point group symmetry and the Nd atom is 9-coordinated in an irregular polyhedron. The average Nd—N distance (2.649 Å) is longer than the average Nd—O(2.493 Å). All four CH_3COO^- groups are bidentate ligands which connect to Nd as bridges while the O(4) atom is the μ_3 bridge oxygen and links two Nd atoms. The Nd—Nd distance is relatively short (3.974 Å). Cryomagnetic investigations (4.5–300 K) reveal a weak antiferromagnetic coupling with $J = -0.16$ cm^{-1}. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: neodymium; acetato; binuclear complex; synthesis; structure; magnetism.

Recently, the study of molecular-based magnets involving transition metals has been an active research field [1–9]. Introduction of lanthanide elements into these magnets might have great prospect since their **f** orbitals can accommodate more unpaired electrons than the **d** orbitals of transition metals. In fact, it has been demonstrated that lanthanides play an important function in permanent magnetism [10]. There are, however, only very few reports on this [11]. In addition, when lanthanides react with carboxylic acids and their derivatives, due to different ligand-bridging fashions, the structures of the resultant complexes are various and give rise to important effects on their optical, electronic and magnetic properties [12,13]. Investigations in this field may provide the basis for applying these sort of complexes.

EXPERIMENTAL

Preparation of $[Nd_2(phen)_2(ONO_2)_2(CH_3COO)_4]$

0.15 g phen., 0.2 g 8-hydrocyquinoline, 3 cm^3 water, 0.4 g CH_3COOH and 20 cm^3 acetone were fully mixed and 0.3 g $Nd(NO)_3 \cdot 6H_2O$ was resolved in 20 cm^3 acetone. Afterwards, the two solutions prepared above were mixed with stirring at room temperature, giving immediately a yellow solution which was kept at room temperature, and after one week pale yellow-pink crystals separated out. Found: C, 38.3; H, 2.8; N, 8.3; Nd, 28.3. Calc. for $C_{32}H_{28}N_6Nd_2O_{14}$, C, 38.1; H, 2.8; N, 8.3 and Nd, 28.6%.

Structure determination and refinement

Crystallographic data for the complex are given in Table 1. The treatment of the data was carried out on a VMS Computer using SHELXTL-Plus programs. The structure was solved by direct methods and refined with full matrix least-squares. The function minimized was $\Sigma\omega(F_o - F_c)^2$, where weighting scheme $\omega^{-1} = \sigma^2(F) + 0.0002F^2$ was used. At the same time, the extinction correction was made. An anisotropic thermal motion model was used for all non-hydrogen atoms, whilst the hydrogen atoms were placed in the

Largest difference hole	−0.71 e Å^{-3}

calculated positions which fixed the isotropic thermal parameters.

Magnetic measurements

Magnetic susceptibilities were measured with a MPMS-7 type Superconducting Quantum Magnetometer in the temperature range 4.5–300 K and in a field of 10 KGS. The effective magnetic moments were calculated from the equation $\mu_{eff} = 2.828(\chi_m T)^{1/2}$, where χ_m is the molar magnetic susceptibility corrected for diamagnetism of constitutional atoms. The final data corrections were made using Pascal's constants.

RESULTS AND DISCUSSION

Description and discussion of the structure

The selected bond lengths and bond angles of complex $[Nd_2(phen)_2(ONO_2)_2(CH_3COO)_4]$ are listed in Table 2. The molecular structure and the packing of the molecules in unit cell of the complex are shown in Figs 1 and 2. The structure analysis demonstrates that

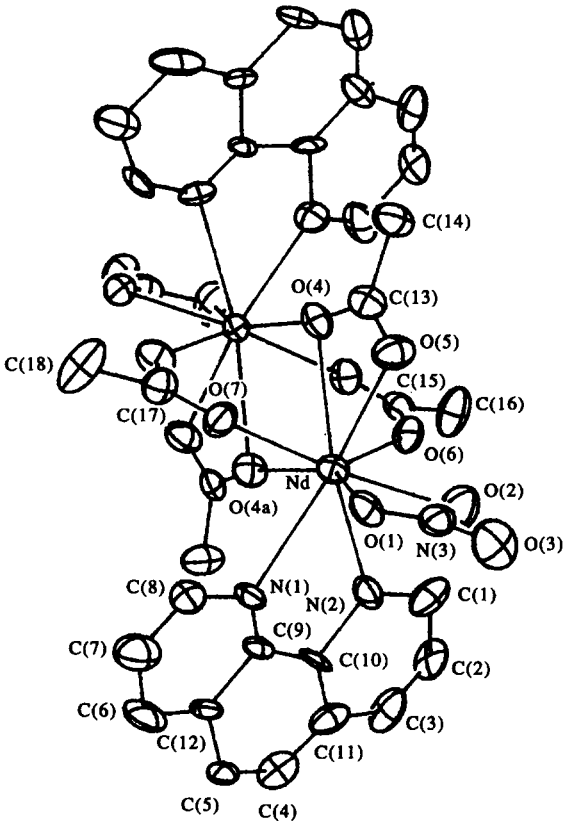

Fig. 1. The molecular structure of $[Nd_2(phen)_2(ONO_2)_2(CH_3COO)_4]$.

the $[Nd_2(phen)_2(ONO_2)_2(CH_3COO)_4]$ molecule is a binuclear Nd complex in which there are four CH_3COO^- group bridges. This molecule possesses C_2 symmetry, where the two-fold axis pass through atoms C(15), C(16) and C(17), and is parallel to the *b* axis of the cell. The C(18) atom is distributed on the both sides of this two-fold axis with occupancy factor of 0.5. The molecule contains two 9-coordinate (N_2O_7) irregular polyhedra with Nd at the center. The two ligand N atoms come from the phen ligands, with Nd—N bond lengths of 2.589(2) and 2.709(2) Å respectively. Two ligand O atoms come from a bidentate ONO_2 ligand, another five O atoms come from four CH_3COO^- groups, and the range of Nd—O bond lengths is 2.355(4)–2.707(3) Å. The four CH_3COO^- groups may be classified into two cases: two of them are simple bidentate bridges for each of which two oxygen atoms connect two Nd atoms respectively, but the other two chelate in such a way that one oxygen atom connects one Nd atom while the other O(4) or O(4a) connects two Nd atoms simultaneously becoming a μ_3-O atom. Therefore the coordination number of each Nd atom is 9. The separations of Nd—O(4) and Nd(A)—O(4) are 2.707(3) and 2.370(5) Å, respectively. So that Nd—Nd is relatively short, only 3.974(1) Å. This structure character of the title complex probably favors the magnetic coupling between the parallel electrons located on the two Nd^{3+} (f^3) ions which may contribute to the magnetism of the whole molecule.

The 8-membered ring constituted by two CH_3COO^- groups and two Nd atoms forms the molecular equatorial plane. The NO_3^- plane is approximately parallel to the equatorial plane (the dihedral angle is 20.0°) and another two CH_3COO^- and phen groups which are normal to each other with the dihedral angle 88.7°, are almost perpendicular to the equatorial plane with the respective dihedral angles of 83.3 and 99.3°.

Magnetic studies

The temperature dependence of molar magnetic susceptibility, χ_m, the magnetic moment, μ_{eff}, and χ_m^{-1} are depicted in Figs 3, 4 and 5. From Fig. 3 it is clearly seen that at room temperature χ_m is very small and varies very slowly with decreasing *T*. It is only at very low temperature ($T \sim 8$ K) where the magnetic susceptibility shows a dramatic change. In the complex two Nd^{3+} have the same coordination-surroundings, their *f* orbitals are occupied by 3 spin-parallel electrons respectively, i.e., their spin $S_1 = S_2 = 3/2$. Therefore, the magnetism of the complex arises from the Nd^{3+}—Nd^{3+} magnetic coupling. From Fig. 4 it can be seen that as *T* decreases the μ_{eff} decreases, which demonstrates that there is an antiferromagnetic coupling between the Nd^{3+} ions. Furthermore, if we treat $\chi_m^{-1} \sim T$ curve (in Fig. 5) as linear and extrapolate it intersecting the *T* axis; the crossing will be at the side of $-T$, which agrees with the $1/\chi = (T + \theta)/C$ [14]. All of these phenomena show that this complex possesses the character of the anti-ferromagnetic material.

In terms of the isotropic Heisenberg model, the Hamiltonian representing the magnetic interaction between two paramagnetic ions can be written as $\hat{H} = -2J\hat{S}_1\hat{S}_2$ where $\hat{S}_1$ and $\hat{S}_2$ stand for the spins of two Nd^{3+}, and *J* is the exchange integral between them. As $J > 0$, their interaction is ferromagnetic, and as $J < 0$ it is antiferromagnetic. By means of the model, the title complex has two Nd^{3+} ions of $S_1 = 3/2$ and $S_2 = 3/2$ so that the following expression of molar magnetic susceptibility can be deduced theoretically [15]:

$$\chi_m(\text{theor.}) = \frac{Ng^2\beta^2}{KT} \times \left[\frac{e^{-5J/KT} + 5e^{-3J/KT} + 14}{e^{-6J/KT} + 3e^{-5J/KT} + 5e^{-3J/KT} + 7}\right]$$

where *N* denotes Avogadro constant, *K* is Boltzmann constant, β is Bohr magnetron, *J* and *g* is magnetic parameter for evaluation, *T* is the absolute temperature. By using the least-squares method, a program is made in order to make χ_m(exp.) better simulate χ_m (theory.), shown in Fig. 3. After the simulation is optimized, the obtained magnetic parameter

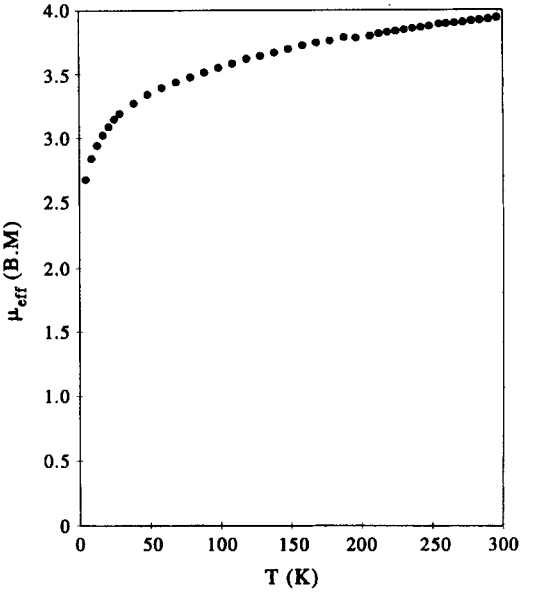

Fig. 4. Temperature dependence of μ_{eff}.

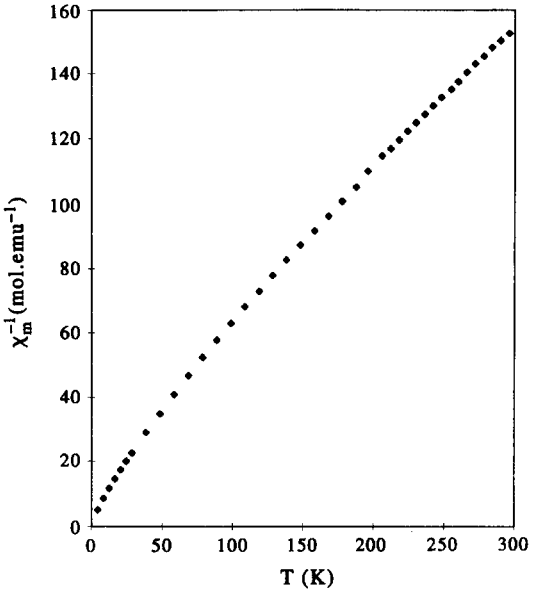

Fig. 5. Temperature dependence of $1/\chi_m$.

$J = -0.16$ cm^{-1} and the $g = 1.7$. The value of J reveals that a weak antiferromagnetic coupling between Nd—Nd ions in the complex.

(Received 5 July 1996; accepted 25 September 1996)

Abstract—The zinc isomaleonitrile dithiolate (Zn(*i*-MNT)) reacts with 3-methylpyridine(3-mpy) to form a novel and stable adduct containing three coordinated 3-mpy molecules which was characterized by elemental analyses, IR and ^{1}H NMR. The crystal structure determination reveals that the Zn atom in tris(3-methylpyridine)[(dimercaptomethylene)propanedinitrilato-S,S′)] zinc(II) is in a distorted trigonal bipyramidal geometry with the N(1)S(1)N(3) occupying the equatorial plane and the N(2)S(1) occupying the apical positions. © 1997 Elsevier Science Ltd. Keywords: crystal structure; adduct; 3-methylpyridine; isomaleonitrile dithiolate; zinc(II) complex.

Recently, zinc complexes containing S_4, S_3N, or S_2N ligand cores have continued to receive increasing attention, owing to them acting as structural models of the immediate ligand environment of zinc in DNA-binding proteins and certain zinc-containing enzymes [1,2]. Furthermore, the volatile zinc thiolato and nitrogen containing ligand complexes are also very important MOCVD precursors for semiconducting materials, because zinc sulfides are widely used as phosphors, long-wavelength windows and catalysts [3]. Also, metal isomaleonitrile dithiolate(*i*-MNT) complexes and their reaction products with a variety of Lewis bases have been extensively investigated [4]. Like most of the bidentate complexes containing dithiolates such as dithiocarbamate, dialkyldithiophosphate and carbonadithiolate, Singh *et al.* suggested that the reaction of M(*i*-MNT)(M = Zn, Cd, Hg) with Lewis bases also destroyed the original polymeric structure to yield the mono-, bis- and tetrakis-(Lewis base) adducts [5,6]. To our knowledge, no metal(II) complexes have been found to form a stable tris (Lewis base) adduct. However, surprisingly it is found here that Zn(*i*-MNT) reacts with 3-methylpyridine to yield an adduct with three molecules of coordinated 3-methylpyridine. We report here the synthesis, spectral properties and X-ray crystal structure of [(dimercaptomethylene) propane dinitrilato-S, S′] tris (3-methypyridine) zinc(II) [Zn(*i*-MNT)(3-mpy)$_3$].

EXPERIMENTAL

Synthesis of Zn(*i*-MNT)(3-mpy)$_3$

Zinc chloride (1 mmol) was dissolved in 20 cm^3 absolute ethanol, to the clear solution was slowly added 20 cm^3 EtOH and $CHCl_3$ (1 : 1) solution of 1 mmol of [dimercaptomethylene propanedinitrilato-S, S′] dipotassium [K_2(*i*-MNT)]. Then excess 4-methylpyridine (4-mpy) was added dropwise to the yellow solution. The yellow columnar single crystal suitable for X-ray structure determination were obtained after the solution evaporated at room temperature for a few weeks. Yield 73.8%. Found: C, 54.4; H, 4.3; N,

Physical measurements

The IR spectrum was recorded on KBr pellets in the 4000–400 cm^{-1} and 500–100 cm^{-1} in Nujol mull modes using a Nicolet 170SXFTIR spectrophotometer. ^{1}H NMR spectrum (pyridine-d_5) was obtained using a Bruker AM 500 spectrometer at room temperature.

Crystallographic analysis

A yellow column single crystal with the approximate dimension 0.50 × 0.50 × 0.50 mm was mounted on an Enraf-Nonius CAD-4 diffractometer. X-ray data were collected with graphite-monochromated Mo-K_α radiation ($\lambda = 0.71069$ Å) at room temperature using the ω-2θ scan technique. Cell-parameters and an orientation matrix for data collection were obtained from least-square refinement, using the setting angles of 21 reflections in the range $20.02 \leqslant 2\theta \leqslant 29.68°$. A total of 3981 independent reflections ($R_{int} = 0.015$) were measured in the range $0 \leqslant 2\theta \leqslant 50°$ (h = 0–10, k = −13–13, l = −14–14), 3460 of which, with $I > 3\sigma(I)$, were used in the development and refinement of the structure. No significant intensity decay of three standard reflections recorded after every 300 reflections was observed. The intensity data were corrected for Lorentz and polarization effects. An empirical absorption correction based on a series of ψ-scans with minimum and maximum correction coefficient 0.9161 and 1.000, respectively, was applied [7].

The structure was solved by direct methods using MITHRIL [7]. The heavy atom Zn was located in an E map and the remaining non-H atoms were located using DIRDIF [8]. H atoms were placed in geometrically calculated positions (C—H = 0.95 Å) and were included in the structure factor calculations but not refined. The structure was refined by full-matrix least-squares techniques with anisotropic displacement parameters for all atoms. All calculations were performed on a VAX3100 computer using the TEXSAN program package [9]. The maximum and minimum peak values in the final difference Fourier map are 0.33 and −0.69 e Å^3, respectively. Crystal data and data collection parameters are summarized in Table 1. The atomic coordinates, thermal parameters and structure factors have been deposited with the editor as supplementary data.

RESULTS AND DISCUSSION

The results of elemental analyses, IR, and ^{1}H NMR spectra have shown that the reaction of Zn(*i*-MNT) with 3-methylpyridine forms the adduct. In the IR spectra of Zn(*i*-MNT)(3-mpy)$_3$, the characteristic absorption band of $\nu_{C\equiv N}$ (2175 cm^{-1}) was observed, in good accord with that of M(*i*-MNT) (M = Zn, Cd and Hg) [4]. Also, many bands at 3041(w), 1610(m), 1583(m), 1486(m), 1455(m), 1357(s), 1225(m), 1194(m), 1129(m), 1105(m), 1053(m), 984(w, sh),

Table 2. Selected bond distances (Å) and angles (°) for [Zn(*i*-MNT)(3-mpy)$_3$]

Zn—N(1)	2.053(2)	Zn—N(2)	2.260(3)
Zn—N(3)	2.050(2)	Zn—S(1)	2.308(1)

947(s), 876(s), 787(m) and 704(s) cm^{-1}, respectively, were found. It is interesting to note that in the far-IR spectrum of Zn(*i*-MNT)(3-mpy)$_3$, a new medium absorption band appeared at 409 cm^{-1}, quite different from that found in Zn$_2$(*i*-MNT)$_2$(3-mpy)$_4$ [10]. Similarly, the ν_{Zn-N} (368(m) and 319(w) cm^{-1}) and ν_{Zn-S} (249(s) and 231(s) cm^{-1}) modes were also observed in the title adduct, in good agreement with those in Zn(en)(*i*-MNT) [4]; three medium bands were found at 190(m), 170(m) and 133(m) cm^{-1}, respectively. Furthermore, in the ^{1}H NMR spectrum of Zn(*i*-MNT)(3-mpy)$_3$, four group signals at 8.58(s, 2H, o-

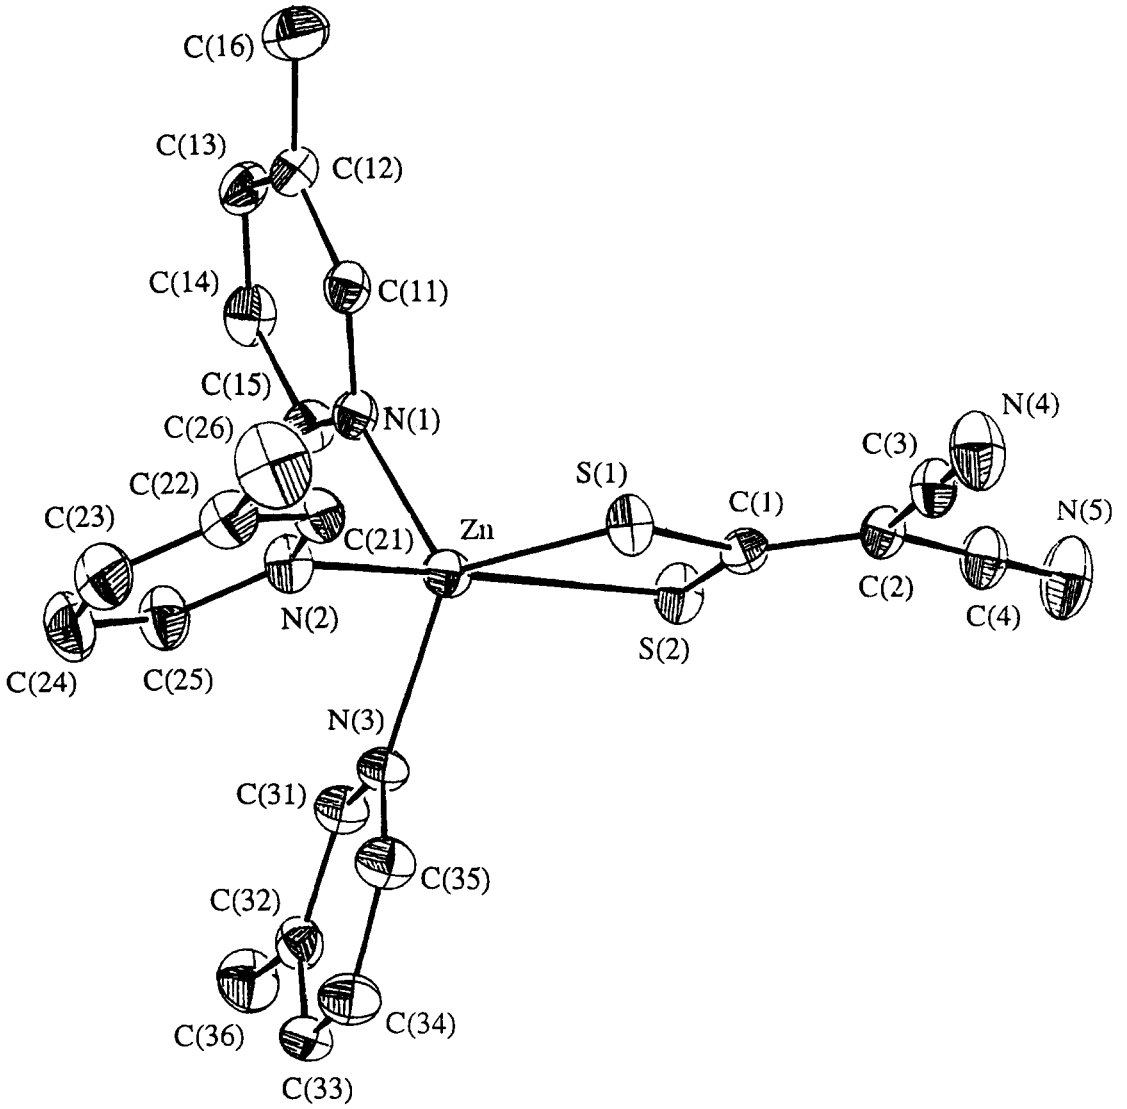

Fig. 1. ORTEP plot (30% probability thermal ellipsoids) of the [Zn(*i*-MNT)(3-mpy)$_3$] with the numbering scheme.

py), 7.37(d, 1H, p-py), 7.14(m, 1H, m-py) and 2.12(s, 3H, —CH_3) ppm, were observed, in agreement with the structure of Zn(*i*-MNT)(3-mpy)$_3$.

The selected bond distances and angles are listed in Table 2. The structure of Zn(*i*-MNT)(3-mpy)$_3$ is shown in Fig. 1, and stereoview of the molecular packing Zn(*i*-MNT)(3-mpy)$_3$ is depicted in Fig. 2. The crystal structural determination of Zn(*i*-MNT)(3-mpy)$_3$ (Fig. 1) reveals that the Zn atom is in a distorted trigonal bipyramidal environment with the N(1)S(1)N(3) occupying the equatorial plane and the N(2)S(1) occupying the two apical positions. A unique feature in the title adduct is that Zn(*i*-MNT) reacts with three nitrogen base molecules to form a novel and stable tris(3-methylpyridine) adduct (Fig. 2). As far as we know, this is the first crystallographically characterized example of the reaction of metal(II) complex with Lewis base forming stable adduct with three molecules of coordinated Lewis base. Generally speaking, the metal(II) complexes react with Lewis bases to yield the adducts with mono-, bis- and tetrakis-(Lewis base). Furthermore, a similar phenomenon in the low-valent coordination chemistry of the element groups 4 and 5 has also been observed [5]. It is worth noting that the lanthanide(III) complexes and other M(III) complexes (M = Nb, Ta, Cr etc.) have recently been found to be examples of structurally characterized adducts with three molecules of Lewis base [11]. Additionally, the Zn(*i*-MNT)(3-mpy)$_3$ having a monomeric structure is quite different from that of Zn_2(*i*-MNT)$_2$(4-mpy)$_4$ in which Zn(*i*-MNT) reacts with 4-methylpyridine to yield an eight-membered ring dimer and still remains dithiolato μ-bridge mode even though an adduct has effectively been formed [4]. The Zn—N (2.050(2)–2.260(3) Å) and Zn—S(2.308(1)–2.698(1) Å) bond distances exhibit much great variations, probably due to the Zn atom adopting a distorted trigonal bipyr-

amidal geometry in which three atoms, N(1), S(1) and N(3), describe an approximate equatorial plane and the two apical sites are occupied by the N(2) and S(2) atoms from an asymmetrically coordinating *i*-MNT ligand. The two Zn—N bond lengths from the equatorial plane are in good agreement with those of (2.064(3) Å, 2.045(4) Å, 2.057(6) ~ 2.037(6) Å and 2.035(4)–2.077(3) Å) found in $Zn(S_6)(py)_2$ [12], $Zn(S_6)(N\text{-}Melm)_2$ [1], $Zn(S\text{-}2,3,5,6\text{-}Me_4C_6H)_2(1\text{-}Me\text{-}imid)_2$ [13] and $Zn_2(i\text{-}MNT)_2(4\text{-}mpy)_4$ [10], respectively. Similarly, no significant difference of the Zn—S bond distances is observed, compared with $Zn(S_6)(py)_2$ (2.286(1) Å) [12], $Zn(S_6)(N\text{-}Melm)_2$ (2.317(1) Å) [1], $Zn(S\text{-}2,3,5,6\text{-}Me_4C_6H)_2(1\text{-}Me\text{-}imid)_2$ (2.301(2) ~ 2.298(2) Å) [13] and $Zn_2(i\text{-}MNT)_2(4\text{-}mpy)_4$(2.317(1)–2.321(1) Å [10], respectively. On the other hand, the bond angle of S(1)—Zn—S(2) is 71.86(3)°, significantly smaller than that of S(1)—Zn—S(2)′ (110.80(5)°), probably due to the dithiolato ligand in the latter bridging the two zinc atoms [10]. As expected, the bond distances of C—N, C—C and C—S are unexceptional.

(Received 24 May 1996; accepted 25 September 1996)

Abstract—Trivalent lanthanide complexes of the type $[Ln(Me_2Dtc)_4]H_2NMe_2$ (Ln = La, Pr—Nd, Sm—Ho; Me_2Dtc = *N*,*N*-dimethyldithiocarbamate) have been prepared and characterized by means of elemental analyses, IR spectra, electronic spectra, ^1H NMR spectra and conductivity measurements. The X-ray crystal and molecular structure of the neodymium complex has been determined from diffractometer data. There are two independent $[Nd(Me_2Dtc)_4]H_2NMe_2$ monomers in each unit cell; the metal coordination number is 8. Spectroscopic properties of the complexes are discussed. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: lanthanide(III); *N*,*N*-dimethyldithiocarbamate; complex; synthesis; spectroscopic property; crystal structure.

The first well-characterized trivalent lanthanide dithiocarbamate was reported by Brown [1] and further confirmed by Ciampolini [2] by X-ray single crystal structure determination. In recent years some new lanthanide dithiocarbamates have been prepared [3–7] but crystal structures were few [6,7]. Common to all these earlier works is the observation that the lanthanide dithiocarbamate complexes under study were unstable to moist conditions and atmosphere; anhydrous lanthanide salts must be used and water must be excluded during preparation. Siddall [8] had managed to prepare the light lanthanide complexes $[Ln(^tBu_2Dtc)_4]$ $HNEt_3$ (Ln = La,Pr,Nd,Sm) using hydrated lanthanide nitrates and thought that the steric effect in R_2NCSS^- should play an important role in the stability of this kind of complex. We now report the synthesis and structure of $[Ln(Me_2Dtc)_4]$ H_2NMe_2 complexes which are sufficiently stable to be prepared and handled in the ordinary laboratory atmosphere.

EXPERIMENTAL

Materials

Dimethylammonium dimethyldithiocarbamate ($Me_2Dtc \cdot H_2NMe_2$) was prepared according to literature procedure [9]. Hydrated lanthanide chlorides (or perchlorates) were prepared by dissolving lanthanide oxides (AnalaR) in 1:1 chloric (or perchloric) acid. All other chemicals were AnalaR grade and were used without further purification.

Synthesis

To a solution of 0.18 mmol of hydrated lanthanide chlorides (or perchlorates) in 5 cm^3 of ethanol was added a solution of 0.72 mmol of $Me_2Dtc \cdot H_2NMe_2$ in 10 cm^3 of ethanol. The mixture was stirred at room temperature for about 30 min

*Present address: Department of Chemistry, Zhongshan University, Guangzhou 510275.

†Author to whom correspondence should be addressed.

when a precipitate appeared. The precipitate was filtered, washed several times with ethanol and dried *in vacuo* over P_4O_{10}-$CaCl_2$ for 48 h. The yield was about 80%.

A single crystal of the neodymium complex was obtained by the following procedure: $Nd(ClO_4)_3 \cdot nH_2O$ (0.18 mmol) and $Me_2Dtc \cdot H_2NMe_2$ (0.72 mmol) were dissolved in 20 cm^3 acetonitrile. To this clear solution was slowly added 5 cm^3 ether. The mixture was left standing overnight and a single crystal suitable for X-ray crystal determination appeared. The complex contains one acetonitrile molecule which is apt to escape and the crystal effloresces quickly once it is removed from the mother liquor.

X-ray measurements and structure determination

The crystal used for the structure determination was about $0.48 \times 0.50 \times 0.60$ mm in size. It was mounted in a sealed quartz capillary containing some mother liquor. X-ray diffraction intensity were collected at 21°C on an R3M/E diffractometer with graphite-monochromated Mo-K_α radiation, using the $\theta/2\theta$ scan technique. Two standard reflections were measured every 98th scan. A total of 9531 reflections which were collected in the range $2 \leqslant 2\theta \leqslant 46°$ yielded 9338 unique data in which 5884 had $I \geqslant 3\sigma(I)$. Data were corrected for Lorentz-polarization factors, but no correction was made for absorption. The intensities of the reflections decayed about 12% during the data collection period, and the data were corrected for this effect.

The structure was solved using direct methods followed by Fourier difference syntheses, and refined by full-matrix least-squares methods with anisotropic thermal factors for all non-hydrogen atoms and with hydrogen atoms in calculated position; weighting scheme: $w = [1-\exp(-5)(\sin(\theta/\lambda)^2]/[\sigma^2(F) + 0.00015F^2]$; final $R = 0.0309$, $Rw = 0.0308$. The maximum and minimum residual electron densities in the final difference map were 0.555 and -0.438 e $Å^{-3}$. All calculations were carried out on an Eclipse S140 computer using the SHELXTL (1985) program. Data collection and refinement parameters are summarized in Table 1.

Other measurements

Carbon, nitrogen and hydrogen analyses were determined using a Carlo-Erba 1106 elemental analyser, while metal ion contents were estimated with EDTA using xylenol orange as the indicator. IR spectra were recorded on a Nicolet-170 SX FT-IR spectrophotometer using KBr discs in the range 4000–220 cm^{-1}. Electronic spectra were recorded on a Shimadzu UV-260 spectrophotometer in the 190–900 nm region in the acetonitrile solution. ^1H NMR spectra were measured on an FT-80A spectrometer in $CDCl_3$ solution with TMS as internal standard. Conductivity measurements were carried out with a DDS-11A type conductivity bridge using 10^{-3} mol cm^{-3} solution in acetonitrile at 25°C.

RESULTS AND DISCUSSION

Hydrated lanthanide chlorides or perchlorates can be used directly for preparation of the complexes without any precaution against instability. Complexes prepared in this manner give satisfactory elemental analyses for La, Pr—Nd, Sm—Ho (Table 2). The pink powder of the Er^{3+} complex and yellow powder of the Yb^{3+} complex can also be obtained but they hydrolyse easily, confirming the suggestion that this kind of complex becomes progressively less stable with increasing atomic number [8]. Attempts to synthesize $[Ce(Me_2Dtc)_4]H_2NMe_2$ were accompanied by oxidation to Ce^{4+} [8]. All the complexes thus obtained are stable in air for several months; however, the characteristic colour of the corresponding complex in solution disappears in several hours suggesting that the complexes decompose readily in the solution.

The molar conductances of $[Ln(Me_2Dtc)_4]H_2NMe_2$ measured in aectonitrile at 25°C lie in the range 119–142 Ω^{-1} cm^2 mol^{-1}, indicating that all the complexes are 1 : 1 electrolytes, which is consistent with the formulation obtained from the elemental analyses. The complexes are readily soluble in CH_3CN, CH_2Cl_2, DMSO, DMF, soluble in MeOH, $CHCl_3$, THF, slightly soluble in EtOH, $ClCH_2CH_2Cl$ and insoluble in non-polar organic solvents.

X-ray structure of $[Nd(Me_2Dtc)_4]H_2NMe_2$

Selected bond lengths and angles are given in Tables 3 and 4. Figure 1 shows the structure for the complex; Fig. 2 shows the packing arrangement in the unit cell and Fig. 3 shows the coordination polyhedra of the Nd(1) and Nd(2) atoms in the complex.

As shown in Fig. 1, the structure contains two independent $[Nd(Me_2Dtc)_4]^-$ anions, two $H_2N^+Me_2$ cations and two uncoordinated acetonitrile molecules. In each of the $[Nd(Me_2Dtc)_4]^-$ monomers, the neodymium ion is coordinated to eight sulfur atoms of four Me_2Dtc ligands. A similar structure was found for $V((Me_2Dtc)_4$ [10]. In its crystal structure there are two non-equivalent $V(Me_2Dtc)_4$ monomers also. The coordination polyhedra of both Nd^{3+} atoms can be described as D_2 dodecahedra according to the rule of Blight and Kepert [11], for the calculated value of b is 1.23 for both monomers. However, when comparing the bond angles of two monomers carefully, slight differences can be found. The 16th, 17th and 18th lowest S—Nd(1)—S angles are 90.4°, 92.3° and 104.8°; whilst those of S—Nd(2)—S are 93.2°, 94.6° and 95.7°. So according to the criteria of Haigh [12], the structure of Nd(2) is "normal" dodecahedron

while that of Nd(1) has a distortion towards the bicapped prism.

The bond lengths of Nd(1)—S are 2.885–2.936 Å (mean 2,914 Å) and those of Nd(2)—S are 2.886–2.939 Å). They are nearly identical within the measurement error, approximately the same as found for $[Nd(S_2CNC_4H_6)_4]^-$ (mean 2.908 Å) [6] and are comparable with the La—S bond lengths of Na[La-($Et_2Dtc)_4$] [2] and La[$(S_2CNC_4H_8)_3$ ($C_4H_8O11\cdot H_2O$)] [6] (mean 2.97 Å) taking account of the difference in their ionic radii (La = 1.160, Nd = 1.109 Å).

All the S—C bond lengths of both two monomers are almost equal; in addition, all the bond lengths of N—C(SS) have more double bond character (N—C, 1.47 Å, N=C, 1.30 Å), denoting that the S=C double bond of the ligand is delocalized in the complex.

[a]Acetonitrile.
[b]Hypersensitive bands.

Spectroscopic studies

The IR spectra of all the complexes showing a single ν_{C-S} absorption in the range 980–993 cm^{-1}, whilst the free ligand shows a doublet (962, 987 cm^{-1}). This finding is strongly indicative of the bidentate behavior of the ligand in the complexes [13, 14]. The presence of one strong ν_{C-N} band (1492–1504 cm^{-1}) at higher wavenumbers than in the free ligand (1453 cm^{-1}) gives further confirmation of the above suggested behaviour [15]. The new bands present in the 343–347 cm^{-1} range in the far-IR region may be assigned as the ν_{Ln-S} stretching frequency [15,16].

^1H NMR spectra of $Me_2Dt \cdot H_2NMe_2$ and the lanthanum complex (obtained similar to the preparation of single crystal of neodymium complex) were recorded. δ ($Me_2Dtc \cdot H_2NMe_2$), 2.77 (s, 6H, $H_2N(CH_3)$, 3.58 (s, 6H, $(CH_3)_2NCSS$), 8.06 (s, 2H, H_2NMe_2); δ ($[La(Me_2Dtc)_4]H_2NMe_2$), 2.78 (s, 6H, $H_2N(CH_3)$, 3.51 (s, 24H, $(CH_3)_2N$-CSS), 5.94 (s, 2H, H_2NMe_2), 2.02 (s, 3H, CH_3CN). The proton chemical shift of the ligand shows no significant shift after coordination to the diamagnetic lanthanum ion. However, the similar proton signals and its integral changes confirm the formation of the complexes. The presence of acetonitrile proton signal denotes that there is an acetonitrile molecule in the complex, which is in agreement with the result of the crystal structure determination.

The electronic spectra of the complexes present a

number of interesting features. The dithiocarbamates are strongly reducing ligands, so, as expected, the broad charge transfer band of $[Eu(Me_2Dtc)_4]H_2NMe_2$ in which Eu^{3+} is easily reduced to Eu^{2+} is observed in the visible region (415 nm). It settles the value of the optical electronegativity of Me_2Dtc at about 2.57, in agreement with that obtained for Et_2Dtc by Jörgensen [17].

Additionally, a number of *f–f* transitions are observed in the visible region of the electronic spectra. The relative energy and *J* level and assignment are given in Table 5. They are interesting in two respects [2,18]. First, the oscillator strengths of *f–f* transitions for these lanthanide dithiocarbamates are usually 2–5 times higher than that of the corresponding aqua-ions, especially for those of hypersensitive transitions, they are even up to 9–20 times more intense than the corresponding transitions in the aqua-ions. Second, a general red shift is found for most *f–f* transitions, which is known as the nephelauxetic effect.

The presence of the easily polarizable sulfur donor atoms allows one to expect more covalent character between the soft ligand and the hard lanthanide ions relative to the more common oxygen donor system [19,20]. It has been generally agreed that the nature of the red shift may be conveniently used as a measure of the metal ligand covalent bonding, assessed by Sinha's parameter (δ) and the bonding parameter $(b)^{1/2}$ [21,22]. These parameters have been calculated and compiled also in Table 5. The positive values of bonding parameters and β less than one support the existence of covalent character in the metal–ligand bond. Moreover, covalent bonds increase the configuration interaction which relaxes the selection rule for *f–f* transitions, thus increasing their intensity [23].

The crystal and molecular structure of [bis(aquo)-bis(2-(methylamino)pyridine) copper(II)] dichloride

Antonis G. Hatzidimitriou* and Monir Uddin†

Department of Chemistry, University of Thessaloniki, 54006 Thessaloniki, Greece

(Received 29 July 1996; accepted 23 September 1996)

Abstract—Spectroscopic features of [bis(aquo)bis(2-aminomethylpyridine)copper(II)] dichloride, $[Cu(ampy)_2(H_2O)_2]Cl_2$, are presented and its X-ray crystal structure is described. The IR spectra, ligand field spectra and conductivity measurements confirmed that the chloride anions were not coordinated to the metal ion. The copper(II) cation is coordinated by two water and two bidentate 2-aminomethylpyridine molecules. The chloride anions are rather strongly hydrogen-bonded to two hydrogen atoms of water molecules and two hydrogen atoms of the primary amino group in a distorted tetrahedral arrangement. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: bis(aquo)bis(2-aminomethylpyridine)copper(II)] dichloride; bis(aquo)copper(II) chelate; axial aquo ligands in a copper(II) chelate; tetragonal mixed-ligand copper(II) chelate.

In a number of coordination compounds of 1,2-diamines, α-diimines and related nitrogenous bases that upon chelation form five-membered chelate rings, solvent molecules were found to act as coligands [1,2]. The importance of solvent molecules is exemplified, for instance, in the case of certain iron(II) chelates of 2-aminomethylpyridine (α-picolylamine), ampy, lying near the high spin–low spin crossover [3]. The magnetic behaviour of these chelates was found to be susceptible not only to changes in temperature, pressure and counteranion, but also to occluded solvent molecules. Complexes containing water as a ligand are readily used as precursors for the synthesis of more complicated compounds by replacing coordinated water with another ligand. As the literature examples of copper(II) compounds containing coordinated water are relatively few [2, 4–10] and their importance as precursors of complicated compounds remains great, anhydrous copper(II) dichloride was reacted with ampy in various solvents. The composition of the compound obtained from the reaction in wet ethanol was found to correspond to $CuCl_2 \cdot 2ampy \cdot 2H_2O$. Reaction with $AgNO_3$ and electrochemical measurements indicated the existence of chloride counteranions, while spectoscopic measurements provided evidence that the nitrogenous base and the water molecules were coordinated. The indications that the compound was the [bis(aquo)bis(2-aminomethylpyridine)copper(II)] dichloride, $[Cu(ampy)_2(H_2O)_2]Cl_2$, were confirmed by an X-ray diffraction study of a single crystal. The results of the investigation related to the [bis(aquo)bis(2-aminomethylpyridine)copper (II)] dichloride are presented and discussed in this work.

EXPERIMENTAL

Reagents and preparation of $[Cu(ampy)_2(H_2O)_2]Cl_2$

The synthesis of [bis(aquo)bis(2-aminomethylpyridine)copper(II)] dichloride, $[Cu(ampy)_2(H_2O)_2]Cl_2$, was achieved by dissolving copper(II) dichloride in wet ethanol and reacting it with a stoichiometric amount of 2-aminomethylpyridine (Aldrich). The crystals (mp 175–178°C) were developed by slow evaporation of the solvent under refrigeration. Found: C, 37.3; N, 14.5; H, 5.2%. Required for $C_{12}H_{20}Cl_2CuN_4O_2$: C, 37.3; N, 14.5; H, 5.2%.

Physical measurements and determinations

Carbon, hydrogen and nitrogen were determined by microanalysis using a Perkin–Elmer 240B elemental analyser. Magnetic susceptibility measurements in powdered samples were performed at 25°C employing the Faraday method on a home-build balance calibrated against $Hg[Co(SCN)_4]$. Diamagnetic corrections were estimated from Pascal's constants. Electronic spectra in solution were measured on a Shimatzu 160 A spectrophotometer using 10 mm teflon stoppered quartz cells. The solid-state electronic spectra were obtained from Nujol mulls. IR spectra were obtained by the KBr disc technique and were recorded on a Perkin–Elmer 1600 FT-IR instrument. Additional instruments and techniques mentioned in this work have been described elsewhere [11].

X-ray crystallographic analysis of $[Cu(ampy)_2(H_2O)_2]Cl_2$

Intensities were collected by using a four-circle CAD4-F automatic X-ray diffractometer and graphite-filtered Mo-K_α radiation employing the $\omega/2\theta$ technique. The orientation matrix and refined unit-cell dimensions were obtained from 25 independent reflections of high intensity ($12 \leqslant \theta \leqslant 15°$). Three standard reflections were monitored periodically to detect intensity changes during the course of the data acquisition. The crystal was perfectly stable in the X-ray beam over the period of intensity measurements. The unique reflections were 1172 out of a total of 1799 with $0 \leqslant h \leqslant 9$, $0 \leqslant k \leqslant 8$, $-13 \leqslant l \leqslant 13$. 1005 reflections satisfied the acceptance criterion $I \geqslant 2\sigma(I)$. Systematic absences led to space group $P2_1/c$. Details of crystal data are given in Table 1. All intensities were corrected as usual for Lorentz and polarization effects.

Table 1. Crystal data and experimental details for the structural study of $[Cu(ampy)_2(H_2O)_2]Cl_2$

Formula	$C_{12}H_{20}N_4O_2CuCl_2$

Linear absorption coefficient, μ (cm^{-1})	13.82

The copper position was deduced employing the SHELX-86 program [12] and used to compute a first-approximation electron-density synthesis, which revealed the position of all remaining atoms except the hydrogens. After least-squares refinements with the non-hydrogen atoms, the hydrogen atoms were also located in the difference Fourier map and those of the aromatic carbon atoms were in their expected position to which they were positioned geometrically after each refinement cycle. The positions of the hydrogen atoms of the methylamino group were also determined from difference Fourier maps and their coordinates were refined using slack constraints, N—H, C—H = 1.09(4) Å and angles around the carbon and the nitrogen atoms 109(3)°. All pertient calculations were performed using the CRYSTALS program [13]. The figures of the clinographic projections were produced with the ORTEPII program [14]. Refinement was carried out by full-matrix least-squares, with unit weight to all reflections. At the end of the isotropic stage of the refinement the DIFABS [15] absorption correction method was applied with an average coefficiency of 0.998. The function minimized in the least-squares refinement was $\Sigma w(|F_0| - |F_c|)^2$, where $|F_0|$ and $|F_c|$ are the observed and calculated structure factor amplitudes. Final $\Delta(\rho)\text{max}/\Delta(\rho)\text{min} = 0.25/-0.22$ e Å^{-3}. Agreement factors are defined as $R = \Sigma(|F_0| - |F_c|)/\Sigma(|F_0|) = 0.0258$ and $R_w = |\Sigma w(|F_0| - |F_c|)^2/\Sigma w(|F_0|)^{21/2} = 0.0272$. Further experimental details are deposited with the Editor.

RESULTS AND DISCUSSION

The stoichiometry of the compound resulting from the reaction of copper(II) dichloride with 2-(aminomethyl)pyridine in wet ethanol indicated the presence of water molecules, while the electrical conductivity in aqueous solution ($\Lambda_M = 196$ S cm^2 mol^{-1}) suggested [16] that the chloride anions do not interact covalently with copper(II). The broad ligand-field band with maximum at 1.70 μm^{-1} suggested the presence of a CuN_4O_2 chromophore [2,17], implying that the water molecules are bonded to copper. Additional information on the nature of interactions of the nitrogenous base and the water molecules with the metal, if any, were sought from the IR spectrum of the compound.

The bands emanating from the stretching vibrations of the primary amino group [18] are shifted appreciably to lower frequencies in relation to the free nitrogenous base and are observed at 3203 and 3117 cm^{-1}. On the other hand, the band present in the spectrum of the ligand at 1591 cm^{-1} and assigned to the stretching vibration of the aromatic C=N bond is shifted to higher frequency and in the spectrum of the complex occurs at 1608 cm^{-1}, suggesting that the

electronic density of the aforementioned bond has increased after coordination. A broad band peaking at 3381 cm^{-1} in conjunction with the absence of a band in the region 381 to 261 cm^{-1} attributable to free water, suggested that the water is coordinated [19,20], as has been observed in copper(II) chelates in which water displaces a halide anion that becomes the counteranion [4–10]. Further evidence of the ligation of ampy as bidentate ligand and the coordination of water was obtained from the X-ray diffraction analysis.

In the unit cell of the compound $[Cu(ampy)_2(H_2O)_2]Cl_2$ there are four copper atoms. The distance separating the metal atoms is greater than 6 Å and precludes copper–copper bonding interactions. The copper atom is surrounded by four nitrogen and two oxygen atoms symmetrically disposed in a distorted octahedral environment. Actually, in the immediate vicinity of copper are found only the four nitrogen atoms that lie in a plane encompassing the copper centre (plane 1, $3.128x - 6.503y - 5.094z = 1.564$) and the copper–nitrogen distances fall in the range usually observed for Cu—N(heterocyclic) ligands [2]. The intraligand distance separating the nitrogen atoms of the ligated 2-aminomethylpyridine [2.656(3) Å] indicated [3] that the nitrogenous base acts as a bidentate ligand forming five-membered chelate rings, the bite angle being 82.9(1)° (Table 2). The aromatic part of the methylaminopyridine ligand is perfectly planar and in the same plane also lies the carbon atom that links the pyridine ring with the amino group. The deviation of the C(6) carbon atom from the pyridine plane is smaller than the error. The terminal nitrogen atom N(2) is found 0.23(5) Å below the pyridine plane and the heteroaromatic plane forms with the coordination plane a dihedral angle of 6.4(4)°. The primary amine nitrogen and the sp^2 hybridized nitrogen atoms occupy, respectively, positions *trans* to each other and the interatomic distances indicated that the Cu—N(sp^2) bond is slightly longer than the observed length of the Cu—N(sp^2) bond (Table 2).

While the nitrogens of the bidentate ligand occupy equatorial positions, the oxygen atoms of the water molecules rather than the electronegative chloride anions are placed in axial positions. In the doubly charged bis(aquo)bis(2-aminomethylpyridine)copper(II) cation, $[Cu(ampy)_2(H_2O)_2]^{2+}$, the distance of the two oxygen atoms from copper is 2.562(3) Å and is within the range of bonding interactions termed "semicoordination" [2]. The long Cu—O bonds indicate appreciable tetragonal distortion ($T = 0.783$). Charge neutralization is effected by the chloride anions that are distanced 4.242(1) Å from the copper atom and are symmetrically disposed so that the metal atom becomes an inversion centre. A clinographic projection of the molecule is shown in Fig. 1.

The chlorine counteranions are placed in such a way so as to interact rather strongly with hydrogen atoms of the amino groups and the water molecules. Actually the interatomic distances of Cl(1) from H(10) and the symmetry related H(9)′, H(7)″ and H(8)# are: 2.35(4), 2.40(4), 2.45(4) and 2.52(4) Å, respectively. The corresponding nonbonding chlorine–oxygen and chlorine–nitrogen distances are: Cl(1)···O(1) 3.166(3), Cl(1)···O(1)′ 3.184(3), Cl(1)···N(2)″ 3.293(3), Cl(1)···N(2) 3.307(3) Å. It seems that these hydrogen-bonding interactions enfeeble the axial interaction of the water molecules with the copper ion and this weakening further contributes to the removal of the degeneracy of the ^2E_g ground state of copper(II) and results in a Jahn–Teller stabilization by splitting in $^2A_{1g}$ and $^2B_{1g}$. The hydrogen bonding is probably responsible for the low solubility of the compound in most solvents but the strongly polar ones.

(Received 8 December 1995; accepted 23 September 1996)

Abstract—Extraction behavior of nine types of trivalent lanthanide ions from three types of aqueous solutions containing an alkaline metal ion such as lithium, sodium or potassium ion into chloroform was investigated with three types of extractants: 37,38,39,40,41,42-hexakis(carboxymethoxy)-5,11,17,23,29,35-hexakis(1,1,3,3-tetramethylbutyl)calix[6]arene and the cone conformational type of 25,26,27,28-tetrakis(carboxymethoxy)-5,11,17,23-tetrakis(1,1,3,3-tetramethylbutyl)calix[4]arene as well as *p*-(1,1,3,3-tetrametylbutyl)phenoxyacetic acid as the monomeric analog of their calixarene derivatives. The uptake behaviors of the three types of coexisting alkaline metal ions with the calix[4]arene carboxylate derivative and the monomeric analog were also investigated by measuring the chemical shifts of proton NMR spectra. It was found that the calix[4]arene derivative selectively extracted sodium ions, while lithium and potassium ions were hardly extracted, and also found that when sodium ion is contained in the feed solution, the order of extraction selectivity for rare earth metal ions with the calix[4]arene derivative was much changed from an ordinary system containing no sodium ion. That is, in the absence of sodium ion, the calix[4]arene derivative preferentially extracted the light lanthanides with greater ionic radii while in the presence of sodium ion it extracts the heavy lanthanides with smaller ionic radii. It was suggested that the cyclic tetramer preferentially extracts sodium ion at first and then the sodium-loaded calix[4]arene extract lanthanide ions, as a "preorganized" extractant. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: calixarene carboxylate; extraction; lanthanide; selectivity; preorganized; co-extraction.

Calixarene derivatives have been attracting much attention as novel types of macrocyclic host compounds [1–3]. Their high recognition as an ionophore is one of their remarkable features as a specific receptor. Their features as a receptor are as follows: [3,4] (1) macrocyclic phenolic oligomer; (2) having cyclic phenolic hydroxyl groups which are useful for the building-up of the functionalized host molecules; (3) having several-sized cavities for including the guest molecules.

In a previous study, we synthesized 37,38,39,40,41,42-hexakis(carboxymethoxy)-5,11,17,23,29,35-hexakis(1,1,3,3-tetramethylbutyl)calix[6]arene and 25,26,27,28-tetrakis(carboxymethoxy)-5,11,17,23-tetrakis(1,1,3,3-tetramethylbutyl)calix[4]arene as well as *p*-(1,1,3,3-tetramethylbutyl)phenoxy acetic acid as their monomeric analog to investigate their extraction behavior for lanthanide ions from the aqueous solution prepared by mixing nitric acid and glycine and found only a small difference in the selectivity among lanthanide ions even by the two types of cyclic extractants with different ring sizes [5].

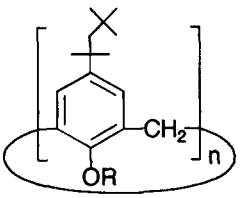
A number of studies have been reported on the

* Author to whom correspondence should be addresssed.

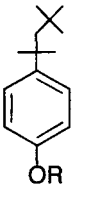
extraction of alkaline metal ions with calixarenepolyols and calixarene derivatives having ester-, amide- and ketone groups [6–15]. Ferguson *et al.* reported that a cone conformational type of calix[4]arene derivative selectively gives rise to a complex with sodium ions, while calix[6]arenes forms complexes not only with a sodium ion but also with a potassium ion [11]. Therefore, it was suggested that calixarene derivatives with an ionizable functional group have a high possibility to form complexes with alkaline metal ions. In addition, other studies have been also reported on the extraction of multivalent metal ions with calixarene derivatives [5, 16–18]. In the majority of these studies, an alkaline metal ion was added to an aqueous solution to keep the ionic strength constant. However, there has been no paper discussing the effect of coexisting alkaline metal ions on the extraction behavior of multivalent metal ions.

In a previous study, cone coformation types of 25,27-bis(carboxypropoxy)-26,28-bis(carboxymethoxy)-5,11,17,23-tetrakis(1,1,3,3-tetramethylbutyl)calix[4]arene and 25,26,27,28-tetrakis(carboxymethoxy)-5,11,17,23-tetrakis(1,1,3,3-tetramethylbutyl)calix[4]arene were synthesized to investigate the extraction of the copper(II) ion in the absence or presence of sodium ions [18] and we found that these extractants co-extracted sodium ions together with copper ions in the presence of the former ion, and that the uptake of sodium ion accompanied the structural change of the extractants resulting in the enhancement of extractability of the copper ion.

In the present paper, we report the effect of three types of coexisting alkaline metal ion, lithium, sodium or potassium ion, on the extraction behavior of lanthanide ions with calixarene carboxylate derivatives. Complex formation was elucidated by utilizing the chemical shift of proton NMR for the cyclic tetramer as well as the monomeric analog in the absence or presence of an alkaline metal ions. The chemical shifts of proton NMR were also utilized to obtain information regarding the complexation of calix[4]arene derivatives with alkaline metal ions [10, 12].



EXPERIMENTAL



Reagents

The chemical structures of the calixarene carboxylate derivatives employed in the present work are shown in Fig. 1. The synthesis of these compounds was reported in a previous paper [5].

Distribution study

An organic solution was prepared by diluting each extractant into analytical grade of chloroform to desired concentrations ($\mathbf{1}_6$ and $\mathbf{1}_4$; 5 mM, $\mathbf{1}_1$; 20 mM). The following three types of aqueous stock solutions of rare earth metal ions were prepared by dissolving

$\mathbf{1}_n$: R = CH_2COOH (n = 4 (cone conformation) / 6)

$\mathbf{1}_1$: R = CH_2COOH

Fig. 1. Chemical structures of the extractants.

analytical-grade rare earth chlorides into 0.1 mol dm^{-3} nitric acid solution or into the aqueous mixture of 0.1 mol dm^{-3} glycine and 0.1 mol dm^{-3} alkaline hydroxide. (When a precipitate was formed in the solution, the former one was added.) The first stock solution contains La, Pr and Nd, the second contains Sm, Eu and Gd, and the third contains Ho, Er and Y. The initial pH was adjusted by mixing the stock solutions at an arbitrary volume ratio. An equal volume of organic and aqueous phases (10 cm^3) was mixed and shaken vigorously for 16 h at 30°C. After the phase separation, the equilibrium concentrations of lanthanide ions in the aqueous phase were measured by an inductively coupled plasma atomic emission spectrometer (Seiko model SPS 1200AR). The equilibrium pH in the aqueous solutions were measured by a pH meter (Beckmann model Ø45).

Study of proton NMR

The study of proton NMR was conducted for the complexes of alkaline metal ions with $\mathbf{1}_4$ and $\mathbf{1}_1$. The condition for the preparation of the sample solutions was similar to those of distribution study. The organic solution was prepared by diluting $\mathbf{1}_4$ or $\mathbf{1}_1$ into chloroform-*d* to the same concentrations as those used in the distribution study, i.e. the concentrations of $\mathbf{1}_4$ and $\mathbf{1}_1$ were 5 and 20 mol m^{-3}, respectively. The aqueous solutions were prepared by dissolving analytical-grade lithium, sodium or potassium nitrate into deuterium oxide. The concentration of alkaline metal ions was 0.1 mol dm^{-3}. Organic phase 0.8 cm^3 and 0.5 cm^3 of the aqueous phase were mixed and shaken vigorously for 16 h at 30°C. After the phase separation, the proton NMR of the organic phase was measured at 50°C for $\mathbf{1}_4$ and at 20°C for $\mathbf{1}_1$ (Jeol model GX-270).

RESULTS AND DISCUSSION

Distribution study

The effect of pH on the distribution of lanthanide ions in the extraction with $\mathbf{1}_6$ in the presence of lithium ions and with $\mathbf{1}_4$ in the presence of sodium ions is

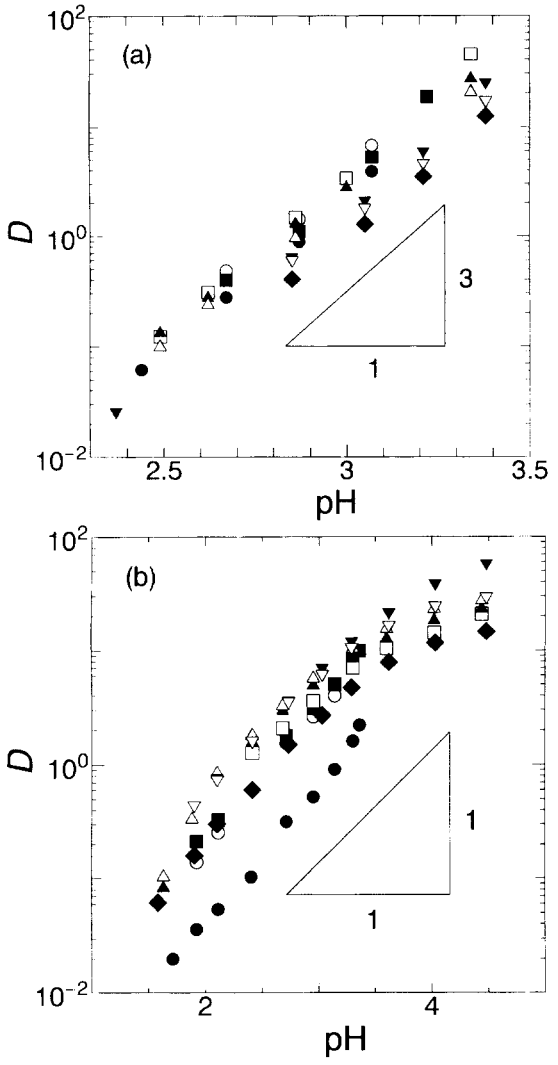


Fig. 2. Effect of pH on distribution ratio: (a) with $\mathbf{1}_6$ in the system containing lithium ions; (b) with $\mathbf{1}_4$ in the system containing sodium ions; La(●), Pr(○), Nd(■), Sm(□), Eu(▲), Gd(△), Ho(▼), Er(▽), Y(◆).

shown in Figs. 2(a) and (b), respectively, as typical experimental results. All plots in Fig. 2(a) lie on straight lines with the slope of 3, whereas those in Fig. 2(b) appear to lie on straight lines with the slope of 1. In the other extraction systems from an aqueous phase containing each alkaline metal ion with each extractant, a similar linear relationships to Fig. 2(a) was observed between the logarithm of the distribution ratio and pH. Table 1 summarizes the values of the slopes for the linear relationship observed in all the extraction systems in the present study. For a comparison, those observed in the absence of an alkaline metal ion are also listed. In the extraction of trivalent lanthanides based on a cation-exchange mechanism, the slope of pH dependency should be equal to 3. Actually, those observed in the extraction system without alkaline metal ions are close to 3, which is consistent with the above consideration. However, in some extraction systems, large deviations of the slopes from 3 were observed. The following should be taken into consideration to clarify the reason why the slopes are not consistent with the valence of lanthanide ions:

(1) Lanthanides are extracted accompanied by anionic species in the aqueous phase such as nitrate anion, partly neutralizing the positive charge of the lanthanide ion.
(2) Lanthanides give rise to complexes with glycine in the aqueous phase, suppressing the extraction.
(3) The extractants co-extract alkaline metal ion during the extraction of the lanthanides. In the third case, the extraction of alkaline metal ion might affect the extraction behavior of lanthanide ions.

The possibility of the first and second reasons can be excluded, because lanthanide ions hardly form a complex with nitrate anion [19] and glycine existing as a zwitterion, which is also difficult to form a complex with a metal cation under the present acidic condition. Concerning the third reason, the coextraction of alkaline metals has been confirmed by the previous study on the extraction of copper(II) with $\mathbf{1}_4$ [18]. For the extraction with $\mathbf{1}_4$, the possibility of the following four reactions may be inferred:

$$Ln^{3+} + \overline{(H_4R)_2} \rightleftarrows \overline{Ln(HR)(H_2R)} + 3H^+ \quad (1)$$

Table 1. Slope values of pH dependency in each system

Involved alkali metal	Extractant	La	Pr	Nd	Sm	Eu	Gd	Ho	Er	Y

$$2M^+ + \overline{(H_4R)_2} \rightleftarrows 2\overline{(M \cdot R_3H)} + 2H^+ \quad (2)$$

$$Ln^{3+} + 2M^+ + \overline{(H_4R)_2} \rightleftarrows \overline{Ln \cdot 2M \cdot (R)(HR)} + 5H^+ \quad (3)$$

$$Ln^{3+} + M^+ + \overline{(H_4R)_2} \rightleftarrows \overline{Ln \cdot M(HR)_2} + 4H^+ \quad (4)$$

where Ln, M and H_4R denote lanthanide metal, alkaline metal and $\mathbf{1}_4$, respectively. The extractant $\mathbf{1}_4$ was confirmed to exist mainly as a dimeric species in chloroform in the previous paper [5].

In the absence of alkaline metal ion, the complexation formation is considered to proceed through the reaction (1), while in the presence of alkaline metal ions, all of the reactions (1)–(4) should be taken into account. If the extraction of lanthanides takes place preferentially to an alkaline metal ion, only eq. (1) which takes place in the absence of alkaline metal ions and gives the pH dependency with the slope of 3 has to be taken into account. These are the cases observed in the extraction of all lanthanides with $\mathbf{1}_6$ in the presence of lithium and in that of light lanthanides in the presence of potassium with $\mathbf{1}_6$, as well as that of heavy lanthanides with $\mathbf{1}_4$. On the contrary, if the extraction of alkaline metals takes place preferentially to those of lanthanides, the release of three protons caused by the extraction of the lanthanide can be neglected, because the concentration of the lanthanide ion is much lower than those of alkaline metal ion and the extractant. Consequently, in the pH region where lanthanide ion was extracted, reaction (2) has only to be taken into account and the apparent slope of pH dependency should be 1. Actually, this interpretation satisfies the experimental results for the extraction of all lanthanides with $\mathbf{1}_4$ in the presence of sodium ions. The extraction in the other systems is considered to take place according to the simultanious reactions of all of the four reactions, which gives the complicated dependency of slopes with pH.

The selectivity series among lanthanides in the present work was evaluated in terms of $pH_{0.5}$, the pH at which 50% extraction is achieved, owing to the extremely complicated extraction reactions as mentioned above. The relations between the $pH_{0.5}$ with each extractant and the reciprocal of ionic radius of the lanthanide element (in hexa-coordination) in the presence of lithium, sodium and potassium ions are shown in Figs 3(a)–(c), respectively. Furthermore, the result in the absence of an alkaline metal observed in the previous work is also shown in Fig. 3(d) for comparison. The plots all lie on convex curves with maximum points. For the extraction in the absence of alkaline metal ion, the maximum point for $\mathbf{1}_6$ is located at praseodymium. In the presence of lithium or sodium, it is also located at praseodymium, whereas for that in the presence of potassium, it is shifted toward heavier lanthanides and is located at samarium, whose ionic radius is smaller than that of praseodymium. In the extraction with $\mathbf{1}_4$, the maximum points were also located at praseodymium, regardless of whether lithium or potassium is present or not, whereas in the presence of sodium it was located at gadolinium, which is smaller than praseodymium. Especially, the shift for the extraction with $\mathbf{1}_4$ in the presence of sodium was the most significant among all cases. The reasons why the drastic change in the selectivity to lanthanides took place in the extraction with $\mathbf{1}_4$ in the presence of sodium can be interpreted in relation to our recent study on the extraction of copper with calix[4]arene derivatives [18]. That is, in the co-extraction of sodium ion together with copper (II) ions by 25,27-bis(carboxymethoxy)-26,28-bis(carboxypropoxy)-5,11,17,23-tetrakis(1,1,3,3-tetramethylbutyl)calix[4]arene, we reached the following conclusions:

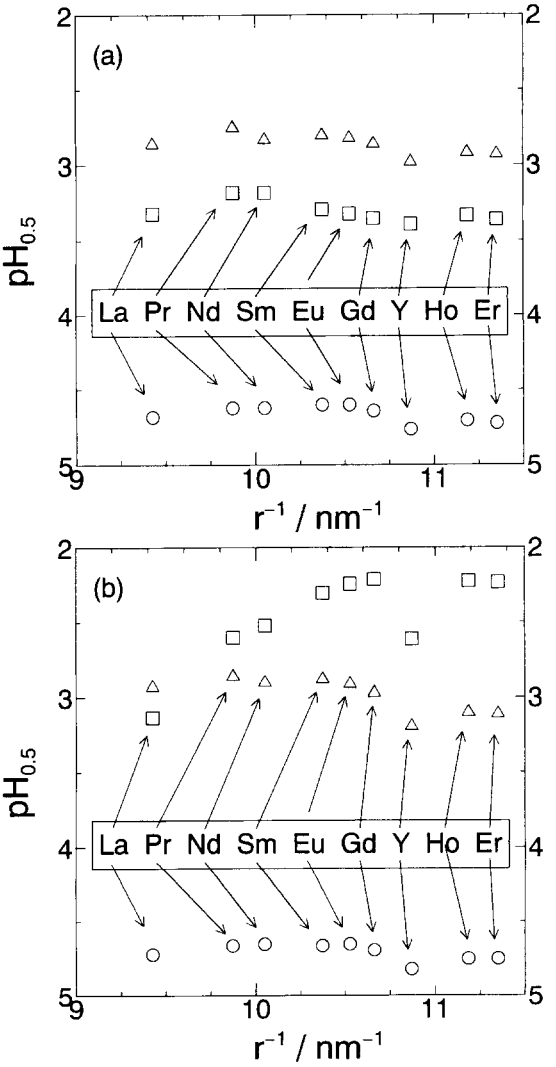

Fig. 3. Relation between $pH_{0.5}$ and reciprocal of ionic radius of each lanthanide element: △: $\mathbf{1}_6$, □:$\mathbf{1}_4$, ○:$\mathbf{1}_1$. (a) in the system containing lithium, (b) sodium, (c) potassium and (d) no alkali metal ion.

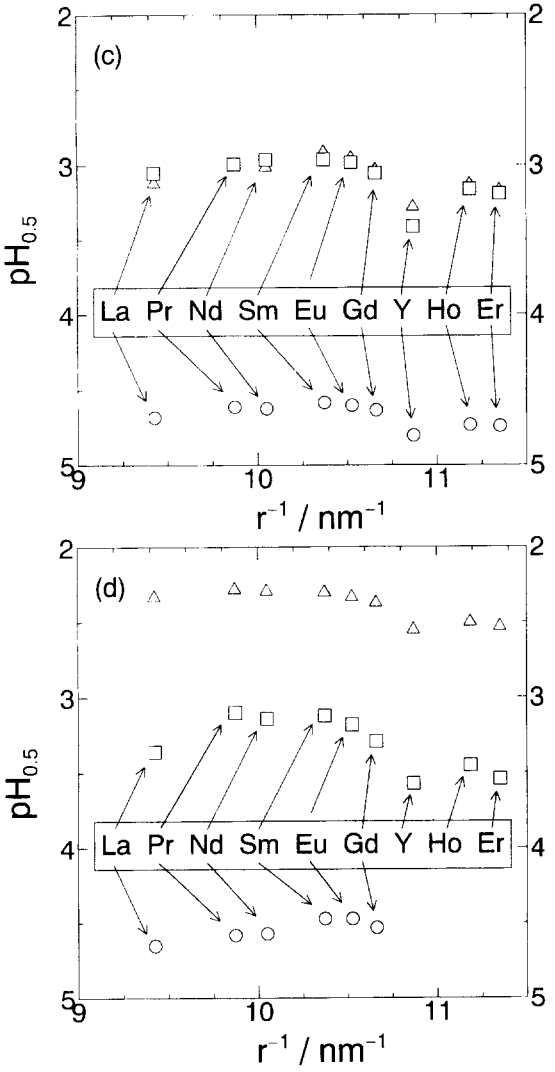

Fig. 3—*Continued.*

(1) Calix[4]arene derivatives exibit the sodium-selectivity (i.e. the ionic diameter of sodium ion fits the cavity size of the calix[4]arene).
(2) In the presence of sodium, the extractant $\mathbf{1}_4$ co-extracts a sodium ion together with a divalent copper ion.
(3) The uptake of sodium ions with the cyclic tetramer gives rise to a structural change, that is, it increases structural "rigidity" and provides "preorganization" in the structure of the extractant.
(4) The extractability is much enhanced due to the chelate effect regardless of the electric repulsion between sodium and copper ions.

Based on these points of view concerned with the extraction of copper, it is reasonable to consider that the similar co-extraction also takes place in the extraction of the lanthanides. The uptake of sodium ions causes a structural change and preorganizes the extractant $\mathbf{1}_4$, which results in the change of the selectivity to the lanthanides.

On the other hand, the change of the selectivity to lanthanides with $\mathbf{1}_6$ was smaller than that with $\mathbf{1}_4$ and, in addition, no change was observed in all the cases in the extraction with $\mathbf{1}_1$, which are interpreted as follows:

(1) The flexibility of $\mathbf{1}_6$ is higher than that of $\mathbf{1}_4$ owing to its greater ring size.
(2) The ring inversion of $\mathbf{1}_6$ is not suppressed and the ring conformation is not fixed on the cone type, whereas $\mathbf{1}_4$ is fixed on the cone conformation.
(3) Since the extractant $\mathbf{1}_1$ is a monomeric and acyclic derivative it is, therefore, the most flexible among all the extractants.
(4) The coordination ability of its phenoxy oxygen is considered to be very weak and the co-extraction with $\mathbf{1}_1$ may be difficult.

The pH region where lanthanides are extracted was considered as follows. In the extraction with $\mathbf{1}_6$, the addition of alkaline metals shifted the $pH_{0.5}$ to higher pH region compared with that in the absence of alkaline metal ions. This means that the extraction of lanthanide ion was suppressed due to the extraction of alkaline metal ion based on the acidic dissociation. Contrarily, in the extraction with $\mathbf{1}_4$, the $pH_{0.5}$ in the presence of lithium or potassium was the same with that in the absence of alkaline metal ion, while in the presence of sodium, the significant shift of the $pH_{0.5}$ to lower pH was observed in comparison with the other systems. The extractant $\mathbf{1}_4$ specifically extracts the sodium ion since its ionic diameter fits to the cavity size of $\mathbf{1}_4$. It is considered that the uptake of the sodium ion makes the extractant rigid and preorganized to change it so as to specifically accept other metal ions whose ionic diameter fits with the preorganized ring size. In the extraction with $\mathbf{1}_1$, the $pH_{0.5}$ in the presence of alkaline metals was the same as that in their absence, because $\mathbf{1}_1$ preferentially extracts the lanthanides than those of the alkaline metal ions.

Study of proton NMR

The results mentioned above suggest that coexisting alkaline metal ions might participate in the extraction of lanthanide ions with $\mathbf{1}_6$ and $\mathbf{1}_4$. In order to confirm the participation of alkaline metal ions in the lanthanide extraction, proton NMR studies were conducted.

Figure 4 shows proton NMR spectra for cone-type of $\mathbf{1}_4$ in deuterated chloroform and for the organic phase after being contacted with the aqueous phase containing a lithium, sodium or potassium ion. For the peaks in the system of lithium or potassium, an evident chemical shift cannot be observed, although slight indications were present. On the other hand, for all peaks in the system with sodium ions, evident shifts

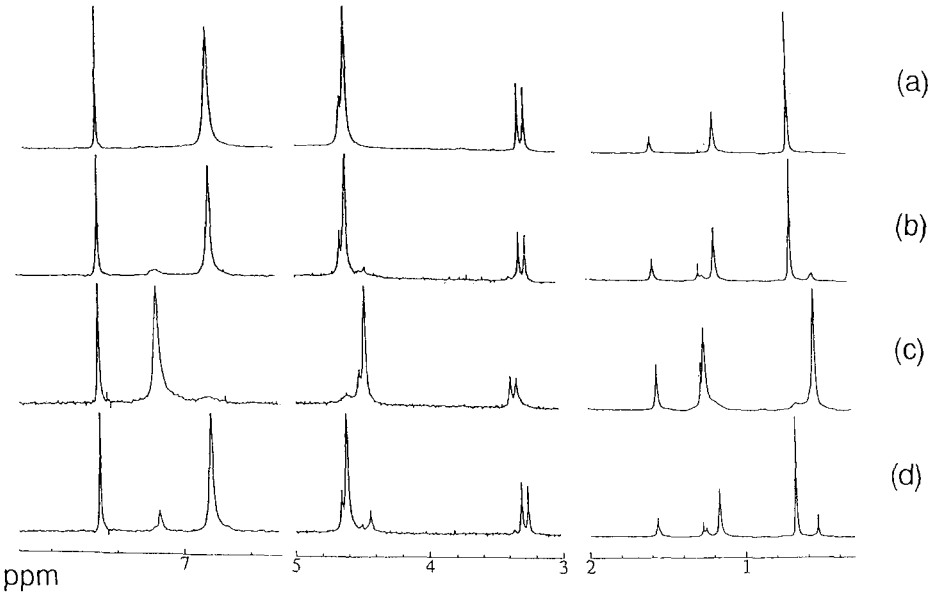

Fig. 4. ^{1}H NMR spectra of $\mathbf{1}_4$: (a) original, (b) in the system containing lithium, (c) sodium, (d) potassium ions.

were observed; these shifts are ascribable to the ring current of the benzene ring and symmetry change [10, 12]. These results clearly indicate that $\mathbf{1}_4$ extracts the sodium ion while lithium and potassium ions are not extracted.

The proton NMR spectra of $\mathbf{1}_1$ were not observed. That is, the peaks of all systems in the presence of alkaline metal ions were the same as the original peaks. Any chemical shift of the peaks cannot be observed in all the systems, which means that $\mathbf{1}_1$ does not extract the three kinds of alkaline metal ion.

For $\mathbf{1}_6$, clear spectra were not obtained in deuterated

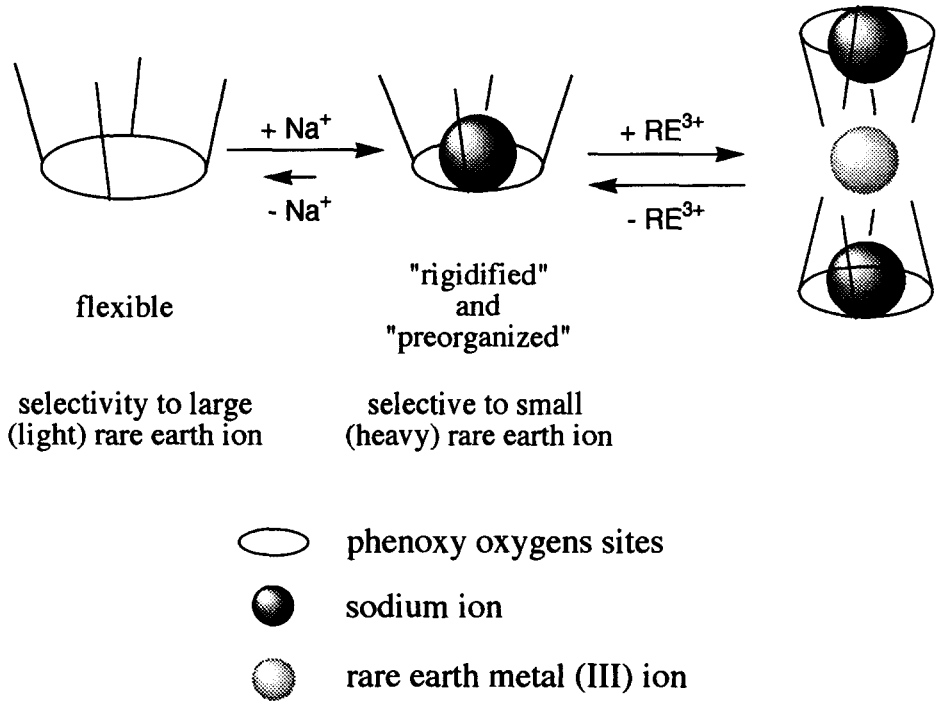

Fig. 5. Extraction models of $\mathbf{1}_4$ in the system in the presence of sodium ions.

chloroform around room temperature, owing to the flexible conformation of $\mathbf{1}_6$.

Extraction model of calix[4]*arene derivative in the system containing sodium ions*

Similar to the extraction model of the copper(II) ion with the calix[4]arene derivative in the presence of sodium ions, the extraction model for lanthanide ions with $\mathbf{1}_4$ in the presence of sodium ions can be schematically shown in Fig. 5. Since the lowering of $pH_{0.5}$ was observed during the extraction of sodium ion with $\mathbf{1}_4$, it is considered that the uptake of the sodium ion takes place according to an ion-exchange mechanism where one positive charge of the sodium ion is neutralized with one carboxylic group of $\mathbf{1}_4$ and the other coordination sites of the sodium ion are saturated with other carbonyl groups and phenoxy oxygens. As a result, all of the carboxyl groups of $\mathbf{1}_4$ might be combined at the near position with sodium ion, rigidifying and preorganizing the extractant. The resulting assembly of carboxyl groups results in the change of selectivity from light lanthanides with a large ionic radii to heavy ones with small ionic radii. (The results for $\mathbf{1}_6$ in the potassium system may support the above consideration.)

From the result of the present work, we have found that a preorganized extractant might have a high separation efficiency for lanthanides due not only to the rigidity, but also the chelate effect. This concept may be able to apply to the molecular design of novel types of extractants and to a separation of difficult separative series of metals.

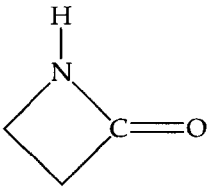
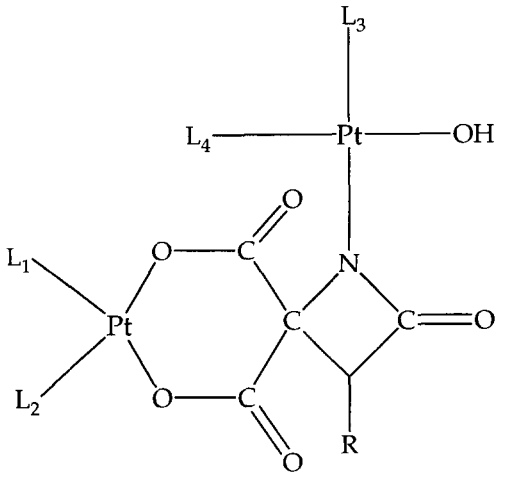
(Received 3 September 1996; accepted 20 September 1996)



Abstract—A number of platinum(II) and palladium(II) complexes **3** and **4** containing amido ligands derived from β-propiolactam (2-azetidinone, Haz) have been synthesised in high yield by the silver(I) oxide-mediated reactions of the complexes *cis*-$[MCl_2L_2]$ [M = Pt, L = cycloocta-1,5-diene (COD) or PPh_3; M = Pd, L = 2,2′-bipyridine (BIPY) or 1,10-phenanthroline (PHEN)] with 2-azetidinone. Displacement of the COD ligand allowed the synthesis of a number of other derivatives containing phosphine, phosphite and isocyanide ligands. Electrospray mass spectrometry has also been used to further characterize these complexes, to probe the strength of binding of the amide ligands and to investigate the ability of the complexes to act as metallo-ligands towards other mono-, di- and trivalent cations. A detailed study on the bis(triphenylphosphine) platinum complex **3b** shows that fragmentation, induced by higher cone voltages, proceeds initially *via* loss of a deprotonated azetidinone monoanion (az^-) ligand, yielding $[Pt(az)(PPh_3)_2]^+$. Upon further increasing the cone voltage, cyclometallation of one of the triphenylphosphine ligands occurs. Complex **3b** readily forms adducts with a range of alkali-metal cations, Ag^+, divalent cations (Ba^{2+}, Cu^{2+}, Zn^{2+} and Pb^{2+}) and a trivalent cation (Pr^{3+}). Complex **3b** shows selectivity for Na^+ ions over other alkali-metal cations in forming a dipositively charged aggregate of the type $[2M + 2Na]^{2+}$ at low cone voltages. The X-ray structure of complex **3b** is also reported. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: platinum; palladium; amide; azetidinone; electrospray.



The interactions of small-ring organic molecules with metal complexes is of fundamental interest, since the metal may participate in ring-opening reactions, forming metallacyclic and other complexes [1]. As a specific example, the oxidative addition of propiolactone to low-valent platinum, rhodium and iridium complexes has been found to give five-membered ring metallalactone complexes [2]. Organic lactams may also coordinate to metal centres as the monoanion, *via* the amide nitrogen [3,4]. In view of the general interest in the chemistry of late transition-metal amide complexes [5] we wished to synthesize platinum and palladium complexes derived from the four-membered ring lactam 2-azetidinone (β-propiolactam) **1** [6]. Compounds containing derivatives of this ring system form the important class of β-lactam antibiotics. Since a number of transformations of azetidinone ring systems are catalysed by palladium complexes [7], understanding the different possible interactions of such ring systems with metal centres may provide valuable information on the role of the metal centre.

Mercury(II) complexes containing the monoanion of 2-azetidinone have been described previously and found to be precursors for the construction of supramolecular coordination assemblies [3]. Transition-metal amide complexes containing the M—NRC(O)—moiety are of some interest for their ability to act as ligands towards other metal centres, generating novel polymeric and macrocyclic structures [4].

The only platinum or palladium derivatives of **1** which have been reported to data appear to be the binuclear ammine complexes **2**. These have been demonstrated to have good antitumour activity against mouse leukemia [8], offering a further impetus for studying the chemistry of platinum-group metal amide complexes [9]. In this work, the synthesis and electrospray mass spectrometric characterisation of amide complexes derived from 2-azetidinone is described, together with an X-ray crystal structure determination on one derivative.

idinone (β-propiolactam) **1** in refluxing dichloromethane mediated by silver(I) oxide afforded high yields of the amido complexes **3a** and **b**, respectively, as white, air-stable crystalline solids. In analogous fashion, reaction of $[PdCl_2L_2]$ [L_2 = 2,2′-bipyridine (BIPY), or 1,10-phenanthroline (PHEN)] gave the palladium(II) complexes **4a** and **b** as yellow microcrystalline solids. The complexes have been fully characterized by multinuclear NMR and IR spectroscopies, elemental microanalysis and electrospray mass spectrometry.

Silver(I) oxide has been demonstrated to be a useful reagent for the synthesis of platinum-group metal amide complexes [10–12], providing that an electron-withdrawing substituent is present on the nitrogen atom. Advantages of the silver(I) oxide method include ease of product workup (the byproducts are silver chloride and water), and the non-necessity for dried solvents.

The labile COD ligand of **4a** can be readily displaced by other tertiary phosphines [$P(CH_2CH_2CN)_3$ and $Ph_2PCH_2PPh_2$ (DPPM)], triphenyl phosphite, 2,6-xylylisocyanide (XyNC), or *tert*-butylisocyanide giving a series of ligand-substituted derivatives **3c–g**. No reaction was observed between **4a** and triphenylarsine, and the COD complex was recovered unreacted. Microanalytical data and selected additional characterization data (melting points and IR spectroscopic data) for the azetidinone complexes are summarized in Table 1.

NMR spectroscopy

The ^1H and $^{13}C\{^1H\}$ NMR spectra of complexes **3** and **4** are consistent with their formulation as complexes containing the N-bonded azetidinone monoanion. In the ^1H NMR spectrum of the COD Pt complex **3a** two CH_2 resonances are observed, at δ 3.16 and 3.01, with the former assigned as the CH_2 adjacent to the more electron-withdrawing carbonyl group. Both CH_2 groups appear as triplets due to $^3J(H,H)$ coupling of 4.1 Hz. By comparison, the parent 2-azetidinone shows a triplet at δ 3.27 [$^3J(H,H)$-4.3 Hz] due to the CH_2CO protons, but a doublet of triplets at δ 2.98 for the CH_2N protons, due to additional coupling [$^3J(H,H)$-1.7 Hz] to the amide NH proton. A broad signal at δ 6.2 in 2-azetidinone due to the NH proton was not observed in any of the complexes **3** or **4**. The $^{13}C\{^1H\}$ NMR spectrum of **3a** showed singlets due to the $CH_2C(O)$ and CH_2N carbons at δ 41.1 and 38.5, respectively, and a singlet due to the two amide carbonyl groups at δ 174.1. The corresponding values for 2-azetidinone are δ 38.5, 35.2 and 169.1, respectively.

For the complexes containing phosphine ligands, typified by **3b**, the ^1H spectra were slightly more complex, although two CH_2 resonances were again observed for each complex. One, at δ 2.40, appeared as a slightly broadened triplet [$^3J(H,H)$-7.3 Hz] and is assigned as the CH_2CO protons, while the other (due to the CH_2N protons) was a broad unresolved singlet, as a result of additional four-bond coupling to the phosphine ligand(s). Confirmation of the above spectral assignment in complex **3b** was achieved by a ^{13}C–^1H correlation spectrum.

The $^{31}P\{^1H\}$ NMR spectrum of complex **3b** showed a single resonance with satellites due to coupling to ^{195}Pt, with $^1J(Pt,P)$-3054 Hz. This compares well with other platinum(II)-amide complexes [10,13].

Assignment of the NMR spectra of the palladium complexes was based on the assignment for the platinum complexes. Interestingly, for the BIPY Pd complex **4a**, the chemical shift difference between the two types of CH_2 protons was relatively small, and in the PHEN complex **4b**, these protons appeared as a somewhat broad unresolved singlet, due to coincidental chemical shifts. Upon examination of the carbon spectrum for this complex two separate CH_2 resonances were observed, at δ 40.9 and 39.0.

Electrospray mass spectrometry (ESMS) study

ESMS is a relatively recent mass spectrometric ionisation technique, ideally suited to the study of polar, high molecular weight molecules [14]. The technique

typically gives strong parent ions, which may be multiply charged and, therefore, can be used as an additional means of characterization, supplementary to more traditional spectroscopic and crystallographic techniques. However, the ability to select the amount of fragmentation in the ESMS system allows the potential to study the stability of coordination complexes. In addition, since the sample is introduced as a solution, *in situ* reactions of the complexes with various reagents is readily facilitated, using small quantities of material. Accordingly, the azetidinone complexes **3** and **4** have been investigated by electrospray mass spectrometry, using a CH_3CN/H_2O mobile phase; ESMS data are summarized in Table 2. For all major ions observed there was excellent agreement between the observed and calculated isotope patterns.

A detailed study on the triphenylphosphine platinum complex **3b** has been carried out in order to study the fragmentation patterns in this class of compound. ES spectra of **3b** recorded at three different cone voltages (20, 40 and 80 V) are shown in Fig. 1 (a–c, respectively). At 20 V the major peak was the "parent" ion $[M + H]^+$ (*m/z* 860), although there was an additional reasonably intense peak at *m/z* 1737, which is assigned to the aggregate $[2M + NH_4]^+$. One possible structure for this aggregate is given by **5a,** where two bidentate bis(amide) complexes hydrogen-bond with the NH_4^+ ion. The presence of "basic" carbonyl groups thus provide a mechanism for chemical ionisation *via* protonation or aggregation with NH_4^+ ions. Aggregate formation involving ammonium ions is reasonably frequently observed, although for this particular case it is interesting that only exceedingly weak corresponding species $[2M + H]^+$ (*m/z* 1720) and $[M + NH_4]^+$ (*m/z* 877) are observed. The larger aggregate ion $[3M + 2NH_4]^{2+}$ was observed as a weak peak at *m/z* 1306. The source of the NH_4^+ ions in this system is undoubtedly the acetonitrile mobile phase, since traces of NH_3 and NH_4^+ are ubiquitous in this solvent.

Upon increasing the cone voltage to 40 V, fragmentation of complex **3b** occurs. The principal change is loss of one of the azetidinone ligands as a monoanion (az^-) giving $[M - az]^+$ as the principal ion at *m/z* 789, i.e. $[Pt\{NC(O)CH_2CH_2\}(PPh_3)_2]^+$. It is noteworthy that the $[3M + 2NH_4]^{2+}$ aggregate ion was not observed at 40 V, though the aggregate ion $[2M + NH_4]^+$ was observed together with $[2M + H]^+$, these two peaks being of approximately equal intensity. Upon further increasing the cone voltage to 80 V, Fig. 1(c), the aggregate ions were only of low intensity, the species $[M - az]^+$ was the principal ion, and a new ion at *m/z* 718 was observed. The latter is assigned as the complex **6** containing a cyclometallated triphenylphosphine ligand. We have previously observed similar behaviour for a number of platinum complexes containing triphenyl-phosphine or -phosphite ligands [11,15]. Cyclometallation thus appears to provide a mechanism for loss of the second azetidinone amide ligand; the observation that the

5b; M = Ba, n = 2

6

monoamide complex $[M - az]^+$ is stable to relatively high cone voltages (e.g. 80 V) which suggests that the platinum–nitrogen bond possesses significant stability.

In a similar fashion to **3b**, the positive-ion spectrum for the triphenylphosphite complex **3e** gave intense $[M + H]^+$ (*m/z* 956) and $[2M + NH_4]^+$ (*m/z* 1928) ions, again with no evidence of the corresponding $[M + NH_4]^+$ or $[2M + H]^+$ ions. As result of the strong signal intensity, and spectral simplicity, is it suggested that triphenylphosphite ligands may facilitate ESMS analysis of coordination complexes, particularly when other "basic" functional groups are absent. For the other complexes, aggregate ions of the type $[2M + H]^+$, $[2M + NH_4]^+$ and from time to time $[2M - az]^+$ were observed, as indicated in Table 1. The relative intensities of these appeared to vary somewhat with the complex and from day to day.

Complexes **3** and **4** readily add adventitious quantities of Na^+ (most likely leached from glassware) and the spectra often showed a small peak for $[M + Na]^+$ in addition to the peak for $[M + H]^+$. These observations suggested that the *cis*-diamide groups may be suitably disposed for coordination towards metal centres. Electrospray mass spectrometry was used to evaluate the possibilities for undertaking coordination chemistry with these new complexes, using the triphenylphosphine platinum complex **3b** as a typical example. There are a number of advantages to using ESMS to probe coordination chemistry; very small quantities of material may be used and once promising metal–ligand combinations have been identified, then the ESMS results can be used to subsequently direct synthetic studies on the macroscopic scale. ESMS has been used previously for the *in situ* study of coordination chemistry. Applications include studies of metal-binding peptides and proteins [16], metal complexes of ascidian-derived peptides [17] and ligand exchange processes of coordination complexes [18].

Complexation studies with added metal salts

Mass spectra of the triphenylphosphine platinum complex **3b** were recorded with addition of small quantities of various metal salts; results are sum-

marized in Table 3. Experiments were carried out with added LiCl, NaCl, KCl, CsCl, $AgNO_3$, $Cu(NO_3)_2$, $Ba(NO_3)_2$, $Pb(NO_3)_2$, $Pb(OAc)_2$, $Zn(OAc)_2$, $BeSO_4$ and $Pr(NO_3)_3$. In all cases, excellent agreement was obtained between the observed and calculated isotope pattern for all major ions.

(a) *With monovalent cations.* For mixtures of **3b** and the alkali metal cations ($cat^+ = Li^+$, Na^+, K^+ and Cs^+) a large peak for $[M + cat]^+$ was typically observed, often with other species. As a typical example, the positive-ion ES spectrum of **3b** with added NaCl is shown in Fig. 2, which shows $[M + Na]^+$ as the main platinum-containing species. Other ions observed were $[M + H]^+$, $[3M + 2Na]^{2+}$ and $[2M + Na]^+$. Examination of the isotope distribution patterns for the $[M + cat]^+$ ions at relatively high cone voltages (e.g. 40 V) yields only the pattern for the $[M + cat]^+$ ion. However, for the $[M + Na]^+$ ion, upon recording the isotope pattern at cone voltages of 20 V or less, additional peaks at half-mass separation grew in, as illustrated in the inset to Fig. 2. These are assigned to the dication $[2M + 2Na]^{2+}$. What is particularly noteworthy is that such a dication was *only observed in the case of sodium*; no $[2M + 2cat]^{2+}$ ions were observed for Li^+, K^+ or Cs^+ even at very low cone voltages (5 V). While of the origin of this selectivity is uncertain, it is possible that the bite angle of the two *cis* amide carbonyls is optimized for coordination to an ion the size of Na^+.

It is worth noting that the use of added alkali metal salts as an ionization reagent has been employed previously, for example in the analysis of polyethers by addition of lithium ions [19], and in the use of anhydrous KI for a range of organic compounds in aprotic solvents [20]. Coordination chemistry of metal complexes with alkali-metal cations has been studied previously by ESMS, for example for the tripodal oxygen and nitrogen ligands $[(\eta^5\text{-}C_5H_5)Co\{P(O)(OR)_2\}_3]$ and $[HB(pz)_3]^-$ (pz = pyrazolyl) [21] and Schiff bases [22]. The attachment of an alkali-metal cation is promoted by the presence of hard, basic oxygen (or nitrogen) atoms in the molecule. The Li^+ ion readily formed an adduct with **3b**, and, as a result of the high charge density of this ion, the mono acetonitrile solvate $[M + Li(MeCN)]^+$ is observed up to moderate cone voltages (40 V).

When $AgNO_3$ is added to a solution of **3b**, in addition to the expected $[Ag(NCMe)_x]^+$ ions ($x = 1$ or 2), the main platinum species observed was the expected $[M + Ag]^+$ at m/z 967. An additional peak at m/z 1138 could be assigned as the dimeric species

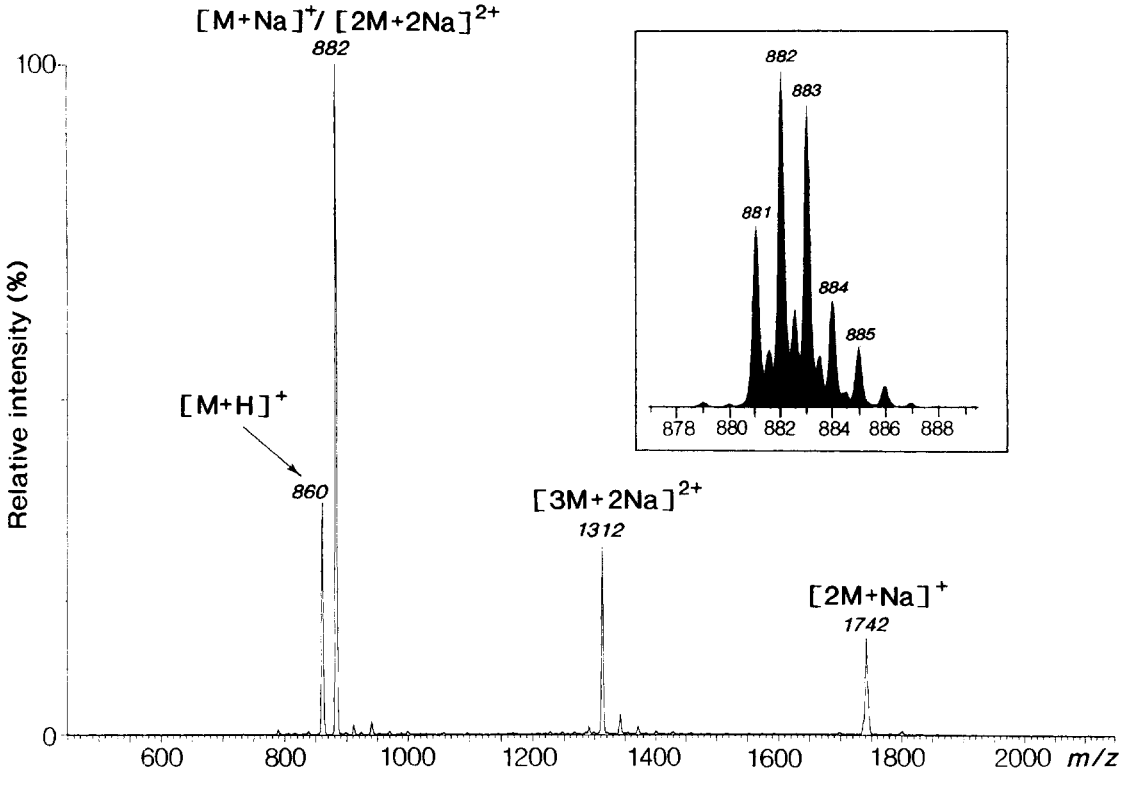

Fig. 2. Positive-ion electrospray spectrum of $[Pt\{NC(O)CH_2CH_2\}_2(PPh_3)_2]$ (**3b**) (= M) at a cone voltage of 20 V, with added NaCl, showing peak assignments. The inset shows the isotope distribution pattern for the m/z 882 ion, indicating the presence of the $[M + Na]^+$ and $[2M + 2Na]^{2+}$ ions.

Table 3. Electrospray mass spectrometric data for complexes of **3b** with added metal salts[a,b]

Mixture	Cone voltage (V)	Principal ions (m/z)
3b + LiCl	5	$[M + Li]^+$ (866), $[M + Li(MeCN)]^+$ (907)
3b + NaCl	20	$[M + H]^+$ (860), $[M + Na]^+$ (882), $[3M + 2Na]^{2+}$ (1312), $[2M + Na]^+$ (1742)
3b + KCl	20	$[M + H]^+$ (860), $[M + K]^+$ (898), $[3M + 2K]^{2+}$ (1328), $[2M + K]^+$ (1758)
3b + CsCl	20	$[M + H]^+$ (860), $[M + Cs]^+$ (992), $[M + 2Cs + Cl]^+$ (1161), in addition to peaks due to Cs^+, $[Cs_2Cl]^+$, $[Cs_3Cl_2]^+$ etc.
3b + $AgNO_3$	20	$[M + Ag]^+$ (967), $[2M + 2Ag + NO_3]^+$ (1138)
3b + $Ba(NO_3)_2$	20	$[Ba(MeCN)_3]^{2+}$ (130), $[Ba(MeCN)_4]^{2+}$ (151), $[Ba(MeCN)_5]^{2+}$ (171), $[Ba(MeCN)_6]^{2+}$ (191), $[BaNO_3(MeCN)]^+$ (241), $[BaNO_3(MeCN)_2]^+$ (282), $[BaNO_3(MeCN)_3]^+$ (323), $[M + Ba]^{2+}$ (498), $[M + Ba(MeCN)]^{2+}$ (519), $[M + Ba(MeCN)_2]^{2+}$ (539), $[M - az]^+$ (789), $[M + H]^+$ (860), $[2M + Ba]^{2+}$ (928), $[M + BaNO_3]^+$ (1058), $[3M + Ba]^{2+}$ (1357)
3e + $Ba(NO_3)_2$	20	$[M + Ba]^{2+}$ (546.5), $[M + Ba(MeCN)]^{2+}$ (566.5), $[M + Ba(MeCN)_3]^{2+}$ (587.5), $[M + H]^+$ (956), $[2M + Ba]^{2+}$ (1024), $[M + BaNO_3]^+$ (1155), $[3M + Ba]^{2+}$ (1502), $[2M + BaNO_3]^+$ (2110), together with Ba-MeCN-NO_3 species as indicated for **3b** above.
3b + $Pb(NO_3)_2$	20	$[M - az]^+$ (789), $[M - az + MeCN]^+$ (830), $[M + H]^+$ (860), $[M + PbNO_3]^+$ (1129)
3b + $Pb(OAc)_2$	20	$[M - az]^+$ (789), $[M + H]^+$ (860), $[2M + Pb]^{2+}$ (963), $[M + PbOAc]^+$ (1126), $[3M + Pb]^{2+}$ (1393), $[2M + NH_4]^+$ (1738), $[2M + PbOAc]^+$ (1985)
3b + $Cu(NO_3)_2$	20	$[M + Cu(MeCN)]^{2+}$ (482), $[M + Cu(MeCN)_2]^{2+}$ (502), $[M - az]^+$ (789), $[M - az + MeCN]^+$ (830), $[M + H]^+$ (860), $[2M + Cu]^{2+}$ (891), $[2M + 2H + NO_3]^+$ (923), $[M + CuNO_3]^+$ (985)
3b + $Zn(OAc)_2$	20	$[M + Zn(MeCN)]^{2+}$ (483), $[M + Zn(MeCN)_2]^{2+}$ (503), $[M + H]^+$ (860), $[2M + Zn]^{2+}$ (892), $[M + Zn(OAc)]^+$ (982)
3b + $BeSO_4$	5	$[M - az + MeCN]^+$ (830), $[M + H]^+$ (860)
3b + $Pr(NO_3)_3$	20	$[M + Pr(MeCN)_4]^{3+}$ (388), $[M + Pr(NO_3)]^{2+}$ (531), $[M + Pr(NO_3)(MeCN)]^{2+}$ (551.5), $[M + Pr(NO_3)(MeCN)_2]^{2+}$ (572), $[M + Pr(NO_3)(MeCN)_3]^{2+}$ (592.5), $[M - az]^+$ (789), $[M + H]^+$ (860), $[2M + Pr(NO_3)]^{2+}$ (961), $[M + Pr(NO_3)_2]^+$ (1124), $[M + Pr(NO_3)_2(MeCN)]^+$ (1165)

[a]Species are identified by the major peak in the isotope distribution pattern.
[b]Haz = 2-azetidinone.

$[2M + 2Ag + NO_3]^+$; analogous species were not observed for the alkali-metal cations.

(b) *With divalent cations.* Somewhat more complex spectra resulted upon addition of divalent metal ions to solutions of **3b,** although with some common features. As a typical example, the positive-ion spectrum obtained for a mixture of **3b** and $Ba(NO_3)_2$ is shown in Fig. 3. Overall, very similar results were obtained when a mixture of the triphenylphosphite complex **3e** and $Ba(NO_3)_2$ was investigated, indicating that the triphenylphosphite ligands do not confer any special coordinating properties. The predominant species in the spectra are the dications $[M + Ba(MeCN)_x]^{2+}$ ($x = 0$–2), $[2M + Ba]^{2+}$ and $[3M + Ba]^{2+}$. The monocations $[M + BaNO_3]^+$ and $[2M + BaNO_3]^+$ can also be observed as weak ions, and residual $[M + H]^+$ is also observed. A number of solvated barium cations, including $[Ba(MeCN)_x]^{2+}$ ($x = 2$–6) and $[BaNO_3(MeCN)_y]^+$ ($y = 1$–3) were additionally observed. One possibility for the structure of the barium complex $[2M + Ba]^{2+}$ is given by **5b,** analogous to the possible structure proposed for the ammonium ion aggregate **5a**.

Two lead salts were investigated with complex **3b**; $Pb(NO_3)_2$ and $Pb(OAc)_2$. Only limited success was achieved with the nitrate, the major peaks in the spectrum being $[M - az]^+$ and $[M - az + MeCN]^+$. Presumably these arise due to degradation of the parent complex, possibly by protonolysis from HNO_3 in the metal salt. In this case, the ion $[M + PbNO_3]^+$ was only observed as a weak ion. For $Pb(OAc)_2$, however, similar species to those with Ba^{2+} were found, *viz.* $[2M + Pb]^{2+}$, $[3M + Pb]^{2+}$, $[M + Pb(OAc)]^+$ and $[2M + Pb(OAc)]^+$.

With **3b** and $Zn(OAc)_2$ or $Cu(NO_3)_2$ ($= AX_2$) similar features to those found for Ba^{2+} and Pb^{2+} were again observed, with $[M + AX]^+$ being the major ion observed, followed by $[2M + A]^{2+}$, $[M + A(MeCN)]^{2+}$ and $[M + A(MeCN)_2]^{2+}$, as indicated in Table 3. It is significant that the ions $[3M + Zn]^{2+}$ and $[3M + Cu]^{2+}$ were small for these metals. This appears to be consistent with coordination of the

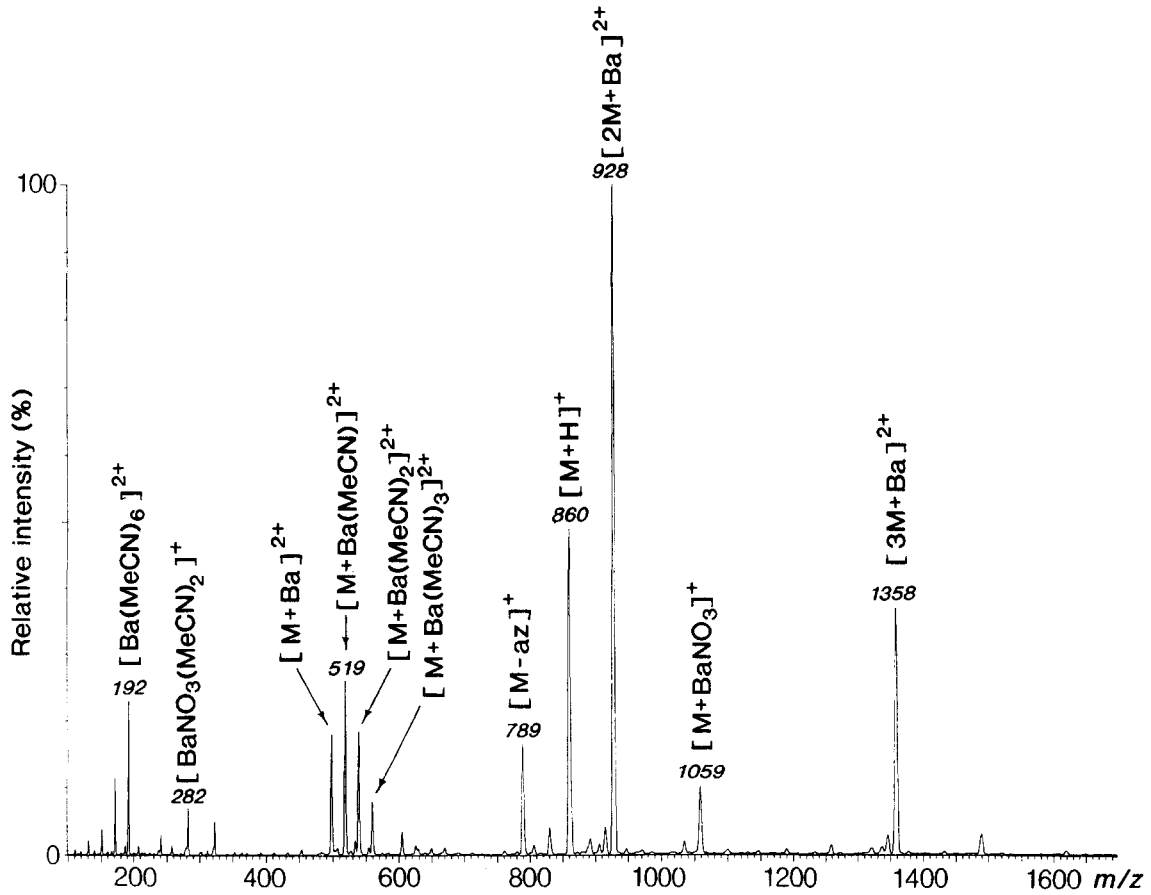

Fig. 3. Positive-ion electrospray spectrum of a mixture of complex **3b** and $Ba(NO_3)_2$ (cone voltage 20 V), showing the peak assignments.

azetidinone complexes to the added metal ions, since it would be anticipated that the larger Pb^{2+} and Ba^{2+} ions would adopt higher coordination numbers than Zn^{2+} or Cu^{2+}.

$BeSO_4$ showed markedly different behaviour, with no Be^{2+} adducts being detected. Instead, the spectrum yielded the $[M + H]^+$ species and the ion $[M - az + MeCN]^+$, presumably as a result of the expected hydrolysis of the aquated Be^{2+} ion generating H^+, with subsequent protonolysis of a platinum–amide bond. No further studies were carried out with this ion.

(*c*) *With a trivalent cation* Pr^{3+}. As a representative example of a trivalent cation salt, $Pr(NO_3)_3$ was studied with **3b**. A lanthanide ion was chosen, since these are less acidic than other tripositive cations such as Al^{3+} and Fe^{3+}. As anticipated, the spectra were rather more complex than those for divalent cations, and appeared to be much more variable. Some of the identifiable ions are listed in Table 3. The observed ions generally conform to the type predicted based on the divalent cation complexes, for example, $[2M + Pr(NO_3)_2]^{2+}$, $[M + Pr(NO_3)_2]^+$, $[M + PrNO_3]^{2+}$ and $[M + Pr(MeCN)_4]^{3+}$.

X-ray structure determination on the platinum complex **3b**

A single-crystal X-ray diffraction study has been carried out on the triphenylphosphine complex **3b**.

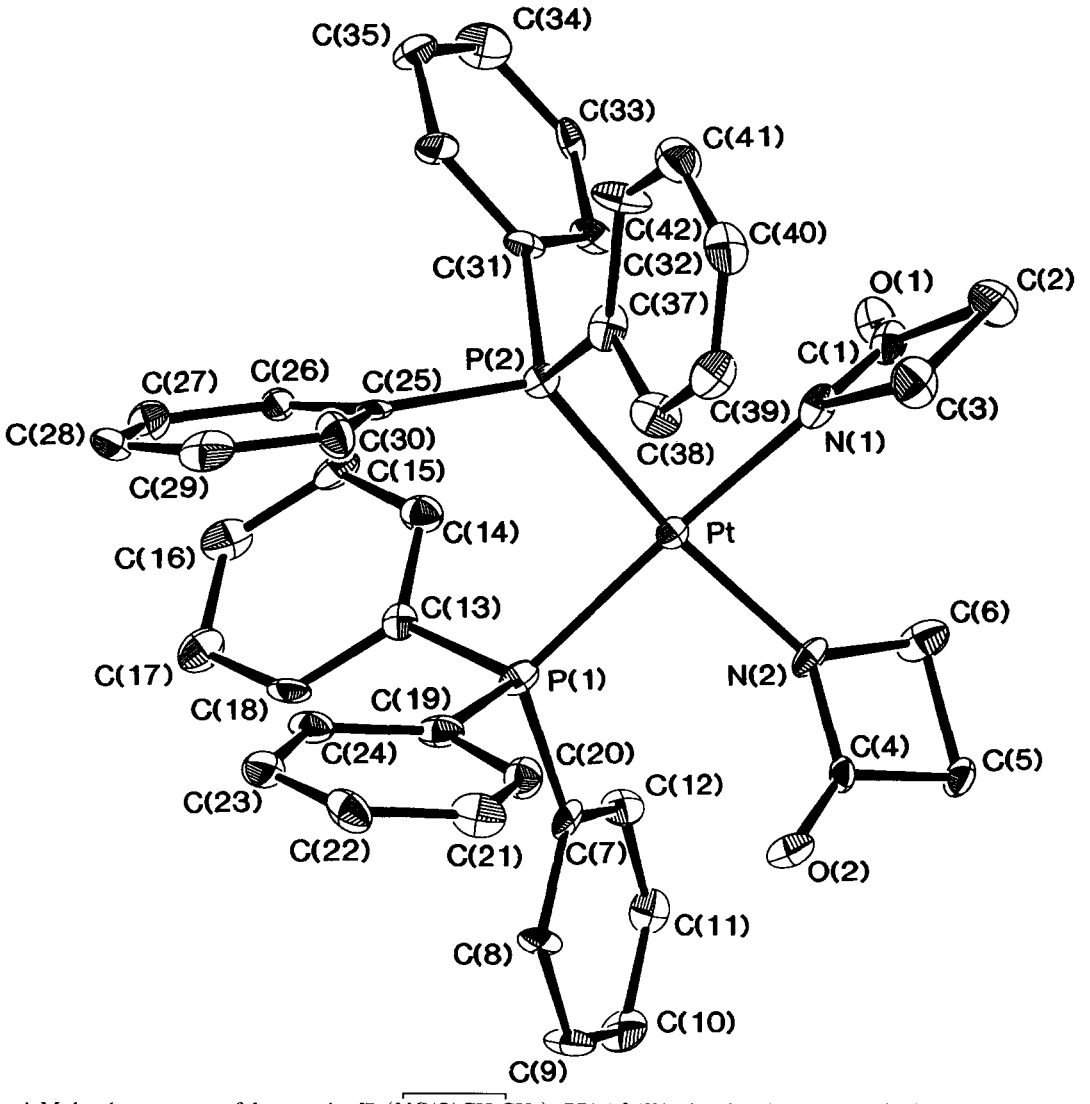

Fig. 4. Molecular structure of the complex $[Pt\{\overline{NC(O)CH_2CH_2}\}_2(PPh_3)_2]$ (**3b**), showing the atom numbering scheme. Thermal ellipsoids are shown at the 30% probability level. All hydrogen atoms and the dichloromethane molecule of crystallization have been omitted.

The molecular structure is shown in Fig. 4, together with the atom numbering scheme, while Table 4 gives bond distances and angles. The crystal of **3b** also contains one dichloromethane molecule per molecule of platinum complex. Elemental microanalytical data for this complex suggest that part of this solvent of crystallization is lost upon vacuum drying. Additionally, crystals of **3b** slowly turn opaque upon standing at room temperature in air.

The complex contains the expected approximately square-planar platinum atom, coordinated in *cis*-fashion to two triphenylphosphine ligands and two deprotonated 2-azetidinone ligands, bonded *via* the lactam nitrogens. The N(1)—Pt—N(2) bond angle [85.8(4)°] is slightly reduced from the idealized 90°, while the P(1)—Pt—P(2) angle is slightly larger [96.6(1)°], reflecting the steric bulk of the triphenylphosphine ligands. The platinum–amide bonds are equal in length [Pt—N(1) 2.05(1); Pt—N(2) 2.03(1) Å].

The planes of the two four-membered rings are twisted away from each other, resulting in one carbonyl group pointing above and the other below the platinum coordination plane. Thus, should both carbonyl ligands be involved in coordination to metal ions, rotation about the platinum–amide bonds is required. The carbonyl bonds [C(1)—O(1) 1.28(1); C(4)—O(2) 1.25(1) Å] are somewhat longer than in the parent 2-azetidinone, 1.226(1) Å [6(a)]. Additionally, the CH_2—N bond distances of **3b** [N(2)—C(6) and N(1)—C(3) both 1.52(2)Å] appear longer than in 2-azetidinone [1.467(2) Å], although the N—C(O) bond distances are comparable, within experimental error. An analogous distortion was not observed in an N-mercurated derivative of 2-azetidinone, which has been crystallographically characterized as a complex with erbium nitrate [3a].

In conclusion, a number of platinum and palladium complexes containing the deprotonated 2-azetidinone ligand have been prepared. Electrospray mass spectrometry indicates that these complexes interact with metal cations and we are currently investigating the chemistry of these complexes as metalloligands.

EXPERIMENTAL

^1H and ^{13}C ^1H NMR spectra were recorded in $CDCl_3$ solution on a Bruker AC300P spectrometer at 300.13 and 75.47 MHz, respectively, with $SiMe_4$ (δ 0.0) as reference. ^{31}P ^1H NMR spectra were recorded in $CDCl_3$ solution on a JEOL JNM FX-90Q spectrometer with 85% H_3PO_4 (δ 0.0) as external reference. IR spectra were recorded as KBr discs on a

BioRad FTS40 spectrometer and melting points were determined using a Reichert Hotstage apparatus, and are uncorrected.

Electrospray mass spectra were obtained in positive-ion mode using a VG Platform II mass spectrometer and a 1:1 v/v acetonitrile: water mobile phase. The compounds were dissolved in the mobile phase to give a solution typically of approximate concentration 0.1 mM and spectra were recorded on the freshly prepared solutions. The diluted solution was injected into the spectrometer *via* a Rheodyne injector fitted with a 0.1 cm^3 sample loop. A Thermo Separation Products SpectraSystem P1000 LC pump delivered the solution to the mass spectrometer source (60 °C) at a flow rate of 0.01 $cm^3\ min^{-1}$, and nitrogen was employed both as a drying and nebulizing gas. Cone voltages were typically varied from 5 to 80 V, in order to investigate the effect of higher voltages on fragmentation of parent ions. Confirmation of all species in this ESMS study is aided by comparison of the observed and predicted isotope distribution patterns. Theoretical isotope distribution patterns were calculated using the *Isotope* computer program [23].

The complexes described are all air-stable and reactions were carried out in reagent grade dichloromethane with no further purification or drying. Light petroleum refers to the fraction boiling in the range 40–60 °C. The compounds $[PtCl_2(COD)]$ [24], $[PdCl_2(BIPY)]$ [25], $[PdCl_2(PHEN)]$ [26], $P(CH_2CH_2CN)_3$ [27] and 2,6-xylylisocyanide [28] were prepared *via* literature procedures. 2-Azetidinone (Aldrich), triphenylarsine (Fluka), triphenylphosphine (Pressure Chemical Co.), bis(1,2-diphenylphosphino)methane (Aldrich), silver(I) oxide (BDH), 2,2′-bipyridine (BDH), 1,10-phenanthroline (BDH) and triphenylphosphite (BDH) were used as received. Metal salts used in the electrospray study were of AR grade. The complex *cis*-$[PtCl_2(PPh_3)_2]$ was prepared *via* ligand displacement of COD from $[PtCl_2(COD)]$ using 2 mol equiv. of PPh_3 in dichloromethane solution.

Synthesis of $[Pt\{\overline{NC(O)CH_2CH_2}\}_2(COD)]$ (**3a**). A solution of $[PtCl_2(COD)]$ (200 mg, 0.535 mmol) and 2-azetidinone (77 mg, 1.083 mmol) in dichloromethane (20 cm^3) with silver(I) oxide (700 mg, excess) was refluxed for 4 h. Filtration to remove the insoluble silver salts afforded a colourless solution which was reduced in volume to *ca* 5 cm^3. Addition of light petroleum (*ca* 60 cm^3) gave a white microcrystalline solid which was filtered off, washed with a small quantity of light petroleum and dried *in vacuo* to give complex **3a** (220 mg, 93%). NMR: $^{13}C\ ^1H$, δ(C) 174.1 (s, CO), 97.5 [s, PtCH, ^1J(Pt,C)-121.1 Hz], 41.1 [s, CH_2CO, ^3J(Pt,C)-17.4 Hz], 38.5 [s, CH_2N, ^1J(Pt,C)-42.7 Hz] and 30.3 (s, CH_2, COD); ^1H, δ(H) 5.90 [s, 4 H, COD CH, ^2J(Pt,H)-55.5 Hz], 3.16 [t, 4 H, CH_2CO, ^3J(H,H)-4.1 Hz], 3.10 [t, 4 H, CH_2N, ^3J(H,H)-4.1 Hz], 2.6–2.2 (m, 8 H, COD CH_2).

Synthesis of cis-$[Pt\{\overline{NC(O)CH_2CH_2}\}_2(PPh_3)_2]$. (**3b**). A solution of *cis*-$[PtCl_2(PPh_3)_2]$ (400 mg, 0.506 mmol) and 2-azetidinone (37 mg, 0.521 mmol) in dichloromethane (25 cm^3) with silver(I) oxide (800 mg, excess) was refluxed for 8 h. Filtration to remove the silver salts afforded a pale brown solution, which was reduced in volume to *ca* 20 cm^3. Addition of light petroleum (*ca* 60 cm^3) gave pale pink prisms of **3b**, which were dried *in vacuo*. Yield (310 mg, 71%). Several recrystallizations from dichloromethane-light petroleum gave colourless microcrystals. NMR: $^{13}C\ ^1H$, δ 174.6 (s, CO), 134.6–127.8 (m, Ph), 53.5 (s, CH_2Cl_2), 40.2 [s, CH_2CO, ^3J(Pt,C) not resolved], and 37.8 [*pseudo*-t, CH_2N, $|^3J(P,C)_{trans} + {}^3J(P,C)_{cis}|$-4.4; ^2J(Pt,C)-*ca* 74 Hz]; ^1H, δ 7.54–7.15 (m, 30 H, Ph), 5.26 (s, 1 H, CH_2Cl_2), 2.40 [t, 2 H, CH_2CO, ^3J(H,H)-7.3 Hz] and 2.32 (s, br, CH_2N). Relative assignment of the CH_2 resonances was confirmed by means of a ^{13}C–^1H correlation spectrum. $^{31}P\ ^1H$, δ(P) 9.0 [s, ^1J(Pt,P)-3054 Hz].

Synthesis of $[Pd\{\overline{NC(O)CH_2CH_2}\}_2(BIPY)]$ (**4a**). A suspension of $[PdCl_2(BIPY)]$ (100 mg, 0.300 mmol) and 2-azetidinone (44 mg, 0.619 mmol) in dichloromethane (30 cm^3) with silver(I) oxide (0.6 g, excess) was refluxed for 4 h. Filtration to remove the silver salts afforded a yellow solution. The silver salts were extracted with an additional 30 cm^3 of dichloromethane and the solutions combined. Reduction in the volume of the solution to *ca* 40 cm^3, followed by addition of diethyl ether (*ca* 100 cm^3) gave pale lemon-yellow microcrystals of **4a**, which were filtered off and dried *in vacuo*. Yield 52 mg, 43%. NMR: ^1H, δ(H) 8.53 [d, 2 H, BIPY, J(H,H)-4.5 Hz], 8.37 [d, 2 H, BIPY, J(H,H)-8.0 Hz], 8.08 [dt, 2 H, BIPY, J(H,H)-7.9, 1.2 Hz], 7.35 [t, br, 2 H, BIPY, J(H,H)-6.2 Hz], 3.09 [m, second-order, 8 H, CH_2] and 2.1 (s, br, 4 H, H_2O).

Synthesis of $[Pd\{\overline{NC(O)CH_2CH_2}\}_2(PHEN)]$ (**4a**). A suspension of $[PdCl_2(PHEN)]$ (150 mg, 0.420 mmol) and 2-azetidinone (59.6 mg, 0.838 mmol) in dichloromethane (30 cm^3) with silver(I) oxide (0.6 g, excess) was refluxed for 3 h. The silver salts were removed by filtration and the volume of the filtrate reduced to *ca* 25 cm^3, whereupon crystallization commenced. Diethyl ether (50 cm^3) was added and the pale lemon–yellow microcrystals filtered off, washed with ether (10 cm^3) and dried *in vacuo*. Yield 135 mg (70%). NMR: ^1H, δ(H) 9.02 [d, 2 H, PHEN, J(H,H)-5.1 Hz], 8.52 [d, 2 H, PHEN, J(H,H)-8.2 Hz], 7.98 [d, 2 H, PHEN, J(H,H)-0.5 Hz], 7.76 [dd, 2 H, PHEN, J(H,H)-5.2, 5.6 Hz], 3.17 (s, 8 H, CH_2); $^{13}C\ ^1H$, δ(C) 177.6 (s, CO), 152.7, 146.2, 138.4, 129.7, 127.1, 125.4 (s, phen), 40.9 (s, CH_2CO), 39.0 (s, CH_2N).

Ligand substitution reactions with **3a**—*general method*

To a solution of complex **3a** in dichloromethane (1 cm^3) was added an excess of the ligand (as indicated), followed by light petroleum (5 cm^3) and the product allowed to crystallize. The solid was filtered off and

washed with two 5 cm^3 portions of light petroleum and dried *in vacuo*.

With tris(2-cyanoethyl)phosphine. Complex **3a** (60.0 mg, 0.135 mmol) and $P(CH_2CH_2CN)_3$ (54.0 mg, 0.280 mmol) gave a white powder of **3c** (98 mg, 100%). The product is sparingly soluble in all common organic solvents.

With DPPM. Complex **3a** (41.5 mg, 0.094 mmol) and DPPM (38 mg, 0.099 mmol) gave pale yellow needles of **3d** (36.0 mg, 54%). NMR: ^1H, δ(H) 7.77–7.37 (m, 20 H, Ph), 4.31 [t, 2 H, CH_2, DPPM, ^2J(P,H)-9.9, ^3J(Pt,H)-45.9 Hz], 3.21 [t, 4 H, CH_2CO, ^3J(H,H)-4.0 Hz] and 2.91 [t, br, 4 H, CH_2N, ^3J(H,H)-3.9 Hz]; ^{13}C ^1H, δ(C) 174.8 (s, CO), 133.2–128.5 (m, Ph), 53.5 [t, CH_2, DPPM, J(P,C)-31.5 Hz, J(Pt,C) not discernible], 41.8 (s, CH_2CO) and 37.1 [*pseudo*-t, $|^3J(P,C)_{trans} + {}^3J(P,C)_{cis}|$-4.8, ^2J(Pt,C)-52.2 Hz]; ^{31}P ^1H δ(P)-58.8 [s, ^1J(Pt,P)-2678 Hz].

With P(OPh)$_3$. Complex **3a** (42 mg, 0.095 mmol) and $P(OPh)_3$ (4 drops, excess) gave white crystals of **3e** (85 mg, 94%). NMR: ^{13}C ^1H, δ(C), 174.3 (s, CO), 151.0, 129.8, 125.3, 120.6 (s, Ph), 40.1 [s, br, CH_2CO, J(Pt,C) not discernible], 37.5 [*pseudo*-t, $|J(P,C)_{trans} + J(P,C)_{cis}|$-14.6 Hz, J(Pt,C) not discernible]. ^1H, δ(H) 7.33–7.17 (m, 30 H, Ph), 2.42 (s, br, 4 H, CH_2N), 2.10 [t, br, 4 H, CH_2CO, ^3J(H,H)-7.8 Hz]. ^{31}P ^1H, δ(P) 76.5 [s, ^1J(Pt, P)-4761 Hz].

With 2,6-xylyl isocyanide (XyNC). Complex **3a** (39 mg, 0.088 mmol) with XyNC (36 mg, 0.27 mmol) gave colourless crystals of **3f** (42.8 mg, 81%). NMR: ^{13}C ^1H, δ(C) 175.2 (s, CO), 135.9, 130.0, 128.2, 126.2 (s, Xy), 40.9 [s, CH_2CO, J(Pt,C)-21.4 Hz], 37.5 [s, CH_2N, J(Pt,C)-65.8 Hz] and 18.6 (s, Me). ^1H, δ(H) 7.26–7.08 (m, 3 H, Xy), 3.24 [t, 4 H, CH_2CO, ^3J(H,H) 4.1] 3.03 [t, 4 H, CH_2N, ^3J(H,H) 4.1, J(Pt, H)-*ca* 14 Hz].

With tert-butyl isocyanide. In a similar fashion to the synthesis of **3f,** reaction of **3a** (46 mg) with excess Bu^tNC gave 21 mg of **3g**. NMR: ^{13}C ^1H, δ(C) 175.2 (s, CO), 97.5 (m, CPt), 40.8 [s, CH_2CO, J(Pt, C)-20.2 Hz], 37.4 [s, CH_2N, J(Pt, C)-63.4 Hz] and 29.9 [s, Bu^t, J(Pt, C)-*ca* 5 Hz]. ^1H, δ(H) 3.14 [t, 4 H, CH_2CO, ^3J(H,H)-4.1 Hz], 2.97 [t, 4 H, CH_2N, ^3J(H,H)-4.1 Hz], 1.54 (s, 18 H, Bu^t).

With triphenylarsine. No reaction was observed at room temperature and the COD complex was recovered unreacted, as evidenced by ^1H NMR.

X-ray structure determination of **3b**

Prismatic pale pink crystals were obtained by slow recrystallization from dichloromethane–light petroleum. All X-ray measurements were carried out on a Rigaku AFC6S diffractometer using Mo-K_α radiation (λ = 0.71069 Å). Calculations were performed on a VAXstation 3500 computer by using the TEXSAN 5.0 software [29] and in the later stages on a Silicon Graphics Personal Iris 4D35 computer with the teXsan 1.7 package [30].

Relevant crystallographic data are listed in Table 5. Unit-cell dimensions were determined by applying the setting angles of 25 high-angle reflections. Three standard reflections were monitored during the data collection and showed no significant variance. The intensities were corrected for absorption by applying ψ scans of several reflections with the transmission factors ranging from 0.73–1.00.

Table 5. Summary of crystal data and intensity collection for $[Pt\{\overline{NC(O)CH_2CH_2}\}_2(PPh_3)_2]$ (**3b**) · CH_2Cl_2

Empirical formula	$C_{43}H_{40}Cl_2N_2O_2P_2Pt$
Formula weight	944.74
Crystal dimensions (mm)	0.26 × 0.22 × 0.32
Crystal system	Monoclinic
Lattice parameters	a = 19.321(2) Å
	b = 9.764(2) Å
	c = 21.746(4) Å
	β = 108.64(1)°
	V = 3887(2) Å^3
Space group	$P2_{1/n}$ (no. 14)
Z	4
D_{calc} (g cm^{-3})	1.61
Radiation	Mo-K_α (λ = 0.71069 Å)
μ(Mo-K_α) (cm^{-1})	39.04
Absorption corrections	ψ scans (transmission factors: 0.73–1.00)
Temperature (°C)	−120
$2\theta_{max}$ (°)	46
No. of reflections measured	Total: 5975
	Unique: 5780 (R_{int} = 0.027)
No. of reflections [$I > 3\sigma(I)$]	3472
No. of variables	469
Residuals R, R_w	0.044, 0.058
Goodness of fit	1.63
Maximum peak in final difference map (e Å^{-3})	1.0

The structure was solved by direct methods in SIR88 [31]. Full-matrix least-squares refinement with anisotropic displacement parameters for all non-hydrogen atoms yielded the final R of 0.044 ($R_w = 0.058$). All hydrogen atoms were found in difference-Fourier maps and included in calculations without further refinement. The final difference map was essentially featureless with the highest peak of 1.0 e $Å^{-3}$ close to the Pt atom. The results of the refinement are presented in Table 5.

Further details of the structure investigation, together with lists of final atomic coordinates, thermal parameters, and complete bond distances and angles, and structure factors may be obtained from the Cambridge Crystallographic Data Centre, or from the authors on request.

Polymeric metal complexes of the "extended reach" ligand N_1,N_1'-*p*-phenylenedimethylene-bis(pyrazole)

Juxiang Chen, David M. L. Goodgame,* Stephan Menzer and David J. Williams

Chemistry Department, Imperial College of Science, Technology and Medicine, London SW7 2AY, U.K.

(Received 29 August 1996; accepted 20 September 1996)

Abstract—The preparation is reported of the "extended reach" ligand N_1,N_1'-*p*-phenylenedimethylene-bis(pyrazole) (*p*-XBPZ) and a range of its complexes with Mn^{II}, Co^{II}, Ni^{II}, Cu^{II}, Zn^{II} and Cd^{II}, for which pertinent spectroscopic data are also given. The compounds $Co(p\text{-XBPZ})(NO_3)_2$ (**1**) and $Cd_2(p\text{-XBPZ})_3(NCS)_4$ (**2**) have been studied by X-ray crystallography. Compound **1** has a chain structure in which octahedrally coordinated cobalt centres are linked by *p*-XBPZ ligands, with the nitrate groups being bonded in asymmetric bidentate fashion. In compound **2**, pairs of Cd atoms are linked by both NCS and *p*-XBPZ bridges so as to form ladder-like tapes which, in turn, are cross-linked by further *p*-XBPZ ligands resulting in a complex sheet polymeric structure comprising an array of 8-, 30- and 44-membered rings. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: X-ray structures; polymeric complexes; bis(pyrazole) ligand; cadmium thiocyanate.

There is currently appreciable interest in metal complexes which form extended networks, because of the prospects they offer for the development of new materials with useful chemical or physical properties. A variety of synthetic approaches has been employed, exploiting changes in, *inter alia*: (a) the nature of the donor atoms or groups bonded to the metal ions; (b) the length, flexibility, and conformational preferences of the 'spacer' bridges connecting the donor groups; (c) the coordination geometry at the metal centres or, in some cases, combinations of metal centres [1].

