11. SUMMARY 14

1. INTRODUCTION TO THE GENERAL CONCEPTS OF DINUCLEAR OXIDATIVE ADDITION

Malcolm Chisholm stated some years ago,[1] "What one metal can do, two metals can do better". There is considerable evidence that chemistry associated with multinuclear metal species[2] can be significantly different from the chemistry that occurs with molecules containing only a single metal atom. In their book, Collman, Hegedus, Norton and Finke have described[3] some very interesting examples involving two metal atoms. Chisholm,[4a] Balch,[4b,4c] Cowie[4d] and our group[4i,5d] have discussed results involving metal–metal bond formation and rupture with di- and trinuclear species. Bosnich[4e] demonstrated with dinuclear Pd, Rh and Ir complexes that proximity factors can nega-

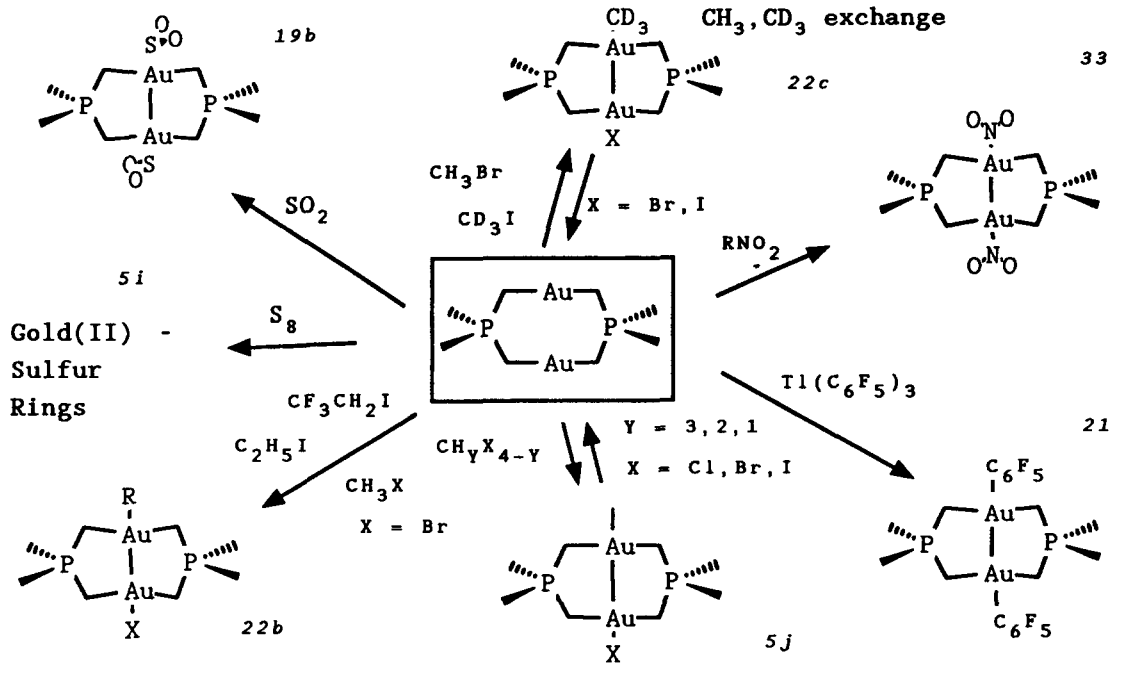

Fig. 1. Reactions of dinuclear gold(I) ylides with various small molecules. A lead paper describing the chemistry is listed in italics.

tively influence oxidative addition in dinuclear systems in which the metal atoms "were within a cooperative distance", but not capable of metal–metal bond formation. Stobart[4f] examined the oxidative addition of alkyl halides and halogens to $[Ir(\mu\text{-pz})L_2]_2$, pz = pyrazoyl and L = CO, cyclooctadiene or PPh_3, CO mixtures. These reactions produce a two-centre two-electron addition with the formation of a metal–metal bond. However, with alkyl- and arylamido ligands, Ahmed[4h] showed that CH_3I addition to $[IrB(CO)_2]_2$ (B = NHR^- or NH_2^-) produces a Ir^{III}–Ir^{I} complex, while I_2 gives the metal–metal bonded Ir^{II}–Ir^{II} species. Also the oxidative addition chemistry at dinuclear Pt centres has been described recently in a review by Anderson.[4g]

One of the important aspects of dinuclear systems is the ability of the two metal atoms to form a metal–metal bond, thereby stabilizing a reactant, a product or an intermediate. Alternatively, the second metal atom may inhibit[4e] the reaction of a normally reactive centre, either through steric or electronic properties or both. Studies in this area with dinuclear gold(I) complexes were pioneered by Schmidbaur and expanded by ourselves and others.[5] They have demonstrated a rich reaction chemistry with this element (Fig. 1), a chemistry which depends upon the ability of the two (or more) metal atoms to interact with each other. The implications of this chemistry for the understanding of oxidative addition processes[4i,6] in dinuclear and polynuclear complexes is the focus of this report. A very well presented description of the recent organometallic chemistry of gold by Grohmann and Schmidbaur should be consulted for more general information than is contained in this report.[5l]

2. GENERAL FEATURES OF THE OXIDATIVE ADDITION PROCESS

Oxidative addition at a single metal centre is described as a one- or two-electron exchange between the metal atom and the molecule being added.[3] The one-electron process is "radical" in character, while the two electron exchange most often is described in terms of nucleophilic substitution, S_N2.

In dinuclear compounds the distance between these metal atoms can influence the oxidative addition chemistry. The metal atoms may be held close by bridging ligands or by other bonding interactions. The specific electronic properties of both of the metal atoms, therefore, can influence the observed chemistry. Widely separated metal atoms are expected to behave relatively independently (Fig. 2), but if the metal atoms are close, factors related to the extent of metal–metal interactions and the electronic properties of the metal atoms as adjusted by the ligands must be considered.

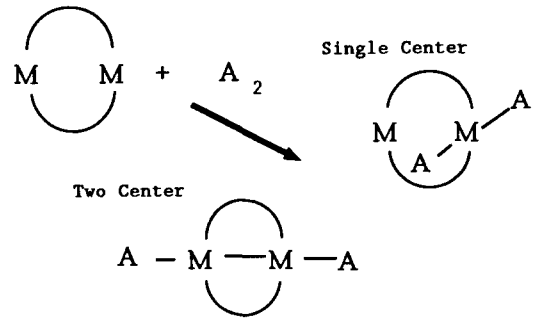

Fig. 2. Oxidative addition to dinuclear complex.[5d]

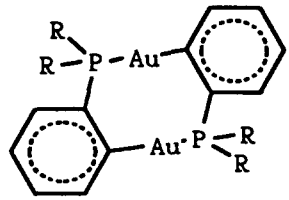
Goddard and Low[6] have discussed the role of electronic structure in oxidative addition. They suggest that an electronic promotion occurs at the metal centre undergoing "oxidation". The promotion is considered from a closed or pseudo-closed-shell ground state configuration to an open-shell configuration, which can be associated with a (excited state) configuration suitable for bonding to the molecule being added. In the case of the closed shell d^{10} complexes such as Au^{I} or Pt^{0} this open-shell configuration is $d^{9}s^{1}$. Hence, the greater the energy separation between the d^{10} and $d^{9}s^{1}$ configurations, the more difficult the oxidative addition process. Table 1 lists the closed-shell to open-shell (HOMO–LUMO) energy separation[7] for ions of interest to this report. In the Goddard–Low model,[6] excitation to the open-shell configuration, *not oxidation* (ionization), is the key to understanding the reactivity.

Although there are obvious features in common between the oxidative addition studies described in this report and studies involving open-shell ions such as Ir^{I} or Pt^{II}, the specific influence of completely filled electronic levels at the metal atom is different enough from system to system that electronic generalizations become less reliable. Hence, this report will focus on the oxidative addition of closed-shell metal species, with one important exception on which calculations have been performed.[4i] For closed-shell d^{10} metal atoms or ions, the experimentally observed pattern of closed-shell to open-shell energy separation determined from spectroscopic data[7] parallels the oxidative addition process. For the ions important to this report the energy separation pattern is: $Hg^{II} > Ag^{I} \gg Au^{I} > Pd^{0} > Pt^{0}$. The greater the energy separation, the more difficult it is to achieve oxidative addition. Conversely, the smaller the energy separation between the closed- and open-shell configurations, the easier the addition. This concept is very similar to the idea of Chatt,[8] who stated that the stability of organometallic compounds closely follows their HOMO–LUMO

Table 1. Promotion energies ("HOMO–LUMO gap separations") and ionization potentials for some ions important to oxidative addition reactions (eV)

Ion	HOMO–LUMO gap (eV)[a]	Ionization potential (eV)
Cu^{I}	2.715	20.292
Ag^{I}	4.959	21.49
Au^{I}	1.859	20.52
Pt^{0}	0.744	9.00
Pd^{0}	0.814	8.337
Tl^{I}	6.137	20.4
Pb^{II}	7.488	15.03
Hg^{II}	5.306	34.2

[a] The energy separation between the closed-shell atomic configuration and the lowest open-shell configuration.



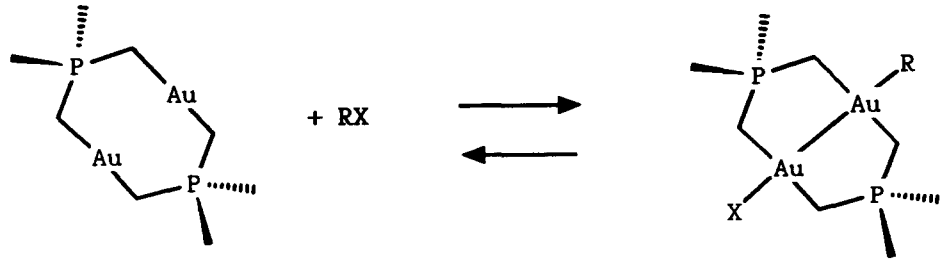
separation. Changing the HOMO–LUMO separation by using different co-ligands at the metal centre changes the reactivity of the complex, a concept widely utilized in organometallic syntheses.

3. OXIDATIVE ADDITION IN DINUCLEAR AND POLYMETALLIC SYSTEMS

With dimetallic and polymetallic systems, the excited-state energy as well as the ground-state energy will be influenced by the close proximity of another metal atom. Spectroscopic evidence suggests that metal–metal bond formation[9] contributes to the description of the excited state with some of these species. Obviously, metal–metal bond formation makes the "open-shell" excited state more accessible relative to the case in which no metal–metal bond can form, for example, when the metal atoms are well separated.

Electron-accepting metal centres or ligands adjacent to the metal atom undergoing the initial attack during the oxidative addition can be expected to stabilize the HOMO or "closed-shell" ground state through electron exchange. This increases the HOMO–LUMO separation, thereby making oxidative addition less favourable. Similarly, cation charge and pi-bonding from adjacent metal atoms or ligands also can be expected to increase the HOMO–LUMO separation, diminishing the tendency for oxidative addition, relative to uncharged or electron-rich anionic complexes or those complexes with strongly donating ligands.

Experimental differences are observed in the ease of small molecule oxidative addition to various dinuclear gold(I) complexes having different charges or ligand atoms on the metal centres. For example, with $[Au_2(diphos)_2]^{2+}$, diphos = $Ph_2PCH_2PPh_2$, a cationic complex with pi-accepting phosphorus ligands, halogen addition does not occur,[10] even with very strong oxidants such as Cl_2. However, with the neutral complex $[Au_2(o\text{-}PC)_2]$, o-PC = $Ph_2P—C_6H_4$,



containing the strongly basic phenyl ligands, iodine readily adds.[11] In both types of compound, the Au···Au distance is *ca* 3.0 Å. Several dinuclear gold complexes with C—Au—S and S—Au—S coordination[12] also exist with Au···Au separations of *ca* 3.0 Å and are known to add halogens (see below), but less readily than the ylide complexes of Fig. 1.

Accumulated data regarding the reactivity of dinuclear and polynuclear metal complexes is consistent with the idea that neighbouring metal atoms and coordinated ligands influence the oxidative addition process both positively and negatively.

Methyl iodide oxidative addition across two metal atoms with metal–metal bond formation was first reported in 1975 by Schmidbaur[13a,13b] for a dinuclear gold(I) ylide complex and shortly thereafter by Gray[14] for the $[Rh_2(bridge)_2]^{2+}$, bridge = $NCCH_2CH_2CN$. X-ray structural results were not easily obtained for either complex. The gold complex is photosensitive and easily decomposes into the metal–metal bonded diiodide product. However, Basil successfully crystallized this complex, which has the structure we reported[15] in 1982. Structures also have been reported for products having CH_3Br and CH_3I across metal–metal Rh—Rh[16] and Pd—Pd[17] bonds, but these adducts had been obtained by protonation of methylene bridged A-frame intermediates.

4. OXIDATIVE ADDITION TO DINUCLEAR GOLD(I) COMPLEXES

In general, alkyl halide oxidative addition reactions that have been studied with dinuclear gold ylide complexes follow the kinetic and thermodynamic patterns expected for S_N2-type nucleophilic

Equilibrium: CF_3CH_2I >> CH_3CH_2I

Kinetics: $PhCH_2Br$ (120) >> CH_3Br (20) >> $(CH_3)_3SiCH_2Br$ (1)

Fig. 3. Alkyl halide oxidative addition, thermodynamics and rates with relative rates in parentheses.

reactions[18] summarized in Fig. 3. The Au^I centres have been established to be nucleophilic through structural characterization of the SO_2 adduct.[19] The reactions with methyl halides are chemically reversible in solution and also in the solid state.

Not only do dinuclear Au^I ylide complexes undergo a two-electron oxidative addition with metal–metal bond formation, but oxidation by four electrons also can occur, producing products which can be isolated and structurally characterized.[20] Since the four-electron oxidation proceeds through a metal–metal bonded Au^{II} intermediate, this metal–metal bond must be broken while producing the Au^{III} products. A number of these reactions have produced well characterized products (Fig. 4). We also have observed ligand exchange to occur at the Au^{II} centres without oxidation.[21] However, oxidative addition to the dinuclear Au^{II} complexes often gives radical products. Except for the CH_2 insertion reactions into the metal–metal bond using diazomethane and the known two-step addition of dihalomethanes to the dinuclear ylide complexes, which also apparently involve a CH_2 insertion,[5e] it is not known what role metal–metal bonding interactions play in influencing the course of these reactions. Therefore, detailed consideration will not be given in this report to the four-electron

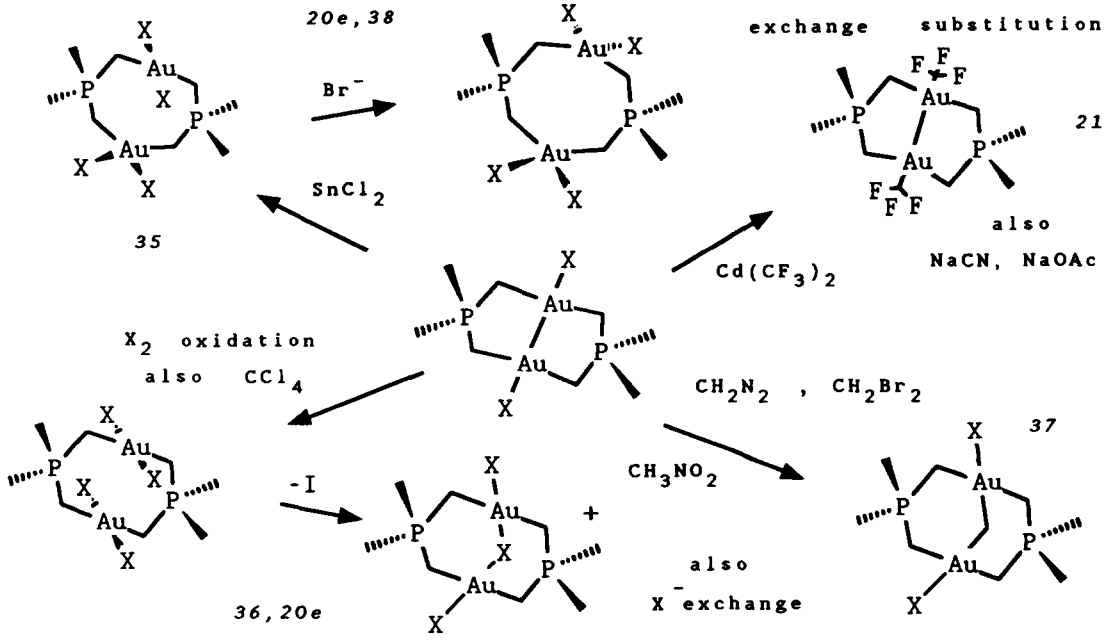


Fig. 4. Reactions of dinuclear gold(II) complexes.

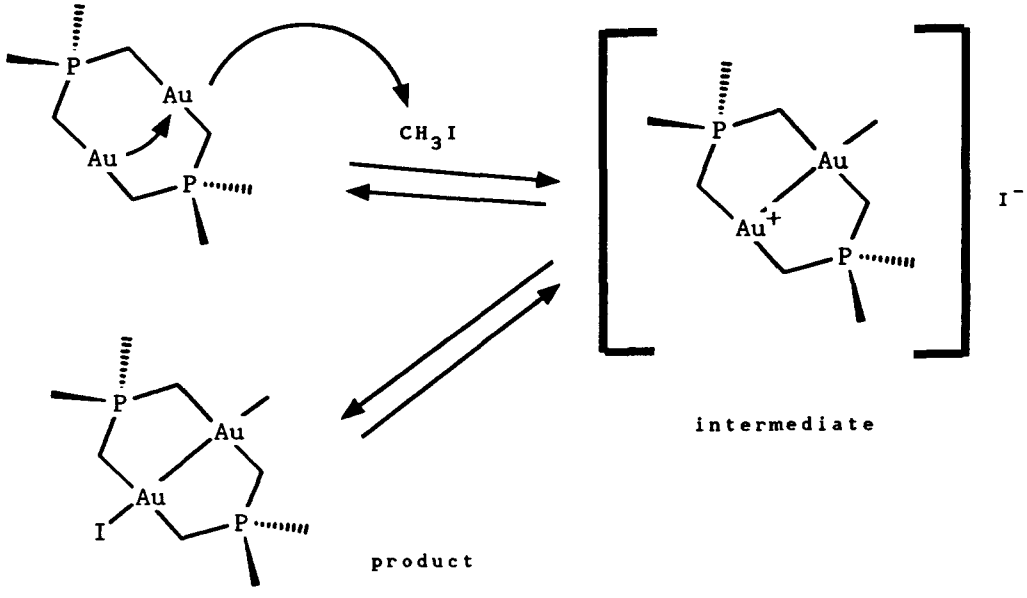
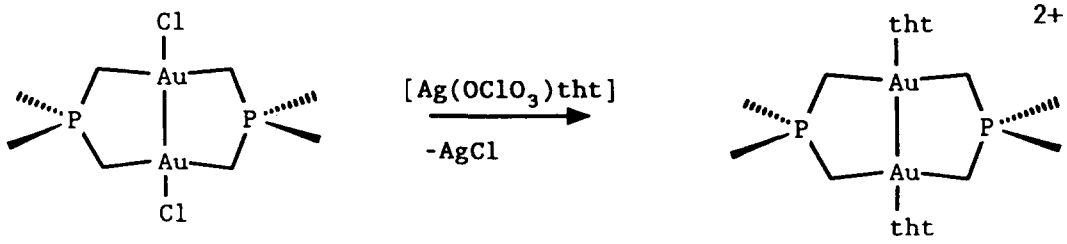
oxidative addition process, the radical oxidative additions or oxidative additions from dinuclear Au^{II} to Au^{III} species, although some dinuclear Au^{II}/Au^{III} chemistry will be described.

5. DOES THE INITIAL OXIDATIVE ADDITION INVOLVE BOTH METAL CENTRES?

The oxidative addition scheme proposed for the dinuclear Au^{I} complexes (Fig. 5) suggests that metal–metal bonding promotes the formation of an ionic intermediate. While a cationic product of this type has not been characterized structurally, a related species has been characterized by Uson, Laguna and Laguna.[22a] This dicationic species has a short, 3.6 Å, metal–metal bond. Thus cationic Au—Au bonded intermediates are very reasonable intermediates in the dinuclear oxidative addition process. Comparative structural data for the CH_3CH_2I and CF_3CH_2I adducts suggests ionization of the I^- in the ethyl adduct is more facile than in the case of the thermodynamically more stable trifluoroethyl iodide adduct.[22b] Furthermore, halide exchange at the Au^{II} centres is known to be rapid.[22c] How certain are we that metal–metal bond formation occurs in the initial oxidation step? After all, a mixed-valent Au^{I}/Au^{III} intermediate could be formed initially and then rapidly rearrange to the observed products. More will written on this point.

The best evidence we have that nucleophilic attack by a Au^{I} centre on the addend molecule involves metal–metal bond formation originates from the structural results obtained with the SO_2 adduct.[19] In addition to establishing the nucleophilicity of the Au^{I}, which produces a pyramidal geometry about the S atom,[39] The $Au^{I} \cdots Au^{I}$ distance shortens to 2.838 from 2.976 Å. The donation of electron density from gold to the SO_2 is accompanied by increased metal–metal bonding. Although formal "oxidation" does not occur with SO_2, the process is similar to what is expected in a Goddard–Low[6] oxidative addition, but with incomplete electron transfer to the ligand centres. There is an overall two-electron deficiency for the formation of three sigma bonds along the S—Au—Au—S axis. (The SO_2 contributes no electrons to the addition while each Au^{I} atom contributes two electrons to the axial sigma bonds.) Alternatively, it may be argued that the shortened gold distance has resulted from the removal of repulsive electron density at the Au^{I} centres by the SO_2. Notably, the Au^{I} atoms in this complex are coordinated by four ligand atoms in an approximate plane, a rare occurrence with Au^{I}. The author is aware of only three other examples, a pentanuclear gold complex reported by Uson,[22] the SO_2 adduct to the trinuclear [Au···Pt···Au] complex described below[19] and a recently characterized tetranuclear complex,[23] in which $[Au(TPA)_3]^+$, TPA = 1,3,5-triaza-7-phosphoraadamantane, coordinates through Au^{I} to $[Au_2\ (i\text{-MNT})_2]^{2+}$, i-MNT = $[S_2CC(CN)_2]^{2+}$.





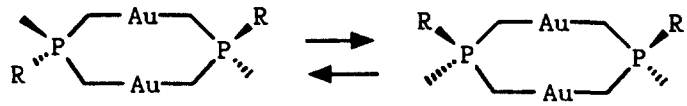


Fig. 5. Anchimerically assisted nucleophilic addition.

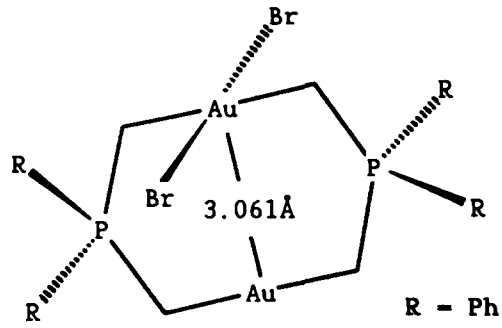
There is related evidence that metal–metal bonding accompanies the donation of electron density to small molecules interacting with the Au^{I} atoms. Several years ago, Schmidbaur and his students[24] recognized that a mixture of different dinuclear ylide complexes exchanged ligands slowly enough that the various isomers could be separated on a column. This observation requires that Au—C bond rupture occur, a process likely to be influenced by either by intermolecular Au · · · Au interactions, or by solvent effects, since ring opening would leave a Au^{I} centre coordinated only to one C atom. In our effort to synthesize the dinuclear ylide complex of $[(CH_2)_2P(CH_3)C_6H_5]^-$ to examine the question of Au—C bond lability, it was discovered[19b] that the standard basic conditions for synthesis led to the crystallization of only the *trans* isomer. This isomer rearranged in solution, slowly forming an approximately 53 : 46 mixture of the *trans* and *cis* forms. The *cis* form has not been structurally characterized, but is clearly identified in the NMR patterns obtained. Oxidative addition of halogens or other oxidants leads to crystallization of *trans* dinuclear Au^{II} products which do not undergo further rearrangement.[25]



trans *cis*

The *trans* to *cis*/*trans* rearrangement was found to be general acid catalysed. Strong protonic acids such as HCl are known to symmetrically cleave[26] the eight-membered ring, with deuterium incorporation into the ylide using DCl. However, CD_3COOD catalyses the isomerization without introducing D into the complex. Since SO_2, Ph_3PAuCl and other Lewis acids also catalyse the isomerization, it was suggested[19b] that rearrangement occurs via the formation of an adduct such as the structurally characterized SO_2 adduct with its shortened Au · · · Au interaction, an adduct of a type similar to the initial electrophilic interaction suggested for small molecules undergoing oxidative addition at the Au^{I} centre.

6. EVIDENCE THAT OXIDATIVE ADDITION DOES NOT FIRST FORM A MIXED-VALENCE Au^{III}/Au^{I} SPECIES

Although the SO_2 studies are consistent with a nucleophilic attack by a Au^{I} centre on the adduct, which is assisted by metal–metal bond formation, it remained plausible that the addition occurs first at one centre to form a Au^{III} species, followed by a rapid rearrangement to the dinuclear Au^{II} product observed. Structural data for the addition of I_2 to $[Au(MTP)]_2$ clearly established that both the homovalent and the mixed-valent species were formed with this halogen.[27] However, ligand rearrangement also occurs causing the Au^{III} centre to have *trans*-AuC_2I_2 coordination. The dinuclear MTP species with added Cl_2 or Br_2 crystallize as Au^{II} products,[28] but the C_s-$[Au^{I}Au^{III}(MTP)_2Cl_2]$ could be formed starting with the $Au^{III}(MTP)_2Cl$.[20a] Thus, a synthesis of the mixed-valent ylide complex with Cl or Br ligands seemed reasonable, especially if these materials were not intermediate in the formation of the homovalent Au^{II} products. Furthermore, Schmidbaur had previously demonstrated that the dimethyl product is C_s-$\{Au^{I}Au^{III}[(CH_2)_2PPh_2]_2Me_2\}$, at least in solution,[29] Uson *et al.*[30] had demonstrated that the dinuclear complex $R_2Au_2[(\mu\text{-}PPh_2)_2NH]$, $R = C_6F_5$, was oxidized to a metal–metal bonded Au^{II} species, which then rearranged in polar solvents to a mixed-valent Au^{III}/Au^{I} product, a rearrangement we also reported[40] for the dinuclear ylide complexes.

The synthesis of C_s-$\{Au^{I}Au^{III}[\mu\text{-}(CH_2)_2PPh_2]_2Br_2\}$, was accomplished[20b,20e] by oxidizing $\{Au^{II}[\mu\text{-}(CH_2)_2PPh_2]CN\}_2$ with excess Br_2 in CH_2Cl_2 or by reducing the *trans,trans*-tetrabromide with AgCN in CH_2Cl_2. Both this material and the chloride analogue [Au···Au, 3.052(2) Å] were insufficiently soluble as the CH_2Cl_2 solvates to perform solution NMR studies of the rate of rearrangement to the Au^{II}/Au^{II} product. If the material was heated in contact with the solvent, the product formed from the resulting solution is largely the Au^{II}/Au^{II} species.

This data appears to mitigate strongly against a mixed-valent Au^{III}/Au^{I} species being formed first in the oxidative addition process. However, this assumes that the initial oxidative addition product is a mixed-valent species, in which the halide atoms are *trans* to each other on the Au^{III} centre. Since dinuclear Au^{III}/Au^{III} species had been synthesized and characterized, in which the halides (or sulfur-containing ligands) were *cis* on both centres and also species *cis* on one centre and *trans* on the other,[20e] the possibility remained that oxidative addition involves *cis* addition at one centre followed by rearrangement to the stable Au^{II}/Au^{II} product. Schmidbaur had reported the formation of *trans* asymmetric Au^{III}/Au^{I} cations from the reaction of $\{Au[\mu\text{-}CH_2)PPh_2]X\}_2$ (X = Br, Cl or I), with neutral ylides, $CH_2 = PR_3$ (R_3 = Me_3, $MePh_2$ or Ph_3). These complexes had been characterized by NMR and ^{197}Au Mössbauer spectroscopies.[32]

The reaction of BrCN with $Au_2[\mu\text{-}(CH_2)_2PPh_2]_2$ leads to three products, as determined from the ^{1}H NMR patterns and by crystallographic characterization of isolated products. The Au^{I}/Au^{III} dibromide product found (Fig. 6) in the *cis* form was isolated from the mixture of products after dissolution in CH_2Cl_2 and layering with benzene or hexane, while being exposed to sunlight or a UV source.[41] Unfortunately, overexposure produces gold mirrors, but defining the conditions for "overexposure" have not yet been achieved. The formation of the *cis* Au^{I}/Au^{III} product was reproduced, however, and the material was characterized by X-ray crystallography. With regard to the topic of this report, the *cis* adduct at the Au^{III} centre does not undergo transformation into the

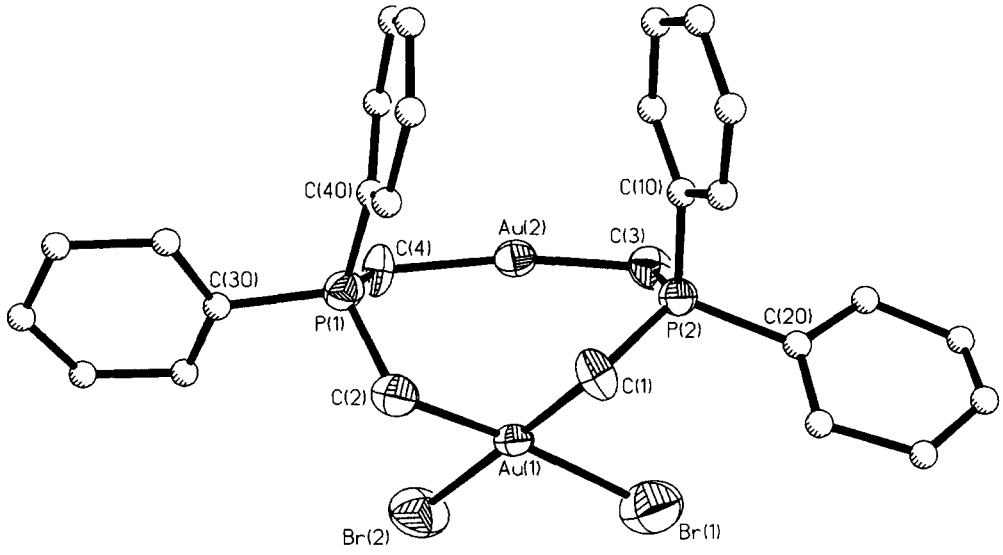


Fig. 6. Thermal ellipsoid drawing of the structure of the *cis*-Au^{I} $Au^{III}[\mu\text{-}(CH_2)_2PPh_2]Br_2$.

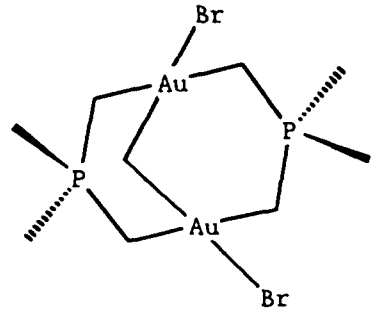
symmetrical Au^{II} material. Thus, *cis* oxidative addition at one centre followed by rearrangement cannot be important to the oxidative addition process itself.



While oxidative addition of symmetrical oxidants invariably leads [5d] to symmetrically ligated (*trans*) metallocycles, $\{Au[\mu\text{-}(CH_2)PPh_2]X\}_2$ (X = Br, Cl, CN,[37] OOCPh,[42] NO_3[33] and C_6F_5[21]) and metathesis can be used to produce new symmetrically ligated complexes (X = CF_3[21]), asymmetrically ligated species also $\{Au[\mu\text{-}(CH_2)PPh_2]XY\}_2$ have been synthesized from the oxidative addition of alkyl halide reagents: X = Br, Y = Me, CH_2Ph, $CH_2C(O)Ph$,[43] CH_2CN, $CHCl_2$; X = Cl, Y = CCl_3;[36] X = I, Y = Me,[15] CH_2CH_3,[44] CH_2CF_3,[44] CH_2SiMe_3,[5d] CH_2Cl.[46] In fact, the kinetics of the alkylhalide addition follows a pattern typically expected[5d] for S_N2 processes. The addition furthermore was shown to be reversible with the addition product stability greatly dependent[44] on the presence of electron-withdrawing groups on the alkyl moiety.

7. RADICAL INTERMEDIATES

Nitroalkanes oxidatively add to $[Au(ylide)]_2$ to produce NO_2 coordination and carbon-based radical products.[33] While the initial step may be a non-radical oxidative addition for this system, as suggested for the alkyl halides, followed by rapid homolytic Au—C bond cleavage induced by the strong *trans*-labilizing effect of the NO_2, this reaction is sufficiently complicated that further study is essential to determine what bearing it has, if any, on binuclear oxidative addition. Radical coupling of the THF solvent is known to occur. The addition of CH_3NO_2 to the Au^{II} species, $Au_2(ylide)_2(OBz)_2$, OBz = benzoate, causes insertion of $CHNO_2$ into the Au—Au bond.[33] Radical processes also appear to be involved in the formation of the products in these systems.

Although strong evidence exists in many oxidative addition reactions[45] that a one-electron first step can occur in oxidative addition (electron transfer to the addend) to form a metal-based cation radical, evidence for such radical intermediates with the dinuclear gold compounds appears limited and is greatest in systems involving the addition of nitroalkanes,[33] disulfides[19b,47] or diselenides,[48] sulfur[49] and the addition of strong oxidants, which have sterically blocked C centres such as[36] CCl_4 or centres which are only weakly aurophilic such as in benzoylperoxide.[42] While no Au^I/Au^{II} radical intermediates have been characterized, nor have they been observed from ESR studies, uncharacterized "blue" intermediates sometimes are observed. Evidence for radicals was found with the CCl_4 addition, in which there was the formation of sufficient $HCCl_3$ in THF to account for the Au^{II} and Au^{III} products isolated. However, even with CCl_4, a metal–metal bonded Cl—Au(μ-ylide)$_2$Au—CCl_3 adduct could be isolated and structurally characterized.[36] Metal–metal interactions also could promote an electron-transfer first step in the oxidative addition process.

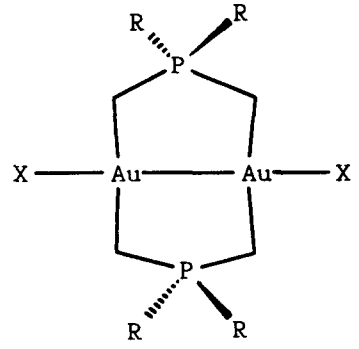
The oxidative addition of small molecules to the dinuclear Au^{II} species also can occur by one-electron steps or a two-electron process. Structural evidence,[5e] although weakened by a crystallographic disorder, suggests that the second step in the formation of μ-methylene Au^{III} derivatives

formed from the addition of CH_2Br_2 and its analogues to the dinuclear Au^I complexes occurs by insertion of CH_2 into the Au—Au bond. Diazomethane also adds across the Au—Au bond in dinuclear Au^{II} species.[50]

In general, the formation of the dinuclear Au^{III} species (Fig. 4) must be accompanied by metal–metal bond rupture of Au^{II} products. Direct oxidation to Au^{III} species does not occur with weakly oxidizing species such as alkyl monohalides. since the Au^{II} centres are considerably less nucleophilic in the dinuclear Au^{II} species than in the dinuclear Au^I complexes, electron-transfer and radical

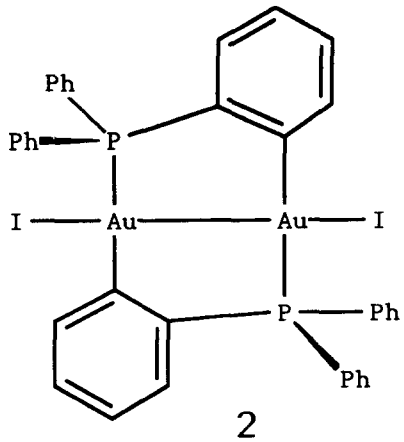
intermediates are likely to be more important in the oxidation of Au^{II} species than the Au^{I} compounds. The HOMO in the Au^{II} species is metal–metal bonding and metal–halide antibonding, giving rise to a strong transannular influence of the alkyl group on the metal–halide distance. This lengthening of the Au–halide bond compared with similar bonds in mononuclear sigma-bonded compounds has been described as an *amplified* structural *trans* influence.[5d]

Although the dinuclear Au^{III} complexes rapidly react with the dinuclear Au^{I} ylide dimers to form Au^{II} products, only symmetrical Au^{II} products have been isolated to date by this route. Furthermore, kinetic and mechanistic studies designed to determine whether this reaction follows atom-transfer or electron-transfer dynamics have not been performed. The lability of the Au^{II}-halide bond in the presence of the dinuclear Au^{I} species may impede the development of meaningful mechanistic studies.



8. OXIDATIVE ADDITION OBSERVATIONS WITH OTHER DINUCLEAR GOLD(I) COMPLEXES

The fact that dinuclear diphos complexes of Au^{I} do not oxidatively add small molecules prompted us to examine the possibility of addition to other dinuclear Au^{I} species. Isolated, characterized products have been obtained by us and others for the species listed in Fig. 7. As stated above, the iodide products undergo rearrangement to mixtures which contain Au^{I}/Au^{III} products. The $[Au_2(i\text{-}MNT)_2X_2]^{2-}$ species are compounds which slowly rearrange[51] in solution to Au^{III} and Au^{I} products. This rearrangement has been studied kinetically and is found to be first order in added halide. Thus, the presence of free halide nucleophiles presumably impacts upon the product distributions found in the oxidative additions to dinuclear Au^{I} species, such as reactions observed with $Au_2(MTP)_2$ and even the ylide complexes. Qualitatively, rearrangement to Au^{I}/Au^{III} products appears to be associated with the electrophilic nature of the Au^{II} centres in the oxidative addition product. With P—Au—C, S—Au—C or S—Au—S coordination at the Au^{II} centres, halide exchange is facile and the metal centres are sufficiently electrophilic so that rearrangements are found. Burmeister suggested[52] that even the well-known $Au_2(dtc)_2$, dtc = dialkyldithiocarbamate, forms a symmetric Au^{II} product when oxidized with halogens. However, the material was found to be too unstable to isolate at room temperature. The anionic charge associated with the *i*-MNT complex, in which the Au^{I} product has a nearly identical coordination structure to that of the Au^{I} dithiocarbamate, appears to give the Au^{II} species, $[Au_2(i\text{-}MNT)_2X_2]^{2-}$, greatly increased stability. The fact that the stability of these species in solution changes in the order $Cl^- > Br^- > I^-$ follows closely the increased nucleophilicity of any halide freed by ionization. This observation may account for some of the difficulty our group had initially[13] in reproducing Schmidbaur's observation of CH_3I addition to the ylide complex, although the primary problem was the sensitivity of the complex to UV light.[5d]



9. IMPLICATIONS OF THE GODDARD–LOW OXIDATIVE ADDITION CONCEPT TO THE DINUCLEAR GOLD(I) CHEMISTRY

The oxidative addition chemistry described above follows nicely the Goddard–Low concepts. Basic ligands attached to the Au^{I} centres enhance the ease of closed-shell to open-shell formation. The open-shell configuration on the Au^{I} centre to which the small molecule is initially added involves a *d*-orbital perpendicular to the axis of ligand coordination to the Au^{I} and directed, at least partially, toward the adjacent Au^{I} centre. As long as this distance is around 3.0 Å or less, an Au—Au bond can form, leaving the second metal atom "open". With alkyl halides, nucleophilic attack by the Au^{I} on the C atom with metal–metal bond formation and heterolytic C-halide bond rupture (Fig. 5) leaves the second gold centre coordinately unsaturated and the overall charge of the complex cationic. Hence, the reaction pattern is the same as observed for oxidative addition to square planar complexes, but gives a product with the addition across the Au—Au bond. The fact that the cationic $[Au_2(diphos)_2]^{2+}$ complexes do not oxidatively add small molecules or otherwise easily oxidize appears directly related to the apparent increase in the energy required to obtain the open-shell configuration with phosphine ligand coordination and the positive charge on the complex.

The presence of another metal ion centre such as Hg^{2+} or Tl^{+} adjacent to the Au^{I} in dinuclear MTP complexes also prevents the oxidative addition.[53] While the charge may be important with

Hg^{2+}, the neighbouring group influence is most likely to be the failure of the two adjacent metal atoms to be able to form a good electron pair bond.

+

PF_6^- or BPh_4^-

Yet, with all of the studies performed to date with dinuclear Au^I complexes, some uncertainty still remains regarding the specific role the adjacent metal atom plays in electronically influencing the oxidative addition. While the Goddard–Low concept appears to explain the results observed

for dinuclear oxidative addition, a clearer understanding of the impact of the electronic properties of the adjacent metal center comes from studies of the chemistry of linear trinuclear species.

10. OXIDATIVE ADDITION TO LINEAR TRINUCLEAR SPECIES

Direct evidence for a positive electronic influence of a neighbouring metal atom on the oxidative addition process, with a resultant metal–metal bond formation, can be observed in the chemistry of linear trimetallic species. The process that leads to "terminal addition" (Fig. 8) is a typical two-electron oxidative addition. This product is the expected product as long as the metal atom in the middle of the linear array, M, allows addition to take place. The two-electron oxidative addition which produces the four sigma bonds, the "*trans* addition", cannot occur with metal–metal bond formation unless M contributes electrons and orbitals to the process. Four sigma bonds cannot form from a two-electron oxidative addition event.

The Goddard–Low concept of oxidative addition pinpoints the metal atoms, M, for which the *trans* addition might become possible. Assuming that the unoxidized species has M in planar coordination, a filled orbital near the HOMO and an empty orbital near the LUMO in energy must be found which can be involved in the bonding. To form metal–metal bonds, these orbitals must be directed largely along the metal–metal axis. Open-shell formation at M′ can induce bonding to M, but it also must promote an electron into an empty orbital at M. This orbital becomes an open-shell orbital which allows bonding to the other M′. Consequently, A_2 adds across the three-metal-atom array. Should M not have available orbitals for bonding to M′ nor two electrons to contribute to the bonding process, single centre oxidative addition might occur providing the neighbouring metal atom did not inhibit addition totally as observed in many dinuclear systems.

Single-centre oxidative addition has been observed with the trinuclear pyrazolate (pyra) species tris-(μ-3,5-triphenylpyrazolato)trigold(I). When the planar complex $[Au^{I}(pyra)]_3$ is oxidized with halogens or even with *aqua regia* the mixed-valent product $[Au^{III}Cl_2Au_2(I)(pyra)_3)]$ is obtained, which has been structurally characterized (Fig. 9). The distance between gold atoms is *ca* 3.3 Å in the unoxidized and oxidized materials.

The MTP ligand furnished us with an opportunity to synthesize linear trinuclear species in which the oxidative addition process could be tested.[54] By reacting [PPN][Au(MTP)$_2$] with K_2PtCl_4 the product *trans*-$[Au^{II}(\mu\text{-MTP})_2Pt(\mu\text{-MTP})_2Au^{II}]Cl_2$ was obtained and studied structurally (Fig. 10). The unoxidized precursor $[Au^{I}(\mu\text{-MTP})_2Pt(\mu\text{-MTP})_2Au^{I}]$ was formed from [PPN][Au(MTP)$_2$] by reaction with *cis*-$PtCl_2(SEt_2)_2$. Oxidation with halogens or with $PhICl_2$ cleanly forms the Au^{II} product, which can be reduced back to the Au^{I} material with $LiCH_3$. Oxidation shortens the Au—Pt distance from 3.03 to 2.66 Å. In these complexes the Pt atom is planar and four-coordinate to the S atoms of the bridging MTP ligands. Aside from the formation of the terminal metal–halide bonds and the shortening of the Au—Pt distance, the geometric changes found upon oxidation of the complex are small.

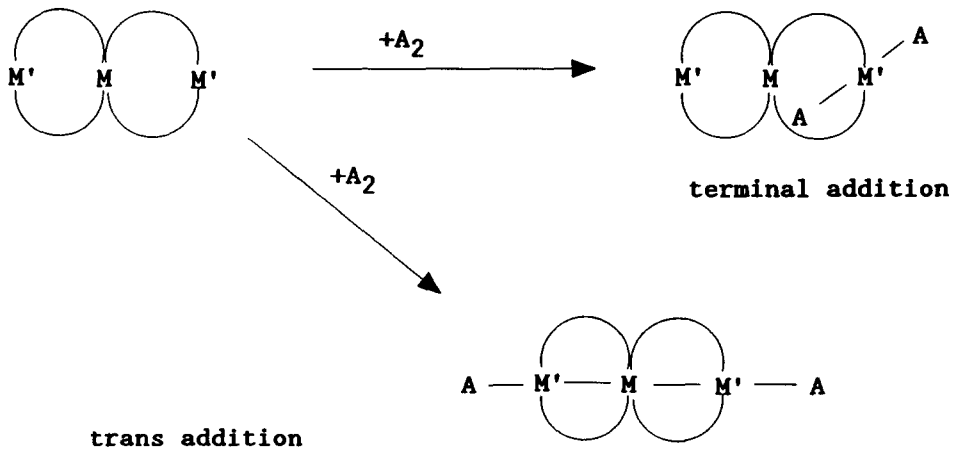

Fig. 8. Oxidative addition to linear trinuclear species.

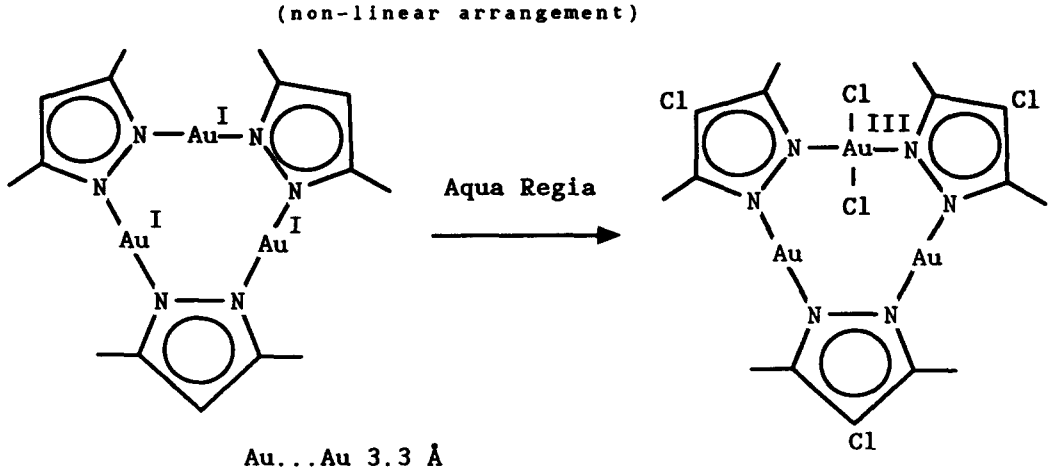

Fig. 9. Oxidation of tris-(μ-3,5-triphenylpyrazolato)trigold(I) with *aqua regia*.

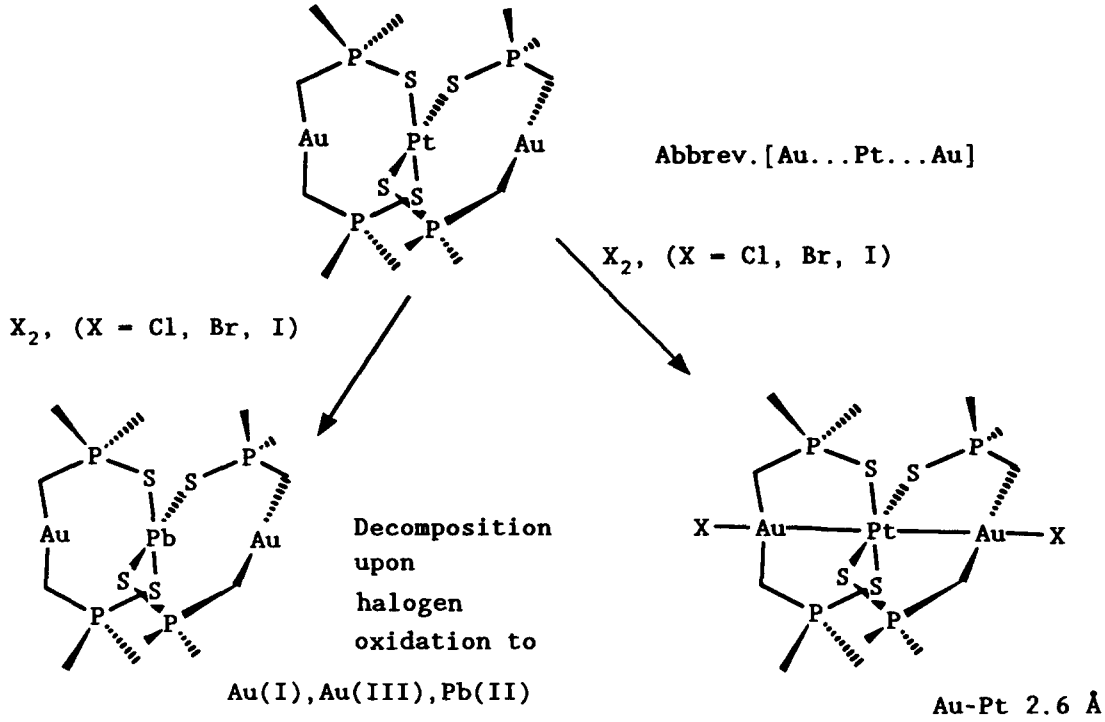

Fig. 10. Linear trinuclear [Au···Pt···Au] and [Au···Pb···Au] complexes with the ligand MTP.

As in the dinuclear gold ylide complexes, SO_2(g) also adds[19a] to the [Au^I(μ-MTP)$_2$Pt(μ-MTP)$_2$Au^I]. The shortening of the Au—Pt distance to 2.868 Å and the pyramidal geometry about the coordinated S atom bonded to the Au entirely parallels the observations made with the SO_2 addition to the dinuclear ylide complex. Thus, the nucleophilic interaction of the gold centres with the SO_2 leads to partial "oxidation" of the complex, with full oxidative addition occurring upon halogen addition.

Fenske–Hall calculations[4i] show that the HOMO in the linear trinuclear complex [Au···Pt···Au] is antibonding with respect to the metal–metal interaction along the linear metal axis. Oxidation results in the formation of a bonding HOMO along this axis. While it is convenient to describe the gold atoms as the atoms being oxidized, the correct description is that a [Au—Pt—Au]$^{2+}$ moiety bridged by the MTP and coordinated to the halides is formed.

A Goddard–Low description of this trinuclear oxidative addition process implies that the closed-shell d^{10} Au^{I} centre becomes an open-shell species upon interaction with the oxidant and induces an "excitation" of the Pt^{II} in the middle of the complex. The unoxidized complex has a typical, well-studied PtS_4 coordination with a HOMO involving significant d_{z^2} character and a LUMO with substantial p_z character. The filled d_{z^2} orbital falls along the metal–metal axis. Promotion of an electron from this orbital to the p_z orbital produces an "open-shell" configuration, which induces the formation of the open-shell configuration for the second gold atom. Electron pair bonds are formed between the gold and platinum atoms.

The Goddard–Low description of the oxidative addition process for the trinuclear species suggests that the metal atom in the middle of the complex must have electrons to contribute to the bonding and low-lying "open-shell" excited state. Several metal ions in addition to Pt^{II} are reasonable candidates such as Ir^{I} or Pd^{II}, but to date trinuclear MTP species with these ions as the metal in the middle have not been characterized. However, Pb^{II} in the complex $[Au^{I}(\mu\text{-MTP})_2Pb(\mu\text{-MTP})_2Au^{I}]$ does occupy essentially the same coordination position as Pt^{II}, Fig. 10.[55] The geometry is not rigorously square planar about the Pb^{II} as it is with the Pt^{II}, but the tetrahedral distortion is very small. The $Au^{I}\cdots Pb^{II}$ distance is about the same as $Au^{I}\cdots Pt^{II}$ distance, 3.0 Å. Oxidation of this complex with $PhICl_2$ or halogens leads to decomposition. Stoichiometric studies with $PhICl_2$ indicate that the oxidation produces approximately equal molar quantities of Au^{I}, Au^{III} and Pb^{II} species. There appears to be no stability to any oxidized trinuclear product.

Since the four coordinate Pb^{II} in the centre of the trinuclear $(Au\cdots Pb\cdots Au)$ complex contains no low-lying empty orbitals, promotion from the s^2 configuration of the ion must be into antibonding Pb—S orbitals. In fact, Fenske–Hall calculations[55] indicate that the HOMO in this system is largely Pb(6*S*) in character, with bonding and antibonding contributions from the Au atoms. The SHOMO is bonding in character, making oxidation considerably more difficult than with the Pt complex where the HOMO is antibonding. Promotion to the LUMO produces no net metal–metal bonding as apparently occurs with $[Au\cdots Pt\cdots Au]$ (Fig. 11).

The chemistry of a third linear trinuclear MTP complex[4i] further relates to the Goddard–Low model of oxidative addition. This cation $[Hg_2Pt(MTP)_4]^{2+}$ (Fig. 12) is exactly isoelectronic with the $[Au\cdots Pt\cdots Au]$ species. However, it undergoes no oxidation chemistry with mild halogenation. Various salts of the cation have been characterized, but chemical oxidative addition has not been achieved in any case. In this system which is structurally similar to the other complexes, the HOMO has no Hg—Pt character and is largely associated with the Pt—S coordination. The LUMO does have Pt—Hg bonding associated with it. However, promotion of the closed-shell Hg^{2+} to its open-shell configuration is very difficult energetically. It appears to be a "dead" system to oxidative addition.

11. SUMMARY

The oxidation or attempted oxidation by small-molecule oxidants of the linear $[Au\cdots Pt\cdots Au]$, $[Au\cdots Pb\cdots Au]$ and $[Hg\cdots Pt\cdots Hg]^{2+}$ require us to acknowledge that neighbouring-atom electronic features can both inhibit and promote the oxidative addition process. A similar type of electronic influence appears prevalent in the oxidative addition to dinuclear Au^{I} complexes and probably exists whenever the Goddard–Low concept of oxidative addition can involve both metal atoms in the process. Metal–metal bond formation accompanying the oxidative addition stabilizes intermediates which lead to the formation of products in which the addend adds across the metal–metal bond(s). The promotion of the oxidative addition will depend on the ease of closed-shell to open-shell promotion of the neighbouring atom as well as the atom to which the adduct initially interacts. Such behaviour presumably exists in many systems wherein bimetallic heterogeneous catalysis is more effective than in the monometallic system.

Acknowledgements—The author thanks the large number of students and postdoctorals who have contributed to the studies described in this report. Their names are in the references. Three postdoctoral colleagues stand out for their special contributions, H. H. Murray, III, Suning Wang and Richard J. Staples. The National Science Foundation and The Welch Foundation made our studies possible. The author also thanks the Penguin Foundation for support with a Wilhelm Manchot Research Professorship at the Technical University of Munich and to numerous excellent discussions with Professor Hubert Schmidbaur of that institution and Professor F. A. Cotton and Michael B. Hall of Texas A&M University.

(Received 30 April 1996; accepted 28 May 1996)

Abstract—Hydrated lead(II) dimethylacetate forms hexanuclear units $[Pb_6(O_2CCH(CH_3)_2)_{12}]4H_2O$ in the solid state consisting of a ring of four lead atoms linked by oxygen atoms belonging to chelated carboxylates, with two further lead atoms linked to the ring by bridging carboxylate oxygens. Water molecules are coordinated to four lead atoms. There are pairs of Pb atoms with 7, 6 and 5-fold coordination in the molecular unit. The hexanuclear molecularity is retained in solution but Pb^{207} NMR measurements indicate different 5-coordinate sites are formed. Copyright © 1996 Elsevier Science Ltd

Keywords: lead(II); dimethylacetate; carboxylate; structure; Pb^{207} NMR.

As an aid to synthetic studies of the reactions of lead carboxylates with metal alkoxides in organic solvents [1] we have required a lead carboxylate which is reasonably soluble either in simple alcohols or toluene, preferably in both. Such a compound is lead dimethylacetate which, when isolated in a hydrated form, is readily soluble in a number of common organic solvents including ethanol, both iso- and normal propanols and benzene or toluene. This behaviour contrasts with that of the acetate which is sparingly soluble in alcohols and does not dissolve in benzene or toluene. We present the results of an X-ray structural study of the dimethylacetate compound which has disclosed the existence of hexanuclear molecular units in the solid state rather than the polymeric form of the acetate and other characterized lead carboxylates [2].

EXPERIMENTAL

Molecular weights were obtained using a Knauer Type II vapour phase osomometer (VPO) in benzene solution at 60°C using benzil as standard. Pb^{207} NMR measurements were performed on a Bruker AM-300 instrument. Chemical shifts were measured in ppm with $PbMe_4$ as an external standard for Pb^{207} NMR spectra. The latter measurements were converted to values relative to $Pb(NO_3)_2$ by adding 2961 [3]. Microanalysis was by CMAS (Melbourne).

Lead dimethylacetate hydrate

Dimethylacetic acid (Me_2CHCO_2H) (2.32 cm^3, 24.9 mmol) was dissolved in toluene (20 cm^3) and yellow PbO (2.78 g, 12.5 mmol) added to the solution. The mixture was refluxed until all but a trace of the solid had dissolved. The solution was filtered hot and crystals formed as the filtrate cooled. The solid was filtered and dried by pumping under reduced pressure (10^{-2} Torr). Yield: 95%. M.pt. 96–97°C. Found: C, 24.6; H, 4.1. Calc. for $C_{48}H_{92}O_{28}Pb_6$: C, 24.4; H, 3.9%. Mol. wt. (VPO) (benzene, 60°C) 2400 ± 50 (theor. for $C_{48}H_{92}O_{28}Pb_6$, 2360). Pb^{207} NMR spectrum (toluene) 300 K: δ = 1667, 2170, 2661, 2709 ppm.

Crystallographic study of $[Pb(O_2CCH(CH_3)_2)_2]_6 \cdot 4H_2O$

A sample of the compound was recrystallized from toluene and a representative clear tabular crystal from the batch of approximate dimensions 0.25 ×

Table 1. Crystallographic data for $[Pb_6(O_2CCH(CH_3)_2)_{12}]4H_2O$

Compound	$C_{48}H_{92}O_{28}Pb_6$
Formula weight	2360
Crystal system	Monoclinic
Space group	$P2_1/n$
a (Å)	12.770(4)
b (Å)	20.479(6)
c (Å)	14.407(5)
α (°)	90
β (°)	110.82(3)
γ (°)	90
V (Å^3)	3522(2)
Density calc. (g cm^{-3})	2.23
Z	2
T (°C)	−80(1)
λ (Mo-K_α) (Å)	0.71073
μ (Mo-K_α) (mm^{-1})	14.47
F(000)	2192
Scan mode	w, 1.40° range
2θ range (°)	3.5–55.0
Scan rate (° min^{-1})	2.49–10.19
Data collected	8007
Data used [$F \geqslant 6s(F)$]	3477
$R(wR)$	0.071 (0.092)

0.24×0.15 mm was used for data collection. Intensity measurements were made on a Nicolet R3m/V diffractometer using graphite monochromated Mo-K_α radiation. Relevant crystallographic data are collected in Table 1. Three standard reflections monitored every 197 reflections showed no significant variation in intensity over the data collection period. Intensity data were corrected for Lorentz and polarization effects. A face indexed numerical absorption correction was applied on seven crystal faces, the maximum and minimum transmission factors being 0.040 and 0.153 respectively. Atomic scattering factors for neutral atoms were taken from literature values [4] and corrected for anomalous dispersion. All calculations were performed on a MicroVAX 2000 computer. The program for least squares refinement was that of Sheldrick [5]. The structure was solved by conventional Patterson and Fourier methods. Final refinement was by full matrix least squares employing anisotropic thermal parameters for Pb and isotropic thermal parameters for all other non-hydrogen atoms. Hydrogen atoms were positioned in geometrically idealized positions (C—H 0.96 Å) and given a single isotropic thermal parameter, fixed at 0.08 Å^2. At convergence (190 variables, 3477 observed data) R was 0.071 and wR, 0.092, where $wR = \Sigma(|F_o - F_c|)w^{1/2}/\Sigma|F_o|w^{1/2}$ and $w = [s^2(F_o) + 0.0084F_o^2]^{-1}$. The goodness-of-fit value $(\Sigma w(|F_o| - |F_c|)^2/(N_{observns} - N_{params})]^{1/2}$ was 0.87. The highest peak in the difference-Fourier synthesis was 4.6 e Å^{-3}.

RESULTS AND DISCUSSION

Properties of lead dimethylacetate

The reaction between PbO and dimethylacetate acid in undried toluene proved to be a convenient method of synthesis for the lead salt. The compound was isolated as a hydrate readily soluble in toluene and a variety of other solvents. Its molecular weight in benzene, determined by vapour phase osmometry, indicated a considerable degree of association corresponding to the presence of hexanuclear species. Its Pb^{207} NMR spectrum showed four resonances, two having equivalent intensities at 1667 and 2170 ppm and a further two of approximately half the intensity of the first two were observed close together at 2661 and 2709 ppm.

The structure of $[Pb(O_2CCH(CH_3)_2)_2]_6 \cdot 4H_2O$

Previous X-ray crystal studies of lead carboxylates have shown them to be polymeric because of carboxylate bridging. The carboxylate group may bridge between two metal atoms with an oxygen bonded to each as in the sparingly water soluble, anhydrous lead(II) formate [2] which has a three dimensional structure solely defined by such non-chelating, carboxylate bridges. Alternatively the group can be a chelating ligand to one metal atom and may also bridge through one or both of its oxygen atoms to neighbouring metal atoms. This mode of coordination is found in lead(II) acetate trihydrate [2, 6, 7] and the pentafluorobenzoate [2]. Both carboxylate groups are chelated to each lead atom in these compounds while one or both carboxylate groups are further coordinated to neighbouring lead atoms through carboxylato oxygen leading to chain structures for these species. Water molecules are also coordinated to each lead in the case of the acetate and contribute to the chain formation by hydrogen bonding contacts. A chain structure has also been observed for the crotonate [8] while in addition to single and bridging chelated groups, hydrogen bonding between carboxyl and hydroxyl groups causes a three dimensional structure to be formed by the glycollate [9]. Such structural features no doubt contribute to the low solubility of lead carboxylates in weakly solvating solvents such as alcohols and their general insolubility in non-polar solvents.

In hydrated lead(II) dimethylacetate, each lead atom is chelated by two carboxylate groups, at least one of which is coordinated to a neighbouring Pb atom. This basic "building block" format is similar to that leading to the polymeric structures of the acetate, pentafluorobenzoate and crotonate. However it is likely that the bulkiness of the $CH(CH_3)_2$ group prevents an infinite chain structure being formed and leads to the form of the present compound. Crystals of hydrated lead dimethylacetate contain hexanuclear

units consisting of a ring of four Pb atoms linked by single oxygen bridges from chelated carboxyls with a further two "terminal" lead atoms each linked to a ring-lead atom by two oxygen bridges derived from their chelated carboxyl groups (Fig. 1). Indeed the structure can be alternatively viewed as forming by the dimerization of two short Pb_3 chains. There are chelating, "non-bridging" carboxylate groups attached to each of the terminal and two of the ring Pb atoms. The Pb—O distances show marked asymmetry in the "non bridging" chelated carboxylates attached to the terminal Pb atoms (Pb(1)—O(1) 2.710 Å, Pb(1)—O(2) 2.368 Å) whereas there is virtually symmetric bonding of the analogous "non bridging" carboxylate groups to Pb atoms in the ring (Pb(3)—O(11) 2.510 Å, Pb(3)—O(12) 2.507 Å).

Single water molecules are coordinated to the two "terminal" Pb atoms and the ring Pb atoms to which they are bridged. These variations in coordination behaviour lead to the existence of three, differently coordinated Pb atoms in the hexanuclear units. Using an arbitrary length of approximately 2.8 Å to define maximum bonding interactions (this being the sum of the two ionic radii [10]), data in Table 2 show that Pb(1) may be considered as 6-coordinate, Pb(2) 7-coordinate and Pb(3) 5-coordinate. This contrasts with the Pb atoms in the acetate, formate and pentafluorobenzoate where 8-fold coordination is found. Longer range contacts between Pb(3) and O(10) at 2.832(20) Å and the inter-molecular contact with O(3) at 2.899(2) Å may contribute further bonding interactions, increasing local coordination numbers to 6 or 7.

The molecule in solution

The molecular weight data shows that the hexanuclear structure of the compound is essentially retained in benzene solution. However four sharp Pb^{207} resonances are observed with two well spaced chemical shifts of 1167, 2170, and two close together at 2661 and 2709 ppm instead of the three expected on the basis of the crystal structure. The peaks are in the ratio 2 : 2 : 1 : 1. There is relatively little information at present correlating chemical shift with coordination number among metal-organic lead(II) compounds, nevertheless some conclusions can be drawn from existing data. Table 3 lists Pb^{207} chemical shifts for compounds whose solid state structures have been determined or for which a comparable derivative has been studied and for which solution molecular weight measurements have indicated that the solid state molecularity has at least been retained. Coordination number 4 appears associated with shifts in the range 4152–5032 ppm while 5-coordinate compounds show values in the range 2558–3883 ppm. In this connection, the compound $[Pb_2Ti_2(\mu\text{-}O)(OAc)_2(OPr^i)_8]$, which has been shown by structural analysis to contain both 4 and 5-coordinate Pb in the crystal [14] has been found by us [1] to show two Pb^{207}

[c] Coordination No. 5 based on structures of compounds listed below.

resonances* both considerably moved upfield from the 4–5000 ppm range suggested to indicate 4-coordinate Pb(II) and being within or close to the range indicated for other 5-coordinate Pb compounds. This suggests the possibility that in solution the Pb/Ti compound undergoes a structural readjustment such that each Pb atom becomes 5-coordinate.

There do not appear to be other appropriate compounds with X-ray structurally defined 6 or 7 coordination for Pb^{II} for which Pb^{207} NMR data are also available to be used for comparison. However, one may conclude that increased coordination around a Pb atom will lead to increased shielding, resulting in an upfield shift of the corresponding Pb^{207} resonance. Therefore it can be anticipated that Pb atoms with coordination numbers of 6 and higher should display chemical shifts at successively higher fields than for 4 and 5-coordinate compounds. Thus in the case of Pb dimethylacetate, the resonance at 1667 ppm is assigned to the 7-coordinate Pb(2) and (2a) atoms and that at 2170 ppm to the 6-coordiate atoms Pb(1) and (1a). The remaining resonances, found close together at 2661 and 2709 ppm, are within the range for 5-coordinate Pb^{II} as defined above. The crystal structure data do not show any obvious differences between the ligand arrangements or Pb—O bond lengths at the 5-coordinate Pb(3) and Pb(3a) sites which could lead to different Pb^{207} resonances being observed for the two atoms. It can only be concluded therefore that some relaxation of the coordination arrangements existing in the crystal at Pb(3) and Pb(3a) occurs in solution, such as the lengthening of one or more Pb—O bonds, which allows the essential 5-coordinate form to be retained but causes a distinct structural difference to exist between the sites.

* An earlier report [14] mentioned only a single resonance at 3016 ppm with the comment that the molecule is fluxional.

(Received 17 April 1996; accepted 28 May 1996)

Abstract—Polymeric silver(I) cyanoacetate contains the classical bis(carboxylato-*O*,*O*′) bridged metal dimer arrays in which each pair of adjacent metal atoms is doubly bridged by co-planar carboxylate groups in the *syn-syn* conformation. These dimeric units are extended into a polymeric chain by terminal linkage of all cyano-nitrogen atoms to silver atoms of adjacent dimer units. In this manner, an individual cyanoacetate anion is *O*,*O*′,*N*-bonded to three different silver centres. EHMO calculations suggest weak direct metal–metal interactions can result from the mixing of metal *s* and *p* orbitals into the d^{10} shells. Reactions of silver(I) or sodium cyanoacetates with $[(\eta\text{-}C_5H_5)_2TiCl_2]$ afford the bis(cyanoacetato) complex $[(\eta\text{-}C_5H_5)_2Ti(O_2CCH_2CN)_2]$ which has a solid state structure involving *O*-unidentate carboxylate groups, the cyano-nitrogen atoms not being bonded to a metal. This compound can also be prepared from $[(\eta\text{-}C_5H_5)_2Ti(CH_3)_2]$ and cyanoacetic acid.

Keywords: carboxylate; cyanoacetate; cyclopentadienyl; silver; structure; titanium.

Although metal carboxylates are probably the most important and ubiquitous group of compounds with metal–oxygen–carbon bonds, few metal cyanoacetates have been investigated, particularly from a structural standpoint. The small number that have been studied show sufficient structural differences to suggest a rich variety of potential coordination modes in further examples. Thus both *O*-unidentate and *O*,*O*′;*O*-chelating and bridging cyanoacetate ligands are found [1] in $\{[Nd(O_2CCH_2CN)_3(DMF)(H_2O)]\cdot H_2O\}_n$ whereas in $[Fe_3(\mu_3\text{-}O)(O_2CCH_2CN)_6(H_2O)_3]$ the cyanoacetate groups are all *O*,*O*′-bridging bidentate [2]. Cadmium cyanoacetate contains [3] equal numbers of *O*,*O*′;*O*-bridging bidentate and *O*,*O*′;*N*-bridging tridentate cyanoacetate ligands. Finally, the copper(I) compounds $[Cu(O_2CCH_2CN)(PCy_3)_2]$, $[Cu(O_2CCH_2CN)(PPh_3)_2]_2$ and $[Cu(O_2CCH_2CN)_2H(PPh_3)_2]$ involve *O*-unidentate, *O*,*N*-bridging bidentate and, remarkably, *N*-unidentate cyanoacetate groups, respectively [4, 5]. In the light of these established coordination motifs, we have determined the structure of silver(I) cyanoacetate, this example being chosen because of the current interest [6] by several research groups in the structural chemistry of silver(I) carboxylates as a class of compounds.

Although a few silver(I) carboxylates, e.g. the 2,4-dichlorophenoxyacetate [7], contain mononuclear silver(I) units extended into oligomeric or polymeric structures by bridging carboxylate ligands, the basic unit found in the majority of silver(I) carboxylates is that of a bis(carboxylato-*O*,*O*′)disilver(I) dimer. Compounds containing this unit have been sub-divided [8], into four major types, A–D. Using this categorisation, the structure of the previously unreported cyanoacetate is shown here to be a new example of type B. It has also been used to synthesise $[(\eta\text{-}C_5H_5)_2Ti(O_2CCH_2CN)_2]$, the structure of which shows it to be a metal cyanoacetate containing solely unidentate *O*-cyanoacetato ligands.

EXPERIMENTAL

Unless otherwise stated, all reactions and operations were carried out under dry nitrogen gas.

* Author to whom correspondence should be addressed.

Cyanoacetic acid and bis(η-cyclopentadienyl) titanium dichloride (Aldrich Chemicals Co.) were used without further purification. Bis(η-cyclopentadienyl)dimethyltitanium was prepared from the dichloride and methyllithium in diethyl ether. Tetrahydrofuran and diethyl ether were purified prior to use by distillation over sodium benzophenone. Other solvents were stored over molecular sieves for several days before use. Infrared spectra were recorded on a Nicolet 510P FTIR spectrophotometer as Nujol or hexachlorobutadiene mulls. ^{1}H and ^{13}C NMR spectra were recorded on Jeol JNM GX270 and EX400 spectrometers.

Preparation of silver(I) cyanoacetate

A solution of silver nitrate (1.91 g, 11.3 mmol) in water (10 cm^3) was added dropwise to a stirred solution of cyanoacetic acid (0.96 g, 11.3 mmol) and sodium hydroxide (0.45 g, 11.3 mmol) in water (50 cm^3). After 20 min the resulting white precipitate was filtered, washed with portions of water, ethanol and diethyl ether and dried *in vacuo*, all operations being carried out in subdued light with final storage in the dark. Yield: 1.56 g, 72%. (Found: C, 18.8; H, 1.0; N, 7.4. $C_3H_2AgNO_2$ requires C, 18.8; H, 1.0; N, 7.3%). IR: 2953 m, 2923 m [ν(CH$_2$)]; 2269 m, [ν(CN)]; 1608 sh, 1566 s, [ν_{asym}(CO$_2$)]; 1456 s, 1400 s, [ν_{sym}(CO$_2$)]; 1366 m, [CH$_2$ scissors]; 1273 ms, [CH$_2$ wag]; 1208 mw, [CH$_2$ twist]; 963 m, [CH$_2$ rock]; 928 m, [ν(C—CN)]; 912 w, [ν(CC)]; 721 m, br [CO$_2$ scissors] cm^{-1}. ^{1}H NMR (D_2O, 270 MHz), δ 3.47 (s, CH$_2$); ^{13}C NMR (D_2O, 67.8 MHz), δ 169.3 (CO$_2$), 117.5 (CN), 26.0 (CH$_2$).

The crystal used in the structure determination was selected from a crop grown from the filtrate of the above reaction after storage in the absence of light for two months.

Preparation of bis(cyanoacetato)bis(η-cyclopentadienyl)titanium(IV)

Method A. Bis(η-cyclopentadienyl)titanium dichloride (0.50 g, 2.0 mmol) and sodium cyanoacetate (0.56 g, 5.2 mmol) were placed in a flame-dried flask fitted with a reflux condenser and stirrer and freshly distilled tetrahydrofuran (25 cm^3) added. The solvent was refluxed under nitrogen for 1 h after which time the orange solution produced was cooled, filtered and evaporated to dryness to give a bright orange solid. Yield: 0.46 g, 66%.

Blood-red octrahedra suitable for single crystal X-ray crystallography were obtained by slow evaporation of a chloroform solution under nitrogen. (Found: C, 55.4; H, 4.0; N, 8.0. $C_{16}H_{14}N_2O_4Ti$ requires C, 55.5; H, 4.1; N, 8.1%). IR: 2255 m, [ν(CN)]; 1666 vs, [ν_{asym}(CO$_2$)]; 1308 vs, [ν_{sym}(CO$_2$)]; C_5H_5 vibrations at 3110, 3098, 1447, 1019 and 826 cm^{-1}. ^{1}H NMR ($CDCl_3$, 270 MHz), δ 3.47 (s, 4H, CH$_2$); 6.63 (s, 10H, C_5H_5); ^{13}C, δ 26.9 (CH$_2$); 115.2 (CN); 119.4 (C_5H_5); 167.2 (CO$_2$).

Method B. Bis(η-cyclopentadienyl)titanium dichloride (0.50 g, 2.0 mmol) was dissolved in degassed water (40 cm^3) by stirring for 2 h. A solution of sodium cyanoacetate (1.00 g, 9.3 mmol) in water (10 cm^3) was then added and stirring continued for a further hour at room temperature. The product was obtained by extraction from the aqueous phase using three 50 cm^3 portions of dichloromethane which were then dried over $MgSO_4$. Slow evaporation of this solution gave, after filtration, red crystals. Yield: 0.53 g, 75%.

Method C. Chloroform (40 cm^3) was added to a mixture of bis(η-cyclopentadienyl)titanium dichloride (0.50 g, 2.0 mmol) and silver cyanoacetate (1.15 g, 6.0 mmol) and the reactants stirred in the dark for 1 h at room temperature. Filtration to remove silver chloride followed by evaporation of the orange chloroform solution produced a red crystalline solid. Yield: 0.56 g, 81%.

Method D. A solution of bis(η-cyclopentadienyl)dimethyltitanium (50 mg, 0.24 mmol) in freshly distilled tetrahydrofuran (3 cm^3) was added with stirring to a solution of cyanoacetic acid (41 mg, 0.48 mmol) in tetrahydrofuran (2 cm^3). Methane was evolved and the solution darkened from a pale to a deep orange colour. Evaporation of the solvent *in vacuo* gave a bright red crystalline solid. Yield: 69 mg, 83%.

Products from methods B–D gave good C, H and N analyses and identical NMR spectra to those given above in Method A.

X-ray crystallography

Crystal data, data collection and refinement details for both compounds are given in Table 1 and selected bond lengths and angles in Tables 2 and 3. Additional material for each structure is available from the Cambridge Crystallographic Data Centre and comprises final fractional atomic coordinates, thermal parameters, hydrogen atom coordinates and further bond lengths and angles. The asymmetric unit of silver cyanoacetate produced using ORTEX [9] is shown in Fig. 1 along with the labelling scheme, the polymeric arrangement being depicted in Fig. 2. The asymmetric unit of the titanium compound is shown in Fig. 4.

Data were collected at room temperature on a CAD-4 automatic four-circle diffractometer using Mo-K_α radiation. The diffraction intensities were corrected for Lorentz and polarisation effects but not for absorption. The silver structure was solved by direct methods [10,11], using SHELX86 and refined using SHELX93. The titanium structure was solved [12] by Patterson methods, and refined using SHELX76. In the final least squares cycles all atoms were allowed to vibrate anisotropically. In the silver structure hydrogen atoms were included at calculated positions where relevant, whereas in the titanium structure hydrogens were included at calculated positions on the cyclo-

imental) in D_2O and the infrared data are in accord with the structure determined by X-ray diffraction. For example, the differences of 150–160 cm^{-1} between the infrared symmetric and asymmetric CO_2 stretches are in accord with the *syn–syn* bridging mode of the carboxylate ligands.

The type B structure [8] of silver(I) cyanoacetate (Fig. 2) is that of an infinite sheet polymer based on a bis(carboxylato-*O*,*O'*) bridged Ag_2L_2 dimer with an Ag–Ag distance of 2.894(1) Å. This distance, which is exactly that found in the metal itself, is very similar to the Ag–Ag bond length in other silver carboxylate structures based on dimeric units (range from 2.778 Å in the 3-hydroxy-4-phenyl-2,2,3-trimethylcyclohexanecarboxylate [17] to 3.005 Å in the maleate [6a]). Distances in this range have often been regarded

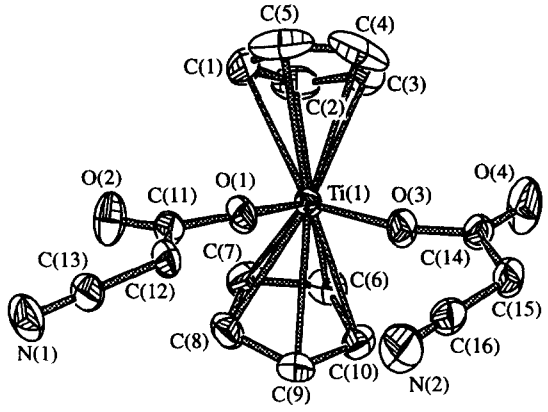

Fig. 4. The asymmetric unit of bis(cyanoacetato)bis(cyclopentadienyl)titanium(IV) with atom labelling. Thermal ellipsoids are represented at the 30% probability level.

as indicative of direct metal–metal interaction [8]. However, others have taken the view that short metal–metal distances in dimers of this type do not necessarily imply bonding [18]. This facet is explored later.

Within the eight-membered centrosymmetric dimers, the silver atoms are bridged by co-planar carboxylato-*O,O'* ligands in the *syn–syn* conformation. The Ag—O distances [2.187(4), 2.198(5) Å] and O—Ag—O angle, 162.6(2)° are comparable to those of other dimeric silver carboxylates (Ag—O distances range from 2.158(3) Å [19] to 2.387(3) Å [6a] and O—Ag—O angles from 155.8(1)° [8] to the exceptional 171.8(1)° [19]). The dimers are extended into a polymeric sheet-like structure (Fig. 2) by the formation of silver-cyano nitrogen bonds positioned axially with respect to the Ag_2 units. As a result, each eight-membered Ag_2L_2 ring is adjoined to a twelve-membered $AgOCCH_2CNAgOCCH_2CN$ ring with Ag—N distances of 2.370(6) Å. Although the C—C—N angle of the cyanomethyl moiety is close to 180° [177.3(6)°], the C—N—Ag angle shows a considerable departure from linearity [154.4(5)°]. This non-linearity is also apparent in the structures of $[Cd(O_2CCH_2CN)_2]$ [3], [C—N—Cd, 164.3(5)° where the cyanoacetate groups are *N*-bonded in addition to *O,O'*-chelated to cadmium atoms], in $[Cu(O_2CCH_2CN)_2H(PPh_3)_2]$ [5] with a C—N—Cu angle of 153.3(3)° and in $[Cu(O_2CCH_2CN)(PPh_3)_2]_2$ [4] with a C—N—Cu angle of 162.0(4)°.

As a result, the silver atoms in the compound are coordinated by two carboxylato-oxygen atoms and a cyano-nitrogen atom in a T-shaped array [O—Ag—N, 99.6(2), 97.7(2)°] thus rendering a tridentate cyanoacetate. If an additional bond is considered between Ag(1) and Ag(1a), (related by the operator $-x, 1-y, -z$), then the coordination at each metal can be regarded as distorted square planar [Ag—Ag—O, 81.94(14), 80.97(13)°]. The supramolecular packing arrangement is such that the separations between successive infinite polymer sheets precludes any significant inter-sheet associations, e.g. the shortest Ag · · · Ag distance (generated by the operator $-x+1, -y+1, -z$) is 3.273(1)Å.

Within the individual *O,O'*-bridging carboxylate groups, the C—O, C—CH_2, C—CN and C—N bond lengths and related angles are very much in accord with those previously reported for $[Fe_3(\mu_3\text{-}O)(O_2CCH_2CN)_6(H_2O)_3]$ [2] and $[Cd(O_2CCH_2CN)_2]$ [3]. The C≡N cyano-bond length, 1.157(10) Å, is slightly longer than that in the iron trimer [2] where there is no *N*-donation to a further metal. In the cadmium salt [3] there is little apparent difference between *N*-bonded and free cyano bond lengths at 1.139(9) and 1.132(10) Å, respectively.

Returning to the question of direct metal–metal bonding in the silver cyanoacetate, we have examined the molecule using an EHMO approach, the aims being to estimate the Ag—Ag bond strength and to evaluate the effect that the ligand set has on such a bond. The approach closely follows that used previously by Hoffmann [16] when investigating d^{10}–d^{10} interactions between copper(I) centres.

A portion of the solid state structure (Fig. 3) having an Ag_2^{2+} core surrounded by four cyanoacetate ligands, two of which were *O,O'*-bonded and two *N*-bonded to Ag with a consequent overall charge of −2, was taken as the basis for the calculations. This portion was treated as two fragments, the Ag_2^{2+} core and the four $NCCH_2CO_2^-$ groups, to allow comparison of any Ag—Ag bonding in an isolated Ag_2^{2+} cation with that in the whole complex. An interaction diagram for an Ag_2^{2+} cation with a separation of 2.894 Å (as found crystallographically), constructed using only the 4*d* orbitals on silver, indicates a repulsive interaction (positive binding energy of +0.019 eV and an overlap population of −0.001 electrons) relative to two isolated Ag^+ centres. However, by including silver 5*s* and 5*p* orbitals in the calculation the interaction becomes more attractive (negative binding energy of −0.163 eV and an overlap population of +0.053 electrons) than two isolated Ag^+ centres. These results bear close similarity with those of Hoffmann [16] for Cu_2^{2+}, who showed that the favourable interaction arose primarily from *s*, p_z and d_{z^2} orbital mixing, resulting in an increase in the bonding character of the σ-orbital and a reduction in the antibonding character of the σ* orbital. Using the parameters obtained from the crystal structure, we have also looked at the effect of the cyanoacetate groups, arranged as in Fig. 3, on the Ag—Ag bond. Introduction of the ligand set generates an enhanced attractive Ag—Ag interaction, the Ag—Ag orbital overlap population increasing from +0.051 electrons to +0.062 electrons. The Ag—N and Ag—O overlap populations of +0.22 and +0.20 electrons are similar to that found for adsorbed atomic oxygen on a silver (110) surface [15].

A more detailed consideration of the gross atomic orbital populations shows that in comparison to the isolated Ag_2^{2+} cation, the *d–d* population in the com-

plex decreases from 9.97 to 9.93 whereas the *s* and *p* populations increase to a greater extent (from 0.026 to 0.422) for the 5*s* and from 0.009 to 0.297 for the 5*p* orbitals, respectively) giving an overall increase in the Ag–Ag orbital overlap population. Introducing the cyanoacetate groups seems to increase *s*, *p* and *d* orbital mixing, enhancing the *s* and *p* orbital contributions to the Ag–Ag interaction relative to the isolated Ag_2^{2+} cation i.e. moving towards a $d^9s^np^{1-n}$ electron configuration. These calculations therefore consolidate the view expressed by others of the existence of a positive Ag–Ag interaction promoting the stabilisation of dinuclear silver(I) carboxylates.

Bis(cyanoacetato)bis(η-cyclopentadienyl)titanium(IV)

This compound has been prepared in good yield from reactions of the dichloride with sodium cyanoacetate in either tetrahydrofuran or water, the dichloride with silver cyanoacetate in chloroform or the dimethyl with cyanoacetic acid in tetrahydrofuran. Infrared bands assigned to the asymmetric and symmetric carboxyl stretches differ in frequency by 358 cm^{-1} indicative of unidentate carboxylate bonding, as confirmed (Fig. 4) by the single-crystal X-ray structure determination. The two non-coordinated oxygen atoms O(2) and O(4) are well beyond possible bonding distances to titanium (3.598 and 3.657 Å). Unidentate carboxylate coordination has been previously established for the bis(η-cyclopentadienyl)titanium(IV) benzoate, (both monoclinic (α) [20] and orthorhombic (β) [21] modifications), the *m*-methoxybenzoate [22], the *o*-methoxybenzoate [23] and the trifluoroacetate [24]. On occasions [25] infrared data have been interpreted as indicating the presence of bidentate chelating carboxylate groups in various bis(η-cyclopentadienyl)titanium(IV) carboxylates but such an arrangement has not been confirmed to date by crystallography.

Consideration of the bond lengths and angles of the two cyanoacetate groups show that differences between them are rather insignificant, a situation quite unlike that of the orthorhombic form of the benzoate [21] and the *m*-methoxybenzoate [22] where the two carboxylate ligands are distinctly different (e.g. benzoate [21]: Ti—O—C angles of 135.2(3) and 168.7(3)°, Ti—O bond lengths of 1.894(4) and 1.995(3) Å and C—O bond lengths of 1.275(5) and 1.300(4) Å; *cf.* cyanoacetate Ti—O—C angles of 147.4(2) and 143.5(2)°, Ti—O bond lengths of 1.966(4) and 1.963(4) Å and C—O bond lengths of 1.284(4) and 1.282(4) Å). For the benzoate, the shorter Ti—O bond lengths and larger Ti—O—C bond angles have been rationalised [21] as indicating the presence of a strong Ti—O π-interaction supplementing the σ-bonding for *one* of the benzoate groups only, this allowing achievement of an effective 18-electron configuration rather than a formal count of 16 valence electrons. Conversely, the monoclinic form of the benzoate [20] and, clearly, the cyanoacetate have near-equivalent carboxylate groups with unexpectedly large Ti—O—C angles (when compared with typical M—O—C angles in unidentate carboxylate complexes) and short Ti—O bond lengths implying the attainment of an effective 18-electron configuration by additional Ti—O π-bonding for *both* carboxylate groups. This proposal is supported by some EHMO calculations of Hoffmann *et al.* [20] on the model compound $[(\eta\text{-}C_5H_5)_2Ti(O_2CH)_2]$.

Bond lengths and angles within the cyanoacetate ligands, Table 3, show the expected features such as C—C—N angles close to 180° and C≡N bond lengths (1.137(5) and 1.140(5) Å) slightly shorter than those of, for example, the silver salt (1.157(10) Å) where the cyano-group is *N*-bonded to a further metal atom. As expected, for unidentate carboxylate coordination there is a significant difference in the C—O bond lengths depending on whether the oxygen atom is coordinated to titanium (1.282(4) and 1.284(4) Å) or not (1.202(4) and 1.195(4) Å).

For the cyclopentadienyl ligands, the average C—C bond length of 1.366(6) Å and the average C—C—C bond angles of 108.0(4)° are in line with values from other $[(\eta\text{-}C_5H_5)_2TiX_2]$ structure determinations ([20] and references therein). The centroids of the cyclopentadienyl ligands, Z, and the two bonded oxygen atoms define a much distorted tetrahedral array around the metal with a Z—Ti—Z angle of 131.5(2)° and an O—Ti—O angle of 89.3(2)°. The distances from the metal atom to the centroids of the cyclopentadienyl rings (Ti—Z) of 2.053 and 2.061 Å and Ti—C bond lengths of between 2.330(5) and 2.391(5) Å (average 2.362 Å) are again in excellent agreement with comparable distances in other bis(η-cyclopentadienyl)titanium(IV) compounds [20].

There are several contacts between cyclopentadienyl carbons on different rings which are less than the van der Waals contact between two aromatic rings of 3.4 Å indicative of crowding around the metal resulting from the presence of ten carbon and two oxygen atoms.

Asymmetric diorganotellurides containing substituted pyridyl groups—synthesis and ligation with palladium(II) and platinum(II). Crystal structure of $[Pd\{4\text{-}MeC_6H_4TeCH_2CH_2\text{-}2\text{-}(C_5H_4N)\}Cl_2]\cdot 2CHCl_3$

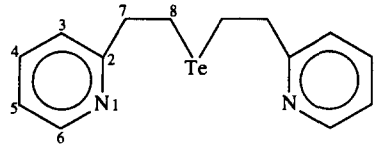
Abu Khalid and Ajai K. Singh*

Department of Chemistry, Indian Institute of Technology, New Delhi-110016, India

(Received 3 April 1996; accepted 20 May 1996)

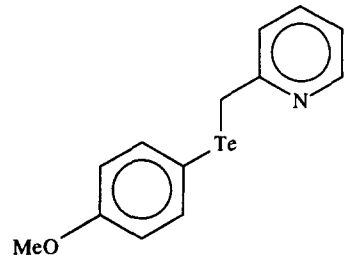
Abstract—A (N,Te,N) ligand 2-(2-pyridoethyletelluro)ethylpyridine (**1**) has been synthesized by reacting *in situ* generated Na_2Te with 2-(2-chloroethyl)pyridine. The Pd^{II} and Pt^{II} complexes of stoichiometry $[MCl\cdot\mathbf{1}]Cl$ have been studied. The deshielding of *ortho* protons of pyridine and CH_2Te signal (up to 0.5 ppm) indicate that **1** ligates in a tridentate mode. The red shift (20–25 cm^{-1}) in ν(Te—C(alkyl)) supports the involvement of Te in coordination. Molecular weights and Λ_M values of these complexes support their ionic nature (1 : 1 electrolyte). The reactions of 2-(chloromethyl)pyridine and 2,6-bis(chloromethyl)pyridine with ArTeNa (Ar = 4-$MeOC_6H_4$) could not produce (N,Te) and (Te,N,Te) ligands comprising pyridyl groups. The $CHCl_3$ present as a solvent in these reactions reacted with ArTeNa resulting in $(ArTe)_2CH_2$. To understand the behaviour of Te donor site *vis-à-vis* pyridyl group the single crystal structure of $Pd\{4\text{-}MeC_6H_4TeCH_2CH_2\text{-}2\text{-}(C_5H_4N)\}Cl_2\cdot 2CHCl_3$ was solved. An *endo*, puckered chelate ring is formed by (N,Te) ligand. The *trans* influence of the pyridyl group appears to be lower or comparable to that of tellurium. Copyright © 1996 Elsevier Science Ltd

Keywords: diorganotelluride; palladium; platinum; synthesis; complexation; structure.



The ligation of asymmetric diorganotellurides has received attention in the recent past [1,2]. Some neutral ligands having "hard" donor centres *viz.*, N and O along with "soft" donor tellurium have been synthesized and explored for their ligation behaviour. Most of the ligands containing Te and N atom as donor atoms [3] have amino nitrogen. A few ligands having a donor set of pyridine nitrogen and tellurium have also been studied [4–6]. Since the pyridine nitrogen has good coordinating capability, it was thought worthwhile to design new hybrid telluroether ligands containing pyridine nitrogen as a donor. In the present paper the synthesis of a (N,Te,N) ligand, its complexation with Pd^{II} and Pt^{II}, the results of attempted synthesis of **2** and **3** and as a consequence of these attempts the resulted novel synthesis of $(ArTe)_2CH_2$ and crystal structure of palladium(II) complex of **4** are reported.

EXPERIMENTAL



The synthesis of $(4\text{-}MeOC_6H_4)_2Te_2$ [7] and the ligand **4** [6] were carried out by published methods. 2-(2-Chloroethyl)pyridine, 2-(chloromethyl)pyridine and 2,6-bis(chloromethyl)pyridine were synthesized by chlorination [8] of the corresponding alcohols.

IR spectra in the range 200–4000 cm^{-1} were recorded on a Nicolet 5DX FT-IR spectrometer in KBr/CsI pellets and far-IR spectra in the range 30–700 cm^{-1} were recorded in polyethylene on a Perkin-Elmer 1700X FT-IR spectrometer. ^1H and $^{13}C\{^1H\}$ NMR spectra were recorded on a JEOL FX100 FT-NMR spectrometer at 99.5 and 25 MHz respectively using Me_4Si as an internal standard. UV-visible spectrophotometer of Hitachi model 330 was used to rec-

ord electronic spectra. Conductance measurements were made on *ca* 1 mM solution using the Metrohm 660 conductometer and molecular weights were determined using a Knauer vapour pressure osmometer. Elemental analyses were performed on a Perkin-Elmer elemental analyzer 240C. $^{125}Te\{^1H\}$ NMR spectra were recorded at 126 MHz (using $(CH_3)_2Te$ as an external standard) on a Bruker AMX-400 FT-NMR spectrometer.

Single crystal structure of $[PdCl_2 \cdot 4]$

The X-ray diffraction data of crystals of $[PdCl_2 \cdot 4]$ grown from chloroform solution were collected on an Enraf-Nonius CAD-4 diffractometer using nickel filtered Cu-K_α radiation ($\lambda = 1.518$ Å). The intensities were measured at azimuth position corresponding to minimum absorption using an imaginary crystal with infinitely small thickness but infinitely large surface area (flat psi mode). The ω-2θ scan mode was used. The $2\theta_{max}$ was 152° and h, k, l ranges were 0 to +10, −9 to +9 and −11 to +11, respectively. Of the 3594 reflections collected, 3357 were unique and out of which 3069 were with $I \geqslant 3\sigma$. The intensities were corrected for Lorentz and polarization effects. The semi-empirical absorption corrections were also applied.

The initial coordinates of Pd, Pt and Te were determined using SHELXS 86 [9(a)]. The remaining atoms were located from successive difference Fourier maps. The refinement was carried out by full-matrix least-squares procedures using SHELX 76 [9(b)] for positional parameters and initially isotropic and finally anisotropic temperature factors for all the non-hydrogen atoms. The atomic scattering factors were taken from the literature [10]. All the calculations were performed on a Microvax II computer using SDF plus V.30 system of crystallographic program. The crystallographic data are given in Table 1.

Synthesis of 2-(2-*pyridoethyltelluro*)*ethylpyridine*(**1**)

Tellurium powder (2 g, 16 mmol) and sodium borohydride (5 g dissolved in 10 cm^3 of 10% NaOH) were refluxed in water (50 cm^3) till a colourless solution of Na_2Te was obtained. 2-(2-Chloroethyl) pyridine (4.2 g, 32 mmol) dissolved in 5 cm^3 of ethanol was added drop-wise to the solution of Na_2Te and the mixture was refluxed for 2 h with vigorous stirring. The ligand thus formed was extracted into chloroform (250 cm^3). The extract was washed with water and dried over anhydrous sodium sulfate. On removing chloroform under reduced pressure the red liquid was obtained. Yield: 91%, b.p. 134°C. Mol. wt.: Found (Calc.): 320 (307). Analyses: Found (Calc.): Te, 40.9(41.6)% NMR (^1H, $CDCl_3$, 25°C) δ: 3.3(t, 4H, H_7+H_8) 7.39(m, 4H, H_3+H_5), 7.58 (m, 2H, H_4), 8.55 (d, 2H, H_6); ($^{13}C\{^1H\}$, $CDCl_3$, 25°C) δ: 2.2(C_8), 40.3(C_7), 120.2(C_3), 122.3(C_5), 135.6(C_4), 136.5(C_2), 148.2(C_6); ($^{125}Te\{^1H\}$ $CDCl_3$, 25°C) δ: 167. IR (cm^{-1}): 495 [ν(Te—C (alkyl))], 408 (δ(N—C)).

Synthesis of [PdCl · **1**]Cl *and* [PtCl · **1**]Cl

Potassium tetrachloropalladate(II) or platinate(II) (0.15 or 0.20 g, 0.5 mmol) was dissolved in 5 cm^3 of water. A solution of ligand **1** (0.17 g, 0.5 mmol) in 5 cm^3 of acetone was added to it with rapid stirring at room temperature. The stirring was continued further for 15 min. The precipitate was filtered immediately, washed with water and hexane successively and dried *in vacuo*. The results of elemental analyses and spectral data are given below.

[PdCl · **1**]Cl: Yield: 68.5%. Mol. wt.: Found (Calc.): 270(517), m.p. 100°C (d). Analyses: Found (Calc.): C, 32.9 (33.5); H, 3.2 (3.1); N, 5.1 (5.5)%. NMR(^1H, $CDCl_3$, 25°C) δ: 3.33–3.91(m, 8H, H_7+H_8), 7.42–7.72 (m, 6H, $H_3+H_4+H_5$), 8.88 (d, 2H, H_6). IR(cm^{-1}): 469[ν(Te—C(alkyl)], 424 (δ(C—N), 295(ν(Pd—Cl)).

[PtCl · **1**]Cl: Yield: 82%. Mol. wt.: Found (Calc.) 320(606), m.p. 112°C (d). Analyses: Found (Calc.): C, 27.5 (27.7); H, 2.5 (2.6); N, 4.7 (4.6)%. NMR(^1H, $CDCl_3$, 25°C)δ, 3.09–3.58(m, 8H, H_7+H_8), 7.42–7.72(m, 6H, $H_3+H_4+H_5$) 9.05(d, 2H, H_6); ($^{125}Te\{^1H\}$, DMSO-d_6: 25°C) δ 515. IR (cm^{-1}): 474[ν(Te—C(alkyl))], 425 (δ(C—N)), 335(ν (Pt—Cl)).

Synthesis of **2** and **3**

The sodium 4-metoxyphenyltellurolate was reacted with 2-(chloromethyl)/2,6-bis(dichloromethyl)pyridine by the procedure described for the synthesis of **4** earlier [6]. However, in both the cases ditelluride was recovered. On carrying out the reactions in the presence of $CHCl_3$ bis(4-methoxyphenyltelluro) methane resulted. The reaction of chloroform with [NaTeAr] separately also resulted in the same product. The synthesis procedure is given below:

Synthesis of bis(4-*methoxyphenyltelluro*)*methane*

The solution of sodium 4-methoxyphenyltellurolate generated *in situ* by borohydride reduction of bis(4-methoxyphenyl)ditelluride (1.88 g, 4 mmol in 50 cm^3 of ethanol), was mixed with chloroform (5 cm^3, 10 mmol) in one lot, under refluxing condition. The reaction mixture was further refluxed for 30 min. On cooling to 0°C, crystals separated out which were washed successively with water, ethanol and hexane and dried *in vacuo*. Yield: 85%, m.p. 98°C (lit. value 99–102°C) [16]. Found (Calc.): C, 37.1(37.2); H, 3.3(3.3)%.

Synthesis of [$PdCl_2$ · 4]

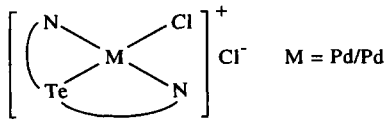
Potassium tetrachloropalladate (0.15 g, 0.5 mmol) was dissolved in 7 cm^3 of water. A solution of **4** (0.5 mmol) made in 5 cm^3 of methanol was added dropwise to palladium(II) solution with stirring at room temperature. The mixture was further stirred at room temperature for 1 h. The resulting orange precipitate was filtered, washed twice with water and diethyl ether and recrystallized from chloroform. Yield: 72%, m.p. 118°C(d), Mol. wt.: Found (Calc.): 510(502). Analyses: Found (Calc.): C, 33.0(33.5) H, 3.1(3.0); N, 2.9(2.8)%. NMR (^1H, DMSO-d_6, 25°C)δ: 2.31–4.20 (m, 7H, $H_7+H_8+CH_3$), 6.94–7.78(m, 8H, Ar + pyridine protons) 9.00 (d, 1H, H_6). IR (cm^{-1}): 460 [ν(Te—C(alkyl))], 424(δ(C—N)), 329, 295 (ν(Pd—Cl)).

RESULTS AND DISCUSSION

The ligand **1** has been synthesized by the reaction of eq. 1. The synthesis

$$Te \xrightarrow{NaBH_4} Na_2Te + 2ClCH_2CH_2 2\text{-}(C_5H_4N) \qquad (1)$$

of **2** and **3** by reacting the appropriate halide with [4-$MeOC_6H_4TeNa$] did not succeed. On attempting the reaction by taking [ArTeNa] in aqueous phase and 2-(chloromethyl)/2,6-bis(dichloromethyl)pyridine in chloroform the product was bis(4-methoxyphenyltelluro)methane. On reacting chloroform separately with the tellurolate in the presence of base $NaBH_4$, bis(4-methoxyphenyltelluro)methane was formed in good yield (>80%) which is the highest compared to other synthetic routs reported earlier [11–16]. Moreover, the chloroform based present synthetic route is less time-consuming and free from the requirements of special techniques. The most plausible mechanism of the synthesis of $(4\text{-}MeOC_6H_4Te)_2CH_2$ from $CHCl_3$ seems to be the following (eq. (2)),



$$CHCl_3 \xrightarrow{OH^-} CCl_3^- \rightarrow :CCl_2 \xrightarrow{ArTe^-}$$

$$(ArTe)_2C: \xrightarrow{BH_4^-} (ArTe)_2CH^- \xrightarrow[solvent]{H^+} (ArTe)_2CH_2. \quad (2)$$

The **1** and its Pd^{II} and Pt^{II} complexes have been authenticated by elemental analyses and spectral data given in the experimental section.

The ^1H NMR spectrum of **1** shows multiplets for H_7 and H_8 rather than two triplets as observed in the spectrum of its precursor 2-(2-chloroethyl)pyridine at 3.9 and 3.2 ppm respectively. The upfield shift (0.7 ppm) of H_8 in the spectrum of ligand **1** with respect to its precursor may be due to replacement of chlorine atoms by the less electronegative tellurium. This shielding of H_8 results in its merger with the H_7 signals. The signal due to H_6 appears downfield as compared to other ring protons of pyridine because the electronegative nitrogen deshields the *ortho* carbon and hydrogen linked to it. The assignments of H_4, H_3 and H_5 protons in ^1H NMR spectrum of **1** are in agreement with those of alkyl pyridines.[17].

The molecular weights of [PdCl·**1**]Cl and [PtCl·**1**]Cl indicate that in solution they behave as a 1 : 1 electrolyte, which is supported by their Λ_M values (135 and 129 ohm^{-1} cm^2 mol^{-1}, respectively). The comparison of ^1H NMR spectrum of **1** with those of [PdCl·**1**]Cl and [PtCl·**1**]Cl reveals that signal of H_6 (proton *ortho* to pyridine nitrogen) undergoes deshielding (0.33/0.50 ppm) and signals having contribution from H_8 are also affected similarly. This indicates that **1** acts as a tridentate ligand coordinating with Pd and Pt in these complexes through Te and two pyridine nitrogen atoms. In the $^{125}Te\{^1H\}$ NMR spectrum of **1** the lone signal was observed at 167 ppm which is in agreement with the ^{125}Te NMR signals of other dialkyl tellurides [15]. The ^{125}Te NMR, spectrum of [PtCl·**1**]Cl shows a signal highly deshielded with respect to that of **1** (even after taking into account the solvent effect) which indicates that in this complex **1** ligates through tellurium. The coupling satellites were not observed due to the low solubility of the complex. The red shifted (20–25 cm^{-1}) ν(Te—C(alkyl)) appearing in the IR spectra of Pd/Pt complexes with respect to that of **1** further supports the ligation of **1** through tellurium. The electronic spectra of both the complexes exhibit three bands around 25, 30 and 42 kK. The first one of these bands seems to arise from $^1A_{ig} \rightarrow {}^1B_{ig}$ transition of complexed Pd/Pt having square planar coordination geometry. The other two bands seem to originate from intraligand transitions. Thus the following structure seems to be most plausible for both the complexes.

M = Pd/Pd

Neither [PdCl·**1**]Cl nor [PtCl·**1**]Cl gave crystals suitable for X-ray diffraction, therefore to understand the Pd—Te bond in conjunction with the Pd—N(pyridine) bond the crystal structure of [$PdCl_2$·**4**], a closely related complex, was explored.

Crystal structure [$PdCl_2$·**4**]

The structure of [$PdCl_2$·**4**] in the solid state consists of discrete molecules. For each complex molecule two molecules of $CHCl_3$ are present, in their crystal. The molecular structure of the complex and a packing diagram are shown in Figs 1 and 2 respectively. Selected bond lengths and bond angles are given in Table 2. The chelate ring (Fig. 1) adopts an *endo*-puckered conformation with respect to C(2) and Pd. The aromatic ring makes an angle of 110.3° with respect to the square planar geometry while the pyridine ring is

inclined to it by 55.2°. The Pd—Te bond length in the present structure is slightly shorter than the value 2.525(1) Å observed in the crystal structure of [Pd{*meso*-PhTe$(CH_2)_3$TePh}Br_2] [18]. The Te-C(7) bond length is compatible with earlier reported Te—C(alkyl)bond distances. The Pd—N bond length in the present structure is somewhat shorter than the earlier reports on Pd—N(pyridine) bond lengths [19]. This is probably caused by steric influence of the large tellurium on the six membered chelate ring. The Pd—Cl bond *trans* to tellurium is longer than the other. This in conjunction with a similar observation made earlier for the Pt^{II} complex of a (Te, S) ligand [20] indicates that the *trans* influence of Te should not be underestimated and lability originating due to this is worth exploring. The C—C bond lengths of benzene ring are between 1.358(16) and 1.434(18) Å and their C—C—C bond angles are between 115.1(13) and 123.3(12)° as expected. Similarly the pyridine ring bond length and bond angles are normal [C—C bond length 1.377(19) to 1.419(23) Å, C—N bond length ~ 1.356(18) Å and C—C—C/C—C—N/C—N—C bond angles 117.4(12)–123.4(13)°].

(Received 20 March 1996; accepted 22 May 1996)

Abstract—$[Ni_2(dien)_2(NCS)_4(H_2O)]$ (**1**) and $[Ni(aepn)(NCS)_2]_n$ (**2**) (where dien = bis(2-aminoethyl)amine and aepn = *N*-(2-aminoethyl)-1,3-propanediamine) have been synthesised from solution. Single crystal X-ray structure analyses of **1** and **2** reveal that the metal atoms in both the complexes display distorted octahedral geometry with the triamine coordinating facially in **1** and meridionally in **2**. The dinuclear $[Ni_2(dien)_2(NCS)_4(H_2O)]$ unit in **1** is bridged *via* a thiocyanate moiety while in **2** the nickel(II) octahedra form a polymeric chain. The species **1** on deaquation at ~165°C followed by cooling yields a conglomerated mass (**1a**). The species **2** melts at ~230°C which on cooling yields conglomerated mass (**2a**). Both **1a** and **2a** are amorphous; the former reverts to **1** in a humid atmosphere. Copyright © 1996 Elsevier Science Ltd

Keywords: nickel(II) thiocyanate; bis(2-aminoethyl)amine; *N*-(2-aminoethyl)-1,3-propanediamine; thermal analysis; single crystal structure; triamine.

Curtis *et al.* [1] reported the syntheses of $NiL(SCN)_2$ (where L = bis(2-aminoethyl)amine (dien) and bis(3-aminopropyl)amine (dpt)) and proposed structures with one bridging thiocyanate and one N-bonded terminal thiocyanate in *cis* position on the basis of IR spectroscopy. For the corresponding anhydrous and hydrated chloro complexes, it was suggested that the terminal chlorine atoms (in the anhydrous form) or the water molecules (in the hydrated form) are in the *trans* position. Cannas *et al.* [2] reported the X-ray crystal structures of $CdLCl_2$ [(where L = dien, dpt and *N*-(2-aminoethyl)-1,3-propanediamine (aepn)] and observed noticeable differences in the structures on increasing the chain length of the triamine; i.e. $Cd(dien)Cl_2$ is polymeric while $Cd(aepn)Cl_2$ and $Cd(dpt)Cl_2$ are dimeric with *cis* and *trans* configuration, respectively. This led us to assume that the corresponding nickel(II) complexes with several counter anions (Cl^-, Br^- and NCS^- etc.) should also show structural differences. Starting with the $Ni(NCS)_2$ salt of three triamines (dien, aepn and dpt) we have been able to synthesise the single crystals of dien and aepn complexes. The present paper reports the syntheses and X-ray structure analyses of $[Ni_2(dien)_2(NCS)_4(H_2O)]$ and $[Ni(aepn)(NCS)_2]_n$ along with their thermal properties in the solid state.

EXPERIMENTAL

Materials

Bis(2-aminoethyl)amine (dien) and *N*-(2-aminoethyl)-1,3-propanediamine (aepn) was purchased from the Aldrich Chemical Company Inc. and used as received. Nickel(II) thiocyanate was prepared by the standard procedure as reported by Sarma and Poddar [3]. All other chemicals used were of AR grade.

Physical measurements

The thermal analysis (TG-DTA) was carried out on a Shimadzu DT-30 thermal analyser in dynamic atmosphere of dinitrogen (flow rate: 30 cm^3 min^{-1}). The sample (particle size within 150–200 mesh) was heated in a platinum crucible at a rate of 10°C min^{-1} with inert alumina as reference. The enthalpy change of phase transition was calculated using a Perkin–Elmer DSC-2 differential scanning calorimeter, with indium metal as calibrant (rate of heating 10°C min^{-1}). The instruments used for recording the IR spectra (KBr disc at ambient), electronic spectra (nujol mull), elemental analyses and effective magnetic moments at ambient temperature (22°C) were as reported earlier [4].

Preparation of $[Ni_2(dien)_2(NCS)_4(H_2O)]$ (**1**)

The triamine(dien) (1 mmol) was added dropwise to nickel(II) thiocyanate (1 mmol) dissolved in ethanol (10 cm^3). The resulting blue solution was kept in a desiccator. After a few days fine blue crystals were separated out, filtered, washed with ethanol and dried in a desiccator. Found: C, 25.0; H, 4.8; N, 24.4; Ni, 20.3. Calc. for $C_{12}H_{28}N_{10}Ni_2OS_4$ (**1**): C, 25.0; H, 4.8; N, 24.4; Ni, 20.4%. μ_{eff} = 3.1 B.M.;* λ_{max} = 807, 540 and 360 nm.

Preparation of $[Ni(aepn)(NCS)_2]_n$ (**2**)

The triamine (aepn) (1 mmol) was added dropwise to nickel(II) thiocyanate (1 mmol) dissolved in ethanol (10 cm^3). The resulting bluish pink solution on slow evaporation in a desiccator yielded the desired bluish pink coloured crystalline complex. The crystals were separated, washed with ethanol and dried in a desiccator. Found; C, 28.7; H, 5.0; N, 23.8; Ni, 20.0. Calc. for $C_7H_{15}N_5S_2Ni$ (**2**): C, 28.7; H, 5.1; N, 23.9; Ni, 20.1%. μ_{eff} = 3.1 B.M.; λ_{max} = 827, 781, 556 and 369 nm.

* Non-S.I. Unit employed: B.M. 9.27×10^{-24} Am^2.

X-ray diffraction structural study

Single crystals suitable for X-ray analysis were obtained by recrystallization of **1** and **2** from acetonitrile–methanol mixture (1:1) and acetonitrile respectively.

A single crystal of complex **1** was mounted on a Nicolet R3m/V diffractometer, while the crystal of complex **2** was mounted on an Enraf-Nonius CAD4 diffractometer. Lattice constants, orientation matrices were determined by least-squares refinement of the angular settings of 25 well-centred reflections. Crystal data collection and structure solution parameters for complexes are summarised in Table 1.

Intensity data were collected using Mo-K_α radiation (λ = 0.71073 Å) for complex **1** and Cu-K_α radiation (λ = 1.5418 Å) for complex **2** with ω-2θ scan technique. Three control reflections monitored at regular intervals during the X-ray exposures indicated no significant variation in the intensities. All data were corrected for Lorentz and polarisation effects. An empirical absorption correction [5] based on ψ-scan was applied to both the cases. The structures were solved by Patterson techniques followed by Fourier syntheses and refined through full-matrix least-squares calculations. Anisotropic refinements were carried out for the non-hydrogen atoms. The hydrogen atoms were introduced in the final structure-factor calculations at idealized positions with fixed isotropic thermal parameters. Complex neutral-atom scattering factors [6] were used throughout. Calculations were carried out using SHELXS 86 [7], SHELXL 93 [8], PARST [9] and ORTEPII [10] programs. Selected bond lengths and angles of complexes **1** and **2** are listed in Table 2.

RESULTS AND DISCUSSION

Following the method of preparation of Curtis *et al.* it was observed from the TG-curve and elemental analysis that $Ni(dien)(NCS)_2$ is always associated with 0.5 molecule of water. This is also true when **1** is synthesised by adding the ligand (dien) straight to $Ni(NCS)_2$ in aqueous solution (*viz.* experimental). IR, electronic spectra, magnetic susceptibility and conductance data are similar to those reported earlier [1] and corroborate the six-coordinated structure of the complex. The mono triamine complexes can exist in *fac*- and *mer*-isomeric forms and can be distinguished by the inspection of IR spectra [11,12] in the region 1500–1400 cm^{-1}, ~1250 cm^{-1} and 850–700 cm^{-1} for —CH_2 bending, —NH wagging and —NH_2 rocking respectively. In the present case the compound possesses CH_2-bending at 1430 cm^{-1}, 1440 cm^{-1}, 1460 cm^{-1} and 1480 cm^{-1}, NH_2-rocking at 770 cm^{-1}, 790 cm^{-1}, 810 cm^{-1} but no NH-wagging at 1250 cm^{-1}, which are compatible with the *fac* isomer. From the IR spectra it is not clear whether the water molecule is coordinated to nickel(II) or not. It has been found

from simultaneous TG-DTA analysis that the elimination of water takes place at relatively high temperature (~165°C) indicating that the water molecule is likely to be coordinated to nickel(II).

Although Curtis *et al.* reported the syntheses of $NiL(NCS)_2$ (where L = dien and dpt) but no such mono complex of $Ni(NCS)_2$ with aepn ligand has been reported so far. We have synthesised $Ni(aepn)(NCS)_2$ and its electronic spectra and magnetic susceptibility measurement indicate that $Ni(aepn)(NCS)_2$ possesses six-coordinated octahedral geometry. The conductivity measurement (Λ_m = 57 ohm^{-1} cm^2 mol^{-1} in methanol) indicates that both the thiocyanate ions are coordinated to nickel(II) centre. The IR spectrum shows that aepn is chelated. This complex may also exist in two isomeric forms i.e. *fac-* and *mer-* like its dien analogue. However, it is not possible to distinguish between the isomers from the IR spectra due to lack of similar reports in literature. Assuming tridentacy of aepn, to satisfy six-coordinated octahedral geometry in $Ni(aepn)(NCS)_2$, one of the thiocyanate ions is expected to be bridged. The bridging thiocyanate usually shows the ν_{CN} band well above 2100 cm^{-1} [13]. But the ν_{CN} frequency of this complex is at 2090 cm^{-1}. Thus bridging of thiocyanate can not be ascertained.

Description of structures of $[Ni_2(dien)_2(NCS)_4(H_2O)]$ (**1**) *and* $[Ni(aepn)(NCS)_2]_n$ (**2**)

ORTEP views of the complexes **1** and **2** with atom labelling scheme are shown in Figs 1 and 2. Complex **1** consists of neutral dinuclear $[Ni_2(dien)_2(NCS)_4(H_2O)]$ units in *cis* configuration bridged *via* thiocyanates. The coordination polyhedra around the two metal centres in complex **1** are best described as distorted octahedrons with N_5O and N_5S chromophores, respectively. The distortions from ideal octahedral geometry are due to the asymmetric nature of the binding ligands and are refined in the deviations of the angles formed at the metal centres (Table 2) from 90°. Three ligand nitrogen atoms, N(2), N(4), N(5) and the aqua O atom, O(1), around Ni(1) define an equatorial plane and the remaining two N atoms [N(1), N(3)] are in axial positions; Ni(1) being displaced by 0.095(3) Å towards N(1). The corresponding equatorial plane about Ni(2) is defined by S(2) (sulfur atom of bridging NCS moiety), N(7), N(9) and N(10) [Ni(2) is deviated by 0.004(3) Å towards N(6)]; N(6) and N(8) occupying the axial sites. The dihedral angle between the two equatorial planes is 44.3(2)°. The two five-membered chelate rings associated with each metal centre display envelope conformations and are approxi-

tance in both the complexes, in the range 2.051(3)–2.137(6) Å, are consistent with the corresponding values for nickel(II)–triamine systems with octahedral metal coordination (Table 3).

Thermal analysis

$Ni_2(dien)_2(NCS)_4(H_2O)$ (**1**) (blue) upon heating starts to lose water at 110°C and becomes dehydrated at 165°C showing an endothermic peak at 150°C (ΔH = 46.7 kJ mol^{-1}) in its DTA curve. The dehydrated species (**1a**) (deep blue) is found to be conglomerated. When cooled to ambient temperature and powdered, **1a** transforms to $Ni_2(dien)_2(NCS)_4H_2O$ (**1**) on keeping in a humid atmosphere for about 12 h. But it is stable in a desiccator. Ni(aepn)$(NCS)_2$ (**2**) (blue) upon heating melts (230°C, ΔH = 53.3 kJ mol^{-1}) which on cooling yields a conglomerated mass (**2a**) which is stable in the open atmosphere.

Magnetic moment and electronic spectra (μ_{eff} = 3.0 B.M., λ_{max} = 575 and 400 nm for **1a**; μ_{eff} = 3.0 B.M., λ_{max} = 560 and 380 nm for **2a**) of both **1a** and **2a** are typical of octahedral nickel(II). The IR spectra of both the species are broad in comparison to the spectra of the parent species. The X-ray powder diffraction patterns show that the species (**1a** and **2a**) are amorphous although the hydrated species **1** and **2** are crystalline in nature.

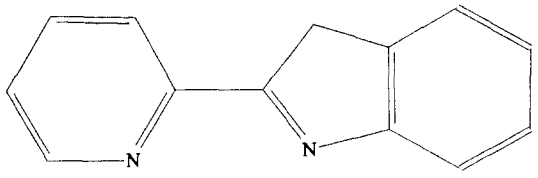
(Received 19 March 1996; accepted 22 May 1996)



Abstract—The magnetic properties of a hexacoordinated iron(II) complex with the bidentate ligand pyridylbenzimidazole (pybzim), $[Fe(pybzim)_3](ClO_4)_2 \cdot H_2O$, (**1**), have been investigated by AC susceptometry, ^{57}Fe-Mössbauer, ESR and NMR spectroscopy. The temperature dependence of the AC magnetic susceptibility for a powder sample showed essentially diamagnetic behaviour below 85 K and paramagnetism (μ_{eff}/μ_B = 4.5–5.3, $S = 2$) above 160 K, obeying the Curie–Weiss law. Spin crossover behaviour can be found within the temperature range 90–160 K; it is centered at 141 K. The Mössbauer spectra confirm the susceptibility measurements: the area fraction of the high-spin quadrupole doublet plotted against temperature shows a curve similar to that deduced from susceptibility measurements. The complex is ESR silent in the X-band mode: neither the powder sample (77 K and 300 K) nor a methanolic solution exhibit an ESR signal. NMR measurements in methanol, acetone, nitromethane, acetonitrile and dimethylsulfoxide show an increasing magnetic moment μ_{eff}/μ_B from 1.6 (220 K, acetone) to 5.2 (325 K, DMSO), respectively. The spin-crossover transition of a freshly prepared powder sample is complete. However, time evolution causes (within months) an increasing admixture of iron(III), which was proved by magnetic susceptibility measurement, ^{57}Fe-Mössbauer, ESR and electronic spectra of the complex. Copyright © 1996 Elsevier Science Ltd

Keywords: spin-crossover; iron(II); magnetic susceptibility; Mössbauer spectra; NMR spectra; ESR spectra.

Spin-crossover phenomena ($S = 0$ to $S = 2$ transition) are well documented for various Fe^{II} complexes [1, 2]. Among them $[Fe(phen)_2(NCS)_2]$, $[Fe(phen)_2(NCSe)_2]$ and $[Fe(bpy)_2(NCS)_2]$ represent prototypes for broad studies using different experimental techniques. It should be pointed out that $[Fe(phen)_3]X_2 \cdot nH_2O$ complexes keep their spin state unchanged under temperature variation: they are either low-spin, $^1A_1$ ($S = 0$), intermediate spin, $^3T_1$ ($S = 1$) or high-spin, $^5T_2$ ($S = 2$) [3]. Generally, some asymmetry in the ligand sphere can produce an appropriate balance between the ligand field strength and the spin pairing energy leading thus to the conditions necessary for the spin crossover.

In this context it is interesting that $[Fe(pybzim)_3]X_2 \cdot nH_2O$ is a spin crossover system, which has been studied already by various techniques (pybzim = 2-(2′-pyridyl) benzimidazole, see Chart 1) [4–8]. In the solid state, however, the actual behaviour varies with the counter anion, e.g., X = BPh_4^-, BF_4^-, PF_6^-, NO_3^-, Br^-, I^- and ClO_4^- [9–12]. Also the conditions of the preparation may cause different magnetic properties [13]. Additionally, in solution the nature of the solvent affects the spin transition [14].

The perchlorate complex was prepared as a monohydrate as well as a dihydrate exhibiting different magnetic properties [11]. The monohydrate is interesting because its spin transition is rather sharp

* Authors to whom correspondence should be addressed.

and apparently complete at room temperature. This may allow industrial applications using the spin-switching technique of the monohydrate complex.

However, oxidation of iron(II) to iron(III) may occur depending on time and sample handling, and these traces may interfere with quantitative analysis of magnetic data, but are usually not accounted for. Therefore we prepared $Fe(pybzim)_3(ClO_4)_2 \cdot H_2O$ complex which was subjected to a detailed magnetochemical investigation using powder sample AC (alternating current) magnetic susceptibility measurements, Mössbauer and ESR spectroscopy. NMR and electronic spectra in solution were recorded and analyzed.

EXPERIMENTAL

Synthesis

The iron(II) salt, $Fe(ClO_4)_2 \cdot 6H_2O$, was of reagent grade (Merck). Ethanol (96%) was used as received. The ligand 2-(2′-pyridyl)benzimidazole (pybzim) was prepared according to the method of Addison [15]. A solution of $Fe(ClO_4)_2 \cdot 6H_2O$ (1 mmol, 0.363 g) in ethanol (10 cm^3) was added to a hot solution of the ligand (3 mmol, 0.586 g) in ethanol (35 cm^3). The transparent red solution was heated under stirring for approx. 30 min, then allowed to cool and crystallize. The dark Bordeaux-red solid was filtered off, washed with a small amount of ethanol and dried at 60°C. The Bordeaux-red adduct changed during drying to a pale red polycrystalline solid. Yield: 78%. Found: C, 51.1; H, 3.5; N, 14.7. Calc. for $[C_{36}H_{27}Cl_2FeN_9O_8] \cdot H_2O$: C, 50.4, H, 3.4; N, 14.7%.

IR spectra

The IR spectra were taken at room temperature in Nujol suspension using a FTIR spectrometer (Philips, model PU9800). Peaks at 3576 and 3495 cm^{-1} confirm the presence of water in the sample. No such peaks occur in pure Nujol and for the free ligand, respectively.

TGA and DSC measurements

Thermal properties were investigated by thermogravimetric (Shimadzu, model TGA-50) and calorimetric (Shimadzu, model DSC-50) measurements within the range of room temperature to 400°C (sample mass 0.70 mg). Decomposition starts at 248°C with a mass loss of 22%; the TGA curve reaches a plateau at 300°C and the decomposition continues (at 400°C with increasing temperature the mass loss is 48%). The DSC curve exhibits a sharp exothermic peak centered at 250°C indicating "an explosion" of the perchlorate. Thus no liberation of crystal water was observed.

Electronic spectroscopy

Electronic spectra were recorded at room temperature using a UV spectrometer (Carl Zeiss, model M40). As the iron(II) may be oxidized to Fe^{III}, the spectroscopic determination of the Fe^{III}/Fe^{II} ratio was based on the following principles.

(i) Phosphato ions can bind Fe^{III} into thermodynamically stable, nearly colourless phosphato-Fe^{III} complexes.
(ii) Ascorbic acid is able to reduce quantitatively Fe^{III} to Fe^{II} complexes.
(iii) The spectral characteristics of the complex $[Fe(phen)_3]^{2+}$ are well known ($\lambda_{max} = 510$ nm; $\varepsilon_{510} = 1.12$ M^{-1} μm^{-1}) and this complex is redox stable relative to oxygen.

In a methanolic solution of **1** the eventual Fe^{III} portion was first trapped by phosphoric acid. Then the content of Fe^{II} was determined by addition of an excess of solid 1,10-phenantroline and measuring the absorbance at 510 nm. Then phosphato–Fe^{III} complexes were reduced by adding solid ascorbic acid leading to the formation of $[Fe(phen)_3]^{2+}$ and the total amount of Fe^{II} was determined as above. From the difference the content of Fe^{III} results.

Magnetic susceptibility measurements

Temperature variation of the magnetic susceptibility was recorded with an AC susceptometer [16] (LakeShore, models 7221 and 7130). The experimental parameters were: $f = 666.7$ Hz, $H_{AC} = 320$ Am^{-1}, $m = 0.09405$ g, 105 data points between 77–300 K. The recorded voltage was corrected to the signal of the free sample holder (an evacuated nylon made container) positioned at the same level within the detecting coils as the sample. The measurements were done several times and they were averaged to eliminate the data scattering for these low signals.

^{57}Fe-*Mössbauer spectra*

The Mössbauer spectra were taken (4.2 K–300 K) using a conventional transmission spectrometer [17]. ^{57}Co(Rh) was used as a source and the isomer shift data are given relative to α-Fe at room temperature. The sample was measured over a period of four months and the data were analyzed by a least squares fit routine assuming Lorentzian lines.

ESR spectra

The ESR data were recorded using an X-band spectrometer (Bruker, ER 200D SRC) at room temperature as well as at 77 K.

NMR spectra

Proton NMR spectra in different solvents were recorded using a 250 MHz spectrometer (Bruker, AC 250 FT) and analyzed by the Evans method as described elsewhere [18].

RESULTS

Characterization of a freshly prepared sample

Based on the unchanged absorbance of the Fe^{II} phenanthroline complex (within experimental error $\pm 1\%$) we found that there is no detectable amount of Fe^{III} present in the freshly prepared sample.

Analogously, the absence of an ESR signal at room temperature and 77 K brings evidence that neither iron(III) nor any free radicals are present in the freshly prepared sample.

Susceptibility measurements

The recorded mass susceptibility has been converted to molar susceptibility and corrected for underlying diamagnetism with $\alpha_{dia} = -5.66 \times 10^{-9}$ m^3 mol^{-1} [19]. The molar magnetic susceptibility χ'_{mol} shows a paramagnetic ($S = 2$) behaviour of the complex from 300 to 160 K. Below 160 K, spin crossover transition occurs, leading to a reduction of χ'_{mol} (μ_{eff}) nearly to the zero at 85 K (Fig. 1). The low-temperature data (below 85 K) indicate diamagnetism ($S = 0$) within experimental error.

No hysteresis was observed in the χ'_{mol} *vs* T curve on heating/cooling within the experimental error. It can be concluded that the spin crossover in the given sample falls into "class I" of a complete and sharp interconversion [2].

The effective magnetic moment was evaluated as $\mu_{eff}/\mu_B = 798(\chi'_{mol}\ T)^{1/2}$ in SI units. Its room temperature value is calculated as $\mu_{eff}/\mu_B = 5.20$ and decreases according to a straight line down to $\mu_{eff}/\mu_B = 4.70$ at 160 K. The spin only value is $\mu_{eff}/\mu_B = 4.90$.

In order to analyze the magnetic data quantitatively three models were applied to describe the temperature dependent part of the magnetic susceptibility.

The well-known Curie–Weiss law (the model **1**) is presented in the form

$$\chi'_{mol} = C_0 g_{av}^2 [S(S+1)/3]/(T-\theta) \qquad (1)$$

where $C_0 = N_A \mu_0 \mu_B^2/k$ comprises fundamental physical constants, $S = 2$ is the spin number of the complex, θ the Weiss constant and g_{av} is the isotropic magnetogyric factor.

An application of the zero-field splitting (the model **2**) is based on the spin Hamiltonian in the form

$$\hat{H}_a = \mu_B B g_a \hat{S}_a + D[\hat{S}_z^2 - S(S+1)/3] + E(\hat{S}_x^2 - \hat{S}_y^2) \qquad (2)$$

for $a = x, y, z$. The basis set consists of five spin functions ($S = 2$). Here D represents the axial zero-field splitting parameter, which accounts for magnetic asymmetry of systems with $S > 1/2$. This causes a splitting of the spin quintet state into three sublevels: a singlet ($M_S = 0$), and two Kramers doublets ($M_S = \pm 2$) separated by D and $4D$, respectively. The rhombic zero-field splitting parameter E is usually neglected. Using this approximation the magnetic sus-

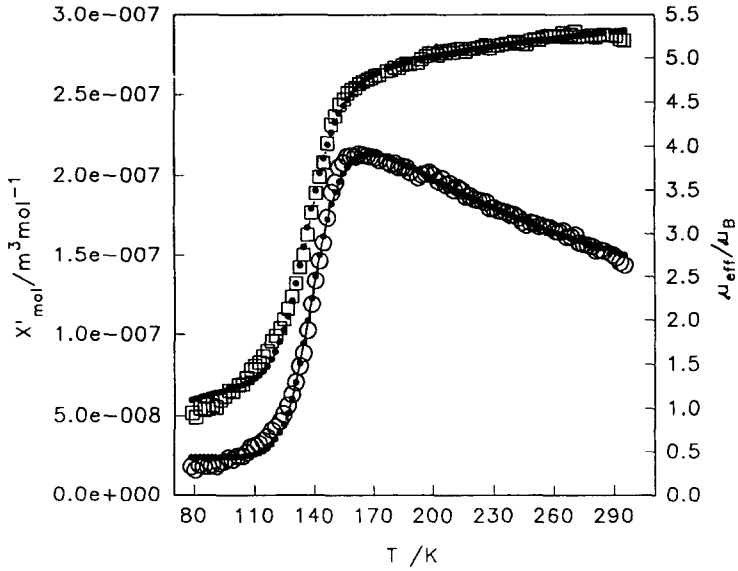


Fig. 1. Temperature variation of the molar magnetic susceptibility (χ'_{mol}, circles) and the effective magnetic moment (μ_{eff}/μ_B, squares) for **1**. Full points, theoretical fit (see text).

ceptibility components can be expressed in terms of analytic functions

$$\chi_{\parallel} = (C_0 g_{\parallel}^2/T)(2e^{-x}+8e^{-4x})/(1+2e^{-x}+2e^{-4x}) \tag{3}$$

$$\chi_{\perp} = (C_0 g_{\perp}^2/T)[(6/x)(1-e^{-x}) + (4/3x)(e^{-x}-e^{-4x})]/(1+2e^{-x}+2e^{-4x}) \tag{4}$$

with $x = D/kT$. The magnetogyric factor, in principle, is anisotropic. The average molar paramagnetic susceptibility is given by

$$\chi_{hs} = (\chi_{\parallel}+2\chi_{\perp})/3 \tag{5}$$

The last model (the model **3**) assumes a combined effect of the axial distortion due to the ligand field and spin-orbit coupling within the $^5T_2$ term with the Hamiltonian

$$\hat{H}_a = \mu_B B[G\hat{L}_a + g_a\hat{S}_a] + J_\lambda \hat{L}\cdot\hat{S} + \Delta[\hat{L}_z^2 - L(L+1)/3] \tag{6}$$

Here $G = -k$ accounts for the orbital reduction factor and its sign is given by the isomorphism between $^5T_2$ and ^5P terms [20]. The coupling parameter $J_\lambda = -k\lambda = k\xi/2S$ contains the (positive) spin-orbit coupling constant ($\xi_0 = 400$ cm^{-1} for Fe^{2+}); Δ is the axial crystal field splitting parameter. The basis set contains 15 functions as they result from the direct product of three orbital functions ($L = 1$) and five spin functions ($S = 2$). Due to the axial symmetry, two directions (a parallel, $\hat{H}_x$, and perpendicular, $\hat{H}_x = \hat{H}_y$) should be distinguished.

Attempts to reproduce the recorded susceptibility curve over the whole temperature interval were successful when the following function was considered

$$\chi'_{mol} = c_{hs}(\chi_{hs}+\alpha_{hs}) + (1-c_{hs})\alpha_{ls} \tag{7}$$

The expression $c_{hs} = f(T)$ gives the molar fraction of the high-spin complex (see later) and α_{hs} represents its temperature-independent paramagnetism. The susceptibility of the low-spin complex is expected to be positive and temperature independent, given by α_{ls} term. The temperature independent term increases with presence of low-lying excited states and therefore we assume that α_{ls} is substantial (the low-spin state has thermally accessible excited states).

Using the recorded χ'_{mol} *vs* T data the molar fraction of the high-spin complex is readily calculated as

$$c_{hs} = (\chi'_{mol}T - \chi_{ls}T)/(\chi_{hs}T - \chi_{ls}T) \tag{8}$$

with $\chi_{ls}T = 1.3\times10^{-6}$ m^3 mol^{-1} K^{-1} and $\chi_{hs}T = 44.14\times10^{-6}$ m^3 mol^{-1} K^{-1} as maximum value.

In order to fit the c_{hs} values to a smooth curve the domain model has been assumed. Although it has limitations it is probably effective in this particular case when no hysteresis is observed. The theoretical curve then becomes [21]

$$c_{hs} = 1/\{1+\exp[(n\Delta H/R)(1/T-1/T_C)]\} \tag{9}$$

Here n is the averaged number of magnetic active entities within the domain, ΔH the enthalpy and T_C the temperature of the transition, respectively.

The actual fitting procedure contains six free parameters: g_{av}, θ, $h = n\Delta H/R$, T_C, α_{hs} and α_{ls} when the Curie–Weiss law for the paramagnetic part is applied. For the zero-field splitting model we have $g_\perp$, $g_\parallel$, D, h, T_C, α_{hs} and α_{ls}. However, the g-tensor components taken as free parameters were found effectively dependent and thus we returned back to g_{av}. For the model **3** there were seven free parameters: G, J_λ, Δ, h, T_C, α_{hs} and α_{ls} (the electronic magnetogyric factor $g_{av} = 2$ was frozen). The error function to be minimized was

$$F = \sum_i (\chi_i^c - \chi_i^o)^2 \tag{10}$$

The quality of the regression was expressed by the agreement factor

$$R = \frac{\sum_i [(\chi_i^o)^2 - (\chi_i^c)^2]}{\sum_i (\chi_i^o)^2} \tag{11}$$

The final set of magnetic parameters is collected in Table 1. It should be noted that α_{hs} is determined accurately from precise high-temperature data. On the other hand, the D-parameter of the zero-field splitting at low temperature disappears, due to the spin switch to $S = 0$. Therefore, these parameters should be considered only as the first estimates. The quality of the fit is quite good for higher temperature and the deviations of theoretical and experimental data below 100 K is not critical (see Fig. 1).

The fitted high-spin molar fraction function (9), i.e. the domain model, compared with the experimental c_{hs} function (8) show limited degree of agreement (Fig. 2). Evidently, for a better description there is required a more flexible theoretical function.

As the sample under investigation was measured several times over months, a small increase in the susceptibility below 80 K was observed. Therefore, a reinvestigation of the same sample encapsulated in the sample holder for six months with temperatures down to 20 K was performed. While cooling down the susceptibility passed through a minimum and then increased like a typical paramagnet. This shows that a paramagnetic impurity (PI) gains significance with time. However, even a small paramagnetic admixture has dramatic consequences to the effective magnetic moment at low temperature, which increases considerably. This point will be discussed later.

The content of the PI has been estimated as follows. For a Curie paramagnet the plot χ'_{mol} *vs* $(1/T)$ is a straight line. Based on low temperature data only the slope of the regression line determines the Curie constant C_{mol}. This obeys the relationship

$$C_{mol} = C_0 g^2 [S(S+1)/3]\rho \tag{12}$$

where measured $C_{mol} = 1.7762\times10^{-6}$ m^3 mol^{-1} K,

known $C_0 = 4.714 \times 10^{-6}$ m^3 mol^{-1} K and estimated $g = 2$ and $S = 5/2$ for the high-spin Fe^{III} evaluates the molar fraction of PI to $\rho = 0.032$.

ESR measurements

For a freshly prepared sample no ESR absorption signal was observed either at 77 K or at 300 K. This may result from rapid spin-lattice relaxation effects characteristic for Fe^{II} complexes. Also a methanolic solution of the complex is ESR silent, which may follow from the zero-field splitting: the spin quintet ($S = 2$) is split into a singlet ($M_S = 0$) and a pair of Kramers doublets ($M_S = \pm 1$ and $M_S = \pm 2$). Since the selection rule $\Delta M_S = \pm 1$ restricts the allowed transitions, the $M_S = 0$ to -1 transition is observable only at high fields or high microwave frequencies when the zero-field splitting $|D|$ is high.

Characterization of a half-year old sample

A six-month old sample was remeasured by ESR and no signal was evident at room temperature. At 77 K, however, a very broad absorption maximum appeared with the centre at $g_{eff} = 5.95$. This indicates the presence of iron(III) in the sample.

In order to determine the content of iron(III) quantitatively, the electron spectroscopic determination was repeated and 5.2% of Fe^{III} was found.

Mössbauer measurements

The Mössbauer spectra of a three and a six month old sample respectively were measured within a temperature range 4.2–295 K. They exhibit two quadrupole doublets: the former (small splitting) is associated with the $S = 0$ state whereas the latter (large splitting) corresponds to $S = 2$ (Fig. 3).

Since the intensities of the resonance lines depend upon the Debye–Waller factors for the states involved, it is difficult to measure quantitatively the fractions of the $^1A_1$ and $^5T_2$ species present at any given temperature. If we assume the two different states to have the same Debye–Waller factors, the ratio of the area under the $^5T_2$ lines to the total spectra area will give an approximate measure of the high spin species. The area fraction associated with the high-spin complex, P_{hs}, is plotted *vs* temperature (Fig. 4). The data derived from a computer fit are collected in Table 2. The spin crossover is sharp and centered at 140 K. The application of the domain model (8) to fit the P_{hs} *vs* T data yields $n\Delta H/R = 1123$ K and $T_C = 141$ K, which is in good agreement with the AC susceptibility data.

From a chemical point of view, the *s*-electrons should give the dominant contribution to the isomer shift and the *d*- and *p*-electrons to the quadrupole splitting [22]. The isomer shift of the high spin complex is more positive than that of the low spin counterpart. This can be interpreted due to different symmetry

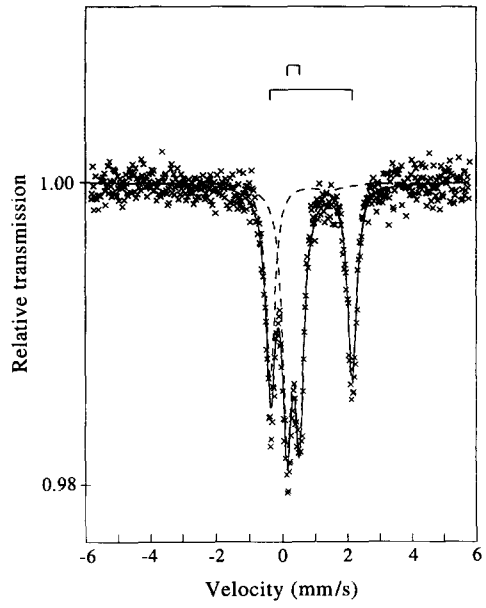

Fig. 3. Representative Mössbauer spectrum of **1** at 140 K.

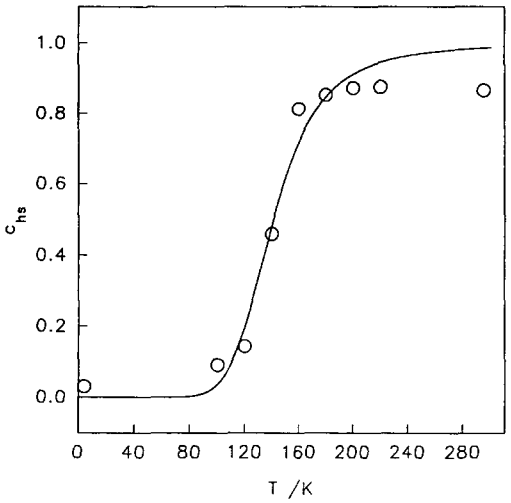

Fig. 4. Temperature dependence of the Mössbauer area fraction of the high-spin quadrupole doublet for **1**. Solid, domain model theoretical curve.

of the *d*-electrons, where asymmetry in the high spin ($^5T_2$) compared to the low spin ($^1A_1$) causes a change in the electric field gradient, i.e. decreasing *s*-electron density at the iron nucleus. This is in good agreement with known measurements.

Fe^{III} admixtures can be observed in Mössbauer experiments in concentrations at least higher than 5%. In addition, the range of isomer shift and quadrupole splitting in Fe^{II} low spin is overlapping with Fe^{III} high spin. Nevertheless, Fe^{III} high spin can be determined, because it looks like a time dependent hs/ls ratio. Remeasuring of the six months old sample allowed to estimate 6% of Fe^{III} with an isomer shift of 0.02 mm s^{-1}.

Table 2. Mössbauer data[a]

NMR measurements

NMR measurements were performed in solution, using methanol (MeOH), acetone (Ac), nitromethane (NM), acetonitrile (AN) and dimethylsulfoxide (DMSO) as solvents, at temperatures limited by solvent properties (Table 3). The temperature variation of the effective magnetic moment (evaluated by means of the Evans method) allows the conclusion that spin crossover occurs also in solution. In contrast to the solid state, the spin transition in solutions is a gradual process belonging to the "Group II" [23].

The solution measurements are complicated by two effects: (i) ligand dissociation at higher temperature, and (ii) deprotonation of the acidic imidazole N—H group. Products of the ligand dissociation, the solvated complexes of $[Fe(pybzim)_2L_2]^{2+}$, $[Fe(pybzim)L_4]^{2+}$ and $[FeL_6]^{2+}$ type possess a decreased ligand field strength manifesting itself in the stabilization of the high-spin state. A three step deprotonation will increase the electron density at the donor nitrogen atom of the imidazole ligand. This is reflected

Table 3. Magnetic moments obtained from NMR using Evans method for various solvents on $[Fe(pybzim)_3](ClO_4)_2$

T K	MeOH μ_{eff}/μ_B	Ac μ_{eff}/μ_B	AN μ_{eff}/μ_B	NM μ_{eff}/μ_B	DMSO μ_{eff}/μ_B

220	3.21	1.60			

in the strengthening of the Fe—N bond and consequently the ligand field splitting increases. The greater the ligand field strength, the better the stabilization of the low-spin rate.

In methanol the spin transition is already observable at 220 K and culminates at 300 K. Even better resolution of the spin crossover is seen in acetone (Fig. 5). In contrast, in acetonitrile only a small variation of the effective magnetic moment is seen within 270 to 320 K. In nitromethane and dimethylsulfoxide only the high-spin state is stabilized within the accessible temperature range.

DISCUSSION

As already mentioned, the complex under investigation has been characterized as a spin crossover system by several groups [9–11, 13]. An inspection of Table 4 shows that the published data differ each from other and also our set of characteristics is different. The particular factors associated with the composition and/or structure of the complex which may affect the spin-crossover are as follows:

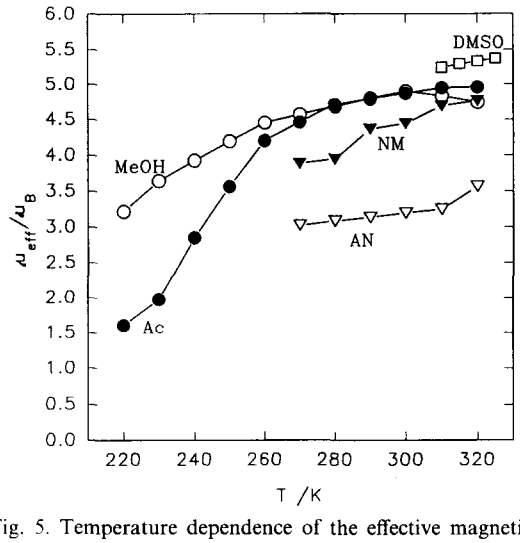

Fig. 5. Temperature dependence of the effective magnetic moment in solutions.

(i) the way of preparation, at least the presence of acidic media, can alter the acidity of the hydrogen atom associated with the imidazole nitrogen;
(ii) the variable content of water, particularly a reversible aquation and/or liberation of a second crystalline water molecule;
(iii) possible stabilization of either *mer*-, *fac*-, or both isomers of $[Fe(pybzim)_3]^{2+}$ complex;
(iv) the possible presence of Fe^{III} impurities can alter the magnetic data and their interpretation as well;
(v) the published susceptibilities correspond to the thermal equilibrium (thermal susceptibilities in the static magnetic field) as opposed to the AC susceptibility, which is a frequency (f) dependent quantity (adiabatic magnetic susceptibility) deviating from the thermal limit ($f \rightarrow 0$). To our knowledge the AC magnetic susceptibilities are always lower than their thermal equilibrium counterparts.

The arguments leading us to consider a simple zero-field splitting model (the model **2**) can be summarized as follows. The ground electronic state of the hexacoordinate Fe^{II} high-spin complexes is $^5T_{2g}$. The asymmetry of the pybzim ligand allows, in principle, the existence of two geometrical isomers; the *mer*- and *fac*-isomers having C_{2v} and C_{3v} symmetry, respectively. The magnetic-perturbation Mössbauer spectra indicate that there it is the *mer*-isomer which is present [11]. Therefore within the C_{2v} symmetry only an orbital singlet is possible so that the basis set consists of five spin functions only. The value of $D = -73$ cm^{-1} indicates a considerable zero-field splitting, consistent in sign with the negative Weiss constant for the model **1**.

The model **3** is approximately of the same quality but the parameters received have a different meaning. The most important finding is a rather high axial crystal field splitting $\Delta = -617\ cm^{-1}$ which may have a consequence that in the temperature interval concerned only the lowest (of 15) states are effectively populated. This might be a basis for the justification

Table 4. Results of various investigations on $[Fe(pybzim)_3](ClO_4)_2 \cdot nH_2O$[a]

[c] One year old sample.

of the model **2**. The orbital reduction factor $k = 0.8$ and the spin-orbit coupling constant $\xi = 371$ cm^{-1} (evaluated from G and J_λ values) sound very reasonable.

The temperature independent paramagnetism for the high-spin complex, however, is much higher than that expected for Fe^{II} complexes. This may have roots in the presence of an undetermined amount of a paramagnetic impurity of Fe^{III} with $S = 5/2$ which apparently raises the measured data over the whole temperature interval.

A one-year-old sample was remeasured on Faraday type balances (field $B = 1.5$ T, $T = 294$ K) and $\mu_{eff}/\mu_B = 5.52$ was found.

Despite the minor effect of different diamagnetic corrections that may have been applied for recorded susceptibility data we plotted the published susceptibility data *vs* temperature together with our data set (Fig. 6).

On first sight it is evident that the published data exhibit a minimum followed by a susceptibility increase on cooling typical for the presence of a paramagnetic impurity (PI) manifesting itself at low temperature. Having different amounts of PI, the differences in displayed magnetic moments are not surprising (Fig. 7).

The content of PI was estimated as described above: $\rho^{(13)} = 0.129$ and $\rho^{(11)} = 0.0525$ are calculated for data according to refs 13 and 11, respectively.

Thus we can conclude, that the system under study, when freshly prepared, exhibits a rather sharp spin crossover centered at 140 K, which is almost complete above 160 K. Below 100 K some residual paramagnetism remains, which can be interpreted as the temperature independent paramagnetic contribution for the low-spin state. A paramagnetic impurity represented by iron(III) appears over a period of time which enhances the paramagnetism of the sample also at low temperature and apparently increases the effective magnetic moment.

Abstract—The 1,2-diaminepropane platinum(II) cantharidinate was synthesized by reacting sodium cantharidinate with 1,2-diaminepropane diiodo platinum(II) in aqueous solution. The crystal structure of the platinum complex was determined by X-ray diffraction. The complex is a binuclear molecule, in which each platinum ion is coordinated by two carboxylic oxygen atoms from two different cantharidinates and two amine nitrogen atoms from the same 1,2-diaminepropane molecule. The platinum(II) ion takes a typical square planar configuration. Copyright © 1996 Published by Elsevier Science Ltd

Keywords: platinum complex; cantharidine; synthesis; structure determination.

The success of cisplatin has stimulated widespread searching for more effective and lower toxicity antitumor platinum complexes [1]. By introducing an O-donor ligand as the leaving group, a series of new platinum complexes, so-called second generation anticancer drugs, have been developed. Among others the diamineplatinum(II) cyclobutyl 1,1-dicarboxylate, (carboplatin, JM-8) is the most outstanding one [2–4]. Meanwhile, if some antitumor drug can be combined into these platinum complexes as a ligand, it might produce unexpected results. Cantharidine has long been used as a Chinese medicine [5]. In the past three decades several studies showed that cantharidine and its derivatives present potential antitumor capability against lung, colon and breast cancer [6–8]. A number of platinum cantharidine complexes have been synthesized. Here we wish to report the synthesis and crystal structure of 1,2-diaminepropane platinum(II)-2,3-dimethyl-7-oxobicyclo-[2,2,1]-heptane-2,3-bicarboxylate (cantharidinate).

EXPERIMENTAL

Preparation and analysis of the complex

The title complex was prepared according to the following reactions:

$$K_2PtCl_4 + 4KI \rightarrow K_2PtI_4 + 4KCl \quad (1)$$

$$K_2PtI_4 + NH_2CH_2CH(NH_2)CH_3 \rightarrow Pt[NH_2CH_2CH(NH_2)CH_3]I_2 + 2KI \quad (2)$$

$$Pt[NH_2CH_2CH(NH_2)CH_3]I_2 + 2AgNO_3 + H_2O \rightarrow [Pt(NH_2CH_2CH(NH_2)CH_3)(H_2O)_2](NO_3)_2 + 2AgI\downarrow \quad (3)$$

$$[Pt(NH_2CH_2CH(NH_2)CH_3)(H_2O)_2](NO_3)_2 + C_6H_6O(CH_3)_2(COONa)_2 \rightarrow [Pt(NH_2CH_2CH(NH_2)CH_3)(C_6H_6O(CH_3)_2(COO)_2)] + NaNO_3. \quad (4)$$

The hydrolysis of $Pt[NH_2CH_2CH(NH_2)CH_3]I_2$ was employed in the dark for 24 h. The appropriate ligand was dissolved in NaOH with vigorous stirring; the final pH of the solution was about 6.8. The solution was stirred at 4°C and finally the pale yellowish crystal collected. Found: C, 27.7; H, 3.8; N, 5.9; Calc: 27.4; H, 4.7; N, 6.2%. $\nu_{(C=O)}$ 1600 cm^{-1}, $\nu_{(C\ O\ C)}$ 990, 920 cm^{-1}, $\nu_{(NH)}$ 3400 cm^{-1}, $\nu_{(Pt-N)}$ 410, 422 cm^{-1}.

Crystallography

$[C_{26}H_{38}N_5O_{10}NaPt_2][4H_2O]$, fw = 1065.85, monoclinic, a = 13.297(3), b = 19.089(4), c = 15.999(2) Å,

*Author to whom correspondence should be addressed.

$\beta = 103.29(2)°$, $V = 3952.2$ Å^3, space group $P2_1/a$, $Z = 4$, $D_c = 1.791$ g/cm^3, μ (M_o-K_α) = 72.16 cm^{-1}, $\lambda = 0.71073$ Å.

Data collection and processing

Data were collected on an Enraf–Nonius CAD4 diffractometer on the ω-2θ scan mode ($0 \leqslant \theta \leqslant 25°$) with graphite-monochromated M_o-K_α radiation, 5528 reflections were measured, of which 3574 reflections with $I \geqslant 3\sigma(I)$ were considered to be observed and used in the refinement. The data were corrected for Lorentz and polarization factors.

Structure analysis and refinement

The structure was solved by the heavy-atom method. The position of platinum was obtained from the Patterson function. The difference electron density map revealed all the non-hydrogen atoms. All atoms except hydrogen were refined anisotropically with full-matrix least-squares. The hydrogen atoms were assigned a common refined isotropic thermal parameter and allowed to ride on their parent atoms. The final values of R and R_w are 0.053 and 0.068, respectively.

RESULTS AND DISCUSSION

The crystal structure of the title complex is shown in Fig. 1. Selected bond lengths and bond angles are listed in Table 1. Interestingly, this is a binuclear molecule of platinum. Each platinum is coordinated by two nitrogen atoms of 1,2-diaminepropane and two oxygen atoms of carboyxlates, each one from different cantharidinate molecules. Two Pt(2)—N bond lengths are 2.073 and 2.100 Å respectively, then the Pt(2)—O bonds have almost identical lengths (2.056 and 2.052 Å). The central platinum atoms are both coordinated by two nitrogen and two oxygen atoms with essentially a square planar coordination configuration, but the two PtN_2O_2 geometries are not really identical and show different tetrahedral distortions from the normal square planar geometry. The Pt(1) plane has a square pyramidal pattern, on the other hand, the geometry around Pt(2) is very slightly puckered; the N(2′) and O(3′) atoms are above the mean $Pt(2)N_2O_2$ plane, whilst N(2′) and O(3′) lie below it (see the Table of Least-Squares Planes). The O(3′)—Pt(2)—N(2′) groups [176.2(3)°] are essentially linear. It is noteworthy that the bridging oxo-oxygen atom on the cantharidinate molecule did not participate in the coordination to the platinum ion, instead it binds to sodium, and thus strengthens the

Abstract—The organo titanium(IV)trifluoride $[C_5H_4(SiMe_3)]TiF_3$, **2**, has been reduced with zinc and manganese, respectively. As an intermediate product from these reactions the tetra-nuclear Ti^{III} cluster $\{[C_5H_4(SiMe_3)]_2TiF_2\}_3Ti$, **3**, has been obtained. By oxidative fluorination using AgF complex **3** was converted to the titanium(IV) complex $[C_5H_4(SiMe_3)]_2TiF_2$. Reduction of $(C_5H_5)_2TiF_2$ with gallium led to the formation of $[(C_5H_5)_2TiF_2]_3Ga$, **7**. Copyright © 1996 Elsevier Science Ltd

Keywords: organometallic; titanium; cluster; fluoride.

Recently, the reduction of cyclopentadienyl substituted titanium trifluorides has been carried out for the first time. In contrast to the analogous reduction of the corresponding titanium chlorides reaction intermediates were isolated and have been characterised by X-ray structural analysis. The use of activated alkali- and alkaline earth metals in the reaction using $Cp'TiF_3$ ($Cp' = C_5H_4(SiMe_3)$, C_5H_4Me, C_5H_5) leads to the formation of clusters with varying molecular size [1, 2]. The clusters possess $Cp'TiF_2$ units which are connected by alkali- and alkaline earth fluorides. The molecules demonstrate that molecular solids such as NaF, MgF_2 and CaF_2 can be used as ligands in organometallic chemistry. However, the reduction of titanocene difluoride using aluminium resulted in the generation of the complex $[(C_5H_5)_2TiF_2]_3Al$, **1** [3]. This result demonstrates that the number of organic substituents at the titanium center can act as a tuning factor in determining the size of the clusters. Herein we report on the reduction of the half-sandwich fluorides of titanium using transition metals and the reaction of titanocene difluoride with gallium.

RESULTS AND DISCUSSION

As described previously the reaction of $HgCl_2$ activated zinc with $(C_5Me_5)TiCl_3$ leads exclusively to the titanium(III) complex $(C_5Me_5)TiCl_2$ [4, 5]. In contrast to this result we found that no reaction takes place using the corresponding titanium fluoride $(C_5Me_5)TiF_3$ and zinc under the same reaction conditions. Obviously $(C_5Me_5)TiF_3$ has a higher reduction potential compared to the chloro derivative and hence cannot be reduced by zinc. The reducing potential can be altered by changing the coordinated ligand ($C_5Me_5 \rightarrow C_5H_4(SiMe_3)$). Indeed, $[C_5H_4(SiMe_3)]TiF_3$, **2**, and an excess of zinc in THF react within 2 days to give a green–blue solution from which blue crystals were obtained after condensing a small amount of hexane onto the reaction mixture. Unexpectedly the mass spectrum of the blue crystals showed fragments for $[C_5H_4(SiMe_3)]_2TiF$ (341, 64%) and $[C_5H_4(SiMe_3)]_2TiF$ minus methyl (326) as the base peak indicating that these titanocene(III) fluoride moieties are the building blocks of the product. Accordingly,

† Dedicated to Professor Erwin Weiß on the occasion of his 70th birthday.

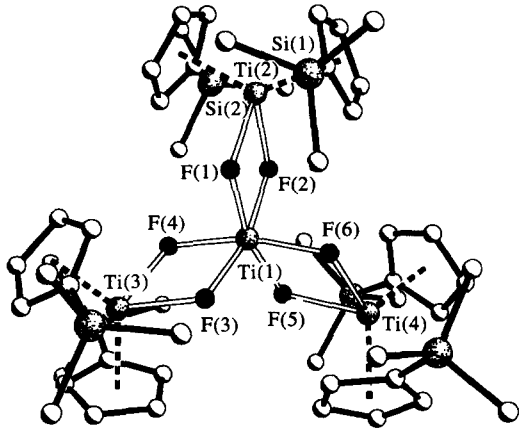

Fig. 1. Molecular structure of $\{[C_5H_4(SiMe_3)]_2TiF_2\}_3Ti$, **3**, average bond length (Å) and angles (°) (Cp′ = $C_5H_4(SiMe_3)$-centroid): Ti(1)—F 1.974(2), Ti(2),(3),(4)—F 2.097(2), Ti—Cp′ 2.045(2); F—Ti(1)—F (inside the Ti_2F_2 kite shaped four-membered rings) 75.6(1), F(equatorial)—Ti(1)—F (equatorial) 95.3(1), F(axial)—Ti(1)—F(axial) 165.0(1), F—Ti(2),(3),(4)—F 70.5, Cp′—Ti—Cp′ 133.9(1).

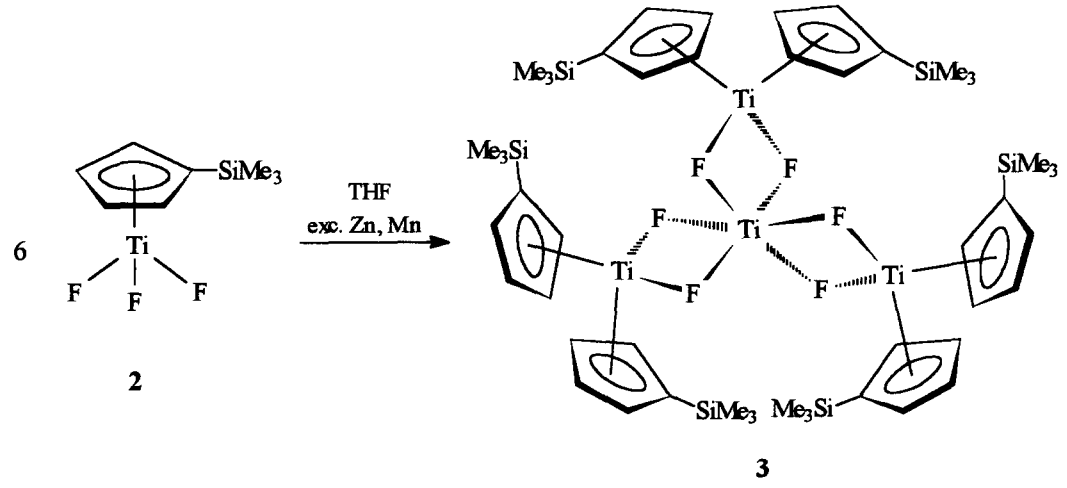
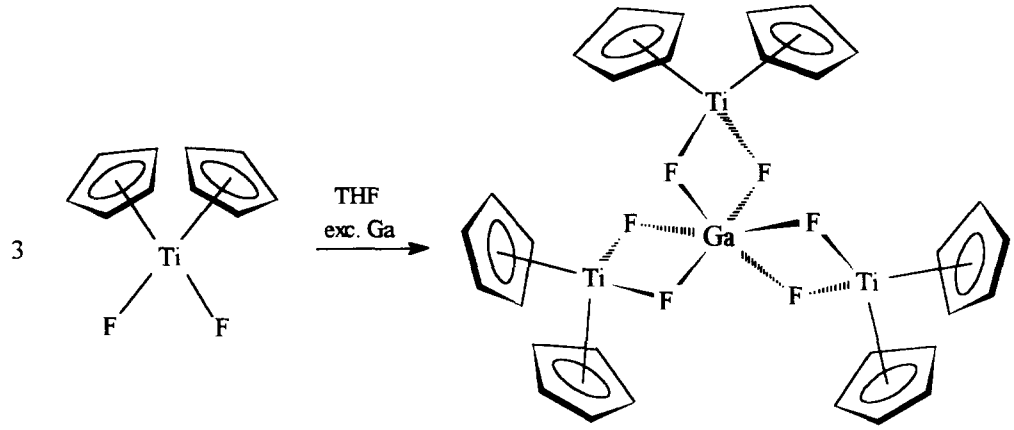
$[C_5H_4(SiMe_3)]_2TiF_2$ could be obtained after oxidative fluorination using AgF. The sublimation point as well as the mass, ^1H and ^{19}F NMR spectroscopic data of $[C_5H_4(SiMe_3)]_2TiF_2$ are in agreement with those given in the literature [6].

The X-ray structural analysis of the blue crystals reveals three $[C_5H_4(SiMe_3)]_2TiF_2$ moieties arranged around a central titanium atom (Ti(1)) in a propeller blade geometry (Fig. 1).



The central Ti(1) atom in $\{[C_5H_4(SiMe_3)]_2TiF_2\}_3Ti$, **3**, is coordinated to six μ_2 bridging fluorine atoms to give a distorted octahedral TiF_6 polyhedron. **3** is isotype to $[(C_5H_5)_2TiF_2]_3Ti$, **4**, although C_3 symmetry is prevented due to the trimethylsilyl substituents at the C_5 perimeter of the cyclopentadienyl ligand. **4** can be obtained in the reaction of $(C_5H_5)_2TiF_2$, **5**, with $(C_5H_5)_2Ti(CO)_2$ in the molar ratio of 1 : 1 [3]. Remarkably, the central Ti(1)—F bonds are 0.12 Å (av. 1.974(2)) shorter than the Ti—F bonds in the periphery (av. Ti(2),(3),(4)—F 2.097(2)), although one might have expected the opposite because of sterical crowding. However, both values are in good accordance with the related distances in **4**. The mean "propeller blade angle" in **3** (the intersection angle of the orthogonals of the best Ti_2F_2 planes) of 82.7° is very similar to that in **4** (86.5°).

Complex **3** can also be obtained when **2** is reacted with activated manganese under the same reaction conditions as those used for the reduction of **2** with zinc.



To the best of our knowledge the migration of the $C_5H_4(SiMe_3)$ substituent to a metal center of a half sandwich complex forming a metallocene unit is reported herein for the first time. The opposite case, the detachment of one of the C_5H_5 rings of metallocenes in redox processes is well known, e.g. in the formation of mono cyclopentadienyl substituted titanium oxygen and sulfur clusters from the oxidation reactions of $(C_5H_5)_2Ti(CO)_2$ with H_2O [7, 8] and H_2S, respectively [9].

It is noteworthy that the direct synthesis of **3** from the reduction of $[C_5H_4(SiMe_3)]_2TiF_2$ using activated titanium fails. On the other hand, the reduction of $(C_5H_5)_2TiF_2$, **5**, and $(C_5H_4Me)_2TiF_2$ with activated aluminium leads to complexes **1** and $[(C_5H_4Me)_2TiF_2]_3Al$, **6**, respectively [3]. The single crystal structure analysis reveals **6** to be similar to the structure determined for **3** and **4**: the TiF_6 octahedron is replaced by an AlF_6 octahedron. Obviously, the driving force for the formation of **6** is the excess of heat of formation energy resulting from the formation of the aluminium–fluorine bonds. This way of stabilisation is in contrast to that observed for the formation of the reduction product when zinc and manganese were used as reducing agents.

In order to achieve the minimum energy of the metal–fluorine bond which is necessary to incorporate

Scheme 1.

5 7

Scheme 2.

a certain metal into the complex we aimed at reacting gallium and indium with **5**. While gallium metal reacts with **5** to give the expected product $[(C_5H_5)_2TiF_2]_3Ga$, **7**, the reducing power of elemental indium apparently is not high enough to promote the related reaction.

Single crystals of **7** suitable for X-ray diffraction were obtained from n-hexane/THF solution. **7** crystallises in the space group $R\bar{3}c$ with the central gallium atom on the $\bar{3}$ axis. This axis can be regarded as the shaft of the propeller molecule. The structure of **7** in the solid state is analogous to that of **1** revealing the distorted GaF_6 octahedron as the central unit (Fig. 2).

The gallium–fluorine distances are about 0.10 Å longer than the related aluminum–fluorine bonds in **1** while the titanium–fluorine distances in both complexes **1** (mean 2.095 Å) and **7** (2.106 Å) differ only marginally. The distances of the titanium atoms in **3** and **7** to the center of the C_5 perimeters are almost identical, and hence not affected by the presence of silyl substituents. The planes of the three four-membered GaF_2Ti propeller blades intersect at an angle of 85.3°.

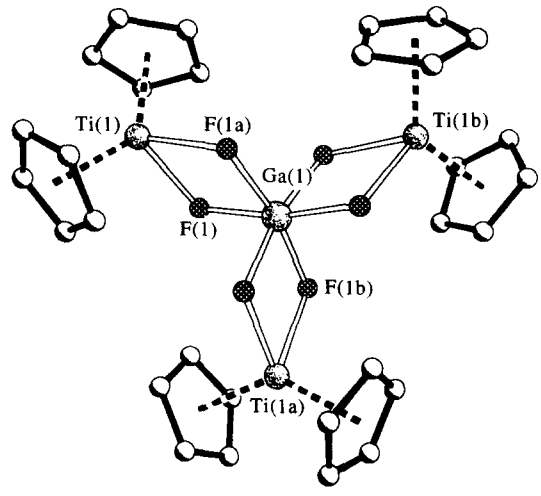


Fig. 2. Molecular structure of $[(C_5H_5)_2TiF_2]_3Ga$, **7**, bond length (Å) and angles (°) (Cp = C_5H_5-centroid): av. Ga(1)—F 1.912(2), Ti(1)—F(1) 2.106(2), Ti(1)—Cp 2.052(1); F(1)—Ga(1)—F(1a) (inside the GaF_2Ti kite-shaped four-membered rings) 78.4(1), F(equatorial)—Ga(1)—F(equatorial) 94.1(1), F(axial)—Ga(1)—F(axial) 168.7(1), F(1)—Ti(1)—F(1a) 70.0(1), Cp—Ti—Cp 134.5(1).

In spite of the fact that these complexes are paramagnetic, (as can be verified from their ESR signals [10]) reasonably sharp resonances (especially **3**) in the ^1H and ^{19}F NMR experiment were obtained. The chemical shifts are within the expected regions. However, for **7** just a broad singlet in the ^{19}F NMR spectrum could be detected. Related NMR measurements for the previously discussed complexes **4** and **6** have not been carried out. The result leads to the conclusion that the mean electron contribution at the titanium centers in **3** need to be unsymmetric.

EXPERIMENTAL

Materials and measurements

All manipulations were carried out under argon using standard Schlenk techniques. Elemental zinc, manganese and gallium as well as mercury(II)chloride and silver fluoride were used as purchased (Aldrich). $[C_5H_4(SiMe_3)]TiF_3$, **2** [11], and $(C_5H_5)_2TiF_2$, **5** [11], were prepared according to literature methods. IR spectra were obtained on a Perkin–Elmer Bio-Rad FTS-7 spectrophotometer as Nujol mulls between KBr plates, NMR spectra on Bruker AM 250 and WP 80 SY, mass spectra on Finnigan MAT 8230 and Varian MAT CH 5. Micro analyses were performed at the analytical laboratory of the Institut für Anorganische Chemie Göttingen and the Mikroanalytisches Laboratorium Beller, Göttingen.

Synthesis of $\{[C_5H_4(SiMe_3)]_2TiF_2\}_3Ti$, **3**

A solution of $[C_5H_4(SiMe_3)]TiF_3$ (0.97 g, 4.0 mmol) in THF (40 cm^3) was added to zinc and manganese powder (about 8.0 mmol), respectively, which has been activated by stirring with $HgCl_2$ (2 mg) for several hours in THF (20 cm^3). The mixture was stirred for 2 days at ambient temperature. During this time the colour of the solution changed from yellow–orange to blue. The solution was concentrated to 20 cm^3 and, after addition of n-hexane (60 cm^3), filtered through celite. The filtrate was concentrated again to 30 cm^3 and kept at 0°C for 2 days to afford the product as blue crystals. Yield: 50% (Zn), 80% (Mn). M.p. 335°C (decomp). Found: C, 51.0; H, 7.0; F, 9.9. $C_{48}H_{78}F_6Si_6Ti_4$ requires: C, 51.1; H, 6.9; F, 10.1%. IR: 3043 m, 1248 s, 1176 s, 1058 s, 906 s, 873 s, 813 s, 756 s, 492 s, 403 s cm^{-1}. MS (EI): 360 $\{[C_5H_4(SiMe_3)]_2TiF_2$, 8%$\}$, 341 $\{[C_5H_4(SiMe_3)]_2TiF$, 64%$\}$, 326 $\{[C_5H_4(SiMe_3)]_2$ TiF—Me, 100%$\}$. ^1H NMR ($CDCl_3$, TMS): 6.55–6.44 (m, 4H), 0.21 (s, 9H) ppm. ^{19}F NMR ($CDCl_3$, $CFCl_3$): 72 ppm.

Synthesis of $[(C_5H_5)_2TiF_2]_3Ga$, **7**

A suspension of $(C_5H_5)_2TiF_2$ (0.50 g, 2.3 mmol) in THF (30 cm^3) was added to a mixture of gallium (0.56 g, 8.0 mmol) and $HgCl_2$ (2 mg) in THF (30 cm^3) which has been stirred for activation for several hours. The reaction mixture was stirred for 3 days during which time the colour of the solution turned from yellow to blue. The solution was separated from surplus gallium by filtration through celite and concentrated to 20 cm^3. Blue crystals of the product are formed when n-hexane (20 cm^3) was condensed slowly to the solution. Yield: 0.65 g (39%). M.p. 335°C (decomp). Found: C, 49.2; H, 4.8; F, 16.5. $C_{30}H_{30}F_6Ti_4Ga$ requires: C, 50.1; H, 4.2; F, 15.9%. IR: 3110 m, 1013 m, 805 s, 489 s, 404 s, 379 m, 354 m cm^{-1}. MS (EI): 216 $[(C_5H_5)_2TiF_2$, 52%$]$, 197 $[(C_5H_5)_2TiF_2$—F, 100%$]$. ^{19}F NMR ($CDCl_3$, $CFCl_3$): 92 (broad) ppm.

X-ray data collection, structure solution and refinement

Intensities for all structures were collected on a Stoe-Siemens-AED instrument with graphite-monochromated Mo-K_α radiation (λ = 71.073 pm). Data were collected from oil-coated rapidly cooled crystals [12] at low temperatures with a profile-fitted method [13]. The structures were solved by direct methods with SHELXS-90 [14]. All structures were refined by full-matrix least-squares procedures on F^2, using SHELXL-96 [15]. The hydrogen atoms were geometrically idealized and refined using a riding model. The disorder of one of the six Me_3Si- groups present in **3** over two positions was refined by using distance similarity restraints. Relevant crystallographic data for **3** and **7** are listed in Table 1. Further details on the crystal structure analysis are available on request from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, U.K. by quoting the full journal citation.

(Received 19 April 1996; accepted 20 May 1996)

Abstract—A ternary copper(I) complex with ethylene and tetramethylethylenediamine(tmen) has been prepared and the structure characterized by the single crystal X-ray method. The copper atom is coordinated to two nitrogen atoms of tmen and an ethylene molecule in a trigonal-planar arrangement. The C=C bond distance of 1.36(1) Å is slightly longer than that of the free ethylene (1.335 Å). In the ^{1}H NMR study, chemical shifts of ethylene protons at 5.46 ppm move upfield (4.16 ppm) upon coordination to copper(I). This indicates that the π back donation from copper to the ethylene is rather weak compared with other metal–ethylene systems. Copyright © 1996 Elsevier Science Ltd

Keywords: crystal structure; copper(I) complex; copper(I)-ethylene bonding; tetramethylethylenediamine; ^{1}H NMR.

The nature of metal-olefin bonding has been the subject of numerous theoretical studies [1–3]. The Dewar–Chatt–Duncanson concept [4] regarding olefins as σ donors and π acceptors has been used to explain most of the features observed in olefin bondings and shown to be readily applicable to the bonding of other types of unsaturated molecules.

We are interested in whether σ donation or π back-donation is dominant in the olefin complexes of copper(I) from its bonding difference with aromatic N-ligand and aliphatic N-ligand [5]. Some ethylene complexes of copper(I) with aromatic N-ligand have been characterized by the single crystal X-ray method [6] but no aliphatic N-ligand. It has been reported that π back-donation in the Cu–ethylene bond of ternary copper(I) complexes $[Cu(biL)(C_2H_4)]^+$ is promoted with increasing basicity of biL, where biL is 1,10-phenanthroline or its derivatives [5]. In this paper, we report the synthesis and structure of a copper(I) ethylene complex with an aliphatic N-ligand tetramethylenediamine(tmen), $[Cu(tmen)(C_2H_4)]ClO_4$. The nature of the copper(I) ethylene bonding is also discussed.

EXPERIMENTAL

General

The preparation was carried out under dry, purified nitrogen and ethylene by using the standard Schlenk or vacuum line technique. Tetrakis(acetonitrile) copper(I) perchlorate was prepared according to the literature procedures [8]. Ethanol treated with Mg/I_2 was refluxed for 5 h. Acetonitrile was purified according to the literature procedure [9]. Reagent grade tetramethylethylenediamine(tmen) was obtained from Wako Pure Chemical, Inc. All other chemicals were of reagent grade and used without further purification.

Synthesis of $[Cu(tmen)(C_2H_4)]ClO_4$

Tmen (22.5 cm^3, 30 mmol) was added to a solution of tetrakis(acetonitrile)copper(I) perchlorate (55.9 mg,

30 mmol) in ethanol (5.0 cm^3) under ethylene at 0°C. The colorless solution was sealed in a glass tube and left standing at 5°C. After 2 days, colorless crystals of the complex suitable for X-ray diffraction studies were obtained which were filtered off and dried under ethylene gas. Found: C, 31.4; H, 6.2; N, 9.3. Calc. for $C_8H_{20}N_2CuClO_4$: C, 31.3; H, 6.6; N, 9.1%.

X-ray structure analysis

A crystal was coated with paraffin to avoid decomposition in the air. Diffraction data were obtained on a Rigaku AFC-6S four-circle diffractometer. Crystal data and details of measurements for the compound are summarized in Table 1. Three standard reflections were monitored every 100 measurements, and the decay of their intensities was within 5%. Reflection data were corrected for Lorentz and polarization effects. Empirical absorption corrections were applied.

The structure was solved by the heavy-atom method and refined anisotropically for non-hydrogen atoms by full-matrix least-squares calculations. Reliability factors are defined as $R = \Sigma(|F_o| - |F_c|)/\Sigma(|F_o|)$ and $R_w = \{\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_c|^2\}^{1/2}$. All hydrogen atoms were placed in calculated positions, but their parameters were not refined.

Atomic scattering factors and anomalous dispersion terms were taken from the usual sources. The calculations were performed on the FACOM M 780 computer at Data Processing Center of Kyoto University by using the programme system TEXSAN.

Selected bond distances and angles are listed in Table 2.

^{1}H NMR spectroscopy

^{1}H NMR spectra were obtained in $(CD_3)_2CO$ at 200 MHz with a JEOL FX-200 NMR spectrometer, and chemical shifts are given in ppm relative to tetramethylsilane as an internal reference.

RESULTS AND DISCUSSION

Molecular structure

The molecular structure of $[Cu(tmen)(C_2H_4)]ClO_4$ together with the atomic numbering scheme is given in Fig. 1. The structure consists of a discrete monomeric $[Cu(tmen)(C_2H_4)]^+$ cation and an uncoordinated perchlorate anion. Each copper(I) ion involves a trigonal planar coordination environment comprising two N atoms of tmen and one molecule of ethylene. The perchlorate anion is not coordinated to the copper atom as the closest contact between its oxygen and the metal centre is 3.124(9) Å. The averaged Cu—C(olefin) distances of 1.96 Å is in the range of 1.93–2.07 Å observed in the previously reported ternary copper(I) complexes Cu(biL) $(C_2H_4)ClO_4$ where biL is an aromatic nitrogenous ligand such as 2,2′-dipyridine, or 1,10-phenanthroline [7].

The C=C distance of 1.36(1) Å found in [Cu

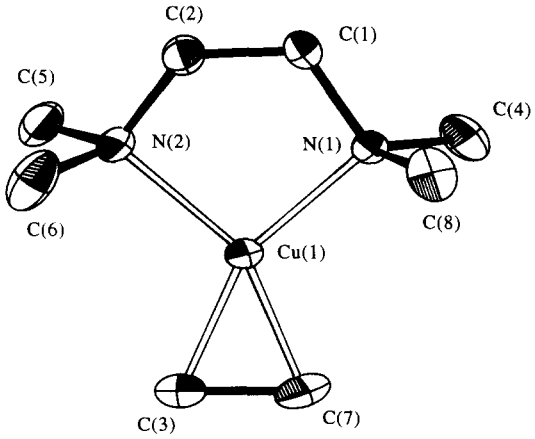

Fig. 1. Molecular structure of $[Cu(tmen)(C_2H_4)]^+$.

$(tmen)(C_2H_4)]ClO_4$ is slightly longer than that for the free ethylene molecule (1.335 Å (average)), but compares well with those in $[Cu(bpy)(C_2H_4)]ClO_4$ (1.346–1.360 Å), [7], and $[Cu(phen)(C_2H_4)]ClO_4$ (1.361 Å) [7]. Ethylene exhibits a C=C stretching frequency coupled with $\delta_s(CH_2)$ at 1623 cm^{-1}, whereas the copper(I) ethylene complex with tmen shows the stretching frequency at 1525 cm^{-1} upon coordination. The decreasing of the C=C stretching frequency is thought to correspond roughly to the increase in the π character of the double bond [10], which will be discussed in the following section.

^1H *NMR spectra*

^1H NMR spectra of tmen, ethylene, and $[Cu(tmen)(C_2H_4)]^+$ at −90°C are shown in Fig. 2. The resonances of free tmen at 2.29 ppm(1-H) and 3.83 ppm(2-H) shifted to 2.73 ppm and 3.78 ppm in the ethylene complex, respectively. Such a downfield shift of the resonances of tmen is generally observed with coordination to a metal ion [5,11,16]. In contrast, the resonance of the olefinic protons of ethylene at 5.43 ppm moves upfield (to 4.16 ppm) upon coordination. This agrees with the trend that olefin π complexation for most transition metals results in shielding of the olefinic protons. The ^1H NMR chemical shifts of the olefinic protons with the other ternary Cu^I complexes of aromatic nitrogenous ligands are 4.84 ppm for $[Cu(bpy)(C_2H_4)]^+$, 5.02 ppm for $[Cu(phen)(C_2H_4)]^+$ [5,11]. The ^1H NMR spectra of the present complex demonstrate the formation of the ternary copper(I) complex with ethylene and tmen in solution.

The ^1H NMR resonances of the olefinic protons in these ternary systems shifting upfield is due to increased shielding of the protons caused by the π back-donation. The magnitude of this shift is dependent on basicity of the N-ligands (aromatic) as described above [5]. It is expected from this fact that the upfield shifts in ternary Cu^I ethylene complexes with aliphatic N-ligand tmen should be larger compared with the aromatic N-ligands, because the pK_a value (basicity) for tmen ($pK_{a1} = 9.15$, $pK_{a2} = 5.91$, the average value = 7.53) is generally higher than that for phen and its derivatives ($pK_a = 4.10$–6.58). In fact the chemical shift for the former indicates a larger upfield shift (4.16 ppm) than for the latter (4.72–5.34 ppm). The results clearly indicate that the σ donation of the tmen nitrogens to copper(I) is enhanced as the nitrogen basicity increases and the resulting electron-rich copper promotes π back-donation in the copper–ethylene bonding.

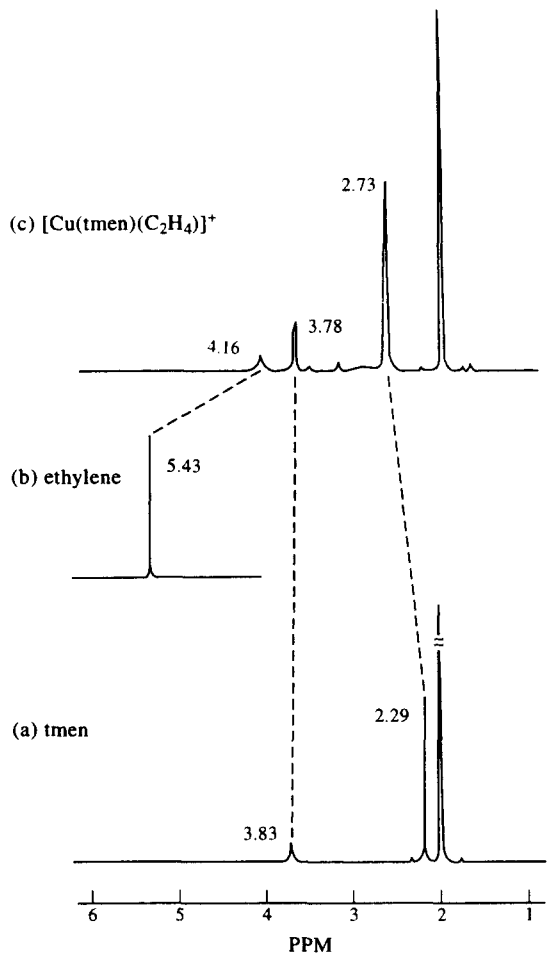

Fig. 2. ^1H NMR spectra of (a) tmen, (b) ethylene, (c) $[Cu(tmen)(C_2H_4)]^+$ in acetone-d_6 at −90°C.

It is worth noting that a linear relationship between C=C distances and ^1H NMR chemical shifts of the ethylene for the metal–ethylene complexes is shown in Fig. 3 with data referring to Table 3, indicating that the metal–ethylene bonding can be correlated with the ^1H NMR chemical shifts. All copper(I) ethylene complexes exhibit shielding of olefinic protons, similar to the ethylene complexes of rhodium (3.1 ppm), [12] platinum (2.0 ppm [13], and nickel (1.9 ppm) [12b, 14]. In contrast, only the silver(I) ethylene complex exhibits deshielding (5.7 ppm) [12b]. A delicate difference in metal–olefin bonding nature can be quali-

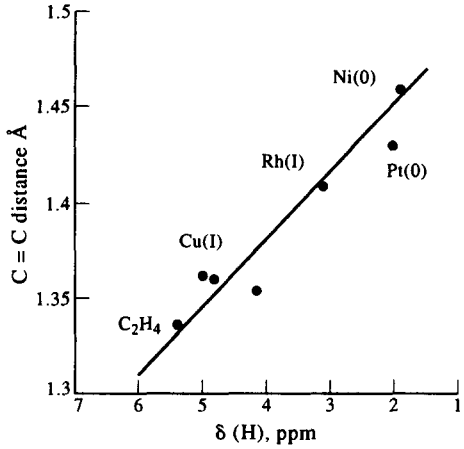

Fig. 3. Plot of ^{1}H NMR chemical shifts of the olefinic protons of ethylene in $[Cu(tmen)(C_2H_4)]^+$ at −90°C against C=C distances of ethylene.

Table 3. C=C distances and ^{1}H NMR chemical shifts of ethylene metal complexes

	C=C distances (Å)	$\delta(^1H)$ (ppm)	Reference
C_2H_4	1.337	5.4	[5]
$Cu(tmen)(C_2H_4)$	1.354	4.16	This work

(Received 10 April 1996; accepted 20 May 1996)

Abstract—The title complex was synthesized by reaction of sodium isonicotinate with manganese(III) acetylacetonate. The single crystal structure of the complex was determined by X-ray diffraction. Around the Mn^{III} atom the octahedral coordination polyhedron is tetragonally elongated. An isonicotinate anion coordinates to the Mn^{III} atom through the pyridine nitrogen atom in the axial direction with a Mn—N bond of 2.293(3) Å, while two acetylacetonate anions chelate to Mn^{III} in the equatorial plane with average Mn—O length of 1.91 Å. Copyright © 1996 Elsevier Science Ltd

Keywords: isonicotinato; acetylacetonato; manganese(III) complex; synthesis; crystal structure; Jahn–Teller distortion.

Manganese chemistry has been receiving a great deal of attention. Manganese ions are found to play an important role in some biological enzymes such as manganese superoxide dismutase (SOD), non-heme catalases and photosystem-II. This stimulated a desire to understand the structural chemistry of Mn in different oxidation states [1–3]. Octahedral complexes of high-spin Mn^{III} are also expected to be susceptible to Jahn–Teller distortions [4–7] causing them to deviate from identical Oh symmetry by either a trigonal distortion or a tetragonal elongation or compression. The studies on manganese ions chelated by biochemical reagents have been ongoing in our laboratory with the aim of mimicking the chemical environment of manganese enzymes. As a part of our study we report here the synthesis and structure of $[Mn(acac)_2(i\text{-}nic)(H_2O)]$.

EXPERIMENTAL

Synthesis

To an aqueous solution of $MnAc_2 \cdot 4H_2O$ (1.98 g, 8 mmol in 20 cm^3) acetylacetone (2 g, 20 mmol) was added, followed by dropwise addition of an aqueous solution of $KMnO_4$ (0.216 g, 2 mmol in 10 cm^3). After stirring for about 15 min at room temperature, the sodium isonicotinate solution prepared previously (10 mmol in 20 cm^3) was added with continuous stirring for 30 min. After filtering and standing the solution for several days, the well-shaped crystals of the title complex were obtained from the filtrate.

X-ray structure analysis

Preliminary examination of the crystal and data collection were performed on an Enraf-Nonius CAD-4 diffractometer. Intensity data were collected by ω-2θ scans using graphite monochromated Mo-K_α radiation. A total of 1856 independent reflections were measured with 2θ up to 50°, of which 1490 observed reflections [$I > 3\sigma(I)$] were employed in the structure refinements. Both Lp correction and empirical absorption correction were applied. The structure was solved by the Patterson method followed by Fourier syntheses. The crystallographic parameters are summarized in Table 1.

RESULTS AND DISCUSSION

Synthesis

The described synthetic procedures offer convenient routes for the preparation of the title complex. The

$MnAc_2 \cdot 4H_2O$ can be substituted by either $MnCl_2 \cdot 4H_2O$ or $MnSO_4 \cdot H_2O$. But the dark brown title complex is always accompanied by a white crystalline compound, which was found to be an Mn^{II} complex, bis(isonicotinato)tetraaquamanganese(II), by the later X-ray structure analysis.

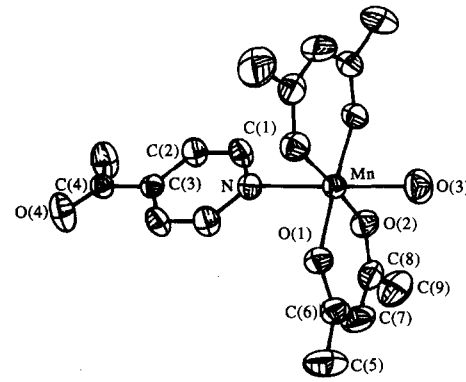

Fig. 1. ORTEP drawing (50% probability thermal ellipsoids) and labelling scheme for the non-hydrogen atoms of $[Mn(acac)_2(i\text{-nic})]$.

Structure

The molecular structure of the title complex is shown in Fig. 1. In the crystal the molecule is located about the twofold axis. The Mn^{III} atom has an elongated octahedral coordination geometry as shown in Table 2. The axial Mn—O(H_2O) bond is about 0.2 Å longer than the Mn—O(acac) bond in the equatorial plane. The axial Mn—N(i-nic) bond distance is about 0.3 Å longer than the Mn—N bond in the equatorial plane found in $[Mn(phen)_2Cl_2]NO3$ [9], and comparable to those in the axial direction of reported Mn^{III} complexes, for example in $Mn(acac)_2(NCS)$ [4], $Mn(acac)_2(N_3)$ [6], Mn(TPP)(N_3) [8], Mn(TPP)(NCS)(py) [4] and Mn(TPP)(Cl)(py) [10]. These

observations are consistent with a Mn^{III} in the high-spin state. Both the C3—C4 bond length of 1.521(5) Å and the dihedral angle of 9.6° between the carboxyl group and the pyridine plane suggest no conjugation between the pyridine ring and the carboxyl group. This agrees with nicotinate complexes reported previously [11]. The acac ligand is highly coplanar but not perpendicular to the twofold axis. The dihedral angle between two acac ligands, related by a twofold axis, is 170.4°. The torsional angles of O1—Mn—N—C1* [15.1°] and O1—Mn—N—Cl [164.9°] indicate that the pyridine ring does not bisect the dihedral angle between acac ligands (see Fig. 2). The short non-bonded O1—C1 atomic separation of 3.184 Å implies van der Waals contact between the pyridine ring and the acac ligand. This is also comparable to a previous report [12]. In the unit cell, the extensive hydrogen-bonding network exists among carboxyl O atoms, coordinated and uncoordinated water molecules. The crystal packing is mainly through hydrogen bonding. Van der Waals forces also contribute to the crystal packing.

(Received 2 April 1996; accepted 17 May 1996)

Abstract—Sodium potassium citrato molybdate $K_2Na_4[(MoO_2)_2O(cit)_2]\cdot 5H_2O$ has been prepared by the reaction of potassium trihydrogen citrate and sodium molybdate. Analysis of the crystal structure reveals that the anion of the complex contains a bent $(MoO_2)O(MoO_2)$ core with an Mo—O—Mo angle 142°. Each molybdenum has a distorted octahedral coordination and citrato ligands are tridentate to the two molybdenum atoms via the deprotonated hydroxy-, α- and β-carboxyl groups. Principal dimensions are: $[Mo{=}O(t)]_{av}$, 1.706(4); $[Mo{-}O(b)]_{av}$, 1.899(3); $[Mo{-}O(hydroxy)]_{av}$, 1.944(3); $[Mo{-}O(\alpha\text{-carboxy})]_{av}$, 2.207(3), and $[Mo{-}O(\beta\text{-carboxy})]_{av}$, 2.264(3) Å. The IR, ^1H and ^{13}C NMR spectra are in agreement with this structure.

Keywords: oxomolybdenum(VI); molybdate(VI); citric acid citrate; nitrogenase; crystal structure.

Molybdenum is a trace element which plays an important role in different living plants and animal organisms [1]. It is known that some types of small biomolecules such as hydroxycarboxylic acids are strong molybdenum binders. Recent studies on the nitrogenase enzyme revealed its active site as a cage-like $MoFe_7S_9$ homocitrate cluster, in which the octahedral coordination sphere of the Mo within the cluster consists of three sulfides, a nitrogen atom from the imidazole group of a histidine residue, and two oxygen atoms from the hydroxy group and α-carboxyl moiety of homocitric acid [2], alternative polycarboxylic acids including citric, malic and citramalic by *in vitro* syntheses of the FeMo-co displayed N_2 reduction activity well above the background limits [3]. This prompted an investigation of the coordination chemistry of oxomolybdenum citrato complexes.

Citric acid (H_4cit) has been found to act usually as a polydentate ligand, generally involving the central hydroxy and carboxyl group [4]. Of the four ionizable protons, three or four usually dissociate upon coordination, and a citrate with the charge −2 is less common. Its complexes with oxomolybdenum have been studied in the solid and in solution [5–13]. The first well characterized citrato molybdate was reported as $[Me_3N(CH_2)_6NMe_3]_2[Mo_4O_{11}(Hcit)_2]\cdot 12H_2O$ [8], and later a similar Mo:cit ratio 2:1 compound was prepared as $K_4[Mo_4O_{11}(Hcit)_2]\cdot 6H_2O$ [10]. Formation of 1:1 ratio complex was obtained as early as $K_2[MoO_3(OH)(H_3cit)]\cdot 2H_2O$ and $K_3[MoO_4(H_3cit)]\cdot 2H_2O$ [9], later $K_4[(MoO_2)_2O(Hcit)_2]\cdot 5H_2O$, $K_6[(MoO_2)_2O(cit)_2]\cdot 7H_2O$ and $K_4[MoO_3(cit)H_2O]$ [12] were obtained by precipitation from aqueous solution at pH 4–8. These complexes have been characterized by a variety of methods, however, the isolation of molybdenum(VI) citrate complexes in crystalline form suitable for X-ray structural analysis has been quite difficult [13]. The present X-ray analysis of the title compound shows that potassium trihydrogen citrate reacts with sodium molybdate to give the sodium potassium oxocitrato molybdate(VI) dimer, which shows a bent $(MoO_2)O(MoO_2)$ core configuration, and the molybdenum(VI) atoms are coordinated tridentately by the oxygen atoms of hydroxy- and carboxylate of quadridentate citrate anion. The

^1H and ^{13}C NMR spectroscopy suggest this dimeric structure also exists in solution.

EXPERIMENTAL

All reagents are commercially available. Potassium trihydrogen citrate was prepared from the reaction of equimolar citric acid and sodium hydroxide. Infrared spectra were recorded as Nujol mulls between KBr plates using a Nicolet 740 FT-IR spectrometer. The ^1H and ^{13}C NMR spectra were recorded on a Varian UNITY 500 NMR spectrometer.

Preparation of sodium potassium citrato molybdate $K_2Na_4[(MoO_2)_2O(cit)_2]\cdot 5H_2O$

Sodium molybdate (20 mmol) was reacted with an excess potassium trihydrogen citrate in a water bath. The resulting mixture was filtered, cooled and crystallized. The solid was collected and washed to give a white solid (6.0 g, 66%). Found: C, 15.4; H, 1.9. Calc. for $C_{12}H_{18}O_{24}Na_4K_2Mo_2$: C, 15.9; H, 2.0%; IR(KBr): ν_{asym} (C=O) 1644 vs, 1588 s; ν_{sym} (C=O) 1398 vs, ν (Mo=O) 950 s, 902 s, ν (Mo—O_b) 715 s, cm^{-1}, ^1H NMR δ_H (500 MHz, D_2O) ppm: 2.714 (4H, J_{AB} 16.0 Hz, CH_{2B}), 2.516 (4H, J_{AB} 16.5 Hz, CH_{2A}); ^{13}C NMR (500 MHz, D_2O) ppm: 186.111, 185.490 $(CO_2)\alpha$, 178.372, 178.323, 178.275, 178.111 $(CO_2)_\beta$, 85.738, 84.843 (≡C—O), 46.131, 45.834, 45.119, 44.791, 44.085, 43.788 ppm (=CH_2).

Crystals of suitable quality for the subsequent X-ray diffraction studies were obtained as transparent plates by slow evaporation of a related solution of the title compound at room temperature. The resulting crystals were sealed to prevent loss of water molecules.

X-ray data collection, structure solution and refinement

Crystallographic data for the citratomolybdate are summarized in Table 1. Diffraction data were collected on an Enraf-Nonius CAD-4 diffractometer with graphite monochromated Mo-K_α radiation at 296 K. Lp factor, anisotropic decay and empirical absorption corrections were applied. The structure was solved by heavy atom methods and refined by full-matrix least-squares procedures with anisotropic thermal parameters for all the non-hydrogen atoms. All H atoms were located on a difference Fourier map and refined isotropically. All calculations were performed on a 486 DX2/66 microcomputer using MoLEN software package.

RESULTS AND DISCUSSION

The title compound was prepared by the reactions of sodium molybdate and excess potassium trihydrogen citrate (KH_3cit). Note a similar reaction of sodium tungstate or ammonium metavanadate with citric acid has been reported [14,15]. However, the pH values in the reactions are controlled easily by citrate anions acting as both reactant and buffer agent. The loss of protons suggest the reaction (1), which corresponds to $[(MoO_4)_p(Hcit)_q(H^+)_r]^{(2p+3q-r)-}$ stoichiometry of 2:2:4 showed in potentiometry, spectrophotometry, differential pulse polarography and calorimetry [13].

$$2MoO_4^{2-} + 2H_3cit^- \rightarrow [(MoO_2)_2O(cit)_2]^{6-} + 3H_2O \quad (1)$$

Similarly, good yield of citrato tungstate could be obtained by the reaction of sodium tungstate with sodium trihydrogen citrate as reaction (2).

$$2WO_4^{2-} + 2H_3cit^- \rightarrow [(WO_2)_2O(cit)_2]^{6-} + 3H_2O \quad (2)$$

This is also true for the reaction of ammonium metavanadate with potassium dihydrogen citrate as (3).

$$2VO_3^- + 2H_2cit^{2-} \rightarrow [VO_2(cit)]_2^{6-} + 2H_2O \quad (3)$$

The complex crystallizes in the space group $P2_1/n$. Its structure is depicted in Fig. 1. Selected atomic distances and bond angles are given in Table 2.

The dimeric anion consists of the common oxo-bridged $[Mo_2O_5]^{2+}$ entity which is noncentrosymmetric. The angle of Mo—O—Mo is 144.7(2)°, which is intermediate between the values of strictly 180° in $[(MoO_2)_2O(C_2O_4)_2(H_2O)_2]^{2-}$ and 136° in $[(MoO)_2O(O_2)_4(H_2O)_4]^{2-}$ [16,17]. The two terminal oxo groups are in a *cis*-configuration. Each molybdenum atom is six-coordinate with approximately octahedral geometry. The terminal and bridging oxo-groups adopt a *fac*-stereochemistry. The *trans* positions are occupied by a fully deprotonated tridentate citrate. The coordination mode is similar to the proposed structure of citrato cubane $MoFe_3S_4$ cluster $(Et_4N)_2[MoFe_3S_4Cl_3(H_2cit)]$, and probably the hydroxy group in the cubane should be deprotonated [18].

Although no symmetry is imposed upon the molecule, there is a pseudo-twofold axis that passes through the bridging oxygen, which is perpendicular to the Mo—Mo vector. The lists of chemically equi-

valent bond distances and angles (Table 2) illustrate the approximately twofold symmetry. The configuration is consistent with one of the proposed structures of 1 : 1 dinuclear complex of molybdenum(VI) and citrate [7, 12, 13]. The Mo—O distances can be classified into three types with the order Mo=O (unshared oxygen) (1.694 ~ 1.713 Å) < Mo—O (bridging oxo group) (1.882 ~ 1.916 Å) ≈ Mo—O(hydroxy) (1.930 ~ 1.958 Å) < Mo—O(α-carboxy) (2.196 ~ 2.217 Å) ≈ Mo—O(β-carboxy) (2.250 ~ 2.278 Å). The Mo(1,2)—O(1) distances (av. 1.899 Å) are very close to those in $[(MoO_2)_2O(C_2O_4)_2(H_2O)_2]^{2-}$ (1.876 Å) [16] and $[(MoO_2)_2O(Hnta)_2]^{2-}$ [1.880 Å, $H_3nta = N(CH_2CO_2H)_3$] [19]. The Mo(VI)—O(hydroxy) distances (av. 1.944 Å) are similar to those in $[MoO_2(Hmal)_2]^{2-}$ (H_3mal = malic acid) (1.939 Å) [20] and $[MoO(O_2)_2(H_2cit)]^{2-}$ (2.011 Å) [21]. The Mo—O (α-carboxy) distances (av. 2.207 Å) and the longest Mo—O (β-carboxy) (av. 2.264 Å) show weak coordination of the carboxyl group with Mo^{VI}. The Mo—O (β-carboxy) is shorter than those already reported tetramers $[(MoO_2)_4O_3(Hcit)_2]^{4-}$ (2.323 Å) [14] and $[(MoO_2)_4O_3(R\text{-mal})_2]^{4-}$ (2.296 Å) [22] (Table 3).

Due to the Mo—O single bond which exists in the dimer and the existence of the monomer in narrow pH range [12], the equilibrium for the dimerization reaction might proceed easily as follows:

$$2[MoO_3(Hcit)(H_2O)]^{3-} \rightleftharpoons [Mo_2O_5(cit)_2]^{6-} + 2H_2O$$

Moreover, like the citratovanadates, the protonation and deprotonation of citratomolybdate might have less influence on the dimeric structure [23]. This means the different p, q, r in $[(MoO_4)_p(Hcit)_q(H^+)_r]^{(2p+3q-r)-}$ like [2, 2, 4], [2, 2, 5], [2, 2, 6] can be transformed in solution without changing the dimeric structure of citratomolybdate as following:

$$[Mo_2O_5(cit)_2]^{6-}$$

$$\rightleftharpoons [Mo_2O_5(Hcit)(cit)]^{5-} \rightleftharpoons [Mo_2O_5(Hcit)_2]^{4-}$$

The crystal structure comprises discrete $[(MoO_2)_2O(cit)_2]^{6-}$ anions, sodium or potassium cations and water molecules. Waters of crystallization are distributed throughout the cell and together with various of the anion oxygens, make the sodium or potassium cations six-coordinate.

Moreover, the complex exhibits the following infrared absorption bands: ν_{asym} (COO): 1644 vs, 1588 s, ν_{sym} (COO): 1398 vs, ν (Mo=O): 950 s, 902 s cm^{-1}, and ν (Mo—O_b—Mo): 715 s. The separation (Δ) between ν_{asym} and ν_{sym} is 246 and 190 cm^{-1}, which is greater than the value of 150 cm^{-1} for uncomplexed sodium citrate salt, implying the presence of free or unidentately coordinated carboxyl groups. The strong band at 715 cm^{-1} is assigned to the symmetric Mo—O—Mo stretch in agreement with previous studies. There is no other band at higher energy that can be assigned to asym stretching consistent with a bent disposition of the bridge. The Mo=O bands give rise to two major bands around 900 cm^{-1}, characteristic of the symmetric and asymmetric stretches of the *cis*-dioxo groups.

In the ^1H NMR spectra the methylene protons of citric acid give rise to an AB quartet which shifts with pH [24]. Complexation with molybdenum(VI) leads to a slightly distorted AB quartet with $\delta q = 2.714$, 2.516 ppm respectively, indicating that both CH_2CO_2 arms are almost equivalent [12]. The shifts of the ^{13}C resonances (in comparison with those for citrate) [12, 24] of the alcoholic and α-carboxylic function show that the citrate is coordinated through these two groups, while the β-carboxylic region only a small shift is observed, indicating that the bonding to molybdenum is weak.

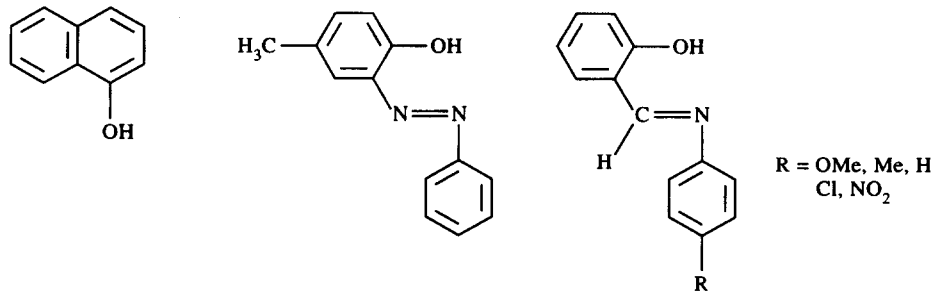
Department of Chemistry, Inorganic Chemistry Section, Jadavpur University, Calcutta 700 032, India

(Received 13 February 1996; accepted 16 May 1996)

Abstract—Seven complexes of the type $[Ru^{III}(PPh_3)_2(L)Cl_2]$ (where L = 8-quinolinolate, 4-methyl-2-(phenylazo)phenolate and salicylal-diminate anion) have been synthesized by the reaction of $[Ru(PPh_3)_3Cl_2]$ with HL. These complexes are one-electron paramagnetic and show rhombic ESR spectra in 1 : 1 dichloromethane-toluene at 77 K. In CH_2Cl_2 solution, these complexes show intense LMCT transitions in the visible region together with weak ligand-field transitions at lower energies. Each of these complexes shows a ruthenium(III)–ruthenium(II) reduction (−0.12 to −0.40 V *vs* SCE) and a ruthenium(III)–ruthenium(IV) oxidation (0.78–0.88 V *vs* SCE) in acetonitrile solution. The potentials of the ruthenium(III)–ruthenium(II) reduction vary linearly with the nature of substituent in L. The $[Ru^{III}(PPh_3)_2(L)Cl_2]$ complexes react with bidentate chelating ligands (L′ = 8-quinolinolate anion, 2,2′-bipyridine, 1,10-phenanthroline) to afford complexes of type $[Ru(PPh_3)_2(L)(L')]^{n+}$. These complexes are diamagnetic and show intense MLCT transitions in the visible region. The potential of the ruthenium(II)–ruthenium(III) couple in these complexes depend on the nature of both L and L′. Copyright © 1996 Elsevier Science Ltd

Keywords: ruthenium phenolates; synthesis; characterization; redox properties.



The present work has developed from our interest in the chemistry of ruthenium in different coordination spheres [1]. We have observed that coordination of ruthenium by phenolate oxygen is very effective in stabilizing the higher oxidation states of this metal [2]. In this study, phenolic ligands of three different types have been used, which are 8-quinolinol (HQ, **1**), 4-methyl-2-(phenylazo)phenol (Hap, **2**) and salicylaldimine (Hsal-R, **3**). All these ligands (abbreviated in general as HL, where H stands for the acidic hydrogen) bind to a metal ion as bidentate N,O-coordinator *via* dissociation of the phenolic proton. It may be noted here that the ruthenium chemistry of these ligands has received relatively little attention [3–5]. Herein we report the synthesis and characterization of a group of complexes of type $[Ru^{III}(PPh_3)_2(L)Cl_2]$ and their spectroscopic and electron-transfer properties. Reactivity studies, involving the dissociation of Ru—Cl bonds, are also described.

EXPERIMENTAL

Materials

Commercial ruthenium trichloride, purchased from Arora Matthey, Calcutta, India was converted to $RuCl_3 \cdot 3H_2O$ by repeated evaporation with concentrated hydrochloric acid. Triphenylphosphine (PPh_3), triethylamine (Et_3N), 2,2′-bipyridine (bpy), 1,10-phenanthroline (phen) and 8-quinolinol (HQ) were purchased from SD Fine Chemicals, Bombay, India. $[Ru(PPh_3)_3Cl_2]$ was prepared by following a reported procedure [6]. The salicylaldimine ligands were prepared by reacting equimolar amounts of salicylaldehyde and the respective amine in hot ethanol. The 4-methyl-2-(phenylazo)phenol ligand was prepared by coupling diazotized aniline with *p*-cresol. Purification of acetonitrile and dichloromethane and preparation of tetraethylammonium perchlorate (TEAP) for electrochemical work were performed as reported earlier [1a]. All other chemicals and solvents were reagent grade commercial materials and were used as received.

Preparation of complexes

The seven $[Ru(PPh_3)_2(L)Cl_2]$ complexes were synthesized by using a general procedure. Yields varied in the range 80–90%. Specific details are given for one complex.

$[Ru(PPh_3)_2(Q)Cl_2]$. To a mixture of $[Ru(PPh_3)_3Cl_2]$ (100 mg, 0.10 mmol) and 8-quinolinol (15 mg, 0.10 mmol) was added dichloromethane (40 cm^3). The resulting solution was stirred for 30 min. The volume of the solvent was reduced by evaporation and hexane was added to it upon which $[Ru^{III}(PPh_3)_2(Q)Cl_2]$ started separating out as a dark-coloured solid. This was collected by filtration, washed thoroughly with hexane and dried in air. The yield was 70 mg, 83%.

$[Ru(PPh_3)_2(Q)_2]$. To a solution of $[Ru(PPh_3)_2(Q)Cl_2]$ (100 mg, 0.12 mmol) and 8-quinolinol (17 mg, 0.12 mmol) in acetonitrile (40 cm^3) was added triethylamine (24 mg, 0.24 mmol). The resulting solution was refluxed for 1 h upon which the colour of the solution changed from green to yellowish red. The solution was cooled and concentrated by evaporation. Ether was then added to the solution and $[Ru(PPh_3)_2(Q_2)]$ separated out as a brown microcrystalline solid. It was filtered, washed with water and ethanol and dried in air. The yield was 95 mg, 87%.

$[Ru(PPh_3)_2(ap)(phen)]ClO_4$. To a solution of $[Ru^{III}(PPh_3)_2(ap)Cl_2]$ (100 mg, 0.11 mmol) and 1,10-phenanthroline (22 mg, 0.11 mmol) in acetonitrile (40 cm^3) was added triethylamine (22 mg, 0.22 mmol). The colour of the solution changed from green to yellowish red upon refluxing the solution for 1 h. The solution was then cooled to room temperature and a saturated aqueous solution of $NaClO_4$ (10 cm^3) was added to it. $[Ru^{III}(PPh_3)_2(ap)(phen)]ClO_4$ precipitated as a dark solid, which was collected by filtration, washed with ice-cold water and dried *in vacuo* over P_4O_{10}. Recrystallization of this crude product from acetonitrile–toluene solution gave $[Ru(PPh_3)_2(ap)(phen)]ClO_4$ in the pure state. The yield was 75 mg, 60%.

$[Ru(PPh_3)_2(sal\text{-}H)(bpy)]ClO_4$. This was prepared by following the same above procedure using $[Ru(PPh_3)_2(sal\text{-}H)Cl_2]$ and bpy instead of $[Ru(PPh_3)_2(ap)Cl_2]$ and phen, respectively.

Physical measurements

As described earlier [1a].

RESULTS AND DISCUSSION

Synthesis and characterization

The reaction of $[Ru(PPh_3)_3Cl_2]$ with an equimolar quantity of HL in dichloromethane solution at ambient temperature afforded the $[Ru(PPh_3)_2(L)Cl_2]$ complexes [eq. (1)] in good yields. In total seven complexes have been prepared using different phenolic ligands.

$$[Ru^{II}(PPh_3)_3Cl_2] + HL \rightarrow [Ru^{III}(PPh_3)_2(L)Cl_2] + H^+ + e^- \quad (1)$$

It is interesting to note here that during the course of this synthetic reaction ruthenium undergoes a one-electron oxidation. In view of the low ruthenium(III)–ruthenium(II) reduction potential in these complexes (*vide infra*) oxygen in the air appears to be the probable oxidant [7].

Elemental (C, H, N) analytical data (Table 1) confirm the compositions of these complexes. Magnetic susceptibility measurements show that these complexes are one-electron paramagnetic (Table 1), as expected for complexes of ruthenium(III) (low-spin d^5, $S = 1/2$). The infrared spectra of these complexes contain many sharp bands of different intensities due to vibrations arising from the coordinated PPh_3, L and Cl^- and are therefore complex in nature. No attempt has been made to assign individual bands. However, comparison of the IR spectra of these $[Ru(PPh_3)_2(L)Cl_2]$ complexes with that of $[Ru(PPh_3)_3Cl_2]$ shows that besides small shifts in frequencies, some vibrations are common in both the spectra (e.g. vibrations near 520, 540, 690 and 740 cm^{-1}) which are due to the common PPh_3 ligand. Some additional bands are observed in the spectra of the $[Ru(PPh_3)_2(L)Cl_2]$ complexes which are obviously due to the coordinated phenolic ligand L. Two sharp bands of medium intensity, observed in all the com-

plexes near 315 cm^{-1} and 330 cm^{-1}, have been attributed to the ν(Ru—Cl) stretching mode [8]. The infrared spectral data are therefore in good agreement with the compositions of these complexes.

The $[Ru(PPh_3)_2(L)Cl_2]$ complexes may exist in four geometrical isomeric forms. However, it is well known that complexes containing the $Ru^{III}(PPh_3)_2$ moiety prefers the *trans* geometry [3b, 9] and hence we assume a similar structure, with the two PPh_3 ligands *trans* to each other, for these $[Ru(PPh_3)_2(L)Cl_2]$ complexes. In this geometry the two Ru—Cl bonds are non-equivalent and hence are expected to vibrate at different energies, as actually observed in the infrared spectra (*vide supra*). The $[Ru(PPh_3)_2(L)Cl_2]$ complexes are soluble in acetonitrile and dichloromethane producing green solutions. Conductivity studies in acetonitrile show that these complexes behave as non-electrolytes in solution, indicating that the chloride ligands do not dissociate in solution. Electronic spectra of these complexes have been recorded in dichlormethane solution. Spectral data are presented in Table 1 and selected spectra are shown in Fig. 1. All the seven complexes display two or three intense absorptions, one of which appears in the visible region while the others extend into the UV region. These are probably due to allowed metal-to-ligand charge-transfer transitions. A low-intensity absorption at lower energy is also displayed by all these complexes which is discussed below.

ESR spectra of three representative complexes, *viz.*, $[Ru^{III}(PPh_3)_2(Q)Cl_2]$, $[Ru^{III}(PPh_3)_2(sal\text{-}H)Cl_2]$ and $[Ru^{III}(PPh_3)_2(ap)Cl_2]$ have been recorded in 1 : 1 dichloromethane–toluene solution at 77 K. A selected spectrum is shown in Fig. 2 and the g-values are given in Table 2. All the three complexes show rhombic spectra with three distinct g-values. The rhombicity of the spectra reflects the asymmetry of electronic environments around ruthenium in these complexes. Under the combined influence of this low-symmetry and spin-orbit coupling, the three t_2-levels get well separated. Hence two electronic transitions (transition energies ΔE_1 and ΔE_2; $\Delta E_1 < \Delta E_2$) within these three levels are probable. These transition energies have been computed (Table 2) using the observed g-values: the g-tensor theory of low-spin d^5 complexes [10] and a reported method [11]. The ΔE_2 transitions in all these three complexes have indeed been observed close to the theoretically predicted values as a low-intensity absorption (Table 1, Fig. 1) whereas the ΔE_1 transitions fall in the IR region and could not be detected. The ESR spectral data therefore show that these ruthenium(III) complexes are significantly distorted

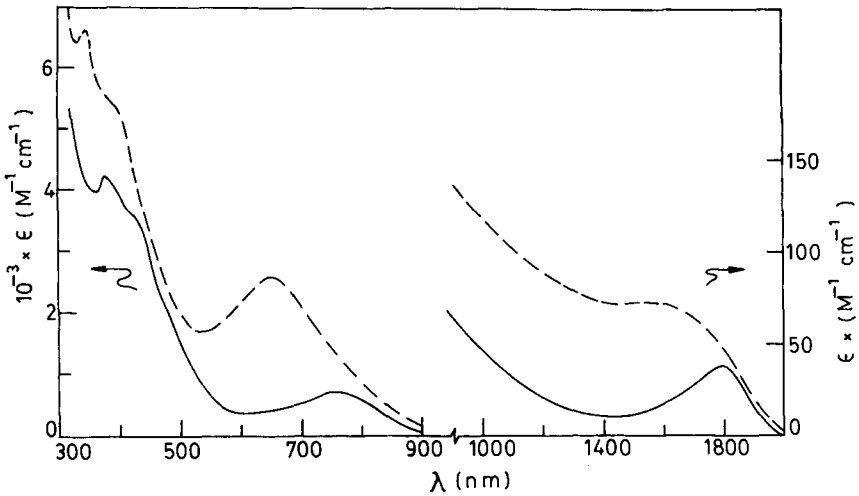

Fig. 1. Electronic spectra of $[Ru(PPh_3)_2(Q)Cl_2]$ (——) and $[Ru(PPh_3)_2(sal\text{-}H)Cl_2]$ (– – –) in dichloromethane solution.

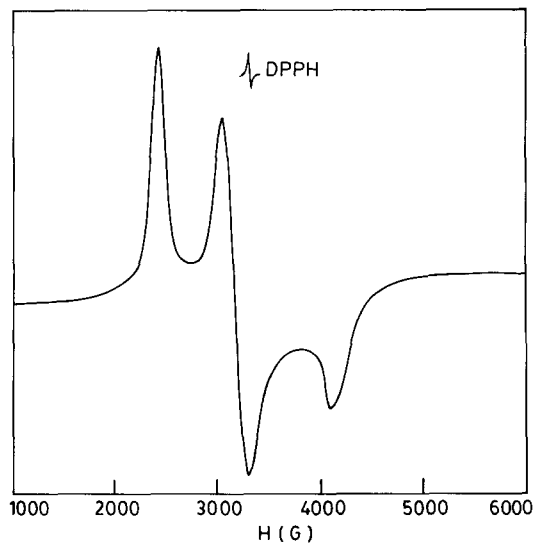

Fig. 2. ESR spectrum of $[Ru(PPh_3)_2(Q)Cl_2]$ in 1 : 1 dichloromethane–toluene at 77K.

from ideal octahedral geometry, which is understandable by simple examination of the coordination sphere consisting of three different P—Ru—P, N—Ru—Cl and O—Ru—Cl axes.

Cyclic voltammetric studies

Electron-transfer properties of the $[Ru(PPh_3)_2(L)Cl_2]$ complexes have been studied in acetonitrile solution (0.1 M TEAP) by cyclic voltammetry. A selected voltammogram is shown in Fig. 3

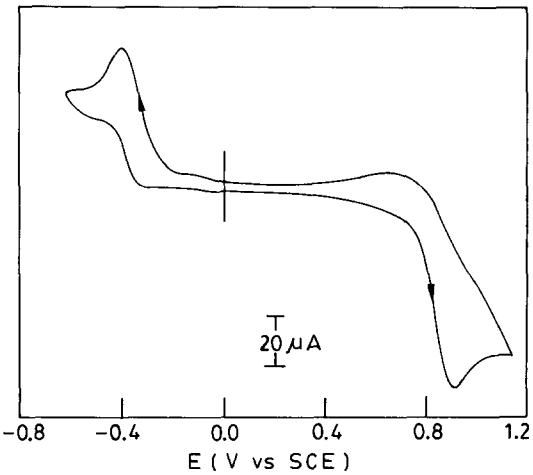

Fig. 3. Cyclic voltammogram of $[Ru(PPh_3)_2(Q)Cl_2]$ in acetonitrile solution (0.1 M TEAP) at a scan rate of 50 mV s^{-1}. The solute concentration was 10^{-3} M.