Extended reach ligands with pyridine rings as the donor groups have been shown to be particularly useful for forming networks [1a,b,2], catenanes [3], macrocyclic squares [4] and macrobicyclic cages [5]. In contrast, although there is a well-established coordination chemistry of simple pyrazoles, and of chelating pyrazolylborates and bispyrazoles, less attention appears to have been paid to the network-forming capabilities of ligands containing pyrazole donor groups, linked through their nitrogen atoms by spacer units designed to achieve more extended arrays. The ligand N_1,N_1'-ethylenebis(3,5-dimethylpyrazole) has been shown to bridge three $PdCl_2$ units to form a 21-membered trimetallic macrocycle.[6] We report here some complexes with the ligand N_1,N_1'-*p*-phenylenedimethylenebis(pyrazole) (**I**, *p*-XBPZ). The results of full X-ray characterization of two of them—$Co(p\text{-XBPZ})(NO_3)_2$ (**1**) and $Cd_2(p\text{-XBPZ})_3(NCS)_4$ (**2**)—demonstrate that extended chains or sheets of metallocyclic rings can be obtained with pyrazole ligands of this type.

EXPERIMENTAL

Preparation of compounds

N_1,N_1'-p-*phenylenedimethylenebis(pyrazole)*. This was prepared by the method previously used for N,N'-*p*-phenylenedimethylenebis(pyridin-4-one) [1g] with pyrazole in place of pyridin-4-one. The product was recrystallized from methanol from which it formed a hemi-methanol solvate (38% yield, mp = 103–105°C). Found: C, 68.7; H, 5.9; N, 22.7. Calc. for $C_{14}H_{14}N_4 \cdot 0.5MeOH$: C, 68.7; H, 6.0; N, 22.1%. MS 238 (M+). (The constitution of the ligand is also confirmed by the structures of complexes **1** and **2**.)

Metal complexes of p-XBPZ

In most cases, the complexes were obtained by mixing solutions of the appropriate, hydrated metal halide or nitrate salt (AR or reagent grade) and *p*-XBPZ in 1:2 mole ratio (*ca* 0.08 mmol in metal salt) in hot ethanol. A 1:1 mol ratio of *p*-XBPZ and metal salt was used in the preparation of $Co(p\text{-XBPZ})(NCS)_2$ and a 3:1 ratio was employed for $Co(p\text{-XBPZ})X_2$ (X = Cl, Br, I, NO_3), $Ni_2(p\text{-XBPZ})_3(NO_3)_4$ and $Ni(p\text{-XBPZ})Br_2$, with a mixed ethanol/2,2-dimethoxypropane solvent system being used for the nickel bromide complex. Solutions of the metal thiocyanates were prepared metathetically from the stoichiometric amounts of the appropriate metal nitrate and sodium thiocyanate in ethanol followed by removal of the sodium nitrate. The solid complexes which separated on slow concentration of the solutions at room temperature were collected, washed with a small amount of the solvent used for the reaction and air-dried.

Analytical data (Microanalytical Laboratory, Imperial College) are given in Table 1.

Crystallography

Crystal data. For $Co(p\text{-XBPZ})(NO_3)_2$ (**1**): $C_{14}H_{14}CoN_6O_6$, $M = 421.2$, orthorhombic, space group *Pbca*, $a = 14.878(4)$, $b = 13.883(2)$, $c = 17.288(3)$ Å, $U = 3570.9(13)$ Å^3, $Z = 8$, $D_c = 1.567$ Mg m^{-3}, μ(Mo-K_α) = 1.006 mm^{-1}, $\lambda = 0.71073$ Å, $F(000) = 1720$. Violet block, crystal dimensions 0.20 × 0.34 × 0.40 mm.

For $Cd_2(p\text{-XBPZ})_3(NCS)_4$ (**2**): $C_{23}H_{21}CdN_8S_2$, $M = 586.0$, triclininic, space group $P\bar{1}$, $a = 9.1177(9)$, $b = 9.784(2)$, $c = 15.4728(14)$ Å, $\alpha = 90.038(10)$, $\beta = 105.549(7)$, $\gamma = 111.489(11)^\circ$, $U = 1229.8(3)$ Å^3, $Z = 2$, $D_c = 1.583$ Mg m^{-3}, μ(Mo-K_α) = 1.086 mm^{-1}, $\lambda = 0.71073$ Å, $F(000) = 590$. Colourless plate, crystal dimensions 0.10 × 0.33 × 0.40 mm.

Data collection and processing

Siemens P4/PC diffractometer, ω-scan method ($4.66 < 2\theta < 45^\circ$ for **1**, $4.5 < 2\theta < 50^\circ$ for **2**), graphite-monochromated Mo-K_α radiation, room temperature. For compounds **1** and **2** 2336 and 4339 independent reflections, respectively, were measured; 1710 [$|F_o| > 4\sigma(|F_o|)$] and 3928 [$|F_o| > 4\sigma(|F_o|)$] were considered observed and were corrected for Lorentz and polarization factors.

Structure analysis and refinement

Both structures were solved by the heavy-atom method. All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were idealized (C—H 0.96 Å), assigned isotropic thermal parameters, $U(H) = 1.2_{eq}(C)$, and allowed to ride on their parent carbon atoms. Refinements were by full-matrix least-

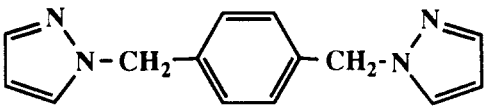
squares on F^2 to give: for **1**, $R_1 = 0.0433$, $wR_2 = 0.0950$; for **2**, $R_1 = 0.0337$, $wR_2 = 0.0858$. The maximum and mean shift/errors in the final refinement were 0.005 and 0.001, respectively, for **1** and 0.002 and 0.000 respectively, for **2**, and the maximum and minimum residual electron densities in the final ΔF map were 0.245 and -0.250 e Å^{-3}, respectively, for **1** and 0.871 and -0.959 e Å^{-3}, respectively, for **2**. Computations were performed using the SHELXTL-PC system version 5.03 [7]. Important bond lengths and angles for compound **1** are listed in Table 2 and those for compound **2** are given in Table 3.



Spectroscopy

Spectroscopic measurements were made as described previously[8].

RESULTS AND DISCUSSION

Our principal objective in the present work was the synthesis of crystalline complexes of **I** so that its capacity for forming extended arrays could be determined by single crystal X-ray diffraction methods. Ligand **I** readily gave a range of solid compounds with the halides, nitrates or thiocyanates of Mn^{II}, Co^{II}, Ni^{II}, Cu^{II}, Zn^{II} and Cd^{II} (Table 1). In most cases the products isolated had the stoichiometry ML_2X_2 even when the reactants employed were in a 2:1 or 3:1 L:M mole ratio, but a few compounds of the types $M_2L_3X_4$ or ML_2X_2 were also formed.

Despite the range of compounds prepared, it proved difficult to obtain crystals of the appropriate quality for single crystal X-ray study, but in two cases, $Co(p\text{-XBPZ})(NO_3)_2$ (**1**) and $Cd_2(p\text{-XBPZ})_3(NCS)_4$ (**2**), this was achieved and their structures are discussed below. Some further, more limited, information about the coordination geometry of the metal ions in the other complexes was obtained by spectroscopic methods

and this is summarised after the discussion of the X-ray results.

Structure of $Co(NO_3)_2$(p-XBPZ) (**1**)

The X-ray structure of $Co(NO_3)_2$(*p*-XBPZ) (**1**) confirms the 1 : 1 stoichiometry and reveals a *catena*-structure, wherein octahedrally coordinated cobalt centres are linked *via cis*-coordinated *p*-XBPZ ligands (Fig. 1). The nitrate groups are bonded in bidentate fashion but, consistent with their small 'bite' angle [58.4(1) and 58.7(1)° at N(22) and N(26), respectively], the geometry at Co is severely distorted. Whereas the Co—N distances to the two pyrazole groups are similar [2.044(4) and 2.067(4) Å to N(18) and N(1) respectively], subtending an angle of 94.4° at cobalt, there is a marked asymmetry in the Co—O bond lengths for each nitrate. The bonds *trans* to N(1) and N(18) are significantly longer, by *ca* 0.25 Å, than those *trans* to the oxygen atoms (Table 2).

Analysis of the *p*-XBPZ ligand conformation reveals a skewed relationship between the pyrazole and *p*-xylyl rings, with mean torsional twists about the N(5)—C(6) and C(6)—C(7) bonds of 22 and 51° and about C(10)—C(13) and C(13)—N(14) of 21 and 81°, respectively. Accompanying this geometry is a noticeable enlargement from tetrahedral of the angle at C(6) and C(13) to *ca* 114° in each case, indicating an element of strain in the polymer chain. This is further demonstrated by a bowing of the *p*-xylyl spacer, with the C(6)—C(7) and C(10)—C(13) bonds subtending an angle of *ca* 12°.

The polymer chain propagates *via* a *c*-glide to produce zigzag chains that extend in the *c*-direction (Fig. 2). Adjacent chains in the crystallographic *b*-direction pack in register with each other ("V in V") to form pseudo-sheets. Adjacent "sheets" are offset so as to produce an approximately antiphase relationship

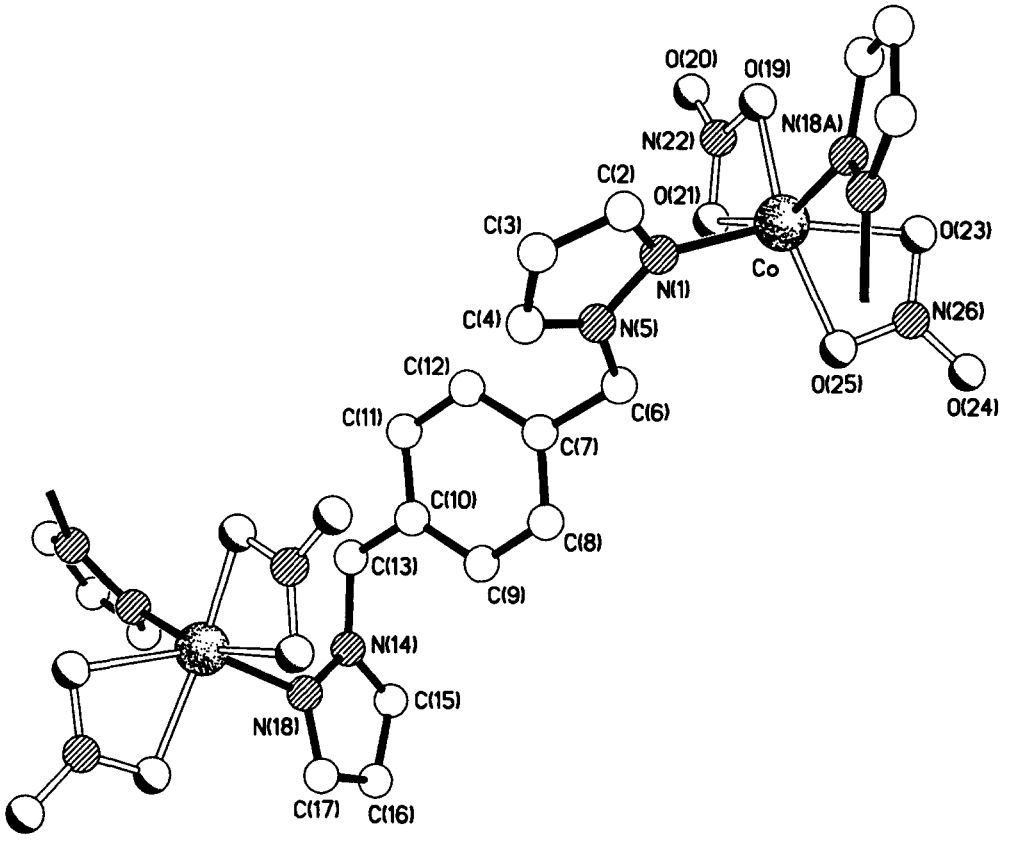

Fig. 1. The coordination geometry about Co in the structure of **1** showing also the form of the *p*-XBPZ ligand binding between adjacent Co centres.

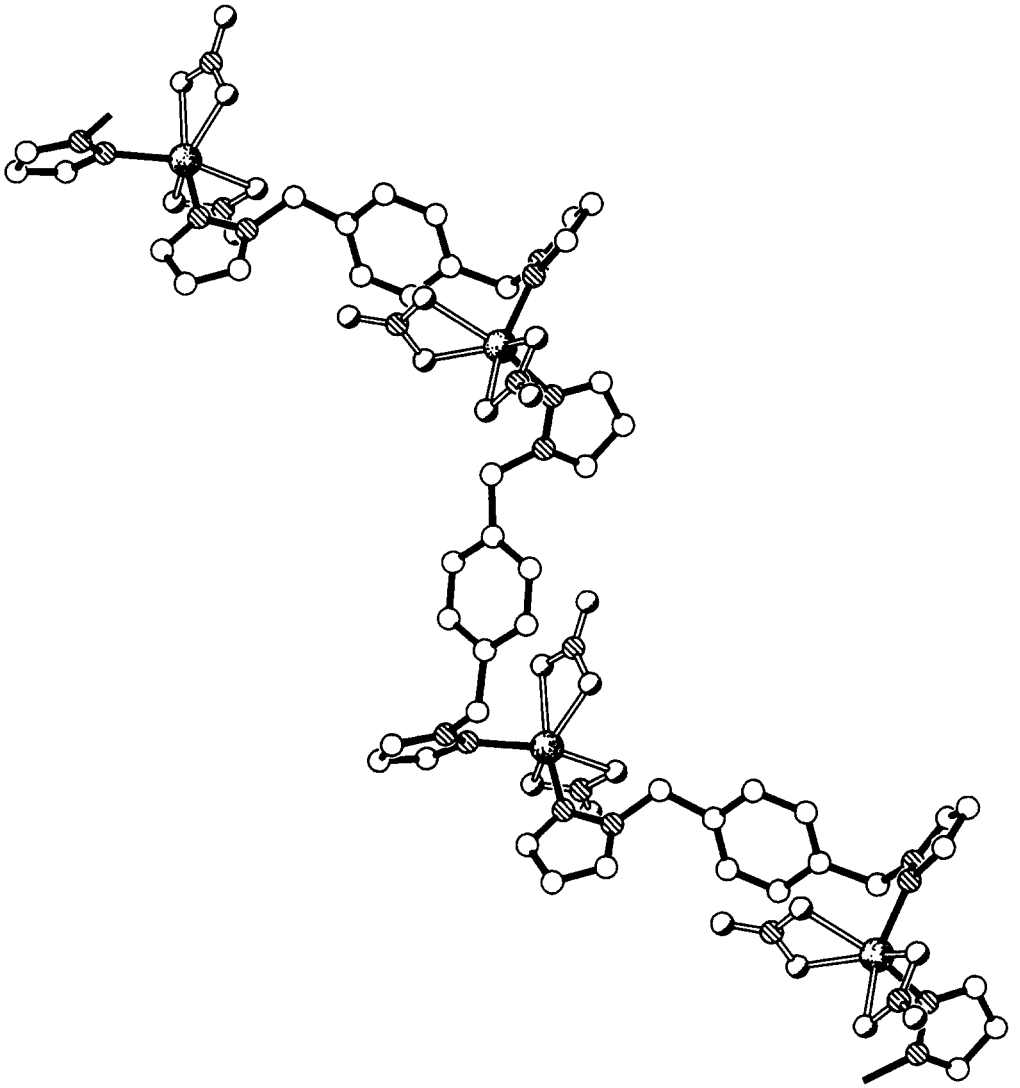

Fig. 2. Part of the polymer chain structure adopted by **1** in the solid state.

when viewed down the *a*-direction. There appear to be no important inter-chain interactions other than normal van der Waals.

Structure of $Cd_2(NCS)_4$(p-XBPZ)$_3$ (**2**)

The X-ray analysis of $Cd_2(NCS)_4$(*p*-XBPZ)$_3$ (**2**) (Fig. 3) shows the coordination environment about the cadmium atom to be essentially square pyramidal with the basal sites occupied by two *trans*-disposed independent isothiocyanate ligands and by two nitrogen atoms, one from each of two *p*-XBPZ ligands. The axial site is occupied by a nitrogen atom of a third *p*-XBPZ ligand. Approaching the "vacant" octahedral site at a noticeably longer distance (2.74 Å) is the S atom of a symmetry-related NCS group.

Within the basic square pyramid, the angles at Cd are in the ranges 81.2(1)–103.6(1) and 164.7(1)–174.9(1)° (Table 3). The Cd—N distances fall into three distinct groups: the longest are those to the *trans*-disposed pyrazole nitrogen atoms [2.453(3) and 2.497(3) Å], of intermediate length, 2.386(3) Å, is that to the axial pyrazole N atom, whilst the shortest distances are to the two *trans*-isothiocyanates.

With the exception of one of the NCS groups [that associated with N(31) and S(33)] the remaining ligands serve to link the Cd centres to create a polymeric array. One linkage in this process is the formation of two thiocyanate bridges between pairs of

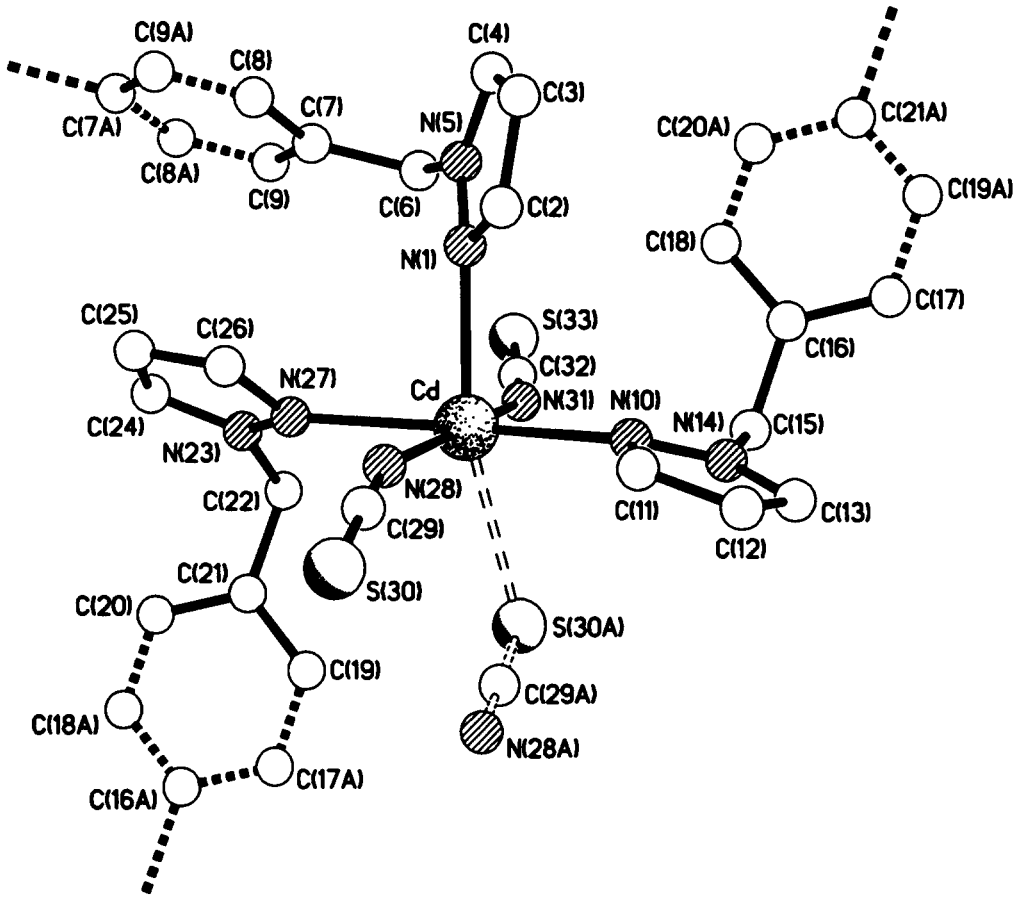

Fig. 3. The square-pyramidal coordination geometry at Cd in **2**, showing also the approach of a symmetry-related NCS ligand to the "vacant" coordination site.

C_i symmetrically related Cd atoms (Fig. 4). The associated non-bonded Cd···Cd separation is 5.81 Å.

Although the complex has a 2 : 3 Cd : *p*-XBPZ stoichiometry, there are only two crystallographically independent types of *p*-XBPZ ligand (A and B). Each of these plays a different role in generating the overall polymer structure. Pairs of A-type ligands bridge lattice-translated Cd centres to form extended ladder-like tapes as depicted in Fig. 4. Type B ligands then cross-link adjacent tapes to form the two-dimensional polymeric array illustrated in Fig. 5; this array extends in the 011 plane.

In forming this array the *p*-XBPZ ligand adopts two distinctly different comformations, both of which again differ from that observed in the structure of **1**. Within the ladder-like tapes the pyrazole and *p*-xylyl rings are in an "open-book" conformation with the

coordinated nitrogen atoms *anti*-disposed with respect to each other. The cross-linking ligands (type B) are C_i symmetric, with the pyrazole and *p*-xylyl rings being approximately orthogonal; the mean torsional twist about the N(5)—C(6) bond is *ca* 77°.

Spectroscopic studies

The electronic spectra of the deep blue compounds Co(*p*-XBPZ)X_2 (X = Cl, Br, I, NCS) in the solid state are characteristic [9] of a "tetrahedral" MN_2X_2 coordination geometry, showing (Table 4) three strong, overlapping bands in the range 6000–9000 cm^{-1} [transitions to components of $^4T_1(F)$] and a strong, multicomponent band in the visible region [transitions to components of $^4T_1(P)$]. The electronic spectrum of Ni(*p*-XBPZ)Br_2 (Table 4) also indicates a tetrahedral geometry.[9] For the compounds Co(*p*-XBPZ)Cl_2 and Zn(*p*-XBPZ)Cl_2 further evidence [10] for tetrahedral coordination geometry is afforded by their low frequency IR spectra, which have ν(M—Cl) bands at 330 and 305 cm^{-1} for M = Co and at 313 and 294 cm^{-1} for M = Zn. [Our instrumental low-frequency limit of 250 cm^{-1} precluded reliable assignment of the analogous ν(M—Br) and ν(M—I) bands in the other complexes of this type.] However, in the absence of full X-ray characterization, we cannot determine whether the *p*-XBPZ ligand connects these tetrahedrally coordinated metal centres into chains or individual rings, as we have made a number of examples of both of those structure types with "extended reach" O-donor [1f,11] or S-donor [12] ligands.

As expected from the results of the X-ray study, the electronic spectrum of Co(*p*-XBPZ)$(NO_3)_2$ (**1**) is typical of distorted octahedral coordination geometry about Co^{II}. A basically octahedral geometry is also clearly indicated by the electronic spectra of Ni(*p*-XBPZ)$_2(NCS)_2$ and Ni_2(*p*-XBPZ)$_3(NO_3)_4$ (Table 4). From its IR spectrum, the former of these two complexes contains N-bonded non-bridging thiocyanates [ν(CN) 2077 cm^{-1}] and it is likely that the *p*-XBPZ ligand serves to bridge *trans*-Ni(*p*-XBPZ)$_2(NCS)_2$ units into a sheet polymer.

The X-band EPR spectra of polycrystalline samples of Mn(*p*-XBPZ)$_2Cl_2\cdot H_2O$ and Mn(*p*-XBPZ)$_2Br_2$ show the presence of very pronounced zero-field splitting (Fig. 6). They are of the type found for simple Mn^{II} compounds containing tetragonally distorted octahedral MnN_4X_2 chromophores, where N represents a ligand such as 4-methylpyridine [13], so we conclude that they comprise arrays of *trans*-MnN_4X_2 (X = Cl or Br) units linked into sheets by the bridging capacity of the *p*-XBPZ ligand. Interestingly, the Mn···Mn distances in such arrays are sufficient to avoid any significant magnetic interaction between the Mn centres, which would lead to loss of the EPR spectral fine structure, as found for short bridges such as halide bridges.[14]

The X-band EPR spectra of polycrystalline samples of Cu(*p*-XBPZ)X_2 (X = Cl, NO_3) are of the axial type with $d_{x^2-y^2}$ ground state; the g values are g_{xy} = 2.057 and g_z = 2.271 for the chloride and g_{xy} = 2.059 and g_z = 2.304 for the nitrate. For both compounds the g_{xy} and g_z bands are very clearly resolved indicating that, as with the manganese(II) complexes referred to above, the bridging action of the *p*-XBPZ ligand separates the copper centres sufficiently to avoid any significant magnetic interaction between them. The EPR spectrum of a powdered sample of Cu(*p*-XBPZ)Br_2, however, simply gave a broad band centred on g_{eff} = 2.13 suggesting that bromide bridges are present in this case.

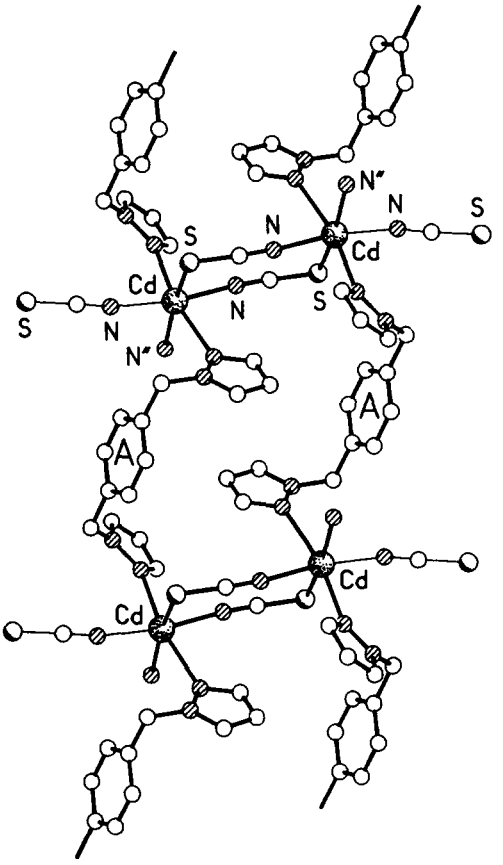

Fig. 4. Part of the ladder-like "tapes" of molecules in **2**, the "rungs" being formed by pairs of NCS bridges and the "uprights" by type A *p*-XBPZ ligands.

In summary, the results of this work show the ability of the *p*-XBPZ ligand to form both linear and sheet polymers. However, the X-ray studies additionally revealed an absence of a consistent conformational relationship between the pyrazole and *p*-xylyl rings and this renders it difficult reliably to predict the type of networks that may be constructed using this ligand as a bridging unit.

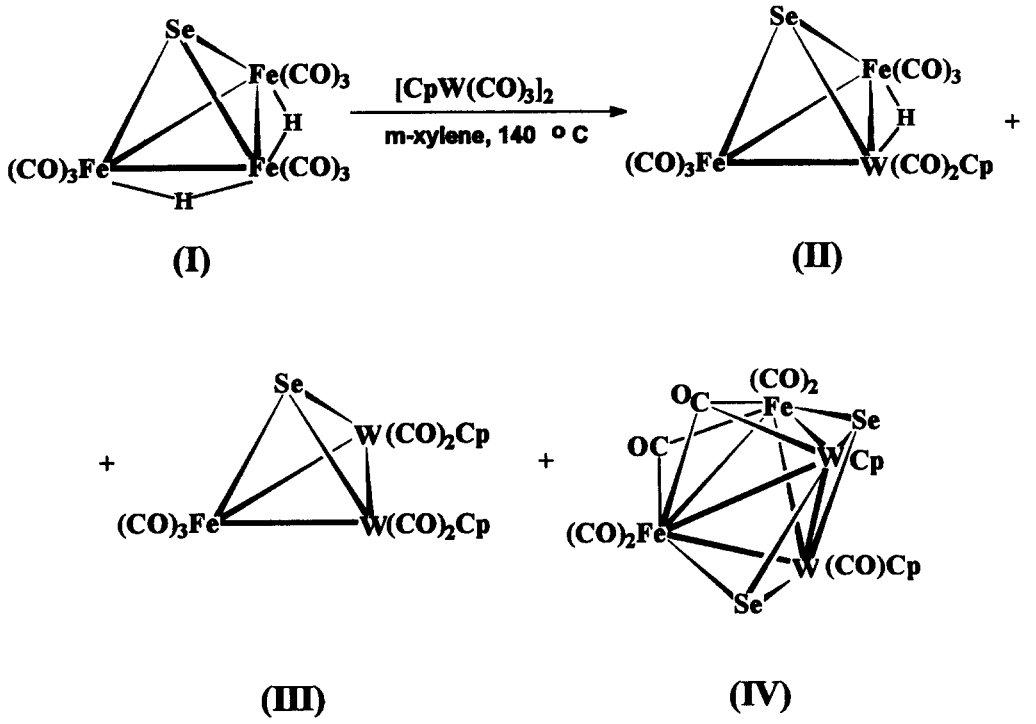
Institute of Inorganic Chemistry, Siberian Division of RAS, Acad. Lavrentyev str. 3, Novosibirsk 630090, Russia

(Received 20 August 1996; accepted 20 September 1996)

Abstract—The reaction of $[(\mu\text{-H})_2Fe_3(\mu_3\text{-Se})(CO)_9]$ with $[CpW(CO)_3]_2$ (Cp = η^5-C_5H_5) has been reinvestigated. In addition to tetrahedral heterometal clusters described previously the minor product $[Fe_2W_2(\mu_3\text{-Se})_2(\mu_3\text{-CO})(\mu\text{-CO})(CO)_5Cp_2]$ has been isolated. Its crystal and molecular structure has been determined by X-ray methods. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: iron; selenium; tungsten; heterometal clusters; synthesis; crystal and molecular structure.

The reactions of $(\mu\text{-H})_2Fe_3(\mu_3\text{-X})(CO)_9$ (X = Se, Te) with $[CpM(CO)_3]_2$ (M = Mo, W) have been determined previously to result in the heterometal cluster complexes $(\mu\text{-H})Fe_2M(\mu_3\text{-X})(CO)_8Cp$ and $FeM_2(\mu_3\text{-X})(CO)_7Cp_2$ (X = Se, Te) as the major products.[1–4] However, in addition to these there have been detected some minor products which have not been isolated yet. In this work one of the minor products has been obtained and its structure has been determined by X-ray analysis.



EXPERIMENTAL

The reaction of $(\mu\text{-H})_2Fe_3(\mu_3\text{-Se})(CO)_9$ (**I**) with $[CpW(CO)_3]_2$ was carried out as described previously [1]. After separation of the $(\mu\text{-H})Fe_2W(\mu_3\text{-Se})(CO)_8Cp$ (**II**) and $FeW_2(\mu_3\text{-Se})(CO)_7Cp_2$ (**III**) complexes the residue on the top of the chromatography column was eluted with benzene, resulting in an additional brown fraction which was collected and evaporated *in vacuo*. The solid thus obtained was extracted with toluene and an excess of pentane was layered on the solution. Two days later several crystals of $[Fe_2W_2(\mu_3\text{-Se})_2(\mu_3\text{-CO})(\mu\text{-CO})(CO)_5Cp_2]$ (**IV**) were isolated.

X-ray structure determination

The composition and the structure of **IV** were determined by X-ray analysis from an octahedrally shaped single crystal obtained by a slow diffusion of pentane to a toluene solution of the cluster. Crystallographic data: $C_{17}H_{10}Fe_2O_7Se_2W_2$, Mol. wt 963.57, orthorhombic, $Pna2_1$, $a = 13.276(1)$, $b = 11.999(1)$, $c = 12.990(2)$ Å, $V = 2069.3(4)$ Å^3, CAD-4 diffractometer, λ(Mo-K_α), room temperature, $\theta/2\theta$ scans with $V_{2\theta} = 2.5$–$19.5°$ min^{-1} up to $2\theta_{max} = 50°$. A total of 1895 independent reflections (1802 without systematic absences) was measured. An absorption correction was applied by using the azimuthal scan curve around the (222) reflection. The structure was solved by direct methods (SHELXS-86 [5]) and refined by the full-matrix least-squares method on F^2 (SHELXL-93 [6]).

Scheme 1.

The hydrogen atoms were refined in the rigid-body approximation (C—H 0.96 Å). Final R values: $R(F) = 0.0259$, $wR(F^2) = 0.0584$ for 1629 $F_{hkl} > 4\sigma(F)$, $R(F) = 0.0310$, $wR(F^2) = 0.0594$ for all 1802 reflections used. Atomic coordinates and thermal parameters are deposited in the Cambridge Crystallographic Database.

RESULTS AND DISCUSSION

Synthesis

It was previously mentioned [2,3] that the reactions of $(\mu\text{-H})_2Fe_3(\mu_3\text{-X})(CO)_9$ with $[CpM(CO)_3]_2$ (X = Se, Te; M = Mo, W) can be described as a cooperative decomposition of the initial complexes following a spontaneous condensation of active intermediate products to more stable heterometal cluster compounds. The set of the products now determined for the reaction of **I** with $[CpW(CO)_3]_2$ (Scheme 1) allows one to propose possible ways of intermediate fragmentation of the initial complexes.

Probably, the intermediate thermal decomposition derivatives of **I** are the products of a stepwise mononuclear iron carbonyl group elimination, i.e. the unstable diiron selenide and/or monoiron selenide carbonyl complexes.

For $[CpW(CO)_3]_2$ one can propose two activated pathways: a dissociation of the dimer complexes to mononuclear derivatives and an elimination of two carbonyl groups resulting in a highly reactive $[CpW(CO)_2]_2$ complex containing a triple W≡W bond.

If this is really so, the cluster **II** can be considered as the product of the addition of the mononuclear tungsten intermediate complexes to the diiron selenide species. Compounds **III** and **IV** can be described as the products of a sequential addition of the monoiron selenide species [for example, $(CO)_3FeSe$] to a triple W≡W bond following an elimination of some CO ligands.

Crystal and molecular structure of **I**

The molecular structure is shown in Fig. 1. Selected bond distances are given in the Fig. 1 caption. Cluster **IV** is revealed to be isostructural with $[Fe_2Mo_2(\mu_3\text{-}Te)_2(\mu_3\text{-}CO)(\mu\text{-}CO)(CO)_5Cp]$ (**V**), taking into account the difference between $Pna2_1$ and $Pn2_1a$ cell settings [7–9]. A molecule of **IV** is also very similar to a molecule of **V**. It contains the Fe_2W_2 tetrahedron and two μ_3-Se atoms on the FeW_2 faces, the μ_3-carbonyl ligand on the Fe_2W face and the μ-carbonyl on the Fe—Fe edge (Fig. 1). In **IV** as well as in **V** the μ_3-CO ligand is coordinated non-symmetrically: Fe—C bonds are rather longer than the W—C (Mo—C) bond. The μ-CO ligand is coordinated symmetrically in both compounds. No short non-bonding contacts have been found in the molecular crystal packing of **IV**.

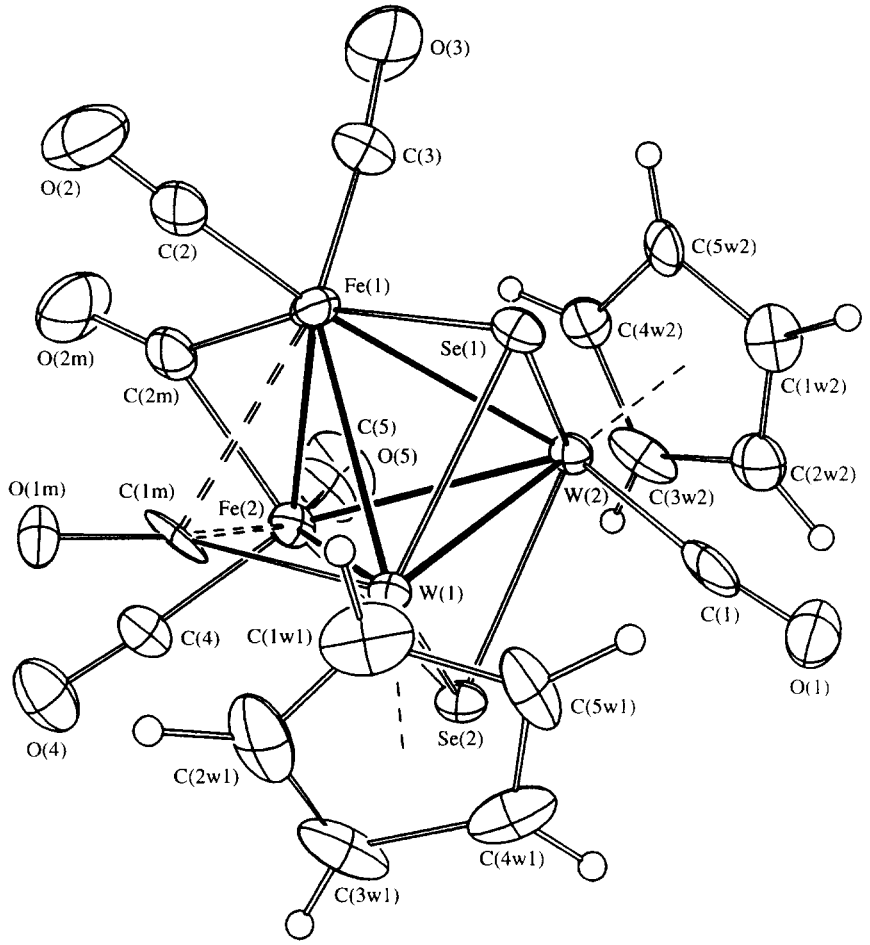

Fig. 1. The molecule of **IV** (40% probability ellipsoids). Cluster core is emphasized by solid lines. Long C(1m)—Fe(1) and C(1m)—Fe(2) bonds are shown by dashed lines. (Received 19 August 1996; accepted 20 September 1996)

Abstract—Two new copper(II) complexes with physiologically active ligands containing both pyridine ring and cyclic β-diketones with different ring members were obtained with the metal to ligand ratio 1 : 2. The structure and coordination mode of both complexes were studied using IR and EPR methods. The AM1 method was applied for calculating the structure of 5,7-dioxo-6-(2-pyridyl)-6,7-dihydro-5H-dibenzo (a,c)cycloheptene and its Zn^{II} complex. It is shown that the structure of both complexes is a tetragonal one and the coordination is realized *via* the hydroxy O and N of the pyridine ring. © 1997 Elsevier Science Ltd. Keywords: metal(II) complexes; cyclic-β-diketones; structure; AM1 calculations; EPR.

The physiological activity of many heterocyclic derivatives of 1,3-indandione (**I**), namely phthalones (**II**), is well documented and some of them (especially pyrophthalone **III**) are used as therapeutic agents.[1–3] They exhibit mainly anticoagulant [4–6] but also antiinflammatory and analgesic activity [7,8]. In addition they have proved to be excellent complexating agents [9–15].

I

In the present paper the results obtained on the Cu^{II} complexes with the related ligands containing six- and seven-membered rings, namely 2-(2-pyridyl)-2,3-dihydrophenalene-1,3-dione (**IV**, L_1) and 5,7-dioxo-6-(2-pyridyl)-6,7-dihydro-5H-dibenzo(a,c)cycloheptene (**V**, L_2) are reported, as it is shown that the physiological activity of the cyclic β-diketones depends strongly on the ring dimension. It is proved that five- and six-membered ring compounds **III** and **IV** are anticoagolants, while compound **V** on the contrary shows coagulant action [16].

procedure. For the purpose the anhydride (25 g, 0.126 mol) of naphthalic acid (finely ground), anhydrous $ZnCl_2$ (12 g, 0.088 mol), freshly finely ground, and 2-methylpyridine (14 g, 0.15 mmol) were mixed and refluxed (230°C) with stirring for 10 h. After cooling the reaction mixture was ground finely and mixed with 200 cm^3 1% HCl solution. After filtration the residue was washed repeatedly with water and heated again with 200 cm^3 25% HCl solution to boiling. The reaction mixture was filtered off and the extract dried with anhydrous Na_2SO_4, then evaporated to dry residue and recrystallized from dioxane. M.p. 273–274°C, yield 24%.

III

Synthesis of 5,7-*dioxo*-6-(2-*pyridyl*)-6,7-*dihydro*-5H-*dibenzo*(*a*,*c*)*cycloheptene* (**V**, L_2). The compound was obtained as described in the literature [18] by reflux at 240°C of α-picoline diphenic anhydride and anhydrous $ZnCl_2$ for 10 h. The dark green product was washed with dilute HCl solution and water and recrystallized from ethanol. M.p. 201–202°C, yield 30%.

Anal. data for $C_{20}H_{13}NO_2$ (mol.wt 299.31) Calc. (Found): C, 80.2 (79.9); H, 4.4 (4.5); N, 4.7 (4.2)%.

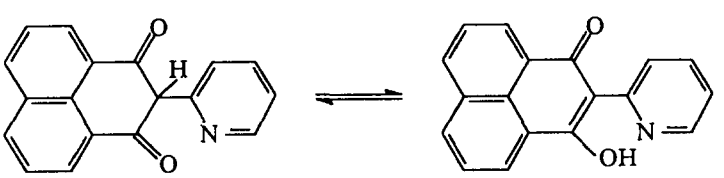
^{1}H NMR [$CDCl_3$, 360 K, δ (ppm), J (Hz)]: 18.53 (1H, OH); 8.24 (tt, 1H, J = 9.7, 1.4, 1.0, H-11); 8.09 (dd, 1H, J = 5, 0.5, H-14), 7.89 (d, 2H, J = 7.3, H-4,4′); 7.76 (dtd, 1H, J = 8, 1.8, 1.6, 1.7, H-13); 7.65 (d, 2H, J = 7.5, H-7,7′); 7.47 (5d, 4H, J = 8, 1.5, H-5,5′, 6,6′); 7.04 (dtd, 1H, J = 6.5, 1, H-12).

Synthesis of Cu^{II} *complexes.* Ethanolic solutions (1×10^{-3} M) of the ligands were mixed with a water solution of $Cu(NO_3)_2$ (5×10^{-3} M) in 1 : 2 metal-to-ligand ratio and then 0.1 M NaOH solution was added to the reaction mixture to give pH 5. Brown and green precipitates were formed with L_1 and L_2, respectively. After filtration the complexes were washed repeatedly with ethanol and dried over P_4O_{10} for a week.

Anal. data for $Cu(L_1)_2$ ($C_{36}H_{20}N_2O_4Cu$) (mol. wt 608.08): Calc. (Found): C, 71.1 (70.9); H, 3.3 (3.6); N, 4.6 (4.9); Cu, 10.4 (10.0)%.

Anal. data for $Cu(L_2)_2$ ($C_{40}H_{24}N_2O_4Cu$) (mol. wt 660.15): Calc. (Found): C, 72.8 (72.4); H, 3.7 (3.9); N, 4.2 (4.3); Cu, 9.6 (9.8)%.

Analytical procedures



Nitrogen was determined by the Kjeldahl method (treatment for 12 h). Copper was determined complexometrically at pH 8 (indicator murexide) after ashing the samples and dissolving the residue in 2 HNO_3 : 1 H_2O solution.

Physical measurements

The solid-state IR spectra were obtained using a "Specord 75 IR" (Carl-Zeiss, Jena; 4000–400 cm^{-1} range) and this of L_2 in $CHCl_3$ solution—on an FT-IR spectrometer "Bruker Vector 22". The NMR spectra were taken on a "Bruker DRX 250" FT-NMR spectrometer (TMS as internal reference) and the EPR spectra—on an X-band spectrometer "ERS-220" (Carl-Zeiss, Jena; g-marker DPPH).

Quantum-chemical calculations

The semiempirical AM1 method [19] was used during the study of the different tautomeric forms of 5,7-

IV (L_1)

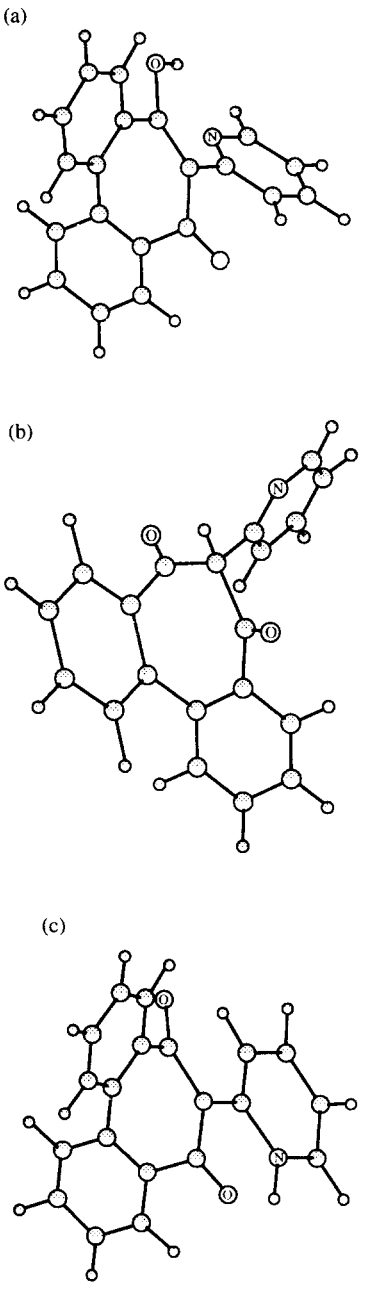


Fig. 1. AM1-calculated structures of the three tautomeric forms of 5,7-dioxo-6-(2-pyridyl)-6,7-dihydro-5H-dibenzo (a,c)cycloheptene (V, L_2): A (hydroxy), B (dioxo) and C (dioxo-imino).

dioxo-6-(2-pyridyl)-6,7-dihydro-5H-dibenzo(a,c) cycloheptene and its Zn^{II} complex. The AM1 parameters of the zinc atom reported by Dewar and Merz [20] were used. AM1 calculations were performed using the program GAMESS [21]. The geometry of the tautomers and the complex were completely optimized without any geometrical restrictions using algorithms [22,23] implemented in GAMESS for geometry searches. The gradient optimizations were terminated when the gradient length over all optimized

parameters was reduced to 1.0×10^{-4} Hartree Bohr^{-1}.

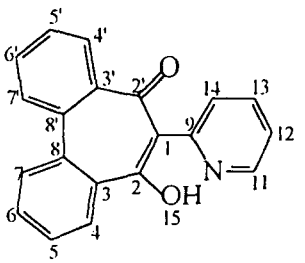
RESULTS AND DISCUSSION

Calculated structure of 5,7-dioxo-6-(2-pyridyl)-6,7-dihydro-5H-dibenzo(a,c)cycloheptene

The 2,3-dihydrophenalene-1,3-dione part of L_1 being a conjugated aromatic system is expected to be planar, while the structure of the seven-membered ring system 5,7-dioxo-6-(2-pyridyl)-6,7-dihydro-5H-dibenzo(a,c)cycloheptene should be nonplanar. For that reason AM1 calculations were performed in order to obtain structural information and to elucidate the most stable tautomer in solution. L_2 may exist in three tautomeric forms, A (hydroxy), B (dioxo) and C (oxo-imino), as shown in Fig. 1. It can be seen from results listed in Table 1 that AM1 calculations predict the "hydroxy" tautomer A as most stable. As it was expected strong deviations from planarity were observed for the seven-membered ring (Fig. 1). The torsional angle between both benzene rings in the biphenyl fragment of L_2 was calculated to be 42.2°. This result is very close to AM1 calculated (40.6°) [24] and experimental value determined in the vapor phase (44.4°) in biphenyl [25].

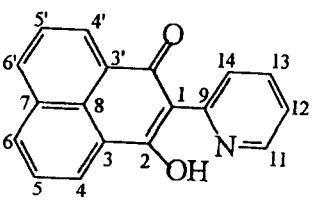
The comparison of the calculated and experimentally obtained ($CHCl_3$ solution) IR spectrum of L_2 (Table 2) proved the existence of L_2 in its "hydroxy" tautomeric form (A).

Structure of metal(II) complexes with L_1 and L_2



The analytical data obtained show the formation of Cu^{II} complexes with an M : L ratio of 1 : 2.

Structural information concerning the coordination mode and geometry of the complexes was obtained using IR and EPR spectroscopic data. In Table 2 selected IR data for both the free ligands and their Cu^{II} complexes are given.



The IR data for the $Cu(L_1)_2$ complex indicate coordination *via* the hydroxy group as the ν_{OH} is not observed in the complex spectrum. On the other side two $\nu_{C=O}$ bands were observed. One of them is with higher frequency similar to other Cu^{II} complexes with cyclic β-diketones,[11] thus indicating the presence of an uncoordinated C=O group. The second $\nu_{C=O}$ band with lower frequency is likely due to a C=O group engaged in hydrogen bonding.

It seems very likely that chelation with the hydroxy group and the pyridine nitrogen atom (**VI**) is realized.

The EPR data obtained are in agreement with this supposition. The powder sample of the complex shows a two-component anisotropic EPR spectrum both at low and ambient temperatures ($g_\parallel = 2.215$, $g_\perp = 2.067$). Such a spectrum with $g_\parallel > g_\perp$ is typical of a Cu^{II} complex with rhombic (or distorted tetrahedral) structure [26]. Additional information was obtained from the frozen HMPA solution spectrum of the complex. It also shows a two-component anisotropic spectrum with $g_\parallel = 2.291$ and $g_\perp = 2.072$. In this spectrum the parallel component exhibits a four-component hfs

[b]$CHCl_3$ solution.

due to $^{63,65}Cu$ ($I = 3/2$, $A_{2,3}^{Cu} = 146$ Oe), while the perpendicular component shows a partially resolved shfs of five lines ($A^N \sim 14$ Oe) due to two ^{15}N ($I = 1$), thus confirming the coordination of two pyridine N atoms to Cu^{II} (coordination number 4).

EPR studies on the $Cu(L_2)_2$ complex in a broad temperature range (−160–40°C) also provided structural information (Table 3).

The polycrystalline sample data show significant temperature dependence. At low temperatures (−160 to −40°C) an isotropic EPR spectrum was obtained, showing a realization of tetrahedral structure for this 1:2, M:L complex. At higher temperatures (above −40°C) a two-component anisotropic EPR signal was observed, indicating a strong deviation from the regular structure.

In order to check the supposition for N-coordination solution EPR spectra of the $Cu(L_2)_2$ complex were recorded and the data obtained are shown in Table 4. All solution spectra exhibit three-component anisotropic signals, the only exception being the signal in acetonitrile (An, two-component anisotropy).* The g_3 ($g_\parallel$) component shows four-component hfs due to $^{63,65}Cu$ ($I = 3/2$) and the g_3 ($g_\perp$)—a partially resolved shfs due to two N atoms ($I = 1$) from the pyridine rings, thus confirming the coordination of the N atoms to Cu^{II}. Also at ambient temperature the chloroform spectrum of $Cu(L_2)_2$ ($g_{iso} = 2.082$) shows both four-component hfs due to $^{63,65}Cu$ ($I = 3/2$) ($A_{iso}^{Cu} = 82$ Oe) and five-component shfs due to 2 N atoms ($A^N = 12$ Oe).

The IR data available (Table 2) are in agreement with this supposition. In the $Cu(L_2)_2$ spectrum no band due to ν_{OH} is observed, while this at 1620 nm is ascribed to $\nu_{C=O}$ engaged in hydrogen-bonding.

It is also evident that no significant solvent effect on the EPR parameters is observed (Table 4, with the exception of An), although the solvents used ($CHCl_3$, DMSO and HMPA) possess quite different donor ability [27]. These data rule out the possibility of solvent coordination at the 5th and 6th sites (along the z-axis), indicating a significant steric hindrance of the ligand. All these experimental data suggest the realization of a distorted tetrahedral structure.

Table 3. EPR data for the $Cu(L_2)_2$ complex (powder sample) at different temperatures

[a]Calculated according to the relation $g_{iso} = 2/3\, g_\perp + 1/3\, g_{II}$.

Since the AM1 method could not be used for calculating copper(II) complexes (no Cu parameters are available), the corresponding Zn^{II} complex was calculated although all attempts to synthesize the $Zn(L_2)_2$ complex failed. The structural data obtained are presented in Fig. 2 and Table 5. Not surprisingly, the calculated $Zn(L_2)_2$ structure proved to be tetrahedral, supporting the suggestion for a tetrahedral structure of the $Cu(L_2)_2$ complex. The dihedral angle O—Zn—O—C was calculated to be 113°. The bond lengths Zn—O and Zn—N were found to be 2.086 and 2.040 Å, respectively. Similar bond lengths (Zn—O 2.15 and Zn—N 2.03 Å) were determined for other Zn^{II} complexes with bidentate O, N-ligand using X-ray diffraction analysis [28], thus supporting the reliability of the structural data obtained using the AM1 method. It should be mentioned that a ligand-to-metal dative bond is formed as electron-density transfer from Zn to ligand was found.

Supplementary material. All structural data (bond lengths and angles) of both calculated structures are available on request.

*Evidently in this case the specific solvent effect is observed.

(Received 10 September 1996; accepted 18 September 1996)

Abstract—The coordination compounds $[Cu(acv)_2(H_2O)_3](NO_3)_2 \cdot H_2O$ (**I**) (acv = acyclovir) and $CuCl_2 \cdot acv$ (**II**) have been prepared. Different techniques (IR, electronic reflectance, ESR spectroscopy, thermal analysis, magnetic measurements) have been used to determine the properties of these compounds and also to elucidate the bonding in **II**. The molecular structure of **I** has been determined by X-ray crystallography and shows the coordination geometry at copper to be square pyramidal with two acv molecules bound through N-7 in *trans* basal positions, the other coordination sites being occupied by aqua ligands. The oxygen atom of the carbonyl group is not involved in intramolecular hydrogen bonding to the coordinated aqua ligands. There is a pattern of base-pair recognition between C_i symmetrically related molecules. A comparison of the properties of the new compounds (**I** and **II**) with previously isolated $[Cu(acv)_2(Cl)_2(H_2O)_2]$ (**III**) is also reported. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: 2′-deoxyguanosine analogue; acyclovir—antiherpes agent; copper(II) complexes; crystal structure; molecular recognition.

There is an increasing interest in the stereochemistry of nucleic acid component–metal ion interactions. The development of nucleoside analogues such as acv (Scheme 1) [1,2], which inhibits specific processes in herpes-infected cells, has encouraged the study of new compounds which may possess antiviral properties by affecting enzymes in infected cells. The majority of enzymes in infected and uninfected cells require metal ions for activity and this is one source of the potential antiviral properties in metal chelating agents [3].

The majority of our work is concerned with the copper(II) ion and we have already reported the crystal structure of **III** as well as that of Cu–acvmp (acvmp = acyclovir monophosphate) complex [4–6].

Scheme 1.

In the first of these compounds, $[Cu(acv)_2Cl_2(H_2O)_2]$, the copper(II) atom is bonded to two *trans* positioned acv ligands monodentately through N-7, the other two coordination sites being occupied by water molecules. Water molecules are hydrogen bonded to O-6. Two transversal bonds to Cl atoms are longer, thus forming distorted centrosymmetrical octahedral molecules [4,5]. In the other complex, $[Cu(acvmp)_2(H_2O)_2]\cdot H_2O$, the coordination geometry at copper is again slightly distorted octahedral [6]. The copper atom occupies an inversion centre and is coordinated to N-7 of the acvmp ligand, the oxygen of a water molecule and the oxygen of the phosphate group of an adjacent ligand molecule thus forming a polymeric structure.

Some platinum complexes with acv and its acetylated derivatives have also been reported [7,8].

Several copper(II) complexes of nucleotides, nucleosides and their analogues have also been examined by X-ray crystallography [9–17]. A variety of different coordination modes are found in these structures.

Here we report the crystal structure of the newly synthesized compound **I** which is distinctively different from **III**. The synthesis of **II** is reported and also a comparison of the physical and chemical properties of these compounds are given.

EXPERIMENTAL

Syntheses

Compound **I**. Copper(II) nitrate (0.215 g) was dissolved in distilled water and acv (0.100 g) was added slowly to the stirring solution. The green solution was kept at room temperature and after a few days green crystals were formed. The crystals were filtered off, washed and air dried.

Compound **II**. Copper(II) chloride dihydrate (0.152 g) was dissolved in absolute ethanol. After addition of acv (0.100 g) a green precipitate formed immediately. The precipitate was filtered, washed and air dried. The results were the same if methanol was used instead of ethanol.

Compound **III**. This was prepared as reported elsewhere [5].

Analyses and physical measurements

The analyses of carbon, hydrogen and nitrogen were carried out on a Perkin–Elmer 204C microanalyser.

Copper(II) ion was determined volumetrically using 0.010 M EDTA and Murexid indicator. Calculated (found) for **I**: C 27.1 (26.8); H 4.2 (4.3); N 23.7 (23.7); Cu 9.0 (9.3), and for **II**: C 26.7 (26.5); H 3.1 (3.2); N 19.5 (19.1); Cu 17.7 (17.3%). IR spectra were recorded in the solid state (KBr pellets), some samples were recorded on Nujol mulls between CsI windows on a Perkin–Elmer 1720X FT-IR spectrometer. Conditions: range 4000–220 cm^{-1}, resolution 2 cm^{-1}, number of scans 10. TG-DTG data were recorded in the temperature range from 25–500°C (300°C) in a stream of dry air on Mettler TA-3000 and TA-2000 thermobalances. Heating rate was 5°C/min. Reflectance spectra were recorded on a Beckman spectrophotometer D.K.2 in the range 300–2600 nm. Room temperature magnetic susceptibility measurements were carried out by a Sherwood Scientific balance, Cambridge Research Laboratory, England. *Q*-band ESR spectra were obtained with a Bruker ER 200D-SCR spectrometer and *X*-band ESR spectra with Varian E 12 spectrometer. All samples were measured as polycrystalline solids.

Crystallographic determination

A green crystal of dimensions $0.20\times0.30\times0.50$ mm^3 was used for the single-crystal determination. Data were collected on a Siemens P4/PC diffractometer with graphite-monochromated Mo-K_α radiation, using ω-scans ($3.0 < 2\theta < 50.0°$). 4815 independent reflections were measured, of which 4029 had $|F_o| > 3\sigma(|F_o|)$ and were considered to be observed. The data were corrected for Lorentz and polarization factors but not for absorption. The crystallographic parameters were as follows: $C_{16}H_{30}CuN_{12}O_{16}$, $M_r = 710.1$, triclinic, $a = 8.250(2)$, $b = 10.158(2)$, $c = 18.299(4)$ Å, $\alpha = 94.65(2)$, $\beta = 97.89(2)$, $\gamma = 113.95(2)°$, $V = 1372.1(4)$ Å^3, space group $P\bar{1}$, $Z = 2$, $D_c = 1.719$ g cm^{-3}, $\mu(Mo-K_\alpha) = 8.95$ cm^{-1}, $F(000) = 734$.

The structure was solved by direct methods and the non-hydrogen atoms were refined anisotropically. The positions of the hydroxy, amino and aqua hydrogen atoms were determined from a ΔF map and refined isotropically subject to N—H and O—H distance constraints. The positions of the remaining H atoms were idealized C—H = 0.96 Å, assigned isotropic thermal parameters $U(H) = 1.2\ U_{eq}(C)$ and allowed to ride on their parent carbon atoms. Refinement was by full-matrix least squares based on F to give $R = 0.0395$, $R_w = 0.073$ [$w^{-1} = \sigma^2(F) + 0.0004F^2$]. The mean and maximum shift/error ratios in the final refinement were 0.013 and 0.279, respectively, and the maximum and minimum residual electron densities in the final ΔF map were 0.47 and -0.37 e Å^{-3}, respectively.

Computations were carried out on a 386 PC using the SHELXTL PC program system [18]. Atomic coordinates, bond lengths and angles and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

Crystal structure of **I**

The copper(II) ions have a slightly distorted square-pyramidal coordination (*cf.* distorted octahedral in

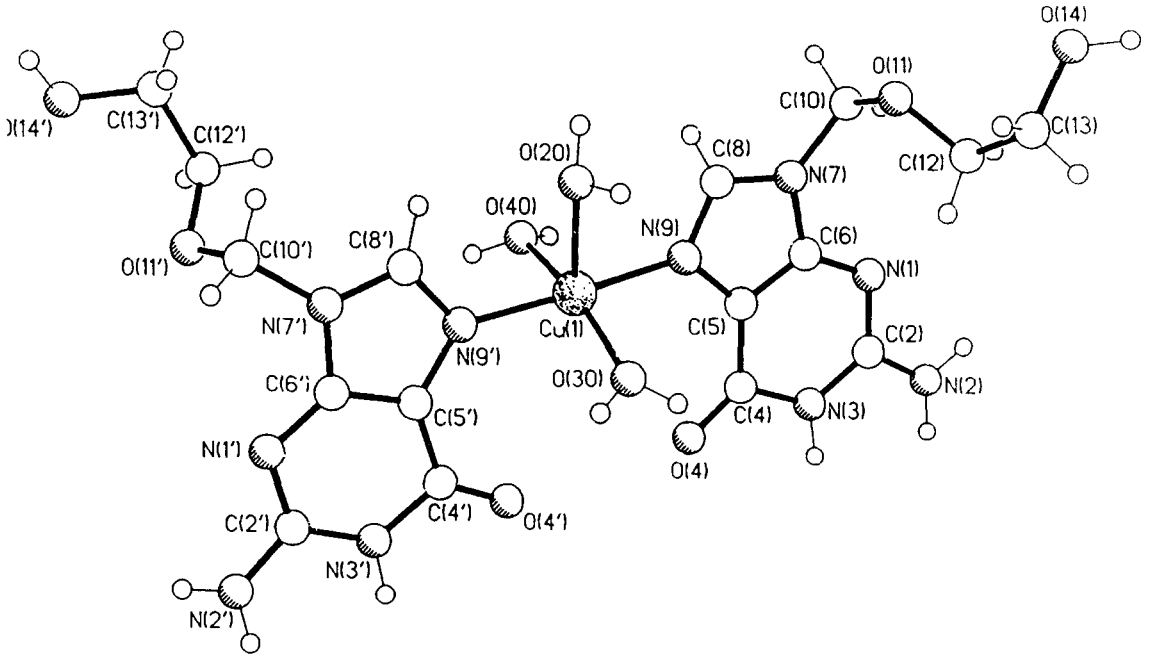

Fig. 1. View of compound **I** with atomic labelling. Note that crystallographic numbering is different from the conventional chemical numbering scheme.

III) (Fig. 1) with two acyclovir ligands bonded monodentately to copper(II) *via* N-7 in *trans* basal positions; Cu—N distances are 2.002(2) and 1.995(2) Å, respectively. The three other coordination sites are occupied by aqua ligands with Cu—O distances of 1.961(3) and 2.002(3) (basal) and 2.220(2) Å (axial). There is only a small departure from linearity for the N—Cu—N angle [177.7(1)°], the two *trans* aqua ligands representing the principal distortion from an ideal square-pyramidal geometry, the O(40)—Cu(1)—O(30) angle being 164.7(1)°. The Cu atom lies 0.12 Å above the mean plane of the four basal atoms in the direction of the axial aqua ligand. Table 1 gives selected bond lengths and bond angles of the compound.

The guanine rings are practically coplanar with a molecular torsion angle C(5)N(9)...N(9')C(5') of 0.3° and are in a *syn* conformation. They are both rotated by *ca* 70° out of the basal coordination plane thus precluding any intramolecular hydrogen bonding between the O(4) carbonyl groups and the coordinated aqua ligands. The closest approach of one of the aqua hydrogen atoms [on O(30)] to the carbonyl oxygen atoms [O(4)] is 2.67 Å. Both acyclic chains are folded with a *gauche* conformation.

The absence of any intramolecular hydrogen bonding is in striking contrast to the interactions observed in the majority of the related complexes [11–14,16].

Inspection of the packing of the molecules reveals a pattern of base-pair recognition with centrosymetrically related complexes hydrogen bonded *via* a series of donor–acceptor interactions (Fig. 2). These hydrogen-bonding interactions extend to include the acv hydroxyl groups to form tapes that propagate in the (101) direction in the crystals. Adjacent parallel and overlapping tapes are cross-linked by additional hydrogen bonds involving the aqua ligands, the included water molecules and the nitrate anions.

IR spectra

Previous work on similar compounds [5,19,20] permits us to assign some potentially informative bands. Thus, for free acv the reasonably pure C=O stretching vibration appeared at 1715 cm^{-1}, and the C—O of the acyclic chain at 1106 cm^{-1}, while the band at 1610 cm^{-1} is due essentially to the purine ring vibrations (Table 2). In compound **I** the shift of the C=O stretching vibration was very small and could be ascribed to hydrogen bonding of the carbonyl group. The very similar frequency found in compound **II** suggests a similar role of the carbonyl group in the structure.

In both compounds the shifts in the acyclic C—O and the purine ring vibrations are very small. Indeed, the order of the purine ring frequencies (acv > **I** > **II**) is the same as the order of the C=O frequencies, and may reflect changes in the coupling of these modes, as well as the direct effect of the coordination. The small changes in the C—O frequency are attributed to differences in conformation [21].

Thermal analysis

The thermal decomposition of compound **III** starts at approximately 100°C. The first stage of decompo-

sition indicates the loss of two molecules of water. Both estimated (5.55%) and calculated (5.80%) mass losses are in reasonable agreement. The dehydrated compound is stable in a short temperature interval (148–165°C) only and after that decomposes slowly. The dehydration of compound **I** is similar to ordinary nitrate(V) salts. The process is obscured by simultaneous decomposition of nitrate(V) ion.

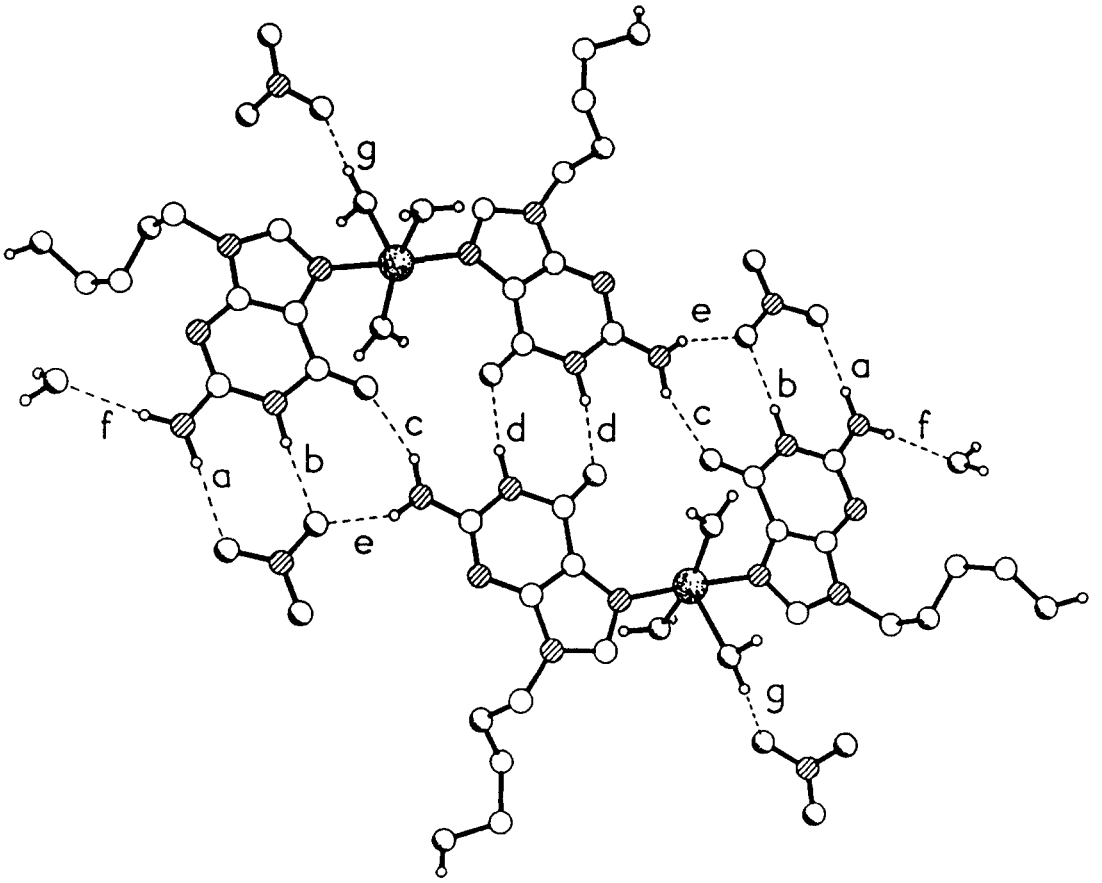

Fig. 2. The pattern of base recognition between centrosymmetrically related molecules of **I**. Hydrogen bonding geometries: N···O, N—H, H···O distances (Å), N—H···O angles (°); (a) 2.95, 0.90, 2.05, 176; (b) 2.94, 0.90, 2.04, 175; (c) 2.82, 0.90, 2.00, 149; (d) 2.79, 0.90, 1.90, 171; (e) 2.95, 0.90, 2.10, 157; (f) 3.00, 0.90, 2.11, 173; O···O, H—O, H···O distances (Å), O—H···O angle (°); (g) 2.75, 0.90, 1.90, 156.

TG analysis confirmed the absence of water in compound **II**. We have calculated the contents of the copper(II) ion in this compound from the end mass loss. This value was in good agreement with volumetrically determined copper(II) contents.

Electronic spectra

The diffuse reflectance spectra of the three compounds are very similar and only pure *d–d* transitions have been assigned (Fig. 3). The results for both compounds, the crystal structures of which were solved, suits perfectly the published data of structurally related complexes [22]. It is hard to predict anything in the case of compound **II**, except that a tetrahedral geometry is unlikely.

Magnetic susceptibility data and ESR spectroscopy

All values of μ_{eff} lie between 1.80 and 1.95 which is the characteristic range of magnetically dilute complexes. This means that individual copper(II) ions are well separated from each other and the interactions between them cannot occur.

ESR spectra of all the compounds were obtained at *X*- and *Q*- band. The *Q*-band spectra of all of them, showed some separation of g_x and g_y, with an essentially rhombic coordination geometry, which is in agreement with the crystal structures (Table 3). No firm prediction could be made about the structure of **II**, except that, as shown by the electronic spectrum.

Table 3. ESR g values for some coordination compounds of copper(II) and acv

it is unlikely to be tetrahedral. Since the infrared spectrum shows that the C=O is probably not coordinated, the most likely structure would seem to involve unsymmetrical halide bridging between copper ions.

(Received 18 July 1996; accepted 18 September 1996)

Abstract—The complexes $[ML_2]$ (M = Cu and Ni) were prepared by electrochemical oxidation of the appropriate metal in a solution of 2-(2-pyridyl)-*N*-tosylethylamine in acetonitrile. The crystal and molecular structures of bis{4-methyl-*N*-(2-pyridin-2-yl-ethyl)benzenesulfonamide}copper(II) and bis{4-methyl-*N*-(2-pyridin-2-yl-ethyl)benzenesulfonamide}nickel(II) were determined by X-ray diffraction. Both compounds are isotypical and crystallize in the triclinic space group $P\bar{1}$ with one molecule in the unit cell. In both structures the metal atoms are in a distorted square-planar environment defined by two amide and two pyridyl nitrogen atoms. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: electrochemical synthesis; copper complex; nickel complex; amide complex; X-ray.

Previous work from our laboratories has shown that electrochemical methods can be used to prepare metal complexes of ligands having acid donor groups. The nature of the acid groups studied ranges from O—H (carboxylic acids, phenols, alcohols, enolizable carbonylic compounds) [1–3], N—H (pyrrole, imidazole) [1,4] to S—H (thiols) [1,5–10] or Se—H [1]. This paper extends this work to the case of secondary amides, in particular, ligands containing tosyl amide groups, as shown in the figure.

* Authors to whom correspondence should be addressed.

EXPERIMENTAL

Acetonitrile, 2-aminoethylpyridine, tosyl chloride and all other reagents were commercial products and were used as supplied. Metals (Ega Chemie) were used as *ca* 2×2 cm^2 plates.

The ligand (HL) was prepared by the reaction of equimolar amounts of the amine and the tosyl chloride in dichloromethane. A diluted solution of NaOH was added to the mixture until pH 8 and a white product was obtained and filtered at the pump upon a sintered glass funnel. The ligand was recrystallized from dichloromethane and dried *in vacuo*. Its purity was checked by recording its IR and ^{1}H NMR spectra.

Electrochemical synthesis

The electrochemical method was similar to that described by Tuck and co-workers [11]. The cell was

a 100-cm^3 tall-form beaker fitted with a rubber bung through which the electrochemical lead entered the cell. The anode was suspended from a platinum wire. The tosyl derivative was dissolved in acetonitrile, and a small amount (*ca* 20 mg) of tetraethylammonium perchlorate was added to the solution as a current carrier. Direct current was obtained from a purpose-built d.c. power supply. In both cases, hydrogen was evolved at the cathode. The cells can be summarized as:

$$Pt_{(-)}/CH_3CN + HL/M_{(+)} \quad M = Cu, Ni.$$

[CuL_2]. The electrochemical oxidation of copper metal in a solution of the ligand (0.2 g) in CH_3CN (50 cm^3) for 2 h at 20 mA resulted in the loss of 94 mg of metal from the anode ($E_f = 1.0$ mol F^{-1}). The reaction mixture was filtered to remove any precipitated particles of metal, and the filtrate was left to concentrate by evaporation at room temperature. A crystalline product identified as [CuL_2] was isolated: Found: C, 54.5; H, 4.6; N, 9.1; S, 9.3. Calc. for $C_{28}H_{30}N_4O_4S_2Cu$: C, 54.7; H, 4.9; N, 9.1; S, 10.4%.

[NiL_2]. The oxidation of nickel in a solution of the ligand (0.42 g) in acetonitrile (50 cm^3) for 2 h at 20 mA led to the dissolution of 45 mg of the metal ($E_f = 0.51$). Crystals of a compound identified as [NiL_2] were isolated by evaporation of the solution: Found: C, 55.0; H, 5.2; N, 9.3; S, 10.7. Calc. for $C_{28}H_{30}N_4O_4S_2Ni$: C, 55.2; H, 5.0; N, 9.2; S, 10.5%.

Physical measurements

The C, N, H and S analyses of the complexes were determined on a Carlo–Erba EA 1108 microanalyser. IR spectra were recorded as KBr mulls on a Perkin–Elmer 180 spectrophotometer. The proton NMR spectra were recorded on Bruker WM 250 MHz spectrometer using CD_3CN as solvent. Chemical shifts were referenced to TMS as internal standard.

Crystal structure determination

Crystal data for [CuL_2] (**1**). $C_{28}H_{30}CuN_4O_4S_2$, $M = 614.22$, triclinic, space group $P\bar{1}$, $a = 7.427(2)$, $b = 8.442(2)$, $c = 11.988(3)$ Å, $\alpha = 84.00(2)$, $\beta = 74.135(10)$, $\gamma = 72.221(10)°$; $Z = 1$, $D_c = 1.485$ g cm^{-3}. Prismatic greenish caramel crystals with dimensions $0.10 \times 0.30 \times 0.35$ mm^3.

Crystal data for [NiL_2] (**2**). $C_{28}H_{30}N_4NiO_4S_2$, $M = 609.39$, triclinic, space group $P\bar{1}$, $a = 7.428(2)$, $b = 8.314(2)$, $c = 11.950(3)$ Å, $\alpha = 83.54(2)$, $\beta = 73.26(1)$, $\gamma = 72.82(1)°$, $Z = 1$, $D_c = 1.500$ g cm^{-3}. Amber prismatic crystal with dimensions $0.10 \times 0.15 \times 0.25$ mm^3.

Data collection and processing. Enraf–Nonius CAD4 diffractometer fitted with graphite-monochromatized Mo-K_α radiation, $\lambda = 0.71073$ Å. The $\omega/2\theta$ scan technique was employed to measure the intensities for 5244 and 5171 reflections up to a maximum Bragg angle of 31° in both compounds. Cell parameters were refined by least-squares procedure on the setting angles of 25 reflections ($8.1 < \theta < 15.0°$ for **1** and $8.1 < \theta < 15.2°$ for **2**) [12]. No decomposition of the crystals occurred during the data collection. Corrections were applied for Lorentz and polarization effects and for absorption ($\mu = 0.99$ and 0.91 mm^{-1} for **1** and **2**, respectively) [13]. A total of 5244 and 5171 reflections were collected, respectively, of which 4345 (**1**) and 4285 (**2**) were unique ($R_{int} = 0.030$ and 0.057), and of these 4345 for **1** and 4285 for **2** satisfied the $I > 2.0\sigma(I)$ criterion of observability and were used in the subsequent analysis.

Structure analysis and refinement

The structures were solved by direct methods [14] and refined by a full-matrix least-squares procedure based on F^2 [15]. Non-hydrogen atoms were refined with anisotropic displacement parameters. Hydrogen atoms were located from difference Fourier synthesis and refined with isotropic displacement parameters, except those of the methyl group of the copper compound. The refinement proceeded smoothly to convergence with a maximum, Δ/σ of 0.001 when $R = 0.055$, $R_w = 0.118$ and $GOF = 1.024$ (goodness-of-fit) for 227 variables for the copper complex; $R = 0.072$, $R_w = 0.11$ and $GOF = 1.011$ for 239 variables for the nickel complex. Correction for extinction was made in the last cycle of refinement [16]. The analysis of variance showed no special features and the maximum and minimum residual electron density peaks in the final difference map were +0.64 and −0.51 e Å^{-3}, respectively for the copper complex and +0.50 and −0.42 e Å^{-3}, respectively for the nickel complex.

Atomic scattering factors and anomalous dispersion corrections for all atoms were taken from ref. [17]. The atomic positions, full lists of bond lengths and angles and other crystallographic data have been deposited as Supplementary Publication No. CSD. Copies can be obtained through the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen, Germany.

RESULTS AND DISCUSSION

The electrochemical oxidation of Cu and Ni in acetonitrile in the presence of 2-(2-pyridyl)-*N*-tosylethylamine (HL) proved to be a simple, direct route to compounds of general formula [ML_2]. The reaction can be represented as:

$$M + 2HL \rightarrow [ML_2] + H_2.$$

In both cases the electrolysis gave dark solutions

from which crystalline products were isolated by concentration. These compounds are air stable and insoluble in common organic solvents but soluble in CH_3CN.

In the case of the copper complex, the value of the electrochemical efficiency (moles of metal dissolved per Faraday of charge, E_f) was 1.0 mol F^{-1}. This, together with the formation of H_2 at the cathode, is compatible with the formation of Cu^I at the anode and subsequent oxidation to Cu^{II} in the solution.

$$\text{cathode:}\quad HL + e^- \rightarrow \tfrac{1}{2}H_2(g) + L^-$$

$$\text{anode:}\quad Cu + L^- \rightarrow [CuL] + e^-$$

$$[CuL] + HL \rightarrow [CuL_2] + \tfrac{1}{2}H_2(g).$$

These oxidation steps have been observed in other electrochemical processes involving copper as anode [18].

With Ni the value of E_f, 0.51 mol F^{-1}, is compatible with the process:

$$\text{cathode:}\quad 2HL + 2e^- \rightarrow H_2(g) + 2L^-$$

$$\text{anode:}\quad Ni + 2L^- \rightarrow [NiL_2] + 2e^-.$$

The molecular structures of $[CuL_2]$ *and* $[NiL_2]$

The crystals contain individual $[ML_2]$ (M = Cu, Ni) neutral molecules. ORTEP [19] drawings of the molecular structures of both complexes are presented in Fig. 1 together with the atomic-labelling system adopted. Selected bond distances and angles are listed in Tables 1 and 2.

Both structures are isotypic. In the complexes, the metal atom is located on a crystallographic symmetry centre and is coordinated to the sulphonamide nitrogen and pyridine nitrogen atoms of two symmetry-related moities.

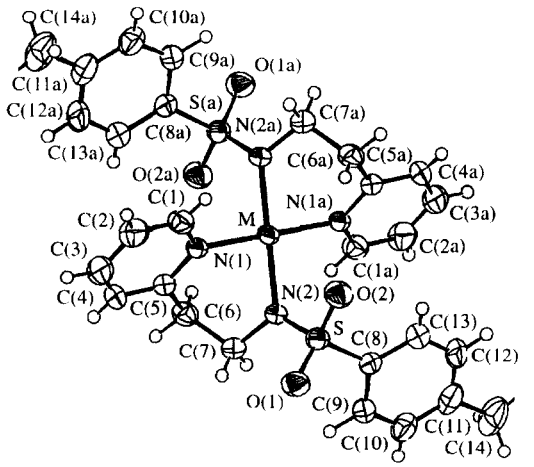

Fig. 1. The molecular structure of bis{4-methyl-N-(2-pyridin-2-yl-ethyl)benzenesulfonamide}M^{II}, where M = Ni, Cu.

The coordination geometry around the copper is square planar. Bond angles involving the copper atom and adjacent nitrogen atoms are 87.66(10) and 92.34(10)°.

The Cu—N bond distances are similar. The average value for the Cu—N_{py} bond distance, 2.002(5) Å, is similar to those reported for a number of four-coordinated square-planar copper complexes of pyridine and pyridine derivatives; for instance, 1.982(6) Å (average value) in dibromobis(2-methylpyridine) copper(II) [20] or 2.028(3) Å (average value) in bis[2-(2-aminoethyl)pyridine]copper(II) iodide [21]. Similarly, the average value for the Cu—N_{amide} bond distance, 1.922(2) Å, is very similar with the value 1.931(2) Å observed in bis-(*N*-phenylpyridine-2-carboxamido)copper(II) [22].

The configuration around the nickel atom is slightly distorted square planar with bond distances Ni—N_{py} 1.897(3) and Ni—N_{amide} 1.904(3) Å. These bond distances are similar to those found in related nickel square-planar complexes with both pyridine and amide nitrogen atoms as donors [23].

The ligand geometry in both complexes is similar to other substituted aminoethylpyridines, with the chelating portion of the group retaining the six-membered ring boat conformation.

The pyridine ring is approximately planar, with no atom deviating from the least-squares plane by more than 0.06 Å. Bond distances and angles are similar to those reported for other substituted pyridines.

Spectroscopic studies

None of the IR spectra of the complexes show bands assignable to ν(NH) at 3050 cm^{-1} in the spectrum of the free ligand, indicating that the amide hydrogen atom is lost during the electrochemical process. The bands attributable to the pyridine ring are shifted to higher frequencies as a consequence of the coordination through the pyridine nitrogen atom.

The ^1H NMR spectra for the ligand and Ni complex were recorded in CD_3CN as the solvent and the data reinforce the above conclusions. Thus the spectrum of the free ligand shows a peak around δ 6.1 assignable to the NH hydrogen. This signal is absent in the spectrum of the nickel complex, indicating the deprotonation of the ligand in the electrochemical process. The peak assignable to the α hydrogen of the pyridine ring is shifted downfield in the spectrum of the complex, in accordance with coordination of the ligand to the nickel atom through the pyridine nitrogen atom.

(Received 25 June 1996; accepted 18 September 1996)

Abstract—A series of 1,1′-bis[*N*-formyl-*N*′-substituted thiourea]ferrocene derivatives was synthesized through the reaction of 1,1′-bis[formyl isothiocyanate]ferrocene and various primary amines, with high yields after simple and convenient purification. All the compounds were characterized by elemental analysis, IR and ^{1}H NMR spectra. Intramolecular hydrogen bonding between the formyl carbonyl group and the proton attached to N′ was found to be common in this kind of compound. Cyclic voltammetric analysis revealed that the substituents on the N′ atom affect the electrochemical behaviour of the ferrocenyl group *via* the intramolecular hydrogen bonded ring. The crystal structure of 1,1′-[*N*-formyl-*N*′-*p*-chlorophenylthiourea]ferrocene was determined showing the character of the intramolecular hydrogen bonding. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: ferrocene; acyl thiourea; intramolecular hydrogen bonding; electrochemistry.

Many acyl thiourea compounds have been widely studied for their insecticidal, antibacterial and pesticidal activities and promoting effect on plant growth [1,2]. It has been found that intramolecular hydrogen bonding is common in *N*-ferrocenoyl-*N*′-monosubstituted thiourea derivatives, which form a novel kind of polychelate ligand ready to complex with transition metal ions [3,4]. Whether intramolecular hydrogen bonding exists in 1,1′-disubstituted acyl thiourea ferrocene compounds is still another question to be investigated. In an extensive study, 1,1′-bis[*N*-formyl-*N*′-substituted thiourea]ferrocene derivatives were synthesized through the reaction of 1,1′-bis[formyl isothiocyanate]ferrocene with various primary amines. The existence of intramolecular hydrogen bonding was confirmed by IR ^{1}H NMR spectra and single crystal X-ray diffraction.

EXPERIMENTAL

All reagents and solvents were of analytical or chemical grade quality. Acetone was dried by refluxing with P_2O_5 for 3–4 hours after treatment with anhydrous potassium carbonate. KSCN was baked before use. Aromatic amines were vacuum distilled or recrystallized. Aliphatic amines were used directly without further purification.

Elemental analysis (C, H, N) were performed on a CHN-Corderm7-3 autoanalyser. Melting points were determined on a PHMK melting point apparatus (from Germany) and are uncorrected. ^{1}H NMR spectra were recorded on a Jeol FX-90QNMR, spectrometer, using $CDCl_3$ or DMSO-d_6 as solvent and TMS as internal standard. IR spectra were carried out with a Nicolet-FT-IR5-DX infrared spectrophotometer. X-ray diffraction data were obtained using an Enraf Nonius CAD4 diffractometer with graphite-monochromated Mo-K_α radiation ($\lambda = 0.071073$ nm). The crystal belongs to the monoclinic, space group $P2_1/n$, $a = 8.435(1)$, $b = 23.088(8)$, $c = 13.307(3)$ Å, $\beta = 95.70(1)°$, $V = 2597(2)$ Å^3, $z = 4$, $D_c = 1.575$ g cm^{-3}, $\mu = 9.804$ cm^{-1} and $F(000) = 1248$. A total of 3240 independent reflections was collected in the range $4.0 < \theta < 46.0°$ by 2θ–θ scan, at room temperature (299 ± 1 K), of which 1690 were accepted as observable [$I \geqslant 3\sigma(I)$]. The intensities were fully corrected

for Lp factors and empirical absorption. The crystal structure was solved by direct phase determination method (MULTAN82). One independent Fe atom was located on an E map. The other non hydrogen atoms were found in the successive difference Fourier syntheses. The hydrogen atoms were not included in the refinement and calculations of structure factors. The coordinates and anisotropic thermal parameters of non-hydrogen atoms were refined by full-matrix least-squares methods and converged to $R = 0.053$ and $R_w = 0.061$ with unit weights. The highest electron density on the final difference Fourier map was found to be 0.45 e $Å^{-3}$. All calculations were performed on a PDP11/44 computer using the SDP-PLUS program system.

Cyclic voltammetric experiments were performed on a BAS-100B electrochemical analyser equipped with a three electrode assembly with 0.1 mol dm^{-3} TBAFB (Bu_4NBF_4) as support electrolyte and CH_2Cl_2 as solvent. The working electrode was a ϕ 1.5 mm platinum disk embedded in a cobalt glass seal and was polished consecutively with polishing alumina and diamond suspensions between runs. The 0.1 M $AgNO_3$/Ag (in 0.1 M Bu_4NBF_4-DMSO) was the reference electrode. A platinum filament was used as an auxiliary electrode.

Synthesis of 1,1′-*bis(formyl isothioncyaate)ferrocene* (**I**)

KSCN (0.533 g, 5.5 mmol) was dissolved in acetone (15 cm^3) and added dropwise to the 20 cm^3 acetone solution of 2.5 mmol $Fc(COCl)_2$ and refluxed for 30 min. The red acetone solution of $Fc(CONCS)_2$ was obtained on filtration of KCl and used *in situ* for the following reactions without further separation and purification.

Reaction of aromatic amines and aminoferrocene with **I**

Taking *p*-chloroaniline as an example. *p*-Chloroaniline (0.65 g, 5 mmol) dissolved in acetone (20 cm^3) was added dropwise to the acetone solution of 2.5 mmol $Fc(CONCS)_2$ and a red solid rapidly appeared. The mixture was refluxed for 2 h and the red powder obtained by filtration was washed with acetone. A total of 1.39 g was collected, yield 91%.

Reaction of aliphatic amines with **I**

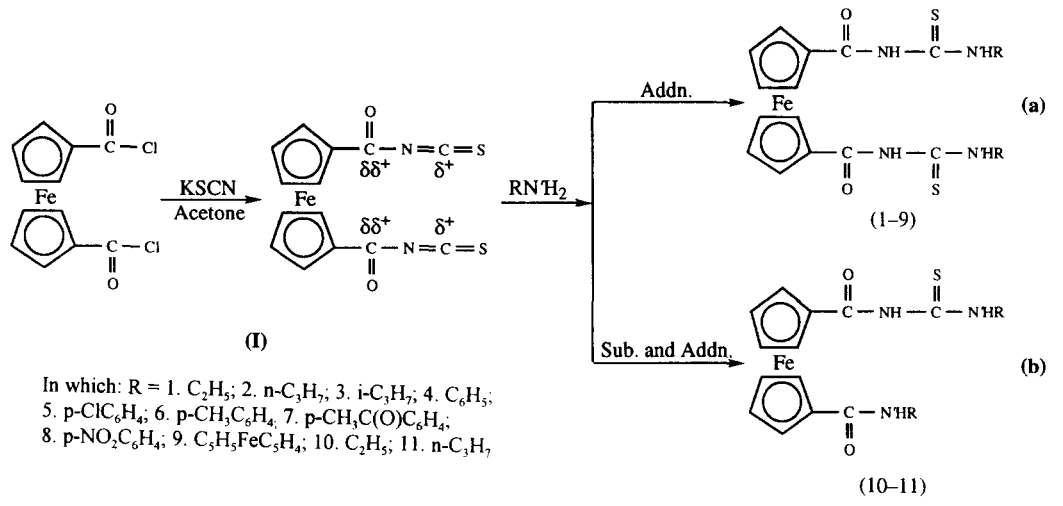
Taking isopropyl amine as an example. An acetone solution of isopropyl amine (5 mmol) was added to the aforesaid acetone solution of $Fc(CONCS)_2$ and refluxed for 5 h. After removal of acetone by distillation, the residue was dissolved in the minimum amount of $CHCl_3$, and 0.96 g orange–red crystal was eluted from a neutral Al_2O_3 (200–300 mesh) chromatographic, column, yield 81%.

RESULTS AND DISCUSSION

General characterization

Analytical and physical data for the 11 compounds are given in Table 1. Compounds **1**–**3** are very soluble in acetone, diethyl ether, chloroform and dichloromethane and are soluble in benzene and hot alcohol, but are insoluble in petroleum ether. Compounds **4**–**9** can be dissolved in DMF, DMSO and other non-protic solvents.

Reactivity of **I** *towards primary amines*



The intermediate 1,1′-bis[formyl isothiocyanate] ferrocene (**I**) was synthesized and reacted with aliphatic amines *in situ* under mild condition. There are two competing reactive sites in **I** as shown in Scheme 1.

If RNH_2 attacks the carbon atom in the isothiocyanate group ($C^{\delta+}$), addition of RNH_2 to the C=N double bond takes place, resulting in the thiourea product. An alternative site for RNH_2 to attack is

Scheme 2.

the carbonyl carbon atom ($C^{\delta\delta+}$). In this case, the isothiocyanate group is substituted by the amino group, thus the amide product is anticipated. Unlike its monosubstituted ferrocene derivative analogue, whose reaction with primary amines gave only the addition product, the reaction of (**I**) with aliphatic amines involved competition between addition and substitution. Both products were isolated through column chromatography. In the case of aromatic primary amines, owing to their lower nucleophilicity, they were reacted with (**I**) under reflux. The products precipitated from the solution directly. No substitution took place and only the addition form was collected.

IR spectra

The medium–strong $\nu_{C=O}$ band in the IR spectra of all the compounds appears at about 1671 cm^{-1}, apparently decreasing in wavenumber compared with the ordinary carbonyl absorption (1710 cm^{-1}) (see Table 2). This is interpreted as being a result of its conjugate resonance with the ferrocenyl group and the possible formation of intramolecular hydrogen bonding with N′—H. In addition, the abnormal intensity ratio between $\nu_{C=O}$ and δ_{CNH} (1515–1550 cm^{-1}, vs) bands revealed that intramolecular hydrogen bonding might exist in this kind of compound (as shown in Scheme 2) [5]. No $\nu_{S\ H}$ absorption was observed in the region 2600–2500 cm^{-1}, indicating that the compounds do not exist in the thioenol form. The $\nu_{C=N}$ band appears at about 1269 cm^{-1} and is much weaker than $\nu_{C=O}$ and δ_{CNH} in intensity. It is presumed to be the mixed vibration of δ_{OCN} and ν_{N-H}. A strong band at about 1319–1355 cm^{-1} is assigned to the stretching vibration of the thione group. There is a weak or medium intensity singlet peak at 3300 cm^{-1} in the IR spectra of compounds **1–9**, indicating the presence of the secondary amino group. It is attributed to ν_{N-H}, whereas the $\nu_{N'-H}$ band shifts to 3010–3230 cm^{-1} and becomes broad and weak because of the intramolecular hydrogen bond formation. In the IR spectra of compounds **10** and **11**, there are three ν_{N-H} absorptions at 3279, 3246 and 3164 cm^{-1}, respectively, and two $\nu_{C=O}$ bands, one very strong at 1630 cm^{-1} and the other comparatively weak at about 1671 cm^{-1}. With respect to other regions, there is little difference compared with compounds **1–9**. All of the above facts support structure (b) in Scheme 1, in which one side chain gives the addition product while the other undergoes substitution.

Nujol IR spectra were also recorded and it was shown that there are no ν_{O-H} and ν_{S-H} bands. This indicates that compounds **1–11** exist in the keto-thione form.

^{1}H *NMR spectra*

In the ^{1}H NMR spectra of compounds **1–9** (Table 3), the signals of the cyclopentadienyl protons shift downfield owing to their proximity to the carbonyl group with δ_{ortho} (4.74–5.46) > δ_{meta} (4.48–4.78), displaying the characteristics of AA′BB′ coupling, since the two Cp rings are in the same chemical environment. There are two kinds of Cp rings in compound **9**, with four being monosubstituted and two unsubstituted. The former gives AA′BB′ coupling and altogether five Cp bands are observed. δ_{N-H} appears at 8 9 ppm. The downfield δ 12.50 peak is assigned to

$\delta_{N'-H}$ owing to the deshielding effect of intramolecular hydrogen bond formation. In compounds **7** and **8,** δ_{N-H} and $\delta_{N'-H}$ approach δ 11.00 and 13.00 owing to the electron-withdrawing groups on the phenyl ring. All of this evidence tallies with the structures drawn from their IR spectra.

Three amino protons were observed in the ^1H NMR spectra of compounds **10** and **11,** two of which are similar to those of the aforesaid compounds, while the other appears at δ 6.00, belonging to the amide proton. Besides, the cyclopentadienyl proton signals are too complicated to differentiate. With the aid of elemental analysis data, the structures of **10** and **11** are presumed to be (b). This further confirmed the conclusion derived from the IR spectra.

To demonstrate the existence of intramolecular hydrogen bond, ^1H NMR spectra of compounds **1** and **10** at different concentrations with $CDCl_3$ as solvent were recorded. It was found that the most downfield peak remains unchanged.

Electrochemistry

Cyclic voltammetric data of compounds **1–9** and ferrocene are listed in Table 4. The CV curves of compounds **2** and **9** are depicted in Figs 1 and 2.

One pair of reversible redox peaks was observed in compounds **1–8,** indicating that they undergo a one-electron redox reaction. Their $\bar{E}_p$ values at about 0.85

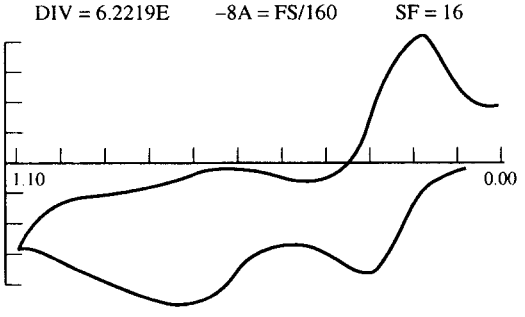

Fig. 2. Cyclic voltammogram of compound **9**.

V are higher than that of ferrocene (0.262 V), thus revealing that the acyl thiourea group is an electron-withdrawing group. In addition, at the same rate of scanning, their redox potentials are influenced by the properties of the substituents on the N′ atom. The more electron withdrawing the substituent is, the higher the $\bar{E}_p$ value becomes. For example, at the same scanning rate of 400 mV s^{-1}, $\bar{E}_p$ of compound **8** (*p*-NO_2) is 0.886 V, while that of compound **6** (*p*-CH_3) is 0.857 V. This is explained as follows: the strong electron-withdrawing property of *p*-NO_2 ($\sigma = 0.78$) and electron-donating property of *p*-CH_3 ($\sigma = -0.17$) can affect the electrochemical behaviour of the ferrocenyl group *via* the intramolecular hydrogen bonding planes.

There are two pairs of redox peaks in the CV curve of compound **9**, showing the characteristics of a multi-component redox system [6]. This is interpreted as resulting from two different kinds of ferrocenyl groups. The two monosubstituted ferrocenyls are electrochemically identical and are oxidized at the same potential, releasing two electrons at the same time. Their E_p (0.237 V) is lower than that of ferrocene, owing to the electron-donating properties of the amino group. Whereas the E_p value of the disubstituted ferrocenyl group (0.674 V) is higher than that of ferrocene, again confirming the electron-withdrawing properties of the acyl thiourea group.

Single crystal X-ray diffraction

To further confirm the existence of intramolecular hydrogen bonding the crystal structure of compound **5** was determined. X-ray analysis reveals that in each molecule there exist two independent intramolecular hydrogen bonds between the carbonyl oxygen and the hydrogen atom on N′ in either —C(O)—NH—C(S)—N′H— moiety, forming two parallel six-membered rings. The planar rings are approximately in the same plane as the cyclopentadienyl rings to which they are attached. The two phenyl rings are basically parallel as well. The molecular structure of compound **5** is depicted in Fig. 3. Table 5 lists the least squares planes of relevant groups and the dihedral angles

(Received 12 July 1996; accepted 16 September 1996)

Abstract—The title complex, $[Mn_3O(C_6H_5COO)_6(py)_3]\cdot 2CH_3CN$ (py = pyridine), has been prepared. Single-crystal X-ray analysis revealed a μ_3-oxo-bridged $Mn_2^{III}Mn^{II}$ structure, in which each manganese atom has a distorted octahedral environment. The Mn(1) atom is readily assigned as a Mn^{III} centre from the Mn—(μ_3-O) distance [1.819(5) Å]. The remaining Mn(2) and Mn(3) atoms are essentially equivalent in crystallography, indicating an electronic delocalization between Mn^{II} and Mn^{III} atoms. © 1997 Elsevier Science Ltd. Keywords: crystal structure; trinuclear complex; manganese complex; μ_3-oxo centred metal carboxlate; mixed-valence complex; electronic delocalization.

The study of manganese polynuclear complexes has been important for understanding the structure and reactivity of manganese sites in biological systems [1,2], and in the quest to obtain molecular species with large spin ground states [3]. Trinuclear complexes of the general formulation of $[Mn_3O(RCO_2)_6L_3]^{0,1+}$ (L = py, H_2O) are known as good starting materials for synthesizing manganese polynuclear complexes [4]. In previous work, we have established that treatment of $[Mn_3O(CH_3COO)_6(py)_3]\cdot py$ (**1**) with 2,2′-bipyridyl-3,3′-dicarboxylic acid (H_2bpc) and triethylamine gave a novel linear trinuclear manganese(II) complex [5]. In this study, the title complex was isolated unexpectedly under the same conditions using $[Mn_3O(C_6H_5COO)_6(py)_2(H_2O)]\cdot 0.5CH_3CN$ (**2**) instead of the acetate derivative **1**. The crystal structure has been investigated.

EXPERIMENTAL

Preparations

All chemicals were obtained from commercial sources and used without further purification. $[Mn_3O(C_6H_5COO)_6(py)_2(H_2O)]\cdot 0.5CH_3CN$ (**2**) was prepared according to the literature method [6].

$[Mn_3O(C_6H_5COO)_6(py)_3]\cdot 2CH_3CN$. An acetonitrile solution containing 0.1 mmol of both H_2bpc and triethylamine was added to an acetonitrile solution of 0.2 mmol of **2** in a total volume of 15 cm^3, and the mixture was allowed to stand for several days to give black prisms. Found: C, 59.3; H, 4.4; N, 5.3. Calc. for $C_{61}H_{51}Mn_3N_5O_{13}$: C, 59.7; H, 4.2; N, 5.7%.

X-ray structure determination

Intensity data were collected on a Siemens R3m/V diffractometer using Mo-K_α radiation at 293 K. Although the unit cell has tetragonal geometry, on the basis of extinction conditions and correct structure solution, the orthorhombic space group $P2_12_12_1$ was chosen. Crystal parameters and details of the data collection and refinement are given in Table 1. The structure was solved by direct phase determination and refined by the blocked-diagonal least-squares method. Hydrogen atoms were placed in their calculated positions. All calculations were carried out using the SHELXTL-PC program package. The final

RESULTS AND DISCUSSION

The crystal consists of trinuclear $[Mn_3O(C_6H_5COO)_6(py)_3]$ units and contains CH_3CN as solvent of crystallization in a 1:2 ratio. As shown in Fig. 1, the title complex features a μ_3-oxo-bridged trinuclear manganese structure, where each manganese atom has a distorted octahedral environment composed of the μ_3-oxo O(1) atom and four oxygen atoms from bridging benzoate groups and a terminal pyridine nitrogen atom. Such a structure is often seen in transition metal basic carboxylates [6,7]. The molecule approximates to C_{2v} symmetry and the geometry around Mn(2) and Mn(3) is very similar. The distances Mn(1)—Mn(2), Mn(1)—Mn(3) and Mn(2)—Mn(3) are 3.284, 3.285 and 3.403 Å, respectively, showing that the [Mn(1)Mn(2)Mn(3)] is an isosceles triangle. The central O(1) atom lies slightly above the Mn_3 plane (0.0085 Å). The charge on the complex necessitates a mixed-valence $Mn^{III}_2Mn^{II}$ description. The Mn(1) atom is readily assigned as an Mn^{III} centre, since the Mn(1)—O(1) distance [1.819(5) Å] is the shortest of the Mn—O distances. Thus, one of Mn(2) and Mn(3) is an Mn^{II} atom, the other a Mn^{III} atom. However, these two Mn atoms are essentially equivalent crystallographically, suggesting an electronic delocalization between them. In fact, the distances Mn(2)—O(1) 1.972(5) Å, Mn(3)—O(1) 1.966(5) Å are just close to the average value [1.975 Å of Mn^{II}, Mn^{III}—(μ_3-O)] distances observed in the valence-trapped complex **2**, in which Mn^{II}, Mn^{III} atoms are distinguished from each other [6]. Averaging of Mn^{II}, Mn^{III}—(μ_3-O) distances is also observed in complex **1**, which shows an electronic delocalization between all three Mn atoms [6]. It is interesting that the delocalization occurs only between two Mn atoms in the title complex in contrast to the valence-trapped complex **1** and non-valence-trapped complex **2**. Such a μ_3-oxo-centred metal carboxylate has not been reported so far to our knowledge.

(Received 12 July 1996; accepted 16 September 1996)

Abstract—Two complexes of diaqua-bis(ethylenediamine)copper(II) with anions of *N*-carboxyglycine and ethylenediaminebiscarboxylic acid $[Cu(en)_2(H_2O)](OOCCH_2NHCOO)\cdot H_2O$ (**1**) and $[Cu(en)_2(H_2O)_2](OOCNHCH_2CH_2NHCOO)\cdot 2H_2O$ (**2**) were synthesized and investigated by single-crystal X-ray analysis and IR spectroscopy. Compound **1** was obtained by direct synthesis upon interaction of copper powder with glycine hydrochloride in methanol solution upon heating in air. Compound **2** was isolated as a result of a reaction between a copper(II) anionic complex with pyruvoylamide oxime (H_2pox) of composition K[Cu(pox)(Hpox)] with ethylenediamine and formaldehyde in methanol solution. In both cases formation of carbamate anions is connected with uptake of atmospheric carbon dioxide by the reaction mixtures. The crystal structures of **1** and **2** comprise $[Cu(en)_2H_2O)_2]^{2+}$ cations, carbamic acids anions and solvate water molecules. The complex cations of **1** and **2** consist of two ethylenediamine molecules coordinated in the equatorial plane [Cu—N = 2.007(3)–2.024(3) Å for **1** and 1.996(2) and 2.022(2) Å for **2**], and water molecules occupying the apical positions of distorted octahedra [Cu—O = 2.591(3) and 2.741(3) Å for **1** and 2.556(3) Å for **2**]. The extended hydrogen bond system in **1** and **2** unites the elements of the structures. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: carbon dioxide; direct synthesis; copper(II) complexes; carbamates; crystal structure; IR spectroscopy.

Removal of carbon dioxide from gaseous streams is an important procedure in different industrial technologies. One of the ways used in industry to eliminate carbon dioxide from gas mixtures is its absorption by liquid amines or their solutions [1] with formation of carbamates. As a rule, such interactions take place upon cooling to 0°C because CO_2 is liberated at higher temperatures owing to dissociation of the carbamates [2]. Most synthetic methods for aliphatic carbamates suggest the interaction of carbon dioxide with amines in alcoholic solutions at −10 to 0°C [3–5]. Recently, a method of CO_2 absorption on a silica gel containing 3-aminopropyl groups bonded to surface atoms of silicon at room temperature was reported [6] which led to the formation of surface carbamate groups.

Studying the results of direct synthesis of metal complexes with amines [7–9] and reactions of template condensation of amide-containing anionic complexes [10] with primary amines and formaldehyde, we noted that in some cases, when the reactions proceed in methanol solutions in air, unexpected products form owing to the uptake of carbon dioxide from the air. It is important that CO_2 absorption proceeds at room temperature or even upon heating. In order to study the nature and structure of these carbamate-containing products, and taking into account the fact that carbamates derived from primary amines and their metal complexes are poorly structurally characterized, we performed the X-ray single crystal and IR investigation of two new compounds. The present paper reports these results.

EXPERIMENTAL

All chemicals were commercial products of reagent grade and used without further purification. IR

spectra (KBr pellets) were recorded on an UR-20 spectrometer (Carl Zeiss Jena) in the region 400–4000 cm^{-1}.

Synthesis of $[Cu(en)_2(H_2O)_2](OOCCH_2NHCOO) \cdot H_2O$

Copper powder (0.63 g, 10 mmol) and glycine hydrochloride (1.1g, 1 mmol) were placed into the reactor, then 25 cm^3 of methanol and 2 cm^3 (30 mmol) of ethylenediamine were added. The reaction mixture was heated at 50–60°C upon continuous stirring for 20–25 min in the air until the complete dissolution of the copper powder was achieved. The solution formed was cooled and set aside in the air at room temperature for 24 h. Then isopropanol (20 cm^3) was added, and the blue crystalline product formed was filtered off and dried. Single crystals suitable for X-ray analysis were obtained by recrystallization from methanol. Yield 0.8 g (47%). Found: C, 23.9; H, 6.8; N, 20.2; Cu, 18.3. Calc. for $C_7H_{25}N_5O_7Cu$: C, 23.7; H, 7.1; N, 19.7; Cu, 17.9%.

Synthesis of $[Cu(en)_2(H_2O)_2](OOCNH_2CH_2NHCOO) \cdot 2H_2O$

K[Cu(pox)(Hpox)] (0.304 g, 1 mmol) prepared according to the literature method [11] was suspended in methanol (15 cm^3), then paraformaldehyde (0.060 g, 2 mmol) dissolved in methanol (10 cm^3) was added with the addition of 1 drop of 10% KOH in methanol and ethylenediamine (0.060, 1 mmol). The mixture obtained was heated at 60°C upon continuous stirring for 2 h in the air, then cooled and set aside for crystallization. The brown oil, after 3–4 weeks in the air, produced blue crystals of the title complex which were separated by hand from the bulky oil, washed with ethanol and dried in a dessicator. Yield 0.15 g (37%). Found: C, 24.2; H, 7.2; N, 20.8; Cu, 16.0. Calc. for $C_8H_{30}N_6O_8Cu$: C, 23.9; H, 7.5; N, 20.9; Cu, 15.8%.

Crystallographic data collection and structure determination

Crystal data and experimental details are presented in Table 1. The accurate unit-cell parameters and the orientation matrix were calculated from the setting angles of 24 reflections using the least-squares technique. Intensities were collected using an Enraf–Nonius CAD-4 diffractometer in the ω–2θ scan mode using Cu-K_α (for **1**) and Mo-K_α (for **2**) radiation. The intensities of three standard reflections, monitored every 100 intensity scans showed no evidence of crystal decay. Corrections for Lp effects, but not for absorption, were applied.

The positions of copper atoms and some non-hydrogen atoms were determined by direct methods, then the remaining non-hydrogen atoms were located in subsequent Fourier syntheses and refined by the full-matrix least-square technique using the SHELXL 93 program [12]. Neutral atom scattering factors and anomalous dispersion terms used in the refinement were taken from reference [13], real and imaginary components of anomalous dispersion were included for all non-hydrogen atoms. All the hydrogen atoms were localized from a difference Fourier map and their positional and isotropic displacement parameters were included in the final stage of the refinement. A weighting scheme of the form $w = 1/\sigma^2(F_0^2) + (0.0523P)^2 + 1.23P$ and $w = 1/\sigma^2(F_0^2) + (0.0417P)^2 + 1.05P$ [where P is defined as $F_0^2 + 2F_c^2)/3$] was applied for **1** and **2**, respectively. The bond distances and angles are listed in Tables 2 and 3.

RESULTS AND DISCUSSION

The structures of the complexes **1** and **2** are presented in Figs 1 and 2, respectively. The packing diagrams are presented in Figs 3 and 4. Both structures are ionic and consist of the complex cations $[Cu(en)_2(H_2O)_2]^{2+}$, anionic carbamic acid residues and the solvate water molecules. Complex **1** contain the anion of *N*-carboxyglycine, complex **2**, the anion of ethylenediaminebiscarbonic acid. The elements of the structure are joined to each other in the crystal packing by means of extended systems of hydrogen bonds where the protons belonging to the water molecules or NH_2 and NH groups act as donors (Figs 3 and 4). Parameters for the hydrogen bonds are listed in Tables 4 and 5.

The complex cations in **1** and **2** consist of two ethylenediamine molecules that coordinate the central atom in the equatorial plane in chelate mode, and two water molecules occupying the apical positions of the severely elongated octahedra (Figs 1 and 2). The Cu—N distances in both complexes are in the range of 1.996(2)–2.024(3) Å which is normal for Cu—N-(amine) bonds. The bite angles are decreased to 83.73(11)–84.78(7)°. Similar geometrical parameters for the coordination sphere have been reported for other diaqua-bis(ethylenediamine)copper(II) salts [14–17]. As the copper atom in **2** occupies the partial position ($\frac{1}{4}$, $\frac{1}{4}$, $\frac{1}{2}$) the coordination polyhedron is centrosymmetric (symmetry D_{4h}), the central and the donor atoms lie in the same plane. In **1** the donor atoms lie in the same plane (the maximal deviations do not exceed 0.01 Å), the copper atom is situated 0.05 Å above the plane of best fit towards the closer axial donor atom O(1). In **2** the long axial contact Cu—O(4) of 2.556(2) Å is in fact coincident with those found in other structures containing the centrosymmetric $[Cu(en)_2(H_2O)_2]^{2+}$ cation (2.580 Å [14] and 2.572 Å [15]). In compound **1** these distances are different [Cu—O(1) 2.591(3) and Cu—O(2) 2.741(3) Å]. This is probably owing to non-equivalence of the hydrogen bonds formed by the O(1) and O(2) atoms. The latter is involved in an additional acceptor hydro-

gen bond, N(5)—H···O(2) (Table 4), which leads to elongation of the Cu—O(2) axial contact. Somewhat shorter values of Cu—O distances were seen in the only reported structure containing the non-centrosymmetric cation (2.514 and 2.674 Å) [17]. The five-membered chelate rings in both cations possess the *gauche* conformation with the carbon atoms deviating from the CuNN planes by 0.27–0.40 Å.

In the anion of ethylenediaminebiscarbonic acid (compound **2**) the C—O distances of the carboxylic moieties C(4)—O(1) and C(4)—O(2) are equal [1.267(2) Å], the angle O(1)—C(4)—O(2) is 123.7(2)°. In compound **1** one can observe the differences in C—O distances in the carboxylic moieties [1.242(2)–1.271(4) Å] which arise probably as a result of the non-equivalence of hydrogen bonds involving the carboxylic oxygen atoms. The values of the corresponding bond angles are: O(4)—C(5)—O(5) 124.7(3); O(6)—C(7)—O(7) 124.9(2)°. Such values for the geometrical parameters are typical of free deprotonated carboxylic groups [18]. The angular geometry around the nitrogen atoms in both anions approaches trigonal planar. The N—C(carboxyl) bond distances (in **1**: N(5)—C(7) 1.376(4); in **2**: N(3)—C(4) 1.345(3) Å] indicate their partly double bonded nature. This is because of the participation of the nitrogen atom in the delocalization of the electron density from the C—O bonds, which is characteristic of amides [19]. As a result, the CH_2—NH—COO^- moieties in both anions are nearly planar (the deviations of the atoms from the mean planes do not exceed 0.03 Å). In the case of ethylenediaminibiscarbaminate complex (**2**) the anion consists of two such planar fragments related by a two-fold axis and linked by the C(3)—C(3a) bond with a tor-

sion angle N(3)—C(3)—C(3a)—N(3a) of 54.5°. Note, that the values of the bond distances and angles for both carbamate anions are close to those reported for N-(2-ammonioethyl)carbamate [20].

In the IR spectra of compounds **1** and **2** the bands corresponding to the ν_s and ν_{as} modes of the COO^- group are seen (**1**: 1418 and 1585 cm^{-1}; **2** 1421 and 1582 cm^{-1}, respectively). In compound **1**, however, these bands carry noticeable shoulders (at 1410 and 1575 cm^{-1}) which are probably a result of non-equivalence of two carboxylic groups in *N*-carboxyglycinate. In the region of 2850–3000 cm^{-1} the small bands for the ν(C—H) vibrations are observed: the intensive bands for the ν(C—N) vibrations are indicated at 1040 (**1**) and 1052 (**2**) cm^{-1}. The positions of the IR bands are close to those reported for the ethylenediaminebiscarbonic acid disodium salt [21].

(Received 18 June 1996; accepted 16 September 1996)

Abstract—Mononuclear cobalt(II) complexes $Co(mbt\text{-}N)_2(PBu^n_3)_2$ (**1**) (Hmbt = 2-mercaptobenzothiazole; PBu^n_3 = tri-n-butyphosphine) and $Co(mbt\text{-}S,N)_2(dppe)\cdot MeCN$ (**2**) [dppe = 1,2-bis(diphenylphosphino) ethane] were synthesized and characterized by X-ray crystallography, IR and EPR spectra, cyclic voltammetric data and magnetic susceptibility measurements. The Co atom in (**1**) exhibits an approximate square-planar geometry with the heterocyclic N-donors from mbt bonding to the cobalt atom in a monodentate mode. Complex (**2**) has a distorted octahedral environment of Co with both the exocyclic-S and the hetero-N donors of mbt bound to the cobalt atom in a bidentate chelating mode. The Co atom in both complexes shows spin state of $S = \frac{3}{2}$ with μ_{eff} of 4.25 and 4.40 μ_B for **1** and **2**, respectively. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: ternary cobalt complex; 2-mercaptobenzothiazole ligand; X-ray structure; tertiary phosphine.

Although metal complexes of thiolates with the participation of phosphine have been actively investigated and a broad variety of compounds with a great degree of complexity and nuclearity has been obtained [1–14], the area of phosphine cobalt complexes with heterocyclic thiolates as coligands has scarcely been touched. As a heterocyclic thiolato ligand with potential S and N donors, 2-mercaptobenzothiazole (Hmbt) is interesting not only because of the structural chemistry of its multifunctional coordination modes (unidentate-N, unidentate-$S_{exocyclic}$ or bidentate-N:S) [15], but also because of the formation of complexes with biological activities and with practical applications such as anticorrosion and as accelerators in the rubber vulcanization process [16–18]. Until now, the only Co–mbt complex with a known structure has been $Co(mbt)(py)_2$ [19], despite the fact that complexes of Zn [20,21], Cd [21–24], and Cu [25] are known. Our interest in phosphine-participated Co complex formation has been extended to mixed mbt and tertiary phosphines. Herein we report the syntheses of two complexes with different coordination geometries: four-coordinate, square-planar $Co(mbt\text{-}N)_2(PBu^n_3)_2$ (**1**) and six-coordinate, distorted octahedral $Co(mbt\text{-}N:S)_2(dppe)\cdot MeCN$ (**2**), by using monodentate and 1,2-bidentate phosphines, respectively.

EXPERIMENTAL

All operations were carried out under pure dinitrogen with Schlenk type apparatus. Reagents 2-mercaptobenzothiazole (Hmbt), tri-n-butyphosphine

Part II: Kang, B. S., Zhang, H. X., Gao, H. R., Zhou, Z. Y., Wu, B. M., Mak, T. C. W., Lin, Z. and Chen, Z. N., *Acta Chim. Sinica*, 1997, in press.

(PBu^n_3) and 1,2-bis(diphenylphosphino)ethane (dppe) were purchased from Aldrich and used as obtained. Anhydrous cobaltous chloride was prepared by refluxing $CoCl_2 \cdot 6H_2O$ in $SOCl_2$ according to the literature method [26]. Acetonitrile, DMF and MeOH were dried, distilled and flushed with pure dinitrogen or argon for 5 min before use.

Synthesis

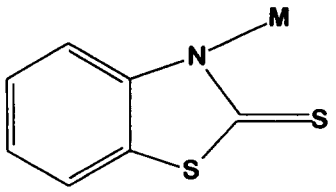
Co(mbt-*N*)$_2$(PBu^n_3)$_2$ (**1**). To a mixture of Hmbt (0.34 g, 2 mmol), Na metal (0.046 g, 2 mmol) and PBu^n_3 (1 cm^3, 4 mmol) in 20 cm^3 of MeOH was added 0.26 g (2 mmol) of anhydrous $CoCl_2$ with stirring. After stirring for 3 h at room temperature, the solution was filtered and the dark green filtrate kept at 5°C for several days to given 0.15 g (9.0% yield based on Co) of dark brown cubic crystals of **1**. IR (KBr, cm^{-1}): 1585w, 1456s, 1423s, 1410s, 1392s, 1251m, 1088s, 1038s, 1014s, 969s, 905w, 891w, 754s, 724m, 690m, 656w, 615w, 592w, 503w, 432w and 424w.

Co(mbt-*N*:*S*)$_2$(dppe) (**2**). To a mixture of Hmbt (0.34 g, 2 mmol), Na metal (0.046 g, 2 mmol) in 1.5 cm^3 of MeOH and dppe (0.80 g, 2 mmol) in 20 cm^3 of MeCN was added 0.26 g (2 mmol) of anhydrous $CoCl_2$ with stirring. After refluxing for 3 h, the solution was filtered and the dark filtrate was kept at room temperature for one week to give 0.34 g (21.6% yield based on Co) of dark brown block crystals of **2**. IR (KBr, cm^{-1}): 1584m, 1562w, 1484w, 1456m, 1434s, 1377s, 1275w, 1249m, 1173s, 1159s, 1122m, 1093s, 1029s, 1014s, 999s, 876w, 843w, 829w, 750s, 727s, 690vs, 609w, 552w, 530s, 509m, 492m and 428w.

Crystal structure determination

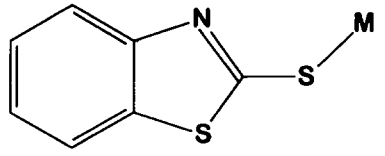
Single crystals of compounds **1** and **2** with suitable dimensions were mounted on glass fibres and data collections were performed on diffractometers as shown in Table 1 using graphite-monochromated Mo-K_α radiation ($\lambda = 0.71073$ Å). The crystallographic data, data collection and structure refinement parameters are summarized in Table 1.

The coordinates of the metal atoms were determined by direct methods and the remaining non-hydrogen atoms were located from successive Fourier difference syntheses. The structures were refined by full-matrix least-square techniques with anisotropic thermal parameters for the non-hydrogen atoms. The positions of the hydrogen atoms were isotropically added to the structural factor calculation but not refined. All calculations were performed on an IBM PC/486 computer with the Siemens SHELXTL-PC program package [27]. Selected atomic distances and bond angles are presented in Tables 2 and 3 for **1** and **2**, respectively.



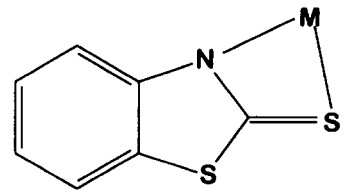
Physical measurements

Infrared spectra were recorded on a Nicolet 510 FT-IR spectrophotometer. Powder EPR spectra were recorded on a Bruker 2000-SRC spectrometer. Cyclic voltammetric measurements were performed on a HDV-7B potentiostat equipped with a DCD-3 low frequency–super low frequency functional generator and a LZ32-204 X-Y recorder in a three-electrode cell with platinum working and auxiliary electrodes and a saturated calomel electrode (SCE) as reference. The supporting electrolyte was $NBu^n_4BF_4$ (0.1 mol dm^{-3}) and the scan rate was 100 mV s^{-1}. Magnetic susceptibilities were measured on a model CF-1 superconducting extracting sample magnetometer at a magnetic field of 1.0 T.



RESULTS AND DISCUSSION

As a versatile heterocyclic thiolato ligand with S and N donors, 2-mercaptobenzothiazole exhibits three different coordination modes known to date, bonding to metal ions through N or exocyclic S donors in monodentate terminal mode, or bidentate chelating mode, as shown in **I–III**.



So far, modes **I–III** have all been found in Zn complexes [20,21], while no Cd complex has been found in mode **I** [21–24]. However, no regularities have been found and no rules can be followed so as to predict which mode will occur in a transition metal complex. The aforementioned complexes usually contain N-base or dialkyldithiocarbamate as coligands. No previous report has been made involving a phosphine

as coligand. When mono- and bi-dentate phosphines were used in this work, four- and six-coordinate complexes **1** and **2** were obtained respectively, with different coordination modes for Hmbt.

The structures of **1** and **2** are depicted in Figs 1 and 2, respectively. Complex **1** possesses a square-planar CoP_2N_2 core with the donor atoms P supplied by two PBu^n_3 ligands and N by two mbt ligands, where the latter are in the monodentate-N form, **I**. To our knowledge this is the first example containing mbt in a square-planar configuration as confirmed by X-ray analysis, although complexes with tetrahedral, square pyramidal, trigonal bipyramidal and octahedral geometries have all been reported previously [15–25]. Interestingly, when the monodentate tertiary phosphine is substituted by a 1,2-bidentate diphosphine, dppe, the six-coordinated Co^{II} complex **2** with a $CoP_2N_2S_2$ core in a distorted octahedron was formed.

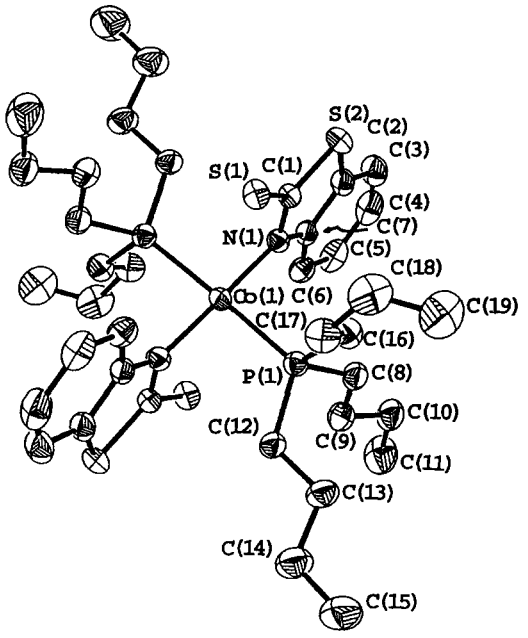

Fig. 1. Structure of Co(mbt-*N*)$_2$(PBu$^n_3$)$_2$ (**1**).

In this complex, the two mbt ligands coordinate to Co^{II} in bidentate-*N*:*S* form **III** with the S atoms in *trans* [S(1)—Co—S(3) 157.7(1)°] and N atoms in *cis* orientations [N(1)—Co—N(2) 92.4(1)°]. It is worthwhile noting that whether in **1** or **2**, with or without Co—S ligation, the C—S$_{exocyclic}$ distances remain within the range 1.68–1.69 Å, indicating that even with chelation of S to Co in **2**, the Co—S bond must be rather weak. This weak ligation is indeed shown by the longest average Co—S distance of 2.711 Å being found in **2**, of all the mbt-ligated complexes shown in Table 4. In general, the mbt ligand remains in the thione form after coordination.

The evidence for the formation of the four-membered chelate ring CoSCN in complex **2** comes from the decrease of the M—N—C(S) angle from 109.4° in **1** to 103.9°. The thiazole rings do not vary much between the two complexes, with N—C (to sulfur) averaging 1.32 Å, possessing a certain degree of double bond character and with N—C (to benzylidene) averaging 1.39 Å, more of a single bond. Since the N—C bond distance is 1.35 Å in the free ligand benzothiazole-2-thione [28] this is also considered evidence for delocalization in the ring system. The Co—P distance is shorter (by 0.08 Å) and Co—N longer (by 0.06 Å) in **2** compared with the corresponding bonds in **1**, probably owing to the different electronic effects of P and N atoms in square-planar or octahedral coordination sites. A definitive explanation for this result would be difficult before more complexes have been obtained for comparison. Comparing with the similarly octahedrally N:S-coordinated Cd complexes [Cd(mbt)$_3$] [24], Cd(mbt)$_2$(py)$_2$ [21], or Cd(mbt)$_2$(bipy) [22], complex **2** possesses the smallest M—S—C chelate angle (average 70.1°) and the largest M—N—C chelate angle (average 103.9°) within the four-membered chelate ring, as shown in Table 4.

The cyclic voltammograms of complexes **1** and **2** in both DMF and MeCN are depicted in Figs 3 and 4, respectively. The CV data are summarized in Table 5. Complex **1** in DMF showed two rather weak reductions (E_1 and E_2) probably caused by some impurities in addition to a strong reduction wave (E_3) at -1.25 V, which shifted 200 mV to -1.45 V and grew higher if the CV was measured after allowing the solution to stand under argon for 20 h. This phenomenon is presumably an indication of coordination of the complex by the coordinating solvent DMF, as complex **1** has the Co atom in a square-planar environment with two vacant sites available. Similarly, complex **1** in MeCN also showed a strong reduction peak (E_3) at -1.25 V which grew with time. This solvated, reduced species $[Co(mbt)\text{-}N)_2(PBu^n_3)_2(solvent)_2]$ underwent oxidation to give two waves (E_4 and E_5) at $+0.63$ and $+1.10$ V (in DMF) and -0.56 and $+0.54$ V (in MeCN), respectively. The electrochemical process could be expressed as follows:

$$[Co(mbt)_2(PBu^n_3)_2]^0 \xrightarrow{E_3}$$

$$[Co(mbt)_2(PBu^n_3)_2(solvent)_2]^{1-} \xrightarrow{E_4}$$

$$[Co(mbt)_2(PBu^n_3)_2(solvent)_2]^0 \xrightarrow{E_5}$$

$$[Co(mbt)_2(PBu^n_3)_2(solvent)_2]^{1+}$$

The six-coordinated complex **2** showed three pseudo-reversible redox couples in DMF with the two high potential couples (E_2 and E_3) merged into a broad irreversible reduction wave when the solvent is changed to the less polar MeCN, in which **2** is less soluble. In addition, two irreversible oxidation waves were observed similarly to **1**, in which the one near $+0.50$ V could be caused by dppe, as the free ligand has a similar wave in this region. The CV patterns of both complexes change with time, indicating that the redox behaviours are quite complicated in these solvating solvents, and also that decomposition or oxidation of complexes might also complicate the matter.

At 300 K, the effective magnetic moments μ_{eff} are 4.25 and 4.40 μ_B for **1** and **2**, respectively, both values are greater than the $S = \frac{3}{2}$ spin-only value (3.87 μ_B) and therefore indicate a fair amount of orbital contribution to both compounds. Upon decreasing the temperature, the μ_{eff} remains almost unchanged. Obviously, no appreciable intermolecular magnetic interactions or zero-field splitting effects are present in the two mononuclear cobalt(II) complexes. The EPR spectra of both complexes exhibit two signals with the g values being 2.03 and 4.75 for **1** and 2.16 and 5.32 for **2**, which are characteristic of square-planar and octahedral cobalt(II) ions with $S = \frac{3}{2}$, respectively [29].

(Received 24 May 1996; accepted 16 September 1996)

Abstract—X-ray structural analyses have been made on single crystals of *mer*(*N*)-[Co(5-dptma)$(NO_2)_2$] (**A**), *mer*(*N*)-[CoCl(5-dptma)(H_2O)] Br (**B**), *mer*(*N*)-[CoCl(5-dptma)(H_2O)]ClO_4 (**C**) and *mer*(*N*)-[CoCl(5-dptma)(H_2O)] NO_3 (**D**), where H(5-dptma) is *N*, *N*-bis(3-aminopropyl)glycine. Complex **A** crystallizes in the monoclinic space group $P2_1/c$ as a racemate; complex **B** in the monoclinic space group $P2_1/n$ as a racemate; complex **C** in the orthorhombic space group $P2_12_12_1$ as a conglomerate; and complex **D** in the orthorhombic space group $Pna2_1$ as a racemate. In these complexes, the tripod quadridentate 5-dptma coordinates to cobalt(III) with its three nitrogen atoms on a meridian of the coordination octahedron and with the six-membered chelate rings assuming the chair conformation. In **A** the molecular planes of the NO_2 ligands are anchored by intramolecular and intermolecular hydrogen bonds to the amine protons. The molecular planes of the aqua ligands in **B, C** and **D** are anchored by two intermolecular hydrogen bonds; one with the carbonyl oxygen atom and the other with the counter anion. © 1997 Elsevier Science Ltd. Keywords: crystal structure; aquachloro cobalt(III) complex; dinitro cobalt(III) complex; *N*,*N*-bis(3-aminopropyl)glycinato chelate; conglomerate; spontaneous resolution.

In our recent paper, we have described the preparation of several cobalt(III) complexes bearing the new quadridentate ligand 5-dptma, where 5-dptma is *N*,*N*-bis(3-aminopropyl)glycine, $(H_2NCH_2CH_2CH_2)_2NCH_2COOH$ [1]. In this report, we describe the X-ray crystal structures of four complexes: *mer*(*N*)-[Co(5-dptma)$(NO_2)_2$] (**A**), *mer*(*N*)-[CoCl(5-dptma)(H_2O)]Br (**B**), *mer*(*N*)-[CoCl(5-dptma)(H_2O)]ClO_4 (**C**), *mer*(*N*)-[CoCl(5-dptma)(H_2O)]NO_3 (**D**). We are interested in the chiral property of these crystals. It is well known that cobalt(III) complexes often dissolve spontaneously or crystallize as a conglomerate. For the positively charged dinitrotetraaminecobalt(III) complex, it has been pointed out that intramolecular hydrogen bonds between the NO_2 ligands and the adjacent amine proton lead to conglomerate formation, whereas blocking of such hydrogen bonds by counter anions leads to racemate formation [2]. In the present paper, we investigate the crystallization behaviour of the non-electrolyte dinitrocobalt(III) complex **A**, which is not accompanied by a counter anion. On the other hand we have recently reported the spontaneous resolution of two aquachloro complexes bearing tripod quadridentate ligands: *trans*(*O*)-[Co(aeida)Cl(H_2O)] and *mer*(*N*)-[CoCl(i-dtma)(H_2O)]ClO_4 (**E**), where H_2aeida is *N*-(2-aminoethyl)-*N*-(carboxymethyl)glycine and H(i-dtma) is *N*,*N*-bis(2-aminoethyl)glycine [3]. We expected additional examples of this type of complex to form a

conglomerate. Our present complex, **C**, is of similar constitution to **E**. The 5-dptma ligand is composed of two aminopropyl side chains and the i-dtma ligand is composed of two aminoethyl side chains. We have compared the crystallization behaviour of **C** and **E** and examined the effect of the variation of the counter anion on the crystallization behaviour of the *mer*(*N*)-$[CoCl(5\text{-dptma})(H_2O)]^+$.

EXPERIMENTAL

Preparation of the complexes

The complexes were prepared as described previously [1].

Structure determination

These were carried out as described elsewhere [3]. The refinement details are shown in Table 1. In the case of complex **C**, the maximum residual electron density in the difference Fourier map of the final model is rather high. However, it cannot be ascribed to a solvated water molecule, because the peak is only 1.5 Å from Cl(2). The oxygen atoms in the perchlorate ion have equivalent temperature factors (B_{eq}) greater than 12 Å^2, which suggested disorder or pseudo-rotation of the perchlorate ion. The rather large R (R_w) factor and S value may be attributed to this disorder or rotation.

Observation on the conglomerate for the crystal of **C**

Because of the D_2 crystal point group and $Z = 4$, the chirality has been examined by the test of the R factor ratio [4]. The R_w factor for the structure refinement without anomalous dispersion effects was 0.060 for 119 variables and 1445 observations. Inclusion of the anomalous dispersion gave the R_w factors of 0.0606 and 0.0667 for this and its enantiomeric structure, respectively, which yielded the R_{w_1}/R_{w_2} ratio of 1.10. The corresponding significance point is $R_{b,N,\ \alpha} = R_{1,1326,0.005} = 1.003$, so that the enantiomeric structure can be rejected with a probability greater than 99.5% [5]. This result has encouraged us to examine the spontaneous resolution. Selected 21 Bijvoet pairs (2θ range about 20°) were remeasured carefully within a scan speed of 4° min^{-1} (in ω), in which the equivalent reflections ($hkl, h-k-l, -hk-l, -h-kl$ and $-h-k-l, -hkl, h-kl, hk-l$) were averaged. A table for comparison of the intensities of the 21 Bijvoet pairs was prepared. Then, a second single crystal from the same batch was subjected to the same measurement and comparison. The signs of inequality for all the Bijvoet pairs of the second crystal have been reversed compared with

those of the first one. Thus, we have concluded that this complex salt crystallizes as a conglomerate.

RESULTS AND DISCUSSION

The molecular structures of *mer*(*N*)-[Co(5-dptma)$(NO_2)_2$] (**A**), *mer*(*N*)-[CoCl(5-dptma)(H_2O)]Br (**B**), *mer*(*N*)-[CoCl(5-dptma)(H_2O)]ClO_4 (**C**) and *mer*(*N*)-[CoCl(5-dptma)(H_2O)]NO_3 (**D**) are shown in Figs 1–4, respectively, with atomic-numbering systems. The bond lengths and angles are given in Table 2, with important hydrogen bonds listed in Table 3. In complexes **A**, **B**, **C** and **D**, the tripod quadridentate 5-dptma coordinates to cobalt(III) with its three nitrogen atoms on a meridian of the coordination octahedron [*mer*(*N*) coordination mode]. For complexes **A** and **C**, it conforms with the previous *mer*(*N*) assignment on the glycinato proton resonance spectra [1]. Complexes **A**, **B** and **D** crystallize as racemates, whereas **C** is a conglomerate.

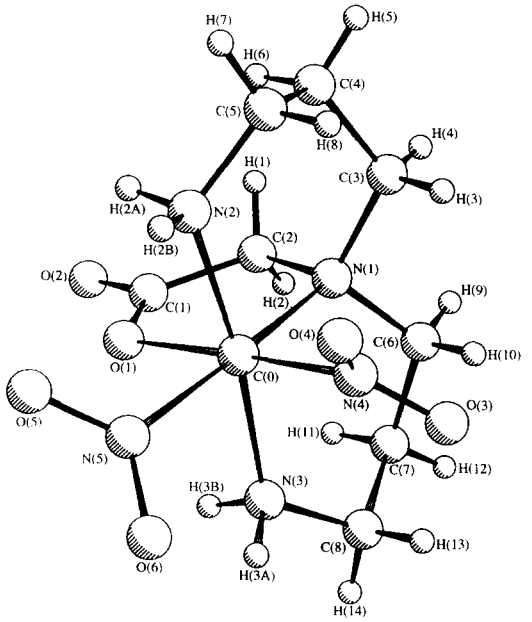

Fig. 1. Molecular structure of *mer*(*N*)-[Co(5-dptma)$(NO_2)_2$] (**A**) and the atomic numbering system.

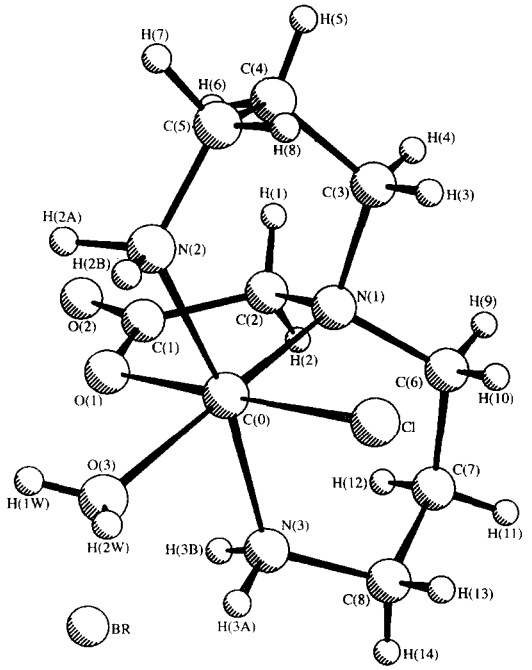

Fig. 2. Molecular structure of *mer*(*N*)-[CoCl(5-dptma)(H_2O)]Br (**B**) and the atomic numbering system.

In the crystal of **A**, the two NO_2 ligand planes are anchored through three intramolecular and two intermolecular hydrogen bonds to the amine protons (Table 3). Of the three aquachloro complex salts **B**, **C** and **D**, only the perchlorate salt **C** crystallizes as a conglomerate. In this case, the variation of the counter anion affects the crystallization behaviour. It is interesting that *mer*(*N*)-[CoCl(i-dtma)(H_2O)]ClO_4 (**E**) is also a perchlorate salt. Both **C** and **E** crystallize in the $P2_12_12_1$ space group as conglomerates, in spite of the different chelate ring constitution: a six-membered ring in **C** and a five-membered ring in **E**. All the six-membered chelate rings formed by the coordinating 5-dptma ligand assume the chair conformation in **A**–**D**. In **A**–**D**, the corresponding coordination bond lengths are of similar magnitudes to one another (Table 2). In **A** the Co—N(5) bond length is longer by 0.05 Å than the Co—N(4) length. The former bond, in the *trans* position to the Co tertiary amine bond, is weak. In this connection the derivation process of **C** from the dichloro precursor can be explained as follows [1]. In complex **C** the aqua ligand exists at the *trans* position to the tertiary amine (Fig. 3). One infers that the chloro ligand at the *trans* position to the tertiary amine may be labile in *mer*(*N*)-[$CoCl_2$(5-dptma)]. In complexes **A**–**D**, the corresponding bond lengths of the 5-dptma ligand are of similar magnitudes to one another. The N(1)—Co—N(2) angle (*ca* 93°) in **A** differs significantly from the corresponding angles (*ca* 98°) in **B**, **C** and **D**. However, these magnitudes are within the experimentally found N—Co—N angles 90–100° for a six-membered chair chelate [6–8]. The Co—N(1), Co—N(2) and Co—N(3) bond lengths in **C** are *ca* 0.04 Å longer than the corresponding ones in **E** [3]. This may be ascribed to the bulky six-membered chelate rings in **C**. In compensation for this the Co—O(3) bond length in **C** is shorter by *ca* 0.03 Å than the corresponding one in **E** [3]. The N(2)—Co—N(3) angle (167.4°) in **C** differs significantly from the corresponding angle (186.4°) in **E**, which may also be ascribed to the bulkiness of the six-membered chelate in **C**.

The molecular planes of the aqua ligands in **B**, **C** and **D** are anchored by two intermolecular hydrogen bonds; one with the carbonyl oxygen O(2) and the other with the counter anion (Table 3). In relation to these hydrogen bonds, O(3) atoms in **B**, **C** and **D** deviate by 0.16, 0.07 and 0.18 Å, respectively, from the plane defined by the Co, Cl, N(1) and O(1) atoms.

(Received 6 August 1996; accepted 12 September 1996)

Abstract—A new cyano-bridged polymeric mixed-valence Cu^{II}/Cu^{I} complex, $[Cu(dien)_2(CN)_2Cu(CN)]_n$ (**2**) (dien = diethylenetriamine) has been prepared by the partial reduction of the OH-bridged binuclear complex $[Cu_2(dien)_2(OH)](ClO_4)_3$ (**1**) with sodium cyanide. The X-ray crystal structure shows that **1** is a polymeric, linear mixed-valence Cu^{I}/Cu^{II} complex and consists of a one-dimensional three-coordinated $[Cu^{I}(CN)]_n$ chain, in which the Cu^{I} atoms are linked by two disordered CN bonding groups. The structure of each Cu^{II} atom consists of a square-pyramidal five-coordinate environment, in which the basal plane is formed by the three nitrogen atoms of the dien ligands and one carbon atom of the terminal cyanide group, and the apical position is occupied by the nitrogen atom of a bridging cyano ligand. This is the first example of one Cu^{II} centre coordinating with two different bonding types of the terminal Cu^{II}—CN and the bridging Cu^{II}—NC in a polymeric complex. The cryomagnetic behaviour has been investigated in the temperature range 4.2–300 K. There is a weak antiferromagnetic interaction between two intrachain copper(II) ions with $J = -0.47\ cm^{-1}$.

Keywords: Copper complexes; mixed-valence Cu^{I}/Cu^{II} complexes; polymeric copper complexes; X-ray structure; magnetic property.

It is well known that in aqueous solution copper(II) is easily reduced to copper(I) by cyanide and that simple C-bonded cyano complexes of copper(II) are unstable at normal temperatures with respect to reduction and cannot be isolated [1]. Nevertheless, it has been shown that by choosing ligands (e.g. amines) that have good σ-electron donor character and strongly prefer to coordinate to Cu^{II} rather than Cu^{I} ions, it is possible to stabilize the Cu^{II}—CN coordination bonding. To date, several such complexes have been reported: the mononuclear, $[Cu^{II}(phen)(CN)](NO_3)$ [2], $[Cu(bipy)_2(CN)])NO_3]$ [3], [Cu(cyclps)(CN)] [4], $[Cu(Me_6tren)(CN)](ClO_4)$ [5], the CN-bridged binuclear, $[Cu_2([14]\text{-}4,11,\text{-dien-}N_4)(CN)](ClO_4)$ [6], $[Cu_2(tren)(CN)_2](BPh_4)_2$ [7], and $[(Cu(Me_6tren))_2(CN)](ClO_4)$ [5], and the CN-bridged polynuclear $[Cu(Me_5\text{-dien})(CN)]_n(CF_3SO_3)_n$ [5]. In addition, a few cyano-bridged Cu^{I}/Cu^{II} mixed-valence complexes of $[Cu(en)_2][Cu_2(CN)_5H_2O]$ [8] $[Cu^{II}(en)_2]_3[Cu^{I}_6(CN)_6(SeCN)_6]$ [9], and $[Cu_2(L)(CN)](ClO_4)_2$ (L = N,S-containing macrocyclic ligand) [10] have been reported, but there are no cyanide groups directly coordinated to the Cu^{II} ion as C-bonded Cu^{II}—CN in these complexes. Most recently, a series of model molecular complexes of cytochrome-*c* oxidase containing the $[Fe^{III}$—CN—$Cu^{II}]$ bridge unit has been prepared by Holm *et al.* [5,11] and structurally characterized, but there are no stable C-bonded Cu^{II}—CN of $[Fe^{III}$—CN—$Cu^{II}]$ fragments reported in this series. Furthermore, to the best of our knowledge, only one example of a Cu^{II}/Cu^{I} mixed-valence stable polymer complex, $[Cu^{I}_4(CN)_6Cu^{II}(NH_3)_2]_n$ with cyano-bridged Cu^{I}—CN—Cu^{II} prepared from the reaction of $[Cu^{I}CN]$ with $[Cu^{II}(NH_3)_4]^{2+}$, has been reported [12]. In this example the two copper(I) units, a linear

* Author to whom correspondence should be addressed.

$[Cu(CN)_2]$ chain and a trigonal $[Cu(CN)_3]$ chain are bridged by cyanide ligands and there was no magnetic interaction between the Cu^{II} ions.

Undoubtedly the stable copper(II)–cyanide linkage formation is dependent on the chemical reduction process and the types of ligands that will stabilize coordination of cyanide [1]. The aim of this paper is to deal with the first example of the cyano-bridged polymeric mixed-valence complex $[Cu^{II}(dien)(CN)_2Cu^{I}(CN)]_n$ (**2**) (dien = diethylenetriamine) with a very unusual five-coordination of Cu^{II} containing a terminal C-bond Cu^{II}—CN and a bridging Cu^{II}—NC—Cu^{I} bonding. This compound was prepared by the reduction of the known OH-bridged binuclear complex $[Cu^{II}(dien)_2(OH)](ClO_4)_3$ (**1**) with sodium cyanide in methanol. The preparation, structural and cryomagnetic studies of this binuclear complex **1** have been reported [13,14]. The structure of $[Cu^{II}(dien)_2(OH)](ClO_4)_3$ consists of a discrete binuclear molecule where the two copper(II) atoms are bridged by a single OH group with Cu^{II}—OH—Cu^{II} angles of 128° and an intramolecular Cu^{II}—Cu^{II} distance of 3.43 Å and weaker interactions with oxygens from three perchlorate ions, with a strong antiferromagnetic interaction between two copper(II) ions. We chose this OH-bridged binuclear copper(II) complex for reduction with NaCN since from the viewpoint of the dien ligand in **1** it has the capability to stabilize Cu^{II}—CN bonding and also because such a complex would be relevant to the development of model systems for active sites of biological interest [15]. Additionally, cyanide is an irreversible inhibitor of the copper-oxidized enzymes; specifically, its toxicity has been traced to bimetallic oxidases such as cytochrome-*c* oxidase [16] and a haemocyanin [17]. Herein the preparation, X-ray crystal structure, spectroscopic and magnetic properties of the complex **2** are reported. In addition, for comparison, the structure of the OH-bridged binuclear complex **1** was reconfirmed by X-ray crystallographic analysis.

EXPERIMENTAL

Preparation of complexes

$[Cu_2(dien)_2(OH)](ClO_4)_3$ (**1**) was prepared following the method initially described by Curtis and Powell [13]. To a solution of $Cu(ClO_4)\cdot 6H_2O$ (1 mmol) in water (10 cm^3) were added diethylenetriamine (dien) in ethanol (15 cm^3). The resulting blue solution changed to blue-violet on adding of $Na_2CO_3\cdot 10H_2O$ (5 mmol). Deep blue-violet crystals of $[Cu_2(dien)_2(OH)](ClO_4)_3$ were obtained by slow evaporation at room temperature. These were collected by filtration, washed with water and air dried. Found: C, 15.0; H, 4.0; N, 12.9. Calc. for $C_8H_{17}N_6O_{13}Cl_3Cu_2$: C, 14.8; H, 4.2, N, 13.0%.

$[Cu(dien)(CN)_2Cu(CN)]_n$ (**2**). To a solution of $[Cu_2(dien)_2(OH)](ClO_4)_3$ (**1**) (30 mg, 0.04 mmol) in methanol were added 15 cm^3 of methanol containing an excess amount (18 mg) of NaCN. During the addition of NaCN the solution turned to light blue with subsequent precipitation of a white substance. The mixture was filtered off and the light blue filtrate was transferred to a beaker and allowed to stand at ambient temperature. After several days well-formed light blue crystals suitable for X-ray analysis were isolated, filtered off and dried *in vacuo*. Found: C, 31.4; H, 4.1; N, 22.6. Calc. for $C_7H_{13}N_6Cu_2$: C, 31.4; H, 4.3; N, 22.6%.

Physical measurements

Infrared spectra were recorded on a Bio-Rad FTS-40FTIR spectrophotometer as KBr pellets in the 4000–400 cm^{-1} region. *X*-band (9.8 GHz) EPR spectra at 298 K were recorded on a Bruker ECS-106 spectrometer. Cryomagnetic susceptibilities of the polycrystalline samples were measured between 4.2 and 300 K at a field of 1 T using a Quantum Design Model MPMS computer-controlled SQUID magnetometer. Diamagnetic corrections were made using Pascal's constants.

Crystal structure determinations for **1** *and* **2**

The X-ray crystallographic data of a dark blue crystal (0.40 mm × 0.45 mm × 0.60 mm) of **1** and a light blue plate (0.35 mm × 0.45 mm × 0.45 mm) of **2**, were collected with graphite-monochromatized Mo-K_α radiation at 25°C using an Enraf–Nonius CAD-4 diffractomer, and are given in Table 1. Cell parameters were calculated from the least-squares fitting of setting angles for 25 reflections. The ω–2θ scan technique to

a $2\theta_{max}$ value of 55.0° for **1** and 160.0° for **2** was used. A total of 2736 reflections for **1** and 1830 for **2** were measured, of which 2730 for **1** and 1830 for **2** with $I > 2.0\sigma(I)$, were used in further calculations. The structures were solved by the heavy-atom method. Full-matrix least-squares anisotropic refinement for all non-hydrogen atoms yielded $R_f = 0.054$, $R_w = 0.065$ and *GOF* (goodness-of-fit) = 2.11 for **1** and $R_f = 0.026$, $R_w = 0.026$ and $GOF = 16$ at convergence. All calculations were performed using the NRCVAX computer crystallographic software package [18]. Disorder was observed in the chain-bridging cyano groups of **2**. Selected bond distances and angles for **1** and **2** are given in Tables 2 and 3, respectively. Complete crystal data, atomic coordinates, full listings of bond distances and angles and the anisotropic thermal parameters for **1** and **2** are available as supplementary material, and have been deposited at the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

The chemical reduction of $[Cu_2(dien)_2(OH)](ClO_4)_3$ (**1**) in excess methanolic solution of NaCN yielded a one-dimensional chain structured Cu^{I}/Cu^{II} mixed-valence complex, $[Cu^{II}(dien)(CN)_2Cu^{I}(CN)]_n$ (**2**) and some white solid identified as $NaClO_4$. Complex **2** was isolated in low yield (*ca* 20%), but was air stable in solution and in the solid state for a long period.

IR spectra

The most relevant IR feature is the presence of bridging and terminally bound CN stretching vibrations. In general, the ν(CN) frequency should be significantly greater for the bridging case than for the terminal one. Therefore, complex **2** exhibits very sharp double ν(CN) bands at 2133 and 2118 cm^{-1} in KBr, suggestive of the absorptions for the bridging CN and the terminal CN stretching vibrations, respectively [5–7,11].

Description of the structures

The structure of **1** (as shown in Fig. 1) consists of a binuclear $[Cu_2(dien)_2(OH)]^{3+}$ cation with three ClO_4^- anions, which is the same as previously found [14]. Nevertheless, in our system, only one ClO_4^- group oxygen atom was coordinated to the Cu^{II} centre with a Cu(2)—O(2) bond distance of 2.481(9) Å and the oxygens of the other two ClO_4^- groups interact

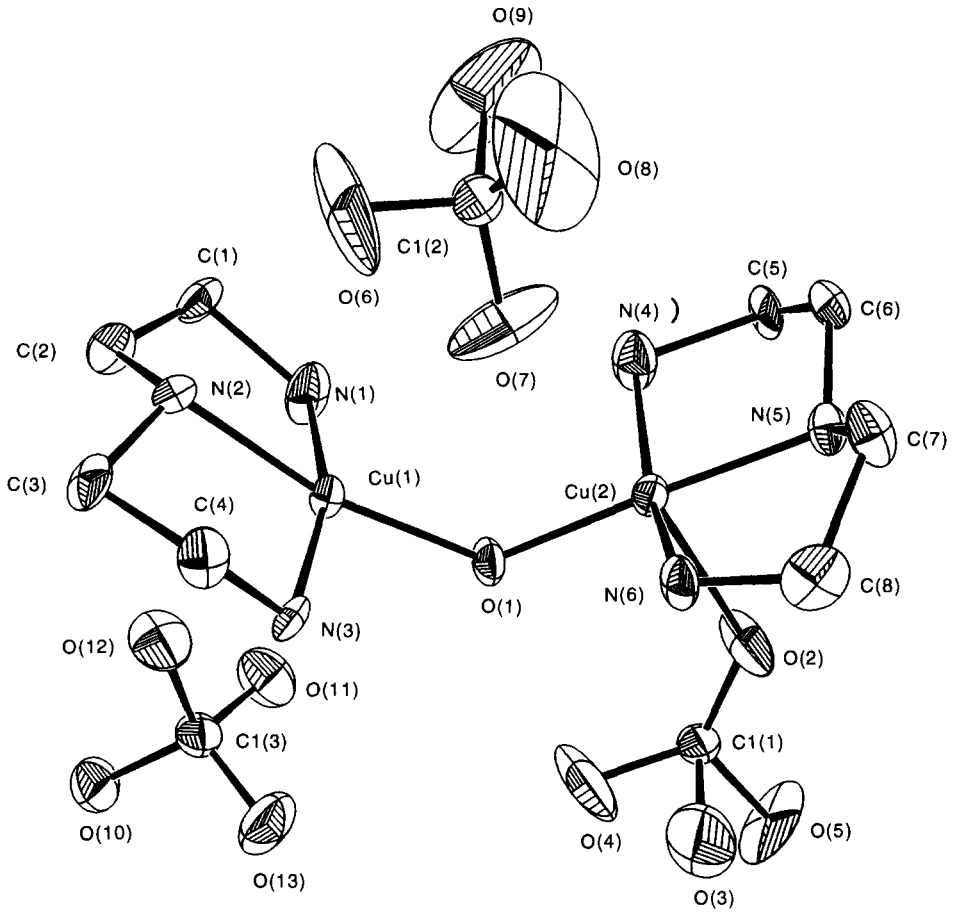

Fig. 1. ORTEP stereoview of $[Cu_2(dien)_2(OH)](ClO_4)_3$ (**1**) with atom-numbering scheme and vibrational ellipsoids at the 30% probability level.

only with Cu^{II}. These $Cu\cdots OClO_3$ interactions are very weak, at 2.608(10) [Cu(1)—O(12)], 2.746(14) [Cu(2)—O(7)] and 2.894(21) Å [Cu(1)—O(7)], and are probably electrostatic rather than covalent. The two copper atoms are bridged by a hydroxo group with the Cu(1)—OH—Cu(2) angle of 129.1(4)° and the intermolecular Cu(1)—Cu(2) separation of 3.4320(17) Å being close to those previously reported by Julve and co-workers [14]. The bridging Cu—O distances of 1.893(10) and 1.960(7) for Cu(1)—O(1) and Cu(2)—O(1), respectively agree closely with those previously reported [14].

The structure of the title compound $[Cu^{II}(dien)(CN)_2Cu^{I}(CN)]_n$ (**2**) consists of a one-dimensional skeleton formed by the polymeric mixed-valence Cu^{I}/Cu^{II} chain through the cyanide bridges as shown in Figs 2 and 3. The layer structure of this polymer is illustrated in Fig. 4. As shown in Fig. 2, the copper(II) atom, Cu(2), takes a distorted square-pyramidal coordination with three nitrogen atoms of the dien ligand, one carbon atom of the terminal CN ion and a nitrogen atom of CN in the apical position, which is linked with the copper(I) atom of the polymer chain. In the polymer chain, the copper atom, Cu(1), is in trigonal-planar coordination (three C—Cu^{I}—C bond angles are 120°) with D_{3h} symmetry.

It is important to note that due to static disorder, in the bridging CN groups with Cu^{I} the Cu^{I} atom bonded as Cu—CN, and the other bonded as Cu—NC, are almost identical; this means that discrimination between the N and C atoms of the N group linking the Cu^{I} centres is impossible, and they are assumed to have 50% probability for each of the C and N designated as NC, in the structure refinement. The bond length of NC—NCb 1.138(4) Å is slightly longer than that of 1.127(4) Å for C(4)—N(4) which link with the Cu^{II} atom. In the Cu^{II} site, the Cu^{II}—C(3) distance of 1.971(3) Å found here compares favourably with the distances found in the other C-bond Cu^{II}—CN complexes mentioned above [2–7]. The Cu(2)—N(CN) bond length of 2.171 Å is significantly longer than the mean Cu(2)—N(dien) bond length

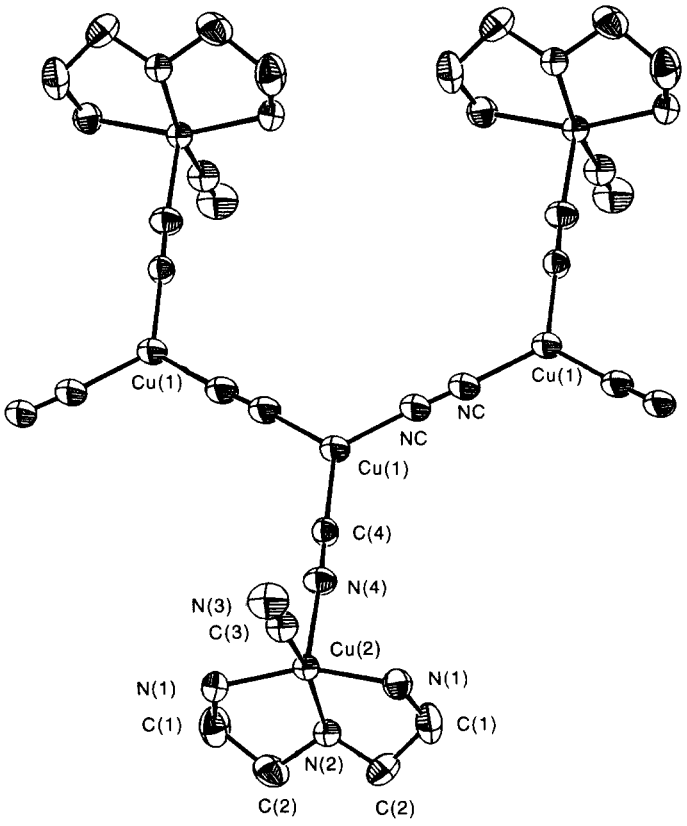

Fig. 2. ORTEP stereoview of $[Cu(dien)(CN)_2Cu(CN)]_n$ (**2**) with atom-numbering scheme and vibrational ellipsoids at the 30% probability level.

of 2.038 Å, which is within the normal range. The C(3)—N(3) bond length of 1.133(5) Å of the bridging CN is slightly longer than the terminal N(4)—C(4) distance of 1.127(4) Å. The nearest intrachain and interchain Cu^{II}—Cu^{II} separations are 6.2214(13) and 7.124(3) Å, respectively, and are likely to cause a very weak magnetic interaction between two copper(II) ions.

Magnetic properties

The *X*-band (9.8 GHz) polycrystalline EPR spectrum at 298 K for **2** was found to exhibit an axially elongated pyramidal copper(II) centre, with $g_{\parallel} = 2.21$ and $g_{\perp} = 2.03$. Magnetic susceptibility measurements from 300 to 4.2 K have been made for complex **2** as shown in Fig. 5, as the effective moments μ_{eff} and χ_m *vs.* *T*. In the temperature range studied, the μ_{eff} value of 2.10 μ_B at 300 K is slightly lower than the value of 2.45 μ_B expected for a non-coupled, two $S = \frac{1}{2}$ spin system, and decreases slowly with decreasing temperature, reaching 1.44 μ_B at 4.2 K. This decrease can be owing to intramolecular and/or intermolecular antiferromagnetic exchange interactions between the nearest Cu^{II} ions. Although there is not a detailed model for our complex mixed-valence system, we tried to reproduce the susceptibility of this compound by a modified Bleaney–Bowers susceptibility expression for the two-spin systems of $S = \frac{1}{2}$

$$\chi_m = 2Ng^2\beta^2/k(T-\theta)[\{1/(3+x^{-1})](1-\rho)\} + \rho/4] + N, \quad (1)$$

$x = \exp(-J/kT)$, the parameter θ is the Curie–Weiss constant, which accounts the intermolecular interaction between Cu^{II}—Cu^{II} of the interchain, let $\theta = zJ'$ (interchain coupling parameter) [19], ρ is the fraction of mononuclear paramagnetic impurity, N_z is the temperature-independent paramagnetism and the other symbols have their usual meaning. Where we have assumed the isotropic g value in calculation, the best result of the least squares fitting to Eq. (1) gives $g_i = 2.12$ (obtained from averaged g value of EPR data), $J = -0.47\ cm^{-1}$, $zJ' = -0.26\ cm^{-1}$, $\rho = 0.06$ and $N_z = 200 \times 10^{-6}\ cm^3\ mol^{-1}$. Figure 5 illustrates a plot of χ_m and μ_{eff} *vs.* *T* for **2**, with the solid line corresponding to the fitted parameters quoted above. The values of $J = -0.47\ cm^{-1}$ and $zJ' = -0.26\ cm^{-1}$

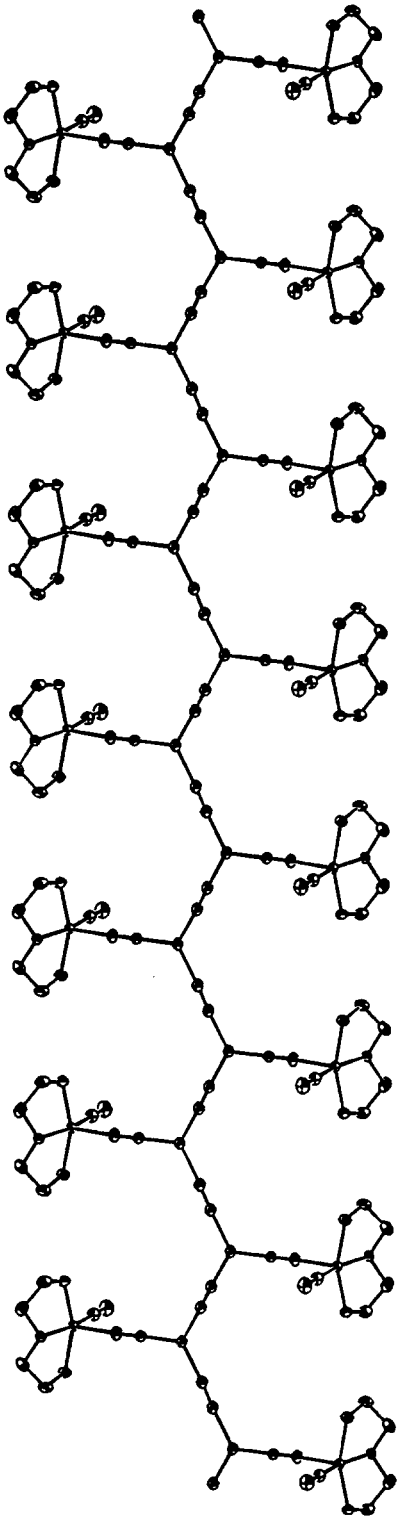

Fig. 3. View of the one-dimensional polymeric chain of **2**.

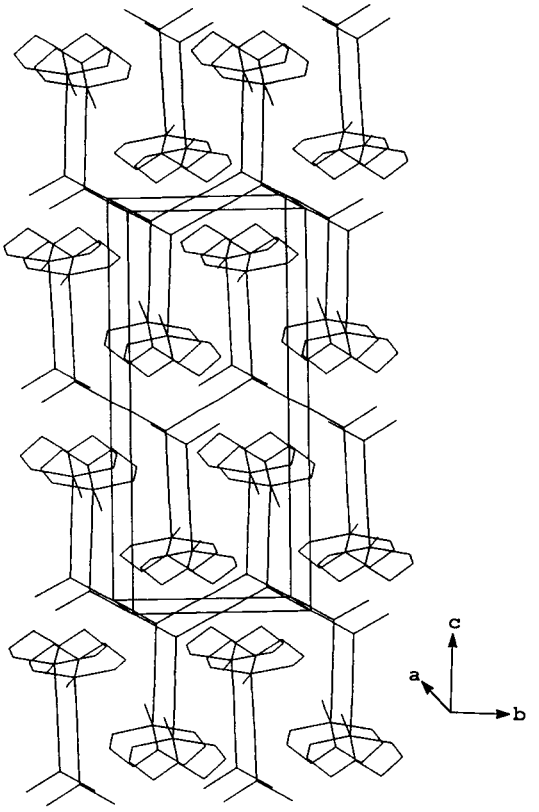

Fig. 4. Interchain molecular arrangement in the crystal of **2**, showing the layer structure.

are relatively much smaller, these may be due to a large separation, 6.22 and 7.12 Å, of the nearest magnetic Cu^{II} ions of the intrachain (through —NC—Cu^{I}—CN—bridge) and the interchain [through Cu^{II}—CN···NH(dien)Cu^{II} interaction] respectively, in **2**.

In summary, **2** is a new example of a mixed-valence Cu^{I}/Cu^{II} polymeric complex with the stable Cu^{II}—CN and Cu^{II}—NC bondings that resulted from the direct partial reduction of the OH-bridged binuclear copper(II) complex **1** by NaCN. The terminal C-bonded Cu^{II}—CN is stabilized by three nitrogen atoms of the dien ligand and one nitrogen atom of the bridged NC—Cu^{I}. Although the detailed mechanistic aspects for the partial reduction for the present system and related systems were not elucidated at present, this work is in progress.

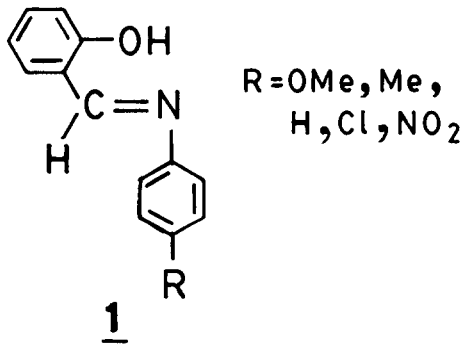
Chemistry of ruthenium phenolates. Synthesis, characterization and redox properties of a group of salicylaldiminato complexes of ruthenium

Nimai Chand Pramanik and Samaresh Bhattacharya*



Department of Chemistry, Inorganic Chemistry Section, Jadavpur University, Calcutta 700 032, India

(Received 18 June 1996; accepted 16 August 1996)

Abstract—A group of five mixed ligand ruthenium(II) complexes of general formula $[Ru(bpy)(sal\text{-}R)_2]$ (bby = 2,2′-bipyridine, sal-R = salicylaldiminate anion) has been synthesized and characterized. The complexes are diamagnetic (low spin d^6, $S = 0$) and show intense MLCT transitions in the visible region in solution. In acetonitrile solution they all show a reversible ruthenium(II)–ruthenium(III) oxidation in the range −0.3 to 0.04 V versus SCE, followed by another reversible ruthenium(III)–ruthenium(IV) oxidation in the range 1.1 to 1.3 V versus SCE. The potential of these two oxidations is sensitive to the nature of the substituent R in the sal-R ligand. A reversible bpy reduction is also observed near −1.9 V versus SCE. The five $[Ru^{III}(bpy)(sal\text{-}R)_2]^+$ complexes have been synthesized by chemical oxidation of their respective ruthenium(II) precursors by iodine, and isolated as perchlorate salts. These oxidized complexes are paramagnetic (low spin d^5, $S = 1/2$) and show rhombic ESR spectra at 77 K. They show intense LMCT transitions in the visible region in acetonitrile solution, together with weak ligand-field transitions at lower energies. Chemical reduction of these ruthenium(III) complexes by hydrazine gives back the parent ruthenium(II) complexes. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: ruthenium salicylaldiminates; synthesis; characterization; redox properties.

The present work has originated from our interest in the chemistry of ruthenium in different coordination environments in general [1], and the chemistry of ruthenium phenolates in particular [2]. In the present study we have used salicylaldimine, abbreviated in general as Hsal-R (**1**; where H stands for the dissociable phenolic proton), as the principal ligand.

1

The two donor atoms of this ligand are of opposite natures. The phenolate oxygen is a hard donor and is known to stabilize the higher oxidation states of ruthenium [3], whereas the imine nitrogen is relatively much softer and is a recognized stabilizer of the lower oxidation states of this metal [4]. It is interesting to note that the chemistry of ruthenium salicylaldiminates has not been much explored [2c–e,5]. However, in all known ruthenium salicylaldiminate complexes, the effect of phenolate oxygen coordination is seen to win over that of imine nitrogen coordination. For example, in the tris-salicylaldiminate complexes, the trivalent state of ruthenium is highly stabilized, which is reflected in the low ruthenium(III)–ruthenium(II) reduction potential [5a]. This also indicates that chelation by salicylaldiminate alone can not stabilize the +2 state of ruthenium, and in order to have a stable salicylaldiminate complex of ruthenium(II) at least one of the three salicylaldiminate ligands of $[Ru(sal\text{-}R)_3]$ needs to be replaced by a strong π-acid ligand. In this context we wish to report here the chemistry of some

* Author to whom correspondence should be addressed.

bis-salicylaldiminate complexes of ruthenium. To satisfy the remaining two coordination sites of the $Ru(sal\text{-}R)_2$ moiety, 2,2′-bipyridine (bpy), which is a familiar stabilizer of ruthenium(II), has been used as the coligand. The synthesis, characterization and redox properties of a group of $[Ru(bpy)(sal\text{-}R)_2]$ complexes are described in this paper.

EXPERIMENTAL

Materials

Commercial ruthenium trichloride, purchased from Arora Matthey, Calcutta, India, was converted to $RuCl_3 \cdot 3H_2O$ by repeated evaporation to dryness with concentrated hydrochloric acid. 2,2′-Bipyridine was purchased from Loba, Bombay, India. $[Ru(bpy)Cl_3]$ was synthesized following a reported procedure [6]. The salicylaldimine ligands were prepared by reacting equimolar amounts of salicylaldehyde and the respective amine in hot ethanol. Purification of acetonitrile and preparation of tetraethylammonium perchlorate (TEAP) for electrochemical work were performed as reported in the literature [7]. All other chemicals and solvents were reagent grade commercial materials and were used as received.

Preparation of complexes

The $[Ru^{II}(bpy)(sal\text{-}R)_2]$ and $[Ru^{III}(bpy)(sal\text{-}R)_2]ClO_4$ complexes were synthesized following two general methods. Details are given for two representative cases only.

$[Ru^{II}(bpy)(sal\text{-}H)_2]$. $[Ru(bpy)Cl_3]$ (100 mg, 0.28 mmol) was suspended in ethanol (40 cm^3) and Hsal-H (135 mg, 0.69 mmol) was added to it, followed by an ethanolic solution of NaOH (28 mg, 0.70 mmol). The mixture was refluxed for 3 h under nitrogen. The solvent was then evaporated and the solid mass thus obtained was washed thoroughly with water followed by hexane, and dried *in vacuo* over P_4O_{10}. Recrystallization from a 1:1 dichloromethane/hexane solution gave $[Ru(bpy)(sal\text{-}H)_2]$ as a dark brown crystalline solid. Yield: 140 mg, 72%.

CAUTION ! Perchlorate salts of metal complexes are potentially explosive. Care should be taken in handling such samples.

$[Ru^{III}(bpy)(sal\text{-}H)_2]ClO_4$. $[Ru(bpy)(sal\text{-}H)_2]$ (100 mg, 0.154 mmol) was dissolved in acetonitrile (30 cm^3) and to it was added a solution of iodine (40 mg, 0.16 mmol) in acetonitrile. The resulting solution was stirred for 15 min. The initial dark brown colour turned to deep green within 5 min. A saturated aqueous solution of $NaClO_4$ (10 cm^3) was then added and the solution was kept in the refrigerator for 24 h. $[Ru(bpy)(sal\text{-}H)_2]ClO_4$ precipitated as a deep green microcrystalline solid which was collected by filtration, washed with cold water and dried *in vacuo* over P_4O_{10}. Yield 80 mg, 69%.

Physical measurements

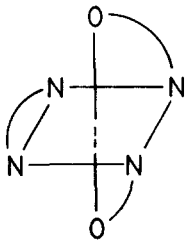
Microanalyses (C, H, N) were performed using a Perkin–Elmer 240C elemental analyser. IR spectra were obtained on a Perkin–Elmer 783 spectrometer with samples prepared as KBr pellets. Electronic spectra were recorded on a Hitachi U-3400 spectrophotometer. Magnetic susceptibilities were measured using a PAR 155 vibrating sample magnetometer. ^1H NMR spectra were obtained on a Hitachi R-60 FT-NMR spectrometer using TMS as the internal standard. X-band ESR spectra were recorded on a Varian E-109C spectrometer fitted with a quartz Dewar for measurement at 77 K (liquid nitrogen) and the spectra were calibrated with DPPH ($g = 2.0037$). Solution electrical conductivities were measured using a Philips PR9500 bridge with a solute concentration of 10^{-3} M. Electrochemical measurements were made using the PAR model 370-4 electrochemistry system incorporating the following components: 174A polarographic analyser, 175 universal programmer, RE0074 X-Y recorder, 173 potentiostat, 179 digital coulometer, 377 cell system. All electrochemical experiments were performed under dinitrogen. A planar Beckman 39273 platinum inlay working electrode, a platinum wire auxiliary electrode and an aqueous saturated calomel reference electrode (SCE) were used in a three-electrode configuration. A platinum wire gauge working electrode was used in the coulometric experiments. All electrochemical data were collected at 298 K and are uncorrected for junction potentials.

RESULTS AND DISCUSSION

Synthesis and characterization

The reaction of $[Ru(bpy)Cl_3]$ with the salicylaldimines proceeds smoothly in refluxing ethanol in the presence of NaOH to afford the $[Ru(bpy)(sal\text{-}R)_2]$ complexes in good yields [Eq. (1)]. It may be noted here that during the course of this synthetic reaction, ruthenium undergoes a one-electron reduction.

$$[Ru(bpy)Cl_3] \xrightarrow[EtOH]{HL,NaOH} [Ru(bpy)(sal\text{-}R)_2] \quad (1)$$



The solvent may serve as the reductant. Using five different Hsal-R ligands, five such complexes have been synthesized. The compositions of these complexes have been confirmed by their elemental (C, H, N) analytical data (Table 1). Magnetic susceptibility measurements show that all these complexes are diamagnetic, as expected for complexes of ruthenium(II) (low spin d^6, $S = 0$).

As the salicylaldiminate ion is an unsymmetrical bidentate ligand, $[Ru(bpy)(sal\text{-}R)_2]$ complexes may exist in three different geometrical isomeric forms, **2**, **3** and **4**. Both **2** and **3** have a C_2 axis, which indicates

4

that the two sal-R ligands and the two pyridine rings of bpy are equivalent. In the case of **4**, there is no C_2 axis and hence all the hydrogens present in the complex may give rise to separate ^{1}H NMR signals (provided no overlap of signals occur). The ^{1}H NMR spectrum of [Ru(bpy)(sal-OMe)$_2$], recorded in $CDCl_3$ solution, shows two methyl signals of equal intensity at δ 3.58 and 3.74. This clearly shows that this complex has structure **4**. Similarly, two equally intense methyl signals are observed at δ 1.83 and 2.08 in the ^{1}H NMR spectrum of [Ru(bpy)(sal-Me)$_2$], indicating the same stereochemistry, **4**, for this complex. Therefore we assume structure **4** for all five [Ru(bpy)(sal-R)$_2$] complexes.

The [Ru(bpy)(sal-R)$_2$] complexes are soluble in acetonitrile, dichloromethane, chloroform, *etc.*, producing intense brown solutions. Conductivity measurements show that these complexes are non-electrolytes in solution, as expected. The electronic spectra have been recorded in acetonitrile solution and spectral data are given in Table 1 and selected spectrum is shown in Fig. 1. All five complexes show several intense absorptions in the visible region, which are due to allowed metal-to-ligand charge-transfer transitions. Multiple charge-transfer transitions in these complexes may result from lower symmetry splitting of the metal level, the presence of different acceptor orbitals and the mixing of singlet and triplet configurations in the excited state through spin–orbit coupling [8]. Such spectral behaviour has been observed before in similar mixed ligand complexes [1d].

Cyclic voltammetric studies

The electron transfer properties of the [Ru(bpy)(sal-R)$_2$] complexes have been studied in acetonitrile solution by cyclic voltammetry. Vol-

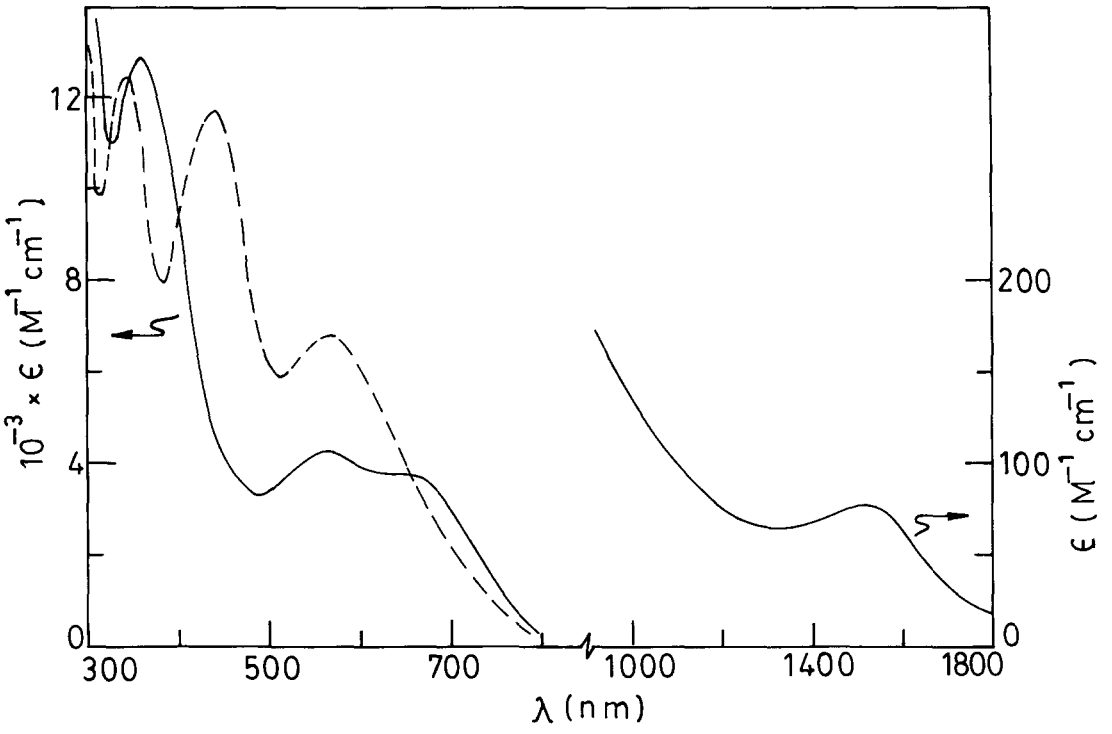

Fig. 1. Electronic spectra of $[Ru^{II}(bpy)(sal\text{-}H)_2]$ (– – –) and $[Ru^{III}(bpy)(sal\text{-}H)_2]ClO_4$ (——) in acetonitrile solution.

tammetric data are presented in Table 1 and a representative voltammogram is shown in Fig. 2. All these complexes show three voltammetric responses, two metal-centred oxidations and one ligand (bpy)-based reduction. We shall first consider the ligand-based reduction. A one-electron reduction near −1.9 V (all potentials are referenced to SCE) is displayed by all these complexes which is assigned to the reduction of the coordinated bpy [Eq. (2)].

$$[Ru^{II}(bpy)(sal\text{-}R)_2] + e^- \rightleftharpoons [Ru^{II}(bpy)(sal\text{-}R)_2]^- \quad (2)$$

The one-electron nature of this couple has been established by comparing its current heights with those of the ruthenium(II)–ruthenium(III) couple displayed by all these complexes near −0.1 V (see below). It is well known [9] that each bpy can successively accept two electrons in its lowest unoccupied molecular orbital. Hence, in these [Ru (bpy)(sal-$R)_2$] complexes two successive one-electron reductions are expected of which only the first reduction is actually observed. The second reduction, which is expected to occur at much more negative potentials, is not observed owing to solvent cut-off.

The metal-centred oxidations will now be

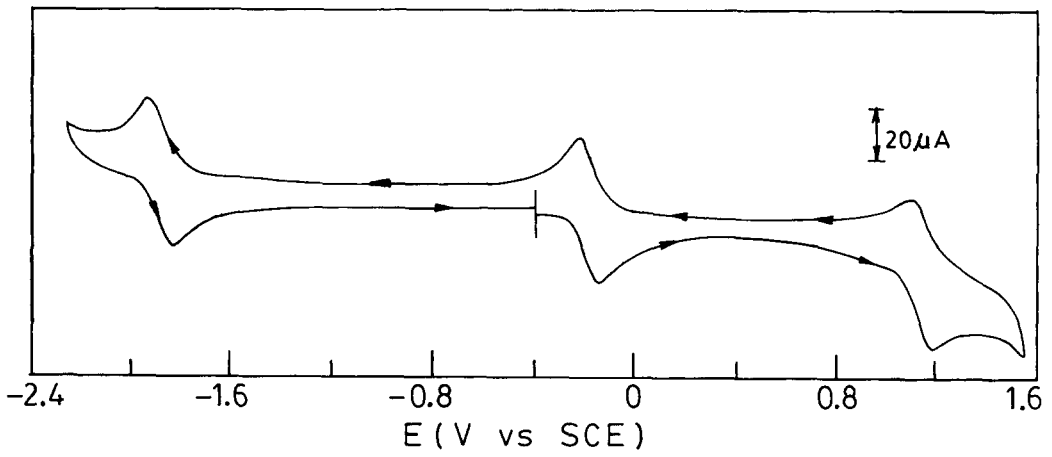

Fig. 2. Cyclic voltammogram of $[Ru^{II}(bpy)(sal\text{-}H)_2]$ in acetonitrile solution (0.1 M TEAP) at a scan rate of 50 mV s^{-1}. The solute concentration was 1×10^{-3} M.

considered. All these complexes show a reversible one-electron oxidation in the range −0.26 to 0.04 V, which is assigned to the ruthenium(II)–ruthenium(III) oxidation [Eq. (3)].

$$[Ru^{II}(bpy)(sal\text{-}R)_2] \rightleftharpoons [Ru^{III}(bpy)(sal\text{-}R)_2]^+ + e^- \quad (3)$$

Therefore the replacement of only one sal-R ligand of $[Ru(sal\text{-}R)_3]$ by bpy has indeed caused a significant increase in the stability of the +2 state of ruthenium. For example, the ruthenium(II)–ruthenium(III) couple is observed at −0.83 V in $[Ru(sal\text{-}H)_3]$ [5a], while the same couple appears at −0.17 V in $[Ru(bpy)(sal\text{-}H)_2]$. The positive shift of 660 mV reflects the ability of bpy to stabilize the bivalent state of ruthenium. It is interesting to note here that a gradual decrease in the potential of the ruthenium(II)–ruthenium(III) couple is observed in the series: $[Ru(bpy)_3]^{2+}$, 1.30 V [10]; $[Ru(bpy)_2(sal\text{-}H)]^+$, 0.63 V [2d]; $[Ru(bpy)(sal\text{-}H)_2]$, −0.17 V; $[Ru(sal\text{-}H)_3]$, −0.83V [5a]. The plot of these E^0_{298} values versus the number of bpy ligands in these $[Ru(bpy)_n(sal\text{-}H)_{3-n}]$ ($n = 0, 1, 2, 3$) complexes is linear (Fig. 3). A similar linear plot is obtained in any other $[Ru(bpy)_n(sal\text{-}R)_{3-n}]$ series. This correlation shows the relative ability of the sal-R and bpy ligands to stabilize the +3 and +2 states of ruthenium.

The potential of the ruthenium(II)–ruthenium(III) couple in the $[Ru(bpy)(sal\text{-}R)_2]$ complexes is found to be sensitive to the nature of the substituent R in the salicylaldiminate ligand. The formal potential (E^0_{298}) increases with increasing electron withdrawing character of R. The plot of E^0_{298} versus 2σ [σ = Hammett constant of R [11]; OMe = −0.27, Me = −0.17, H = 0.0, Cl = 0.23 and NO_2 = 0.78] is linear (Fig. 4) with $\rho = 0.14$ V (ρ = reaction constant of this couple [12]). It is clear from this plot that a single substituent on the sal-R ligand, which is six bonds away from the electroactive metal centre, can influence the metal oxidation potential in a predictable manner.

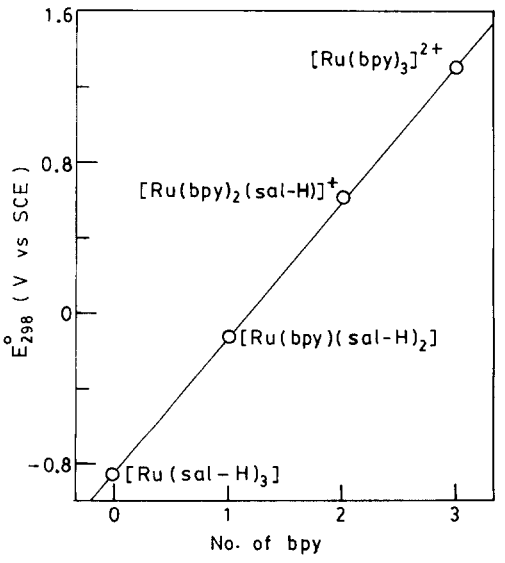

Fig. 3. Variation of ruthenium(II)–ruthenium(III) potential in $[Ru(bpy)_n(sal\text{-}H)_{3-n}]$.

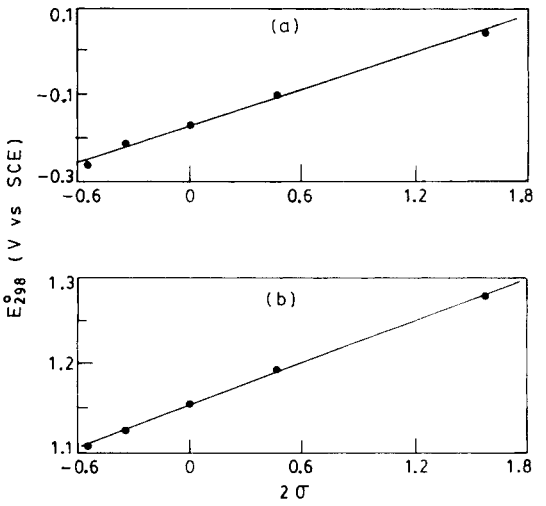

Fig. 4. Least-squares plot of E^0_{298} values of (a) Ru^{II}/Ru^{III} couple *versus* 2σ and (b) Ru^{III}/Ru^{IV} couple *versus* 2σ.

All the $[Ru(bpy)(sal\text{-}R)_2]$ complexes show a second, reversible one-electron oxidation in the range 1.1–1.3 V which is assigned to the ruthenium(III)–ruthenium(IV) oxidation [Eq. (4)].

$$[Ru^{III}(bpy)(sal\text{-}R)_2]^+ \rightleftharpoons [Ru^{IV}(bpy)(sal\text{-}R)_2]^{2+} + e^- \quad (4)$$

The potential of this oxidation is *ca* 500 mV more positive than that in the respective $[Ru(sal\text{-}R)_3]$ complexes [5a], which is owing to the strong π-acidity of the bpy ligand, as discussed above. The potential of this oxidation also correlates linearly with the Hammett constant (σ) of R (Fig. 4). The slope in this case is $\rho = 0.09$ V, which indicates that this ruthenium(III)–ruthenium(IV) oxidation potential is relatively less sensitive to the nature of R than the ruthenium(II)–ruthenium(III) oxidation potential.

$[Ru^{III}(bpy)(sal\text{-}R)_2]^+$ *complexes*

The reversibility of the ruthenium(II)–ruthenium(III) couple in the $[Ru(bpy)(sal\text{-}R)_2]$ complexes, and its relatively low potential, point to the possibility of the oxidized complex, $[Ru^{III}(bpy)(sal\text{-}R)_2]^+$, being stable on a much longer time-scale. To investigate this, the $[Ru(bpy)(sal\text{-}R)_2]$ complexes have been oxidized in acetonitrile solution (0.1 M TEAP) by constant-potential coulometry near 0.3 V. The oxidations have been smooth and quantitative [n (number of electron-transfer) = 0.97] affording deep green solutions of $[Ru^{III}(bpy)(sal\text{-}R)_2]^+$ which show similar cyc-

lic voltammograms to their respective precursors, except that the ruthenium(II)–ruthenium(III) couple now appears as a reductive response. Upon coulometric reduction of the green solutions near −0.5 V, deep brown solutions of $[Ru(bpy)(sal\text{-}R)_2]$ are obtained. The $[Ru^{III}(bpy)(sal\text{-}R)_2]^+$ complexes have also been synthesized by chemical oxidation of $[Ru^{II}(bpy)(sal\text{-}R)_2]$ in acetonitrile solution by iodine and the complex cations have been isolated as perchlorate salts in the solid state. Microanalytical data (Table 2) agree well with the compositions of these complexes. Conductivity measurements in acetonitrile solution show that these complexes behave as 1 : 1 electrolytes (Table 2), as expected. Electronic spectra recorded in acetonitrile solution show intense absorptions in the visible region together with a weak absorption at lower energies (Table 2, Fig. 1). The intense absorptions in the visible region are probably owing to ligand-to-metal charge-transfer transitions. The low intensity absorptions in the near-IR region are discussed below. Addition of hydrazine hydrate to the deep green solution of $[Ru(bpy)(sal\text{-}R)_2]ClO_4$ in acetonitrile brings about an instantaneous reduction affording a deep brown solution of $[Ru(bpy)(sal\text{-}R)_2]$.

The $[Ru(bpy)(sal\text{-}R)_2]ClO_4$ complexes are one-electron paramagnetic (Table 2), which corresponds to the +3 oxidation state of ruthenium (low spin d^5, $S = \frac{1}{2}$) in these complexes. ESR spectra of these complexes have been recorded in 1 : 1 dichloromethane/toluene solution at 77 K. All five complexes show rhombic ESR spectra with three distinct g-values (Fig. 5, Table 3). The rhombic nature of the spectra indicates the asymmetry of the electronic environment around ruthenium in these complexes. This asymmetry is understandable in terms of the stereochemistry of these complexes (**4**, *vide supra*) which has no C_2 axis. The observed spectra may be considered as pseudo-axial, consisting of a rather isolated signal near 1.90 ($g_\parallel$ in the axial case) and two relatively close signals near 2.25 and 2.10 (rhombic

component of g_1). Accordingly, the axial distortion (Δ) that splits the t_2 level into a and e components is expected to be larger than the rhombic distortion (V), which splits e (Fig. 5). Spin–orbit coupling causes further changes in the energy gaps. Thus, two electronic transitions (transition energies ΔE_1 and ΔE_2; $\Delta E_1 < \Delta E_2$) are possible within these three levels. All these energy parameters have been computed (Table 3) using the observed g-values, the g-tensor theory of low spin d^5 complexes [13] and a reported method [14]. The axial distortion is indeed larger than the rhombic one. The ΔE_2 transition has been observed in the spectra of all $[Ru(bpy)(sal\text{-}R)_2]^+$ complexes near the predicted energies (Table 2). However, the ΔE_1 transition could not be detected because the solvent (acetonitrile) itself is not transparent in this region.

(Received 27 June 1996; accepted 7 August 1996)

Abstract—The solid-state structure of di-*tert*-butyl indium chloride, $[(Bu^t)_2In(\mu\text{-}Cl)]$, has been determined by X-ray diffraction and consists of polymeric $[—In—Cl—]_\infty$ chains arranged in an unusual saw-tooth pattern motif. The indium atom is in a severely distorted coordination environment approximated as a capped trigonal-planar geometry. The structure of $[(Bu^t)_2In(\mu\text{-}Cl)]_\infty$ is compared with $[(Me)_2In(\mu\text{-}Cl)]_2$. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: indium; chloride; polymer; Group 13.

The alkyl halide compounds, R_2MX and RMX_2, of the Group 13 metals are almost exclusively dimeric in solution and the gas phase (**I**) [1,2]. This structure is ordinarily continued in the solid state for aluminum and gallium. In contrast, the alkyl halide compounds of indium exist in a wide variety of solid-state structures. The alkyl indium dihalides are predominantly polymers [3], while the structures observed for the dialkyl indium halides range from simple halide bridged dimers [4–7] to infinite chain [8] and three-dimensional [9–12] structures. We have previously suggested that the solid-state structure of alkyl indium halides is controlled by both the desire of the indium to maximize its coordination number and the intermolecular interactions of the alkyl (and aryl) ligands [5]. As part of our continuing investigations aimed at gaining a fundamental understanding of the factors that determine the structure and bonding in Group 13 compounds, we report the unusual polymeric structure of $[(Bu^t)_2In(\mu\text{-}Cl)]_\infty$.

(I)

RESULTS AND DISCUSSION

The dialkyl indium chloride $[(Bu^t)_2In(\mu\text{-}Cl)]_\infty$ was prepared according to the literature methods [13] and recrystallized from CH_2Cl_2. The structure consisting of $(Bu^t)_2InCl$ moieties arranged to form infinite $[—In—Cl—]_\infty$ chains along the crystallographic *b*-axis, is shown in Fig. 1; selected bond lengths and angles are given in Table 1. The In(1)—Cl(1)—In(1a) angle [126.5(6)°] is significantly larger than those observed in $In(\mu\text{-}Cl)_2In$ units [4–7]. The *tert*-butyl groups are positioned above and below the plane defined by the indium and chlorine atoms. While the '$(Bu^t)_2In$' moieties have a fixed position, the chlorine atoms exhibit disorder along the polymer chain, resulting in a reversal of the conformation of the indium center, see Fig. 2.

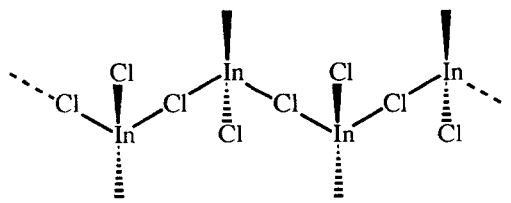
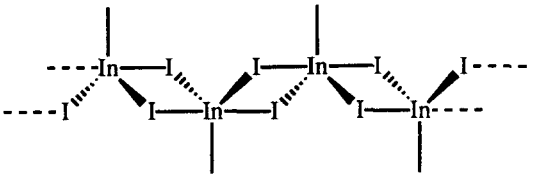
While the indium center is four-coordinate, its coordination geometry is unusually distorted from idealized tetrahedral. In fact, the sum of the intraligand angles for C(1), C(2) and Cl(1) (357°) is what would be expected for a trigonal planar environment (i.e. 360°) rather than the base of a tetrahedral environment (328.5°). The coordination of the indium is therefore best described as capped trigonal planar or trigonal bipyramidal with a vacant coordination site. In either description the capped or axial In—Cl bond one would expect to be the longest. For example, in the case of a trigonal bipyramid structure the axial In—Cl bond would be significantly longer based upon a consideration of the relative In *s* and *p* character in the respective In—Cl bonds; axial (*p*) *vs* equatorial (sp^2). This is counter to that observed for the relative In—Cl bond lengths; In(1)—Cl(1) = 2.58(1) and In(1)—Cl(1a) = 2.523(1) Å. One rationalization for the shorter 'axial' In—Cl bond can be derived by consideration of the bonding orbitals for a trigonal bipyramidal structure in which only a single axial ligand is present (**II**). The lack of a *trans*-ligand should result in an unusually strong and therefore short 'axial' bond.



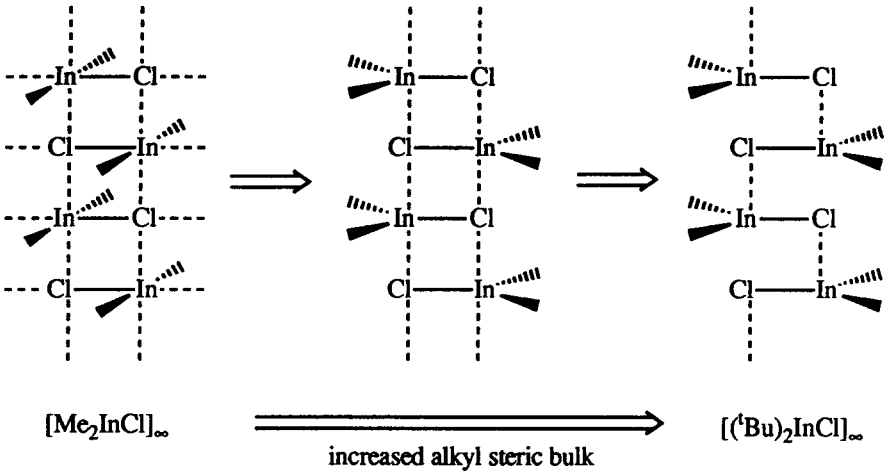
(II)



Polymeric chain structures have been reported for the alkyl (and aryl) indium dihalides, $[(R)In(\mu\text{-}X)_2]_x$, however, no polymeric chain structures have been reported for the mono halides. The shape of the —In—Cl— chain is unusual in having a saw-tooth pattern (**III**) unlike the zigzag (**IV**) or double chain (**V**) motifs previously observed for the dihalides [1,5].

(III)

(IV)



(V)

The solid-state structure of $[Me_2In(\mu\text{-}Cl)]_x$ as determined by X-ray crystallography consists of an infinite sheet-like lattice which may be considered as infinite [In—Cl] ladders linked together. Although the structure of $[(Bu^t)_2In(\mu\text{-}Cl)]_x$ and $[Me_2In(\mu\text{-}Cl)]_x$ appear disparate, they are in fact related as shown in Scheme 1. Examination of a space filling structure suggests that the steric bulk of the *tert*-butyl groups in $[(Bu^t)_2In(\mu\text{-}Cl)]_x$ precludes the inter-ladder interactions present in $[Me_2In(\mu\text{-}Cl)]_x$. Furthermore, the ladder structure is disrupted by intrachain steric interactions. Thus, the structure of $[(Bu^t)_2In(\mu\text{-}Cl)]_x$ may be considered as being derived from that of $[Me_2In(\mu\text{-}Cl)]_x$ as a result of being stretched like a concertina (*cf.* Scheme 1). The observation of a dimeric structure for $[(Mes)_2In(\mu\text{-}Cl)]_2$ indicates that the polymeric chain structure is destabilized completely with sterically demanding substituents [4]. It is interesting to speculate the continuum of structures for $[R_2In(\mu\text{-}Cl)]_n$ with increasing steric bulk of the alkyl groups. In particular, the cross over points between infinite sheets, ladders, polymeric chains and dimeric structures.

EXPERIMENTAL

A crystal of $[(Bu^t)_2In(\mu\text{-}Cl)]_x$ was sealed in a glass capillary under argon and mounted on the goniometer of an Enraf–Nonius CAD-4 automated diffractometer. Data collection and cell determinations were performed in a manner previously described [14]. The location of the majority of non-hydrogen atoms were obtained by using a Patterson, while the remaining atomic coordinates were determined through the generation of difference-Fourier maps using *MolEN* [15]. The chloride atoms were shown to have a disorder and were therefore refined with 50% occupancy. Attempts to solve the structure in either *C*2 or *Cm* also resulted in a disordered structure (the former results in two 0.5 occupancy chlorines and the latter in extra In positions). All non-hydrogen atoms [except C(13) and C(23)] were refined anisotropically. Hydrogen atoms were included and constrained to 'ride' upon the appropriate atoms [d(C—H) = 0.95 Å, U(H) = 1.2 B_{eq}(C)]. A summary of cell parameters, data collection and structure solution is given in Table 2. Scattering factors were taken from [16].

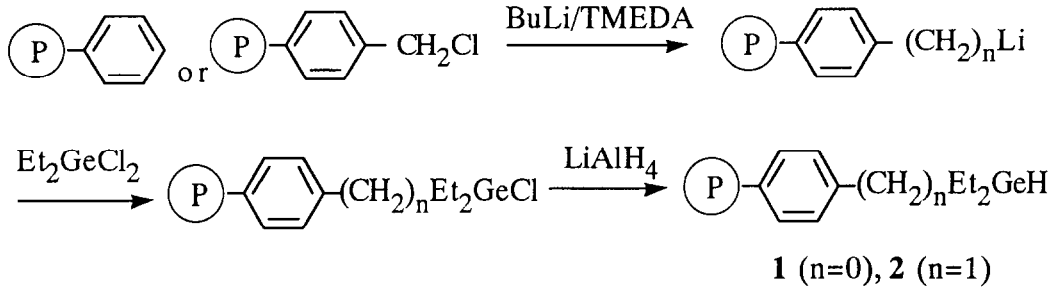
(Received 4 September 1996; accepted 20 September 1996)

Abstract—Polystyrene-supported organogermanium hydrides were prepared by functionalization of a polystyrene or by functionalization of a styrene followed by polymerization. The germyl groups were separated from the aromatic ring of polystyrene by methylene units in the polymeric germanium hydrides. The germanium hydrides reduced organic halides with catalyst under mild conditions in the order: C—I > C—Br > C—Cl. © 1997 Elsevier Science Ltd. All rights reserved.



Keywords: polystyrene-supported; hydrogermane; reduction.

Reduction of organic halides involving halogen abstraction reaction by silyl and stannyl radicals has been investigated extensively and the synthetic utility of these reductions, especially with organotin hydrides, has been widely established [1–7]. Recently, reduction of organic halides by organogermanium hydrides has been also of considerable interest in a point of moderate reactivity combined with high selectivity and no toxic character as compared with silicon and tin hydrides [8,9]. In the course of our investigations on germyl radicals [4,10–15] we required polymer-supported germanium hydrides. The insoluble polymer-supported germanium hydrides in common organic solvents would easily be separated after use simply by filtering and would be recyclable. The polymer-supported germanium hydrides would also retain their integrity during chemical reactions. Several syntheses and their application of polymer-supported tin hydrides have been reported [16–21], but there is no study of polymeric germanium hydrides so far.

In this paper, we report the synthesis of polystyrene-supported germanium hydrides (**1**–**3**) and their reduction of organic halides.

The preparation of polystyrene-supported germanium hydrides, **1**–**3** is outlined below (Schemes 1 and 2). Polystyrene was lithiated with butyllithium/TMEDA and then reacted with diethyldichlorogermane to give poly(*p*-diethylchlorogermyl)styrene. The poly(*p*-diethylhydrogermyl) styrene **1** was obtained by treating the poly(*p*-diethylchlorogermyl)styrene with excess lithium aluminum hydride (LAH) in reflux THF for 1 h. The polystyrene-supported germanium hydride **1** was analysed by solid-state NMR, FT-IR (νGe—H: 2018 cm^{-1}) and XPS spectra (Ge content: 3.8 mmol g^{-1}, degree of functionalization = 0.28). The second polystyrene-supported germanium hydride **2**, in which the germyl moiety was separated from the aromatic ring by methylene, was prepared by similar method of **1**. Thus, polystyrene was chloromethylated [21], lithiated with butyllithium/TMEDA and reacted with diethyldichlorogermane to afford poly(*p*-diethylchlorogermylmethylene)styrene. The target polystyrene-supported germanium hydride **2** was obtained by reduction of the diethylchlorogermane polymer with excess LAH in reflux THF. The polymer **2** was iden-

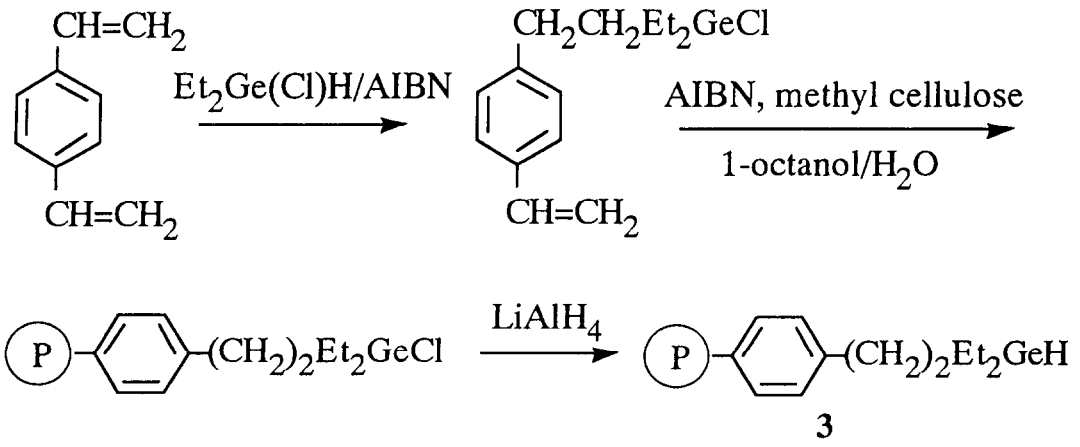
Scheme 1.

tified with solid NMR, FT-IR (νGe—H: 2015 cm^{-1}) and XPS spectra (Ge content: 3.8 mmol g^{-1}, degree of functionalization = 0.28).

The third polystyrene-supported germanium hydride **3**, in which the germyl group was separated from the aromatic ring by two methylene units, was prepared by polymerization of a substituted styrene.[19] *p*-Vinylphenethyldiethylchlorogermane was obtained by hydrogermylation of *p*-divinylbenzene with diethylchlorogermane under free-radical conditions. The germyl-substituted styrene was polymerized directly without the need for any further operations such as stabilization. The polystyrene-supported chlorogermane was reduced with LAH to give the poly(*p*-diethylhydrogermylethylene)styrene **3**. The polymeric germanium hydride **3** was identified by NMR, FT-IR and XPS analysis (νGe—H: 2000 cm^{-1}, Ge content: 4.0 mmol g^{-1}, degree of functionalization = 0.30).



The polymer-supported germanium hydrides **1**–**3** are insoluble in organic solvents. Therefore, the reagents can easily be separated after use simply by filtering and can be regenerated after their reactions with organic substrates.

Polystyrene-supported germanium hydrides **1**–**3** are capable of reducing organic halides simply by heating with free-radical initiators. Table 1 summarizes the results in the reduction of alkyl and aryl halides as determined by GPC.

Tables 1 and 2 show the results of reduction of octyl and phenyl halides with the polymer **1**–**3** catalysed by DTBP. Organic halides were clearly reduced to the corresponding reduction products. No coupling products were detected. The observed order of reactivity falls in the order **3** > **2** > **1**. This is because decreasing steric crowding around the germanium atoms, as the number of methylene groups is increased, will cause a rise in the reactivity of the germanium hydride. The reactivity of the halogen atoms falls in the sequence: I > Br > Cl for **1**–**3**. The ease of reaction decreasing in the order: RX > PhX for organic halides. These features are in accord with those found in homolytic reduction of organic halides with trialkylgermyl hydrides previously reported [11].

Polyhalobenzenes are reduced stepwise, which makes it possible to carry out the selective reduction of polyhalides. *o*-Bromochlorobenzene and *o*-dibromobenzene are reduced with **1**–**3** stepwise to afford chlorobenzene and bromobenzene, respectively. The order of reactivity is **3** > **2** > **1**.

A typical procedure is as follows. A mixture of poly(*p*-diethylhydrogermane)styrene **1** (0.11 g, 0.16 mmol), octyl iodide (0.25 g, 1.03 mmol) and DTBP (0.003 g, 0.02 mmol) was placed in a Pyrex tube. The tube was degassed by evacuation and then filled with argon. After heating for 20 h at 135°C, the mixture was filtered and washed twice with ether (10 cm^3). The organic layer was analysed by GC and GC-MS.

Run	Polymer	Organic halide	Product (Yield/%)[b]
1	**1**	PhI	PhH (38)
2	**1**	PhBr	PhH (13)
3	**1**	PhCl	PhH (0)
4	**2**	PhI	PhH (44)
5	**2**	PhBr	PhH (trace)
6	**2**	PhCl	PhH (0)
7	**3**	PhI	PhH (55)
8	**3**	PhBr	PhH (45)
9	**3**	PhCl	PhH (trace)

[a]At 135 C, for 20 h.
[b]GC yield.

Regeneration of the used polymer: the polymer washed twice with ether and reduced with LAH in refluxing THF for 1 h.

The extent of regeneration of polymer-supported germanium hydrides **1**–**3** several times later is 90%.

Equation 1.

The yield of the first regeneration for polystyrene-supported tin hydrides has been reported to be 30 40% [17].

In conclusion, polystyrene-supported germanium hydrides **1**–**3** reduce organic halides under mild conditions. An advantage to the polymer is easier process, clean and simple work-up of the products and recyclable reagents.

Acknowledgments—The authors thank Dr Riichi Niside of Nissan Auto Co. Ltd for measuring the XPS of polymer-supported germanium hydrides. We also thank Mitsubishi Material Co. Ltd for a gift of tetrachlorogermane.

Mono- and dinuclear copper(II) complexes of a Schiff base ligand, 4′,5′-bis(salicylideneimino)benzo-15-crown-5

Serdar Karaböcek[a]* and Nevin Karaböcek[b]

Departments of [a]Chemistry and [b]Science Education, Karadeniz Technical University, Trabzon, Turkey

(Received 30 April 1996; accepted 16 October 1996)

Abstract—Mono- and dinuclear copper(II) complexes with a tetradentate Schiff base, 4′,5′-bis(salicylideneimino)benzo-15-crown-5, ($SALH_2$) have been prepared and characterized by elemental analyses, magnetic moments, IR, UV/VIS, and ESR spectral studies. The elemental analyses, stoichiometry and the spectroscopic data of the complexes indicate that the copper(II) ions are coordinated by the dianion of the ligand. IR spectra show that the ligand acts in a tetradentate manner and coordinates throught (C=N) and (C—O) groups. The geometry of the metal chelates is discussed with the help of magnetic and spectroscopic measurements. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: Schiff base; crown ether; copper complexes; mononuclear; dinuclear; metallobiosites.

Numerous copper-containing proteins utilize molecular oxygen in respiratory and biosynthetic functions. The best studied copper proteins, hemocyanin and tyrosinase, serve, respectively, in O_2 transport and in activating O_2 for the oxidation of tyrosine. Many excellent papers have been published during the last two decades on the preparation and properties of model copper complexes. Particular attention was devoted to their correlation with the active site of metalloenzymes and metalloproteins containing dinuclear metallocenters in order to elucidate the factors that determine the reversible binding and activation of O_2 in various natural oxygen transport systems and mono- and dioxygenases and to mimic their activity [1–3]. A number of dinuclear complexes based on acylic and linear ligand systems have been prepared and investigated for oxygen uptake [4–6]. Particular interest has been devoted to the synthesis and characterization of homo binuclear compounds. Such metal complexes have been prepared by using an acyclic ligand (Fig. 1(B)) containing a coordination site which can link one metal ion in the inner N_2O_2 [7–9].

In the present study, we have used a Schiff base prepared from salicylaldehyde and 4′,5′-diaminobenzo-15-crown-5. This ligating system provides an additional active site besides conferring on the copper(II) ion a square-planar N_2O_2 environment (Fig. 1) which not only mimics the active site in galactose oxidase [8, 9] but also has a role in molecular magnetism.

EXPERIMENTAL

Preparation of the Schiff base

$SALH_2 \cdot H_2O$, [4′,5′-bis(salicylideneimino)benzo-15-crown-5] was prepared as reported previously [10].

Preparation of [Cu(SAL)$CuCl_2$]

A solution of $CuCl_2 \cdot 2H_2O$ (2 mmol, 340.0 mg) in EtOH was added to the ligand (1 mmol, 506 mg) suspended in 10 cm^3 of EtOH and the mixture was stirred for 2.5 h at room temperature. A brown product was filtered off, washed with EtOH and Et_2O and dried over P_4O_{10}. Found: C, 48.0; H, 4.0; N, 3.9; Cu, 18.5. Calc. for [$C_{28}H_{28}N_2O_7Cl_2Cu_2$]: C, 47.9; H, 4.0; N, 4.0; Cu, 18.1%.

Preparation of [Cu(SAL)$(ClO_4)_2$]

The ligand (1 mmol, 506 mg) suspended in 10 cm^3 EtOH was added to the solution of $Cu(ClO_4)_2 \cdot 6H_2O$

*Author to whom correspondence should be addressed.

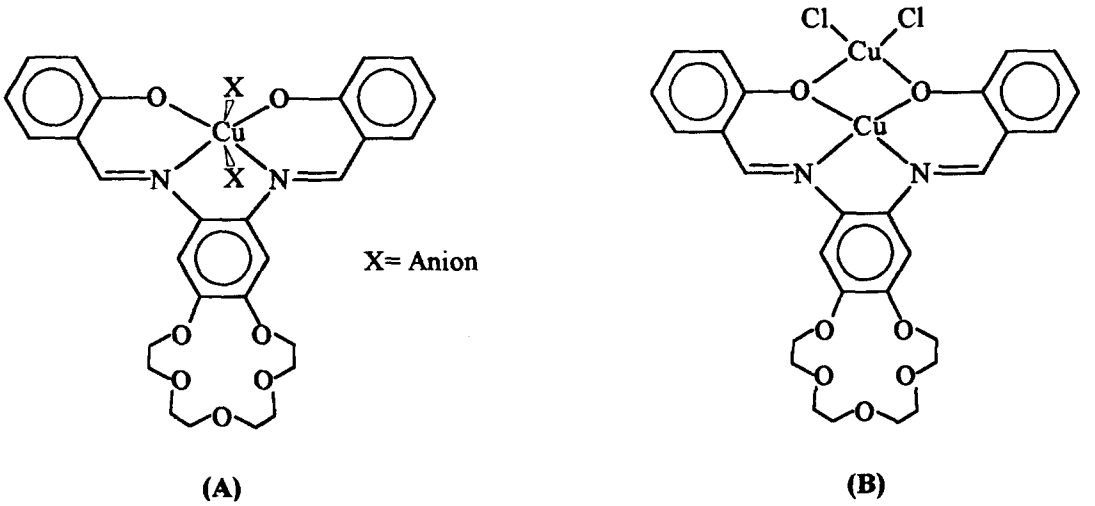

Fig. 1. 4′,5′-bis(salicylideneimino) benzo-15-crown-5. ($SALH_2$)-copper(II) complexes: (A), mono; and (B), binuclear.

(1 mmol, 370.5 mg) in EtOH, and the mixture was stirred for 3 h at room temperature. The brown product was filtered off, washed with EtOH and Et_2O and dried over P_4O_{10}. Found: C, 39.9; H, 3.5; N, 3.4; Cu, 7.5. Calc. for $[C_{28}H_{28}N_2O_{15}Cl_2Cu]$: C, 40.1; H, 3.3; N, 3.3; Cu, 7.6%.

Preparation of $[Cu(SAL)X_2 \cdot Y$ ($X = OAc^-$, $HCOO^-$; $Y = H_2O$)

To a solution of $Cu(ClO_4)_2$ (1.2 mmol, 445 mg), NaOAc/HCOONa as appropriate (1 equiv.) was added and the mixture stirred until dissolved. The ligand (1 mmol, 506 mg) suspended in EtOH was added and the mixture stirred for 3 h at room temperature. The greenish coloured products were filtered, washed with EtOH and Et_2O and dried over P_4O_{10}. $[Cu(SAL)(OAc)_2]$: Found: C, 55.5; H, 5.1; N, 4.1; Cu, 9.1. Calc. for $[C_{32}H_{34}N_2O_{11}Cu]$: C, 56.0; H, 5.0; N, 4.1; Cu, 9.3%. $[Cu(SAL)(HCOO)_2] \cdot H_2O$: Found: C, 53.5; H, 4.8; N, 4.0; Cu, 9.3. Calc. for $[C_{30}H_{32}N_2O_{12}Cu]$: C, 53.3; H, 4.7; N, 4.1; Cu, 9.4%.

Preparation of $[Cu(SAL)(SCN)_2 \cdot H_2O$

To a solution of $CuCl_2 \cdot 2H_2O$ (1.2 mmol, 204.0 mg) in EtOH, a saturated solution of KSCN was added, until no further precipitation of KCl was obtained. This solution was centrifuged and filtrate was added to the ligand (1 mmol, 506 mg) suspended in 10 cm^3 of EtOH, the mixture was stirred for 3 h at room temperature. The deep brown precipitate was filtered and washed with EtOH and Et_2O and dried over P_4O_{10}. Found: C, 57.1; H, 5.5; N, 9.0; Cu, 10.1. Calc. for $[C_{30}H_{30}N_4O_8S_2Cu]$: C, 56.4; H, 4.7; N, 8.8; Cu, 9.9%.

Instrumentation

C, H, N were analysed microanalytically. Copper was estimated spectrophotometrically. Electronic spectra were obtained on a Varian DMS-90 spectrophometer. ESR measurements were made with a Varian model 109 C E-line X-band spectrometer fitted with a quartz Dewar for measurements at liquid nitrogen temperature, IR spectra were obtained on a Perkin–Elmer 598 spectrophotometer in KBr pellets. Room temperature magnetic susceptibility measurements were done on a PAR model 155 vibrating sample magnetometer.

RESULTS AND DISCUSSION

ESR spectroscopy

X-Band ESR studies of the copper(II) complexes were obtained in DMSO. The spectra reveal the presence of less than four components. The broadening of the $g_\perp$ line and splitting is due to the overlap of $g_\parallel$ and $g_\perp$ components, further indicating a lowered site symmetry [11, 12]. The $g_\parallel$ is in the range 2.19–2.22 as observed in mononuclear complexes (Table 1). A clear five-line pattern emerges on the $g_\parallel$ component with ≈ 15 G. Thus the ESR data supports the binding of the tetradentate ligand with two N and two O donor sites to the copper(II) ion, providing a square planar geometry, the other axial sites being occupied by the coordination anion [7]. Figure 2 shows the ESR spectra of the $[Cu(SAL)CuCl_2]$ complex in frozen DMSO. The value of the coupling constant evaluated from the peaks is *ca* 119 G. This value is nearly half of that found for the present mononuclear complexes (Table 1). This situation could arise when two equivalent copper(II) ions are coupled *via* an exchange interaction, in a dinuclear complex.

Magnetic susceptibility

The room temperature solid state magnetic moment data of the copper(II) complexes are reported in Table 1. Mononuclear copper(II) complexes showed normal magnetic moments. The $[Cu(SAL)CuCl_2]$ complex shows μ_{eff} value of 1.51 B.M., indicating an exchange coupled dimeric complex, a structure supported by the ESR study also. The stoichiometry is in keeping with copper(II) complexes reported with similar tetradentate Schiff base ligands [7,13].

Electronic and IR spectroscopy

The ligand was dissolved in MeOH/NaOH and shows characteristic UV–vis spectra of the Schiff base group. The absorption bands are given in Table 1. The electronic spectra of all complexes measured in dimethylsulfoxide showed intense absorptions around 400 nm which are assigned to charge-transfer transition from the $p\pi$ orbitals of the donor atoms to the d orbitals of the metal (Table 1). In the mono copper(II) complexes, d–d transitions were observed around 500–600 nm. The energy of the d–d transition suggests a distorted tetragonal copper(II) complex [14].

In general, the complexes exhibited very similar IR features. This is indirect evidence that the complexes are of similar structures. In the IR spectra of these complexes (OH) stretching vibrations have disappeared and there is no distinct shift in (C=N) stretches after complex formation. The band assigned to ν(C—O) is shifted to higher frequency by 20–25 cm^{-1} in the complexes [15]. The band assigned to ν(C–N) shows a shift of 20–40 cm^{-1} towards a lower frequency. A strong band at *ca* 1600 cm^{-1}, which shifts by 30–50 cm^{-1} towards lower frequency upon coordination is assigned to ν(C=N). The significant shifts in ν(C—N), ν(C—O) and ν(C=N) upon complexation support the concept of coordination of the ligand through the azomethine nitrogen.[10] In the acetate complex sharp bands at 1440 and 1680 cm^{-1} are assigned to the unidentate binding mode of the acetate group. The ν(C=N) stretching frequencies are generally lower for coordinated SCN. This could possibly be due to a sulfur bonded thiocyanate. IR data confirms the binding of the copper(II) by O and N donor groups of the present ligand and supports the tentative structure of the complexes (Fig. 1).

As a conclusion, in the present study, we have demonstrated the preparation of a Schiff base ligand providing N_2O_2 donor array and a crown ether moiety, and its mono- and dinuclear copper complexes. All the spectral data supported a distorted tetragonal

geometry for copper(II) ions. Since such copper complexes have potential use in organic synthesis for the catalysis of a wide range of primary alcohols to the corresponding aldehydes, and may mimic specific types of copper-containing enzymes, their structural and functional identification is necessary for their applications.

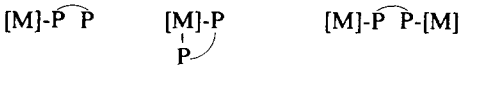
Monodentated, bridged and chelated behaviour of diphosphines towards the fragment CpFe (dppe)$^+$

Carlos Díaz* and Eyleen Araya

Departamento de Química, Facultad de Ciencias, Universidad de Chile, Santiago, Casilla 653, Chile



(Received 3 September 1996; accepted 14 October 1996)

Abstract—The reaction of CpFe(dppe)I with $Ph_2P(CH_2)nPPh_2$ ($n = 1$, dppm; $n = 2$, dppe; $n = 3$, dppp; $n = 4$ dppb) in the presence of NH_4PF_6 afforded the novel mononuclear complexes [CpFe(dppe)(η^1-dppm)]PF_6 (1) and [CpFe(dppe)(η^1-dppe)]PF_6(2) when $n = 1$ or 2 or the binuclear [CpFe (dppe)-PPh_2-$(CH_2)_2$ PPh_2-CpFe (dppp)] $(PF_6)_2$ (3) and [CpFe (dppe) $PPh_2(CH)_2PPh_2$-CpFe (dppb)] $(PF_6)_2$ (4) when $n = 3$ or 4. These two bimetallic complexes present two slightly different sites caused by the two different chelate diphosphines linked to the iron atoms and evidenced by ^{31}P-NMR spectroscopy. The two metallic fragments however could not be distinguished by cyclic voltammetry. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: iron complexes; monodentate diphosphines; chelated diphosphines.

Transition-metal complexes containing diphosphine ligands have been the subject of numerous investigations in recent years, in part because of their potential applications in homogeneous catalysis [1]. The stabilization of organometallic complexes with metals in low oxidation states by tertiary phosphine ligands is widely known [2]. Thus the good donor properties of phosphine ligands together whith their moderately Π-acceptor capacity lead to electron rich organometallic fragments [3–7]. The replacement of carbonyl by diphosphine ligands in $CpM(CO)_2X$ systems, produce variations of *ca* 1.9 V in their oxidation potential [5–7]. The high electron richness of fragments of the type CpFe(P-P) (P-P = tertiary diphosphine) permit the stabilization of alkylidine [8], vinylidene [9] and methylene [10] groups. Recently we have reported the preparation of a series of complexes containing neutral ligands of the type $\{CpFe(dppe)L\}PF_6$ $Cp = \eta^5$-C_5H_5, where dppe = $Ph_2P(CH_2)_2PPh_2$, L = sulfur donor ligand THF, pyridine and $P(n\text{-Bu})_3$ [11–14]. With the phosphine ligand, stable compounds in good yield were obtained. This prompted us to investigate the reaction of CpFe(dppe)I [12] with the series of diphosphines $Ph_2P(CH_2)_nPPh_2$ ($n = 1$–4) about which this paper is concerned.

In general diphosphines can to act toward metal fragments as η^1− monodentate mode of coordination, η^2-chelating mode of coordination as well as μ-bridging mode of coordination.

η^1-mode η^2-mode μ-mode

As have been previously pointed out the chelating tendency decreases as the chain length in $Ph_2P(CH_2)nPPh_2$, increases being greatest for $n = 2$ [2]. This arises from the known stability of the five membered ring chelate. Thus dppe forms numerous stable chelate complexes [11–14; 27,28]. Less common complexes containing dppe as bridge have also been reported [17,18,29,30,32,35]. Unidentate dppe complexes are rare, however some examples have been reported [19,29,31,33–35].

Complexes containing dppp and dppb are more scarce than those with dppm and dppe ligands. With dppp some chelate and bridged complexes have been reported [17–19,22,33–35]. The complex Fe_3Te_2 $(CO)_9$(dppp) containing the η^1-dppp ligand was reported. For dppb, few reports illustrating their chelating and bridging behaviour have appeared [19,22, 23].

Thus, it appears that the mode of coordination of

*Author to whom correspondence should be addressed.

a diphosphine depends on the following three factors: (i) the length of the chain linking the phosphorous atoms; (ii) the steric properties of the fragment [M]; and (iii) the electron richness of the fragment [M].

However, the form in which these three factors influence the mode of coordination of a diphosphine is as yet unclear.

The most studied, dppm, exhibits a great ability to form bridged [2,15–20] binuclear complexes, although the chelate behaviour is also common [2,19,21,22]. Some complexes containing the monodentate dppm have also been reported [2,23–26].

This paper reports an example where the three coordination modes of diphosphines are involved, which are strongly influenced by the steric properties of the fragment CpFe dppe$^+$.

RESULTS AND DISCUSSION

The reaction of CpFe(dppe)I [12] with diphenylphosphinomethane, and with diphenylphinoethane in methanol in the presence of NH_4PF_6 as halide abstractor afforded the brown solids [CpFe(dppe)(η^1-dppm)]PF_6, **1** and [CpFe(dppe)(η^1-dppe)]PF_6, **2** respectively (see scheme, Fig. 1). Structure of the new complexes was established unequivocally by ^{31}P-NMR spectroscopy [23]. The ^{31}P-NMR spectrum of **1** is shown in Fig. 2 and indicates, in addition to the PF_6 signal, three types of phosphorus atoms in the ratio 2:1:1. The doublet at the lowest field is assigned to P_c phosphorus atoms of the chelate dppe ligand (see Table 1).

The doublet nature of this signal arises from their splitting with the P_b phosphorus atom of the monodentate diphosphine ligand. The high-field doublet of triplets corresponds to P_b, the coordinated phosphorus of the monodentate dppm; which is split into a doublet by the uncomplexed P_a and is further split into triplets by the two chemically equivalent atoms P_c of the dppe chelate. The high-field doublet, which has a chemical shift very similar to that of free dppm [15] is assigned to a the uncoordinated phosphorus atom P_a. Similar analysis for **2** gave the ^{31}P-NMR data presented in Table 1.

For comparison, in Table 2 are collected ^{31}P-NMR data for other complexes containing monodentate diphosphine ligands. It is evident that for a given complex [M]-P_bP_a the chemical shift of the coordinated phosphorus atom varies considerably depending on the nature of the metal and of the auxiliary ligands around the metal.

For dppm, δ ^{31}P-NMR values vary from 20–33 ppm for $W(CO)_3$ bipy to 76.4 ppm for the $Fe(CO)_3$ fragment. For a constant metal, δ ^{31}P depends on the withdrawing properties of the auxiliary ligand. Similar tendency is observed for complexes with monodentate dppe. On the other hand the chemical shift for the uncoordinated phosphorus atom is near to the value for the free diphosphines. A characteristic range for unidentate dppm between −22.49 and −29.57 ppm can be viewed from Table 2 while that for unidentate dppe values from −10.49 to −14.1 were observed.

The new complexes were also characterized by elemental analysis, IR, ^{1}H-NMR and UV–visible spectroscopic methods as well as by voltammetric methods.

The ^{1}H-NMR spectra of the complexes **1** and **2** exhibit the characteristic proton signals of the CpFe dppe$^+$ [12,14] moiety; a multiplet between 7–8 ppm corresponding to C_6H_5 group of dppe and dppm, a singlet around 4.5 ppm assigned to a C_5H_5 proton and the methylene protons of dppe and dppm around 1.5 ppm and 2.1–2.7 ppm respectively.

The IR spectra of the complexes **1** and **2** exhibit the expected bands of the CpFedppe moiety [36]. The UV–visible spectra of **1** and **2** shows the lowest absorp-

tion band around 440 nm (see Table 3). This maximum which has been assigned to a *d–d* transition [13] appears in the expected range for [CpFe(dppe)L]$^+$ complexes where L is a phosphorus donor ligand [14].

Using cyclic voltammetry, we observe that the complexes **1** and **2** undergo a single oxidation in CH_2Cl_2. Complex **1** shows a chemically irreversible oxidation due probably to decomposition of the oxidized product. For complex **2** the ratio of anodic to cathodic peak currents is near unity indicating a chemically reversible process. Data are shown in Table 4. The oxidation peak values for complexes **1** and **2** compare well with that of [CpFe(dppe)(*n*-Bu_3P)]PF_6 [14]; (0.77 V).

The reaction of CpFe(dppe)I with diphenylphosphinopropane and with diphenylphosphinobutane in methanol, in the presence of NH_4PF_6 afforded the binuclear complexes [CpFe(dppe)-μ-dppe-Fe(dppp)Cp]$(PF_6)_2$ [3] and [CpFe(dppe)-μ-dppe-Fe(dppb)Cp]$(PF_6)_2$ [4] (see Fig. 1), respectively, the structure of these compounds was also established by ^{31}P-NMR spectroscopy. The ^{31}P-NMR spectrum of 3 (see Fig. 3) consists of two doublets, two triplets and the expected septet signal of PF_6. Consistently with the structure proposed, the signal of the unco-

ordinated phosphorus atom is absent. The lowest field doublet at 89.46 ppm is assigned to P_c phosphorus atoms of the chelated dppe ligand, by comparison with the values found for the fragment CpFe(dppe)$^+$ in **1** and **2** (see Table 1). The other doublet is assigned to a phosphorus atom of the chelated dppp ligand linked to the other iron atom. The doublet nature of these two signals arise from their splitting with the phosphorus atom of the bridged dppe. The two triplets at high-field are assigned to the phosphorus atom of the bridged dppe ligand. As expected, the chemical shift values of the phosphorus atom linked to the CpFe(dppe) fragments are very similar (almost identical) for **3** and **4**, while those of the other phosphorus atom exhibit a chemical shift value different for **3** and **4**.

The small but different chemical shift values for the two phosphorus atoms of the bridged dppe indicate that the phosphorus nuclei "see" two slightly different chemical environments arising from the different chelate diphosphines coordinated to the CpFe fragment. Large differences between the chemical shift of the phosphorus atoms of bridged dppe have been found in binuclear systems [30] [$(CO)_5$ M-$PPh_2(CH_2)_2PPh_2$-M′$(CO)_5$] (M, M′ = Cr, Mo and W). Consistently with the proposed structure for **3** and **4** their ^{1}H-NMR spectra exhibit two singlets corresponding to the C_5H_5 proton linked to the different fragments Fe(dppe) and

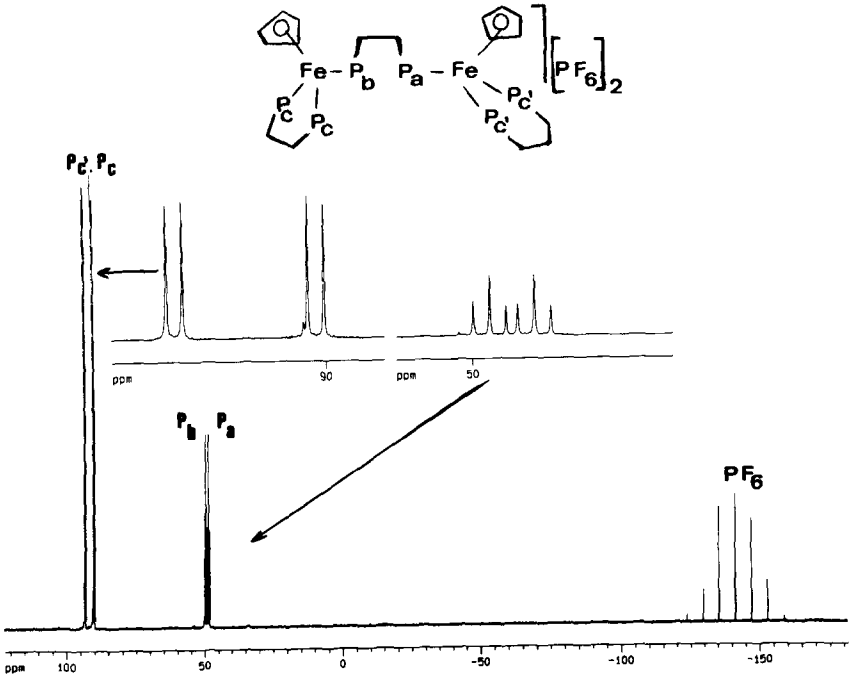

Fig. 3. ^{31}P-NMR spectrum of [CpFe(dppe)-μ-dppe-CpFe(dppp)]$(PF_6)_2$ in CD_2Cl_2 solution at room temperature.

Fe(dppp) in **3** and Fe(dppe) and Fe(dppb) in **4**. The differences between the chemical shift values for C_5H_5 in the different metal environment of each one of the binuclear complexes are comparable to those found in [CpFe(dppe)-CN-CpFe(dppe)]PF_6 [11] and [CpFe(dppe)-C≡C-$(CH_2)_2$-CN-Fe(dppe)Cp]PF_6 [27]. Proton signals for the group C_6H_5 and $P(CH_2)nP$ of the diphosphines were observed normally (see Table 2).

The UV-visible spectra of **3** and **4** exhibit a similar absorption pattern to those of the mononuclear **1** and **2**, which indicate that the environment of the Fe atoms is very similar. In agreement with this the cyclic voltammograms for **3** and **4** exhibit only one oxidation wave as is shown in Table 4. Reversibility parameters indicate a chemical and electrochemical reversible process for the two complexes. The somewhat broad oxidation waves suggest the presence of two oxidation waves with close values of oxidation potential, corresponding to the CpFedppe and CpFe(dppp) (for **3**), CpFe(dppe) and CpFe(dppb) (for **4**) fragments. Alternatively the only oxidation wave observed could be attributed to a two-electron oxidation [37].

The formation of the complexes **3** and **4** containing two different diphosphines chelated to the iron atoms and both with the bridged dppe could be due to the high bridging tendency of the dppe ligand, when the fragments joined by the diphosphine are bulky, as in the CpFe(dppe) [38]. On the other hand the chelating ability of high membered diphosphines $Ph_2P(CH_2)n$ PPh_2 is not unusual [39]. Thus the formation of complexes **3** and **4** involve the opening of the five membered chelate ring Fe(dppe) which is typical behaviour in these type of fragments [34,40].

Notwithstanding the above consideration it surprising that the incoming ligands adopt chelating positions despite giving six- and seven-membered rings (while the ligand becomes bridging) and no formation of the symmetrical complexes [CpFe(L-L)-μ-dppe-FeCp(L-L)]$^+$ has been detected in the product even when excess of the L-L was used.

Until now we have no explanation for this.

EXPERIMENTAL

Infrared spectra were recorded on a FT-Bruker-66 V spectrometer in Nujol. NMR spectra were recorded on a Bruker AMX 300 spectrometer in dichloromethane-d_2 with TMS (H) $\delta = 0.0$ ppm as internal standard or 85% H_3PO_4 and downfield positive to the reference as external standard for the ^{31}P measurements.

UV–visible absorption spectra were recorded using a varian DMS-90 spectrophotometer with 1 cm optical path cuvettes.

Electrochemical measurements were made on a Parc model 370 electrochemistry system, using a three electrode device, employing a carbon glassy working electrode, platinium wire counter electrode and saturated calomel reference electrode.

Solutions were 10^{-3} M in the complex and 0.1 M in $[NBu_4]PF_6$ as supporting electrolyte. Under the same experimental conditions, $E_{1/2}$ for the ferrocene–ferrocenium complex was 0.64 V with peak separations of about 0.060 V (internal standard).

Reactions were carried out under nitrogen using

standard Schlenk-tube techniques. Diethylether and *n*-hexane were dried over sodium and distilled.

$Ph_2P(CH_2)PPh_2$, $Ph_2P(CH_2)_2PPh_2$, $Ph_2P(CH_2)_3PPh_2$, and $Ph_2P(CH_2)_4PPh_2$ were purchased from Aldrich and used without additional purification. CpFe(dppe)I was prepared by a previously reported method [12].

Preparation of the complexes

Synthesis of [CpFe(dppe)(η1-dppm)]PF_6 (**1**)

A solution of CpFe(dppe)I (0.15 g, 0.23 mmol) in CH_3OH (30 cm^3) was stirred with dppm (013 g 0.33 mmol) in the presence of NH_4PF_6 (0.08 g, 0.49 mmol) at room temperature for 20 h. The solvent was removed under reduced pressure and the residue extracted with CH_2Cl_2 and filtered through Celite. Then reduced in volume and *n*-hexane/diethylether 4:1 mixture was added. The maroon powdered precipitate was twice washed with the same mixture and dried under reduced pressure. Yield: 0.14 g (59%). Found: C, 63.2; H, 5.0. Calc. for $C_{56}H_{51}F_6P_5Fe$: C, 64.1; H, 4.9%.

Synthesis of [CpFe(dppe)(η1-dppe)]PF_6 (**2**)

To a solution of CpFe(dppe)I (0.15 g, 0.23 mmol) and $Ph_2P(CH_2)_2PPh_2$ (0.14 g, 0.35 mmol) in CH_3OH (30 cm^3) was added NH_4PF_6 (0.08 g, 0.49 mmol). The mixture was stirred for 20 h at room temperature. After evaporation of the solvent the solid residue was extracted with CH_2Cl_2 (20 cm^3) and the solution filtered through Celite. Then solvent was partially evaporated under reduced pressure and then diethylether was added. The maroon solid precipitate was twice washed with ether and dried. Yield: 0.14 g (57%). Found: C, 64.2; H, 5.1. Calc. for $C_{57}H_{53}F_6P_5Fe$: C, 64.4; H, 5.0%.

Synthesis of [CpFe(dppe)-μ-dppe-CpFe(dppp)]$(PF_6)_2$ (**3**)

A stirred solution of CpFe(dppe)I (0.15 g, 0.23 mmol) in CH_3OH (30 cm^3) was treated with $Ph_2P(CH_2)_3PPh_2$ (0.14 g, 0.34 mmol) in the presence of NH_4PF_6 (0.08 g, 0.49 mmol) at room temperature. After 20 h the reaction mixture was evaporated to dryness. The residue was dissolved in a minimum amount of CH_2Cl_2 and filtered through Celite. The solution was concentrated to a *ca* 5 cm^3 and then diethylether was added. The orange precipitate was washed twice with the same solvent and dried *in vacuo*. Yield: 0.13 g (50%). Found: C, 61.7; H, 5.2. Calc. for $C_{89}H_{84}F_{12}P_8Fe_2$: C, 62.4; H, 4.8%.

Synthesis of [*CpFe(dppe)-μ-dppe-CpFe(dppb)*]$(PF_6)_2$ (**4**)

A mixture of CpFe(dppe)I (0.15 g, 0.23 mmol) and $Ph_2P(CH_2)_4PPh_2$ (0.15 g, 0.35 mmol) in the presence of NH_4PF_6 (0.08 g, 0.49 mmol) were stirred in CH_3OH (30 cm^3) at room temperature for 20 h. After this the solvent was removed *in vacuo* and the solid residue extracted with CH_2Cl_2, filtered through Celite and the solution concentrated to *ca* 10 cm^3. After this $(C_2H_5)_2O$ was added and the orange solid washed with the same solvent. The resultant solid was dried under reduced pressure. Yield: 0.18 g (73%). Found: C, 63.2; H, 5.0. Calc. for $C_{90}H_{86}F_{12}P_8Fe_2$: C, 61.6; H, 4.9%.

(Received 27 August 1996; accepted 14 October 1996)

Abstract—The zinc(II) complex of the tetraaza macrocyclic ligand 3,14-dimethyl-2,6,13,17-tetraazatricyclo[14,4,$0^{1.18}$,$0^{7.12}$]docosane(**L**), $[Zn(L)(H_2O)_2](Cl)_2$ (**1**) and its structural characterization is reported. The zinc(II) ion adopts a tetragonally elongated octahedral geometry with an average Zn—N distance of 2.099(2) Å and a Zn—O distance of 2.388(3) Å. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: zinc(II) complex; 14-membered tetraaza macrocycle.

Zinc(II) complexes of macrocyclic polyamines have been of great interest due to their importance as models of zinc-containing enzymes such as carbonic anhydrases, carboxypeptidases, glyoxalase I, etc. [1–5]. For mononuclear complexes of macrocyclic polyamines, Zn^{II}-triamines [6–8] and Zn^{II}-tetraamines [9,10] have been the most widely studied models due to their similarity in structural, thermodynamic, and kinetic properties with carbonic anhydrases. The coordination environments around Zn^{II} ions in those complexes are usually a distorted tetrahedron or a square pyramid with one water molecule bound to Zn^{II} ions in which the pK_a values (H_2O) lie 7.3–9.8 [2,11,12]. Since the zinc bound water molecule plays a fundamental role in the catalytic mechanism and the pK_a value of water in that complex appears to be dependent on the chelate ligands, we were quite interested in the synthesis of Zn^{II} complex with modified tetraamine macrocycle, 3,14-dimethyl-2,6,13,17-tetraazatricyclo[14,4,$0^{1.18}$, $0^{7.12}$]docosane(**L**). Interestingly enough, the crystal structure of this complex indicates that the Zn^{II} ion adopts an axially elongated octahedral environment with two *trans* water molecules and four equatorial nitrogens from the macrocycle. This result contrasts with other reports in which they assumed or determined that the Zn^{II} ions with related macrocycles take only one water molecule [1,2,6]. In this study we describe the synthesis and structure of this interesting diaquo Zn^{II} tetraamine macrocycle.

L

EXPERIMENTAL

General

All solvents were reagent grade and purified as described elsewhere prior to use [13]. Distilled water was used for all reactions. $ZnCl_2$, 1,2-diaminocyclohexane, methyl vinyl ketone, perchloric acid, and $NaBH_4$ were purchased from Aldrich Chemical

*Author to whom correspondence should be addressed.

Co. and used without further purification. Infrared spectra of solid complexes were recorded on a Perkin–Elmer Paragon 1000 FT-IR spectrophotometer between 4000 and 400 cm^{-1} as Nujol mulls on KBr plates. ^1H and ^{13}C NMR spectra were recorded at room temperature on a Bruker WP 300 spectrometer. Elemental analyses were performed by Korea Research Institute of Chemical Technology, Taejeon, Korea.

Preparation of neutral ligand (**L**)

The ligand **L** was prepared according to previously published procedures [14,15]. IR (Nujol, cm^{-1}): 3289(νNH), 1359, 1313, 1268, 1248, 1216, 1159, 1137, 1083, 1054, 1019, 913, 871, 837, 808, 766, 721, 621, 566, 502. MS(EI) Calc. (Found) m/z: 336(336) $[M]^+$. Calc. (Found) for $C_{20}H_{40}N_4$: C, 71.4 (71.6); H, 12.0 (12.0); N, 16.6 (16.8)%.

Preparation of $[Zn(\mathbf{L})(H_2O)_2](Cl)_2$ (**1**)

A methanol solution of **L**(200 mg, 0.59 mmol) and $ZnCl_2$(80 mg, 0.59 mmol) was heated at reflux for 2 h. The solution was allowed to cool to room temperature and was then filtered. The filtrate was evaporated to dryness. The product was redissolved in a minimum amount of water. After the solution was allowed to stand at room temperature over a period of several days, white crystals formed. Recrystallization from water/acetonitrile (1 : 1), filtration, washing with diethyl ether, and drying *in vacuo* produced a white solid (236 mg, 79% based on **L**). IR (Nujol, cm^{-1}): 3336(νOH), 3249(νOH), 3153(νNH), 3105(νNH), 1643(νHOH), 1309, 1280, 1176, 1099, 1011, 993, 968, 906, 800, 666. Calc. (Found) for $ZnC_{20}H_{44}N_4O_2Cl_2$: C, 47.2 (47.3); H, 8.7 (8.6); N, 11.0 (11.1)%. ^{13}C NMR ($CDCl_3$): δ 59.8, 56.4 (cyclohexane ring carbon), 47.6, 40.3, 34.2 (N—C—C—C—N), 29.6, 29.1, 24.4, 24.3 (cyclohexane ring carbon), 14.9 (—CH_3). ^1H NMR ($CDCl_3$): δ 1.41 (d, 6H, —CH_3), 2.23 (s, 4H, H_2O).

X-ray structural determination

Suitable crystals of **1** were grown by slow evaporation of aqueous solutions at room temperature. A colorless crystal of **1** of dimensions 0.50 × 0.36 × 0.20 mm was selected for diffraction study. Crystals were unprotected from the atmosphere. Data were collected on an automated Enraf-Nonius CAD-4 diffractometer with Mo-K_α radiation ($\lambda = 0.71069$ Å) employing ω-2θ scan mode at 293 K. The unit cell parameters and orientation matrix were obtained by the least squares fit of 25 reflections. Crystallographic data and refinement details are presented in Table 1. The intensity data were reduced using Lorentz and polarization corrections but no absorption correction was applied. After the reduction step all calculations were performed using the NRCVAX PC software package [16]. Trial models for the structures were obtained from phase sets generated from the SOLVER multistation software of NRCVAX. All non hydrogen atoms were placed with a combination of difference Fourier and least squares calculations. Methyl group hydrogen atoms were located from difference Fourier maps, other hydrogen atoms were placed in calculated positions. Anisotropic thermal parameters were used for all non hydrogen atoms and isotropic thermal parameters were used with the hydrogen atoms. Hydrogen atom positions were fixed during the least squares process. Selected interatomic distances and angles for **1** are listed in Table 2. Full crystallographic details, atomic coordinates, interatomic distances and angles, hydrogen atom coordinates and anisotropic displacement parameters for **1** have been deposited with the editor as supplementary material. Structure factor tables may be obtained directly from the authors.

RESULTS AND DISCUSSION

The reaction of **L** with equimolar amount of $ZnCl_2$ yielded colorless **1**. In common with Zn^{II} complexes of most saturated polyaza macrocyclic ligands, **1** in crystalline solids was stable to air indefinitely. The ^1H NMR spectrum of **1** was complicated by sets of several unresolved multiplets over a range of 1.0–3.5 ppm. Proton decoupled ^{13}C NMR spectrum of this compound clearly shows ten resolved singlets indicating that the complex contains ten different kinds of carbon atoms. **1** was soluble in water, nitromethane, dimethylforamide, and chloroform. The infrared spectrum of **1** contains characteristic ligand bands in addition

to the bands due to coordinated water molecules. Absorptions at 3336 cm^{-1} and 3249 cm^{-1} were assignable to antisymmetric and symmetric OH stretchings, and a band at 1643 cm^{-1} was assigned to HOH bending vibration of coordinated water [17]. The bands originated from water disappear upon heating **1** to 100°C for several hours *in vacuo*. Such a behavior is consistent with the loss of molecules of water in the complex.

Structure of **1**

Figure 1 shows the structure of **1** determined by single crystal X-ray crystallography. This is also the first report on the Zn^{II} complex of **L** studied by X-ray crystallography. Most of the related macrocyclic polyamines and their derivatives were earlier reported to form a five-coordinate Zn^{II} complexes with an aquo ligand. However, their solid state structures determined by X-ray crystal structure analysis are scarce [2–12]. The crystal structure of **1** consists of $[Zn(\mathbf{L})(H_2O)_2]^{2+}$ complex cation and two Cl^- anions. The coordination environment around Zn^{II} ion shows an axially elongated octahedron with two oxygen atoms of water molecules and four nitrogen atoms of the macrocyclic ligand. An inversion center exists on the central Zn^{II} ion. The structure of **1** is very similar to that of $[Cu(\mathbf{L})(H_2O)_2](Cl)_2$ which was described

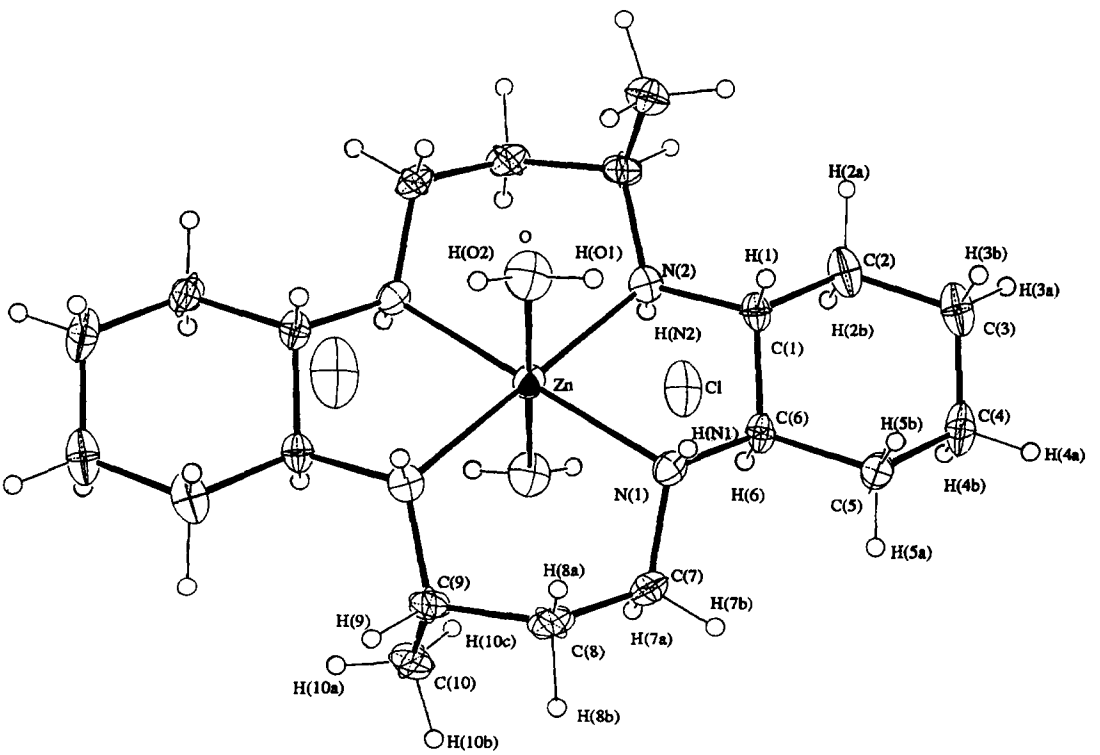

Fig. 1. ORTEP drawing of **1** with atom-labeling scheme.

Table 3. Hydrogen-bond parameters (Å,) for $[Zn(L)(H_2O)_2](Cl)_2$ (**1**)

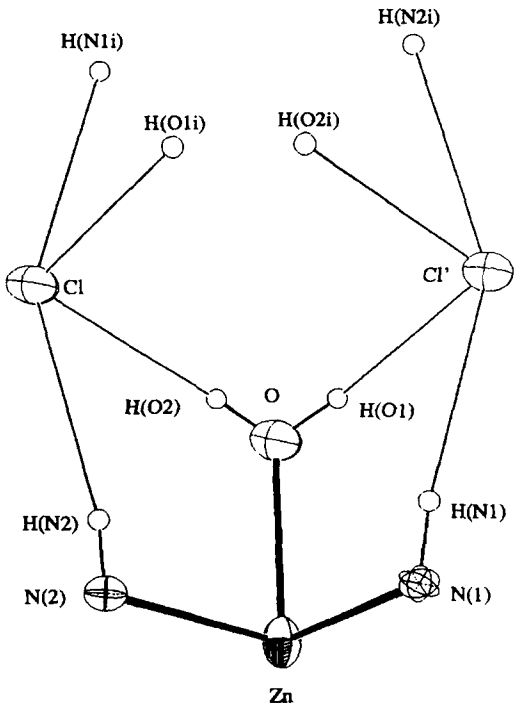

Fig. 2. Hydrogen-bond system of **1**.

recently by us [18]. The ligand skeleton of the complex contains two cyclohexane rings and two gauche five-membered and two chair six-membered chelate rings with most stable trans-III conformation. The bond distances of Zn—N in this complex are 2.084 (2) Å and 2.113 (2) Å, which are comparable to those found in $Zn(O_2COCH_3)([14]aneN_4)(ClO_4)$ (2.111 (3) Å and 2.088(3) Å) [9]. The determined distance of 2.388(3) Å is, to our best knowledge, the longest reported in a complex of this type. The average Zn—O (O = terminal aquo) distance is 2.090 ± 0.061 Å determined for 56 structures [19]. The longer Zn—O bond distance may be explained by the four hydrogen bonding chelate rings consisted of chlorides, water molecules, secondary amines of macrocycle, and the central Zn^{II} ion (Table 3 and Fig. 2). Under this situation, the coordination of the water molecules to the central Zn^{II} ion seems to be stabilized although the Zn—O bond distance is longer [20].

Abstract—The neodymium nitrate complex with 1,4-bis(phenylsulfinyl)butane(bphsb)$[Ln(bphsb)_2(NO_3)_3]_n$ has been synthesized and characterized. The X-ray crystal structure determination of the complex indicates that bphsb and neodymium(III) ion form a polymeric chain involving 18-membered macrocycles, each macrocycle comprising two neodymium(III) ions. The adjacent metal centres are linked by the bridging ligand. Each neodymium ion is ten-coordinated and the coordination geometry is a distorted 4,4-bicapped square antiprism. The IR and absorption spectra of solid and solution for the complex were also studied. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: neodymium; 1,4-bis(phenylsulfinyl)butane; crystal structure; complex of polymeric chain; 18-membered macrocycle; absorption spectrum.

Synthesis and characterization of lanthanide polynuclear complexes are important for developing the nature and applications of lanthanide metal–metal interaction in lasers, light-conversion molecular devices and paramagnetic contrast enhancing agents in magnetic resonance imaging [1–3].

Appropriate choice of metal and polydentate ligand is the key in forming polynuclear complexes. It is noticed that the number and types of atoms between the bridging units and the nature of terminal group of polydentate ligand which are important in preparing lanthanide polynuclear complexes. We chose 1,4-bis(phenylsulfinyl)butane (bphsb) as bridging ligand containing two phenyl terminal groups and having a separation of six atoms between coordinated atoms in order to obtain a polynuclear complex. A polynuclear europium(III) complex has been prepared by reaction of $Eu(NO_3)_3$ and bphsb [4]. It is shown that this ligand is the preferred bridging ligand for forming polynuclear complexes. We report here the results of synthesis, crystal structure and spectroscopic studies of a novel homopolynuclear neodymium complex of 1,4-bis(phenylsulfinyl)butane with a polymeric chain involving 18-membered macrocycles.

EXPERIMENTAL

Synthesis of complex $[Nd(bphsb)_2(NO_3)_3]_n$

1 mmol of hydrated neodymium nitrate dissolved in 10 cm^3 of anhydrous methanol was dehydrated by the addition of 2 cm^3 triethylorthoformate. The solution was added dropwise to 4 cm^3 anhydrous methanol solution of ligand (bphsb, 3 mmol). The mixture was stirred at 70–80°C for 6 h. Small precipitate was filtered, the filtrate was allowed to evaporate slowly at room temperature, and after a week, reddish single crystals were obtained. Found: C, 39.8; H, 4.2; N, 4.0. Calc. for $C_{32}H_{36}N_3S_4O_{13}Nd$: C, 40.7; H, 3.8; N, 4.4%.

Physical measurements

The IR spectrum of the complex in the 4000–400 cm^{-1} range (as KBr pellets) was recorded on a WHF-30 model spectrometer. Conductivity of the complex in the methanol solution (10^{-3} mol dm^{-3}) was measured at room temperature using a DDS-11A conductometer. Thermal analysis in air was carried out on a PCT-1 analyzer. Electronic spectrum of the methanol solution of the complex was recorded in the 190–325 nm range and solid and solution spectra in the 800–350 nm range were also measured at room temperature on a Shimadzu UV-240 spectrophotometer.

The X-ray data collection was performed at 299 ± 1 K on an Enraf-Nonius CAD4 diffractometer with graphite-monochromated Mo-K_α radiation (=0.071073 nm) in ω-2θ scan mode. Reflections were collected in the range of $2 \leqslant \theta \leqslant 23°$. An empirical absorption correction was applied. The crystal structure was solved by direct methods (MULTAN82). The final refinement was by the full-matrix least squares method. All the calculations were carried out on a PDP11/44 and IBM-486 computer using a SDP-PLUS program system.

Crystallographic data for the title complex is listed in Table 1.

RESULTS AND DISCUSSION

The complex has the stoichiometry [Nd(bphsb)$_2$(NO$_3$)$_3$]. The electrical conductance values ($\sim$0 s mol^{-1} cm^2) of the complex in methanol indicate that the complex behaves as a non-electrolyte. The complex is air stable at room temperature. Thermal analysis of the complex shows that decomposition started above 215°C. In the IR spectrum of the complex, the S=O band is shifted to lower frequencies (986 cm^{-1}) than that for the free ligand (1039.8 cm^{-1}), which indicate coordination through the oxygen of the S=O moieties of the bphsb. The IR spectral data also show that absorption peaks of bidentate coordinated nitrate ions (C_{2v}) present at 1458($\nu_1(A_1)$), 1334($\nu_4(B_1)$), 1020($\nu_2(A_1)$), 820($\nu_3(A_1)$), 740 cm^{-1} ($\nu_5(B_1)$) and 1774($\nu_2 + \nu_5$), 1746 cm^{-1} ($\nu_2 + \nu_6$) [5].

Description of the crystal structure

Selected bond lengths and angles are listed in Tables 2 and 3. A table of atomic coordinates and equivalent isotropic displacement coefficients and structure factors are included as supplementary material.

Single crystal structure analysis shows the complex to have the stoichiometry [Nd(bphsb)$_2$(NO$_3$)$_3$)] and to be polymeric structure (Figs 1 and 2). Each neodymium centre is ten-coordinated and is bound to one oxygen atom of each of four bphsb ligands and three bidentate nitrates. The Nd—O distances lie in two groups, those to the sulfoxide oxygen atoms in the range 0.2416–0.2503 nm and those to nitrate oxygens in the range 0.2548–0.2620 nm. The coordinated geometry is best described as a 4,4-bicapped square antiprism with O(1), O(8), O(13), O(31), O(4), O(2), O(22), O(32), forming the vertices with bi-capped by O(12) and O(21) for Nd(1) (Fig. 3).

Adjacent neodymium centers are linked *via* oxygens of bphsb ligands which form a chain linked system of a polymeric molecule. The bphsb ligands perform a bridging function. Each chain system comprises 18-membered macrocyclic rings, each containing two neodymium(III) ions. In each chain system, the arrangement of the 18-membered macrocyclic rings is ordered (Fig. 2).

The stoichiometry and structure of the crystal products obtained from the methanol solution of bphsb for neodymium(III) and europium(III) nitrate are not the same. The neodymium(III) ion afforded the complex [Nd(bphsb)$_2$(NO$_3$)$_3$]$_n$, molar ratio (M : L) = 1 : 2, but europium(III) ion gave the compound of stoichiometry [Eu(bphsb)$_{1.5}$(NO$_3$)$_3$]$_n$ [4], molar ratio

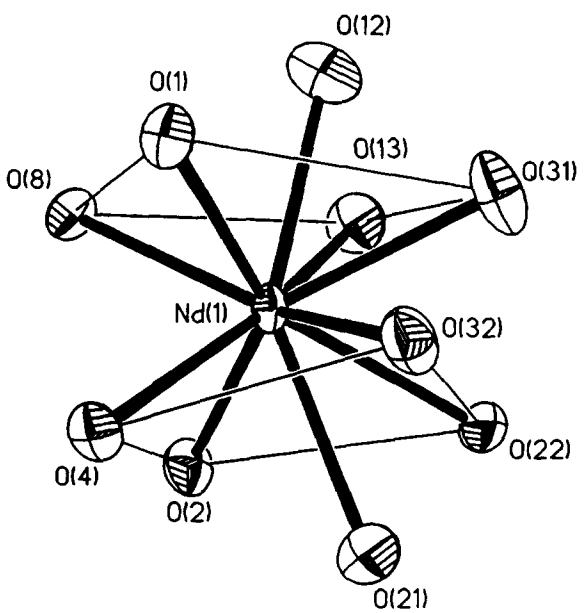

Fig. 3. The coordination around each Nd atom.

(M : L) = 1 : 1.5. These results may be due to the size of the lanthanide ion influencing complex type and structure, the europium polynuclear complex [Eu(bphsb)$_{1.5}$(NO$_3$)$_3$]$_n$ is a supramolecular compound with a framework structure [4].

Spectral properties

The absorption spectra of the methanol solution and solid for the complex were examined. The absorption spectra of solution and solid in the visible region show *f–f* transitions. Tentative assignments and strengths for the bands are given in Table 4. The average values of Sinha's parameter (δ) [6] for solution and solid case suggest a very weak covalent character for the metal–ligand bonding.

The absorption spectrum of solution in the range 190–330 nm shows that n–π^* transition (212 nm) of S=O of bphsb and π–π^* transitions (239 and 270 nm) of phenyl of bphsb.

Novel pentacoordinated ruthenium(II) complexes with a NNS chelating ligand: synthesis, characterization and electrochemical studies

Mosarraf Hossain, Shyamal Kumar Chattopadhyay† and Saktiprosad Ghosh*

Department of Inorganic Chemistry, Indian Association for the Cultivation of Science, Calcutta 700 032, India.

(Received 29 May 1996; accepted 14 October 1996)

Abstract—The NNS chelating donor *N*-2-mercaptophenyl-(2′-pyridyl)methylenimine (PabtH) reacted with $Ru(PPh_3)_3Cl_2$ to give a series of ruthenium(II) complexes Ru(Pabt) $(PPh_3)X$ {X = Cl(**1**), Br(**3**)}, Ru(Pabt) $(PPh_3)_2Cl$ (**2**), [Ru(Pabt) $(PPh_3)L]ClO_4$ {L = 1-Meimz (**2a**), 2-Meimz (**1c**)}, [Ru(Pabt) (PPh_3) $(L')_2]ClO_4$ {L′ = 1-Meimz (**1a**), imz (**1b**), H_2O (**1f**)} and [Ru(Pabt) (PPh_3) (L-L)]ClO_4 {L-L = bpy (**1d**), Phen (**1e**); bpy = 2, 2′-bipyridine, Phen = 1,10-phenanthroline}. They have been characterized using IR, UV–vis, {^1H and ^{31}P} NMR, EPR, magnetic susceptibility at room temperature, measurement of molecular weight, molecular conductance in solution and elemental analysis. The stabilisation of the pentacoordinated 16-electron complexes (**1, 3, 1c** and **2a**) is attributed to $p\pi$ donation by the sulfur atom of the ligand Pabt. Square pyramidal structure is proposed for these pentacoordinated complexes. Electron transfer behaviour of all the complexes has been explored by cyclic voltammetry in CH_2Cl_2 and CH_3CN using TEAP as the supporting electrolyte. The five-coordinated complexes display cathodically shifted oxidation waves in CH_2Cl_2, when TEACl was used as supporting electrolyte. Linear correlation of electrochemical data in terms of Lever's electrochemical parameter E_L and the energy of metal to ligand charge transfer band has been attempted. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: pentacoordination; ruthenium(II) complexes; mixed ligand complexes; NNS-ligand; chemical reactivity; electrochemical studies.

The chemistry of nitrogen–sulfur chelating ligands has witnessed phenomenal growth during the last decade. This was stimulated particularly by the discovery of the occurrence of similar donor environment in the prosthetic groups of several oxidoreductases [1,2]. However, one of the metal ions that has received little attention in such studies is ruthenium, probably because of its non-availability in biological systems. The relatively small amount of work so far carried out on ruthenium complexes involving such ligands indicate that they exhibit very interesting redox, electronic and structural characteristics [3–9]. It is also well known that chelating nitrogen–sulfur donors can stabilise complexes of unusual oxidation states [10–15] and uncommon coordination numbers of metal ions [13–16]. Such complexes are also known to participate in diverse redox reactions [17–19], sometimes even forming complete electrochemical series [17]. In this chemical milieu, the chemistry of ruthenium ligated to nitrogen–sulfur chelating ligands promises to be quite fascinating. This paper reports the synthesis and reactivity of ruthenium complexes of the NNS chelating ligand N-2-mercaptophenyl (2′-pyridyl) methylenimine (PabtH), which affords a few ruthenium complexes with unusual coordination number. Exploration of the redox behaviour of the ruthenium complexes of PabtH itself and those in which other coligands are present in the first coordination sphere of the ruthenium centre receives appropriate attention in this work.

EXPERIMENTAL

Physical measurement

Carbon, hydrogen and nitrogen analyses were performed in a Perkin–Elmer 240 C,H,N analyser and halogens were estimated by the reported method.[20] IR spectra were recorded with a Perkin-Elmer 783 Spectrophotometer using the KBr and polythene powder wafer techniques. Thermogravimetric (TG) and differential thermal analysis (DTA) were done in a Shimadzu DT-30 thermal analyser. Electronic spectra of the compounds were taken on a Shimadzu Model UV-2100 UV–vis recording spectrophotometer. Electrical conductance data in solution were collected using a Philips PR-9500 conductivity bridge fitted with a dip-type cell calibrated with 0.02 M KCl solution. Static susceptibility measurements at room temperature were made with the help of a Princeton Applied Research Model 155 vibrating-sample magnetometer using $Hg[Co(SCN)_4]$ as the calibrant. Molecular weight in CH_2Cl_2 was determined by KNAUER model Vapor Pressure Osmometer connected to a Recorder (type 11.15) using benzil as the calibrant. Proton NMR spectra were recorded on a Varian XL100 FT-NMR spectrometer using TMS as internal indicator. $\{^{31}P\}$NMR spectrum was recorded in $CDCl_3$ using 85% H_3PO_4 as external reference. Electron spin resonance spectra were recorded on a Varian E4 X-band EPR spectrometer, using diphenylpicrylhydrazyl (dpph) as an internal field marker. Electrochemical studies were done with the help of a PAR Model 370-4 electrochemistry system, 174A polarographic analyser, 175 universal programmer, RE 0074 X-Y recorder at 298 K. All these experiments were carried out under dry nitrogen. A planar Beckman model 39273 platinum-inlay working electrode, a platinum-wire auxiliary electrode and a saturated calomel electrode (SCE) as the reference electrode were used in the three-electrode configuration. The saturated calomel electrode (SCE) was separated from the sample compartment by a salt bridge connected by glass frit filled with the solvent (0.1 M supporting electrolyte) for the measurement. Under these experimental conditions the ferricenium–ferrocene couple was located at 0.42 V. In controlled potential electrolysis, a platinum mesh was used as working electrode and the auxiliary electrode was separated from the solution by a sintered glass disk.