Table 2. ESR g values and derived energy parameters of ruthenium(III) complexes

Compound	g values[a]			Derived energy parameters (cm^{-1})	
	g_1	g_2	g_3	ΔE_1	ΔE_2
$[Ru(PPh_3)_2(Q)Cl_2]$	2.7263	2.0985	1.6225	2300	5700
$[Ru(PPh_3)_2(sal\text{-}H)Cl_2]$	2.4508	2.2265	1.8424	3800	6400
$[Ru(PPh_3)_2(ap)Cl_2]$	2.3862	2.1962	1.8695	4100	6800

[a] ESR spectra recorded in 1 : 1 dichloromethane–toluene at 77 K.

and voltammetric data are given in Table 1. All these complexes show a ruthenium(III)–ruthenium(II) reduction [eq. (2)] on the negative side of SCE and a ruthenium(III)–ruthenium(IV) oxidation [eq. (3)] on the positive side.

$$[Ru^{III}(PPh_3)_2(L)Cl_2 + e^- \rightleftharpoons [Ru^{II}(PPh_3)_2(L)Cl_2]^- \quad (2)$$

$$[Ru^{III}(PPh_3)_2(L)Cl_2] \rightleftharpoons [Ru^{IV}(PPh_3)_2(L)Cl_2]^+ + e^- \quad (3)$$

In $[Ru(PPh_3)_2(Q)Cl_2]$ both electron-transfer processes take place irreversibly at -0.40 V and 0.85 V, respectively, which indicates that in the NOP_2Cl_2 coordination sphere the $+3$ state of ruthenium is stable while the $+2$ and $+4$ states are not. The ruthenium(III)–ruthenium(II) potential in this complex is 430 mV less than that in $[Ru(PPh_3)_2(bpy)Cl_2]$ (0.39 V) [1a] which indicates that relative to bpy, 8-quinolinolate is a much better stabilizer of ruthenium(III). This is due to the recognized ability of phenolate oxygen to stabilize the higher oxidation states of ruthenium. In $[Ru(PPh_3)_2(ap)Cl_2]$, the ruthenium(III)–ruthenium(II) reduction and ruthenium(III)–ruthenium (IV) oxidation are observed at -0.22 V and 0.78 V respectively. In $[Ru(PPh_3)_2(sal\text{-}R)Cl_2]$ complexes the irreversible ruthenium(III)–ruthenium(IV) oxidation is observed near 0.85 V and remains virtually insensitive to the substituent R. However, the ruthenium(III)–ruthenium(II) reduction potential varies as R is varied. The plot of this reduction potential *vs* the Hammett substituent constant [12] of R is linear (Fig. 4) with $\rho = 0.20$ V [13]. This shows that ruthenium(III)–ruthenium(II) reduction potential in the $[Ru(PPh_3)_2(sal\text{-}R)Cl_2]$ complexes can be finetuned by varying R in the salicylaldiminate ligand.

Reactivities

Solution electrical conductivity studies have shown (*vide supra*) that the chloride ligands of the $[Ru(PPh_3)_2(L)Cl_2]$ complexes do not dissociate in solution. This indicates the strong bonding between trivalent ruthenium and chloride ion. However, both the chloride ligands can be displaced from the coordination sphere under mild condition by bidentate chelating ligands (L′). Such reactivity studies have been restricted to only three representative complexes, *viz.* $[Ru(PPh_3)_2(Q)Cl_2]$, $[Ru(PPh_3)_2(sal\text{-}H)Cl_2]$ and $[Ru(PPh_3)_2(ap)Cl_2]$. Reaction of these complexes with another ligand (L′) in the presence of NEt_3 affords new complexes of the type $[Ru(PPh_3)_2(L)(L')]^+$ [eq. (4)] in decent yields. Two types of L′, monoanionic (8-quinolinolate anion, Q) and neutral (2,2′-bipyridine, bpy; 1,10-phenanthroline, phen) have been used and three complexes [L = L′ = Q; L = sal-H, L′ = bpy and L = ap, L′ = phen] have been synthesized. Triethylamine primarily serves the function of a reducing agent for the ruthenium(III) complexes thereby facilitating the dissociation of the Ru(II)—Cl bond (formed due to the reduction) followed by the subsequent incorporation of the L′ ligand. It is interesting to note here that ruthenium undergoes a one-electron reduction during the course of the synthetic reaction [eq. (4)].

$$[Ru^{III}(PPh_3)_2(L)Cl_2] \xrightarrow[EtOH/reflux]{Et_3N,L'} [Ru^{II}(PPh_3)_2(L)(L')]^+ \quad (4)$$

The characterization data of these $[Ru(PPh_3)_2(L)(L')]^+$ complexes [14] are given in Table 1. Microanalytical data agree well with the compositions of these complexes. All the three complexes are diamagnetic, confirming the $+2$ oxidation state of ruthenium (low-spin d^6, $S = 0$) in these complexes. IR spectra of the $[Ru(PPh_3)_2(L)(L')]^+$ complexes show many vibrations, some of which are also observed in the spectra of their respective precursors. Some additional bands are observed in the fingerprint region of the spectra of $[Ru(PPh_3)_2(L)(L')]^+$, which are obviously due to the new coordinated ligand L′. The ν(Ru—Cl) vibrations observed in the spectra of the precursor complexes, are absent as expected. Intense bands are observed near 1100 cm^{-1} and 620 cm^{-1} in the spectra of $[Ru(PPh_3)_2(sal\text{-}H)(bpy)]ClO_4$ and $[Ru(PPh_3)_2(ap)(phen)]ClO_4$ due to the presence of ClO_4^-.

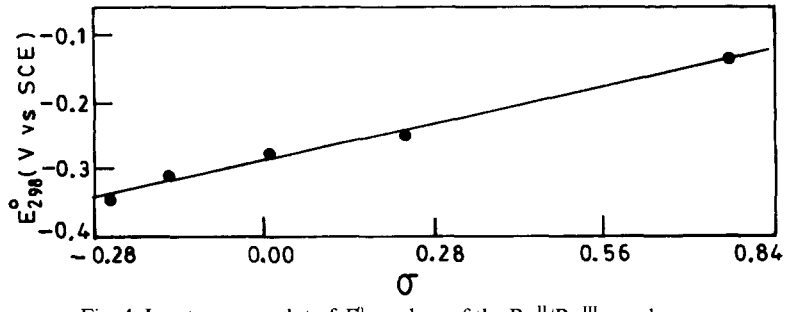

Fig. 4. Least-squares plot of E^0_{298} values of the Ru^{II}/Ru^{III} couple *vs* σ.

The spectral and cyclic voltammetric properties of $[Ru(PPh_3)_2(Q)_2]$, synthesized by us from $[Ru(PPh_3)_2(Q)Cl_2]$, are virtually identical to those of the *trans–trans–trans* isomer of this complex reported earlier [3b]. Hence $[Ru(PPh_3)_2(Q)_2]$, synthesized by us, is assumed to have the completely *trans* geometry. The $[Ru(PPh_3)_2(sal\text{-}H)(bpy)]^+$ and $[Ru(PPh_3)_2(ap)(phen)]^+$ complexes can exist in only one geometrical isomeric form provided the two PPh_3 ligands are *trans*, as assumed in their respective precursors. The displacement of the two chloride ions from $[Ru(PPh_3)_2(L)Cl_2]$ by L′ [eq. (4)] therefore takes place without any gross change of stereochemistry.

All the three $[Ru(PPh_3)_2(L)(L')]^+$ complexes are soluble in acetonitrile. Conductivity measurements show that in solution $[Ru(PPh_3)_2(sal\text{-}H)(bpy)]ClO_4$ and $[Ru(PPh_3)_2(ap)(phen)]ClO_4$ complexes behave as 1 : 1 electrolytes (Λ_M = 140 and 155 ohm^{-1} cm^2 M^{-1} respectively) while $[Ru(PPh_3)_2(Q)_2]$ is a non-electrolyte, as expected. Electronic spectra of these three complexes have been recorded in acetonitrile solution (Table 1). Each complex shows several intense absorptions in the visible region which are probably due to allowed metal-to-ligand charge-transfer transitions.

Redox properties of the $[Ru(PPh_3)_2(L)(L')]^+$ complexes have been studied in acetonitrile solution (0.1 M TEAP) by cyclic voltammetry. Voltammetric data are given in Table 1. A reversible ruthenium(II)–ruthenium(III) oxidation is displayed by all three complexes, the potential of which varies as L and L′ are varied. In $[Ru(PPh_3)_2(sal\text{-}H)(bpy)]^+$, this oxidation takes place at 0.72 V, which is approximately 1 V more positive than that of the ruthenium(II)–ruthenium(III) couple in $[Ru(PPh_3)_2(sal\text{-}H)Cl_2]$. This shows that replacement of two chloride ions by one bpy stabilizes the bivalent state of ruthenium to a great extent. A similar shift in the ruthenium(II)–ruthenium(III) potential was observed in the pair: $[Ru(bpy)_2Cl_2]$, (0.30 V) [15] and $[Ru(bpy)_3]^{2+}$, (1.30 V) [16]. One quasi-reversible one-electron reduction is observed in $[Ru(PPh_3)_2(sal\text{-}H)(bpy)]^+$ at -1.39 V, which is assigned to the reduction of the coordinated bpy. Each bpy is expected to show two one-electron reductions [17]. The second one-electron reduction of bpy, which is expected to occur at much more negative potential, has not been observed due to solvent cut-off. In $[Ru(PPh_3)_2(ap)(phen)]^+$, the ruthenium(II)–ruthenium(III) couple appears at 0.76 V, which is again $\sim$1 V more positive than that in $[Ru(PPh_3)_2(ap)Cl_2]$, as in the previous case. The one-electron reduction of phen is observed as a quasi-reversible process in $[Ru(PPh_3)_2(ap)(phen)]^+$ at -1.43 V.

(Received 3 April 1996; accepted 9 May 1996)

Abstract—The geometry and electronic states of five-coordinate copper(II) complexes, [Cu(dgepH$_{-2}$)] and [Cu(pcepH$_{-2}$)], are discussed on the basis of the absorption and ESR(X- and Q-band) spectra in solid and solution states, where dgepH$_{-2}$ and pcepH$_{-2}$ represent the divalent anion of 1,8-di(dimethylglycinoyl)-1,4,8-triazaoctane and 1,8-dipicolinoyl-1,4,8-triazaoctane, respectively. These complexes exhibit the spectral features of the intermediate geometries between square pyramidal(SP) and trigonal bipyramidal(TBP). The magnitude of distortion from TBP to SP was estimated by utilizing the vibronic-coupling treatment of the electronic states. Copyright © 1996 Elsevier Science Ltd

Keywords: five-coordinate copper(II) complex; electronic spectra; ESR; geometry; square pyramid; trigonal bipyramid.

For the copper(II) ion, which usually forms complexes with four nearby donor atoms arranged approximately in a plane with the possibility of one or two more distant axial donors, five-coordinate complexes with a variety of donor groups have become of considerable interest stereochemically or spectrochemically, as well as biologically.[1,2] The stereochemistry of five-coordinate copper(II) complexes has been reviewed and discussed comprehensively by Hathaway.[3] Most adopting geometries are intermediate between square pyramidal(SP) and trigonal bipyramidal(TBP). Reinen *et al.* have discussed the electronic states of the intermediate geometry by the vibronic-coupling treatment.[4–6]

This paper reports the spectroscopic properties of copper(II) complexes of dgep (1,8-di(dimethylglycinoyl)-1,4,8-triazaoctane) and pcep (1,8-dipicolinoyl-1,4,8-triazaoctane). These ligands are linear unsymmetrical pentadentate which could form a 5,5,6,5-membered tetra-fused chelate, and they have two amide groups in inner parts and two dimethyl-substituted amino groups or two pyridyl groups as the terminal donor groups. For the pyridyl-terminal ligand, pcep, the preparation and the absorption spectra of its copper(II) complex have been already reported.[7] Here the geometry and the electronic states of these copper(II) complexes will be discussed on the basis of the absorption and X- and Q-band ESR spectra in solid and solution states.

EXPERIMENTAL

Preparations

The ligand, dgep, was synthesized by refluxing a methanolic mixture of N,N-dimethyl glycine methyl ester and N-(2-aminoethyl)-1,3-propanediamine according to the method similar to that for pcep.[7] From the aqueous solution containing equimolar amounts of copper(II) hydroxide and dgep, a non-ionic complex, [Cu(dgepH$_{-2}$)], was isolated as dark-blue plates, which was ascertained by elementary analyses and IR spectral measurements (dgepH$_{-2}$ represents the divalent anion of dgep). Found: C, 44.4; H, 8.0; N, 19.9. Calc. for $CuC_{13}H_{27}N_5O_2$: C, 44.8; H, 7.8; N, 20.1%. The IR spectrum of the isolated

* Author to whom correspondence should be addressed.

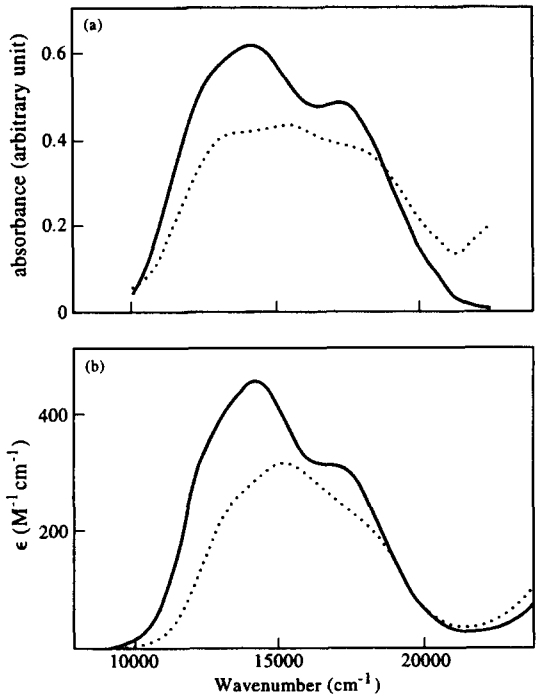
complex shows a strong band around 1590 cm^{-1}, but no band in the region of 1620–1650 cm^{-1}, which indicates that the two amide groups are deprotonated and coordinate to copper(II) ion through the negative amide nitrogens.[8] The complex of pcep, [Cu(pcepH$_{-2}$)], was also prepared according to the literature.[7]

Spectral measurements

Solution and solid-state electronic absorption spectra were measured with a Hitachi U-3400 spectrophotometer at room temperature. The solid-state spectra were obtained by means of the Nujol mull technique. Solution and powder ESR spectra (X- and Q-bands) were recorded on a JES-FE3XG spectrometer at room and liquid-nitrogen temperatures. DPPH was used as standard (g = 2.003$_7$). Infrared spectra were recorded on a Jasco A-3 spectrophotometer as KBr pellets.

RESULTS AND DISCUSSIONS

Figure 1 shows the visible absorption spectra of [Cu(dgepH$_{-2}$)] in the solid-state (a) and methanol solution (b), together with those of [Cu(pcepH$_{-2}$)]. The solid-state (powder in Nujol mull) spectrum of [Cu(dgepH$_{-2}$)] exhibits two peaks at 14,300 and 17,200 cm^{-1}: the low-energy band is more intense and accompanied by a shoulder around 12,800 cm^{-1}. This spectral pattern is typical of a five-coordinate copper(II) complex with a TBP-based geometry.[3,9] The bands of 14,300 and 17,200 cm^{-1} are tentatively assigned to the symmetry-allowed $A_1' \rightarrow E'$ and forbidden $A_1' \rightarrow E''$ transitions, respectively, in D_{3h} symmetry.[5,9] In Fig. 2 are illustrated the qualitative term diagrams for Cu^{2+} ion in ligand fields of D_{3h} (TBP), C_{4v} (SP) and intermediate C_{2v} symmetry.[5] The shoulder band around 12,800 cm^{-1} suggests the splitting of the E′ state due to the geometric distortion of D_{3h} to C_{2v}. The split of the TBP E″ state, however, will not be observed as distinct bands, because its splitting energy is rather small.[9]



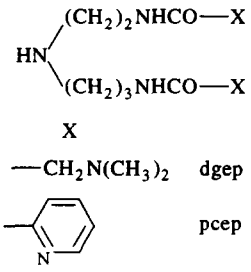


Fig. 1. Powder ((a): mull transmittance) and solutions ((b): methanol) absorption spectra of [Cu(dgepH$_{-2}$)] (——) and [Cu(pcepH$_{-2}$)] (– – –).

Scheme 1.

A methanol solution of [Cu(dgepH$_{-2}$)] exhibits a very similar spectrum to that seen in the solid-state, indicating that the TBP-based geometry is basically maintained also in methanol. Another remarkable feature of this solution spectrum is its extremely intense magnitude with an ε_{max} (molar absorptivity) value over 450 M^{-1} cm^{-1}; this spectrum is probably the most intense ever observed for the *d–d* transitions of discrete copper(II) complexes. The corresponding complex of pcep, [Cu(pcepH$_{-2}$)], also shows a considerably intense absorption bands (ε_{max} = 310 M^{-1} cm^{-1}). Therefore, the linkage of the donor groups, common in dgepH$_{-2}$ and pcepH$_{-2}$, will bring about the large geometrical distortions around the CuN_5 chromophore which serve to break the orbital-forbidden character of the *d–d* transitions a great deal. The bulkiness of the terminal dimethyl-substituted amino groups of dgep would play an additional role to the distortion.

The X-band ESR spectrum (Fig. 3) of [Cu(dgepH$_{-2}$)] in methanol at liq. N_2 temperature was entirely different from those usually observed for ordinary tetragonal copper(II) complexes. The *g* values, which are very helpful in determining the geometry of five-coordinate copper(II) complexes, were hard to evaluate from this spectrum due to the signal-overlapping. Then, the Q-band ESR of the methanol solution sample was measured at liq. N_2 temperature (Fig. 4a). The Q-band spectrum obtained clearly displayed three different *g* tensors with well-resolved hyperfine structures in the g_z and g_x signals, which strongly indicates a rhombic ligand field.[3] The *g* values observed for its powder samples at room temperature were almost the same as those for the frozen methanolic sample (Fig. 4b), which suggests

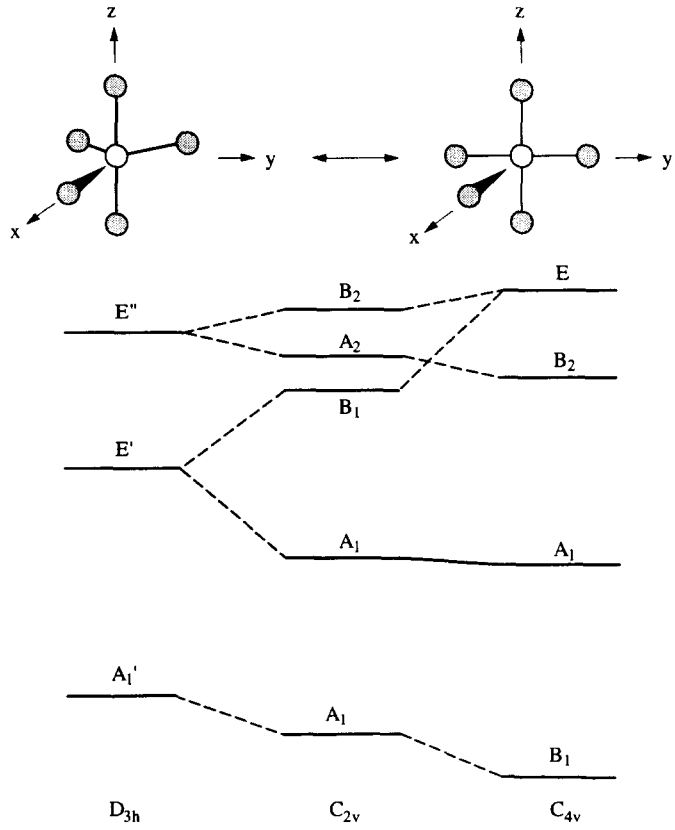

Fig. 2. Term diagrams for copper(II) ion in the ligand fields of D_{3h} (TBP), C_{4v} (SP) and intermediate C_{2v} symmetry.[5]

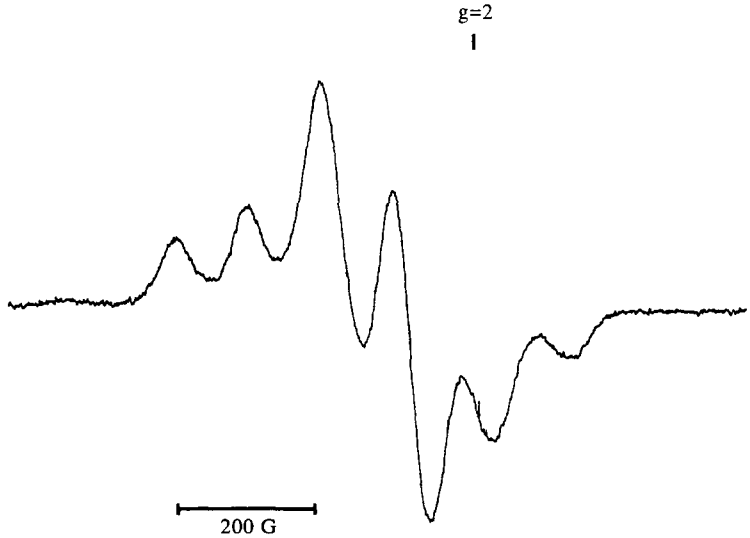

Fig. 3. X-Band ESR spectrum of [Cu(dgepH$_{-2}$)] in methanol at liq. N_2 temperature.

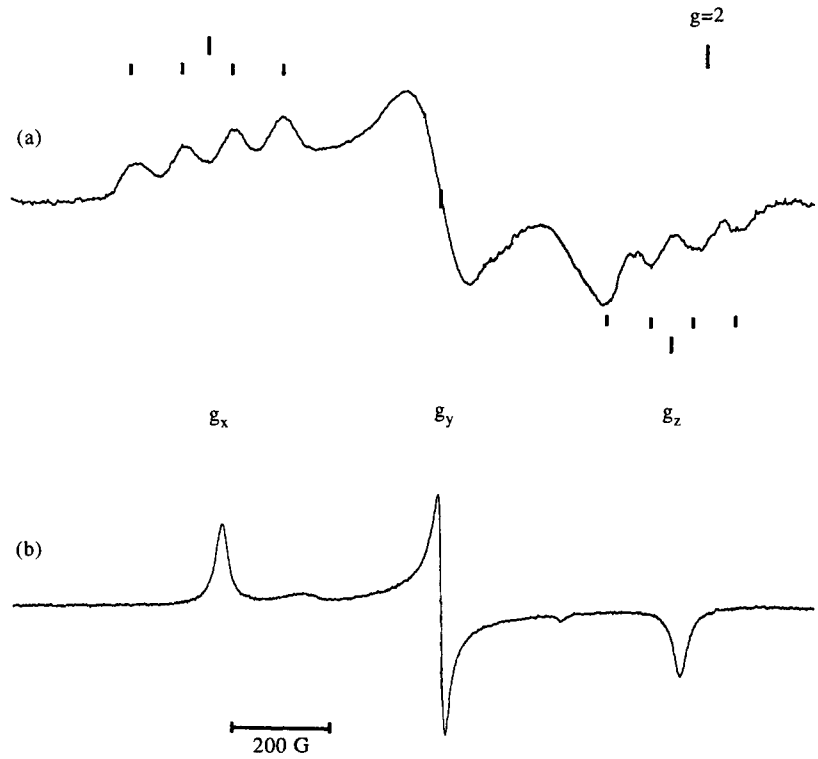

Fig. 4. Q-Band ESR spectra of [Cu(dgepH$_{-2}$)]; (a): in methanol at liq. N_2 temperature, (b): powder at room temperature.

that the powder g tensors also equate with the g values of the local molecular structure with no exchange between neighbouring copper(II) chromophores.

The ligand-field absorption and ESR spectral parameters found for [Cu(dgepH$_{-2}$)] and [Cu(pcepH$_{-2}$)] are summarized in Table 1, together with those of some related complexes with CuN_5 chromophores. The CuN_5 geometries of these related complexes have been determined by X-ray crystal analyses; $[Cu(NH_3)(tren)](ClO_4)_2$[10] and $[Cu(en)(dien)](ClO_4)_2$[11] are nearly regular TBP and SP, respectively, while $[Cu(NH_3)(bpy)_2](BF_4)_2$[12] and [Cu(SS-chxn)(pmdt)]$(ClO_4)_2$[13] are intermediate between TBP and SP. From the comparison of these spectral data, it seems reasonable to conclude that [Cu(dgepH$_{-2}$)] and [Cu(pcepH$_{-2}$)] take on the intermediate geometries.

The ground-state wave function of a five-coordinate copper(II) complex with an intermediate geometry (C_{2v}) between TBP(D_{3h}) and SP(C_{4v}), which has been derived by Reinen *et al.*,[4-6] is expressed by

$$\varphi_g = (1+c^2)^{-1/2}\{d_{z^2} + cd_{x^2-y^2}\}, \qquad (1)$$

where the coordinate system is defined as that shown in the top of Fig. 2. The mixing coefficient is $c = 0$ for TBP(d_{z^2} ground state) and $c = 1/3^{1/2}$ for SP ($d_{z^2-y^2}$ ground state). The g values are expressed as follows, according to this ground state function,[5]

$$g_z = g_0 + \frac{8c^2}{1+c^2}u_z,$$

$$g_y = g_0 + \frac{2c^2}{1+c^2}\left(1-\frac{\sqrt{3}}{c}\right)^2 u_y,$$

$$g_x = g_0 + \frac{2c^2}{1+c^2}\left(1+\frac{\sqrt{3}}{c}\right)^2 u_x, \qquad (2)$$

where g_0 is a value for a free ion (2.0023). The orbital contributions u_i are defined as

$$u_i = \frac{k_i^2\zeta_0}{\Delta E_i}\ (i = z, y, x), \qquad (3)$$

where k_i and ζ_0 ($=830$ cm^{-1}) are covalency factors and the spin–orbit coupling parameter of the free Cu^{2+} ion, respectively. the ΔE_i energies refer to the d–d transitions ΔE_i ($i = z, y, x$): $A_1 \rightarrow B_1$, B_2, A_2 in C_{2v} symmetry (Fig. 2).

By use of the observed ΔE_i energies, the mixing coefficient c and covalency factors k_i can be so estimated as to reproduce the experimental g values. For [Cu(dgepH$_{-2}$)], for example, the two absorption bands at 14,300 and 17,200 cm^{-1} (Table 1) are assigned to $A_1 \rightarrow B_1$ and to the unresolved $A_1 \rightarrow A_2$, B_2, respectively, in C_{2v} symmetry as mentioned above. With these transition energies, a set of $c = 0.2$–0.25 and $k_{av}(=k_z \approx k_y \approx k_x) \approx 0.70$ can reproduce best the

[h] ref. 10.

experimental g values. This implies that the CuN_5 chromophore is considerably distorted to SP: $c = 0$ for regular TBP and $c = 0.577$ for regular SP. Similarly, for [Cu(pcepH$_{-2}$)] (the transition energies: 15,500 cm^{-1} for $A_1 \rightarrow B_1$ and 17,900 cm^{-1} for $A_1 \rightarrow A_2$, B_2) the values of $c = 0.3$–0.35 and $k_{av} \approx 0.72$ are derived. The larger c value indicates that the degree of distortion from TBP to SP is larger. The small difference in the covalency factor k_{av}, which is used as an empirical parameter, between these two complexes probably reflects the variation of the terminal donor groups, dimethylamino compared to pyridyl.

For the X-ray analyzed complexes cited in Table 1, $[Cu(NH_3)(bpy)_2](BF_2)_2$ and [Cu(SS-chxn)(pmdt)] $(ClO_4)_2$, such estimations of the c and k parameters are also performed. With the transition energies of 12,800 cm^{-1} ($A_1 \rightarrow B_1$) and 15,500 cm^{-1} ($A_1 \rightarrow A_2$, B_2) of the former, a set of $c = 0.15$–0.2 and $k_{av} \approx 0.74$ can best reproduce the observed g values. For the latter complex, the broad band around 15,000 cm^{-1} is tentatively assigned to the unresolved $A_1 \rightarrow B_1$, B_2, A_2 and the shoulder at 11,500 cm^{-1} assigned to $A_1 \rightarrow A_1$ in C_{2v} symmetry (Fig. 2). Therefore, with the same energy (15,000 cm^{-1}) to the transitions of $A_1 \rightarrow B_1$, A_2, B_2, the parameters are refined; $c \approx 0.35$ and $k_{av} \approx 0.70$ are the best set. These parameter values indicate that the CuN_5 geometry of $[Cu(NH_3)(bpy)_2](BF_4)_2$ is less distorted to SP from TBP than that of [Cu(SS-chxn)(pmdt)]$(ClO_4)_2$, in good agreement with the magnitude of distortion calculated by using the bond angles (the τ-values of 77% TBP for the former and 57% TBP for the latter).[12,13]

(Received 6 February 1996; accepted 7 May 1996)

Abstract—The title complex $[(DMNP)_2(MNP)_2SiMo_{12}O_{40}\cdot 2DMF]$ (where DMNP is $MeNC_5H_4NMe_2$, MNP is $MeNC_5H_4NHMe$ and DMF is N,N-dimethyl formamide) has been synthesized and characterized by elemental analysis, XPS, ESR and IR spectra studies. The X-ray crystal structure revealed that the title complex possesses a noncentrosymmetrical arrangement in the unit cell.

Keywords: crystal structure; charge-transfer; donor; acceptor; polyoxometalate; Keggin structure.

In the last few years there has been a rapidly growing number of reports in the literature addressing the use of polyoxometalates (POM) in many fields of research such as catalysis, biology, medicine and materials science.[1–3] Numerous heteropoly anions can be reversibly reduced to mixed-valence species (heteropoly "blues" and "browns") by addition of various specific numbers of electrons, which are delocalized over a significantly large number of atoms of the heteropoly framework, retaining the gross structure of the oxidized anions.[4] The above property of polyoxoanions makes them attractive precursors for the preparation of charge-transfer hybrid salts made up of organic donors and inorganic acceptors derived from the polyoxometalates.[5] By use of the special properties of the polyoxoanion such as Keggin structures $M_{12}O_{40}^{n-}$ ($M = Mo$, W; $n = 3$–4), our aim is to design and synthesize molecular materials with the applications in non-linear optics, photorefractive effect and magnetism.

Here, we report the preparation of a charge-transfer salt by use of the organic donor DMNP and inorganic acceptors $(TBA)_4SiMo_{12}O_{40}$ (TBA = tetrabutylamino). The compound was characterized by IR, UV–Vis spectra, ESR measurements. The X-ray structure determination reveals that the title complex has non-centrosymmetric character, and probably possesses non-linear optical properties. The lost methyl of the N atom may be catalyzed by the polyoxometalate. Further related work is being done.

EXPERIMENTAL

All chemicals were reagent grade and used without further purification. The polyoxometalate $(TBA)_4$

* Author to whom correspondence should be addressed

$SiMo_{12}O_{40}$ was synthesized according to the procedure described earlier.[6] The DMNP was obtained by the literature method.[7]

Preparation of $(DMNP)_2(MNP)_2SiMo_{12}O_{40} \cdot 2DMF$

To a solution of $(TBA)_4SiMo_{12}O_{40}$ (0.3 mmol, 0.69 g) in 50 cm^3 acetonitrile, the DMNP-iodide (1.2 mmol, 0.422 g) was added. The mixture was refluxed for 2 h. After cooling to room temperature, the green precipitate was filtered by suction and washed three times with acetonitrile. Yield: 0.63 g, 90%. The green crystals of the title complex were obtained from DMF solution by diffusion of ether. Found: C, 17.8; H, 2.9; N, 6.0. Calc. for $C_{36}H_{62}Mo_{12}N_{10}O_{42}Si$: C, 17.6; H, 2.8; N, 5.7%.

Physical measurements

Elemental analysis was performed on a Perkin–Elmer 240C analytical instrument. The IR spectrum was recorded on a Nicolet FT–IR 170SX spectrophotometer with KBr pellet in the range of 4000–400 cm^{-1}. The solid state reflectance spectrum was recorded on a Shimadzu UV–240 spectrophotometer. Electronic spectra was obtained on a Shimadzu UV–3100 spectrometer in solution. The powder ESR spectrum was carried out using a Bruker 2000–SRC spectrometer at 110K. XPS was performed on a VG ESCALAB MK-II.

X-ray structure determination of the complex

A green prism crystal of size $0.30 \times 0.32 \times 0.60$ mm was used for data collection. The data were collected using a Siemens P4 four-circle diffractometer with graphite monochromated Mo-K_α radiation (λ = 0.71073 Å) using $\theta/2\theta$ scan mode. Intensities were measured for 9717 reflections of which 8695 independent reflections, and the 8692 observed reflections ($I > 2.0\sigma(I)$) were used for further computation. The data were corrected for Lorentz and polarization effects during data reduction using XSCANS.[8]

Structure solution and refinement

The structure was solved by direct methods using SHELXL86[9] and refined on F^2 by Full-matrix least-squares methods using SHELXL93.[10] All non-hydrogen atoms were refined anisotropically, but the hydrogen atoms were refined isotropically. The final reliability factor was R = 0.0517. All computations were performed on an IBM compatible 486/DX2 personal computer. The crystal data and the parameters of data collection and refinement are listed in Table 1. The final atomic coordinates, the thermal parameters, together with observed and calculated structure factors, have been deposited as supplementary material with the Editor, from whom copies are available on request.

RESULTS AND DISCUSSION

IR spectrum

Comparing the IR spectra of the title compound with the IR spectra of $(TBA)_4SiMo_{12}O_{40}$, the vibrational band of Mo=O_d band of the title compound has a red shift from 954(s) cm^{-1} to 946(s) cm^{-1}. The bands of Mo–O_b–Mo and Mo–O_c–Mo both have red shifts from 890(w) cm^{-1}, 797(vs) cm^{-1} to 880(w) cm^{-1} and 787(vs) cm^{-1}, respectively,[11] due to the presence of partial charge transfer between the organic donor and polyoxometalate acceptor. This has been verified by the later ESR spectra and the central SiO_4 tetrahedron has been little influenced by the electron transfer, so the vibrational frequency of the Si–O bond remains unchanged at 900(vs) cm^{-1}. The band at 1655(vs) cm^{-1} is due to the C=O vibration from DMF molecule of the compound. The υ(N–H) vibration appears at 3046 cm^{-1}, which provides evidence of the loss of a methyl group from DMNP to give MNP.

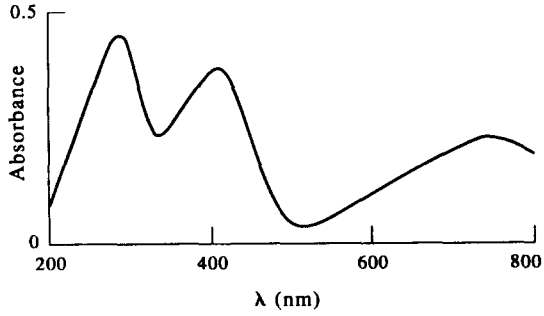

Fig. 1.

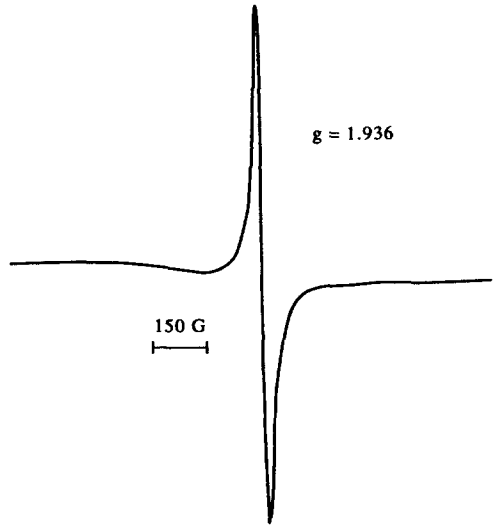

Fig. 3.

Electronic spectra

Figure 1 shows the reflectance electronic spectra of the title compound. The bands are 282 nm and 418 nm belong to O → Mo and *d–d* transition of MoO_6 octahedra, respectively.[12] The band at 740 nm is assigned to intervalence charge transfer ($Mo^{5+} \rightarrow Mo^{6+}$) IVCT band of $[SiMo_{12}O_{40}]^{5-}$, which indicates that electron transfer occurs between the organic substrate and polyoxoanion, converting $[SiMo_{12}O_{40}]^{4-}$ to the heteropoly blue $[SiMo_{12}O_{40}]^{5-}$.

Figure 2 compares the UV spectra of the title compound with the $(TBA)_4SiMo_{12}O_{40}$ dissolved in DMF. The title compound has a broad band at 790 nm similar to that of the solid, which is assigned to an $Mo^{5+} \rightarrow Mo^{6+}$ IVCT band. The solution of $(TBA)_4SiMo_{12}O_{40}$ has very weak absorption that can be omitted in the wavelength range. The above results indicate that the charge-transfer of the polyoxometalate anion is obviously influenced by the presence of DMNP.

ESR spectra

The ESR spectrum of the title complex at 110K is shown in Fig. 3. The spectrum reveals the presence of a single isotropic signal g = 1.936, which is ascribed to the Mo^{5+}, which is close to those observed in similar polyoxoanions containing Mo^{5+} (S = 5/2) species.[6,13] No hyperfine splitting of the ESR signal of Mo^{5+} of the complex has been observed due to the rapid intra-ionic hopping of the unpaired electron being comparable with the ESR time-scale.[4]

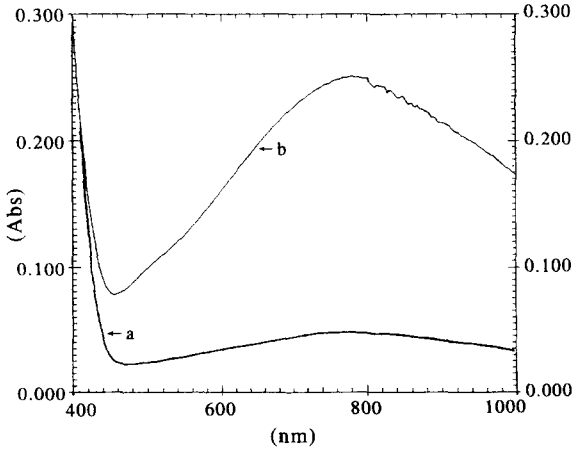

Fig. 2.

XPS study

X-ray photoelectron spectroscopy provides useful information on the oxidation state of the metal ion in the polyoxometalates, and can assess the stoichiometric ratio of the elements present in the compounds. The binding energies of $Mo3d_{5/2}$ in the title compound and tetraalkylammonium polyoxomolybdenum(VI) are 232.4ev and 232.3ev respectively. The binding energy of O_{1s} in the title compound is 530.5ev, which is also close to that of $(TBA)_4SiMo_{12}O_{40}$ (530.2ev). The above effects are due to the fact that the molybdenum atoms are all equivalent and the value of the binding energy is quite close to the value found for the completely oxidised anion. The existence of reduced molybdenum in the polyoxoanion cannot be ruled out as this is of class IIIA of the Robin and Day scheme.[14] In this case, the shift in energy would be very small as the extra electron is delocalized over all the molybdenum atoms.

X-ray crystal structure

The bond distances and angles of the title complex are listed in Tables 2 and 3, respectively. The crystal structure of the polyoxoanion and a stereoview of the molecular packing are shown in Figs 4 and 5, respectively. The analysis of the crystal structure reveals that the compound possesses the $P2_1$ space group, which is non-centrosymmetric. There exists the

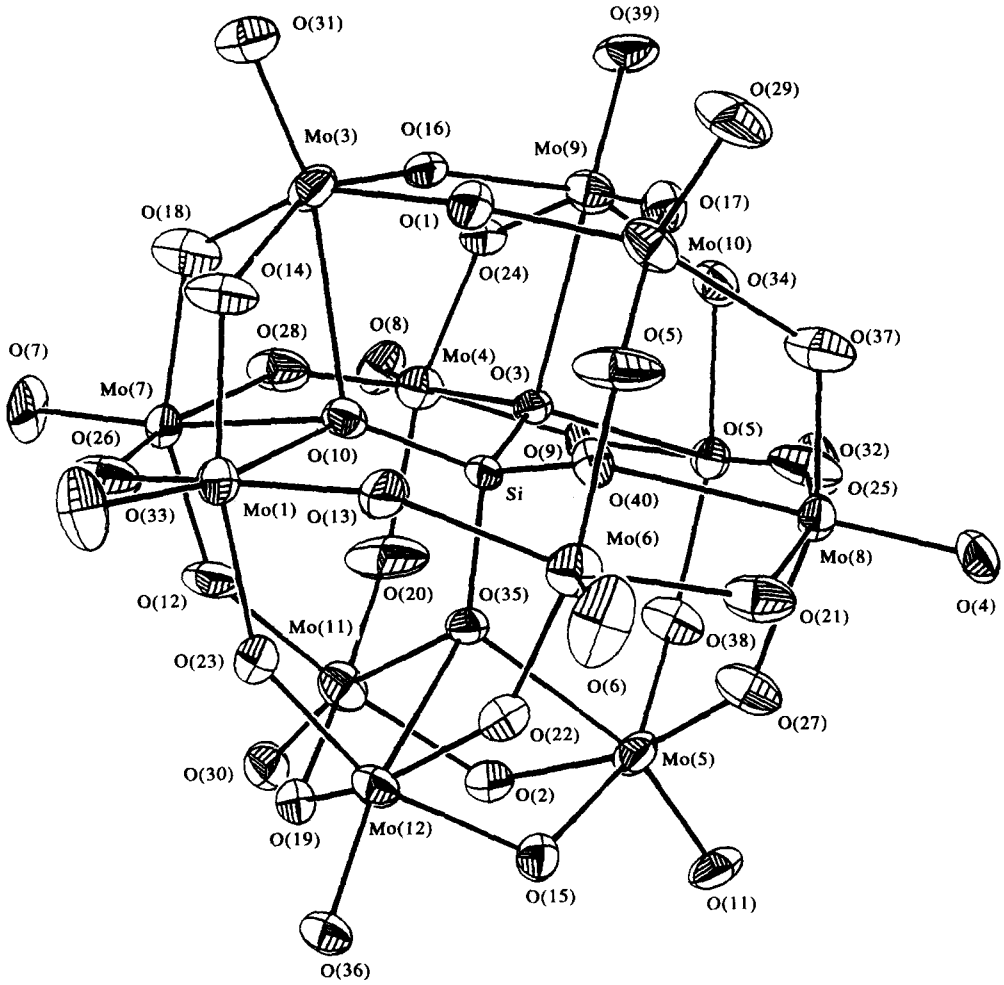

Fig. 4.

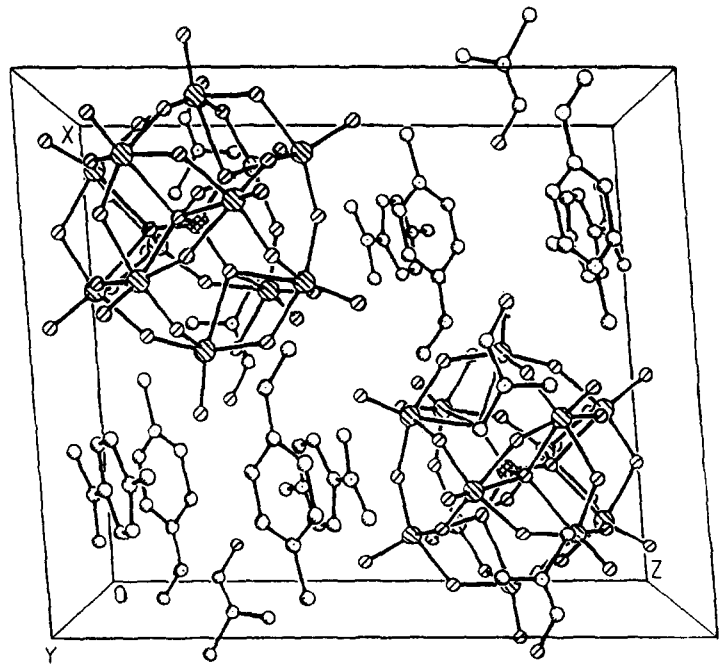

Fig. 5. Crystal packing of the title compound viewed down the *Y* axis.

Keggin structure of the $[SiMo_{12}O_{40}]^{4-}$ anion built up of four Mo_3O_{13} groups which result from the association of three edge-sharing MoO_6 octahedra. The four Mo_3O_{13} groups tetrahedrally surround the central Si heteroatom in such a way that the full unit has T_d symmetry.[4] This situation is rare in salts containing $XM_{12}O_{40}$ which form easily a disordered pseudo-Keggin polyoxoanion.[15] The polyanion has four kinds of oxygen atoms. O_a (the oxygen atoms in SiO_4 tetrahedra), O_b (the bridging oxygen atoms within one triplet group of MoO_6 octahedra), O_c (the bridging oxygen atoms between two triplet groups of MoO_6 octahedra) and O_d (the terminal oxygen atoms).

The sets of Mo–O bond lengths corresponding to the four types of oxygen atoms, central tetrahedron Mo–O_a 2.319(8)–2.428(10) Å, bridging Mo–$O_{b,c}$ 1.800(9)–2.081(10) Å, and terminal Mo–O_d 1.636(13)–1.683(9) Å are in the expected range.[16] The Si–O_a distances are in the range of 1.580(9)–1.683(10) Å. The organic cations of the title complex can be divided into two types DMNP and MNP. From the least-squares planes in the compound, the two types organic cation are planar. The counterpart dihedral angle between the two planes of DMNP and MNP is in the range of 17.37(0.59)–19.81° (0.54) in the unit cell. The shortest distances between polyoxoanion and organic donor is 3.00 Å[N(4B)···O(21)], and 3.08 Å[C(14A)···O(34)], which is shorter than the Van der Waals distance (3.20 Å). This may explain why charge transfer occurs between the polyanion and organic cation. The relevant bond distances and angles of the organic cations are in the range of related compounds,[17,18] and are not discussed further here.

(Received 21 November 1995; accepted 3 May 1996)

Abstract—Starting from 1,10-phenanthroline, a series of novel ligands(L), imidazo[f]1,10-phenanthroline (IP), 2-phenylimidazo[f]1,10-phenanthroline (PIP) and the derivatives, and their complexes $[Ru(bpy)_2L]^{2+}$ have been synthesized and characterized. The effects of different electron donor and acceptor groups on the ^1H NMR, electronic absorption and emission spectra were studied. Time-resolved luminescence studies revealed that the addition of calf thymus DNA into the complex solution results in increases for both the emissive intensities and excited state lifetimes, and indicates that the electron group on L has no significant effect on the intercalation binding mode between DNA and the complexes. Copyright © 1996 Elsevier Science Ltd

Ruthenium(II) polypyridine complexes have received great interest for their unique combination of chemical stabilities, redox properties, luminescence emission and excited state lifetimes.[1] Recently a great deal of attention has been attracted to the recognition of DNA secondary structure with octahedral ruthenium(II) complexes, which is an important issue of biochemistry and biophysics.[2,3,4] It has been shown experimentally that the size and the shape of the ligand affected the interaction of the complex with DNA. However, the effect of an electron donor or acceptor group in the potential intercalating ligand, or in other words, the hydrogen bonding ability of the ligand on the interaction has not yet been studied systematically to our knowledge.

In our previous letters,[5,6,7] we reported the synthesis of the first two novel ligands, imidazo[f]1,10-phenanthroline (IP) and 2-phenylimidazo[f]1,10-phenanthroline (PIP), and their ruthenium complexes, and we studied the DNA-binding properties of $[RuL'L]^{2+}$ (L′ = 2,2′-bipyridine(bpy) or 1,10-phenanthroline(phen); L = IP or PIP) using electronic absorption, circular dichroism and steady state emission spectroscopy. The experiments showed that IP and PIP can intercalate into DNA base pairs. In this paper, we report the synthesis of three derivatives of PIP, 2-(4′-chlorophenyl)imidazo[f]1,10-phenanthroline(CLP), 2-(4′-hydroxyphenyl)imidazo[f]1,10-phenanthroline (HOP) and 2-(4′-nitrophenyl)imidazo [f]1,10-phenanthroline (NOP) (shown in Scheme 1), and studies on the emission properties of $[Ru(bpy)_2L]^{2+}$ (L = IP, PIP, CLP, HOP, NOP) bound to DNA using transient luminescent spectroscopy. Because bpy has no or very weak intercalating ability to DNA base pairs,[8] the DNA–Ru intercalating behavior is ligand L dependent.

Scheme 1.

EXPERIMENTAL

All starting materials were commercially available and of analytical grade quality. Calf thymus DNA was dissolved in doubly distilled water containing 5 mM tris(hydroxymethyl)aminomethane (tris), 50 mM NaCl and pH = 7.2. DNA concentration was determined by $\varepsilon_{260} = 6600\ M^{-1}\ cm^{-1}$ ($\varepsilon_{260}/\varepsilon_{280} > 1.9$).

Elemental analyses were carried out using a Perkin–Elmer 240 analyser. The ^1H NMR spectra were recorded on a JEOL FX90Q spectrometer (90 MHz) using $CDCl_3/d_6$–DMSO as solvent and Me_4Si as internal reference. The UV–vis spectra were obtained on a Shimadzu MPS-2000 spectrophotometer. The emission experiment was conducted with an excimer laser (Lambda Physik EMG 201 MSC) pumped dye laser (Lambda Physics model FL2002) system. The nominal pulse width and the linewidth of the dye laser output is 10 ns and 0.18 cm^{-1}, respectively. Fluorescence of the sample is collected by two lenses into a monochromator and detected by a photomultiplier and processed by a Boxcar Averager (EG&G model 162) and a microcomputer. The dye laser emission was at 450 nm, about the absorption maximum of metal to ligand charge transfer (MLCT) complexes. The concentration of ruthenium complex and DNA was 1×10^{-5} and 4.7×10^{-4} M, respectively.

Synthesis of ligands (L)

Scheme 1 shows the two-step synthetic procedure. First, 1,10-phenanthroline was oxidized to 1,10-phenanthroline-5,6-dione according to literature[9] except for using methanol as recrystallization solvent instead of methylbenzene. Then, an imidazole ring preparation method established by Steck and Day[10] was applied to produce the ligands. The crude products were separated by 60–100 mesh silica gel with ethanol as eluent and recrystallized from aqueous ethanol to get yellow crystals. Their melting points are all above 310°C. The data of elemental analyses and ^1H NMR spectra are given in Table 1.

Synthesis of complexes $[Ru(bpy)_2L]^{2+}$

The mixture of 0.5 mmol of cis-$[Ru(bpy)_2Cl_2]\cdot 2H_2O$[11] and the equivalent L in 20 cm^3 of methane and 10 cm^3 of water was refluxed under argon for 2 hours and then most of methanol was evaporated withdrawing the condenser. The red solution was chromatographically separated by SP-Sephadex C-25 with 0.1 M NaCl of 4 : 1 acetone/water solution as eluent. The saturated solution of sodium perchlorate was added dropwise to precipitate the complex microcrystal. The composition and analyses are shown in Table 2.

RESULTS AND DISCUSSION

^1H *NMR spectra*

For all the five ligands, a broad peak appears at 13–14 ppm, which is assigned to the imidazole ring H–N since it conforms basically to the description for benzoimidazole.[12] That is to say, the above proton quickly exchanges between the two nitrogens of the imidazole ring. So the molecules of all the ligands show C_{2v} symmetry in solutions, leading to that the protons H-1 and H-2 (positions 1 and 2, see Table 1), H-3 and H-4, H-5 and H-6, H-9 and H-10, H-11 and H-12 are chemically equivalent, respectively.

Comparing the ^1H spectra of PIP, CLP, HOP and NOP, we can find the influence of substituents Cl,

[a] Calculated values are given in parentheses.

[b] The chemical shifts lower than 5 due to crystal ethanol or water are omitted.

[c] The numbering of positions related to hydrogen atoms is shown below for HOP as an example:

–OH and $-NO_2$ on the chemical shifts of their nearby protons. The group $-NO_2$ has strong electron accepting ability so it makes the chemical shifts of H-11(12), H-9(10) and even H-7 of NOP move downfield significantly relative to those of PIP. As the opposite, the electron donating property of –OH creates the upfield of H-11(12), H-9(10) and H-7 of HOP relative to PIP. Whereas the electron attracting by induction and the electron repelling by conjugation seem to be offset, so the values of δ(H-11, 12), δ(H-9, 10) and δ(H-7) are almost identical for CLP and PIP, respectively.

Electronic spectra

The wavelengths (λ_{max}) and the extinction coefficients (ε_{max}) of the absorption maxima of the ligands and the complexes are summarized in Table 3. The electronic spectra of the ligands are illustrated in Fig. 1. The spectrum of NOP appears obviously different from the others. A new peak at 372 nm emerges due to the chromophoric effect of $-NO_2$, and the ε_{max}'s of NOP decrease, probably because the electron transfer involved with $-NO_2$ contains some composition of $n \rightarrow \pi^*$ forbidden transfer.

The electronic spectra of the complexes are quite similar to that of $[Ru(bpy)_3]^{2+}$. Those of $[Ru(bpy)_2(PIP)]^{2+}$, $[Ru(bpy)_2(CLP)]^{2+}$ and $[Ru(bpy)_2(HOP)]^{2+}$ are almost identical. Along with the expansion of π delocallization from IP to PIP to NOP, the MLCT band of the corresponding complex shifts red from 455 to 458 to 461 nm.

Two characteristics of $[Ru(bpy)_2(NOP)]^{2+}$ are worthy of note. First, the band of NOP at 372 nm shifts blue to 360 nm in $[Ru(bpy)_2(NOP)]^{2+}$, owing to the coordination of NOP to Ru. Second, the absorption of the MLCT band of $[Ru(bpy)_2(NOP)]^{2+}$ is stronger than that of the other four complexes. It appears that the electron accepting property of $-NO_2$ makes the MLCT more easily occur.

Emission properties

The emission properties of the complexes themselves and in the presence of calf thymus DNA in Tris buffer at ambient temperature were studied by time-

Table 2. Data of elemental analyses of complexes

Complex	%Found(%Calc.)		
	C	H	N

[a] The solvent is ethanol for all ligands and water for all complexes.

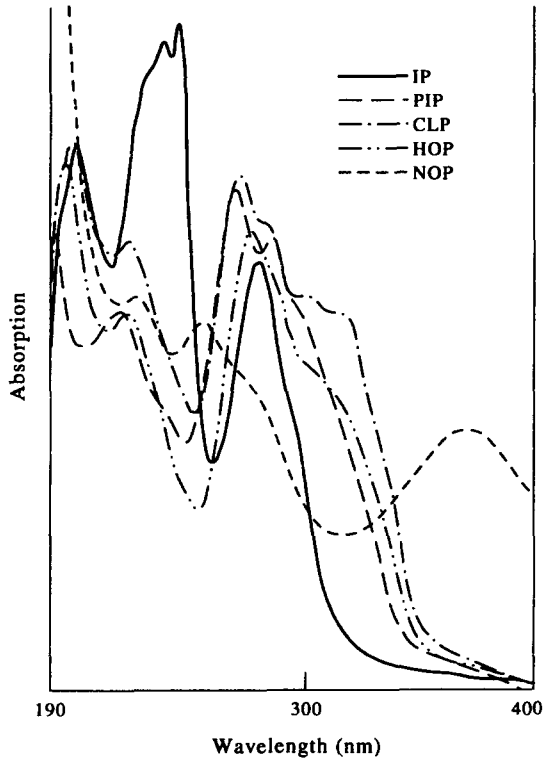

Fig. 1. Electronic spectra of ligands (——) IP, (— — —) PIP, (—·—·—) CLP, (—··—··—) HOP, (– – –) NOP.

resolved emission spectroscopy. The relevant data are collected in Table 4. We observe the relatively strong photoluminescence of $[Ru(bpy)_2L]^{2+}$ (L = IP, PIP, CLP and HOP) compared to that of $[Ru(bpy)_3]^{2+}$ but no emission of $[Ru(bpy)_2(NOP)]^{2+}$. The strong electron accepting group $-NO_2$ seems to have emission quenching ability. This could be explained in terms of the photo excited electron being captured by the end $-NO_2$ group and being unable to give emission to return to the ground state.

In fact, the different influences of substituents, Cl, –OH and $-NO_2$ on the MLCT based electron transfer have been observed in the electronic spectra of the complexes as discussed above. The conclusions derived from the absorption and emission spectra are quite coincident.

The intensity and lifetime of $[Ru(bpy)_3]^{2+}$ remains constant no matter whether DNA is present. But those of $[Ru(bpy)_2L]^{2+}$ (L = IP, PIP, CLP and HOP) increase significantly when bound to DNA. These kinds of increase have been demonstrated by most researchers as proofs that the potential intercalation ligand penetrates into the DNA base pairs thus the complex gets into a hydrophobic environment and avoids the quenching effect of solvent water molecules. So $[Ru(bpy)_3]^{2+}$ does not bind to calf thymus DNA by intercalation, which is consistent with the previous report.[8] Whereas the intercalation mode exists between $[Ru(bpy)_2L]^{2+}$ (L = IP, PIP, CLP and HOP) and calf thymus DNA. Our previous studies using other photophysical measurement have shown the intercalation of $[Ru(bpy)_2(IP)]^{2+}$ and $[Ru(bpy)_2(PIP)]^{2+}$ into calf thymus DNA.[6] So it can be concluded that the substituents Cl, –OH on the PIP ligand do not change the binding mode and the potential hydrogen bonding abilities of Cl and –OH seem to give no contribution.

Table 4. Emission properties of $[Ru(bpy)_2L]^{2+}$

L	bpy	IP	PIP	CLP	HOP	NOP
λ_{max}(nm)	617	625	615	616	606	—
I_0[b]	1	2.62	2.64	2.27	3.02	—
τ_0(ns)	410	556	462	585	450	—
I_D[b]	1.09	5.14	5.99	5.55	5.94	—
τ_D(ns)	418	1383	1456	1586	975	—

[a] I_0 and τ_0, I_D and τ_D denote the integrated luminescence intensity and lifetime at emission maximum (λ_{max}) with DNA ([DNA]/[Ru] = 47) and without DNA, respectively

[b] The values of I_0 and I_D are ratios to that of $[Ru(bpy)_3]^{2+}$ by assuming I_0 of the latter in the abscence of DNA as 1.

For the complex $[Ru(bpy)_2NOP]^{2+}$ we detected no photoluminescence both in the absence and the presence of calf thymus DNA. Barton *et al.*, have discovered a 'light switch' complex $[Ru(bpy)_2(dppz)]^{2+}$ (dppz is dipyrido[3,2–a : 2′,3′-c]phenanzine),[13] which displays no detectable luminescence in aqueous solution, but intense luminescence in the presence of double helical DNA to which it binds avidly by intercalation. This was due to the extreme sensitivity of the excited state to quenching by water; in DNA, the complex into the helix was protected from the aqueous solvent, thereby preserving the luminescence. But for $[Ru(bpy)_2NOP]^{2+}$, the 'quenching' of emission is caused by the electron acceptor group $-NO_2$ in the complex structure itself, so it is not sensitive to the environment. Therefore, the non-emissive behaviour of $[Ru(bpy)_2NOP]^{2+}$ does not imply that it cannot interact with DNA by intercalation.

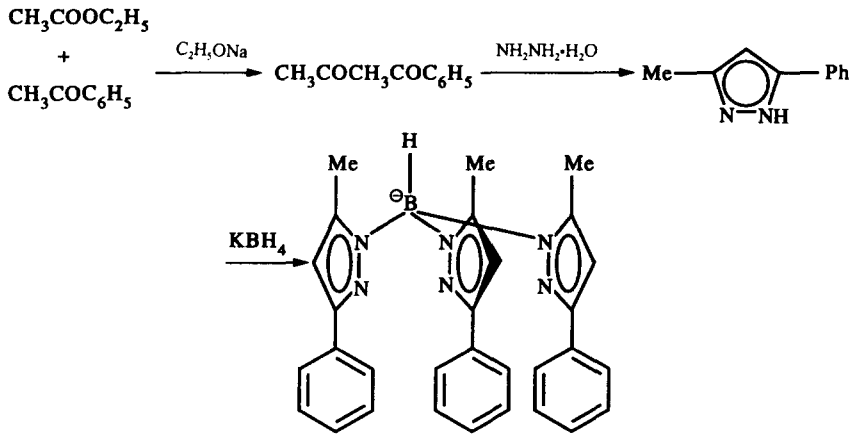
Abstract—Potassium hydrotris(3-phenyl-5-methylpyrazol-l-yl) borate and the zinc complex, [η^3-HB(3-Ph-5-Mepz)$_3$Zn(NO$_3$)], were synthesized and characterized by elemental analysis and ^{1}H NMR. Crystal structure determination shows that the coordination environment about the Zn centre is distorted tetrahedral. Copyright © 1996 Elsevier Science Ltd

Keywords: model compound; synthesis; characterization; crystal structure.

In the active center of zinc-containing enzymes, the zinc ion is almost always coordinated in a tetrahedral fashion.[1] Three of the four coordination sites are occupied by amino acid side chains while the fourth coordination site is occupied by a "functional" group OH or a water molecule. This basic L_3ZnX arrangement has been found in several metalloprotein crystal structure determinations,[2] and various model studies have applied it.[3–5] Because of the lability of zinc complexes and their diverse coordination possibilities, it is difficult to obtain this simple coordination pattern in model complexes. Thus, the work on models of zinc-containing enzymes has centred on the design of chelating ligand that approximates the distorted four-coordination active site, and one way of obtaining functional model compounds of this type is the use of tridentate ligands, which provide an appropriate set of donor atoms and a favourable stereochemical configuration.



Recently, we reported substituted hydrotris(pyrazolyl)borate ligands (*e.g.* 3,5-dimethyl or 3-phenyl) and their stable tetrahedral complexes L_3MX (M = Cu[6], X = PPh_3; M = Zn,[7] X = Br)$_4$. In particular, zinc complexes of the latter ligand imitate structurally the active site of the carbonic anhydrase. In order to obtain a series of functional tetrahedral L_3ZnX species and study their structure–function relationship, in this paper we report the synthesis, characterization and the crystal structure of zinc complex with (3-phenyl-5-methylpyrazol-l-yl)borate ligand.

EXPERIMENTAL

Preparation and analyses of the complex

All chemicals were of reagent grade. C, H, N were determined by a Carbo Erba 1106 Elemental Analyzer, ^{1}H NMR spectra were obtained on a Bruker MSL 300MHz spectrometer using $CDCl_3$ as solvent and TMS as an internal reference. The synthetic route of the ligand, potassium hydrotris(3-phenyl-5-methylpyrazol-l-yl)borate, KHB(3-Ph-5-Mepz)$_3$, is shown in Scheme 1, and the synthesis method refers to the published procedure.[8] Zinc nitrate (2 mmol) was added to 20 cm^3 of methanol, and to this stirred solu-

tion was added all at once a THF solution of the crude ligand (2 mmol), and some white solid material was separated. Water (100 cm^3) was added into the solution, then a white precipitate was filtered and washed thoroughly with hot water and then with methanol. The white solid was recrystallized from toluene and dried in a vacuum desiccator. Found: C, 59.4; N, 15.7; H, 4.6%. Calc. for $C_{30}H_{28}O_3N_7BZn$ (611): C, 59.0; N, 16.1; H, 4.6%. ^1H NMR ($CDCl_3$) δ ppm 2.32 (s, 9H, Me), 6.35 (m, 3H, pz), 7.3–7.7 (m, 15H, Ph).

Crystal structure determination

Crystals of the title compound were obtained by slowly cooling the hot toluene solution to room temperature, and a colourless platelet of 0.20 × 0.20 × 0.30 mm was chosen for the X-ray structural measurement. All crystallographic data were collected with a Rigaku AFC7R diffractometer using Mo-K_α radiation (λ = 0.71069 Å) in the ω-2θ scan mode. 3231 reflections were independent, and 2433 reflections with $I > 3.00\sigma(I)$ were used for the calculations after an empirical absorption correction based on ψ scans. The structure was solved by direct methods. The non-hydrogen atoms were refined anisotropically. The final cycle of full matrix least-squares refinement was converged with $R = 0.039$, $Rw = 0.047$ (unweighted and weighted agreement factors resp.).

RESULTS AND DISCUSSION

The compound [η^3-HB(3-Ph-5-Mepz)$_3$Zn(NO_3)] was synthesized and characterized by spectroscopy and an X-ray crystal structure determination. The crystallographic data are listed in Table 1, bond distances and angles are listed in Tables 2 and 3. An ORTEP plot and a unit cell packing diagram are presented in Figs 1 and 2, respectively.

The crystal structure analysis clearly shows that three phenyl rings form a cage-like pocket, the zinc ion is coordinated by three pyrazole nitrogen atoms and a nitrato oxygen atom, and the coordination environment about the zinc centre is distorted tetrahedral with the O(1)—Zn—N (120.8–130.3°) and the N—Zn—N angle (90.4–98.8°). The Zn—N bond distance (2.04 Å) falls into the range for normal zinc complexes with the tris(pyrazolyl)hydroborato ligand, while the Zn—O bond distance (1.94 Å) is slightly longer than the value of 1.85 Å found in [η^3-HB(3-Bu^t-5-Mepz)$_3$ZnOH].[9] This coordination environment around zinc in the title complex also compares

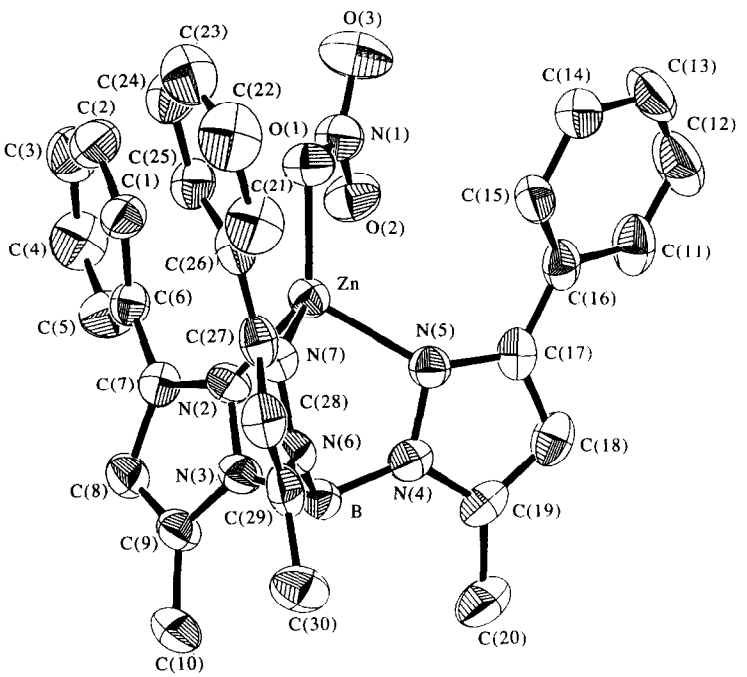

Fig. 1. The structure of [η^3-HB(3-Ph-5-Mepz)$_3$Zn(NO$_3$)].

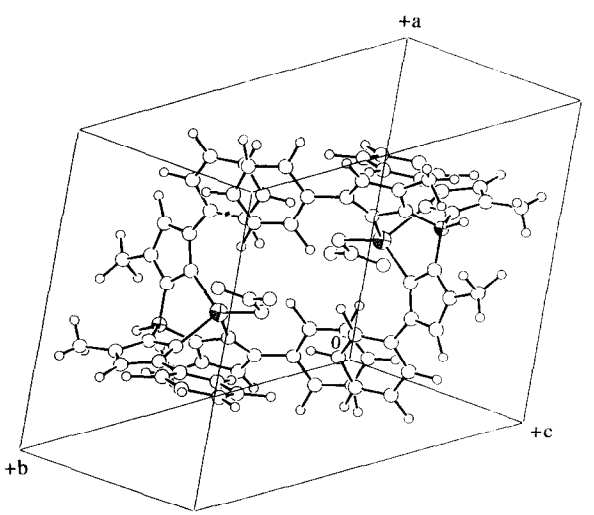

Fig. 2. Unit cell packing diagram for [η^3-HB(3-Ph-5-Mepz)$_3$Zn(NO$_3$)].

reasonably well with the theoretical calculation for the active site of carbonic anhydrase with bond lengths with angles of Zn—O = 1.96 Å, Zn—N = 2.10 Å, and O—Zn—N = 117.6°.[10] The B—N bond lengths (av. 1.55 Å) and N—B—N angles (av. 108.6°) correspond to the normal value for other metal complexes with pyrazolylborate ligand.[11] The title compound is an interesting active site model of carbonic anhydrase in three respects: first, the pocket around zinc in L_3ZnX has enough room for a monodentate X or a small ligand as substrate; second, the zinc ion in the complex has the same (N, N, N, O) donor set as in carbonic anhydrase; third, the nitrato ligand is isoelectronic with hydrogen carbonate, the substrate of carbonic anhydrase.

Synthesis and characterization of novel phthalocyanines peripherally fused to four 20-membered tetraaza-dioxamacro cycles

Yasar Gok* and S. Zeki Yildiz

Department of Chemistry, Karadeniz Technical University, 61080 Trabzon-Turkey

(Received 31 January 1996; accepted 1 May 1996)

Abstract—New metal-free **3** and metallophthalocyanines **4–5** (M = Ni or Zn) substituted with four 20-membered tetraaza-dioxa macrocycles from 21,22-dicyano-2,8,11,17-tetra-(toluene-p-sulfonyl)-1,2,3,4,5,6,7,8,9,10,11,12,13,14,15,16,17,18-octadecahydrox[*l*] [2,8,11,17]tetraaza [4,13]dioxadicontine (**2**) are described. Cyclotetramerization of the substituted phthalonitrile (**2**) leads to a product very soluble in common organic solvents. The characterization of the compounds was accomplished by elemental analysis, ^1H, ^{13}C NMR, IR, UV–vis and MS spectral data. Copyright © 1996 Published by Elsevier Science Ltd

The phthalocyanine macrocycles are of considerable interest owing to their fascinating electronic and optical properties. In recent years, a large number of phthalocyanine derivatives has been prepared to facilitate the exploitation of these properties such as gas sensors, electrophotography, fuel cells, solar energy conversion, non-linear optics, catalysis and the photodynamic therapy of cancer.[1] The attractive and challenging characteristics of the phthalocyanines are their great variety, chemical stability, the relative ease with which they can be synthesized and the strong dependence of their properties on peripheral and axial substitution patterns.[2] In this context, substitution on the aromatic groups of phthalocyanine by various groups such as crown ether, thiacrown or mixed donor macrocycle leads to new products having additional functionalities or properties.[3] Among these are supramolecular systems which consist of two identical molecular entities coexisting together without the assistance of covalent binding.[4] The notable feature of these compounds is that they exhibit spectral properties different from those of the individual molecular units.

Phthalocyanine-bridged tetrakis(benzocrown ether)s include crown ether-substituted phthalocyanines and tetrakis(benzocrown ether) containing phthalocyanines. These polytopic ligands consist of a phthalocyanine core to which four benzocrown ether moieties are attached. Attachment of crown ether units to the phthalocyanine ring significantly increases the solubility of phthalocyanine in many organic solvents leading to significant advances in research such as biological modelling, homogeneous catalysis, alkaline or earth alkaline and lanthanide metal extractions.[5] Although incorporation of macrocyclic groups such as crown ethers, tetraaza, diazatrioxa or diza-dioxa macrocycles onto the periphery of phthalocyanine are well known and continue to be the subject of increasing research activity, tetraazadioxa macrocycles which contain a larger cavity than the usual crown or mixed donor macrocycles are relatively few.[6] For this reason, attention has been focused on their synthesis and characterization with new substituents.

Recently, activity in our laboratory has focused upon synthesizing and understanding the properties of novel types of aza-oxa mixed macrocycle or ionophore substituted metal-free and transition metal phthalocyanines.[6] The present paper reports the synthesis of free and transition metal-complexed phthalocyanines containing four 20-membered teraaza-dioxa macrocyclic moieties in the molecule. The major opportunities offered by these novel phthalocyanines are the capability of binding five cations.

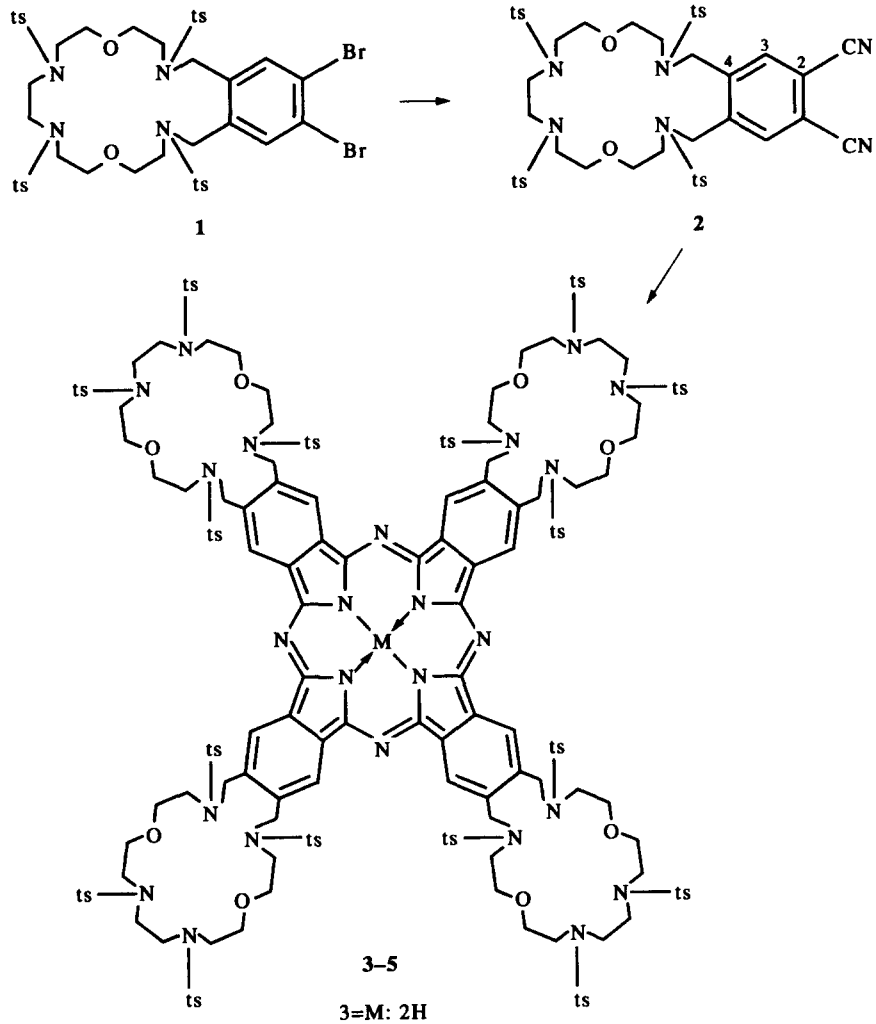
RESULTS AND DISCUSSION

21,22-Dicyano-2,8,11,17-tetra(toluene-p-sulfonyl)-1,2,3,4,5,6,7,8,9,10,11,12,13,14,15,16,17,18-octadecahydrobenzo[*l*] [1,7,10,16]tetraaza[4,13]-dioxacyclodicontine (**2**) was obtained from the dibromo derivative by refluxing in DMF with 3 equi-

* Author to whom correspondence should be addressed.

valents of CuCN.[7] The free phthalocyanine was obtained by heating a mixture of dicyano substituted tetraaza-dioxa macrocycle with hydroquinone in a sealed tube.[8] The metallophthalocyanines were prepared from the dicyano derivative of the macrocycle and the corresponding metal salts in high-boiling anhydrous solvents (*e.g.* dimethylformamide or quinoline). The yields were satisfactory and depended upon the transition metal ion.

The most obvious feature of free phthalocyanine and metallophthalocyanines is their extensive solubility in common organic solvents such as, chloroform, dichloromethane, dimethylformamide and dimethylsulfoxide. The solubilities in chloroform or dichloromethane are higher than those of similar complexes containing only crown ether[9] or tetraaza macrocyclic substituents. The unusual solubilities of these compounds are due to the bulky group substitution.[10]



Elemental analyses, IR, ^{1}H and ^{13}C NMR, MS and UV–vis spectra confirm the proposed structures of the compounds. The preparation of **2** has been accomplished in a 78% yield by the reaction of **1** with CuCN in dry DMF. In the IR spectrum of **2**, the intense absorption band at 2222 cm^{-1} corresponds to the C≡N groups. The C—Br stretching vibration observed at 645 cm^{-1}, belonging to **1**, disappears after the conversion into the dicyano derivative. The rest of the spectrum is closely similar to that of **1** including the characteristic vibrations of tosyl and ether groups. This spectrum exhibits characteristic frequencies at 3029 (Ar–H), 2962–2860 (C–H), 1345 and 1148 (SO_2) cm^{-1}. In the ^{1}H NMR spectrum of **2**, the singlet at $\delta = 2.42$ ppm and multiplets at $\delta = 7.78$–7.61, 7.38–7.23 correspond to methyl and aromatic protons. The chemical shifts belonging to methylene protons connecting nitrogen and oxygen show different values at $\delta = 3.45$–3.36 ppm (CH_2–O) and at $\delta = 3.25$–2.94 ppm (CH_2–N) as expected. The other methylene chemical shift which is connected to the phenyl ring was observed at $\delta = 4.45$ ppm as a singlet. The proton-decoupled ^{13}C NMR spectral data given below are also in accord with the expected structure. The carbon resonances of the *p*-tolylsulfonyl groups appear at $\delta = 143.72$, 135.72, 129.89, 128.12, 127.08 and 126.88 ppm. The other chemical shifts belonging to aromatic, methyl, nitrile and aza-oxa crown carbons appear at $\delta = 141.72$ (C_4), 134.88 (C_3), 113.88 (C_2) ppm (aromatic), at $\delta = 116.08$ ppm (C≡N), at $\delta = 49.49$–46.65 ppm (N–CH_2), at $\delta = 69.93$–68.11 ppm (O–CH_2) and at $\delta = 21.33$ (Ar–CH_3) ppm. The fast atom bombardment mass spectrum (FAB-positive) of **2** shows the expected molecular ion peak at $m/z = 1003$ $[M+1]^+$.

The metal free phthalocyanine **3** was synthesized by heating a mixture of dicyano derivative of tetraza-dioxa macrocycle (**2**) with hydroquinone in a Schlenk system. Metal free phthalocyanine (**3**) was obtained 38% yield. The IR spectra of **3** is very similar to that of **2**. A diagnostic feature of the phthalocyanine formation from dicyano derivative (**2**) is the disappearance of the C≡N stretching vibration at 2222 cm^{-1} of the precursor compound. Another difference is the presence of N–H stretching and bending vibrations assigned to bands at 3305 and 1028 cm^{-1}, respectively.[8] The ^{1}H NMR spectrum of **3** indicates aromatic protons at $\delta = 7.85$–7.22 ppm, aliphatic ether protons at $\delta = 3.77$–3.48 (CH_2–O) and nitrogen connected CH_2 groups at $\delta = 3.40$–3.18 ppm. A common feature of these spectra of metal-free phthalocyanines is the broad absorptions probably caused by the aggregation of phthalocyanine. Also the NH protons of this compound (**3**) could not be observed due to this phenomenon. Because of the distinct ring current of the 18π electron system of the inner phthalocyanine core, the protons are characteristically shifted to low or high field.[11] The molecular ion species in the FAB mass spectrum which is analyzed as solution in chloroform are observed in accord with calculated value. The molecular mass fragment ions corresponding to the molecular ion and cleavage of the two tosyl groups from **3** appear at $m/z = 4011$ $[M+1]^+$ and 3700, respectively.

In order to obtain the metallophthalocyanine **4–5**, the dinitrile derivative **2** was directly treated with the anhydrous transition metal salts [$NiCl_2$ or $Zn(O_2CMe)_2$]. The yields obtained were satisfactory although the workup conditions were cumbersome. The metallophthalocyanine **4** was obtained in 46.8% yield and the other compound **5** was obtained in 60% yield. The intense green products are very soluble in a number of solvents such as dichloromethane, chloroform, carbon tetrachloride, tetrahydrofuran, dimethyl formamide and dimethyl sulfoxide.

Elemental analyses, ^{1}H NMR, IR, MS and UV-vis spectra confirm the proposed structures of the metallophthalocyanines. In the IR spectrum of **2**, the intense absorption vibrations at 2222 cm^{-1} corresponding to the C≡N groups disappear after their conversion into the metallophthalocyanines (**4–5**). The rest of the IR spectra are very similar to those of **2** including the characteristic vibrations of tosyl, crown and aza-crown groups. In the ^{1}H NMR spectrum of **4** and **5**, the chemical shifts belonging to aromatic, crown and aza-crown groups at $\delta = 7.93$–7.27, 7.88–7.16, 3.92–3.63, 3.89–3.57, 3.44–3.07 and 3.36–2.97 ppm were observed after the cyclotetramerization, respectively. Broad NMR absorptions were observed for nickel(II) and zinc(II) phthalocyanines possibly due to aggregation. The mass spectrum (FAB positive) of **4** [$m/z = 4067$ $(M+1)^+$] supports the structure of nickel(II) phthalocyanine. The fast atom bombardment mass spectrum of **5** shows the molecular ion peak at 4074 $[M+1]^+$ and another peak at 3454 attributed to the loss of four tosyl groups [M-4Ts].

The phthalocyanines **3–5** show typical electronic spectra with two strong absorption regions, one of them in the UV region at about 240–345 nm (B band) and the other in the visible part of the spectrum at

Scheme 1.

670–700 nm (Q band). In extremely dilute solutions (*ca* 10^{-6} M), the metal-free or metallophthalocyanines behave as monomers in organohalide solution.[11] Increasing the concentration leads to aggregation which is easily observed by the values of the Q bands which shift to higher energies and by the decrease in the molar absorption coefficient. While the N-tosylated phthalocyanines are soluble in chloroform, their spectra in this solvent exhibit an intense Q band at the lowest energy region at 686, (**3**), 677 (**4**) and 691 nm (**5**) which the sharp band or shoulder around 630 nm [627 (**3**), 617 (**4**) and 629 (**5**)] can be attributed to aggregation.[12] On the other hand, while the monomeric species, in extremely dilute chloroform solution, with D_{2h} symmetry (metal-free derivative) shows two intense absorptions around 690 nm, that having D_{4h} symmetry gives only a single band in this region.[13]

EXPERIMENTAL

^{1}H and ^{13}C NMR spectra were recorded on a Varian XL-300 NMR spectrometer. IR and UV-vis recorded on a ATIunicam FT-IR in KBr pellets and a GBC 911 UV-vis spectrophotometer, respectively. Fast atom bombardment (FAB positive, matrix: *m*-nitro benzyl alcohol) mass spectra were measured on a VG Auto-Spec from VG Analytical. The elemental analyses were determined by a Hewlett–Packard 185 analyzer. 21,22-Dibromo-2,8,11,17-tetra(toluene-p-sulfonyl)-1,2,3,4,5,6,7,8,9,10,11,12,13,14,15,16,17,18-octadecahydrobenzo[*l*] [1,7,10,16]tetraaza[4,13]dioxacyclodicontine (**1**) was prepared according to the reported procedure.[6] Commercially available pure grade CuCN, $NiCl_2$, $Zn(O_2CMe)_2$ and solvent dried and purified by conventional procedures,[14] were used.

21,22-*Dicyano*-2,8,11,17-*tetra*(*toluene*-*p*-*sulfonyl*)-1,2,3,4,5,6,7,8,9,10,11,12,13,14,15,16,17,18-*octadecahydrobenzo*[*l*] [1,7,10,16]*tetraaza*[4,13]*dioxacyclodicontine* (**2**)

A two-necked round-bottom flask fitted with a condenser was evacuated, refilled three times with argon and then flamed under high vacuum. Under argon, the flask was charged with CuCN (1.2 g, 13.5 mmol), argon saturated anhydrous dimethyl formamide (25 cm^3) and the dibromo derivative of tetraaza-dioxa macrocycle (5 g, 4.5 mmol) (**1**) and the mixture was heated gradually to 175°C. It was then kept at this temperature for 12 h. During this time, the resulting solution became dark brown. Then the heating was stopped and the reaction mixture was allowed to cool to room temperature, opened to air and diluted with aqueous NH_4OH (57 cm^3) and air was passed through the solution for 24 h. The end of this period, the solution became dark blue and a green precipitate formed. The reaction mixture was filtered through Celite and washed with dilute NH_4OH (10%) and water, until the filtrate was neutral. This crude precipitate was then dried and extracted with chloroform and then dried with $NaSO_4$. This mixture was filtered and the filtrate evaporated to dryness. The oily product obtained was refluxed in ethanol (75 cm^3) for 4 h and cooled to room temperature. To this solution n-hexane was added gradually until the precipitation was completed then the product was isolated as a tannish powder by stirring in n-hexane (150 cm^3) for 2 days. The powder was collected by filtration, washed with cold ethanol and n-hexane and then dried *in vacuo*. Yield 3.5 g (78%), m.p. 105°C. ^1H NMR ($CDCl_3$): δ 7.78–7.61 (m, 10H, Ar–H), 7.38–7.23 (m, 8H, Ar–H), 4.45 (s, 4H, CH_2–Ar), 3.45–3.36 (m, 8H, O–CH_2), 3.25–2.94 (m, 12H, N–CH_2), 2.42 (s, 12H, CH_3) ppm. ^{13}C NMR ($CDCl_3$): δ 143.72 (Ts–Ar), 141.75 (C_4), 135.74 (Ts–Ar), 134.88 (C_3), 129.89 (Ts–Ar), 128.12 (Ts–Ar), 127.08 (Ts–Ar), 126.88 (Ts–Ar), 116.08 (C≡N), 113.88 (C_2), 69.93–68.11 (O–CH_2), 49.49–46.65 (N–CH_2), 21.33 (Ar–CH_3) ppm. IR (KBr): 3029 (Ar–H), 2962–2860 (C–H), 2222 (C≡N), 1605, 1451, 1345 (SO_2), 1148, 1136, 1076, 995, 821, 695 cm^{-1}. Mass spectrum (FAB positive): m/z 1003 $[M+1]^+$. Found: C, 57.3; H, 5.2; N, 8.2; Calc. for $C_{48}H_{54}N_6O_{10}S_4$: C, 57.5; H, 5.4; N, 8.4%.

Metal-free [*hexadecakis*(N-*p*-*tosyl*)-*tetrakis*-*macrocyclophthalocyanine*], **3**

A mixture of dicyano derivative of macrocycle (**2**) (0.80 g, 0.8 mmol) and hydroquinone (0.09 g, 0.8 mmol; purified by sublimation) was placed in a Schlenk tube under argon, gently heated, and subsequently heated at 200°C for 10 h. After cooling to room temperature a dark green product was obtained. The crude product was dissolved in chloroform, washed with water and filtered and then dried over anhydrous $MgSO_4$. The green solution was concentrated *in vacuo* and n-hexane was added dropwise into this solution to obtain dark-green metal-free phthalocyanine. The resulting dark green precipitate was filtered off, washed with n-hexane and then with diethyl ether and dried *in vacuo*. Yield 0.30 g (38%). ^1H NMR ($CDCl_3$): δ 7.85–7.22 (m, 72H, Ar–H), 4.49 (s, 16H, Ar–CH_2), 3.77–3.48 (m, 32H, OCH_2), 3.40–3.18 (m, 48H, NCH_2), 2.47 (s, 48H, CH_3). IR (KBr): 3305, 3033 (Ar–H), 2950–2848 (C–H), 1638, 1597, 1462, 1352 (SO_2), 1173, 1028, 1007, 839, 711 cm^{-1}. UV-vis λ_{max} · (log ε) (in $CHCl_3$, 10^{-4} M): 686sh (5.86), 627, (4.09), 338 sh (4.98), 288 (4.71), 263 (5.24), UV-vis λ_{max} · (log ε) (in $CHCl_3$, 10^{-6} M): 695 (6.32), 635sh (4.31), 342 (5.19), 294 (5.04), 270 (5.37). Mass spectrum (FAB positive): m/z 4011 $[M+1]^+$, 3700 [M-2Ts]. Found: C, 57.3; H, 5.3; N, 8.2. Calc. for $C_{192}H_{218}N_{24}O_{40}S_{16}$: C, 57.4; H, 5.4; N, 8.4%.

[*Hexadecakis*(N-*p*-*tosyl*)-*tetrakis*-*macrocyclephthalocyaninato*]*nickel*(II), **4**

Compound **2** (0.5 g, 0.5 mmol), anhydrous $NiCl_2$ (0.016 g, 0.125 mmol) and anhydrous dimethyl formamide (1 cm^3) were mixed in a Schlenk tube under argon and then the mixture was heated and stirred at 165°C for 36 h under inert atmosphere. After cooling to room temperature, the dark blue mixture was diluted with methanol (50 cm^3) until the crude product precipitated. It was filtered off and washed with hot ethanol. The precipitate was dissolved in chloroform (12 cm^3) and then reprecipitated by adding methanol. In order to obtain metallophthalocyanine and to remove unreacted organic material, the crude product was dissolved in 1,1,2,2-tetrachloroethane (4 cm^3) and reprecipitated with hexane. The precipitate was filtered off, washed with methanol and diethyl ether and then dried *in vacuo*. Yield 0.24 g (46.8%). ^1H NMR ($CDCl_3$): δ 7.93–7.27 (m, 72H, Ar–H), 4.45 (s, 16H, AR–CH_2), 3.92–3.63 (m, 32H, OCH_2), 3.44–3.07 (m, 48H, NCH_2, 2.53 (s, 48H, CH_3). IR (KBr): 3042 (Ar–H), 2943–2859 (C—H), 1642, 1447, 1339 (SO_2), 1150, 1083, 1001, 833, 702 cm^{-1}. UV-vis λ_{max} · (log ε) in $CDCl_3$, 10^{-4} M): 677 (5.61), 617sh (3.52), 338 (5.17), 300sh (4.06), 273 (4.14), 244 (5.12). UV-vis λ_{max} · (log ε) (in $CDCl_3$, 10^{-6} M): 684 (5.88), 629sh (3.74), 345 (5.32), 310sh (4.27), 276 (4.27), 250 (5.29). Mass spectrum (FAB positive): m/z 4067 $[M+1]^+$. Found: C, 56.3; H, 5.1; N, 8.0. Calc. for $C_{192}H_{216}N_{24}O_{40}S_{16}Ni$: C, 56.6; H, 5.3; N, 8.3%.

[*Hexadecakis*(N-*p*-*tosyl*)-*tetrakis*-*macrocyclephthalocyaninato*]*zinc*(II), **5**

A mixture of **2** (0.50 g, 0.5 mmol), anhydrous $Zn(O_2CMe)_2$ (0.034 g, 0.18 mmol) and anhydrous quinoline (1 cm^3) was placed in Schlenk tube and heated to 195–200°C under argon with stirring and held at this temperature for 10 h. After cooling to room temperature the dark blue mixture was diluted with ethanol (5 cm^3) and filtered. The crude product

was dissolved in chloroform, washed with water and then dried over anhydrous $MgSO_4$. After filtration, the filtrate was concentrated (10 cm^3) and ethanol was added dropwise to this solution with stirring. The precipitate formed was filtered off, washed with ethanol then with diethyl ether and dried *in vacuo*. Yield 0.30 g (60%). ^1H NMR ($CDCl_3$): δ 7.88–7.16 (m, 72H, Ar–H), 4.47 (s, 16H, Ar–CH_2), 3.89–3.57 (m, 32H, OCH_2), 3.36–2.97 (m, 48H, NCH_2), 2.55 (s, 48H, CH_3). IR (KBr): 3036 (Ar–H), 2949–2867 (C–H), 1636, 1603, 1443, 1341, (SO_2), 1163, 1123, 1092, 1000, 829, 724 cm^{-1}. Abstract—The novel Cu_2Zn_2 superoxide dismutase (Cu_2Zn_2SOD) mimic compound $[Cu(appn)](ClO_4)_2 \cdot H_2O$ [where appn = N,N′-propylenebis(2-actoylpyridineiminato)] has been prepared. Single-crystal X-ray analysis revealed that the copper(II) ion has a distorted square-pyramidal environment very similar to that of Cu_2Zn_2SOD: the basal positions are occupied by four nitrogen atoms from the Schiff base ligand and the apical position by an oxygen atom of a hydrate molecule. The Cu—N and Cu—O bond lengths are 1.972(2)···2.029(2) and 2.326(2) Å, respectively. Copyright © 1996 Elsevier Science Ltd

The coordination chemistry of Schiff base ligands derived from 2-pyridyl ketones has found more and more applications in biological modelling of Cu_2Zn_2 superoxide dismutase (Cu_2Zn_2SOD) recently.[1–4] Up to now several Cu_2Zn_2SOD mimic complexes have been synthesized and identified structurally, such as [N,N′-butylenebis(2-acetylpyridineiminato)]copper(II)diperchlorate[2] $[Cu(apy)L](ClO_4)_2$ (apy = 2-acetylpyridine and L = N-ethylene(2-acetylpyridineimine)],[3] [N,N′-bis(2-pyridyl-phenyl)menthylene-1,4-butanediamine]-(N,N′,N″,N‴)-copper(II). However, their coordination environments are not very similar to that of Cu_2Zn_2SOD due in part to there being no coordinated hydrate occupying the apical position of the pyramid, while the copper atom in Cu_2Zn_2SOD is located in the centre of a distorted square pyramidal of five coordinating atoms [four nitrogen atoms of four histidylimidazolate residues (his-44,46,61,118) form the base and the water molecule occupies the apical site, Fig. 1]. In our previous work $\{[Cu(bppn)](ClO_4)_2\}_2 \cdot H_2O$ [bppn = N,N′-propylenebis(2-benzoylpyridineiminato)] was prepared and crystallized, but the hydrate is not coordinated

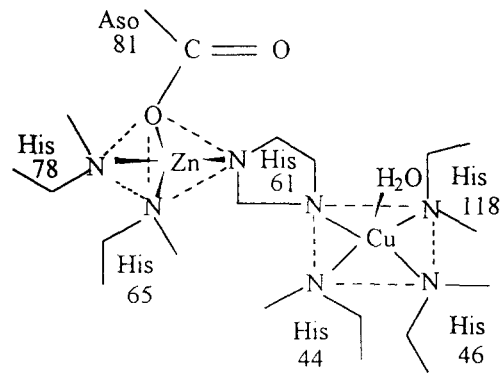

Fig. 1. The active site of Cu_2Zn_2 superoxide dismutase.

and the copper(II) ions have distorted tetrahedronal coordination environment. As a continuation of this work, we have prepared a new Cu_2Zn_2SOD mimic complex, $[Cu(appn)](ClO_4)_2 \cdot H_2O$; its crystal structure showed that the copper(II) atom has a coordination geometry very similar to that of Cu_2Zn_2SOD.

EXPERIMENTAL

Preparation of $\{[Cu(bppn)](ClO_4)_2\}_2 \cdot H_2O$

All chemicals were commercial materials and were used without further purification.

To 30 cm^3 methanolic solution containing both $Cu(ClO_4)_2 \cdot 6H_2O$ (0.76 g, 2.07 mmol) and 2-acetylpyridine (0.5 g, 4.13 mmol), a solution of 1,3-propane diamine in MeOH (10 cm^3) was added dropwise while stirring. The solution was refluxed and stirred for 1 h, then the reaction mixture turned into a deeply blue colour. The blue block crystals were formed when the solution was cooled to room temperature. The crystals were separated and washed with ethanol, yield 45.8%. A single crystal suitable for X-ray determination was obtained from recrystallization in acetonitrile. Found: C, 36.3; H, 3.9; N, 9.9. Calc. for $C_{17}H_{22}CuCl_2N_4O_9$: C, 36.4; H, 3.9; N, 10.0%.

Measurements

C, H and N analyses were performed on a Perkin–Elmer 240 elemental analyser; IR and far-IR spectra were recorded on a Nicolet FTIR 170SX spectrophotometer with KBr discs in the 4000–400 and 500–100 cm^{-1} regions, respectively. Electronic spectra were recorded on a Shimadzu-UV 3100 spectrometer in a solution of acetonitrile at a concentration of 3.0×10^{-3} M. EPR was obtained on a Brucker ER 200D-SRC spectrometer at 120 K. Cyclic voltammetry was measured on a PARC M273 electrochemical analyser at a complex concentration of 1×10^{-3} M in twice distilled water with 0.08 M KCl (A.R. recrystallized before use) as the supporting electrolyte. A platinum wire working electrode, a platinum plate auxiliary electrode and a saturated calomel electrode (S.C.E.) reference electrode were employed.

Data collection and structure solution

Diffraction data were collected on a Siemens P4 diffractometer using graphite-monochromated Mo-K_α radiation ($\lambda = 0.71073$ Å). The scan mode was $\theta/2\theta$. 6500 reflections were measured ($1.85 \leqslant \theta \leqslant 27.51°$, $-1 \leqslant h \leqslant 11$, $-1 \leqslant k \leqslant 23$, $-18 \leqslant l \leqslant 18$), of which 5145 were unique [R(int) = 0.0328] and used in the structure refinement.

Crystal data. $C_{17}H_{22}N_4CuCl_2O_9$, $M = 560.83$, monoclinic, space group $P2_1/c$, $a = 9.021(3)$, $b = 17.780(3)$, $c = 14.082(3)$ Å, $\beta = 92.00(1)°$, $V = 2257.3(1.0)$ Å^3, $Z = 4$, $D_c = 1.650$ g cm^{-3}, $\mu = 12.61$ cm^{-1}, $F(000) = 1148$.

The structure was solved by direct methods using SHELXS86[9] and refined using SHELXL93.[10] The coordinates and the anisotropic thermal parameters for the non-hydrogen atoms were refined by full-matrix least-squares on F^2. The hydrogen atoms of the methylene and methyl groups were placed in calculated positions (two H atoms in the water molecule were not included) and refined using a riding model (C—H = 0.96, N—H = 0.90 Å; $U_{iso} = 0.08$), the other hydrogen atoms were located from ΔF maps and refined isotropically. All non-hydrogen atoms were refined with anisotropic thermal parameters. Calculations were carried out on a PC. The final cycle of refinement on $|F|^2$ included 468 variable parameters and converged with $R = 0.0411$, $R_w = 0.1169$ [$I > 2\sigma(I)$], S = 1.051, final difference-Fourier synthesis: $-0.364 \leqslant \Delta\rho \leqslant 0.530$ e Å^{-3}. The atomic coordinates, thermal parameters and structure factors have been deposited with the Editor as supplementary data.

RESULTS AND DISCUSSION

Description of the crystal structure

Selected bond distances and bond angles of the title complex are listed in Table 1. Figures 2 and 3 show the cation configuration and the molecular arrangement of $[Cu(appn)](ClO_4)_2 \cdot H_2O$ in the unit cell, respectively. The coordination geometry of the copper(II) atom closely resembles that of Cu_2Zn_2SOD. A distorted square-pyramid configuration is formed with four nitrogen atoms from the Schiff base ligand as the base and the oxygen atom of water molecule occupying the apical site, while the copper(II) atom is located approximately in the centre of the pyramid base. $[Cu(apy)L](ClO_4)_2$ or $CuPuPhePy(ClO_4)_2$ as previously reported[3,4] have a similar distorted square-pyramidal geometry, but the oxygen atom in the apical position is from the 2-acetylpyridine ligand or perchlorate ion rather than the hydrate molecule, which makes it more difficult for the complexes to change their configurations. The Cu—N bond distances [1.979(2)–2.029(2) Å] of $[Cu(appn)](ClO_4)_2 \cdot H_2O$ are normal coordination bonds and are in good agreement with those found in other mimic copper(II) complexes derived from the 2-pyridal ketones.[2–5] The Cu—O bond length is 2.326(2) Å and shorter than that in SOD (2.80 Å), while the Cu—N bond distances of the title complex are shorter than those in SOD (2.04–2.14 Å), suggesting the present complex possesses lower activity than SOD.

The dihedral angle between the two pyridine ring planes I [N(1), C(1), C(2), C(3), C(4), C(5)] and II [N(4), C(13), C(14), C(15), C(16), C(17)] is 30.49°. Cu^{II} and four N atoms composed are approximate planar square, but the coplanarity is poor. The structure of CuN_4 is obviously distorted towards a tetra-

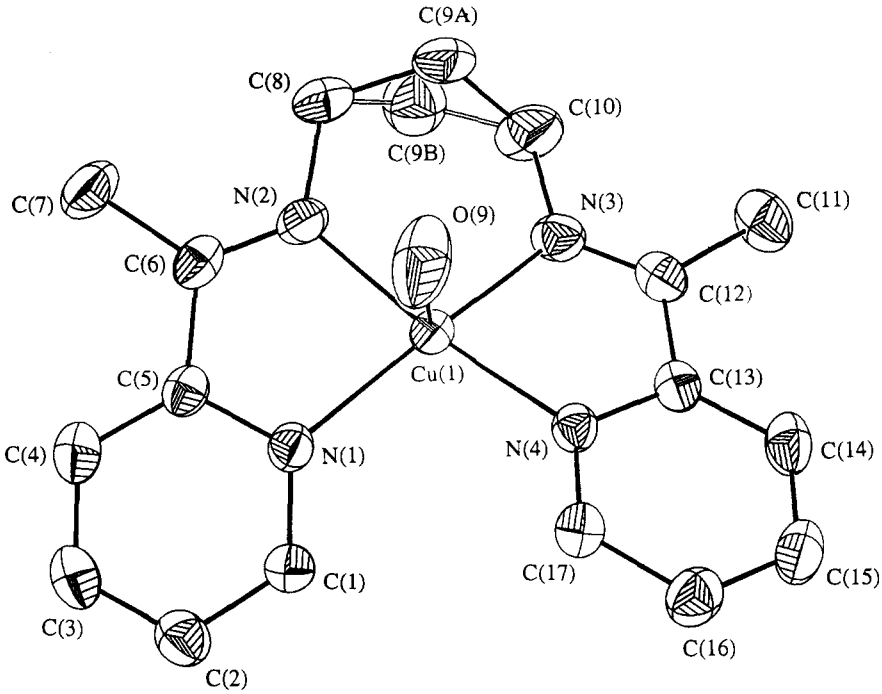

Fig. 2. Perspective view of the complex cation with the atomic numbering scheme.

hedron. Similar trends were observed in previously reported mimic compounds such as [N,N′-butylenebis(2-acetylpyridineiminato)] copper(II) diperchlorate,[2] $[Cu(apy)L](ClO_4)_2$ (apy = 2-acetylpyridine and L = N-ethylene(2-acetylpyridineimine)],[3] [N,N′-bis(2-pyridyl-phenyl)menthylene-1,4-butanediamine]-(N,N′,N″,N‴)-copper(II).[4]

The coordinated water molecule is hydrogen-bonded with perchlorate ions (Table 2). The H—O—H···O contacts range from 2.802(0.020) to 2.97(0.011) Å, indicating the hydrogen bonds are of medium strength.[11] Furthermore, extensive hydrogen bonds involve the perchlorate oxygen atoms [O(1), O(2), O(4), O(6), O(7), O(8)], pyridine ring and carbon chain, and the C···O contacts vary from 3.100(0.018) to 3.358(0.027) Å, suggesting the hydrogen bond strength is weaker than those of the former.

IR, EPR and electronic spectra

In the $\nu(O—H)_{water}$ region of the IR spectrum, $[Cu(appn)](ClO_4)_2 \cdot H_2O$ shows at least two strong and sharp bands around 3519 and 3467 cm^{-1}, mainly attributed to the presence of coordinated water.[10] The medium band at 1631 cm^{-1} was assigned to the C=N stretching vibration of the Schiff's base linkages. A strong and broad band at 1093 cm^{-1} was assigned to be typical of the uncoordinated perchlorate. The strong band at 622 cm^{-1} and weak band at 413 cm^{-1} could be assigned to the in-plane and out-of-plane

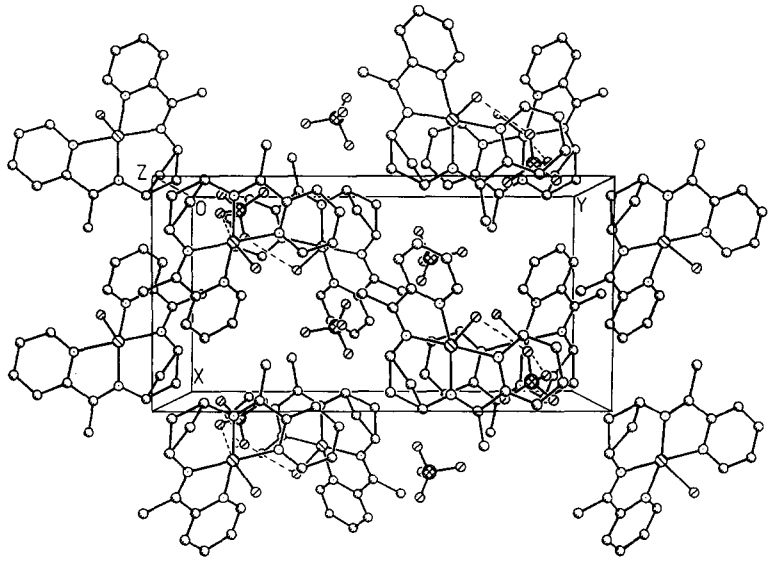

Fig. 3. Unit cell packing diagram.

C(2)···O(7A)[f]	3.335(0.009)	C(4)···O(8A)[g]	3.410(0.012)
C(11)···O(2B)[h]	3.358(0.027)		

Symmetry code: [a] x, y, z; [b] $-x, -y, -z+2$; [c] $-x, +y-1/2, -z+1/2+1$; [d] $-x+1, -y, -z+2$; [e] $-x+1, +y+1/2, -z+1/2+1$; [f] $x+1, -y+1/2, +z-1/2$; [g] $-x+1, +y-1/2, -z+1/2+1$; [h] $-x, +y+1/2, -z+1/2+1$.

pyridine ring deformation vibrations, respectively, as previously suggested.[5,8] Other far-IR spectra bands at 386(m), 305(m), 322(m) and at 249(w), 263(w), 241(w), 208(s) cm^{-1} may be assigned to $\nu(Cu—N_{Schiff})$ and $\nu(Cu—N_{ring})$, respectively. Because metal–nitrogen stretching vibrations are often coupled with other normal modes of vibration of the same symmetry, especially ring vibrations.[12] The above attribution of the Cu—N stretching vibrations are only approximate. In addition, the appearance of a new medium band at 397 cm^{-1} is assigned to $\nu(Cu—O_{water})$.[13]

$[Cu(appn)](ClO_4)_4 \cdot H_2O$ displays an electronic spectra band at 626.0 nm (110 $M^{-1}\,cm^{-1}$) in MeCN. It is typical of *d–d* transitions of Cu^{II} in a weak tetragonal field and in accord with those reported for SOD mimic compounds.[4]

The EPR spectrum of the title complex consists of only a quasisymmetric signal centred at $g = 2.076$, which is quite unusual and very different from those of other mimic complexes. The latter always exhibit anisotropic features; the main cause is probably due to the presence of extensive disorder in the structure.

Electrochemistry

The cyclic voltammogram of $[Cu(appn)](ClO_4)_2 \cdot H_2O$ was measured in aqueous solution in the range 2.0 to −2.2 V. The complex is electrochemically active and displays an irreversible one-electron ($i_{pa}/i_{pc} = 1.0$; $E_{pa} = -0.26$ V; $E_{pc} = -0.460$ V; $\Delta E_p = 200$ mV) reduction wave at −0.36 V versus SCE, which is assigned to Cu^{II}/Cu^{I}. The value of $E_{1/2}$ is comparable to those reported SOD mimic compounds (from −0.264 to −0.504 V) and exhibits more positive reduction potential than that of another similar Schiff base mimic complex derived from propane diamine-1,2: $[Cu(appn)](ClO_4)_2$ (reduction potential −0.472 V).[1] The former researchers indicated that the more positive the reduction potential of the mimic compound, the higher its relative activity,[1] suggesting the $[Cu(appn)](ClO_4)_2 \cdot H_2O$ should give better result in simulating superoxide dismutase than the previously reported $[Cu(appn)](ClO_4)_2$.

Synthesis and spectroscopic characterization of (trialkyl/triaryl)-phosphine gold(I) thiocyanate complexes

M. Naseem Akhtar, Anvarhusein A. Isab,* A. R. Al-Arfaj and M. Sakhawat Hussain

Department of Chemistry, King Fahd University of Petroleum and Minerals, Dhahran 31261, Saudi Arabia

(Received 19 April 1996; accepted 26 April 1996)

Abstract—$R_3PAuS^{13}C^{15}N$ (where R_3P = Me_3P, Et_3P, *i*-Pr_3P, *p*-$TolPh_2P$, Ph_3P and cyanoethylphosphine CEP) complexes have been prepared. The Au—NCS/Au—SCN ratios for these complexes have been determined, using IR spectroscopy (ν_{CN} integrated absorption intensity ratios). The observation that the Au—NCS/Au—SCN ratio increases as the *trans* influence of the phosphine ligand increases is completely in agreement with the trend predicted by the antisymbiotic *trans* influence theory. In the solid state only the S-bonded isomer of each complex is observed. The ^{13}C, ^{15}N and ^{31}P NMR chemical shifts of these complexes were also measured and are compared with $R_3PAu^{13}C^{15}N$ complexes. The results show that unlike $R_3PAu^{13}C^{15}N$ complexes, which undergo disproportionation in solution, the $R_3PAuS^{13}C^{15}N$ complexes do not undergo disproportionation. Copyright © 1996 Elsevier Science Ltd

Gold(I) has a strong tendency to form linear two-coordinate complexes of the type L—Au—X, where "L" is a neutral Lewis base (e.g. phosphines, thioethers, etc.) and "X" is a halide, pseudohalide, aryl or alkyl group.[1–3] These complexes are usually formulated as neutral complexes, but since gold(I) is generally labile, there exists the possibility of ligand redistribution in solution to form the symmetrically substituted complexes of the type $[AuL_2]^+$ and $[AuX_2]^-$, as shown in eq. (1).

$$2L—Au—X \rightleftharpoons [AuL_2]^+ + [AuX_2]^- . \quad (1)$$

It has been reported[4] that anionic cyano(thiolato)gold(I) complexes, $[RSAuCN]^-$, are in equilibrium with substantial concentrations of $[Au(CN)_2]^-$ and $[Au(SR)_2]^-$ in aqueous solution. This ligand redistribution reaction is also observed in cyano (alkyl,aryl)phosphinegold(I) complexes.[2,5,6]

The thiocyanate is an ambidentate ligand, which can bind to the central metal via "S" or "N" atom. Thus, L—Au—SCN linear complexes appeared to be an ideal system to study the antisymbolic *trans* effect in class (b) metals, because there is no effect of steric hinderance since the ligands are present on opposite sides of the molecule and also due to the neutral nature of the complexes they are not susceptible to the counter-ion effect. Moreover, the IR spectra become very simple to analyse due to the presence of only two ligands.

The concept of antisymbiotic *trans* influence predicts that the site *trans* to a strong *trans* directing ligand will become harder in complexes of class (b) metals. It has been found[7,8] that in the solid state, thiocyanate is bonded only via "S" to the gold atom. However, Burmeister and Melpolder[9,10] have observed this antisymbiotic trend in a series of solutions of linear L—Au—SCN complexes using IR; the L—Au—NCS/L—Au—SCN ratio increases as the *trans* effect of the "L" phosphine ligand increases.

In the present study we have prepared a series of doubly labelled $R_3PAuS^{13}C^{15}N$ (where R_3P = Me_3P, Et_3P, *i*-Pr_3P, *p*-$TolPh_2P$, Ph_3P and cyanoethylphosphine CEP) complexes to see whether ligand redistribution reactions and the antisymbiotic *trans* effect is observed in these types of gold(I) complexes using ^{13}C, ^{31}P, ^{15}N NMR and IR spectroscopy.

EXPERIMENTAL

Reagents

$KS^{13}C^{15}N$ (50%) was purchased from Merck Sharp and Dohme, Canada. Sodium tetrachloroaurate dihydrate, phosphine ligands (trimethyl, triethyl, tiphenyl, tri-isopropyl, triscyanoethyl and paratollyldiphenyl) were obtained from Stream Chemical Co., U.S.A.; CD_3OD and dichloromethane were obtained from Fluka Chemical Co.

R_3PAuCl

The R_3PAuCl complexes were prepared by the addition of phosphine ligands to the ethanolic solution of $NaAuCl_4$, as described in the literature.[11,12]

$R_3PAuS^{13}C^{15}N$

R_3PAuCl was dissolved in acetone and 1 equiv. of $AgNO_3$ was added to produce R_3PAuNO_3 in solution by precipitation of AgCl[7]. Then 1 equiv. of an aqueous solution of $KS^{13}C^{15}N$ (50% labelled) was added to the solution of R_3PAuNO_3 and was stirred for 1 h. The solution was then placed under vacuum to remove the solvent. Finally, a white crystalline solid was recovered, which was washed several times with deionized water to remove KNO_3, then with ethanol and ether. The elemental analysis, melting points and % yield for $R_3PAuSCN$ complexes are given in Table 1.

IR spectroscopy

The solid-state IR spectra of $R_3PAuS^{13}C^{15}N$ complexes were recorded on a Perkin–Elmer IR 180 spectrophotometer using KBr pellets. While a Perkin–Elmer 1600 FT series was used to measure solution IR spectra in the ν_{CN} region.

The ratios of the ν_{CN} integrated absorption intensities of N-bonded/S-bonded thiocyanates were calculated as follows.[10] The IR stretching region was recorded using the linear absorbance mode rather than the linear transmittance mode. The low-energy tail of the high-energy absorption band was drawn in (an estimate) and the resulting envelops were traced on paper, which were carefully cut out and weighed on a Mettler balance. The weight of the N-bonded band was divided by that of S-bonded band giving an N-bonded/S-bonded ratio.

^{13}C, ^{15}N *and* ^{31}P *NMR spectroscopy*

The ^{13}C NMR spectra were measured at 50.30 MHz on a Varian XL-200 spectrometer operating in the pulsed Fourier transform mode. The ^{13}C NMR measurements were made with broad-band ^1H decoupling.

The ^{15}N NMR spectra were obtained at 20.28 MHz on a Varian XL-200 spectrometer using CD_3OD solutions at the probe temperature of 297 K. The chemical shift for ^{15}N NMR spectra were measured using sealed $NH_4^{15}NO_3$ as an external reference, which has a resonance at 375.11 ppm relative to pure CH_3NO_2, 380.2 ppm.[13,14] We did not measure the T_1 values of any resonance. The spectral conditions were: 5.0 s delay time, 16 K data points, spectral width 10 000 Hz, pulse width 6.0 μs (20°), and 10 mm multinuclear probe. Approximately 60 000 scans were accumulated for each sample.

The ^{31}P NMR spectra were obtained at 80.98 MHz on a Varian XL-200 spectrometer using the above solutions at the probe temperature 297 K. The ^{31}P NMR chemical shifts were measured from external reference 1% TMP.[16] The spectral conditions were: 1.0 s delay time, 32 K data points, spectral width 4000 Hz, pulse width 5.0 μs, 10 mm multinuclear probe. Approximately 10 000 scans were accumulated for each sample.

The ^{13}C, ^{15}N and ^{31}P NMR chemical shifts for various $R_3PAuS^{13}C^{15}N$ complexes are given in Tables 2 and 3.

RESULTS AND DISCUSSION

The ^{31}P-$\{^1H\}$ NMR spectra of $R_3PAuS^{13}C^{15}N$ (where R_3P = Me_3P, Et_3P, *i*-Pr_3P, *p*-$TolPh_2P$, Ph_3P and cyanoethylphosphine CEP) complexes were measured in their methanolic solution. In each case a single sharp resonance was observed. There was no splitting due to $^3J(^{31}P—^{13}C)$ or $^4J(^{31}P—^{15}N)$. The ^{31}P chemical shifts for all $R_3PAuS^{13}C^{15}N$ complexes are given in Table 2.

The ^{13}C-$\{^1H\}$ NMR spectra of $R_3PAuS^{13}C^{15}N$ complexes were recorded with the same solutions used for ^{31}P NMR studies. Two broad resonances were observed in low-field region of $Me_3PAuS^{13}C^{15}N$, $Et_3PAuS^{13}C^{15}N$,

i-$Pr_3PAuS^{13}C^{15}N$ and $CEPAuS^{13}C^{15}N$ complexes for $—AuS^{13}C^{15}N$ and $—Au^{15}N^{13}CS$ linkage isomers. The $^1J(^{13}C—^{15}N)$ was not resolved in these complexes due to exchange between S-bonded and N-bonded isomers. The resonance due to S-bonded isomer was more intense and was at low field compared with the N-bonded isomer. In the case of p-$TolPh_2PAuS^{13}C^{15}N$ the two resonances for S-bonded and N-bonded isomers were resolved as doublets, while in the case of the $Ph_3PAuS^{13}C^{15}N$ complex only one broad resonance was resolved for both linkage isomers. The ^{13}C chemical shifts for all $R_3PAuS^{13}C^{15}N$ complexes are given in Tables 2 and 3.

The $^{15}N[^1H]$ NMR spectra of some solutions of $R_3PAuS^{13}C^{15}N$ complexes were also recorded, but due to the low sensitivity of the instrument, low solubility of the complexes and only 50% labelled ^{15}N, the signal-to-noise ratio was very poor. We were able to obtain the resonances for i-$Pr_3PAuS^{13}C^{15}N$, $Et_3PAuS^{13}C^{15}N$ and $Me_3PAuS^{13}C^{15}N$ complexes only, in the region 231–233 ppm. In the case of i-$Pr_3PAuS^{13}C^{15}N$ two broad resonances were resolved for S-bonded and N-bonded linkage isomers. The $^1J(^{13}C—^{15}N)$ was not resolved due to exchange between linkage isomers, while in the other complexes only one broad resonance was resolved without any splitting for both isomers. The ^{15}N chemical shifts for $R_3PAuS^{13}C^{15}N$ complexes are given in Table 2. The typical ^{31}P, ^{13}C and ^{15}N NMR spectra of i-$Pr_3PAuS^{13}C^{15}N$ are shown in Fig. 1.

The solution IR spectra of all $R_3PAuSCN$ complexes, except CEPAuSCN, in dichloromethane yielded two separate absorption bands in the region 2122–2129 cm^{-1} for the S-bonded isomer, while the other in the region 2082–2091 cm^{-1} for N-bonded isomer,[10] which are given in Table 4. In the case of CEPAuSCN due to very low solubility, the solution IR spectrum was not very good and two separate absorption bands were not resolved. A typical solution IR spectrum of i-$Pr_3PAuSCN$ in the ν_{CN} region is shown in Fig. 2. It was observed that the N-bonded isomer was a minor component in all $R_3PAuSCN$ complexes, since the integrated absorption intensity of the ν_{CN} band of an N-bonded thiocyanate is generally an order of magnitude larger[5] than that of an S-bonded thiocyanate. However, it is clear that the proportion of N-bonded isomer increases as the *trans* influence of the phosphine ligand increases. If the assumption is made that the intensity of the N-bonded

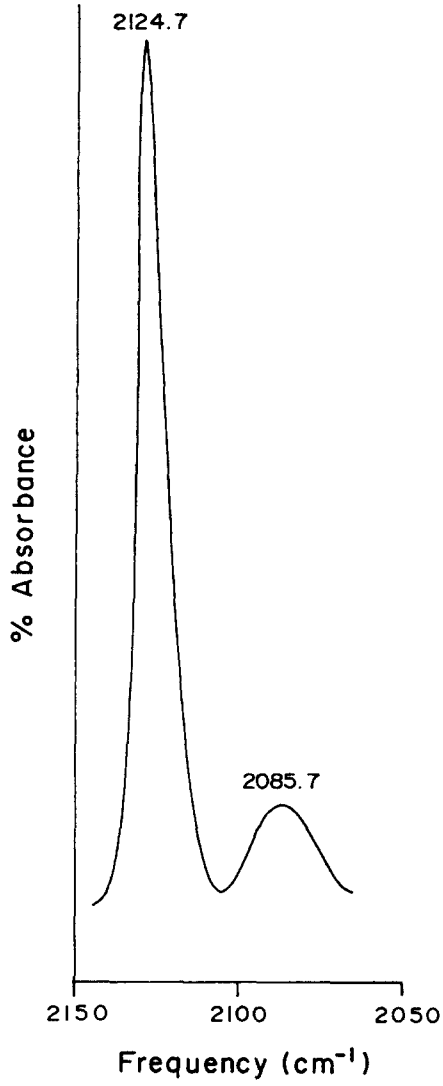

Fig. 2. The IR spectrum of 0.50 M Pri-$_3PAuS^{13}C^{15}N$ in dichloromethane in the absorption mode for the "SCN" group.

isomer is exactly 10 times that of the S-bonded isomer, then the per cent of N-bonded isomer present at equilibrium can be calculated[10] as follows: $10X(1-X)$ = Au—NCS/Au—SCN ratio; $10X$ is the per cent of N-bonded isomer present in the solution.

The ratios of integrated absorption intensities of ν_{CN} IR absorption bands and per cent of N-bonded isomer present in the solution of all $R_3PAuSCN$ complexes are given in Table 4. The solid-state IR spectra of all $R_3PAuSCN$ complexes showed that only the S-bonded isomer is present in the solid form. Apparently the crystal packing favours the geometry of this isomer.

The ^{31}P NMR spectra of R_3PAuCN complexes gave[5,6] two separate resonances for $[(R_3P)_2Au]^+$ and R_3PAuCN species due to ligand redistribution reactions. However, in the present studies for all $R_3PAuS^{13}C^{15}N$ complexes only one resonance is observed, which indicates that there is no ligand redistribution reaction in $R_3PAuS^{13}C^{15}N$ complexes or that it is so fast that it cannot be resolved on the NMR time scale. In the case of $R_3PAu^{13}C^{15}N$ complexes we have measured $^2J(^{31}P—^{13}C)$ and $^3J(^{31}P—^{15}N)$ coupling constants, but in this case we were unable to find any splitting due to $^3J(^{31}P—^{13}C)$ or $^4J(^{31}P—^{15}N)$, which means that in $R_3PAuS^{13}C^{15}N$ complexes the exchange between "S"-bonded and "N"-bonded SCN is so fast that this splitting is not resolved.

The ^{13}C-$\{^1H\}$ NMR studies are also consistent with the observations of ^{31}P NMR studies. The ^{13}C NMR gave rise to two broad resonances for linkage isomers, but the resonance due to $[Au(S^{13}C^{15}N)_2]^-$ was not observed, which indicates that there is no ligand redistribution reaction as shown in eq. (1). While in the case of $R_3PAu^{13}C^{15}N$ complexes two separate resonances were observed[6] for $R_3PAu^{13}C^{15}N$ and $[Au(^{13}C^{15}N)_2]^-$ species due to ligand redistribution reactions.

The ^{15}N NMR spectra of $R_3PAuS^{13}C^{15}N$ complexes was considered to be the most important technique to probe the S-bonded and N-bonded "SCN" ligand in this series of complexes. However, due to low sensitivity of the instrument only one broad resonance was resolved in the region 231–233 ppm for both S-bonded and N-bonded linkage isomers. However, a single resonance in the ^{15}N NMR spectra of $R_3PAuS^{13}C^{15}N$ complexes supports the results of ^{13}C and ^{31}P NMR studies that ligand redistribution reactions do not occur in this series of complexes, otherwise ^{15}N resonances due to $R_3PAuS^{13}C^{15}N$ and $[Au(S^{13}C^{15}N)_2]^-$ species would have been observed as shown in eq. (1).

The formation constants ($\log\beta_2$) for $[Au(CN)_2]^-$ and $[Au(SCN)_2]^-$ are reported[17] to be 39.0 and 17.0, respectively. The R_3PAuCN complexes readily undergo ligand redistribution reactions as shown in eq. (1) due to the large formation constant of $[Au(CN)_2]^-$, while this ligand redistribution reaction is not favourable in $R_3PAuSCN$ complexes due to the small formation constant of $[Au(SCN)_2]^-$.

A correlation that is frequently used to determine the relative basicity of phosphines is the electronic parameter ν_{CO} for $[R_3PNi(CO)_3]$ complexes (values tabulated by Tolman[18]). A decrease in the ν_{CO} value indicates a net increase in the electron-donating ability of a phosphine. Figure 3 shows an opposite behaviour of dependence of $\delta(^{13}C)$ of CN and SCN groups of $R_3PAu^{13}C^{15}N$ and $R_3PAuS^{13}C^{15}N$, respectively, on ν_{CO} values of different phosphines. In $R_3PAu^{13}C^{15}N$ complexes $\delta(^{13}C)$ decreases with an increase in the ν_{CO} value of phosphines due to the involvement of π-bonding between gold(I) and the —CN group.[6] While in $R_3PAuS^{13}C^{15}N$ complexes there is no π-bonding between gold(I) and the —SCN group, therefore, the basicity of the phosphine is effecting $\delta(^{13}C)$ directly, i.e. an increase in the basicity of phosphine causes more donation of electron towards gold(I), which in turn increases the effective nuclear charge on the "C" atom causing an upfield shift of $\delta(^{13}C)$.

The solution IR spectroscopy has been observed to be the most successful technique for the study of antisymbiotic *trans*-effect in $R_3PAuSCN$ complexes. Figure 4 shows a linear relationship between the *trans* effect (basicity) of phosphines and the % N-bonded isomer in all complexes, except that of $Ph_3PAuSCN$. As the *trans* effect of phosphines increases (basicity

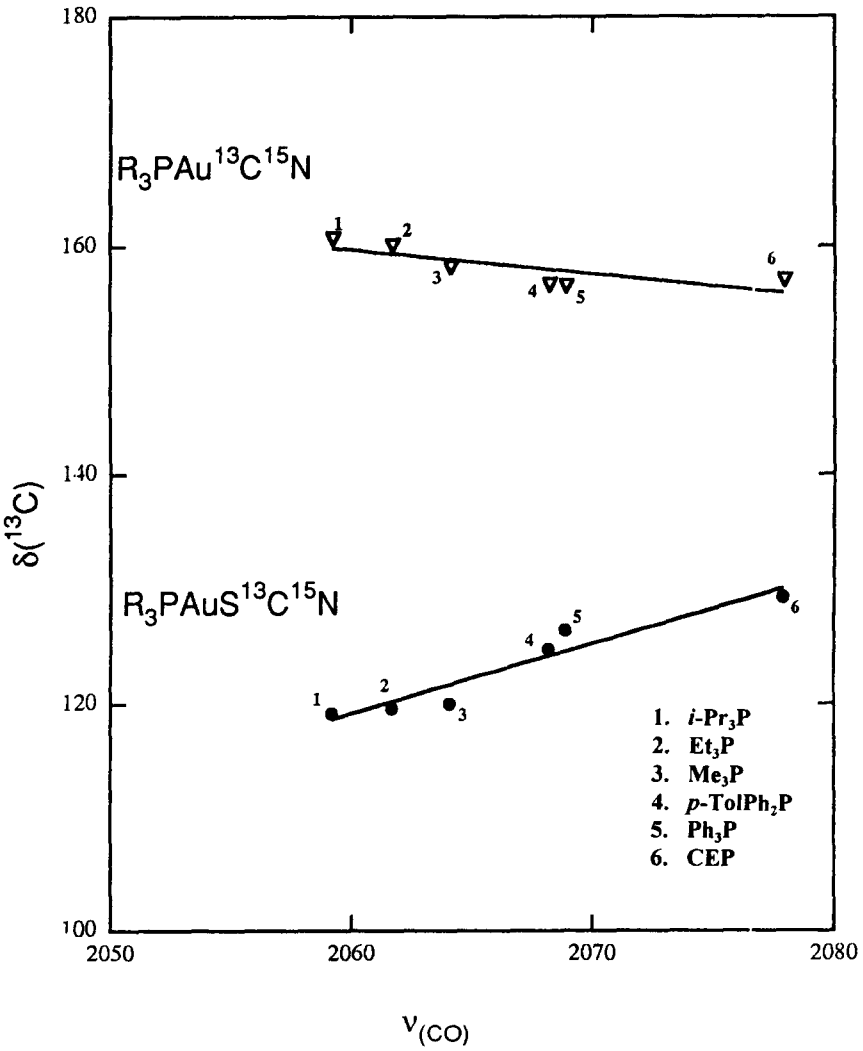

Fig. 3. Plot of ^{13}C NMR chemical shifts of $R_3PAu^{13}C^{15}N$ and $R_3PAuS^{13}C^{15}N$ complexes versus ν_{CO}. The solid lines are regression lines. The ^{13}C NMR chemical shift values for $R_3PAu^{13}C^{15}N$ complexes are taken from reference 5.

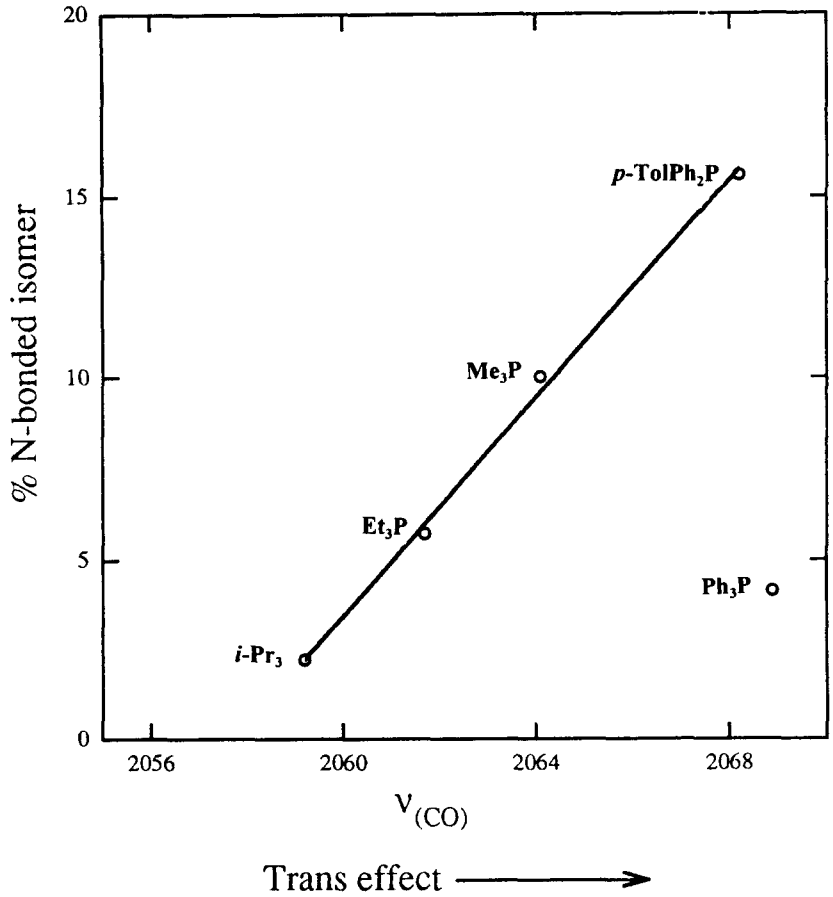

Fig. 4. Plot of % N-bonded isomer in $R_3PAuS^{13}C^{15}N$ complexes versus ν_{CO} of the phosphines. The solid line is regression line. Note: The value of $Ph_3PAuS^{13}C^{15}N$ is not included in the regression.

decreases) it causes decrease in the strength of the "Au—P" bond, which in turn favours the "NCS"-bonded isomer.[10]

This linkage isomerism can be explained on the basis of bridging of the "SCN" group between two gold species. The "—Au—SCN" bond undergoes cleavage and a new "—Au—NCS" bond with an "SCN" group of other species is formed. In this way $R_3PAuSCN$ complexes do not undergo disproportionation during linkage isomerism as is observed in R_3PAuCN complexes.

CONCLUSION

The results of this study follow the results exhibited by other class (b) metal systems[15] and add further support to the concept of the antisymbiotic *trans* influence[9,10,19] as being the primary electronic effect which causes certain coordination sites on class (b) metals to exhibit class (a) behaviour. When a soft ligand is placed *trans* to thiocyanate, as in LAuSCN, the stronger the *trans* director L becomes, the more N-bonding is observed, which is exactly what would be expected. In this case steric control of the bonding mode of the thiocyanate does not interfere with the interpretation of the results. The ^{13}C, ^{31}P and ^{15}N NMR spectroscopy shows that these complexes do not undergo ligand redistribution reactions as in the case of R_3PAuCN complexes.

Acknowledgements—We are thankful to Mr Khurshid Aalam from the Research Institute KFUPM for running IR spectra of the complexes. This research was supported by the King Fahd University of Petroleum and Minerals Research Committee under project No. CY/CYANIDE/175.

(Received 12 March 1996; accepted 23 April 1996)

Abstract—A series of compounds of the type $[MCl_2(amidine)_2]_n$, M = Mn, Co and Ni, has been prepared in high purity and yield by solubilizing otherwise insoluble metal chlorides in the presence of neutral amidines in refluxing toluene. As crystalline solids, they are stable in air for several days. The compounds are excellent starting materials for the formation of dinuclear compounds. A complete chemical and structural characterization is provided for the penta-coordinated dimanganese compound $[MnCl_2(HDPhF)_2]_2$, **I** (DPhF = diphenylformamidinato), the mononuclear compounds $CoCl_2(HDPhBz)_2$, **II** (DPhBz = diphenylbenzamidinato), and $NiCl_2(HDTolF)_2$, **III** (DTolF = di-*p*-tolylformamidinato). The HDPhF analogue of **III** reacts with a strong base to give the dinuclear species $Ni_2(DPhF)_4$ (**IV**), the structure of which is also reported here. Copyright © 1996 Elsevier Science Ltd

The use of amidinato ligands of the type $RNC(R')NR^-$ has met with considerable success for the preparation of transition metal complexes, especially of the dinuclear type.[1] In part 1[2] of this two-part report, the synthesis and structural characterization of a series of divalent metal chloride formamidines, M^{II} = Fe, Co and Pt was described.

At the time, we indicated that "the facility with which they form and the high purity in which they are isolated, as well as their favourable solubility characteristics, make them attractive starting materials for the preparation of other formamidinato complexes". In this paper we will show that our predictions were correct and will present the synthesis and characterization of new $MCl_2(amidine)_2$ compounds for M = Mn, Co and Ni as well as that of the dinuclear compound $Ni_2(DPhF)_4$.

EXPERIMENTAL

Materials and methods

All manipulations were performed under an atmosphere of nitrogen using standard Schlenk techniques. Samples for spectroscopic characterization were prepared in a Vacuum Atmospheres drybox under an atmosphere of argon. Toluene, THF and hexanes were purified by conventional methods and were freshly distilled from Na/K alloy under nitrogen immediately prior to use. $MnCl_2$, $CoCl_2$ and $NiCl_2$ were purchased from Aesar. Both

* Author to whom correspondence should be addressed.

$CoCl_2$ and $NiCl_2$ were refluxed for 20 min with thionylchloride (obtained from Fisher Scientific), then dried under vacuum prior to use. Celite 545 (not acid washed) was purchased from Spectrum Chemical; *n*-butyllithium (1.6 M solution in hexanes) and HDPhF were purchased from Aldrich Chemical Co.; HDTolF was prepared according to a slight modification of a published procedure,[3] HDPhBz was prepared by a literature method.[4] Elemental analyses were provided by Canadian Microanalytical Service Ltd. IR spectra were obtained as Nujol mulls between CsI plates on a Perkin–Elmer 16PC FT-IR spectrophotometer and magnetic susceptibility measurements were made using in a Johnson–Matthey MSB-1 balance.

$[MnCl_2(HDPhF)_2]_2$ (I)

$MnCl_2$ (1.00 g, 7.94 mmol) was refluxed in THF for 2 h and the solvent was then eliminated under vacuum. To the activated solid was added HDPhF (3.01 g, 15.9 mmol). Warm toluene (50 cm^3) was then added to the mixture which was refluxed for 30 min while stirring. The yellowish solution was quickly filtered while hot and left undisturbed for 1 day in a Dewar flask. Many single crystals of the compound were collected by filtration and washed with hexanes (2×10 cm^3). Yield: 3.00 g (76%). Found: C, 60.6; H, 4.8; N, 10.8. Calc. for $C_{52}H_{48}Cl_4Mn_2N_8$: C, 60.2; H, 4.7; N, 10.8%. IR (Nujol, cm^{-1}): 3340(s), 3185(m), 3109(m), 2723(w), 1639(s), 1601(s, sh), 1586(s), 1377(s), 1320(s), 1205(s), 1179(m), 1072(w), 1027(w), 975(w), 895(m), 753(s), 696(s), 630(s). The magnetic susceptibility corresponded to a magnetic moment of 5.88 BM per $MnCl_2(HDPhF)_2$ unit.

$CoCl_2(HDPhBz)_2$ (II)

$CoCl_2$ (0.13 g, 1.0 mmol) and HDPhBz (0.50 g, 1.84 mmol) were stirred together in toluene (15 cm^3) and heated overnight. The mixture was then filtered through Celite to remove excess $CoCl_2$. The filtrate was layered with hexanes (20 cm^3) and allowed to stand at room temperature for 24 h, then placed in a freezer at $-20°C$ for another 24 h. Crystals of the compound, some of which were suitable for X-ray diffraction, were collected by filtration and washed with hexanes (2×10 cm^3). Yield: 0.48 g (70%). Found: C, 62.7; H, 5.2; N, 7.2. Calc. for $C_{38}H_{32}Cl_2CoN_4$: C, 62.2; H, 4.4; N, 7.6%. IR (Nujol, cm^{-1}): 3155(w), 3100(w), 2854(s), 1622(m), 1607(s), 1583(s), 1565(s), 1411(s), 1377(s), 1239(w), 1205(m), 1073(w), 1026(w), 830(m), 789(s), 772(s), 703(m). The magnetic susceptibility corresponded to a magnetic moment of 4.40 BM.

$NiCl_2(HDTolF)_2$ (III)

$NiCl_2$ (0.39 g, 3.0 mmol) and HDTolF (0.90 g, 4.0 mmol) were stirred together in toluene (20 cm^3) and warmed to 100°C as the colour changed from pale yellow to green. After about 1 h the mixture was dried *in vacuo* and hexanes (20 cm^3) were added. The mixture was heated and quickly filtered to remove any unreacted ligand. The remaining dark green solid was redissolved in toluene (10 cm^3) and filtered to remove the excess $NiCl_2$. The yield after drying was 0.70 g (61%). Crystals suitable for study by X-ray diffraction were obtained by dissolving 0.05 g of the green solid in toluene (5 cm^3), layering with hexanes and cooling the solution to $-20°C$. Large green block-shaped crystals formed within 48 h. IR (Nujol, cm^{-1}): 3188(m), 3100(m), 1651(s), 1607(m), 1589(m), 1520(m), 1505(s), 1377(m), 1312(s, br), 1221(m), 1201(m), 1018(w), 989(m), 808(m), 753(w), 720(w), 571(w), 506(m), 496(w). The magnetic susceptibility corresponded to a magnetic moment of 3.54 BM.

$Ni_2(DPhF)_4$ (IV)

A solution of $NiCl_2(HDPhF)_2$ (0.10 g, 0.19 mmol), synthesized in the same manner as $NiCl_2(HDTolF)_2$, in toluene (15 cm^3) was prepared and cooled to $-78°C$. $NaEt_3BH$ (0.1 cm^3, 0.10 mmol) was added to the stirring solution and the resultant dark green–brown mixture was stirred and kept at $-78°C$. After 1 h, *n*-butyllithium (0.24 cm^3, 0.38 mmol) was slowly added and the mixture immediately changed to a deep brown colour. After the mixture had warmed to room temperature, it was filtered through Celite and the filtrate was layered with hexanes (20 cm^3) and stored at $-20°C$. Within 2 days, dark brown crystals had formed at the bottom of the tube. The yield of this reaction was not optimized.

Structure determinations

Geometric and intensity data for **I** were collected at room temperature on a Rigaku AFC5R rotating Cu anode diffractometer, data for **II**, **III** and **IV** were gathered at $-60°C$ on an Enraf–Nonius FAST area detector system, utilizing the software program MADNES.[5] Detailed procedures have previously been described.[6]

Unit-cell refinement for **I** utilized 25 reflections in the range $35 \leqslant 2\theta \leqslant 50°C$. For **II**, **III** and **IV** indexing was performed on 50 reflections taken

from three 10° ω-rotations in the range $0 \leqslant \omega \leqslant 100°$ and unit-cell refinement used 250 reflections in the range $20 \leqslant 2\theta \leqslant 32°$. In each case, the cell dimensions and Laue group were confirmed with axial images. All data were corrected for Lorentz and polarization effects. Three strong reflections measured periodically throughout the data collection for **I** showed no significant decay. An empirical absorption correction based on six ψ-scans was applied for **I**. Data were processed into SHELX format using the program TEXSAN[7] and ABSURD[8] for **I**, **II**, **III** and **IV**, respectively.

In all structures, the positions of heavy atoms were found in direct methods E-maps using the software solution program in SHELXTL.[9] Subsequent cycles of least-squares refinement followed by difference-Fourier synthesis produced the positions of the remaining non-hydrogen atoms. For purposes of structure factor calculations, hydrogen atoms were placed in idealized positions. Details of data collection and refinement are given in Table 1. Selected bond distances and angles for **I**, **II**, **III** and **IV** are listed in Tables 2, 3, 4 and 5, respectively. Supplementary data for **I**, **II**, **III** and **IV** have been deposited with the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

$[MnCl_2(HDPhF)_2]_2$

The best way to prepare **I** is to start with finely divided $MnCl_2$ prepared by eliminating THF from $Mn(THF)_2Cl_2$[10] and then refluxing it with HDPhF in toluene. A brief refluxing time and the filtration of the hot reaction mixture are crucial steps to obtain good yields of the pure and homogeneous crystalline product.

The molecular structure of **I** is shown in Fig. 1. In the solid state the compound is composed of discrete dinuclear molecules. Each molecule possesses crystallographically imposed C_i symmetry. The manganese atoms are bound to five groups, namely two neutral HDPhF molecules, one terminal and two bridging chloride ions. A long metal–metal separation [3.798(2) Å] and a magnetic moment which corresponds to five unpaired electrons precludes the existence of any type of manganese–manganese bond. The dinuclear molecule is internally stabilized by the presence of short (3.11 Å) contacts between N(4) and Cl(2) due to an intramolecular hydrogen bond.

As seen in Table 2, the distribution of atoms about the manganese atom, as well as the bond distances, is very irregular. The Mn—N(3) bond, where N(3) is almost *trans* to Cl(1A), is 0.12 Å longer than the Mn—N(1) bond. The bond asymmetry is also observed for the bridging chloride ions. The Mn—Cl(1) bond distance is *ca* 0.26 Å shorter than that of Mn(1A)—Cl(1). As it is frequently encountered in compounds which contain both terminal and bridging groups, the former bond is slightly shorter.

$CoCl_2(HDPhBz)_2$

In our earlier study[2] we prepared $CoCl_2(HDTolF)_2$ by a melt reaction using $CoCl_2$ and HDTolF. We have found that such reactions sometimes yield a product that is slightly oily and, therefore, further purification steps are sometimes needed. If the reagents are refluxed in toluene the reaction preceeds more cleanly and in higher yields. We suggest the latter procedure as well as the use of an excess of $CoCl_2$ for the preparation of **II**. $CoCl_2(HDPhBz)_2$ displays the characteristic blue colour of tetrahedral Co^{II} compounds. Its reactivity is similar to that of its HDPhF analogue. The structure is illustrated in Fig. 2 and is very similar to the previously described $CoCl_2(HDPhF)_2$. The two chloride ions and a nitrogen atom of each HDPhBz group complete the pseudo-tetrahedral coordination sphere. As with all other known tetrahedral $MCl_2(amidine)_2$ compounds, there are N—N···Cl hydrogen bonds which help stabilize the molecules. In **II**, Cl(1) and N(4), and Cl(2) and N(2) have separations of 3.25 and 3.19 Å, respectively. Presumably the presence of hydrogen bonds contributes significantly to the observed chemical stability of the crystalline samples of $MCl_2(amidine)_2$, M = Mn, Fe, Co and Ni, as well as to the facility with which they are crystallized.

$NiCl_2(HDTolF]_2$ (**III**)

While the synthesis of this compound proceeds quite poorly as a melt reaction, it goes smoothly by refluxing in toluene, occurring in a fashion similar to the preparations of **I** and **II**. It is important to note, however, that the reflux reaction must be stopped after a relatively short time, otherwise a flocculent white solid precipitates from the reaction mixture. This solid renders the reaction mixture difficult to filter and its production dramatically lowers the yield of **III**. The white solid has not been characterized, but based on its colour and insolubility may be an oligomeric or polymeric Ni^{II} octahedral species. It is also very important to use strictly anhydrous $NiCl_2$. The magnetic susceptibility of **III** (3.54 BM) falls within the range expected for tetrahedral Ni^{II} complexes.[11]

The structure of **III** is shown in Fig. 3. The aver-

N(2)—Ni—N(4)	90.6(4)	N(2)—Ni—Ni(A)—N(4A)	14.9(4)

[a] Atoms labelled with an "A" are related by a two-fold axis.

age Ni—Cl and Ni—N bond lengths are 2.249(2) and 2.005(1) Å, respectively. Short distances between the chloride ions and the protonated nitrogen atoms of the HDTolF molecules are a clear indication of the presence of hydrogen bonds. The Cl(1)—N(4) distance is 3.11 Å and the Cl(2)—N(2) separation is 3.20 Å.

In general, the trend of slightly shorter C—N (imido) as compared with C—N(amine) bond distances observed in other complexed and uncomplexed neutral amidines[12] is also seen here. Surprisingly, only a few tetrahedral Ni^{II} species containing an N_2Cl_2 donor ligand set have been characterized by X-ray crystallography. When the nitrogen donor ligand is 3,4-dihydro-1-phenyl-1H-[1,4]-oxazino[4,3-a]-benzimidazole, average Ni—Cl and Ni—N distances are reported as 2.23(1) and 2.00(5) Å, respectively.[13] The crystal structure of dichlorobis [2,4-bis(isopropylamino)-6-methoxy-1,3,5-triazene] nickel(II) has also been reported,[14] in which the Ni^{II} centre exists in a distorted tetrahedral environment and also has two long [2.700(7) Å] contacts with oxygen atoms of the ligands. Average Ni—Cl and Ni—N bond lengths for this compound are 2.281(2) and 2.017(8) Å, respectively.

$Ni_2(DPhF)_4$ (**IV**)

The action of a strong base on the HDPhF analogue of **III** yields crystal of $Ni_2(DPhF)_4$, which is in all important respects identical with the previously reported $Ni_2(DTolF)_4$.[15] Its molecular structure is

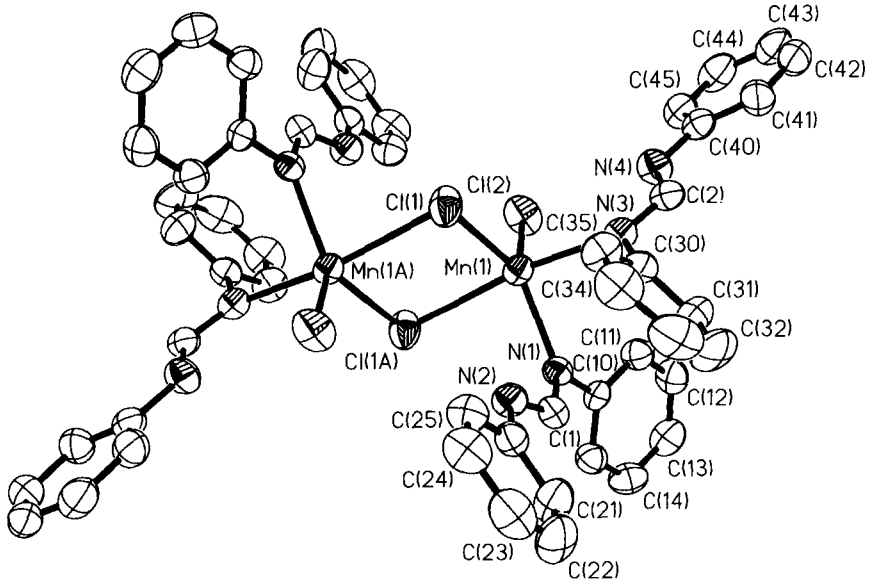

Fig. 1. Thermal ellipsoid plot of the dinuclear compound $[MnCl_2(HDPhF)_2]_2$. Atoms are represented by their 50% probability ellipsoids.

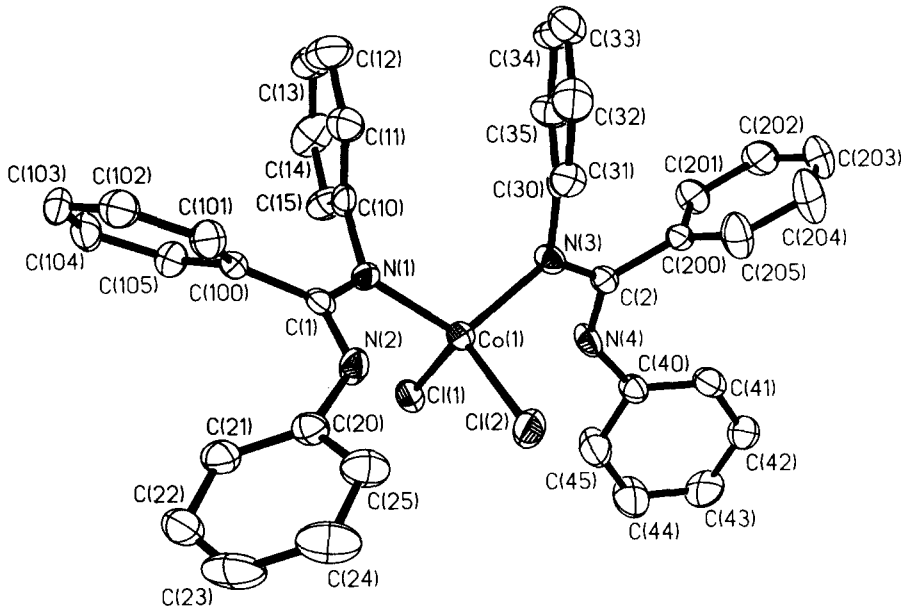

Fig. 2. Structural representation of $CoCl_2(HDPhBz)_2$. Atoms are represented by their 50% probability ellipsoids.

shown in Fig. 4. The long Ni—Ni separation [2.490(3) Å] is consistent with the absence of a bond. Four amidinato groups form bridges between the metal atoms, which have an essentially square planar coordination.

The main interest in the preparation of **IV** was to show that there exists a general pathway to the synthesis of dinuclear amidinato compounds from species of the type $MCl_2(amidine)_2$. Table 6 contains a listing of several compounds of the types $M_2(amidinato)_3$ and $M_2(amidinato)_4$. Some of them have been made exclusively from mononuclear $MCl_2(amidine)_2$ compounds; those of the types $Fe_2(amidinato)_4$, $Fe_2(amidinato)_3$ and $Co_2(amidinato)_3$ cannot be made using other classical synthetic pathways.

We have now been able to prepare various $MCl_2(amidine)_2$ compounds for M = Mn, Fe, Co, Ni and Pt. Except for the latter, our present results indicate that their preparation and purification is best accomplished if the reaction of the corresponding finely divided anhydrous metal dichloride and the amidine is carried out in a toluene solution. The fact that the stoichiometry is correct to produce the corresponding tetrabridged dimetal(II) species of elimination of 2 equiv. of HCl indicates that their use will probably produce a significant number of metal–metal bonded compounds, especially those of the post-chromium elements of the first transition series, which until now have been very difficult to synthesize.

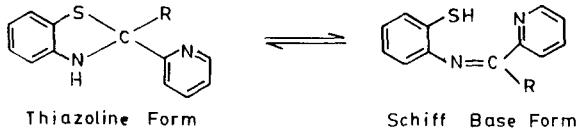
Ruthenium(II) complexes with two N–S donors: 2-(2-pyridyl)benzothiazoline and 2-methyl-2-(2-pyridyl)benzothiazoline: synthesis, reactivity and electrochemistry

Mosarraf Hossain, Shyamal Kumar Chattopadhyay* and Saktiprosad Ghosh†

Department of Inorganic Chemistry, Indian Association for the Cultivation of Science, Calcutta 700 032, India

(Received 21 November 1995; accepted 17 April 1996)

Abstract—An interesting array of Ru^{II} complexes of the two NNS chelating ligands 2-(2-pyridyl)benzothiazoline ($\mathbf{L_1H}$) and its methyl analogue 2-methyl-2-(2-pyridyl) benzothiazoline ($\mathbf{L_2H}$) have been synthesized and characterized. Diverse coordination behaviour of the ligand ($\mathbf{L_1H}$) encompassing its (a) neutral bidentate, (b) monoacid tridentate and (c) monoacid bidentate character are amply illustrated in this study. However, $\mathbf{L_2H}$ was found to behave only in the tridentate fashion. The complexes synthesized were of the type $Ru_2(L)_2X_2$ [where L = L_1, X = Cl (**1**); Br (**2**); and L = L_2, X = Cl (**6**); Br (**7**)], *trans* and *cis* $[Ru(L_1H)_2Cl_2]\cdot 2H_2O$ [(**3**) and (**5**)], $[Ru(L_1H)_2(H_2O)Cl]ClO_4$ (**4**) and $Ru(L_1)(L_1H)Cl$ (**8**). Several mixed-ligand complexes containing substituted imidazoles and bipyridine were also isolated and in some of them the ligand is found to be coordinated as a neutral bidentate NS chelating agent. The chemical and electrochemical reactivity patterns of these complexes were explored. Plausible structural representation of the reported complexes are proposed from the analysis of spectroscopic and cyclic voltammetric data. Copyright © 1996 Elsevier Science Ltd



Keywords: ruthenium complexes; diverse coordination behaviour; chemical reactivity; N–S donor ligands; mixed ligand complexes.

Sulfur and nitrogen-coordinated transition-metal ions are found to constitute the active centres of several oxidoreductases such as hydrogenase, xanthine oxidase and nitrogenase.[1,2] Studies on the structure and reactivity of transition-metal complexes of N–S donor ligands are, therefore, expected to make a valuable contribution to the understanding of the functions of these enzymes at the molecular level.[1]

The sulfur atom present in such ligands is also known to stabilize uncommon oxidation states of the coordinated metal ions,[3–8] to generate uncommon coordination numbers in the resultant complexes[6–9] and to participate in a variety of interesting redox reactions.[10–12] In contrast to the detailed studies of the chemistry of N–S donor complexes of other transition metals, the chemistry of ruthenium ligated to such donors has been rather ill-explored. We have previously reported the synthesis of ruthenium complexes of biologically relevant N-S donor ligands such as thiosemicarbazides[13] and thiosemicarbazones.[14] It has been observed that 2-(2-pyridyl)-benzothiazoline ($\mathbf{L_1H}$), which itself is not a Schiff base ligand, is known to form the corresponding classical Schiff base (Fig. 1) complexes with mainly first transition ions.[15] In this paper we report the synthesis, reactivity and electrochemistry of a series of mono- and binuclear Ru^{II} complexes of 2-(2-pyridyl)-benzothiazoline ($\mathbf{L_1H}$) and its methyl analogue 2-methyl-2-(2-pyridyl)benzothiazoline ($\mathbf{L_2H}$). Our recent work revealing the antitumour properties of ruthenium complexes of some selected

Fig. 1.

N–S donor ligands[16] has enhanced our interest in the redox chemistry of the reported ruthenium complexes.

EXPERIMENTAL

Ruthenium trichloride received from Arora-Matthey, India, was converted to $RuCl_3 \cdot 3H_2O$ by repeated evaporation to dryness with concentrated hydrochloric acid. The ligand (2-(2-pyridyl) benzothiazoline ($\mathbf{L_1H}$) was prepared by a reported procedure.[8] The ligand 2-methyl-2-(2-pyridyl) benzothiazoline ($\mathbf{L_2H}$) was synthesized following a similar procedure using 2-acetyl pyridine in place of pyridin-2-carboxaldehyde. All other chemicals used for preparative work were of reagent grade and were used without further purification. Reagent-grade solvents were dried and distilled by the usual methods.[17] The solvents were stored over molecular sieves (4 Å). Commercial tetraethylammonium bromide was converted to pure tetraethyl ammonium perchlorate (TEAP) by the reported procedure.[16] Dinitrogen gas was purified by successively bubbling it through alkaline dithionite and concentrated sulfuric acid.

Preparation of the complexes

All operations were carried out under dinitrogen using deaerated dry solvents.

$Ru_2(L_1)_2Cl_2$ (**1**) *and* $Ru_2(L_1)Br_2 \cdot 2H_2O$ (**2**). Ruthenium chloride (130 mg, 0.5 mmol) was dissolved in degassed methanol (30 cm^3) and the ligand (L_1H 214 mg, 1 mmol) in degassed methanol (30 cm^3) was added, drop by drop, over a period of 3 h with constant stirring. The mixture was stirred for further 3 h and the resultant precipitate was filtered, washed with methanol and dried *in vacuo* over fused $CaCl_2$. The analytical results pointed to a polymeric composition such as $Ru_3(C_{12}N_2H_9S)_2Cl_4$ and the product was rejected.

The violet filtrate (pH = 3) was concentrated to half of its original volume in a rotaevaporator. Excess degassed diethylether was then added when a violet compound precipitated out. It was filtered, washed thoroughly with diethylether and dried over fused $CaCl_2$. Analytical results indicated the composition $Ru_2(C_{12}N_2H_9S)_2Cl_2$.

The compound $Ru_2(L_1)_2Br_2 \cdot 2H_2O$ (**2**) was obtained by a similar procedure except $RuBr_3$ was generated *in situ* by refluxing ruthenium chloride (130 mg) with 5 equiv. of LiBr in methanol for 45 mins. The resultant solution was cooled and reacted with the ligand. The first polymeric residue was rejected and the expected compound was isolated from the mother liquor (pH 3) by the method described earlier. The compound analysed as $Ru_2(C_{12}N_2H_9S)_2Br_2 \cdot 2H_2O$.

trans-$[Ru(L_1H)_2Cl_2] \cdot 2H_2O$ (**3**). To a solution of the ligand (214 mg, 1 mmol) in degassed methanol (20 cm^3) ruthenium chloride (130 mg, 0.5 mmol) in degassed methanol (30 cm^3) was added slowly and the reaction mixture was stirred for 4 h. The residue produced was filtered off and rejected. The light violet filtrate (pH 6) was concentrated to one third of its original volume in a rotaevaporator and excess diethylether was added. The precipitated complex was filtered, washed with deaerated Et_2O and dried *in vacuo* over fused $CaCl_2$. The dark violet compound analysed as $Ru(C_{12}N_2H_{10}S)_2Cl_2 \cdot 2H_2O$.

$[Ru(L_1H)_2(H_2O)Cl]ClO_4$ (**4**). This complex was prepared by a method similar to that employed for complex **3**. The final isolation was carried out in the following way: To the concentrated (in a rotaevaporator) filtrate excess deaerated aqueous $NaClO_4$ solution was added and it was allowed to stand in a refrigerator. The precipitated compound was filtered and washed thoroughly with deaerated water. It was dried and analysed as $[Ru(C_{12}N_2H_{10}S)_2(H_2O)Cl]ClO_4$.

cis-$[Ru(L_1H)_2Cl_2]$ (**5**). Solid $Ru_2(L_1)_2Cl_2$ (**1**; *ca* 100 mg) was stirred continuously in degassed dichloromethane (100 cm^3), over 12 h under nitrogen. The solid compound dissolved slowly and the resultant blue solution was filtered and the residue was rejected. The CH_2Cl_2 solution was slowly evaporated at room temperature when a brown complex was obtained. The compound analysed as $Ru(C_{12}N_2H_{10}S)_2Cl_2$.

$Ru_2(L_2)_2Cl_2 \cdot 2H_2O$ (**6**) *and* $Ru_2(L_2)_2Br_2$ (**7**). These compounds were prepared by following the same procedure used for the preparation of $Ru_2(L_1)Cl_2$ (**1**) and $Ru_2(L_1)_2Br \cdot 2H_2O$ (**2**), except that the ligand $\mathbf{L_2H}$ was used in place of $\mathbf{L_1H}$. The compounds isolated from the filtrate (pH = 4) were analysed as $Ru_2(C_{13}N_2H_{12}S)_2Cl_2 \cdot 2H_2O$ and $Ru_2(C_{13}N_2H_{12}S)_2Br_2$.

$Ru(L_1)(L_1H)Cl$ (**8**) *and* $[Ru(L_1)(L_1H)(1\text{-Meimz})]ClO_4 \cdot CH_2Cl_2$ (**9**). $Ru_2(L_1)_2Cl_2$ (**1**, 100 mg) was taken in a conical flask and CH_2Cl_2 (15 cm^3) was added. The mixture was stirred for 15–20 min under nitrogen. 1-Methylimidazole (1-Meimz; *ca* 1

cm^3) was added and the solution was stirred for 20 h. The resultant dark blue–violet solution was filtered and was evaporated nearly to dryness. Deaerated water (20 cm^3) was then added with stirring. The mixture was allowed to stand for 5 min and then filtered through a sintered glass crucible. The solid residue was recrystallized from CH_2Cl_2. It analysed as $Ru(C_{12}N_2H_9S)(C_{12}N_2H_{10}S)Cl$.

To the filtrate (blue–violet) excess deaerated aqueous $NaClO_4$ solution was added and allowed to stand in a refrigerator. The separated solid was filtered, washed thoroughly with deaerated water and dried over fused $CaCl_2$. It was recrystallized from dichloromethane. The recrystallized product was analysed as $Ru(C_{12}N_2H_9S)(C_{12}N_2H_{10}S)(C_4N_2H_6)ClO_4 \cdot CH_2Cl_2$.

$[Ru(L_2)(1\text{-Meimz})(H_2O)_2]ClO_4$ (**10**). Solid $Ru_2(L_2)_2Cl_2 \cdot 2H_2O$ (**6**; 240 mg) and 1-Meimz (2.5 cm^3) in methanol (50 cm^3) was stirred for 24 h under nitrogen. The solution was filtered and the volume of the filtrate was reduced in a rotaevaporator to *ca* 10 cm^3. Excess deaerated aqueous $LiClO_4$ solution was added to this concentrated solution and the resultant precipitate was allowed to settle in a refrigerator. It was filtered and washed thoroughly with deaerated water. The compound was recrystallized from CH_2Cl_2 and dry CH_3OH mixture. It analysed as $[Ru(C_{13}N_2H_{11}S)(C_4N_2H_6)(H_2O)_2]ClO_4$.

$[Ru(L_1)(bpy)ClO_4] \cdot H_2O$ (**11**). $Ru_2(L_1)_2Cl_2$ (**1**; 175 mg, 0.25 mmol) was taken in CH_3CN (15 cm^3). To it 2,2′-bipyridine (bpy; 80 mg, 0.5 mmol) was added followed by CH_3CN (25 cm^3). The mixture was refluxed under nitrogen for 30 h. The residue was filtered and rejected. The volume of the filtrate was reduced in a rotaevaporator and excess deaerated aqueous $LiClO_4$ solution was added. The precipitate formed was allowed to settle in a refrigerator (0.5 h), filtered and washed with deaerated water and Et_2O. The dried compound was recrystallized from CH_2Cl_2 and analysed as $[Ru(C_{12}N_2H_9S)(C_{10}N_2H_8)ClO_4] \cdot H_2O$.

$[Ru(L_2)(bpy)(H_2O)]ClO_4$ (**12**). This compound was prepared by a method similar to that of complex **11** using $Ru_2(L_2)_2Cl_2 \cdot 2H_2O$ (**6**) as the starting material. The dried compound was recrystallized from CH_2Cl_2 and analysed as $Ru(C_{13}N_2H_{11}S)(C_{10}N_2H_8)(H_2O)ClO_4$.

Physical measurements

Carbon, hydrogen and nitrogen were analysed in a Perkin–Elmer 240 C,H,N analyser. IR spectra were recorded as KBr pellets using a Perkin–Elmer 783 spectrophotometer. Solution electrical conductivity was measured with a Philips PR-9500 conductivity bridge fitted with a dip-type cell calibrated with 0.02 M KCl solution. Static susceptibility measurements at room temperature were made using a Princeton Applied Research Model 155 vibrating sample magnetometer using Hg[Co $(SCN)_4$] as the calibrant. ^1H NMR spectra were recorded with a Varian XL100 FT-NMR spectrometer using TMS as the reference. Electronic spectra were recorded using a Shimadzu Model UV-2100 spectrophotometer. EPR spectra were recorded on a Varian E-4 X-band EPR spectrometer using dpph as the internal field marker. Cyclic voltammetric studies were carried out with a Bioanalytical system CV-27 Electrochemical analyser and a BAS X-Y recorder at 298 K. The experiments were performed in a one-compartment cell equipped with a platinum working electrode (BAS), a platinum auxiliary electrode and a standard calomel electrode (SCE) as the reference which was separated by a salt bridge connected to the solvent through a glass frit tip. Electrochemical measurements in CH_3CN were made by employing 0.1 M tetraethylammonium perchlorate (TEAP) as the supporting electrolyte. Under these experimental conditions the ferricenium–ferrocene couple was located at 0.42 V versus SCE.

RESULTS AND DISCUSSION

The ruthenium compounds reported in this study are sufficiently pure and gave satisfactory analytical results, as listed in Table 1. The conductance data (Table 1) also support the proposed formulation of the compounds. Diamagnetic nature of all the complexes suggests the presence of +2 oxidation state of ruthenium. The IR and UV–vis spectral data are listed in Table 2 and Table 3, respectively. The redox behaviour of all the complexes has been examined in acetonitrile (0.1 M TEAP) at a platinum working electrode using cyclic voltammetry (Table 4).

We have chosen the novel N–S donor system 2-(2-pyridyl)benzothiazoline (**L_1H**), which (a) reduces the Ru^{III} starting materials ($RuCl_3$ or $RuBr_3$) to Ru^{II} and (b) coordinates as a bidentate N–S donor in the thiazoline form as well as the NNS^- donor Schiff base form generated through a metal-induced ring opening process. Although **L_1H** is found to be coordinated in either tridentate or bidentate manner, **L_2H** is found to behave only in a tridentate fashion. However, the products obtained are highly dependent on experimental conditions such as medium of the reaction, order of addition of reactants, etc.

It has been observed that 2-(2-pyridyl)-benzothiazoline, which is not itself a Schiff base ligand, forms classical Schiff base complexes with many

metal ions.[15] Later, Que *et al.* reported[18] that the Schiff base derived from the condensation of saclicylaldehyde and bis(2-aminophenyl)disulfide can undergo ring closure leading to the formation of thiazole ring when reacted with $FeCl_3 \cdot 6H_2O$ in hot MeOH and allowed to stand for several weeks. The thiazole derivative formed *in situ* is found to act as a bidentate ligand coordinating through the thiazole nitrogen and the deprotonated phenolic oxygen of the salicylaldehyde moiety.

So, it is quite possible that the Schiff base from one of the NSS^- donor of $\mathbf{L_1H}$ can undergo cyclization during its reaction with $RuCl_3$ and subsequent crystallization of the product leads to the formation of the corresponding thiazoline form coordinating preferably through the thiazoline sulfur and the pyridine ring nitrogen; the N–S coordination is preferred to the N–N mode because the acceptor centre Ru^{II} is a second-row transition-metal ion and a reasonably soft acceptor. Thus, both the ring opening of 2-(2-pyridyl)-benzothiazoline ($\mathbf{L_1H}$) leading to the formation of the NNS tridentate donor Schiff base N-2-mercaptophenyl(2′-pyridyl)-methylenimine and the ring closure of the coordinated Schiff base to the corresponding thiazoline derivative behaving as a bidentate NS donor can take place. The recyclization of the coordinated Schiff base form is probably promoted by bringing the thiolato sulfur and the carbon atom of the C=N moiety in the Ru^{II} complex in an appropriate position required for such a ring closure.

The compound $Ru_2(L_1)_2Cl_2$ (**1**) obtained by the addition of ligand to metal ion is represented as:

1

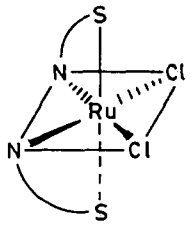
[a] $\nu_{ClO_4^-}$.

In this proposed dimeric formulation both the ligands are present in the deprotonated Schiff base form acting in a monoanionic NNS^- tridentate manner, dimerization taking place through thiolate sulfur bridging. In the Schiff base all the atoms are in conjugation and hence all the N-S donor atoms are planar.[19] The presence of two ruthenium(II) centres are indicated by two successive one-electron oxidations of **1** corresponding to two Ru^{II}/Ru^{III} oxidations commonly observed for the related type of binuclear Ru^{II} complexes. The presence of only one ν(Ru—Cl) mode in the IR spectrum of **1** along with its non-electrolyte nature in solution and the results of elemental analysis support the proposed formulation. The corresponding data for **6** suggests the same type of sulfur-bridged dimeric formulation. Reasons for ruling out the alternative chloro-bridged structure is included in the discussion on the electrochemistry of the complexes. The corresponding bromide containing complexes **2** and **7**, quite logically, should have a similar formulation, the chlorides being replaced by the bromide ions. The ^1H NMR spectra of the ligand L_1H and L_2H exhibit signals at δ 5.12 and δ 5.63 ppm, which are assigned to the N—H proton and confirmed by D_2O exchange experiment. The absence of such N—H proton signals in complexes **1**, **2**, **6** and **7** indicates that the Schiff base form of ligand is present in them. These results endorse the proposed structural representation of the compounds **1**, **2**, **6** and **7**.

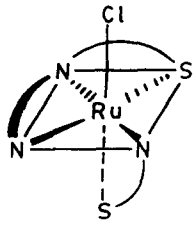
The δ 4.51 ppm signal observed in the ^1H NMR spectrum of **3** is assigned to the N—H proton and is confirmed by the D_2O exchange experiment. This points to the presence of the benzothiazoline form of the ligand in **3** which may be represented as:



3

The *trans* disposition of the two coordinated chloride is evident from the non-electrolyte nature of **3** and the presence of only one ν(Ru—Cl) band in its IR spectrum.

Compound **4**, prepared by treating a solution of **3** in methanol with aqueous $NaClO_4$ solution, obviously, has a structure similar to that of **3**, with one of the two coordinated halogens of **3** replaced by one water molecule. This is corroborated by the uni-univalent electrolytic nature of **4** in solution.

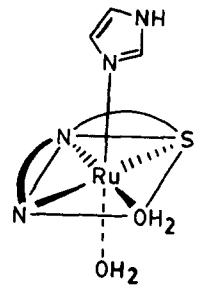


When **1** is stirred in CH_2Cl_2, it dissolved partly forming a blue solution from which the compound **5** was isolated. Compound **5** is found to be a non-electrolyte and its analytical results point to the composition $Ru(L_1H)_2Cl_2$. Compound **5** is EPR

silent even at 77 K, corroborating the proposed formulation. The presence of two different ν(Ru—Cl) bands in its IR spectrum clearly indicates the *cis*-disposition of the two coordinated chlorides, both the ligands being present in the thiazoline form. The sulfur bridges appear to become disrupted in CH_2Cl_2 solution and the effectively 1 : 1 binuclear complex **1** experiences ligand disproportionation or metal disproportionation to yield a 1 : 2 metal: ligand chelate, the ligand moieties undergoing cyclization simultaneously. This dissolution in CH_2Cl_2 leads to the generation of 1 : 2 species in solution is an acceptable proposition because a series of complexes containing two L_1H ligands and other co-ligands are obtained by treating the CH_2Cl_2 solution of complex **1** with different reagents. However, complex **1** behaves differently when it is dissolved in acetonitrile, because compound **11** is isolated from this solution. Thus, compound **5** may be represented as:

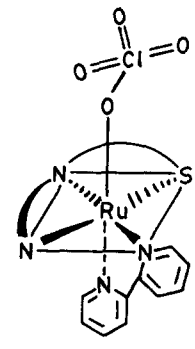
5

Treatment of a CH_2Cl_2 solution of **1** with excess 1-methylimidazole followed by the addition of water leads to the formation of $Ru(L_1H)(L_1)Cl$ (**8**). It is proposed to have the structure:



8

which is arrived at from its analytical data, non-conducting nature in solution and the single ν(Ru—Cl) bands in its IR spectrum.



When the CH_2Cl_2 solution of **1** is treated with excess 1-Meimz followed by a concentrated aqueous ClO_4^- solution, **9** is produced. Elemental analysis, the uni-univalent electrolytic nature in solution and the single CH_3 proton signal in NMR spectrum indicates that its formulation should be similar to that of **8**, with the coordinated Cl^- being replaced by a 1-Meimz moiety. The EPR inactivity even at 77 K also corroborated the proposed formula of the compounds **8** and **9**.

Compound **11** was prepared by treating the acetonitrile solution of **1** by bipyridine in 1 : 1 molar proportion, followed by excess aqueous ClO_4^- solution. The proposed structure was arrived at from elemental analysis and IR spectral characteristics (*vide infra*), which showed the ClO_4^- ion to be coordinated to the ruthenium acceptor centre. However, as this compound exhibits a uni-univalent electrolytic behaviour on dissolution in acetonitrile, the ClO_4^- moiety is rather weakly coordinated. Compound **12**, in the L_2H series, appears to have a similar structure, the only difference being the presence of a coordinated H_2O in place of the coordinated ClO_4.

Elemental analysis data of compound **10**, obtained by treating **6** first with excess 1-Meimz and then with aqueous ClO_4^- solution, may be assigned the formulation $[Ru(L_2)(1\text{-Meimz})(H_2O)_2]ClO_4$. It behaves as 1 : 1 electrolyte in solution and its IR spectra indicates the presence of ionic perchlorate. These observations point to the following probable structure for **10**.

10

11

IR spectra

The important IR bands of the ligands L_1H and L_2H and their metal complexes are listed in Table 2. All chloro complexes exhibit a medium intensity band at $\sim$320 cm^{-1} due to the ν_{Ru-Cl} vibration. However, the ν_{Ru-Br} signal could not be detected because it is beyond the detection limit of our instrument. The absence of any band at 2400–2500 cm^{-1} corresponding to ν_{S-H} points to the absence

b = broad, sh = shoulder

of the free S–H moiety in all the complexes.[20] The overlapping $\nu_{C=N}$ and $\nu_{C=C}$ mode present in the free ligand around 1570 cm^{-1} suffer a positive shift of ~40 cm^{-1}, indicating coordination of the ligand through its pyridine nitrogen[21] and this is corroborated by the shift of pyridine ring vibrations (at 620 and 420 cm^{-1}) in all the complexes. The ligand band around 750 cm^{-1}, assigned to the ν_{CS} vibration, suffers a positive shift of 15–20 cm^{-1} on complexation[22] and is symptomatic of metal–sulphur bond formation. The presence of a broad band in the 1030–1140 cm^{-1} range in all perchlorate-containing complexes is an indication of the non-participation of ClO_4^- in coordination,[14] the only exception being complex **11**, in which this broad band is split into sharp bands at 1090, 1120

$Ru(L_1)(bpy)ClO_4 \cdot H_2O$ (**11**)	0.87(60)
$[Ru(L_2)(bpy)(H_2O)]ClO_4$ (**12**)	E_{pa} = 0.82

[a] Working electrode platinum; reference electrode SCE; $E_{1/2} = 0.5\ (E_{pa} + E_{pc})$; $\Delta E_p = E_{pc} - E_{pa}$, where E_{pc} and E_{pa} are cathodic and anodic peak potentials, respectively.

[b] Supporting electrolyte 0.1 M TEAP, solute concentration 10^{-3} M. Scan rate 50 mV s^{-1}.

and 1150 cm^{-1}. This is indicative of the presence of coordinated perchlorate[23] in complex **11**. New bands of weak to medium intensity lying below 500 cm^{-1} are assigned to the coupled ν(M—N) and ν(M—S)[24] vibrations.

Electrochemistry

Dimeric complexes (**1**, **2**, **6**, *and* **7**). The redox behaviour of the compounds has been examined in CH_3CN (0.1 M TEAP) at a platinum working electrode using cyclic voltammetry. All potentials are referenced to SCE. Results are given in Table 4. All the complexes exhibit two successive reversible to irreversible oxidative couples at positive potentials. The complexes $Zn(L_1)_2$ and $Zn(L_2)_2$ do not show any such reversible couple in the potential range studied and this precludes oxidation of the coordinated ligands under the present experimental conditions. The electrochemical behaviour of these complexes can be logically interpreted in terms of the sulfur-bridged dimeric structure (**1**), the observed difference of $E_{1/2}$ (**2**) and $E_{1/2}$ (**1**) being a common feature of such binuclear species.[6,25] The two distinct oxidative peaks indicate two $Ru^{II/III}$ couples, which corresponds to the process (1).

$$[Ru_2(L)_2X_2] \xrightarrow{-e} [Ru_2(L)_2X_2]^{+}$$

$$[Ru_2(L)_2X_2]^{+} \xrightarrow{-e} [Ru_2(L)_2X_2]^{+2}$$

where

$$L = L_1/L_2\ ;\quad X = Cl^-/Br^-. \qquad (1)$$

At slow scan rate (v = 50 mV s^{-1}) the peak-to-peak separation, ΔE_p, is found to be 70–100 mV, showing that the process is almost reversible and the current heights for both the couples correspond to one-electron transfer processes. The observed ΔE_p values are larger than the ideal Nernstian value of 59 mV as is observed for other binuclear complexes[26] and are possibly due to uncompensated solution resistance.[27] It has also been suggested that the large ΔE_p values could result from the close proximity of the two waves.[27]

The alternative chloro-bridged structure can be easily excluded by comparing the potential differences of the two successive oxidations observed here with those reported for sulfur-bridged and chloro-bridged dimeric five-coordinated complexes.[6,7] Thus, the proposed formulation for the dimeric sulfur-bridged penta-coordinated complexes is quite logical.

Monomeric complexes. The electron-transfer behaviour of the monomeric complexes has been examined in CH_3CN by cyclic voltammetry at a platinum electrode. The mononuclear complex **3** exhibits two reversible peaks at 0.42 and 0.71 V and an irreversible peak at 1.03 V. The one-electron change responsible for the peak at 0.42 V was checked coulometrically. The i_{pa}/i_{pc} of **1** indicated its reversible nature. On repeated scanning the wave retains its original shape, pointing to the high reversibility of the electrode reaction. The appreciable conductance value of **3** in acetonitrile in comparison to that of compound **5** with a similar formula indicated partial dissociation of the halides from the coordination sphere of the metal ion in complex **3**. This is also supported by the formation of the complex **4** from **3** replacing one Cl^- by a ClO_4^-. Therefore, the entire electrochemical process can be rationalized in terms of the process (2).

$$\textit{trans}\text{-}[Ru^{II}(L_1H)_2Cl_2] \xrightarrow[E_{1/2}=0.42\,V]{-e} [Ru^{III}(L_1H)_2Cl_2]^{+1}$$

$$\textit{trans}\text{-}[Ru^{II}(L_1H)_2Cl_2 \xrightarrow{CH_3CN} [Ru^{II}(L_1H)_2Cl \cdot CH_3CN]^{+}Cl^-$$

$$[Ru^{II}(L_1H)_2Cl \cdot CH_3CN]^{+} \xrightarrow[E_{1/2}=0.71\,V]{} [Ru^{III}(L_1H)_2Cl \cdot CH_3CN]^{2+}. \qquad (2)$$

An irreversible anodic wave at $E_{pa} = 1.0$ V observed in the cyclic voltammogram of the compound **3** probably corresponds to the process (**3**).

$$[(CH_3CN)Ru(L_1H)_2Cl]^+Cl^- \xrightarrow[E_{pa}=1.0\,V]{-e} [(CH_3CN)Ru(L_1H)_2Cl]^+ + Cl. \quad (3)$$

The process (**3**) actually corresponds to the oxidation of Cl^- to a chlorine radical,[28] the oxidation of chloride from KCl in CH_3CN being known to occur at the same potential.

The mononuclear compounds **4**, **5** and **8** exhibit a reversible couple at 0.40 V due to the Ru^{II}/Ru^{III} oxidation, as observed in the case of **3**.

In the case of monocationic complexes **9–12**, the $E_{1/2}$ values are more positive compared with those of the neutral complexes due to the electrostatic effect. The one-electron oxidation of all these complexes are assigned to Ru^{II} to Ru^{III} oxidation. Thus, the above electrochemical results corroborated the proposed dimeric and monomeric formulations for the complexes.

Electronic spectra

All the complexes exhibit highly rich electronic spectra (Table 3). Most of them exhibit two low-energy bands in the visible region, which probably correspond to an electronic excitation from a metal *d* level to the π^* level of the ligand. When the spectra of **3** and **5** are compared, compound **3** is found to exhibit MLCT bands at 565 and 395 nm, whereas in compound **5** three MLCT bands are located at 583, 522 and 395 nm. This observation is compatible with the proposed *trans–cis* structure.[14,29] Moreover the only MLCT band in the spectra of the complexes **1**, **2** and **6** is in good agreement with the proposed symmetric dimeric structure. Some additional bands are present in the different mixed chelate complexes, the nature and position of which are found to be dependent on the nature of coligands present.

The higher energy band of all the complexes at 315, 250 and 216 nm are due to intra-ligand transitions. The band at 290 nm in compounds **11** and **12** corresponds to the presence of bipy, as observed in other bipyridyl complexes.[30,31]

CONCLUSION

This study adequately illustrates the diverse ligational behaviour of the ligands 2-(2-pyridyl) benzothiazoline and 2-methyl-2-(2-pyridyl) benzothiazoline towards the Ru^{II} acceptor centre. The profound influence of the reaction conditions (nature of the solvents, order of addition of reactants, presence of the coligands and their nature, etc.) on the nature of the products isolated is strikingly exposed. The spectroscopic and electrochemical data have contributed significantly towards the proposed structural representation of the reported complexes.

Preparation and crystal structures of two polymeric silver(I) complexes of betaine derivatives

Ping-Rong Wei,* Qi Li, Bo-Mu Wu† and Thomas C. W. Mak‡

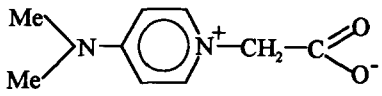
Department of Chemistry, The Chinese University of Hong Kong, Shatin, New Territories, Hong Kong

(Received 1 April 1996; accepted 15 April 1996)

Abstract—Polymeric silver(I) complexes of two betaine derivatives, namely $[\{Ag_2(L^1)_2(NO_3)(H_2O)\}_n](NO_3)_n$ (**1**) and $[\{Ag_4(L^2)_3\}_n](ClO_4)_{4n}\cdot 3nH_2O$ (**2**) [L^1 = 4-dimethylaminopyridinioacetate, *p*-$Me_2NC_5H_4N^+CH_2CO_2^-$; L^2 = 1,4-diazoniabicyclo[2.2.2]octane-1,4-dipropionate; $^-O_2C(CH_2)_2N^+(CH_2CH_2)_3N^+(CH_2)_2CO_2^-$], have been prepared and characterized by X-ray crystallography. Complex **1** exhibits a zigzag chain structure *via* comparatively weak metal–carboxylate linkages between adjacent bis(carboxylato-*0,0′*)-bridged dimers, in which the coordination spheres of two independent Ag^I atoms are each completed by an unidentate nitrate or aqua ligand at a much longer contact. Complex **2** consists of three independent infinite zigzag chains running parallel to the *b* direction, in which the Ag^I atoms are cross-linked by double betaine ligands in the end-to-end mode. The Ag···Ag separation [2.750(2) Å] in one infinite chain based on bis(carboxylato-*0,0′*)-bridged centrosymmetric dimeric units is the shortest one hitherto found among silver(I) complexes and hence indicative of a significantly stronger metal–metal interaction. Copyright © 1996 Elsevier Science Ltd

Keywords: silver(I) complex; betaine; 1,4-diazoniabicyclo[2.2.2]octane-1,4-dipropionate; coordination polymer; carboxylate; dimeric complex.

The poor solubility and light-sensitive nature of silver(I) carboxylates present practical difficulties in their structural characterization.[1] The reported crystal structures of silver(I) carboxylates consist mostly of discrete dimers or polymeric chains/networks constructed by the linkage of dimeric subunits and the structures have been classified into four principle types.[2] Type A contains discrete [Ag_2(carboxylate-*0,0′*)$_2$] dimers without any axial ligand;[3] B and C have similar dimeric structures with the axial sites occupied by one and two ligands, respectively, and they are commonly polymeric species,[2,4] and D comprises dimeric subunits that are extended into a step polymer through the linkage of each metal centre to a carboxylate group of an adjacent dimer,[5,6] while the modified type D has an additional axial ligand attached to each metal atom.[7,8] The unusual polymeric structure of $[Ag_3(Me_2N^+(CH_2CO_2^-)CH_2CO_2^-)_2\}_n](ClO_4)_n$ that is based on trimeric units has been reported.[9]



By virtue of their overall charge neutrality, betaine ($Me_3N^+CH_2CO_2^-$, IUPAC name: trimethylammonioacetate) and its derivatives can be used to prepare soluble metal complexes in which the metal centre may bear additional anionic ligands. In view of this, the use of betaine ligands provides a ready synthetic access to new polymeric silver(I) complexes. In our latest studies we have determined the crystal structures of several silver(I) complexes of betaines[10] and established some new structural types.[9]

As a sequel to this work, the present report describes the preparation and X-ray analysis of two new polymeric silver(I) complexes, namely $[\{Ag_2(L^1)_2(NO_3)(H_2O)\}_n](NO_3)_n$ (**1**) and $[\{Ag_4(L^2)_3\}_n](ClO_4)_{4n}\cdot 3nH_2O$ (**2**) [L^1 = 4-dimethylaminopyridinioacetate, p-$Me_2NC_5H_4N^+CH_2CO_2^-$, L^2 = 1,4-diazoniabicyclo [2.2.2]octane-1,4-dipropionate, $^-O_2C(CH_2)_2N^+(CH_2CH_2)_3N^+(CH_2)_2CO_2^-$].

L^1

L^2

EXPERIMENTAL

Preparation

Silver(I) nitrate and silver(I) perchlorate were purchased from BDH. The betaines L^1 and L^2 were synthesized as described previously.[11,12] IR spectra were recorded from KBr pellets in the range of 4000–400 cm^{-1} on a Perkin–Elmer 1600 FT-IR spectrometer.

$[\{Ag_2(L^1)_2(NO_3)(H_2O)\}_n](NO_3)_n$ (**1**). Solutions of $AgNO_3$ (85 mg, 0.5 mmol) and L^1 (180 mg, 1.0 mmol) in distilled water (3.0 cm^3 each) were mixed at *ca* 60°C with stirring and then ethanol was diffused into the resulting solution for a week to give colourless needle-like crystals of **1**. IR data (KBr): 3381.3(s), 3262.4(s), 3078.7(m), 2945.4(w), 1658.9(vs), 1621.3(s), 1568.1(s), 1542.1(w), 1383.6(s), 1300.4(m), 1211.8(m), 1185.4(w), 1130.4(w), 1070.4(w), 1034.7(w), 947.2(w), 903.2(w), 826.4(m), 751.6(m), 682.1(m), 589.8(w) cm^{-1}.

$[\{Ag_4(L^2)_3\}_n](ClO_4)_{4n}\cdot 3nH_2O$ (**2**). A solution of $AgClO_4$ (104 mg, 0.5 mmol) dissolved in distilled water (3.0 cm^3) was added to a solution of L^2 (256 mg, 1.0 mmol) in distilled water (3.0 cm^3) at *ca* 60°C with stirring. After the resulting clear solution was cooled to room temperature and allowed to stand at room temperature for several days, colourless crystals of **2** were formed. IR data (KBr): 3460.8(s), 3007.8(m), 2963.8(w), 1592.1(s), 1540.0(w), 1463.7(w), 1416.0(w), 1384.6(s), 1319.4(w), 1281.1(w), 1113.9(s), 1086.5(s), 923.4(w), 846.4(w), 825.4(w), 743.1(w), 626.2(m) cm^{-1}.

X-ray crystallography

Data processing parameters and details of the structural analysis are summarized in Table 1. The intensity data of complex **1** were measured on a Siemens R3m/V diffractometer according to established procedures.[13] The raw data were processed with the learnt-profile procedure[14] and absorption corrections were applied by fitting a pseudo-ellipsoid to the ψ-scan data of selected strong reflections over a range of 2θ angles.[15] The intensity data of complex **2** were measured on a MSC/Rigaku RAXIS-IIC imaging plate system with a rotating anode Mo K_α X-ray source (λ = 0.71073 Å, 50 kV, 150 mA)[16] and corrected for absorption through correlation of symmetry-equivalent reflections using the REQAB program.[17] The direct method yielded all the non-hydrogen atoms and the hydrogen atoms of the double betaine ligands were generated geometrically (C—H = 0.96 Å) and allowed to ride on their respective parent carbon atoms. The nitrate group and perchlorate group exhibit disorder and distance restraints of N—O = 1.22±0.010, O···O = 2.11±0.020 and Cl—O = 1.41±0.010, O···O = 2.13±0.020 Å, respectively, were applied. The final refinement cycles were performed by full-matrix least-squares with anisotropic thermal parameters for all non-hydrogen atoms and assigned isotropic thermal parameters for hydrogen atoms. All computations were performed on a PC-486 computer with the SHELXTL-PLUS program package.[18] Analytic expressions of neutral-atom scattering factors were employed and anomalous-dispersion corrections were incorporated.[19(a)] Selected bond distances and bond angles are listed in Table 2. Supplementary materials comprising atomic coordinates and thermal parameters have been deposited at the Cambridge Crystallographic Data Center and observed and calculated structure factors are available from the corresponding author on request.

RESULTS AND DISCUSSION

$[\{Ag_2(L^1)_2(NO_3)(H_2O)\}_n](NO_3)_n$ (**1**).

Complex **1** is a coordination polymer based on bis(carboxylate-*0,0′*)-bridged dimers containing two crystallographically independent silver(I) atoms in different coordination geometries (Fig. 1), with the carboxylate group of L^1 acting in the *syn–syn* bridging mode [C(1)—O(1) 1.229(2) Å, O(1)—C(1)—O(2) 128.1(4)°, C(1)—O(2) 1.236(5) Å, O(3)—C(10)—O(4) 128.3(4)°, C(10)—O(3) 1.233(3), C(10)—O(4) 1.254(5) Å]. The intra-dimer Ag···Ag separation [2.881(2) Å] is slightly smaller than that (2.89 Å) in metallic silver[19(b)] and thus suggestive of a comparable extent of metal–metal interaction. The intra-dimer Ag—O distances and O—Ag—O angles are in the range 2.203(4)–2.270(4) Å and 169.8(1)–153.0(1)°, respectively, being comparable to those

found in the dimeric structures of several known silver(I) carboxylates.[10(c),(d)] As illustrated in Fig. 2, the present structure is extended into a stairs-like polymer running parallel to the *b* axis via comparatively weak metal–carboxylate linkages [Ag(1)—O(2b) 2.611(4), Ag(2)—O(4a) 2.665(4) Å] between adjacent dimers, generating rhombic Ag_2O_2 units as found in the type D and modified type D structures. A similar example has recently been found in a tetranuclear silver(I) carboxylate, $[\{Ag_2(4\text{-}FC_6H_4CH_2CO_2)_2(H_2O)_2\}_2]$,[20] in which a pair of Ag_2(carboxylate-*0,0′*)$_2$ dimers are linked together through weak axial metal–carboxylate bonds [2.498(4) Å], resulting in a centrosymmetric rhombic Ag_2O_2 unit. The coordination spheres of silver atoms Ag(1) and Ag(2) are completed by an unidentate nitrate ligand [2.501(4) Å] and an aqua ligand [O(1w)] of much longer contact [2.660(4) Å], respectively, at the axial site. It is noteworthy that the axial nitrate and aqua ligands lie on opposite sides if the mean plane of the bridged dimeric unit, giving a new modified type D structure different from that found in $[\{Ag_2(Me_3N^+CH_2CH_2CO_2^-)_2(NO_3)_2\}_n]$, where the axial nitrate ligands lie on the same side of the dimeric Ag_2(carboxylate-*0,0′*)$_2$ plane.[10(c)] The molecular skeleton of L^1 in complex **1** possesses approximate C_s symmetry, as the mean deviations of two sets of atoms O(1), O(2), C(1), C(2), N(1), C(5), N(2) and O(3), O(4), C(10), C(11), N(3), C(14), N(4) to their least-squares planes are 0.030 and 0.010 Å, respectively. The carboxymethyl groups are nearly perpendicular to the dimethylaminopyridinio skeletons, the relevant torsion angles C(1)—C(2)—N(1)—C(7) and C(10)—C(11)—N(3)—C(16) being 86.4 and −90.4°, respectively. The conformation of the L^1 ligand is thus similar to that in its hydrate form.[11]

$[\{Ag_4(L^2)_3\}_n](ClO_4)_{4n}\cdot 3nH_2O$ (**2**)

The structure of complex **2** comprises cationic polymeric chains and discrete perchlorate anions plus lattice water molecules (Fig. 3). There are three crystallographically independent silver(I) atoms with different coordination environments in the asymmetric unit. Atoms Ag(1) and Ag(2), located at Wyckoff position 4(*c*) of symmetry *m*, are bonded nearly linearly to two unidentate carboxylate groups from different double betaine ligands [Ag(1)—O(1) 2.142(2), Ag(2)—O(4) 2.160(2) Å, O(1)—Ag(1)—O(1b) 165.3(1), O(4)—Ag(2)—O(4b) 167.7(1)°] in a manner similar to that in [(4-chloro-2-methylphenoxy)ethanoato-0,0′]silver(I).[21] The most notable structural feature is that the pair of unidentate carboxylate groups attached to atoms Ag(1) and Ag(2) [Ag(1)—O(1)—C(1) 108.8(2), Ag(2)—O(4)—C(7) 110.6(2)°] bear a *syn* relationship with dihedral angles between them of 21.2 and 14.8°, respectively. The coordination geometry about the Ag(3) atom is based on the usual type A bis(carboxylate-*0,0′*)-bridged centrosymmetric dimeric subunit [Ag(3a)—O(5)—C(13) 120.0(2), Ag(3)—O(6)—C(13) 126.6(2)°], in which the Ag···Ag separation [2.750(2) Å] is even smaller than the shortest one [2.778(5) Å] hitherto reported in a binuclear silver(I) carboxylate, namely bis(3-hydroxy-2,2,3-trimethyl-4-phenylcyclohexanecarboxylato-*0,0′*)disilver(I) dihydrate[22] and hence indicative of a metal–metal inter-

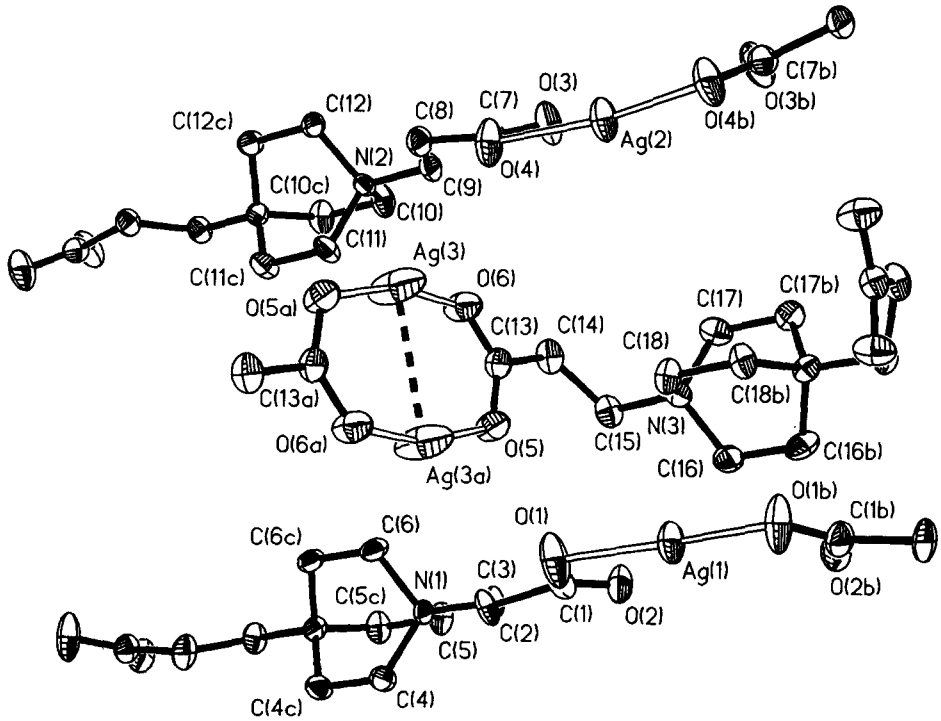

Fig. 3. Perspective view (35% thermal ellipsoids) showing the coordination environment of the three independent silver(I) atoms in **2** and the atom labelling scheme. Symmetry codes are given in Table 2.

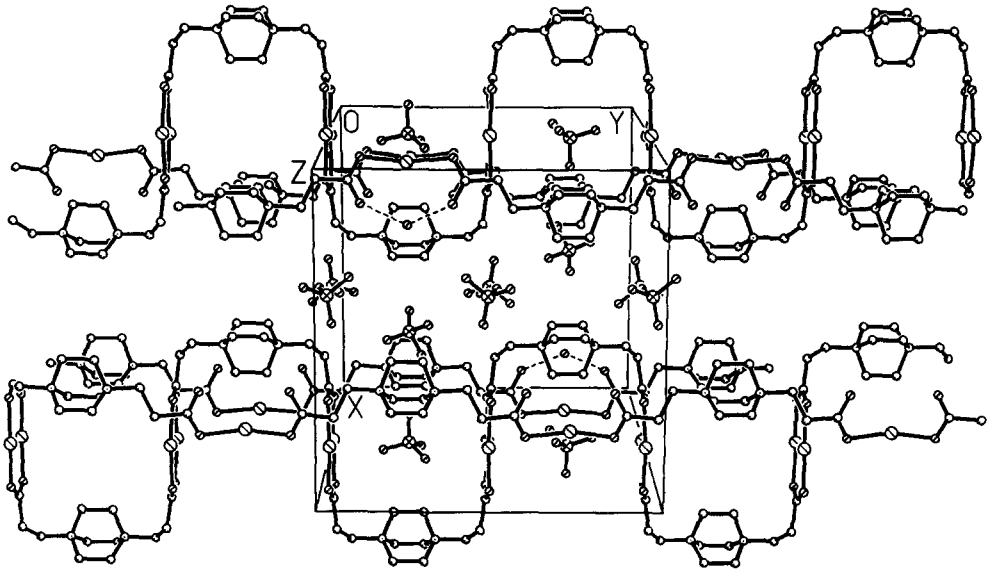

Fig. 4. Projection of the crystal structure of **2** along the *c* axis showing the one-dimensional polymeric chain structure running parallel to the *b* axis.

action even stronger than that (2.89 Å) in metallic silver.[19(b)] The intra-dimer Ag—O distances [2.187 (3)–2.196(3) Å] and O—Ag—O angle [165.6(1) °] are comparable to those in complex **1**. There are three half molecules of L^2 in the asymmetric unit of complex **2**. Ligand L^2 has symmetry *m* bisecting all three CH_2—CH_2 bonds of the central cage with pairs of carboxylato groups oriented nearly parallel to each other, being conformationally quite different from that in $[\{Zn(L^2)_2\}_n](ClO_4)_{2n}$,[12] in which the molecular skeleton of the double betaine ligand L^2 exhibits C_2 symmetry with one carboxylato group nearly perpendicular to the other.

In the crystal structure of complex **2**, as illustrated in Fig. 4, the double betaine ligand L^2 coordinates the silver(I) atoms in the end-to-end mode to form three independent infinite zigzag chains running parallel to the *b* direction; note that the infinite chain composed of dimeric subunits takes the shape of a square wave. The lattice water molecule [O(1w)] forms donor hydrogen bonds [O(1w)···O(3) 2.805 Å] with an uncoordinated carboxylato oxygen atom [O(3)] and its symmetry equivalent. The perchlorate groups, one of which exhibits orientional disorder, are packed in the (200) family of planes. The crystal structure is built up from a stacking of these chains such that the inter-chain interactions are mainly of the van der Waals type.

Direct synthesis and crystal structure of a mixed-valence copper complex

Larisa A. Kovbasyuk, Olga A. Babich and Vladimir N. Kokozay*

Department of Chemistry, Kiev Shevchenko University, 252033 Kiev, Ukraine

(Received 21 March 1996; accepted 15 April 1996)

Abstract—The mixed-valence complex $[Cu^{II}(DMF)_4][Cu^{I}_4(SCN)_4(CN)_2]$ (DMF = N,N-dimethylformamide) has been synthesized using a direct method of interaction and characterized by X-ray crystallography. The complex consists of layers formed by polymeric $[Cu^{I}_4(SCN)_4(CN)_2]^{2-}_n$ anions and the $[Cu^{II}(DMF)_4]^{2+}$ cations disposed between anionic layers.
Copyright © 1996 Elsevier Science Ltd

Keywords: mixed-valence complex; copper; direct synthesis; X-ray structure.

Staged oxidation of copper metal to copper(II) in the non-aqueous solutions of complexing agents[1] reveals a possibility of the direct synthesis[2] of mixed-valence complexes. The search for suitable conditions and systems showed that the presence of thiocyanate ions in the reaction mixture promotes formation of the above-mentioned complexes.

Under interaction of copper powder with N,N-dimethylformamide solutions of methyl-, dimethyl-, trimethylammonium thiocyanate or with ammonium thiocyanate in the presence of aminoacetic acid the formation of mixed-valence complexes $[Cu^{II}(DMF)_4][Cu^{I}_4(SCN)_4(CN)_2]$ has been discovered. The presence of cyano groups in the compound composition can be explained by the hydrolysis of dithiocyan[3] formed from ammonium or alkylammonium salts:

$$3(SCN)_2 + 4H_2O \rightarrow 5HNCS + H_2SO_4 + HCN$$

The presence of sulfate ions in the reaction mixture has been confirmed by analytical tests.

EXPERIMENTAL

All chemicals were commercial products of reagent grade, used without further purification. Methyl-, dimethyl- and trimethylammonium thiocyanate were synthesized from the corresponding alkylammonium chlorides and potassium thiocyanate in acetone solution under an exchange reaction. All experiments were carried out in air.

Synthesis of $[Cu^{II}(DMF)_4][Cu^{I}_4(SCN)_4(CN)_2]$

For the preparation of the complex the following method was used: Cu (0.63 g, 10 mmol), $(CH_3)_2$ NH*HSCN (1.55 g, 15 mmol) and N,N-dimethylformamide (20 cm^3) were placed in a flask in the above order. The mixture was heated to 50–60°C and stirred until the complete dissolution of copper (30–40 min). The resulting dark green solution was cooled and then isopropanol (15 cm^3) was added. The crystals were separated over 2 weeks and dried *in vacuo*; yield 1.4 g (80%). Found: C, 23.7; H, 3.0; N, 15.5; Cu, 34.6. Calc. for $Cu_5C_{18}H_{28}H_{10}O_4S_4$: C, 24.2; H, 3.2; N, 15.7; Cu, 35.5%.

Crystal structure determination

Crystallographic measurements were obtained at 20°C using an Enraf–Nonius CAD-4 diffractometer operating in the ω-2θ scan mode (the ratio of the scanning rates was $\omega/\theta = 1.2$). The intensity data were collected within the range $4.68 \leqslant \theta \leqslant 55.95°$ using graphite-monochromated Mo-K_α radiation. Accurate unit-cell parameters and the orientation matrix for data collection were obtained from least-squares refinement, using the setting angles of 24 reflections in the range $13 < \theta < 15°$. The structure was solved by direct methods and refined by full-matrix least-squares techniques in the anisotropic approximation using SHELXL-93.[4] The positions of the hydrogen atoms were idealized and included in the calculations of the structure factors as the fixed contributions. The crystallographic data are summarized in Table 1.

Symmetry transformations used to generate equivalent atoms: (a) $\{-x+1, -y, -z\}$; (b) $\{-x, -y, -z\}$; (c) $\{-x, -y+1, -z\}$; (d) $\{x, y+1, z-1\}$.

Convergence was reached at the agreement factor listed in Table 1.

DISCUSSION

A fragment of the crystal structure of the complex with the atomic labelling schemes and a perspective view of the packing in the unit cell are shown in Fig. 1. Selected bond distances and angles are given in Table 2. The Cu(1) atom of $[Cu^{II}(DMF)_4][Cu^{I}_4(SCN)_4(CN)_2]$ occupies a special (1/2, 0, 0) position, while the other atoms are located in general positions.

The polymeric anion is formed by infinite $\{—Cu—SCN—\}_n$ chains stretching along $y0z$ plane. These chains are linked in pairs by contacts between copper(I) and sulfur atoms of the thiocyanate groups with the formation of the planar four membered Cu_2S_2 cycles. The angles at the copper(I) and sulfur atoms in the Cu_2S_2 cycle are approximately 94 and 86°, respectively. The similar chain and cyclic structural fragments are known;[5,6] however, it is necessary to note non-equivalent Cu^I—S— bonds in the examined structure. Thus, the interatomic Cu^I—S distance in the $\{—Cu—SCN—\}_n$ chains is *ca* 2.36(4) Å (e.g. d[Cu(2)—S(1)] = 2.376(2) Å; d[Cu(3)—S(2) < x, $y+1, z>$] = 2.352(2) Å, which allows the postulation of covalent bonds; whereas the Cu^I—S bond length which links $\{—Cu—SCN—\}_n$ chains in pairs is *ca* 2.78(3) Å (e.g. d[Cu(3)—S(2b) < $-x, -y, -z>$] = 2.829(3), d[Cu(3)—S(2b) < $-x, -y, -z>$ = 2.729(3) Å]; which is essentially more than the sum of ionic radii of copper(I) and sulfur atoms.[7] The angles between least-squares planes of CuNCSCu′ N′C′S′ atoms (the mean deviation from planarity is 0.0225 Å) and CuSCu′S′ atoms is 70°.

The twin chains formed are linked in a layer by bridging cyanide groups (Fig. 2). Thus, the anionic layer comprises two crystallographically independent copper(I) atoms. Both copper(I) atoms have a distorted tetrahedral environment [angles at the copper(I) atom range from 108 to 123°], but Cu(2) is bonded to two sulfur and one nitrogen atom of the thiocyanate group and a carbon atom of the cyanide group, whereas the environment of the Cu(3) is completed by the nitrogen atom of the cyanide group. The values of interatomic distances Cu(I)—N and Cu(I)—C agree well with reported ones for known mixed-valence compounds.[8]

The complex cations $[Cu^{II}(DMF)_4]^{2+}$ are disposed between anionic layers. The Cu^{II} atoms are covalently linked with four oxygen atoms of DMF [d(Cu—O) *ca* 1.94(3) Å, O—Cu—O = 180°]. Weak Cu···S contacts [d Cu(1)—S(1)] = 3.047 Å; S(1)—Cu—S(1a) < $1-x, -y, -z>$ = 180°] with each second sulfur atom in twin $\{—Cu—SCN—\}$ chains (Fig. 1) provide total electroneutrality of the complex. Taking into consideration these contacts, the coordination environment of the Cu^{II} possesses tetragonal bipyramidal geometry. The DMF molecules are struc-

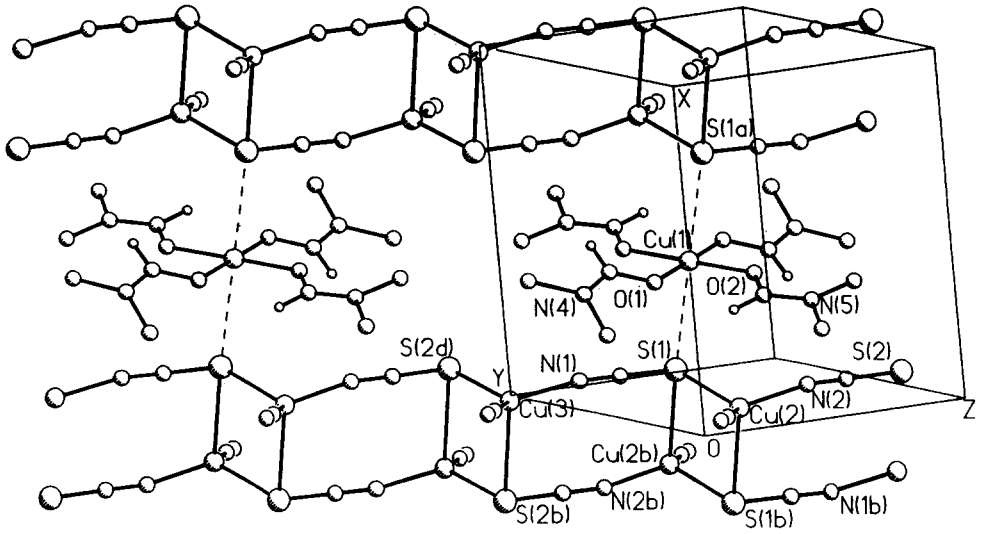

Fig. 1. Crystal structure of $[Cu^{II}(DMF)_4][Cu^{I}_4(SCN)_4(CN)_2]$ [(a), (b) and (d) refer to the following equivalent positions relative to the $<x,y,z>$ sets: $\{-x+1,-y,-z\}$, $\{-x,-y,-z\}$ and $\{x,y+1,z-1\}$, respectively].

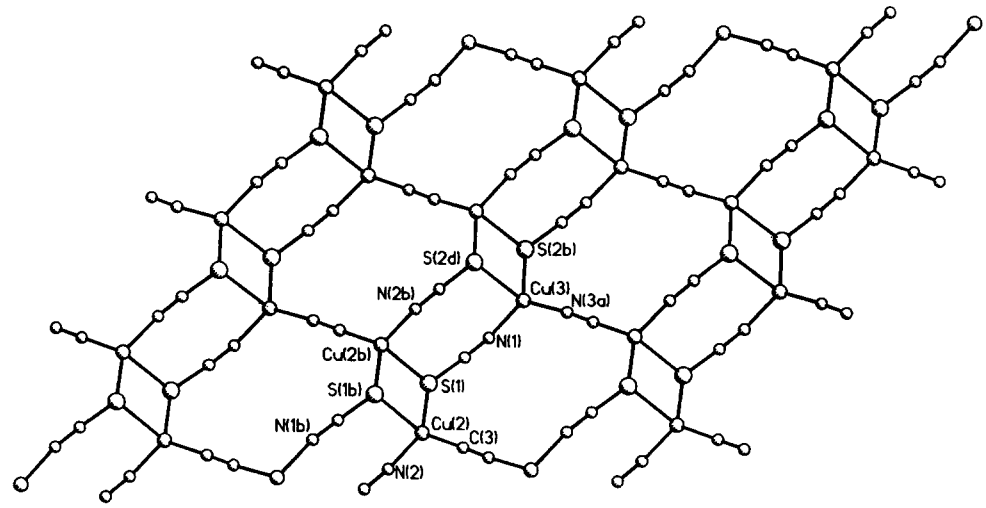

Fig. 2. View of the structure of $[Cu^{I}_4(SCN)_4(CN)_2]^{2-}_n$ anionic layer [(a), (b) and (d) refer to the following equivalent positions relative to the $<x,y,z>$ sets: $\{-x+1,-y,-z\}$, $\{-x,-y,-z\}$ and $\{x,y+1,z-1\}$, respectively].

turally normal and deviate slightly from a planar structure. The angle between the least-squares planes of the atoms of neighbouring DMF molecules is 27°. Such mutual disposition can be explained by steric hindrances which arise as a result of repulsion of bulky methyl radicals in an idealized planar $[Cu^{II}(DMF)_4]^{2+}$ cation.

(Received 23 February 1996; accepted 15 April 1996)

Abstract—Reaction of the bis(imido) complex $[Mo(NR)_2(\eta^2\text{-}S_2CNEt_2)_2]$ ($R = 2,6\text{-}Pr^i_2C_6H_3$) with excess hydrogen sulfide leads to the low yield formation of $[Mo_2(NR)_2(\eta^2\text{-}S_2CNEt_2)_2(\mu\text{-}S)(\mu\text{-}\eta^2\text{-}\eta^2\text{-}S_2)]$, shown by crystallography to contain both μ-S and $\mu\text{-}\eta^2\text{-}\eta^2\text{-}S_2$ ligands bridging the molybdenum–molybdenum vector [2.797(2) Å], features which have recently been ascribed to MoS_3 and $MoS_3 \cdot nH_2O$. Copyright © 1996 Elsevier Science Ltd

Keywords: molybdenum; sulfide; dithiocarbamate; imido reduction; dimeric.

Molybdenum trisulfide (MoS_3) and other group 6 trichalcogenides were first prepared at the beginning of the last century,[1] yet somewhat surprisingly, and despite a large number of studies, their structures are still not well understood. The local structure has been postulated to be based on chains of face-sharing MoS_6 octahedra with alternating long and short molybdenum–molybdenum distances,[2,3] or trimolybdenum units,[4] the latter being inferred from reactivity studies. Recently, on the basis of molybdenum K-edge EXAFS measurements of MoS_3 and $MoS_3 \cdot nH_2O$, Hibble *et al.* have proposed that the layers consist of Mo_2S_9 building blocks linked by vertex or edge-sharing of octahedra (**A**).[5] The molybdenum atoms are in close proximity (2.76 Å), being bridged by both sulfido and disulfide ligands, the overall formulation being described as $Mo(S^{2-})_2(S_2^{2-})_{0.5}$. This then provides an oxidation state of +5 for each metal centre, the observed diamagnetism being ascribed to the presence of a metal–metal bond.

At a molecular level, a large range of sulfur-containing dimolybdenum complexes have been prepared and characterized.[6] For example, addition of sulfur to $[Cp^*Mo(CO)_2]_2$ affords three such complexes, namely $[Cp^*_2Mo_2(\mu\text{-}\eta^2\text{-}\eta^2\text{-}S_2)(S)_2]$, $[Cp^*_2Mo_2(\mu\text{-}\eta^2\text{-}\eta^2\text{-}S_2)(\mu\text{-}S)_2]$ and *trans*-$[Cp^*MoS(\mu\text{-}S)_2]$,[7] while sulfur-rich $[Cp^*_2Mo_2(\eta^2\text{-}S_2)(\mu\text{-}\eta^1\text{-}\eta^1\text{-}S_2)(\mu\text{-}\eta^1\text{-}\eta^1\text{-}S_2)_2]$ has also been prepared.[8] Despite this wide-range of dimolybdenum complexes with a variety of sulfur ligands,[6] as far as we are aware, no molecular dimolybdenum complex has previously been prepared which contains the essential features of the dimolybdenum building blocks proposed by Hibble *et al.*,[5] namely, bridging S^{2-} and $\eta^2\text{-}\eta^2\text{-}S_2^{2-}$ ligands, two molybdenum (V) centres in close proximity and an octahedral coordination geometry at each of these centres.

During recent studies of molybdenum imido complexes we have prepared a number of sulfido-bridged dimolybdenum complexes,[9] together with mononuclear bis(imido) complexes of the type $[Mo(NR)_2(\eta^2\text{-}S_2CNEt_2)_2]$.[10] While carrying out reactivity studies of the latter, we sought to replace one of the imido ligands with a disulfide moiety and found that addition of excess hydrogen sulfide was a successful strategy.[11] In the case of the bulky imido complex $[Mo(N\text{-}2,6\text{-}Pr^i_2C_6H_3)_2(\eta^2\text{-}S_2CNEt_2)_2]$ (**1**), however, as well as isolating high yields of the desired disulfide complex $[Mo(N\text{-}2,6\text{-}Pr^i_2C_6H_3)(\eta^2\text{-}S_2)(\eta^2\text{-}S_2CNEt_2)_2]$ (**2**), a further low-yield dimolybdenum product was isolated which displays *all* of the structural features of the Mo_2S_9 building-blocks proposed by Hibble *et al.*, together with a weak intramolecular

interaction which may model the interactions between chains.

RESULTS AND DISCUSSION

Purging a dichloromethane solution of [Mo(N-2,6-$Pr^i_2C_6H_3$)$_2$(η^2-S_2CNEt_2)$_2$] (**1**) with hydrogen sulfide resulted in a slow reaction over 2 days to afford, after chromatography, the known disulfide complex [Mo(N-2,6-$Pr^i_2C_6H_3$)(η^2-S_2CNEt_2)$_2$] (**2**), 68%,[12] together with the new dimolybdenum complex [Mo_2(N-2,6-$Pr^i_2C_6H_3$)$_2$(η^2-S_2CNEt_2)$_2$(μ-S)(μ-η^2-S_2)] (**3**) in 13% yield. The latter is an air-stable, diamagnetic, pale orange crystalline solid and single crystals were grown upon slow diffusion of methanol into a dichloromethane solution. Characterization was made on the basis of analytical and spectroscopic data, while in order to elucidate the precise nature of the structure a crystallographic study was carried out the results of which are summarized in Fig. 1 and Table 1.

1 **2** **3**

As can be clearly seen, the molecule contains all the essential features of the proposed Mo_2S_9 unit in molybdenum trisulfide. It consists of equivalent molybdenum(V) centres separated by 2.797(2) Å and spanned approximately symmetrically by a sulfido [Mo(1)—S(1) 2.349(3), Mo(2)—S(1) 2.337(3) Å] and somewhat more asymmetrically by a disulfide ligand. Each molybdenum centre also carries both a dithiocarbamate and an imido ligand, such that there is a *cis* relative configuration at adjacent centres. The molybdenum–imido bonds [Mo(1)—N(3) 1.74(1), Mo(2)—N(4) 1.716(9) Å] are within the range associated with molybdenum(V) and molybdenum(VI)[9,13] complexes of this ligand, for example, the molybdenum–nitrogen bond in **2** is 1.734(3) Å.[12] Ignoring the metal–metal bond, the coordination geometry about each molybdenum(V) centre can be described as approximately octahedral, albeit with considerable distortions.

In light of comparisons with molybdenum trisulfide and related compounds, it is worth considering the central core of the molecule in more detail. The two ends of the disulfide ligand have quite different coordination environments. For example, while S(3) lies approximately *trans* to the imido ligands [N(3)—Mo(1)—S(3) 151.5(3), N(4)—Mo(2)—S(3)

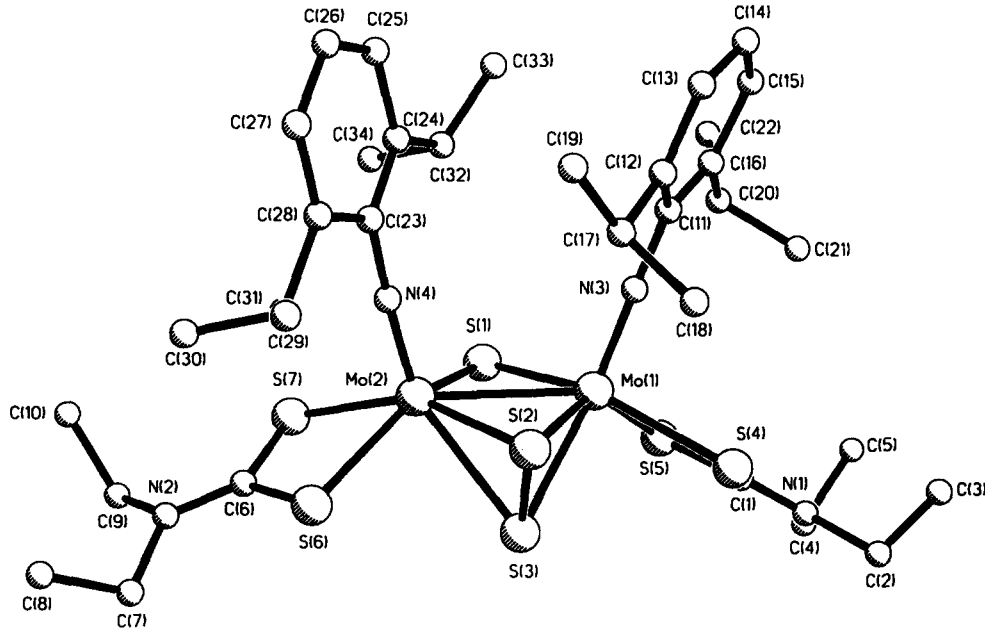

Fig. 1. Molecular structure of **3**.