Chemicals

$RuCl_3$ was obtained from Arora-Matthey Limited. 2-(2-Pyridyl)benzothiazoline (PabtH) [15], $Ru(PPh_3)_3Cl_2$ and $Ru(PPh_3)_3Br_2$ were prepared using the published procedure [21,22]. All other chemicals used for preparative work were of reagent grade and were used without further purification. Reagent grade solvents were dried and distilled by the usual methods [23]. Tetraethylammonium perchlorate (TEAP) was prepared from tetraethylammonium bromide (Fluka AG) by following a standard procedure [24]. All reactions were performed under dry nitrogen.

Preparation of $Ru(Pabt)(PPh_3)Cl$ (**1**) *and* $Ru(Pabt)(PPh_3)_2Cl$ (**2**). Solid $Ru(PPh_3)_3Cl_2$ [120 mg, 0.125 mmol] in 20 cm^3 benzene was refluxed with a benzene (5 cm^3) solution of 2-(2-pyridyl) benzothiazoline [54 mg, 0.25 mmol] for 2 h. A brown complex **1** separated from hot solution. The mixture was cooled and filtered under nitrogen. The residue was washed several times with degassed benzene and dried over fused $CaCl_2$. Yield 63 mg (82%).

The volume of the filtrate was reduced to one-third in a rota-evaporator, excess of degassed ether was added to it and the mixture was allowed to settle (5 min). Compound **2** separated out and was filtered, washed thrice with degassed ether and dried *in vacuo*. Yield 10 mg (9%).

When the above reaction was carried out in benzene using (1 : 1) molar ratio of the reactants, compound **1** separated out from the hot solution, being the only product in this reaction. When the reaction was carried out in CH_2Cl_2 using 1 : 1 molar ratio of reactants, the compound **1** had to be precipitated by the addition of excess degassed ether.

Preparation of $Ru(Pabt)(PPh_3)Br$ (**3**). This complex was prepared by a method similar to that of complex **1** using $Ru(PPh_3)_3Br_2$ as the starting material. Yield 70 mg (85%).

Preparation of $[Ru(Pabt)(PPh_3)(1\text{-}Meimz)_2]ClO_4 \cdot 1.5CH_2Cl_2$ (**1a**). ***Warning***: Perchlorate salts of metal complexes are potentially explosive [25]. To a stirred solution of $Ru(Pabt)(PPh_3)Cl$ (**1**) [1 mmol] in 40 ml dichloromethane, excess [~100 mmol] 1-methylimidazole (1-Meimz) was added and the mixture was stirred at room temperature for 24 h. The volume was then reduced to 10 cm^3 in a rotaevaporator. To this concentrated solution, excess petroleum ether (60–80 °C) was added and the mixture was allowed to settle [10 min] in a refrigerator. When an oily product settled down, the supernatant liquid was decanted off, the oily compound was dissolved in acetone and excess ether was added. The separated oily product was again dissolved in methanol and excess degassed aqueous solution of $LiClO_4$ was added to it. A granular compound precipitated out. It was filtered, washed thoroughly with degassed water and dried over fused $CaCl_2$. The compound was recrystallised from degassed CH_2Cl_2. Yield 600 mg (62%).

Preparation of $[Ru(Pabt)(PPh_3)(imz)_2]ClO_4 \cdot 0.5 CH_2Cl_2$ (**1b**), $[Ru(Pabt)(PPh_3)(2\text{-}Meimz)]ClO_4$ (**1C**). ***Warning***: Perchlorate salts of metal complexes are potentially explosive [25]. These two compounds were synthesized and purified by the above procedure using imidazole (imz) and 2-methylimidazole (2-Meimz), respectively, in place of 1-methylimidazole. The complexes **1a, 1b** and **1c** can also be prepared using methanol as the solvent. Yield of **1b** was 495 mg (58%). Yield of **1c** was 360 mg (48%).

Preparation of [Ru(Pabt)(PPh_3)(1-Meimz)]ClO_4 (**2a**). ***Warning***: Perchlorate salts of metal complexes are potentially explosive [25]. This compound was prepared and purified by reacting Ru(Pabt) (PPh_3)$_2$Cl (**2**) with excess 1-methylimidazole following the procedure used for **1a**. Yield 320 mg (42%).

Preparation of [Ru(Pabt)(PPh_3)(bpy)]Cl · 1.5CH_2Cl_2 (**1d**) *and* [Ru(Pabt)(PPh_3)(phen)]Cl · CH_2Cl_2 (**1e**). To a dichloromethane [40 cm^3] solution of Ru(Pabt) (PPh_3) Cl (**1**) [1.0 mmol], a solution of 10 ml of 2,2′-bipyridine (bpy) and 1,10-phenanthroline (phen) [1.05 mmol] was added and the mixture was refluxed for 7 h. The volume of the resultant solution was reduced to 5 cm^3 in a rotaevaporator and excess petroleum ether was added. The precipitated compound was allowed to settle and then filtered. The residue was stirred with ether twice to remove excess 2,2′-bipyridine/1,10-phenanthroline. It was then filtered and dried over fused $CaCl_2$. Both **1d** and **1e** were recrystallised from degassed CH_2Cl_2. Yield of **1d** was 350 mg (39%). Yield of **1e** was 440 mg (49%).

Preparation of [Ru(Pabt)(PPh_3)(H_2O)$_2$]ClO_4 (**1f**). ***Warning***: Perchlorate salts of metal complexes are potentially explosive [25]. To a methanolic solution 50 cm^3 of Ru(Pabt) (PPh_3)Cl (**1**) [0.5 mmol], aqueous silver perchlorate solution [0.6 mmol in 10 cm^3 H_2O] was added with stirring. The mixture was refluxed with stirring for about 1h, cooled and filtered through a sintered bed funnel (G4) to remove AgCl. The volume of the filtrate was reduced to 10 cm^3 and aqueous $LiClO_4$ solution was added in excess. The compound that separated out was filtered, thoroughly washed with water and dried over fused $CaCl_2$. It was recrystallised from CH_2Cl_2. Yield 370 mg (52%).

RESULTS AND DISCUSSION

The ligand PabtH exists in the benzothiazoline form [26] in the free state and is transformed to the corresponding Schiff base in the presence of either a base or a metal ion (Fig. 1). The complexes **1** and **3** of general formula Ru(Pabt)(PPh_3)X [X = Cl, Br respectively] were isolated by the reaction of Ru (PPh_3)$_3$$X_2$ with the ligand in 1 : 2 molar ratio in refluxing benzene and Ru(Pabt) (PPh_3)$_2$Cl (**2**) was isolated from the filtrate of **1**. When the reaction was carried out in benzene using 1 : 1 molar ratio of the reactants, compound **1** separated out from hot benzene as the only product. When Ru(PPh_3)$_3$$Cl_2$ was reacted with one mole of PabtH in refluxing CH_2Cl_2 **1** was obtained as the sole product, while **3** was isolated as the only product when Ru(PPh_3)$_3$$Br_2$ was used. Molecular weight determination in CH_2Cl_2 [Molecular weight of **1**, Exp. = 601, Calc. = 611.79; **3**, Exp. = 639, Calc = 656.19] clearly indicated the monomeric nature of **1** and **3**. The penta-coordinated complex **1** reacted with excess of different N-donor ligands (imidazole, 1-methylimidazole and 2-methylimidazole) producing hexacoordinated complexes [Ru(Pabt) (PPh_3) (B)$_2$]ClO_4 [where B = imz, 1-Meimz] and also the pentacoordinated species [Ru(Pabt) (PPh_3) (2-Meimz)]ClO_4. Moreover, complex **1** reacted with bidentate N—N donor ligands such as 2,2′-bipyridyl or *o*-phenanthroline in 1 : 1 molar ratio to produce hexacoordinated [Ru(Pabt)(PPh_3)(L—L)]Cl type complexes [where L—L = bipy, *o*-phen]. Another pentacoordinated complex [Ru(Pabt)(PPh_3)(1-Meimz)]ClO_4 (**2a**), was obtained by reacting Ru(Pabt) (PPh_3)$_2$Cl (**2**) with excess 1-Meimz in CH_2Cl_2 and subsequent treatment with a concentrated aqueous $LiClO_4$ solution. The aquo complex **1f** was prepared by Cl^- abstraction from Ru(Pabt)(PPh_3)Cl using $AgClO_4$ in methanol solution. For convenience the different synthetic routes for the preparation of various ruthenium complexes are summarised in Equation I. The compounds gave satisfactory analytical results (Table 1) which are in good agreement with the assigned formulation. The formula of compounds **1a**, **1c** and **2a** were also checked by {^{1}H}NMR spectrum using the integration ratio of the methyl proton signal to those of the residual proton signals. The conductance data (Table 1) also supports the proposed formulation of the compounds **1a–1f** and **2a** as 1 : 1 electrolytes [27] with their anion Cl^- or ClO_4^- not participating in coordination. However compound **1**, **2** and **3** are nonelectrolytes and hence contain coordinated halide. This is supported by the presence of the ν(Ru—Cl) bands in their IR spectra (*vide infra*). The diamagnetic nature of all the complexes suggests the presence of the +2 oxidation state of ruthenium. The complexes (**1a–1f, 2a**) are highly soluble in common organic solvents. The complexes **1**, **2** and **3** are moderately soluble in CH_3CN, but fairly soluble in CH_2Cl_2.

Infrared spectroscopy

The ligand PabtH exhibits a strong band at 3190 cm^{-1} due to ν(N—H) vibration [15], which is absent

[a] = MeCN, X = Cl or Br

in the complexes **1, 2** and **3**. This strongly suggests that the ligand is present in its Schiff base form, in which it is known [26] to act as a monoanionic tridentate ligand coordinating through pyridine N, imine N and thiolato S. In the spectra of the mixed ligand complexes **1a–1e** and **2a,** there seems to be extensive mixing between the bands of the main ligand (Pabt) and those of the coligand bases. This makes precise assignment of the individual vibrations to definite vibrational modes very difficult. However, absence of any band at 2400–2500 cm^{-1} due to ν(S—H) in all these complexes indicates that the ligand is coordinated to the metal through the thiolato sulfur [28]. A medium intensity band at 1585 cm^{-1} assigned to ν(CN) vibration in the ligand is red shifted by $\sim$40 cm^{-1} in the complexes due to coordination [9,29] of the azomethine nitrogen to the Ru^{II} centre. The ν(CS) band present at 750 cm^{-1} in the ligand is lowered by $\sim$5 cm^{-1} on complexation and indicates M—S bond formation [30]. The pyridine ring vibration at 620 cm^{-1} and 420 cm^{-1} are blue shifted by *ca* 10 cm^{-1} because of the coordination through the pyridine ring nitrogen. In addition, the presence of a broad band around 1100 cm^{-1} in the IR spectra of the complexes **1a–1c, 1f** and **2a** indicates that ionic ClO_4^- is present in these complexes [9]. The band at 300 cm^{-1} and 320 cm^{-1} in complexes **1** and **2** respectively can be assigned as ν(Ru—Cl) band [8, 31]. However, we could not detect the ν(Ru—Br) for the compound **3** up to 300 cm^{-1}, which is the detection limit of our instrument.

$\{^1H\}$NMR spectroscopy

The $\{^1H\}$NMR spectra of the ligand PabtH exhibits a signal at 5.12 ppm which is assigned to the N—H proton and is confirmed by D_2O exchange experiment. The complexes **1, 2** and **3** do not exhibit the characteristic N—H proton signal and indicate that in the metal complexes the ligand is present in its deprotonated form of the Schiff base. All the complexes exhibit proton signals in the aromatic region 6.8–7.6 ppm, which cannot be properly assigned due to overlap of corresponding signals of PPh_3 and the ligands. The compound $[Ru(Pabt)(PPh_3)(1\text{-Meimz})_2]ClO_4$ (**1a**) in $CDCl_3$ exhibits two methyl signals of almost equal intensity at 3.51 ppm and 3.66 ppm indicating *cis* disposition of the two coordinated 1-methylimidazoles. The complex **2a** which contains only one 1-Meimz moiety, exhibits two signals of equal intensity (in $CDCl_3$) at 3.50 ppm and 3.63 ppm, whose combined integration corresponds to one methyl proton. This may indicate that two isomers of square pyramidal geometry (*vide infra*) coexists in solution.

Electronic spectroscopy

The electronic spectrum of 2-(2-pyridyl) benzothiazoline consists of three bands at 232, 255 and 310 nm, characteristic of the cyclic form. These may be attributed to the σ–σ^*, π–π^* and n–π^* benzenoid transitions [32]. All the complexes exhibit rich electronic spectra (Table 2) characteristic of the

complexes of Pabt with other metals [15]. However, correct assignment of the bands is difficult without detailed analysis. In the UV-visible region there are generally two bands near 460–550 nm and 350–450 nm regions. The high extinction coefficient of the bands indicate that they are mainly of charge transfer origin. Among them, the lower energy band is probably due to a MLCT transition from the Ru^{II} centre to the Pabt ligand. This is supported by the fact that the plot (Fig. 4(a) and Fig. 4(b)) of $E_{Ru^{III}/Ru^{II}}$ (*vide infra*) *vs* the above MLCT transition expressed in eV gives a straight line, as has been observed for similar systems [5,33]. However, for bipyridine and orthophenanthroline complexes the above assignments are not unambiguous as transitions from Ru^{II} $d\pi$ to π^* of bpy or phen occur in the same region [33]. The band at 220–325 nm region is due to intraligand transitions.

Proposed structure of the complexes

The complexes Ru(Pabt)(PPh_3)X [X = Cl (**1**) and X = Br (**3**)] are five-coordinated and probably square pyramidal. The five-coordinated nature of these complexes is supported by the molecular weight determination of Ru(Pabt) (PPh_3)Cl. TG-DTA traces clearly exhibit the absence of any water or solvent molecule in the complexes. The formation of such five-coordinated square pyramidal complexes is supported by Sellmann's work on a series of complexes of sulfur and nitrogen-sulfur donors. Sellmann reported the reaction of [Ru(PPh_3)$_2$(dttd)] and [Ru(PPh_3)$_2$(bmae)] [where dttd$^{2(-)}$ = 2,3,8,9-dibenzo-1,4,7,10-tetrathiadecane(−2), bmae$^{2(-)}$ = 1,2-bis(2-mercaptoanilino)ethane(−2)] with CO proceeds through the unsaturated 5-coordinated intermediate [3,34]. Moreover, he succeeded in isolating the distorted square pyramidal [Ru(^{bu}bmae)]$_2$ [where ^{bu}bmae$^{2(-)}$ = 1,2-bis(2-mercapto-3,5-di-^{t}butyl-anilino)ethane (2−)] having a vacant coordination site [35]. The formation of stable five-coordinated complexes **1** and **3** and lability of the six-coordinated complex **2** [to form five-coordinated **2a**] is probably due to the stabilisation of five-coordinated 16 electron species through $p\pi$ donation by sulfur as suggested by Sellmann [3,34,35].

It has also been proposed that complexes of five-coordinated d^6 ions are best classified as square-pyramidal [36] which is in agreement with the second-order Jahn–Teller effect [37,38]. This view, taken along with the fact that most of the reported five-coordinated complexes of ruthenium are square pyramidal with varying degree of distortions, has induced us to propose that the five-coordinated complexes reported in this study also possess square pyramidal coordination geometry. As the ligand (Pabt) is planar [25] due to conjugation of all the atoms present, two isomeric arrangements are possible for the square pyramidal geometry (Fig. 2). Among these two possibilities, isomer "**a**" containing PPh_3 in axial position is expected to be more stable, both from steric as well as electronic point of view. The isomer "**b**" may be stabilised from the agostic interaction of H atom from the PPh_3 ligand [39] which is known to stabilise Ru(PPh_3)$_3$Cl$_2$. Formation of **1a, 1b, 1d** and **1e** can then be easily explained by replacement of equatorial X and occupation of the vacant axial position by two N donor atoms of two imidazoles or a bipyridyl/phenanthroline.

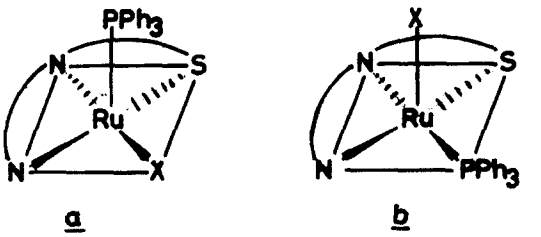

Fig. 2. Two possible isomeric arrangements of Ru(Pabt)(PPh_3)Cl (**1**)

The structure of six-coordinated complexes [Ru(pabt) (PPh_3)$_2$Cl] (**2**) is established by $\{^{31}P\}$NMR spectrum in $CDCl_3$, which exhibits a single sharp peak at 20.2 ppm indicating that the two PPh_3 groups are trans to each other [40]. Thus the square plane is occupied by the ligand Pabt and a chloride (Fig. 3(a)).

The probable structure of the complex [Ru(pabt) (PPh_3)(2-Meimz)]ClO_4 (**1c**) is shown in (Fig. 3(b)). Molecular model shows that the CH_3^- group on the ligated 2-Meimz sterically restricts the access of a second 2-Meimz at the vacant sixth position of Ru.

Cyclic voltammetry. The electron transfer behaviour of all the complexes has been examined in dichloromethane and acetonitrile solvents, containing 0.1 M TEAP using cyclic voltammetric technique (scan rate 200 mV s^{-1}). The results are summarised in Table 3.

The complexes exhibit reversible oxidative responses in the potential range 0.3–1.0 V. The compound **1** exhibits a one electron anodic wave at a $E_{1/2}$ of 0.40 V *vs* SCE in both the solvents which corresponds to the process (**I**).

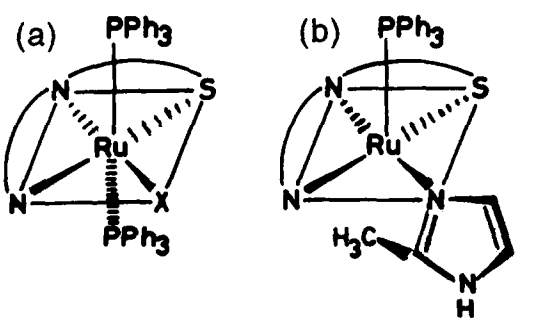

Fig. 3. (a) Possible structure of Ru(Pabt)(PPh_3)$_2$Cl (**2**); (b) Possible structure of [Ru(Pabt)(PPh_3)(2-Meimz)]ClO_4 (**1c**).

Table 3. Cyclic voltammetric results for [a,b] Ru^{II} complexes in 0.1 M TEAP at 298 K

[d]Corresponding cathodic wave E_{pc} = 0.45 V.

$$Ru(NNS^-)(PPh_3)Cl \underset{+e}{\overset{-e}{\rightleftharpoons}} [Ru^{III}(NNS^-)(PPh_3)Cl]^+. \quad \textbf{(I)}$$

This assignment is justified by the fact that, when compound **1** is oxidised chemically with iodine in dichloromethane solution, the EPR spectrum of the oxidised species at 77 K is found to be highly anisotropic. It is known that Ru^{III} compounds give rise to highly anisotropic EPR spectra [23]. The g values ($g_1 = 2.12$, $g_2 = 2.29$ and $g_3 = 2.59$), as well as a large separation of 530 G between the lowest and highest field peak indicates that the unpaired electron is predominantly metal centred [41]. So the above oxidation involves a metal based redox orbital. Complex **3**, the bromo analogue of **1**, exhibits a peak at $E_{1/2}$ = 0.44 V in dichloromethane, which is consistent with a reaction similar to the one described by process (**I**). But when compound **3** is scanned in MeCN it reveals an irreversible anodic wave at E_{pa} = 0.66 V. The anodic shift of this peak is probably due to the solvent participation [42].

When the scanning is extended to higher positive potentials, it reveals ill-defined peaks which may be due to ligand oxidation or can be attributed to oxidation of triphenyl phosphine [43].

When the voltammogram of **1** is run in dichloromethane with TEACL as the supporting electrolyte a cathodic shift of the anodic peak is observed (Table 3). The negative shift of the first anodic peak ($E_{1/2}$ = 0.19 V) can be explained considering direct coordination of Cl ion to the metal centre of the coordinatively unsaturated complex, prior to its participation in electrolysis [19]. The involvement of the Cl facilitates the oxidation of the complex by decreasing the overall positive charge of the complex ion [process (**II**)].

$$Ru^{II}(NNS^-)(PPh_3)Cl \underset{-Cl^-}{\overset{+Cl^-}{\rightleftharpoons}} [Ru^{II}(NNS^-)(PPh_3)Cl_2] \underset{+e}{\overset{-e,0.19}{\rightleftharpoons}} Ru^{III}(NNS^-)(PPh_3)Cl. \quad \textbf{(II)}$$

The corresponding bromo complex **3** exhibits similar behaviour. The five coordinated complexes **1c** and **2a** similarly display cathodically shifted oxidation waves in dichloromethane when TEACL used as supporting electrolyte.

The six-coordinated complex **2** displays an anodic wave at 0.63 V. Here, due to the presence of additional PPh_3 in the sixth position, Ru^{III}/Ru^{II} potentials are anodically shifted [44]. This happens because the presence of an extra PPh_3 results in a HOMO with different energy. The reductive couple at −0.08 V of same current height may be due to Ru^{II}/Ru^{I} reduction as reported earlier [45].

As expected, the $E_{1/2}$ values of the cationic complexes (**1a–1f**) and **2a** are more positive compared to the neutral [46] parent complexes **1** and **3**. The one-electron change of the complexes **1d** and **1e** was checked coulometrically [for **1d** n = 0.98 (1.15 V); for **1e** n = 1.03 (1.15 V)]. It is obvious that in all the complexes the oxidation potential values in CH_2Cl_2 are greater than those in MeCN, due to the difference in solvent polarity.

During the cyclic voltammetric study of the complex **1e** in acetonitrile solution using TEAP as the supporting electrolyte, attention was drawn to an interesting observation. Gradual addition of PPh_3 to the solution of the complexes caused an increase in the i_{pa}/i_{pc} value at 0.98 V accompanied by a small anodic shift. This may happen due to the interaction between **1e** or its oxidised species with PPh_3, the latter

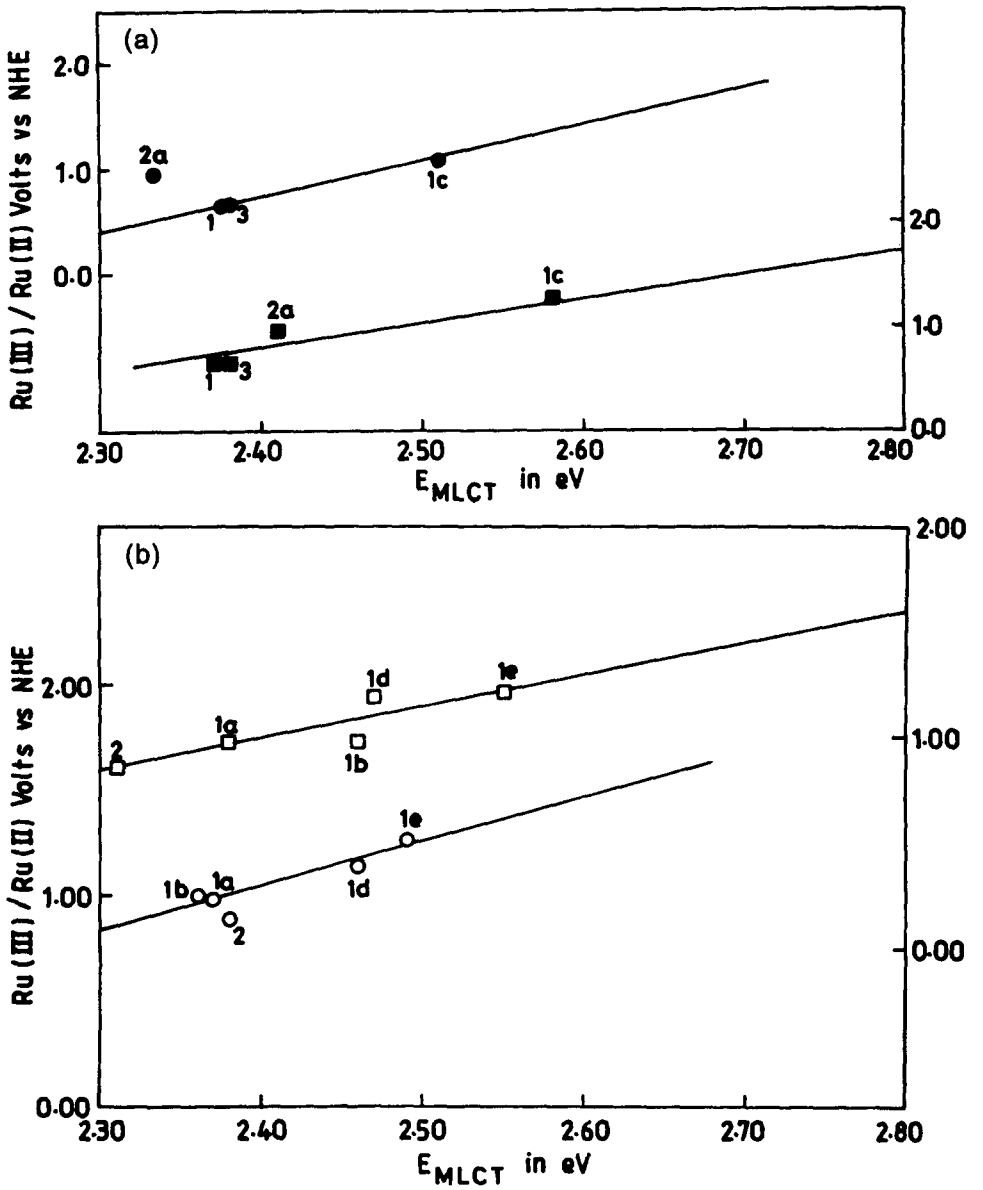

Fig. 4. Plots of observed Ru^{III}/Ru^{II} potentials ($E_{1/2}$) against the energy of the metal-to-ligand charge transfer transition (E_{MLCT}) of (a) six-coordinated complexes: (bottom, open circles) measured in CH_2Cl_2 and referred to left-hand y-axis; (top, open square) measured in CH_3CN and referred to right-hand y-axis. All data are *vs* NHE (1 V *vs* SCE = 1.242 V *vs* NHE); (b) five-coordinated complexes: (top, closed circles) measured in CH_2Cl_2 and referred to left-hand y-axis; (bottom, closed square) measured in CH_3CN and referred to right hand y-axis. All data are *vs* NHE (1 V *vs* SCE = 1.242 V *vs* NHE).

undergoing catalytic oxidation. The complex **1d** also behaves similarly. Similar observations were made in dichloromethane solution. Such observations were recorded previously for electrochemical reduction of molybdenum complexes [47–49].

It is possible to compare the observed $E_{1/2}$ values of Ru^{III}/Ru^{II} couples of the six-coordinated complexes with that calculated according to the linear relation given by Lever in organic solvents, based on his electrochemical ligand parameter E_L [50]. Two least-square lines (Fig. 5) obtained are as follows: dichloromethane: $E_{Ru^{III/II}} = 0.73\,[\Sigma E_L] + 0.30$; acetonitrile: $E_{Ru^{III/II}} = 0.80[\Sigma E_L] + 0.22$.

This linear correlation of $E_{1/2}$ values with ΣE_L parameter suggests that the assignment of $E_{1/2}$ values for Ru^{III}/Ru^{II} couples in these complexes are self-consistent and there are no synergic interactions between the metal and the ligand.

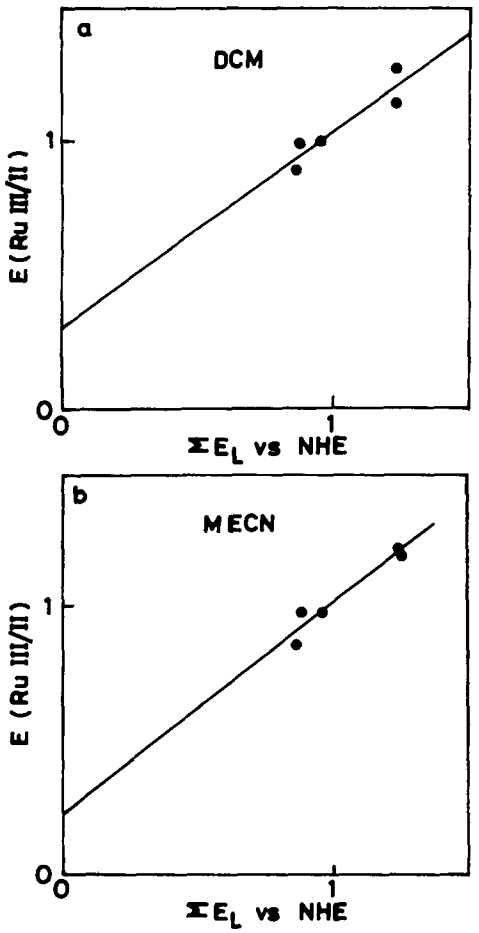

Fig. 5. Plot of observed Ru^{III}/Ru^{II} potentials against ΣE_L of six-coordinated complexes (a) measured in CH_2Cl_2, (b) measured in CH_3CN. All data are *vs* NHE (1 V *vs* SCE = 1.242 V *vs* NHE). Taking $E_{Pabt} = 0.33$, calculated from Lever's equation [50].

Chemistry of a transition metal cluster substituted carboxylic acid: synthesis and structure of $Cd_2\{(CO)_9Co_3(\mu_3\text{-}CCO_2)\}_4[CH_3(OCH_2CH_2)_4OCH_3]$

Xinjian Lei, Maoyu Shang and Thomas P. Fehlner*

Department of Chemistry and Biochemistry, University of Notre Dame, IN 46556, U.S.A.

(Received 17 June 1996; accepted 9 October 1996)

Abstract—The reaction of the cluster substituted carboxylic acid $[(CO)_9Co_3(\mu_3\text{-}CCO_2H)]$ with $Cd(CH_3CO_2)_2 \cdot H_2O$ in the presence of tetraethylene glycol dimethyl ether(TGM) afforded the binuclear complex $[Cd_2\{(CO)_9Co_3(\mu_3\text{-}CCO_2)\}_4(TGM)]$. The solid state structure shows that the cluster carboxylate ligands act as chelating and asymmetrical bridging ligands, respectively, and the TGM ligand exhibits a conformation not previously observed. The coordination number of each cadmium atom is seven, resulting in a coordination geometry consisting of a distorted trigonal capped square-based polyhedron. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: cadmium carboxylate; cobalt cluster; polyether ligand.

We are interested in defining the properties of a transition metal cluster as a substituent and have incorporated this interest in a strategy for the synthesis of large cluster arrays. Thus, by using the transition metal cluster substituted carboxylic acid $[(CO)_9Co_3(\mu_3\text{-}CCO_2H)]$ in an exchange reaction with metal acetates, [1,2] in a reaction with metal alkyls,[3–6] and in a reaction with metal alkoxides,[7] a number of compounds with new structure types and unusual properties were isolated. For example, $[Pb\{(CO)_9Co_3(\mu_3\text{-}CCO_2)\}_2]_n$ resulted from the reaction of $Pb(CH_3CO_2)_2 \cdot 3H_2O$ and $(CO)_9Co_3(\mu_3\text{-}CCO_2H)$,[2] $Zn_4O\{(CO)_9Co_3(\mu_3\text{-}CCO_2)\}_6$, from the reaction of $ZnEt_2$ and $(CO)_9Co_3(\mu_3\text{-}CCO_2H)$,[3,6] and $[Ti_6(\mu_3\text{-}O)_4(\mu\text{-}OEt)_4(OEt)_8\{(CO)_9Co_3(\mu_3\text{-}CCO_2)\}_4]$ from the reaction of $Ti(OEt)_4$ with $(CO)_9Co_3(\mu_3\text{-}CCO_2H)$ [7]. In these cases the chemistry is straightforward, i.e. the cluster functions like an organic substituent albeit with different properties. In other cases, the fragile nature of metal clusters yields unexpected products. For example, heating a reaction mixture of $CdMe_2$ and $(CO)_9Co_3(\mu_3\text{-}CCO_2H)$ gave rise to $[\{\mu_3\text{-}Co(CO)_3\}Cd_3\{(CO)_9Co_3(\mu_3\text{-}CCO_2)\}_3(THF)_3]$ [4].

The structural chemistry of cadmium carboxylates is separately of interest because of the various coordination geometries of cadmium and coordination modes of carboxylate groups. The structures of mono cadmium carboxylates are almost all three-dimensional polymeric species with Cd coordination numbers of up to eight and in which the carboxylate groups act in both chelating and bridging modes [8,9]. As noted, the structurally characterized compound isolated from the reaction of $CdMe_2$ with $(CO)_9Co_3(\mu_3\text{-}CCO_2H)$ [4] was not the simple cluster cadmium carboxylate expected, i.e., $Cd\{(CO)_9Co_3(\mu_3\text{-}CCO_2)\}_2 \cdot n\text{-}THF$, and an alternative pathway was investigated. The reaction of $Cd(CH_3CO_2)_2 \cdot H_2O$ and $(CO)_9Co_3(\mu_3\text{-}CCO_2H)$ has now been explored and in this paper we report a cluster cadmium complex $Cd_2\{(CO)_9Co_3(\mu_3\text{-}CCO_2)\}_4[CH_3(OCH_2CH_2)_4OCH_3]$, **1**, which contains asymmetrical bridging and chelating cluster carboxylate ligands, as well as a linear polyether ligand, tetraethylene glycol dimethyl ether (TGM).

EXPERIMENTAL

All operations were conducted under dinitrogen using standard Schlenk techniques. Solvents were distilled before use from drying agents under N_2 as described below: sodium benzophenone ketyl for hexane and tetrahydrofuran; P_2O_5 for CH_2Cl_2. $(CO)_9Co_3(\mu_3\text{-}CCO_2H)$ was prepared according to the literature methods [6,10]. $Cd(CH_3CO_2)_2 \cdot H_2O$ and tetraethylene glycol dimethyl ether(TGM) were used directly as received from Aldrich. FT-IR was measured on a Nicolet 205 spectrometer. Elemental analyses were performed by M-H-W Laboratories, Phoenix, AZ.

Synthesis of $Cd_2\{(CO)_9Co_3(\mu_3\text{-}CCO_2)\}_4(TGM)$

In a typical procedure, $Cd(CH_3CO_2)_2 \cdot H_2O$ (0.2 mmol; 0.066 g) and $(CO)_9Co_3(\mu_3\text{-}CCO_2H)$ (0.4 mmol; 0.194 g) were loaded into a 100 cm^3 Schlenk flask equipped with a rubber septum and a magnetic stirring bar. This flask had been evacuated and refilled with dinitrogen several times before 15 cm^3 of THF was added to the flask *via* syringe with rapid stirring. The reaction mixture was stirred for 20 h at room temperature to give a purple solution. THF was removed *in vacuo*. The solid obtained was dissolved in 10 cm^3 of THF and to the solution was added 0.05 cm^3 (0.2 mmol) of TGM. The mixture was stirred for 10 h to give a purple solution and then the THF was removed *in vacuo*. The solid obtained was dissolved in 15 cm^3 of CH_2Cl_2 and the purple solution was layered by hexane. After several days, black block-like crystals appeared on the upper wall of the flask. The yield is 10% based on Co.

Spectroscopic and analytical data for $Cd_2\{(CO)_9Co_3(\mu_3\text{-}CCO_2)\}_4(TGM)$. Found: C, 27.3; H, 1.0. Calc. for $Cd_2Co_{12}O_{49}C_{54}H_{22}$: C, 27.2; H, 0.93%. IR(KBr, cm^{-1}): 2106 m, 2047 vs,br, 1537 m,sh, 1531 m, 1373 m, 1344 w,sh, 1092 w, 782 m, 765 w, 701 m, 552 m, 529 m, 502 v, 407 w.

Crystal structure

A black block-like crystal was mounted on the top of a glass fiber and data were collected on an Enraf-Nonius CAD4 diffractometer equipped with graphite crystal monochromated Mo-K_α radiation at room temperature. The data were corrected for Lorentz and polarization effects, and linear decay. And an empirical absorption correction was also applied. The structure was solved by the MULTAN direct method followed by successive difference Fourier syntheses. Full-matrix least-squares refinements were employed. All non-hydrogen atoms were refined with anisotropic thermal parameters in the final cycle, $R = 0.03678$, $R_w = 0.04314$, and GOF = 1.265 (528 variables refined) for 3466 reflections with $F_0^2 > 3\sigma(F_0^2)$. The detailed crystallographic data are given in Table 1.

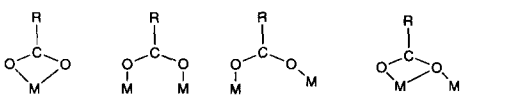
RESULTS AND DISCUSSION

Synthetic studies

The reaction of $Cd(CH_3CO_2)_2 \cdot H_2O$ and $[(CO)_9Co_3(\mu_3\text{-}CCO_2H]$ in THF gave rise to a red–brown solid after the THF was removed *in vacuo*. According to the solid state IR (KBr, cm^{-1}: 2107 m, 2041 vs, 1540 w,br, 1363 m, 1334 m,sh, 750 w, 707 w, 550 w, 504 m, 471 w,sh), the product is probably $[Cd\{(CO)_9Co_3(\mu_3\text{-}CCO_2)\}_2 \cdot n\text{THF}]$. However, all attempts to obtain crystals of this product suitable for X-ray diffraction were unsuccessful. In order to satisfy the requirement of a high coordination number with a single ligand, the polydentate ligand $CH_3(OCH_2CH_2)_4OCH_3$ (TGM) was introduced into this system. Compound **1**, $Cd_2\{(CO)_9Co_3(\mu_3\text{-}CCO_2)\}_4[CH_3(OCH_2CH_2)_4OCH_3]$ crystallized very nicely from the solution. The solid state IR exhibits the bands characteristic of the CO ligands of the cluster substituents at 2106, 2047 cm^{-1} and the carboxylate groups at 1537, 1531, 1373, 1344 cm^{-1} which are significantly different from those of the initial product.

Structural studies

There are four molecules in a unit cell and an asymmetric unit consists of one cadmium atom, two cluster ligands, and a half of TGM. As shown in Fig. 1, compound **1** is a binuclear species with a formula $Cd_2\{(CO)_9Co_3(\mu_3\text{-}CCO_2)\}_4[CH_3(OCH_2CH_2)_4OCH_3]$ which is located on a crystallographic two-fold axis. The two-fold axis runs through O1 and the middle of Cd—Cd′. Figure 2 shows the core structure of **1** and selected atomic distances and angles are listed in Table 2. The coordination geometry of each cadmium atom is best described as a distorted trigonal capped square-based polyhedron with four oxygen atoms from the cluster ligands and three from TGM.



First consider the polyether ligand which is interesting in terms of its conformation. Iwamoto *et al.* [11–15] investigated the effect of the coordination on molecular conformations of the complexes of polyether $RO(CH_2CH_2O)_nR$ with MCl_2(M = Hg, Cd). They found that TGM (tetraethylene glycol dimethyl ether) shows different coordination modes, i.e. either coordinated to one or two metal atoms, which lead to different molecular conformations. In **1** TGM is symmetrically coordinated to two cadmium atoms and is different from those of the known compounds where TGM is coordinated to one metal atom or asymmetrically chelated to two metal centres. As we can see from Table 2, the C—C bonds (1.50 Å) of TGM are comparable to those [15] of the TGM-$CdCl_2$ complex and slightly shorter than a normal single C—C bond (1.54 Å). The C—O bond distances range

from 1.41 to 1.46 Å, while those [15] of TGM-$CdCl_2$ range from 1.41 to 1.48 Å. The C—O—C angles (111.0 to 119.5°) are larger than the C—C—O angles (104.6 to 109.4°). The largest C(1)—O(1)—C(1)′ angle may be related to the bridging character of the O(1) atom which is coordinated to two cadmium atoms. The three oxygen atoms of TGM are almost co-planar with the Cd atom to which they are coordinated (Table 3). The Cd—O distances range from 2.48 to 2.58 Å and the longest one is to O(1). The torsional angles of TGM are given in Table 4 where it is seen that all C—O bonds are trans (172.3–175.2°) except for the C—O bonds connected to O(1) atom, which have a torsional angle of 86.71°. Thus, the conformation of TGM is totally different from those of the known TGM complexes such as TGM-$HgCl_2$ and TMG-$CdCl_2$ [14,15]. The conformational difference may be connected to the steric effect of the cluster ligands.

Next consider the carboxylate ligands for which a variety of coordination modes are known (Chart 1) [16]. The acetate group acts most frequently as a symmetrical bridging ligand i.e. *syn-syn* mode, such as in copper acetate [17] and basic carboxylates $[M_3O(OAc)_6]^+$(M = Fe, Mn) [18,19]. In some cases the acetate ligand functions not only as a bridging ligand, but also a chelating ligand [9]. However the bidentate chelating mode, as shown in the case of zinc and uranyl acetates,[20,21] is not as common, presumably because the chelate ring is a four-membered one. Asymmetrical bridging, i.e. *anti–syn* mode, is also rare and only a few examples are known, such as $Cu(O_2CH)_2(H_2O)$ and $Cu(O_2CH)_2$(Royal blue) [22,23]. As with the metal acetates, we have observed *syn–syn* bridging cluster carboxylate ligands in most of the cluster derivatives prepared to date [1–7,24].

As shown in Table 5, the coordination modes of the cluster ligands fall into two types: bidentate chelating and *anti–syn* bridging. Hence there are two distinct Cd—O distances, involving both cluster carboxylate groups; Cd—O(11) 2.197 Å, Cd—O(12) 2.287 Å, and Cd—O(21) 2.270 Å, Cd—O(22) 2.417 Å. The Cd—O distances observed in **1** lie in the shorter range of those found in other cadmium acetates, such as CaCd $[OAc]_4 \cdot H_2O$(2.289(7) to 2.677(8) Å) [8] and $Cd(OAc)_2 \cdot H_2O$ [9] (2.294(4) to 2.597(4) Å) in which the acetate groups are both chelating and bridging.

Table 5. Comparison of coordination modes and Cd—O distances (Å) of carboxylate groups in **1** and related cadmium carboxylate compounds

Compound	Chelating	*Syn–syn* bridging	*Anti–syn* bridging	Chelating and bridging	Reference
$Cd\{(CO)_9Co_3$	2.270(6)		2.197(6)		This work
$(\mu_3\text{-}CCO_2)\}_4$(TGM)	2.417(6)		2.287(6)		
$\{\mu_3\text{-}(CO)_3Co\}Cd_3\{(CO)_9Co_3$		2.221(7)			4
$(\mu_3\text{-}CCO_2)\}_3(THF)_3$					
$Cd(CH_3CO_2)_2 \cdot 2H_2O$				2.297(4)	9
				2.294(4)	
				2.597(3)	
$Ca[Cd(CH_3CO_2)_4] \cdot 6H_2O$				2.289(7)	8
				2.677(8)	
$[Cd(HOC_6H_4CO_2)_2 \cdot 2H_2O]_2$	2.332(2)			2.271(2)	25
	2.429(1)			2.314(1)	
				2.535(2)	
$[Cd(CF_3CO_2)_2 \cdot PPh_3]_2$		2.266(19)			26

The Cd—O distances (2.197, 2.287 Å) for the chelating cluster ligand are significantly shorter than those of the chelating acetate group (2.304(4), 2.546(4) Å) in $Cd(OAc)_2 \cdot H_2O$. For the *anti–syn* cluster bridging ligands, the Cd—O distance for the oxygen atom occupied *anti*-position (Cd—O(21), 2.270(6) Å) is much shorter than that of oxygen atom occupied *syn*-position (Cd—O(22), 2.417(6) Å). However, both are shorter than those of acetate groups acting as chelating and bridging. As shown in Table 3, the chelating cluster carboxylate group (C(10), C(11), O(11), O(12)) and Cd are coplanar. And the *anti–syn* bridging cluster carboxylate group (C(20), C(21), O(21), O(22)) are also coplanar with Cd while Cd′ is far away from the plane. This is consistent with the *anti*-mode character of the cluster carboxylate ligand. The C—O distances (average 1.27(1) Å) and O—C—O angles (121.7°) for the cluster carboxylate groups are in the normal range found for the acetate compounds.

The Cd···Cd separation (3.741 Å) is comparable to that of $[Cd(HOC_6H_4CO_2)_2 \cdot H_2O]_2$ (3.715 Å) [25] and much longer than those of $[Cd(CF_3CO_2)_2 \cdot PPh_3]_2$(3.452 Å), [26] and TMG-$CdCl_2$ (3.457 Å), [15] which is also bridged by an oxygen atom from TGM. The Cd···Cd distance in **1** is also significantly larger than that (2.98(3) Å) of $\{\mu_3\text{-}Co(CO)_3\}Cd_3\{(CO)_9Co_3(\mu_3\text{-}CCO_2)\}_3(THF)_3$ [4] in which the cluster ligands are in the *syn–syn* coordination mode. As expected the Co—Co distances, as well as the other structural metrics of the cluster ligands in **1** are in the normal range found for the uncoordinated cluster acid [6].

CONCLUSIONS

Cadmium complexes with organic carboxylic acids having monocarboxylate groups, two functional groups, and dicarboxylate groups generally have polymeric structures with coordination numbers of up to eight [9,27–33]. Only a few like $[Cd(HOC_6H_4CO_2)_2 \cdot H_2O]_2$,[25] $[Cd(CF_3CO_2)_2 \cdot PPh_3]_2$,[26] and $[Cd(HOC_6H_4CO_2)_2 \cdot (pyridine)_3]$ [25] are dimeric or monomeric species. The steric bulk of the tricobalt cluster substituted carboxylate ligand leads to complexes having a lower coordination number. We have observed that $[Pb\{(CO)_9Co_3(\mu_3\text{-}CCO_2)\}_2]_n$ has a coordination number of six whereas related organic lead carboxylates have coordination numbers greater than six [2]. Thus, the unusual conformation of TGM and the coordination modes of the cluster carboxylates in **1** are ascribed to the different steric and electronic effects of the cluster substituent relative to organic substituents.

Supplementary data available from the Cambridge Crystallographic Data Centre. Positional parameters and estimated equivalent isotropic thermal parameters, anisotropic thermal parameters, full list of atomic distances and angles.

(Received 16 September 1996; accepted 4 October 1996)

Abstract—Reactions of complexes $[\{(\eta^5\text{-}C_5Me_5)MCl_2\}_2]$ (M = Rh, Ir) and $[\{(\eta^6\text{-}MeC_6H_4Pr^i)RuCl_2\}_2]$ with the ligand Ph_2PCH_2SPh in acetone solution led to neutral complexes with the general formula $[(ring)MCl_2(\eta^1\text{-}Ph_2PCH_2SPh\text{—}P)]$ (**1–3**). These compounds react with thallium tetrafluoroborate in acetone solution to yield new cationic complexes in which the ligand is acting in its chelate P,S-donor fashion, $[(ring)MCl(\eta^2\text{-}Ph_2PCH_2SPh\text{—}P,S)]BF_4$ (**4–6**). When the removal of the chloride ligand in complexes **1–3** was carried out in the presence of a stoichiometric amount of Ph_2PCH_2SPh, cationic compounds containing two P-donor monodentate ligands of the type $[(\eta^5\text{-}C_5Me_5)MCl(\eta^1\text{-}Ph_2PCH_2SPh\text{—}P)_2]BF_4$ (**7** and **8**) were obtained. The structure of the iridium derivative $[(\eta^5\text{-}C_5Me_5)IrCl(\eta^2\text{-}Ph_2PCH_2SPh\text{—}P,S)]BF_4 \cdot Me_2CO$ has been determined by single-crystal X-ray diffraction methods. The complex cation contains a C_5Me_5 group occupying three coordination positions of a distorted octahedral iridium centre, a bidentate chelate P,S-bonded ligand and a chloride atom completing the coordination sphere. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: diphenylphosphino(phenylthio)methane; rhodium; indium; ruthenium.

There is currently much interest in the synthesis of mono- and bimetallic platinum-group metal complexes containing, short-bite, unsymmetrical ligands such as (diphenylarsino)(diphenylphosphino)methane,[1] 2-(diphenylphosphino)pyridine,[2] diphenylphosphino(methylthio)methane,[3] diphenylphosphino(benzylthio)methane [4] and diphenylphosphino(phenylthio)methane [5].

In particular, the P and S donor site ligands are described as monodentate P-donor ligands in Pd^{II}, Pt^{II}, Rh^{I} and Ir^{I} complexes, or as bidentate bridging P,S-donor ligands in bimetallic complexes with similar (Pd—Pd, Pt—Pt, Rh—Rh) or dissimilar (Pd—Rh) metal centres [3–5]. In these compounds the ligands acquire a head-to-tail arrangement and the metal centres are bonded by a metal–metal bond. However, only few examples of complexes with these ligands acting in its chelate bidentate form are reported.

In this paper we describe the preparation of mononuclear neutral complexes of the general formula $[(ring)MCl_2(\eta^1\text{-}Ph_2PCH_2SPh\text{—}P)]$ [(ring)M = $(\eta^5\text{-}C_5Me_5)Rh$ (**1**), $(\eta^5\text{-}C_5Me_5)Ir$ (**2**), $(\eta^6\text{-}p\text{-}MeC_6H_4Pr^i)Ru$ (**3**)] and the related cationic complexes of the types $[(ring)MCl(\eta^2\text{-}Ph_2PCH_2SPh\text{—}P,S)]BF_4$ [(ring)M = $(\eta^5\text{-}C_5Me_5)Rh$ (**4**), $(\eta^5\text{-}C_5Me_5)Ir$ (**5**), $(\eta^6\text{-}p\text{-}MeC_6H_4Pr^i)Ru$ (**6**)] and $[(ring)MCl(\eta^1\text{-}Ph_2PCH_2SPh\text{—}P)_2]BF_4$ [(ring)M = $(\eta^5\text{-}C_5Me_5)Rh$ (**7**), $(\eta^5\text{-}C_5Me_5)Ir$ (**8**)]. The structure of the complex $[(\eta^5\text{-}C_5Me_5)IrCl(\eta^2\text{-}Ph_2PCH_2SPh\text{—}P,S)]BF_4$, determined by single-crystal X-ray diffraction, is also reported.

EXPERIMENTAL

Elemental analyses (C, H and S) were made with a Perkin–Elmer 240C microanalyser. IR spectra were

*Author to whom correspondence should be addressed.

recorded on a Bruker IFS-25 spectrophotometer using KBr pellets. Conductivities were measured in *ca* 5×10^{-4} M acetone solutions using a WTW LF-521 conductimeter. ^1H (200 MHz) and ^{31}P ^1H (81 MHz) NMR spectra were recorded on a Bruker AC-200P spectrometer and the chemical shifts are reported in ppm relative to Me_4Si and 85% H_3PO_4 (positive shifts downfield) in D_2O as internal and external standards, respectively.

All reactions were carried out by Schlenk techniques under purified nitrogen. Reagent-grade solvents were dried, distilled and stored under a nitrogen atmosphere. The starting complexes $[\{(\eta^5\text{-}C_5Me_5)MCl_2\}_2]$ (M = Rh, Ir),[6] $[\{(\eta^6\text{-}MeC_6H_4Pr^i)RuCl_2\}_2]$ [7] and the ligand Ph_2PCH_2SPh [5b] were prepared by published procedures.

Preparation of $[(\eta^5\text{-}C_5Me_5)MCl_2(\eta^1\text{-}Ph_2PCH_2SPh\text{—}P)]$ [M = Rh (**1**), Ir (**2**)]

1: To a suspension of the binuclear complex $[\{(\eta^5\text{-}C_5Me_5)RhCl_2\}_2]$ (124 mg, 0.2 mmol) in acetone (10 cm^3) the ligand Ph_2PCH_2SPh (123 mg, 0.4 mmol) was added with an immediate formation of a red solid. After stirring the mixture for 1 h, the solid complex was filtered off, washed with diethylether and air-dried. The complex was recrystallized from chloroform–diethylether. Yield: 167 mg (68%). Found: C, 56.8; H, 5.7; S, 5.3. Calc. for $C_{29}H_{32}Cl_2PRhS$: C, 56.4; H, 5.2; S, 5.2%.

2: To a solution of the binuclear complex $[\{(\eta^5\text{-}C_5Me_5)IrCl_2\}_2]$ (159 mg, 0.2 mmol) in dichloromethane (15 cm^3) was added the ligand Ph_2PCH_2SPh (123 mg, 0.4 mmol). The colour of the solution changed from orange to yellow. The solution was stirred at room temperature for 1 h and then evaporated to a small volume (3–5 cm^3). The addition of *n*-hexane caused the precipitation of a yellow solid, which was filtered off, washed with *n*-hexane and crystallized from dichloromethane–*n*-hexane. Yield: 240 mg (85%). Found: C, 49.1; H, 4.2; S, 4.7. Calc. for $C_{29}H_{32}Cl_2PIrS$: C, 49.4; H, 4.6; S, 4.7%.

Preparation of $[(\eta^6\text{-}MeC_6H_4Pr^i)RuCl_2(\eta^1\text{-}Ph_2PCH_2SPh\text{—}P)]$ (**3**)

To a solution of complex $[\{(\eta^6\text{-}MeC_6H_4Pr^i)RuCl_2\}_2]$ (122 mg, 0.2 mmol) in dichloromethane (15 cm^3) a stoichiometric amount of the ligand Ph_2PCH_2SPh (123 mg, 0.4 mmol) was added and the mixture was stirred for 1 h. The solution obtained was concentrated and chromatographed on Kieselgel (HF_{254} type 60) using $CHCl_3$: *n*-hexane (2 : 1) as eluent. The solution was evaporated to dryness, the residue extracted with $CHCl_3$, and the complex isolated as red crystals by addition of *n*-hexane. Yield: 215 mg (87%). Found: C, 56.8; H. 4.9; S. 5.1. Calc. for $C_{29}H_{31}Cl_2PRuS$: C, 56.7; H, 5.1; S, 5.2%.

Preparation of $[(\eta^5\text{-}C_5Me_5)MCl(\eta^2\text{-}Ph_2PCH_2SPh\text{—}P,S)]BF_4$ [M = Rh (**4**), Ir (**5**)]

To a solution of complex **1** or **2** (0.15 mmol) in acetone (10 cm^3) was added a stoichiometric amount of $TlBF_4$ (44 mg, 0.15 mmol). The resulting mixture was stirred for 8 h. During this time TlCl was precipitated and the colour of the solution changed from orange (**1**) or yellow (**2**) to pale yellow. The solution was filtered off through Kieselguhr, concentrated to a small volume and the complexes precipitated by addition of diethylether or *n*-hexane. (**4**) Orange crystals from chloroform–diethylether. Yield: 70 mg (69%). Found: C, 51.5; H, 4.3; S, 4.9. Calc. for $C_{29}H_{32}BClF_4PRhS$: C, 52.0; H, 4.8; S, 4.8%. Λ = 131 $cm^2\ mol^{-1}\ ohm^{-1}$. **5**: Yellow crystals from acetone–diethylether–pentane. Yield: 109 mg (96%). Found: C, 46.9; H, 4.5; S, 4.0. Calc. for $C_{29}H_{32}BClF_4PIrS \cdot C_3H_6O$: C, 47.1; H, 4.7; S, 3.9%. Λ = 126 $cm^2\ mol^{-1}\ ohm^{-1}$.

Preparation of $[(\eta^6\text{-}MeC_6H_4Pr^i)RuCl(\eta^2\text{-}Ph_2PCH_2SPh\text{—}P,S)]BF_4$ (**6**)

To a solution of complex **3** (92 mg, 0.15 mmol) in acetone (15 cm^3) was added a stoichiometric amount of $TlBF_4$ (44 mg, 0.15 mmol). After stiring the mixture for 12 h, the TlCl formed was filtered off through Kieselghur and the solution evaporated to a small volume. Careful addition of *n*-hexane gave red–orange crystals. Yield: 70 mg (70%). Found: C, 52.2; H, 4.9; S, 4.7. Calc. for $C_{29}H_{31}BClF_4PRhS$: C, 52.3; H, 4.7; S, 4.8%. Λ = 141 $cm^2\ mol^{-1}\ ohm^{-1}$.

Preparation of $[(\eta^5\text{-}C_5Me_5)MCl(\eta^1\text{-}Ph_2PCH_2SPh\text{—}P)_2]BF_4$ [M = Rh (**7**), Ir (**8**)]

To a solution of 0.1 mmol of complex **1** (62 mg) or **2** (70 mg) in acetone solution (10 cm^3) was added the ligand Ph_2PCH_2SPh (31 mg, 0.1 mmol) and the stoichiometric amount of $AgBF_4$ (195 mg, 0.1 mmol). Solid AgCl was formed and the colour of the solution changed from orange to yellow. After stirring for 24 h the mixture was filtered off, the solution was concentrated to a small volume and the complexes precipitated as yellow solids by careful addition of *n*-hexane. The complexes were filtered, washed with *n*-hexane and dried *in vacuo*. **7**: Yield: 33 mg (36 %). Found: C, 58.3; H, 5.3; S, 6.4. Calc. for $C_{48}H_{49}BClF_4P_2RhS_2$: C, 59.0; H, 5.1; S, 6.6%. **8**: Yield: 48 mg (48 %). Found: C, 53.5; H, 4.8; S, 6.0. Calc. for $C_{48}H_{49}BClF_4P_2IrS_2$: C, 54.1; H, 4.6; S, 6.0%.

Crystal structure of complex **5**

A yellow, parallelepiped-shaped crystal, of approximate dimensions 0.22 × 0.22 × 0.20 mm, obtained from a slow diffusion of diethylether into an acetone

solution of the complex, was selected for structure determination by X-ray diffraction. Intensity data were collected on a Siemens R3m/v diffractometer in $\theta/2\theta$ scan mode, using graphite-monochromated MoK_α radiation ($\lambda = 0.71073$ Å). 4492 reflections collected gave 4272 independent reflections ($R_{int} = 0.0199$), of which 2899 had $I < 2\sigma(I)$. Semi-empirical corrections for absorption, *via* psi-scans, were applied to the intensities.

A summary of the crystal data and relevant refinement parameters are presented in Table 1. The structure was solved by direct methods and refined on F^2 by full-matrix least-squares calculations, using all 4272 reflections. Non-H atoms were refined anisotropically. H atoms were placed at geometrically idealized positions with C—H = 0.96 Å and were allowed to ride over their parent C atoms with the isotropic displacement parameter U_{iso} equal to the equivalent isotropic U_{eq} of the attached C atom. Final $R(F)$ [$I < 2\sigma(I)$] was 0.034. All calculations were performed with the Siemens SHELXTL [8] and SHELXL-93 [9] programs. The absolute structure was determined using SHELXL-93 routine to refine the Flack parameter x which converged to 0.001(9).

Tables of positional and thermal parameters, full list of bond distances and angles, short contacts, least-squares planes with dihedral angles, and listing of observed and calculated structure factors have been deposited with the Editor as supplementary material.

RESULTS AND DISCUSSION

The binuclear complexes $[\{(\eta^5C_5Me_5)MCl_2\}_2]$ (M = Rh, Ir) and $[\{\eta^6\text{-}MeC_6H_4Pr^i)RuCl_2\}_2]$ react with the ligand diphenylphosphino (phenylthio)methane, Ph_2PCH_2SPh, in acetone or dichloromethane solution by cleavage of the chlorine bridges to yield neutral complexes with the ligand acting as a unidentate P-donor ligand, in accord with the general equation:

$$1/2[\{(ring)MCl_2\}_2] + Ph_2PCH_2SPh \longrightarrow [(ring)MCl_2(\eta^1\text{-}Ph_2PCH_2SPh\text{—}P)]$$

where (ring)M = $(\eta^5\text{-}C_5Me_5)$Rh (**1**), $(\eta^5\text{-}C_5Me_5)$Ir (**2**) and $(\eta^6\text{-}p\text{-}MeC_6H_4Pr^i)$Ru (**3**).

The ^{1}H NMR spectra of complexes **1**–**3** exhibit a doublet resonance in the range δ 4.1–4.4 ppm assigned to methylene protons of the ligand together with the expected signals of coordinated rings. Their ^{31}P ^{1}H NMR spectra show a doublet resonance for complex **1** and a singlet resonance for complexes **2** and **3**. In all cases the signals are substantially shifted to low field compared to those of the free ligand (coordination shifts in the range $\Delta\,\delta P = 21$–54 ppm). Relevant NMR chemical shifts and coupling constants are listed in Table 2.

Complexes **1**–**3** slowly react in acetone solution with thallium tetrafluoroborate at room temperature to give non soluble thallium chloride and the corresponding cationic complexes with the ligands acting in their bidentate chelate fashion, according to the general equation:

$$\mathbf{1\text{–}3} + TlBF_4 \longrightarrow [(ring)MCl(\eta^2\text{-}Ph_2PCH_2SPh\text{—}P,S)]BF_4 + TlCl$$

where (ring)M = $(\eta^5\text{-}C_5Me_5)$Rh (**4**), $(\eta^5\text{-}C_5Me_5)$Ir (**5**) and $(\eta^6\text{-}p\text{-}MeC_6H_4Pr^i)$Ru (**6**).

Table 1. Crystallographic data for complex **5**

Empirical formula	$C_{32}H_{38}BClF_4IrOPS$
Formula weight	816.11
Crystal system	Orthorhombic
Space group	$Pna2_1$
Unit cell dimensions	$a = 16.172(4)$ Å, $\alpha = 90.0°$
	$b = 11.782(3)$ Å, $\beta = 90.0°$
	$c = 17.754(4)$ Å, $\gamma = 90.0°$
Volume (Å^3)	3382.8(14)
Z	4
Density (calculated) (Mg m^{-3})	1.602
Absorption coefficient (mm^{-1})	4.181
$F(000)$	1616
θ range for data collection (°)	2.07–28.06
Index ranges	$0 \leqslant h \leqslant 21$, $0 \leqslant k \leqslant 15$, $-23 \leqslant l \leqslant 0$
Absorption correction	Semi-empirical, *via* psi-scans
Maximum and minimum transmission	0.931 and 0.762
Data/restraints/parameters	4272/0/378
Weighting scheme	$1/[\sigma^2(F_o^2) + (0.0356\,P)^2]$, where $P = [\text{Max}(F_o^2,0) + 2F_c^2]/3$
Goodness-of-fit on F^2	0.872
Final R indices [$I > 2\sigma(I)$]	$R(F) = 0.0339$, $wR(F^2) = 0.0641$
R indices (all data)	$R(F) = 0.0648$, $wR(F^2) = 0.0705$
Largest difference peak and hole (e Å^{-3})	1.111 and −0.766

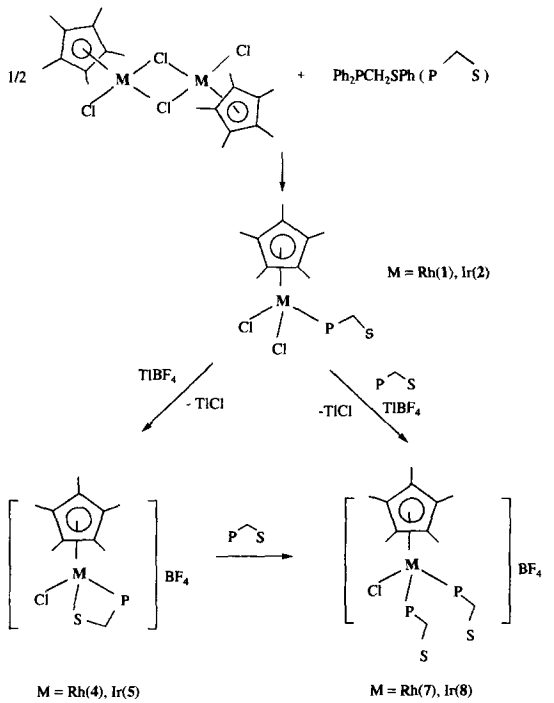
[a]Measured in $CDCl_3$ at room temperature. Chemical shifts relative to Me_4Si and H_3PO_4 (85%) in D_2O as standards. s, singlet; d, doublet; dd, doublet of doublets; t, triplet; m, multiplet; br, broad. All complexes show multiplets in the region 7.0–8.0 ppm corresponding to phenyl groups of the ligands.

[b]$\Delta\delta P$ = [δP(monodentate complex)-δP(free ligand)] (free ligand: $\delta P = -19.40$ ppm).



[c]The resonance of the H_b proton is masked by the signals of phenyl rings.

[d]This signal is superposed with those of the ring protons of the *p*-cymene ligand. This assignment was made with the aid of double irradiation techniques.

These cationic complexes were isolated as stable microcrystalline solids and behave as 1 : 1 electrolytes in acetone solution. Their ^{1}H NMR spectra exhibit the expected resonances of the coordinated ring and two resonances which correspond to the non-equivalent protons H_a and H_b. The proton endo to the chlorine atom is labelled H_a and is assigned to the highest field resonance on the basis of results obtained for related complexes containing bis(diphenylphosphine)methane(dppm) or their chalcogenides derivatives as chelate ligands [10]. Complex **5** shows only a doublet of doublets at δ 5.07 ppm for the H_a proton. The H_b proton appears in the range δ 7.0–8.0 ppm and is masked by the phenyl resonances of the ligand. This assignment is based on the NMR results obtained for the similar complex [(η^5-C_5Me_5)IrCl(η^2-$MeSCH_2SMe$—S,S)]BF_4, which shows two doublet resonances for the methylene protons at δ 5.56 (H_a) and 7.28 (H_b) ppm [11]. The ^{1}H NMR spectrum of complex **6** shows two doublets of doublets resonances assigned to H_a and H_b with their corresponding different ^2J(PH) couplings.

The ^{31}P $\{^1H\}$ NMR of complexes **4–6** show a shift of the signals to high field respect to the starting neutral complexes **1–3**, respectively. The large shielding of P atom ($\Delta\delta P$ = 31–37 ppm) is the typical behaviour of a coordinated P atom, which is part of a four-membered chelate ring, where the conformational change produces an increase in their electron density [12]. The decrease in the value of the phosphorus–rhodium coupling constant in complex **4** [^1J(RhP) = 120.5 Hz] with respect to complex **1** [^1J(RhP) = 141.3 Hz] suggests that the formation of the chelate ring causes a decrease of the σ character of the metal–phosphorus bond.

The addition of an excess of the ligand Ph_2PCH_2SPh to an acetone solution of complexes **4** and **5** causes the cleavage of the labile metal–thioether bond to form new cationic complexes in which the ligands are acting in their monodentate P-donor form, [(η^5-C_5Me_5)MCl(η^1-Ph_2PCH_2SPh—P)$_2$]BF_4, where M = Rh (**7**) and Ir (**8**). These compounds have not been isolated as pure samples by this synthethic method and always contain traces of the cor-

Scheme 1

responding starting derivatives. However, the direct reaction of complexes **1** and **2** with a stoichiometric amount of the ligand in the presence of $TlBF_4$ led only to the formation of complexes **7** and **8**, respectively. All these reactions are represented in Scheme 1.

At room temperature (25°C) the ^1H NMR spectra of complexes **7** and **8** exhibit the expected triplet resonance for the permethylated ring and two broad multiplet resonances assigned to different methylene protons. When the temperature is raised to 60°C, these broad signals split in a doublet of multiplets with a $^2J(HH) \simeq 14.5$ Hz. With cooling at −60°C only very broad signals were observed. The $^{31}P\{^1H\}$ NMR spectra at room temperature show a doublet and singlet resonances for complexes **7** and **8**, respectively. The doublet signal shown by complex **7**, centred at δ 26.64 ppm [$^1J(RhP) = 133.9$ Hz], is shifted to high field respect to that of the starting complex **1** [δ 34.29 ppm; $^1J(RhP) = 141.3$ Hz], indicating the existence of π-backbonding from the metal centre to the phosphorus atom. This effect causes a decrease of the σ character of the Rh—P bond and, consequently, a decrease of the phophorus–rhodium coupling.

In order to obtain an unambiguous characterization of complex **5**, an X-ray diffraction study was undertaken. Table 3 lists the relevant bonds distances and angles. Figure 1 shows a perspective ORTEP view of the cation, showing the metal centre with a pseudo-octahedral geometry, commonly referred as "three-legged piano stool" configuration, with the centroid of the pentamethylcyclopentadienyl ligand occupying the centre of three octahedral sites, the diphenylphosphino(phenylthio)methane ligand bonded to the iridium atom through the phosphorus and sulfur atoms and a chloride atom completing the coordination sphere.

The methyl substituents are bent away from the iridium atom and the Ir—C(ring) distances span the range 2.161(7)–2.238(8) Å and compares well with those found in other pentamethylcyclopentadienyl iridium complexes [8b,13].

The Ir—S distance, 2.402(3) Å, is larger than those found in the thioether–iridium(III) complex [IrCl(1,4,8,11-tetrathiocyclotetradecane)]BPh_4 [average: 2.293(4) Å],[14] and is similar to the distances found in the thiolate complex $[Ir(S_2CNEt_2)_3]$ [average: 2.370(2) Å][15] and the phosphine sulfide complex $[(\eta^5\text{-}C_5Me_5)Ir\{PO(OMe)_2\}\{\eta^2\text{-}(SPPh_2)_2CH_2\}]BF_4$ [average: 2.398(2) Å].[8b] The Ir—P distance, 2.303(3) Å, compares well with those found in the phosphine–iridium(III) complexes $[IrH(\eta^1,\eta^3\text{-}C_8H_{12})(dppm)]$ [Ir—P: average 2.288(2) Å][16] and $[IrCl_2(CO)_2(\mu\text{-}CO)(\mu\text{-}dppm)]$ [Ir—P: average 2.330(3) Å] [17]. The Ir—Cl separation, 2.381(2) Å, is similar to those found in related complexes containing the "$(C_5Me_5)Ir$" moiety, as in the mono-

Table 3. Selected bond lengths (Å) and bond angles (°), with e.s.d.s in parentheses

Ir—C(1)	2.229(9)	Ir—P	2.303(3)
Ir—C(2)	2.169(10)	Ir—S	2.402(3)
Ir—C(3)	2.174(9)	Ir—Cl	2.381(2)
Ir—C(4)	2.161(7)	P—C	1.854(9)
Ir—C(5)	2.238(8)	S—C	1.836(10)
P—C(11)	1.819(9)	P—C(21)	1.823(14)
S—C(31)	1.781(10)		
P—Ir—Cl	86.99(9)	S—C—P	96.4(5)
P—Ir—S	71.51(9)	Ir—S—C	91.6(3)
Cl—Ir—S	89.59(9)	Ir—P—C	94.3(3)
Ir—S—C(31)	118.0(4)	Ir—P—C(11)	122.1(3)
Ir—P—C(21)	118.4(4)	C(11)—P—C(21)	105.5(5)

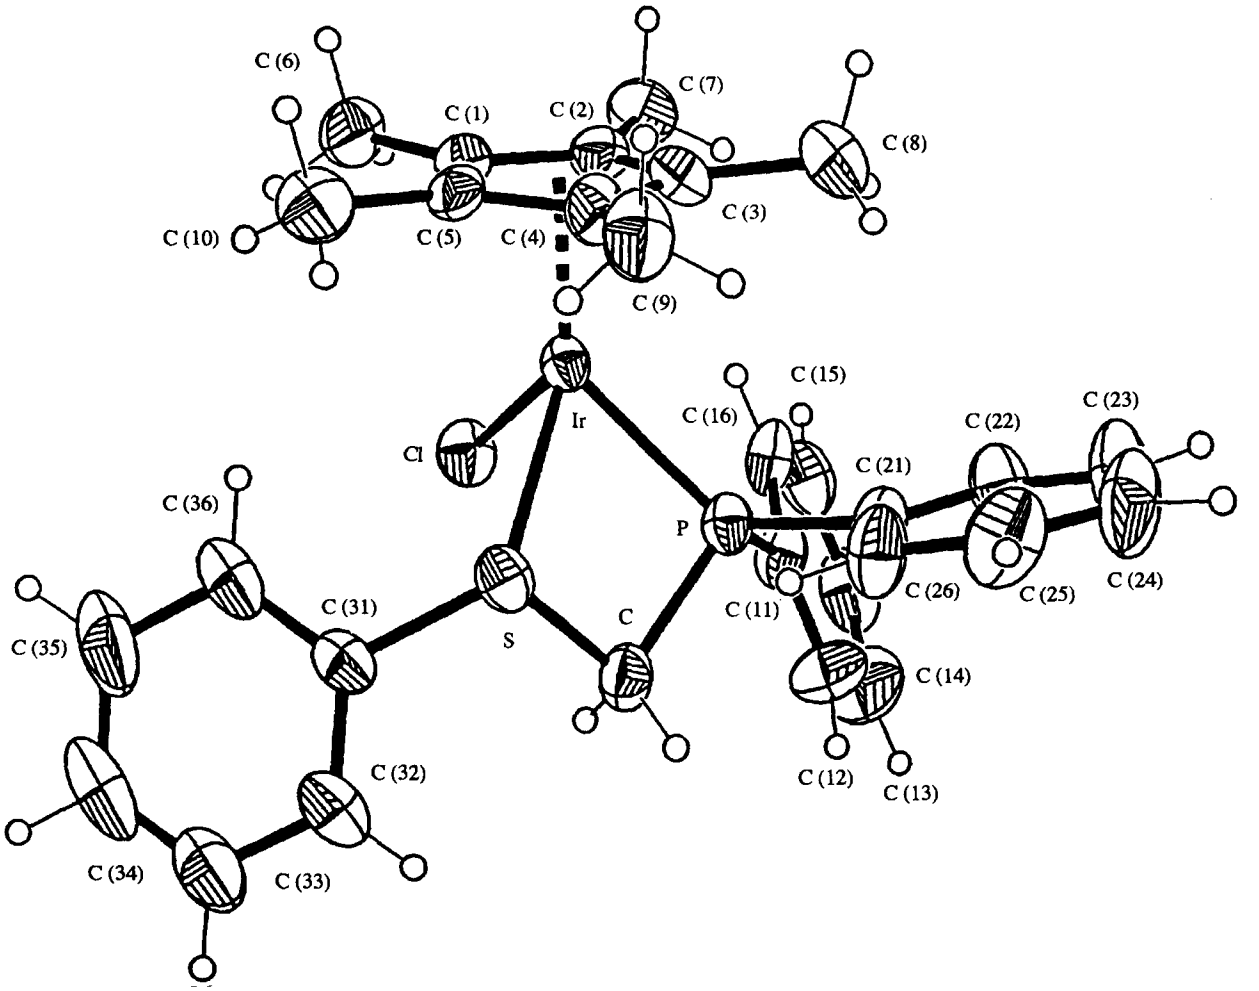


Fig. 1. ORTEP view of the cation in complex **5**, with 40% probability ellipsoids and atom numbering. H atoms are drawn as circles of arbitrary radius.

nuclear complexes $[(\eta^5\text{-}C_5Me_5)IrCl(\text{L-prolinate})]$ [Ir—Cl: 2.417(3) Å] and $[(\eta^5\text{-}C_5Me_5)IrCl(\text{L-histidine})]Cl$ [Ir—Cl: 2.402(5) Å] [18].

The P—C [1.854(9) Å] and S—C [1.836(10) Å] distances in the coordinated chelate ligand are similar to those found in the A-frame complexes containing the related bidentate bridging ligand $Ph_2PCH_2SCH_2Ph$, $[Pd_2Cl_2(\mu\text{-}Ph_2PCH_2SCH_2Ph)]$ [P—C: 1.87(2) and P—S: 1.77(3) Å][4b] and $[Rh_2Cl_4(CO)_2(\mu\text{-}Ph_2PCH_2SCH_2Ph)]$ [P—C: 1.840(5) and P—S: 1.813(3) Å] [4a]. However, the angle P—C—S 96.4(5)°, is smaller than the corresponding angle observed in the ligand of the above mentioned A-frame complexes: P—C—S: 104.2(8) and 108.3(8)°, respectively.

The synthesis and X-ray crystal structure of $S{=}CS_2C_2B_{10}H_{10}$

James D. McKinney, Thomas A. Hamor, Christopher J. Jones* and Keith Paxton

School of Chemistry, the University of Birmingham, Edgbaston, Birmingham B15 2TT, U.K.

(Received 12 September 1996; accepted 4 October 1996)

Abstract—The reactions of 1,2-dicarbadodecaborane-1,2-dithiol with tetrachloroethene, oxalyl chloride, phosgene, triphosgene and thiophosgene have been examined and $S{=}CS_2C_2B_{10}H_{10}$ isolated. The crystal structure of $S{=}CS_2C_2B_{10}H_{10}$ reveals a stacked arrangement of the planar $\{S_2C{=}S\}$ moieties present in the molecule, but intermolecular distances are all greater than the van der Waals contact distance, the shortest S···S distance of 3.552(1) Å lying between the singly bonded sulfurs, $S(CB_{10}H_{10}C)\cdots S(CB_{10}H_{10}C)$. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: dicarbaborane; thione; disulfur heterocycle; crystal structure.

Tetrathiafulvalene, TTF (Fig. 1), has played an important role in the development of new molecular materials, in particular stacked salts exhibiting electrical conductivity [1]. Elaboration of the TTF structure has given rise to a number of TTF analogues including BEDT-TTF [2] and *bis*benzotetrathiafulvalene, **1** (Fig. 1) [3]. Transition metal complexes exemplified by $[Ni(dmit)_2]^{2-}$ $\{dmitH_2 = S{=}CS_2C_2(SH)_2\}$ (Fig. 1) have also been synthesized [4]. Such compounds may be used to prepare new molecular materials and to allow the relationship between molecular structure and bulk properties to be examined in more detail. In order to provide a further example of a compound containing a $\{C_2S_2C{=}\}_2$ core, but in a rather different molecular environment from that found in existing examples of TTF analogues, we have been seeking a synthetic route to the carborane containing TTF analogue $B_{10}H_{10}C_2S_2C{=}CS_2C_2B_{10}H_{10}$, **2** (Fig. 1). This compound contains two sterically bulky 1,2-$C_2B_{10}H_{10}$ cages linked by a tetrathioethene moiety to give a structure incorporating a TTF core, but terminated by carborane cages. There are two features in this structure which distinguish it from other TTF derivatives. Firstly, the steric bulk of the carborane cages would create clefts above and below the $\{S_2C{=}CS_2\}$ moiety into which small planar molecules might fit. Secondly, the electron-withdrawing effects of the carborane cages might be expected to modify the electronic properties of the TTF like centre, increasing its electron affinity compared with TTF itself. In an attempt to make inroads into this area of chemistry we set out to try to synthesize **2**. Since benzene-1,2-dithiol is known to be a precursor for the preparation of **1**,[3] it was hoped that 1,2-dicarbadodecaborane-1,2-dithiol,[5] $3H_2$ (Fig. 1) might undergo similar reactions to afford **2**. A number of synthetic routes for converting **3** to **2** were investigated and these included the reactions of 1,2-dicarbadodecaborane-1,2-dithiol with tetrachloroethylene, oxalyl chloride, triphosgene, phosgene and thiophosgene.

RESULTS AND DISCUSSION

Synthetic studies

In the presence of the organic base $C_{10}H_8(NMe_2)_2$ (**4**, proton sponge), $3H_2$ failed to react with tetrachloroethylene. Only the salt [**4**H][**3**H] was isolated from the reaction mixture. This compound was identified by positive ion fast atom bombardment mass spectrometry {(+)FABMS} and by IR, ^1H and ^{11}B NMR spectroscopy [6]. The reaction between $3H_2$ and oxalyl chloride in the presence of **4** afforded an orange

*Author to whom correspondence should be addressed.

hygroscopic compound. The (+)FABMS spectrum of this product contains an ion envelope based at *m/z* 215, which corresponds to $4H^+$, together with an ion based at *m/z* 403. The negative ion FABMS {(−)FABMS}spectrum contains its highest mass ion cluster at *m/z* 402 which may correspond with the ion $[C_2B_{10}H_{10}(\mu\text{-}S_2)_2C_2B_9H_{10}]^-$ (**5**, Fig. 1). It is possible, therefore, that the positive ion at *m/z* 403 corresponds with the protonated form of this disulfide $[C_2B_{10}H_{10}(\mu\text{-}S_2)_2C_2B_9H_{11}]^+$. The IR spectrum of the product contains a strong IR band assigned to ν_{max}(BH) at 2500 cm^{-1}, showing the presence of the boron cage in addition to bands attributable to aromatic C—H deformations in the region 1400–1600 cm^{-1}. The conductivity of a 10^{-4} mol dm^{-3} solution of the compound in acetonitrile showed that the product was a 1 : 1 electrolyte and elemental analyses for C, H and N are consistent with the formulation $[4H][C_2B_{10}H_{10}(\mu\text{-}S_2)_2C_2B_9H_{10}]$. The failure to produce the expected product **2** in this reaction reflects the difference in reactivity between the carborane cage and the benzene ring.

No reaction between $3H_2$ and phosgene or triphosgene was observed in the presence of **4**. However, the reaction between $[Bu_4N]_2[Zn3_2]$ and phosgene afforded a white crystalline solid. The (−)FABMS of the product contains, as its highest mass species, an ion cluster based at *m/z* 223, which corresponds to the carbonyl species $(C_2B_9H_{10}S_2CO)^-$ (**6**, Fig. 1), whilst the (+)FABMS spectrum contains an ion at *m/z* 242, which corresponds to the Bu_4N^+ cation. A strong IR band assigned to ν_{max}(BH) was observed at *ca* 2550 cm^{-1}, showing the presence of the boron cage. A strong absorption band at 1626 cm^{-1} is also observed in the spectrum and may be due to a carbonyl stretch $\{\nu_{max}(CO)\}$, although this is at a much lower frequency than the 1671 cm^{-1} reported for ν_{max}(CO) in $C_5H_4S_4CO$ (**7**, Fig. 1) [7]. The conductivity of a 10^{-4} mol dm^{-3} solution of the compound in acetonitrile showed that the product was a 1 : 1 electrolyte and elemental analyses for C, H and N are consistent with the formulation $[Bu_4N][C_2B_9H_{10}S_2CO]$.

In the reactions described above, the use of carbonyl compounds with $3H_2$ in the presence of base appears to result in some degradation of the carborane cage to produce *nido*-$C_2B_9H_{11}^-$ derivatives. The oxophilic nature of the boron presumably contributes to this reactivity and so, to circumvent these degradation reactions, $3H_2$ was instead reacted with thiophosgene. This reaction afforded an orange oil from which yellow crystals of compound **8** (Fig. 1) were isolated by sublimation. The IR spectrum of **8** contains a strong IR band assigned to ν_{max}(BH) at 2550 cm^{-1}, showing the presence of the carborane cage. In addition, an

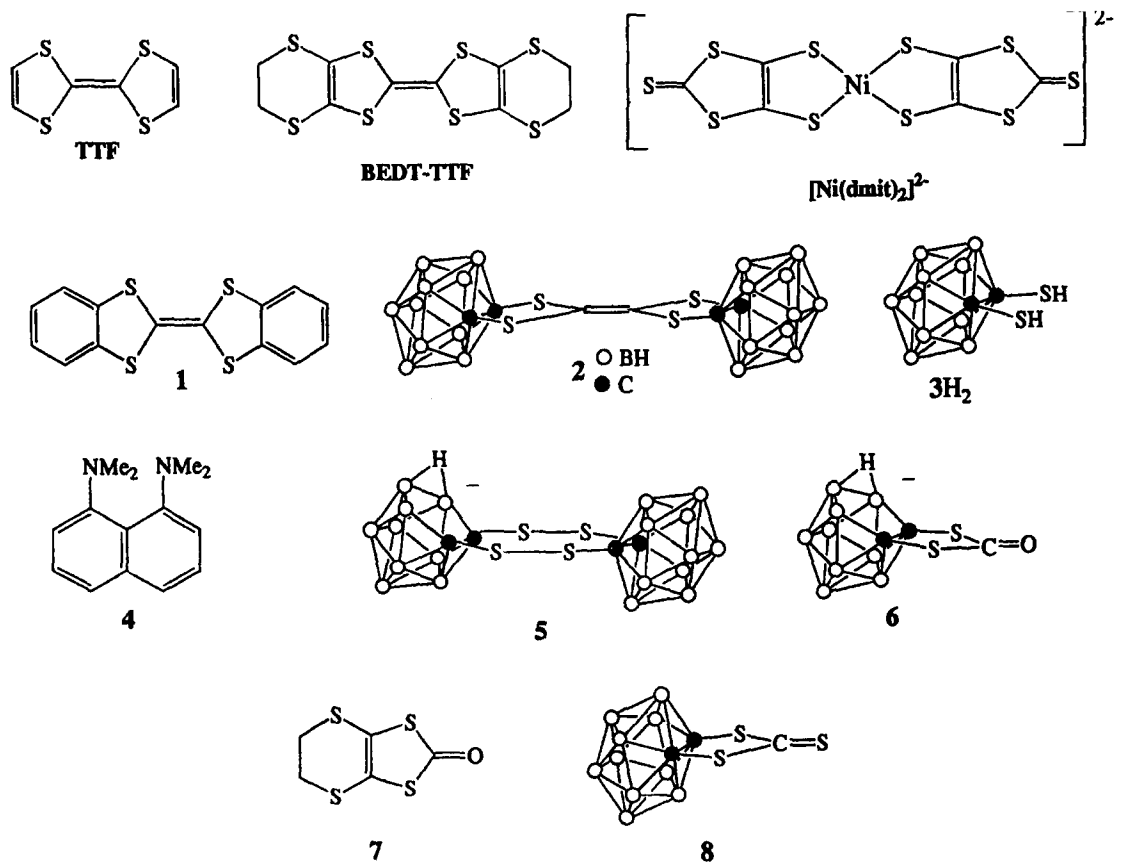

Fig. 1. Structural formulae of TTF, BEDT-TTF, $[Ni(dmit)_2]^{2-}$, **1**, **2**, $3H_2$, **4**, **7** and **8** and proposed structures for **5** and **6**.

intense absorption band is also present at 1091 cm^{-1}, which may be due to ν_{max}(CS); in the thione analogue of **7** ν_{max}(CS) appears at 1065 cm^{-1} [7]. The EI mass spectrum of **8** contains a molecular ion cluster based on m/z 250 with a second ion cluster at m/z 206 attributable to $[M - CS]^+$. The formulation of **8** as $C_2B_{10}H_{10}S_2C{=}S$ was confirmed by the single crystal X-ray diffraction study described below. Coupling of **8** would lead to the TTF analogue $(C_2B_{10}H_{10}S_2C)_2$. However, attempts to effect this coupling using reaction conditions described in published methods for related systems [8] were unsuccessful.

The electrochemical properties of $C_2B_{10}H_{10}S_2C{=}S$ were investigated using cyclic voltammetry. In dichloromethane solution **8** was reduced at a potential of -1.01 V, although the reduction process was both electrochemically and chemically irreversible. No oxidation wave was observed in the potential range 0 to $+1.4$ V. These results clearly demonstrate that **8** is not easily reduced or oxidised and so is not well suited for forming charge-transfer compounds with electron donors or acceptors.

Structural studies

The crystal structure of $C_2B_{10}H_{10}S_2C{=}S$ is shown in Fig. 2 [9]. The molecule has two-fold (C_2) symmetry, atoms S(2) and C(2) lying on the axis, which also passes through the centres of the C(1)—C(1*) and B(4)—B(4*) bonds. The S(2)—C(2) bond length is 1.621(3) Å, which is significantly shorter than the other C—S bonds in the molecule and corresponds in length to a C=S double bond [10,11]. This establishes the formulation of the molecule as a thione, $R_2C{=}S$. The other C—S bond lengths correspond to single bonds with C(1)—S(1) [1.781(2) Å] longer than the bond between S(1) and the sp^2-hybridized C(2) [1.747(2) Å]. Boron–boron and boron–carbon bonds in the cage range from 1.743 to 1.793, mean 1.778(4) Å, and 1.704 to 1.749, mean 1.727(12) Å, respectively. These values are in good agreement with those given by Allen *et al.*,[11] 1.775 Å for B—B and 1.716 Å for B—C in comparable cage structures [11]. The carbon–carbon bond length at 1.632(3) Å is similar to the long C—C lengths commonly found in dicarbadodecaborane structures [mean 1.659(2) Å for 104 structures extracted from the CSD] [12].

The molecules appear to pack in the crystal so that the C=S functions stack one on top of another (Fig. 3) [13]. However, there are no intermolecular contact distances shorter than the sum of the van der Waals radii, so that there is little or no π–π orbital overlap between these moieties. There are no abnormally short intermolecular contact distances. The closest S···S intermolecular contact is between single-bonded sulfurs, S(1)···S(1*), 3.552(1) Å (see Fig. 3).

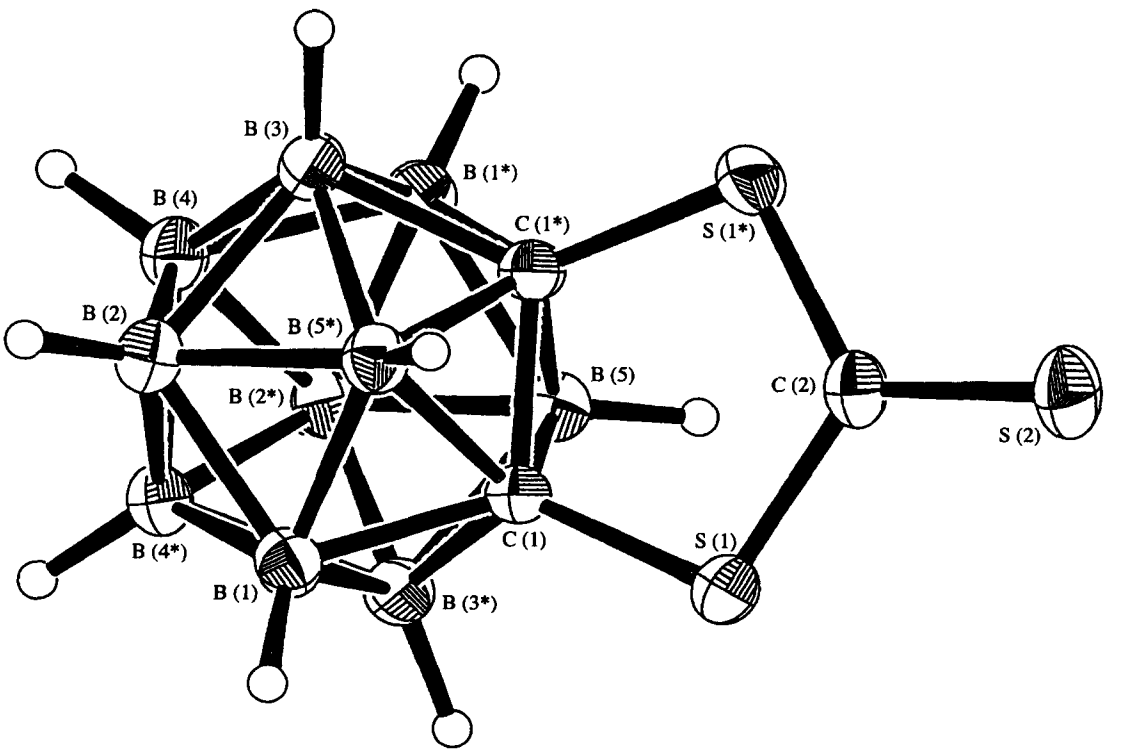

Fig. 2. ORTEP [9] view of the molecule of $C_2B_{10}S_2C{=}S$. Ellipsoids are drawn at the 50% probability level. "Starred" atoms are related to the corresponding unstarred ones by a crystallographic two-fold symmetry axis.

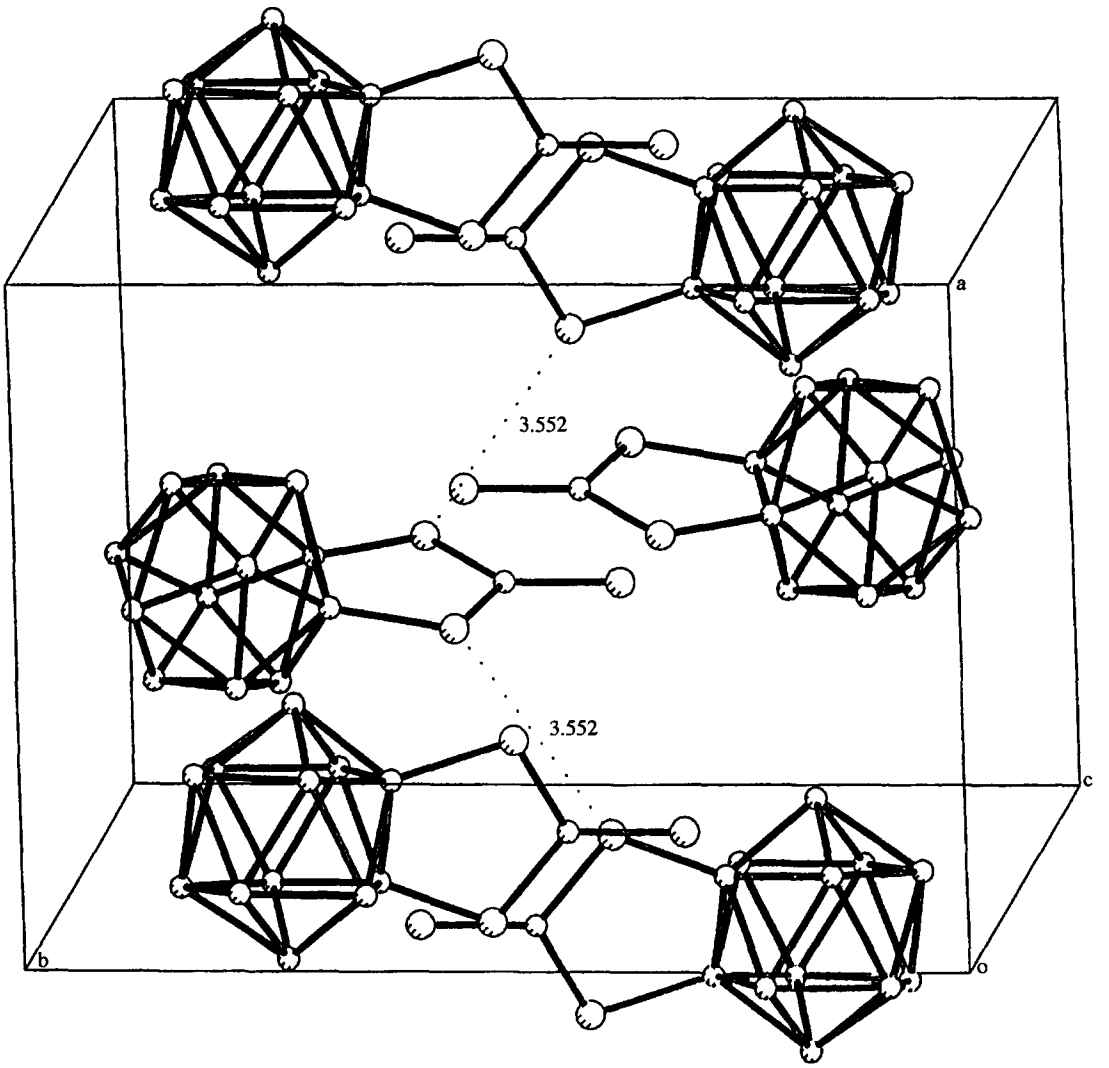

Fig. 3. Packing diagram for $C_2B_{10}S_2C{=}S$ showing the S···S contacts.[13]

EXPERIMENTAL

Synthetic studies

Reaction solvents were purified by distillation under nitrogen from standard drying agents before use. The reagents TTF [14] and $C_2B_{10}H_{10}(SH)_2$.[5] were prepared by literature methods. All commercial chemicals were pre-dried before use, but otherwise were used as received unless otherwise stated. Reactions were carried out under an atmosphere of dry nitrogen. IR spectra were recorded from KBr discs using a Perkin–Elmer 1600 series FT-IR spectrophotometer. ^{11}B NMR spectra were recorded at 87 MHz from dichloromethane and acetonitrile solutions using a Jeol GX270 spectrometer and ^{13}C (25 MHz) NMR spectra were recorded using a Brucker AC300 spectrometer. Mass spectra were recorded using a Kratos RF80 instrument with positive or negative ion fast atom bombardment of a *meta*-nitrobenzyl alcohol (NOBA) matrix. Conductivity measurements were recorded using a PTI 58 digital conductivity meter. Elemental analyses were performed by the Microanalytical Service, School of Chemistry, University of Birmingham or the Microanalytical Service, School of Chemistry, University of Sheffield.

Reaction of $C_2B_{10}H_{10}(SH)_2$ *with oxalyl chloride*

Proton sponge **4** (0.214 g, 1.0 mmol) was dissolved in THF (10 cm^3) and the solution added dropwise to a solution of $C_2B_{10}H_{10}(SH)_2$ (0.100 g, 0.48 mmol) in THF (10 cm^3). After vigorous stirring oxalyl chloride (0.032 g, 0.25 mmol) was added with caution. An immediate colour change from colourless to orange was observed. The solvent was removed *in vacuo* and the product purified by column chromatography using dichloromethane/hexane (50 : 50) as the eluants. The second orange band was collected and the solvent

removed *in vacuo* to yield an amorphous orange solid (0.090 g, 86%). Found: C, 35.3; H 6.5; N, 3.5. $C_{20}H_{40}B_{20}N_2O_2S_4$ requires: C, 35.1; H, 5.9; N, 4.1%. ν_{max} (BH): 2546 cm^{-1}, ^{11}B $\{^1H\}$ (CH_2Cl_2) δ: −18.74, −24.85, −26.12, −29.65 ppm; ^{13}C NMR ($CDCl_3$) δ: 165.2, 142.1, 135.7, 132.7, 126.2, 125.9, 125.1 ($C_{14}H_{19}N_2$), 83.1 ppm ($C_2B_{10}H_{10}(SH)_2$); mass spectrum *m/z* (*I* %): (+)FABMS, 215 (100) $[C_{14}H_{19}N_2]^+$, 200 (9) $[C_{13}H_{16}N_2]^+$, (−)FABMS, 402 (100) $[C_2B_9H_{10}S_4C_2B_{10}H_{10}]^-$. Λ_m 166 Ω^{-1} cm^2 mol^{-1}.

Preparation of $[Bu_4N]_2[Zn^{II}(C_2B_{10}H_{10}S_2)_2]$

$C_2B_{10}H_{10}(SH)_2$ (1.00 g, 4.8 mmol) was dissolved in THF (20 cm^3) and $ZnCl_2$ (0.34 g, 2.5 mmol) was added. The suspension was heated under reflux for 16 h. The solution was allowed to cool to room temperature. $[Bu_4N]Cl$ (1.39 g, 5.0 mmol) was dissolved in deionised water (5 cm^3) and added dropwise with stirring to this solution over a 10 min period. The solution was then stirred for a further hour, the solvent removed *in vacuo* and the residue dissolved in dichloromethane (10 cm^3). Any residual solid was removed by vacuum filtration. The solution was warmed (35°C) and hexane added until the product just started to precipitate. On standing a white microcrystalline solid deposited (2.12 g, 92%). Found: C, 44.8; H, 8.3; N, 4.0. $C_{36}H_{92}N_2S_4B_{20}Zn$ requires: C, 44.9 H, 9.6; N, 2.9%. ν_{max}(BH) 2559s cm^{-1}; ^{11}B $\{^1H\}$ (CH_2Cl_2) δ: −19.42, −25.70, −26.88, −29.00 ppm; mass spectrum *m/z* (I%): (+)FABMS, 242 (100) $[Bu_4N^+]$.

Reaction between $[Bu_4N]_2[Zn^{II}(C_2B_{10}H_{10}S_2)_2]$ *and phosgene*

A solution of phosgene in toluene (1.93 M, 0.17 cm^3) was added to a solution of $[Bu_4N]_2[Zn^{II}(C_2B_{10}H_{10}S_2)_2]$ (0.15 g, 0.16 mmol) in toluene (10 cm^3) and the mixture stirred vigorously for 30 min at room temperature then heated under reflux for a further 2 h. The solvent was removed *in vacuo* to yield a white solid which was collected and recrystallized twice from dichloromethane/hexane to yield large needle-shaped crystals (0.054 g, 78%). Found: C, 48.8; H, 10.0; N, 3.0. $C_{19}H_{46}B_9OS_2$ requires: C, 49.0; H, 10.0; N, 3.0%. ν_{max} (BH) 2538s, ν_{max} (C=O) 1626s cm^{-1}; mass spectrum *m/z* (I%): (+)FABMS, 242 (100) $[Bu_4N]^+$; (−)FABMS, 223 (100) $[C_2B_9H_9S_2CO]^-$, Λ_m 171 Ω^{-1} cm^2 mol^{-1}.

Preparation of $C_2B_{10}S_2C{=}S$ (**8**)

To an ice-cold, nitrogen blanketed solution of $C_2B_{10}H_{10}(SH)_2$ (0.25 g, 1.2 mmol) in THF (25 cm^3), thiophosgene (0.17 g, 1.5 mmol) was added with stirring to this solution over a 10 min period. The mixture was stirred vigorously for 30 min at 0°C, allowed to warm up to room temperature, heated under reflux for 2 h, allowed to cool to room temperature and any solid was removed by vacuum filtration. The filtrate was then evaporated *in vacuo* and the $C_2B_{10}H_{10}S_2C{=}S$ formed was extracted from the orange residue using dry hexane. The hexane solution was filtered under vacuum and the filtrate then evaporated *in vacuo* to yield a yellow solid. Further purification was achieved by sublimation at room temperature *in vacuo* (0.144 g, 48%). Found: C, 18.7; H, 4.7; N, 0.00. $C_3H_{10}B_{10}S_3$ requires: C, 14.4; H, 4.0; N, 0.00%. ν_{max} (BH) 2611s, 2601s, 2589, ν_{max} (C=S) 1092 cm^{-1}; mass spectrum *m/z* (I %): EI, 250 (100) $[M]^+$, 206 (44) $[M - CS]^+$, 173 (41) $[M - CS_2]^+$, 161 (25) $[M - C_2S_2]^+$; Λ_m 0 Ω^{-1} cm^2 mol^{-1}.

Structural studies

1197 independent reflections (θ 3 to 27°), with $I > \sigma(I)$, measured on a Rigaku R-AXIS II area detector diffractometer, were used in the analysis.

Crystal data. $C_3H_{10}B_{10}S_3$, $M_r = 250.4$, orthorhombic, space group *Pcca*, $a = 9.478(5)$, $b = 13.137(7)$, $c = 9.669(6)$ Å, $U = 1204$ $Å^3$, $Z = 4$, $D_c = 1.381$ g cm^{-3}, μ(Mo-K_α) = 0.566 mm^{-1}, $\lambda = 0.71069$ Å.

The structure was determined [15] by direct methods and refined [16] by least-squares using anisotropic thermal parameters for all the non-hydrogen atoms. Hydrogen atoms were located from difference maps and were refined with isotropic temperature factors. Final $R = 0.0352$ for 1069 observed reflections [$I > 2\sigma(I)$] and 0.0464 for all 1197 data. Residual electron density in a final difference map was within the range −0.31 to 0.18 e $Å^{-3}$.

Supplementary material. Atomic coordinates, thermal parameters, full lists of bond lengths and angles, crystal data and refinement details.

(Received 25 June 1996; accepted 4 October 1996)

Abstract—Oxovanadium(IV) complexes of aroyl hydrazone Schiff bases, *viz.* salicyloyl, nicotinoyl and benzoyl hydrazones, have been synthesized and characterized by elemental analysis, spectroscopy (IR and UV–vis) methods, magnetic susceptibility, EPR measurements, molar conductance and cyclic voltammetry studies. The room-temperature magnetic moments of the complexes are in the range 0.97–1.03 B.M. and are indicative of the presence of anti-ferromagnetic exchange. A binuclear structure has been proposed for the complexes.

Keywords: Schiff base complexes; oxovanadium(IV); aroyl hydrazones; magnetic moments.

The oxovanadium(IV) ion, VO^{2+}, is considered to be the most stable oxocation of the first-row transition metal ion [1]. It forms stable anionic, cationic and neutral complexes with various types of ligands. Monomeric and five coordinate oxovanadium(IV) complexes are formed with several bidentate Schiff bases, but dimeric and five- or six-coordinate complexes are formed with tridentate Schiff bases [2–5]. Recently, there has been considerable research interest in the study of the magnetic exchange behaviour of polymetallic oxovanadium (IV) complexes [4]. The dibasic tridentate ligands are expected to give such polymetallic oxovanadium complexes, since these ligands will satisfy the valence as well as the coordination number of the metal ion by forming the polymetallic complexes. It is also known that the coordination complexes of aroylhydrazones act as enzyme inhibitors [6] and are useful due to their pharmacological applications [7–9]. In view of the above, we report the synthesis and characterization of some oxovanadium(IV) complexes of benzoyl, salicyloyl and nicotinoyl hydrazones derived from benzoic acid hydrazide, salicylic acid hydrazide and nicotinic acid hydrazide with 4-benzoyl-3-methyl-1-phenyl-5-pyrazolone (BMPHP) and 4-nitrobenzoyl-3-methyl-1-phenyl-5-pyrazolone (NBMPHP). The complexes were characterized by elemental analysis, molar conductance, spectroscopic methods (IR and UV–vis), magnetic susceptibility, EPR measurements and cyclic voltammetry.

EXPERIMENTAL

Synthesis of ligands

4-Benzoyl-3-methyl-1-phenyl-5-pyrazolone (BMPHP) and 4-nitrobenzoyl-3-methyl-1-phenyl-5-pyrazolone (NBMPHP) were prepared according to the reported method [10]. The ligands, BMPHP-BH (**1a**), BMPHP-SH (**2a**), BMPHP-NH (**3a**), NBMPHP-BH (**4a**), NBMPHP-SH (**5a**) and NBMPHP-NH (**6a**) were prepared by a general method in which a 1:1 hot ethanolic solution of BMPHP or NBMPHP and benzoic acid hydrazide (BH), salicylic acid hydrazide (SH) and nicotinic acid hydrazide (NH) were taken and refluxed for 3–4 h. After cooling, the solution was then poured into an excess of distilled water (250 cm^3), whereupon a yellow precipitates of the ligands were obtained from their respective solutions. The precipitate thus obtained

was filtered, washed with water and then dried *in vacuo*. Yield 60–70%.

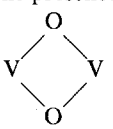
Synthesis of oxovanadium(IV) *complexes*

Vanadyl sulfate was used as a precursor for the synthesis of oxovanadium(IV) complexes. In a general procedure, the oxovanadium(IV) Schiff base complexes $[V_2O_2(BMPHP\text{-}BH)_2]$ (**1b**), $[V_2O_2(BHPHP\text{-}SH)_2]$ (**2b**), $[V_2O_2(BMPHP\text{-}NH)_2]$ (**3b**), $[V_2O_2(NBMPHP\text{-}BH)_2]$ (**4b**), $[V_2O_2(NBMPHP\text{-}SH)_2]$ (**5b**) and $[V_2O_2(NBMPHP\text{-}NH)_2]$ (**6b**) were prepared by adding a hot methanolic solution of the Schiff base ligand to the hot methanolic solution of vanadyl sulphate in a 2 : 1 ratio, respectively, and the resulting solution was refluxed for 6 h. On cooling the reaction mixture, the precipitates of the complexes were obtained from their respective solutions, which were then filtered, washed with methanol and then dried *in vacuo*. Yield 55–60%.

All the chemicals and solvents used in this study were of analytical reagent grade.

Physical measurements

Microanalyses (C,H,N) of the ligands and complexes were carried out on a Carlo-Erba 1106 elemental analyser. Solution electrical conductivity was measured at 298 K using a Digisun Electronics Conductivity meter. IR spectra were recorded on FTS-40 FT-IR instrument (Bio-Rad, USA) as Nujol mulls/KBr pellets. Electronic spectra were recorded in DMF solution on a Shimadzu UV-160 spectrophotometer. Magnetic susceptibility measurements (Gouy Balance) were made at room temperature using $CuSO_4 \cdot 5H_2O$ as a calibrant. EPR spectra of the samples were recorded as powder samples at room temperature using DPPH as the *g*-marker. Cyclic voltammetry traces of the complexes were recorded on a Princeton Applied Research Model 384B polarographic analyser.



RESULTS AND DISCUSSION

The analytical data and IR data of the ligands are presented in Table 1. In the IR spectra of ligands $\nu_{(O\text{-}H)}$, $\nu_{(N\text{-}H)}$, $\nu_{(C\text{-}O)}$, $\nu_{(C\text{=}N)}$ and $\nu_{(C\text{-}O)}$ appear at 3510, 3360–3300, 1650, 1630–1610 and 1180–1185 cm^{-1}, respectively. The structure of the tridentate Schiff base ligands in general can be written as shown in Scheme. I(a).

Vanadyl sulfate reacts with these tridentate ligands in methanol to give stable VO^{IV} ligand-bridged binuclear complexes **1b–6b**. The analytical and IR data for the complexes **1b–6b** (Table 1) support the given formulation for the complexes. The low molar conductance values (7–10 Ω^{-1} cm^{-1} mol^{-1}) of freshly prepared solutions of the complexes **1b–6b** in acetonitrile solvent showed that they are non electrolytes.

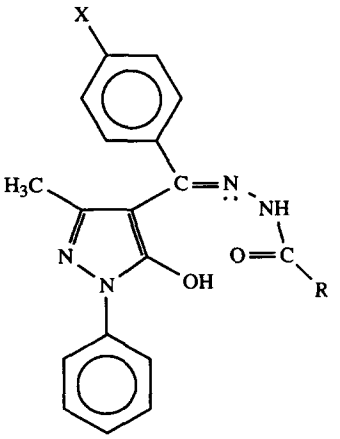
IR spectra

In the IR spectra of the complexes (Table 1), the $\nu_{(v=o)}$ mode [11] was seen in the region 940–960 cm^{-1}. The bands due to $\nu_{(N\text{-}H)}$ and $\nu_{(C\text{-}O)}$ were absent in all the complexes and the presence of bands at 1600 and 1595 cm^{-1} suggests the enolization of the —C=O of the aroyl keto group giving rise to the —C=N—N=C moiety [12]. Of the two bands at 1600 and 1595 cm^{-1}, one may be due to the new $\nu_{(C\text{=}N)}$ and the other may be attributed to the original $\nu_{(C\text{=}N)}$, which has undergone shift to lower wavenumber by 20–25 cm^{-1}, suggesting the coordination of azomethine nitrogen to the metal center. This enolization is further evidenced by the appearance of a new band due to $\nu_{(C\text{-}O)}$, which was observed in the region 1171–1200 cm^{-1} (Table 1). The increase in original pyrazolone based $\nu_{(C\text{-}O)}$ 1210–1215 cm^{-1} compared with the free ligand suggests its coordination to the metal center. This shift of $\nu_{(C\text{-}O)}$ 1180–1210 cm^{-1} by 20–30 cm^{-1} may be due to the presence of

bridge formed by the enolic oxygens [13–15]. In all the complexes the peak due to $\nu_{(O\text{-}H)}$ was absent, indicating the deprotonation of the —OH group. In complexes **2b** and **5b** the peak due to salicyloyl —OH was intact and its $\nu_{(C\text{-}O)}$ did not show any shift compared with the free ligand (1140 cm^{-1}), indicating its nonparticipation in complexation.

Electronic spectra

Usually, the electronic spectra of the square-pyramidal oxovandium(IV) complexes (d^1) are characterized by the presence of three absorption bands corresponding to $d_{xy} \rightarrow d_{xz}$, d_{yz}, $d_{xy} \rightarrow d_{x^2-y^2}$ and $d_{xy} \rightarrow d_{z^2}$ transitions [16]. Similarly, in the electronic spectra of the present complexes three absorption bands were observed in the ranges 13,240–15,300, 18,100–20,000 and 23,200–23,410 cm^{-1}. The second band at 18,100–20,000 cm^{-1} appeared as a shoulder. The band due to LMCT may have merged with the third band (23,200–23,410 cm^{-1}).



Magnetic measurement

The oxovanadium(IV) ion belongs to the $S = 1/2$ system. The magnetically dilute oxovanadium(IV) complexes usually exhibit magnetic moments close to their spin-only value of 1.73 B.M. The magnetic moments of the present complexes at room temperature were found to be in the range 1.02–1.08 B.M.

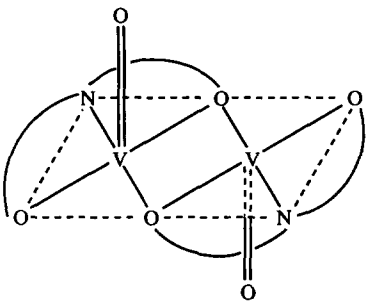


Table 1. Decomposition temperature (T_d), magnetic moments (μ_{eff}), elemental analysis, IR data, EPR parameters and cyclic voltammetry data for the Schiff base ligands (**1a–6a**) and VO^{IV} Schiff base complexes (**1b–6b**)

Scheme 1

(Table 1), which were significantly lower than the spin-only value. There exist several reports in the literature on oxovanadium(IV) complexes with tridentate Schiff base ligands having subnormal magnetic moments [17]. The low magnetic moments may arise due to the antiferromagnetic spin–spin interation between the neighboring oxovanadium (IV) centers [18].

The EPR spectra of the complexes recorded for polycrystalline solid complexes at room temperature exhibited a weak band at 1600 G due to a spin forbidden $\Delta M_s = \pm 2$ transition [18]. This indicates the presence of triplet state dimeric species. The $g_\perp$ and $g_\parallel$ values for the complexes **1b–6b** are 1.98 + 0.02 and 1.97 ± 0.02, respectively, with $g_{av} = 1.97 \pm 0.02$ (Table 1). The EPR spectra of all the complexes are similar, indicating the similarity in the structure of these complexes.

Cyclic voltammetry

The cyclic voltammograms (scan range +1.3 to −1.8 V *vs* Ag/AgCl) for the complexes **1b–6b** in acetonitrile consist of an irreversible reduction wave in the range −0.48 to −0.796 V (Table 1). This irreversible reduction may be attributed to reduction of V^{IV} to V^{III}. The V^{IV} to V^{V} oxidation in complexes **1b–3b** occurred at +0.85 V (irreversible), whereas for complexes **4b–6b** (with Schiff bases of NBMPHP) the same occurred at +1.65 to +1.70 V. The corresponding Schiff base ligands **4a–6a** did not exhibit any oxidation wave in this region, but showed a reversible redox couple at −0.98 ± 0.03 V. The reduction of V^{IV} in **4b–6b** is relatively easy compared with that in **1b–3b**, whereas its oxidation is apparently difficult in **4b–6b** requiring potentials as high as +1.65 V. Electrochemical measurements of oxovanadium(IV) complexes with tridentate dibasic Schiff base ligands are reported [19] to show oxidation to V^{V} and reduction to V^{III} at +0.98 to +1.26 and −1.08 to −1.50 V *vs* SCE, respectively.

Thus, on the basis of the above discussions, it is evident that the present Schiff base ligands behave as dibasic tridentate ligands which on reaction with VO^{2+} form stable binuclear oxovanadium(IV) com-

plexes bridging through enolic oxygens. The neighboring vanadyl groups participate in spin–spin exchange interaction leading to subnormal magnetic moments. A square-pyramidal geometry is proposed for the binuclear complexes, as shown in Scheme I(b).

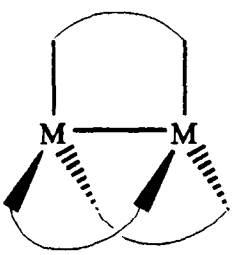
(Received 22 August 1996; accepted 2 October 1996)



Abstract—A method for the preparation of $Mo_2(DTolF)_3Cl_2$, **I**, $DTolF^- = [N,N'$-di-*p*-tolylformamidinate] and $Mo_2(DPhF)_3Cl_2$, **II**, $DPhF^- = [N,N'$-diphenylformamidinate] from the reaction of the corresponding tetraformamidinate compound with one equivalent of ferrocenium chloride and chlorotrimethylsilane is described. X-ray crystallography shows that the structures of both of these mixed valent compounds are essentially the same. Each structure consists of three bridging amidinate ligands with two chloride ions *trans* to one of the amidinate ligands and the molecule has virtual C_{2v} symmetry. The metal–metal bond lengths are 2.1510(5) Å for **I** and 2.148(1) Å for **II**. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: dimolybdenum(II,III), tribridged; formamidinato; starting material; crystal structure.

One of the most prevalent motifs in the chemistry of dinuclear transition metal compounds is the so-called tetragonal lantern structure in which two metal centers are bridged by four ligands, such as carboxylates and amidinates [1].

Recently, we prepared a new class of dinuclear compounds in which the dinuclear unit is bridged by three amidinate ligands. These neutral trigonal lantern complexes, known only for Fe [2] and Co [3], possess an idealized D_{3h} symmetry.

We hope to prepare more of the latter using other transition metals. However, we have encountered a lack of potential starting materials. One obvious approach is the reduction of tetraformamidinates containing the M_2^{4+} core with subsequent elimination of one of the bridging groups, but this has not been successful in our hands. Thus, we have decided to seek other methods.

A recent report [4], described the preparation and

*Authors to whom correspondence should be addressed.

structural characterization of $Tc_2(DPhF)_3Cl_2$, which contains three bridging formamidinate groups and a chloride attached to each Tc atom. This type of structural arrangement looks very appealing for the accomplishment of our goal. Unfortunately, the reaction by which it was synthesized yielded a mixture of the tribridged and the tetrabridged species, $Tc_2(DPhF)_4Cl$. In this paper, we report the synthesis and structural characterization of two new dimolybdenum complexes of the type $Mo_2(DArF)_3Cl_2$ prepared by a designed route in good purity and yield.

EXPERIMENTAL

Material and methods

All manipulations were carried out by employing standard Schlenk techniques under nitrogen. Tetrahydrofuran, toluene, diethyl ether, and hexanes were freshly distilled from Na/K benzophenone, and dichloromethane was distilled from CaH_2 prior to use. *N,N'*-Diphenylformamidine (HDPhF) and $(CH_3)_3SiCl$ were purchased from Aldrich and used as received. Chlorotrimethylsilane solutions were freshly prepared in THF prior to use. Ferrocenium chloride was prepared by bubbling Cl_2 through a hexane solution of ferrocene. Di(*p*-tolyl)formamidine (HDTolF) was synthesized by high temperature condensation between toluidine and triethyl orthoformate using a slightly modified published procedure [5]. $Mo_2Cl_4(PPh_2Me)_4$ [6], $Mo_2(DPhF)_4$ and $Mo_2(DTolF)_4$ [7] were prepared as reported. Infrared spectral data were recorded as KBr pellets using a Perkin–Elmer 16PC FT-IR spectrophotometer at 2 cm^{-1} resolution. Electronic absorption spectra were measured on a Cary 17 spectrophotometer. Elemental analyses were performed by Canadian Microanalytical Service, Delta, British Columbia. Single crystal X-ray diffraction studies were done on an Enraf-Nonius FAST diffractometer equipped with an area detector, utilizing the software program MADNES [8].

$Mo_2(DTolF)_3Cl_2$ (**I**)

In a 200 cm^3 round-bottom flask, 0.544 g (0.501 mmol) of $Mo_2(DTolF)_4$ was dissolved in 40 cm^3 of THF and 60 cm^3 of toluene. A ferrocenium chloride solution, prepared by dissolving 0.112 g (0.507 mmol) of $[Cp_2Fe]Cl$ in 20 cm^3 of THF, was added slowly over a 25 min period. The color of the solution changed from bright yellow to dark brown. The resulting solution was stirred for 1 h at room temperature, after which, 0.51 mmol of $(CH_3)_3SiCl$ was added. The solution was refluxed for 2 h. After removal of the solvent, the brown free-flowing powder was washed with several small portions of Et_2O and then several small portions of hot hexanes. The solid was dissolved in 17 cm^3 of CH_2Cl_2 and layered with hexanes to yield a large crop of dark brown crystals (0.241 g, 51.4%) of **I**. Found: C, 57.6; H, 4.9; N, 8.9; Cl, 8.5. Calc. for $Mo_2Cl_2N_6C_{45}H_{45}$: C, 57.9; H, 4.9; N, 9.0; Cl, 7.6%. IR (KBr, cm^{-1}): 3026(w), 2919(w), 2858(w), 1609(w), 1517(s), 1505(vs), 1311(s), 1298(s), 1213(s), 1113(w), 1017(w), 967(w), 936(m), 822(m), 813(m), 499(w), 488(w), 416(m). UV/vis (CH_2Cl_2): λ = 515(sh) nm; 445 nm; 278 nm.

$Mo_2(DPhF)_3Cl_2$ (**II**)

In a 200 cm^3 round-bottom flask, 0.486 g (0.500 mmol) of $Mo_2(DPhF)_4$ was suspended in 40 cm^3 of THF and 40 cm^3 of toluene. Ferrocenium chloride (0.510 mmol) was added slowly from a solid addition tube over a 20 min period. The resulting dark brown solution was stirred for 1 h at room temperature, after which, 0.50 mmol of $(CH_3)_3SiCl$ was added. The solution was refluxed for 1 h and then filtered to remove unreacted $Mo_2(DPhF)_4$. The filtrate was evaporated to dryness, leaving behind a free-flowing brown powder. The solid was washed with several small portions of hexanes and then several small portions of Et_2O. This solid was dissolved in 14 cm^3 of CH_2Cl_2 and layered with hexanes to yield dark brown needles (0.096 g, 23%) of **II**. Found: C, 55.1; H, 4.0; N, 9.8; Cl, 9.6. Calc. for $Mo_2Cl_2N_6C_{39}H_{33}$: C, 55.2; H, 3.9; N, 9.9; Cl, 8.4%. IR (KBr, cm^{-1}): 3059(w), 3033(w), 2931(w), 1592(m) 1583(m), 1517(s), 1487(s), 1306(s), 1212(s) 1027(m), 938(s), 766(m), 755(s), 695(s), 689(s), 530(w), 490(m). UV/vis (CH_2Cl_2): λ = 540(sh) nm; 435 nm; 330(sh) nm; 275 nm.

Structure determination

Crystals of **I**,* grown from slow diffusion of CH_2Cl_2 and hexanes, were examined under a mixed layer of the mother liquor and mineral oil in air. A suitable crystal was mounted on top of quartz fiber with grease and transferred to a goniometer head under a nitrogen flow at −60°C. The cell parameters were obtained from an auto-indexing routine and were refined with 250 strong reflections in the 2θ range of 18.1 to 41.6°.

*The structure of **II** is similar to that of **I**, except that the substituents on the amidinato nitrogen atoms are phenyl groups instead of *p*-tolyl. Because the data set had a low data to parameter ratio, (4.7 : 1 for $I > 2\sigma(I)$) we did not attempt a complete refinement of the structure. However, the chemical composition was clear from the preliminary study. It crystallizes in space group $P2_1/n$ with the following unit cell parameters: a = 18.647(3), b = 15.796(4), c = 24.552(6) Å, β = 90.06(2)°, V = 7231(3) Å^3, and Z = 8. Data were collected at −105°C on an Enraf-Nonius CAD-4 diffractometer with Mo-K_α radiation. The unit cell contains two independent molecules. The Mo(1)—Mo(2) and Mo(3)—Mo(4) bond distances are 2.143(2) and 2.149(2) Å, respectively. Further crystal data and atomic coordinates for **II** have been deposited with the Cambridge Crystallographic Data Center.

Axial lengths and Laue symmetry (2/m) were confirmed by axial photographs. Details for data collection have been fully described elsewhere [9]. Data were corrected for Lorentz and polarization effects, and an absorption correction was applied using the program SORTAV [10]. The structure was solved by direct methods [11] and was refined using SHELXL-93 [12]. All non-hydrogen atoms were refined anisotropically. Details of data collection and refinement are presented in Table 1. Supplementary data have been deposited with the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

Syntheses

Our first approach to preparing $Mo_2(DTolF)_3Cl_2$ and $Mo_2(DPhF)_3Cl_2$ involved a modification of the procedure used to prepare $Tc_2(DPhF)_3Cl_2$. $Tc_2(DPhF)_3Cl_2$ was synthesized from a one-electron oxidation of $Tc_2Cl_4(PEt_3)_4$ with excess molten formamidine, eq. (1):

$$Tc_2Cl_4(PEt_3)_4 + \text{excess HDPhF} \xrightarrow[-HCl,\ -PEt_3]{140\ ^\circ C} Tc_2(DPhF)_3Cl_2 + Tc_2(DPhF)_4Cl. \quad (1)$$

However, after refluxing a solution of $Mo_2Cl_4(PPh_2Me)_4$ with excess HDPhF in *o*-dichlorobenzene, the only product isolated from the reaction was the yellow tetraformamidinate compound, $Mo_2(DPhF)_4$, in 41% yield, and no oxidation of the dimetal core was observed. This led us to choose an alternative synthetic route that entailed deliberate oxidation of the tetraformamidinate compound followed by replacement of one of the formamidinate ligands by two chloride ions.

The syntheses of **I** and **II** can be summarized by the following two steps (eqs. (2) and (3)).

$$Mo_2(DArF)_4 + [Cp_2Fe]Cl \longrightarrow [Mo_2(DArF)_4]Cl + Cp_2Fe, \quad (2)$$

$$[Mo_2(DArF)_4]Cl + (CH_3)_3SiCl \longrightarrow Mo_2(DArF)_3Cl_2 + \text{"}(CH_3)_3Si\text{-}DArF\text{"}, \quad (3)$$

$$DArF = DTolF^-, DPhF^-.$$

The first step involves oxidation of the dimolybdenum tetraformamidinate by $[Cp_2Fe]Cl$. The oxidation of $Mo_2(DTolF)_4$ to $[Mo_2(DTolF)_4]^+$ has been previously reported using $AgPF_6$ [7]. The advantage of the ferrocenium chloride in this synthesis is two fold: (1) it is an efficient one-electron oxidizing agent, and (2) it provides one equivalent of the chloride ion needed to form the final product. The second equivalent of chloride is furnished by $(CH_3)_3SiCl$ which also aids in removal of one of the formamidinate ligands, driven by the formation of the strong N—Si bond. Since the ferrocene (produced in the first step) does not interfere with the second step, the conversion is easily accomplished as a "one-pot" synthesis.

Both **I** and **II** are dark brown, air-stable solids. However, it is interesting to note the disparity between the yields of **I** and **II**. This can best be explained on the basis of the solubility of the starting materials. If

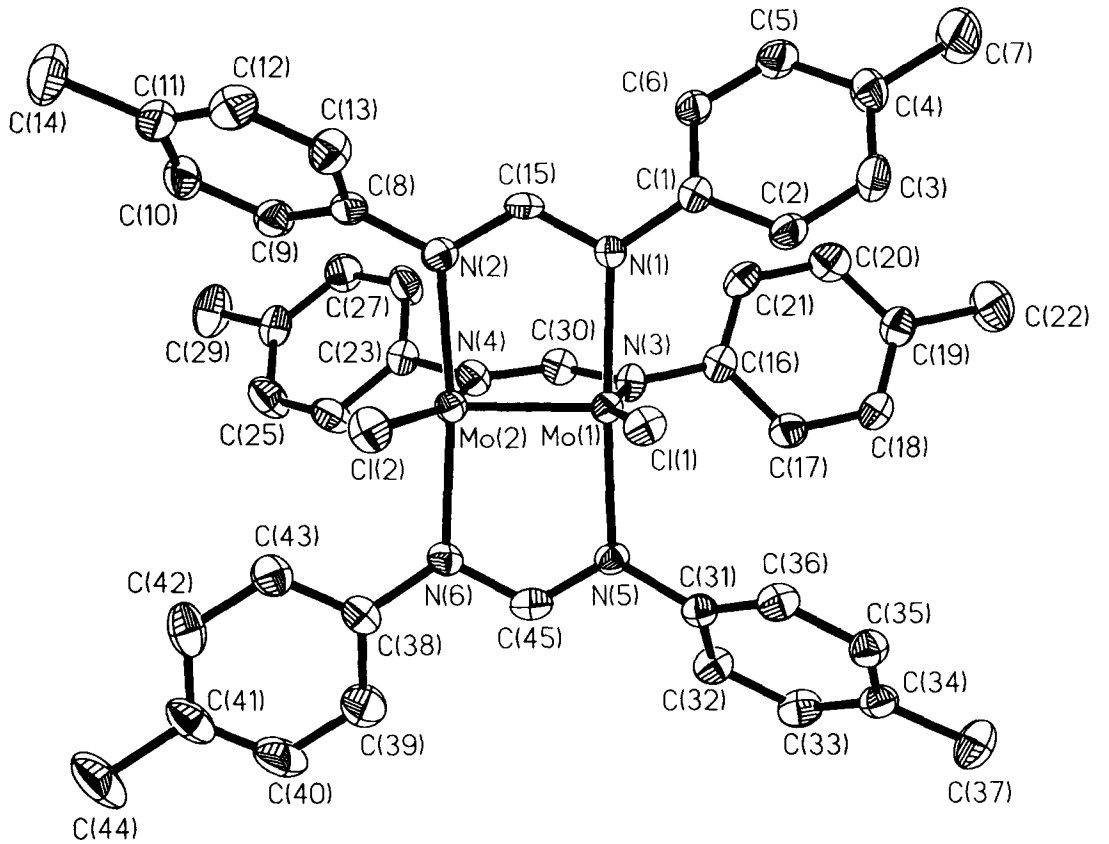

Fig. 1. A drawing of the molecular structure of **I**. Atoms are represented by their 50% probability ellipsoids.

the overall yield of the reaction is determined by the amount of the oxidized intermediate produced in the first step, then the limited solubility of $Mo_2(DPhF)_4$ reduces the concentration of $[Mo_2(DPhF)_4]^+$, and hence the yield of **II**. In fact, even when the $[Cp_2Fe]Cl$ was added slowly to $Mo_2(DPhF)_4$ over a 20 min time period, there was still unreacted starting material present. In contrast, $Mo_2(DTolF)_4$ dissolved completely and the crystalline yield for **I** increased to more than twice that of **II**.

Structural results

The molecular structure of **I** is shown in Fig. 1. There is one independent molecule within the asymmetric unit. The structure features three amidinato ligands bridging the dimetal core in the typical lantern or paddlewheel array. The two *cis* chloride ligands occupy the fourth coordination site on each of the metal atoms. The molecule has approximate C_{2v} symmetry; the C_2 axis bisects the Mo—Mo bond, and passes through the methine carbon, C(30).

Selected bond distances and angles for **I** are presented in Table 2. The Mo(1)—Mo(2) distance is 2.1510(5) Å which is comparable to the Mo—Mo distance of 2.122(3) Å found in $[Mo_2(DTolF)_4]PF_6$ [7]. The chlorine atoms are directed away from each other as evidenced by the N(3)—Mo(1)—Cl(1) and N(4)—Mo(2)—Cl(2) angles of 158.5(1)° and 162.2(1)°, respectively.

Summary

We have described a useful synthetic route for the preparation of dichlorotrisamidinato $Mo_2^{II,III}$ compounds. The structural characterization of these compounds demonstrates the *cis* arrangement of the chloride ligands. Currently, our efforts are directed towards removal of these chloride ligands, through reductive elimination, so as to leave a neutral trigonal lantern complex of molybdenum.

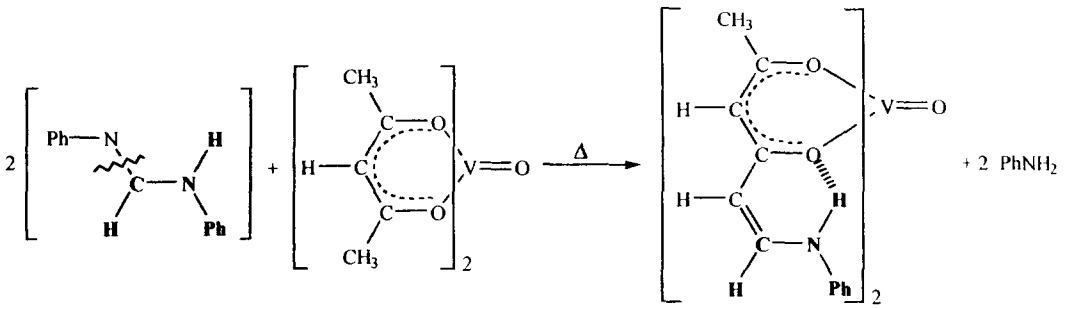
(Received 12 August 1996; accepted 2 October 1996)

Abstract—A formally three-coordinate silver(I) complex, $Ag(HDPhF)_2(OSO_2CF_3)$ (**1**), has been prepared from the reaction of $AgSO_3CF_3$ with HDPhF (HDPhF = *N*,*N*′-diphenylformamidine) in toluene and characterized through spectroscopic methods and single-crystal X-ray diffraction studies. The silver atom is bound through one nitrogen atom each to two neutral formamidine ligands and weakly coordinated to the triflate anion through an oxygen atom. The AgN_2O group is practically planar with an N—Ag—N angle of 142.3(2)° and O—Ag—N angles of 122.4(2) and 92.0(1)°. Hydrogen bonding possibly related to the mechanism of formamidine cleavage seen in other complexes occurs between oxygen atoms of the triflate anion and amine hydrogen atoms in **1**. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: silver; three-coordinate; hydrogen bonding; crystal structure; formamidine complex.



Although formamidinates $[RNC(H)NR]^-$ can bind in a variety of modes [1], we have been interested in them primarily as bridging ligands in dinuclear molecules which contain metal–metal bonds [2]. We have found that one of the best methods for preparing divalent compounds is to react $MCl_2(formamidine)_2$ complexes [3] with methyllithium, which deprotonates the neutral ligands to afford compounds of the type $M_2(formamidinate)_4$ [4].

More recently we have observed that under suitable conditions, formamidines or formamidinate ligands undergo cleavage at a C—N bond. For example, a tantalum compound containing both the RNCH and NR fragments of a formamidinate ligand has been isolated in our laboratory [5]. In other cases, the ligand fragments react further with other ligands attached to the metal ion to produce new species as in the reaction of $VO(acac)_2$ with HDPhF shown in the scheme below [6].

We believe that in many of these reactions the formamidine probably binds to the metal center before undergoing cleavage. For this reason, it is important to study the bonding modes of formamidines in various complexes. As mentioned above, we have synthesized and studied several compounds in which the tetrahedrally coordinated central atom is bound to two halide ions and to two neutral formamidines; however, no other compounds of this type having other coordination geometries have been studied in detail.

While attempting oxidations with silver ions in the presence of formamidines, we observed that coordination can also occur between Ag^+ and HDPhF. It is well known that silver can form a variety of compounds having different coordination numbers. For example, silver in its +1 oxidation state most commonly exhibits twofold linear or fourfold tetrahedral coordination [7], but there are also complexes

Scheme 1.

known in which Ag^I is formally three-coordinate. Among these are $(Me_2NC_6H_4PEt_2)_2AgI$ [7], diphenyl bis(pyrazolyl)borate complexes [8], and mononuclear and dihalide-bridged dinuclear complexes containing tricyclohexylphosphine [9]. In this paper we report the synthesis and characterization of the three-coordinate mononuclear complex $Ag(HDPhF)_2SO_3CF_3$ (**1**) (HDPhF = *N*,*N*′-diphenylformamidine) in which each ligand is bound to Ag^I through one nitrogen atom or an oxygen atom of a weakly coordinated triflate anion.

EXPERIMENTAL

General procedures

The reaction was performed under dry nitrogen, but the solid product was handled in air; measures were taken to protect the reaction mixture and the product from light, however. Toluene and hexanes were freshly distilled under nitrogen from sodium/potassium benzophenone ketyl. *N*,*N*′-diphenylformamidine and silver triflate were purchased from Aldrich Chemical Co.; the HDPhF was washed with warm ethanol and dried under reduced pressure prior to use. The IR spectrum of **1** was obtained on a Perkin Elmer 16 PC FT-IR spectrometer using a KBr matrix. The ^1H NMR spectrum was obtained on a Varian 200XL-E spectrometer in CD_2Cl_2. Elemental analyses were performed by Canadian Microanalytical Services, Ltd.

Preparation

In a typical experiment 0.25 g (9.7×10^{-4} mole) of $AgSO_3CF_3$ and 0.39 g (2.0×10^{-3} mole) of HDPhF were combined in a flask which was then evacuated for about 1 h to remove any residual moisture. About 30 cm^3 of toluene was added, whereupon nearly all of the solid dissolved. The reaction mixture was refluxed for 1 h to afford a clear solution with a slight beige tint. About 50 cm^3 of isomeric hexanes was layered onto the cooled mixture; after a week, colorless crystals had formed and the mixture was placed in a freezer overnight. An additional 20 cm^3 of hexanes was added and the mixture was stirred and replaced in the freezer. The product, a pale beige-colored semicrystalline solid, precipitated and was collected by filtration. The yield was 0.36 g (57.3% based on $AgSO_3CF_3$). IR (cm^{-1}): 2962(w), 1681(s), 1587(s), 1488(s), 1449(w), 1261(s), 1209(m), 1166(m), 1098(m), 1025(s), 987(w), 912(w), 900(w), 805(s), 754(s), 695(s), 652(m), 634(m), 601(w), 575(w), 518(m), 506(m), 431(w). ^1H NMR (ppm): complex multiplets of split peaks centered at 7.20 and 7.35 (phenyl C—H protons), sharp singlet at 8.25 (methine protons). Elemental analysis: Found: C, 49.6; N, 8.6; H, 3.8. Calc: C, 49.9; N, 8.6; H, 3.7%. Single crystals suitable for X-ray diffraction studies were obtained by combining about 40 mg of **1** with 10 cm^3 of toluene, filtering off any undissolved material, layering the solution in a Schlenk tube with 15 cm^3 of hexanes, and placing the tube in a freezer. Needlelike crystals formed within two weeks.

X-ray crystallography

Data were collected on a Rigaku AFC5R diffractometer (Cu-K_α radiation) equipped with a rotating anode at room temperature using procedures described elsewhere [10]. A set of 25 reflections for cell indexing were found using an automated search routine. The cell dimensions and Laue group were confirmed with axial photographs. Data were collected using ω-2θ scans and corrected for Lorentz and polarization effects; an absorption correction based on ψ-scans was applied. The structure was developed using SHELXS-86 and SHELXL-93 [11]. All of the non-hydrogen atoms were found in a direct methods *E*-map; the hydrogen atoms were placed in idealized positions. All of the atoms were refined anisotropically by full-matrix least-squares methods; the refinement on F^2 converged to $R_1 = 0.042$, $wR2 = 0.102$ for $I > 2\sigma(I)$. Other information pertinent to the data collection and structure solution are

given in Table 1. A representation of **1** showing the atom labeling scheme is given in Fig. 1. Selected bond lengths and angles are given in Table 2. Supplementary data have been deposited with the Cambridge Crystallographic Data Centre.*

RESULTS AND DISCUSSION

The reaction between $AgSO_3CF_3$ and HDPhF in toluene produces $Ag(HDPhF)_2SO_3CF_3$ (**1**), a three-coordinate complex in which two neutral formamidine ligands are each bound *via* one nitrogen atom to the silver ion and the triflate anion is bound through an oxygen atom as shown in Fig. 1. The Ag—N distances are 2.179(4) Å and 2.206(4) Å while the Ag—O distance is relatively long at 2.575(4) Å. The N—Ag—N angle is 142.3(2)° and the silver atom is located 0.40 Å out of the plane defined by the oxygen and nitrogen atoms coordinated to the metal atom. The Ag—N distances in **1** are comparable to those found in $Ag(en)ClO_4$ [12] (2.17(1) Å) which exhibits linear twofold coordination, but longer than those found in $[Ag(NH_3)_2]Ag(NO_2)_2$ [13] (2.112(6) and 2.117(6) Å) which also contains linear N—Ag—N units; they are, however, shorter than those found in the planar, three-coordinate complex $Ag(dmp)NO_3$ [14] (dmp = dimethylphenanthroline) (2.283(6) and 2.300(5) Å) and in the nearly tetrahedral complex $Ag(py)_4ClO_4$ [15] (py = pyridine) (2.322(3) Å).

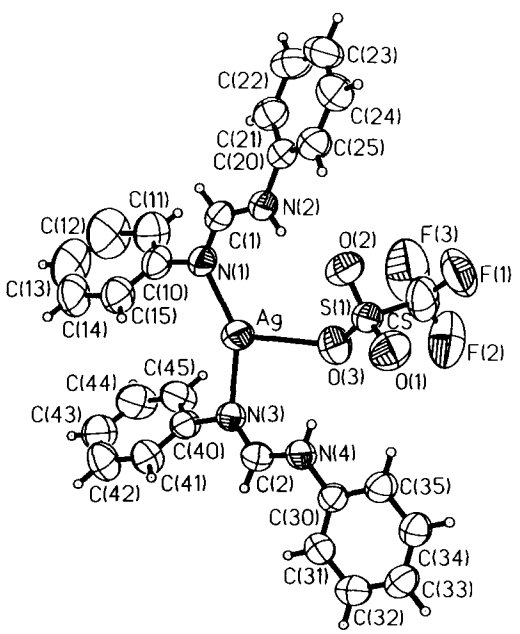

Fig. 1. Thermal ellipsoid plot of $Ag(HDPhF)_2SO_3CF_3$. Atoms are represented by their 50% probability ellipsoids.

*Supplementary material available: Tables of positional parameters, full tables of displacement parameters and molecular dimensions (7 pages).

Threefold coordination is uncommon for Ag^I complexes; consequently, there are few opportunities available for comparison of **1** with known compounds. Bruce and coworkers have reported the structure of $Ag[P(p\text{-}MeC_6H_4)_3][BPh_2(pyrazolyl)_2]$ [8], and while this complex is not strictly analogous to **1**, it displays a similar coordination geometry about the silver atom, which is bound to the pyrazolyl nitrogen atoms at 2.194(4) Å and 2.411(4) Å and to the phosphorus atom at 2.351(1) Å; the larger of the P—Ag—N angles is 160.3(1)°. In this case, as in that of **1**, the silver atom in its +1 oxidation state is bound to two ligands and weakly coordinated to a third; this coordination is relatively weak as born out by the long bond distances, but strong enough to cause significant deviation of the P—Ag—N and N—Ag—N angles from the linearity common to two-coordinate Ag^I complexes.

Our interest in **1** lies primarily in the coordination mode of and the hydrogen bonding exhibited by the neutral formamidine ligands through the N(4)—O(3) and N(2)—O(2) distances of 2.950(6) Å and 2.966(6) Å, respectively. With the hydrogen atoms placed in idealized positions, the H(4A)···O(3) distance is 2.127 Å and the O(2)···H(2A) distance is 2.167 Å; the O(3)—H(4A)—N(4) and O(2)—H(2A)—N(2) angles are 160.0 and 154.3°, respectively. These molecular dimensions are consistent with the presence of hydrogen bonds.

Cleavage of formamidines during reactions with transition metals has been observed in several instances in our laboratories, notably in the reaction between $VO(acac)_2$ and HDPhF with concomitant release of aniline [6]. We believe that hydrogen bonding similar to that exhibited in **1** by the amine hydrogen atoms of the neutral formamidine ligands may play a crucial role in the mechanism by which the ligands are cleaved in other reactions. It is possible that in the reaction between $VO(acac)_2$ and HDPhF, the formamidine initially coordinates to the metal atom at the vacant site opposite to the vanadyl oxygen atom to form a pseudooctahedral intermediate stabilized by hydrogen bonding between the amine hydrogen atom and a coordinated acac oxygen atom. The coordinated HDPhF would then attack the methyl carbon of the acac and subsequently undergo C—N bond cleavage to release aniline and form the new ligand 6-(phenylamino)-2,4-hexanedionate. The pseudooctaheral intermediate would display an O—V—N angle of approximately 90°. One of the formamidines in **1** is coordinated in just such a manner, forming an angle of 92.0(1)° with the silver atom and the coordinated triflate oxygen atom shown in Fig. 2. This fact and the presence of stabilizing intramolecular hydrogen bonding in **1** lends credence to our assumptions regarding the mechanism by which HDPhF is cleaved during its reaction with $VO(acac)_2$. Further investigations into the chemistry of amidine ligands, particularly into their cleavage reactions, are currently underway in our laboratories.

An investigation of P,P′-di(2-ethylhexyl) methanediphosphonic acid and some of its metal complexes†

Albert W. Herlinger,[a]* John R. Ferraro,[b] Renato Chiarizia[b] and E. Philip Horwitz[b]

[a]Department of Chemistry, Loyola University Chicago, Chicago, Illinois, 60626 U.S.A.; [b]Chemistry Division, Argonne National Laboratory, Argonne, Illinois, 60439 U.S.A.

(Received 5 August 1996; accepted 2 October 1996)

Abstract—Copper(II), iron(III), europium(III), thorium(IV) and uranium(VI) complexes of P,P′-di(2-ethylhexyl) methanediphosphonic acid, H_2DEH[MDP], were prepared along with calcium and sodium salts. The compounds were characterized by elemental analysis, infrared spectroscopy, and vapor phase osmometry (VPO). Infrared spectra reveal that the asymmetric, $\nu_{asym}(POO^-)$, and symmetric, $\nu_{sym}(POO^-)$, phosphorus–oxygen stretching modes of the ligand are sensitive to the nature of the metal ion present in the compound. The dramatic variation in $\nu_{asym}(POO^-)$ with metal ion indicates a wide range in strength of the metal–diphosphonate interaction. The shift of both $\nu_{asym}(POO^-)$ and $\nu_{sym}(POO^-)$ to lower energies relative to their values in the sodium salt indicates symmetrical coordination of the phosphonate groups through chelate and/or bridging interactions. The difference $\Delta\nu$ between the POO^- stretching frequencies, $[\nu_{asym}(POO^-)-\nu_{sym}(POO^-)]$, becomes smaller as the ionic potential of the metal ion increases.

H_2DEH[MDP] was found by VPO to be dimeric in toluene at 25°C in the 0.2–0.005 *m* concentration range. Dimerization is achieved through strong intermolecular hydrogen bonding between the phosphoryl and P—OH groups of two H_2DEH[MDP] molecules. Pre-equilibration with water or 1.0 *M* nitric acid does not effect the aggregation of the ligand in toluene. The apparent aggregation numbers measured for H_2DEH[MDP] solutions contacted with aqueous metal ions indicate that the ligand has a tendency to form polynuclear complexes. Aggregation increases with increasing metal ion concentration, deprotonation of the P—OH groups, and the ionic potential of the metal ion. The absence of nitrate ion in these solutions shows that, under high metal loading conditions, cations are extracted from aqueous nitric acid by H_2DEH[MDP] with displacement of hydrogen ions. Ligand band shifts indicate that when excess un-ionized H_2DEH[MDP] is present in solution, the phosphoryl oxygen atoms of the acid participate in the complexation process. © 1997 Elsevier Science Ltd. Keywords: alkyl diphosphonic acids; metal complexes; P,P′-di(2-ethylhexyl) methanediphosphonic acid.

Diphosphonic acids have been recognized for a number of years as powerful complexing agents for metal ions [1]. Recent studies have shown that simple diphosphonate ligands form much stronger complexes with lanthanides [2] and actinides [3] than analogous polycarboxylic acid complexants. The strong acidity of the diphosphonic acid group and its ability to chelate metal ions through ionized phosphonic acid groups and P=O groups permits the formation of metal complexes of high stability under very acidic conditions. Since most actinide processing is carried out in acid, this property suggests that suitable diphosphonate ligands have great potential for use in decontamination of nuclear waste streams and the recovery of transuranic elements in the nuclear fuel cycle.

In P,P′-di(2-ethylhexyl) methanediphosphonic acid, two of the four acidic protons of the parent acid have been replaced by alkyl groups to make the

H_2DEH[MDP]

molecule lipophilic, and therefore, soluble in water immiscible solvents. Thus, H_2DEH[MDP] can be used in solvent extraction and extraction chromatographic procedures. This novel ligand functions in highly acidic media and exhibits an extraordinary selectivity for iron(III) and actinides in all valence states. The remarkable phase separation properties and high distribution ratios of H_2DEH[MDP] led to the development of a new extraction chromatographic resin called Dipex [4]. This resin will find application in procedures for the separation of actinides from complex mixed acidic waste as well as from environmental and biological samples. H_2DEH[MDP] is formally similar to a dicarboxylic acid but little information is available about its fundamental coordination chemistry. Interest in the Dipex resin and the complexation chemistry of alkyl substituted diphosphonic acids prompted this investigation.

The extraction of metal ions at tracer concentration levels by H_2DEH[MDP] was recently investigated in *o*-xylene and found to be quite unusual [5]. The metal extraction reactions written in this study were based on the limited information available in the literature which indicated that H_2DEH[MDP] should be dimeric in *o*-xylene [6–8]. The actual state of aggregation of the ligand in aromatic solvents, however, is not known. Di(2-ethylhexyl) phosphoric acid, HDEHP, is dimeric in benzene [9], but mono(2-ethylhexyl) phosphoric acid, H_2MEHP, the monofunctional analog of H_2DEH[MDP], forms much larger aggregates. H_2MEHP is reported to have an aggregation number as high as 12 in benzene [9,10]. Thus, there is a question as to whether the aggregation behavior of H_2DEH[MDP] is similar to that of dibasic H_2MEHP or if it is limited to the formation of dimeric aggregates like monobasic HDEHP.

Knowledge about the aggregation state of an extraction reagent is necessary to understand its metal extraction chemistry. In our earlier study, the extractant dependencies for Fe^{III}, Am^{III} and U^{VI} were observed to decrease continuously with aqueous phase acidity from a value of about 2 in 5 M HNO_3 to a value of almost zero in 0.1 M acid [5]. The variation in extractant dependency was tentatively attributed to an increase in the aggregation of the ligand which occurs when the ionization of H_2DEH[MDP] increases as a result of being in contact with solutions of low acidity. In the related H_2MEHP-Eu^{III} system, the variation in the extractant dependency was shown to be due to changes in the aggregation state of the organophosphorus acid in different solvents [10]. In *n*-decanol, which depolymerizes the ligand, the extractant dependency is three; in toluene, with an aggregation number for H_2MEHP of 12, the extractant dependency is one.

Thus, the goals of the present study were: 1. To measure the extent of aggregation of H_2DEH[MDP] in an aromatic diluent; 2. to measure the extent of aggregation of metal complexes of H_2DEH[MDP] which tends to polymerize according to extraction data [5]; 3. to characterize the metal–ligand interactions in H_2DEH[MDP] complexes and solution species formed under high metal loading extraction conditions.

EXPERIMENTAL

Materials

Reagent grade $Ca(NO_3)_2 \cdot 4H_2O$, $Cu(NO_3)_2 \cdot 3H_2O$, and $Fe(NO_3)_3 \cdot 9H_2O$ obtained from Mallinckrodt Chemical Co. were used without further purification. Reagent grade $Th(NO_3)_4 \cdot 4H_2O$ from J. T. Baker Chemical Co. and $UO_2(NO_3)_2 \cdot H_2O$ from Fisher Scientific Co. were used as received. Aqueous solutions were prepared using Ultrex reagent nitric acid (J. T. Baker Chemical Co.) and water obtained from a Milli-Q2 purification system. Eu_2O_3 obtained from Apache Chemical Co. was dissolved in nitric acid and used to prepare a Eu^{III} stock solution. The metal ion concentration in this solution was determined to be 0.88 M by titration with EDTA. The stock solution was used to prepare a 0.05 *m* Eu^{III} solution by dilution with 1.0 M HNO_3. "Baker Analyzed" Photrex reagent for spectrophotometry toluene was used without further purification for the VPO measurements. The metal extraction data reported earlier for H_2DEH[MDP] were obtained in *o*-xylene [5]. Toluene was used for the osmometric measurements since the low volatility of *o*-xylene would cause the equilibration time required for each VPO measurement to be excessively long. The aggregation behavior of H_2DEH[MDP] and the metal complexes should be very similar in these two aromatic diluents. Bibenzyl obtained from Aldrich Chemical Co. was recrys-

tallized twice from methanol and dried overnight *in vacuo* at 45°C, m.p. 51.0–52.2°C after recrystallization.

Measurements

Apparent aggregation numbers were measured in toluene by VPO using a Corona Wescan 117 Molecular Weight Apparatus. The temperature was maintained at 25.0 ± 0.1°C by operating two Neslab constant temperature baths in series. The instrument was calibrated using standard toluene solutions of bibenzyl. A plot of measured voltage *vs* bibenzyl molality gave a slope of 10,320 μV/m for an instrument calibration constant. All residual traces of moisture and volatile organic compounds were removed from $H_2DEH[MDP]$ by dissolving the ligand in toluene and evaporating the solvent under reduced pressure at 60°C. The ligand was shown to be 99% pure by potentiometric titration with standard base after this treatment. The solutions used in the osmometric measurements, including those containing metal species, were prepared by quantitative dilution of standard 0.10 m $H_2DEH[MDP]$ solutions. The solvent used for the dilutions and as the reference in the VPO measurements was subjected to conditions similar to those used for the extractions, i.e. pre-equilibration with aqueous nitric acid of the appropriate concentration in the absence of metal ion. The VPO measurements were carried out on solutions in order of increasing concentration. Each data point corresponds to the average of 3–5 voltage measurements.

Metal ions were introduced into the solutions used for the VPO measurements by vortex mixing equal volumes of aqueous and toluene solutions that were ~0.05 m in metal ion and 0.10 m in $H_2DEH[MDP]$, respectively. The resulting mixture was centrifuged to form two layers which were physically separated by pipet. Metal ion analyses of the aqueous phase before and after extraction were performed by the ANL Analytical Chemistry Division using ICP-AES. The concentration of metal ion in the organic phase was determined by mass balance from the difference between the two values. The aqueous Fe^{III}, Eu^{III}, Th^{IV}, and U^{VI} solutions used were 1.0 M in HNO_3 while the aqueous Ca^{II} and Cu^{II} solutions were 0.01 M in HNO_3. In an earlier investigation, $H_2DEH[MDP]$ was shown to be highly effective in the extraction of iron(III) and actinide ions from 1 M HNO_3 [5]. Although Cu^{II} was not included in the initial study, it was assumed that conditions which lead to high extraction of Ca^{II}, i.e. 0.01 M HNO_3, would be required for effective extraction of Cu^{II}.

The molecular weights of the iron and uranyl $H_2DEH[MDP]$ compounds which are soluble in toluene were determined using the Corona Wescan molecular weight apparatus. A 0.045 mmole sample of the compound was dissolved in 3 g of dry toluene for the VPO measurements. The results of these single concentration point determinations indicate that the complexes are highly polymerized in toluene.

Infrared spectra were obtained on a Nicolet 510P PC/IR Fourier Transform Spectrometer operating in the 4800–400 cm^{-1} region. Routine spectra were recorded collecting 32 scans at 4 cm^{-1} resolution. Solid samples were run as KBr pellets and checked as Nujol mulls supported on KBr plates. Spectra in the 650–150 cm^{-1} range were obtained on a Bruker 98 Vacuum FT-IR Interferometer. Solid samples were run as CsI pellets referenced against CsI. These were checked as Nujol mulls supported on polyethylene plates. The spectrum of $H_2DEH[MDP]$ was obtained as a liquid film supported on KBr plates and as a 0.10 m toluene solution in a liquid IR cell with NaCl windows. The solution spectrum was recorded at 2 cm^{-1} resolution after collecting 256 scans. Spectra of the solution samples used in the VPO measurements were also recorded using the liquid cell. Solution spectra were measured with toluene in the cell as the background.

^1H and ^{31}P NMR spectra were recorded in $CDCl_3$ on a 300 MHz General Electric Omega 300 spectrometer. Chemical shifts are relative to internal TMS and external 85% H_3PO_4 for ^1H and ^{31}P spectra, respectively. Melting points were recorded on an Arthur H. Thomas, Hoover capillary melting point apparatus using a calibrated thermometer. Elemental analyses were performed by Galbraith Laboratories, Inc., Knoxville, TN. Metal ion analyses for the metal compounds were performed by the Analytical Chemistry Division of ANL using ICP-AES. Solid samples were weighed into a platinium crucible and ignited in air at 1100°C. The residue was fumed with concentrated H_2SO_4 and made up to the final volume with dilute nitric acid. The relative uncertainty in the metal ion analysis is estimated to be ~5%.

Preparation of compounds

P,P′-di(2-ethylhexyl) methanediphosphonic acid. The title compound was prepared by the reaction of 2 equivalents of 2-ethylhexanol with methane diphosphonic acid in dry tetrahydrofuran following the procedure of Burger and Anderson [11] as described previously [5]. The proton decoupled ^{31}P NMR spectrum shows a single resonance at δ 19.87 ppm. The ^1H NMR spectrum shows peaks at δ 11.27 (s), 3.98 (b, m), 2.44 (t, $J_{P\text{-}H}$ = 21.4 Hz), 1.55 (p, J = 5.7 Hz), 1.27 (m), and 0.88 (m) ppm with relative intensities of 2 : 4 : 2 : 2 : 16 : 12. Titration with standard base gave an equivalent weight of 202.6 ± 2 daltons. Found: C, 50.6; H, 9.9; P, 15.2; O, 24.2; Calc. for $C_{17}H_{38}O_6P_2$; C, 51.0; H, 9.6; P, 15.5; O, 24.0%.

$Na_2(C_{17}H_{36}O_6P_2)$. The sodium salt of $H_2DEH[MDP]$ was obtained by titrating a 0.1673 g (0.4178 mmol) sample of the acid in contact with 10 cm^3 of water with 0.10 M NaOH. After addition of 0.8377 mmol of base, the solution was evaporated to dryness under a stream of nitrogen using low heat.

The resulting residue was dried *in vacuo* at 70°C for 12 h. The infrared spectrum of this white waxy solid indicates that the salt is isolated as a hydrate.

$Fe_2(C_{17}H_{36}O_6P_2)_3$. An iron(III) complex of $H_2DEH[MDP]$ was prepared by shaking a 0.10 *m* toluene solution of $H_2DEH[MDP]$ with an equal volume of a 0.10 *m* aqueous iron(III) nitrate solution that was 1 M in HNO_3. A copious off-white precipitate formed immediately upon contacting the two solutions. The liquids were removed by pipet and the oily residue washed with several portions of water and toluene. The solid was collected by filtration, washed with hexane, and dried *in vacuo* at 60°C to an off-white powder. Yield: 169 mg (0.124 mmol), 61%. Found: C, 46.5; H, 8.3; P, 14.8; Fe, 8.0, O, 22.4; Calc. for $Fe_2C_{51}H_{108}O_{18}P_6$: C, 46.9; H, 8.3; P, 14.2; Fe, 8.5; O, 22.0%. The complex is polymeric in toluene with the molecular weight determined by VPO to be 69,400 daltons.

$Th(C_{17}H_{36}O_6P_2)_2$. A 0.4009 g (1.0011 mmol) sample of $H_2DEH[MDP]$ was exactly neutralized with an equivalent amount of aqueous NaOH. The pH of the resulting solution was adjusted to 6 with nitric acid and slowly added to 0.3737 g (0.6768 mmol) of $Th(NO_3)_4 \cdot 4H_2O$ dissolved in 0.1 M HNO_3. A white precipitate formed almost immediately upon mixing the two solutions. After stirring several minutes at room temperature, the precipitate was collected by filtration, washed with several portions of warm water, ethanol, and pentane, and dried *in vacuo* at 60°C overnight. Yield: 327.7 mg (0.3185 mmol), 63.6%. Found: C, 39.6; H, 7.0; Th, 22.3; Calc. for $ThC_{34}H_{72}O_{12}P_4$: C, 39.7; H, 7.0; Th, 22.5%. The compound is insoluble in water, toluene, hexane, ethanol, and acetone.

$UO_2(C_{17}H_{36}O_6P_2) \cdot 2H_2O$. A 0.2046 g (0.5109 mmol) sample of $H_2DEH[MDP]$ was exactly neutralized with an equivalent amount of aqueous NaOH. The pH of the resulting solution was adjusted to 6 with nitric acid and slowly added to 0.3194 g (0.6360 mmol) of $UO_2(NO_3)_2 \cdot 6H_2O$ dissolved in 0.10 M HNO_3. The yellow precipitate which formed immediately upon mixing the two solutions was stirred for several minutes, collected by filtration, and washed with several portions of warm water and ethanol. Recrystallization from a 50 : 50 v : v pentane–ethanol mixture gave large yellow crystals of a pentane soluble hydrate. The crystals were amorphous and unsuitable for X-ray analysis. The uranyl compound proved to be very difficult to dissolve for analysis by ICP-AES and required two digestion attempts. The relative uncertainty in the metal ion analysis in this case is estimated to be ~10%. Yield: 235.3 mg (0.3428 mmol), 67.1%. Found: C, 30.5; H, 5.6; U, 31.1: Calc. for $UC_{17}H_{40}O_{10}P_2$: C, 29.0; H, 5.7; U, 33.8%. The complex is polymeric in toluene with the molecular weight determined by VPO to be 11,340 daltons.

$Eu_2(C_{17}H_{36}O_6P_2)_3$. A 0.1443 g (0.3604 mmol) sample of $H_2DEH[MDP]$ dissolved in a mixture of 3 cm^3 of toluene and 17 cm^3 of isopropanol was exactly neutralized with an equivalent amount of aqueous NaOH. The nominal pH of the solution was adjusted to 6 with nitric acid and slowly added to 0.0811 g (0.240 mmol) of $Eu(NO_3)_3$ dissolved in water. After stirring the reaction mixture overnight at room temperature, the solvent was removed under a stream of N_2 using low heat. The residue was washed with several portions of hot water, collected by filtration, and dried *in vacuo* at 60°C. Found: C, 41.2; H, 7.3; Eu, 18.8; Calc. for $Eu_2C_{51}H_{108}O_{18}P_6$: C, 40.9; H, 7.3, Eu, 20.3%. The infrared spectrum of this compound indicates that it is initially isolated from solution as a hydrate.

$Ca(C_{17}H_{36}O_6P_2)$. A 0.2717 g (0.6785 mmol) sample of $H_2DEH[MDP]$ was exactly neutralized with an equivalent amount of 0.1000 M NaOH. The pH of the resulting solution was adjusted to 7 with nitric acid and slowly added to 0.1715 g (0.7262 mmol) of $Ca(NO_3)_2 \cdot 4H_2O$ dissolved in water. The flocculent precipitate, which formed immediately upon mixing the two solutions, was isolated by filtration, washed with several portions of hot water and ethanol, and dried *in vacuo* at 65°C. Yield: 214 mg (0.488 mmol), 71.9%. Found: C, 46.7; H, 8.1; Ca, 8.7: Calc. for $CaC_{17}H_{36}O_6P_2$: C, 46.6; H, 8.3; Ca, 9.1%.

$Cu(C_{17}H_{36}O_6P_2)$. A 0.2105 g (0.526 mmol) sample of $H_2DEH[MDP]$ was exactly neutralized with an equivalent amount of aqueous NaOH. The pH of the resulting solution was adjusted to 6 with nitric acid and slowly added to 0.1375 g (0.569 mmol) of $Cu(NO_3)_2 \cdot 5H_2O$ dissolved in 0.001 M HNO_3. The blue precipitate which formed almost immediately upon mixing the two solutions was stirred overnight at room temperature, collected by filtration, washed with several portions of warm water and acetone, and dried *in vacuo* at 70°C. Yield: 101 mg (0.226 mmol), 43.0%. Found C, 44.8; H, 7.8: Calc. for $CuC_{17}H_{36}O_6P_2$: C, 44.2; H, 7.8%. The infrared spectrum of this compound indicates that it is initially isolated from solution as a hydrate.

RESULTS

Osmometry

Figure 1 compares the results of the vapor phase osmometry measurements for $H_2DEH[MDP]$ with those for the monomeric standard bibenzyl. The VPO data indicate that $H_2DEH[MDP]$ is dimeric in toluene at 25°C. These results are similar to those for the di-*n*-octyl [7] and di-*n*-butyl [8] esters of methanediphosphonic acid which are reported to be dimeric in chloroform at room temperature. The linearity of the $H_2DEH[MDP]$ data indicates that the dimerization constant in toluene is sufficiently large so that the ligand is dimeric over the entire concentration range investigated. Partial neutralization of the acid has a significant effect on the apparent aggregation number, η, where η = molecular weight/formula

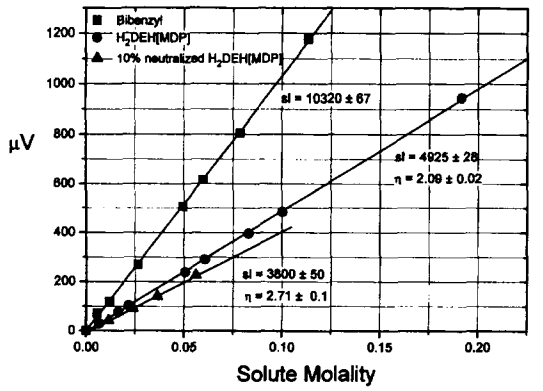

Fig. 1. Osmometric measurements for bibenzyl and $H_2DEH[MDP]$ in toluene at 25°C; sl = slope, η = aggregation number.

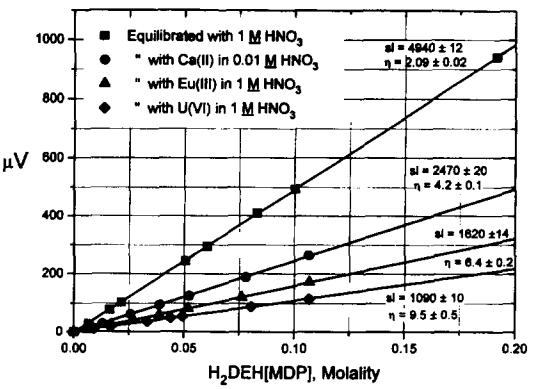

Fig. 3. Osmometric measurements for $H_2DEH[MDP]$ in toluene at 25°C after equilibration with aqueous solutions of Ca^{II}, Eu^{III}, and U^{VI} as described in the Experimental Section; sl = slope, η = aggregation number.

weight = bibenzyl slope/$H_2DEH[MDP]$ slope. Neutralization of approximately 10% of the $H_2DEH[MDP]$ in a sample, for example, resulted in a 35% increase in the calculated η value.

Figure 2 shows the effect of acid and the presence of metal ions on the aggregation of $H_2DEH[MDP]$. Cu^{II} is not extracted by $H_2DEH[MDP]$ from 1.0 M nitric acid and the measured η value is virtually unchanged. Cu^{II} is extracted from 0.01 *M* HNO_3 and the η value calculated for the ligand doubles. Fe^{III} and Th^{IV} are extracted almost quantitatively from 1 M HNO_3. $H_2DEH[MDP]$ solutions containing these metal ions give rise to the highest measured aggregation numbers. Figure 3 shows the results for samples pre-equilibrated with aqueous nitric acid solutions of Ca^{II}, Eu^{III}, and UO_2^{2+}. These metal ions also substantially increase the aggregation of $H_2DEH[MDP]$.

The results of the aggregation measurements are reported in Table 1. Pre-equilibration with water or 1.0 M nitric acid does not effect the aggregation of the ligand. The degree of aggregation, however, increases with increasing metal ion concentration and deprotonation of the P—OH groups. The η values in Table 1

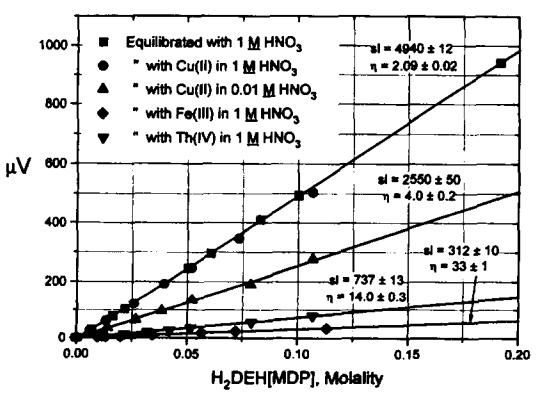

Fig. 2. Osmometric measurements for $H_2DEH[MDP]$ in toluene at 25°C after equilibration with 1 *M* HNO_3 and aqueous solutions of Cu^{II}, Fe^{III}, and Th^{IV} as described in the Experimental Section; sl = slope, η = aggregation number.

Table 1. Apparent aggregation number η for 0.10 *m* $H_2DEH[MDP]$ solutions

Metal ion	molality	[L]:[M]	η
None	—	—	2.09 ± 0.02
Ca^{II}	0.025	4.0	4.2 ± 0.1
Cu^{II}	0.042	2.4	4.0 ± 0.1
Eu^{III}	0.028	3.7	6.4 ± 0.2
U^{VI}	0.067	1.5	9.5 ± 0.5
Th^{IV}	0.040	2.5	14 ± 0.3
Fe^{III}	0.048	2.1	33 ± 1.0

do not correspond to the aggregation numbers for the metal compounds described in the experimental section. Rather, the values represent the average state of aggregation of $H_2DEH[MDP]$ in solutions containing an extracted metal species and more ligand than required for stoichiometric salt formation. The values are roughly proportional to the ionic potential (e/r) of the metal ions and are a qualitative indication of the tendency of metal ions to polymerize $H_2DEH[MDP]$. It is evident from the [L]:[M] ratios and the apparent aggregation numbers that the metal ions investigated, with the exception of Ca^{II}, form polynuclear complexes with $H_2DEH[MDP]$. The molecular weights for the iron and uranyl compounds, which are soluble in toluene, were measured (*vide supra*) and the calculated η values (159 and 17, respectively) verify this observation.

Infrared spectra

$H_2DEH[MDP]$. The infrared spectrum of $H_2DEH[MDP]$ in toluene is shown in Fig. 4. There are no absorption bands in this spectrum which can be attributed to free hydroxyl groups. The three broad bands of medium intensity which are characteristic of the P(O)(OH) group of an alkyl phosphonic acid appear at 2716, 2324, and 1675 cm^{-1}. While there is

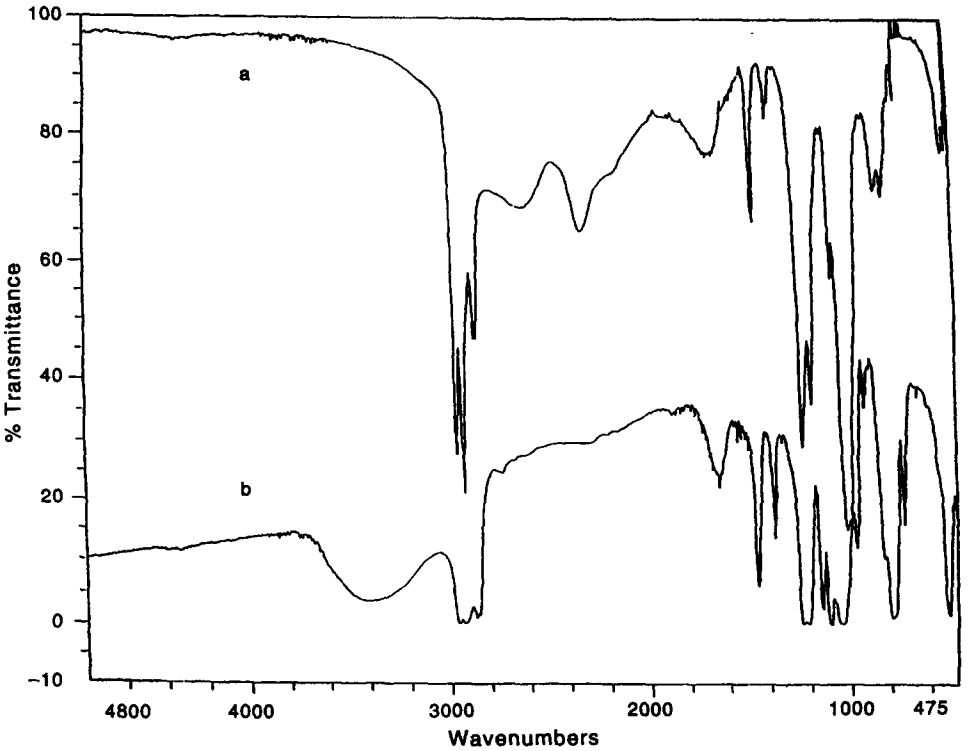

Fig. 4. The infrared spectra of 0.10 *m* H_2DEH[MDP] in toluene (a) and a KBr pellet of Na_2(DEH[MDP]) (b).

some controversy over the assignment of these bands, it is generally agreed that their presence is unequivocal evidence of a strongly hydrogen bonded phosphonic acid [9,10]. These bands disappear upon salt formation as expected. This behavior is similar to that reported earlier for the di-*n*-octyl [7] and di-*n*-butyl [8] esters of methanediphosphonic acid and related organophosphorus acids [14]. The stretching and bending vibrations of the 2-ethylhexyl group appear in the conventional regions characteristic of alkyl groups. The absorption frequencies of these bands are listed in Table 2.

Some of the strongest absorption bands in the spectrum of H_2DEH[MDP] occur in the 950–1250 cm^{-1} region. The frequencies and tentative assignments of the bands in this region are compared with those for 2-ethylhexyl phosphonic acid, H_2[EHP], and mono(2-ethylhexyl) phosphoric acid, H_2MEHP in Table 3. The major bands in this region are typically broad and complex in structure. This suggests that some of the bands may not represent pure vibrational modes and may have components of several vibrations. The thin film spectrum of H_2DEH[MDP], for example, has a single very broad strong band at 1221 cm^{-1} while the higher resolution solution spectrum shows two well resolved bands close to this energy. By comparison with the spectrum of the sodium salt and related organophosphorus acids [12–14] these bands are tentatively assigned as phosphoryl absorptions. The appearance of two bands in this region in the solution spectrum may be due to symmetric and asymmetric stretching motions of the two P=O groups in the molecule, a Fermi resonance, or two different types of hydrogen bonding in the dimer (*vide infra*).

The P—OR stretching vibration in H_2DEH[MDP] occurs as a very strong band in the 1020–1050 cm^{-1} region. There are no bands in this region of the spectrum of H_2[EHP] which has no ester groups. The P—OR band generally appears at somewhat higher energy in the metal compounds than in the free acid. The P—OH stretching vibration for H_2DEH[MDP] is clearly evident as a strong band in the solution spectrum at 1007 cm^{-1}. This band is absent in the spectra for all the metal compounds. The band of medium intensity at 1082 cm^{-1} most likely arises from either C—O bond stretching or deformation of the alkyl chain. This band is too high in energy and too low in intensity to be either a P—OH or P—OR vibration. The absorption bands for the P—OH and P—OR stretching vibrations for a monoester of an alkyl phosphonic acid typically are strong and appear in the characteristic frequency ranges of 990–1029 cm^{-1} and 987–1042 cm^{-1}, respectively [13].

Metal compounds. The absorption frequencies for the metal compounds prepared in this study are listed in Table 2. In all cases, the stretching and bending vibrations of the 2-ethylhexyl group appear at nearly the same frequency as in the free acid. The C—C stretching motion of the alkyl chain gives rise to an absorption band of weak-to-medium intensity at *ca* 975 cm^{-1}. The sodium, copper, europium, and uranyl compounds, as initially isolated, have bands in the

Results reported for solid salts are for spectra obtained with KBr and CsI disks checked against Nujol mull spectra. vs = very strong, s = strong, m = medium, w = weak, vw = very weak, br = broad, sh = shoulder.

conventional regions characteristic of water of hydration. The uranium compound exhibits additional bands at 923 and 872 cm^{-1} which are ascribed to ν_3 and ν_1 of the uranyl ion, respectively [15].

The frequencies and tentative assignments of the absorption bands in the 950–1250 cm^{-1} region for the metal compounds are listed in Table 4. The highest energy bands in this region are assigned to $\nu_{asym}(POO^-)$ and $\nu_{sym}(POO^-)$, respectively. Ionized organophosphorus compounds containing the PO_2^- group show two absorption bands attributable to the asymmetric and symmetric POO^- stretching vibrations of the anion. The frequency of the asymmetric stretching mode, $\nu_{asym}(POO^-)$, is typically higher than that of the symmetric stretching mode, $\nu_{sym}(POO^-)$. In the spectra of salts of monoesters of alkylphosphonic acids, these bands generally fall within the overall frequency region of 1153–1245 cm^{-1} and 1053–1110 cm^{-1}, respectively [13]. While the energy of both stretching modes in these compounds depends upon the metal ion present, $\nu_{asym}(POO^-)$ is especially sensitive to the nature of the cation. The frequency of the asymmetric stretching mode decreases dramatically as the degree of aggregation induced by the metal ion increases. The decrease in $\nu_{asym}(POO^-)$ may be interpreted to indicate an increase in the strength of the metal–diphosphonate interaction. Of the compounds listed in Table 4, $\nu_{asym}(POO^-)$ appears at the highest energies in the sodium and calcium compounds and at the lowest energy in the iron compound. Thus, the binding of sodium and calcium to the ligand appears to be relatively weak while the other metal ions are bound more strongly to H_2DEH[MDP].

Both the symmetric and asymmetric POO^- stretching frequencies are lower in the metal complexes than in the sodium salt. The decrease observed in $\nu_{asym}(POO^-)$ upon complexation essentially rules out monodentate coordination of the phosphonate

groups. Coordination of a single oxygen of a PO_2^- group would result in considerably different P—O bond orders and the asymmetric stretching frequency should increase. Symmetrical coordination of the phosphonate groups through chelate and/or bridging interactions, on the other hand, could reduce the bond order of both P—O bonds by the same amount and both $\nu_{asym}(POO^-)$ and $\nu_{asym}(POO^-)$ should decrease.

The absorptions in the region below 600 cm^{-1} are very similar to those reported earlier for monobasic [16] and dibasic [14] organophosphorus acids. The compounds reported in Table 2 have two bands in the 450–540 cm^{-1} region where the O—P—O and C—P—O deformation modes generally appear [12,13]. The bands are at nearly the same energy in H_2DEH[MDP] and are sensitive to the metal ion present. Upon salt formation, the energy separation between the two bands increases. The energy difference between the bands is smallest in the sodium salt and greatest in the iron complex. Although there is no way to differentiate unambiguously between the two bands based on the available data, it appears on the basis of the frequency shifts that the higher energy band is the O—P—O deformation. Assuming that this assignment is correct, the higher energy of the O—P—O deformation mode in the metal complexes is consistent with increased strength in the metal-ligand interaction.

Metal containing H_2DEH[MDP] *solutions.* The infrared spectra of the metal containing solutions of H_2DEH[MDP] used for the VPO measurements cannot be reproduced simply by adding the spectrum of a metal salt to that of the dimer. The excess ligand in these samples appears to be intimately associated with the metal containing species in solution. In fact, with the exception of the uranium and iron compounds, excess ligand is required to solubilize these otherwise insoluble salts. The spectra resemble that of a single species rather than a physical mixture of the metal salt and the dimer. The spectra of the iron, thorium, and uranyl containing solutions are very similar to those of the corresponding metal complexes. These samples have the highest aggregation numbers and the lowest ligand-to-metal ion concentration ratios. It is clearly evident from the solution stoichiometry, the calculated η values, and the molecular weight of the iron and uranyl salts that these solutions contain polynuclear species.

In spite of the 25–50% excess ligand present in the iron, thorium and uranium containing solutions, there are no obvious absorption bands which correspond to unionized P—OH or uncomplexed P=O groups of the free dimer (see Table 5). The spectra appear to be that of the salt into which the excess H_2DEH[MDP] has been incorporated with complete disruption of the dimer bonding. The spectrum of the iron containing solution is virtually indistinguishable from that of solid Fe_2(DEH[MDP])$_3$, see Fig. 5. The most obvious difference is that the P—O bands are slightly broadened and appear at somewhat higher energy in the solution spectrum. Dilution of the iron sample with 0.1 *m* H_2DEH[MDP] yields a spectrum which becomes progressively more like that of the dimer until the two are virtually indistinguishable at a fourfold dilution. The absorption maxima of the most intense P—O stretching bands at a 1 : 1 dilution occur at 1183 and 1030 cm^{-1}, with band envelopes that are very similar to those observed for the calcium, copper, and europium samples. These changes suggest that the structure of the extractant–metal complex may change with different loading conditions.

The spectra of the calcium, copper, and europium-containing solutions are intermediate between those of the metal compound and the H_2DEH[MDP] dimer. These solutions show the greatest number of absorption bands in the P—O stretching region. The bands are broad, poorly resolved, shifted in energy, and changed in relative intensity compared with the dimer or the metal compound. The observed bands correspond to P—OR and P=O groups as well as ionized and un-ionized P—OH groups (*vide infra*). The frequencies of these bands are somewhat different from the values observed in the spectra of the ligand or the metal salts. The greatest differences occur for europium where the frequency of the highest energy band in the P—O stretching region of the VPO sample is 33 cm^{-1} higher and 34 cm^{-1} lower than the corresponding bands in the spectra of the salt and dimer, respectively. The spectra appear to be those of the partially-ionized dimer in which the hydrogen bonding has been disrupted by the metal ion. The solution stoichiometry and the η values indicate that the copper

and europium samples contain binuclear complexes while the calcium sample contains a mononuclear species.

There are a number of features of the solution spectra which indicate that the P=O groups of the excess un-ionized H_2DEH[MDP] in the samples participate in the complexation process. In the thorium solution spectrum, a new band appears in the phosphoryl stretching region at 1181 cm^{-1}. This band is 57 cm^{-1} lower in energy than the highest phosphoryl stretching vibration in the H_2DEH[MDP] dimer. In the europium solution spectrum, the P=O band is shifted 34 cm^{-1} to lower energy. The corresponding band shift is 11 cm^{-1} for the calcium solution. The broadness and frequency shifts of the P—O bands in the uranium and iron containing samples suggest that additional vibrational components are present. Addition of H_2DEH[MDP] to the iron sample progressively shifts the frequency of the most intense band in the P—O stretching region to higher energy. In an equal volume mixture of the iron solution and 0.10 *m* H_2DEH[MDP], the highest energy P—O band is 55 cm^{-1} lower in energy than the phosphoryl stretching vibration of the dimer. Phosphoryl band shifts of this magnitude have been used to establish that the P=O group is the preferred coordination site in neutral bifunctional carbamoyl–phosphoryl extractants [17].

The copper, europium, and uranium-containing solutions show absorption bands at ~3400 cm^{-1} and ~1640 cm^{-1} typical of water coordinated to a metal ion. Coordination of water to a metal ion does not preclude chelation or bridging by the diphosphonate

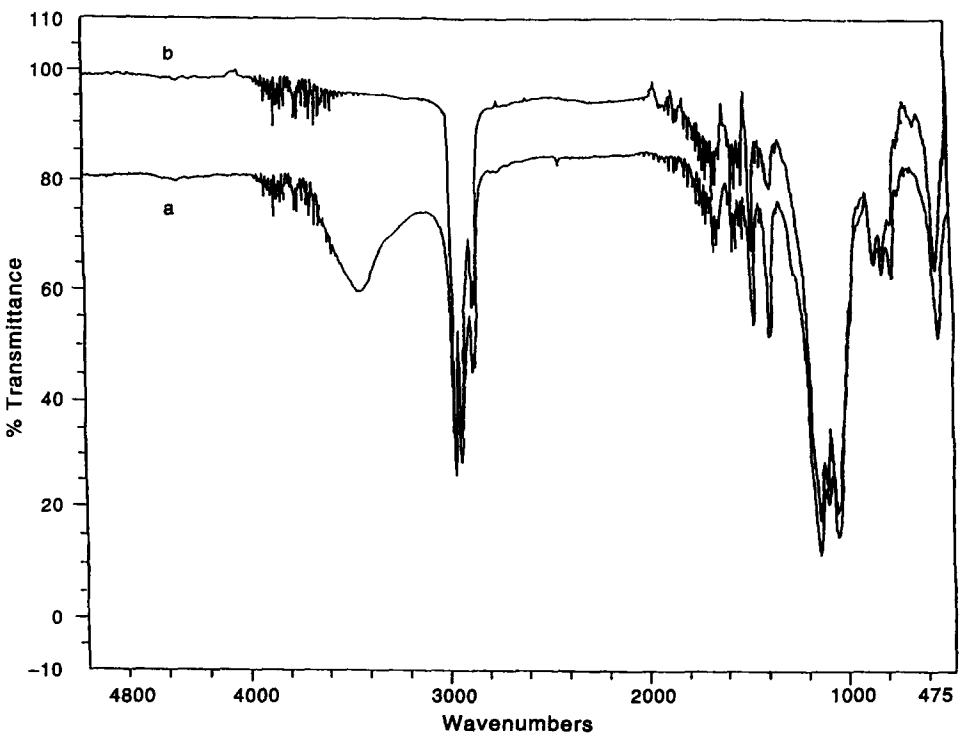

Fig. 5. The infrared spectra of a KBr pellet of solid $Fe_2(DEH[MDP])_3$ (a) and 0.05 *m* Fe^{III} extracted into 0.10 *m* H_2DEH[MDP] in toluene (b).

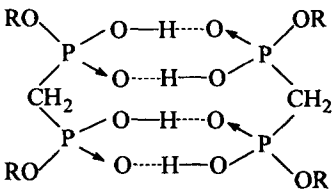
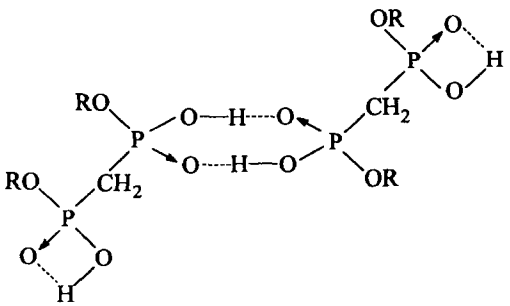
ligand. Physico-chemical studies and molecular mechanics calculations performed on Eu^{III} complexes of some related diphosphonate ligands show that the complexes exhibit a hemispherical geometry with metal coordinated water molecules occupying space left by the ligand [18].



DISCUSSION

Pre-equilibration with water or nitric acid does not affect H_2DEH[MDP] aggregation in toluene. This observation rejects the hypothesis that variations in extractant dependencies with aqueous acidity could be due to changes in ligand aggregation. Ionization of the phosphonic acid groups in the presence of metal ions, however, dramatically increases the aggregation of H_2DEH[MDP]. The linearity of the VPO data and the solution IR spectra suggest that a single solution species may be present, but the aggregation numbers for these samples must be interpreted with caution. The calculated η value represents the average state of aggregation of all solution species present and does not necessarily refer to a single species. For example, the solutions could be physical mixtures of the dimer and highly polymerized metal complexes. While this conclusion was rejected based upon observed ligand band shifts, highly aggregated species like those in the iron system may contain a range of similar but different sized aggregates. Small angle neutron scattering experiments are currently underway to address this possibility.



There are no absorption bands in the spectra of the VPO samples that would indicate the presence of nitrate ion. Additionally, the intensities of the P(O)(OH) bands in the 1600–2750 cm^{-1} region are quantitatively reduced as expected based on the stoichiometric amount of metal ion present in solution. The absence of nitrate ion and the diminished intensity of the P(O)(OH) bands indicates that under high metal loading conditions, extraction of metal ions by H_2DEH[MDP] proceeds with the displacement of hydrogen ions. These results are in contrast to those of our earlier extraction study [5] which was carried out under very low metal loading conditions. The extraction data indicated that at very low metal ion concentrations, iron(III) and tetra- and hexavalent actinides are extracted by H_2DEH[MDP] with little or no H^+ ion displacement. The data also indicated that under these conditions, the ligand is coordinated to the metal primarily through the neutral P=O groups. Based on these observations, it appears that metal extraction by H_2DEH[MDP] can occur by different pathways which depend upon reaction conditions. At very low metal ion concentrations, metal extraction apparently proceeds by a solvation process involving the phosphoryl oxygen atoms of the ligand. At high metal ion concentrations, the extraction process changes from solvation to ion exchange with acidic protons of the ligand being displaced by the metal ion.

Thomas has thoroughly discussed the use of frequency ranges, band intensities, and band contours as diagnostic tools for assigning infrared bands in the spectra of organophosphorus compounds [12,13]. Monoesters of alkylphosphonic acids have a band of medium-to-strong intensity in the 1170–1225 cm^{-1} region with a characteristic band shape that arises from the P=O stretching vibration. The band is broadened and reduced in frequency as a result of strong hydrogen bonding to the P—OH group. The P—OH and P—OR groups are both characterized by a strong absorption band at about 1000 cm^{-1}. There is no evidence in molecules with two or more ester groups that the groups interact to give symmetric and asymmetric vibrational bands. In the case of higher normal esters, a second absorption band is usually found between 939–982 cm^{-1} that is assigned to a C—C stretching vibration. Thomas also reports that the P—CH_2—P group gives rise to characteristic symmetric and asymmetric stretching vibrations in the 720–770 cm^{-1} and 780–845 cm^{-1} regions, respectively. All these vibrations are observed in the spectra of the compounds reported in Table 2.

Two possible structures for the H_2DEH[MDP] dimer are shown in Fig. 6. Molecular modeling energy minimization calculations reveal that, as an isolated species, the open hydrogen bonded structure B is significantly more stable than the closed cyclic structure A [19]. The infrared data indicate that strong hydrogen-bonding is responsible for the stability of the dimer. The absorption bands associated with the phosphonic acid functionality of the ligand are broad and

A

B

Fig. 6. Possible structures for the H_2DEH[MDP] dimer.

appear at relatively low frequencies. This behavior is characteristic of O—H groups that are strongly involved in hydrogen bonding to phosphoryl oxygen atoms. The P=O stretching vibrations are also highly perturbed and occur at lower frequencies than normal for a P=O bond [12,13]. The appearance of two phosphoryl stretching bands lends support for structure B since two distinctly different types of hydrogen bonds are present, i.e. intramolecular as well as intermolecular hydrogen bonds.

Under favorable circumstances, ligand band shifts can be used to obtain qualitative information about ligand coordination modes in metal complexes. This approach has been used extensively for carboxylic acids [20,21] which are formally similar to the monoesters of phosphonic acids and the same bonding arguments should apply. In both classes of acids, the X—O bonds of the uncomplexed anion are equivalent. Upon coordination to a metal ion, $\nu_{asym}(XOO^-)$ and $\nu_{sym}(XOO^-)$ of the XO_2^- group should shift to higher or lower frequencies depending on the structure of the metal complex formed. The X—O bonds are no longer equivalent if monodentate coordination occurs. In monodentate carboxylate complexes, $\nu_{asym}(COO^-)$ and $\nu_{sym}(COO^-)$ shift to higher and lower frequencies, respectively. Monodentate coordination of the PO_2^- groups in the diphosphonate complexes reported in Table 4 thus can be ruled out on the basis of the direction of the band shifts.

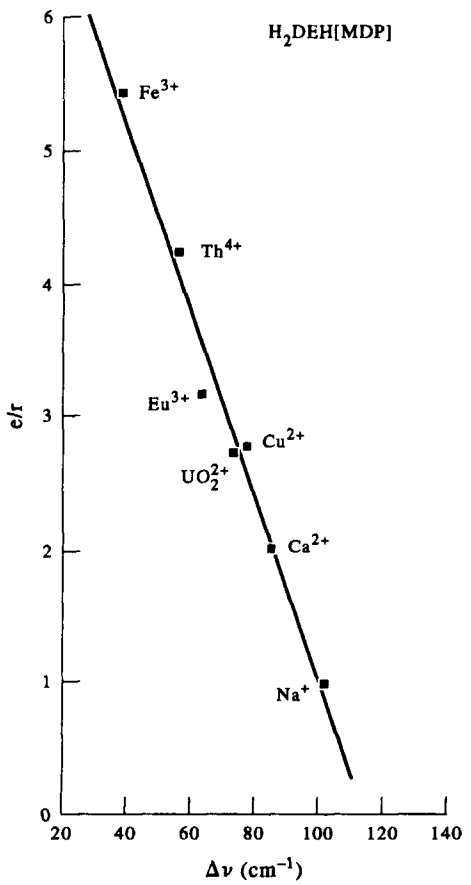


Fig. 7. A plot of the ionic potential of the metal ion, e/r, versus the difference between $\nu_{asym}(POO^-)$ and $\nu_{sym}(POO^-)$, $\Delta\nu$, in H_2DEH[MDP] compounds, where e = ion charge and r = Shannon ionic radius.

Figure 7 shows a plot of the ionic potential (charge/radius) of the metal ion versus the observed frequency difference $\Delta\nu$, $[\nu_{asym}(POO^-) - \nu_{sym}(POO^-)]$, for the H_2DEH[MDP] compounds. The difference between the POO^- stretching frequencies in these diphosphonate compounds becomes smaller as the ionic potential of the metal ion increases. A similar correlation has been observed for ionic complexes of organophosphoric acids of the type $(RO)_2PO(OH)$ [22].

The separation between $\nu_{asym}(COO^-)$ and $\nu_{sym}(COO^-)$ may be used to distinguish between bridging and chelating coordination modes for carboxylate ligands. The difference between these frequencies is considerably larger for a bridged complex than it is for a chelate complex [20, 21]. The $\Delta\nu$ values observed for the H_2DEH[MDP] compounds are much smaller than those reported for carboxylate complexes. The small separations and absence of model complexes of known structure make it difficult to distinguish unambiguously between bridging and chelating coordination modes. Based on ligand geometry and the extensive polymerization of the complexes, it is likely that both coordination modes are utilized so that the metal ions can achieve their preferred coordination numbers.

Acknowledgements—The authors wish to express their gratitude to the Analytical Chemistry Division of ANL for analyses performed, to Paul G. Rickert for preparing the P,P′-di(2-ethylhexyl) methanediphosphonic acid, to Herb Diamond for help with the VPO measurements, and to Ken L. Nash for helpful discussions. One of us (AWH) wishes to thank Loyola University for a research leave of absence and ANL for support under the Faculty Research Leave at Argonne program.

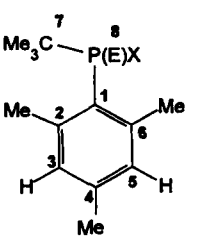
Tert-butyl-2,4,6-trimethylphenylphosphine—a chiral secondary phosphine with bulky substituents: synthesis and NMR spectroscopic studies

William McFarlane* and Christian T. Regius

Department of Chemistry, University of Newcastle, Newcastle upon Tyne NE1 7RU, U.K.

(Received 10 September 1996; accepted 30 September 1996)

Abstract—The preparation and characterization of the secondary phosphine Bu^{t}MesPH [Mes = 2,4,6-$(CH_3)_3C_6H_2$—], its precursor Bu^{t}MesPCl, and its chalcogenides Bu^{t}MesP(E)H (E = O, S, Se) are described. Their ^{1}H, ^{13}C and ^{31}P NMR spectra are reported and show that rotation about the P—Mes bond is hindered with $\Delta G\ddagger$ ranging from 56 to 88 kJ mol^{-1}. Two-dimensional proton ROESY spectra indicate a single preferred conformation in solution which is determined by the need to minimize the Bu^t-Mes interaction in all cases.
© 1997 Elsevier Science Ltd. All rights reserved.



Keywords: secondary phosphine; bulky substituent; chirality; NMR; ROESY; hindered rotation.

Tertiary phosphines with bulky substituents are important for their ability to stabilize unusual metal oxidation states and coordination geometries in their complexes and in this connection those with *tert*-butyl (Bu^t) or 2,4,6-trimethylphenyl (Mes) substituents have been extensively studied [1]. Also of continuing interest in the context of asymmetric synthesis are phosphines, which are chiral at phosphorus, well known examples being *tert*-butylmethylphenylphosphine [2] and (2-aminophenyl)methylphenylphosphine [3].

Less work has been carried out on secondary phosphines in either of these categories, although Mes_2PH [4] and Bu^t_2PH [5] are well characterized, as are the chiral secondary phosphines *tert*-butylphenylphosphine [5] and (2-aminophenyl)phenylphosphine [3]. Normally, in secondary phosphines ready P—H exchange leads to rapid racemization and to our knowledge there is only one report of the successful resolution of a free chiral secondary phosphine, namely, (-)-methyl-mesitylphosphine [6], and even in this case only a diastereomeric form has been isolated. The title secondary phosphine Bu^{t}MesPH (**2**) is therefore of considerable interest and we report here its synthesis and those of its precursor Bu^{t}MesPCl (**1**) and its chalcogenides Bu^{t}MesP(E)H (E = O, S, Se, **3**–**5**) together with one- and two-dimensional ^{1}H, ^{13}C and ^{31}P and dynamic NMR studies, which reveal hindered rotation about the P—Mes bond and the nature of the preferred conformation in solution.

RESULTS

The reaction between 2,4,6-trimethylphenylmagnesiumbromide and Bu^tPCl_2 in 1,2-dimethoxyethane gave Bu^{t}MesPCl (**1**) as an off-white waxy solid; this was then reduced with $LiAlH_4$ in diethylether to **2**, which was isolated as a colourless somewhat air-sensitive liquid. The reaction of **2** with aqueous H_2O_2 gave Bu^{t}MesP(O)H (**3**) and with elemental sulfur and selenium gave Bu^{t}MesP(S)H (**4**) and Bu^{t}MesP(Se)H (**5**), respectively. The identities of **3** and **4** were confirmed by elemental analysis and of

all five by ^{1}H, ^{13}C and ^{31}P NMR spectroscopy (see Tables 1 and 2).

NMR spectral assignments were confirmed by ^{1}H{^{31}P} decoupling experiments and HMQC [7] and HMBC [8] two-dimensional ^{1}H/^{13}C correlation spectra. For **4** and **5** hindered rotation of the Mes group led to inequivalence of the proton and carbon 2- and 6-methyl and 3- and 5-phenyl resonances at all accessible temperatures (up to 413 K), although there was some line broadening of the 2- and 6-proton methyl res-

Table 3. Thermodynamic parameters for rotation about the P—Mes bond of **1–4**

	Bu^{t}MesPCl	Bu^{t}MesPH	Bu^{t}MesPHO	Bu^{t}MesPHS
$\Delta H\ddagger$ (kJ mol^{-1})	67.8 ± 3.4	56.6 ± 3.2	65.4 ± 1.8	—
$\Delta S\ddagger$ (J mol^{-1} K^{-1})	30.4 ± 12.6	17.2 ± 12.7	27.6 ± 6.6	—
$\Delta G\ddagger$ (295 K, kJ mol^{-1})	57.8	55.5	57.3	88.1[a]

[a]Estimate based on line-broadening measurements at 393 K and corrected to 295 K on the assumption that $\Delta S\ddagger \sim 25$ J mol^{-1} K^{-1}.

onances of **4** at 393 K in naphthalene which made it possible to derive $\Delta G\ddagger$ for the barrier to rotation. In the cases of **1, 2** and **3** lower barriers to rotation led to separate resonances only at temperatures below ambient and their ^{1}H and ^{13}C parameters are therefore quoted at 233, 210 and 248 K, respectively. The program gNMR [9] was used to simulate the spectra given by the 2,6-methyl and 3,5-ring protons in the temperature ranges of 233–296 for **1**, 223–295 for **2** and 248–330 K for **3** and the resulting thermodynamic parameters from Eyring plots for the barrier to rotation of the Mes group are in Table 3.

Figure 1 shows the fit of calculated and experimental spectra for the 2,6-methyl protons of **2**.

In order to assess the conformational distribution in **1–5** a series of proton rotating frame nuclear Overhauser effect (ROESY [10]) spectra was obtained. These used a spin-locking (mixing) time of 250 ms and in them negative off-diagonal peaks indicate protons that are spatially close. Figure 2 shows a typical spectrum obtained from **2** at 210 K (rotation slow on the NMR timescale). The spectrum also shows some positive off-diagonal peaks due to residual chemical exchange at this temperature associated with the (slow) rotation of the 2,4,6-trimethylphenyl group.

DISCUSSION

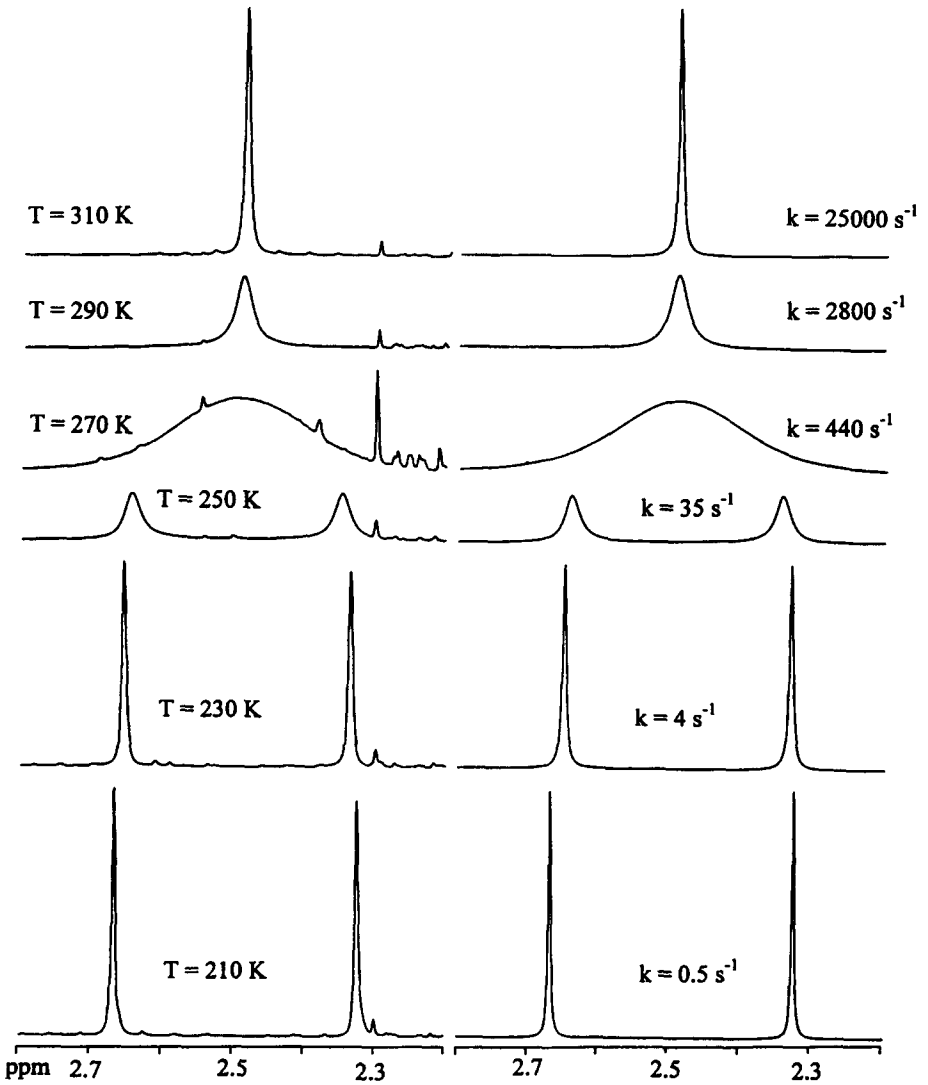
The cone angle [11] of **2** can be estimated at 160°, which is significantly larger than those for Ph_3P (145°) and Bu^t_2PH (150°), but smaller than that for Mes^t_2PH (170°). It should be noted, however, that in metal complexes a secondary phosphine may be able to rotate about the P—metal bond into a position which minimizes steric interactions between its bulkier groups and the other substituents of the metal and hence its *effective* cone angle may be considerably smaller than that calculated in the usual way.[11] The pattern of cone angles for Bu^t_2PH, Bu^{t}MesPH and Mes_2PH is paralleled by their $^1J(^{31}P—H)$ coupling constants which are 197, 215.8 and 234 Hz, respectively.

$^1J(^{31}P—H)$ for **2** is thus almost identical to the mean (215.5 Hz) of the other two and this presumably reflects corresponding trends in the phosphorus hybridization and interbond angles at phosphorus. As expected, chalcogenization leads to substantial increases in $^1J(^{31}P—H)$ arising from greater *s*-character for the phosphorus hybrid orbital forming the P—H bond.

In contrast to the foregoing, $\delta(^{31}P)$ for **2** [−49.3 ppm] differs significantly from the mean [−36 ppm] of those for Bu^t_2PH [20 ppm] and Mes_2PH [−92 ppm], whereas group contribution theory [12] would predict close correspondence. On this basis using values of the group contributions σ^P for Bu^t and Mes derived from Bu^t_3P and Mes_3P the predicted ^{31}P chemical shifts of Bu^t_2PH, Bu^{t}MesPH and Mes_2PH are +25, −24 and −72 ppm, respectively, and so it appears that the Mes rather than the *tert*-butyl group is the principal origin of the discrepancy. This may be because restricted rotation about the P—C_{ipso} bond leads to a strong dominance of particular conformers in **2** and indeed in Mes_3P itself. The ^{31}P chemical shifts of compounds **1** and **3–5** are in the expected ranges.

The observation of pairs of resonance signals from the off-axis nuclei of the Mes groups of **1–5** indicates not only that rotation is slow about the P—C_{ipso} carbon bond, but that pyramidal inversion at phosphorus is also slow on the NMR time scale. In secondary phosphines this latter process is catalysed both by bases (*via* R_2P^-) and by acids (*via* $R_2P^+H_2$) and information on energy barriers is sparse. However, in $PhPr^iPH$ $\Delta G\ddagger$ for the inversion exceeds 97.5 kJ mol^{-1} corresponding to a rate of *ca* 6.6 s^{-1} at 413 K, so it seems likely that the $\Delta G\ddagger$ of *ca* 56 kJ mol^{-1} in **2** is associated exclusively with the rotation rather than inversion. In the cases of **3–5** neither base- nor acid-catalysed mechanisms can facilitate inversion and so the observed barriers must relate solely to rotation.

The observed barriers to rotation of the Mes group in these molecules are surprisingly high in view of the small size of the hydrogen substituent on phosphorus and the fact that we find that at temperatures down to 188 K the corresponding process is essentially unhindered in Mes_2PH and $Mes_2P(S)H$. From cone angle considerations Mes is apparently bulkier than Bu^t so the contrary might have been expected. Inspection of molecular models shows that whilst a *rotating* Mes group is indeed considerably bulkier than a *tert*-butyl group, a pair of Mes groups can mesh and rotate concertedly thus reducing their effective combined bulk; however, no such cog-wheel gearing is possible for a Bu^t/Mes pair. It is this that accounts for the



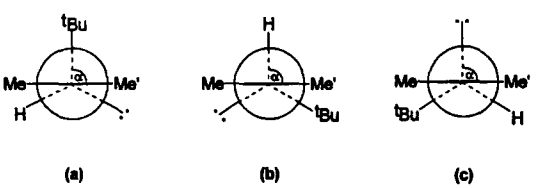


Fig. 1. Experimental (left) and calculated (right) 500 MHz NMR spectra of the aromatic-CH_3 protons of Bu^{t}MesPH in toluene-d_8 for different temperatures and exchange rates.

difference between **2** and Mes_2PH, and also between their corresponding derivatives. Taken together our results provide firm evidence for concerted (cog-wheel) rotation of the Mes groups in Mes_2PH and its derivatives. In the cases of Mes_3P and Mes_3PS such concerted rotation is parity forbidden and in accord with this the value of $\Delta G\ddagger$ for rotation of a Mes group is substantial in these molecules [13].

Projections down the P—C_{ipso} bond of three conformations of one enantiomer of **2**, which minimize interaction between the ortho-methyls of the Mes group and (a) the *tert*-butyl group, (b) the P—hydrogen and (c) the phosphorus lone pair are shown below, where the angle α is expected to be *approximately* 90°.

In view of the large bulk of *tert*-butyl, (a) is likely to be the dominant conformer and this was confirmed by the proton two-dimensional rotating frame nuclear Overhauser (ROESY) experiment performed at 210 K and illustrated in Fig. 2.

At this temperature the rate of rotation (exchange) is *ca* 0.5 s^{-1} and thus the 2- and 6-methyl protons display mutual positive chemical exchange peaks as do the 3- and 5-aromatic protons. Nonetheless, the rate of exchange is sufficiently slow for significant differential N.O.E.s to be observed. The crucial ones are:

(i) *Strong* N.O.E. from P—H to Me at δ 2.32 and

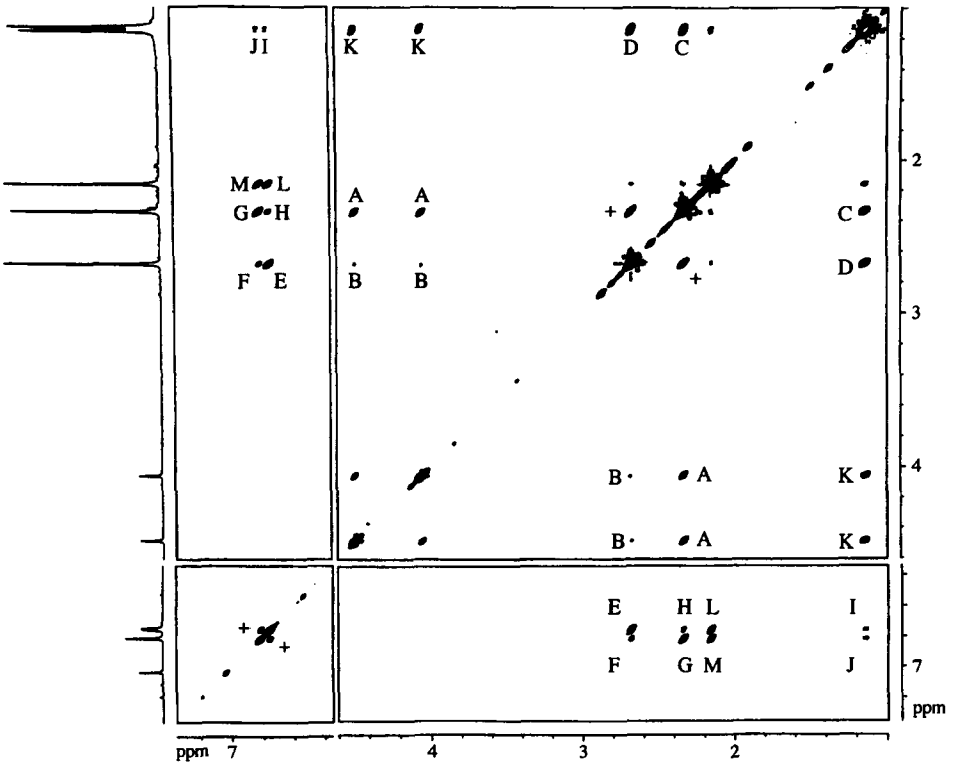

Fig. 2. 500 MHz proton ROESY spectrum of Bu^{t}MesPH in toluene-d_8 at 210 K with spin-locking (mixing) time of 250 ms. Off-diagonal peaks marked + are positive and arise from chemical exchange. The negative off-diagonal peaks referred to in the text are: A: P-H/Me6; B: P-H/Me2; C: Bu^t/Me6; D: Bu^t/Me2; E: Me2/H3; F: Me2/H5; G: Me6/H5; H: Me6/H3; I: Bu^t/H3; J: Bu^t/H5; K: Bu^t/P—H; L: Me4/H3; M: Me4/H5.

a very weak N.O.E. to Me at δ 2.67. This rules out conformer (b).

(ii) Approximately *equally* strong N.O.E.s from Bu^t to Me at δ 2.67 *and* δ 2.32. This is consistent with (a), but not with (b) or (c).

(iii) Strong N.O.E. from Me at δ 2.67 to aromatic H at δ 6.73 and weak to aromatic H at δ 6.80. Strong N.O.E. from Me at δ 2.32 to aromatic H at δ 6.80 and weak to aromatic H at δ 6.73. This gives the relative assignments of the Mes protons.

(iv) Approximately *equally* weak N.O.E.s from both aromatic protons to Bu^t. This is consistent with conformer (a). There are also approximately equally strong N.O.E.s between the aromatic protons and Me4, and between Bu^t and P—H.

We therefore conclude that the dominant conformation of **2** is (a) and that in the numbering scheme position 2 corresponds to Me′ and position 6 to Me. Corresponding ROESY spectra were obtained for **3–5** and confirmed that for each of these the dominant conformation is also (a). Thus for all of these, the positions 2 and 3 are on the side of the Mes ring adjacent to the phosphorus lone pair. In the case of **1** the absence of a proton attached to P prevents any such determination, but it is clear that the dominant conformation is (a) for this species also, in view of the equality of the n.O.es from the Bu^t to each ring methyl group.

There is a clear stereochemical dependence of the P—H and P—C couplings in the Mes groups in these species. Thus, for **2** pathways involving a *ca* 30° dihedral angle between the P-lone pair direction and the Mes plane (i.e. positions 2 and 3) $^4J(^{31}P—H)$, $^2J(^{31}P—^{13}C)$ and $^3J(^{31}P—^{13}C_{Mes})$ are much larger than when the dihedral angle is *ca* 150° (positions 5 and 6). It is likely that this also applies to **1**, although in this case the assignment is not certain. For the P^V derivatives **3–5** only $^4J(^{31}P—H)$ displays such a *marked* stereochemical dependence and is larger for the 150° dihedral angle. The one-bond P—C couplings show the expected dependence on phosphorus oxidation state and hybridization, it being likely that they are negative in **1** and **2** and positive in **3–5**.

The oxide **3** was also modelled using the program QUANTA [14] and in the range 0–180° a plot of energy against the dihedral angle α showed only one minimum, with a barrier height of 62 kJ mol^{-1}. Thus, the modelled minimum structure corresponds to conformer (a) with the angle α close to 90° and no significant predicted contributions from (b) and (c). The calculated barrier height agrees remarkably well with that found experimentally.

It is clear that the large difference in bulk between

tert-butyl and H imposes special conformational constraints upon the Mes group in **2** and its derivatives. This is likely to be an important feature of the complexes of this chiral secondary phosphine ligand in which barrier to rotation of the Mes group could exceed 90 kJ mol^{-1} and this may well facilitate their optical resolution and affect their catalytic behaviour.

EXPERIMENTAL

^1H and ^{13}C NMR spectra were obtained on a Bruker AMX 500 spectrometer at frequencies of 500.13 and 125.75 MHz, respectively, on samples contained in 5 mm o.d. spinning tubes. ^{31}P NMR spectra were recorded on a JEOL FX90Q spectrometer at 36.2 MHz. Chemical shifts are to high frequency of internal t.m.s. for ^1H and ^{13}C, and external 85% H_3PO_4 for ^{31}P. Proton phase-sensitive ROESY spectra were acquired using the sequence 90°–t_1–spinlock–acquire(t_2) with phase cycling by the time-proportional incrementation method. Typically 32 transients were acquired into 1024 data points for each of the 512 values of t_1 and then Fourier transformed into a 1024 × 1024 matrix after weighting in each dimension with a sine-bell function. The spin-locking field had $\gamma B_1/2\pi$ = 5000 Hz.

All materials were handled under dry dinitrogen and diethylether and 1,2-dimethoxyethane were dried over sodium/benzophenone.

Chloro-tert-*butyl*-2,4,6-*trimethylphenylphosphine* (**1**)

MesMgBr (100 cm^3, 0.1 molar in diethylether, ALDRICH) was placed in a three-necked flask. The ether was removed under reduced pressure and replaced by 50 cm^3 of dimethoxyethane. To the resulting stirred yellow suspension Bu^tPCl_2 (15.8 g, 100 mmol) in dimethoxyethane (50 cm^3) was added over 0.5 h. Stirring for 1 h yielded a white suspension. The solvent was removed under reduced pressure and the resulting off-white solid was extracted with *ca* 100 cm^3 of diethylether. The ether was distilled off and the product was distilled at 145°C/0.5 torr (m.p. 34°C, yield 83%), $\delta(^{31}P)$ = 111.0 ppm.

Tert-*butyl*-2,4,6-*trimethylphenylphosphine* (**2**)

A solution of $Bu^tMesPCl$ (20 g, 83 mmol) in diethylether (50 cm^3) was added dropwise to a suspension of $LiAlH_4$ (1.6 g, 42 mmol) in diethylether (50 cm^3) at 0°C. The mixture was stirred for 2 h at 22°C and then filtered. The filtrate was washed with deaerated water (50 cm^3) and the organic layer was dried over magnesium sulfate and the diethylether was removed under reduced pressure. Distillation at 90°C/0.5 torr gave the product (yield 87%) as a colourless air-sensitive oil, $\delta(^{31}P)$ = −49.3 ppm.

Tert-*butyl*-2,4,6-*trimethylphenylphosphineoxide* (**3**)

A solution of Bu^tMesPH (1 g, 0.84 mmol) in dichloromethane (10 cm^3) was stirred vigorously with 5 cm^3 of 5% aqueous H_2O_2 for 1 h. The water layer was removed and the dichloromethane was removed under reduced pressure. The remaining white solid was dissolved in diethylether and recrystallized at −18°C to give **3** as white powder in 87% yield, m.p. 99°C, $\delta(^{31}P)$ = 33.7 ppm. Found: C, 69.3; H, 9.6. $C_{13}H_{21}OP$ requires: C, 69.6; H, 9.4%.

Tert-*butyl*-2,4,6-*trimethylphenylphosphinesulfide* (**4**)

Bu^tMesPH (1 g, 0.84 mmol) in dichloromethane (cm^3) was reacted with elemental sulfur (27 mg, 0.84 mmol; 10 h, 22°C) to give **4** as a white solid after the solvent was removed under reduced pressure. Recrystallization from dichloromethane/methanol yielded **4** as colourless crystals (yield 84%), m.p. 90°C, $\delta(^{31}P)$ = 31.3 ppm. Found: C, 65.0; H, 9.1. $C_{13}H_{21}PS$ requires: C, 64.9; H, 8.8%

Tert-*butyl*-2,4,6-*trimethylphenylphosphineselenide* (**5**)

The corresponding reaction of Bu^tMesPH with elemental selenium gave **5** as off-white crystals, m.p. 93°C (yield 83%), which turned into a yellowish solid in air after 5 h. $\delta(^{31}P)$ = 12.6 ppm, $^1J11(^{77}Se—^{31}P)$ = 703.2 Hz.

(Received 4 September 1996; accepted 30 September 1996)

Abstract—Reaction of $[VO(acac)_2]$ with *S*-methyl 3-(2-hydroxyphenyl) methylenedithiocarbazate (H_2L^1) and its nitro- (H_2L^2) and bromo derivatives (H_2L^3) as tridentate heterodonor $(ONS)^{2-}$ ligands offers a basic VO(ONS) core. In the presence of bidentate (N,N′) donor ancillary ligands, various mono- and dinuclear oxovanadium(IV) complexes [VOL(2,2′-bipy)] (**1–3**), [VOL(Phen)] (**4, 5**) and [LOV(μ-4,4′-bipy)VOL] (**6–8**) were obtained. The compounds have been characterized by EPR, electronic and FAB mass spectroscopic studies. The X-ray crystal structure of a representative compound [VOL^2(2,2′-bipy)] (**2**) is reported and shows the presence of the tridentate ONS ligand occupying the meridional sites leading to distorted octahedral geometry. The nitrogen donor, occupying an apical position has a *trans*-labilizing influence, resulting in elongation of the V=O terminal bond. Magnetic susceptibility and EPR spectral studies indicate non-interacting nature ($|J| \approx 0$) of the vanadium(IV) unpaired electrons in the dinuclear complexes (**6–8**). © 1997 Elsevier Science Ltd. Keywords: oxovanadium(IV) complex; sulfur coordination; crystal structure; EPR; FAB mass spectroscopy.

Recognition of vanadium as an essential trace element [1–4] has generated increasing interest in the structure and function of its complexes found in the living organisms [5,6]. The minimal structures of the vanadium active sites as delineated by EXAFS and other spectroscopic investigations have shown a distinct preference of this metal center for N- and/or O-coordinated environments provided by the histidine imidazole, tyrosine phenolate and carboxylate oxygen of the protein residues [7–10]. In order to gain an insight into how vanadium might function in relatively intricate biomolecules, it is worthwhile to acquire information on the basic coordination chemistry of this element with simple biomimetic ligands. Information level in this area is becoming enriched from the outcome of some recent studies on small molecular complexes with interesting structure and spectroscopic properties. In most of these investigations nitrogen and/or oxygen donor ligands are used to bind the metal center in the oxidation states from +3 to +5 at limited nuclearity range [11–24].

Studies on the coordination chemistry of vanadium in ligand environments containing sulfur unlike those with O/N donor systems, have only started gaining momentum in view of the use of this metal center as catalysts in the oxidation of organic sulfide into sulfoxides [25] and the expected catalytic role of vanadium (IV) in dehydrosulfurization of crude oil,[26] apart from the ambitious goal of modeling the Fe/V cofactor of alternative vanadium nitrogenase [27]. A number of vanadium complexes in complete [28–30] and partial [31–34] sulfur environments, covering a wide nuclearity and oxidation state range have been reported in recent years to meet the above objectives.

For quite some time we have been working on an ambitious project of exploring the reactivity, redox and spectroscopic properties of structurally interesting metal complexes in sulfur-containing ligand environments [35–37]. Herein we report oxovanadium(IV) complexes of some tridentate (ONS) ligands, *viz.* *S*-methyl 3-(5-R-2-hydroxyphenyl)-

NO_2	H_2L^2
Br	H_2L^3

methylenedithiocarbazates [R = H (H_2L^1), NO_2 (H_2L^2) and Br (H_2L^3)], which are of intrinsic interest because of the formation of a basic VOL core having one or more vacant coordination site(s) to potentially bind an ancillary ligand. Alternatively, the available site could be involved in bridging to a second vanadium center, forming a dinuclear complex. In this paper the synthesis of both mono- and dinuclear oxovanadium(IV) complexes of the ligands H_2L^1–H_2L^3 is described. Magnetism, EPR, positive-ion FAB mass and electronic spectroscopic properties of the complexes have been examined and the crystal and molecular structure of a representative complex (**2**) is reported.

EXPERIMENTAL

Materials

Carbon disulfide, hydrazine hydrate (both from E. Merck), methyl iodide (Loba), acetyl acetone (Fluka) and salicylaldehyde (BDH) were freshly distilled before use. Vanadium pentoxide (Loba), 2,2′-bipyridyl, 4,4′-bipyridyl, 1,10-phenanthroline, 5-bromosalicylaldehyde and 5-nitrosalicylaldehyde (all from Aldrich) were used as received. [VO(acac)$_2$] [38] and *S*-methyl dithiocarbazate [39] were prepared following published procedures. Solvents were dried by conventional methods [40] and distilled under nitrogen prior to use. All the reactions were carried out under dry nitrogen.

Preparation of ligands

S-Methyl 3-(2-hydroxyphenyl)methylenedithiocarbazate (H_2L^1). A solution of salicylaldehyde (2.45 g, 20 mmol) in ethyl alcohol (10 cm^3) was added with stirring to a hot solution of *S*-methyl dithiocarbazate (2.44 g, 20 mmol) in the same solvent (60 cm^3). The mixture was heated on a steam bath for 10 min and allowed to cool in the air. Crystalline product (off-white in color) was obtained and recrystallized from ethyl alcohol. Yield: 3.85 g (85%); m.p. 206°C.

The remaining ligands H_2L^2 (m.p. 192°C) and H_2L^3 (m.p. 215°C) were prepared similarly using appropriate derivatives of salicylaldehyde and their purity confirmed by elemental analysis, UV–vis and ^{1}H NMR spectra.

Preparation of complexes

[VOL^1(2,2′-bipy)] (**1**). To a stirred dichloromethane (20 cm^3) solution of [VO(acac)$_2$] (0.40 g, 1.5 mmol) was added a solid sample of the ligand H_2L^1 (0.34 g, 1.5 mmol) and the mixture was heated to reflux for 10 min. The solution turned brown at this stage. A stoichiometric amount of 2,2′-bipyridyl (0.24 g, 1.5 mmol) was then added and the solution was refluxed further for *ca* 30 min. The clear solution was combined with 10 cm^3 of petroleum ether (40–60°C fraction), cooled to room temperature and allowed to stand overnight in the air. Crystals which formed were filtered, washed with Et_2O and dried *in vacuo*. Recrystallization was carried out from CH_2Cl_2/*n*-hexane. Yield: 0.35 g (80 %). Found: C, 50.7; H, 3.5; N, 12.3. Calc. for $C_{19}H_{16}N_4O_2S_2V$: C, 51.0; H, 3.5; N, 12.5%. IR (KBr disc): ν(C=N), 1590s; ν(C—O/phenolate), 1585s; ν(V=O), 960s; ν(C—S), 650m cm^{-1}. μ_{eff}(solid, 25°C), 1.75 μ_B.

[VOL^2(2,2′-bipy)] (**2**). This compound was prepared following the same procedure as described for **1**, using the appropriate tridentate ligand H_2L^2. Yield: 80%. Found: C, 45.8; H, 3.0; N, 14.2. Calc. for $C_{19}H_{15}N_5O_4S_2V$: C, 46.3; H, 3.0; N, 14.2%. IR (KBr disc): ν(C=N), 1590s; ν(C—O/phenolate) 1580s; ν(V=O), 960s; ν(C—S), 660m cm^{-1}. μ_{eff}(solid, 25°C), 1.72 μ_B.

[VOL^3(2,2′-bipy)] (**3**). This compound can be synthesized similarly using H_2L^3 as the tridentate ligand with 75% yield. Found: C, 43.0; H, 2.7; N, 10.5. Calc. for $C_{19}H_{15}N_4O_2S_2BrV$: C, 43.3; H, 2.8; N, 10.6%. IR (KBr disc): ν(C=N), 1590s; ν(C—O/phenolate) 1570s; ν(V=O), 960s; ν(C—S), 650m cm^{-1}. μ_{eff} (solid, 25°C), 1.71 μ_B.

Remaining mononuclear oxovanadium(IV) complexes (**4** and **5**) were prepared following an identical procedure as adopted for **1–3** but using 1,10-phenanthroline as the bidentate ligand.

[VOL^1(phen)] (**4**). Yield: 80%. Found: C, 52.8; H, 3.2; N, 11.8. Calc. for $C_{21}H_{16}N_4O_2S_2V$: C, 53.5; H, 3.4; N, 11.9%. IR (KBr disc): ν(C=N), 1585s; ν(C—O/phenolate) 1570s; ν(V=O), 950s; ν(C—S), 640m cm^{-1}. μ_{eff}(solid, 25°C), 1.74 μ_B.

[VOL^2(phen)] (**5**). Yield: 78%. Found: C, 48.2; H, 2.8; N, 13.3. Calc. for $C_{21}H_{15}N_5O_4S_2V$: C, 48.8; H, 2.9;

N, 13.5%. IR (KBr disc): ν(C=N), 1595s; ν(C—O/phenolate), 1545s; ν(V=O), 950s; ν(C—S), 660m cm^{-1}. μ_{eff} (solid, 25°C), 1.72 μ_B.

[$L^1OV(\mu$-4,4′-bipy)VOL^1] (**6**). To a stirred solution of [$VO(acac)_2$] (0.40 g, 1.5 mmol) in acetonitrile (20 cm^3) was added a stoichiometric amount of the ligand H_2L^1 (0.34 g, 1.5 mmol) in solid form. The resulting mixture was heated to reflux for 10 min when a clear brown solution was obtained. A solid sample of 4,4′-bipyridyl (0.13 g, 0.8 mmol) was then added and the mixture was refluxed again for *ca* 30 min to ensure completion of the reaction. A clear deep green solution obtained at this stage was cooled to room temperature to obtain the microcrystalline product, which was collected by filtration, washed with Et_2O and dried *in vacuo*. The compound has very poor solubilities in most of the common organic solvents except dmf. Several attempts to recrystallize from dmf were unsuccessful. Yield: 0.42 g (58 %). Found: C, 45.2; H, 3.0; N, 11.5. Calc. for $C_{28}H_{24}N_6O_4S_4V_2$: C, 45.5; H, 3.2; N, 11.4%. IR (KBr disc): ν(C=N), 1600s; ν(C—O/phenolate), 1540s; ν(V=O), 990s; ν(C—S), 645m cm^{-1}. μ_{eff} per mol (solid, 25°C), 2.40 μ_B.

The remaining dinuclear compounds (**7** and **8**) were obtained following the same procedure as described for **6** using 4,4′-bipyridyl and the appropriate tridentate ligands.

[$L^2OV(\mu$-4,4′-bipy)VOL^2] (**7**). Yield: 42%. Found: C, 40.2; H, 2.5; N, 13.3. Calc. for $C_{28}H_{22}N_8O_8S_4V_2$: C, 40.5; H, 2.6; N, 13.5%. IR (KBr disc): ν(C=N), 1600s; ν(C—O/phenolate), 1548s; ν(V=O), 980s; ν(C—S), 665m cm^{-1}. μ_{eff} per mol (solid, 25°C), 2.32 μ_B.

[$L^3OV(\mu$-4,4′-bipy)VOL^3] (**8**). Yield: 40%. Found: C, 38.1; H, 2.3; N, 13.5. Calc. for $C_{28}H_{22}N_6O_4S_4Br_2V_2$: C, 37.5; H, 2.4; N, 13.5%. IR (KBr disc): ν(C=N), 1600s; ν(C—O/phenolate), 1580s; ν(V=O), 980s; ν(C—S), 650m cm^{-1}. μ_{eff} per mol (solid, 25°C), 2.38 μ_B.

Physical methods

Details of IR, UV–vis and magnetic measurements have been described elsewhere [36]. X-band EPR spectra in solution at room temperature as well as in the frozen state (77 K) were recorded on a Bruker model ER 220-SRC spectrometer and positive-ion fast atom bombardment (FAB) mass spectra using Kratos MS80RF or VG Pro/Spec Electrospray instruments. Elemental analyses for C, H and N were performed in this laboratory (IACS) with a Perkin–Elmer 2400 analyser.

X-ray crystallography

Intensity data for a brown crystal of **2** (0.10 × 0.24 × 0.37 mm), obtained from CH_3CN solution by slow evaporation, was measured at 293 K on a Rigaku AFC6R diffractometer fitted with graphite monochromatized Mo-K_α radiation, λ = 0.71073 Å; the ω : 2θ scan technique was employed to measure data such that θ_{max} was 25.0°. No decomposition of the crystal occurred during the data collection and only absorption corrected data [41] which satisfied the $I \geq 3.0\sigma(I)$ criterion were used in the subsequent analyses. Relevant crystal data are summarized in Table 1. The structure was solved by direct methods [42] and refined by a full-matrix least-squares procedure based on F [43]. Non-H atoms were refined with anisotropic thermal parameters and H atoms were included in the model at their calculated positions (C—H 0.97 Å). At convergence R = 0.044 and R_w = 0.039 [sigma weights, $1/\sigma^2(F11)$]; final refinement details are collected in Table 1. Scattering factors for all atoms were those incorporated in the TEXAN program.[43] The atom labeling scheme employed is shown in Fig. 1, drawn with the ORTEP [44] program at 30% probability ellipsoid. Selected bond distances and angles are given in Table 2. The TEXAN [43] package, installed on an Iris Indigo workstation, was employed in all calculations.

RESULTS AND DISCUSSION

Refluxing [$VO(acac)_2$] with the tridentate (ONS) ligands (1 : 1 mol ratio) under nitrogen in dichloromethane or acetonitrile yielded oxovanadium(IV) compounds in moderate to high yields (40–80%) in the presence of a Lewis base needed to complete the vacant metal coordination site(s). Thus, mono- (**1**–**5**) and dinuclear oxovanadium(IV) compounds (**6**–**8**) were obtained using 2,2′-bipyridyl, 1,10-phen-

anthroline and 4,4′-bipyridyl as the neutral donors. The mononuclear complexes (**1–5**) are soluble in CH_2Cl_2 and dmf, while their dinuclear counterparts (**6–8**) are only soluble in dmf. All these compounds are air stable in the solid state. In solution also they are fairly stable and undergo slow decomposition only on prolonged standing.

IR spectra of the free ligands have several prominent bands appearing at *ca* 3100, 2960 and 1040 cm^{-1} due to ν(O—H), ν(N—H) and ν(C=S) stretching modes, respectively, which are altogether missing in the complexes. Further screening reveals the appearance of a new band in the complexes at 650 cm^{-1} due to the ν(C—S) stretch. All these indicate (ONS) mode of chelation by the thioenol form of the ligands in the present series of complexes [45]. In addition, the complexes display a strong V=O terminal stretch appearing at 990 cm^{-1} in the pentacoordinated complexes (**6–8**) as against 960 cm^{-1} observed with the octahedral vanadium(IV) complexes (**1–5**), containing a coordinated nitrogen atom *trans* to the terminal oxo group. The results clearly indicate the structural *trans* effect of the coordinated nitrogen atom in the mononuclear complexes (as confirmed by X-ray structure analyses, see later) that leads to weakening of the V=O terminal bond [32].

FAB mass spectra

Positive-ion FAB mass spectra of two representative compounds **4** and **6** have been recorded in *m*-nitrobenzyl alcohol matrix. The spectrum of [VOL^1(phen)] (**4**) features a molecular ion peak (MH^+) at *m/z* 472 together with fragmentation peaks at *m/z* 263 and 247, most likely corresponding to the positive ions $[VO_2(phen)]^+$ and $[VO(phen)]^+$, respectively. The most abundant peak at *m/z* 366 probably corresponds to the fragment $[VO(phen)(—N=N—CSSCH_3)]^+$. The FAB spectrum of [$L^1OV(\mu$-4,4′-bipy)$VOL^1$] (**6**, Fig. 2) contains a molecular ion (MH^+) peak at *m/z* 739, which is much less intense in comparison to many of those due to fragments. Two most intense peaks observed at *m/z* 448 and 292 due to positive ions [VOL^1(4,4′-bipy)H]$^+$ and [VOL^1H]$^+$ signify gradual break down of the molecule.

Description of structure

The molecular structure of **2** is shown in Fig. 1 and important geometric parameters are listed in Table 2. The unit cell is comprised of discrete molecular entities with the closest non-H intermolecular contact of 3.186(8) Å occurring between the O(9′) and C(11″) atoms (symmetry operation: 0.5-*x*, 0.5-*y*, *z*). The V atom in **2** is octahedrally coordinated by the S, O and N donor atoms of the tridentate ligand, the two N atoms of the bipyridyl ligand and the oxo atom; the arrangement of the tridentate ligand is such that it defines the meridion in a distorted octahedral geometry. That both of the five- and six-membered rings which are formed upon coordination of L^2 are almost planar are seen in the magnitude of the V/S(1)/C(1)/N(2), V/O(7)/C(6)/C(5) and V/N(3)/C(4)/C(5) torsion angles of −7.4(6), 14.8(9) and −8.2(9)°, respectively. There is a small disparity in the V—N bond distances involving the 2,2′-bipyridyl ligand, which can be related to the greater *trans* influence of the oxo group on the V—N(11) bond.

Determination of structure of the dinuclear compound was not possible as the complexes (**6–8**) eluded all attempts to grow diffraction quality crystals.

Magnetism and EPR

Oxovanadium(IV) complexes are magnetically straightforward. At room temperature (298 K) the observed values of magnetic moments (Table 3) for the mononuclear complexes (**1–5**) are in the range 1.71–1.75 μ_B, as expected for a simple $S = 1/2$ paramagnet with d_{xy}-based ground state.[46] EPR spectra of these complexes have essentially identical features both in the fluid (CH_2Cl_2/toluene, 1 : 10 v/v at 298 K) as well as in the frozen solution (77 K). At room temperature, a typical spectrum (**2**) shows an eight-line pattern: $\langle g \rangle$, 1.977 and $\langle A \rangle$, 84 × 10^{-4} cm^{-1}, characteristic of an unpaired electron being coupled to a vanadium nuclear spin (^{51}V, 99.76 atom %, $I = 7/2$). In the frozen state, the same solution displays well-resolved axial anisotropy with two sets of eight-line patterns. The corresponding spin-Hamiltonian parameters are $g_\parallel$, 1.956 ($A_\parallel$, 153 × 10^{-4} cm^{-1}) and $g_\perp$, 1.986 ($A_\perp$, 51 × 10^{-4} cm^{-1}) summarized in Table 3. Inspection of these data reveals a close agreement between the spectral parameters obtained at room temperature and in the frozen solution [$\langle g \rangle = 1/3(g_\parallel + 2g_\perp)$; $\langle A \rangle = 1/3(A_\parallel + 2\ A_\perp)$], thus indicating the molecules retaining their structural identity in solution throughout this temperature range. Another interesting feature that deserves mention are the small hyperfine coupling constants (both $A_\parallel$ and $A_\perp$) and relatively large $g_\perp$ values when compared with those for related complexes in N/O donor environments [22, 47]. This indicates moderate π-interaction of sulfur in the present ligand system, leading to increased delocalization of the vanadium unpaired electron [48].

At room temperature the dinuclear vanadium(IV) complexes (**6–8**) exhibit a similar eight-line pattern as observed with the mononuclear complexes (Table 3). A representative spectrum (**8**) is shown in Fig. 3 (inset) which provides an ideal example of a dinuclear vanadium(IV) spectrum with $|J| \approx 0$ [49]. The spectrum in the frozen solution (Fig. 3) has an axial profile with no feature due to "forbidden" $\Delta M_s \pm 2$-triplet singlet transition, appearing in the half-field region [50]. The spin–spin interactions in these compounds are so insignificant that each unpaired electron virtually interacts with only one vanadium center. Mag-

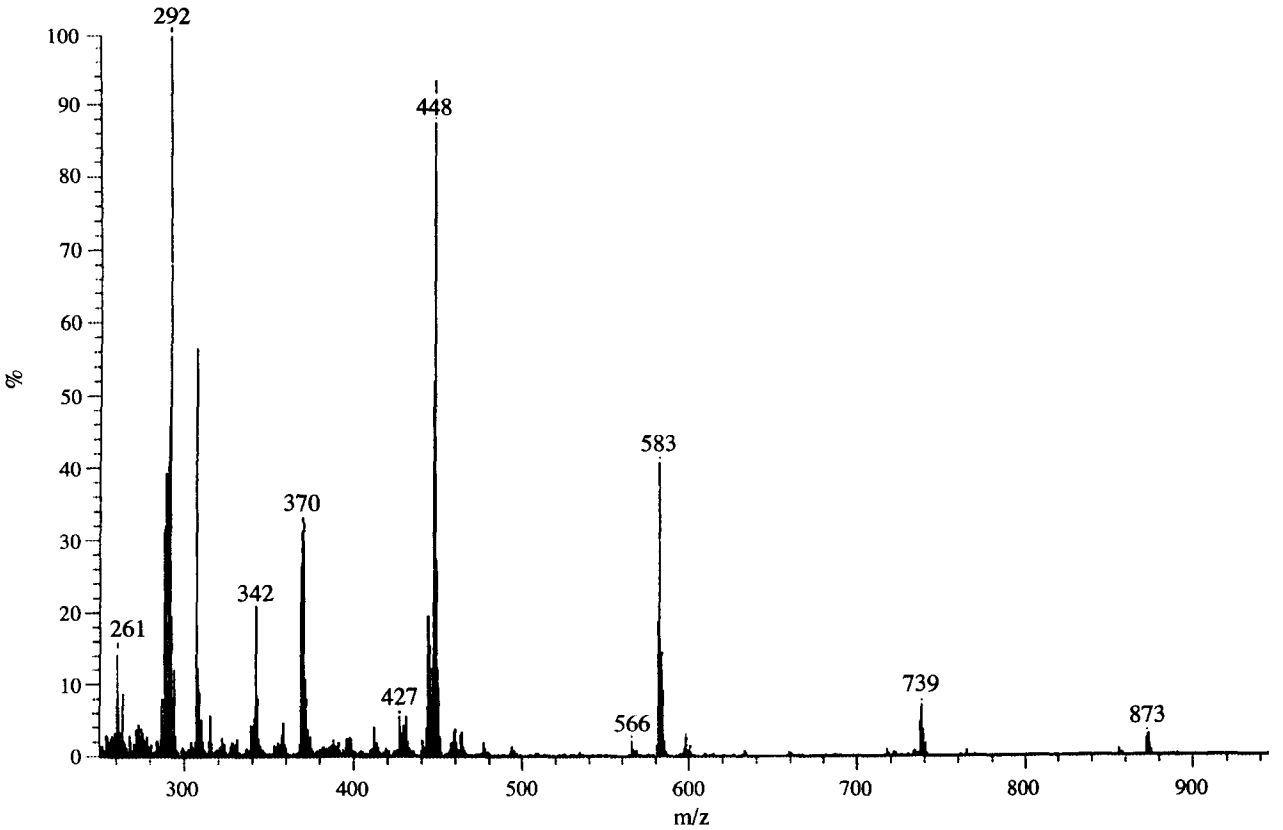

Fig. 2. Positive-ion FAB mass spectrum of [L¹OV(μ-4,4′-bipy)VOL¹] (**6**) in *m*-nitrobenzyl alcohol matrix.

netic moments in the polycrystalline state of these compounds are in the range 2.38–2.42 μ_B per mole, equivalent to *ca* 1.73 μ_B per vanadium(IV) center. The results also speak in favor of the dinuclear vanadium(IV) systems with $|J| \approx 0$ as established from EPR spectroscopy.

Electronic spectra

The electronic spectra of these complexes are summarized in Table 4. The divanadium complexes (**6–8**) in dmf solution show three low intensity (ε, 120–380 $dm^3\ mol^{-1}\ cm^{-1}$) ligand-field transitions, characteristic of vanadyl complexes having C_{4v} symmetry [50]. A representative spectrum (**6**) is shown in Fig. 4(a) along with the absorption manifold (inset) for such complexes based on the Ballhausen and Gray model [51]. Observed bands at 820 nm (ε, 220 $dm^3\ mol^{-1}\ cm^{-1}$), 655 nm (290 $dm^3\ mol^{-1}\ cm^{-1}$) and 546 nm (ε, 380 $dm^3\ mol^{-1}\ cm^{-1}$) are labeled I, II and III corresponding to electronic transitions from d_{xy} to (d_{xz}, d_{yz}), $d_{x^2-y^2}$ and d_{z^2}, respectively.

In mononuclear complexes (**1–5**) bands I and II are poorly resolved and appear under a broad envelope, centered at 720 nm as shown in the Fig. 4(b) for a representative compound (**1**) in CH_2Cl_2. Careful

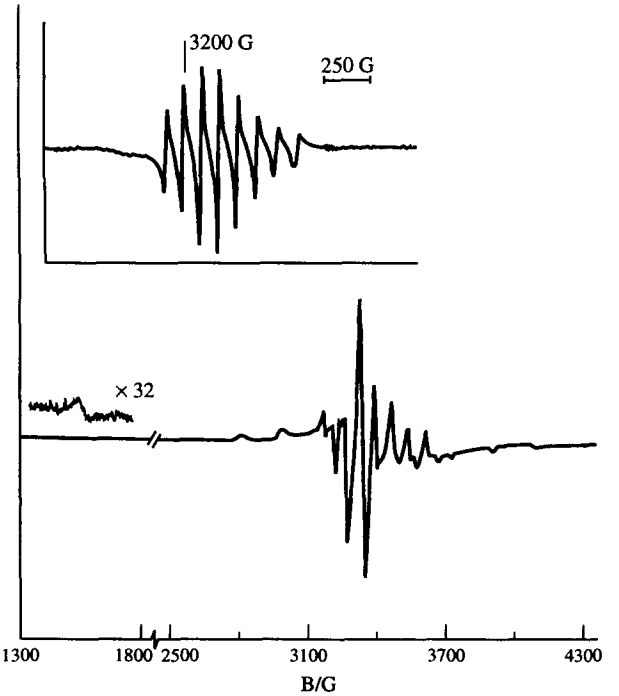

Fig. 3. The X-band EPR spectrum of [$L^3OV(\mu$-4,4′-bipy)VOL^3] (**8**) in frozen solution (dmf/toluene 1 : 10 v/v, 77 K). The inset shows the spectrum of the same solution at room temperature (298 K).

scrutiny (by second derivative plot) of this spectrum reveals the peak positions at *ca* 770 and 695 nm for bands I and II, respectively. Band III is missing and probably masked by the tail of a charge-transfer band appearing in the near-UV region (426 nm, 8100 dm^3 mol^{-1} cm^{-1}). The addition of a sixth donor ligand *trans* to the terminal V=O bond in **1–5** thus exerts a destabilizing force to alter the energetic of orbital manifold (Fig. 4, inset), so that transition to e (d_{xz}, d_{yz}), band I, and $a_1(d_{z^2})$, band III, are blue shifted compared with their dinuclear counterparts (**6–8**).

In addition to the *d–d* bands, the oxovanadium(IV) compounds (**1–8**) also have a strong charge-transfer band in the 440–380 nm region (ε, 7050–43800 dm^3 mol^{-1} cm^{-1}), the position of which is tunable by the substituent X (X = H, NO_2 and Br) in the tridentate ONS ligand (Table 4). We interpret this band as ligand-to-metal charge-transfer (l.m.c.t., $PhO^- \rightarrow V$) in origin. All remaining bands appearing in the UV region are due to ligand internal transitions.

Acknowledgements—We gratefully acknowledge support of this work by the Council of Scientific and Industrial Research, New Delhi, and thank Mr P. R. Ashton (Birmingham University, U.K.) and Dr S. B. Kumar (Universitat de Barcelona, Spain) for their help in recording the FAB mass and EPR spectra, respectively. The Australian Research Council is thanked for the support of the crystallographic facility.

(Received 30 August 1996; accepted 30 September 1996)

Abstract—The title compound, [ClFe(thiazole)$_4$-O-FeCl$_3$] (**1**) has been synthesized by the hydrolysis of anhydrous FeCl$_3$ in an ethanol–thiazole solvent mixture. Compound **1** consists of a tetrahedrally coordinated OFeCl$_3$ group bridged by the oxo ligand to an Fe(thiazole)$_4$Cl group, wherein the thiazole groups occupy the equatorial positions in an octahedral coordination polyhedron. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: thiazole; iron; μ-oxo complex.

EXPERIMENTAL

IR spectra were recorded (Nujol mull) in the 300–5200 cm^{-1} range on a Perkin–Elmer FT-IR 2000 spectrophotometer. ^{1}H NMR spectra were recorded on a Varian INOVA-500 spectrometer using DMSO-d_6 as a solvent and the chemical shifts reported in ppm *vs* TMS. Elemental analyses were carried out on a LECO CHNS-900 elemental analyser. Anhydrous FeCl$_2$, FeCl$_3$ and thiazole were obtained from commercial sources and used as received. Ethanol was of A.R. grade and was used both with and without further purification.

Reactions of FeCl$_2$ *and* FeCl$_3$ *with thiazole*

When warm ethanolic (A.R. grade) solutions of FeCl$_2$ (6 mmol, 16 cm^3) and thiazole (12 mmol, 2 cm^3) were mixed with stirring, a yellow–orange powder was immediately precipitated. The precipitate was washed with ether and benzene and dried *in vacuo*. In common with the polymeric species Cu(thiazole)$_2$X$_2$ (X = Cl and Br)[1], the precipitate was insoluble in common organic solvents, but soluble in DMF. IR measurements indicate the presence of thiazole, while elemental analyses suggest a molecular formula Fe(thiazole)$_2$Cl$_2$ (**2**). Attempts to grow single crystals of this compound have thus far been unsuccessful. Found: C, 24.6; H, 2.0; N, 9.4; S, 21.6. Calc. for **2**: C, 24.7; H, 2.0; N, 9.1; S, 21.2%. IR (Nujol): *ν*(ligand) 608(m), 737(m), 808(m), 879(w), 912(w), 1060(w), 1112(w), 1231(w) cm^{-1}.

No precipitate was formed when the analogous reaction was carried out with FeCl$_3$ (4 mmol, 16 cm^3) and thiazole (12 mmol, 2 cm^3). When freshly distilled ethanol was used under dry Ar, a clear yellow–orange solution was obtained. Upon allowing to stand for 24 h in a refrigerator orange polycrystals were formed. IR spectra and elemental analysis of this compound suggest a molecular formula: Fe(thiazole)$_3$Cl$_3$ (**3**). Thus far, recrystallizations of this compound have failed to produce single crystals. Found: C, 26.0; H, 2.1; N, 9.9; S, 23.1. Calc. for **3**: C, 25.9; H, 2.2 N, 10.1; S, 23.0%. IR (Nujol): *ν*(ligand) 609(s), 730(m), 823(s), 876(m), 911(m), 1048(s), 1111(m), 1234(m) cm^{-1}.

When A.R. grade ethanol was used with no further purification, the solution filtered and allowed to stand in air for 2–3 days, orange polycrystals of **3** as well as orange–brown single crystals of the title compound (**1**) were formed. In instances when substantial amounts of water may have been present in the ethanol, product **3** did not crystallize. For both **1** and **3**,

*Author to whom correspondence should be addressed.

IR spectra confirmed the presence of thiazole. Found: C, 23.9; H, 1.9; N, 8.9; S, 20.9. Calc. for **1**: C, 23.6; H, 2.0; N, 9.2; S, 21.0%. IR (Nujol): ν(ligand, cm^{-1}) 319(m), 353(m) 613(m), 747(w), 841(vs-broad), 878(w), 912(m), 1051(s), 1114(w), 1235(w). ^1H NMR (DMSO-d_6) δ (ppm): 7.81 and 8.00 (8H), 9.19 (4H).

Crystal structure determination

Measurements were made on Rigaku AFC7R diffractometer at ambient temperature using monochromated Mo-K_α radiation ($\lambda = 0.71069$ Å). An orange–brown single crystal of **1** was mounted at the top of a glass fibre. Cell constants were obtained by least-squares analysis of 23 strong reflections in the range $29.7 < 2\theta < 30.0°$. Details of crystal data, data collection and structure refinement are summarized in Table 1.

The intensity data were corrected for Lorentz and polarization effects and an empirical absorption correction based on azimuthal scans of several reflections was also applied. The structure of **1** was solved by direct methods and developed by alternating cycles of difference-Fourier syntheses and full-matrix least-squares refinements. The positions of the iron, chlorine, oxygen and nitrogens were determined unequivocally, as were the carbons [C(1), C(2) and C(3)] and sulfur [(S(1)] of one of the thiazole ligands. The remaining three thiazole ligands displayed static disorder between adjacent carbon and sulfur sites, due to 180° rotations about their Fe—N bonds. In these cases the disorder was modeled by refinement of jointly occupied S/C sites. The minority component of these jointly occupied sites is indicated by a primed label, such that the site S/C′ contains a majority of sulfur, while the adjacent C/S′ site is constrained so as to give an equal proportion of carbon. The occupation factors of sulfur atoms were refined only at the S/C′ sites, while the C′ and S′ occupation factors were constrained so as to give fully occupied sites. The non-hydrogen atoms were refined anisotropically, with the exception of the atoms at the disordered sites, which, along with the hydrogen atoms, were refined isotropically. Hydrogen atoms were located using difference-Fourier synthesis. Neutral atom scattering factors were taken from [2] and anomalous dispersion corrections were taken from [3]. Crystallographic calculations were carried out with a teXsan crystallographic software package of Molecular Structure corporation (1985, 1992).

RESULTS AND DISCUSSION

The chemical reactivity of iron(II) chloride with thiazole does not appear to be substantially different to that observed for copper(II) halides. Although the structure of $Fe(thiazole)_2Cl_2$ (**2**) has not been confirmed by X-ray crystallography, its solubility, as well as its elemental analysis and IR spectrum, suggest that it has a similar structure to that of polymeric $Cu(thiazole)_2Cl_2$.[1] While numerous examples of M^{II}-thiazole-halides (M = Co, Ni, Cu, Zn and Pd) [4] have been characterized, analogous compounds based on transition metals of 3+ oxidation state are rare. The compound $Fe(thiazole)_3Cl_3$ (**3**) appears to be moisture-sensitive; not forming when the water content of the ethanol solutions is too high and oxidizing in the presence of air to $Fe_2O(thiazole)_4Cl_4$ (**1**). In this respect, the chemistry of formation of **1** is similar to that of $[Hpy]_2[Fe_2OCl_6]\cdot py$ (py = pyridine)[5].

The compound **1** crystallizes in the monoclinic space group $P2_1/c$ with $a = 9.626(5)$, $b = 15.484(4)$, $c = 15.544(5)$ Å $\beta = 90.58(3)°$, $V = 2316(1)$ Å^3 and $Z = 4$. The crystal structure of **1** is shown in Fig. 1. Selected bond lengths and bond angles are given in Table 2.

Compound **1** is comprised of an —$OFeCl_3$ tetrahedral group that corner-shares its oxygen with an octahedral —$OFe(thiazole)_4Cl$ group, such that the thiazole ligands occupy the equatorial positions and

[a] Bond length and bond angle averaged over disordered thiazole ligands.
[b] Bond angle averaged over all thiazole ligands.

the oxo and chloro ligands occupy the axial positions. To our knowledge **1** is the first oxo-bridged di-iron complex to show both tetrahedral and octahedral coordination about iron.

The tetrahedral —$OFeCl_3$ fragment of **1** has many structural features in common with complex salts containing the μ-oxo-bis(trichloro-iron(III)) dianion (for a comprehensive review of these complex salts see [6]), including a Fe(2)—O bond length of 1.758(3) Å (Fe—O ~ 1.756 Å) [6] as well as approximately regular tetrahedral bond angles of Cl—Fe(2)—Cl_{av} = 108.5(7) and O—Fe(2)—Cl_{av} = 110.4(1)°. The average Fe(2)—Cl bond length in **1** [2.222(2) Å] is also similar to those found in this family of compounds (2.20–2.23 Å)[6].

The single Fe(1)—Cl(1) bond [2.387(2) Å] in the octahedral fragment of **1** is substantially longer than the Fe—Cl bonds in the tetrahedral fragment, possibly due to a significant *trans*-influence with the bridging oxygen. The oxo link in **1** with a Fe—O—Fe angle of 169.2(2)° is at the upper end of the range of angles (146.5–170.8°) observed in complex salts containing μ-oxo-bis(trichloro-iron(III)) dianions [6].

Nitrogen coordination in oxo-bridged di-iron species is commonly observed *via* phthalocyaninato and porphyrinato ligands [7]. In these compounds, iron shows a tendency towards square-pyramidal coordination, with average apical Fe—O distances of ~1.75 Å and basal Fe—N distances of ~2.08 Å. Pseudo-octahedrally coordinated oxo-bridged di-iron compounds that contain nitrogen-bound ligands are relatively rare. There are, however, examples to be found in complexes containing the $[Fe_2O(phenanthroline)_4(H_2O)_2]^{4+}$ ion[8]. A notable difference between the average Fe—N bond lengths *cis* (~2.15 Å) and *trans* (~2.26 Å) to the oxo ligand is observed for these compounds, again suggesting a significant *trans* influence [8]. The average of the Fe(1)—N bond lengths in **1** [2.178(5) Å] is similar to the distances between Fe and *cis*-N in $[Fe_2O(phenanthroline)_4(H_2O)_2]^{4+}$. In both cases, these distances are indicative of nitrogen bonds to high-spin iron(III); while considerably shorter average Fe—N bond lengths (~1.973 Å) are observed in low-spin complex ions such as $[Fe(phenanthroline)_3]^{3+}$ [9]. The octahedral arrangement about Fe(1) in **1**, with average N—Fe—N angles of 90.8(2)°, average O—Fe(1)—N angles of 91.3(2)° and a O—Fe(1)—Cl angle of 178.2(2)° is substantialy more regular than those found in complex salts containing the $[Fe_2O(phenanthroline)_4(H_2O)_2]^{4+}$ cation [8].

Static disorder between the S site and the site corresponding to C(2) in the ordered thiazole was found to present in three of the four thiazole ligands; this being due to 180° rotations about the Fe—N bonds. Bond lengths and angles observed for the non-disordered thiazole ligand are almost identical to those found for the copper compound $Cu(thiazole)_2Cl_2$ [1]. As one might anticipate, identification of hydrogen positions was only possible for the ordered thiazole ligand and the carbon atoms adjacent to the nitrogen atom in the disordered ligands.

The principal IR absorption bands observed for **1**, **2** and **3** are similar to those of the thiazole ligands found in other metal-thiazole-chlorides such as $M(tz)_2Cl_2$ (M = Co and Cu)[10]. Notably, the broad, very strong peak observed at 841 cm^{-1} in the IR spectra of **1** is not present in the spectra of **2, 3** or the latter polymeric bis-thiazole compounds and may be attributed to an antisymmetric Fe—O—Fe stretching mode [5]. The absorption bands at 353 and 319 cm^{-1}, corresponding to antisymmetric and symmetric $FeCl_3$ stretches, respectively, were found only in the IR spectrum of **1**. Given the absence of these terminal vibrational modes in the IR spectrum of **2**, as well as the elemental analysis of this compound we propose a structure similar to that of the above polymeric species.

The ^1H NMR spectrum of **1**, indicates three relatively broad singlets in the aromatic region centred at 7.81 and 8.00 and 9.19 ppm (the widths at half-height are $\nu_{1/2}$ = 45, 54 and 60 Hz, respectively), each corresponding to four protons per molecule. Free-rotation about the Fe—N bonds in solution at room temperature should give the three chemically distinct hydrogen signals in the ^1H NMR spectrum. It should be noted that the three proton resonances in free thiazole occur at 7.40, 7.94 and 8.86 ppm. This discrepancy with the above observed values, as well as the broad line widths of these singlets is indicative of the presence of paramagnetic high-spin iron(III).

(Received 24 May 1996; accepted 30 September 1996)

Abstract—The redox properties of octakis(hexylthio)-substituted phthalocyanines with 2H, Zn^{II} and Cu^{II} in the phthalocyanine core have been investigated by cyclic voltammetry in dichloromethane and the energies of photo-excitation and oxido-reduction processes have been compared. Two successive one-electron reduction and one-electron oxidation processes were observed for the complexes used in this work. The displacement of two protons in the inner core with metal ion was found to shift the first reduction potential of phthalocyanine ring to more negative values as a result of the π-back donation of the filled d_π of metal ion into the empty *pc*-π^* orbitals. The evaluation of cyclic voltammetry data together with the absorption spectra showed that photo-excitation arises from the orbitals below the HOMO for all the complexes used in this work. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: phthalocyanines; electrochemistry; cyclic voltammetry; zinc; copper.

The redox properties of phthalocyanines (Pcs) are critically related to most of their industrial applications [1,2]. The aromatic 18 π-electron system of pcs with the usual two negative charges enables oxidation and reduction on the macrocycle before any redox process on the central metal ions such as Ni^{II}, Cu^{II} or Zn^{II}. Here the energies of photo-excitation and oxido-reduction processes can be compared while both are occurring on the highest energy orbitals [3].

A limiting factor for the solution studies on pcs is the insolubility of the parent compound. Peripheral substitution with bulky substituents or the use of donor solvents capable of binding to axial positions of the central metal ion have been two practical ways to overcome this hindrance. In the previous works on macrocycle-substituted pcs we have accomplished the synthesis of very soluble examples in a wide range of organic solvents [4–8]. In addition to novel functionalities such as alkali [4,5] or transition metal [7, 8] ion binding, ion channel formation,[9] enhanced conductivity, [10] etc., the solubility of pc products has been reached up to 10^{-3} mol dm^{-3} level [4,5]. Also recently new soluble derivatives with eight alkylthio substituents have been synthesized through cyclotetramerization of 4,5-bis(hexylthio)phthalonitrile which has been prepared directly from the 4,5-dichloro-compound with hexanethiol [11]. In the present work, the redox properties of these soluble pcs with 2H, Zn^{II} and Cu^{II} in the pc core (H_2htpc, Znhtpc and Cuhtpc, Fig. 1) have been investigated by cyclic voltammetry in dichloromethane (DCM) and the results are evaluated together with their absorption spectra in the visible range.

RESULTS AND DISCUSSION

Cyclic voltammetry data for H_2htpc, Zn(htpc) and Cu(htpc) are shown in Table 1. Voltammetric behaviours of Zn(htpc) and Cuhtpc on the oxidation side are similar to H_2htpc. Figure 2 shows the cyclic voltammogram (CV) of Zn(htpc) on sweeping to positive potentials. All pcs used in this work gave two quasi-reversible one-electron oxidation couples with the peak separations (ΔE_p) of 0.090–0.105 V. The half peak potentials of Zn(htpc) and Cu(htpc) for each oxidation couple had approximately the same values

*Author to whom correspondence should be addressed.

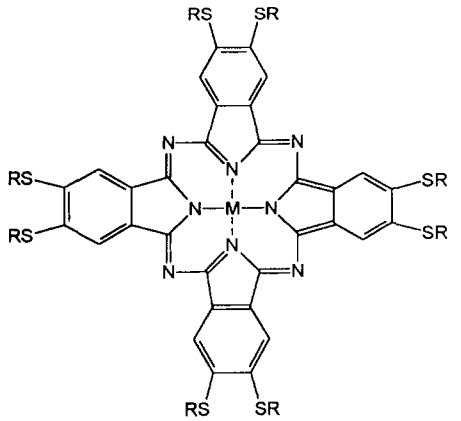

Fig. 1. Octakis (hexylthio)-substituted phthalocyanines [R: C_6H_{13}; M: 2H (H_2htpc), Zn^{II} (Zn(htpc)) or Cu^{II} (Cu(htpc))].

as with those of H_2htpc. The similarities in oxidation potentials between these phthalocyanines indicate that both the first and the second oxidation couples are ligand based. Two successive ring oxidations from the non-degenerate $a_{1u}(\pi)$ orbital of the pc ligand are possible in metal phthalocyanine complexes [12]. The potentials shown in Table 1 [0.585–0.805 V vs saturated calomel electrode (SCE)] are in the range reported for pc ligand oxidation [1,13,14] in H_2pc and metal pc complexes, providing an additional support for pc ring oxidation and hence corresponds to the formation of π-cation radical species.

The cyclic voltammetry of Zn(htpc) was reported previously on the glassy carbon electrode in dimethylformamide by Takahashi *et al.* [15]. They reported that the adsorption and irreversible oxidation had been observed on the oxidation side. In our work, voltammetric behaviour of Zn(htpc) on Pt in the oxidation side was found to be considerably different compared with the previous report. The CV of Zn(htpc) displays two quasi-reversible one-electron oxidation peaks with the corresponding two cathodic peaks. The peak current of the first oxidation (Oxd 1 in Fig. 2) was found to be higher than that of the second oxidation (Oxd 2 in Fig. 2) and also the value of i_{pc}/i_{pa} for the first oxidation process is less than unity, suggesting decomposition of the first oxidation product. However, decomposition should be very slow and ineffective with respect to the electron transfer rate since the second oxidation and re-reduction peaks are observed. The controlled-potential electrolysis of Zn(htpc) at 0.7 V and 0.9 V *vs* SCE did not show the adsorption of Zn(htpc) or its oxidation products on

platinium gauze electrode. The shape of the CV of Zn(htpc) in the oxidation side is also consistent with the absence of adsorption. The difference in the voltammetric behavior of Zn(htpc) in the oxidation side compared with the previous work [15] may be attributed to the use of DCM as the solvent in this work. The potentials of the first oxidation and two reduction processes of Zn(htpc) (Table 1) are in accord with those measured for the analogous compound with octakis(butylthio) substituents.

Voltammetric behaviors of H_2htpc, Zn(htpc) and Cu(htpc) on the reduction side are significantly different from each other. Figures 3 and 4 show the CVs of H_2htpc on sweeping to negative potentials at 0.050 and 0.250 V s^{-1}, respectively. H_2htpc gives two one-electron reduction peaks without the corresponding anodic waves on the reverse sweep at 0.050 V s^{-1}. However, an anodic peak (AP2 in Fig. 4) was observed at the scan rate of 0.250 V s^{-1}, which appears to correspond to the second reduction process. The first reduction process is irreversible since it has no coupled re-oxidation peak. The value of $E_p - E_{p/2}$ for Red1 peak was found to be 0.070 V and $i_{pc}/v^{1/2}$ was constant, suggesting a diffusion controlled one-electron reduction. The absence of the re-oxidation peak for the first reduction process should not indicate that the monoanion of H_2htpc is unoxidizable. In our previous work, [16] the first reduction process of tetra-crown-ether-substituted metal-free phthalocyanine in dimethylsulfoxide displayed the anodic peak on the reverse sweep. Changing the peripheral substituents or the solvents used are not expected to make such a drastic effect on the voltammetric behavior of the pc ring. The absence of the anodic peak for the first reduction process may be attributed to a fast chemical reaction which follows the first electron transfer and produces a reducible but unoxidizable species (EC process). The shape of the Red1 peak is consistent with the EC process. The value of i_{Red2} is considerably higher than that of i_{Red1}, indicating the adsorption of the species produced by the EC process. $i_{Red2}/v^{1/2}$ was found to increase with increasing scan rate providing additional support for the adsorption. The appearance of a re-oxidation peak at 0.250 V s^{-1} indicates that the transfer of the second electron to the metal free complex is also followed by a chemical reaction.

The CV of Zn(htpc) in the reduction side at 0.050 V s^{-1} (Fig. 5) displayed two reduction processes (Red1 and Red2) with coupled re-oxidation peaks, the wave shapes and peak splittings ($\Delta E_p = 0.080$ V for Red1 and $E_p = 0.100$ V for Red2), which indicate reversible and quasi-reversible one-electron transfer processes without coupled chemical reactions. The

half peak potentials for the reduction couples of Zn(htpc) are in accord with those previously reported, [14,15,17–19] the small differences being due to solvent and substituent effects.

The CV of Cu(htpc) (Figs 6 and 7) displayed a reduction peak (Red1,2) on sweeping to negative potentials with two anodic peaks (AP2 and AP1) on the reverse scan. The reduction of Cu(htpc) by controlled-potential electrolysis at the potential of Red1,2 peak afforded a two-electron redox process. However, the appearance of two re-oxidation peaks on the reverse sweep probably suggests that reduction of Cu(htpc) occurs in two successive one-electron steps. The potential difference between the first and the second reduction processes should be considerably small leading to the formation of a composite wave (Red1,2 peak in Fig. 6). The formation of the composite wave may be related to the fact that the singly reduced copper phthalocyanines are known to be unstable compared with the other metal phthalocyanines [20]. While the difference between the peak potentials of AP2 and AP1 is 0.20 V at 0.050 V s^{-1} (Fig. 6), it becomes 0.30 V at 0.250 V s^{-1} (Fig. 7). This voltammetric behaviour indicates that the first reduction process of Cu(htpc) is more irreversible than the second reduction process since the anodic peaks shift to more positive potentials with increasing scan rate. Therefore, two re-oxidation peaks are observed clearly due to the different irreversibility of the first and the second electron transfer processes, whereas only one cathodic peak is observed on sweeping to negative potentials.