Table 1. Selected bond lengths (Å) and angles (°) for **3**

Mo(1)—Mo(2)	2.797(2)	Mo(1)—S(1)	2.349(3)
Mo(1)—S(2)	2.370(4)	Mo(1)—S(3)	2.551(5)
Mo(2)—S(1)	2.337(3)	Mo(2)—S(2)	2.383(4)
Mo(2)—S(3)	2.657(5)	Mo(1)—N(3)	1.74 (1)
Mo(2)—N(4)	1.716(9)	S(2)—S(3)	1.936(6)
Mo(1)—S(1)—Mo(2)	73.3(1)	Mo(1)—S(2)—Mo(2)	72.1(1)
Mo(1)—S(3)—Mo(2)	64.9(1)	Mo(1)—N(3)—C(11)	177.0(9)
Mo(2)—N(4)—C(23)	174.4(9)		

145.2(3)°], S(2) is *cis* to both [N(3)—Mo(1)—S(2) 105.4(3), N(4)—Mo(2)—S(2) 100.4(3)°]. A further major difference is their relative orientations with respect to the sulfido-bridge, with S(2) lying approximately in the $Mo_2S(1)$ plane (0.034 Å), while S(3) lies some 2.00 Å from this plane. This difference in sulfur environments is manifested in the very different metal–sulfur bond lengths. Thus, S(2) lies significantly closer to the binuclear metal centre [Mo(1)—S(2) 2.370(4), Mo(2)—S(2) 2.383(4) Å] than S(3) [Mo(1)—S(3) 2.551(5), Mo(2)—S(3) 2.657(5) Å], while the binding of the latter is quite asymmetric. It is interesting to compare this highly asymmetric disulfide unit with respect to the highly symmetric arrangement the same ligand adopts in the molybdenum(IV) dimer $[Cp^*_2Mo_2(\mu\text{-}\eta^2\text{-}\eta^2\text{-}S_2)(\mu\text{-}S)_2]$, where the four molybdenum–sulfur bonds vary only by 0.006 Å (average 2.446 Å).[7] The origin of the pronounced lengthening of the bonds to S(3) is probably the strong *trans* influence of the imido ligands,[13] however, it may in part be due to the *trans* influence of the bridging sulfido ligand. The sulfur–sulfur bond within the disulfide unit of 1.936(6) Å is also elongated somewhat with respect to related dimolybdenum complexes[6] and again is probably also a result of the movement of S(3) away from the binuclear centre. Thus, the central core of **3** closely resembles the proposed Mo_2S_9 layer forming units in molybdenum trisulfide.

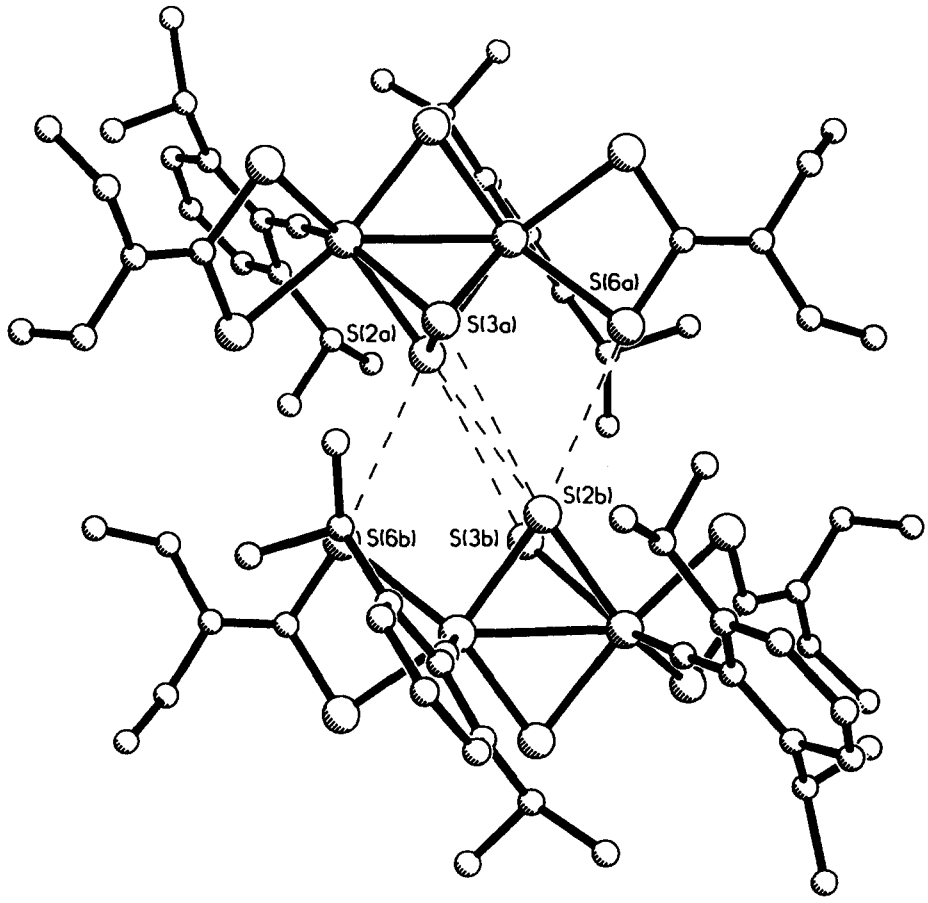

Fig. 2. Part of the packing diagram for **3** showing the association of two dinuclear units.

While these features have not previously been observed at a dimolybdenum centre, a number of complexes have been prepared that are related to **3**. These include the mixed-valence complex $[(Me_2S)_2Cl_2Mo(\mu\text{-}\eta^2\text{-}\eta^2\text{-}S_2)(\mu\text{-}S)MoCl_3(SMe_2)]$[14] and the ditungsten selenide complex $[W_2Cl_8(\mu\text{-}Se)(\mu\text{-}\eta^2\text{-}\eta^2\text{-}Se_2)]^{2-}$,[15] however, in both of these the dichalcogenide bridges the dinuclear centre in an approximately symmetrical manner.

The polymeric chains which are believed to make up the structure of molybdenum trisulfide must be held together via weak long-range interactions. Examination of a packing diagram of **3** reveals the presence of weakly bound dimeric units, as shown in Fig. 2. These are held together primarily by long-range interactions between the disulfide moieties [S(2a)—S(2b) 3.483, S(2a)—S(3b) 3.566 Å] and the disulfide and one of the dithiocarbamate ligands [S(2a)—S(6b) 3.458 Å], the former providing some clue as to the nature of the interchain interactions in molybdenum trisulfide and related chalcogenides.

The mode of formation of **3** is as yet unknown, however, the mononuclear disulfide **2** is not an intermediate. We have previously prepared related dithiocarbamate-stabilized bis(sulfido)-bridged dimolybdenum(V) complexes, which contain a puckered $Mo_2(\mu\text{-}S)_2$ core[9] and the formation of **3** can be envisaged to result from further sulfur addition to the latter, that is at the position occupied by S(3).

EXPERIMENTAL

General procedures[9] and the synthesis of **1**[10] were as previously described.

Synthesis of $[Mo_2(N\text{-}2,6\text{-}Pr^i_2C_6H_3)_2(\mu^2\text{-}S_2CNEt_2)_2(\mu\text{-}S)(\mu\text{-}\eta^2\text{-}\eta^2\text{-}S_2)]$ **(3)**

A dichloromethane (20 cm^3) solution of **1** (0.25 g, 0.34 mmol) was purged with H_2S for approximately 5 min to obtain a saturated solution and then left to stir for 3 days. The solution was purged with nitrogen to remove excess H_2S and the solvent was removed under vacuum. The solid residue was absorbed onto alumina and purified by chromatography on deactivated alumina. Elution with dichloromethane–light petroleum (b.pt 40–60°C) (1:4) afforded a brown band which yielded unreacted **1** (0.06 g); elution with dichloromethane: light petroleum (3:7) afforded an orange band, which yielded **3** (0.04 g, 13%); elution with dichloromethane: light petroleum (2:3) afforded a purple band which yielded **2** (0.11 g, 68%). Recrystallization of **3** was effected upon slow mixing of dichloromethane solutions with methanol. Data for **3**: ^{1}H NMR ($CDCl_3$): δ 6.84 (t, 1H, J = 7.5 Hz), 6.81 (t, 1H, J = 7.5 Hz), 6.72 (d, 2H, J = 7.6 Hz), 6.68 (d, 2H, J = 7.6 Hz), 4.04–3.88 (m, 4H, CH_2), 3.79 (sept, 1H, J = 6.8 Hz, C*H*Me$_2$), 3.66 (sept, 1H, J = 6.8 Hz, C*H*Me$_2$), 3.43–3.29 (m, 4H, CH_2), 1.34–1.28 (tx4, 12H, J = 7.1 Hz, CH_2CH_3), 0.97–0.91 (dx4, 24H, J = 6.8 Hz, CH*Me*$_2$); ^{13}C NMR ($CDCl_3$): δ 207.7, 206.1 (S_2CN), 153.7, 152.1 (*ipso*), 147.9, 146.3 (*o*-C_6H_3), 126.6–121.3 (m, aromatic), 45.7–44.5 (m, CH_2), 28.9–27.4 (m, *C*HMe$_2$), 23.7–23.0 (m, CH*Me*$_2$), 12.9–12.3 (m, CH_2CH_3). We ascribe the complex nature of these spectra to the restricted rotation about the N—C bond of the imido ligands. IR (KBr): 1510m, 1459m, 1438m, 1384m, 1262s, 1096s, 1021s, 803s, 669w, 549w, 468w and 454w cm^{-1}. Found: C, 43.9; H, 5.8; N, 5.7. $C_{34}H_{54}N_4S_7Mo_2$ requires: C, 43.7; H, 5.8; N, 6.0%.

Single-crystal X-ray structure determination of **3**

Intensity data were collected on a crystal of dimensions $0.42 \times 0.28 \times 0.08$ mm mounted on a Nicolet R3mV diffractometer, by the ω scan technique ($5 \leqslant 2\theta \leqslant 45°$). From the 6182 measured data (5415 unique measurements), 3489 with $I \geqslant 3\sigma(I)$ were considered observed. The structure was solved via direct methods and refined by full-matrix least squares to R and R' values of 0.058 and 0.058. Structure solution utilized the SHELXTL PLUS program[16] on a Micro Vax II computer. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were placed in idealized positions (C—H 0.96 Å) and assigned a common isotropic thermal parameter (U = 0.08 Å^2). Three standards showed no drop in intensity during data collection. A summary of the crystal data, structure solution and refinement parameters is given in

Table 2. Atomic coordinates, thermal parameters and bond lengths and angles have been deposited at the Cambridge Crystallographic Data Centre.

(Received 31 January 1996; accepted 10 April 1996)

Abstract—The thermal behaviour of dppf [dppf = 1,1bis(diphenylphosphino)ferrocene] and $dppfMCl_2$ [M = Ni, Pd, Pt] in dry air has been investigated by thermal analysis and the final decomposition products were characterized by Rutherford backscattering spectrometry, infrared spectroscopy, Mössbauer spectroscopy and X-ray powder diffractometry. Thermal decomposition mechanisms, the thermal stability as well as the composition and final residues are influenced by the MCl_2 fragments. The thermal stability decreases in the order dppf > $dppfNiCl_2$ > $dppfPtCl_2$ > $dppfPdCl_2$. The analysis of the RBS spectra of the final decomposition products shows that the phosphorus atoms are not lost during the heating, while all the chlorine has evolved as Cl_2 gas. The Mössbauer and X-ray results show the formation of several iron phosphates besides nickel metaphosphate, nickel oxide, metallic Pd and Pt. Copyright © 1996 Elsevier Science Ltd

The chemistry of organometallic compounds represents an important branch of chemistry, particularly because of the use of these compounds as homogeneous catalysts[1] and as precursors to heterogeneous catalysts.[2] The heterogeneous catalysts are used in various important catalytic reactions such as oxidation,[3] metathesis,[4] olefin polymerization[5] and hydrogenation.[6] In particular, heterogeneous catalysts containing metallic Pd, Pt or NiO have received special attention, for example, in the oxidation of carbon monoxide,[7] naphtha reforming,[8] paraffin dehydrogenation[8] and conversion of benzoic acid to phenol.[9] However, the heterogeneous catalytic systems present some disadvantages related essentially with regio- and stereo-selectivity and for these reasons several trials to develop synthetic routes to prepare compounds that present higher selectivity and activity have been performed.[10] Among the synthetic routes used, one process resides in the thermal decomposition of organometallic compounds. For that, thermal analysis has become in recent years an important tool for providing information about the thermal decomposition mechanism and for the production of heterogenous materials which can be used as catalysts.[11] The use of heterobimetallic compounds as precursors to obtain new heterogeneous materials seems to be very attractive since they have two different metallic species not

directly bonded but close enough to interact and produce synergic effects which can result in interesting catalytic properties.

In this context, the present work reports on the thermal behaviour of heterobimetallic compounds of the type $dppfMCl_2$ [dppf = 1,1-bis(diphenylphosphino) ferrocene and M = Ni, Pd, Pt] (see Scheme 1) and the characterization of the final decomposition products by Rutherford backscattering spectrometry, infrared spectroscopy, Mössbauer spectroscopy and X-ray powder diffractometry.

EXPERIMENTAL

Starting materials and instrumental

All the syntheses were carried out under purified argon in a Schlenk apparatus. Solvents were purified and dried by specific methods.[12] $PdCl_2$, $PtCl_2$, $NiCl_2 \cdot 6H_2O$ and dppf were purchased from Aldrich Chemicals and used without further purification. The compounds $dppfMCl_2$ [dppf = 1,1-bis(diphenylphosphino)ferrocene and M = Ni,Pd,Pt] were prepared by methods described in the literature.[13–15]

Thermogravimetric analysis

Thermogravimetric analyses (TG) were carried out under dynamic flow of dry synthetic air (25 cm^3 min^{-1}) and a heating rate of 20°C.min^{-1} using a TGS-2 Perkin–Elmer Thermoanalyser.

Rutherford backscattering spectrometry

The Rutherford Backscattering Spectrometry (RBS) spectra were obtained using the 4 MV Van de Graaff Accelerator of the Physics Department, at PUC-RJ, in Rio de Janeiro. The principle of RBS was presented in ref. 16. The calculations of the stoichiometric ratios of the decomposition products were performed using the full expression for the differential scattering cross-section.[16] The errors involved in the detection, counting and calculation of the stoichiometric ratios lead to an overall error of 10%.

Infrared spectrometry

Infrared spectra (IR) were recorded on a Mattson 3020 FTIR spectrophotometer in the range 4000–400 cm^{-1} with the samples in the form of potassium bromide pellets at room temperature.

Mössbauer spectroscopy

The Mössbauer spectra were recorded at room temperature on a conventional constant acceleration Mössbauer spectrometer using the standard transmission geometry. The employed source was ^{57}Co in a rhodium matrix. The experimental data were fitted by simple least-squares procedures in a IBM/PC® compatible microcomputer, using special software.[17] Typical errors for the Mössbauer areal fraction are smaller than 3%.

X-ray diffractometry

X-ray diffractograms were obtained with a Kristalloflex 810 Siemens diffractometer with a step $2\theta = 0.05°$ and using Cu K_α radiation (1.542 Å). The peaks were identified using the ASTM data cards.[18]

RESULTS AND DISCUSSION

Organometallic compounds decompose when submitted to high temperatures, usually generating as final products metallic oxides, pure metal particles or inorganic salts. The composition of the final products, however, depend on several variables such as the decomposition atmosphere (oxidising, reducing or inert), the heating rate, the organic ligands and metal centers present in the organometallic compounds. In the present work, the thermal decomposition of dppf and some of its derivatives containing group 10 metals was performed. The purpose of this study was, on the one hand, to reveal the influence of the MCl_2 moiety (M = Ni, Pd, Pt) on the initial decomposition temperature of the precursors using thermogravimetric analysis and, on the other hand, to characterize the final decomposition products using several techniques (RBS, IR, Mössbauer spectroscopy and X-ray diffractometry). The results obtained and some discussion based on them will be presented hereafter.

Thermogravimetric analysis

The TG curves of the compounds **1–4** performed under dry synthetic air are shown in Fig. 1, while their corresponding data are displayed in Table 1.

The decomposition of **1** starts above 376°C with an abrupt mass loss. The TG curve shows two steps in the temperature range 376–788°C which were attributed to the pyrolysis and oxidation of the phosphorus ligands. The final deep grey residue was identified as a mixture of compounds formed mainly

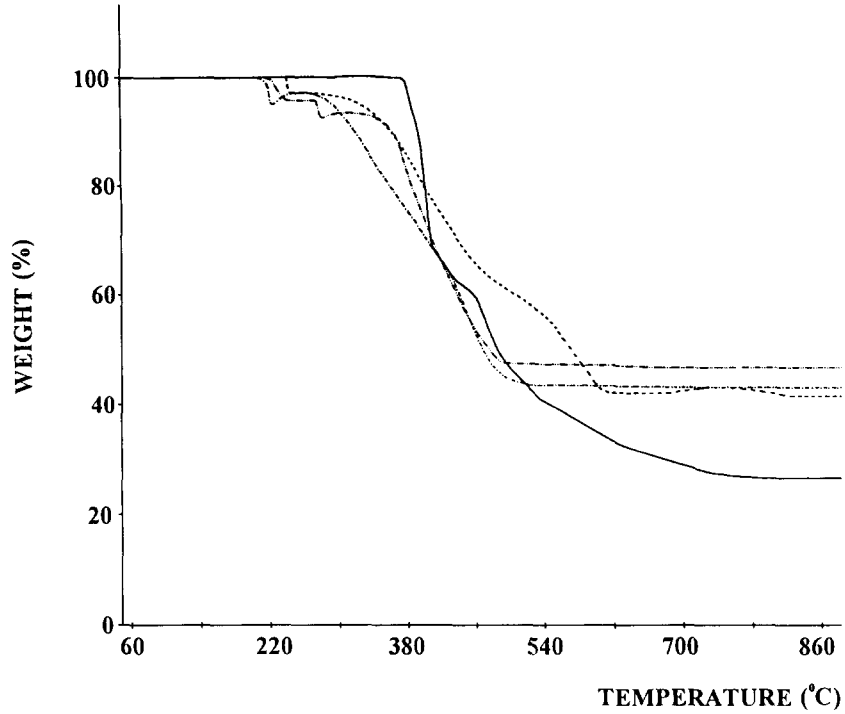

Fig. 1 TG curve of dppf (—), dppfNiCl$_2$ (– – –), dppfPdCl$_2$ (– · – · –) and dppfPtCl$_2$ (– · · – · · –) in dry air.

Table 1. Thermal analysis data for compounds **1–4**

Compound	Step	T_i (°C)	T_f (°C)	Δm (%)
dppf	1	376	458	40.90
	2	458	788	32.90
				(73.80)
dppfNiCl$_2$	1	240	246	2.22
	2	246	460	30.67
	3	460	543	7.55
	4	543	606	13.33
				(53.77)
dppfPdCl$_2$	1	215	224	4.44
	2	224	242	−2.22
	3	268	486	51.11
				(53.33)
dppfPtCl$_2$	1	220	239	3.73
	2	274	279	3.46
	3	279	300	−0.88
	4	322	487	45.33
				(51.64)

T_i = initial temperature; T_f = final temperature; Δm = mass variation; Total percentual mass losses are showed in parentheses for each compound.

by iron phosphates (see Mössbauer and X-ray results).

The TG curve of **2** shows that its thermal degradation starts above 240°C. The first decomposition step suggests, by mass calculation, the loss of Cl_2 and the uptake of O_2. This first step is followed by mass losses associated with the combustion of the organic ligands. In the range 685–819°C a small mass gain is observed, probably due to the sample oxidation, followed by an additional small mass loss attributed to the conversion of these compounds into less oxygenated ones. A constant mass was reached at 819°C and the pale yellow residue was identified as a mixture of iron and nickel phosphates and nickel oxide (see Mössbauer and X-ray results).

The thermal decomposition of **3** starts at 215°C with a mass loss attributable to, as observed for **2**, the loss of Cl_2 and the uptake of O_2. In the second step (224–242°C) a consumption of O_2, associated with a mass gain occurs, followed by a third step associated with the pyrolysis of the organic ligands. A constant mass was reached at 486°C and the deep grey residue was identified as a mixture of Pd(0) and iron phosphates (see Mössbauer and X-ray results).

The TG curve of compound **4** shows that its thermal degradation starts above 220°C. At somewhat higher temperatures, two steps probably associated with the loss of chlorine and the uptake of O_2 take place. Between 322 and 487°C, a mass loss occurs which was attributed to the pyrolysis and breakdown of the $CpPPh_2$ fragments. A constant mass was reached at 487°C and the final grey residue was identified as a mixture of Pt(0) and iron phosphates (see Mössbauer and X-ray results).

Summarizing the above results it was seen that the complexes **2–4** liberate Cl_2 at the beginning of the decomposition process. All complexes are oxidized but the thermal processes themselves and the composition of the final residues are influenced by the nature of the group 10 metal. The initial decomposition temperatures of **2–4** are lower than that of its

precursor **1**, probably due to the coordination of metallic centres to organic ligands, *via* the formation of M–P bonds (see Scheme 1), destabilizing the heterobimetallic compounds. A thermal destabilization was also seen to occur when sulfur or oxygen were bonded to $CpPPh_2$ fragments.[19]

RBS spectra

RBS was used to determine the stoichiometric ratio among the various elements of the samples after their thermal decomposition. The RBS spectra were obtained using α-particle beams and the geometry described in the caption of Fig. 2, which is sketched in the top of this figure. The samples were homogeneous tablets made from a randomly oriented powder of the thermal decomposition products with a certain amount of BN, used as an inert load. The spectrum of the decomposition products of dppf is shown in Fig. 2a, while in Fig. 2b is shown the spectrum of the decomposition products of $dppfPdCl_2$. From the relative intensities of the signals, the atomic ratio between two given elements could be calculated. The main results obtained from the analysis of the spectra were: (i) P was not lost during the thermal decomposition process. The P/Fe ratio in the case of the compounds **1**, **3** and **4** remained equal to 2 before and after decomposition. In the case of $dppfNiCl_2$ a ratio P/(Fe+Ni) = 1 was found. In this last case a direct P/Fe ratio could not be determined. Ni and Fe have very similar masses and, for that, their signals cannot be resolved by RBS even at 2 MeV (the greater the incident energy the greater will be the mass resolution) and in the spectrum they appear superimposed. However, if the assumption that Fe/Ni = 1 is considered (Fe/Pd and Fe/Pt ratios equal to 1 were found for the other compounds), a P/Fe = 2 will be found, meaning that neither Ni nor P are lost during the thermal

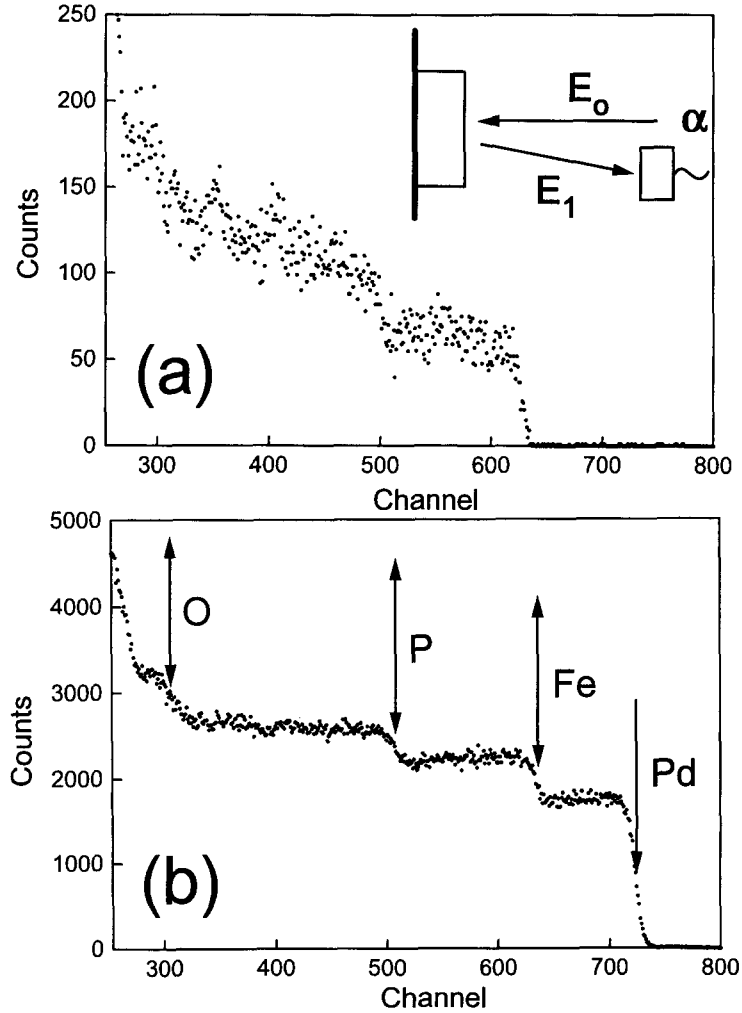

Fig. 2 Rutherford Backscattering spectra obtained from the final decomposition products of dppf (a) and $dppfPdCl_2$ (b). The energy of the incident α-particle beam was 2.0 MeV. The incidence angle was 0° with the sample normal, and the detection angle was 165° with respect to the incidence direction of the beam. A scheme of this geometry, showing also the sample and the detector, is sketched in the top of Fig. 2a. The arrows in spectrum 2b indicate the outermost position of the respective elements in the samples.

decomposition process; (ii) A great amount of O, an element that was not present in the molecules before thermal treatment, was found in the samples after it. The ratio O/Fe varied from sample to sample, indicating the presence of different oxygenated compounds. Nevertheless, the O/P ratio was found to be between **4** and **5** in all cases, indicating the presence of, for example, a phosphate (PO_4) and an oxide. These results were confirmed by Mössbauer spectroscopy and X-ray diffractometry (see other results below); (iii) The amount of C was seen to remain roughly (the C signal was somewhat hidden by the N signal coming from the BN) about 60% in the case of the dppf decomposed sample but in a much smaller amount, around 30%, in the case of the bimetallic samples; (iv) Cl must have been almost or completely transformed into a gas, since in the RBS spectra no traces of it were found. This fact coincides with the observation from the TG that during the first heating steps Cl_2 was released.

Infrared spectra

The IR spectra of the final decomposition compounds are very similar. In the range 3100–2990 cm^{-1}, no stretching bands corresponding to $\nu_{C\,H}$ were observed, indicating that the organic molecules were decomposed during the heating process, as expected. Several strong superimposed bands were found, however, in the region of 1350–900 cm^{-1}, which were attributed to the $\nu_{P\,O}$ modes[20] and indicate the formation of phosphates. These results agree with those obtained from RBS spectra and also with those from Mössbauer spectroscopy and X-ray diffraction which will be presented below.

Mössbauer spectra

The Mössbauer spectrum of the decomposition products of dppf (Fig. 3A) could be fitted with four doublets corresponding to two Fe^{2+} sites (I and II), and two Fe^{3+} sites (III and IV) (see Table 2). The site I was assigned to $Fe_3(PO_4)_2$[21] while the site II could not be assigned to any particular compound, but its large δ and Δ characterizes an Fe^{2+} compound. The two Fe^{3+} compounds have parameters very close to the ones observed for iron (III) phosphates.[21–23] From this fitting, a $Fe^{2+}:Fe^{3+}$ proportion of 58:42 was found. Looking closer at this Mössbauer spectrum it is evident that other iron compounds are present that were not identified but the presence of iron carbides, α-FeOOH and Fe_2O_3 was ruled out.[21,24–25]

The Mössbauer spectrum of the decomposition products of **2** (Fig. 3B) could be fitted with three sites (V, VI, and VII in Table 2). Site V corresponds to an Fe^{2+} compound present in a small amount (4%). Sites VI and VII have hyperfine parameters characteristic of Fe^{3+} compounds which are very close to the ones observed for iron phosphates.[21–23] These compounds correspond to 96% of the total amount of iron present

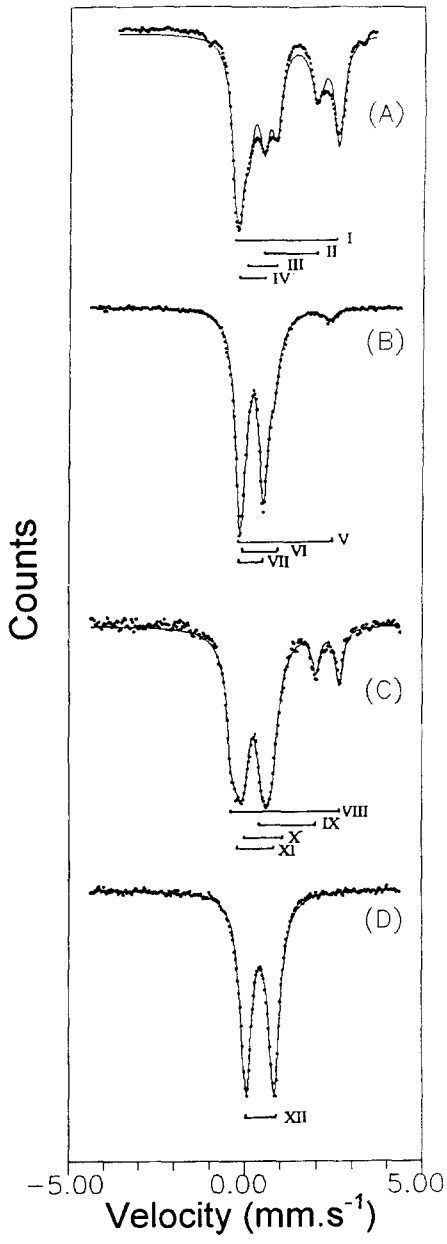

Fig. 3. Mössbauer spectra of the final decomposition products of compounds **1**–**4**: (A) dppf; (B) dppfNiCl_2; (C) dppfPdCl_2; (D) dppfPtCl_2.

in the sample. The presence of the magnetic compound $NiFe_2O_4$ in the final decomposition residue of **2** could be excluded since there is no evidence of the presence of any magnetic compound even in a Mössbauer spectrum obtained with a maximum velocity of 12.25 mm/s.[26]

The Mössbauer spectrum of the decomposition products of **3** (Fig. 3C) shows, as in the case of complex **2**, that a high proportion of Fe^{3+} compounds is present in the sample ($Fe^{2+}:Fe^{3+}$ = 23:77). The data could be well fitted with four doublets, two corresponding to Fe^{2+} compounds (VIII and IX in Table

Table 2. Mössbauer parameters for final decomposition products

Decomposition products of	Site	Proportion (%)	Oxidation state	δ (mm/s)	Δ (mm/s)	Γ (mm/s)
dppf	I	34	Fe^{2+}	1.23	2.88	0.33
	II	24	Fe^{2+}	1.31	1.50	0.42
	III	30	Fe^{3+}	0.54	0.78	0.33
	IV	12	Fe^{3+}	0.28	0.66	0.26
$dppfNiCl_2$	V	4	Fe^{2+}	1.24	2.45	0.34
	VI	24	Fe^{3+}	0.49	0.84	0.37
	VII	72	Fe^{3+}	0.28	0.67	0.32
$dppfPdCl_2$	VIII	13	Fe^{2+}	1.24	3.02	0.26
	IX	10	Fe^{2+}	1.33	1.51	0.27
	X	41	Fe^{3+}	0.48	0.80	0.46
	XI	36	Fe^{3+}	0.28	0.80	0.45
$dppfPtCl_2$	XII	100	Fe^{3+}	0.55	0.78	0.39

δ = Isomer shift referred to metallic iron at room temperature (zero shift); Δ = Quadrupole splitting; Γ = Linewidth. Typical standard deviations of these parameters were 0.01 mm/s.

2) and two having hyperfine parameters characteristic of Fe^{3+} compounds (X and XI).

The Mössbauer spectrum of the decomposition products of complex **4** (Fig. 3D) was the simplest one. It shows the presence of only one doublet (site XII in Table 2) whose hyperfine parameters are characteristic of an Fe^{3+} compound. Since only iron(III) metaphosphate was identified in the X-ray diffractogram (see below), the doublet was assigned to this compound.

The above results show a great tendency to the dppf and its derivatives, when submitted to thermal treatment under specific conditions (see experimental section), to form various iron phosphates. It is interesting to note that another iron phosphine derivative, $[Fe(CO)_3(PPh_3)_3]$, when submitted to thermal decomposition under the same conditions, produced only $FePO_4$ and Fe_2O_3.[27] These results indicate that the organic ligands present in the organometallic compound influence its thermal behaviour and the composition of the final products after thermal treatment.

The Mössbauer results also show that the presence of a second transition metal coordinated to dppf decreased the Fe^{2+}/Fe^{3+} ratio. In the case of the thermal decomposition of **4**, an extreme case was reached where 100% of Fe^{3+} was found.

The Mössbauer spectroscopy is a useful technique to characterize the final decomposition products. However, it is limited in the sense that, in the present work, only iron compounds can be detected by it. In order to have a more thorough idea of all the present compounds, a complementary technique had to be used. In the present case, X-ray diffraction was chosen to further clarify the decomposition process products.

X-ray diffractograms

The X-ray diffractogram of the decomposition products of **1** (Fig. 4A) was a very complex one. However, compounds such as iron(II) pyrophosphate, $Fe_4(P_2O_7)$ (ASTM card file 24-526),[17]

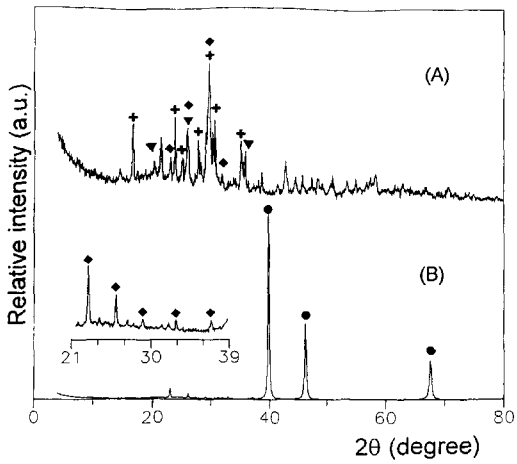

Fig. 4. X-ray diffractograms of the final decomposition products of the compounds: (A) dppf and (B) $dppfPtCl_2$. The crystalline phases identified in the samples are: (◆) $Fe(PO_3)_3$; (●) Pt; (▼) $FePO_4$; (+) $Fe_4(P_2O_7)$.

iron(III) metaphosphate, $Fe(PO_3)_3$ (ASTM 7-184)[17] and iron(III) phosphate, $FePO_4$ quartz like phase (ASTM card file 17-837)[17] could be identified. The peaks of the $Fe_3(PO_4)_2$, if present were hidden by the amorphous baseline or by other peaks. This amorphous feature was partially assigned to the formation of amorphous carbon, since the RBS spectrum indicated a high amount of carbon and neither iron carbonates nor iron carbides were identified in the Mössbauer spectrum. There was also no evidence of the presence of iron oxides, at least as major products.

In the X-ray diffractograms of the final decomposition products of the heterobimetallic compounds, the decrease in the number of phases present was noticeable. In the diffractogram of the final decomposition products of **2** it was possible to assign peaks to the presence of NiO (ASTM card file 22-1189)[17], $Ni(PO_3)_3$ (ASTM card file 28-708)[17] and $FePO_4$ quartz like phase (ASTM card file 17-837), while in the case

of the final decomposition products of **3**, the X-ray diffractogram showed the formation of metallic palladium (ASTM card file 5-0686)[17] as the major product, besides other iron compounds such as $Fe(PO_3)_3$. The presence of palladium oxide was expected thermodynamically ($\Delta H_f^0 = -20\,kcal/mol$; $T_{decomp} = 877°C$) during the thermal treatment of **3** under an oxidizing atmosphere. Nevertheless the presence of PdO in the final decomposition product was ruled out, suggesting that the presence of the iron atom in the organometallic compound makes the reduction of the Pd atom easier. This unexpected behaviour contrasts with the results obtained from the thermal decomposition of other palladium complexes, which do not contain iron and produce palladium oxide as the major product.[28-29] It must be mentioned that due to the complexity of the decomposition products diffractograms of the Ni and Pd bimetallic compounds some peaks could not be assigned to any of the probable phases in the JCPDS files. On the other hand, the final decomposition products of **4** (Fig. 4B) were fully identified. The X-ray diffractogram showed the presence of metallic platinum (ASTM card file 4-802)[17] and $Fe(PO_3)_3$ (ASTM 7-184). Platinum oxide was not observed, as expected from its thermodynamic data ($\Delta H_f^0 = 41\,kcal/mol$; $T_{decomp} = 507°C$).

In conclusion, the results of the present work have demonstrated that the coordination of the group 10 metals of dppf promotes the thermal destabilization of the heterobimetallic complexes. The final decomposition products consist on a mixture of inorganic compounds, containing O and P but not Cl. Their composition and proportion depend on the MCl_2 moiety. It was also seen that the presence of the second transition metal coordinated to dppf promotes the formation of the Fe phosphates in their higher oxidised state (Fe^{3+}). Current studies are under way to investigate the thermal decomposition of other organometallic compounds and the catalytic application of their final decomposition products.

Abstract—The Ni(II) complex of dioxo[13]aneN$_4$ ligand bearing two 8-methylquinoline as additional donor pendants (H_2L) has been prepared and its crystal structure and properties studied. The Ni^{II} atom is in square-planar coordination whilst the two 8-methylquinoline pendants are not coordinated. In contrast, in the Cu(II) analogue CuL(2), the Cu(II) atom is five coordinate and forms a distorted square-pyramidal configuration with one of the quinoline pendants coordinated. Electrochemical studies of 1 in aqueous solution revealed that L can further stabilize the trivalent state of nickel [$E_{1/2}(+2 \rightarrow +3) = 0.60$ V versus SCE] compared with unsubstituted L° [$E_{1/2}(+2 \rightarrow +3) = 0.92$ V versus SCE]. This behaviour is also in contrast with that observed for CuL under the same conditions. An unusual red-shift was observed for the maximum absorption band of the electronic spectrum of NiL in comparison to that of NiL°. Copyright © 1996 Elsevier Science Ltd

Keywords: crystal structure; electrochemical; nickel complex; dioxo[13]aneN$_4$; 8-methylquinoline.

The chemistry of macrocyclic dioxotetraamines has attracted much interest and has been extensively studied in recent years.[1–5] Such compounds are unique chelators for some transition metal ions, *eg.*, they can selectively coordinate Cu^{2+}, Ni^{2+}, Co^{2+}, Pt^{2+}, etc., with simultaneous dissociation of two protons from the amido groups, giving neutral complexes designated as MLH_{-2}.[1,2] They bear the dual features of macrocyclic tetraamines and oligo-peptides, and have many interesting functions and biological relevance.[1,4] Their transition metal complexes have shown some interesting properties and function as important models for metalloproteins and oxygen carriers.[4] Macrocyclic oxotetraamines can stabilize the trivalent state of Cu and Ni in aqueous solution,[5] and may be used as effective oxidants and redox catalysts.[6] Such compounds can also serve as models for galactose oxidase.[7] Furthermore, some of these compounds may function as powerful chelating agents.[8]

However, up to now, most of the reported studies have been concerned with their chemistry in solution since it is difficult to obtain single crystals of macrocyclic dioxotetraamine complexes for structural studies.[9] Herein, we report the crystal structure and

properties of the nickel complex of a dioxo[13]aneN$_4$ (dioxo[13]aneN$_4$ = 1,4,7,10 - tetraazacyclotridecane-11,13-dione) ligand bearing two 8-methylquinoline as additional donor pendants (Scheme 1). Striking differences have been found to exist between the nickel and copper complexes of this ligand. To our knowledge, this is the first example of the crystal structure for the nickel complex with dioxo[13]aneN$_4$ ligand.

EXPERIMENTAL

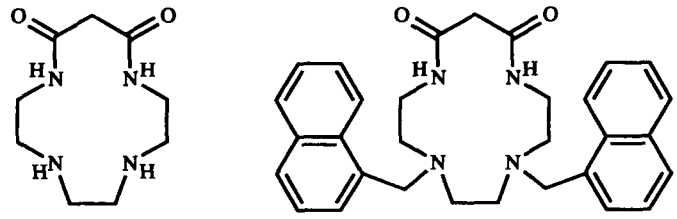
Materials

All the starting materials and solvents for synthesis were obtained commercially and purified by standard method prior to use. Dioxo[13]aneN$_4$ (H_2L°, 1,4,7,10-tetraazacyclotridecane-11,13-dione) was prepared according to a modified literature method.[10] The procedure for the synthesis of H_2L has been described elsewhere.[11] All the other reagents for syntheses and analyses were of analytical grade. FT-IR spectra were taken on a 170SX (Nicolet) spectrometer. Elemental analysis was performed on a P–E 240C analyzer.

Preparation of NiL · 3H$_2$O(1)

For complex 1, a single crystal suitable for X-ray analysis was obtained by mixing a 1 : 1 molar ratio of Ni(CH$_3$COO)$_2$ and L in deoxygenated H$_2$O. A NaOH solution was used to adjust the pH to ~9. The solution was heated to ~60°C for ~15 min. The yellow reaction mixture was filtered and the filtrate was allowed to stand. A single crystal suitable for X-ray analysis was obtained by slow evaporation of the solvent. Found: C, 57.0; H, 6.1; N, 13.5 Calc for $C_{29}H_{36}NiN_6O_5$: C, 57.3; H, 6.0; N, 13.8%. IR(KBr pellet): 807, 840, 1038, 1281, 1385, 1458, 1496, 1546, 1579 (C=O), 2855, 2952, 3400 cm^{-1}.

Electrochemical studies



Cyclic voltammetric measurements were performed with a PARC Model 273 electrochemical apparatus in aqueous solution at 25 ± 0.05°C with 0.50 mol/dm^3 sodium sulfate (Na$_2$SO$_4$) as supporting electrolyte and the solution was bubbled with pure Ar gas. The concentration of the complexes of L° or L was kept at 2×10^{-3} mol · dm^{-3} (1 : 1 ligand and nickel or copper sulfate aqueous solution). The pH was adjusted with concentrated NaOH or H_2SO_4 solution. The cyclic voltammograms, with scan rates of 100 or 200 mV/sec, were evaluated graphically. A three-electrode system was employed; glassy carbon as working electrode, saturated calomel electrode (SCE) as reference and Pt coil as counter electrode.

Spectroscopic studies

Electronic spectra were recorded on a Shimadzu UV-240 spectrophotometer. The solution was prepared by mixing 1 : 1 molar ratio of ligand and metal acetate in methanol solution at 25°C. The pH value of the solution was adjusted by concentrated NaOH methanol solution.

X-ray structural determinations

A crystal (approximately 0.15 × 0.2 × 0.2 mm) was mounted on an Enraf-Nonius CAD-4 diffractometer equipped with a graphite crystal monochromator for data collection. The determination of unit cell parameters and the data collection were carried out with MoKα radiation (λ = 0.71073 Å). Unit cell dimensions were obtained by least-square refinement of the setting angles of 25 reflections. The intensities of reflections were measured with the ω-2θ scan mode in the range of $2 < \theta < 25°$ at room temperature. A total of 4358 independent reflections were collected and 1630 reflections with $I > 3\sigma(I)$ were considered to be observed and used in the subsequent refinement. Corrections for LP factors were applied to the data, and the structures were solved by direct method (MULTAN 82). Most of the atoms were located from an E-map. The other non-hydrogen atoms were determined with successive differential Fourier syntheses. Final refinement by full matrix least-squares methods was carried out with anisotropic thermal parameters for non-hydrogen atoms. Convergence resulted in unweighted and weighted (unit weights for all observed reflections) agreement factors of 0.063 and 0.067. The highest peak in the final difference Fourier map had a height of 0.67 e/Å^3. The hydrogen atoms were treated as "riding" on their attached atoms, and refined isotropically. All the calculations were per-

formed on a PDP11/44 computer, using the SDP-PLUS program package.

RESULTS AND DISCUSSION

Crystal structure

Figure 1 shows an ORTEP drawing of NiL(1) with 35% probability thermal ellipsoids. Crystallographic and data collection parameters are displayed in Table 1. Selected bond distances and bond angles are listed in Table 2.

The square-planar N_4 coordination of four nitrogens with Ni^{II} is evident with the dioxo[13]aneN$_4$ moiety composed of two NH's and two deprotonated amide N^-'s. These four donor atoms, N(1), N(2), N(3) and N(4), are nearly coplanar. The two quinoline pendants remained uncoordinated to Ni(II). In contrast, in the analogous copper(II) complex CuL (Fig. 3), Cu(II) is five coordinate, forming a distorted pyramidal configuration in which one of the pendant quinolines coordinates to Cu(II) from the apical position. The apical Cu(II)–N(II) distance of 2.240(5) Å is longer than those of the basal Cu–N distances, suggesting the weaker coordination of the pendant nitrogen due to the Jahn–Teller effect. In NiL, the two quinoline pendants are on different sides of the plane of the macrocycle and the macrocycle takes a *trans* conformation, whereas in the analogue CuL(2), the two quinoline pendants are on the same side of the plane of the dioxo[13]aneN$_4$ and the macrocycle takes a *cis* conformation.[11]

As anticipated, the two deprotonated amide nitrogens [N(3) and N(4)] have stronger coordination bonds [Ni–N^- bond average 1.847(4) Å] than those for tertiary amines [N(1) and N(2)] (1.915(4) Å). Different molecules of the complex in the unit cell link each other with water molecules *via* hydrogen bonds and the structure is thus stabilized (see Fig. 2).

The different coordination configurations between NiL(1) and CuL(2) may partly be due to the fact that the ionic radius of nickel(II) is smaller than that of Cu(II).[3b] The cavity of the 13-membered ring is about right for Ni(II) but too small for Cu(II). Thus, the Ni(II) ion can completely fall into the least-square plane of dioxo[13]aneN$_4$, preventing the quinoline pendant from coordinating to Ni^{II} due to steric constraints. Whereas, the Cu(II) ion cannot completely fall into the tight cavity of dioxo[13]aneN$_4$ and this allows the quinoline pendant to coordinate easily to Cu(II). Furthermore, Ni(II) ions (with d^8 electronic configuration) usually assume square-planar coordination in strong ligand fields (as L').

Electrochemical studies

The electrochemical data of the nickel(II) complexes of ligands L' and L studied in aqueous solution (0.5 mol/L Na_2SO_4 at 25°C), are summarized in Table 3. All the cyclic voltammograms showed one quasi-

reversible oxidation wave. The $Ni^{III/II}$ potential of complex 1, 0.60 V *vs* SCE, is lowered by 0.32 V as compared to that of NiL° complex under similar conditions ($E_{1/2}$ = 0.92 V *vs* SEC),[1a] implying that the quinoline N-substituted L ligand can further stabilize the trivalent oxidation state of Ni compared with unsubstituted L°. This behaviour is also in contrast to that observed for the analogous CuL (see Table 3). The displacement of Na_2SO_4 for $NaClO_4$ as supporting electrolyte did not significantly alter the $E_{1/2}$ values of the above mentioned complexes.

This fact can be interpreted in terms of more or less favourable fitting of Cu(II)/Cu(III) and Ni(II)/Ni(III) ions in the macrocyclic cavity and the different electronic configurations of the two metal ions. The change from Cu(II) into Cu(III) state (d^8 low spin) involves a drastic reduction of the metal ion radius. In the case of the square-planar complex of Cu(III) with a deprotonated tripeptide, a Cu(III)-N(deprotonated amido) distance of 1.80 Å and a Cu(III)-N(amino) distance of 1.90 Å have been found.[12] Such distances fit quite well with the 13-membered cavity. So in CuL, when Cu(II) is oxidized to Cu(III), the smaller Cu(III) ion would fall into the least-squares plane of the basal four nitrogens. This causes the coordination of the pendant N(11) to Cu(III) to become quite difficult or impossible due to steric constraints. Since the N-substitution increases the steric constraint of the macrocycle ring and lowers the coordinative ability of the macrocycle, the Cu(III) ion in CuL is therefore not as stable as in unsubstituted L°. Whereas in the case of nickel, the change from low spin Ni(II) to high spin Ni(III) involves an increase of the ionic radius.[3b] When Ni(II) is oxidized to Ni(III) in NiL, the larger Ni(III) ion will rise out from the least-squares plane of dioxo[13]aneN$_4$ (like that for Cu(II) in CuL) and it becomes possible for the quinoline pendant to coordinate to it. Ni(III) is thus stabilized in NiL.

Spectroscopic studies

The absorption maxima data of the present Ni complexes in MeOH solution are listed in Table 3. The *d–d* transition band of the nickel(II) of NiL significantly shifts to higher wavelength than that of NiL° (from 415 nm of NiL° to ~470 nm of NiL, shifted by *ca* 50 nm). This fact indicates that the in-plane bonding in NiL was lowered due to the N-substitution by the quinoline pendants. This behaviour is similar to that observed for CuL.[11]

(Received 17 October 1995; accepted 9 April 1996)

Abstract—The compound, tris(2-aminoethyl)amine-4,5-diazafluorene-9-hydrazine copper(II) perchlorate complex, $[Cu(C_6H_{18}N_4)(C_{11}H_8N_4)](ClO_4)_2$ (**1**), has been designed, synthesized and characterized. The X-ray analysis reveals that the copper(II) is coordinated by four nitrogen atoms from tris(2-aminoethyl)amine (tren) and two nitrogen atoms from 4,5-diazafluorene-9-hydrazine (dzfh) to form an unusual (4+1+1′) six-coordinate geometry. This structure is very rare, and to our knowledge, is a unique example of a tripodal copper(II) complex with an asymmetric bidentate phenanthroline derivative. The 110 K ESR and electronic reflectance spectra studies demonstrate that the coordinated geometry of copper(II) is quite similar to square-based pyramidal stereochemistry, instead of the trigonal bipyramidal stereochemistry, which is the common structure for $[Cu(tren)L]^{2+}$ (L = monodentate ligand) complexes. The electronic and variable-temperature ESR spectra in absolute DMF suggest that the two nitrogen atoms of the dzfh coordinate to the copper(II) ion in the two-dimensional fluxional model. For comparison, the complex, $Cu(tren)(Py)(ClO_4)_2$ (Py is pyridine) (**2**), was also synthesized and characterized. Copyright © 1996 Elsevier Science Ltd

Tripodal complexes have attracted much attention because of their importance in biochemistry.[1,2,3] These compounds provide adequate model systems for enzymes in some cases. Five-coordinate tripodal copper(II) complexes are quite common, but no six-coordinate ones have been reported so far. On the other hand, the associative mechanism has been

suggested for the ligand-exchange and ligand-substitution reactions for $[Cu(tren)L]^{2+}$ [where tren is tris(2-aminoethyl)amine, L is a monodentate ligand],[4,5] the structure of the associative complex in the reaction has not been determined, and no associative complex has been observed owing to its instability.

In our laboratory, $[Cu(tren)(L\text{–}L)]^{2+}$ complexes have been designed and synthesized, where L–L is a strong chelated ligand, such as 2,2′-bipyridine, 1,10-phenanthroline and their derivatives.[6] This idea comes from: (i) the strong chelated ligand, such as 2,2′-bipyridine, should make the $[Cu(tren)(L\text{–}L)]^{2+}$ cation form a six-coordinate stereochemistry, which has the same coordination number as the associative complex; (ii) the relatively rigid tripodal construction of tren has a strong tendency to form five-coordinated complexes of copper(II). These two strongly differing tendencies should make the $[Cu(tren)(L\text{–}L)]^{2+}$ cation form an unusual $(4+1+1')$ structure, in which the complex has five stronger coordinated atoms and a weak semi-coordinated atom. The structure of these new kind of tripodal copper(II) complexes should be similar to that of the associative complex in the ligand-substitution reaction of $[Cu(tren)L]^{2+}$.

We report here the synthesis, characterization and crystal structure of one such complex, $[Cu(C_6H_{18}N_4)(C_{11}H_8N_4)](ClO_4)_2$ (**1**), where $C_6H_{18}N_4$ is tris (2-aminoethyl)amine (tren) and $C_{11}H_8N_4$ is 4,5-diazafluorene-9-hydrazine (dzfh).

For comparison the five-coordinated complex, $[Cu(tren)(Py)](ClO_4)_2$ (**2**), was also synthesized and characterized (Py is pyridine).

EXPERIMENTAL

CAUTION! Perchlorate salts of metal complexes with organic ligands are potentially explosive, only small amounts of material should be handled.

Materials and preparations

All chemicals were reagent grade and used without further purification. 4,5-Diazafluorene-9-hydrazine was prepared using the literature method.[7] The complex of $[Cu(tren)](ClO_4)_2$ was synthesized according to the procedure described earlier,[8] but using $Cu(OAc)_2 \cdot H_2O$ and $NaClO_4$ instead of $CuCl_2 \cdot 2H_2O$ and KSCN.

$[(tren)Cu(dzfh)]ClO_4)_2$ (**1**). To a solution of $[Cu(tren)](ClO_4)_2$ (1 mmol, 0.408 g) in ethanol/acetonitrile (1 : 1) (30 cm^{-3}) was added 4,5-diazafluorene-9-hydrazine (1 mmol, 0.196 g). The mixture was refluxed for 3 h. After cooling to room temperature, the precipitate was filtered by suction and dried *in vacuo* over silica. Yield: 0.483 g, 80%, m.p. 237°C (decomp.). Λ_M (DMF, 1.03×10^{-3} mol dm^{-3}, 20°C): 156 Ω^{-1} cm^2 mol^{-1}. Magnetic moment: $\mu_{eff} = 1.98$ B.M. IR (cm^{-1}): ν(N—H) 3418s, 3332s, 3280s; ν(C=N) 1644s, 1579s; ν(Cl—O) 1090vs, 993s, 623m; ν(Cu—N(3°)] 525s. Found: C, 34.2; H, 4.1; N, 19.3. Calc. for $C_{17}H_{26}Cl_2CuN_8O_8$: C, 33.8; H, 4.3; N, 18.8%.

$[(tren)Cu(Py)](ClO_4)_2$ (**2**).[9] The complex was obtained as blue needle crystals in a similar manner to **1**. Yield: 85%, m.p. 217°C (decomp.). Λ_M (DMF, 1.53×10^{-3} mol dm^{-3}, 20°C); 140 Ω^{-1} cm^2 mol^{-1}. Magnetic moment: $\mu_{eff} = 2.08$ B.M. IR (cm^{-1}): ν(N—H) 3339s, 3287s; ν(C=N) 1608s; ν(Cl—O) 1091vs, 995s, 623m; ν[Cu—N(3)] 530s. Found: C, 26.7; H, 4.6; N, 13.9. Calc. for $C_{11}H_{23}Cl_2CuN_5O_8$: C, 27.1; H, 4.8; N, 14.4%.

Physical measurements

Elemental analyses were performed on a Perkin–Elmer 240C analytical instrument. Molar conductances were measured at 25°C in DMF solutions on a DDS-11A conductometer. Magnetic measurement on a powder sample was carried out with a CAHN 2000 Faraday-type magnetometer at 293K. IR spectra were recorded on a Nicolet 170SX FT spectrophotometer as KBr pellets in the range 4000–500 cm^{-1}. The far-IR spectra (500–100 cm^{-1}) were recorded as Nujol mulls between polyethylene sheet. Electronic reflectance spectra were recorded on a Shimadzu 240 spectrophotometer. Electronic spectra in absolute DMF were performed on a Shimadzu 310 spectrophotometer. The 110 K ESR spectra of complexes, and the variable-temperature ESR spectra of **1** in absolute DMF solutions, were measured using a Bruker 200D-SRC spectrometer.

Crystallography

Data collection. A prismatic crystal of **1**, of size $0.20 \times 0.04 \times 0.03$ mm, was obtained by slow evaporation of its ethanol/acetonitrile (5 : 1) solution at room temperature. We had some difficulties finding a good crystal. Attempts to improve the size of the crystals by many recrystallizations were unsuccessful. The data were collected using a Siemens SMART CCD system with monochromated Mo-K_α ($\lambda = 0.71073$ Å) radiation. The data were corrected for Lorentz and polarization effects during data reduction using SHELXTL5.[10] From a total of 9127 reflections measured for $2\theta \leqslant 46.6°$ ($11 \leqslant h \leqslant 11$, $-16 \leqslant k \leqslant 11$, $-16 \leqslant k \leqslant 16$), 3435 were independent and 2678 reflections were considered observed using the criteria $I > 2\sigma(I)$.

Structure solution and refinement. The structure was solved by direct methods using SHELXS86[11] and refined on F^2 by full-matrix least-squares methods using SHELXL93.[12] All non-hydrogen atoms were refined anisotropically. All the hydrogen atoms were generated geometrically and refined using the riding model with the isotropic thermal parameters set to 1.2 times of the atom they ride on. Final conventional $R(F) = 0.1072$ and $wR(F^2) = 0.1886$ for $I > 2\sigma(I)$ with weighting scheme, $w = 1/[\sigma^2(F^2) + (0.0093P)^2 + 19.4233P]$ where $P = (F_0^2 + 2F_c^2)/3$. The maximum and minimum residual electron densities of the difference Fourier map are 0.627 and -0.547 eÅ^{-3}. The molecular graphics were plotted using SHELXTL/PC.[13] All computations were performed on an IBM compatible 486/DX2 personal computer. The crystal data are summarized in Table 1. Supplementary crystallographic data have been deposited at the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

Crystal structure

For comparison, the main bond distances and bond angles of complexes **1** and **2** are listed in Table 2 and the labelled ORTEP plot of the molecular cation structures are shown in Figs 1 and 2, respectively. The copper(II) ion in complex **1** is coordinated by four nitrogen atoms from tren and one nitrogen atom from dzfh, to form a distorted square-based pyramidal geometry (the geometric parameter τ is 0.43),[14] with the sixth, potentially bonding position occupied by N(5) at 2.956(9) Å from the copper, a distance that is considered as weak "semi-coordination".[15] The crystal structure of complex **2** has been published elsewhere.[9] The copper(II) ion in complex **2** is coordinated by four nitrogen atoms from tren and one nitrogen atom from Py to form a regular trigonal-bipyramidal geometry (the geometric parameter τ is 0.95). It can be seen that the structure of complex **1** is very different from that of complex **2** and the general $[Cu(tren)L]^{2+}$ system (the τ value is often close to 1.0[14]).

It is very important to note that the dzfh acts as an asymmetric bidentate ligand in complex **1**. The

high complexation of dzfh and the relatively rigid tripodal construction of tren, which often enforces a five-coordination on copper(II) ion,[16] make this unusual coordinated structure quite stable. The best evidence for the very weak coordination of Cu—N(5) is the unusual trigonally distorted square-based pyramidal stereochemistry, which can be thought of as six coordinate $(4+1+1')$.[15,17] The atoms N(2), N(83) and N(1) from the equatorial plane, and the atoms N(5) and N(93) are in the axial positions. This may be confirmed by the bond length data that the Cu—N(93) is 0.23 Å longer than the other four Cu—N bonds. In fact, the axial bonds of most six-coordinate copper(II) complexes are often elongated as a result of the Jahn–Teller effect. Because of the relatively rigid geometry of tren, the Cu—N(93) bond is shorter than the usual axial Cu—N bond in the elongated octahedral geometry,[15,18] and this may be one of the reasons that the other axial Cu—N bond [Cu—N(5)] is longer than the usual axial Cu—N bond. This structure is very rare, and to our knowledge, it is a unique example of a tripodal copper(II) complex with an asymmetric bidentate phenanthroline derivative.

Electronic spectra

(*a*) *Electronic reflectance spectra.* Figure 3 shows the electronic reflectance spectra of complexes **1** and **2**. The spectral data are summarized in Table 3. The complexes absorb light in the same region of the visible spectrum; yet their spectra are quite different. Complex **1** has a band maximum at 15,600 cm^{-1} and a lower energy shoulder at 11,900 cm^{-1};

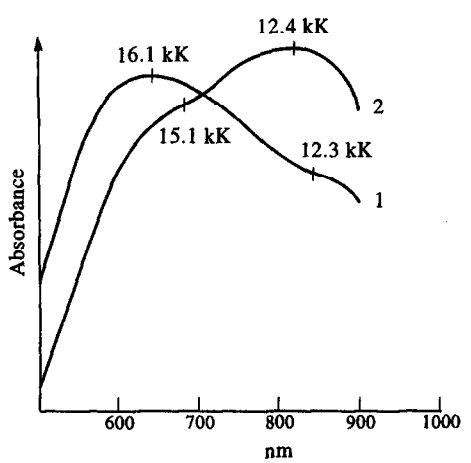

Fig. 3. Electronic reflectance spectra of **1** and **2**.

Table 3. Electronic spectral data for **1** and **2** (cm^{-1}).

Complex	Bands (cm^{-1}) (ε_{max})[a]	
1		
(in DMF)	13,500(100)	11,900(112)
(Gaussion analysis	I 15,000, II 12,400	III 11,000, IV 9700
(reflectance of solid)	15,600	11,900
2		
(in DMF)	14,300(95)	12,300(141)
(reflectance of solid)	14,700	12,200

[a] ε_{max} in units of M^{-1} cm^{-1}.

while complex **2** has a maximum at 12,200 cm^{-1} and a high-energy shoulder at 14,700 cm^{-1}. Both spectra agree with those previously reported for $[Cu(NH_3)5]^{2+}$[19] and $[Cu(tren)(NH_3)]^{2+}$,[20] respectively. This result may demonstrate that complex **1** has a distorted square-based pyramidal geometry, instead of the trigonal bipyramidal stereochemistry which is very common in five coordinated tris(2-aminoethyl)amine copper(II) complexes. The assignment of the electronic reflectance spectra of copper(II) has been extensively discussed in the literature.[15] It would be reasonable to assign the intense band of complex **1** at 15,600 cm^{-1} as the d_{xz}, $d_{yz} \rightarrow d_{x^2-y^2}$ transition and the shoulder at 11,900 cm^{-1} as the $d_{z^2} \rightarrow d_{x^2-y^2}$ transition with the $d_{xy} \rightarrow d_{x^2-y^2}$ transition at $\approx$14,000 cm^{-1} in the Gaussian analysis.[21] This assignment is in agreement with that suggested for other square-based pyramidal copper(II) complexes.[14,15,20]

A tentative assignment of the electronic reflectance spectra of the $[Cu(tren)L]^{2+}$ cations has been suggested; namely the band maximum at 12,200 cm^{-1} of complex **2** as the d_{xy}, $d_{x^2-y^2} \rightarrow d_{z^2}$ transition, the less intense shoulder at 14,700 cm^{-1} as the d_{xy}, $d_{yz} \rightarrow d_{z^2}$ transition. This shows the characteristics of the trigonal-bipyramidal stereochemistry.[9,15,20,21]

(*b*) *Solution electronic spectra.* Figure 4 shows the electronic spectra of complex **1** and **2** in DMF at room temperature. It is obvious that the electronic spectrum of complex **1** is quite different to that in the solid state, which indicates that the stereochemistry of complex **1** has changed in solution. Variable-solvent spectra show that the electronic spectrum of complex **1** has no visible change in different organic solvent, such as acetonitrile and DMF. Therefore, the equilibrium

$$Cu(tren)(dzfh)^{2+} + S \rightarrow Cu(tren)(S)^{2+} + dzfh$$

(where S represents solvents) does not exist in solution. Considering the asymmetric coordination of the dzfh ligand, the different stereochemistries in

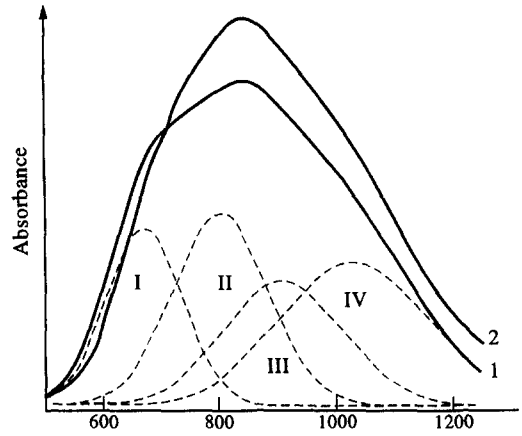

Fig. 4. The electronic spectra in absolute DMF solutions of complexes **1** and **2**.

the solid state and in solution may be attributed to the transformation of the two nitrogen atoms of dzfh in solution. If the sum of Gaussian-shaped bands corresponding to the different types of transition are reproduced with good accuracy,[22,23] four bands can be observed. Bands I and III are quite similar to those of the solid state, which can be assigned as d_{xy}, $d_{yz} \rightarrow d_{x^2-y^2}$ and $d_{z^2} \rightarrow d_{x^2-y^2}$ of the square-based pyramidal complex; while bands II and IV are quite similar to those of the solid state spectrum of the *cis* distorted octahedral copper(II) complex[24] in which two nitrogen atoms of dzfh coordinate to the copper(II) ion in the two-dimensional fluxional model and can be assigned as d_{yz}, $d_{x^2-y^2}$, $d_{xz} \rightarrow d_{z^2}$ and $d_{xy} \rightarrow d_{z^2}$. These results may demonstrate that not only does the square-pyramidal stereochemistry exist which has the lowest potential wells I and II (Fig. 5) in the solution, but also that the *cis* distorted octahedral stereochemistries with different Cu—N(2) and Cu—N(5) bond distances exist, which have a higher potential energy than those of wells I and II. The populations of the different stereochemistries may be controlled

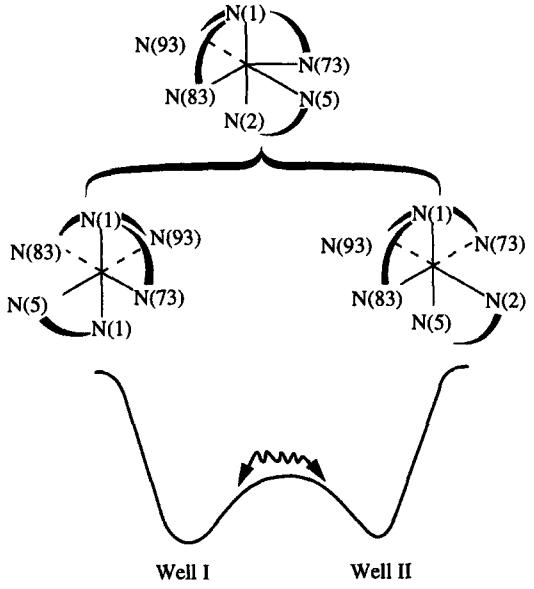

Fig. 5. The two-dimensional fluxional disorder model of the pseudo *cis* distorted octahedral geometry with qualitative potential energy wells diagram.

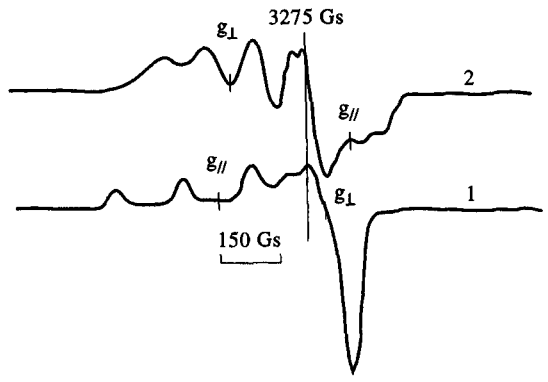

Fig. 6. ESR spectra of the complexes **1** and **2** in frozen absolute DMF solutions.

by temperature and potential energy of the chromophore CuN_4NN'.

ESR spectra

(*a*) 110 *K ESR spectra.* The ESR spectra of complexes **1** and **2** are shown in Fig. 6, the data for the ESR spectra are summarized in Table 4. The spectrum of **1** involves an intense $g_\parallel$ signal with clear resolution of the four copper hyperfine lines, $g_\parallel = 2.228$, $A_\parallel = 16.82 \times 10^{-3}$ cm^{-1} and a very intense $g_\perp$ signal with $g_\perp = 2.021$, $A_\perp = 13.02 \times 10^{-3}$ cm^{-1}. The fact that $g_\parallel > g_\perp$ confirms a square-based pyramidal stereochemistry in complex **1**.[14,15] While the spectrum of **2** shows a line shape characteristic of a complex with two different g-values, but the reverse of that of complex **1**, with $g_\parallel = 1.992$, $A_\parallel = 7.41 \times 10^{-3}$ cm^{-1} and $g_\perp = 2.182$, $A_\perp = 11.86 \times 10^{-3}$ cm^{-1}. This fact, $g_\perp > g_\parallel$, agrees with the trigonal bipyramidal stereochemistry established for the $[Cu(tren)L]^{2+}$ system.[9,15,20,21]

(*b*) *Variable-temperature ESR of* **1** *in DMF solution.* In order to obtain further insight into the coordination geometry of complex **1** in solution, the variable-temperature ESR spectra were observed (Fig. 7). It can be seen that the solution coordination of complex **1** is significantly temperature dependent. The $d_{x^2-y^2}$ ground state in the frozen solution (200, 160 and 110 K) shows a dominant tetragonal component in the solution stereochemistry. The ESR spectra in solution (290 and 240 K) show the isotropic spectra of the copper(II) ion. From the g-value of the solution stereochemistry, which is bigger than that of the frozen state, we can suggest that there exist other stereochemistries with bigger g-values, except the square-based pyramidal stereochemistry. Considering the asymmetric coordination of dzfh and the electronic spectrum, the stereochemistries with bigger g-values

Table 4. ESR spectral data for complex **1** and **2** in absolute DMF.

Complex	Temperature	$g_\parallel$	$A_\parallel$[a]	$g_\perp$	$A_\perp$	g_{iso}
1	287K					2.133
	240K					2.103
	200K	2.228	16.83	2.026	10.26	2.093
	160K	2.228	16.83	2.023	12.44	2.091
	110K	2.228	16.82	2.021	13.02	2.090
2	110K	1.992	7.41	2.182	11.86	2.119

[a]A values are $\times 10^3$ cm^{-1}.

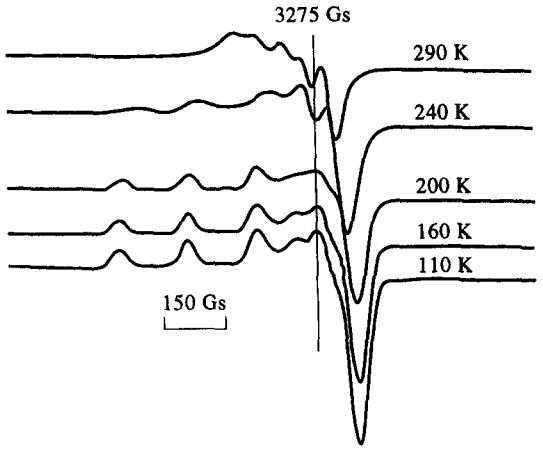

Fig. 7. The variable-temperature ESR spectra of complex **1** in absolute DMF solution.

are best referred to the pseudo *cis* distorted octahedral stereochemistries, in which the two nitrogen atoms of dzfh coordinate to the copper(II) ion in the two-dimensional fluxional model.[25,26]

Consequently, the electronic and variable-temperature ESR spectra suggest that the structure of complex **1** in solution is not the genuine stereochemistry of the copper(II) ion, but arises as a consequence of the pseudo-dynamic Jahn–Teller effect[27] generating a two-dimensional fluxional model involving a static distorted square-based pyramidal (4+1+1′) structure, with nearly equal thermal population of the two lowest potential wells I and II corresponding to the square-base pyramidal geometry and a higher potential barrier corresponding to the *cis* distorted octahedral stereochemistry, with a different bond distance ratio of Cu—N(2) : Cu—N(5) from 0.68 to 1.47. The highest potential barrier corresponds to the *cis* distorted octahedral stereochemistry with two equal Cu—N(2) and Cu—N(5) bond distances.

It is very interesting to speculate on the significance of the structure of complex **1** for the model associative complex in the associative mechanism for the ligand-exchange and ligand-substitution reactions of $[Cu(tren)L]^{2+}$, owing to their importance in studying the elementary steps in the catalytic cycles of enzymes, such as Cu—Zn SOD, involving substitution reactions at the copper sites.[28,29]

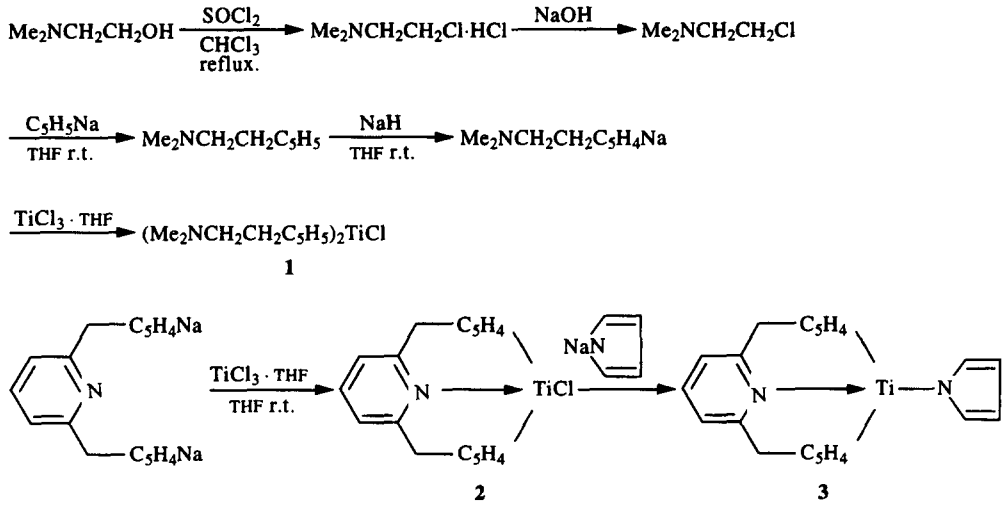
(Received 16 January 1996; accepted 19 March 1996)

Abstract—Three substituted cyclopentadienyl titanium(III) complexes with intramolecular amino group coordination have been prepared and the crystal structure of $(C_5H_4CH_2CH_2NMo_2)_2TiCl$(**1**) has been determined.

In recent years there has been considerable interest in metallocycles which are often involved in a number of significant catalytic reactions, such as olefin polymerization[1] and isomerization.[2] Previous studies in our group have focused on the chemistry of substituted cyclopentadienyl titanium complexes, their syntheses, structure and catalytic reactions.[3] We are now interested in investigating terminal amino group coordinated titanium complexes, specially in the low valent state. Such coordination may provide a model for studying the mechanism of Ziegler–Natta polymerization of olefin with titanocene complexes as catalysts. Here we report the syntheses and structural studies of three terminal amino substituted cyclopentadienyl titanium (III) complexes. The synthetic route is shown in Scheme 1.



Compounds **1–3** have been characterized by ^{1}H-NMR, MS, IR and elemental analysis and provided satisfactory spectroscopic and analytical data. The crystal structure of **1** has been determined and is shown in Fig. 1.

The structure of **1** reveals that there is only one atom of nitrogen in the side chain coordinated to titanium atom with a N—Ti bond length 2.428 Å, and the other nitrogen is not coordinated to the metal. We have also determined the X-ray photoelectron spectrometry (XPS) of compounds **1–3** and compared them with their analogues. The results are shown in Table 1.

Compared with the analogous complex, the N1*s* binding energy (B.E.) in complex **1** is increased 1.9 eV and Ti $2p_{3/2}$ of that is decreased 0.2 eV. The results show that there is a N → Ti coordination bond which is consistent with the molecular structure. Similarly, the changes of N1*s* and Ti $2p_{3/2}$ binding energies in complex **2** are +0.8 eV and −0.4 eV respectively. It also gives evidence of N → Ti coordination in complex **2**. The same coordination exists in complex **3** supposedly.

Footnotes

1. All new compounds provided satisfactory analytical and spectroscopic data.

The typical synthetic procedure and selected analytical data for compounds **1–3** are as follows.

1. A solution of $(CH_3)_2NCH_2CH_2CpNa$ (10.02 mmol) in THF was added dropwise to a solution of $TiCl_3 \cdot 3THF$ (1.86 g, 5.01 mmol) in THF. It was stirred for 6 h. The solvent was removed. The residue was extracted and a blue green powder 1.23 g (Yield 69%) was obtained. m.p. 130–132°C, MS (*m*/*z*): 355 (M^+, 21); 320 (M—Cl, 27).

2. By using the same procedure as the complex **1**, it gave dark blue solid, yield 81.6%. MS (*m*/*z*): 316 (M^+, 100); 280 (M—Cl—H, 96).

3. After the reaction of  and $TiCl_3 \cdot 3THF$ was completed,  was added. The solvent was removed, the residue was extracted, and a dark blue crystal was obtained. MS (*m*/*z*): 347(M^+, 43); 281  .

2. Crystal data for Compound **1**: $C_{18}H_{28}ClN_2Ti$. Molecular Weight: 355.77; Data collection was made on a Siemens R 3m/v Diffractometer using Mo-K_α radiation and a highly orientated graphite crystal monochromator. The crystal structure was solved by direct methods using a Siemens SHELXTL PLUS (VMS) System and refined by full-matrix least-squares. Crystal size 0.15 × 0.15 × 0.25 mm; green blue prism, orthorhombic; space group: $P2_12_12_1$; a = 9.190(5), b = 10.814(7), c = 18.410(13), V = 1830(2) Å^3, Z = 4, D_c = 1.292 g cm^{-1}; $F(000)$ = 756; *Mo*-K_α (λ = 0.71073); 2θ Range: 3.0 to 50.0°; reflections collected: 3630; independent reflection: 3235 (R_{int} = 3.20%), observed reflections: 1398 ($P > 5.0s(f)$); R = 0.0687, $R\omega$ = 0.0558. Mononuclear cadmium(II) halide complexes of triphenylphosphoniobutyrate, $[CdCl_2L_2 \cdot H_2O]$ and $[CdX_2L_2]$ (X = Br, I)(L = $Ph_3P^+(CH_2)_3CO_2^-$)

(Received 1 April 1996; accepted 13 June 1996)

Abstract—Three mononuclear cadmium(II) complexes containing the tertiary phosphine betaine ligand triphenylphosphoniobutyrate, $Ph_3P^+(CH_2)_3CO_2^-$, (L) have been synthesized and characterized by single crystal X-ray analysis. In $CdCl_2L_2 \cdot H_2O$ (**1**) the cadmium(II) atom is coordinated by pairs of unidentate betaine ligands and chloro ligands in a tetrahedral environment, and the primarily discrete species are joined by donor hydrogen bonds from the solvated water molecules to the pendant oxygen atom of the betaine ligands to form a dimer. In $CdBr_2L_2$ (**2**) the cadmium(II) atom is coordinated in a similar manner, but one Cd—Br distance is so long that it may be considered as a weak interaction. In CdI_2L_2 (**3**) the betaine ligands act differently in the bidentate chelate and unidentate modes. Copyright © 1996 Elsevier Science Ltd

Keywords: mononuclear complex; triphenylphosphoniobutyrate; cadmium(II) halide; crystal structure.

The coordination chemistry of cadmium in both the non-biological and biological areas has attracted the interest of many researchers [1]. Recently, the ^{113}Cd nucleus has been utilized as an excellent metallobioprobe owing to its favorable NMR properties as compared to some native metal ions, e.g. Zn^{II}, Ca^{II} and MG^{II} [2–6].

In the coordination chemistry of cadmium(II), complexes with carboxylic acid or carboxylic acid-like ligands figure prominently [1–7]. This is ascribed to two factors. First of all, cadmium(II) has a d^{10} electron configuration which rules out ligand–field stabilization in its complexes and, as a consequence, adapts well to a variety of stereochemical environments. A recent statistical survey of 200 crystal structures of cadmium(II) complexes of low molecular weight showed that cadmium(II) has coordination numbers of 4, 5 and 6 in about 19, 8 and 56%, respectively [8]. Another statistical study on the structural aspects of metal ion–carboxylate interactions showed that the maximum deviation of the cadmium(II) atom from the carboxylate plane can reach up to ~1.5 Å, but for most transition metal ions such as manganese(II, III), cobalt(II, III), nickel(II), iron(II, III), copper(I, II) and zinc(II), they tend to lie in the carboxylate plane [9]. This means the cadmium(II) ion is more accommodating to the arrangement of carboxylate ligands in its coordination sphere. Secondly, the carboxylato group has a π-conjugated system with two lone pairs on each oxygen atom, which facilitate a variety of coordination modes to metal ions [10–18]. These two factors are also responsible for the relative scarceness of cadmium(II) carboxylates containing both monomeric and discrete oligomeric units.

Recently, we studied the interaction of a tertiary phosphine betaine triphenylphosphoniopropionate, $Ph_3P^+(CH_2)_2CO_2^-$, with various cadmium(II) salts, and a series of tetrakis-μ-carboxylato-*O*,*O*′dicadmium(II) complexes were synthesized and fully characterized by single crystal X-ray analysis. It has been suggested that the occurrence of these complexes can be attributed to the steric effect of the bulky Ph_3P group [19]. A subsequent investigation of the reaction of $Ph_3P^+(CH_2)_2CO_2^-$ with cadmium(II) salts led to the formation of mono-, bi-, tri- and tetranuclear cadmium(II) complexes containing discrete units [20]. In the present paper, we report the reaction of CdX_2 (X = Cl, Br, I) with triphenylphosphoniobutyrate, $Ph_3P^+(CH_2)_3CO_2^-$, which has one more —CH_2— spacer than $Ph_3P^+(CH_2)_2CO_2^-$, and three new mononuclear cadmium(II) complexes have been syn-

* Author to whom correspondence should be addressed.

thesized and characterized by single crystal X-ray analysis.

EXPERIMENTAL

Synthesis

$Ph_3P^+(CH_2)_3CO_2^-$ was synthesized by a literature method [21]. Solvents and other chemicals were used as purchased.

All three complexes $[CdCl_2\{Ph_3P(CH_2)_3CO_2\}_2]\cdot H_2O$ (**1**), $[CdBr_2\{Ph_3P(CH_2)_3CO_2\}_2]$ (**2**) and $[CdI_2\{Ph_3P(CH_2)_3CO_2\}_2]$ (**3**) were prepared by the same procedure. To a mixture of $Ph_3P^+(CH_2)_3CO_2^-$ (340 mg, 1.0 mmol) and cadmium(II) halide [$CdCl_2\cdot 2H_2O$ (115 mg, 0.5 mmol), $CdBr_2$ (130 mg, 0.5 mmol), or CdI_2 (175 mg, 0.5 mmol)] was added distilled water (*ca* 5 cm^3), and a white precipitate formed immediately. After the slurry was stirred for about 5 min at *ca* 60°C, dimethylformamide (dmf) was added until the precipitate dissolved completely. Colorless prismatic crystals of **1–3** were obtained after the solutions were allowed to stand for two days at ambient temperature (yield: 280 mg, 62% for **1**; 250 mg, 52% for **2**; 310 mg, 58% for **3**).

X-ray data collection and structure refinement

Information concerning X-ray data collection and structure refinement is summarized in Table 1. The intensities for complexes **1–3** were collected at 290 K in the ω-scan mode [22] on a Nicolet R3m/V (for **2** and **3**) and a Siemens P4/PC (for **1**) diffractometer using Mo-K_α radiation ($\lambda = 0.71073$ Å), respectively. Unit-cell parameters were calculated from least-squares fitting of the 2θ angles for 25 selected strong reflections. Crystal stability was monitored by recording three check reflections at intervals of 120 data measurements, and no significant variation was detected. Empirical absorption correction based on azimuthal scans was applied to the intensity data processing for **1** and **3**.

The crystal structures of all three complexes were solved by direct methods. All non-hydrogen atoms were refined anisotropically by full-matrix least squares. The hydrogen atoms of the ligands were placed in their calculated positions with C—H = 0.96 Å, assigned fixed isotropic thermal parameters, and allowed to ride on their respective parent carbon atoms. These hydrogen atoms were included in the structure factor calculations, but their positions were not varied.

All calculations were carried out on a PC 486 using the SHELXTL-PLUS program package [23]. Analytical expressions of neutral-atom scattering factors were employed, and anomalous dispersion corrections were incorporated [24]. The selected bond lengths and angles for **1–2** are listed in Table 2.

RESULTS AND DISCUSSION

Structures of $[CdCl_2\{Ph_3P(CH_2)_3CO_2\}_2]\cdot H_2O$ (**1**) *and* $[CdBr_2\{Ph_3P(CH_2)_3CO_2\}_2]$ (**2**)

Complex **1** crystallizes with a packing of discrete $[CdCl_2\{Ph_3P(CH_2)_3CO_2\}_2]$ molecules and lattice water molecules, while complex **2** consists of discrete $[CdBr_2\{Ph_3P(CH_2)_3CO_2\}_2]$ molecules only. As illustrated in Figs 1 and 2, the structures of both complexes are very similar. The cadmium(II) atom is coordinated by two unidentate $Ph_3P^+(CH_2)_3CO_2^-$ ligands [Cd—O = 2.232(4) and 2.213(2) Å for **1**, 2.148(7) and 2.037(7) Å for **2**, respectively; Cd···O (pendant = 2.809(2) and 2.981(2) Å for **1**, 2.826(7) and 2.847(7) Å for **2**) and two halo ligands [Cd—Cl = 2.463(1) and 2.469(1) Å for **1**, Cd—Br = 2.580(2) and 2.926(2) Å for **2**] in a slightly distorted tetrahedral environment (the bond angles around the cadmium(II) atom lies in the range of 98.6(1)–128.2(1)° for **1** and 92.2(2)–127.0(3)° for **2**].

The two Cd—O bonds in **1** are nearly identical and similar to those found in tetrakiscarboxylato-*O*,*O*′-bridged dicadmium(II) anions $[Cd_2X_2\{Ph_3P(CH_2)_2CO_2\}_4]^{2+}$ (X = Cl, NO_3) [2.236(7)–2.251(6) Å] [19] in which the carboxylate groups act in a *syn–syn* bidentate bridging mode. The Cd—Cl bond lengths in **1** are well within the Cd—Cl(terminal) bond lengths [2.436–2.458 Å] [25a] found in four-coordinated cadmium(II) complexes. The torsion angles Cd(1)—O(1)—C(22)—O(2) at −9.3° and Cd(1)—O(3)—C(44)—O(4) at 7.1° indicate that the cadmium(II) atom nearly lies in the plane of each of the carboxylate groups. On the other hand, the two carboxylate groups are approximately mutually perpendicular with a dihedral angle of 99.9°. Two monomeric molecules are bridged by donor hydrogen bonds from the lattice water molecule to the pendant oxygen atoms of the betaine ligands[O(1W)···O(4) = 2.899(4) and O(1W)···O(2a) = 2.858(4) Å, O(4)···O(1W)···O(2a) = 126.7°] to form a dimeric structure.

For complex **2**, the two Cd—O bond lengths are markedly different and significantly shorter than those in **1**. In addition, one Cd—Br bond is well comparable to the average Cd—Br(terminal) bond length of 2.588 Å [25b] in four-coordinated cadmium(II) complexes and is much shorter than the other Cd—Br bond. The Cd—Br(2) bond length of 2.926(2) Å is so long that it may be considered as a secondary interaction between the Cd^{II} atom and the Br atom, so that the coordination environment about the cadmium(II) atom in **2** is better described as distorted pyramidal rather than distorted tetrahedral, and the change of coordination geometry may be responsible for the shorter Cd—O distances in **2** than in **1**. However, the torsion angles Cd(1)—O(1)—C(22)—O(2) and Cd(1)—O(3)—C(44)—O(4) [−8.2 and 10.7°] and the dihedral angle between the two carboxylate groups [81.3°] are similar to those in complex **1**.

$R = \Sigma\Delta/\Sigma|F_o|$, $R' = [\Sigma w\Delta^2/\Sigma|F_o|^2]^{1/2}$ and $S = [w\Delta^2/(n-p)]^{1/2}$ where $w = [\sigma^2F_o)+K|F_o|^2]^{-1}$, $\Delta = ||F_o|-|F_c||$; 10^4 K = 80, 100 and 100 for complexes **1**, **2** and **3**, respectively. Extinction parameter χ = 0.00036, 0.00147 and 0.00008 for complexes **1**, **2** and **3**, respectively where the "corrected" calculated structural factor $F_{corr} = F_c(1+0.002\chi F_c^2/\sin 2\theta)^{-1/4}$.

Crystal structure of $[CdI_2\{Ph_3P(CH_2)_3CO_2\}_2]$ (**3**)

Complex **3** also comprises discrete molecules $[CdI_2\{Ph_3P(CH_2)_3CO_2\}_2]$ packed in the crystal lattice. However, unlike **1** and **2** the cadmium(II) atom in **3** is five-coordinated in a distorted square-pyramidal geometry (Fig. 3) with the oxygen atoms of both $Ph_3P^+(CH_2)_3CO_2^-$ ligands and one iodo ligand forming the base, and the other iodo ligand occupying the axial position. The most distorted bond angle is O(1)—Cd(1)—O(2) = 54.4(4)°. Of the two betaine ligands, one acts in the asymmetric bidentate chelate mode [Cd—O = 2.238(10) and 2.497(10) Å, Δ(Cd—O) = 0.259 Å] and the other in the unidentate mode [Cd—O = 2.232(8) Å]. The Cd—O(unidentate) bond length is comparable with those in $[Cd\{Ph_3P(CH_2)_2CO_2\}_4(H_2O)_2](ClO_4)_2\cdot 2H_2O$ [Cd—O = 2.219(5) and 2.231(4) Å [20] in which the cadmium(II) atom is coordinated by four unidentate $Ph_3P^+(CH_2)_2CO_2^-$ betaine ligands. The two Cd—I bond lengths of 2.809(2) and 2.844(3) Å are significantly longer than the average Cd—I bond length of 2.750 Å [25c] and those [2.701(1) and 2.706(1) Å] found in $[CdI_2\{Ph_3P(CH_2)_2CO_2\}]$ [20] in which the Cd^{II} atom is also penta-coordinated but in a very different coordination geometry. The dihedral angle between the two carboxylate groups of 84.8° is comparable to those in **1** and **2**. In addition, the dihedral angle between the plane CdI(1)I(2) and O(3)C(44)O(4) of 89.4° indicates that the orientation of the pendant oxygen atom of the carboxylate group C(44)O(3)O(4) is dictated by the repulsive interaction between it and the two iodo ligands.

The bidentate chelate mode is found in cadmium(II) complexes of many carboxylic acids, such as $[Cd(PA)_2(H_2O)_2]$ (PAH = phenoxyacetic acid) in which the cadmium(II) atom is six-coordinated with two symmetrically chelated carboxylato groups lying in the equatorial plane [Cd—O = 2.363(4) and 2.365(4) Å] [26]. It also occurs commonly in cadmium(II) complexes of amino acids, such as aqua(L-glutamato)dicadmium(II) hydrate [Cd—O = 2.317(5), 2.458(5) Å] in which the cadmium(II) atom is six-coordinated, triaquabis(L-glutomato) cadmium(II) hydrate [Cd—O = 2.361(5), 2.502(5) and 2.368(5), 2.499(5) Å] and aqua(glycyl-L-glutamato) cadmium(II) hydrate [Cd—O = 2.277(5), 2.867(5) and 2.331(5), 2.435(5) Å] in each of which the cadmium(II) atom is seven-coordinated with two carboxylato groups acting in the bidentate chelate mode [27], as well as dichlorobis (glycylglycine) cadmium(II) [Cd—O = 2.255(5), 2.602(5) Å] in which

the cadmium(II) atom is six-coordinated [27]. Betaine ligands exhibiting the bidentate chelate mode are found in $[Cd(Et_3BET)(\mu\text{-}Cl)_2]_n$ ($Et_3BET = Et_3N^+(CH_2)_2CO_2^-$) [Cd—O = 2.407(2), 2.435(2) Å] in which the cadmium(II) atom is six-coordinated [28], in $[CdCl_2\{Ph_3P(CH_2)_2CO_2\}_2]\cdot 7H_2O$ [Cd—O = 2.306 (9), 2.567(9) and 2.287(8), 2.576(8) Å] in which the cadmium(II) atom is six-coordinated with a pair of chelated carboxylato groups [20], in *trans*-$Cd(H_2O)_4[Cl_2Cd(\mu\text{-}Cl)\{Ph_3P(CH_2)_2CO_2\}]_2\cdot 4H_2O$ [Cd—O = 2.290(6), 2.541(7) Å] in which the cadmium(II) atom is five-coordinated [20]. In all these examples the Δ(Cd—O) value lies in a wide range of 0.002–0.590 Å which indicates that the steric strain imposed by the formation of a four-membered chelate ring can be released by having one carboxylato oxygen atom strongly coordinating to the cadmium(II) and the other loosely bound. It should be noted that in many cadmium(II) carboxylates the center of mass of the pair of oxygen atoms of a chelated carboxylato group can be taken as a ligand site in considering the corresponding idealized polyhedral geometry [20,29]. In complex **3** the angles between the vectors from cadmium(II) to the midpoint of a line linking O(1) with O(2), and to O(3), I(1) and I(2) vary in the range 96.9–126.2°, which lie within ± 17% of the ideal tetrahedral

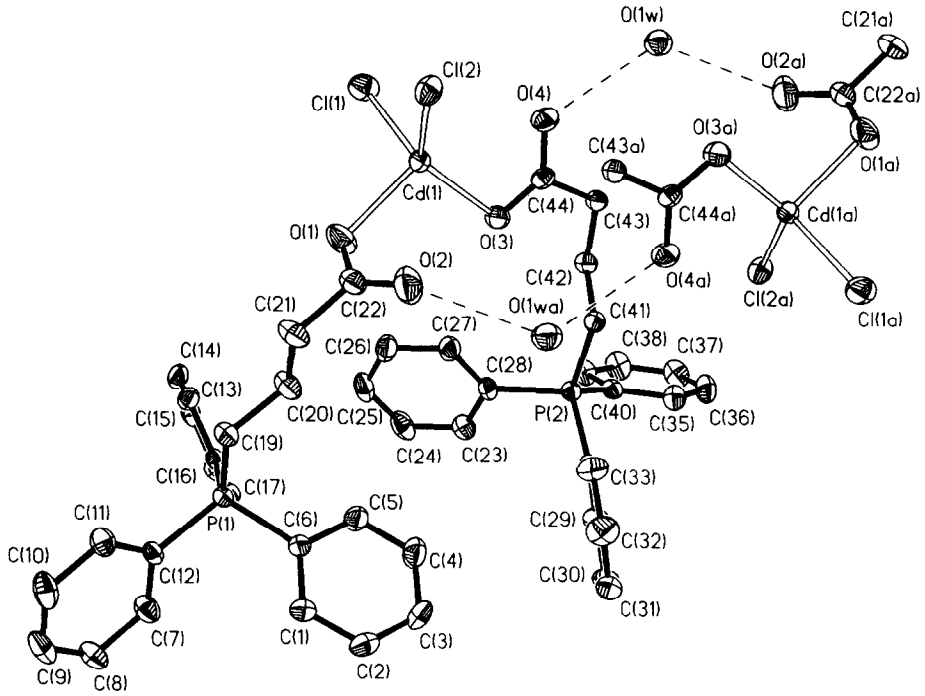

Fig. 1. Molecular structure and atom numbering of $[CdCl_2\{Ph_3P(CH_2)_3CO_2\}_2]\cdot H_2O$ **1**. Hydrogen atoms are omitted for clarity, and hydrogen bonds are indicated by broken lines. The thermal ellipsoids are drawn at the 35% probability level.

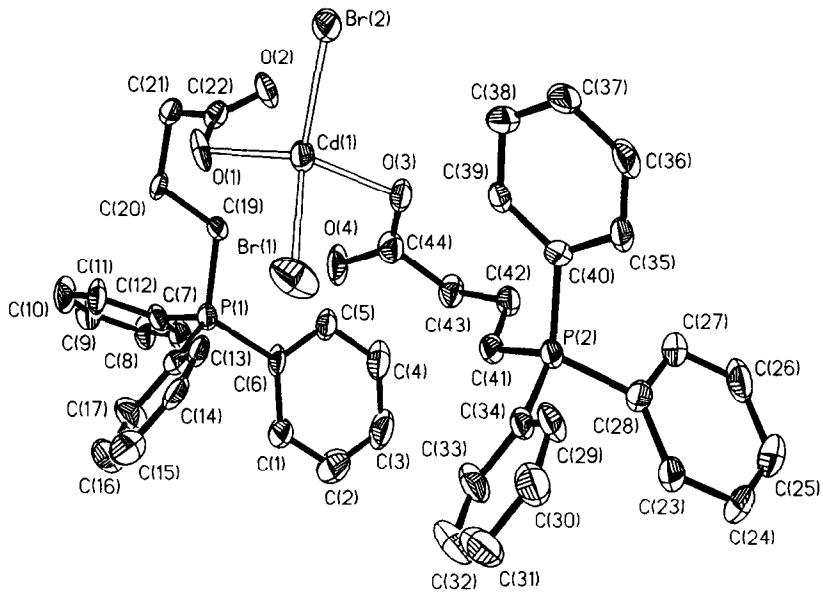

Fig. 2. Molecular structure and atom number of $[CdBr_2\{Ph_3P(CH_2)_3CO_2\}_2]$ **2**. Hydrogen atoms are omitted for clarity. The thermal ellipsoids are drawn at the 35% probability level.

bond angle. This suggests that the Δ(Cd—O) value is mainly influenced by the coordination geometry around the cadmium(II) atom.

Although the unidentate coordination mode commonly exists in zinc(II) carboxylates such as $[Zn(H_2O)_4L_2]$ and $[Zn(H_2O)_2L_2]$ (HL = 2,4-dichlorophenoxyacetic acid) [30], as well as zinc(II) complexes of tertiary amine betaines such as $[Zn(pyBET)(H_2O)Cl_2]$, $[Zn(pyBET)_2Cl_2]$ (pyBET = $C_5H_5N^+CH_2CO_2^-$), $[Zn(BET)_2Cl_2]\cdot H_2O$ (BET =

$Me_3N^+CH_2CO_2^-$) [31] and $[Zn(ppBET)_2Cl_2]$ [32] (ppBET = $C_5H_5N^+(CH_2)_2CO_2^-$), it is relatively rare in cadmium(II) carboxylates owing to the much larger radius of Cd^{II} as compared with Zn^{II} and the tendency of Cd^{II} to form polymeric species with neighboring Cd^{II} atoms through μ-*O,O'*-bridging by carboxylate groups. A plausible reason for the ease of the $Ph_3P^+(CH_2)_3CO_2^-$ betaine ligand to act in the unidentate mode to yield monomeric metal complexes is that its flexible alkyl chain enables the bulky Ph_3P group to be positioned close to the metal center and thus hinder the approach of another mononuclear species.

(Received 29 February 1996; accepted 5 June 1996)

Abstract—The binding abilities of several polypyrazolylborato ligands ($Tp^{\#}$) toward nitrato bis(cyclohexylphosphine)Cu^{I} have been investigated. Complexes of empirical formula $(Cy_3P)_2Cu \cdot Tp^{\#}$ ($Tp^{\#}$ = Bp or pzTp) and $(Cy_3P)Cu \cdot Tp^{\#}$ ($Tp^{\#}$ = Tp, Tp^{Me}, Tp* or Tp^{*Cl}) have been synthesized and characterized through analytical and spectral (IR, ^{1}H, ^{13}C and ^{31}P NMR) measurements. The compound $(Cy_3P)_2Cu \cdot pzTp$ is fluxional at room temperature. In the crystal structure of the title compounds the copper atom is found in a strongly distorted tetrahedral coordination (the N—Cu—N and N—Cu—P angles range from 87.5(1) to 90.8(1)° and from 120.8(1) to 130.3(1)°, respectively. Comparison is made with related phosphino copper(I) derivatives.

Keywords: polypyrazol-1-ylborates; cyclohexylphosphine Cu^{I}; X-ray; ^{31}P; synthesis; derivatives of copper(I).

Metal derivatives containing poly(pyrazolyl)borato ligands have been widely investigated by inorganic, organometallic and bioinorganic chemists [1,2]. Recently, the tris(pyrazolyl)borato ligand system [$Tp^{\#}$] has found widespread use in the study of copper chemistry, a metal which plays a relevant role in the synthesis of catalytic systems [3,4] and models for biomimetic studies [4–8]. Phosphino-copper(I) derivatives have also potential applications in microelectronic technology [9].

In previous papers, the synthesis and characterization of bis(triarylphosphine)copper(I) derivatives with bis(azolyl)alkanes [10] and bis-, tris- and tetrakis(pyrazolyl)borato ligands have been described [11,12]. Now, we have extended our studies to the interaction of poly(pyrazolyl)borato ligands Bp, $Tp^{\#}$ ($Tp^{\#}$ = Tp, Tp^{Me}, Tp*, Tp^{*Cl}) and pzTp (Fig. 1) with a more sterically hindered Cu^{I} acceptor as $(Cy_3P)_2Cu^{I}$.

In this paper we describe the synthesis and spectroscopic characterization of six new Cu^{I} derivatives and also the solid state structural study of two of them, namely $[HB\text{-}(\mu\text{-}pz)_3\text{-}CuP(Cy)_3]$ and $[HB\text{-}(\mu\text{-}3,5\text{-}Me_2pz)_3\text{-}CuP(Cy)_3]$. We have observed that the diversity of stoichiometries and geometries in these kind of complexes is strongly dependent on the steric and electronic requirements of the donors employed. The factors affecting the stoichiometry and the coordination number are here discussed and rationalized

on the basis of steric and electronic arguments (for example Tolman's cone angle [13]).

EXPERIMENTAL

All solvents were dried by standard techniques. The reagents were obtained from Aldrich Chemical Co. and from Alfa. The samples were dried *in vacuo* to constant weight (20°C, *ca* 0.1 Torr). Concentration was always carried out under reduced pressure (water aspirator). Elemental analyses were carried out in-house with a Fisons Instruments 1108 CHNS-O Elemental analyzer. IR spectra from 4000 to 100 cm^{-1} were recorded with a Perkin-Elmer System 2000 FT-IR, instrument. ^1H, ^{13}C and ^{31}P NMR spectra were recorded on a VX-300 Varian spectrometer operating at room temperature (300 for ^1H, 75 for ^{13}C and 121.4 MHz for ^{31}P) or on a Varian Gemini-200 (200 MHz for ^1H, 50 MHz for ^{13}C). Melting points were taken on an IA 8100 Electrothermal instrument. The electrical resistances of solutions were measured with a Crison CDTM 522 conductimeter at room temperature.

All manipulations of Cu^I complexes were executed under dinitrogen to avoid any oxidation to Cu^{II}.

Synthesis of the donors

The donors Bp, Tp, Tp^{Me}, Tp*, Tp^{*Cl} and pzTp were prepared by published methods [14].

Synthesis of nitrato[bis{tricyclohexylphosphine}copper(I)]

The starting compound $\{(Cy_3P)_2CuNO_3\}$ was prepared according to the literature [15].

[Bis(tricyclohexylphosphine)copper(I)dihydridobis(pyrazol-1-yl)borato] (1)

A dichloromethane solution (25 cm^3) of bis(tricyclohexylphosphine) copper(I)nitrate (680 mg, 1.0 mmol) was added to a stirred dichloromethane suspension (30 cm^3) of potassium dihydrobis(1*H*-pyrazol-1-yl)borate (186 mg, 1 mmol) under a stream of N_2. After 3 h stirring the solid (KNO_3) was filtered and washed with dichloromethane (20 cm^3). The filtered solution was evaporated to dryness; the residue was purified from dichloromethane–heptane affording product **1** (460 mg, 0.6 mmol). Compound **2** was obtained similarly.

[(Tricyclohexylphosphine)copper(I)hydridotris(1H-pyrazol-1-yl)borato] (3)

A dichloromethane solution (25 cm^3) of bis(tricyclohexylphosphine)copper(I)nitrate (680 mg, 1.0 mmol) was added to a stirred dichloromethane suspension (30 cm^3) of potassium hydridotris(1H-pyrazol-1-yl)borate (250 mg, 1.0 mmol) under a stream of N_2. After 3 h stirring the solid (KNO_3) was filtered and washed with dichloromethane (20 cm^3). After slow evaporation of the solvent, the residue was recrystallized from acetonitrile-Et_2O, affording complex **3** (410 mg, 0.74 mmol). Compounds **4–6** were prepared similarly.

X-ray crystallography

Crystals and experimental data are summarized in Table 1. Colourless crystals of compound $Cy_3PCu \cdot Tp$ (**3**) were obtained from an acetonitrile/diethyl ether solution. For data collection one sample was used of approximate dimensions $0.2 \times 0.2 \times 0.3$ mm. The cell parameters were refined by least squares from angular position of 12 reflections in the range $7 < 2\theta < 26°$.

Colourless crystals of compound $Cy_3PCu \cdot Tp^* \cdot CH_3CN$ (**5A**) were obtained from an acetonitrile/diethyl ether solution and the data were collected from a crystal of about $0.15 \times 0.15 \times 0.2$ mm. The cell parameters were refined by least squares from angular positions of 14 reflections in the range $7 < 2\theta < 18°$.

Both crystals were mounted on a CS automatic four-circle diffractometer equipped with a Huber goniometer [16] using graphite monochromatized Mo-K_α radiation ($\lambda = 0.710689$ Å). The data were

collected at room temperature for $3 < 2\theta < 60°$ using an ω scan technique with a $\Delta\omega = 1°$. The scan rate was automatically chosen according to the peak intensity in the range 2.0–30.0° min^{-1}. Background counts were taken with stationary crystal with an offset of 0.5° at each end of the scan, and a total background to scan time ratio of 0.5. The intensities of three standard reflections were monitored every 97 reflections during the data collections in order to evaluate the decay. Data were corrected for Lorentz and polarization effects and for decay, but not for absorption.

Both of the structures were solved by direct methods by using SIR 92 structure determination package [17]. All the non-hydrogen atoms were refined by full-matrix least-squares methods with anisotropic thermal parameters. For the compound $Cy_3PCu \cdot Tp$ (**3**) the hydrogen atoms were introduced in the final refinement in idealized positions (C—H = 0.96 Å). Each hydrogen atom was assigned arbitrarily the equivalent isotropic temperature factor of the parent carbon atom and allowed to ride on it.

For the compound $Cy_3PCu \cdot Tp^* \cdot CH_3CN$ (**5A**), which crystallizes with a molecule of solvent in the asymmetric unit, the hydrogen atoms of the methyl groups, which are affected by large amplitude thermal motion, were introduced in calculated positions for the two more-populated conformations revealed by the Fourier difference. Their occupancy factor was kept fixed during the final refinement to 0.5. Otherwise each hydrogen atom was treated as described previously for the compound $Cy_3PCu \cdot Tp$ (**3**).

All calculations were carried out on a PC using the SIR CAOS [18] and SHELXTL [19] packages.

RESULTS AND DISCUSSION

The copper(I)polypyrazolylborato complexes **1**–**6** were synthesized from the interaction of bis(cyclohexylphosphine)copper(I)nitrato with potassium salts of the ligands, in dichloromethane suspension in accordance with the following equations:

$$(Cy_3P)_2CuNO_3 + KTp^{\#} \rightarrow KNO_3 + (Cy_3P)_2Cu \cdot Tp^{\#} \quad (I)$$

($Tp^{\#}$ = Bp, pzTp)

$$(Cy_3P)_2CuNO_3 + KTp^{\#} \rightarrow KNO_3 + Cy_3P + (Cy_3P)Cu \cdot Tp^{\#} \quad (II)$$

($Tp^{\#}$ = Tp, Tp^{Me}, Tp*, Tp^{*Cl})

All reactions resulted in the formation of the desired products in fair yields.

The complexes were generally purified from acetonitrile/Et_2O: $Cy_3PCu \cdot Tp^*$ (**5**) crystallizes also with a molecule of CH_3CN (compound **5A**). It is worth noting that the ligand pzTp, even if it is more sterically hindered with respect to Tp, is not able to act as tridentate donor by displacing a phosphine group.

The compounds **1**–**6** gave satisfactory elemental analyses. They are soluble in CH_2Cl_2, $CHCl_3$, DMSO and acetone. In the last solvent they are non-electrolytes (Table 2). This is in reasonable agreement with the neutral structures proposed in Fig. 2. In $CHCl_3$ (concentration in the range $1.0–2.0 \times 10^{-2}$ m), the ratio r between the vaporimetric molecular weight

[c] Melting with decomposition.

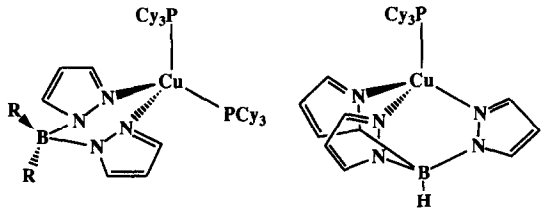

Fig. 2. Structures of the copper(I) derivatives.

and the formula weight for compound **1** lies in the range 0.70–0.80 and indicates that this complex presumably dissociates partly in this solvent in accordance with eq. III:

$$(Cy_3P)_2Cu \cdot Bp \rightleftharpoons (Cy_3P)Cu \cdot Bp + Cy_3P \quad \text{(III)}$$

All the complexes **1–6** were characterized through infrared (Nujol mull and chloroform solution) (Table 3) and ^1H, ^{13}C, and ^{31}P NMR spectra (Tables 4–5).

Infrared data

The IR spectra (Table 3) show several bands which may be taken as diagnostic of the poly(pyrazol-1-yl)borato ligands: weak and medium vibrations at about 3100 cm^{-1} due to C—H stretching in the pyrazolic ring, several more intense absorptions between 1600 and 1500 cm^{-1} typical of ring breathing [20] and finally in the derivatives **1** and **3–6,** one or two weak bands due to B—H stretching, generally unchanged with respect to those observed in the spectra of potassium salts of the ligands [21]. In the far-IR region the weak bands in the range 400–380 cm^{-1} are likely due to P—C stretching modes [22], whereas some weak absorptions at *ca* 300 cm^{-1}, absent in the spectra of both the starting copper(I) derivative and poly(pyrazolyl)borato ligands, are tentatively assigned to Cu—N stretching modes, also on the basis of previous reports in literature [23].

No significant differences were observed between the spectra in Nujol mull and those recorded in chloroform solution.

We have observed that the bis(tricyclohexyl-phosphine)derivatives **1–6** were more oxygen sensitive than the previously reported triphenylphosphine analogues [11,12]. Indeed, when the compounds **1–6** were dissolved in chloroform and exposed to air, their solutions turned deep green or blue, two characteristic colours of copper(II) derivatives.

^1H, ^{31}P and ^{13}C-NMR spectra

The ^1H and ^{13}C-NMR spectra (Tables 4 and 5) show the signals due to ligand moieties in the expected position and multiplicity [14] (e.g. for ^1H: two doublets and a pseudo-triplet for the derivatives of Bp, pzTp and Tp, two doublets for the Tp^{Me} pyrazole ring protons, together with a Me singlet, a singlet for 4-H and two singlets for the 3- and -5-Me in the Tp* derivative, and finally two Me singlets for Tp^{*Cl}). On comparison between the chemical shift related to the same type of proton in the starting potassium poly-

(pyrazol-1-yl)borates and in the corresponding phosphinocopper(I) derivatives **1–6**, generally we have found downfield resonances in the case of H(5), CH_3—C(5) and CH_3—C(3) and upfield resonances in the case of H(4), whereas only a negligible shift was detected in the case of H(3). This is likely due to change in electron density of azole ring upon coordination of the donor to copper ion. Differences in chemical shifts of the cyclohexyl protons with respect to the starting $(Cy_3P)_2CuNO_3$ [15] are not significant. In all the ^1H and ^{13}C we observed one set of signals for each magnetically equivalent nucleus. Assuming that a tetrahedral coordination, similar to that found in the crystal structures of derivatives **3** and **5A**, is operating in solution also in the case of derivative **2**, we hypothesized a fluxional behaviour of this compound which likely requires a fast concomitant breaking and formation of the Cu—N bond. This behaviour is analogous to those observed in the corresponding $(Ar_3)_2Cu(I)\cdot pzTp$ [12]. In the ^{13}C-NMR spectra we found a pattern of chemical shifts in keeping with what has been previously described [14].

The ^{31}P NMR spectra of complexes **1–6** are reported in Table 4. In all the cases we observed only a single resonance. This is due to a fluxional behaviour of these complexes. The signal observed for the (pyrazol-1-yl)boratocopper(I) derivatives **1–6** appears downfield with respect to those observed for the free tricyclohexylphosphine signal (11.8 ppm). $\Delta\delta^{31}P = \delta^{31}P_{complex} - \delta^{31}P_{ligand}$, the difference in shift between the free phosphine and copper(I) complexes is in the order of 6–14 ppm. The shift is smaller than those observed in platinum and gold complexes [24]. These acceptors are more electronegative than phosphorus and inductively they withdraw electron density from the phosphorus atom which experiences a greater net magnetic field. In the ^{31}P NMR spectrum of the derivative **1** we found a broad signal upfield shifted with respect to those reported for derivatives **2–6**. This is likely due to instability of complex **1** in solution which undergoes rapid ligand exchange in accordance with equilibrium III.

Description of the molecular structures of $Cy_3PCu\cdot Tp$ (**3**) *and* $Cy_3PCu\cdot Tp^*\cdot CH_3CN$ (**5A**)

Perspective drawings of $Cy_3PCu\cdot Tp$ (**3**) and $Cy_3PCu\cdot Tp^*\cdot CH_3CN$ (**5A**) are shown in Figs 3 and 4 together with the numbering scheme. Selected interatomic distances and angles are reported in Tables 6 and 7. In both derivatives the copper atom is tetracoordinate, being bonded to one phosphorus atom of Cy_3P and three nitrogen atoms of the tridentate Tp and Tp*. The copper atom is in a strongly distorted tetrahedral environment: the N—Cu—N and N—Cu—P angles are in the range 87.5(1)–90.8(1)° and 120.8(1)–130.3(1)°, respectively. This finding is probably due to remarkable steric hindrance of the tricyclohexylphosphine [13] and Tp ligands. The

Cu—N bond lengths [**3**: 2.093(2), 2.095(2) and 2.104(2) Å; **5A**: 2.106(2), 2.133 and 2.147(2) Å] are somewhat longer than those observed previously in other copper(I)-azole compounds [25], suggesting a weak bonding interaction between the poly(pyrazol-1-yl)borate and the copper(I) acceptor.

Interesting features involving the metal coordination environment are recognizable comparing the structures of the compounds through some characteristic parameters such as those reported in Table 8. While the bond distances Cu(I)—N and Cu(I)—P are greater in **5A** than in **3**, the mean N—Cu—N (bite angles) and N—Cu—P angles in **5A** and in **3** are similar. In the phosphorus environment, besides the already cited lengthening of the Cu—P bond in **5A**, the C(ipso)—P mean bond distance is slightly greater in **5A** than in **3**, the angles C(ipso)—P—C(ipso) are significantly wider in **5A** than in **3**. Substitution of Me for hydrogen in position 3 of the pyrazole rings clearly makes the Tp$^{\#}$ sterically more demanding. Indeed, methyls show close contacts with the cyclohexyl groups whose shortest values range from 3.868 to 3.723 Å. The widening of C—P—C angles in **5A** at P are a consequence of the longer distance from Cu and are reflected, in part, in the enlarged C(ipso)—P distances.

Comparing the Cu—P bond lengths in the complexes **3** and **5A** with the corresponding ones in the precursors Cy_3P—$CuNO_3$ [15] or Cy_3P—$CuClO_4$ [26] a contraction of such bonds is observed on complex formation. This is to be expected on the basis of the actual oxidation state of Cu. In the precursors the phosphine is bonded to an essentially ionic metal centre, while in the complexes they are bonded to a nearly neutral one. This makes the retrodonation of electron density, from Cu to P low-lying antibonding orbitals, more effective and so the bond is stronger and shorter.

The greater value of Cu—P bond length in **5A** with respect to **3** may indicate that the overall donating power of Tp* is here lower than that of Tp for steric reasons. Since Tp* is known to be a better donor to non-hindered centres (in particular to the proton) this behaviour is likely due to steric hindrance. Indeed, recalling that the Cu—N bond lengths are greater in **5A** than in **3** as well, it may be concluded that the Me substituted ligand Tp* is here somewhat prevented from an approach so close to the bulky metal moiety as that of unsubstituted Tp.

It is also of interest to compare the present structure of **3** with the previously obtained one of $Ph_3PCu \cdot Tp$ [12] besides the N—Cu—N, N—Cu—P, and C—P—C angles which are similar and underscore the homogeneity of the complexes, the Cu—N and Cu—P bond lengths are greater in **3** than in $Ph_3PCu \cdot Tp$. This offers the chance to compare the Cu moieties (instead of the ligand ones, *vide supra*) in their contribution to steric hindrance. Here again the lengthenings observed in **3** (*vs* $Ph_3PCu \cdot Tp$) are accounted for by the same motivations as above. The P—C lengths are not comparable in this case since the carbon atoms have different hybridizations. Although the differences in the angles are slight it may be noted that the increase in N—Cu—P value for **3** is consistent with a consequent decrease of the N—Cu—N one. This, taken together with the C—P—C increase, depict a situation in which the bulky Cy_3PCu moiety demands more space and slightly compresses the Tp moiety.

Supplementary material available

Full tables of bond lengths and angles, tables of atomic coordinates and equivalent displacement coefficients, tables of observed and calculated structural factors, anisotropic thermal parameters for non-H atoms as well as hydrogen atom parameters are available as supplementary material.

(Received 10 April 1996, accepted 3 June 1996)

Abstract—The title single chain complex **1** was obtained from reaction of ammonium tetrathiotungstate, silver nitrate and tris(hydroxy-methyl)-amino-methane in DMF, and the title double-chain complex **2** from the recrystallization of **1** in ethanol and a little amount of water. The anionic structure of **1** is a $[WAgS_4]_n$ linear chain, and that of **2** is a $[WAgS_4]_n$ double chain which can be viewed as two zigzag —SWSAg— chains bridged by μ_2-S atoms. In **2**, H_2O molecules and $NH_3C(CH_2OH)_3^+$ cations interact with each other through hydrogen bonding and form a two-dimensional network supramolecular structure. The inversion of configurations from **1** to **2** by re-self-assembly of $[WAgS_4]$ fragments, as well as IR spectra of both complexes, is described.

Keywords: chalcogenides; clusters; silver compounds; tungsten compounds; polymeric tungsten–silver–sulfur complexes; structures.

The chemistry of compounds containing thiotungstate and thiomolybdate has developed rapidly in recent years because of the following main factors [1]: (1) interest in the various geometric structural types; (2) their relevance to Mo—Cu antagonism and the core structure of nitrogenase; (3) research on non-linear optical properties on some of such compounds [2]. Recently, a series of compounds with several novel structural types has been synthesized in our laboratory, using thiotungstate and thiomolybdate as reactants, such as $\{M_4Cu_4S_{12}\}$ [3], $\{M_4Cu_8S_{12}\}$ [3], $\{M_2CuS_4\}$ [4], $\{M_2Cu_2S_4\}$ [5], $\{M_2M'_6S_6(SCMe_3)_2\}$ [6] (M = Mo, W; M′ = Cu, Ag) and $\{(\mu_6\text{-S})Cu_6S_6(S_2)_6Mo_6O_6\}$ [7].

Polymeric transition metal chalcogenides have attracted much attention because they have many useful properties that are derived from the low-dimensional solid state structure [8]. In the tungsten(molybdenum)–silver–sulfur system, the general configuration of polymeric chalcogenides is linear chain [9], such as $[(PPh_4)\cdot(AgMoS_4)]_n$ [9a, b], $[(AgMS_4)\cdot(4\text{-MePyH})]_n$ [9c] $[(tmenH_2)\cdot(W_2Ag_2S_8)\cdot(tmen)\cdot(H_2O)]_n$ [9d] and $[(AgWS_4)\cdot(HNEt_3)\cdot(DMF)]_n$ [9e] (M = Mo, W; tmen = *N,N,N′,N′*-tetramethylethylenediamine). Herein, the detailed syntheses, characterization and structures of briefly-reported $[WS_4Ag\cdot NH_3C(CH_2OH)_3\cdot H_2O]_n$ (double-chain) **2** with novel one-dimensional polymeric cluster anions and two-dimensional network hydrogen-bonding cations and its precursor $[WS_4Ag\cdot NH_3C(CH_2OH)_3\cdot 2DMF]_n$ (single-chain) **1** are reported [10], additionally, the inversion of configuration from **1** to **2** is described.

EXPERIMENTAL

All manipulations were carried out in air. $(NH_4)_2WS_4$ was synthesized according to the literature [11]. The other chemicals were used as purchased. Elemental analyses were performed by the Elemental

* Author to whom correspondence should be addressed.

Analysis Laboratories of our Institute. IR spectra were recorded on a Nicolet Magna 750 FT-IR spectrometer.

Preparation of $[WS_4Ag \cdot NH_3C(CH_2OH)_3 \cdot 2DMF]_n$ **(1)**

$AgNO_3$ (0.34 g, 2 mmol) and $NH_2C(CH_2OH)_3$ (0.12 g, 1 mmol) were dissolved in 10 cm^3 of DMF. To this solution was added a solution of $(NH_4)_2WS_4$ (0.35 g, 1 mmol) in 10 cm^3 of DMF, and then the dark precipitate was filtered off. After 3 days, 0.39 g of orange crystals of **1** were obtained by allowing Et_2O vapor to diffuse into the orange–red filtrate. Found: C, 17.9; H, 3.9; N, 6.3; S, 18.4; W, 26.4. Calc: C, 17.5; H, 3.8; N, 6.1; S, 18.6; W, 26.7%. IR (KBr pellet, cm^{-1}), W-μ_2-S 439.7.

Preparation of $[WS_4Ag \cdot NH_3C(CH_2OH)_3 \cdot H_2O]_n$ **(2)**

The complex **2** was the only product of recrystallization of **1** in EtOH containing a little water. Several drops of water were added to a solution of **1** (0.40 g, 0.58 mmol) in 20 cm^3 of EtOH. Dark-red crystals of **2** (0.27 g, 0.48 mmol) were obtained by allowing the solution to stand in air for 3 days. Found: C, 8.7; H, 2.6; N, 2.4; S, 22.5; W, 32.5. Calc: C, 8.6; H, 2.5; N, 2.5; S, 22.9; W, 32.8%. IR (KBr pellet, cm^{-1}), W-μ_2-S 445.5 and 476.4.

Crystal structure determination

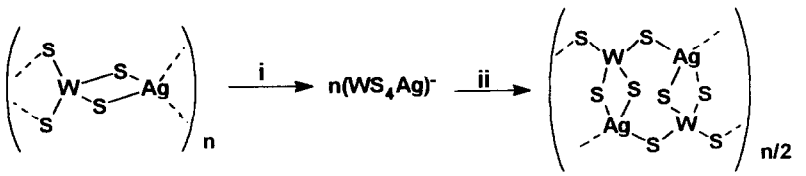
Crystals of **1** were selected and enveloped with epoxide resin, and as with the selected crystals of **2** were mounted on glass fibers for single-crystal X-ray diffraction experiments. The crystallographic and machine data are given in Table 1. Diffraction data were collected on a RIGAKU AFC-5R diffractometer for both complexes by use of Mo-K_α radiation ($\lambda = 0.71069$ Å) at room temperature. Cell constants and orientation matrices were obtained from least-squares by using setting angles of 20 reflections for **1** and **2** in the range $12 < 2\theta < 50°$. Intensities were corrected for polarization and Lorentz factors and for absorption by using empirical psi-scan data and the method of Walker and Stuart (DIFABS) [12].

The structures were solved by direct method using MULTAN, and the positions of two heavy atoms were obtained from E-map. The remaining non-hydrogen atoms were located from difference Fourier map. No attempt was made to locate hydrogen atoms for either structural determination. In complex **1**, oxygen atoms of two DMF groups are disordered, and these two DMF groups and the $NH_3C(CH_2OH)_3^+$ cation were rigidly refined. The direction of the polar axis (z) was determined using the Rogers method for **1** [13]. The refinement of structures of both complexes was performed by full-matrix least-squares techniques using the MolEN program package [14]. Metal and sulfur atoms were refined anistropically for both complexes. All calculations were carried out on a COMPAQ PROLINEA 4/50 computer. Atomic scattering factors were taken from [15].

RESULTS AND DISCUSSION

The reactions involved in the synthesis of **1** have shown that tris(hydroxy-methyl)-amino-methane can somewhat retard the formation of the dark precipitate of AgS and can be conducive to the stability of the linear chain $[WAgS_4]_n$.

The inversion of configuration between two polymeric chalcogenides is very rare. Hydrogen bonding is undoubtedly the driving force of the inversion of configuration from **1** to **2** (see Scheme 1). When water was added to the solution of **1** in EtOH, strong hydrogen-bonding interaction occurred between H_2O molecules and $NH_3C(CH_2OH)_3^+$ cations. Water and this hydrogen-bonding interaction can cause the linear chains $[WAgS_4]_n$ to be decomposed into $[WAgS_4]^-$ fragments. The supramolecular cationic structure formed through hydrogen bonding can affect a re-self-assembly of these anionic fragments, on the other hand, the latter can also drive the former to transform from the disordered state to the ordered state. Both of them interact with each other; finally, the novel double-chain polymeric cluster anions, as well as two-dimensional network hydrogen-bonding cations, were formed and crystallized from the solution. The attempt to synthesize the isomorphous molybdenum complex of **2** was unsuccessful.



The structure of a portion of the anion of **1** is shown in Fig. 1. Selected geometric parameters of **1** are listed in Table 2. In this linear anion chain, the arrangement of the metal atoms (W, Ag) is almost linear with the bond angles of W—Ag—W(c) and Ag—W—Ag(a) being 176.4(5) and 176.4(3)°, respectively. The W atom retains its tetrahedral coordination by four sulfur atoms as in WS_4^{2-}. The Ag atom attached to the WS_4 moiety displays a distorted tetrahedron [94.1(4)–119.1(9)°]. The AgS_2W units are planar, and neighboring ones perpendicular to each other along this polymeric chain. The average W—Ag distance of 2.931 Å in complex **1** is shorter than the corresponding values in discrete molecules, such as 2.971 Å in $[WS_4Ag_2(PPh_3)_3 \cdot 0.8CH_2Cl_2]$ [16], 2.997 Å in $[Ag_4W_2S_8(PPh_3)_4]$ [17] and 3.080 Å in $[WS_4Ag_3(PPh_3)_3(S_2P(OCH_2CH_3)_2]$ [18], and also shorter than the value in a similar polymeric linear-chain complex $[AgWS_4 \cdot 4\text{-MePyH}]_n$ [9c] (2.949 Å).

As shown in Fig. 2, the anionic structure of **2** can be viewed as two zigzag —SWSAg— chains bridged by μ_2-S atoms. Selected geometric parameters of **2** are listed in Table 3. Each metal atom is coordinated by four μ_2-S atoms with an approximate tetrahedral geometry, but the coordination geometry of Ag atoms is more distorted with bond angles varying from

92.1(2) to 126.7(2)°. The average W—S and Ag—S distances are 2.204 and 2.565 Å, respectively, similar to those in other complexes, such as 2.22 and 2.52 Å in **1** and 2.206 and 2.533 Å in $[AgWS_4 \cdot 4\text{-MePyH}]_n$ [9c], the W—Ag distance of 2.980(2) Å can be comparable with those of 2.971 Å in $[(PPh_3)_3Ag_2WS_4 \cdot 0.8CH_2Cl_2]$ [16], 2.997 Å in $[Ag_4W_2S_8(PPh_3)_4]$ [17] and 3.080 Å in $[WS_4Ag_3(PPh_3)_3(S_2P(OCH_2CH_3)_2$ [18], but longer than those values found in linear chain polymeric complexes, such as 2.931 Å in **1** and 2.949 Å in $[AgWS_4 \cdot 4\text{-MePyH}]_n$ [9c]. The crystal structure determination shows that μ_2-S atoms in complex **2** are in two different environments, this is also reflected in the split of the ν(W-μ_2-S) IR stretching vibration peak (IR spectrum: ν(W—μ_2-S) 476.4 and 445.5 cm^{-1}).

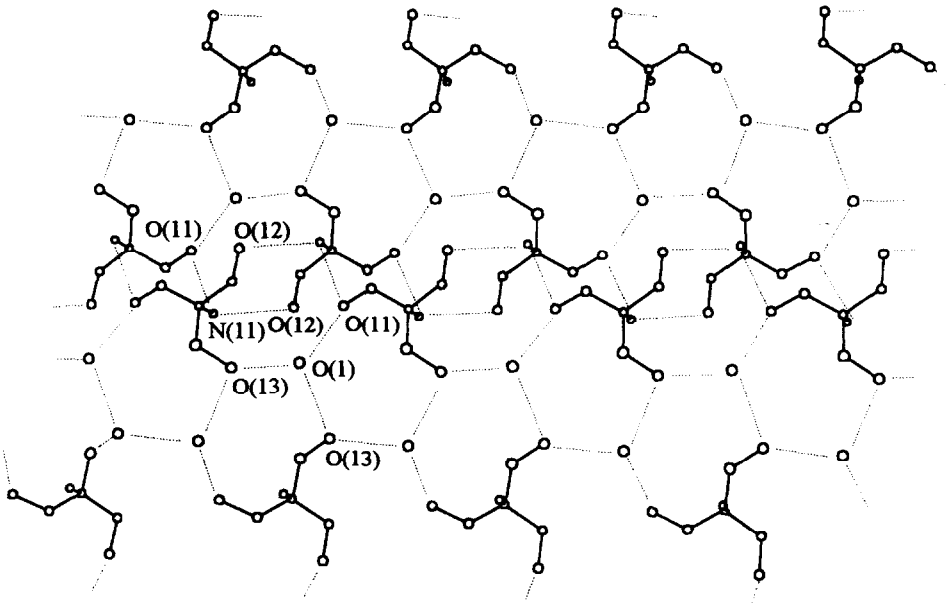

Fig. 3. A portion of two-dimensional network hydrogen-bonding cationic structure of **2**.

gen-bonding supramolecular cationic structure is shown in Fig. 3. Corresponding with the synthetic phenomena, water molecules play a crucial role in the network hydrogen-bonding structure. Hydrogen bond distances and angles are listed in Table 4. Through hydrogen bonding, H_2O groups bridge three neighboring $NH_3C(CH_2OH)_3^+$ cations. The distances of O(1)···O(11), O(1)···O(13a) and O(1)···O(13b) are 2.70, 2.73 and 2.83 Å, respectively, and the angles of O(11)···O(1)···O(13a), O(11)···O(1)···O(13b) and O(13b)···O(1)···O(13b) are 108, 119 and 106°, respectively. Similarly, a $NH_3C(CH_2OH)_3^+$ cation, acts as a μ_2 bridge between two neighboring $NH_3C(CH_2OH)_3^+$ cations. The distances of N(11)···O(11c) and N(11)···O(12d) are both 2.86 Å, and the angles of O(11c)···N(11)···O(12d) is 96°. This kind of hydrogen bonding structure is conducive to the stability of the complex **2**. The packing drawing of complex **2** is shown in Fig. 4. The polymeric double-chain cluster anions are arrayed between two cationic hydrogen-bonding "walls".

In the 3000–3500 cm^{-1} region of the IR spectra, both complexes display complicated absorption bands of N—H and O—H stretching vibrations. The very strong absorption bands in the spectra of **1** at 1668 and 1645 cm^{-1} are dominated by C=O double-bond stretching vibration; additionally, the strong single absorption peak at 440 cm^{-1} can be attributed to W—μ_2—S absorption vibration. Although sulfur atoms of complex **2** are all μ_2-S atoms, they are in two different environments according to the crystal structure determinations; so the W—μ_2—S absorption vibration of **2** appears in two different positions, 476 and 445 cm^{-1}.

(Received 13 February 1996; accepted 3 June 1996)

Abstract—A new tris(phenoxy oxygen) bridged bicadmium(II) polyaza cryptate has been synthesized by [2 + 3] Schiff-base condensation of tris(3-aminopropyl)amine with sodium 2,6-diformyl-4-methylphenolate in the presence of $Cd(ClO_4)_2 \cdot 6H_2O$. The crystal structure, characterization of spectra and molar conductivity shows that two cadmium(II) atoms were bridged by three phenoxy oxygen atoms. Each cadmium(II) located in a seven coordination environment (N_4O_3). The coordination geometry around the Cd^{II} is a capped distorted octahedron. Copyright © 1996 Elsevier Science Ltd

Keywords: cadmium(II); cryptate; crystal structure; polyaza; binuclear; phenoxy oxygen bridge.

Pilkington and Robson [1] obtained a new kind of macrocyclic ligand in 1970 by template condensation of 2,6-diformyl-4-methylphenol with diamines. They have strong donors, namely, phenoxy oxygen atoms as well as amine nitrogen atoms, therefore they played excellent roles in catalysis and biological simulation [2,6] for their special coordination ability with transition metal ions. Recently Gagne [7], Nelson [8] and others [9] synthesized successfully several transition metal cryptates with interesting structures by [2 + 3] Schiff base condensation of tris(3-aminoethyl)amine (tren) with 2,6-diformyl-4-methylphenol (dmp). But so far few reports have been made of cryptates synthesized by condensation of corresponding aldehydes with tris(3-aminopropyl)amine (trpn, the analogue of tren). The cryptates synthesized by using trpn are expected to be more versatile in host–guest properties for flexible long chain of trpn. We have obtained the first penta-nuclear silver(I) cluster [10] by condensation of trpn with dmp in the presence of silver(I). In this paper we report the synthesis, characterization and X-ray crystal structure of the μ-oxo ligand binuclear cadmium(II) cryptate (Fig. 1).

EXPERIMENTAL

Materials

2,6-Diformyl-4-methylphenol (dmp) was prepared using the method described by literature [11]. Sodium 2,6-diformyl-4-methylphenolate was obtained by mixing equimolar amounts of dmp and NaOH in ethanol. Tris(3-aminopropyl)amine was prepared by a modified literature method [12] with a purity of over 99%. All starting materials were of chemical purity.

Physical measurements

Solution electrical conductivity was measured by a BDS-A numerical conductometer (Jiangsu, China) with solution concentrations of $\sim 10^{-4}$ mol dm^{-3} in acetonitrile. IR spectra were measured as KBr discs using a Nicolet 5DX FT-IR spectrophotometer. Electronic spectra were recorded on a Shimadzu UV-240 spectrophotometer.

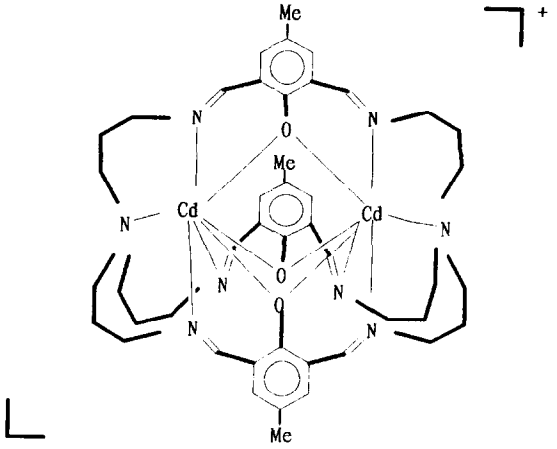

Fig. 1. The structure of the cryptate cation $[Cd_2H_{-3}L]^+$.

Preparation of cryptate

$[Cd_2H_{-3}L]ClO_4 \cdot 2CH_3OH$. To a stirred solution of sodium 2,6-diformyl-4-methylphenolate (0.1395 g, 0.75 mmol) and $Cd(ClO_4) \cdot 6H_2O$ (0.262 g, 0.625 mmol) in 30 cm^3 absolute methanol was added dropwise a solution of tris(3-aminopropyl)amine (0.094 g, 0.5 mmol) in 15 cm^3 absolute methanol at 0°C. After stirring for 2 h at 35°C, the yellowish microcrystals were precipitated and filtered off, washed with methanol and dried *in vacuo*, yield 65%. Found: C, 49.7; H, 5.3; N, 9.6; Cd, 19.3. Calc. for $C_{47}H_{65}N_8O_9ClCd_2$: C, 49.2; H, 5.7; N, 9.8; Cd, 19.6%. IR (cm^{-1}, KBr): 3452(br, ν(OH)(CH_3OH)); 1631(s, ν(C=N)); 1539(s, ν(Ar·O)); 1089(ClO_4). UV–vis (λ_{max}(nm), CH_3CN) 240(28000 mol^{-1} dm^3 cm^{-1}); 430(1×10^5). Λ_M(CH_3CN, 301 K) 100 S cm^2 mol^{-1}. The yellowish crystals $[Cd_2(H_{-3}L)]ClO_4$ suitable for X-ray structure determination were obtained by slow evaporation of the mother liquor at ambient temperature.

CAUTION. Perchlorate salts of metal complexes with organic ligands are potentially explosive. Only small amounts of material should be prepared, and these should be handled with caution. The complexes described in this report have, so far, been found to be safe when used in small quantities.

X-ray crystal structure determination of $[Cd_2(H_{-3}L)]ClO_4$

Crystal data

$C_{45}H_{57}N_8O_7ClCd_2$, M = 1082.27, yellowish plate crystal, dimensions $0.9 \times 0.15 \times 0.05$ mm, monoclinic, space group $P2_1/n$(#14), a = 15.847(0), b = 15.891(0), c = 18.058(0) Å, β = 95.24(0)°, V = 4528.41(0) Å^3, F(000) = 2220, Z = 4, D_c = 1.59 g cm^{-3}, T = 296 K, μ = 10.52 cm^{-1}.

Data collection and refinement of the crystal structure

A single crystal of dimensions $0.9 \times 0.15 \times 0.05$ mm was mounted on a glass fibre. The diffraction data were collected on an Enraf-Nonius CAD4 four-cycle diffractometer with graphite-monochromated Mo-K_α radiation (λ = 71069 Å) using an ω-2θ scan mode with ω scan width $0.65 + 0.350 \tan\theta$, scan rate 5.49° min^{-1}; a total of 7459 independent reflections were collected in the range $2 < 2\theta < 48°$, of which 4245 reflections with $I > 3\sigma(I)$ were used in the structure determination and refinement after Lp corrections. The structure was solved by the directed methods program MITHRIL. The remaining non-hydrogen atoms were located from a difference Fourier map. Hydrogen atoms were introduced in calculated position but not refined. The final least-square cycle gave R = 0.068, Rw = 0.078 ($w = 1/\sigma^2(F_o)$). The maximum and minimum residuals had heights of 1.08 e Å^{-3} and −1.34 e Å^{-3}. All calculations were performed using the programs contained in the TEXSAN package.

RESULTS AND DISCUSSION

Characterization of the cryptate

In the infrared spectrum a strong peak appears at 1630 cm^{-1} corresponding to the stretching vibration of imino C=N bonds, but shows no symmetric or unsymmetric stretching frequencies (3280 and 3330 cm^{-1}) for the NH_2 groups, nor of the strong peaks at 1650–1700 cm^{-1} for the carbonyl groups. This means that all the NH_2 and CO groups have been condensed into C=N bonds. A broad band at *ca* 3400 cm^{-1} characteristic of the OH group of CH_3OH showed that methanol molecules exist in the crystal of the cryptate, in agreement with elemental analysis, but are lost during the growth of the single crystal for X-ray structure determination. The strong peak at 1090 cm^{-1} without splitting showed that ClO_4^- does not take part in coordination with the Cd^{II} atom. This is also confirmed by molar conductivity of the cryptate (Λ_M = 100 S cm^2 mol^{-1}) which is attributable to 1 : 1 electrolyte. Two intense absorptions in electronic spectrum of the cryptate are designated to π–π^* transitions of the K band of the benzene rings and of C=N groups.

Description of the structure of $[Cd_2H_{-3}L]ClO_4$

A perspective view of cation $[Cd_2H_{-3}L]^+$ and a packing diagram are displayed in Figs 2 and 3, respectively. The selected bond distances and bond angles are given in Tables 1 and 2, respectively.

Figures 2 and 3 show that each unit cell contains four molecules of cryptates and each molecule of cryptate consists of complex cation $[Cd_2H_{-3}L]^+$ and one

amine nitrogen N(1) is the capping atom. Three phenoxy oxygen atoms act as the bridges between Cd(1) and Cd(2). The least square planes 1, 2 or 3 consist of Cd(1), Cd(2) and O(1), O(2) or O(3), respectively. The dihedral angles between planes 1 and 2, 1 and 3 or 2 and 3 are 110.51, 119.85 and 129.64°, respectively. Cd(2) is similar to Cd(1) in coordination environment but slightly different to Cd(1) in distortion degree of the capped octahedron. The bond distances of Cd(1)—N(imine) and Cd(2)—N(imine) are in the range of 2.32–2.41 Å. Six bond distances between two Cd atoms and three phenoxy oxygen atoms are in the range of 2.25–2.40 Å, among them the bond distances of Cd(1) are approximate to those of Cd(2). This range of the bond lengths of Cd—μ—Oph is close to those reported by Drew *et al.* [8]. The bond distances of Cd(1)—N(1) and of Cd(2)—N(4) are 2.60 and 2.65 Å, respectively, implying weak interaction between Cd atoms and bridgehead nitrogen atoms. But in a similar cadmium cryptate synthesized by condensation of tren with dmp, the corresponding bond distance of Cd—N (bridgehead) is 2.787 Å [8], quite larger than that reported in this paper. In addition, the distance between Cd(1) and Cd(2), 3.472 Å, is larger than that of corresponding cryptate of tren (3.436 Å), this is due to the lengthening of carbon chain enlarging the cavity of the cryptate. However the flexibility of carbon chain strengthens the coordination ability of bridgehead nitrogen atoms and thus stabilizes the structure of cryptate.

A novel structure arrangement of molybdenum dimethylglyoxime complexes. Compounds with $MoON_2C_2$ six-membered rings

R. M. Ramadan,* M. S. A. Hamza and A. S. Attia

Chemistry Department, Faculty of Science, Ain Shams University, Cairo, Egypt

(Received 2 February 1996; accepted 3 June 1996)

Abstract—Thermal reactions of $Mo(CO)_6$ with dimethylglyoxime (H_2DMG) in THF solutions, either in vacuum or under atmospheric pressure, gave three compounds with formulae $Mo(H_2DMG)_3$, **I**, $Mo_2O_6(H_2DMG)_2$, **II** and $Mo_2O_4(CO)_2(H_2DMG)_2$ **III**. Spectroscopic studies of these complexes revealed that H_2DMG is bonded to the molybdenum through the nitrogen atom of one oxime moiety and the oxygen of the other moiety. The hydrogen atom of the latter oxime was transferred to the nitrogen of the same group to form an NH group. ^1H NMR studies of compounds **II** and **III** at various temperatures showed that the hydrogen atom of this NH group was rigid on the NMR time scale while the hydrogen atom of the other oxime was fluxional. A mechanism involving terminal-bridge CO and O exchange was proposed to explain the stereochemical nonrigidity of these complexes. Appearance of a resonance at about 7.1 ppm in the ^1H NMR spectra of **II** and **III** due to a deshielded CH proton suggested some sort of aromaticity in these six membered chelates. Copyright © 1996 Elsevier Science Ltd

Keywords: dimethylglyoxime; molybdenum; coordination isomers; stereochemical nonrigidity; spectra; ligands.

Trans-bis (dimethylglyoximato) metal complexes have been known for many years [1]. They presented excellent models for many important species in biology [2]. However, investigation of other dimethylglyoxime complexes such as tris(dimethylglyoximates) and dinuclear metal complexes were not performed until recently [3–5]. Our interest in the chemistry of molybdenum complexes containing chelates with oxygen and nitrogen donors [6,7] has prompted us to investigate the reactions of molybdenum hexacarbonyl with dimethylglyoxime. It was expected that dimethylglyoxime would bind to the molybdenum atom from the two nitrogen atoms of the oxime moieties. However, different structural features were observed in this study. Also, the complexes reported here represent unique examples of the stereochemical non-rigidity of the —NOH proton.

EXPERIMENTAL

Materials

Molybdenum hexacarbonyl, $Mo(CO)_6$ and dimethylglyoxime (H_2DMG) were supplied from Aldrich Chemical Co., Inc.

Complex syntheses

$Mo_2O_4(CO)_2(H_2DMG)_2$. $Mo(CO)_6$ (0.1 g, 0.38 mmol) and H_2DMG (0.05 g, 0.43 mmol) were mixed together in a sealed tube containing ~20 cm^3 of tetrahydrofuran solvent. The mixture was degassed with one freeze–thaw cycle and then heated for 24 h at 80°C. The colour of the solution was changed to brown. The reaction mixture was cooled and the solvent was removed on a vacuum line. The brown residue left was washed several times with boiling petroleum ether (60–80). The complex was then recrystallized from THF to yield brown crystals (yield

56%). The complex was left to dry *in vacuo* for ~3 h. The compound was found to be air stable.

$Mo(H_2DMG)_3$ *and* $Mo_2O_6(H_2DMG)_2$. A mixture of $Mo(CO)_6$ (0.13 g, 0.49 mmol) and H_2DMG (0.08 g, 0.69 mmol) in about 30 cm^3 THF was heated to reflux under atmospheric pressure for 2 days. The colour of the reaction mixture was changed to brown and a dark brown solid was isolated. The reaction mixture was then cooled and the dark brown precipitate was separated by filtration. The isolated residue was purified by boiling it several times with tetrahydrofuran followed by washing with hot petroleum ether. The complex was recrystallized from dimethylformamide to give the dark brown compound $Mo_2O_6(H_2DMG)_2$. The complex was left to dry on a vacuum line (yield 38%) and it was found to be air stable.

From the brown filtrate of the reaction mixture, the solvent was removed on a vacuum line to yield a brown residue. The residue was washed several times with boiling petroleum ether and then recrystallized from THF. The brown crystals, $Mo(H_2DMG)_3$, were dried on a vacuum line. The complex (yield 46%) was found to be air stable.

Physical measurements

The IR measurements were carried out on a Unicam-Mattson 1000 FT-IR spectrometer with the use of KBr discs. UV–vis measurements were performed on a Perkin-Elmer Lambda 4β spectrophotometer with the use of 10 mm quartz cells. Samples of concentrations *ca* 1×10^{-6} M in dimethylsulfoxide (DMSO) were measured against the solvent in the reference cell. NMR measurements were performed on a Bruker AC300 MHz spectrometer. The samples were dissolved in DMSO-d_6 using tetramethylsilane (TMS) as internal reference. Besides the spectroscopic studies, all the complexes were characterized by elemental analysis and mass spectroscopy. The data are given in Tables 1–3.

RESULTS AND DISCUSSION

Reaction of molybdenum hexacarbonyl with dimethylglyoxime under atmospheric pressure, yielded the tris-derivative $Mo(H_2DMG)_3$ as well as the dinuclear complex $Mo_2O_6(H_2DMG)_2$ (eq. (1)). On the other hand, reaction of $Mo(CO)_6$ and H_2DMG *in vacuo* resulted in the formation of only one product, $Mo_2O_4(CO)_2(H_2DMG)_2$ (eq. (2)).

$$Mo(CO)_6 + H_2DMG \xrightarrow{\text{reflux in air}} \underset{\mathbf{I}}{Mo(H_2DMG)_3} + \underset{\mathbf{II}}{Mo_2O_6(H_2DMG)_2} \quad (1)$$

$$Mo(CO)_6 + H_2DMG \xrightarrow{\text{vacuum}} \underset{\mathbf{III}}{Mo_2O_4(CO)_2(H_2DMG)_2} \quad (2)$$

Table 3. The UV–vis data for dimethylglyoxime and its molybdenum complexes in dimethylsulfoxide solvent

Compound	λ (nm)
H_2DMG	270
$Mo(H_2DMG)_3$	271, 483[a]
$Mo_2O_6(H_2DMG)_2$	263, 528[a]
$Mo_2O_4(CO)_2(H_2DMG)_2$	264, 300, 385, 459

[a] Broad.

Dimethylglyoxime exists in isomeric oxime and nitroso forms. Thus, its IR spectrum shows stretching frequencies due to free and bonding OH, NH and N=O bonds. The IR spectrum of the tris product, $Mo(H_2DMG)_3$, shows an almost identical pattern as that of dimethylglyoxime itself (Fig. 1). On the other hand, the vibrational spectra of $Mo_2O_6(H_2DMG)_2$ and $Mo_2O_4(CO)_2(H_2DMG)_2$ complexes are completely different from that of H_2DMG (Fig. 2). However, it is interesting that all the three molybdenum complexes display frequencies in the IR

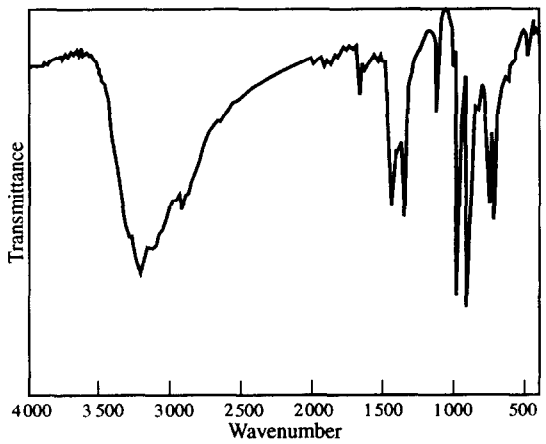

Fig. 1. The IR spectrum of $Mo(H_2DMG)_3$ complex.

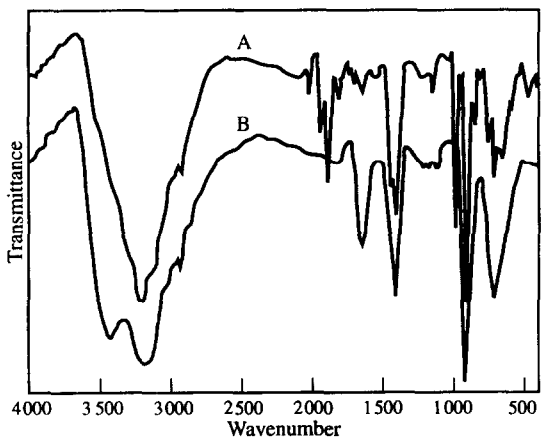

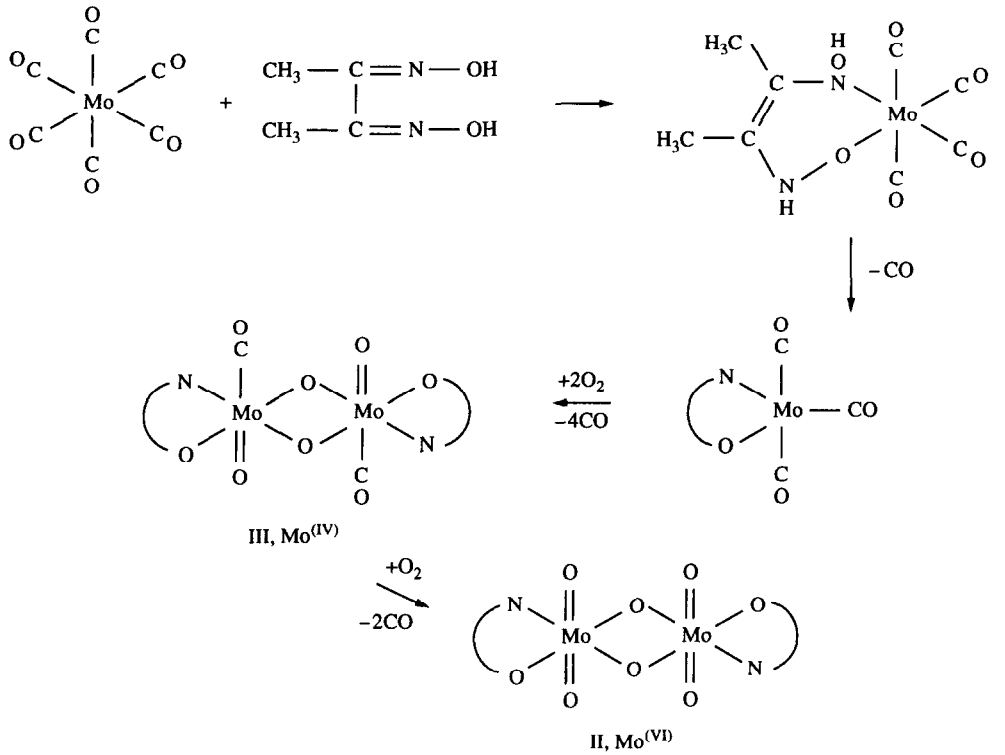

Fig. 2. The IR spectrum of (A) $Mo_2O_4(CO)_2(H_2DMG)_2$ complex, and (B) $Mo_2O_6(H_2DMG)_2$ complex.

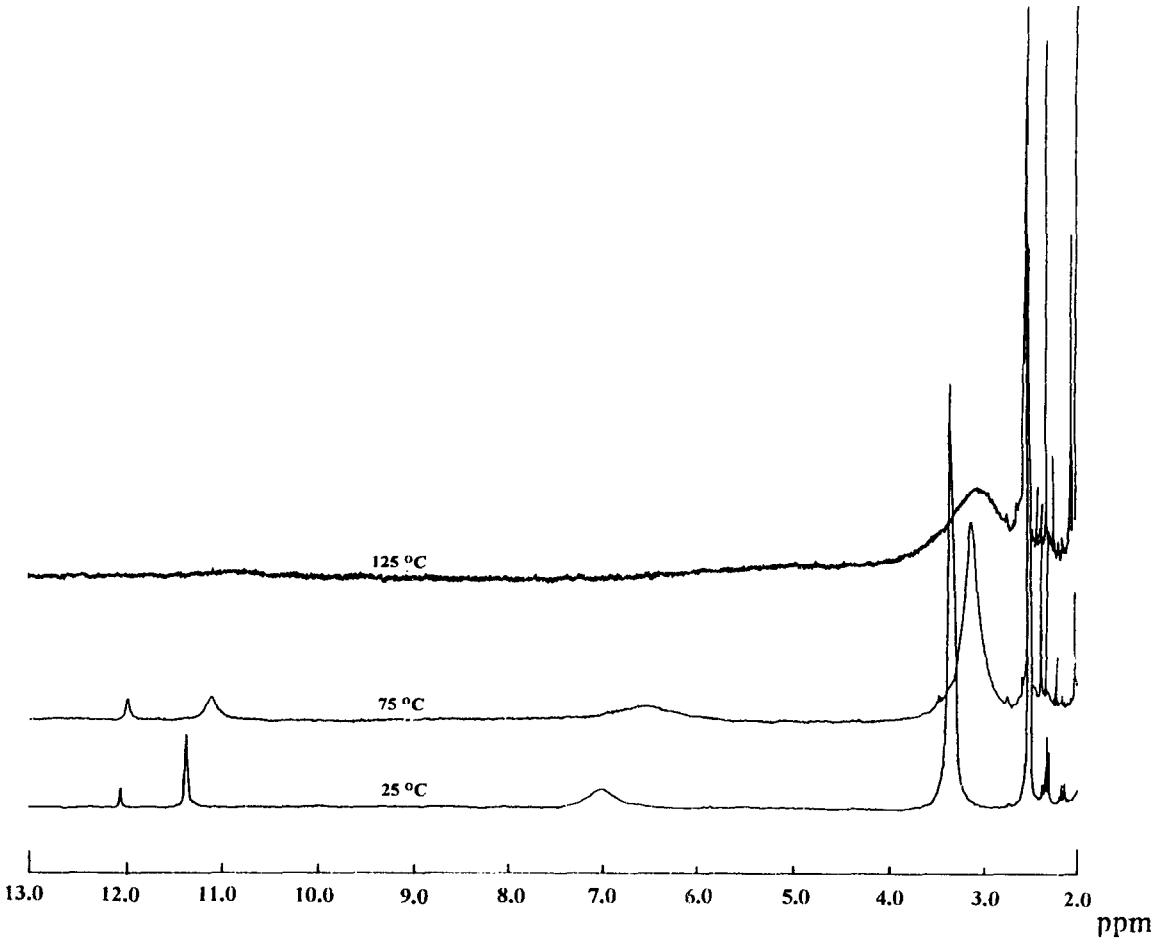
spectra due to ν_{NH} bonds (Table 2). It was expected that this ν_{NH} band of H_2DMG would disappear from the spectra of the complexes. Therefore, the presence of these NH bands, which are also confirmed by ^1H NMR (*vide infra*), suggests that the bonding between the molybdenum atom and H_2DMG is from a nitrogen atom of one oxime group and the oxygen atom of the other group to form a chelate of a six membered ring. This unusual bonding for dimethylglyoxime was only observed previously in the dinuclear copper complex $Cu_2(DMG)(HDMG)(H_2DMG)$ where the dimethylglyoximato (DMG) moiety bridged the two copper atoms from an oxygen atom [5]. On the contrary, the crystal structure of the *tris*-(dimethylglyoxime)ruthenium(II) dichloride has shown that the ruthenium atom is bonded to H_2DMG from the two nitrogen atoms [6]. However, the unusual bonding observed here may be attributed to the larger size of the molybdenum with respect to that of ruthenium. Dimethylglyoxime as well as its three molybdenum complexes all showed bands due to free and bonded OH groups (Table 2). Also, the $Mo_2O_4(CO)_2(H_2DMG)_2$ showed four CO frequencies in the terminal and bridging metal carbonyl regions confirming the presence of the complex in two isomeric forms with terminal and bridged CO groups. We were unable to separate these two isomers. They may exist in equilibrium even in the solid state. Some bands due to terminal Mo=O and bridged Mo—O—Mo bonds were detected from the IR spectra of the two complexes $Mo_2O_6(H_2DMG)_2$ and $Mo_2O_4(CO)_2(H_2DMG)_2$, Table 2. It is interesting to speculate that the latter two complexes were prepared through the intermediate $Mo(CO)_3(H_2DMG)$. Reaction of oxygen with such intermediate would result in the formation of the products [6], Scheme 1.

Investigation of the molybdenum dimethylglyoxime complexes by ^1H NMR showed dramatic changes in the spectra. The ^1H NMR spectrum of $Mo(H_2DMG)_3$ in DMSO-d_6 displayed, besides the resonance of the methyl groups, two singlets at 3.36 and 11.37 ppm due to the protons of the NH and OH groups. The signal due to NH group was slightly broadened which is usual for a hydrogen atom bonded to a nitrogen atom (^{14}N, $I = 1$). The resonance of OH was sharp and occurred within the range for partially hydrogen-bonded OH of aromatic systems [8]. The proton NMR spectra of both $Mo_2O_6(H_2DMG)_2$ and $Mo_2O_4(CO)_2(H_2DMG)_2$ showed in addition to those signals, a broad signal at about 7.2 ppm. The $Mo_2O_4(CO)_2(H_2DMG)_2$ also showed a singlet due to a free OH at 12.06 ppm with a ratio of 1 : 5 to that of the 11.37 ppm signal (Fig. 3). This set of signals of free and bonded OH groups suggested the existence of two isomers for this complex in solution with the one having free OH groups representing about 20% abundance. Interestingly, heating the solutions of either $Mo_2O_6(H_2DMG)_2$ or $Mo_2O_4(CO)_2(H_2DMG)_2$ at 75°C resulted in broadening of all the signals. Further heating to 125°C led the signals at 12.06, 7.02 and

Scheme 1



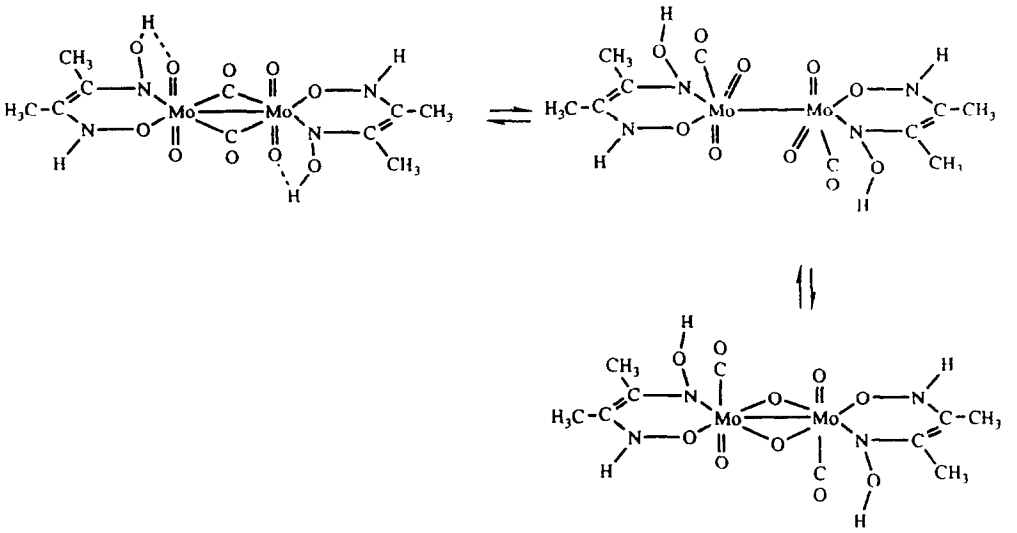


Fig. 3. The ^{1}H NMR spectra of $Mo_2O_4(CO)_2(H_2DMG)_2$ at various temperatures.

Scheme 2

11.37 ppm of the $Mo_2O_4(CO)_2(H_2DMG)_2$ to collapse into the base line (Fig. 3). It is noteworthy that the signal at 3.34 ppm due to the proton of NH group was still present in the spectrum. Thus, the proton of this group was rigid at this temperature on the NMR time scale. Unfortunately, we could not obtain ^1H NMR spectra at higher temperatures to detect the average signal due to decomposition of the complexes. Therefore, this fluxional behaviour of these two complexes indicated that the protons of the free and bonded OH groups were exchangeable. Also, the presence of a broad band around 7.1 ppm (a strong deshielded CH proton) may indicate that the OH proton transferred to one of the carbon atoms in the six membered chelate. The presence of such signal as well as the appearance of the OH signals around 11.3–12.0 ppm may imply aromaticity in the six membered ring formed. Contribution of the lone pairs of the nitrogen and oxygen atoms with the odd electron in the p_z of each carbon atom along with an appropriate $d\pi$ orbital from the molybdenum atom may be responsible for such aromaticity [9].

A mechanism is proposed to explain the stereochemical non-rigidity of these complexes, Scheme 2. Such a mechanism has several attractive features: it permits the other ligands such as O or CO to be involved in the exchange. Such an intermediate could allow carbonyl exchange to occur by a terminal-bridge mechanism. It also provides a pathway by which the OH proton can transfer to a carbon atom of the six membered ring.

The electronic absorption spectrum of dimethylglyoxime in DMSO showed only a single absorption band in the UV range at 270 nm. This band hardly changed in the case of the tris derivative $Mo(H_2DMG)_3$. However, hypsochromic shifts of this band were observed in the spectra of the other two complexes, $Mo_2O_6(H_2DMG)_2$ and $Mo_2O_4(CO)_2(H_2DMG)_2$, (Table 3). In addition, the UV–vis spectra of all the three complexes displayed visible bands due to the n–π^* transitions. Furthermore, the $Mo_2O_4(CO)_2(H_2DMG)_2$ complex illustrated another visible band confirmed the existence of this complex in two isomeric forms (Table 3).

(Received 25 April 1996; accepted 28 May 1996)

Abstract—Two mixed ligand complexes of picolinic acid and cadmium(II) azide or thiocyanate, namely catena-μ(1,1)-azido-μ(N,O,O,O′-picolinato)cadmium(II) (**1**) and catena μ(N,S)-thiocyanato-μ(N,O,O,O′-picolinato)cadmium(II) (**2**) have been prepared and characterized by spectroscopic and X-ray crystallographic methods. The coordination environment of the cadmium(II) atom in complex **1** is a distorted octahedron. Each metal atom is chelated by a picolinato anion via its ring nitrogen N(1) [Cd—N = 2.356(6) Å] and a carboxylate oxygen atom O(1). O(1) is further coordinated to another cadmium atom to form cyclic Cd_2O_2 units [Cd—O = 2.327(5) and 2.459(5) Å]. O(2) links a third metal centre. The cyclic Cd_2O_2 units are connected by μ(1,1) bridging azido groups to form sheets of polyhedra which are arranged normal to the long *c*-axis of the unit cell. Complex **2** features distorted octahedral cadmium atoms, N,O,O,O′-tetradentate chelating bridging picolinato anions, μ(N,S) bridging thiocyanato ligands and one-dimensional chains of polyhedra which are oriented along the *b*-axis of the monoclinic unit cell. The IR and Raman spectra are also reported and correlated with the structures of the complexes. The vibrational bands of diagnostic value are compared to the values of the free acid. Keywords: cadmium complexes; X-ray structure analysis; thiocyanate; azide; picolinato complexes; vibrational spectroscopy.

Picolinic acid (pic-H), also called pyridine-2-carboxylic acid, and its derivatives have a broad spectrum of physiological effects on the activity functions of both animal and plant organisms which are attributed to their ability to form complexes with transition metals [1]. This acid may function as a neutral ligand as found in the structures of $[K(pic\text{-}H)_2(H_2O)_2][AuBr_4]\cdot(pic\text{-}H)_2$ [2], and $Ag(C_5H_4NCO_2H_{1/2})\cdot H_2O$ [3], or as a picolinate anion [4–9]. The picolinate anion may act as a N,O-bidentate chelating ligand as found in the structure of $[Mg(pic)_2(H_2O)_2]\cdot 2H_2O$ [6] or as a N,O,O′-tridentate chelating bridging ligand, coordinating *via* the ring nitrogen and the two carboxylate oxygen atoms as in the structure of $[Cu(pic)_2]\cdot 2H_2O$ [10].

Recently we established that picolinic acid coexists as neutral and anionic N,O-bidentate ligands in $[Mn(pic)(pic\text{-}H)(Cl)]_2$ [11], as N,O,O-tridentate chelating bridge ligand in $[Mn(pic)(N_3)(H_2O)]_n$ [12] and as N,O,O,O′-tetradentate ligand in the structure of $[Cu(pic)Cl]_n$ [13]. Thus a substitution of one of the two picolinato anions in the parent $[M(pic)_2]$ complex by other anions, e.g. Cl^- or N_3^-, leads to new modes

* Authors to whom correspondence should be addressed.

of bonding of the picolinato anion. As the azide and thiocyanate anions are versatile ligands that can bind metals atoms in a variable manner [14–20], we used both anions to replace one of the two picolinate anions in the parent complex $[Cd(pic)_2]_n$ [7], in order to appraise the influence of these anions on the mode of bonding of each other. The synthesis and structural characterizations of the title complexes, as elucidated by spectroscopic and X-ray crystallographic methods are the subject of this paper.

EXPERIMENTAL

Picolinic acid was obtained from Aldrich and the other chemicals were of analytical grade quality.

Preparation of $[Cd(picolinato)(N_3)]_n$ *complex* (**1**)

Complex **1** was prepared by mixing 4 cm^3 of an aqueous solution of $CdCl_2$ (0.2 g, 1 mmol) and picolinic acid (0.3 g, 2.5 mmol) in 3 cm^3 ethanol. To this clear solution an aqueous solution of NaN_3 (0.13 g, 2 mmol) in 2 cm^3 distilled water was added dropwise and the solution was shaken thoroughly after each addition. The clear solution, was allowed to stand over several days to produce colourless crystals. The crystals were filtered, washed with a very little amount of ethanol, air dried and stored in a desiccator. Found: C, 26.0; H, 1.6; N, 20.4; Cd, 40.5. Calc.: C, 26.1; H, 1.5; N, 20.3; Cd, 40.6%.
CAUTION: Cadmium azides can be explosive under grinding or heating!

Preparation of $[Cd(picolinato)(NCS)]_n$ *complex* (**2**)

Complex **2** was prepared by mixing 4 cm^3 of an aqueous solution of $CdCl_2$ (0.2 g, 1 mmol) and picolinic acid (0.3 g, 2.5 mmol) in 8 cm^3 ethanol/water (1 : 1). To this clear solution an aqueous solution of KSCN (0.2 g, 2 mmol) in 3 cm^3 distilled water was added dropwise with thorough shaking. The clear solution was allowed to stand over 10 days to produce colourless crystals. Found: C, 28.8; H, 1.4; N, 9.5; Cd, 38.3. Calc.: C, 28.7; H, 1.4; N, 9.6; Cd, 38.4%.

Physical measurements

Procedures and instruments used for other physical measurements are as described previously [11].

X-ray crystallography

A modified STOE four circle diffractometer was used for single crystal X-ray measurements. Orientation matrix and lattice parameters were obtained by least-squares refinement of the diffraction data from 20 (compound **1**) and 31 (compound **2**) reflections in the 2θ range 13–25°. Intensity data were collected at 298(1) K using graphite crystal-monochromatized Mo-K_α radiation ($\lambda = 0.71069$ Å) and processed in the usual way (corrections: LP factor, absorption [21] for compound **2**, no extinction correction).

The structures were solved *via* the heavy-atom procedures and Fourier syntheses (following full-matrix least-squares, with scattering factors calculated using the data from [22]). All non-hydrogen atoms were refined with anisotropic displacement factors. Hydrogen atoms were identified in difference maps and included in the refinements with isotropic U values, but with constraints applied to the positional parameters. The programs DIFABS [21] SHELX-76 [23], SHELXS-86 [24], PLATON [25] and THE XRAY SYSTEM [26] were used for computations. Crystallographic data and processing parameters are given in Table 1, selected bond distances and bond angles in Table 2. Positional parameters, anisotropic displacement parameters, hydrogen atom coordinates, a full list of bond lengths and angles and observed and calculated structure factors have been deposited with the Editor as supplementary material; copies are available on request.

RESULTS AND DISCUSSION

The interaction between cadmium(II) ions and picolinic acid in ethanolic solution, in the presence of sodium azide or thiocyanate afforded colourless complexes (**1**) and (**2**). Both complexes have the same general formula Cd(picolinato)X, and are insoluble in many polar and non-polar solvents indicating their polymeric nature.

Figure 1 illustrates the principal structural features of the Cd(picolinato)(N_3) complex (**1**). Each cadmium atom is six-coordinated in a distorted octahedron geometry. The picolinate anion chelates a cadmium atom, Cd(1), *via* its ring nitrogen atom N(1) and a carboxylate oxygen atom O(1) to form a five-membered ring. The chelate ring deviates only 0.12 Å from planarity, the distance N(1)···O(1) is 2.719(8) Å. The oxygen atom O(1) is further coordinated to another cadmium centre, Cd(1c), to form cyclic Cd_2O_2 units. The second oxygen atom O(2) of the carboxylate group bridges a third cadmium atom Cd(1d). Thus the picolinato anion behaves as a N,O,O,O′-tetradentate chelating bridging ligand in this complex. The centrosymmetric dimeric Cd_2O_2 units are connected by $\mu(1,1)$ bridging azido groups to form sheets of polyhedra. These sheets of polyhedra are arranged normal to the long c-axis of the unit cell (Fig. 2). Conforming to the general characteristics of coordinated azides [14, 15], the $\mu(1,1)$ azido group is linear and asymmetric [angle N—N—N = 179.1(10) and N(11)—N(12) = 1.209(10)°, N(12)—N(13) = 1.132 (11) Å]. The di-$\mu(1,1)$ mode of bridging azide has previously been found in the structures of $[Cu_2(t\text{-Bupy})_4(N_3)_2]^{2+}$ [27], $[(CO)_3Mn(N_3)_3Mn(CO)_3]^-$ [28], $[Cu(2\text{-ampy})(N_3)_2(H_2O)]_2$ [29], $[Pd_2(N_3)_6]^{2-}$ [30],

[Cu(2-Bzpy)$(N_3)_2$]$_2$ [17], and [Cu(3-pic)$(N_3)_2$]$_n$ [31]. The structure of the title complex is, however, novel in that the μ(1,1) azido bridging occurs between a pair of Cd_2O_2 units rather than simply between a pair of metal atoms. The Cd—N(N_3) bond distances given in Table 2 are slightly shorter than corresponding values [2.340 to 2.350 Å] found in the structure of Cd (pyridine)$(N_3)_2$ containing only μ(1,3) bridging azides [15]. The average Cd—N(N_3) distances in previously reported crystal structures of $K_2Cd(N_3)_4$ and $KCd(N_3)_3 \cdot H_2O$ [32] are 2.37 Å; a corresponding value of 2.35(4) Å has been observed in the structure of $Tl_8Cd_3(N_3)_{14}$ [33]. All cadmium(II) centres of the latter three compounds are six-coordinated with distorted octahedral geometries.

The most notable feature of the present structure is the coordination mode of the picolinato anion. To our knowledge this type of bonding has been observed only once in the structure of [Cu(picolinato)Cl]$_n$ [13]. In this latter complex each picolinate anion serves as a tetradentate ligand: N(1) and O(2) are coordinated to the same Cu^{II} centre whereas O(1) is bonded to a neighbouring Cu(1c) centre and each O(2) is further bonded to the latter Cu(1c) giving rise to distorted tetragonal bipyramidal environments around the copper atoms.

The present structure of complex **1** differs from that found for the complex [Mn(picolinato)$(N_3(H_2O)]_n$ (**3**), although **3** contains centrosymmetric dimeric units Mn_2O_2 and distorted octahedron manganese atoms [12]. In this manganese complex the picolinate anion acts as a N,O,O-tridentate chelating bridging ligand. The dimeric units, however, are connected by μ(1,3) bridging azido ligands to form a two-dimensional layer structure along the *ab*-plane of the unit cell.

The principal structural features of complex **2** are given in Fig. 3. As in the structure of the azido complex **1**, each cadmium atom is distorted octahedrally coordinated and the picolinato anions serve as a N,O,O,O′-tetradentate chelating bridging ligand but behaving in a different manner. Whereas in complex **1** the picolinato anion is coordinated to three different cadmium centres, in complex **2** the picolinato anion is coordinated *via* N(1) and O(1) to Cd(1) forming also a chelating five-membered ring. The chelate five-membered ring deviates only 0.09 Å from planarity and the N(1)···O(1) distance is 2.679(5) Å. O(1) and O(2) are further coordinated to the Cd(1c) centre forming an additional chelating four-membered ring [deviation from planarity = 0.05 Å, O(1)···O(2) = 2.200(4) Å]. As a consequence the cadmium atoms and O(1) atoms of the picolinate anions are forming the back-bone of a zigzag chain structure oriented along the short *b*-axis of the monoclinic unit cell.

The thiocyanato groups are functioning in the μ(N,S) mode to bridge each cadmium atom with its second nearest cadmium neighbour within the zigzag chain: i.e.: Cd(1)···Cd(1b), Cd(1c)···Cd(1d), and so on (Figs 3 and 4). Two of the Cd—O bond lengths

[2.355(3) and 2.293(3) Å] in complex **2** are slightly longer than corresponding values [2.327(5) and 2.247(5) Å] in complex **1**. The Cd···Cd distances in complex 2 are 4.461(2) and 5.879(2) Å, whereas Cd···Cd distances of 3.756(1), 4.008(2) and 5.496(2) Å have been observed in complex **1**. The Cd—N(pic) distance of 2.315(6) Å in complex **2** is shorter than the Cd—N(pic) bond length [2.356(6) Å] in complex **1**. The thiocyanato ligand is linear [<NCS = 178.8(4)°]. The C—S bond length of 1.646(4) Å found in the present complex is larger than, whereas the N—C distance of 1.148(6) Å is equal to

corresponding values [1.626(9) for S—C and 1.140(11) Å for N—C] found in [Mn(H-quin)(quin)(NCS)$(H_2O)_2$] complex (H-quin is quinaldic acid) with terminal nitrogen bonded thiocyanato ligands [34].

The structure of complexes **1** and **2** differ from that of the parent complex $[Cd(picolinato)_2]_n$ (**4**), although it contains octahedrally coordinated cadmium atoms and centrosymmetric dimeric units Cd_2O_2. Complex **4**, however, contains two independent chelating picolinato anions; in one the chelating carboxylate oxygen atom bridges the second cadmium centre of the dimer, whereas in the other the non-chelating carboxylate oxygen atom bridges a neighbouring dimer

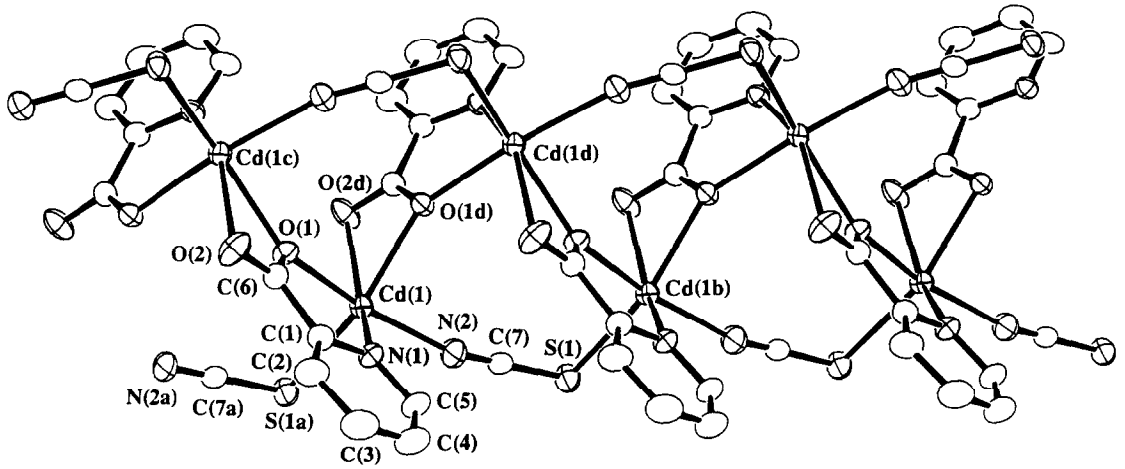

Fig. 3. The molecular geometry and atom numbering scheme of [Cd(picolinato)(NCS)]$_n$ (**2**). Symmetry code according Table 2b.

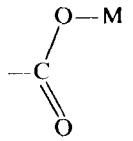
[7]. Picolinato anion was found to coexist as bi- and tetradentate ligands in the structure of the complex $[Na_2Co(pic)_2(N_3)_2(H_2O)_6][Co(pic)_2(N_3)_2]\cdot 2H_2O$ [35]. The complex anion $[Co(pic)_2(N_3)_2]^-$ contains a bidentate picolinato anion whereas the picolinate ligands in the complex cation serve as tetradentate ligands. The tetradentate picolinato anions, however, link the cobalt(II) and sodium centres, rather than two metal centres of the same type.

The room temperature IR and Raman spectra of the crystalline picolinic acid and its cadmium(II) azido and thiocyanato complexes, (**1**) and (**2**), together with tentative assignments of the bands are given in Table 3.

In the high frequency region of the spectrum of free acid where hydrogen bonding of the type (O—H···O) involving the carboxylic acid group, very broad bands centered around 3400 cm^{-1}, and hydrogen bonding of the type (O—H···N) is indicated by the presence of broad, medium strong bands near 2560, 2150 and 2050 cm^{-1}. These bands are completely absent in the spectra of both complexes. The IR and Raman spectra of free picolinic acid exhibit the following bands (cm^{-1}): 1719, 1655 (IR), 1691, 1655 (R) as [ν_{as} (COO^-)], 1307 (IR), 1302 (R) as [$\nu_s(COO^-)$], 1410 (IR), 1410 (R) as [δ(OH) in plane], 966 (IR) as [δ(OH) out of plane], 688, 680 (IR), 676 (R) as [δ(COO)] in accordance with earlier work [36,37]. Compared to the free acid, both complexes show a substantial decrease of the ν_{as}(COO) to 1635–1630 (IR) and 1635–1638 (R) and a consequent increase of the ν_s(COO) to around 1380 (IR) and 1400 (R), which are characteristic of bonding type (II) rather than (I) [38].



The vibrations related to the pyridine moiety spread over all the spectra are broad, similar to those of the pyridine itself and slightly shifted to higher wave numbers in the solid complexes. The bands at 364 and 334 cm^{-1} which appeared in the Raman spectrum of complex **1** are tentatively assigned to the ν[Cd—N(N_3)], as these bands are absent in the spectra of free acid and complex **2**. The bands around 240–200 cm^{-1} (R) are assigned to ν(Cd—N(pic)] in both complexes.

Complex **1** contains asymmetric azido groups as revealed by X-ray crystallography. As a consequence, the three vibration modes of the azide are both infrared and Raman active. The results given in Table 3 agree well with this expectation. The ν_{as} which is Raman-inactive in the symmetric azide, appears as a split band of medium intensity at 2085, 2070 cm^{-1} (R) and 2080 cm^{-1} vs, (IR), whereas the ν_s mode appears at 1340 sh, 1287 cm^{-1}, s (IR) and 1300 cm^{-1}, ms (R). The appearance of this latter mode in the IR and the former in the Raman spectrum strongly support the

asymmetric nature of the azide ligand in complex **1**. The infrared spectrum of the thiocyanato complex **2** shows a strong band at 2080 cm^{-1} due to ν(C—N) mode suggesting N-bonded thiocyanate. This result is not consistent with the X-ray structure of this complex with ν(N,S)-thiocyanate and hence two bands, above and below 2000 cm^{-1}, are expected [39]. The Raman spectrum of **2**, however, exhibits two peaks at 2125 and 2085 cm^{-1} as expected from the crystallographic result.

Molybdenum(VI) complex formation. Equilibria and thermodynamic quantities for the reactions with malate

J. J. Cruywagen,* E. A. Rohwer and R. F. van de Water†

Department of Chemistry, University of Stellenbosch, Stellenbosch 7600, South Africa

(Received 3 April 1996; accepted 28 May 1996)

Abstract—Complex formation between molybdate and malate has been investigated in the pH range 1.5–7.5 by potentiometric, spectrophotometric and enthalpimetric titrations at 25°C in 1.0 mol dm^{-3} (Na)Cl. The "best" reaction model comprises mononuclear, dinuclear and tetranuclear complexes. The formation constants of the complexes, denoted by β_{pqr}, where the subscripts p, q, and r refer to the stoichiometric coefficients in the general formula $[(MoO_4)_p(mal)_qH_r]$, have the values: log $\beta_{111} = 7.47$, log $\beta_{112} = 13.23$, log $\beta_{113} = 15.87$, log $\beta_{122} = 15.48$, log $\beta_{123} = 20.13$, log $\beta_{124} = 24.14$, log $\beta_{213} = 20.10$, log $\beta_{214} = 24.35$, log $\beta_{224} = 28.06$, log $\beta_{225} = 32.01$, log $\beta_{428} = 52.92$, log $\beta_{429} = 54.35$, log $\beta_{4210} = 55.27$, and log $\beta_{4411} = 69.92$. Enthalpy and entropy changes for complexes occurring in sufficiently high concentrations were calculated from the calorimetric data using these formation constants. $\Delta H^\circ_{111} = -47.9$, $\Delta H^\circ_{112} = -55.5$, $\Delta H^\circ_{113} = -57$, $\Delta H^\circ_{122} = -77.0$, $\Delta H^\circ_{123} = -83$, $\Delta H^\circ_{124} = -85.6$, $\Delta H^\circ_{213} = -75$, $\Delta H^\circ_{224} = -85$, $\Delta H^\circ_{225} = -85$, $\Delta H^\circ_{428} = -232$, $\Delta H^\circ_{429} = -214$, $\Delta H^\circ_{4210} = -197$, and $\Delta H^\circ_{4411} = -221$ kJ mol^{-1}. Thermodynamic parameters for the protonation of malate in 1.0 mol dm^{-3} (Na)Cl have also been determined: log $\beta_{011} = 4.44$ and log $\beta_{012} = 7.57$; $\Delta H^\circ_{011} = -2.0$, and $\Delta H^\circ_{012} = -6.5$ kJ mol^{-1}. Copyright © 1996 Elsevier Science Ltd

Keywords: molybdate; molybdenum(VI); complexation; thermodynamic quantities; malic acid.

Previous studies of the complexation of molybdate with malate [malic acid, $H_3mal = CH(OH)(COOH)CH_2COOH$)] revealed the existence of a number of complexes in solution [1–9]. Although some typical stoichiometries such as 1:1, 1:2, and 2:1 for the molybdate to malate ratio have been proposed, the composition and stability of most complexes are still uncertain. Some contradictory reports seem to be the result of different conditions used in experiments as well as problems with the unequivocal interpretation of data pertaining to solutions containing various combinations of complex ions [4,7,8]. A thorough NMR study [7] showed the existence of four complexes in the pH range 4–7.5, namely a 2:1 (presumably 4:2), a 1:1 and also two 1:2 species which appeared to be geometrical isomers. A comprehensive polarimetric investigation by Beltrán *et al.* [8] over a wider pH range, 1–8, indicated the existence of six different complexes which for brevity are herein represented by the stoichiometric coefficients of the reactants molybdate, malate and protons: $[1,1,1]^{3-}$, $[1,1,2]^{2-}$, $[1,2,2]^{4-}$, $[2,2,4]^{4-}$, $[2,2,5]^{3-}$ and $[4,2,8]^{4-}$. Formation constants for three of these species were calculated using straight line extrapolation methods. These authors differ from some others in that both mono- and dinuclear complexes of a 1:1 molybdate to malate stoichiometry are proposed.

Examples of salts of complex ions that have been crystallized and of which the structures have been determined by X-ray analysis are $[NH_4]_4[Mo_4O_{11}(mal)_2]\cdot H_2O$ [6], $[NH_4]_4[Mo_4O_{11}(mal)_2]\cdot 6H_2O$ [10] and $Cs_2[MoO_2(Hmal)_2]\cdot H_2O$ [11]. The existence of these compounds is strong evidence for the occurrence in solution of the complex ions $[4,2,8]^{4-}$ and $[1,2,4]^{2-}$. Other compounds which have been prepared and chemically analyzed [11] are the salts of the complex ions $[1,2,2]^{4-}$ and $[1,2,3]^{3-}$, namely $Cs_4[MoO_2(mal)_2]\cdot 3H_2O$ and $(NH_4)_3[MoO_2H(mal)_2]\cdot H_2O$.

The occurrence of protonated forms of different types of complexes can lead, depending on the con-

ditions, to strong overlap of their stability regions. Knowledge about species distributions, based on reliable formation constants for all complexes, is therefore essential and ought to provide the necessary insight to resolve conflicting interpretations of experimental results obtained under diverse conditions.

In this paper we report the results of a potentiometric, spectrophotometric and enthalpimetric investigation of the complexation of molybdate with malate. A reaction model and set of equilibrium constants have been established which give a satisfactory description of the complexation behaviour under different conditions. Not only could these results be used for a meaningful evaluation of some previous research work, but also served as basis for a calorimetric investigation of the system and the determination of enthalpy and entropy changes of all but the very minor complexes. By comparing these thermodynamic quantities with those determined previously for other α-hydroxy-carboxylates a consistent and coherent picture of the complexation behaviour of molybdenum(VI) with this type of ligand was established.

EXPERIMENTAL

Reagents and solutions

All reagents were of analytical grade (Merck, BDH, Aldrich) and solutions were prepared with water obtained from a Millipore Milli-Q system. Sodium molybdate stock solution was prepared from the recrystallized salt $[Na_2MoO_4]\cdot 2H_2O$ and standardized gravimetrically as described previously [12]. Hydrochloric acid was standardized indirectly against potassium hydrogenphthalate by titration with sodium hydroxide. Sodium chloride was purified as described previously [12]. Malic acid was used as received but its purity was checked by titration with sodium hydroxide. Malate solutions were prepared by accurate neutralization of malic acid.

Potentiometric titrations

Mixtures of sodium molybdate and sodium malate (80 cm^3) were titrated with hydrochloric acid at 25°C using either a Metrohm 636 Titroprocessor or a Metrohm Dosimat. All solutions were made 1.0 mol dm^{-3} with respect to chloride ions by addition of the appropriate amount of recrystallized sodium chloride. To exclude carbon dioxide from the system a stream of purified nitrogen was passed through 1.0 mol dm^{-3} NaCl and then bubbled slowly through the titration solution. The initial concentrations (mol dm^{-3}) of molybdate and malate were as follows: 0.005, 0.005; 0.01, 0.01; 0.05, 0.05; 0.02, 0.01; 0.01, 0.005; 0.01, 0.02 and 0.025, 0.10, thus obtaining solutions with equal concentrations of molybdate and malate or an excess of one of these reactants. The pH_c range covered was 7.5–1.5. In the final computer treatment of the data some of the duplicate titrations were left out in order to limit the data to 600 points. The protonation constants of malate were determined by potentiometric titration of solutions (80 cm^3 0.05 mol dm^{-3}) with 1.0 mol dm^{-3} hydrochloric acid.

The free hydrogen ion concentration, h, was determined by measuring the potential, E^0, to ±0.2 mV using a Ross combination electrode (Orion) with a 3.0 mol dm^{-3} KCl bridge solution. Equation (1) was used to calculate h from the measured potential at each titration point:

$$E = E^0 + 59.16 \log h + E_j \qquad (1)$$

Values for E^0 and E_j (the liquid junction potential) were determined from titrations of 1.0 mol dm^{-3} NaCl with HCl as described by Rossotti [13]. For brevity $-\log h$ is denoted by pH_c.

Spectrophotometric titrations

A GBC 920 UV/VIS double beam spectrophotometer equipped with a Peltier thermocell was used for absorption measurements. The solution in the titration cell, kept in a thermostatted water-bath at 25°C, was stirred with a non-electric immersion magnetic stirrer. Absorbances were measured in the wavelength range 206–320 nm with intervals of 3 nm using quartz cuvettes of pathlength 1.0 cm; the composition of the reference solution was that of the ionic medium, i.e. 1.0 mol dm^{-3} NaCl. The concentration of both molybdate and malate in the reaction vessel was 1.0×10^{-4} mol dm^{-3}. The titrant solution contained in addition to hydrochloric acid and sodium chloride (0.1 and 0.9 mol dm^{-3}) also molybdate and malate at the same concentration as the test solution. The hydrogen ion concentration was measured as described for the potentiometric titrations. Twenty-one spectra were recorded at pH_c intervals of ~ 0.2 in the range 5.6–1.5. A similar titration of malate (1.6×10^{-3}) with hydrochloric acid was carried out from which the protonation constants of malate as well as the individual spectra of $Hmal^-$ and H_2mal were calculated using the program SQUAD [14]. The spectra were supplied to the program for the treatment of the absorption data pertaining to complexation. In the wavelength range used the absorption of malate species is very small compared to that of molybdate.

Calorimetric titrations

An isothermal calorimeter, Tronac model 1250, was used for the enthalpy measurements. Solutions containing molybdate and malate (25.0 cm^3) were titrated with 1.0 mol dm^{-3} hydrochloric acid from a precision microburette (2.5 cm^3). The initial concentrations (mol dm^{-3}) of molybdate and malate were as follows: 0.01, 0.04; 0.03, 0.03; 0.03, 0.05 and 0.05, 0.20. The

data were collected automatically by means of a personal computer using software supplied by Tronac. Separate titrations of malate (0.02 mol dm^{-3}) with hydrochloric acid (1.0 mol dm^{-3}) were performed to determine the enthalpy involved in the protonation of malate. Again, all solutions were made 1.0 mol dm^{-3} with respect to chloride by addition of the appropriate amount of recrystallized sodium chloride. Titrations were carried out in duplicate. The data were corrected for the endothermic heat of dilution of hydrochloric acid titrated into sodium chloride by using results of previous blank titrations [15].

RESULTS AND DISCUSSION

Potentiometric investigation

The various protonation, condensation and complexation reactions that can take place when a solution containing molybdate and malate is acidified are represented by the general equation (2).

$$p\mathrm{MoO_4^{2-}} + q\mathrm{Hmal^{2-}} + r\mathrm{H^+} \rightleftharpoons [\mathrm{COMPLEX}]^{(2p+2q-r)-} \quad (2)$$

The malate anion is formulated as $\mathrm{Hmal^{2-}}$ to show the proton of the α-hydroxyl group which (in the pH range in question) is released only when complexation takes place. Overall formation constants are denoted by $\beta_{p,q,r}$ in accordance with the description of species in terms of the stoichiometric coefficients of the reactants, for example, [0, 1, 2] for malic acid.

The results of some representative titrations of malate and of mixtures of molybdate and malate with hydrochloric acid are shown in Fig. 1 as plots of F against pH_c. The function F (eq. 3) represents the fraction of the total negative charge neutralized due to protonation where H, B and C are the analytical concentrations of acid, molybdate and malate, respectively.

$$F = (H-h)/(2B+2C) \quad (3)$$

An F value of 1.0 therefore indicates an average charge of zero for the species in solution. For a solution containing only malate species $F \simeq 0.98$ at $pH_c \sim 1.5$ indicating almost complete protonation to H_3mal (Fig. 1). For mixtures of molybdate and malate at the same pH_c the much lower value of $F = 0.8$ shows that protonation of the complexes are more difficult than protonation of malate itself. However, in the region of higher pH_c the curves show that significant complexation already occurs before malate is protonated.

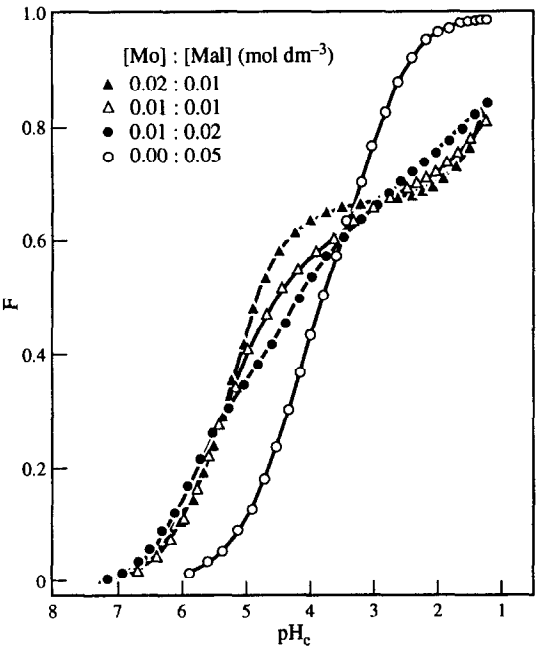

Fig. 1. Plots of function F versus pH_c for some representative potentiometric titrations.

To create conditions that would be favourable for the formation of complexes with stoichiometry other than a 1 : 1 ratio of molybdate to malate an excess of either molybdate or malate was used. In the treatment of the data it was therefore important to consider all side-reactions of uncomplexed molybdate and malate with protons. The molybdate species $[HMoO_4]^-$, $[MoO_3(OH_2)_3]$, $[MoO_2(OH)(OH_2)_3]^+$, $[HMo_2O_7]^-$, $[Mo_7O_{24}]^{6-}$, $[HMo_7O_{24}]^{5-}$, $[H_2Mo_7O_{24}]^{4-}$, $[H_3Mo_7O_{24}]^{3-}$, $[Mo_8O_{26}]^{4-}$ and $[HMo_2O_6]^+$ were taken into account using previously determined equilibrium constants pertaining to 1.0 mol dm^{-3} NaCl medium at 25°C [16–18]. In the final calculations (limited to data at $pH_c > 1.5$) however, it turned out that only four of these species were really necessary to account for uncomplexed molybdate, namely $[MoO_3(OH_2)_3]$, $[Mo_7O_{24}]^{6-}$, $[HMo_7O_{24}]^{5-}$ and $[H_3Mo_7O_{24}]^{3-}$. Due to the formation of complexes having a 2 : 1 molybdate to malate stoichiometry the amount of uncomplexed molybdate was relatively small. The calculation of stability constants and model testing were performed with the computer program SUPERQUAD [19].

The protonation constants of malate in 1.0 mol dm^{-3} NaCl were determined in separate titrations. The values obtained, $\log \beta_{011} = 4.44$ and $\log \beta_{012} = 7.57$ are the same as the literature values at this ionic strength [20].

On account of our previous experience with systems of this type all possible complex species with $p = 1$–4 and having reasonable q and r values have been considered in the calculations to find the "best" reaction model. SUPERQUAD automatically rejects species for which the relative standard deviation of the formation constant is greater than 33% (or $3\sigma > 0.43$ log units). The final model comprises fourteen species of which only the $[2, 1, 4]^{2-}$ has a standard deviation of greater than 7%, actually 16%, and its existence is therefore much less certain than that of the other species. A value for $s = 0.97$ (sample standard deviation) [19] based on errors of 0.01 cm^3 in the volume and 0.002 in the pH_c implies a very good fit. Although the fit could be improved marginally by the addition

of some very minor species, these species were not included in the best model. For example, inclusion of a $[4,4,9]^{7-}$ species for which a relatively large standard deviation of 18% in the value of the formation constant was calculated caused a lowering of s from 0.97 to 0.95. The distribution of the complexes as a function of pH_c at concentrations chosen to illustrate the stability regions are shown in Figs 2 and 3.

The molybdenum–malate stoichiometry of the complexes is typical of those previously observed for other comparable molybdenum ligand systems [21]. In particular, the model is very similar to that obtained for molybdenum(VI) with citrate as ligand. The difference between citrate and malate is the extra carboxylate group of citrate which remains uncoordinated and therefore affords additional protonation possibilities for a particular complex. Accordingly, analogues of protonated citrate complexes, such as the $[1,1,4]^{-}$, $[2,1,5]^{2-}$ and $[2,2,6]^{4-}$ do not occur in the molybdenum–malate system. In general the malate complexes are a little less stable than the analogous citrate complexes, e.g. the formation constant of the $[1,1,1]^{3-}$ malate complex is about one log unit smaller than that of the $[1,1,1]^{4-}$ citrate complex.

Classified in terms of molybdenum–malate stoichiometry there are six different types of complexes protonated to various degrees. With the exception of the 4:4 type, salts of all types have been isolated in the solid state either as malate or citrate complexes. Thus, salts of the $[1,2,2]^{4-}$, $[1,2,3]^{3-}$, $[1,2,4]^{2-}$ and $[4,2,8]^{4-}$ malate complexes have been prepared, e.g. $Cs_4[MoO_2(mal)_2]\cdot 2.5H_2O$ [11], $[NH_4]_3[MoO_2H(mal)_2]\cdot H_2O$ [11], $Cs_2[MoO_2(Hmal)_2]\cdot H_2O$ [11] and $[NH_4]_4[Mo_4O_{11}(mal)_2]\cdot 6H_2O$ [6,10]. Citrate analogues of the latter complex are also known and have been structurally characterized by X-ray analysis, e.g. $[Me_3N(CH_2)_{6NMe3})]_2[Mo_4O_{11}(Hcit)_2]\cdot 12H_2O$ [22]. Other citrate complexes [23] of molybdenum which have been obtained by precipitation from aqueous solution and have stoichiometries which correspond with those of malate complexes now identified are potassium salts of $[1,1,1]^{4-}$, $[2,2,4]^{6-}$ and $[2,2,6]^{4-}$. These complexes have been characterized by chemical analysis and various other methods. A complex of composition $M_2[Mo_2O_5(OH)H_2O(Hcit)]\cdot 0.5H_2O$ where M^+ is K^+ or NH_4^+ and which corresponds to $[2,1,5]^{2-}$ has also been reported [24].

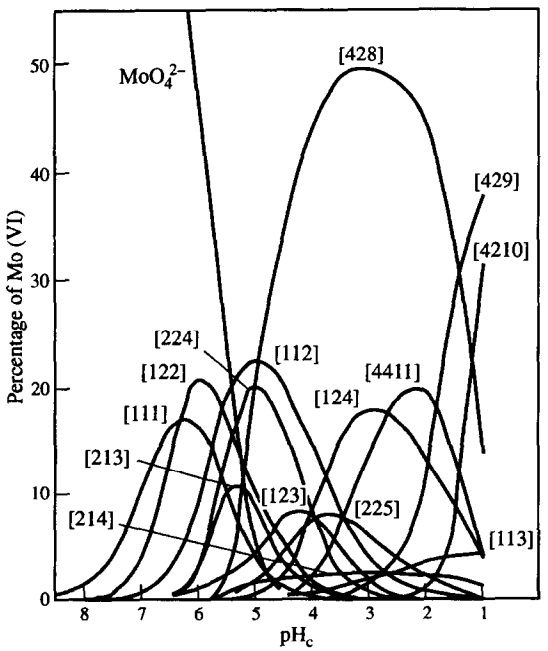

Fig. 2. Distribution of species in the molybdenum(VI) malate system as a function of pH_c for an equimolar solution of 0.05 M.

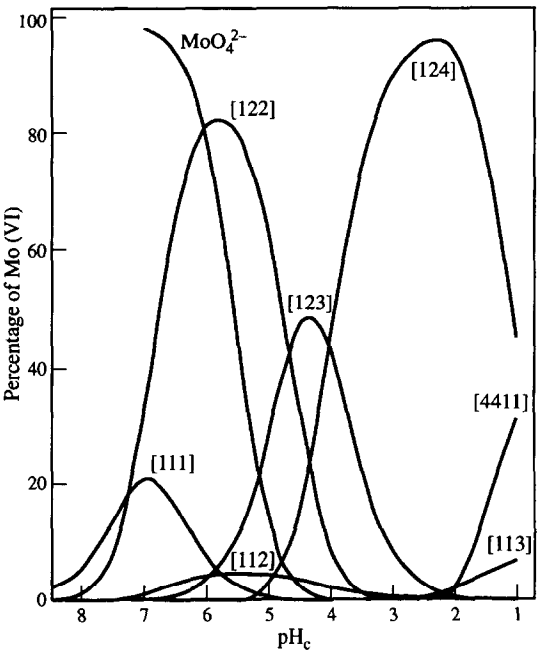

Fig. 3. Distribution of species in the molybdenum(VI) malate system as a function of pH_c. Total concentrations of molybdate and malate are 0.05 M and 0.20 M, respectively.

If tridentate coordination of malate, similar to that of citrate [21], is assumed, structures with five- and six-membered rings with molybdenum will be formed as shown in Fig. 4 for the 1:1 and 2:2 type of complexes. Tridentate coordination is expected to have a stabilizing effect on these complexes affording them to compete successfully with the $[1,2,r]$ complexes under suitable conditions. The typical behaviour of α-hydroxycarboxylic acids towards molybdenum(VI) and tungsten(VI) is to form particularly stable 1:2 rather than 1:1 and 2:2 complexes (*cf.* last section).

The reaction model established and the available formation constants can now be employed to calculate species distributions pertaining to conditions of previous investigations. For example the distribution of the $[4,2,8]^{4-}$ and $[2,2,4]^{4-}$ complexes correlate well

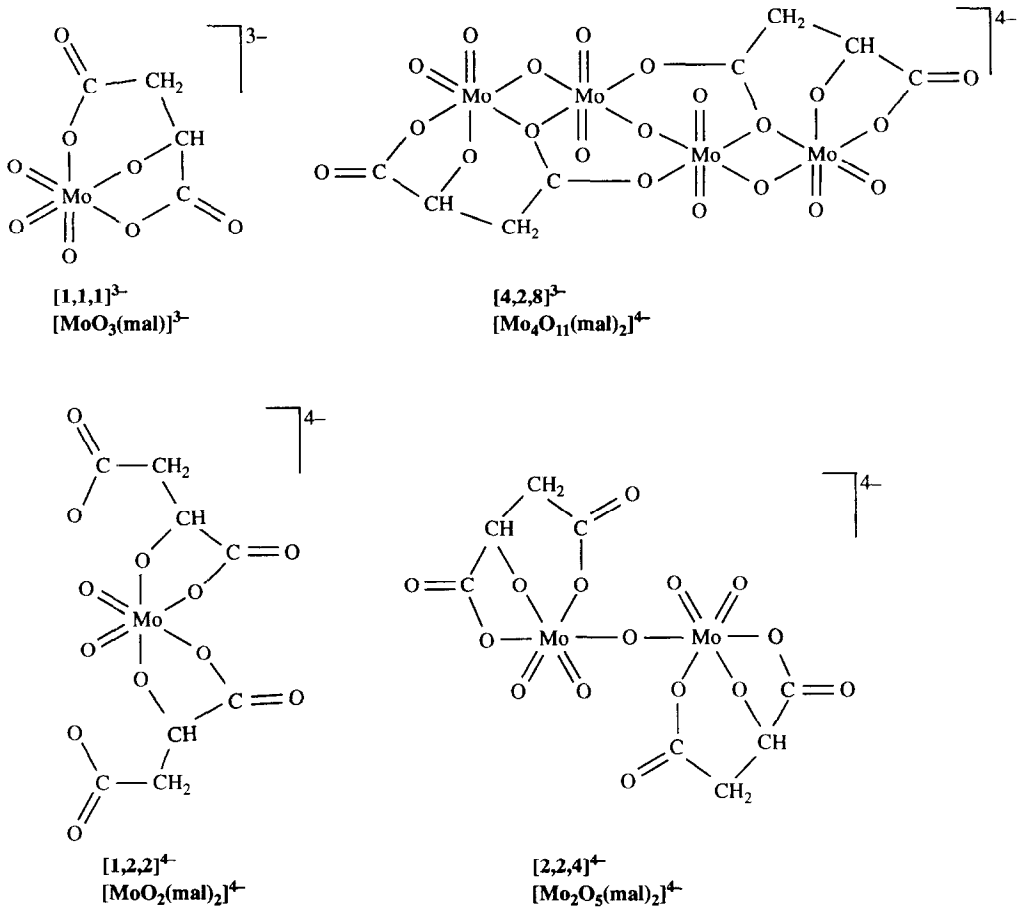

Fig. 4. Known and proposed structures for mononuclear [11], dinuclear and tetranuclear [6, 10] complexes of molybdenum(VI) with malate.

with the Job curves constructed from NMR data by Caldeira *et al.* [7]. As pointed out by these authors inherent limitations of Job's method prevented firm conclusions about the 2 : 1 and 1 : 1 stoichiometries proposed for the first two complexes. The calculated distribution curves, taking into account all complexes as well as side-equilibria of uncomplexed molybdate and malate, clearly show that the maxima of the Job curves for the $[4,2,8]^{4-}$ and $[2,2,4]^{4-}$ complexes (at pH = 5 and 1 mol dm^{-3} solution) would occur at a mole ratios of smaller than 2 : 1 and 1 : 1, respectively as was observed by these authors. Further, the Job curves for their complexes *b* and *a*, identified as 1 : 2 species, tally with distribution curves for the $[1,2,2]^{4-}$ and $[1,2,3]^{3-}$ complexes. However, the distinct NMR spectra observed for these two complexes showed that they cannot just differ in the degree of protonation and geometrical isomers were suggested [7].

The results of the present investigation also concur with the conclusions of a polarimetric study [8] regarding the stoichiometry and approximate stability regions of the six complexes $[111]^{3-}$, $[112]^{2-}$, $[1,2,2]^{4-}$, $[2,2,4]^{4-}$, $[2,2,5]^{3-}$ and $[4,2,8]^{4-}$. In particular, there is a close correlation between the change in rotatory power and the distribution curve of the $[4,2,8]^{4-}$ complex with the change in malic acid/molybdate ratio at constant pH values 3 and 4. The values obtained by graphical extrapolation for the formation constants of three complexes namely, log $\beta_{111} = 8.2$ (7.47), log $\beta_{122} = 13.9$ (15.48) and log $\beta_{224} = 22.6$ (28.06) differ appreciably from those now determined (shown in parentheses). However, considering the complexity of the system, the extrapolated values should be regarded as reasonable approximations.

Spectrophotometric investigation

First the individual spectra of the malate species have been determined from 17 experimental spectra in the pH_c range 5.7–1.3. Compared to the spectra of the molybdate species the absorption of the malic acid species is almost negligible (Fig. 5). The values calculated for the protonation constants using the program SQUAD [14] agreed very well with those obtained by potentiometry, shown in parentheses, log $\beta_{011} = 4.43 \pm 0.02$ (4.44), log $\beta_{012} = 7.59 \pm 0.06$ (7.57).

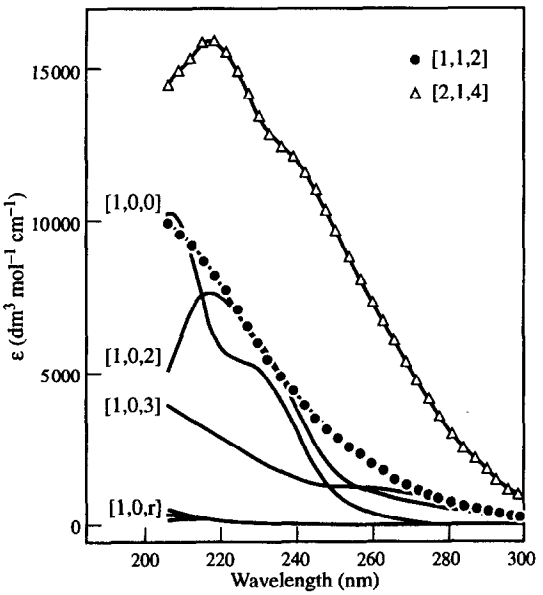

Fig. 5. Calculated molar absorption spectra of the [1, 1, 2] and [2, 1, 4] complexes and of the various malate species, [0, 1, *r*]. The spectra of the uncomplexed molybdenum(VI) monomers are also shown.

Complexation was then investigated by measuring the absorption of solutions of molybdate and malate at very low concentration (1×10^{-4} mol dm^{-3} in the pH_c range 5.6–1.5. Under these conditions the system is only just simple enough to extract useful formation constants and absorption spectra of two complexes, namely the $[1, 1, 2]^{2-}$ and $[2, 1, 4]^{2-}$. The expected maximum percentage concentrations of these complexes (based on the potentiometric results) were 50 and 20%, respectively. The $[1, 1, 3]^{-}$ complex reaches a maximum concentration of $\simeq$ 5%. Rather than neglecting it in the calculations its formation constant was supplied to the program and the calculations carried out on the basis that is has the same spectrum as the $[1, 1, 2]^{2-}$ complex. The known protonation constants and spectra of the malate species were supplied to the program. Also given were the protonation constants of monomeric molybdate β_{101}, β_{102} and β_{103} and the spectrum of $[HMoO_4]^-$ [16,25,26]. The values obtained for the formation constants were as follows: $\log \beta_{112} = 13.34$ (13.23) and $\log \beta_{214} = 24.33$ (24.35). The agreement with the values determined by potentiometry, given in parentheses, is better than what one would expect considering the uncertainties involved in the method. Reassuring also, is the good agreement between the spectra now calculated for the [102] and $[103]^+$ species and those previously determined [26]. As noted in the previous section the greatest uncertainty was associated with the $[2, 1, 4]^{2-}$ complex. Having provided additional evidence for its existence and also verifying the value of the formation constant of the $[1, 1, 2]^{2-}$ complex the reaction model could be accepted with confidence to be used as a basis for an enthalpimetric study.

Enthalpimetric investigation

The results obtained in some of the enthalpimetric titrations are shown in Fig. 6 where the total amount of heat measured, Q, is plotted against the molar ratio of acid added to molybdate. (The curves do not start at the origin because the enthalpy of the first few data points, before a steady state is reached, are not included.) The different shapes of the two curves (b) and (c) at the same molybdate concentration but with different malate concentrations reflect the change in relative concentrations of the complexes. Above a 1 : 1 mole ratio of acid to molybdate more heat is developed for the solution having an excess of malate because of the higher percentage of [1, 2, *r*] complexes. For the solution with a four fold excess of malate the [1, 2, *r*] species dominate (*cf* Fig. 3) and in keeping with this complete conversion to the $[1, 2, 2]^{4-}$ complex is indicated by a distinct break in the curve occurring at a 2 : 1 mole ratio of acid to molybdate (Fig. 6).

The enthalpy changes for the formation of the complexes were calculated from the measured heat, Q, corrected for dilution effects,

$$Q = \Sigma n_{pqr} \Delta H^{\circ}_{pqr} \qquad (4)$$

where n_{pqr} is the number of moles formed and ΔH°_{pqr} the molar enthalpy change of a given species [*p*, *q*, *r*]

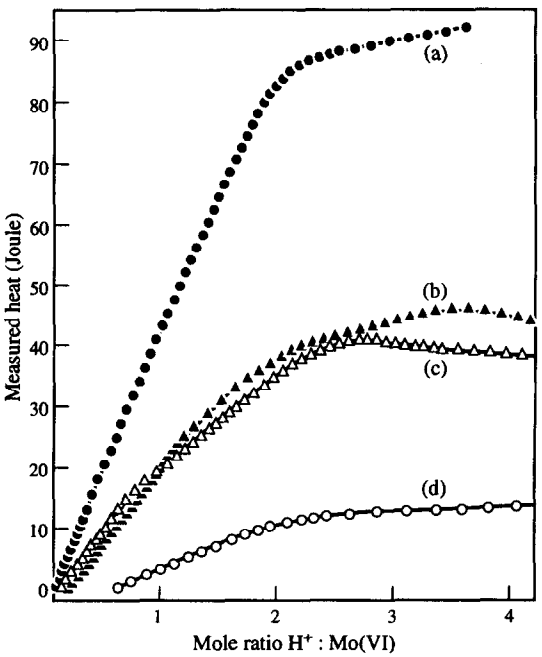

Fig. 6. Measured heat as a function of the molar ratio of acid to molybdate for titrations of the following solutions ([Mo] : [mal]) with hydrochloric acid: (a) 0.05 M : 0.20 M; (b) 0.03 M : 0.05 M; (c) 0.03 M : 0.03 M; and (d) 0.01 M : 0.04 M.

at 25°C in 1.0 mol dm^{-3} (Na)Cl medium. The set of linear equations obtained from corresponding Q and n_{pqr} values were solved for the unknown ΔH°_{pqr} parameters using a BMDP least squares program [27].

The n_{pqr} values at each titration point were calculated, in a subroutine supplied to the BMDP program, from the concentrations of the species obtained by simultaneous solution of the three mass-balance equations (5)–(7)

$$B = b + \Sigma p\beta_{pqr} b^p c^q h^r \quad (5)$$

$$C = c + \Sigma q\beta_{pqr} b^p c^q h^r \quad (6)$$

$$H = h + \Sigma r\beta_{pqr} b^p c^q h^r \quad (7)$$

where b, c, and h are the equilibrium concentrations of $[MoO_4]^{2-}$, $Hmal^{2-}$ and H^+, respectively.

The enthalpy changes for the protonation of $Hmal^{2-}$ in 1 mol dm^{-3} NaCl, $\Delta H^{\circ}_{011} = -2.0$ kJ mol^{-1} and $\Delta H^{\circ}_{012} = -6.5$ kJ mol^{-1} were determined in separate titrations and treated as fixed parameters in the calculation of the ΔH°_{pqr} values of the complexes. The small enthalpy changes are typical for this type of protonation reaction which is normally entropy driven [28]. The enthalpy changes for the protonation of malate can be compared with those of citrate in the same ionic medium, i.e. $\Delta H^{\circ}_{011} = -1.3$ kJ mol^{-1} and $\Delta H^{\circ}_{012} = -5.8$ kJ mol^{-1}. Literature values for malate [20] pertaining to ionic strength 0.1 mol dm^{-3} are $\Delta H^{\circ}_{011} = 0.59$ kJ mol^{-1} and $\Delta H^{\circ}_{012} = -2.84$ kJ mol^{-1}.

The ΔH° values calculated for the various complexes are listed in Table 1. Because the maximum percentage concentration of the $[2,1,4]^{3-}$ complex under the experimental conditions never exceeded 5% a realistic value for its enthalpy change could not be evaluated from the data. Rather than neglecting this complex, the quite reasonable approximation, based on results of this and previous investigations [21], was made that the enthalpy change for a complex and its protonated form has about the same value. The data were therefore treated on the assumption that $\Delta H_{213} = \Delta H^{\circ}_{214}$. Since ΔH°_{213} could be calculated with reasonable accuracy the approximation only affected the value of ΔH°_{214}.

The quite favourable enthalpy change for complexation is typical for molybdate and is the result of an increase in coordination number of molybdenum from four to six. The enthalpy changes determined for the formation of mononuclear molybdenum–malate complexes of the type $[1,1,r]$ concur with values previously reported for other α-hydroxycarboxylate ligands which are typically about −50 to −60 kJ mol^{-1} [21]. The agreement between the enthalpy changes for comparable malate and citrate complexes reflects the similarity in their structures. The enthalpy change for the $[Mo_4O_{11}(mal)_2]^{4-}$ and $[Mo_4O_{11}(Hcit)_2]^{4-}$, for example, are −232 and −251 kJ mol^{-1}, respectively. The more favourable entropy change for the citrate complex [21] ($T\Delta S = 118$) compared with that of the malate complex ($T\Delta S^{\circ} = 70$) is in keeping with the two extra protons involved in its formation; the increase in $T\Delta S$ per protonation is typically 20–25 kJ mol^{-1} and it is also seen that the value of $T\Delta S^{\circ}$ for $[Mo_4O_{11}(Hmal)_2]^{2-}$ is

the same as that of $[Mo_4O_{11}(Hcit)_2]^{4-}$. The tetranuclear complex $[Mo_4O_{11}(mal)_2]^{4-}$ is an important species even at relatively low concentrations because compared to most of the mono- and dinuclear complexes occurring in the same pH_c region it has a very favourable ΔH° ($\sim$ 60 kJ mol^{-1} per Mo atom or per mal^{3-}). Assuming that it has the same structure in solution as in the solid state, the extra stability is most likely due to the manner in which the malate ligands are utilized in connecting the two dimeric $Mo_2O_5^{2+}$ units. Both oxygen atoms of each of the β-carboxylate groups are coordinated to molybdenum which implies a more favourable enthalpy change per malate because of the extra bond energy. Further, due to the absence of free carboxylate groups and the unavailability of negatively charged (formally) oxygens the enthalpy change for the protonation of the $[4,2,8]^{4-}$ complex is positive resulting in rather small protonation constants.

Noteworthy is the very favourable enthalpy change for the $[1,2,2]^{4-}$ complex (about -80 kJ mol^{-1} per Mo atom) and which explains its greater stability compared to other complexes occurring in the same pH region. When compared with the $[1,1,1]^{3-}$ complex, for example, it gains in stability because of the formation of two stable five-membered rings as against one five- and one six-membered ring in the $[1,1,1]^{3-}$ complex. Also to be considered is the enthalpy cost involved in the ionization of the alcoholic proton in the formation of the 1 : 1 complex, but which can be regained (with profit) *via* a water molecule when two ligands are coordinated to form the $[1,2,2]^{4-}$ complex. The prominence of 1 : 2 complexes in the case of α-hydroxycarboxylic acids has been noted in previous papers and especially for monocarboxylates such as lactate and madelate [29, 30].