Zn(pc) has frequently been selected as a candidate for the investigation of ligand-based redox processes, while the zinc(II) ion exhibits a stable oxidation state during the electrochemical measurements [3,14,15,17,21,22]. The potentials which appeared on the reduction side on the voltammograms of Zn(htpc) and Cu(htpc) are similar to one another. The reduction processes for both Zn(htpc) and Cu(htpc) are thought to be ligand based, as reported for most metal phthalocyanines [3,12,13,21,23].

The displacement of two protons with the zinc(II) ion shifts the first reduction potential of the pc ring to more negative values [−0.70 V for H_2htpc and −0.83 V for Zn(htpc)]. This voltammetric behaviour has been also observed previously with various metal free and metal phthalocyanines [13,20,24] and may be attributed to the increase in the negative charge of the pc ring as a result of the strong coordination of nitrogen atoms to the metal ion. The π-back-donation of the filled d_π of the metal ion into the empty pc-π^*-orbitals and the polarization of the ligand due to the E_g symmetry with the displacement of protons with metal ion was previously reported [25] as providing an additional support for the negative shift in the reduction potential of the pc ring. Although it was not possible to determine the first reduction potential of Cu(htpc) due to the formation of the composite wave, it is clear from the potential of Red1,2 peak that the

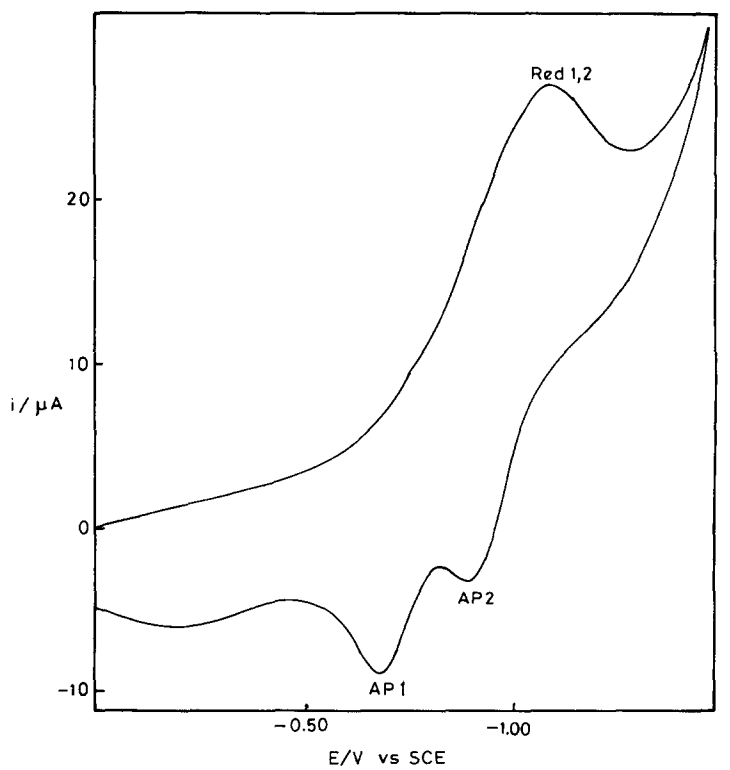

Fig. 6. Cyclic voltammogram of Cu(htpc) (5×10^{-4} M) on sweeping to negative potentials in DCM with $v = 0.050$ V s^{-1}.

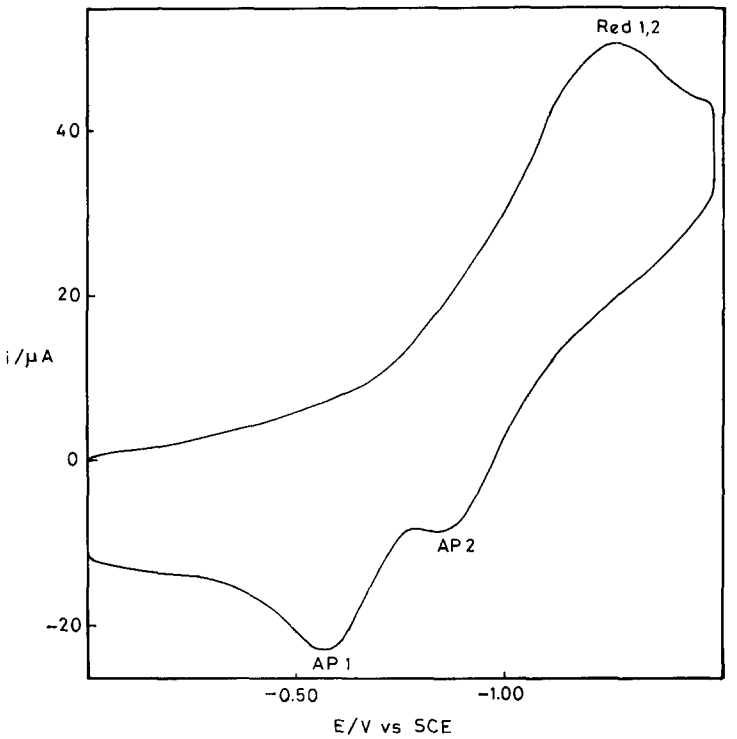

Fig. 7. Cyclic voltammogram of Cu(htpc) (5×10^{-4} M) on sweeping to negative potentials in DCM with $v = 0.250$ V s^{-1}.

first electron transfer to Cuhtpc should occur at a more negative potential with respect to H_2htpc. On the other hand, the presence of metals coordinated to nitrogen atoms of the pc ring did not make an important effect on the oxidation potentials [20]. For all complexes used in this work, the first oxidation and the first reduction can be supposed to involve the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO), respectively. On the other hand, the main peaks of the Q band in the UV–vis spectra of metal free and metal phthalocyanines have been attributed to the electronic transition from the HOMO to the LUMO [$b_{2g} \rightarrow e_g(\pi^*)$ for metal free and $a_{1u}(\pi) \rightarrow e_g(\pi^*)$] for metal phthalocyanines [25,26]. The UV–vis absorption spectra of the complexes used in this work have been reported previously [11]. The main peaks of the Q band in H_2htpc appeared at 740 and 700 nm corresponding to the non-degenerate transitions to the split $e_g(\pi^*)$ LUMO, which splits at the lower symmetry of the D_{2h} H_2htpc species to give two bands labelled Q_x and Q_y, respectively [27–29]. The UV–vis spectra of both Zn(htpc) and Cu(htpc) showed a peak at 710 nm. The difference between the first oxidation and the first reduction potentials [1.35 V for H_2htpc and 1.475 V for Zn(htpc)] do not match the energies of the π–π^* transition visible absorption bands [1.77 and 1.67 eV for H_2htpc and 1.75 eV for Zn(htpc)], indicating that photo-excitation arises from the orbitals below the HOMO for the all phthalocyanines used in this work.

EXPERIMENTAL

Cyclic voltammetry was performed with a Princeton Applied Research (PAR) Model 273 potentiostat, controlled by an external computer. Cyclic voltammograms were collected with the usual three electrode set up and recorded using an X-Y recorder (RE 0091). For cyclic voltammetry, a platinium wire served as a counter electrode and a commercial saturated calomel electrode (SCE) was employed as the reference electrode. The working electrode was a platinium plate, polished with a water suspension of Al_2O_3 before each experiment. The last polishing was done with a particle size of 50 nm. The SCE was separated from the solution by a double bridge containing saturated KCl adjacent to the SCE, and dimethylsulfoxide and carrier adjacent to the solution in order to minimize liquid–liquid junction potentials. Controlled-potential electrolysis was performed at the constant potentials corresponding to the CV peak potentials of the phthalocyanines with the bulk electroylsis of 5×10^{-4} mol dm^{-3} solutions using platinium gauze working and counter electrodes and SCE.

Dichloromethane (DCM), dried over molecular sieves, was used as the solvent in the experiments. Electrochemical grade tetrabutylammonium perchlorate (TBAP) was employed as the supporting electrolyte in a 0.1 mol dm^{-3} concentration.

Reaction of tetrakis[(3-pyridylmethyl)oxy] *p-tert*-butylcalix(4)arene with $KAuCl_4$ and K_2PtCl_6. New pyridinocalix(4)arene adducts of gold(III) and platinum(IV)

Angela F. Danil de Namor,* Felix J. Sueros Velarde and Mercedes C. Cabaleiro

(Received 3 April 1996; accepted 30 September 1996)

Abstract—Tetrakis[(3-pyridylmethyl)oxy]*p-tert*-butylcalix(4)arene prepared from *p-tert*-butylcalix(4)arene and 3-chloromethylpyridine under basic conditions was characterized by ^1H and ^{13}C NMR. Protonation constants of this ligand in methanol at 298.15 K derived from potentiometric data are reported. Au^{III} and Pt^{IV} adducts of tetrakis[(3-pyridylmethyl)oxy]*p-tert*-butylcalix(4)arene have been isolated. It is concluded that this calixarene derivative displaces chloride ions from the coordination spheres of the central atoms in $AuCl_4^-$ and $PtCl_6^-$ species, engaging itself in direct interaction with Au^{III} and Pt^{IV}. © 1997 Elsevier Science Ltd. Keywords: calixarenes; gold(III) complexes; platinum(IV) complexes; macrocycles; tetrakis [3-pyridylmethyl)oxy]*p-tert*-butylcalix(4)arene; adduct formation.

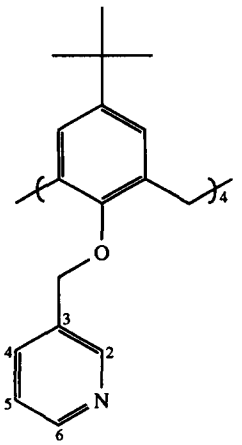
Calixarene chemistry has been the subject of considerable research in recent years [1,2]. A great deal of the interest generated by these macrocycles is attributed to the possibility of introducing functional groups in the lower or upper rim of these compounds in order to target particular ionic or neutral species. Among lower rim calixarene derivatives so far synthesized are those reported by Bottino and Pappalardo [3] and by Shinkai [4] known as pyridinocalix(n)arenes (n = 4 [3], 6 [3,4], 8 [3,4]). In these compounds, carbon atoms (C-2) next to the nitrogens in the pyridine rings are linked *via* a methylene bridge to the phenolic oxygens of the parent calixarenes. Thus, the cooperative effect of the mixed donor atoms, oxygen and nitrogen enable these ligands to interact not only with transition metals, but also with alkali and lanthanide cations. Our interest in the extraction of precious metals led us to the design of a new pyridinocalix(4)arene: tetrakis[(3-pyridylmethyl)oxy]*p-tert*-butylcalix(4)arene (**1**). The main feature of this novel ligand relative to others previously reported is that the present arrangement facilitates the availability of the pyridyl nitrogens (rather than the phenolic oxygens), which are suitable active centres for coordination with gold(III) and platinum(IV) compounds. This paper reports for the first time investigations based on spectrophotometric (IR and ^1H NMR) of **1** and its interaction with $KAuCl_4$ and K_2PtCl_6 compounds in solution.



EXPERIMENTAL

Chemicals

p-tert-Butylcalix(4)arene, 3-chloromethyl pyridine, sodium hydride and tetrahydrofuran (HPLC grade) were purchased from Aldrich. *p-tert*-Butylcalix(4)arene was dried over P_2O_5 *in vacuo* at 100°C for at least 12 h before use.

N,N-Dimethylformamide (Fisons, HPLC grade) was stored over molecular sieves (4 Å) before use. Ethyl acetate, dichloromethane, hexane, sodium sulfate, acetonitrile, $KAuCl_4$ and K_2PtCl_6 were purchased from Fisons. Acetonitrile, hexane and meth-

anol were HPLC grade. For the potentiometric titrations, perchloric acid 70%, redistilled (99.999% grade), purchased from Aldrich was used. Methanol was often used without further purification. However, when the water content tested by Karl Fischer titration was higher than 0.05%, this was removed by refluxing the solvent with magnesium in the presence of iodine (0.5 g I_2/5 g Mg) and distilled. The middle fraction of the distillate was used.

Synthesis of tetrakis [(3-*pyridylmethyl*)*oxy*]p-*tert*-*butylcalix*(4)*arene*

This ligand was prepared by treatment of a THF/DMF solution of *p-tert*-butylcalix(4)arene with 3-chloromethyl pyridine under basic conditions. Details are as follows: sodium hydride (5.158 g, 129 mmol) and *p-tert*-butylcalix(4)arene (2.15 g, 3.85 mmol) were suspended in a mixture of tetrahydrofuran (75 cm^3) and *N*,*N*-dimethylformamide (20 cm^3). The reaction mixture was stirred for 40 min at room temperature and a yellow-greyish suspension was formed. Then, 3-chloromethyl pyridine hydrochloride (7.04 g, 42.9 mmol) was added. The flask containing the mixture was placed in an oil bath and heated at 45°C for a period of 5 h. The course of the reaction was monitored by TLC using hexane : ethyl acetate (4 : 1) and dichloromethane : methanol (9 : 1) mixtures as developing solvents. The solvents were removed under reduced pressure and the organic materials were twice extracted with dichloromethane (100 cm^3). After drying the organic layer with sodium sulphate, the solvent was removed *in vacuo*. The viscous residue was treated with acetonitrile and activated charcoal in order to remove impurities. After filtration and cooling, white crystals were obtained in 56% yield (2.20 g, 2.17 mmol). The compound was recrystallized from acetone. Microanalyses were carried out at the University of Surrey. Found: C, 80.6; H, 7.6; N, 5.5. Calc. for $C_{68}H_{76}N_4O_4$: C, 80.6; H, 7.6; N, 5.5%.

Potentiometric determination of the protonation constants of **1** *in methanol at* 298.15 K

Potentiometric measurements were carried out with an ABU12 Radiometer autoburette interfaced to a microprocessor model Hanna H1 8417 in conjunction with a PHM 82 potentiometer and an Ingold pH combination electrode. All titrations were performed at 298.15 ± 0.10 K in a water-jacketed vessel. Potentiometric data were collected by using an acquisition program and these were recorded as a matrix of time–voltage pairs. Before each measurement, the electrode was calibrated by using a standard solution of perchloric acid (standardized against sodium hydroxide using phenolphalein as indicator) in methanol. For the determination of pK_a values a solution of **1** in methanol was titrated at 298.15 K against a standard solution of perchloric acid. About 110 points were recorded by this titration mode. A Miniquad program was used to analyse the data. All titrations were carried out in triplicate. For the calculation of pK_a values, the autoprotolysis constant of methanol at 298.15 K was considered.

Spectrophotometric studies on the interaction of **1** *with gold*(III) *in methanol*

The interaction of **1** with gold(III) in methanol was studied by spectrophotometry using a Pye Unicam PU8720 UV–vis scanning spectrophotometer. Thus, a methanolic solution of $KAuCl_4$ (2.15×10^{-3} mol dm^{-3}) was titrated against a solution of **1** in methanol (2.55×10^{-3} mol dm^{-3}) over ligand/metal ratio concentrations from 0.12 to 0.95. The absorption spectra was recorded over the 230–500 nm wavelength range.

Isolation of gold(III) *and platinum*(IV) *complexes*

The preparation of gold and platinum complexes was carried out by extraction using mutually saturated solvents. Thus, a solution of the ligand in dichloromethane (0.15 g, 0.15 mmol in 40 cm^3 of solvent) was treated with an aqueous solution of $KAuCl_4$ (0.94 mmol). Thus, for the preparation of the gold complex of **1**, a solution of the ligand (0.15 mmol) in dichloromethane (40 cm^3) was shaken for a few hours with an aqueous solution (40 cm^3) of KCl (1.013 mol dm^{-3}) containing $KAuCl_4$ (0.94 mmol) at 298.15 K (pH = 4.8). Then, the organic layer was dried over Na_2SO_4, filtered and evaporated *in vacuo*. The yellow product was dried over P_2O_5 *in vacuo* (yield 90%) and characterized by elemental analysis. Found: C, 36.8; H, 3.4; N, 2.3. Calc. for $C_{68}H_{76}N_4O_4Au_4Cl_{12}$: C, 36.7; H, 3.4; N, 2.5%. For the preparation of the platinum complex, a solution of the ligand (0.08 mmol) in

dichloromethane (25 cm^3) was shaken for a period of 12 h with an aqueous solution (100 cm^3) of K_2PtCl_6 (0.32 mmol). Before extraction the pH of the aqueous solution was 2.5. After separating the water and organic phases the latter was dried over Na_2SO_4, filtered and evaporated *in vacuo*. The bright yellow product was dried over P_2O_5 *in vacuo* (95% yield) and characterized by elemental analysis. Found C, 57.1; H, 5.4; N, 3.8. Calc. for $C_{68}H_{76}N_4O_4H_2PtCl_6$: C, 57.4; H, 5.5; N, 3.9%. IR measurements were recorded on a Perkin–Elmer 2000 Fourier transform instrument.

RESULTS AND DISCUSSION

^1H *and* ^{13}C *NMR spectra of tetrakis* [(3-*pyridylmethyl*)*oxy*]p-tert-*butylcalix*(4)*arene* (**1**)

The ^1H NMR spectrum of **1** in $CDCl_3$ at 300 K exhibits three sets of resonance centred at δ 8.56 (H-2 and H-6), 7.48 (H-4) and 7.12 ppm (H-5) characteristic of the pyridyl moiety. The spectrum also shows a singlet at δ 4.84 ppm for the methylene groups adjacent to the phenolic oxygens, a pair of doublets at δ 3.96 and 2.80 ppm (J = 12.6 Hz) corresponding to the protons of the methylene bridge and a singlet for the *tert-butyl* groups. These spectral features are compatible with calix(4)arene derivatives in their cone conformation[5]. This is reinforced by a ^{13}C NMR line at δ 31.00 ppm arising from the $ArCH_2Ar$.[6]

Protonation constants

Due to the nature of this ligand (four pyridine moieties) in searching for cation–ligand interactions the affinity of **1** for the proton was investigated in order to select the pH at which any possible metal ion–ligand interaction could be studied without the competitive effect of the proton. Thus, Table 1 lists the protonation constants of **1** in methanol at 298.15 K. These are referred to the following processes where Pyr_4 Calix (4) denotes **1**:

$$Pyr_4Calix(4) + H^+ \xrightarrow{\log K_{p1}} HPyr_4Calix(4)^+ \quad (1)$$

$$HPyr_4Calix(4)^+ + H^+ \xrightarrow{\log K_{p2}} H_2Pyr_4Calix(4)^{2+} \quad (2)$$

$$H_2Pyr_4Calix(4)^{2+} + H^+ \xrightarrow{\log K_{p3}} H_3Pyr_4Calix(4)^{3+} \quad (3)$$

$$H_3Pyr_4Calix(4)^{3+} + H^+ \xrightarrow{\log K_{p4}} H_4Pyr_4Calix(4)^{4+} \quad (4)$$

Table 1. Protonation constants of tetrakis[(3-pyridylmethyl)oxy]*p-tert*-butylcalix(4)arene in methanol at 298.15 K

$\log K_{p1}$	5.71
$\log K_{p2}$	4.52
$\log K_{p3}$	4.12
$\log K_{p4}$	3.59

It is quite clear from the data shown in Table 1 that each pyridine group in the calix(4)arene unit behave quite independently from each other, since the difference in log K_p values for the first and fourth protonation is ~2 log units. The neutral macrocycle is the strongest base and as such it shows the highest proton affinity.

These data can be used to calculate the percentages of the various species as a function of solution pH's. Unlike for acids in their neutral form, the medium effect for the dissociation (or the reverse, association) of cationic acids in the various solvents is very small, since no new charge fields [see eqs (1)–(4)] are originated in the process. Therefore, the data shown in Table 1 provide a good indication about the pH to be chosen to investigate the possible isolation of a gold(III) complex of **1**.

Complexation studies with gold(III) *and platinum*(IV)

As discussed in the experimental section, complexation of gold(III) and $Pyr_4Calix(4)$ was obtained by extracting an aqueous solution of $KAuCl_4$ containing an excess of KCl with an equal volume of a solution of the ligand in dichloromethane.

The UV spectrum of this compound showed that the absorption maximum at 320 nm corresponding to $KAuCl_4$ was shifted to 308 nm in the complex, suggesting that a change in the coordination shell of the metal has occurred. In the IR spectra (KBr) the band arising from the pyridyl group (1578 cm^{-1} for the free ligand) appears at a higher frequency (1609 cm^{-1}), indicating that the pyridyl residues are involved in the complexation. A comparison of ^1H NMR spectrum of the $(AuCl_3)_4Pyr_4Calix(4)$ complex with that of the free ligand revealed that the resonances due to H-2 and H-6 (see structure) move downfield on complexation ($\Delta\delta$ = 0.57 and 0.55 ppm, respectively). A similar pattern of deshielding effects, although more pronounced, was found [7] for the proton resonances of pyridine coordinated to $ZnCl_2$ and to $AlCl_3$ when compared with those of the corresponding protons in the free pyridine molecule ($\Delta\delta$H-2 and H-6 $\geqslant \Delta\delta$ H-4 $\geqslant \Delta\delta$H-3 and H-5).

Attempts to study the interaction of **1** with K_2PtCl_6 under the same pH conditions as those selected for the isolation of the gold(III) complex were hindered by the low solubility of the platinum salt in KCl. Therefore, K_2PtCl_6 aqueous solution (pH 2.7) was extracted by an equal volume of the dichloromethane solution of **1**, following the procedure described in the experimental section. The IR spectrum of this complex showed that the band at 1578 cm^{-1} for the free ligand is replaced by both a residual absorption at the same wavelength and a coordination band at 1609 cm^{-1}. The complex also exhibits a strong maximum at 3420

cm^{-1}, indicating the presence of the NH bonding, although no band between 2500 and 3200 cm^{-1} corresponding to NH^+Cl^- was observed. These facts can be accounted for in terms of a complex species containing both pyridyl coordination and free pyridinium ions. This interpretation is reinforced by inspection of the ^1H NMR spectral changes which occur in the calixarene protons after interaction with the platinum salt. It revealed that whereas the absorptions due to H-4 and H-5 in the free ligand appear as a set of unresolved resonances in the 6.80–7.60 ppm region; in the complex, those centred at δ 8.56 (H-2 and H-6) are replaced by two equally intense signals at δ 9.31 and 8.50 ppm, suggesting the presence of two different types of pyridyl moieties. The shift from δ 8.56 to 9.31 ppm ($\Delta\delta = 0.75$ ppm) experienced by half of the pyridyl protons adjacent to the nitrogen is not very different from that exhibited by the 2 and 6 protons signal of the protonated pyridine ($\Delta\delta = 0.53$ ppm) when compared with the free ligand. Further inspection of the ^1H NMR spectra showed that the resonances due to the methylene protons adjacent to the oxygen (one singlet in the free ligand) appear in the Pt^{IV} complex as two unresolved doublets at $\delta = 4.70$ and 4.59 ppm. Furthermore, three sets of doublets were observed for the $ArCH_2Ar$ protons in the region $\delta = 4.30$–2.73 ppm in an approximate ratio of 2 : 1 : 1 (one set in the free ligand), which reveals the presence of three types of bridge methylene groups and two types of phenoxy methylene protons indicating that the species has lost the symmetry shown by the parent calixarene.

From the above discussion we conclude that this novel ligand displaces chloride ions from the coordination spheres of the central atoms in $AuCl_4^-$ and $PtCl_6^{2-}$ species, engaging itself in direct interaction with Au^{III} and Pt^{IV}. As far as the gold(III) adduct is concerned each of the pyridyl nitrogens participates in the coordination process.

Consequently, four $AuCl_3$ moieties are coordinated per unit of calix(4)arene [eq.(5)].

$$Pyr_4Calix(4) + 4\,KAuCl_4 \xrightarrow{CH_2Cl_2} Au_4Pyr_4Calix(4)Cl_{12} + 4\,KCl \quad (5)$$

As far as Pt^{IV} is concerned, microanalysis data in conjunction with the spectral properties described above lead us to conclude that each calix(4)arene coordinates to one $PtCl_4$ unit by providing two of its pyridyl nitrogens likely to be in proximal positions (two chloride ions are abstracted) to complete the octahedral arrangement required by the central atom, while the remaining pyridine rings in **1** carry protonated nitrogens. The overall process is represented as follows:

$$Pyr_4Calix(4) + K_2PtCl_6 + 2H^+ \xrightarrow{CH_2Cl_2} H_2{}^{2+}Pyr_2PtCl_4Pyr_2Calix(4) + 2\,KCl \quad (6)$$

Given that (a) the solubility of **1** in water is negligible, (b) *via* a pH switching mechanism the free ligand can be recovered from either the gold(III) or indeed the platinum(IV) adducts, this new pyridinocalix(4)arene is a potential extracting agent for the removal of Au^{III} and Pt^{IV} compounds from aqueous solutions. Attempts to isolate suitable crystals for X-ray crystallographic studies in order to investigate the structures of these adducts in the solid state (which may or may not be the same of that in solution) are now in progress.

(Received 4 June 1996; accepted 16 September 1996)

Abstract—The crystal and molecular structure of bis[2-(2-benzoxazolyl)phenol-*N*]dichloropalladium(II), was determined by the single-crystal X-ray diffraction. The palladium atom is at the symmetry centre in a square-planar geometry, where two 2-(2-benzoxazolyl)phenol (Hbxp) molecules are coordinated with their N atoms as unidentate ligands in the *trans* position. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: palladium(II) complex; 2-(2-benzoxazolyl)phenol; synthesis; X-ray analysis.

2-(2-Benzoxazolyl)phenol (Hbxp) has been known as an analytical chelating reagent for many bivalent metals such as zinc, cadmium and copper. Of these, the structures of the copper(II) and cadmium(II) complexes have already been determined by single-crystal X-ray diffraction [1]. As a result of ongoing work on the synthesis of the complexes of Hbxp, Furuhashi and workers have reported the synthesis and X-ray structure of the iron(III) [2], platinum(II) [3] and platinum(V) [4] complexes. In the iron(III) complex, Hbxp acts as a uninegative ion, bxp^-, coordinating to the metal atom through its benzoxazolyl-N and phenolato-O atoms and forming a chelate ring as reported in the cases of copper(II), cadmium(II) and palladium(II) [1]. In the case of platinum(V), Hbxp not only coordinates as a uninegative bxp^-, but the crystal contains neutral, uncoordinating Hbxp molecules. In the platinum(II) complex, Hbxp acts as a unidentate non-charged Hbxp ligand coordinating through its benzoxazolyl-N atom. Owing to a twisting of the planes of the two Hbxp ligands in the *cis* position of the square-planar Pt^{II}, two kinds of optical isomers could be obtained simultaneously. We have now obtained a new palladium(II) complex of Hbxp, $PdCl_2(Hbxp)_2$, in crystal form, which is different from that reported by Urdy [5]. The crystal and molecular structures were determined by the single-crystal X-ray diffraction technique.

EXPERIMENTAL

Synthesis of bis[2-(2-*benzoxazolyl*)*phenol*]*dichloropalladium*(*II*)

A solution of Hbxp (0.55 g) in n-propanol (150 cm^3) was added to a solution of *trans*-bis(benzonitrile)dichloropalladium [6] (0.5 g) in n-propanol (50 cm^3). The mixture was left standing for about 20 days. A light precipitate was removed by shaking and decanting, fresh n-propanol was added and this action was repeated many times until the light precipitate was completely removed, leaving a heavy precipitate. The residual orange–yellow crystals were dried on a porous sheet and in a desiccator over silica gel. Found: C, 52.1; H, 3.1; N, 4.6. Calc. for $C_{26}H_{18}N_2O_4Cl_2Pd$: C, 52.1; H, 3.1; N, 4.7%.

Crystal structure determination

The crystal used for the X-ray analysis was chosen from the synthesized product, then shaped into a $0.40 \times 0.40 \times 0.45$ mm^3 block. The crystallographic data and some experimental conditions used to obtain the intensity data are given in Table 1. The reflections were collected on a Rigaku AFC-5S automated four-circle diffractometer with the graphite-monochromated Mo-K_α radiation ($\lambda = 0.7107$ Å) [scan speed: 4° min^{-1} (θ)] at the University of Tokyo using the ω–θ scan technique.

Structure determination

The structure of the complex was solved using Patterson and Fourier syntheses. The positional and thermal parameters were refined by the full-matrix, least-squares procedure. At the final stage, all the non-hydrogen atoms were refined anisotropically. All the calculations were carried out with the SHELXS-86 [7] and the SHELXL-93 [8] programs for crystal structure determination.

RESULTS AND DISCUSSION

Selected bond lengths and bond angles for the title complex are given in Tables 2 and 3. Although there are two crystallographically independent complex molecules, each of which is positioned at the centre of symmetry, they are almost identical so only one is shown in Fig. 1, which shows the palladium complex as viewed from above the coordination plane. The complex molecules have the *trans* configuration with two Cl atoms and two Hbxp molecules, which act as neutral unidentate ligands through the N atoms of the oxazolyl rings. The Pd—Cl and Pd—N distances are 2.299 and 2.002 Å, respectively. These values are a little shorter than the values expected from the sum of Shannon's ionic radii [9] (Pd—N = 2.10;

Pd—Cl = 2.45 Å). The two phenol rings are also headed in opposite directions with a little twisting between the plane of the metal atom and the plane of the oxazolyl ring, the dihedral angle between the oxazoryl ring and the phenol ring being 128.90°. Thus, this palladium complex as a whole is in complete symmetry with the palladium atom at the symmetry centre of the complex molecule in a square-planar configuration. This is different from the palladium(II) complex reported by Urdy [5]. He obtained the complex formulated as $Pd(bxp)_2$, the ligand acting as a uninegative bidentate. We have synthesized the complex in a neutral medium which is different from Urdy's method, which used a basic medium.

A projection of the unit cell along the *b*-axis is shown in Fig. 2. The complex molecules are arranged in parallel and are laid along the *a*-axis.

(Received 15 April 1996; accepted 15 September 1996)

Abstract—Copper(II) and nickel(II) complexes of 2,3-butanedione bis(N(3)-methyl-, bis(N(3)-dimethyl-, bis(pyridyl- and bis(hexamethyleneiminylthiosemicarbazone), (H_2Bu3M, H_2Bu3DM, H_2Bupip and H_2Buhexim, respectively) have been prepared and studied spectroscopically. The four thiosemicarbazones have been characterized by their melting points, as well as IR, electronic and NMR (^{1}H, ^{13}C) spectra. The four coordinate copper(II) complexes have been studied by EPR spectroscopy and the copper(II) and nickel(II) complexes by a number of the spectroscopic techniques mentioned above. Upon formation of these complexes, loss of the N(2)H hydrogens occurs and the ligands coordinate to the metal centers as dianionic, tetradentate N_2S_2 ligands. The crystal structures of H_2Bupip and the nickel(II) complex of 2,3-butanedione N3-methyl-phenylthiosemicarbazone, [Ni(Bu3MPh)], have been solved. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: bis(thiosemicarbazone); copper; nickel; crystal structure.

During the past several years a large number of heterocyclic tridentate NNS [1,2] and ONS [1–3] chelating thiosemicarbazones has been studied extensively. However, a lesser effort has been directed to the synthesis and characterization of metal complexes of tetradentate N_2S_2 bis(N3-substituted thiosemicarbazone) ligands [4,5]. Crystal structure determinations have shown that 1,2-bis(thiosemicarbazones) form square-planar N_2S_2 tetradentate ligands with copper(II) and that sulfurs of adjacent molecules coordinate weakly in the axial positions [6,7]. Due to the antitumor activity of α-diketone and α-ketoaldehyde bis(thiosemicarbazones) [8]as well as their metal complexes [9], a series of copper(II) and nickel(II) complexes of 2,3-butanedione bis(N(3)-substituted thiosemicarbazones) have been prepared; characterization of these complexes includes spectroscopic and physical techniques. The crystal structures of a representative 2,3-butanedione bis(thiosemicarbazone), H_2Bupip, and nickel(II) complex, [Ni(Bu 3MPh)] are included (Figs 1 and 2, respectively).

EXPERIMENTAL

N(3)-methylthiosemicarbazide was purchased from Aldrich and used without further purification. N(3)-dimethyl-, piperidyl and hexamethyleneiminylthiosemicarbazide were prepared by the method described by Scovill [10]. The different 2,3-butanedione bis(N(3)-substituted thiosemicarbazones) were prepared by stirring 2,3-butanedione and an excess (greater than 2:1 mol ratio thiosemicarbazide to 2,3-butanedione) of the desired thiosemicarbazide in absolute ethanol with a few drops of H_2SO_4 added to catalyse the reaction. The purity of these bis(thiosemicarbazones) has been confirmed by their ^{1}H and ^{13}C NMR spectra. The metal complexes were prepared with a 2–4 h reflux of an absolute ethanol solution of the bis(thiosemicarbazone) with an equimolar amount of copper(II) or nickel(II) acetate. The volume was reduced on a warm plate (35°C) until sufficient solid was present, filtered with suction, washed to apparent dryness with anhydrous diethyl ether and dried at 35°C. Partial elemental analyses were performed by National Chemical Consulting,

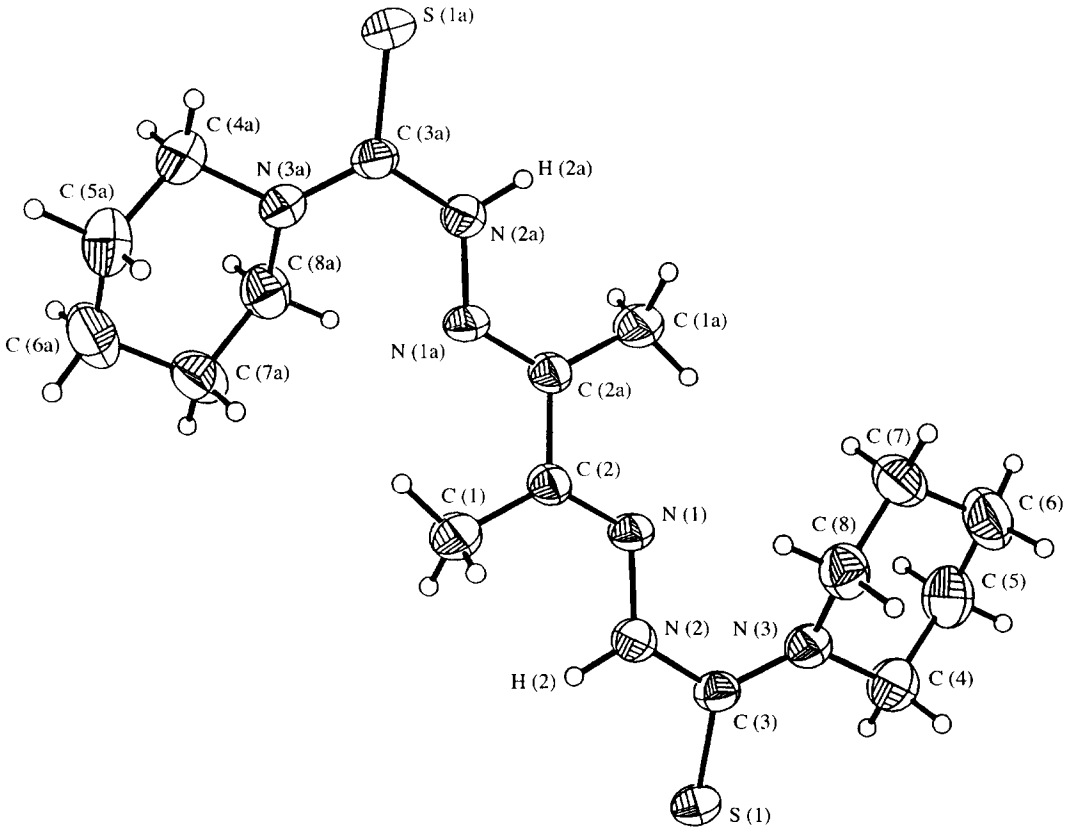

Fig. 1. A perspective view of H_2Bupip.

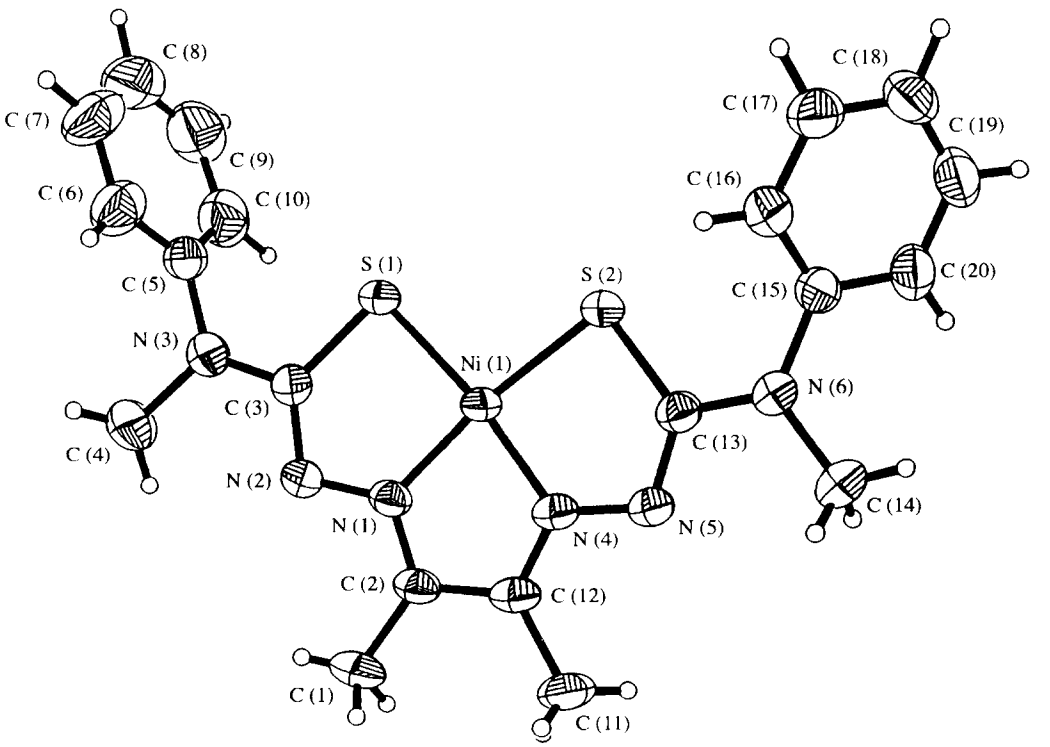

Fig. 2. A perspective view of [Ni(Bu3MPh)].

Inc. of Tenafly, NJ, and the spectral methods and instrumentation were accomplished as follows: molar conductivities were measured with a Beckmann Conductivity Bridge using 10^{-3} M solutions, magnetic susceptibilities were determined with a Johnson–Matthey Magnetic Susceptibility balance, IR spectra were recorded as Nujol mulls between CsI plates using a Perkin–Elmer 760 spectrometer, electronic spectra were acquired as Nujol mulls impregnated on pieces of filter paper and as DMF solutions in conventional quartz 1 cm cells with a Perkin–Elmer 330 spectrometer, EPR spectra were recorded with a Varian E104 spectrometer using a conventional insert Dewar and calibrated with DPPH and NMR spectra were acquired with a Varian 300 MHz Gemini spectrometer using $CDCl_3$ or dimethyl sulfoxide-d_6 as the solvent. Residual chloroform and tetramethylsilane peaks were used as internal references in $CDCl_3$ and DMSO-d_6, respectively.

The crystals of H_2Bupip, [Ni(Bu3MPh)] and [Ni(Buhexim)] (a crystal of this latter compound could not be solved with sufficient accuracy except to show the mode of coordination) were grown by slow diffusion of diethyl ether (−10 C) into chloroform. Data were collected for H_2Bupip on a Nicolet P3/F diffractometer and for [Ni(Bu3MPh)] on a Siemens P4 diffractometer. A yellow laminar of H_2Bupip having dimensions 0.40 × 0.36 × 0.04 mm and a black rectangular crystal of [Ni(Bu3MPh)] having dimensions 0.64 × 0.35 × 0.26 mm were mounted in random orientation on glass fibers. Crystal stability was monitored using three standard reflections every 97 reflections for both compounds. 1181 reflections were collected and 983 unique reflections, 876 ($F > 3\sigma F$) were used in the structure solution and refinement of H_2Bupip; 7462 reflections were collected and 6012 unique reflections, 3342 ($F > 6\sigma F$) were used in structure solution and refinement of [Ni(Bu3MPh)]. Semi-empirical absorption corrections were applied for both crystals. The structures were solved by direct methods [11] and refined by the full-matrix least-squares technique with anisotropic temperature factors for the non-H atoms. The coordinates of the C—H atoms were constrained, the N—H atoms were refined and both assigned a fixed isotropic temperature factor, $U = 0.06$ Å^2. The minimized function was $\Sigma\ w(F_o - F_c)^2$ with, $w = [\sigma^2(F_o) + 0.0016(F_o)^2]^{-1}$ and $w = [\sigma^2(F) + 0.0004F^2$ for H_2Bupip and [Ni(Bu(4)MPh)], respectively. The residual electron density was within −0.35 and 0.25 e Å^{-3} and −0.26 and 0.63 e Å^{-3} for H_2Bupip and [Ni(Bu3MPh)], respectively. Scattering factors were taken from International Tables for X-ray Crystallography (1974, Vol. IV).

RESULTS AND DISCUSSION

Table 1 shows a summary of crystal data and X-ray analysis information for H_2Bupip and [Ni(Bu3MPh)]. Selected interatomic distances are compiled in Table 2 and bond angles in Table 3; the supplementary material contains a complete list of bond distances and angles, the mean plane equations and the hydrogen bonding parameters, as well as a list of the final positional and equivalent isotropic thermal parameters of the non-H atoms for both compounds. Since H_2Bupip is centrosymmetric, its supplementary material is based on one half the molecule. Tables 2 and 3 are arranged to compare the analogous bonds in the two compounds. Perspective views, as well as the numbering system, for H_2Bupip and [Ni(Bu3MPh)] are shown in Figs 1 and 2, respectively, and the packing of the molecules in Figs 3 and 4.

The two thiosemicarbazone moieties of H_2Bupip are located on opposite sides of the four carbon butyl backbone which minimizes their intramolecular interactions. Therefore, no intramolecular hydrogen bonding interactions are available for N(2)H (or N(3)H of H_2Bu3M). The two thiosemicarbazone moieties of the centrosymmetric H_2Bupip are, of course, identical, and the values for only one are listed in Tables 2 and 3, respectively. The C(3)—N(3) bond distance of 1.329(4) Å is considerably shorter than 1.371(4) Å for N(2)—C(3) and the former bond is not much longer than the 1.288(3) Å found for azomethine C(2)—N(1), which is formally a double bond. All three of these C—N bonds are considerably shorter than the single N(3)—C(4) and N(3)—C(8) bonds of the piperidyl ring (i.e. *ca* 1.466 Å). Thus, all three of the C—N bonds of the thiosemicarbazone moiety have significant double bond character (C(2)—N(1) > C(3)—N(3) > C(3)—N(2)).

The bond angles about C(3) show the steric effect of the bulky piperidyl substituent. The S(1)—C(3)—N(3) angle with the piperidyl nitrogen is 124.5(4)° compared with 117.4(4)° for the thiosemicarbazone's S(1)—C(3)—N(2) angle. The thiosemicarbazone moiety, C(2)—N(1)—N(2)—C(3)—N(3)—S(1) has a mean plane deviation of 0.122 Å with N(2) showing the greatest displacement of 0.337(3) Å. The dihedral angle between C(1)—C(2)—N(1)—N(2) and the remainder of the thiosemicarbazone moiety, N(2)—C(3)—N(3)—S(1) is 34.4(1)° due to a twisting of the moiety. The torsion angle of N(1)—N(2)—C(3)—S(1) is 146.1(5)° and is due primarily to the repulsion of S(1) and the piperidyl substituent, as well as weak intermolecular hydrogen bonding between N(2)H and a neighboring molecule's S(1) (Fig. 3).

The two thiosemicarbazone moieties of [Ni(Bu3MPh)] possess some significantly different bond lengths and angles so that values for both are included in Tables 2 and 3. Upon complexation the azomethine bond, C(2)—N(1), although coordinated to Ni^{II} *via* this nitrogen, is only slightly longer in [Ni(Bu3MPh)] than in H_2Bupip. In contrast, on change from a thione to a thiolato function and coordination by the sulfur atom, the S(1)—C(3) and S(2)—C(13) bonds are lengthened by *ca* 0.7 Å. Also, the N(2)—C(3) and

N(5)—C(13) bonds, which formally become double bonds on coordination, are shortened by *ca* 0.5 Å. Other bonds of the thiosemicarbazone moiety, as well as the carbon–carbon bond, C(2)—C(12), between the two azomethine groups, undergo smaller changes on coordination. As expected, the Ni—S bonds are longer than the Ni—N bonds by *ca* 0.3 Å. A crystal of [Ni(Buhexim)] has a similar structure, but we were unable to solve it with sufficient accuracy to comment further.

The bond angles about the nickel(II) center are indicative of the sizes of the donor atoms. The S(1)—Ni(1)—S(2) angle is 102.12(5)°, the S(1)—Ni(1)—N(1) and S(2)—Ni(1)—N(4) angles are 87.3(1) and 87.2(1)°, respectively, and the N(1)—Ni(1)—N(4) angle is 83.3(2)°. The mean plane

deviation of the nickel coordination center, Ni(1)—S(1)—S(2)—N(1)—N(4) is 0.016 Å with N(1) having the greatest displacement of 0.042(2) Å. The three five-membered chelate rings also deviate from planarity as follows: Ni(1)—N(1)—C(2)—C(12)—N(4), Ni(1)—N(1)—N(2)—C(3)—S(1) and Ni(1)—N(4)—N(5)—C(13)—S(2) have mean plane deviations of 0.019, 0.022 and 0.015 Å, respectively. In the first plane, Ni(1)—N(1)—C(2)—C(12)—N(4), the Ni atom is essentially in the plane, the two nitrogens slightly below the plane [0.028(2) Å] and the two carbons slightly above the plane [0.023(3) Å]. The angles between the coordinate plane, Ni(1)—N(1)—S(1)—S(2)—N(4), and the two phenyl rings, C(5)—C(6)—C(7)—C(8)—C(9)—C(10) and C(15)—C(16)—C(17)—C(18)—C(19)—C(20), are 80.1(1) and 50.1(1)°, respectively. Compared with the uncomplexed thiosemicarbazone moiety of H_2Bupip, which has a mean plane deviation of 0.122 Å, the coordinated thiosemicarbazone moieties,

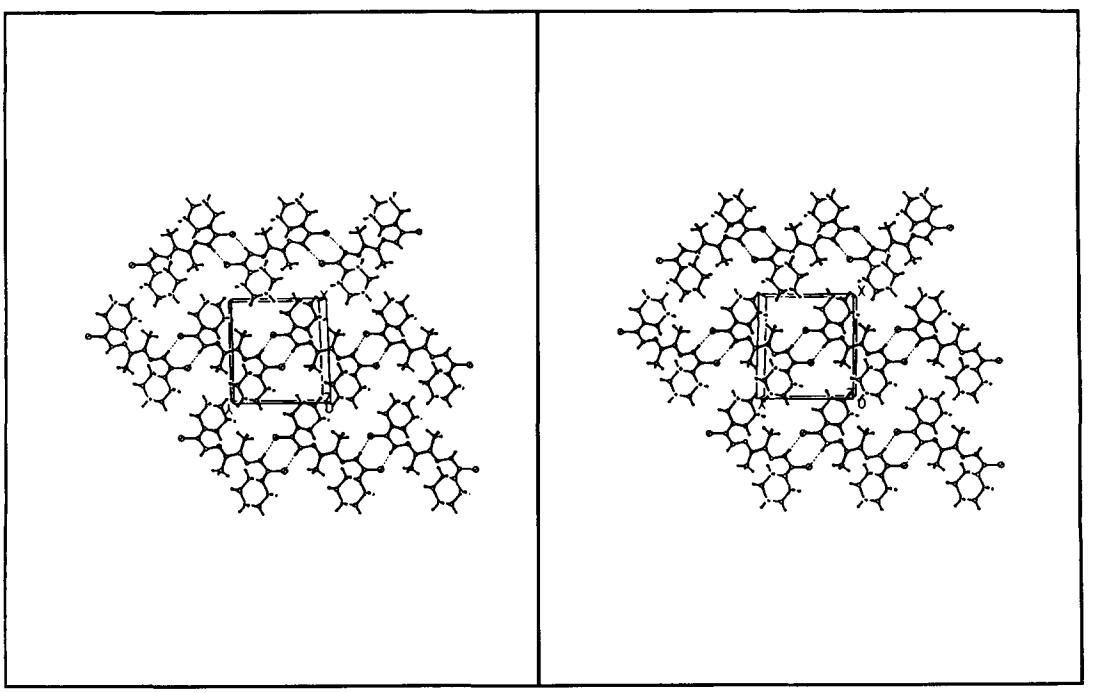

Fig. 3. Packing arrangement for H_2Bupip.

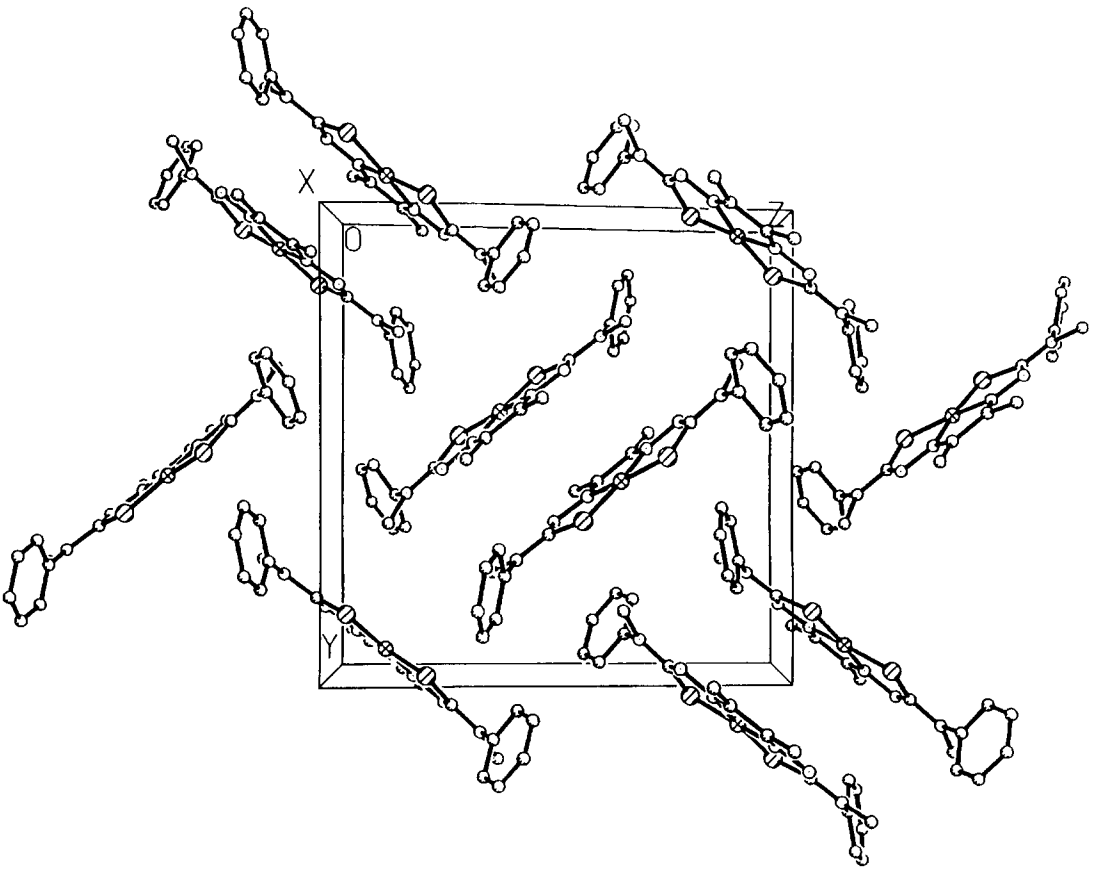

Fig. 4. Packing arrangement for [Ni(Bu3MPh)].

C(2)—N(1)—N(2)—C(3)—S(1)—N(3) and C(12)—N(4)—N(5)—C(13)—S(2)—N(6), are considerably more planar having mean deviations of 0.017 and 0.009 Å, respectively.

In Table 4 selected bond distances and angles are compiled for 2-keto-3-ethoxybutyraldehyde bis(thiosemicarbazone), H_2KTS,[12] a heterocyclic N(3)-substituted thiosemicarbazone [13] and some metal complexes [5,14,15] to compare with the values reported here for H_2Bupip and [Ni(Bu3MPh)]. Comparing the bond distances of H_2KTS to those of H_2Bupip shows that N(1)—N(2), N(2)—C(3) and C(3)—N(3) are shorter for H_2KTS, but the bond angles are similar. In contrast, the bonds in [Ni(BuBzTHZ)], where BuBzTHZ is the dianion of 2,3-butanedione bis(benzylthiohydrazone) are more similar to those of [Ni(Bu3MPh)]. For example, the C(2)—N(1) bond distances are nearly the same and the small changes in the other bond distances in Table 4 for the two complexes probably represent the differences in the two ligands. The structure of HAchexim, 2-acetylpyridine 3-hexamethyleneiminyl-thiosemicarbazone, is the bifurcated form where the hydrogen shifts to the azomethine nitrogen and hydrogen bonds to the pyridyl N and thiol S. A result of this bifurcated hydrogen bonding is that the thiosemicarbazone moiety is conjugated resulting in a bright yellow solid. Even with this drastic change, the bond lengths within the thiosemicarbazone moiety for H_2Bupip and HAchexim are nearly the same. However, the bond angles in the azomethine part of the moiety, which is involved in hydrogen bonding, are considerably different. For example, C(2)—N(1)—N(2) is *ca* 117.4° for H_2Bupip, but 125° for HAchexim and N(1)—N(2)—C(3) is *ca* 119° for H_2Bupip, but 110.8° for HAchexim.

A comparison of the bond distances and angles of the thiosemicarbazone moieties of [Ni(Bu3MPh)] with those of [Cu(KTS)] [6] shows no major differences even though bonding to nickel(II) by thiosemicarbazone moieties is considerably stronger than for copper(II).[15] The M—N bond distances are *ca* 1.850(2) and 1.970(5) Å for [Ni(Bu3MPh)] and [Cu(KTS)], respectively; the M—S bond distances of *ca* 2.155(1) and 2.265(1) Å also show stronger bonding to the nickel(II) center. However, the nickel(II) complex of 2,3-butanedione bis(benzylthiohydrazone),[14] [Ni(BuBzTHZ)], has almost identical Ni—N and Ni—S bond distances of *ca* 1.853(2) and 2.151(1) Å, respectively. Unfortunately, the bond angles for this complex were not reported. [Ni(Pe3DH)]NCS, where Pe3DH is the anion [loss of C(3)*H*] of 2,4-pentanedione bis(thiosemicarbazone), would be expected to be considerably different from the other

Table 4. Comparison of thiosemicarbazone moiety bond distances and angles for H_2Bupip, H_2KTS and some heterocyclic thiosemicarbazones (the estimated standard deviations for these structures are comparable to those shown in Table 2)

[a]2-Keto-3-ethoxybutyraldehyde-bis(thiosemicarbazone).[12]
[b]Ketone thiosemicarbazone.
[c]Aldehyde thiosemicarbazone.
[d]2-Acetylpyridine 3-hexamethyleneiminylthiosemicarbazone.[13]
[e]Nickel(II) complex of 2,3-butanedione bis(benzylthiohydrazone).[14]
[f]Copper(II) complex of 3-ethoxy-2-oxobutyraldehyde bis(thiosemicarbazone).[6]
[g]Nickel complex of 2,4-pentanedione bis(thiosemicarbazone).[5]

metal complexes since its thiosemicarbazone moieties do not lose the N(2)*H*s on complexation.[5] Information in Table 4 confirms that the bonds of [Ni(Pe 3DH)]NCS are considerably different from those of [Ni(Bu(4)MPh)], [Ni(BuBzTHZ)] and [Cu(KTS)].

The ^{1}H NMR spectral assignments for the CH_3 functions of the butyl backbone, as well as N(2)*H* and N(3)*H* are listed in Table 5 for the series of 2,3-butanedione N(3)-substituted bis(thiosemicarbazones) along with their diamagnetic nickel(II) complexes. The CH_3 assignments are essentially the same for the various bis(thiosemicarbazones); differences are expected for the spectrum of H_2Bu3M, which was recorded in DMSO-d_6 due to its low solubility in $CDCl_3$. Also, the thiosemicarbazone moiety's N(2)*H* chemical shift is essentially the same (i.e. δ = 8.348–8.422) for the various bis(thiosemicarbazones). These chemical shifts indicate an absence of hydrogen bonding, consistent with the two thiosemicarbazone moieties being on opposite sides of the butyl backbone. N(3)*H* is assigned at δ = 10.200 in the spectrum of H_2Bu3M, indicating hydrogen bonding with DMSO-d_6.

Upon complexation the bis(thiosemicarbazones) are deprotonated and the N(2)*H* signals are absent in the ^{1}H NMR spectra of the nickel(II) complexes. In the spectrum of [Ni(Bu3M)] the N(3)*H* appears at δ = 7.670, indicating hydrogen bonding to the DMSO

Table 6. Colors, magnetic susceptibilities and partial elemental analyses of copper(II) and nickel(II) complexes of 2,3-butanedione bis(N(3)-substituted thiosemicarbazones)

Compound	Color	C	H	μ (B.M.)
[Cu(Bu3M)]	Brown	29.5(29.9)	4.3(4.4)	2.4
[Cu(Bu3DM)]	Red–brown	34.4(34.3)	5.3(5.2)	1.6
[Cu(Bupip)]	Red–brown	44.4(44.7)	6.1(6.1)	1.8
[Cu(Buhexim)]	Red–brown	47.1(47.2)	6.6(6.6)	2.0
[Ni(Bu3M)]	Dark green	30.0(30.3)	4.5(4.5)	0.0
[Ni(Bu3DM)]	Brown	34.7(34.8)	5.3(5.3)	0.0
[Ni(Buhexim)]	Dark green	47.7(48.3)	6.7(6.7)	0.0

solvent molecules does not occur in the complex. The thiosemicarbazone moiety arms of a free ligand are on opposite sides of the butyl backbone and, therefore, the N(3)H functions are in a more open environment in H_2Bu3M than in [Ni(Bu3M)]. This steric crowding, as well as electronic effects, may account for the lack of hydrogen bonding by DMSO in the ^{1}H NMR spectrum of [Ni(Bu3M)]. In the nickel(II) complex's spectra the butyl backbone CH_3 peaks are shifted upfield (δ = 1.872–1.918) compared with the uncomplexed thiosemicarbazones due to shielding of the protons *via* π-back-bonding by the metal center into the azomethine π system. Also shown in Table 5 are the ^{13}C resonances showing significant shifts on complexation. *C*=S shifts upfield by 2–4 ppm consistent with the increase in bond distance resulting in a less polar carbon. The C=N bond distance is essentially unchanged on coordination, but *C*=N shifts downfield by 7–9 ppm in the complexes suggesting considerable back donation into the π-electron system by the nickel(II) center.

The colors, partial elemental analyses and magnetic susceptibilities for the isolated metal complexes are shown in Table 6. Most of the complexes are various shades of brown and two of the nickel(II) complexes are dark green. The nickel complexes are diamagnetic indicative of square-planar N_2S_2 tetradentate coordination. The copper(II) complexes are paramagnetic and have magnetic moments close to the theoretical spin only value (1.73 B.M.). Thus, a square-planar N_2S_2 ligation about the copper(II) ion is probable.

The IR spectral assignments most useful for determining the ligand's mode of coordination are listed in Table 7. The shift of ν(C=N) spectral bands of the bis(thiosemicarbazones) from 1550–1578 to 1540–1568 cm^{-1} for the metal complexes indicates the coordination of the azomethine nitrogen. The formation of the complexes and simultaneous loss of the protons from the thiosemicarbazone moieties produces a second carbon–nitrogen double bond, which often complicates this portion of the spectrum. Also, the bands having considerable ν(C=S) character shift from the range 822–843 cm^{-1} in the bis(thiosemicarbazones) to the lower energy range 750–778 cm^{-1} for the metal complexes indicating coordination of the thiolato sulfur atoms. Bands in the 343–375 cm^{-1} region have been assigned to ν(MS) and bands in the 428–465 cm^{-1} region to the ν(MN) supporting the coordination of the ligands as tetradentate N_2S_2 chelating agents [16].

Listed in Table 8 are the band maxima of the solid state and solution (DMF) electronic transitions for the four thiosemicarbazones and their copper(II) and nickel(II) complexes. Omitted from Table 7 are the higher energy $\pi \rightarrow \pi^*$ transitions (*ca* 42,000 cm^{-1}), which are not significantly altered on complex formation. The $n \rightarrow \pi^*$ transitions associated with the azomethine and thioamide functions are found at *ca* 29,000–33,000 and 24,000–29,000 cm^{-1}, respectively, in the solid-state spectra. In solution three bands are observed; the higher energy $n \rightarrow \pi^*$ band appears to have been resolved into two peaks for many of the compounds.

The spectra of the complexes of both metal ions generally show the higher energy band unshifted and a second band at about 29,000 cm^{-1}. This latter band has been assigned by others to a S(σ) $\rightarrow$ Cu^{II} charge transfer band [14]. The spectra of the heavier nickel(II) complexes have a band at a similar energy which we assign to S(σ) $\rightarrow$ Ni(II). The lower energy $n \rightarrow \pi^*$ band in the thiosemicarbazone spectrum is apparently shifted to higher energy in the spectra of the metal complexes and it also contributes to the band in the 29,000 cm^{-1} region. Additional bands in the 20,000–21,000 cm^{-1} region of the spectra of the copper(II) complexes and 22,000–24,000 cm^{-1} for the nickel(II) complexes are due to S(π) $\rightarrow$ M^{II} charge transfer bands [17,18]. Solid-state spectra of the copper(II) complexes, except for [Cu(Bu3M)], have $d \rightarrow d$ bands at *ca* 18,000 and 14,000 cm^{-1}, $^2B_{1g} \rightarrow {}^2E_g$ and $^2B_{1g} \rightarrow {}^2B_{2g}$, respectively, which is consistent with a planar stereochemistry. In DMF solution the number of $d \rightarrow d$ bands is reduced to one and the single band is shifted to higher energy, suggesting weak interaction with the solvent. This shift also shows that solid-state interactions are important for the copper(II) complexes.

As shown by crystal structure determinations of related copper complexes,[6,7] sulfur atoms from adjacent coordination spheres weakly interact in the axial positions of the copper(II) center of each CuN_2S_2 chromophore. The spectra of the nickel(II) complexes do not have bands below 10,000 cm^{-1}, consistent with

their planar coordination. Like the copper(II) complexes there are two bands in the solid-state spectra assignable to $d \rightarrow d$ transitions. However, the single band occurring in their solution spectra is at considerably lower energy than found for the copper(II) complexes, indicating that interaction with the solvent is considerably stronger for the nickel(II) complexes. That is, the solid-state interaction between neighboring complexes in the nickel(II) compounds must be less than for the copper(II) complexes, but interaction with the DMF solvent molecules appears to be greater for the nickel(II) complexes.

Table 9 contains the solid-state and solution (DMF) EPR parameters for the copper(II) complexes. As would be expected, the values for $g_\perp$ (or $g_\parallel$) are rather low, indicating considerable covalency, a consequence of two sulfur donor atoms in the coordination spheres. Of the complexes studied [Cu(Bu3M)] has the highest value for $g_\perp$, 2.113, while the other three complexes have $g_\perp$ below 2.100 at room temperature. This suggests that the bonding to sulfur is weaker for [Cu(Bu3M)], when there is a N(3)H present, than when hydrocarbon substituents are attached to the thioamide nitrogen, N(3). On cooling to 77 K all values for $g_\perp$ increase, suggesting greater interaction with the sulfur donor atoms of adjacent copper(II) centers at the lower temperature. A small increase in $g_\perp$ ($g_\parallel$) also occurs in the frozen solution

Table 9. EPR spectra the copper(II) complexes of 2,3-butanedione bis(N(3)-substituted thiosemicarbazones)

Compound	Phase	Temperature[a]	$g_{\parallel}$ or g_1	g_2	$g_{\perp}$ or g_3	g_{av} or g_0	$A_{\parallel}$(G)	A_0(G)

		77 K	2.102		2.022	2.049	195	

[a]RT = room temperature.

spectra, suggesting a weak interaction with solvent molecules, although the increase of 0.01 is considerably less than 0.03–0.04 observed for Cu(NNS)Cl centers [18]. Also, the values of g_0 for the room-temperature solution spectra are not much higher than the room-temperature solid state g_{av}. This is in agreement with the electronic spectra of the copper(II) complexes, which indicated that although there was some interaction with solvent molecules, it is not substantial. The large values for both A_0 and A are consistent with the strong planar bonding that exists in these complexes. A 1% [Cu(Bupip)]/[Ni(Bupip)] solid produces a spectrum with the copper hyperfine lines, and the highest field parallel feature is nicely resolved to show the nitrogen superhyperfine lines ($A_N = 18$ G) in a 1:2:3:2:1 ratio consistent with the coordination of two equivalent nitrogen donor atoms. The perpendicular feature is also resolved, but falls right on the third parallel feature making interpretation difficult.

The covalency parameter, α^2, in frozen DMF equals 0.635, 0.633, 0.659 and 0.629 for [Cu(Bu3M)], [Cu(Bu3DM)], [Cu(Bupip)] and [Cu(Buhexim), respectively, indicating considerable covalency in their bonding. This value is at the lower end of the range 0.63–0.84 proposed [19] for CuN_4, as would be expected with sulfur in place of two nitrogens in the coordination sphere. The Racah parameters, $k_{\parallel}$ and $k_{\perp}$, have values of 0.43, 0.55; 0.42, 0.59 and 0.46, 0.55 for [Cu(Bu3DM)], [Cu(Bupip)] and [Cu(Buhexim)], respectively. These values also show that there is considerable covalent nature [20] in the metal–ligand bonding of these complexes and that in-plane π-bonding is more important than out-of-plane π-bonding.

Each compound of this study was subjected to antifungal testing against *Paecillomyces variotii* at 1000 μg cm^{-3} concentrations with the following results: H_2Bu3M showed no activity, H_2Bu3DM yielded a small inhibition zone of 8.0 mm (6.0 mm = no activity), H_2Bupip gave a large inhibition zone of 32.6 mm and H_2Buhexim, a zone of 21.8 mm. H_2Bupip was active at 100 μg cm^{-3} (zone of inhibition = 25.9). None of the nickel(II) complexes showed any activity, and [Cu(Bupip)] and [Cu(Buhexim)] were inactive. [Cu(Bu3M)] and [Cu(Bu3DM)] showed small zones of 9.1 and 10.1 mm, respectively. Like other thiosemicarbazones tested for antifungal activity, the substituent attached at N(3) plays a significant role in the compounds activity [21]. Also, the copper(II) complexes, which are often more active than the uncomplexed thiosemicarbazone [22,23], are less active in this series of compounds.

(*Received* 26 *February* 1996; *accepted* 15 *September* 1996)

Abstract—The interaction of several β-diketones [pentane-2,4-dione, 1,3-diphenylpropane-1,3-dione, 1,1,1-trifluoro-4(2-thienyl)butane-2,4-dione] and their sodium salts with complexes of the type $[ML(CH_3COO)_2]X\cdot n(H_2O)$, where M is La^{III}, Eu^{III} or Y^{III}, L is the macrocyclic ligand $C_{22}H_{26}N_6$, X is Cl^- or CH_3COO^- and n is 4–9, was investigated in solution by NMR and luminescence spectroscopy. A number of crystalline $\{ML\}$-(β-diketonate) complexes were isolated and characterized; the structure of one member of the series, $[EuL(CH_3COO)\{(C_6H_5CO)_2CH\}](CH_3COO)\cdot 6(H_2O)$, was established by X-ray crystallography. The structure is ionic; the 10-coordinate Eu^{III} is bonded to the six nitrogens of the macrocyclic ligand, two oxygens of a bidentate acetate and two oxygens of the chelating β-diketonate. The coordinated acetate and the β-diketonate are situated on opposite sides of the $\{EuL\}$ macrocycle; an uncoordinated acetate provides charge neutrality.

Keywords: lanthanides; macrocycles; β-diketones; luminescence.

The structures and properties of the lanthanide(III) complexes of the formula $[ML(OAc)_2]X\cdot nH_2O$, where M is a trivalent lanthanide, AcO is acetate, L is the six-nitrogen-donor macrocyclic ligand $C_{22}H_{26}N_6$ (Fig. 1), X is chloride or acetate and n is 4–9, have been extensively investigated [1–10]. The Eu^{III} complex, which exhibits long-lived, UV-excited luminescence in aqueous solution at room temperature,[3] has attracted considerable attention as a prototype of a new class of luminescent markers for cytology and immunology [12,13]. It was also reported that the luminescence of the $[EuL(Ac)_2]^+$ macrocyclic entity can be considerably enhanced by substitution of the acetates with other counterion ligands [8]. These results suggested that a study of the interaction between β-diketonates and the $\{ML\}$ macrocycles could be especially interesting, since β-diketonates are

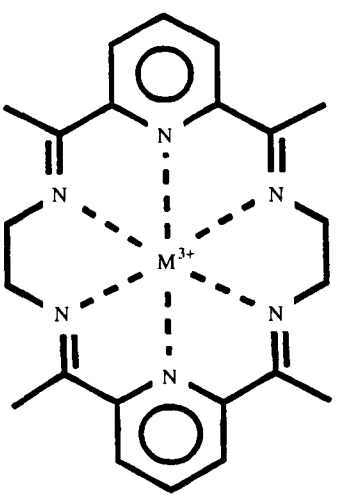

Fig. 1. Schematic formula of the $\{ML\} = \{M(C_2H_{26}N_6\}^+$ macrocyclic moiety.

known to form very stable complexes with the lanthanide(III) ions [14(a–c)] and their Eu^{III} complexes are highly luminescent [15].

The lanthanides selected for this study were Eu^{III}, for its luminescence, and La^{III} because it is diamagnetic and allows reliable assignments of NMR spectra. The lanthanide-like Y^{III} was also investigated because its ionic radius and coordination properties closely resemble those of Eu^{III}. The β-diketones selected were 1,1,1-trifluoro-4(2-thienyl)butane-2,4-dione and 1,3-diphenylpropane-1,3-dione, the anions of which are known to form highly stable [14(b,d)] and luminescent [15] complexes with the free Eu^{III} ion; pentane-2,4-dione was also investigated because the structures [16] and stabilities [14(a–c)] of its complexes with lanthanide(III) ions are well established.

EXPERIMENTAL

Materials and procedures

Pentane-2,4-dione (acetylacetone, HACAC), 1,3-diphenylpropane-1,3-dione (dibenzoylmethane, HDBM) and 1,1,1-trifluoro-4(2-thienyl)butane-2,4-dione (thenoyltrifluoroacetone, HTTFA), from Aldrich Chemical Co., were distilled or recrystallized before use. Sodium pentane-2,4-dionate, NaACAC, and sodium 1,3-diphenylpropane-1,3-dionate, NaDBM, were prepared from the diketones and sodium metal (1 : 1 mol ratio) in anhydrous ethanol, followed by evaporation to dryness under reduced pressure and recrystallization from methanol/diethyl ether. The macrocyclic complexes $[ML(OAc)_2]Cl\cdot 4(H_2O)$ and $[ML(OAc)_2]Ac\cdot 9(H_2O)$ were prepared as previously described [1,8]. Deuterated and spectrograde solvents (Aldrich) were used as received. Microanalyses were performed by Atlantic Microlabs, Atlanta, GA (for C, H, N) and Galbraith Laboratories, Knoxville, TN (for S, Cl).

NMR spectra. Experiments were carried out with a GE QE-300 spectrometer at ambient temperature (24–26°C). Chemical shifts (as δ for ^1H spectra) are reported in ppm; coupling constants, J, are given in Hz; other abbreviations are specified in Table 1. Proton spectra were referenced to tetramethylsilane (TMS, 0.00) or to the residual proton signal of the solvent: $CHCl_3$, 7.26(1); CD_3OD, 3.30(5); deuterodimethylsulfoxide, DMSO-d_6, 2.49(5). ^{13}C spectra were referenced to the solvent signal: $CDCl_3$, 77.0(3); CD_3OD, 49.0(7); DMSO-d_6, 39.5(7). Assignments of ^{13}C spectra were confirmed by attached proton test (APT) and heteronuclear correlation (HETCOR) experiments. For the paramagnetic Eu^{III} complexes, both proton and ^{13}C chemical shifts varied slightly with sample concentration and moisture content; integrations were within ±10% of expected values.

IR spectra. Spectra were obtained on a Perkin–Elmer Model 1600 FT instrument (4000–500 cm^{-1}). Samples were examined as KBr pellets and as mulls in hexachlorobutadiene (4000–1800 and 1500–1300 cm^{-1}, on NaCl disks) and Nujol (1800–1500 and 1300–400 cm^{-1}, on KBr disks); no difference was observed between the two sets of spectra in KBr and those in mulls. Absorption frequencies are reported in cm^{-1}; abbreviations: s = strong, m = medium, w = weak, br = broad, v = very; an asterisk indicates an absorption only partly resolved from an adjacent stronger peak.

Absorption, emission and excitation spectra. UV–vis absorption spectra (230–600 nm) were recorded on a Shimadzu 265 UV–vis spectrophotometer. Excitation spectra (230–550 nm) and emission spectra (550–710 nm) of the {EuL}-(β-diketonate) complexes were recorded on a SLM 8000 spectrofluorimeter, using methanol solutions.

Syntheses of solid complexes

The complexes were prepared by the general procedures outlined below; all were obtained as hydrates. Different samples of the same complex, although identical in every other respect, occasionally contained different amounts of lattice water; in such cases, formulae and microanalyses (Table 2) are reported only for one hydrate. All solid complexes were stable to air and moisture at room temperature; they gradually lost water when heated between 35 and 110°C, but rapidly rehydrated upon cooling in a moist atmosphere. Complexes containing chloride and acetate counterions were very soluble in chloroform, methanol, ethanol and other polar organic solvents; they were insoluble in diethyl ether, hydrocarbons and water. Complexes containing perchlorate counterions were sparingly soluble in dimethylsulfoxide and dimethylformamide; they were insoluble in other common solvents and water. In the following, the abbreviations ACAC, DBM and TTFA indicate the mono-negative anions of the corresponding diketones.

(1) *Reaction of HDBM with* $[ML(OAc)_2]X\cdot n(H_2O)$, *where* M = La^{III}, Eu^{III} *or* Y^{III}, X = Cl *or* OAc *and* n = 4 or 9. The complex (2×10^{-4} mol) was dissolved in methanol (5 cm^3), solid HDBM was added and the mixture was warmed with stirring at *ca* 50°C until all HDBM had dissolved. The resulting pale yellow solution was cooled and diluted with diethyl ether until a slight persistent cloudiness formed. The mixture was gravity filtered, discarding the solid; the clear solution was further diluted with diethyl ether to a persistent milky cloudiness and stored in a freezer. A small amount of a pale yellow solid formed after several days; it was filtered off, washed with diethyl ether and dried at 60°C in air. Additional fractions of yellow crystals were similarly obtained by successive dilutions of the clear filtrate with diethyl ether, followed by prolonged cooling in a freezer. Each fraction was examined for homogeneity with a microscope and characterized by IR and ^1H NMR spectra. Various HDBM-to-{ML} mole ratios

were used: 1:1 and 2:1 for {LaL} and {YL}; 1:1, 2:1, 3:1, 4:1 and 5:1 for {EuL}.

All fractions from the 1:1 ratio experiments, as well as the first fractions from the higher ratio experiments, were mixtures (white and yellow crystals) consisting of the parent complex (40–60%) and of a species with a 1:1 DBM-to-{ML} ratio. Subsequent fractions from experiments with 2:1 or higher HDBM-to-{ML} ratios appeared homogeneous (yellow plates or prisms) and a few consisted only of the 1:1 DBM-to-{ML} complex. Fractions that contained the residual parent complex (10–20%) were further treated with an excess of HDBM until pure 1:1 DBM-to-{ML} complexes were obtained (formulae given below); the total yields of 1:1 DBM-to-{ML} complexes ranged from 30 to 50% in different experiments. No species with a DBM-to-{ML} ratio higher than 1:1 was observed in these experiments.

IR absorptions and selected assignments. EuL(DBM)(OAc)Cl·5.5(H_2O) and YL(DBM)(OAc)Cl·5.5(H_2O): 3425 s, br, ν(OH), water; 3072 vvw; 2919 w; 2849 vvw*; 1643 m, ν(C=N), imine; 1590 m-s, ν(C=N), pyridine and ν(C--O/C--C), DBM; 1549 s, ν(COO)asym., Ac; 1519 s; 1472 w*; 1449 m; 1384 s, ν(C--O/C--C), DBM and ν(COO)sym., Ac; 1302 w; 1249 vw; 1220 vw*; 1198 m-w; 1155 vvw; 1126 vvw; 1067 m-w; 1020 vvw*; 1002 m-w; 932 w; 814 m; 767 vw*; 720 m; 691 vvw*; 673 vvw*; 644 vvw; 597 w; 515 w. LaL(DBM)$(Ac)_2$·2(H_2O) and EuL(DBM)$(Ac)_2$·9(H_2O) had nearly identical spectra, except that the absorptions at 1554 and 1400 cm^{-1} were more intense and broader.

NMR Spectra. LaL(DBM)$(OAc)_2$·2(H_2O), EuL(DBM)(OAc)Cl·5.5(H_2O) and YL(DBM)(Ac)Cl·5.5(H_2O): Proton spectra, Table 1. LaL(DBM)$(OAc)_2$·2(H_2O): ^{13}C NMR spectrum (CD_3OD), 16.35 (CH_3, macrocycle), 24.08 (CH_3, Ac), 53.99 (CH_2), 127.22 (β-C, pyridine), 127.78, 129.20, 131.88 (phenyl), 142.24 (γ-C, pyridine), 156.51 (α-C, pyridine), 170.56 (C=N). The signals of the —COO (acetate), CH (DBM) and C--O (DBM) were not observed.

(2) *Reaction of* NaDBM *with* [ML$(OAc)_2$]Cl·4(H_2O), *where* M = La^{III}, Eu^{III} *and* Y^{III}. The complex (2×10^{-4} mol) and NaDBM were placed in chloroform (10 cm^3) and warmed to *ca* 50°C until all NaDBM had dissolved and a yellow solution containing a small amount of a white semi-gelatinous solid had formed. The mixture was cooled and gravity filtered, discarding the solid. The subsequent procedure was similar to that described for the reaction with HDBM. The following NaDBM-to-{ML} ratios were used: 1:1 and 2:1 for {LaL} and {YL}, 1:1, 2:1 and 3:1 for {EuL}. The 1:1 experiments gave cream-colored powdery products with 1:1 DBM-to-{ML} ratio, identical to those obtained with HDBM (yields, 60–70%). Higher DBM-to-{ML} ratios gave orange–yellow powdery products (yields, 55–60%), which were found to contain (source of evidence in parentheses): no acetate (IR, ^1H NMR spectra), no chloride (chemical analysis), water and/or hydroxide (IR spectra), {ML}:DBM ratios ranging from 1.9 to 2.3 (^1H NMR spectra) and no other organic species (^1H NMR spectra). These products did not give C,N,H microanalyses corresponding to well-defined stoichiometries; they were considered to be mixtures in which the +3 ionic charge of the {ML} moiety was balanced by a combination of DBM and OH^- counterions, present in non-integral ratios. A sample with DBM-to-{EuL} ratio = 2.3 was treated with excess $NaClO_4$ in methanol. Tiny bright yellow crystals of EuL$(DBM)_2(ClO_4)$·H_2O separated slowly from solution at room temperature; they were filtered off, washed with methanol and dried at 60°C.

IR absorptions and selected assignments. 3432 m-w, br, ν(OH), water; 3056 w; 3926 w; 1644 m, ν(C=N), imine; 1597 s, ν(C=N), pyridine and ν(C--O/C--C), DBM; 1554 s; 1515 s; 1478 m; 1456 m; 1398 vs, ν(C--O/C--C), DBM; 1308 w; 1288 w; 1247 vw; 1218 vw; 1194 w; 1151 vw; 1092 s, $\nu(ClO_4)$asymm.;

1023 vw; 1003 vw; 940 vvw; 813 w; 723 m; 692 w; 622 w; 519 vw.

^1H NMR spectrum (*DMSO*-d_6). Table 1.

(3) *Reaction of* HTTFA *with* $[ML(OAc)_2]Cl \cdot 4(H_2O)$, *where* M = La^{III}, Eu^{III} *and* Y^{III}. The reaction was carried out as described for HDBM; the HTTFA-to-{ML} ratios employed were 1 : 1, 2 : 1 and 3 : 1. Several fractions were isolated in each experiment; no further treatment with HTTFA was performed. Fractions obtained from 1 : 1 and 3 : 1 experiments were mixtures from which no single complex was isolated. Fractions obtained from 2 : 1 experiments (total yields 80–85%) appeared homogeneous under a microscope (small almond-coloured platelets or needles) and consisted of single species with a 2 : 1 TTFA-to-{ML} ratio.

IR absorptions and selected assignments. $LaL(TTFA)_2Cl \cdot 2.5(H_2O) \cdot 0.25(C_4H_{10}O)$, $EuL(TTFA)_2Cl \cdot 2(H_2O)$ and $YL(TTFA)_2Cl \cdot H_2O$: 3417 m, br, ν(OH), water; 3070 vw; 2929 vvw; 1645 m*, ν(C=N), imine; 1610 vvs; 1595 sh, ν(C=N) pyridine; 1534 s; 1508 w*; 1500 m-w; 1467 w*; 1458 m-w; 1412 s; 1376 m;1351 m; 1306 vvs; 1292 sh; 1245 m-w; 1229 m-w; 1186 m; 1137 s; 1184 vvw*; 1060 w; 1006 w; 934 w; 859 vw; 815 w; 784 m; 746 w; 715 w; 678 w; 639 m-w; 578 m-w.

NMR spectra. The proton spectra of $LaL(TTFA)_2(OAc)_{0.5}Cl_{0.5} \cdot 2.5(H_2O)$ and $YL(TTFA)_2Cl \cdot H_2O$ are given in Table 1; the spectrum of $EuL(TTFA)_2Cl \cdot 2(H_2O)$ was not assigned. ^{13}C NMR spectrum of $LaL(TTFA)_2(Ac)_{0.5}Cl_{0.5} \cdot 2.5(H_2O)$ ($CDCl_3$): 16.52 (CH_3, macrocycle), 52.49 (CH_2), 90.67 (CH, TTFA, unconfirmed assignment), 125.8 (β-C, pyridine), 128.30, 128.55, 131.97 (thienyl), 140.78 (γ-C, pyridine), 154.94 (α-C, pyridine), 168.14 (C=N), 179.91 (C--O, TTFA or COO, Ac; unconfirmed assignment). The signal of the CH_3, Ac was not observed.

(4) *Reaction of* HACAC *and* NaACAC *with* $[ML(OAc)_2]Cl \cdot 4(H_2O)$, *where* M = La^{III}, Eu^{III} *and* Y^{III}. The reaction with HACAC was carried out as described for HDBM, except that a large excess of the diketone was used (1 cm^3 of HACAC for 2×10^{-4} mol of complex) and the mixture was refluxed for 1 h and then allowed to stand at room temperature for several hours before addition of diethyl ether. All fractions isolated in each experiment (colourless powders) were mixtures consisting of the parent complex and minor quantities of a species with a 1 : 1 ACAC-to-{ML} ratio. Repeated treatment with excess HACAC resulted in a gradual increase of the 1 : 1 ACAC-to-{ML} species, but no product completely free from the parent complex was isolated.

The reaction with NaACAC was carried out as described for NaDBM, using 1 : 1, 2 : 1 and 3 : 1 Na ACAC-to-{ML} ratios. All reactions gave mixtures (colourless powders) from which several samples were isolated by fractional crystallization and were identified by IR and ^1H NMR spectra (approximate yields in parentheses are relative to the $[ML(Ac)_2]Cl \cdot n(H_2O)$ parent complex). The 1 : 1 reaction gave: (1) unreacted NaACAC, (2) the parent complex (40–60%) and (3) the same 1 : 1 ACAC-to-{ML} complex observed for HACAC (10%), containing a small amount of parent complex. The 1 : 2 and 1 : 3 reactions gave: (1) a very small quantity of a $M(ACAC)_3(H_2O)_n$ complex, identified by comparison with an authentic sample; (2) a {ML} species containing no ACAC or acetate (10–20%); (3) a species with 1 : 1 ACAC-to-{ML} ratio (20%), containing a small amount of parent complex. For Y^{III} and Eu^{III}, repeated recrystallization of fraction (3) from methanol/diethyl ether gave small samples (5%) with 1 : 1 ACAC-to-{ML} ratios and free of parent complex. These species contained chloride (chemical analysis) as well as hydroxide (IR spectra) and were considered to be mixtures in which the cationic charges of the $\{YL(ACAC)(Ac)\}^+$ and $\{EuL(ACAC)\}^{2+}$ moieties were balanced by chloride and hydroxide ions, present in non-stoichiometric ratios.

IR absorptions and selected assignments. YL(ACAC) (Ac) $(Cl_x,OH_{1-x}) \cdot n(H_2O)$: 3470–3400 m, vbr and 3200 sh, ν (OH), water and OH^-); 3073 vw; 3007 vw; 2965 vw; 2911 vw; 1644 m, ν(C=N), imine; 1592 vvs, ν(C---11-O/C---C), ACAC and ν(C=N), pyridine; 1560 s*, ν(COO) asymm., Ac; 1513 s; 1441 s; 1398–1991 s, br, ν(C---O/C---C), ACAC and ν(COO) symm., Ac; 1295 w; 1265 m-w; 1250 m-w; 1195 m; 1155 vw; 1125 vw; 1067 vw; 1006 m; 934 vw; 916 w; 818 w; 815 w; 743 m; 712 vw; 671 m-w; 592 vw. The spectrum of the Eu^{III} complex was nearly identical, except for differences in the relative intensities of the absorptions in the 1660–1380 cm^{-1} region.

NMR spectra. YL(ACAC) (Ac) $(Cl_x,OH_{1-x}) \cdot n(H_2O)$: Proton spectrum in Table 1. ^{13}C NMR spectrum ($CDCl_3$): 15.88 (CH_3, macrocycle); 23.9, 26.93 (CH_3, ACAC and Ac; not individually assigned); 52.50 (CH_2); 124.47 (β-C, pyridine); 140.75 (γ-C pyridine); 153.24 (α-C pyridine); 165.37 (C=N). The signals from COO, Ac and from CH and C---, ACAC were not observed. EuL(ACAC) $(Cl_x,OH_{1-x})_2 \cdot n(H_2O)$: Proton spectrum in Table 1. ^{13}C NMR spectrum ($CDCl_3$, assignments not confirmed by HETCOR): −21.13 (CH_3, ACAC); −12.79 (CH_3 macrocycle); 62.21 (CH_2); 108.29 (β-C pyridine); 145.15 (α-C pyridine), 149.58 (γ-C pyridine); 164.67 (C=N); 180.81 (C---O, ACAC). The signal from CH, ACAC was not observed.

"NMR titrations and scrambling" experiments

$[EuL(OAc)_2]Cl \cdot 4(H_2O)$ was "titrated" with β-diketones or sodium β-diketonates as follows: The proton spectrum of the titrating ligand alone (0.03 M in CD_3OD) was recorded first; an equimolar amount of the solid "parent complex", $[EuL(OAc)_2]Cl \cdot 4(H_2O)$, was added and the spectrum was recorded again. Further equimolar aliquots of (solid or liquid) ligand were then added stepwise, recording

the spectrum after each addition. The spectrum of each "titration step" was assigned by comparison with the spectra of the titrant, of the parent complex and of the respective [EuL(β-diketonate) (OAc)]$^+$ complex; the approximate ratio of the two complexes was estimated from the integrated intensities of suitable signals. The initial spectrum of the diketone also gave the percentage of enol form present in solution: 80–84% for HACAC and over 90% for both HDBM and HTTFA, in agreement with the literature.[14(a)] The following results were obtained: (1) HACAC/[EuL(OAc)$_2$]$^+$ ratios, 1:1, 2:1, 3:1, 4:1, 5:1; corresponding [EuL(ACAC) (Ac)]$^+$/[EuL(Ac)$_2$]$^+$ ratios, 0.3:1, 0.6:1, 0.8:1, 1.2:1, 1.7:1. (2) NaACAC/[EuL(OAc)$_2$]$^+$ ratio, 1:1; [EuL(ACAC)(OAc)]$^+$/[EuL(Ac)$_2$]$^+$ ratio, 1:1; at higher titrant/macrocycle ratios gradual decomposition of the {EuL} moiety occurred. (3) HDBM/[EuL(OAc)$_2$]$^+$ ratios, 1:1, 2:1, 3:1; corresponding [EuL(DBM) (Ac)]$^+$/[EuL(OAc)$_2$]$^+$ ratios, 2:1, 7:1, 13:1; higher titrant/macrocycle ratios were prevented by insufficient solubility of HDBM. (4) NaDBM/[EuL(OAc)$_2$]$^+$ ratio, 1:1; [EuL(DBM)(OAc)]$^+$/[EuL(Ac)$_2$]$^+$ ratio, 2:1; at higher titrant/macrocycle ratios, severe broadening of signals occurred. (5) HTTFA/[EuL(OAc)$_2$]$^+$ ratios, 1:1, 2:1; corresponding [EuL(TTFA)(OAc)]$^+$/[EuL(OAc)$_2$]$^+$ ratios, 0.7:1, 5:1; at higher titrant/macrocycle ratios, complete OAc-by-TTFA replacement occurred but signals were severely broadened.

Proton NMR spectra were recorded for YL(TTFA)$_2$Cl·H$_2$O (1.3×10^{-2} M in CD_3OD) in the presence of HTTFA, with HTTFA/{YL(TTFA)$_2$}$^+$ mol ratios = 1:1, 2:1 and 3:1. Each spectrum showed the signals of the {YL(TTFA)$_2$}$^+$ moiety and of (uncoordinated) HTTFA in the expected ratio and unchanged relative to the parent species. In contrast, the signals of the coordinated TTFA, although unshifted, became progressively broader as the HTTFA concentration increased. The spectrum of the 3:1 solution was monitored over a period of 1 week; no change was observed.

Anion exchange reaction were studied as follows: Spectra were recorded separately for EuL(DBM)(OAc)Cl·5.5(H$_2$O) and YL(OAc)$_2$Cl·4(H$_2$O), each dissolved in $CDCl_3$. The two solutions were mixed (1:1 mol ratio) and the spectrum of the mixture was recorded immediately. The procedure was repeated using YL(DBM)(OAc)Cl·5.5(H$_2$O) and EuL(OAc)$_2$Cl·4(H$_2$O). In both experiments, the spectrum of the mixture showed the presence of {YL(OAc)$_2$}, {YL(DBM) (OAc)}, {EuL(OAc)$_2$} and {EuL(DBM) (OAc)}; the intensity ratio for the —CH_3— (macrocycle) signals of {YL(DBM) (OAc)} and {YL(OAc)$_2$}, which occur in a region free from other signals, was approximately 1:1.

Absorption, emission and excitation spectra

All {ML}-(β-diketonate) complexes (1×10^{-4} M in methanol) had two broad absorptions with maxima at *ca* 250 nm ($\varepsilon = 3.8$–3.9×10^4) and *ca* 295 nm ($\varepsilon = 1.4$–2.0×10^4); in addition, the {ML}-DBM complexes absorbed at *ca* 365 nm ($\varepsilon = 1.7 \times 10^4$) and the (ML}-TTFA complexes absorbed at *ca* 347 nm ($\varepsilon = 2.9 \times 10^4$). For each {ML}-diketonate complex, the absorption spectrum essentially consisted of the superimposed spectra of [ML(OAc)$_2$]Cl·4((H$_2$O) [3] and of the respective [M(β-diketonate)$_3$(H$_2$O)$_n$] complex [16]. No appreciable differences were observed among the absorption spectra of different {ML} entities containing the same β-diketonate.

The excitation spectra of the {EuL}-(βdiketonate) complexes, obtained by monitoring the $^5D_0 \rightarrow {}^7F_2$ Eu^{III} emission at 618 nm, matched the respective absorption spectra in the 290–400 nm region, except that the 365 and 347 nm excitation bands of {Eu}-DBM and {EuL}-TTFA, respectively, had much higher relative intensities than the corresponding absorption bands. No Eu^{III} emission was observed for irradiation into the 250 nm absorption.

The emission spectra of the {Eu}-(β-diketonate) complexes were very similar, in regard to patterns and energies, to the spectrum of [EuL(OAc)$_2$]Cl·4(H$_2$O),[3] but differed in intensities. Under comparable experimental conditions, and taking the [EuL(OAc)$_2$]Cl·4(H$_2$O) as unit reference, the emission intensities of the {EuL}-(β-diketonate) complexes varied approximately as follows: {Eu}-ACAC, 1.5; {Eu}-DBM, 5; {EuL}-TTFA, 50.

The emission intensities of methanol solutions containing 2×10^{-4} M [EuL(OAc)$_2$]Cl·4(H$_2$O) and increasing mole ratios (0.0–4.0, by 0.5 increments) of the β-diketone or sodium β-diketonate were measured under comparable instrumental conditions. With HACAC, only minor enhancement of the emission intensity was observed at all ratios; with NaACAC, the emission intensity nearly doubled at NaACAC-to-{EuL} = 0.5:1, then decreased at higher ratios. With HDBM, the intensity gradually increased to about three times its initial value for HDBM-to-{EuL} = 2.5 and 3.0, then decreased slightly; with NaDBM, an approximate four-fold increase was achieved for 1.5 and 2.0 ratios, followed by a sharp decrease at higher ratios. With HTTFA, the intensity gradually increased to approximately 30 times its initial value for HTTFA-to-{EuL]} = 3.0, then remained constant.

Crystal data for [EuL(DBM) (OAc)](OAc)·6H$_2$O = $EuC_{41}H_{55}O_{12}N_6$. $M_r = 975.89$, monoclinic, space group $P2_{1/c}$, $a = 13.787(4)$, $b = 10.055(3)$, $c = 32.408(5)$ Å, $\beta = 101.88(3)^\circ$, $V = 4396(2)$ Å^3, $Z = 4$, $D_x = 1.47$ Mg m^{-3}, λ = (Mo-K_α) = 0.71069 Å, μ(Mo-K_α) = 1.49 mm^{-1}, $F(000) = 2008$, $T = 293$ K.

A prismatic yellow crystal of dimensions 0.40 × 0.52 × 0.30 mm was centred on a four-circle Philips PW1100 (Febo System) diffractometer with graphite-monochromated (Mo-K_α) radiation (λ = 0.71069 Å). The orientation matrix and preliminary unit-cell dimensions were determined from 30 reflections found by mounting the crystal at random, vary-

ing the orientation angles χ and ϕ over a range of 120°, with $7 \leqslant \theta \leqslant 9°$. For the determination of precise lattice parameters, 40 strong reflections with $10 \leqslant \theta \leqslant 13°$ were considered; integrated intensities for *hkl* reflections ($h = \pm 17$; $k = 0 \rightarrow 12$, $l = 0 \rightarrow 42$) were measured in the interval $\theta = 2$–28°, using $\theta/2\theta$ scans. Three standard reflections, 4,0,2; −3,1,8 and −2,1,10, were collected every 200 reflections. There were no significant fluctuations of intensities other than those expected from Poisson statistics. The intensity data were corrected for Lorentz–polarization effects and for absorption, as described by North *et al.* [17]. No correction was made for extinction.

The structure was solved by heavy atoms methods [18]. Refinement was carried out by full-matrix least-squares; the function minimized was $\Sigma w(F_o^2 - F_c^2)^2$, with weighting scheme $w = 1/[\sigma^2(F_o^2) + (0.0132P)^2 + 8.54P]$, where $P = \max(F_o^2 + 2F_c^2)/3$. All non-hydrogen atoms were refined with anisotropic thermal parameters. The H atoms were located from difference-Fourier maps and refined isotropically, except for those belonging to the methyl groups which were placed in calculated positions with fixed, isotropic thermal parameters (1.2 U_{equiv} of the parent carbon atom). For a total of 665 parameters, $wR' = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2]^{1/2} = 0.077$, $S = 1.186$ and conventional $R = 0.0257$, based on F values of 7302 reflections having $F_o^2 \geqslant 3\sigma(F_o^2)$. Scattering factors were taken from.[19] Structure refinement and final geometrical calculations were carried out with SHELXL-93 [20] and PARST [21] programs, drawings were produced using ORTEPII [22]. Supplementary material is available from the author on request.

RESULTS AND DISCUSSION

Synthesis of the complexes

The results obtained in the reactions between the $[ML(OAc)_2]X \cdot n(H_2O)$ complexes and the β-diketones (HACAC, HDBM or HTTFA) were quite similar for M = La^{III}, Eu^{III} or Y^{III} and depended primarily on the β-diketone and on the mole ratio of the reactants. With HTTFA at 2:1 or higher (β-diketone)-to-{ML} ratios, the acetates present in the parent complex were both readily replaced by TTFA anions; cream-coloured crystalline complexes of formulae $[LaL(TTFA)_2]Cl \cdot 2(H_2O) \cdot 0.25(C_4H_{10}O)$, $[EuL(TTFA)_2]Cl \cdot 2(H_2O)$ and $[YL(TTFA)_2]Cl \cdot (H_2O)$ were obtained in high yields. With HDBM, only one acetate was replaced by a DBM anion even after repeated treatment with a large excess of the β-diketone; the resulting pale yellow crystalline complexes had formulae $[EuL(DBM)(OAc)]Cl \cdot 5.5(H_2O)$, $[YL(DBM)(OAc)]Cl \cdot 5.5(H_2O)$, $[LaL(DBM)(OAc)](OAc) \cdot 2(H_2O)$, $[EuL(DBM)(OAc)](OAc) \cdot 6(H_2O)$ and $[EuL(DBM)(OAc)](OAc) \cdot 9(H_2O)$. When NaDBM was used as reactant, both acetates of the parent complex were replaced; a di-substituted Eu^{III}-DBM complex was isolated as the perchlorate salt, $[EuL(DBM)_2](ClO_4) \cdot (H_2O)$ (bright yellow tiny crystals). Finally, reaction with HACAC in large excess produced 1:1 {ML}-(ACAC) species, but always contaminated by appreciable quantities of the parent complex. With NaACAC, mixtures of mono-substituted complexes with compositions corresponding to $YL(ACAC)(OAc)(Cl_x,OH_{1-x}) \cdot n(H_2O)$ and $EuL(ACAC)Cl_x(OH)_{2-x} \cdot n(H_2O)$ were isolated in low yields; minor quantities of the non-macrocyclic $[M(ACAC_3] \cdot n(H_2O)$ complexes were also formed.

The acid strengths of the three β-diketones in anhydrous methanol, which was the solvent used for the above reactions, may be expected to vary in the order: HDBM ≪ HTTFA ⩽ HACAC ≪ HAc. For the corresponding β-diketonates, the tendency to coordinate with the {LaL}, {EuL} and {YL} entities may be expected to vary in the order: OAc ≪ ACAC < TTFA ⩽ DBM. Although these trends are based on literature data [14(a–c)] obtained under conditions very different from those of the present work, they do provide some rationalization of the results reported above. The HTTFA is more effective than HDBM in replacing the acetates of $[ML(OAc)_2]^+$ chiefly because its acid form has a much greater tendency to deprotonate; this factor overrides the slightly lower affinity of TTFA for the M^{III} ions. Conversely, HACAC, although comparable to HTTFA in acidity, produces a less coordinating conjugate anion and is less effective as a reagent in acetate-replacement reactions.

For acetate-replacement reactions carried out with sodium β-diketonates, the outcome should depend primarily on the affinity of the β-diketonate for the M^{III} ions; these reactions, however, are complicated by the high concentration of OH^- ions that results from the hydrolysis of β-diketonate in the presence of traces of moisture. An example is the base-catalysed hydrolysis of the {ML} macrocycles, which takes place to some extent in the presence of NaACAC and results in the release of the metal ions and formation of their tris-acetylacetonates.

Crystal structure of $[EuL(DBM)(OAc)](OAc) \cdot 6(H_2O)$

The complex is ionic. The structure of the cationic coordination entity is illustrated in Fig. 2; selected bond lengths and angles are listed in Table 3. The Eu^{III} ion is 10-coordinate and the ligand environment consists of the six nitrogen atoms of the macrocycle and of four oxygen atoms, two from a chelating β-diketonate and two from a chelating acetate. The exocyclic acetate and β-diketonate ligands are situated on opposite sides of the macrocycle, with the four oxygen donor atoms in a slightly distorted tetrahedral arrangement. A non-coordinated acetate provides charge neutrality and the clathrated water molecules

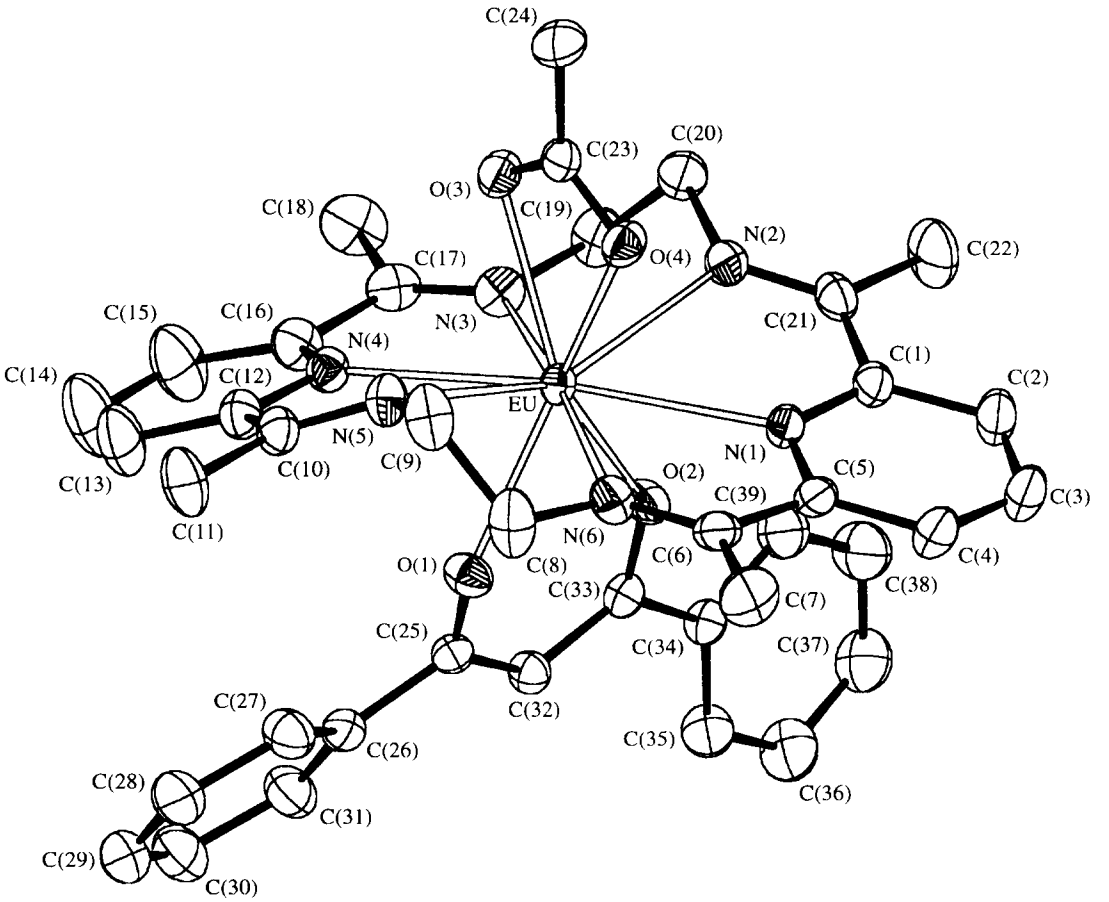

Fig. 2. ORTEP view of the complex cation $[EuL(DBM)(Ac)]^+$. (Ellipsoids are at 40% probability.)

(six per complex unit) form a network of hydrogen bonds that extends throughout the crystal and involves the ionic acetate (Fig. 3 and Table 4) with relatively strong interactions (H---O $\simeq$ 1.8 Å), as well as the coordinated acetate with weaker interactions (H---O $\simeq$ 2.6 Å).

The Eu-macrocycle moiety has the "folded butterfly" conformation typical for complexes of the $C_{22}H_{26}N_6$ ligand and consists of two quasi-planar "wings" that contain the pyridine rings and are hinged at the —CH_2—CH_2— side chains with an interplanar angle of 144.21(8)°. The β-diketonate ligand is situated on the concave side of the macrocycle, with its two phenyl rings rotated by 140.5(2)° relative to one another. The chelation plane of the β-diketonate, aligned with the fold line of the macrocycle, is tilted toward one of the macrocycle wings and forms an angle of 56.0(1)° with it; the angle with the other wing is 88.4(1)°. In the wing closer to the β-diketonate, the deviations of the atoms from the best mean-plane range from −0.0155(4) to 0.106(4) Å; deviations from planarity in the other wing range from −0.094(4) to 0.084(4) Å.

A comparison of $[EuL(DBM)(OAc)](OAc)\cdot 6H_2O$ with $[EuL(OAc)_2](OAc)\cdot 9(H_2O)$ [8] and $[EuL(OAc)_2]Cl\cdot 4(H_2O)$ [5] shows similarities as well as differences. In each complex the exocyclic anionic ligands are staggered and their chelation planes are nearly perpendicular to one another {in $[EuL(DBM)(OAc)]^+$ the O—C—O plane of the acetate and the O=C—CH—C=O plane of the β-diketonate form an angle of 89.0(2)°}. However, the "wings" of the macrocycle are more open when the bulkier β-diketonate is present on the concave side; the macrocycle fold-angle increases from 122.50(7)° in $[Eu(OAc)_2L](OAc)\cdot 9(H_2O)$ [8] and 132.37(6)11° in $[EuL(OAc)_2]Cl\cdot 4(H_2O)$ [5] to 144.21(8)° in $[EuL(DBM)(OAc)](OAc)\cdot 6(H_2O)$. The two Eu—O(acetate) bond lengths in $[EuL(DBM)(OAc)]^+$ are identical to one another [Eu—O(3) 2.506(3); Eu—O(4) 2.508(3) Å] and similar to those found in the $[EuL(OAc)_2]^+$ complexes; the two Eu—O (diketonate) bond lengths are also very close to one another [Eu—O(1) 2.376(3), Eu—O(2) 2.394(3) Å]. Consistent with the partial double bond character of metal-(β-diketonate) coordination, the Eu—O (diketonate) bonds are appreciably shorter than the Eu—O(acetate) bonds; this shortening of the Eu—O bonds on the β-diketonate side of the macrocycle is accompanied by a lengthening of the Eu—N bonds of $[EuL(DBM)(OAc)]^+$ relative to $[EuL(OAc)_2]^+$. As in the latter, however, the Eu—N distances of

$[EuL(DBM)(OAc)]^+$ fall into three equal pairs [Eu—N(imine 2,5) 2.624(3), Eu—N(pyridine) 2.656(4) and Eu—N (imine 4,5) 2.685(4) Å]. The corresponding Eu—N distances (all in Å) for $[EuL(OAc)_2](OAc)\cdot 9(H_2O)$ [8] are 2.570(2), 2.604(3) and 2.642(3); those of $[EuL(OAc)_2]Cl\cdot 4(H_2O)$ [5] are 2.607(3), 2.638(3) and 2.658(3).

The ring puckering analysis of the six-nitrogen system of $[EuL(DBM)(OAc)]^+$ shows a boat conformation with puckering constants $Q = 0.950(4)$ Å, $\theta = 90.2(2)°$ and $\phi = 58.8(2)°$; in contrast, the ring conformation of $[Eu(OAc)_2L](OAc)\cdot 9(H_2O)$ [8] is slightly twisted and that of $[EuL(OAc)_2]Cl\cdot 4(H_2O)$ [5] is of the twist-boat type. This comparison provides further evidence of the high flexibility of the $C_{22}H_{26}N_6$ macrocyclic ligand, which can adjust its conformation to the requirements of exocyclic ligands, external counterions and lattice water molecules.

NMR spectra

The ^1H NMR spectra of the complexes are summarized in Table 1. For each complex, the spectrum consists of the superimposed patterns of the lanthanide-macrocycle [5] and of the lanthanide-coordinated β-diketonate,[16] confirming that the {ML} species retain their integrity in solution and the β-diketonates exhibit their usual bidentate chelating coordination. However, the spectra of the {EuL}-(β-diketonate) and {YL}-(β-diketonate) complexes present a unique feature, in that the CH_2 groups of the

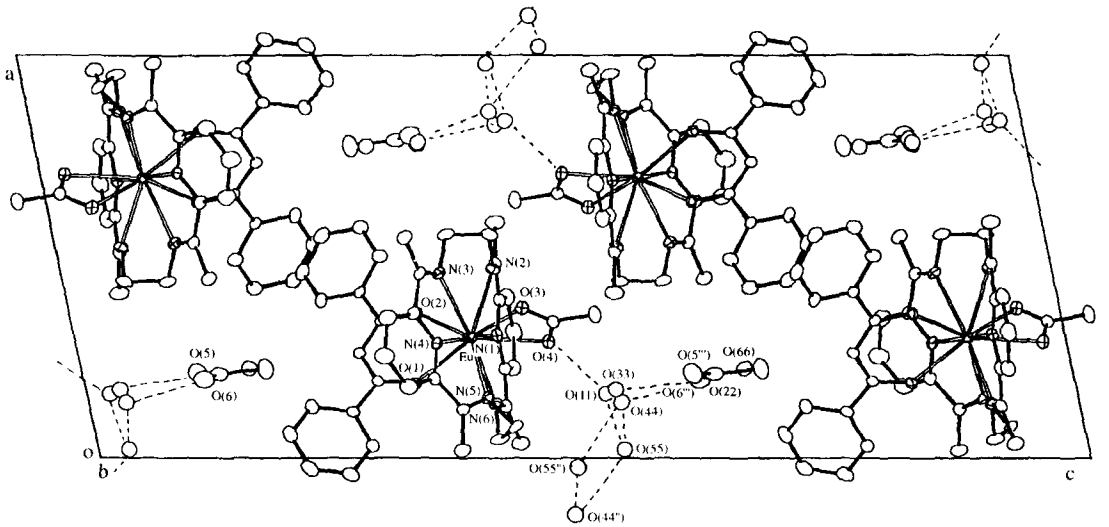

Fig. 3. Crystal packing of [EuL(DBM)Ac)](Ac)·6(H_2O), including anions and water molecules, and showing hydrogen bond interactions.

macrocycle di-imine side-chains, =N—CH_2—CH_2—N=, give rise to two distinct signals in a 1 : 1 ratio, instead of the sharp singlet observed for the same macrocycles when coordinated to other anionic ligands. [In contrast, the spectrum of the {LaL}-(β-diketonate) shows the usual CH_2 singlet.] In the {ML}-(β-diketonate) complexes of Eu^{III} and Y^{III}, therefore, the four CH_2 groups are no longer equivalent but constitute two distinct pairs; in turn, this means that the symmetry of the macrocycle, usually attained through a rapid interconversion of different conformers, is substantially reduced by coordination of the β-diketonate ligand(s). The effect is far more marked in $CDCl_3$ than in more ionizing solvents such as CD_3OD or DMSO-d_6 and is most likely related to the high stability and/or inertness of the β-diketonate ligands when coordinated to the (relatively) small Eu^{III} and Y^{III} ions.

The CH_2 region in the ^1H NMR spectrum of {YL}(DBM)(OAc)Cl·5.5(H_2O) in $CDCl_3$ is shown in Fig. 4, together with a Newman projection along the —CH_2—CH_2— side chains and a coupling scheme consistent with the observed splitting pattern. The observed vicinal coupling constants ($J_{AC} = J_{BD} = 12$, $J_{AD} = J_{BC} = 6$ Hz) suggest a nearly eclipsed arrangement in which the H_A—C—C—H_D angle is quite similar to the H_B—C—C—H_C angle. (In a staggered conformation, J_{BC} would be about 10 Hz and J_{AD} would be only 2 Hz.) The proposed scheme is qualitatively consistent with the Karplus correlation, which

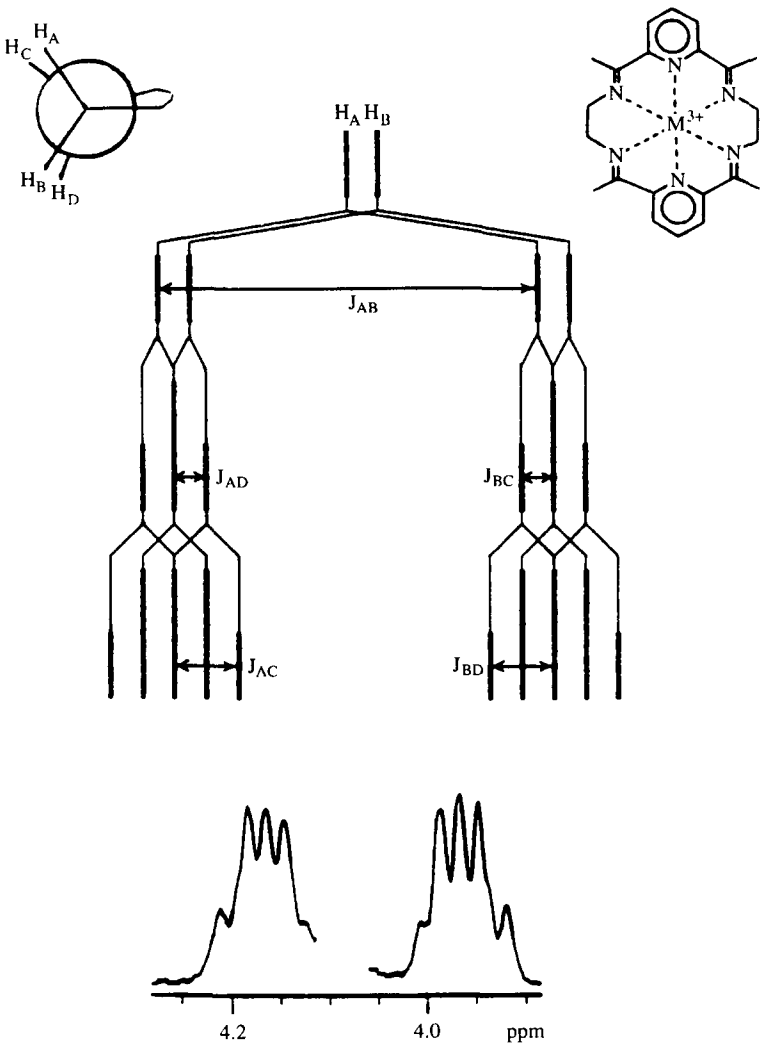

Fig. 4. Proton NMR spectrum of $[YL(DBM)(Ac)](Ac) \cdot 5.5(H_2O)$ in $CDCl_3$ solution: —CH_2 signals and coupling scheme. The chemical shifts of H_A and H_C are very close, as are those of H_B and H_D; accordingly, H_C and H_D have been omitted from the scheme for simplicity.

predicts a J value of 8 Hz for a dihedral angle near 0° and a J value of 4 Hz for a dihedral angle near 120°.

Proton NMR spectra were obtained for series of solutions containing the same concentration of $[ML(OAc)_2]Cl \cdot 4(H_2O)$ and increasing mole ratios of β-diketone. In each case the amount of {ML}-(β-diketonate) relative to residual $[ML(OAc)_2]^+$ increased with the amount of added β-diketone, but the extent of increase differed greatly for the three β-diketones and varied in the order HTTFA ≫ HDBM ≫ HACAC. These spectra also showed the presence of both coordinated β-diketonate and free β-diketone, but of only one kind of acetate. Similar results were obtained when increasing amounts of HTTFA were added to a solution of the pre-formed $[YL(TTFA)_2]Cl \cdot H_2O$ complex, although the signals of coordinated TTFA were severely broadened.

Different results were obtained when NaACAC or NaDBM were used as "titrants". At 1 : 1 (β-diketonate)-to-{ML} ratio, signals of both the {ML}-(β-diketonate) and the residual parent complex were present, but only the signals of coordinated β-diketonate were observed. At higher (β-diketonate)-to-{ML} ratios, replacement of coordinated acetate by β-diketonate appeared to be complete but reliable assignments were prevented by severe broadening of the signals and, for NaACAC, by gradual decomposition of the {ML} entity.

In the "anion scrambling" experiments, the spectra of chloroform solutions obtained by mixing in a 1 : 1 mole ratio $\{EuL(OAc)_2\}$ and {YL(DBM)(OAc)} or

{YL(OAc)$_2$} and {YL(DBM)(OAc)} showed the presence of the four macrocyclic species resulting from an approximately even redistribution of the DBM and OAc anions.

The results of the "NMR titrations and scrambling" experiments indicate that in the [ML(β-diketonate)(OAc)]$^+$ species the exchange between coordinated and free β-diketonate is fast on the NMR time scale and so is the exchange between coordinated and free acetates. In contrast, the exchange of β-diketonate between different {ML} entities, although it reaches equilibrium within the short time required for the NMR experiment, is slow on the NMR timescale and so is the exchange between coordinated β-diketonate and free β-diketone, which involves ionization of the diketone-enol.

Luminescence of the Eu^{III} *complexes*

The {EuL}-(β-diketonate) complexes investigated in this work exhibit enhanced luminescence relative to [EuL(OAc)$_2$]Cl·4(H$_2$O), without significant changes in the patterns and energies of the emission spectra; this shows that the coordination symmetry of the emitting Eu^{III} is essentially unchanged, in agreement with the structure established by X-ray crystallography for [EuL(DBM)(OAc)](OAc)·6(H$_2$O). In contrast, the absorption spectra of the {EuL}-(β-diketonate) complexes differ markedly from the absorption spectrum of [EuL(OAc)$_2$]Cl·4(H$_2$O),[3] as they consist of the superimposed patterns of the {EuL} entity and of the Eu-bound β-diketonate;[16] when the latter absorb intensely in the 340–370 nm region, which is best suited for energy transfer to the Eu^{III} ion, their contribution to the excitation process becomes dominant. Thus, irradiation into the 365 nm absorption of the {Eu}-DBM species results in an emission intensity approximately five times higher than that of [EuL(OAc)$_2$]Cl·4(H$_2$O) [3] and a nearly 50-fold enhancement occurs for irradiation into the 355 nm absorption of {Eu}-TTFA (Fig. 5); only a minor enhancement (less than two-fold) occurs instead when the {Eu}-ACAC complex is irradiated into its β-diketonate absorption at *ca* 300 nm. The luminescence of the {EuL}-DBM and {Eu}-TTFA complexes, therefore, must be due primarily to the efficient antenna role of the respective β-diketonates; the protection from vibrational deactivation provided by the bulky and hydrophobic substituents (phenyl, thienyl and trifluoromethyl groups) also undoubtedly contributes to the enhanced luminescence.

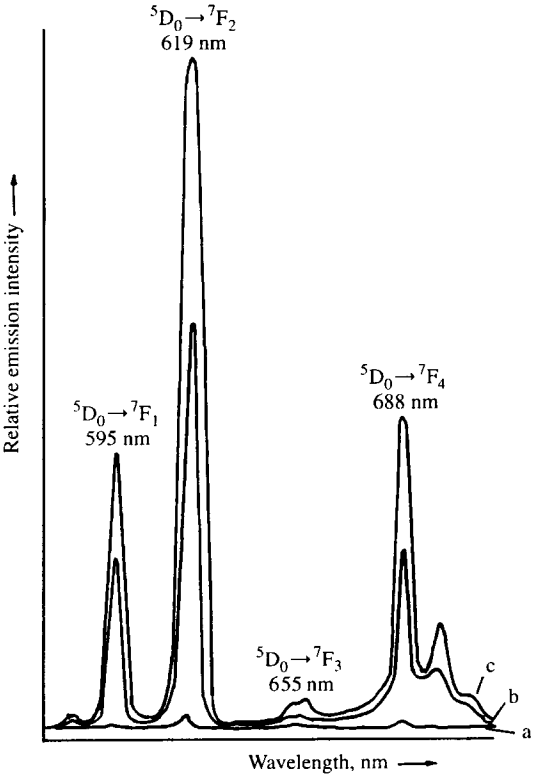

Fig. 5. Emission spectra: (a) [EuL(Ac)$_2$]Cl·4(H$_2$O), $\lambda_{excit.}$ = 310 nm; (b) HTTFA and [EuL(Ac)$_2$]Cl·4(H$_2$O) in 2.5:1 mol ratio, $\lambda_{excit.}$ = 355 nm; (c) [EuL(TTFA)$_2$]Cl·2(H$_2$O), $\lambda_{excit.}$ = 355 nm. (Methanol solutions, 1×10^{-4} M Eu^{III}; identical instrumental settings.)

CONCLUSIONS

The results of this study show that the reaction of β-diketones or β-diketonates with the lanthanide(III) macrocyclic complexes [ML(OAc)$_2$L]$^+$ results solely in anion metathesis. The β-diketonates replace either one or both acetates of the original complex, depending on the nature of the diketonate and the reaction conditions, but do not abstract the lanthanide from the uncharged macrocyclic ligand. Since β-diketonates have a very strong affinity for the lanthanide(III) ions, this behaviour confirms the unique resistance of the {ML} systems to metal release under the influence of strongly competing ligands—an essential property if any of these complexes is to be used as a bio-marker.

The crystallographic analysis of [EuL(DBM)(OAc)](OAc)·6(H$_2$O) has shown that in the solid {ML}-(β-diketonate) complexes the β-diketonates behave as usual as bidentate chelating ligands and that the metal-macrocycles retain their usual folded configuration. In solution, the {ML}-(β-diketonate) complexes remain undissociated and the {ML} entities of Eu^{III} and Y^{III} no longer exhibit the conformational fluxionality that characterizes their complexes with other anionic ligands. Also, in {ML}-(β-diketonate) complexes the coordinated β-diketonates do not exchange rapidly, at least not on the NMR time scale, with "free" β-diketones; this inertness contrasts with the rapid exchange observed for other anionic organic ligands previously studied in association with the {ML} species.

Finally, TTFA was found to be an extremely effective luminescence-enhancing ligand the {EuL}

moiety. This enhancement, which is another important factor in the development of Eu macrocycles as luminescent bio-markers, appears to result chiefly from the "antenna role" of the TTFA chelate, which absorb light in a spectral region suitable for efficient energy transfer to the Eu^{III} centre. Furthermore, the stability/inertness of the TTFA-{ML} coordination, as well as the bulk and hydrophobicity of the thienyl and trifluoromethyl groups of TTFA, provide increased protection of the excited Eu^{III} from vibrational deactivation by solvent molecules.

(Received 25 June 1996; accepted 3 September 1996)

Abstract—On coordination to $Ru(terpy)(bipy)^{2+}$ (terpy = 2,2′:6′,2″-terpyridine, bipy = 2,2′-bipyridine), acetonitrile is converted to acetamide in aqueous basic solution, through hydroxide attack with a catalytic factor of *ca* 3×10^3 ($k_{OH} = 4.6\times10^{-3}$ M^{-1} s^{-1}). This is a remarkable effect for a d^6 transition metal in the (II) oxidation state, and can be ascribed to π backbonding from the metal to the polypyridyl ligands, which makes the ruthenium(II) centre more electropositive than ruthenium(II) in the $Ru(NH_3)_5^{2+}$ moiety. The final hydrolysis product is the $[Ru(terpy)(bipy)(OH)]^+$ complex, since amides, being poor π-acceptor ligands, are rapidly released from the coordination sphere of ruthenium(II). © 1997 Elsevier Science Ltd. Keywords: base hydrolysis; acetonitrile complexes; ruthenium(II); polypyridine; catalysis; π-backbonding.

The hydrolysis of nitrile groups catalysed by transition metal complexes has been extensively studied in aqueous solutions, in part because of the connection to enzymatic proteolytic reactions [1]. Large metal-promoted acceleration of the rate of basic nitrile hydrolysis has been observed, especially when the metal is trivalent. Thus, $Co^{III}(NH_3)_5$ enhances the rate of acetonitrile conversion into acetamide [2] by a factor of *ca* 10^6, while $Ru^{III}(NH_3)_5$ has a catalytic factor of *ca* 10^8, over the free ligand value [3]. In contrast, $Ru^{II}(NH_3)_5$ has little or almost no effect on this rate [3], a result attributed to π backbonding from ruthenium(II) into the nitrile group, which increases the electron density at the nitrile C atom and thus makes it less susceptible to nucleophilic attack by hydroxide ion. We have been interested in the general properties of mono- and di-nuclear complexes derived from the $Ru^{II}(terpy)(bipy)$ group (terpy = 2,2′:6′,2″-terpyridine; bipy = 2,2′-bipyridine) [4]. In a recent paper [5], we reported a nitrile hydrolysis reaction induced by oxidation of the dinuclear complex $[(terpy)(bipy)Ru^{II}(4\text{-}CNpy)Ru^{II}(NH_3)_5]^{4+}$ (4-CNpy = 4-cyanopyridine). There, we attributed the observed rate enhancement to an inductive effect of the $Ru^{II}(terpy)(bipy)$ moiety acting as a remote substituent. Now, we wish to report on a rate increase owing to an electronic effect caused by direct coordination of a nitrile group to $Ru^{II}(terpy)(bipy)$, the catalytic factor being remarkable for a divalent transition metal complex.

EXPERIMENTAL

Syntheses

The previously reported PF_6^- salt of the $[Ru(terpy)(bipy)(NCCH_3)]^{2+}$ ion was prepared by a modified technique [6]. A solution of 83 mg of $[Ru(terpy)(bipy)(Cl)](PF_6)$, prepared as described in ref. [7], dissolved in 30 cm^3 of MeCN/ethylene glycol (2:1 v/v) was refluxed for 2 h. Then, the solution was rotoevaporated to 8 cm^3, cooled and sorbed on to a neutral alumina column, previously equilibrated with MeCN/toluene (1:2 v/v). MeCN/toluene was used as an eluent, followed by pure MeCN. The last fraction was collected and the solvent was removed by evaporation. The solid residue was dissolved in 10 cm^3 of water and then 1 g of NH_4PF_6 was added. The red-orange precipitate was filtered off, washed with cold water and diethyl ether and dried *in vacuo* over P_4O_{10}. It was recrystallized from acetone/ether. Yield: 75 mg (74%). The Br^- salt of the ion $[Ru(terpy)(bipy)(NCCH_3)]^{2+}$ was obtained by dissolving 50 mg of the PF_6^- salt in 5 cm^3 of acetone and adding 1 g of $Bu_4^nN^+Br^-$

* Author to whom correspondence should be addressed.

NBr in 3 cm^3 of Me_2CO. The precipitate was collected by filtration, washed with cold acetone and dried *in vacuo* over P_4O_{10}. Yield: 34 mg (81%).

Materials, instrumentation and techniques

All chemicals were reagent grade and used as received. Triply distilled water was used for all kinetic determinations.

pH measurements were carried out with a precision of ± 0.05 pH units, using a Luftman–Reliance II pH meter. UV–visible spectra were run with a Shimadzu UV-160A spectrophotometer, equipped with a thermostatted cell compartment.

Stock solutions of NaOH were prepared at the desired total concentrations. A fresh solution of $[Ru(terpy)(bipy)(NCCH_3)]^{2+}$ in water was used for each set of experiments. Absorbance *vs* time data were recorded at a value of $\lambda = 453$ nm (maximum of the initial complex). Duplicate or triplicate runs were made at each value of pH and temperature. Rate constants were obtained by least-squares fits of $\ln(A_t - A_\infty)$ *vs* time t, which were linear up to three half-lives. The estimated error in the base hydrolysis rate constant k_{OH} is $\pm 5\%$.

RESULTS AND DISCUSSION

Figure 1 shows consecutive spectra obtained at pH = 12.5 and $T = 25.0$°C of an aqueous solution of $[Ru(terpy)(bipy)(NCCH_3)]^{2+}$ ($C = 4.4 \times 10^{-5}$ M). The metal-to-ligand charge transfer (MLCT) absorption band at $\lambda_{max} = 454$ nm (same value in MeCN) [6] is shifted to higher wavelengths, reaching a value of $\lambda_{max} = 500$ nm after 1 day. Isosbestic points are observed at 470 and 390 nm. These changes are indicative of an hydrolysis process followed by aquation; *i.e.* a reaction of the coordinated ligand followed by a substitution process. The observed final peak value is coincident with that of the $[Ru(terpy)(bipy)(OH)]^+$ ion [8]. To confirm the identity of the product, one drop of 6 N HCl was added to this last solution. As shown in Fig. 2, a value of $\lambda_{max} = 475$ nm obtains, which agrees very well with the already reported value for the $[Ru(terpy)(bipy)(OH_2)]^{2+}$ ion [8].

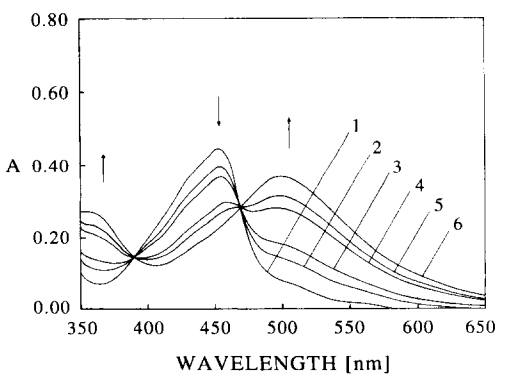

Fig. 1. Spectra obtained after adding 0.05 M NaOH to an aqueous solution of $[Ru(terpy)(bipy)(NCCH_3)]^{2+}$, $C = 4.4 \times 10^{-5}$ M, at $T = 25.0$°C. Approximate times of reaction are: 1) 0 h; 2) 1 h, 3) 2 h; 4) 6 h; 5) 8 h; 6) 24 h.

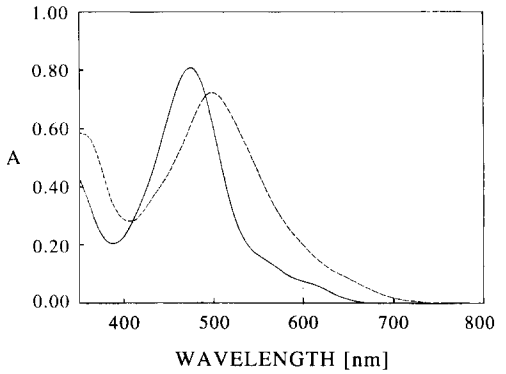

Fig. 2. Absorption spectra of the hydrolysed products of the complex $[Ru(terpy)(bipy)(NCCH_3)]^{2+}$ at pH = 11.9 (– – –) and at pH = 0 (——), $C = 7.0 \times 10^{-5}$ M.

The value obtained for $k_{obs} = 4.7 \times 10^{-4}$ s^{-1} at pH = 13.0 ($\mu = 0.1$ M) is several orders of magnitude higher than that of the expected rate constant for a ligand substitution process [9]. Thus, after adding excess pyrazine (pz) to the $[Ru(terpy)(bipy)(NCCH_3)]^{2+}$ ion at pH = 5.0, no evidence of formation of $[Ru(terpy)(bipy)(pz)]^{2+}$ ($\lambda_{max} = 428$ nm) [4] was obtained after several days. On the other hand, the acetamide ligand was aquated very rapidly, since, as usually found in Ru^{II} complexes [10], amides are poor π-acceptor ligands and are thus rapidly released from the coordination sphere of Ru^{II}.

As shown in Table 1, the observed first-order rate constants k_{obs} for the hydrolysis process vary linearly with $[OH^-]$. From the rate law $k_{obs} = k_{OH}[OH^-]$, a value of $k_{OH} = 4.6 \times 10^{-3}$ M^{-1} s^{-1} was calculated, which can be compared with other metal-catalysed hydrolysis second-order rate constants for acetonitrile, as shown in Table 2. The value obtained for the complex studied in this work is intermediate between those of the acetonitrile complexes of $Ru^{II}(NH_3)_5$ and $Co^{III}(NH_3)_5$. The catalytic factor is *ca* 3×10^3 over the free ligand value. This effect is quite remarkable for a d^6 transition metal in the (II) oxidation state and can

be ascribed to π backbonding from the metal to the polypyridyl ligands, which makes the Ru^{II} centre more electropositive than the Ru^{II} centre in the $Ru^{II}(NH_3)_5$ moiety. The ability of Ru^{II} to promote the hydrolysis of a nitrile group when coordinated to π-acceptor ligands was previously detected in a work [11] on the stability of aqueous solutions of $[Ru(bipy)_2(4\text{-}CNpy)_2]^{2+}$.

The values of k_{OH} as a function of temperature are shown in Table 3. The variation of $\ln(k_{OH}/T)$ with $(1/T)$ is displayed in Fig. 3. From Eyring's rate equation [12], values of $\Delta H^{\#} = (74 \pm 4)$ kJ mol^{-1} and $\Delta S^{\#} = (-42 \pm 12)$ J mol^{-1} K^{-1} are determined, which compare reasonably well with other nitrile hydrolysis activation parameters. For example, values of $\Delta H^{\#} = 63.2$ kJ mol^{-1} and $\Delta S^{\#} = -84$ J mol^{-1} K^{-1} have been obtained for the base-catalysed reaction of 2-cyano-1,10-phenthroline [13]. These values indicate the operation of an associative process.

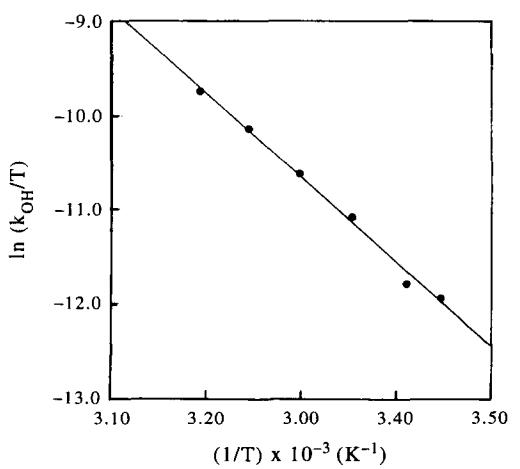

Fig. 3. Eyring plots for base hydrolysis of [Ru(terpy)(bipy)$(NCCH_3)]^{2+}$ in aqueous solutions.

By following the arguments already pointed out by Deutsch *et al.* [14], we can anticipate that the orbitals of $Ru(terpy)(bipy)^{2+}$ are not as basic as those of $Ru(NH_3)_5^{2+}$, because of the presence of the π electron-accepting polypyridyl ligands. Therefore, the Ru^{II} centre in $Ru(terpy)(bipy)^{2+}$ is capable of stabilizing a bimolecular reaction mechanism, either in the H_2O_2 oxidation of a chalcogenoether [14], or in the hydroxide attack on a nitrile group, as reported here. Work in progress in our laboratory will address the extent of the catalytic action of the $Ru(terpy)(bipy)^{2+}$ moiety on the hydrolysis rate of other nitrile derivatives.

(Received 31 January 1996; accepted 30 August 1996)

Abstract—Nickel(II) complexes of two tridentate N.N.S-chelating ligands, 3-hydroxyiminobutanonethiosemicarbazone (L_1H_2) and 3-hydroxyiminobutanone (4-phenylthiosemicarbazone) (LH_2), have been synthesized and characterized by elemental analysis, IR, UV–vis spectroscopy and cyclic voltammetric studies. The structure of $Ni(LH_2)_2(NO_3)_2 \cdot H_2O$ has been determined by single-crystal X-ray diffraction. Nickel(II) is in a distorted octahedral N_4S_2 donor environment; one of the nitrate groups exhibits partial disorder.

Keywords: nickel(II) complexes; hydroxyiminobutanonethiosemicarbazone; X-ray structure; spectroscopic studies; cyclic voltammetry.

The chemistry of divalent and trivalent nickel complexes with nitrogen–sulfur donor ligands has received much attention [1–11] particularly since the discovery [10–12] that a number of dehydrogenases contain nickel at their active sites, surrounded by more than one thiolate ligand, as well as one or two nitrogen donors. Nickel(II) is also used as a spectroscopic probe in metal replacement studies of other metalloenzyme systems [13–17]. Although a variety of nitrogen–sulfur donors have been investigated, thiosemicarbazides and thiosemicarbazones have received inadequate attention. We have been studying complexes of thiosemicarbazides and thiosemicarbazones [19–25] of a number of metal ions for the past few years. The emphasis has been on the synthesis of new compounds, the characterization by different physicochemical methods, exploration of their chemical reactivity and biological activity (such as antibacterial and antitumour properties) and determination of structures of key members of this series of complexes by X-ray crystallography, with the final objective of

* Author to whom all correspondence should be addressed.

arriving at a fruitful structure–activity correlation. In this paper we report our studies on the ligational behavior of 3-hydroxyiminobutanonethiosemicarbazone (L_1H_2) and its 4-phenyl derivative (LH_2) towards nickel(II). The X-ray crystal structure of one of the nickel compounds, $Ni(LH_2)_2(NO_3)_2 \cdot H_2O$, is also reported. The ligand 3-hydroxyiminobutanonethiosemicarbazone is known to be effective against vaccina infection in mice, probably acting through chelation of some essential metal ions [26,27]. It is also known [19] that the antibacterial activity of the ligand decreases on introduction of a phenyl ring at the hydrazinic end of the thiosemicarbazide moiety. However, a proper understanding of the actual mechanism of action requires detailed knowledge of the ligational behaviour of the thiosemicarbazone and structural features of its metal complexes. The present work is an attempt to contribute to research in this direction.

Table 1. Analytical data[a] of the complexes

Complex	Analysis (%)		
	C	H	N
$Ni(TSCDAMO)_2Cl_2 \cdot 2H_2O$	23.5 (23.3)	4.5 (4.7)	22.0 (21.8)
$Ni(TSCDAMO)_2Br_2 \cdot 2H_2O$	19.9 (19.9)	4.1 (4.0)	18.5 (18.6)

EXPERIMENTAL

Chemicals

$NiCl_2 \cdot 6H_2O$, $NiBr_2 \cdot 6H_2O$ and $Ni(NO_3)_2 \cdot 6H_2O$ were obtained from Merck (India). The ligands 3-hydroxyiminobutanonethiosemicarbazone (TSCDAMO) and 3-hydroxyiminobutanone(4-phenylthiosemicarbazone) (4PhTSCDAMO) were prepared by reported methods [18,19]. All other chemicals were of reagent grade and were used without further purification.

Preparation

The metal complexes were prepared by reacting an aqueous solution (15 cm^3) of 1 mmole of the appropriate nickel salt, with an alcoholic solution (30 cm^3) of 2 mmole of the ligand for 2 h. The pH of the solution was adjusted to between 2–3 by addition of the appropriate acid ($HCl/HBr/HNO_3$). The resultant brown solution was allowed to evaporate at room temperature where upon dark brown crystalline compounds separated out. The crystals were collected by filtration, washed successively with cold ethanol and water and dried over fused calcium chloride.

The different instrumental techniques used for characterization of the compounds have been described in our earlier paper [28]. Analytical data are presented in Table 1.

Crystallography

Crystal data. $C_{22}H_{30}N_{10}O_9S_2Ni$, $M = 701.4$, triclinic, space group $P\bar{1}$ $a = 14.983(2)$, $b = 13.202(2)$, $c = 8.193(1)$Å, $\alpha = 91.54(1)^\circ$, $\beta = 77.38(1)^\circ$, $\gamma = 100.58(4)^\circ$, $U = 1554.4$ Å^3 (unit-cell parameters were calculated from least-squares fitting of 2θ angles of 25 selected strong reflections): λ(Mo-$K\alpha$) = 0.71073 Å, $D_M = 1.51$ g cm^{-3}, $Z = 2$, $D_c = 1.498$ g cm^{-3}, brown crystals $0.21 \times 0.25 \times 0.18$ mm^3, μ(Mo-$K\alpha$) = 0.816 mm^{-1}, $F(000) = 728$.

Data collection and processing. A total of 9458 reflections were collected (of which 7390 were unique) on a Rigaku AFC6 diffractometer at 298 K using graphite-monochromated Mo-$K\alpha$ radiation by ω–2θ mode, with $2\theta_{max}$ of 70° and a scan speed of 4° min^{-1}. Crystal stability was monitored by recording three check reflections at intervals of every 100 measurements. No significant variation in the intensity of these monitoring reflections was observed. Reorientation checking was done where $|w_{cal} - w_{obs}| > 0.2$. The time allowed for background count was constant (7 s). Intensities were corrected for Lorentz and polarization effects, but not for absorption.

Structure analysis and refinement. The structure was solved by Patterson and heavy-atom methods. Full-matrix least-squares refinement of the positional and isotropic thermal parameters of the non-hydrogen atoms resulted in a residual index of 0.17. Thermal parameters of two oxygen atoms O(5) and O(6), belonging to the nitrate group 2 were significantly high. Refinement was then carried out with anisotropic thermal parameters. The thermal parameters of the above-mentioned two atoms were very high at the end of the first cycle. An electron density map computed at this state indicated that there may be partial disorder in this region of the molecule. In subsequent refinement, the atoms of this nitrate group were kept fixed with final isotropic thermal parameters. Refinement of the remaining non-hydrogen atoms with anisotropic thermal parameters converged to the R value to 0.12. Twenty-two hydrogen atoms were located from successive difference electron density maps. Seven hydrogen atoms were placed at calculated positions. The positional and isotropic thermal parameters ($U = 0.05$ Å^2) of all the hydrogen atoms were kept fixed in the last two cycles of refine-

ment. The final R value was 0.097 with 4756 observed reflections $[I > 2.5\sigma(I)]$, $R_w = 0.106$, $w = [\sigma^2|F_o| + 0.033|F_o|^2]^{-1}$. The maximum value of shift/e.s.d. was 0.20 in the last cycle. The maximum residual electron density in a final difference electron density map was 2.4 eÅ^{-3}, lying close to the disordered nitrate group. Patterson synthesis and refinement were carried out using SHELX 76 [29]. Atomic scattering factors were taken from *International Tables for X-ray Crystallography* [30].

RESULTS AND DISCUSSION

Description of crystal structure

The ORTEP plot of one asymmetric unit is shown in Fig. 1, along with the atom-numbering scheme. The asymmetric unit consists of a nickel atom, coordinated by two molecules of the ligand (H_2L); two nitrate ions and a molecule of water remain uncoordinated. For the sake of convenience of discussion these two molecules of the ligand are designated as ligand A and ligand B and the individual atoms in the ligand are identified with suffix A and B where necessary. Selected bond distances and bond angles are listed in Table 2.

Each of the ligand molecules acts in a tridentate manner coordinating through the thione sulfur, the imine nitrogen and oxime nitrogen. The nickel atom is in a distorted octahedral environment, with each ligand occupying a meridional plane, which favours extensive delocalization of the electron cloud. The best description of the geometry around nickel is obtained when $S(1)_A$, $N(4)_B$, $N(4)_A$ and $S(1)_B$ are considered to form a square plane and $N(3)_A$ and $N(3)_B$ act as axial ligands. Angles generated at the Ni^{II} centre by the chelating donor points (N and S) differ slightly in the two coordinating ligands (Table 2). It appears that the angles at the Ni^{II} centre in the chelate rings are controlled to some extent by the ligand geometry.

N(4)—C(10)—C(8)	112.6(6)		114.8(7)
C(8)—C(10)—C(11)	122.4(7)		119.8(8)
N(4)—C(10)—C(11)	125.0(7)		125.4(9)

are comparable to those in the nickel(II) complexes of 1-formylisoquinolinethiosemicarbazone [31] and 1-formylpyridinethiosemicarbazone [32].

As expected [32], the sulfur and imine nitrogen atoms in both molecules of the ligand are in the *cis* conformation with respect to the C(7)—N(2) bonds. The two donor nitrogen atoms, N(3) and N(4), in A and B also lie *cis* to each other. The hydrogen atoms attached to the oxime oxygen atoms could not be located.

The phenyl rings in ligands A and B are almost planar, while the thiosemicarbazide chains deviated from planarity. The dispositions of the phenyl rings with respect to the thiosemicarbazide moiety are different in the two molecules of the ligand. The dihedral angle between the mean planes of the phenyl ring and that calculated with S, C(7), N(2) and N(3) are 114.8(3)° and 18.5(2)° in A and B, respectively. The atoms N(3), C(8), C(10) and N(4), which form a five-membered ring with nickel, are almost planar in both ligand molecules.

Table 3. Selected torsion angles (°) with estimated standard deviations in parentheses

N(3)—C(8)—C(10)—C(11)	−178.3(7)	−176.2(8)

The crystal structure is stabilized by ionic interaction, van der Waals forces and a network of hydrogen bonds involving the water molecules, the nitrate ions and the donor atoms from the ligand molecules (Fig. 2). All the hydrogen atoms available for forming hydrogen bonds are involved in hydrogen bonding. Each of the hydrogen atoms bonded to $N(1)_A$, $N(2)_A$ and $N(1)_B$ and one of the hydrogen atoms, H(82), of the water molecule participate in formation of one hydrogen bond. The other hydrogen atom of the water molecule accepts three hydrogen bonds. Figure 2 shows a view of the crystal packing.

IR spectra

The IR spectrum of the complex recorded in a KBr disk exhibited a broad bond spanning the 3400–3100 cm^{-1} region, probably arising from the overlap of the ν_{OH} modes of the lattice water with the ν_{NH} and ν_{OH} modes of the ligand. the $\nu_{C=N}$ (imine) band observed at 1590 cm^{-1} in the free ligand was shifted towards

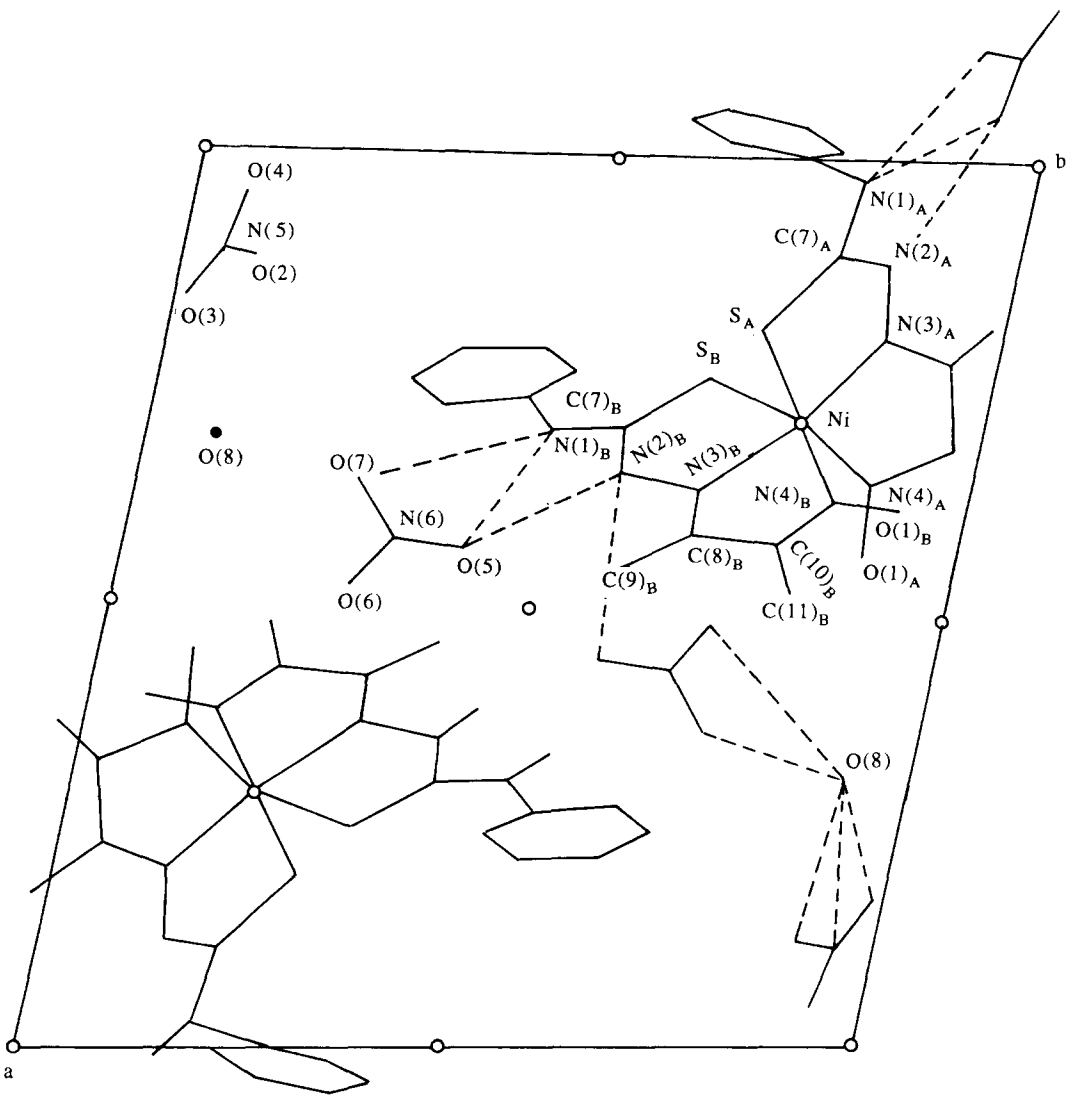

Fig. 2. The crystal structure of bis[3-hydroxyiminobutanone(4-phenylthiosemicarbazone)] nickel(II) nitrate, monohydrate.

lower wavenumber by 10–15 cm^{-1}, indicating involvement of the imine nitrogen, N(3), in coordination [22–24]. Participation of the oxime nitrogen N(4), in coordination was indicated by a positive shift of 20 cm^{-1} of the ligand $\nu_{C=N}$ (oxime) mode at 1440 cm^{-1}, as well as a hypsochromic shift of 30 cm^{-1} of the $\nu_{N=O}$ mode around 1010 cm^{-1}. The ν_{CS} mode of the ligand at 750 cm^{+1} is lowered by 10–15 cm^{-1}, indicating participation of the thione sulfur in coordination [22–24].

Magnetic moment and electronic spectra

The magnetic moment, measured at 303 K, was found to be in the range 2.95–3.20 B.M. which is quite normal for octahedral Ni^{II} complexes.

The electronic spectra of the complexes recorded in alcohol and Nujol mull, exhibit two bands of comparable intensity ($\varepsilon \sim 100$) at 990 and 800 nm. The band around 800 nm is broad and seems to be made up of two overlapping bands. The band around 990 nm is assigned to the $^3A_2 \rightarrow {}^3T_2$ (ν_1) transition and that around 800 nm to overlapping of the spin-allowed transition $^3A_2 \rightarrow {}^3T_1$ (ν_2) with the spin-forbidden transition $^3A_2 \rightarrow {}^1E$ [33]. Another band of comparable intensity at 550 nm is observed in the mull spectrum. This may arise because of splitting of the ν_2 band in the low symmetry ligand field present in the complex [33]. The ν_3 band is masked by the high intensity charge transfer bands at 450 and 350 nm in Nujol, which shift to 390 and 300 nm, respectively, in ethanol solution. The first CT band is probably a MLCT transition, whereas the second CT band is probably a result of an intraligand transition. From the spectra

the crystal field splitting (10 Dq) produced by two TSCDAMO/4PhTSCDAMO ligands around the Ni^{+2} centre is found to be 10,100 cm^{-1}. This may be compared with the 10Dq value obtained for the $Ni(TSC)_3^{+2}$ complex [34] of 10,000 cm^{-1}.

Cyclic voltammetry

On an initial positive scan all the complexes exhibit an irreversible oxidation around 0.95–1 V. The free ligands and their zinc complexes, however, do not undergo oxidation up to 1.2 V. This strongly suggests that the above anodic peak is owing to Ni^{II}/Ni^{III} oxidation. As mentioned earlier, the Ni^{II} complex is in a distorted octahedral environment. After oxidation, the resultant Ni^{III} complex, being a d^7 species, would undergo Jahn–Teller distortion which would result in a severe strain on the octahedral complex, ultimately leading to dissociation of the ligand from the complex. This may explain the irreversible nature of the complex.

On cathodic scan the TSCDAMO complexes exhibit four reductions at −0.65 (irreversible), −1.13 (irreversible), −1.375 (reversible, $\Delta E = 100$ mV) and −1.61 V (quasi-reversible, $\Delta E = 120$ mV). It is well known [35] that oximes undergo reduction in $2e^-$ steps. In the first step a ketimine is formed, which is then reduced to amine. In the present case the first two peaks at −0.65 and −1.13 V are assigned to the reduction of the oxime part of the ligand. The other two cathodic couples at −1.375 and −1.61 V are assigned to the reduction of the imine part of the thiosemicarbazone moiety. For 4PhTSCDAMO complexes a similar behavior is observed, except that there is a slight cathodic shift of the reductive couples; moreover, the 1st, 3rd and the 4th couples are irreversible in this case, while the 2nd couple behaves reversibly.

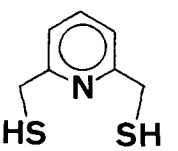
(Received 8 January 1996; accepted 30 August 1996)



Abstract—2,6-Bis(mercaptomethyl)pyridine (H_2L) and its binuclear nickel(II), palladium(II) and platinum(II) complexes, containing the dianion as a bridging ligand, were prepared and characterized by physicochemical and spectroscopic data. Square-planar geometries are proposed for these divalent metal complexes. Cyclic voltammetry of Ni_2L_2 in DMSO shows a reversible one-electron reduction wave at -1.48 V *vs* a $Ag/AgBF_4$ reference electrode. Quantitative reduction of this complex by controlled potential electrolysis at -1.80 V yielded the corresponding Ni^I product as shown by ESR spectroscopy. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: pyridine derivative; binuclear metal complexes.

Interest in the synthesis, magnetic, spectroscopic and electrochemical properties of bridged polynuclear complexes has risen considerably in recent years because of their importance in the understanding of the mechanism of magnetic interactions between metal ions [1,2].

The behaviour of the mercaptide ion as a donor in transition metal complexes has not been subjected to such detailed study as a number of other donor groups. This arises, in part, because the mercapto group often gives metal ion derivatives that are extremely insoluble, bridged or even polymeric. Furthermore these substances are easily oxidized. These properties greatly complicate the characterization of mercapto complexes. However, the theoretical interest and biological importance of mercaptans means that elucidation of the manner of interaction of this functional group with metal ions is of great interest [3].

One of the most distinguishing properties associated with the mercaptide group is its ability to react readily with many metals to form complexes containing sulfur bridges and, in order to investigate the characteristics of the mercaptide complexes further, particularly the bridging and reactivity of coordinated sulfur atoms, the present work was undertaken. The ligand studied, H_2L = 2,6-bis(mercaptomethyl) pyridine (**1**), is similar to 2-(2-mercaptoethyl)pyridine and β-mercaptoetylamine in its donor atoms, but differs in stereochemistry and type of nitrogen atom and in the size of the chelate ring it may form.

EXPERIMENTAL

Materials

Published methods were used to prepare 2,6-bis(bromomethyl)pyridine [4], and 2,6-bis(mercaptomethyl)pyridine [5–7]. Solvents used for synthetic and spectroscopic work were distilled over appropriate drying agents prior to use. All other

* Author to whom correspondence should be addressed.

chemicals were of analytical grade, available commercially. Unless otherwise stated the reactions were carried out under dry dinitrogen, but the final work-up was performed in air.

Physical measurements

The IR spectra were recorded on a Perkin–Elmer model 983 spectrophotometer using KBr or CsBr disks. The spectra were calibrated against the 1603 cm^{-1} band of polystyrene. Mass spectra were obtained from A.E.I. MS9, MS12 or MS30 spectrometers at 70 eV. Measurements of *d–d* transitions in the visible and near-IR region were taken with a Cary recording spectrophotometer model 17D, while a Pye Unicam PU8800 spectrophotometer was used for recording the visible and UV spectra. Conductance measurements were made using a Wayne Kerr universal bridge. The conductivity cell was calibrated with aqueous KCl. The electrochemical measurements were made on a Princeton Applied Research (PAR) electrochemistry system, model 170. All readings were taken using three potentiostatic systems and are quoted referenced to an external silver/silver(I) pseudo-reference electrode with tetra-*n*-butylammonium tetrafluoroborate (0.1 M) as supporting electrolyte. Magnetic moments were recorded on a John Matthey magnetic susceptibility balance model MSB1. Microanalyses were performed by the Cambridge University Microanalytical Department. ESR spectra were measured on a Varian E109 model spectrophotometer (*X*-band).

Preparation of bis[2,6-*bis*(*mercaptomethyl*)*pyridino*] *dinickel*(II)

Method I. Nickel sulfate hexahydrate (6 g, 22.8 mmol) was dissolved in concentrated ammonia solution ($d = 0.880$ g cm^{-3}, 20 cm^3) and water (75 cm^3). To this solution was added, with stirring, 2,6-bis (mercaptomethyl)pyridine (1.98 g, 11.6 mmol) dissolved in methanol (15 cm^3). A light brown precipitate was formed immediately. The solid was separated by filtration and dried *in vacuo* over sulfuric acid. Yield 2.23 g, 85.5%

Method II. Nickel chloride hexahydrate (1.19 g, 5 mmol) was dissolved in absolute ethanol (50 cm^3). To this solution was added slowly, with stirring, 2,6-bis(mercaptomethyl)pyridine (0.86 g, 5 mmol) in absolute ethanol (13 cm^3). A light brown precipitate was formed immediately and separated by filtration, washed with absolute ethanol, and diethyl ether and then dried *in vacuo* over sulfuric acid. Yield 0.95 g, 82.6%.

Preparation of bis[2,6-*bis*(*mercaptomethyl*)*pyridino*] *dipalladium*(II)

Potassium chloride (0.3 g, 4 mmol) and palladium chloride (0.3 g, 1.7 mmol) were dissolved in water (50 cm^3) and concentrated ammonium hydroxide (17 cm^3). Upon stirring and warming all the solid had dissolved. To this solution was added, with stirring, 2,6-bis(mercaptomethyl)pyridine (0.4 g, 2.3 mmol) dissolved in water (2.5 cm^3) and 30 drops of concentrated hydrochloric acid. An orange precipitate was formed immediately. Stirring was continued for 10 minutes, then the solution was filtered and the orange solid washed with water, methanol and diethyl ether and dried *in vacuo* over sulfuric acid. Yield 0.58 g, 90%.

Preparation of bis[2,6-*bis*(*mercaptomethyl*)*pyridino*] *diplatinum*(II)

Platinum chloride (0.3 g, 1.1 mmol) and potassium chloride (0.3 g, 4 mmol) were dissolved in water (17 cm^3) and concentrated ammonium hydroxide (10 cm^3). Upon stirring and warming all the platinum chloride had dissolved. To this solution was added, with stirring, 2,6-bis(mercaptomethyl)pyridine (0.2 g, 1.2 mmol) dissolved in methanol (10 cm^3). A pale yellow precipitate formed at once. The mixture was warmed, with stirring, for 1 h and then filtered. The pale yellow solid was washed with water, methanol and diethyl ether and dried *in vacuo* over sulfuric acid. Yield 0.54 g, 87%.

RESULTS AND DISCUSSION

The ligand 2,6-bis(mercaptomethyl)pyridine was prepared from a mixture of 2,6-bis(bromomethyl) pyridine with thiourea and reacted with nickel(II), palladium(II) and platinum(II) salts to form, preferentially, binuclear metal complexes. The complexes were all amorphous precipitates. In strongly ammoniacal solution or in neutral methanolic solution, complexes of stoichiometry M_2L_2 were formed. The analytical data supporting the stoichiometry of these complexes are given in Table 1 together with the molar conductivity values. The complexes are believed to be dimeric. Their solubilities are quite low but after heating and prolonged shaking they can be dissolved to a small extent in DMSO, DMF, CH_2Cl_2, chloroform or nitromethane. The palladium(II) and platinum(II) complexes proved to be very insoluble in both polar and non-polar solvents. The conductivity measurement of the Ni_2L_2 complex in DMSO, DMF and nitromethane shows that it is a non-electrolyte (Table 1).

Transition metal ions tend to expand their coordination number if an electron donor group is available. Treatment of planar four-coordinate complexes with pyridine usually results in expansion of the coordination number to six [8]. However, the reaction of pyridine with Ni_2L_2, Pd_2L_2 or Pt_2L_2 failed to produce such a derivative and the starting materials were recovered unchanged.

The pertinent IR absorption bands of these com-

plexes are reported in Table 2 and are all consistent with the absence of the band associated with the S—H stretching vibrational mode (2250 cm^{-1}). The spectra of these complexes show similarities to one another and exhibit four characteristic bands in the 1600—1400 cm^{-1} region attributable to the pyridine ring. The presence of ν(M—S) and ν(M—N) at *ca* 350 and 420 cm^{-1}, respectively, support coordination by the ligand [9].

The mass spectra of the nickel(II), palladium(II) and platinum(II) complexes showed two principal peaks: one corresponding to the dimeric molecular weight and the other one corresponding to a half molecular weight owing to formation of the monomer. The mass spectrum of the nickel(II) complex exhibited the highest mass peaks centred around m/z 456; this corresponds to a dimeric formulation, Ni_2L_2, which has an expected m/z 454 based on ^{58}Ni and ^{32}S. In the same way, Pd_2L_2 and Pt_2L_2 complexes display no mass peaks above the band of isotopic peaks centred around m/z 550 and 728, respectively, which correspond to expected molecular weights based on ^{106}Pd and ^{195}Pt isotopes.

Magnetic moment measurements of the Ni_2L_2, Pd_2L_2 and Pt_2L_2 complexes show that they are diamagnetic, suggesting that they have square-planar structures. They are low-spin d^8 transition metals without unpaired electrons. The electronic spectrum of Ni_2L_2 was recorded in DMSO, DMF, methanol and acetonitrile and two peak bands at 17,510 and 23,750 cm^{-1} appeared clearly resolved and they were assigned to $^1A_{1g} \rightarrow {}^1A_{2g}$ and $^1A_{1g} \rightarrow {}^1B_{1g}$ transitions, respectively, in a square-planar geometry [10]. The diamagnetic nature of the complexes supports the above geometry. The electronic spectrum of Ni_2L_2 also displays bands above 30,000 cm^{-1} which can be assigned to the S → M charge transfer and L → L* transitions of the dinegative ligand, consistent with other sulfur ligands [10,11].

Based on physicochemical and spectroscopic data a possible sulfur-bridged dimeric structure may be assumed for the divalent square-planar complexes (Fig. 1). These complexes are analogous to the 2-(2-mercaptoethyl)pyridine and β-mercaptoethylamine complexes described previously [12].

Electrochemistry and ESR spectrum of the Ni_2L_2 *complex*

The cyclic voltammetry of the nickel(II) complex was investigated in DMSO as solvent with 0.1 M in tetra-n-butylammonium tetrafluoroborate as supporting electrolyte. The complex dissolved freely in DMSO to yield a deep brown solution. Figure 2 shows a voltammogram for the nickel(II) complex indicating that the compound underwent a fully reversible one-electron reduction at −1.48 V *vs* Ag/$AgBF_4$ reference electrode. Cyclic voltammetry at a scan rate 100 mV s^{-1} showed a peak separation ($E_{pc} - E_{pa}$) of 70 mV and with the ratio of the peak cathodic and anodic currents being nearly 1.0, suggesting that the electrode

reactions approach Nernstian behaviour. The high negative reduction potential nickel(II) → nickel(I) shows that the metal ion is highly stabilized by the strong sigma-donor properties, which overcomes the π-acceptor properties of the ligand [13]. The nickel(I) was generated and characterized using controlled potential electrolysis and ESR techniques, respectively.

One cannot distinguish between an authentic Ni^{I} species and Ni^{II}-stabilized ligand radical species on the basis of magnetic moment measurements alone. An advantage of ESR studies is that one can in fact distinguish between the two possibilities. The ESR measurements for the one-electron reduction product show an axially symmetric spectrum with $g_{\perp} < g_{\parallel}$ suggesting a d^9, Ni^{I} configuration, i.e. $(e_g)^4(a_{1g})^2(b_{2g})^2(b_{1g})^1$. An isotropic ESR spectrum with no hyperfine splitting and a g value very nearly equal to the free electron value (2.0023) should be expected in the case of a Ni^{II}-stabilized ligand radical species. The reduction of the Ni^{II} complex in DMSO with supporting electrolyte was carried out by the controlled potential technique at −1.80 V under a constant stream of argon. The colour of the initial solution slowly changed from brown to black. The ESR spectrum of this solution as a DMSO glass at 77 K showed two g values in accord with previous ESR results of this d^9 species with similar ligands [14]. The g values, $g_{\parallel} = 2.091$ and $g_{\perp} = 2.051$, are consistent with the presence of a $S = \frac{1}{2}$ complex ligated by groups with δ-donor properties [15,16]. The hyperfine coupling patterns owing to ^{61}Ni nuclear spin $I = \frac{3}{2}$ (1.19% natural abundance) could not be completely resolved, probably as a result of the influence of the supporting electrolyte. This phenomenon, whereby added salts improve the resolution, has been noted by other authors [17]. The ESR spectrum of the Ni^{I} complex at 77 K can be seen in Fig. 3. In the absence of information such as the nickel hyperfine coupling constant, it is not possible to estimate the extent of delocalization of the unpaired electron on to the ligand [18].

Attempts to characterize further the nickel(I) complex were unsuccessful. The dark brown electrolysed solution at −1.80 V was transferred by syringe to a Schlenk tube and the nickel(I) species was isolated as an oil by the addition of dry, oxygen-free diethyl ether followed by evaporation under reduced pressure. The oil remaining could not be crystallized on trituration with a little cold MeOH.

Abstract—The photochemically-induced CO substitution reactions of $[M(CO)_6]$ (M = Cr, Mo, W) have been investigated in the presence of triphenylphosphine (PPh_3) and γ-alumina. The metal loading was determined by Rutherford backscattering spectrometry (RBS) and the generated species were analysed by Fourier transform IR spectroscopy (FT-IR) and ^{13}C NMR spectroscopy. The metal loading on the alumina surface was seen to increase with the irradiation time reaching 0.6, 0.8 and 3.4% for Cr, W and Mo, respectively. The ligand cone angle plays an important role in the case of Cr, where only the *trans* disubstituted species was found on the alumina surface. However, it is less important for the two other metals, where the *cis* compound was formed preferentially and the electronic *cis*-labilization factor seems more important. After grafting, only the disubstituted species was seen to remain on alumina evidencing a stronger interaction with the support than in the case of the monosubstituted and the hexacarbonyl compounds. © 1997 Elsevier Science Ltd. Keywords: metal carbonyl derivatives; alumina; Group 6 metals; substitution reactions; characterization.

Transition metal carbonyls anchored on various inorganic supports, such as alumina, zeolite and silica, have been intensively studied due to their catalytic properties. Their behavior is of particular interest as precursors that lead by decomposition to highly dispersed metals on the support surface and to low-valence metal catalysts without reduction treatments. These catalysts can be several times more active, in reactions such as metathesis of alkenes, hydrogenation of CO or alkenes, than their analogous supported metal oxides systems that have higher valences [1].

Group 6 metal carbonyls anchored on inorganic oxides have been extensively studied since the pioneering researches of Burwell *et al.* [2] and Smith *et al.* [3] on the decarbonylation and catalytic properties of $[Mo(CO)_6]$ and its derivatives subcarbonyl species immobilized on the Al_2O_3 surface. In particular, chromium(VI) compounds supported on silica are among the most used and studied catalyst systems in petrochemistry. Among them, the Philips catalyst Cr/SiO_2 is largely employed for the low-pressure polymerization of ethylene. This supported catalyst can be achieved by several routes, such as deposition of $[Cr(CO)_6]$, followed by thermal treatment, among others [4].

Supported molybdenum systems can act as catalysts for hydrogenation, hydrotreating, metathesis, isomerization and hydrogenolysis reactions. The surface structure of thermally reduced catalysts (a reduction step is necessary in order to activate such systems) has often three or four Mo oxidation states, depending on the reduction temperature. A more recent application for immobilized molybdenum systems is the attempt to replace the expensive rhodium in the three-way catalysts that contain supported platinum, palladium and rhodium, which are widely used in automobile exhaust converters. The Pd–Mo interaction in such systems was very recently proposed to be achieved *via* the immobilization of either a bimetallic cluster $[Pd_2Mo_2(Cp)_2(CO)_6(PPh_3)_2]$ or the organometallic precursors $[PdCl_2(PhCN)_2]$ and $[Mo(CO)_6]$ on MgO [5]. The supported tungsten compound applications

* Author to whom correspondence should be addressed.

resemble those of molybdenum. In particular, it is worth mentioning the activity of $[W(CO)_6]$ in propene metathesis, when anchored on Al_2O_3, SiO_2, ZrO_2 and ThO_2.

Besides their catalytic activity, the hexacarbonyl complexes of Cr, Mo and W have been suggested to be viable precursors to film growth due to their high vapor pressures and their photolability in the UV region [6]. Thus, continuous wave visible [7] and excimer lasers [8] have been mentioned to deposit conformal metal films for microelectronic applications.

In order to combine the catalytic activity of the Group 6 metal carbonyls with their intrinsic photosensitivity we have chosen a convenient route to obtain a metallic deposit on alumina, in the presence of triphenylphosphine and activated by UV radiation. In a previous work [9] the photochemically induced CO substitution reactions of $[Cr(CO)_6]$ with the tertiary group 15 of ligands (LPh_3, where L = P, As or Sb, Ph = phenyl), in the presence of γ-alumina was demonstrated to induce the exclusive generation of the [*trans*-$Cr(CO)_4(PPh_3)_2$] species on the support surface. Upon descending the group series, a neat reduction in the stereospecificity of the species being immobilized on the support was observed. This difference was attributed to the concomitant decrease in the cone angle [10] and, therefore, to the steric effect of the ligand L.

In the present work the metal loading on alumina surface from Group 6 metal carbonyls and their derivatives by photochemical activation was investigated by Rutherford backscattering spectrometry (RBS), Fourier-transform IR spectroscopy (FT-IR) and ^{13}C NMR spectroscopy. The metal loading dependence on the irradiation time was followed by RBS, while by FT-IR and ^{13}C NMR the chemical species present in the decanted solution and on alumina, as well as those extracted from the support were identified.

EXPERIMENTAL

Materials

The starting materials $[Cr(CO)_6]$, $[Mo(CO)_6]$, $[W(CO)_6]$ and PPh_3 were purchased from Aldrich Chemical Co. The Al_2O_3 (Oxyde C, 90 $m^2\ g^{-1}$) provided by Degussa was treated at 723 K in air for 3 h and then *in vacuo* for 1 h. The solvents (purum grade) were deoxygenated and dried with Na. Gaseous Ar and N_2 were purified by passage over BASF catalyst and through molecular sieves.

Primary sample preparation

All the experiments were performed under inert atmosphere using the Schlenk technique. Metal carbonyls were supported on alumina by mixing the pretreated support (400 mg) and a pentane solution of the metal hexacarbonyls (40 cm^3, 2% M) at room temperature for 30 min under stirring.

Photochemical reactions

The photochemical reactions were performed under an inert atmosphere using a Philips HPL-N (125 W) UV lamp fitted into a Pyrex cold finger. The minimum transmitted UV wavelength was limited by the Pyrex glass to 220 nm. In a typical photochemically induced CO substitution reaction $[Cr(CO)_6]/\gamma$-Al_2O_3 and PPh_3 were added to pentane. The resulting slurry was placed inside the photochemical reactor. The solutions were irradiated up to 360 min, but samples of the solution and of the solid phase were withdrawn at regular intervals to be analysed.

Fourier-transform IR spectroscopy (FT-IR)

Transmission FT-IR spectra were recorded at room temperature on a FT Mattson 3020 spectrometer (2 cm^{-1} resolution). The study was restricted to the mid-IR region (4000–1100 cm^{-1}) due to strong bulk absorption of alumina in the low wavenumber region. The solution was analysed with a pair of matched NaCl solution cells (0.10 mm pathlengths), while the solid phases were analysed as Nujol mulls. These solid samples were analysed as withdrawn from the reactor and after they were washed with pentane. The spectra were calibrated against the 1601.4 cm^{-1} band of a standard polystyrene film.

^{13}C NMR spectroscopy

The ^{13}C NMR spectra were obtained in $CDCl_3$ solution in a Varian Gemini VXR 200 MHz instrument and externally referred to TMS. The spectra were recorded after 20,000 scans at room temperature. The pulse width was 45° and a pulse delay of 1.5 s was used. The relaxing agent $[Cr(acac)_3]$ was added in all samples to overcome the long T_1 relaxation time of the carbonyl resonance. The species on the alumina surface were extracted with CH_2Cl_2 or THF prior to measurement.

Rutherford backscattering spectrometry (RBS)

The principle of RBS is to place a sample in the pathway of a monoenergetic ion beam originating from an ion accelerator and to detect the particles that are elastically scattered in the coulombic field of the sample atomic nuclei. The most common incident beam is $^4He^+$ and the detector (normally a surface barrier detector is used to detect the scattered particles) is usually place at 165° with respect to the incidence direction of the beam, characterizing a backscattering geometry (see the scheme sketched in the

top of Fig. 1). The energy of the scattered particles depends, among other factors [11], on the incidence energy, on the atomic mass of the atoms involved and on the depth in the sample where the scattering event occurred. In the RBS spectra shown in Fig. 1 the energy of the scattered particles is proportional to the channel number. In the present work the samples were homogeneous tablets made from a randomly oriented alumina powder after washing with pentane, with the organometallic compound supported on the surface of the grains. The samples' depth homogeneity is revealed by the plateaus in the Al and Mo signals in the spectra of Fig. 1: when an incident particle penetrates the sample it loses kinetic energy by interactions with the electrons of the medium before and after being scattered by energy by interactions with the electrons of the medium before and after being scattered by the nuclei. The kinetic energy that is lost depends on the composition of the sample and on the length of the trajectory (or depth) of the incident ion in the material. Each RBS spectrum shown in Fig. 1 can be decomposed in the Mo, Al and O signals, giving rectangular-shaped individual contributions, which added up constitute the experimental spectrum. Since the height of the signal corresponding to a certain element is proportional to the density of that element in the sample, the Mo/Al ratio, for example, can be calculated from the ratio of the two signal heights (Mo to Al). The RBS spectra of the present work were obtained using α-particle beams with energies of 0.8 and 2.0 MeV. The incidence direction was perpendicular to the sample surface and detection angle was 165° with respect to the direction of the beam.

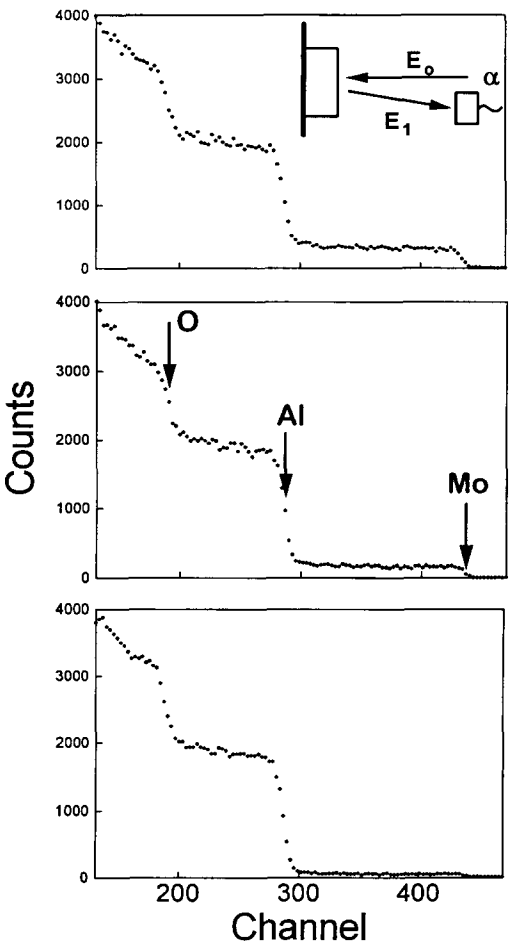

Fig. 1. Rutherford backscattering spectra obtained from samples of $[Mo(CO)_6]$ whose pentane solution together with PPh_3 and Al_2O_3 was irradiated with UV light. These spectra correspond, from bottom to top, to samples withdrawn after 1, 4 and 6 h of irradiation. The energy of the incident α-particle beam was 2.0 MeV. The incidence angle was 0° with the sample normal and the detection angle was 165° with respect to the incidence direction of the beam. A scheme of this geometry, also showing the sample and the detector, is sketched in the top of the figure. The arrows in the second spectrum indicate the outermost position of the corresponding elements in the samples.

RESULTS AND DISCUSSION

RBS results

RBS was used throughout this work to determine the metal loading on the alumina surface before and after photochemical activation. Figure 1 shows the RBS spectra corresponding to some steps of the reactions induced by UV light in the case of irradiating a $[Mo(CO)_6]$ pentane solution, PPh_3 and Al_2O_3, from which the Mo/Al_2O_3 atomic ratios could be calculated. It is noticeable that the increase of the irradiation time (from bottom to top of Fig. 1) increases the height of the Mo signal while maintaining the Al and O signals at a constant level, indicating a growth of the Mo loading on the alumina surface. The dependence of metal loading on irradiation time from 0 to 6 h is summarized in Fig. 2 for the three metals. The ever increasing behavior of Mo loading on alumina with the reaction time contrasts with the saturating behavior of Cr and W. In these two last cases, a surface saturation about 0.8% for W and 0.6% for Cr is reached. In fact, in a preliminary study [12] of the first steps, these trends were already evidenced. The present work confirms those trends for much longer UV irradiation times.

FT-IR results

Figure 3 represents the IR transmission spectra of $[Cr(CO)_6]/\gamma$-Al_2O_3 and PPh_3 reaction restricted to the ν(CO) region of the products. The top figure corresponds to spectra of chromium carbonyl derivatives in the solution, withdrawn from the reactor, after stopping stirring and letting alumina to decant; the bottom figure shows spectra corresponding to the derivatives supported on alumina. The solution spectra (Fig. 3, top) show a strong band at 1987 cm^{-1} (T_{1u} mode of $[Cr(CO)_6]$). The low-intensity band situated

at 1965 cm^{-1}, which is more visible in the spectrum that corresponds to the nonirradiated sample, is attributed to the isotopic effect pertinent to ^{13}CO. A band at 1945 cm^{-1} corresponding to the $E+A_1^2$ axial modes of C_{4v} pentacarbonyl species $[Cr(CO)_5PPh_3]$, appears mainly in the irradiated spectrum. The A_1^1 radial mode is also present at 2063 cm^{-1} in this spectrum.

In the solid phase (Fig. 3, bottom) the presence of $[Cr(CO)_5L]$ adsorbed on alumina surface can be observed by the presence of the bands at 2061 and 1937 cm^{-1}. The shift of the bands to low energy, compared with the same species in solution, especially of the $E+A_1$ mode, reflects the interaction of the metal carbonyls with the support: the Al^{3+} Lewis acid sites weakens the CO bond. The [*trans*-$Cr(CO)_4(PPh_3)_2$] species was evidenced by the band at 1879 cm^{-1} (E_u mode of D_{4h} symmetry). These spectra confirm our previous results [9] with this system. When the solid obtained in such conditions is washed with pentane, only the [*trans*-$Cr(CO)_4(PPh_3)_2$] species remains on the surface, the monosubstituted species being completely washed out. This fact suggests that the disubstituted species have a stronger interaction with the solid surface than the other species. The weak band at 1984 cm^{-1} shows the presence of traces of $[Cr(CO)_6]$ remaining after irradiation.

The solution phase IR spectra corresponding to the reaction with molybdenum (Fig. 4, top) show a behavior similar to the chromium one. The T_{1u} $[Mo(CO)_6]$ band at 1989 cm^{-1} and that of the monosubstituted C_{4v} species (1950 cm^{-1}, $E+A_1^2$ axial modes) appear. The alumina surface spectra (Fig 4, bottom) exhibit a more complex pattern, when compared with Cr, revealing the presence of several adsorbed species (see Table 1): traces of $[Mo(CO)_6]$ immobilized species (1986 cm^{-1}) are present plus the C_{4v} monosubstituted species (2071 cm^{-1}, A_1^1; 1947 cm^{-1}, $E+A_1^2$). Furthermore, the band centered to 1887 cm^{-1} and the shoulder around 1915 cm^{-1}, together with band centered at 2020 cm^{-1} (A_1^1) suggest

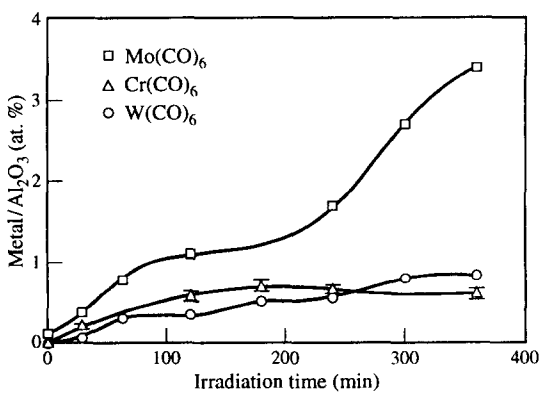

Fig. 2. Metal loadings on the γ-alumina surface, obtained from the RBS spectra, as a function of the irradiation time for the organometallic precursors: (□) $[Mo(CO)_6]$ (△) $[Cr(CO)_6]$ (○) $[W(CO)_6]$. The isotherms were obtained at room temperature. Typical statistical error bars associated with the Rutherford backscattering technique are given for the case of Cr coverage results. The lines are not fittings, they are used to guide the eyes.

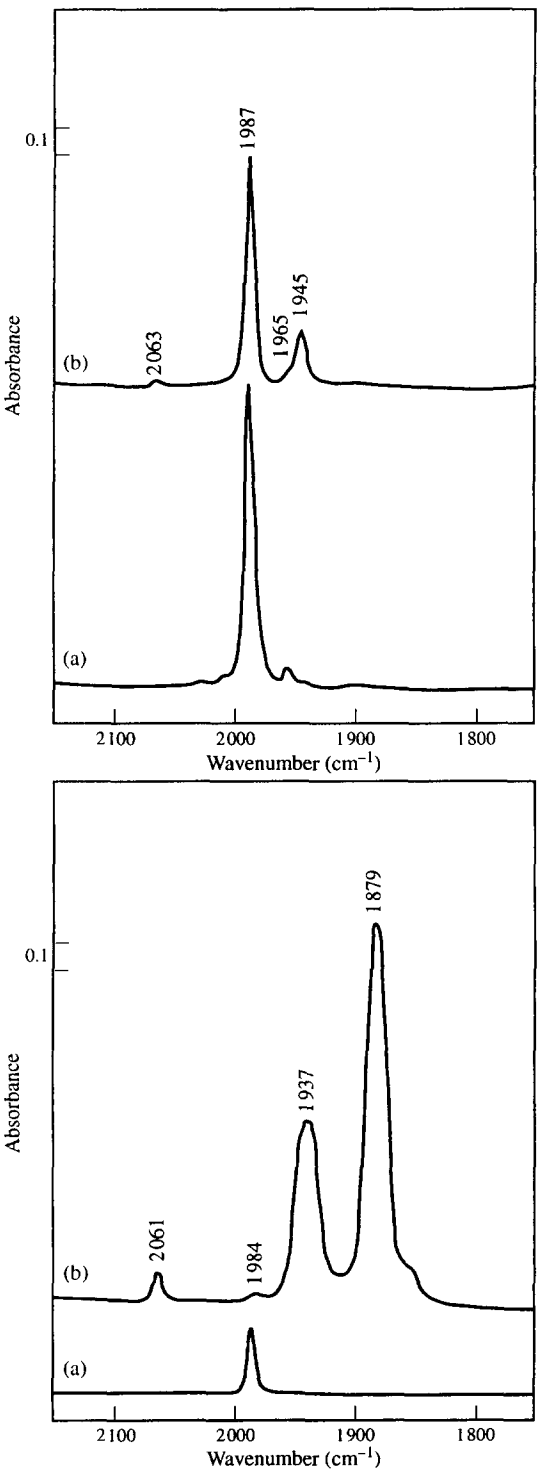

Fig. 3. IR spectra in the ν(CO) region of the products of the photochemically induced reaction of $[Cr(CO)_6]$ supported on Al_2O_3 with PPh_3 in pentane: top—solution phase, bottom—solid phase in nujol; (a) zero time, (b) 120 min.

the presence of [*cis*-$Mo(CO)_4(PPh_3)_2$] in analogy with similar compounds [13]. The strong band at 1901 cm^{-1} can be assigned to the E_u mode of the disubstituted *trans* species. After successive pentane washings, the support IR spectrum shows the presence of mainly the disubstituted species.

The [$W(CO)_6$] reaction spectra for both the solution and the solid phase show a similar behavior to that of Mo (Table 1). In solution, the presence of the hexacarbonyl and the monosubstituted pentacarbonyl species are observed and on the alumina surface the *cis* disubstituted species is confirmed besides [$W(CO)_5L$] and traces of the hexacarbonyl. There is no evidence for the *trans* disubstituted species ($\sim$1900 cm^{-1}). As in the preceding cases, after pentane washing only the disubstituted species remain on the support. Once again, these results suggest that the disubstituted species interact more strongly with the support than the monosubstituted and hexacarbonyl ones.

The same photochemical reactions in the absence of phosphine lead to the same general features in the IR spectra. However, after pentane washings no subcarbonyl species remain on alumina.

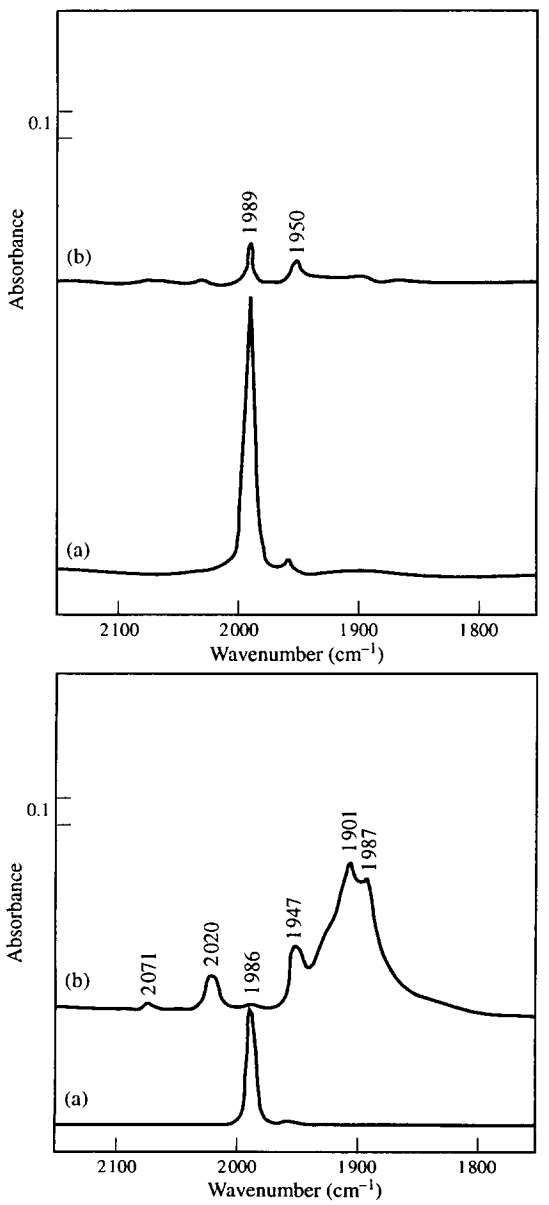

Fig. 4. IR spectra in the ν(CO) region of the products of the photochemically induced reactions of [$Mo(CO)_6$] supported on Al_2O_3 with PPh_3 in pentane: top—solution, bottom—solid phase in nujol; (a) zero time, (b) 120 min.

NMR results

^{13}C NMR spectra of the species generated in solution and anchored on alumina were obtained, giving the following result: the spectrum of the species generated in solution evidences the presence of [$Mo(CO)_6$] (200.8 ppm), the sextets due to Mo^{95} and Mo^{97} both with $I = 5/2$, and [$Mo(CO)_5L$] with *cis* CO chemical shifts appearing as a doublet around 205.5 ppm ($J_{^{13}C\text{-}M^{31}P} \approx 9.0$ Hz) and the δ_{CO}^{trans} around 210.1 ppm ($J_{^{13}C\text{-}M^{31}P} \approx 23.0$ Hz) in agreement with the data in the literature [14]. The spectrum of the species generated in the solid phase evidences the presence of [$Mo(CO)_5L$] (the doublet around 206.2 ppm corresponding to δ_{CO}^{cis}). The doublet attributed to the *trans* monosubstituted species is underneath one of the triplets of the *cis* disubstituted species around 215.4 ppm, (the other triplet appears at 210.4 ppm), ($J_{^{13}C\text{-}M^{31}P} \approx 8.0$ Hz). (On the other hand, the *trans*-disubstituted compound shows one triplet around 211.9 ppm, $J_{^{13}C\text{-}M^{31}P} \approx 9.0$ Hz.) The amount of this compound is seen to be smaller than the one of the *cis* species. The bands integration shows roughly a *trans*:*cis* ratio of 1:3, confirming the suspect of the existence of the *trans* species in the IR spectra, but in a smaller amount compared with the *cis* species.

DISCUSSION

In solution and in the presence of very weak coordination solvents, the generation of [$Mo(CO)_5$(solvent)] transients takes place [15]. In the presence of nucleophiles, such as phosphines and pyridine, the [$Mo(CO)_5$(solvent)] species undergo rapid thermal or photochemical substitution to produce [$Mo(CO)_5L$] and further reaction leads to the disubstituted species. In the present work, the photodissociations of [$Mo(CO)_6$] (M = Cr, Mo, W) in the presence of alumina and triphenylphosphine followed different trends, depending on the metal. From the analyses of the IR spectra, one sees that no metal remains on the support for zero irradiation time after pentane washings, evidencing a weak interaction between the precursor and the alumina surface. It is worth mentioning here that although no carbonyl species were detected by IR, the RBS measurements indicate that *ca* 0.01% in the case of Cr and W, and a relative higher

value of 0.1% in the case of Mo, remain anchored on the support. Although the different information provided by each technique (IR detects the ν(CO) associated to $[Mo(CO)_x]$ species, while RBS measures the metal coverage of the surface no matter its chemical environment), the total metal loading determined by RBS after washing must come necessarily from a small amount of $[Mo(CO)_6]$ not removed from the support, since the total decarbonylation and production of a bare metal or metal oxide at room temperature without any activation is unlikely. This evidences the greater sensitivity of the RBS technique when compared with IR under the present experimental conditions.

From the adsorption isotherms (Fig. 2), it is noticeable that Mo presents the steepest slope. These metal loadings come exclusively from the subcarbonyl species generated photochemically in the presence of phosphine. The higher metal loading for Mo confirms the phosphine substitution reaction tendency of such metal carbonyl, when compared with the two others [16,17]. The photolability tendency of Group 6 is Mo > Cr > W. So, based on the determination of the metal loadings by RBS, one can say that under the present experimental conditions $[Mo(CO)_6]$ has the most remarkable photolability. The relative easy formation of $[Mo(CO)_4]$ and $[Mo(CO)_3]$ by photolysis of $[Mo(CO)_6]$ in low-temperature matrices compared with Cr and W is also mentioned in the literature [18].

Besides the photolability inherent to each parent metal carbonyl, it is observed that the photogenerated surface species depend on the metal atom size. For Cr, the ligand cone angle directed the substitution reaction to produce only the *trans* disubstituted species on the alumina surface. It is worth mentioning that $[Cr(CO)_6]$ derivatives present, whenever it is allowed, *cis–trans* isomerism [19]. In this case, however, no evidence for *cis* species was found. As the metal atom size increases, the *cis* compounds were formed preferentially, accompanied with some *trans* species generation, according to IR and NMR data for molybdenum. For these larger atoms, the ligand cone angle has almost no influence on the products and a mixture of disubstituted compounds is generated on the alumina surface.

Conclusions

The photochemical reactions of the Group 6 metal carbonyls with triphenylphosphine and the alumina surface showed different behaviors depending on the M—CO bond strength and on the atomic size of the metal. The metal loading on the alumina surface was found to be $[Cr(CO)_6] < [W(CO)_6] < [Mo(CO)_6]$. For chromium, the cone angle of the ligand directed the reaction to produce only the *trans* disubstituted species on the alumina surface. No evidence for the *cis* species was found from the IR spectra. On the other hand, for the larger metals molybdenum and tungsten, the *cis* compound was formed preferentially, although the observed presence of the *trans* species in the case of Mo in a smaller ratio is noted. In these two later cases, the ligand cone angle does not seem to influence very much the kind of the originated products. After grafting, only the disubstituted species remain on alumina evidencing a stronger interaction with the support than in the case of the monosubstituted, and the hexacarbonyl compounds.

Abstract—Deprotonation of the primary phosphine complex $[Mo(CO)_5(PPhH_2)]$ generated $[Mo(CO)_5(PPhH)]^-$, a chiral anionic ligand which reacted readily with *cis*- or *trans*-$[PtCl_2(PEt_3)_2]$ *via* facile nucleophilic substitution of one or both chloride ligands to afford *trans*-$[PtCl(PEt_3)_2(\mu\text{-}PPhH)\{Mo(CO)_5\}]$ (**1**) and *cis*- and *trans*-$[Pt(PEt_3)_2(\mu\text{-}PPhH)_2\{Mo(CO)_5\}_2]$ (**2**), respectively. These are rare examples of heterometallic complexes containing primary phosphido bridges. Compound **1** can be described either as the square-planar Pt^{II} complex with the anionic ligand $PPhH\{Mo(CO)_5\}^-$ or as the Pt-Mo phosphido-bridged dimer *trans*-$[PtCl(PEt_3)_2(\mu\text{-}PPhH)\{Mo(CO)_5\}]$. As a phosphido-bridged heterobimetallic **1** possesses an exceptionally large Pt—P—Mo angle [120.9(1)°] reflecting the long Pt—Mo nonbonding interaction (4.5 Å). Compound **2** can correspondingly be described either as a phosphido-bridged $PtMo_2$ trimer or a square-planar arrangement of two neutral PEt_3 and two anionic $PPhH\{Mo(CO)_5\}$ ligands at Pt. The low-temperature $^{31}P\{^1H\}$ NMR spectrum of **1** showed several ABXY spin systems together with their associated ABXYM (M = ^{195}Pt) counterparts and variable-temperature studies revealed the dynamic interconversion of several rotametric isomers arising from restricted rotation about the Pt—Pμ bond. The $^{31}P\{^1H\}$ NMR spectrum of *trans*-**2** shows its two possible *RR*/*SS* and *meso* diastereoisomers, the latter existing in clearly identifiable rotameric forms which interconvert slowly at −75°C. We note very different values between ^2J(P—P) and $^1J(^{195}Pt—P)$ for the anionic ligands $[PPhH\{Mo(CO)_5\}]^-$ and PEt_3, unattributable to bond length variation but which must reflect reduced *s*-orbital contribution to the Pt—P bond of the anionic phosphines $PPhH\{Mo(CO)_5\}$.© 1997 Elsevier Science Ltd. Keywords: platinum; molybdenum; bridging PHPh; X-ray structures.

There has been an explosive growth in the synthesis, characterization and reactivity of heterometallic complexes, many of which comprise metals with very different electronic and coordinative properties [1]. Stephan's review article in 1989 highlighted the large number of heterobimetallics supported by a variety of different bridging ligands [2]. The desire to develop these early–late heterobimetallics has been driven by the belief that they should react with substrates in a cooperative manner [3]. Although there are few examples of successful cooperativity between electron-poor early transition metals and electron-rich transition metal centres, there have been several noteworthy approaches towards achieving this goal. Recent reports by Bergman [4] and Braunstein [5] serve to highlight the value of designed synthesis to achieve participation from each metal. Bergman's elegant syn-

thesis and reactivity studies with an imido-bridged zirconium–iridium heterometallic clearly demonstrates a cooperativity in its reactions with both polar and non-polar X—H bonds. In contrast, Braunstein and co-workers have shown that the reactivity of iron–platinum heterometallics depends markedly on the nature of the bridging ligand. Following a recent highlight by Herberhold and Jin [6] focusing on heterometallics with polar metal–metal bonds, Chisholm *et al.* [7] suggested that the reactivity anticipated for such early–late heterometallics could be achieved by asymmetric homometallic complexes with polar W—W bonds (W^{VI}—W^{II}) with the metals in vastly different coordination environments.

Although heterobimetallics with various bridging ligands [8] have been prepared the predominant use of the phosphido ligand (PR_2) [9] can be attributed to: (i) the ease of synthesis via the bridge-assisted method [10], (ii) stabilization of the metal–atom framework during chemical transformation [11] and (iii) the presence of a ^{31}P nucleus which is useful for probing solution-state structures and fluxionality [12]. However, several recently reported transformations involving phosphido ligands set limits on their use for framework-stabilizing since they do not invariably behave as innocent bridging ligands [13]. Of the many phosphido-bridged heterometallic complexes reported, most contain two bridging ligands and Baker *et al.* [14] recently surveyed the area of diphosphido-bridged ELHB compounds up to 1990. However, current efforts have focused on the preparation of singly-bridged μ-phosphido binuclear complexes without metal–metal bonds [15] with large M—P—M′ angles. Particularly noteworthy are $[Cp_2M(H)(\mu\text{-}PR_2)M'(CO)_5]$ (M = Mo, W; M′ = Cr, Mo, W) and $[CpFe(CO)_2(\mu\text{-}PR_2)W(CO)_4L]$ (L = PMe_3, CH_3CN) prepared by the groups of Kubicki [15a] and Shyu, respectively [15c].

The synthesis of μ-PR_2 Pt—M (M = Mo, W) heterometallics continues to be of considerable scientific interest despite their limited applications. Geoffroy and co-workers have reported a number of such complexes dominated by M—M′ bonding interactions [16] and later Powell demonstrated that oxidative addition of the P—H bond of secondary phosphine complexes to zero-valent platinum centres is an efficient route to heterobimetallics, including $[(CO)_4M(\mu\text{-}PR_2)(\mu\text{-}H)Pt(PPh_3)_2]$ [M = Mo, W] [17]. The catalytic activity of diphenylphosphido-bridged heterometallics have been evaluated by Mathieu [18] and there have been studies on metal-assisted substitutions *via* M—M bond formation [19].

This report follows our discovery of some unusual structural and spectroscopic characteristics of chiral MoPt heterometallics bridged by the primary phosphido ligand PPhH. We have recently reported [20] that nucleophilic substitution of chloride in $[PtCl_2(dppe)]$ by the chiral anionic ligand $[Mo(CO)_5(PPhH)]^-$ affords the phosphido-bridged Mo_2Pt trimer $[Pt(\mu\text{-}PPhH)_2\{Mo(CO)_5\}_2(dppe)]$ (**3**). The $^{31}P\{^1H\}$ NMR spectra of **3** are quite remarkable, highlighting this technique in elucidation of structure and of solution-state fluxional processes. We report the synthesis, spectroscopic and structural characterization of the heterometallic complexes *trans*-$[PtCl(PEt_3)_2(\mu\text{-}PPhH)\{Mo(CO)_5\}]$ (**1**) and *cis*- and *trans*-$[Pt(PEt_3)_2(\mu\text{-}PPhH)_2\{Mo(CO)_5\}_2]$ (**2**), each containing chiral primary phosphido bridges.

EXPERIMENTAL

General consideration

Standard double manifold vacuum-line techniques were used for all chemical manipulations and all reactions were performed under dry nitrogen. All solvents were dried prior to use, hexane and tetrahydrofuran over sodium/benzophenone and dichloromethane over P_2O_5. Reactions were monitored by IR spectroscopy and TLC (Baker flex, silica gel 1B-F). Products were purified by column chromatography (330 × 30 mm) with silica gel (70–230 mesh) or TLC on silica gel plates (20 × 20 cm, Merck, TLC grade, Aldrich Chemical Co.). Solution IR spectra were recorded on a Perkin–Elmer 983 spectrometer using calcium fluoride cells. ^1H NMR spectra were recorded on Varian VXR400 or XL200 spectrometers and all ^{31}P NMR spectra were recorded on a Varian VXR400 instrument at 162.0 MHz and referenced to external 85% H_3PO_4. Elemental analysis were carried out in the Analytical Laboratory at University College London. All chemicals except where stated were used as obtained from commercial sources and the starting materials $[PtCl_2(PEt_3)_2]$ [21] and $[Mo(CO)_5(PPhH_2)]$ [22] were prepared as reported.

Reaction of $[Mo(CO)_5(PPhH)]^-$ *with* cis-$[PtCl_2(PEt_3)_2]$

A solution of $[Mo(CO)_5(PPhH_2)]$ (0.1264 g, 0.4 mmol) in dry THF (50 cm^3) was treated with the base DBU (0.160 cm^3, 1.1 mmol). The reaction mixture was stirred for 10 min and a solution of $[PtCl_2(PEt_3)_2]$ (0.090 g, 0.18 mmol) in THF (5 cm^3) was added dropwise. After stirring for a further 20 min, the solvent was removed under reduced pressure to leave a brown–orange oil, which was dissolved in a minimum of dichloromethane and chromatographed on silica gel plates. Elution with dichloromethane/*n*-hexane (2/3, v/v) afforded three well-separated bands. The fastest band gave *trans*-$[Pt(PEt_3)_2(\mu\text{-}PPhH)_2\{Mo(CO)_5\}_2]$ (**2**), which was crystallized from dichloromethane/ethanol and vacuum-dried to afford colourless crystal of **2** (0.025 g, 24%). IR [ν(CO), cm^{-1}, C_6H_{14}]: 2061 (w), 1938 (s), 1924 (sh). Found: C, 33.6; H, 4.3; P, 11.8. Calc. for $C_{34}H_{42}Mo_2O_{10}P_4Pt$ (mol.wt = 1121.61): C, 36.3; H, 3.7; P, 11.1%. The second minor bad was identified spectroscopically as *cis*-$[Pt(PEt_3)_2(\mu\text{-}PPhH)_2\{Mo(CO)_5\}_2]$ (**2**) and crys-

[b] Recorded CD_2Cl_2 at −80° C.
[c] Recorded in $CDCl_3$ at room temperature.

tallization form dichloromethane/ethanol gave colourless crystals of *cis*-**2** (0.010 g, 9.7%). IR [ν(CO), cm^{-1}, C_6H_{14}]: 2063 (w), 1935 (s), 1929 (sh). The final band to elute was identified as *trans*-$[PtCl(PEt_3)_2(\mu\text{-}PPhH)\{Mo(CO)_5\}]$ (**1**). Crystallization from dichloromethane/ethanol drying *in vacuo* afforded colourless crystalline **1** (0.017 g, 16.5%). IR [ν(CO), cm^{-1}, C_6H_{14}]: 2057 (w), 1928 (s), 1901 (sh). Found: C, 34.0; H, 4.4; Cl, 5.2. Calc. $C_{23}H_{36}ClMoO_5P_3Pt$ (mol.wt = 811.98): C, 33.7; H, 3.9; Cl, 4.4%.

X-ray structure analysis of **1** *and* trans-**2**

Colourless crystals of **1** and *trans*-**2** were grown from dichloromethane/ethanol at room temperature. A suitable crystal of each was glued to a glass fibre using epoxy resin and mounted on a goniometer head. Unit-cell parameters were obtained from least-squares refinement of 30 orientation reflections in the range $10 < 2\theta < 30°$ for **1** and 26 orientation reflections in the range $6 < 2\theta < 27°$ for **2**, selected from a rotation photograph.

Collection and reduction of intensity data. Details of the intensity data collection parameters for **1** and *trans*-**2** are presented in Table 2. The intensity data for both **1** and **2** were collected at 294 K on a Nicolet R3v/m automatic four-circle diffractometer using graphite monochromated Mo-K_α ($\lambda = 0.71073$ Å) radiation with the diffractometer operating in the ω–2θ scan mode. Three standard reflections monitored every 100 measurements showed no significant deviations during the data collection. Empirical absorption corrections for **1** and *trans*-**2** were made by the Ψ-scan method (maximum and minimum transmission factors were 0.950 and 0.511 for **1** and 0.966 and 0.636 for *trans*-**2**). Reflections were considered observed when $I_0 > 3\sigma(I_0)$.

Solution and refinement of the intensity data. The structures were solved by direct methods, followed by full-matrix least-squares refinement of positional and thermal parameters and subsequent conversion to anisotropic coefficients for all non-hydrogen atoms. All hydrogen atoms except those bonded directly to P were included in idealized positions and allowed to ride on carbon atoms with C—H distances fixed at 0.86 Å and isotropic thermal parameters at 0.08 $Å^2$. The function minimized in the least-squares calculations was $\Sigma w(|F_o| - |F_c|)^2$. The weighted R value is defined as $Rw = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2}$. All calculations were performed on a MicroVax II computer running SHELXTL PLUS (G. M. Sheldrick, Package for crystal structure determination, University of Göttingen, 1986). Further details are available as supplementary material (atomic coordinates, bond distances, bond angles, anisotropic thermal parameters and hydrogen atom positions) deposited at

RESULTS AND DISCUSSION

Reaction of the chiral anion $[Mo(CO)_5(PPPhH)]^-$ with *cis*-$[PtCl_2(PEt_3)_2]$ proceeds rapidly at room temperature to afford, after chromatographic work-up, a mixture of $[PtCl(PEt_3)(\mu\text{-}PPhH)\{Mo(CO)_5\}]$ (**1**) and *cis*- and *trans*-$[Pt(PEt_3)_2(\mu\text{-}PPhH)_2\{Mo(CO)_5\}_2]$ (**2**) complexes containing primary phosphido bridges.

Elemental analytical data for **1** was insufficient to distinguish between $[PtCl(PEt_3)(\mu\text{-}PPhH)\{Mo(CO)_5\}]$ and $[Pt(PEt_3)_2(\mu\text{-}PPhH)_2\{Mo(CO)_5\}_2]\cdot CH_2Cl_2$. However, $^{31}P\{^1H\}$ NMR spectroscopy confirmed its structure as well as giving considerable insight into a fluxional process in solution. The $^{31}P\{^1H\}$ NMR spectrum of **1** contains two distinct types of resonance. Our assignment of the high-field triplet

resonance ($\delta = -66.0$ ppm) to the bridging phosphido ligand was confirmed by its large one-bond phosphorus–hydrogen coupling constant [$^1J(P\mu—H) = 287$ Hz] consistent with previous observations [22]. Note that a high-field chemical shift (δ +50 to −200 ppm) for a phosphido bridge indicates the presence of a metal–metal bond, while low-field resonances (δ +50 to 300 ppm) imply non-bonded metal atoms [12]. An exchange-broadened low-field resonance [$\delta = +11.5$ ppm], although uninformative, confirmed the presence of PEt_3 ligands. The room-temperature triplet phosphido resonance [$^2J(PEt_3$-$P\mu) = 25.0$ Hz] is consistent with the presence of two PEt_3 ligands *cis* to the anionic phosphine $[PPhH\{Mo(CO)_5\}]^-$. The low-temperature $^{31}P^1H$ NMR spectrum of **1** (CD_2Cl_2, −75°C) several rotational isomers in slow exchange (*vide infra*). Also, the PEt_3 ligands each couple to ^{195}Pt with different $^1J(^{195}Pt—PEt_3)$ values (2413 and 2526 Hz), although these are in the range expected for mutually *trans* tertiary phosphines [23]. $^1J(^{195}Pt—P\mu)$ (2078 Hz) is lower than expected for a phosphorus donor *trans* to a chloride, based on the value for PEt_3 *trans* to chloride in *cis*-$[PtCl_2(PEt_3)_2]$ [$^1J(^{195}Pt—PEt_3) = 3500$ Hz] [23]. We have previously noted a similar low value for $^1J(^{195}Pt—P\mu)$ for coordinated $[PPhH\{Mo(CO)_5\}]^-$, consistent with lower *s*-orbital contribution to the Pt-phosphido bond compared with Pt-phosphine bonds of similar length. The values of $^2J(PEt_3—PEt_3)$ (366 Hz) and $^1J(^{195}Pt—PEt_3)$ (2413 and 2526 Hz) for **1** are close to those expected for complexes containing *trans*-tertiary phosphines [23,24] indicating that there is, if any, only a weak dependence on the nature of the *cis* ligand. Note that $^2J(P—P)$ values for *trans*-phosphines are typically an order of magnitude greater than those of their *cis* counterparts [24].

Two products analysing as $[Pt(PEt_3)_2(\mu\text{-}PPhH)_2\{Mo(CO)_5\}_2]$ (**2**) were isolated from the reaction of *cis*-$[PtCl_2(PEt_3)_2]$ with $[PPhH\{Mo(CO)_5\}]^-$ and $^{31}P\{^1H\}$ NMR spectroscopy was used to identify these as *cis*-**2** and *trans*-**2**. Both isomers are formed from pure *cis* or a mixture of *cis*- and *trans*-$[PtCl_2(PEt_3)_2]$. One striking characteristic of the $^{31}P\{^1H\}$ NMR spectrum of *cis*-**2** is that $^2J(PEt_3—P\mu)$ (200 Hz) is lower than expected for *trans* tertiary phosphines [24], but large enough to confirm the presence of a PEt_3 *trans* to $[PPhH\{Mo(CO)_5\}]^-$. We have recently reported [20] similar spectroscopic characteristics for $[Pt(\mu\text{-}PPhH)_2\{Mo(CO)_5\}_2(dppe)]$ (**3**) in which $^2J(Pdppe—P\mu)$ for $[PPhH\{Mo(CO)_5\}]^-$ *trans* to dppe was 213.0 Hz. The reduced $^2J(P—P\mu)$ values in *cis*-**2** and in **3** are also paralleled by lower $^1J(^{105}Pt—P\mu)$ coupling constants [$^1J(^{195}Pt—PEt_3) = 2277.7$ Hz and $^1J(^{195}Pt—P\mu) = 1400.6$ Hz for *cis*-**2** and $^1J(^{195}Pt$-dppe) = 2323.0 Hz and $^1J(^{195}Pt—P\mu) = 1450.0$ Hz for **3**] emphasizing the unusual spectroscopic characteristics associated with the $[PPhH\{Mo(CO)_5\}]^-$ ligand. The close structural and spectroscopic similarities of *cis*-**2** and **3** are further highlighted by their distinctive non-first-order AA′XX′ spin systems. Each set of resonances for **2** results from the superposition of two spin systems, an AA′XX′ corresponding to isotopomers with no ^{195}Pt and an AA′XX′M spin system for the ^{195}Pt isotopomer. Figure 1 shows the $^{31}P\{^1H\}$ NMR spectrum of *cis*-**2** together with an accurate computer simulation of its AA′XX′ region. This simulation was obtained by fixing the *trans* coupling constants at +200 Hz, measured directly from the spectrum, and varying the *cis* coupling constant which refined at $^2J(PEt_3—P\mu) = -15$ Hz. We [25] and others [26] have previously noted that *cis* and *trans*-$^2J(P—P)$ coupling constants are of opposite sign in the sign-simulated $^{31}P\{^1H\}$ spectra of complexes containing four coplanar phosphorus donor ligands. The most notable differences between the $^{31}P\{^1H\}$ NMR spectra of *cis*-**2** and **3** is the absence of line broadening and the observation of only a single diastereoisomer for *cis*-**2**.

The $^{31}P\{^1H\}$ spectral characteristics of *trans*-**2** are markedly different to those of *cis*-**2** and consistent with *trans*-PEt_3 ligands. Its room-temperature $^{31}P\{^1H\}$ NMR spectrum contains two sets of resonances, signals for PEt_3 ($\delta = +0.7$, 1.2 ppm) as well as high-field signals ($\delta = -71.4$, −68.5 ppm) for a phosphido ligand bridging non-bonded metal atoms [13,17a–c]. The most striking spectral feature of *trans*-**2** is that the PEt_3 resonance of the minor diastereoisomer is a sharp triplet resonances flanked by ^{195}Pt satellites, while that of the major diastereoisomer appears as a broad featureless resonance. The value of $^1J(^{195}Pt—PEt_3)$ for the minor diastereoisomer (2512 Hz) is similar to that in *trans*-$[PtCl_2(PEt_3)_2]$ [23] and supports a *trans* arrangement of these ligands. The lower $^1J(^{195}Pt—P\mu)$ coupling constant (1146.0 Hz) confirms our previous observation of reduced $^1J(^{195}Pt—P\mu)$ and $^2J(P—P\mu)$ values associated the $[PPhH\{Mo(CO)_5\}]^-$ ligand. Specifically, $^1J(^{195}Pt—P\mu)$ is approximately 50% that of $^1J(^{195}Pt—PR_3)$ in complexes with similar bond lengths. The value of $^{31}P^1H$ NMR spectra in studying Pt-phosphido complexes has been noted [27]. For instance, several characteristics of the recently reported phosphido-bridged complex $[(HBut_2P)_2Pt(\mu\text{-}H)(\mu\text{-}PBut_2)Pt(H)(PBut_2H)][BF_4]$ [27a] parallel features of the $^{31}P\{^1H\}$ NMR spectrum of *cis*- and *trans*-**2** including reduced values of $^1J(^{195}Pt—P\mu)$ and $^2J(P—P\mu)$.

Finally, *trans*-**2** contains two chiral primary phosphido bridges and, as with **3**, we assign the two sets of $^{31}P\{^1H\}$ NMR resonances to the *meso* and *racemic* diastereoisomers.

X-ray structures of trans-$[PtCl(PEt_3)_2(\mu\text{-}PPhH)\{Mo(CO)_5\}]$ (**1**) *and* trans-$[Pt(PEt_3)_2(\mu\text{-}PPhH)_2\{Mo(CO)_5\}_2]$ (**2**)

The unusual $^{31}P\{^1H\}$ NMR spectroscopic characteristics associated with **1** and **2** together with the presence of rare examples of chiral phosphido bridges has prompted single-crystal X-ray structural studies.

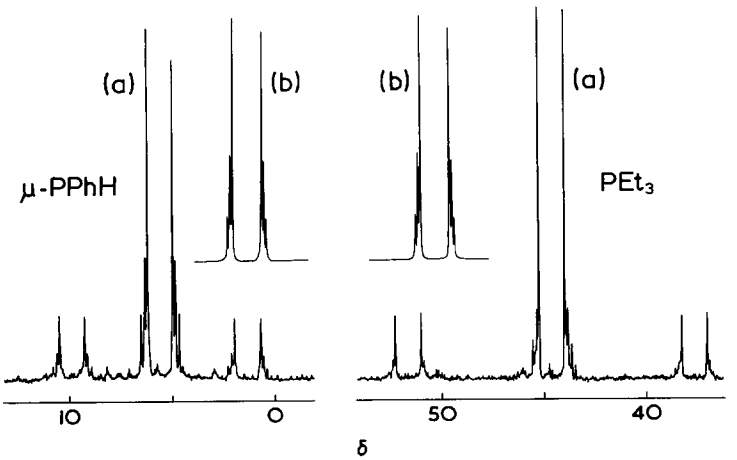

Fig. 1. $^{31}P\{^1H\}$ NMR spectra of *cis*-$[Pt(PEt_3)_2(\mu\text{-}PPhH)_2\{Mo(CO)_5\}_2]$ (**2**) in $CDCl_3$ (a) together with an accurate spin simulation, (b) illustrating the non first-order AA'XX' nature of its spin system.

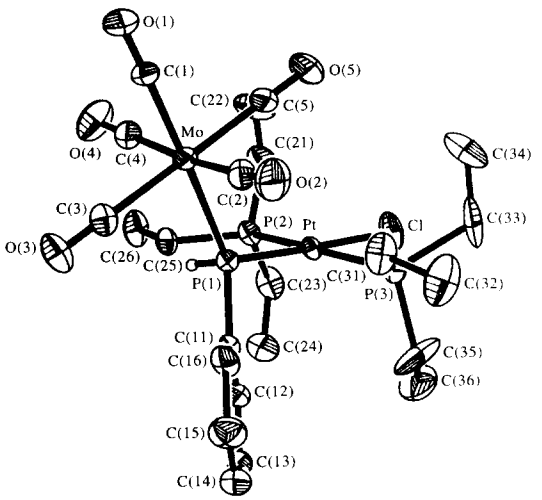

Fig. 2. Perspective ORTEP view of the molecular structure of *trans*-$[PtCl(PEt_3)_2(\mu\text{-}PPhH)\{Mo(CO)_5\}]$ (**1**) showing the square-planar coordination geometry at platinum.

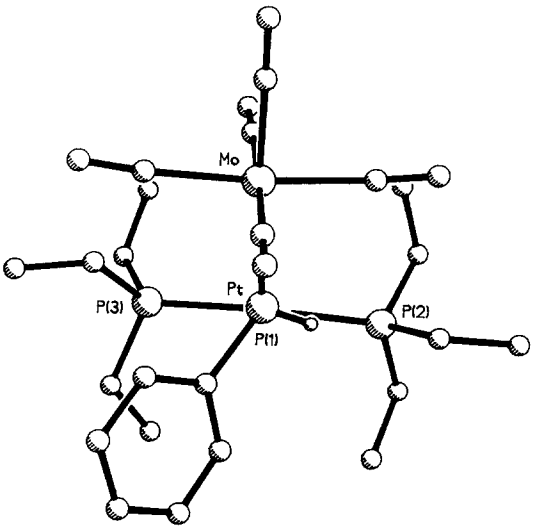

Fig. 3. View down the P(1)—Pt—Cl axis of $[PtCl(PEt_3)_2(\mu\text{-}PPhH)\{Mo(CO)_5\}]$ (**1**) showing the conformation about the Pt—$PPhHMo(CO)_5$ bond.

(a) Trans-**1**. The molecular structure of **1** in Fig. 2 unequivocally identifies it as *trans*-$[PtCl(PEt_3)_2(\mu\text{-}PPhH)\{Mo(CO)_5\}]$ (**1**), a μ-PPhH-bridged Mo—Pt dimer. Selected bond lengths and bond angles in Table 3. An alternative projection (Fig. 3) illustrates the PtP_3Cl planar arrangement of ligands, which successfully accounts for its unusual $^{31}P\{^1H\}$ NMR spectroscopic characteristics (*vide infra*).

The crystal structure of **1** reveals that only a single chloride ligand has been substituted by $[PPhH\{Mo(CO)_5\}]^-$ resulting in a Pt^{II} coordination sphere comprised of one chloride, one $[PPhH\{Mo(CO)_5\}]^-$ and two PEt_3 ligands. The geometry about the platinum centre is essentially square planar [Cl—Pt—P(1) = 177.5(1) and P(1)—Pt—P(2) = 169.9(1)°] with the larger angles of P(1)—Pt—P(2) = 95.6(1) and P(1)—Pt—P(3) = 93.8(1)° compared with P(2)—Pt—Cl = 83.3(1) and P(3)—Pt—Cl = 87.4(1)°, reflecting a greater steric demand of the anionic phosphine over chloride. The Pt—P(1)—Mo angle of 120.9(1)° is comparable to those recently reported for $[Pt(\mu\text{-}PPhH)_2\{Mo(CO)_5\}_2(dppe)]$ [21] and $[Cp_2W(H)(\mu\text{-}PPh_2)W(CO)_5]$ [15], rare examples of singly bridged heterometallics without metal–metal bonds. The Pt—Mo non-bonded distance in **2** [Pt—Mo = 4.255 Å], one of the longest to be reported, is responsible for the high-field shifted $^{31}P\{^1H\}$ NMR signal of the phosphido ligand [13,17]. The platinum-phosphido bond in **1** is considerably shorter [Pt—P(1) = 2.288(3) Å] than those in **3** [Pt—P_{av} = 2.362(3) Å], which presumably reflects the smaller *trans* influence of the chloride ligand compared with dppe. However, the value of $^1J(^{195}Pt—P\mu)$ is too low and the bond too long for $[PPhH\{Mo(CO)_5\}]^-$ to be treated as a "simple" phos-

phine [for example in *trans*-$PtCl_2(PEt_3)_2$, Pt—P = 2.258(4) Å]. Finally, the geometry about molybdenum is octahedral with a molybdenum–phosphorus distance [Mo—P(1) = 2.601(3) Å] greater than in $[Mo(CO)_5(PMe_3)]$ (2.5082 Å) [28], possibly reflecting the greater steric requirements of $[PPhH\{Mo(CO)_5\}]^-$. However, the axial carbonyl bond length [Mo—C(1) = 1.972(1) Å] is characteristic of a Mo—C bond *trans* to a phosphino donor while the equatorial Mo—C bond lengths are unexceptional. Compound **1** can thus be described either as (i) a square-planar Pt^{II} with three phosphorus donor ligands and one chloride or (ii) a rare example of a primary phosphido-bridged Mo—Pt heterobimetallic containing an exceptionally large Mo—P—Pt bond angle.

(b) Trans-**2**. The molecular structure of *trans*-**2** is shown in Figs 4 and 5 with a selection of bond lengths and angles in Table 4. *trans*-**2** crystallizes in the monoclinic space group $P2_1/a$ with two independent molecules in the asymmetric unit and with platinum located on an inversion centre. The projection of *trans*-**2** in Fig. 4 clearly identifies it as a trinuclear phosphido ligand compound, whilst that in Fig. 5 emphasises its alternative description as a square-planar Pt^{II} complex containing two *trans*-PEt_3 and two *trans*-$[PPhH\{Mo(CO)_5\}]^-$ ligands. Notable features include the exceptionally large Pt—P—Mo angles [Mo(1)—P(1)—Pt(1) = 126.1(2) and Mo(2)—P(3)—Pt(2) = 130.0(2)°], the largest phosphido bridging angles to be reported, as well as long Pt—Mo non-bonded distances [Pt(1)—Mo(1) = 4.504(2) and Pt(2)—Mo(2) = 4.573(2) Å]. The asymmetric bridging mode of the phosphido ligand in **2** [Pt(1)—P(1) = 2.407(5), Pt(2)—P(3) = 2.397(4) and Mo(1)—P(1) = 2.644(5), Mo(2)—P(3) = 2.648(5) Å] is a common feature of heterometallic phosphido-bridged complexes. These platinum–phosphido bond lengths are among the longest reported, far greater than that in **1** reflecting the stronger *trans* influence of $[PPhH\{Mo(CO)_5\}]^-$ compared with chloride. As for **1** the axial Mo—CO bonds are substantially longer than their equatorial counterparts supporting the significant *trans* influence associated with the μ-PPhH group.

Although **2** contains a PtP_4 planar arrangement of ligands, it adopts a staggered conformation of *trans*

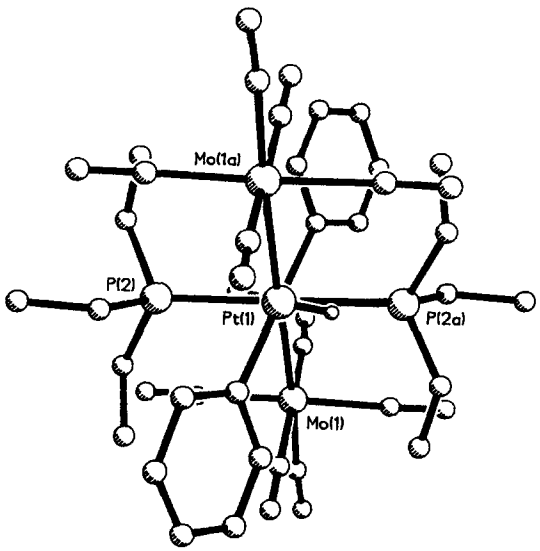

Fig. 5. A projection down the P(1)—Pt(1)—P(1a) axis of *trans*-$[Pt(PEt_3)_2(\mu\text{-}PPhH)_2\{Mo(CO)_5\}_2]$ (**2**) showing the staggered nature of the *trans* ligands and the disposition of the substituents at phosphorus with respect to this plane.

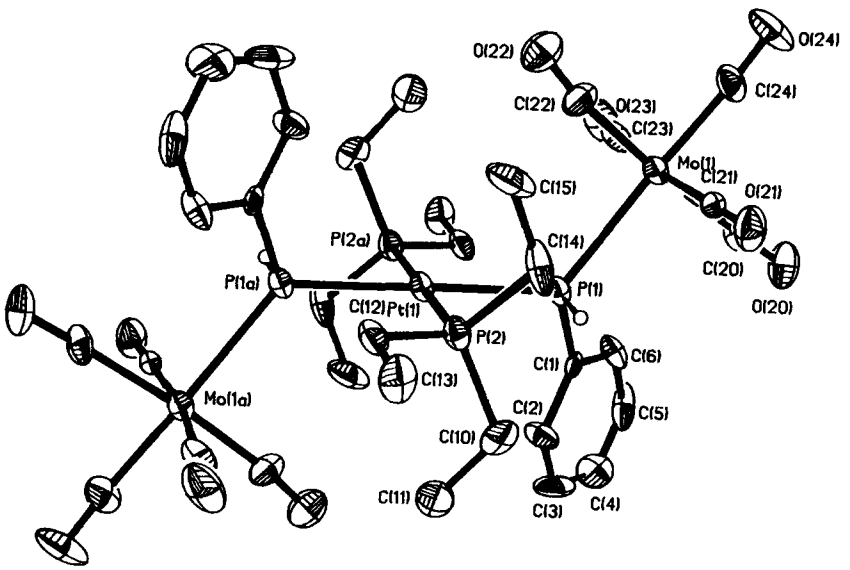

Fig. 4. Perspective ORTEP view of the molecular structure of one independent molecule of *trans*-$[Pt(PEt_3)_2(\mu\text{-}PPhH)_2\{Mo(CO)_5\}_2]$ (**2**) showing the square-planar coordination at platinum which lies at a centre of symmetry.

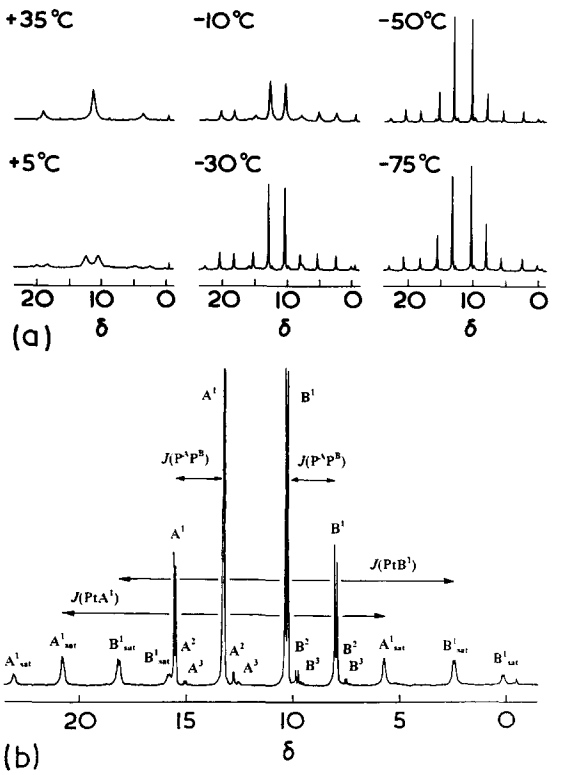

Fig. 6. (a) Variable-temperature $^{31}P^{1}H$ NMR spectra of $[PtCl(PEt_3)_2(\mu\text{-}PPhH)_2\{Mo(CO)_5\}]$ (**1**) in the PEt_3 region (AB part of ABX spectrum, plus ^{195}Pt satellites) showing the broadening and collapse of signals for three rotational isomers. (b) $^{31}P^{1}H$ NMR spectra of **1** (CD_2Cl_2, −75°C), major ABX (A^1B^1) and minor (A^2B^2 and A^3B^3) rotational isomers and assignment of the $^1J(^{195}Pt—PEt_3)$ and $^2J(P^{A^1}P^{B^1})$ coupling constants for the major isomer. The ^{195}Pt satellites for the minor isomers were not detected, although the main signals are qualitatively equivalent to those of the major isomer.

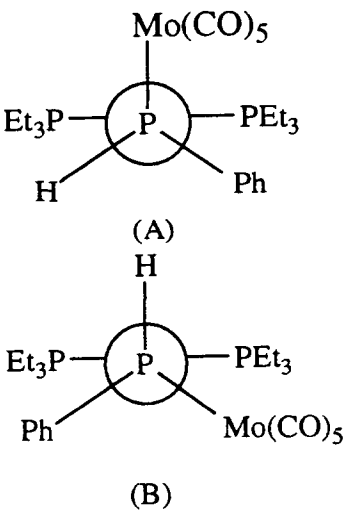
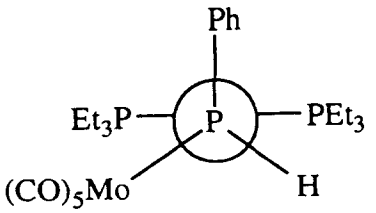


ligands with the bulky $[Mo(CO)_5]$ substituents in an *anti* arrangement, presumably the sterically least demanding conformation. This contrasts with our recent characterization of several square-planar complexes, each of which contains four phosphorus donor ligands with substituents on *trans* ligands eclipsed [29]. Compound **2** is only the second example of a phosphido-bridged heterometallic trimer with the four unique substituents attached to the phosphido ligand, Ph, H, Mo and Pt. Therefore, both *meso* and *racemic* forms are expected, however, the crystal for which the structure was determined was that of the *meso* stereoisomer, *RS*-$[Pt(PEt_3)_2(\mu\text{-}PPhH)_2\{Mo(CO)_5\}_2]$.



Rotational isomers of trans-**1** *and* trans-**2**: *a variable-temperature* $^{31}P\{^1H\}$ *NMR study*

Relatively high rotation barriers in octahedral metal complexes containing four coplanar phosphines are common [25,29a]. However, we recently found evidence for rotational isomers of $[Pt(\mu\text{-}PPhH)_2\{Mo(CO)_5\}_2(dppe)]$ (**3**), a molecule containing two neutral and two anionic phosphines. Line broadening in the $^{31}P\{^1H\}$ NMR spectra of **1** and *trans*-**2** prompted us to undertake a variable-temperature study, which also revealed that rotational isomers of these molecules could be observed and that their interconversion is slow at −80°C.

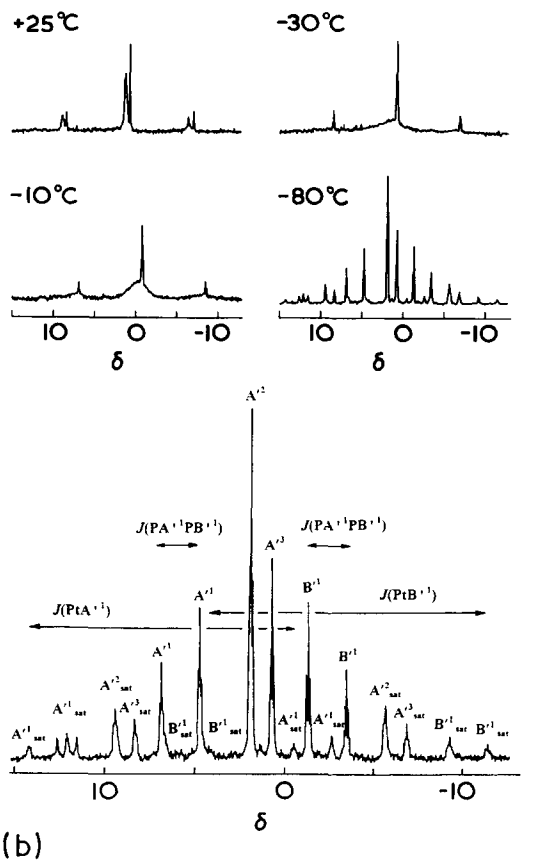
(a) Trans-**1**. A representative set of $^{31}P^{1}H$ NMR spectra for **1**, in the PEt_3 region, is shown in Fig. 6(a) together with our assignment of the low temperature limiting spectrum (−75°C) in Fig. 6(b).

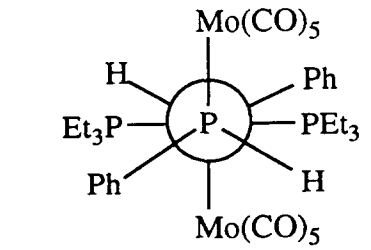
The room-temperature spectrum of **1** contains a sharp high-field triplet resonance [δ −66.4, $^1J(^{195}Pt—P\mu)$ = 2078 Hz] for the phosphido bridge and an exchange broadened resonance (δ = +10.5 ppm) corresponding to the PEt_3 ligands. The low-temperature $^{31}P^{1}H$ NMR spectrum of **1** unequivocally established the presence of three isomers, a dominant one (94%) characterized by an AB quartet [δ +9.0(B^1), +14.1 (A^1)] together with low concentrations of two others (A^2B^2 and A^3B^3, 5 and 1%, respectively), each with similar spectroscopic features. The diastereotopic PEt_3 ligands couple to the bridging phosphido with different $^2J(PEt_3—P\mu)$ values [$^2J(PP)$ = 17.3 Hz (B^1) and $^2J(PP)$ = 9.6 Hz (A^1)] and flanked by ^{195}Pt satellites also of different magnitude [$^1J(^{195}Pt—P^{A^1})$ = 2413.0 Hz and $^1J(^{195}Pt—P^{B^1})$ = 2526.4 Hz], although both values are in the range expected for *trans*-PEt_3 ligands [22]. Figure 6(b) also identifies the two low concentration species, each with a similar AB quartet resonance flanked by ^{195}Pt satellites [δ +8.6 (B^2), +13.7 (A^2) and +8.4 (B^3), 13.6 (A^3)] again with different values of $^2J(PEt_3—P\mu)$ [$^2J(P\mu—P^{A^2})$ = 9.0, $^2J(P\mu—P^{B^2})$ = 15.0, $^2J(P\mu—P^{A^3})$ = 9.6, $^2J(P\mu—P^{B^3})$ = 15.4 Hz]. These three sets of resonances have been assigned to three conformational isomers each with an ABX spin system. We believe that the predominant ABX (A_1B_1) at low temperature belongs to rotamer (A), the sterically least hindered conformer and that found in the crystal. Rotamers (B) and (C) with the bulky $[Mo(CO)_5]$ substituents in closer proximity to the PEt_3 are sterically more demanding and much less populated. At higher temperatures rapid rotation about the

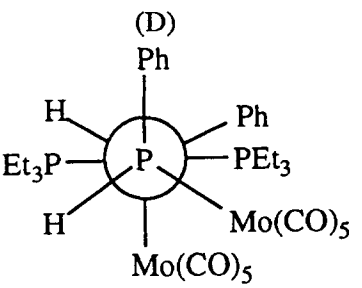
(C)

Pt—Pμ bond interconverts these rotamers to afford the exchange broadened spectrum illustrated in Fig. 6(a) (+35°C).

(b) Trans-**2**. The room-temperature $^{31}P\{^1H\}$ NMR spectrum of **2** contains two sets of resonances, each with signals in the phosphido and PEt_3 regions consistent with the two possible non-interconverting diastereoisomeric forms. While the resonances belonging to the minor diastereoisomer are sharp those corresponding to the major stereoisomer are broad and featureless. A representative set of $^{31}P\{^1H\}$ NMR spectra are illustrated in Fig. 7(a) with our assignment of the low-temperature limiting spectrum in the PEt_3 region, shown in Fig. 7(b). The low-temperature limiting spectrum of *trans*-**2** [Fig. 7(b)] consists of three sets of resonances in significant abundance, two belonging to the major (*meso*) diastereoisomer [an A triplet of an $(AX)_2$ spin system at δ +1.8 (A'^2) and the AB part of an ABXY pattern at δ +5.8 and −2.4 for A'^1 and B'^1, respectively] and the other, another A triplet of an $(AX)_2$ system, to the minor (*rac*) diastereoisomer [δ +0.7 (A'^3)]. These isomers have been designated $A'^1B'^1$, A'^2 and A'^3 to distinguish them from those associated with **1** shown in Fig. 6. Fractional crystallization of *trans*-**2** provided sufficient sample to confirm, by $^{31}P\{^1H\}$ NMR spectroscopy, that the exchange broadened resonance corresponds to the *meso* stereoisomer, for which the crystal structure was determined. Once separated by crystallization, there is no conversion of the *meso* into the *rac* stereoisomer.







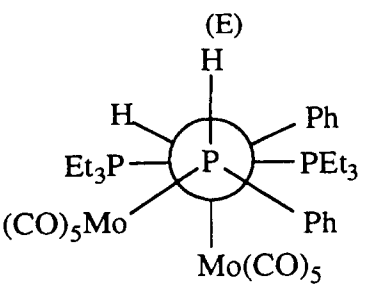


Fig. 7. (a) Variable-temperature $^{31}P^1H$ NMR spectra of a diastereomeric mixture of *trans*-$[Pt(PEt_3)_2(\mu\text{-}PPhH)_2\{Mo(CO)_5\}_2]$ (**2**) in the PEt_3 region. (b) $^{31}P^1H$ NMR spectrum of *trans*-**2** (CD_2Cl_2, −80°C), major ($A'^1B'^1$) and (A'^2) and minor (A'^3) diastereoisomers illustrating their $^1J(^{195}Pt—PEt_3)$ and $^2J(PEt_3—P\mu)$ coupling constants.

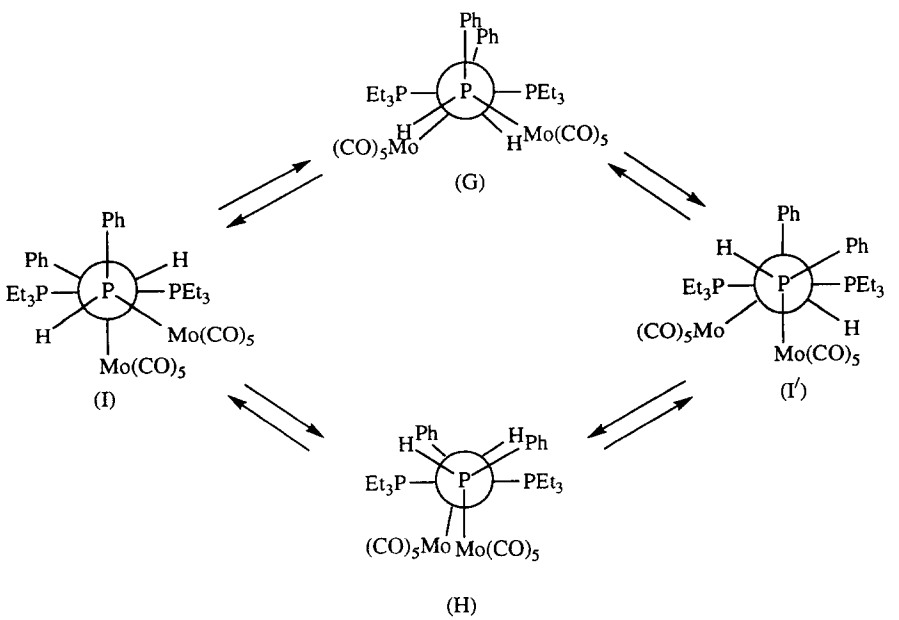
(F)

The *meso*-stereoisomer contains pairs of staggered *trans*-phosphines for which there should exist three possible rotamers, (D)–(F). However, only one of these, rotamer (D), contains magnetically equivalent PEt_3 ligands which must therefore correspond to the triplet resonance at δ +0.7, while either rotamer (E) or (F) could give rise to the ABXY pattern. Above −80°C these resonances start to broaden and at



+35°C rotamers (D), (E) or (F) exchange *via* rotation about their Pt—Pμ bonds.

In contrast the $^{31}P\{^1H\}$ NMR spectrum of the minor *RR/SS* diastereoisomer is unchanged over the temperature range +25 to −80°C. The observed A_2X_2 pattern is not consistent with any one static staggered rotamer since the PEt_3 ligands are necessarily non-equivalent. However, its spectra could be rationalized in terms of one of the eclipsed rotamers (G) or (H). An alternative view is that the lowest energy rotamer is the staggered form (I), which is in rapid equilibrium with its enantiomer (I′) by the mechanism shown in Scheme 1, which leads to PEt_3 exchange. However, why should the equilibrium in Scheme 1 be very fast even at −80°C, whereas the equilibria between (D) and (E) or (F) are much slower? Although the projections shown are reminiscent of ethane-type conformations, the dominant steric interactions are between *cis* ligands and not between the mutually *trans*-PPhH$\{Mo(CO)_5\}$ groups. Thus, the barrier to rotation is a consequence of the movement of the H, $Mo(CO)_5$ or Ph substituents past the *cis*-PEt_3 ligands. In the equilibria in Scheme 1, the Ph and $Mo(CO)_5$ groups do not migrate from one side of the Pt coordination plane to the other and only the H substituents are required to migrate past the PEt_3 ligands. Hence, the energy barriers for these rotational equilibria are much lower than for the interconversion of (D) with (E) or (F), which requires the Ph or $Mo(CO)_5$ substituents to slide past the PEt_3 ligands. On this model, equilibria in Scheme 1 must be fast enough for coalescence temperatures to be well below −80°C. In spite of these arguments we have no experimental evidence to discriminate between (G), (H) and (I).

The fluxionality of **1** and **2** is best understood by considering them as square-planar Pt^{II} complexes with PtP_3Cl and PtP_4 arrangements of ligands. Some time ago we reported detailed variable-temperature $^{31}P\{^1H\}$ NMR studies of the tetrakisphosphine complexes $[IrCl_2(PMe_2Ph)_3L][ClO_4]$ (L = PMe_3, PMe_2Ph, $PMePh_2$) [25,29a] which revealed the existence of rotameric forms that interconvert slowly at −50°C. It appeared that a general requirement for the occurrence of these rotamers was the presence of four coplanar phosphines. More recently we revealed that line broadening effects in the $^{31}P\{^1H\}$ NMR spectrum of $[Pt(\mu\text{-}PPhH)_4\{Mo(CO)_5\}_2(dppe)$ (**3**) resulted from restricted rotation about the Pt—Pμ bond generating rotational isomers. The similarity between $[Pt(\mu\text{-}PPhH)_2\{Mo(CO)_5\}_2(dppe)]$ (**3**) and $[PtCl(PEt_3)_2(\mu\text{-}PPhH)\{Mo(CO)_5\}]$ (**1**) and *trans*-$[Pt(PEt_3)_2(\mu\text{-}PPhH)_2\{Mo(CO)_5\}_2]$ (**2**) suggests they too may have accessible rotameric forms. For **1** this results in population of the sterically least demanding rotamer (A) with only very low concentrations of less favourable (B) and (C), while restricted rotation at the Pt—Pμ bonds in *meso*-**2** gives rise to rotamers (D) and one of either (E) or (F). In contrast *RR/SS*-**2** is either the conformationally rigid eclipsed rotamer (G) or (H) or the highly dynamic staggered rotamer (I).

Correlation of $^1J(^{195}Pt—P)$ *and* Pt—P *bond lengths*

Correlation between $^1J(^{195}Pt—P)$ and Pt—P bond lengths in platinum(II) phosphine complexes, a parameter sensitive to the *s*-orbital character of the Pt—P bond, has been the focus of several investigations [17,22]. Powell reports a close correlation between the $^1J(^{195}Pt—P\mu)$ and platinum phosphorus distances for several heterometallic complexes and our observations for complexes **1**–**2** support this, provided

Scheme 1.

ligands of the same type are compared, that is we have to distinguish between tertiary and anionic phosphines in order to obtain credible correlations. Powell has also suggested that the decreasing values of $^1J(^{195}Pt—P)$ with increasing bond length reflect a change in *s*-orbital overlap in the platinum–phosphorus bond [17b,c]. We too have observed a similar trend with $^1J(^{195}Pt—P\mu) = 2135$ Hz *trans* to chloride in **1** [Pt—P = 2.288(3) Å] and $^1J(^{195}Pt—P\mu) = 1450$ Hz *trans* in dppe in $[Pt(\mu\text{-}PPhH)_2\{Mo(CO)_5\}_2(dppe)]$ (**3**) [Pt—P = 2.361(3) Å]. Thus, the values of $^1J(^{195}Pt—P)$ for tertiary phosphines do reflect the Pt—P distances as do those of $^1J(^{195}Pt—P\mu)$ for $[PPhH\{Mo(CO)_5\}]^-$, which are, in general, considerably lower than their tertiary phosphine counterparts of similar bond length. An examination of the $^1J(^{195}Pt—P\mu)$ values in **1** and *cis*-**2** (i.e. 2135 Hz and 1400.6 Hz for **1** and **2**, respectively) illustrates the effect of the *trans* ligand on this parameter, clearly demonstrating that ligands with a strong *trans* influence lead to reduced $^1J(^{195}Pt—P\mu)$ values and that these are considerably lower than their tertiary phosphine counterparts with similar *trans* ligands. These reduced $^1J(^{195}Pt—P\mu)$ values are illustrated by comparing $[PtCl(PEt_3)_2(\mu\text{-}PPhH)\{Mo(CO)_5\}]$ (**1**) with *cis*-$[PtCl_2(PEt_3)_2]$ for which $^1J(^{195}Pt—P\mu) = 2135$ Hz and $^1J(^{195}Pt—PEt_3) = 3500$ Hz in the absence of significant *cis* effects.

Conclusions

While the synthetic approach described here extends the utility of the bridge-assisted approach for constructing heterometallic complexes, the thrust of our effort has been the structural and spectroscopic characterization of rare examples of heterometallic complexes bridged by chiral primary phosphido bridges. The heterometallic complexes *trans*-$[PtCl(PEt_3)_2(\mu\text{-}PPhH)\{Mo(CO)_5\}]$ (**1**) and *cis*- and *trans*-$[Pt(PEt_3)_2(\mu\text{-}PPhH)_2\{Mo(CO)_5\}_2$ (**2**) have been prepared by the nucleophilic substitution of chloride in *cis*-$[PtCl_2(PEt_3)_2]$ by the chiral anion $[PPhH\{Mo(CO)_5\}]^-$. Information contained in their $^{31}P\{^1H\}$ NMR spectra has provided insight into the nature of their accessible rotational isomers. The exchange broadened $^{31}P\{^1H\}$ NMR spectra of **1** and *trans*-**2** have been explained in terms of the presence of several rotameric forms which interconvert by rotation about their Pt—Pμ bonds, an interpretation supported by similar observations for $[Pt(\mu\text{-}PPhH)_2\{Mo(CO)_5\}_2(dppe)]$ (**3**). *cis*-**2** with PEt_3 *trans* to $[PPhH\{Mo(CO)_5\}]^-$ is characterized by reduced values of $^2J(PEt_3—P\mu)$ (200 Hz) and $^1J(^{195}Pt—P\mu)$ (1400.6 Hz) compared with values reported for mutually *trans* neutral phosphines for which values close to 300 Hz and 2500 Hz would have been expected. These reduced Pt—P and P—P coupling constants are consistent with a lower *s*-orbital contribution to the Pt—P bond for the anion $[PPhH\{Mo(CO)_5\}]^-$ compared with their tertiary phosphine counterparts. We conclude that the spectroscopic characteristics of **1** and *cis*- and *trans*-**2** can most aptly be accounted for by considering them as square-planar Pt^{II} complexes containing phosphorus donor ligands rather than μ-PPhH bridged heterometallics. Finally, the P—H functionalities of the primary phosphido bridges in **1** and **2** are sites of additional reactivity not available to their μ-PR_2 (R = alkyl or aryl) bridged counterparts, thus, complexes of this type allow new developments in heterobimetallic reactivity.

Supplementary material available. Further details for **1** and *trans*-**2** are available as supplementary material (atomic coordinates, anisotropic thermal parameters, bond distances and bond angles, hydrogen-atom coordinates) deposited at the Cambridge Crystallographic Centre. Structure factors are available from the author upon request.

(Received 25 April 1996; accepted 6 August 1996)

Abstract—The reaction of $[Ag(dppm)(NO_3)]_2$ with sodium phenylacetate and dppm in THF at room temperature gave rise to the silver complexes $[Ag(dppm)(O_2CCH_2Ph)]_2$ (**1**) and $[Ag_2(dppm)_3](NO_3)_2$ (**2**), respectively. Their crystal structures have been determined by single crystal X-ray diffraction analysis. Complex **1** is binuclear with a silver–silver separation of 3.080 Å and bridged by two dppm ligands. The cation in complex **2** possesses a Ag_2P_6 core with Ag—Ag distance of 2.987 Å and the silver atoms are each coordinated by three phosphorus atoms in an ideal trigonal-planar environment. Their IR, Raman, ^1H and ^{31}P NMR spectroscopic properties are also reported. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: Silver(I) complexes; dinuclear; synthesis; crystal structure; Raman spectra; NMR spectra.

Bis(diphenylphosphino)methane (dppm) complexes containing the $M_2(dppm)_2$ structural unit have been intensively investigated [1–7]. A key feature in the chemistry of this class of the complexes is the relatively stable and nearly planar M_2P_4 framework and two silver atoms are connected by a pair of bridging dppm ligands. The stable M_2P_4 framework places much of the burden for any structural adjustment on the substrate species themselves and on any additional ligand present. This feature is presumably one of the chief reasons for their unusual bonding, reactivity and catalytic properties. There are many examples of binuclear complexes with the formula of $M_2(dppm)_2X_2$ (M = Ag, Au, Pd and Pt; X = univalent anion) [1–7]. To our knowledge, for complexes with $M_2(dppm)_3$ fragment, only $Pd(dppm)_3$ [8] and $Pt_2(dppm)_3$ [9] have been structurally characterized. Recently, we started our investigation on the syntheses of polynuclear silver cluster compounds containing mixed phosphine and carboxylate ligands and obtained a series of silver(I) complexes. In this paper, we report the syntheses and structural characterization along with the spectroscopic properties of two silver(I) complexes with mixed bis(diphenylphosphino)methane and phenylacetate ligands, namely $[Ag(dppm)(O_2CCH_2Ph)]_2$ (**1**) and $[Ag_2(dppm)_3](NO_3)_2$ (**2**), in which the dppm ligand bridges two silver atoms to form the dimers with Ag_2P_4 core in **1** and Ag_2P_6 core in **2**.

EXPERIMENTAL

All manipulations were carried out under N_2 unless otherwise indicated. $[Ag(dppm)(NO_3)]_2$ was prepared according to literature methods [2]. NaO_2CCH_2Ph was prepared by the stoichiometric neutral reaction of HO_2CCH_2Ph with NaOH in H_2O/EtOH. Dppm was purchased from Fluka. Elemental analyses were performed by the Analytical Chemistry Group of this institute.

Instrumentation

^1H and ^{31}P NMR spectra were recorded on a Varian Unity-500 spectrometer. $CDCl_3$ was used as solvent,

and TMS and 85% H_3PO_4 as standards. IR and Raman spectra were measured on a Niclet Magna 750 spectrophotometer and on a Niclet 910FT spectrophotometer, respectively.

Synthesis of $[Ag(dppm)(O_2CCH_2Ph)]_2$ (**1**)

NaO_2CCH_2Ph (0.40 g, 0.25 mmol) and $[Ag(dppm)(NO_3)]_2$ (2.80 g, 0.25 mmol) were mixed in THF (30 cm^3) under ambient conditions. The reaction solution was stirred overnight and the resulting white precipitate was filtered. The solution upon evaporation in air yielded colorless air- and light-stable prismatic crystals (1.92 g, 61%). The complex is very soluble in CH_2Cl_2, soluble in THF or CH_3CN and insoluble in alcohol, DMF or DMSO. Found: C, 63.4; H, 4.8; Ag, 17.0; P, 10.0. Calc. for $C_{66}H_{58}O_4P_4Ag_2$: C, 63.2; H, 4.7; Ag, 17.2; P, 9.9%. IR (KBr, cm^{-1}): 410 m, 440 s, 473 s, 4785, 507 m, 518 m, 571 s, 615 m. Raman (KBr, cm^{-1}): 143 m, 167 m, 219 w, 272 w, 360 w. ^1H NMR (ppm, TMS as standard): 3.52, 3.75, 7.17, 7.25, 7.40. ^{31}P NMR (ppm, 85% H_3PO_4 as standard): 5.74 (doublet, $J = 218$ Hz) and 4.61 (doublet, $J = 239$ Hz).

Synthesis of $[Ag_2(dppm)_3](NO_3)_2 \cdot 3H_2O$ (**2**$\cdot 3H_2O$)

$[Ag(dppm)(NO_3)]_2$ (2.80 g, 0.25 mmol) and dppm (1.82 g, 0.50 mmol) were mixed in THF and MeOH (30 cm^3, v:v = 2:1) under ambient conditions. The reaction solution was stirred overnight and then filtered. The filtrate was kept in 4°C for 2 weeks to yield colorless air- and light-stable prismatic crystals of **2**$\cdot 3H_2O$ (1.48 g, 39%). The complex is soluble in THF or CH_3CN and slightly soluble in alcohol, DMF or DMSO. Found: C, 58.6; H, 4.5; N, 1.9; Ag, 14.2; P, 11.8. Calc. For $C_{75}H_{72}N_2O_9P_6Ag_2$: C, 58.2; H, 4.7; N, 1.8; Ag, 14.0; P, 12.0%. IR (KBr, cm^{-1}): 417 m, 446 s, 473 s, 515 m, 518 m. Raman (KBr, cm^{-1}): 137 m, 197 w, 227 m, 254 w, 351 w. ^1H NMR (ppm, TMS as standard): 3.53, 7.14, 7.37. ^{31}P NMR (ppm, 85% H_3PO_4 as standard): 2.32.

X-ray crystal structural determination

The colorless prismatic crystals of complex **1** and **2**$\cdot 3H_2O$ suitable for single-crystal X-ray diffraction analysis were grown by slow diffusion of hexane into the sample solution in THF. All data were measured on an MSC/Rigaku RAXIS-II imaging plate diffractometer. Determination of the crystal class, orientation matrix and cell dimensions were performed according to established procedures. All data processing was performed on a 486 PC computer using the SHELXTL-PLUS system. Analytical expressions of neutral-atom scattering factors were employed and anomalous corrections were incorporated. Both struc-

tures were solved with the Patterson superposition method. The positions of all hydrogen atoms were generated geometrically (C—H bond fixed at 0.96 Å), assigned isotropic thermal parameters and allowed to ride on their respective parent C atoms. For complex **1**, the refinement of all non hydrogen atoms with anisotropic temperature factors and all hydrogens with isotropic temperature factors led to convergence; for compiles **2**·3H$_2$O, the refinement of all non hydrogen atoms of cation with anisotropic temperature factors and all atoms of hydrogen, anion and solvent molecules with isotropic temperature factors led to convergence. Owing to the high disorder of NO_3^-, the R values for complex **2**·3H$_2$O are higher. Crystallographic data for **1** and **2**·3H$_2$O are listed in Table 1 and selected bond distances and angles in Table 2.

RESULTS AND DISCUSSION

Syntheses

The reaction of [Ag(dppm)(NO$_3$)]$_2$ with 2 equiv. of sodium phenylacetate in THF at room temperature gave rise to the binuclear silver complex [Ag(dppm)(O$_2$CCH$_2$Ph)]$_2$ (**1**),

$$[Ag(dppm)(NO_3)]_2 + 2NaO_2CCH_2Ph = [Ag(dppm)(O_2CCH_2PH)]_2 + 2NaNO_3$$

while the reaction of [Ag(dppm)(NO$_3$)]$_2$ with 2 equiv. (one-fold excess) of dppm in THF and MeOH at room temperature gave rise to another binuclear silver complex **2**.

$$[Ag_2(dppm)(NO_3)]_2 + dppm(excess) = [Ag(dppm)_3](NO_3)_2$$

Clearly, complex **1** was prepared by the simple ligand substitution reaction, however, complex **2** might be obtained from the addition reaction of dppm to complex of [Ag(dppm)(NO$_3$)]$_2$.

Spectroscopic properties

Both complex **1** and **2**·3H$_2$O have been characterized by IR, Raman, ^{1}H and ^{31}P NMR spectra. The ^{31}P NMR spectra of the complex **1** shows two resonance peaks at 5.74 [doublet, $J(^{107,109}Ag—^{31}P) = 218$ Hz] and 4.61 [doublet, $J(^{107,109}Ag—^{31}P) = 239$ Hz], which is downfield of the signal of the respective free ligand and indicates that

there are two different ^{31}P spin systems, while that of complex **2** appears as a broad single resonance peak at 2.32, which may be due to the weak interaction of $^{107,109}Ag$—^{31}P and cannot be resolved at room temperature. The shielding is less pronounced for **1** compared with that for **2**.

^1H NMR spectra of complex **1** and **2** in CD_2Cl_2 at ambient temperature exhibit phenyl resonances in the range of 7.14–7.40 ppm and the methylene resonance as a broad unresolved multiplet with the chemical shifts of 3.52–3.75 ppm. The proton chemical shifts of both complex **1** and **2** are similar to the respective free ligands.

The Raman spectra of lower frequency region show that complex **1** has absorption peaks at 360, 272, 219, 167 and 143 cm^{-1} and complex **2** at 351, 254, 227, 197 and 137 cm^{-1}. Using assignments made for $[M_2(dppm)_2X_2]$ and $[M_2(dppm)_3]$ (M = Pd, Pt; X = Cl, Br) [13], the following assignment can be deduced: for complex **1**, $\nu_{(Ag\text{-}P)}$, 360 cm^{-1}; $\delta_{(C\text{-}P\text{-}C)}$ 272 cm^{-1}; $\delta_{(P\text{-}Ag\text{-})}$, 219 and 167 cm^{-1}, for complex **2**, $\nu_{(Ag\text{-}P)}$, 351 cm^{-1}; $\delta_{(C\text{-}P\text{-}C)}$ 254 cm^{-1}; $\delta_{(P\text{-}Ag\text{-}P)}$, 227 and 197 cm^{-1}.

The 400–4000 cm^{-1} region of IR spectra for both complexes is the diphosphine and phenylacetate ligand fingerprints and very little changes are observed upon complexation with silver atoms.

Structure description

Both complexes have been unequivocally characterized by single-crystal X-ray analysis. The molecular structure of **1**, which possesses a crystallographic centrosymmetry, $\bar{1}$, is depicted in Fig. 1. The structure consists of a neutral dimmeric molecular unit with two silver atoms bridged by a pair of bridging dppm ligands to give an eight-membered $Ag_2P_4C_2$ ring, similar to the structure of $[Ag(dppm)(NO_3)]_2$ [2]. In addition, each silver atom is coordinated by one oxygen atom from a terminal phenylacetate group. Therefore, each silver atom is in a highly distorted $AgOP_2$ trigonal planar coordinated environment.

Complex **2** is composed of a discrete cation, $[Ag_2(dppm)_3]^{2+}$ with crystallographic $6/m$ symmetry, two nitrate anions NO^{3-} and three H_2O molecules. The cation structure is very similar to that of palladium(0) and platinum (0) complexes of $[Pd_2(dppm)_3$ [8] and $[Pt_2(dppm)_3]$ [9]. The structure is a dimer with two silver atoms bridged by three dppm ligands. The geometry of each silver atom is exactly in an ideal trigonal planar environment. The cation structure with thermal vibration ellipsoids and the adopted number scheme is shown in an ORTEP drawing (Fig. 2).

The Ag—P bond distance in complex **2** is 2.482(4) Å,

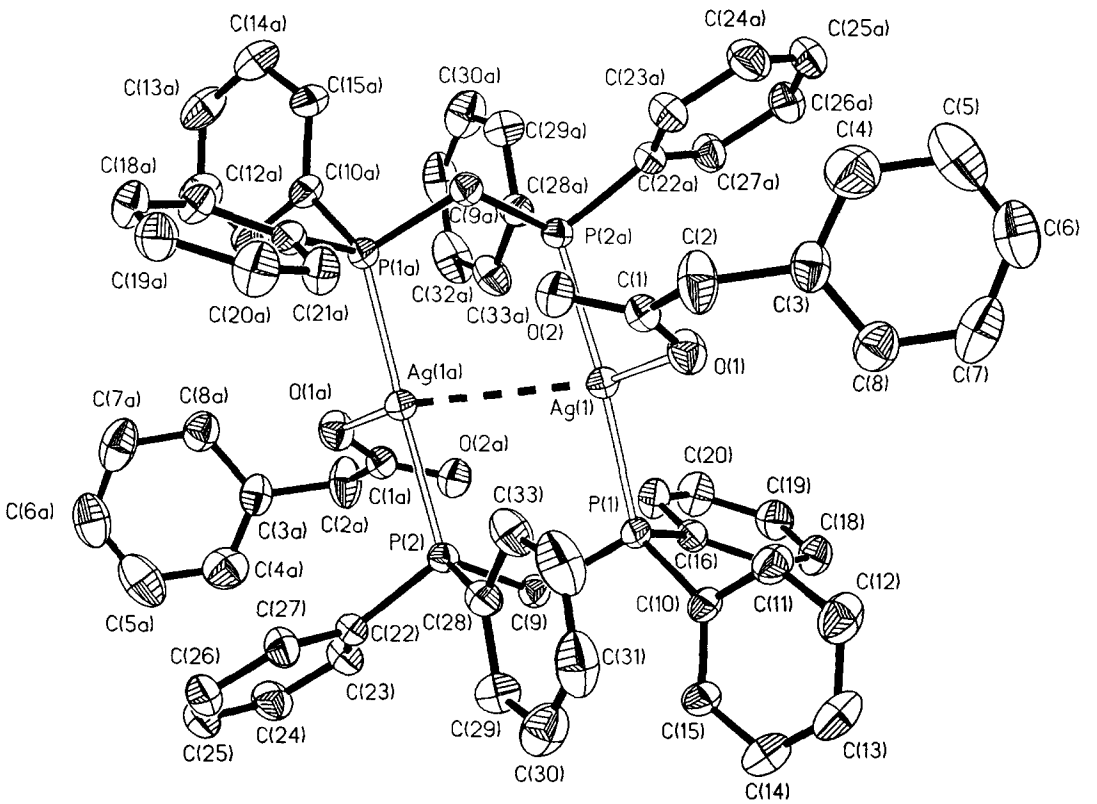

Fig. 1. Perspective view of complex **1**. Hydrogen atoms are omitted and 30% probability ellipsoids are displayed.

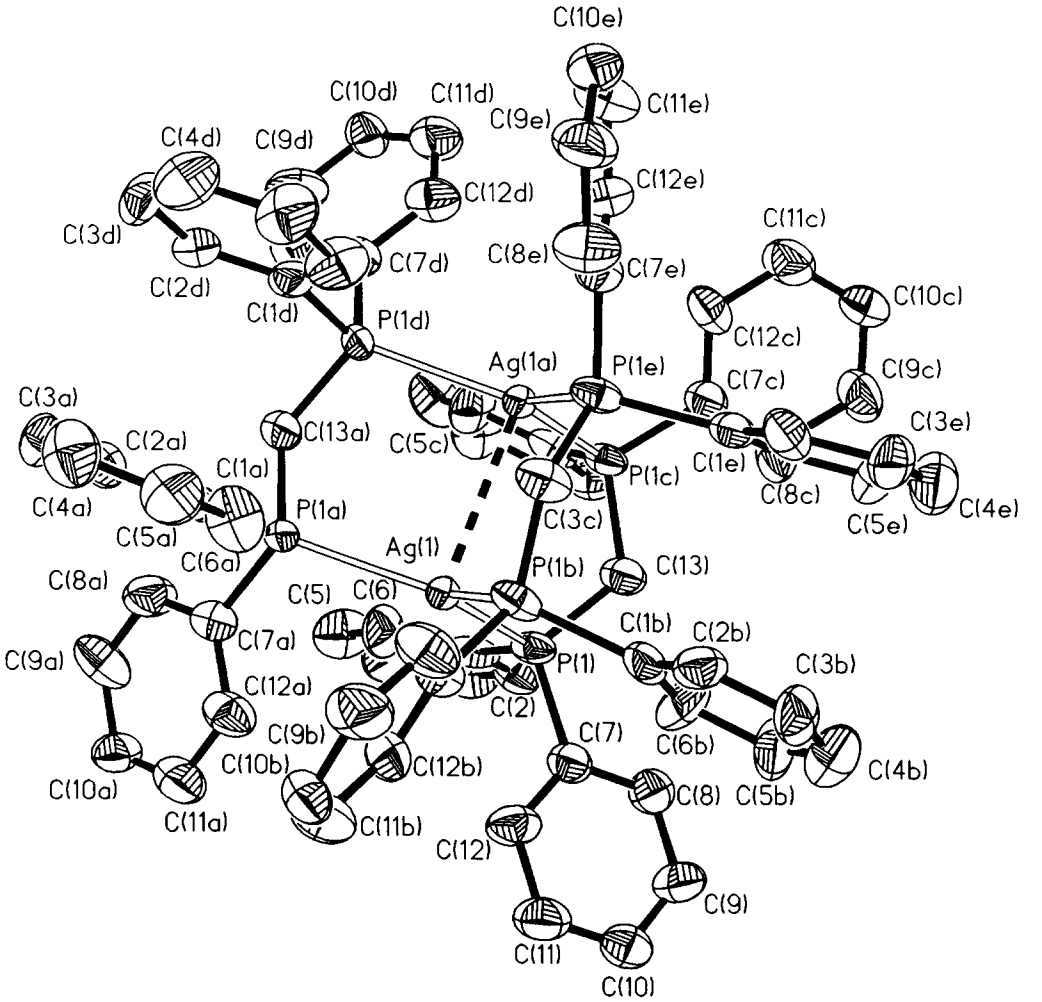

Fig. 2. Perspective view of $[Ag_2(dppm)_3]^{2+}$ in complex **2**. Hydrogen atoms are omitted and 30% probability ellipsoids are displayed.

which is significantly longer than the distance of 2.434(5) Å in complex **1** and those found in silver(I)–dppm complexes of [Ag(dppm)(O$_2$CCH$_2$Ph)]$_2$ [2.434(5) Å], [Ag(dppm)(NO$_3$)]$_2$ [2.426(2) Å] [2] and is slightly longer than those found in silver(I)–triphenylphosphine complexes of [Ph$_3$PAgI]$_4$ [2.455(5) Å][10], [(Ph$_3$P)$_2$Ag(NCS)]$_2$ [2.455(3) Å] [11]. The observed Ag—O distance of 2.328(3) Å in **1** is much shorter than the distances of 2.418(5) Å and 2.689(6) Å found in [Ag(dppm)(NO$_3$)]$_2$ [2]. The Ag···Ag distance of 3.080(1) Å in **1** is significantly longer than that of 2.987(2) Å in **2** and comparable to Ag$_2$(dppm)$_2$(NO$_3$)$_2$ 3.085(1) Å [2], but shorter than the sum of the van der Waals radius (3.4 Å) of the silver atom [12].