CONCLUSION

Depending on the concentration of molybdate and malate several complexes occur in varying quantities in the pH_c range 1.5–7.5. Complexes with six different stoichiometric ratios of molybdate to malate have been identified, namely 1 : 1, 1 : 2, 2 : 2, 2 : 1, 4 : 2 and 4 : 4. The stoichiometry of these complexes are the same as those of molybdenum citrate complexes except that citrate complexes afford additional protonation possibilities because of the extra uncoordinated carboxylate group. The complexes can be described as follows: the mononuclear complexes $[MoO_3(mal)]^{3-}$ and $[MoO_2(mal)_2]^{4-}$ and their protonated forms, the dinuclear complexes $[Mo_2O_5(mal)_2]^{4-}$ and $[Mo_2O_6(mal)(H_2O)_2]^{3-}$ and their protonated forms, and finally the tetranuclear complexes $[Mo_4O_{11}(mal)_2]^{4-}$ and $[Mo_4O_{10}(OH)(Hmal)_4]^{5-}$ of which the latter has no protonated forms in the pH_c range in question. Thermodynamic quantities for the complexes have been determined and compared with those previously reported for molybdenum–citrate complexes.

(Received 7 May 1996; accepted 22 May 1996)

Abstract—Reaction of a 1 : 1 mixture of the appropriate phenylenediamine (e.g. 4-methyl-1,2-phenylenediamine 4-chloro-1,2-phenylenediamine) and alkylenediamine (e.g. ethylenediamine and propylenediamine) with 2,4-pentanedione in presence of nickel(II) salt gave a series of asymmetrical nickel(II) complexes of the $[Me_4\text{-}RBzo[X]tetraeneN_4]^{2-}$ ligand (where R = CH_3 or Cl; X = 14 or 15). These complexes were investigated by means of mass, infrared, NMR and electronic spectra. Hammett plots of the ^{13}C NMR resonances of methine carbons for $[Ni\text{-}(Me_4\text{-}RBzo[X]tetraeneN_4]$ complexes (where R = CH_3, H, Cl or NO_2; X = 14 or 15) *vs* σ_p were linear and had slopes of 2.97 and 2.63 for 14-membered and 15-membered complexes, respectively.

Keywords: template synthesis; asymmetrical nickel(II) macrocycle.

Studies of tetraaza[14]annulene nickel(II) complex, which was obtained by the template condensation of 1,2-phenylenediamine with 2,4-phentanedione in the presence of nickel(II) ion as first described by Jäger [1], have been widely investigated on account of their structural features in common with the porphyrin [2, 3]. However, most macrocyclic complexes [4–7] obtained by the Jäger method were symmetrical complexes and examples of asymmetrical complexes synthesized by this method are rare.

In a previous paper [8], we reported that the asymmetrical nickel(II) complexes with tetraaza[X]benzo macrocycles, $[Ni(Me_4\text{-}Bzo[14]tetraeneN_4)]$ (**14H**), $[Ni(Me_4\text{-}NO_2Bzo[14]tetraeneN_4]$ (**14NO$_2$**), $[Ni(Me_4\text{-}Bzo[15]tetraeneN_4)]$ (**15H**) and $[Ni(Me_4\text{-}NO_2Bzo[15]tetraeneN_4)]$ (**15NO$_2$**), could be obtained by the reaction of a 1 : 1 mixture of the appropriate phenylenediamine (e.g. 1,2-phenylenediamine and 4-nitro-1,2-phenylenediamine) and alkylenediamine (e.g. ethylenediamine and propylenediamine) with 2,4-pentanedione in the presence of a nickel(II) salt.

This paper describes the synthesis of the new asymmetrical nickel(II) macrocycles, $[Ni(Me_4\text{-}CH_3Bzo[14]tetraeneN_4)]$ (**14CH$_3$**), $[Ni(Me_4\text{-}ClBzo[14]tetraeneN_4]$ (**14Cl**), $[Ni(Me_4\text{-}CH_3Bzo[15]tetraeneN_4)]$ (**15CH$_3$**), $[Ni(Me_4\text{-}ClBzo[14]tetraeneN_4)]$ (**15Cl**) by a procedure similar to that described for the complexes mentioned above. Also, we have studied the effect of varying the substituent R groups (R = CH_3, H, Cl and NO_2) in $[Ni(Me_4\text{-}RBzo[14]tetraeneN_4)]$ (X = 14 and 15) using ^1H and ^{13}C NMR spectra.

EXPERIMENTAL

Physical measurements

The EI mass spectra for **14CH$_3$**, **14Cl**, **15CH$_3$** and **15Cl** were determined with a JEOL MS-DX 300 gas chromatograph mass spectrometer at 70 eV using a direct inlet system. The infrared spectra in the area of the 400–4000 cm^{-1} were obtained as disks in KBr on a Perkin-Elmer 1430 IR spectrophotometer. UV–vis electronic absorption spectra were recorded on a Shimadzu UV-265 double beam spectrophotometer for chloroform solutions at room temperature. ^1H (300 MHz) and ^{13}C (75.5 MHz) NMR spectra were recorded on a Bruker instrument in $CDCl_3$ at room temperature and the chemical shifts were given in ppm

relative to tetramethylsilane as an internal reference standard. Elemental analyses of the new complexes were performed at the Kolon R&D Center.

Preparation of the new complexes

All reagents and solvents used were of analytical grade.

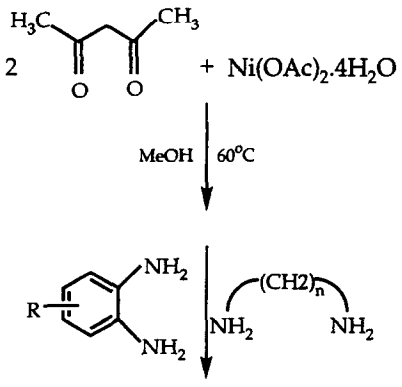
[Ni(Me_4-CH_3Bzo[14]tetraeneN_4)], **14CH$_3$**. Under a N_2 atmosphere, 0.04 mol (4g) of 2,4-pentanedione was added to the methanol (50 cm^3) solution of nickel(II) acetate tetrahydrate (5 g, 0.02 mol). To the hot (60°C) mixture were added 4-methyl-1,2-phenylenediamine (2.5 g, 0.02 mol) and ethylenediamine (1.2 g, 0.02 mol). The solution was refluxed until precipitation of the product was complete. The hot solution was filtered, washed with hot methanol, and air-dried. The product was recrystallized from dichloromethane–methanol (1 : 1) mixture. Yield: 30%. Found: C, 62.6; H, 6.5; N, 15.4. Calc. for $C_{19}H_{24}N_4Ni$: C, 62.2; H, 6.6; N, 15.3%; IR(KBr disc): ν(C=C) and ν(C=N) 1528, 1482, 1420; ν(aromatic) 750 cm^{-1}; UV–vis, (ε) in $CHCl_3$, nm: 548 (2680), 376 (24960); EIMS: m/z (relative intensity) 368 (43.9), 367 (32.2), 366 (100), 365 (35.2).

[Ni(Me_4-ClBzo[14]tetraeneN_4)], **14Cl**. This was prepared from 2,4-pentanedione (4 g, 0.04 mol), nickel(II) acetate tetrahydrate (5 g, 0.02 mol), 4-chloro-1,2-phenylenediamine (2.9 g, 0.02 mol), ethylenediamine (1.2 g, 0.02 mol) and methanol (50 cm^3), following the above procedure. Yield: 31%. Found: C, 55.5; H, 5.2; N, 14.3. Calc. for $C_{18}H_2N_4ClNi$: C, 55.8; H, 5.5; N, 14.5%; IR(KBr disc): ν(C=C) and ν(C=N) 1526, 1472, 1420; ν(aromatic) 768 cm^{-1}; UV–vis, (ε) in $CHCl_3$, nm: 547 (3140), 381 (25470); EIMS: m/z (relative intensity) 388 (61.1), 387 (31.1), 386 (100), 385 (22.4).

[Ni(Me_4-CH_3Bzo[15]tetraeneN_4)]. **15CH$_3$**. This was prepared from 2,4-pentanedione (4 g, 0.04 mol), nickel(II) acetate tetrahydrate (5 g, 0.02 mol), 4-methyl-1,2-phenylenediamine (2.5 g, 0.02 mol), propylenediamine (1.5 g, 0.02 mol) and methanol (50 cm^3), following the above procedure. Yield: 55%. Found: C, 62.9; H, 6.8; N, 14.8. Calc. for $C_{20}H_{26}N_4Ni$: C, 63.0; H, 6.9; N, 14.5%; IR(KBr disc): ν(C=C) and ν(C=N) 1526, 1472, 1420; ν(aromatic) 758 cm^{-1}; UV–vis (ε) in $CHCl_3$, nm: 559 (2100), 385 (21800); EIMS: m/z (relative intensity) 382 (37.5), 381 (22.8), 380 (100).

[Ni(Me_4-ClBzo[15]tetraeneN_4)], **15Cl**. This was prepared from 2,4-pentanedione (4 g, 0.04 mol), nickel(II) acetate tetrahydrate (5 g, 0.02 mol), 4-chloro-1,2-phenylenediamine (2.9 g, 0.02 mol), propylenediamine (1.5 g, 0.02 mol) and methanol (50 cm^3), as described above. EIMS: m/z (relative intensity (402 (58.2), 401 (24.2), 400 (94.1), 387 (66.7), 386 (21.7), 385 (100).

RESULTS AND DISCUSSION



Synthesis of the asymmetric macrocyclic complexes

The asymmetrical macrocyclic complexes of **14R** and **15R** series were prepared following the synthetic route shown in Scheme 1. The initial step in the synthesis involves the formation of a nickel(II) acetylacetonate complex that functioned as a template for condensation of a 1 : 1 mixture of appropriate 1,2-phenylenediamine and alkylenediamine to produce the desired macrocycles. Also, we attempted to prepare the other similar **16R** series such as **16CH$_3$**, **16H**, **16Cl** and **16NO$_2$** from the reaction of the appropriate phenylenediamine and butylenediamine with 2,4-pentanedione in the presence of nickel(II) salt. However, these complexes were not produced. Elemental analyses of **14CH$_3$**, **14Cl**, **15CH$_3$** and **15Cl** given in the Experimental section are consistent with these formulations.

Mass, IR and electronic spectra of the new complexes

The mass spectral data of **14CH$_3$**, **14Cl**, **15CH$_3$** and **15Cl** are given in the Experimental Section. The EI mass spectra for **14CH$_3$**, **14Cl** and **15CH$_3$** show the presence of a molecular ion M^+ at m/z 366 (^{58}Ni), 386 (^{35}Cl, ^{58}Ni) and 380 (^{58}Ni), respectively. These peaks are the base peaks in each mass spectrum. While **15Cl** exhibits a molecular ion M^+ at m/z 400 (^{35}Cl, ^{58}Ni) which is not a base peak. All complexes show masses of the major fragment $[M\text{-}CH_3]^+$ at m/z 351, 371, 365 and 385, respectively. The masses of the fragment at m/z 351 and 365 for **14Cl** and **15Cl** corresponds to $[M\text{-}Cl]^+$, but the relative intensities are very small.

The characteristic IR bands of the four complexes display strong bands around 1550–1520, 1480 and

[Ni(Me_4-RBzo[X]tetraeneN_4)]

Scheme 1.

1420 assignable to ν(C=C) and ν(C=N). This observation indicates the formation of the conjugated six membered chelate ring in the reaction [9]. The aromatic bands of these complexes also occur at around 750 cm^{-1}.

The electronic absorption spectral data for **14CH$_3$**, **14Cl**, **15CH$_3$** and **15Cl** are given in the Experimental section. The absorption bands ranging from 370 to 570 nm are reasonably attributed to $\pi \rightarrow \pi^*$ transitions within the ligand molecular and charge transfer (CT) transitions from metal to ligand since the molar extinction coefficients of the bands (2100–25,470 M^{-1} cm^{-1}) are much larger than those commonly assigned to ligand-field bands which were obscured by intense $\pi \rightarrow \pi^*$ and CT transition bands [10]. These results are supported by similar observations with tetraaza [14]annulene nickel(II), **14R** and **15R** (where R = H or NO_2) reported earlier [4,8].

^{1}H *NMR spectra*

Consistent with a diamagnetism of the new macrocyclic nickel(II) complexes, **14CH$_3$**, **14Cl**, **15CH$_3$** and **15Cl** gave well-resolved ^{1}H NMR spectra. The assignments were made by the comparisons of the spectra with those of other macrocyclic nickel(II) complexes reported earlier [5,11]. ^{1}H NMR chemical shifts and their assignments for the complexes, **14CH$_3$**, **14Cl**, **15CH$_3$** and **15Cl** are listed in Table 1. The δ-carbon sites of the diiminate framework of the tetraaza [14] annulene nickel(II) complex have been found to be a reactive nucleophilic center named the methine site. Thus, the chemical shift values in NMR spectra of the methine sites for **14R** and **15R** series are worth special mention. The methine proton peaks (H′ and H″) for **14CH$_3$** and **15CH$_3$** with a methyl substituent and those for **14Cl** and **15Cl** with a chloro substituent on the phenyl ring are nonequivalent and show two singlets, respectively (see Table 1). These peaks of **14CH$_3$** and **15CH$_3$** show slight upfield shifts (about 0.02–0.04 and 0.02–0.03 ppm) relative to the 5.03 and 4.88 ppm of **14H** and **15H** with no substituent on the phenyl ring, respectively. On the other hand, the peaks of **14Cl** and **15Cl** show slight downfield shifts (0.02–0.03 and 0.01–0.02 ppm) relative to **14H** and **15H** [12]. The results are attributed to the shielding and deshielding effect of the substituents on the phenyl ring.

^{13}C *NMR spectra and Hammett plot*

^{13}C NMR data and their assignments for **14CH$_3$**, **14Cl**, **15CH$_3$** and **15Cl** are presented in Table 2 and the resonances of methine carbons for **14R** and **15R** series shown in Fig. 2. The resonances of methine carbons for **14CH$_3$**, **14Cl**, **15CH$_3$** and **15Cl** are also shifted upfield or downfield relative to **14H** and **15H** which are in agreement with the corresponding ^{1}H NMR spectral behavior. The **14R** and **15R** series contains macrocycles with various electron donor and withdrawing groups that have different σ_p values [13]. The effect of the substituents on the resonances of methine carbons for these complexes was examined by means of a Hammett plot. Figure 3 shows that the relationship between $\Delta\delta$ [15] and σ_p is linear with a slope of 2.97 (a correlation coefficient of 0.99) for the **14R** series and with a slope of 2.63 (a correlation coefficient of 0.99) for the **15R** series, respectively. In view of the similarity of structures of **14R** and **15R** series, the difference in their slopes seems unexpectedly great. When intramolecular repulsion of chelate ring alkylene groups and diiminate framework are considered, the positional changes seem rational. This difference between the **14R** and **15R** series in the repul-

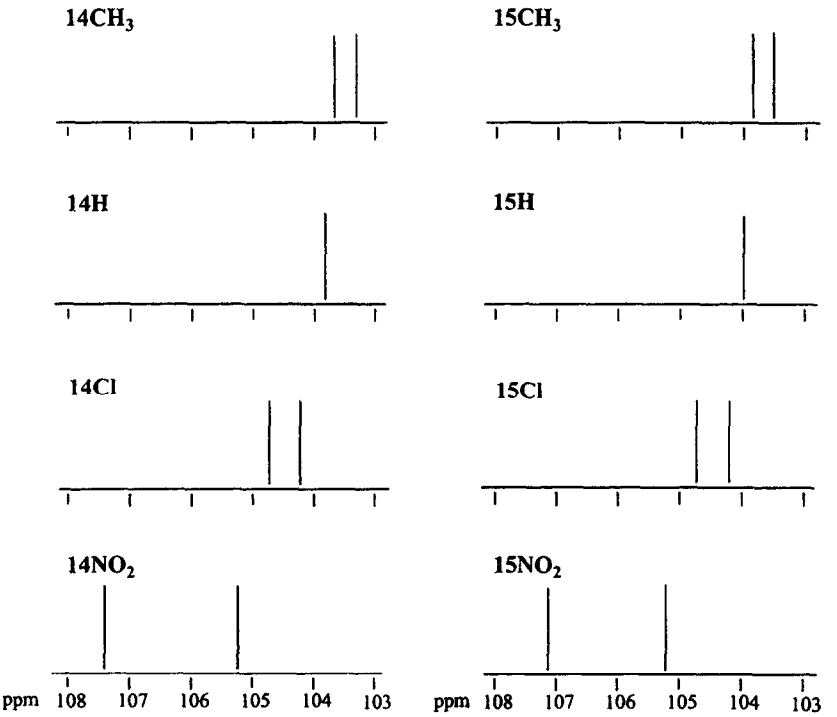

Fig. 2. The ^{13}C NMR spectra of the resonances of methine carbons for **14R** and **15R** series. Those of **14H**, **14NO$_2$**, **15H** and **15NO$_2$** are referred to in ref. 8.

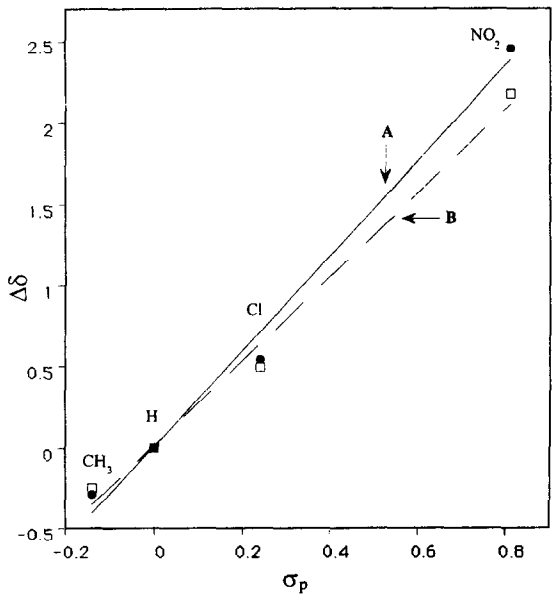

Fig. 3. Hammett plot of $\Delta\delta$ *vs* σ_p. A, **14R** series (corr = 0.99, slope = 2.97); B, **15R** series (corr = 0.99, slope = 2.63). $\Delta\delta$ = the average values of the resonances of methine carbons for complexes with substituent − the resonance of methine carbons corresponding to those with no substituent.

sion are exhibited in the Hammet plot as slope difference of 0.34. Interestingly, these slopes are similar to those of the oxidation potentials for metalloporphyrins with β substituents located on the pyrrole residues of the porphyrin ligand [16,17].

The resonances of the methine carbon for the 14R and 15R series are significantly affected by substituents on the phenyl ring.

12. Although the magnitudes of these shifts are very

small, they are proportional to the magnitude of the Hammett parameter of substituents. This is supported by a downfield shifts in ref. 8 about 0.13–0.21 and 0.05–0.17 ppms for **14NO$_2$** and **15NO$_2$** relative to **14H** and **15H,** respectively.

13. As pointed out elegantly by Kadish *et al.* in Ref. 14, the exact choice of which Hammett parameter to use, i.e. σ_p, σ^+, σ^-, etc., is not clear. We have chosen σ_p because the correlations are linear and it offers comparisons to the widest range of literature data.

(Received 2 April 1996; accepted 22 May 1996)

Abstract—The novel dinuclear copper(II) complex has been prepared by reaction of tacd with $Cu(MeCO_2)_2 \cdot H_2O$ in ethanolic solution. The crystal structure shows that a pair of copper(II) atoms separated at 3.288(1) Å are bridged by a μ_2-HO^- and a μ_2-carboxylato-*O*,*O*′ group into a dinuclear structure in which each copper(II) atom is capped by a tacd ligand, resulting in a distorted trigonal-bipyramidal N_3O_2 coordination environment about the copper(II) atom with the Cu—N bonds at 2.040(5)–2.144(4) Å, Cu—O bonds at 1.895(2)–1.970(3) Å. Copyright © 1996 Elsevier Science Ltd

Keywords: copper(II); triazacyclodecane; carboxylate; hydroxide; synthesis; crystal structure.

Macrocyclic triamines are of current interest in the synthesis of metal complexes of biological significance. A large number of metal complexes containing this kind of tripodal ligand, especially the derivatives of nine-membered triazacyclonane and 12-membered triazacyclododecane, have been synthesized and their structures and properties studied [1–5]. We have used the less well known 10-membered macrocycle triazacyclodecane (tacd) to synthesize two monomeric complexes, $[M(tacd)_2]^{2+}$ ($M = Cu^{2+}, Zn^{2+}$) [6], and two chloro-bridged dimeric complexes $[M_2(tacd)_2Cl_2]^{2+}$ ($M = Cu^{2+}, Zn^{2+}$) [7], and the structural investigations demonstrated that the 10-membered ring is more flexible in coordination to metal ions. We now report the preparation and structural characterization of a novel (μ_2-hydroxo-μ_2-carboxylato-*O*,*O*′)-bridged dinuclear copper(II) complex with tacd, namely $[Cu(HO)(MeCO_2)(tacd)_2](ClO_4)_2$ (**1**).

EXPERIMENTAL

Preparation

The ligand tacd was synthesized by a modification of the literature method [8], and complex **1** was prepared as follows: To an aqueous ethanolic solution (80%, 15 cm^3) of $Cu(MeCO_2)_2 \cdot H_2O$ (0.1 g, 0.5 mmol) was added tacd (0.07 g, 0.5 mmol), and the mixture was stirred for 20 min at 60°C, followed with addition of an aqueous solution (3 cm^3) containing $NaClO_4$ (0.07 g). The pH value of the resulting solution was adjusted to *ca* 6. After slow evaporation of the blue solution, blue polyhedral crystals of complex **1** were deposited. Found, C 27.7, H 5.7, N 12.0. Calc. for $C_{16}H_{38}Cl_2Cu_2N_6O_{11}$: C 27.9, H 5.6, N 12.2%. IR data

Crystallography

$C_{16}H_{38}Cl_2Cu_2N_6O_{11}$, mol. wt. 688.50, orthorhombic, space group *Pnma* (no. 62), $a = 13.309(3)$, $b = 12.754(3)$, $c = 16.432(3)$ Å, $V = 2789.2(10)$ Å^3, $Z = 4$, $D_c = 1.640$ Mg m^{-3} $F(000) = 1424$, Mo-K_α($\lambda = 0.71069$ Å), $\mu = 17.88$ cm^{-1}.

Intensity data (crystal size $0.2 \times 0.2 \times 0.3$ mm; $2\theta_{max} = 50°$, 2564 unique (data) were collected at 21°C on an Enraf-Nonius CAD4 diffractometer using the ω-2θ scan mode. An empirical absorption correction was applied to the data. The structure was solved with direct methods using SAPI-91 program [9], and full-matrix least-squares refinement was performed with SHELXL-93 program [10]. The non-hydrogen atoms were refined anisotropically. Hydrogen atoms of the organic ligands were generated geometrically (C—H = 0.96 Å), assigned isotropic temperature factors and included in the structure-factor calculations. Analytical expressions of neutral-atom scattering factors were employed, and anomalous dispersion corrections were incorporated [11]. The final $R_1(R_{w2})$ value was 0.083 (0.260) for 181 parameters and 152 observed reflections with $I \geqslant 2\sigma(I)$. The high values reflect the poor quality of the crystal. No improvement in the structure could be achieved by using the space group $Pn2_1a$. The selected interatomic distances and bond angles are listed in Table 1. Supplementary materials including non-hydrogen and hydrogen atomic coordinates, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

The crystal structure of complex **1** consists of discrete $[Cu_2(HO)(MeCO_2)(tacd)_2]^{2+}$ cations and perchlorate anions. As illustrated in Fig. 1, a pair of Cu^{II} atoms separated at a non-bonding distance of 3.288(1) Å are bridged by a μ_2-hydroxo and a μ_2-carboxylato-*O*,*O*′ group into a dinuclear unit, in which each Cu^{II} atom is capped with the tripodal tacd ligand. A crystallographic mirror plane bisects the dinuclear unit through the acetate carbon atoms and the hydroxo oxygen atom. The Cu^{II} atom is coordinated by three nitrogen atoms of the tacd ligand, one oxygen atom of the hydroxo group and one oxygen atom of the carboxylato group, resulting in a distorted trigonal-bipyramidal N_3O_2 environment with the axial positions occupied by the N(1) and O(2) atoms. The most distorted bond angle of the polyhedron is N(2)—Cu(1)—N(3) at 82.3(2)°. The Cu—N bond lengths fall in range of 2.040(5)—2.144(4) Å, which are slightly shorter than those found for the octahedral $[Cu(tacd)_2]^{2+}$ cations [6]. The hydroxo Cu(1)—O(1) bonds (1.895(2) Å) are significantly shorter than the carboxylato Cu(1)—O(2) bond (1.970(3) Å). The Cu—O—Cu bond angle is at 120.2(3)°, indicative of sp^2 hybridization.

It is noteworthy to mention that dinuclear complexes comprising analogous μ_2-hydroxo-μ_2-carboxylato bridge or μ_2-alkoxo-$\mu_2$carboxylato bridge are not commonly observed, and only two examples have previously been reported [12,13]. Moreover, similar dinuclear structures have been uncovered in some metalloenzymes, such as the zinc enzyme phospholipase-C and the iron enzyme ribonucleotide reductase [14,15], where the Zn···Zn and Fe···Fe distances are 3.30 Å and 3.20 Å, respectively, being strikingly similar to the Cu···Cu distance in complex **1**. Hence further exploration of analogous complexes containing zinc or iron ions will be of interest.

A new copper(II)lead(II) heterotetranuclear complex containing 2-dimethylaminoethanol: direct synthesis and structure

Olga Yu. Vassilyeva,* Vladimir N. Kokozay, Nadezhda A. Zhukova and Larisa A. Kovbasyuk

Department of Inorganic Chemistry, Kiev Shevchenko University, Volodimirska st., 64, Kiev 252033, Ukraine

(Received 26 March 1996; accepted 22 May 1996)

Abstract—The heterotetranuclear $Cu^{II}Pb^{II}$ complex containing 2-dimethylaminoethanol has been synthesized using copper powder and PbI_2 as starting materials and characterized by X-ray crystallography. The crystal comprises dimeric centrosymmetric molecules $\{Cu_2Pb_2[(CH_3)_2NCH_2CH_2O]_4I_4(DMSO)_2\}$ bridged by oxygen atoms of chelated 2-dimethylaminoethoxo groups, and DMSO molecules of crystallization. The nearest copper coordination environment has a somewhat distorted square planar geometry. The coordination geometry around the Pb atom is a highly distorted octahedron. The bridging oxygen atoms arrange a strictly planar central Pb_2O_2 rhombus in the structure of the complex. Copyright © 1996 Elsevier Science Ltd

Keywords: heteronuclear complexes; crystal structure; direct synthesis.

Exploring a new structural class of coordination compounds, namely heteronuclear complexes, may allow the discovery of agents that possess biological properties quite different from those of mononuclear complexes. The design of heteronuclear complexes is of importance in investigations concerning the mutual influences of several metal centers on the electronic, magnetic and electrochemical properties of such heteronuclear systems. Many heteronuclear compounds, especially ones containing copper and lead, have been obtained as complexes of binucleating macrocycles. The binucleating macrocycle derived from the 2:2 condensation of 2,6-diformyl-4-methylphenol and propane-1,3-diamine and related macrocycles have been extensively used for studies on homo- and heterobinuclear complexes and the synthetic work is rather complicated [1–3]. Our aim in this study was to establish an efficient synthetic method to obtain desirable heteronuclear complexes, first of all containing simpler ligands (e.g. aminoalcohols). In our previous study direct synthesis was successfully applied for the preparation of numerous homonuclear complexes and some of them possess unusual crystal structures and indicate biological activity [4–9]. Direct synthesis and the structural features of the heteronuclear $Cu^{II}Pb^{II}$ complex containing the 2-dimethylaminoethoxo ligand are reported.

EXPERIMENTAL

All chemicals were commercial products of reagent grade, used without further purification.

Synthesis of $\{Cu_2Pb_2[(CH_3)_2NCH_2CH_2O]_4I_4(DMSO)_2\} \cdot 2DMSO$

For the preparation of the compound the following method was used: copper powder (0.32 g, 5 mmol) PbI_2 (2.31 g, 5 mmol), DMSO (5 cm^3) and 2-dimethylaminoethanol (1.5 cm^3, 15 mmol) were placed in a flask in the above order. The mixture was heated in air up to 60°C and stirred until total dissolution of Cu and PbI_2 was observed (40–50 min). The clear green solution obtained was allowed to stand at room temperature for 2 h; then crystals separated from the solution. The crystals were filtered, washed with i-PrOH, and finally dried *in vacuo* at room temperature; yield 3.04 g (71%). Found: H, 3.7; C, 16.9; N, 3.2;

* Author to whom correspondence should be addressed.

Determination of the structure

Crystallographic measurements were made at 293 K using an Enraf-Nonius CAD-4 diffractometer operating in the ω-2θ scan mode (the ratio of the scanning rates was ω-θ = 1.2). The intensity data were collected within the range $1.6 \leqslant \theta \leqslant 23°$ using graphite-monochromated Mo-K_α radiation. The accurate unit cell parameters and the orientation matrix for data collection were obtained from least-squares refinement, using the setting angles of 24 reflections in the range $13 < \theta < 15°$. Crystal data, details of data collection and structure refinement parameters are summarized in Table 1. The structure was solved by direct methods and refined by full-matrix least-squares computations in the anisotropic approximation. The positions of the hydrogen atoms were idealized and included in the calculations of the structure factors as the fixed contributions. Convergence was reached at the agreement factors listed in Table 1; largest peak in final difference map 1.732 e/Å^3 at a distance from the lead atom of 1.15(1) Å. Corrections for the Lorentz and polarization effects as well as an empirical correction for absorption using the DIFABS [12] were applied. Observed and calculated structure factors, anisotropic thermal parameters, atomic coordinates, full lists of interatomic distances, bond angles and torsion angles are given in the supplementary material.

The structure of the complex $\{Cu_2Pb_2[(CH_3)_2NCH_2CH_2O]_4I_4(DMSO)_2\} \cdot 2DMSO$ with the atomic labelling scheme and the perspective view of the unit cell packing are shown in Figs 1 and 2. Selected bond lengths and bond angles are contained in Table 2.

RESULTS AND DISCUSSION

The crystal comprises dimeric centrosymmetric molecules $\{Cu_2Pb_2[(CH_3)_2NCH_2CH_2O]_4I_4(DMSO)_2\}$ bridged by oxygen atoms of chelated 2-dimethylaminoethoxo groups, and DMSO molecules of crystallization in the lattice cavities (Figs 1 and 2). The S atom in the last-mentioned molecules is disordered and has partial occupancy of 0.8 and 0.2 in two positions: S(21) and S(22), respectively.

The two oxygen, O(1) and O(2), and two nitrogen atoms, N(1) and N(2) of the two coordinated 2-dimethylaminoethoxo groups form the copper coordination environment, which has a somewhat distorted square planar geometry. The values of interatomic distances Cu—N, Cu—O and angles at the copper atom O—Cu—N (Table 2) agree well with reported ones for copper complexes containing aminoalcohols [13]. The maximum deviation of oxygen and nitrogen atoms from the least-squares plane is 0.13(1) Å, while the copper atom is shifted from this plane by approximately 0.20(1) Å towards the iodine atom I(2) $\{1-x, 1-y, -z\}$. The interatomic separation d[Cu···I(2) $\{1-x, 1-y, -z\}$] = 3.167(2) Å is too long for a covalent interaction [13–15], but is significantly less than the sum of the van der Waals radii of the named atoms [r(Cu) 1.9, r(I) 2.1 Å] [13–15], to all appearances this is evidence of a peculiar interatomic interaction [14].

The close lead atom coordination environment is formed by three oxygen atoms of 2-dimethylaminoethoxo groups, O(1), O(2) and O(2) $\{1-x, 1-y, -z\}$ and an oxygen atom of a coordinated DMSO molecule, O(3); appropriate bond distances are 2.343(7)–2.601(7) Å (Table 2). The remote iodine atoms, I(1) and I(2), located at a distance from the lead atom of 3.285(1)–3.390(1) Å, complete the coordination of lead to give a highly distorted octahedral configuration. The lead–iodine interatomic distances exceed the average length of the covalent bond of these atoms and, therefore, these contacts have very little covalent character [13, 15]. The Pb···I(2) distance is elongated compared with Pb···I(1) one (Table 2) probably because of the bridging of the I(2) to the copper atom. It should be noted that Pb···Cu and Pb···Cu $\{1-x, 1-y, -z\}$ separations (3.394(2) and 3.634(2) Å, respectively) are similar to those of $Cu^{II}Pb^{II}$ complexes of macrocycles (3.344(3)–3.577(2)

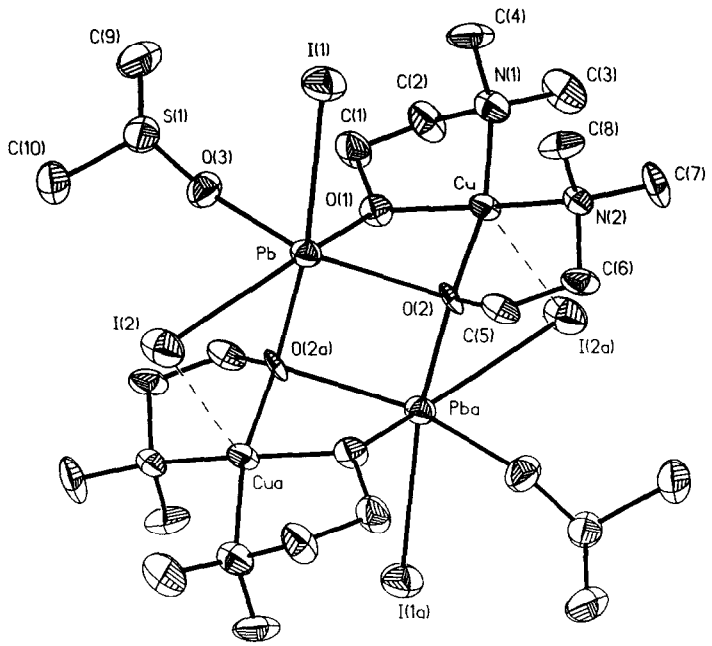

Fig. 1. Perspective view of the $\{Cu_2Pb_2[(CH_3)_2NCH_2CH_2O]_4I_4(DMSO)_2\}$ complex with 40% probability of thermal ellipsoids ("a" denotes the equivalent positions $\{1-x, 1-y, -z\}$; hydrogen atoms are omitted; the additional interaction is shown as dashes).

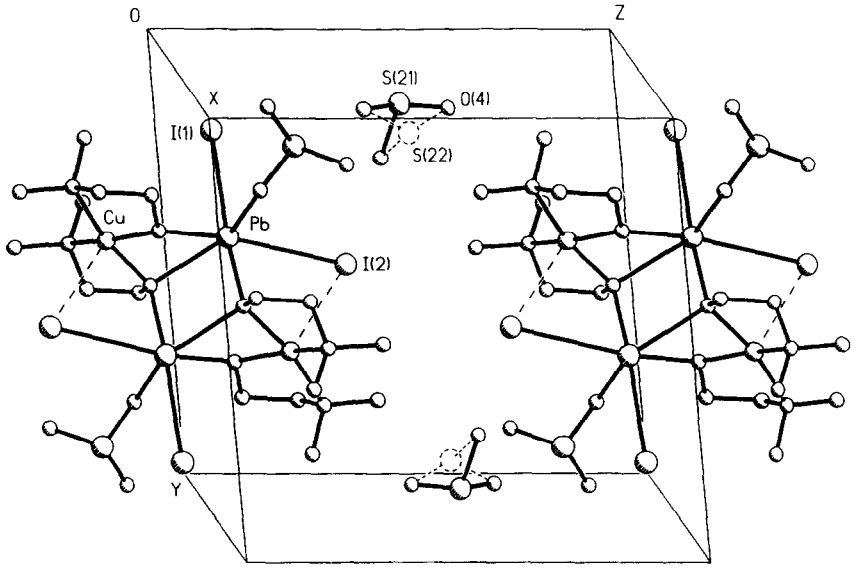

Fig. 2. A fragment of the $\{Cu_2Pb_2[(CH_3)_2NCH_2CH_2O]_4I_4(DMSO)_2\} \cdot 2DMSO$ crystal structure (the minor component of the disordered sulfur atoms are shown as dotted circles).

Å) [1–3]. Another common feature is the existence of oxygen atoms bridging both metal centers: phenolic ones and oxygen atoms of acetate groups in the case of $Cu^{II}Pb^{II}$ complexes of macrocycles and oxygen atoms of 2-dimethylaminoethoxo groups in the case of the complex under consideration. This leads to the arrangement of a strictly planar central Pb_2O_2 rhombus in the structure of $\{Cu_2Pb_2[(CH_3)_2NCH_2CH_2O]_4I_4(DMSO)_2\} \cdot 2DMSO$.

The 2-dimethylaminoethoxo groups are structurally normal [d(O—C) *ca* 1.42(2), d(C—C) *ca* 1.48(2)–1.51(2), d(C—N) *ca* 1.48(2)–1.49(2), d(N—C(terminal) *ca* 1.45(2)–1.51(2) Å) and are coordinated to copper *via* oxygen and nitrogen atoms, forming five-membered puckered rings with the *gauche* configuration [the torsion N—C—C—O angles are *ca* 49(2)–52(1)°]. The coordinated DMSO molecules [d(O—S) 1.508(9), d(S—C) *ca* 1.75(2)–1.76(2) Å, O—S—C 105.1(7) and C—S—C 98.3(9)°] are structurally normal [13].

Direct synthesis and crystal structure of zinc thiocyanate complexes with 1,4-diazabicyclo(2,2,2)octane

Svitlana R. Petrusenko, Vladimir N. Kokozay* and Igor O. Fritsky

Department of Chemistry, Kyiv Shevchenko University, 252033 Kyiv, Vladimirska st. 64, Ukraine

(Received 21 March 1996; accepted 22 May 1996)

Abstract—A direct method of synthesis of zinc thiocyanate complexes with 1,4-diazabicyclo(2,2,2)octane (or triethylenediamine, Ten) is reported. The main peculiarities of interaction of zinc oxide with non-aqueous (methanol, acetonitrile, *N*,*N*-dimethylformamide = DMF, dimethylsulfoxide = DMSO) solutions of ammonium thiocyanate in the presence of Ten were investigated. The crystal structures of the compounds $[Zn_2(NCS)_4(NH_3)_2Ten]$ (**I**), $(HTen)_2[Zn(NCS)_4]$ (**II**) and $[Zn(NCS)_2(Ten)DMSO]$ (**III**) were determined by X-ray diffraction. The complexes contain four (**I**) and five (**III**) coordinate zinc atoms linked by μ_2-bridging nitrogen atoms of Ten forming the dimeric and polymeric molecules respectively; the complex (**II**) has an ionic-type crystal lattice with $(HTen)^+$ cations and $[Zn(NCS)_4]^{2-}$ anions. Keywords: direct synthesis; zinc(II); methylenediamine; X-ray structure; thiocyanate; 1,4-diazabicyclo(2,2,2)-octane.

Previously, nickel(II) thiocyanate complexes with triethylenediamine of original crystal structure have been synthesized by the direct (one-stage) method based on reaction of metal powder with a solution of an ammonium salt and an appropriate ligand [1,2]. In continuation of the elaboration of direct methods for synthesis of coordination compounds with bioactive ligands we studied the interaction of zinc oxide with non-aqueous (methanol, acetonitrile, DMF, DMSO) solutions of ammonium thiocyanate in the presence of Ten and herein report the main results of these investigations, including details of the preparation and the structural features of several complexes.

EXPERIMENTAL

Synthesis and analytical data

All chemicals were commercial products of reagent grade, used without further purification; all experiments were carried out in air. Examples of the preparation of the complexes are presented below.

Synthesis of $(HTen)_2[Zn(NCS)_4]$

Zinc oxide (0.41 g; 0.005 M) ammonium thiocyanate (1.42 g; 0.02 M) and triethylenediamine (1.12 g; 0.01 M) were placed into the reactor and then 20 cm^3 of acetonitrile was added. The reaction mixture was heated to boiling and stirred for 2–3 min to complete the solution of the oxide. Yield: 2.2 g (83%).

Synthesis of $[Zn(NCS)_2(Ten)DMSO]$

Zinc oxide (0.41 g; 0.005 M) ammonium thiocyanate (0.76 g; 0.01 M) and triethylenediamine (0.56 g; 0.005 M) were placed into the reactor and then 20 cm^3 of DMSO was added. The reaction mixture was heated upon constant stirring during 1 h. Undissolved residue of zinc oxide was filtered off, the solution obtained was cooled. Yield: 0.6 g (32%).

Synthesis of $[Zn_2(NCS)_4(NH_3)_2Ten]$

Zinc oxide (0.41 g; 0.005 M) ammonium thiocyanate (1.42 g; 0.02 M) and triethylenediamine

(0.56 g; 0.005 M) were placed into the reactor and then 20 cm^3 of methanol was added. The oxide dissolution proceeds spontaneously for 2–3 min. In 10–15 min formation of the crystalline precipitate from the solution was observed. Yield: 0.3 g (24%). The rest of the product could be isolated as the amorphous residue by precipitation of the filtered solution.

All complexes prepared were characterized by elemental analysis (Table 1) and infrared spectra (4000–400 cm^{-1}, KBr). The identification and investigation methods are analogous to those described previously [3]. The compounds $[Zn_2(NCS)_4(NH_3)_2Ten]$, $[Zn(NCS)_2(Ten)DMSO]$ and $(HTen)_2[Zn(NCS)_4]$ were studied by X-ray diffraction.

Crystal structure determination

Crystallographic data, parameters of data collection and refinement are listed in Table 2. X-ray data were collected on an Enraf Nonius CAD-4 diffractometer (graphite-monochromatized radiation) operating in the $w/2\theta$ scan mode with a ratio of the scanning rates of $w/\theta = 1/2$. The geometrical corrections were taken into account upon reducing the intensities to the structure amplitudes.

The structures were solved by the heavy atom method, the zinc atoms were located from the Patterson maps. The refinements were carried out anisotropically for non-hydrogen atoms and isotropically for H-atoms using SHELXS-93 [4,5].

Selected bond distances and angles are presented in Tables 3–5. Lists of atomic coordinates, observed and calculated structure factors, anisotropic thermal parameters and all bond distances and angles have been deposited as "Supplementary material".

RESULTS AND DISCUSSION

One can see in Table 1 that the composition of the synthesized complexes depends to a large extent on the nature of the solvent, and in the case of DMF and DMSO on the molar ratio ZnO : NH_4NCS as well. Note that the excess of the ammonium salt influences significantly the reaction rate and the degree of conversion of the oxide. For example, the complete dissolution of the zinc oxide proceeds in 3–5 min in all the solvents upon four-fold excess of ammonium thiocyanate, whereas it does not occur completely in the case of ZnO : NH_4NCS = 1 : 2 ratio even upon heating (up to 50–90°C) for 1.5 h.

The crystalline complexes were formed by cooling the reaction mixture, or in the case of DMF solutions by precipitation with the isopropanol–ether mixture.

All compounds obtained are colourless and have low solubilities in water.

In the IR spectra of the synthesized complexes only the ν(CN) vibration of the thiocyanate group (2070 and 2090 cm^{-1}) coordinated *via* the nitrogen atom can be identified easily. The bands corresponding to ν(CO) = 1670 and ν(SO) = 1020 cm^{-1} vibrations of the coordinated DMF and DMSO, respectively, were observed in the spectra of compounds III and IV [6, 7].

The crystal structure of compound **I** consists of molecular dimeric centrosymmetric complexes $[(SCN)_2(NH_3)Zn{-}(\mu_2\text{-Ten}){-}Zn(NH_3)(NCS)_2]$ (Fig. 1) which are linked by van der Waals interactions ($S \cdots S$ = 3.39–3.62 Å; $S \cdots N(NH_3)$ = 3.04–3.29 Å) [10]. The complex molecules form columns along the z direction, so that the $Zn(1) \cdots Zn(2)$ line is perpendicular to this direction (Fig. 2). The columns are related between themselves by 2_1 screw axes and the symmetry centres. The Zn(1) and Zn(2) atoms are in a distorted tetrahedral environment of four nitrogen atoms belonging to two thiocyanate groups, the ammonia molecule and the bridging Ten molecule. The differences in Zn—N distances are rather considerable: the largest is Zn—$N(NH_3)$ ($\approx$1.99 Å); the Zn—N(Ten) ($\approx$1.94 Å) are somewhat shorter and the Zn—N(NCS) ($\approx$1.85 Å) are the shortest. The Zn(1) and Zn(2) polyhedra differ noticeably by two Zn—N(NCS) bond distances: for the Zn(1) polyhedron this difference is 0.07 Å, for Zn(2) it is 0.19 Å. Significant deviations of the bond angles from tetra-

hedral are noted: 98.3–121.5° for Zn(1) and 93.9–118.3° for Zn(2). The non-equivalent character of the thiocyanate groups is reflected in different values of the bond angles Zn—N—C which vary in the range of 164.3–171.9°. However, there is no correlation between these angles and the corresponding Zn—N distances. At the same time one can notice the correlation between the Zn—NCS distances and N—C and C—S distances in the corresponding thiocyanate groups: the shortened N—C and C—S distances correspond to shorter Zn—N bonds. For example, Zn(2)—N(3) = 1.754(6); N(3)—C(3) = 1.031(9); C(3)—S(3) = 1.426(7) Å; Zn(2)—N(4) = 1.946(8); N(4)—C(4) = 1.140(4); C(4)—S(4) = 1.586(8) Å.

The geometrical parameters of the Ten molecule are close to those normally observed. The torsion angles along the C—C bond for the NCCN fragments are -5.4–(-7.0)° which reflect their gauche-conformation with a low degree of deviation from the

planar conformation. The deviations found take intermediate values between the corresponding values observed in the structures of $Ni(HTen)_2(NCS)_4$ (13.8–15.8°) [1] and $HTen(NCS)\cdot 0.5H_2O$ (1–2°) [8].

In the compound **III** the bridging function of Ten is realized as well (Fig. 3) which leads, unlike the compound **I**, to the formation of polymeric chains. Those chains are packed along the y direction of the crystal (Fig. 4), and are linked by van der Waals interactions. The monodentate thiocyanate groups and the DMSO molecules are oriented approximately perpendicular to the chain direction. The coordination environment of the zinc atom is an elongated trigonal bipyramid formed by two donor nitrogen atoms of the bridging Ten molecules, two nitrogen atoms of the terminal thiocyanate groups and the oxygen atom of the DMSO molecule. As the N(1), N(1a) and N(2), N(2a) atoms are symmetrically related, the linear and angular distortions of the polyhedron are not significant. They are characterized by elongated axial Zn—N(Ten) distances and small deviations of the bond angles near the zinc atom in the equatorial plane (118 and 123°). The Zn—N(Ten) distances in **III** are found to be significantly longer than the corresponding distances in structure **I** (Tables 2, 3).

The NCCN fragments in the Ten molecules are observed to be planar.

In contrast to **I** and **III**, the compound **II** is ionic and consists of complex anions $[Zn(NCS)_4]^{2-}$ and $(HTen)^+$ cations which are linked into polymeric chains by means of hydrogen bonds N(7)—H···N(6) and N(5)—H···N(8) (Fig. 5A) [11]. The H-bonds parameters NH···N between the protonated Ten molecules are: d(N(7)···N(6)) = 2.82, d(N(7)···H) = 0.91, d(H···N(6)) = 1.92 Å, <N(7)NH(6) = 172.5°; d(N(5)···N(8) $(-0.5+x,\ 0.5-y,\ 0.5+z)$) = 2.78, d(N(5)—H) = 0.85, d(H···N(8) $(-0.5+x,\ 0.5-y,\ 0.5+z)$) = 1.94 Å, <N(5)HN(8) $(-0.5+x,\ 0.5-y,\ 0.5+z)$) = 168.6°. Unlike the related compound $(H_2Ten)[ZnCl_4]$, which has a similar structure, the isolated two-fold protonated cations $(H_2Ten)^{2+}$ are present [9]. In the analogous complex $Ni(HTen)_2(NCS)_4$ reported earlier [1] the protonated Ten molecules are coordinated to the central atom.

The complex cation $[Zn(NCS)_4]^{2-}$ is a distorted tetrahedron: the Zn—N bond lengths are in the range 1.94–1.98 Å; deviations of values from tetrahedral of the bond angles at the central atom are 0.3–5.8°. The ZnNC angle values vary from 166.3 to 173.2° (Table 5, Fig. 5B). The coordinated thiocyanate groups are in fact linear.

The conformation of NCCN fragments in $(HTen)^+$ cations is slightly different from that in the planar neutral ligand: the corresponding torsion angles do not exceed 3.3°.

In the crystal packing the complex anions form a

framework with hexagonal channels which are filled by polymeric chains of the $(HTen)^{+}$ cations arranged parallel to the *xz* plane (Fig. 6).

In all the structures determined the significant deviations of the geometrical parameters of the coordination polyhedra from regularity are observed as probably connected with the rigid conformation ability of the bicyclic ligand.

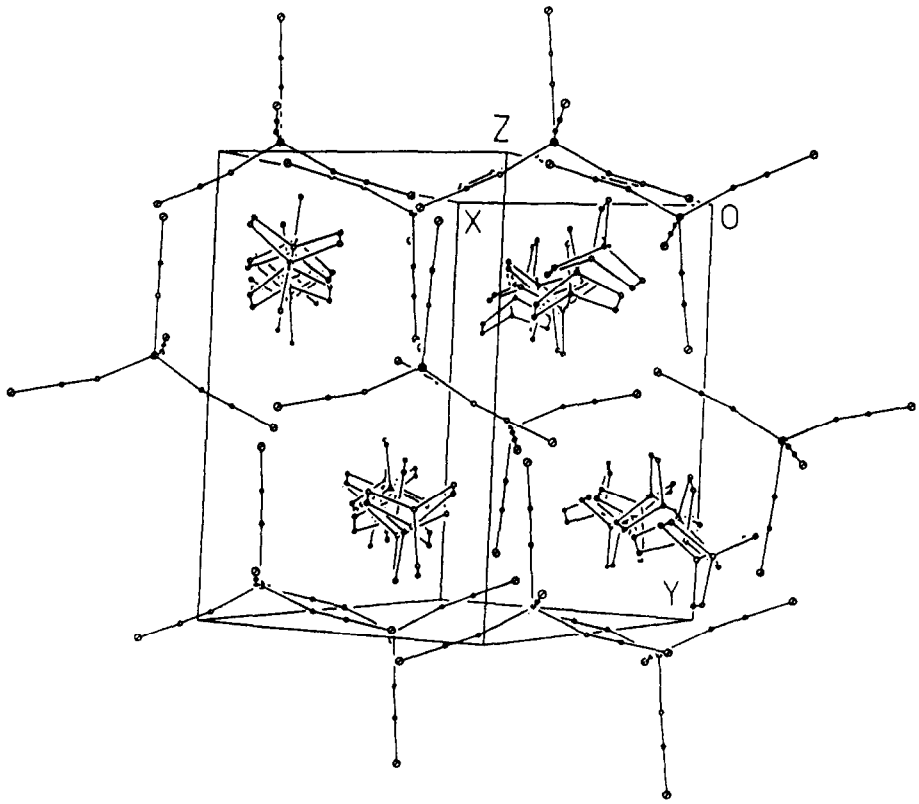

Fig. 6. Perspective view of the unit cell packing for $(HTen)_2[Zn(NCS)_4]$.

Istituto di Chimica dei Materiali del C.N.R. Area della Ricerca di Roma, C.P. 10, via Salaria Km 29.500, 00016 Monterotondo Stazione, Roma, Italy

(Received 21 December 1995; accepted 22 May 1996)

Abstract—The spectroscopic and electrochemical properties of the complexes $[M\{NRNC(S)SMe\}_2]$ (M = Ni or Pt; R = C_6H_4OMe-4 or $C_6H_4NO_2$-4) and of the anionic derivatives $[AsPh_4]$ $[M\{N(C_6H_4NO_2\text{-}4)NC(S)SMe\}_2]$ (M = Ni or Pt) were investigated. Heating of $[Ni\{NC_6H_4OMe\text{-}4)NC(S)SMe\}_2]$ led to [Ni{N[4-MeOPhN(4-MeO)C_6H_3]NC(S)SMe}(NCS)]. Copyright © 1996 Elsevier Science Ltd

Keywords: complexes; nickel; platinum; methyldithiocarbazates; dithiolene-like; electron-transfer.

We have previously investigated the coordination properties of methyldithiocarbarzate $NH_2NHC(S)SMe$ and its 3-substituted derivatives in platinum [1], nickel [2], copper [3] and palladium [4] complexes prepared under different chemical conditions. The ligands are generally coordinated through thiono sulfur and terminal nitrogen atoms in neutral or anionic deprotonated form; the deep coloured complexes containing the doubly deprotonated ligands are dithiolene-like and belong to electron-transfer series. These compounds show similarities with complexes of dithiosemicarbazides, containing doubly deprotonated ligands, which are known to be deeply coloured and to belong to electron-transfer series [5, 6]. We have observed that the properties and reactivity of the complexes of N(3) substituted dithiocarbazic esters strongly depend on the substituent and on the metal. Here we report an extention of our researches on dithiolene-like complexes of nickel and platinum with $NH(4\text{-}MeOC_6H_4)NHC(S)SMe$ and $NH(4\text{-}O_2NC_6H_4)NHC(S)SMe$, containing electron-releasing and electron-attracting substituents on N(3), respectively.

EXPERIMENTAL

Materials

The chemicals were commercial analytical grade reagents and used without further purification, except for the solvents employed for electrochemical measurements which were purified as described in ref. [7]. Nitrogen gas was an ultra-high purity commercial product. All the compounds were dried *in vacuo* (1 torr) over P_4O_{10}, unless otherwise stated.

Preparation of the ligands

The compounds NHRNHC(S)SMe (R = 4-$MeOC_6H_4$ or 4-$O_2NC_6H_4$) were prepared following the methods reported in Ref. [4].

Preparation of the complexes

$[Ni\{N(C_6H_4OMe\text{-}4)NC(S)SMe\}_2]$**1a**. A solution of $NiCl_2 \cdot 6H_2O$ (5.50 mmol) in water (30 cm^3) was added to a solution of $NH(C_6H_4OMe\text{-}4)NHC(S)SMe$ (1.1 mmol) in EtOH (40 cm^3). Ammonium hydroxide (1 mol dm^{-3}) was added until pH 9. After 12 h stirring

in an open vessel the product was filtered off and dried. Yield 73%.

$[Ni\{N(C_6H_4NO_2\text{-}4)NC(S)SMe\}_2]$ **1b**. This complex was prepared as above starting from solutions of $NiCl_2 \cdot 6H_2O$ (1.0 mmol in 20 cm^3 of water) and $NH(C_6H_4NO_2\text{-}4)NHC(S)SMe$ (2.0 mmol in 80 cm^3 of EtOH). After addition of ammonium hydroxide stirring was continued for 12 h. Yield 61%.

$[AsPh_4]$ $[Ni\{N(C_6H_4NO_2\text{-}4)NC(S)SMe\}_2]$ **1c**. The compound $NH_2NH_2 \cdot H_2O$ (10 cm^3) was added to a stirred and heated suspension of **1b** (24.0 mmol) in EtOH (40 cm^3). After formation of a dark-red solution the heating was stopped. At room temperature a solution of $AsPh_4 \cdot H_2O$ (24.0 mmol) in H_2O (20 cm^3) was added. After 45 min of stirring the dark-violet compound was filtered off, washed with water and dried. Yield 74%.

$[Ni\{N[C_6H_3(OMe\text{-}4)NC_6H_4(OMe\text{-}4)]NC(S)SMe\}(NCS)]$ **1d**. A solution of **1a** (2.0 mmol) in CS_2 (100 cm^3) was boiled for 1 h. The solution was left at $-40°C$ for 12 h and the separated product was filtered off and dried. Yield 40%.

$[Pt\{N(C_6H_4OMe\text{-}4)NC(S)SMe\}_2]$ **2a**, $[Pt\{N(C_6H_4NO_2\text{-}4)NC(S)SMe\}_2]$ **2b** and $[AsPh_4][Pt\{N(C_6H_4NO_2\text{-}4)NC(S)SMe\}_2]$ **2c** were prepared as reported for the compounds **1a**, **1b** and **1c**, respectively, starting from solutions of $K_2[PtCl_4]$. Yields: **2a** 30%, **2b** 70%, **2c** 84%.

Physical measurements

Analytical data for the complexes are given in Table 1. Microanalyses were performed by Microanalytical Service of the Area della Ricerca di Roma del CNR. The UV/VIS reflectance spectra of the finely powdered solids were obtained on a Cary 5 spectrophotometer fitted with a standard reflectance attachment and MgO in the reference beam. Solution spectra were recorded at room temperature on Perkin-Elmer 330 spectrophotometer (10^{-3} mol dm^{-3}). Infrared spectra were determined (200–4000 cm^{-1}) on a Perkin-Elmer 16FPC FT-IR spectrophotometer as Nujol or poly(chlorotrifluoroethylene) mulls. Magnetic measurements were performed on solid samples with a Gouy balance calibrated with $HgCo(SCN)_4$.

Table 1. Analytical data for nickel and platinum complexes

Compound	Colour	Analysis (%)[a] C	H	N	S
1a	Dark brown	42.6 (42.3)	3.9 (3.9)	10.8 (11.0)	23.6 (25.1)
1b	Dark green	35.8 (35.5)	2.4 (2.6)	15.3 (15.5)	23.2 (23.7)
1c	Dark violet	52.2 (51.9)	4.0 (3.7)	9.0 (9.0)	13.6 (13.9)
1d	Black	43.7 (43.9)	3.7 (4.0)	11.8 (12.1)	20.5 (20.8)
2a	Green	33.1 (33.4)	2.8 (3.1)	8.4 (8.7)	19.5 (19.8)
2b	Green	28.6 (28.4)	1.9 (2.1)	12.3 (12.4)	18.7 (18.9)
2c	Dark green	45.0 (45.3)	3.0 (3.2)	8.2 (7.9)	12.4 (12.1)

[a]Required values are given in parentheses.

Electrochemical measurements

D.C. polarography and cyclovoltammetry were performed, as reported in Ref. [7], with an Amel model 471 three-electrode multifunctional assembly. The working electrode was a standard Amel pulsing or stationary electrode and the counter electrode was a platinum wire. A $Hg|Hg_2Cl_2$, NaCl (saturated, aq)|agar-NaCl (aq)|agar (1.5%, w/v)-dmf-water (40%, v/v)-NEt_4ClO_4 (saturated)|methyl cellulose (5%, w/v)-dmf-NEt_4ClO_4 (saturated) sintered-glass disc (dmf = dimethylformamide) served as reference electrode. Its potential was 2.2 mV *vs* an aqueous saturated calomel electrode (SCE), the liquid junction potential being included. All potentials reported in Tables 3 and 4 are quoted with respect to the reference electrode with an accuracy of ± 5 mV.

RESULTS AND DISCUSSION

Preparation and properties of nickel and platinum complexes

The compounds $NHRNHC(S)SMe$ ($R = C_6H_4OMe\text{-}4$ or $C_6H_4NO_2\text{-}4$) reacted readily with K_2PtCl_4 or $NiCl_2$ in aqueous ethanol. If the medium is made strongly basic, crystalline, intensely coloured, diamagnetic compounds **1a, 1b, 2a** and **2b**, which contain doubly deprotonated ligands, are formed. We assume that there is a progressive deprotonation of the ligands, in accord with reports on dithiolene-like complexes of thiosemicarbazides [5,6] and with our reports on the reactions of $NH_2NHC(S)SMe$ and its 3-substituted derivatives with K_2PtCl_4 [1], $NiCl_2$ [2], $CuCl_2$ [3] and $K_2[PdCl_4]$ [4]. The complexes are soluble in most organic solvents, showing differences depending on the substituent in the phenyl ring. The NO_2-substituted compounds are the least soluble. The complexes can be electrochemically reduced giving anionic complexes whereas only some of them can be oxidized giving cationic complexes. They can be easily reduced by $NH_2NH_2 \cdot H_2O$ to monoanionic complexes. We have isolated and characterized $[AsPh_4][Ni\{N(C_6H_4NO_2\text{-}4)NC(S)SMe\}_2]$ **1c** and $[AsPh_4][Pt\{N(C_6H_4NO_2\text{-}4)NC(S)SMe\}_2]$ **2c**. The complex $[Ni\{N(C_6H_4OMe\text{-}4)NC(S)SMe\}_2]$ **1a** shows peculiar behaviour when crystallized from boiling CS_2. The complex formally loses one mole of MeSH giving the new compound $[Ni\{N[4\text{-}MeOPhN(4\text{-}MeO)C_6H_3]NC(S)SMe\}(NCS)]$. We already observed simi-

lar behaviour for the complexes [Ni{NPhNC(S)SMe}$_2$] [2], [Pd{NPhNC(S)SMe}$_2$] [4] and [Pd{N(C_6H_4OMe-4)NC(S)SMe}$_2$] [4] which gave rise to the complexes [Ni{$PhNC_6H_4$NNC(S)SMe}(NCS)], [Pd {N(C_6H_4NPh-2)NC(S)SMe}(NCS)]·0.5C_6H_6, [Pd{N[C_6H_3(OMe-4)NC_6H_4(OMe-4)]NC(S)SMe}(SCN)]·0.5C_6H_6, respectively. The complexes obtained show structural differences and we note that the reaction does not take place when the metal is platinum and when NO_2 groups are present in the ligands.

Infrared spectra

The absorption bands, which in the spectra of the ligands NHRNHC(S)SMe are attributed to ν(N—H) (3199 and 3103 cm^{-1} for R = C_6H_4OMe-4, 3281 and 3115 cm^{-1} for R = $C_6H_2NO_2$-4) [4] are no longer present in the spectra of the corresponding nickel and platinum complexes [M{NRNC(S)SMe}$_2$] **1a, 1b, 2a** and **2b** confirming that both N atoms of the ligands are deprotonated. Moreover the spectra show bands attributable to ν(M—N) and to ν(M—S) in the ranges 490–405 and 393–303 cm^{-1}, respectively, supporting N—S chelation of the ligands. In the spectrum of [Ni{N[4-MeOPhN(4-MeO)C_6H_3]NC(S)SMe}(NCS)] a sharp absorption at 2100 cm^{-1} is assigned to ν(C≡N) of the isothiocyanato group, as found in [Ni{NCC_6H_4Ph-2)NC(S)SMe}(NCS)] [2].

Electronic spectra

Data are given in Table 2. The electronic spectra of the complexes **1a, 1b, 2a** and **2b** are very similar and show features common to dithiolene-like complexes with electron-transfer properties (see Figs 1 and 2). The prominent strong bands in the range 11,000–13,000 cm^{-1} are assigned to ligand-to-metal c.t. absorptions in accord with our previous reports on similar complexes of platinum [1], nickel [2], copper [3] and platinum [4]. The spectrum of **1d** (see Fig. 3) shows very similar features to the spectra of [Ni{N-[$PhNC_6H_4$]NC(S)SMe}(NCS)] and [Pd{N[4-MeO PhN(4-MeO)C_6H_3]NC(S)SMe}(SCN)]·0.5C_6H_6, as we have already reported [2,4].

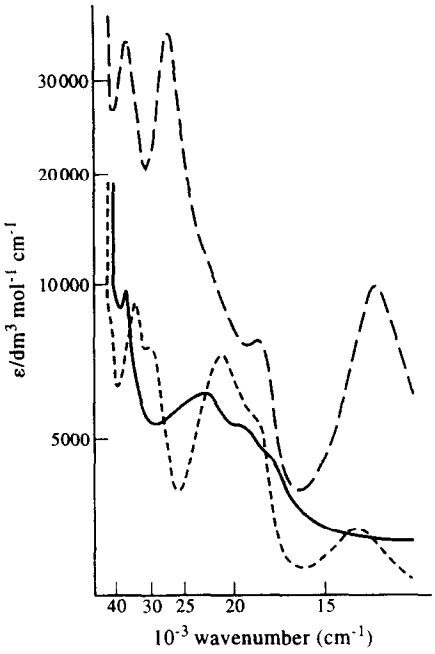

Fig. 1. Electronic spectra in CH_2Cl_2 of complexes **1a** (– – –), **1b** (— — —) and **1c** (— · —).

Electrochemical measurements

Cyclovoltammetric and polarographic data are reported in Tables 3 and 4. The voltage range 0 to +1.5 V was explored in the oxidation mode and the range 0 to −1.5 V in the reduction mode. The data concerning the compounds with doubly deprotonated ligands show that the nickel and platinum complexes belong to electron-transfer series as is usual for dithi-

olene and dithiolene-like complexes with five-membered delocalized chelate rings (Scheme 1).

The nickel and platinum complexes show well-defined waves corresponding to one-electron quasi-reversible processes as inferred from the values of $E_{3/4}-E_{1/4}$ in d.c. voltammetry (slopes in Tables 3 and 4) and from the cyclicvoltammetric anodic/cathodic or cathodic/anodic current ratios, which are close to the theoretical value for a one-electron reversible process. The complexes **1a** and **2a** show oxidation and reduction waves corresponding to processes leading to the formation of the cations 1 and 2 and the anions

[e]Calculated using $E_{3/4}$–$E_{1/4}$.

4 and 5. The complexes **1c** and **2c**, corresponding to the anions 4, were studied instead of the neutral complexes because their low solubility prevented electrochemical measurements. They show oxidation waves corresponding to the processes leading to formation of the neutral complexes 3 and reduction waves corresponding to the processes leading to the anions 5. The complex **1d** containing isothiocyanate anion shows two reduction waves corresponding to processes leading to mono- and di-anionic forms. We note that the reduction potentials of the complexes containing NO_2 group are at lower values with respect to the values we found for dithiolene-like complexes of nickel and platinum with other 3-substituted dithiocarbazic esters [1, 2, 3, 4], according to the strong electron-attracting effect of the group.

Acknowledgement—The authors wish to thank Mr F. Dianetti for microanalysis.

(Received 12 April 1996; accepted 20 May 1996)

Abstract—The complexes $[Cu(\mu\text{-L})Cu(bipy)(EtOH)](ClO_4)_2$ **2a** and $[Cu(\mu\text{-}^1L)Cu(bipy)(H_2O)](ClO_4)_2 \cdot H_2O$ **2b** [where H_2L = *N,N'*-bis(1,3-dimethyl-5-nitrosopyrimidine-2,4-(1H,3H)-dion-6-yl)propylenediamine; H_2^1L arises from H_2L by elimination of a CO molecule from one of the pyrimidine rings] have been obtained from the reaction of the precursor $[Cu(\mu\text{-HL})Cu(H_2O)_2(CH_3CH_2OH)](ClO_4)_3$ **1** with bipy and $Cu(ClO_4)_2 \cdot 6H_2O$, respectively. The structures of **2a** and **2b** have been solved by X-ray crystallographic methods. The structure of **2a** is made up of $[Cu(\mu\text{-L})Cu(bipy)(EtOH)]^{2+}$ cations and two semi coordinated perchlorate anions. The [Cu(1)L] fragment coordinates to the external Cu(2) ion through the two deprotonated oximate oxygens to afford a dinuclear structure with double *syn-syn* nitroso-oximate bridge and an intramolecular Cu–Cu distance of 3.731(1) Å. The Cu(1) exhibits a CuN_4O_2 pseudooctahedral coordination polyhedron whereas the geometry around the Cu(2) ion is distorted square-pyramidal CuN_2O_2O. The structure of **2b** consists of $[Cu(\mu\text{-}^1L)Cu(bipy)(H_2O)]^{2+}$ cations, two perchlorate anions and one lattice water molecule. The coordination of the $[Cu(^1L)]$ unit to the external Cu(2) ion takes place through the two nitroso-oximate groups, one of them disordered on two sets of crystallographic positions, one with a 63% occupancy and the other with a 37% occupancy. The intramolecular Cu(1)—Cu(2) distance is 3.655(3) Å. The Cu(1) occupying the inner site of the $^1L^{2-}$ ligand exhibits a 4+1 CuN_4O (63%) $[CuN_3O_2$ (37%)] coordination environment whereas the Cu(2) atom is in a distorted square-pyramidal CuN_2O_3 (63%) $[CuN_3O_2$ (37%)] environment. The dinuclear fragments of **2a** and **2b** are almost planar with dihedral angles between the mean basal coordination planes of 4.1(2)° and 4.6°, respectively. Both **2a** and **2b** are diamagnetic at room temperature, so that $J < -1000$ cm^{-1}. The structural and magnetic data for these complexes have been compared with those of similar compounds, but no correlation between the magnitude of the exchange interaction and the degree of deviation from planarity is evident. In view of this and to rationalize the influence of the distortion from planarity on the magnetic properties in oximate-bridged complexes, MO Extended Hückel calculations have been performed. Magnetostructural studies on polynuclear metal complexes are of continuing interest for coordination chemists since they can provide the understanding of fundamental factors governing their magnetic properties. This knowledge can be applicable for the design and preparation of new molecular materials exhibiting expected magnetic properties such as molecular-based magnets [1], or to deduce the structure of active sites in metalloproteins with interacting paramagnetic centers [2].

To design and synthesize polynuclear metal complexes, one of the best and common strategies is the use of mononuclear complexes as ligands. These complexes must contain donor groups for another metal ion or metal complex with empty coordination sites. Typical examples of this class of mononuclear precursors are the oximato copper(II) complexes [3], which can coordinate another metal ion through the deprotonated oximate oxygens, leading to oximate-bridged homo- and heteropolynuclear metal complexes [4,5]. Previously, we reported the synthesis and characterization of a dinuclear copper(II) complex of formula $[Cu(\mu\text{-HL})Cu(H_2O)_2(CH_3CH_2OH)](ClO_4)_3$ **1**, which was obtained by the reaction of the multidentate dioxime ligand *N,N'*-bis(1,3-dimethyl-5-nitroso pyrimidine-2,4-(1H,3H)-dion-6-yl)propylenediamine, H_2L, with an excess of Cu^{2+} [4h]. In this complex, the copper(II) ion occupying the external site must be coordinated by the nitroso-oximate oxygens atoms and by labile ligands (CH_3OH or H_2O), which can be easily replaced by a chelate ligand. This route allowed us to obtain a series of new dinuclear complexes with different "end-cap" ligands. In the present paper we report on the structures and magnetic properties of two oximate-bridged dinuclear copper(II) complexes, both containing 2,2'-bipyridyl (bipy) as "end-cap" ligand, which were obtained from the same precursor **1**.

EXPERIMENTAL

The ligand *N,N'*-bis(1,3-dimethyl-5-nitroso-pyrimidine-2,4-(1H,3H)-dion-6-yl) propylenediamine (H_2L) and the complex $[Cu(\mu\text{-HL})Cu(H_2O)_2(CH_3CH_2OH)](ClO_4)_3$ **1** were prepared as previously described [4h,5g].

Synthesis of the complexes

CAUTION! Perchlorate salts of metal complexes are potentially explosive. Only a small amount of material should be prepared, and it should be handled with caution.

$[Cu(\mu\text{-L})Cu(bipy)(EtOH)](ClO_4)_2$ **2a**. 2,2'-bipyridyl (0.23 g, 1.5 mmol) was added to a suspension of **1** (0.46 g, 0.5 mmol) in 50 cm^3 of ethanol/water/acetonitrile (10 : 1 : 1). After a few minutes at 60°C, a black solution was obtained, which was filtered to remove any amount of insoluble material. Suitable black crystals for X-ray analysis were obtained by evaporation of the solution at room temperature. Yield: 72%. Found: C, 34.6; H, 3.6; N, 15.0; Cl, 7.9; Cu, 13.3. Calc. for $C_{27}H_{32}N_{10}O_{15}Cl_2Cu_2$: C, 34.7; H, 3.4; N, 15.0; Cl, 7.6; Cu, 13.6%.

$[Cu(\mu\text{-}^1L)Cu(bipy)(H_2O)](ClO_4)_2 \cdot H_2O$ **2b**. Copper(II) perchlorate (0.30 g, 0.8 mmol) and bipyridyl (0.12 g, 0.8 mmol) were successively added to a stirred suspension of **1** (0.46 g, 0.5 mmol) in 50 cm^3 of ethanol/water (10 : 1) and the mixture was refluxed for one hour. From the resulting solution, black crystals of **2b** were separated by slow evaporation at room temperature. Yield: 31%. Found: C, 32.0; H, 3.5; N, 15.3; Cl, 7.7; Cu, 14.0. Calc. for $C_{24}H_{30}N_{10}O_{15}Cl_2Cu_2$: C, 32.1; H, 3.3; N, 15.6; Cl, 7.9; Cu, 14.2%.

Physical measurements

Microanalysis and magnetic susceptibility data were obtained as already described [5g].

X-ray data collection and structure determination of the compounds

Single-crystal data collection of **2a** was performed at 296 K with a Nicolet P3F diffractometer using monochromized Mo-K_α radiation. The unit cell parameters were determined by least-squares refinement of 25 carefully centered reflections. The data obtained were correct for Lorentz and polarization effects and for dispersion. Also, a correction for empirical absorption (Ψ scan) was applied. The space group, $P2_1/c$, was confirmed by systematic absences and structure analysis. The structure was solved by Patterson method [6] and successive Fourier maps. The solvent ethanol molecule coordinated to Cu(2) is partly disordered with the oxygen atom O(30) occupying two positions, and refinements yielded site occupation parameter 0.441(8) for O(30A) and 0.559(8) for O(30B). In the final refinements the non-hydrogen atoms of the disordered ethanol molecule were refined isotropically. The methyl groups were refined as rigid groups with group isotropic displacement parameters. The rest of the non-hydrogen atoms were refined with anisotropic displacement parameters. The hydrogen atoms were placed at their calculated positions (C—H = 0.96 Å and U(H) equal to U of bonded atom), except those of the disordered ethanol molecule, which were not positioned. All refinements were performed using XTAL3.0 program system [7], which minimized the function $\Sigma w(|F_o| - |F_c|)^2$, where $w = 1/\sigma F^2$.

Single-crystal data collection of **2b** was performed at 193 K with a Rigaku AFC-7S diffractometer using graphite monochromatized Mo-K_α radiation and MSC/AFC Diffractometer Control Software (Molecular Structure Corporation, 1993) [8]. Data were corrected for Lorentz and polarization effects. The structure was solved by direct methods and refined by

full-matrix least-squares using programs in SHELXTL/PC package [9]. One nitroso-oximate group is disordered with site occupancy factor of 0.63(4) for atoms labelled N(14A) and O(14A) and 0.37(4) for N(14B) and O(14B). H atoms were placed on calculated positions (C—H = 0.96 Å) except those of the water molecules, that were refined as a rigid group (O—H = 0.85 Å), all with fixed isotropic temperature factor of 0.08 Å^2.

Crystal data and details of data collections of the **2a** and **2b** complexes are listed in Table 1.

RESULTS AND DISCUSSION

On treating H_2L with an excess of copper(II) perchlorate hexahydrate in ethanol, the complex with the empirical formula $[Cu(\mu\text{-}HL)Cu(H_2O)_2(CH_3CH_2OH)](ClO_4)_3$ **1** was obtained [4h]. This dinuclear complex can react with 2,2′-bipyridyl to afford the complex $[Cu(\mu\text{-}L)Cu(bipy)(EtOH)](ClO_4)_2$ **2a**, in which bipy has replaced the labile ligands coordinated to the external copper(II) in **1**. However, when $[Cu(bipy)]^{2+}$ was used instead of bipy as counterpart, the dinuclear $[Cu(\mu\text{-}^1L)Cu(bipy)(H_2O)](ClO_4)_2 \cdot H_2O$ **2b** complex was isolated. $(^1L)^{2-}$ is obtained from L^{2-} by elimination of one CO molecule from one of the pyrimidine rings, leading to an imidazole ring.

Crystal structure of **2a**

The structure of complex **2a** consists of dinuclear $[Cu(\mu\text{-}L)Cu(bipy)(EtOH)]^{2+}$ cations and two semi-coordinated perchlorate atoms. A perspective view of the dinuclear copper(II) cation with the atom-labelling scheme is given in Fig. 1. Selected bonds lengths and angles are listed in Table 2.

As expected, the external copper(II) ion, Cu(2), is coordinated by the unit [Cu(1)L] through the two diatomic *syn-syn* nitroso-oximate groups to afford a dinuclear complex with Cu(1)—Cu(2) distance of 3.731(1) Å.

The Cu(1) ion occupies the inner site of the double deprotonated ligand L^{2-} exhibiting a pseudo-octahedral coordination. Four short bonds of *ca* 1.98 Å are formed with N(5), N(6), N(15) and N(16), that are practically coplanar (deviations from the least-square plane lower than 0.044 Å). The Cu(1) ion is lifted 0.103(1) Å from the N_4 mean basal plane toward the oxygen atom O(33) belonging to a perchlorate anion, which occupies one of the axial positions at a distance of 2.404(5) Å. The other axial position is occupied by the oxygen atom O(37) of the second perchlorate anion with a Cu(1)—O(37) distance of 2.660(7) Å.

Within the [Cu(1)L] fragment, the bond lengths and angles do not significantly differ from those observed in the complex $[CuL(H_2O] \cdot 3H_2O$ [5g].

The coordination geometry around the Cu(2) ion is distorted square pyramidal, CuN_2O_2O. The basal plane is defined by the two nitroso-oximate O(5) and O(15), and the two bipyridyl N(18) and N(29) atoms with distances of about 1.92 and 2.00 Å, for Cu—O and Cu—N, respectively. The fifth position is occupied at a longer distance of about 2.29 Å by a disordered oxygen atom O(30) from the molecule of ethanol, with occupancy factor of 0.441(8) and 0.559(8) for O(30A) and O(30B), respectively.

Bipy coordinates to Cu(2) in a bidentate fashion. As usual, the N(18)—Cu(2)—N(29) angle is significantly smaller than 90° (80.3(2)°) as consequence of the geometric constraints of the bipyridyl ring system. The equatorial atoms are not coplanar but pair-wise distorted, so that O(15) and N(18) are lifted 0.118(6) and 0.143(6) Å, respectively, above the mean basal plane whereas O(5) and N(29) are located 0.106(6) and 0.158(6) Å, respectively, below the plane. The Cu(2) atom sticks out from the mean basal plane N_2O_2 by 0.213(1) Å toward the axially-bonded ethanol molecule.

The dinuclear fragment $[Cu(\mu\text{-L})Cu(bipy)]^{2+}$ cation is practically planar. Thus, the dihedral angle between the plane defined by Cu(1)N(5)N(15)O(5)O(15) and Cu(2)O(5)O(15)N(18)N(29) is 4.1(2)°.

Crystal structure of **2b**

The asymmetric unit of **2b** contains one $[Cu(\mu\text{-}^1L)Cu(bipy)(H_2O)]^{2+}$ cation, two perchlorate anions, one of them semi-coordinated, and one lattice water molecule. A perspective view of the dinuclear cation with the atom-labelling scheme can be observed in Fig. 2. Selected bond lengths and angles are listed in Table 3.

The most interesting feature of the structure results from the elimination of one CO molecule of one pyrimidine ring in L^{2-} leading to an imidazole ring. It is interesting to note that a similar decarbonilation process has been observed for the same ligand L^{2-} in the complex $[Cu(ClO_4)(\mu\text{-}^1L)Ni(Me_3[12]N_3)](ClO_4)\cdot H_2O$ [5g], and other uracil derivatives. For instance, when an aqueous solution of 1,3-dimethyl-5,6-diaminouracil is treated with ferric chloride, 1,3-dimethyl-2,4,5-imidazolinetrione is obtained in good yield [10].

As can be seen in Fig. 2, the coordination of the $[Cu(1)^1L]$ unit to the external copper(II) ion, Cu(2), takes place through the two NO groups, giving rise to a dinuclear copper(II) complex with a Cu(1)—Cu(2) distance of 3.655(3) Å. One of the NO groups, the N(14)—O(14), is disordered, exhibiting two different bridging conformations. The first one (0.63(4) occupancy factor) is of *syn* type, like that of the non-disordered NO group, whereas the second one (0.37(4) occupancy factor) is *O*-monoatomic with a Cu(1)—O(14B)—Cu(2) angle of 128(1)°. This last conformation of the NO group is rather uncommon and it has been only observed in the complexes $[Cu(ClO_4)(\mu\text{-}^1L)Ni(Me_3[12]N_3)](ClO_4)\cdot H_2O$ [5g] and $\{[Cu_2(dmg)(Hdmg)(H_2dmg)]_2(SO_4)\}$ $2.5H_2O$ [4f]. It seems that the elimination of the CO molecule from one of the pyrimidine rings of H_2^1L enables the *O*-monoatomic bridging mode of the NO group bonded to the imidazole ring.

The Cu(1) ion occupying the internal site of the $^1L^{2-}$ ligand exhibits a 4 + 1 coordination environment. Four short bonds of *ca* 1.98 Å are formed with N(5), N(6), N(10), and with either N(14A) (63%) or O(14B) (37%). The fifth position is occupied at a longer distance of 2.47(1) Å by an oxygen atom, O(31) from a perchlorate anion. The copper(II) ion is lifted 0.077(4) and 0.089(4) Å toward the apical positions from the N_3O and N_4 mean basal planes, respectively.

The coordination of the ligand to Cu(1) results in the formation of two five- and one six-membered chelate ring in the case of the Cu(1)—N(14A)—O(14A)—Cu(2) bridging conformation, and two six- and one five-membered chelate ring for the Cu(1)—O(14B)—Cu(2) conformation.

The copper atom Cu(2) is in a distorted square-pyramidal environment. The four nearest neighbours at about 2.0 Å are the O(5), either O(14A) or N(14B) from the unit $[Cu(1)^1L]$, and the N(18) and N(29) belonging to the terminal ligand bipy. The fifth position is occupied by the O(30) atom belonging to a water molecule. The deviations of the Cu(2) from the basal planes N(18)N(29)O(5)O(14A) and N(18)N(29)O(5)O(14B) are 0.194(4) and 0.183(4) Å, respectively.

As in **2a,** the dinuclear fragment is almost planar, with a dihedral angle between the coordination planes of 4.6(1)°. Bond lengths and angles of bipy in **2a** and **2b** are very close and similar to those found for other 2,2′-bypyridyl containing complexes.

Magnetic properties

Both **2a** and **2b** complexes are diamagnetic at room temperature. This diamagnetism reveals a strong antiferromagnetic coupling between copper(II) ions, so that the only state thermally populated, even at room temperature, is the $S = 0$. In accordance with this, the polycrystalline EPR spectra of both complexes show no signal at this temperature.

These data can only give an estimation of the lower limit of the exchange coupling parameter J, which must be placed at $J < -1000\ cm^{-1}$. This magnetic behaviour is not unexpected in view of the remarkable ability of the oximato bridge to mediate strong antiferromagnetic exchange interactions between paramagnetic centers, either in *syn*, *anti* or *o*-monoatomic conformation [4]. It must be pointed out that, in spite of the numerous examples of oximato-bridged copper(II) complexes reported so far, no clear magnetostructural correlations have been established.

Nevertheless, from the magnetic data of centrosymmetric oximate-bridged dicopper systems (compounds **a–d** in Table 4), some general conclusions can be drawn: (i) The bond lengths Cu—N_{oxime}, Cu—O_{oxime}, N_{oxime}—O_{oxime} and the Cu—Cu distance do not show any kind of correlation with the magnetic properties; (ii) compounds with planar or nearly planar $Cu(NO)_2Cu$ skeleton are always perfectly coupled even at room temperature. Although the same general trends seem to be followed for the large number of well characterized trinuclear and non-centrosymmetric dinuclear copper(II) complexes reported in the recent past years, no correlation between the magnitude of the exchange coupling and the degree of deviation from planarity is evident (see Table 4). Thus, for instance, the di- and trinuclear compounds (**i**) and (**m**) given in Table 4 are practically coupled at room temperature despite their high deviations from planarity. In view of this, a rationalization of these apparently contradictory results is needed.

In order to evaluate the influence of some structural parameters, connected with the distortion from planarity, on the magnetic properties MO Extended-Huckel calculations have been performed by means of the CACAO program. [16]. The parameters used were the standard of the program, and the oximate system modelized. The bond parameters used were Cu—NH_3, 2.10 Å; Cu—O and Cu—N, 1.95 Å; N—O, 1.32 Å; C—N, 1.30 Å; NH_3—Cu—NH_3, 80°; N—Cu—O, 106° and C—N—O, 115°. From this basic scheme, calculations have been performed for the following geometries: square-planar, 4+1 planar and 4+1 coordination with the copper atom lifted 0.5 Å toward the apical position and finally for the chair distortion with dihedral angle of 30°. The σ^* molecular orbitals ϕ_g and ϕ_u are obtained from the

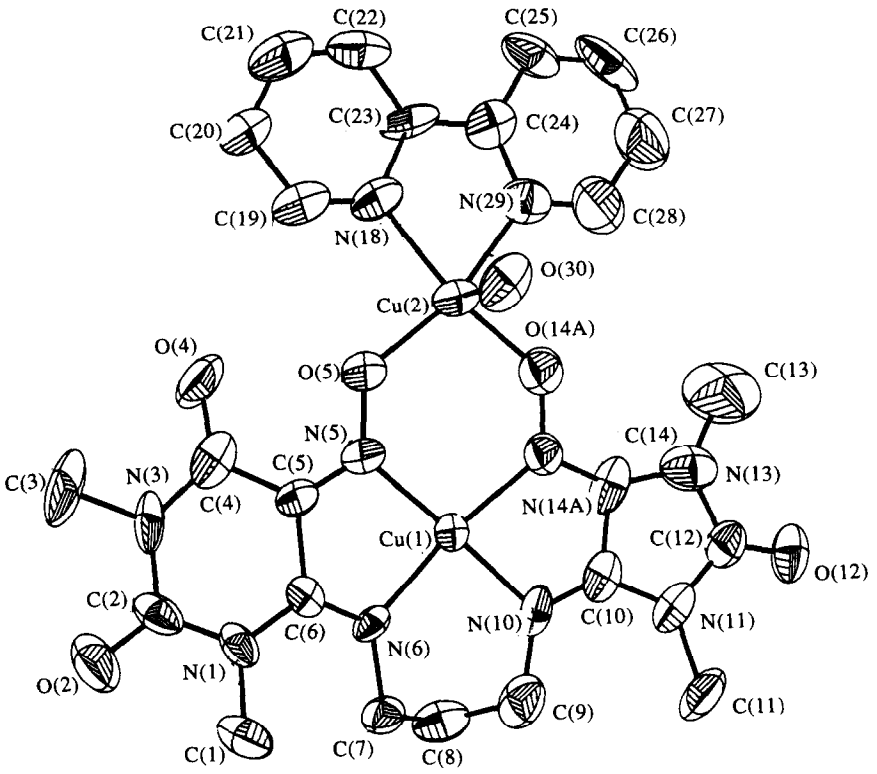

Fig. 2. Perspective view of the cation $[Cu(\mu\text{-}L^1)Cu(bipy)(H_2O)]^{2+}$ **2b**.

interaction of the symmetrical and antisymmetrical combinations of the copper d_{xy} orbitals and the similar combinations of the oximato ligands. In the ϕ_u orbital the interaction between $2p$ oxygen and nitrogen orbitals of the oximato bridge is bonding in character whereas in ϕ_g is of antibonding type and therefore, ϕ_g is much higher in energy than ϕ_u. The value of the energy gap $\Delta = \phi_g - \phi_u$ (0.205 eV) which, according to the Hoffmann's model, is the determining factor for the antiferromagnetic contribution to J (singlet–triplet energy difference), is in agreement with the large triplet–singlet energy difference observed for planar oximate-bridged copper(II) complexes. In addition, the results of these calculations show that the HOMO-LUMO energy gap is practically not affected by the apical coordination to copper(II), and moreover, either the displacement of the copper atom out of the coordination basal plane or the dihedral angle between the basal and oximate planes only decrease moderately the energy gap (about 10%) for the extremely large values of those parameters used in the calculations. This result is not unexpected in view of the pseudospherical symmetry of the lobes of the oximato MO involved in the superexchange pathway. This symmetry allows a considerable deviation from planarity of the $Cu(NO)_2Cu$ core without a significant decrease of the overlap between the interacting orbitals. From these results it should be concluded that the superexchange coupling in copper-oximato systems is very strong but a simple relation between planarity and J parameter is not consistent. We feel that other factors, such as the nature of oximate ligand itself and the nature of the "end-cap" ligands, may be, at least, as important in determining the exchange interactions as the structural parameters in the bridging fragment. In fact, all the dinuclear and trinuclear copper complexes containing the dimethyglyoxime ligand are coupled at room temperature even though some of them exhibit considerable distortions from planarity (compounds **i** and **m**). Moreover, the complexes $[Cu(L^7)Cu(phen)(H_2O)_2](ClO_4)_2$ [4c] and $[Cu(L^6)Cu(bipy)(H_2O)](ClO_4)_2 \cdot H_2O$ [4g] containing the same dioximate ligand (L^6 is 3,3′-aminopropylenedinytrilobis(2-butanoneoximate)) but different "end-cap" ligands (phen or bipy), have quite separate $2J$ values of -866 and -674 cm^{-1}, respectively, in spite of the fact that both exhibit similar deviations from planarity (the dihedral angles in the $Cu(NO)_2Cu$ cores are 29 and 26.7°, respectively). In order to gain insight into this subject, more examples of oximate-bridged complexes are needed, preferably closely related ones displaying variation over only one of the structural parameters.

(Received 4 April 1996; accepted 17 May 1996)

Abstract—The reaction of the tridentate rigid ligand PNP (2,6-bis(diphenylphosphinomethyl)pyridine) with $RuCl_2(PPh_3)_3$ led to the formation of two new ruthenium(II) complexes, $RuCl_2(PNP)(PPh_3)$ (**1**) and $[RuCl(MeCN)(PNP)(PPh_3)]Cl$ (**2**), which were analytically and spectroscopically characterized. The X-ray diffraction study of **1** shows that the PNP ligand coordinates Ru in a meridional mode, and reveals some steric congestion within the complex. Copyright © 1996 Elsevier Science Ltd

Keywords: ruthenium(II) complexes; tridentate ligands; X-ray analysis.

Homogeneous catalysis by transition metal complexes provides mild and selective routes to various chemicals of industrial importance [1] and the search for new efficient catalysts remains an important objective.

Ruthenium complexes have received considerable interest as catalysts for the hydrogenation of various substrates, particularly in the enantioselective reduction of ketones and alkenes [2]. We have been interested in the use of tridentate ligands for such catalytic reactions and have reported recently the synthesis of a family of C_2-symmetric chiral tridentate diphosphine ligands [3]. The coordination chemistry of the simplest achiral member of this family, 2,6-(diphenylphosphinomethyl)pyridine (hereafter designated PNP), has been well studied, but with few applications of the obtained complexes in catalysis [4–7]. As a result of the rigid backbone and fused five membered ring chelation about the metal centre, this PNP ligand should in preference form meridional rather than facial complexes. This is noteworthy because when the chiral C_2-symmetric ligand analogues are used, the C_2 axis can be preserved in the *mer* but not in the *fac* arrangement. This will be important in enantioselective reactions, as the number of diastereoisomeric forms of catalytic intermediates will thus be limited and permit greater stereocontrol of the reaction [8].

PNP

We report here the synthesis and characterization of two new ruthenium(II) complexes bearing the PNP ligand, including a structure analysis by X-ray diffraction methods.

EXPERIMENTAL

General

All experiments were carried out under a nitrogen or argon atmosphere, using a vacuum line or Vacuum Atmospheres glovebox equipped with Dri-Train HE-493 inert gas purifier. Conductivity measurements were performed with a WTW LF535 apparatus. ^1H (300 MHz) and $^{31}P\{^1H\}$ (121.5 MHz, broadband

* Author to whom correspondence should be addressed.

decoupled) NMR spectra were recorded in $CDCl_3$ on a Bruker AC300 instrument and referenced to Me_4Si and 85% aqueous H_3PO_4, respectively. FT-IR spectra were recorded on a Perkin-Elmer 1600 Series spectrometer on KBr pellets. FAB MS spectra and elemental analyses were carried out by the corresponding facilities at the Centre de Recherche de Chimie, Université Louis Pasteur, Strasbourg. Methylene chloride and acetonitrile were distilled under nitrogen over calcium hydride, and pentane over sodium. PNP [4] and $RuCl_2(PPh_3)_3$ [9] were prepared following literature methods.

Preparation of $RuCl_2(PNP)(PPh_3)$ (**1**)

A solution of PNP (100 mg, 0.210 mmol) and $RuCl_2(PPh_3)_3$ (210 mg, 0.219 mmol) in 20 cm^3 CH_2Cl_2 was refluxed for 15 min. The orange solution obtained was left at 0°C for 24 h, and **1** precipitated as orange crystals that were collected by filtration, washed with pentane and dried *in vacuo*. Yield: 94%. FAB MS *m/z* (assignment, relative intensity): 909.0 (M^+, 66%), 874.0 ([M—Cl]$^+$, 45%), 838.1 [M—2Cl—H]$^+$, 28%), 647.0 ([M—PPh_3]$^+$, 100%), 612.0 ([M—Cl—PPh_3]$^+$, 59%), 576.0 ([M—2Cl—H—PPh_3]$^+$, 72%). ^1H NMR δ (ppm): 7.57–7.00 and 6.90–6.83 (m, 38 H, $H_{arom.}$), 4.54 (t, 4H, CH_2).

Preparation of [RuCl(MeCN)(PNP)PPh_3)]Cl (**2**)

A solution of PNP (100 mg, 0.210 mmol) and $RuCl_2(PPh_3)_3$ (210 mg, 0.219 mmol) in 20 cm^3 CH_3CN was refluxed for 30 min. The dark yellow solution obtained was left at 0°C for 24 h, and a small crop of crystals of **1** precipitated. After filtration, the filtrate was concentrated and left again for 24 h at 0°C. Fine yellow crystals were collected by filtration, washed with pentane and dried *in vacuo*. Yield: 85%. Found: C, 64.2; H, 4.6; N, 2.8. Calc. for $C_{51}H_{45}N_2P_3Cl_2Ru$: C, 64.4; H, 4.8; N, 2.9%. FAB MS *m/z* (assignment, relative intensity): 915.1 [M—Cl]$^+$, 19%), 874.1 ([M—Cl—CH_3CN]$^+$, 100%), 838.1 ([M—H—2Cl—CH_3CN]$^+$, 46%), 612.0 ([M—Cl—CH_3CN—PPh_3]$^+$, 73%), 576.0 ([M—H—2Cl—CH_3CN—PPh_3]$^+$, 87%). ^1H NMR δ (ppm): 7.75–7.09 and 6.90–6.84 (m, 38 H, $H_{arom.}$), 4.86 and 4.53 (2dt, 2 × 2H, CH_2), 1.73 (s, 3H, CH_3CN).

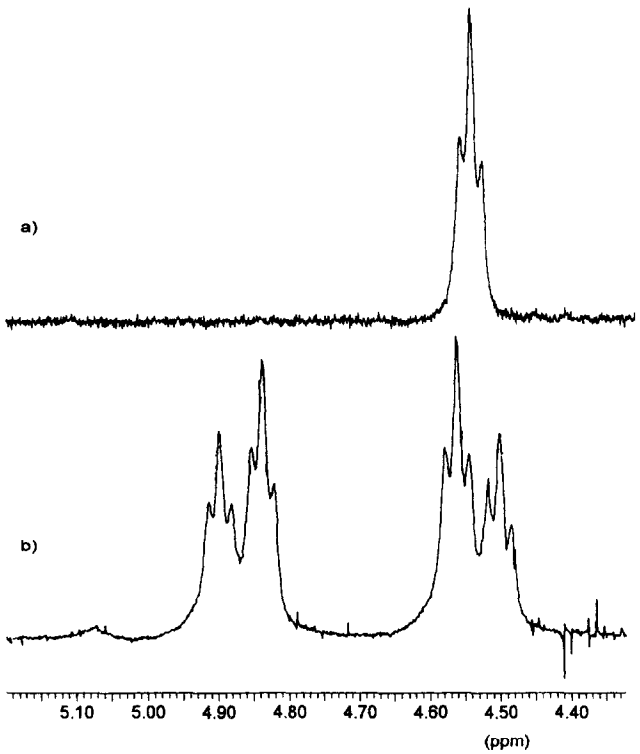
RESULTS AND DISCUSSION

The reaction of PNP with a slight excess of $RuCl_2(PPh_3)_3$ in refluxing methylene chloride leads to the neutral complex $RuCl_2(PNP)(PPh_3)$ (**1**) as an orange, air-stable, diamagnetic crystalline solid in excellent yield. Two IR bands (KBr pellet) are observed at 1599 and 1565 cm^{-1} which are characteristic of a coordinated pyridine [4]. In addition, a weak band at 328 cm^{-1} is indicative of two mutually *trans* chlorides, according to the interpretation given by Bianchini and coworkers for an analogous ruthenium complex [10]. The $^{31}P\{^1H\}$ NMR spectrum of **1** in $CDCl_3$ exhibits a doublet at 35.3 ppm and a triplet at 41.8 ppm ($^2J_{PP}$ = 28.6 Hz), these chemical shifts falling in the range expected for coordinated PNP and PPh_3 ligands [7,11]. The two PNP phosphorus atoms are thus chemically equivalent and coupled to the phosphorus of a triphenylphosphine located in a *cis* position, as indicated by the magnitude of the coupling constant.

The ^1H NMR spectrum shows a triplet at 4.54 ppm attributed to the methylene protons (Fig. 1(a)). This is typical of an $A_2A'_2XX'$ system where each proton is virtually coupled to the two equivalent phosphorus nuclei ($|{}^2J_{HP}+{}^4J_{HP'}| = 9.7$ Hz). Such a situation has been frequently described in the literature concerning other PNP coordination compounds [6, 7] and is characteristic of a meridional coordination, where the two protons of each CH_2 moiety are chemically equivalent. Therefore the molecule possesses a plane of symmetry that comprises the three donor atoms of PNP, so that PPh_3 necessarily lies *trans* to the pyridine nitrogen.

The X-ray diffraction study of **1** · CH_3CN confirms this interpretation (Fig. 2) [12]. Selected bond distances and angles are given in Table 1. **1** appears as a monomeric complex with a somewhat distorted octahedral geometry around the ruthenium. Importantly, it is confirmed that the PNP ligand coordinates the metallic center in a tridentate meridional mode, with the triphenylphosphine ligand *trans* to pyridine. It is probable that the alternative *cis* configuration would be unstable because of an increased steric hindrance between the phenyl groups on the three phosphorus atoms.

All Ru—P (2.340–2.368 Å), Ru—Cl (2.412, 2.426 Å) and Ru—N (2.168(2) Å) distances lie within the normal range [13]; in particular, the ruthenium–phosphorus and ruthenium–chloride bond lengths compare well with the corresponding bond lengths observed by Bianchini *et al.* in the closely related complex *mer*-$RuCl_2[nPrN(CH_2CH_2PPh_2)_2](PPh_3)$ [14]. The values of the P(1)—Ru—N and P(2)—Ru—N bond angles (78.60, 79.31°) are also very close to Bianchini's data (79.45, 80.69°), or to the value of 80.3(1)° found by DuBois *et al.* [7] for the N—Pd—P angle in the cationic complex $[Pd(PNP)(PEt_3)]^{2+}$. The ruthenium atom lies approximately in the plane defined by the nitrogen and the three phosphorus atoms, with a deviation of only 0.018 Å. The four ligands *cis* to PPh_3 are all bent away from PPh_3, as illustrated by the reduced Cl(1)—Ru—Cl(2) angle (171.81(3)°) and the even smaller P(1)—Ru—P(2) angle (157.90(3)°). A large Cl(2)—Ru—P(2) angle of 95.49(3)° is observed, while the Cl(1)—Ru—P(2) angle is normal (88.17(3)°). The reason for this is probably that Cl(2) is sterically hindered by C(49) and therefore bent away from P(2). These considerations of the bond distances and angles in $RuCl_2(PNP)(PPh_3)$ show that the molecule is sterically congested, as seven phenyl groups and two chlorides are forced together in close proximity. In comparison, the $RuCl_2[nPrN(CH_2CH_2PPh_2)_2](PPh_3)$ and $[Pd(PNP)(PEt_3)]^{2+}$ complexes suffer less steric



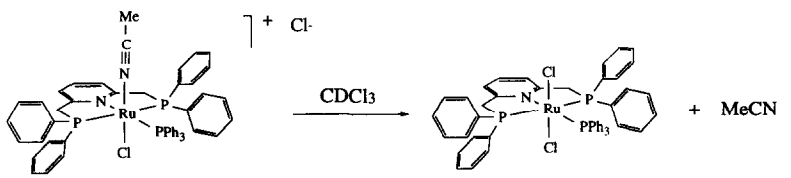


Fig. 1. ^{1}H NMR signals of the PNP methylene protons in $CDCl_3$; (a) complex **1**; (b) complex **2**.

hindrance, probably because in the first case nPrN($CH_2CH_2PPh_2$)$_2$ is more flexible than PNP, and in the second PEt_3 is less bulky than PPh_3 and further, the complex bears no axial ligand.

When the reaction of PNP on $RuCl_2(PPh_3)_3$ is performed in acetonitrile instead of methylene chloride and at higher temperature (MeCN reflux), yellow crystals of **2** are obtained in good yield, **1** now being present as a by-product. Like **1**, **2** is diamagnetic and stable in the air. Its elemental analysis is consistent with the formula $RuCl_2(MeCN)(PNP)(PPh_3)$. The value of the molar conductivity of **2** in acetonitrile is 106 Ω^{-1} cm^2 mol^{-1} at a 2×10^{-3} M concentration, which falls within the expected range (92–199 Ω^{-1} cm^2 mol^{-1}) for a 1:1 electrolyte in this solvent [15]. The FAB-MS spectrum of **2** (NBA matrix) exhibits a signal at m/z 915.1; this value and the isotope profile structure fit a molecular peak [M—Cl]$^+$ formulated as $RuCl(MeCN)(PNP)(PPh_3)^+$. The IR spectrum of **2** shows two bands at 2276 and 2351 cm^{-1} characteristic of an end-on coordination of the acetonitrile ligand [7, 16]. Further, the bands in the 1500 1600 cm^{-1} region are very similar to those displayed in the spectrum of **1** (1598 and 1562 cm^{-1}), indicative of a coordination of Ru^{II} by the central pyridine moiety.

The $^{31}P\{^1H\}$ NMR spectrum of **2** resembles very much that of **1** (doublet at 31.3 ppm and triplet at 42.0 ppm; $^2J_{PP}$ = 26.5 Hz). However the PNP methylene signals now appear in the ^{1}H NMR spectrum as a set of two doublets of triplets centered at 4.53 ppm and 4.86 ppm, corresponding to an AA′BB′XX′ system [6a] (Fig. 1(b)). The two methylene protons borne by each carbon are no longer equivalent, and a *gem* coupling constant of 16.9 Hz is observed. Each of them is virtually coupled to the phosporus atoms, with slightly different coupling constants ($|^2J_{HP}+{}^4J_{HP'}| = 8.9$ and 9.4 Hz). The plane of symmetry observed for **1** (*vide supra*) is lost, indicating the presence of two different axial ligands.

When **2** is allowed to stand in $CDCl_3$ for 24 h, the solution turns from yellow to orange and orange crystals form. ^{31}P and ^{1}H NMR analyses indicate that the totality of **2** has been converted into **1**:

Cl(2)—Ru—P(1)	84.20(3)	Ru—P(2)—C(19)	97.32(8)
Cl(2)—Ru—N	87.31(6)	Ru—P(3)—C(38)	118.98(9)
Cl(2)—Ru—P(2)	95.49(3)	P(1)—C(13)—C(14)	112.0(2)
Cl(2)—Ru—P(3)	93.76(3)	C(18)—C(19)—P(2)	108.4(2)
P(1)—Ru—N	79.31(6)	C(13)—C(14)—N	117.0(2)
P(1)—Ru—P(2)	157.90(3)	N—C(18)—C(19)	116.7(2)
P(1)—Ru—P(3)	102.90(2)	C(14)—N—C(18)	118.4(2)

A straightforward interpretation of this observation is that the chloride anion and the acetonitrile compete as a ligand for ruthenium, the competition being in favour of MeCN when it is used as the solvent, and in favour of Cl^- in a solvent of low polarity such as chloroform.

CONCLUSION

We have prepared and characterized two new ruthenium(II) complexes with the PNP ligand where it is found to be bound in a meridional way to the metal. An X-ray crystallographic study has shown

that the presence of triphenylphosphine as an ancillary ligand induces important steric constraints in these complexes. Experiments are under way in our laboratory to study the catalytic properties of these and similar complexes and in particular those of the chiral analogues of the PNP for asymmetric catalysis. It will be of interest to compare our findings with the closely related results reported by Zhang *et al.* in a publication that appeared during the preparation of this manuscript [17].

(Received 1 April 1996; accepted 17 May 1996)

Abstract—The complexation equilibria of (2-thiazolin-2-yl)hydrazine hydrochloride (TzHyHCl) with zinc(II) and cadmium(II) have been studied in aqueous solution at 298 K and 0.1 M ionic strength in $NaClO_4$. The formation constants were determined and are discussed in terms of the characteristics of the ligand. The compounds $[ZnCl(TzHy)_2]Cl$ and $[Cd(TzHy)(\mu\text{-}Cl)_2]_n \cdot nH_2O$ have been isolated and their crystal structures determined. In the Zn^{II} compound, the geometry around the central atom is a distorted trigonal-bipyramid composed of four nitrogen atoms from two TzHy ligands and one chlorine. The Cd^{II} complex is polymeric, with octahedrally coordinated cadmium linked into infinite chains by double (μ-chloro) bridges. The coordination sphere around each cadmium center is completed by two nitrogen atoms from a TzHy ligand. In both cases, the crystal structure is stabilized by an extensive hydrogen-bond network. Keywords: zinc(II) complex; cadmium(II) complex; thiazoline; hydrazine.

In a previous paper [1], we have described the crystal structure of (2-thiazolin-2-yl)hydrazine hydrochloride (TzHyHCl) together with its coordination behaviour and equilibria study with nickel(II) in aqueous solution as well as the isolation and crystal structure of the compound diaquabis[(2-thiazolin-2-yl)hydrazine]nickell(II) chloride dihydrate. In this paper we report our investigations of the coordination behaviour of TzHyHCl with Zn^{II} and Cd^{II} in aqueous solution. Likewise, the solid phase obtained by the reaction between the ligand and the aforementioned divalent cations have been characterized by elemental analysis, and X-ray diffraction.

EXPERIMENTAL

Reagents

The ligand (2-thiazolin-2-yl)hydrazine hydrochloride (TzHyHCl) was prepared according to a reported procedure [2], taking into account published modifications [3] and recrystallized from ethanol.

Zinc(II), and cadmium(II) stock solutions were prepared and standardized as usual [4]. The ionic strength of the solutions was adjusted to a perchlorate con-

* Author to whom correspondence should be addressed.

centration of 0.1 M by addition of sodium perchlorate. Sodium hydroxide stock solutions were prepared by dilution of a concentrated solution of sodium hydroxide, according to Kolthoff *et al.* [5]. These solutions were kept under CO_2-free atmosphere and standardized by titration against potassium hydrogen phthalate. All other chemicals were AR grade and used without further purification.

Preparation of the complexes

The crystals of Zn^{II} and Cd^{II} complexes were prepared, in the same manner as analogous nickel ones, by evaporation of relevant water solutions, as described elsewhere [1]. Found: C, 19.7; H, 3.7; N, 22.7; S, 17.2; Zn, 17.4. Calc. for $C_6H_{14}Cl_2N_6S_2Zn$: C, 19.4; H, 3.8; N, 22.7; S, 17.3; Zn, 17.6%. Found: C, 11.5; H, 2.7; N, 13.1; S, 9.0; Cd, 34.2. Calc. for $C_3H_9Cl_2N_3OSCd$: C, 11.3; H, 2.8; N, 13.2; S, 10.0; Cd, 35.3%.

Instrumental procedures

Chemical analyses of carbon, hydrogen, nitrogen and sulfur were performed by means of microanalytical methods using a Perkin–Elmer 240C microanalyser. In both complexes, the metal content was estimated by thermogravimetry as oxide for the Zn^{II} and as sulfide in the case of Cd^{II}. IR spectra were recorded on a Perkin–Elmer FT-IR 1720 spectrophotometer, using KBr as dispersing agent. TG studies were carried out on a Mettler TA-4000 instrument. The procedures and apparatus used for potentiometric measurements were described in detail previously [1]. Briefly, measurements were made at 25 ± 0.1°C and 0.1 M ($NaClO_4$) ionic strength. The electrode system was calibrated in terms of hydrogen ion concentration by performing strong acid versus strong base titrations [6]. Concentration of ligand in the experimental solutions was always 2×10^{-3} mol dm^{-3}, and successive 1:1, 2:1 and 3:1 ligand-to-metal ratios were investigated. The numerical analysis of all the experimental e.m.f. data were carried out with the computer program SUPERQUAD [7]. All calculations were performed on an IBM RS/6000 computer (Computer Center, University of Extremadura). X-ray powder diffraction was obtained through a Philips PW-1700 diffractometer using Cu-K_α radiation.

Crystal structure determinations

Crystal data, data collection and refinement details for $[ZnCl(TzHy)_2]Cl$ and $[Cd(TzHy)(\mu\text{-}Cl)_2]_n \cdot nH_2O$ are given in Table 1. Examination of three standard reflections, monitored after 97 scans, showed no sign of crystal deterioration. The data were corrected for Lorentz and polarization effects, and were also corrected for absorption effects using an empirical method based on azimuthal scan data. The structures were solved by direct methods and subsequent Fourier differences using the SHELXTL-IRIS program [8] and refined by full-matrix least-squares. The H-atoms were located from a differential Fourier synthesis, and included in the calculation with estimated isotropic displacement parameters without refinement (riding model). All calculations were performed with a Silicon Graphics Iris Indigo XS24.

Thermal parameters and atom coordinates have been deposited with the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

The analytical results agree with the molecular formulae $C_6H_{14}Cl_2N_6S_2Zn$ and $C_3H_9Cl_2N_3OSCd$ for the colourless Zn^{II} and Cd^{II} complexes, respectively.

Potentiometric studies

The final stoichiometries and formation constants of the complexes formed were determined by means of the computer program SUPERQUAD [7] to identify that which, according to χ^2, best fitted the experimental data. The chemical models yielding the best fits between the measured and calculated titration curves, together with the refined formation constants, and statistical parameters (SIGMA and χ^2), are compiled in Table 2. Metal hydrolysis reactions of the sort described by Baes and Mesmer [9] were incorporated into every chemical model tried. It was verified that all the proposed species (denoted as $M_p(TzHy)_qH_r$) existed in significant concentrations over a reasonable data range.

It can be seen that for the $TzHyHCl/Zn^{II}$ system while in the titration curve with a relation ligand: metal of 1:1, the apparently simple model of 111 satisfied the experimental data; in the titration curve 2:1 the combination of complexes 111 and 122 gave the best agreement. With respect to the relation ligand: metal of 3:1, the model chosen, formed by 122 and 133, resulted in a satisfactory numerical and graphical fitting. With respect to the $TzHyHCl/Cd^{II}$ system, it can also be seen from the aforementioned Table 2 that all titration curves contain the complex 133. In addition to this species the existing experimental evidence was sufficient to determine with accuracy that the 111 complex is present in the titrations with relative ligand: metal of 1:1 and 2:1. The experimental results show that in all $M_p(TzHy)_qH_r$ complexes detected q has the same value as that of r, which may be taken as evidence that in the $TzHyHCl/Zn^{II}$

and $TzHyHCl/Cd^{II}$ systems only the species $(TzHyH)^+$ acts as ligand.

Description of the structures

The structure of $[ZnCl(TzHy)_2]Cl$ consists of $[ZnCl(TzHy)_2]^+$ cations and chloride anions. Figure 1 shows the molecular structure of the cation complex and the atom numbering system used. Selected bond lengths, angles and the hydrogen contacts are listed in Table 3. Within the cation, the geometry around the zinc atom may be described as a distorted trigonal-bipyramid, according to the value of 0.84 found for the index of trigonality $\tau[\tau = (\beta - \alpha)/60$, where α and β are the N(6)—Zn—N(3) and N(4)—Zn—N(1) bond angles, respectively] [10]. The coordination polyhedron comprises one chlorine atom [Cl(1)] and two thiazolinic nitrogens [N(1), N(4)] in the equatorial positions, and two terminal hydrazinic nitrogens [N(3), N(6)] in axial positions. The zinc atom lies 0.034 Å out of the plane of the N(1), N(4) and Cl(1) atoms toward the N(3) atom. The whole molecule

exhibits pseudo-C_2 symmetry with the C_2 axis passing through the Zn—Cl(1) bond.

The Zn—Cl(1) distance of 2.271(2) Å is comparable to the value observed for other five-coordinate zinc(II) complexes [11]. The Zn—N(axial) distances [2.231(5) Å and 2.312(6) Å] are appreciably longer than the Zn—N(equatorial) distances [2.010(5) Å and 2.046(6) Å]. Several molecular orbital treatments of trigonal-bipyramidal coordination have predicted contradictory results about the relative strength of axial *vs* equatorial bonds for $(n-1)d^{10}$ systems. In this sense, Herlinger *et al.* [12] have pointed out that the crystal packaging effects could play an important role in the nonequivalency of the bond lengths. According to the above, and neglecting the electronic factors due to the central atom, our data can be explained by the result of two contributions: one is the different hybridation of the nitrogen atoms in the hydrazine

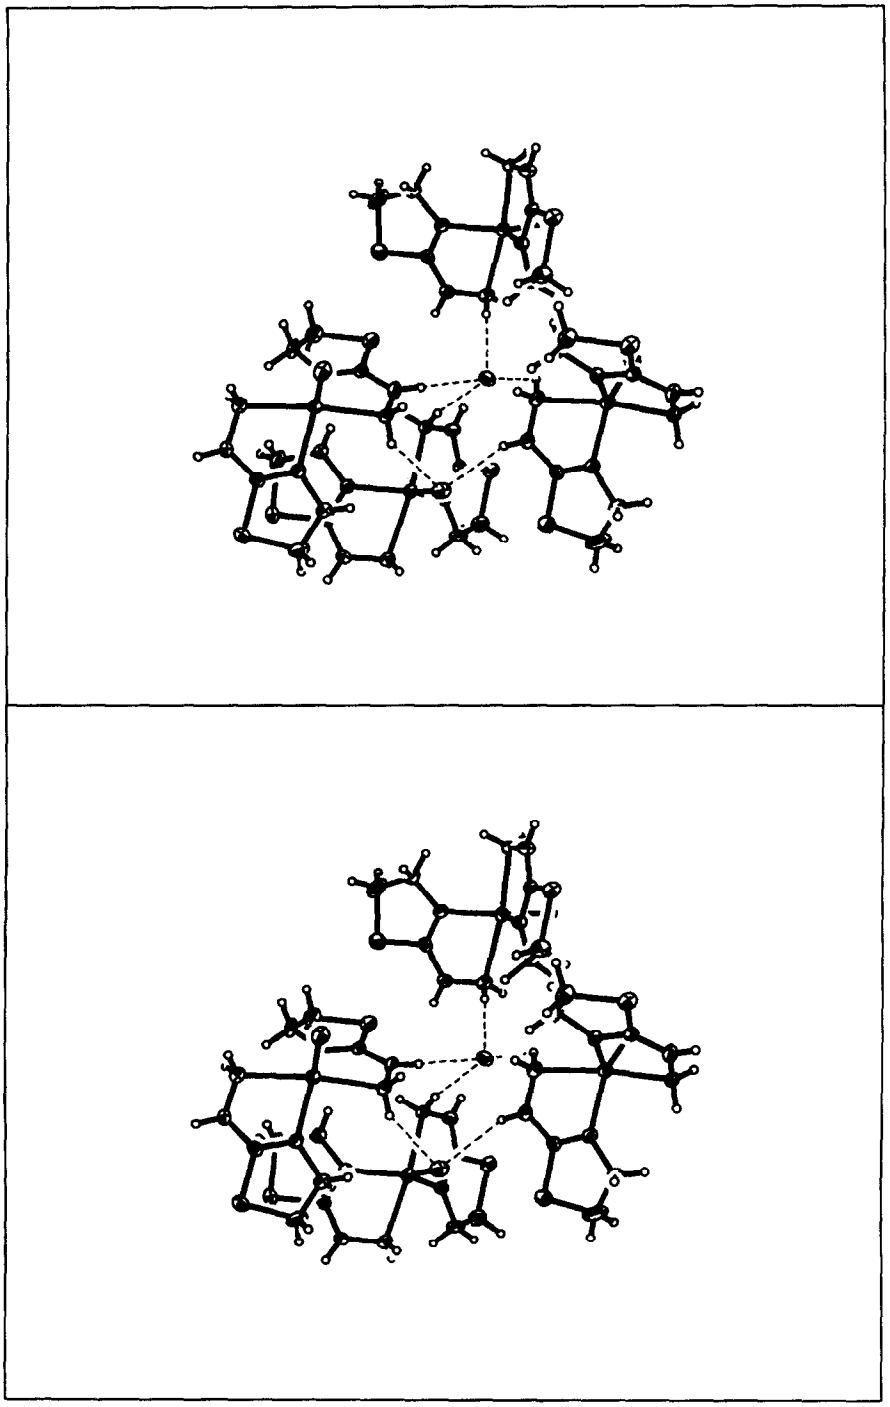

Fig. 2. Stereoscopic view of the hydrogen bond network of $[ZnCl(TzHy)_2]Cl$.

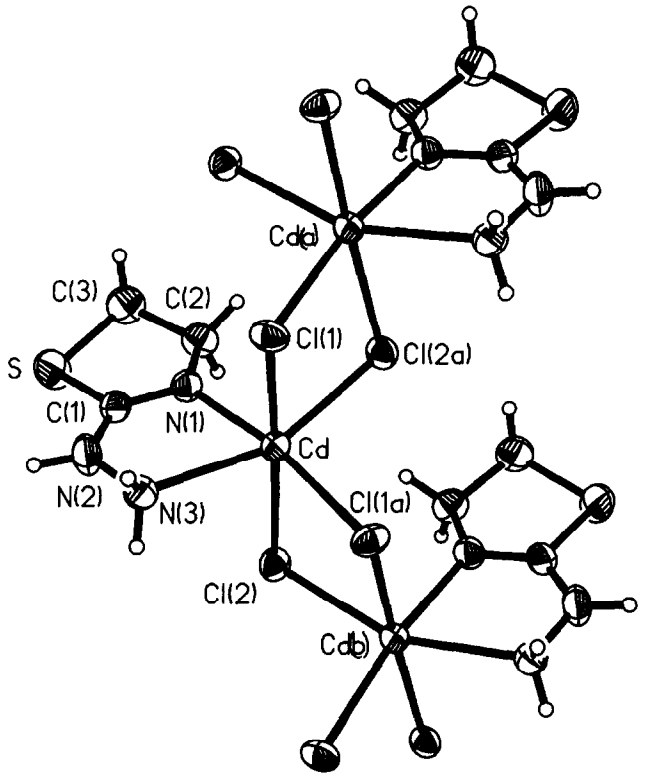

Fig. 3. View of the polymeric chain in $[Cd(TzHy)(\mu\text{-}Cl)_2]_n \cdot nH_2O$, showing the atom-numbering scheme. The thermal ellipsoids are drawn at a 50% level.

($\sim sp^3$) and in the thiazoline ($\sim sp^2$) which leads to a decrease of the covalent radius of nitrogen. The other is the different behaviour of these atoms in the formation of hydrogen bonds. Thus, N(1) and N(4) do not participate in hydrogen bonding, whereas N(6) forms two strong hydrogen bonds and N(3) is involved in one weak and one strong hydrogen bond.

The two five-membered chelate rings are essentially planar, with maximum mean-plane deviations observed for the thiazolinic nitrogens [N(1) 0.046 Å, N(4) 0.076 Å]; the angle between the normals to the best chelate planes is 53.2°. Bonds lengths and angles in the organic ligands are similar to those obtained in TzHyHCl and $[Ni(TzHy)_2(H_2O)_2]Cl_2 \cdot 2H_2O$ [1] and indicate that the organic moiety preserves the thiazoline-hydrazine form. The puckering parameters for the S(1)—C(1)—N(1)—C(2)—C(3) thiazoline ring ($q_2 = 0.150$ Å and $\phi_2 = 135.1°$) describe a slightly distorted form intermediate between envelope and half-chair conformations [13]. For the other thiazoline ring, with $q_2 = 0.117$ Å and $\phi_2 = 139.4°$, the value is close to the value (144°) appropriate to one envelope conformation with apex at C(6).

As pointed out above, the crystal packaging is determined by a network of hydrogen bonds in which all hydrazinic nitrogen atoms act as hydrogen donors, while the chloride anion [Cl(2)] and coordinated chlorine [Cl(1)] act as acceptors. A stereoscopic view showing this network is given in Fig. 2.

The cadmium compound contains water molecules of crystallization and polymeric $[CdCl_2(TzHy)]_n$ chains in which the units are linked by double (μ-chloro) bridges. The chains run along the crystallographic *c* axis. A view of one segment of the polymer is given in Fig. 3. Selected bond lengths, angles and the hydrogen contacts are listed in Table 4. The octahedral coordination sphere of Cd^{II} is completed by two *cis* nitrogen atoms from the TzHy ligand which acts as didentate. The octahedron is appreciably distorted with the ligand–metal–ligand bite angles varying between 104.6(1)° and 72.2(1)°.

The chlorine bridges are very asymmetric; while the Cd—Cl(1a) [2.556(1) Å] and Cd—Cl(2a) [2.605(1) Å] distances are similar to those found in several compounds involving chlorine bonded to two cadmium atoms [14–17], the Cd—Cl(1) [2.745(1) Å] and Cd—Cl(2) [2.719(1) Å] distances are significantly greater and are comparable with the distances found for chlorine atoms bonded to three cadmium atoms [17–20]. In similar form to that observed in the zinc(II) complex, and for analogous reasons, the metal–hydrazinic nitrogen bond Cd—N(3) [2.449(2) Å] is longer than the metal–thiazolinic nitrogen bond Cd—N(1) [2.241(2) Å].

Likewise in the zinc(II) complex, the chelate ring is planar, with maximum mean-plane deviation for the thiazolinic nitrogen N(1) [0.042 Å]. Complexation to the metal does not dramatically affect the geometry

of the organic ligand, although the thiazoline ring is here more puckered than in the other compounds containing the TzHy moiety [1]. The puckering parameters for the thiazoline ring ($q_2 = 0.293$ Å and $\phi_2 = 137.7°$) indicate a conformation near to envelope with apex at C(3) [13].

Into the chains, the Cd···Cd separations 3.901(1) Å (x, $0.5-y$, $-0.5+z$ and x, $0.5-y$, $0.5+z$) are in good agreement with values obtained in ammonium cadmium chloride [21] and related complexes. The shortest Cd···Cd separation intra chains is 6.643(1) Å ($1-x$, $-y$, $-z$).

Besides normal van der Waals interactions, the structure is stabilized by a complicated hydrogen-bond network (Fig. 4) in which each water molecule participates in four hydrogen bonds, acting as bridge between three adjacent chains. Moreover, contact between neighbouring chains is reinforced by direct

hydrogen bonds involving terminal hydrazinic nitrogen N(3) as donors and Cl(1) as acceptors.

(Received 12 March 1996; accepted 17 May 1996)

Abstract—The reaction of $RhCl_3 \cdot 3H_2O$ with Hdamo and PPh_3 (Hdamo = diacetyl monoxime = C_4H_7NO), both in the absence (**1**) and in the presence of $HClO_4$ (**2**) afforded the complex Rh(damo)$(PPh_3)_2Cl_2$. The reaction of the acidic water/ethanolic solution of $[Rh(H_2O)_6]^{3+}$ with Hdamo and PPh_3 (**3**) gave the mixture of the isomers of the compound $[Rh(damo)_2(PPh_3)_2]ClO_4$ (**3A** and **3B**). A similar mixture of isomers was formed when $[Rh(H_2O)_6]^{3+}$ reacted with H_2dopn (H_2dopn = 3,9-dimethyl-4,8-diazaundeca-3,8-diene-2,10-dione dioxime) and PPh_3 (**4**). Two isomers (**4A** = **3B**) and [Rh*cis*-$(damo)_2$*cis*-$(PPh_3)_2$]$ClO_4 \cdot CHCl_3$ (**4B**) have been isolated. All the compounds were characterized by elemental analysis NMR and IR spectroscopy. Single-crystal X-ray diffraction studies were carried out on the complex **4B**. In this compound the coordination environment around rhodium(III) is pseudooctahedral composed of two *cis*-oxime nitrogen atoms [av. Rh—N = 2.031(3) Å], two *trans*-oxime oxygen atoms [av. Rh—O = 2.026(2) Å] and two *cis*-phosphine phosphorus atoms [av. Rh—P = 2.403(1) Å]. Copyright © 1996 Elsevier Science Ltd

Keywords: rhodium complexes; rhodoxime complexes; monoxime complexes; crystal structure.

Until recently the chemistry of rhodium compounds with bidentate oximato ligands was by and large limited to the presence of two dioximato groups, coordinated to a metal center through four nitrogen atoms. For these substances ligands in the equatorial plane are equivalent and perturbations were largely the result of varying the axial ligands or the nature of the R group of the dioximato ligands [1–6].

There are no reports of rhodium complexes containing monoximato ligands (Fig. 1) with donor atoms other than nitrogen. An exception is the complex of rhodium(III) with the 3-methoxy-3-methyl-2-butanone oxime [7]. The starting material used for syntheses of most rhodium compounds with dioximes is $RhCl_3 \cdot 3H_2O$. Very recently studies on a reaction between $[Rh(H_2O_6]^{3+}$, H_2dmg (H_2dmg = dimethylglyoxime) and $[Rh(H_2O)_6]^{3+}$, H_2dmg and PPh_3 resulted in isolation of complexes [Rh $(dmgH)_2(L)_2]ClO_4$, (L = H_2O, PPh_3) [8], which are impossible to obtain in syntheses using the former starting material. This prompted us to carry out the reactions in a few different systems:

(**1**) $RhCl_3 \cdot 3H_2O + Hdamo + PPh_3$
→ Rh(damo)$(PPh_3)_2Cl_2$

(**2**) $RhCl_3 \cdot 3H_2O + Hdamo + PPh_3/HClO_4$
→ Rh(damo)$(PPh_3)_2Cl_2$

(**3**) $[Rh(H_2O)_6]^{3+} + Hdamo + PPh_3/HClO_4$
→ $[Rh(damo)_2(PPh_3)_2]ClO_4$
3A and/or **3B**

(**4**) $[Rh(H_2O)_6]^{3+} + H_2dopn + PPh_3/HClO_4$
→ $[Rh(damo)_2(PPh_3)_2]ClO_4$
4A and/or **4B**

The complex containing one $damo^-$ anion [Rh (damo)$(PPh_3)_2Cl_2$] has been found as the product of the reactions (**1**) and (**2**) whereas three isomeric forms of the compound $[Rh(damo)_2(PPh_3)_2]ClO_4$ with two coordinated $damo^-$ ions have been identified as the

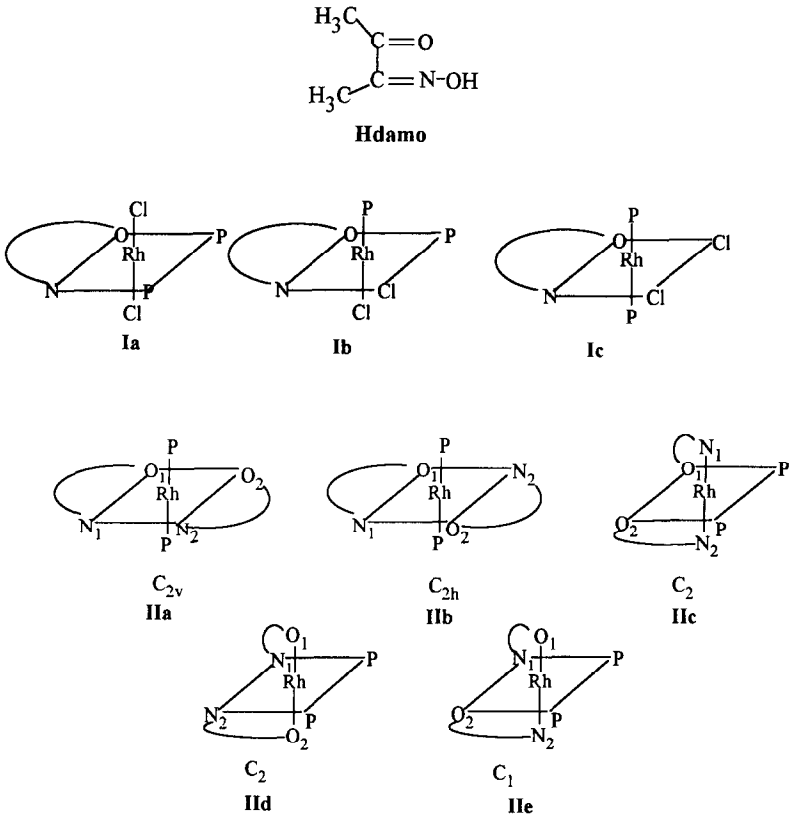

Fig. 1. Possible substitution products for compounds of general formula (I) $Rh(damo)L_2Cl_2$ and (II) $[Rh(damo)_2L_2]ClO_4$, (L = PPh_3 = P).

products of the reactions (**3**) and (**4**). Complexes containing mixed hetero donor atoms in the basal plane are far more complex with respect to their electronic and/or structural effects than rhodium dioximates. The effect of such changes is bound to reflect on the electronic structure of the rhodium center as well as on potential chemistry that may occur in the axial and/or equatorial direction of a given isomer.

As seen in Fig. 1, there are few possible geometrical isomers for compounds of general formula [Rh (damo)L_2Cl_2] (L = PPh_3) and $[Rh(damo)_2L_2]ClO_4$, (L = PPh_3) for five-membered N,O-chelation which is common for most metal complexes with oximes, although six-membered O,O-chelation cannot be excluded [9].

As far as we are aware complexes presented in this paper are the first examples of rhodium compounds containing diacetyl monoximato ligands.

EXPERIMENTAL

Physical measurements

UV–vis spectra were monitored on a Hewlett-Packard 8452A rapid scan dioda-array spectrometer. The NMR spectra were recorded on a Bruker spectrometer (^1H at 300.13 MHz, ^{13}C at 75.47 MHz, ^{31}P at 121.496 MHz) with solvent signals being used as internal standards for ^1H and ^{13}C, and external 85% H_3PO_4 for ^{31}P. Infrared spectra were measured in the range 4000–400 cm^{-1} as KBr disks on a Nicolet FTIR spectrophotometer.

Materials

$RhCl_3 \cdot H_2O$ was purchased from Aldrich. The compound $[Rh(H_2O)_6]ClO_4$ was synthetized according to the method of Ayres and Forrester in the reaction of $RhCl_3 \cdot 3H_2O$ with concentrated perchloric acid. Solutions were standardized spectrophotometrically by using the known absorption spectrum of $[Rh(H_2O)_6]^{3+}$, with peaks at 311 (ε = 67.4 M^{-1} cm^{-1}) and 396 nm (ε = 62) [10]. H_2Dopn was prepared by literature method [11]. All other chemicals were of reagent grade and were used as commercially obtained.

CAUTION! Perchlorate salts of metal complexes are potentially explosive. Only a small amount of material should be prepared, and it should be handled with caution.

Synthesis of $Rh(damo)(PPh_3)_2Cl_2$ (*Reaction* **1**). Hdamo ligand (0.082 g, 0.81 mmol) dissolved in 10 cm^3 of hot ethanol was combined with $RhCl_3 \cdot 3H_2O$ (0.104, 0.4 mmol) in 3 cm^3 of warm ethanol. The solution was refluxed for 5 min. PPh_3 (0.209 g, 0.8 mmol) dissolved in 10 cm^3 of hot EtOH was next

added and the solution was heated under reflux for 15 min. The initial red colour of the solution turned to dark yellow, and was filtered while hot. Upon standing at ambient temperature, the mixture deposited the yellow microcrystalline product which was filtered off, washed with small portions of ethanol, diethyl ether, and air-dried. Yield: 0.25 g (79%). Found: C, 60.0; H, 4.3; N, 1.7. Calc. for $RhC_{40}H_{36}N_1P_2O_2Cl_2$: C 60.2; H, 4.5; N, 1.7%. NMR spectra ($CDCl_3$), δ (ppm): ^1H: 1.054(s) (CH_3(CO)) (3H), 1.42(s) (CH_3(CN)) (3H), 7.28–7.75(m) aromatic (30H); ^{31}P: 18.56(d), ^1J(Rh,P) = 91.9 Hz.

Reaction **2**. A hot ethanolic solution (10 cm^3) of Hdamo (0.083 g, 0.82 mmol) was added to a 3 mol dm^{-3} $HClO_4$ solution in water (10 cm^3) containing $RhCl_3 \cdot 3H_2O$ (0.104, 0.4 mmol). The resulting solution was kept under reflux for 2 h. PPh_3 (0.215 g, 0.82 mmol) dissolved in 20 cm^3 of hot ethanol was added to the reaction mixture. After 1 h heating the solution was filtered and left to stand at room temperature. The yellow microcrystalline product was filtered off, washed with ethanol, diethyl ether and air-dried. Yield: 0.18 g (57%). Found: C, 59.9; H, 4.43; N, 1.70. Calc. for $RhC_{40}H_{36}N_1P_2O_2Cl_2$: C, 60.2; H, 4.5; N, 1.7%. NMR spectra ($CDCl_3$), δ (ppm): ^1H: 1.054(s) (CH_3(CO)) (3H), 1.42(s) (CH_3(CN)) (3H), 7.28–7.75(m) aromatic (30H); ^{31}P: 18.55(d) ^1J(Rh—P) = 91.9 Hz; ^{13}C: 12.36 (CH_3(C—N)), 23.05 (CH_3(CO)), 128.43 (P(m-C_6H_5)$_3$), 129.14(vt) (P(i-C_6H_5)$_3$), 131.02 (P(p-C_6H_5)$_3$), 135.67(P(o-C_6H_5)$_3$), 152.26 (C—N), 200.27 (C—O). No IR bands due to the ClO_4^- anion were detected.

Synthesis of $[Rh(damo)_2(PPh_3)_2]ClO_4$ (*Reaction* **3**). To a solution of $[Rh(H_2O)_6]^{3+}$ (1.02 mmol) in 3 mol dm^{-3} $HClO_4$, Hdamo (0.204 g, 2.04 mmol) in 15 cm^3 of hot ethanol was added and the resulting mixture refluxed for 2 h. PPh_3 (0.46 g, 2.04 mmol) dissolved in 20 cm^3 of hot EtOH was added and reaction mixture heated under reflux for 20 min. After filtration while hot the solution was cooled to room temperature. The product crystallized out as pale yellow microcrystals, which were filtered off, washed with ethanol and diethyl ether and air-dried. Yield: 0.37 g (40%). Found: C, 56.9; H, 4.4; N, 3.0. Calc. for $RhC_{44}H_{42}N_2P_2O_8Cl$: C, 57.0, H, 4.6; N, 3.0%. IR (as KBr pallets): medium band at 623 cm^{-1} due to $\nu(ClO_4^-)$. NMR spectra of the isolated precipitate indicated two components: **3A** and **3B**.

3A. NMR spectra, δ (pm): ^1H ($CDCl_3$) 0.92 s (CH_3(CO)) (6H), 1.59 s (CH_3(CN)) (6H), 7.4–7.59 (aromatic) (30H); (CD_2Cl_2): 0.88 s (6H), 1.55 s (6H), 7.57–7.49 m (30H), ^{31}P ($CDCl_3$): 21.2 d ^1J(Rh,P) = 97.2 Hz; (CD_2Cl_2): 21.42 ^{1}J(Rh,P) = 97.6 Hz, ^{13}C (CD_2Cl_2): 11.63 (CH_3(CN)), 23.82 (CH_3(CO), 125.6 d (P(i-C_6H_5)$_3$), 129.1 vt (P(m-C_6H_5), 132.4 s (P(p-C_6H_5), 134.6 vt (P(o-C_6H_5)$_3$), 157.4 (C—N), 204. (C—O).

3B. NMR spectra, δ (ppm): ^1H ($CDCl_3$): 0.96 s (CH_3(CO)) (6H), 1.55 s (CH_3(CN)) (6H), 7.37–7.48 m (aromatic) (30H), (CD_2Cl_2): 0.93 s (6H), 1.48 s (6H), 7.38–7.55 (m) (30H), ^{31}P ($CDCl_3$): 20.62 d ^1J(Rh,P) = 92.9 Hz; (CD_2Cl_2): 20.82 d ^1J(Rh,P) = 92.9 Hz, ^{13}C (CD_2Cl_2): 10.71 (CH_3(CN)), 23.3 (CH_3(CO), 125 d (P(i-C_6H_5)$_3$), 129.1 vt (P(m-C_6H_5), 132.4 s (P(p-C_6H_5), 134.3 vt (P(o-C_6H_5)$_3$), 153.1 (C—N), 202.7 (C—O).

Reaction **4**. The solution of $[Rh(H_2O)_6]^{3+}$ (1.1 mmol) in 3 mol dm^{-3} $HClO_4$ was combined with the hot ethanolic solution in H_2Dopn (0.227 g, 1.2 mmol). The solution was refluxed for 2 h; during this time a brown–yellow solution with a concomitant formation of a white solid resulted. After reduction of the solution volume down to 3–5 cm^3, the white precipitate was filtered off, washed with a small amount of ethanol, ethyl ether and air dried. Yield: 0.285 g (90%). Found: C, 13.3; H, 4.5; N, 10.2. Calc. for $C_3H_{12}N_2O_8Cl_2$: C, 13.1; H, 4.4; N, 10.2%. IR (as KBr disk): 629 cm^{-1} due to ν (ClO_4^-). NMR spectra (D_2O): ^1H: 2.11 CH_2 (2), 3.15 CH_2 (4). The clear brown–yellow filtrate was next charged with 0.61 g (2.3 mmol) of PPh_3 dissolved in warm ethanol. After 1 h of heating the solution was cooled to room temperature. The brownish–golden precipitate (**4A**) deposited as a first crop was filtered off, washed with ethanol, diethyl ether and air-dried. Yield: 0.31 g (30%). Found: C, 57.0; H, 4.6; N, 2.9. Calc. for $RhC_{44}H_{42}N_2P_2O_8Cl$: C, 57.0; H, 4.6; N, 3.0%. IR (as KBr disc): 625 cm^{-1}, ν (ClO_4^-). NMR spectra, δ (ppm): ^1H ($CDCl_3$): 0.96 s (CH_3(CO)) (6H), 1.55 s (CH_3(CN)) (6H), 7.4–7.6 m (aromatic) (30H); (CD_2Cl_2): 0.93 s (6H), 1.48 s (6H), 7.38–7.55 m (30H): (dmso-d_6): 0.89 s (6H), 1.57 s (6H), 7.3–7.65 m (30H); ^{31}P ($CDCl_3$): 20.6 d ^1J(Rh,P) = 93 Hz); (CD_2Cl_2): 20.8 d ^1J(Rh,P) = 93 Hz; ^{13}C (CD_2Cl_2): 10.81 (CH_3(C—N)), 23.34 (CH_3(C—O)), 125.23 (vt) (P(i-C_6H_5)$_3$), 129.22 vt (P(m-C_6H_5), 132.52 s (P(p-C_6H_5), 134.69 vt (P(o-C_6H_5)$_3$), 157.5 (C—N), 204.1 (C—O).

When the solution was allowed to stand overnight, the second crop **4B** crystallized out as the yellow microcrystals, which after filtration and washing with ethanol and diethyl ether were air-dried. Dark yellow single crystals [Rh*cis*-(damo)$_2$*cis*-$(PPh_3)_2$]$ClO_4 \cdot CHCl_3$ were obtained by slow evaporation in a refrigerator from a $CHCl_3$/EtOH solution of the crop **4B**. Yield: 0.25 g (25%). Found: C, 51.4; H, 4.2; N, 2.6. Calc. for $RhC_{45}H_{43}N_2P_2O_8Cl_4$: C, 51.6; H, 4.1; N, 2.7%. IR (as KBr disc): 625 cm^{-1}, ν (ClO_4^-). NMR spectra ($CDCl_3$), δ (ppm): ^1H: 1.33 s (CH_3(CO)) (6H), 2.36 s (CH_3(CN)) (6H), 7.3–7.5 (m) aromatic (30H); ^{31}P: 17.2 d ^1J(Rh,P) = 103.9 Hz; ^{13}C: 12.16 (CH_3(C—N)), 26.05 (CH_3(C—O)), 125.65 vt, (P(i-C_6H_5)$_3$), 129.4 (P(m-C_6H_5)$_3$), 132.2 (P(p-C_6H_5)$_3$), 134.6 (P(o-C_6H_5)$_3$), 153.2 (C—N), 209.83 (C—O).

X-ray diffraction

Preliminary examination of the crystal of [Rh*cis*-(damo)$_2$*cis*-$(PPh_3)_2$]$ClO_4 \cdot CHCl_3$ by Weissenberg photographs indicated the triclinic system. Data were

collected on a Kuma KM-4 κ-axis diffractometer with graphite-monochromated Mo-K_α radiation using the ω-2θ scan mode. 6427 independent reflections measured were observed ($F > 4\sigma(F)$). Three standard reflections showed no variation. Data were corrected for Lorentz and polarization effects. Experimental details are given in Table 1. The structure was solved using SHELXS-86 [12] and refined by full-matrix least-square methods using SHELXL-93 [13] with anisotropic thermal parameters for non-H atoms. In the final cycles of the refinement H-atom parameters were included. Scattering factors were those incorporated in the SHELXL-93 program.

RESULTS AND DISCUSSION

X-ray studies of [Rhcis-(damo)$_2$cis-(PPh$_3$)$_2$]ClO$_4$·CHCl$_3$

The crystal structure consists of [Rh(damo)$_2$(PPh$_3$)$_2$]$^+$ cations, ClO$_4^-$ anions and solvate CHCl$_3$ molecules, held together by electrostatic and van der Waals interactions, Fig. 2. Bond lengths and angles are given in Tables 2 and 3, respectively. The complex cations contain a pseudooctahedral arrangement of two PPh$_3$ ligands *cis*- to each other, and two bidentate damo$^-$ anions. The latter coordinate to the rhodium(III) ions in a chelating fashion through the oxime nitrogens and carbonyl oxygen atoms, forming five membered rings which remain planar. The complex cations have nearly C_2 symmetry. The rhodium atom is displaced out of the plane defined by two *cis*-oxime nitrogen and two *cis*-phosphorus atoms of PPh$_3$ by 0.0107(3) Å towards the O(4) oxime atom. The P(1)-Rh-P(2) angle, 98.42(4)°, is somewhat greater than the ideal angle of 90°. The angles: O(2)—Rh—O(4), 168.8(1)°, N(1)—Rh—P(1), 172.8(1)° and N(2)—Rh—P(2), 171.96(9)° are not strictly *trans*. This decrease is attributable to the presence of two bulky PPh$_3$ ligands in the *cis* position. The bite angles of the two chelates: O(2)—Rh—N(1) and O(4)—Rh—N(2) are similar, 78.7(1) and 79.1(1)° respectively. The Rh—P bonds, 2.401(1) and 2.406(1) Å, are slightly shorter than 2.447(1) in [Rh(dmgH)$_2$(PPh$_3$)(C$_2$H$_3$)] [17] and 2.461(2) Å in [Rh(dmgH)$_2$(PPh$_3$)(C$_2$H$_5$)] [18] but longer than 2.327(1) Å in Rh(dmgH)$_2$(PPh$_3$)Cl [19]. The average Rh—N distance 2.031(3) Å is long compared to the known rhodium(III) complexes containing the dmgH ligands in the equatorial plane, as well as to the compound of formula [Rh(ether oxime)$_2$Cl$_2$] [7]. In Rh(dmgH)$_2$(PPh$_3$)Cl, [Rh(dmgH)$_2$(PPh$_3$)(C$_2$H$_3$)], [Rh(dmgH)$_2$(PPh$_3$)(C$_2$H$_5$)] and [Rh(ether oxime)$_2$Cl$_2$], the average Rh—N bond lengths are 1.992(4), 1.957(2), 1.948(6) and 1.958(3) Å, respectively. The torsion angles N(1)—C(1)—C(2)—O(2) and N(2)—C(5)—C(6)—O(4) are 2.40(5) and 2.08(5)° respectively. The dihedral angle between these planes is 109.5(5)°. The N—C—C—O planes are perpendicular to the N(1)N(2)P(1)P(2) coordination plane. The rhodium atom is displaced 0.252(3) Å from the N(1)C(1)C(2)O(2) plane, and 0.197(3) Å from the N(2)C(5)C(6)O(4) plane. The O(1) and O(3) atoms are displaced 0.043(3) Å and −0.043(3) Å, respectively from these damo planes. The C(1)—C(2) and C(5)—C(6) bond lengths average 1.407(5) Å, and are in good agreement with a C(sp^2)—C(sp^2) double bond value for carbon in trigonal hybridization. As far as the carbon–oxygen and nitrogen–oxygen bonds are concerned, the average values 1.270(4) Å and 1.247(4) Å respectively, reveal a significant percentage of double-bond character in both ligands. Finally the carbon–nitrogen bond, 1.337(5) Å is in good agreement with single bond values. Of special note is the mutual position of rings C$_{21}$—C$_{26}$ and C$_{41}$—O$_{46}$ bound to the two different phosphorus atoms of the PPh$_3$ ligands, P$_1$ and P$_2$, respectively. The angle between these planes is 3.5°, indicating them to be almost parallel.

in the reaction (**2**), carried out in the presence of the perchloric acid. No IR bands due to the ClO_4 anion were detected in the isolated complex and its composition has been revealed to be like that of the reaction (**1**), on the basis of elemental analysis and NMR data. The formation of the complex is evidenced by the movement of the 1.87 and 2.31 ppm methyl protons for the Hdamo ligand to higher field upon coordination to the rhodium(III) centre in the compound being discussed. The ^{31}P NMR spectra show one doublet at 18.55 ppm with the ^1J(Rh,P) coupling constant of 92 Hz. Very similar values have been found for the complexes: Rh(dmgH)$_2$(PPh$_3$)$_2$Cl (92 Hz) [2] and [Rh(dmgH)$_2$(PPh$_3$)$_2$]ClO$_4$ (91 Hz) [8] for phosphorus atoms *trans* to each other. This suggests that the substitution reactions of $RhCl_3 \cdot 3H_2O$ with the diacetyl monoxime led to the mononuclear complex having one damo$^-$ anion and two Cl^- ions in the equatorial plane and two PPh_3 ligands in *trans* axial arrangement, independently of the reaction conditions used, Fig. 1, Ib and/or Ic.

Reaction **3**. Compounds of a general formula [Rh(damo)$_2$(PPh$_3$)$_2$]ClO$_4$ have been found to be the products of the reaction between $[Rh(H_2O)_6]^{3+}$ and Hdamo. The ^1H, ^{31}P and ^{13}C NMR spectra showed the formation of two geometrical isomers: **3A** and **3B**. These isomers have always been found to coprecipitate together. In the ^1H spectra of the isomer **3A**, the methyl resonances are observed at 0.92 and 1.59 ppm, whereas for **3B** at 0.96 and 1.55 ppm (in $CDCl_3$). The ^{31}P spectra show the doublets at 21.2 ppm (^1JRh,P = 97 Hz) and 20.6 ppm (^1JRh,P = 93 Hz) for the isomers **3A** and **3B**, respectively. We postulate the structures IIa and IIb with two *trans* PPh_3 groups

in axial positions (Fig. 1) for the products being described, on the base of the ^1J(Rh,P) coupling constants registered for these species, literature data as well as for a *cis, cis* isomer determined both by the X-ray (*vide supra*) and the NMR measurements (*vide infra*). However, X-ray structures of single crystals are needed to distinguish the isomers.

Reaction **4**. A condensation product of the diacethyl monoxime and a diaminopropane is 3.9-dimethyl-4,8-diazaundeca - 3,8 - diene - 2,10 - dione dioxime H_2dopn [11]. Syntheses of many cobalt compounds with this ligand resulted in the description of very interesting Costa-type complexes, models of Vit.B_{12} [14–16]. Attempts to synthesise the rhodium analgoues using $RhCl_3 \cdot 3H_2O$ as starting reagent failed to yield the desired species. The reaction between $[Rh(H_2O_6)]^{3+}$ and H_2dopn confirmed the instability of this ligand in the presence of water and acid [11]. The elemental analyses of these reaction products gave excellent agreement with calculated values for the complex of formula $[Rh(damo)_2(PPh_3)_2]ClO_4$ and the species $[(H_2N)_2C_3H_6] \cdot 2HClO_4$, the second decomposition product of H_2dopn. The formation of the latter was also confirmed by the IR and NMR spectra measurements. Fractional crystallisation of the reaction mixture allowed the separation of two different complexes of rhodium(III). The first crystallised product (**4A**) appeared to have identical ^1H, ^{31}P and ^{13}C NMR spectra with those of the isomer **3B** described above. The second rhodium(III) species (**4B**), characterised both spectroscopically and crystallographically, has been proved to be the isomer with two Rh—N bonds of the monoxime and two Rh—P bonds of the PPh_3 molecules on the rhodium ion *cis* to their own kind, and two Rh—O bonds in the *trans* arrangement (Fig. 2, IId.) In the ^1H NMR spectrum the CH_3 groups protons are shifted downfield whereas the PPh_3 groups in the ^{31}P spectrum are shifted upfield in comparison with the complexes having the triphenylphosphine ligands in the *trans* position to each other. Simultaneously the ^1J(Rh,P) coupling constant has been demonstrated to be *ca.* 10 Hz higher for the former. This suggests the metal to phosphine π-donation to be more effective in the *cis* stereochemistry than in the *trans* arrangement.

These compounds are stable to air as solids when kept in the dark. However, in contrast to the well-known stability of dioximato rhodium(III) complexes, the monoximato derivatives are labile both in solution and when exposed to light.

Results described in this paper raise interesting questions with respect to the factors that determine the isomer distribution for these reaction systems. This is probably related to the reaction conditions, e.g. pH, thermodynamic preference and the mechanism of the exchange process. More detailed kinetics and thermodynamic studies are needed before we can solve these problems. The different substrates used in the syntheses clearly demonstrate the effect of the ligands (Cl^-, H_2O) coordinated to the rhodium center on the

nature of the substitution products. To our knowledge no rhodium(III) complexes with the monoxime ligands have hitherto been reported. Thus the syntheses of rhodium compounds with hetero donor molecules like Hdamo opens new ways for the study of rhodium oximato species.

Mesomorphic dithiocarbamate complexes

Daniel J. Price, Michael A. Wali and Duncan W. Bruce*

Department of Chemistry, University of Exeter, Stocker Road, Exeter EX4 4QD, U.K.

(Received 3 April 1996; accepted 13 May 1996)

Abstract—Complexes of 4-(4′-alkyloxyphenylethyl)piperidine dithiocarbamates with nickel, palladium, copper and zinc have been formed. The nickel and copper complexes are mesomorphic showing smectic phases S_C and crystal B mesophases. Copyright © 1996 Elsevier Science Ltd

Keywords: metallomesogens; dithiocarbamates.

Metal-containing liquid crystals are of great interest [1]. With such systems it is possible to introduce desirable properties inherent in metal complexes, such as high electronic polarisability, colour and paramagnetism, into liquid crystalline systems. This combination of novel electronic and magnetic molecular properties with the macroscopic supramolecular ordering of a mesophase is likely to lead to a variety of new and interesting effects. Many such modifications to these physical properties would be extremely difficult to achieve in purely organic materials.

Although the first metallomesogens were reported over 80 years ago [2] it is only recently that this field has attracted more serious and systematic study. The advent of this more focused research followed reports of the now classic nickel dithiolene complexes of Giroud and Mueller-Westerhoff (Fig. 1) [3]. Since these first compounds, relatively few liquid-crystalline sulfur coordination complexes have been synthesised and studied. Ohta [4] and ourselves [5] have reported the liquid crystalline behaviour of some 4-alkyloxydithiobenzoate complexes (Fig. 2), while Ohta also reported derivatives of the dithiolenes above (Fig. 3) which showed columnar mesophases [6]. More recently, Hoshino-Miyajima [7] demonstrated for the first time mesomorphism in complexes of piperazine dithiocarbamates (Fig. 4).

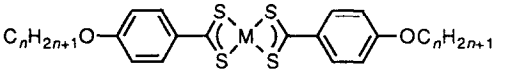

Fig. 2. Mesomorphic dithiobenzoates.

We too have turned our attention to 1,1-dithiolato systems. Simple dithiocarbamate complexes have been extensively studied [8] and thus have a well-developed chemistry, offering great synthetic flexibility. We report here on the synthesis and characterisation of some new piperidine dithiocarbamate complexes of nickel, palladium, copper and zinc. We describe the observed mesomorphism and try to rationalise this behaviour with respect to the ligand and to the effect of the metal centre. In-mesophase EPR studies of these complexes have already been reported [9].

RESULTS AND DISCUSSION

The mesogenic complexes, **3**, were prepared by the multistep synthesis outlined in Scheme 1. The 4-alkyloxy-4′-stilbazoles are mesomorphic, and were synthesised by a procedure we have described previously [10]. Catalytic hydrogenation of the butyloxy and hexyloxy stilbazole derivatives with platinum(IV) oxide (Adams catalyst) gave the 4-substituted piperidine (**1**; $n = 4, 6$). Deprotonation of these secondary amines and subsequent reaction with carbon disulfide gave the sodium salt of the dithiocarbamate ligand (**2**; $n = 4, 6$), the reaction of which with an appropriate divalent metal salt yielded the complexes (**3**; M = Ni, Pd, Cu, Zn; $n = 4, 6$). These complexes were sparingly soluble in most organic solvents and the palladium derivatives tended to decompose in chlorinated solvents. By analogous synthetic procedures, we have also made a variety of other simple piperidine dithiocarbamate complexes (Fig. 5) **4**–**7** (the unsubstituted piperidine derivative), **5** (4-phenylpiperidine), **6** (4-nonylpiperidine) and **7** (3-octyloxypiperidine). We include these non-mesomorphic materials because they make for a useful comparison with our mesomorphic complexes, **3**, and those complexes of Hoshino-Miyajima [7]. They also give an indication of the large differences in melting points that simple structural modifications of dithiocarbamate metal complexes can afford.

The mesomorphism of these materials was studied by optical microscopy and differential scanning calorimetry. The phases and the transition temperatures were assigned on the basis of the microscopy and are given in Table 1.

The simple piperidine derivative, **4** melted at 306°C with decomposition. Addition of the phenyl group in the 4-position, **5**, raised the melting point to 333°C (with decomposition), while further substitution by a nonyl group in the 4-position of the phenyl ring, **6**, decreased the melting point to 238°C. However, most impressive was the reduction in the melting point to 68°C if 3-octyloxy substitution was employed. (This material, **7**, is not strictly comparable, because it is a mixture of two enantiomers and another diasterioisomer; consequently there may be a considerable depression in melting point with respect to a single, pure component.) That simple substitution gives such a large range of crystal stabilities suggests that with suitable molecular design, mesomorphic behaviour may be attainable.

An interesting comparison can be made between our nickel complex **6** (m.p. 238°C) and a similar compound of Hoshino-Miyajima [7], namely the bis(4-octylpiperazine-1-dithiocarbamato) complex of palladium(II). This complex exhibited an enantiotropic nematic phase, melting at 209°C and clearing at 237°C. Since palladium derivatives tend to melt at a few degrees above their nickel congeners, we attribute this difference in phase behaviour to the difference in the ring structures. Our piperidine derivative is rigid, and inversion of the nitrogen in the 1-position is not possible since it is conjugated through the sulfur to the metal. This rigidity of the piperidine ring is supported by the NMR data for all our substituted

Scheme 1. Reagents and conditions: (i) H_2, PtO_2 in AcOH; (ii) NaOH, CS_2 in EtOH; (iii) $Pd_3(AcO)_6$ $NiCl_2 \cdot 6H_2O$, $CuSO_4 \cdot 5H_2O$ or $Zn(AcO)_2$ all in EtOH and H_2O.

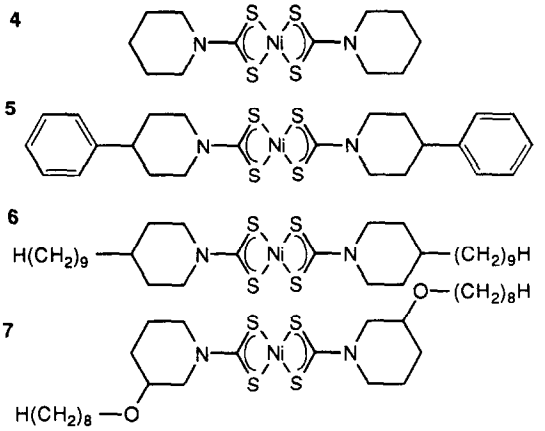

Fig. 5. Non-mesomorphic dithiocarbamate nickel complexes.

Table 1. The mesomorphism of the dithiocarbamate complexes: Transition temperatures are given in °C. Enthalpies, ΔH, in parentheses, are given in kJ mol^{-1}; monotropic phase transitions are indicated in parentheses; [a] signifies the transition was accompanied by thermal decomposition

derivatives, in which axial and equatorial protons are non-equivalent and the couplings are well resolved. However, Hoshino-Miyajima reported the piperazine derivatives in solution and at room temperature to have equivalent axial and equatorial protons. The mechanism for this is quite clearly rapid inversion of the nitrogen in the 4-position, on an NMR timescale, causing a conformational interconversion between chair forms, in which the 4-substituent always remains equatorial. It is this inversion that destabilizes the crystal and does not appear to be detrimental to the mesomorphism, revealing a nematic phase which cannot be seen in the more rigid piperidine complex [6].

Of the mesogenic complexes, **3**, only the nickel and copper derivatives showed liquid-crystalline behaviour, the palladium and zinc complexes being non-mesomorphic. Both the nickel and copper complexes (**3**; M = Ni, Cu; $n = 6$) showed similar phase behaviour. On cooling from the isotropic liquid (**3**; M = Ni, Cu; $n = 6$) a highly birefringent, schlieren texture of a S_C phase was observed. This phase was quite viscous and cohesive and no two brush schlieren could be seen. Further cooling saw a transition to a crystal B phase, in which a mosaic texture and a few focal conic domains were observed. That it was possible to focus well on the texture would seem to preclude the possibility of identification as an S_I phase.

This similarity in phase behaviour of the nickel and copper derivatives is not wholly unsurprising, as typically they adopt essentially isostructural square planar geometries. However, in the solid state, the copper dithiocarbamates tend to associate as weakly bound

dimers, so as to give each of the copper centres a square pyramidal geometry. That this is a weak interaction is indicated by the fact that dissolution in polar solvents invariably generates the monomeric species. We envisage that at the temperatures of the mesophase there is more than sufficient energy to break the dimer, and this is supported by the remarkable similarity to the mesomorphism of monomeric nickel derivative. This square planar geometry, leaves large uncoordinated areas above and below the plane, which are potentially free for dynamic, lateral intermolecular metal/ligand (sulfur) and metal/metal interactions. Originally we had considered the possibility that such interactions might promote the formation of the observed smectic phases, however the observation of a nematic phase in the dithiocarbamate complexes of Hoshino-Miyajima [7] means that this cannot be the case. Thus, the observed smectic behaviour is more likely to be due simply to the alternate areas of high and low polarisability present in the structure.

The palladium derivative (**3**; M = Pd; $n = 4$) was expected to adopt a similar structure to the nickel congener. However that no mesomorphism was observed was probably due simply to the alkyl chain not being sufficiently long to depress the melting point sufficiently to uncover the phase behaviour. No monotropic phases were observed as upon melting, thermal and chemical decomposition occurred. In the zinc derivative (**3**; M = Zn, $n = 6$), no mesomorphism was observed, rather a simple melting into an isotropic state. Simple zinc dithiocarbamates have a great propensity to form dimers in the solid state, which at least in the case of the dithiobenzoate complexes which we studied, persist into the mesophase. Thus, it is not entirely clear why these systems are not mesomorphic.

EXPERIMENTAL

Microanalyses were performed at the Universities of Sheffield and Leeds. IR spectra were recorded as KBr discs on a Perkin–Elmer 1600 Series FTIR. UV spectra were recorded on a Philips PU 8720 UV–vis scanning spectrophotometer. Proton NMR were recorded on a Bruker ACL250 spectrometer; proton chemical shifts are quoted relative to internal $CDCl_3$ or CD_2Cl_2, all proton couplings are in Hz; for structural assignments refer to Fig. 2. Mass spectra were recorded on a Kratos MS25 instrument with a DS55 data system. The mesomorphism was studied by polarising optical microscopy using a Carl Zeiss Labpol microscope equipped with a Linkam TH600 hot stage and a PR600 temperature controller, and by differential scanning callorimitry with a Perkin–Elmer DSC7 instrument. The transition temperatures and phase types were assigned on the basis of the microscopy studies. All chemicals were used as received unless otherwise specified.

4-(4′-Butyloxyphenethyl)piperidine (**1**; $n = 4$)

To a solution of *trans*-4-butyloxy-4′-stilbazole (1.51 g, 5.95×10^{-3} mol), in glacial acetic acid (100 cm^3), platinum(IV) oxide (147 mg, 6.48×10^{-4} mol) was added. The mixture was placed under a hydrogen atmosphere, stirred vigorously and the uptake of hydrogen monitored. After 4 equivalents of hydrogen had reacted, the reaction was stopped. The acetic acid was distilled off under high vacuum, the residue was taken into dichloromethane (150 cm^3), washed with water (5×30 cm^3), and saturated brine solution (1×20 cm^3). The organic phase was dried over anhydrous magnesium sulphate, filtered and the solvent removed under reduced pressure. Crystallisation from methanol gave the colourless, crystalline product 4-(4′-butyloxyphenethyl)-piperidine (0.307 g, 21%). m.p. 91.6°C; (Found: C, 77.7; H, 10.4; N, 5.1. $C_{17}H_{27}ON$ requires C, 78.1; H, 10.4; N, 5.4%); δ_H (250 MHz; $CDCl_3$) 0.97 (3H, t, $^3J_{AB}$ 7.3, H^A), 1.10–1.30 (4H, m br, H^{Ja} and H^B), 1.40–1.60 (4H, m br, H^{Je} and H^H), 1.60–1.80 (3H, m, H^C and H^J), 1.91 (2H, t br, $^2J_{KaKe} = {}^3J_{KaJa}$ 11, H^{Ka}), 2.55 (2H, m, H^G), 2.90 (1H, s, H^L), 2.97 (2H, d, $^2J_{KeKa}$ 11, H^{Ke}), 3.93 (2H, t, $^3J_{DC}$ 6.5, H^D), 6.81 (2H, AA′XX′, $^3J_{FE}$ 8.5, J 2.5, H^E), 7.07 (2H, AA′XX′, $^3J_{EF}$ 8.5, J 2.5, H^F).

Sodium 4-(4′-butyloxyphenethyl)piperidine dithiocarbamate (**2**; $n = 4$)

4-(4′-Butyloxyphenylethyl)piperidine (150 mg, 5.74×10^{-4} mol) and sodium hydroxide (34.2 mg, 8.55×10^{-4} mol) were dissolved in ethanol (10 cm^3) and heated under reflux for 30 mins. Carbon disulfide (5.0×10^{-2} cm^3, 8.5×10^{-4} mol) was added. This solution was cooled to room temperature over a period of 1 h. The product, sodium (4(4′-butyloxyphenethyl) piperidine dithiocarbamate was not isolated but was used *in situ*.

Bis-[4-4′-butyloxyphenethyl)piperidine dithiocarbamatol nickel (II) (**3**; M = Ni; $n = 4$)

To the solution of sodium 4-(4′-butyloxyphenylethyl)piperidine dithiocarbamate (2.8×10^{-4} mol) in ethanol (10 cm^3), a solution of nickel (II) chloride hexahydrate (33 mg, 1.4×10^{-4} mol) in water (2 cm^3) was added. The green product precipitated immediately. The mixture was stirred for 1 hour, filtered, and the crude product washed with water, methanol, ethanol, pentane and hot acetone. Recrystallisation from dichloromethane yielded the product, bis[4-(4′-*n*-butyloxyphenethyl)piperidine dithiocarbamato] nickel (II), (39 mg, 42%). (Found: C, 59.0; H, 7.2; N, 3.8. $C_{36}H_{52}O_2N_2S_4Ni$ requires C, 59.1; H, 7.26; N, 3.8%); δ_H (250 MHz; $CDCl_3$) 0.96 (6H, t, $^3J_{AB}$ 7.2, H^A), 1.20 (4H, quart, $^2J_{JaJe} = {}^3J_{JaKa} = {}^3J_{JaI}$ 12.5, H^{Ja}), 1.35–1.70 (10H, m br, H^B, H^H and H^I), 1.73 (4H, quin, $^3J_{CD} = {}^3J_{CB}$ 7.0, H^C), 1.83 (4H, d br, $^2J_{JeJa}$ 12.5, H^{Je}),

2.50 (4H, t br, $^3J_{GH}$ 8.1, H^G), 2.92 (4H, d*t*, $^2J_{KaKe}$ = $^3J_{KaJa}$ 13, $^3J_{KaJe}$ 3, H^{Ka}), 3.92 (4H, *t*, $^3J_{DC}$ 6.6, H^D), 4.48 (4H, d br, $^2J_{KeKa}$ 13, H^{Ke}), 6.78 (4H, AA′XX′, $^3J_{FE}$ 8.5, H^F), 7.07 (4H, AA′XX′,$^3J_{EF}$ 8.5, H^E).

The synthesis of all other derivatives was carried out in a similar manner to that described above.

4-(4′-*Hexyloxyphenethyl*)*piperidine* (**1**; n = 6)

δ_H (250MHz; $CDCl_3$) 0.90 (3H, t, $^3J_{AB}$ 9.5, H^A), 1.15–1.37 (8H, m br, H^{Ja} and H^B), 1.37–1.58 (4H, m br, H^{Je} and H^H), 1.58–1.83 (3H, m, H^C and H^I), 1.91 (2H, t br, $^2J_{KaKe}$ = $^3J_{KaJa}$ 10.4, H^{Ka}), 2.55 (2H, m, H^G), 2.88 (1H, s, H^L), 2.97 (2H, d, $^2J_{KeKa}$ 10.4, H^{Ke}), 3.92 (2H, t, $^3J_{DC}$ 6.5, H^D), 6.81 (2H, AA′XX′, $^3J_{FE}$ 8.4, J 2.5, H^E), 7.07 (2H, AA′XX′, $^3J_{EF}$ 8.4, J 2.5, H^E).

(Received 23 February 1996; accepted 1 May 1996)

Abstract—The cryptate complex $[Gd(L)(DMF)] \cdot KSCN \cdot CH_3CN \cdot 3H_2O$ has been synthesized by the reaction of gadolinium isothiocyanate and potassium thiocyanate with cryptate $[Na(H_2L)]$, which was prepared by a (2+3) Schiff-base condensation of tris(2-aminoethyl)amine and 2,6-diformyl-4-methoxyphenol in the presence of NaOH. The Gd atom is encapsulated in the cryptand with an unsymmetric eight-coordinate environment. Copyright © 1996 Elsevier Science Ltd

Keywords: gadolinium; cryptate; complex; cryptand; synthesis; structure.

Much current attention has been devoted to the design and synthesis of lanthanide complexes of macrocyclic ligands [1]. Their studies are extensively correlated with many emerging fields of application, such as supramolecular devices [2–4], luminescent labels and fluorescent probes in biological and medical applications [5], magnetic resonance imaging [6] and catalytic cleavage of RNA [7], etc. The lanthanide complexes of phenol-based two-dimensional macrocyclic ligands have been extensively studied up to 1995. Drew [8] reported several kinetically stable lanthanide complexes of phenol-based protonated cryptands (three-dimensional macrobicyclic ligands). Recently, we synthesized a series of lanthanide cryptates with deprotonated analogous cryptands. Herein we describe the synthesis and crystal structure of $[Gd(L)(DMF)] \cdot KSCN \cdot CH_3CN \cdot 3H_2O$. Owing to the compartment coordination, the cryptate possesses an unsymmetrical mononuclear eight-coordinate conformation.

EXPERIMENTAL

Gadolinium isothiocyanate was prepared from the reaction of gadolinium chloride (99.9%, China) and potassium thiocyanate. Tris(2-aminoethyl)amine and 2,6-diformyl-4-methoxyphenol were prepared by the modified methods according to Kimura [9] and Hu [10], respectively. Elemental analysis was carried out by the analytical division of the State Key Laboratory of Structural Chemistry. NMR, IR and UV-vis spectra were recorded on Varian Unity 500, Perkin–Elmer 577 and Shimadzu UV-3000 instruments, respectively.

Synthesis of $[Na(H_2L)]$

To a stirred suspension of NaOH (0.060 g, 1.5 mmol) and 2,6-diformyl-4-methoxyphenol (0.270 g, 1.5 mmol) in anhydrous methanol (50 cm^3) was added dropwise an anhydrous methanol solution (50 cm^3) of tren (0.146 g, 1 mmol) at room temperature over 1 h. The resulting orange precipitate was filtered off and recrystalized from chloroform, yield 71%. Found: C,

62.6; H, 6.5; N, 15.2. Calc. for $C_{39}H_{47}N_8O_6Na$: C, 62.7, N, 15.0%. ^1H NMR (d_6-DMSO, TMS): δ 13.78 (s(br), 2H, ph-OH), 8.45 (s(br), 6H, imino-CH), 6.94 (s(br), 6H, ph-H), 3.67 (s, 9H, OCH_3), 3.59, 3.55 (d, 12H, H_2C—N (imino)), 2.81 (s(br), 12H, H_2C—N (bridgehead)). IR (cm^{-1}, KBr disc.): 3543w (υ_{OH}), 3411, 3244, 3012, 2995, 2939, 2906, 2842, 2810, 1643s ($\upsilon_{C=N}$), 1597, 1460, 1317, 1259, 1155, 1051, 960, 815, 754. UV–vis spectrum (CH_3CH): 258 (ε_{mol} 14900 dm^3 cm^{-1} mol^{-1}), 370 nm (10000).

Synthesis of [Gd(L)(DMF)]·KSCN·CH_3CN·$3H_2O$

A mixture of [Na(H_2L)] (0.149 g, 0.2 mmol) in acetonitrile (20 cm^3) and aqueous gadolinium isothiocyanate (0.176 g, 0.4 mmol) and potassium thiocyanate (0.02 g, 0.2 mmol) in ethanol (30 cm^3) was stirred and heated for 0.5 h. The reaction solution was filtered and the yellow filtrate stood for several minutes, yellow microcrystals were isolated. The crude product is redissolved into DMF by slow diffusion of ether over a week, yellow crystals suitable for X-ray structure determination were obtained, yield 75%. Found: C, 47.4; H, 5.1; N, 13.7. Calc. for $C_{45}H_{61}N_{11}O_{10}SGdK$: C, 47.2; H, 5.4; N, 13.5%. IR (cm^{-1}, KBr disc.): 3420w (υ_{OH}), 2056s (υ_{SCN}), 1652s ($\upsilon_{C=N}$), 1636sh, 1604, 1545, 1470, 1345, 1295, 1220, 1037, 796. UV–vis spectrum (CH_3CN): 260 (ε_{mol} 14300), 475 nm (11800).

X-ray crystal structure determination of [Gd(L)(DMF)]·KSCN CH_3CN·$3H_2O$

A yellow block crystal encapsulated with gel possessing approximate dimensions $0.35 \times 0.25 \times 0.25$ mm was mounted on a glass fibre in a random orientation. The unit cell parameters were determined from least-squares refinement of the setting angle ($12 < \theta < 14°$), for 19 reflections. Intensity data were recorded on an Enraf–Nonius CAD4 diffractometer at 23°C, using graphite-monochromated Mo-K_α radiation ($\lambda = 0.71073$ Å). A total of 9640 reflections were measured, of which 9207 were unique and 5963 with $\imath > 3.0\ \sigma\ (\imath)$ were used in the refinement (ω-2θ scan type, $2\theta_{max} = 50°$, scan rate 1–7° min^{-1} in ω). Three representative reflections were measured every 120 mins, no significant decay was observed. Lorentz-polarization and empirical absorption corrections were applied. Intensities of equivalent reflections were averaged. The structure was solved by Patterson heavy-atom method using MolEN [11] program, which revealed the coordinates of the Gd atom. The remaining non-hydrogen atoms were located in succeeding difference Fourier syntheses. Hydrogen atoms were located theoretically and not refined. The K atom is disordered. All calculations were performed on a COMPAQ PL4/50 computer. See details in Table 1.

RESULTS AND DISCUSSION

Cryptate [Na(H_2L)] was synthesized by a facile sodium template reaction as shown in Scheme 1.

Only one phenolic proton was replaced by NaOH in the formation of the cryptand, resulting in a mono sodium cryptate. This template effect is different from the sodium template synthesis of phenol-based two-dimensional macrocycles [12]. The cavity size plays an important role in synthesis of the sodium cryptate. The IR spectra show no bands with the characteristic stretching frequency of the carbonyl groups and the primary amine groups. However, the cryptate possesses a very strong absorption band at 1643 cm^{-1}, assigned to the imino stretching mode, supporting the Schiff-base linkage. There are some broad peaks in its ^1H NMR spectra, perhaps resulting from a rapid conformational exchange. At room temperature, distinguishable NMR splitting similar to the unsymmetric sodium mononuclear cryptates described by Nelson *et al.* [13–14] was not observed.

Scheme 1.

Scheme 2.

The complex $[Gd(L)(DMF)]\cdot KSCN\cdot CH_3CN\cdot 3H_2O$ was synthesized as shown in Scheme 2.

The crude product isolated from CH_3CN—EtOH is difficult to dissolve in normal solvents. Thus the pure thiocyanate coordinate cryptate failed to be obtained. When redissolved in DMF, the crystals composed of a Gd cryptate [Gd(L)(DMF)] and a KSCN were obtained. In the IR spectra, the very strong vibration absorption of SCN is observed at 2056 cm^{-1}. The crystal structure of [Gd(L)(DMF)] is illustrated as Fig. 1.

The Gd^{III} ion is linked to one bridgehead nitrogen (N1) and three imino-nitrogen atoms (N(11), N(21) and N(31)) as well as three phenol-oxygen atoms (O(1), O(2) and O(3)), forming a $N_4(O\text{-})_3$ coordination inside the cryptand. DMF acts as another O donor to the Gd atom. The other nitrogen donors of the cryptand (N(2), N(12), N(22) and N(32)) are not bonded to the Gd atom. The cryptand gives three coordinated imino N donors (N(11), N(21), N(31)) at one side, and three uncoordinated imino N atoms (N(12), N(22), N(32)) at another side. Thus, the metal ion is eight-coordinate and is unsymmetrically encapsulated in the cryptand. The coordination geometry about the Gd atom can be considered as a distorted dodecahedron, being isostructural with the complexes of the neutral cryptand [8]. This unsymmetric conformation was also observed in mononuclear Na^+, Zn^2, Pb^{2+} and Cd^{2+} complexes of neutral phenol-based cryptands [13, 14]. Selected bond lengths (Å) and angles (°) are shown in Table 2.

The average Gd—O (phenol) distance is 2.316 Å,

consistent with the range in the complexes of phenol-based cryptands [8] and macrocyclic [15] as well as tripodal hemi-cage ligands [16,17]. The average Gd—N (imino) bond distance is 2.529 Å, being shorter by 0.1 Å than that in the normal macrocyclic complexes [1]. Comparing the bond lengths of C=N, we can see that the average distance of coordinated imino groups is shorter by 0.05 Å than that of uncoordinated ones, showing that coordination caused π electron of bis(iminophenol) moieties of the cryptand to be transferred to the metal ion. The distances of Gd···N (uncoordinated) are in the range of 4.45(1)-5.74(1) Å. This size may be expected to provide coordination to a second metal ion, but the second lanthanide or sodium ion failed to be encapsulated possibly owing to their high coordination numbers or large radii. In other words, this compartment cryptand only recognizes selectively one lanthanide(II) ion or sodium ion.

(Received 8 February 1996; accepted 26 April 1996)

Abstract—The Strauss reaction is regioselective and unique for the head-to-head coupling of terminal acetylenes. For the success of the catalytic conversion, the presence of copper(I) carboxylate is necessary. The corresponding carboxylic acid may be used pure, as solvent, or diluted in non-nucleophilic solvents. However, its presence in excess is also necessary. The formation of the product, 1,4-dialkylenynes, shows some stereoselectivity. The *E* isomer is always dominant in the mixture, but the *E*/*Z* ratio may be manipulated by the steric effects of the R groups of the carboxylic acid and of the monomers as well. The nucleophilic solvents such as H_2O, ROH and phosphine ligands inhibit the catalytic reaction. The isolated products are the copper acetylides or its phosphine complexes, respectively. Mesitylacetylene and *p*-nitrophenylacetylene do not undergo the catalytic conversion. However, the former gives the cross-product with phenylacetylene. The possible mechanism of the reaction is discussed and the suggested pathway is supported with computational calculations. Copyright © 1996 Elsevier Science Ltd

Seeking simple synthetic routes to enynes becomes extremely important since these compounds not only appear in natural products, but can also be used as building blocks for more complex hydrocarbon structures.

1-Alkynes dimerize in different ways producing head-to-head **1**, head-to-tail **2** and cumulene **3** products [eq. (1)].

(1)

Dimerization of 1-alkynes has been extensively studied with a variety of transition-metal catalysts. $[Cr(O\text{-}Bu\text{-}n)4]/ZnEt_2$,[1] $[RhCl(PPh_3)]_3$,[2] $Pd(OAc)_2$/tris(2,6-dimethoxyphenyl-phosphine),[3] $[Rh(PMe_3)_2Cl]_2$[4] and $(\eta^5\text{-}C_6Me_5)_2TiCl_2/RMgX$[5] are representative catalysts for head-to-tail dimerization of 1-alkynes to convert them to **2**.

Cationic Lewis-base free zirconocene complexes such as $\{Zr(C_5Me_5)_2Me\{B(4\text{-}C_6H_4F)_4\}$ also form **2**. However, this catalyst is particularly efficient for the oligomerization of terminal acetylenes.[6] Strauss coupling, the non-oxidative head-to-head coupling of terminal alkynes produces both the *Z* and the *E* isomers of the corresponding enynes **1**.[7] Similar head-to-head couplings with yields up to 21% of the (*Z*)-enyne is observed when phenylacetylene is heated with the catalytic amount of cationic hydride of ruthenium. $[Ru(CO)H(CN\text{-}Bu^t)(C_5H_5N)(PPh_3)_2]\cdot PF_6$ catalyses the dimerization of phenylacetylene in ethanol giving an *E* and *Z* mixture of 1,4-diphenylbuten-3-ynes.[8] Ruthenium complexes, such as [Ru(cod)(cot)] (cod = 1,5-cyclooctadiene, cot = cyclooctatriene) and $[Ru(CO)(PPh_3)_3(H)_2]$, are unique catalysts to convert 1-alkynes to cumulene derivatives **3**.[9] A similar reaction takes place with trimethysilyl[10] or with *t*-butylacetylene.[11] In all these cases 1,3-enynes appear to be the by-products of the reaction.

Mechanisms of Ti-, Rh- and Ru^{II}-catalysed dimerization reactions have been analysed in great detail.[4,5,8] However, not much is known about the mechanism of Cu^I-catalysed dimerization of 1-alkynes.

In this work we report our investigation of the mechanism of copper-mediated head-to-head dimer-

ization of 1-alkynes by analysing the effects of different parameters on the progress of this convenient reaction.

RESULTS

The standard Strauss reaction was carried out by refluxing alkylacetylenes and Cu_2O in glacial acetic acid under nitrogen. A mixture of (*Z*)- and (*E*)-1,4-dialkyl butenyne was obtained. A small amount (~%1) of 1,4-dialkyl butadiyne was also formed. The progress of the reaction was followed by the colour of the mixture. The brick red colour of the initial solution was changed in about 1 h over yellow to blue–green, accompanied by the separation of metallic copper. The orange and blue–green colour of the solution results from the formation of the intermediates such as alkylacetylide and $Cu(OAc)_2$ sequentially.

The progress and yield distribution of the reaction was affected by the variations of the solvents, catalyst components, alkyl groups of the monomers as well as upon the addition of the secondary ligands, such as PR_3, ROH and H_2O, to the reaction mixture.

Variation of the catalyst components

It was attempted to catalyse the reaction by sequentially replacing the metallic and anionic part of the catalyst. In the presence of the acetates of the monovalent and divalent main group elements such as Na^I, Li^I and Mg^{II}, the dimerization did not occur. The starting compounds were completely recovered. The same experiments with the acetates of the d^{10} transition metals Ag^I and Hg^{II} resulted in the corresponding acetylide formation in stoichiometric amounts. The d^8, d^6 and d^5 complexes Ni^{II}, Cr^{III} and Fe^{III} are totally inactive under the applied standard reaction conditions. A d^9 complex, the copper(II) acetate, also catalysed the dimerization of the terminal acetylenes, giving a similar product distribution as the Cu^I-catalysed reactions. It is shown, however, that the real catalyst here is again the Cu^I species, which is formed by the disproportionation of the initial Cu^{II} complexes.[12]

The anionic part of the catalyst is also very important. As with Cu^I, the presence of the carboxylate is also necessary for the success of the catalytic Strauss reaction. It may be introduced directly as copper(I) acetate or may be produced in the reaction mixture over the precursors such as the oxide or acetylides of Cu^I when the carboxylic acids are used as solvents [eqs (2) and (3)].

$$Cu_2O + CH_3COOH \rightarrow 2CuOAc + H_2O \quad (2)$$

$$R{-}C{\equiv}Cu + CH_3COOH \rightleftharpoons CuOAc + R{-}C{\equiv}C{-}H. \quad (3)$$

The conjugate bases of strong inorganic acids like the halides are not suitable as catalyst components. The existence of the equilibrium in eq. (3) has been proven by deuterium exchange.[12]

Solvent and ligand effects

The Strauss reaction succeeds only in the presence of excess carboxylic acids. Carboxylic acids may be used as solvents in pure or in diluted form. In the repeated experiments using Cu^IOAc, in the absence of simple carboxylic acids, using either excess of the monomer or different solvents such as *n*-decane, nitrobenzene, *n*-butanol and dichloroacetic acid, the dimerization did not occur.[13] The reaction was stopped at the acetylide formation step, except in dichloroacetic acid. In this solvent the acetylide formation was not observed. A 1 : 1 mixture of the carboxylic acid with the above-mentioned solvents gave different results. In the presence of nitrobenzene the reaction was complete, as in the standard condition, in *ca* 1 h with the same product distribution. The presence of *n*-decane reduced the rate of the reaction significantly. Here, the reaction terminated in 3 h, with the same product composition. In the presence of *n*-butanol the dimerization failed. Only Cu^Iacetylide was isolated from the reaction mixture. Similar results were obtained when the reaction was repeated in aqueous acetic acid (90%). The reaction was stopped at the acetylide formation step. The addition of an equivalent amount of the trialkyl phosphine resulted in the formation of the corresponding Cu^Ialkylacetylide trialkyl phosphine complex, without the formation of the expected enynes.

Substituent effects

The progress and product distribution of the Strauss reaction depends strongly on the nature of the alkyl groups of the monomer and of the carboxylic acids used as solvents.

The results of the experiments concerning the latter effect are given in Table 1, with the steric parameters, *V*, of the alkyl groups, evaluated from the van der

Table 1. Product distribution of the phenylacetylene dimerization depending on the steric effects of the alkyl groups of the carboxylic acid used as solvents

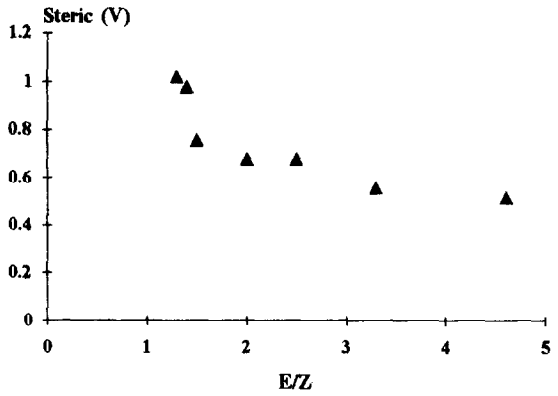

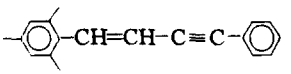

Fig. 1. Correlation between the E/Z ratio and steric parameters of the substituents.

Waals radius.[14] Steric parameters roughly correlate with the E/Z ratio (Fig. 1).

Comparative experiments in glacial acetic acid, using phenylacetylene and 1-hexyne, gave a different product distribution. The E/Z ratio was changed from 4.6 to 1.7 when the phenyl group was replaced by the *n*-butyl group. The attempted dimerization of the *p*-nitrophenylacetylene and mesitylacetylene failed. Only their copper(I) acetylide complexes were isolated.

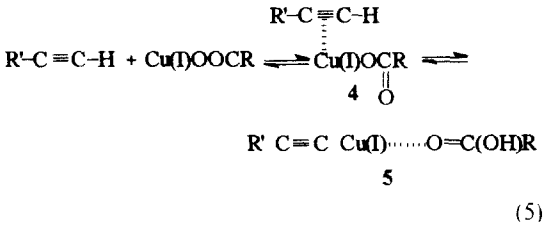
Cross-dimerization of *p*-nitrophenylacetylene with the mesityl and phenylacetylene compounds also failed. The copper(I) *p*-nitrophenylacetylide complex was formed if mesitylacetylene was used as the reaction partner. In the presence of phenylacetylene, only the corresponding dimer of phenylacetylene with an E/Z ratio of 2.5 was formed. Cross-dimerization of phenyl and mesitylacetylenes was successfully accomplished. Approximately 23% of the homodimer of phenylacetylene (E/Z: 3.1) and 13% of the cross-dimer (E/Z: 3.3) were formed. The formation of the cross-dimer was regioselective. In the isolated product, while the phenyl group is attached to the acetylenic end, the mesityl group is connected to the olefinic end of the molecule.[15]

In the MS spectra of both isomers the characteristic peak of mesitylacetylide was not observed, the most eminent peak, m/z: 101, corresponding to phenylacetylide fragment.

DISCUSSION

It can be concluded from the foregoing experimental facts that there are four significant steps in the catalytic dimerization of the terminal acetylenes:

(i) the acetylide formation from the monomer;
(ii) C—C bond formation;
(iii) the protonation of the intermediate to give the free dimer and to regenerate the catalyst;
(iv) termination of the catalytic cycle.



For the sake of clarity each step will be discussed separately.

(i) *Formation of the acetylide*

As mentioned above, the presence of the carboxylate anions is essential for the formation of the corresponding acetylides, which are the real intermediates of the Strauss reaction. The carboxylate anion might be introduced directly as metal salts or may be generated *in situ* in carboxylic acid solvents using suitable precursors [eq. (4)].

$$Cu_2O + 2RCOOH \rightarrow 2CuOCOR + H_2O. \quad (4)$$

However, the formation of the carboxylates is not sufficient for the acetylide formation. Also the presence of strong π-bonding transition metals is necessary. Obviously, the terminal acetylenes are sufficiently activated upon complexation with the d^{10} transition metals, such as Cu^{I}, Ag^{I} and Hg^{II}, to donate the acetylenic proton to a weak base such as the carboxylate anions [eq. (5)].

(5)

Complexes **4** and **5** are not isolated. However the structure of the related phosphine complexes are known.[16] Furthermore the properties of the corresponding $Ag^{I}OTf$ complex have been studied and it has been shown that the deuterium exchange rate of the terminal acetylenes increased more than 10^5 upon complexation. In the suggested mechanism the incorporation of the silver acetylide formation was excluded.[17] In our labelling experiment we have also observed a fast deuterium exchange under the standard Strauss reaction conditions. We believe, however, that in the presence of a relatively strong base, such as the carboxylate anion, the loss of deuterium from the penylacetylene-1-D should involve the intermediate acetylide formation.

Failure of the acetylide formation, in the experiments using dichloroacetic acid as solvent, might be attributed to the weakness of the conjugate base of the dichloroacetic acids. The basicity of dichloroacetates is *ca* 3.5×10^3-fold lower than the simple alkyl carboxylates in aqueous solution. In order to obtain an idea about the degree of activation by complex formation, we have calculated the theoretical acidities of the terminal acetylenes and of some acidic solvents used in this study. The semiempirical method,

PM3, was used to calculate the AH and A^- values in eq. (6). The experimental heat of formation of H^+ (366.05 kcal mol^{-1}) was used in the calculation of the AH value.

$$AH \rightleftharpoons A^- + H^+$$

$$\Delta H_A = H_f^{A^-} + H_f^{H^+} - H_f^{AH}. \quad (6)$$

In Table 2 along with the theoretical acidities and heat of formation, H_f, HOMO and LUMO energy levels of the monomers and its conjugate bases calculated using the PM3 and EHM methods are given as well as the results of the similar calculation for acetic acid and dichloroacetic acid used as solvent given together. According to these calculations, in the presence of the acetate anion, the acidity of the phenylacetylene should be increased by *ca* 30 kcal mol^{-1} for the generation of a significant amount of phenylacetylide in the equilibrium. On the other side, generation of the same moiety by the dichloroacetate anion required much higher energy, *ca* 45 kcal mol^{-1}. Another interesting feature concerning the dichloroacetic acid is its relatively low ionization potential. The HOMO of this molecule corresponds mainly to the lone-pair electrons of the chlorine atom. So, the dichloroacetic acid may compete with the acetylenic compounds for the complexation with Cu^I and restrict the above-suggested activation. Results of the EHM calculations indicate a considerable amount of bonding interaction between the copper and chlorine atoms, the overlap population being 0.165.[18] Probably both effects are responsible for the failure of the acetylide formation in dichloroacetic acid.

Concluded from the MO calculations and in terms of the hard–soft interaction, the rate of formation of the intermediate **4** should increase in the following sequence:

mesitylacetylene > phenylacetylene > 1-hexyne > *p*-nitrophenylacetylene

Hence, the substrate-selective formation of the *p*-nitrophenylacetylide in the cross-coupling experiments should be thermodynamic controlled formation of the intermediate complex **5**. Although it is expected that in the first stage of the reaction, electron-rich monomers should be preferentially complexed.

(ii) C—C *bond formation*

The next step of the coupling reaction is the coordination of another monomer to the sphere of Cu^I acetylide to give the HOMO- or cross-coupling products [eq. (7)]:

$$R'—C{\equiv}C—Cu + R''C{\equiv}C—H \rightleftharpoons \begin{matrix} H—C{\equiv}C—R'' \\ \vdots \\ R'C{\equiv}C—Cu \end{matrix} \rightleftharpoons \underset{\mathbf{6}}{\begin{matrix} \\ \\ \\ \end{matrix}}$$

$$R'—C{\equiv}C—CH{=}C(Cu)R'' \quad (7)$$

7

There is no direct experimental evidence for the formation of complex **6**. All attempts to isolate the olefinic complex by quenching experiments failed. The study isolable compound was the copper(I) alkylacetylide. Inhibition of the catalytic cycle, in the presence of sigma-electron-donating ligands such as H_2O and R—O—H, indicates the instability of this intermediate. However, a structurally similar phosphine complex, $PhC{\equiv}CCuPPh_3$, was isolated by trapping experiments and is strong evidence for its formation. This isolated phosphine complex may be accepted as a good model for the proposed intermediate **6**. The structure of the phosphine complex, $Ph—C{\equiv}C—CuP(CH_3)_3$ was resolved by X-ray diffraction analysis.[19] The complex contains tetrameric units in an orthombic cell formally built up from $[(Me_3P)_2Cu]^+$ and $[(Ph—C{\equiv}C)_2Cu]^-$ units. The copper which coordinates the phosphine molecules interacts with the ethynyl groups of the $(Ph—C{\equiv}C)_2Cu$ units to give a tetrahedral structure,

whereas the copper bearing the ethynyl groups interacts with the triple bond of another ethynyl in the unit, giving a trigonal structure. Unlike the polymeric copper(I) acetylides, the phosphine complexes have rather good solubilities. It is known that 1 : 1 acetylide/phosphine complexes are dimeric in nitrobenzene and rather more associated in benzene.[20]

The formation of complex **6** should be substrate-selective and electron-rich monomers should be preferred. So a high percentage of the cross-product should be expected from the mesityl/*p*-nitrophenylacetylene mixture. However, neither HOMO- nor cross-coupling products were formed from these monomers. In the case of mesitylacetylene the steric effect of the *ortho*-methyl groups must be the probable reason for the failure of the HOMO-coupling products, since it has a comparable acidity with the phenylacetylene and more suitable HOMO–LUMO energy levels of a soft–soft type interaction. Indeed it gives the expected cross-product with phenylacetylene [R′ = mesityl in eq. (7)]. The reason for the failure of coupling in the experiments involving *p*-nitrophenylacetylene may be due to the low nucleophilicity of the generated acetylides as the PM3-method predicted charge densities implies.

The Strauss reaction shows high regioselectivity, leading to head-to-head coupling product formation. The observed regioselectivity might be explained by considering the possible structure of the intermediate **6**. Probably it is a dinuclear complex, similar to the isolated phosphine complex, with only one coordination site available for olefinic ligands for each copper atom. As mentioned above, the equivalent amounts of the secondary ligands are sufficient to stop the catalytic reaction. The possibility of the formation of a mononuclear complex as an active catalyst is excluded since it should have more than one available coordination site. To visualize the possible structure of the intermediates we have undertaken molecular mechanics (MMX) calculations. Calculations with a dinuclear complex, taking the structure of the phosphine complex as the model, indicates that in the most stable structure, the coordinated terminal acetylenes are oriented opposite the acetylide groups to minimize the repulsive interaction (Fig. 2). In this structure the C(1), C(3), C(4) and Cu(2) atoms are almost in the same plane and in suitable positions for head-to-head coupling. Overall, it is a type of *cis*-addition with the formation of the alkenyl copper complex with an *E* configuration in the double bond. The same complex might be generated upon interaction of the C(1), C(3′), C(4′) and Cu(2) atoms, although they are not in the same plane. An alternative head-to-tail coupling is less possible from the estimated structure.

As mentioned above with silver(I) salts the acetylide formation was observed, but the reaction was not catalysed, probably due to structural reasons. Unlike copper(I), the triphenyl phosphine complexes of silver(I) acetylide has a linear chain structure.[21]

Cu_1 - C_1 : 1.83	Cu_2 - C_1 : 2.13
Cu_1 - C_3 : 3.14	Cu_2 - C_3 : 2.09
Cu_1 - C_4 : 3.94	Cu_2 - C_4 : 2.32
Cu_1 - $C_{3'}$: 3.20	Cu_2 - $C_{4'}$: 2.27
Cu_1 - $C_{4'}$: 3.54	Cu_1 - C_2 : 2.65

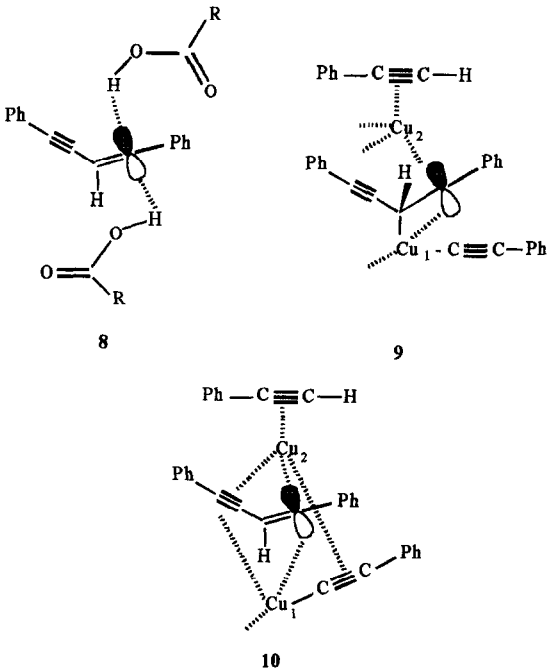
$C_1Cu_1C_{1'}$: 104°
$Cu_1C_1Cu_2$: -12°

Fig. 2. Estimated structure of the intermediate acetylenic copper acetylide complex.

(iii) *Protonation of intermediate alkenyl-copper compound* **7**

Following the foregoing discussion, only the formation of the *E* isomer of the 1,4-dialkylenyne should be expected, if the protonation of the intermediate alkenyl copper is stereospecific. Indeed it has been observed that the hydrolysis of the simple alkenyl copper compounds proceeds with retention of the stereochemistry.[22] In our experiments, however, we have obtained a mixture of the *E*/*Z* isomer in a ratio depending on the nature of the alkyl group of the carboxylic acid used as solvent. In separate experiments it was shown that both isomers are configurationally stable under the applied reaction conditions. Variation of the product composition is mainly affected by steric factors. The solvents have approximately the same pK_a values, but different steric effects. The *E*/*Z* ratio shows a linear dependency with the steric substituent parameters of the alkyl groups (Fig. 1).

Hence, the product composition is determined by the kinetics of the reaction. The carboxylic acid molecules should be incorporated in the structure of the activated complex in this step. A similar observation was made on the hydrolysis of (*E*)-1,2-diarylpropenylcopper. Here, depending on the hydrolysing agent and the solvent, a mixture of the *E*/*Z* isomers of the product was obtained.[23] Primary electrophilic attack of the H^+ on the alpha carbon atom followed by free-rotation of the Cα—Cβ bond was suggested to explain the observed isomerization. The suggested mechanism, however, cannot explain the observed steric effects on the product composition of the Strauss reaction. The following mechanistic



possibilities may give a better explanation for this experimental fact:

(a) Considering the relatively high thermal conditions of the Strauss reactions and the thermal instability of the vinyl-copper compounds, the formation and release of a vinyl carbanion from the intermediate may be expected. The resonance-stabilized molecule should have a V-shaped intermediate **8** (given in Scheme 1), resulting in an unsymmetrical environment on the *sp*-hybridized carbanion centre.

This geometry facilitates the attack of the bulky carboxylic acid from the less hindered side, thus leading to the formation of the less stable *Z* isomer in increasing amounts.

(b) Displacement of the sigma bonds between the two copper atoms, leading to the formation of a carbene-like structure, **9** (given in Scheme 1) stabilized from both sides by copper atoms, would generate again an unsymmetrical structure. The attack of the carboxylic acids, coordinated on both copper atoms or in the free form, would again be facilitated from the less hindered side leading to *Z* isomer formation.

(c) As a combination of both of the two suggestions above, it is imaginable that the generated carbanion remains within the copper complex and is stabilized equally well by both copper atoms. In the above estimated structure **10** of the intermediate given in Scheme 1, the anionic carbon is almost equidistant to both copper atoms. The distance between the copper atoms is smaller than the initial complex. All these imply a three-centre bond formation. Again, in this structure the attack of the carboxylic acid leading to the formation of the *Z* isomer is facilitated. Further calculations are necessary to make a decision among the suggested pathways.

Scheme 1.

(iv) *Termination of the catalytic cycle*

It has been shown experimentally that when no more monomer is left in the reaction medium, copper(I) alkyl acetylide disporportionates to copper(II) and metallic copper [eq. (8)] with the formation of a small amount of diyne. This has been monitored by the formation of the blue colour of copper(II) salts and separation of metallic copper from the reaction mixture.

$$(R{-}C{\equiv}C{-}Cu)_4 \xrightarrow{-2Cu} [(RC{\equiv}C)_2Cu]_2 \longrightarrow$$
$$R{-}C{\equiv}C{-}C{\equiv}C{-}R + (R{-}C{\equiv}C{-}Cu)_2. \quad (8)$$

METHODS

The theoretical calculations were carried out on a 486-IBM compatible PC, by using the standard PM3 procedure with the normal (RHF) version as implemented in the MOPAC (6.version) program, the FORTICON8 program for performing extended Huckel calculations (QCPE 344) and the PCMODEL PI(89.0) Serena software for MMX calculations. All geometries were found by minimizing the energy without making any assumptions.

EXPERIMENTAL

All reactions were carried out under nitrogen. Solvents were dried over suitable reagents and freshly distilled under nitrogen before use. Copper(I) oxide, copper(II) oxide, copper(II) chloride and magnesium(II) acetate were Analar grade. Copper(II) acetate, nickel(II) acetate, lithium(I) acetate, mercury(II) acetate, iron(II) nitrate and chromium(II) acetate were obtained from BDH. Copper(I) acetate,[21] copper(I) phenylacetylide,[22] *cis*-1,4-diphenylbutenyne,[23] *trans*-1,4-diphenylbutenyne[24] and 1,4-diphenylbutadiyne[25] were prepared by known procedures. Ph—C≡C—D was synthesized by heating Ph—C≡C—H with D_2O at 40° for 24 h in the presence of CaO.[26] ^1H NMR showed that the product was 80% deuterated. Na(1) acetate was from Fisher. All the acetylenic compounds, tri-*n*-butylphosphine and triphenylphosphine, were purchased from Aldrich.

IR spectra were recorded on a Perkin–Elmer SP 1200 spectrophotometer (only characteristic bands are given). ^1H NMR spectra were recorded on Varian H A 100 spectrometers with $CDCl_3$ solutions containing tetramethylsilane as an internal standard. Mass spectra were determined using a Varian CH 8 mass spectrometer. For analytical GLC a Packard Becker 409 gas chromatograph was used with 1.8 M 5% SE 30 on Gas Chrom Q using benzene as internal standard. To analyse the products obtained from cross-dimerization reactions a Perkin–Elmer F2 gas

chromatograph was used with a column packed with 30 M SE 54. The *trans*-stilbene was used as an internal standard. GC-MS analysis was carried out with Finigan MAT model 3620 instrument.

Strauss coupling of phenylacetylene

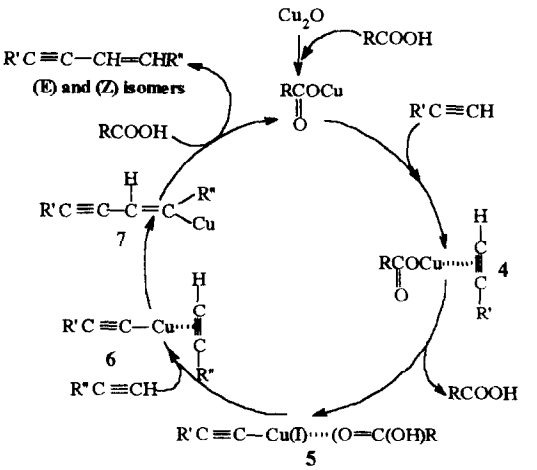
Cu_2O (0.52 g, 0.0036 mol) was added to glacial acetic acid (100 cm^3) boiling under nitrogen. To this Ph—C≡C—H (5 cm^3, 0.045 mol) was added. After 1 h the colour of the solution became green. The solution was cooled, then extracted with ether. The ether phase was neutralized by concentrated $NaHCO_3$ solution. Then washed with H_2O. The organic layer was dried over $MgSO_4$ and ether was evaporated. The crude product was dissolved in benzene and analysed by GC.

The same procedure has been used in other coupling reactions, where different 1-alkynes, catalysts and solvents have been used, respectively.

Isolation of trialkylphosphine copper(I) acetylide complex

Copper(I) acetylide (1.5 g, 0.01 mol) was added to glacial acetic acid (120 cm^3) boiling under nitrogen. When the salt dissolved, the colour of the solution became orange–red. To this triphenylphosphine (25 g, 0.01 mol) was added. The colour of the solution disappeared. The clear solution was heated at 114°C for 1 h and glacial acetic acid was removed *in vacuo*. The crude product crystallized from alcohol and petroleum ether mixture. The IR spectrum of the product was the same as that of Ph—C≡C—Cu(PPh_3) given in the literature.[20] IR (cm^{-1}): ν(C≡C) 2043, ν(monosubstituted benzene) 680, 750, 1580, 1470, 1430. The same procedure was used for isolation of the tri-n-butylphosphine copper(I) phenylacetylide complex. IR (cm^{-1}): ν(C≡C) 2020, ν(C—H aromatic) 2950, 2890.

The quenching experiment



Cu_2O (0.52 g, 0.0036 mol) was added to glacial acetic acid (100 cm^3) boiling under nitrogen atmosphere. To this Ph—C≡C—H (5 cm^3, 0.45 mol) was added. As soon as the colour of the mixture turned orange–red, the reaction was stopped. The mixture was cooled to room temperature. The quantitative analyses of copper was made on the sample of crude product. The sample (0.3 g) was heated with dilute HNO_3 (15 cm^3). The solution was heated vigorously. The yellow solution was extracted with ether and H_2SO_4 was added to the aqueous layer. The solution was evaporated to 5 cm^3 and reheated to evaporate HNO_3. To the resulting solution Na_2CO_3 was added at room temperature and its pH adjusted to 4. Then KI (10 g) was added to the solution, which was kept in the dark for 10 min and then titrated with 0.1 N $Na_2S_2O_3$. Starch solution was used as an indicator. The sample contained 38.6% copper.

The cross-Strauss coupling of mesitylacetylene and phenylacetylene

Glacial acetic acid (5 cm^3) was boiled under nitrogen for 30 min. To this *trans*-stilbene (0.1 g used as internal standard), Cu_2O (10.4 mg, 7.8×10^{-5} mol) and mesitylacetylene (0.14 cm^3, 9.7×10^{-4} mol) were added. A yellow suspension formed. The colour of the suspension became more yellow after the gradual addition of Ph—C≡C—H (0.1 cm^3, 9.8×10^{-4} mol). The mixture was heated under reflux for 3 h, H_2O (20 cm^3) was added and the mixture was filtered. The filtrate was then extracted with ether. The ether extracts were neutralized with Na_2CO_3, then washed with H_2O. The ether phase was dried over $MgSO_4$, filtered and concentrated to 5 cm^3. The crude products were characterized by comparison of the GC retention times of the authentic samples and by means of GC-MS analysis.

CONCLUSION

The Strauss reaction is unique for the head-to-head coupling of terminal acetylenes. Although it has been known for more than 90 years, and a version of which has found industrial application, there are still some questions about the mechanism of this reaction. In Scheme 2, a catalytic cycle of the dimerization is given depending on the experimental facts and on the foregoing discussions. In this scheme the active complex **5** has been shown as monocentric, for the sake of clarity. However, it is most likely for this expected intermediate to have a dinuclear structure. Further experimental and theoretical information is needed to clarify the dependency of the product composition and to explain the failure of the catalytic conversion under certain conditions.

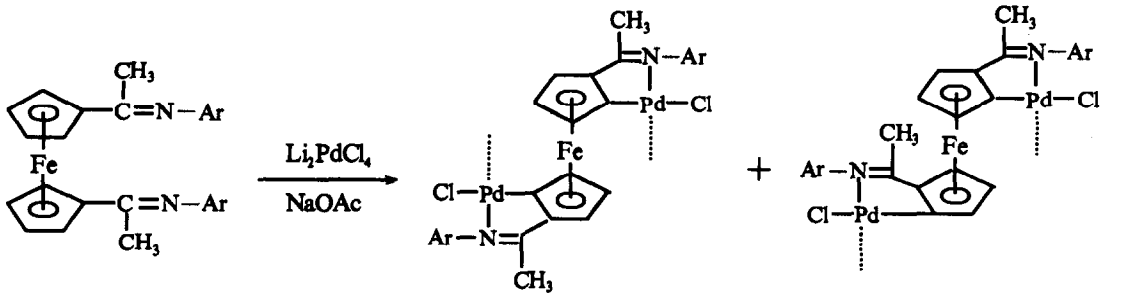
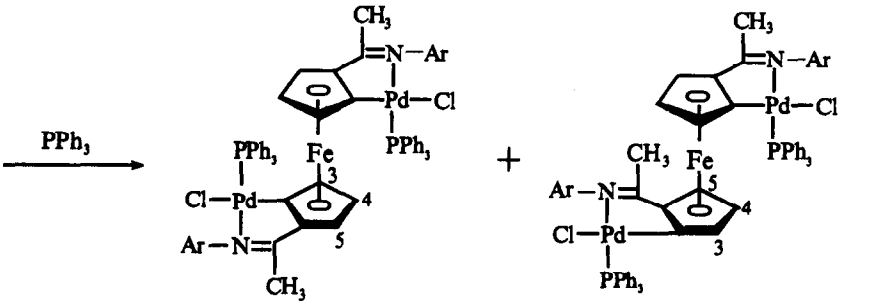
(Received 18 January 1996; accepted 7 February 1996)



Abstract—Double cyclopalladation of 1,1′-bis[(arylimino)ethyl]ferrocenes with Li_2PdCl_4 followed by treatment with PPh_3 afforded *meso* and *dl* stereoisomers of bis(palladium) complexes and the individual stereoisomers were isolated successfully by column chromatography. The composition and the structure of the metallocycles were characterized by elemental analysis, IR and ^1H NMR spectroscopy. A mechanism for the formation of stereoisomers in the cyclopalladation reaction was suggested. Copyright © 1996 Elsevier Science Ltd

The chemistry of cyclometalated compounds, especially those containing N-donor ligands and palladium is one of the most advanced areas of modern organometallic chemistry. These cyclopalladated compounds have been successfully used in organic syntheses, catalysis, asymmetric synthesis, photochemistry, and as potential biologically active materials.[1] More recently, the cyclopalladation of some ferrocenylimines has been reported by López's and our laboratories. It was found that the reaction occurred predominantly at the *ortho* position of the substituted Cp ring to afford the corresponding cyclopalladated derivatives.[2,3] But double cyclopalladation of 1,1′-disubstituted ferrocene is scarce, only the double cyclopalladations of 1,1′-diacetylferrocene bis (acetylhydrazone)[4] and N,N,N′,N′-tetramethylferrocene-1,1′-dicarbothioamide[5] have been reported in the literature. In the present paper, we report our studies on the synthesis and characterization of the stereoisomers of bis[palladium(II)] complexes of 1,1′-bis[(arylimino)ethyl]ferrocenes.



RESULTS AND DISCUSSION

The novel bisferrocenylimines [(η^5—C_5H_4 CMe=NAr)$_2$Fe] designated as bis (FKM)] were synthesized by the reaction of bis-acetylferrocene with the corresponding amine in the presence of freshly activated Al_2O_3.[6] The cyclopalladation reaction was carried out with bis(FKM) **1** and two mole equivalents of Li_2PdCl_4 and anhydrous sodium acetate in CH_2Cl_2—MeOH mixed solvent at room temperature for about 20 h, then the solvent was evaporated *in vacuo* to give a brown–red solid which was tentatively assigned to be a polymeric or dimeric dipalladio derivative **2**. Given the high solubility of **2** in chloroform, dichloromethane etc., the formation of the dimeric form is highly possible. Owing to the inevitable contamination by the bis adducts of $PdCl_2$ with ligand **1** formed in the cyclopalladation reaction and the decomposition of the products during purification by column chromato-

Ar = *p*-$CH_3OC_6H_4$ (**a**), *p*-$CH_3C_6H_4$ (**b**), C_6H_5 (**c**), *p*-ClC_6H_4 (**d**), *p*-BrC_6H_4 (**e**), *p*-$NO_2C_6H_4$ (**f**), *m*-$CH_3C_6H_4$ (**g**), *m*-ClC_6H_4 (**h**), *m*-BrC_6H_4 (**i**).

graphy on silica gel, a pure sample of **2** was not isolated. The brown–red solid was directly subjected to bridge-splitting reaction with ligand triphenylphosphine to produce the *meso* and *dl* monomeric stereoisomers (the total yields of *meso* and *dl* isomers are 15–46%), which is a typical reaction of a chlorine-bridged binuclear complex of palladium.[7] What is most interesting is that the *meso* and *dl* isomers can be separated successfully by silica gel column chromatography except for **3a** and **3b**, which provided the key to an interpretation of the spectra. The homoannular ring formed by chelation of a ferrocenylimine ligand to Pd^{II} also displays stereoisomerism arising from planar chirality. All the new compounds **3** are air stable powders, and very soluble in chloroform, dichloromethane, and slightly soluble in methanol. The yields, analytical data and IR data of the compounds are shown in Table 1, and the ^1H NMR data in Table 2. The compounds **3** melt at high temperature (>200°C) and with decomposition.

The IR spectral features of *meso* and *dl* isomers are very similar to each other. No absorption bands can be found at 1000 cm $^{-1}$ and 1100 cm^{-1}, which indicated the substitution of two cyclopentadienyl rings.[8] The C=N absorptions (~1570 cm^{-1}) in **3** are shifted to lower energy by ~50 cm^{-1} in comparison with those of the corresponding bis(FKM), indicating the coordination of nitrogen to palladium through its lone pair of electrons.[9] The strong absorption at about 745 cm^{-1} and 690 cm^{-1} observed in **3**, being the feature of monosubstituted phenyl ring, are assigned to the δ(CH) of PPh_3.

The assignments of the signals of the Cp ring protons in ^1H NMR spectra of two isomers are similar to the mono (palladium) complex $[PdCl\{(\eta^5\text{—}C_5H_5)Fe(\eta^5\text{—}C_5H_3CMe{=}NAr)\}(PPh_3)]$. The chemical shifts are different between the isomers because the Cp ring protons are in different magnetic environments. The pair of the proton signals for Cp rings and C-methyl group for the individual stereoisomers, *meso*-3c and *dl*-3c, occur at 3.09, 4.15, 4.16, 1.62 and 2.84, 3.98, 4.23, 2.10 ppm, respectively, compared with 3.37, 4.11, 4.45, 2.06 ppm for the mono (palladium) analogue. It seems impossible that the cyclopentadiene rings of the ferrocene moiety in the two isomers could adopt the eclipsed configuration, because of the significant steric interactions between the cyclopentadienyl substituents, although it is recognized[10] that the balance between intramolecular ring interactions and intermolecular packing forces usually

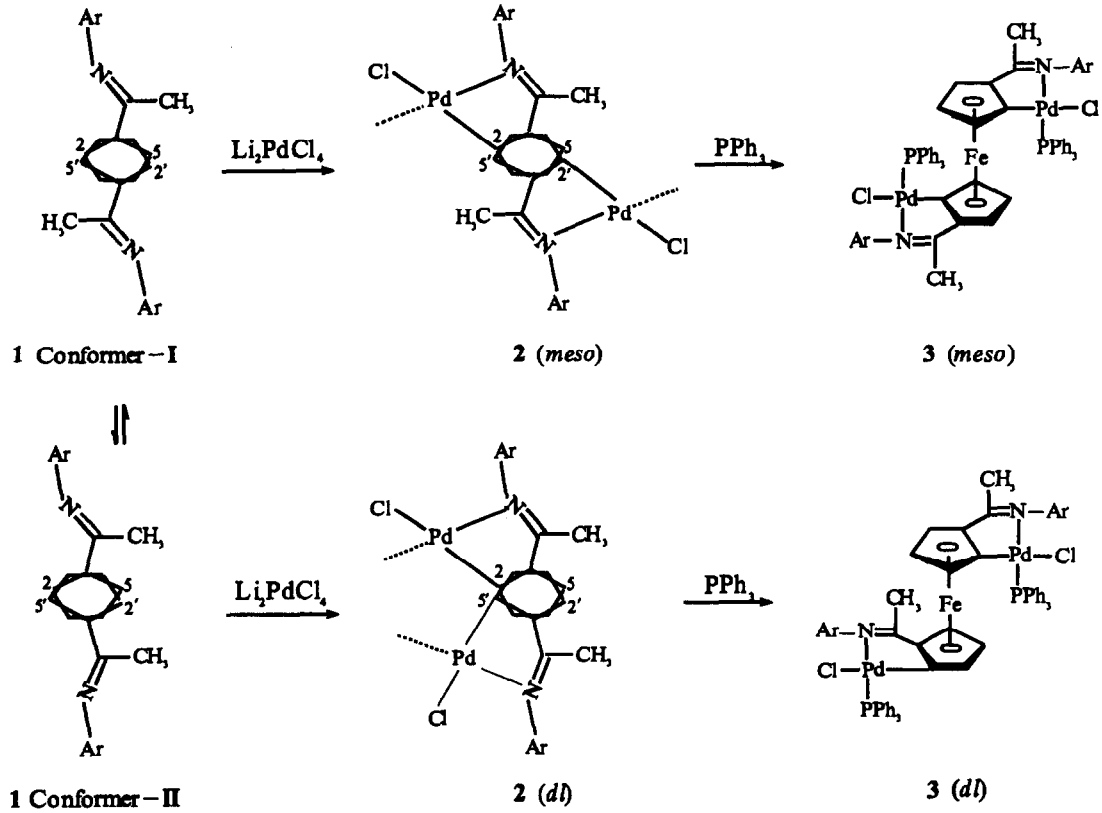
[a] Chemical shifts in ppm, TMS as the internal standard.

results in a preference for an eclipsed conformation of the cyclopentadiene rings. In the *dl* configuration, protons 3-H can be shielded by two PPh_3 groups, whereas in the *meso* configuration protons 3-H are shielded only by one PPh_3 group. According to ^{1}H NMR study of the mono(palladium) complex one can conclude that the shielding effect of the PPh_3 group is very large. For example, in comparison with the di-μ-chloro-bridged cyclopalladated complex [{Pd[(η^5—C_5H_5)Fe(η^5—C_5H_3CMe = NAr)] (μ—Cl)}$_2$] (Ar = *p*—$C_6H_{13}OC_6H_4$, *p*—$C_{12}H_{25}OC_6H_4$ and *p*—$C_{16}H_{33}OC_6H_4$), the resonance of the substituted Cp protons 3-H, 4-H, 5-H and unsubstituted Cp ring protons in their corresponding monomeric cyclopalladated triphenylphosphine derivatives shifts to upfield significantly by *ca* 0.48, 0.16, 0.20, 0.47 ppm, respectively.[11] So in the present cases, the signals of protons 3-H in *dl* form should appear at upfield by comparison with those in *meso* form. Thus we suggest that in each separation, the band possessing the highest R_f value contains the *meso* form and the second band contains *dl* form. In general, the chemical

shifts of protons in Cp ring show no dependence on substituents in the N—phenyl ring, this may be due to the nonplanarity between the ferrocenyl ring and the N—phenyl ring, which can influence the transmission of the electronic effects of the substituents in the phenyl ring through the C=N bond to the ferrocenyl moiety.

A proposed explanation for the formation of stereoisomers in cyclopalladation reactions of a bis(palladium) complex is shown in Scheme 1. The bis(FKM) may exist in the forms of conformer-I and conformer-II; double cyclopalladation of I and II affords the corresponding *dl* and *meso* isomers, respectively, which in *meso* product, the sites of electrophilic attack are at 2- and 2′-positions whereas attack on the 2- and diametrically opposite side 5′-position leads to the *dl* form. After the two chelate rings are formed, interconversion of the stereoisomers is not possible without breaking the σPd—C bond of one chelate ring.

EXPERIMENTAL



Materials and instruments

^{1}H NMR spectra were recorded on a Bruker AM 400 spectrometer, using $CDCl_3$ as the solvent and tetramethylsilane as an internal standard. IR spectra were recorded on a Perkin-Elmer FTIR 1750 spectrophotometer. Elemental analyses were determined with a Carlo Erba 1106 elemental analyser. Chromatographic work was carried out using silica gel under reduced pressure.