The P—Ag—P bond angles of 149.2° in the complex **1** is significantly larger than the corresponding P—Ag—P angle of 138.3(1)° found in [Ag(dppm)(NO$_3$)]$_2$ and 133.69(9)° in [Ag(dmpm)Br]$_2$ [13] [dmpm = bis(dimethylphosphino)methane]. This value is essentially intermediate between 180° (linear structure) and 120° (ideal trigonal planar structure). The average P—Ag—O bond angle of 103.8° is comparable to that observed in [Ag(dppm)(NO$_3$)]$_2$ [2]. The Ag(1a)···Ag(1)—P(1) and Ag(1a)···Ag(1)—P(2) are 93.7(1) and 78.2(1)°, respectively, while the bond angle of Ag(1a)···Ag(1)—O(1) is 129.9(1)°, clearly indicating the nonlinearity of the Ag···Ag—O$_2$C— arrangement. All P—Ag—P bond angles in complex **2** are exactly 120°, indicating the coordination geometry of each silver atom is an ideal trigonal planar. The comparison of M—M and M—P distances as well as P—M—P angles in selected binuclear palladium, platinum and silver complexes are listed in Table 3.

The NO$_3$ group shows apparent disorder, but the atom positions correspond to trigonal coordination of nitrogen atom with slightly short bond (1.29 Å). The O—N—O angles deviate from 120° by an average of 10°.

Neutral and cationic monocarbonyl derivatives of palladium(II). X-ray crystal structure of $[Pd(8\text{-mq})(CO)(SPPh_3)]ClO_4$

Irene Ara, Juan Forniés,* Rafael Navarro, Violeta Sicilia and Esteban P. Urriolabeitia

Departamento de Química Inorgánica, Instituto de Ciencia de Materiales de Aragón, Universidad de Zaragoza-C. S. I. C., 50009 Zaragoza, Spain

(Received 23 September 1996; accepted 30 October 1996)

Abstract—Carbonylation of $[Pd(8\text{-mq})(OCMe_2)_x]ClO_4$ (8-mq = 8-quinolylmethyl-C,N) in CH_2Cl_2/Me_2CO at low temperature gave $[Pd(8\text{-mq})(OClO_3)(CO)]$. Reactions of $[Pd(8\text{-mq})(OClO_3)(CO)]$ with anionic (Cl^-, Br^-, I^-) or neutral ($SPPh_3$, $SPMe_2Ph$) nucleophiles in a 1 : 1 molar ratio resulted in the displacement of the weakly coordinated $OClO_3^-$ group and the formation of the corresponding neutral $[Pd(8\text{-mq})(X)(CO)]$ (X = Cl, Br, I) or cationic $[Pd(8\text{-mq})(CO)L]ClO_4$ (L = $SPPh_3$, $SPMe_2Ph$) carbonyl complexes. The cationic complexes, $[Pd(8\text{-mq})(CO)L]ClO_4$, were synthesized by the reaction of $[Pd(8\text{-mq})(OClO_3)(SPPh_3)]$ or $[Pd(8\text{-mq})(\mu\text{-}SPMe_2Ph)]_2(ClO_4)_2$ with CO. The X-ray structure of a cationic palladium carbonyl derivative, $[Pd(8\text{-mq})(CO)(SPPh_3)]ClO_4$, is reported. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: carbonyl; palladium; cationic; cyclometallated.

Palladium compounds have been used as catalysts in some of the most important homogeneous catalytic processes involving CO [1]. Insertion of CO in a Pd—C σ-bond is an elementary step which should occur through intermediates in which the coordinated carbonyl and organic groups are located in the *cis* position [2]. This ability to form acyl derivatives adds to the general tendency of Pd^{II} compounds to be reduced to lower oxidation states by carbon monoxide and to the lability of the Pd—CO bond, justifying the small number of organocarbonylpalladium(II) complexes that have been reported and characterized [3]. Most of them have been structurally studied on the basis of spectroscopic data (mainly IR) and only very recently have the crystal structures of seven such compounds: $[PdX_3(CO)]^-$ (X = Cl, Br) [4], $[PPh_3(CH_2Ph)][Pd(C_6H_3Me\text{-}2,NO_2\text{-}6)Cl_2(CO)]$ [5], $[Pd(\eta^3\text{-}C_4H_7)(SnCl_3)(CO)]$ [6], [2-(CO)-2-(PPh_3)-*closo*-2,1-$PdTeB_{10}H_9(PPh_3)]BF_4$ [7], [*cis*-$Pd(SO_3F)_2(CO)_2$] [8] and [(phen)Pd $(C(O)CH_3)(CO)]$ $Ar'_4B \cdot CH_2Cl_2$ [9], been reported.

The main synthetic routes for the preparation of palladium carbonyls involve the displacement of weakly coordinated ligands by CO [9,10]. Working on C,N-cyclometallated compounds of Pd^{II}, we have prepared several complexes with this kind of ligand: $[Pd(8\text{-mq})(NCMe)_2]ClO_4$ [11], $[Pd(8\text{-mq})(OClO_3)(SPPh_3)]$ [12], $[Pd(8\text{-mq})(\mu\text{-}SPMe_2Ph)]_2(ClO_4)_2$ and $[Pd(8\text{-mq})(OCMe)_x]^+$ (*in situ*), and we have found that they are very good precursors for the preparation of new carbonyl complexes of Pd^{II}.

Herein we report the synthesis and characterization of some cationic and neutral thermally stable carbonylpalladium(II) complexes, as well as the molecular structure of one of the cationic derivatives, $[Pd(8\text{-mq})(CO)(SPPh_3)]ClO_4$.

EXPERIMENTAL

General procedures

Infrared spectra were recorded on a Perkin–Elmer 883 IR spectrometer using Nujol mulls between polyethylene plates. NMR spectra were recorded on a Varian Unity-300 or a Bruker ARX-300 spectrometer in $CDCl_3$ or acetone-d_6, using the solvent signal as an

*Author to whom correspondence should be addressed.

internal standard for ^1H and ^{13}C $\{^1H\}$, and H_3PO_4 (85%) as external reference for ^{31}P $\{^1H\}$. Elemental analyses were performed on a Perkin–Elmer 240-B microanalyser. Molar conductivity measurements were performed on a Philips P.W. 9509 digital conductimeter in approximately 5×10^{-4} M acetone solutions. [Pd(8-mq)($OClO_3$)($SPPh_3$)] [12] and [Pd(8-mq)(μ-Cl)]$_2$ [13] were prepared by literature methods.

[Pd(8-mq)(μ-I)]$_2$

[Pd(8-mq)(μ-Cl)]$_2$ (0.200 g, 0.352 mmol) and $AgClO_4$ (0.146 g, 0.704 mmol) were stirred in acetone (20 cm^3) for 1 h, and then the AgCl formed was filtered off. NBu_4I (0.260 g, 0.704 mmol) was added to the resulting solution giving rise to the precipitation of a yellow solid, which was separated by filtration, washed with acetone and vacuum dried (0.212 g, 80% yield). Found: C, 32.0; H, 1.8; N, 3.5. Calc. for $C_{20}H_{16}I_2N_2Pd_2$: C, 32.0; H, 2.2; N, 3.7%. IR (Nujol, cm^{-1}): 8-mq 1591 m, 1581 s, 1506 vs, 1071 s, 1052 vs, 816 vs, 776 vs, 751 vs, 666 m.

[Pd(8-mq)(μ-$SPMe_2Ph$)]$_2$(ClO_4)$_2$

[Pd(8-mq)(μ-Cl)]$_2$ (0.120 g, 0.211 mmol) and $AgClO_4$ (0.087 g, 0.422 mmol) were stirred in THF (20 cm^3) for 30 min and then the AgCl formed was filtered off. $SPMe_2Ph$ (0.72 g, 0.422 mmol) was added to the resulting solution and the mixture was stirred for 30 min. Following this, the solvent was concentrated to *ca* 5 cm^3 and the precipitated yellow solid was separated by filtration (0.197 g, 90% yield). Found: C, 41.9; H, 3.7; N, 2.9. Calc. for $C_{36}H_{38}Cl_2N_2O_8P_2Pd_2S_2$: C, 41.7; H, 3.7; N, 2.7%. Molar conductivity (S cm^2 mol^{-1}): 291. IR (Nujol, cm^{-1}): 8-mq 1598 w, 1500 vs, 832 s, 782 m, 778 m, 758 s; $SPMe_2Ph$ 950 s, 912 vs, 745 vs, 688 s, 518 s, 523 s [ν(P—S)]; ClO_4^- 1100 vs, 620 s. ^{31}P $\{^1H\}$ NMR: δ 41.99 (s).

[Pd(8-mq)($OClO_3$)(CO)] (**1**)

[Pd(8-mq)(μ-Cl)]$_2$ (0.200 g, 0.352 mmol) and $AgClO_4$ (0.146 g, 0.704 mmol) were stirred in acetone (20 cm^3) for 30 min, and the AgCl formed was filtered off. The solution was evaporated to *ca* 2 cm^3, then 5 cm^3 of CH_2Cl_2 was added and carbon monoxide was gently bubbled through the resulting pale yellow suspension at −60°C for 10 min. Addition of diethyl ether (25 cm^3) to the suspension afforded a white solid, which was filtered off and dried *in vacuo*. **1** (0.238 g, 90% yield). Found: C, 34.8; H, 1.8; N, 3.6. Calc. for $C_{11}H_8ClNO_5Pd$ (**1**): C, 35.1; H, 2.1; N, 3.7%. Molar conductivity (S cm^2 mol^{-1}): 156. IR (Nujol, cm^{-1}): 8-mq: 1596 w, 1514 vs, 825 s, 788 m, 768 s; $OClO_3^-$ 1144 vs, 1025 vs, 908 vs, 624 s, 612 m; ν(CO) 2140 vs.

[Pd(8-mq)X(CO)] [X = Cl (**2a**), Br (**2b**), I (**2c**)].

X = Cl (**2a**). (a) *Method* 1. To a suspension of [Pd(8-mq)($OClO_3$)(CO)] (**1**) (0.175 g, 0.465 mmol) in CH_2Cl_2 (20 cm^3) was added an equimolar amount of [$PBzPh_3$]Cl (0.180 g, 0.465 mmol) at room temperature. The mixture was stirred for 3 min and filtered to remove a small amount of suspended solid. The addition of cold Pr^{i}OH (80 cm^3, −30°C) to the resulting solution rendered a white solid which was identified by IR spectroscopy as **2a**, with a small amount of [Pd(8-mq)(μ-Cl)]$_2$ as an impurity.

(b) *Method* 2. CO was gently bubbled through a suspension of [Pd(8-mq)(μ-Cl)]$_2$ (0.420 g, 0.739 mmol) in 12 cm^3 of CH_2Cl_2 at −30°C for 15 min. After filtration, the resulting solution was added to cold n-hexane (90 cm^3, −30°C) affording a white solid which was filtered off and dried *in vacuo*. **2a**, (0.16 g, 35% yield). Found: C, 42.1; H, 2.2; N, 4.3. Calc. for $C_{11}H_8ClNOPd$: C, 42.3; H, 2.6; N, 4.5%. IR (Nujol, cm^{-1}): 8-mq 1593 w, 1509 vs, 826 s, 787 s, 768 s, 694 m; ν(Pd—Cl) 290 m; ν(CO) 2112 vs (solid), 2121 (CH_2Cl_2 solution). ^1H NMR (proton labelling is shown in Fig. 1): δ 9.48 (d, H1, $^3J_{1\text{-}2}$ = 5.04 Hz), 8.38 (d, H3, $^3J_{3\text{-}2}$ = 8.30 Hz), 7.72 (d, H6, $^3J_{5\text{-}6}$ = 7.90 Hz), 7.65 (d, H4, $^3J_{4\text{-}5}$ = 7.1 Hz), 7.58 (pt, H5), 7.54 (dd, H2), 3.89 (s, -CH_2-Pd). ^{13}C NMR: δ 151.83, 150.59, 144.24, 139.66, 130.05, 129.11, 128.57, 124.88, 121.67 (C_9H_6N), 30.14 (-CH_2-Pd); 176.98 (CO).

X = Br (**2b**). To a suspension of [Pd(8-mq)($OClO_3$)(CO)] (**1**) (0.049 g, 0.131 mmol) in CH_2Cl_2 (10 cm^3) an equimolar amount of NBu_4Br (0.042 g, 0.131 mmol) was added. The mixture was stirred at room temperature for 5 min and filtered to remove a small amount of suspended solid. The resulting solution was added to cold ^{i}PrOH (60 cm^3, −30°C) giving rise to pure **2b** (0.023 g, 50% yield). Found: C, 37.1; H, 2.2; N, 3.9. Calc. for $C_{11}H_8BrNOPd$: C, 37.1; H, 2.3; N, 3.9%. IR (Nujol, cm^{-1}): 8-mq 1593 w, 1510 vs, 823 s, 776 s, 764 m, 689 m; ν(CO) 2108 vs (solid), 2117 (CH_2Cl_2 solution). ^1H NMR: δ 9.67 (dd, H1, $^3J_{1\text{-}2}$ = 5.09 Hz, $^4J_{1\text{-}3}$ = 1.42 Hz), 8.38 (dd, H3, $^3J_{3\text{-}2}$ = 8.32 Hz), 7.73 (dd, H6, $^3J_{5\text{-}6}$ = 7.80 Hz, $^4J_{4\text{-}6}$ = 1.09 Hz), 7.66 (dd, H4, $^3J_{4\text{-}5}$ = 7.1 Hz), 7.59 (pseudo t, H5), 7.55 (dd, H2), 3.99 (s, -CH_2-Pd). ^{13}C

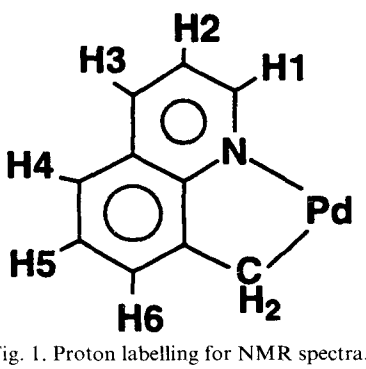

Fig. 1. Proton labelling for NMR spectra.

NMR δ: 152.24, 151.86, 144.29, 139.61, 130.17, 129.23, 128.60, 125.00, 121.99 (C_9H_6N), 32.52 (-CH_2-Pd); 177.65 (CO).

X = *I* (**2c**). (a) *Method* 1. To a suspension of [Pd(8-mq)($OClO_3$)(CO)] (**1**) (0.135 g, 0.360 mmol) in CH_2Cl_2 (10 cm^3) an equimolar amount of PMe_3PhI (0.100 g, 0.360 mmol) was added at room temperature. The mixture was stirred for 5 min and filtered to remove a small amount of suspended solid. Addition of Pr^{i}OH (50 cm^3) to the resulting solution afforded a yellow solid which was separated by filtration and vacuum dried. The solid was identified by IR spectroscopy as **2c** with a small amount of [Pd(8-mq)(μ-I)]$_2$ as an impurity.

(b) *Method* 2. CO was gently bubbled through a suspension of [Pd(8-mq)(μ-I)]$_2$. (0.150 g, 0.200 mmol) in 20 cm^3 of CH_2Cl_2 at -5°C for 30 min. After filtration of the suspended solid the resulting solution was added to cold *n*-hexane (80 cm^3, -30°C) affording **2c** (yield 0.10 g, 62%). Found: C, 32.6; H, 1.9; N, 3.4. Calc. for $C_{11}H_8INOPd$: C, 32.7; H, 2.0; N, 3.5%. IR (Nujol, cm^{-1}): 8-mq 1592 w, 1510 vs, 822 s, 774 vs, 761 m, 682 m; ν(CO): 2103 vs (solid), 2110 (CH_2Cl_2 solution). ^{1}H NMR: δ 9.89 (dd, H1, $^3J_{1\text{-}2}$ = 5.04 Hz, $^4J_{1\text{-}3}$ = 1.30 Hz), 8.35 (dd, H3, $^3J_{3\text{-}2}$ = 8.32 Hz), 7.71 (dd, H6, $^3J_{5\text{-}6}$ = 7.85 Hz, $^4J_{4\text{-}6}$ = 1.0 Hz), 7.64 (dd, H4, $^3J_{4\text{-}5}$ = 7.1 Hz), 7.60 (pseudo t, H5), 7.49 (dd, H2), 4.08 (s, -CH_2-Pd). ^{13}C NMR: δ 151.82, 151.15, 144.64, 139.34, 130.36, 129.40, 128.76, 125.08, 122.44 (C_9H_6N), 35.92 (-CH_2-Pd); 179.22 (CO).

[Pd(8-mq)(CO)($SPPh_3$)]ClO_4 (**3a**)

(a) *Method* 1. $SPPh_3$ (0.109 g, 0.372 mmol) was added to a CH_2Cl_2 suspension (5 cm^3) of **1** (0.14 g, 0.372 mmol) to give a pale yellow solution. The mixture was stirred for 2 min at room temperature and then 15 cm^3 of n-hexane was added. The resulting pale yellow precipitate was filtered off and dried *in vacuo* to give **3a**, (0.200 g, 80% yield).

(b) *Method* 2. Carbon monoxide was gently bubbled through a CH_2Cl_2 (1.5 cm^3) solution of [Pd(8-mq)($OClO_3$)($SPPh_3$)] (0.143 g, 0.223 mmol) for 5 min at -30°C. Addition of n-hexane (20 cm^3) rendered a pale yellow precipitate, **3a** (0.105 g, 70% yield). Found: C, 51.7; H, 3.1; N, 2.1. Calc. for $C_{29}H_{23}ClNO_5PPdS$: C, 52.0; H, 3.5; N, 2.1%. Molar conductivity (S cm^2 mol^{-1}): 150. IR (Nujol, cm^{-1}): 8-mq 1585 w, 1510 vs, 826 s, 788 m, 769 m, 699 s; $SPPh_3$ 758 m, 752 m, 699 s, 690 s, 600 s [ν(P-S)], 511 s; ClO_4^- 1100 vs, 620 s; ν(CO): 2115 vs (solid), 2118 (CH_2Cl_2 soiution). ^{31}P {^{1}H} NMR: δ 45.65 (s). ^{1}H NMR: δ 8.81 (m, H1), 8.41 (d, H3, $^3J_{3\text{-}2}$ = 7.93 Hz), 7-8 (m, H2, H4, H5, H6, $SPPh_3$), 3.98 (s, -CH_2-Pd). ^{13}C NMR: δ 151.09, 150.47, 142.59, 140.69, 130.14, 129.20, 128.91, 125.76, 122.34 (C_9H_6N), 36.57 (-CH_2-Pd); 176.26 (CO).

[Pd(8-mq)(CO)($SPMe_2Ph$)]ClO_4 (**3b**)

(a) *Method* 1. $SPMe_2Ph$ (0.104 g, 0.614 mmol) was added to a CH_2Cl_2 suspension (20 cm^3) of **1** (0.231 g, 0.614 mmol) and the mixture was stirred at room temperature for 5 min. After filtration of the suspended solid, cold Et_2O (100 cm^3, -10°C) was added to the resulting solution giving rise to **3b** (0.110 g, 33% yield).

(b) *Method* 2. Carbon monoxide was bubbled through a suspension of [Pd(8-mq)(μ-$SPMe_2Ph$)]$_2$(ClO_4)$_2$ (0.150 g, 0.145 mmol) in 2 cm^3 of CH_2Cl_2 at -10°C for 10 min. The resulting white solid was isolated by filtration and dried *in vacuo*, **3b** (0.118 g, 75% yield). Found: C, 41.5; H, 3.7; N, 2.7. Calc. for $C_{19}H_{19}ClNO_5PPdS$: C, 41.8; H, 3.5; N, 2.6%. Molar conductivity (S cm^2 mol^{-1}): 172. IR (Nujol, cm^{-1}): 8-mq 1592 w, 1510 vs, 831 s, 789 m, 777 s, 691 s; $SPMe_2Ph$ 958 s, 929 vs, 754 s, 733 s, 563 s [ν(P-S)]; ClO_4^- 1100 vs, 620 s; ν(CO) 2113 vs (solid). ^{31}P {^{1}H} NMR: δ 43.16 (s). ^{1}H NMR: δ 9.52 (m, H1), 8.41 (m, H3), 8.1–7.5 [m, H2, H4, H5, H6, C_6H_5 ($SPMe_2Ph$)], 3.92 (s, -CH_2-Pd), 2.93 [d, $^2J_{P\text{-}H}$ = 15 Hz, Me ($SPMe_2Ph$)]. The low solubility of **3b** prevented ^{13}C {^{1}H} NMR measurements.

Crystallographic studies

Suitable single crystals for X-ray structure determination of [Pd(8-mq)(CO)($SPPh_3$)]ClO_4 (**3a**) were obtained by slow diffusion of a diethyl ether layer into a solution of **3a** (8 mg) in $CHCl_3$ (4 cm^3) at 5°C.

Crystal data. $C_{29}H_{23}ClNO_5PPdS$, yellow, prismatic, M = 670.36, triclinic, space group P-1, a = 10.767(2), b = 10.843(1), c = 14.263(2) Å, α = 85.31(1), β = 73.04(1), γ = 61.40(1)°, V = 1395.1(3) Å^3, Z = 2, D_c = 1.596 g cm^{-3}, λ = 0.71073 Å, T = 200(2) K, crystal size = 0.40 × 0.34 × 0.22 mm, μ(Mo-K_α) = 0.933 mm^{-1}, F(000) = 676.

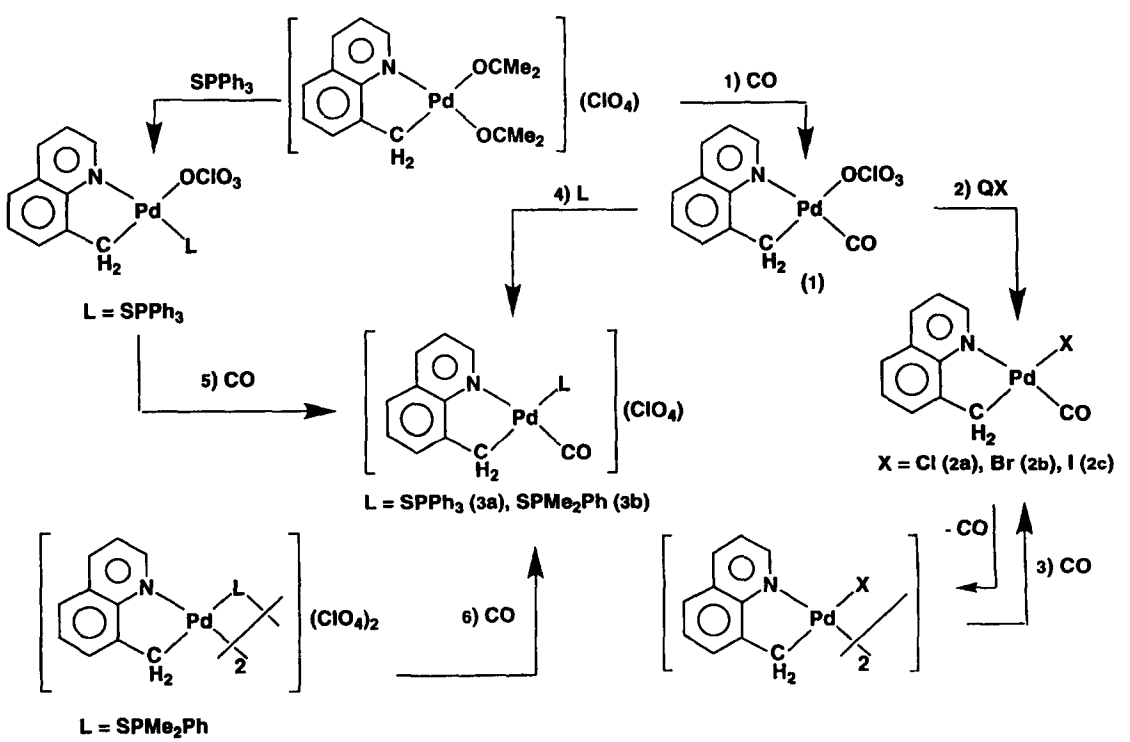
Data collection and processing. Siemens P4 automated four-circle diffractometer equipped with an Oxford Cryosystems low-temperature device, graphite-monochomated Mo-K_α radiation, ω–θ scan technique, 4650 independent reflections collected in two shells ($2\theta < 40°$, $50°$; $0 \leqslant h \leqslant 12$, $-11 \leqslant k \leqslant 12$, $-15 \leqslant l \leqslant 16$), of which 4492 were used in all calculations, three check reflections measured at regular intervals showed no intensity decay. An empirical absorption correction based on psi scans was applied (transmission factors = 0.995 and 0.871).

Structure analysis and refinement. The position of the palladium atom was determined from the Patterson map. The remaining atoms were located in successive difference Fourier syntheses and refined by full-matrix least squares on F^2. All non-hydrogen atoms were refined with anisotropic displacement parameters. H atoms were added at calculated positions with a common isotropic thermal parameter. At final convergence $R[F \geqslant 4\sigma(F)]$ = 0.0302, $wR(F^2$, all data) = 0.0772, $S(F^2)$ = 1.029 for 353 parameters, $w^{-1} = [\sigma^2(F_o^2) + (0.0385\ P)^2 + 1.53\ P]$, $P = 1/3$ [max $(F_o^2, 0) + 2F_c^2$], largest difference peak and hole = 0.996 and -0.560 e/Å^3. All calculations were

performed on a local area VAX cluster (VAX/VMS V5.5) with the Siemens SHELXTL PLUS and SHELXL 93 software packages [14,15].

RESULTS AND DISCUSSION

All the carbonylpalladium complexes described in this paper have been obtained as indicated in Scheme I.



Synthesis and characterization of [Pd(8-mq)($OClO_3$)(CO)] (**1**)

When CO is bubbled through a suspension which contains the solvento species [Pd(8-mq)($OCMe_2$)$_x$]ClO_4 in CH_2Cl_2/Me_2CO (5:2) at −60 °C [Scheme I, (**1**)], the neutral monocarbonyl complex [Pd(8-mq)($OClO_3$)(CO)] (**1**) precipitates. It is important to point out that, although CO is able to displace $OClO_3$ in other palladium complexes (M—$OClO_3$) to produce the corresponding cationic carbonyl derivatives [M—CO]ClO_4 [10a], in this case the neutral monocarbonyl complex is obtained instead of the cationic bis(carbonyl) complex [Pd(8-mq)$(CO)_2$]ClO_4 which could be expected. Compound **1** is a stable solid at room temperature and can be stored at 5 °C for long periods. Compound **1** is only slightly soluble in dichloromethane at room temperature and its solution decomposes very quickly rendering palladium metal. Decomposition can be partially prevented by working at low temperature; however, the solubility of this complex is very low under these conditions which prevents conductivity or NMR studies in solution.

The IR spectrum of **1** shows (see Experimental): (a) characteristic absorptions due to the $OClO_3^-$ ligand [16]; (b) a strong absorption at 2140 cm^{-1} due to ν(CO), which suggests that only one isomer is formed in the reaction. Taking into account the *trans* disposition of the $OClO_3^-$ anion to the C donor atom of the C,N-groups observed in complexes such as [Pd(C_6H_4-N = N-C_6H_5-C,N)($OClO_3$)($SPPh_3$)] [12] and [Pd(8-mq)($OClO_3$)($SPPh_3$)] [12,17], we think that **1** has the structure depicted in Scheme I, in concert with the value of ν(CO) observed for a carbonyl group *trans* to a N donor atom in palladium carbonyl complexes [9,10b,18]. Since the carbonyl complex **1** is slightly stable in solution, we decided to explore its reactivity towards some neutral or anionic ligands (in a 1:1 molar ratio only) in order to establish whether the Pd—CO or Pd—$OClO_3$ is the more inert bond in the presence of nucleophiles.

Reactivity of [Pd(8-mq)($OClO_3$)(CO)] (**1**) *towards anionic ligands. Synthesis of* [Pd(8-mq)X(CO)] (X = Cl, Br, I)

In reactions between [Pd(8-mq)($OClO_3$)(CO)] (**1**) and the halides (X^- = Cl^-, Br^-, I^-) in a 1:1 molar ratio the substitution of the perchlorate anion by the corresponding halides, which are better coordinating ligands, takes place giving rise to [Pd(8-mq)X(CO)] [X = Cl (**2a**), Br (**2b**), I (**2c**)] with small impurities of

Scheme I.

the respective dinuclear compounds $[Pd(8\text{-mq})(\mu\text{-X})]_2$ according to Scheme I (2). The latter seems to be formed by the intermolecular substitution of the CO by the halide. Pure samples of complexes **2a,** and **2c** have also been prepared by bubbling CO through suspensions of the dinuclear complexes $[Pd(8\text{-mq})(\mu\text{-X})]_2$(X = Cl, I) [Scheme I, (3)] [19]. Complexes **2a, b, c** are stable in the solid state at 5 °C for several months, but, at room temperature, their CH_2Cl_2 solutions lose CO slowly, giving rise to the dinuclear derivatives $[Pd(8\text{-mq})(\mu\text{-X})]_2$.

Complexes **2a, b, c** have been characterized by elemental analysis, IR and NMR (^1H, ^{13}C) spectra. The IR spectra in CH_2Cl_2 solution show only one absorption assignable to ν(CO) at 2121 (**2a**), 2117 (**2b**) and 2110 (**2c**) cm^{-1}, respectively, indicating that only one isomer is present in each case. The sequence observed for ν(CO) absorptions in **2a–2c** is similar to that observed in the complexes $[PdX_3(CO)]^-$ [4], $[Pd(C_6H_4\text{-}C(R) = N\text{-}OH)X(CO)]$ [20] and $[Pt(CO)LX_2]$ (X = Cl, Br, I; L = CO, py, aniline) [21] and can be explained by the different electronegativity of the halogens (Cl > Br > I). Moreover, a higher ν(CO) in $[Pd(8\text{-mq})(OClO_3)(CO)]$ (**1**) is also a consequence of the lower nucleophilic character of the $OClO_3^-$ ligand with respect to the X^- halides. The observed values of ν(CO) in **2a–2c** suggest that the CO ligand is *trans* to the N atom of the 8-mq group [18]. In addition, the ν(Pd—Cl) for complex **2a** is in the range observed in palladium chloro complexes with *trans* alkyl or phenyl groups [22]. The structure proposed for complexes **2a, b, c** (Scheme I) is that observed in other complexes of stoichiometry [Pd(CN)XL] (C N = azobenzene-2,*C*,*N*; *N*,*N*-dimethylbenzylamine-2,*C*,*N*; 2-methoxy-3,*N*,*N*-dimethylaminopropyl; X = Cl, Br; L = py, PEt_3, PPh_3) obtained by cleavage of the halide-bridged system of the corresponding binuclear $[Pd(C\ N)(\mu\text{-X})]_2$ (X = Cl, Br) with neutral ligands (L) [23], and indicates that the substitution process [Scheme I (2)] takes place with stereoretention. The ^1H NMR spectra of **2a, b, c** show, in each case, six resonances corresponding to the six chemically inequivalent aromatic protons and a singlet resonance which is due to the methylene protons of the Pd—CH_2 group (see Experimental). The $^{13}C\{^1H\}$ NMR spectra show the expected resonances for all the carbon atoms present in the different molecules, including the CO ligand. It is noteworthy that the moderate stability of these carbonyl complexes at a low temperature (−5 °C) allows a $^{13}C\{^1H\}$ NMR study to be made, which is very unusual for Pd^{II} carbonyl complexes [9].

Reactions of $[Pd(8\text{-mq})(OClO_3)(CO)]$ (**1**) *with* SPR_3. *Synthesis of* $[Pd(8\text{-mq})(CO)L]ClO_4$ [L = $SPPh_3$ (**3a**), $SPMe_2Ph$ (**3b**)]

$[Pd(8\text{-mq})(OClO_3)(CO)]$ (**1**) reacts with the neutral ligands $SPPh_3$ and $SPMe_2Ph$ (monodentate ligands which are able to act as bridging ligands) in a 1 : 1 molar ratio giving rise to $[Pd(8\text{-mq})(CO)L]ClO_4$ [L = $SPPh_3$ (**3a**), $SPMe_2Ph$ (**3b**)], as is indicated in Scheme I (4). Both complexes are thermally stable and decompose between 130 and 140 °C. They have been isolated and fully characterized by elemental analysis, IR and NMR spectroscopy.

The structure of **3a** and **3b** (Scheme I) has been proposed on the basis of these data and confirmed by an X-ray study on **3a**. The IR spectra of these complexes show: (a) absorptions due to the SPR_3 ligands. The absorption due to ν(P—S) appears in both cases at lower frequencies than in the corresponding free ligand [$\Delta\nu$(P—S) = 36 cm^{-1} (**3a**), 20 cm^{-1} (**3b**)]. This small decrease indicates that, in both cases, the SPR_3 ligands act as terminal ligands [12]. (b) One absorption attributable to ν(CO) at *ca* 2120 cm^{-1} confirms the presence of the CO ligand in the complex. (c) Two absorptions at 1100 and 620 cm^{-1}, which are typical of the uncoordinated ClO_4^-(Td) anion [16]. The ^1H NMR spectra of **3a, b** show the resonances for all the groups that were expected to be present in the molecule, although the presence of phenyl groups in $SPPh_3$ and $SPMe_2Ph$ precludes any unambiguous assignment of the aromatic resonances. The $^{31}P\{^1H\}$ NMR spectra show only one singlet and the $^{13}C\{^1H\}$ NMR spectrum of **3a** shows the expected resonances for the cyclometallated group (8-mq) and the terminal CO ligand [9]. All these data confirm that the reactions take place with the substitution of the $OClO_3^-$ ligand by L (L: $SPPh_3$, $SPMe_2Ph$) and that only one of the two possible isomers is formed in both cases. The molecular structure of **3a,** which has been established by an X-ray diffraction study is discussed in detail below, indicates that the CO ligand is *trans* to the N atom (as in all the aforementioned complexes) of the 8-mq; i.e. that the substitution reaction of $OClO_3^-$ by the L ligands on complex **1** [Scheme I (4)] occurred regiospecifically.

Complexes **3a** and **3b** can also be prepared by reacting CO with other starting materials. Thus, **3a** is obtained when CO is bubbled through a dichloromethane solution of $[Pd(8\text{-mq})(OClO_3)(SPPh_3)]$ [Scheme I (5)]. Given the structure of the starting complex $[Pd(8\text{-mq})(OClO_3)(SPPh_3)]$ (which has been unequivocally established by a ^1H–^1H NOESY experiment [17]), in which the $OClO_3^-$ group is *trans* to the σ Pd—C bond and the structure of **3a,** the substitution reaction of $OClO_3^-$ by CO takes place with isomerization and this isomerization process has to occur very quickly since, when the reaction is monitored in CH_2Cl_2 solution by IR spectroscopy, no other isomers are detected. Isomerization processes have been observed previously, i.e. for *trans*-$[PtX_2(CO)L]$ (X = Cl, L = PBu_3, PEt_3, PMe_2Ph, $PMePh_2$, PPh_3, $AsMePh_2$, $AsPh_3$; X = Br, L = PMe_2Ph) [24a], which isomerize to *cis*-$[PtX_2(CO)L]$, the *trans* to *cis* isomerization being dramatically catalyzed by carbon monoxide. The proposed mechanism for CO-catalyzed isomerizations is that of pseudorotation pro-

cesses involving five-coordinate intermediates [24b]. Complex **3b** can also be prepared by carbonylation of the binuclear $[Pd(8\text{-mq})(\mu\text{-SPMe}_2Ph]_2$ [Scheme I (6)] which takes place with cleavage of the bridging system to produce only one isomer.

Molecular structure of $[Pd(8\text{-mq})(CO)(SPPh_3)](ClO_4)$ **(3a)**

The molecular structure of the cationic carbonyl palladium complex $[Pd(8\text{-mq})(CO)(SPPh_3)](ClO_4)$ (**3a**) has been determined by single crystal X-ray diffraction. A drawing of the structure is presented in Fig. 2 and relevant bond distances and bond angles are shown in Table 1.

As can be seen, the cation shows a slightly distorted square-planar geometry around the palladium centre with C(1) and C(2) atoms 0.154(6) Å and 0.126(5) Å away, respectively, from the best least-squares plane defined by the C(1), C(2), N(1), Pd(1) and S(1) atoms. The angle between the normal to this plane and the C(1)—O(1) vector is 95.5(3)° and the Pd—C—O angle is 177.7(4)°. The Pd—C(1) bond length [1.894(4) Å)] is within the range of distances observed in the neutral complex $[Pd(\eta^3\text{-}C_4H_7)(SnCl_3)(CO)]$ [1.947(11) Å] [6] or the cationic $[(phen)Pd(C(O)CH_3)(CO)]Ar'_4B\cdot CH_2Cl_2$ [1.922(11) Å] [9] and the anionic species $[Pd(C_6H_3Me\text{-}2,NO_2\text{-}6)Cl_2(CO)]^-$ [1.853(10) Å] [5], and is shorter than that observed in the cationic derivative [2-(CO)-2-(PPh_3)-*closo*-2,1-$PdTeB_{10}H_9(PPh_3)]^+$ [2.003(9) Å] [7]. Bond distances and angles corresponding to the $PdC_{10}H_8N$ metallocycle are similar to those observed in other complexes involving the 8-mq ligand [25]. The best least-squares planes defined by the $C_{10}H_8N$ ligand and the palladium coordination plane are not coplanar, but rather their dihedral angle is 20.28(5)°. The Pd—S(1) distance, 2.453(1) Å, is longer than that observed in

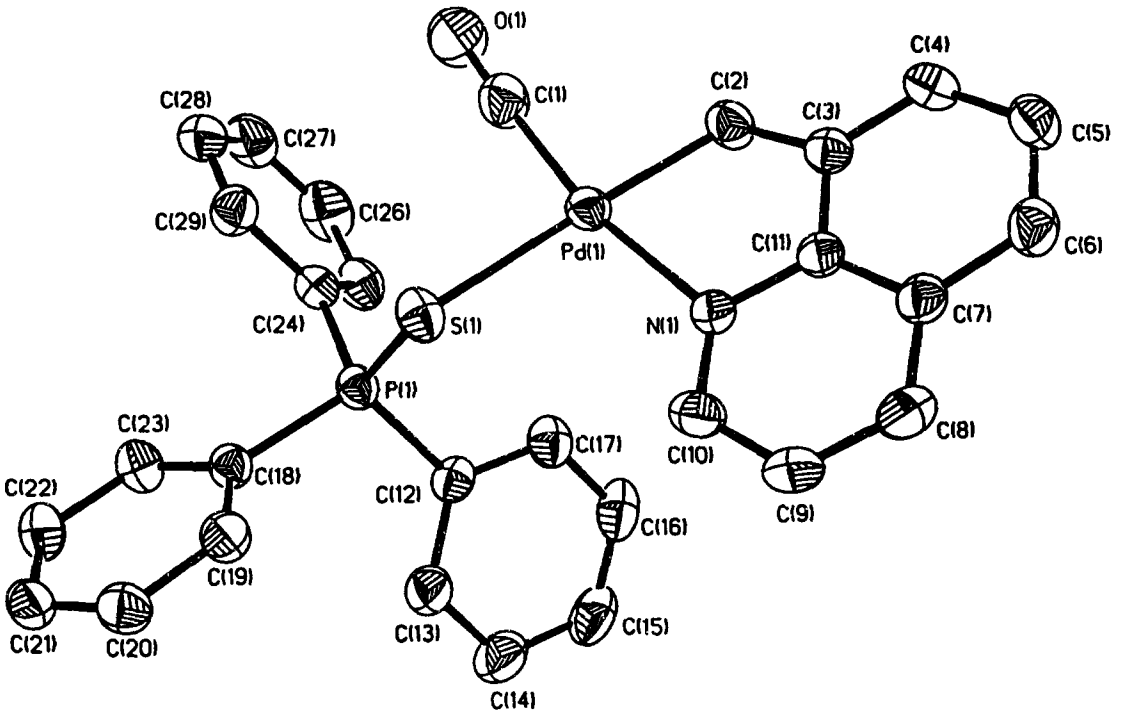


Fig. 2. Molecular structure of the cation $[Pd(8\text{-mq})(CO)(SPPh_3)]^+$ showing the atom numbering scheme. The thermal ellipsoids are drawn at the 50% probability level.

Table 1. Selected bond lengths (Å) and angles (°) for complex $[Pd(8\text{-mq})(CO)(SPPh_3)]ClO_4$ (**3a**)

Pd(1)—C(1)	1.894(4)	Pd(1)—C(2)	2.062(3)
Pd(1)—N(1)	2.084(3)	Pd(1)—S(1)	2.453(1)
C(1)—O(1)	1.123(4)		
C(1)—Pd(1)—C(2)	87.7(2)	C(2)—Pd(1)—N(1)	82.44(12)
N(1)—Pd(1)—S(1)	93.96(7)	C(1)—Pd(1)—S(1)	95.65(12)
O(1)—C(1)—Pd(1)	177.7(4)		

[Pd(az)($OClO_3$)($SPPh_3$)] (az: azobencene-2,C,N) [2.326(1) Å] [12] where the S atom is *trans* to a Pd—N bond, in accord with the greater *trans* influence of a C σ-bonded ligand than a Pd—N-bonded one.

CONCLUSIONS

The synthesis of the neutral [Pd(8-mq)($OClO_3$)(CO)] (**1**), which is moderately stable, allows us to study its reaction with different neutral (SPR_3) or anionic (X^-) ligands. In such processes, the Pd—CO bond is preserved and cationic and neutral carbonyl derivatives of palladium are obtained. However, the usual lability of the Pd—CO bond is also observed in these complexes since intermolecular substitution reactions involving CO displacement take place in their dichloromethane solutions. In spite of this fact $^{13}C\{^1H\}$ NMR data have been obtained for all sufficiently soluble complexes. The δC(CO) value is, in all cases, close to 177 ppm, a similar value to the corresponding resonance found in [(phen)Pd(C(O)CH_3)(CO)]$Ar'_4B \cdot CH_2Cl_2$ [9].

Supplementary material—Tables of atomic coordinates, bond lengths and angles, anisotropic displacement parameters, H-atom coordinates and observed and calculated structure factors, have been deposited at the Cambridge Crystallographic Data Centre.

17. The ^1H–^1H 2D NOESY experiment was performed on compound [Pd(8-mq)($OClO_3$)($SPPh_3$)] at a measuring frequency of 300.13 MHz. The mixing time was 400 ms and the data were acquired into a 512 × 1024 matrix, then transformed into 1024 × 1024 points using a sine window in each dimension. Selective irradiation of the methylene CH_2—Pd resonance produces a clear NOE enhancement at the resonances because of the H_6 proton (see Fig. 1) of the 8-mq ligand and the *ortho*-H protons of the $SPPh_3$ ligand (see Scheme I). This last fact suggests the proximity of the interacting nuclei (i.e. the CH_2 group and the $SPPh_3$ ligand) and, consequently, the *cis* coordination of the $SPPh_3$ ligand relative to the CH_2—Pd bond.

(Received 20 September 1996; accepted 30 October 1996)

Abstract—The nickel(II) complexes $[Ni(nmedtc)(PPh_3)_2]ClO_4$ (**1**) and $[Ni(nmedtc)dppe]BPh_4 \cdot CH_2Cl_2$ (**2**) [nmedtc = *N*-methyl,*N*-ethanoldithiocarbamate, dppe = 1,2-bis(diphenylphosphino)ethane] were prepared and characterized by electronic and IR spectra, and their structures determined by X-ray crystallography. In both complexes the NiS_2P_2 chromophore is planar and the thioureide C—N has double bond character. Hydrogen bond interaction is observed in 1 between the ethanolic group and the perchlorate anion. Electronic and IR spectra confirm the planarity of the chromophores in both complexes and the contribution of the thioureide form in the molecular structure. © 1997 Elsevier Science Ltd. Keywords: nickel; complexes; synthesis; structure.

Group VIII dithiolates containing planar MS_4 chromophores show variable behaviour in their reactions with Lewis bases [1,2]. Soft Pd^{II} and Pt^{II} dithiolates react preferably with soft phosphines to give planar MS_2P_2 chromophores [3,4], but chromophores with square-pyramidal geometry have also been observed in solution for these metals. Detailed structural studies on a variety of MS_2P_2 chromophores have been made [5,6]. Unlike its congeners, Ni^{II} is a borderline acceptor. Ni^{II} complexes of dithiocarbamates are typically planar and contain the NiS_4 chromophore. They react preferably with soft Lewis bases such as phosphines, rather than with hard bases such as NH_3 or pyridine. The symbiotically induced softness and the electronic effects of the substituents on the dithiocarbamate ligands were found to be important in this respect [7,8]. With ligands such as PR_3 or dppe they form planar and diamagnetic complexes [9–11] containing the NiS_2P_2 chromophore. Mixed complexes of the type $[Ni(S_2CNR_2)X(PR_3)]$ were obtained by reacting NiX_2 with dithiocarbamate and PR_3 [12]. Complexes of the type $[Ni(dtc)Cl(PPh_3)]$ and $[Ni(dtc)(PPh_3)_2]ClO_4$ {dtc = $[S_2CN(C_2H_5)_2]^-$, $[S_2CNH(C_2H_4OH)]^-$, $[[S_2CN(C_2H_4OH)_2]$, $[S_2CN(C_5H_{10})]^-$} have also been prepared [13,14].

In order to see the influence of an electronegative substituent such as $-C_2H_4OH$, and of free and chelated phosphines, on the NiS_2P_2 chromophore and on the thioureide C—N bond, we report here the synthesis and structural characterization of two new complexes, $[NiL(PPh_3)]ClO_4$ (**1**), and $[NiL(dppe)]BPh_4 \cdot CH_2Cl_2$ (**2**), where L is the ligand *N*-methyl,*N*-ethanoldithiocarbamate (nmedtc) and dppe = 1,2-bis (diphenylphosphino)ethane.

EXPERIMENTAL

All reagents and solvents employed were commercially available high-grade purity materials (E-Merck) and were used as supplied.

Physical measurements

IR spectra were recorded on Jasco IR-700 spectrophotometer (range 4000–400 cm^{-1}) as KBr pellets. The UV–vis spectra were recorded in $CHCl_3$ solution

*Author to whom correspondence should be addressed.

on the Jasco UVIDEC double-beam spectrophotometer.

Preparation of complexes

Bis(triphenylphosphine)(N-methyl,N-ethanoldithiocarbamato) nickel(II) perchlorate, [Ni(nmedtc)(PPh_3)]ClO_4 (**1**). A mixture of Ni(nmedtc)$_2$ [15] (358 mg, 1 mmol), PPh_3 (520 mg, 2 mmol) $NiCl_2 \cdot 6H_2O$ (120 mg, 0.5 mmol) and $NaClO_4$ (125 mg, 1 mmol) was refluxed for about 3 h in a methanol/dichloromethane solvent mixture (50 cm^3), then concentrated to *ca* 25 cm^3, and allowed to settle for 2 days. The precipitated purple-red compound was filtered off and dried over anhydrous calcium chloride. Well-formed crystals were obtained by recrystallization from a dichloromethane/methanol solution (yield 70%, m.p. 160°C).

[1,2-*Bis(diphenylphosphino*-K,P,P′)*ethane*]-(N-*methyl*,N-*ethanoldithiocarbamato)nickel(II)tetraphenylborate dichloromethane solvate*, [Ni(nmedtc)(dppe)]$BPh_4 \cdot CH_2Cl_2$ (**2**). A mixture of Ni(nmedtc)$_2$ (358 mg, 1 mmol), dppe (400 mg, 1 mmol) and $NaClO_4$(125 mg, 1 mmol) was refluxed in a methanol/dichloromethane solvent mixture (50 cm^3) for about 3 h, concentrated to 25 cm^3 and then allowed to settle for 2 days. The orange–yellow solid separated from the solution was filtered off and dried over anhydrous calcium chloride. Well-formed crystals were obtained by recrystallization from a methanol/dichloromethane solvent mixture (yield 70%, m.p. 165°C).

X-ray crystallography

Details of the crystal data, data collection and refinement parameters for **1** and **2** are summarized in Table 1. Intensity data were collected at ambient temperature (295 K) on a Philips four-circle diffractometer using graphite-monochromated Mo-K_α radiation (λ = 0.71069 Å). Of the 52 non-hydrogen atoms of complex **1**, 16 atoms were refined anisotropically while the phenyl groups were refined isotropically. Bond lengths and bond angles are given in Tables 2 and 3.

RESULTS AND DISCUSSION

IR spectra show ν(C—N) bands at 1550 cm^{-1} for **1** and 1529 cm^{-1} for **2**. The shift in ν(C—N) values to higher wavenumber compared with the parent Ni(nmedtc)$_2$ complex is attributed to the mesomeric drift of electrons from the dithiocarbamate moiety towards the metal. The ν(C—S) bands around 997 cm^{-1}, without any splitting, indicate that the dithiocarbamate ligand is chelated [16]. The electronic absorption spectrum of **1** shows bands at 400, 460, 550 and 570 nm. The strong band at 400 nm can be attributed to metal-to-ligand charge transfer [13], other bands being due to *d–d* transitions: $d_{yz} \rightarrow d_{xy}$ (460 nm), $d_{xz} \rightarrow d_{xy}$ (550 nm) and $d_{x^2-y^2} \rightarrow d_{xy}$ (570 nm). Similar transitions were reported for [Ni(dedtc)(PPh_3)$_2$]$^+$, based on a single crystal polarized spectral study [13,17]. Two absorption bands at 450 and 480 nm in **2** are due to *d–d* transitions.

Structure analysis

The structure of **1**, along with the numbering scheme, is shown in Fig. 1. The crystal contains discrete mononuclear [Ni(nmedtc)(PPh_3)$_2$]$^+$ units which have no significant intermolecular contacts. Four formula units are present in the unit cell. The Ni, S(1), S(2), P(1) and P(2) atoms are coplanar [deviations (Å) from the mean S_2P_2 plane are: S(1) +0.51, S(2) −0.156, P(2) +0.126, P(1) −0.120]. The planarity of the molecule is in keeping with the observed diamagnetism of the complex. Severe distortions with respect to the idealized square-planar geometry are observed in coordination angles: the small S—Ni—S chelation angle [78.4(1)°] is determined by the geometry of the chelate ligand, while the opposite P—Ni—P angle [102.9(1)°] is rather large, probably owing to the high hindrance of the tripenylphosphine groups.

The bidentate ligand, which is essentially planar [apart from the C(4) and O(1) atoms], is inclined by 24.4° with respect to the coordination plane. The Ni—S, as well as the S—C, bond distances are chemically equivalent, showing that the negative charge of the bidentate ligand is equally distributed over the two donor atoms. Moreover, the short C(1)—N distance of 1.31(1) Å, which has double bond character, indicates that the electron density is delocalized over the entire S_2CN moiety. This is supported by the circumstance that the two S—C—N angles are generally greater than the S—C—S one. The O(1)···O(5) contact distance of 2.746(9) Å strongly suggests the presence of a hydrogen bond between the ligand oxygen and the perchlorate anion. Structural details of the dithiocarbamate ligand are normal and comparable with those observed in other compounds [18]. Attempts to obtain suitable crystals of the parent Ni(nmedtc)$_2$ complex in order to carry out a comparative study were unsuccessful.

It is noteworthy that the phenyl groups C(17)–C(22) bonded to P(1), and C(23)–C(28) bonded to P(2), are roughly parallel (the dihedral angle between the two planes is 19.1°) and that the distance of 3.82 Å calculated between the centroids of the two hexagonal rings is compatible with a graphite-type interaction.

Complex **2** is monomeric, with four molecules per unit cell. The structure of **2**, along with the numbering scheme used, is shown in Fig. 2. The molecule is approximately planar, in keeping with the observed diamagnetism [deviations (Å) from the mean S_2P_2 plane are: S(1) +0.042, S(2) −0.45, P(2) +0.042,

P(1) −0.040]. The two carbon atoms of the aliphatic chain between the P atoms are alternatively displaced from the coordination plane by +0.363 [C(17)] and −0.374 Å [C(18)]. The Ni—S, as well as the S—C, bond distances are comparable, showing that the negative charge of the dithiocarbamate ligand is equally distributed over the two donor atoms, as found in **1**. In addition, the short C(1)—N distance of 1.28(2) Å indicates that the electron density is delocalized over the S_2CN moiety and that this bond is double in character. Also, in this compound, the two S—C—N angles are generally greater than the S—C—S ones. One molecule of CH_2Cl_2, which was used as solvent in the preparation of the compound, is present as clathrate in the crystal packing.

Comparison of $[Ni(nmedtc)(dppe)]^+$ with the corresponding $[Ni(nmedtc)(PPh_3)_2]^+$ cation shows that bond lengths and angles compare well in the dithiocarbamato ligands. In particular the S—Ni—S chelation angles [79.4 *vs* 78.4°] and the Ni—S—C angles [mean value 85° in both compounds] are very similar, irrespective of the fact that the CNS_2 plane in $[Ni(nmedtc)(dppe)]BPh_4\cdot CH_2Cl_2$ is inclined by only 8.1° with respect to the coordination plane, while the corresponding dihedral angle is 24.4° in $[Ni(nmedtc)(PPh_3)_2]ClO_4$. On the other hand, a significant difference is observed in the P—Ni—P angles that are subtended by the dppe bidentate ligand, being about 16° smaller than those found in $[Ni(nmedtc)(PPh_3)_2]^+$, where the PPh_3 groups have a higher steric hindrance. Thus, the P—Ni—P angle seems to be greatly influenced by the bulkiness of the phosphorus substitutents.

The Ni—P distances are similar to those reported earlier in [1,2-bis(diisopropylphosphinoethane]carbenenickel(0) [14] [2.175(3) and 2.163(2)Å]. Bond parameters in a series of different bisdithiocarbamates and phosphine-substituted planar nickel complexes are given in Table 4. It is noteworthy that in all the dppe complexes the Ni—P distances are shorter and the P—Ni—P angles are smaller when compared with the corresponding values observed in the PPh_3 complexes.

The structural parameters of the complexes are clearly unaffected by the presence of the alcoholic substituent on the dithiocarbamate ligand. However, the properties of this substituent have been found to influence the reactivity of similar complexes in solution [8].

(Received 29 July 1996; accepted 29 October 1996)

Abstract—A Re^V hydrido complex with bis-1,2-(diphenylphosphine)ethane and triphenylphosphine was employed for the photochemically induced fixation and reduction of dinitrogen. Tetrahydrofuran/cyclohexane (1 : 1) solutions, acidified and non-acidified, were examined in the UV radiation field. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: dinitrogen reduction; photochemistry; catalytic complexes.

One of the most important agricultural problems is "nitrogen hunger", i.e. the lack of nitrogen compounds (needed for protein synthesis) in the soil. Atmospheric dinitrogen, as the most stable diatomic molecule, can be used only by plants living in a symbiosis with bacteria, which activate dinitrogen *in vivo*. In other cases the lack of nitrogen compounds must be supplemented by fertilisers. Industrial production of ammonia using molecular nitrogen requires expensive catalysts and techniques. Chemists have been searching for a long time for a chemical equivalent of *nitrogenase*, a bacterial enzyme allowing chemical reactions of dinitrogen at room temperature and under atmospheric pressure. In our investigations we examined initially the hydrido complexes of molybdenum and tungsten, which, under conditions of pure chemical reduction, give low yields of hydrazine and ammonia, but activated by electromagnetic radiation (γ or UV) become effective catalysts of this process [1–10].

Given the possibility of dinitrogen fixation and reduction in the UV radiation field using a pentahydrido rhenium(V) complex with triphenylphosphine [11], we have examined the usefulness of the $[ReH_5(dppe)(PPh_3)]$ complex for this reaction {dppe = bis-1,2-(diphenylphosphine)ethane, diphos}. This complex should be more effective than the one examined earlier because of the presence of the bidentate phosphine in its coordination sphere. Its higher stability compared with hydrido complexes of tungsten with phosphines is shown, for instance, in a higher value for the force constant of the M—H bond: $f' = 2.167$mdyn Å^{-1} for $[ReH_5(dppe)(PPh_3)]$, while in the case of a tungsten complex with ethyldiphenylphosphine $f' = 1.99$mdyn Å^{-1} (for vibrations of analogous symmetry). The higher stability of hydrido rhenium complexes with water-soluble phosphines may facilitate reduction of dinitrogen in aqueous solutions under homogeneous conditions, whereas tungsten complexes with such phosphines under such conditions decompose, forming tungsten blues.

EXPERIMENTAL

Diphos was synthesised from triphenylphosphine by the standard method [12]. Triphenylphosphine and other reagents were of analytical grade. $[ReH_5(dppe)(PPh_3)]$ was obtained using a literature method [13].

Samples of 10 cm^3 with concentrations of the complex of 1×10^{-3}, 5×10^{-3} and 1×10^{-2} mol dm^{-3}, saturated with a mixture of deoxygenated nitrogen and hydrogen (1 : 3), were irradiated in a cylindrical quartz vessel (diameter 2.5 cm). A tetrahydrofuran/cyclohexane (1 : 1) mixture was used as solvent; the cyclohexane was added in order to minimise C_4H_8O insertion into the rhenium coordination

*Author to whom correspondence should be addressed.

sphere. The gases were bubbled through the vessel at 15 $cm^3\ min^{-1}$ (N_2) and 45 $cm^3\ min^{-1}$ (H_2), which ensured vigorous stirring of the solution. A 100 W Blak-Ray B-100A UV lamp with a blue filter (blocking the visible part of the spectrum) was used to eliminate H_2 and to convert the hydride complex into the unsaturated intermediate compound. In order to maintain constant concentrations, the gases were passed through washers and after their saturation by the solvent they were introduced into the irradiated solution of the rhenium complex. Two series of measurements for each concentration were carried out in acidified and non-acidified solutions. The concentration of sulfuric acid in the sample was 0.1 M. In each of the above cases the irradiation periods were in the range 1–60 min. With times shorter than 4 min, no measurable amounts of molecular nitrogen reduction products were found. The reduced nitrogen reaction products were absorbed from the waste gases in a washer with an aqueous solution of sulfuric acid (*ca* 0.1 mol dm^{-3}).

The light intensity of the lamp was 5.55×10^{13} eV $cm^{-2}\ s^{-1}$. Hydrazine and ammonia were determined by spectrophotometrical methods as described previously [1–4,14]. The concentrations of dinitrogen reduction products were measured both in the irradiated solution and in the sulfuric acid washer.

RESULTS AND DISCUSSION

Curves of ammonia and hydrazine formation are presented in Figs 1 and 2, respectively, showing the dependencies of product molecule numbers *vs* irradiation dose (the courses or the functions were obtained by computer optimisation). These plots present the summarised values of the product's molecule numbers (measured both in irradiated solution and in the washer).

Table 1 presents a comparison of the catalytic efficiencies of the rhenium and tungsten complexes examined. The numbers of cycles have been calculated as in previous papers [1–11].

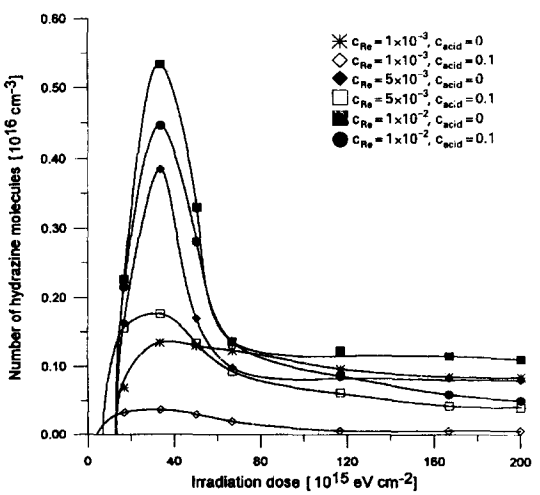

Fig. 1. Formation of hydrazine *vs* irradiation dose in UV-irradiated solutions, solvent: THF–*c*-C_6H_{12} (1 : 1) mixture.

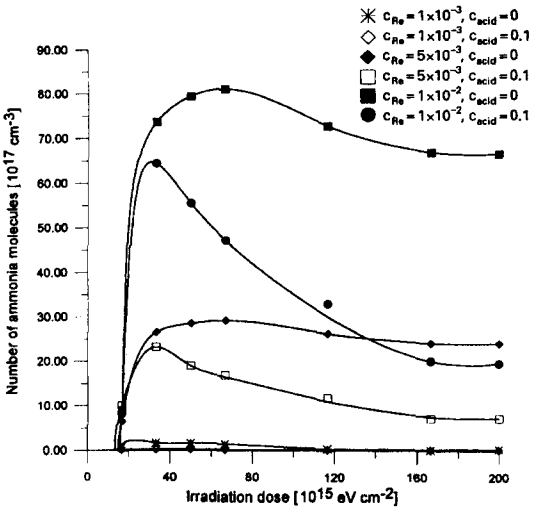

Fig. 2. Formation of ammonia *vs* irradiation dose in UV-irradiated solutions, solvent: THF–*c*-C_6H_{12} (1 : 1) mixture.

The curves obtained do not differ in shape from the dependencies ascertained earlier for tungsten complexes in γ or UV radiation fields. The curves of hydrazine formation show an induction period and a maximum. The induction period is connected to a lack of measurable amounts of dinitrogen complex and consequently a lack of hydrazine for the shortest irradiation times (the lowest doses), while the maximum results from the further reduction of N_2H_4 to ammonia at higher doses of electromagnetic radiation. On the other hand, the induction period in the ammonia formation curves results from the fact that, to make the hydrazine reduction possible, a higher concentration of hydrazine complex is needed. Such a concentration occurs in the range of higher doses. The maxima in ammonia formation curves (less distinct, however, than for tungsten complexes under similar conditions) results from further NH_3 reactions in the sample under irradiation.

As shown by the data in Table 1, the photochemical reduction of molecular nitrogen using rhenium complexes is a cyclic process. Acid addition lowers the catalytic efficiency, owing to lower stability of the $[ReH(N_2)_2(dppe)(PPh_3)]$ complex in acidic solution, compared with $[ReH_5(dppe)(PPh_3)]$.

As for hydrazine, the effect of acid proved to be less distinct than for ammonia. This is in accordance with the assumption that hydrazine forms by reaction with hydrogen atoms in the systems examined.

Based on the above, and on the data from earlier experiments, it can be stated that the mechanism of dinitrogen fixation and reduction using the $[ReH_5(dppe)(PPh_3)]$ complex is analogous to that of the hydrido tungsten complexes with phosphines (both in γ and for UV irradiated fields).

Table 1. Comparison of catalytic efficiencies of rhenium and tungsten hydrido–phosphine complexes (all concentration in mol dm^{-3})

Complex	Complex concentration	Number of cycles at maximum ammonia yield (number of NH_3 moles per 1 mole of Re^V complex)	
		$c_{acid} = 0$	$c_{acid} = 0.1$
$[ReH_5(dppe)(PPh_3)]$	1×10^{-3}	0.90	0.16
$[ReH_5(dppe)(PPh_3)]$	5×10^{-3}	2.91	2.32
$[ReH_5(dppe)(PPh_3)]$	1×10^{-2}	4.05	3.22
$[ReH_5(PPh_3)_3]^a$	1×10^{-2}	2.71	1.80
$[WH_4(dppe)_2]^b$	1×10^{-2}	5.00	4.00

[a]According to ref. 11.
[b]According to ref. 19.

At the first stage hydrogen elimination under the influence of radiation occurs [15–17] and an unsaturated intermediate product forms. Next, the intermediate product is able to coordinate gas molecules present in the sample [16], which under experimental conditions means not only regeneration of the initial complex (with H_2), but also formation of a dinitrogen complex. The last compound is reduced by hydrogen atoms to the hydrazine complex (the possibility of H atom transfer from Re—H groups to other ligands has also been ascertained in other processes [18]). The hydrazine complex formed can undergo decomposition, giving hydrazine (and regenerating unsaturated intermediate product). However, in the range of higher doses of radiation the concentration of the hydrazine complex exceeds the concentration of the dis-dinitrogen complex and increases the probability of further coordinated hydrazine reduction (in comparison with the probability of Re—N_2 group reduction). As a result of coordinated hydrazine reduction by hydrido ions coming from Re—H groups, NH_3 is formed and its induction period results from the reactions proposed above.

Lower yields of photoreduction products and lower catalytic efficiencies in the case of rhenium complexes may result from the fact that as these are more stable than the analogous tungsten complexes, the M—H bond (as shown by force constant comparison) reduces the ease of formation of the unsaturated intermediate product. At irradiation times longer than 60 minutes the decomposition of the catalyst usually occurs (in a γ radiation field the examined complexes are stabilised by the presence of high concentrations of reducing agents, such as solvated electrons and free radicals). Application of rhenium complexes containing phosphines more strongly bonded to the central ion should give higher yields of molecular nitrogen reduction products.

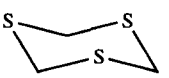
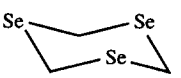
(Received 7 August 1996; accepted 28 October 1996)

Abstract—The reactions between I_2 and the donors (D) 1,3,5-trithiacyclohexane (**1**) and 1,3,5-triselenacyclohexane (**2**), in methylene chloride and hot benzene respectively (1 : 1 I_2 : D molar ratio) give the solid adducts $\mathbf{1}\cdot I_2$ (**I**) and $\mathbf{2}\cdot I_2$ (**II**) whose structures have been solved by X-ray diffraction. The use of an excess of diiodine up to the molar ratio 2 : 1 always gives **II** from **2**, and $\mathbf{1}\cdot 2I_2$ (**III**) from **1**. Compound **I** consists of polymeric chains in which each diiodine bridges between different **1** molecules, while **II** consists of discrete molecular units. The Raman ν(I—I) frequency and I—I bond distance in **I** fits well with the previously found linear correlation. This correlation suggests two different I—I bond distances for **III**. The comparison of the FT-IR and FT-Raman spectra for **II** is consistent with the three-body model for Se—I—I. The association constant between **1** and I_2 in methylene chloride has been also studied both by UV–visible and ^{13}C NMR spectroscopy, giving K values at 21°C in good agreement. © 1997 Published by Elsevier Science Ltd.



Keywords: 1,3,5-trithiacyclohexane; 1,3,5-triselenacyclohexane; diiodine adducts; crystal structure; formation constants.

Compounds containing sulfur/selenium donor atoms (D) react with molecular diiodine to give, in low polarity solvents, molecular charge-transfer (CT) complexes [1], $D\cdot I_2$, according to equilibrium (1):



$$D + I_2 \rightleftharpoons D\cdot I_2 \qquad (1)$$

The strength of the S/Se···I_2 interaction in solution can be assessed by evaluating the formation constant (K) and enthalpy of Eq. (1) by UV–vis spectroscopy. However, Raman and ^{13}C NMR spectroscopy can also give information on this interaction. While 1 : 1 adducts are the products usually identified in solution for I_2/D molar ratios higher than one, different and unpredictable solid compounds can be obtained [2–6] from the solutions of D and I_2. In many instances X-ray crystal structure determination has been proved essential to characterization of the solid products. However, when this is not possible, Raman spectroscopy on solid samples becomes useful to hypothesize structural features [7–11].

Here, attention is focused on the solid adducts obtained by reacting 1,3,5-trithiacyclohexane (**1**) and 1,3,5-triselenacyclohexane (**2**) with I_2, and on the study of equilibrium (1) in dichloromethane solution using **1** as donor, since the high insolubility of **2** in low polar solvents has precluded an analogous study.

The use of **1** and **2** as ligands has been very limited. For **1**, the literature only reports the X-ray structure of a dimeric silver complex [12] and a study in solution [13] on its interaction with π- and σ-acceptors, including molecular diiodine, whereas the coordinative chemistry of **2** has not been explored yet.

On the other hand, in the past decade, thio- and seleno-macrocyclic ethers have been the subject of great interest because of their peculiar coordinating abilities towards both transition and non-transition metal ions [14] and, very recently, towards halides [15–17]. Molecules **1** and **2** present three donor centres and, as mesocycles, can be considered prototypes of thio- and seleno-macrocycles in their interaction with diiodine.

EXPERIMENTAL

Materials

1,3,5-Trithiacyclohexane (**1**) was purchased from Aldrich and purified several times by recrystallization. 1,3,5-Triselenacyclohexane (**2**) was prepared according to the literature [18] and purified by sublimation.

Preparation of compounds **1** · I_2 **(I),** **2** · I_2 **(II)** *and* **1** · $2I_2$ **(III)**

Compounds **I** and **II** were obtained as black crystals with metallic lustre; for **I**, a dichloromethane solution containing **1** and diiodine in a 1 : 1 molar ratio was allowed to stand in air at room temperature until the formation of crystals. For **II**, a mixture of **2** and diiodine (1 : 1 molar ratio) and benzene (100 cm^3 per 100 mg of **2**) was heated in a sealed tube at 80°C until dissolution of **2**. Well-shaped crystals of **II** were formed when the reaction mixture was allowed to cool to room temperature and stand for several days in air. Found (Calc.) for $C_3H_6S_3I_2$; **I**: C, 9.1 (9.1); H, 1.6 (1.5). Found (Calc.) for $C_3H_6Se_3I_2$; **II**: C, 6.8 (6.8); H, 1.1 (1.1%). By standing a mixture of **1** and diiodine (1 : 2 molar ratio) in dichloromethane for several days, a black powder of **III** was obtained. Found (Calc.) for $C_3H_6S_3I_4$; **III**: C, 5.7 (5.5); H, 1.0 (0.9%).

FT-IR and FT-Raman spectra

The FT-IR spectra were recorded as polyethylene pellets (400–50 cm^{-1}) using a Bruker IFS55 fourier transform infrared spectrometer. The FT-Raman spectra (resolution $\pm$ 4 cm^{-1}) were recorded on a Bruker RFS100 Fourier transform Raman spectrometer (400–50 cm^{-1}) operating with an excitation frequency of 1064 nm (Nd–YAG laser). The power level of the laser source was 300 mW. Detection of the signal was made with an indium–gallium–arsenide detector operating at room temperature. The samples were packed as powder into a suitable cell and then fitted into the compartment designed for use with a 180° scattering geometry. No sample decomposition was observed during the experiment.

Spectrophotometric measurements

Spectrophotometric measurements in CH_2Cl_2 solutions were carried out on a Varian model Cary 5 UV–vis NIR spectrophotometer with a temperature controller and connected with an IBM PS 2 type 8513. The spectra of 13 different solutions were recorded in the range 300–500 nm at 15, 20, 25, 30 and 35°C. The choice of concentrations of the reagents was made according to the criteria outlined in ref. [19] and widely discussed in previous papers [1]. However, in all solutions, the concentration of **1** was always kept higher than that of diiodine in order to avoid the formation of adducts other than 1 : 1. Data analysis was carried out with a program based on a non-linear least-squares method [20] optimizing the absorbance values at six different wavelengths for each temperature value. The ΔH have been obtained as mean values of the slopes of the straight lines of $\ln(K \cdot \varepsilon)$ versus $1/T$ obtained at six different wavelengths: $\Delta H = (\Sigma \Delta H_i/\sigma_i)/\Sigma 1/\sigma_i$, $\sigma = [(N\text{-}1)\Sigma\sigma_i^2/(N \cdot n \cdot (N \cdot n\text{-}1))]^{1/2}$, where N and n are the numbers of the different temperatures and wavelengths, respectively.

^{13}C *NMR measurements*

The ^{13}C NMR spectra were recorded at 21°C on a Varian VXR 300 FT-NMR spectrometer, operating at 75.4 MHz frequency. $CDCl_3$ (77.00 ppm) was employed as the external reference. Several CH_2Cl_2 solutions having a $[I_2]^0/[\mathbf{1}]^0$ molar ratio ranging from 0.28 to 8.00 were recorded. The ^{13}C chemical shifts recorded were: δ 35.925, 36.021, 36.116, 36.192, 36.345, 36.440, 36.630, 36.780, 36.878 for solutions having $[\mathbf{1}]^0 = 2.5 \times 10^{-2}$ M (for the last solution $[\mathbf{1}]^0$ was 2.0×10^{-2} M) and $[I_2]^0/[\mathbf{1}]^0 = 0.28$, 0.56, 0.84, 1.12, 1.68, 2.24, 3.36, 5.16, 7.99, respectively.

X-ray crystal structure determination

Details of the data collection and refinement of the structures are reported in Table 1. Crystals of compounds **I** and **II** were mounted on a glass fibre in random orientation. Preliminary examination and data collection were performed with graphite-monochromatized Mo-K_α radiation (0.71073Å) on an Enraf–Nonius CAD4 computer-controlled kappa-axis diffractometer. Cell constants and an orientation matrix for data collection were obtained from least-squares refinement, using the setting angles of 25 reflections. The data were collected at room temperature using a scan rate variable of 2–20° min^{-1} (in ω). Three representative reflections were measured every hour to check the stability of the crystals under

[a] $R = [\Sigma(F_0 - k\|F_c\|)/\Sigma F_0]$; $R_w = [\Sigma w(F_0 - k\|F_c\|)^2/\Sigma w F_0^2]^{1/2}$.
[b] $\text{GOF} = [\Sigma w(F_0 - k\|F_c\|)^2/(N_{\text{observations}} - N_{\text{variables}})]^{1/2}$.

X-ray exposure; these measurements revealed a decay of the scattering power of the crystal which amounts to 27% and 5% for **I** and **II**, respectively. Lorentz polarization and a linear correction for decay were applied to the intensities. An empirical absorption correction based on a series of psi-scans was also applied to the data. The structure was solved using direct methods (MULTAN). The remaining atoms were located in succeeding difference Fourier syntheses. The structure was refined in full-matrix least squares where the function minimized was $\Sigma w(|F_0| - |Fc|)^2$. All the hydrogen atoms were introduced in the structure model at calculated positions (C—H 0.95 Å) and were unrefined. Scattering factors were taken from Cromer and Waber [21]. Anomalous dispersion effects were included in Fc; the values for f' and f'' were those of Cromer [22]. All calculations were performed on a 80486/33 computer using Personal SDP software [23]. Selected interatomic distances and angles for **I** and **II**, respectively, are shown in Table 2. The crystallographic data have been deposited at the Cambridge Crystallographic Data Centre (CCDC).

RESULTS AND DISCUSSION

The reaction between 1,3,5-trithiacyclohexane (**1**, in methylene chloride), and 1,3,5-triselenacyclohexane (**2**, in hot benzene) with molecular diiodine in a 1 : 1 molar ratio gave the solid adducts **1**·I_2 (**I**) and **1**·I_2 (**II**). The use of an excess of diiodine up to molar ratio of 2 : 1 always gave **II** with **2**, and **1**·$2I_2$ (**III**) with **1**. Only **I** and **II** were obtained as crystals suitable for X-ray investigation.

X-ray crystal structures of **I** *and* **II**

The different nature of **I** and **II** is shown from their crystal packings as shown in Figs 1 and 2.

Compound **I** consists of polymeric chains extending along [010] in which each diiodine molecule acts as a bridge in a zig-zag pattern between different 1,3,5-trithiacyclohexane molecules. The S···I interchain contacts range from 4.096(1) to 4.335(1)Å, with an I···I contact of 4.427(1)Å. Compound **II** contains discrete molecular units, **2**·I_2, weakly interacting with each other, with I···I and Se···I intermolecular contacts of 4.243(1)Å and 3.764(1)Å respectively. In both cases the rings are in the chair conformation and the diiodine molecules are bonded equatorially to the sulfur in **I** and to the selenium in **II**, to give almost linear S—I—I and Se—I—I moieties [169.04(2)° and 179.31(2)°]. The adducts with diiodine and interhalogens of similar six-membered ring systems having S/Se heteroatoms such as 1,4-dithiacyclohexane [24],

†Symmetry codes: a = $1 + x, y, z$; b = $-x, 1 - y, -z$; c = $x - 1, y, z$; d = $x - 1, y - 1, z$; e = $1 - x, 1 - y, -z$; f = $x, y - 1, z$; g = $-x, 1 - y, 1 - z$.

1,4-diselenacyclohexane [25] and 1-oxa-4-selenacyclohexane [26], are characterized by the halogen and interhalogen molecules always being bonded equatorially to the sulfur and axially to the selenium, with the exception of 1-selena-4-thiacyclohexane bis(diiodine) [27], where the two diiodine molecules are equatorial. Since molecular crowding is practically the same in all systems, no rationalization was given for this. As expected on the basis of the diversity of sulfur and selenium as donors the Se—I bond distance [2.734(1)Å] is shorter than S—I [3.169(1)Å] and the I—I bond length in **II** [2.944(1)Å] is longer than that in **I** [2.754(1)Å]. The values of these distances fit very well the reported hyperbolic correlations *d*(S—I) *vs* *d*(I—I) and *d*(Se—I) *vs* *d*(I—I) [3,28]. However, the S—I distance is longer than those observed in the adducts $([9]aneS_3)_2 \cdot 4I_2$ [15,16] and $[9]aneS_3 \cdot 3I_2$ [16] ([9]aneS$_3$ = 1,4,7-trithiacyclononane) and is one of the longest of all the reported sulfur adducts [3,25]. Compound **I** is the first case of a polymeric structure for diiodine adducts with a mesocycle molecule containing S/Se. This trend, however, has been observed for macrocycle molecules. [9]aneS$_3$ [15,16] reacts with diiodine to yield two crystalline adducts, the monomeric species $[9]aneS_3 \cdot 3I_2$ and the dimeric $([9]aneS_3)_2 \cdot 4I_2$; only for the latter do the dimeric units form an infinite three-dimensional network through I···I and S···I contacts. [12]aneS$_4$ [29] ([12]aneS$_4$ = 1,4,7,10-tetrathiocyclododecane) with diiodine gives a polymeric adduct $[([12]aneS_4 \cdot I_2)_\infty]$, in which a diiodine molecule bridges symmetrically between two macrocyclic molecules.

Vibrational spectra of **I**, **II** *and* **III**

Since the I—I stretching vibration is Raman active, FT-Raman spectroscopy is useful in studying the I—I bond in the adducts. Previous studies [2,3,5,6,10,11] have shown differences in the vibrational spectra between the adducts of sulfur and selenium, since selenium binds diiodine more strongly than sulfur. In the S···I—I system, although slightly perturbed, the diiodine molecule still retains its identity, whereas the same does not happen in the Se—I—I system, and a three-body model should be used for its description. In the case of weak or medium-weak adducts (I—I bond order > 0.6) [10], the lengthening of the I—I bond induces a downward shift in the ν(I—I) Raman band, which can be roughly correlated to the *d*(I—I)

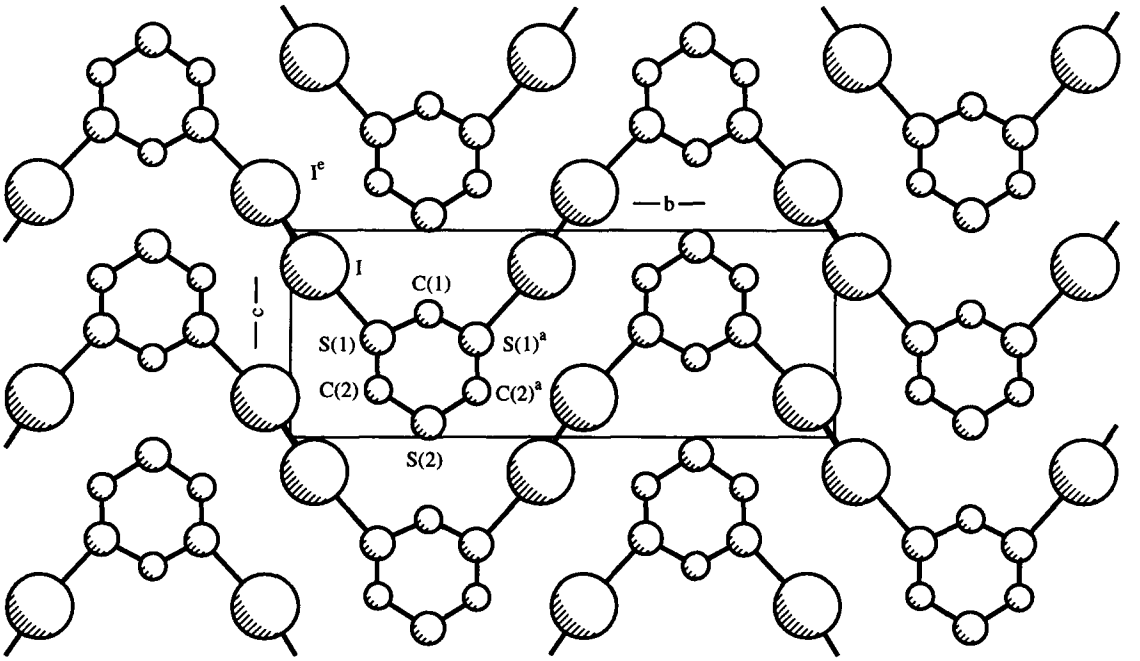

Fig. 1. Crystal packing of **I**.

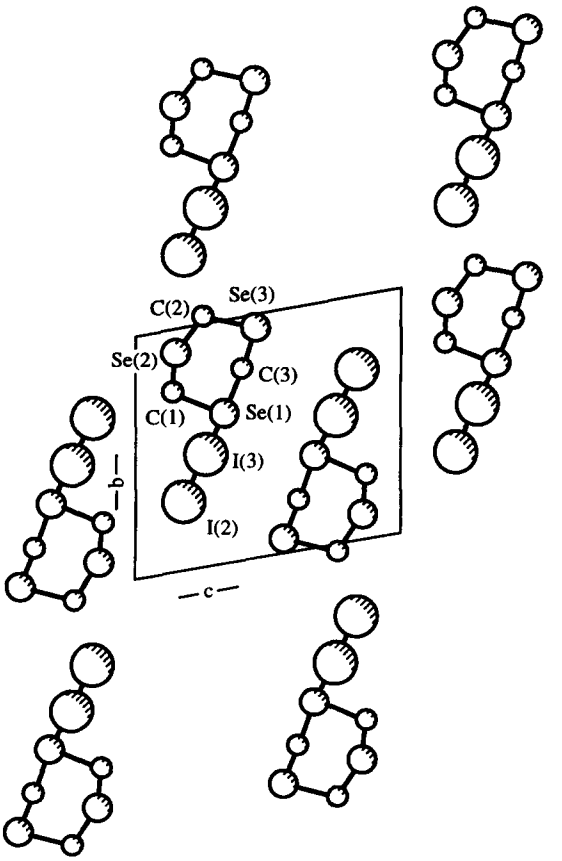

Fig. 2. Crystal packing of **II**.

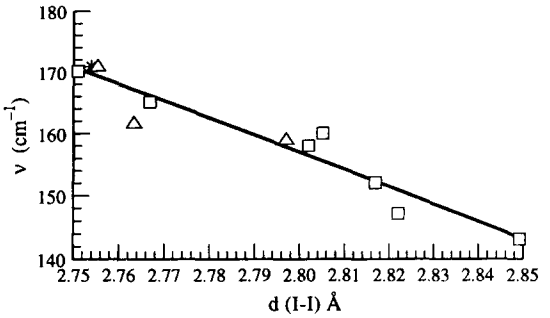

Fig. 3. Linear correlation ($r = 0.984$) between ν(I—I) Raman stretching vibrations and the d(I—I) bond distances in several structurally characterized adducts (ref. 10, squares; ref. 16 triangles; *, this work).

bond distance [10] as shown in Fig. 3 for several structurally characterized adducts.

The data related to **I** [d(I—I) = 2.754 Å and ν(I—I) = 171 cm^{-1}] match the correlation fairly well. The adduct **1**·$2I_2$ (**III**) shows two Raman bands at 177 and 163 cm^{-1}, indicating the presence of two differently perturbed I_2 molecules. From Fig. 3, d(I—I) bond distances of 2.737 and 2.777 Å can be predicted for the two I_2 molecules. This situation is close to that found in ([9]aneS_3)$_2$·$4I_2$ [16], where two Raman peaks at 159 and 171 cm^{-1} agree well with the two types of d(I—I) bond distances [2.792(1), 2.781(1), 2.818(1) Å terminal diiodine (mean value 2.797Å) and 2.755(1)Å bridged diiodine]. In the case of [9]aneS_3·$3I_2$, [16] only one Raman peak has been observed, at 162 cm^{-1}, in accord with the close three d(I—I) distances verified in the structure [2.772(1), 2.786(2), 2.751(2)Å (mean value 2.7636Å)]. On the other hand, 1,4-dithiacyclohexanebis(diiodine) shows two Raman peaks at 162 and 153 cm^{-1}, which should be correlated with two significantly different d(I—I) distances. On the contrary, only one d(I—I) distance [2.787(2)Å] is reported [22a] but the R factor of 0.18 clearly shows that this structure should be reconsidered.

In Fig. 4 the FT-Raman and the FT-IR spectra of **II** are shown superimposed within the range 250–50 cm^{-1}. The Raman spectrum exhibits four main bands at 88, 111, 167 and 220 cm^{-1}. The first three bands can be assigned to δ, ν_s and ν_{as} modes, respectively. As expected for the Se—I—I three-body system, the FT-IR spectrum shows roughly the same bands at 88, 125 (broad) and 165 cm^{-1}.

Association constant of **I** *obtained by UV–vis and* ^{13}C *NMR techniques*

The reaction between molecular diiodine and **1** has been studied in dichloromethane solutions; the presence of an isosbestic point, kept also in excess of I_2, justifies the use of a 1 : 1 model in the data treatment of the equilibrium (1). In Table 3 the association constants evaluated for six wavelengths, their molar

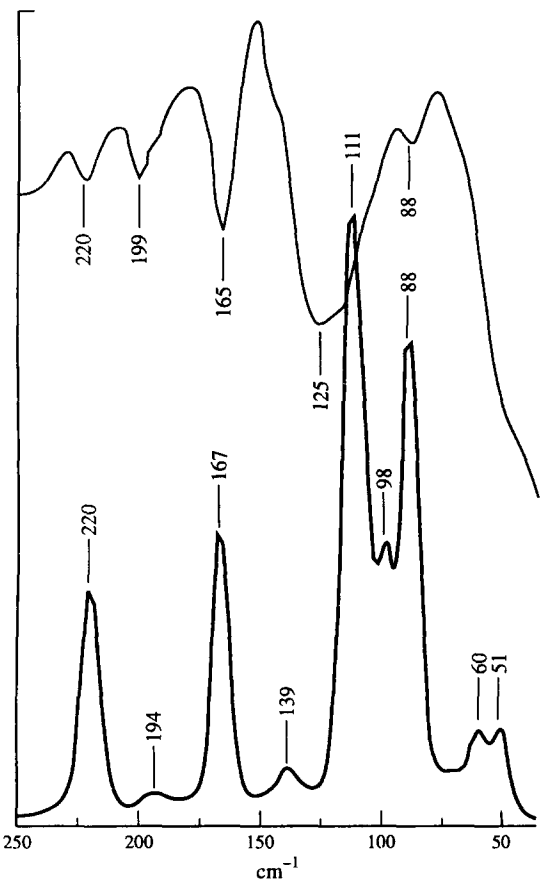

Fig. 4. Superimposed FT-Raman and FT-IR spectra of **II**.

extinction coefficients, the ranges of saturation fraction and the sum of the square deviations are reported. Although the experimental conditions were the best possible [16] the independence of the calculated K and ε values, and consequently the Arrhenius plot, were not satisfactory. To calculate a more reliable ΔH value, the plot of $\ln(K \cdot \varepsilon)$ versus $1/T$ has been adopted (see footnote to Table 3). The association constants and the ΔH values of **I** have been reported in the literature [13] [K 31.2 ± 2.0 dm^3 mol^{-1} at 25°C and −20.8 ± 0.3 kJ mol^{-1}]. However, they were obtained using the Benesi–Hildebrand and Scott equations, whereas our data [K 13 ± 0.7 dm^3 mol^{-1} at 25°C and −26.38 ± 0.04 kJ·mol^{-1}], obtained by a non-least-squares method, are based on an accurate choice of the reagent concentrations.

In order to have an independent method to determine the K value, we also used the ^{13}C NMR technique, by measuring the ^{13}C signal for mixtures of **1** with increasing amounts of diiodine (see Fig. 5a).

As a consequence of equilibrium (1), the ^{13}C chemical shift δ can be correlated to the concentrations of free [**1**] and bonded **1** ([**1**·I_2]) by Eq. (2) [7]:

$$\delta = \delta_1^0[\mathbf{1}]/[\mathbf{1}]^0 + \delta_{1\text{-}I_2}^0[\mathbf{1}\cdot I_2]/[\mathbf{1}]^0 \qquad (2)$$

where $[\mathbf{1}]^0$ is the analytical concentration of **1** while

$\Delta H = -26.38 \pm 0.04$ kJ mol^{-1} and r[b] = 1.000

[a]The saturation fraction (s) is defined as the ratio between the concentration of the adduct and the analytical concentration of the donor.

[b]Correlation coefficient of the plots $\ln(K \cdot \varepsilon)$ *vs* $1/T^0$ obtained for the six wavelengths.

$\delta_1{}^0$and $\delta^0_{1\cdot I_2}$ represent the ^{13}C chemical shift values of pure **1** (35.84 ppm in CH_2Cl_2) and **1** · I_2, respectively. Considering the mass concentration equations and the expression for K it is possible to fit the experimental δ values as a function of K by using a Gauss–Newton iterative cycle [30]. A K value of 12.8 ± 0.1 dm^3 mol^{-1} with $\Sigma r^2 = 0.0178$, where r represents the difference between the observed and the calculated values, is obtained. The calculated values are represented in Fig. 5a and the correspondence with the experimental data is fairly good. The absence of an equilibrium leading to the adduct **1** · $2I_2$ can easily be proved by combining Eq. (2) with the relation $[\mathbf{1}]^0 = [\mathbf{1} \cdot I_2] + [\mathbf{1}]$ to give Eq. (3):

$$(\delta - \delta_1^0)[\mathbf{1}]^0 = (\delta^0_{1\cdot I_2} - \delta_1^0)[\mathbf{1} \cdot I_2] \qquad (3)$$

Hence, by plotting $(\delta - \delta_1^0)[\mathbf{1}]^0$ versus $[\mathbf{1} \cdot I_2]$, calculated from the K value previously obtained, a straight line crossing the origin should be obtained only if the 1 : 1 adduct is formed, and deviation from linearity should be due to 1 : 2 adduct formation. In Fig. 5b this plot is shown and the 1 : 1 model seems to be fully verified up to a $[I_2]^0/[[\mathbf{1}]^0$ ratio of eight ($r = 0.998$), with a $\delta^0_{1\cdot I_2}$ value of 37.48 ppm calculated from the slope of the straight line (Fig. 5b). Whenever the NMR technique requires reagent concentrations ten times higher than those required for the UV–vis technique, by interpolating the K value at 21°C from the data obtained spectrophotometrically, a value of 15.8 dm^3 mol^{-1}, close to 12.8 dm^3 mol^{-1} measured by the NMR technique, is obtained. This fact further supports the reliability of our UV–vis K data with respect to those previously reported [13].

If the value of K for equilibrium (1) at 25°C is compared with that reported for [9]aneS_3 [169(4) dm^3

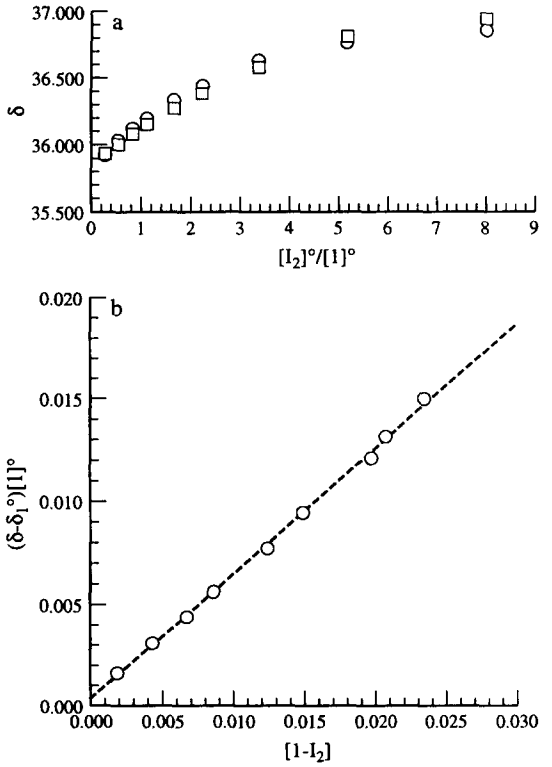

Fig. 5. (a) ^{13}C chemical shifts as a function of increasing amounts of diiodine (circles, experimental; squares, calculated data). (b) Plot of $(\delta - \delta_1{}^0)$ $[\mathbf{1}]^0$ *vs* $[\mathbf{1} \cdot I_2]$ ($r = 0.998$).

mol^{-1}], it can be seen that the sulfur is a better donor in [9]aneS$_3$ [14] than in **1**, perhaps as a consequence of a stronger inductive effect owing to the two CH_2 groups in [9]aneS$_3$.

(Received 30 July 1996; accepted 28 October 1996)

Abstract—The binding modes of *cis*-$Ru^{II}Cl_2(DMSO)_3(DMSO)$ (*cis*-RDT, three out of the four DMSO's are S-bonded to the Ru, while the last one is O-bonded) with 5′-GMP and 5′-AMP in aqueous solution at physiological pH value were investigated by high-resolution ^1H and ^{31}P NMR. A ^1H NMR recognition probe, [*trans*-$en_2Os(\eta\text{-}H_2)](CF_3SO_3)_2$, was used in order to verify further the results. 5′-GMP with *cis*-RDT formed two products, clearly indicating that the guanine N_7 and phosphate group bind to Ru^{II} and form a chelate to the metal center; but binding of 5′-AMP to *cis*-RDT may only occur *via* the phosphate group. © 1997 Elsevier Science Ltd. Keywords: antitumor compound; ruthenium complex; mononucleotides; binding mode; NMR recognition probe; NMR spectra.

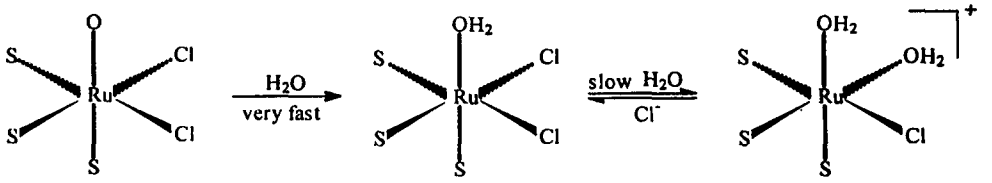
Among the various anticancer metal compounds, ruthenium complexes have shown good antitumor activity [1–3] and a remarkably low toxicity [4], which makes them interesting for possible clinical use [5]. After the discovery of the mutagenic properties [6] and good antineoplastic activity [4] of *cis*-RDT, which suggested that one target of the complex *in vivo* is DNA, many efforts have been made to understand its mechanism of action and to investigate its binding sites to DNA [7]. Despite the success observed with the change of the CD spectrum of poly(dGdC) and poly(dAdT) with *cis*-RDT [8], the binding sites suggested, N_7 of guanine and N_7 of adenine, are only a deduction.

In this paper we present the reaction of *cis*-RDT with 5′-GMP and 5′-AMP in aqueous solution under physiological conditions using the NMR method. In contrast to previous investigations [9,10], we have demonstrated that 5′-GMP can coordinate to the initially achiral *cis*-RDT antitumor agent to form, predominantly, two isomers which have an opposite chirality at Ru^{II}. In a diastereomeric pair of isomers the nucleotide chelates to Ru by N_7 and a phosphate oxygen. We have also demonstrated that 5′-AMP can coordinate to *cis*-RDT through the phosphate group, but the binding of 5′-AMP's N_7 with *cis*-RDT was not observed.



EXPERIMENTAL

cis-RDT was synthesized as already reported [11] and recrystallized from a DMSO/acetone mixture.

The nucleotides, adenosine-5′-monophosphate (AMP), guanosine-5′-monophosphate (GMP) and 2′-deoxyguanosine-5′-monophosphate (dGMP) were purchased from Sigma Chemical Company, purified by precipitation from an aqueous solution and purity was verified with ^1H and ^{31}P NMR spectroscopy. The probe, [*trans*-$en_2Os(\eta\text{-}H_2)](CF_3SO_3)_2$, was a generous gift from Professor Henry Taube and Dr Zeiwei Li, Stanford University, CA, and its purity was checked by ^1H NMR spectroscopy.

Proton and phosphorus NMR were recorded on a VXR-300 MHz NMR spectrometer in D_2O, proton chemical shifts are referenced to DSS as internal standard, and phosphorus chemical shifts are referenced to 85% H_3PO_4 as external standard. The probe, *cis*-RDT and the mononucleotide were mixed as 1 : 1 : 1

Scheme 1.

(each 0.01 mol L^{-1}, pD 7.0) in oxygen-free D_2O. D_2O was thoroughly saturated with nitrogen before use. pH measurements were carried out with an American Scientific pH 1 meter and a Wilmad combination pH electrode. All reported pD values in D_2O are corrected pH readings (pD = pH + 0.44).

RESULTS AND DISCUSSION

The octahedral complex *cis*-RDT dissolved in water shows the dissociation mechanism reported [8] in Scheme 1.

As shown above, *cis*-RDT, once dissolved in water, immediately releases the O-bonded dimethyl sulfoxide molecule, this step is followed by the slow dissociation of a Cl^- anion to give the cationic species.

The NMR spectroscopic data for *cis*-RDT with 5′-GMP and 5′-AMP are shown in Table 1.

When *cis*-RDT (0.01 mol L^{-1}) was incubated with 5′-GMP in a 1 : 1 molar ratio in D_2O at 25 °C, examination of reaction mixtures by ^1H NMR (Fig. 1c) revealed two new major species (**I** and **II**) after 12 h at pD7.0; species **I** and **II** exist in nearly equal amounts and 5′-GMP is nearly all consumed. These suggest that the ratio of 5′-GMP to Ru in the products is 1 : 1. The downfield position of the H_8 signals, δ 8.00 for **I** and 8.20 for **II**, and the downfield position of the H_1, resonance of the sugar, δ 5.78 for **I** and δ 5.97 for **II**, suggests N_7 coordination [12].

The ^{31}P NMR spectrum also reveals consumption of the 5′-GMP, but, more importantly, an unusually far downfield position of the two signals (δ11.29 for **I** and 12.90 for **II**) establishes phosphate group coordination [10,13] (Fig. 1d). The above results are very similar to those for 5′-GMP with *trans*-RDT. A comparison of *cis*-RDT–5′-GMP with *trans*-RDT–5′-GMP is shown in Table 2, and suggests that **I** and **II** are chelate complexes with the N_7 and phosphate group of 5′-GMP bound to the same Ru^{II} center, and that the two species are diastereomers with the same Ru coordination environment, differing primarily in the orientation of the chelate moiety, as shown in Scheme 2.

When *cis*-RDT (0.01 mol L^{-1}) was incubated with 5′-AMP under the same conditions as 5′-GMP, an upfield shift of *ca* 0.1 ppm for H_8 and *ca* 1.7 ppm for ^{31}P signals, but almost unchanged H_2 signals, were observed (Table 1). Protonation of the base function of a nucleotide should cause a downfield shift of the nucleobase proton signals, whilst protonation on the phosphate group should cause an upfield shift of the nucleobase proton signals [14]. Also, diamagnetic metallation of a nucleoside produces effects quite similar to protonation [15]. So, the slight upfield shift of H_8 could be a consequence of the direct phosphate coordination to ruthenium.

In order to further examine the sites of *cis*-RDT at 5′-GMP and 5′-AMP, we used [*trans*-$en_2Os(\eta$-$H_2)]^{2+}$ (Scheme 3) as a ^1H NMR recognition probe. The probe, as previously demonstrated [16], binds readily to a variety of biomolecules such as nucleotides, with its sixth ligand, L, substituted by these biomolecules, which results in the direct coordination of Os^{II} to the donor atoms (such as N, O) of the biomolecules. In each case the binding leads to a characteristic ^1H NMR spectrum for the dihydrogen unit that appears in a spectral window in the range $\delta = 0$ to -20.

When 5′-dGMP was added to a solution of the probe in D_2O at 25°C each solute at 0.01 mol L^{-1}, the phosphate oxygen and N_7 of dGMP both coordinated to the probe, the former being dynamically preferred, and the interaction was complete in 10 min. The equilibrium quotient (K) for the formation of Os^{II}–RPO_4 (dGMP) is 3×10^2, while the latter is thermodynamically preferred, the binding of Os^{II}–N_7(dGMP) is complete in 24 h, and the value of K is

Scheme 2.

Scheme 3.

2.9×10^3. Figure 2 clearly shows the reaction process. The peaks at δ −13.38 and −13.76 grow in 10 min. The second peak is due to phosphate oxygen binding. Meanwhile, a peak at δ −9.93, already discernible after 10 min (Fig 2a), continues to grow at the expense of the others. This peak is assigned to the N_7 binding. There is a competing reaction between D_2O binding, phosphate binding and N_7 binding, which is not in complete equilibrium in 10 min. The affinity of Os^{II} for the D_2O and phosphate is not high and the conversion from D_2O binding and phosphate binding to N_7 binding is almost complete after 24 h (Fig. 2b). Usually the binding of an antitumor metallic agent to dGMP is also *via* N_7 or the phosphate group of dGMP; therefore, if an antitumor metal agent is added to the probe–dGMP binary system, it will compete for these binding sites of dGMP with the probe, and the characteristic peaks due to binding of the probe with phosphate or N_7 of dGMP will change. According to these changes, the binding sites of the antitumor metal complexes to dGMP can be determined.

When dGMP, *cis*-RDT and the probe were mixed at the same time at 25 °C, both of the peaks due to the phosphate binding and N_7 binding diminished obviously in their intensity after 10 min (Fig. 2c) compared with those of the dGMP–probe binary system. After 24 h the peaks for D_2O binding were still present, indicating that N_7 binding of *cis*-RDT has restrained the conversion from D_2O binding to N_7 binding of the

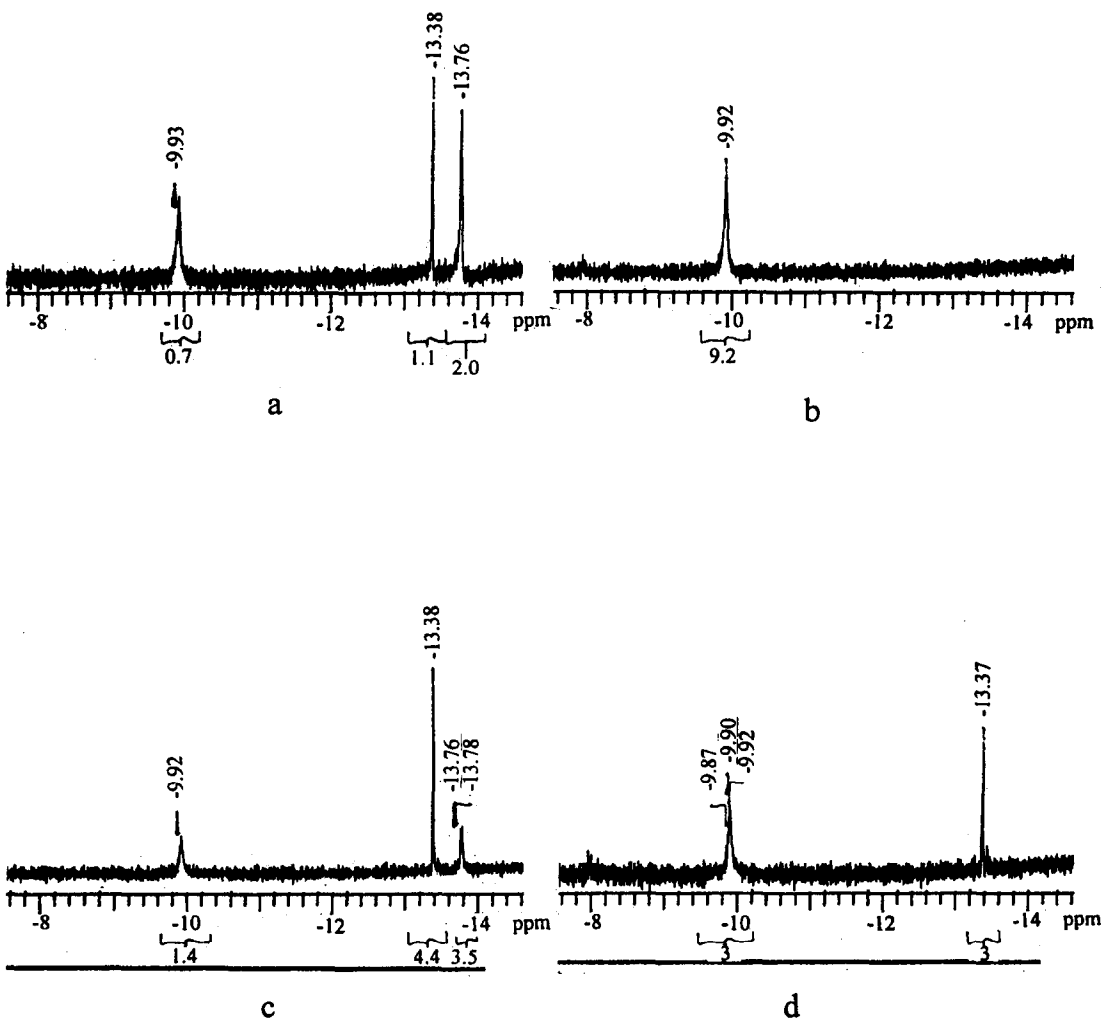

Fig. 2. ^1H NMR spectra (300 MHz) of 5′-dGMP mixed system. (a) Probe with dGMP after 10 min. (b) Probe with dGMP after 24 h. (c) Probe, dGMP and *cis*-RDT after 10 min. (d) Probe, dGMP and *cis*-RDT after 24 h.

probe (Fig. 2d). This result provides further evidence of N_7 and phosphate group coordination.

The interaction process between the probe and AMP is shown in Fig. 3a and b. Because the K value for the formation of Os^{II}–PO_4–AMP is 1.9×10^2, much higher than the corresponding K for the formation of Os^{II}–N_7–AMP, which is 1.2×10 [16], the dominant signal in the AMP–probe system is that of phosphate binding, which appears at δ −13.77, while the signal for N_7 binding is too weak to be observed. It can be seen from Fig. 3c that *cis*-RDT mixed into the AMP–probe system results in the loss of the peak at δ −13.77 after 10 min in contrast to the AMP–probe binary system. After 24 h, the peak due to the phosphate binding has disappeared completely (Fig. 3d). These results suggest that *cis*-RDT can bind to AMP *via* the phosphate oxygen.

^{31}P NMR is a commonly used method to investigate the direct coordination of metal ions to mononucleotides *via* phosphate group [17]. In particular, the case of direct binding leads to a large ^{31}P NMR shift. However, in some cases, the binding of metal ions to phosphate group of mononucleotides, owing to the possible conformation changes or H bond changes in the mononucleotides caused by metal ions, only leads to a small ^{31}P NMR shift (less than 1 ppm) [8,19]. It is difficult to determine which form mentioned above should be responsible for so little ^{31}P NMR changes

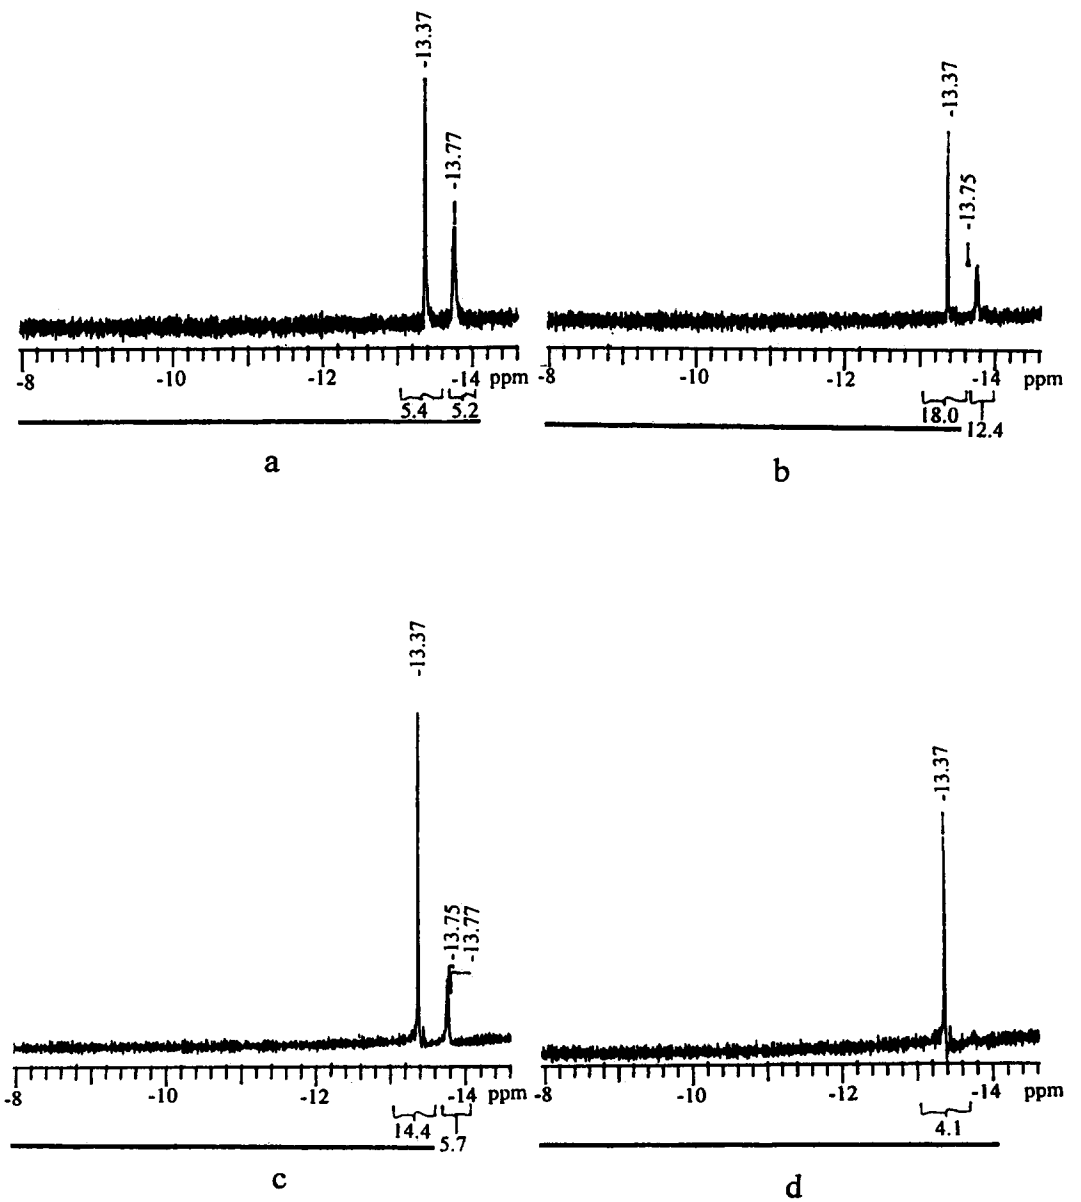

Fig. 3. ^1H NMR spectra (300 MHz) of 5′-AMP mixed system. (a) Probe with AMP after 10 min. (b) Probe with AMP after 24 h. (c) Probe, AMP and *cis*-RDT after 10 min. (d) Probe, AMP and *cis*-RDT after 24 h.

in the case of *cis*-RDT with 5′-AMP, whereas, as demonstrated above, it is easy to distinguish the direct coordination *via* phosphate group using the probe.

As discussed above, the binding mode of *cis*-RDT to AMP is different from that of *cis*-RDT to GMP. The coordination sites are both the phosphate group and N_7 between *cis*-RDT and GMP, but the coordination sites between *cis*-RDT and AMP may be only the phosphate group.

Acknowledgements—The financial support of the National Natural Science Foundation of China and the National Research Laboratories of Natural and Biomimetic Drugs are gratefully acknowledged. We wish to thank Professor Henry Taube and Dr Zaiwei Li for their generous gift of the probe.

Crystal structure of copper(II) pivaloyltrifluoracetonate adducts with *o*-phenanthroline and 2,2′-dipyridyl

O. Yu. Gorbenko,[a] S. I. Troyanov,[a]* A. Meetsma[b] and A. A. Bosak[c]

[a]Chemistry Department, Moscow State University, 119899 Moscow, Russia; [b]Chemistry Department, Groningen University, Nijenborgh 4, 9747 Groningen, The Netherlands; [c]High School of Material Science, Moscow State University, 119899 Moscow, Russia

(Received 23 September 1996; accepted 21 October 1996)

Abstract—The crystal structure of $Cu(pta)_2 \cdot Phen$ has been determined. The phenanthroline ligand occupies a position in the equatorial plane of the tetragonally distorted octahedron with equal Cu—N distances and equivalent β-diketonate-anions. $Cu(pta)_2 \cdot 2,2'$-Dipy is isostructural to $Cu(pta)_2 \cdot Phen$. The volatility of adducts decreases in the sequence $Cu(thd)_2 \cdot Phen$, $Cu(pta)_2 \cdot Phen$ and $Cu(hfa)_2 \cdot Phen$ changing inversely to that of the β-diketonates. The variation of packing mode caused by the difference of the molecular structure is considered to be responsible for the effect. The changes of the electronic spectra of copper(II) β-diketonates caused by adduct formation are discussed. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: copper(II) beta-diketonates; adducts; crystal structure; electronic spectra; volatility.

Copper(II) β-diketonates are well known volatile compounds widely applied as precursors for MOCVD of metallic copper as well as copper-containing oxides [1,2]. The formation of adducts with neutral donor ligands allows us to modify the properties of metal β-diketonates [3,4]. Unexpectedly, there is a lack of information about sublimation characteristics and their correlation to the structure for copper(II) β-diketonate adducts.

There are three possible positions for donor atoms of a neutral bidentate ligand Q in $CuL_2 \cdot Q$ (L is a β-diketonate-anion) with tetragonally distorted octahedral Cu^{II} system (Fig. 1): (a) *trans*-coordination leading to the chain structure like $Cu(acac)_2 \cdot 4,4'$-Dipy[5–7], where acac = acetylacetonate, Dipy- = dipyridyl, (b) *cis*-coordination in the equatorial plane resulting in equal Cu—N distances and equivalent β-diketonate-anions in $Cu(hfa)_2 \cdot 2,2'$-Dipy [8] (hfa = hexafluoracetylacetonate), (c) *cis*-coordination not in the equatorial plane with non-equivalent β-diketonate-anions due to Jahn–Teller distortion. $Cu(thd)_2 \cdot Phen$ (thd = 2,2,6,6-tetramethylheptan-3,5-dionate, Phen = *o*-phenanthroline) is the only example of coordination of type (c) for $CuL_2 \cdot Q$ [9]. The complex of type (c) possesses the lowest symmetry of Cu coordination environment due to both Jahn–Teller distortion and rigidity of ligands.

In the complexes of type (b) and (c) only one of 3 bidentate chelate ligands can place both its donor atoms in the equatorial plane. For π-donating ligand this position is the most preferable [10] so the competition of ligands for such a position could be expected. The complex would be stable if one of the competitive configurations is markedly preferable. If no configuration is preferable then both (b) and (c) structures would be unstable and rearrange to other

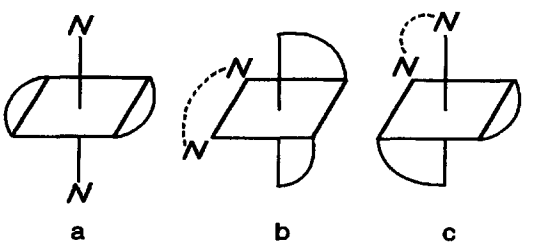

Fig. 1. Possible positions for donor atoms in $CuL_2 \cdot Q$ with tetragonally distorted octahedral Cu^{II} system.

*Author to whom correspondence should be addressed.

coordination modes in the presence of other ligands [11].

Phen or 2,2′-Dipy occupies *cis*-positions in the equatorial plane in tetragonally distorted octahedral Cu-complexes if other ligands are weaker donors like hfa. On the contrary, stronger donor (thd^-) substitutes Phen in *cis*-position of the equatorial plane ($Cu(thd)_2 \cdot Phen$).

Thus, $Cu(pta)_2 \cdot Q$ (pta = pivaloyltrifluoracetonate) is an interesting object for investigation because the competition for the equatorial plane takes place among three pairs of donor atoms: O of the pivaloyl group of β-diketonate, O of the trifluoracetyl group of β-diketonate and N of the neutral donor ligand.

EXPERIMENTAL

Synthetic procedures

$Cu(thd)_2$ and $Cu(pta)_2$ were synthesized by the reaction of stoichiometric amounts of aqueous solution of $Cu(CH_3COO)_2 \cdot H_2O$ and β-diketone and purified by vacuum sublimation at 160 and 130°C, respectively.

To prepare $Cu(hfa)_2$, an equivalent quantity of Hhfa was added to the ethanol suspension of $Cu(CH_3COO)_2 \cdot H_2O$. Then light-green crystals $Cu(hfa)_2 \cdot 2H_2O$ were precipitated from green solution by adding the excess of water. $Cu(hfa)_2$ was obtained by dehydration of $Cu(hfa)_2 \cdot 2H_2O$ during the vacuum sublimation (70–80°C).

$Cu(thd)_2 \cdot Phen$. The solution of unhydrous Phen (5 mmole) and $Cu(thd)_2$ (5 mmole) in 35 cm^3 of dry benzene was prepared. Then benzene was evaporated under aspiration. The green precipitate formed was purified by vacuum sublimation (130°C).

The same synthetic procedure was carried out with $Cu(thd)_2$ and 2,2′-Dipy. No new copper compounds were detected in the solid phase by powder XRD. After vacuum sublimation of the solid residue only $Cu(thd)_2$ and Dipy has been condensed separately due to the temperature gradient in the tube. The same result was obtained even after 3 h stirring of the benzene solution of $Cu(thd)_2$ and 2,2′-Dipy.

$Cu(hfa)_2 \cdot Phen$, $Cu(hfa)_2 \cdot 2,2'$-Dipy, $Cu(pta)_2 \cdot Phen$, $Cu(pta)_2 \cdot 2,2'$-Dipy were synthesised by adding the solid unhydrous N-donor containing ligand (2 mmole) to solutions of β-diketonates (2 mmole) in dry benzene (10 cm^3) and stirring for 30 min. Green precipitates were separated from the solution. About 1 g portions of the adducts were sublimated in vacuum (0.01 torr) without appreciable destruction. Sublimation rate was approximately equal at the temperature 220–240°C, 220–220°C, 180–200°C and 160–180°C, respectively for $Cu(hfa)_2 \cdot Phen$, $Cu(hfa)_2 \cdot 2,2'$-Dipy, $Cu(pta)_2 \cdot Phen$ and $Cu(pta)_2 \cdot 2,2'$-Dipy.

Crystal structure determination

Needle-like single crystals of $Cu(pta)_2 \cdot Phen$ and $Cu(pta)_2 \cdot 2,2'$-Dipy were grown by slow cooling of hot benzene solutions. A crystal of $Cu(pta)_2 \cdot Phen$ had approximate dimensions 0.2 × 0.2 × 0.4 mm. The data were collected on a CAD-4 (Enraf Nonius) diffractometer using Mo-K_α radiation with a graphite monochromator (ω-2θ scan method, θ range 1.7–26.0°). The crystallographic calculations were performed using the SHELXS-86 and SHELXL-93 program packages [12]. The structure was solved using a combination of direct and difference Fourier methods and refined by the full-matrix least-squares technique with anisotropic thermal parameters for all non-hydrogen atoms. The CF_3 and *tert*-Bu groups were found to be disordered in two positions around their C—C axes with the occupancies 0.67 (CF_3) and 0.60 (*tert*-Bu) for the more abundant components. The positions of the hydrogen atoms were calculated at idealized positions and refined in riding mode. Crystal data and structure refinement parameters for $Cu(pta)_2 \cdot Phen$ are given in Table 1. Selected bond lengths and angles are listed in Table 2. $Cu(pta)_2 \cdot 2,2'$-Dipy single crystals were of lower quality. The measurement and the structure determination revealed the same space group and the ligands arrangement around the Cu atom. The structural data are not presented due to too high R_1 value (0.11), However, we believe that both Phen and 2,2′-Dipy adducts are isostructural (Table 1).

Powder diffraction measurement (θ-2θ scan) was performed with DRON-3M diffractometer using Co-K_α radiation in the range of 2θ 6–50°. The comparison of the diffraction patterns $Cu(pta)_2 \cdot Phen$ and $Cu(pta)_2 \cdot 2,2'$-Dipy as well as $Cu(hfa)_2 \cdot Phen$ and $Cu(pta)_2 \cdot 2,2'$-Dipy allows us to conclude that the compounds in the pairs are isostructural.

Electronic spectroscopy

Electronic spectra were measured with absorption spectrofotometer KFK-3 in the range 12,500–25,000 cm^{-1} using a 1 cm cuvette. Benzene was used as a solvent. Components were mixed to achieve total concentration 0.01 mol/l, but solutions of $Cu(pta)_2 \cdot Phen$ and $Cu(hfa)_2 \cdot Phen$ were already saturated under such conditions with about half of the adduct weight being dissolved.

RESULTS AND DISCUSSION

The molecular structure of $Cu(pta)_2 \cdot Phen$ is shown in Fig. 2. $Cu(pta)_2 \cdot Phen$ belongs to the type (b) like $Cu(hfa)_2 \cdot 2,2'$-Dipy [8]. Many structural features, for instance, the position of Cu (and neutral donor ligand) on a twofold axis as well as bond lengths in the CuO_4N_2 distorted octahedron are similar for both complexes. The twofold axis requires the Cu—N bonds to be equal (2.029 Å). There are also two pairs of Cu—O bonds: Cu—O(1) 2.246 Å, Cu—O(2) 1.970 Å. The corresponding bond lengths for $Cu(hfa)_2 \cdot 2,2'$-Dipy are: Cu—N 1.998 Å, Cu—O(1) 2.296 Å,

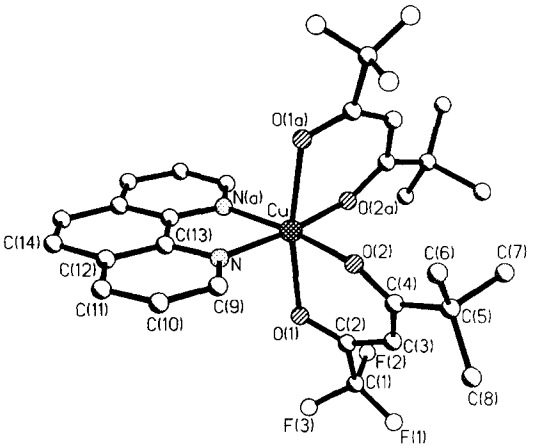

Fig. 2. Molecular structure of $Cu(pta)_2 \cdot Phen$.

Cu—O(2) 1.967 Å. The small elongation of Cu—N bond correlates to the change of β-diketone acidity (Hhfa is a stronger acid than Hpta), which is generally reciprocal to the donor ability of β-diketonate ligand.

Oxygen atoms of the pivaloyl group of β-diketonates occupy positions in the equatorial plane and oxygen atoms of the trifluoracetyl groups are pushed out to the apical positions. The result is in agreement with the relative donor ability of carbonyl groups taking into account the opposite inductive effects of *tert*-Bu and CF_3 groups.

It is noteworthy that both C—O bond lengths are nearly the same in contrast to $Cu(hfa)_2 \cdot 2,2'$-Dipy, where the C—O bonds are significantly different*. The difference could be expected considering the change of Cu—O bond lengths: the shorter Cu—O bond corresponds to the longer C—O bond. Evidently in the case of pta-complexes, the effect is compensated by the inductive effect of the groups attached to the chelate ring. The same is valid for C—C bonds in the chelate ring: they are different in $Cu(hfa)_2 \cdot 2,2'$-Dipy**, but nearly equal in the pta-complexes. Thus nearly symmetrical π-system occurs in the chelate ring of pta.

Due to the rigidity of ligands the bond angles in the CuO_4N_2 polyhedron deviate from those of the tetragonally stretched octahedron. Nevertheless, the distortion is smaller as compared to that in $Cu(thd)_2 \cdot Phen$ (type(c)). Phen or 2,2′-Dipy requires N—Cu—N angle markedly lower than 90°. As a result the O—Cu—O angle in the equatorial plane is more than 90°. The Cu—O bonds directed to the apical oxygen atoms deviate from the normal to the equatorial plane by 6°. The latter effect is probably due to repulsion from the π-electron system of Phen. Thus the molecule would possess a dipole directed along the twofold axis because of the displacement of CF_3 groups to one side of the molecule.

*1.261 and 1.218 Å.
**1.385 and 1.433 Å.

The dipole interaction probably plays an important role in the packing of $CuL_2 \cdot Q$ molecules in the crystal. The packing of $Cu(pta)_2 \cdot Phen$ molecules, shown in Fig. 3(a), consists of separate layers. In each layer the dipoles of the neighbouring molecules are antiparallel and the attraction of dipoles is maximal. The packing of molecules in the crystal of $Cu(thd)_2 \cdot Phen$ is quite different (Fig. 3(b)). Interaction of aromatic systems of Phen ligands from the neighbouring molecules determines the packing in the structure. For low symmetrical $Cu(thd)_2 \cdot Phen$ the mutual antiparallel orientation of dipoles is less probable.

The packing mode correlates with the volatility of the adducts. Even qualitative estimation by sublimation temperature at the same pressure (0.01 torr) given in the experimental part supports this viewpoint. The sublimation temperature increases in the order $Cu(thd)_2 \cdot Phen < Cu(pta)_2 \cdot Phen < Cu(hfa)_2 \cdot Phen$ significantly. The sequence is opposite to the sequence of the volatility of copper(II) β-diketonates [13,14]. In the latter case the oxygen atoms of the β-diketonates form a rectangle around the copper atom and the whole molecule is planar [15]. The volatility is determined by interaction of peripheral groups of ligands, the repulsion of fluorinated groups being stronger than that of alkyl groups. The lower sublimation temperature of 2,2′-Dipy adducts than Phen adducts may be caused by the change in the molecule dipole due to lower repulsion between the π-electron

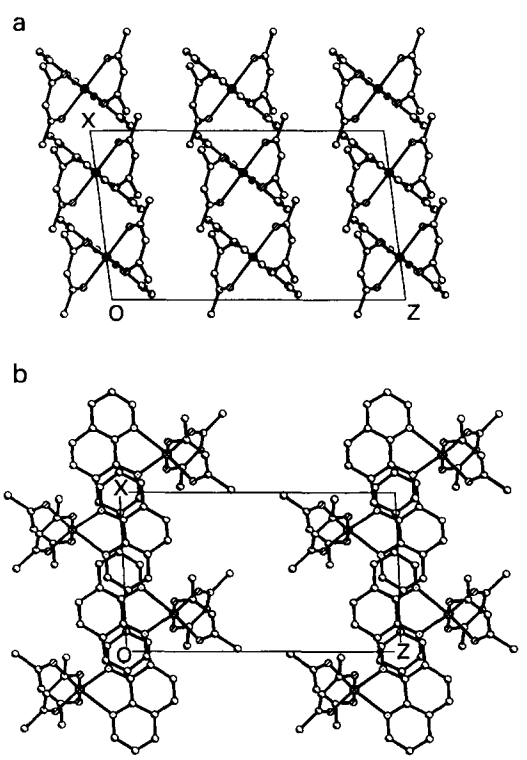

Fig. 3. Molecular packing of copper(II) β-diketonates adducts: $Cu(pta)_2 \cdot Phen$ (a), $Cu(thd)_2 \cdot Phen$ (b). F atoms and Me groups are omitted for clarity.

system of the neutral ligand and the apical oxygen. But details of molecular structure to support the idea are missing.

The results obtained should be taken into account in the flash and aerosol MOCVD [16,17] of complex copper oxides, like high T_c superconductors. If Phen is added to stabilize β-diketonates of some other metals, the ligand exchange can influence the volatility of the copper precursor.

Electronic spectra are known to be very similar for various copper(II) β-diketonates [18]. A broad band visible envelope can be resolved into Gaussian components. The procedure for the spectrum of a solution [19,20] results in two Gaussian bands centered nearby 18,000 and 15,000 cm^{-1}. Our data (Table 3) are in agreement with the results: the spectra are similar for complexes with both fluorinated and unfluorinated, symmetric and asymmetric ligands.

Polarized spectra of single crystals [19,21] of copper(II) β-diketonates revealed three *d–d* absorption bands at 18,000, 15,000 and 14,000 cm^{-1}. The effective spectroscopic symmetry of the chromophore O_4 is close to D_{2h} even for asymmetrical β-diketonate like benzoylacetonate [21]. For correct assignment of the bands it is necessary to define the molecular coordinate system. The preferable choice of the coordinate frame is as follows: *z* axis is normal to the rectangular chromophore group O_4, *x*,*y* axes are along the auxiliary C_2 axes. The highest *d*-orbital is σ-antibonding d_{xy}. As d_{xz} and d_{yz} states are almost degenerate for the group D_{2h}, $d_{xz} \rightarrow d_{xy}$ and $d_{yz} \rightarrow d_{xy}$ transitions give one band at 18,000 cm^{-1}. The bands at the lower energies are $d_{z^2} \rightarrow d_{xy}$ and $d_{x^2-y^2} \rightarrow d_{xy}$ [21].

In the adduct of type (b) chromophore O_4N_2 has effective symmetry C_{2v}. The coordinate frame is modified so that the *x* axis is parallel to the C_2 axis. The only adduct studied previously is $Cu(hfa)_2 \cdot$ 2,2′-Dipy [22] (a range from 8000 to 18,000 cm^{-1} only was inspected). The $d_{z^2} \rightarrow d_{xy}$ transition was found to be shifted to the infra-red (9500 cm^{-1}). It is quite understandable taking into account that apical donors destabilize the d_{z^2} orbital. Other transitions form a wide band at about 14,000 cm^{-1}.

Similar spectra were observed for all adducts of type (b) studied (Table 3). These data allow us also to conclude that (1) d_{xz} and d_{yz} orbitals are still almost degenerate; (2) 2,2′-Dipy and Phen produce approximately the same ligand field; (3) change of hfa for pta has minor influence on the band energies. The $d_{z^2} \rightarrow d_{xy}$ transition in the infra-red could not be measured in our work.

Additionally the more intense band was observed at 22,000–23,000 cm^{-1} for adducts of type (b). Strong absorption at the energies higher than 24,000 cm^{-1} is typical for all complexes studied and originates through charge transfer from β-diketonate, but only adducts of type (b) reveal the extra band. As the position of a neutral bidentate ligand in the equatorial plane is necessary for the appearance of the band we can assign the absorption to the charge transfer from this ligand.

The electronic spectrum of $Cu(thd)_2 \cdot$ Phen is difficult to predict because of the low molecular symmetry. The observed absorption spectrum is very similar to that of $Cu(thd)_2$ or $Cu(thd)_2$ and 2,2′-Dipy (1 : 1) benzene solutions. Thus, the formation of adduct of type (b), but not of type (c), can be easily registered by electronic spectroscopy of the benzene solutions.

CONCLUSIONS

As can be seen from Table 4 the occurrence of $CuL_2 \cdot Q$ structure depends on the nature of β-diketonate ligand. Decrease of HL acidity results in the change of the preferable coordination type. The competition of ligands for the place in the equatorial plane of tetragonally stretched octahedral coordination sphere of Cu^{II} is a dominating factor for their arrangement. We have found that some $CuL_2 \cdot Q$, including $Cu(hfa)_2 \cdot$ Phen, $Cu(hfa)_2 \cdot$ 2,2′-Dipy, $Cu(pta)_2 \cdot$ Phen, $Cu(pta)_2 \cdot$ 2,2′-Dipy, are able to evaporate congruently in vacuum. Nevertheless $Cu(thd)_2 \cdot$ Phen (structure type (c)) has a lower sublimation temperature than the complexes of structure type (b) in spite of the presence of the fluorinated β-diketonate ligands.