A lithium tetrachloropalladate(II) solution in methanol (0.1 M) was prepared by stirring two equivalents of anhydrous lithium chloride and one equivalent of anhydrous palladium chloride in methanol until a homogeneous solution was formed. The novel bisferrocenylimines were synthesized by the reaction of bis-acetyl-ferrocene with the corresponding amine in the presence of freshly activated Al_2O_3.[6]

General procedure for the double cyclopalladation of **1**

A solution of lithium tetrachloropalladate(II) in 5 cm^3 of methanol (0.13 g of Li_2PdCl_4, 0.5 mmol) was added to a solution of bisferrocenylimines (0.25 mmol) and anhydrous sodium acetate (41 mg, 0.5 mmol) in 16 cm^3 of dichloromethane/methanol (8 : 1, v/v). The mixture was stirred at room temperature for about 20 h, then the solvent evaporated *in vacuo* until a brown–red solid formed. The crude brown–red product was washed several times with

Scheme 1.

a small amount of methanol, then without further purification, it was treated with PPh_3 (0.13 g, 0.5 mmol) in CH_2Cl_2 at room temperature for 0.5 h. The product was separated by passing through a short silica gel column with CH_2Cl_2 as eluent, which the first band (the highest R_f value) contained the *meso* form and the second band contained the *dl* form. After the evaporation of the solvent, the residue was recrystallized from dichloromethane–petroleum ether (60–90°C) to give *meso*-**3** and *dl*-**3** with the yields shown in Table 1.

Iridium complexes with secondary phosphines: synthesis and X-ray crystal structure of $[IrCl(Bu^t_2PH)_3]$

H.-C. Böttcher,* Marion Graf and Kurt Merzweiler

Department of Chemistry, Martin Luther University, Halle-Wittenberg, Kurt-Mothes-Str. 2, D-06120 Halle/Saale, Germany

(Received 24 May 1996; accepted 13 June 1996)

Abstract—The reaction of $[\{IrCl(COE)_2\}_2]$ (**1**) (COE = cyclooctene) with Bu^t_2PH in hexane at room temperature gave the complex $[IrCl(Bu^t_2PH)_3]$ (**2**) which has been fully characterized by both spectroscopic and crystallographic methods. **1** reacts with carbon monoxide to give the Vaska-type complex *trans*-$[IrCl(CO)(Bu^t_2PH)_2]$ (**3**). Copyright © 1996 Elsevier Science Ltd

Keywords: iridium; complex; mononuclear; secondary phosphines; crystal structure.

Recently we reported the synthesis and X-ray crystal structures of the new phosphido-bridged heterobimetallic complexes $[FeIr(CO)_5(\mu\text{-}PBu^t_2)(Bu^t_2PH)]$ and $[CoIr(CO)_5(\mu\text{-}H)(\mu\text{-}PBu^t_2)(Bu^t_2PH)]$ by reaction of $[IrCl(Bu^t_2PH)_3]$ (**2**) with $[Fe(CO)_5]$ and $K[Co(CO)_4]$/$AgPF_6$, respectively [1]. In view of **2** we have to remark that the number of reports on the synthesis of low-valent mononuclear complexes containing late transition metals with secondary phosphines as ligands is notably low [2]. The analogous complex to **2**, namely $[RhCl(Bu^t_2PH)_3]$, was described by Masters and Shaw [3]. Concerning the chemistry of $[\{RhCl(Bu^t_2PH)_2\}_2]$ [4] we were interested in the synthesis of the corresponding iridium analogue. As starting material we used $[\{IrCl(COE)_2\}_2]$ (**1**) [5], which was often applied in syntheses of iridium–chloro complexes containing phosphines, for instance $[IrCl(PPr^i_3)_2]$ [6–8], and also other authors used the latter species prepared *in situ* in the same way [9,10]. Furthermore, reactions of **1** with some secondary phosphines (in excess) in alcoholic medium in the presence of perchlorate or tetraphenylborate were described, yielding four-coordinate complexes $[Ir(R_2PH)_4]^+$ [11]. Bennett and Latten reported the synthesis of $[IrCl(PPh_3)_3]$ by reaction of **1** with an excess of the phosphine in petroleum ether [12]. In accordance with these observations we found that reaction of **1** with Bu^t_2PH in hexane at room temperature during 2 h (even under various molar ratios) yielded exclusively the complex $[IrCl(Bu^t_2PH)_3]$ (**2**) isolated in *ca* 95%.† At present we have no evidence for species with the formula $[IrCl(COE)L_2]$ (L = PPr^i_3, [7]; L = PF_3, [13]) or $[IrCl(COE)L_3]$ (L = PMe_3, [14]). In the ^1H NMR spectrum (C_6D_6) of **2** the presence of three chemically inequivalent phosphine ligands in the molecule is

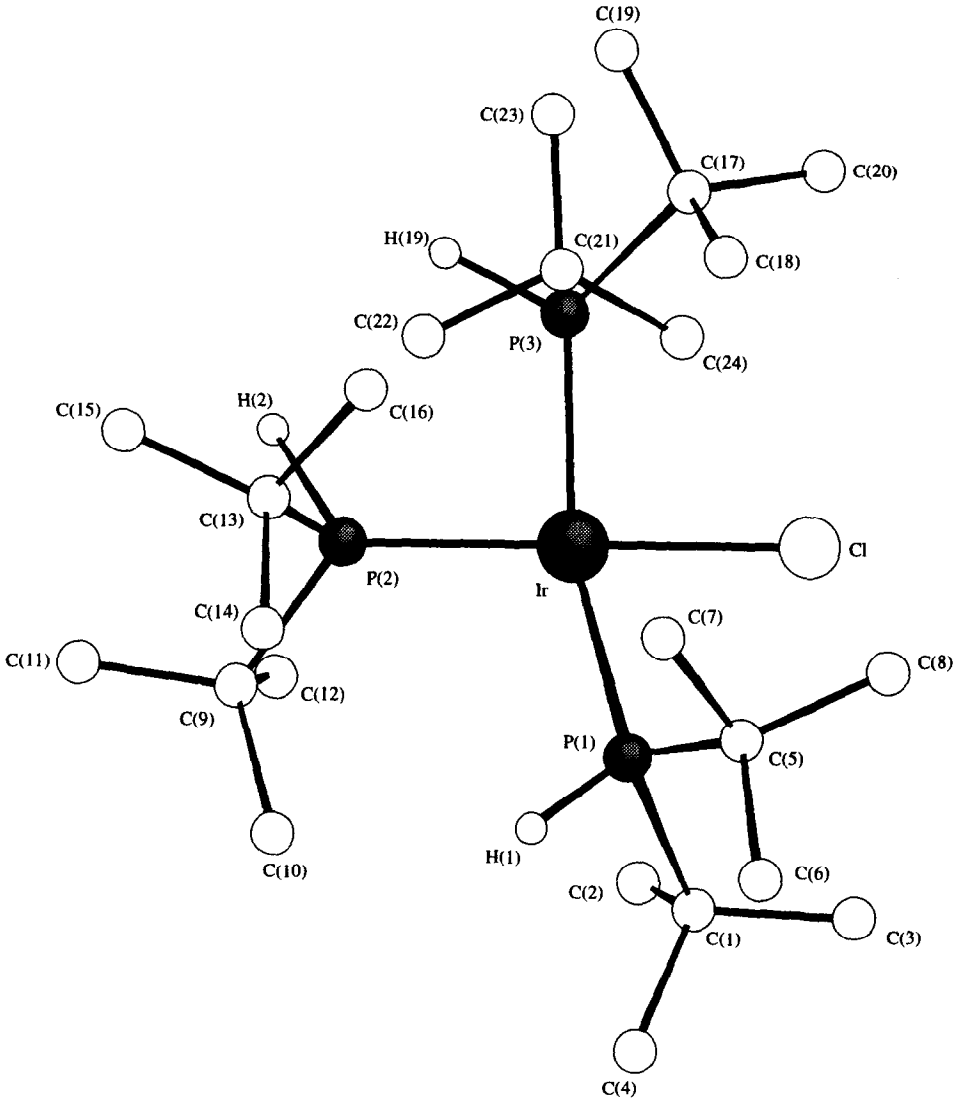

Fig. 1. Molecular structure of $[IrCl(Bu^t_2PH)_3]$ (**2**). Selected bond lengths (Å) and angles (°): Ir—Cl 2.396(1), Ir—P(1) 2.319(1), Ir—P(2) 2.231(1), Ir—P(3) 2.299(1), P(1)—C(1) 1.918(5), P(2)—C(9), 1.897(5), P(3)—C(21) 1.888(5); P(1)—Ir—Cl 84.9(1), P(1)—Ir—P(2) 100.0(1), P(2)—Ir—Cl 169.9(1), P(2)—Ir—P(3) 90.0(1), P(3)—Ir—Cl 87.1(1), P(3)—Ir—P(1) 164.7(1).

clearly indicated. This fact is also confirmed by the $^{31}P\{^1H\}$NMR data, an AMX spin system is observed with a large *trans* coupling (J_{PP} = 339.5 Hz) and the corresponding *cis* couplings of 19.5 and 19.6 Hz, respectively. As observed for similar constituted complexes this effect could be assigned to slowing rotation about the P—Ir and P—(*t*-Bu) bonds [15]. In contrast to **2** for $[IrCl(PPh_3)_3]$ in the $^{31}P\{^1H\}$NMR spectrum an A_2B (almost A_2X) pattern was observed [12].

Complex **2** has been structurally characterized by single crystal X-ray crystallography.* The molecular structure is shown in Fig. 1. The angle P(3)—Ir—P(1) is 164.7(1)° and the P(2)—Ir—Cl angle is 169.9(1)°, therefore the coordination geometry around the iridium atom can be described as a distorted square-planar arrangement. This configuration is forced on the molecule by the bulk of the phosphine ligands. The Ir—Cl distance was found to be 2.396(1) Å and is slightly longer than expected probably also by reason of the sterical hindrance of the bulky ligands. The iridium–phosphorus bond lengths Ir—P(1) with 2.319(1) and Ir—P(3) 2.299(1) Å lie in the usual range observed for phosphines in *trans* position to each other. The ligand P(2) is situated in *trans* position to the chloride ligand and the Ir—P(2) distance is with 2.231(1) Å in the average by 0.08 Å shorter than Ir—P(1) and Ir—P(3). Such an effect was also observed in the molecule $[Ir(C_6F_5)(PEt_3)_2(PEt_2F)]$, for instance [16]. In this case the two Ir—P distances in *trans* position to each other are longer than the third Ir—P bond (av. 0.1 Å).

*Crystal data for $C_{24}H_{57}ClIrP_3$, **2**: M = 666.26, monoclinic, space group $P2_1/n$, a = 8.738(1), b = 20.813(4), c = 16.961(1) Å, α = 90.00, β = 96.49(1), γ = 90.00°, V = 3064.9(7) Å^3, Z = 4, D_c = 1.444 mg m^{-3}, Mo-K_α radiation, λ = 0.71073 Å, μ(Mo-K_α) = 4.610 mm^{-1}, F(000) = 1360, T = 220 K, orange plate. The crystal used for data collection had the dimensions 0.2 × 0.2 × 0.1 mm. 5603 intensity data were collected on a Stoe STADI-4 diffractometer using graphite monochromated Mo-K_α radiation (range $1.55 \leqslant \theta$ 25.01°; $-10 \leqslant h \leqslant 10$, $0 \leqslant k \leqslant 24$, $-14 \leqslant l \leqslant 20$), 5402 independent reflections (R_{int} = 0.0607). The structure was solved by direct methods using SHELXS-86 and refined by full-matrix least-squares on F^2 (all non-hydrogen atoms anisotropic) using SHELXL-93 [17]. Final R_1 = 0.0287, [$I > 2\sigma(I)$], wR_2 = 0.0695 (all data). Full details of the structure determination have been deposited at the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-76344 Eggenstein-Leopoldshafen, Germany, from where this material may be ordered on quoting the full literature citation and the reference number CSD 5933.

The reactivity of compound **2** towards small molecules such as carbon monoxide and ethylene was investigated. **2** was quickly transformed in hexane under a slow stream of carbon monoxide into the Vaska-type complex *trans*-$[IrCl(CO)(Bu^t_2PH)_2]$ (**3**) in nearly quantitative yield. **3** was characterized by the known spectroscopic data [15]. With ethylene (hexane, 4 h) no reaction was observed, and therefore these results resemble the corresponding reactions of $[IrCl(PPh_3)_3]$ [12].

Synthesis and X-ray crystal structure of $[Li(C_4H_8O)_4][Yb(NPh_2)_4]$

Wai-Kwok Wong,[a]* Lilu Zhang,[a] Feng Xue[b] and Thomas C. W. Mak[b]

[a]Department of Chemistry, Hong Kong Baptist University, 224 Waterloo Road, Kowloon, Hong Kong

[b]Department of Chemistry, The Chinese University of Hong Kong, Shatin, N.T., Hong Kong

(Received 25 April 1996; accepted 5 June 1996)

Abstract—The interaction of $Yb(NPh_2)_2Cl$ with one equivalent of $Li[(CH_2)(CH_2)PPh_2]$ in tetrahydrofuran gave the unexpected dark red complex $[Li(C_4H_8O)_4][Yb(NPh_2)_4]$ (**1**) in 30% yield. An X-ray diffraction study reveals that the lanthanide–amide *ate* complex is composed of a discrete cation $[Li(C_4H_8O)_4]^+$ and a discrete homoleptic tetrahedral Yb-amide anion $[Yb(NPh_2)_4]^-$. Copyright © 1996 Elsevier Science Ltd

Keywords: ytterbium(III); structure; discrete homoleptic amide anion; diphenylamide; homoleptic amide complex; lanthanide–amide *ate* complex.

Lanthanide amide complexes are excellent synthetic precursors for lanthanide-alkoxides [1], phosphides [2] and thiolates [3] which can be prepared *via* protonolysis of the lanthanide–amide bond with alcohols, phosphines and thiols, respectively. Homoleptic three-coordinate lanthanide amide complexes had been known for some time [4], however, it was not until recently that homoleptic tetra-coordinate lanthanide amide *ate* complexes had been reported [5,6]. There are relatively few structural characterization studies on lanthanide–amide *ate* complexes [6,7], particularly those containing a discrete homoleptic tetra-coordinate lanthanide–amide *ate* anion. In this communication, we report the X-ray crystal structure of a Yb-amide complex with a discrete homoleptic tetra-coordinate Yb-amide *ate* moiety.

The interaction of $Yb(NPh_2)_2Cl$ with one equivalent of $Li[(CH_2)(CH_2)PPh_2]$ in tetrahydrofuran for 16 h, work up gave the unexpected dark red crystals of stoichiometry $[Li(C_4H_8O)_4][Yb(NPh_2)_4]$† (**1**) in 30% yield after recrystallization from a toluene solution. The structure of **1** was established by an X-ray diffraction study.‡ A perspective drawing of **1** is shown in Fig. 1; and selected bond lengths and bond angles are given in the caption.

The crystal structure analysis revealed that **1** is composed of a discrete cation and a discrete anion. In

Selected bond lengths (Å) and bond angles (°): Yb(1)—N(1), 2.201(9); Yb(1)—N(2), 2.216(9); Yb(1)—N(3), 2.188(9); Yb(1)—N(4), 2.241(9); N(1)—C(1), 1.398(12); N(1)—C(7), 1.391(12); N(2)—C(13), 1.388(12); N(2)—C(19), 1.417(12); N(3)—C(25), 1.395(12); N(3)—C(31), 1.388(12); N(4)—C(37), 1.382(13); N(4)—C(43), 1.412(13); Li(1)—O(1), 1.90(2); Li(1)—O(2), 1.88(2); Li(1)—O(3), 1.90(2); Li(1)—O(4), 1.91(2); N(1)—Yb(1)—N(2), 112.8(3); N(1)—Yb(1)—N(3), 106.7(4); N(1)—Yb(1)—N(4), 110.9(4); N(2)—Yb(1)—N(3), 111.7(3); N(2)—Yb(1)—N(4), 104.0(4); N(3)—Yb(1)—N(4), 110.8(3); C(1)—N(1)—C(7), 116.0(9); C(13)—N(2)—C(19), 115.0(9); C(25)—N(3)—C(31), 118.2(9); C(37)—N(4)—C(43), 119.9(9).

$[Li(C_4H_8O)_4]^+$, the Li atom adopts a tetrahedral geometry with four molecules of tetrahydrofuran coordinated to the Li atom *via* the oxygen atoms. The Li—O distances and the O—Li—O angles are normal and lie in the range 1.88 (2)–1.91 (2) Å and 108.1 (10)–111.3 (11)°, respectively. The anion $[Yb(NPh_2)_4]^-$ can be described as a distorted tetrahedron with the Yb atom coordinated by four terminal NPh_2 groups. The Yb—N distances ranging from 2.188 (9)–2.241 (9) Å are longer than the terminal Yb—N(silylamide) bonds of the three-coordinate $Yb[N(SiMe_3)_2]_3$ complex [2.158(13) Å] [8] and shorter than the terminal Yb—N(silylamide) bond of the five-coordinate $Yb[OC(CMe_3)(2\text{-}CH_2NC_5H_3Me\text{-}6)_2]_2[N(SiMe_3)_2]$ complex [2.260 (5) Å] [9]. The N—Yb—N angles ranging from 104.0(4)–112.8 (3)° are typical of a slightly distorted tetrahedron. The N atoms of the amide groups adopt a planar geometry with C—N—C angles ranging from 115.0(9)–119.9(9)° and can be considered as sp^2 hybridized. Lanthanide *ate* complexes with homoleptic NR_2 groups have been structurally characterized recently [6,7]. However, in all of them the cation and the anion moieties of the complexes are linked together *via* two bridging amide groups. Notably **1** is the first structurally characterized lanthanide amide *ate* complex to comprise a discrete cation and a discrete homoleptic tetra-coordinate lanthanide–amide anion.

2θ angles for 25 selected strong reflections. Crystal stability was monitored by recording three check reflections at intervals of 150 data measurements, and no significant variation was detected. An empirical absorption correction based on Ψ-scans was applied, resulting in relative transmission factors ranging from 0.880 to 1.035 [10]. A total of 5416 unique reflections ($4° \leqslant 2\theta \leqslant 50°$) were measured and 3224 reflections have $I \geqslant 2\sigma(I)$. The structure was solved by the direct method using SHELXTL-PLUS [11] and refined against F^2 using SHELXL-93 [12]. Non-hydrogen atoms were refined anistropically by full-matrix least-squares. Hydrogen atoms were placed in their calculated positions (C—H bond fixed at 0.96 Å) and allowed to ride on their respective parent carbon atoms. Analytical expressions of neutral-atom scattering factors were employed, and anomalous dispersion corrections were incorporated [13]. The final *R*, *Rw* values were 0.048, 0.112.

(Received 30 April 1996; accepted 27 June 1996)

Abstract—The monosolvate (MeCN) of niobium(V) chloride has been structurally characterized. The metal is six coordinate with a somewhat distorted octahedral geometry in which the four equatorial chlorine atoms are coplanar but are clearly bent towards the bound axial acetonitrile ligand, mean N_{ax}—Nb—Cl_{eq} 83.62(12)°. The Nb—Cl bond distances lie in the range 2.249(2)–2.319(2) Å and the metal to ligand distance, Nb—N, is 2.236(4) Å. Copyright © 1996 Elsevier Science Ltd

Keywords: structure; niobium(V); acetonitrile; adduct; octahedral.

Niobium(V) and tantalum(V) chlorides, which enjoy a common dimeric halogen-bridged structure [1], are conveniently soluble in Lewis donor solvents such as alkyl cyanides [2], ethers and thioethers [3] to give mononuclear adducts that can be used as suitable precursors for a wide range of metal(V) complexes *via* ligand exchange reactions. However, with nitrogen donor ligands such as pyridine, trimethylamine, γ-picoline, bipyridyl and 1,10-phenanthroline there is an attendant problem, *viz.*, reduction to the +4 oxidation state is commonplace [4].

In this paper we report the salient structural features of the acetonitrile solvate $NbCl_5(MeCN)$ following room temperature X-ray diffraction studies.

EXPERIMENTAL

All manipulations were carried out under argon using standard Schlenk vacuum-line techniques. Acetonitrile was purified following the recommended procedure [5], stored over P_4O_{10} and distilled under argon prior to use. $NbCl_5$ was used as supplied commercially (Aldrich).

Preparation of $NbCl_5(MeCN)$

$NbCl_5$ (6.0 g, 22.2 mmol) was placed in a dried thimble and extracted (Soxhlet) with acetonitrile (100 cm^3) over a period of 4 h. On cooling the resulting yellow solution (0°C) a large crop of yellow, barrel-shaped crystals separated out. These were collected, washed with n-hexane (2 × 20 cm^3) and pumped to dryness *in vacuo* at room temperature. (Yield 5.2 g, 16.8 mmol). Found: C, 7.7; H, 0.9; N, 4.5; Nb, 29.7; Cl, 56.8. Calc. for $C_2H_3NNbCl_5$: C, 7.7; H, 1.0; N, 4.5; Nb, 29.8; Cl, 57.0%.

X-ray crystallography

Crystal data are given in Table 1, together with refinement details. Data were collected with Mo-K_α radiation using the MARresearch Image Plate System. The crystal was positioned at 75 mm from the image plate. A total of 95 frames were measured at 2° intervals with a counting time of 2 min. Data analysis was carried out with the XDS program [6]. The structure was solved by heavy atom methods. The non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms were included in geometric positions and given thermal parameters equivalent to 1.2 times the carbon atom to which they were attached. The structure was refined using SHELXL [7]. All calculations were carried out on a Silicon Graphics R4000 workstation at the University of Reading. A complete listing of bond distances and angles is given in Table 2. Supplementary material including atomic coordinates, tables of thermal par-

RESULTS AND DISCUSSION

$NbCl_5(MeCN)$ was obtained as yellow, barrel-shaped crystals from direct Soxhlet extraction of niobium(V) chloride with acetonitrile. The product shows rapid hydrolysis/decomposition on the slightest exposure to the atmosphere but individual crystals can be easily manipulated into Lindemann tubes under argon.

The crystal and molecular structure of this mono-solvate $NbCl_5(MeCN)$ shows a six-coordinate, essentially octahedral, metal geometry with acetonitrile acting as a conventional σ-donor ligand. See Fig. 1 for the atom numbering scheme.

For $NbCl_5(MeCN)$ the observed metal–chlorine bond distances lie in the range 2.249(2)–2.319(2) Å with a mean value of 2.293 Å. Terminal Nb—Cl bond lengths that can be cited for comparison include: the parent halide $(NbCl_5)_2$ 2.25 Å [1]; $CpNbCl_4(PMePh_2)$ 2.4127(8), 2.3965(8), 2.4168(8), 2.4315(9) Å [8]; $Cp^*NbCl_4(CN\text{-}2,6\text{-}Me_2C_6H_3)$ 2.396(3)–2.435(3) Å [9]; $[Cp_2NbCl_2][SbF_6]$ mean 2.341 Å [10]; $[Cp_2Nb(CH_2SiMe_3)Cl][PF_6]$ 2.362(3) Å [11]; $[Cp_2NbCl_2][BF_4]\cdot CH_3CN$ 2.343(1) Å [12]; $[NbCl_4(O)(THF)]^-$ 2.378(4), 2.387(4), 2.376(4) Å [13]; Cp_2NbCl_2 2.464(5), 2.475(4) Å [14]; $CpNbCl_3(dppe)\cdot C_6H_5CH_3$ 2.479(3), 2.460(5), 2.473(6) Å [15]; *cis*-$NbCl_4(MeCN)_2$ 2.328(7), 2.343(6), 2.349(4) Å [16]; *trans*-$NbCl_4L_2$, where

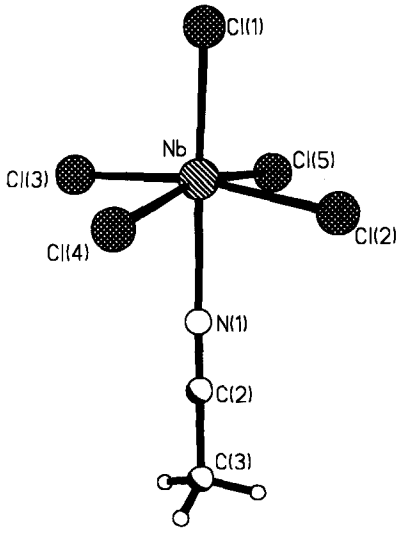

Fig. 1. The molecular structure of $NbCl_5(MeCN)$ including the atomic numbering.

L = PEt_3 2.357(3), 2.374(4) Å and L = PPh_2Et 2.401(1), 2.333(1) Å [17]; $[CpNb(CNCMe_3)_4Cl]^+$ 2.505(4) Å [13]; $[Cp^*NbCl_2[CN\text{-}2,6\text{-}Me_2C_6H_3]_3]$ 2.575(2), 2.546(2) Å [9]. These values are in accord with a perceptible lengthening in Nb—Cl bond length as the metal oxidation state decreases from +5 to +4 to +3, as might be anticipated; no such variation with metal oxidation state is observed for the Nb—N linkage, i.e. $NbCl_5(MeCN)$ (this study) 2.236(4) Å and *cis*-$NbCl_4(MeCN)_2$ 2.220(13) Å [16]. The binding of the acetonitrile (solvent) molecule is linear Nb—N—C 178.4(5), N—C—C 179.5(6)°. The arrangement of the five chlorine atoms around the central metal is slightly distorted from the ideal octahedral geometry. The four equatorial chlorine atoms are coplanar within experimental error, but are clearly bent back towards the coordinated acetonitrile molecule and away from the remaining axial chlorine atom. The metal is displaced from this plane by 0.22 Å and the resulting N_{ax}—Nb—Cl_{eq} angles lie in the range 81.94(13)–85.30(12)° mean 83.62(12)°. These deviations most probably originate from intramolecular steric/packing requirements rather than any intermolecular forces, and are seen to reflect the larger steric bulk of Cl_{ax} versus N_{ax}, especially since this axial chlorine has the shortest of the metal–chlorine bonds, at 2.249(2) Å.

Following the same approach we have isolated $TaCl_5(MeCN)$ as small white flakes. Found: C, 6.0; H, 0.7; N, 3.5; Ta, 45.2; Cl, 44.3. Calc. for C_2H_3N $TaCl_5$: C, 6.0; H, 0.8; N, 3.5; Ta, 45.3; Cl, 44.4%. The compound is isomorphous with its Nb^V counterpart as confirmed by X-ray diffraction studies. Cell data: monoclinic, space group $P2_1/c$, $a = 6.115(8)$, $b = 10.193(9)$, $c = 15.878(12)$ Å, $\beta = 97.08(1)°$. Data were collected and the structure proved to be similar to that of the Nb analogue but the determination was of insufficient quality to report here.

Acknowledgements—We thank the University of Warwick for a postgraduate studentship award (to T.J.W.). Financial support by the EPSRC and the University of Reading for the image plate system is gratefully acknowledged and we thank Mr A. W. Johans for technical assistance with the X-ray crystallographic studies.

The first X-ray crystallographic characterization of a dialkylaminomethylenephosphonic acid: synthesis of crystalline *N,N'*-diethylaminomethylenephosphonic acid, its protonation equilibria, and the stabilities of its complexes with lead(II)

Nick Choi, Maria Constantinou, David Hyatt, Ray W. Matthews,* Mary McPartlin and Ian J. Scowen

School of Applied Chemistry, University of North London, Holloway Road, London N7 8DB, U.K.

(Received 2 February 1996; accepted 27 June 1996)

Abstract—The X-ray crystal structure of *N,N'*-diethylaminomethlenephosphonic acid (LH_2) shows the molecule to be present as the N-protonated zwitterion. The unusually large P—C—N angle [120.1(3)°] is apparently owing to steric factors arising from the "eclipsed" conformation of the ethyl methylene carbon atoms and phosphonate oxygen atoms. Potentiometric titration and determination of the pH dependence of δ^{31} (P) were used to elucidate the protonation equilibria for LH_2. Stoichiometric stability constants for complexes of LH_2 with lead(II) provide evidence that LH_2 is selective for lead(II) over most transition metal ions [$\log \beta_{PbLH}$(PbLH): 11.55±0.12(011); 16.92±0.15(012); 18.3±0.5(013); 7.45±0.18(110); 14.81±0.35(111); −0.49±0.33(01-1)]. Keywords: 1-aminophosphonic acid; *N,N'*-diethylaminomethylenephosphonic acid; protonation; stability constants; lead complexes; X-ray structure.

A large number of recent patent applications demonstrate the importance of 1-aminoalkylphosphonic acids in industry [1], and their potential in medical applications has been indicated [2]. Among the most widely used is diethylenetriamine-*N,N,N',N'',N''*-pentamethylenephosphonic acid; available under various trade names such as "DEQUEST" and "BRIQUEST", its detergent and metal ion-complexing abilities are utilized in textile and paper processing. The wide applicability of such compounds provides the stimulus for current interest in studies of their protonation equilibria and of their complicated complexing behaviour towards metal ions [3]. Such studies on the larger polymethylenephosphonates are, however, limited by the plethora of protonation and coordination sites [4]. Simpler aminomethylenephosphonic acids, e.g. *N,N'*-diethylaminomethylenephosphonic acid (LH_2), the subject of the present study, serve as models for understanding the behaviour of more complex systems. Work of this type is often limited by the difficulties experienced in isolating 1-aminoalkylphosphonic acids [5] from the Moedritzer–Irani reaction [6], the most commonly used method of preparation, a problem particularly manifest for aminomethylenephosphonic acids derived from secondary amines [6]. Previous investigations by Carter *et al.* [7] and Wozniak and Nowogrocki [8] of the protonation equilibria of LH_2 yielded pK_a values of $[LH]^-$ and $[LH_2]$ only. Stoichiometric stability constants for complexes of LH_2 with Mg^{II}, Ca^{II} [7] and Cu^{II} [8] were also determined. Protonation equilibria and the stabilities of complexes with a range of metal ions have been studied for a number of simple 1-aminomethylenephosphonic acids closely related to LH_2, e.g. $R_nN(CH_2PO_3H_2)_{3-n}$ (R = Me, [7,9] Et; [7,10] n = 0, 1 or 2), $R'HNCH_2PO_3H_2$ (R' = H [10,11], Me, Et [8]). For the series of 1-aminomethylenephosphonic acids

* Author to whom correspondence should be addressed.

$Et_nN(CH_2PO_3H_2)_{3-n}$ ($n = 0$, 1 or 2), X-ray crystal structure determinations have been reported only for the compounds with $n = 0$ [12] and 1 [13].

We have developed a method for obtaining LH_2 in pure form, allowing the first solid state characterization of a l-aminomethylenephosphonic acid derived from a secondary amine, and demonstrating that the molecule is present as the N-protonated zwitterion. A detailed study of its protonation equilibria has provided a value for the pK_a of $[LH_3]^+$ for the first time, together with those for LH_2 and $[LH]^-$. Stoichiometric stability constants for complexes with lead(II) over the pH range 4.6–8.7 show that the complex species formed at low pH is predominantly $[PbLH]^+$ and that this, with increasing pH, deprotonates to give PbL and, ultimately, $[PbL(OH)]^-$. There is evidence that the ligand is selective for lead (II) over most first row transition metals, indicating a potential use for ligands of this type in the removal of this toxic metal.

EXPERIMENTAL

Preparation of N,N′-*diethylaminomethylenephosphonic acid* (LH_2)

The compound LH_2 was prepared using a method developed from the general procedure described by Moedritzer and Irani [6] for the synthesis of l-aminomethylenephosphonic acids.

Aqueous diethylamine (70%, 23.3 g, 0.25 mol) was dissolved in a mixture of ice and water (250 cm^3) and treated with aqueous hydrochloric acid (6 mol dm^{-3}, 40 cm^3) in portions while stirring and cooling. Phosphorous acid (16.4 g, 0.20 mol) was added and the mixture was brought to reflux. Aqueous formaldehyde (40%, 22 cm^3, 0.30 mol) was added to the refluxing mixture over 60 min and refluxing was continued for a further 8 h. The reaction mixture was concentrated under reduced pressure and then treated with propylene oxide (*ca* 50% excess) at 40°C. Further concentration under reduced pressure yielded a pale yellow oil which was treated with an equal volume of ethanol/acetone (*ca* 3 : 1 v/v). After storage in a stoppered vessel for three months, the mixture yielded a white crystalline solid which was isolated by filtration, washed with cold ethanol and desiccated *in vacuo* over phosphorus pentoxide for 24 h. [Yield: 13.2 g (40%). M.p. 195–197°C). Found: C, 36.6; H, 8.7; N, 8.5. Calc. for $C_5H_{14}NO_3P$: C, 35.9; H, 8.4; N, 8.4%.]

Crystals suitable for X-ray diffraction studies were obtained from a mixture of LH_2 (0.30 g, 0.002 mol) and a solution of n-butylstannoic acid (0.40 g, 0.002 mol) in toluene (100 cm^3). The mixture was heated under reflux for 6 h using a Dean–Stark trap, and then left to stand overnight at room temperature before being filtered. Square crystals were isolated from the filtrate after storage in a stoppered container for four months. [Recovery: 0.27 g (87%). M.p. 210–212.1°C. Found: C, 35.8; H, 8.5; N, 8.3%]. IR (16 mm KBr disc): $\bar{\nu}_{max}/cm^{-1}$: *ca* 3420br, 2964m, 2935m, 2873m, 2758w, 2660w, 1636m, 1468m, 1124s br, 1005 s, 878w, 772w, 686w, 576m, 513s. ^1H NMR (D_2O): δ 3.37 (approx. quintet, CH_3CH_2), 3.28 [d, CH_2-P, $^2J(HP) = 13.0$ Hz], 1.31 [t, CH_3, $^3J(HH) = 7.3$ Hz]. ^{13}C NMR (D_2O): δ 52.39 [d, CH_3CH_2, $^3J(CP) = 4.4$ Hz], 51.44 [d, CH_2-P, $^1J(CP) = 136.8$ Hz], 11.15 (CH_3). ^{31}P NMR (D_2O): δ 8.45 [t, $^2J(PH) = 13.0$ Hz].

Crystal structure determination

Crystal data. $C_5H_{14}NO_3P$, $M = 167.15$, monoclinic, space group $P2_1/n$ (non-standard setting of No. 14), $a = 7.708(2)$, $b = 11.398(3)$, $c = 9.435(2)$ Å, $\beta = 105.3(2)°$, $U = 799.54$ Å^3, $Z = 4$, $F(000) = 360$, $D_c = 1.389$ g cm^{-3}, μ(Mo-K_α) = 2.9 cm^{-1}.

Data collection. X-ray intensity data were collected on a colourless translucent crystal of dimensions $0.20 \times 0.20 \times 0.15$ mm^3, using a Philips PW1100 four-circle diffractometer with Mo-K_α radiation ($\lambda = 0.71069$ Å) from a graphite monochromator, in the θ-range $3 \leqslant \theta \leqslant 25°$ and with a scan width of 0.90°, as described previously [14]. A total of 1582 reflections were scanned and equivalent reflections were merged to give 843 unique reflections with $I/\sigma(I) > 3$.

Structural solution and refinement [15]. The coordinates of the phosphorus and oxygen atoms were located by direct methods. The positions of the remaining non-hydrogen atoms were found from successive difference Fourier maps. A difference Fourier synthesis calculated using data with $\sin\theta < 0.35$ revealed the positions of the acidic protons, and all the carbon-bonded hydrogen atoms were included in idealized positions (C—H 1.08 Å) with their thermal parameters fixed at 0.08 Å^2. In the final cycles of full-matrix least-squares refinement all non-hydrogen atoms were assigned anisotropic thermal parameters and converged at $R = 0.0469$ and $R_w = 0.0486$ with weights of $1/\sigma^2(F)$ assigned to individual reflections. The final difference Fourier synthesis showed no residual maximum greater than 0.3 eÅ^{-3}.

Potentiometric measurements

Potentiometric titrations were carried out in aqueous solution, under an atmosphere of water-saturated, CO_2-free nitrogen, using a purpose-built automated titration apparatus [16]. All reagents used were of analytical grade (e.g. BDH AnalaR) or better (e.g. BDH ARISTAR); water was deionized by reverse osmosis (to BS3978 grade 1 specification) and degassed, as appropriate, by refluxing under nitrogen. Solution potential was measured using a glass electrode referenced to a large calomel electrode *via* a salt bridge. The titration environment was maintained at 25.0 ± 0.1°C by water circulating through jackets sur-

rounding both the titration cell and the calomel electrode. Data for each point in the titration were recorded when the averages of two successive sets of potential measurements (typically 60 in each set) were stable to within 0.05 mV. All titrations were carried out at constant ionic strength (0.1 mol dm^{-3}) provided by KNO_3 as the supporting electrolyte. Aqueous HNO_3/KNO_3 (0.004 mol dm^{-3} and 0.096 mol dm^{-3}, respectively; 25 cm^3) in the titration cell was titrated against carbonate-free aqueous KOH (0.1 mol dm^{-3}) to determine the cell calibration constants E_0 and pK_w. Similar titrations with (a) added LH_2 (*ca* 1×10^{-3} mol dm^{-3}) and (b) LH_2 (*ca* 1×10^{-3} mol dm^{-3}) and the appropriate metal nitrate salt ([M]:[L] *ca* 1:1, 1:2 or 1:3) gave data for determination of, respectively, pK_a values and stability constants for the metal complexes. Metal ion concentrations in stock solutions were determined by titration with aqueous EDTA solution [17].

Typically, 200 data points were collected for each titration in the pH range *ca* 2.5–11.0. Three titrations were performed for the free ligand, three for the ligand/Pb^{II} system, and at least two for each ligand/M^{II} system (M = Co, Ni, Cu, Zn and Cd). Using the program SUPERQUAD [18], variously 128–195 titration points were used in data analyses to obtain pK_a values and 29–36 points were used to determine log K values for the Pb^{II} complexes.

NMR spectra

The pH dependence of the ^{31}P NMR spectrum for LH_2 was determined by monitoring $\delta(^{31}P)$ during titration of a solution of LH_2 (*ca* 0.02 mol dm^{-3}) in an initially acid H_2O/D_2O medium at constant ionic strength ($[HNO_3] = 0.04$ mol dm^{-1}, $[KNO_3] = 0.96$ mol dm^{-3}, 10% D_2O v/v, $I = 1.0$ mol dm^{-3}) against aqueous KOH (1.0 mol dm^{-3}) in an NMR tube (o.d. 10 mm). All reagents were of purities that matched those used in the potentiometric measurements. Aliquots of base (normally 0.012 cm^3, but 0.006 cm^3 near 'end-point' regions) were delivered from a motorized piston burette (Metrohm Dosimat 655). After addition of each aliquot, the pH of the solution was determined in the NMR tube using a thin stem combination electrode (Russell) linked to a Corning 150 pH/ion meter and calibrated against potassium hydrogen phthalate (pH *ca* 4.0) and phosphate (pH *ca* 6.9) buffers [17]. Thereafter, the $^{31}P\{^1H\}$ broad band decoupled NMR spectrum was obtained on the spinning sample at 32.29 MHz on a Bruker WP80 NMR spectrometer.

Chemical shifts were referenced to external 85% H_3PO_4 by sample substitution. The reference was contained in a 5 mm (o.d.) coaxial tube within a 10 mm (o.d.) NMR tube containing a solution of LH_2 identical to that used at the start of the titration. Reference signals were recorded after every five data points and showed variations of <0.05 ppm. At the end of the titration, a volume of base solution, equal to the total delivered in the titration, was added to the solution surrounding the aqueous H_3PO_4 reference tube. Subsequent determination of the ^{31}P NMR spectrum showed the position of the reference signal to be independent of the pH of the solution providing the lock signal. A satisfactory spectrum was obtained at each titration point with *ca* 100 transients, pulse length 1.0 μs, delay 3.0 s, spectral width 1602 Hz and 16 K data points.

Routine ^1H, ^{13}C and ^{31}P NMR spectra were obtained on a Bruker AM250 spectrometer using TSP-d_4 (^1H, ^{13}C) and external aqueous H_3PO_4 (^{31}P) as references.

RESULTS AND DISCUSSION

The syrupy ligands resulting from evaporation of the reaction mixtures in the preparation of 1-aminoalkylphosphonic acids from secondary amines by the Moedritzer–Irani reaction retain significant amounts of hydrochloric acid which cannot be easily removed [6]. Removal of hydrochloric acid may be important in overcoming the reluctance of these liquids to crystallize, so, in the synthesis of LH_2, the syrup was treated with propylene oxide at 40 °C [19]; both the oxide and its addition product with HCl were removed under reduced pressure. The pure aminophosphonic acid was obtained in good yield, although crystallization was a very lengthy process. This allowed the first X-ray crystallographic determination of LH_2. Isolation of the anion $[LH]^-$ as the K^+ salt has been previously reported [7].

Full characterization of LH_2 was carried out on the recrystallized sample, which was also used for X-ray diffraction studies. A notable feature of the ^1H NMR spectrum obtained at 250 MHz in D_2O is the slightly broadened "quintet" [$^3J(HH) \approx 7.6$ Hz] assigned to $-CH_2CH_3$. Aside from the expected coupling to the methyl protons, further coupling to phosphorus [$^4J(HP)$] is ruled out by the expected magnitude of such long-range coupling (<1 Hz) and the absence of the appropriate pattern in the ^{31}P NMR spectrum. We conclude that these methylene protons are rendered anisochronous by the prochiral nitrogen atoms, the normally fast nitrogen inversion process being sufficiently slowed by protonation of the nitrogen atoms in the zwitterionic species which are exclusively present below pH *ca* 9 (*vide infra*). The "quintet" pattern can be accounted for by overlap of the quartets arising from the anisochronous methylene protons with a chemical shift difference of *ca* 0.03 ppm. At 80 MHz, the multiplet becomes a broad "quartet" and a simulation indicates the geminal coupling to be *ca* -2 Hz.

Protonation equilibria

Values of protonation constants for LH_2 determined as the mean of several independent refinements

Table 1. Protonation constants for LH_2 and stability constants for complexes of LH_2 with Pb^{II}[a]

mlh	$\log \beta_{mlh}$[b]	$\log K_{mlh}$

11−1	−0.49±0.33[d]	−7.94±0.51[e]

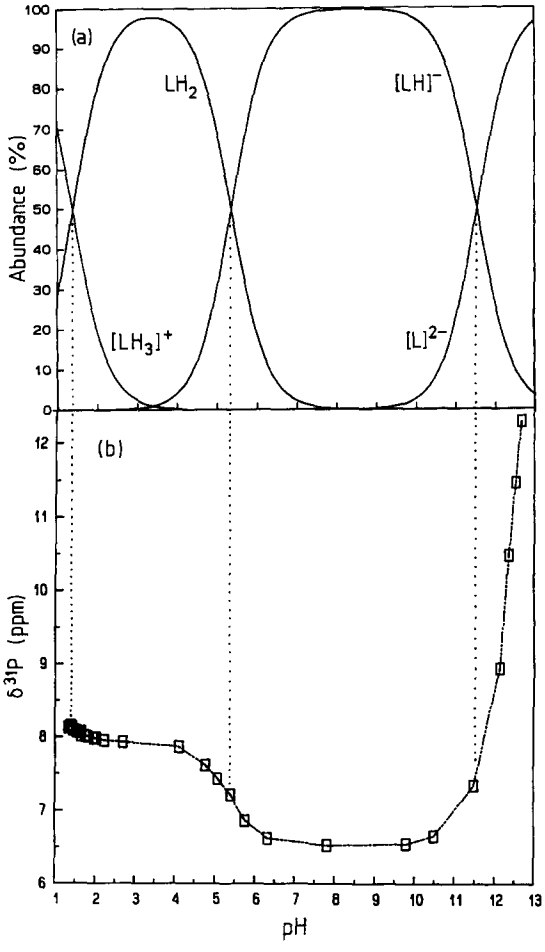
[a] Data obtained at constant ionic strength, $I = 0.1$ mol dm^{-3}, KNO_3; 25.0±0.1 °C. Convention β_{mlh} for $M_mL_lH_h$; $L = Et_2NCH_2PO_3^{2-}$. Values of $\log \beta_{mlh}$ and $\log K_{mlh}$ are unweighted means of values obtained for each satisfactory refinement of each titration data set; error limits encompass the range of values obtained for each $\log \beta_{mlh}$ (and $\log K_{mlh}$).

[b] $\beta_{mlh} = [M_mL_lH_h]/[M]^m[L]^l[H]^h$. Values obtained by previous workers are given in the parentheses.

[c] $K_{0lh} = [LH_h]/[LH_{h-1}][H]$.

[d] $\{Pb(H_2O)_n\}^{2+} + L \rightleftharpoons \{Pb(L)(H_2O)_{n-1}(OH)\}^- + H^+$; $\beta_{11-1} = [\{Pb(L)(H_2O)_{n-1}(OH)\}^-][H^+]/[\{Pb(H_2O)_n\}^{2+}][L]$.

[e] $\{Pb(L)(H_2O)_n\} \rightleftharpoons \{Pb(L)(H_2O)_{n-1}(OH)\}^- + H^+$; $K_{11-1} = [\{Pb(L)(H_2O)_{n-1}(OH)\}^-][H^+]/[\{Pb(L)(H_2O)_n\}]$; $\log K_{11-1} = \log \beta_{11-1} - \log \beta_{110}$.



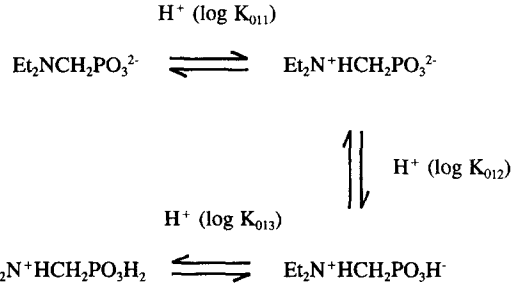


Fig. 1. (a) Distribution of ligand species derived from LH_2 as a function of pH calculated [20] using values of $\log \beta_{0lh}$ determined in aqueous KNO_3 ($I = 0.1$ mol dm^{-3} KNO_3) (this work); (b) pH dependence of $\delta(^{31}P)$ for LH_2 in aqueous KNO_3 ($I = 1.0$ mol dm^{-3}). Dotted lines indicate correlation between 'half-neutralization' points in (a) and inflections on curves in (b).

of the data from three titrations are given in Table 1. Relatively large intratitration (different refinements on the same data set) and intertitration variations in the value of $\log \beta_{013}$ were found (evident in the error limits on this value) and presumably arise because of the low abundance of the tri-prontonated ligand (<10% at pH 2.4; see Fig. 1a).

Previous potentiometric investigations by Wozniak and Nowogrocki [8] of the protonation equilibria of LH_2 yielded pK_a values of $[LH]^-$ and LH_2 only. The present study (Table 1) yielded, additionally, a pK_a value for $[LH_3]^+$. The results for $[LH]^-$ and LH_2 agree most closely with the values obtained by Wozniak and Nowogrocki under similar conditions ($I = 0.1$ mol dm^{-3}, KNO_3), and less so with those reported by Carter *et al.* [7] from solutions of higher ionic strength [$I = 1.0$ mol dm^{-3}, (KNO_3)]. The latter authors point out that complexation of K^+ by the ligand may significantly affect the magnitude of $\log K_{011}$ in these experiments.

The first protonation step has been assigned [7] to protonation of the nitrogen on the basis of ^1H and ^{31}P NMR spectra obtained for solutions of LH_2 with the addition of, respectively, 0, 1, 2 and 3 equivalents of NaOD. The protonation scheme (Scheme 1) implied by these results was confirmed in the present study by comparison of a detailed investigation of the pH dependence of the ^{31}P NMR spectrum for LH_2 with the species distribution plot (Fig. 1).

The empirical utility of ^{31}P shielding/deshielding effects in determining the protonation sequence for 1-aminomethylenephosphonic acids has been firmly established; deprotonation of the phosphonic acid function shielding the ^{31}P nucleus [7, 21–25] and deprotonation of amine sites causing deshielding [7, 23, 25]. Two inflections are apparent below pH 7 and both are in regions of the curve where the ^{31}P NMR signal moves to higher field with increasing pH. This

Scheme 1.

is consistent with stepwise deprotonation of the phosphonic acid function $[LH_3]^+$. Larger changes in $\delta(^{31}P)$ above pH 10, but this time to lower field with increasing pH, correlate with increasing abundance of the fully deprotonated form of LH_2 and are characteristic of amine deprotonation. Intrinsic ^{31}P chemical shifts for $[LH]^-$ and for the zwitterion LH_2 are determined, by inspection, as δ 6.5 and 7.9.

Crystal structure of LH_2

The molecular structure of LH_2 in the solid state is shown in Fig. 2a and selected bond lengths and angles for are given in Table 2. All the acidic hydrogen atoms were located directly; LH_2 is zwitterionic with the nitrogen atom and one phosphonate oxygen atom each being protonated. Neglecting the proton on the phosphonate oxygen atom, the molecule has, overall, virtual C_s symmetry about the plane containing the nitrogen–carbon–phosphorus linkage.

The angle subtended by the nitrogen and phosphorus atoms at C(1) is extremely large [N(1)—C(1)—P 120.1(3)], and significantly greater than the corresponding values (110.9–117.9°) found for other 1-aminomethylenephosphonic acids [12, 13, 25–28]. This marked distortion from an approximately tetrahedral environment for the methylenephosphonate carbon appears to be caused by steric factors arising indirectly from the staggered conformation about the P—C(1) bond (Fig. 2b) which results in the ethyl carbon atoms, C(21) and C(31), being "eclipsed" by the phosphonate oxygen atoms O(2) and O(1), respectively, so that very short contact distances result [H(21b)···O(2) 2.48 and H(31b)···O(1) 2.39 Å]. Attempts to minimize these interactions can also be seen in enlargement of the angles at nitrogen involving the ethyl and methylenephosphonate carbon atoms [C(21)—N(1)—C(1) 113.7(3) and C(31)—N(1)—C(1) 114.0(3)] relative to the angle between the two ethyl groups [C(21)—N(1)—C(31) 110.2(3)]. It appears that repulsion between the phosphonate and ethyl groups causes the latter to be 'pushed' away from the phosphonate and towards each other. Steric factors appear to be less important in the other two members of the series $Et_nN(CH_2PO_3H_2)_{3-n}$, compared with the diethyl derivative LH_2. Where either the ethyl group is absent ($n = 0$), or only one is present ($n = 1$), the C—N—C angles are fairly close in value, being within the narrow range 112.2–113.1° [12, 13].

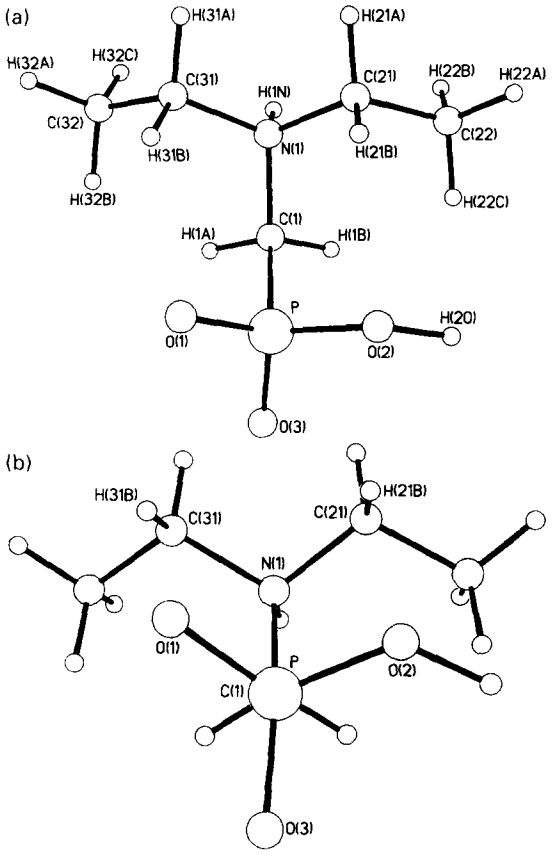

Fig. 2. Molecular structure of LH_2; (a) general view; (b) viewed along the P—C(1) bond to show the 'eclipsed' conformation of phosphonate oxygen and methylene carbon atoms.

The geometry around the phosphorus atom is substantially distorted from tetrahedral. Two patterns of P—O bond lengths are commonly found for 1-aminoalkylphosphonic acids: (a) two long P—O(H) distances in the range 1.548–1.527 Å and one shorter P=O distance (1.492–1.465 Å) corresponding to the doubly protonated group [12, 25, 27, 29]; (b) one long P—O(H) distance (1.578–1.538 Å) and two shorter P=O distances (1.514–1.486 Å) for monoprotonated groups [12, 13, 25–27, 29, 30]. The P—O distances in LH_2 most closely match pattern (b), although the longer of the two 'short' distances [P—O(3) = 1.520(3) Å] is at the upper end of the range, presumably owing to the involvement of O(3) in strong intermolecular hydrogen bonding (Fig. 3). Assignment of partial double bond character to the bonds from the non-protonated oxygen atoms [O(1) and O(3)] is supported by the angular deviations from tetrahedral geometry at phosphorus; the repulsion between these bonds results in the angle between them [114.3(2)] being significantly larger than the other O—P—O angles [111.6(2) and 111.7(2)].

Hydrogen bonds between the protonated nitrogen atoms and the non-protonated oxygen atoms [O(1′)] in molecules related by the 2_1 screw axis result in an infinite helical chain of molecules along the *b*-axis direction (Fig. 3). A second, stronger, intermolecular hydrogen bond gives rise to "dimer" bridge units by linking the protonated oxygen atom, O(2), and the non-protonated oxygen atom, O(3′), of centrosymmetrically related molecules. Therefore, adjacent helical chains are linked through these dimer bridges to form a two-dimensional hydrogen-bonded sheet.

Table 2. Selected bond lengths (Å) and angles (°) for $[LH_2]$

P—O(1)	1.487(3)	P—O(2)	1.543(3)

Complex formation

An investigation of complex formation between LH_2 and a range of metal ions (M^{II}; M = Co, Ni, Cu, Zn, Cd, Pb) was attempted using the potentiometric titration technique. For each metal ion, at least two titrations, each at different [M] : [L] ratios, were carried out. However, only titrations of LH_2 in the presence of Pb^{II} yielded results from which reliable $\log\beta$ values could be calculated. For all the other metal ions investigated, precipitation occurred at higher pH and, with the exception of Cu^{II}, there was no evidence of complex formation at low pH; this is consistent with $\log\beta$ values for Mg^{II} and Ca^{II} previously reported [7]. In the case of Cu^{II}, titration curves indicated appreciable complex formation, but at pH values too close to the point of precipitation to allow reliable refinement, although stability constants for some Cu^{II} complexes have been reported by Wozniak and Nowogrocki [8]. The precipitates observed during our titrations are ascribed to hydrolysis products; the potentiometric titration curve for $Co(NO_3)_2$ in the absence of LH_2 shows irregularities at pH *ca* 8.5 which mimic those observed for titrations in the presence of LH_2.

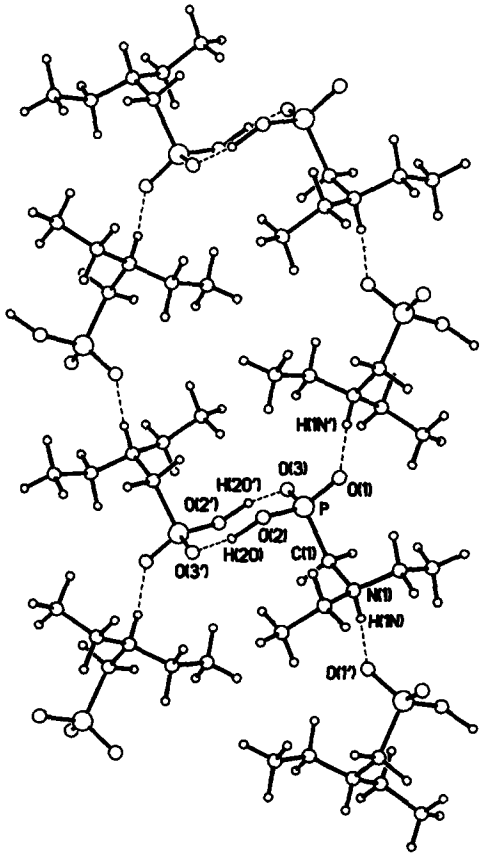

Fig. 3. Two-dimensional hydrogen-bonded sheet of molecules of LH_2. Intermolecular distances (Å): N(1)···O(1′) 2.67, O(2)···O(3′) 2.54.

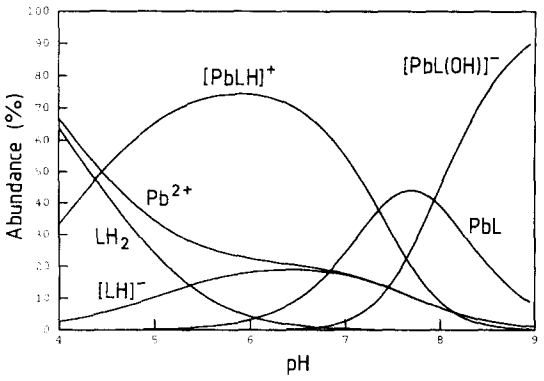
In contrast, the titration curves for LH_2 in the presence of Pb^{II} were smooth and showed no evidence of precipitation. Analysis of titrations at [M] : [L] ratios of *ca* 1 : 1, 1 : 2 and 1 : 3, respectively, gave the stability constants (Table 1) for the species [PbL], $[PbLH]^+$ and $[PbL(OH)]^-$ and showed no evidence for the species $[PbL_2]^{2-}$, $[Pb(OH)]^+$ or $[PbLH_2]^{2+}$. Comparison of the distribution diagram for LH_2 (Fig. 1a) with those for the system with $[Pb^{II}]/[LH_2] = 1$ over a range of Pb^{II} concentrations showed that, in the pH range 4.6–8.7 and for $[Pb^{II}] > ca\ 0.005$ mol dm^{-3} (e.g. Fig. 4), the species $[LH]^-$, which dominates the proton equilibria, is largely replaced by the protonated complex $[PbLH]^+$, which, as the pH is increased, deprotonates to give PbL. The latter complex is presumably aquated and itself deprotonates to yield $[PbL(OH)]^-$.

The stability constants for complexes of metal ions with LH_2 are evidently much lower than for those with *N*-ethyliminobis(methylenephosphonic acid), $EtN(CH_2PO_3)_2$ (L^1H_4); e.g. $\log\beta_{11h}$ ($h = 0, 1$) values for Cu^{II} with LH_2 (7.46 and 14.12, respectively [8]) are substantially lower than those for Cu^{II} with L^1H_4 (13.5 and 18.1, respectively [31]). This also applies to



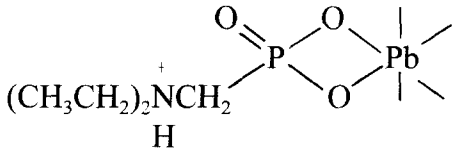


Fig. 4. Species distribution diagram for complexes of LH_2 with Pb^{II} calculated [20] for $[Pb^{II}] = [LH_2] = 0.01$ mol dm^{-3}.

complexes with Pb^{II} (for L^1H_4, $\log\beta_{110} = 11.18$ and $\log\beta_{111} = 17.73$ [31]). These results are consistent with the stability constants determined by Sawada *et al.* [9] for the methyl analogues of LH_2 and L^1H_4, and reflect the enhanced basicity of the ligands containing two (rather than one) methylenephosphonic acid functions.

The rather high values of $\log\beta_{110}$ found for Pb^{II} complexes with LH_2 and L^1H_4 are similar to those found for Cu^{II} [8,31], the transition metal ion expected to form the most stable complexes according to the Irving–Williams series [32]. Enhanced stability for complexes of Pb^{II} with some other l-aminoalkylphosphonic acids has also been observed [11, 33] suggesting that l-aminoalkylphosphonic acids may offer reagents for selective complexation of this toxic heavy metal.

It is likely that, in all of the three Pb^{II} complexes with LH_2, the lead atom is coordinated to at least one phosphonate oxygen atom. Although only a few crystal structures of metal complexes with aminoalkylphosphonic acids have been reported [28,34–38], all show this coordination mode. In only three cases has additional N-coordination being demonstrated [35–37]. Excluding the N-coordinated complexes, a characteristic feature of the solid state structures of these complexes is their polymeric nature [28,34–39]; however, it is unlikely that such structures would be present to any significant extent in solution.

While the question of whether there is a Pb—N bond in the species PbL remains unresolved, the stability constants provide information about the structure of the monoprotonated complex, $[PbLH]^+$. The first protonation constant ($\log K_{111}$) of the complex [PbL] is *ca* 2 log units larger than the second protonation constant ($\log K_{012}$) of the ligand. Since K_{012} characterizes the first protonation of the phosphonate group, it follows [9] that [PbL] is protonated at the nitrogen atom, reflecting the high proton affinity of the nitrogen atom of aminoalkylphophonates (e.g. refs [8, 9]). A possible structure of $[PbLH]^+$, consistent with these observations, is represented by **I**.

It is worth noting that structure **I** includes a bidentate, chelating phosphonate group. This arrangement has not been observed in solid state structures of l-aminoalkylphosphonic acid complexes with metal ions [28,34–39] with ionic radii up to and including that of Cd^{2+} (1.09 Å) [40]. However, chelating phosphonate groups have been found for the Ca^{II} complex of *N*-phosphonomethylglycine [41] and in the structure of the Pb^{II} complex of piperazine-1,4-diylbis-(methylene)-bis(phosphonic acid) [39]; it may be that the larger Ca^{2+} and Pb^{2+} ions (ionic radii, 1.20 and 1.33 Å [40], respectively) are required to accommodate the small angle (O—P—O) subtended at the ligand by the donor oxygen atoms.

(Received 3 April 1996; accepted 24 June 1996)

Abstract—The complexations of the 13-group metals (Ga^{III}, In^{III} and Tl^{III}) with 7-[(2-hydroxy-5-chlorophenyl)azo]-8-hydroxyquinoline-5-sulfonate(hpaq) were studied. In Ga^{III}-complexation, hpaq coordinates to Ga^{III} to form a yellow complex through a fast process and then this yellow complex slowly changes to a red complex. The rate constant of the slow process is independent of the experimental Ga^{III} concentration, indicating the presence of a linkage isomerism. In the cases of In^{III}- and Tl^{III}-complexations, no linkage isomerism was observed. Copyright © 1996 Elsevier Science Ltd

Keywords: complexation; multidentate ligand; 13-group metal; Ga^{III}; linkage isomerism; kinetics.

In the course of the studies on the coordination selectivities of the azo system multidentate ligands toward various metal ions [1–10], the evidence for linkage isomerism in the complexation between Al^{III}, one of the 13-group elements, and hpaq has been reported in detail [11].

Afterwards, it was found that Ga^{III} also showed similar linkage isomerism in the complexation with hpaq [11], but not in the cases of the In^{III}- and Tl^{III}-hpaq complexations, because the 13-group elements in the trivalent state is basically a consequence of the systematical increase in softness and ionic radius in the order $Al^{III} < Ga^{III} < In^{III} < Tl^{III}$.

This paper describes an investigation of the complexation equilibria, kinetics and reaction mechanisms of the hpaq-complexations with Ga^{III}, In^{III} and Tl^{III}.

EXPERIMENTAL

Ligands and metal ion source

The preparation of hpaq has been described elsewhere [11]. All the metallic ions M^{III} were prepared as aqueous perchlorate solutions from metallic Ga (Wako, 99.99%), $In(OH)_3$ (Aldrich) and Tl_2O_3 (Wako), respectively.

Measurements

All the measurements (except polarograms) are the same as those reported in the previous paper [11]. Polarograms were recorded on a Yanaco Polarographic Analyzer P-1100 in an aqueous solution containing 0.1 mol dm^{-3} KNO_3 as the supporting electrolyte, and 0.01% gelatin as the maximum suppressor. A three-electrode cell was used for measurements, in which the working electrode was a dropping mercury electrode (DME); the auxiliary electrode was a platinum coil. The DME had the following characteristics: $m = 2.02$ mg s^{-1}, $t = 1.00$ s/drop at -0.5 V versus SCE, in electrolytic solution at $-\log[H^+] = 7.0$.

The observed rate constant, k_{obs}, was calculated from the gradient of the linear relation of logarithmic absorbance change versus t on the basis of eq. (1):

$$\ln[(A_i - A_\infty)/(A_t - A_\infty)] = k_{obs}t \qquad (1)$$

where A_i, A_t, and A_∞ refer to the absorbances at the initial state, at time t, and at the infinite equilibrium state of the kinetic process, respectively. For the Ga^{III}-complexation, $k_{obs(fast)}$ and $k_{obs(slow)}$ of the first(fast) and second(slow) steps were calculated independently

*Author to whom all correspondence should be addressed.

according to eq. (1), because the two steps took place with different time scales. All the pH were corrected by using the activity coefficient $f_{H^+} = 0.83$ at 25°C [12].

RESULTS AND DISCUSSION

Electronic absorption spectra of complexes

In Fig. 1 the spectral changes for the slow process of the Ga^{III}-hpaq complexation from 0 min (a), corresponding to the yellow complex $Ga(Hhpaq)^+$-N,O, to 80 min (b), corresponding to the red complex Ga (hpaq)-O,N,O are shown. In this period the colour of the solution changes gradually from yellow to red. The spectra have two clear isosbestic points at 17.5×10^3 and 20.9×10^3 cm^{-1}; this finding means that the yellow complex [spectrum (a)] changes quantitatively to the red complex [spectrum (b)]. As shown below in the kinetics discussion, this spectral change was not influenced by the initial Ga^{III} concentration, suggesting an intramolecular rearrangement of coordination sites, from N,O-bidentate to O,N,O-tridentate complexes.

Polarograms

In addition to the reasoning for the coordination sites from the above electronic spectra, a mutual comparison of reduction potentials between the azo group in free hpaq and in the metal complexes provides direct information to judge whether or not the azo N-atom coordinates to metal ions.

In comparison with the relation between $-\log[H^+]$ and reduction potentials ($E_{1/2}$) of the azo group in free hpaq ($E_{1/2} = 0.038 + 0.058 \log[H^+]$, $r = 0.999$), the potentials for the Ga^{III}-hpaq complex between $-\log[H^+] = 2$–8, which were measured after the yellow complex was completely converted to the red complex, are shifted negatively by about 160 mV, then at $-\log[H^+] > 8$ the potentials lie on the same reduction potentials of free hpaq because of a hydrolysis of the complex, showing a stabilization by a negative shift effect [13,14]. In other words, one of the N-atoms in the azo group coordinates evidently to Ga^{III}. For the In^{III}-hpaq set, on the other hand, the potentials are almost the same as those of free hpaq. This result shows that an N-atom in the azo group does not coordinate to In^{III}, showing the coordination at only 8-hydroxyquinoline moiety as N,O-bonding.

In this polarographic study, reduction potentials of a Tl^{III}-complex were not obtained because Tl^{III} is reduced (at +0.72 V) prior to the reduction of the azo group.

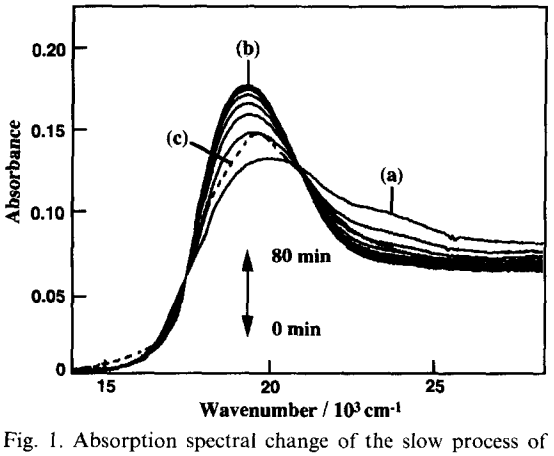

Fig. 1. Absorption spectral change of the slow process of Ga^{III}-hpaq complex from 0 (a) to 80 min (b) at $-\log[H^+]$ 1.95. Spectrum (c): free H_2hpaq^- at $-\log[H^+]$ 5.50. Other spectra show intermediate complex from yellow to red. $[Ga^{III}] = 3.00 \times 10^{-4}$ mol dm^{-3}, [hpaq] = 2.00×10^{-5} mol dm^{-3}.

Complexation equilibria and stability constants

Complexation equilibria are summarized in Table 1, in which the pH ranges, where complexations occur, to judge a reacting hpaq species, the maximum wavenumbers (with molar absorptivities), and the stability constants calculated from the equations described below are listed. All of the compositions of the complexes were determined by the continuous variation method. A sharp and single maximum at the hpaq (or metal) mole fraction of 0.5 was obtained for all the M^{III}-hpaq sets, indicating clearly the presence of 1 : 1 complexes as listed in Table 1. It is necessary to discuss the stability constants and kinetic consideration to take into account such species as $[M(OH)(H_2O)_5]^{2+}$ besides $[M(H_2O)_6]^{3+}$ (hereafter, abbreviated as MOH^{2+} for the former and M^{3+} for the latter, respectively).

On the basis of the characteristic spectral features of the complexes and the $-\log[H^+]$ ranges where the complexations occur, and thus the equilibration modes listed in Table 1, all of the complexation equilibria may be represented as follows:

$$M^{3+} + H_2hpaq^- = M(hpaq) + 2H^+$$

Accordingly, stability constants $\beta_{M(hpaq)}$ can be calculated from eq. (2),

$$\begin{aligned}\log \beta_{M(hpaq)} &= \log\{[M(hpaq)]/[M^{3+}][hpaq^{3-}]\} \\ &= \log\{[M(hpaq)]/[H_2hpaq^-]\} \\ &\quad + 2\log[H^+] - \log[M^{3+}] \\ &\quad + \log K_{(hqOH)} K_{(phOH)} + \log(\alpha_M \alpha_L), \end{aligned} \quad (2)$$

where, $[M^{3+}]$ refers to experimental initial concentration (all the mixtures are composed of $[M^{3+}] \gg [hpaq]$ as experimental conditions, *ca* 10–50 : 1). The protonation constants [11], $K_{(hqOH)} = 10^{7.04}$ and $K_{(phOH)} = 10^{10.30}$, are used for the calculation. α_M

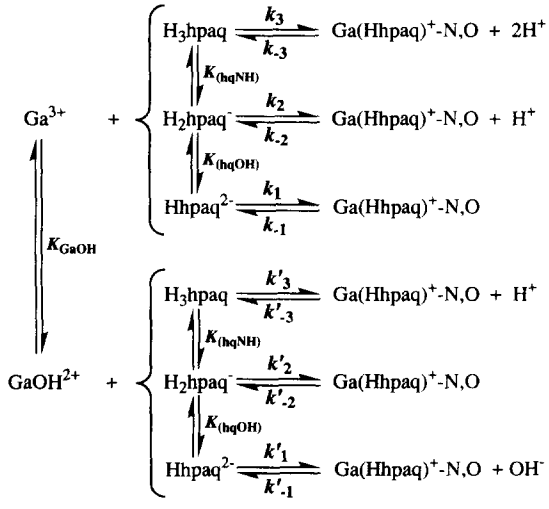
Table 1. Complexing pH range, equilibrium mode, maximum wavenumber (molar absorptivity), and stability constants for metal-complexes

Ligand	pH Range	Equilibrium	$\nu_{max}/10^3(\varepsilon_{max}/10^4)$	$\log\beta_{ML}$
hpaq	0.58–1.66	$Ga^{3+}+H_2hpaq^- \Leftrightarrow Ga(hpaq)\text{-}O,N,O+2H^+$	17.9(0.85)	33.9_2
hpaq	2.27–3.00	$In^{3+}+H_2hpaq^- \Leftrightarrow In(hpaq)\text{-}N,O+2H^+$	21.7(0.62)	18.6_2
hpaq	2.06–3.01	$Tl^{3+}+H_2hpaq^- \Leftrightarrow Tl(hpaq)\text{-}N,O+2H^+$	21.7(0.79)	25.4_6
baq[a]	0.16–2.68	$Ga^{3+}+H_2baq \Leftrightarrow Ga(baq)^+\text{-}N,O+2H^+$	25.0(4.25)	18.1_3

[a] baq = 7-[(4-chlorophenyl)azo]-8-hydroxyquinoline-5-sulfonate.

$(=1+K_{MOH}/[H^+])$ is side reaction coefficients by monohydroxo complexes MOH^{2+}, in which $K_{MOH}=[MOH^{2+}][H^+]/[M^{3+}]=10^{-3.10}$ for Ga^{3+}, $10^{-3.50}$ for In^{3+}, and $10^{-1.20}$ mol dm^{-3} for Tl^{3+} are used for the correction [15]. And, α_L $(=1+K_{(hqNH)}K_{(hqOH)}K_{(phOH)}[H^+]^3+K_{(hqOH)}K_{(phOH)}[H^+]^2+K_{(phOH)}[H^+])$ is also side reaction coefficient by the protonation of hpaq, in which the value [11] $K_{(hqNH)}=10^{2.98}$ was used for the correction. All the stability constants $\log\beta_{M(hpaq)}$ were calculated by finding a $-\log[H^+]$ value at $\log[M(hpaq)]/[H_2hpaq^-]=0$ from a straight line with a gradient *ca* 2. The stability constants obtained are listed in Table 1 with an indication of coordinating donor atoms.

Kinetics of fast process for Ga^{III}*-hpaq complexation*



The Ga^{III}-hpaq complexation can be treated in terms of two consecutive reactions with different time scales: fast complexation to form the yellow complex $Ga(Hhpaq)^+$-N,O ($k_{obs(fast)}$), followed by a slow intramolecular change to the red complex Ga(hpaq)-O,N,O ($k_{obs(slow)}$). Each reaction step obeyed the first-order kinetics. By eq. (1), a fine linear relation was obtained between the logarithmic absorbance change with time for more than half-life periods at 19.8×10^3 cm^{-1}. By taking into consideration the protonation constants of hpaq, the hydrolysis constants of Ga^{III}, the stability constants of the 1:1 complex, and the more rapid attainment of equilibria for the protolytic process [16], the fast formation of the complex $Ga(Hhpaq)^+$-N,O is considered to proceed as shown in Scheme 1. Here, six possible reaction pathways are proposed with their rate equations by using the steady state approximation:

$$\begin{aligned}
&d[Ga(Hhpaq)^+\text{-}N,O]/dt\\
&=[Ga^{3+}]\{k_3[H_3hpaq]+k_2[H_2hpaq^-]\\
&\quad+k_1[Hhpaq^{2-}]\}+[GaOH^{2+}]\{k'_3[H_3hpaq]\\
&\quad+k'_2[H_2hpaq^-]+k'_1[Hhpaq^{2-}]\}\\
&\quad-[Ga(Hhpaq)^+-N,O]\{k_{-3}[H^+]^2\\
&\quad+(k_{-2}+k'_{-3})[H^+]+k'_{-1}[OH^-]+(k_{-1}+k'_{-2})\}.
\end{aligned}\tag{3}$$

Here, k_i and k'_i denote the rate constants for the forward reactions concerning $[Ga^{3+}]$ and $[GaOH^{2+}]$, and k_{-i} and k'_{-i} those for the backward reactions related to $[Ga(Hhpaq)^+\text{-}N,O]$, respectively. Under the pseudo-first-order kinetic conditions with respect to Ga^{III} concentration, the forward rate constant k_i can therefore be obtained from the experimental relation of $k'_{obs(fast)}$ as a function of $[H^+]$, as eqs (4) and (5).

$$\begin{aligned}
&k'_{obs(fast)}\\
&=([H_ihpaq^{(3-i)-}]/[Hhpaq^{2-}])\\
&\quad\times\left\{\sum_{i=1}^{3}(k_i+k'_i[GaOH^{2+}]/[Ga^{3+}])\right\}\\
&=k_3K_{(hqNH)}K_{(hqOH)}[H^+]^2+(k_2K_{(hqOH)}\\
&\quad+k'_3K_{(hqNH)}K_{(hqOH)}K_{GaOH})[H^+]\\
&\quad+k'_1K_{GaOH}[H^-]^{-1}+(k_1+k'_2K_{(hqOH)}K_{GaOH}).
\end{aligned}\tag{4}$$

$$\begin{aligned}
k'_{obs(fast)}=k_{obs(fast)}/\{&1/\beta'_{Ga(Hhpaq)\text{-}N,O}\\
&+C_{Ga}/(K_{(hqNH)}K_{(hqOH)}[H^+]^2\\
&+K_{(hqOH)}[H^+]+1)(1+K_{GaOH}[H^+]^{-1})\},
\end{aligned}\tag{5}$$

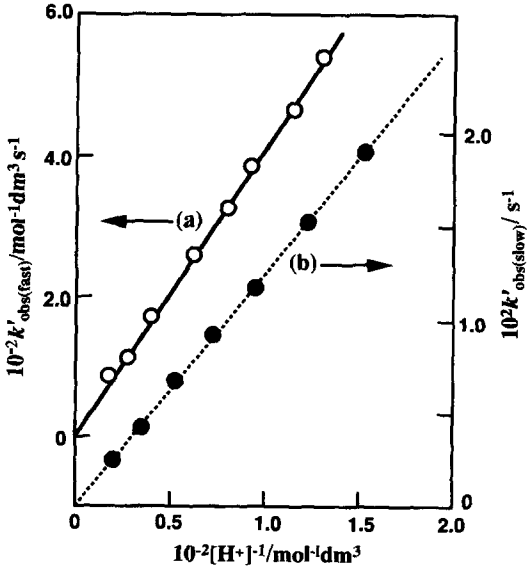
Scheme 1. Possible pathways of fast Ga^{III}-hpaq complexations.

where, $\beta'_{Ga(Hhpaq)\text{-}N,O} = [Ga(Hhpaq)^+\text{-}N,O]/[Ga^{3+}][Hhpaq^{2-}]$. However, no real value of $\beta'_{Ga(Hhpaq)\text{-}N,O}$ could be obtained directly in this study, accordingly, the value $\beta_{Ga(baq)\text{-}N,O} = 10^{18.1}$, which was calculated separately (see Table 1), was tentatively used for the calculation. C_{Ga} corresponds to an experimental Ga^{III} concentration ($= [Ga(Hhpaq)^+\text{-}N,O] + [Ga^{3+}] + [GaOH^{2+}]$). From eq. (4), it was found that the experimental data plots of $k'_{obs(fast)}$ are proportional only to the $[H^+]^{-1}$ term with a zero intercept [Fig. 2(a)], from which it has become apparent that the formation of complex $Ga(Hhpaq)^+$-N,O proceeds *via* reaction pathway, $GaOH^{2+} + Hhpaq^{2-} \rightarrow Ga(Hhpaq)^+\text{-}N,O + OH^-$.

Kinetics of slow process for Ga^{III}*-hpaq complexation*

In the slow process, the observed rate constant, $k_{obs(slow)}$, does not depend on C_{Ga} at a constant $[H^+]$. This fact, once again, indicates evidently that the slow process corresponds to an intramolecular rearrangement of the Ga^{III}-hpaq complex between two possible coordination modes. Scheme 2 shows the equilibria among four possible species of the Ga^{III}-hpaq complexes. Therefore the formation of the red complex, Ga(hpaq)-O,N,O, can be expected to proceed *via* four reaction pathways, with rate equations as given in eq. (6).

$$\begin{aligned} &d[Ga(hpaq)\text{-}O,N,O]/dt \\ &\quad = -d[Ga(Hhpaq)^+\text{-}N,O]/dt \\ &\quad = (k_A[A] + k_B[B] + k_C[C] + k_D[D]) \\ &\qquad - [Ga(hpaq)\text{-}O,N,O]\{k_{-A}[H^+] \\ &\qquad + (k_{-B} + k_{-C}) + k_{-D}[OH^-]\}, \end{aligned} \tag{6}$$



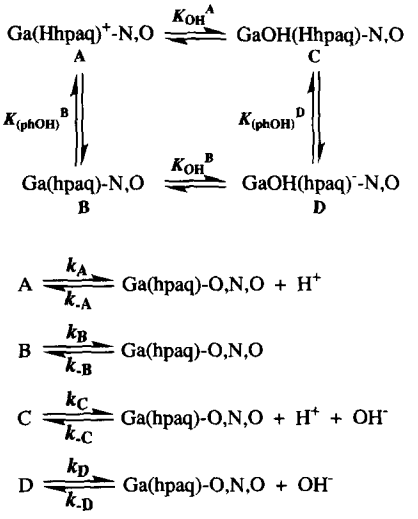


Fig. 2. Plots of (a) $k'_{obs(fast)}$ and (b) $k'_{obs(slow)}$ *vs* $[H^+]^{-1}$ of Ga^{III}-hpaq complexes. $[Ga^{III}] = 2.00 \times 10^{-4}$ mol dm^{-3}, [hpaq] $= 2.00 \times 10^{-5}$ mol dm^{-3}, absorbance at 530 nm.

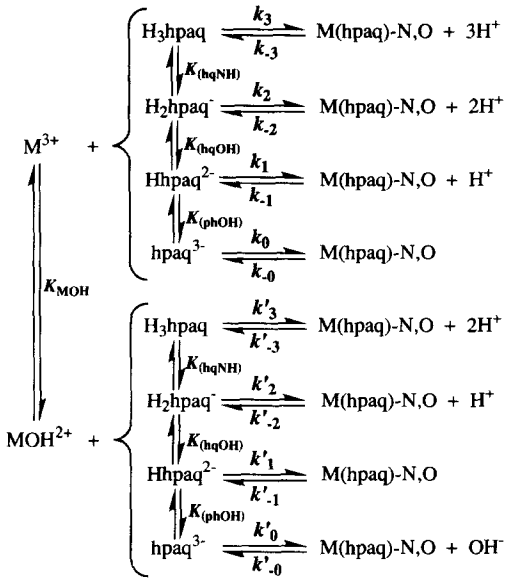
Scheme 2. Pathways of slow Ga^{III}-hpaq complexations.

where k_i and k_{-i} are the rate constants for the forward and reverse pathways of the slow reaction step related to the complex species i, respectively. By defining the modified rate constant, $k'_{obs(slow)}$, which can be defined by the use of eq. (7) from the $k_{obs(slow)}$ value determined experimentally:

$$k'_{obs(slow)} = k_{obs(slow)}/\{1/\beta_{Ga(hpaq)\text{-}O,N,O} + 1/(1 + K_{(phOH)}[H^+])(1 + K_{GaOH}/[H^+])\}, \tag{7}$$



where, $\beta_{Ga(hpaq)\text{-}O,N,O}$ is the stability constant of the complex $[Ga(hpaq)\text{-}O,N,O]/[Ga^{3+}][hpaq^{3-}]$, eq. (8) can then be derived from Scheme 2:

$$k'_{obs(slow)} = k_A K^B_{(phOH)}[H^+] + (k_B + k_C K^D_{(phOH)} K^A_{OH}) + k_D K^B_{OH}[H^+]^{-1}. \tag{8}$$

Here, $K^B_{(phOH)}$ and $K^D_{(phOH)}$ refer to the protonation constants of the species B and D, and K^A_{OH} and K^B_{OH}, to the hydrolysis constants of Ga^{III} in the species A and B, respectively. However, since we have not obtained these constants directly, in the following treatment, $K^A_{(phOH)}$ and $K^D_{(phOH)}$ were approximated to $K_{(phOH)}$ ($= 10^{10.30}$), K^A_{OH} and K^B_{OH} to K_{GaOH} ($= 10^{-3.10}$), respectively. From eq. (8), only the plots of $k'_{obs(slow)}$ *vs* $[H^+]^{-1}$ show a linear relation with a zero intercept [Fig. 2(b)]. This result strongly indicates that the intramolecular rearrangement takes place through the pathway of the complex species D, $GaOH(hpaq)^-$-N,O.

Kinetics of In^{III}*- and* Tl^{III}*-complexations*

The kinetics of the In^{III}- and Tl^{III}-complexations were also studied, for comparison, under pseudo-first-order kinetic conditions with respect to M^{III} concentrations. The results showed that linkage isom-

$M^{3+} = In^{III}$ and Tl^{III}

Scheme 3. Possible pathways of In^{III}- and Tl^{III}-hpaq complexations.

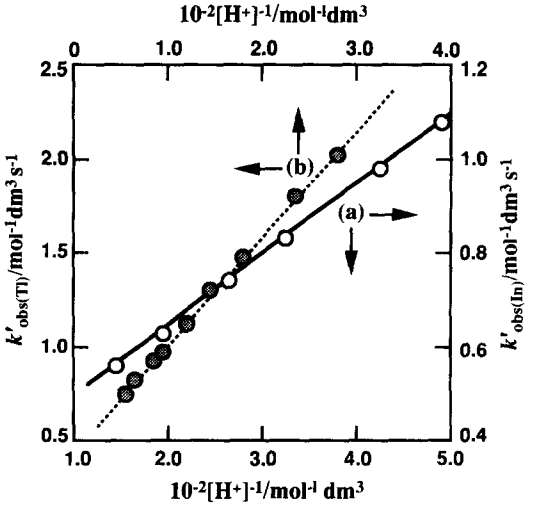


Fig. 3. Plots of (a) $k'_{obs(In)}$ and (b) $k'_{obs(Tl)}$ *vs* $[H^+]^{-1}$ of hpaq-complexation. $[M^{III}] = 2.00 \times 10^{-4}$ mol dm^{-3}, [hpaq] $= 2.00 \times 10^{-5}$ mol dm^{-3}, absorbance at 570 nm for In^{III}-complexation and 550 nm for Tl^{III}-complexation, respectively.

erism for the complexations of In^{III} and Tl^{III} with hpaq was not observed, and these reactions were slow, just as in the case of the second step of the Ga^{III}-hpaq complexation.

The eight possible pathways of both complexations through a wide $-\log[H^+]$ range are shown in Scheme 3. By the same kinetic treatments from Scheme 3 as those for the fast Ga^{III}-complexation, the modified rate constant, k'_{obs}, is also expressed as a function of $[H^+]$ as eq. (9).

$$k'_{obs} = ([H_i hpaq^{(3-i)-}]/[hpaq^{3-}]) \times \left\{ \sum_{i=0}^{3} (k_i + k'_i[MOH^{2+}]/[M^{3+}]) \right\}$$

$$= k_3 K_{(hqNH)} K_{(hqOH)} K_{(phOH)} [H^+]^3 + (k_2 K_{(hqOH)} K_{(phOH)} + k'_3 K_{(hqNH)} K_{(hqOH)} K_{(phOH)} K_{MOH})[H^+]^2 + (k_1 K_{(phOH)} + k'_2 K_{(hqOH)} K_{(phOH)} K_{MOH})[H^+] + k'_0 K_{MOH}[H^+]^{-1} + (k_0 + k'_1 K_{(phOH)} K_{MOH}), \quad (9)$$

where K_{MOH} denotes K_{InOH} and K_{TlOH}. According to eq. (9), only the plots of k'_{obs} *vs* $[H^+]^{-1}$ show linear relation with zero intercept as shown in Fig. 3. This means that both reactions of In^{III} and Tl^{III} with hpaq proceed *via* $MOH^{2+} + hpaq^{3-} \rightarrow M(hpaq)\text{-}N,O + OH^-$. The various rate constants obtained are summarized in Table 2 together with those of the Al^{III}-complexation [11] for comparison.

The rate constant of the fast process to form $Ga(Hhpaq)^+$-N,O ($k'_1 = 5.2 \times 10^3$ mol^{-1} dm^3 s^{-1}) is somewhat larger than that for $Al(Hhpaq)^+$-N,O ($k'_1 = 5.4 \times 10^2$ mol^{-1} dm^3 s^{-1}). This may be explained in terms of the complexity of the Al^{III}-hydroxo system involving dimeric and polymeric structures etc. [17], it requires longer time to form the reacting monohydroxo species, $AlOH^{2+}$, compared with that for $GaOH^{2+}$.

Table 2. Kinetic parameters of M^{III}-complexations (with Al^{III}-complexations [11]) at $\mu = 0.10(KNO_3)$, 25.0 ± 0.5 C

Pathway	Rate constant/mol^{-1} dm^3 s^{-1}	Remark
$GaOH^{2+} + Hhpaq^{2-}$	$k'_1 = (5.2 \pm 0.3) \times 10^3$	fast step, $K_{GaOH} = 10^{3.10}$
$Ga(Hhpaq)^+$-N,O(OH)	$k_D = (1.5 \pm 0.4) \times 10^{-1}$	slow step, k_D/s^{-1}
$InOH^{2+} + Hhpaq^{2-}$	$k'_0 = (4.7 \pm 0.3) \times 10^0$	$K_{InOH} = 10^{-3.50}$
$TlOH^{2+} + Hhpaq^{2-}$	$k'_0 = (9.1 \pm 0.3) \times 10^{-2}$	$K_{TlOH} = 10^{1.20}$
$AlOH^{2+} + Hhpaq^{2-}$	$k'_1 = (5.4 \pm 0.3) \times 10^2$	fast step, $K_{AlOH} = 10^{4.49}$
$Al(Hhpaq)^+$-N,O(OH)	$k_D = (4.8 \pm 0.4) \times 10^{-3}$	slow step, k_D/s^{-1}

All of the pathways involve monohydroxo complexes MOH^{2+}; this finding seems to be reasonable from the pH ranges where the complexations occur (Table 1), judging from the K_{MOH} values described above. A sequence of the rate constants for the reactions of $MOH^{2+} + Hhpaq^{2-}$ (k'_1, for $M = Ga^{III}$, and k'_0 for $M = In^{III}$ and Tl^{III}) is in the order $Ga^{III} > In^{III} > Tl^{III}$. This sequence may be a reflection of an increase of softness through Ga^{III} to Tl^{III}.

Finally, the linkage isomerism is observed only in the sets of Al^{III}- and Ga^{III}-hpaq, but not in those of In^{III} and Tl^{III}. A molecular model of these sets clearly shows that, in case of the In^{III} and Tl^{III}-sets, the O,N,O-tridentate chelate rings are scarcely formed due to the large ionic radii of In^{III} and Tl^{III}.

(Received 7 May 1996; accepted 22 June 1996)

Abstract—Complexes $(Et_4N)_2[Pd_2(mp)_2(Hmp)_2]$ (**1**) and $[Pd(mpo)_2]$ (**2**) synthesized from the reactions of palladium chloride with 2-mercaptophenol (H_2mp) and 2-mercaptopyridine N-oxide (Hmpo) or 2,2′-dithiobis(pyridine N-oxide) (dtpo), respectively, have been characterized by X-ray diffraction analyses and studied by IR, Raman, ^1H and ^{13}C NMR, and EI-MS techniques. The palladium atoms in the two compounds are in square planar environments. The average Pd—O distances are 2.009 Å and 2.043 Å for **1** and **2**, respectively. The results of EHMO calculations show that the Pd—O bonds are weaker than the Pd—S bonds in both compounds and large delocalized π bonds extend in the $(mp)_2Pd_2S_2$ plane in **1** and in the $Pd(mpo)_2$ plane in **2**. The reaction of $[Ni(mpo)_2]$ with $[Pd(COD)Cl_2]$ led to the formation of **2** also, which implies that the bidentate O : S ligand mpo readily transfers from the Ni^{II} to the Pd^{II} ion. Keywords: palladium complexes; 2R; Raman; NMR; EI-MS; X-ray crystal structures.

Interest in the coordination chemistry of thiolato transition-metal complexes arises in part from the fact that the thiolato group mimics the ligation of cysteinyl residues in proteins [1]. We have studied a series of transition metal complexes with 1,2-bidentate sulfur-containing ligands such as 2-mercaptophenol (H_2mp) [2–7] and 2-mercaptopyridine N-oxide (Hmpo) [8–10], of which H_2mp has been found to be a multifunctional ligand in its ligation to transition metal atoms with versatile coordination modes. Recently Zhu *et al.* [11–14] have found that some simple metal complexes, particularly those of palladium complexes containing sulfur ligands, possess the ability of selective-hydrolytic cleavage of proteins and peptides. The regioselectivities of these hydrolyses vary with substrate. The mechanisms are complicated and it is not clear whether the palladium(II) may activate the C—N bond, or deliver H_2O. Also, since characterized structures with both Pd—S and Pd—O bonds in the same molecule are rare, it is necessary to study complexes with S and O ligations in detail in order to elucidate the reaction mechanism. This contribution reports the syntheses and physicochemical characterizations of $(Et_4N)_2[Pd_2(mp)_2(Hmp)_2]$ [15] (**1**) and $[Pd(mpo)_2]$ (**2**). EHMO calculations have been carried out, indicating large delocalized π bonds extending in the $(mp)_2Pd_2S_2$ plane in **1** and in the $Pd(mpo)_2$ plane in **2**.

EXPERIMENTAL

Air-sensitive manipulations were carried out under dry dinitrogen. Standard Schlenk-tube, vacuum-line and syringe techniques were utilized. Solvents were

* Authors to whom correspondence should be addressed.

dried by standard methods and redistilled before use. 2-Mercaptophenol (H_2mp), sodium 2-mercaptopyridine N-oxide (Nampo), 2,2′-dithiobis(pyridine N-oxide) (dtpo) and palladium chloride were all commercially available and used without further purification. [Pd(COD)Cl2] [16] (COD = 1,5-cyclooctanediene) and [Ni(mpo)$_2$] [8] were prepared by literature methods.

Physical measurements and instrumentation

Elemental analyses were performed by the analytical laboratory of this Institute. Infrared spectra were measured on a Nicolet Magna-750 FT-IR or a Bio-Rad FTS-40 spectrometer, in KBr discs. Raman spectra were recorded on a Nicolet 910 FT-Raman spectrometer using Raman 1064 nm laser source at a resolution of 2 cm^{-1} with 200–400 scans. NMR spectra were measured in DMSO-d_6 solutions on a varian Unity-500 spectrometer operating at 499.98 MHz for ^{1}H, and 124.71 MHz for ^{13}C; the internal reference was $SiMe_4$ in all cases (ppm). Mass spectra were obtained at 70 eV on a Finnigan Mat 312 GC-MS spectrometer by the direct inlet method.

Preparation of $(Et_4N)_2[Pd_2(mp)_2(Hmp)_2]$ (**1**)

To a solution of Na_2mp (0.80 g, 5.0 mmol) in absolute EtOH (20 cm^3) was added a solution of [$PdCl_2$] (0.34 g, 2.0 mmol) in MeCN (30 cm^3) within 10 min at room temperature. After stirring for 30 min until the color no longer changed, the brown solution was filtered and combined with Et_4NCl (0.50 g, 3.0 mmol) in EtOH (10 cm^3). Brown precipitates formed immediately and the solution was kept at 5°C for a few hours and then filtered. The crude product was recrystallized from DMF/MeCN (5 : 1, v/v) to give 0.8 g of brown needle crystals (yield 41%). Found: C, 49.1; H, 5.9; N, 2.6; S, 12.5. Calc. for $C_{40}H_{58}N_2O_4Pd_2S_4$: C, 49.4; H, 6.0; N. 2.9; S, 13.2%. ^{1}H NMR: 11.02 (s, *HO*), 8.79 (dd, $^3J_{16,15}$ = 8.0 Hz, $^4J_{16,14}$ = 1.5 Hz, H16), 6.92 (dt, $^3J_{14,13}$ = 6.5 Hz, $^3J_{14,15}$ = 7.7 Hz, $^4J_{14,16}$ = 1.5 Hz, H14), 6.83 (dt, $^3J_{26,25}$ = 7.2 Hz, $^4J_{26,24}$ = 1.0 Hz, H26), 6.60 (dd, $^3J_{13,14}$ = 6.5 Hz, $^4J_{13,15}$ = 1.5 Hz, H13), 6.58 (dt, $^3J_{24,23}$ = 7.7 Hz, $^3J_{24,25}$ = 7.5 Hz, $^4J_{24,26}$ = 1.0 Hz, H24), 6.55 (dd, $^3J_{15,14}$ = 7.7 Hz, $^3J_{15,16}$ = 8.0 Hz, $^4J_{15,13}$ = 1.5 Hz, H15), 6.31 (dd, $^3J_{23,24}$ = 7.7 Hz, $^4J_{23,25}$ = 1.0 Hz, H23), and 6.29 (dt, $^3J_{25,24}$ = 7.5 Hz, $^3J_{25,26}$ = 7.2 Hz, $^4J_{25,23}$ = 1.0 Hz, H25). ^{13}C NMR: 167.0 (C22), 158.4 (C12), 137.1 (C16), 134.6 (C21), 127.2 (C26), 126.3 (C11, C14), 121.7 (C24), 119.3 (C15), 117.8 (C13), 115.3 (C23, C25). IR (CsI, cm^{-1}): ν(OH) 3452(w), ν(aryl-H) 3047(m), ν(C=C) 1556(s), ν(C—O) 1230(vs), 1171(s), ν(C—S) 1056(m), 1026(m), ν(Pd—O) 379(m), ν(Pd—S) 313(w), 297(m), 295(m).

Preparation of [Pd(mpo)$_2$] (**2**)

Route (a): To a suspension of dtpo (0.38 g, 1.5 mmol) and NaOMe (0.10 g, 1.85 mmol) in MeOH/MeCN (50 cm^3, 1 : 1, v/v) was added [$PdCl_2$] (0.18 g, 1.0 mmol). After stirring for 20 h at room temperature, the solution developed a brown color and was filtered. The filtrate gave deep brown prismatic crystals of **2** (yield 60%) on standing at 5°C, which were collected by filtration. Found: C, 33.4; H, 2.1; N, 7.7; S, 17.7. Calc. for $C_{10}H_8N_2O_2PdS_2$: C, 33.5; H, 2.2; N, 7.8; S, 17.9%. ^{1}H NMR: 8.41 (dd, $^3J_{1,2}$ = 6.7 Hz, $^4J_{1,3}$ = 1.2 Hz, H1), 7.62 (dd, $^3J_{4,3}$ = 8.4 Hz, $^4J_{4,2}$ = 1.8 Hz, H4), 7.46 (dt, $^3J_{3,2}$ = 7.2 Hz, $^3J_{3,4}$ = 8.4 Hz, $^4J_{3,1}$ = 1.2 Hz, H3), and 7.18 (dt, $^3J_{2,3}$ = 7.2 Hz, $^3J_{2,1}$ = 6.7 Hz, $^4J_{2,4}$ = 1.8 Hz, H2). ^{13}C NMR: 156.4 (C5, C10), 138.0 (C1, C6), 130.9 (C3, C8), 127.8 (C2, C7), 119.5 (C4, C9). IR (CsI, cm^{-1}): ν(aryl-H) 3094(m), 3067(m), ν(C=C) 1547(vs), ν(N—O) 1246(vs), ν(C—S) 1042(m), ν(Pd—O) 392(m), ν(Pd—S) 338(w), 315(w), 294(w), 248(m).

Route (b): A mixture of [$PdCl_2$] (0.18 g, 1.0 mmol) and Nampo (0.60 g, 4.0 mmol) in MeOH/MeCN (80 cm^3, 1 : 1, v/v) was stirred for 2 h and filtered. The precipitate was recrystallized from DMF to give brown plate crystals of **2** (yield 72%). The IR spectrum and crystal parameters are identical to that obtained by route (a).

Route (c): To a solution of Ni(mpo)$_2$ (0.08 g, 0.26 mmol) in CH_2Cl_2 (10 cm^3) was added a solution of [Pd(COD)Cl_2] (0.074 g, 0.26 mmol) in CH_2Cl_2 (10 cm^3). A yellow precipitate formed immediately and the product **2** was recrystallized from DMF (5 cm^3) (yield 65%). The IR spectrum and crystal parameters are identical to that obtained by route (a) or (b).

Crystallography

Intensity data for single crystals of $(Et_4N)_2$ $[Pd_2(mp)_2(Hmp)_2]$ **1** and [Pd(mpo)$_2$] **2** were collected at room temperature with Mo-K_α radiation (graphite monochromator), λ = 0.71073 Å. The data sets were corrected for Lorentz and polarization effects and for absorption employing an analytical procedure. Crystal data are compiled in Table 1.

The structures were solved by the Patterson method and refined by a full-matrix least-squares procedure based on *F*. Final refinement details are also given in Table 1. The maximum residual electron density peaks in the final difference maps are 1.03 e Å^{-3} for **1** and 0.57 e Å^{-3} for **2**, located in the vicinity of the Pd atoms.

Molecular orbital calculations

Extended-Hückel molecular orbital (EHMO) calculations with charge iteration (sense* charge dependence) and weighted H_{ij} were carried out by using the

ICON 8 version. A total of 164 and 81 valence orbitals involving five d orbitals of Pd were employed for **1** and **2**, respectively. The parameters of Pd atom were taken from [17].

RESULTS AND DISCUSSION

Syntheses

Excess of mp is necessary to obtain the compound $(Et_4N)_2[Pd_2(mp)_2(Hmp)_2]$ **1**. If the molar ratio of mp : $[PdCl_2]$ is decreased from 2.5 : 1 to 2.0 : 1, a highly air-sensitive crystalline product was isolated, which cannot be identified under present conditions. Treatment of $[PdCl_2]$ with Nampo (route (b)) or with the organic disulphide dtpo under strongly basic condition (route (a)) gave the compound $[Pd(mpo)_2]$ **2**. In the attempt to use the S donor in $[Ni(mpo)_2]$ to coordinate further, it is interesting to find that compound **2** was obtained from the reaction of $[Ni(mpo)_2]$ with $[Pd(COD)Cl_2]$ (eq. 1). This reaction suggests that the bidentate-O : S ligand mpo has transferred from Ni^{II} to Pd^{II}, in contrast with bidentate-N : S ligand aminoethanethiolate which transferred from Pd^{II} to Ni^{II} [18].

$$Pd(COD)Cl_2 + Ni(mpo)_2 \rightarrow Pd(mpo)_2 + NiCl_2 + COD \quad (1)$$

Molecular vibration spectra

The IR and Raman (see Fig. 1) spectra of complex **1** showed the vibrations of C—S bonds appearing at 1056 and 1026 cm^{-1} as two peaks while only one peak at 1042 cm^{-1} was present in **2**. The typical absorptions of C—O bonds for **1** appear at 1230 and 1171 cm^{-1}. It is interesting to note that the absorption peaks of the N—O bonds of **2** are both very strong at 1246 cm^{-1} for the IR and Raman spectra and the N—O bending vibration is at 416 cm^{-1}. The stretching vibrations of Pd—O bonds have been observed at 378 (IR) and 399, 385 and 366 cm^{-1} (Raman) for **1** and

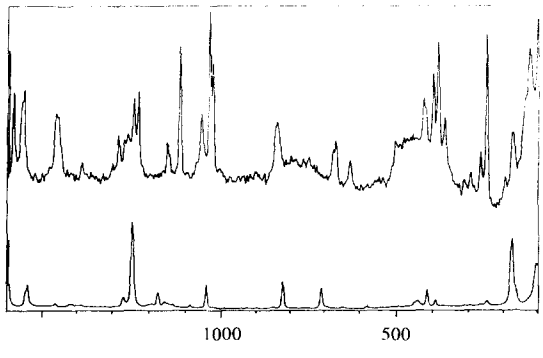

Fig. 1. Raman spectra of compounds **1** (upper) and **2** (lower).

391 cm^{-1} (IR and Raman) for **2**, which are comparable to the values of 395–340 cm^{-1} in triangulo-hexa-μ-acetatopalladium(II) [19] and are lower than that of 464 cm^{-1} in acetylactonatopalladium(II) [20]. The Pd—S stretching vibrations are in the range of 313–295 cm^{-1} for both **1** and **2** in their molecular vibration spectra, consistent with ν(Pd—S) (388–240 cm^{-1}) [21,22]. It also seems reasonable to assign bands in the range of 100–140 cm^{-1} to O—Pd—S bending vibrations.

EI-MS characterization

The molecular ion peak of **1** in a positive EI-MS spectrum was not observed, but the fragment $[Pd(Hmp)_2]^+$ peak with low abundance (2%) appeared and decomposed to produce the ions $[Pd(Hmp)_2—O]^+$ (45%), $[Pd(Hmp)_2—CO]^+$ (3%) and $[Pd(Hmp)_2—Cs]^+$ (4%). Ions $[PdO(S)]^+$ (100%) and $[PdS]^+$ (29%) were also observed together with one of the major ions $[Hmp]^+$ (56%). The MS spectrum of $[Pd(mpo)_2]$ **2** is similar to the other complexes containing mpo ligand [23] with the ions: M^+ (100%), $[M^+—O]$ (5%), $[M^+—2O$ or $S]$ (9%), $[M^+—SC]$ (85), $[M^+—2S]$ (2%), $[M^+—2O—2S]$ (6%), $[M^+—mpo]$ (3%), $[M^+—mpo—O]$ (20%), $[M^+—mpo—S]$ (8%), $[M^+—mpo—CS]$ (88%), $[M^+—mpo—S—O]$ (25%), $[PdO(S)]^+$ (5%), $[mpo]^+$ (4%) and $[mpo—O]^+$ (6%).

NMR spectra

The ^1H and ^{13}C NMR spectra of complex **2** are easy to assign, however, those of the dinuclear anion of **1** cannot be analyzed simply owing to the fact that the mp ligands is of the ABCD system and in the two kinds of terminal and bridging coordination modes. The ^1H signals overlap in the region of 6–7 ppm, and only ten ^{13}C signals appear in its ^{13}C NMR spectrum although there should be twelve inequivalent carbons, in which the signals at 126.3 and 115.3 ppm may be the overlapped peaks estimated roughly from their intensity. Consequently, some 2D NMR techniques have been applied to assign the NMR spectra.

The signal at 11.03 ppm comes from the hydroxy proton of the bridging mp ligand which forms a strong intermolecular hydrogen bond with the oxygen atoms of the terminal mp ligand [O(1)···O(2*), 2.596 Å]. This fact indicates clearly that the dinuclear anion also exists in the DMF solution. The other ^1H signals in the region of 6–9 ppm can be assigned into two groups: 8.79 [H(16)], 6.92 [H(14)], 6.60 [H(13)], and 6.55 [H(15)]; 6.83 [H(26)], 6.58 [H(24)], 6.31 [H(23)], and 6.29 [H(25)], by the ^1H–^1H COSY and simulated spectra. However, which group of signals are contributed by the bridging or terminal mp ligand cannot be assigned. Then the ^1H–^{13}C HMBC (Heteronuclear Multiple Bond Connectivity) spectrum was recorded [24]. The ^1H signal at 11.03 ppm of hydroxy proton correlates to the ^{13}C one at 117.8 ppm [C(13)] in ^1H–^{13}C HMBC spectrum, and the C(13) signal also correlates to the signal at 6.60 [H(13)] ppm in the ^1H–^{13}C HMQC spectrum (Fig. 2), suggesting that the former group signals should be ascribed to the protons of the bridging mp ligand and the latter group to the terminal mp ligand.

The ^{13}C signal at 115.3 ppm correlates to both H(23) and H(25) in the HMQC spectrum, implying that the 115.3 ppm signal is contributed from both C(23) and C(25). Accordingly, the C(13) (117.8), C(14) (126.3), C(15) (119.3), C(16) (137.1), C(24) (121.7), and C(26) (127.2) were assigned. In the HMBC spectrum, the ^{13}C signal at 126.3 ppm [contributed partially from C(14)], not only correlates to H(16) owing to the result of C(14), but also to H(13) and H(15), demonstrating that the 126.3 ppm signal is also contributed from C(11). The last three signals: 167.0 ppm correlating to H(26) and H(24), 158.5 to H(16) and H(14), and 134.6 ppm to H(25) and H(23) in the HMBC spectrum, indicate that they are C(22), C(12), and C(21), respectively.

Description of the structures

The molecular structures of the anion $[Pd_2(mp)_2(Hmp)_2]^{2-}$ of **1** and the compound $[Pd(mpo)_2]$ **2** are illustrated in Figs 3 and 4, respectively. Selected structural parameters are listed in Tables 2 and 3.

The dinuclear anion of **1** consists of two equivalent molecular fragments related by a crystallographic inversion center. The two Pd, four S, two O atoms and the two phenyl rings in the terminal ligands are essentially coplanar, while the planes of the two phenyl rings in the bridging ligands are tilted by 68.6° from the $mp_2Pd_2S_2$ plane. The structure is quite similar to that reported for $(Et_4N)_2[Ni_2(mp)_2(Hmp)_2]$ [2].

The molecule of **2**, which is also quite similar to that of $[Ni(mpo)_2]$ [8], has a palladium atom in the centre of the nearly square planar PdS_2O_2 unit with the two mpo ligands in the *cis* configuration. The whole molecule exhibits a *pseudo*-C_{2v} symmetry with

the C_2 axis passing through the palladium atom and the mid-points of S(1)···S(2) and O(1)···O(2).

The Pd—S bond length of av. 2.412 Å of **2** are somewhat longer than those terminal (2.280 Å) and bridging (av. 2.322 Å) Pd—S bonds of **1**, and than that reported (2.296 Å) [25]. The Pd—O bond of av. 2.043 Å in **2** is also slightly longer than that in **1** (2.009 Å) and that in the tetrachlorocatechol complex $[Pd(C_6Cl_4O_2)(PPh_3)_2]$ (av. 2.033 Å) [26], and than the values reported for $[Pd\{PhC(O)CC(O)Me\}_2]$ (1.98 Å) [27]. The long Pd···Pd* distance of 3.404(1) Å indicates that a Pd···Pd* bonding interaction seems unlikely. The relatively short C—S distances (av. 1.73 Å) in **2** show partial double bond character as they are nearly 0.1 Å shorter than the normal covalent distance (1.81 Å) [28] for a C—S single bond, and also definitely shorter by 0.04–0.05 Å than that in **1**. This feature results in the fact that complexes with mpo ligands have little ability to bridge another metal ion through the sulfur atom to form polynuclear complexes. The bite angles O—Pd—S of **2** (85.6°) are smaller than that in **1** (86.6°). The Pd—S—C angle of 96.8° for **1** of the terminal ligand, and of 98.0° (average) for **2** show the bonding orbital of the chelating sulfur atoms are mainly of *p* character, and the oxygen atom of Pd—O—C (118.0°) in **1** and of Pd—O—N (115.8°) in **2** show more of sp^2 character.

Table 3. Selected atomic distances (Å) and bond angles (°) for $[Pd(mpo)_2]$, **2**

Theoretical calculations

The Pd—O bonds with the average bond order 0.275 and 0.277 for **1** and **2**, respectively, are a lot weaker than the Pd—S bonds (av. 0.458 and 0.408 for **1** and **2**, respectively).

The HOMO at −10.806 eV of the anion of **1** consisting of the atomic orbital: Pd(1.4%), O(3.4%), S(17.6%) and C(74.8%), shows that the HOMO involves 23% *d-p* π component and 77% C—C π component. The LUMO at −9.469 eV contains the atomic orbital: Pd(36.9%), O(23.6%) and S(37.2%), in which *d-p* π* character is obvious.

The HOMO at −11.380 eV of **2** contains: Pd(3.9%), O(33.1%), S(24.4%) and C(34.9%), involving 63.7% *d-p* π and 36.3% C—C π components. Similar to that of **1**, the LUMO at −9.466 eV consisting of the atomic orbitals: Pd(33.8%), O(16.5%) and S(42.3%), shows also significant *d-p* π* character.

The facts mentioned above indicate that there are some large delocalized π bonds extending in the $(mp)_2Pd_2S_2$ plane in **1** and in the $Pd(mpo)_2$ plane in **2**. The energy gap (1.915 eV) between LUMO and HOMO in the anion of **1** is larger than that of **2** (1.337 eV), which suggests that the mixing of the *d-p* π with π of the phenyl ring is better in **1** than in **2**.

Abstract—Addition of $Pt_2(PPh_3)_4(\mu\text{-}S)_2$, **1**, to an equimolar quantity of $Cu(NO_3)(PPh_3)_2$ gave $[CuPt_2(PPh_3)_5(\mu_3\text{-}S)_2]NO_3$, **2a**, which readily reacted with NH_4PF_6 giving $[CuPt_2(PPh_3)_5(\mu_3\text{-}S)_2]PF_6$, **2b**. Further addition of a molar equivalent of **1** to **2b** gave rise to a pentanuclear $\{CuPt_4\}$ complex of $[Cu\{Pt_2(PPh_3)_4(\mu_3\text{-}S)_2\}_2]PF_6$, **3**. Complex **3** was also obtained from the direct 2 : 1 addition of **1** to $[Cu(CH_3CN)_4]PF_6$. Complexes **2** and **3** have been characterized by IR and $^{31}P\text{-}\{^1H\}$ NMR spectroscopy and in the case of **2b** single crystal X-ray crystallography. The geometry of Cu^{I} in **2b** is three-coordinate and Y-shaped. It represents the first crystallographically characterized mixed-metal complex of **1** with a trigonal-planar heterometal. The unexpectedly short non-bonding Cu—Pt distances (av. 2.869(4) Å) are associated with a more open $\{Pt_2S_2\}$ butterfly core (θ 137.5(5)°). Some theoretical aspects of these geometric peculiarities are discussed. Copyright © 1996 Elsevier Science Ltd

Keywords: copper; platinum; sulfide; aggregate; crystal structure; phosphine.

Designed syntheses of heterometallic platinum sulfide complexes have been established with the use of $Pt_2(PPh_3)_4(\mu\text{-}S)_2$, **1**, as a versatile metalloligand [1–10]. With appropriate Lewis acids, polynuclear aggregates with 3 [1–8], 4 [8], 5 [9], and 6 [10] metal centres can be assembled. The butterfly-shape of the dithiol ligand with a changeable bite angle and a flexible hinge angle stabilizes a variety of geometries of the heterometal (M) (e.g. linear [8], angular [4], T-shaped [10], tetrahedral [5, 6, 9], square-planar [1, 2, 9], square pyramidal [6], trigonal bipyramidal [7] etc.). Its ability to function as a unidentate [8], bridging [10] and chelating ligand [1–7, 9], coupled with an adjustable flow of electron donation/acceptance of the phosphines and thiol centres [11] further makes this one of the most powerful metalloligands known to date.

All the polyheterometallics assembled from **1** do not show active metal–metal interaction (hence the term "aggregates" [1a]), with $[Ag_2\{Pt_2(PPh_3)_4(\mu_3\text{-}S)_2\}_2]^{2+}$ [10] as the only notable exception (Ag—Ag 2.815(4) Å). The metal centres are generally brought to vicinity ($\geq$3.0 Å) by capping sulfur ligands. In this paper, we report the activity of **1** towards Cu^{I} to give $[CuPt_2(PPh_3)_5(\mu_3\text{-}S)_2]^+$, **2**, which captures another molecule of **1** in an aggregate expansion reaction to give $[Cu\{Pt_2(PPh_3)_4(\mu_3\text{-}S)_2\}_2]^+$, **3**. There is no crystallographic report in the literature that **1** can function

* Authors to whom correspondence should be addressed.

as a chelating ligand on a metal which favors a trigonal-planar geometry. The bite angle of **1** among the aggregates is found to be largest in $[GaPt_2Cl_2(PPh_3)_4(\mu_3\text{-}S)_2]^+$ (83.9(1)°) [6], which is still significantly smaller than the ideal trigonal-planar angle of 120°. The inter-relationship of the chelate bite, dihedral angle of the $\{Pt_2S_2\}$ butterfly, and the metal–metal distance is discussed in this paper.

RESULTS AND DISCUSSION

Mixing of $Cu(NO_3)(PPh_3)_2$ with **1** (1 : 1 molar ratio) in MeOH gives an addition compound $[CuPt_2(PPh_3)_5(\mu_3\text{-}S)_2]NO_3$, **2a**. The product shows typical (1 : 1) ionic behavior in MeOH and the ionic nitrate group is verified by a strong IR band at 1384 cm^{-1}. The intensity ratio of the Cu- and Pt-coordinated phosphines is approximately 1 : 4 in the $^{31}P\text{-}\{^1H\}$ NMR spectrum. Complex **2a** undergoes metathesis easily with NH_4PF_6 to give $[CuPt_2(PPh_3)_5(\mu_3\text{-}S)_2]PF_6$, **2b**. Both **2a** and **2b** slowly decompose in solution (e.g. in THF and CH_2Cl_2) in air to give an unknown deep-blue complex, presumably a Cu^{II} species. This decomposition is probably facilitated by phosphine dissociation as it is inhibited by doping of the solution with excess PPh_3. There is, however, no evidence for phosphine addition to **2**. The complex is also inert to displacement of PPh_3 by a bidentate phosphine such as dppe or dppf (dppf = 1,1′-bis(diphenylphosphino) ferrocene). However, displacement by an additional molar equivalent of **1** rapidly occurs to give $[Cu\{Pt_2(PPh_3)_4(\mu_3\text{-}S)_2\}_2]^+$, **3**. Such rapid displacement of a good σ-donor such as PPh_3 was not expected. The chelating ability of **1** on Cu^I appears to provide some stability to **3**. Similar pentametallic complexes with two chelating ligands of **1** coordinated to a central metal have been reported for Ni^{II}, Hg^{II}, and Pd^{II} [9, 12]. They are almost invariably synthesized from a Lewis acid with good labile ligands such as PhCN or Me_2S. Complex **3** can also be obtained from the reaction of **1** with $[Cu(CH_3CN)_4]^+$ in 2 : 1 molar ratio.

A single-crystal X-ray diffraction study was carried out on **2b**. Data collection and refinement are summarized in Table 1. Selected bond lengths and angles are listed in Tables 2 and 3, respectively. The structure shows a near-symmetrical chelation of the dithiol ligand **1** on a Cu^I centre with PPh_3 completing a trigonal planar configuration (Fig. 1). With an acute bite angle ∠S(1)—Cu—S(2) of 84.6(2)° and two similar but significantly larger angles ∠P(3)—Cu—S (139.4(2) and 135.7(2)°), the local geometry is best described as "Y-shaped". Such geometry (trigonal planar or Y-shaped) has not been found among the vast variety of mixed-metal aggregates formed from **1**. Similar complexes formed from AuCl and $AuCl(PPh_3)$ give two-coordinate linear Au^I or a distorted linear geometry with Au strongly bonded to one sulfur and weakly to the other [8]. On the contrary, the heterometal atom, *viz.* Cu in **2b** is approximately equidistant to both sulfur atoms (Cu—(μ_3-S) 2.269(5) and 2.303(5) Å). These lengths (av. 2.286(5) Å) are marginally longer than those of Cu—(μ_3-S) in $[PPh_4]_2[Cu_3WCl_3(\mu\text{-}S)_2(\mu_3\text{-}S)_2]$ [13] (ranging from 2.247(5) to 2.279(5) Å) and those in $[Cu(SP(CH_3)_3)Cl]_3$ [14] (av. 2.265(1) Å), but significantly shorter than those in $[Et_4N][(Ph_3P)_2Cu(\mu\text{-}S)_2W(\mu\text{-}S)_2FeCl_2]$ [15] (av. 2.374(2) Å).

Other bonding features of **2b** are comparable to those found in the other heterometallics except that the non-bonding distances of Cu···Pt is unexpectedly short (av. 2.869(2) Å). This distance is significantly shorter than the Co—Pt distances (3.066(4) Å) in the related $[CoPt_2Cl_2(PPh_3)_4(\mu_3\text{-}S)_2]$ [5] although the atomic size of Co (1.28 Å) and Cu (1.3 Å) are similar [16]. The shorter Cu···Pt separation is especially peculiar when one considers that the oxidization state of Cu^I is lower than that of Co^{II}. Other similar aggregates invariably show typical non-bonding M···Pt separations, e.g. Ag···Pt distances in $[Ag_2\{Pt_2(PPh_3)_4(\mu_3\text{-}S)_2\}_2][PF_6]_2$ [10] range from 3.450(3) to 3.905(3) Å. Nevertheless, with a triangular core comprising 16-

Pt(2)···Cu(3)	2.864(2)		

Scheme 1. Addition reaction of $Pt_2(PPh_3)_4(\mu\text{-}S)_2$ with Cu^I. (*i*) $Cu(NO_3)(PPh_3)_2$ (1 : 1 molar ratio to **1**); (*ii*) $[Cu(CH_3CN)_4]PF_6$ (1 : 2 molar ratio to **1**); (*iii*) **1**; P = PPh_3.

electron sq-planar Pt^{II} and trigonal-planar Cu^I, no Pt—Pt or Cu—Pt bond is envisaged.

Another peculiar feature is the large hinge angle of the $\{Pt_2S_2\}$ butterfly core along the S···S axis. This angle is a subject of our recent discussion; it shows a linear relationship with the atomic radii of the heteroatoms [11]. With Cu (At. Rad. 1.28, Cov. Rad. 1.38 Å) and Ga (At. Rad. 1.4, Cov. Rad. 1.26 Å) [17] being similar in size, it is surprising that the $\{Pt_2S_2\}$ hinge angle in **2b** (137.5(5)°) is significantly larger than that in $[GaPt_2Cl_2(PPh_3)_4(\mu_3\text{-}S)_2]^+$ (123.1(2)°) [6].

In an attempt to gain insight into some structural aspects of the molecule, notably the short Cu···Pt distances and the unexpectedly large $\{Pt_2S_2\}$ dihedral angle, we have performed Fenske–Hall MO calculations [18]. The calculated overlap populations indicate no bonds between the Cu and Pt atoms. It may thus be inferred that the short distances are due to the Cu—S bonds and the large dihedral angle.

Why then is the dihedral angle larger than expected, and does it not follow the trend of the angle increasing with the size of the heterometal? A clue can be found in the high percentage of sulfur p_z orbital (see details of alignment [19]) used in Cu—S bonding (78.0 and 75.6% compared to 54.6 and 56.3% for the $GaCl_2^+$ adduct [6], in which the M—S bond lengths are about the same, 2.296 and 2.292 Å; in both cases the dihedral angle was set at 123.1°). It has been shown [11] that the percentage of sulfur p_z in the lone pair orbital used to interact with the heterometal increases with the size of the dihedral angle. Thus, the large dihedral angle in **2b** is consistent with the higher percentage of sulfur p_z needed to bind to Cu.

The question then naturally arises as to possible reasons for the latter. A compelling reason is that unlike all the other compounds considered in the past, Cu has a ligand coordinated along the z-axis.* Good σ- and moderate π-interaction between Cu and PPh_3, along with the fact that the S—Cu—S angle is extremely small for a trigonal planar geometry, suggest that the Cu p_z orbital is more involved in bonding to PPh_3 (Table 4), at the expense of the Cu—S bonds, which could also use some interaction involving Cu p_z. (This may account for the weak Cu—S bonds). The Cu p_y orbital, on the other hand, is relatively available; from geometrical considerations, this orbital alone interacts best with the sulfur p_z orbitals, hence the increased use of the latter. In support of the foregoing argument, the ratio of the partial heterometal p_z/p_y to sulfur overlap populations is 0.52 on average for **2b** (dihedral angle adjusted to 123.1°), while for the Ga compound the ratio is 0.62.

Another relevant observation is that, in all the compounds considered in the past (including a $CoCl_2$ adduct [5]), the heterometal uses its d_{yz} orbitals, in

* Also, PPh_3 is neutral and not negative like the ligands in the other compounds; at this point the authors are unsure about the effects of ligand charge.

Table 3. Selected bond angles (°) for $[CuPt_2(PPh_3)_5(\mu_3\text{-}S)_2]PF_6$, **2b**

P(3)—Cu(3)—S(1)	135.7(2)	P(3)—Cu(3)—S(2)	139.4(4)

P(2B)—Pt(2)—P(2A)	101.9(2)	Pt(1)—S(1)—Pt(2)	89.9(2)
Pt(2)—S(2)—Pt(1)	89.7(2)		

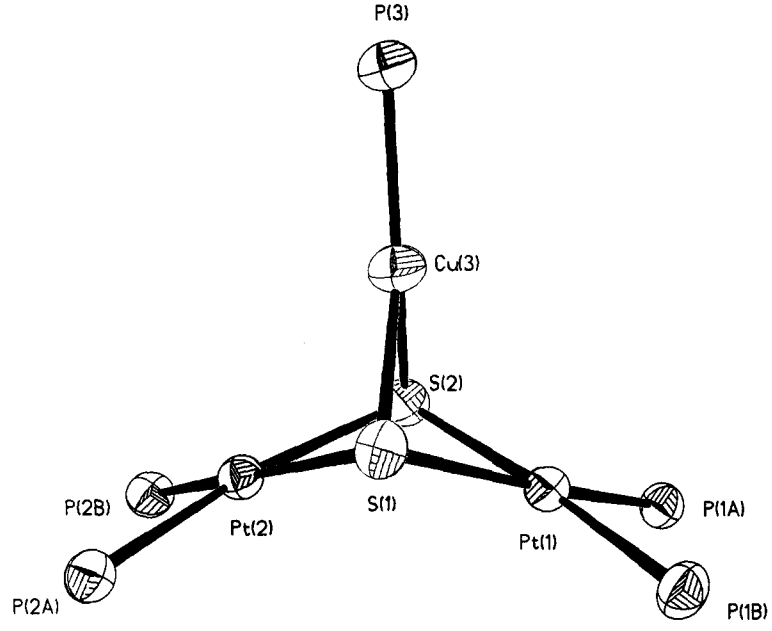

Fig. 1. ORTEP plot of the structure of the molecular cation in $[CuPt_2(PPh_3)_5(\mu_3\text{-}S)_2]PF_6$, **2b** (phenyl groups omitted for clarity).

addition to its *s* and *p* orbitals, to bind to sulfur. Note that this is possible for d^7 Co^{II} since the d_{yz} orbital is less than half-filled. (The d_{xz} orbital, which is Co—Cl antibonding and mixes a little with the d_{yz} orbital, is empty.) In contrast, all the *d* orbitals in Cu^I are filled, and thus cannot be used for σ-bonding. Use of the d_{yz} orbital may result in a high percentage of sulfur p_y.

Recent theoretical work [20] by Capdevila *et al.* on $Pt_2(PPh_3)_4(\mu\text{-}S)_2$ and its alkyl adducts demonstrated that the energetic cost of varying the dihedral angle is relatively small. From our experience in dealing with adducts of $Pt_2(PPh_3)_4(\mu\text{-}S)_2$ in which the heterometal caps the two sulfur ligands, we have found quite generally [21] that as the dihedral angle decreases, the Pt—S overlap populations decrease, whilst those between the heterometal and sulfur increase. This observation, which holds true for this work (see Cu—S overlap population in Table 4), could account for the shorter Pt—S bonds in **2b** than in the $GaCl_2^+$ adduct (average 2.388 Å). It also implies that the Cu—S bonds are relatively weak, thus offering an additional explanation for the easy decomposition of **2** in solution.

In a $BiCl_3$ adduct studied earlier, it was found that the Bi—Cl bonds became stronger as the dihedral angle increases* [21]. In contrast, the Cu—P overlap population decreases (see Table 4); this is partly due to the increased use of the Cu p_z orbital to bind to the S p_y orbitals. The latter are made more available

* We have not calculated this for the other compounds.

Table 4. Relevant overlap populations for $[CuPt_2(PPh_3)_5(\mu_3\text{-}S)_2]^+$, with $\{Pt_2S_2\}$ dihedral angle at 137.5° (experimental value) and 123.1° (angle for $[GaPt_2Cl_2(PPh_3)_4(\mu_3\text{-}S)_2]^+$ in which the M—S bond lengths are about the same as in the present case). Calculations for an intermediate value are consistent with the trend

Dihedral angle	137.5	123.1
Cu—P	0.3931	0.3912
Cu p_z—P	0.2394	0.2379
Cu—S	0.1760	0.1833
	0.2014	0.2078
Cu—S p_y	0.0381	0.0432
	0.0409	0.0458
Cu—S p_z	0.1429	0.1429
	0.1579	0.157
Cu p_y—S	0.0732	0.0733
	0.0746	0.0736
Cu p_z—S	0.0302	0.0334
	0.0397	0.0430

because of less utilization in binding to Pt when the dihedral angle decreases. It is likely that the opening up of the dihedral angle is due to an effort to optimize the Cu—P interaction, which, from Table 4, appears to be significantly stronger than the Cu—S bonds.

EXPERIMENTAL

Materials and Methods

All reactions were performed in air. All solvents were analytical grade and were used without further purification. $Pt_2(PPh_3)_4(\mu\text{-}S)_2$ [22], $Cu(NO_3)(PPh_3)_2$ [23] and $[Cu(CH_3CN)_4]PF_6$ [24] were synthesized according to literature methods. Elemental analyses were conducted in the Microanalytical Laboratory in our department. $^{31}P\text{-}\{^1H\}$ NMR spectra were run on a Bruker ACF 300 spectrometer with H_3PO_4 as external reference at 298 K. Infrared spectra were taken in KBr disc on a Perkin-Elmer 1600 FT-IR spectrophotometer. Conductivity was measured by using a STEM Conductivity 1000 meter.

Synthesis of $[CuPt_2(PPh_3)_5(\mu_3\text{-}S)_2]X$ (X = NO_3^-, **2a**, PF_6^-, **2b**)

$Pt_2(PPh_3)_4(\mu\text{-}S)_2$ (0.15 g, 0.1 mmol) was added to the solution of $Cu(NO_3)(PPh_3)_2$ (0.066 g, 0.1 mmol) in MeOH (10 cm^3). The orange suspension was stirred for a few min to give a clear orange solution. After stirring further for 30 min to ensure complete reaction, the solution was filtered and the filtrate was evaporated to dryness *in vacuo* to obtain a crude orange product. This product was purified by recrystallization from CH_2Cl_2/hexane to yield **2a** (0.151 g, 70%). (Found: C 56.2; H 4.0; Cu 3.2; N 0.8; P 7.7; Pt 19.1; S 3.6. Calc. for $C_{90}H_{75}CuNO_3P_5Pt_2S_2$: C 57.2; H 4.0; Cu 3.4; N 0.7; P 8.2; Pt 20.6; S 3.4%). $\nu(NO_3^-)$ 1384s cm^{-1}. Λ_m (10^{-3} M, MeOH) 76 ohm^{-1} cm^2 mol^{-1}. δp ($CDCl_3$) 20.7 (4P, t, ^1J(P—Pt) = 3104 Hz, ^3J(P—Pt) = 22 Hz) and 1.9 (1P, s).

$[CuPt_2(PPh_3)_5(\mu_3\text{-}S)_2]PF_6$, **2b** was prepared by treating **2a** with NH_4PF_6 in MeOH. (Found: C 54.8; H 3.7; P 10.2; S 3.3. Calc. for $C_{90}H_{75}CuF_6P_6Pt_2S_2$: C 54.8; H 3.8; P 9.5; S 3.2%). $\nu(PF_6^-)$ 839 vs cm^{-1}.

Synthesis of $[Cu\{Pt_2(PPh_3)_4(\mu_3\text{-}S)_2\}_2]PF_6$, **3**

To a suspension of **1** (0.15 g, 0.1 mmol) in CH_3CN (20 cm^3) was added with stirring $[Cu(CH_3CN)_4]PF_6$ (0.019 g, 0.05 mmol). The orange suspension turned dark-blue immediately. After the mixture was stirred for 10 min, the suspension dissolved completely to result in a red-brown solution. Further stirring for 2 h was followed by filtration, after which the filtrate was concentrated *in vacuo* to *ca* 10 cm^3. Addition of Et_2O gave rise to a red–brown precipitate which was isolated and purified by recrystallization from CH_2Cl_2/hexane to yield **3** (0.101 g, 60%). (Found: C 53.4; H 3.7; Cu 1.9; P 8.4; Pt, 21.5; S 4.2. Calc. for $C_{144}H_{120}CuF_6P_9Pt_4S_4$: C 53.8; H 3.7; Cu 2.0; P 8.7; Pt, 24.3; S 4.0%). δp ($CDCl_3$) 5.81 (t, ^1J(P—Pt) = 4023 Hz), $\nu(PF_6^-)$ 839 vs cm^{-1}.

Complex **3** could be similarly obtained by stirring **1** (0.075 g, 0.05 mmol) with **2b** (0.098 g, 0.05 mmol) in THF (15 cm^3) for 1 h. The resultant clear red-brown solution was similarly treated to obtain **3** (0.070 g, 41%).

X-ray crystallography of complex **2b**

Orange single crystals of **2b** were obtained by slow evaporation of a sample solution in CH_2Cl_2/MeOH (1:3) in air. A crystal with approximate dimensions of 0.13 × 0.20 × 0.32 mm was used for structure determination. Data collection was performed at 293(2) K with Mo-K_α radiation (λ = 0.71073 Å) on a Siemens R3m/v diffractometer equipped with a graphite monochromator and ω-2θ scan mode. Unit cell parameters were determined using 20 reflections obtained from a random search routine. Two intensity standards were measured every 98 reflections; no significant variation of intensity was observed. The data were corrected for Lorentz and polarization effects; semi-empirical absorption correction was also applied.

The structure was solved by direct methods and difference Fourier maps. Full-matrix least-squares refinement was carried out with anisotropic temperature factor for all non-hydrogen atoms. Hydrogen atoms were placed on calculated positions (C—H 0.96 Å) and assigned isotropic thermal parameters riding on their parent atoms. Initial calculations were carried out on a PC using SHELXTL PC software package; SHELXL-93 [25] was used for the final refinement.

Electronic and bonding properties of mixed-ligand copper(II) complexes of *N*-(2-picolyl)picolinamide (pmpa). X-ray crystal structures of [Cu(pmpa)(4-methylimidazole)(H_2O)](H_2O)(ClO_4) and [Cu(pmpa)(4-methylpyridine)(H_2O)](H_2O)(ClO_4)

(Received 24 May 1996; accepted 19 June 1996)

Abstract—Mixed-ligand *N*-(2-picolyl)picolinamidocopper(II) complexes, [Cu(pmpa)(L)(X)·nH_2O] [pmpa = *N*-(2-picolyl)picolinamide anion; L = imidazole (n = 0, 1 or 2), *N*-methylimidazole (n = 0 or 1), 4-methylimidazole (4MImH) (n = 0 or 2), pyridine (n = 0), 2-methylpyridine (n = 0), 3-methylpyridine (n = 0), 4-methylpyridine (4Mpy) (n = 2), and NH_3 (n = 2); X = ClO_4^- or BF_4^-], have been synthesized and characterized by elemental analyses, and electronic, vibrational, and EPR spectroscopic measurements. Molecular structures of [Cu(pmpa)(4MImH)(H_2O)](H_2O)(ClO_4) (**1**) and [Cu(pmpa)(4Mpy)(H_2O)](H_2O)(ClO_4) (**2**) have been determined by X-ray diffraction methods. Both complexes are square pyramidal with the pmpa and the heterocyclic unidentate ligands forming the basal plane and a H_2O molecule on the apical position. The dihedral angles of the heterocyclic unidentate nucleus and the CuN_4 basal plane are 79.3° for **1** and 74.5° for **2**. The structures of other pmpa complexes are suggested to be square pyramidal or square planar based on their spectroscopic data. The sequence of d orbitals is assigned as $d_{x^2-y^2} \gg d_{z^2} > d_{yz} > d_{xy} > d_{xz}$ for the square pyramidal complexes and $d_{x^2-y^2} \gg d_{yz} > d_{xy} > d_{xz} > d_{z^2}$ for the square planar complexes. The significant rise in energy of the d_{yz} orbital suggests that the central amido of the pmpa ligand is a strong π-donor. Copyright © 1996 Elsevier Science Ltd

Keywords: *N*-(2-picolyl)picolinamidocopper(II) complexes; X-ray structures; visible spectra; EPR spectra; bonding; Gaussian analysis.

In the course of our studies on copper(II)—N bonding properties in mixed-ligand copper(II) complexes containing a tridentate and a heterocyclic unidentate ligand, we have found that the structures of these complexes and the orientations of the heterocyclic nuclei vary depending on the bonding abilities of the tridentate ligands. Thus, the diethylenetriamine (dien) complex, [Cu(dien)(4-methylimidazole)(ClO_4)$_2$] [1], has an elongated octahedral structure with the heterocyclic ring of the unidentate ligand tilted by 41.2° from the CuN_4 coordination plane, whereas the elongated octahedral terpyridine (terpy) complex, [Cu(terpy)(4-methylimidazole)(H_2O)(BF_4)](BF_4) [2], and the square pyramidal glycylglycinato (glygly) complex, [Cu(glygly)(acetylhistamine)] [3], have the corresponding imidazole nucleus lying nearly perpendicular and parallel, respectively, to the [Cu(tridentate)(heterocyclic unidentate)] coordination plane. The variation in orientation of the unidentate heterocyclic nuclei has been ascribed to the π-bonding abilities of the tridentate ligands, specifically, the central donating moieties *trans* to the unidentate ligand. Based on the Gaussian resolved d–d spectra, the central pyridine of terpyridine is suggested a π-acceptor and the central amido of glycylglycinate is a π-donor.

* Author to whom correspondence should be addressed.

Recently, we have found that the dianionic dipicolinato (dipic) complex, [Cu(dipic)(*N*-methylimidazole)] [4], has a square planar structure with the imidazole ring coplanar with the coordination plane. The dipicolinate has been suggested to be a π-donor. Since pyridine type ligands are potential π-acceptors [5, 6], the drastic change in the π-bonding capability has been attributed to the ionic bonding in the dipicolinato complex.

Because of the importance of peptide complexes in biological systems, studies have been focused on the bonding properties of the anionic amido moiety to reveal the origin of its π-donating ability. Herein, we report the structures and spectroscopic properties of mixed-ligand *N*-(2-picolyl)picolinamidocopper(II) complexes and elucidate their electronic structures and bonding properties.

EXPERIMENTAL

Materials and preparations

Picolinic acid (Aldrich), 2-(aminomethyl)pyridine (Aldrich), *N*-methylimidazole (Aldrich), 4-methylimidazole (Merck), imidazole (Merck), 2-methylpyridine (TCI), 3-methylpyridine (TCI), 4-methylpyridine (TCI), pyridine (Merck), $POCl_3$ (Merck), $Cu(ClO_4)_2 \cdot 6H_2O$ (Aldrich), and organic solvents were used as received. $Cu(BF_4)_2 \cdot 6H_2O$ was prepared from CuO and HBF_4.

N-(2-picolyl)picolinamide [7] was prepared as follows: to an anhydrous dichloromethane (100 cm^3) solution of picolinic acid (6.16 g, 0.05 mole), triethylamine (5.05 g, 0.05 mole) and 2-(aminomethyl)pyridine (5.40 g, 0.05 mole), phosphorus oxychloride (7.67 g, 0.05 mole) in dichloromethane (40 cm^3) was added dropwise with constant stirring at 0°C. An additional amount of triethylamine (10.1 g, 0.1 mole) was added. After reaction at 0°C for 1.5 h and at room temperature for an additional 1 h, the contents were neutralized with aqueous sodium bicarbonate. The organic layer was separated and evaporated to give a viscous residue. Yield, 7.65 g (72%).

The pmpa complexes were prepared by the following general procedure: To a CH_3OH solution (10 cm^3) of $Cu(ClO_4)_2 \cdot 6H_2O$ (0.37 g, 1 mmol) and the unidentate ligand (2 mmol), *N*-(2-picolyl)picolinamide (0.21 g, 1 mmol) in CH_3OH (5 cm^3) was added. After reaction for 2 h, the solution was stored overnight to yield crystalline products, which were filtered and washed with ether and dried *in vacuo* over P_4O_{10}.

[Cu(pmpa)(py)(ClO_4)]. Purple. Yield 82%. M.p. 210°C (dec). IR (cm^{-1}): ν (amido) 1640 s, 1609 s, 1601 s; ν (ClO_4) 1094 vs, 932 m, 623 s; δ (py) 432 m; ν [Cu—N(pmpa)] 359 m, 284 m, 255 m; ν [Cu—N(py)] 318 m. Found: C, 44.2; H, 3.3; N, 11.9. Physical measurements

IR spectra were recorded as Nujol mulls or KBr pellets on a BIO-RAD FTS-40 FTIR spectrometer. GBC 914 and Hitachi U-3501 spectrophotometers were used for electronic spectra measurement. Solid samples were recorded as Nujol mulls on Whatman No. 1 filter paper. EPR spectra were obtained by using a Bruker ER 200D spectrometer and calibrated with DPPH ($g = 2.0037$). A VAX 3300 computer-controlled Enraf-Nonius CAD-4 diffractometer was used for crystal data collection. Elemental analyses were carried out by the microanalysis laboratories of Taiwan University, Taipei.

Structure determination and refinement

Details of crystal data and processing parameters are summarized in Table 1. Twenty-five independent reflections with $12.26 \leqslant 2\theta \leqslant 28.44°$ for **1** and $21.46 \leqslant 2\theta \leqslant 30.46$ for **2** were used for least-squares determination of the crystal systems and the cell constants. Diffractometer examination of the reciprocal lattice showed the space group to be $P\bar{1}$ for both complexes. Intensity data (ω-θ scan, $2\theta \leqslant 50$) were collected at 298 K for four octants of the sphere ($0 \leqslant h \leqslant 8$, $-12 \leqslant k \leqslant 12$, $-15 \leqslant l \leqslant 16$ for **1**; $0 \leqslant h \leqslant 8$, $-12 \leqslant k \leqslant 12$, $-15 \leqslant l \leqslant 15$ for **2**), and corrected for Lorentz and polarization effects, but not for absorption. Three standard reflections were monitored every 2 h and showed no signs of crystal deterioration. The structures were solved by direct methods using Personal SDP software incorporated SIR for **1** and SHELXS for **2** [8-10] and refined by full-matrix least-squares on F values. Scattering factors and anomalous dispersion correction terms were taken from the *International Tables for X-ray Crys-*

tallography [11]. The hydrogen atoms included in the refinement were located in succeeding difference Fourier syntheses after the non-hydrogen atoms were refined anisotropically. All calculations were done on a 80486/33 PC. Additional material deposited comprises structure factors, atomic coordinates, anisotropic thermal parameters, and a full list of bond lengths and angles.

RESULTS AND DISCUSSION

Description of structures

The molecular structures of the 4-methylimidazole complex **1** and the 4-methylpyridine complex **2** are shown in Figs 1 and 2, respectively. Selected bond lengths and angles are listed in Table 2. Their structures are very similar. The copper(II) ions are bound by the tridentate anionic pmpa and a unidentate N-donor ligand forming a basal plane and a H_2O on the z axis to complete a [4 + 1] elongated square pyramidal structure. The copper(II) ions are slightly above the CuN_4 plane in both complexes. The deviations from the least-squares plane through the CuN_4 atoms are N(1) −0.0029, N(2) −0.0557, N(3) −0.0044, N(4) −0.0554 and Cu 0.1184 Å for **1** and N(1) −0.0384, N(2) −0.0208, N(3) −0.0390, N(4) −0.0310 and Cu 0.1293 Å for **2**. Their Cu—N bond lengths of *ca* 2.0 Å for the two terminal pyridines of pmpa are comparable to the usual Cu—N(py) bond lengths [12–15], but the Cu—N(amido) distances of 1.910(4) Å for **1** and 1.904(4) Å for **2** are short. The bite angles of the pmpa ligand are *ca* 81°. The unidentate N-donor ligands of both complexes are bound somewhat tightly [1.960(4) Å for **1** and 1.986(4) Å for **2**] and are nearly perpendicular to the CuN_4 plane [dihedral angle 79.3° for **1** and 74.5° for **2**]. There are hydrogen bonds between the H_2O molecules, O(6)—O(7), 2.875 Å for **1** and 2.686 Å for **2**, and between the perchlorate and the imidazole ligand, N(5)—O(5) 2.955 Å, in complex **1**. The bond lengths and angles of the ligands are in the normal ranges. It is noteworthy that the amide C=O of 1.26 Å and C—N of 1.31 Å are the same as those observed in [Cu(glygly)(acetylhistamine)] (C=O, 1.257(7) Å; C—N, 1.310(7) Å) [3]. This is a good indication of π-delocalization through the N—C—O amide skeleton for these complexes. Moreover, the very short Cu—N(amido) distances in these three complexes strongly imply the analogy in their bonding modes. The dimensions of the perchlorate anions are also normal, but the thermal vibrations are large for the perchlorate in complex **2**.

Spectroscopic studies

The visible and EPR spectroscopic data for the pmpa copper(II) complexes are listed in Table 3. The complexes exhibiting a single broad band in their solid state mull spectra can be divided into two groups: one with the λ_{max} at 581 to 606 nm and the other at 554 to 574 nm. Both complexes **1** and **2** belong to the former group suggesting that the structures of these complexes are square pyramidal. The apical H_2O molecule

of the water containing complexes of the first group can be identified by the appearance of one or two sharp OH stretching peaks in the 3500 cm^{-1} region. The latter group, consisting of complexes mainly with a pmpa and a unidentate ligand, is likely of square planar structure in agreement with the strong ligand field strengths. The structure of [Cu(pmpa)(2Mpy)(ClO_4)], however, is believed to be square pyramidal due to its λ_{max} at 601 nm. The complexes, [Cu(pmpa)(NMIm)](ClO_4)(H_2O) and [Cu(pmpa)(NH_3)](ClO_4)(H_2O)$_2$, are also square planar because of their high ligand field strengths. In addition, the water molecules are probably not bound to the central copper, because no sharp O—H stretching peaks appear in the 3500 cm^{-1} region. In methanol solution, all of the complexes show λ_{max} in the 600 nm region indicating coordination of solvent molecules to give square pyramidal structures.

The powder EPR spectra are generally of axial type [16], namely, $g_\parallel > g_\perp > 2$. Some square planar complexes showed exchange coupling. The spectra in methanol glass matrix exhibit the fine structures of rhombic spectral features. There are six superhyperfine components with relative intensities close to the values of 1 : 2 : 3 : 3 : 2 : 1 for the $A_\parallel$(Cu) and $A_\parallel$(N) and followed by another set of five components of 1 : 2 : 3 : 2 : 1 for the $A_\perp$(N) as illustrated in Fig. 3. It is proper to designate the y axis along the Cu—N

[d] Not observed.

[e] Exchange coupling.

(amido) in the CuN_4 plane and the x axis parallel to the direction of the two copper-pyridine (pmpa) bonds. Apparently, the bonding strengths along the x and y directions are different. The energy levels of d_{yz} and d_{xz} are, therefore, non-degenerate. For the NH_3 complex, the superhyperfine coupling is not obvious. Two sets of rhombic spectra were observed for the 2-methylpyridine complex. All of the g_z and A_z values are not much varied, suggesting that these complexes comprise a very similar CuN_4 square plane very much similar to those observed in complexes **1** and **2**.

The infrared spectra data for the pmpa complexes are given in the Experimental section. There are usually two relatively sharp O—H stretching absorptions in the 3500 cm^{-1} region assignable for H_2O molecule bound directly to the central copper ion analogous to the structures of complexes **1** and **2**. The amide CO and CN stretching peaks are lowered by *ca* 30–40 cm^{-1} as compared with those of the free ligand. The Cu—N (pmpa) stretches were tentatively assigned at *ca* 350, 280 and 250 cm^{-1} and the Cu—N stretches for the unidentate ligands at *ca* 320 cm^{-1}.

Electronic structures and bonding properties

The *d–d* spectra of the complexes were deconvoluted into Gaussian component bands. Starting from a set of four trial peaks, computer iteration processes for curve fitting were carried out until a minimum value of the reliability factor, R (see Table 4), was reached. Each of the complexes had an excellent fit with $R <$ *ca* 0.5% and showed a resulting set comprising four Gaussian peaks. Representative examples are shown in Fig. 4. The peak positions are presented in Table 4 along with their half-height widths and relative peak areas. Attempts to fit with three component peaks were less satisfactory; the R values were

higher. In addition, the rhombic EPR spectroscopic data of these complexes suggest nondegeneracy for the d_{xz} and d_{yz} orbitals.

Because the complexes consist of a common tridentate pmpa and a unidentate ligand in the coordination plane, the following effects are anticipate: first, the $d_{x^2-y^2}$ level, being most involved in the copper-unidentate ligand bonding, will be considerably varied in energy due to the bonding capabilities of the unidentate ligands in the xy plane, resulting in shifts for all of the d–d transitions; secondly, defining the y axis along the Cu—N(2) bond, the d_{yz} level will not be affected by changing the unidentate ligand and the shift in the $d_{yz} \rightarrow d_{x^2-y^2}$ will mainly reflect the varying of the $d_{x^2-y^2}$ level; thirdly, the d_{xz} level will virtually not be affected, because the two coordinated groups of the terminal pyridine moieties are alike in the x direction. The shift in the $d_{xz} \rightarrow d_{x^2-y^2}$ transition will again reflect the variation of the $d_{x^2-y^2}$ level; finally, the d_{xy} level may be affected by changing the unidentate ligands and the shift in the $d_{xy} \rightarrow d_{x^2-y^2}$ transition will reflect the variation of the π-bonding capabilities of the unidentate ligands.

In this context, the energy difference between the d_{xz} and d_{yz} levels is expected to be nearly constant for these mixed-ligand pmpa copper(II) complexes. Inspecting the Gaussian component peaks, the lowest energy peak in the square pyramidal complexes, and the highest energy peak in the square planar complexes, both having the smallest intensity, can be assigned as $d_{z^2} \rightarrow d_{x^2-y^2}$ transition as reported in many square pyramidal copper(II) complexes [16–19], and in square planar copper(II) complexes [4]. The energy differences between the highest and the lowest peaks of the remaining three peaks are 3.5 ± 0.1 kK. The sequence of the d orbitals is therefore designated as $d_{x^2-y^2} \gg d_{z^2} > d_{yz} > d_{xy} > d_{xz}$ for the square pyramidal complexes and as $d_{x^2-y^2} \gg d_{xz} > d_{xy} > d_{yz} > d_{z^2}$ for the square planar complexes. Although the energy differences between the d_{xy} and d_{xz} orbitals are also nearly constant (1.8 ± 0.1 kK), an alternative assignment is less likely. Because the bonding capabilities of the anionic amido are very similar for the pmpa and the glygly ligands (*vide supra*), a difference of 3.5 kK is reasonably in agreement with the value observed for the glygly complexes [3]. Strong π-interactions along the y axis are in accordance with the very short Cu—N(2) bonds.

Because the d_{xz} level is raised relative to the d_{yz} orbital, we conclude that the central amido moiety of the pmpa ligand is a strong π-donor in these complexes. This is analogous to the central amido moiety of the glycylglycinate ligand. But unlike the glygly complexes, the unidentate heterocyclic ligands in the pmpa complexes are nearly perpendicular to the equatorial coordination plane. Obviously, steric hindrance is the major factor preventing the heterocyclic nucleus from lying coplanarly with the equatorial coordination plane. Another difference is that preparation of glygly complexes containing pyridine type ligands, except 4-dimethylaminopyridine, has failed. It is likely that a π-donating ligand is required by the *trans* amido of glygly ligand. However, this is not the case in the present study. We suspect that the dianionic nature of the glygly ligand has important effects on the bondings. Further studies in this direction are in progress.

(Received 24 May 1996; accepted 18 June 1996)

Abstract—The synthesis of a series of Ru^{II} complexes with the thioether ligand [9]aneS_3 and various polypyridyl ligands was carried out using $[Ru(dmso)_4Cl_2]$ as a starting material. The first synthetic step involved the introduction of the thioether ligand and the isolation of the compound $[Ru([9]aneS_3)(dmso)Cl_2]$. The polypyridyl ligands were then exchanged to give a series of complexes $[Ru([9]aneS_3)(X)(Cl)]^+$ (X = 1,10-phenanthroline (phen), 2,2′-bipyridyl (bpy), 4,4′-diphenyl-2,2′,-bipyridyl (dbp) and 4,7′-diphenyl-1,10-phenanthroline (dip)). These complexes were characterised by NMR and UV spectra. The complexes with X = phen and bpy were crystallised and single crystal X-ray diffraction studies carried out. Distorted octahedral coordination geometry was observed for both complexes. The equatorial planes are formed by two macrocyclic sulfur donor atoms and two nitrogen atoms from polypyridyl ligands (bpy or phen). The hexa-co-ordination is achieved *via* a chlorine and the remaining sulfur, macrocyclic atom. The [9]aneS_3 macrocyclic ligand adopts a [333] facial arrangement. The results from NMR studies for $[Ru([9]aneS_3)(phen)Cl]^+$ and $[Ru([9]aneS_3)(bpy)Cl]^+$ indicate that both complexes exist as two forms in solution with C_S symmetry consistent with a [333] facial arrangement. Keywords: Ru^{II}; [9]aneS_3 complexes; polypyridyl ligands; crystal structures; NMR.

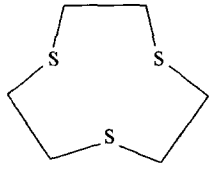
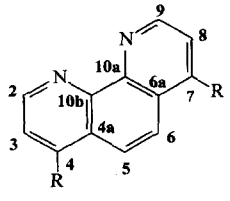
The interaction of ruthenium based compounds with DNA has seen much work over the last five years. Ruthenium polypyridyl complexes have been extensively studied following the work of Barton *et al.* [1] where the interaction of the two isomers of $[Ru(1,10\text{-phenanthroline})_2Cl_2]$ with B-DNA was explored. These studies [1–12] have found that there are a number of possible modes of interaction of Ru complexes with DNA, these include: intercalation, whereby the polypyridyl ligand is inserted (fully or partially) between the stacked bases of the DNA double helix, surface binding, within one of the DNA grooves, and covalent binding where ligands in the Ru complex are replaced by heteroatoms of the DNA bases (normally the nitrogen of guanine) [2]. Spectroscopic studies have proved to be especially useful in probing the interactions between the Ru complexes and DNA.



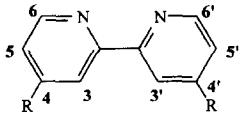
Following the work of Rosenberg *et al.* [13] in 1969 with *cis*-platin the search to find similar anti-tumor agents has been ceaseless. In the last few years, following the studies of Barton *et al.* a number of possible compounds of Ru have been discovered; Alessio *et al.* [14] found that *trans*-$[Ru(dmso)_4Cl_2]$ showed promising anti-tumor activity with adjacent guanines being the preferred interaction site on DNA while Keppler *et al.* [15] Carried out an extensive study of various Ru complexes finding that $[Ru(Im)_2Cl_4]$(ImH) and $[Ru(Ind)_2Cl_4](IndH)$, where Im = imidazole and Ind = indazole, show anti-tumor activity.

* Authors to whom correspondence should be addressed.



These *in vitro* studies of Ru complexes have shown that the number and type of polypyridyl, and ancillary ligands have a profound effect on the manner and type of interaction with biomolecules. Factors such as the ability of the ligands to form H-bonds or favourable VDW interactions with the functional groups of the DNA bases have been found to play a determining role in binding. A first step in the design of Ru complexes with selective DNA binding characteristics is the choice of a suitable ligand followed by the structural characterisation of the complex.

The use of macrocyclic polyamines and polythioethers in transition metal chemistry has been considerable as these ligands are thermodynamically and kinetically inert and also have the ability to stabilise unusual oxidation states (e.g. Rh^{II}) [16]. Krotz *et al.* [17] synthesised a series of Rh^{III} complexes with cyclic polyamines or [12]aneS_4 and a 9,10-diaminophenanthrene ligand in order to probe specific binding interactions to DNA. A systematic variation of thioether-polypyridyl ligands complexed to Ru^{II} would allow conclusions to be drawn as to the structural characteristics of these compounds and the role these play in DNA binding,the goal being the design of a complex with specific DNA binding characteristics. The first step in this process is, therefore, the synthesis and characterisation of the Ru^{II} based complexes followed by the determination of their three dimensional structure.



In this paper the synthesis (from $[Ru(dmso)_4Cl_2]$) of a number of $[Ru([9]aneS_3)(X)Cl]$ complexes (X = 1,10-phenanthroline (phen), 2,2′-bipyridyl (bpy), 4,4′-diphenyl-2,2′-bipyridyl (dbp) and 4,7′-diphenyl-1,10-phenanthroline (dip)) is reported along with their spectroscopic characterisation. The structures of $[Ru([9]aneS_3)(1,10\text{-phenanthroline})Cl]^+$ and $[Ru([9]aneS_3)(2,2'\text{-bipyridyl})Cl]^+$ are compared in solution by NMR and in the solid state by X-ray crystallography.

Scheme 1.

RESULTS AND DISCUSSION

The NMR characterisation of these complexes in solution show a number of interesting aspects. Compounds **1** and **2** seem to exist in solution in 2 forms. The ^1H spectrum for the aromatic region of complex **1** is shown in Fig. 1. In a symmetric complex with C_{2v} symmetry a 1,10-phenanthroline ligand would be expected to have 4 groups of resonances from the protons at positions ; 9/2, 8/3, 7/4 and 6/5 (see diagram 1). Complex **1** shows 8 groups of peaks suggesting that 2 forms exist in solution in the ratio 3 : 1. The peaks at 9.19(d, 5.2 Hz), 8.30(d, 8.2 Hz), 7.72(d of d, 8.4 and 5.2 Hz) and 7.62(s) ppm are from the 9/2, 7/4, 8/3 and 6/5 protons of the major form. The minor form has peaks at 9.34 (d, 5.2 Hz), 8.58(d, 8.3 Hz), 7.99(s) and 7.86(d of d, 8.2 and 5.2 Hz) ppm. The peaks from the macrocyclic ring are second order, therefore it is difficult to determine whether there are 2 sets of peaks for the thioether ligand. The ^{13}C spectra for the aromatic region and the macrocyclic region for complex **1** are shown in Figs 2a and 2b. The aromatic region shows 6 sets of peaks for the major form ; 152.8 (C9/C2), 146.9 (C10a/C10b), 137.2 (C7/C4), 130.2 (C4a/C6a), 127.1 and 125.5 (C8/C3 or C6/C5) ppm. The minor form has peaks at ; 153.6 (C9/C2), 147.4 (C10a/C10b), 138.3 (C7/C4), 130.6 (C4a/C6a), 127.5 and 125.8 (C8/C3 or C6/C5) ppm. The ^{13}C peaks of the thioether ligand also show 2 forms. The major form has peaks at 34.1, 32.1 and 31.3 ppm and the minor at 33.6, 31.6 and 31.1 ppm. Again the ratio is around 3 : 1. It is clear from the ^{13}C data that the complex has 2 forms in solution and that the thioether ligand has 2 sets of peaks. A 2D NOESY spectrum of complex **1** was recorded to check the assignment and through space connectivities for the 2 forms. Cross peaks were observed between the thioether protons and the H-9/H-2 proton on the phenanthroline ring for both forms indicating the minor set of peaks arise from a complexed form of phenanthroline and not from the free ligand.

The NMR data for complex **2** also suggests two forms in solution. The ^1H spectrum of the aromatic region for complex **2** is shown in Fig. 3. Resonances at 9.01(d, 5.6 Hz) (H-6/6′), 8.38(d, 8.1 Hz) (H-4/4′), 8.06(m) (H-5/5′) and 7.56(m) (H-3/3′) ppm are from the major form. The minor form has peaks at 9.11(d, 5.6 Hz), 8.47(d, 8.2 Hz), 8.17(m) and 7.66(m) ppm. The ratio between the forms is 3 : 1. The ^{13}C spectrum of complex **2** is shown in Fig. 4. The aromatic peaks for the major form are at 156.4 (C2/2′), 152.8 (C6/6′), 138.4 (C4/4′), 127.2 (C5/5′) and 123.6 (C3/3′) ppm. The minor form has peaks at 156.9, 153.3, 139.3, 127.5 and 123.8 ppm. The thioether ligand for complex **2** has peaks at 34.3, 32.1 and 31.1 ppm for the major form and at 33.8, 31.7 and 31.3 ppm for the minor form.

The fact that two sets of resonances are seen for the polypyridyl and thioether ligands in complexes **1** and **2** in solution is most probably a result of the thioether

ring having 2 different conformations in solution when complexed. As only three ^{13}C peaks are seen for the [9]aneS$_3$ ligand for each form (Fig. 2b) the ligand must adopt conformations where a plane of symmetry runs through the Ru, Cl and one sulfur atom and bisects the angle N—Ru—N for the polypyridyl ligand. Therefore both forms must have C_S symmetry.

The single crystal X-ray diffraction studies of complexes [Ru([9]aneS$_3$)(phen)Cl]Cl·3H$_2$O and [Ru([9]aneS$_3$)(bpy)Cl]Cl·3H$_2$O indicate hexa-coordination for the Ru centres. Molecular diagrams with corresponding atomic labelling schemes are shown in Figs 5 and 6 for cations [Ru([9]aneS$_3$)(phen)Cl]$^+$ and [Ru([9]aneS$_3$)(bpy)Cl]$^+$, respectively. The selected bond lengths, angles and endocyclic torsion angles are listed in Table 1. The structural parameters associated with the Ru coordination spheres show distorted octahedral geometry for both complex cations. The equatorial planes are formed by two macrocyclic sulfur donor atoms and two nitrogen atoms from polypyridyl ligands (bpy or phen). The hexa-coordination is achieved *via* a chlorine and the remaining sulfur macrocyclic atom.

In complex **1**, the axial Ru—S bond length [Ru—S(3) = 2.272(2) Å] is shorter than equatorial bond lengths [Ru—S(1) = 2.291(2) and Ru—S(2) = 2.284(2) Å]. A more pronounced differential *trans* influence is observed for complex **2**, where the Ru—S(3) bond length is 2.287(2) and the Ru—S(2) and Ru—S(1) bonds are 2.316(2) and 2.320(2) Å respectively. These facts suggest that in addition to a σ-*trans* effect, the competitive π acceptance of polypyridyl ligands plays an important role in determining

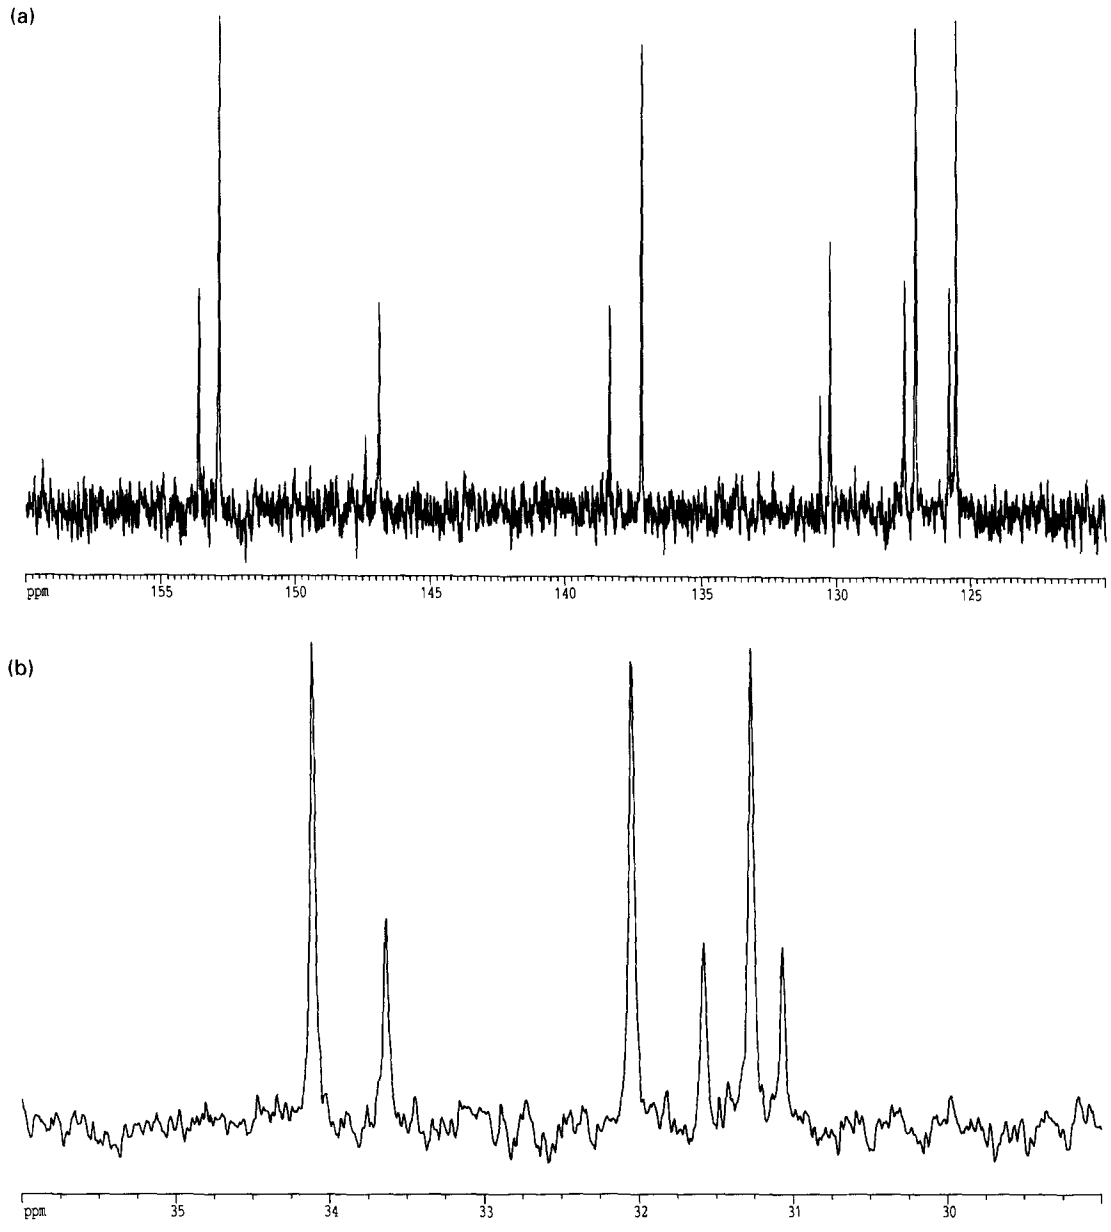

Fig. 2. (a) The aromatic region of the ^{13}C spectrum in D_2O at 303 K of complex **1**. (b) The aliphatic region of the ^{13}C spectrum of complex **1**.

the Ru—S bond lengths. The average bond lengths Ru—N 2.089(2) **1** and 2.106(2) **2** are similar to those observed for the octahedral complex $[Ru(NCMe)_3([9]aneS_3)]^{2+}$ 2.065(5) Å [18].

The angles in the equatorial plane involving the nitrogen atoms and metal centre differ from ideal octahedral values due to the small bite-angles of phen and bpy (78.8(2) and 78.0(2)° respectively). These values are similar to those seen for the octahedral complexes $[Ru([12]aneS_4)(phen)]^{2+}$ 79.5(4) and $[Ru([12]aneS_4)(bpy)]^{2+}$ 77.7(4) [19]. The remaining angles around the ruthenium atom in both cation complexes are very close to ideal octahedral values.

The conformation of any macrocyclic ligand can be described by a set of endocyclic torsion angles using an extended Dale nomenclature [20]. For example, the $[9]aneS_3$ macrocycle in complex cations **1** and **2** have values of the S—C—C—S, C—S—C—C and C—C—S—C torsion angles (listed in Table 1) which lead to a [333] conformation in the Dale nomenclature. This conformation has been found for many transition metal complexes characterised by X-ray diffraction where the $[9]aneS_3$ ligand adopts a facial arrangement [21]. The free $[9]aneS_3$ ligand also adopts, in the solid state, this conformation [22]. A molecular dynamics and mechanics study, in the gas

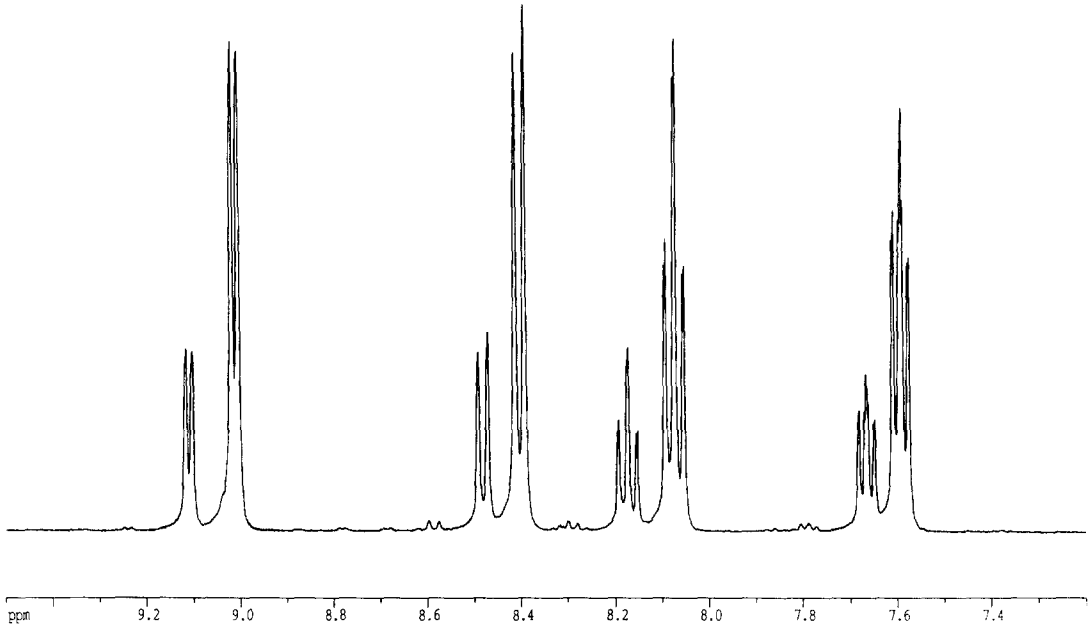

Fig. 3. The aromatic region of the ^1H spectrum of complex **2** in D_2O at 303 K.

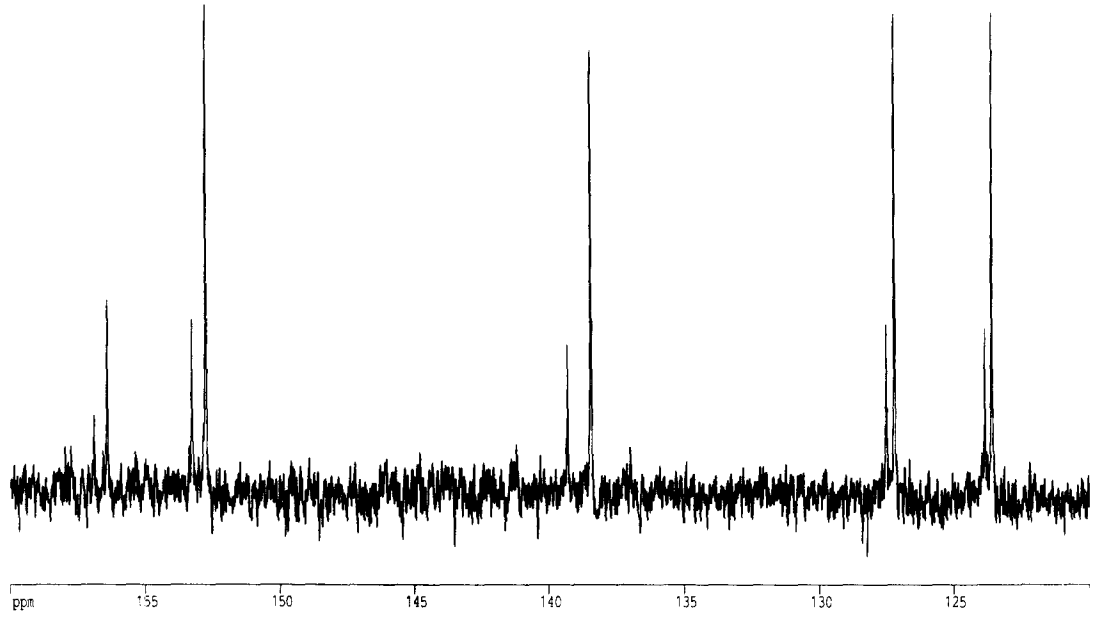

Fig. 4. The ^{13}C spectrum, of the aromatic region of complex **2**.

phase [23], gave 13 conformations with energies ranging from 4.5 to 8.3 kcal/mol, the lowest energy conformation again having a [333] arrangement.

Selected intermolecular contacts are given in Table 2. In crystals of both complexes, the backbone hydrogens of the macrocyclic ligand are involved in interactions with waters of crystallization (C—H $\cdots$ O) and chlorine anions (C—H $\cdots$ Cl). The distances of these interactions are close to the sum of van der Waals radii for H,Cl and H,O and could be considered as weak hydrogen bonds.

The results from the X-ray study are consistent with the NMR spectroscopic data for the complexes $[Ru([9]aneS_3)(phen)Cl]^+$ in solution, in that octahedral coordination with one thioether and one polypyridyl ligand is observed. However, the fact that the complexes **1** and **2** exist as two forms in solution and only one form is seen in the solid state suggests that

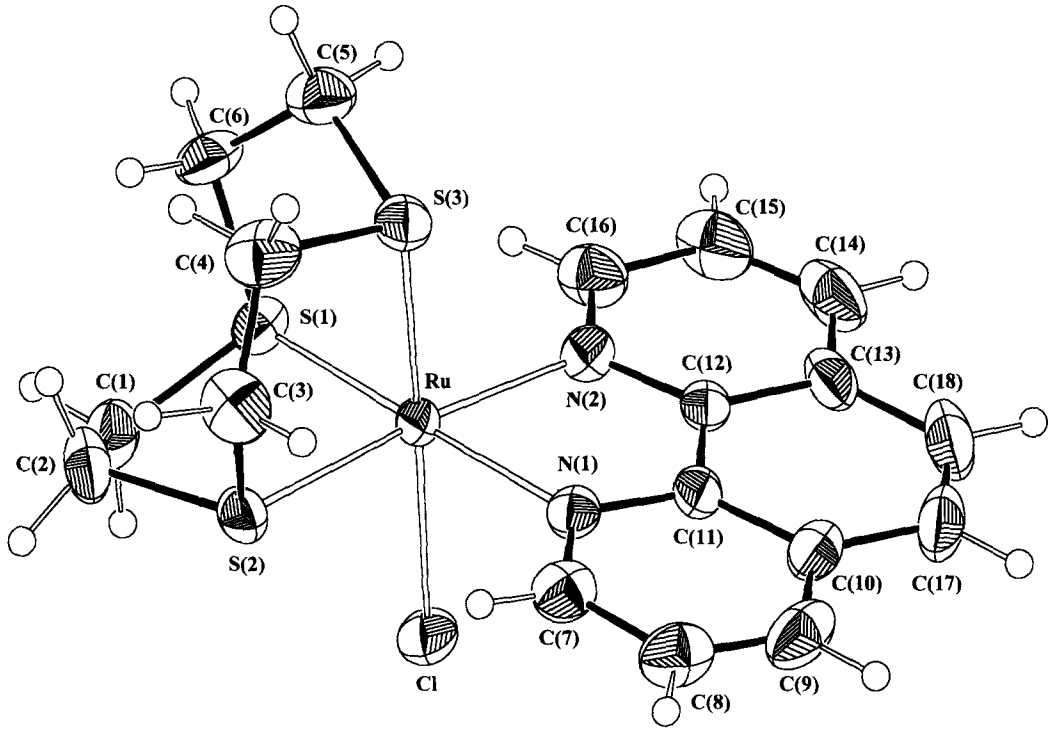

Fig. 5. Molecular structure of the $[Ru([9]aneS_3)(phen)Cl]^+$ complex cation showing the atomic labelling scheme. Thermal ellipsoids are drawn at the 30% probability level and the hydrogen atoms are represented with a U_{iso} of 0.01 Å^2.

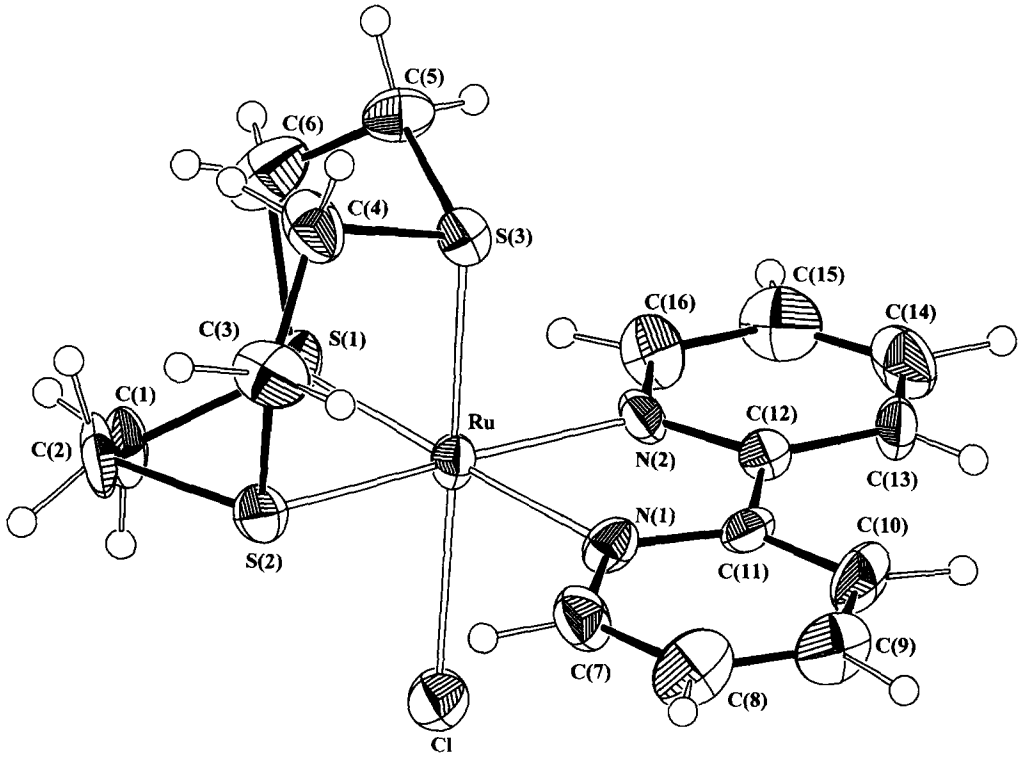

Fig. 6. Molecular structure of the $[Ru([9]aneS_3)(bpy)Cl]^+$ complex cation showing the atomic labelling scheme. Details are as in Fig. 5.

crystal packing forces, namely the hydrogen bonds C—H···O and C—H···Cl stabilize the conformation adopted by the macrocycle in the solid state. These forces are absent in solution allowing the [9]aneS$_3$ ligand to adopt two different conformations (both with C_S symmetry).

EXPERIMENTAL

The ligands [9]aneS$_3$, phen, bpy, dbp, and dip were purchased from the Aldrich Chemical Company and used without further purification.

Syntheses

[Ru(dmso)$_4$Cl$_2$]. The synthesis of [Ru(dmso)$_4$Cl$_2$] was carried out according to the method of Evans *et al.* [24] NMR: ^{1}H D_2O: 3.49, 3.48, 3.46, 3.43, 3.42, 3.37, 3.33 (dmso); ^{13}C, 46.73, 46.50, 45.70, 45.11, 44.67, 44.31 (all ppm). UV/Vis: λ_{max} nm($\varepsilon \times 10^{-3}$ M^{-1} cm^{-1}); 352(0.43), 312(0.33), 220(11.1), 202(26.9).

[Ru([9]aneS$_3$)(dmso)Cl$_2$]. [Ru(dmso)$_4$Cl$_2$] (0.5g, 1 mmol) was added to 0.186 g of [9]aneS$_3$ (1 mmol) in ethanol (*ca* 30 ml). The resulting suspension was refluxed for 90 min at 80 C. A colour change from pale to bright yellow indicated reaction. The solution was concentrated and a bright yellow solid obtained. The product was washed with ethanol and dried (0.39 g, 88%). [Note: care must be taken not to use excess [9]aneS$_3$ otherwise [Ru([9]aneS$_3$)$_2$]$^{2+}$ results.] NMR: ^{1}H D_2O; 3.38s(1.5 H), 3.35s(2.4 H), 3.26s(1.5 H), (dmso): 3.00–2.60m(12 H, [9]aneS$_3$); ^{13}C; 43.54, 43.50, 42.12, 35.02, 34.53, 34.39, 33.50, 33.29, 31.64, 31.01, 29.21, (all ppm). UV/Vis: λ_{max} nm($\varepsilon \times 10^{-3}$ M^{-1} cm^{-1}); 425(0.26), 352(0.40), 210(24.7).

[Ru([9]aneS$_3$)(1,10-phenanthroline)Cl]Cl (**1**). 1,10-phenanthroline (0.48 g, 2.42 mmol, 5% excess) was added to a solution of [Ru([9]aneS$_3$)(dmso)Cl$_2$] (0.1 g, 0.23 mmol) in ethanol. The yellow solution was refluxed for 15 min at 80 C or until a colour change to orange indicated reaction had taken place. The solution was concentrated until a yellow/orange needle or "glass wool"-like solid was obtained. On standing, large orange crystals developed. These were washed with water and dried (0.12 g, 95%). NMR: ^{1}H D_2O; {9.34d, 9.19d} 2H, {8.58d, 8.30d} 2H, {7.99s, 7.62s} 2H, {7.72q, 7.86q} 2H (phen), 3.1–2.3m (12H, [9]aneS$_3$); ^{13}C, 153.6, 152.8, 147.7, 146.9, 138.3, 137.2, 130.6, 130.2, 127.5, 127.1, 125.8, 125.5 (phen), 34.11, 33.64, 32.05, 31.58, 31.27, 31.07 ([9]aneS$_3$). UV/Vis: λ_{max} nm ($\varepsilon \times_3$)10^{-3} M^{-1} cm^{-1}); 411(3.0), 356(3.1), 297(9.6)sh, 260(22.2), 224(24.4), 200(36.0).

[Ru([9]aneS$_3$)(2,2′-bipyridyl)Cl]Cl (**2**). A 2% excess of 2,2′-bipyridyl (0.13g, 0.858 mmol) was added to 0.250 g of [Ru([9]aneS$_3$)(dmso)Cl$_2$] (0.36 g, 0.836 mmol) in ethanol. The yellow solution was refluxed for 20 min at 80 C and an orange/red solution obtained. The solution was concentrated to dryness and redissolved in EtOH/H_2O. On standing, orange/red crystals were obtained (0.42 g, 98%). NMR: ^{1}H D_2O; {9.11d, 9.01d} 2H, {8.47d, 8.38d} 2H, {8.17t, 8.06t} 2H, {7.66t, 7.56t} 2H (bpy); 2.96–2.21m 12H ([9]aneS$_3$): ^{13}C, 156.9, 156.4, 153.3, 152.8, 139.3, 138.4, 127.5, 127.2, 123.6 (phen), 34.27, 33.80, 32.09, 31.65, 31.34, 31.10 ([9]aneS$_3$). UV/Vis; λ_{max} nm($\varepsilon \times_3$)10^{-3} M^{-1} cm^{-1}); 413(3.0), 315(4.6), 283(15.7), 241(24.1), 203(24.1).

[Ru([9]aneS$_3$)(4,4′-diphenyl-2,2′-bipyridyl)Cl]Cl (**3**). The ligand 4,4′-diphenyl-2,2′-bipyridyl (0.062 g, 0.201 mmol) was added to a solution of [Ru([9]aneS$_3$)(dmso)Cl$_2$] (0.085 g, 0.197 mmol) in ethanol. Reflux for 2 h at 80 C gave an orange/brown solution. After concentration the brick-coloured precipitate was collected and dried (0.11 g, 84%). NMR: ^{1}H D_2O; 9.07d 2H, 9.00s 2H, 8.03d 4H, 7.90d 2H, 7.60m 6H (dbp), 3.20–2.60m 12H ([9]aneS$_3$). UV/Vis: λ_{max} nm($\varepsilon \times 10^{-3}$ M^{-1} cm^{-1}); 422(5.4), 295(26.9), 250(21.0), 202(36.5).

[Ru([9]aneS$_3$)(4,7′ - diphenyl - 1,10-phenanthroline)Cl]Cl (**4**). To the complex [Ru([9]aneS$_3$)(dmso)Cl$_2$] (0.2 g, 0.464 mmol) in ethanol was added 0.157 g (0.472 mmol) of 4,7′-diphenyl-1,10-phenanthroline. After refluxing for 2 h at 80 C a yel-

low/orange solution was obtained. Concentration of the solution yielded an orange solid (0.29 g, 91%). NMR: ^{1}H D_2O; 9.46d 2H, 8.12s 2H, 7.88d 2H, 7.87–7.59m 10H (dip), 3.29–2.64m 12H ([9]aneS_3). UV/Vis: λ_{max} nm($\varepsilon \times 10^{-3}$ M^{-1} cm^{-1}); 386(5.2), 276(28.5), 223(24.3), 205(38.6).

NMR spectroscopy

All spectra were recorded in either a Bruker AMX spectrometer operating at 300 MHz or a Bruker ARX spectrometer operating at 400 MHz. The ^{1}H spectra were obtained using 16k data points and a sweep width of 14.04 ppm. Deuterated methanol of D_2O were used as solvents with chemical shifts being referenced to HOD (4.75 ppm) or CD_2HOD (3.35 ppm). ^{13}C spectra were recorded using a sweep width of 250 ppm with 32k data points. Full proton decoupling was used. External dioxan (66.5 ppm) was used as a chemical shift reference. The 2D NOESY [25] spectrum (800 ms mixing time) was recorded at 400 MHz. A sweep width of 14.04 ppm and a recycle delay of 10 s was used. The number of t_1 increments was 512 with 8 scans being co-added for each increment. The number of data points used was 2048. The final matrix size was 2K × 2K with a qsine window applied in both dimensions.

Crystallographic measurements and processing

The pertinent crystal data and refinement details for complexes **1** and **2** are given in Table 3. Single crystal data for complex **1** were collected with an Enraf-Nonius CAD-4 diffractometer, using a graphite-monochromated Mo-K_α radiation ($\lambda = 0.71069$ Å). The unit cell parameters were calculated by least-squares refinement of 25 well centred reflections within the range $10 < \theta < 15°$. The intensity data were collected by ω-2θscan mode. Three strong reflections were measured every 3600 s and their intensities did not show appreciable decay. The data were corrected for absorption and polarization effects with CAD-4 software.

Data for complex **2** were collected with a MAR-research image plate system, using a graphite-monochromated Mo-K_α radiation ($\lambda = 0.71069$ Å). Single crystal was positioned at 75 mm from the plate. An exposure time of 2 min was used per 2° frame collected. Data analysis was carried out with XDS program [26]. Intensities were not corrected for absorption effects.

Structure analysis and refinement

The positions of the ruthenium atoms were obtained from three-dimensional Patterson maps and

[a] $w = 1/[\sigma^2(F_o^2) + (aP)^2 + bP]$, $P = [\mathrm{Max}(F_o^2) + 2F_o^2]/3$.

the remaining non-hydrogen atom positions by successive difference Fourier synthesis. The methylenic hydrogens were included in the refinement in calculated positions for idealized tetrahedral geometry while the aromatic hydrogens were found from difference Fourier maps. The hydrogen atoms of water molecules in both complexes were not found in final Fourier maps and were not included in the refinement. The hydrogens were refined with global isotropic thermal parameters. Anisotropic temperature factors were used for all non-hydrogen atoms. The structures were refined by least squares methods until convergence was achieved. The final refinements were made on F^2 using a weighting system, with the form $w = 1/[\sigma^2(F_o^2) + (aP)^2 + bP]$, $P = [\mathrm{Max}(F_o^2) + 2F_o^2]/3$ (see Table 3).

All calculations required to solve and refine the structures were carried out with SHELXS86 [27] and SHELX93 [28]. The atomic scattering factors were taken from [29]. The molecular diagrams were drawn with ORTEP II [30].

Additional material is available from the Cambridge Crystallographic Data Centre and comprises atomic coordinates, thermal parameters and the remaining bond lengths and angles.

Abstract—The η^5-Bz_5C_5 ligand-containing trimetallic complexes $[\eta^5\text{-}Bz_5C_5(CO)_3M]_2Hg$ (M = Cr, Mo, W) were synthesized from the *in situ* reaction of phenylmercuric chloride with corresponding transition metal lithium salts $[\eta^5\text{-}Bz_5C_5(CO)_3M]$ Li in THF, whereas the η^5-$HO_2CC_5H_4$ ligand-containing trimetallic complexes $[\eta^5\text{-}HO_2CC_5H_4(CO)_3M]_2Hg$ were synthesized through hydrolysis of their corresponding esters in the presence of $KOH/EtOH/H_2O$, followed by acidification. These compounds were characterized by elemental analysis, IR, ^1H NMR and MS spectroscopy, while the structure of $[\eta^5\text{-}Bz_5C_5(CO)_3W]_2Hg$ was determined by an X-ray diffraction analysis. Keywords: η^5-pentabenzylcyclopentadienyl; η^5-carboxycyclopentadienyl; group 6 metals; mercury; crystal structure.

In view of the theoretical and practical importance of metal–metal bonded compounds [1], the organometallic complexes containing M—Hg—M (M = Cr, Mo, W) structural moieties have so far received considerable attention [2–4]. However, although the trimetallic M—Hg—M complexes containing mono-substituted cyclopentadienyl ligand have been known for several years [2–4], the study concerning their chemical reactions and synthesis regarding the M—Hg—M complexes containing poly-substituted cyclopentadienyl ligand has not been reported as yet. In order to further understanding of the properties of this kind of complex containing mono-substituted cyclopentadienyl ligand and to prepare the novel M—Hg—M complexes carrying η^5-pentabenzylcyclopentadienyl ligand η^5-Bz_5C_5, we initiated this study. Herein we report the synthesis and characterization of the new complexes $[\eta^5\text{-}HO_2CC_5H_4(CO)_3M]_2Hg$ and $[\eta^5\text{-}Bz_5C_5(CO)_3M]_2Hg$ (M = Cr, Mo, W) including the single-crystal structure of $[\eta^5\text{-}Bz_5C_5(CO)_3W]_2Hg$ determined by X-ray diffraction analysis.

RESULTS AND DISCUSSION

Synthesis and characterization of $[\eta^5\text{-}HO_2CC_5H_4(CO)_3M]_2Hg$ (**2a–2c**)

On the basis of our work for synthesizing $[\eta^5\text{-}RC_5H_4(CO)_3M]_2Hg$ (M = Cr, Mo, W; R = CO_2Me, CO_2Et) (**1**) [3], an effort has been made to study further the preparation of their hydrolysis derivatives **2**. Fortunately, it was found that the M—Hg—M structural unit in the starting complexes **1** is quite stable towards both acidic and alkaline conditions; the starting complexes **1**, after the action of $NaOH/EtOH/H_2O$ and followed by acidification of the intermediate potassium salt with HCl/H_2O, gave rise to the cor-

1 **2**

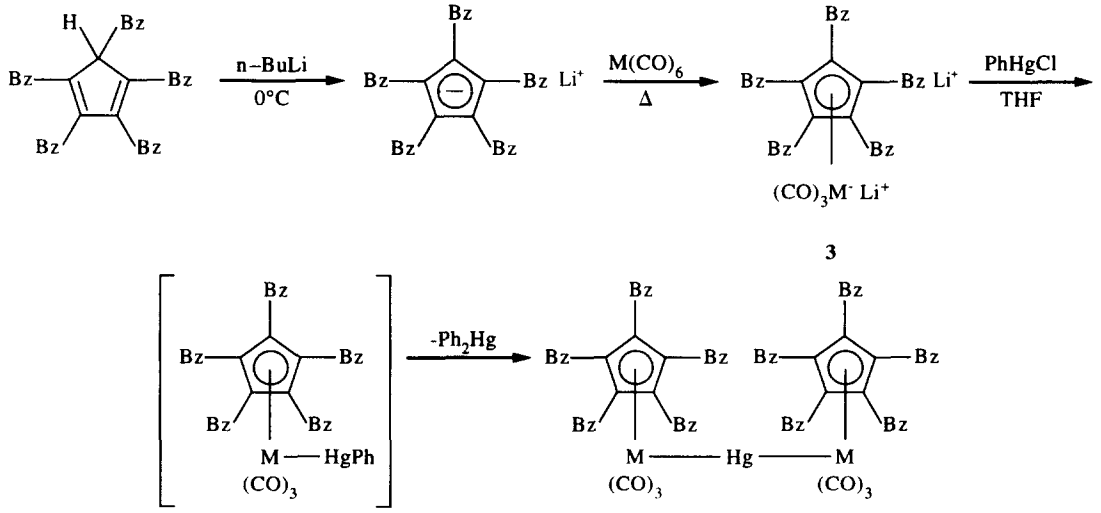
R = CO_2Me, CO_2Et **2a** : M = Cr; **2b** : M = Mo; **2c** ; M = W

Scheme 1.

responding derivatives **2** in moderate yields, as shown in Scheme 1.

Products **2a–2c** are air-stable yellow solids and soluble in THF, DMSO and acetone but not in CH_2Cl_2 and other non-polar solvents. All of them were fully characterized by elemental analysis, IR, ^1H NMR and mass spectroscopies. In the IR spectra of **2a–2c,** there are three strong to very strong absorption bands in the range of 1884–1967 cm^{-1}, characteristic of their terminal carbonyls, one strong absorption band at about 1680 cm^{-1} and one broad band at about 3430 cm^{-1} characteristic of their carbonyl and hydroxyl group in the carboxylic substituent, respectively. Their ^1H NMR spectra have a pair of apparent triplets, in which the downfield triplet has been assigned to the H(2, 5) protons of the substituted cyclopentadienyl ring, while the upfield triplet is assigned to the H(3, 4) protons. Additionally, the triplet assigned to H(2, 5) or H(3, 4) is located in the lowest field in the case of the tungsten compound **2c,** the intermediate field for the molybdenum compound **2b** and in the highest field for the chromium compound **2a** and there are larger differences in chemical shifts between the corresponding triplets of **2a** and **2b** than between those of **2b** and **2c**. It follows that the ^1H NMR behaviour of the functionally substituted cyclopentadienyl ring of **2a–2c** are similar to that of starting complexes and other electron-withdrawing functional analogs [2, 3, 5]. It is worth pointing out that the ^1H NMR spectrum of the carboxylic functionality was not observed in the field as low as $\delta = 15$ ppm, perhaps due to the D/H exchange between **2** and the solvent DMSO.

Synthesis and characterization of $[\eta^5\text{-}Bz_5C_5(CO)_3M]_2$ Hg **(4a–4c)**



Similar to the lithium or sodium salts of monosubstituted cyclopentadienyltricarbonyl group 6 metal anions [2–4], the pentabenzylcyclopentadienyl analogs $\eta^5\text{-}Bz_5C_5(CO)_3MLi$ (**3**) derived from sequential reactions of pentabenzylcyclopentadiene, *n*-BuLi and group 6 metal carbonyls $M(CO)_6$, reacted with phenylmercuric chloride in THF to give the expected trimetallic compounds **4a–4c**. According to the related mechanistic study [3], the compounds **4a–4c** were most likely produced by a symmetrization process of the active bimetallic intermediate $\eta^5\text{-}Bz_5C_5M(CO)_3$-HgPh formed by a condensation reaction of **3** with PhHgCl, as shown in Scheme 2.

Compounds **4a–4c** are air-stable yellow crystalline solids, whose melting points increase in the order of **4a** < **4b** < **4c**. The yields of **4a–4c** are much lower than those of the analogs containing $\eta^5\text{-}C_P$ or $\eta^5\text{-}RC_5H_4$ ligand [2–4], the reason for which could be attributed to the special electronic and steric effects of $\eta^5\text{-}Bz_5C_5$ ligand [6–10] relative to those of $\eta^5\text{-}C_P$ and η^5-mono-substituted cyclopentadienyl ligand. For **4a–4c** all the characterizing data of the elemental analysis, IR and ^1H NMR spectroscopy are in good agreement with the structures shown in Scheme 2. However, it is worth noting that compounds **4a–4c** contain not only terminal carbonyls, but also bridging carbonyls. This is because in each of their IR spectra there is one strong absorption band at about 1860 cm^{-1} besides two absorption bands at the region of 1884–1959 cm^{-1}.

X-ray crystallography

In order to determine the structure of compounds **4a–4c** and establish the type of carbonyls in these compounds, an X-ray diffraction analysis for **4c** was undertaken. To the best of our knowledge, this is the first single-crystal molecular structure determination of an M—Hg—M trinuclear organometallic containing $\eta^5\text{-}Bz_5C_5$ ligand, although those of $\eta^5\text{-}Bz_5C_5$-containing mononuclear [8–10] and dinuclear [11] organometallics and $\eta^5\text{-}C_P$ [2, 12] or $\eta^5\text{-}RC_5H_4$ [3,4] containing M—Hg—M organometallics are known. Table 1 lists the crystallographic data. Table 2 and Table 3 list the selected bond lengths and bond angles, respectively. Figure 1 shows its molecular structure.

As seen from Fig. 1 complex **4c** consists of one mercury atom and two identical organometallic structural units $\eta^5\text{-}Bz_5C_5(CO)_3W$. The central Hg atom is located on a crystallographic inversion center so that the W—Hg—W skeleton is exactly linear ($\angle$W—Hg—W = 180°) and two substituted cyclopentadienyl rings are parallel and lie in a *trans* position with respect to the linear W—Hg—W axis. This is also the case for the ethoxycarbonylcyclopentadienyl molybdenum analog [3] but different from its parent compound, which is non-centrosymmetric and has a *cis* configuration of cyclopentadienyl ligands with respect to the W—Hg—W axis [2]. The bond angles

C(1)—C(10)	1.52(1)	Hg—C(01)	2.843(9)

W—C(01)—O(1) and W—C(02)—O(2) [174(1) and 177(1)°, respectively] and Hg—W—C(01) and Hg—W—C(02) [72.2(3) and 69.9(3)°, respectively] indicate that the C(01)—O(1) and C(02)—O(2) carbonyl ligands are linear semi-bridging. Since the W—C(01) and Hg···C(01) distances D_1 and D_2 are 1.94(1) and 2.84(3) Å, for C(01)—O(1) the bridge asymmetry parameter $\alpha = 0.47$; since W—C(02) and Hg···C(02) distances D_1 and D_2 are 1.98(1) and 2.78(6) Å, for C(02)—O(2) $\alpha = 0.41$ ($\alpha = D_2 - D_1/D_1$) [13–14]. Apparently, the second W atom also has attached two corresponding carbonyls since **4c** is centrosymmetric. So, the fact that the semi-bridging cabonyls exist in **4c** is in good agreement with its IR spectroscopic data.

It is worth pointing out that for each of the two η^5-Bz_5C_5 ligands in complex **4c** four phenyl groups bonded to C(10), C(30), C(40) and C(50) of the benzyl substituents are situated on the opposite side of the tungsten atom with respect to substituted cyclopentadienyl ring, while the phenyl group attached to C(20) of the benzyl substituent approaches the tungsten atom. Similar to the mononuclear analogs of cobalt [6], manganese [7] and molybdenum [10], this

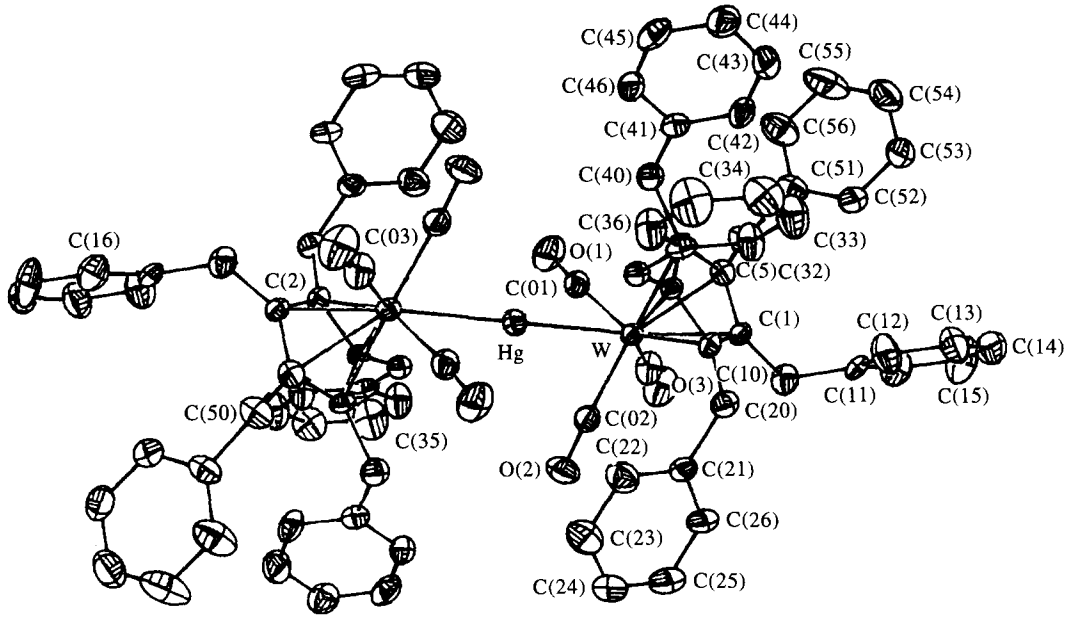

Fig. 1. Molecular structure of **4c**.

could be possibly caused by the smallest gap between the two phenyl groups bound to C(10) and C(30). However, this is not the case because the non-bonding distance of C(11)···C(31) (6.235 Å) lies midway between those of C(11)···C(41) (6.508 Å) and C(31)···C(51) (6.203 Å). So, besides the intramolecular non-bonding interactions, the intermolecular interactions could also be one of the reasons for this geometric arrangement of the five phenyl groups in complex **4c**. However, the real reasons remain unclear and further study is needed.

EXPERIMENTAL

The reactions were carried out under highly prepurified tank nitrogen. Diglyme and THF were rigorously dried and deoxygenated by distillation from Na/benzophenone ketyl. Bz_5C_5H [10], *n*-BuLi [15] and $[\eta^5\text{-}RO_2CC_5H_4(CO)_3M]_2Hg$ (M = Cr, Mo, W; R = CO_2Me, CO_2Et) [3] were prepared according to the literature. $M(CO)_6$(M = Cr, Mo, W) was purchased from Strem Chemicals Inc. and PhHgCl from Alfa Ventron. Silica gel for column chromatography was of about 300–400 mesh. Silica gel for TLC was GF-254 (10–40 μm). IR spectra were recorded on a Nicolet FT-IR 5DX spectrophotometer, ^1H NMR spectra on a Jeol FX 90Q spectrometer. Elemental analysis and MS determinations were performed by a 240 C analyzer and HP 5988A spectrometer, respectively. Melting points were determined on a Yanaco MP-500 apparatus.

Synthesis of $[\eta^5\text{-}HO_2CC_5H_4(CO)_3Cr]_2Hg$ (**2a**)

A 100 cm^3 two-necked flask equipped with a magnetic stir-bar, a serum cap and a reflux condenser, was charged with 0.697 g (0.96 mmol) of $[\eta^5\text{-}EtO_2$

$CC_5H_4(CO)_3Cr]_2Hg$, 20 cm^3 of C_2H_5OH and a solution prepared from 0.291 g (5.19 mmol) KOH and 10 cm^3 of distilled water. The reaction mixture was stirred for 8–10 h at about 40°C until TLC showed no starting complex left. After cooling to room temperature, the reaction mixture was filtered and to the filtrate was added about 50 cm^3 of distilled water followed by treatment with concentrated HCl until the yellow solid precipitated completely. The solid was filtered out and washed first with distilled water until the filtrate reached to the neutral and then washed with CH_2Cl_2 several times. Drying of the washed solid *in vacuo* gave 0.311 g (48%) of **2a** as a yellow solid, m.p. 158°C (dec.). Found: C, 31.6; H, 1.6. Calc. for $C_{18}H_{10}Cr_2HgO_{10}$: C, 31.3; H, 1.5%. IR (KBr, disc): νOH, 3435 (br.), $\nu_{C\equiv O}$, 1959(vs), 1915(s), 1893(vs), $\nu_{C=O}$, 1688(s) cm^{-1}. ^1H NMR (DMSO, δ, ppm): 5.29 [t, 4H, 2(H^3, H^4)], 5.67 [t, 4H, 2(H^2, H^5)]. MS(EI, Cr^{52}), *m/z* (relative intensity): 245 [$HO_2CC_5H_4Cr(CO)_3^+$, 7.3], 217[$HO_2CC_5H_4Cr(CO)_2^+$, 15.7], 202(Hg^+, 62.5), 189[$HO_2CC_5H_4Cr(CO)^+$, 17.2], 161($HO_2CC_5H_4Cr^+$, 56.8), 109($HO_2CC_5H_4^+$, 0.4), 65($C_5H_5^+$, 12.6), 52(Cr^+, 60.7), 45(CO_2H^+, 2.9).

Synthesis of [η^5-$HO_2CC_5H_4(CO)_3Mo]_2Hg$ (**2b**)

The same procedure for **2a** was followed, but the reagents were changed as follows: 0.597 g (0.74 mmol) of [η^5-$MeO_2CC_5H_4(CO)_3Mo]_2Hg$ and 0.201 g (3.59 mmol) of KOH; or 0.75 g (0.90 mmol) of [η^5-EtO_2C-$C_5H_4(CO)_3Mo]_2Hg$ and 0.219 g (3.91 mmol) of KOH. The former reaction gave 0.449 g (78%) of **2b,** while the latter reaction gave 0.589 g (84%) of **2b,** as a yellow solid, m.p. 195°C (dec.). Found: C, 27.7; H, 1.3. Calc. for $C_{18}H_{10}HgMo_2O_{10}$: C, 27.8; H, 1.3%. IR (KBr, disc): ν_{OH}, 3443 (br.), $\nu_{C\equiv O}$, 1967(vs), 1922(s), 1893(vs), $\nu_{C=O}$, 1680(s) cm^{-1}. ^1H NMR (DMSO, δ, ppm): 5.76[t, 4H, 2(H^3, H^4)], 6.14 [t, 4H, 2(H^2, H^5)]. MS(EI, MO^{98}), *m/z* (relative intensity): 291[HO_2C-$C_5H_4Mo(CO)_3^+$, 4.0], 263[$HO_2CC_5H_4Mo(CO)_2^+$, 2.9], 247[$C_5H_5Mo(CO)_3^+$, 1.2], 235[$HO_2CC_5H_4Mo(CO)^+$, 2.8], 207($HO_2CC_5H_4Mo^+$, 3.2), 202(Hg^+, 26.2), 66($C_5H_6^+$, 31.4), 45(CO_2H^+, 7.1).

Synthesis of [(η^5-$HO_2CC_5H_4(CO)_3W]_2Hg$ (**2c**)

The same procedure for **2a** was followed, but the reagents were changed as follows: 0.272 g (0.277 mmol) of [η^5-$MeO_2CC_5H_4(CO)_3W]_2Hg$ and 0.069 g (1.23 mmol) of KOH. 0.205 g (78%) of **2c** was given as a yellow solid, m.p. 224°C (dec.). Found: C, 22.7; H, 1.0; Calc. for $C_{18}H_{10}HgO_{10}W$: C, 22.7; H, 1.1%. IR (KBr, disc): ν_{OH}, 3418 (br.), $\nu_{C\equiv O}$, 1967(vs), 1909(s), 1885(vs), $\nu_{C=O}$, 1688(s) cm^{-1}. ^1H NMR (DMSO, δ, ppm): 5.84 [t, 4H, 2(H^3, H^4)], 6.20 [t, 4H, 2(H^2, H^5)]. MS(EI, W^{185}), *m/z* (relative intensity): 202(Hg^+, 40.3), 185(W^+, 18.5), 109($HO_2CC_5H_4^+$, 28.9), 64($C_5H_4^+$, 14.0), 45(CO_2H^+, 38.5).

Synthesis of [η^5-$Bz_5C_5(CO)_3Cr]_2Hg$ (**4a**)

A 100 cm^3 two-necked flask equipped with a magnetic stir-bar, a serum cap and a reflux condenser, was charged with 1.24 g (2.4 mmol) of η^5-Bz_5C_5H and 20 cm^3 of diglyme. To this mixture was added an equimolar aliquot of *n*-BuLi/hexane at 0°C and the solution turned to deep purple. After continuous stirring for 15 min, 0.538 g (2.4 mmol) of $Cr(CO)_6$ was added and the reaction mixture heated at about 130°C overnight. Solvent was removed at reduced pressure and 20 cm^3 of THF was added to give a THF solution of the salt η^5-$Bz_5C_5(CO)_3CrLi$. To this salt, 0.70 g (2.4 mmol) of PhHgCl was added at about 0°C and the solution turned to bright-yellow rapidly. After stirring for an additional 1 h, solvent was removed at reduced pressure to give a residue, which was extracted with CH_2Cl_2. The extracts were subjected to column chromatography and TLC separation with 50% CH_2Cl_2/petroleum ether as eluent, followed by recystallization from 50% CH_2Cl_2/petroleum ether to give 0.045 g (3%) of **4a** as a yellow solid, m.p. 140–142°C. Found: C, 68.2; H, 4.7. Calc. for $C_{86}H_{70}Cr_2HgO_6$: C, 68.7; H, 4.7%. IR (KBr, disc): $\nu_{C\equiv O}$, 1942(vs), 1885(s), 1860(vs) cm^{-1}. ^1H NMR ($CDCl_3$, δ, ppm): 3.90(s, 20H, $10CH_2$), 6.40–7.32(m, 50H, $10C_6H_5$).

Synthesis of [η^5-$Bz_5C_5(CO)_3Mo]_2Hg$ (**4b**)

A 100 cm^3 two-necked flask equipped with a magnetic stir-bar, a serum cap and a reflux condenser, was charged with 1.24 g (2.4 mmol) of η^5-Bz_5C_5H and 20 cm^3 of THF. The mixture was stirred and cooled to 0°C. To this mixture was added an equimolar aliquot of *n*-BuLi/hexane at 0°C. After stirring for 15 min, 0.62 g (2.4 mmol) of $Mo(CO)_6$ was added and the reaction mixture refluxed for about 24 h to give the salt η^5-$Bz_5C_5(CO)_3MoLi$. To this salt was added 0.70 g (2.4 mmol) of PhHgCl at about 0°C and the reaction mixture stirred for an additional 1 h. After the same work-up as that in the preparation of **4a,** 0.085 g (5%) of **4b** was given as a yellow solid, m.p. 188–189°C. Found: C, 64.8; H, 4.4. Calc. for $C_{86}H_{70}HgMo_2O_6$: C, 64.9; H, 4.4%. IR (KBr, disc): $\nu_{C\equiv O}$, 1959(vs), 1909(s), 1868(vs) cm^{-1}. ^1H NMR ($CDCl_3$, δ, ppm): 3.97(s, 20H, $10CH_2$), 6.70–7.27(m, 50H, $10C_6H_5$).

Synthesis of [η^5-$Bz_5C_5(CO)_3W]_2Hg$ (**4c**)

The same procedure for **4a** was followed, but use of 0.84 g (2.4 mmol) of $W(CO)_6$ instead of $Cr(CO)_6$ to give 0.121 g (6%) of **4c** as a yellow solid, m.p. 200–202°C. Found: C, 58.4; H, 3.8. Calc. for $C_{86}H_{70}HgO_6W_2$: C, 58.4; H, 4.0%. IR (KBr, disc): $\nu_{C\equiv O}$, 1950(vs), 1893(s), 1860(vs) cm^{-1}. ^1H NMR ($CDCl_3$, δ, ppm): 4.00(s, 20H, $10CH_2$), 6.63–7.25(m, 50H, $10C_6H_5$).

Single-crystal structure determination of [η^5-Bz_5C_5 $(CO)_3W]_2Hg$ (**4c**)

A yellow crystal measuring $0.16 \times 0.20 \times 0.50$ mm^3 obtained by recrystallization from CH_2Cl_2/hexane in a refrigerator, was mounted on a glass fiber and placed on an Enraf-Nonius CAD4 diffractometer equipped with a graphite monochromator. A total of 6386 independent reflections were collected at room temperature with Mo-K_α ($\lambda = 0.71069$ Å) radiation by ω-2θ scan mode, of which 4202 independent reflections with $I \geqslant 3\sigma(I)$ were considered to be observed and used in the subsequent refinement. Data were corrected for Lp factors.

The positions of tungsten and mercury atoms were found in an E-map by direct methods and the remaining non-hydrogen atoms found in the succeeding difference Fourier syntheses. The final refinement by full-matrix least-squares method used anisotropic thermal parameters for non-hydrogen atoms. All calculations were performed on a MICRO-VAX I computer using TEXSAN program system.

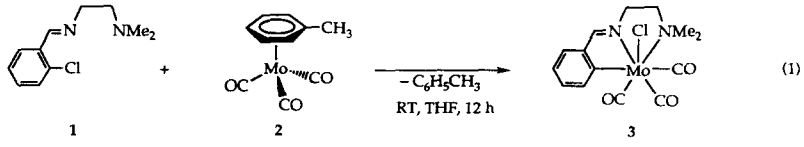
(Received 2 May 1996; accepted 18 June 1996)

Abstract—Reaction of the Schiff base ligand **1**, prepared by the condensation of 2-chlorobenzaldehyde and *N*,*N*-dimethylethylenediamine with $(\eta^6\text{-}C_6H_5CH_3)Mo(CO)_3$ **2** resulted in the formation of the seven-coordinate molybdenum(II) metallacycle, **3**, by oxidative addition of the strong aromatic C—Cl bond at molybdenum(0). The metallacycle **3** undergoes migratory insertion with electron-deficient internal acetylenes to afford novel η^2-vinyl complexes **4**, resulting in net replacement of a C—Cl bond by a C—C bond. Copyright © 1996 Elsevier Science Ltd

Keywords: oxidative addition; molybdenum; alkyne; insertion; bond activation; metallacycle.



Organometallic η^2-vinyl complexes are of interest because of a variety of catalytic chemical transformations postulate the crucial participation of vinyl intermediates stabilized by a metal centre [1]. Most synthetic approaches to η^2-vinyl complexes have involved the external attack of nucleophiles (hydrides [2], thiols and thiolates [3], nitrogen [4] and phosphorus [5] reagents) on coordinated alkyne ligands. If the metal is electronically saturated, only an η^1-vinyl complex is formed [6].

Recently, we demonstrated that a rare migration reaction of a highly fluorinated ligand takes place at a tungsten(II) metal centre to afford robust η^2-vinyl compounds [7]. Importantly, it was shown that known oxidative addition chemistry, in conjunction with migratory insertion of unsaturated organic compounds, can be employed for the activation [8] and chemical modification [9] of C—F bonds.

We now report that this chemistry can be extended to chlorinated aromatic compounds and exploited for the construction of novel molybdenum(II) η^2-vinyl complexes. The key features of this work is that net replacement of an aromatic carbon–chlorine bond by a carbon–carbon linkage occurs under mild conditions *via* sequential oxidative addition and alkyne insertion at a molybdenum carbonyl complex.

RESULTS AND DISCUSSION

The Schiff base ligand **1** was prepared by condensation of 2-chlorobenzaldehyde and *N*,*N*-dimethylethylenediamine in ethanol and purified as a yellow oil by vacuum distillation [10]. As depicted in Eq. (1), treatment of a tetrahydrofuran solution of

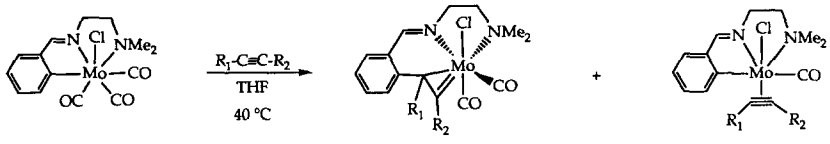
(η^6-$C_6H_5CH_3$)$Mo(CO)_3$ **2** [1], which generates the complex $Mo(CO)_3(thf)_3$ (thf = tetrahydrofuran) *in situ*, with **1** at room temperature for 12 h, affords a dark green solution from which **3** crystallizes as a dark green solid in 66% isolated yield.

Compound **3** exhibits several spectroscopic features that are virtually identical to structurally characterized tungsten(II) and platinum(IV) metallacycles [10,12]. Thus, **3** was formulated as a seven-coordinate molybdenum(II) metallacycle which was produced by chelate-assisted oxidative addition of the aromatic C—Cl bond in **1** to molybdenum(0). Loss of the C_{3v} symmetry of $Mo(CO)_3(thf)_3$ (ν_{CO} = 1920, 1790 cm^{-1}) was noted by the presence of three distinct carbonyl stretches at 2017, 1944 and 1903 cm^{-1} for **3** in thf solution.



As shown in Fig. 1, the ^1H NMR spectra for **3** displays four distinct and highly coupled multiplet resonances (δ 4.55, 4.34, 3.90 and 2.41) for the methylene protons on the ethylene backbone; each integrate to one proton. This non-equivalence illustrates not only the chirality of the seven-coordinate molybdenum(II) metal centre but also the retained coordination of the ligand in solution. As evidenced by the presence of three uncoupled singlet resonances (δ 230.1, 224.1 and 223.8) for the carbonyl ligands at low field in the ^{13}C $\{^1H\}$ NMR spectrum, **3** is static on the NMR time-scale. In fact, the presence of three carbonyl resonances for complex **3** must reflect the rigid nature of the η^3-[C,N,N'] imine chelate ligand, as seven-coordinate complexes typically undergo non-rigid processes at the metal centre [13]. In contrast, related seven-coordinate tungsten(II) carbonyl systems containing a saturated monoanionic η^3-[C,N,N'] ligand exhibit dynamic behaviour at room temperature [14]. A carbon APT spectrum of **3** allowed for the facile identification of the iminic carbon and the metal-bound carbon as singlets at δ 178.4 and 169.6, respectively. The remaining aryl, methylene and methyl carbons afford eight additional resonances which are consistent with a capped octahedral structure for these compounds, with the aryl carbon as the capping group as noted for crystallographically characterized tungsten analogues [10,12,15].

The ability of this system to engage in facile C—Cl cleavage is attributed to several factors associated with ligand design. The nitrogen donor ligand supports a very basic metal centre which is required for oxidative addition. The chelating nature of the ligand is crucial since it reduces the entropic barrier to reaction by placing the C—Cl bond in close proximity to the Mo^0 metal centre. No evidence of bimolecular C—Cl activation of 2-chlorobenzaldehyde or chlorobenzene with **2** has been observed. Finally, the restricted conformation as well as the extended conjugation imparted by the imine moiety in the resulting metallacycle **3** are also important for promoting C—Cl activation in this system.

That cleavage of the carbon–chlorine bond (94 kcal/mol) [16] takes place in the presence of a C—H bond (110 kcal/mol) [16] is not surprising; however, that the facile cleavage of the robust C—Cl bond occurs under such mild conditions is noteworthy if one considers that carbon–chlorine bond activation is a fundamental step in the development of metal-based catalysts for the functionalization of chlorocarbons.

Reactivity studies

Further elaboration of the system was achieved by reaction of the molybdenum(II) chloride metallacycle **3** with internal acetylenes. As illustrated in Eq. (2),

υ_{CO} = 1976, 1822 cm^{-1}
4b: R_1 = Ph; R_2 = CH_3
υ_{CO} = 1971, 1873 cm^{-1}

5a: $R_1 = R_2$ = Ph
υ_{CO} = 1921 cm^{-1}
5b: R_1 = Ph; R_2 = CH_3
υ_{CO} = 1925 cm^{-1}

treatment of **3** with either diphenyl acetylene or 1-phenyl-1-propyne in thf under reduced pressure at 40°C affords a dark green solution composed of two complexes, **4** and **5**, in a 3 : 1 ratio as quantified by ^1H NMR spectroscopy *via* integration of the imine resonance for each compound. The product ratio remained constant throughout the course of the reaction, which suggests that the resulting complexes are not interconvertible under the reaction conditions, and neither compound is an intermediate in the formation of the other. The minor product was identified as the unstable four-electron donor complex **5**. The major product in both systems was recognized as the η^2-vinyl complexes **4**, which were isolated in 50–55% yield as moderately air-stable, green crystalline solids.

Only the η^2-vinyl complexes were isolable from the reaction mixture. The existence of the four-electron donor complexes **5** was established through careful *in situ* IR monitoring of the strong IR band due to the single carbonyl ligand, and by comparison of spectral

features to related, structurally characterized tungsten(II) fluoride systems in which four-electron donor complex formation is favoured by the electron-rich alkynes [7a].

Diagnostic resonances in the ^{13}C $\{^1$H$\}$ NMR spectra of **4a** and **4b** illustrate the salient features [17] of the η^2-vinyl systems. As shown in Fig. 2 for **4a,** the carbenoid character of C_α is reflected by a large downfield chemical shift at δ 258.2, whereas the four-coordinate carbon, C_β, has a significant upfield shift and resonates at δ 46.1 [18, 19]. Similarly, **4b** displays C_α at δ 264.2 and C_β at δ 41.2. Importantly, compounds **4** possess spectroscopic parameters compatible with other monomeric d^4 η^2-vinyl complexes as presented in Table 1 [2, 20].

Consistent with the low symmetry of the molecules, the pseudo six-coordinate η^2-vinyl complexes evince two carbonyl resonances that are located at δ 226.1 and 220.0 for **4a** and at δ 227.2 and 222.3 for **4b**. Interestingly, these η^2-vinyl complexes do not manifest any dynamic behaviour on the NMR time-scale. This contrasts the η^2-vinyl systems reported by Green and co-worker [2e], Templeton and co-workers [20], and Davidson and co-workers [3a,3c,5c,5d] that undergo a surfeit of fluxional processes that are attributed to a windshield wiper-type motion (less than 90 rotation)

[(Tp′)(CO)$_2$Mo(η^2-CPh=CH—CH=N(Me)(Bu^t)][BF$_4$]	242.6	40.7	20
4a	258.1	46.1	This work
4b	264.2	41.2	This work

of the η^2-vinyl fragment. Presumably, the steric constraint imposed by the rigid tridentate η^3-[C,N,N′] chelate ligand prevents this classical windshield wiper motion from occurring (rotation of the η^2-vinyl ligand). Any dynamic process would require a disconnection/reconnection between C_β and the aromatic carbon, which is highly unlikely.

The ^{1}H NMR spectra for **4a** and **4b** are essentially identical to that of **3,** the only difference being the resonances of the η^2-vinyl substituents. The 1-phenyl-1-propyne insertion product, **4b,** displays CO stretching frequencies somewhat lower than those of the diphenylacetylene insertion product, **4a,** which is probably an indication that the methyl group provides more electron density to the metal centre than the phenyl group, as would be expected. The assessment of the regiochemistry for the insertion of 1-phenyl-1-propyne was based upon the similarity of the spectral features of **4b** to those of a structurally characterized tungsten(II) fluoride 1-phenyl-1-propyne η^2-vinyl complex [21].

Consistent with the generally faster rates of CO dissociation for second row metals [22], the overall rate of η^2-vinyl formation is greater for the molybdenum(II) chloride than the tungsten(II) fluoride system. No information is available on the relative rates of migratory insertion since this reaction is fast at room temperature, as noted in the tungsten(II) fluoride system [7].

The η^2-vinyl complexes are chemically robust towards multiple insertions into the Mo—C_{aryl} bond. Although decomplexation of the metal as $Mo(CO)_6$ could be promoted by heating the η^2-vinyl complexes in the presence of 3 atm. CO(g), the resulting organic fragment could not be identified. This contrasts with other related later transition metal complexes, which readily undergo multiple insertion reaction with activated acetylenes to form large metallacycle complexes as well as heterocyclic ring systems upon metal extrusion [23].

Several groups have reported the preparation of η^2-vinyl complexes by external nucleophilic addition to four-electron donor alkyne ligands [2–5,17]. This work provides rare examples of η^2-vinyl formation involving intramolecular nucleophilic attack by the pendant aryl group [7]. A two-electron donor alkyne complex may be a common intermediate in these transformations which could either participate in the migratory insertion reaction or lose CO to afford the four-electron donor alkyne complex. It is interesting to note that the four-electron donor alkyne complex and the η^2-vinyl complexes are not interconvertible moieties, even in the presence of CO.

We have demonstrated that under mild conditions chelate-assisted oxidative addition of strong aromatic carbon–chlorine bonds in suitably designed ligands occurs at molybdenum(0) to afford seven-coordinate molybdenum(II) metallacycles. Further elaboration of the C—Cl bond is effected upon reaction of the molybdenum(II) metallacycle with electron-deficient acetylenes to produce molybdenum(II) η^2-vinyl complexes in which net replacement of a C—Cl bond with a C—C bond has ensued. Although these ligand-based systems are limited with respect to catalytic chemistry, they clearly serve as model compounds for the systematic study of structure and reactivity directed towards catalytic activation and functionalization of carbon–chlorine bonds.

EXPERIMENTAL

General procedures

All manipulations involving air-sensitive reagents were performed under purified nitrogen using standard Schlenk techniques or a Vacuum Atmosphere glovebox [25]. Tetrahydrofuran (thf) was dried with CaH_2 and distilled under nitrogen from sodium benzophenone ketyl radical. Diethyl ether and hexanes were dried with 4 Å molecular sieves and distilled under nitrogen from sodium benzophenone ketyl radical. Methylene chloride was dried and distilled under nitrogen from P_2O_5. Toluene was distilled under nitrogen from sodium metal. Literature methods were employed in the synthesis of $(\eta^6$-$C_6H_5CH_3)Mo(CO)_3$ [11]. All other chemicals were obtained from commercial sources and were used without further purification.

^{1}H- and ^{13}C-{^{1}H} NMR spectra were obtained on Varian XL-300 spectrometers at 300 and 75 MHz, respectively. All chemical shifts are reported in δ

(ppm) units with the following abbreviations: d = doublet, m = multiplet, q = quartet, s = singlet, and t = triplet. Deuterated methylene chloride ^1H NMR spectra were assigned to δ 5.32 and $^{13}C\{^1H\}$ NMR spectra were assigned to δ 53.8. For ^1H and $^{13}C\{^1H\}$ NMR spectra taken in $CDCl_3$, tetramethylsilane was used as an internal reference at δ 0.00. IR spectra were recorded using a Mattson model Galaxy Series 3000 FTIR spectrometer operating with 4.0 cm^{-1} resolution or a BioRad model FTS-40 FTIR spectrometer operating with a resolution of 2.0 cm^{-1}. Solution spectra were obtained in 0.1 mm CaF_2 cells. Solid-state spectra were obtained as KBr pellets for spectral acquisition. Melting points were obtained in open capillary tubes and reported in °C. Elemental analyses were performed by Atlantic Microlab, Norcross, GA.

Preparation of the compounds

Compound **1**. 2-Chlorobenzaldehyde (10.5 g, 0.119 mol) was dissolved in 100 cm^3 of a 75% ethanol/25% benzene solution. One equivalent of *N,N*-dimethylethylenediamine (16.7 g, 0.119 mol) was then added. The resulting solution was heated to boiling until the volume was reduced to approximately one-third. The remaining solvent was then removed by rotary evaporation to yield a yellow oil which was purified by short path vacuum distillation (b.p. 85–88°C, 0.15 mmHg) to yield **1** (20.4 g, 0.0968 mol), 81%. ^1H NMR ($CDCl_3$): δ 8.72 (s, 1H, N=CH); 8.02 (m, 1H, Ar-*H*); 7.28 (m, 3H, Ar-*H*); 3.76 (t, 2H, C=NCH_2); 2.63 (t, 2H, NCH_2); 2.29 (s, 6H, NCH_3). $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ 157.9 (s, N=CH); 134.6 (s, Ar-C_{quat}); 132.8 (s, Ar-C_{quat}); 130.9 (s, Ar-*C*H); 129.2 (s, Ar-*C*H); 128.0 (s, Ar-*C*H); 59.64 (s, NCH_2); 45.43 (s, NCH_3).

Compound **3**. A 100-cm^3 Schlenk flask equipped with a stir bar was charged with (η^6-$C_6H_5CH_3$)$Mo(CO)_3$ **2** (3.02 g, 11.1 mmol) and flushed with nitrogen. Freshly distilled thf (30 cm^3) was added by syringe, and the resulting green-yellow $Mo(thf)_3(CO)_3$ solution was degassed and placed under nitrogen. The ligand **1** (2.43 g, 11.5 mmol) was placed in another Schlenk flask with freshly distilled thf (15 cm^3). The ligand solution was degassed and transferred by syringe to the $Mo(thf)_3(CO)_3$ solution resulting in a colour change to red within 5 min. Over the course of 12 h the solution slowly turned green, and IR spectroscopy confirmed the reaction was complete (ν_{CO} = 2017, 1944, 1903 cm^{-1}). The solvent was removed and the crude product redissolved in a minimal amount of CH_2Cl_2 and filtered through a pad of Celite to remove insoluble particulate matter. The volume was reduced and the product **3** was recrystallized by cooling a 1:5 CH_2Cl_2/Et_2O solution to −10 C for 24 h. Isolation by vacuum filtration gave 2.87 g (7.34 mmol, 66% yield) of **3** as a green crystalline solid. M.p. 116–118 C (dec.); IR ν_{CO} (KBr): 2010, 1938(sh), 1927, 1890 cm^{-1}. Found: C, 41.6; 3.8; N, 6.7. Calc. for $C_{14}H_{15}ClMoN_2O_3 \cdot 1/3\ CH_2Cl_2$ (418.98 g/mol): C, 41.1; H, 3.8; N, 6.7%. Note: CH_2Cl_2 was observed in the NMR spectra. ^1H NMR ($CDCl_3$): δ, 8.59 (s, 1H, N=CH); 7.78 (m, 1H, Ar-*H*); 7.72 (m, 1H, Ar-*H*); 7.17 (m, 2H, Ar-*H*); 4.55 (m, 1H, C=NCH_2); 4.34 (m, 1H, C=NCH_2); 3.90 (m, 1H, NCH_2); 2.80 (s, 3H, NCH_3); 2.65 (s, 3H, NCH_3); 2.41 (m, 1H, NCH_2). $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ 230.1 (s, CO); 224.1 (s, CO); 223.8 (s, CO); 178.4 (s, N=CH); 169.6 (s, Mo-C); 145.5 (s, Ar-C_{quat}); 144.1 (s, Ar-*C*H); 131.8 (s, Ar-*C*H); 129.4 (s, Ar-*C*H); 123.6 (s, Ar-*C*H); 59.92 (s, NCH_2); 54.03 (s, NCH_2); 53.39 (s, NCH_3); 51.82 (s, NCH_3).

Compound **4a**. Under a nitrogen atmosphere, a 100-cm^3 Schlenk flask equipped with a magnetic stir bar was charged with **3** (0.22 g, 0.58 mmol) and diphenylacetylene (0.27 g, 1.5 mmol). Freshly distilled thf (25 cm^3) was added by syringe and the green slurry was degassed and heated to 40°C under reduced pressure to yield a maroon-coloured solution within 1 h. IR monitoring confirmed the reaction was complete in 4 h (ν_{CO} = 1976, 1882 cm^{-1}). Precipitation was achieved by the addition of hexanes and cooling to −10°C for 20 h. Isolation by filtration followed by hexane (2 × 20 cm^3) and Et_2O (5 × 50 cm^3) washings gave 0.17 g (0.31 mmol, 55% yield) of a red–brown powder, **4a**. M.p. 150–152 C (dec.); IR ν_{CO} (KBr): 1973, 1883 cm^{-1}. Found: C, 59.5; H, 4.8; N, 5.1. Calc. for $C_{27}H_{25}ClMoN_2O_2$ (540.90 g/mole): C, 60.0; H, 4.7; N, 5.2%. ^1H NMR (CD_2Cl_2): δ 8.52 (s, 1H, N=CH); 7.91 (m, 1H, Ar-*H*); 7.68 (m, 1H, Ar-*H*); 7.51 (m, 4H, Ar-*H*); 7.39 (m, 2H, Ar-*H*); 6.97 (m, 2H, Ar-*H*); 6.81 (m, 2H, Ar-*H*); 6.44 (m, 2H, Ar-*H*); 4.87 (m, 1H, C=NCH_2); 3.79 (m, 1H, C=NCH_2); 4.34 (m, 1H, C=NCH_2); 3.02 (m, 3H, NCH_3); 2.95 (m, 1H, NCH_2); 2.95 (s, 3H, NCH_3); 2.46 (m, 1H, NCH_2). $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ 258.1 (s, W=C_αPh); 226.1 (s, CO); 220.0 (s, CO); 166.31 (s, N=CH); 149.5 (s, Mo-C); 142.4 (s, Ar-C_{quat}); 140.0 (s, Ar-C_{quat}); 137.4 (s, Ar-C_{quat}); 135.1 (s, 2C, Ar-*C*H); 134.4 (s, 2C, Ar-*C*H); 130.9 (s, 2C, Ar-*C*H); 129.9 (s, Ar-*C*H); 129.5 (s, 2C, Ar-*C*H); 129.4 (s, Ar-*C*H); 129.0 (s, Ar-*C*H); 127.3 (s, Ar-*C*H); 126.8 (s, Ar-*C*H); 122.9 (s, Ar-*C*H); 62.51 (s, NCH_2); 61.01 (s, NCH_2); 56.06 (s, NCH_3); 53.78 (s, NCH_3); 46.1 (s, W-C_βPh).

Compound **4b**. Under a nitrogen atmosphere, a 100-cm^3 Schlenk flask equipped with a magnetic stir bar was charged with **3** (0.28 g, 0.72 mmol) and 1-phenyl-1-propyne (0.21 g, 1.8 mmol). Freshly distilled thf (30 cm^3) was added by syringe and the green slurry was degassed and heated to 40°C under reduced pressure to yield a red-green coloured solution within 1 h. IR monitoring confirmed the reaction was complete in 3 h (ν_{CO} = 1971, 1873 cm^{-1}). Precipitation was achieved by the addition of hexanes and cooling to −10°C for 20 h. Isolation by filtration followed by hexane (2 × 20 cm^3) and Et_2O (5 × 50 cm^3) washings gave 0.17 g (0.36 mmoles, 50% yield) of green-brown powder, **4b**. M.p.

Cadmium(II) halide complexes of pyrazine

Rosa D. Bailey and William T. Pennington*

Department of Chemistry, Clemson University, Clemson, SC 29634-1905, U.S.A.

(Received 22 September 1995; accepted 18 June 1996)

Abstract—Pyrazine forms 1 : 1 complexes with cadmium(II) halides, CdX_2 · pyrazine (X = Cl, Br, I). The structures of all three members of this series have been determined by single-crystal X-ray diffraction. All of the complexes crystallize as infinite CdX_2 chains in which cadmium atoms are doubly bridged by pairs of halide atoms; pyrazine ligands complete the pseudo-octahedral coordination of the cadmium atoms and link the CdX_2 chains to form extended two-dimensional layers. While this type of coordination is fairly common for chloro and bromo derivatives, the iodo compound represents, to the best of our knowledge, the first example of an iodo derivative with this coordination. In each case the layers stack along the crystallographic *a*-axis to complete the structure. In the bromo and iodo complexes, which are isomorphous, the pyrazine ring planes are perpendicular to the plane of the layer. The chloro derivative has a very similar structure; however, the pyrazine rings are rotated by 19.3° away from perpendicular, bringing the *ortho*-C—H groups into close proximity [2.89 (2) Å] to a chloride atom. Keywords: cadmium halides; extended solids; C—H · · · Cl hydrogen-bonding.

In the search for molecular-based materials with interesting properties, much attention has been given to one-, two- and three-dimensional extended solids involving cadmium [1–5]. Cadmium is well suited for this, as its d^{10} configuration permits a wide variety of geometries and coordination numbers (four, five and six are common [6] and seven [3] and eight [7] are known). This structural diversity is particularly evident in cadmium(II) halide complexes. Complexes of the type CdX_2L_2 (X = Cl or Br; L = pyridine or similar small, monodentate ligand) typically form halogen-bridged chain compounds with six-coordinate, pseudo-octahedral cadmium [8]. However, in a number of studies, systematic structural variations over the halide series have been observed [9,10]. These variations have been attributed to factors such as crystal packing, hydrogen-bonding forces and halide dimensions [6], ease of disruption of the cadmium halide framework and relative Cd—X bond strength [9], and the increasing softness of the heavier halides [10]. Additional structural variation can be incorporated by replacing the monodentate ligands with a bidentate ligand (L′) to form complexes of the type CdX_2L'. A series of complexes, CdX_2(pyrazine) for X = Cl, Br and I (compounds **I–III**, respectively), which we have prepared and structurally characterized, are here discussed as an example of the structural variation that can occur in this class of compounds.

EXPERIMENTAL

Preparations

Pyrazine and all cadmium halides were obtained from Aldrich Chemical Company and were used as received; solvents were obtained from commercial houses and were dried and purified by standard techniques and stored over activated sieves. The compounds were prepared by combining ethanol (95%) solutions of the reactants in stoichiometric ratio. If dilute solutions were used, X-ray quality crystals could be grown by simply allowing the ethanol to evaporate slowly. At greater concentrations an immediate precipitate formed. The precipitate was redissolved for each compound by slight acidification of the solution; slow evaporation of the solvent from this acidic solution yielded data quality crystals, as well. The crystals were isolated by rinsing with cold ethanol and hexane, and dried under nitrogen. Powder diffraction spectra, used to identify solid phases in bulk, were measured on a Scintag XDS/2000 *θ–θ*

diffractometer with Cu-$K_{\alpha 1}$ radiation (λ = 1.54060 Å) and an intrinsic germanium solid-state detection system (results can be found in the supplementary material). Far IR (500–100 cm^{-1}) and IR (4000–500 cm^{-1}) spectra were obtained as KBr pellets or as Nujol mulls in sealed polyethylene bags on Nicolet 20F and 510 spectrometers, respectively. Carbon, hydrogen, nitrogen analyses were performed by Atlantic Microlabs, Norcross, GA.

$CdCl_2(C_4H_4N_2)$ (**I**). Pyrazine (0.101 g, 1.24 mmol) was dissolved in ethanol (100 cm^3) and added to a solution of $CdCl_2$ (0.229 g, 1.25 mmol) in ethanol (100 cm^3). Slow evaporation yielded 0.206 g (62.6%) of prismatic crystals; m.p. >500°C. IR (cm^{-1}): 3104, 3049, 2919, 2858, 1601, 1474, 1425, 1388, 1172, 1129, 1055, 808, 746, 622, 446, 222, 178, 121. Elemental analyses: Found (Calc.): C, 18.5 (18.2); H, 1.6 (1.5); N, 10.7% (10.6%).

$CdBr_2(C_4H_4N_2)$ (**II**). Pyrazine (0.104 g, 1.30 mmol) was dissolved in ethanol (100 cm^3) and added to a solution of $CdBr_2 \cdot 4H_2O$ (0.426 g, 1.24 mmol) in ethanol (100 cm^3). Slow evaporation yielded 0.365 g (83.7%) of parallelepiped crystals; m.p. 447–449°C. IR (cm^{-1}): 3099, 3037, 2932, 1653, 1487, 1413, 1160, 1129, 1042, 789, 447, 280, 202, 180, 120. Elemental analyses: Found (Calc.): C, 13.8 (13.6); H, 1.1 (1.1); N, 7.9% (8.0%).

$CdI_2(C_4H_4N_2)$ (**III**). Pyrazine (0.102 g, 1.27 mmol) was dissolved in ethanol (100 cm^3) and added to a solution of CdI_2 (0.457 g, 1.25 mmol) in ethanol (100 cm^3). Slow evaporation yielded 0.470 g (84.4%) of light yellow, prismatic crystals; m.p. 409–412°C. IR (cm^{-1}): 3098, 3018, 1659, 1418, 1387, 1270, 1166, 1128, 1048, 795, 448, 172, 104. Elemental analyses: Found (Calc.): C, 11.0 (10.8); H, 0.9 (0.9); N, 6.1% (6.3%).

X-ray crystallography

All measurements were made at 22±1°C with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) on either a Rigaku AFC7R (compounds **I** and **II**) or a Siemens R3m/V (compound **III**) diffractometer. Unit-cell dimensions and an orientation matrix were determined from the setting angles of several high-order reflections. Intensities were measured using an $\omega/2\theta$ scan technique at a speed of 4–32°/min for compounds **I** and **II** and 2°/min for **III**. The intensities of three reflections remeasured periodically throughout data collection fluctuated by less than ±1%, indicating crystal and electronic stability. The data were corrected for absorption (empirical, based on ψ-scans) and for Lorentz and polarization effects. The structures were solved by direct methods and refined on F by full-matrix least-squares techniques. Non-hydrogen atoms were refined with anisotropic thermal parameters and hydrogen atoms were refined isotropically. The weighting scheme was based on counting statistics and included a factor (0.0005) to downweight intense reflections. The final difference Fourier map for each of the structures was featureless. Scattering factors were taken from Table 2.2B and the real and anomalous dispersion corrections from Table 2.3.1 of ref. [11]. Relevant crystallographic data is given in Table 1. All calculations were performed using a combination of SHELXTL-Plus [12] and TEXSAN [13]. Atomic coordinates have been

RESULTS AND DISCUSSION

General description of structures

A general view of CdX_2(pyrazine) showing the atomic numbering scheme is shown in Fig. 1. Selected bond distances and angles for the three compounds are given in Table 2.

All of the complexes crystallize as infinite CdX_2 chains in which cadmium atoms are doubly bridged by pairs of halide atoms; pyrazine ligands bonded in *trans*-positions complete the pseudo-octahedral coordination of the cadmium atoms and link the CdX_2 chains to form extended two-dimensional layers. The layers stack along the crystallographic *a*-axis, with adjacent layers related by C-centring, to complete the structure (Fig. 2; in Figs 2–4, the cadmium atoms are represented as boundary ellipsoids, the halide atoms as hatched ellipsoids, the nitrogen atoms as solid spheres, the carbon atoms as partially shaded circles and the hydrogen atoms as open circles). This layered structure is similar to that observed in CuX_2(pyrazine) (X = Br, Cl) [14]; the only major difference being the asymmetric nature of the halide bridges [Cu—Br distances of 2.427(2) and 3.034(2) Å] in the Cu^{II} complex, which is due to the pseudo-Jahn Teller distortion of the d^9 metal centre.

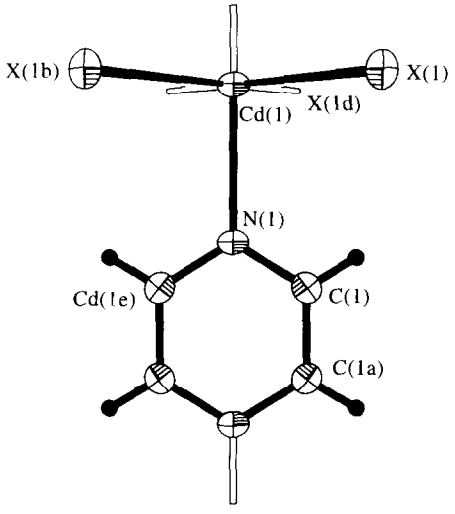

Fig. 1. A general view (50% probability ellipsoids) of CdX_2(pyrazine) showing the atom-numbering scheme used. Atom labels containing a lower case character were generated by the corresponding symmetry operation listed in Table 2.

Symmetry operations: a: $x, 1-y, z$; b: $-x, -y, 1-z$; c: $-x, -y, -z$; d: $x, y, 1+z$; e: $-x, y, -z$.

The bonding distances and angles within the pyrazine ring for each of the complexes are typical of those observed in other compounds in which pyrazine bridges two metal centres [15].

Crystal structure of **I**

The cadmium atom lies on a crystallographic $2/m$ site at the origin; the twofold axis is coincident with the Cd—N bonds and the chloride ions lie on the mirror plane. The pyrazine ring also possesses $2/m$ symmetry, as it is situated about a site at $(0\,1/2\,0)$; a third $2/m$ site lies at the mid-point between the two bridging chloride ions at $(0\,0\,1/2)$. Adjacent cadmium atoms in the chloride-bridged chain are related by translation along the *c*-axis; adjacent chains in a layer are related by translation along the *b*-axis.

The Cd—N bond length of 2.386(4) Å is within the range of similar $Cd—N_{aromatic}$ bonding distances [2.36(6) $Å_{mean}$; 2.248(2)–2.448(6) $Å_{range}$] [16]. The Cd—Cl bond length of 2.612(2) Å is also within the range of typical values [2.62(4) $Å_{mean}$; 2.576(7)–2.731(2) $Å_{range}$] [17].

Crystal structure of **II**

The cadmium atom lies on a crystallographic *mmm* site at the origin. The pyrazine ring lies on the mirror plane perpendicular to the *c*-axis and the bridging halides lie on the mirror plane perpendicular to the *b*-axis. The layer is bisected by the mirror plane perpendicular to the *a*-axis. As in **I**, adjacent cadmium atoms in the bromide-bridged chain are related by translation along the *c*-axis, and adjacent chains in a layer are related by translation along the *b*-axis.

The Cd—N bond length of 2.397(3) Å observed in **II**, is slightly longer (2.75 σs) than that in **I**, but is still within the range of typical $Cd—N_{aromatic}$ bonding distances [16]. The Cd—Br bond length of 2.752(1) Å is experimentally equivalent to the value of 2.73(1) Å observed in $CdBr_2$(dioxane) [18], which has a similar layered structure. It has been observed that the length of Cd—Br distances in related compounds is depen-

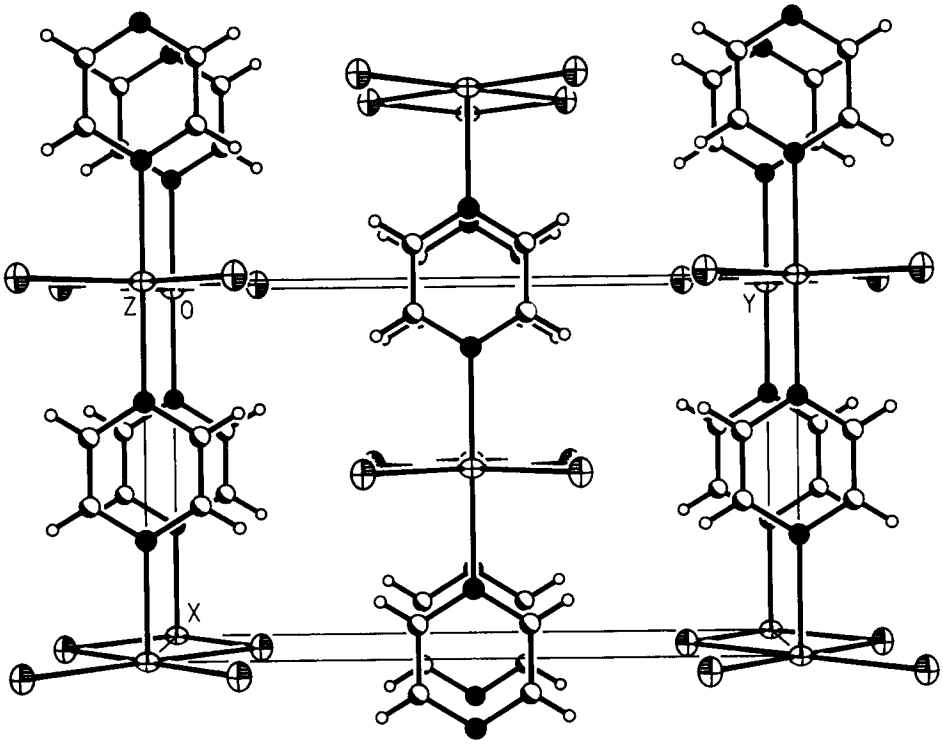

Fig. 2. Stacked layers of CdX_2(pyrazine) viewed down the *c*-axis, parallel to the CdX_2 chains.

dent on the nature of the atom bonded in a *trans* position [17e]. We have been unable to locate any compounds, other than $CdBr_2$(dioxane), in which bromine atoms are bonded in mutually *trans* positions of an octahedral cadmium coordination sphere. However, the value observed in **II** is within the range of values observed for a variety of $CdBr_2$ complexes [2.74(4) $Å_{mean}$; 2.691(1)–2.819(2) $Å_{range}$] [19].

Crystal structure of **III**

Compound **III** is isomorphous with **II**, the primary difference in the two structures being those expected as a result of the larger size of the iodine atoms.

The Cd—N bond length of 2.423(3) Å is somewhat longer than that observed in **I** (9.2 σs) and **II** (8.7 σs) and approaches the upper limit of observed Cd–$N_{aromatic}$ values [16]. To the best of our knowledge, this compound represents the first example of a complex with an octahedral CdI_4N_2 coordination sphere with bridging iodine atoms in *trans* positions. The Cd—I bond length of 2.947(1) Å is within the range of values for compounds in which cadmium atoms are bridged by iodine atoms [2.9(1) $Å_{mean}$; 2.741(1)–3.109(1) $Å_{range}$] [20].

Comparison of structures

In compounds **II** and **III** the pyrazine ring planes are perpendicular to the layers, while in **I** the rings are rotated by 19.3° away from the perpendicular to the layer (Fig. 3). This rotation lowers the symmetry of the layer from *mmm* to 2/*m*, resulting in the observed difference in crystal system and space group for **I** relative to **II** and **III**. This rotation appears to be owing to intra-layer C—H···Cl hydrogen bonding (Fig. 4). The H···Cl distance of 2.89(2) Å and the C—H···Cl angle of 129(1)° are both within the range of values attributed to this type of interaction (H···Cl = 2.569–2.944 Å; C—H···Cl = 119.3–169.2°) [21]. Packing differences for chloro versus bromo and iodo derivatives have recently been attributed to the presence of this type of interaction in a series of $Zn_2X_2L_2$ complexes (X = Cl, Br, I; L = oxo ligands) [22].

The increased Cd—N distance down the halide series might be a result of steric interactions between the pyrazine ring and the halide atoms within a CdX_2(pyrazine) layer. However, compression of the Cd—N distance in **II**, from the observed value of 2.397(3) Å to 2.386(4) Å, the value observed for **I**, would result in intra-layer contacts of 3.642 Å for N···Br, 3.731 Å for C···Br and 3.304 Å for H···Br, all of which are well outside the sum of van der Waal's radii for the atoms involved (H 1.20 Å [22], C 1.70 Å, N 1.55 Å, Br 1.85 Å, I 1.98 Å) [23]. Compression of the Cd—N distance in **III**, from the observed value of 2.423(3) Å to the value found in **I**, would also result in contacts much longer than their van der Waal's sums (N···I 3.792 Å, C···I 3.840 Å and H···I 3.360 Å). A more likely explanation for this trend is that

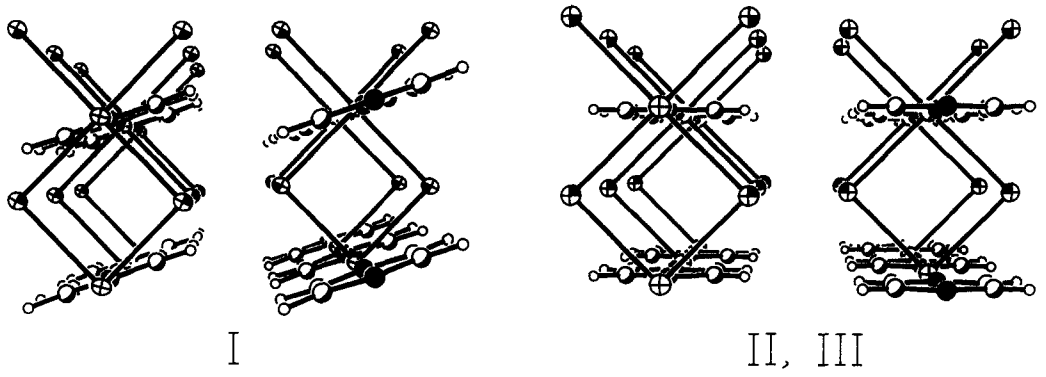

Fig. 3. Comparison of CdX_2(pyrazine) layers.

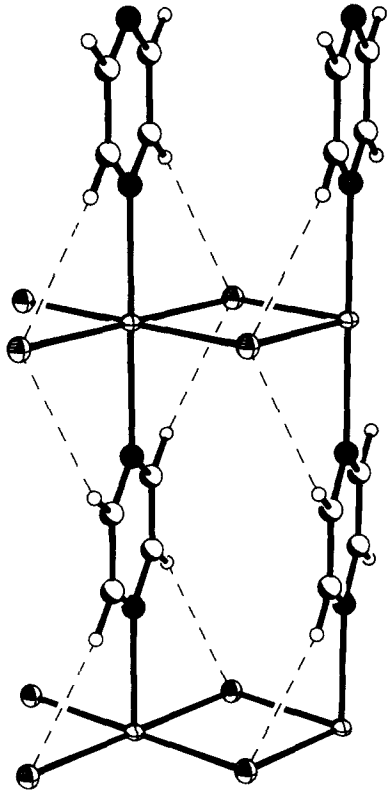

Fig. 4. Intra-layer C—H · · · Cl hydrogen bonding in **I**.

there is increased electron density at the cadmium with the heavier, softer halogens. This has been suggested as the reason for similar systematic structural changes observed in a series of cadmium halide complexes with chelating nitrogen macrocyclic ligands [10].

CONCLUSIONS

Systematic structural changes in the CdX_2(pyrazine) complexes can be attributed to steric factors associated with the increasing size of the bridging halides, down the series, and to electronic factors associated with the increasing softness of the heavier halogens. The symmetry breaking which occurs for the chloride derivative is associated with the presence of C—H · · · Cl hydrogen bonding which is not present for the bromo and iodo complexes. It is interesting to note that in a crystallographic study of a number of MX_2(pyridine)$_2$ complexes, the symmetries of the chloro derivatives have been found to be different to those of the heavier halo complexes [24]. Our continuing investigation of these types of complexes will examine the structural influence of C—H · · · Cl interactions.

Selective reactions (hydrolysis or debenzotriazolation) of bis(benzotriazol-1-yl) methylimine by metal(II) salts

S. Thambidurai and S. K. Ramalingam*

School of Chemistry, Madurai Kamaraj University, Madurai 625 021, India

(Received 24 May 1996; accepted 17 June 1996)

Abstract—The reactions of bis(benzotriazol-1-yl)methylimine (BBTMI) with acetates and chlorides of Cu^{II}, Ni^{II}, Co^{II}, Zn^{II}, Cd^{II} and Mn^{II} were studied in ethanol. While the metal acetates induced debenzotriazolation to form 1-cyanobenzotriazole and benzotriazole, the chlorides induced hydrolysis of BBTMI to form 1,1′bis(benzotriazol-1-yl)carbonyl. These intermediates subsequently formed the mixed ligand complexes [1-cyanobenzotriazolediacetato M(II)] and [benzotriazolatochloro M(II)] respectively. The chemo-selectivity of the reactions could be attributed to a facile cleavage of one of the M—O bonds of the bidentately bound acetates and to the acidic nature in the case of the chloride solution. Copyright © 1996 Elsevier Science Ltd

Keywords: bis(benzotriazol-1-yl)methylimine; chemoselectivity; hydrolysis; debenzotriazolation; facile metal-oxygen bond cleavage; metal salts.

The reactions of N-unsubstituted imines are rarely reported in the literature since in many cases either the isolation of the imines themselves is difficult or even when formed many of them decompose or cyclise. Nevertheless, Tsutsumi *et al.*, and Smith *et al.*, studied the conversion of some aldimines to nitriles [1,2]. Katritzky *et al.*, reported the debenzotriazolation of N-unsubstituted imines which yielded cyanamide [3]. In a study of metal mediated organic reactions we have earlier reported that the imine BBTMI underwent debenzotriazolation upon using labile metal diketones in non-aqueous medium to bring about ultimately γ-cyanation on β-diketone ring [4]. The same substrate, however, was found to be without action on analogous but inert chelates. This was attributed to a facile breaking of one of the M—O bonds, accumulating a negative charge on the coordinated ligand which was responsible for further reaction. In this context it is of interest to test the influence of two different simple metal salts, one fully ionizing (chlorides) and the other partly ionizing (acetates), to test whether different end products could be obtained. The present paper reports the chemoselective reactions, *viz.* debenzotriazolation and hydrolysis of BBTMI brought about by the metal(II) acetates and chlorides respectively.

EXPERIMENTAL

Metal salts used were of reagent grade. Bis(benzotriazol-1-yl)methylimine was prepared by a method described in an earlier reported paper [4]. IR spectra were recorded on a Perkin-Elmer 577 spectrometer, and ^{1}H NMR spectra on a R 32 Bruker Instrument.

Reaction of BBTMI with acetates of Cu^{II}, Ni^{II}, Co^{II}, Zn^{II}, Cd^{II} and Mn^{II}

A mixture of equimolar amounts (0.002 mole) of the metal(II) acetate and the imine in 40 cm^3 of ethanol was kept stirred for 30 min. 1-Cyanobenzotriazolediacetatometal(II) complex which precipitated as a solid from the clear reaction mixture was filtered and washed with methanol and water.

Reaction of BBTMI chlorides of Cu^{II}, Ni^{II}, Co^{II}, Zn^{II} and Cd^{II}

An ethanolic solution containing 0.002 mole each of metal(II) chloride and BBTMI was kept stirred for

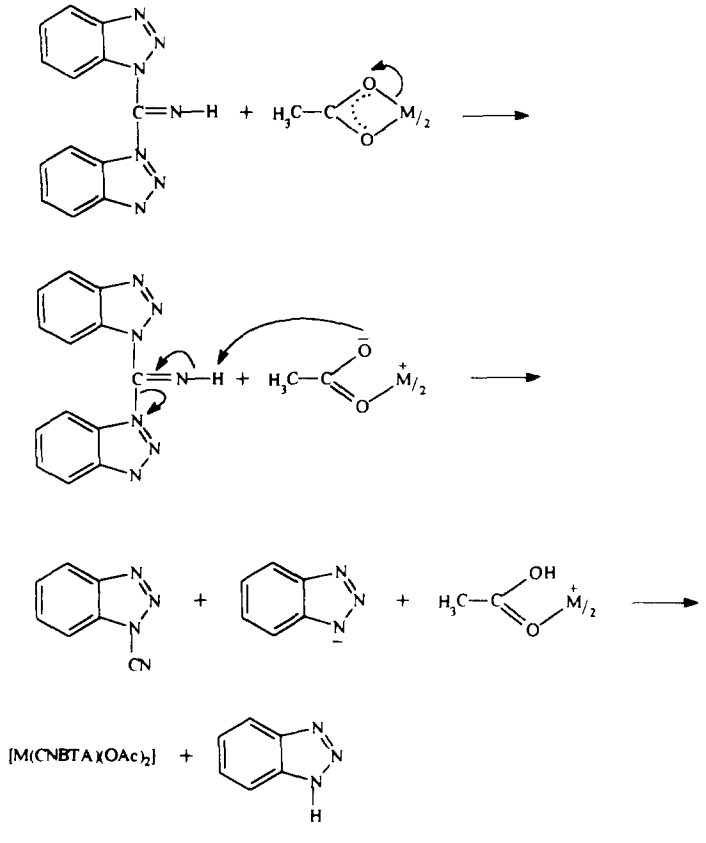
2 h. The solid benzotriazolatochlorometal(II) complex formed was filtered and washed with methanol.

RESULTS AND DISCUSSION

The reaction of acetates and chlorides of metal(II) ions with BBTMI yielded new dimeric 1-cyanobenzotriazolediacetatometal(II) and the known benzotriazolatochlorometal(II) complexes whose elemental analysis and physical characteristics are given in Table 1. The reaction products reveal that the metal(II) acetates induce debenzotriazolation to form 1-cyanobenzotriazole and benzotriazole and chlorides bring about hydrolysis to form 1,1′bis(benzotriazol-1-yl)carbonyl *in situ*. The chemo-selectivity of the BBTMI in undergoing a specific reaction with either the metal(II) acetates or chlorides and to bring about a specific reaction either debenzotriazolation or hydrolysis can be explained as follows:

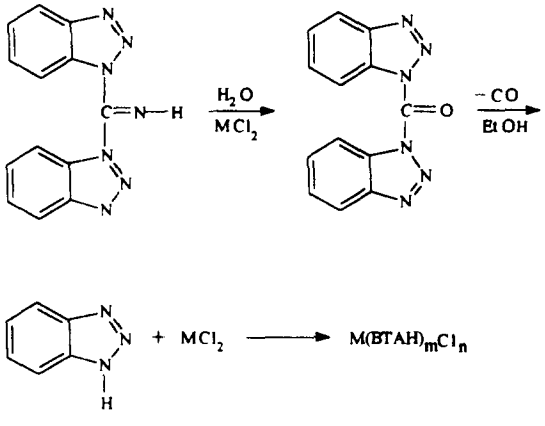
1. In metal(II) acetates, the acetate group is bidentately bound to the metal ion. The cleavage of one of the facile M—O bonds places a negative charge on the oxygen atom of the acetate group rendering it a nucleophilic centre to bring about debenzotriazolation. The schematic steps are given below. We have earlier described the debenzotriazolation of BBTMI brought about by labile β-diketonates which involved the M—O bond cleavage as a key factor. This observation lends support for the above scheme.



2. On the other hand metal chlorides seem to play a different role. They being a salt of weak base and strong acid, are necessarily acidic in ethanolic medium too. Such chlorides then bring about acid catalysed hydrolysis of BBTMI. The steps involved are: the formation of the ultimate product, *viz.* the benzotriazolatochloro complex, is obtained *via* decarbonylation of the intermediate 1,1′bis(benzotriazol-1-yl)carbonyl. This is possible due to the latter being a carbonylating agent [5]. The filtrate of the reaction product does not show the presence of any 1-substituted benzotriazoles, testifying the hydrolysis and the subsequent decarbonylation. However, the products in the filtrate could not be fully identified.

Identification

(*i*) *Benzotriazole chloro metal*(II). Elemental analysis shows that copper and cadmium complexes have the composition Cu(Cl)(BTA) and $Cd(BTAH)Cl_2$ respectively while other metal complexes have the composition $M(BTAH)_2Cl_2$. The identity of the complexes was confirmed by comparison with the spectra of authentic samples, prepared by the reported method [6].



(*ii*) 1-*Cyanobenzotriazolediacetato metal*(II). The IR spectrum shows a strong absorption at 2180 cm^{-1} due to νCN which reveals the presence of a cyano group. The spectrum also shows bands attributable to benzotriazole, *viz.* at 745, 790, 1190, 1210 and 1270 cm^{-1}. The presence of an absorption band in the region 1630–1615 cm^{-1} is assignable to carbonyl stretching of the unidentately coordinated acetate groups [7]. The NMR spectrum of the zinc complex clearly indicates the presence of 1-cyanobenzotriazole and acetate groups through the appearance of the following peaks at 2.5 δ (s, 6H), 7.56 δ (s, 2H) and 8.1–8.3 δ (AA′BB′, 2H).

The identity of 1-cyanobenzotriazole is also confirmed by comparison of the demetallated ligand part with 1-cyanobenzotriazole prepared by the reported method [3].

XPS and chiroptical studies on ternary lanthanide complexes of D-camphor-β-sulfonic acid and 1,10-phenanthroline

Dong Hengshan, Ma Hongzhu, Wang Bo and Yang Shiyan*

State Key Laboratory of Oxo Synthesis and Selective Oxidation, Lanzhou Institute of Chemical Physics, Chinese Academy of Sciences, Lanzhou 730000, P.R. China

(Received 1 April 1996; accepted 17 June 1996)

Abstract—Nine new chiral complexes of the type $Ln(Phen)_2L_2Cl$ (Ln = La^{III}, Pr^{III}, Nd^{III}, Ce^{III}, Sm^{III}, Eu^{III}, Tb^{III} and Ho^{III}, Phen = 1,10-phenanthroline, L = D-camphor-β-sulfonate ion) have been synthesized and characterized on the basis of elemental analysis, molar conductance, electronic, IR, XPS, circular dichroism (CD) and fluorescence spectra. A seven coordinated model has been proposed for these complexes. Copyright © 1996 Elsevier Science Ltd

Keywords: XP spectra; ternary lanthanide complexes; D-camphor-β-sulfonic acid; 1,10-phenanthroline; circular dichroism; fluorescence spectra.

In our earlier communications [1,2] we reported the preparation and properties of the lanthanide(III) complexes of D-camphor-β-sulfonic acid. As no chiroptical study on ternary lanthanide(III) complexes of D-camphor-β-sulfonic acid and 1,10-phenanthroline have been reported so far, in continuation of our systematic investigation of chiroptical lanthanide(III) chemistry we report here the synthesis and discussion of some of these complexes.

EXPERIMENTAL

Methods and materials

The reagents and solvents used were of AR grade and were used without further purification. Lanthanide(III) chlorides were made from the oxide and hydrochloric acid. Sodium D-camphor-β-sulfonate was made from sodium hydroxide and the acid.

Preparation of the complexes

The same method for the synthesis of all of these complexes was adopted. In a typical reaction to a sodium of 1,10-phenathroline (2 mmol) in anhydrous EtOH (30 cm^3), lanthanide(III) chloride (1 mmol) in EtOH (10 cm^3) was added, and the mixture was refluxed for 1 h. The white solids were separated and filtered, washed with EtOH and dried *in vacuo* (80 mm Hg) at 80°C for 1 h. The $Ln(Phen)_2Cl_3$ were obtained in the yield of 80–90%.

The solid, $Ln(Phen)_2Cl_3$ (1 mmol) was dissolved in absolute MeOH (30 cm^3), sodium D-camphor-β-sulphonate (3 mmol) in MeOH (20 cm^3) was added dropwise and the mixture was refluxed for 1 h. The white products were separated and filtered, washed with MeOH followed by Et_2O and dried *in vacuo* (80 mm Hg) at 80°C for 2 h.

Chemical and physical analyses

The lanthanide(III) contents in these complexes were determined by titration with EDTA in the presence of a buffer solution using xylenol orange as the indicator. C, H, N, S and Cl contents of the compounds were determined by standard procedures.

Molar conductance at room temperature was measured in 10^{-3} mol l^{-1} DMF solution using a DDS-IIA molar conductometer. IR spectra were taken on a NIC-5DX spectrophotometer (CsI pellets) in the range of 200–4000 cm^{-1}. Electronic spectra of the

* Author to whom correspondence should be addressed.

complexes in 10^4 mol l^{-1} DMF solution were recorded on a DJ-240 UV–vis spectrophotometer. The X-ray photoelectron spectra were measured on a PH1-550 spectrometer using Mg-K_α radiation (hν = 1253.6 eV). The peak areas and peak positions for the analyses were determined using a linear background. The accuracy of the measured BE values is $\pm$0.1 eV. All XP spectra were referenced to an assumed C 1*s* binding energy of 284.6 eV. Circular dichroism (CD) spectra were obtained at 20°C with a Cary Mode 60 spectropolarimeter with a CD model 6001 accessory in the 200–700 nm region. The molecular ellipticity (θ1) values are adjusted to an enantiometric excess (ee) of 100%. Fluorescence spectra of the complexes in 10^{-5} mol l^{-1} DMF were recorded on a 3070E spectrometer.

RESULTS AND DISCUSSION

Physical and analytical data on the new complexes are given in Table 1. Analytical results conform to the formula $Ln(Phen)_2L_2Cl$. The complexes are air stable and insoluble in ether, EtOH, acetone, THF and moderately soluble in MeOH and soluble in DMF and DMSO. The Λ_M values in DMF solution (Table 1) suggested that they are non-electrolytes [3]. The thermal analysis revealed that all the complexes are anhydrous.

IR spectra

The important bands observed in the IR spectra of the ligands as well as in their metal complexes are given in Table 2 along with their assignments.

The absorption bands of ν(C=O) at 1740 cm^{-1} in the ligand (NaL) and its metal complexes remains almost unchanged, indicative of the carbonyl oxygen being uncoordinated. Two stretching vibrations of —SO_3, $\nu_{as}(SO_3)$ and $\nu_s(SO_3)$ in the spectra of the complexes are observed at *ca* 1200 and 1047 cm^{-1} with the $\Delta\nu(SO_3)$ = 153 cm^{-1}. Comparing with the ligand, the two bands at 1190 and 1043 cm^{-1} with the difference $\Delta\nu(SO_3)$ = 147 cm^{-1} suggest that the —SO_3 group is coordinated with the metal ion in unidentate form. The band at 1620 cm^{-1} in the free ligand (Phen) attributed to the ν(C=N) stretching vibration shifts to lower frequencies at 1600 cm^{-1}, and the phen ring stretching vibration shifts from 1355 to 1346 cm^{-1} after complexation indicating that the nitrogen atoms are coordinated to the metal ion. Furthermore, three new bands are observed at *ca* 510, 320 and 270 cm^{-1} in the complexes assigned to ν(Ln—O), ν(Ln—N), and ν(Ln—Cl), respectively, confirms the participation of the ligands in the complexation [4, 5].

Electronic spectra

The electronic spectra of the complexes are similar, but are different from these of the ligands (Table 1).

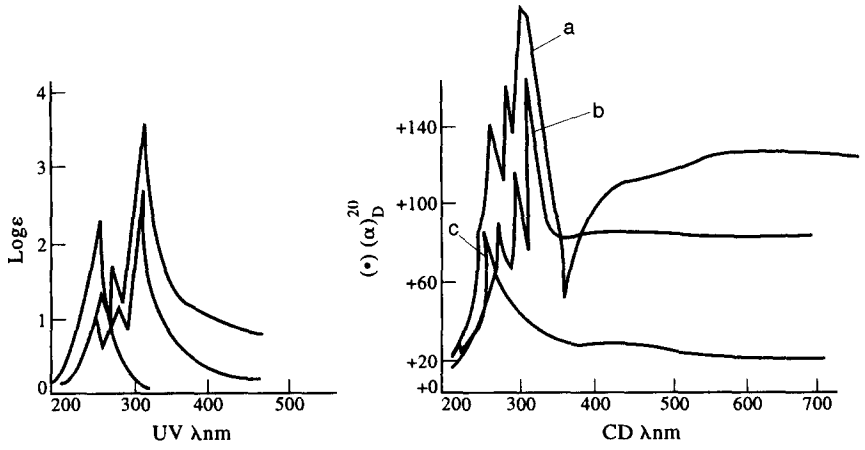

Fig. 1. CD(···) and electronic spectra of the complexes. (a) $Eu(Phen)_2L_2Cl$; (b) $La(Phen)_2L_2Cl$ and (c) NaL.

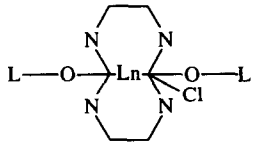
The bands are observed at *ca* 295 and 320 nm of the complexes due to the phen purple-shifted 4–8 nm relative to the free ligand, indicating the coordination of the nitrogen atom to the metal. The band at *ca* 280 nm and purple-shifted 5–10 nm in the complexes is attributed to the ν(C=O) absorption of L [4,5], indicating complexation.

Fluorescence spectra

A strong red-fluorescence of the solid complexes $Eu(Phen)_2L_2Cl$ and $Tb(Phen)_2L_2Cl$ was observed under a ultraviolet lamp (λ = 254 nm) but the solution fluorescence (1×10^{-5} mol l^{-1} DMF) of the complexes is very weak and a broad band at 404 nm of Eem are observed at Eex 345 nm for Eu^{III} complexes and Eex 364 nm for Tb^{III} complexes, respectively, indicating that the fluorescence is due to the interaction of phen with L. The result was confirmed by the determination of the solution (1×10^{-5} mol l^{-1} DMF) of the gel prepared from phen and HL in the mol ratio 1:1.



XP spectra

To obtain further insight concerning the nature of bonding, XP spectra of the complexes and ligands were recorded in the powder form at room temperature (25°C), and it was found that the data of atomic molar percent determined is very close to the elemental result. The electron BEs of the metal and the values of N 1*s*, O 1*s*, S 2*p* and Cl 2*p* are given in Table 3. The values for Ln 3*d* or 4*d* electron BE in the complexes are approximately the same and support the oxidation number of three.

The N 1*s* and S 2*p* electron spectra of the complexes are symmetric and their deconvolution revealed that related to the free ligands, the N 1*s* and S 2*p* BEs are both shifted lower, this can be explained as due to the increase of the electron density coordinated to the ligands and it is consistent with the electronic spectra date. The O 1*s* electron spectra of the complexes are asymmetric and deconvolution yields two components with an intensity ratio 1:3. The weaker component with a higher BE value at *ca* 532.7 eV remain almost unchanged and belongs to oxygen of the carbonyl, the more intense component with a lower BE value belongs to the oxygen of SO_3 group. The values are slightly lower than that of the NaL ligand [6].

CD spectra

The distinct positive Cotton effect of the spectra of the complex and the ligand (NaL) are observed (Table 4, Fig. 1), the positive value at *ca* 280 nm of the complexes is diagnostic of the preferred conformer with (s)-absolute configuration is dominant for dichroic absorption similar to a positive effect in the ligand [7].

On the basis of the above discussions a seven coordinated number bonding model is proposed for the complexes.

Abstract—The interaction of *N,N'-bis*[*o*-(diphenylphosphino)benzylidene]ethylenediamine (immpho) with one and two equivalents of $[(\eta^5\text{-}C_5Me_5)Ru(CH_3CN)_3]^+$ (generated *in situ* from the reaction of $[(\eta^5\text{-}C_5Me_5)RuCl_2]_n$ with excess Zn granular in CH_3CN) in CH_3CN at room temperature gave $[(\eta^5\text{-}C_5Me_5)Ru(immpho)]_2[ZnCl_4]$ (**I**) and $\{[(\eta^5\text{-}C_5Me_5)Ru(CH_3CN)]_2[immpho]\}\{ZnCl_4\}$ (**II**) in 80% and 71% yield, respectively. Upon UV irradiation, immpho reacted with equal molar of $[(\eta^5C_5H_5)Fe(\eta^6\text{-mesitylene})][BF_4]$ in CH_3CN at room temperature to give $[(\eta^5\text{-}C_5H_5)Fe(immpho)][BF_4]$ (**III**) in 41% yield. Compounds **I**–**III** have been fully characterized by analytical and spectroscopic methods. The structures of **II** and **III** have been established by X-ray diffraction. Keywords: ruthenium(+2); iron(+2); ruthenium(+2) dimer; diiminodiphosphine; cyclopentadienyl; pentamethylcyclopentadienyl.

We have been interested in the chemistry of diiminodiphosphines as these are polydentate ligands containing both phosphorus and nitrogen donor atoms which could behave as soft and hard bases, respectively, and act as bridging ligands for the preparation of heterometallic complexes with hard and soft metal centres. We have shown that these ligands exhibit a very rich coordination chemistry and can behave as bridging, *bi-*, *tri-* and *tetra*-dentate ligands depending on the reaction conditions [1–6]. As a tridentate ligand, the diiminodiphosphine ligand exhibits different modes of coordination toward different metal centres. The diiminodiphosphine ligands coordinate to the Group 6 metals (Cr, Mo) *via* the two imino groups and one of the phosphino groups with one of the phosphino groups remaining uncoordinated [2,6]; and coordinate to the Group 11 metals (Cu, Ag) *via* the two phosphino groups and one of the two imino groups only with one of the imino groups remaining uncoordinated [4,6]. In this paper, we report the coordination mode of *N,N'-bis*[*o*-(diphenylphosphino)benzylidene]ethylenediamine (immpho), a diiminodiphosphine ligand, toward Group 8 metals, Fe and Ru.

RESULTS AND DISCUSSION

Preparation of $[(\eta^5\text{-}C_5Me_5)Ru(immpho)]_2[ZnCl_4]$ (I)

An acetonitrile solution of $[(\eta^5\text{-}C_5Me_5)Ru(CH_3CN)_3]^+$, generated *in situ* from the reaction of $[(\eta^5\text{-}C_5Me_5)RuCl_2]_n$ with excess Zn granular in CH_3CN, was slowly added to a solution of CH_2Cl_2 containing one equivalent of immpho at room tem-

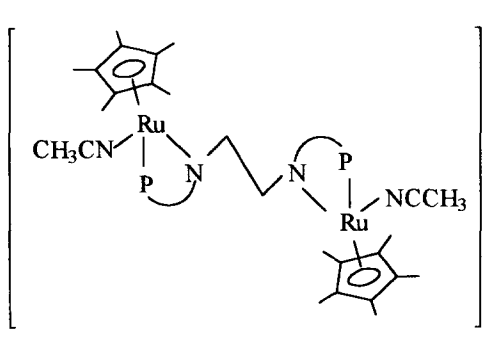
perature; after stirring the solution for an additional 12 h, work up gave dark-red crystals of stoichiometry $[(C_5Me_5)Ru(immpho)]_2[ZnCl_4]\cdot 2H_2O$, **I**$\cdot 2H_2O$, in good yield (80%) after recrystrallization from a CH_3CN/Et_2O mixture. The IR spectrum of **I** exhibits a $\nu_{C=N}$ stretch at 1626 cm^{-1} for the imino groups. The $^{31}P\text{-}\{^1H\}$ NMR spectrum of **I** exhibits two singlets of relative intensity 1 : 1 at δ 43.6 and -15.6 ppm which correspond to a coordinated and an uncoordinated phosphorus, respectively. This suggests that the immpho ligand behaves as a tridentate ligand with one of its phosphino groups remaining uncoordinated. This is further supported by the ^1H NMR spectrum of **I** which exhibits two broad multiplets of relative intensity of 1 : 1 at δ 9.80 and 8.18 ppm which corresponds to the —C*H*=N— proton of the uncoordinated and the coordinated benzylidene, respectively. Other than the phenyl protons, the ^1H NMR spectrum of **I** also exhibits a singlet at δ 1.09 ppm for the —C*H*$_3$ protons of the pentamethylcyclopentadienyl ring indicating that the pentamethylcyclo pentadienyl ring is bonded to the ruthenium metal in an η^5 fashion. Based on the above spectroscopic data, the following structure can be assigned to **I**.

This is confirmed by an X-ray diffraction study [7] which shows that the diiminodiphosphine ligand acts as a tridentate ligand with one of the two phosphino groups and the two imino groups coordinated to the ruthenium metal and an uncoordinated phosphino group.



However, when the above reaction was carried out in the reverse order, that is by adding a CH_2Cl_2 solution of immpho into an equal molar solution of $[(\eta^5\text{-}C_5Me_5)Ru(CH_3CN)_3]^+$, generated *in situ* from the reaction of $[(\eta^5\text{-}C_5Me_5)RuCl_2]_n$ with excess Zn granular in CH_3CN, the $^{31}P\text{-}\{^1H\}$ NMR spectrum of the reaction mixture showed that a mixture of **I** and **II** (*via infra*) were obtained. Dark-red crystals of stoichiometry $\{[(\eta^5\text{-}C_5Me_5)Ru(CH_3CN)]_2[immpho]\}\{ZnCl_4\}$, **II**, were obtained in good yield (71%) after recrystallization from a CH_3CN/Et_2O mixture. The IR spectrum of **II** exhibits a $\nu_{C=N}$ stretch at 1637 cm^{-1} for the imino groups. The $^{31}P\text{-}\{^1H\}$ NMR spectrum of **II** exhibits only a singlet at δ 43.2 ppm. This suggests that the two phosphino groups of the immpho ligand were coordinated and equivalent. Other than the phenyl protons, the ^1H NMR spectrum of **II** also exhibits a broad multiplet of relative intensity of 2 at δ 8.30 ppm for the —C*H*=N— protons of the coordinated benzylidenes; two broad singlets of relative intensity 2 : 2 at δ 4.55 and 4.40 ppm for the —NCH_2CH_2N— protons; and a singlet of relative intensity of 30 at δ 1.40 ppm for the —C*H*$_3$ protons of the pentamethylcyclopentadienyl rings, indicating that the two pentamethylcyclopentadienyl rings are equivalent and bonded to the ruthenium metals in an η^5 fashion. Based on the above spectroscopic data the following structure can be assigned to **II**.

The structure of **II** was confirmed by an X-ray diffraction study. Crystals of stoichiometry $\{[(\eta^5\text{-}C_5Me_5)Ru(CH_3CN)]_2[immpho]\}\{ZnCl_4\}\cdot 2CH_3CN\cdot 2H_2O$ suitable for X-ray diffraction study were grown by slow diffusion of diethyl ether into a concentrated solution of **II** in CH_3CN. A perspective drawing of **II** is shown in Fig. 1. Selected bond lengths and bond angles are given in Table 1. The solid state structure is consistent with the spectroscopic data. The dimeric species is centro-symmetric with the pentamethylcyclopentadienyl rings bonded to the ruthenium metals in η^5-fashion having the Ru—C bond lengths ranging from 2.17(2) to 2.21(2) Å and the immpho ligand acted as a bidentate ligand having an imino group and a phosphino group coordinated to each of the two $[(\eta^5\text{-}C_5Me_5)Ru(CH_3CN)]^+$ moieties. Similar bonding behaviour has been reported for the immpho ligand [1]. Within the diiminodiphosphine ligand, the N(1)—C(11) bond length of 1.47(2) Å and the N(1)—C(12) bond length of 1.34(2) Å are in agreement with the C—N and C=N bond distances, respectively.

When a CH_3CN solution of equal molar of $[(\eta^5C_5H_5)Fe(\eta^6\text{-mesitylene})][BF_4]$ and immpho was irradiated at ambient temperature for 12 h, work up gave dark-red crystal of stoichiometry $[(\eta^5C_5H_5)Fe(immpho)][BF_4]\cdot CH_2Cl_2$, **III**$\cdot CH_2Cl_2$, in moderate yield (42%) after recrystallization from a CH_2Cl_2/Et_2O mixture. The IR spectrum of **III** exhibits a $\nu_{C=N}$ stretch at 1632 cm^{-1} for the imino groups. The $^{31}P\text{-}\{^1H\}$ NMR spectrum of **III** exhibits two singlets of relative intensity 1 : 1 at δ 67.8 and -12.6 ppm which correspond to a coordinated and an uncoordinated phosphorus, respectively. This suggests that the immpho ligand behaves as a tridentate ligand with one of its phosphino groups remaining unco-

ordinated. The resonances of the ^{1}H NMR spectrum of **III** are rather broad, indicating that the complex may be weakly paramagnetic. Other than the phenyl protons, the ^{1}H NMR spectrum of **III** exhibits two broad multiplets of relative intensity 1 : 1 at δ 9.45 and 8.76 ppm for the —C*H*=N— protons of the uncoordinated and coordinated benzylidene, respectively; two broad multiplets of relative intensity 2 : 2 at δ 4.70 and 3.75 ppm for the —NCH_2CH_2N— protons; and a broad singlet of relative intensity of 5 at δ 2.45 ppm for the protons of the cyclopentadienyl rings, indicating that the cyclopentadienyl ring is bonded to the iron metal in an η^5 fashion. The unusual high field shift of the cyclopentadienyl protons may probably be due to the weak paramagnetism of the complex. The above spectroscopic data suggest that the structure of **III** is similar to that of **I**.

This is confirmed by an X-ray diffraction study. Crystals of stoichiometry [(η^5-C_5H_5)Fe(immpho)][BF_4]·0.5CH_2Cl_2 suitable for X-ray diffraction study were grown by slow diffusion of diethyl ether into a concentrated solution of **III** in CH_2Cl_2. A perspective drawing of **III** is shown in Fig. 2. Selected bond lengths and bond angles are given in Table 2. The solid state structure is consistent with the spectroscopic data. The structure shows that the cyclopentadienyl ring is bonded to the iron metal in η^5 fashion with the Fe—C bond lengths ranging from 2.05(1) to 2.10(1) Å; and the immpho ligand acts as a tridentate ligand with one of the two phosphino groups and the two imino groups coordinated to the iron metal and an uncoordinated phosphino group. Within the diiminodiphosphine ligand, the N(1)—C(8) and the N(2)—C(27) bond lengths are 1.27(1) and 1.28(1) Å, respectively, and are in agreement with the C=N bond distance.

The present study shows that the mode of coordination of the diiminodiphosphine as a tridentate

ligand toward Group 8 metals (Fe and Ru) is similar to that of Group 6 metals; that is having one of the two phosphino groups and the two imino groups coordinated to the metal and the other phosphino group remaining uncoordinated. This may be a general trend for the diiminodiphosphine, acting as a tridentate ligand, coordinating to Group 8 metals.

EXPERIMENTAL

Microanalyses were performed by the Shanghai Institute of Organic Chemistry, Chinese Academy of Sciences, China. IR spectra (KBr pellets) were recorded on a Nicolet Nagna-IR 550 spectrometer; data are given in cm^{-1}. NMR spectra were recorded on a JEOL EX270 spectrometer. Chemical shifts of $^{31}P\{^1H\}$ NMR spectra were referenced to external 85% H_3PO_4. Chemical shifts of ^1H NMR spectra were referenced to internal deuterated solvents and then recalculated to TMS = δ 0.00 ppm. Low resolution mass spectra (LRMS) were obtained on a Finnigan MAT SSQ-710 spectrometer in FAB (positive) operation mode and are reported as m/z.

All operations were carried out under nitrogen or *in vacuo*. All chemicals used were of reagent grade. Solvents were dried by standard procedures. Distilled and deaerated prior to use. Melting points were taken in sealed capillaries and are uncorrected. Photochemical reactions were conducted at room temperature with a 450-W Conrad-Hanovia 7825

medium-pressure mercury lamp. $RuCl_3 \cdot 3H_2O$ was purchased from Aldrich and used without further purification. Immpho [6], $[(\eta^5C_5Me_5)RuCl_2]_n$ [8] and $[(\eta^5C_5H_5)Fe(\eta^6\text{-mesitylene})][BF_4]$ [9] were prepared according to literature methods.

Preparation of $[(\eta^5\text{-}C_5Me_5)Ru(immpho)]_2[ZnCl_4]$ (**I**)

A solution of $[(\eta^5\text{-}C_5Me_5)RuCl_2]_n$ (0.30 g, 1.0 mmol) and granular Zn (1.2 g, 18.5 mmol) in methanol (10 cm^3) was refluxed for 10 min. Then CH_3CN (10 cm^3) was added to the methanol solution and the resultant solution was maintained refluxing for another 5 h. The colour of the reaction mixture changed to orange. Upon cooling to room temperature, the solution was filtered. The filtrate was then added dropwise to a stirring solution of immpho (0.61 g, 1.0 mmol) in CH_2Cl_2 (10 cm^3). The reaction mixture was allowed to stir at room temperature for another 12 h to give a dark-red solution. The solvents were removed *in vacuo* to give a dark-red residue. The residue was redissolved in a minimum amount of CH_3CN and chromatographed on a silica gel column (2 × 15 cm) using CH_3CN as an eluant. The dark-red band obtained was concentrated to *ca* 5 cm^3 and then diethyl ether was added until the solution just turned cloudy. The CH_3CN/diethyl ether mixture was then cooled to −20 °C to give dark-red crystals, which were filtered and dried *in vacuo*. Yield: 0.83 g, 79%; m.p. 220–223 C. Found: C, 62.2; H, 5.1; N, 2.8. Calc. for $(C_{100}H_{98}N_4P_4Cl_4ZnRu_2)\cdot 2H_2O$: C, 62.4; H, 5.3; N, 2.9%. IR (cm^{-1}, in KBr): 3440 br, s, 3052 m, 2902 m, 1626 m, 1584 w, 1476 m, 1432 s, 1384 w, 1294 w, 1268 w, 1218 w, 1090 m, 1070 w, 1022 m, 920 w, 746 s, 694 vs, 508 s, 490 m. $^{31}P\text{-}\{^1H\}$ NMR ($CDCl_3$): uncoordinated PPh_2 group, δ −15.6(s) ppm; coordinated PPh_2 group, δ 43.6(s) ppm. ^1H NMR ($CDCl_3$): —C*H*=N— proton of uncoordinated benzylidene, δ 9.80 (1H, m) ppm; —C*H*=N— proton of coordinated benzylidene, δ 8.18 (1H, m) ppm; phenyl protons, δ 6.80–7.80 (28H, br, m) ppm; —NCH_2CH_2N— protons, δ 3.90–4.20 (4H, br, m) ppm; H_2O protons, δ 2.01 (2H, s) ppm; CH_3 protons, δ 1.09 (15H, s) ppm.

Preparation of $\{[(\eta^5\text{-}C_5Me_5)Ru(CH_3CN)]_2[immpho]\}\{ZnCl_4\}$ (**II**)

A solution of $[(\eta^5\text{-}C_5Me_5)RuCl_2]_n$ (0.30 g, 1.0 mmol) and granular Zn (1.2 g, 18.5 mmol) in methanol (10 cm^3) was refluxed for 10 min. Then CH_3CN (10 cm^3) was added to the methanol solution and the resultant solution was maintained refluxing for another 5 h. The colour of the reaction mixture changed to orange. Upon cooling to room temperature, the solution was filtered and stirred. Then a solution of immpho (0.30 g, 0.5 mmol) in CH_2Cl_2 (10 cm^3) was then added dropwise to the orange filtrate. The reaction mixture was allowed to stir at room temperature for another 12 h to give a dark-red solution. The solvents were removed *in vacuo* to give a dark-red residue. The residue was redissolved in a minimum amount of CH_3CN and chromatographed on a silica gel column (2 × 15 cm) using CH_3CN as an eluant to give a dark-red band. The solvent of the dark-red band was removed *in vacuo* to give a dark-red residue which was redissolved in a minimum amount of CH_2Cl_2. Then diethyl ether was added to the CH_2Cl_2 solution until it just turned cloudy. The CH_2Cl_2/diethyl ether mixture was then cooled to −20 °C to give dark-red crystals, which were filtered and dried *in vacuo*. Yield: 0.47 g, 71%; m.p. 231–232 °C. Found: C, 56.0; H, 5.2; N, 4.2. Calc. for $(C_{64}H_{70}N_4P_2Cl_4ZnRu_2)\cdot 0.5H_2O$: C, 55.9; H, 5.2; N, 4.1%. IR (cm^{-1}, in KBr): 3433 br, s, 3051 w, 2920 s, 2853 m, 1701 w, 1637 m, 1560 w, 1477 m, 1435 s, 1374 w, 1298 w, 1261 mw, 1188 w, 1089 s, 1068 m, 1026 s, 912 w, 800 m, 746 s, 730 m, 699 vs, 528 vs, 486 m. $^{31}P\text{-}\{^1H\}$ NMR ($CDCl_3$): coordinated PPh_2 group, δ 43.2(s) ppm. ^1H NMR ($CDCl_3$): —C*H*=N— protons, δ 8.34 (2H, br, m) ppm; phenyl protons, δ 6.68–7.80 (28H, br, m) ppm; —NCH_2CH_2N— protons, δ 4.55 (2H, br, s) and 4.40 (2H, br, s) ppm; —CH_3 protons of CH_3CN, δ 1.52–1.63 (6H, m) ppm; —CH_3 protons of C_5Me_5, δ 1.40 (30H, br, s) ppm.

Preparation of $[(\eta^5\text{-}C_5H_5)Fe(immpho)][BF_4]$ (**III**)

A solution of $[(\eta^5\text{-}C_5H_5)Fe(\eta^6\text{-mesitylene})][BF_4]$ (0.33 g, 1.0 mmol) and immpho (0.60 g, 1.0 mmol) in CH_3CN (30 cm^3) was irradiated at room temperature for 12 h. The colour of the solution changed from yellow to red–brown. The solvent of the resultant solution was removed *in vacuo* to give dark-red residue. The residue was redissolved in a minimum amount of CH_3CN and chromatographed on a silica gel volume (2 × 15 cm) using CH_3CN as an eluant to give a dark-red band. The solvent of the dark-red band was removed *in vacuo* to give a dark-red residue which was redissolved in a minimum amount of CH_2Cl_2. Then diethyl ether was added to the CH_2Cl_2 solution until it just turned cloudy. The CH_2Cl_2/diethyl ether mixture was then cooled to −20 °C to give dark-red crystals, which were filtered and dried *in vacuo*. Yield: 0.34 g, 42%; m.p. 182–184 °C. Found: C, 61.9; H, 4.5; N, 3.0. Calc. for $(C_{45}H_{39}N_2P_2BF_4Fe)\cdot CH_2Cl_2$: C, 61.6; H, 4.6; N, 3.1%. IR (cm^{-1}, in KBr): 3053 w, 2956 w, 2923 m, 2854 w, 1623 m, 1582 w, 1480 w, 1435 s, 1387 w, 1262 w, 1268 w, 1084 vs, 1055 vs, 1037 vs, 840 w, 815 w, 751 s, 698 s, 532 m, 519 s, 466 m. $^{31}P\text{-}\{^1H\}$ NMR (CD_2Cl_2): uncoordinated PPh_2 group, δ −12.6(s) ppm; coordinated PPh_2 group, δ 67.8(s) ppm. ^1H NMR (CD_2Cl_2): —C*H*=N— proton of uncoordinated benzylidene, δ 9.45 (1H, br, s) ppm; —C*H*=N— proton of coordinated benzylidene, δ 8.76 (1H, br, s) ppm; phenyl protons, δ 6.80–7.80 (26H, br, m) and 6.00 (2H, br, s) ppm; —NCH_2 CH_2N— protons, δ 4.60–4.83 (2H, br, m) and 3.52–4.00 (2H, br, m) ppm; C_5H_5 protons, δ 2.45 (5H, br, s) ppm. LRMS (FAB: +ve) m/z: 725.

X-ray diffraction studies

The general procedures for the X-ray diffraction studies are described as below. Crystals were mounted on glass fibres with epoxy resin. Intensity data were collected on a Rigaku AFC7R diffractometer with graphite monochromated Mo-K_α radiation ($\lambda = 0.71073$ Å) using ω-2θ scans ($2\theta_{max} \leqslant 45°$) at room temperature. The data were corrected for Lorentz, polarization effects and absorption correction using ψ-scan method [10]. Crystal data, data collection parameters, and results of the analysis are given in Table 3. The structures were solved by Direct Methods (SIR88) [11] and refined by full matrix least-squares technique. For compound **II,** an acetonitrile and a water molecule are found in the asymmetric unit. They were refined to give relatively high thermal displacement parameters. For compound **III,** a partially occupied solvate of dichloromethane is revealed in the asymmetric unit and their atomic positional and thermal parameters were refined with occupancy 0.5. With this model, the refinement converged to give the best R and Rw factors and more reasonable thermal parameters for this solvate. The hydrogen atoms were generated in their idealized positions (C—H bond fixed at 0.95 Å) and included in structure factor calculations but not refined. All calculations were performed on a Silicon-Graphics computer using the program package Texsan [12] from MSC.

Synthesis and thermal behaviour of $(NH_4)_2Be(IO_3)_4 \cdot 2H_2O$

M. Georgiev and M. Maneva*

Department of Inorganic Chemistry, University of Chemical Technology and Metallurgy, 8 Kl.Ohridski Str., 1756 Sofia, Bulgaria

(Received 13 February 1995; accepted 17 June 1996)

Abstract—A new binary salt $(NH_4)_2Be(IO_3)_4 \cdot 2H_2O$ has been synthesised, and identified by elemental analysis, X-ray powder diffraction, IR spectra, DTA and DSC. The IR spectra show two absorption bands at 860 cm^{-1} and 460 cm^{-1}. The new compound showed thermal stability up to 160°C. A diagram of the thermal decomposition was offered by identifying the intermediate product. The kinetic parameters (E^* and A) were investigated on the basis of the TG data, and the kinetic equations were determined. It was proved that the process takes place in the kinetic region. Keywords: binary iodates; thermal decomposition; IR spectra; DSC; X-ray; kinetic parameters.

A number of publications [1–7] contain results from our investigations of beryllium iodates that have not been sufficiently studied. However, there are no data about binary beryllium iodates and this suggested to us to synthesize such iodates since they, much like the iodates, can be expected to possess valuable electrical properties.

The aim was to study the conditions of synthesis of a binary salt between NH_4IO_3 and $Be(IO_3)_2 \cdot 4H_2O$, the compound obtained being identified and described by the methods of quantitative analysis, DTA, DSC, TG, IR and X-ray.

EXPERIMENTAL

The initial products used in the synthesis of the newly obtained binary iodates were NH_4IO_3 and $Be(IO_3)_2 \cdot 4H_2O$. Solid $Be(IO_3)_2 \cdot 4H_2O$ was added to 0.2 M solution of $Be(IO_3)_2 \cdot 4H_2O$ heated to 70°C in quantities corresponding to the stoichiometric ratio $NH_4IO_3 : Be(IO_3)_2 \cdot 4H_2O = 2:1$. The solution obtained was filtered through a fibreglass filter and left to crystallise in a desiccator over H_2SO_4 or in the open at room temperature. The crystals were filtered off and dried.

The compound was analysed quantitatively: Be was determined by heating the substance to BeO at 900°C, I_2 was determined iodometrically [8] and NH_4^+ was determined with sodium tetrafluoroborate [9].

The data from the quantitative analysis of the newly synthesised compound agreed fairly well with those calculated for $(NH_4)_2Be(IO_3)_4 \cdot 2H_2O$, namely:

Table 1. Quantitative analysis data

	Be	NH_4^+	I
Theoretical, %	1.1	4.6	65.0
Experimental, %	1.1±0.1	5.1±0.1	65.1±0.5

The thermal investigations were carried out with MOM-OD-102 Paulic-Erday in the 20–1000°C temperature interval at a heating rate of 10°C min^{-1} and 200 mg sample. The DSC curves were taken on a Perkin-Elmer 4 at the rate of 10°C min^{-1} and 5 mg sample in the 30–400°C temperature interval. The IR spectra were taken in the 4000–2800 cm^{-1} interval in a hexachloroburadiene suspension and in the 3800–200 cm^{-1} interval in KBr tablets on a Philips PU 9712 spectrophotometer.

The X-ray data were obtained on DRON VM-1 powder diffractometer using Cu K_α radiation ($\lambda = 1.5418$ Å). They were processed using the computer programme ITO and LSUCR [16].

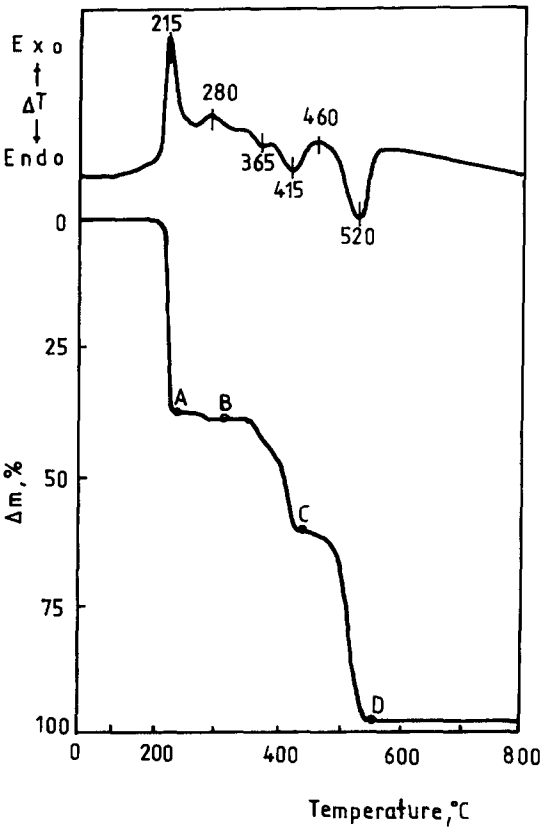

Fig. 1. DTA and TG curves of $(NH_4)_2Be(IO_3)_4 \cdot 2H_2O$.

RESULTS AND DISCUSSION

The DTA and TG curves of $(NH_4)_2Be(IO_3)_4 \cdot 2H_2O$ are shown in Fig. 1, while the DSC curves are shown in Fig. 2. The IR spectra are shown in Fig. 3, while Fig. 4 shows also the spectra of the products obtained from the thermal decomposition of the initial compound at 220°C and 320°C.

The compound crystallises in the triclinic crystallographic system with the following lattice parameters: $a = 7.514$ (1), $b = 9.824$ (2), $c = 6.689$ (2) Å, $\alpha = 103.29$ (2), $\beta = 106.14$ (2) and $\gamma = 107.17$ (1)°, $V = 443.0$ (1) Å^3; 2θ range (°) 9.869–82.868; reflections collected 543; pyknometrical density, 2.947 g cm^{-3}; $Z = 1$.

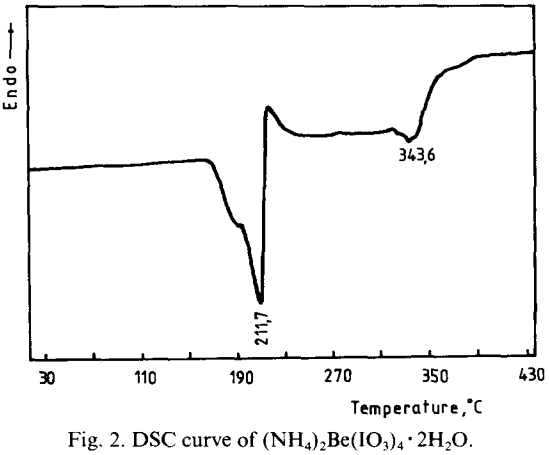

Fig. 2. DSC curve of $(NH_4)_2Be(IO_3)_4 \cdot 2H_2O$.

The course of the TG and DSC curves on Figs 1 and 2 showed that the compound is stable until 160°C, while the initial NH_4IO_3 undergoes decomposition at around 200°C with an exothermal effect [10], $Be(IO_3)_2 \cdot 4H_2O$ melts at $T_{max} = 70$°C and is dehydrated at $T_{max} = 95$°C [1]. These data are not recorded in the DTA of the newly obtained compound either (Fig. 1). This is yet another proof that what we have is a new compound with its IR spectra (Fig. 3). Its absorption curve in the 3200–3000 cm^{-1} region due to the stretching oscillations of the N—H bond from NH_4^+ differs in its character and position from those of NH_4IO_3. It is comparatively broader and is shifted toward the higher frequencies by about 40 cm^{-1}.

The stretching oscillations of the OH— groups from the hydrate water lie partially in this region, hence it is difficult to obtain a more accurate identification of the maximums observed in the absorption band. An analogous shift is to be observed also in the antisymmetric bending vibration (ν_4) of NH_4^+ (Fig. 3a) lying at 1410 cm^{-1}, compared to 1390 cm^{-1} in NH_4IO_3 [14]. Also noteworthy is the character of the stretching vibrations of the I—O bond from IO_3^- (ν_1 and ν_3) lying in the 850–650 cm^{-1} region. They appear as an absorption band broader than in NH_4IO_3 and $Be(IO_3)_2 \cdot 4H_2O$ (Fig. 3) and this character is probably due to structurally different iodate groups in the compound. The weak though distinct absorption band at 860 cm^{-1} may be attributed to Be—O. It appears as a shoulder in the $Be(IO_3)_2$ and $Be(IO_3)_2 \cdot 4H_2O$ spectra [5,6]. According to [12] the vibration at 460 cm^{-1} may refer to the Me—O—IO_2 groups or to the Be—O—IO_2 groups, respectively. This is to be expected, having in mind that the coordination saturation of Be^{2+} in the examined compound can be realised only by the incorporation also of the OIO_2— group in its polyhedron, due to shortage of hydrate water. This is confirmed by the fact that this particular absorption band is not found in the spectrum of $Be(IO_3)_2 \cdot 4H_2O$ containing $[Be(H_2O)_4]^{2+}$ but is found in $Be(IO_3)_2$. The coordination of Be^{2+} in the latter can be effected likewise solely by the oxygen of IO_3^-. The poor absorption band at 315 cm^{-1} is attributed to the Be—O bond from the BeO_4— group, this vibration being observed also in the spectrum of $Be(IO_3)_2 \cdot 4H_2O$ [4,5] (Fig. 3c).

Information about the thermal behaviour of the newly obtained compound is furnished by the DTA, DSC and TG curves in the investigated temperature range. For instance, corresponding to the exoeffect with $T_{max} = 215$°C (after DTA) is a sharp decrease of the mass of the sample $\Delta m = 38.3\%$. These changes can be attributed to the simultaneous dehydration and decomposition of $(NH_4)_2Be(IO_3)_4 \cdot 2H_2O$ to the obtaining of a solid product from HIO_3 and $Be(IO_3)_2$ according to the following equation:

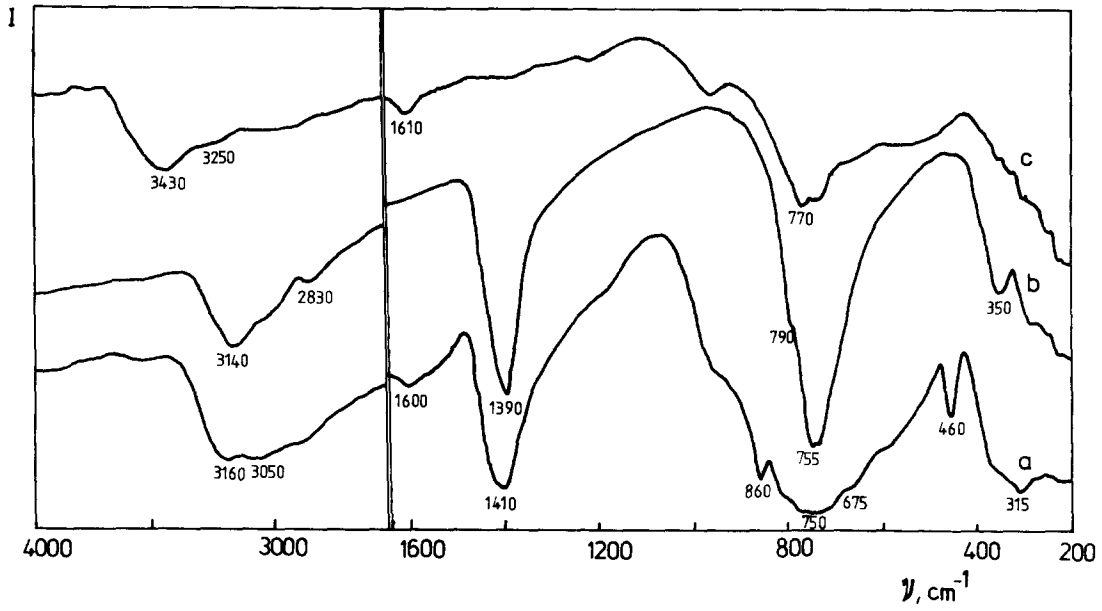

Fig. 3. IR spectra of (a) $(NH_4)_2Be(IO_3)_4 \cdot 2H_2O$; (b) NH_4IO_3; and (c) $Be(IO_3)_2 \cdot 4H_2$.

$$4.5[(NH_4)_2Be(IO_3)_4 \cdot 2H_2O] \rightarrow 3HIO_3 + 4.5Be(IO_3)_2 + \text{gaseous products} \quad (1)$$

The mass of the solid product calculated from equation (1) is $\Delta m = 61\%$. This value is in very good agreement with the experimental data from TG curves (Fig. 1). The product isolated from point A (Fig. 1) at $T = 220°C$ has been identified with its IR spectrum (Fig. 4). It shows both the characteristic absorption bands of the free HIO_3, most typical of which is that at 640 cm^{-1} related to the I—O—(H) bond, and those characteristic of $Be(IO_3)_2$.

The exoeffect observed is the result of a complex multi-stage process which includes both endo- and exo-processes. The latter are related mainly to the oxidation of NH_3 to different terminal products such as N_2O, NO, N_2 and H_2O [12]. The course of the respective TG-curve shows a sharp change up to $T = 220°C$. Indicative of the complex nature of this process is also the type of the respective peak observed

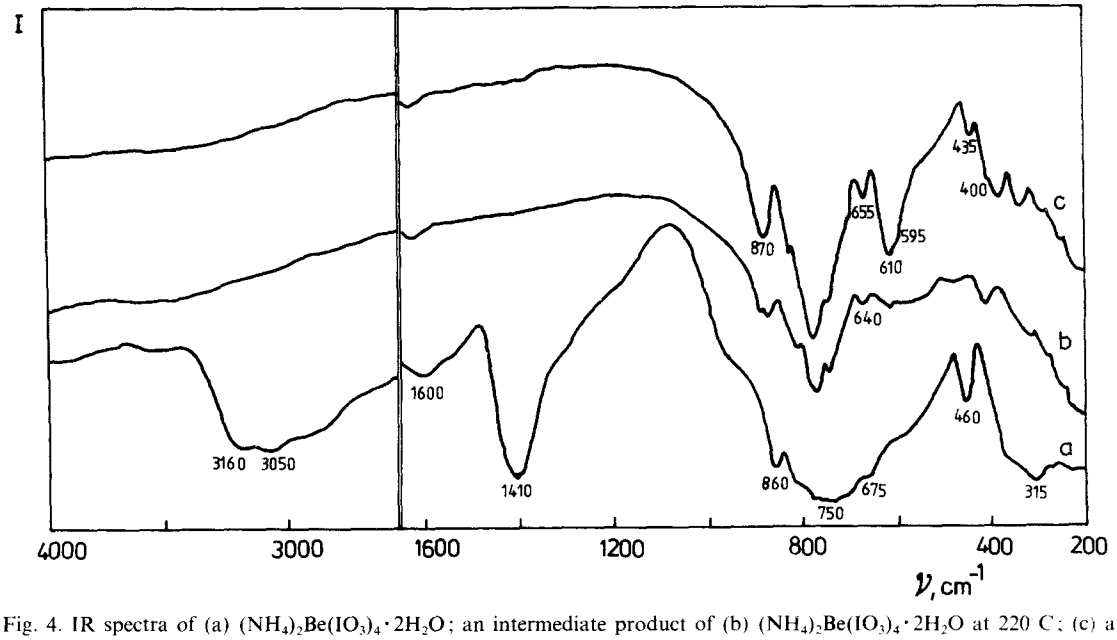

Fig. 4. IR spectra of (a) $(NH_4)_2Be(IO_3)_4 \cdot 2H_2O$; an intermediate product of (b) $(NH_4)_2Be(IO_3)_4 \cdot 2H_2O$ at 220 C; (c) at 320°C.

in DSC (Fig. 2) whose $T_{max} = 211.7°C$ and $\Delta H_{ph.tr.} = -147.5$ kJ mol^{-1}. It clearly distinguishes between two different exothermal effects which overlap partially. The TG-curve changes slowly in the 220–340°C temperature interval, the decrease in the mass for this interval alone being 0.5%; in other words it decreases by 39.5% from the beginning to this point. Corresponding to this part of the TG is an endoeffect in DTA which may be due to polymerisation and dehydration of HIO_3 according to the diagram.

$$3HIO_3 \rightarrow HI_3O_8 + H_2O$$

and crystallisation of the HI_3O_8 obtained (the exoeffect at 280°C is not related to changes in the mass—Fig. 1). This assumption is proved experimentally by the identification of a sample isolated in this interval (point B from TG on Fig. 1). Its IR spectra is presented in Fig. 4c and it shows the absorption bands characteristic of HI_3O_8 and of $Be(IO_3)_2$. The first one is identified by the stretching vibration of the I—O—I— group (characteristic for this acid) at 435, 400, 610 and 595 cm^{-1} [13–15]. The remaining absorption bands are of $Be(IO_3)_2$, according to [4, 6].

The endoeffect at $T_{max} = 365°C$ is attributed to the decomposition of HI_3O_8 following the diagram

$$2HI_3O_8 \rightarrow H_2O + 3I_2O_5$$

whereas that at $T_{max} = 415°C$ is attributed to the decomposition of I_2O_5 to O_2 and I_2. The release of I_2 can be visually ascertained as well. These two processes are not divided in the TG curve and show a common change in the mass $\Delta m = 60\%$, the theoretical one being $\Delta m = 54\%$. The 6% difference between the experimental and theoretical values can be explained by the partial decomposition within this interval of the $Be(IO_3)_2$ which is in the system. This assumption is corroborated by the change in Δm connected with the further decomposition of the pure $Be(IO_3)_2$ obtained at point C. Its presence is indicated by the course of the DTA and DTA and TG curves and by the nature of the residual product.

The exoeffect at $T_{max} = 468°C$ is related to the decomposition of $Be(IO_3)_2$, while the endoeffect at $T_{max} = 520°C$ is related to the decomposition of I_2O_5. The terminal product from $(NH_4)_2Be(IO_3)_4 \cdot 2H_2O$ is BeO. The overall theoretical change of the mass of the initial sample to BeO is 97.0%, recorded from the TG curve, while the theoretically calculated one is 96.8%. The BeO residue has been proved by X-ray powder diffraction and by the methods of IR spectroscopy. The data obtained fully coincided with those presented in [1–3].

The kinetic analysis used a computer program written in BASIC and based on a manual procedure for determining E^*_{deh} and A under non-isothermal conditions [17–20]. The general differential method was applied and the basic equation of non-isothermal kinetics was used in a logarithmic form [19].

$$\ln\left[\frac{d\alpha/dT}{F(\alpha)}\right] = \ln\frac{A}{b} - \frac{E^*}{R}\frac{1}{T}$$

where $\alpha = (m_0 - m_T)/(m_0/m_{end})$ is the conversion degree, m_0 and m_{end} are the initial and final mass of the hydrate in g, and m_T is the mass (in g) for a given T; b is the rate of heating in K s^{-1} ($b = dT/d\tau$), A is the pre-exponential factor in s^{-1}, $R = 8.314$ J K^{-1} mol^{-1}, and $F(\alpha)$ is the kinetics model (in a differential form).

The 25 kinetic equations taken from the relevant literature [17–19] describe a process of the type:

$$A(\text{solid}) \rightarrow B(\text{solid}) + C(\text{gas})$$

Numerical differentiation of the experimental $\alpha - T$ data is made after their approximation with a cubic parametric B-spline, as described in [18], which reflects most accurately the nature of the non-isothermal data processed.

The kinetic analysis involves determining the kinetic equations $F(\alpha)$, from those introduced into the program (25 in all), for which the dependence of ln $[(d\alpha/dT)/F(\alpha)]$ on $1/T$ is linear. The criteria for selecting $F(\alpha)$ are the values of the calculated correlation coefficients R and standard deviation σ. In cases where the dehydration process takes place in several stages, the kinetic analysis was carried out for each state separately.

The values obtained for the kinetic parameters of the principal stages of the process are shown in Table 2.

It follows from an analysis of the kinetic data (Table 2) determined under non-isothermal conditions that

Table 2. Kinetic data about the process of thermal decomposition of $(NH_4)_2Be(IO_3 \cdot 2H_2O)$ from the TG-curve

Temperature interval, °C	E^* kJ mol^{-1}	ln A, s^{-1}	Kinetic equation	R^*	σ^{**}
180–220	130	1.47	$F = (1-\alpha)^{2/3}$	0.9276	0.0803
360–400	42	14.92	$F = [(1-\alpha)^{-1/2} - 1]^{-1}$	0.9857	0.0086
400–420	120	52.56	$F = 1$	0.9999	0.0005
450–520	373	29.31	$F = \alpha(1-\alpha)$	0.9818	0.0141

R^* Correlation coefficient, σ^{**} Mean quadratic deviation, E^* Activation energy.

the principal stages of the process take place in the kinetic region. For the 360–400°C temperature interval the kinetic equation is of the diffusion type.

Binuclear oxomolybdenum(V) complexes with mercaptocarboxylic acids: synthesis, characterization and electrochemistry

Subhasis Mitra, Hiranmay Biswas and Pinaki Bandyopadhyay*

Department of Chemistry, University of North Bengal, Darjeeling, PIN 734 430, India

(Received 17 April 1996; accepted 13 June 1996)

Abstract—A number of stable bis(μ-oxo) and μ-oxo-μ-sulfido binuclear oxomolybdenum(V) complexes of the type $R_2[Mo_2O_4L_2]\cdot 5H_2O$ (**1**) and $R_2[Mo_2O_3SL_2]\cdot 5H_2O$ (**2**) with different mercaptocarboxylic acids (H_2L) have been synthesized (where H_2L = 2-mercaptobenzoic acid, 2-mercaptoproprionic and 3-mercaptopropionic acid, and $R = Ph_4P^+$). The complexes have been characterized by elemental analysis, conductivity measurement and spectral (IR, UV-VIS and ^{1}H-NMR) data. The electrochemical behaviour of the complexes in DMF have also been examined by cyclic voltammetry at a glassy carbon electrode. Copyright © 1996 Elsevier Science Ltd

Keywords: binuclear oxomolybdenum complexes; bis(μ-oxo) bridge; μ-oxo-μ-sulfido bridge; mercaptocarboxylic acids; cyclic voltammetry.

Relevance of the molybdenum–sulfur bond to bioinorganic chemistry is well known [1–7] because of its presence in different molybdoenzymes. Some attention [8–12] has been given to oxomolybdenum(V) complexes of different mercaptocarboxylic acids. In continuation of our interest in this area [12], we now report the synthesis, spectroscopic characterization and electrochemical behaviour of binuclear oxomolybdenum complexes of mercaptocarboxylic acids with bis(μ-oxo) bridge and μ-oxo-μ-sulfido bridge. The mercaptocarboxylic acids used were 2-mercaptobenzoic acid (H_2L^1), 2-mercaptopropionic acid (H_2L^2) and 3-mercaptopropionic acid (H_2L^3).

EXPERIMENTAL

Materials

Sodium dithionite (E. Merck, India), hydrazine dihydrochloride and 3-mercaptopropionic acid (Merck, Germany), tetraphenylphosphonium chloride and 2-mercaptopropionic acid (Fluka AG, Switzerland) were used as received. 2-Mercaptobenzoic acid (Fluka AG, Switzerland) was purified by sublimation at reduced pressure as reported elsewhere [13].

Synthesis of complexes

$[(PPh_4)]_2[Mo_2O_4(L^1)_2]\cdot 5H_2O$ (**1a**). A solution of 2-mercaptobenzoic acid (0.3 g, 1.94 mmol) in methanol (15 cm^3) was added to a solution of sodium molybdate dihydrate (0.48 g, 1.98 mmol) in water (15 cm^3). A solution of sodium dithionite (0.175 g) in water (10 cm^3) was added to the above mixture and the pH of the solution was adjusted to *ca* 5.5. A solution of tetraphenylphosphonium chloride (0.75 g, 2.0 mmol) in water (10 cm^3) was added to the above mixture dropwise with stirring. Yellow precipitate appeared and it was collected by filtration, washed with water and dried *in vacuo*. Yield: 0.450 g, (*ca* 17%). Found: C, 55.5; H, 3.7; Mo, 13.9; S, 4.6. Calc. for $C_{62}H_{58}Mo_2O_{13}P_2S_3$: C, 56.0; H, 4.4; Mo, 14.5; S, 4.8%. Δ_M (in DMF) = 136 Ω^{-1} cm^2 mol^{-1}.

$[(PPh_4)]_2[Mo_2O_4(L^2)_2]\cdot 5H_2O$ (**1b**) was prepared using a similar method as described above. Yield: *ca* 25%. Found: C, 52.1; H, 4.4; Mo, 15.3, S, 5.0. Calc. for $C_{54}H_{58}Mo_2O_{13}P_2S_2$: C, 52.6; H, 4.7; Mo, 15.6; S, 5.2%. Δ_M (in DMF) = 137 Ω^{-1} cm^2 mol^{-1}.

* Author to whom correspondence should be addressed.

$[(PPh_4)]_2[Mo_2O_3S(L^1)_2]\cdot 5H_2O$ (**2a**). To a solution of sodium molybdate dihydrate (0.96 g, 3.96 mmol) in water (15 cm^3), hydrochloric acid (5 cm^3) was added followed by the addition of solid hydrazine dihydrochloride (1.0 g, 10 mmol). Then the mixture was heated over a water bath for 2 h and the hot solution was taken in a polythylene bottle containing $Na_2S\cdot 2H_2O$ (0.455 g, 4.0 mmol). The mixture was stirred till its temperature reached 298 K. A solution of 2-mercaptobenzoic acid (0.615 g, 4.0 mmol) in methanol (15 cm^3) was added to the above mixture with stirring and filtered the black precipitate off. The pH of the filtrate, cooled in an ice-bath, was raised to *ca* 12 with 13 M NaOH and the solution was kept at 278 K overnight. A yellow precipitate appeared which was washed with methanol and dissolved in water (15 cm^3). A solution of tetraphenylphosphonium chloride (0.5 g, 1.3 mmol) dissolved in water (10 cm^3) was added to it. A yellow precipitate was separated off, filtered, washed with water and dried *in vacuo*. Yield: 0.25 g (*ca* 47%). Found: C, 54.9; H, 3.9; Mo, 14.1, S, 6.9. Calc. for $C_{62}H_{58}Mo_2O_{12}P_2S_3$: C, 55.4; H, 4.3; Mo, 14.3; S, 7.1%. Δ_M (in DMF) = 134 Ω^{-1} cm^2 mol^{-1}.

$[(PPh_4)]_2[Mo_2O_3S(L^2)_2]\cdot 5H_2O$ (**2b**) and $[(PPh_4)]_2[Mo_2O_3S(L^3)_2]\cdot 5H_2O$ (**2c**). These complexes were prepared following the procedure for (**2a**), except that the pH was raised to *ca* 8 after the addition of mercaptocarboxylic acids. Yield: *ca* 12 (**2b**) and 18% (**2c**). Found (**2b**): C, 51.8; H, 4.2; Mo, 14.9; S, 7.4. Calc. for $C_{54}H_{58}Mo_2O_{12}P_2S_3$: C, 51.9; H, 4.6; Mo, 15.4; S, 7.7%. Δ_M (in DMF) = 136 Ω^{-1} cm^2 mol^{-1}. Found (**2c**): C, 51.5; H, 4.0; Mo, 15.1; S, 7.5. Calc. for $C_{54}H_{58}Mo_2O_{12}P_2S_3$: C, 51.9; H, 4.6; Mo, 15.4; S, 7.7%. Δ_M (in DMF) = 132 Ω^{-1} cm^2 mol^{-1}.

Physical measurements

The elemental analyses data, electrical conductance data, IR and electronic spectra were obtained as previously described [12]. The ^1H NMR spectra were recorded using a GE NMR QE 300 MHz, JEOL GSX400 or Varian EM-390 CW NMR spectrometer. Cyclic voltammetric measurements were done under dry nitrogen using a PAR model 370-4 electrochemistry system as reported earlier [12]. The potentials reported are uncorrected for junction potentials.

RESULTS AND DISCUSSION

The synthetic approach employed for the preparation of the complexes (**1**) involves the reaction of different mercaptocarboxylic acids with $Na_2MoO_4\cdot 2H_2O$ in the presence of sodium dithionite [14] as the reducing agent at pH 5.5. The pH of the reaction mixture plays an important role in the formation of complexes (**1**) and dithiodicarboxylic acid becomes the major product below pH 4.5. The existence of bis(μ-oxo) Mo^V complex with 3-mercaptopropionic acid (H_2L^3) in solution has been reported elsewhere [9]. Complexes (**2**) were synthesized by the preparation of the $[Mo_2O_3S]^{2+}$ core [15] followed by the addition of mercaptocarboxylic acids. In this synthetic route, precipitation of μ-oxo μ-sulfido complexes occurred in the higher range 8–12 depending upon the individual ligand.

The elemental analyses data of the complexes correspond to the above formulations. All the complexes are stable in air at room temperature and soluble in coordinating organic solvents. The molar conductance data indicate that all the complexes behave as 2 : 1 electrolytes [16].

The infrared spectra of all the complexes (Table 1) exhibit a very strong band in the range of 950–965 cm^{-1}, characteristic of the symmetric stretching vibration mode of the terminal Mo=O bond [17–20]. Although only the intense symmetric stretching mode is observed, this would agree with the prediction of a *cis*-disposition of the terminal Mo=O groups in the molybdenum(V) binuclears [21–23]. All the compounds exhibit the antisymmetric and symmetric stretching bands of Mo—O bridge bond [24,25] in the region 746–757 cm^{-1} and 453–470 cm^{-1} respectively. In the μ-oxo μ-sulfido complexes two prominent bands in the region 678–681 cm^{-1} and 415–422 cm^{-1} belong to the antisymmetric and symmetric stretching modes, respectively of the Mo—S bridge [21,22]. The intense antisymmetric ν_{COO} stretch of the metal bound carboxylate group [24,25] appear in the region 1590–1666 cm^{-1} (Table 1). The involvement of deprotonated thiol group in metal binding [26,27] is evident from the absence of ν_{SH} band in the region of 2400–2600 cm^{-1}. The strong and very broad absorption band between 3340–3495 cm^{-1} indicates the presence of water molecules in all the complexes [25].

The diamagnetic behaviour of all the complexes (**1**) and (**2**) at room temperature originates from strong coupling of the spins of the molybdenum(V) centres *via* dioxo or oxo-sulfido bridges. The ^1H NMR of all complexes (Table 1) show complete absence of the signal for sulfhydryl and carboxylic protons of free mercaptocarboxylic acids. This confirms the participation of different mercaptocarboxylic acids in coordination to molybdenum(V) through carboxylate anion and deprotonated sulfhydryl group. This is also supported by the remarkable shift of methylene proton signals to lower field in ^1H NMR spectra of complexes (**1b**), (**2b**) and (**2c**) containing mercaptopropionic acids [27]. ^1H NMR spectra of all complexes studied exhibit H_2O peak in the region 1.95–3.55 ppm (Table 1) depending upon the nature of the solvents. The H_2O peak shifts to higher field on shaking with D_2O.

The electronic spectral data of the complexes are given in Table 1. The strong absorptions around 290 nm and 430 nm are assigned [23] to intra-ligand and LMCT band, respectively.

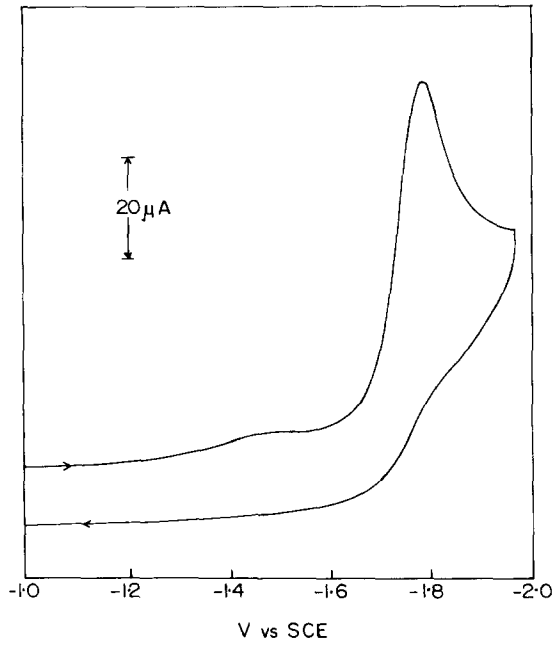

Fig. 1. Cyclic voltammogram of complex (**2c**) ($\sim 0.7 \times 10^{-3}$ M) in DMF (0.1 M in TBAP, 298 K) at glassy carbon electrode; scan rate 50 mV s^{-1}.

The electron transfer behaviour of complexes (**1**) and (**2**) have been examined voltammetrically in DMF (0.1 M in tetrabutylammonium perchlorate) at a glassy carbon electrode. All potentials (Table 1) are measured at 298 K and are referenced to saturated calomel electrode (SCE). All complexes undergo a reduction near -1.8 V and on scan reversal the anodic peak is virtually unobservable (Fig. 1). On comparison with the cathodic peak current of authentic two-electron reactions [28], the observed cathodic responses of complexes (**1**) and (**2**) show that the processes are of two-electron nature. Careful examination of the cathodic peak potentials reveals that the reduction potentials remain almost unaffected on variation of the different mercaptocarboxylates. This observation suggests that the electron transfer process is primarily localised on the metal centres. The single-step two-electron transfer implies that both the molybdenum(V) centers in complexes are reduced to molybdenum(V) simultaneously. The non-observance of anodic peak suggests that the reduced species, i.e. molybdenum(IV) binuclear complexes, undergo transformation to redox inactive products at a faster rate than the voltammetric time scale. In contrast to the prevalent two-step one-electron reduction of binuclear molybdenum(V) complexes having μ-oxo μ-sulfido bridge [20,28–30] in non-aqueous media, the one-step two-electron response of complexes (**1**) and (**2**) occurs rarely.

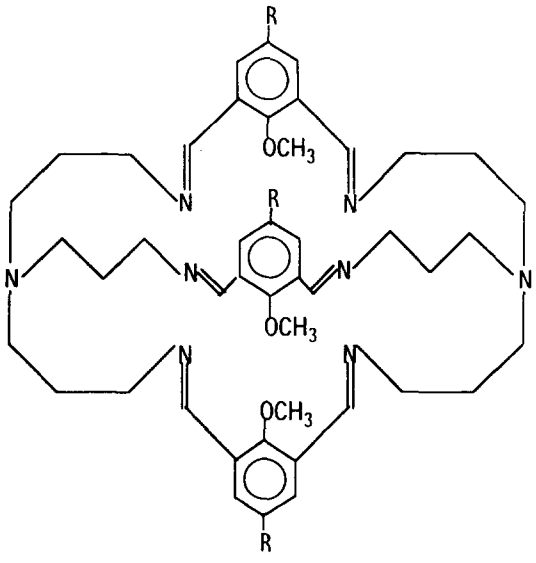
Abstract—Four binuclear and one polymeric silver complex of octaaza Schiff-base cryptands were synthesized by [2+3] condensation of tris(3-aminopropyl)amine (trpn) or tris(2-aminoethyl)amine (tren) with 5-R-2-methoxy-1,3-benzenedicarboxaldehyde (R = OCH_3, CH_3, Br or Ph) in the presence of excess of Ag^I ion. The polynucleating and extended coordination nature of the trpn-derived cryptand L^1 (R = OCH_3) was established by X-ray structure of $[\{Ag(Ag_2L^1)\}n][(ClO_4)_3 \cdot 2CH_3CN \cdot CH_3OH \cdot 2H_2O]_n$. The polymeric cation $[\{Ag(Ag_2L^1)\}_n]$ can be described as the bridge-twisted binuclear (Ag_2L^1) units linked together by silver atoms *via* a linear N—Ag—N bridging bonding mode in alternate (inward, outward) conformations relative to the benzene rings, resulting in an infinite single helical chain. The benzene rings in the helix chain are almost parallel to each other, with a π—π stacking distance of 3.84 Å. The coordination behaviour of cryptands have also been studied by NMR spectroscopy in solution. Copyright © 1996 Elsevier Science Ltd



Keywords: cryptands; silver; cryptates; polymer; helix; structure.

Cryptands with large cavities and multiple recognizing functions have recently received a great deal of attention as hosts for metal ions which form cryptates from mono- to poly-nuclear [1,2]. The metal complexes are potentially important in the emerging fields of biomimetric chemistry [3], molecular electronics and supramolecular devices [4,5].

Polyaza Schiff-base cryptands and their metal complexes have been developed since Lehn [6] and Nelson [7] and their co-workers reported an efficient and facile synthetic method, based on [2+3] Schiff-base condensation of tris(2-aminoethyl)amine (tren) with rigid aromatic dialdehydes without template. This method opens a wide variety of new tren-derived polyaza Schiff-base and resulting amine cryptands and their mono- [8–10] bi- [11–15] and poly- [16–19] nuclear, cascade [20–22] and compartment [23–25] cryptates, which have been devoted to the studies of metal–metal bonding, magnetic coupling, electrochemical and photochemical processes, and modeling the active site of metalloproteins and metalloenzymes (especially, Cu, Zn-superoxide dismutase) [22]. However, only a few analogues derived from tris(3-aminopropyl) amine(trpn) with corresponding compounds have been reported to date [12,26–29]. This tardiness may in part be attributed to the labour involved in synthesis and characterization. It was anticipated that trpn, due to its longer chains than those of tren, would form cryptands and their metal complexes with novel conformations and host–guest properties. Recently, we reported a range of new binuclear polyaza cryptands by template condensation of trpn with 5-R-2-methoxy-1,3-benzenedicarboxaldehyde (R = OCH_3, CH_3, or Br). It is interesting that there are three variants of silver(I) cryptate with L^1 (R = OCH_3), two of which were described as a basket [27] and a bridge-twisted [28] shape. Here we present the third variant

* Author to whom correspondence should be addressed.

which possesses an infinite structure with single helix chain. Very few silver(I) polymeric helicates of all-nitrogen cryptands have been reported, although several silver(I) polymeric cryptates of poly-oxygen donor cryptates were structurally characterized earlier [30, 31]. Additionally, in order to elucidate the coordination nature of this type of ligands, we studied a series of silver(I) cryptates with trpn- and tren-derived Schiff-base octaaza-cryptands by NMR spectroscopy in solution (Fig. 1).

EXPERIMENTAL

Materials and physical measurements

In our earlier publications [27,28], we reported the physical measurements and synthesis of trpn, dialdehydes, and binuclear cryptates of L^1 ($R = OCH_3$), L^2 ($R = CH_3$) and L^3 ($R = Br$). 5-Ph-2-methoxy-1,3-benzenedicarboxaldehyde and tren were prepared with methods by Hu [32], and Kimura [33], respectively.

$[\{Ag(Ag_2L^1)\}_n][(ClO_4)_3 \cdot 2CH_3CN \cdot CH_3OH \cdot 2H_2O]_n$ (1)

To a stirred solution of $AgNO_3$ (0.425 g, 2.5 mmol) and 2,5-dimethoxy-1,3-benzenedicarboxaldehyde (0.582 g, 3.0 mmol) in anhydrous ethanol (100 cm^3) was added dropwise a solution of trpn (0.376 g, 2.0 mmol) in anhydrous ethanol (50 cm^3). After stirring for 3–4 h at 45°C, the mixture was filtered. Then an excess of $NaClO_4 \cdot H_2O$ (1.2, 10 mmol) in ethanol (20 cm^3) was added to the filtrate, yellowish microcrystals were isolated. This is a mixture of binuclear and polymeric complexes, characterized as $(Ag_{2.5}L^1)(ClO_4)_{2.5} \cdot 2H_2O$. Found: C, 41.1; H, 4.9; N, 8.0; Ag, 19.4. Calc. for $C_{48}H_{70}N_8O_{16}Ag_{2.5}Cl_{2.5}$: C, 41.0; H, 5.0; N, 8.2; Ag, 19.2%. The yellow block crystals of **1** suitable for X-ray analysis were obtained by slow diffusion of ether into 1 : 1 $CH_3CN \cdot CH_3OH$ solution, yield 58%. Found: C, 39.0; H, 5.0; N, 8.7; Ag, 19.8. Calc. for $C_{53}H_{80}N_{10}O_{21}Ag_3Cl_3$: C, 39.2; H, 4.9; N, 8.6; Ag, 19.9%. ^1H NMR(CD_3CN, TMS): δ 8.61, 8.59(d, 4H, HC=N); 8.52(s(br), 2H, HC=N); 7.10 (m, 4H, Ph-H); 6.52(s(br), 2H, Ph-H); 4.11–3.98 (m, 12H, CH_2—N(imino)); 3.78(s, 9H, 2-OCH_3); 3.40(s, 9H, 5-OCH_3); 3.00 ~ 2.78(m, 12H, CH_2—N-(bridgehead)); 1.96 ~ 1.92(m, 12H, CH_2). ^{13}C NMR (CD_3CN, TMS): δ 162(C=N); 155 ~ 152, 130, 114 (Ph-C); 65 ~ 64(CH_2—N(imino)), 57 ~ 55(CH_2—N (bridgehead)), 29(CH_2). Λ_{mol} (CH_3CN, 295 K): 378 S cm^2 mol^{-1}. IR(cm^{-1}): 3535w (νOH(H_2O)), 1637s(νC=N).

A similar procedure was adopted to synthesize the following complexes.

$[Ag_2L^4](ClO_4)_2$ (2)

Yellowish needle crystals of **2** (yield 83%). Found: C, 54.2; H, 4.9; N, 7.9; Ag, 15.5. Calc. for $C_{63}H_{72}N_8O_{11}Ag_2Cl_2$: C, 53.9; H, 5.2; N, 8.0; Ag, 15.4%. ^1H NMR(CD_3CN, TMS): δ 8.64(s(br), 2H, HC=N); 8.11, 7.95(d(br), 4H, HC=N); 7.66 (s(br), 2H, Ph(1)-H); 7.40(s(br), 2H, Ph(1)-H); 7.37 ~ 7.26(m, 15H, Ph(2)-H); 6.73(s(br), 2H, Ph(1)-H);

4.25, 4.17, 4.01(m, 12H, CH_2—N(imino)); 3.41, 3.39, 3.38(m, 9H, OCH_3); 3.16, 2.92, 2.72(m, 12H, CH_2—N(bridgehead)); 2.12, 1.99, 1.80(m, 12H, CH_2). Λ_{mol} (CH_3CN, 295 K): 331 S cm^2 mol^{-1}. IR(cm^{-1}): 1655 s(νC=N). UV–Vis spectrum (CH_3CN, 295 K): 280(ε_{mol} 23130), 316 nm (5820).

$[Ag_2L^5](ClO_4)_2 \cdot 4H_2O$ (**3**)

Yellowish microcrystals (yield 96%). Found: C, 40.0; H, 4.8; N, 9.2; Ag, 17.4. Calc. for $C_{42}H_{62}N_8O_{18}Ag_2Cl_2$: C, 40.2; H, 5.0; N, 8.9; Ag, 17.2%. ^1H NMR (CD_3CN, TMS): δ 8.85 (s, 4H, HC=N); 8.50(d, 2H, HC=N); 7.80(s, 2H, Ph-H); 7.45(s, 4H, Ph-H); 4.0 ~ 3.5(m, 30H, $OCH_3 + CH_2$—N (imino)); 2.95(m, 12H, CH_2—N-(bridgehead)). Λ_{mol} (CH_3CN, 295 K): 344 S cm^2 mol^{-1}. IR (cm^{-1}): 3472w (νOH(H_2O)); 2918, 2840(νCH), 1635s(νC=N). UV–vis (CH_3CN, 295 K): 340 (ε_{mol} 16000); 280 nm(10200).

$[Ag_2L^6](ClO_4)_2 \cdot 4H_2O$ (**4**)

White microcrystals (yield 83%). Found: C, 41.8; H, 4.8; N, 9.5; Ag, 18.0. Calc. for $C_{42}H_{62}N_8O_{15}Ag_2Cl_2$: C, 41.9; H, 5.1; N, 9.3; Ag, 17.9%. ^1H NMR(CD_3CN, TMS): δ 8.79; 8.52 (d, 6H, HC=N); 8.02, (s(br), 2H, Ph-H); 7.83(br, 4H, Ph-H); 3.85 ~ 3.54(m, 30H, CH_2—N (imino) + CH_3 + OCH_3); 3.00(m, 12H, CH_2—N (bridgehead). Λ_{mol} (CH_3CN, 295 K): 335 S cm^2 mol^{-1}. IR(cm^{-1}): 3481w (νOH(H_2O)); 2919, 2838(νCH); 1637s(νC=N). UV–vis spectrum (CH_3CN, 295 K): 320(ε_{mol} 14600), 280 nm(9800).

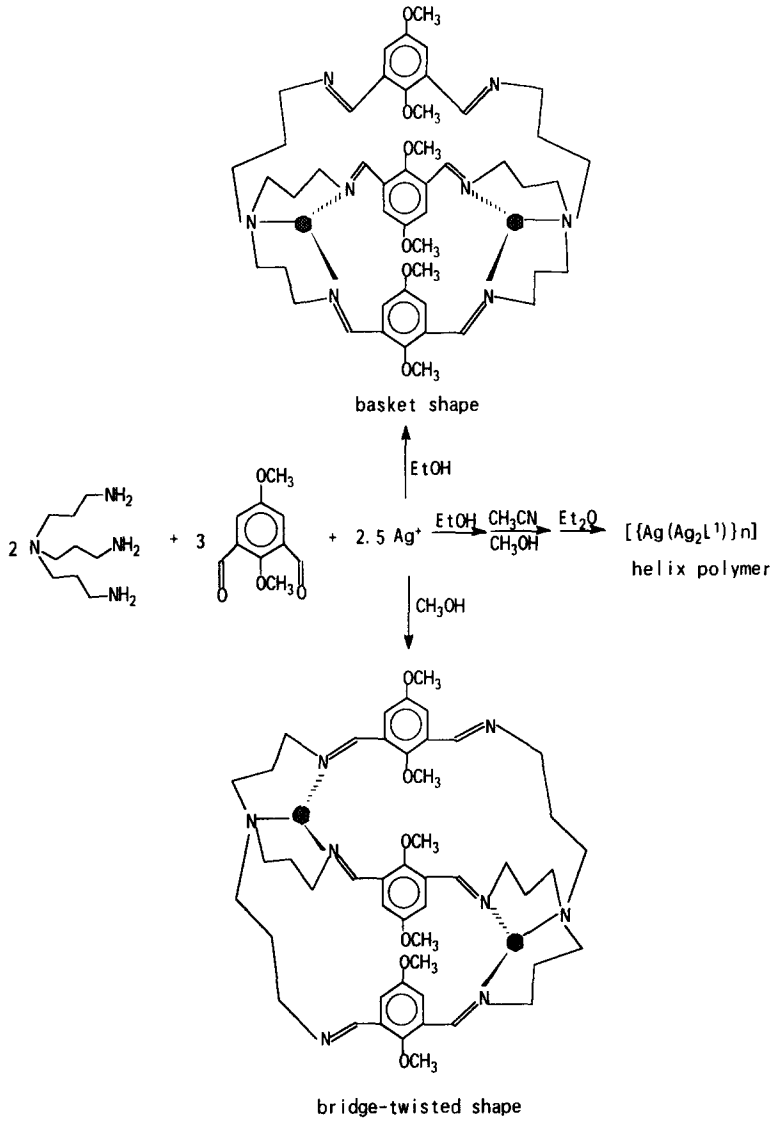
$[Ag_2L^7](ClO_4)_2 \cdot 2H_2O$ (**5**)

Yellow microcrystals (yield 80%). Found: C, 32.8; H, 4.0; N, 7.9; Ag, 15.0. Calc. for $C_{39}H_{55}N_8O_{16}Ag_2Br_3Cl_2$: C, 33.0; H, 3.9; N, 7.9; Ag, 15.2%. ^1H NMR (CD_3CN, TMS): δ 8.78(br, 4H, HC=N); 8.55(s(br), 2H, HC=N); 8.06(m, 6H, Ph-H); 3.98–3.85(m, 21H, $OCH_3 + CH_2$—N (imino)); 2.99 (m, 12H, CH_2—N(bridgehead)). Λ_{mol}(CH_3CN, 295 K): 311 S cm^2 mol^{-1}. IR(cm^{-1}): 3473w (νOH(H_2O)); 2912, 2844(νCH), 1637s(νC=N). UV–vis spectrum (CH_3 CN): 315(ε_{mol} 12500), 285 nm(7500).

X-ray crystal structure determination of $[\{Ag(Ag_2L^1)\}_n][(ClO_4)_3 \cdot 2CH_3CN \cdot CH_3OH \cdot 2H_2O]_n$ (**1**)

Crystal data. Formula $C_{53}H_{80}N_{10}O_{21}Ag_3Cl_3$, M = 1623.23, crystallizes from 1 : 1 acetonitrile–methanol with diffusion of ether as yellow blocks of photosensitive crystals, monoclinic space group $P2_1/c$, a = 13.308(3), b = 22.256(9), c = 23.066(9) Å, β = 102.18(2)°, V = 6678(4) Å^3, Z = 4, D_{calc} = 1.61 g cm^{-3}, $F(000)$ = 3312, graphite-monochromated Mo-K_α radiation (λ = 0.71069 Å), T = 296 K, μ (Mo-K_α) = 10.58 cm^{-1}. Enraf-Nonius CAD 4 diffractometer.

Data collection and processing. A single crystal encapsulated with gel, possessing approximate size 0.40 × 0.40 × 0.40 mm was mounted on a glass fibre and used for structure determination. The unit cell parameters were determined from least-squares refinement of the setting angles ($13.98 < \theta < 14.40$°) for 25 reflections. Using ω scan technique (scan speed < 5.49 min^{-1} scan width = $0.80 + 0.35 \tan\theta$, $0 \leqslant h \leqslant 15$, $-26 \leqslant k \leqslant 0$, $-27 \leqslant l \leqslant 27$), 12,423 unique reflections were collected to a maximum 2θ value of 50°. 4450 reflections with $I \geqslant 2\sigma(I)$ were used in the structural refinement. There was a linear decay during data collection, according to the intensities of three standard reflections (5, −12, 3; 6, −11, 2; −6, 11, −2) which were measured every 300 reflections (the final decay to 86.8%). Corrections for Lorentz-polarization, decay and absorption were applied, the latter using the DIFABS procedure [34]. The data were averaged (R_{int} = 0.82%).



Structure analysis and refinement. The locations of silver atoms were determined by direct methods. The remaining non-hydrogen atoms were located through successive least-squares refinements on difference Fourier map using the TEXSAN(V2.1) structure solution package [35]. All of the non-hydrogen atoms were refined anisotropically, and the hydrogen atoms were included in calculated positions. The final least-squares cycle R = 0.097 and Rw = 0.091. The weighting scheme was $w^{-1} = \sigma^2(F)$. The polymeric silver cryptate is very sensitive to light, resulting in the poor quality of the data. Several atoms in the flexible ligand and solvents had high thermal motion and possibly disordered, although we were unable to refine a satisfactory model. The largest peak in final difference map is 1.33 e Å^{-3}. All calculations were performed on a Micro-VAX 3100 computer.

RESULTS AND DISCUSSION

Synthesis of cryptates

Using the same template technique, we synthesized the cryptates of trpn-derived cryptands $L^1 \sim L^4$ and tren-derived cryptands $L^5 \sim L^7$ in high yields (Fig. 1). Due to the steric hindrance, the cryptand derived from tren and 5-phenyl-2-methoxy-1,3-benzenedicarboxaldehyde was not obtained.

These cryptates were characterized as binuclear complexes, with the exception of the cryptates of L^1 (R = OCH_3). The cryptates of L^1 were obtained as three variants in different solvents. As shown in Scheme 1, the solvent plays an important role in isomerization and polymerization of the cryptates of L^1. From the highly polar solvents (methanol or acetonitrile), the product crystallizes with bridge-twisted

Scheme 1.

binuclear cryptate or depolymerizes in solution. From lower polarity solvents (ethanol or mixing with ether), the product crystallizes as basket-shaped binuclear cryptate or polymerizes in solution.

In addition, the appropriate excess of template material is also necessary in the synthesis of the polymeric cryptate of L^1, but does not effect the formation of the other cryptates.

NMR studies of coordinate conformations

All cryptates have similar IR and electronic spectroscopic features, consistent with our previous results [27,28]. All binuclear cryptates are easy to dissolve in acetonitrile and exhibit 1 : 2 electrolytic behaviour, while the polymeric cryptate **1** is difficult to dissolve in acetonitrile but easy to dissolve in DMSO or DMF and behaves as a 1 : 2 or 1 : 3 electrolyte. This is a significant difference between the polymeric cryptate and the binuclear cryptates.

The three variants of L^1 gave the same ^1H NMR or electronic spectra in CH_3CN solution, showing that the polymeric complex is not maintained and is depolymerized into binuclear cryptates.

Both the conformations of the binuclear cryptates (basket or bridge-twisted shapes as shown in their crystal structure [27,28]) are not distinguishable in

solution. Their proton chemical shifts give broad peaks, perhaps caused by the rapid exchange between the two conformations. To further elucidate the substituent and cavity size effects in coordinate conformation of the cryptands, we estimated supplementally the contribution of non-equivalent coordination to the proton chemical shifts of benzene rings in the cryptands based on our published results [27]. Their values are given in Table 1.

Since there are two conformations (basket and bridge-twisted shapes) for the cryptates, δ_c, δ_f, S_c and S_f need to be redefined. Here δ_c and δ_f denote the proton chemical shifts resulting from the coordinated and from the non-coordinated imino groups respectively. S_c and S_f denote the total contributions of the coordinated and of the non-coordinated, respectively. $|\delta_c-\delta_f|$ represents the non-equivalency in the cryptand ligand.

It can be seen from Table 1 that all of the complexes

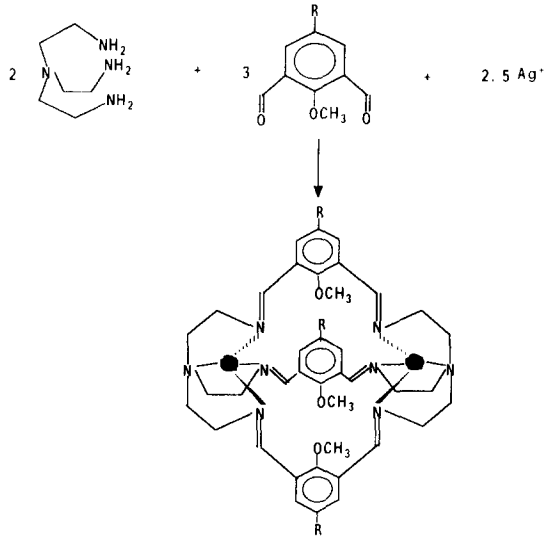


Table 1. The contribution of non-equivalent coordination to the proton chemical shifts of benzene rings in cryptates (ppm)

Cryptand	5-R	δ_c	δ_f	S_c	S_f	$\delta_c-\delta_f$
L^1	OCH_3	7.10	6.51	+0.41	−0.18	+0.59
L^2	CH_3	7.35	6.75	+0.38	−0.22	+0.60
L^3	Br	7.66	7.00	+0.31	−0.35	+0.66
L^4	Ph	7.66	6.73	+0.34	−0.59	+0.93
L^5	OCH_3	7.45	7.80	+0.76	+1.11	−0.35
L^6	CH_3	7.85	8.02	+0.86	+1.05	−0.09
L^7	Br	8.06	8.06	+0.71	+0.71	0

Values of L^2 and L^3 are quoted from [27]. $S_c = \delta_c - 7.26 - \Sigma$ s, $S_f = \delta_f - 7.26 - \Sigma$ s.

of trpn-derived cryptands ($L^1 \sim L^4$) have positive values of S_c and negative values of S_f. This indicates that all trpn-derived cryptates possess similar coordinate conformation. The S_c with positive value shows that the coordination of the equivalent four imino groups causes a deshielding effect, resulting in downfield shifts of the proton of benzene rings; meanwhile, the S_f with negative value shows the other two non-coordinated imino groups cause a shielding effect, resulting in upfield shifts of the proton of the benzene rings. Thus, all of the complexes of trpn-derived cryptands possess similar three-coordinate environment about each silver atom in solution, consistent with the crystal structures [27,28] of cation $[Ag_2L^1]^{2+}$. However, both S_c and S_f values of the complexes of tren-derived cryptands are positive, showing that all imino nitrogen donors are coordinated to silver atoms, resulting in deshielding effects. Thus, all of the complexes of tren-derived cryptands have approximately equivalent coordination for each imino N donor.

The values of $|\delta_c-\delta_f|$ have two sequences as follows:

Sequence I:

$$L^4(R = Ph) > L^3(R = Br) > L^2(R = CH_3) \approx L^1(R = OCH_3);$$

Sequence II:

$$L^5(R = OCH_3) > L^6(R = CH_3) > L^7(R = Br).$$

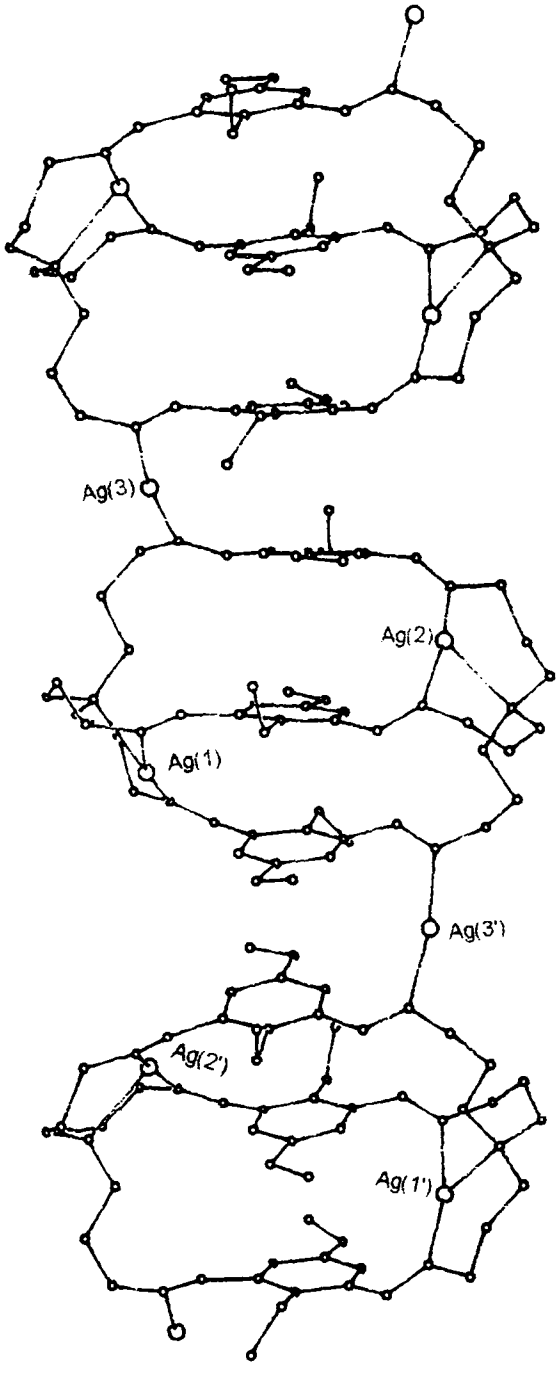
Comparison of sequence I with sequence II shows that the trpn-derived cryptands possess much larger non-equivalency than tren-derived cryptands. This may be due principally to the non-equivalent coordination of imino N donors of trpn-derived cryptands. The $L^4(R = Ph)$ possesses the highest value of $|\delta_c-\delta_f|$, attributed not only to the non-equivalent coordination but also to the steric effect of the substituents.

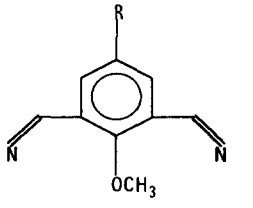
The crystal structures [27,28] reveal that internuclear distances of the two binuclear cryptates of L^1 are 7.468 (basket) and 8.266 Å (bridge-twisted), respectively. This shows that trpn-derived cryptand possesses a wide range of variable cavity size to satisfy the three coordination requirement of silver(I), resulting in large coordination non-equivalency for imino nitrogen donors.

The X-ray structure analysis and NMR studies [7, 11] show that the binuclear Ag^I complexes of cryptand derived from tren and phenyldialdehyde without substituent (i.e. isophthalaldehyde and terephthalaldehyde) possess equivalent four-nitrogen coordination about each silver atom. When we introduced a 2,5-substituent to benzene rings, the steric hindrance results in a little non-equivalency but does not change the four-coordination nature of the tren-derived cryptands, due to the rigidity of bridging chains and little variable cavity size.

Description of the helix structure of the polymeric cryptate **1**

The crystal structure of the polymeric cation complex $[\{Ag(Ag_2L^1)\}_n]$ is shown in Fig. 2. It consists of binuclear (Ag_2L^1) units linked together by silver atoms *via* a linear N—Ag—N bridging bonding mode. Selected interatomic distances and bond angles for **1** and a comparison with its precursor are given in Table 2. The fragment structure of the polymeric cryptate is shown in Fig. 3.





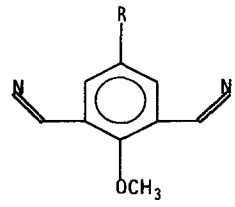


Fig. 2. A perspective view of the polymeric cation helix chain. $[\{Ag(Ag_2L^1)\}_n]$.

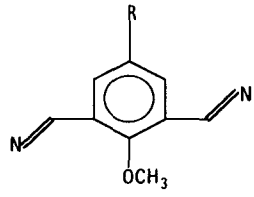

The fragment of the polymeric cryptate consists of Ag(3) and binuclear cryptate (Ag(1) Ag(2)L^1). Ag(3) is the bridging atom of inter-cavity. Both Ag(1) and Ag(2) are the bridging atoms of intra-cavity. In the cavity of (Ag_2L^1), Ag(1) and Ag(2) are situated in the different regions separated by the twisted bis (iminobenzene) bridging link consisting of N(5), N(6) and connected benzene ring. Each silver atom coordinates to three nitrogen atoms, two imino nitrogens and a bridgehead nitrogen, which has a slightly distorted trigonal environment. There are three possible arrangements of the C=N bonds relative to benzene rings illustrated as follows:

(in-, in-)

(out-, out-)

(in-, out-)

In the cavity, the twisted chain array composed of coordinate atoms and metal atoms N(3) → N(2) → Ag(1) → N(6) → N(5) → Ag(2) → N(8) → N(7) can be described as alternate (in-, out-) conformation. This coordinate chain possesses (out-, in-, Ag, in-, out-, Ag, out-, in-) conformation to form an S shape. The above-mentioned structural features are just equivalent to those of the bridge-twisted binuclear cryptate with the same cryptand [28], apparently being distinct from the basket shape out-, out-, Ag, out-, out-, Ag, out-, out-) [27]. Consequently, we consider that the bridge-twisted variant acts as a precursor unit to assemble the polymeric cryptate. By comparison of their bond lengths and angles (Table 2), we can further understand the relationship between them.

The average bond length of Ag—N (imino) of the polymeric cryptate is close to that of the precursor (2.18 Å). The average Ag—N (bridgehead) distance

Table 3. benzene ring planes in cryptate **1**

Plane	Orthonormal equation (e.s.d.)	Atoms
1	$0.0453x+0.9984y-0.0352z-3.3161=0$ (0.0097) (0.0006) (0.0093) (0.0762)	C(5) ~ C(10)
2	$0.1058x-0.9943y-0.0120z+6.4197=0$ (0.0093) (0.0010) (0.0092) (0.0782)	C(19) ~ C(24)
3	$0.1445x-0.9842y-0.1025z+10.3989=0$ (0.0093) (0.0017) (0.0095) (0.0734)	C(33) ~ C(38)

Dihedral: 1 ∧ 2 = 170.92(59); 1 ∧ 3 = 166.51(61); 2 ∧ 3 = 5.67(1.57)°.

of the former is 2.47 Å, being 0.03 Å longer than that of the latter. This indicates that the coordination between Ag and N (imino) in the former is slightly stronger than that in the latter, while the coordination between Ag and N (bridgehead) in the former is weaker than that in the latter.

It is noted that the corresponding bond angles and non-bond distances of the polymeric complex are quite different from the precursor. For example, the distance Ag(1)···N(7) or Ag(2)···N(3) is 0.9 Å, and Ag(1)···Ag(2) is 0.1 Å longer than that of the precursor. Moreover, in the cavity, the coordinate bond angle about the silver atom (N(6)—Ag(1)—N(2), N(6)—Ag(1)—N(1), N(8)—Ag(2)—N(5), or N(5)—Ag(2)—N(4)) is reduced by 5 ~ 8°, compared with the corresponding angle of the precursor. These changes were caused by the formation of the infinite chain *via* N(3)—Ag(3)—N(7) inter-cavity bridging bond.

The bond angle of inter-cavity bridge N(3)—Ag(3)—N(7) is 169.7(7)°, being 2.8 ~ 3.6° larger than that of the intra-cavity bridge N(6)—Ag(1)—N(2) or N(8)—Ag(2)—N(5). Both the inter-cavity bridge and intra-cavity bridge satisfy the distorted linear configuration of silver(I). The difference between the polymeric cryptate and its precursor reflects the steric requirement of the assembly process from the bridge-twisted shape to infinite chain. If we only take the linear N—Ag—N bonding coordination mode into consideration, the polymeric cation $[\{Ag(Ag_2L^1)\}_n]$ can be described as the conjugate bis(iminobenzene) moieties linked together *via* linear N—Ag—N bridges (inter- and intra-cavity) in alternate (in-, out-) conformations, resulting in the formation of an infinite single-helix chain. The helical array runs parallel to the crystallographic *b* axis.

As shown in Table 3, all benzene rings in the single helix chain are approximately parallel to each other, with a π–π stacking distance of 3.84 Å. Additionally, its isostructural analogous copper(I) and gold(I) polymeric cryptates were also synthesized in further studies.

(Received 21 August 1995; accepted 13 June 1996)

Abstract—Pseudohalide complexes of the type $M\{ONC(CN)_2\}_2L_2$, with M = Cu, L = imidazole (iz), 1-methylimidazole (meiz); M = Ni, Co, L = meiz, $Cu\{ONC(CN)_2\}_2(meiz)_4$ $M\{ONC(CN)_2\}_2(iz)_4$, with M = Ni, Co, and $M\{N(CN)_2\}_2L_2$, with M = Cu, Co, L = meiz; M = Ni, L = iz, meiz have been prepared and characterized by spectroscopic and magnetic techniques. The crystal structure of $Cu\{ONC(CN)_2\}_2(meiz)_4$ has been determined by the X-ray diffraction method. The Cu^{II} environment is elongated pseudooctahedral, composed of four tertiary meiz nitrogens and two nitrosodicyanomethanide oxygens in longer axial distances. According to spectroscopic results, the remaining compounds show octahedral (Ni, Co) or pseudooctahedral (Cu) structures, realized in the M : L = 1 : 2 and probably also in the 1 : 4 compounds by bridging pseudohalide function. Such bridging is evidenced by magnetic properties of $Cu\{ONC(CN)_2\}_2(meiz)_2$, being affected by exchange coupling between the paramagnetic metal ions. Copyright © 1996 Elsevier Science Ltd

Keywords: nitrosodicyanomethanide; dicyanamide; X-ray structure; IR spectra; electronic spectra; magnetism.

The nitrosodicyanomethanide anion, $ONC(CN)_2^-$, contains as a ligand various donor atoms, but is preferentially coordinated through the nitroso–nitrogen or oxygen atom [1–6], depending on the character of the central atom. No well-documented case of oxygen coordinated nitrosodicyanomethanide in a transition *d*-metal complex is known until now. Further the $ONC(CN)_2^-$ anion can also act as a bidentate bridging ligand using its cyano nitrogen for additional binding [2,7,8].

Another pseudohalide used as a ligand in this work, the dicyanamide anion $N(CN)_2^-$, although potentially bidentate, much prefers forming coordination bonds *via* the cyano nitrogen [9]. This ligand shows more pronounced tendency to bridging function than

* Author to whom correspondence should be addressed.

nitrosodicyanomethanide [7], ligating either through both cyano or through amide and cyano nitrogens [9]. Even two isomers of $Cu\{N(CN)_2\}_2(imidazole)_2$ were isolated differing just by the mode of dicyanamide bridging [10].

In earlier papers the preparative and physical investigations of nitrosodicyanomethanide complexes of Cu^{II}, Co^{II}, Ni^{II} with ligands of pyrazole type [7,8], as well as of dicyanamide complexes of Cu^{II} and Co^{II} with imidazole and its methylderivatives [10,11] were performed. In further work, we have carried out a research of nitrosodicyanomethanide and dicyanamide complexes of Cu^{II}, Ni^{II}, Co^{II} with imidazole (iz) and 1-methylimidazole (meiz), including the X-ray crystallographic study of $Cu\{ONC(CN)_2\}_2(meiz)_4$.

EXPERIMENTAL

Preparation of the compounds

$Cu\{ONC(CN)_2\}_2(iz)_2$. Solutions of 2.5 mmol of $Cu(NO_3)_2 \cdot 3H_2O$ in 5 cm^3 of water and of 5.0 mmol of $NaONC(CN)_2$ in 5 cm^3 of water were mixed. The system obtained was alkalized with 2 cm^3 of 25% NH_3 and poured into a solution of 5.0 mmol of iz in 20 cm^3 of methanol. Under continuous stirring a suspension was formed which was filtered off and washed with diethylether. Yield 84%.

$Cu\{ONC(CN)_2\}_2(meiz)_4$. A solution of 5.0 mmol of $Cu(NO_3)_2 \cdot 3H_2O$ in 15 cm^3 of water and 20 mmol of meiz were poured into a solution of 11 mmol of $NaONC(CN)_2$ in 20 cm^3 of water. A green solution was formed from which a crystalline product was separated and washed with diethylether. Yield 81%.

$Cu\{ONC(CN)_2\}_2(meiz)_2$. A solution of 5.0 mmol of $Cu(NO_3)_2 \cdot 3H_2O$ in 3 cm^3 of water and 10 mmol of meiz were poured into a solution of 11 mmol of $KONC(CN)_2$ in 4 cm^3 of water. Under continuous stirring an oily suspension was formed from which a solid was isolated and washed with diethylether. Yield 79%.

$M\{ONC(CN)_2\}_2(iz)_4$ and $M\{ONC(CN)_2\}_2(meiz)_2$ (M = Ni, Co). Solution of 5.0 mmol of $M(NO_3)_2 \cdot 6H_2O$ in 6 cm^3 of water and of 11 mmol of iz or meiz in 8 cm^3 of water were poured into a solution of 11 mmol of $KONC(CN)_2$ in 5 cm^3 of water. Under continuous stirring the products in the form of microcrystalline powders were isolated and washed with methanol or diethylether. Yields 78–91%.

$M\{N(CN)_2\}_2L_2$ (M = Cu, Ni, Co; L = iz, meiz). Solutions of 4.0 mmol of $Cu(NO_3)_2 \cdot 3H_2O$ or $M(NO_3)_2 \cdot 6H_2O$ (M = Ni, Co) in 5 cm^3 of water and a solution of 8.5 mmol of $KN(CN)_2$ in 8 cm^3 of water were mixed with a solution of 9.0 mmol of L in 8 cm^3 of methanol. Under continuous stirring the respective compounds were precipitated and washed with 1 : 1 mixture of water and methanol. Yields 80–92%.

Analyses

Metal was determined chelatometrically after decomposition of the compounds by H_2SO_4 and $K_2S_2O_8$. The elemental analyses were carried out using a Carlo-Erba C,H,N-analyser. The analytical data are listed in Table 1.

X-ray structure analysis and refinement

A single crystal of dimension $0.15 \times 0.30 \times 0.45$ mm was used for data collection. The data were collected at 293(2) K on a Stoe-Siemens AED diffractometer using the ω-2θ scan technique with Mo-K_α filtered radiation ($\lambda = 0.71069$ Å). Lattice parameters were obtained by least-squares refinement of 48 reflections at $35.5 \leqslant 2\theta \leqslant 48.7°$. A total of 4374 reflections were collected ($2.2 \leqslant \theta \leqslant 25.0°$, $-10 \leqslant h \leqslant 10$, $-10 \leqslant k \leqslant 7$, $-12 \leqslant l \leqslant 12$), 2420 unique, of which 2327 with $F_o > 4\sigma(F_o)$ were considered as observed; $R_{int} = 0.0152$ and $R(\sigma) = 0.0179$. The intensities of three standard reflections were monitored every 3 h; no significant systematic fluctuation was found. Pro-

[a] $w = 1/[s^2(F_o^2) + (0.0354P)^2 + 0.254P]$, where $P = (F_o^2 + 2F_c^2)/3$.

gram DIFABS [12] ($\mu = 0.838$ mm^{-1}) was used for absorption correction.

The structure was solved by Patterson methods using SHELXS86 [13] and refined on F^2 by SHELXL93 [14]. A difference map of the anisotropically refined structure gave the positions of all hydrogen atoms which were constrained: C—H = 0.93 or 0.96 Å for C—H and CH_3, respectively, with U(H) = 1.2 U_{eq} (C). In the final cycle of full-matrix least-squares refinement $R = 0.0295$ and $wR = 0.0748$. Geometrical analysis was performed using the program PARST [15].

Details about the data collection, the structure analysis and refinement are given in Table 2. Bond lengths and angles, atomic coordinates, displacement parameters and lists of structure factors for $Cu\{ONC(CN)_2\}_2(meiz)_4$ are deposited [16].

Physical measurements

The IR spectra were recorded using Philips Analytical PU9800 FTIR spectrometer in KBr disks (4000–400 cm^{-1}) and in Nujol mulls (500–200 cm^{-1}). The electronic spectra (0.4–2.8 μm^{-1}) were obtained on samples diluted by MgO with a Beckman UV 5240 spectrophotometer. Magnetic susceptibilities in the temperature range 4.2–*ca* 300 K were measured as described in detail previously [17].

RESULTS AND DISCUSSION

Description of the structure of $Cu\{ONC(CN)_2\}_2(meiz)_4$

The molecular entity $Cu\{ONC(CN)_2\}_2(meiz)_4$, with the detailed labeling of the atoms, is shown in Fig. 1. Significant bond lengths and angles are given in Table 3.

The central Cu^{II} atom, occurring in a special crystallographic position, is surrounded by four nitrogens of meiz molecules, forming the square basis of a distorted octahedron; the respective Cu—N bond lengths are 2.020(2) and 2.002(1) Å. The apical sites of the octahedron are occupied by two oxygens from nitrosodicyanomethanide anions at distances of 2.537(1) Å. The coordination geometry is therefore an elongated octahedron, the axial distances being considerably longer than the equatorial ones. There is an intricate system of hydrogen bonds as well as van der Waals contacts, as can be seen in Table 3.

It should be mentioned that in all the known nitrosodicyanomethanide complexes of *d*-elements the $ONC(CN)_2^-$ anions are coordinated through the nitroso nitrogen [1–4]. Thus, the structure solved here is the first example of the nitrosodicyanomethanide O-coordination in a *d*-metal complex.

Infrared spectra

The infrared spectra (Table 4) of the compounds under study contain in the middle region some bands characteristic for the ligation mode of the pseudohalide present [1–6,9]. The M^{II}: L = 1:2 nitrosodicyanomethanide complexes show the ν_{as}(CNO) and ν_s(CNO) frequencies in comparison with those in free $ONC(CN)_2^-$ ion [1,2,4] shifted by *ca* 93 cm^{-1} to

higher values. These shifts are regarded as a strong indication of metal–ligand bonding through nitroso nitrogen: M—N(O)C(CN)$_2$ [1–3].

In the case of $Cu\{ONC(CN)_2\}_2(meiz)_4$ the oxygen ligation of $ONC(CN)_2^-$ should be distinctly manifested by the frequency change of the ν(C—N) and ν(N=O) vibrations. Köhler *et al.* [1,4] pointed out that O-bonded $ONC(CN)_2^-$ should have shifted the ν(C—N) mode to higher frequencies but the ν(N=O) mode to lower ones. The compound $Cu\{ONC(CN)_2\}_2(meiz)_4$ has bands at 1305 and 1285 cm^{-1} which can be assigned to the ν(C—N) and ν(N=O) vibrations, respectively. Since for the free $ONC(CN)_2^-$ ion the ν(CNO) modes occur in the regions of 1325 and 1275 cm^{-1} [1,2,4], both observed frequencies are only little changed in comparison with the respective free ion frequencies. In all likelihood this fact is caused by weak axial Cu—ONC(CN)$_2$ bonding, changing only insignificantly the bond electron density in the system C—N—O.

The Ni^{II}— and Co^{II}—ONC(CN)$_2$ complex of iz represent a further interesting case, since they exhibit an unusually great number of bands assignable to the ν(CNO) modes [1–5]. These bands should suggest the presence of two bonding non-equivalent ONC(CN)$_2$ groups, *viz.* coordinated and non-coordinated ones; the presence of the latter groups is supported especially by the bands around 1260 cm^{-1}.

For all nitrosodicyanomethanide complexes the (C≡N) modes are split by ≈25–10 cm^{-1}. Since in KONC(CN)$_2$ and AgONC(CN)$_2$ this mode is split nearly to the same extent [1,4] (asymmetric and symmetric C≡N stretches), no structural importance may be ascribed to this phenomenon.

From the dicyanamide complexes, the Ni^{II} and Co^{II} derivatives exhibit three bands belonging to the ν(C≡N) stretches, whose positions are mostly in good agreement with the bidentate N(CN)$_2$ groups [9]. On the other hand, $Cu\{N(CN)_2\}_2(miz)_2$ has both ν(C≡N) values well in the ranges for monodentate N(CN)$_2$ groups, although with respect to its polymeric structure (see next section) all N(CN)$_2$ groups must be bridging bidentate; similar inconsistencies were already observed in a number of other cases [11,17,19].

In the far-IR region the bands belonging to the M—N stretching vibrations were tentatively assigned (Table 4). In $Cu\{ONC(CN)_2\}_2(meiz)_4$ the symmetry of the CuN_4O_2 skeleton is nearly D_{2h} and 15 skeletal modes can be expected, nine of which are infrared active ($3B_{1u}+3B_{2u}+3B_{3u}$). Two of these modes appearing between ≈280–260 cm^{-1} can be assigned to the Cu—N stretches in the equatorial plane (B_{2u}, B_{3u}). It is clear that the Cu—O stretch (B_{1u}) cannot be observed in the far-IR region investigated here, since modes involving atoms at such long distances are usually revealed about 100 cm^{-1} and lower [20].

The remaining nitrosodicyanomethanide complexes show two to four absorptions between ≈335–≈240 cm^{-1} which can be attributed to the M—N stretching vibrations. These absorptions naturally comprise Cu—N stretches involving nitrogens from both ligand kinds; for bridged Ni^{II} and Co^{II} systems not only M—NO but also the M—NC stretches should contribute. On the analogy of nitrosodicyanomethanide complexes of Cu^{II} and Co^{II} with methylpyrazoles [7], it might be expected that the ν(M—N) frequencies are lowered approximately in the order of M—NO > M—NC > M—N(L) but a more detailed appreciation cannot be made at this stage.

The dicyanamide complexes exhibit a similar num-

ber of absorptions between 290–≈230 cm^{-1} assignable to the M—N stretches as the previous complex group, however, some of these absorptions may also belong to the present ligands. Since none of the ν(M—N) frequencies occur above *ca* 300 cm^{-1}, the $N(CN)_2$ groups are very likely bridging through both cyano nitrogens [9,21].

Solid state electronic spectra

The electronic spectra (Table 5) of the copper(II) complexes with the Cu^{II} : L ratio of 1 : 2 exhibit broad visible bands resolved on the side of lower wavenumbers into one or two shoulders. The *d–d* spectral characteristics indicate the elongated pseudo-octahedral environment of the Cu^{II} central atom [22–25] in a polymeric structure. The equatorial positions are occupied by two tertiary nitrogens from the imidazole ligands and two nitroso or cyano nitrogens from the pseudohalides. In the axial sites are very likely located two cyano nitrogens from the pseudohalides of adjacent moieties [3,7,9,19].

From the relative positions of the *d–d* band maxima as well as the low-energy shoulders it is clear, that the tetragonal distortion [23,25] increase in the order of $Cu\{N(CN)_2\}_2(meiz)_2 < Cu\{ONC(CN)_2\}_2(meiz)_2 < Cu\{ONC(CN)_2\}_2(iz)_2$. If we tentatively assign the observed *d–d* absorptions to the pertinent transitions in D_{4h} symmetry according to Fig. 2, the ligand field parameter *Dq* can be calculated using the relation [24] $10\,Dq = \delta_3 - (1/2)\,\delta_1 - (1/3)(\delta_3 - \delta_2)$. The *Dq* values fluctuate around 870 cm^{-1}, inconsistently with the positions of both pseudohalides in the spectrochemical series [2], but in agreement with the relative basicity of iz and meiz [26].

The compound $Cu\{ONC(CN)_2\}_2(meiz)_4$ shows one broad unresolved band, which comprises all four *d–d* transitions in a low symmetry ligand field, thus, the *Dq* parameter cannot be calculated.

All nickel(II) complexes have electronic spectra with three spin-allowed *d–d* absorptions, being characteristic of octahedral surrounding of the Ni^{II} central atom [27]. The Ni^{II} : L = 1 : 2 compounds apparently adapt polymeric structures, similarly built as in the copper(II) compounds of the same type, but practically without tetragonal distortion. The compound $Ni\{ONC(CN)_2\}_2(iz)_4$ might have a molecular structure with monodentate $ONC(CN)_2$, but also a polymeric structure in which one half of $ONC(CN)_2$ groups bridges square-planar fragments $Ni(iz)_2$; the remaining $ONC(CN)_2$ groups should be anionic. A structure of this kind was recently established by X-ray crystallography for $Cu\{C(CN)_3\}_2(pyrazole)_4$ [28].

The spin-allowed absorptions in the increasing energy order are assigned to the transitions $^3T_{2g} \leftarrow {}^3A_{2g}$, $^3T_{1g}(F) \leftarrow {}^3A_{2g}$, and $^3T_{1g}(P) \leftarrow {}^3A_{2g}$; in the $ONC(CN)_2$ complexes the latter one is resolved only as a shoulder on the strong UV absorption. The *Dq* values are somewhat higher than for the copper(II) complexes and no explicit trend is perceptible. The β values, indicating the degree of covalency, are higher in the case of the $N(CN)_2$ complexes.

The cobalt(II) complexes have in their electronic spectra two spin-allowed *d–d* absorptions, whose positions give evidence for octahedral coordination geometry of the Co^{II} atom [29]. In substance structures of the same type can be postulated as for the corresponding nickel(II) complexes. The low and high energy absorptions are assigned to the transitions $^4T_{2g} \leftarrow {}^4T_{1g}(F)$ and $^4T_{1g}(P) \leftarrow {}^4T_{1g}(F)$ (in the $N(CN)_2$ complexes as a broad shoulder). The *Dq* values are very similar to those of the nickel(II) complexes and even so, the β values of the $N(CN)_2$ complexes (adding $Co\{N(CN)_2\}_2(iz)_2$ [11]) are obviously higher. Moreover, the β values in comparison with those of the corresponding nickel(II) complexes are—except for one case— practically invariably lower.

In the case of all nitrosodicyanomethanide complexes, between *ca* 1.9–2.9 μm^{-1} one or two absorptions occur, which belong to the transition in the $ONC(CN)_2$ group [2,4,30] or to some low-lying charge-transfer transition.

Table 5. Electronic spectral data for the compounds

Magnetism

The compound $Cu\{ONC(CN)_2\}_2(meiz)_2$ shows a sub-spin value of room temperature magnetic moment, ≈ 1.60 B.M., therefore temperature dependence of its magnetic susceptibility was measured (Fig. 3). The results obtained were fitted to the Curie–Weiss law in the higher-temperature region (Table 6). In the lowest temperature region some departures from the Curie–Weiss law behavior occur. The μ_{eff} values, though lower than the spin-only value, are only slightly temperature dependent (Fig. 3). One possibility for this behavior is some Cu^I species, but from the preparative point of view this is very unlikely, as no apparent reducing agent is present in the reaction system. Samples from different preparations were measured at room temperature and their magnetic moments were in the range of 1.59 ± 0.02 B.M. Furthermore, in the presence of Cu^I we should observe a non-linear course of the function $(\chi_{Cu})^{-1} = f(T)$.

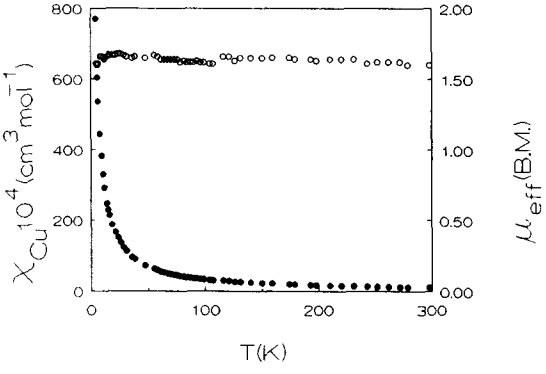

Fig. 3. Temperature dependence of molar susceptibility and effective magnetic moment for $Cu\{ONC(CN)_2\}_2(meiz)_2$.

The sub-spin copper μ_{eff} value may suggest that magnetism of the compound is influenced by both antiferromagnetic and ferromagnetic coupling between the magnetic Cu^{II} centers, which are bridged through the $ONC(CN)_2$ groups under formation of a polymeric system. In this system, two kinds of pathway for superexchange process are available, which can realize both ferromagnetic and antiferromagnetic exchange interaction. The orthogonal σ-orbitals of nitrosodicyanomethanide can mediate a ferromagnetic coupling, but the delocalized π-orbitals of this ligand can propagate an antiferromagnetic coupling. The latter coupling outweighs the former one to

Table 6. Parameters of the Curie-Weiss law for $Cu\{ONC(CN)_2\}_2(meiz)_2$ and $Co\{ONC(CN)_2\}_2(iz)_4$

Compound	Temperature range (K)	C (cm^3 K mol^{-1})	θ (K)	R^a
$Cu\{ONC(CN)_2\}_2(meiz)_2$	20–298	0.325	+2.5	2.52×10^{-2}
$Co\{ONC(CN)_2\}_2(iz)_4$	20–297	2.99	−18.4	7.05×10^{-2}

[a] The value $R = \sum_{i=1}^{n} [\chi_M(calc)_i - \chi_M(expt)_i]^2$ is the criterion determining the best fit.

cause an observed sub-spin lowering of μ_{eff}, but in their influence upon temperature behavior of μ_{eff} both kinds of magnetic exchange practically cancel out. The mutual ratio of greatness of these two kinds of magnetic interactions depends on the bridge geometric factors, mode of the polymeric system arrangement, its dimensionality, etc.

In this complex situation and in the absence of X-ray crystallographic data it seems that further attempts to rationalize the established magnetic properties are not justifiable. But it is important to note that complexes $Cu\{C(CN)_3\}_2$(3,4,5-trimethylpyrazole)$_2$ [31] and $Ni\{C(CN)_3\}_2$(2-methylbenzimidazole)$_2$ [17] were ascertained to show very similar magnetic behavior, but its fitting to the two-dimensional model in the first case did not lead to satisfying results.

For $Co\{ONC(CN)_2\}_2(iz)_4$ the temperature dependence of magnetic susceptibility was also measured (Fig. 4) and Curie–Weiss law parameters in the higher temperature region were calculated (Table 6). The experimental μ_{eff} values (4.73 B.M. at 297 K) with temperature decrease (Fig. 4) are very moderately lowered up to *ca* 100 K (4.60 B.M. at 99 K) and afterwards they fall continually more expressively as far as 2.52 B.M. at 4.2 K. In the low-temperature region the Curie–Weiss law is not obeyed by the susceptibility data.

The temperature behavior of μ_{eff} can be rationalized by the presumption of spin-orbit coupling in the octahedral $^4T_{1g}$ term [32]. Thus, the magnetic results cannot clear up the matter of the binding function of the $ONC(CN)_2$ group, because it is rather difficult to discover the potential presence of some magnetic exchange in combination with the spin-orbit effects. Similar magnetic behavior as that of $Co\{ONC(CN)_2\}_2(iz)_4$, only with somewhat less steep low temperature falling of the μ_{eff} values, but showing an anomalously low μ_{eff} value even at room temperature, was discovered for $Co\{N(CN)_2\}_2$(2-methylbenzimidazole)$_2$ having, according to the spectral results, polymeric octahedral structure with bridging $N(CN)_2$ groups [17]. The X-ray crystallography would be very desirable, but we were not able to obtain single crystals of $Co\{ONC(CN)_2\}_2(iz)_4$, nor of its Ni^{II} analogue.

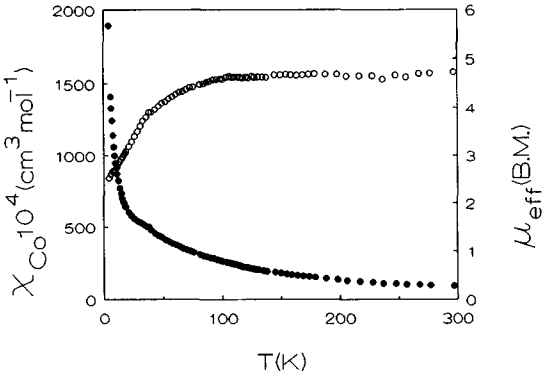

Fig. 4. Temperature dependence of molar susceptibility and effective magnetic moment for $Co\{ONC(CN)_2\}_2(iz)_4$.

(Received 25 April 1996; accepted 5 June 1996)

Abstract—The complexes α-Mo_2Cl_4[(R,R)-Me-DuPHOS]$_2$, **1**, and α-Mo_2Cl_4[(S,S)-Me-DuPHOS]$_2$, **2**, were prepared by reactions of $(NH_4)_5Mo_2Cl_9$ with (R,R)-Me-DuPHOS and (S,S)-Me-DuPHOS, respectively, in methanol. Their UV–vis and circular dichroism spectra have been recorded and the X-ray crystal structure of **1** has been determined. The chiral disphosphine ligands are chelated to the metal centers with an average twist angle of 5.2° about the metal–metal bond in the clockwise direction. The absorption spectra are typical for compounds with a Mo—Mo quadruple bond. The lowest energy bands at 690 nm for both **1** and **2** can be assigned to $\delta_{xy} \rightarrow \delta_{xy}^*$ transitions. The CD spectra of both ccomplexes **1** and **2** show two prominent bands at 695 and 520 nm and form mirror images of each other. Copyright © 1996 Elsevier Science Ltd

Keywords: quadruple bond; chelating diphosphine; circular dichroism; twist angle; chirality; CD sign rule.

Dimetallic complexes of the type $Mo_2X_4(PP)_2$, where PP is a disphosphine ligand and X is Cl, Br or I, have been extensively studied during recent years [1]. All the molecules of this type have d^4–d^4, Mo_2^{4+} moieties with two phosphorus atoms and two halogen atoms ligating to each of the molybdenum atoms. This type of complex can exist in two isomeric forms, i.e., α (chelating) and β (bridging), as shown in Fig. 1. In the α isomer the two phosphorus atoms of the same disphosphine ligands are coordinated to the same molybdenum metal centers, the chelate rings are *trans* to each other and the ligators are eclipsed. In the β isomer the similar atoms are disposed *trans* to each other and the two *trans* MoX_2P_2 units are rotated about the Mo—Mo quadruple bond such that the Mo—P (or the Mo—X) bond in one unit may or may not eclipse the Mo—P (or the Mo—X) bond in the other. Thus

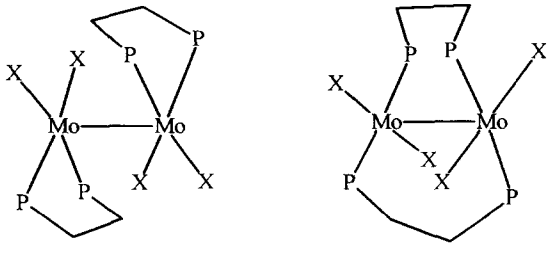

Fig. 1. Schematic drawing of the α (left) and β (right) isomer of an $Mo_2X_4(PP)_2$ compound.

*Author to whom correspondence should be addressed.

the torsional angle (P—Mo—Mo—P) may have any value $\geqslant 0°$.

Two types of chiral complexes of the form $Mo_2X_4(PP)_2$ have been structurally characterized. The first type has "class I" chromophores [2], that is, inherently chiral chromophores, and their CD spectra can be explained by the CD sign rule (Fig. 2) [3], which has been verified with the syntheses and structural characterization of the complexes, β-Mo_2X_4[(S,S)-dppb]$_2$ (X = Cl or Br) [4], β-Mo_2Cl_4[(S,S)-diop]$_2$ and β-Mo_2Cl_4[(R,R)-diop]$_2$ [5]. The other type of chiral complex has "class II" chromophores, [2] that is, an intrinsically achiral chromophore that displays chiroptical effects through perturbation by chiral surroundings. The chiral complex β-Mo_2Cl_4[(S,S)-dppm]$_2$ [6], which has an approximately 0° torsional angle, appears to belong to this category. The one-electron static coupling mechanism was invoked to explain the CD spectrum for this complex.

Here we report the first structurally characterized complexes that contain chiral, chelating disphosphine ligands and quadruply bonded chromophores. The preparation, structure, and optical activity of these chiral complexes form the subject of this report.

EXPERIMENTAL

General procedures

All manipulations were carried out under dry, oxygen-free nitrogen by using Schlenk techniques, unless otherwise noted. Solvents were dried and deoxygenated by refluxing over the appropriate reagents before use. Methanol was purified by distillation from magnesium, *n*-hexane from sodium/benzophenone, and dichloromethane from P_2O_5. The Visible absorption spectra were recorded on a Hitachi U-2000 spectrophotometer. The Circular Dichroism (CD) spectra were recorded on an Aviv 62A DS spectrometer. The NMR spectrum was recorded on a Bruker 200 MHz NMR spectrometer.

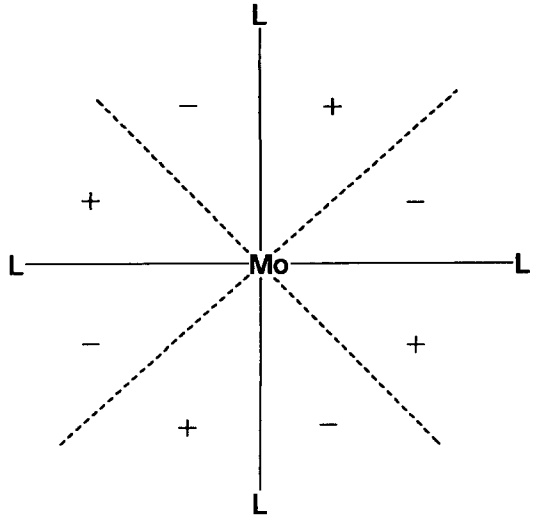

Fig. 2. Sector diagram for the $\delta_{xy} \rightarrow \delta^*_{xy}$ transition of a chiral $Mo_2L_nL'_{8-n}$ complex (CD sign rule).

Starting material

The complex $(NH_4)_5Mo_2Cl_9$ was prepared according to a previously reported procedure [7]. The reagents 1,2-bis[(2R,5R)-2,5-dimethylphospholano] benzene, (R,R)-Me-DuPHOS, and 1,2-bis[(2S,5S)-2,5-dimethylphospholano]benzene, (S,S)-Me-Du PHOS, were purchased from Strem Chemical Co.

Preparation of α-Mo_2Cl_4[(R,R)-Me-DuPHOS]$_2$ *and* α-Mo_2Cl_4[(S,S)-Me-DuPHOS]$_2$.

$(NH_4)_5Mo_2Cl_9$ (0.10 g, 0.16 mmol) and (R,R)-Me-DuPHOS or (S,S)-Me-DuPHOS (0.10 g, 0.33 mmol) were placed in a flask containing 15 cm^3 CH_3OH. The mixture was then stirred at room temperature for 3 h to yield a yellow–green solid and a yellow–green solution. The yellow–green product was filtered, washed by CH_3OH and ether and then dried under reduced pressure. Yield: 0.035 g (34.40%) for **1** and 0.051 g (50.20%) for **2**. Uv–vis: 675 nm in CH_2Cl_2 and 690 nm in THF. $^{31}P\{^1H\}$-NMR ($CDCl_3$): 63.65 (d, $J_{P\text{-}P}$ = 10.74 Hz, 63.49 (d, $J_{P\text{-}P}$ = 10.74 Hz) ppm.

X-ray crystallography

The diffraction data of α-Mo_2Cl_4[(R,R)-Me-DuPHOS]$_2$ were collected on a Siemens P4 diffractometer at 25°C, which was equipped with graphite-monochromated Mo—K_α (λ_α = 0.71037 Å) radiation. Data reduction was carried out by standard methods with use of well-established computational procedures [8]. Basic information pertaining to crystal parameters and structure refinement is summerized in Table 1. Table 2 lists selected bond distances and angles.

A yellow–green crystal of α-Mo_2Cl_4[(R,R)-Me-DuPHOS]$_2$ was mounted on the top of a glass fiber with epoxy cement. The unit cell constants were determined from 25 reflections with 2θ in the range from 24 to 27°. These were consistent with the monoclinic crystal system, and the space group was subsequently determined to be $P2_1$ from the systematic absences.

Routine $\theta-2\theta$ data collection was used to scan a possible 8516 data points in the range $4 < 2\theta < 50°$. The structure factors were obtained after Lorentz and polarization correlations. Empirical absorption based on azimuthal (ψ) scans of reflections of Eulerian angle χ near 90° were applied to the data. The positions of heavy atoms, including two molybdenum atoms, were located by direct methods. The remaining atoms were found in a series of alternating difference Fourier maps and least-square refinements. Anisotropic thermal parameters were used for all the atoms except the

hydrogen atoms. The positions of the hydrogen atoms were fixed as riding models during the least-square refinements. The final residuals of the first refinement were $R = 0.0340$, $Rw = 0.0375$ and $S = 1.05$ with a (R,R) configuration for the ligands. An inversion of coordinates was made and the structure was refined to convergence with $R = 0.035$, $Rw = 0.039$ and $S = 1.09$. The results clearly confirmed that the (R,R) isomer was indeed correct. The reported *R* values for the structure [(COD)Rh((S,S)-Me-DuPHOS)]SbF_6 were $R = 0.046$ and $Rw = 0.035$ while its (R,R)-enantiomorph refined to $R = 0.049$ and $Rw = 0.039$ [9].

RESULTS AND DISCUSSION

Syntheses and structures

The yellow-green title complexes α-Mo_2Cl_4[(R,R)-Me-DuPHOS]$_2$, **1**, and α-Mo_2Cl_4[(S,S)-Me-DuPHOS]$_2$, **2**, were prepared by reactions of $(NH_4)_5Mo_2Cl_9$ with (R,R)-Me-DuPHOS and (S,S)-Me-DuPHOS, respectively in methanol. Crystals suitable for X-ray diffraction measurement were obtained by hexane-induced crystallization from a dichloromethane solution. The crystal of **1** conforms to the space group $P2_1$ with two molecules in the unit cell. Figure 3 shows the ORTEP diagram for **1**. It is seen from Fig. 1 that each molybdenum atom is coordinated with two chlorine atoms and two phosphorus atoms. The two phosphine ligands are chelated to the Mo centers to form five-membered rings. The achiral phosphorus atom of the free phosphine ligands become chiral upon coordination to the molybdenum atoms. The 1,2-phenylene unit remains essentially planar upon coordination of the phospholane moieties. However, in contrast to the slight (5.95) dihedral twist out of the P—Rh—P plane in the complex [(COD)Rh((S,S)-Me-DuPHOS)]SbF_6 [9], a large (average 25.8) dihedral twist out of the P—Mo—P plane is observed for **1**. The Mo—Mo bond distance of 2.147(1) Å for **1** is similar to those observed in α-Mo_2Cl_4(dppe)$_2$ (2.140(2) Å) [10], *anti*-α-Mo_2Cl_4(dpdt)$_2$ (2.147(1) Å) [11], and *anti*-α-Mo_2Cl_4(dpdbp)$_2$ (2.149(1) Å) [12]. Table 3 lists the important bond distances and angles for some structurally characterized quadruply-bonded complexes with chelating disphosphine ligands. It is noted that the average Mo—P bond distance is shorter for complex **1**, which indicate that Duphos ligands chelate the molybdenum atoms better than the other disphosphine ligands which possess two aryl substituents on phosphorus atoms. Complex **1** is the first structurally characterized compound of the type $Mo_2X_4(PP)_2$ in which the P in the free ligand is a cyclophosphine.

Figure 4 shows a view of the inner part of **1** looking down the Mo—Mo bond. It is seen that the twist includes the low Cl(1)—Mo(1)—Mo(2)—P(3) and P(1)—Mo(1)—Mo(2)—Cl(3), 3.3 and 5.6 , respectively, in counterclockwise direction and the high Cl(2)—Mo(1)—Mo(2)—P(2) and P(2)—Mo(1)—Mo(2)—Cl(4), 17.7 and 12.0 , respectively, in clockwise direction. The average value (χav) is taken as $\chi_{av} = 1/4(\chi_1 + \chi_2 + \chi_3 + \chi_4)$, where χ_1–χ_4 are the four smallest angles looking down the Mo—Mo bond, and is found to be 5.2 in the clockwise direction.

Absorption spectra

The absorption spectra (Fig. 5) are typical for compounds with a Mo—Mo quadruple bond. The lowest energy bands at 690 nm in THF solvent (675 nm in CH_2Cl_2) can be assigned to $\delta_{xy} \rightarrow \delta^*_{xy}$ transitions. The second lowest energy bands appear at 503 nm and can most probably be assigned to the forbidden transition $\delta_{xy} \rightarrow \delta_{x^2-y^2}$. The absorption energy of the lowest energy band is similar to those of the structurally characterized chelating complexes, i.e., 677 nm for α-Mo_2Cl_4(dppe)$_2$ [10], 675 nm for *anti*-α-Mo_2Cl_4(dpdt)$_2$ [11], and 669 nm for *anti*-α-Mo_2Cl_4(dpdbp)$_2$ [12].

CD spectrum

Figure 6 shows the CD spectra for **1** and **2** in THF solvent. It is seen that the phases of the CD bands

under the $\delta_{xy} \rightarrow \delta^*_{xy}$ transition (695 nm) and $\delta_{xy} \rightarrow \delta_{x^2-y^2}$ transition (520 nm) of one complex are opposite to each other. It is also clearly seen that there is a mirror-image relationship between the spectra of the enantiomeric molecules **1** and **2**. This is expected since the ligands of the enantiomeric pair have opposite conformational preference that they produce isomers with opposite chiralities.

The previous discussion about the relationship between the absolute chirality of a twisted $Mo_2L_nL'_{8-n}$ molecule and the sign of the CD band for the $\delta_{xy} \rightarrow \delta^*_{xy}$ transitions can be summarized in a sector diagram as shown in Fig. 2. The CD sign rule predicts that the sign of the CD band under the $\delta_{xy} \rightarrow \delta^*_{xy}$ transitions of the conformer with $0 < \theta < 45°$ are opposite to those with $45 < \theta < 90°$ and the signs of the $\delta_{xy} \rightarrow \delta^*_{xy}$ transitions are opposite to those of $\delta_{xy} \rightarrow \delta_{x^2-y^2}$ transitions. According to the CD sign rule, complex **1** should show a positive sign for the $\delta_{xy} \rightarrow \delta^*_{xy}$ transitions. However, both the solution sample

prepared by dissolving the powders of complex **1** or **2** in THF solvents and the solid sample obtained by mulling powders as KBr disks displayed negative CD signs for the $\delta_{xy} \rightarrow \delta^*_{xy}$ transition, as shown in Fig. 6 for the solution spectra. It is noted that the average twist angle of about 5.2° in the clockwise direction is derived by taking the average of the four smallest angles looking down the Mo—Mo bond. Among the four angles there are two in the clockwise direction and the other two in the counterclockwise direction, which were observed in the crystal. Since the α-form complexes have no ligand constraints that limit the rotation of the Mo—Mo metal bond as β-form complexes, it is possible that the configuration and magnitude of the average twist angles in solution and in solid are not the same as that obtained in the crystal. The CD spectra of the crystals were not measured since a large amount of crystal was not available. It is safe to say that the twist angles of complexes **1** and **2** are still small (less than about 5°) in the solution. This can be verified by the fact that the g values ($g = 2R/D$ or $\Delta\varepsilon/\varepsilon$), which can be related to the twist angle by the equation $g = g_{max} \tan 2\theta$ [3], for the corresponding $\delta_{xy} \rightarrow \delta^*_{xy}$ transitions are about 2.4×10^{-4} and 9.2×10^{-4} for **1** and **2**, respectively in THF solvent. These are the smallest g values measured for quadruply-bonded complexes in the solution state. For example the g value for the complex [4] Mo_2Cl_4[(S,S)-dppb]$_2$ which has a twist angle of 22° is 5.8×10^{-3}. It is also noted that the g values for $\delta_{xy} \rightarrow \delta_{x^2-y^2}$ transition (4.9×10^{-3} and 9.1×10^{-3} for complexes **1** and **2**, respectively) are approximately an order of magnitude larger than those for the corresponding $\delta_{xy} \rightarrow \delta^*_{xy}$ transitions. The chelated complexes α-Mo_2Cl_4(S-chairphos)$_2$ and α-Mo_2Cl_4(R-dppp)$_2$ were reported to show no measurable CD spectra under either the $\delta_{xy} \rightarrow \delta^*_{xy}$ or $\delta_{xy} \rightarrow \delta_{x^2-y^2}$ transitions [3].

(Received 27 March 1996; accepted 5 June 1996)

Abstract—Reaction of μ-$S_2Fe_2(CO)_6$ with Mo≡Mo triply bonded dimers $[\eta^5\text{-}RC_5H_4(CO)_2Mo]_2$ in CH_2Cl_2 at room temperature gave clusters $[(\eta^5\text{-}RC_5H_4)_2(\mu_3\text{-}CO)_2Mo_2Fe_2(\mu_3\text{-}S)_2(CO)_6]$ (**1a**, R = MeCO; **1b**, R = MeO_2C; **1c**, R = EtO_2C), whereas μ-$S_2Fe_2(CO)_6$ reacted with W≡W triply bonded dimers $[\eta^5\text{-}RC_5H_4(CO)_2W]_2$ to afford the clusters $[(\eta^5\text{-}RC_5H_4)_2(\mu_3\text{-}CO)_2W_2Fe_2(\mu_3\text{-}S)_2(CO)_6]$ (**2a**, R = MeO_2C; **2b**, R = EtO_2C) and $[[\eta^5\text{-}RC_5H_4(CO)_2]_2W_2Fe(\mu_3\text{-}S)(CO)_3]$ (**3a**, R = MeO_2C; **3b**, R = EtO_2C). While clusters **1a–1c** could also be produced by reaction of μ-$S_2Fe_2(CO)_6$ with Mo—Mo singly bonded dimers $[\eta^5\text{-}RC_5H_4(CO)_3Mo]_2$ in refluxing toluene, the reaction with W—W singly bonded dimers $[\eta^5\text{-}RC_5H_4(CO)_3W]_2$ failed to give the corresponding dimers **2a–2b** and **3a–3b**. In addition, cluster **1a** reacted with $NaBH_4$ in MeOH at room temperature to give the bis-hydroxyl derivative $[[\eta^5\text{-}MeCH(OH)C_5H_4]_2(\mu_3\text{-}CO)_2Mo_2Fe_2(\mu_3\text{-}S)_2(CO)_6]$ (**4**), whereas it afforded mono- and bis-hydrazone derivatives $[(\eta^5\text{-}MeCOC_5H_4)\ [\eta^5\text{-}2,4\text{-}(NO_2)_2C_6H_3NHNC(Me)C_5H_4](\mu_3\text{-}CO)_2Mo_2Fe_2(\mu_3\text{-}S)_2(CO)_6]$ (**5**) and $[[\eta^5\text{-}2,4\text{-}(NO_2)_2C_6H_3NHNC(Me)C_5H_4]_2(\mu_3\text{-}CO)_2Mo_2Fe_2(\mu_3\text{-}S)_2(CO)_6]$ (**6**) when reacted with 2,4-dinitrophenylhydrazine in EtOH at room temperature. All the new clusters were characterized by elemental analysis and spectroscopic methods, as well as for **1b** by X-ray diffraction techniques. Copyright © 1996 Elsevier Science Ltd

Keywords: group 6 metal–metal bonds; μ-$S_2Fe_2(CO)_6$; reactions; Fe/S/Mo (W) clusters; crystal structure.

In recent years there has been growing interest in group 6 metal/iron/sulfur clusters. This is most likely due to (i) the fact that some important biological systems contain such cluster cores, e.g. a Mo/Fe/S core in nitrogenase [1]; (ii) the potential applications of these clusters in hetero- and homogenous catalytic processes [2] and (iii) the novelty and diversity of the structures generated by means of various coordination modes of the sulfur atoms in the clusters [3]. So far, it has been reported that reactions of μ-$S_2Fe_2(CO)_6$ with group 6 metal–metal triply bonded dimers $[\eta^5\text{-}RC_5H_4(CO)_2M]_2$ (M = Mo, W; R = H, Me, M = Mo, R = MeO_2C) give a series of M/Fe/S cluster complexes [4–8], among which the clusters containing electron-withdrawing substituents on the cyclopentadienyl ring are little known. In order to prepare such interesting clusters, we carried out the reaction of μ-$S_2Fe_2(CO)_6$ with triply bonded dimers $[\eta^5\text{-}RC_5H_4(CO)_2M]_2$ or with singly bonded dimers $[\eta^5\text{-}RC_5H_4(CO)_3M]_2$ (M = Mo, W; R = electron-withdrawing functionality) and transformation reactions of functional substituents on cyclopentadienyl rings of some products. A preliminary account of the synthesis and structure of **1b** has been given [8]. Herein we further describe the detailed reaction procedures, the proper-

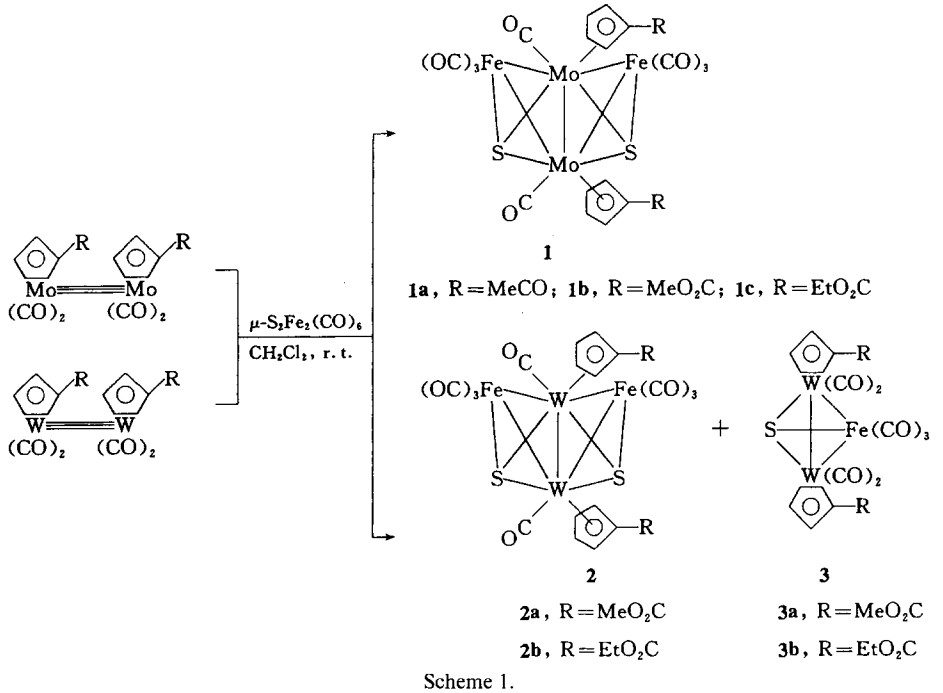
ties and structural characterization of all the M/Fe/S clusters **1a–c, 2a–b** and **3a–b** obtained through this study.

RESULTS AND DISCUSSION

Synthesis and characterization of **1a–c, 2a–b** *and* **3a–b**



An equimolar amount of $[\eta^5\text{-}RC_5H_4(CO)_2Mo]_2$ reacted with $\mu\text{-}S_2Fe_2(CO)_6$ in CH_2Cl_2 at room temperature to give $Mo_2Fe_2S_2$ clusters $[(\eta_5\text{-}RC_5H_4)_2(\mu_3\text{-}CO)_2Mo_2Fe_2(\mu_3\text{-}S)_2(CO)_6]$ (**1a–c**), while the reaction of $[\eta^5\text{-}RC_5H_4(CO)_2W]_2$ gave $W_2Fe_2S_2$ clusters $[(\eta^5\text{-}RC_5H_4)_2(\mu_3\text{-}CO)_2W_2Fe_2(\mu_3\text{-}S)_2(CO)_6]$ (**2a–b**) and W_2Fe clusters $[[\eta^5\text{-}RC_5H_4(CO)_2]_2W_2Fe(\mu_3\text{-}S)(CO)_3]$ (**3a–b**) (Scheme 1).

Among these cluster compounds while **3a** was previously reported [9], **1a–c, 2a–b** and **3b** are new. Their formulation has been characterized by elemental analysis (for **2a** the satisfactory C/H analysis could not be obtained but FD mass spectroscopy gave its parent ion peak at *m/z* 1014) and by spectroscopic methods. Their IR spectra displayed three kinds of carbonyl absorption bands, one $\nu_{(CO)}$ band in the range of 1680–1721 cm^{-1} attributed to the carbonyls of the organic substituents, another $\nu_{(CO)}$ band between 1803–1844 cm^{-1} due to the semibridging carbonyls bonded to Mo or W atoms, and the third $\nu_{(CO)}$ consisting of three to four absorption bands in the range of 1893–2057 cm^{-1} attributed to the terminal carbonyls attached to iron atoms. The ^1H NMR spectra of **1a–c** and **2b** showed two apparent triplets at δ 5.07–6.16 ppm, while that of **2a** exhibited two broad singlets centered at δ 5.50 and δ 5.80 ppm. The downfield triplet or singlet was assigned to H^2 and H^5 close to the substituent of cyclopentadienyl ring and the upfield one to H^3 and H^4 remote from the substituent, since the substituents in cyclopentadienyl rings are electron-withdrawing [10]. Similar to **3a** [9], the four protons H^2—H^5 of **3b** showed two broad singlets upfield attributed to H^3 and H^4, and one multiplet downfield to H^2 and H^5.

As we know, the triply bonded dimers $[\eta^5\text{-}RC_5H_4(CO)_3M]_2$(M = Mo, W) were prepared by thermolysis of the corresponding singly bonded dimers $[\eta^5\text{-}RC_5H_4(CO)_3M]_2$. In order to make the synthetic procedures for those M/Fe/S clusters more convenient, we carried out the reactions of $\mu\text{-}S_2Fe_2(CO)_6$with the singly bonded dimers directly. As a result, the reaction of Mo—Mo singly bonded dimers $[\eta^5\text{-}RC_5H_4(CO)_3Mo]_2$ (R = MeCO, MeO_2C, EtO_2C) with $\mu\text{-}S_2Fe_2(CO)_6$ in toluene at reflux produced **1a–c** in 18%, 11% and 6% yield, respectively, whereas that of W—W singly bonded dimers $[\eta^5\text{-}RC_5H_4(CO)_3W]_2$ (R = MeO_2C, EtO_2C) did not give any isolable corresponding W/Fe/S cluster complexes.

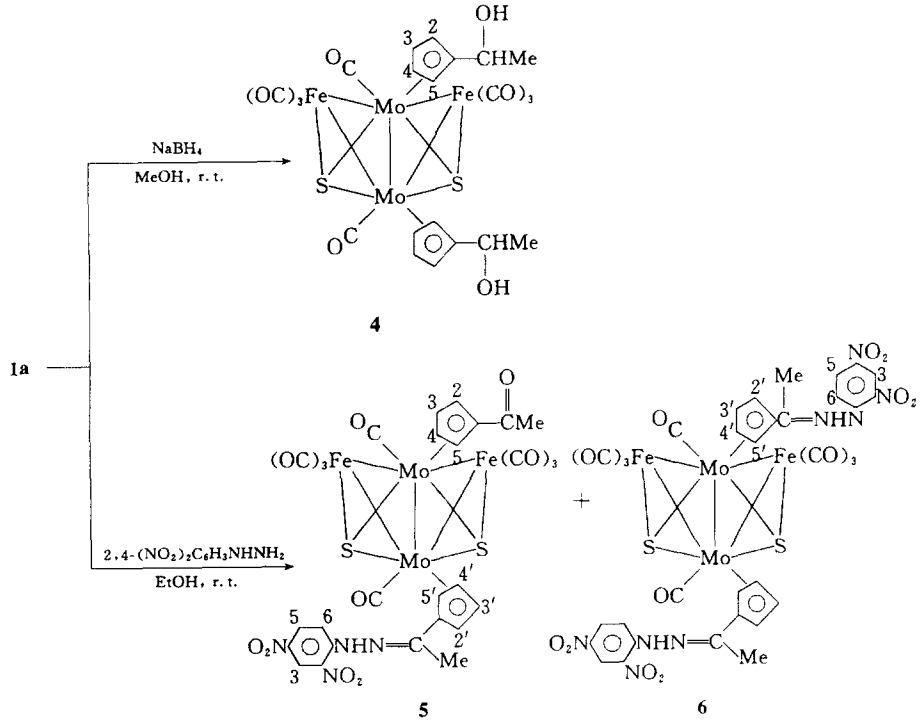
Synthesis and characterization of **4–6**

On the basis of synthesis of the above functionally substituted cyclopentadienyl compounds, an effort has been made to prepare their derivatives through transformation reactions of their functional substituents on cyclopentadienyl rings. It was found that **1a** reacted with $NaBH_4$ in MeOH at room temperature for 3 h to afford the hydroxyl derivative $[\eta^5$-

Scheme 1.

$MeCH(OH)C_5H_4]_2(\mu_3\text{-}CO)_2Mo_2Fe_2(\mu_3\text{-}S)_2(CO)_6$ (**4**) in 78% yield, whereas its reaction with 2,4-dinitro phenylhydrazine at room temperature gave rise to corresponding mono- and bis-hydrazone derivatives $[(\eta^5\text{-}MeCOC_5H_4)$ $[\eta^5\text{-}2,4\text{-}(NO_2)_2C_6H_3NHNC(Me)C_5H_4](\mu_3\text{-}CO)_2Mo_2Fe_2(\mu_3\text{-}S)_2(CO)_6]$ (**5**) and $[[\eta^5\text{-}2,4\text{-}(NO_2)_2C_6H_3NHNC(Me)C_5H_4]_2(\mu_3\text{-}CO)_2Mo_2Fe_2(\mu_3\text{-}S)_2(CO)_6]$ (**6**), as shown in Scheme 2.

Derivatives **4**–**6** are deep brown colored, air-stable solids. The combustion analyses for **4**–**6** coincide with their compositions. The IR spectrum of **4** exhibited a broad $\nu_{(OH)}$ band centred at 3400 cm^{-1}, a bridging $\nu_{(CO)}$ at 1803 cm^{-1} and four terminal $\nu_{(CO)}$ bands in the range of 1950–2041 cm^{-1}. The IR spectrum of **5** showed a $\nu_{(CO)}$ band of acyl group at 1671 cm^{-1}, a $\nu_{(C=N)}$ band at 1614 cm^{-1}, a bridging $\nu_{(CO)}$ band at 1794 cm^{-1} and five terminal $\nu_{(CO)}$ bands at 1816–2057 cm^{-1}, whereas that of **6** displayed a $\nu_{(C=N)}$ band at 1614 cm^{-1}, a bridging $\nu_{(CO)}$ band at 1844 cm^{-1} and three terminal $\nu_{(CO)}$ bands at 1893–2041 cm^{-1}. The ^1H NMR spectrum of **4** indicated the presence of the functionally substituted cyclopentadienyl ligand η^5-$MeCH(OH)C_5H_4$. However, the ^1H NMR pattern of H^2—H^5 of the cyclopentadienyl rings is quite complicated and overlaps with the α-protons of the functional substituents. This might be attributed to the influences of the chiral substituent CH(OH)Me generated through reduction of the acyl group. In the ^1H NMR spectrum of **5** there was a multiplet at δ 1.96–2.36 ppm attributed to methyl groups attached to C=O and C=N double bonds, whereas in that of **6** there was one singlet at δ 2.16 ppm assigned to the methyl group on the C=N double bond. For the ^1H NMR spectrum of the substituted cyclopentadienyls **5** showed one singlet downfield assigned to the protons close to two different substituents and one doublet upfield to those remote from two different substituents, whereas **6** exhibited two multiplets attributed to the protons close to and remote from two same substituents respectively. In addition, the ^1H NMR spectra of **5** and **6** all indicated the presence of other hydrogen atoms in the functionally substituted cyclopentadienyl ligand η^5-$2,4\text{-}(NO_2)_2C_6H_3NHNC(Me)C_5H_4$.



X-ray diffraction analysis for **1b**

Dark-brown crystals of **1b** were grown by slow evaporation of its THF solution at room temperature, and an X-ray diffraction analysis was undertaken. Selected bond distances and angles are listed in Tables 1 and 2, respectively. The molecular structure is shown

Table 1. Selected bond distances (Å)[a]

in Fig. 1. The molecule consists of a butterfly metal cluster core Mo_2Fe_2 with molybdenum atoms in the hinge positions. Each wing face Mo_2Fe is capped by a μ_3-S atom *trans* to two iron atoms with respect to the Mo—Mo bond. Each molybdenum atom is coordinated by a η^5-$MeO_2CC_5H_4$ ligand and a semibridging carbonyl ligand, whereas each iron atom is bonded to three terminal carbonyls. Overall, the structure is very similar to that of its parent cluster [(η^5-$C_5H_5)_2(\mu_3$-$CO)_2Mo_2Fe_2(\mu_3$-$S)_2(CO)_6$] [6]. The butterfly angle and the Fe(2)—Fe(2a) non-bonding distance in **1b** are 108.57° and 3.930 Å, respectively. These values are slightly larger than those of its parent cluster (104.1° and 3.833(5) Å, respectively) [6]. Thus the two Mo_2Fe wings of **1b** are more open. Since the distances of C(4)—Fe(2), C(4)—Fe(2a) and C(4)—Mo(1) are 2.637, 2.683 and 1.992(25) Å, respectively, the asymmetric parameters [11] of the semibridging carbonyl C(4)O(4) are 0.32 and 0.35. These parameters are smaller than those of its parent cluster [6]. Based on the symmetry, the other carbonyl C(4a)O(4a) is also semibridging and μ_3-coordinated to one Mo atom and two Fe atoms. The X-ray diffraction analysis confirmed both semibridging carbonyls

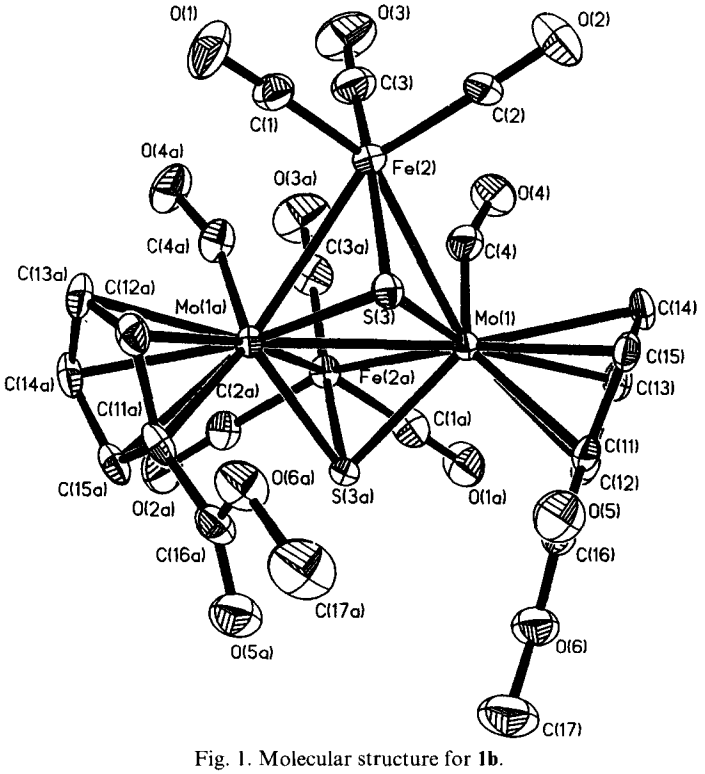

Fig. 1. Molecular structure for **1b**.

and terminal carbonyls present in the molecule of **1b**, which is in good agreement with its IR data as discussed above.

EXPERIMENTAL

All reactions were performed under purified tank nitrogen using vacuum line techniques. Toluene was distilled from Na/benzophenone ketyl under nitrogen. Dichloromethane, methanol and ethanol were deoxygenated by bubbling N_2 for about 15 min prior to use. $NaBH_4$ and 2,4-dinitrophenylhydrazine were used as purchased from commercial origin. μ-$S_2Fe_2(CO)_6$ [12], $[\eta^5$-$RC_5H_4(CO)_3M]_2$ (R = MeCO, MeO_2C, EtO_2C; M = Mo, W) [13] and $[\eta^5$-$RC_5H_4(CO)_2M]_2$ (R = MeCO, MeO_2C, EtO_2C; M = Mo, W) [14–15] were prepared according to literature methods. Preparative TLC was carried out on glass plates (26 × 19 cm) coated with silica gel G (10–40 μm). IR spectra were recorded on Nicolet FT-5DX and Nicolet Magna FT-750 infrared spectrophotometer. ^{1}H NMR spectra were recorded on Joel FX 90Q and Bruker AC-P200 spectrometers. C/H analyses and MS determinations were performed by a Perkin-Elmer 240C analyzer, and an HP 5988A and M-80 LC/MS spectrometers, respectively. Melting points were determined on a Yanaco MP-500 apparatus.

Preparation of **1a**

A two-necked flask (100 cm^3) fitted with a magnetic stir-bar, a rubber septum, and a nitrogen inlet tube was charged with 0.500 g (0.965 mmol) of $[\eta^5$-$MeCOC_5H_4(CO)_2Mo]_2$, 0.324 g (0.965 mmol) of μ-$S_2Fe_2(CO)_6$ and 40 cm^3 of CH_2Cl_2. The mixture was stirred at room temperature for 10 h. Solvent was removed under reduced pressure and the residue was dissolved in 5 cm^3 of acetone. The solution was subjected to TLC separation using 6 : 1 benzene : ether as eluent to give three bands. The upper two purple and red bands were known compounds $S_2Fe_3(CO)_9$ and $[\eta^5$-$MeCOC_5H_4(CO)_3Mo]_2$ [13]. The third dark-brown band was **1a** (0.179 g, 23%), m.p. 300°C(dec.). Found: C, 32.9; H, 1.7. Calc. for $C_{22}H_{14}Fe_2Mo_2O_{10}S_2$: C, 32.8; H, 1.7%. IR(KBr, disk): $\nu_{C\equiv O}$, 1803 s, 1967 vs, 2008 s, 2032 vs, 2057 vs; $\nu_{C=O}$, 1680 s cm^{-1}. ^{1}H NMR ($CDCl_3$, δ, ppm): 2.44(s, 6H, $2CH_3$), 5.07[t, 4H, 2(H^3, H^4)], 6.16[t, 4H, 2(H^2, H^5)]. Preparation of **1c**

The 100 cm^3 flask was charged with 0.500 g (0.865 mmol) of $[\eta^5$-$EtO_2CC_5H_4(CO)_2Mo]_2$, 0.300 g (0.872 mmol) of μ-$S_2Fe_2(CO)_6$ and 40 cm^3 of CH_2Cl_2. Similar work-up as above was followed using CH_2Cl_2 as eluent to give three bands. The upper two were known compounds $S_2Fe_3(CO)_9$ and $[\eta^5$-$EtO_2CC_5H_4(CO)_3Mo]_2$ [13]. The third dark-brown band was **1c** (0.157 g, 21%), m.p. 203°C(dec.). Found: C, 33.1; H, 1.9. Calc. for $C_{24}H_{18}Fe_2Mo_2O_{12}S_2$: C, 33.3; H, 2.1%. IR(KBr, disk): $\nu_{C\equiv O}$, 1827 s, 1959 s, 1983 s, 2024 vs, 2049 s; $\nu_{C=O}$, 1712 s cm^{-1}. ^{1}H NMR ($CDCl_3$, δ, ppm): 1.42(t, 6H, $2CH_3$, J = 7.2 Hz), 4.38(q, 4H, $2CH_2$, J = 7.2 Hz), 5.16[t, 4H, 2(H^3, H^4)], 6.00[t, 4H, 2(H^2, H^5)].

Preparation of **2a** *and* **3a**

The 100 cm^3 flask was charged with 0.500 g (0.689 mmol) of $[\eta^5$-$MeO_2CC_5H_4(CO)_2W]_2$, 0.237 g (0.689 mmol) of μ-$S_2Fe_2(CO)_6$ and 30 cm^3 of CH_2Cl_2. Similar work-up as above was followed using 4 : 1 CH_2Cl_2 : petroleum ether as eluent to give four bands. The upper three were $S_2Fe_3(CO)_9$, $[\eta^5$-$MeO_2CC_5H_4(CO)_3W]_2$ [13] and **3a** [9] (0.036 g, 6%). The fourth dark-brown band was **2a** (0.017 g, 2%), m.p. 76–77°C. IR(KBr, disk): $\nu_{C\equiv O}$, 1844 m, 1893 s, 1950 vs, 1983 vs, 2049 vs; $\nu_{C=O}$, 1721 s cm^{-1}. ^{1}H NMR ($CDCl_3$, δ, ppm): 3.92(s, 6H, $2CH_3$), 5.50[br. s, 4H, 2(H^3, H^4)], 5.80[br. s. 4H, 2(H^2, H^5)]. MS(FD), *m/z*(^{56}Fe, ^{184}W, rel. int.): 1014(M^+, 4.9%).

Preparation of **2b** *and* **3b**

The 100 cm^3 flask was charged with 0.500 g (0.675 mmol) of $[\eta^5$-$EtO_2CC_5H_4(CO)_2W]_2$, 0.238 g (0.692 mmol) of μ-$S_2Fe_2(CO)_6$ and 30 cm^3 of CH_2Cl_2. Similar work-up was followed using 3 : 1 CH_2Cl_2 : petroleum ether as eluent to give four bands. The upper two were

$S_2Fe_3(CO)_9$ and $[\eta^5\text{-}EtO_2CC_5H_4(CO)_3W]_2$ [13]. The third brown band was **3b** (0.078 g, 12%) and the fourth dark-brown band was **2b** (0.050 g, 7%). **3b**: m.p. 98–99°C. Found: C, 29.9; H, 2.1. Calc. for $C_{23}H_{18}FeO_{11}SW_2$: C, 29.8; H, 2.0%. Reaction of $[\eta^5\text{-}MeCOC_5H_4(CO)_3Mo]_2$ *with* $\mu\text{-}S_2Fe_2(CO)_6$

A two-necked flask (100 cm^3) fitted with a magnetic stir-bar, a rubber septum, and a reflux condenser topped with a nitrogen inlet tube was charged with 0.582 g (1.014 mmol) of $[\eta^5\text{-}MeCOC_5H_4(CO)_3Mo]_2$, 0.352 g (1.023 mmol) of $\mu\text{-}S_2Fe_2(CO)_6$ and 25 cm^3 of toluene. The mixture was refluxed for 5 h. Solvent was removed under reduced pressure and the residue was subjected to column chromatography using 1 : 5 ether : CH_2Cl_2 as eluent to give dark-brown solid **1a** (0.150 g, 18%).

Reaction of $[\eta^5\text{-}MeO_2CC_5H_4(CO)_3Mo]_2$ *with* $\mu\text{-}S_2Fe_2(CO)_6$

The 100 cm^3 flask was charged with 0.600 g (0.990 mmol) of $[\eta^5\text{-}MeO_2CC_5H_4(CO)_3Mo]_2$, 0.570 g (1.657 mmol) of $\mu\text{-}S_2Fe_2(CO)_6$ and 30 cm^3 of toluene. Similar work-up was followed to give dark-brown solid **1b** (0.072 g, 11%).

Reaction of $[\eta^5\text{-}EtO_2CC_5H_4(CO)_3Mo]_2$ *with* $\mu\text{-}S_2Fe_2(CO)_6$

The 100 cm^3 flask was charged with 0.600 g (0.946 mmol) of $[\eta^5\text{-}EtO_2CC_5H_4(CO)_3Mo]_2$, 0.488 g (1.419 mmol) of $\mu\text{-}S_2Fe_2(CO)_6$ and 30 cm^3 of toluene. Similar work-up was followed to give dark-brown solid **1c** (0.050 g, 6%).

Reaction of $[\eta^5\text{-}MeO_2CC_5H_4(CO)_3W]_2$ *with* $\mu\text{-}S_2Fe_2(CO)_6$

The 100 cm^3 flask was charged with 0.600 g (0.767 mmol) of $[\eta^5\text{-}MeO_2CC_5H_4(CO)_3W]_2$, 0.396 g (1.153 mmol) of $\mu\text{-}S_2Fe_2(CO)_6$ and 30 cm^3 of toluene. Similar work-up was followed. Apart from $S_2Fe_3(CO)_9$ and unreacted $[\eta^5\text{-}MeO_2CC_5H_4(CO)_3W]_2$, no other compounds were isolated.

Reaction of $[\eta^5\text{-}EtO_2CC_5H_4(CO)_3W]_2$ *with* $\mu\text{-}S_2Fe_2(CO)_6$

The 100 cm^3 flask was charged with 0.282 g (0.231 mmol) of $[\eta^5\text{-}EtO_2CC_5H_4(CO)_3W]_2$, 0.174 g (0.507 mmol) of $\mu\text{-}S_2Fe_2(CO)_6$ and 390 cm^3 of toluene. Similar work-up was followed. Apart from $S_2Fe_3(CO)_9$ and unreacted $[\eta^5\text{-}EtO_2CC_5H_4(CO)_3W]_2$, no other compounds were isolated.

Preparation of **4**

The 100 cm^3 was charged with 0.100 g (0.124 mmol) of **1a** and 10 cm^3 of methanol. During stirring 0.044 g (1.16 mmol) of $NaBH_4$ was added. The mixture was stirred at room temperature for 3 h. Solvent was removed under reduced pressure and the residue was dissolved in 5 cm^3 of acetone. The solution was subjected to TLC separation using 1 : 2 acetone : petroleum ether as eluent to give dark-brown solid **4** (0.078 g, 78%), m.p. 223°C(dec.). Found: C, 32.8; H, 2.2. Calc. for $C_{22}H_{18}Fe_2Mo_2O_{10}S_2$: C, 32.6; H, 2.2%. IR(KBr, disk): $\nu_{C\equiv O}$, 1803 s, 1950 vs, 1983 s, 2016 vs, 2041 s; ν_{O-H}, 3400 cm^{-1}. ^1H NMR ($CDCl_3$, δ, ppm); 1.52(d, 6H, $2CH_3$), 2.64(br. s, 2H, 2OH), 4.72–5.92[m, 10H, 2CH, 2(H^2—H^5)].

Preparation of **5** and **6**

The 100 cm^3 flask was charged with a solution of 0.065 g (0.081 mmol) of **1a** in 5 cm^3 of THF and 10 cm^3 of absolute ethanol. To this solution was added 2 cm^3 of 2,4-dinitrophenylhydrazine solution which was prepared by dissolving 1.0 g of 2,4-dinitrophenylhydrazine in 5 cm^3 of 98% concentrated sulfuric acid, 10 cm^3 of water and 35 cm^3 of 95% ethanol. The mixture was stirred at room temperature for 30 min to give a precipitate. The precipitate was filtered out, washed successively with water, ethanol and petroleum ether and subjected to TLC separation using CH_2Cl_2 as eluent to give brown solid **6** (0.011 g, 12%) and dark-brown solid **5** (0.035 g, 44%). **5**: m.p. 300°C(dec.). Crystal structure determination of **1b**

Suitable crystals of **1b** for X-ray diffraction study were obtained by slow evaporation of its THF solution at room temperature. Details of crystal parameters, data collections and structure refinements are given in Table 3. A brown crystal measuring $0.2\times0.3\times0.2$ mm was mounted on a glass fibre and placed on an Enraf-Nonius CAD4 diffractometer equipped with a graphite monochromator. A total of 1657 independent reflections was collected at room temperature, with Mo-K_α radiation ($\lambda = 0.71073$ Å) by the ω-2θ scan mode. Of the total reflections, 1565 reflections were considered to be observed with $I \geqslant 3\sigma(I)$ and used in structure solution and refinement. Data were corrected by Lorentz and polarization effects and empirical absorption. The structure was solved by the direct method. Mo, Fe and most of other non-hydrogen atoms were located by the E-map. Remaining non-hydrogen atoms were found in succeeding difference Fourier syntheses. The final refinement by full matrix least-squares method with anisotropic thermal parameters for non-hydrogen atoms converged to unweighted and weighted agreement factors of 0.029 and 0.038. The highest peak on the final difference Fourier map had a height of 0.56 e/Å^3. All calculations were performed on a PDP 11/44 and an IBM 486 computer using the SDP-PLUS and SHELXS program packages.

Study of Cu^{II} binuclear complexes of binucleating hexadentate ligands

C. A. Sureshan and P. K. Bhattacharya*

Department of Chemistry, Faculty of Science, M.S. University of Baroda, Baroda 390 002, India

(Received 8 December 1995; accepted 3 June 1996)

Abstract—Three types of tridentate binucleating Schiff base ligands have been synthesised by condensation of 5,5′-methylenebis-salicylaldehyde with aminoalcohols, aminoacids or aminoethylpyridine. These ligands have two sets of tridentate phenolate O^-, azomethine N and O^-, COO^- or pyridyl nitrogen coordination sites. The binuclear Cu^{II} complexes of these ligands have been prepared and their spectral, magnetic and electrochemical properties have been studied. On the basis of these experimental results long range spin exchange interaction between two copper centres has been indicated. Copyright © 1996 Elsevier Science Ltd

Keywords: copper(II) complexes; binuclear complexes; hexadentate ligands; Schiff base; binucleating ligands; magnetic interactions.

In recent years the study of binuclear copper(II) complexes has been a subject of considerable interest because of their structural, magnetic, ESR and electrochemical properties.

In our laboratory Cu^{II} complexes of binucleating ligands with two bidentate sites separated by aromatic rings have been studied earlier [1–3]. In such complexes with π delocalised bridges, the spin exchange has been suggested to be through σ bonds [4,5]. Spin exchange interaction between Cu^{II} centres separated by σ bonding aliphatic chain has also been studied [6–9]. In the present study, binucleating ligands with two tridentate coordination sites have been synthesised. They are of three types. The first type of ligand was obtained by the condensation of 5,5′-methylenebis-salicylaldehyde (MBS) and aminoalcohols. These ligands have phenolate O^-, azomethine N and alkoxide O^- coordination sites. The second type of ligands was prepared by the condensation of above mentioned dialdehyde (MBS) and aminoacids and have phenolate O^-, azomethine N and carboxylate COO^- coordination sites. The third type of ligands was prepared by the condensation of MBS with aminoethylpyridine and have phenolate O^-, azomethine N and pyridyl N coordination sites. Binuclear complexes of these ligands with Cu^{2+} ions have been prepared and characterized by spectral, magnetic and electrochemical studies.

EXPERIMENTAL

Chemicals

5′5-Methylenebis-salicylaldehyde (MBS) was prepared by the method reported earlier [10]. Glycine (gly), α-alanine (α ala), phenylalanine (pha), valine (val), ethanolamine (ea), propanolamine (pa), 2-aminobutanol (L_2ab), aminoethylpyridine, methanol, dimethylformamide, tetrabutylammonium tetrafluoroborate and $CuCl_2 \cdot 2H_2O$ used were of A.R. grade.

Preparation of binucleating ligands using MBS and aminoalcohols (I)

5′5-Methylenebis-salicylaldehyde (5 mmol) was dissolved in 50 cm^3 of benzene and to this 10 mmoles of aminoalcohol (ea, pa, L_2ab) solution in 20 cm^3 of benzene was added dropwise. The solution was refluxed for 3 h and the azeotrope was separated. Excess benzene was distilled out and the solid obtained was washed thoroughly with benzene and recrystallized from benzene. Yield: compound I_A 1.1 gm (62%); compound I_B 1.2 gm (65%); compound I_C 1.2 gm (63%).

Preparation of binucleating ligand using MBS and aminoacids (II) *or aminoethylpyridine* (III)

MBS (5 mmol) was suspended in 150 cm^3 of methanol. To this 10 mmoles of aminoacid (gly, ala, val or

pha) or aminoethylpyridine were added. The solutions were stirred for about five hours. The volumes of methanol were reduced to ~20 cm^3. The yellow crystalline products separated were washed with benzene and recrystallized from methanol. Yield: compound II_A 1.1 gm (62%); compound II_B 1.2 gm (60%); compound II_C 1.5 gm (66%); compound II_D 1.9 gm (70%); compound III_A 1.2 gm (53%).

Method I

Synthesis of binuclear complexes of ligand I *and* II

(a) To 2 mmol of binucleating ligand I or II in 50 cm^3 methanol, were added 8 mmoles of lithium methoxide, to raise the pH. This solution was added to 4 mmoles of $CuCl_2 \cdot 2H_2O$ in 10 cm^3 methanol. The resulting product was stirred for 1 h, filtered, washed thoroughly with methanol and dried *in vacuo*.

(b) To 2 mmol of MBS and 4 mmol of aminoalcohol (ea, pa, L_2ab) or aminoacid (gly, ala, pha, val) in 50 cm^3 of methanol, 8 mmol of lithium methoxide were added to raise the pH. The solutions were stirred for 2 h, 4 mmol of $CuCl_2 \cdot 2H_2O$ in 20 cm^3 of methanol were added. The reaction mixture was further stirred for one hour, the complex formed was filtered, washed with methanol and dried *in vacuo*.

Method II

(*a*) *Synthesis of binuclear complex of ligand* III *with* ClO_4^- *counter ion*

2 mmol of ligand III were dissolved in 25 cm^3 of methanol and to this were added 4 mmol of $Cu(ClO_4)_2 \cdot 6H_2O$ in 15 cm^3 methanol. The solution was stirred for 1 h. The solid obtained was filtered and washed with methanol and dried *in vacuo*.

(*b*) *Synthesis of binuclear complex of ligand* III *with* Cl^- *counter ion*

2 mmol ligand III were dissolved in 25 cm^3 methanol and to this were added 4 mmol of $CuCl_2 \cdot 2H_2O$ in 15 cm^3 methanol. The solution was stirred for ~10 h. The solid obtained was filtered and washed with methanol and dried *in vacuo*.

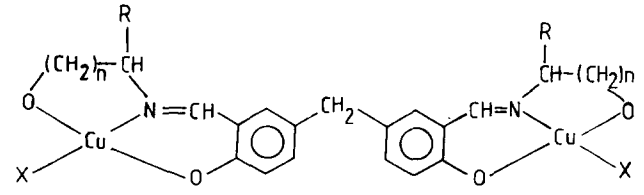
Physical measurements

C and H analyses were performed on Coleman analyzer model-33 and nitrogen was estimated by Dumas' method. Copper was estimated gravimetrically as copper oxide. Magnetic measurements were carried out using a Gouy balance at room temperature. The analytical data have been presented in Table 1. IR spectra (as KBr pellets) were recorded on a Shimadzu IR 408 spectrophotometer. The electronic spectra were recorded on a Shimadzu UV–vis spectrophotometer UV-240. Their diffuse reflectance spectra were recorded on the same instrument, equipped with spherical reflectance assembly, using $BaSO_4$ as a reference material. Thermogravimetric studies were carried out by using as thermal analyser, a Shimadzu D.T. 30 instrument. The ESR spectra were recorded by using a Varian E-15 spectrometer and TCNE was used as the marker.

The electrochemical unit consisted of model 174A polarographic analyzer, universal programmer, *x-y* recorder, platinum working electrode and Pt wire auxiliary electrode. $Ag/AgNO_3$ was used as the reference electrode.

RESULTS AND DISCUSSION

The analyses of the complexes correspond to the following binuclear formula (Fig. 1).



Electronic spectra

The electronic spectra of complexes II_B, II_C, II_D and III_A in DMF solution exhibit a broad band in the region 630–690 nm and four bands at 500, 380, 270 and 240 nm. Similar bands are observed in reflectance spectra of the complex also. The band in the 630–690 nm region corresponds to *d–d* transitions and is

Fig. 1.

indicative of square planar geometry around the metal ion. The ligand occupies three positions with one water molecule completing the fourth coordination position [11,12]. The band at around 500 nm is a charge transfer band from phenolate oxygen to Cu^{II}. The bands 380, 270, 245 nm have previously been assigned to ligand related $\pi_1^* \leftarrow \pi$ and $\pi_2^* \leftarrow \pi$ transition [13,14] and appear in all spectra. They are consistent with dianionic form of Schiff base formed by salicylaldehyde and amino acids and their complexes previously reported [15–17]. This confirms the presence of the salicylaldimine group. The complexes I_A, I_B, I_C and II_A are insoluble and hence only reflectance spectra could be recorded. The bands appearing at 630–690 nm, 500, 380, 270 and 245 nm are similar to the spectra for the complexes II_B, II_C and II_D. The reflectance spectrum of complex III_B shows *d–d* band in the region 830–860 nm. Compared to the perchlorate containing complex III_A and neutral complexes I and II the bands in the complex III_B occurs at lower energy. Further, the spectra of II_B, II_C and II_D in DMF and III_A in DMF or dioxan/water solution do not show significant change from the reflectance spectra, whereas III_B on dissolution in water/dioxan exhibits spectra different from that in solid phase. A broad *d–d* band is observed in the range 630–690 nm similar to all other complexes in solution. This shows that there may be chloride bridges in the III_B complexes resulting in tetranuclear complexes. The chloride bridges break on dissolution in water with consequent change in the spectrum. The fact that the neutral complexes I and II and perchlorate complex III_B show no significant change on dissolution, indicates the absence of inter-dinuclear complex interaction in these complexes.

IR spectra

The IR spectra obtained for these complexes are in agreement with proposed structures. For the IR spectrum of the complex III_A perchlorate band is observed at 1100 cm^{-1}. The band at ~900 cm^{-1} is absent and there is no splitting of the 1100 cm^{-1} band indicating that perchlorate is tetrahedral and is outside the coordination sphere.

Magnetic and ESR data

Room temperature magnetic measurements showed μ_B 1.1–1.3 for binuclear complexes. These lower magnetic moments indicate antiferromagnetic interaction between the two metal centers at room temperature. The ESR spectra of samples I_C, II_A, II_B and II_D were carried out at room temperature in powder form and for III_A the spectra were recorded at room temperature in powder form as well as frozen solution spectra in DMF. The g values are shown in Table 2 and one spectrum is shown in Fig. 2. Observation of $g_\parallel$ and $g_\perp$ indicates tetragonal distortion and supports square planar structure. Even though the antiferromagnetic interaction is there the $\Delta ms = 2$ i.e., half field signals are not observed, probably due to large zero field splitting [6,18].

As the two metal atoms are far apart and the molecule is not flexible, the interaction can be through σ and π orbitals over the bridging atom. The p_x orbitals of the two phenoxo O^- combine with two Cu^{II} $d_{x^2-y^2}$ orbitals with unpaired electron. This results in the formation of two bonding and two antibonding molecular orbitals. The ligand atom orbitals which have less energy are comparable with the bonding molecular orbitals and ligand electrons occupy the bonding molecular orbitals. The two metal atom electrons occupy the antibonding molecular orbitals. They may be singly occupied in the two antibonding molecular orbitals, resulting in triplet state. If there is significant separation between the two antibonding orbitals there is pairing of electrons in the lower energy antibonding molecular orbital, resulting in antiferromagnetic spin coupling and a singlet state. The extent of spin exchange depends on the separation between the energies of singlet and triplet state (^2J). There is a temperature-dependent mixture of the singlet and triplet states and consequent lowering in the magnetic moment at room temperature. Long range spin exchange in bridges with delocalised π orbitals

Table 2. Electrochemical data and ESR parameters of some complexes

have been extensively studied and in these cases also the exchange interaction is considered to be through σ orbitals [4,5]. In binuclear complexes with aliphatic bridges also spin exchange has been observed and X-ray crystal structure study shows that there is no interdinuclear complex interaction in such complexes [8,9], and hence antiferromagnetic interaction has been attributed to spin polarization of σ electrons. However, in the absence of X-ray and variable temperature magnetic data, attributing such a low magnetic moment, in the present study, to interaction through —CH_2— bridge is tentative and formation of tetranuclear structure, involving interdinculear interaction [19,20] cannot be ruled out.

Electrochemical studies

Cyclic voltammetric data of the complexes were recorded in DMF medium. The Schiff base ligands do not exhibit any redox peaks in the potential range investigated 0—1.7 V. The C.V. of mononuclear complex Cu (sal, ala) H_2O shows one quasireversible peak at $\sim -0.92/0.64$ corresponding to Cu^{II}/Cu^{I} couple. The electrochemical properties of four binuclear complexes II_B, II_C, II_D and III_A were studied. The electrochemical data are given in Table 2. A representative cyclic voltammogram is shown in Fig. 3. All these complexes exhibit completely irreversible behaviour. The binuclear complexes exhibit two reduction peaks which correspond to the stepwise reduction of two Cu^{II} centers to Cu^{I}:

$$Cu^{II}Cu^{II} \xrightarrow{+1e} Cu^{I}Cu^{II} \xrightarrow{+1e} Cu^{I}Cu^{I}.$$

The possibility that these two peaks correspond to simultaneous reduction of the two copper centres to Cu^{I} and finally to Cu^{0} is ruled out, since the mononuclear complex Cu (sal, ala) H_2O shows only one step reduction $Cu^{II} \rightarrow Cu^{I}$. The two-step reduction in the binuclear complexes indicates interaction between the two paramagnetic Cu^{II} centers [21]. This is in agreement with the magnetic data showing antiferromagnetic interaction.

The comparison of the reduction potentials of complexes II_B, II_C and II_D with that of complex III_A shows that the reduction of $Cu^{II} \rightarrow Cu^{I}$ in complex III_A occurs at less negative potential than that of complex II_B, II_C and II_D. This can be explained by σ and π

bonding nature of the ligands. In complexes II_B, II_C and II_D there is one phenolate O^-, one carboxylate COO^- and one imine coordination, where as in complex III_A there is one O^- coordination, one imine and one pyridyl N coordination. As there are two σ bonding in the first case the Cu^{II} gets reduced to Cu^{I} at more negative potential. In the second case III_A due to π bonding pyridyl nitrogen the $Cu^{II} \rightarrow Cu^{I}$ reduction occurs at less negative potential.

Thermogravimetric data

The thermogravimetric analysis (TGA) indicates loss of one water molecule per metal atom in the range of 180–200°C for the complexes. Loss of water at such high temperatures indicates that the H_2O molecules are coordinated and not lattice held. This is in agreement with C, H, N analysis presented in Table 1.

(Received 7 April 1996; accepted 28 May 1996)

Abstract—The preparation, crystal structure, infrared and Raman spectra are reported for zinc hypophosphites, $Zn(hyp)_2$ and zinc hypophosphite monohydrate, $Zn(hyp)_2 \cdot H_2O$ (hyp = H_2PO_2). Both structures are polymeric, and the coordination geometry of zinc is octahedral. In $Zn(hyp)_2$ the coordination is to six oxygen atoms of the hypophosphite groups, and in $Zn(hyp)_2 \cdot H_2O$, *via* one oxygen atom of a water molecule, and five hypophosphite oxygen atoms. The hypophosphite vibrational modes give rise to multiple structures in the infrared and Raman spectra, and these bands are interpreted under unit cell group selection rules in a consistent manner with the crystallographic data. The infrared spectral region between 1940–2350 cm^{-1} comprises numerous combination bands, whose intensities are enhanced through Fermi resonance with the P—H stretching modes. The breadth and wavenumbers of water modes observed in the vibrational spectra of $Zn(hyp)_2 \cdot H_2O$ indicate the presence of medium-strong hydrogen bonding to hypophosphito-oxygen atoms. The X-ray data show a slight lengthening of the mean P—O bond distance, and shortening of the mean P—H distance for the hydrated compound. Whereas the changes in PH_2 stretching, and PH_2 and PO_2 bending wavenumbers between the two compounds are as expected from this, the PO_2 stretching modes show that change of the unit cell group symmetry must also be considered. The mean Zn—O bond distance is similar (near 2.1 Å) in both $Zn(hyp)_2$ and $Zn(hyp)_2 \cdot H_2O$, and the infrared active Zn—O antisymmetric stretching modes are observed near 328 and 300 cm^{-1}, respectively. Structural factors, in addition to the cation ionic radii, determine the trends in M^{II}-(O-hypophosphito) antisymmetric stretching modes for other divalent cations. Keywords: infrared; Raman; hypophosphite complex; metal–ligand stretching vibration.

We have previously reported crystallographic and spectroscopic data for uranium(IV) hypophosphite compounds, $U(H_2PO_2)_4$ [1] and $UCl(H_2PO_2) \cdot 2H_2O$ [2] and $UBr(H_2PO_2)_3 \cdot 2H_2O$ [3]. In all of these compounds, the coordination geometry of the cation is square antiprismic. All structures were found to be polymeric, with the hypophosphito group acting as a bridging ligand between tetravalent cationic centres. The present study extends the investigations of the structural and spectral characteristics of hypophosphite compounds to those of the divalent cation zinc, for which the usual coordination number is four or six. Far infrared spectra and power diffraction data have previously been reported for $Zn(hyp)_2$ [4] (hyp = H_2PO_2). Brun *et al.* [5] have also reported infrared spectra and power diffraction data for other anhydrous divalent metal hypophosphites. Mayants and Matrosov [6] have reported infrared data for a compound identified as $Zn(hyp)_2 \cdot 0.5H_2O$ only on the basis of phosphorus elemental analysis.

EXPERIMENTAL

Syntheses of $Zn(hyp)_2$ *and* $Zn(hyp)_2 \cdot H_2O$

Both compounds were prepared from the reaction of 2 g of ZnO, or $ZnSO_4 \cdot 7H_2O$ (RG, Reidel-de-Haën) with 20 cm^3 of hypophosphorous acid (50% aqueous, RG, Reidel-de-Haën). The anhydrous compound was prepared at temperatures between 40–60°C, and the

* Author to whom correspondence should be addressed

hydrate between 4–25°C. Crystals were filtered from the liquor, quickly washed with water and air-dried. The crystals of the monohydrate were well-formed, stable in air, and up to 1 cm in length. Small needles were obtained, in several preparations, for the anhydrous compound, and thin plates formed on the surface of the solution in others.

Analytical results

A survey analysis of a single crystal of $Zn(hyp)_2 \cdot H_2O$ by a Jeol T300 scanning electron microscope, using electron microprobe analysis, showed only the presence of the elements Zn and P, with a mass ratio 0.98 (s.d. = 0.06). The calculated mass ratio Zn/P for $Zn(hyp)_2 \cdot H_2O$ is 1.055. Calc. (found) % by mass for $Zn(hyp)_2 \cdot H_2O$: Zn 30.6 (30.8 ± 0.13 by AAS); P 29.0 (29.8 by ICP-AES); H 2.8 (2.7 ± 0.23 by CHN analyser); H_2O 8.4 % (9.7% by loss in mass at 105°C). The Raman spectrum of the product obtained by heating the monohydrate at 105°C is identical with the spectrum of freshly prepared crystals at 40–60°C, sealed immediately in a capillary tube. Some bands in the infrared spectra of the dehydration product, at 105°C, of the monohydrate showed different relative intensities from those in the spectra of freshly-prepared samples, however. This change in composition must have occurred during the mulling process, since the Raman spectra show that these two initial products are identical. Very weak, sharp bands at 1661, 3324, 3449 and 3531 cm^{-1} were observed in the infrared spectra of $Zn(hyp)_2$, attributed to $\delta(H_2O)$, $2\delta(H_2O)$, ν_s, ν_{as} (H_2O) of weakly bound water. Calc. (found) % by mass for $Zn(hyp)_2$: Zn 33.5 (33.3 ± 0.10); P 31.7 (28.0); H 2.1% (2.0 ± 0.27).

Spectroscopic measurements

Raman spectra were recorded at room temperature using < 20 mW of 476.5 nm or 514.5 nm argon ion laser radiation. The resolution of the Spex 1403DM system was set at 2 cm^{-1}. Infrared Nujol mull spectra (4000–400 cm^{-1}) were recorded using Bomen MB120 and Perkin Elmer PE1600 spectrometers.

X-ray analyses

The details of the crystal parameters, data collection and structure refinement are given in Table 1. Raw intensities collected on a Nicolet R3m/V four-circle diffractometer at 294 K were processed with the profile fitting procedure of Diamond [7], and corrected for absorption using ψ-scan data. [8]. The zinc atom was located by the Patterson method, and the coordinates of the other non-hydrogen atoms and the hydrogens of the aqua ligands were obtained from successive difference Fourier synthesis. The hydrogen atoms of independent hypophosphite groups were generated geometrically. All non-hydrogen atoms were subjected to anisotropic refinement, and the hydrogen atoms were fixed and assigned the same isotropic temperature factor in structure factor calculations. Computations were performed using the SHELXTL–PLUS programme package [9] on a 486 PC. Analytic expressions of scattering factors for neutral atoms were employed, and anomalous dispersion corrections were incorporated [10]. The residual extrema in the last difference map all lie in the neighbourhood of the zinc atom.

RESULTS

Crystal structures of $Zn(hyp)_2$ *and* $Zn(hyp)_2 \cdot H_2O$

The atomic coordinates and thermal parameters are listed as supplementary data. Bond lengths and bond angles are given in Table 2.

$Zn(hyp)_2$. Figure 1(a) shows that the coordination sphere about the zinc atom comprises four symmetry-related oxygens derived from O(1), and two more distant oxygens from O(2), in a slightly distorted octahedral geometry. The two independent phosphorus atoms in the unit cell, P(1) and P(2), are each situated at a C_{2v} symmetry site. The bond distance P(1)—O(1) is about 1% longer than the distance P(2)—O(2). Both hypophosphito ligands exhibit a bridging complexation mode to generate a polymeric layer-type structure, but the oxygens of type O(1) are equidistant from two zinc atoms, whereas those of type O(2) coordinate with one zinc atom only. A stereoview of the crystal structure is shown in Fig. 2(a); note that the coordination layers match the (001) family of planes.

$Zn(hyp)_2 \cdot H_2O$. The eight phosphorus atoms in the unit cell form two distinct sets, 4P(1) and 4P(2), each with C_1 site symmetry. The phosphorus–oxygen bond distances in each of the hypophosphite anions are slightly (< 1%) different. For P(1), the bonds are labelled P(1)—O(1) and P(1)—O(2) and for P(2), the hypophosphito oxygens are O(3) and O(4). As shown in Fig. 1(b), the 6-coordination geometry of zinc involves one oxygen, O(1W), of a water molecule, three oxygens of P(2), and two oxygens of P(1). The Zn—O bond distances are shortest for the coordination with the oxygens of P(1). The longer Zn—O(1W) distance is similar to that of Zn—O(4c), with the Zn—O(4b) distance being longest. The O(4) atoms are linked to two zinc atoms, whereas all other oxygens link to only one zinc atom. The hypophosphito groups therefore bridge two or three zinc centres, generating a three-dimensional polymeric network. The hydrogen bonds between the water molecule and the oxygen of P(1), O(1W)...O(1g), are nearly linear, and comparable in length to those in ice. Weaker, bent hydrogen bonds, O(1W)...O(1h), also involve the water molecules. A stereoview of the crystal structure is shown in Fig. 2(b).

Vibrational spectra of $Zn(hyp)_2$ *and* $Zn(hyp)_2 \cdot H_2O$

The free C_{2v} hypophosphite anion has nine non-degenerate modes of vibration:

$$\Gamma(\text{vib}, C_{2v}) \in \{4a_1; a_2; 2b_1; 2b_2\} \quad (1)$$

of which all are potentially Raman and infrared active, except for the a_2 mode which is infrared inactive. Normal coordinate calculations, deuteration studies, and the use of polarized radiation (cited in [2]), have enabled the assignments of specific vibrational motions from infrared and Raman data. The present study aimed to point out the distinctions between the spectra of $Zn(hyp)_2$ and $Zn(hyp)_2 \cdot H_2O$, and to investigate the spectral consequences resulting from the polymeric, rather than discrete molecular ion structures.

The Raman spectra of $Zn(hyp)_2$ and $Zn(hyp)_2 \cdot H_2O$ are shown in Fig. 3, and the wavenumbers are tabulated together with infrared data in Table 3. In many cases, multiple structure is observed in the spectra, and this correlates with one of the hypophosphite normal modes of vibration through the unit cell group analysis.

Spectra of $Zn(hyp)_2$

For $Zn(hyp)_2$, each molecular anion normal mode associated with each type of phosphorus atom transforms unchanged at the respective $H_2PO_2^-$ C_{2v} site, and gives rise to two unit cell group (C_{2h}) modes. For a_1 or a_2 molecular ion modes, these unit cell group modes are $a_g + a_u$, whereas for b_1 or b_2 modes, the

unit cell group modes are $b_g + b_u$. The gerade unit cell group modes are Raman active, and the ungerade modes are infrared active. To summarize, each molecular hypophosphite mode is expected to give rise to two infrared bands and two Raman bands. The difference between the infrared (or the Raman) wavenumbers of the molecular anion mode reflects the different environments of the two hypophosphite sites. The difference between the infrared and the Raman wavenumbers for a vibration at a particular site reflects the strength of the unit cell group vibrational coupling. The observed spectra are too complex for a simple interpretation, but are consistent with the above selection rules in that no more than two infrared and two Raman bands are observed for each moiety mode and that the mutual exclusion rule is obeyed (Table 3).

Spectra of $Zn(hyp)_2 \cdot H_2O$

In this case, the hypophosphite site group for each of the two sites is C_1 and the unit cell group is C_{2h}.

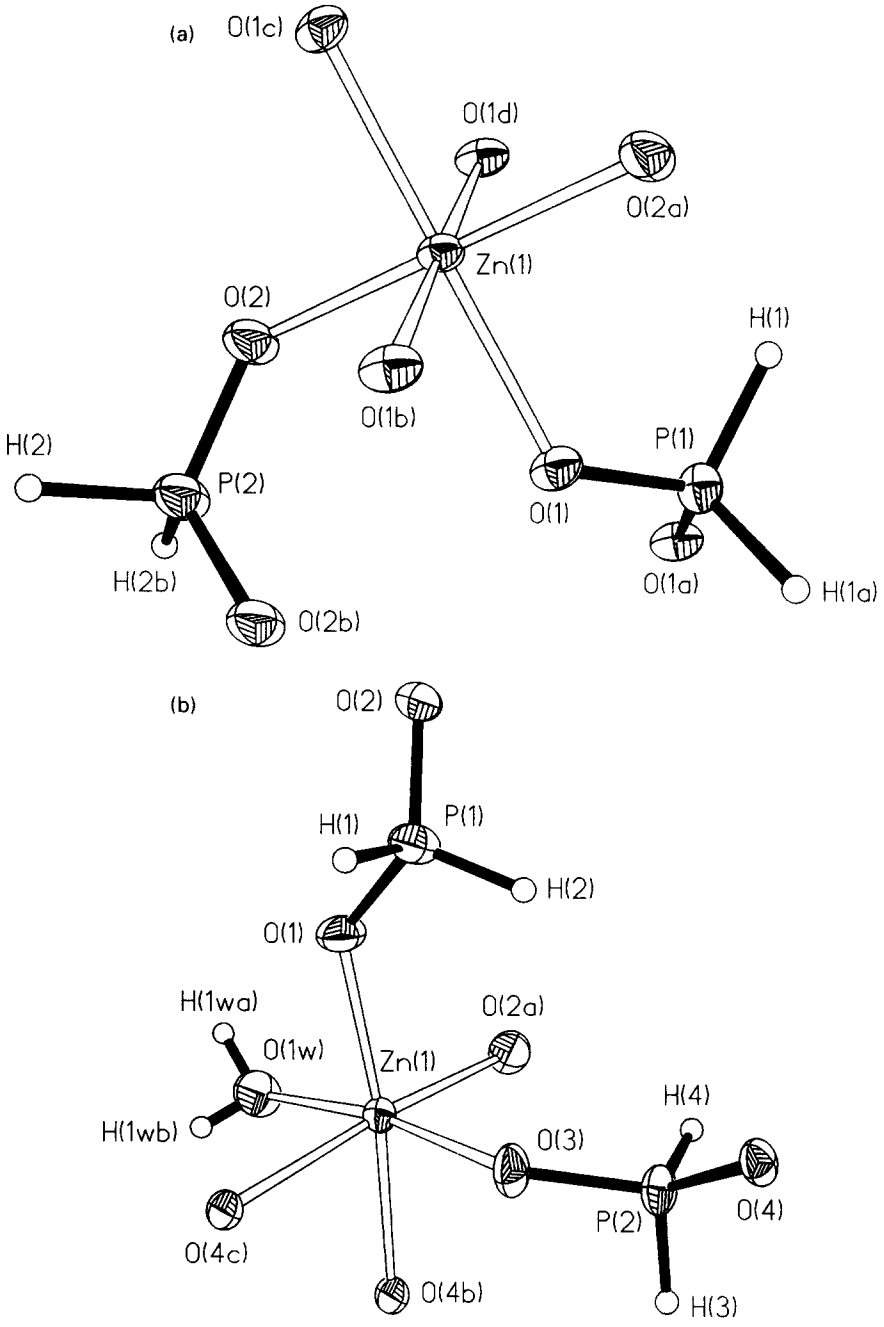

Fig. 1. Perspective views showing the atom numbering schemes and the coordination geometries about the zinc atoms in (a) $Zn(hyp)_2$ and (b) $Zn(hyp)_2 \cdot H_2O$. Symmetry codes are as given in Table 2.

The selection rules indicate that at each hypophosphite site, each parent anion mode gives rise to two potentially active infrared bands and two Raman bands in each case: i.e. to 4 IR and 4 Raman bands, with mutual exclusion. It is clear that not all of these are resolved in the room temperature unpolarized spectra, but more features are observed than in the spectra of $Zn(hyp)_2$. Other differences between the infrared spectra of the two compounds arise from the consequences of the presence of water in $Zn(hyp)_2 \cdot H_2O$. The water modes of vibration in this crystal are assigned in Table 3. Medium-strong hydrogen-bonding is indicated from the broad, medium-energy OH_2 stretching bands. The PO_2 scissor mode is at higher energy in $Zn(hyp)_2 \cdot H_2O$ than the anhydrous compound, since the longer mean P—O bond distance (1.509 Å, compared with 1.506 Å in $Zn(hyp)_2$) accompanies the closure of the (mean) OPO angle by 1.6°. A longer (mean) P—O bond distance in $Zn(hyp)_2 \cdot H_2O$ would enable contraction of the P—H bond length and an opening of the HPH angle and this is reflected by the PH_2 stretching and scissoring modes

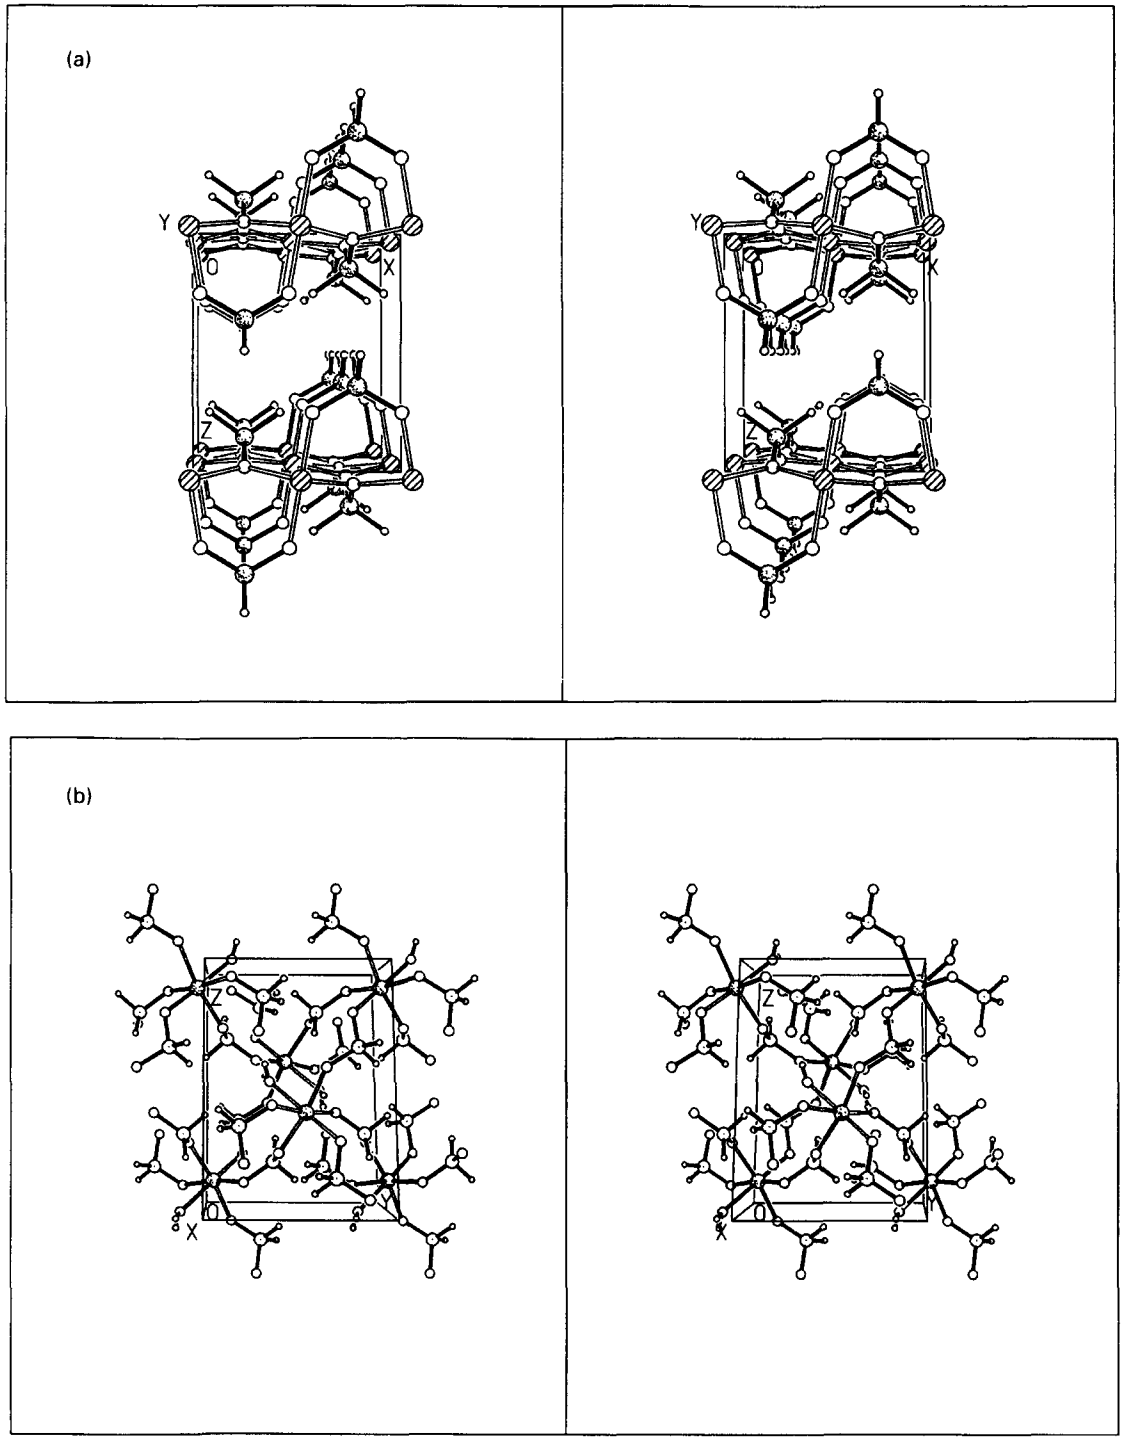

Fig. 2. Stereoview of the crystal structures of (a) $Zn(hyp)_2$ (the origin of the unit cell lies at the upper left corner, with x pointing from left to right, y toward the reader, and z downward) and (b) $Zn(hyp)_2 \cdot H_2O$ (the origin of the unit cell lies at the lower left corner with x toward the reader, y from left to right and z upward).

of the two compounds. The wavenumber of the P—O antisymmetric stretch normally shifts to lower energy upon hydrogen bonding [11,12]. However, in the present case, the changes in spectral selection rules from one crystal to another may complicate these simple arguments and a new, high energy feature is observed at 1180 cm^{-1} in the hydrated compound.

The low energy profiles of the PH_2 stretching bands in the infrared and Raman spectra of $Zn(hyp)_2$ and $Zn(hyp)_2 \cdot H_2O$ are broadened, and numerous features

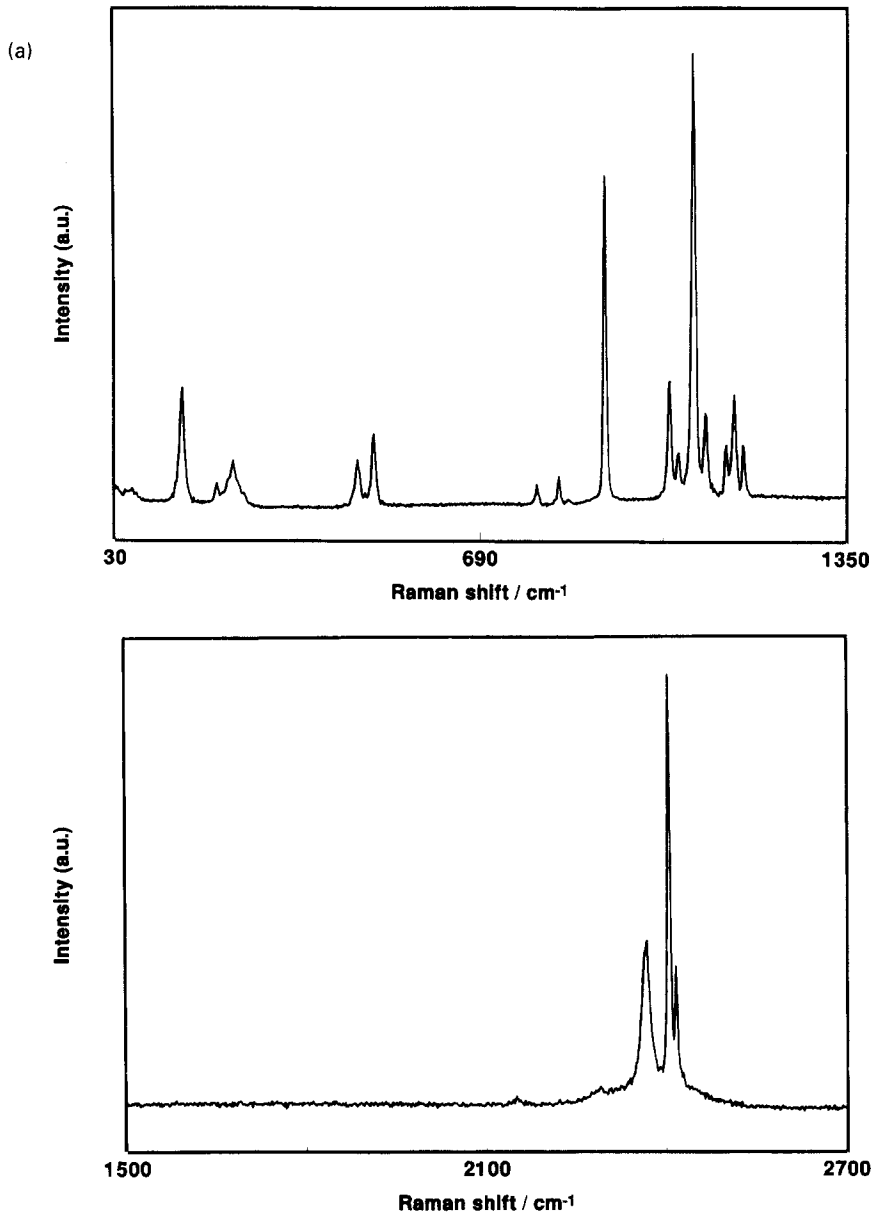

Fig. 3. 300 K Roman spectra of (a) $Zn(hyp)_2$ and (b) $Zn(hyp)_2 \cdot H_2O$ between 30 and 2700 cm^{-1}.

are superimposed. These infrared combination bands are assigned, in the case of $Zn(hyp)_2 \cdot H_2O$, in Table 4, and part of their intensities may be attributed to Fermi resonance with the PH_2 stretching modes. The assignments follow zero wavevector unit cell group selection rules, so that each combination band comprises one infrared active and one Raman active mode. To high energy of the PH_2 stretching bands, weak combination bands are observed which may involve one quantum of the OH_2 bending mode together with one quantum of the PH_2 rock, and/or combinations of P—H stretching modes with lattice modes (Table 4). Very weak bands are observed in the Raman spectrum near 1858 cm^{-1} and between 1940–1962 cm^{-1}, which are assigned to combination modes involving the PO_2 symmetric stretch with the PH_2 rock and PH_2 twist respectively.

Zinc–oxygen modes of vibration

Abenoza *et al.* [13] have assigned Mg—O vibrational modes in $Mg(hyp)_2 \cdot 6H_2O$, using a model of O_h site symmetry for the $Mg(OH_2)_6^{2+}$ moiety. The infrared active Mg—O antisymmetric stretch and the Raman active symmetric stretch were assigned at 430 cm^{-1} and 363 cm^{-1}, respectively. The Mg—O bond distances in $Mg(hyp)_2 \cdot 6H_2O$ (to O in H_2O, near

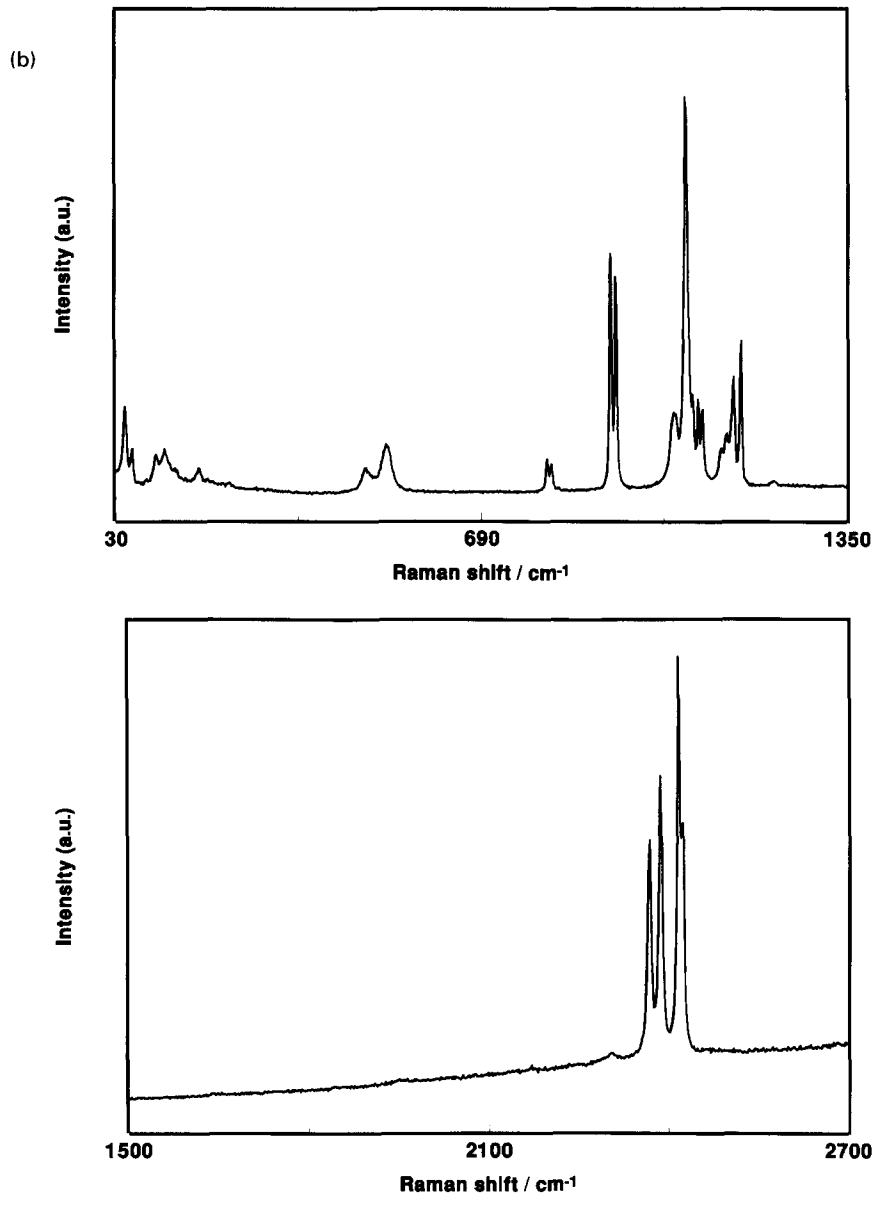

Fig. 3 – *continued.*

2.055 ± 0.011 Å [14]), are shorter than the mean Zn—O bond distances in $Zn(hyp)_2$ (to O in $H_2PO_2^-$, 2.108 Å) and $Zn(hyp)_2 \cdot H_2O$ (2.098 Å). The far infrared spectrum of $Zn(hyp)_2$ has been reported by Brun and Dumail [4]. A medium intensity band at 323 cm^{-1} and a weaker feature at 355 cm^{-1} were assigned to Zn—O antisymmetric stretching. The wavenumber of the stronger band is in agreement with the present study, and the bands could be attributed to ε_u and α_{2u} (D_{4h}) molecular point group components, associated with stretching of the long and short Zn—O bonds. This interpretation would neglect the coupling between different metal centres. The Raman data from the present study may indicate a symmetric stretching mode of Zn—O character at lower energy, near 245 and 234 cm^{-1} in $Zn(hyp)_2$ and $Zn(hyp)_2 \cdot H_2O$, respectively. Numerous Raman bands are observed below 230 cm^{-1} for $Zn(hyp)_2$ and $Zn(hyp)_2 \cdot H_2O$, so that specific assignments are tentative (Table 3) and are based upon the study of Abénoza and Martin [15].

A survey of the data for infrared-active M^{II}—O(hypophosphito) stretching mode wavenumbers in other complexes is collected in Table 5. $Cu(hyp)_2$ readily decomposes but has been shown to be isomorphous with $Zn(hyp)_2$ and $Co(hyp)_2$ [4]. Our infrared spectrum of $Cu(hyp)_2$ shows a resemblance to that of $Zn(hyp)_2$, but the wavenumber of ν(Cu—O) is different from that previously reported [19]. The G matrix element of this mode ν_{as} (M—O) in O_h symmetry is $(m_M)^{-1} + 2(m_O)^{-1}$, being virtually independent of the mass of the cation M. Although the wavenumbers show some relation to the cation ionic radii, it is clear

[a]The internal $H_2PO_2^-$ modes are labelled according to the parent C_{2v} vibrations. Extensive mixing of the vibrational modes occurs, especially in the region 1000–1200 cm^{-1}, so that the assignment of a band to a specific vibrational coordinate is not implied.

that other factors such as the different crystal structures play a role in their magnitudes.

DISCUSSION

The compounds $Zn(hyp)_2$ and $Zn(hyp)_2 \cdot H_2O$ exhibit two- and three-dimensional polymeric structures respectively, with the hypophosphite anions acting as bridging ligands between metal centres. The zinc coordination is octahedral, but some hypophosphite oxygen atoms coordinate to one zinc atom only whereas others coordinate to two. The essential difference in the zinc coordination sphere for the two compounds is that one of the six oxygen atoms corresponds to a water molecule in the case of $Zn(hyp)_2 \cdot H_2O$. It is not surprising that the vibrational spectra of these polymeric compounds are also complex, but the multiple structure observed for internal anion modes in

the infrared and Raman spectra is consistent with the predictions of unit cell group selection rules. It is emphasized that the vibrational spectra are not amenable to interpretation under "free molecule" selection rules, as has been attempted elsewhere [16,17] where structural data have not been available. Anhydrous zinc hypophosphite is apparently not isostructural with other divalent metal hypophosphites, where M = Ca, Cd, Sr, Pb, Ba [5], but appears to be isostructural with M = Cu, Co [4].

(Received 10 April 1996; accepted 20 May 1996)

Abstract—The structures of $[Nd_2(Acc^6)_6(H_2O)_6](ClO_4)_6 \cdot (H_2O)_6$ (**1**) $[Er_2(Acc^6)_4(H_2O)_8](ClO_4)_6 \cdot (H_2O)_{11}$ (**2**) and $[Ca_5(Acc^6)_{12}(H_2O)_6](ClO_4)_{10} \cdot (H_2O)_4$ (**3**) (Acc^6 = 1-aminocyclohexane-1-carboxylic acid) have been determined by X-ray crystallography. The lanthanide complexes **1** and **2** are dimeric in which two lanthanide cations are bridged by four carboxylato groups of Acc^6 molecules. In addition, the neodymium complex (**1**) features the unidentate coordination of the carboxyl group of an Acc^6 molecule in place of a water molecule in the erbium complex (**2**). The coordination number in both **1** and **2** is eight. The calcium Acc^6 complex (**3**) is polymeric; three different calcium environments are observed in the asymmetric unit. Two calcium ions are hexa-coordinated and one is hepta-coordinated. Considerable differences are observed between the solid state structures of Ln^{III} and Ca^{II} complexes of Acc^6. Copyright © 1996 Elsevier Science Ltd

Keywords: lanthanide–amino acid complexes; crystal structures; 1-aminocyclohexane-1-carboxylic acid.

Lanthanide ions are often used as probes of Ca^{II} binding sites in biological systems. The ability of lanthanides to mimic Ca^{II} in diverse situations arises from the similarity in the sizes of the ions and their strong affinity to form complexes with oxygen donor ligands [1,2]. In continuation of our studies on amino acid [3] and peptide [4] complexes of lanthanides, we report here the structures of the lanthanide and calcium complexes of 1-aminocyclohexane-1-carboxylic acid (Acc^6).

The use of non-protein amino acid residues in the synthesis of peptides with restricted conformational flexibility has acquired increasing importance in the design of specifically folded analogues of biologically active peptides [5]. α,α-Dialkylated residues [—NH—CR^1R^2—CO—) have proved valuable in the construction of conformationally constrained peptide backbones [6–8]. The studies on Acc^6 residues of the N-blocked amino acids and peptides showed that the amino function is almost always found in the axial position [9–11]. The zwitterionic amino acid (Acc^6) is the only case where the amino function is equatorial [9]. In this context, it would be interesting to study the metal complexes of zwitterionic Acc^6 to assess the conformational preference of the amino group.

EXPERIMENTAL

Lanthanide perchlorates were prepared from the respective lanthanide oxides. 1-Aminocyclohexane 1-

* Author to whom correspondence should be addressed.

carboxylic acid (Acc^6) was prepared according to the literature procedure [12, 13].

Synthesis of $[Nd_2(Acc^6)_6(H_2O)_6](ClO_4)_6 \cdot (H_2O)_6$ **(1)** *and* $[Er_2(Acc^6)_4(H_2O)_8](ClO_4)_6 \cdot (H_2O)_{11}$ **(2)**

Lanthanide perchlorate hexahydrate (3.64×10^{-4} mol) and Acc^6 (0.05 g, 3.64×10^{-4} mol) were dissolved in 5 cm^3 of distilled water. On slow evaporation of the solution at room temperature, crystals of lanthanide-Acc^6 complexes were obtained. Yield: $\approx 75\%$.

Synthesis of $[Ca_5(Acc^6)_{12}(H_2O)_6](ClO_4)_{10} \cdot (H_2O)_4$ **(3)**

Calcium perchlorate (0.09 g, 2.80×10^{-4} mol) and Acc^6 (0.04 g, 2.80×10^{-4} mol) were dissolved in 5 cm^3 of distilled water. On slow evaporation of the solution at room temperature crystals of calcium perchlorate-Acc^6 complex were isolated. Yield: 70%.

Satisfactory C, H, N analysis could not be obtained for the complexes because of their hygroscopic nature. Lanthanide metal contents were determined by titration with EDTA using xylenol orange as the indicator and correspond to the empirical formulae noted above.

X-ray crystal structure analysis of **1–3**

A suitable crystal of each compound was mounted in a Lindemann capillary and sealed to protect it from moisture. The data were collected on an Enraf-Nonius CAD-4 diffractometer using graphite monochromated Mo-K_α radiation. The structures were solved by Patterson and Fourier techniques and refined by full matrix least squares procedures [14, 15]. All the non-hydrogen atoms were refined anisotropically. The methylene hydrogen atoms of the cyclohexane ring were fixed at geometrically calculated positions (C—H = 0.9 Å) and included in the structure factor calculations. The water and NH_3^+ hydrogen atoms were not located. This may be the reason for the high R-factor observed for complex **3**, which contains the relatively lighter calcium atoms compared to the other heavy atom structures **1** and **2**. The details pertaining to the data collection and refinement are given in Table 1.

RESULTS AND DISCUSSION

Spectroscopic data for the complexes

The Acc^6 complexes of neodymium (**1**), erbium (**2**) and calcium (**3**) perchlorates are prepared by dissolving stoichiometric amounts of Acc^6 and the respective metal salt in water. Slow evaporation of the resultant solution gave crystalline complexes in high yield. These complexes possess the characteristic color of the lanthanide ion.

The infrared spectra of the complexes show a broad and strong absorption in the 3300–2300 cm^{-1} region which can be assigned to the O—H and NH_3^+ stretching vibrations superimposed on each other. The strong band in the region 1600–1500 cm^{-1} arises from the asymmetric stretching vibration of the carboxylato group. The strong absorptions in the region of 1170–1050 and 620–630 cm^{-1} are assigned to ν_3 and ν_4 vibrations of the perchlorate ion.

The structure of the lanthanide-Acc^6 complexes in solution has been investigated by ^{13}C NMR spectroscopy. For this purpose, the ^{13}C resonances of Acc^6 are monitored upon successive addition of praseodymium perchlorate solution. The praseodymium complexes are expected to have a similar structure to that of the neodymium complex [16]. The advantage of using Pr^{3+} for NMR measurements is that it induces large chemical shifts, without causing appreciable line broadening compared to the Nd^{3+} ion [16]. Upon successive addition of praseodymium perchlorate solution, the resonances of carboxyl carbon (δ value in free Acc^6: 177.6 ppm, $\Delta\delta$: 1 ppm) and the carbon which is directly bonded to the carboxyl group (δ value in free Acc^6: 61.6 ppm, $\Delta\delta$: 6 ppm) show maximum chemical shift variations compared to the other resonances. Irrespective of the concentration of the praseodymium salt, only a single resonance is observed for the carboxyl carbon. This observation suggests that there is a dynamic equilibrium between differently coordinated carboxyl groups of the Acc^6 in solution. The X-ray crystal structure of the neodymium-Acc^6 complex shows two different types of coordination of the carboxyl group of Acc^6 (see below).

X-ray crystal structures

X-ray crystal structure analysis of neodymium-Acc^6 **(1)** *and erbium-Acc^6* **(2)** *complexes.* The structures of neodymium and erbium complexes were determined by X-ray crystallography. Perspective views of the molecules are shown in Figs 1 and 2. The selected bond distances and angles are listed in Table 2.

In both neodymium and erbium complexes, the two lanthanide ions are bridged by the carboxylato groups of four Acc^6 molecules. In the neodymium complex, in addition, each neodymium ion is also coordinated to a unidentate carboxyl group of an Acc^6 molecule. Such a unidentate coordination of the carboxyl group of an amino acid to lanthanides is observed for the first time. However, this type of unidentate carboxylato group is present in the solid state structures of the trifluoroacetato and *meta*-hydroxybenzoato complexes, $[Pr(O_2CCF_3)_3 \cdot 3H_2O]$ [17] and $[Ln_2(O_2C C_6H_4OH\text{-}3)_6(H_2O)_6] \cdot 2H_2O$ (Ln = Sm or Er) [18].

The metal to ligand ratio is 1 : 3 in the neodymium-Acc^6 complex but in the erbium-Acc^6 complex, it is decreased to 1 : 2 and the unidentate Acc^6 molecule is replaced by a water molecule. This difference is a

consequence of the decreased ionic radius of the Er^{3+} ion compared to the Nd^{3+} ion as a result of "lanthanide contraction". In both **1** and **2**, the coordination number of the lanthanide ion is eight and the geometry around the metal is that of a square antiprism. The amino acids exist in the zwitterionic form and the perchlorate ions are outside the coordination sphere. In the neodymium complex **1**, the distance between the unidentate carboxylato oxygen [O(5)] and the neodymium ion is (2.485(3) Å) which is longer than the average distance of the bridging carboxylato oxygens to the neodymium ion (Table 2). The latter distances fall into two ranges [the mean of Nd(1)—O(2) and Nd(1)—O(3) is 2.447(3) Å; the mean of Nd(1)—O(1)′ and Nd(1)—O(4)′ is 2.375(4) Å]. The non-bonding distance between O(6) and Nd(1) ion is 3.912(4) Å. In both neodymium and erbium complexes, the average distance between the carboxylato oxygens and metal ion is shorter than the distance of the coordinated water oxygen to the metal.

X-ray crystal structure analysis of calcium-Acc^6 (**3**) *complex*. The structure of the calcium-Acc^6 complex (**3**) is shown in Fig. 3. The Acc^6 molecules are in their zwitterionic form and the perchlorate groups are outside the coordination sphere. The unit cell consists of five calcium atoms with one of them (Ca(3)) lying at the centre of inversion so that the asymmetric unit corresponds to the formula $[Ca_{2.5}(Acc^6)_6(H_2O)_3](ClO_4)_5 \cdot (H_2O)_2$. Unlike the lanthanide complexes of Acc^6, the calcium complex is polymeric with carboxylato bridges. Three different calcium environments are observed in the asymmetric unit, two calcium ions are hexa-coordinated with an octahedral geometry and one calcium ion is hepta-coordinated with pentagonal bipyramidal geometry. The Ca(1) and Ca(2) are bridged by three carboxylato groups of Acc^6 and Ca(2) and Ca(3) are bridged by two carboxylato groups. Each of the two centrosymmetrically related calcium ions Ca(1) and Ca(1)′ bears a chelated carboxylato group which also bridges

the other calcium ion. Thus the carboxylato groups between Ca(1) and Ca(1)′ act as tridentate ligands.

The selected bond distances and angles are listed in Table 3. The distance between Ca(1)···Ca(1)′ (4.046(3) Å) is shorter than the distance between Ca(1)···Ca(2) (4.382(3) Å) or Ca(2)···Ca(3) (4.487 (2) Å). The Ca(1)—O(2) distance (2.365(6) Å) is shorter than the Ca(1)′—O(2) distance (2.737(4) Å).

Cyclohexyl ring conformation

The endocyclic cyclohexane ring angles in **1, 2** and **3** are close to an almost perfect chair conformation for the cyclohexane ring. The mean value is $\pm 54(1)^\circ$ as found for several Acc^6 containing compounds [9–12].

The amino functional group in the complexes **1**-**3** occupies an axial position with respect to the Acc^6 moiety. This feature is also observed in other Acc^6 containing compounds [10–12] except in the free zwitterionic Acc^6 where the amino functional group is in an equatorial position [9].

Comparison of the structures of lanthanide–amino acid complexes

Prior to this study, the structures of the lanthanide complexes of glycine [19], L-alanine [20] and α-amino isobutyric acid (Aib) [3] have been reported. In all these complexes, the amino acids exist in their zwitterionic form and the perchlorate or chloride ions reside outside the coordination sphere of the metal.

The glycine complex $[Nd_2(Gly)_6(ClO_4)_6 \cdot 9H_2O]$ [19] is polymeric with carboxylato bridges between two neodymium ions. The asymmetric unit consists of dimers in which neodymium ions are bridged by four glycine molecules; two of them act as bidentate ligands while the other two act as tridentate ligands chelating to one metal and bridging to the other metal. Each of the neodymium ion dimers, is linked to another such dimer by two carboxylato bridges. The L-Ala [20] and Aib [3] complexes of lanthanides are dimeric with four bridging carboxylato groups. The same feature is also observed in the lanthanide complexes of Acc^6 reported here. In addition, in the Nd-Acc^6 complex, a unidentate Acc^6 is present.

Comparison of the structures of calcium–amino acid complexes

The calcium-Acc^6 complex (**3**) shows considerable differences from the Ca-glycine complex. In the Ca-Acc^6 complex, bidentate and tridentate mode of bonding of the carboxylato groups are observed whereas in the calcium-glycine complex bidentate and unidentate bonding of the aminoacid are observed. In the calcium

glycine complex [21], the coordination number for calcium is seven but in the calcium-Acc^6 complex, both six and seven coordinated calcium ions are observed.

Comparison of the structures of lanthanide and calcium amino acid complexes

Lanthanide complexes of Acc^6 show considerable structural differences from the calcium complex of Acc^6. The neodymium and erbium complexes of Acc^6 are dimeric whereas the Ca–Acc^6 complex is polymeric. In the Ca–Acc^6 complex both bi- and tridentate carboxylato bridges are present; in contrast, only bidentate carboxylato groups are present in the erbium-Acc^6 complex and bidentate and unidentate carboxylato groups are present in the neodymium–Acc^6 complex. Pronounced differences are also observed between the modes of binding of glycine to lanthanides and calcium as revealed by the structures of $[Nd_2(Gly)_6(ClO_4)_6\cdot 9H_2O]$ [19] and $[CaI_2(Gly)_3H_2O]$ [21]. In the calcium–glycine complex, only one glycine carboxylato group bridges two calcium ions while the other two glycine molecules are coordinated to a calcium ion in a unidentate fashion. On the other hand, the neodymium–glycine complex contains both bidentate and tridentate carboxyl groups (see above).

CONCLUSION

The results reported here reinforce our earlier conclusion [3,4] that there can be considerable variation in the modes of binding of amino acids to lanthanides as compared to calcium ions. The difference in the precise binding geometries suggests that structural alterations may accompany the interaction of lanthanides with calcium ion binding sites in biological systems.

(Received 17 April 1996; accepted 13 May 1996)

Abstract—The sandwich-like bis(phthalocyaninato)lanthanide(III) complexes $Ln[Pc'(R)_8]_2$ (Ln = Eu, Gd; Pc′ = 2,3,9,10,16,17,23,24-octasubstituted phthalocyaninate; R = H, n-C_7H_{15}, OC_5H_{11}) have been prepared by treating $Ln(acac)_3 \cdot nH_2O$ (Ln = Eu, Gd; acac = acetylacetonate) with dilithium phthalocyaninate or with the corresponding disubstituted phthalonitriles in the presence of 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU). The spectroscopic and electrochemical properties of the substituted sandwich complexes have been investigated and compared with those of the unsubstituted analogues. The matrix-assisted laser desorption/ionisation time-of-flight mass spectrometry (MALDI-TOF-MS) and electrospray ionisation mass spectrometry (ESI-MS) have also been employed to unambiguously characterise this novel class of compounds for the first time. Copyright © 1996 Elsevier Science Ltd

Since the discovery of electrochemically generated multicolour response in a solid film of bis(phthalocyaninato)lutetium(III) in 1970 [1], there has been a growing interest in the sandwich-like bis(phthalocyaninato) metal complexes. Apart from the electrochromic behaviour [2], this class of compounds also exhibits unusual electrical [3], magnetic [4], and mesogenic [5] properties. Most of the studies have so far focused in the unsubstituted bis(phthalocyaninato) complexes, in particular, of lutetium. It can be envisaged that by introducing substituents on the periphery of the phthalocyanine macrocycles rationally, the intrinsic properties of the molecule can be altered which may eventually tailor the bulk characteristics of the material. Substitution may also increase the solubility of complexes which facilitates the fabrication process. However, substituted bis(phthalocyaninato) metal complexes have been relatively little studied [5–9]. This paper describes the synthesis, spectroscopic characterisation and electrochemistry of the europium(III) and gadolinium(III) sandwich complexes of octasubstituted phthalocyanines.

EXPERIMENTAL

Hexanes and amyl alcohol were distilled from anhydrous $CaCl_2$ and sodium, respectively. 1,2,4-Trichlorobenzene (TCB) was dried over 4 Å molecular sieves and distilled under reduced pressure. All other reagents and solvents were used as received. The lanthanide acetylacetonates [10], 4,5-bis(pentyloxy) phthalonitrile [11], 4,5-diheptylphthalonitrile [12], and dilithium phthalocyaninate [$Li_2(Pc)$] [13] were prepared according to the literature prescriptions.

The ^1H NMR spectra were recorded on a Bruker WM 250 spectrometer (250 MHz). Spectra were referenced internally using residual solvent resonances relative to tetramethylsilane ($\delta = 0$). The UV–vis and near-IR absorption spectra were obtained on a Hitachi U-3300 and a Hitachi U-3100 spectrophotometers, respectively. IR spectra were recorded on a Nicolet 205 FT-IR spectrometer as KBr pellets. MALDI-TOF spectra were recorded on a Bruker bench TOF mass spectrometer equipped with a standard UV-laser desorption source. ESI mass spectra were measured on a Bruker APEX 47e ultra-high resolution Fourier transform ion cyclotron resonance (FTICR) mass spectrometer. Cyclic vol-

tammetry measurements were performed with a Princeton Applied Research (Model 273A) potentiostat. The cell used comprised a vacuum-tight chamber fitted with inlets for a glassy carbon working electrode, a platinum wire auxiliary electrode and a Ag–$AgNO_3$ reference electrode. Typically, experiments were carried out using *ca* 10 cm^3 of 0.1 mol dm^{-3} tetrabutylammonium hexafluorophosphate in dichloromethane containing *ca* 2 mg of sample under nitrogen at ambient temperature.

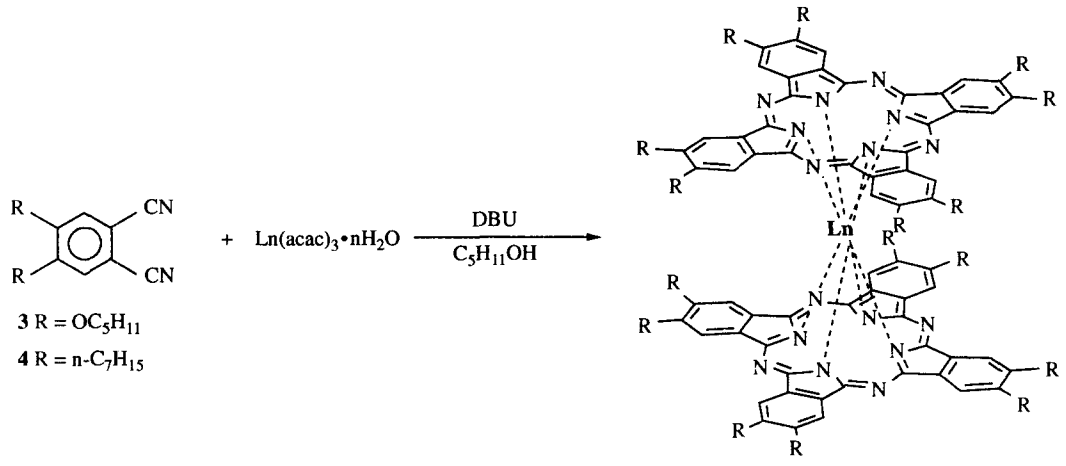
Preparation of bis(phthalocyaninato)lanthanide(III) *complexes* $Ln(Pc)_2$[Ln = Eu (**1**), Gd (**2**)]

A mixture of $Li_2(Pc)$ (53 mg, 0.1 mmol) and $Ln(acac)_3 \cdot nH_2O$ (Ln = Eu, Gd) (150 mg, 0.3 mmol) in TCB (10 cm^3) was refluxed for 10 h under nitrogen. The resulting dark blue solution was cooled and evaporated under reduced pressure to give a residue which was chromatographed on a silica gel column with $CHCl_3$ as eluent. A pale blue band containing a trace amount of the metal-free phthalocyanine $(Pc)H_2$ was developed followed by a greenish-blue band which was collected and concentrated. The crude product was purified by recrystallisation from a mixture of $CHCl_3$ and MeOH. Yield for Ln = Eu (19 mg, 32%). Yield for Ln = Gd (15 mg, 25%).

Preparation of bis[2,3,9,10,16,17,23,24-*octakis*(*pentyloxy*)*phthalocyaninato*]*lanthanide*(III)*complexes* $Ln[Pc'(OC_5H_{11})_8]_2$[Ln = Eu (**5**), Gd (**6**)]

Under a slow stream of nitrogen, a mixture of 4,5-bis(pentyloxy)phthalonitrile (**3**) (300 mg, 1.00 mmol), DBU (78 mg, 0.51 mmol) and $Ln(acac)_3 \cdot nH_2O$ (Ln = Eu, Gd) (30 mg, 0.06 mmol) was heated in amyl alcohol (4 cm^3) under reflux for 8 h to give a dark greenish-blue solution. The volatiles were removed *in vacuo*, then the residue was chromatographed with $CHCl_3$/hexanes (2 : 3) as eluent. Firstly, a green band was developed which contained a small amount of the metal-free phthalocyanine $[Pc'(OC_5H_{11})_8]H_2$ as determined by UV–vis spectrometry. Then a dark greenish-blue band containing the sandwich compound was developed which was collected and evaporated under reduced pressure. The crude product obtained was further purified by the same chromatographic procedure. Yield for Ln = Eu (121 mg, 79%). ^1H NMR [$(CD_3)_2SO + CDCl_3$ + hydrazine hydrate]: δ 10.64 (br s, 16 H, Pc′-H), 4.16 (br s, 32 H, OCH_2), 2.70–2.86 (m, 32 H, OCH_2CH_2), 2.32 (quintet, J = 7.3 Hz, 32 H, $OCH_2CH_2CH_2$), 2.02 (sextet, J = 7.3 Hz, 32 H, CH_2CH_3), 1.42 (t, J = 7.3 Hz, 48 H, CH_3). IR (KBr): 2965m, 2922m, 2856m, 1589w, 1500w, 1456m, 1372m, 1315m, 1272m, 1194m, 1094w, 1044w, 856w, 762w cm^{-1}. Yield for Ln = Gd (115 mg, 75%). IR (KBr): 2956m, 2926m, 2856m, 1606m, 1500m, 1456s, 1372m, 1317m, 1276s, 1194m, 1094w, 1044w, 863w, 762w cm^{-1}.

Preparation of bis(2,3,9,10,16,17,23,24-*octaheptylphthalocyaninato*)*lanthanide*(III)*complexes* $Ln[Pc'(C_7H_{15})_8]_2$[Ln = Eu (**7**), Gd (**8**)]



A mixture of 4,5-diheptylphthalonitrile (**4**) (150 mg, 0.46 mmol), DBU (39 mg, 0.26 mmol) and $Ln(acac)_3 \cdot nH_2O$ (Ln = Eu, Gd) (23 mg, 0.05 mmol) in amyl alcohol (2 cm^3) was refluxed for 13 h under a slow stream of nitrogen. The mixture was cooled to room temperature then filtered to remove most of the metal-free phthalocyanine $[Pc'(C_7H_{15})_8]H_2$, which was washed with amyl alcohol (2 cm^3). The combined filtrates were concentrated under reduced pressure then chromatographed with $CHCl_3$/hexanes (2 : 3) as eluent. After eluting out the residual $[Pc'(C_7H_{15})_8]H_2$, a dark blue solution containing the sandwich compound was collected and rotary-evaporated. The crude product was further purified by recrystallisation from a mixture of $CHCl_3$ and MeOH. Yield for Ln = Eu (92 mg, 72%). ^1H NMR [$(CD_3)_2SO$ + $CDCl_3$ + hydrazine hydrate]: δ 11.06 (br s, 16 H, Pc′-H), 4.31 (br s, 32 H, Pc′-CH_2), 3.13 (br s, 32 H, CH_2), 2.50 (br s, 32 H, CH_2), 2.21 (br s, 32 H, CH_2), 1.77–1.93 (m, 64 H, CH_2), 1.23 (t, J = 7.0 Hz, 48 H, CH_3). IR (KBr): 2965m, 2923s, 2856s, 1456m, 1371w, 1320s, 1106m, 756m, 722m cm^{-1}. Yield for Ln = Gd (87 mg, 68%). IR (KBr): 2964m, 2924s, 2848s, 1456s, 1369w, 1320s, 1102m, 757m, 724m cm^{-1}.

RESULTS AND DISCUSSION

Treatment of $Ln(acac)_3 \cdot nH_2O$ (Ln = Eu, Gd) with $Li_2(Pc)$ in TCB produced the sandwich complexes $Ln(Pc)_2$[Ln = Eu (**1**), Gd (**2**)] in moderate yields. The UV–vis spectra of the crude products obtained after chromatographic purification showed two broad bands at *ca* 640 nm and 670 nm in the Q band absorption region of phthalocyanines. The former band assignable to the species $LnH(Pc)_2$ or $[Ln(Pc)_2]^-$ diminished [2,8c] while the latter band assignable to the neutral $Ln(Pc)_2$ increased in intensity during further purification [14]. It suggested that the species $LnH(Pc)_2$ or $[Ln(Pc)_2]^-$ might be the primary products which converted slowly to the corresponding $Ln(Pc)_2$ in air.

In attempts to synthesise the substituted analogues of $Ln(Pc)_2$, we prepared the dilithium salt of 2, 3, 9, 10, 16, 17, 23, 24-octakis(pentyloxy)phthalocyanine $Li_2[Pc'(OC_5H_{11})_8]$ by treating 4,5-bis(pentyloxy) phthalonitrile (**3**) with lithium in amyl alcohol [6b]. The electronic absorption spectrum of the resulting green solution showed characteristic bands of metal phthalocyaninates [λ_{max} in $CHCl_3$: 355 nm (B band), 675 nm (Q band)]. The dilithium salt generated *in situ* was then treated with $Eu(acac)_3 \cdot nH_2O$ in refluxing TCB. The reaction gave a significant amount of the metal-free phthalocyanine $[Pc'(OC_5H_{11})_8]H_2$ with no indication of formation of the sandwich complex.

The substituted bis(phthalocyaninato)lanthanide

Scheme. 1.

(III) complexes $Ln[Pc'(R)_8]_2$ (Ln = Eu, Gd; R = OC_5H_{11}, n-C_7H_{15}) can however be prepared in good yields by treating the corresponding phthalonitriles with $Ln(acac)_3 \cdot nH_2O$ and DBU in amyl alcohol (Scheme 1). The reactions gave small amounts of metal-free phthalocyanines as the side products which were separated readily from the sandwich complexes by column chromatography and were characterised with UV–vis spectrometry {λ_{max}(nm) in $CHCl_3$: 348, 602, 636, 664 and 702 for $[Pc'(OC_5H_{11})_8]H_2$; 344, 610, 644, 672 and 708 for $[Pc'(C_7H_{15})_8]H_2$}. Satisfactory elemental analyses of these sandwich complexes could not be obtained even after repeated column chromatography and recrystallisation. As pointed out earlier [6c,15], this is quite usual for this class of compounds. Nevertheless, the new sandwich compounds were unambiguously characterised with a wide range of spectroscopic methods including ^{1}H NMR, UV–vis, near-IR, MALDI-TOF-MS and ESI-MS.

It is well documented that the sandwich complexes $Ln(Pc)_2$ can be formulated as $Ln^{3+}(Pc^{2-})(Pc^{\bullet -})$ or more precisely as $Ln^{3+}(Pc_2)^{3-}$ in which the unpaired electron delocalises in both of the Pc rings [16]. Because of the paramagnetic nature of these species, they are usually NMR silent. Recently, L'Her and coworkers have shown that by adding hydrazine hydrate (1% v/v) to solutions of lutetium sandwiches in deuterated dimethylformamide or dimethylsulfoxide, satisfactory NMR data can be obtained because the paramagnetic neutral species are reduced to the corresponding anions in which both of the macrocycles are diamagnetic dianions [6b,c]. By using a similar strategy, we could obtain ^{1}H NMR spectra of the europium complexes **5** and **7**. As these complexes are only sparingly soluble in $(CD_3)_2SO$, the spectra were measured in $CDCl_3$ and $(CD_3)_2SO$ (v/v 1 : 1) in the presence of *ca* 5% (v/v) hydrazine hydrate. Both spectra showed a broad downfield band at δ 10.64 (for **5**) or 11.06 (for **7**) due to the ring protons together with signals assignable to the protons in the side chains. ^{1}H NMR spectra of the gadolinium complexes **6** and **8** could not be obtained due to the strong paramagnetic nature of the metal centre.

The electronic absorption spectra of **5–8** were similar to those of other bis(phthalocyaninato)lanthanide(III) complexes and could be assigned similarly [6b, 7, 17]. Fig. 1 gives the UV–vis and near-IR spectra of compound **8**, which show two B bands at 329 and 355 nm, a Q band at 686 nm and two π-radical anion bands at 492 and 925 nm. Interestingly, the splitting of the B bands has rarely been observed previously [5c]. A broad near-IR absorption peaking at 1633 nm was also observed which could be attributed to an intramolecular ring-to-ring charge transfer, from dianion to radical anion [17].

The electronic spectral data for compounds **5–8** are

summarised in Table 1. The data for unsubstituted **1** and **2** are also included for comparison. It can be seen that all of the absorptions are red-shifted when substituents are introduced onto the macrocycles. For example, the Q band is red-shifted by 7–8 nm in compounds **5** and **6** or 16–19 nm in compounds **7** and **8**. It is also worth noting that the lower-energy near-IR band of the europium complexes appears at longer wavelength than that of the corresponding gadolinium complexes. The compounds **1** and **2** also give a lower energy charge transfer band compared with the Dy (1536 nm), Tm, Yb and Lu (1530 nm) analogues [17]. These are consistent with the results reported recently showing that for $Ln(Por)_2$ [18] and Ln(Pc)(Por) [19] (Por = general porphyrinato dianion), when the ionic radius of the central metal ion increases, the absorption maximum of the lower-energy near-IR band is shifted to longer wavelength.

Compounds **5–8** were also mass-measured using two newly developed desorption/ionisation techniques, namely matrix-assisted laser desorption/ ionisation (MALDI) and electrospray ionisation (ESI). Fig. 2 shows a typical positive-ion MALDI time-of-flight mass spectrum of compound **5** using pretreated all-*trans*-retinoic acid as matrix. Poly(ethylene glycol) was used as internal calibrant. Apart from the envelop of peaks originating from the poly(ethylene glycol), an intense ion signal corresponding to the intact singly-charged molecular ion was observed. Ion signals with mass-to-charge ratio less than 500 were commonly attributed to the ions derived from the matrix materials. In all cases, the molecular ion was either the most abundant high mass ion or the only high mass ion present in the mass spectrum. Because of the low resolution of the time-of-flight mass spectra, only average molecular masses can be assigned which are tabulated in Table 2.

The ESI mass spectra of compounds **5–8** were measured using a FTICR mass spectrometer with chloroform as solvent. The molecular ions were essentially the only ions present in the mass spectra. Fig. 3 displays the molecular-ion region in the spectrum of **5** in which distinct isotopic distribution can be observed. The relative abundance of the isotopic cluster is in good agreement with the simulated spectrum of $\{Eu[Pc'(OC_5H_{11})_8]_2\}^+$ as shown in the top-insert. It is therefore concluded that the observed molecular ions were monocations rather than protonated species. The mass spectral results are summarised in Table 2.

Cyclic voltammetric studies revealed that compounds **5–8** undergo one reversible oxidation and one reversible reduction. The data are listed in Table 3, which also includes the half-wave potentials ($E_{1/2}$) of related sandwich compounds for comparison. The potentials were referenced to the ferrocenium–ferrocene couple at +0.355 V relative to the saturated calomel electrode (SCE), and the reversibility was judged by comparison of the separation between the anodic and cathodic potentials at various scan rates

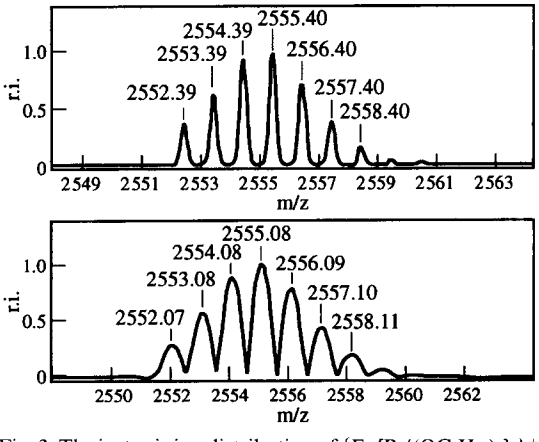

Fig. 3. The isotopic ion distribution of $\{Eu[Pc'(OC_5H_{11})_8]_2\}^+$ ($\mathbf{5}^+$) observed in the ESI mass spectrum of **5**. The top spectrum shows the corresponding simulated pattern.

with that of the ferrocenium–ferrocene internal standard [20].

It is generally believed that all of the redox processes in this class of compounds occur on the conjugated macrocyclic ligands; the oxidation state of the central metal ion does not change [6c,7,21]. Thus by incorporating electron donating groups onto the macrocycles, the compound should become more reducing and less oxidising. This is well demonstrated by the $E_{1/2}$ values of **5**–**8** obtained (Table 3). The eight pentyloxy and n-heptyl groups greatly increase the electron density in the macrocycle to roughly the same extent. It is worth mentioning that the difference between the oxidation and reduction potentials, which is a good estimate of the thermal activation energy for the conduction process in these sandwich complexes [22], remains relatively constant (*ca* 0.40 V) in this series of compounds.

(Received 1 April 1996; accepted 13 May 1996)

Abstract—The electronic spectra of aqueous Cr^{VI} solutions in the pH range 3–11 have four isosbestic points, located at 246, 293, 338 and 441 nm. These positions are independent of the total concentration of Cr^{VI}. The existence of the isosbestic points indicates that only two species are present, namely CrO_4^{2-} and $Cr_2O_7^{2-}$, and that $HCrO_4^-$ is spectrophotometrically undetectable. This conclusion is further supported by factor analysis, which gives the number of linearly independent species in solution to be two, and also by the method of spectral displacement. At the isosbestic points absorbance is linear in total Cr^{VI} concentration. In this sense Beer's law is valid, and the results can be used for analytical purposes. Copyright © 1996 Elsevier Science Ltd

Current interest in protonated oxochromium(VI) species originates in the role these species play in the corresponding mechanisms of substitution or redox reactions. It is well known [1] that replacement of an oxide ion by a hydroxide, results in a dramatic increase of both self-lability and of the lability of the other ligands. In oxidations by tetraoxoanions *via* a bridged pathway, fast protonation is a prerequisite. For oxidations by CrO_4^{2-} and/or $Cr_2O_7^{2-}$ in particular, it is important to know whether $HCrO_4^-$ is present in significant amounts or not. This is more so in biological systems, in order to understand the mutagenic action of Cr^{VI} compounds, which depends on their ability to cross the cell membrane, and to react with the components of the cell [2].

In the early literature it was believed that aqueous solutions of chromium(VI), at pH 3 to 11, in addition to CrO_4^{2-} and $Cr_2O_7^{2-}$, also contain $HCrO_4^-$. The methods used to study these systems include freezing point and conductivity measurements [3], potentiometry [4], spectrophotometry [5,4d–f], vapour pressure measurements [6], and calorimetry [7]. Reference 4f contains the bibliography up to 1960.

In none of these papers is the existence of $HCrO_4^-$ questioned, and this confidence was transferred to the textbooks and comprehensive works dealing with the subject [8]. Yet the early results do *not prove* the existence of $HCrO_4^-$; they are merely consistent with it, but they can be interpreted without assuming its existence. Furthermore Michel and Machiroux [9] failed to find direct Raman evidence for the existence of $HCrO_4^-$, and came to the conclusion that in aqueous Cr^{VI} solutions, at pH 3–11, there is no $HCrO_4^-$, that only two species are present in detectable amounts, namely $Cr_2O_7^{2-}$ and CrO_4^{2-}, related to each other through the equilibrium:

$$2CrO_4^{2-} + 2H^+ \rightleftharpoons Cr_2O_7^{2-} + H_2O \quad \log K_1 = 14.85 \tag{1}$$

the value of K_1 being given at zero ionic strength and 25°C.

On the basis of these data estimates [10] of the percentages of various species, which include $HCrO_4^-$, were questioned. Moreover, Michel and Cahay [11] extended their investigation to more acidic solutions, up to 12 M HNO_3 and again, they found no evidence for protonated species.

Hence the matter of the existence of $HCrO_4^-$, in considerable equilibrium amounts, cannot be considered settled, and this is what the present paper deals with. We tried to detect $HCrO_4^-$ using an assortment of sensitive UV–vis spectrophotometric techniques, and it was found, that its concentration, instead of being as high as 99.6% (pH 4, $[Cr^{VI}]_{total} = 10^{-6}$ M)or

* Author to whom correspondence should be addressed.

91.05% (pH 4, $[Cr^{VI}]_{total} = 10^{-3}$ M) as estimated [10], it is within experimental error zero. The affinity of CrO_4^{2-} and $Cr_2O_7^{2-}$ for protons, and for that matter of the protonated forms as well for a second proton, is extremely small.

EXPERIMENTAL

The solutions were prepared using proanalysis $Na_2Cr_2O_7$ (Mallinckrodt) and doubly distilled water. Air was excluded by purging with argon, passed through a NaOH solution in order to avoid formation of carbonates, which interfere with the spectrum at short wavelengths [4]. The pH was adjusted with NaOH or $HClO_4$ and measured with an E520 Metrohm–Herisau pH-meter. Electronic spectra were obtained with a Hitachi U-2000, in quarts cell.

RESULTS AND DISCUSSION

Among the concentrations of CrO_4^{2-}, $HCrO_4^-$ and $Cr_2O_7^{2-}$, at different pH values, there is no linear relation of the form:

$$\alpha[CrO_4^{2-}] + \beta[HCrO_4^-] + \gamma[Cr_2O_7^{2-}] = 0$$

α, β, γ being pH-independent constants, not all zero [12]. Hence, if all three species were contributing to light absorbance at different wavelengths, the corresponding matrix would have rank three [13]. However, factor analysis [14] shows that there are only two significant elements in the diagonalized matrix, i.e., that the rank is two. Since CrO_4^{2-} and $Cr_2O_7^{2-}$ are known to exist at high and low pH values, respectively, we must conclude that these are the only species present; $HCrO_4^-$ is not present in measurable amounts, even at the pH values where it was believed to dominate [10].

The spectra at different pH values and different total Cr^{VI} concentrations exhibit four well-defined isosbestic points at 246, 293, 338, and 441 nm (Fig. 1). The spectra in this figure were obtained at constant ionic strength (1 M $NaClO_4$). If in addition to the total concentration and the pH, a third variable is changed, namely ionic strength, slightly different spectra are obtained, but the change in the environment does not seem to affect the electronic transitions themselves, nor the positions of the isosbestic points.

It is seen in Fig. 1 that the position of the isosbestic points does not depend on the total concentration of Cr^{VI} or pH.

The absorbance at the isosbestic points at various totals Cr^{VI} concentrations are given in Table 1. The corresponding average absorptivities per chromium equivalent are $\varepsilon_{441} = (2.45 \pm 0.05) \times 10^2$, $\varepsilon_{338} = (1.59 \pm 0.1) \times 10^3$, $\varepsilon_{293} = (1.34 \pm 0.08) \times 10^3$, $\varepsilon_{246} = (2.19 \pm 0.1) \times 10^3$. For at least three orders of magnitude in the concentration, at the isosbestic points, Beer's law is valid, as indicated by the constant values of the ratio

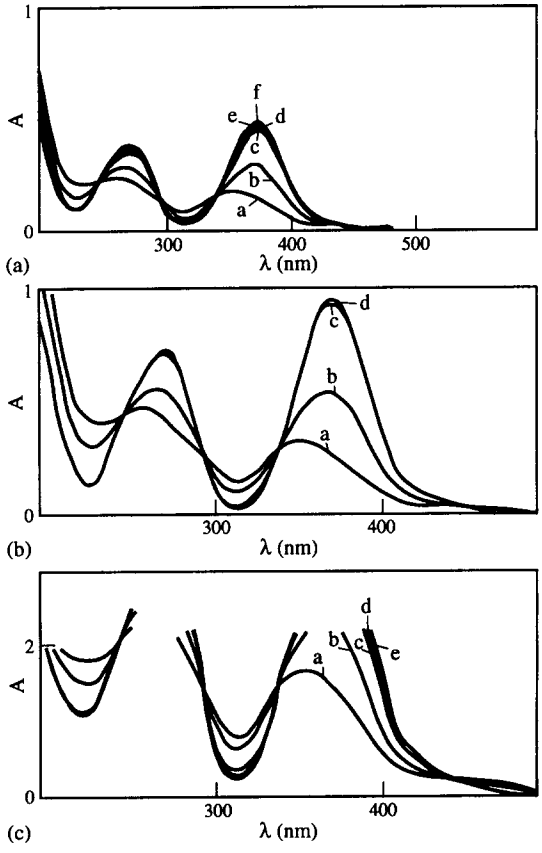

Fig. 1. Spectra (Absorbance) of Cr^{VI} solutions at various total Cr^{VI} concentrations and pH values, at constant ionic strength 1 M $NaClO_4$, 28°C. (a) $[Cr^{VI}]_{total} = 1.0 \times 10^{-4}$ M, pH, a:4, b:5, c:6, d:7, e:8, f:9; 1 cm cell. (b) $[Cr^{VI}]_{total} = 1.0 \times 10^{-3}$ M, pH, a:3, b:5, c:7 8, d:9; 0.2 cm cell. (c) $[Cr^{VI}]_{total} = 1.0 \times 10^{-2}$ M, pH, a:3, b:5, c:7, d:8, e:9; 0.1 cm cell.

$A_{isosb}/[Cr^{VI}]_{total}$, and this can obviously be used analytically; knowledge of the distribution among species is not necessary.

The behaviour at the isosbestic points should be contrasted with that at the rest of the spectrum, where Beer's law is not valid.

For a long time, the appearance of isosbestic points was considered to be proof for the existence of only two absorbing species in a system [15]. Later, this assumption was questioned, but our system is not among the special cases examined [16]. The appearance of the four isosbestic points, combined with the factor analysis results, must be taken as strong evidence for the existence of only two species indeed.

However, for further support we applied the method of spectral displacement, developed by T. Nowicka-Jankowska [17]. According to this method, if we take the linear combinations of absorbances at two wavelengths, differing by a constant $\Delta\lambda$:

$$\xi_{1,2} = \alpha A_1 + \beta A_2$$

Table 1. Absorbances[a] at the four isosbestic points of Cr^{VI} solutions in the pH range 3–11. In parenthesis Abs/$[Cr^{VI}]_{total}$

Total Cr^{VI} (M)	A_{441}	A_{338}	A_{293}	A_{246}
1.6×10^{-5}	0.004 (250)	0.025 (1562)	0.022 (1375)	0.034 (2125)
6.6×10^{-5}	0.016 (242)	0.013 (1712)	0.087 (1318)	0.140 (2121)
1.0×10^{-4}[b]	0.024 (240)	0.154 (1540)	0.125 (1250)	0.220 (2200)
6.0×10^{-4}	0.150 (250)	1.025 (1708)	0.825 (1375)	1.450 (2416)
1.0×10^{-3}[b]	0.24 (240)	1.53 (1520)	1.25 (1250)	2.17 (2170)
1.0×10^{-2}[b]	2.5 (250)	15.0 (1500)	14.6 (1460)	21.2 (2120)

[a] All measurements but the last were made with 1 cm quartz cells at 28°C. The concentrated solutions (10^{-2} M) were measured in 0.1 and 0.2 cm cells, respectively and the values were multiplied by 10 and 5 to be comparable with the others.

[b] Ionic strength 1 M ($NaClO_4$).

the new curve should also have isosbestic points. What this means in practical terms is that if we displace the spectra by a given $\Delta\lambda$ (positive or negative) and then take the sum or difference or any linear combination of the original spectra with the displaced ones, if there is a hidden peak or shoulder, this combination *will not* have isosbestic points. Generally, the linear combination of the displaced spectra with the original one may:

(1) Still have isosbestic points, which is strong evidence that the original isosbestic points were real, and that only two species exist;

(2) The new curves cross each other but not at common points, which indicates that the original isosbestic points were coincidental;

(3) The curves do not cross each other. In this case there is no new information.

In our case we varied three experimental variables (pH, total Cr^{VI}, ionic strength) and scanned the entire spectrum, which was recorded in digital form, every 2 nm, applying the method with different $\Delta\lambda$'s, and coefficients α and β. In fact, we used 60 values of $\Delta\lambda$, from -30 to $+30$ nm and a random choice of α and β; this essentially means an infinite number of combinations. In all cases the isosbestic points either persisted or there was no crossing of the curves.

The Cambridge Structural Database (1989) contains no $HCrO_4^-$ entry, and Gmelin gives only one relevant compound, $KHCrO_4^-$, assumed to be present in mixed crystals with $KMnO_4$. This, combined with the Raman evidence and the evidence presented here, lead to the conclusion that hydrogen chromate is a strong acid, and by analogy with the H_2SO_4/HSO_4^- couple, H_2CrO_4 is expected to be even stronger; this is probably the reason why these species were not detected.

The fact then that $HCrO_4^-$ was not observed directly by modern Raman techniques and in the present investigation indicate the presence, in equilibrium mixtures, of CrO_4^{2-} and $Cr_2O_7^{2-}$ only, unless, in the case of the spectroscopic data, it is accepted that $Cr_2O_7^{2-}$ and $HCrO_4^-$ have exactly the same spectrum, which is very unlikely [18]. The hypothetical O_3CrOH has C_{3v} symmetry, the same as the O_3CrO chromophore of dichoromate, and resemblance is expected, but not the identity required to explain the accuracy and the persistence of the position of the isosbestic points.

On a more general, and perhaps more important basis, it is noted that the rate laws of many substitution and redox reactions with oxoanions [1], including those of Cr^{VI}, allow no doubt for the existence of protonated species, not however necessarily in quantities detectable by Raman and or UV–vis spectroscopic techniques. Yet, even with a small quantity of protonated species (equilibrium or steady state) the corresponding reaction is greatly accelerated, and the proton catalyzed term becomes comparable with the non-catalyzed one. The increase in lability due to the protonation must be orders of magnitude greater than that estimated on the basis of the hitherto accepted equilibrium quantities of $HCrO_4^-$.

Saito and Sasaki point out [19] that if the rate constants for substitution reactions for Cr^{VI} on one hand, and Mo^{VI}, W^{VI} on the other, are compared on the basis of the rate laws [20].

$$\text{Rate} = k[HCrO_4^-][X][H^+] \quad (2)$$

$$\text{Rate} = k'[MO_4^{2-}][X][H^+] \quad M = Mo, W \quad (3)$$

the conclusion is reached that $HCrO_4^-$ is much less reactive than MoO_4^{2-} or WO_4^{2-}. However, k in (2) is actually $k''K[H^+]$, where K the equilibrium constant for the formation of $HCrO_4^-$. The small reactivity of $HCrO_4^-$ may be due to the small value of K; this is essentially our claim. A common mechanism for the Cr, Mo, and W oxoanions [20] (possibly concerted) then becomes possible.

Similar remarks can probably be made for oxygen exchange, and oxidation reaction as well.

Acknowledgements—The authors wish to thank Mr N. Liadakis who prepared the P.C. software for the application of the spectral displacement method.

(Received 8 February 1996; accepted 13 May 1996)

Abstract—The title complex has been synthesized and characterized by X-ray diffraction. The Ag^I atom is in a distorted square pyramidal geometry with two pyridyl nitrogen atoms, one alkylamine nitrogen atom from TLA and two oxygen atoms from the nitrate group which is coordinated as a bidentate ligand. There are two different independent configurations in the same unit cell, and the internuclear distance Ag(1) ··· Ag(2) is 9.246 Å. The solution behaviors of $Ag(TLA)NO_3$ have been further studied with ^1H NMR. The two β-protons on each pyridine are resolved from each other and are assigned to the two peaks at 7.50 and 7.08 ppm. The methene protons and methyl protons are shifted slightly upfield compared with those of free TLA due to the formation of coordinate bonds of $N_{pyridyl}$ with Ag^I atom. Keywords: silver(I) complex; synthesis; crystal structure; tris(6-methyl-2-pyridylmethyl)amine; ^1H NMR; spectroscopic study.

Studies of mononuclear and polynuclear complexes have attracted much interest in recent years. The main reason is probably that many metalloproteins and enzymes have multi-metal sites which are essential for their biological and catalytic functions. Thus, the syntheses, and crystal structures of new complexes are of significance for understanding the biological phenomena and exploiting artificial models. The tripodal tetradentate ligands including nitrogen atoms are versatile and useful for assembly new molecules, because they can be coordinated to many transition metal ions to form new compounds as biomimetic systems. For instance, the complexes of iron with tris(2-pyridylmethyl)amine (TPA) have been studied as the models of methyl monooxydase (MMO) [1,2], copper complexes with the same ligands, as the models of copper protein [3,4], and nickel complexes, as the models of carbon monoxide dehydrogenase (CODH) [5,6]. It is reported that some Ag^I complexes show excellent antimicrobial activities against some bacteria [7]. More recently, we have synthesized some new complexes by using tripodal ligands [8,9]. In order to extend our knowledge in this field, we now report the synthesis, spectroscopic properties and X-ray crystal structure of the complex of $AgNO_3$ with [tris(6-methyl-2-pyridylmethyl)]amine (TLA), which is a potential tripodal tetradentate ligand.

EXPERIMENTAL

Materials and general methods

All of the starting materials and solvents for synthesis were of analytical grade as purchased commercially and used without further purification. IR absorption spectra were recorded on a 170SX (Nicolet) FT-IR spectrophotometer using KBr discs. Elemental analysis was taken on a Perkin–Elmer ana-

Structure 1. TLA ligand.

lyzer model 240. ^{1}H NMR was recorded on a Bruker AC-P200 spectrometer (200 MHz, 25°C) in CD_3OD. Chemical shifts (in ppm) are referenced to the residual protonic solvant peaks.

Synthesis

The TLA ligand was prepared by using the published procedure [10]. A solution of $AgNO_3$ (0.170g, 1 mmol) in 50 cm^3 absolute methanol was added to a stirred solution of TLA (0.40g, 1.2 mmol) in 60 cm^3 absolute methanol. After stirring for 1–1.5 h, the mixture was filtered and then covered with a piece of black material (to avoid light). By slow evaporation of the filtrate at room temperature, colourless crystals of $Ag(TLA)NO_3$(1) suitable for X-ray structure determination were obtained. Found: C, 50.0; H, 5.0; N, 14.0. Calc. for $C_{21}H_{24}N_5O_3Ag$: C, 50.2; H, 4.8; N, 13.9%.

Crystallographic studies

The crystal and intensity data were obtained from a crystal mounted on a glass fibre and using an Enraf–Nonius CAD-4 diffractionmeter equipped with a graphite monochromator. The determination of unit cell parameters and the data collection were performed with Mo–k_α radiation ($\lambda = 0.71073$ Å). Unit cell dimensions were obtained by least-square refinements of setting angles of 25° reflections. The structure was solved by direct methods (MULTAN 82) [11]. The metal atoms were located from an E-map. The location of the other non-hydrogen atoms was achieved by successive difference Fourier syntheses. Final refinement by full matrix least-square methods was carried out with anisotropic thermal parameters for non-hydrogen atoms. All the calculations were performed on a PDP 11/44 computer using the SDP-PLUS program systems [12]. The crystallographic data and data collection parameters for the complex 1 are summarized in Table 1.

RESULTS AND DISCUSSION

Crystal structure of $Ag(TLA)NO_3$

A perspective view of 1 and a packing diagram are shown in Figs 1 and 2, respectively. Selected bond lengths and bond angles are given in Table 2.

It can be seen from Fig. 1 that in the same unit cell there are two independent metal configurations which are somewhat different. Each Ag^I atom lies in the distorted square pyramidal environment composed of one amine nitrogen atom [N(1) or N(5)], two pyridyl nitrogen atoms [N(2) and N(3) or N(6) and N(7)] and two oxygen atoms [O(11) and O(12) or O(21) and O(22)] from the nitrate. The nitrogen atoms of two pyridyl groups from TLA [one includes N(2) and N(6), the other includes N(3) and N(7)] coordinate to the silver(I) atoms. One of the 2-pyridylmethyl arms in the potentially tetradentate TLA ligand remains uncoordinated to the metal centre. The distances Ag(1)–N(1) and Ag(2)–N(5) are 2.462(11) and 2.482(10) Å, respectively, and they are longer than normal ones. This indicates a weaker interaction between silver(I) and the tertiary nitrogen [13]. The distances between Ag(1)–N(3) (2.466 Å) or Ag(2)–N(7) (2.504 Å) are longer than Ag(1)–N(2) (2.346 Å) or Ag(2)–N(6) (2.331 Å), respectively. This may be due to the steric effect of the coordinated nitrate ligand which pushes away the coordinated pyridyl group [N(3), C(21), C(22), C(23), C(24), C(25)] or [N(7), C(51), C(52), C(53), C(54), C(55)] from the nitrate group [N(11), O(11), O(12), O(13)] or [N(12), O(21), O(22), O(23)], respectively. The nitrate group which lies in the *trans*-position to the coordinated pyridyl groups is coordinated to the Ag^I atom as a bidentate ligand with Ag(1)–O(11) = 2.483(13) Å, Ag(1)–O(12) = 2.605(12) Å or Ag(2)–O(21) = 2.411(9) Å, Ag(2)–O(23) = 2.686(10) Å, and these are normal coordinated bonds. However, there are no chemical bonds formed between the Ag(1) or Ag(2) and the pyridyl nitrogen of the other pyridyl group which

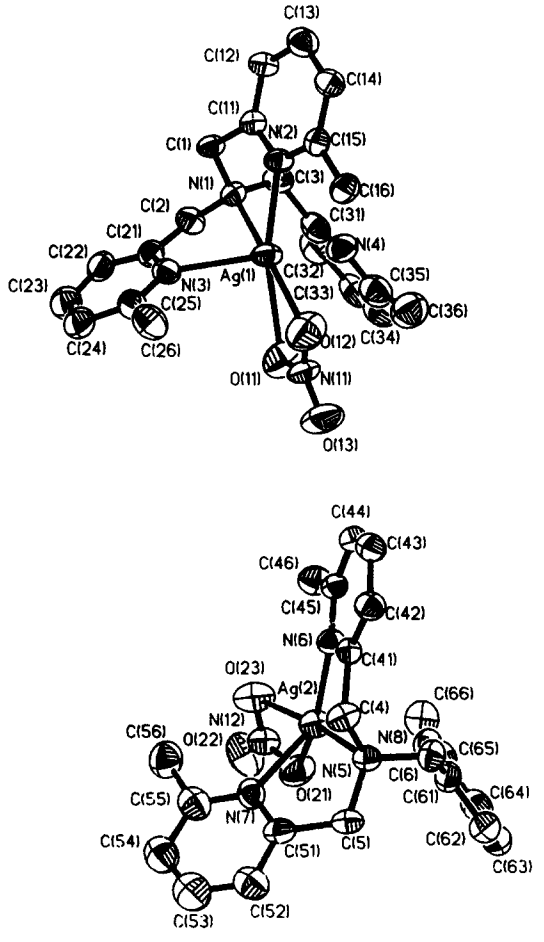

Fig. 1. ORTEP view and labeling scheme for $Ag(TLA)\cdot NO_3$.

includes N(4) or N(8), and the distances of Ag(1)···N(4) and Ag(2)···N(8) are 2.699 Å and 2.686 Å, respectively. The distance of O(13)···C(44) is 3.253 Å, and there is no interaction between the two atoms and the distance of Ag(1)···Ag(2) is 9.246 Å. Apparently there are two kinds of different independent molecular structures in the same unit cell. The Ag^{I} atoms are situated out of the coordinated pyridyl planes 1 [C(11), C(12), C(13), C(14), C(15), N(2)] and plane 2 [C(21), C(22), C(23), C(24), C(25), N(3)] or 4 [C(41), C(42), C(43), C(44), C(45), N(6)] and 5 [C(51), C(52), C(53), C(54), C(55), N(7)] by 0.43 Å or 0.33 Å. The dihedral angles between planes 1 and 2 or planes 4 and 5 are 50.03 or 54.36 , respectively. The dihedral angles between planes 2 and 3 [C(31), C(32), C(33), C(34), C(35) N(4)] or planes 5 and 6 [C(61), C(62), C(63), C(64), C(65), N(8)] are 81.46 or 79.90 , respectively.

Spectroscopic studies

In the IR spectra of $Ag(TLA)NO_3$, the broad bands appearing at about 3434 cm^{-1} imply the existence of water, but no water molecule is coordinated to Ag^{I} in the crystal structure. The strong peaks at 1596, 1575, 1462 cm^{-1} are attributed to the vibration of pyridyl rings. There are two new stronger absorption bands of 1 at 1384 and 1309 cm^{-1} which are assigned to the nitrate group [14]. ^{1}H NMR data and spectra are shown in Table 3 and Fig. 3, respectively. From the ^{1}H NMR data of complex 1, it can be seen that the chemical shift appearing at 7.65 ppm implies the py-γ-H. The two β-protons on each pyridyl ring are

Table 3. The ^1H NMR data of complex 1 and assignment

Chemical shift (ppm)	py–β–H	py–γ–H	$-CH_2-$	$-CH_3-$
TLA	7.22, 7.18	7.64	3.97	2.57
$Ag(TLA) \cdot NO_3$	7.50, 7.08	7.65	3.80	2.47

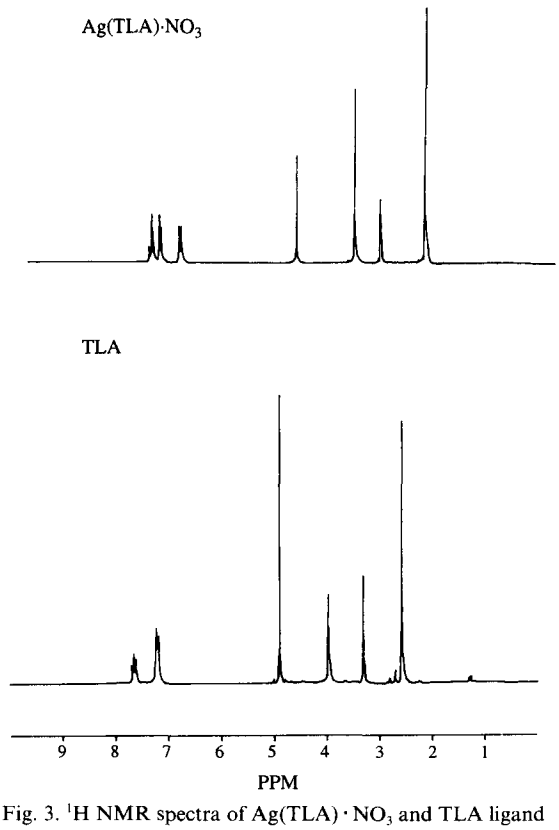

Fig. 3. ^1H NMR spectra of $Ag(TLA) \cdot NO_3$ and TLA ligand in CD_3OD.

resolved from each other and are assigned to the two peaks at 7.50 and 7.08 ppm. The proton number ratio of the three pyridyl-H peaks at 7.65, 7.50 and 7.08 ppm is 1 : 1 : 1. The chemical shift of the methylene potons is at δ 3.80 ppm and that of methyl protons is at δ2.47 ppm, and the proton number ratio of the two peaks is 2 : 3, and they are shifted slightly upfield compared with those of TLA because of the formation of coordination bonds of $N_{pyridyl}$ with Ag^I atom.

Supplementary material—Full details of the crystal data and data collections, thermal parameters, bond distances and angles, mean plane and dihedral angles between the planes, listings of observed and calculated structural factors for complex 1 are available from the authors on request.

Acknowledgements—The project was financially supported by the Elementary Organic Chemistry Institute Key laboratory and the National Natural Science Foundation of China.

(Received 9 January 1996; accepted 13 May 1996)

Abstract—The complex $[Cu_2(bpy)_2(C_2O_4)(H_2O)_2][Cu(bpy)(C_2O_4)](NO_3)_2$ has been synthesized by electrophilic attack of $[Cu(bpy)(H_2O)_2]^{2+}$ on $K_3[Cr(C_2O_4)_3]$ (where bpy stands for 2,2′-bipyridyl). The crystal structure of the complex consists of a binuclear species $[Cu_2(bpy)_2(C_2O_4)(H_2O)_2]^{2+}$ and a mononuclear species $[Cu(bpy)(H_2O)(C_2O_4)]$. The temperature dependences of the magnetic susceptibilities of the complex have been studied in the 4.2–300 K range, giving the exchange integral $J = -340\ cm^{-1}$, indicating rather strong antiferromagnetic interaction between the copper(II) ions within the binuclear unit. Copyright © 1996 Elsevier Science Ltd

Keywords: trinuclear copper complex; crystal structure; magnetic properties.

Polymetallic complexes with extended bridged structures are of current interest due to spin-exchange and charge transfer between metal ions and the domain of metalloenzymes and novel magnetic materials [1,2].

The oxalate has been proved to be an appropriate bridging unit to design magnetic centers and many oxalato-bridged complexes have been reported [1,3–7]. However, to our knowledge, only a few crystal structures showing this binding feature of oxalates have been determined by X-ray diffraction methods. In this paper, we report the synthesis, characterization and structural and magnetic study of a new trinuclear copper complex of formula $[Cu_2(bpy)_2(C_2O_4)(H_2O)_2][Cu(bpy)(C_2O_4)](NO_3)_2$, where bpy refers to 2,2′-bipyridyl. Furthermore, we have attempted to verify the reaction mechanism of electrophilic attack of the $[Cu(bpy)(H_2O)_2]^{2+}$ ion on the coordinated oxalate ligands in tris(oxalato)chromate(III) ion which emerged mainly from the work of Goswami *et al.* [7, 8] and Basok *et al.* [9].

EXPERIMENTAL

Materials

$K_3[Cr(C_2O_4)_3]$ and $Cu(bpy)(NO_3)_2 \cdot 3H_2O$ were prepared by the literature methods [10,11]. 2,2′-bipyridine(bpy) was of analytical grade.

Synthesis of $[Cu_2(bpy)_2(C_2O_4)(H_2O)_2][Cu(bpy)(C_2O_4)](NO_3)_2$

To 420 mg (1 mmol) of $Cu(bpy)(NO_3)_2 \cdot 3H_2O$ stirred in 10 cm^3 of H_2O was added a solution of 163 mg (0.33 mmol) of $K_3[Cr(C_2O_4)_3]$ in 10 cm^3 of H_2O. Sky-blue single crystals suitable for X-ray investigations were obtained by slow evaporation at room temperature of the mixed aqueous solutions over 2 weeks. (Found: C, 40.6; H, 2.5; N, 11.4; Cu, 19.0. Calc. for $[C_{34}H_{28}N_8O_{16}Cu_3]$: C, 41.0; H, 2.8; N, 11.3; Cu, 19.1%.)

Measurements

Elemental analyses for carbon, hydrogen and nitrogen were carried out on Perkin–Elmer elemental analyser model 240. Metal contents were determined by EDTA titration. Variable temperature magnetic susceptibilities were measured on a vibrating sample magnetometer Model CF. Diamagnetic corrections were made with Pascal's constants for all the constituent atoms, and the magnetic moments were calculated by the equation $\mu_{eff} = 2.828\ (\chi_M T)^{1/2}$.

X-ray structure determination

A blue single crystal of $[Cu_2(bpy)_2(C_2O_4)(H_2O)_2][Cu(bpy)(C_2O_4)](NO_3)_2$, having the approximate dimensions $0.2 \times 0.3 \times 0.3$ mm, was mounted on a glass fibre. Determination of the unit cell and data collection were performed with MoK_α radiation ($\lambda = 0.71074$ Å) on a CAD4 diffractometer equipped with a graphite monochromator. A total of 4205 independent reflections was collected by the $\omega - 2\theta$ scan technique in the range $2^\circ \leqslant \theta \leqslant 23$, from which 2498 reflections [$I \geqslant 3\sigma(I)$] were corrected for Lorentz and Polarization factors.

The complex crystallizes in the monoclinic space group C2/c with $a = 21.700(4)$, $b = 10.446(3)$, $c = 16.005(2)$ Å and $\beta = 95.63(1)^\circ$, $V = 3610(2)$ Å^3, $Mr = 995.27$, $Z = 4$, $Dx = 1.839$ cm^{-2}, F(000) = 2012.

The structure was solved by direct methods (MULTAN 82). The copper atom positions were located from an E-map. The other non-hydrogen atoms were determined with successive difference-Fourier syntheses. The final refinement by the full-matrix least-squares method with anisotropic thermal parameters for the non-hydrogen atoms converged with the unweighted and weighted agreement factors 0.050 and 0.053, respectively. The highest peak in the final difference Fourier map had a height of 0.96 eÅ^{-3}. All calculations were performed on a PDP 11/44 computer using the SDP-PLUS program system. The related bond lengths and angles for the complex are given in Table 1.

RESULTS AND DISCUSSION

The crystal structure of the complex

The crystal structure consists of a binuclear species $[Cu_2(bpy)_2(C_2O_4)(H_2O)_2](NO_3)_2$ and a mononuclear species $[Cu(bpy)(C_2O_4)]$. A sketch of the unit cell is shown in Fig. 1. A perspective view of $[Cu_2(bpy)_2(C_2O_4)(H_2O)_2]^{2+}$ is shown in Fig. 2. The $[Cu_2(bpy)_2(C_2O_4)(H_2O)_2]^{2+}$ ion is centrosymmetric, with the symmetry centre at the mid-point of the C(1)—C(1)′

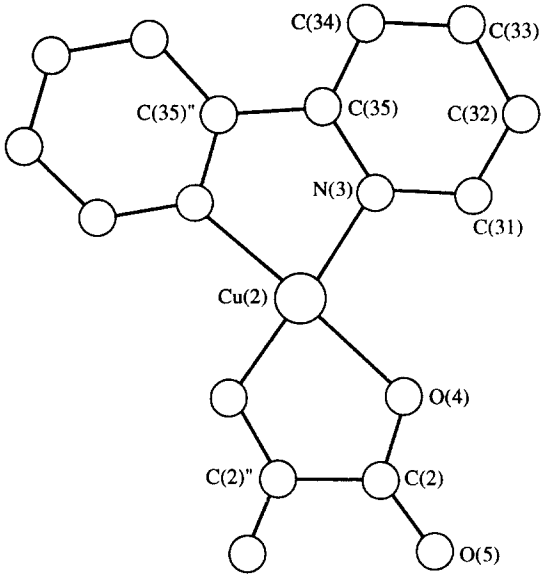
bond. The coordination polyhedron of Cu(1) is formed by two oxygen atoms O(1), O(2) of $C_2O_4^{2-}$, two nitrogen atoms N(1), N(2) of bpy and O(3) of H_2O. The Cu(1) is five coordinate and lies only 0.138 Å away from the least-squares plane through the atoms N(1), N(2), O(1), O(2). The in-plane Cu—O bond distances average 1.97(8) Å and Cu—N bond distances are 1.98(9) Å and 1.97(1) Å, respectively, which are in the normal range. The Cu(1)—O(3) bond distance is 2.247 Å. Thus, the coordination geometry around the copper(1) ion can be described as a distorted tetragonal pyramid.

A perspective view of the mononuclear species is shown in Fig. 3. In $[Cu(bpy)(C_2O_4)]$, copper(2) is four coordinate with a square planar environment: from two oxygen atoms O(4), O′(4) from $C_2O_4^{2-}$ and two nitrogen atoms(s) N(3), N′(3) from bpy. Copper(2) lies on a 2-fold axis and on the least-squares plane though the N(1), N(2), O(1), O(2). The in-plane Cu—O and Cu—N bond distances average to 1.91(8) Å and 1.95(2) Å which are the normal values. The complex $[Cu_2(bpy)_2(C_2O_4)(H_2O)_2][Cu(bpy)(C_2O_4)](NO_3)_2$ was synthesized by electrophilic attack of $[Cu(bpy)(H_2O)_2]^{2+}$ on the coordinated oxalate ligands of the tris(oxalato)chromate(III) ion. Mechanistic studies of this type have been reported [7–9]. In line with these studies, the reaction scheme shown below can be envisaged for the formation of the title compound.



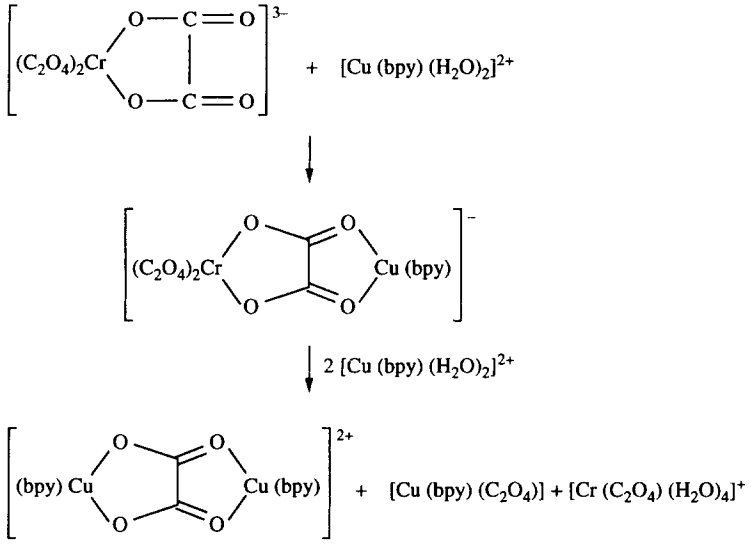


Fig. 3. A perspective view of $[Cu(bpy)(C_2O_4)]$.

Magnetic properties

Variable-temperature susceptibility data in the range 4.2–300 K were collected for the title complex. The X-ray structure analysis has shown that binuclear $[Cu_2(bpy)_2(C_2O_4)(H_2O)_2]^{2+}$ is present in the title complex, in which the two copper ions are bridged by oxalate. The other copper ions in $[Cu(bpy)(C_2O_4)]$ appear to be essentially isolated. Therefore we tried to fit the magnetic data to a theoretical expression (Eq. (1)) based a model which takes into account exchange interaction within the $[Cu_2(bpy)_2(C_2O_4)(H_2O)_2]^{2+}$ unit and neglects interactions involving the remaining copper ion:

$$\chi_M = \frac{2Ng^2\beta^2}{KT}\left[3+\exp\left(\frac{-2J}{KT}\right)\right]^{-1} + \frac{N\beta^2g^2}{4KT}. \quad (1)$$

χ_M denotes the susceptibility per trinuclear complex, the second term denotes the contribution of

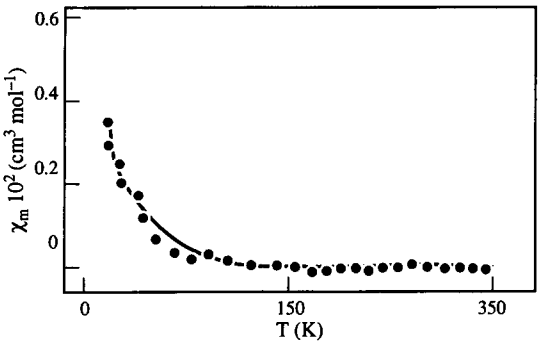

Fig. 4. Temperature variation of the magnetic susceptibility of complex. This curve was calculated using Eq. (1).

the copper ion in mononuclear species [Cu(bpy)$(H_2O)(C_2O_4)$] and the remaining symbols have their usual meanings. As shown in Fig. 3, good fits to experimental data were obtained for $J = -340$ cm^{-1}, $g = 2.12$. The agreement factor F defined here as $F = \Sigma[(\chi_M)_{obs} - (\chi_M)_{calc}]^2/(\chi_M)_{obs}$ is then equal to 1.1×10^{-4}.

For the binuclear species $[Cu_2(bpy)_2(C_2O_4)(H_2O)_2]^{2+}$ the coordination geometry around each copper(II) ion is approximated to square pyramidal. The Cu—oxalato—Cu core is almost planar. In this 4+1 environment, the Cu^{II} unpaired electron is described by a d_{xy} type orbital pointing from the metal toward the four nearest neighbours in an antibonding fashion [12, 13]. This coordination geometry is the most favourable to achieve a strong antiferromagnetic interaction through the oxalato bridge since the magnitude of the antiferromagnetic contribution, related to the square of the overlap between the magnetic orbitals centered on each Cu^{II} ion, is essentially governed by their delocalization onto the oxygen atoms of the oxalato bridge [13].

(Received 8 December 1995; accepted 15 April 1996)

Abstract—Ten new chiral complexes of optical Schiff base ligand (NaHL) derived from D-camphor-β-sulfonic acid and *o*-aminophenol with La^{III}, Pr^{III}, Nd^{III}; Sm^{III}, Eu^{III}, Gd^{III}, Tb^{III}, Dy^{III}, Ho^{III} and Er^{III} have been synthesized and characterized by elemental analysis, molar conductance, XPS, fluorescence, IR, electronic spectra and magnetic susceptibility measurements and thermal (TG,DTA,DTG) methods. Their dominant conformers were determined from CD spectra and supported by ^{1}H NMR data. Copyright © 1996 Elsevier Science Ltd

Keywords: lanthanide; complexes; chiroptical; Schiff base; D-camphor-β-sulfonic acid; preparation.

In our earlier paper,[1] we have reported the preparation and properties of several chiral lanthanide(III) complexes of D-camphor-β-sulfonic acid. The paper continues in that direction and as part of our studies on the coordination chemistry of chiral lanthanide(III) complexes we describe here the synthesis and discussion of some of these complexes derived from D-camphor-β-sulfonic acid.

EXPERIMENTAL

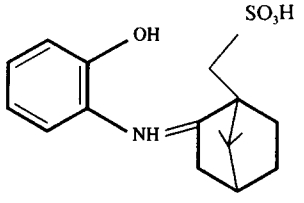
Methods and materials

The chemical reagents used were of AR grade and employed without further purification. Lanthanide(III) perchlorate were made from the oxide and perchloric acid.

Preparation of the ligand (NaHL)

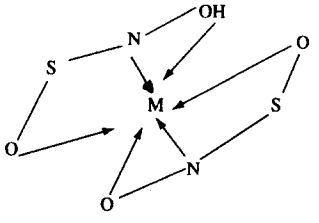
The ligand (NaHL) were isolated as the sodium salt by boiling a mixture of D-camphor-β-sulfonic acid, *o*-amoinophenol and NaOH under reflux (1 : 1 : 1 molar ratio) in dry MeOH. The product gave satisfactory elemental analysis, IR and ^{1}H NMR spectra.

Preparation of the complexes



The same synthesis method for the complexes was adopted. In a typical reaction, an EtOH solution of the lanthanide(III) perchlorate and the Schiff base ligand in 1 : 2 molar ratio was stirred for 2 h followed by concentration to small volume and cooled, whereupon the product precipitated. It was filtered off, washed with cooled EtOH followed by Et_2O and dried *in vacuo*.

Characterization of the complexes



Lanthanide, C, H, N and S contents of the ligand and complexes were estimated by standard procedures. Molar conductance values at room temperature were measured in 10^{-3} M MeOH solution using a DDS-IIA molar conductor. Room-temperature magnetic susceptibility measurements were made on solid samples by the Guoy method using $Hg[Co(CNS)_4]$ as calibrant. IR spectra were recorded

* Author to whom correspondence should be addressed.

in CsI pellets using an NIC-5DX spectrophotometer in the region 200–4000 cm^{-1}. Electronic spectra were recorded on a DJ-240 UV–vis spectrophotometer with 10^{-3} M solutions of the complexes in MeOH. Fluorescence spectra of the complexes in MeOH solution were obtained using an X-ray 3070E fluorescence spectrophotometer. The X-ray photoelectron spectra were measured on a PHI-550 spectrometer using Mg-K_α radiation. The samples were finely pulverized and set on a gold holder as thin disks. The X-ray gun operated at 15 KV and 20 mA taking C1s binding energy (284.8 eV) as a standard. The background pressure during the measurements was lower than 10^{-6} Pa. All spectra were recorded using the same spectrometer parameters of 20 eV pass energy and 6 mm slit width. The peak areas and peak positions for the measured BE value is ± 0.05 eV. The ^1H NMR spectra were measured on a Bruker AC 80 spectrometer using DMSO-d_6 solvent. CD spectra were obtained at 20°C with a Cary model 60 spectroplarimeter with a CD model 6001 accessory. Thermal analysis were made under nitrogen between room temperature and 800°C using a thermoflex Q-1500D meter.

ligand

bonding model

RESULTS AND DISCUSSION

Physical and analytical data for the trivalent lanthanide(III) complexes are given in Table 1. The complexes have the general formulae [La(HL)L], where Ln = La, Pr, Nd, Sm, Eu, Gd, Tb, Dy, Ho and Er. The complexes are insoluble in ether, petroleum and benzene, moderately soluble in chloroform, dichloromethane and THF and soluble in methanol, ethanol, acetone, DMSO and water. The complexes are air stable and can exist in alkazid solution even in strong basic aqueous solution such as 6 M NaOH to form a clear yellow solution and in acidic solution such as concentrated hydrochloride acid to form a clear red solution. Λ_M values in methanol solution (concentration range $0.8–1.0 \times 10^{-3}$ M, Table 1) indicate that the complexes behave as non-electrolytes.[2]

IR spectra

The main IR bands with their tentative assignments are listed in Table 2. For the complexes several additional bands are present, indicative of an unneutralized coordinated phenolic OH group. The bands at 3370 cm^{-1} in the ligand due to phenolic ν(OH) group has shifted up to *ca* 3400 cm^{-1} in the complexes. The ν(C—O) mode coupled with the δ(OH) mode of the phenolic OH group are observed at 1400 cm^{-1}, which is some broadened possibly due to coordination. While the ν(C=N) band at 1639 cm^{-1} has shifted down to 1600 cm^{-1} in the complexes, indicating participation of the azomethine nitrogen[3,4] in the complexation. Two stretching vibrations of —SO_3—, $\nu_{as}(SO_3)$ and $\nu_s(SO_3)$, in the spectra of the complexes are observed at *ca* 1205 and 1143 cm^{-1}, a higher frequency by *ca* 10 cm^{-1} and lower by 30 cm^{-1}, respectively, compared with the bands at 1215 and 1170 cm^{-1}, which assigned are to $\nu(SO_3)$ of the ligand, NaHL. Bands assignable to ν(Ln—O) and ν(Ln—N) are observed at *ca* 510 and 340 cm^{-1}, respectively.[5]

Electronic spectra and magnetic properties

The electronic spectra (Table 3) of the complexes reveal the presence of most of the ligand bands. A strong peak observed at 293 nm and a weak one at 262 nm are attributed to the $\pi \rightarrow \pi^*$ transition of the —C=N group and phenyl, respectively. Comparing with the ligand, a red shift at *ca* 10–15 and 2–3 nm is observed respectively, which indicates bonding between the lanthanide(III) ion and the ligand.[6,7] Additionally, new bands are observed in the 410–450 nm region and a high-intensity structureless continum is observed almost up to 500 nm. These characteristics may be related to electronic transitions based mainly on the ligand moieties and ligand-to-metal charge-transfer bands may be present.

The paramagnetic behaviour of the lanthanide(III) ion is consistent with the presence of unpaired electrons. The room-temperature magnetic moments of all the complexes show very little deviation from the Van Vleck values,[8] indicating little participation of 4*f*-electrons in bond formation.

CD spectra

The CD spectra data in the range 200–600 nm of the lanthanide complexes and the ligand NaHL are

given in Table 3. The complexes and ligand show the positive cotton effect, the positive value at *ca* 310 nm is diagnostic of the preferred conformation (refer to the salicylidienamino chirality rule) and the conformer is dominant for dichroic absorption which next to the chiral centre.[9] The positive cotton effect at *ca* 450 nm in all these complexes may be attributed to a charge-transfer transition from a ligand $p\ \pi$ orbital to a $5d$ or $4f$ orbital of the lanthanide(III) ion and related to the distortion of the chelate ring system.[10] It is likely that other conformers [by rotation about the (N—C α) band] are absent as the observed CD curves and for the lanthanide(III) complexes prepared the overall electronic situation is much the same, as indicated by the almost identical electronic spectra.

Eu^{III} and Tb^{III} complexes have been recorded under the excitation. $\lambda = 333.7$ nm, with high resolution. The room-temperature emission show some structuring in each of the transition regions, for Eu(HL)L, with $^5Do \rightarrow {}^7F_1$ and $^7F_2$ at 591 and 624 nm, respectively, which suggest a strong magnetic dipole character of the Eu—L bonding, for Tb(HL)L, with $^5D_4 \rightarrow {}^7F_6$, $^7F_5$, $^7F_4$ and $^7F_3$ at 490, 542, 587 and 614 nm, respectively, which can be attributed to ligand-field-induced changes in the inherent transition probabilities of the respective $^5D_4 \rightarrow {}^7F_4$ transition processes compared with the related hydrated ions.

^{1}H *NMR spectra*

The ^{1}H NMR data of the lanthanide(III) complexes indicate that only one set of signals is observed for the phenolic (—OH) hydrogen at 5.1 ppm (1 H,s) compared with the ligand at 5.3 ppm (1H,s) and other functional groups, indicating that the two residues in these complexes (Ln : L ratio 1 : 2) are in identical chemical environments on the ^{1}H NMR spectra.

XPS spectra

To investigate the nature of bonding, XPS spectra of the complexes and ligand were recorded. The results of the XPS semi-quantitative analyses of the surface layers are in agreement with the sample composition and the ratio of La : C : O : S : N is *ca* 1 : 33 : 8 : 2 : 2, which is consistent with the elemental analysis data. Only one symmetric sulfur 2*p* peak for all the complexes was observed, but the BE value is a little higher than that of the ligand, while the nitrogen 1*s* peak of the C=N group appeared at 400.5 eV and shows an identical chemical environment. The O1*s* peaks of the complexes are complicated. However, attempts have been made to identify some important information regarding the mode of bonding. Compared with the ligand, their deconvolution yields three components with an intensity ratio 1 : 1 : 3. The more intense component with BE value at 530.6 eV belongs to the oxygen of the $-SO_3$ group. The weaker components of the O1*s* peaks at 531.6 and 533.0 eV are assigned to the deprotoned and protoned phenolic oxygen, respectively. It may be reasonably inferred from the above discussion that an overall coordination number of six is achieved in all these complexes and a plausible octahedral structure proposed.

Thermal analysis

Thermal data (*ca* 5 C min^{-1}) indicate that the complexes sustain weight loss in the 160–540 °C region and are less thermally stable than the ligand and that the complexes are anhydrous. The main features of the complex follow this pattern. The complexes decompose exothermally in four main steps: the first corresponding to a loss of the C=N group and phenolic group in range 160–204 C; the second probably corresponding to a decarbonization process and the sulforite compound may be formed between 231–308 C; the third contacted with the loss of sulfur dioxide under 340–470 °C; the fourth linking to the pyrolysis of the organic matter existing in these complexes and together with the crystallization at 450–540 C. The final product of the decomposition is the lanthanide(III) oxide, as confirmed by X-ray diffraction detection and IR spectroscopy, as well as from the experimental and expected weight losses.

Abstract—N,N′-Di(*p*-tolylformamidine), HDTolF, reacts with an ether solution of methyl lithium to give $Li_2(\mu\text{-DTolF})_2(Et_2O)_2$ (**I**), while N,N′-diphenylformamidine, HDPhF, reacts with a THF solution of MeMgCl to give the bioctahedral molecule $(DPhF)(THF)Mg(\mu\text{-THF})(\mu\text{-Cl})_2Mg(THF)(DPhF)$ (**II**), in which one of the THF molecules is bonded to both Mg atoms. Crystal structures of **I**, **II**, as well as the neutral molecule HDTolF (**III**) and the salt $[H_2DTolF][BF_4]$ (**IV**) are presented. The neutral molecule shows distinct amine and imine C—N distances, while the ionic species show identical C—N distances. Copyright © 1996 Elsevier Science Ltd

Amidinato ligands of the type $[RNC(R')NR]^-$ have been especially useful for the preparation of classic lantern-type dinuclear species with the general formula $[M_2(amidinato)_4]^{0,1,2+}$.[1] At present, this type of ligand forms dinuclear compounds with a greater variety of metal atoms than any other ligand, including the well-known carboxylates. Frequently, new compounds show interesting characteristics such as very short interatomic distances between metal atoms which lead to high magnetic anisotropies, such as in the case of $V_2(DTolF)_4$ [DTolF = di(*p*-tolylformamidinate)]. Other fascinating properties are displayed by the new type of dinuclear compounds of the type $M_2(amidinato)_3$, M = Fe, Co,[2] which show a very large number of unpaired electrons [seven in the case of $Fe_2(DPhF)_3$].

In general, when the amidinato groups bridge two metal atoms in a symmetrical way their C—N distances are similar, as expected from the delocalization of π-electrons. The same is true when they chelate, as in $M(amidinato)_3$ compounds.[3]

However, many other bonding modes are possible,[4] in which inequalities of the C—N distances are found. Some differences are clearly present when the parent amidine coordinates to the metal atom in compounds such as in $MCl_2(amidine)_2$, M = Fe, Co, Pt and Mn,[5] where short and long imide and amine distances are well-defined. Such differences are also observed in some,[6] but not all,[7] neutral amidines structurally characterized.

In our studies we have also found that in acidic conditions amidines are capable of forming cations, as in $[H_2DTolF][CoCl_3(HDTolF)]$.[5a] Even though this type of cation is easily formed there are very few crystallographically well-characterized compounds where such cations are present. One of the few examples is that of $[H_2DPhAc][C_2O_4]$ (DPhAc = diphenylacetamidinate).[8]

We present detailed crystallographic work on cationic, neutral and anionic amidine ligands in this paper. The latter were obtained by reaction of butyl lithium (or methyl lithium) and the Grignard reagent MeMgCl, which are some of the most frequently employed reagents to form the anionic species used in the preparation of many transition metal complexes.

We also show some of the structural characteristics which differentiate anions from cations and neutral amidines.

EXPERIMENTAL

Materials and methods

Manipulations were performed under nitrogen using standard Schlenk techniques, except for the syntheses of HDTolF and $[H_2DTolF][BF_4]$. Solvents were purified by conventional methods and were freshly distilled under nitrogen prior to use. All other reagents were purchased from Aldrich and were used as received. IR spectra were recorded on a Perkin–Elmer 16PC FT-IR spectrophotometer as Nujol mulls between KBr plates. ^{1}H NMR spectral measurements were performed on a JEOL-JNM GX-200 spectrometer.

$[Li_2(\mu\text{-DTolF})_2(Et_2O)_2]$ (I)

An ether solution of 1.4 M methyl lithium (1.5 cm^3, 2.1 mmol) was slowly added to a cold (−30°C) solution of HDTolF (0.45 g, 2.0 mmol) in Et_2O (40 cm^3). The resulting pale yellow solution was allowed to warm to room temperature with stirring. Partial evaporation of the solvent (30 cm^3) under reduced pressure gave **I** as a white precipitate. The product was collected by filtration and washed with hexanes (2 × 5 cm^3). Yield 0.58 g, 95%. Crystals suitable for X-ray analysis were obtained from an Et_2O solution at −20°C. IR (cm^{-1}): 2980–2832(br, s), 1664(m), 1608(w), 1587(w), 1522(sh, w), 1507(m), 1468(s), 1449(s), 1377(s), 1312(m), 1303(sh, w), 1202(m), 987(w), 936(w), 827(sh, w), 818(w), 807(m), 721(m), 583(w), 515(w), 696(w). ^{1}H NMR (C_6D_6, δ, ppm): 8.20 (CH), 6.97, 6.93, 6.88, 6.83 (arom.), 2.14 (*p*-CH_3), 3.28 (CH_2) and 1.13 (CH_3).

[(DPhF)(THF)Mg(μ-THF)(μ-Cl)$_2$Mg(THF)(DPhF)] (II)

To HDPhF (2.00 g, 10.2 mmol) suspended in toluene (20 cm^3) at −70°C was added a 3.0 M THF solution of MeMgCl (3.4 cm^3, 10.2 mmol). The mixture was slowly allowed to return to room temperature. As bubbling occurred, a thick suspension was formed. Most of the solid dissolved upon addition of toluene (40 cm^3) at 35°C. The solvent was removed *in vacuo*. The greyish solid was extracted with toluene (30 cm^3) at 40°C and was filtered. The remaining solid was discarded. To the pale yellow solution was added a layer of hexanes (20 cm^3). After 2 days at room temperature large colourless crystals were filtered and washed with hexanes (2 × 10 cm^3). After drying over a stream of dry nitrogen the yield was 1.58 g (43%). IR (cm^{-1}): 1682(vs), 1651(s), 1587(s), 1376(m), 1310(s, br), 1209(s), 1171(w), 1153(w), 1076(w), 1029(w), 986(w), 899(w), 806(w), 754(s), 695(s), 593(w), 519(w). ^{1}H NMR (C_6D_6, δ, ppm): 7.81 (CH), 7.25, 7.20, 7.10, 7.04, 7.00, 6.93, 6.65 (arom.), 3.87 (THF), 1.78 (THF).

HDTolF (III)

N,N′-Di(*p*-tolyl)formamidine was prepared by a slightly modified published procedure.[9] The product was washed repeatedly with warm hexanes. Single crystals of **III** were obtained from toluene/hexanes at −15°C. IR (cm^{-1}): 3200–2831(br, s), 1658(m), 1606(w), 1586(m), 1505(sh, w), 1459(s), 1377(s), 1311(m), 1301(m), 1200(w), 852(sh, w), 828(w), 817(sh, w), 808(m), 720(m), 582(w), 570(w), 514(w), 496(w). ^{1}H NMR (C_6D_6, δ, ppm): 12.28 (NH), 8.01 (CH), 6.99, 6.94, 6.93, 6.88 (arom.) and 2.14 (CH_3).

$[H_2DTolF][BF_4]$ (IV)

To a solution of HDTolF (0.20 g, 0.88 mmol) in diethyl ether (20 cm^3) was added dropwise a solution of $HBF_4 \cdot Et_2O$ (85%, 0.25 cm^3) in diethyl ether (10 cm^3). The resulting precipitate was filtered and washed with diethyl ether (3 × 15 cm^3). After drying *in vacuo*, the yield was 0.26 g (92%). Single crystals of **IV** suitable for X-ray diffraction studies were obtained by slow diffusion of a layer diethyl ether into a methylene chloride solution of **IV**. IR (cm^{-1}): 3275(m), 3225(m), 3165(m), 3113(m), 3065(m), 1695(s), 1613(m), 1595(m), 1560(w), 1516(s), 1347(s), 1314(m), 1290(w), 1217(m), 1145(m), 1129(m), 1105(s), 1060(s), 1018(s), 965(m), 911(w), 835(m), 819(s), 801(m), 766(m), 642(w), 524(m), 509(s), 446(m), 431(w). ^{1}H NMR (d$_6$-acetone, δ, ppm): 9.16 (CH), 7.49, 7.45, 7.34, 7.29 (arom.), 2.35 (CH_3).

Structure determinations

Geometric and intensity data for **I** and **II** were measured on an Enraf–Nonius FAST area-detector system utilizing the program MADNES.[10] Data were collected at room temperature on a Rigaku AFC5R diffractometer equipped with a rotating Cu anode for **III** and **IV**. Detailed procedures have been described previously.[11,12]

Reflections for cell indexing were found by an automated search routine (Rigaku) or using 50 reflections taken from three 10° ω rotations in the range $0 \leqslant \omega \leqslant 110°$ (FAST). In each case, the cell dimensions and correct Laue group were confirmed by axial images. For **I** and **II**, the refined cell used 250 reflections in the range $20 \leqslant 2\theta \leqslant 32°$, and data collection was performed with the detector set at a distance of 40 mm and a swing angle of 22.5°. All data were corrected for Lorentz and polarization effects. An empirical absorption correction based on a series of

psi-scans was applied to the data for compounds **III** and **IV**. A correction for extinction was applied to the data for **IV** [refined extinction parameter $x = 0.0017(4)$].[13]

The structures for **I**, **II** and **III** were solved by direct methods and refined using the SHELXTL[14] structure refinement package, structure **IV** was refined using SHELXL-93.[15] For **I** and **II** the structure factors were calculated with hydrogen atoms placed at the expected positions. Except for the methyl protons, all other hydrogen atoms were refined isotropically for **III**. For **IV** the positions of the hydrogen atoms were determined from the difference-Fourier map, and were refined using a common isotropic displacement parameter.

The bridging THF molecule in **II** was found to be conformationally disordered, attempts to model the disorder failed. This disorder is shown by the large displacement parameters of the constituent carbon atoms. Pertinent information regarding data collection and refinement is given in Table 1. Selected bond distances and angles are given in Tables 2, 3, 4 and 5 for compounds **I**, **II**, **III** and **IV**, respectively. Supplementary data for **I**, **II**, **III** and **IV** have been deposited with the Cambridge Crystallographic Data Centre.*

RESULTS AND DISCUSSION

$[Li_2(\mu\text{-DTolF})_2(Et_2O)_2]$

The reaction of butyllithium or methyllithium with HDTolF in the presence of Et_2O affords crystals of a dilithium compound. As far as we know this is the first time that a crystal structure has been determined on a lithium amidinato compound in spite of the fact that these compounds are so widely used in the preparation of transition-metal amidinato complexes. The reason for the lack of crystal structure determinations is probably the facility which the crystals lose ether.

The crystal structure of **I** reveals a centrosymmetric

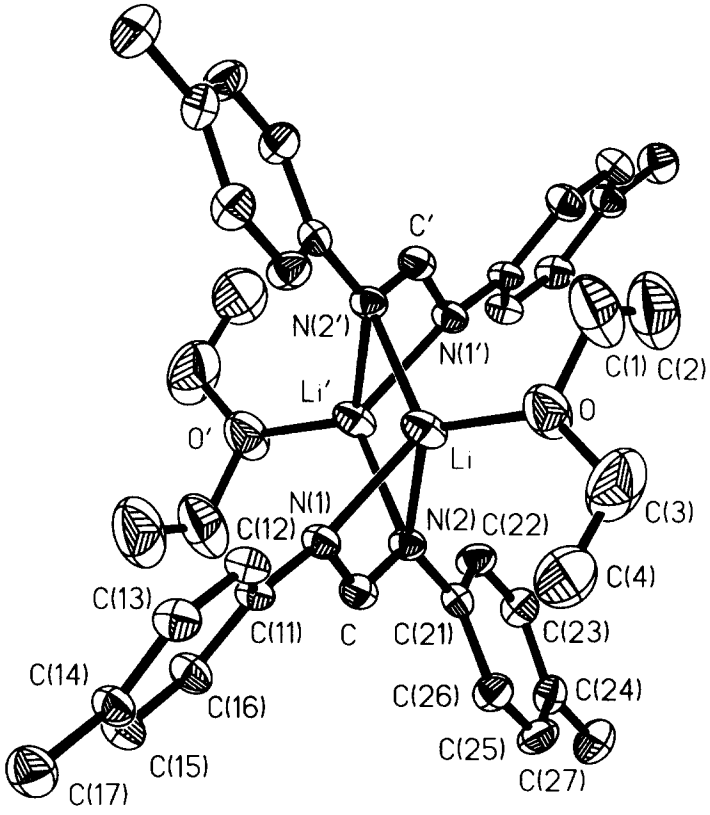

Fig. 1. A drawing of the molecular structure of $Li_2(\mu\text{-DTolF})_2(Et_2O)_2$. Non-hydrogen atoms are represented by their 30% probability ellipsoids.

dinuclear molecule. The ligand bonding mode is unusual in that each DTolF group has one nitrogen atom bonded exclusively to a lithium atom but the second nitrogen atom is bonded to each of the two lithium atoms. The fourth coordination site of each pseudo-tetrahedral lithium atom is occupied by an oxygen atom of a diethylether molecule as seen in Fig. 1.

The three-way bonding mode has been observed only once before in a triazenide compound of rhodium.[16] Perhaps we will see this type of bonding mode more frequently in the future.

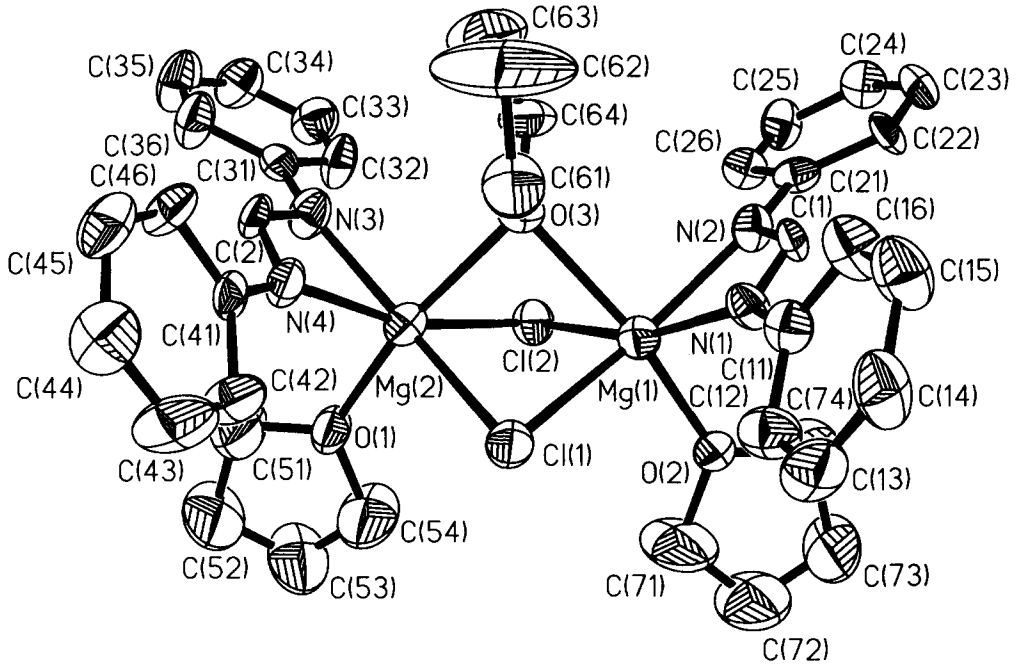

Fig. 2. Perspective view of the dinuclear (THF)(DPhF)Mg(μ-Cl)$_2$(μ-THF)Mg(DPhF)(THF) molecule showing the atom labelling scheme. Non-hydrogen atoms are represented by their 40% probability ellipsoids.

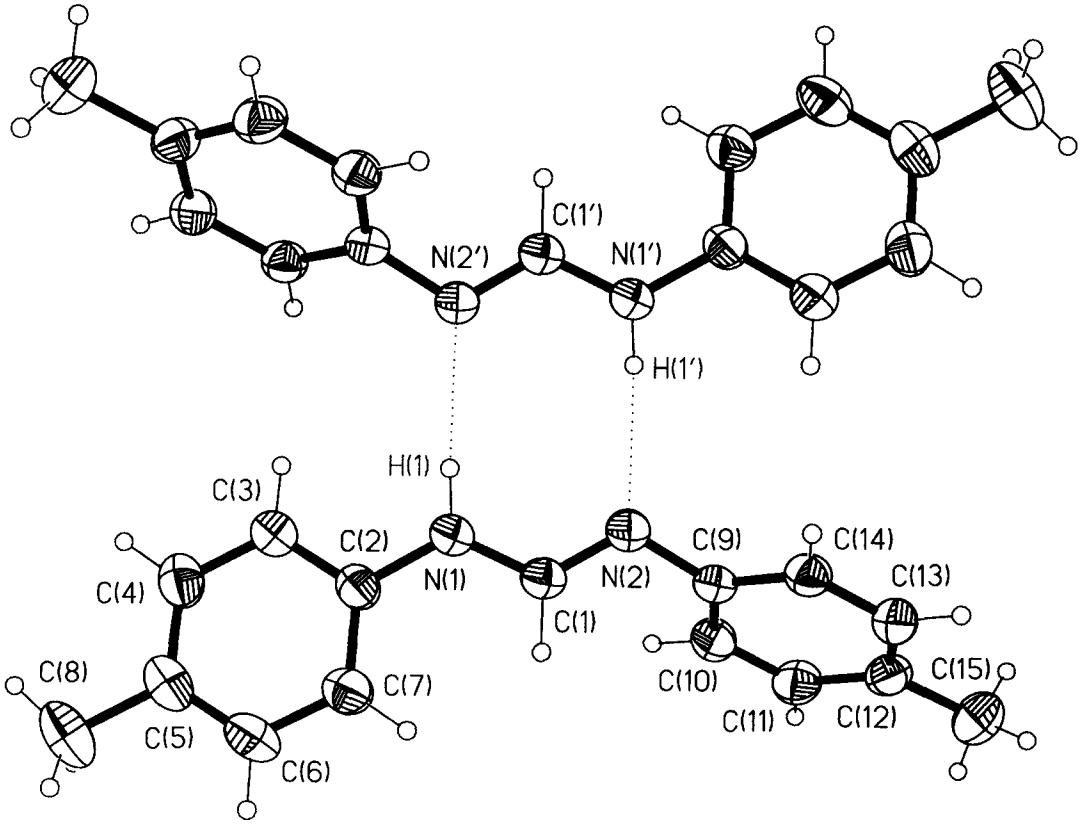

Fig. 3. A plot of a pair of HDTolF molecules showing the hydrogen bonding interactions. Non-hydrogen atoms are represented by their 40% probability ellipsoids. Hydrogen atoms are drawn as arbitrarily sized circles.

As expected, the shortest Li—N bond is the unshared bond [2.045(8) Å]. The second nitrogen atom has two different bonds to the lithium atoms [2.078(8) and 2.231(9) Å]. The shorter Li—N bond lengths are in good agreement with those of typical lithium to pyridine-like ligands and lithium amides.[17] The Li—O distance is also very similar to those found in other compounds such as $[LiBr \cdot Et_2O]_4$.[18]

(THF)(DPhF)Mg(μ-Cl)$_2$(μ-THF)Mg(DPhF)(THF)]

When the deprotonation of HDPhF is carried out using a Grignard reagent, MeMgCl, in the presence of THF it affords crystals of **II**. It is a dinuclear compound consisting of a face-sharing bioctahedron.

Each DPhF group is chelated to a Mg atom. The coordination sphere is completed by a THF molecule, two bridging chloride ions and a bridging THF molecule which is essentially *trans* to the singly coordinated THF, as seen in Fig. 2. This is only the second time that such μ-type coordination has been observed in a THF molecule. The first one was in $[(C_5H_4Me)TiF_3]_2$ (μ-THF).[19] However, this point was not emphasized in that report. The bridge is somewhat similar to that formed by tetrahydrothiophene, THT, in $[MCl_6(\mu\text{-THT})_3]^{2-}$, M = Nb, Ta.[20] In **II** both terminal Mg—O bonds are *ca* 0.3 Å shorter than the bridging ones. The Mg—O—Mg bridge is nearly symmetrical with distances of 2.322(6) and 2.357(6) Å.

HDTolF

The molecular structure of **III** is shown in Fig. 3. The compound forms dimers in which the molecules are associated by a pair of hydrogen bonds. The two molecules are related by a crystallographic inversion centre. The hydrogen atom bonded to the nitrogen atom was located on a Fourier map and was refined without constraints to give a N—H distance of 0.88(2) Å. The N—C—N skeleton shows well-defined C—N amine bonds [1.340(2) Å] and imine bonds [1.277(2) Å]. The difference of 0.06 Å in these bonds compares reasonably well with those in other amidine compounds as shown in Table 6. An exception might appear to be that of N,N′-di(*p*-chlorophenyl) formamidine (HDClPhF), which is reported to form dimers that contain identical skeletal C—N bond lengths as well as H atoms located at the midpoint between the pairs of nitrogen atoms. Our results as well as the others shown in Table 6 support the probable existence of the disorder in the structure of HDClPhF as hinted in the publication.

Another important feature shown in the structure of **III** is the marked difference found in the C—N—C bond angles. The one at the amine nitrogen is 7.5° greater than that at the imine nitrogen. A similar pattern is observed in other amidines including those

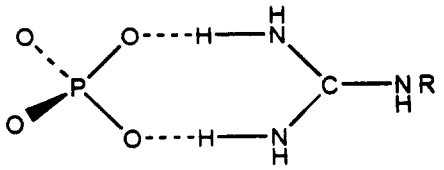
where the amidine is coordinated to a metal atom as shown in Table 6.

$[H_2DTolF][BF_4]$



A drawing of the salt is shown in Fig. 4. There is a crystallographic two-fold axis along the methyne C—H bond that requires the C—N bonds of the N—C—N skeleton to be identical, contrary to the case with the neutral molecule, compound **III**. Equality of the N—C bond lengths is also observed in another structurally characterized cationic amidinium salt,[8] as well as in most symmetrically bonded amidinato complexes. As in the neutral parent species, the C—N—C bond angles for **IV** are greater than 120°. The two N—H groups are directed towards the $[BF_4]^-$ anion and participate in hydrogen bonding with the F atoms of the anion H · · · F = 1.88(5) Å; consequently, the tolyl groups are swept back to the other side of the cation. In contrast to the acetamidinium ion in the structure of $[H_2DPhA][C_2O_4]$, the entire H_2DTolF cation is nearly planar, exhibiting only a small dihedral angle [7.4(9)°] between the plane described by N(1), C(1), N(1) and the plane of the tolyl rings.

A partial packing diagram for compound **IV** is shown in Fig. 5 and a more extended one in Fig. 6. In addition to generalized electrostatic attractions that occur in all ionic crystals, these crystals are also stabilized by hydrogen bonds from the two N—H groups of each cation to two of the fluorine atoms of a BF_4^- ion. These crystallographically equivalent hydrogen bonds have the dimensions:

This nice fit of the cations to the BF_4^- anion is reminiscent of the way in which the cationic guanidyl groups of arginine residues nicely fit onto phosphate

ions by the formation of pairs of hydrogen bonds (**I**),[21] in certain phosphatases.

Closer examination of Figs 5 and 6 shows that there may be still another set of localized interactions that are necessary for the stabilization of the beautiful structure shown. It would appear that certain C—H bonds are attracted to the other two fluorine atoms of each BF_4^- ion. Thus C(1) lies at 3.387(4) Å of F(2) and F(2)′. The C(1)—H(1)···F(2) angles are 154(2)° and the C(1)—H(1) and H(1)···F(2) distances are 0.96(5) and 2.50(5) Å, respectively. In addition, there are two equivalent C(3)—H(3)···F(2) interactions that are also practically linear, 170(2)°, with a C(3)—F(2) distance of 3.404(4) Å and C(3)—H(3) and H(3)···F(2) distances of 0.93(3) and 2.49(4) Å, respectively. When compared with C—H···O-type hydrogen bonds,[22] these C—H···F interactions seem to merit serious consideration as C—H···F hydrogen bonds.[23]

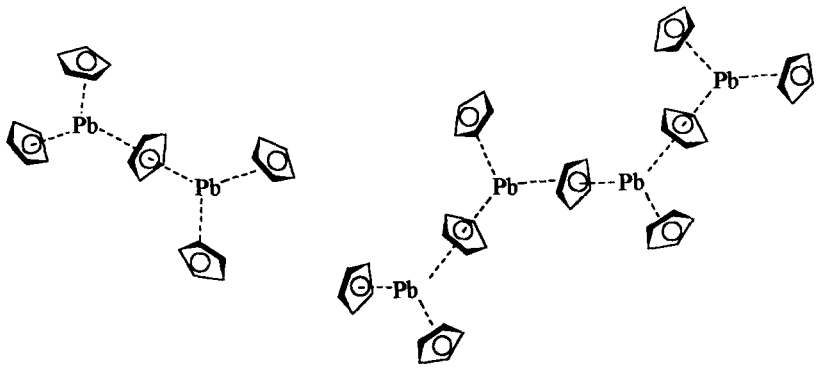
1. INTRODUCTION

There has been a resurgence of interest in the coordination chemistry of heavy p-block elements in recent years, and this review is concerned with reports of new coordination chemistry of lead(II) that have been published during this renaissance. Since it is a rather large area of chemistry, this report is not comprehensive, but even limiting it to only the most interesting examples has allowed the inclusion of many varied compounds. The expansive literature dealing with macrocyclic ligands is treated in a separate section as it merits being considered as a "special case" of coordination chemistry.

Of all p-block elements, lead(II) has a particular fascination for coordination chemists, as it can adopt many different geometries in its complexes, allowing a degree of tolerance for ligand configurations which is not seen in, for example, *d*-block elements. Coupled with the ability to bind well to both hard and soft donor atoms, these properties make lead(II) an interesting metal to study, forming as it often does complexes which are different from those which might be conventionally expected.

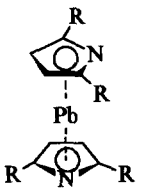
The toxic nature of lead and its widespread occurrence in the environment, subsequent to its many applications in technology, adds a focus to the search for powerful and selective lead binding materials and ligand systems. For example, there is no oral chelator available for therapeutic uses in the treatment of lead poisoning that has been specifically designed for lead. Certainly much remains to be discovered in the field of lead coordination chemistry, despite the large body of work already published, of which this review covers only a part.



2. CONVENTIONAL LIGANDS

2.1. *Group* 14: *donor ligands*

The family of substituted plumbocenes has been expanded to include examples where 1,2,3,4,1′,2′,3′,4′ = Ph, 5,5′ = 4-(*t*-Bu)Ph [1], and where 1,2,3,4,5,1′,2′,3′,4′,5′ = Ph [2] or Me [3]. The half sandwich complexes [Cp*PbX] (where X = Cl^-, $[BF_4]^-$ or $CF_3SO_3^-$) were also prepared [8] and their exchange reactions with 2,2′ bipyridyl (bipy) and 1,10 phenanthroline (1,10 phen) explored.

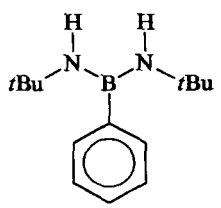


The reaction of plumbocene with an excess of [LiCp] yields the fascinating compound $[Li(12\text{-}C\text{-}4)]_2$

$[(C_5H_5)_9Pb_4][(C_5H_5)_5Pb_2]$, **1**, crystallised on addition of a crown of ether to the reaction mixture. The structure comprises both triple and quintuple decker sandwich moieties [4].

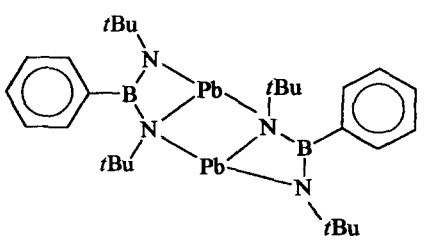
The two anions present in 1.

Heteroatom analogues of $(Cp)^-$ have been used to prepare the plumbocene like complex **2** where R = (*t*-Bu). The crystal structure of **2** reveals a tilt angle of 142.7° indicating that as with other plumbocene type compounds, the remaining lone pair on the lead is stereochemically active [5].



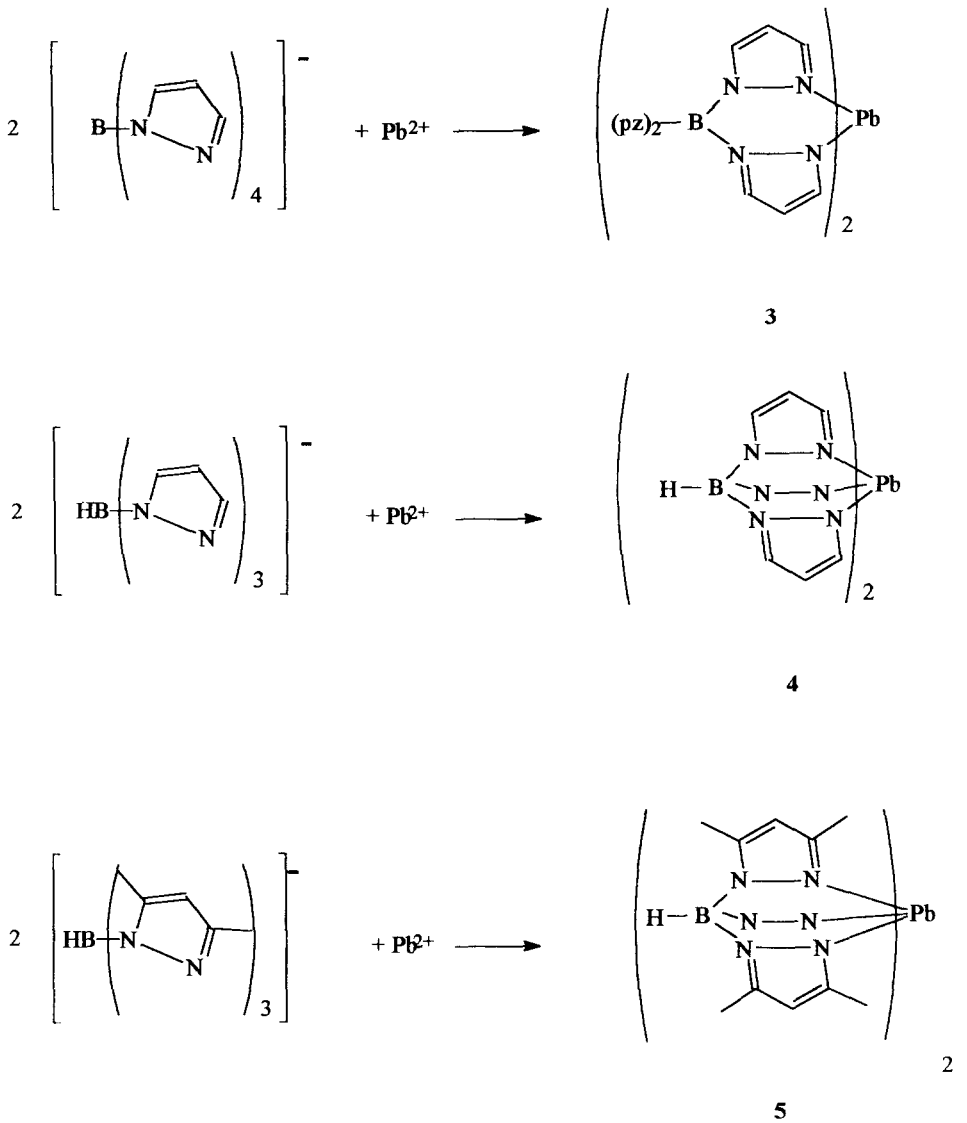
2

2.2. *Group* 15 : *nitrogen ligands*



Aminoborane ligands have widespread utility in the coordination chemistry of most metals and lead(II) is no exception. The interaction of polypyrazolylborates with simple lead(II) salts yields a variety of products, depending upon the substitution of the Tp ligands and the reaction stoichiometry (Scheme 1).

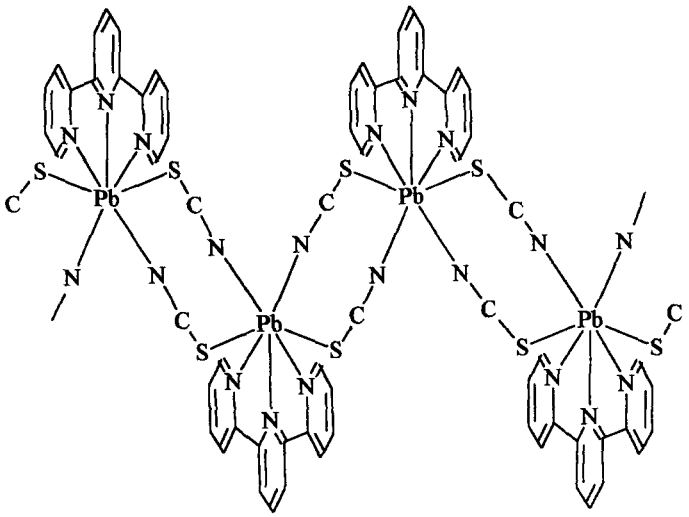
Compounds **3, 4,** and **5** were analysed by X-ray crystallography to reveal a distorted trigonal bipyramidal (TB) geometry for **3,** and irregular octahedral geometries for both **4** and **5** [6].



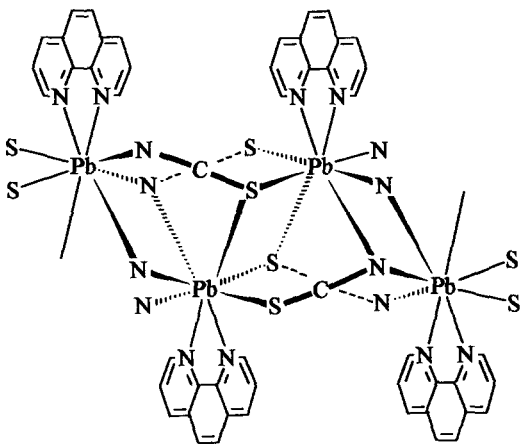
The dilithium salt of the aminoborane **6** reacts with lead(II) chloride to give the dimeric compound **6a** where in each of the lead(II) centres is tricoordinate, exhibiting two kite shaped [PbNBN] rings linked together through two further Pb–N bonds [7]. A related structural motif is seen in $[Pb(NR_2)]_4$ [8].

6

6a



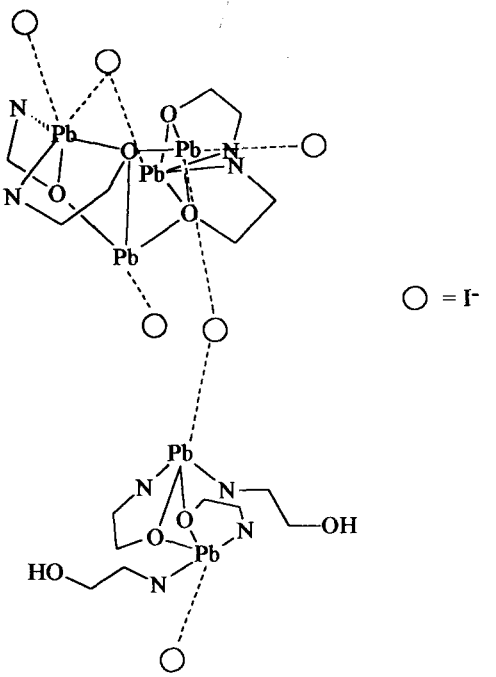
Scheme. 1.



The synthesis of $[(t\text{-Bu})(Ph)C{=}N]_8Pb \cdot Li(THF)$ from the reaction of benzonitrile and *t*-butylithium with lead(II) chloride was reported, a further example of tricoordination of lead(II) as well as being the first reported imino complex of lead(II) [9]. The product exists in the solid state as a regular tetrahedron, with the lead(II) in the apical position and the three imino nitrogens defining the basal triangle. The lithium bridges the three nitrogens on the opposite face of the triangle to the lead and coordinates a molecule of THF.

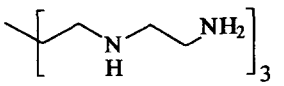
The versatile ligand triazacyclononane forms 1 : 1 complexes with lead(II) nitrate and with lead(II) perchlorate. In the solid state these both form irregular hexacoordinate complexes with intermolecular bridging through the oxygen atoms of the nitrate or perchlorate counterions to form arrays in the solid state that show considerable similarity despite the apparent steric differences between nitrate and perchlorate ions [10]. The stability of the 1 : 1 complex in aqueous solution has been measured at $\log K = 10.35$ [10].

Complexes formed between lead(II) thiocyanate and (1,10 phen) and 2,2′ : 6′2″ terpyridine (terpy) have been investigated [11,12]. Despite the seeming simplicity of the system a variety of compounds can be prepared by subtle adaption of the reaction stoichiometry, including **7** and **8**.



7

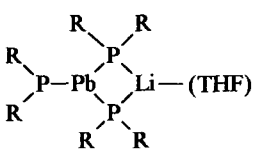
8



The linear polymer **7** comprises $[Pb(terpy)]^{2+}$ units lined by four bridging thiocyanates to two further $[Pb(terpy)]^{2+}$ units. Compound **8** is again a linear polymer with an octacoordinate lead(II) binding to one (1,10 phen) and six bridging thiocyanates, connecting each lead(II) to four neighbouring lead(II) centres [12].

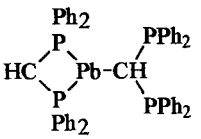
The neutral bidentate ligand tetramethylethylenediamine (tmeda) reacts with lead monoxide in the presence of ammonium iodide to yield the simple chelated complex $[Pb(tmeda)_2I_2]$ [13] which has a linear polymer array of $[Pb(tmeda)]^{2+}$ units linked by bridging iodides to give an overall irregular octahedral geometry to the plead(II) centre. By the same authors, the analogous reaction with ethanolamine replacing tmeda was explored [14] resulting in the slightly more unusual compound $[Pb_6(Ea)_6(HEa)_2I_6]$ **9**.

9



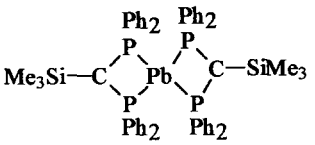
Nitrilotriacetamide (NTA) has been used to prepare a 1 : 1 complex $[(NTA)Pb(NO_3)](NO_3)$ [15]. This decacoordinate structure represents the highest coordination number routinely observed for lead(II), exhibiting in the solid state a configuration which suggests that the remaining lone pair is steroechemically inactive in this compound. Stability constants are reported for the formation of complexes of 5-(4′-amino-2′-azabutane)-5-methyl-3,7-diazanonane-1,9-diamine, **10,** with lead(II) in water ($\log K = 9.2$) [16]. This tripodal ligand is related to macrocyclic ligands such as cryptands, ($\log K$ for (2,2,2-crypt) with lead(II) in MeOH = 12.5) [17].

10



2.3. *Group* 15 : *phosphorus ligands*

The first report of a simple compound of empirical formula $[Pb(PR_2)_2]$ was from Cowley *et al* [18]. These dimeric neutral complexes form from the reaction of lead(II) chloride with lithium di-*t*-butylphosphide in stoichiometry 1 : 2, the nature of the product was confirmed by X-ray crystallography [18]. The same reaction in 1 : 3 stoichiometry gives the trisubstituted anionic lead compound **11** [19].

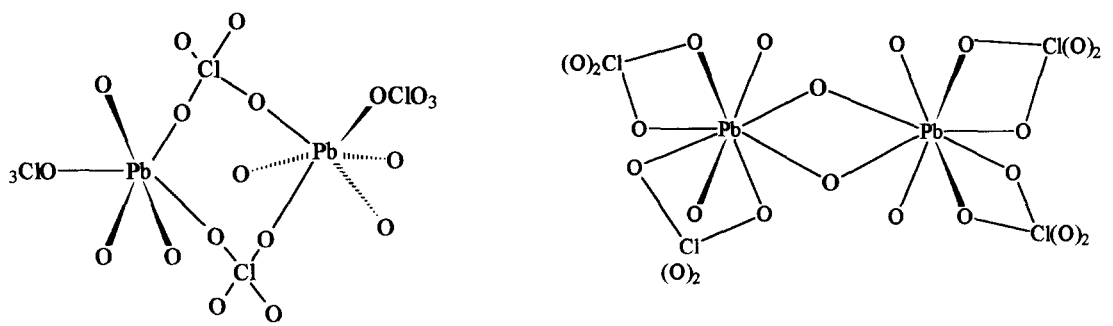


11

An excellent and thoroughgoing study of complexes of the phosphorus analogue of the well-known *bis*-(trimethylsilyl)amide was reported by Buhro *et al.* [20]. Perhaps unsurprisingly, the complex of empirical formula $[Pb(P(SiMe_3)_2)]$ is not monomeric, but dimeric. The structural characterisation of this complex shows a puckered (Pb_2P_2) ring, with a terminal phosphide on each lead(II) centre, the whole crystallising with a *cis*-configuration [20].

12

A further example of tricoordinate lead(II) is given by Balch and Oran. The lithium salt of deprotonated *bis*-(diphenylphosphino)methane (dppm) reacts with lead(II) chloride to give **12**, and the trimethylsilyl substituted analogue of dppm forms a tetracoordinate species **13** [21]. NMR studies reveal that at ambient temperatures both molecules are fluxional, **12** exchanging between a tri- and a tetracoordinate species, (between η^1 C- bound and η^2 $(P)_2$- bound), **13** exchanging between different tetracoordinate geometries [21].

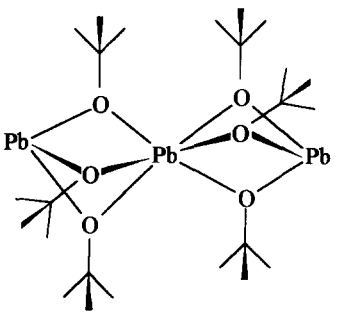


13

2.4. *Group* 16 : *oxygen ligands*

Tetrameric $[Pb_4(OH)_4](N)_3)_4$ was isolated from a basic aqueous solution of lead(II) nitrate, and the X-ray structure reported [22]. The compound exists in the solid state as a cubane type arrangement of four lead(II) atoms occupying four opposite corners of a cube with four hydroxyl ions completing the array. This remarkable ion is an important addition to the understanding of the speciation of lead(II) ions in aqueous solution, and is unusual of its kind.

A number of compounds have been isolated from the system $Pb(ClO_4)_2$/DMSO, and crystal structures were reported for $Pb(DMSO)_x(ClO_4)_2$, where $x = 3$ or 5 [23]. Two isomers were isolated for the case $x = 3$ (**14**) where the bridging oxygen is either from a perchlorate or a DMSO moiety. The report also contains a useful discussion on the potential difficulties of relating the composition of species in solution to the nature of the species which crystallise therefrom.

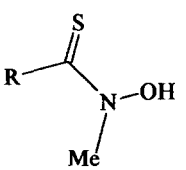


O = DMSO Oxygen

Perchlorato and DMSO bridged isomers of 14

Lead(II) alkoxides have received much attention particularly due to their potential application as precursors to metal films. In another extensive study by Buhro *et al.* [24] the alcoholysis of $Pb[N(Si(Me)_3)]_2$ with various

alcohols was shown to lead to a series of alkoxides with varying structural features. Sterically undemanding alcohols (isopropanol, 2-methoxyethanol) give linear polymeric compounds $[Pb(OR)_2]_n$ where the lead exhibits a distorted trigonal bipyramidal structure, bound to four μ^2 alkoxide oxygens. More encumbered alcohols (*t*-butanol, neopentyl alcohol) form tri-metallic compounds $[Pb_3(OR)_6]$ (**15**) [24]. Using an excess of alcohol, or by direct reactions of lead(II) chloride with an excess of sodium alkoxides, products of the type $[Pb_4(OR)_6]$ can be formed [25].



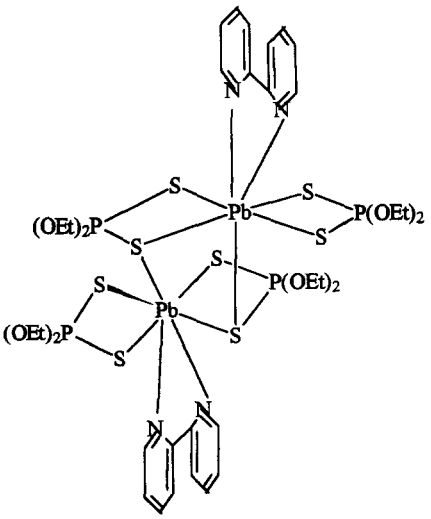
15

A similar polymeric motif is seen in the product of the reaction of lead monoxide with triethanolamine $[N(CH_2CH_2OH)_3]$ and ammonium iodide [26] which comprises a repeating $[Pb_4I_4N(CH_2CH_2)_3(EtOH)_2(EtOH)]$ unit, where triethanolamine is a tetradentate ligand, doubly deprotonated. A structurally related compound is reported by Veith *et al.* [27].

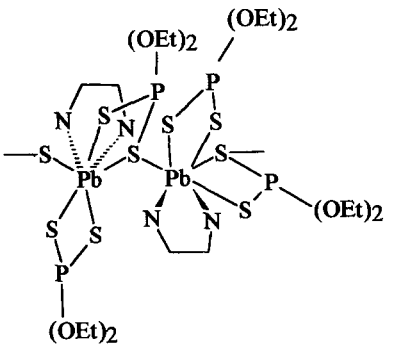
Aminosquaric acid reacts with lead(II) nitrate in methanol solution to give $[Pb(C_4O_3CH_2)\cdot 2H_2O]_n$ where each octacoordinate lead(II) is bound once to each of four aminosquarate residues and to the oxygens of four μ^2 bridging water molecules [28]. Another seemingly simple system, lead(II) acetate and phthalic acid, has been shown by crystallography to give a series of interesting products [29]. The mixed compound lead(II) acetophthalate comprises three distinct lead(II) centres, each of which exhibit a different coordination geometry.

2.5. *Group* 16: *sulfur and selenium ligands*

Thiohydroxamates (**16**) have been show to form simple 2:1 complexes with lead where R = Ph, Me. Both complexes exhibit a distorted trigonal bipyramidal geometry in the solid state [30]. Dithiocarbamate complexes have been investigated by vibrational spectroscopy [31], mass spectroscopy, ^{207}Pb NMR and electrochemical techniques [32]. Whilst it is proposed that $[RNCS_2]^-$ is always present as a bidentate ligand, these ligands are shown in some cases to be labile in experiments measuring the rate of scrambling of ligands in mixtures of the type $\{[Pb(S_2CNR)_2]+[Pb(S_2CNR')_2]\}$ [32].



16

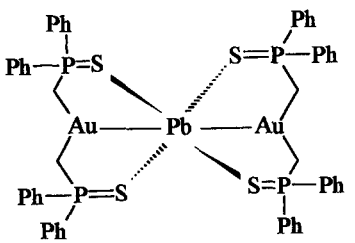


The dipotassium salt *bis*-(2,2-dicyanoethylene-1,1-dithiolato)plumbate was isolated as a hydrate from the reaction of lead(II) acetate with the potassium dithiolate. The anion exhibits a pyramidal geometry in the solid state by X-ray crystallography, a disposition found by calculation to be favoured over a planar arrangement by 25 kJ mol^{-1} [33].

An elegant investigation of the simple yet significant diothiolate complex [Pb(ethane-1,2,-dithiolate)] reveals that the compound exists in the solid state as an extended array, with intermolecular Pb–S interactions giving an overall hexacoordinate configuration to the oligometric lead centres [34]. Less tractable was the $[Pb(C_4S_4)]_n$ tetrathiosquarate complex of lead(II), a high melting insoluble violet polymer [35].

Thiophosphates of various kinds have been shown to form complexes with lead(II) [36–38]. The mixed complexes $[Pb(S_2P(OEt)_2(bipy)]_2$ and $[(Pb(S_2P(OEt)_2)_2(en)]_n$ shown in **17** have been prepared and their isolation has been used to infer a mechanism for the reaction of simple amines with [lead(II)*bis*-(O,O) dialkyldithiophosphates] [36].

The dimeric $[Pb(bipy)(S_2P(OEt)_2)_2]_2$

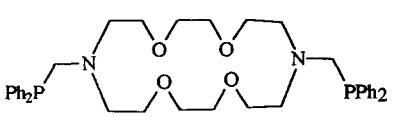


The repeating unit of $[(Pb(S_2P(OEt)_2)_2(en)]_n$

17

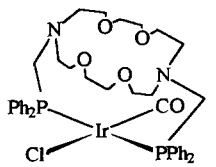
Inorganic chelate rings have enjoyed much popularity recently and lead(II) has been complexed by tetraphenyldithiomidophosphinate, which forms a simple neutral 2 : 1 complex with a trigonal bipyramidal geometry in the solid state [37], giving a complex which comprises two [PbSPNPS] rings.

A slightly more sophisticated system reported by Fackler *et al.* [38] uses an organogold dithiophosphinate **18** to prepare 2 : 1 complex of octahedral geometry exhibiting two Au–Pb interactions of 2.896 and 2.963 Å.



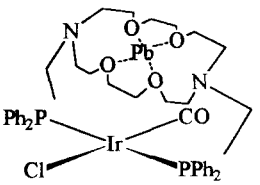
18

The dianion *bis*-(2,2-dicyanoethylene-1,1-diselenato)plumbate was prepared from the reaction of lead(II) acetate and the potassium salt of the diselenodicyanoethylene, and isolated as the tetraphenyl arsonium salt.



The solid state structure of this by X-ray methods is found to be intermediate between square pyramidal and trigonal bipyramidal [40].

2.6. *Miscellaneous*



The diphosphine **19** which has a crown ether backbone has been coordinated to an [Ir(Cl)(CO)] fragment to yield **19a** which can further bind [Pb^{2+}] in the crown ether function to give the dication **19b**. The Pb–Ir distance in the crystal structure is 3.117 Å [41]. The related complex **20** is reported by the same authors [42] which exhibits shorter Pb–Ir interactions (2.855 and 2.831 Å), and is an example of tricoordinate lead(II). This tricoordination is also observed in a complex reported by Lappert and Power [43] where the sterically encumbered species $Pb[N(Si(Me)_3)_2]$ acts as a two electron donor ligand complexing to [η3(allyl)PdCl]. Although this seems an isolated example for lead(II), both tin(II) and germanium(II) form a range of complexes of this type [43].

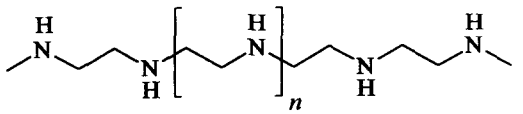
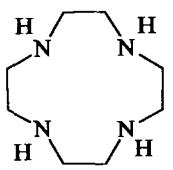
20



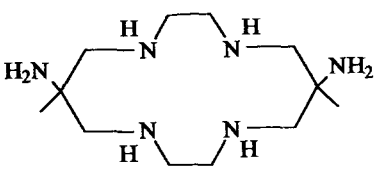
3. MACROCYCLIC LIGANDS

3.1. *Nitrogen donor macrocyclic ligands*

Lead(II) is a popular metal amongst macrocyclic chemists in part because it exhibits a wide degree of flexibility in the geometry and coordination number of its complexes. A comparative study of complexes of lead(II) with linear and cyclic polyamines reveals an enhancement in stability in smaller cyclic amines over their straight chain analogues, an enhancement which decreases as the size of the polyamine increases [44]. In addition, the larger cyclic polyamines form bi- and tri-nuclear complexes of good stability, and the crystal structure of $[30]aneN_{10}Pb_2(ClO_4)_4$ is also reported. The values for log K for mononuclear complexes do not vary greatly for **22–24**, with **21** exhibiting a significantly higher stability. Values for the analogous linear amines **26** and **27** are very close to those seen for **22** and **23**, with the log K for **28** greater than log K for **24**.



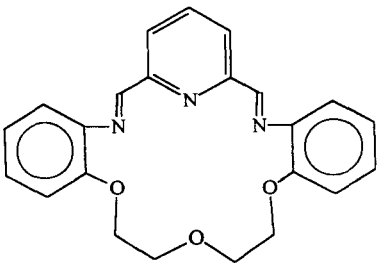
$n = 1$, **21**, $\log K = 14.13$
$n = 2$, **22**, $\log K = 10.02$
$n = 3$, **23**, $\log K = 10.83$
$n = 4$, **24**, $\log K = 9.77$



$n = 2$, **25**, $\log K = 9.97$
$n = 3$, **26**, $\log K = 9.86$
$n = 4$, **27**, $\log K = 10.37$
$n = 5$, **28**, $\log K = 11.32$

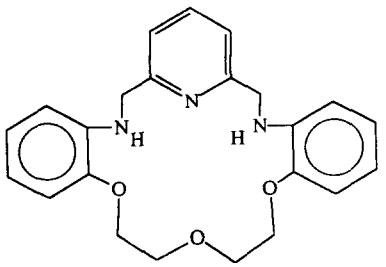
In a related study, a series of tetraazacycles and oxatriazacycles with various spacing groups were prepared and their stabilities with lead(II) and other metals were investigated, with the highest value of log K reported for the 1 : 1 complex with lead(II) of the smallest tetraazacycle ligand, **29**, ($\log K = 15.9$) [45]. Tetraazacycle **30**, incorporating two pendant amine functions allowing a potentially hexadentate ligand was prepared and its 1 : 1 complex with lead(II) examined by X-ray crystallography [46]. The compound has in the solid state all six amine groups bound to the lead centre and the nonacoordinate geometry is completed by one molecule of water and two oxygens form a perchlorate anion. The log K of this species is reported as 11.8.

29



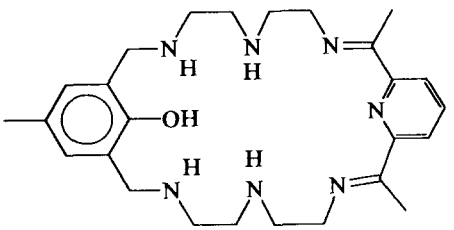
30

An unusual result arising from the interaction of lead(II) nitrate and 24(pyridinium)-C-6 is reported by Cramer *et al.* [47] where the product which is formulated as[Pb(24(pyridinium)-C-6)]$(NO_3)_6$ is revealed by crystallography to contain a $[Pb(NO_3)_6]^{4-}$ ion and [24(pyridinium)-C-6]$^{4+}$ with an empty cavity.

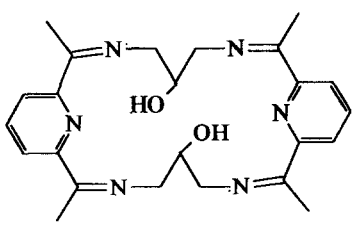


3.2. *Nitrogen/oxygen mixed donor macrocyclic ligands*

A wide variety of N,O donor macrocycles have been reported in coordination studies with lead(II). Ligands of this class derived from Schiff base condensations on pyridine-2,6-dicarboxaldehyde (**31**–**36**) have been widely

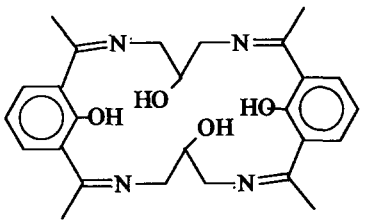


studied. A 1 : 1 complex of lead(II) with ligand **31** was reported with bidentate nitrates lending an overall decacoordination for the metal [48]. The reduced form of the ligand is also reported with a concomittant change of conformation of its lead(II) complex associated with the increased flexibility of the ligand. The macrocycle **33** contains phenolic and pyridine donor sites, and forms a complex with lead(II), $[Pb_2(L)]$ which is a linear polymer in the solid state [49]. The potentially octadentate macrocycle **34,** which comprises alcohol and pyridine donor groups, forms 1 : 1 complexes with lead(II) [50] despite a similar configuration to **35,** which forms both mono- and bi-nuclear complexes [51].

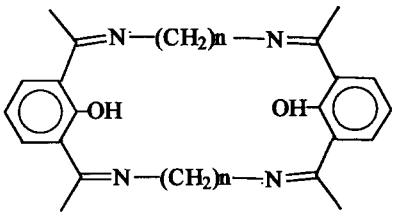


31

32



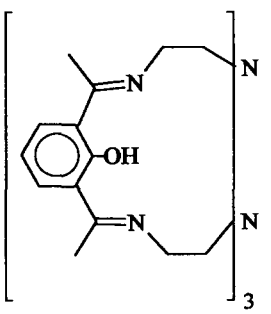
33



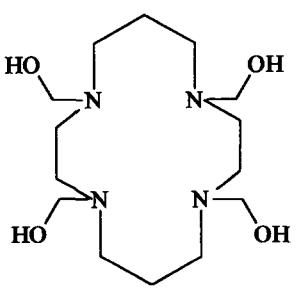
34

36 and **37** are two- and three-dimensional analogues of the same ligand type. **37** forms a 1 : 1 complex with a heptacoordinate configuration [52] whereas **36** is reported to form an intriguing dimetallic complex, $[Pb(Cu\mathbf{36})_2](ClO_4)_2$ [53].

An elegant ^{13}C NMR study on the fluxional processes seen for the lead(II) complex of **38** [54,55] reveals that a hexacoordinate structure is favoured in solution with exchange between the four pendant groups, the macrocyclic donor atoms being bound throughout the exchange process.

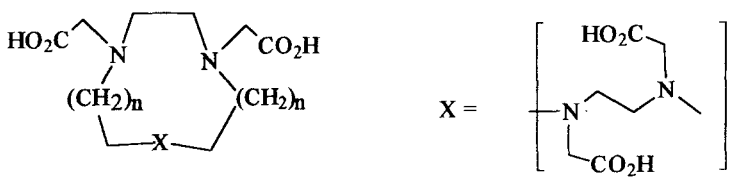


35

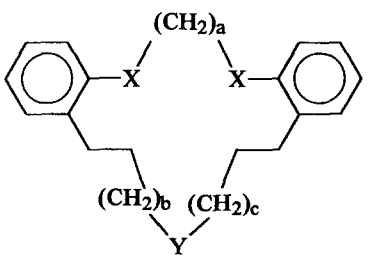


n = 2 or 3

36

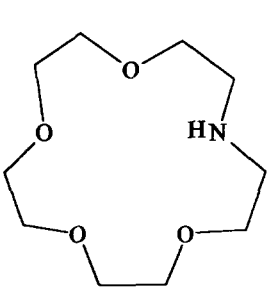


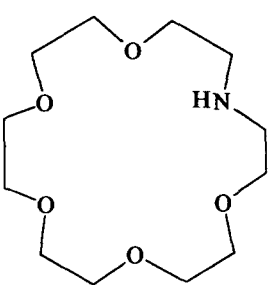
37



38

A series of ligands based upon **39** were prepared and their relative binding efficiency with lead(II) was investigated to elucidate preference for binding site type, with 1,4,7,10-tetraazacyclododecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid forming the most stable complex of this family of ligands [56]. An expansive series of ligands of general formula **40** were reported and their complexation behaviour with lead(II) investigated [57, 58]. The crystal structure of the complex formed between lead(II) and **40** where X = S, Y = NH was reported. The highest log *K* value for this set of ligands is observed for the case where all donor atoms are nitrogens (log *K* = 9.5), decreasing to a minimum when all X,Y donor sites are thioethers (log *K* ~ 3). This comprehensive study illuminates the preferences of lead(II) for donor atom type, maintaining as it does a fixed structure and configuration to the ligands, changing only donor atom type.

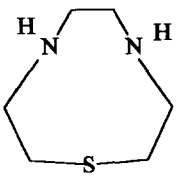




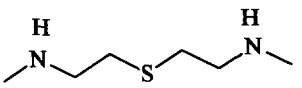
39

where a = 1-4, b = c = 2
X = (NH), O, S
Y = (NH), O, S

40



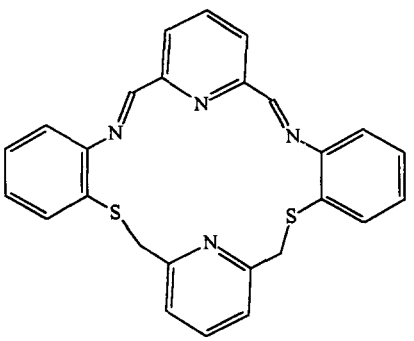
41 **42**



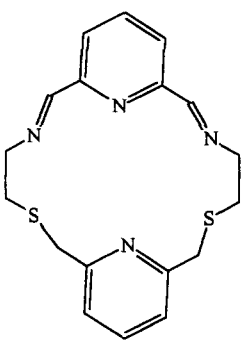
The azacrown ethers 1,4,7,10-tetraoxa-13-azacyclopentadecane (**41**) and 1,4,7,10,13-pentaoxa-16-aza-cyclooctadecane (**42**) have been show to form more stable complexes with lead(II) than their oxygen analogues 15-C-5 and 18-C-6, (*vide infra*) with log *K* $[Pb(\mathbf{41})]^{2+}$ = 6.0 (*cf* 3.92) [59] $[Pb(\mathbf{42})]^{2+}$ = 8.4 (*cf* 6.99) [60]. Structural characterisation of $[Pb(\mathbf{41})(NO_3)_2]$ shows an asymmetric structure with the pentadentate macrocycle bound on one side of the lead(II) with two bidentate nitrate groups bound on the other face, giving a significantly distorted coordination sphere, whereas $[Pb(\mathbf{42})(NO_3)_2]$ has a planar equatorial disposition of the hexadentate macrocycle, with the two bidentate nitrate functions disposed on opposite sides, giving an altogether more symmetrical decacoordinate structure [61].

3.3. *Nitrogen/sulfur mixed donor macrocyclic ligands*

A comparison of ring and chain configurations of the ligands [9]aneN$_2$S and atam (**43**) and their complexes with lead(II) was given by Herman *et al.* [62]. The relatively low values for log K (6.9 and 5.3, respectively) compare well with the result reported by McPartlin *et al.* [57, 58] where inclusion of thioether functions reduced ligand efficiency relative to the nitrogen analogue. The neutral mixed S,N donor ligands. **44a, 44b** and their complexes with lead(II) were reported by Murphy *et al.* [63]. The crystal structure of the complex [Pb(**44a**)(MeOH)(H$_2$O)](ClO$_4$)$_2$ was also given.



[9]aneN$_2$S



atam

43

44a

44b

3.4. *Oxygen donor macrocyclic ligands*

The structure of the complex [Pb(15-C-5)(SCN)$_2$] has been shown in the crystal structure to comprise two distinct types of coordinated lead(II). In one, the lead is octacoordinate binding five oxygens from the crown ether and three thiocyanato N atoms, the second being similarly bound to the crown ether and one thiocyanato N and two thiocyanato S atoms [64]. IR studies of the prepared complex in the solid state show bands consistent with this change in going from S- to N- bound thiocyanates [64]. Single crystal X-ray structures of the complexes [Pb18-C-6(SCN)$_2$], and [Pb(*cis-anti-cis*dicyclohexyl 18-C-6(SCN)$_2$] were reported along with spectroscopically characterised [Pb(*cis-syn-cis*dicyclohexyl 18-C-6(NCS)$_2$] [65]. In both structures the lead(II) exists in a hexagonal bipyramidal array, with the macrocycle describing the median plane. For [Pb(*cis-anti-cis*dicyclohexyl 18-C-6(SCN)$_2$] both thiocyanate groups are monodentate S bound, whereas in [Pb18-C-6(SCN)$_2$] one is monodentate S bound, the other monodentate N bound [65].

The complex formed from lead(II) acetate and 18-C-6 has also been investigated in the solid state, revealing a somewhat different configuration [66]. The decacoordinate [Pb18-C-6(CH$_3$CO$_2$)$_2$] has both bidentate acetate groups disposed *cis* on one side of the lead(II) and the hexacoordinate crown ether on the opposite face (cf [Pb(**42**)(NO$_3$)$_2$] (*vide supra*).

Sulfur donor macrocycles based upon trithiacycladecane have been shown to complex lead(II) with moderate stability, although no critical stability data has been reported [67].

4. CONCLUSION

The conclusion that is drawn from the foregoing collection of reported research is that there is a wealth of lead(II) coordination chemistry. It is not bounded by the constraints of a requirement for a particular ligand

conformation, nor by a requirement for a specific donor atom type, forming complexes with coordination number ranging from three to ten, with many donor atom types. The significance that lead has as an environmental contaminant and as a poison to humans ensures its future as a metal of interest to coordination chemists.

(Received 14 June 1996; accepted 2 July 1996)

Abstract—A Schiff-base polyoxaazamacrocycle derived from 2,5-diformylfuran and 1,5-bis(2-aminophenoxy)-3-oxapentane was obtained by a template procedure as mononuclear lanthanide(III) and lead(II) complexes. In the absence of the metal salt the macrocycle was not formed. The complexes were characterized by elemental analysis, molar conductivity, mass spectrometry and IR, ^{1}H NMR and ^{13}C NMR spectroscopy. The reduction of the Pb^{II} complex with sodium borohydride yielded a novel polyoxaazamacrocycle containing a furan head and aromatic lateral units; the X-ray crystal structure of its methanol inclusion compound is reported.

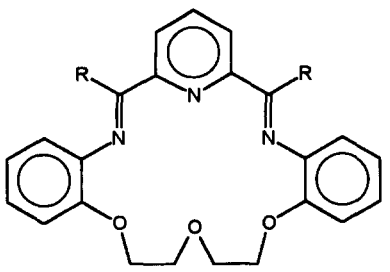
Keywords: template synthesis; lanthanide(III) complexes; polyoxaazamacrocycle; Schiff base; inclusion compound; X-ray crystal structure.

The coordination chemistry of macrocyclic ligands is a fascinating area which has attracted the attention of inorganic chemists. Macrocyclic ligands form stable complexes with lanthanides and they serve as a springboard to explore the coordination chemistry of these metal ions. The ability of lanthanide(III) metal ions to promote the Schiff-base condensation of the appropriate diamine and dicarbonyl precursors, resulting in the formation of metal complexes of otherwise inaccessible macrocyclic ligands, is well established [1,2].



In previous papers [3,4] we have reported the template synthesis of lanthanide(III) complexes of polyoxaaza Schiff-base macrocycles containing aromatic, head and lateral units (L^1, L^2). Herein, we describe an extention of the investigation of the Ln^{III}-promoted synthesis to the macrocycle L^3, which contains a furan head unit, instead of pyridine. In addition, using lead as the templating agent, we have prepared the corresponding complex of L^3 which can be reduced in order to obtain the novel polyoxaazamacrocycle, L^4.

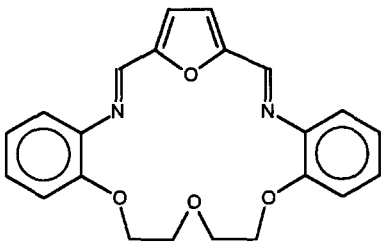
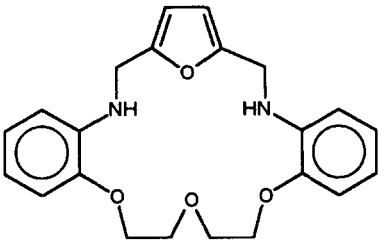
EXPERIMENTAL

Measurements



Elemental analyses, ^{1}H and ^{13}C NMR and mass spectra were carried out by Servicios Generales de Apoyo a la Investigación de la Universidad de La Coruña: elemental analyses were carried out on a Carlo Erba EA 1108 elemental analyser; ^{1}H and ^{13}C NMR spectra were recorded using a Bruker AC 200 F spectrometer and FAB-mass spectra using a Fisons



L1 a) R = H b) R = Me

L2 a) R = H b) R = Me

L3

L4

Quattro mass spectrometer with 3-nitrobenzyl alcohol as the matrix. The IR spectra were recorded, as KBr discs, using a Perkin–Elmer 1330 spectrophotometer.

Conductivity measurements were carried out in 10^{-3} mol.dm^{-3} dimethylformamide solutions at 20°C using a Crison Micro CM 2201 conductivimeter.

Chemicals and starting materials

2,5-Diformylfuran was prepared according to the literature method [5], and 1,5-bis(2-aminophenoxy)-3-oxapentane was prepared by reduction of the corresponding dinitro precursor [3]. Metal salts were commercial reagents from Aldrich and Alfa Laboratories, used without further purification. Solvents were of reagent grade purified by the usual methods.

Condensation between 2,5-diformylfurane and 1,5-bis(2-aminophenoxy)-3-oxapentane in the absence of metal ions

A methanolic solution of 1,5-bis(2-aminophenoxy)-3-oxapentane (1 mol in 20 cm^3) was added dropwise to methanolic solution of 2,5-diformylfuran (1 mmol in 25 cm^3) with stirring and heating. The solution was gently refluxed with magnetic stirring for *ca* 18 h. The solid was filtered off and washed with diethyl ether and air dried. No identifiable product could be isolated.

Reaction of 2,5-diformylfurane and 1,5-bis(2-aminophenoxy)-3-oxpentane in the presence of lanthanide(III) ions

To a refluxing solution of 2,5-diformylfuran (1 mmol) in methanol (50 cm^3) was added a solution of hydrated lanthanide nitrate (1 mmol) in methanol (25 cm^3). The solution was stirred vigorously and heated while a methanolic solution of 1,5-bis(2-aminophenoxy)-3-oxapentane (1 mmol in 50 cm^3) was slowly added. After the addition was complete, the resulting solution was refluxed for *ca* 24 h. The brown powder precipitated was filtered off, washed with diethyl either and dried *in vacuo* (Ln = La, Ce). The complexes of Nd, Eu, Ho, Pr, Sm and Gd were recovered from the resulting solution after evaporation and addition of diethyl ether.

All products appear to be air stable and are soluble in dimethylformamide.

Reaction of 2,5-diformylfurane and 1,5-bis(2-aminophenoxy)-3-oxapentane in the presence of lead(II) perchlorate

To a refluxing solution of 2,5-diformylfuran (1 mmol) in methanol (50 cm^3) was added a solution of hydrated lead(II) perchlorate (1 mmol) in methanol (50 cm^3). The solution was stirred vigorously and heated while a methanolic solution of 1,5-bis(2-aminophenoxy)-3-oxapentane (1 mmol in 50 cm^3) was slowly added. Reflux was maintained for *ca* 24 h. After filtration, the lead complex was recovered from the solution. M.p.: 245–250°C. (decomp.) Found: C, 32.0; H, 2.5; N, 3.8%. Calc. for $[PbL^3](ClO_4)_2 \cdot H_2O$: C, 33.0; H, 2.7; N, 3.5%.

Preparation of the reduced Schiff base macrocycle L^4

To a refluxing solution of 2,5-diformylfuran (2 mmol) and hydrated lead nitrate (2 mmol) in meth-

anol (125 cm^3) was slowly added a methanolic solution of 1,5-bis(2-aminophenoxy)-3-oxapentane (2 mmol in 50 cm^3). After the addition was complete, the resulting solution was refluxed for *ca* 24 h. The lead–Schiff base complex thus formed was reduced *in situ* with $NaBH_4$. The solid formed was filtered off and extracted with dichloromethane. The filtrate was rotary-evaporated to dryness, dissolved in water, filtered and extracted with dichloromethane.

The product recovered from the CH_2Cl_2 solution was recrystallized from acetonitrile/methanol (5 : 1) to give a methanol inclusion compound of L^4 as pale yellow crystals suitable for X ray diffraction. Yield: 40%. M.p.: 206–207 C. Found: C, 66.9; H, 6.65; N, 6.9. Calc. for $L^4 \cdot CH_3OH$: C, 67.0; H, 6.8; N, 6.8%. ^{13}C NMR [$(CD_3)SO$]: 66.70, 69.05, 108.24, 109.75, 109.85, 116.54, 120.90, 136.93, 145.43, 151.20.

Structure determination of $L^4 \cdot CH_3OH$

Suitable pale yellow single crystals of the methanol inclusion compound of L^4 were obtained by cooling an acetonitrile/methanol (5 : 1) solution.

Crystal data. $C_{23}H_{28}N_2O_5$; M = 412.47. Crystallizes as pale yellow oblongs; crystal dimensions $0.48 \times 0.23 \times 0.23$ mm^3. Orthorhombic, $a = 20.808(6)$, $b = 15.212(4)$, $c = 6.641(2)$ Å, $U = 2102.1(10)$ $Å^3$, $Z = 4$, $D_c = 1.303$ g cm^{-3}, space group *Pnma* (D_h^{16}, No. 62), Mo-K_α radiation ($\lambda = 0.71073$ Å), μ(Mo-K_α) = 0.092 mm^{-1}, $F(000) = 880$.

Data collection and processing. Three-dimensional, room temperature X-ray data were collected in the range $3.5 < 2\theta < 45$ on a Nicolet R3 diffractometer by the ω scan method. Of the 1997 reflections measured, all of which were corrected for Lorentz and polarization effects (but not for absorption), 1092 independent reflections exceeded the significance level $|F|/\sigma(|F|) > 4.0$. The structure was solved by direct methods and refined by full-matrix least-squares methods on F^2. Hydrogen atoms were included in calculated positions and refined in riding mode. Refinement converged at a final $R = 0.0488$ ($wR_2 = 0.1366$, for all unique 1438 data, 142 parameters, mean maximum δ/σ 0.000, 0.000), with allowance for thermal anisotropy of all non-hydrogen atoms. Minimum and maximum final electron density: 0.237 and 0.299 e $Å^{-3}$. A weighting scheme $w = 1/[\sigma^2(F_o^2) + (0.0768*P)^2 + 0.2855*P]$ where $P = (F_o^2 + 2*F_c^2)/3$ was used in the latter stages of refinement. Complex scattering factors were taken from the program package SHELXL93 [6] as implemented on the Viglen 486dx computer. Bond lengths and angles, with estimated standard deviations, are listed in Table 1.

Anisotropic thermal vibrational parameters with e.s.d.s., atom position parameters and observed structure amplitudes and calculated structure factors have been deposited at the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

Complexes of lanthanides with L^3

The reaction between furan-2,5-dicarbaldehyde and 1,5-bis(2-aminophenoxy)-3-oxapentane in a 1 : 1 molar ratio in methanol yields a garnet coloured solid which appears to be a mixture of monomeric and possible polymeric products. We have previously found that lanthanide(III) ions can act as effective templates in the formation of oxaaza Schiff base macrocycles derived from 1,5-bis(2-aminophenoxy)-3-oxapentane and 2,6-diformyl- and 2,6-diacetylpyridine [3,4] and Fenton and co-workers have studied the complexation of L^3 with alkaline earth metals, proving that the higher alkaline earth ions (Ca^{2+}, Sr^{2+} and Ba^{2+}) can act as effective templates in the formation of this macrocycle [7,8]. Owing to the similar radii of lanthanide and alkaline earth metal cations it was therefore of interest to investigate the potential application of lanthanide ions as templating ions for the formation of L^3.

When a 1+1 condensation between equimolar amounts of 2,5-diformylfuran and 1,5-bis(2-aminophenoxy)-3-oxapentane was carried out in the presence of hydrated lanthanide(III) nitrates in refluxing methanol for *ca* 24 h, complexes of L^3 with La^{3+}, Ce^{3+}, Nd^{3+}, Eu^{3+} and Ho^{3+} in 1 : 1 ratio were formed in good yields (Table 2).

The complexes were characterized by elemental analysis (C, H, N), molar conductance, mass spectrometry and IR spectroscopy. The analytical and conductivity data are presented in Table 2. The former are consistent with the general formula $[LnL^3][NO_3]_3 \cdot xH_2O \cdot yEt_2O$. The conductivity data in dimethylformamide (dmf) are in the range reported [9] for 2 : 1 electrolytes in this solvent for lanthanum and cerium compounds, and in the range reported [9] for 1 : 1 electrolytes for the europium and holmium complexes. The sparing solubility of the neodymium complex in different solvents restricted the conductivity measurements.

All the complexes have similar IR spectra (Table 3), indicating that they have similar structures. The absence of carbonyl and amine bands, together with the appearance of an imine band at *ca* 1615 cm^{-1}, indicates that condensation and cyclization has occurred [10]. Information about the bonding mode of the nitrate ions may also be obtained from the IR spectra. The free nitrate ion has relatively high symmetry (D_{3h}). When a nitrate ion becomes coordinated in monodentate, bidentate or bridged fashion its effective symmetry is reduced to only C_{2v} or C_s. This causes the degeneracies to split and all modes to be infrared active. Hence, it is possible to distinguish between ionic and coordinated nitrate groups [11]. The presence of a band at 1384 cm^{-1} is characteristic of ionic nitrate present in the outer coordination sphere [12]. The absorption bands occurring in the regions 1466–1452, 1294–1288 and 1040–1030 cm^{-1}

Ho	1612	1452; 1384; 1290; 1030

are assignable to the ν(N=O), $\nu_a(NO_2)$ and $\nu_s(NO_2)$ vibrations [13] and clearly identify these species as containing coordinated nitrate groups. The two highest frequency bands are separated by *ca* 160 cm^{-1}. This magnitude indicates a strong interaction between oxygen atoms from the nitrate with the lanthanide ions and it is typical of bidentate coordination [14,15].

The FAB-mass spectra of the complexes show the peak corresponding to the free macrocycle L^3 at m/z 377, which confirms the monomeric [1 + 1] nature of the ligand. The mass spectrum of the holmium complex shows a peak corresponding to $[HoL^3(NO_3)_2]^+$ at m/z 666.

Even though the presence of the lighter lanthanide(III) ions is essential for the formation of the diimine macrocycle L^3, the corresponding complexes seems to lose the metal very easily. When the complexes are dissolved in dimethyl sulfoxide, a precipitate is observed in a few minutes and the ^1H and ^{13}C NMR spectra of all resultant solutions are identical and correspond to the free macrocycle L^3: δ_H 3.89 (t, 4 H, —CH_2—O), 4.22 (t, 4 H, —CH_2—O), 6.96–7.38 (m, 10 H, furan H and aryl H), 8.60 (s, 2 H, CH=N) and δ_C 68.96, 70.20, 115.19, 117.38, 118.09, 121.52, 128.19, 138.88, 144.00, 153.44, 153.75.

Condensation between equimolar amounts of 2,5-diformylfuran and 1,5-bis(2-aminophenoxy)-3-oxapentane in the presence of praseodymium, samarium and gadolinium nitrates yielded products whose

elemental analyses (Table 4) agreed with the general formula $[Ln(L^3)_2](NO_3)_3 \cdot xH_2O \cdot yEt_2O$. The IR spectra show bands corresponding to imine and nitrates in the same range as was found for the La, Ce, Nd, Eu and Ho complexes. The FAB-mass spectra show the peak corresponding to the free macrocycle L^3 at *m/z* 377. The behaviour in dimethyl sulfoxide is similar to that found for the complexes of La, Ce, Nd, Eu and Ho, and the NMR spectra correspond to the free macrocycle L^3 (no signals of dialdehyde and amine are observed). From this, it seems that Pr, Sm and Gd also act as templates in the formation of L^3.

Complex of lead with L^3

Condensation between equimolar amounts of 2,5-diformylfuran and 1,5-bis(2-aminophenoxy)-3-oxapentane in the presence of lead(II) perchlorate in refluxing methanol for *ca* 24 h yielded a complex with formula $[PbL^3](ClO_4)_2 \cdot H_2O$. The presence of the imine band at 1620 cm^{-1}, together with the absence of carbonyl and amine bands in the IR spectrum indicated that condensation and cyclization had occurred. Bands attributable to perchlorate appear at 1120 and 630 cm^{-1}.

Table 4. Analytical data (%)[a] for the complexes $[Ln(L^3)_2][NO_3]_3 \cdot xH_2O \cdot yEt_2O$

Ln	*x*	*y*	C	H	N
Pr		1	50.2 (50.0)	4.6 (4.3)	8.9 (8.5)
Sm	1	—	47.7 (47.7)	4.2 (3.8)	8.3 (8.8)
Gd	—	2	53.0 (52.1)	4.5 (4.8)	8.3 (7.9)

[a] Required values are given in parentheses.

The FAB-mass spectrum of the complex exhibits a peak corresponding to the free macrocycle, as well as a peak at *m/z* 683 which corresponds to $[PbL^3(ClO_4)]^+$.

Unlike the lanthanide complexes, the lead compound does not undergo demetallation in dimethyl sulfoxide and the ^1H NMR spectrum shows signals at δ 3.93 (4 H, $-CH_2-O$), 4.28 (t, 4H, $-CH_2-O$), 7.03–7.45 (m, 10 H, furan H and aryl H), 8.87 (s, 2 H, CH=N). When this spectrum is compared with the one for the free macrocycle, some changes in the chemical shifts are observed: the most important one occurs for the imine proton signal which is shifted downfield by *ca* 0.27 ppm. The ^{13}C NMR spectrum exhibits signals at δ 67.34, 69.92, 113.76, 118.60, 119.44, 121.62, 129.03, 145.61, 153.17, 153.41.

Reduction of the lead(II) complex $[PbL^3]^{2+}$ with sodium borohydride yielded a novel polyoxaazamacrocycle, L^4, whose IR spectrum did not show the band attributable to the imine bond but displayed bands attributable to >NH groups.

Crystal structure of $L^4 \cdot CH_3OH$

Single crystals of this macrocycle, as a methanol inclusion compound, suitable for X-ray analysis were obtained on cooling an acetonitrile/methanol (5:1) solution. The crystal structure is shown in Figs 1 and

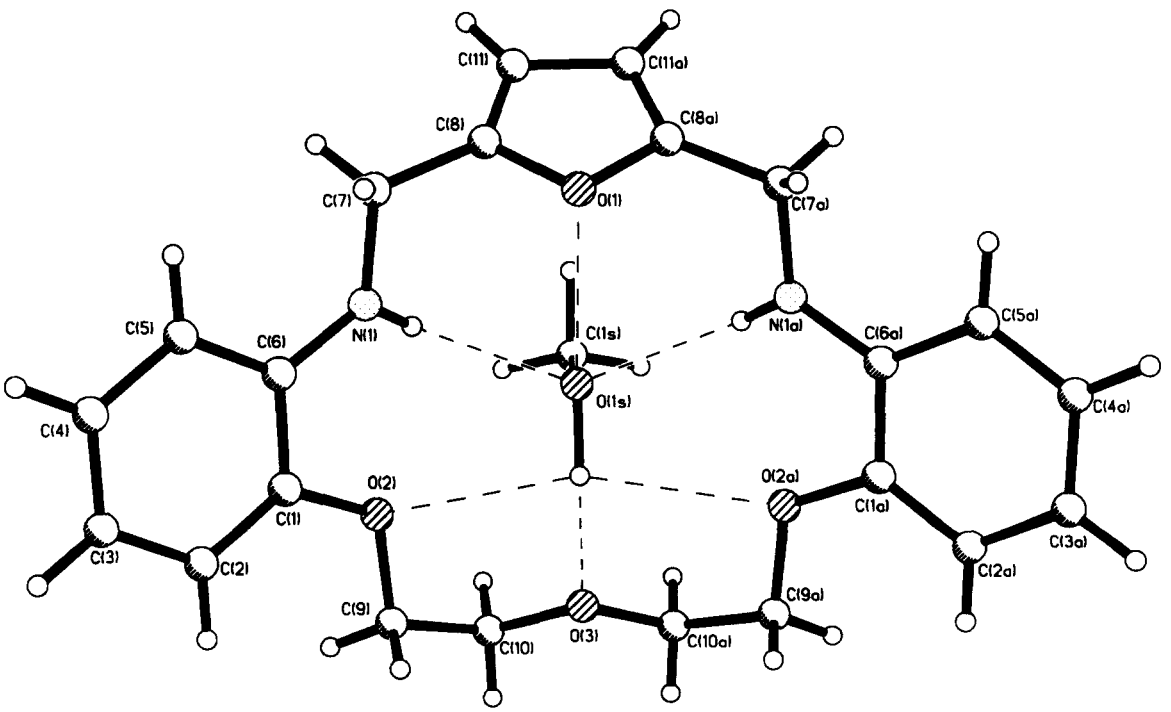

Fig. 1. Top view of the molecular structure of the methanol inclusion.

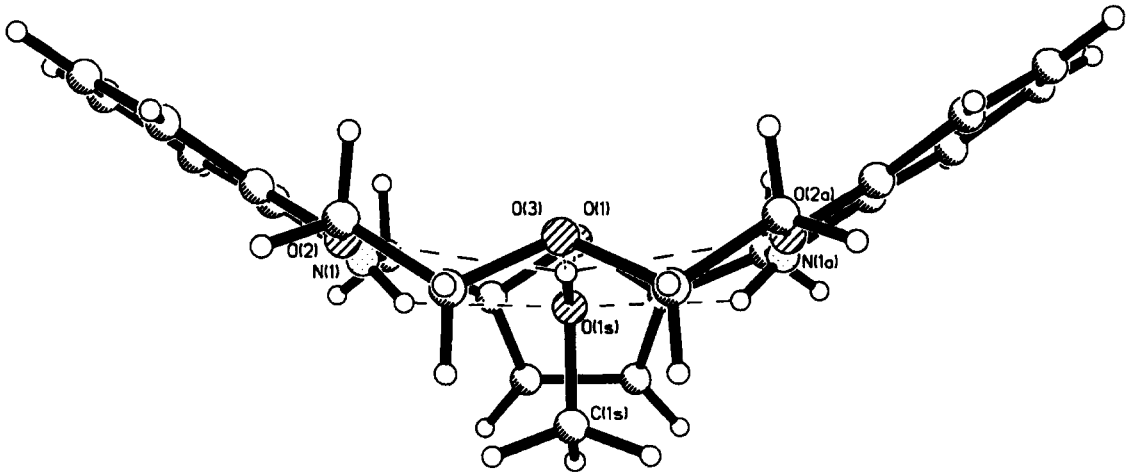

Fig. 2. Side view of the host–guest unit.

2. The molecular geometry is characterized by a crystallographic mirror plane running through O(3) and dividing the furan ring. Heteroatoms are coplanar and the furan ring and both of the benzene nuclei are bent towards opposite sides of the assumed plane, probably to avoid steric overcrowding. The guest methanol is involved in a strong, almost linear, hydrogen bonding interaction between the central oxygen of the polyether chain and the guest hydroxyl [O(1s)···O(3) 2.796, HO(1s)···O(3) 1.667, O(1s)···HO(1s)···O(3) 172.2°] and seems to be involved with both NH groups of the host and the guest oxygen [O(1s)···N(1) 2.956, O(1s)···HN(1) 2.200 Å, O(1s)···HN(1)···N(1) 141°].

The perfect accommodation of the guest methanol by the host molecule is also obvious from steric reasons; that is, the "endo" orientation of the lipophilic methyl group with respect to the host cavity.

The ^{1}H NMR spectrum of a dimethyl sulfoxide solution, derived from the crystals from which the X-ray sample was selected, show peaks corresponding to the macrocycle at δ 3.80 (d, 4 H, —CH_2—N), 4.10 (t, 4 H, —CH_2—O), 4.21 (t, 4 H, —CH_2—O), 4.62 (t, 2 H, —NH), 6.34 (s, 2 H, furan H), 6.60 (m, 4 H, aryl H), 6.80 (m, 4 H, aryl H), together with a doublet centred at δ 3.158 due to the methyl group of the methanol.

Any attempt to prepare complexes of this macrocycle with lanthanide(III) nitrates by direct reaction of the lanthanide salt with L^4 in acetonitrile or methanol were unsuccessful.

(Received 14 June 1996; accepted 2 July 1996)

Abstract—Three new dinuclear tin complexes, $[Me_2Sn(2\text{-}OC_6H_4CH{=}NCH\{Pr^i\}COO)]SnMe_2Cl_2$ (**1**), $[Me_2Sn(2\text{-}OC_{10}H_6CH{=}NCH_2COO)]SnMe_2Cl_2$ (**2**) and $[Ph_2Sn(2\text{-}OC_{10}H_6CH{=}NCH_2COO)]SnPh_2Cl_2$ (**3**), were prepared and characterized by spectroscopic studies and elemental analyses as a 1 : 1 adduct between diorganotin dichloride (acceptor) and bicycloazastannoxide (donor). A full X-ray crystal structure analysis was performed on **3** and the results confirmed that the donor and the acceptor moieties of **3** are bonded with an Sn—O bond distance of 2.307 Å. Keywords: X-ray structure; diorganotin(IV) complexes; spectroscopic studies.

The chemotherapeutic properties, especially the anti-tumour activities of diorganotins, continue to be the focus of many reports [1,2]. Recent studies have shown that many diorganotin(IV) compounds exhibit anti-tumour activity against human tumour cell lines: in particular the symmetric diorganotin diesters [3] derived from iminodiacetic acid and 2,6-pyridinedicarboxylic acid, as well as the bicyclic diorganotin monocarboxylates [4] like dialkyltin derivatives of dipeptides.

In addition to this biological activity, diorganotin carboxylates are of interest for structural reasons [5]. Dimethyltin iminodiacetate monohydrate [6] and bis[aquadi-n-butyl(2,6-pyridine-dicarboxylato)tin (IV)] [7], both analogues of bicyclic diorganotin dicarboxylates, were reported to crystallize as dimers, with a seven-coordinate distorted pentagonal bipyramidal structure around the tin atom. In contrast, the bicyclic diorganotin monocarboxylates, like dialkyltin diglycylglycinates [4,8] and diorgano(*N*-arylidene-α-aminoacidato)tin(IV) complexes [9–11], were reported to be monomeric, with the tin atom in a distorted trigonal bipyramidal geometry and the carboxylate moiety in the tridentate ligand in unidentate mode. In line with these studies on the chemistry of bicycloazastannoxides [9–11] we now report the donating property of the carbonyl oxygen in bicyclic diorganotin monocarboxylates *via* the synthesis and characterization of the molecular adduct between diorganotin dichloride and *N*-(2-oxidoarylideneaminoacidato)diorganotin(IV). The results of a full X-ray structural analysis of $[Ph_2Sn(2\text{-}OC_{10}H_6CH{=}NCH_2COO)]SnPh_2Cl_2$, a new dinuclear tin adduct, are also presented.

EXPERIMENTAL

Carbon, hydrogen and nitrogen analyses were performed in the Schwarzkopf Microanalytical Labora-

* Author to whom correspondence should be addressed.

tory, Woodside, New York, U.S.A. The ^1H and ^{13}C NMR spectra of the samples dissolved in $CDCl_3$ were recorded on a Jeol FX90 MHz spectrometer with TMS as internal standard. IR spectral data of the compounds were recorded using a Perkin–Elmer model 1725 FT-IR spectrometer in the frequency range 4000–450 cm^{-1}. About 5 mg of sample were used for the preparation of KBr disks and 2–10 scans were accumulated for an FT-IR spectrum.

Diphenyltin dichloride was recrystallized in hexanes, and dimethyltin dichloride from Aldrich Chemical Co. was used without purification. Diorgano(*N*-arylidene-α-aminoacidato)tin(IV) were prepared according to published procedures [9–11].

Preparation of the 1 : 1 *adduct of diorgano*(N-*arylidene-α-aminoacidato*)*tin*(IV) *and diorganotin dichloride*

(*a*) $[Me_2Sn(2\text{-}OC_6H_4CH{=}NCH\{Pr^i\}COO)]SnMe_2Cl_2$ (**1**). To $Me_2Sn(2\text{-}OC_6H_4CH{=}NCH\{Pr^i\}COO)$ (0.43 g, 1.1 mmol) in benzene (7 cm^3) was added dimethyltin dichloride (0.26 g, 1.1 mmol) in cm^3 benzene (3 cm^3). The mixture was heated to boiling (2 min). On cooling, petroleum ether (b.p. 60–80°C) was added dropwise until the solution turned turbid (10 cm^3). In the freezer, a yellow solid (0.6 g, 86% yield) was deposited which was recrystallized from benzene/hexanes to give the 1 : 1 adduct, $[Me_2Sn(2\text{-}OC_6H_4CH{=}NCH\{Pr^i\}COO]SnMe_2Cl_2$, m.p. 135–135°C. Found: C, 32.6; H, 4.13; N, 2.5. Calc. for $C_{16}H_{25}Cl_2NO_3Sn_2$: C, 32.7; H, 4.3; N, 2.4%. IR (cm^{-1}): 1622 $\nu(OCO_{asym})$. ^{13}C NMR: δ 173.06 (COO); 173.55 (CH=N); 73.91 (=NCH—); 2.00, 0.16 ($SnMe_2$); 15.68, 19.02, 18.45 (Pr^i); 168.91, 137.84, 135.97, 122.65, 117.76, 117.40 (aromatic carbons). ^1H NMR: δ 8.41 (CH=N); 3.96 (NCH-$\{Pr^i\}$CO); 2.3–2.5, 1.14, 1.06 ($CHMe_2$); 1.17, 0.83 ($SnMe_2$); 7.9–7.2 (ArH).

(*b*) $[Me_2Sn(2\text{-}OC_{10}H_6CH{=}NCH_2COO)]SnMe_2Cl_2$ (**2**). To a stirred solution of $Me_2Sn(2\text{-}OC_{10}H_6CH{=}NCH_2COO)$ (0.78 g, 2 mmol) in toluene (60 cm^3) was added dimethyltin dichloride (0.50 g, 0.2 mmol) in toluene (30 cm^3). The mixture was heated to boiling and the solvent was removed (*ca* 40 cm^3) by evaporation *in vacuo*. On cooling to 4°C, the yellow adduct, $Me_2Sn(2\text{-}OC_{10}H_6CH{=}NCH_2COO)Me_2SnCl_2$ (1.1 g, 83% yield), m.p. 178–180°C was obtained. Found: C, 34.5; H, 3.8; N, 2.9. Calc. for $C_{17}H_{21}Cl_2NO_3Sn_2$: C, 34.3; H, 3.6; N, 2.4%. IR (cm^{-1}): 1620 $\nu(OCO_{asym})$. ^{13}C NMR: δ 171.68 (COO); 167.20 (CH=N); 57.54 (=NCH_2—); 15.63, 1.18 ($SnMe_2$); 171.43, 139.30, 133.83, 129.33, 128.76, 126.93, 124.46, 123.71, 118.86, 108.32 (aromatic carbons). ^1H NMR: δ 9.23 (CH=N); 4.47 (NCH_2CO); 1.17, 0.83 ($SnMe_2$); 7.9–7.2(ArH).

(*c*) $[Ph_2Sn(2\text{-}OC_{10}H_6CH{=}NCH_2COO)]SnPh_2Cl_2$ (**3**). Preparation of compound **3** was accomplished according to the procedure used for **2**. Diphenyltin dichloride (0.70 g, 2 mmol) and $Ph_2Sn(2\text{-}OC_{10}H_6CH{=}NCH_2COO)$ (1.0 g, 2 mmol) were refluxed in benzene (80 cm^3). The product (1 g, 58% yield) was recrystallized from benzene at room temperature to give crystals of $[Ph_2Sn(2\text{-}OC_{10}H_6CH{=}NCH_2COO)]SnPh_2Cl_2$, m.p. 188–190°C. Found: C, 54.0; H, 3.6; N, 1.9. Calc. for $C_{37}H_{29}Cl_2NO_3Sn_2$: C, 52.7; H, 3.5; N, 1.7%. IR (cm^{-1}): 1618 $\nu(OCO_{asym})$. ^{13}C NMR: δ 172.78 (COO); 166.63 (CH=N); 57.82 (=NCH_2—); 171.52, 140.45, 137.60, 137.23, 136.37, 135.15, 133.69, 131.61, 130.92, 129.61, 129.09, 127.29, 124.57, 124.16, 118.42, 108.48 (aromatic carbons). ^1H NMR: δ 9.18 (CH=N); 4.44 (NCH_2CO); 7.9–7.2 (ArH).

X-ray crystallography of $[Ph_2Sn(2\text{-}OC_{10}H_6CH{=}NCH_2COO)]Ph_2SnCl_2$

Crystal data. $C_{37}H_{29}Cl_2NO_3Sn_2$, F.W. = 843.9, monoclinic, $C2/c$; $a = 27.055(7)$, $b = 16.221(4)$, $c = 17.445(4)$ Å; $\beta = 115.44(4)°$; $D_{calc} = 1.622$ Mg m^{-3}; $F(000) = 3328$; $V = 6914(3)$ $Å^3$; $\mu = 1.64$ mm^{-1} for $Z = 8$. A total of 6296 reflections were collected from a selected single crystal of dimensions $0.30 \times 0.30 \times 0.20$ mm^3 using a Siemens R3M/V2000 diffractometer with Mo-K_α radiation by ω scan (2.50 to 30.00° min^{-1} between $3.0 < 2\theta < 50.0°$). These intensity data were reduced and corrected for Lorentz and polarization factors resulting in a total of 6137 independent reflections. The structure was solved by direct methods [12] and refined by full-matrix least squares on F [the total of observed reflections: 4251 ($F > 4\sigma(F)$)] using SHELXTL PLUS. The tin, carbon, nitrogen, oxygen and chlorine atoms were refined with anisotropic thermal parameters. Hydrogen atoms were placed at calculated positions with assigned isotropic thermal parameters. The final refinement gave $R = 0.042$ and $R_w = 0.050$ (data-to-parameter ratio: 10.4 : 1). Selected bond angles and interatomic distances are listed in Table 1.

Supplementary material, including non-hydrogen and hydrogen atomic coordinates and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre, and observed and calculated structural factors are available upon request from the corresponding author.

RESULTS AND DISCUSSION

The crystal structure of $[Ph_2Sn(2\text{-}OC_{10}H_6CH{=}NCH_2COO)SnPh_2Cl_2$ reveals a monomeric 1 : 1 donor–acceptor dinuclear tin complex (Fig. 1). Each of the two tin atoms, Sn(1) and Sn(2), has a five-coordination geometry in a distorted trigonal bipyramidal arrangement.

The Sn(1) atom lies in the ligand plane and forms a five-membered and a six-membered chelate ring with the ligand. Thus, the two phenyl groups and the imino nitrogen take up the equatorial positions, while the oxygen atoms, O(2) and O(14A), take up the axial

C(1)—C(2)	1.406(8)	O(14)—Sn(2)—C(41)	89.2(2)
C(1)—C(11)	1.407(7)	Cl(1)—Sn(2)—C(51)	112.3(2)

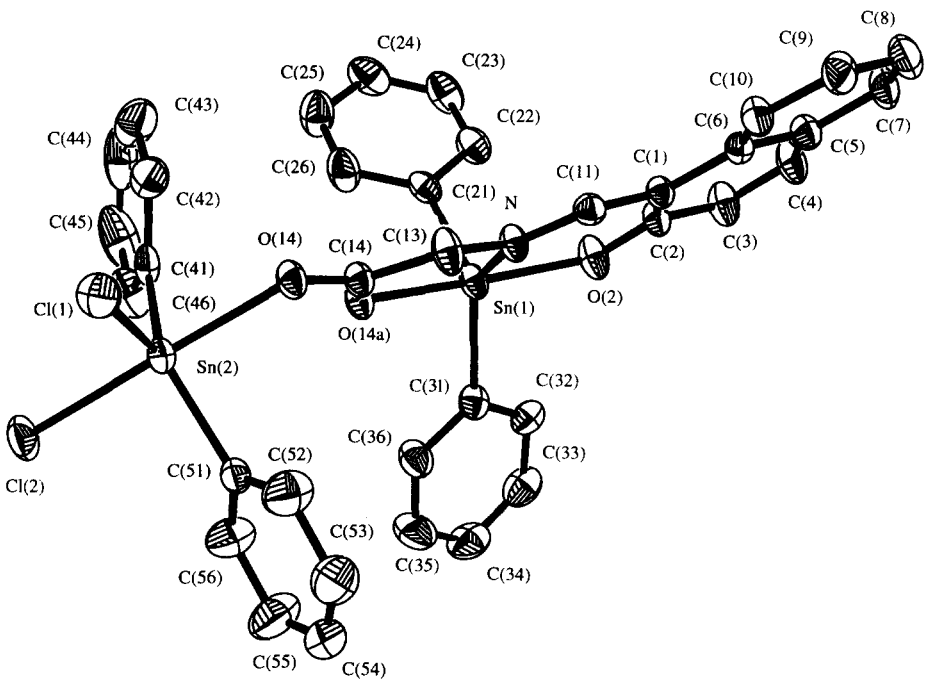

Fig. 1. Molecular structure and crystallographic numbering scheme employed for $[Ph_2Sn(2\text{-}OC_{10}H_6CH{=}NCH_2COO)]SnPh_2Cl_2$.

sites around the Sn(1) atom. The bond lengths and bond angles (Table 1) around the Sn(1) atom, including Sn(1)—N (2.136 Å), Sn(1)—O(2) (2.068 Å); O(2)—Sn(1)—O(14A) (159.5°) and N—Sn(1)—O(14A) (75.8°), remain practically unchanged compared with the donor, $Ph_2Sn(2\text{-}OC_{10}H_6CH{=}NCH_2COO)$ [11].

The Sn(2) atom, which forms the acceptor fragment of the title compound **3**, is bonded to the carbonyl oxygen, O(14), with an Sn(2)—O(14) bond distance of 2.307 Å. Thus, the Sn(2) atom is surrounded by O(14) and Cl(2) along the axial direction while the second chlorine atom, Cl(1), and the *ipso* carbons, C(41) and C(51), of the two phenyl groups form the equatorial plane. The trigonal bipyramidal geometry of Sn(2) is distorted as indicated by bonding angles of 135.6(2), 112.3(2), 110.9(2) and 176.6(1)° for C(41)—Sn(2)—C(51), C(51)—Sn(2)—Cl(1), Cl(1)—Sn(2)—C(41) and Cl(2)—Sn(2)—O(14), respectively.

All the phenyl rings in **3** are nearly planar, with very small deviations of 0.0050(4) for C(21)–C(26),

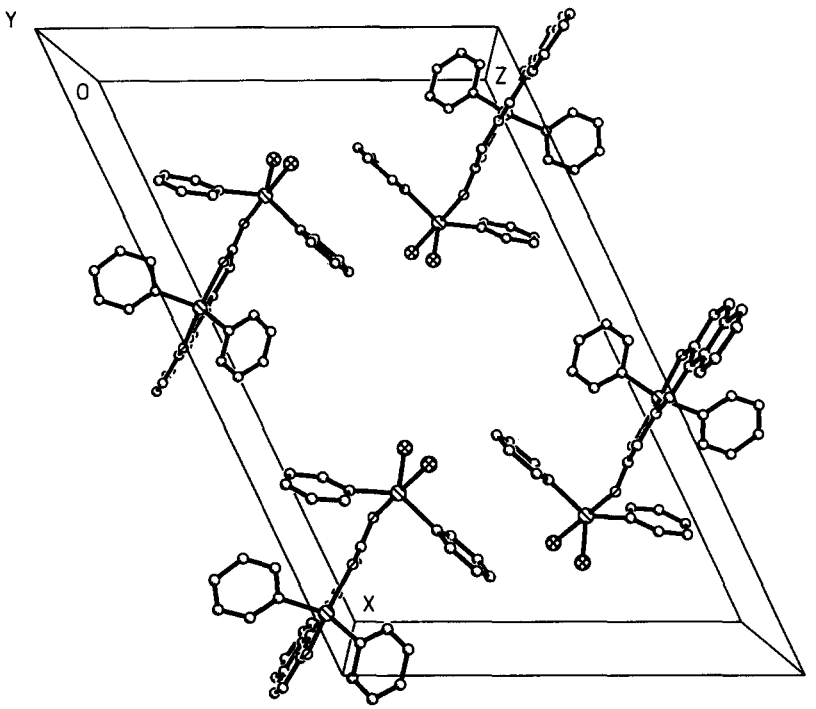

Fig. 2. The packing view of the unit cell of $[Ph_2Sn(2\text{-}OC_{10}H_6CH{=}NCH_2COO)]SnPh_2Cl_2$.

0.0079(5) for C(31)–C(36), 0.0109(6) for C(41)–C(46) and 0.0027(6) for C(51)–C(56). The naphthyl ring formed by C(1)–C(10) is close to coplanar with the O(2), Sn(1), O(14A), C(14), C(13), N and C(11) atoms, with a deviation of 0.0778(4) Å [Sn(1) plane] (Fig. 2). The crystal structure of **3** (Fig. 2) adopts a "butterfly-shape" headed by Sn(2) with the four phenyl rings as the "wings" and the Sn(1) plane as the "body". The dihedral angles between the "body" and the "wings" are 112.7(4) [C(21)–C(26)], −136.2(5) [C(31)–C(36)], 104.1(6) [C(41)–C(46)] and −101.7(6)° [C(51)–C(56)].

The IR carbonyl stretching frequency appears as a strong broad band at 1680 cm^{-1} for $Ph_2Sn(2\text{-}OC_{10}H_6CH{=}NCH_2COO)$ [11] and shifts by 62 cm^{-1} for **3**, confirming the interaction between the Sn and the carbonyl oxygen atoms. Similar shifts were observed for the adducts **1** and **2**. The proton and ^{13}C NMR spectra for **1**, **2**, and **3** are very similar. Compared with their respective donors, a shift in the carbonyl ^{13}C absorption (*ca* 0.3–0.5 ppm) was observed. The marked similarities in the spectra of the three adducts, which have the same stoichiometry and are prepared in like manner, provide strong evidence that they are isostructural with each other.

Reaction of $[Ru_3(CO)_{12}]$ with 2-(chloromethyl)pyridine, syntheses of pyrid-2-ylacetyl ruthenium(II) complexes and crystal structure of $[RuCl(C_5H_4N\text{-}2\text{-}CH_2CO)(CO)(PPh_3)_2]$

(Received 6 June 1996; accepted 1 July 1996)

Abstract—The cycloruthenated pyrid-2-ylacetyl complex $[\{RuCl(C_5H_4N\text{-}2\text{-}CH_2CO)(CO)_2\}_2]$ (**1**) was obtained by reaction of $[Ru_3(CO)_{12}]$ with an excess of 2-(chloromethyl)pyridine in refluxing toluene. Subsequent reaction of **1** with two equivalents of triphenylphosphine in refluxing benzene afforded the bis(phosphine) derivative $[RuCl(C_5H_4N\text{-}2\text{-}CH_2CO)(CO)(PPh_3)_2]$ (**2**). X-ray analysis of **2** shows that the complex is monomeric with the ruthenium atom coordinated by ring nitrogen and acyl carbon atoms from the cycloruthenated pyrid-2-ylacetyl group, *cis* chlorine and carbonyl carbon atoms, and *trans* phosphorus atoms, to form a distorted octahedral geometry. Copyright © 1996 Elsevier Science Ltd

Keywords: ruthemium(II) complex; triruthenium dodecacarbonyl; oxidative addition; nitrogen heterocycle; X-ray structure; 2-(chloromethyl)pyridine.

We have previously studied the reactions of 2-(chloromethyl)- and 2,6-bis(chloromethyl)-pyridine (abbreviated as 2-cmpy and 2,6-cmpy, respectively) with low-valent palladium and rhodium complexes. For example, 2-cmpy reacted with $[Pd(PPh_3)_4]$ to give a C,N-bridged dinuclear complex $[\{PdCl(\mu\text{-}C_5H_4N\text{-}2\text{-}CH_2)PPh_3\}_2]$, [1] while 2,6-cmpy gave a tandem tetranuclear complex $[\{Pd_2Cl(\mu\text{-}Cl)[\mu\text{-}C_5H_3N\text{-}2,6\text{-}(CH_2)_2](PPh_3)_2\}_2]$ in addition to a dinuclear complex analogous to that mentioned above [2]. In the reaction with $[RhCl(PPh_3)_3]$, 2-cmpy afforded C,N-chelated mononuclear complexes *cis* (PP)- and *trans* (PP)-$[RhCl_2(C_5H_4N\text{-}2\text{-}CH_2)(PPh_3)_2]$, whereas 2,6-cmpy gave the corresponding *cis* (PP) and *trans* (PP) complexes or a novel dinuclear complex $[Rh_2Cl_4\{C_5H_3N\text{-}2,6\text{-}(CH_2)_2\}(PPh_3)_2]$ according to the reactant's mole ratio, in which the 2,6-dimethylpyridine-α,α'-diyl ligand is C,N-chelated to one rhodium atom and bound to the second one in an η^3-pseudo-1-aza-allylic fashion [3].

Recently, much attention has been devoted to the reactivities of dodecacarbonyltriruthenium towards N-donor ligands, especially those containing N heterocycles [4]. The reaction of the carbonyl cluster with pyridine gave a cycloruthenated complex $[Ru_3(\mu\text{-}H)(\mu\text{-}C_5H_4N)(CO)_{10}]$ [5]. Similar μ-hydrido-triruthenium cluster complexes have been obtained with 2-aminopyridine [6] and pyridine-2-thiol [7]. Although the reactions with other substituted pyridines, like 2-pyridinecarbinol [8], 2-pyridone [6] and 2-(diphenylphosphino)pyridine [9], have been investigated too, no reactions with halo- and halomethyl-substituted pyridines have been described to our knowledge. Here, we report on the products obtained from reaction of $[Ru_3(CO)_{12}]$ with 2-cmpy, followed by reaction with triphenylphosphine.

EXPERIMENTAL

All the reactions were performed under nitrogen, using solvents that were redistilled under argon. The reagent 2-cmpy was freed from its hydrogen chloride

* Author to whom correspondence should be addressed.

adduct by the action of NEt_3. The carbonyl cluster $[Ru_3(CO)_{12}]$ was purchased from Aldrich Chemical Company Inc. and used without further purification. IR spectra were obtained as Nujol mulls with a JASCO A-702 spectrophotometer. ^1H and ^{13}C NMR spectra were recorded on Jeol JNM GX-400 instrument at 400 and 100 MHz, respectively. ^{31}P NMR spectra were measured using a Jeol α-400 instrument at 24.2 MHz. Internal TMS (^1H, ^{13}C) and external H_3PO_4 (^{31}P) were used as references. FAB-mass spectra were obtained with a Jeol JMS AX-500 spectrometer in the positive-ion mode using 3-NBA as a matrix, dichloromethane as a solvent and xenon as a bombardment gas.

Reaction of $[Ru_3(CO)_{12}]$ *with* 2-cmpy. *Synthesis of* $[\{RuCl(C_5H_4N\text{-}2\text{-}CH_2CO)(CO)_2\}_2]$ (**1**)

To a suspension of $[Ru_3(CO)_{12}]$ (0.31 g, 0.48 mmol) in toluene (10 cm^3) was added 2-cmpy (7.1 mmol), and the mixture was heated at 110°C for 2 h. A wine-red solution was obtained at 90°C and then a precipitate separated out gradually, which was collected, washed with ether and dried *in vacuo*. Yield 0.40 g (89%). Yellow ochre. IR (cm^{-1}): ν(CO) 2020, 1975, 1952, 1930(sh), 1665. ^1H NMR (CD_3CN): δ 4.14, 3.80 (2H, ABq, J = 20.5 Hz, CH_2); Py-ring 7.48 (1H, t, J = 6.7 Hz, H^5), 7.56 (1H, d, J = 7.9 Hz, H^3), 7.97 (1H, t, J = 7.3 Hz, H^4), 8.81 (0.8H, br s, H^6), 9.51 (0.2H, br s. $H^{6'}$). ^{13}C NMR (CD_3CN): δ 63.3 (CH_2); Py-ring 123.7, 124.0 (C^3, C^5), 140.3 (C^4), 150.3 (C^6), 162.6 (C^2). Found: C, 34.3; H, 1.9; N, 4.5: Calc for $C_9H_6ClNO_3Ru$: C, 34.6; H, 1.9; N, 4.5%.

Reaction of **1** *with* PPh_3. *Synthesis of the bis(phosphine) derivative* $[RuCl(C_5H_4N\text{-}2\text{-}CH_2CO)(CO)(PPh_3)_2]$ (**2**)

A suspension of **1** (0.06 g, 0.20 mmol) in benzene (8 cm^3) containing PPh_3 (0.13 g, 0.55 mmol) was heated at 80°C for 2 h. In a few minutes the suspension turned pink. The crude product was filtered, washed with diethyl ether and dried *in vacuo*. Recrystallization from $CHCl_3/Et_2O$ gave **2** (pink). After drying, the residue was redissolved in dichloromethane and diethyl ether was added to reprecipitate **2** (white). Total yield 97%. The pink and white products were the same based on their NMR data. IR (cm^{-1}): ν(CO) 1928, 1605. ^1H NMR ($CDCl_3$): δ 2.96 (2H, s, CH_2); Py-ring 6.37 (1H, triple d, J = 7.3, *ca* 2 Hz, H^5), 6.93 (1H, d, J = 7.3 Hz, H^3), 7.36 (1H, triple d, J = 7.3, *ca* 2 Hz, H^4), 8.21 (1H, d, J = 7.3 Hz, H^6); PPh_3 7.1–7.5. ^{13}C NMR($CDCl_3$): δ 62.1 (CH_2), 120.0 (C^5), 122.7 (C^3), 135.9 (C^4), 152.1 (C^6), 161.2 (C^2); PPh_3 127–135. ^{31}P NMR ($CDCl_3$): δ 32.9. FAB-MS *m/z*: 809 (M^+), 774 ($M-Cl^+$), 746 ($M-Cl-CO^+$), 717 ($M-Cl-2CO^+$). Found: C, 65.2; H, 4.4; N. 1.8. Calc. for $C_{44}H_{36}ClNO_2P_2Ru$: C, 65.3; H, 4.5; N, 1.7%.

X-ray crystallography

Pale yellow crystals of **2**·Et_2O were obtained by slow evaporation from a chloroform/diethyl ether solution. A crystal of appropriate dimensions, $0.40 \times 0.22 \times 0.15$ mm^3, mounted in a glass capillary was used for data collection at a temperature of 23°C on a Rigaku AFC5R diffractometer with graphite-monochromated Cu-K_α (λ = 1.54178 Å) radiation and the ω–2θ scan technique. Accurate cell dimensions and crystal orientation matrices were determined by least-squares refinement of 25 reflections ($57.9 < 2\theta < 59.8°$) for complex **2**·Et_2O. A total of 7041 reflections were collected to a maximum 2θ value of 120.2°; 6710 of them were unique, and of these 4933 were assumed as observed [$I > 3.0\ \sigma\ (I)$], and were used for refinement (506 parameters), converging to R = 0.037 and R_w = 0.048. For all these structures the data were corrected for Lorenz, polarization, and absorption effects. A decay correction was also applied.

The structure of **2**·Et_2O was solved by the heavy-atom Patterson methods (DIRDIF92 PATTY) [10] and expanded using Fourier techniques. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were located on a ΔF map and refined isotropically. The maximum and minimum peaks on the final difference Fourier map, and goodness-of-fit corresponded to 0.41 and -0.42 $eÅ^{-3}$, and 1.67, respectively. All calculations were performed using the teXsan [11] crystallographic software package.

Crystal data for **2**·Et_2O. Formula = $[C_{44}H_{36}ClNO_2P_2Ru][C_4H_{10}O]$, F.W. = 883.37, monoclinic, space group $P2_1/c$ (No. 14), a = 13.015(4), b = 15.611(3), c = 21.257(3) Å, β = 93.15(2)°, V = 4312(1) $Å^3$, Z = 4, $D_{calc.}$ = 1.360 g cm^{-3}.

RESULTS AND DISCUSSION

Reactions of $[Ru_3(CO)_{12}]$ with an excess of 2-cmpy in refluxing toluene afforded the cycloruthenated dinuclear complex $[\{RuCl(C_5H_4N\text{-}2\text{-}CH_2CO)(CO)_2\}_2]$ (**1**). Complex **1** is insoluble in non-coordinating solvents, but readily dissolves in CH_3CN, from which the complex could not be recovered as a pure solid. Bridge-splitting reaction and subsequent substitution of the one carbonyl group of **1** with triphenylphosphine in a benzene suspension at 80°C gave the monomeric, organic-soluble bis(phosphine) derivative $[RuCl(C_5H_4N\text{-}2\text{-}CH_2CO)(CO)(PPh_3)_2]$ (**2**). Such a substitution of the carbonyl group with triphenylphosphine has been observed in the complexes $[\{RuCl(phpy)(CO)_2\}_2]$ and $[\{RuCl(bzqn)(CO)_2\}_2]$ (Hphpy = 2-phenylpyridine; Hbzqn = benzo[*h*]quinoline) and is explained by the skeletal conjugation of the cyclometalated organic groups [12]. The ^{31}P NMR spectrum of **2** in $CDCl_3$ shows a sharp singlet, and hence the *trans*-bis(phos-

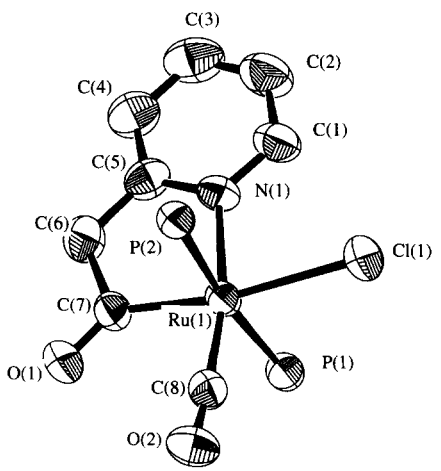
phine) structure can be assigned for **2**. The ^{1}H NMR spectrum of **2** in $CDCl_3$ exhibits a sharp singlet assignable to the CH_2 group, indicating that complex **2** has a symmetrical plane including the pyridyl and cycloruthenated rings. Two geometrical isomers of *trans* (N, CO) and *trans* (N, Cl) are possible for **2**. The IR spectrum of this complex exhibits a comparatively low frequency ν(CO) band. This low stretching frequency of the carbonyl group is known to reflect the structure possessing the carbonyl group *trans* to a nitrogen donor ligand [13,14]. X-ray analysis finally established the exact structure of **2** (Fig. 1). Selected bond lengths, bond angles and torsion angles are listed in Table 1.

The structure is monomeric and has a distorted octahedral geometry. The ruthenium atom is coordinated by the N, C (acyl), C (carbonyl) and Cl atoms in an equatorial plane and the two axially situated phosphorus atoms. The pyrid-2-ylacetyl group is cycloruthenated and constitutes a five-membered ring with the ruthenium atom. The pyridyl and cycloruthenated rings are almost coplanar to one another.



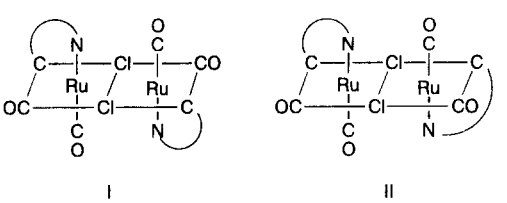


Fig. 1. The crystal structure of **2** with hydrogen and phenyl carbon atoms omitted for clarity. The solvent of crystallization is also omitted.

As is to be expected from the above discussion, the carbonyl group is situated in the position *trans* to the ring nitrogen atom. The bite angle (N(1)—Ru(1)—C(7)) is relatively small and as a result the angle Cl(1)—Ru(1)—C(8) is spread out. Other bond lengths and angles are generally normal. Complex **2** (pink) is photosensitive and turns white gradually when irradiated with the sunlight. It cannot be ruled out that the *trans* (N, CO) to *trans* (N, Cl) isomerization is responsible for this colour change.

The IR spectrum of **1** shows two strong bands in the terminal carbonyl region suggesting a *cis* arrangement of the two carbonyl groups coordinated to each ruthenium atom in the dinuclear complex [12]. The spectrum also shows an additional ν(CO) band at 1665 cm^{-1} indicating the presence of a CH_2CO group formed by cycloruthenation of the pyrid-2-ylmethyl group followed by CO insertion. The presence of the cycloruthenated pyrid-2-ylacetyl group is also shown by the ^{1}H and ^{13}C NMR spectra of **1** in CD_3CN. In addition to these facts and the consideration mentioned above for the structure of complex **2**, the appearance of the two separate signals (approximately 1 : 4 in intensity) which can be assigned to the H^6 pyridyl ring proton, suggests the coexistence of the two kinds of isomers (**I** and **II**) coming from different

arrangements of the other ligands around the metal. Only a few examples of the cyclometalated pyrid-2-ylacetyl complexes have been described to our knowledge: $[PdCl(C_5H_4N\text{-}2\text{-}CH_2CO)(PPh_3)]$ [1a], $[Mn(C_5H_4N\text{-}2\text{-}CH_2CO)(CO)_4]$ [15] and $[Mo(C_5H_4N\text{-}2\text{-}CH_2CO)(\eta^5\text{—}C_5H_5)(CO)_2]$ [15]. All these complexes, as well as **2**, have a symmetrical plane

including the cycloruthenated ring, and hence the methylene protons appeared as a singlet, while those of complex **1** appear as an AB quartet, indicating that the structure of **1** is unsymmetrical about the cycloruthenated ring. The tendency for metal carbonyl anions to form a cyclic derivation on reaction with 2-cmpy is directly related to the tendency for the derivatives formed from the same metal carbonyl anions and acyl halides to undergo decarbonylation on heating or irradiation [15]. Both of these tendencies are thought to be directly related to the strength of the M—CO bond in these compounds [16].

(Received 24 May 1996; accepted 1 July 1996)

Abstract—The reaction between $[Nb(OPr^i)_5]_2$ and methacrylic acid $[CH_2C(CH_3)CO_2H{=}McOH]$, and subsequent controlled microhydrolysis, gave $[Nb_4(\mu\text{-}O)_4(\mu,\eta^2\text{-}Mc)_4(OPr^i)_8]$ which was characterized by X-ray diffraction. The compound is based on a planar Nb_4O_4 core with terminal isopropoxide ligands, while the functional carboxylates act as bridging chelating ligands. The Nb—O bond lengths vary from 1.840(3) to 2.203(4) Å and follow the order Nb—OR ~ Nb—O < Nb—O(Mc). The Nb—O—Nb angles are bent with values of 146.2(2) and 150.2(2)°, respectively. The polymerization behaviour is discussed. Copyright © 1996 Elsevier Science Ltd

Keywords: niobium; oxoalkoxide; sol–gel; carboxylates; polymerizable ligands.

Hybrid organic–inorganic materials have gained increasing interest over the last few years [1]. The versatility and mild experimental conditions of the sol–gel process allow the incorporation of a large variety of organic functional compounds and thus opens up a large palette of technological applications. The use of heteroleptic alkoxides $M(OR)n-xG_x$ is one of the strategies employed to avoid phase separation between the organic and inorganic components in the final oxide materials. Indeed, such precursors can give access to an inorganic network in which the organic groups G are chemically bonded as a result of differential hydrolysis between the ligands of type OR and G. The organic groups G can be polymerizable, thermo- or photolabile, or mono- or polyfunctionalized. The synthesis of transition metal oxo clusters capped with polymerizable ligands, which can be used to extend the network to form hybrid organic–inorganic polymers, has recently been reported [2].

We have recently shown the limits of the use of 2-hydroxyethylmethacrylate as a ligand for oxophilic metals [3]. Acids were anticipated to provide more stable derivatives [4]. We report here the reaction of $[Nb(OPr^i)_5]_2$ with methacrylic acid followed by subsequent microhydrolysis. The cluster $[Nb(\mu\text{-}O)_4(\mu,\eta^2\text{-}Mc)_4(OPr^i)_8]$ ($Mc = O_2CCMeCH_2$) was thus obtained. Its characterization has been achieved by X-ray diffraction, FT-IR and NMR. Its reactivity was also investigated.

EXPERIMENTAL

All reactions were achieved under inert atmosphere using Schlenk tube techniques. Solvents were dried and purified by distillation. $[Nb(OPr^i)_5]_2$ was obtained according to the literature [5,6]. Methacrylic acid (Aldrich) was stored over molecular sieves, ^1H, ^{13}C NMR and IR spectra were recorded on Bruker AC-200 and IR-FTS 45 spectrometers, respectively. IR spectra were obtained as Nujol mulls between KBr

plates. Analyses were obtained from the Centre de Microanalyses du CNRS.

Synthesis of $[Nb_4(\mu\text{-}O)_4(\mu,\eta^2\text{-}Mc)_4(OPr^i)_8]$

Methacrylic acid (0.225 ml, 2.65 mmol) in toluene (10 cm^3) was slowly added to a solution of $[Nb(OPr^i)_5]_2$ (1.03 g, 1.32 mmol) in toluene (20 cm^3). The reaction medium was stirred at room temperature for 5 h and evaporated. The resulting oil was dissolved in isopropanol (5 cm^3) and a solution of water in isopropanol (0.53 cm^3, 1 M) was added ($h = 0.2$). Crystallization led to 0.52 g (63%) of white, air-sensitive crystals of **1,** soluble in toluene, cyclohexane, THF and diethyl ether, but insoluble in hexane and alcohols. Found: C: 38.8; H: 6.3. Calc. for $C_{40}OH_{76}O_{20}Nb_4C$: 38.5; H: 6.1%. IR (cm^{-1}): 1647m ν(C=C); 1578vs $\nu_{as}(CO_2)$; 1462s, 1416s, $\nu_s(CO_2)$; 1377s, 1130m, 1244m; 1152vs, 1126vs ν(C—O); 1003sh; 998vs ν(Nb—O—Nb); 935m, 854m, 831w, 763sh; 733vs ν(Nb—O—Nb); 605sh, 590vs, 469m, 430m, 401m ν(Nb—OR). ^{1}H NMR (C_6D_6, ppm): δ 6.5, 6.3 (t, 4H (1 : 1), CH, $J = 2.2$ Hz), 5.4, 5.3 (t, 4H (1 : 1), CH, $J = 2.2$ Hz), 5.1 (sept, 4H, OCH, $J = 6.6$ Hz), 4.9 (sept, 4H, OCH, $J = 6.6$ Hz), 2.17s, 1.97 (s, 12H (1 : 1), CH_3), 1.47–1.28 (overlapping of doublets, 48H, CH_3, $J = 6.6$ Hz). ^{13}C NMR (C_6D_6, ppm): δ 174.8, 174.6 (CO_2); 140.6 140.3 ($C{=}CH_2$); 125.5, 125.4 ($CH_2{=}C$); 79.2, 73.9 (CH); 25.6 25.4, 25.2, 25.1 (CH_3, Pr^i); 19.8, 19.3 (CH_3, Mc).

The same product was obtained by reacting $[Nb(OPr^i)_5]_2$ and methacrylic acid directly in isopropanol and hydrolysis ($h = 0.3$), but the yield was lower (20%) owing to some esterification of the methacrylic acid.

Crystallography of $[Nb_4(\mu\text{-}O)_4(\mu,\eta^2\text{-}Mc)_4(Opr^i)_8]$

A selected crystal (obtained directly from the reaction medium) was mounted in a Lindemann glass capillary and set up on an automatic diffractometer. Unit-cell dimensions with estimated standard deviations were obtained from least-squares refinements of the setting angles of 25 well-centred reflections. Two standard reflections were monitored periodically; they showed no change during data collection. Crystallographic data and other pertinent information are summarized in Table 1. Corrections were made for Lorentz and polarization effects. Empirical absorption corrections (Difabs) [7] were applied.

Computations were performed by using CRYSTALS adapted on a MicroVax II [8]. Atomic structure factors for neutral C, O, Nb and H were taken from ref. [9]. Anomalous dispersion was taken into account. The structure was solved by the Patterson method and subsequent Fourier maps. Almost all hydrogen atoms were found on difference maps, the others were geometrically located. Their positions were not refined and they were given an overall isotropic thermal parameter. Non-hydrogen atoms were anisotropically refined. Least-squares refinements with approximation in three blocks to the normal matrix were carried out by minimizing the function $\Sigma w(|F_0| - |F_c|)_2$, where F_0 and F_c are the observed and calculated structure factors. Unit weight was used. Models reached convergence with $R = \Sigma(||F_0| - |F_c||)/\Sigma|F_0|$ and $R_w = [\Sigma w(|F_0| - |F_c|)^2/[\Sigma w(F_0)^2]]^{1/2}$ having the values listed in Table 1. Criteria for a satisfactory complete analysis were the ratios of rms shift to standard deviations being less than 0.1 and no significant features in the final difference map.

Tables of atomic coordinates anisotropic temperature factors, and observed and calculated structure factors have been deposited at the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

The reaction between $[Nb(OPr^i)_5]_2$ and methacrylic acid (1 : 2 stoichiometry) in toluene at room temperature yields an oily product. FT-IR shows the presence of uncoordinated acid (1690 cm^{-1}). Subsequent controlled microhydrolysis (hydrolysis ratio $h = [H_2O]/[Nb(OR)_5]$ of 0.2) in Pr^iOH allowed the isolation of a white crystalline material, **1,** in 63% yield. The same compound was obtained if the reaction and subsequent microhydrolysis were carried out

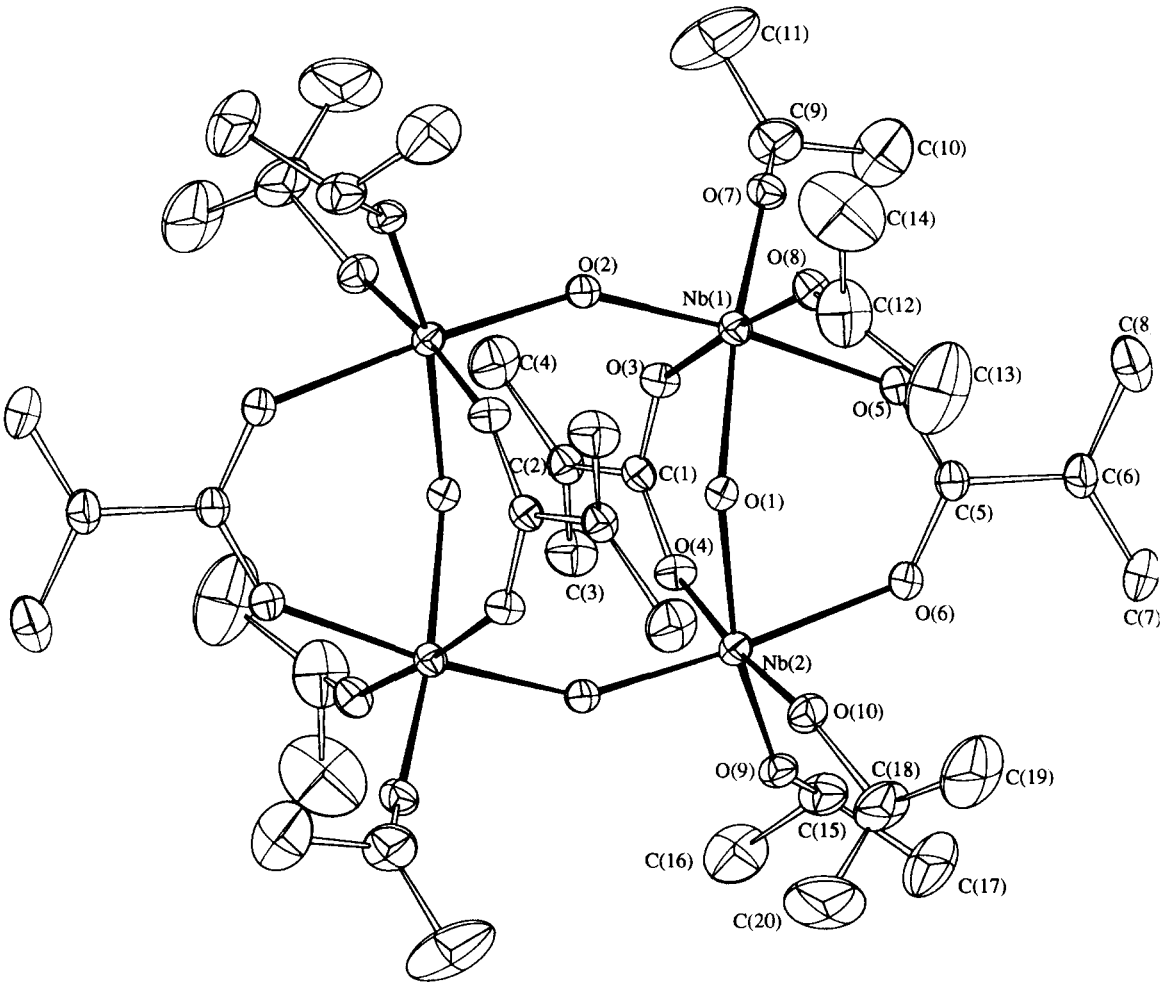

Fig. 1. Molecular structure of $[Nb_4(\mu\text{-}O)_4(\mu,\eta^2\text{-}Mc)_4(OPr^i)_8]$ using the program CAMERON[11] (thermal ellipsoids at 20% probability).

directly in isopropanol, but the yield was lower owing to esterification (as evidenced by the νCO_2 absorption band of the ester at 1721 cm^{-1}), and, thus, simultaneous uncontrolled microhydrolysis. The same compound was also obtained when larger amounts of acid (up to four equivalents) were used. The infrared spectrum of **1** showed the absorption bands characteristic of the CO_2 asymmetric stretching vibration at 1578 cm^{-1} and $\nu_s CO_2$ at 1462 and 1416 cm^{-1}. The difference $\Delta_\nu = \nu_{as}CO_2 - \nu_s CO_2$ for the methacrylate groups suggests chelating or bridging coordination modes [10]. A band at 1647 cm^{-1}, assigned to ν(C=C) vibrations shows the presence of uncoordinated double bonds (1637 cm^{-1} in free methacrylic acid). Strong and sharp absorption bands at 998 and 733 cm^{-1} can be tentatively assigned to Nb—O—Nb vibrations [11]. The ^1H NMR spectra indicate the presence of OPr^i and OMc ligands in a 1 : 2 integration ratio. The presence of two types of signals in a 1 : 1 integration ratio for each ligand furthermore suggests the formation of a species having magnetic non-equivalent surroundings for the isopropoxo and methacrylate ligands.

The identity of compound **1** was established by X-ray diffraction [12]. Its molecular structure consists of a centrosymmetric $Nb_4(\mu\text{-}O)_4(\mu,\eta^2\text{-}Mc)_4(OPr^i)_8]$ species as shown in Fig. 1. Relevant interatomic distances and angles are collected in Table 2. The metal atoms are linked together by bridging methacrylate and μ_2-oxo ligands and they are six-coordinated. The Nb—O bond lengths are in the range 1.840(3)–2.203(4) Å, with the gradation Nb-OPr^i ~ Nb—O < Nb —O(Mc). These data are in agreement with the literature [11]. The structure is built around a nearly planar Nb_4O_4 core with a Nb(1) · · · Nb(2) distance of 3.668(2) Å The niobium–oxo bond lengths vary from 1.889(3) to 1.936(3) Å, thus resulting in a slightly assymmetrical Nb_4O_4 ring. The short Nb—O bond distances indicate some π bonding. The angles at the bridging oxo ligands, O(1) and O(2), are 146.2(2) and 150.2(2)°, respectively [13]. The stereochemistry around the niobium centres is severely distorted

toward a trigonal prism. The ^1H and ^{13}C NMR provide support for the retention of the solid state structure in solution.

Compound **1** can be considered as resulting from the assembly of two $Nb_2O(Mc)_2(OR)_4$ units *via* bridging oxo ligands. The dinuclear unit is structurally analogous to that of $[NbCl_3(O_2CPh)]_2O$ (obtained in low yield by reacting $NbCl_5$ and benzoic acid in 2 : 3 stoichiometry) [14], but two terminal OR ligands have been used here for the hydrolysis condensation reaction. The overall tetranuclear structure of **1** is similar to that of $[Ta_4O_4Cl_8(O_2CC_6H_4Me\text{-}p)_4]$ obtained when the reaction between $TaCl_5$ and the acid is conducted in a 1 : 2 stoichiometry and in refluxing toluene [15]. The special stability of the tetranuclear unit for group 5 carboxylate derivatives is also illustrated by the formation of $Nb_4O_4(OAc)_4(OPr^i)_8$ obtained by reacting $Nb(OPr^i)_5$ and $La(OAc)_3 \cdot 2AcOH$ [16]. The number of oxo ligands in compound **1**, larger than expected on the basis of the hydrolysis ratio, indicates that they are, in part, derived from the carboxylic acid. It can be noted that the carboxylato alkoxide aggregates obtained so far for group 5 metals are of smaller nuclearity than for titanium or zirconium [4].

Compound **1** is soluble in a variety of solvents and its potential as precursor to materials—accessibility of the double bonds of the methacrylate ligands for organic homo- and copolymerization reactions, hydrolytic behaviour— was considered. No evolution of **1** is observed in refluxing THF in the presence of ABN after 2 h ; the unsaturated organic functionalities are probably inaccessible for steric reasons as shown by space-filling models. Compound **1** is, however, a potential candidate for organic microcellular doped solids [17]. Hydrolysis–polycondensation reactions of **1** in isopropanol offer turbid sols.

(Received 10 April 1996; accepted 1 July 1996)

Abstract—Direct reaction between magnesium and 1-methoxy-2-propanol yielded the title complex which has been characterized by X-ray crystallography. The molecular structure consists of a centrosymmetric tetrameric unit in which the Mg atoms are five- or six-coordinated by terminal, triple- and double-bridging chelating alkoxo ligands. Copyright © 1996 Elsevier Science Ltd

Keywords: magnesium; alkoxide; X-ray crystallography; sol–gel; molecular precursor of oxide material.

The increasing application of molecular chemistry in the elaboration of high-technology materials by sol-gel or chemical vapour deposition techniques provides a better understanding of the influence of the organic part on the properties of the precursor (solubility, thermodynamic stability, volatility, etc.) and a better control of the performance of the material. In this context, metal alkoxides have drawn increasing scrutiny as sources of oxide materials [1].

In order to elaborate catalytic V–Mg multicomponent oxide membranes by the sol–gel process, we have investigated the properties of metal alkoxides derived from 1-methoxy-2-propanol [2]. The advantages of the functional alcohols have already been exploited for the sol–gel process [3]. They ensure homogeneous media yielding soluble complexes and slow down the hydrolysis rates [4]. They can also allow the formation of heterobimetallic structures, since they are chelating ligands.

Little structural information about homometallic magnesium alkoxides is known. Dimers with four-membered Mg_2O_2 rings are found in which each magnesium atom is three [5] or four coordinated [6]. A monomeric structure with the sterically hindered 2,4,6-tris(trifluoromethyl)phenoxo group [7] is known. A heterocubane structure forming tetrameric complexes is observed in $[CpMgOEt]_4$ [8] and $Mg(OCH_3)_2 \cdot 2CH_3OH$ [9]. This latter compound, recently characterized by X-ray diffraction, presents an extensive structural disorder which prevents good structure refinement. This feature is frequently observed for alkoxide compounds and makes the structural determination difficult. Structural analyses on heterobinuclear complexes including the Mg atom are more numerous [10]. In particular, the heterometallic aluminium magnesium alkoxides have been investigated with different OR groups since these compounds are sol-gel precursors for $MgAl_2O_4$ [11]. Here, we report the synthesis, the X-ray characterization and the hydrolysis reactions of a novel tetranuclear magnesium alkoxide derived from 1-methoxy-2-propanol.

EXPERIMENTAL

All the manipulations were routinely performed under high purity argon using Schlenk tubes and vac-

* Author to whom correspondence should be addressed.

uum line techniques with solvents purified by standard methods. Before use, magnesium turnings (Prolabo, 99.8% purity) were washed with ether, dried at 110°C in air and purged with argon. Analytical data were obtained from the Centre de Microanalyses du CNRS de Vernaison. IR spectra were obtained as Nujol mulls between KBr plates on an IR-FT Nicolet 5ZDX spectrometer. ^{1}H NMR spectra were recorded on a Bruker AC-200 spectrometer in CD_2Cl_2. Mass spectra were recorded on a 300DX JEOL spectrometer by electronic impact. Thermogravimetric analysis was made under argon and the heating rate was 5°C min^{-1}. Specific area B.E.T. measurements from N_2 adsorption–desorption were performed from ASAP 2000 Micromeritics.

Synthesis of $[Mg(OCH(CH_3)CH_2OCH_3)_2]_4$

Magnesium alkoxide was synthesized from the reaction of magnesium turnings (8 g, 0.329 mol) with 1-methoxy-2-propanol (120 cm^3, 1.228 mol) in toluene (120 cm^3). The mixture was stirred vigorously and heated at reflux temperature until all the metal was consumed (10 h). The resulting grey, fine suspension of particles was filtered off and the colourless filtrate was evaporated to dryness. The white powder obtained was purified by recrystallization. Magnesium alkoxide (5 g) was stirred with 20 cm^3 of n-heptane at 50°C. The addition of 30 cm^3 of toluene changes the initial suspension into a slightly turbid solution. When the temperature reached 60°C a clear solution formed from which colourless crystals sensitive to moist air were formed by a slow decrease of temperature to ambient temperature. Yield based on magnesium: 99%. Found: C, 46.1; H, 8.8; Mg, 12.2. Calc. for $C_8H_{18}MgO_4$: C, 47.4; H, 8.6; Mg, 12.0%. FT-IR (cm^{-1}): 1328sh, 1313w, 1258w, 1205m, 1174sh, 1156sh, 1086s, 987s, 927w, 916w, 869m, 795w, 681w, 585m, 568sh, 520m, 493w. ^{1}H NMR (CD_2Cl_2, ppm): δ 0.98–1.23 (m, CH_3, 3 H), 3.13–3.58 (m, OCH_2 and OCH_3, 5 H), 3.93–4.05 (m, OCH, 1 H). MS (*m/z*, EI$^+$), OR = OCH(Me)CH_2OMe: OMe (100%), $CH_2OCH_3/MgOCH_3$ (65%), $OMeCH_2CH(CH_3)$ (28%), OR (22%), MgO(OR) (3%), Mg(OR)OCH_3 (12%), Mg(OR)($MeOCH_2CH_3$) (1.8%), $Mg(OR)_2$ (1.5%).

Crystallographic study

A suitable crystal of $[Mg(OCH(CH_3)CH_2OCH_3)_2]_4$ was mounted in a Lindemann capillary with a diameter of 0.3 mm on to an Enraf Nonius CAD4 diffractometer with graphite-monochromated Mo-K_α radiation. Unit-cell parameters were obtained from a least-squares fit to automatically centred settings for 25 reflections. The crystal parameters and data collection and structure refinement details are summarized in Table 1. Three standard reflections were monitored every hour and no decay was observed during the data collection. The data were corrected for Lorentz and polarization effects. No correction for absorption was made. The structure was solved by direct methods using the SHELXS-86 program [12]. The structure refinement was carried out using the SHELXL-93 program [13]. Anisotropic temperature factors were used for all non-hydrogen atoms. Hydrogen atoms were placed in calculated positions. The isotropic temperature factors were fixed at 1.5 (for the methylic H) or 1.2 (for the rest of H) times U_{eq} of the corresponding C atoms. The geometric calculations were performed with PLATON [14]. Positional and thermal parameters are available as supplementary material, deposited at the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

We have investigated the synthesis of the 1-methoxy-2-propoxide of magnesium and its reactivity towards water. 1-Methoxy-2-propanol reacted directly with the electropositive magnesium following the exothermic reaction:

$$4Mg + 8HOCH(CH_3)CH_2OCH_3 \xrightarrow{\text{Toluene}} [Mg(OCH(CH_3)CH_2OCH_3)_2]_4 + 4H_2.$$

The IR spectrum of the resulting compound $[Mg(OCH(CH_3)CH_2OCH_3)_2]_4$ (**1**) exhibits bands at 585, 568, 520 and 493 cm^{-1} which belong to ν(Mg—O) stretching frequencies with the characteristic ν(C—O) bands lying at 1258, 1205, 1174 and 1156 cm^{-1}.

The ^{1}H NMR spectrum shows complex signals (multiplets) corresponding to the $OCH(CH_3)CH_2OCH_3$ alkoxide groups which obscure structural conclusions. Thus, the NMR study is complicated by intra- and/or intermolecular exchange phenomema occurring in solution owing to the lability of the alkoxide groups. This common feature of alkoxide chemistry generally requires an X-ray diffraction study for an unambiguous structural characterization.

Mass spectrometry is sometimes used in order to ascertain the degree of condensation, with respect to disproportionation reactions in the vapour phase. Here, the ion of the highest molecular mass can be assigned to $[Mg(OR)_2]^+$. Thus, the mass spectrum does not show the tetrameric nature of the compound as proved by the X-ray diffraction analysis. The ionization method used for mass spectral analysis is that of electronic impact, which causes a strong fragmentation into ions of low molecular mass.

The molecular structure of $[Mg(OCH(CH_3)CH_2OCH_3)_2]_4$ is shown in Fig. 1. Relevant bond lengths and angles are collected in Table 2. The complex consists of a centrosymmetric tetramer in which the four Mg atoms form a nearly perfect rhomb (Table 2). The asymmetric unit is only half of the

tetramer. The Mg(1)···Mg(1a) $[-x, -y, -z]$ distance is close to that of Mg(1)···Mg(2) and, therefore, these three atoms define an almost equilateral triangle [the same disposition is obviously observed for Mg(1), Mg(1a) and Mg(2a)]. Every two neighbouring magnesium atoms are joined by two oxygen atoms. So two O-centred hexagons defined by alternating Mg and O atoms (three of each) can be

observed (Fig. 2). Two coordination geometries around the magnesium atoms are observed. In the first one, Mg(1) is coordinated to six oxygens in a very distorted octahedral disposition: the Mg—O bond lengths are in the range 2.000(4)–2.211(4) Å, and some angles deviate greatly from the ideal values [e.g. 158.3(2)° and 154.9(2)°]. The second coordination geometry, around Mg(2), can be described as a very

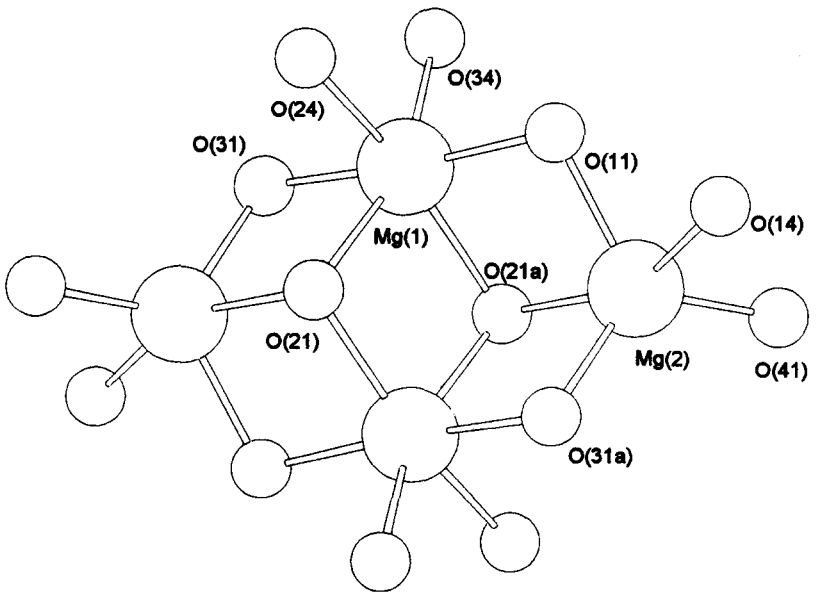

Fig. 2. View of the coordination geometries around the Mg atoms.

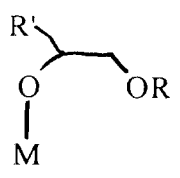
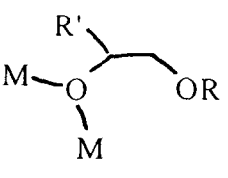
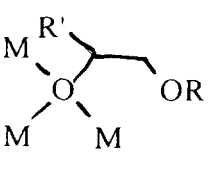
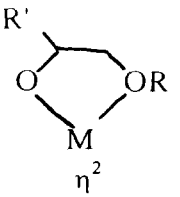
distorted trigonal bipyramid. The basal plane is defined by O(11), O(41) and O(31a) $[-x, -y, -z]$ and shows the shortest Mg—O bond lengths: 1.848(4)–2.010(4) Å. The two Mg—O apical bond lengths are greater: 2.133(3) and 2.272(4) Å. Magnesium coordinated by five oxygens occurs infrequently [7,11a,15]. The functional alkoxides can adopt different types of coordination around the metal atoms (Table 3). In the title compound, three of them have been found: terminal; μ_2, η^2; and μ_3, η^2. The oxygen coordination polyhedron around each five-coordinate magnesium atom results from one terminal monodentate alkoxo group, one μ_2, η^2- and one μ_3, η^2-OR ligands whereas each six-coordinate metal atom is bonded to two μ_2, η^2- and one μ_3, η^2-alkoxide ligands. The μ_3-oxygen, O(21), joins two six-coordinate magnesiums to one five-coordinate magnesium. It is clearly pyramidal (the sum of the Mg—O—Mg angles is 284.59° average). The triple- and double-bridging chelating coordination modes of the alkoxide ligands have been already found in $\{VOCl[OCH(CH_3)CH_2OCH_3]\}_2$, [2a] $[Y_3(OCH_2CH_2OMe)_5(acac)_4]$, [16] $Cd_9(OC_2H_4OMe)_{18}$ [17], $[Y(OC_2H_4OMe)]_{10}$ [18], $[Ca_9(OC_2H_4OMe)_{18}(HOC_2H_4OMe)_2]$ [19] and the cation $[Mg(OCH_2CH_2OMe)_6(DME)_2]^+$ [20]. This latter has been obtained by the reaction of Mg metal with $Hg(SiMe_2Ph)_2$ in DME with the cleavage of the carbon–oxygen bond of 1,2-dimethoxyethane. In this structure, the Mg atoms are joined together in the same way as in **1**.

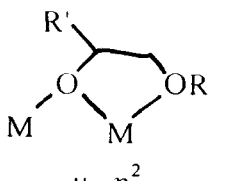
The Mg—O(μ_3, η^2) bond lengths [2.13(4) Å av] and the μ_2, η^2 ones [2.06(4) Å av] are longer than those observed for terminal $[OCH(CH_3)CH_2OCH_3]$ groups [1.848(4) Å]. The same pattern has been already observed for other compounds derived from $HOCH_2CH_2OCH_3$ [17–20]. The Mg—μ_3-O, the Mg—μ_2-O and the Mg—O terminal bond lengths encountered in other magnesium alkoxides are comparable to those observed in **1** [5–8,20].

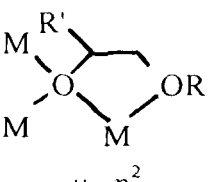












These results show that functional and versatile ligands such as $[OCH(CH_3)CH_2OCH_3]$ allow the magnesium atoms to attain high coordination numbers in clusters.

Compound **1** has good solubility in polar organic solvents such as the parent alcohol, tetrahydrofuran or chlorinated solvents ($CHCl_3$, CH_2Cl_2). It is slightly soluble in toluene and insoluble in aliphatic solvents such as n-heptane. Its solubility has been applied to the sol-gel process. The 1-methoxy-2-propanol solution of **1** was hydrolysed. It gave immediate gelification when $h \geqslant 2$ (h = degree of hydrolysis = $[H_2O]/[M(OR)_n]$) or a sol when $h = 1$, which gelled in a few hours.

The thermogravimetric analysis of **1** shows a four-step process with weight losses at 100, 200, 335 and 380°C. The successive percentages of weight losses are approximately 10, 11, 29 and 23.3%. The successive removal of the organic groups of the molecule shows that compound **1** is not volatile.

The calcination in air at 600°C of the resulting gel provided magnesium oxide which had a specific surface area (130 $m^2 g^{-1}$) higher than that obtained when MgO was synthesized at the same temperature from ionic precursors such as magnesium chloride or nitrate (30 and 85 $m^2 g^{-1}$, respectively). This makes com-

pound **1** an interesting precursor for catalytic applications. Further work on the elaboration of V–Mg multicomponent oxide membranes from this alkoxide compound, as well as their catalytic properties, are in progress.

(Received 16 February 1996; accepted 1 July 1996)

Abstract—The reaction between $Ru_3(CO)_{12}$ with ethyl methacrylate in octane followed by separation by TLC has given the new pentaruthenium cluster $[(\mu\text{-H})_2Ru_5\{\mu_4\text{-}CC(CH_3)COOC_2H_5\}(CO)_{14}]$. The product was characterized by elemental analyses, IR, and NMR and the X-ray was determined by diffraction analysis.

Keywords: cluster; synthesis; pentaruthenium; characterization; ethyl methacrylate; dodecacarbonyl triruthenium.

The investigation of pentaruthenium clusters in recent years has been focused mainly on two aspects; one is the reactivity of the cluster $[(Ru_5(CO)_{15}(\mu_5\text{-}C_2PPh_2)(\mu\text{-}PPh_2)]$ which has been reviewed and reported in several papers [1–7]; the other concerns benzene derivatives of the square pyramidal carbido cluster $Ru_5C(CO)_{15}$ which has been reviewed recently [8, 9].

In the present study, a new pentaruthenium cluster $[(\mu\text{-H})_2Ru_5\{\mu_4\text{-}CC(CH_3)COOC_2H_5\}(CO)_{14}]$ has been synthesized by the direct reaction of $Ru_3(CO)_{12}$ with ethyl methacrylate. The synthesis and characterization of the title cluster is reported herein as well as an X-ray crystal structure determination.

RESULTS AND DISCUSSION

Synthesis and characterization of $[(\mu\text{-H})_2Ru_5\{\mu_4\text{-}CC(CH_3)COOC_2H_5\}(CO)_{14}]$

Treatment of $Ru_3(CO)_{12}$ with ethyl methacrylate in octane gave the new title cluster (Fig. 1). The elemental analysis corresponded to the given formula. The presence of the terminal carbonyl ligands was confirmed by the IR absorptions in the range 1977–2098 cm^{-1}. In the ^1H NMR spectra, characteristic resonances were observed consistent with the structure of the title cluster. In the group of ^{13}C NMR signals δ 64.7 and 28.9 for OC_2H_5, δ 14.3 for CH_3, the small signal at δ 61.5 is due to C(18) (Fig. 2). The seven resonances in the ^{13}C NMR spectrum at δ 184.5, 189.8, 192.3, 192.6, 194.4, 196.1 and 197.4 correspond to the carbonyl ligands coordinated to five ruthenium atoms.

Crystal structure of $[(\mu\text{-H})_2Ru_5\{\mu_4\text{-}CC(CH_3)COOC_2H_5\}(CO)_{14}]$

Suitable crystals of $[(\mu\text{-H})_2Ru_5\{\mu_4\text{-}CC(CH_3)COOC_2H_5\}(CO)_{14}]$ were obtained by slowly lowering the temperature of its $CHCl_3$ solution. The molecular structure and crystal cell is illustrated in Figs 1 and 2. Bond lengths and angles with estimated standard deviations are collected in Tables 1 and 2.

The metal core adopts the shape of a distorted pyramid. One edge is bridged by C(18) and O(15) of the ligands [with Ru(1)—C(18) 2.194(6) and Ru(2)—O(15) 2.122 Å]; C(20) is bonded to four Ru

atoms. The 14 remaining CO ligands are terminal. The double bond in the ligand has been opened, C(20) is coordinated to four different ruthenium atoms Ru(1), Ru(2), Ru(3), Ru(4) and C(18) is coordinated to Ru(1). The oxygen atom O(15) in the ligand is coordinated to Ru(2). The five ruthenium atoms give a square-pyramidal structure. The location of two bridging H atoms in the complex was conjectured to be between Ru(2)—Ru(5) and Ru(1)—Ru(4), respectively. The Ru—Ru distances in

the cluster average 2.877 Å which compares well with the average Ru—Ru distance of 2.85 Å in $Ru_3(CO)_{12}$ [10].

There are several interesting features of the structure. The seven Ru—Ru separations range between 2.78 and 3.04 Å but fall into three groups. (i) The Ru(1)—Ru(2) bond is bridged by C(18), O(15), C(20) [2.811(1) Å]. (ii) The Ru(2)—Ru(3), Ru(3)—Ru(4), Ru(1)—Ru(4) bonds are bridged by C(20) [2.856(1), 2.803(1) and 2.896(1) Å]. (iii) The three non-bridged basal Ru—Ru bonds, the longest Ru(4)—Ru(5), the shortest Ru(3)—Ru(5) and Ru(2)—Ru(5) bonds [3.036(1), 2.787(1) and 2.950(1) Å].

The electron count requires the ligand chain to donate six electrons to the cluster, these come formally from C(18) (one), C(20) (three), O(15) (two) and two come from the two hydrogens. Together with the 14 CO groups (28), the cluster has a 76-cluster valence electron (c.v.e.) configuration.

EXPERIMENTAL

General procedure

All operations were carried out under nitrogen on a standard Schlenk line. Solvents were purified by conventional methods and distilled under nitrogen prior to use. NMR spectra were obtained with a Bruker AM 400 NMR spectrometer. The peak positions are reported downfield of TMS. The IR spectrum was recorded on a Nicolet 10 DX FT-IR spectrometer. The C and H analyses were carried out with a Carlo–Erba 1106 microanalyser. $Ru_3(CO)_{12}$ was prepared as described in the literature [11]. Ethyl methacrylate was obtained commercially and used as received.

Preparation of $[(\mu\text{-H})_2Ru_5\{\mu_4\text{-CC}(CH_3)COOC_2H_5\}(CO)_{14}]$

A solution of $Ru_3(CO)_{12}$ (200 mg, 0.3 mmol) and ethyl methacrylate (100 mg, 0.9 mmol) in octane (50 cm^3) was heated for 22 h at 110°C. After cooling to room temperature the solvent was removed under reduced pressure and the residue was purified by preparative TLC. Eluting with petroleum ether (30–60°C), gave a fraction from which the red cluster $[(\mu\text{-H})_2Ru_5\{\mu_4\text{-CC}(CH_3)COOC_2H_5\}(CO)_{14}]$ (20 mg, 10%) was obtained. Found: C, 23.7; H, 1.0. Calc. for $C_{20}H_{10}O_{16}Ru_5$: C, 23.7; H, 1.0%; IR (KBr pellet) cm^{-1}: 2099 w, 2074 s, 2045 vs, 2025 s, 1993 s, 1977 w. ^1H NMR ($CDCl_3$): δ 1.84 (s, CH_3), 1.25 (t, CH_3), 4.12 (q, CH_2), −21.17, −28.56 (2 × s, Ru—H—Ru). ^{13}C NMR ($CDCl_3$): δ 184.5, 189.8, 192.3, 192.6, 194.4, 196.1, 297.4 (7 × s, CO), 61.52 (d, C(18)), 64.7 (s, CH_2), 29.0 (s, CH_3), 14.3 (s, CH_3).

Single-crystal X-ray diffraction analysis

A red crystal of the title cluster having approximate dimensions of 0.20 × 0.22 × 0.40 mm was mounted on a R3M/E four-circle diffractometer. Graphite monochromated Mo K_α radiation (λ = 0.71073 Å) and a θ–2θ scan type were used to measure the intensity data in the range $2 \leqslant 2\theta \leqslant 45°$. The unit cell was determined and refined with 25 reflections in the 2θ range 9.64–23.74°. Crystal data for $[(\mu\text{-H})_2Ru_5\{\mu_4\text{-CC}(CH_3)COOC_2H_5\}(CO)_{14}]$: $C_{20}H_{10}O_{16}Ru_5$, monoclinic space group $P2_1/c$, a = 10.541(2), b = 13.275(2), c = 20.300(3) Å, $\alpha = \gamma = 90.00(0)$, β = 95.97(1)°, V = 2825.1(9) Å^3, Z = 4, D_c = 2.38 g cm^{-3}, μ(Mo K_α) = 26.2 cm^{-1}, $F(000)$ = 1920. The 3140 independent reflections with $I \geqslant 1.5\,\sigma(I)$ of 4243 measured were corrected for Lorentz and polarization effects.

The structure was solved by the heavy-atom technique and refined by full-matrix least-squares methods. Refinement converged at a final R of 0.0305 (Rw = 0.0250, largest shift/esd −0.039), with allowance for the thermal anisotropy of all non-hydrogen atoms. Complex scattering factors were taken from the program package SHELXTL [12], as implemented on an Eclipse S140 computer, which was used for structure solution and refinement. A weighting scheme $\omega = \{1-\exp\}[-5(\sin\theta/\lambda)^2)/[\sigma^2(F)+0.0001F^2]$ was used in the later stages of refinement. Pertinent results are given in Figs 1 and 2 and Tables 1 and 2. Tables of coordinates, structure amplitudes, thermal and full non-hydrogen parameters have been deposited at the Cambridge Crystallographic Data Centre.

(Received 14 June 1996; accepted 27 June 1996)

Abstract—Acid dissociation constants for the newly isolated dihydrogen *anti*-1,4,8,11-tetraazacyclotetradecane-6,13-dicarboxylate (diacmac), as well as for hydrogen *anti*-6-methyl-1,4,8,11-tetraazacyclotetradecane-6-amine-13-carboxylate (acammac) and *anti*-6,13-dimethyl-1,4,8,11-tetraazacyclotetradecane-6,13-diamine (diammac) are reported. The ligands differ somewhat in their selection of metal ions, which is reflected in the formation constants for complexation (log K_{ML}, 25°C) which have been determined for the d^{10} metal ions Zn^{2+} (diammac, 14.9; acammac, 14.7; diacmac, 26.3), Cd^{2+} (diammac, 10.6; acammac, 16.7; diacmac, 15.9), Hg^{2+} (diammac, 10.5; acammac, 17.3; diacmac, 21.8) and Pb^{2+} (diammac, 10.8; acammac, 10.7; diacmac, 19.0) and the d^5 Mn^{2+} ion (diammac, 6.2; acammac, 12.0; diacmac, 18.3). Differences arise in part from the increasing availability of potential O donors versus N donors in stepping from diammac to diacmac, and imply a clear role for the pendants in binding metal ions. Keywords: macrocycles; metal complexes; formation constants.

Pendant arm analogues of the 14-membered parent macrocycle 1,4,8,11-tetraazacyclotetradecane (cyclam) with groups pendant to the ring at both carbons in the centre of the opposite propyl chains have been described previously [1,2]. Macrocycles with two primary amine groups, one primary amine group and one carboxylate group, or two carboxylate groups attached to these carbons as potential donor groups have been prepared *via* copper(II)-directed condensation of ethane-1,2-diamine complexes with formaldehyde and nitroethane and/or diethyl malonate [3–5]. Subsequent reduction and/or decarboxylation and hydrolysis reactions lead to the three potentially sexidendate macrocycles diammac (**1**) [3], acammac (**2**) 4 and diacmac (**3**). Analogues based on related 1,2-diamines are also known [6]. All these macrocycles can, in principle, exist in two geometric forms, with the potential pendant donor groups in *syn* or *anti* dispositions relative to the macrocyclic ring [1]. Separation and isolation of the two geometric forms of **1** was only established relatively recently [7], as were the differing stability constants for the complexation of metal ions [8]. Both **2** and **3** exist only, or at least predominantly, as the *anti* isomer, arising from control of stereochemistry during their formation reactions [4]. The isolation of **3** as a free ligand salt is described here. Furthermore, a comparison of the variation in selective complexation by this series of ligands has been carried out and is described in this paper.

EXPERIMENTAL

Syntheses

Syntheses of both hydrogen *anti*-6-methyl-1,4,8,11-tetraazacyclotetradecane-6-amine-13-carboxylate (acammac) and *anti*-6,13-dimethyl-1,4,8,11-tetraaza-

1 2 3

cyclotetradecane-6,13-diamine (diammac) and their isolation as hydrochloride salts have been reported previously [4, 7].

Dihydrogen anti-1,4,8,11-*tetraazacyclotetradecane*-6,13-*dicarboxylate hydrochloride*, (H_2*diacmac*·4HCl). Bis(ethane-1,2-diamine)copper(II) perchlorate (16.3 g) was dissolved in methanol (300 cm^3) and heated to 50°C. To this solution were added diethyl malonate (12.5 cm^3), formaldehyde solution (12 cm^3, 38% aq.) and triethylamine (10.5 cm^3), and the solution was refluxed for 3 h. Additional diethylmalonate (2 cm^3) and formaldehyde (2 cm^3) were added, and the solution stirred and allowed to cool slowly to room temperature. Following refrigeration, a pink precipitate was collected, dissolved in water (2 dm^3) and sorbed on to a column of SP-Sephadex C-25 resin (20 cm × 5 cm). Only one major band was recovered upon elution with 1 mol dm^{-3} NaCl. As the volume of the solution was reduced by rotary evaporation, a pink solid precipitated, and was collected washed with ethanol and air dried (1.4 g, 5%). The synthesis was repeated to obtain more of the intermediate tetraethyl 1,4,8,11-tetraazacyclotetradecane-6,6,13,13-tetracarboxylate complex [5]. This complex (2.8 g) was dissolved in methanol (200 cm^3) containing 4 cm^3 of water by heating to 60°C, the pH was raised to > 10 by addition of triethylamine, and the solution stirred for 20 h. After dilution to 2 dm^3 with water, the solution was sorbed on to a column of SP-Sephadex C-25 resin (20 cm × 5 cm) and eluted with 0.2 mol dm^{-3} $NaClO_4$ solution. One major acid-stable band and two minor bands, which were not acid stable and not macrocyclic compounds, were collected. The major band and a solution of 3M HCl (30 cm^3) were placed in separate dropping funnels and added dropwise with stirring to powdered zinc (6 g). The reducing solution was stirred at 60°C after addition for a further 30 min, then filtered to remove reduced copper and unreacted zinc metal. After dilution to 2 dm^3, the solution was sorbed on to a column of Dowex 50Wx2 resin (4 cm × 15 cm), washed with 0.2 dm^3 water and 0.5 mol dm^{-3} HCl, then eluted with 3 mol dm^{-3} HCl, the product being detected by testing small aliquots regularly with copper ions and base addition. The product was taken to dryness on a rotary evaporator, collected, washed with ethanol and diethyl ether, and dried thoroughly (0.9 g). (Found: C, 32.7; H, 6.9; N, 12.8. Calc. for $C_{12}H_{24}N_4O_4 \cdot 4HCl \cdot 0.5H_2O$: C, 32.5; H, 6.6; N, 12.7%; acid content confirmed by potentiometric titration). NMR (D_2O): $^1H\delta$ 3.4–3.9 (q × 3, overlapping); $^{13}C\delta$ 41.0, 45.4, 48.2 174.6.

Physical methods

NMR spectra (in D_2O) were recorded using a Bruker Avance DPX300 spectrometer, with sodium TSP as reference. Elemental analyses were performed by the Australian National University Microanalysis Service. Potentiometric titrations were carried out essentially as described previously [9] using a Metrohm 665 automated burette and an IBM clone computer fitted with a Fylde Scientific pH card connected to a Metrohm combined glass electrode. All measurements were fully automated under control of the IBM clone computer. Titrations were performed at 25.0 ± 0.1°C in constant ionic strength (I = 0.5 mol dm^{-3}, KCl) aqueous solutions under nitrogen. Solutions of ligand (6×10^{-4} mol dm^{-3}), alone and in the presence of 0.9 or 0.5 equivalents of metal ion, were titrated with 83 increments (of 4×10^{-6} dm^3) of 0.4 mol dm^{-3} NaOH. Equilibrium constants were calculated from potentiometric data with a TURBO BASIC version of the program TITFIT [10]. For each system, each titration was repeated at least three times, with good reproducibility (*ca* ± 0.1 log units) in the determined constants.

RESULTS AND DISCUSSION

The macrocycles examined contain four secondary amines and either two pendant primary amines (**1**), one pendant primary amine and one pendant carboxylic acid group (**2**), or two pendant carboxylic acid groups (**3**), all capable of coordination to metal ions. They adopt similar *anti* geometry in terms of location of the pendants relative to the macrocycle plane. The basic fourteen-membered macrocyclic ring in all three, ignoring the pendants, is that of the classical macrocycle cyclam (1,4,8,11-tetraazacyclotetradecane, **4**) in all cases. Although **1** and **2** have been described as free ligands obtained in good yield previously, [4, 7] **3** is accessible by only low-yield routes and the isolation of **3** in an acceptable, though modest yield has not

been detailed earlier. Whereas **1** exists as both *syn* and *anti* isomers [3], both **2** and **3** form only one isomer (*anti*) dominantly or exclusively, which is presumably associated with a relatively strong axial interaction of a pendant carboxylate group during synthesis directing the stereochemistry with high stereospecificity, a process which cannot occur with the poor nitro group pendants that are involved in the synthetic route that eventually yields **1**, All three ligands can act as sexidentate ligands, as has been described in detail for **1** and **2**, and to a limited extent for **3**. The pendant groups enforce boat geometries on the chelate rings to which they are attached when they coordinate to a metal ion, with strain and associated distortions greater in the case of the amine pendant than the carboxylate pendant [4].

The transition from two primary amine pendant donors to two carboxylate pendant donors *via* the species with one of each donor presents an opportunity to examine the influence of different pendants on the metal ion-binding capabilities in a series where the pentants are attached directly to the macrocycle ring. Given the common framework linking **1–4** it is not unreasonable to find that the protonation constants of all ligands are somewhat similar (Table 1) [8,11,12]. In the data presented in Table 1, L is the neutral hexamine (**1**), or else the deprotonated amino acid (**2** and **3**), and hence six protonation steps can be expected for each ligand. The first and second protonations occur with log K_a values near 11 and 10 in all ligands, and are associated with proton addition to the secondary amines in the macrocycle ring, with the protons shared between adjacent pairs of amines within the ring [11,12]. The next two steps in **1** (and the next step in **2**), which are absent in the unsubstituted cyclam, are assigned to protonation of the pendant primary amines. Introduction of the last two protons into the ring only occurs with difficulty, and only one of the two can be observed (log K_a *ca* 2), the final protonation being inaccessible in dilute aqueous acid. Protonation of the two carboxylate groups in **3** and the single group in **2** occur with pK_a values near 4, as anticipated for such groups. Where two acid groups are present, the pK_a values are lower. In both **2** and **3** the protonation assigned to the final amines occurs more readily, presumably as a result of electronic influences of the carboxylate groups, or else as a result of zwitterionic behaviour.

Binding of the d^{10} metal ions shows a significant difference in formation constants for **1** compared with **3**, employing a common model for analysis of titration data, and imply that the pendant groups play a role in metal ion binding. Of the metal ions examined, only zinc(II) has been shown to be capable of (although not necessarily having a preference for) sexidentate coordination to **1** [1], and presumably this will be the case with **2** and **3** also. The significant difference for log K_{ML} from **1** to **3** with zinc ion probably reflects formation of a highly preferred, neutral sexidentate complex with **3**, whereas **1** and **2** may not participate in sexidentate coordination at all under the conditions employed. The other metal ions are too large to be incorporated into the macrocycle ring, and thus differences between ligands are subsequently not generally so marked. However, with **3**, even where metal ions bind in a five-coordinate mode as a square-based pyramid, at least one of the carboxylate pendant groups must be coordinated, whereas **2** has a choice of amine or carboxylate axial donors and **1** only axial amine donors, accounting for differences between **1** and **3** with all metal ions and less substantial differences between **1** and **2**. Both protonated species, MLH and MLH_2, modelled exhibit significantly lower stabilities than ML species, consistent with proton incorporation into the macrocycle which makes binding involving the ring unfavourable, without any obvious trends; these species may involve only simple chelation involving a pendant and one ring secondary amine exo to the ring. A MLH_{-1} species can be modelled reasonably consistently, presumably associated with a deprotonated coordinated water and reduced

Table 1. The logarithms of the protonation and formation constants for **1**, **2** and **3** with various metal ions; some comparative values for cyclam (**4**) are included (charges are omitted for clarity)[a]

coordination by the multidentate ligand. Formation constants with both **2** and **3** appear higher for this species than is the case with **1** for larger metal ions, presumably reflecting an enhanced stability of neutral or anionic species possible only with these ligands and not with **1**.

Whereas zinc can be considered a special case because it alone can accommodate six coordination, with all metal ions there will nevertheless be an interplay between O anion donor versus N donor preference in determining the size of the formation constant. With mercury(II), there is a trend in increasing formation constants for both ML and MLH_{-1} species with increasing number of available O donors, in line with the expected behaviour for O anion donor preference (Hg > Pb > Zn > Cd) [11, 12], but opposed to the expected behaviour for N donor preference (Hg > Cd > Zn > Pb) [11,12]. Lead typically shows a relatively strong O versus N preference, consistent with the step in formation constant from **1** to **3**, whereas, by contrast, Cd typically shows a relatively strong N versus O preference, again consistent with no major change from **1** to **3**. The trend for **3**, whereby log K_{ML} for Zn is significantly higher than that for Cd and Pb, inferring a strong selectivity towards zinc, is similar to that observed with the cyclic polyaminoacid 1,4,7-triazacyclononane-1,4,7-triacetate (log K_{ML} 26.6, Zn; 16.8, Cd; 16.6, Pb) [13]. The trend with the d^5 manganese(II) ion is consistent with an expected preference for O anion donors. Overall, the polyaminoacid diacmac is both a stronger binder of the d^{10} and d^5 metal ions examined compared with diammac, but at the same time more selective, as a result of the mixed donor set offered, including the sterically more efficient carboxylate donors.

T symmetrical gaseous tetra-tert-butyltetraboratetrahedrane: an electron diffraction study

Drahomír Hnyk*

Institute of Inorganic Chemistry, Academy of Sciences of the Czech Republic, CZ-250 68 Řež near Prague, Czech Republic

(Received 14 June 1996; accepted 26 June 1996)

Abstract—The structure of tetra-tert-butyltetraboratetrahedrane in the gas phase has been studied by electron diffraction. Analysis of the experimental data obtained by electron scattering from the tetra-tert-butyltetraboratetrahedrane vapour confirmed that the molecule consisted of a B_4 tetrahedron with a B—B edge distance of 170.4(4) pm. The B—C distances, which coincided with the C_3 axes of the tetrahedron, were determined to be 158.0(6) pm. There is an overall agreement between the solid state and gaseous structures of the B_4C_4 core. The approximately staggered conformations around the C—C and B—C bonds in the gas phase resulted in an overall symmetry of *T*. Copyright © 1996 Elsevier Science Ltd

Keywords: tetraboratetrahedrane; electron diffraction; gas phase; geometry; *T* symmetry; conformations.

The molecules B_4X_4 (X = Cl, R) are of considerable interest because of their four-orbital bonding scheme for the B_4 framework which does not comply with the rule indicating that $n+1$ electron pairs are optimal for *n*-deltahedral framework bonding [1]. According to tensor surface harmonics theory [2] the four electron pairs occupy one radial $S^{\sigma}(a_1)$ orbital and three surface $P^{\pi}(t_2)$ orbitals, the latter being three-fold degenerate. In the electron-precise P_4 molecule two non-bonded surface orbitals possessing e symmetry are also occupied.

The B atoms in the molecule $B_4(Bu^t)_4$ (**1**, Fig. 1) are extremely deshielded [$\delta(^{11}B)$ = 135.4 ppm] [3]; this is also true, but to a lesser extent, for B_4Cl_4 [$\delta(^{11}B)$ = 85.5 ppm] [4]. These high frequency shifts may be satisfactorily reproduced computationally only by taking into account correlated wave functions in the calculations of magnetic properties (*cf.* 139 and 81.4 ppm, respectively, at the GIAO-MP2/TZP′ level of *ab initio* theory) [3].

Although the X-ray diffraction analysis (XRD) of tetra-tert-butyltetraboratetrahedrane, $B_4(Bu^t)_4$ [5], revealed a slight distortion of the B_4C_4 framework from the ideal T_d symmetry (point group in the crystal: C_2), there are no grounds for believing that the gaseous molecule **1** departs from this symmetry at all.

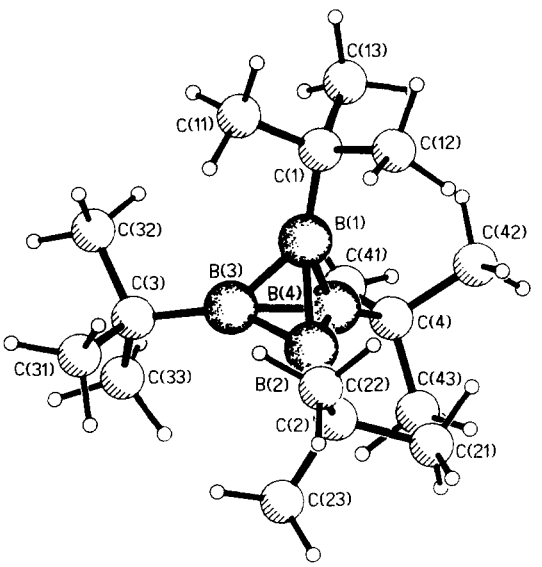

Fig. 1. A view of the $B_4(Bu^t)_4$ molecule in the optimum refinement of the electron diffraction data.

d_{21}	C(1)···H[C(12)]	218.3(4)	9.4(3)	viii
(b) Angular parameters (°)[b]				
p_5	∠BCC	111.7(2)		
p_6	∠CCH	109.7(4)		
p_7	τ_1(Me)	42.4(8)		
p_8	τ_2(Bu^t)	30.0(3)		

[a] The B···H, all other C···H and H···H nonbonded distances were included in the refinement, but they are not listed here. Their fixed vibrational amplitudes, were within the range 10.8–35.0 pm.

[b] Least-squares standard deviations in the last digit are given in parentheses.

[c] Fixed.

[d] The correlation coefficients with p_1 and p_2 are 0.71 and −0.92, respectively; all other elements of the correlation matrix have absolute values of less than 0.70.

[e] Dependent on the Bu^t twist angle (τ_2).

In addition, high quality *ab initio* optimization of the structure of B_4Me_4, which turned out to be a suitable model for **1**, support this assumption unambiguously [3]. In order to verify this assumption the electron-scattering pattern of **1** was analysed and its molecular structure determined.

EXPERIMENTAL

The sample of tetra-tert-butyltetraboratetrahedrane, provided by Professor P. Paetzold, was prepared according to the literature [5]. The purity was established by ^{11}B NMR spectra.

Electron-diffraction patterns were recorded in Kodak electron image plates using the Balzers Eldigraph KDG-2 instrument at the University of Oslo [6,7]. The nozzle was held at 346 K during the experiment. The electron beam was accelerated by a voltage of 42 kV and the electron wavelength and nozzle-to-plate distance were calibrated using the scattering pattern of benzene as a reference. The normal method of data treatment of the Norwegian group was employed [8]. Six plates from the long (498.79 mm), and five from the short (248.90 mm), nozzle-to-plate distances were selected for the analysis. Data from the long and short camera distances used in the refinements were within the ranges $20.0 \leqslant s \leqslant 143.75$ nm^{-1} and $42.5 \leqslant s \leqslant 282.5$ nm^{-1}, respectively [$s = (4\pi/\lambda)\sin(\theta/2)$, where λ, the electron wavelength, was 5.863 pm for both camera distances and θ is the scattering angle]. The least-squares method was applied to molecular intensities modified by s^4. The least-squares refinements were performed with a modified PC version of the program by Seip and co-workers [8]. Atomic scattering factors were taken from ref. [9].

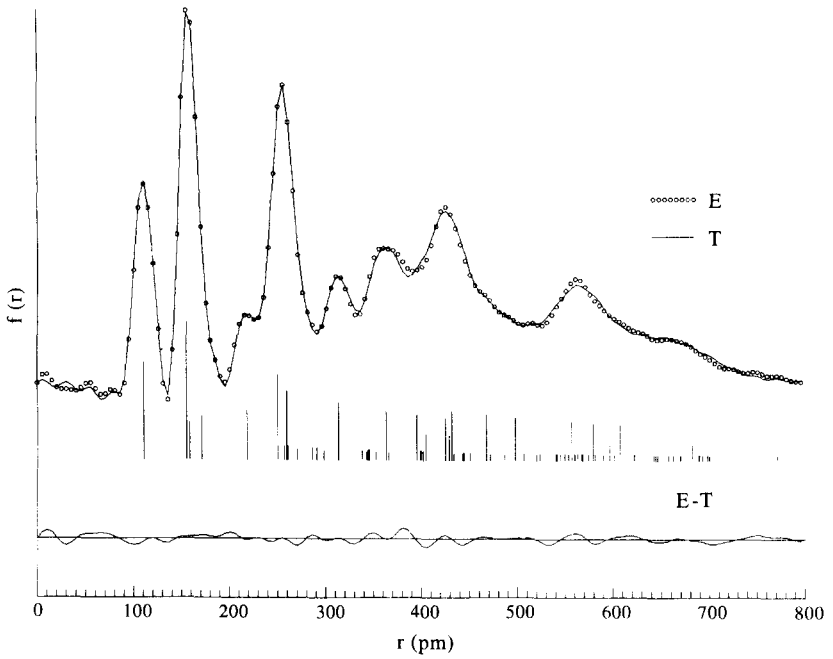

Fig. 2. Radial distribution curves (E, experimental; T, theoretical) calculated with an artificial damping factor exp(−0.000 $02s^2$). Theoretical values are used in the region $0.0 \leqslant s \leqslant 25.0$ nm^{-1}. The positions of the distances excluding H···H are marked with the vertical bars of height proportional to the weight of the distance. The positions of the most important distances can be deduced from Table 1. The difference curve is given below.

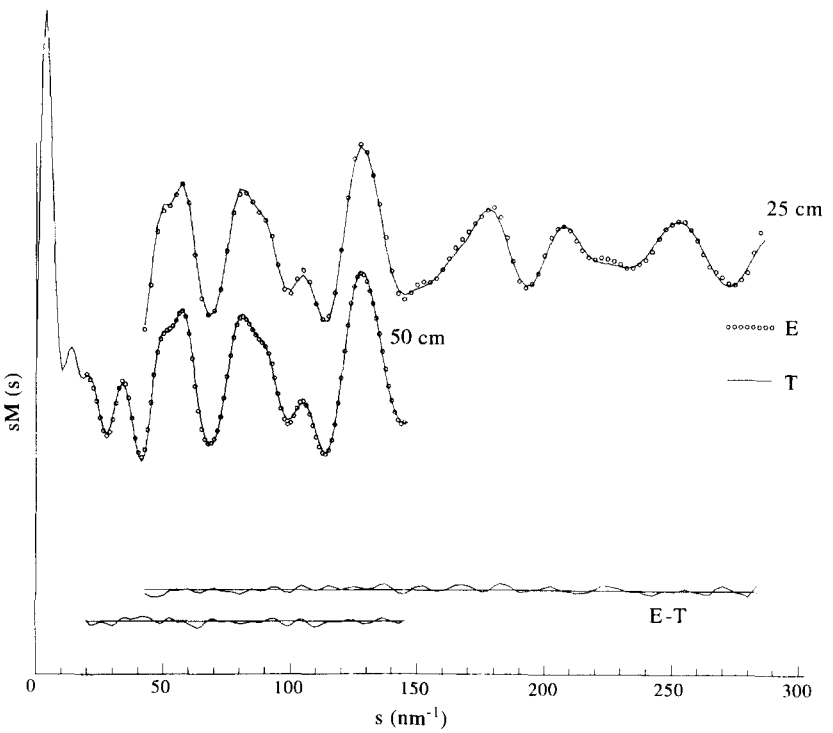

Fig. 3. Molecular intensity curves for the two camera distances (E, experimental; T, theoretical). The difference curves (experimental–theoretical) are also shown.

MOLECULAR MODEL

The molecular model of the boron atom skeleton, used in analysis of electron diffraction data, was based on a tetrahedron, the centre of which coincided with the origin of the coordinate system. C_2 and C_3 symmetry operations (the B—C bonds lay on the C_3 axes) were used to generate the appropriate geometry, including the positions of the four tert-butyl groups attached to the boron atoms of the B_4 core. The structure was then defined by four bonded distances [p_1–p_4; r(B—B), r(B—C), r(C—C), and r(C—H)], and by four angular parameters (p_5–p_8), see Table 1. The latter include the BCC and CCH bond angles as well as the twist angles (τ) of the methyl and tert-butyl groups around the C—C and B—C bonds, respectively. The twist angles τ_1 and τ_2 were defined to be zero when the B(1)—C(1)—C(11)—H (τ_1) and B(2)—B(1)—C(1)—C(12) (τ_2) (and other combinations of atoms according to symmetry) chains of atoms were coplanar and eclipsed. The B(2)—B(1)—C(1)—C(11) twist is consequently $-120°$. Values of τ_1 and $\tau_2 > 0$ indicate clockwise rotation around the C(1)—C(11) and B(1)—C(1) bonds, viewed from C(1) to C(11) and from B(1) to C(1), respectively. Overall the molecule had T symmetry.

RESULTS AND DISCUSSION

The refinement of the geometric parameters proceeded smoothly. It was possible to refine all the parameters, including both the torsion angles. The refinement of the latter led to approximately staggered conformations around the C—C and B—C bonds. The vibrational amplitude of the B—B distance could not be refined, but proved to have little influence on the final geometry. Its fixed value is optimal in terms of the lowest R factor. The success of the determination of conformational interactions between the tert-butyl groups may be judged by reference to the conformationally dependent area in the radial distribution curve; no problems were encountered when fitting the peaks in the range 360–680 pm (Fig. 2). Figure 3 shows the experimental and calculated molecular intensity. The structural details and vibrational amplitudes of the optimum refinement, for which the R factor was 0.065, are listed in Table 1.

There is excellent agreement between the B—B bond lengths established in the two phases [XRD: 170.7(6) pm; the largest standard deviation from those associated with the four different B—B bonds reported in ref. [5] is cited]. Moreover, this nearest-neighbour separation in **1** also agrees quite well with that determined for B_4Cl_4 [GED: 170.3(11) pm [10]; MP2/6–31G*: 169.0 pm [3]]. The B—B bond length is much closer to that for a two-centre, two-electron B—B bond than to that usually found for a n-deltahedral cluster obeying the $n+1$ bonding scheme [11]. The values of the other two distances related to the B_4C_{16} body, the B—C and C—C bond lengths, are in good accord with those of the corresponding average solid state parameters, 157.3(4) and 153.5(4) pm, respectively. For comparison, the B—B and B—C bond lengths in B_4Me_4, as computed at the MP2/6–31G* level of theory, are 168.8 and 156.2 pm, respectively [3].

Acknowledgements—I thank Professor P. Paetzold for providing the sample and his continuous interest during the course of this work, Mr Hans V. Volden for recording the experimental data and Mrs Snefrid Gundersen for technical assistance. I acknowledge the Grant Agency of the Academy of Sciences of the Czech Republic (Grant No. A4032502) for financial support. I am also grateful to Professor David W. H. Rankin for helpful comments.

A new three-dimensional, hydrogen-bonded metal–pteridine complex: synthesis, characterization and crystal structure of diaqua bis(1,3-dimethylpteridine-2,4(1*H*,3*H*)-dione-O^4,N^5) copper(II) nitrate dihydrate

(Received 6 June 1996; accepted 26 June 1996)

Abstract—In absolute methanol, copper(II) nitrate reacted with 1,3-dimethyl-(1*H*,3*H*)-pteridin-2,4-dione (1,3-dimethyllumazine, DMLM) giving a complex with formula $[Cu(DMLM)_2(H_2O)_2](NO_3)_2 \cdot 2H_2O$. This compound has been characterized by means of analytical techniques (elemental analysis and TG), spectral methods (IR, UV–vis–NIR, EPR), magnetic measurements (77–290 K) and single-crystal X-ray diffraction. The copper(II) ion occupies an inversion centre and exhibits an elongated octahedral coordination. The equatorial plane consists of two N(5) atoms of the pteridine ligands and two oxygen atoms from water molecules, and the two axial sites are occupied by two O(4) atoms of the ligands. The non-coordinated water molecules and nitrate anions, as well as the pteridine ligands are involved in a two-dimensional H-bond network, the metal–pteridine moieties being linked to the non-coordinated water molecules and nitrate anions of neighbouring molecules through the O(2) atom of the pteridine ligands. The molecules are packed in planes parallel to the *b*-axis, these planes being stacked at a mean distance of 3.297 Å to each other. A three-dimensional arrangement is defined by the involvement of the coordinated water molecules in a hydrogen bond with one oxygen atom from the uncoordinated water and another oxygen from the nitrate group of the adjacent layers. Keywords: complexes; crystal structure; pteridine; lumazine.

Pteridines, as well as their structurally related flavins and pterins, are biochemically important molecules owing to their capability of undergoing either one- or two-electron transfer reactions through their potentially metal-chelating α-carbonylpyrazine moiety [1, 2]. For this reason, they have attracted great attention from several points of view. These ligands have recently been used as models to determine the reactivity of metal sites in several enzymes [3–13]. Nevertheless, there are only a few X-ray-determined structures [14–22]. Lumazine [pteridine-2,4(1*H*,3*H*)-dione] derivatives were also used as flavin analogues in order to determine the effect of solvent polarity on coordination patterns [23,24].

From another point of view, and in order to explain the control of the cooperative interaction between electron transfer and proton transfer in hydrogen-bonded charge-transfer (HBCT) systems, pteridines have been used as a basic skeleton to construct models in which the establishment of metallosupramolecular H-bonded systems takes place. This interaction could be related to the redox properties of the metal atoms and the stacking interaction between the ligands. This would be a new way to regulate electronic properties in the solid state [25–27].

* Author to whom all correspondence should be addressed.

As a part of a programme aimed at the structural characterization of metal complexes with lumazine methylated derivatives, we now report a complete study, including the crystal structure, of a copper(II) complex with 1,3-dimethyllumazine (hereafter, denoted as DMLM) having a three-dimensional H-bond network, $[Cu(DMLM)_2(H_2O)_2]$ $(NO_3)_2 \cdot 2H_2O$.

EXPERIMENTAL

Synthesis

The pteridine-derived ligand was prepared from water solution with acid pH by adding dropwise a glyoxal solution (*ca* 40%) to a boiling solution of the 5,6-diamino-1,3-dimethyluracil. The resulting solution was stirred for *ca* 6 h and then the 1,3-dimethyllumazine (DMLM) was isolated as a yellow solid.

Synthesis of the title complex was carried out as follows: DMLM (0.192 g, 1 mmol) dissolved in hot MeOH (*ca* 30 ml) was added slowly, with stirring, to $Cu(NO_3)_2 \cdot 3H_2O$ (0.241 g, 1 mmol) dissolved in the minimum amount of methanol. The resulting solution was allowed to stand at room temperature. Following evaporation over several days green crystals were isolated. These were filtered off and air dried. Found: C, 29.7; H, 3.6; N, 21.4; Cu, 7.3. Calc. for $[Cu(DMLM)_2(H_2O)_2]$ $(NO_3)_2 \cdot 2H_2O$: C, 29.8; H, 3.7; N, 21.7; Cu, 7.0%.

Crystallographic study

A prismatic green crystal with dimensions $0.45 \times 0.30 \times 0.25$ mm^3 was mounted in a Stoe–Siemens AED-2 diffractometer ($T = 292$ K) with Mo-K_α radiation ($\lambda = 0.71073$ Å) monochromatized with a highly oriented graphite crystal. The unit cell was determined from 25 random reflections. The intensities were collected using the ω–2θ scan mode, in the range $3.8 < 2\theta < 55°$. A total of 4569 reflections were measured with $-2 \leqslant h \leqslant 11$, $-2 \leqslant k \leqslant 18$, $-13 \leqslant l \leqslant 13$. They were averaged to 2892 independent reflections ($R_{int} = 0.020$), 2075 with $F > 4\sigma(F)$ being retained for structure solution and refinement. Data were corrected for Lorentz and polarization effects but not for absorption. Three standard reflections were monitored every ninety minutes and showed no significant decay in intensity.

Crystal data. $C_{16}H_{24}N_{10}O_{14}Cu$, Formula weight = 644.0, monoclinic, space group, $P2_1/n$ unit-cell dimensions: $a = 8.7460(8)$, $b = 13.874(1)$, $c = 10.678(1)$ Å, $\beta = 92.64(1)°$, $V = 1294.4(4)$ Å^3, $Z = 2$, density (calc.) = 1.652 Mg m^{-3}, absorption coefficient 0.932 mm^{-1}, $F(000) = 662$.

The metal atom was placed in an inversion centre (the only possibility for $Z = 2$), and the remaining atoms were located in successive ΔF maps. Non-H atoms were refined anisotropically by full-matrix least squares and hydrogen atoms from the ligand were idealized whereas those of the water molecules were refined with fixed O—H (0.86 Å) and H—H (1.40 Å) distances. A common isotropic displacement coefficient was refined for all H atoms. A weighting scheme, $w^{-1} = \sigma^2(F) + 0.032\,F^2$, was used and 206 parameters refined.

Final R indices for observed data were $R = 0.047$ and $wR = 0.088$, goodness-of-fit = 0.48. Δ/σ in the last cycle was below 0.015 for non-H atoms, data-to-parameter ratio 10.1:1, ΔF values in the final difference map were -0.43 and 0.39 e Å^{-3}.

All calculations and drawings have been performed on a Microvax II computer (Technical Services of University of Granada) using the Siemens SHELXTL PLUS system.

Apparatus

Microanalyses (C, H, N) were performed by Technical Services of the University of Granada (STUGRA); the metal and water contents of the complex were determined from the TG plot. Conductivity measurements have been carried out using freshly prepared dimethylformamide and dimethylsulfoxide solutions on a Hanna HI8820 instrument. Thermogravimetric studies were carried out under pure air on a Mettler TG-50 thermobalance, using 4.22 mg of sample and a 10°C min^{-1} heating rate. Infrared spectra were obtained on a Perkin–Elmer FT-IR 1760X (KBr pellets, 4000–400 cm^{-1}) and Perkin–Elmer 983G spectrophotometer (polyethylene pellets, 600–180 cm^{-1}). The electron paramagnetic resonance spectrum was obtained in the X-band at room temperature on a Bruker ESP 300E apparatus, with a microwave frequency of 9.79 GHz and a modulation frequency of 100 kHz. Magnetic measurements were carried out on a Manics DSM-8 system between 77 and 290 K. Diffuse reflectance spectra (240–1500 nm) were recorded on a Perkin–Elmer UV–vis–NIR Lambda-19 machine using a $BaSO_4$ pellet as reference.

RESULTS AND DISCUSSION

A view of the molecular unit is shown in Fig. 1 and bond lengths and angles in the coordination sphere and the pteridine ligand are given in Table 1. In the crystal structure, the complex possesses an inversion centre. The metal ion exhibits an elongated octahedral coordination (tetragonality factor $T = 0.85$). The equatorial plane consists of two N(5) atoms [Cu—N(5), 2.026(3) Å] from the pteridine ligands and two water molecules [Cu—O(1w), 1.957(3) Å]; the two axial sites are occupied by two O(4) atoms from the DMLM ligands [Cu—O(4), 2.353(3) Å]. The ratio between the apical metal–ligand bond lengths and the basal ones, R(A/B) $\approx$ 1.18, is lower than that needed ($\leqslant$1.4) to force a square-planar complex [28]. This tetragonal elongation is consistent with the align-

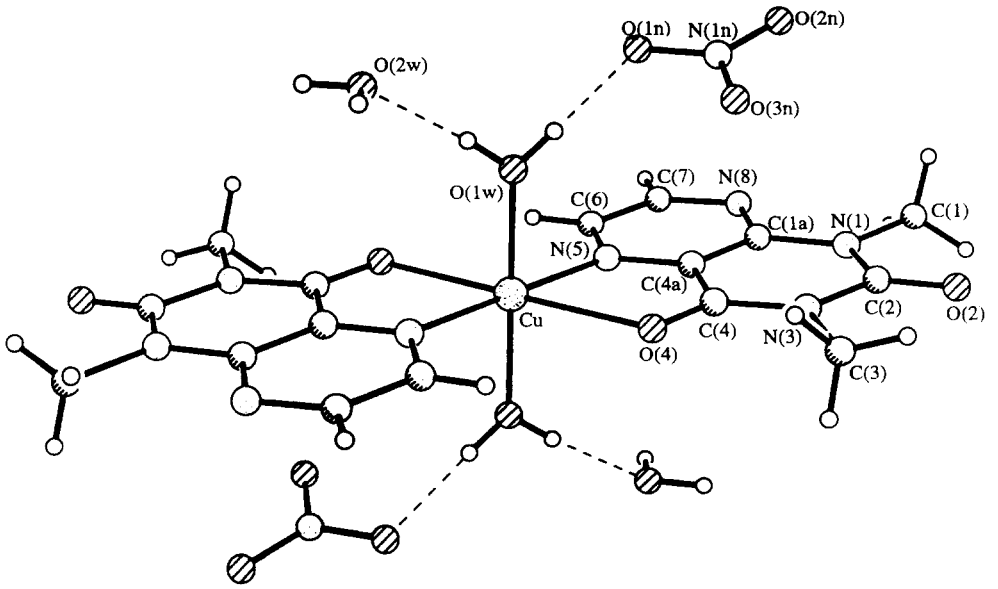

Fig. 1. Molecular drawing and numbering scheme for the monomeric unit.

ment of both O(4) donor atoms in the z-axis, the Cu^{II} ion ground state being $d_{x^2-y^2}$.

The DMLM ligand is practically planar, the greatest deviations being 0.029 Å [O(4)] for the exocyclic atoms and 0.017 Å [C(1a)] for the endocyclic ones. However, the pteridine ligands are not coplanar because the least-squares plane of the DMLM and the coordination plane around the copper atom [Cu, N(5), O(4), N(5′) and O(4′)] deviate slightly from coplanarity and define an acute angle of 4.0°. Owing to the centrosymmetric character of the molecular unit, the distance of the metal ion to the pteridine plane is 0.121 Å, both pteridine planes being parallel but displaced by 0.242 Å from each other. As

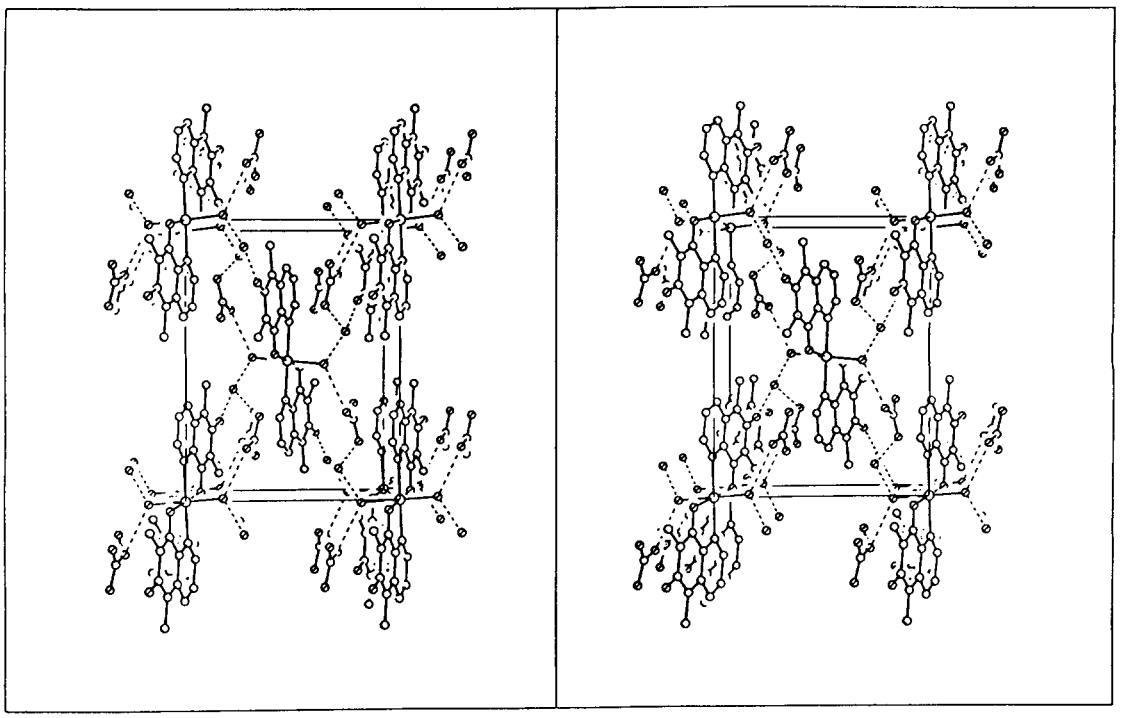

Fig. 2. A view of the hydrogen-bond network and the packing scheme.

expected, all geometric data in the organic ligand indicate significant electronic delocalization; the C(2)—O(2) distance [1.195(6) Å] is a little shorter than that of C(4)—O(4) [1.223(5) Å] as a consequence of the involvement of the O(4) atom in the coordination sphere. This structure is very similar to that by Mitsumi *et al.* [25] for the analogous copper(II) complex with monodeprotonated lumazine; the only difference being the presence of nitrate counteranions because of the inability of DMLM to undergo deprotonation.

Hydrogen bonding plays a very important role in the packing scheme of this compound. The hydrogen-bonding network is shown in Fig. 2 and geometrical data are listed in Table 2. The molecular units are linked in two-dimensional networks perpendicular to the [1 0 3] direction, in which each non-coordinated water molecule establishes two hydrogen bonds, one with the O(2) atom of a pteridine ligand [O(2w)—H(21)···O(2)] and another with the O(2n) of the nitrate group [O(2w)—H(22)···O(2n)]. The coordinated water molecules are hydrogen bonded with a nitrate group [O(1w)—H···O(1n)] and a non-coordinated water molecule [O(1w)—H···O(2w)] of the adjacent layer, thus defining a three-dimensional H-bond network in which the planes containing the metal–pteridine moieties are stacked at a mean distance of 3.297 Å.

Conductivity values obtained in both DMF (110 mho cm^{-1} mol^{-1}) and DMSO (76 mho cm^{-1} mol^{-1}) solutions lie at the lower limit indicated for a 2:1 electrolyte [29]. The thermal decomposition of this compound in air has been studied using TG and DSC plots. These indicate that four water molecules are lost in only one clearly defined step between 77 and 121°C (exp. weight loss 11.7%, calc. 11.2%). The corresponding endothermic peak appears at 103°C (ΔH = 48.3 kJ mol^{-1} H_2O). The desolvated compound is stable at temperatures up to 220°C. At this point, an abrupt weight loss occurs as a consequence of the combustion of the organic matter. The pyrolysis finishes at 400°C, leaving a final residue of copper oxide, as corroborated from the corresponding infrared spectrum.

The infrared spectrum shows bands at 3450 cm^{-1} assignable to ν(O—H) from water. The AM1 semi-empirical method, implemented in the HYPERCHEM 4.0 program, was used to make assignments of the vibrational modes of the IR spectrum. The bands at 1672 and 1737 cm^{-1} may be assigned to a combination of the stretching vibrations of both

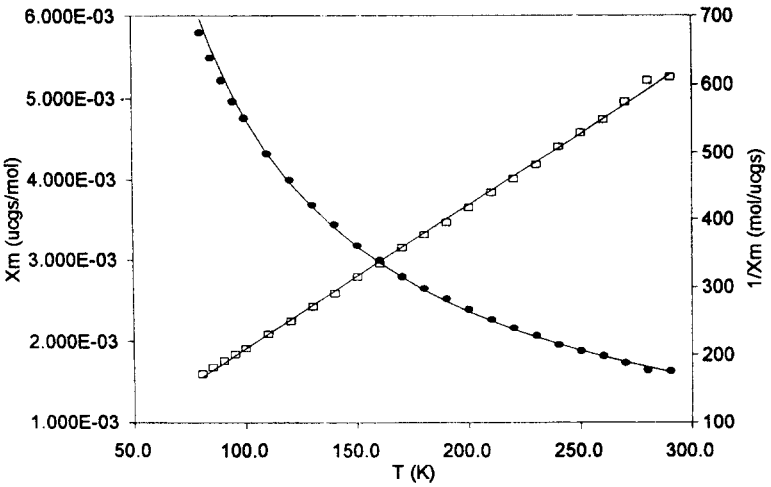

Fig. 3. Molar susceptibility values of the title compound at different temperatures (circles, χ_M; squares, $1/\chi_M$).

exocyclic carbonyl groups, the first being mainly owing to ν(C(4)=O) whereas in the second the greater component seems to be ν(C(2)=O). Other vibration modes related to potential donor atoms may be assigned as follows: ν(C=N) (1602 cm^{-1}), ν(C=C)+ν(C—N) (1483 and 1304 cm^{-1}). These bands appear shifted to higher wavelength by *ca* 10 cm^{-1} with respect to their position in the IR spectrum of the free ligand, the only exception being the band mainly assignable to ν(C(4)=O), which is in accord with the involvement of O(4) and N(5) atoms in the M—L bond [30]. The strong band corresponding to ν(N—O) of the free nitrate group appears at 1385 cm^{-1}. The far-infrared spectrum clearly shows a new band at 245 cm^{-1}, which may be assigned to the ν(Cu—N) vibration [31].

The complex displays an axial EPR powder spectrum with $g_\perp = 2.03$ and $g_\parallel = 2.39$ and may be interpreted, according to refs [32] and [33], by the existence of rhombic symmetry with the tetragonal axes parallel, but where the rhombic component is so small that it is not resolved by the powder technique.

As shown in Fig. 3, molar susceptibility values at different temperatures have been fitted to the Curie law ($\theta = 2.2 \pm 0.7$ K, $C = 0.484 \pm 0.003$ cgsu K mol^{-1}, $r^2 = 0.9996$). The value of θ reveals that only a small antiferromagnetic interaction exists between the metallic centres owing to their tetragonal axes being quasi-parallel but not aligned. The effective magnetic moment for the Cu^{II} atom, once diamagnetic corrections have been made, was 2.04 ± 0.04 B.M. in accord with the existence of magnetically dilute monomeric units [34].

The vis–NIR diffuse reflectance spectrum (25,000–9000 cm^{-1}) shows a broad, asymmetric band at 13,000–20,000 cm^{-1}, with maximum absorbance at 15,100 cm^{-1}. This band is typical for 4+2 tetragonal ("square-plane") copper(II) complexes with the chromophore group CuN_2O_2 [35] and may be deconvoluted into four components (17,000, 15,400, 14,300, 11,800 cm^{-1}) corresponding to the expected transitions in six-coordinated D_{2h} Cu^{II} ion with a $d_{x^2-y^2}$ ground state.

Supplementary material.—A list of structure factors and tables with (i) atomic coordinates and isotropic thermal parameters for non-H atoms, (ii) bond lengths and angles, (iii) anisotropic temperature factors for non-H atoms, (iv) hydrogen atom coordinates and (v) equations of planes and dihedral angles have been deposited at the Cambridge Crystallographic Data Centre.

(Received 28 May 1996; accepted 26 June 1996)

Abstract—The X-ray crystal structure of $Hg(Sulfa)_2 \cdot 2DMSO$ (**1**) was determined. Compound **1** was obtained from the reaction of sulfadiazine (2-sulfanilamidopyrimidine (Sulfa-H)) with mercury(II) acetate in methanol and crystallization in DMSO/methanol. The coordination geometry about the mercury atom is approximately linear [N—Hg: 2.087(4) Å; N—Hg—N: 175.0(2)°]. Two secondary DMSO molecules are loosely bound to the mercury atom, [Hg—O(DMSO): 2.769(7) Å]. No π-aryl stacking interaction was observed in either the solid or solution state. The IR, electronic and ^1H and ^{13}C NMR spectral data for **1** suggest binding of mercury to the sulfonamide nitrogen, in agreement with the crystal structure determination. Keywords: mercury(II) complex; sulfadiazine; X-ray structure; NMR structural elucidation.

Many sulfanilamide derivatives possess antibacterial activity, and sulfadiazine also has a strong antibacterial property. Thus, sulfadiazine compounds are widely used for their bactericidal action and X-ray structures of many of them have been solved [1]. On the other hand, some metal complexes of these ligands promote rapid healing of skin disorders [e.g. the Ag^I complex [2,3]—commercially named "Flammazine" (marketed in Spain by Duphar) or "Silvederma" (marketed in Spain by Aldo Union) is used for human burn treatment and the Zn^{II} complex [4,5] in preventing bacterial infection in burned animals]. The effectiveness of these burn treatment compounds does not appear to depend solely on the presence of a metal ion (slow release of the Ag^I or Zn^{II}) but depends strongly on the nature of the material to which the metal ion is bound [4].

A few Hg^{II} complexes [6] are still used in topical medicine as antiseptics, although it is known that interactions of heavy metal ions with biomolecules can yield potentially toxic effects. In this context we report the synthesis, spectroscopic characterization and X-ray structure determination of $Hg(Sulfadiazinato)_2 \cdot 2DMSO$.

EXPERIMENTAL

Analyses and physical measurements

Analytical measurements were carried out using a Carlo–Erba model 1106 microanalyser. The infrared spectra were registered in the solid state (KBr pellets) on a PE 683 with an infrared data station PE 1600, and the electronic spectra were registered on a PE 552 spectrophotometer. Thermogravimetic data in the temperature range 30–700°C were recorded in a flowing nitrogen atmosphere (heating rate 10°C min^{-1}) on a PE TGA-2 thermobalance. 1D and 2D ^1H and ^{13}C NMR spectra were carried out on a Bruker AMX 300 spectrometer. Proton and carbon chemical shifts in

DMSO-d_6 were referenced to DMSO-d_6 (^{1}H NMR, δ(DMSO) = 2.60 ppm; ^{13}C NMR, δ(DMSO) = 43.5 ppm). The 2D NMR experiments were performed at 20°C without sample spinning.

^{1}H *Detected heteronuclear multiple quantum coherence spectroscopy* (*HMQC*) [7]. The one-bond ^{1}H–^{13}C shift correlation spectra resulted from a 502 × 2048 data matrix with 48 scans (preceded by 16 dummy scans) per t_1 value. Pre-delay was 1.0 s and a 10.3 μs 90° ^{13}C pulse width was used. A sine-bell squared filter was used prior to Fourier transformation in the t_2 and t_1 dimensions.

^{1}H *Detected multiple-bond heteronuclear multiple quantum coherence spectroscopy* (*HMBC*) [8]. The multiple-bond ^{1}H–^{13}C shift correlation spectra resulted from a 479 × 2048 data matrix with 160 scans (preceded by 16 dummy scans) per t_1 value. Pre-delay was 1.0 s and a 10.3 μs 90° ^{13}C pulse width was used. The delay between the first and the second 90° ^{13}C pulses was 75 ms. A sine-bell squared filter was used prior to Fourier transformation in the t_2 and t_1 dimensions.

Rotating frame Overhauser effect spectroscopy (*ROESY*) [9]. The ^{1}H–^{1}H shift correlation spectra resulted from a 237 × 2048 data matrix with 64 scans (preceded by 16 dummy scans) per t_1 value. Pre-delay was 2.0 s and a 5.1 μs 90° ^{1}H pulse width and 2.0 kHz (23 dB) of ^{1}H r.f. power and 22 μs 90° ^{1}H pulse width were used. Mixing time = 500 ms. A sine-bell squared filter was used prior to Fourier transformation in the t_2 and t_1 dimensions. The 2D spectra were processed by using commercial Bruker software.

Sulfadiazine (Roig-Farma) and mercury(II) acetate (Merck) were used without further purification.

Crystallographic studies

Crystallographic studies were performed on a Siemens Nicolet P4 diffractometer with graphite-monochromated Mo-$K\alpha$ radiation (λ = 0.71073 Å). The unit cell and orientation matrix were obtained from 25 randomly oriented reflections. 4653 reflections (4267 independent) were collected using ω–2θ scans in the range ($0 \leqslant h \leqslant 28$, $0 \leqslant k \leqslant 12$, $-26 \leqslant l \leqslant 25$, $2\theta < 60°$), and corrected for Lorentz and polarization effects and empirically (ψ scans) for absorption (transmission range: 0.360–0.702). 3551 reflections with $F_0 > 4\sigma(F_0)$ were retained for solving and refining the structure. The structure was solved by the heavy-atom method and refined by full-matrix least squares on F using anisotropic temperature factors for non-H atoms. Hydrogen atoms were idealized. The final indices were R = 0.042, R_w = 0.043, S = 1.04. Shift/esd in the final cycle was below 0.001. Residues in the final delta (F) map were between −2.26 and 1.09 eÅ^{-3}. All calculations performed with the SHELXTL-Plus program package [10].

Crystal data and structure solution parameters are summarized in Table 1. Tables of crystal data, final atomic coordinates, anisotropic thermal parameters, final hydrogen coordinates and a listing of observed and calculated structure factors are included in the supplementary material, deposited at the Cambridge Crystallographic Data Centre.

Preparation of $Hg(sulfadiazinato)_2 \cdot 2DMSO$), **1**

A mixture of a methanol solution of sulfadiazine (Sulfa-H) and a methanol solution of mercury(II) acetate (2:1) afforded a white precipitate, which was filtered and washed with methanol. The resulting solid was crystallized in DMSO/MeOH (1:25) yielding white prisms (3–5 days) of **1** suitable for X-ray diffraction. The complex obtained exhibited a weight loss between 120 and *ca* 175°C, corresponding to the loss of two DMSO molecules per formula unit (mass loss calc., 18.3%; mass loss found, 18.1%). Found: C, 33.6; H, 3.7; N, 13.6; S, 15.0. Calc. for $C_{24}H_{30}N_8O_6S_4Hg$: C, 33.7; H, 3.5; N, 13.1; S, 15.0%. RESULTS AND DISCUSSION

Description of the structure

The molecular structure of $Hg(Sulfadiazinato)_2 \cdot 2DMSO$ (**1**) and the atom-numbering scheme are shown in Fig. 1. The two deprotonated sulfadiazinato ligands are related by a binary axis through the metal atom and bound to the mercury via the heterocyclic nitrogen in a nearly linear arrangement [N(2a)—Hg—N(2a′) = 175.0(2)°] Table 2). The Hg—N bond distance [Hg—N(2a) = 2.087(4) Å] is similar to previously reported distances in other Hg—N systems [11]. Figure 2a shows the angles corresponding to the trigonal arrangement of the imido nitrogen in the different metal [Ag^I [2,3], Zn^{II} [4,5], Cu^{II} [12] and Hg^{II}]–sulfadiazinato complexes. As can be observed, a more or less distorted trigonal arrangement appears in all of them but the values corresponding most closely to a trigonal arrangement are found in the Hg complex.

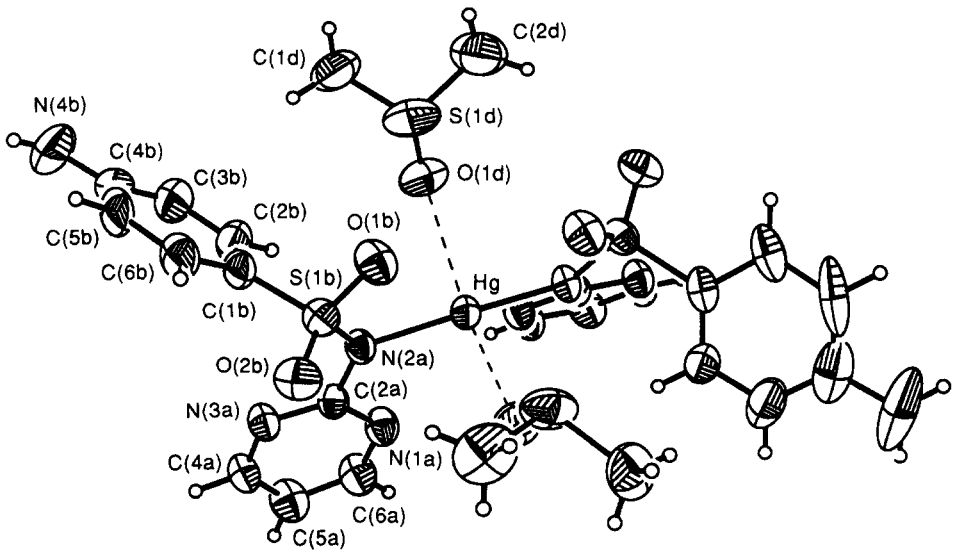

Fig. 1. Molecular structure of the complex showing the atom-numbering scheme.

The C(4b)—N(4b) distance of 1.383(14) Å, is in good agreement with the corresponding bond in sulfadiazine [1.43(3) [1a] or 1.41(2) Å [1b] and other metal–sulfadiazinato complexes [Ag^{I} 1.393(9) Å [2], Zn^{II} 1.377(9) and 1.382(14) Å [5] and Cu^{II} 1.372(17) and 1.373(27) Å [12]], and appreciably shorter than the 1.470(5) Å proposed by Camerman for the length of a C(sp^2)—N(sp^2) single bond [13], suggests considerable double bond character in that bond. There does not appear to be any extension of the phenyl ring electron delocalization to include S(1b), as the S(1b)—C(1b) distance of 1.775(7) Å is a normal single bond. This value is similar to other metal–sulfadiazinato complexes [2–5,12,14]. Analogously, the S(1b)—N(2a) distance [1.654(4) Å] is also nearly a single bond showing no π bond character. The interatomic distance is equivalent to the free ligand [1.65(1) [1a] or 1.66(2) Å [1b]] and Cu^{II} complex [1.657(17) and 1.680(12) Å [12]], but higher than in Ag^{I} [1.600(6) [2,3]] and Zn^{II} [1.568(4) Å and 1.609(4) Å [4,5]] complexes. The S(1b)—O(1b) and S(1b)—O(2b) bonds are very similar but are not completely equal [1.463(4) and 1.453(5) Å, respectively] and are equivalent to the other metal–sulfadiazinato complexes, but higher than in free sulfadiazine [1.41(2) and 1.42(2) Å [1a] or 1.41(1) Å [1b]]. The bond lengths and angles in pyrimidine (mean C—C: 1.397 Å; mean C—N: 1.356 Å, mean angle: 118.8°) and phenyl rings (mean C—C = 1.400 Å; mean C—C—C = 120.0°) are in good agreement with the values observed for such rings in free sulfadiazine and metal–sulfadiazinato complexes studied. The bonding around the sulfur atom is distorted from the ideal tetrahedral geometry. The maximum and minimum values of angles around the sulfur atom are 116.9(3)° [O(1b)—S(1b)—O(2b)] and 106.6(3)° [N(2a)—S(1b)—C(1b)]. A general tetrahedral behaviour is present in all the metal complexes with the same maximum angle (O—S—O), but the minimum varies with each molecule [N—S—C for Ag^{I} and Hg^{II} complexes and O—S—N for Cu^{II} and Zn^{II} complexes and for sulfadiazine).

The molecule maintains a *gauche* conformation (Fig. 2b) about the S(1b)—N(2a) bond with a torsion angle [C(1b)—S(1b)—N(1a)—C(2a)] of −73.3°, similar to the Zn^{II} [−75.4 and −74.0°] and Cu^{II} [−74.6°] complexes, but it is higher than in the ionic sodium 3,5-dimethylsulfadiazinato (−60.6°) [14] and Ag^{I} (−53.9°) complex. On the other hand, although the *gauche* structure between the two rings is very similar in Zn^{II}, Cu^{II} and Hg^{II}, the relative disposition of the metal is clearly different as can be observed by the torsion angles [O(1b)—S(1b)—N(1a)—metal] with values of −36.8, −28.4 and 5.79°.

The crystal packing is depicted in Fig. 3a. The packing of the complex units is governed by long chains formed by weak hydrogen bonds between the NH_2 of the aromatic ring of one complex unit and the N of the two pyrimidines of the next complex unit [N(4b)—H···N(1a) (other complex unit) = 2.44 and N(4b)—H···N(1a)(other complex unit) = 2.90 Å]. On the other hand, no stacking interactions are present in the crystal structure because the aromatic rings are practically perpendicular (Fig. 3b).

Infrared data

The IR spectrum of the complex was recorded down to the far-IR region of 200 cm^{-1} and compared with that of sulfadiazine. Tentative band assignments (cm^{-1}) of some characteristic bands of sulfadiazine were made by analogy with other related systems [15, 16]. The bands at 3355 and 3230 cm^{-1} assigned to ν_a and ν_s (N—H) vibrations of the NH_2 group are significantly shifted with respect to those of the free

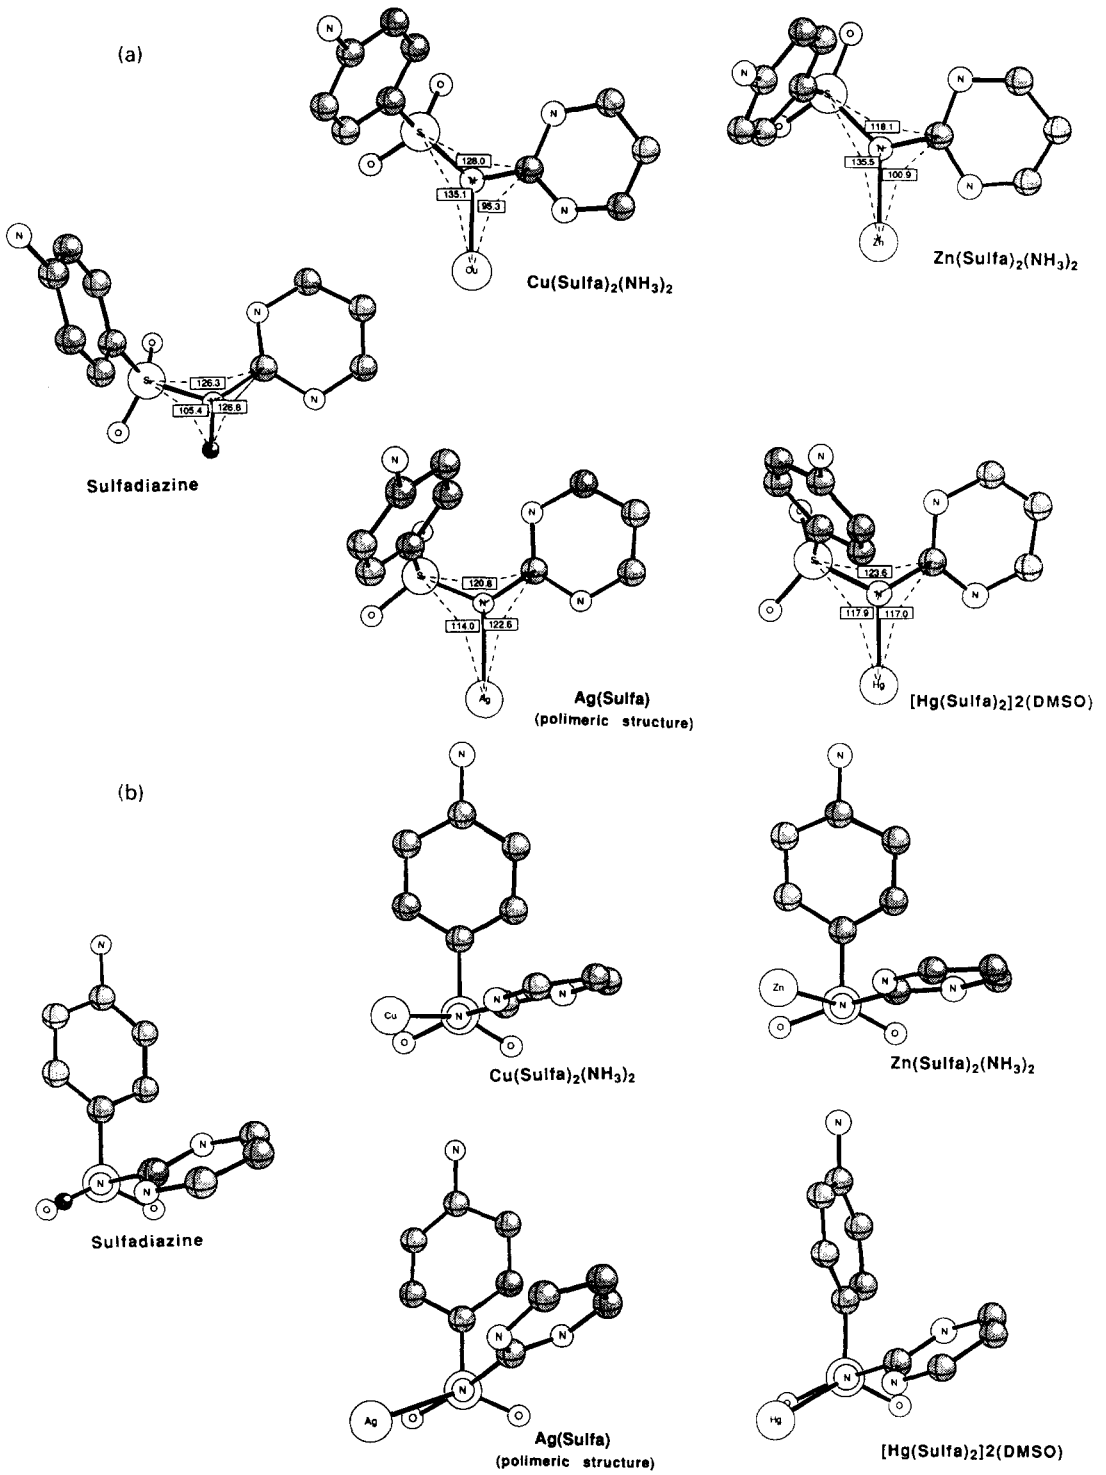

Fig. 2. (a) Trigonal arrangement of imido nitrogen in different metal–sulfadiazine complexes; (b) *gauche* disposition of two aromatic rings of Sulfa in different metal–sulfadiazine complexes. (Data obtained from refs [1a,1b,2–6].)

ligand (3425 and 3360 cm^{-1}) as a consequence of the change in their hydrogen bonding scheme. The strong bands related to ν_a and ν_s of the (SO_2—N) moiety at 1325 and 1155 in the sulfadiazine show important changes upon complexation. The first splits into two peaks at 1360 and 1301 cm^{-1} and the second appears at 1130 cm^{-1}. The band at 945 cm^{-1} corresponding to ν (S—N) is shifted to higher frequencies (980 cm^{-1}) upon complexation [15]. All these changes suggest binding of the mercury atom to the sulfonamide nitro-

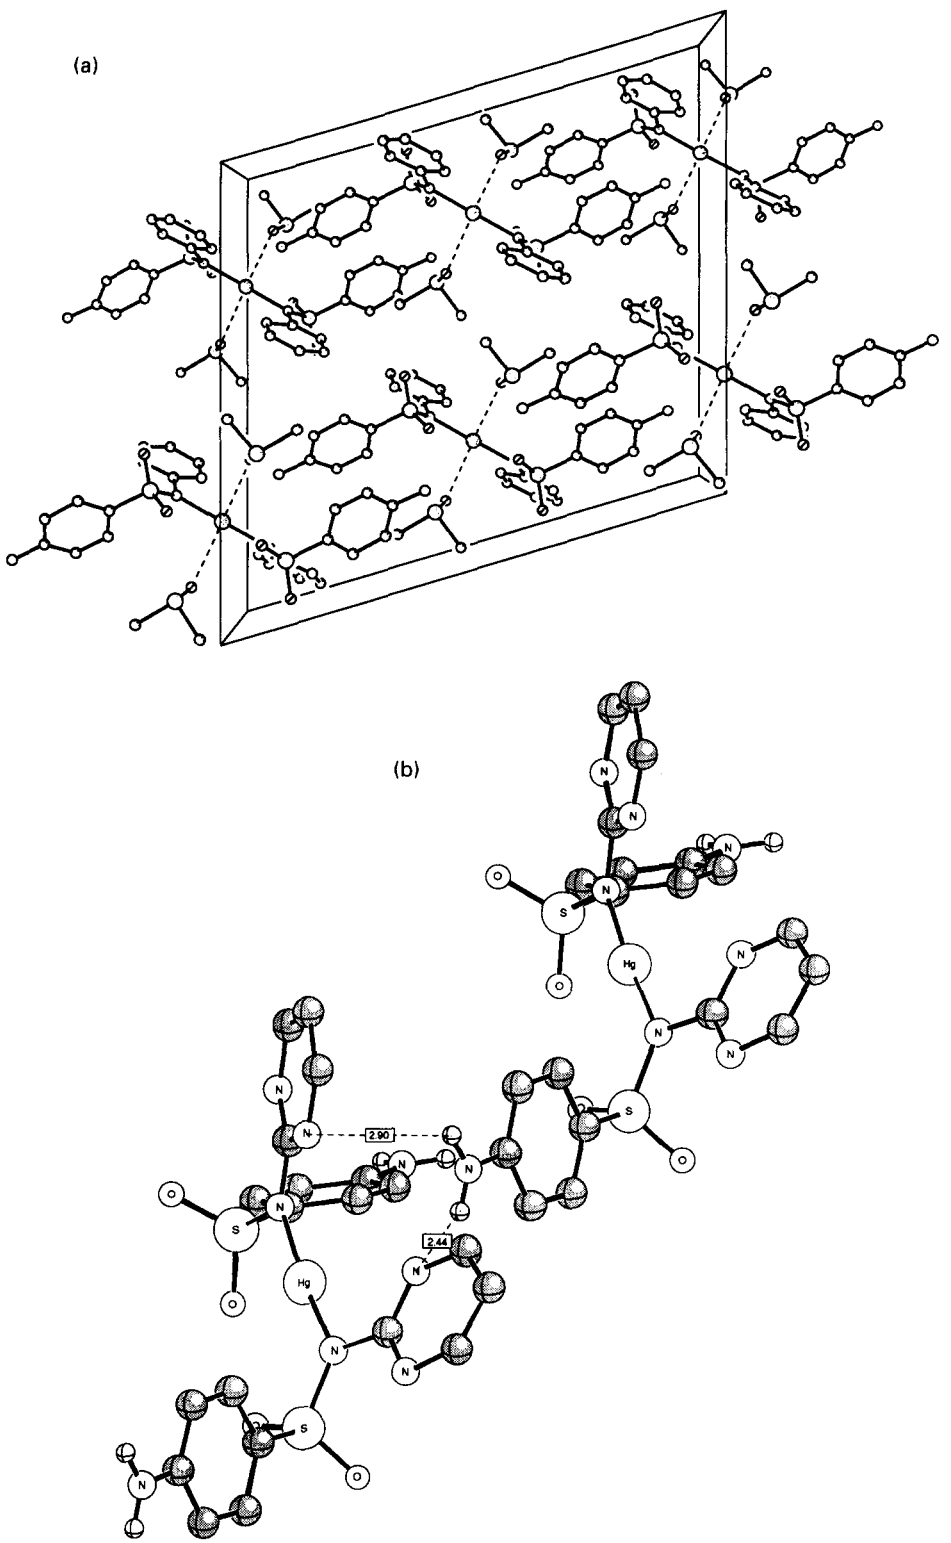

Fig. 3. (a) View of the unit cell down the *b*-axis. (Hydrogen atoms have been omitted for clarity.) (b) Packing of two complex units showing hydrogen bonds between them and the relative disposition of the different aromatic rings. (DMSO and hydrogen atoms have been omitted for clarity.)

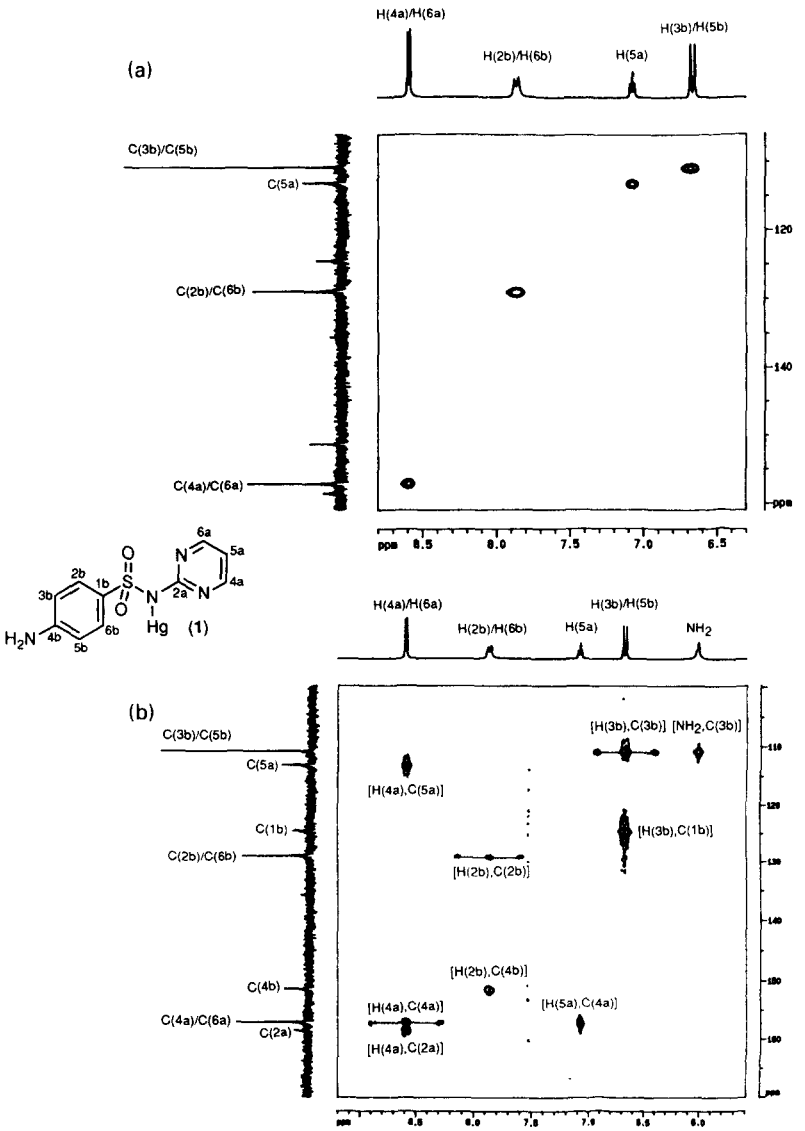
gen. The assignment of the band at 1018 cm^{-1} [ν (S=O)DMSO] [17] in the IR spectrum of the mercury complex suggests that the two DMSO molecules of crystallization are loosely bound to the Hg through the oxygen atom.

Electronic spectra

The electronic spectrum in DMSO of sulfadiazine shows two bands at 273 ($\varepsilon = 3.94 \times 10^6$) and 366 nm ($\varepsilon = 2.9 \times 10^5$), assignable to aromatic ring transitions. No frequency changes were observed in the spectrum of the complex. The intensity of the band near 272 nm decreases sharply upon complexation (3.3×10^5), the second one appearing as a shoulder.

^{1}H and ^{13}C NMR spectra

^{1}H NMR spectra can be easily assigned by $J_{H\,H}$ couplings and ROESY (supplementary material). HMQC (Fig. 4a) and HMBC (Fig. 4b) were used to assign the ^{1}H and ^{13}C NMR spectra of the mercury complex. The ^{1}H and ^{13}C assignments of sulfadiazine and Hg(Sulfadiazinato)$_2$·2DMSO (**1**) are shown in Table 3. The non-protonated carbon resonance of 1 were recognized from the HMQC spectrum and



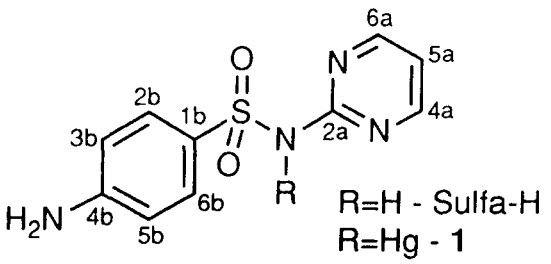


Fig. 4. (a) ^{1}H-detected ^{1}H–^{13}C multiple quantum shift correlation (HMQC) spectrum of [Hg(Sulfa)$_2$]·2DMSO in DMSO-d_6. (b) ^{1}H-detected ^{1}H–^{13}C multiple-bond shift correlation (HMBC) spectrum of [Hg(Sulfa)$_2$]·2DMSO in DMSO-d_6. (Incompletely suppressed "satellite" peaks from C(4a), C(2b) and C(3b) are also present.)

Table 3. ^1H and ^{13}C NMR shift assignments for sulfadiazine (Sulfa-H) and $[Hg(Sulfa)_2]\cdot 2DMSO$ (1) in DMSO-d_6[a]

Assignment	^1H (1)	^1H (Sulfa-H)	$\Delta\delta$ (^1H)[b]	^{13}C (1)	^{13}C (Sulfa-H)	$\Delta\delta$ (^{13}C)[b]
N(2a)—H	—	11.35	—	—	—	—
C(2a)	—	—	—	163.7	161.2	+2.5
C(4a)—H/C(6a)—H	8.59	8.57	+0.02	162.4	162.2	+0.2
C(5a)—H	7.08	7.11	−0.03	118.4	119.5	−1.1
C(1b)	—	—	—	129.8	128.8	+1.0
C(2b)—H/C(6b)—H	7.87	7.70	+0.17	134.3	133.8	+0.5
C(3b)—H/C(5b)—H	6.67	6.65	+0.02	116.0	116.1	+0.1
C(4b)	—	—	—	156.6	157.0	−0.4

[a] Relative to TMS with DMSO-d_6 peak as reference (^1H: 2.60 and ^{13}C: 43.5 ppm).
[b] $\Delta\delta = \delta_{(1)} - \delta_{(Sulfa\text{-}H)}$.

assigned from the HMBC spectrum. Thus C(1b), C(4b) and C(2a) were assigned as the resonances at 129.8, 156.6 and 163.7 from the HMBC correlations to H(3b), H(2b) and H(4a)/H(6a), respectively.

Upon complexation a downfield shift was observed for the C(2a) resonance of Sulfa-H. In addition, the Sulfa-H imino ^1H signal disappeared (Table 3). These changes are consistent with binding of mercury to sulfadiazine through N(2a), as suggested by the X-ray structure. The downfield shift for the C(2a) and H(2b)/H(6b) resonances of Sulfa-H could be related to the proximity of the Hg^{II} atom. No significant changes in ^1H and ^{13}C chemical shifts were observed for other atoms upon complexation, suggesting that, in solution, the aromatic rings are not involved in stacking interactions.

On the other hand, the existence of a nOe between H(2b)/H(6b) and H(4a) indicates, if aggregates do not exist in solution, that the phenyl and the pyrimidyl aromatic rings are, probably, nearer in solution than in the solid structure, because in the crystal the distances are very large [H(2b)···H(4a) = 5.72 and H(6b)···H(4a′) = 6.10 Å for a structural unit $Hg(Sulfadiazinato)_2\cdot 2DMSO$].

(Received 24 May 1996; accepted 26 June 1996)

Abstract—Treatment of $DyCl_3(H_2O)_6$ with thionyl chloride in the presence of tetrahydrofuran provided colourless crystals of $DyCl_3(THF)_{3.5}$, subsequently identified as the ionic salt [*trans*-$DyCl_2(THF)_5$][*trans*-$DyCl_4(THF)_2$] by an X-ray diffraction study. The dysprosium atom in the monocation is seven coordinate with the *trans*-$DyCl_2$ unit [Dy—Cl, 2.624(5) Å] surrounded by five tetrahydrofuran molecules (Dy—O, mean 2.41(2) Å) in a regular pentagonal bipyramidal geometry. For the anion the dysprosium atom is six coordinate with an octahedral geometry comprising four equatorial chlorine atoms (Dy—Cl, mean 2.642(5) Å) and two axial tetrahydrofuran molecules (Dy—O, 2.41(2) Å). Copyright © 1996 Elsevier Science Ltd

Keywords: structure; auto-ionisation; dysprosium(III); tetrahydrofuran; adduct.

Lanthanide halide solvates $MX_3(S)_n$, particularly those involving X = Cl and S = THF, are convenient and useful precursors to organometallic lanthanide species such as alkoxides, hydrides, etc., which, in addition to their intrinsic coordination chemistry, attract considerable commercial interest, e.g. catalytic activity for alkene polymerization [1]. Given that there are no dramatic or wholesale size differences across the lanthanide series M^{III} (Ce → Lu) but rather more subtle variations [2], it might be expected that a common solvation species would dominate. To some extent this is true with the emergence of the structurally characterized seven coordinate pentagonal bipyramidal species $MCl_3(S)_4$, and the related $MCl_3(B)_2$ (B = bidentate ligand). Examples here include: M = Gd, B = dimethoxyethane (DME) [3]; M = Sm, S = THF [4]; M = Sm, 2S (THF) and B = DME [5]; M = Eu, S = pyridine [6]. However, a cursory glance at the literature reveals that the level of solvation is by no means regular, or even predictable, and examples of solvate stoichiometry range from $n = 1.5$ to $n = 4$: typical representatives include $LaCl_3(THF)_{1.5}$ [7]; $CeCl_3(THF)_2$ [7]; $GdCl_3(THF)_3$ [8]; $ErCl_3(THF)_{3.5}$ [8] and $EuCl_3(THF)_4$ [9]. Even for one and the same metal there is often an interesting gradation, e.g. for $NdCl_3(THF)_n$ there are exemplars for $n = 1.5$ [10], 2 [8] and 4 [11].

Specifically, for dysprosium(III), $DyCl_3(THF)_{3.5}$ is the sole representative, but although there are several reports giving synthetic details [7] the structure has not been clarified. Herein we describe the isolation of this particular solvate from the reaction system $DyCl_3(H_2O)_6/SOCl_2/THF$ and its structural identity (X-ray diffraction) as the ion pair [*trans*-$DyCl_2(THF)_5$][*trans*-$DyCl_4(THF)_2$].

EXPERIMENTAL

Manipulations of materials were carried out using Schlenk techniques, in conjunction with a conventional dinitrogen atmosphere glovebox. Solvents were dried over CaH_2, and subsequently over P_4O_{10}, and were distilled over Na/benzophenone in an inert atmosphere prior to use. $DyCl_3(H_2O)_6$ was purchased

* Author to whom correspondence should be addressed.

from Aldrich Chemical Co. and used without further purification. IR spectra were obtained as Nujol mulls between CsI plates using a Perkin–Elmer 580B instrument, and elemental analyses were carried out using a Leeman Labs Inc., PS 1000 sequential inductively coupled plasma (ICP) spectrometer and a CE 440 elemental (C, H, N) analyser.

Preparation of $DyCl_3(THF)_{3.5}$

$SOCl_2$ (25 cm^3, 343 mmol) was added dropwise to a cooled (0°C), stirred solution of $DyCl_3(H_2O)_6$ (6.02 g, 15.97 mmol) in tetrahydrofuran (75 cm^3) and the mixture was heated at reflux for 75 h. Removal of solvent *in vacuo* from the resulting solution afforded an off-white solid which was washed with ether (3×20 cm^3) and hexane (3×20 cm^3) and pumped *in vacuo* at room temperature for several hours. Subsequent recrystallization from THF in the presence of activated charcoal gave the title compound as cubic crystals. Yield 7.24 g, 87.2%. Found: C, 30.8; H, 5.3; Cl, 20.1; Dy, 30.9. Calc. for $C_{28}H_{56}O_7Dy_2Cl_6$: C, 32.3; H, 5.4; Cl, 20.4; Dy, 31.2%. IR $\bar{\nu}_{max}/cm^{-1}$ (Nujol): 1306m, 1170s, 1075m, 1010s, ν_{as}(COC); 919m, 858s, ν_s(COC); 771w, 722s, 668w, 565vw, 497vw (ligand), 276vs br, 240 br sh ν(DyCl).

X-ray crystallography

Crystal data are given in Table 1, together with refinement details. Data were collected with Mo-K_α radiation using the MARresearch Image Plate System. The crystal was positioned at 75 mm from the image plate. A total of 95 frames were measured at 2° intervals with a counting time of 2 minutes. Data analysis was carried out with the XDS program [12]. The structure was solved using direct methods with the SHELX86 program [13]. The non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms were included in geometric positions and given thermal parameters equivalent to 1.2 times those of the atom to which they were attached. An empirical absorption correction was applied [14]. The structure was then refined on F^2 using SHELXL [15]. The light atoms have high thermal motion. All calculations were carried out on a Silicon Graphics R4000 workstation at the University of Reading. Additional material available from the Cambridge Crystallographic Data Centre comprises hydrogen atom coordinates, thermal parameters, a complete set of bond distances and angles and observed and calculated structure factors.

RESULTS AND DISCUSSION

Dehydration of $DyCl_3(H_2O)_6$ using thionyl chloride in an excess of tetrahydrofuran provided colourless cubic crystals of the anhydrous solvate $DyCl_3(THF)_{3.5}$. The infrared spectrum contains characteristic bands at 1010 cm^{-1} ν_{as}(C—O—C), 858 cm^{-1} ν_s(C—O—C) and 276, 240 (sh) cm^{-1} ν(Dy—Cl) with no sign of the presence of water molecules. The true nature of the product was obtained by an X-ray diffraction study which revealed the 1:1 ionic salt [*trans*-$DyCl_2(THF)_5$][*trans*-$DyCl_4(THF)_2$]. The structures of the individual ions are presented in Fig. 1 with the atom numbering scheme used. Selected bond distances and angles for each ion are listed in Table 2. It is interesting that auto-ionization of dysprosium(III) chloride in the strongly polar THF has produced an ion pair comprising seven coordinate $DyCl_2^+$ (solvated) cations and six coordinate $DyCl_4^-$ (solvated) anions. The coordination number seven is commonplace for lanthanide(III) halide complexes, but even under the umbrella of pentagonal bipyramidal geometry perhaps some clear distinction should be made between *neutral* monomeric compounds $MCl_3(S)_4$/$MCl_3(B)_2$ [Type X] and *cationic* species based on solvated MCl_2^+ where auto-ionisation in a polar donor solvent has occurred, i.e. [Type Y]

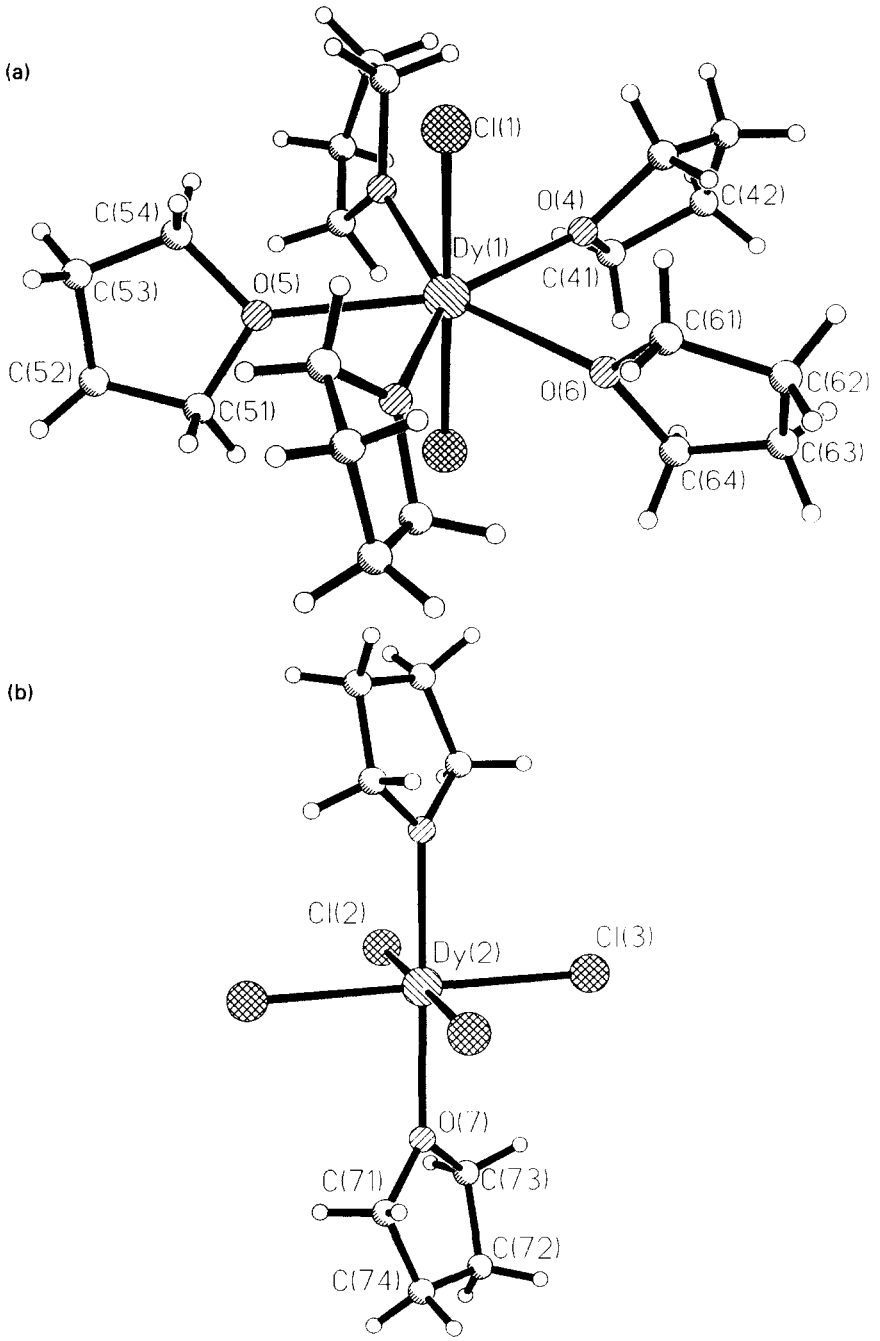

Fig. 1. Perspective views of the structures of (a) the [*trans*-$DyCl_2(THF)_5$]$^+$ cation and (b) the [*trans*-$DyCl_4(THF)_2$]$^-$ anion.

$$2MCl_3(S)_{3.5} \xrightarrow{S} [MCl_2(S)_5]^+ + [MCl_4(S)_2]^-.$$

Examples of each type include: [Type X] M = Gd, B = DME [3]; M = Eu, S = THF [9]; M = Nd, S = THF [11]; M = Sm, 2S(THF) and B(DME) [5]; M = Eu, S = pyridine [6]; M = Sm, S = THF [4]; M = Sm, S = isopropanol [16]; M = Lu, S = THF [17]; M = Y, B = DME [18]. For [Type Y] M = Tb, S = THF [19] and M = Y, S = THF [20] and S = NIM [21] where NIM = *N*-methylimidazole ($C_4H_6N_2$). However, it should be noted that an alternative to [Type Y] exists which features solvated MX_2^+ cations, but not as derived from auto-ionisation, namely, $[SmI_2(THF)_5][Co(CO)_4]$ [22]; $[SmI_2(Ph_2MeP{=}O)_5]I$ [23]; $[YCl(OCMe_3)(THF)_5][PBh_4]$ [24].

In the present structure, the *trans*-$DyCl_2$ unit of the cation is linear with identical Dy—Cl bond distances 2.624(5) Å and Cl—Dy—Cl 179.3(3)°. By way of comparison, the seven coordinate pentagonal bipyramidal (some distortion noted) $DyCl_3$(triethyleneglycol)·18-crown-6 adduct [25] shows an

Symmetry transformations used to generate equivalent atoms; #1 $-x, y, -z+1/2$; #2 $-x+1/2, -y+1/2, -z$.

essentially linear $DyCl_2$ fragment with Cl—Dy—Cl 163.96(8)° and Dy—Cl mean 2.626(2) Å. In a subsequent determination of a more ordered form of this particular molecule [26] the dimensions showed some minor changes, namely Dy—Cl mean 2.607(1); Cl—Dy—Cl 162.65(7)°. Some measure of how close the present structure approaches the ideal is seen by the fact that Cl—Dy—O (ten of these) lie in the range 84.7(4)–95.5(4)° and O—Dy—O (five of these) fall within the very narrow range 72.2(4)–72.7(6)°. The equatorial DyO_5 segment is coplanar; a least-squares plane carried through these six atoms shows deviations of ±0.25 Å. With regard to the bound solvent molecules there is a steric alignment about the Dy←O linkages leaving the individual five-membered rings in a steam-paddle arrangement; the three independent Cl(1)—Dy(1)—O_{ring}—C_{ring} torsion angles are 21.0, 25.1 and 12.2°, indicative that the ring planes are much more axially than equatorially aligned. For the centrosymmetric $[DyCl_4(THF)_2]^-$ anion the coordinated THF molecules are mutually *trans* in axial locations with Dy—O 2.41(2) Å and O—Dy—O, 179.998(1)°. The equatorial $DyCl_4$ unit is perforce planar with Dy—Cl bond distances in the range 2.641(5)–2.644(5), mean 2.642(5) Å and *cis*-Cl—Dy—Cl angles lying between 88.1(2) and 91.9(2)°. There is precious little difference between the anion and cation dimensions; the Dy—Cl bond distances are marginally longer in the anion, but the Dy—O bonds are identical for both. For a direct comparison the neutral six-coordinate $DyCl_3(HMPA)_3$ [27] shows Dy—Cl 2.626(4), 2.637(2) and 2.634(3) Å, mean 2.632(4) Å.

In summary, we note that although solvated lanthanide MCl_2^+ cations with a *trans* pentagonal bipyramidal metal geometry are fairly commonplace, only three previous examples originate strictly from autoionisation. As listed above these are M = Y (Group 3) (two examples) and Tb and all three feature a steam-paddle arrangement of the five equatorial solvent molecules associated with the MCl_2^+ cation. The present structural study confirms a fourth (and still rare) representative with M = Dy, and it is tempting to associate all such "3.5 complexes", both present and future, with this ionic formulation. The question of why the more orthodox mononuclear adduct $DyCl_3(THF)_4$ (Type X) was not obtained, and, indeed, whether it can be obtained, is under evaluation. One point that emerges from the brief survey above is that even with a specific donor solvent (S) such as tetrahydrofuran there is no one singular structural type that encompasses MCl_3–THF complexation. Some of the factors that appear relevant to the observed structural diversity of such complexes have been admirably set out and discussed by Evans *et al* [19].

(Received 24 May 1996; accepted 26 June 1996)

Abstract—$[(CH_3)_4N]_4[H_2MoV_9O_{28}]Cl\cdot 6H_2O$ has been synthesized from ammonium vanadate and molybdenum(VI) oxide in acidic aqueous solution by adding tetramethylammonium chloride, and its structure determined by single-crystal X-ray analysis. The polyoxomolybdovanadate anion has the structure of the decavanadate anion with the molybdenum atom substituted at one "capping" vanadium site. Owing to the $2/m$ symmetry of the anion, this molybdenum atom is randomly distributed over four "capping" metal atom positions. Two hydrogen atoms are bonded to triply bridging oxygen atoms. Copyright © 1996 Elsevier Science Ltd

Keywords: molybdovanadates; crystal structure determination; protonation site.

Molybdovanadates have been studied in aqueous solution by NMR spectroscopy and potentiometry, and a number of polyoxoanion species observed and identified [1–3]. Although the crystal structures of a few molybdovanadate anions have been reported, such as α-$[Mo_6V_2O_{26}]^{6-}$ [4], β-$[Mo_6V_2O_{26}]^{6-}$ [5], $[Mo_8V_5O_{40}]^{7-}$ [6], $[Mo_4V_8O_{36}]^{8-}$ [7] and $[(V^{IV}V^{V}Mo_{10})VO_{40}]^{6-}$ [8,9], none of these structures correlates with any of the major species observed in solution. It seems that crystals appear because of their insolubility rather than the relative stability of the solution species [3]. However, our recent paper revealed the structure of the $[Mo_4V_5O_{27}]^{5-}$ anion as the first example of a structurally characterized molybdovanadate that is dominant in aqueous solution [10].

In general, while the molybdenum-rich region of the molybdovanadates is structurally complex, the vanadium-rich region essentially retains the decavanadate structure characterized by three species containing either one or two (positioned *cis* or *trans*) "capping" vanadium sites substituted by molybdenum atoms [2]. The synthesis and crystal structure determination of $[(CH_3)_4N]_4[H_2MoV_9O_{28}]Cl\cdot 6H_2O$, described here, confirms the results found in solution [1].

EXPERIMENTAL

Reagents and apparatus

All chemicals were of reagent grade and used as purchased from commercial sources. The IR spectrum was recorded in KBr with an FTIR 1600 spectrophotometer in the 4500–450 cm^{-1} region.

Preparation and elemental analyses

The title complex was prepared by mixing a 2M ammonium solution (25 cm^3) of MoO_3 (1.80 g) and a hot water solution (25 cm^3) of NH_4VO_3 (2.9 g). When 2M HCl (13 cm^3) was added to the resulting solution its colour turned to orange. Undissolved NH_4VO_3 was filtered off and solid $(CH_3)_4NCl$ (5.49 g) was added. After standing for 10 days at room temperature orange crystalline product (0.15 g, 0.83%) was filtered off and recrystallized from water solution. Found: C, 12.8; H, 3.5; N, 4.0; Mo, 6.3; V, 30.9; Cl, 2.0. Calc. for $C_{16}H_{62}N_4O_{34}MoV_9Cl$: C, 13.3; H, 4.3; N, 3.9; Mo, 6.6; V, 31.7; Cl, 2.5%. IR (cm^{-1}): 3501m, 3144m, 3034m, 1485s, 1461m, 1448m, 962s, 848s, 751s, 543s.

Crystal structure determination

Crystal data. $C_{16}H_{62}N_4O_{34}MoV_9Cl$, monoclinic, space group $I2/m$, $M = 1444.54$, $a = 10.600(2)$,

$b = 20.117(4)$, $c = 11.129(8)$ Å, $\beta = 92.39(3)^\circ$, $V = 2371(3)$ Å^3, $Z = 2$, $D_X = 2.02$ g cm^{-3}, $F(000) = 1448$, $\mu(\text{Mo-}K_\alpha) = 20.40$ cm^{-1}. A single crystal of dimensions $0.12 \times 0.26 \times 0.38$ mm^3 was used for the data collection on a STOE modified Philips PW1100 diffractometer with graphite-monochromatized Mo-K_α radiation ($\lambda = 0.7107$ Å). Four standard reflections measured every 80 min showed a drop of intensity of 16%. The 3974 reflections (3519 unique) were collected ($2 \leqslant \theta \leqslant 30^\circ$, $-14 \leqslant h \leqslant 14$, $0 \leqslant k \leqslant 28$, $0 \leqslant l \leqslant 15$) by ω scans at room temperature. Data were corrected for decay, Lorentz and polarization effects, and also for absorption (by integration from crystal shape using the ACXR [11] program).

The structure was solved by a heavy-atom method and successive Fourier syntheses. While the Patterson map revealed the positions of three metal atoms in the asymmetric unit, subsequent Fourier maps showed the positions of all other non-hydrogen atoms. Inspection of the difference maps revealed the existence of residual electron density around metal atom M(2) (~ 6 e Å^{-3}) indicating a partial molybdenum substitution at the "capping" vanadium sites. Refinement of site occupancy factors gave a V:Mo ratio of 0.78:0.22. Owing to the overall symmetry of the molybdovanadate anion ($2/m$) the ratio V:Mo was fixed as 0.75:0.25 and, as such, included in the further refinement. The refinement was performed by full-matrix least-squares calculations with anisotropic thermal parameters for all non-hydrogen atoms, V(2) and Mo(2) were refined with the same coordinates and anisotropic thermal parameters. Following the absorption correction all hydrogen atoms were located in a difference Fourier map, and included in structure factor calculations. Since water oxygen O(w1) and hydrogen H(11) are positioned in a mirror plane, the other hydrogen atom H(12), located in a general position, is distributed over two symmetrically related equivalent positions. The calculations converged at $R = 0.030$ over 1948 reflections with $I\xi \geqslant 3\sigma(I)$ and 157 refined parameters, $wR = 0.045$, $w = 0.8011/[\sigma^2(F) + 0.0008F^2]$ and $S = 0.987$. Two low refections (110 and 011) were omitted owing to secondary extinction. The largest remaining difference peak was 0.37 e Å^{-3}. All calculations were performed on an IBM PC/AT compatible microcomputer (processor 80486/66MHz) using the SHELXS86 [12] and SHELX76 [13] programs. The distances and angles were calculated using the CSU program [14], the molecular and crystal structure using ORTEP [15] and PLUTON [16] programs.

RESULTS AND DISCUSSION

The structure of the molybdovanadate anion is shown in Fig. 1 and the packing of anions with surrounding tetramethylammonium cations, chlorine ions and water molecules is shown in Fig. 2. Interatomic distances are listed in Table 1 and hydrogen bonding parameters in Table 2, while the relative

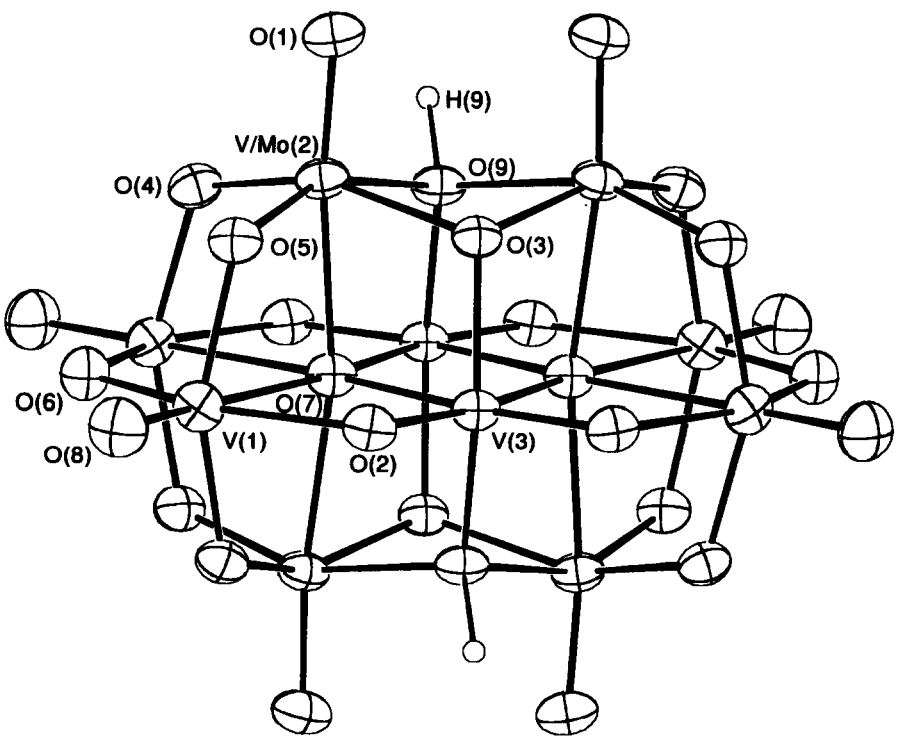

Fig. 1. View of the $[H_2MoV_9O_{28}]^{3-}$ anion with the atomic numbering scheme.

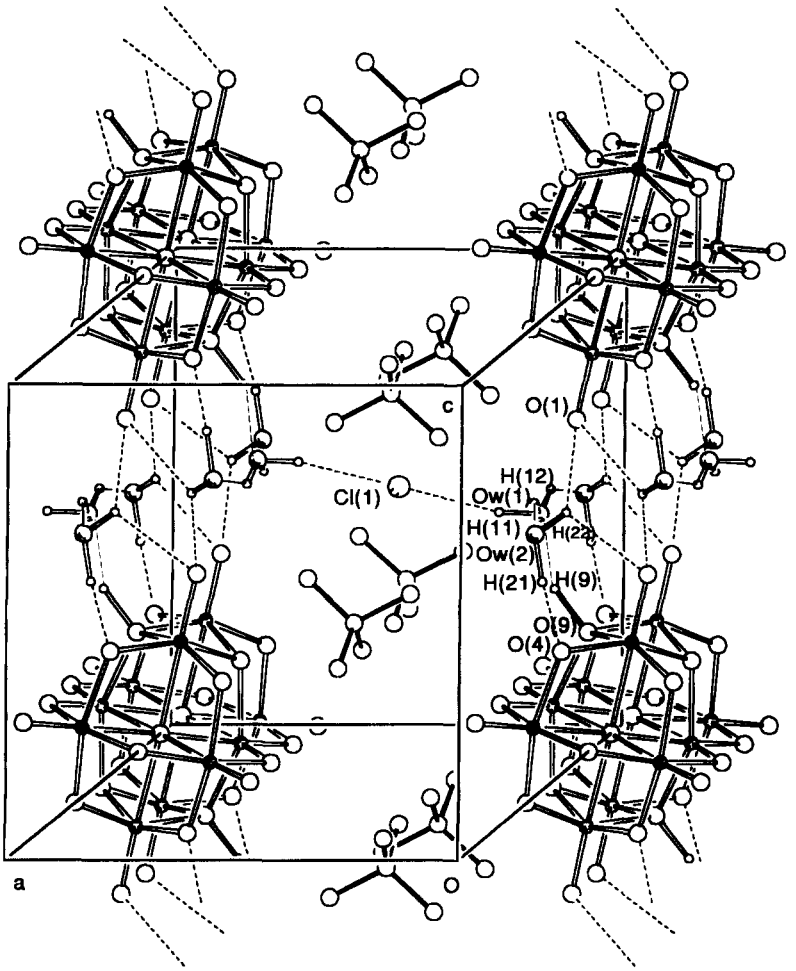

Fig. 2. Part of the unit cell ($0.75 \leqslant y \leqslant 1.25$) of $[N(CH_3)_4]_4[H_2MoV_9O_{28}]Cl \cdot 6H_2O$. Hydrogen bonds are shown by broken lines. Tetramethylammonium hydrogens are omitted for clarity.

values of the M—O bond strengths are given in Table 3. The final atomic coordinates, thermal parameters, and list of observed and calculated structure factors have been deposited as supplementary material at the Cambridge Crystallographic Data Centre.

The monomolybdovanadate anion has a well-known decavanadate structure, built up of 10 edge-sharing MO_6 octahedra. However, since the polyanion has a crystallographically imposed $2/m$ symmetry one molybdenum atom should be distributed over four "capping" metal atom positions. All metal-to-metal distances vary from 3.065 to 3.207 Å and are comparable with those found in the structures of other decavanadate salts [17–22]. The V—O distances within VO_6 octahedra [V(1) and V(3)] are also similar to those already observed and depend upon the type of oxo ligand: bond length to the terminal oxo oxygen $V{=}O_t$ is 1.609 Å, $V—O_b$ bond lengths to the oxygen bonded to two V atoms vary from 1.688 to 2.052 Å, $V—O_{3b}$ bond lengths to the oxygen bonded to three V atoms are 1.921 and 1.929 Å and, finally, $V—O_{6b}$ bond lengths to the oxygen shared between six V atoms are 2.139 and 2.321 Å. The VO_6 octahedra are significantly distorted, with the bond angles at the V atoms ranging from 74.7 to 108.1°. In the "capping" octahedron, with a random distribution of molybdenum and vanadium atoms, the metal-to-oxygen distances are between the values found for Mo—O and V—O bond lengths and vary as follows: to one terminal oxo oxygen atom 1.621 Å, to two doubly bridging oxygens 1.819 and 1.841 Å, to two triply bridging oxygens 2.006 and 2.034 Å, and to one oxygen bridging six metal atoms 2.261 Å. The bond angles at the metal atom range from 75.3 to 105.1°.

The location of proton H(9), bonded to O(9), was of particular interest since it was suggested that the basic oxygen site has an important role regarding the reactivity of such polyanions. The distance between the water oxygen O(w1) and the polyoxo oxygen atom O(9) of 2.968 Å is indicative of a moderately strong hydrogen bond. However, since both protons belonging to water molecule w1 are engaged in the hydrogen bonding with the water oxygen O(w2) and chlorine atom Cl(1), it is reasonable to suppose that the above-

[a] s(V—O) = $[d(V—O)/1.791]^{-5.1}$, s(Mo—O) = $[d(Mo—O)/1.882]^{-6}$, s(O···H) = $[d(O···H)/0.86]^{-2.17}$, s(Mo/V—O) = $\frac{1}{4}s$(Mo—O) + $\frac{3}{4}s$(V—O).
[b] Including s(O···H).

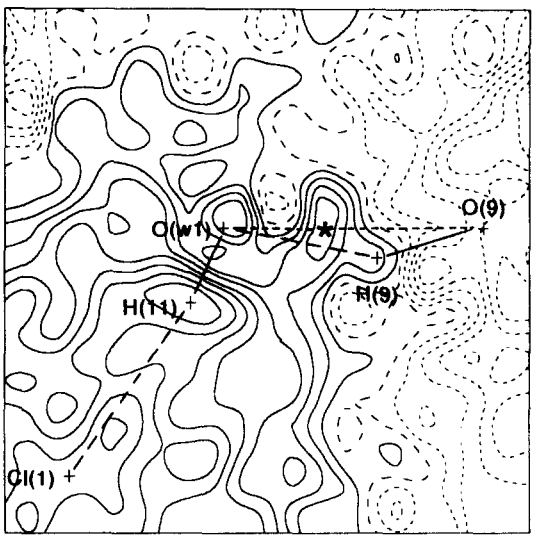

Fig. 3. Contour electron density map in the region around water oxygen O(w1) and polyoxoanion oxygen O(9). Residual peak (0.34 e Å^{-3}), marked by asterisk, indicates a possible dynamic disorder of H(9) between the water molecule and the molybdovanadate anion.

mentioned hydrogen bond O(9)···O(w1) is realized through the hydrogen atom attached to O(9). In this way an endless column is formed along the *c*-axis between the $[H_2MoV_9O_{28}]^{3-}$ anions and water molecules. The columns are mutually interconnected by the lateral O(w1)···Cl(1) hydrogen bond of 3.362 Å.

However, whereas the same location of a hydrogen atom at the triply bonded oxygen atom was also proposed in the paper describing the structure of tetrakis(n-hexylammonium) dihydrogendecavanadate [23], in the structure of tetrakis-adenosinium dihydrogendecavanadate undecahydrate such protonation was assigned to the doubly-bridging oxygen atoms [18]. Our finding is in agreement with the results of ^{17}O NMR spectroscopy and with the suggestion that triply bridging oxygen atoms are favoured protonation sites, whereas the doubly bridging oxygens are a second choice and are protonated to a lesser extent [24]. These results agree well with an analysis of the distribution of the electrostatic potential determined by *ab initio* methods, as well as of the Laplacian charge density calculated for the $[V_{10}O_{28}]^{6-}$ anion [25].

In fact, an additional residual peak close to the water oxygen atom O(w1) found in a final difference electron density map (1.22 Å, 0.34 e Å^{-3}, Fig. 3), is probably indicative of dynamic disorder of H(9) between O(w1) and the polyoxo oxygen atom, O(9).

The protonation of the oxygen atom O(9) is also supported by the bond strength calculation using the relation s(V—O) = $[d(V—O)/1.791]^{-5.1}$ for all non-substituted VO_6 octahedra [26], and s(Mo/V—O) = $\frac{1}{4}s$(Mo—O) + $\frac{3}{4}s$(V—O) for a "capping" Mo/VO_6 octahedron (Table 3). Whereas the bond numbers for oxygens O(1) and O(4), engaged in hydrogen bonding, are close to 2, and correspond to the theoretical value for oxygen atoms, a relatively high value for O(9) of 2.22 is also indicative of a possible disorder of H(9). The M—O bond number within the $(Mo/V)O_6$ octahedron amounts to 5.25, exactly the same value required for the metal site to be occupied by vanadium and molybdenum in the ratio 3 : 1.

Synthesis of tris(dicyclohexylamido) titanium and zirconium chloride and the structure of $(c\text{-Hex}_2\text{N})_3\text{TiCl}$

Zhibang Duan,* Leonard M. Thomas and John G. Verkade†

Department of Chemistry, Iowa State University, Ames, IA 50011, U.S.A.

(Received 24 April 1996; accepted 26 June 1996)

Abstract—Reaction of $MCl_4(THF)_2$ (M = Ti and Zr) with excess $LiNCy_2$ in pentane affords crystalline $(c\text{-Hex}_2\text{N})_3\text{MCl}$ in greater than 70% yields. The products were characterized by ^1H, ^{13}C, ^1H and ^{13}C HETCOR NMR, and MS techniques. Crystalline $(c\text{-Hex}_2\text{N})_3\text{TiCl}$ was also characterized by a single-crystal X-ray structure. Trends in the structural dimensions of $(R_2N)_3\text{TiCl}$ are noted. Copyright © 1996 Elsevier Science Ltd

Keywords: titanium; zirconium; amides; NMR.

Titanium and zirconium nitrides find uses as wear-resistant coatings on machine tools [1], gold substitutes for decorative coatings [2], reflectance and hardness coatings for microelectronic devices [3], diffusion barriers in various semiconductor metallization schemes [4] and as ceramics with high thermal impact resistance [5]. Tris(dialkylamido) halides of these metals, $(R_2N)_3MX$, are of interest because of their potential as single-source MOCVD precursors to their corresponding nitride and carbonitride films, and also for their applications in important synthetic transformations. Thus, $[(Me_3Si)_2N]_3\text{TiF}$ was recently studied for its ability to deposit TiN and TiCN films on silicon and steel substrates under N_2, H_2 and He [6]. Its analogue $(Et_2N)_3\text{TiCl}$ is efficacious as a reagent in titanating allylmetal compounds [7,8], enolates [9], cyanomethyl lithium [10], benzylmagnesium bromide [10] and lithiated hydrazones [11] for use in chemo- and stereoselective additions to carbonyl substrates [10]. Conversion of $(Et_2N)_3\text{TiCl}$ to $(Et_2N)_3\text{TiMe}$ allows the latter to be used for aminomethylation of aromatic aldehydes [10,12]. To our knowledge, however, no reports concerning the ring-substituted analogues $(c\text{-Hex}_2\text{N})_3\text{MCl}$ (M = Ti and Zr) have been reported. In connection with our interest in tricyclic azatranes of group 4 [13] as precursors for MOCVD, we report here the first synthesis and characterization of $(c\text{-Hex}_2\text{N})_3\text{TiCl}$ (**1**) and $(c\text{-Hex}_2\text{N})_3\text{ZrCl}$ (**2**), as well as the molecular and crystal structure of **1**. Trends in the angles around titanium in $(R_2N)_3\text{TiCl}$ derivatives are observed and discussed.

EXPERIMENTAL

General procedures

All reactions were carried out under argon with strict exclusion of moisture using standard Schlenk or dry-box techniques [14]. Solvents were dried over, and distilled from, Na/benzophenone and stored prior to use over 4 Å molecules sieves under argon. Lithium dicyclohexylamide (97%) was purchased from Aldrich and was used as received. $TiCl_4(THF)_2$ and $ZrCl_4(THF)_2$ were synthesized according to literature procedures [15].

NMR spectra were recorded at 20°C on a Nicolet NT300 (^1H) or a Varian VXR300 spectrometer in C_6D_6 using the protio impurity of the solvent as an internal reference for ^1H spectra and the ^{13}C resonance of C_6D_6 as a reference for the ^{13}C NMR spectra. Two-dimensional COSY 90 and HETCOR spectra were recorded on a Bruker DRX 400 spectrometer. Mass spectra were obtained on a Finnigan TSQ 700 instrument or a Kratos MS-50 spectrometer. Melting points (uncorrected) were determined with a Thomas–

Tris(dicyclohexylamido)titanium chloride, **1**

$TiCl_4(THF)_2$ (1.10 g, 3.28 mmol) was added to a suspension of $LiNCy_2$ (2.95 g, 97%, 15.3 mmol) in pentane (90 cm^3) at −78°C. The reaction mixture was warmed to room temperature, stirred for 17 h and then filtered through Celite. The residue was washed copiously with pentane. The filtrate and the washings were combined and concentrated to about 20 cm^3. The solution was kept in a freezer to allow crystals to grow. The crystals were filtered off, washed with cold pentane (4 × 3 cm^3) and dried *in vacuo* to give 1.47 g of product in 72% yield. M.p.: >148°C (dec.). Found: C, 69.2; H, 10.7; N, 6.6. Crystal structure determination of **1**

A yellow crystal of **1** with dimensions of 0.2 × 0.1 × 0.05 mm^3 was mounted on a Siemens P4RA diffractometer for data collection at 213(2) ± 1 K. The unit-cell constants were determined from reflections found from a rotation photograph. Twenty-five reflections in the θ range 15–25° were used to determine precise cell constants. Lorentz and polarization corrections were applied to the data, as were nonlinear corrections based on the decay in the standard reflections. A semi-empirical absorption correction based on azimuthal scans was applied.

The space group *P*1 was chosen based on systematic absences and intensity statistics. This assumption proved to be correct as determined by a successful direct-methods solution [16] and subsequent refinement. All non-hydrogen atoms were placed directly from the *E* map. All non-hydrogen atoms were refined with anisotropic displacement parameters. All hydrogens were treated as riding atoms with individual isotropic displacement parameters. Crystal data and refinement parameters are summarized in Table 1. Selected bond distances and angles are listed in Table 2. There was a significant amount of disorder in the final structure. Some of the atoms associated with the cyclohexyl rings exhibit a high degree of thermal motion. Atoms C(26) and C(29) were refined with a split occupancy of about 51–49% for each site. Refinement calculations were performed on a Digital Equipment Micro VAX 3100 computer using SHELXTL-Plus [16] and SHELXL-93 [17,18].

RESULTS AND DISCUSSION

The reaction of $MCl_4(THF)_2$ (M = Ti and Zr) with $LiNCy_2$ in pentane led to the formation of the title compounds in yields over 70%:

$$MCl_4(THF)_2 + 3LiN(c\text{-Hex})_2 \xrightarrow{\text{pentane}} (c\text{-Hex}_2N)_3MCl + 3LiCl + 2THF. \quad (1)$$

Similar reactions were utilized to prepare $(R_2N)_3MCl$ (R = Me [19], Et [19], and $SiMe_3$ [20] using MCl_4 instead of $MCl_4(THF)_2$.

The molecular structure of $(c\text{-Hex}_2N)_3TiCl$ shown in Fig. 1 displays a distorted tetrahedral titanium

geometry with a propeller-like arrangement of the *c*-Hex_2N groups. There are two independent molecules in the unit cell. The geometries around each of the nitrogens is trigonal planar with average angle sums of 359.7(6)°. However, each of the angles around any given nitrogen is quite different (Table 2) implying a certain amount of flexibility which allows the rings to pack efficiently into the structure. Thus, the angles involving the carbon proximal to the chlorine are 107.5(4), 108.5(4) and 122.8(7)° for C(1)N(1)Ti, C(13)N(2)Ti and C(25)N(3)Ti, respectively, while those containing the carbon distal to the chlorine are 123.5(5), 131.0(6) and 133.6(6)° for C(31)N(3)Ti, C(19)N(2)Ti and C(7)N(1)Ti, respectively. Interestingly, the C—C—C angle sums of the three Cy rings proximal to the chlorine (665–668°) and one of the distal Cy rings [C(31)—C(36) 665°] are not far from the value expected for an unstrained cyclohexane ring (654.0°). However, the other two distal C_6H_{11} rings have angle sums (719°) close to that expected for a planar C_6 ring. Indeed the C(7)–C(12) and the C(19)–C(24) rings are each planar within 0.031 and 0.024 Å, respectively. This structural feature suggests that the distal rings experience substantial steric compression.

Although the overall geometries of $(R_2N)_3TiCl$ for R = Me [19], Et [19], *c*-Hex and $SiMe_3$ [20] are similar, there are significant differences in the dimensions. Table 3 summarizes some of the structural parameters for these complexes. For compound **1**, the average ClTiN and NTiN angles are almost the same. However, it can be seen that the average of the ClTiN angles decreases in the order R = Me > Et > *c*-Hex > $SiMe_3$, with a concomitant increase of the average NTiN angles (Fig. 2). Since the bulk of the R

groups increases in the order Me < Et < *c*-Hex < $SiMe_3$, it is reasonable to assume that increasingly bulky R groups enlarge the NTiN angles and concomitantly shrink the ClTiN angles. Thus, the trends displayed in Fig. 2 seem to be dominated by steric rather than electronic effects of the R groups.

The average C(or Si)NTi angles proximal to Cl are smaller than those distal to Cl (Table 3). Although steric compression among the distal $SiMe_3$ groups in $[(Me_3Si)_2N]_3TiCl$ would give rise to the largest average NTiN angles compared with the corresponding angles in the remaining $(R_2N)_3TiCl$ compounds, the distal SiNTi angle in $[(Me_3Si)_2N]_3TiCl$ is smaller than the distal CNTi angles for the $(R_2N)_3TiCl$ complexes. This suggests that by opening the NTiN angle sufficiently, the distal carbons (or silicon) move radially outwards to locations that permit the distal C (or Si)NTi angle to decrease. The Cl—Ti bond lengths are comparable for complexes with R = Me, Et and *c*-Hex and the same is true for Ti—N bond distances. However, the Cl—Ti bond length [2.259(6) Å] in $[(Me_3Si)_2N]_3TiCl$ is smaller than those in the $(R_2N)_3TiCl$ complexes, while the average TiN distance in the former is longer than in the latter species. Although the more sterically demanding $SiMe_3$ groups may be expected to favour a longer TiN bond, it is not clear on steric grounds why the Cl—Ti bond in $[(Me_3Si)_2N]_3TiCl$ should be shorter, since the average ClTiN angle (which is the smallest among these complexes) is expected sterically to elongate the ClTi bond in $[(Me_3Si)_2N]_3TiCl$. If however, N → Si π bonding is sufficiently strong, the Ti—N bonds are expected to lengthen and the Ti—Cl bond could be expected to shorten *via* a compensatory Cl → Ti π interaction.

Compounds **1** and **2** exhibited a group of peaks at *m/z* 623 and 665, respectively, in their EI mass spectra, which exactly matched the theoretical isotopic pattern for the parent compound, confirming the volatility of this type of compound. Several groups of peaks corresponding to the removal of cyclohexyl, dicyclohexylamine and a combination of both cyclohexyl and dicyclohexylamine from the parent species were

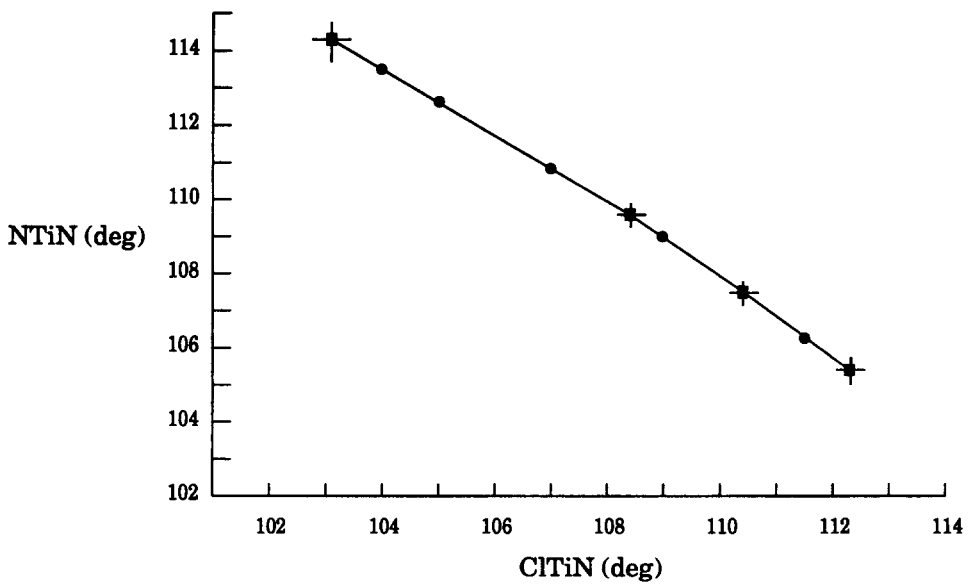

Fig. 2. Plot of average NTiN angle against ClTiN angle in $(R_2N)_3TiCl$. The dots represent values based on the geometrical relationship for a trigonal pyramid $\cos\alpha = -0.500\sin^2\beta + \cos^2\beta$ where α and β are the NTiN and ClTiN angles, respectively. The squares in ascending order of average ClTiN angle and descending average NTiN angle represent R = $SiMe_3$, *c*-Hex, Et, Me in $(R_2N)_3TiCl$. The crosses on the squares are error bars.

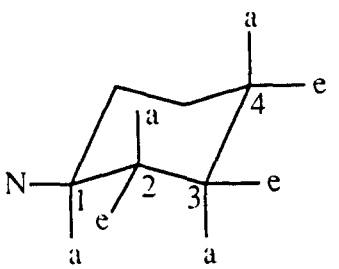
also observed. From the NH_3/CI mass spectrum of the titanium complex, however, only a group of peaks at m/z 624 with low intensity for $(M+H^+)$ and a base peak at m/z 182 for $[HN(c\text{-Hex})_2+H^+]$ were found, probably owing to reactions of the complex with NH_3.



The ^{1}H NMR spectra of **1** and **2** displayed similar patterns, as did the $^{13}C\{^1H\}$ NMR spectra, indicating the isostructural nature of these complexes. Although the ^{1}H NMR spectra in benzene-d_6 exhibited seven signals with different multiplicities (Fig. 3), the $^{13}C\{^1H\}$ spectra showed only four singlets with relative intensities of approximately 1 : 2 : 2 : 1, indicative of the relative numbers of carbon atoms for each cyclohexyl ring. Since the single crystal structure of **1**

revealed a tetrahedral coordination environment about the metal centre, it is reasonable to suggest that both **1** and **2** have virtual C_{3v} symmetry in solution, as was the case for $(Me_2N)_3TiCl$ [19], $(Et_2N)_3TiCl$ [19] and $[(Me_3Si)_2N)_3TiCl]$ [20]. This symmetry accounts for the four carbon resonances observed for **1** and **2** assuming rapid rotation on the NMR time-scale of the six-membered rings around the M—N and N—Cl bonds. The ^{13}C chemical shifts obtained at lower field (75.4 MHz) for **1** and **2** are identical to those obtained at higher field (100.6 MHz). Similar phenomena were observed in their ^1H NMR spectra, except that those obtained at lower field (300 MHz) exhibited much lower resolution than at high field (400 MHz). A depiction for the assignment of the ^{13}C and ^1H NMR spectra is shown below with a indicating the axial protons and e representing the equatorial protons. The assignments of the signals in the ^1H and $^{13}C\{^1H\}$

NMR spectra of **1** and **2** are based on NMR integrations, couplings in the ^1H NMR spectra and on ^1H–^{13}C hetero correlated NMR spectra. The cross-peaks in the ^1H–^{13}C HETCOR 2D NMR spectra of **1** and **2** give the connectivities between the proton and the carbon signals (Table 4). Each of the three carbon resonances at higher field corresponds to two (axial and equatorial) proton signals, while the one at lower field is seen to exhibit one proton resonance which can be assigned to the axial proton in the methine group. This assignment was further confirmed by its coupling pattern of a triplet of triplets, consistent with couplings to the neighbouring two axial and two equatorial methylene protons, respectively. Because axial–axial coupling constants are larger than the axial–equatorial and the equatorial–equatorial couplings in general [21], the 11.3 Hz coupling was assigned to the $H(1_a)H(2_a)$ interaction while the 2.9 and 3.0 Hz couplings were assigned to the $H(1_a)H(2_e)$ couplings for the Ti and Zr complex, respectively. From the ^1H–^1H 2D COSY 90 NMR spectrum (Fig. 3) it can be seen that the $H(1_a)$ proton couples to only two proton signals, which are likely to be $H(2_a)$ and $H(2_e)$. Each of the $H(2_a)$ and $H(2_e)$ signals should be a doublet of doublets of doublets of doublets, owing to the geminal and neighbouring proton couplings. However, simpler coupling patterns with an apparent doublet and an apparent doublet of quartets for these protons were observed, probably owing to accidental overlap. Based on the above discussion, the peaks located at δ 1.66 were assigned to the $H(2_a)$ resonance, for which relatively large axial–axial couplings are expected, while those at δ 2.10 and 2.03 were assigned to the $H(2_e)$ peaks for **1** and **2**, respectively. From the coupling relationship to $H(2_a)$ and $H(2_e)$ in the COSY 90 NMR spectrum (Fig. 3) the H(3) protons were easily recognized. For reasons analogous to the foregoing, the peaks at δ 1.38 were attributed to the $H(3_a)$ resonances which exhibit an apparent doublet of quartets pattern, while those at δ 1.81 were assigned to the $H(3_e)$ resonances, which display an apparent doublet. The signals for $H(4_a)$ and $H(4_e)$ were similarly assigned.

It is noteworthy that the chemical shifts in the titanium compound are more downfield in general than the zirconium derivative for both the ^1H and ^{13}C NMR peaks, except for the $H(2_a)$, $H(3_a)$ and C(2) resonances (Table 4). This may be associated with the differences in metal electronegativities [22]. The same trend was observed for azametallatrane analogues containing these metals [13b].

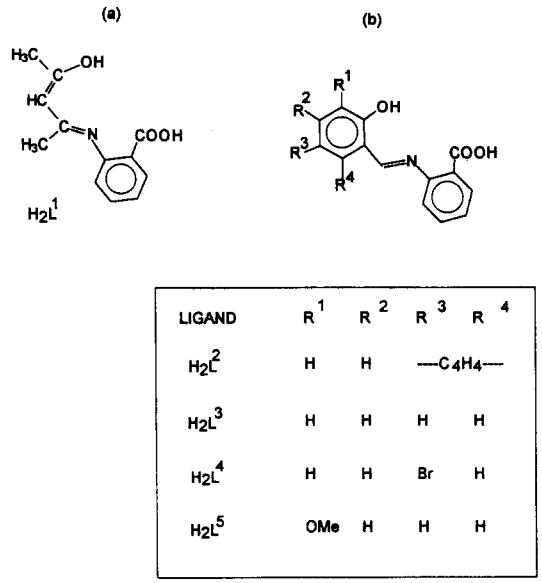
(Received 24 May 1996; accepted 24 June 1996)



Abstract—Anhydrous, dimeric vanadyl(IV) complexes of Schiff bases derived from [1 + 1] condensation of salicylaldehyde (or its derivatives) and anthranilic acid, have been synthesized from CH_3CN and were characterized by elemental analysis, FTIR, EPR, absorption, TGA, cyclic voltammetry and room temperature magnetic susceptibility measurements. These complexes were found to be oxidized by air in polar solvents like MeOH and DMF to V^V products. The $E_{1/2}$ values were found to be around 660 mV indicating that the carboxylate group favours vanadyl(IV) binding when compared to the alkoxo-bound vanadium complexes. Oxidative instability of these complexes are dependent on the substituent on the salicylaldehyde ring and follow an order, 5,6-benzo > H ⩾ 3-OMe in MeOH and DMF. Attempted recrystallization of the dimeric vanadyl(IV) complex from pyridine led to products of oxidation, polymerization and loss of Schiff base ligand. Single crystal X-ray diffraction showed the oxidation product to be a decavanadate with the pyridinium counter cation, $[C_5NH_6]_6\ V_{10}O_{28} \cdot 2H_2O$. When the dinuclear vanadyl(IV) complex was recrystallized from MeOH, it gave a product of mononuclear carboxylate bound octahedral VO^{3+} moiety along with the presence of both MeOH and OMe units in the coordination sphere with a formula, VO(L)(OMe)(MeOH), where L = 1 + 1 Schiff base derived from 5,6-benzosalicylaldehyde and anthranilic acid, as studied through single crystal X-ray diffraction. Copyright © 1996 Elsevier Science Ltd

Keywords: dimeric vanadyl(IV); oxidative instability; decavanadate; mononuclear octahedral VO^{3+}; single crystal X-ray; Schiff bases.

Important structural moieties in the coordination chemistry of vanadium are VO^{2+} and VO_2^+ and relatively few well characterized complexes containing mononuclear VO^{3+} are known [1]. The isolation and characterization of a novel haloperoxidase [2], requiring vanadium in its +5 oxidation state has motivated many [1, 3–6], including us [7–9] to synthesize, characterize and study various ligand systems coordinated to V^V in its LVO_2^{n-} ($n = 0, 1$) or VO^{3+} forms. The binding of the monooxovanadium(V) moiety (VO^{3+}) to the carboxylate oxygen atom is of current interest not only because this has been proposed to be the structural unit in haloperoxidases [10], but also for the fact that very few have been structurally characterized.

As reported in the literature, reaction of Schiff bases formed between salicylaldehyde and amino acids like glycine, alanine and leucine with $VOSO_4$ in alcoholic-aqueous solution resulted in mononuclear water bound vanadyl(IV) complexes [11,12]. Attempts to dehydrate these by heating to 160°C and to study the properties of the anhydrous complexes were unsuc-

cessful [13]. This paper deals with the synthesis of dinuclear vanadyl(IV) complexes of Schiff bases derived from anthranilic acid and salicylaldehyde (and its derivatives) or acetylacetone in poorly coordinating solvents such as CH_3CN, their stability and conversion to V^V products in coordinating solvents like MeOH and DMF. The structure of the ligands is given in Fig. 1. Attempts to crystallize the vanadyl(IV) dimeric complexes from MeOH or pyridine led to oxidized products of different chemical nature and structure and were structurally characterized by single crystal X-ray methods.

EXPERIMENTAL

Materials and methods

All the methods of analysis (i.e. elemental, ICPAES, EPR, UV-vis, ^{51}V NMR, magnetic and X-ray diffractometer) and synthesis of 2-hydroxy-1-naphthaldehyde (5,6-benzosal), 5-bromosalicylaldehyde (5-brsal) and $VO(acac)_2$ are described in our earlier papers [7–9]. Salicylaldehyde (sal) and acetylacetone (Hacac) (SD Fine, India) were distilled before use, other chemicals were used as received from commercial sources. CH_3CN was distilled over CaH_2 and stored over molecular sieves prior to use.

Preparation of Schiff bases

To an ice cooled 3.5 cm^3 (35 mmol) of Hacac in 10 cm^3 EtOH was added 4.1 g (30 mmol) of anthranilic acid dissolved in 20 cm^3 ice cooled EtOH and the mixture was stirred for 10 min while cold. The solution was brought to room temperature and left for 36 h to result in the precipitation of white crystalline material of the Schiff base (H_2L^1) in 36% yield.

The Schiff bases between anthranilic acid and salicylaldehyde or its derivatives were prepared by the addition of methanolic solution of anthranilic acid to methanolic solution of respective aldehydes in a 1 : 1 ratio followed by stirring for 3 h. The Schiff bases H_2L^2 and H_2L^3 precipitated out; H_2L^4 gave an orange precipitate and H_2L^5 an oil on vacuum drying. Yield of the products obtained was in the range 67–70%.

Synthesis of oxovanadium complexes

Complex **1**. To H_2L^1 (0.430 g, 2 mmol) in 30 cm^3 CH_3CN was added $VO(acac)_2$ (0.530 g, 2 mmol) in 50 cm^3 CH_3CN to result in the formation of an immediate green precipitate. This was refluxed for 3 h, cooled and filtered. The green compound was purified by stirring in hot CH_3CN for 2 h, followed by filtration, washing with ether and drying *in vacuo* to give a product with yield of 66% based on vanadium content. IR(cm^{-1}): 1620 ($\nu_{C=N}$), 1550 (ν_{asym} of COO^-), 1400 and 1390 ($\delta_{CH_3} + \nu_{COO^-}$), 990 ($\nu_{V=O}$).

Complex **1a**. Complex **1** was dissolved in pyridine, to result in a brownish-green solution, which after 2 weeks gave orange crystals of **1a** in 23% yield. These crystals lose their crystallinity and change to yellow powder when removed from solvent. IR (cm^{-1}): 3517 (ν_{OH}, free), 3408 (ν_{OH}, H-bonded), 2133 and 2018 (ν_{asym} and ν_{sym} of $C{=}NH^+$), 975 ($\nu_{V=O}$), 835–470 (ν_{asym} and ν_{sym} of V—O—V).

Complex **2**. To H_2L^2 (0.582 g, 2 mmol) suspended in 50 cm^3 hot CH_3CN was added $VO(acac)_2$ (0.530 g, 2 mmol) in 50 cm^3 CH_3CN. This resulted in a red solution followed by the formation of a brown precipitate. The mixture was refluxed for 12 h, cooled and filtered. The brown product was washed by stirring in hot CH_3CN for 3 h followed by filtration. The same purification procedure was employed for a second time. The filtered product **2** was washed with ether and dried *in vacuo* to give a pure product in 66% yield. IR (cm^{-1}): 1620 ($\nu_{C=N}$), 1550 and 1390 (ν_{asym} and ν_{sym} of COO^-), 995 ($\nu_{V=O}$).

Complex **2a**. Complex **2** (0.661 g) was stirred under reflux in 30 cm^3 MeOH for 6 h. The solution was filtered and the filtrate was kept at room temperature to give compound **2a** as dark red crystals suitable for X-ray analysis in 64% yield. IR (cm^{-1}): 3228 (ν_{OH}), 1626 ($\nu_{C=N}$), 1534 and 1389 (ν_{asym} and ν_{sym} of COO^-), 955 ($\nu_{V=O}$).

Complex **3**. $VO(acac)_2$ (0.795 g, 3 mmol) in 50 cm^3 CH_3CN was added to a hot solution of H_2L^3 (0.723 g, 3 mmol) in 50 cm^3 CH_3CN to result in a red solution that immediately gives a minute golden precipitate. The mixture was refluxed for 4 h, cooled to room temperature and filtered. The precipitate was washed by stirring in hot CH_3CN for 2 h, filtered, and then washed with ether and dried *in vacuo*. Yield of pure product is 49%. IR (cm^{-1}): 1620 ($\nu_{C=N}$), 1555 and 1389 (ν_{asym} and ν_{sym} of COO^-), 997 ($\nu_{V=O}$).

Complex **4**. To H_2L^4 (0.638 g, 2 mmol) in 30 cm^3 hot CH_3CN was added $VO(acac)_2$ (0.530 g, 2 mmol) in 40 cm^3 CH_3CN to result in greenish-brown suspension upon addition. The mixture was refluxed for 5 h, cooled and filtered to give a dark yellow precipitate. Purification of this compound was done as described for complex **3** to give a yield of 42%. IR (cm^{-1}): 1622 ($\nu_{C=N}$), 1560 and 1390 (ν_{asym} and ν_{sym} of COO^-), 997 ($\nu_{V=O}$).

Complex **5**. The Schiff base H_2L^5 (6 mmol) was dissolved in 20 cm^3 CH_3CN and to this was added $VO(acac)_2$ (1.590 g, 6 mmol) in 100 cm^3 CH_3CN to result in a dark brown solution followed by immediate precipitation. The mixture was refluxed for 5 h, cooled and filtered to give yellow precipitate. This complex was purified as described for complex **3** to give a pure product in 46% yield. IR (cm^{-1}): 1620 ($\nu_{C=N}$), 1570 and 1390 (ν_{asym} and ν_{sym} of COO^-), 990 ($\nu_{V=O}$). Elemental analysis of all the products is given in Table 1.

X-ray crystallography of **1a**

Single crystal X-ray diffraction data were collected on an Enraf-Nonius CAD4 diffractometer using Mo-K_α radiation. The crystal of **1a** was mounted using a drop of perfluoropolyether and data collection was done at −90°C. Two standard reflections were measured every hour, 3% loss in intensity was detected and was accordingly corrected. The structure was solved using SHELXS86 [14], refined with CRYSTALS [15] and the diagrams were generated using ORTEP [16]. Details of the data collection and refinement parameters are given in Table 2.

The hydrogen atoms bonded to C were placed geometrically (C—H distance 1.00 Å). The hydrogen atoms bonded to N(21), N(31) and O(100) were located from a difference Fourier map and their coordinates and isotropic temperature factors were refined. The hydrogen atoms bonded to C atoms were treated as riding atoms with fixed temperature factor [U(iso) = 0.08]. Full matrix least squares refinement with anisotropic temperature factors for all non-hydrogen atoms was used. Empirical (ψ scan) absorption correction was applied using five reflections.

[a] $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2}$, where a Chebychev weighting scheme was employed.

X-ray crystallography of **2a**

Single crystal X-ray diffraction data were collected on an Enraf-Nonius CAD4 diffractometer using Mo-K_α radiation. Two standard reflections were measured every hour, no systematic variations were observed. The structure was solved using SHELXS86 [14] refined with CRYSTALS [15] and the diagrams were generated using ORTEP [16]. Details of the data collection and refinement parameters are given in Table 2.

In solving the crystal structure of **2a** the hydrogen atoms bonded to C (except to C(41)) were placed geometrically (C—H distance 1.00 Å) whereas Fourier difference syntheses were used to place the hydrogen atom associated with the O(41) and C(41) atoms. Full-matrix least squares refinement with anisotropic temperature factors for all non-hydrogen atoms was used. All hydrogen atoms were treated as riding atoms with fixed temperature factor [U(sio) = 0.08]. Empirical (ψ-scan) absorption correction was applied using three reflections in this structure.

Coordinates and isotropic temperature factors of all non-hydrogen atoms of **1a** and **2a** are given in supplementary data. The bond angles of **1a** are also given in supplementary data

RESULTS AND DISCUSSION

Description of the structure of **1a**

Attempts to crystallize the complexes of **1** and **2** from pyridine resulted in the decomposition along with oxidation of V^{IV} and formation of decavanadate [V^{V}]. Both the complexes gave the same decavanadate crystal with the loss of the Schiff base ligand. The crystals when taken out of the solution lose their crystallinity and change to yellow powder. Many decavanadate salts such as $Na_6V_{10}O_{28}$ [17], $[NH_4]_2Na_2H_2V_{10}O_{28}$ [18], $[(C_5H_5NH)_4][H_2V_{10}O_{28}]$ [19], $[(C_6H_5)_4P]_3H_3V_{10}O_{28}$ [20] and $[(C_6H_{13})NH_3]_4$ $(H_2V_{10}O_{28})$ [21] have been structurally characterized. The new decavanadate with pyridinium counter cation, $[C_5H_6N]_6V_{10}O_{28}\cdot 2H_2O$, in the present case is EPR inactive confirming the oxidation of the vanadium(IV) to (V) in pyridine. The molecular ORTEP of the decavanadate ion at 50% probability is shown in Fig. 2. The crystal packing diagram is shown in Fig. 3. There are five hydrogen bonds in the molecule. Three of these are from pyridinium cations and the other two are from water molecules and all these act as hydrogen donors. N(11), N(21) and N(31) of pyridinium ions form hydrogen bonds with O(7), O(1) and O(3) of the decavanadate anionic unit respectively. The water molecule forms a H-bond with O(13), and also with O(6) of a neighbouring decavanadate unit. Thus, four of the hydrogen bonds are between the decavanadate anions and the corresponding counter cations, whereas in the fifth the water molecule forms hydrogen bonds between two different decavanadate units. Some important bond lengths are given in Table 3. The V—V distances (3.054–3.300 Å) and V—O distances in the decavanadate are similar to the other decavanadates reported. The loss of crystallinity when removed from solvent is presumably due to the partial loss of water or pyridine or both that stabilise the crystal through hydrogen bonding.

In the decavanadate there are three types of vanadium ions present in the ratio of 2 : 2 : 1 based on the nearest oxygen coordination as shown in Fig. 2. These three types are designated as type *a* (V1), type *b* (V2 and V3) and type *c* (V4 and V5). The ^{51}V NMR of **1a** in pyridine showed peaks at −472 and −507 ppm in the intensity ratio 1 : 1 and these are attributable to (type *b*) and (type *c*) vanadium ions respectively. Similar ^{51}V NMR has been reported in the literature [20] for V(*b*-type) and V(*c*-type). However, it was not possible to locate V(*a*-type) possibly due to small intensity and larger line width. Other workers have detected a broad peak around −420 ppm, but

this peak was dependent on the amount of water added during measurement of spectra [20].

The description of structure **2a**

The important bond lengths and angles are given in Table 4. This complex has a distorted octahedral VO^{3+} species in which the terminal oxo and the methanol occupy the apical positions with a *trans* angle of 174.79(4). The tridentate Schiff base and the methoxide together form the basal plane of the molecule. The ORTEP diagram of **2a** is given in Fig. 4. The V—O(1) and the V—O(3) bond distances, 1.890(1) and 1.940(1) Å, are in the range observed for many vanadium Schiff base complexes [1,3–6]. The V atom is displaced towards the terminal oxygen by 0.242 Å

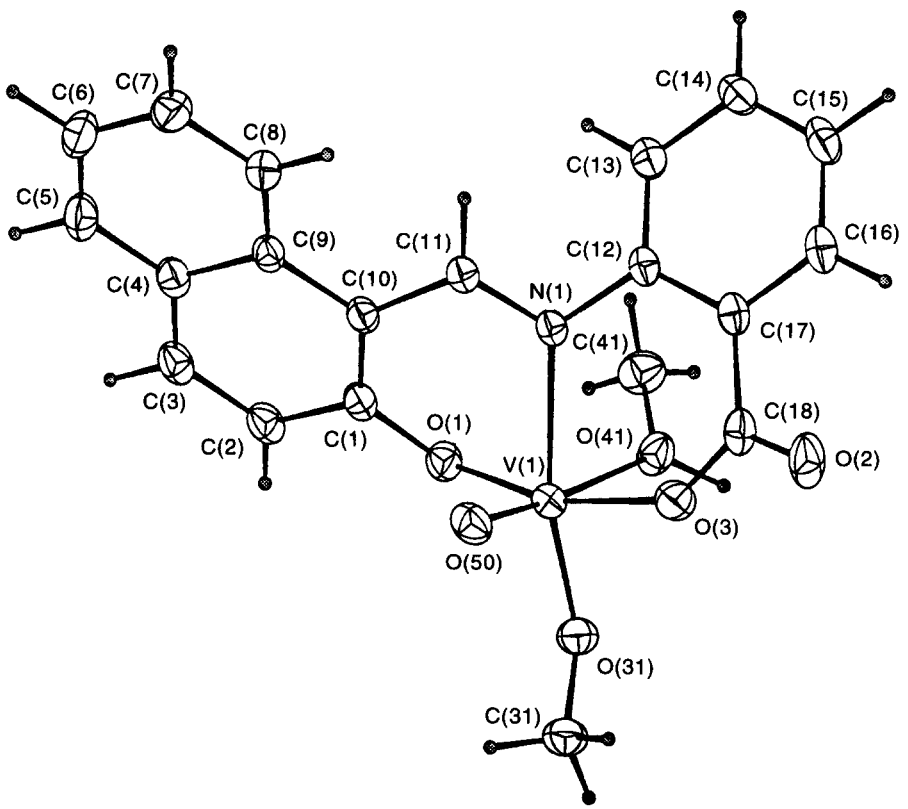

Fig. 4. ORTEP diagram of complex **2a** with thermal ellipsoids at 50% probability.

from the least square plane defined by O(1), O(31), O(3) and N(1). The V=O(50) distance, 1.591(1) Å is close to that observed for six coordinate complexes [22]. There is an intermolecular hydrogen bond between the C=O of the carboxylate and the OH of the methanol group of the neighbouring molecule with O(2)···O(41) distance of 2.668(2) Å. A similar complex LVO(OEt)(HOEt) (H_2L = N-(2-carboxyphenyl)salicyldeneamine) prepared from $VO(OEt)_3$ has been characterized by X-ray diffraction [4], but the present compound is a result of the synthesis through a different route.

Electronic absorption spectra

Complexes **1**–**5** are soluble in donor organic solvents but are insoluble in non-polar solvents. The absorption spectra were measured in the solid state, and in DMF and pyridine solution. The absorption

spectral data is given in Table 5. The reflectance spectra of each of the complexes **1–4** showed three bands in the range 560–585 nm, 740–780 nm and 450–470 nm. Based on the Ballhausen and Gray model [23] the bands are assigned as $^2B_2(d_{xy}) \rightarrow {}^2B_1(d_x2-d_y2)$, $^2B_2 \rightarrow {}^2E(d_{xz}, d_{yz})$ and $^2B_2 \rightarrow {}^2A_1(d_z2)$ transitions, respectively. These values are in agreement with values observed for dimeric five coordinate vanadyl(IV) complexes [24]. However, the third transition (450–475 nm) may also arise from LMCT transition. Three *d–d* bands were observed in solution for **2, 3** and **4** and these were centered around 770 (broad), 550 and 520 nm (sh). The spectra are similar both in DMF and in pyridine solutions. The diffuse reflectance spectrum of complex **5** showed four bands at 780, 655, 562 and 461 nm, however, in solution the bands are observed at 780, 557 and 408 nm.

Stability of complexes **2, 3** and **5** were monitored in DMF solutions, in air, as a function of time using UV-visible absorption spectral studies. While complex **2** showed complete conversion to the V^V form in 2 h, oxidation for **3** and **5** took at least 48 h.

The UV–vis spectrum of complex **1a** showed a doublet centered at 255 and 250 nm and another band at 198 nm. The bands at 255 and 250 nm are assignable to pyridinium cation. The band at 198 nm is due to $O \rightarrow V^V$ charge transfer band. Complex **2a** in DMF showed a band around 550 nm due to LMCT transition.

EPR and magnetic studies

The oxovanadium(IV) complexes are paramagnetic and gave typical axial EPR spectra for frozen samples (77 K) in DMSO. The samples **1–5** showed two sets of overlapping eight line spectra (^{51}V, $I = 7/2$). While the $g_\parallel$ (1.947–1.949) and $g_\perp$ (1.981–1.983) values of the present complexes are similar to those observed for N-salicylideneamino acid complexes, their $A_\parallel$ (183.21–184.29) and $A_\perp$ (66.29–66.86) values deviate considerably [25]. However, the values obtained for complexes **1–5** are close to those reported for the mixed ligand complex of a Schiff base N-(2-carboxyphenyl)salicylideneamine and 8-hydroxyquinoline, and 2,2′-dihydroxyazobenzene and 8-hydroxyquinoline [26]. The large hyperfine coupling constants observed in the present case are due to the weak interaction of carboxylate in delocalization of the unpaired electron density away from the metal center.

The room temperature values of effective magnetic moment per vanadium are in the range 1.70–1.94 B.M. for complexes **1** and **5** corresponding to the d^1 configuration, and showing marginal or negligible electron exchange interactions in these complexes due to carboxylate bridging. Phenolate bridged dimeric complexes have shown weak antiferromagnetic interactions and a magnetic moment of 1.55 B.M. has been reported for the complex bis[oxovanadium(IV)2-(2′-hydroxyphenyl)iminomethylphenato] [27]. Magnetic moment values for alkoxy bridged complexes $[VO(acac)OMe]_2$ was found to be 1.80 B.M. and exhibits only a weak interaction between the vanadium ions [28].

Electrochemical studies

The electrochemical behavior of complexes **1, 3** and **5** were studied by cyclic voltammetry in the range +1.00 to −2.00 V in DMF at Pt working electrode and Ag/AgCl reference electrode using NEt_4Cl or NEt_4Br as supporting electrolyte. Complex **1** showed an irreversible anodic peak at +0.65V and complexes **3** and **5** gave a quasi-reversible cyclic voltammetric response due to VO^{3+}/VO^{2+} couple at $E_{1/2} = +0.66$ (Fig. 5). Complexes with NO_5 core of alkoxo binding showed reduction at more negative potential (−0.41V) [7]. On the other hand, the mixed ligand complexes [1] of N_3O_3 core showed VO^{3+}/VO^{2+} redox behavior in the range +0.61 to +0.80 V where the potentials are similar to those observed for **1, 3** and **5**. While the alkoxy rich dinuclear V^V complexes showed $E_{1/2}$ around −0.42 V, those with carboxylate bound vanadium complexes showed around 0.66 V. The potentials seem to indicate the nature and influence of the bound ligands (alkoxy or carboxylate) on the redox behaviour of vanadium. The potentials also indicate that the alkoxy-bound V^V centers are favoured by about 104 kJ mol^{-1} over the carboxylate bound counterparts. Thus this study strongly suggests the stabilization of V^{IV} center by carboxylate ligands. It is understood from the literature that phenolate and alkoxide donors generally favour VO^{3+} and VO_2^+ centers.

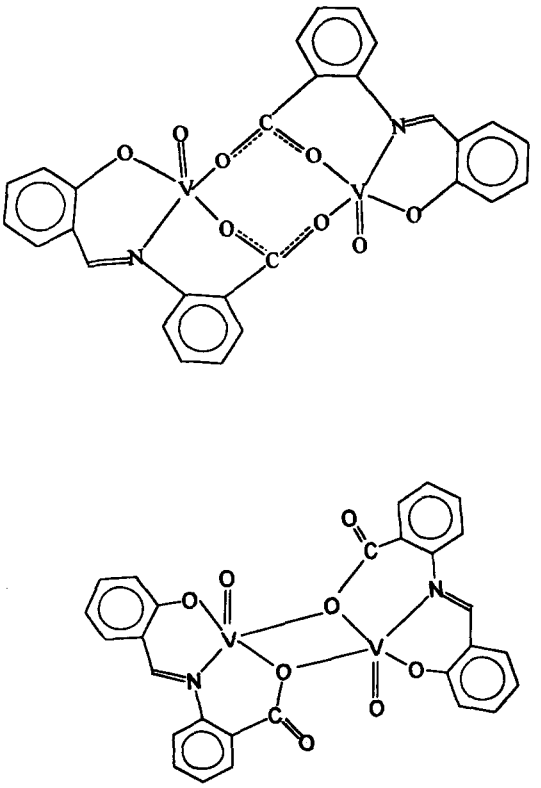

Fig. 6. Schematic representation of the proposed structures of complex **3**.

Thermogravimetric and differential thermal analysis

The thermogravimetric and differential thermal analysis curves for **1** showed that there is no weight loss up to 250°C. However, three weight losses were observed with starting temperatures of 270, 400 and 470°C. The loss of 270°C for complex **1**, which is absent in the other complexes, is attributable to the decomposition of the acetylacetonate and those at higher temperatures are due to the decomposition of the benzene ring. The weight of the final residue at 700°C matches with the V_2O_5 which is 32% of the molecular weight of the compound. Complexes **2**, **3**, **4** and **5** start to lose weight at 400°C and this loss is assigned to the decomposition of the benzene ring. Complex **2a** showed weight loss at 180°C that accounts for 15% of the molecular weight and is attributable to the loss of methanol and a methoxide. The other weight loss is observed at 400°C.

Based on the mono and bidentate nature of the carboxylate group, two possible structures are proposed for **3** as shown in Fig. 6.

(Received 12 April, 1996; accepted 19 June 1996)

Abstract—Dinitrogen activation at the FeMo-cofactor site of nitrogenase was studied based upon the quantum chemical CNDO calculations performed on possible processes of dinitrogen approaching and binding to the FeMo-cofactor. The best dinitrogen binding mode suggested in this article is the dinitrogen-inserting end-on mode, in which one nitrogen atom is located at the geometrical center of the FeMo-cofactor, and another nitrogen atom keeps out of the Fe_4 surface of the Fe_6 prism of the FeMo-cofactor. The mechanism of protonation of dinitrogen at the FeMo-cofactor site is discussed based upon the suggested binding mode.

Keywords: binding mode; calculation; CNDO; dinitrogen; FeMo-cofactor; protonation mechanism.

The structural model proposed by Kim–Rees [1–3] and Bolin [4] for the iron–molybdenum cofactor (FeMoco) of the nitrogenase molybdenum–iron protein, which provides a structural basis for interpreting biological dinitrogen reduction, can be represented by two joined incomplete cubane clusters of composition 4Fe : 3S and 1Mo : Fe : 3S, with three iron atoms from each cluster bridged by what are apparently sulfur atoms. The structure contains six coordinately unsaturated FeS_3 sites with their central Fe atoms located in a trigonal prismatic arrangement. The remaining Mo and Fe atoms, capping the trigonal faces of the Fe_6 (or 6Fe) prism, serve as cluster anchor points. The six-coordinated Mo atom, being bound to three sulfur atoms within the cluster, is ligated by the imidazole group of the His-442 residue, as well as a bidentate homocitrate (HC) through hydroxyl and carboxyl oxygen atoms. It should be pointed out that the nitrogen atom of the imidazole provides two electrons for bonding to Mo. The anchor Fe atom is coordinated by the sulfur atom of the Cys-275 residue. Table 1 lists some interatomic distances selected from the reported structural data based on the X-ray crystallographic analyses [1,3,4] (at 2.7 Å and 2.2 Å resolution), the iron EXAFS [5] and the molybdenum EXAFS [6]. In fact, many structural details about the FeMoco already were derived from earlier EXAFS spectroscopy [7–10].

The FeMoco is regarded as the likely site of substrate binding and reduction [11–13]. In order to reveal some insights into N_2 binding mode, many theoretical calculations including earlier researches [14] of simple metal center models and recent researches [15–20] of the Kim–Rees model, have been performed on some individual structures proposed for the complex of N_2 with the FeMoco. Based on extended Huckel (EHMO) calculations, Deng and Hoffmann [15] suggested that the best N_2 coordinated mode is that one in which N_2 occupies the site of a bridging sulfur and binding in the side-on fashion to two Fe atoms of the FeMoco. However, other researchers [16–19] favor dinitrogen binding modes on the Fe_4 face of the FeMoco. Plass [16] employed the EHMO method to discuss the similarities and differences between the FeMo-, FeV- and FeFe-cofactors as dinitrogen is in the end-on fashion to bind to the Fe_4 face. Shestakov's EHMO calculations [17] also suggested the end-on mode on the Fe_4 face. Dance [18] supposed that dinitrogen is in the side-on fashion to bind the Fe_4 face, and studied various configurations related to the Fe_4 face site using density
